From (32), we have $G_{r,s}(H_0, M_{r,s}) = \psi_{r,s}(M_{r,s}) - \mu_0 H_0 M_{r,s} - \sigma\varepsilon$. Define $\bar{\psi}_{r,s}(M_{r,s})$ and $\bar{G}_{r,s}(H, M_{r,s})$ to be the Helmholtz free energy and Gibbs energy, respectively, written in terms of external variables. When the system is viewed from an

external point of view, the combined effect of the dipole and the imperfections is seen. To find $\bar{\psi}_{r,s}(M_{r,s})$ and $\bar{G}_{r,s}(H, M_{r,s})$, an assumption for the imperfections and nonhomogeneities must be made and, based on that, the contribution to the Helmholtz free energy computed. Another approach is to construct $\bar{\psi}_{r,s}(M_{r,s})$ by studying the equilibrium points of the system for a constant magnetic field.

The equilibrium points for a constant magnetic field in terms of the external variables (H,$M_{r,s}$) can be obtained via two methods:

1. The equilibrium condition can be written for $\bar{G}_{r,s}(H, M_{r,s})$.
2. The system parameters can be transformed to the local variables (H_0, $M_{r,s}$). The equilibrium condition is written for $G_{r,s}(H_0, M_{r,s})$, and the results are transformed back to the external variables.

These two methods must be equivalent.

The equilibrium conditions for $\bar{G}_{r,s}(H, M_{r,s})$ and $G_{r,s}(H_0, M_{r,s})$ are

$$\left(\frac{\partial \bar{G}_{r,s}(H, M_{r,s})}{\partial M_{r,s}}\right)_{T,H} = 0, \qquad \left(\frac{\partial G_{r,s}(H_0, M_{r,s})}{\partial M_{r,s}}\right)_{T,H_0} = 0, \tag{43}$$

where $H = H_0 + s$ and s is assumed constant. Further,

$$\begin{aligned}\left(\frac{\partial G(H_0, M_{r,s})}{\partial M_{r,s}}\right)_{T,H_0} &= \left(\frac{\partial}{\partial M_{r,s}}\right)_{T,H} (\psi(M_{r,s}) - \mu_0 H_0 M_{r,s} - \sigma\varepsilon) \\ &= \left(\frac{\partial}{\partial M_{r,s}}\right)_{T,H} (\psi(M_{r,s}) - \mu_0 H M_{r,s} + \mu_0 s M_{r,s} - \sigma\varepsilon) \\ &= 0.\end{aligned} \tag{44}$$

Now, $\bar{G}_{r,s}(H, M_{r,s})$ equals $G_{r,s}(H - s, M_{r,s})$ or

$$\bar{G}_{r,s}(H, M_{r,s}) = \psi(M_{r,s}) - \mu_0 H M_{r,s} + \mu_0 s M_{r,s} - \sigma\varepsilon. \tag{45}$$

It can be shown that the equilibrium conditions (43) are identical. Defining $\bar{\psi}_{r,s}(M_{r,s})$ so that $\bar{G}_{r,s}(H, M_{r,s}) = \bar{\psi}_{r,s} - \mu_0 H M_{r,s} - \sigma\varepsilon$, analogously with (32), we have

$$\bar{\psi}_{r,s}(M_{r,s}) = \psi(M_{r,s}) + \mu_0 s M_{r,s}. \tag{46}$$

Equation (37) gives the equilibrium magnetization for a dipole. By combining (30), (37), and (46), the equilibrium value of $\bar{\psi}_{r,s}$ for each dipole is obtained:

$$\bar{\psi}^*_{r,s} = \frac{1}{2} Y\varepsilon^2 + \frac{\frac{\mu_0}{2}(H^2 - s^2) - \eta' M_R (Y\gamma\varepsilon M_R - \mu_0 s R_{r,s})}{\eta' - \frac{2Y\gamma\varepsilon}{\mu_0}}. \tag{47}$$

Similar to (39), by assuming a distribution for r and s, the Helmholtz free energy for the entire system can be found using the superposition principle:

$$\psi_{Tot}(\tau(t,r), \varepsilon) = C \int_0^\infty \int_{-\infty}^\infty \bar{\psi}^*_{r,s} \mu(r,s) ds dr. \tag{48}$$

By combining (29), (47), and (48), the following equation is obtained:

$$\begin{aligned}\psi_{Tot}(\tau(t,r), \varepsilon) = \frac{C\mathcal{I}_0}{2} Y\varepsilon^2 + \frac{C}{\eta' - \frac{2Y\gamma\varepsilon}{\mu_0}} \Bigg(&\frac{\mu_0 \mathcal{I}_0 \tau^2(t,0)}{2} - \eta' Y\gamma\varepsilon M_R^2 \mathcal{I}_0 \\ &+ \eta' M_R \mu_0 A - \frac{\mu_0}{2} \mathcal{I}_2 \Bigg),\end{aligned} \tag{49}$$

where $A = \int_0^\infty \int_{-\infty}^\infty R_{r,s} s \mu(r,s) ds dr = 2 \int_0^\infty \int_{-\infty}^{\tau(t,r)} s \mu(r,s) ds dr - \mathcal{I}_1$.

This is the value of the Helmholtz free energy, the storage function for the magnetostrictive system, for any ε and Preisach boundary $\tau(t,r)$. The only nontrivial aspect of calculating $\psi_{Tot}(\tau(t,r),\varepsilon)$ is efficient computation of A. It is seen that the double integral of A is very similar to the double integral used for computing M (27). In fact, any efficient algorithm used for the computation of M can be used here, for example that on [2, p. 37]; only the weight function is slightly different.

4.3. Minimum of the storage function. In this section, the Preisach boundary that globally minimizes the storage function is obtained.

Suppose that when $\tau(t,r)=\tau^*(t,r)$ and $\varepsilon=\varepsilon^*$, $\psi_{Tot}(\tau(t,r),\varepsilon)$ is globally minimized. If ε is held fixed at $\varepsilon=\varepsilon^*$ and $\tau(t,r)$ is changed, $\psi_{Tot}(\tau(t,r),\varepsilon^*)$ is minimized when $\tau(t,r)=\tau^*(t,r)$. This means that $\tau^*(t,r)$ globally minimizes the following function:

$$\psi_{Tot}(\tau(t,r),\varepsilon^*)=\frac{C\mathcal{I}_0}{2}Y\varepsilon^{*2}+\frac{C}{\eta'-\frac{2Y\gamma\varepsilon^*}{\mu_0}}\left(\frac{\mu_0\mathcal{I}_0\tau^2(t,0)}{2}-\eta' Y\gamma\varepsilon^* M_R^2\mathcal{I}_0 + \eta' M_R\mu_0 A-\frac{\mu_0}{2}\mathcal{I}_2\right). \tag{50}$$

The following terms are the only variable parts of the storage function:

$$\begin{aligned} F_1(\tau(t,r))&=\frac{\mu_0\mathcal{I}_0\tau^2(t,0)}{2},\\ F_2(\tau(t,r))&=A. \end{aligned} \tag{51}$$

Assume that the weight function $\mu(r,s)$ is nonnegative for all r and s. Since $\eta'-\frac{2Y\gamma\varepsilon^*}{\mu_0}$ is a positive quantity, if F_1 and F_2 are minimized at the same time, the storage function is minimized. Function F_1 is minimized when $\tau(t,0)=0$. Function F_2 is minimized when A is minimized:

$$A=2\int_0^\infty\int_{-\infty}^{\tau(t,r)} s\mu(r,s)dsdr-\mathcal{I}_1. \tag{52}$$

The sign of the integrand equals the sign of s. This integration is minimized when the region of integration is the subset of the Preisach plane on which the integrand is negative. This is the lower half of the Preisach plane. Thus, the integration is minimized when the boundary $\tau(t,r)=0$. This Preisach plane boundary is shown in Figure 7.

Function F_2 is globally minimized with the boundary $\tau(t,r)=0$. Since for this boundary $\tau(t,0)=0$, this boundary also globally minimizes F_1. This results in global minimization of the storage function.

It is commonly seen that the weight function $\mu(r,s)$ is an even function of s; that is, $\mu(r,s)=\mu(r,-s)$ for all r and s [16, 18]. If this condition holds, by substituting the Preisach boundary $\tau(t,r)=0$ into (41), it is seen that the resulting magnetization is zero. In this case there is no magnetic field H, magnetization M, or flux density B. This state is called the demagnetized state and is the state of lowest "energy" for the system.

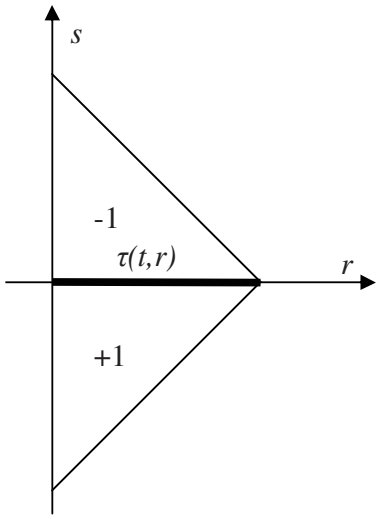

FIG. 7. *The global minimum Preisach boundary.*

5. Storage function in the presence of a constant input. When the stress and magnetic field applied to the system include a constant portion, the system can be simplified by redefining the input as $\bar{u} = \begin{pmatrix} \mu_0(H - H_{const}) \\ \sigma - \sigma_{const} \end{pmatrix}$, while the output is not changed. In this case, the system is passive with the following storage function:

$$\psi^F = \psi_{Tot} - \mu_0 \langle H_{const}, M_{Tot} \rangle - \sigma_{const}\varepsilon, \tag{53}$$

where ψ_{Tot} is the system Helmholtz free energy and M_{Tot} is the system magnetization. This situation is analogous to the example of a spring with a constant imposed force, such as gravity, discussed in section 2.

THEOREM 11. *In the presence of a constant input, the following passivity condition is satisfied when the storage function is* ψ^F*:*

$$\psi_i^F + \int_{t_i}^{t_f} \left\langle \bar{u}, \frac{dX}{dt} \right\rangle dt \geq \psi_f^F. \tag{54}$$

Subscripts i *and* f *denote initial and final conditions, respectively, and* $X = \begin{pmatrix} M \\ \varepsilon \end{pmatrix}$ *is the generalized displacement.*

Proof. If the definition of $\bar{u}$ and ψ^F is substituted into the result of Theorem 10, the result is

$$\begin{aligned} \psi_i^F + \mu_0 \langle H_{const}, M_{Tot,i} \rangle + \sigma_{const}\varepsilon_i + \int_{t_i}^{t_f} \left\langle \bar{u} + \begin{pmatrix} \mu_0 H_{const} \\ \sigma_{const} \end{pmatrix}, \frac{dX}{dt} \right\rangle dt \\ \geq \psi_f^F + \mu_0 \langle H_{const}, M_{Tot,f} \rangle + \sigma_{const}\varepsilon_f. \end{aligned} \tag{55}$$

This simplifies to

$$\psi_i^F + \int_{t_i}^{t_f} \left\langle \bar{u}, \frac{dX}{dt} \right\rangle dt \geq \psi_f^F. \tag{56}$$

Since both M_{Tot} and ε have a lower bound and an upper bound, existence of a lower bound for ψ_{Tot} implies that ψ^F has a lower bound. The proof is complete. ∎

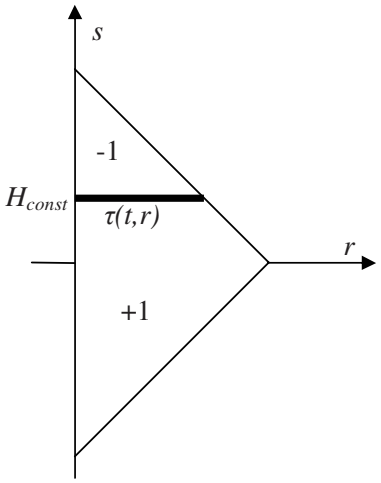

FIG. 8. *The global minimum Preisach boundary in the presence of a constant input.*

The storage function ψ^F can be written as a function of the Preisach boundary $\tau(t,r)$ and ε by combining (49) and (53):

$$\psi^F(\tau(t,r),\varepsilon) = \frac{C\mathcal{I}_0}{2}Y\varepsilon^2 + \frac{C}{\eta' - \frac{2Y\gamma\varepsilon}{\mu_0}}\left(\frac{\mu_0\mathcal{I}_0(\tau(t,0)-H_{const})^2}{2} - \frac{\mu_0\mathcal{I}_0H_{const}^2}{2}\right.$$
$$- \eta' Y\gamma\varepsilon M_R^2\mathcal{I}_0 + \mu_0 H_{const}M_R\eta'\mathcal{I}_0 + \mu_0 H_{const}\mathcal{I}_1$$
$$\left. - \eta' M_R\mu_0\mathcal{I}_1 + \mu_0\eta' M_R\bar{A} - \frac{\mu_0}{2}\mathcal{I}_2\right) - \sigma_{const}\varepsilon, \tag{57}$$

where $\bar{A} = 2\int_0^\infty \int_{-\infty}^{\tau(t,r)}(s - H_{const})\mu(r,s)dsdr$. Using an argument similar to that of the previous section, it can be shown that the following boundary minimizes the storage function:

$$\tau(t,r) = H_{const}. \tag{58}$$

This boundary is shown in Figure 8. For a constant input, this is the state of minimum energy. The magnetization in this state is the anhysteretic magnetization.

6. Conclusions. In this article, magnetostrictive transducers were introduced in a dynamical system framework. Passivity of this system was shown using fundamental physical relations. For the energy-based Preisach model, the system states were defined, and the storage function was computed. System equilibrium points were also identified and discussed.

The passivity results discussed in this paper can be used to show the stability of a closed-loop system. Future work includes the design and optimization of a robustly stabilizing controller for magnetostrictive transducers.

Appendix. The maximization of entropy. In this appendix, it is shown that the entropy function (20) is maximized when $H = 0$.

From subsection 3.4, the following relations define entropy for a paramagnetic sample with N dipoles:

$$\begin{aligned} Z &= \frac{\sinh\left[(J+\frac{1}{2})\eta\right]}{\sinh\left[\frac{1}{2}\eta\right]}, \\ S &= kN\left(\ln Z - \beta\frac{\partial \ln Z}{\partial\beta}\right), \\ \eta &= c\beta\left\|H\right\|, \\ \beta &= \frac{1}{kT}, \end{aligned} \tag{59}$$

where c is a positive constant.

Define $D = \frac{\eta}{2} = \frac{c\beta}{2}\left\|H\right\|$ and $q = 2J+1$. Since J is a positive half-integer, q is an integer greater than one. We can write

$$S = kN\left(\ln\frac{\sinh qD}{\sinh D} - qD\coth qD + D\coth D\right). \tag{60}$$

This function is not defined at $D=0$, but $\lim_{D\to 0} S(D)$ exists:

$$\begin{aligned} \lim_{D\to 0} S(D) &= \lim_{D\longrightarrow 0} kN\left(\ln\frac{\sinh qD}{\sinh D} + \frac{D\cosh D\sinh qD - qD\cosh qD\sinh D}{\sinh D\sinh qD}\right) \\ &= \lim_{D\longrightarrow 0} kN\left(\ln\frac{qD+h.o.t.}{D+h.o.t.} + \frac{\frac{D^4}{6}(2q-2q^3)+h.o.t.}{qD^2+h.o.t.}\right) \\ &= kN\ln q. \end{aligned} \tag{61}$$

For $D\neq 0$, $S(D) = S(-D)$; i.e., this is an even function. We do not need to analyze this function for both positive and negative values of D. For simplicity $D>0$ is studied.

If $D>0$,

$$\frac{dS}{dD} = kN\left(\frac{q^2 D}{\sinh^2 qD} - \frac{D}{\sinh^2 D}\right). \tag{62}$$

It will be shown that for $D>0$, $\frac{dS}{dD} < 0$. Consider the Taylor series of the following expression:

$$\begin{aligned} \sinh qD - q\sinh D &= qD + \frac{q^3D^3}{3!} + \frac{q^5D^5}{5!} + \cdots - qD - \frac{qD^3}{3!} - \frac{qD^5}{5!} - \cdots \\ &= q\left((q^2-1)\frac{D^3}{3!} + (q^4-1)\frac{D^5}{5!} + \cdots\right). \end{aligned} \tag{63}$$

Since $q>1$ and $D>0$ all of the terms in the Taylor series are positive. It follows that

$$\sinh qD - q\sinh D > 0. \tag{64}$$

This inequality can be written as

$$1 < \frac{\sinh qD}{q\sinh D} \tag{65}$$

or

$$1 < \frac{\sinh^2 qD}{q^2 \sinh^2 D}. \tag{66}$$

This inequality can be further written as

$$\frac{q^2}{\sinh^2 qD} - \frac{1}{\sinh^2 D} < 0. \tag{67}$$

By rewriting (62), the terms in (67) appear in the derivative of S with respect to D:

$$\frac{dS}{dD} = kND\left(\frac{q^2}{\sinh^2 qD} - \frac{1}{\sinh^2 D}\right). \tag{68}$$

Since $D > 0$, this implies that $\frac{dS}{dD} < 0$.

Since $\frac{dS}{dD} < 0$, S can be increased by lowering D, or

$$\sup_{D>0} S(D) = \lim_{D\to 0} S(D) = kN \ln q. \tag{69}$$

Since $S(D)$ is an even function, this result can be extended to all values of $D \neq 0$: $kN \ln q$ is an upper bound for $S(D)$.

GUIDED MODES IN PERIODIC SLABS: EXISTENCE AND NONEXISTENCE*

STEPHEN SHIPMAN† AND DARKO VOLKOV‡

Abstract. For homogeneous lossless three-dimensional periodic slabs of fixed arbitrary geometry, we characterize guided modes by means of the eigenvalues associated with a variational formulation. We treat robust modes, which exist for frequencies and wavevectors that admit no propagating Bragg harmonics and therefore persist under perturbations, as well as nonrobust modes, which can disappear under perturbations due to radiation loss. We prove the nonexistence of guided modes, both robust and nonrobust, in "inverse" structures, for which the celerity inside the slab is less than the celerity of the surrounding medium. The result is contingent upon a restriction on the width of the slab but is otherwise independent of its geometry.

Key words. guided mode, periodic slab, photonic crystal, nonexistence in inverse crystals

1. Introduction.

The subject of our investigation is the existence and nonexistence of linear scalar waves guided by periodically structured lossless material slabs (Figure 1). These *guided modes* occur in linear acoustic theory and, in the two-dimensional reduction, in which the structure is invariant in one of the two directions of periodicity, they describe guided polarized electromagnetic fields. Guided modes are characterized by their frequency and Bloch wavevector in the plane of periodicity, and they decay exponentially with distance away from the slab.

We distinguish between two types of guided mode. Those of the first type cannot be destroyed by radiation losses under perturbation because they possess a frequency and wavevector for which no Bragg, or Fourier, harmonics propagate away from the slab (they are all evanescent); we call these *robust guided modes*. Those possessing frequency and wavevector for which some propagating Bragg harmonics exist can be destroyed by radiation loss by "coupling" to these harmonics under perturbation of the structure, frequency, or wavevector. These *nonrobust guided modes* are known to be connected with anomalous scattering behavior in the vicinity of the frequency and wavenumber of the mode.

It is recognized that guided modes as well as the transmission anomalies associated with them will be useful in the design of photonic devices. These phenomena appear in many different photonic structures, and there is a large body of literature devoted to them. We mention just a few references. Anomalous transmission is typically characterized by sharp dips and peaks in the transmission coefficient. An in-depth computational analysis of their relation to leaky modes for slabs that are invariant in the transverse direction is given in Tikhodeev et al. [1]. Explicit asymptotic formulas for very general geometry for some types of perturbations have been calculated by Shipman and Venakides [2]. The connection between transmission enhancement and

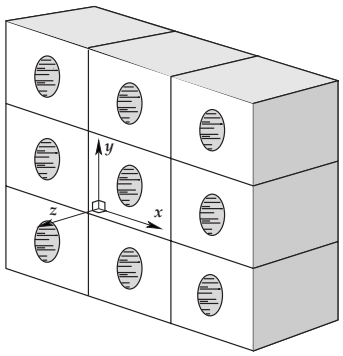

FIG. 1. *A slab structure periodic in the x and y directions and finite in the z direction.*

particular types of guided mode on metal films called "surface plasmons" has been studied in a series of papers by several authors; see [3] and [4], for example. An important class of guided modes that we do not treat here consists of those in optical fibers or periodic pillars (see [5], for example). Our present study focuses on the existence and nonexistence of guided modes in lossless dielectric slabs.

The existence of guided modes can be proved using variational principles. Bonnet-Bendhia and Starling [6] treat two-dimensional electromagnetic structures consisting of lossless penetrable and conducting components in which the dielectric coefficient is essentially an arbitrary function. The treatment of nonrobust modes is more delicate because establishing their existence requires proving the vanishing of the propagating Bragg harmonics. The frequencies of these modes, for a given wavevector, are called (as in [6]) *singular frequencies* of the problem of scattering, or diffraction, of plane waves by the slab.

In our study, we consider three-dimensional homogeneous dielectric structures. In this case we are able to prove a nonexistence theorem for *inverse structures*. An inverse structure is one for which the speed of waves, or the celerity, is higher inside the structure than in the surrounding medium. This result is easily understood through the following example. It is simple to calculate fields that are totally internally reflected within an infinite pane of glass surrounded by air. However, if the roles of the air and the glass are switched, such fields no longer exist. A similar result is expected for slabs with more general geometry. This is the content of Theorem 4.1. The result is subject to a restriction on the width of the slab, which depends on the frequency and wavevector; we do not know if this restriction is necessary or if it is only a artifact of our method of proof.

For the existence theory, we include complete proofs in the appendix (section 6) to make the work coherent and self-contained and in order to set the context and notation for the proof of the nonexistence result.

The governing equation of dynamics is the linear wave equation arising in small-amplitude acoustic theory:

$$\varepsilon \frac{\partial^2}{\partial t^2} w(x,y,z,t) = \nabla \cdot \frac{1}{\mu} \nabla w(x,y,z,t). \tag{1}$$

The positive material parameters ε and μ depend in general on the position within the slab but are constant outside of the slab. We will restrict our analysis to slabs in which these parameters are constant inside. The spatial factor $\tilde{u}(x,y,z)$ of a time-harmonic

solution

$$w(x,y,z,t) = \tilde{u}(x,y,z)\, e^{-i\omega t}$$

is described by the Helmholtz equation

$$\nabla\cdot \frac{1}{\mu}\nabla\tilde{u}(x,y,z) + \varepsilon\omega^2\, \tilde{u}(x,y,z) \;=\; 0. \tag{2}$$

We are interested in solutions of the Helmholtz equation that are of the pseudoperiodic form

$$\tilde{u}(x,y,z) = u(x,y,z)\, e^{i(\kappa_1 x+\kappa_2 y)}, \quad u \text{ periodic in } x \text{ and } y,$$

in which $u(x,y,z)$ has the same periods as the guiding slab structure. The vector $\boldsymbol{\kappa} = \langle \kappa_1, \kappa_2, 0\rangle$ is known as the *Bloch wavevector*, and the field $\tilde{u}$ is called a Bloch wave. Such a solution to the Helmholtz equation gives rise to a solution of the linear wave equation when multiplied by a harmonic factor in t:

$$w(x,y,z,t) = u(x,y,z)e^{i(\kappa_1 x+\kappa_2 y-\omega t)}.$$

This solution is a plane wave traveling in the direction of the vector $\boldsymbol{\kappa}$ with wave number $|\boldsymbol{\kappa}| = \sqrt{\kappa_1^2+\kappa_2^2}$, frequency ω, and speed $\omega/|\boldsymbol{\kappa}|$, modulated periodically through multiplication by the factor $u(x,y,z)$.

Fundamental to the structure of Bloch waves is their decomposition in the x and y variables into Fourier harmonics, often called Bragg harmonics, in the regions away from the slab ($|z|$ sufficiently large):

$$u(x,y,z) = \sum_{m,n=-\infty}^{\infty} (c_{mn}^{+}e^{\nu_{mn}z} + c_{mn}^{-}e^{-\nu_{mn}z})e^{i(mx+ny)}.$$

Each element of the sum is a separable solution to the Helmholtz equation, and the coefficients c_{mn}^{+} and c_{mn}^{-} differ from one side of the slab to the other. The exponents ν_{mn}, as explained in more detail below, are purely imaginary for a finite number of pairs (m,n), corresponding to the *propagating Fourier harmonics*. For all other pairs, assuming $\nu_{mn} \neq 0$ for all (m,n), this exponent is real, and boundedness of u requires that the coefficients of the exponentially growing components vanish. Thus these pairs correspond to the evanescent harmonics. Assuming then that u is bounded, we can say that *a guided mode is supported by the slab structure if the coefficients of all propagating Fourier harmonics vanish.*

The paper is organized as follows. In section 2, we formulate a precise definition of a guided mode in its strong and weak forms. We explain the relation between vanishing propagating Fourier modes and absence of energy loss by radiation. In section 3, we discuss the existence of sequences of material constants, depending on the geometry of the structure, the wavevector, and the frequency, that admit guided modes in the regime of no radiating Fourier harmonics. We also prove the existence of sequences of material constants for structures symmetric about a plane, depending on the frequency and wave number along the plane of symmetry, for which guided modes that travel parallel to the plane of symmetry exist. All of the proofs are deferred to the appendix. In section 4, we prove that guided modes cannot exist in "inverse" slab structures; specifically, we show that, under a suitable restriction on their width, slabs with constant μ and ϵ whose value interior to the slab is less than its value in the exterior, never admit guided modes. In section 5, we show a few numerical computations of nonrobust guided modes.

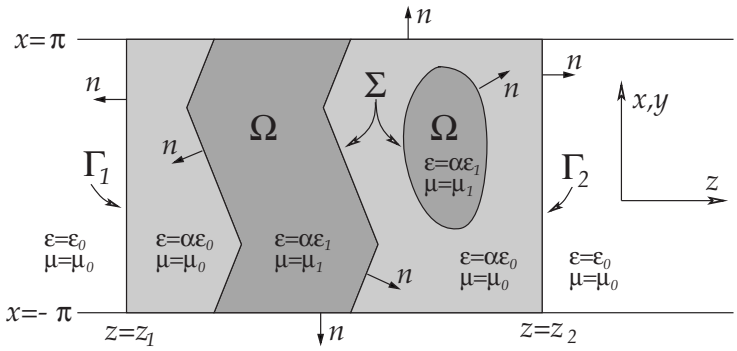

FIG. 2. *A two-dimensional depiction of one period of a possible augmented three-dimensional slab structure.*

2. Mathematical formulation of guided modes. A variational description of guided modes requires truncation of the domain in the z direction (directed away from the slab) and the introduction of an auxiliary parameter α, serving as the eigenvalue, by which the coefficient ϵ is multiplied within the truncated domain (Figure 2). The monotonicity of certain eigenvalue sequences $\alpha_j(\epsilon_1)$ with respect to the interior constant ϵ_1 is utilized in the proof of nonexistence of modes in section 4.

Let $\tilde{\Omega}$ denote a domain in $\mathbb{R}^3$ with C^2 boundary $\partial\tilde{\Omega}$ that is bounded in the z direction and 2π-periodic in the x and y directions (Figure 2). This means that

i. there are numbers $z_1 < z_2$ such that

$$z_1 < \inf\{z : (x, y, z) \in \tilde{\Omega}\} < \sup\{z : (x, y, z) \in \tilde{\Omega}\} < z_2;$$

ii. if $(x, y, z) \in \tilde{\Omega}$, then $(x + 2\pi j, y, z) \in \tilde{\Omega}$ and $(x, y + 2\pi j, z) \in \tilde{\Omega}$ for each integer j.

Let $\mathcal{S}$ denote the infinite square cylinder containing one period of $\tilde{\Omega}$,

$$\mathcal{S} = \{(x, y, z) : -\pi < x < \pi,\ -\pi < y < \pi\},$$

and denote by Ω the part of $\tilde{\Omega}$ contained in $\mathcal{S}$, constituting one period of $\tilde{\Omega}$,

$$\Omega = \tilde{\Omega} \cap \mathcal{S} = \{(x, y, z) \in \tilde{\Omega} : -\pi < x < \pi,\ -\pi < y < \pi\},$$

and by Σ the part of $\partial\tilde{\Omega}$ contained in $\mathcal{S}$,

$$\Sigma = \partial\tilde{\Omega} \cap \mathcal{S}.$$

The boundary $\partial\Omega$ of Ω includes Σ and possibly parts of the boundary $\partial\mathcal{S}$ of $\mathcal{S}$. Denote by $\mathcal{R}$ the part of $\mathcal{S}$ between $z = z_1$ and $z = z_2$,

$$\mathcal{R} = \{-\pi < x < \pi,\ -\pi < y < \pi,\ z_1 < z < z_2\},$$

and by $\Gamma = \Gamma_1 \cup \Gamma_2$ the square parts of the boundary of $\mathcal{R}$ parallel to the xy-plane:

$$\Gamma_1 = \{(x, y, z) : -\pi < x < \pi,\ -\pi < y < \pi,\ z = z_1\},$$
$$\Gamma_2 = \{(x, y, z) : -\pi < x < \pi,\ -\pi < y < \pi,\ z = z_2\}.$$

We fix outward-pointing normal vectors n to all of the surfaces, as shown in Figure 2. Let the piecewise constant functions ε and μ be defined by

$$\varepsilon(r) = \begin{cases} \alpha\epsilon_1, & r \in \Omega, \\ \alpha\epsilon_0, & r \in \mathcal{R} \setminus \Omega, \\ \epsilon_0, & r \in \mathcal{S} \setminus \mathcal{R}, \end{cases} \qquad \mu(r) = \begin{cases} \mu_1, & r \in \Omega, \\ \mu_0, & r \in \mathcal{S} \setminus \Omega, \end{cases} \tag{3}$$

in which ϵ_0, ϵ_1, α, μ_0, and μ_1 are fixed positive numbers.

We will be considering guided modes in the augmented structure consisting of the flat slab in $\mathbb{R}^3$ filling the space between the planes $z = z_1$ and $z = z_2$ with the periodic structure $\tilde{\Omega}$ embedded in it. For $\alpha = 1$, this augmented structure reduces to $\tilde{\Omega}$ itself. We denote the augmented structure by $\tilde{\Omega}_{\text{aug}}$:

$$\tilde{\Omega}_{\text{aug}} = \text{the augmented structure in Figure 2 extended periodically to } \mathbb{R}^3.$$

When referring to $\tilde{\Omega}_{\text{aug}}$, the material constants (3), repeated periodically, are tacitly assumed.

Given a frequency ω and Bloch wavevector $\boldsymbol{\kappa} = \langle \kappa_1, \kappa_2, 0 \rangle$, we seek solutions $\tilde{u} = \tilde{u}(x, y, z)$ of the Helmholtz equation (2) in $\mathcal{S}$ with $\boldsymbol{\kappa}$-pseudoperiodic boundary conditions in x and y, that is,

$$\tilde{u}(\pi, y, z) = e^{2\pi i \kappa_1} \tilde{u}(-\pi, y, z), \quad \partial_n \tilde{u}(\pi, y, z) = -e^{2\pi i \kappa_1} \partial_n \tilde{u}(-\pi, y, z), \tag{4}$$

$$\tilde{u}(x, \pi, z) = e^{2\pi i \kappa_2} \tilde{u}(x, -\pi, z), \quad \partial_n \tilde{u}(x, \pi, z) = -e^{2\pi i \kappa_2} \partial_n \tilde{u}(x, -\pi, z). \tag{5}$$

The minus signs arise because the normal vector n to $\partial\mathcal{S}$ is always taken to point out from $\mathcal{S}$. Such a solution can be extended to a $\boldsymbol{\kappa}$-pseudoperiodic solution in $\mathbb{R}^3$, that is, retaining $\tilde{u}$ to denote this extension,

$$\tilde{u}(x, y, z) = e^{i(\kappa_1 x + \kappa_2 y)} u(x, y, z),$$

in which $u(x, y, z)$ is 2π-periodic in x and y. It is convenient to work with the function u, which has periodic boundary conditions in $\mathcal{S}$:

$$u(\pi, y, z) = u(-\pi, y, z), \quad \partial_n u(\pi, y, z) = -\partial_n u(-\pi, y, z), \tag{6}$$

$$u(x, \pi, z) = u(x, -\pi, z), \quad \partial_n u(x, \pi, z) = -\partial_n u(x, -\pi, z). \tag{7}$$

The Helmholtz equation (2) for $\tilde{u}$ is equivalent to the following modified equation for the periodic factor u:

$$(\nabla + i\boldsymbol{\kappa}) \cdot \frac{1}{\mu} (\nabla + i\boldsymbol{\kappa}) u + \varepsilon\omega^2 u = 0. \tag{8}$$

In the precise formulation of a guided mode below, Condition 2.2, we make clear the implied behavior of a solution to this equation at the surfaces of discontinuity of ε and μ, namely, Σ and Γ.

We take $\boldsymbol{\kappa} = \langle \kappa_1, \kappa_2, 0 \rangle$ to lie in the first symmetric Brillouin zone pertaining to our structure, which is 2π-periodic in x and y, that is,

$$-1/2 \le \kappa_1 < 1/2 \quad \text{and} \quad -1/2 \le \kappa_2 < 1/2.$$

In the intervals $(-\infty, z_1)$ and (z_2, ∞), every periodic solution u of (8) is equal to a superposition of Fourier harmonics:

$$\begin{aligned} u(x, y, z) &= \sum_{m,n=-\infty}^{\infty} (a_{mn}^{+} e^{\nu_{mn} z} + a_{mn}^{-} e^{-\nu_{mn} z}) e^{i(mx+ny)}, \quad z < z_1, \\ u(x, y, z) &= \sum_{m,n=-\infty}^{\infty} (b_{mn}^{+} e^{\nu_{mn} z} + b_{mn}^{-} e^{-\nu_{mn} z}) e^{i(mx+ny)}, \quad z > z_2, \end{aligned} \tag{9}$$

in which

$$\nu_{mn}^2 = -\epsilon_0\mu_0\omega^2 + (m+\kappa_1)^2 + (n+\kappa_2)^2, \tag{10}$$

provided that $\nu_{mn}^2 \neq 0$ for all integer pairs (m,n). If $\nu_{mn}^2 = 0$ for some pair (m,n), then its contribution to the sum (9) must be replaced by

$$\begin{array}{ll} (a_{mn}^+ + a_{mn}^- z)e^{i(mx+ny)}, & z < z_1, \\ (b_{mn}^+ z + b_{mn}^-)e^{i(mx+ny)}, & z > z_2. \end{array} \tag{11}$$

For a finite number of pairs (m,n) we have $\nu_{mn}^2 < 0$, and we take $\operatorname{Im}\nu_{mn} > 0$; these correspond to the harmonics in (9) whose two terms have constant modulus and oscillate as functions of z. We denote this set of *propagating harmonics* by $\mathcal{P}$:

$$\mathcal{P} = \left\{(m,n) \in \mathbb{Z}^2 : \nu_{mn}^2 < 0\right\} \qquad \text{(propagating Fourier harmonics)}. \tag{12}$$

We call the harmonics of the form (11), for which $\nu_{mn}^2 = 0$, the *linear harmonics*. We denote the union of the linear and propagating harmonics by $\tilde{\mathcal{P}}$:

$$\tilde{\mathcal{P}} = \left\{(m,n) \in \mathbb{Z}^2 : \nu_{mn}^2 \leq 0\right\} \quad \text{(linear and propagating Fourier harmonics)}. \tag{13}$$

For a generic set of parameters ϵ_0, μ_0, α, $\boldsymbol{\kappa}$, and ω, there are no linear harmonics; that is, $\tilde{\mathcal{P}} = \mathcal{P}$. For all pairs such that $\nu_{mn}^2 > 0$ we take $\operatorname{Re}\nu_{mn} > 0$; these correspond to the exponential harmonics. We require the solution u to be bounded, so that

$$a_{mn}^- = 0 \quad \text{and} \quad b_{mn}^+ = 0 \quad \text{for all linear and exponential harmonics}, \tag{14}$$

to exclude unbounded growth as $|z| \to \infty$. The harmonics that are exponentially decaying as $|z| \to \infty$ are called the decaying harmonics, or *evanescent harmonics*.

The energy conservation law holds for solutions of the Helmholtz equation. This means that the the time-averaged energy flux through in $\mathcal{S}$ through planes parallel to the xy-plane is independent of z. Only the propagating harmonics contribute to this energy, and equating its values through Γ_1 and Γ_2 gives

$$\sum_{(m,n)\in\mathcal{P}} \nu_{mn}\left(|a_{mn}^+|^2 - |a_{mn}^-|^2\right) = \sum_{(m,n)\in\mathcal{P}} \nu_{mn}\left(|b_{mn}^+|^2 - |b_{mn}^-|^2\right). \tag{15}$$

A *guided mode* u, which we will define precisely in Definition 2.3, is a nonzero solution of the Helmholtz equation with exponential decay as $|z| \to \infty$. If u satisfies the condition (14) of boundedness as well as the vanishing of the linear and propagating harmonics, that is, $a_{mn}^+ = a_{mn}^- = b_{mn}^+ = b_{mn}^- = 0$ for all $(m,n) \in \tilde{\mathcal{P}}$, then u has exponential decay as $|z| \to \infty$, and its periodic extension to $\mathbb{R}^3$ is a guided mode. In the generic case that there are no linear harmonics, that is, $\nu_{mn}^2 \neq 0$ for each (m,n), we may characterize guided modes by the condition that

$$a_{mn}^- = 0 \quad \text{and} \quad b_{mn}^+ = 0 \qquad \text{for all } (m,n) \qquad (\text{if } \tilde{\mathcal{P}} = \mathcal{P}). \tag{16}$$

Indeed, (16) and (15) together imply in this case the *vanishing of all propagating harmonics as well as all exponentially growing harmonics.* In the general case, in which linear harmonics may exist, we must augment this condition to exclude these harmonics explicitly:

$$\begin{array}{lll} a_{mn}^- = 0 \quad \text{and} \quad b_{mn}^+ = 0 & \text{for all} & (m,n), \\ a_{mn}^+ = 0 \quad \text{and} \quad b_{mn}^- = 0 & \text{if} & \nu_{mn}^2 = 0. \end{array} \tag{17}$$

The reason for treating the case of no linear harmonics specially is that the condition (16) is simple. In fact, it is equivalent to the condition that u obey the following Dirichlet-to-Neumann map on Γ defined in terms of the Fourier coefficients of u restricted to Γ_1 and Γ_2:

(18)
$$\begin{array}{lllll} \text{If} & u|_{\Gamma_1} = \sum a_{mn} e^{i(mx+ny)} & \text{and} & u|_{\Gamma_2} = \sum b_{mn} e^{i(mx+ny)}, \\ \text{then} & \partial_n u|_{\Gamma_1} = -\sum \nu_{mn} a_{mn} e^{i(mx+ny)} & \text{and} & \partial_n u|_{\Gamma_2} = -\sum \nu_{mn} b_{mn} e^{i(mx+ny)}, \end{array}$$

in which the sum is over all integer pairs (m, n). This motivates the definition of an operator B on functions defined on Γ, which will enable us to give a precise formulation of a guided mode. For the differential, or strong, formulation, this Dirichlet-to-Neumann map needs to be defined only for twice differentiable functions in $\mathcal{R} \setminus \Sigma$ whose first derivative is continuous up to Γ. We give a refined definition that will accommodate the variational, or weak, formulation, which includes functions in $H^1(\mathcal{R})$, that is, functions belonging to $L^2(\mathcal{R})$ that possess weak first derivatives also belonging to $L^2(\mathcal{R})$. For such functions, a restriction to Γ is well defined as a function in the fractional Sobolev space $H^{1/2}(\Gamma)$, but a normal derivative is not well defined. The Dirichlet-to-Neumann map is replaced by a bounded operator B from $H^{1/2}(\Gamma)$ to its dual space $H^{-1/2}(\Gamma)$, which coincides with the Dirichlet-to-Neumann map (18) when restricted to twice differentiable functions with continuous derivatives up to Γ.

DEFINITION 2.1 (Dirichlet-to-Neumann map B). *Let $f \in H^{1/2}(\Gamma)$ be given, and represent f as $f = (f^1, f^2)$ according to the decomposition $H^{1/2}(\Gamma) = H^{1/2}(\Gamma_1) \oplus H^{1/2}(\Gamma_2)$. Set $\hat{f}_{mn} = (\hat{f}^1_{mn}, \hat{f}^2_{mn})$, where $\hat{f}^{1,2}_{mn}$ are the Fourier coefficients of $f^{1,2}$. Note that $\nu_{mn}\hat{f}_{mn} = (\nu_{mn}\hat{f}^1_{mn}, \nu_{mn}\hat{f}^2_{mn}) \in H^{-1/2}(\Gamma_1) \oplus H^{-1/2}(\Gamma_2) = H^{-1/2}(\Gamma)$, and define Bf through its Fourier coefficients by setting*

$$(\widehat{Bf})_{mn} = \nu_{mn}\hat{f}_{mn} \qquad \textit{(definition of } B\textit{).} \tag{19}$$

We use integral notation to denote the action of the function $Bf \in H^{-1/2}(\Gamma)$ on $g \in H^{1/2}(\Gamma)$, and this action is concretely expressed through the Fourier coefficients of f and g:

$$\int_\Gamma (Bf)g = \sum_{m,n=-\infty}^{\infty} \nu_{mn}(\hat{f}^1_{mn}\hat{g}^1_{mn} + \hat{f}^2_{mn}\hat{g}^2_{mn}). \tag{20}$$

The action of Bf restricted to Γ_j, for $j = 1, 2$, is given by

$$\int_{\Gamma_j} (Bf)g = \sum_{m,n=-\infty}^{\infty} \nu_{mn}\hat{f}^j_{mn}\hat{g}^j_{mn}.$$

If all the ν_{mn} are positive, that is, if $\tilde{\mathcal{P}} = \emptyset$, then B is a positive operator; that is, for each $f \in H^{1/2}(\mathcal{R})$, $\int_\Gamma (Bf)\bar{f} > 0$.

We are now ready to state the condition that allows a precise definition of a guided mode. Condition 2.2 makes precise the behavior of a solution to the Helmholtz equation (8) at the surfaces of discontinuity of the functions ε and μ (see (3)) and enforces the exponential decay through the Dirichlet-to-Neumann operator B. The condition (17) necessary when linear harmonics are present is stated separately for that case (see (21)).

CONDITION 2.2 (strong condition for a guided mode). *Let u be a twice differentiable function in $\mathcal{S} \setminus (\Sigma \cup \Gamma)$ with continuous value and first derivative up to $\partial\mathcal{S}$, Σ,*

and Γ. *Denote by* $\partial_n u_\pm$ *the values of the normal derivative of* u *on* Σ *and* Γ, *where the* $+$*-sign refers to the side toward the direction of the normal vector* n. *If* $\nu_{mn}^2 \neq 0$ *for all* (m,n), *then* u *satisfies the strong condition for a guided mode, provided that*

i. $(\nabla + i\boldsymbol{\kappa})^2 u + \mu_0\epsilon_0\omega^2 u = 0$ *in* $\mathcal{S}\setminus\mathcal{R}$,
ii. $(\nabla + i\boldsymbol{\kappa})^2 u + \alpha\mu_0\epsilon_0\omega^2 u = 0$ *in* $\mathcal{S}\setminus\Omega$,
iii. $(\nabla + i\boldsymbol{\kappa})^2 u + \alpha\mu_1\epsilon_1\omega^2 u = 0$ *in* Ω,
iv. u *is continuous in* $\mathcal{S}$,
v. $\partial_n u_+ = \partial_n u_- = -Bu$ *on* Γ,
vi. $\mu_1(\partial_n u_+ + (i\boldsymbol{\kappa}\cdot n)u) = \mu_0(\partial_n u_- + (i\boldsymbol{\kappa}\cdot n)u)$ *on* Σ,
vii. $u(-\pi,y,z) = u(\pi,y,z)$ *and* $\partial_n u(-\pi,y,z) = -\partial_n u(\pi,y,z)$,
viii. $u(x,-\pi,z) = u(x,\pi,z)$ *and* $\partial_n u(x,-\pi,z) = -\partial_n u(x,\pi,z)$.

If $\nu_{mn} = 0$ *for some* (m,n), *then for each such pair we require, in addition, that the corresponding Fourier coefficient of* u *be zero on* Γ*:*

$$(2\pi)^2(\widehat{u|_{\Gamma_j}})_{mn} = \int_{\Gamma_j} u(x,y,z)e^{-i(mx+ny)} = 0, \quad j = 1,2 \qquad ((m,n)\in\tilde{\mathcal{P}}\setminus\mathcal{P}). \tag{21}$$

Definition 2.3 (guided mode). *A* guided mode *in the augmented periodic slab structure* $\tilde{\Omega}_{aug}$ *is the pseudoperiodic extension to* $\mathbb{R}^3$ *of a function of the form*

$$u(x,y,z)e^{i(\kappa_1 x+\kappa_2 y-i\omega t)},$$

in which u *satisfies the strong Condition* 2.2.

It is possible to restrict analysis to the region $\mathcal{R}$, for if we omit the condition (i) and the first equality in (v), then a function in $\overline{\mathcal{R}}$ (the closure of $\mathcal{R}$) satisfying the remaining conditions can be extended in a unique way to $\mathcal{S}$ such that (i) is satisfied simply by declaring

$$\begin{aligned} u(x,y,z) &= \sum_{m,n=-\infty}^{\infty} a_{mn}e^{\nu_{mn}(z-z_1)}e^{i(mx+ny)}, \quad z\le z_1, \\ u(x,y,z) &= \sum_{m,n=-\infty}^{\infty} b_{mn}e^{-\nu_{mn}(z-z_2)}e^{i(mx+ny)}, \quad z\ge z_2, \end{aligned} \tag{22}$$

in which a_{mn} are the Fourier coefficients of $u|_{\Gamma_1}$ and b_{mn} are the Fourier coefficients of $u|_{\Gamma_2}$, for this function satisfies the condition $Bu = \partial_n u_+ = \partial_n u_-$ on Γ.

We will need a variational formulation for guided modes. The appropriate function space is the periodic subspace $H^1_{\rm per}(\mathcal{R})$ of the Sobolev space $H^1(\mathcal{R})$ of functions in $L^2(\mathcal{R})$ with weak gradients in $L^2(\mathcal{R})$: $H^1_{\rm per}(\mathcal{R})$ is the subspace of functions $f\in H^1(\mathcal{R})$ satisfying $f(-\pi,y,z) = f(\pi,y,z)$ and $f(x,-\pi,z) = f(x,\pi,z)$, where the boundary values of f are well defined by a bounded trace operator to $H^{1/2}(\partial\mathcal{S})$. $H^1_{\rm per}(\mathcal{R})$ is a Hilbert space, retaining the same inner product as $H^1(\mathcal{R})$:

$$(u,v)_{H^1(\mathcal{R})} = \int_{\mathcal{R}} (u\bar{v} + \nabla u\nabla\bar{v}).$$

In referring to the trace of f on Γ, we will be more precise and denote the trace operator by $T: H^1(\mathcal{R})\to H^{1/2}(\Gamma)$, so that the restriction of f to Γ is denoted by Tf.

Condition 2.4 (weak condition for a guided mode, first form). *A function* $u\in H^1_{per}(\mathcal{R})$ *satisfies the weak condition for a guided mode, provided*

$$\int_{\mathcal{R}} \frac{1}{\mu}(\nabla + i\boldsymbol{\kappa})u\cdot(\nabla - i\boldsymbol{\kappa})\bar{v} + \frac{1}{\mu_0}\int_\Gamma (BTu)(T\bar{v}) - \int_{\mathcal{R}} \varepsilon\omega^2 u\bar{v} = 0 \quad \textit{for all} \quad v\in H^1_{per}(\mathcal{R}). \tag{23}$$

In case $\nu_{mn}^2 = 0$ *for any pair* (m,n), *it is required additionally that* $(\widehat{Tf})_{mn} = 0$.

The sesquilinear form in Condition 2.4 is conjugate-symmetric in $H^1_{\text{per}}(\mathcal{R})$ if and only if $\mathcal{P} = \emptyset$. We introduce a subspace X in which it is always conjugate-symmetric, and, in fact, positive, namely, the subspace of functions whose traces on Γ have vanishing Fourier coefficients for $(m,n) \in \tilde{\mathcal{P}}$.

$$(\widehat{Tf})_{mn} = 0 \quad \text{for} \quad (m,n) \in \tilde{\mathcal{P}} \qquad \text{(defining condition for } f \in X\text{)},$$

or, equivalently,

$$\int_{\Gamma_1} (Tf) e^{-i(mx+ny)} = \int_{\Gamma_2} (Tf) e^{-i(mx+ny)} = 0 \quad \text{for} \quad (m,n) \in \tilde{\mathcal{P}} \quad \text{(condition for } f \in X\text{)}.$$

X is closed under the norm of $H^1(\mathcal{R})$. In order to exclude linear and propagating Fourier harmonics from the extension to all of $\mathcal{S}$ of a function f in X, which has well defined normal derivatives on Γ, *it must also be demanded that the normal derivative have vanishing Fourier coefficients for* $(m,n) \in \tilde{\mathcal{P}}$. We give an alternate variational formulation of guided modes in the weak Condition 2.5.

CONDITION 2.5 (weak condition for a guided mode, second form). *A function* $u \in H^1_{per}(\mathcal{R})$ *that possesses a normal derivative on* Γ *satisfies the weak condition for a guided mode, provided that* $u \in X$ *and*

i. $\int_{\mathcal{R}} \frac{1}{\mu} (\nabla + i\boldsymbol{\kappa}) u \cdot (\nabla - i\boldsymbol{\kappa}) \bar{v} + \frac{1}{\mu_0} \int_\Gamma (BTu)(T\bar{v}) - \int_{\mathcal{R}} \varepsilon\omega^2 u\bar{v} = 0$ *for all* $v \in X$,

ii. $(\widehat{\partial_n u|_\Gamma})_{mn} = 0$ *for all* $(m,n) \in \tilde{\mathcal{P}}$.

We prove in Theorem 2.7 that Conditions 2.2, 2.4, and 2.5 are all equivalent. In particular, a function in $H^1_{\text{per}}(\mathcal{R})$ that satisfies Condition 2.4 is in fact regular and satisfies the other two conditions, and Condition 2.5.i actually implies the existence of a normal derivative on Γ.

In section 3, we will show the existence of a sequence of relations between α and ϵ_1, for each choice of ω and $\boldsymbol{\kappa}$, that describe all of the pairs (α, ϵ_1) that support a solution of Condition 2.5.i. Because these solutions are in X, the coefficients in their Fourier expansion for all $(m,n) \in \mathcal{P}$ (see (9)) satisfy

$$|a^+_{mn}| - |a^-_{mn}| = 0 \quad \text{and} \quad |b^+_{mn}| - |b^-_{mn}| = 0,$$

implying the vanishing of energy flux in the z direction.

Condition 2.5.ii indicates that guided modes typically do not exist in the $(\boldsymbol{\kappa}, \omega)$-regime of propagating or linear harmonics ($\tilde{\mathcal{P}} \neq \emptyset$) due to this extra condition that each of these harmonics must satisfy. The vanishing of this finite number of harmonics must be accomplished through the tuning of other parameters of the structure. In particular, if the structure is symmetric about the yz-plane and $\boldsymbol{\kappa} = (0, \kappa_2, 0)$, or it is symmetric about the xz-plane and $\boldsymbol{\kappa} = (\kappa_1, 0, 0)$, then the functions satisfying Condition 2.5.i are symmetric or antisymmetric. We focus on structures with symmetry about the yz-plane. Ω is symmetric about the yz-plane if

$$(x,y,z) \in \Omega \implies (-x,y,z) \in \Omega.$$

In this case, the antisymmetric solutions to (i) also satisfy (ii) for all $(m,n) \in \tilde{\mathcal{P}}$ with m even. Thus, if there is only one propagating mode $(0,0)$ and the rest are evanescent, then Condition 2.5 is satisfied in full, and the solutions therefore represent *nonrobust guided modes* traveling parallel to the plane of symmetry. These modes are nonrobust because, under a general perturbation of κ_1 or the structure itself, the $(0,0)$ harmonic, which is not evanescent, is no longer guaranteed to vanish.

We make the formulation for an antisymmetric nonrobust mode in a symmetric structure precise in Condition 2.6 and Theorem 2.7. For this, we introduce the orthogonally complementary subspaces X^{sym} and X^{ant} of X to treat the case that Ω is symmetric about the yz-plane, $\kappa_1 = 0$, and $\tilde{\mathcal{P}} \neq \emptyset$:

$$X^{\mathrm{sym}} = \{v \in X : v(x,y,z) = v(x,y,z) \text{ a.e. in } \mathcal{R}\},$$
$$X^{\mathrm{ant}} = \{v \in X : v(x,y,z) = v(-x,y,z) \text{ a.e. in } \mathcal{R}\}.$$

It is straightforward to verify that X^{sym} and X^{ant} are orthogonal in the usual H^1 and L^2 inner products on X and with respect to the sesquilinear form on the left-hand side of Condition 2.6.i:

$$X = X^{\mathrm{sym}} \oplus X^{\mathrm{ant}}.$$

CONDITION 2.6 (weak condition for a nonrobust guided mode). *Suppose that Ω is symmetric about the yz-plane and that $\kappa_1 = 0$. A function $u \in H^1_{per}(\mathcal{R})$ satisfies the weak condition for an antisymmetric nonrobust mode, provided $u \in X^{ant}$ and*

i. $\int_{\mathcal{R}} \frac{1}{\mu}(\nabla + i\boldsymbol{\kappa})u \cdot (\nabla - i\boldsymbol{\kappa})\bar{v} + \frac{1}{\mu_0}\int_\Gamma (BTu)(T\bar{v}) - \int_{\mathcal{R}} \varepsilon\omega^2 u\bar{v} = 0$ *for all* $v \in X^{ant}$,

ii. $\tilde{\mathcal{P}} \neq \emptyset$ *and* $(\partial_n \widehat{u|_\Gamma})_{mn} = 0$ *for all* $(m,n) \in \tilde{\mathcal{P}}$ *with* m *odd.*

THEOREM 2.7 (equivalence of strong and weak conditions).

i. *Let u satisfy Condition* 2.2. *Then the restriction of u to $\mathcal{R}$ is in $H^1_{per}(\mathcal{R})$ and satisfies Condition* 2.4.

ii. *Let u satisfy Condition* 2.4. *Then u can be extended to a twice differentiable function in $\mathcal{S} \setminus (\Sigma \cup \Gamma)$ with continuous value and first derivative up to $\partial\mathcal{S}$, Σ, and Γ. This extension satisfies Condition* 2.2, *and u is in X and satisfies Condition* 2.5.

iii. *If u satisfies Condition* 2.5, *then u satisfies Condition* 2.4.

iv. *If u satisfies Condition* 2.6, *then u satisfies Condition* 2.5 *(for $\kappa_1 = 0$).*

3. Existence of guided modes. The theoretical development presented in this section is in essence that followed in [6]. Nevertheless, we feel that complete proofs are necessary to ensure that consistency and mathematical rigor is observed. The proofs are given in the appendix (section 6).

Define the following sesquilinear forms in $H^1_{\mathrm{per}}(\mathcal{R})$:

$$A(u,v) = \int_{\mathcal{R}} \frac{1}{\mu}(\nabla + i\boldsymbol{\kappa})u \cdot (\nabla - i\boldsymbol{\kappa})\bar{v} + \frac{1}{\mu_0}\int_\Gamma (BTu)(T\bar{v}), \tag{24}$$

$$\ell(u,v) = \int_{\mathcal{R}\setminus\Omega} \epsilon_0\omega^2 u\bar{v} + \int_\Omega \epsilon_1\omega^2 u\bar{v}. \tag{25}$$

Notice that A depends on $\boldsymbol{\kappa}$, ω, ϵ_0, μ_0, and μ_1 (the dependence on ω and ϵ_0 is through B—see (19) and (10)), and ℓ depends on ω, ϵ_0, and ϵ_1; neither of them depends on α.

A function $u \in H^1_{\mathrm{per}}(\mathcal{R})$ satisfies the weak condition for a guided mode if and only if $A(u,v) - \alpha\ell(u,v) = 0$ for each $v \in H^1_{\mathrm{per}}(\mathcal{R})$. This is equivalent to the condition that u is an eigenfunction of the map $H^1_{\mathrm{per}}(\mathcal{R}) \to H^1_{\mathrm{per}}(\mathcal{R})^* :: u \mapsto \overline{A(u,\cdot)}$ (the asterisk denotes the dual space) with eigenvalue α in the sense that

$$A(u,\cdot) = \ell(\alpha u, \cdot).$$

If the set of propagating harmonics is empty ($\mathcal{P} = \emptyset$), then A is conjugate-symmetric; that is, $A(u,v) = \overline{A(v,u)}$ for all $u, v \in H^1_{\mathrm{per}}(\mathcal{R})$. Otherwise, it is not due

to the purely imaginary values of ν_{mn} in the definition (2.1) of B for $(m,n) \in \mathcal{P}$. In X, both A and ℓ are conjugate-symmetric, and therefore the eigenvalues α are real.

Define the Rayleigh quotient by

$$J(u) = \frac{A(u,u)}{\ell(u,u)} = \frac{\int_{\mathcal{R}} \frac{1}{\mu} |(\nabla + i\boldsymbol{\kappa})u|^2 + \frac{1}{\mu_0}\int_\Gamma (BTu)(T\bar{u})}{\epsilon_0\omega^2 \int_{\mathcal{R}\setminus\Omega} |u|^2 + \epsilon_1\omega^2 \int_\Omega |u|^2}. \tag{26}$$

Recall that the operator B depends on κ, ω, ϵ_0, and μ_0, but not on ϵ_1. The dependence of $J(u)$ on ϵ_1 comes only in the second term of ℓ. For an exposition of the role of the Rayleigh quotient in the theory of eigenvalues of elliptic operators, the reader may refer to Jost [7, section 8.5] or Gould [8, Chapter II]; a more brief discussion is found in Gilbarg and Trudinger [9, section 8.12].

THEOREM 3.1 (eigenvalue sequences). *There exists a sequence of real numbers (eigenvalues) $\{\alpha_j\}_{j=0}^\infty$ and functions (eigenfunctions) $\{\psi_j\}_{j=0}^\infty$ such that*

i. $0 < \alpha_0 \le \alpha_1 \le \cdots \le \alpha_j \le \cdots$,
ii. $\alpha_j \to \infty$ *as* $j \to \infty$,
iii. $A(\psi_j, v) = \alpha_j \ell(\psi_j, v)$ *for all* $v \in X$,
iv. *if* $A(\psi, v) = \alpha\ell(\psi, v)$ *for all* $v \in X$, *then there is an integer* j *such that* $\alpha = \alpha_j$ *and* $\psi \in span\{\psi_k : \alpha = \alpha_k\}$,
v. *the sequence* $\{\psi_j\}_{j=0}^\infty$ *is an orthonormal Hilbert-space basis for* $L^2(\mathcal{R}, \ell)$.

The eigenvalues and eigenfunctions arise from the process of successive minimization of the Rayleigh quotient:

$$\alpha_j = \inf_{u \in X_j, u \neq 0} J(u) = J(\psi_j), \quad \psi_j \in X_j,$$

in which

$$X_j = \{v \in X : A(\psi_k, v) = 0 \text{ for } k = 0, \ldots, j-1\}.$$

If Ω is symmetric about the yz-plane and $\kappa_1 = 0$, then $\{\psi_j\}_{j=0}^\infty$ is the union of two nondecreasing sequences $\{\psi_j^{sym}\}_{j=0}^\infty$ and $\{\psi_j^{ant}\}_{j=0}^\infty$ from X^{sym} and X^{ant}, respectively. We denote the associated sequences of eigenvalues by $\{\alpha_j^{sym}\}_{j=0}^\infty$ and $\{\alpha_j^{ant}\}_{j=0}^\infty$. The symmetric and antisymmetric eigenfunctions and associated eigenvalues arise from minimization of the Rayleigh quotient over X^{sym} and X^{ant}:

$$\alpha_j^{ant} = \inf_{u \in X_j^{ant}, u \neq 0} J(u) = J(\psi_j^{ant}), \quad \psi_j \in X_j^{ant},$$

in which

$$X_j^{ant} = \{v \in X^{ant} : A(\psi_k^{ant}, v) = 0 \text{ for } k = 0, \ldots, j-1\}.$$

LEMMA 3.2. *The eigenvalues α_j are continuous strictly decreasing functions of ϵ_1, and $\alpha_j \to 0$ as $\epsilon_1 \to \infty$. Similarly, the α_j are continuous strictly decreasing functions of μ_1, and $\alpha_j \to 0$ as $\mu_1 \to \infty$.*

Using this lemma, let us parse Theorem 3.1 in a form in which α is fixed, so that the functions ε and μ given by (3) outside of the domain Ω are fixed. For the sake of argument, let us also fix μ and denote the dependence of α_j on ϵ_1 by $\alpha_j(\epsilon_1)$. Since $\alpha_j(\epsilon_1) \nearrow \infty$ as $j \to \infty$ and because of Lemma 3.2, we may set

$$N_\alpha = \min\left\{j : \lim_{\epsilon \to 0} \alpha_j(\epsilon) > \alpha\right\}$$

and implicitly define a nondecreasing sequence of material parameters $\epsilon_1 = \{E_j(\alpha)\}_{j=N_\alpha}^{\infty}$ and a sequence of corresponding functions $\{\phi_j(\alpha)\}_{j=N_\alpha}^{\infty}$ that satisfy

$$\alpha_j(E_j(\alpha)) = \alpha, \qquad \phi_j(\alpha) = \psi_j(E_j(\alpha)).$$

Because the functions $\alpha_j(\epsilon_1)$ are continuous and strictly decreasing in ϵ, the values $E_j(\alpha)$ are defined uniquely, and, as functions of α, are continuous and strictly decreasing. By Theorem 3.1, these sequences satisfy

$$A(\phi_j(\alpha), v) = \alpha \ell_{E_j(\alpha)}(\phi_j(\alpha), v) \qquad \text{for all } v \in X.$$

If ω and $\boldsymbol{\kappa}$ are such that the medium exterior to $\mathcal{R}$ admits no propagating or linear Fourier harmonics, that is, if $\tilde{\mathcal{P}} = \emptyset$, then each $\phi_j(\alpha)$ can be extended to all of $\mathcal{S}$ as a guided mode, for the second part of Condition 2.5 requiring vanishing of all of these harmonics is vacuously satisfied.

In the case that Ω is symmetric about the yz-plane, $\boldsymbol{\kappa} = \langle 0, \kappa_2, 0\rangle$, and there is only one propagating Fourier harmonic, namely $(0,0)$, the antisymmetric eigenfunctions $\phi_j^{\text{ant}}(\epsilon_1)$ satisfy Condition 2.6 and therefore give rise to nonrobust guided modes.

We summarize these results in the following theorem.

THEOREM 3.3 (existence of guided modes). *For each $\alpha > 0$, there exists a sequence $\{E_j(\alpha)\}_{j=N_\alpha}^{\infty}$ of real numbers and a sequence $\{\phi_j(\alpha)\}_{j=N_\alpha}^{\infty}$ of functions from X such that*

i. *for each $\alpha > 0$, $0 < E_0(\alpha) \le E_1(\alpha) \le \cdots \le E_j(\alpha) \le \cdots$,*
ii. *for each $\alpha > 0$, $E_j(\alpha) \to \infty$ as $j \to \infty$,*
iii. *for each integer $n \ge 0$, $E_j(\alpha)$ is a strictly decreasing function of α, and $E_j(\alpha) \to \infty$ as $\alpha \to 0$,*
iv. *$\phi_j(\alpha)$ satisfies Condition* 2.5.i *for guided modes.*

If ω and $\boldsymbol{\kappa}$ are such that the medium exterior to $\mathcal{R}$ admits no propagating or linear Fourier harmonics, that is, if $\tilde{\mathcal{P}} = \emptyset$, then for each α and each j, the function $\phi_j(\alpha)$ satisfies both conditions of Condition 2.5. *In particular, it can be extended into $\mathcal{S}$ to a function that satisfies Condition* 2.2 *and gives rise to a guided mode*

$$\psi_j(\alpha)(x,y,z)e^{i(\kappa_1 x + \kappa_2 y - \omega t)}$$

in the augmented slab structure defined by the functions (3).

If Ω is symmetric about the yz-plane, $\boldsymbol{\kappa} = (0, \kappa_2, 0)$, and there is only one propagating Fourier harmonic $(0,0)$, the rest being evanescent, then for each α and j the function $\psi_j^{ant}(\alpha)$ satisfies Condition 2.5. *In particular, it can be extended into $\mathcal{S}$ to a function that satisfies Condition* 2.2, *giving rise to a nonrobust guided mode traveling parallel to the yz-plane:*

$$\psi_j^{ant}(\alpha)(x,y,z)e^{(\kappa_2 y - i\omega t)}.$$

An analogous statement holds if Ω is symmetric about the xz-plane.

There are two special cases of interest:

A. Taking $\alpha = 1$ gives the unaugmented structure $\tilde{\Omega}$, as the material properties ε and μ in $\mathcal{S} \setminus \mathcal{R}$ and $\mathcal{R} \setminus \Omega$ coincide:

$$\varepsilon(r) = \begin{cases} \epsilon_0, & r \in \mathcal{S} \setminus \Omega, \\ \epsilon_1, & r \in \Omega, \end{cases} \qquad \text{and} \quad \mu(r) = \begin{cases} \mu_0, & r \in \mathcal{S} \setminus \Omega, \\ \mu_1, & r \in \Omega. \end{cases}$$

Theorem 3.3 gives a sequence of constants $\epsilon_1 = E_j(1)$ for which a guided mode exists, provided the vanishing of all linear and propagating harmonics.

B. Fixing $\epsilon_1 = \epsilon_0$ and $\mu_1 = \mu_0$ corresponds to the case of a slab with no periodic structure, having uniform material properties in $\mathcal{R}$:

$$\varepsilon(x,y,z) = \begin{cases} \alpha\epsilon_0, & z \in \mathcal{R}, \\ \epsilon_0, & z \notin \mathcal{R}, \end{cases} \quad \text{and} \quad \mu(x,y,z) = \mu_0. \tag{27}$$

We analyze this instructive case explicitly in subsection 4.1.

4. Nonexistence of guided modes in inverse structures. An "inverse structure" is one in which the speed of light is higher than the speed of light in the surrounding medium. This means that $\epsilon_1\mu_1 < \epsilon_0\mu_0$. Using the sequences of eigenvalues constructed in section 3, we prove that certain inverse structures cannot support guided modes, robust or nonrobust. Specifically, we fix $\mu_1 = \mu_0 > 0$ arbitrarily and take $0 < \epsilon_1 < \epsilon_0$. Our statement requires an additional restriction on the width of the slab that depends on the material parameters, frequency, and wavevector (33). We do not know whether this restriction arises only as a consequence of our method of proof or whether it is truly necessary.

It is known that under a certain restrictive geometric condition, guided modes do not exist in inverse structures. Theorem 3.5 of [6], extended to three-dimensional structures, amounts to the following conditions for homogeneous slabs:

a. the surface Σ of the slab has two sides, given by $z = f_1(x,y) \le 0$ and $z = f_2(x,y) \ge 0$, where the common domain of f_1 and f_2 is a subset of the square $\{-\pi \le x,y \le \pi\}$;
b. $\epsilon_1\mu_1 \le \epsilon_0\mu_0$; that is, the celerity inside the slab is greater than that outside the slab (as for a film of air within a ceramic matrix).

The first condition is a severe restriction. It excludes, among other types of structures, periodic arrays of ellipses that do not have a major axis parallel to the z-axis and structures that some line parallel to the z-axis intersects in more than one segment.

In addition, it is shown in [6, Theorem 4.1] that, for a given wavevector $\boldsymbol{\kappa}$, the set of frequencies for which a guided mode exists is greater than $|\boldsymbol{\kappa}|/n_+$, where n_+ is the maximum value of $\epsilon\mu$. It follows that, if $\epsilon_1\mu_1 < \epsilon_0\mu_0$, then robust guided modes do not exist.

Our approach to proving the nonexistence of both types of modes for $\mu_1 = \mu_0$ is first to compute explicitly the eigenvalues $\alpha_j(\epsilon_0)$, corresponding to the case $\epsilon_1 = \epsilon_0$, in which the slab $\tilde{\Omega}_{\text{aug}}$ has no genuine periodicity and then to use the restriction on the width (33) to prove that the eigenvalues are all greater than or equal to 1. Finally, since the eigenvalues are decreasing as a function of ϵ_1, we observe that $\alpha_j(\epsilon_1) > 1$ for $\epsilon_1 < \epsilon_0$. As $\alpha = 1$ corresponds to the unaugmented periodic slab structure $\tilde{\Omega}$ with material constant ϵ_1 surrounded by a medium with constant ϵ_0, we conclude that no guided modes exist in $\tilde{\Omega}$ for $\epsilon_1 < \epsilon_0$.

Indeed, if $\epsilon_1 > \epsilon_0$, we have seen that nonrobust modes exist in symmetric structures if κ_1 or κ_2 vanishes. In fact, this restriction is not necessary: in [6], nonrobust modes are constructed for arbitrary Bloch wavevectors for two-dimensional slabs.

4.1. Eigenvalues for a flat slab. We explicitly compute the eigenvalues α_j and corresponding eigenfunctions ψ_j when $\epsilon_1 = \epsilon_0$ and $\mu_1 = \mu_0$ (see (27)). In this situation, the eigenfunctions satisfy the strong form of the Helmholtz equation in $\mathcal{R}$

(with $\psi = \psi_j$ and $\alpha = \alpha_j$):

$$\begin{aligned} &(\nabla + i\boldsymbol{\kappa})^2\psi + \alpha\epsilon_0\mu_0\omega^2\psi = 0 \text{ in } \mathcal{R}, \\ &\psi \in X \quad \text{and} \quad \partial_n\psi|_\Gamma = B\psi, \\ &\psi \text{ has periodic boundary conditions in } x \text{ and } y. \end{aligned} \tag{28}$$

Since $\varepsilon(x, y, z)$ is constant in x and y and $\mathcal{R}$ is bounded by planes parallel to the three coordinate planes, the method of separation of variables is applicable. The separable solutions have the simple form

$$\psi(x, y, z) = \left(A_{mn}e^{\eta_{mn}z} + B_{mn}e^{-\eta_{mn}z}\right)e^{i(mx+ny)}, \quad m, n \in \mathbb{Z}, \tag{29}$$

in which

$$\eta_{mn}^2 = (m + \kappa_1)^2 + (n + \kappa_2)^2 - \alpha\epsilon_0\mu_0\omega^2 \tag{30}$$

and $\operatorname{Im}\eta_{mn} > 0$ if $\eta_{mn}^2 < 0$ and $\operatorname{Re}\eta_{mn} > 0$ if $\eta_{mn}^2 > 0$. If $\eta_{mn} = 0$, then

$$\psi(x, y, z) = (A_{mn} + B_{mn}z)\,e^{i(mx+ny)}. \tag{31}$$

Each solution of the Helmholtz equation with periodic boundary conditions is a series superposition of separable solutions,

$$\psi(x, y, z) = \sum_{m,n=-\infty}^{\infty} \phi_{mn}(z)e^{i(mx+ny)},$$

in which ϕ_{mn} is of the form shown in (29) or (31). Moreover, the conditions that $\psi \in X$ and $\partial_n\psi\,|_\Gamma = B\psi$ impose *independent* conditions on the Fourier harmonics indexed by m and n on the boundary Γ:

$$\begin{aligned} &\left(\widehat{\psi|_\Gamma}\right)_{mn} = 0 \quad \text{for } (m, n) \in \tilde{\mathcal{P}}, \\ &\left(\partial_z\widehat{\psi|_{\Gamma_1}}\right)_{mn} = \nu_{mn}\left(\widehat{\psi|_{\Gamma_1}}\right)_{mn} \text{ and } \left(\partial_z\widehat{\psi|_{\Gamma_2}}\right)_{mn} = -\nu_{mn}\left(\widehat{\psi|_{\Gamma_2}}\right)_{mn} \text{ for } (m, n) \notin \tilde{\mathcal{P}}. \end{aligned} \tag{32}$$

Because of this, if ψ satisfies the Helmholtz equation as well as the boundary conditions (28), then each separable component (29) of ψ in its series representation also satisfies both. Therefore, each solution of (28) is composed of separable solutions.

To find the values of α that admit such solutions and the solutions themselves, we impose the condition (32) on the separable solution (29) or (31) for each pair (m, n). For each fixed $(m, n) \in \tilde{\mathcal{P}}$, the condition (32) is possible only for values of α for which $\eta_{mn}^2 < 0$, which give oscillatory solutions in the interval from z_1 to z_2. In addition, in order for (32) to hold, η_{mn} must be of the form $\eta_{mn} = i\left(\frac{j\pi}{z_2 - z_1}\right)$ for some j (independent of (m, n)), and we thus arrive at a sequence of eigenvalues $\alpha = \alpha_{mnj}$ satisfying

$$\alpha_{mnj}\epsilon_0\mu_0\omega^2 = \left(\frac{j\pi}{z_2 - z_1}\right)^2 + (m + \kappa_1)^2 + (n + \kappa_2)^2, \quad j = 1, 2, 3, \ldots .$$

It is straightforward to deduce from the condition (32) that the constants A_{mn} and B_{mn} in (29) have the same modulus, so that, by multiplying the solution by a unitary number $e^{i\theta}$, we may take $\phi_{mnj}(z)$ to be a shifted sine function inside the region $\mathcal{R}$. These solutions do not represent guided modes because they do not satisfy the second

part of Condition 2.5 requiring the normal derivative of ϕ_{mnj} to vanish, and therefore their extensions to all of $\mathcal{S}$ do not decay as $|z| \to \infty$.

For $(m,n) \notin \tilde{\mathcal{P}}$, the condition (32) amounts to matching a solution that is decaying as $z \to -\infty$ for $z < z_1$ to one that is decaying as $z \to \infty$ for $z > z_2$ through a solution in the interval from z_1 to z_2. This is possible only if the solution in this interval is oscillatory, and this is achievable only when $\eta_{mn}^2 < 0$. By enforcing the decay of the solution as $|z| \to \infty$, we obtain a sequence of eigenvalues $\alpha = \alpha_{mnj}$ with $\alpha_{mnj} \to \infty$ as $j \to \infty$ satisfying

$$\tan \zeta(z_2 - z_1) = \frac{2\nu_{mn}\zeta}{\zeta^2 - \nu_{mn}^2}, \qquad \zeta = \left(\alpha_{mnj}\epsilon_0\mu_0\omega^2 - (m+\kappa_1)^2 - (n+\kappa_2)^2\right)^{1/2}.$$

Again, by multiplying the solution by a unitary number, we may take $\phi_{mnj}(z)$ to be a shifted sine function inside the region $\mathcal{R}$. These solutions satisfy Condition 2.5, even when $\tilde{\mathcal{P}} \neq \emptyset$, as they involve only one Fourier harmonic.

The union of the sequences $\{\alpha_{mnj}\}$, arranged in increasing order, gives the sequence $\{\alpha_j\}$ that we seek.

As ϵ_1 is perturbed away from ϵ_0, the structure attains a genuine periodicity, and separable solutions are no longer valid. Typically all Fourier harmonics are represented in the eigenfunctions so that the guided modes disappear in a regime admitting linear or propagating harmonics. As we have seen, however, antisymmetric nonrobust modes persist, for example, in symmetric structures for which there is only one propagating harmonic, the rest being evanescent.

4.2. Nonexistence of guided modes. We use the foregoing analysis to prove a theorem stating that guided modes do not exist in certain structures in which the interior product of the material coefficients $\mu_1\epsilon_1$ is greater than the exterior product $\mu_0\epsilon_0$.

THEOREM 4.1 (nonexistence of guided modes). *Let $0 < \mu_1 \leq \mu_0$ and $0 < \epsilon_1 \leq \epsilon_0$, and let the frequency ω and wavevector $\boldsymbol{\kappa} = \langle \kappa_1, \kappa_2, 0\rangle$ be given with $\boldsymbol{\kappa}$ in the first Brillouin zone: $-\frac{1}{2} \leq \kappa_1,\kappa_2 < \frac{1}{2}$. Suppose that the slab structure $\tilde{\Omega}$ (Figure 2 with $\alpha=1$) lies between two planes $\{z = z_1\}$ and $\{z = z_2\}$ satisfying*

$$(z_2 - z_1)(\epsilon_0\mu_0\omega^2 - \kappa_1^2 - \kappa_2^2)^{1/2} \leq \pi \tag{33}$$

in the case that $\epsilon_0\mu_0\omega^2 - \kappa_1^2 - \kappa_2^2 \geq 0$, that is, $\tilde{\mathcal{P}} \neq \emptyset$ (otherwise, there is no restriction). Then the slab with material properties

$$\varepsilon(r) = \begin{cases} \epsilon_0, & r \notin \tilde{\Omega}, \\ \epsilon_1, & r \in \tilde{\Omega}, \end{cases} \qquad \text{and} \qquad \mu(r) = \begin{cases} \mu_0, & r \notin \tilde{\Omega}, \\ \mu_1, & r \in \tilde{\Omega}, \end{cases}$$

admits no guided modes at the given frequency and wavevector.

Proof. We begin showing that, for $\epsilon_1 = \epsilon_0, \mu_1 = \mu_0$, the slab admits no guided modes. This is the case of a flat slab analyzed in subsection 4.1. Recall the definition of ν_{mn}^2,

$$\nu_{mn}^2 = -\epsilon_0\mu_0\omega^2 + (m+\kappa_1)^2 + (n+\kappa_2)^2,$$

and define, for each $\alpha > 0$, as before,

$$\eta_{mn}^2(\alpha) = -\alpha\epsilon_0\mu_0\omega^2 + (m+\kappa_1)^2 + (n+\kappa_2)^2.$$

In subsection 4.1, we have seen that the eigenvalues α_j (for $\epsilon_1 = \epsilon_0, \mu_1 = \mu_0$) correspond to eigenfunctions containing a single Fourier harmonic, and we wish to show that all of these eigenvalues are greater than or equal to 1.

For those pairs (m,n) for which $\nu_{mn}^2 > 0$, corresponding to the evanescent Fourier harmonics ($(m,n) \notin \tilde{\mathcal{P}}$), we have seen in subsection 4.1 that the matching conditions at $z = z_1$ and $z = z_2$ require that $\eta_{mn}^2(\alpha) < 0$. From the definitions of ν_{mn}^2 and $\eta_{mn}^2(\alpha)$, we conclude that $\alpha > 1$, so that all the eigenvalues corresponding to the evanescent harmonics are at least greater than 1.

For $(m,n) \in \tilde{\mathcal{P}}$, we still require that $\eta_{mn}^2(\alpha) < 0$. Since $\boldsymbol{\kappa}$ is taken to lie in the first symmetric Brillouin zone, that is, $-1/2 \le \kappa_1 < 1/2$ and $-1/2 \le \kappa_2 < 1/2$, we have (recall that $\operatorname{Im}(\nu_{mn}(\alpha)) > 0$ (p. 692))

$$-i\nu_{mn} \le -i\nu_{00} \quad \text{for all} \quad (m,n) \in \tilde{\mathcal{P}}.$$

According to the discussion of the preceding subsection, to satisfy the boundary conditions at $z = z_1$ and $z = z_2$, α must be chosen such that

$$-i\eta_{mn}(\alpha) = \left(\frac{j\pi}{z_2 - z_1}\right), \quad j \text{ a positive integer.}$$

From condition (33), we obtain

$$-i\eta_{mn}(\alpha) = \frac{j\pi}{z_2 - z_1} \ge j\,(\epsilon_0\mu_0\omega^2 - \kappa_1^2 - \kappa_2^2)^{1/2} \ge -i\nu_{00} \ge -i\nu_{mn},$$

from which it follows that $\alpha \ge 1$, so that all the eigenvalues corresponding to the propagating harmonics are at least 1. As we have mentioned in the previous subsection, these eigenvalues do not correspond to guided modes.

Since the eigenvalues α_j are strictly decreasing in ϵ_1, as well as in μ_1 (Lemma 3.2), we have $\alpha_j > 1$ if both $\epsilon_1 \le \epsilon_0$ and $\mu_1 \le \mu_0$, which proves the theorem. ∎

5. Numerical computations. We compute guided modes for the Helmholtz equation. These are scalar functions u satisfying Condition 2.2, for which $\alpha = 1$. We focus on the case of one propagating Fourier harmonic, and we consider a two-dimensional reduction, in which the slab is constant in the y direction and $\kappa_2 = 0$. In this case, only the $(m,0)$ Fourier harmonics enter the fields. Our method begins with a geometry Ω that is symmetric about the yz-plane (in the two-dimensional reduction to the x and z variables, this implies symmetry about the z-axis) and given values of $\boldsymbol{\kappa}$, ϵ_0, μ_0, μ_1, and ω. The code then computes the values of ϵ_1 which give rise to a solution of the first part of Condition 2.6; in other words, it computes one of the values $E_j(\alpha)$. The second part of the condition is automatically satisfied because only one harmonic is propagating, namely that with $(m,n) = (0,0)$. The corresponding antisymmetric nonrobust guided mode u is also computed.

We use a finite element solver in the finite rectangular region $\mathcal{R}$ for the eigenvalue problem, with ϵ_1 as the eigenvalue, for the Helmholtz equation in two variables, x and z:

$$(\nabla + i\kappa)\cdot(\nabla + i\kappa)u + \epsilon_0\mu_0\omega^2 u = 0 \quad \text{in } \mathcal{R}\setminus\Omega, \tag{34}$$

$$(\nabla + i\kappa)\cdot(\nabla + i\kappa)u = -\epsilon_1\mu_0\omega^2 u \quad \text{in } \Omega, \tag{35}$$

$$\mu_1\,(\partial_n u_+ + (i\boldsymbol{\kappa}\cdot n)u) = \mu_0\,(\partial_n u_- + (i\boldsymbol{\kappa}\cdot n)u) \quad \text{on } \Sigma, \tag{36}$$

$$u(-\pi,z) = u(\pi,z) \quad \text{and} \quad \partial_n u(-\pi,z) = -\partial_n u(\pi,z), \tag{37}$$

$$\partial_n u + \nu_0 u = 0 \quad \text{on the edges } z = z_1 \text{ and } z = z_2. \tag{38}$$

Note that since we assumed that only one harmonic propagates, $\nu_0 = i\sqrt{\epsilon_0\mu_0\omega^2 - |\kappa|^2}$, and condition (38) expresses that there are no incoming harmonics impinging the

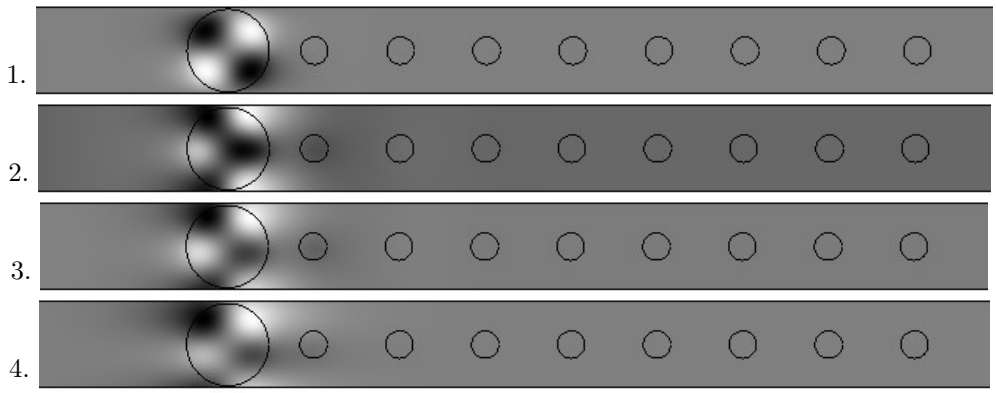

FIG. 3. *Four guided modes in a two-dimensional structure investigated in* [2, Figure 2]. *One period is shown; the structure continues periodically in the vertical direction on the page.* 1: *A nonrobust antisymmetric guided mode at Bloch wavevector zero,* $(\kappa_1, \omega) = (0.0, 0.4017)$. 2 *and* 3: *Nonrobust guided modes at nonzero wave numbers in the direction perpendicular to the line of symmetry,* $(\kappa_1, \omega) = (0.14, 0.3863), (0.22, 0.3707)$. 4: *A robust guided mode,* $(\kappa_1, \omega) = (0.44, 0.3306)$.

rectangular zone $\mathcal{R}$. In fact, condition (38) is a first approximation of the Dirichlet-to-Neumann operator B. If only one harmonic is allowed to propagate and if the rectangular region $\mathcal{R}$ is chosen to be wide enough, it is reasonable to believe that this first approximation leads to an exponentially small error. Numerical methods hinging on this boundary approximation idea have been used in the literature, for example by Kriegsmann [10] and Volkov and Kriegsmann [11], albeit in the case of regular transmission problems instead of eigenvalue problems.

We discretize (34)–(38) by finite elements on a meshing of $\mathcal{R}$, and then solve the discretized problem as an eigenvalue problem in ϵ_1. A function u satisfying (34)–(38) satisfies

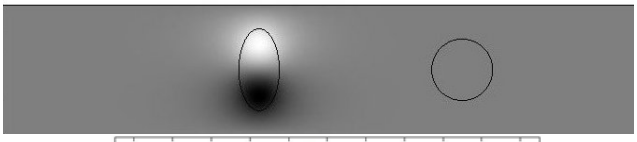
$$0 = \nu_0 \int_\Gamma |u|^2 - \int_{\mathcal{R}} |(\nabla + i\kappa)u|^2 + \epsilon_0\mu_0\omega^2 \int_{\mathcal{R}\setminus\Omega} |u|^2 + \epsilon_1\mu_0\omega^2 \int_\Omega |u|^2.$$

Thus, loosely speaking, if the imaginary part of ϵ_1 is very small, u and $\partial_n u$ are very small on Γ, which is made up by the two narrow edges of the rectangle $\mathcal{R}$. If the rectangle $\mathcal{R}$ is long enough, this simulates the exponential decay expected from a Bloch solution to the Helmholtz equation that is a guided mode.

We first use our numerical method to reproduce a computation of eigenvalues for bound states, which appeared in [2]. The geometry under consideration is that of a dielectric made up of one large circle of radius 3 and eight small circles of radius 1. (The circles are cross sections of rods that extend infinitely in the y direction.) Their centers lie on the line $x = 0$, and two consecutive centers are 2π units of length apart. Fixing $\mu_0 = \mu_1 = 1$, $\epsilon_0 = 1$, $\epsilon_1 = 12$, it was found in [2] that guided modes (referred to as "bound states" in that paper) exist for the pairs $(\kappa_1 = 0.0, \omega = 0.4017)$, $(\kappa_1 = 0.14, \omega = 0.3863)$, $(\kappa_1 = 0.22, \omega = 0.3707)$, and $(\kappa_1 = 0.44, \omega = 0.3306)$. Thus with our present numerical method, we fix $\mu_0 = \mu_1 = 1$, $\epsilon_0 = 1$, and (κ_1, ω) at one of these pairs, and compute values for ϵ_1 for which there appears to be a guided mode. The computations lead to $\epsilon_1 \approx 12.0$, as expected. The corresponding eigenfunction is plotted using grayscale coloring in Figure 3.

The first of these guided modes, at $(\kappa_1 = 0.0, \omega = 0.4017)$, is antisymmetric about the yz-plane. It is nonrobust because it exists in the (κ_1, ω)-regime of one

1.



2.

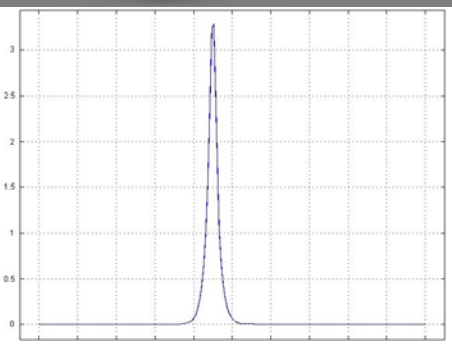


FIG. 4. 1: *Eigenfunction for the first real eigenvalue* $\epsilon_1 \approx 9.762$ *for the parameters* $\omega = 1, \epsilon_0 = 1, \mu_0 = \mu_1 = 1, \kappa = (0, 0)$. 2: *Cross section of the solution along the line* $z = \pi/2$*; the magnitude of the solution is plotted.*

propagating Fourier harmonic, which is suppressed by the symmetry of the structure and the vanishing of κ_1. The last of these modes, at $(\kappa_1 = 0.44, \omega = 0.3306)$, is a robust guided mode, for it exists in the (κ_1, ω)-regime in which all Fourier harmonics are evanescent. A dispersion relation for these is shown in [2].

The other two nonrobust modes are not discussed in the analysis in this paper, for they are in a (κ_1, ω)-regime of one propagating harmonic, but the wave number κ_1 in the x direction is not zero. However, at these two pairs, the coefficient for the one propagating Fourier harmonic happens to be zero; that is, the second part of Condition 2.6 happens to be satisfied. These values of κ_1 and ω occur at points of a complex dispersion curve calculated in [2, Figure 7.2, part 7], at which the imaginary part of the frequency appears to vanish. The existence of nonrobust modes at nonzero wave numbers is proved in the final section of [6].

We also show computations involving geometries that are not exclusively circular. We choose to place two dielectrics, one shaped as an ellipse of focal lengths 1 and 2 and centered at $(-5, \pi)$, the other shaped as a circle of a radius 1 and centered at $(5, \pi)$. Their boundaries appear in Figures 4, 5, and 6. We pick the values $z_1 = -50, z_2 = 50$ to bound the rectangle $\mathcal{R}$. We first assume that $\omega = 1, \epsilon_0 = 1, \mu_0 = \mu_1 = 1, \kappa = (0, 0)$, ensuring that only one harmonic mode propagates. Thus, we know that nonrobust guided modes do exist at certain values of ϵ_1.

The first guided mode that we find corresponds to $\epsilon_1 \approx 9.762$, and is plotted in Figure 4. Values were obtained with a mesh containing 4592 elements. Numerical convergence was verified by either quadrupling the number of mesh elements or changing $z_1 = -50, z_2 = 50$ into $z_1 = -60, z_2 = 60$. These refinements did not change the first four digits of the numerical value for ϵ_1. The numerical method employed finds complex eigenvalues and sorts them in increasing real part order. Some of those eigenvalues do not have a small imaginary part: we ignore them, as they are unrelated to the solutions we are trying to compute. We verify decay of the solution as we move away from the dielectrics. This is illustrated in the graph in Figure 4, which shows the absolute value of the solution along the line $z = \pi/2$. We also show the graphs of the second and third guided modes, still for the same values of $\omega, \epsilon_0, \mu_0, \mu_1, \kappa_1$. They appear in Figure 5.

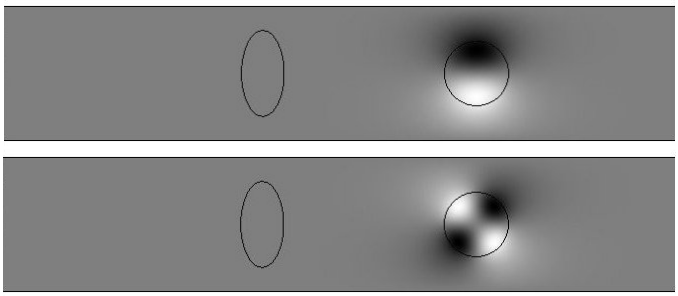

FIG. 5. *Eigenfunctions for the second and third real eigenvalues* $\epsilon_1 \approx 11.00$ *and* $\epsilon_1 \approx 25.66$ *for the parameters* $\omega = 1, \epsilon_0 = 1, \mu_0 = \mu_1 = 1, \kappa_1 = 0$. *These are nonrobust guided modes.*

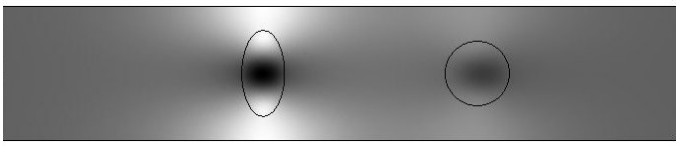

FIG. 6. *Eigenfunction for the third real eigenvalue* $\epsilon_1 \approx 11.42$ *for the parameters* $\omega = 0.3, \epsilon_0 = 1, \mu_0 = 1, \mu_1 = 3, \kappa_1 = 0.4$. *This is a robust guided mode.*

Finally, we compute a robust guided mode with $\kappa_1 \neq 0$. To guarantee existence, we choose values for the material parameters such that no harmonic can propagate. More precisely, we select $\omega = 0.3, \epsilon_0 = 1, \mu_0 = 1, \mu_1 = 3, \kappa_1 = 0.4$. The third eigenfunction for that case is plotted in Figure 6.

6. Appendix: Proofs of theorems.

Proof of Theorem 2.7 (equivalence of strong and weak conditions). Many of the arguments are standard in the literature on elliptic equations; details of the relevant theory can be found in [9, Chapter 8], for example. We confine discussion to the basic elements of the proof and those aspects that are unique to this problem.

i. That the strong formulation satisfies the weak is a matter of application of the divergence theorem (integration by parts). The relevant identity is

$$\nabla\cdot\left[\left(\frac{1}{\mu}\left(\nabla+i\boldsymbol{\kappa}\right)u\right)\bar{v}\right] = \left[\left(\nabla+i\boldsymbol{\kappa}\right)\cdot\left(\frac{1}{\mu}\left(\nabla+i\boldsymbol{\kappa}\right)u\right)\right]\bar{v} + \frac{1}{\mu}\left(\nabla+i\boldsymbol{\kappa}\right)u\cdot\left(\nabla-i\boldsymbol{\kappa}\right)\bar{v}. \tag{39}$$

Applying this identity for a function u that satisfies the strong Condition 2.2, the left-hand side of the weak Condition 2.4.i becomes

$$\begin{aligned} -\int_{\mathcal{R}}\left[\frac{1}{\mu}\left(\left(\nabla+i\boldsymbol{\kappa}\right)^2 u\right)+\varepsilon\omega^2 u\right]\bar{v} \\ +\frac{1}{\mu_0}\int_{\Gamma}\left(Bu+\partial_n u_-\right)T\bar{v} - \int_{\partial\mathcal{R}\setminus\Gamma}\frac{1}{\mu}\partial_n u T\bar{v} \\ +\int_{\Sigma}\left[\frac{1}{\alpha\mu_1}\left(\partial_n u_- + (i\boldsymbol{\kappa}\cdot n)u\right) - \frac{1}{\alpha\mu_0}\left(\partial_n u_+ + (i\boldsymbol{\kappa}\cdot n)u\right)\right]T\bar{v}. \end{aligned} \tag{40}$$

The integral over $\mathcal{R}$ vanishes by properties (i)–(iii), the integral over Γ by property (v), that over $\partial\mathcal{R}\setminus\Gamma$ by properties (vii)–(viii), and the integral over Σ by property (vi).

ii. Let u satisfy Condition 2.4. The functions v of class C^∞ with compact support in $\mathcal{R}\setminus\Sigma$ are contained in $H^1(\mathcal{R})$, and this is sufficient to establish that u satisfies the Helmholtz equation in $\mathcal{R}\setminus\Sigma$ (i)–(iii) and that $u\in H^2(\mathcal{R})$ [9, section 8.3]. Thus u has values on $\partial\mathcal{R}$ (including the interior side of Γ) and Σ that are of class $H^{3/2}$ and normal derivatives of class $H^{1/2}$. Integration by parts, using the Helmholtz equation away from these boundaries, establishes properties (iv)–(viii). The extension of u to all of $\mathcal{S}$ is achieved by the formula (22).

The form of the extension (22) of u to $\mathcal{S}$ outside of $\mathcal{R}$ shows that $a^-_{mn}=b^+_{mn}=0$ for all (m,n). The relation (15) expressing conservation of energy, which is obtained by integration by parts with $v=u$, shows that $a^+_{mn}=b^-_{mn}=0$ for $(m,n)\in\mathcal{P}$. The additional requirement in Condition 2.4 for $\nu^2_{mn}=0$ establishes $a^+_{mn}=b^-_{mn}=0$ for $(m,n)\in\tilde{\mathcal{P}}$. Therefore each harmonic with $(m,n)\in\tilde{\mathcal{P}}$ in the expansion (9) has vanishing value and normal derivative on Γ, implying that $u\in X$ and Condition 2.5.ii are satisfied.

iii. The functions v of class C^∞ with compact support in $\mathcal{R}\setminus\Sigma$ are contained in X, and again we obtain that u satisfies the Helmholtz equation in $\mathcal{R}\setminus\Sigma$ and $u\in H^2(\mathcal{R})$. It suffices to prove that, for each $(m,n)\in\mathcal{P}$, the weak form in Condition 2.5 holds for v such that $(\widehat{v|_{\Gamma_1}})_{mn}=1$, $(\widehat{v|_{\Gamma_1}})_{m'n'}=0$ for $(m',n')\neq(m,n)$, and $(\widehat{v|_{\Gamma_2}})_{m'n'}=0$ for all (m',n') (and similarly with Γ_1 and Γ_2 interchanged). Applying integration by parts for such v together with the Helmholtz equation for u yields for the left-hand side of the equation in the weak Condition 2.4,

$$\text{left-hand side}=\int_{\Gamma_1}(\partial_n u+Bu)\bar v=\big((\partial_n\widehat{u|_{\Gamma_1}})_{mn}-\nu_{mn}(\widehat{u|_{\Gamma_1}})_{mn}\big)=0,$$

in which $(\partial_n\widehat{u|_{\Gamma_1}})_{mn}=0$ by Condition 2.5.ii and $(\widehat{u|_{\Gamma_1}})_{mn}=0$ because $u\in X$.

iv. To prove Condition 2.5.i, it suffices to prove the equality for $v\in X^{\mathrm{sym}}$, which follows from the observation that the integrands are antisymmetric over the regions of integration. To prove part (ii), we observe that the Fourier coefficients with m even are zero because u is antisymmetric in the x-variable. ∎

Recall the sesquilinear forms in $H^1_{\mathrm{per}}(\mathcal{R})$,

$$A(u,v)=\int_{\mathcal{R}}\frac{1}{\mu}\,(\nabla+i\boldsymbol{\kappa})\,u\cdot(\nabla-i\boldsymbol{\kappa})\,\bar v+\frac{1}{\mu_0}\int_\Gamma(BTu)(T\bar v), \tag{41}$$

$$\ell(u,v)=\int_{\mathcal{R}\setminus\Omega}\epsilon_0\omega^2u\bar v+\int_\Omega\epsilon_1\omega^2u\bar v, \tag{42}$$

and that A depends on $\boldsymbol{\kappa}$, ω, ϵ_0, μ_0, and μ_1 (the dependence on ω and ϵ_0 is through B—see (19) and (10)), and ℓ depends on ω, ϵ_0, and ϵ_1; neither form depends on α.

LEMMA 6.1 (estimates). *There exist positive numbers C and δ such that, for all $u,v\in H^1(\mathcal{R})$,*

i. $\min\{\epsilon_0,\epsilon_1\}\|u\|^2_{L^2}\le\ell(u,u)\le\max\{\epsilon_0,\epsilon_1\}\|u\|^2_{L^2}$ *(equivalence of $\|\cdot\|_{L^2}$ and $\ell(\cdot,\cdot)$),*

ii. $|A(u,v)| \le C\|u\|_{H^1}\|v\|_{H^1}$ *(boundedness of A),*
iii. $\delta\|u\|_{H^1}^2 \le A(u,u)$ *(coercivity of A).*

These constants depend on the parameters $\boldsymbol{\kappa}$, ω, ϵ_0, μ_0, *and* μ_1.

Proof.

i. Part (i) is straightforward to verify.
ii. Because the trace operator $T : H^1(\mathcal{R}) \to H^{1/2}(\Gamma)$ and the operator $B : H^{1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ are bounded, there is a constant C_1 such that

$$\left|\int_\Gamma (BTu)(T\bar{v})\right| \le C_1\|u\|_{H^1}\|v\|_{H^1}.$$

This, together with the estimate

$$\begin{aligned}\min\{\mu_0,\mu_1\}\left|\int_{\mathcal{R}} \frac{1}{\mu}\,(\nabla + i\boldsymbol{\kappa})\,u\cdot(\nabla - i\boldsymbol{\kappa})\,\bar{v}\right| &\le \left|\int_{\mathcal{R}} (\nabla + i\boldsymbol{\kappa})\,u\cdot(\nabla - i\boldsymbol{\kappa})\,\bar{v}\right| \\ &\le \|\,(\nabla + i\boldsymbol{\kappa})\,u\|_{L^2}\,\|\,(\nabla + i\boldsymbol{\kappa})\,v\|_{L^2} \\ &\le (\|\nabla u\|_{L^2} + |\boldsymbol{\kappa}|\|u\|_{L^2})\,(\|\nabla u\|_{L^2} + |\boldsymbol{\kappa}|\|u\|_{L^2}) \le C_2\|u\|_{H^1}\|u\|_{H^1},\end{aligned}$$

proves the estimate.
iii. Suppose, to the contrary, that there exists a sequence $\{u_n\}_{n=0}^{\infty}$ from X such that

$$\|u_n\|_{H^1} = 1 \quad \text{and} \quad A(u_n,u_n) \to 0 \text{ as } n\to\infty. \tag{43}$$

Because of the compact embedding of X into $L^2(\mathcal{R})$, we simply assume that there is a function $u \in L^2(\mathcal{R})$ such that

$$\|u - u_n\|_{L^2(\mathcal{R})} \to 0,$$

and from the definition of A, we see that

$$\|\,(\nabla + i\boldsymbol{\kappa})\,u_n\|_{L^2(\mathcal{R})} \to 0,$$

whence

$$\|\nabla u_n + i\boldsymbol{\kappa}u\|_{L^2(\mathcal{R})} \to 0.$$

It follows that $u_n \to u$ in the H^1-norm so that $u \in X$ and

$$(\nabla + i\boldsymbol{\kappa})\,u \;=\; 0,$$

from which we obtain

$$u = C_3 e^{i(\kappa_1 x + \kappa_2 y)} \tag{44}$$

for some constant C. From the convergence of u_n to u in X, the boundedness of T and B, and the definition of A, we have

$$\int_\Gamma (BTu)T\bar{u} = \lim_{n\to\infty}\int_\Gamma (BTu_n)T\bar{u}_n = 0.$$

Since B is a positive operator on $H^{1/2}(\Gamma)$, we obtain $Tu = 0$, and the form (44) therefore gives $u = 0$. This is in contradiction to the supposition that $\|u_n\|_{H^1} = 1$, and (43) is therefore untenable. ∎

Because of the equivalence of the norms $\ell(f,f)$ and $\|f\|_{L^2(\mathcal{R})}$ (Lemma 6.1.ii), we may define $L^2(\mathcal{R},\ell)$ to be the linear space of functions in $L^2(\mathcal{R})$ endowed with the inner product $\ell(f,g)$.

Proof of Theorem 3.1. By the Lax–Milgram theorem, there exists a linear operator $K : L^2(\mathcal{R},\ell) \to X$ such that, for each $f \in L^2(\mathcal{R})$,

$$A(Kf,v) = \ell(f,v) \quad \text{for all } v \in X,$$

and by the sesquilinearity of A and ℓ, we also have

$$A(v,Kf) = \ell(v,f) \quad \text{for all } v \in X.$$

K is self-adjoint in the inner product $\ell(\cdot,\cdot)$ because

$$\ell(Kf,g) = A(Kf,Kg) = \ell(f,Kg) \quad \text{for all } f,\, g \in L^2(\mathcal{R}).$$

In fact, K is positive because

$$\ell(Kf,f) = A(Kf,Kf) > 0 \quad \text{for all } f \in L^2(\mathcal{R}).$$

K is injective because, if $Kf = 0$, then $\ell(f,v) = 0$ for all $v \in X$, and since X contains the functions of class C^∞ with compact support in $\mathcal{R}$, $f = 0$ almost everywhere, so that $f = 0$ in $L^2(\mathcal{R})$. The estimate

$$\delta\|Kf\|_{H^1}^2 \le A(Kf,Kf) = \ell(f,Kf) \le C\|f\|_{L^2}\|Kf\|_{L^2} \le C\|f\|_{L^2}\|Kf\|_{H^1}$$

gives us

$$\delta\|Kf\|_{H^1} \le C\|f\|_{L^2},$$

which shows that K is compact as an operator on $L^2(\mathcal{R})$. As the $L^2(\mathcal{R})$-norm with respect to Lebesgue measure on $\mathcal{R}$ and the norm in $L^2(\mathcal{R},\ell)$ are equivalent, K is compact as an operator on $L^2(\mathcal{R},\ell)$. The spectrum of K therefore consists of a nonincreasing sequence of eigenvalues $\{\lambda_j\}_{j=0}^\infty$ converging to zero, in which eigenvalues are repeated according to multiplicity, and there is a corresponding sequence of eigenfunctions $\{\psi_j\}_{j=0}^\infty$ that form an orthonormal Hilbert-space basis for $L^2(\mathcal{R},\ell)$.

By definition of A and K, we see that, for $\alpha \in \mathbb{R}$,

$$A(u,\cdot) = \alpha\ell(u,\cdot) \iff Ku = \alpha^{-1}u, \tag{45}$$

in which the dot in the second argument of the forms indicates action on X. The sequence of eigenvalues α_j we seek is therefore

$$\{\alpha_j = \lambda_j^{-1}\}_{j=0}^\infty.$$

By Lemma 6.1.i and 6.1.iii,

$$\ell(u,u) \le C_4 A(u,u),$$

which shows that $\alpha_0 > 0$.

We now show that the eigenvalues and eigenfunctions arise from minimization of the Rayleigh quotient. Define

$$\beta_0 = \inf_{u \in X, u \neq 0} J(u).$$

We prove that there exists a nonzero function $\phi_0 \in X$ such that

$$\beta_0 = J(\phi_0) > 0.$$

Let $\{u_n\}_{n=1}^{\infty}$ be a minimizing sequence; that is, $u_n \neq 0$ for each n and $\lim_{n\to\infty} J(u_n) = \beta_0$. By homogeneity of $J(u)$, we may assume that $\ell(u_n, u_n) = 1$ for each n, and since the sequence $\{J(u_n)\}$ is bounded, $\{A(u_n, u_n)\}$ is also bounded. Lemma 6.1.iii shows that $\{\|u_n\|_{H^1}\}$ is bounded.

By the compact embedding of $H^1_{\mathrm{per}}(\mathcal{R})$ into $L^2(\mathcal{R})$, there is a subsequence that is strongly convergent in $L^2(\mathcal{R})$; we simply assume therefore that $\{u_n\}$ is strongly convergent in $L^2(\mathcal{R})$, say to a function ϕ_0. By the second inequality in Lemma 6.1.i, $\ell(\phi_0, \phi_0) = 1$. We now prove that $\|u_n - u_m\|_{H^1} \to 0$ as $m, n \to \infty$. The parallelogram law holds for A:

$$A(u_m - u_n, u_m - u_n) = A(u_m, u_m) + A(u_n, u_n) - A(u_m + u_n, u_m + u_n). \tag{46}$$

Because $\ell(u_n, u_n) = 1$, $A(u_n, u_n) = J(u_n)$, and the sum of the first two terms on the right-hand side of (46) converges to $4\beta_0$. By definition of β_0 and because of the second inequality in Lemma 6.1.i,

$$A(u_m + u_n, u_m + u_n) \geq \beta_0 \ell(u_m + u_n, u_m + u_n) \to \beta_0 \ell(2u, 2u) = 4\beta_0 \quad \text{as } m, n \to \infty.$$

We thus obtain $A(u_m - u_n, u_m - u_n) \to 0$ as $m, n \to \infty$, and from Lemma 6.1.iii, $\|u_n - u_m\|_{H^1} \to 0$. Therefore, $u_n \to \phi_0 \in X$ in the H^1-norm. Part (ii) shows that $A(u_n, u_n) \to A(\phi_0, \phi_0)$ as $n \to \infty$, and therefore

$$J(\phi_0) = \lim_{n\to\infty} J(u_n) = \beta_0.$$

To define β_1 and ϕ_1, we set Y_1 to be the orthogonal complement of $\mathrm{span}\{\phi_0\}$ in X with respect to the sesquilinear form $A(u, v)$,

$$Y_1 = \{v \in X : A(\phi_0, v) = 0\},$$

and define

$$\beta_1 = \inf_{u \in Y_1, u \neq 0} J(u).$$

The proof of the existence of a minimizer ϕ_1 in Y_1 is essentially the same as the proof of the existence of ϕ_0. Continuing in this way, we obtain a sequence $\{Y_j\}$ of subspaces of X, numbers β_j, and functions ϕ_j such that

$$Y_j = \{v \in X : A(\phi_k, v) = 0 \text{ for } k = 0, \ldots, j-1\}$$

and

$$\beta_j = \inf_{u \in Y_j, u \neq 0} J(u) = J(\phi_j), \quad \phi_j \in Y_j.$$

Taking the first variation of the relation $A(u, u) = J(u)\ell(u, u)$ at $u = \phi_j$ and using the fact that J is minimized by ϕ_j in Y_j and that $A(\phi_k, \phi_j) = \ell(\phi_k, \phi_j) = 0$ for $k = 0, \ldots, j-1$, we obtain

$$A(\phi_j, v) = \beta_j \ell(\phi_j, v) \quad \text{for all } v \in X. \tag{47}$$

By definition, ϕ_{j+1} minimizes the same functional as ϕ_j, but over a smaller set, and therefore the sequence $\{\beta_j\}$ is nondecreasing:

$$0 < \beta_0 \le \beta_1 \le \cdots \le \beta_j \le \cdots .$$

Because of (45) and (47), we have

$$\{\beta_j\}_{j=0}^{\infty} \subseteq \{\alpha_j\}_{j=0}^{\infty} \quad \text{and} \quad \operatorname{span}\{\phi_j : j = 0, \ldots, \infty\} \subseteq \operatorname{span}\{\psi_j : j = 0, \ldots, \infty\}.$$

To show for $j = 0, \ldots, \infty$ that $\alpha_j = \beta_j$, that ψ_j can be taken to be equal to ϕ_j, and that $X_j = Y_j$, we prove that any eigenvalue α with eigenfunction $0 \neq \psi \in X$, in the sense that

$$A(\psi, v) = \alpha \ell(\psi, v) \quad \text{for all } v \in X,$$

is necessarily one of the β_j and that ψ is in the span of $\{\phi_j : \beta_j = \alpha\}$. If, to the contrary, $\alpha \neq \beta_j$ for all n, then $A(\phi_j, \psi) = 0$ for all n because

$$A(\psi, \phi_j) = \alpha \ell(\psi, \phi_j) \quad \text{and} \quad A(\phi_j, \psi) = \beta_j \ell(\phi_j, \psi),$$

whence we obtain, from conjugating the first relation and keeping in mind that $\alpha \ge \alpha_0 > 0$ and $\beta_j \ge \alpha_0 > 0$,

$$(\alpha^{-1} - \beta_j^{-1}) A(\phi_j, \psi) = 0.$$

Since $\alpha \neq \beta_j$, we obtain $A(\phi_j, \psi) = 0$, as desired. This implies that $\psi \in Y_{j+1}$ so that

$$\alpha = \frac{A(\psi, \psi)}{\ell(\psi, \psi)} \ge \inf_{u \in Y_j, u \neq 0} J(u) = \beta_j \quad \text{for all } j,$$

which is impossible because $\beta_j \to \infty$. Therefore we may let k be

$$k = \max\{j : \beta_j = \alpha\}.$$

We still have $A(\psi, \phi_j) = 0$ for all j with $\beta_j \neq \alpha$. If we also have $A(\psi, \phi_j) = 0$ for all j with $\beta_j = \alpha$, then

$$\alpha = J(\psi) \ge \inf_{u \in Y_{k+1}, u \neq 0} J(u) = \beta_{k+1} > \beta_k \quad \text{(a contradiction)}.$$

We now see that ψ, which was taken to be an *arbitrary* nonzero element of the eigenspace for α, is such that $A(\psi, \phi_j)$ for some j with $\beta_j = \alpha$. This implies that the eigenspace for α is in fact equal to $\operatorname{span}\{\phi_j : \beta_j = \alpha\}$.

The last part of the theorem on the symmetric and antisymmetric eigenfunctions is proved analogously by replacing X by X^{sym} and X^{ant} and using the fact that these two spaces are orthogonal with respect to the sesquilinear form $A(\cdot, \cdot)$. There are no essential changes in the proof. ∎

The form ℓ depends on the parameter ϵ_1; we make this dependence explicit by introducing the variable ϵ:

$$\ell_\epsilon(u, v) = \int_{\mathcal{R} \setminus \Omega} \epsilon_0 \omega^2 u \bar{v} + \int_\Omega \epsilon \omega^2 u \bar{v}, \tag{48}$$

$$J_\epsilon(u) = \frac{A(u, u)}{\ell_\epsilon(u, u)} = \frac{\int_{\mathcal{R}} \frac{1}{\mu} |(\nabla + i\boldsymbol{\kappa}) u|^2 + \frac{1}{\mu_0} \int_\Gamma (BTu)(T\bar{u})}{\epsilon_0 \omega^2 \int_{\mathcal{R} \setminus \Omega} |u|^2 + \epsilon \omega^2 \int_\Omega |u|^2}. \tag{49}$$

The eigenvalues and eigenfunctions also depend on ϵ, and we denote them by $\alpha_j(\epsilon)$ and $\psi_j(\epsilon)$. Normalizing the eigenfunctions so that $\ell_\epsilon(\psi_j(\epsilon), \psi_j(\epsilon)) = 1$, we have

$$\ell_\epsilon(\psi_j(\epsilon), \psi_k(\epsilon)) = \delta_{jk}, \qquad A(\psi_j(\epsilon), \psi_k(\epsilon)) = 0 \quad \text{for } j \neq k.$$

The compact operator $K = K_\epsilon$ also depends on ϵ,

$$A(K_\epsilon f, v) = \ell_\epsilon(f, v) \quad \text{for all } v \in X, \tag{50}$$

and the eigenvalues of K_ϵ are $\{\alpha_j(\epsilon)^{-1}\}_{j=0}^\infty$ with corresponding eigenvectors $\{\psi_j(\epsilon)\}_{j=0}^\infty$.

LEMMA 6.2. *K_ϵ is continuous in ϵ with respect to the operator norm on K_ϵ.*

Proof. Let $\epsilon_1 > 0$ be given. For an arbitrary variation $\Delta\epsilon > 0$ with $0 < |\Delta\epsilon| < \epsilon_1$, set

$$\Delta K = K_{\epsilon_1+\Delta\epsilon} - K_{\epsilon_1} \quad \text{and} \quad \Delta\ell = \ell_{\epsilon_1+\Delta\epsilon} - \ell_{\epsilon_1}.$$

Applying the defining relation (50) for K_ϵ to $K_{\epsilon_1+\Delta\epsilon}$ and K_{ϵ_1}, with $v = \Delta K f$, and subtracting yields the relation

$$A(\Delta K f, \Delta K f) = \Delta\ell(f, \Delta K f). \tag{51}$$

We have the following lower estimate for the left-hand side of (51),

$$\delta\|\Delta K f\|_{L^2}^2 \leq \delta\|\Delta K f\|_{H^1}^2 \leq A(\Delta K f, \Delta K f),$$

and upper estimate for the right-hand side:

$$|\Delta\ell(f, \Delta K f)| = |\Delta\epsilon| \left| \int_\Omega f \Delta K \bar{f} \right| \leq |\Delta\epsilon| \, \|f\|_{L^2} \, \|\Delta K f\|_{L^2}.$$

Putting these inequalities together, we obtain

$$\|\Delta K f\|_{L^2} \leq \frac{|\Delta\epsilon|}{\delta} \|f\|_{L^2},$$

so that $\|\Delta K\| \leq |\Delta\epsilon|/\delta$. ∎

We now prove the lemma of section 3 that states that the eigenvalues α are continuous strictly decreasing functions of ϵ_1, and $\alpha_j \to 0$ as $\epsilon_1 \to \infty$. A similar result was stated for the μ_1 dependency, but we omit the proof in that case, as it is similar.

Proof of Lemma 3.2. By Lemma 6.2, K_ϵ is continuous in ϵ with respect to the operator norm on K_ϵ, and its spectrum is the set $\{\alpha_j(\epsilon)^{-1}\}_{j=0}^\infty$. Because the eigenvalues of compact operators are continuous functions of the operator in the operator norm (Kato [12, Chapter IV, section 3.5]), we conclude that the functions $\alpha_j(\epsilon)$ are continuous functions of ϵ.

To prove that $\alpha_j(\epsilon)$ is strictly decreasing in ϵ, let ϵ_1 and ϵ_2 be given with $0 < \epsilon_1 < \epsilon_2$, and let an integer $N \geq 0$ be given. Define

$$V_N = \text{span}\{\psi_j(\epsilon_1) : 0 \leq j \leq N\}$$

($V_0 = \{0\}$), in which the eigenvectors $\psi_j(\epsilon_1)$ are orthonormal with respect to $\ell_{\epsilon_1}(\cdot,\cdot)$ and orthogonal with respect to $A(\cdot,\cdot)$:

$$\ell_{\epsilon_1}(\psi_j(\epsilon_1), \psi_k(\epsilon_1)) = \delta_{jk}, \qquad A(\psi_j(\epsilon_1), \psi_k(\epsilon_1)) = 0 \quad \text{for } j \neq k.$$

For each $\psi \in V_N$ with $\ell_{\epsilon_1}(\psi,\psi) = 1$, there are numbers a_j, for $0 \le j \le N$, such that

$$\psi = \sum_{j=0}^{N} a_j \psi_j(\epsilon_1), \qquad \sum_{j=0}^{N} |a_j|^2 = 1,$$

and we obtain $A(\psi,\psi) = \sum_{j=0}^{N} |a_j|^2 A(\psi_j(\epsilon_1), \psi_j(\epsilon_1))$ so that

$$A(\psi,\psi) = J_{\epsilon_1}(\psi) = \sum_{j=0}^{N} |a_j|^2 J_{\epsilon_1}(\psi_j(\epsilon_1)) = \sum_{j=0}^{N} |a_j|^2 \alpha_j(\epsilon_1) \le \alpha_N(\epsilon_1). \tag{52}$$

From the definition of J_ϵ, it is evident that $J_{\epsilon_2}(\phi) \le J_{\epsilon_1}(\phi)$ for each $\phi \in X$; however, we need to show strict inequality for $\phi \in V_N$, which requires showing that, for each nonzero $\phi \in V_N$, it is not true that ϕ is equal to zero almost everywhere on Ω. To this end, let

$$\phi = \sum_{j=0}^{N} b_j \psi_j(\epsilon_1) = 0 \quad \text{a.e. in } \Omega.$$

Set $\beta_j = \alpha_j(\epsilon_1)\epsilon_1\mu_1\omega^2$. As the $\psi_j(\epsilon_1)$ are smooth in Ω, for each $k = 0, \dots, N$, we have

$$0 = \prod_{\beta_j \ne \beta_k} \left((\nabla + i\boldsymbol{\kappa})^2 + \beta_j \right) \phi = \prod_{\beta_j \ne \beta_k} (-\beta_k + \beta_j) \sum_{\beta_j = \beta_k} b_j \psi_j(\epsilon_1) \quad \text{in } \Omega.$$

Since $\prod_{\beta_j \ne \beta_k} (-\beta_k + \beta_j) \ne 0$, we obtain $\sum_{\beta_k = \beta_h} b_k \psi_k(\epsilon_1) = 0$ in Ω. However, $\sum_{\beta_j = \beta_k} b_j \psi_j(\epsilon_1)$ satisfies Condition 2.2, and therefore $\sum_{\beta_j = \beta_k} b_j \psi_j(\epsilon_1)$ is zero in $\mathcal{R}$. As the $\psi_j(\epsilon_1)$ are linearly independent, we infer that $b_j = 0$ for j such that $\beta_j = \beta_k$. As k was chosen arbitrarily from $\{0, \dots, N\}$, we obtain $b_j = 0$ for $0 \le j \le N$. We conclude that $\psi = \sum_{j=0}^{N} a_j \psi_j(\epsilon_1)$ from above is not zero in $L^2(\Omega)$. It follows now from the definitions of J_ϵ and ℓ_ϵ and from (52) that $J_{\epsilon_2}(\psi) < J_{\epsilon_1}(\psi) \le \alpha_N(\epsilon_1)$, and by the homogeneity of J_{ϵ_2} we obtain

$$J_{\epsilon_2}(\phi) < J_{\epsilon_1}(\phi) \le \alpha_N(\epsilon_1) \quad \text{for all } \phi \in V_N. \tag{53}$$

Define, for each $\epsilon > 0$,

$$X_N(\epsilon) = \{ v \in X : A(\psi_j(\epsilon), v) = 0 \text{ for } j = 0, \dots, N-1 \}.$$

The dimension of $V_N \cap X_N(\epsilon_2)$ is at least 1; let ϕ be a nonzero vector in this intersection. We obtain

$$\alpha_N(\epsilon_2) = \inf_{u \in X_N(\epsilon_2), u \ne 0} J_{\epsilon_2}(u) \le J_{\epsilon_2}(\phi) < \alpha_N(\epsilon_1),$$

and we have proved that $\alpha_N(\epsilon)$ is a decreasing function of ϵ.

We now prove that $\alpha_N(\epsilon)$ tends to zero as ϵ tends to infinity. We define the set

$$S = \{ \psi \in V_N : \ell_{\epsilon_1}(\psi,\psi) = 1 \}.$$

S is compact in $L^2(\mathcal{R}, \ell_{\epsilon_1})$ and therefore also in $L^2(\mathcal{R})$. Since $\int_\Omega |\psi|^2$ is continuous in $L^2(\mathcal{R})$ and $\int_\Omega |\psi|^2 \ne 0$ for all $\psi \in S$, there is a number M such that

$$0 < M < \int_\Omega |\psi|^2 \quad \text{for all } \psi \in S.$$

Therefore

$$\ell_\epsilon(\psi,\psi) \geq \epsilon\omega^2 \int_\Omega |\psi|^2 > \epsilon\omega^2 M \quad \text{for all } \psi \in S,$$

and, using (52) for $\epsilon > \epsilon_1$,

$$J_\epsilon(\psi) = \frac{A(\psi,\psi)}{\ell_\epsilon(\psi,\psi)} < \frac{\alpha_N(\epsilon_1)}{\epsilon\omega^2 M} \quad \text{for all } \psi \in S.$$

The dimension of $V_N \cap X_N(\epsilon)$ is at least 1. Let ϕ be a nonzero vector in this intersection, which we may take to be in S. We then obtain

$$\alpha_N(\epsilon) = \inf_{u \in X_N(\epsilon), u \neq 0} J_\epsilon(u) \leq J_\epsilon(\phi) < \frac{\alpha_N(\epsilon_1)}{\epsilon\omega^2 M}. \qquad \square \tag{54}$$

The estimate (54) shows that the eigenvalues decay at least proportionally to $1/\epsilon$.

ESTIMATES FOR ELECTRIC FIELDS BLOWN UP BETWEEN CLOSELY ADJACENT CONDUCTORS WITH ARBITRARY SHAPE*

KIHYUN YUN†

Abstract. It may be well known in practice that high stress concentrations occur in fiber-reinforced composites. There have been several works by analysis to estimate for the stresses between closed spaced fibers. However, the known results on stiff fibers have until now been restricted to the particular case of circular cross-sections. Thus, we extend the blow-up results on the stresses specialized only for disks to the general case of arbitrary shapes. Moreover, we prove that the blow-up rate of the general case is exactly the same as that of disks. Nevertheless, from the viewpoint of methodology, the technique we use is significantly different from the previous one restricted to the case of disks. Referring to antiplane shear problems, these works are reduced to the gradient estimates for the solution to the conductivity problem containing two closely spaced conductors which represent the cross-sections of fibers. We establish a novel representation for the solution on conductors by a probability function. Based on this, the general blow-up results are derived by a simpler method.

Key words. gradient estimates, blow-up, arbitrary shape, conductivity problems, stresses, composite materials

1. Introduction.

This paper is concerned with high stress concentrations between closely spaced stiff fibers in an infinite matrix. According to Budiansky and Carrier [8], unexpectedly low strengths in longitudinal shear have been reported for brittle-matrix, fiber-reinforced composites, and it has been suggested that this might be explained by high stress concentrations between neighboring fibers (see also [5, 9]). However, according to Keller [12], it is difficult to calculate numerically the stresses in a narrow region because the stresses are much larger than elsewhere. Several approaches by analysis have been developed, but the blow-up results on the stresses are restricted to the particular case where fibers have circular cross-sections. Until now there has not been any established result associated with a large class of shapes. This paper presents the blow-up result for a class of shapes which is general enough. Moreover, the blow-up rate is exactly the same as the one for disks.

We consider two parallel elastic fibers embedded in an infinite elastic matrix. We suppose that D_1 and D_2 are very closely spaced inclusions in $\mathbb{R}^2$ which are ϵ apart, representing the cross-sections of the fibers, and the shear moduli of the inclusions are constants a_1 and a_2, different from the constant outside shear modulus 1. Referring to a problem of antiplane shear, we get the following conductivity equation for a given harmonic function H in $\mathbb{R}^2$:

$$\begin{cases} \nabla \cdot \left\{ \left(1 + \sum_{i=1,2} (a_i - 1)\chi(D_i) \right) \nabla u \right\} = 0, \\ u(x) - H(x) = O(|x|^{-1}) \ \text{ as } |x| \to \infty, \end{cases} \tag{1.1}$$

where the function u represents the out-of-plane elastic displacement. For applications to the composite materials, our work focuses on the stresses, represented by ∇u, particularly in the case when ∇H is a uniform field, i.e., $H(x) = A \cdot x$ for some constant vector A. The question of interest is to establish the optimal estimate on $|\nabla u|$ as the separation distance ϵ approaches 0.

We give a brief description of remarkable works by analysis on gradient estimates for solutions. For finite and strictly positive shear moduli (or conductivities) a_1 and a_2, it has been shown by Bonnetier and Vogelius in [7] that $|\nabla u|$ remains bounded for circular touching inclusions with comparable radii. Li and Vogelius derived in [15] a uniform upper bound on $|\nabla u|$ that is independent of the distance ϵ between D_1 and D_2, assuming that the moduli a_1 and a_2 stay away from 0 and ∞. It may be noted that this result of [15] holds for an arbitrary number of inclusions with arbitrary shape and is not restricted to two-dimensional space. Moreover, this result has been extended to elliptic systems by Li and Nirenberg in [14].

However, to explain high stresses occurring between stiff fibers, we should pay attention to the case of the extreme valued shear moduli. For two circular inclusions with $a_1 = a_2 = \infty$ or $a_1 = a_2 = 0$, it has been shown by Ammari, Kang, and Lim [2] and Ammari et al. [4] (see also [8]) that $|\nabla u|$ blows up as the distance ϵ approaches 0 for a special uniform field ∇H. Moreover, the optimal rate of blow-up is $\epsilon^{-1/2}$. These results on blow-up are specialized only for the case of circular inclusions. Thus there has been a strong need for a result that is not only associated with a large class of shapes but also has the same blow-up rate as circular inclusions.

In this paper we present the desirable result: for two inclusions D_1 and D_2 whose shapes are arbitrary enough, $|\nabla u|$ blows up as the distance ϵ approaches 0 for a special uniform field ∇H, and the blow-up rate is exactly $\epsilon^{-1/2}$, which is the known rate in the circular cases.

We now proceed to state the main results of this paper. To do so we need to make our notation and assumption more precise. Let D_{right} be a bounded domain in $\mathbb{R}^+ \times \mathbb{R}$ that is strictly convex at the unique left endpoint $(0,0)$ of this domain, and let D_{left} be a bounded domain in $\mathbb{R}^- \times \mathbb{R}$ that has a right endpoint at $(0,0)$ and a C^2 boundary. In addition, we assume that $\varphi : \mathbb{C}\backslash B_1(0) \to \mathbb{R}^2\backslash D_{\text{right}}$ is a conformal mapping such that $\varphi \in C^2(\mathbb{C}\backslash B_1(0))$ and $\varphi'(z) \neq 0$ for $z \in \partial B_1(0)$ (refer to the Riemann mapping theorem in [1]). We shall not distinguish between $\mathbb{R}^2$ and $\mathbb{C}$ in this paper. Let the domain D_1 and D_2 be as follows:

$$D_1 = D_{\text{right}} + \frac{1}{2}\epsilon \quad \text{and} \quad D_2 = D_{\text{left}} - \frac{1}{2}\epsilon.$$

To consider the case when $a_1 = a_2 = \infty$, given any harmonic function H in $\mathbb{R}^2$, (1.1) is rewritten in the following form:

$$\begin{cases} \triangle u = 0 \quad \text{in } \mathbb{R}^2\backslash\overline{(D_1 \cup D_2)}, \\ u(x) - H(x) = O(|x|^{-1}) \quad \text{as } |x| \to \infty, \\ u|_{\partial D_i} = C_i \text{ (constant), and} \\ \int_{\partial D_i} \partial_\nu u \, ds = 0 \quad \text{for } i = 1, 2. \end{cases} \tag{1.2}$$

The solution u can also be interpreted physically as the voltage potential outside uncharged conductors D_1 and D_2 under the action of applied electric field ∇H (see [10]).

THEOREM 1.1. *Assume the conditions above. Let u be the solution to* (1.2) *for $H(x_1, x_2) = x_1$. If the distance ϵ is sufficiently small, then there exists a strictly*

positive constant C_* independent of ϵ such that

$$|u|_{\partial D_1} - u|_{\partial D_2}| \geq C_*\sqrt{\epsilon} \tag{1.3}$$

and, owing to the mean value theorem,

$$\max_{-\frac{\epsilon}{2}<x_1<\frac{\epsilon}{2}} |\nabla u(x_1, 0)| \geq C_* \left(\frac{1}{\sqrt{\epsilon}}\right). \tag{1.4}$$

As mentioned earlier, we extend the result known only for disks to the general case of inclusions with arbitrary shape. Nevertheless, the technique we use is significantly different from the previous one. In the case of disks, the authors took advantage of Kelvin transform and properties of layer potential which are specialized only for circles in [2, 4, 8]. It is difficult to apply this method to other shaped inclusions even though they are ellipses. Thus, we need to provide a new method for the general case. To do so, we establish a new and easy representation for the difference $u|_{\partial D_1} - u|_{\partial D_2}$ in Lemma 2.3 by a probability function $\partial_\nu w$. Based on this, the blow-up result (1.4) can be derived by a method simpler than the previous ones such as asymptotic expansions related to discontinuous conductivity in [2, 3, 4, 6, 11, 16]. On the other hand, applying the new representation to the recent result of Ammari et al. in [4], we can derive the optimal upper bound of $|\nabla u|$ in Theorem 1.2.

THEOREM 1.2. *Let H and u be the same as in Theorem* 1.1*. In addition, we assume that D_{left} also has a conformal mapping $\psi : \mathbb{C}\backslash B_1(0) \to \mathbb{R}^2\backslash D_{\text{left}}$ with the same regularity conditions as φ. If the distance ϵ is sufficiently small, then we have constants C_1^* and C_2^* independent of ϵ such that*

$$|u|_{\partial D_1} - u|_{\partial D_2}| \leq C_1^*\sqrt{\epsilon} \tag{1.5}$$

and

$$\|\nabla u\|_{L^\infty(\mathbb{R}^2\backslash(D_1\cup D_2))} \leq C_2^* \left(\frac{1}{\sqrt{\epsilon}}\right). \tag{1.6}$$

To summarize the two theorems, Theorem 1.1 provides that $|\nabla u|$ blows up as the distance $\epsilon \to 0$ for a special uniform field and the blow-up rate is not less than $\epsilon^{-1/2}$. It follows from the bound (1.6) in Theorem 1.2 that the rate is exactly $\epsilon^{-1/2}$.

We now consider the case when $a_1 = a_2 = 0$. It is probably relevant to consider the case when $a_1 = a_2 = 0$, because the fibers are there for reinforcement. However, the solution to this case can be interpreted physically as the voltage potential outside nonconductors D_1 and D_2 under the action of applied electric field $\nabla\widetilde{H}$ (see [13]). For any given harmonic function $\widetilde{H}$ in $\mathbb{R}^2$, let $\widetilde{u}$ be the unique solution to the following Neumann problem:

$$\begin{cases} \triangle\widetilde{u} = 0 \quad \text{in } \mathbb{R}^2\backslash\overline{(D_1 \cup D_2)}, \\ \widetilde{u}(x) - \widetilde{H}(x) = O(|x|^{-1}) \quad \text{as } |x| \to \infty, \\ \partial_\nu\widetilde{u} = 0 \ \text{ on } \partial D_i \quad \text{for } i = 1, 2, \end{cases} \tag{1.7}$$

where $\partial_\nu\widetilde{u}$ is the normal derivative of $\widetilde{u}$.

THEOREM 1.3. *Assume that D_{left} is the same as in Theorem* 1.2*, and that C_* and C_2^* are the constants used in Theorems* 1.1 *and* 1.2*, respectively. Let $\widetilde{u}$ be the*

solution to (1.7) *for* $\widetilde{H}(x_1, x_2) = x_2$. *If the distance* ϵ *is small enough, then we have the estimates*

$$\max_{-\frac{\epsilon}{2}<x_1<\frac{\epsilon}{2}} |\nabla \widetilde{u}(x_1, 0)| \geq C_* \left(\frac{1}{\sqrt{\epsilon}}\right) \tag{1.8}$$

and

$$\|\nabla \widetilde{u}\|_{L^\infty(\mathbb{R}^2\setminus(D_1\cup D_2))} \leq C_2^* \left(\frac{1}{\sqrt{\epsilon}}\right). \tag{1.9}$$

Proof. Let u be the voltage potential for $H = x_1$ in Theorem 1.1. By Lemma 2.1, we have

$$u = H + V_1 + V_2,$$

where V_i is a harmonic function in $\mathbb{R}^2\setminus D_i$ and $V_i(x) = O(|x|^{-1})$ as $|x| \to \infty$ for $i = 1, 2$. Owing to Poincaré's theorem, we have a well-defined conjugate harmonic function of V_i, denoted by $\widetilde{V_i}$, for $i = 1, 2$ such that

$$\widetilde{V_1}(x) + \widetilde{V_2}(x) = O(|x|^{-1}) \quad \text{as } |x| \to \infty.$$

Let $\widetilde{u} = \widetilde{H} + \widetilde{V_1} + \widetilde{V_2}$. Then $\widetilde{u}$ satisfies (1.7) and is also a harmonic conjugate function of u. Hence, we have

$$|\nabla u| = |\nabla \widetilde{u}| \ \text{ in } \mathbb{R}^2\setminus\overline{(D_1 \cup D_2)}.$$

Therefore, we have completed the proof. ∎

2. Proof of Theorem 1.1. In this section we will give a proof of the inequality (1.3). The proof is based on (2.6) and Lemma 2.3 which present an interesting representation for the difference $u|_{\partial D_1} - u|_{\partial D_2}$ by a probability function $\partial_\nu w$. Thus we choose a constant C satisfying the inequality $\partial_\nu w \geq C\sqrt{\epsilon}$ (2.15). This inequality completes the proof.

We start by representing the voltage potential u as a function related to H. To do so, we define the operator $R_1 : C^\infty(\mathbb{R}^2\setminus\overline{D_2}) \to C^\infty(\mathbb{R}^2\setminus\overline{D_1}) \cap C(\mathbb{R}^2\setminus D_1)$ as

$$\begin{cases} \triangle R_1(v) = 0 \quad \text{in } \mathbb{R}^2\setminus\overline{D_1}, \\ R_1(v)(x) = O(|x|^{-1}) \quad \text{as } \ |x| \to \infty, \\ (v - R_1(v))|_{\partial D_1} = C \text{ (constant)}, \end{cases} \tag{2.1}$$

where C is a constant dependent on v, and we also define $R_2 : C^\infty(\mathbb{R}^2\setminus\overline{D_1}) \to C^\infty(\mathbb{R}^2\setminus\overline{D_2}) \cap C(\mathbb{R}^2\setminus D_2)$ similarly. It follows from Green's theorem that

$$\int_{\partial_{D_1}} \frac{\partial R_1(v)}{\partial \nu}\, ds = 0.$$

By definition, $H - R_1(H)$ can be interpreted physically as the voltage potential due only to the presence of D_1, under the action of applied electric field ∇H. Since the voltage potential u is due not only to D_1 but also to D_2, we take advantage of R_2. We thus expect $u \sim H - R_1(H) - R_2(H)$. But since $H - R_1(H) - R_2(H)$ is not constant on the boundaries ∂D_1 and ∂D_2, we expect $u \sim H - R_1(H) - R_2(H) + R_2R_1(H) + R_1R_2(H)$ again. These steps can proceed inductively. The process provides the following lemma.

LEMMA 2.1. *For a harmonic function H defined in $\mathbb{R}^2$, the voltage function u is represented as follows:*

$$\begin{aligned} u &= H - R_1(H) - R_2(H) + R_1R_2(H) + R_2R_1(H) \\ &\quad - R_1R_2R_1(H) - R_2R_1R_2(H) + \cdots \\ &= H - R_1(H) - R_2(H) + R_1R_2(H) + R_2R_1(H) \\ &\quad + \sum_{n=1}^{\infty} (R_1R_2)^n(-R_1(H) + R_1R_2(H)) + (R_2R_1)^n(-R_2(H) + R_2R_1(H)). \end{aligned} \tag{2.2}$$

Proof. We choose an interior point p of D_1. Let $\Omega = \{\frac{x-p}{|x-p|^2} \mid x \in \mathbb{R}^2 \backslash D_1\} \cup \{0\}$ and $\Omega_\epsilon = \{\frac{x-p}{|x-p|^2} \mid x \in D_2\} \cup \{0\}$. Then we have $\Omega_\epsilon \subset \Omega$ and the distance $\mathrm{d}(\Omega_\epsilon, \partial\Omega) > 0$. Hence, by the maximum principle and standard estimates, one can choose a positive constant $c < 1$ such that

$$\max_{\Omega_\epsilon} h - \min_{\Omega_\epsilon} h \leq c \left(\max_{\Omega} h - \min_{\Omega} h \right)$$

for any harmonic function h defined in Ω. It follows that

$$\max_{\partial D_2} R_2R_1(v) - \min_{\partial D_2} R_2R_1(v) \leq c \left(\max_{\partial D_1} R_1 v - \min_{\partial D_1} R_1 v \right) \tag{2.3}$$

and, since $R_1(v)(x) = O(|x|^{-1})$ as $|x| \to \infty$, we have

$$\|R_1(v)\|_{L^\infty} \leq \max_{\partial D_1} R_1(v) - \min_{\partial D_1} R_1(v) \tag{2.4}$$

for any $v \in C^\infty(\mathbb{R}^2 \backslash D_2)$. And we can obtain similar results for D_2 and R_2. Since $0 < c < 1$, the expansion (2.2) is well defined and satisfies (1.2). □

In the particular case of circular inclusions, it follows from Lemma 2.1 and Kelvin transforms that the main result (1.4) holds (see [2]). However, it is not easy to apply the asymptotic expansion (2.2) directly to the general case of arbitrary shape. On this account, we would make the expansion (2.2) simpler. We define the operator $K_1 : C^\infty(\mathbb{R}^2 \backslash \overline{D_2}) \to C^\infty(\mathbb{R}^2 \backslash \overline{D_1}) \cap C(\mathbb{R}^2 \backslash D_1)$ as follows:

$$\begin{cases} \triangle K_1(v) = 0 \quad \text{in } \mathbb{R}^2 \backslash \overline{D_1}, \\ K_1(v)(x) \text{ converges to some constant as } \ |x| \to \infty, \\ v = K_1(v) \text{ on } \partial D_1. \end{cases}$$

And we also define K_2 similarly. By the definitions of R_i and K_i $(i = 1, 2)$, we have

$$R_i(v) = K_i(v) + \text{some constant},$$

where the constant is dependent on v.

LEMMA 2.2. *We have*

$$\begin{aligned} u|_{\partial D_1} &= C_0 + \lim_{n\to\infty} (K_2K_1)^n(H)|_{\partial D_1}, \\ u|_{\partial D_2} &= C_0 + \lim_{n\to\infty} (K_1K_2)^n(H)|_{\partial D_2}, \end{aligned} \tag{2.5}$$

where C_0 is a constant.

Proof. Since $K_i(v) = v$ on ∂D_i for $i = 1, 2$, we have

$$\begin{aligned}&(R_1R_2)^n(-R_1(H) + R_1R_2(H)) + (R_2R_1)^n(-R_2(H) + R_2R_1(H))\\ &= c_n + (K_1K_2)^n(-K_1(H) + K_1K_2(H)) + (K_2K_1)^n(-K_2(H) + K_2K_1(H))\end{aligned}$$

for $n = 0, 1, 2, 3, \ldots$, where

$$\begin{aligned}c_n = &\{-(R_1R_2)^nR_1(H) + (R_2R_1)^nR_2R_1(H)\}\,|_{\partial D_2}\\ &+ \{-(R_2R_1)^nR_2(H) + (R_1R_2)^nR_1R_2(H)\}\,|_{\partial D_1}.\end{aligned}$$

By (2.3) and (2.4), we have $\sum_{n=0}^{\infty} |c_n| < \infty$. We thus set $C_0 = \sum_{n=0}^{\infty} c_n$. Then

$$\begin{aligned}u &= H - R_1(H) - R_2(H) + R_1R_2(H) + R_2R_1(H)\\ &\quad + \sum_{n=1}^{\infty}(R_1R_2)^n(-R_1(H) + R_1R_2(H)) + (R_2R_1)^n(-R_2(H) + R_2R_1(H))\\ &= C_0 + H - K_1(H) - K_2(H) + K_1K_2(H) + K_2K_1(H)\\ &\quad + \sum_{n=1}^{\infty}(K_1K_2)^n(-K_1(H) + K_1K_2(H)) + (K_2K_1)^n(-K_2(H) + K_2K_1(H))\\ &= C_0 + \{H - K_1(H)\} + \{-K_2(H) + K_1K_2(H)\} + K_2K_1(H) + \cdots\\ &= C_0 + \lim_{n\to\infty}(K_2K_1)^n(H) \text{ on } \partial D_1. \qquad \square\end{aligned}$$

Hence we conclude that

$$u|_{\partial D_1} - u|_{\partial D_2} = \lim_{n\to\infty}(K_2K_1)^n(H)|_{\partial D_1} - \lim_{n\to\infty}(K_1K_2)^n(H)|_{\partial D_2}. \tag{2.6}$$

In what follows, we consider

$$\lim_{n\to\infty}(K_2K_1)^n(H)|_{\partial D_1}.$$

Now we present an interesting representation for $\lim_{n\to\infty}(K_2K_1)^n(H)|_{\partial D_1}$ in the following lemma. Based on this, the main result would be derived without any asymptotic analysis and layer potentials.

LEMMA 2.3. *Let w be the solution of the following problem:*

$$\begin{cases} \triangle w = 0 \quad \textit{in } \mathbb{R}^2\backslash\overline{(D_1 \cup D_2)},\\ w(x) = O(|x|^{-1}) \quad \textit{as} \quad |x| \to \infty,\\ w|_{\partial D_1} = c_{1\epsilon} \textit{ (constant)},\\ w|_{\partial D_2} = c_{2\epsilon} \textit{ (constant)},\\ \int_{\partial D_1} \partial_\nu w \, ds = 1. \end{cases} \tag{2.7}$$

Then we have

$$\lim_{n\to\infty}(K_2K_1)^n(H)|_{\partial D_1} = \int_{\partial D_1}(\partial_\nu w)H ds.$$

Proof. By definition, we have

$$H = K_1(H) \quad \text{on } \partial D_1.$$

Since $K_1(H)$ is harmonic in D_2 and w is constant on ∂D_2, we have

$$\int_{\partial D_2} w\partial_\nu K_1(H)ds = 0.$$

And since $K_1(H)$ converges to some constant as $|x| \to \infty$ and w is constant on ∂D_1, we also have

$$\int_{\partial D_1} w\partial_\nu K_1(H)ds = 0.$$

It follows from Green's theorem that

$$\int_{\partial D_1} (\partial_\nu w)Hds + \int_{\partial D_2} (\partial_\nu w)K_1(H)ds = 0.$$

Similarly we have

$$\int_{\partial D_2} (\partial_\nu w)K_1(H)ds + \int_{\partial D_1} (\partial_\nu w)K_2K_1(H)ds = 0.$$

Hence we obtain

$$\begin{aligned}
\int_{\partial D_1} (\partial_\nu w)Hds &= \int_{\partial D_1} (\partial_\nu w)K_2K_1(H)ds \\
&= \int_{\partial D_1} (\partial_\nu w)(K_2K_1)^n(H)ds \quad \text{for} \quad n = 1, 2, 3, \dots \\
&= \int_{\partial D_1} (\partial_\nu w) \lim_{n\to\infty} (K_2K_1)^n(H)ds \\
&= \lim_{n\to\infty} (K_2K_1)^n(H). \qquad \square
\end{aligned}$$

Thus we focus on $\partial_\nu w$. We define $\varphi_1 : \mathbb{C}\backslash B_1(0) \to \mathbb{R}^2\backslash D_1$ as $\varphi_1 = \varphi + \frac{\epsilon}{2}$ and the conformal mapping $\Phi : \overline{B_1(0)}\backslash\{0\} \to \mathbb{R}^2\backslash D_1$ as

$$\Phi(z) = \varphi_1\left(\frac{z}{|z|^2}\right),$$

where $\varphi : \mathbb{C}\backslash B_1(0) \to \mathbb{R}^2\backslash D_{\text{right}}$ is the conformal mapping defined in the introduction. Then we have

$$\Phi^{-1}\left(\mathbb{R}^2\backslash\overline{(D_1 \cup D_2)}\right) \subset B_1(0)$$

and

$$\Phi^{-1}(\partial D_1) = \partial B_1(0).$$

We consider the solution W to the following Dirichlet problem:

$$\begin{cases} \triangle W = 0 \quad \text{in } B_1(0)\backslash\overline{\Phi^{-1}(D_2)}, \\ W = 1 \quad \text{on } \Phi^{-1}(\partial D_1) = \partial B_1(0), \\ W = -1 \quad \text{on } \Phi^{-1}(\partial D_2). \end{cases} \tag{2.8}$$

Let $M = \frac{1}{2}(c_{1\epsilon} - c_{2\epsilon})$ and $c_* = \frac{1}{2}(c_{1\epsilon} + c_{2\epsilon})$. Then, even though $w(\Phi(z))$ is not defined at 0, it follows from the decreasing behavior of w at infinity that

$$\begin{cases} w(\Phi(z)) = MW(z) + c_* \quad \text{for } z \in \Phi^{-1}\left(\mathbb{R}^2 \backslash \overline{(D_1 \cup D_2)}\right), \\ \partial_{\nu_{(x)}} w(x) = \left(\frac{M}{|\varphi'(z)|}\right) \partial_{\nu_{(z)}} W(z) \quad \text{for } z \in \partial B_1(0), \end{cases} \tag{2.9}$$

where $x = \Phi(z)$.

Without loss of generality, we assume that

$$B_{r_2}(r_2 + \epsilon - 1) \subset \Phi^{-1}(D_2) \subset B_{r_1}(r_1 + \epsilon - 1), \tag{2.10}$$

where r_1 and r_2 are independent of ϵ for any sufficiently small $\epsilon \geq 0$. (See Lemma 4.1 in the appendix for details.) Then we consider the solution U_1 and U_2 to the following equations:

$$\begin{cases} \triangle U_i = 0 \quad \text{in } B_1(0) \backslash \overline{B_{r_i}(r_i + \epsilon - 1)}, \\ U_i = 1 \quad \text{on } \Phi^{-1}(\partial D_1) = \partial B_1(0), \\ U_i = -1 \quad \text{on } \partial B_{r_i}(r_i + \epsilon - 1) \ \text{ for } i = 1, 2. \end{cases} \tag{2.11}$$

By the maximum principle, we have

$$U_1 \leq W \leq U_2 \ \text{ in } B_1(0) \backslash B_{r_1}(r_1 + \epsilon - 1),$$

and by Hopf's lemma, we have

$$\partial_\nu U_2 \leq \partial_\nu W \leq \partial_\nu U_1 \ \text{ on } \partial B_1(0). \tag{2.12}$$

Lemma 2.4. *We have the conformal mappings Ψ_1 and Ψ_2 such that*

$$\begin{cases} \Psi_1(B_1(0)) = \Psi_2(B_1(0)) = B_1(0), \\ B_{r_1}(r_1 + \epsilon - 1) = \Psi_1\left(B_{1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon})}(0)\right), \\ B_{r_2}(r_2 + \epsilon - 1) = \Psi_2\left(B_{1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon})}(0)\right), \end{cases} \tag{2.13}$$

and for $i = 1, 2$,

$$\Psi_i^{-1}(z) = \left(\beta_i\sqrt{\epsilon} + o\left(\sqrt{\epsilon}\right)\right) \frac{1}{z - (-1 - \gamma_i\sqrt{\epsilon} + o(\sqrt{\epsilon}))} + \kappa_i \quad \text{as } \epsilon \to 0, \tag{2.14}$$

where α_i, β_i, and γ_i are strictly positive constants.

Proof. See section 4.1 in the appendix. □

Moreover, by (2.11) and (2.13), we have

$$U_i(\Psi_i(t)) = -2(\log(1 - \alpha_i\sqrt{\epsilon} + o(\sqrt{\epsilon})))^{-1} \log(|t|) + 1$$

for $t \in B_1(0)$ and

$$\begin{aligned} \int_{\partial B_1(0)} \partial_{\nu(z)} U_i(z) ds(z) &= \int_{\partial B_1(0)} \partial_{\nu(t)} U_i(\Psi_i(t)) ds(t) \\ &= -4\pi(\log(1 - \alpha_i\sqrt{\epsilon} + o(\sqrt{\epsilon})))^{-1} \quad \text{for } i = 1, 2. \end{aligned}$$

Therefore, by (2.9) and (2.12), we have

$$\begin{aligned}\int_{\partial B_1(0)} M\partial_{\nu_{(z)}} W(z)ds(z) &= \int_{\partial B_1(0)} \partial_{\nu(z)} w(\Phi(z))ds(z)\\ &= \int_{\partial D_1} \partial_\nu w(x)ds(x) = 1\end{aligned}$$

and

$$M \geq -\frac{\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{4\pi}.$$

It follows that

$$\begin{aligned}\partial_{\nu_{(z)}} w(\Phi(z)) &= M\partial\nu_{(z)}W(z)\\ \text{by (2.12)} \quad &\geq -\frac{\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{4\pi}\partial\nu_{(z)}U_2(z)\\ &= -\frac{\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{4\pi}\partial\nu_{(t)}U_2(\Psi_2(t))|(\Psi_2^{-1})'(z)|\\ &\geq \frac{\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{2\pi\log(1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon}))}|(\Psi_2^{-1})'(z)|\\ &\geq \frac{\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{2\pi\log(1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon}))}\min_{|z|=1}|(\Psi_2^{-1})'(z)|\\ \text{(2.15)} \qquad \text{by (2.14)} \quad &\geq C\sqrt{\epsilon},\end{aligned}$$

where $z = \Psi_2(t) \in \partial B_1(0)$. And since φ_1' is independent of ϵ, when $H(x_1, x_2) = x_1$, we have

$$\lim_{n\to\infty}(K_2K_1)^n(H)|_{\partial D_1} \geq C_*\sqrt{\epsilon}$$

and, by definition,

$$\lim_{n\to\infty}(K_1K_2)^n(H)|_{\partial D_2} \leq 0.$$

These bounds complete the proof of (1.3). □

REMARK 2.5. *We assumed that D_2 has a C^2 boundary. This regularity condition is used only for choosing r_2 of* (2.10) *in Lemma* 4.1. *We observe that one can prove our estimates on a relaxed regularity condition. For example, even when $D_2 = (-1,0)\times(-1,1) - \epsilon/2$, the estimates* (1.3), (1.4), *and* (1.8) *hold.*

3. The proof of Theorem 1.2. We first prove that the inequality (1.5) holds. This proof is the continuation of the proof of Theorem 1.1. By the argument similar to (2.15), we have

$$\begin{aligned}\partial_{\nu_{(z)}} w(\Phi(z)) &= M\partial\nu_{(z)}W(z)\\ &\leq -\frac{\log(1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{4\pi}\partial\nu_{(z)}U_1(z)\\ &= -\frac{\log(1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{4\pi}\partial\nu_{(t)}U_1(\Psi_1(t))|(\Psi_1^{-1})'(z)|\\ &\leq \frac{\log(1-\alpha_2\sqrt{\epsilon}+o(\sqrt{\epsilon}))}{2\pi\log(1-\alpha_1\sqrt{\epsilon}+o(\sqrt{\epsilon}))}|(\Psi_1^{-1})'(z)|\\ \text{(3.1)} \quad \text{by } \overline{z} = \frac{1}{z} \text{ on } \partial B_1(0), \quad &\leq CP(p_\epsilon\overline{z}),\end{aligned}$$

where $P(x,y)$ is a Poisson kernel and

$$\begin{aligned} p_\epsilon &= -1 + \gamma_1\sqrt{\epsilon} + o(\sqrt{\epsilon}) \\ &= -1 + O(\sqrt{\epsilon}) \in B_1(0) \ \text{ as } \epsilon \to \infty. \end{aligned}$$

One can prove by assuming $\varphi(-1) = 0$ and the regularity conditions of φ on the boundary, instead of the assumption (2.10), that this bound (3.1) holds and $p_\epsilon = -1 + O(\sqrt{\epsilon}) \in B_1(0)$ as $\epsilon \to 0$.

From the definition of φ, $(\varphi(\frac{1}{z}) + c)^{-1}$ is extended to a conformal mapping defined in $B(0)$ for some constant c that attains zero value at $z = 0$. Hence $\varphi(z)$ can be rewritten as follows:

$$\varphi(z) = a_1 z + h\left(\frac{1}{z}\right) \quad \text{for } z \in \mathbb{C} \setminus B_1(0), \tag{3.2}$$

where h is analytic in $B_1(0)$ and a_0 is a nonzero constant. Then for $H(x_1, x_2) = x_1$, we have

$$H(\varphi_1(z)) = \Re\left(a_1 z + h\left(\frac{1}{z}\right)\right) + \frac{\epsilon}{2}.$$

Then we define $\mathbf{H}$ on $\overline{B}_1(0)$ as follows:

$$\mathbf{H}(z) = \Re\left(a_1\overline{z} + h\left(z\right)\right) + \frac{\epsilon}{2} \quad \text{for } z \in \overline{B}_1(0). \tag{3.3}$$

It is easy to see that $\mathbf{H}(z) = H(\varphi_1(\overline{z}))$ on $\partial B_1(0)$, and that $\mathbf{H}$ is a harmonic function in $B_1(0)$ and belongs to $C^1(\overline{B_1(0)})$. Then it follows from Lemma 2.3 that

$$\begin{aligned} 0 \le \lim_{n\to\infty} (K_2K_1)^n(H)|_{\partial D_1} &= \int_{\partial D_1} \partial_\nu w(x) H(x) ds(x) \\ &\le C_1 \int_{\partial B_1(0)} P(p_\epsilon, \overline{z}) H(\varphi_1(z)) ds(z) \\ &= C_1 \ \mathbf{H}(\overline{p_\epsilon}) \\ \text{by } \mathbf{H}(\varphi_1(-1)) = \frac{\epsilon}{2}, \ &\le C_2\sqrt{\epsilon}. \end{aligned} \tag{3.4}$$

Applying the same argument to ψ and D_{left}, we also have

$$0 \ge \lim_{n\to\infty} (K_1K_2)^n(H)|_{\partial D_2} \ge C_2{}'\sqrt{\epsilon}.$$

These bounds are reduced to the inequality (1.5), that is,

$$|u|_{\partial D_1} - u|_{\partial D_2}| \le C_1^*\sqrt{\epsilon}.$$

REMARK 3.1. *We suggest another method to get the inequalities* (3.4) *and* (1.5). *We divide the integration in* (3.4) *into two parts as follows:*

$$\begin{aligned} \int_{\partial B_1(0)} P(p_\epsilon, \overline{z}) H(\varphi_1(z)) ds(z) = &\int_{\partial B_1(0) \ \textit{and} \ |z+1| \le \sqrt[4]{\epsilon}} P(p_\epsilon, \overline{z}) H(\varphi_1(z)) ds(z) \\ &+ \int_{\partial B_1(0) \ \textit{and} \ |z+1| > \sqrt[4]{\epsilon}} P(p_\epsilon, \overline{z}) H(\varphi_1(z)) ds(z). \end{aligned}$$

Then the inequality (3.4) *can also be proved directly without* (3.2). *Moreover, one can prove by using the same partition of integration that the bound* (1.5) *still holds for any harmonic function* H *with* $\partial_{x_2} H(0) = 0$.

We now derive the inequality (1.6). We divide u into four parts as follows:

$$u = x_1 + u_0 + u_1 + u_2$$

such that for $i = 0, 1, 2$, $\Delta u_i = 0$ in $\mathbb{R}^2 \backslash \overline{D_1 \cup D_2}$ and $u_i = O(1)$ as $|x| \to \infty$ with the boundary conditions

$$\begin{cases} u_0 &= u \text{ (constants)} \quad \text{on } \partial D_1 \cup \partial D_2, \\ u_1 &= -x_1 \text{ on } \partial D_1 \quad \text{and } u_1 = 0 \text{ on } \partial D_2, \\ u_2 &= -x_1 \text{ on } \partial D_2 \quad \text{and } u_2 = 0 \text{ on } \partial D_1. \end{cases}$$

Hence, we would estimate them separately.

Estimate for u_0. It follows from the maximum principle for analytic functions that

$$\|\nabla u_0\|_{L^\infty(\mathbb{R}^2 \backslash (D_1 \cup D_2))} \leq \|\partial_\nu u_0\|_{L^\infty(\partial D_1 \cup \partial D_2)}.$$

Thus we estimate $\|\partial_\nu u_0\|_{L^\infty(\partial D_1)}$. There exists a constant C independent of ϵ such that

$$\|\partial_\nu u_0\|_{L^\infty(\partial D_1)} \leq C \|\partial_{\nu(z)} u_0(\Phi(z))\|_{L^\infty(\partial B_1(0))},$$

where Φ is as defined in the proof of Theorem 1.1. By the argument similar to that of (2.12) and (3.1), we can choose a constant C such that for $z \in \partial B_1(0)$

$$\begin{aligned} \left|\partial_{\nu(z)} u_0(\Phi(z))\right| &\leq \left| \frac{1}{2} (u|_{\partial D_1} - u|_{\partial D_2}) \partial_{\nu(z)} U_1(z) \right| \\ \text{by (1.5) and the Poisson kernel } P(p_\epsilon, \cdot), \quad &\leq C \frac{1}{\sqrt{\epsilon}}, \end{aligned}$$

where U_1 is as defined in (2.11). Since u_0 is constant on ∂D_i for $i = 1, 2$, we conclude that

$$\|\nabla u_0\|_{L^\infty(\mathbb{R}^2 \backslash (D_1 \cup D_2))} \leq C_a \frac{1}{\sqrt{\epsilon}}, \tag{3.5}$$

where C_a is a constant independent of ϵ.

Estimate for u_1. Let $\psi_2 : \mathbb{C} \backslash B_1(0) \to \mathbb{R}^2 \backslash D_2$ be the conformal mapping defined by $\psi_2 = \psi - \frac{\epsilon}{2}$ as φ_1. Since $u_1(\psi_2(z)) = 0$ on $\partial B_1(0)$, $u_1(\psi_2(z))$ can be extended harmonically to $\mathbb{C} \backslash (\mathbf{B} \cup \psi_2^{-1}(D_1))$ as follows:

$$-u_1 \left(\psi_2 \left(\frac{z}{|z|^2} \right) \right) \quad \text{for } z \in B_1(0) \backslash \mathbf{B},$$

where $\mathbf{B} = \{ z \mid \frac{z}{|z|^2} \in \psi_2^{-1}(D_1) \}$. The symmetry of the extended $u_1(\psi_2(z))$ occurs on $\partial \mathbf{B}$ and $\partial \psi_2^{-1}(D_1)$. This yields

$$\|\nabla u_1\|_{L^\infty(\mathbb{R}^2 \backslash (D_1 \cup D_2))} \leq C \|\nabla u_1\|_{L^\infty(\partial D_1)},$$

where C is independent of ϵ. We now estimate $\|\partial_\nu u_1\|_{L^\infty(\partial D_1)}$, because the tangential derivative of u_1 on ∂D_1 is not only fixed by $H(x_1, x_2) = x_1$ but also independent of ϵ. Using a linear fractional transform, without loss of generality, we can also assume that

$$B_{r_4}(-1-\epsilon-r_4) \subset \varphi_1^{-1}(D_2) \subset B_{r_3}(-1-\epsilon-r_3),$$

where r_3 and r_4 are independent of ϵ. Then we consider a harmonic function V_3 and V_4 as follows:

$$\begin{cases} \Delta V_i = 0 \quad \text{in } \mathbb{R}^2 \backslash \overline{(B_1(0) \cup B_{r_i}(-1-\epsilon-r_i))}, \\ V_i(z) = O(1) \quad \text{as } |z| \to \infty, \\ V_i(z) = u_1(\varphi_1(z)) = -H(\varphi_1(z)) \quad \text{for } z \in \partial B_1(0), \\ V_i(z) = 0 \quad \text{for } z \in \partial B_{r_i}(-1-\epsilon-r_i) \end{cases}$$

for $i = 3, 4$. Since $u_1(\varphi_1(z)) \le 0$ for $z \in \partial B_1(0)$, it follows from Hopf's lemma that

$$\partial_\nu V_3(z) \le \partial_{\nu(z)} u_1(\varphi_1(z)) \le \partial_\nu V_4(z) \quad \text{for } z \in \partial B_1(0). \tag{3.6}$$

Therefore, we now estimate $\partial_\nu V_3(z)$ and $\partial_\nu V_4(z)$. By a definition similar to K_1 and K_2 in the previous proof, we define the operator $K_\alpha : C^\infty(\mathbb{R}^2 \backslash \overline{B_{r_3}(-1-\epsilon-r_3)}) \to C^\infty(\mathbb{R}^2 \backslash \overline{B_1(0)}) \cap C(\mathbb{R}^2 \backslash B_1(0))$ as

$$\begin{cases} \triangle K_\alpha(v) = 0 \quad \text{in } \mathbb{R}^2 \backslash \overline{B_1(0)}, \\ K_\alpha(v)(z) = O(1) \quad \text{as } |z| \to \infty, \\ (v - K_\alpha(v))|_{\partial B_1(0)} = 0, \end{cases}$$

and $K_\beta : C^\infty(\mathbb{R}^2 \backslash \overline{B_1(0)}) \to C^\infty(\mathbb{R}^2 \backslash \overline{B_{r_3}(-1-\epsilon-r_3)}) \cap C(\mathbb{R}^2 \backslash B_{r_3}(-1-\epsilon-r_3))$ is defined similarly. Indeed K_α is the Kelvin transform for $B_1(0)$ and K_β is the Kelvin transform for $B_{r_3}(-1-\epsilon-r_3)$ simply. Then we define a harmonic function U on $\mathbb{R}^2 \backslash (B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))$ as follows:

$$U = -K_\alpha \mathbf{H}(\overline{z}) + K_\beta K_\alpha \mathbf{H}(\overline{z}) - \sum_{n=1}^{\infty} (I - K_\beta)(K_\alpha K_\beta)^n K_\alpha \mathbf{H}(\overline{z}),$$

where $\mathbf{H}$ is defined at (3.3). By an argument similar to Lemma 2.2 or [2, 4], we have

$$\begin{cases} \triangle U = 0 \quad \text{in } \mathbb{R}^2 \backslash \overline{(B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))}, \\ U(z) = O(1) \quad \text{as } |z| \to \infty, \\ U = 0 \quad \text{for } z \in \partial B_{r_3}(-1-\epsilon-r_3), \\ (U + H(\varphi(z)))\,|_{B_1(0)} = \text{a constant with order } O(\sqrt{\epsilon}) \quad \text{as } \epsilon \to 0. \end{cases}$$

We note that U is a solution to the equation with the circular inclusions. Thus, we can apply Theorem 1.1 of Kang et al. [4] in U. Then we have

$$\|\nabla U\|_{L^\infty\left(\mathbb{R}^2 \backslash (B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))\right)} \le C \left(\frac{1}{\sqrt{\epsilon}}\right).$$

On the other hand, we have

$$\begin{cases} \triangle(V_3 - U) = 0 \quad \text{in } \mathbb{R}^2 \backslash \overline{(B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))}, \\ (V_3 - U)(z) = O(1) \quad \text{as } \ |z| \to \infty, \\ (V_3 - U)(z) = 0 \quad \text{for } z \in \partial B_{r_3}(-1-\epsilon-r_3), \\ (V_3 - U)|_{\partial B_1(0)} = \text{a constant with order } O(\sqrt{\epsilon}) \quad \text{as } \epsilon \to 0. \end{cases}$$

By the same argument as *Estimate for* u_0, we have

$$\|\nabla(V_3 - U)\|_{L^\infty\left(\mathbb{R}^2 \backslash (B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))\right)} \leq C\left(\frac{1}{\sqrt{\epsilon}}\right).$$

These bounds are reduced to

$$\|\nabla V_3\|_{L^\infty\left(\mathbb{R}^2 \backslash (B_{r_3}(-1-\epsilon-r_3) \cup B_1(0))\right)} \leq C\left(\frac{1}{\sqrt{\epsilon}}\right).$$

Similarly, we also obtain

$$\|\nabla V_4\|_{L^\infty\left(\mathbb{R}^2 \backslash (B_{r_4}(-1-\epsilon-r_4) \cup B_1(0))\right)} \leq C\left(\frac{1}{\sqrt{\epsilon}}\right).$$

By (3.6), these bounds yield

$$\|\nabla u_1\|_{L^\infty(\mathbb{R}^2 \backslash (D_1 \cup D_2))} \leq C_\beta\left(\frac{1}{\sqrt{\epsilon}}\right), \tag{3.7}$$

where C_β is a constant independent of ϵ.

Estimate for u_2. This estimate is derived in the same way as u_1.

Therefore, by (3.5) and (3.7) we have completed the proof of (1.6). □

4. Appendix. In this appendix we make up the parts omitted in the proof of Theorem 1.1. We first consider Lemma 2.4.

4.1. How to construct the conformal mapping Ψ_1^{-1}. We now prove Lemma 2.4; that is, we present a method for constructing Ψ_1^{-1}. For convenience, we use two steps to derive it.

• *Step* 1. To make $\Psi_1^{-1}(B_1(0))$ and $\Psi_1^{-1}(B_{r_1}(r_1+\epsilon-1))$ concentric balls, we find

$$f_1(z) = \frac{1}{z - (-1 - \tau(\epsilon)\sqrt{\epsilon})}$$

with $f_1(-1) - f_1(-1+\epsilon) = f_1(-1+\epsilon+2r_1) - f_1(1)$. As ϵ approaches 0, we have

$$\begin{aligned} \lim_{\epsilon \to 0}\left(\frac{1}{\tau(\epsilon)}\right)^2 &= \lim_{\epsilon \to 0} f_1(-1+\epsilon+2r_1) - f_1(1) \\ &= \left(\frac{1}{\gamma_1}\right)^2. \end{aligned}$$

Therefore, we have

$$f_1(z) = \frac{1}{z - (-1 - \gamma_1\sqrt{\epsilon} + o(\sqrt{\epsilon}))}.$$

• *Step* 2. To make $\Psi_1^{-1}(B_1(0))$ a unit disk, we find

$$f_2(z) = \lambda(\epsilon)\sqrt{\epsilon} f_1(z)$$

with $f_2(-1) - f_2(1) = 2$. Then, as ϵ approaches 0, we have

$$\begin{aligned} 2 &= \lim_{\epsilon\to 0} \lambda(\epsilon)\ \sqrt{\epsilon}\ f_1(-1) \\ &= \lim_{\epsilon\to 0} \lambda(\epsilon)\frac{1}{\gamma_1} = \frac{\beta_1}{\gamma_1}. \end{aligned}$$

Therefore, we have

$$f_2(z) = (\beta_1\sqrt{\epsilon} + o(\sqrt{\epsilon}))\frac{1}{z - (-1 - \gamma_1\sqrt{\epsilon} + o(\sqrt{\epsilon}))}$$

and

$$f_2(B_1(0)) = B_1(0) - k_1 \ \text{ for some constant } k_1.$$

Hence, we obtain

$$\Psi_1^{-1}(z) = f_2(z) + k_1,$$

satisfying

$$\Psi_1^{-1}(B_1(0)) = B_1(0). \qquad \square$$

4.2. How to construct the radii r_1 and r_2 satisfying (2.10). To construct them, we provide the variable ϵ to the definitions used in the main proof. Thus D_1 and D_2 are rewritten in the form $D_1(\epsilon) = D_{\text{right}} + \frac{\epsilon}{2}$ and $D_2(\epsilon) = D_{\text{left}} - \frac{\epsilon}{2}$. In addition, we assume that $\varphi : \mathbb{C}\backslash B_1(0) \to \mathbb{R}^2\backslash D_{\text{right}}$ is a bijective conformal mapping with $\varphi(-1) = 0$. Then φ_1 and Φ are rewritten as $\varphi_{1\epsilon} = \varphi + \epsilon$ and $\Phi_\epsilon = \varphi_{1\epsilon}(\frac{z}{|z|^2})$.

For any r and z with $0 < r < 1$ and $r \le |z| \le 1$, we define the ball with radius r, denoted by $B_r[z]$, in $B_1(0)$ whose boundary attains the minimal distance r to $\partial B_1(0)$ at z, i.e.,

$$\mathrm{d}(B_r[z],\ \partial B_1(0)) = \mathrm{d}(z,\ \partial B_1(0)) = r \quad \text{and} \quad z \in \partial B_r[z],$$

where $\mathrm{d}(A, B)$ is the distance between A and B.

LEMMA 4.1. *Let $\epsilon' = d(\partial B_1(0), \partial\Phi_\epsilon^{-1}(D_2(\epsilon)))$, that is, the distance between $\partial B_1(0)$ and $\partial\Phi_\epsilon^{-1}(D_2(\epsilon))$. Then we have a constant C such that*

$$\epsilon < C\epsilon' \qquad \text{for } \ \epsilon < 1. \tag{4.1}$$

We suppose that for each $\epsilon > 0$, z_ϵ is the point at which $\partial\Phi_\epsilon^{-1}(D_2(\epsilon))$ attains the minimal distance ϵ' to $\partial B_1(0)$, i.e., $z_\epsilon \in \partial\Phi_\epsilon^{-1}(D_2(\epsilon))$ and $\epsilon' = d(z_\epsilon, \partial B_1(0))$. Then we have r_1, r_2, and $\epsilon_0 > 0$ such that

$$B_{r_2}[z_\epsilon] \subset \Phi_\epsilon^{-1}(D_2(\epsilon)) \subset B_{r_1}[z_\epsilon] \quad \text{for } \epsilon < \epsilon_0. \tag{4.2}$$

If we use this result (4.2) instead of the assumption (2.10), then we can prove by the same derivation as (2.15) that $\partial_{\nu_{(z)}} w(\Phi(z)) \ge C\sqrt{\epsilon'}$. It follows from (4.1) that (2.15) holds.

Proof. To prove the inequality (4.1), we suppose that p_ϵ is the closest point at which $\partial B_1(0)$ attains the minimal distance ϵ' to $\partial\Phi_\epsilon^{-1}(D_2(\epsilon))$, i.e., $\epsilon' = \mathrm{d}(p_\epsilon, z_\epsilon)$ and $p_\epsilon \in \partial B_1(0)$. Then we obtain

$$\begin{aligned}\epsilon &\le \mathrm{d}(\Phi_\epsilon(p_\epsilon), \Phi_\epsilon(z_\epsilon))\\ &= \mathrm{d}(\Phi_0(p_\epsilon), \Phi_0(z_\epsilon))\\ &\le C\mathrm{d}(p_\epsilon, z_\epsilon) = C\epsilon' \quad \text{for } \epsilon < 1,\end{aligned}$$

where C is a strictly positive constant. Hence, we have completed the proof of (4.1).

To construct the radius r_1, we may assume that the boundary $\partial(\varphi^{-1}(D_{\text{left}}))$ near 0 is the graph of equation $z_1 = f(z_2)$, defined on I, as follows:

$$\begin{cases} f(z_2) + z_2 i \in \partial(\varphi^{-1}(D_{\text{left}})) \quad \text{for} \quad z_2 \in I,\\ f(0) = -1 \quad \text{and} \quad f'(0) = 0,\end{cases}$$

where I is a sufficient small open interval containing 0. Owing to $\varphi \in C^2(\mathbb{C}\backslash B_1(0))$ and the strict convexity of D_{right} at 0, we obtain

$$\frac{d^2 f}{dz_2{}^2}(0) < \left[-\frac{d^2\sqrt{1-z_2^2}}{dz_2{}^2}\right]_{z_2=0}.$$

Hence, one can choose $R_0 > 0$ such that

$$\Phi_0^{-1}\left(\cup_{0\le\epsilon\le 2} D_2(\epsilon)\right) \subset B_{R_0}(-1+R_0) \subset B_1(0).$$

It may be noted that

$$\text{(4.3)} \qquad \begin{cases} \Phi_\epsilon^{-1}(D_2(\epsilon)) = \Phi_0^{-1}(D_2(2\epsilon)) \subset B_{R_0}(-1+R_0) \quad \text{for } \epsilon < 1,\\ R_0 < 1 \quad \text{and} \quad -1 \in \partial B_{R_0}(-1+R_0).\end{cases}$$

Let $\mathbf{S} = \{z \in B_1(0) \mid \Phi_\epsilon(z) \in \partial D_1(\epsilon) \text{ for some } \epsilon \in [0,1]\}$. Then there is a neighborhood N_1 of 0 such that for each $z \in \mathbf{S}\cap N_1$, ϵ is uniquely determined by $\Phi_\epsilon(z) \in \partial D_1(\epsilon)$, and for each ϵ, the boundary $\partial\Phi_\epsilon^{-1}(D_1(\epsilon))$ is connected in N_1. And we define $\kappa(z)$ as the curvature of $\partial\Phi_\epsilon^{-1}(D_1(\epsilon))$ at $z \in \mathbf{S}\cap N_1$. By the continuity of $\kappa(z)$ and $\kappa(0) > R_0^{-1}$, there is a neighborhood N_2 of 0 such that

$$\text{(4.4)} \qquad \begin{cases} \frac{2}{R_0+1} < \kappa(z) \quad \text{for } z \in \mathbf{S} \cap N_2,\\ \text{the boundary} \quad \partial\Phi_\epsilon^{-1}(D_1(\epsilon)) \text{ is connected in } N_2.\end{cases}$$

Let $r_1 = \frac{R_0+1}{2}$. Then we have

$$\cup_{0\le\epsilon\le 1}\Phi_\epsilon^{-1}\left(D_1(\epsilon)\right) \subset B_{R_0}(-1+R_0) \subset B_{r_1}[-1]$$

and can choose a small constant $\delta > 0$ such that

$$\begin{cases} \cup_{0\le\epsilon\le 1}\,\Phi_\epsilon^{-1}\left(D_1(\epsilon)\right) \subset B_{r_1}[z] \cup N_2 \quad \text{for any } z \in B_\delta(-1)\cap B_1(0),\\ B_\delta(-1)\cap B_1(0) \subset N_2.\end{cases}$$

By (4.3) and the relation of $\partial B_1(0)$ and $B_{R_0}(-1+R_0)$, we can obtain a sufficiently small constant $\epsilon_0 > 0$ such that

$$z_\epsilon \in B_\delta(-1) \quad \text{for each } \epsilon < \epsilon_0,$$

where z_ϵ is mentioned above. It follows that

$$\begin{aligned}\Phi_\epsilon^{-1}(D_1(\epsilon)) &\subset (\Phi_\epsilon^{-1}(D_1(\epsilon)) \cap N_2) \cup (\Phi_\epsilon^{-1}(D_1(\epsilon)) \cap N_2^c) \\ &\subset (\Phi_\epsilon^{-1}(D_1(\epsilon)) \cap N_2) \cup B_{r_1}[z_\epsilon] \\ \text{by (4.4)} &\subset B_{r_1}[z_\epsilon].\end{aligned}$$

This means that r_1 is the desirable radius.

To choose the radius r_2, we define $\kappa : [0, \epsilon_0] \times \partial D_{\text{left}} \to \mathbb{R}^+$ by

$$\kappa(\epsilon, z) = \text{the curvature of } \Phi_\epsilon^{-1}\left(\partial D_2(\epsilon)\right) \text{ at } \Phi_\epsilon^{-1}\left(z - \frac{\epsilon}{2}\right).$$

We set $r_2 = \left(\sup\left\{\kappa(\epsilon, z) \mid (\epsilon, z) \in [0, \epsilon_0] \times \partial D_{\text{left}}\right\}\right)^{-1}$. It is easy to prove that

$$B_{r_2}[z_\epsilon] \subset \Phi_\epsilon^{-1}(D_2(\epsilon)) \quad \text{for } \epsilon < \epsilon_0.$$

Therefore we have completed the proof. □

Acknowledgments. The author would like to express his gratitude to Professor Hyeonbae Kang, who suggested the problem studied in this paper and gave useful comments. The author is also grateful to Professor David Kinderlehrer for several helpful discussions and advice. The author proved an estimate only for symmetric inclusions in the first draft. Professor Kinderlehrer's advice stimulated the author to complete this paper for general shapes. The author would also like to thank the referees for their thorough reading of the paper and constructive comments.

MATHEMATICAL ANALYSIS OF AGE-STRUCTURED HIV-1 DYNAMICS WITH COMBINATION ANTIRETROVIRAL THERAPY*

LIBIN RONG†, ZHILAN FENG†, AND ALAN S. PERELSON‡

Abstract. Various classes of antiretroviral drugs are used to treat HIV infection, and they target different stages of the viral life cycle. Age-structured models can be employed to study the impact of these drugs on viral dynamics. We consider two models with age-of-infection and combination therapies involving reverse transcriptase, protease, and entry/fusion inhibitors. The reproductive number $\mathcal{R}$ is obtained, and a detailed stability analysis is provided for each model. Interestingly, we find in the age-structured model a different functional dependence of $\mathcal{R}$ on ϵ_{RT}, the efficacy of a reverse transcriptase inhibitor, than that found previously in nonage-structured models, which has significant implications in predicting the effects of drug therapy. The influence of drug therapy on the within-host viral fitness and the possible development of drug-resistant strains are also discussed. Numerical simulations are performed to study the dynamical behavior of solutions of the models, and the effects of different combinations of antiretroviral drugs on viral dynamics are compared.

1. Introduction.

Since the discovery of the human immunodeficiency virus type 1 (HIV-1) in the early 1980s, the disease has spread in successive waves to most regions around the globe. It is reported that HIV has infected more than 60 million people, and over a third of them subsequently died [10]. Considerable scientific effort has been devoted to the understanding of viral pathogenesis, host/virus interactions, immune response to infection, and antiretroviral therapy.

Over the last decade, there has been a great effort in the mathematical modeling of HIV infection and treatment strategies. These models mainly investigated the dynamics of the target cells and infected cells, viral production and clearance, and the effects of antiretroviral drugs treatment. Perelson et al. [44] and Ho et al. [22] used a simple mathematical model to analyze a set of viral load data collected from infected patients after the administration of a protease inhibitor, and the virion clearance rate, the rate of loss of productively cells, and the viral production rate were estimated. These estimates were minimal estimates since the effects of antiretroviral drugs were assumed to be 100% effective, and cells were assumed to produce new virus immedi-

ately after they were infected [35, 36]. In order to characterize the time between the infection of target cells and the production of virus particles, an intracellular delay was introduced by Herz et al. [19] in a mathematical model to analyze the clinical data. Subsequently, Culshaw and Ruan [3] investigated the effect of the time delay on the stability of the endemical equilibrium in their model. Criteria were presented to guarantee the asymptotic stability of the infected steady state independent of the time delay. In [35], Nelson, Murray, and Perelson studied a generalized model that included a discrete delay and allowed for less than perfect drug effects. The estimation of kinetic parameters underlying HIV infection was improved by the use of a delay differential equation model. In [31, 32], the authors used a gamma distribution function to describe a continuous delay between infection and viral production and found no change in the estimate of δ, the death rate of productively infected cells. However, Nelson and Perelson [36] extended this model and showed that the constancy of δ was due to the assumption of 100% drug effectiveness. When drug effectiveness was less than 100%, the estimate of δ depended on the delay, i.e., the variance and mean of the assumed gamma distribution. Recently, a model including both pharmacokinetics and the intracellular delay has been employed to obtain new estimates of intracellular delay and the antiviral efficacy of ritonavir [7].

Age-structured models have also been developed to study the epidemiology of HIV. Thieme and Castillo-Chavez [52] kept track of an individual's infection age to study the effect of infection-age-dependent infectivity on the dynamics of HIV transmission in a homogeneously mixing population. Kirschner and Webb [24] proposed a model that incorporated age structure into the infected cells to account for the mechanism of AZT (zidovudine) treatment. Recently, for the within-host dynamics of HIV, age-structured models have received increasing interest due to their greater flexibility in modeling viral production and mortality of infected cells [16, 34]. Nelson et al. [34] considered an age-structured model that allowed for variations in the production rate of virus particles and the death rate of infected T cells. For a specific form of the viral production function and constant death rate of infected cells, the authors performed a local stability analysis of the nontrivial equilibrium point. They used numerical simulations to illustrate that the time to reach the peak viral level depended not only on the initial conditions but also on the speed at which viral production achieves its maximum value. Based on this age-structured model, Gilchrist, Coombs, and Perelson [16] used the various life history trade-offs between viral production and clearance of infected cells to derive the within-host relative viral fitness.

In this article, we develop two age-structured models to study HIV-1 infection dynamics. These models extend the existing age-structured models [16, 24, 34] by incorporating combination therapies to study the influence of antiretroviral therapy on the evolution of HIV-1. The first model includes therapy with a combination of a reverse transcriptase (RT) inhibitor and a protease inhibitor, while the second model includes an entry inhibitor and a protease inhibitor. To account for the fact that reverse transcription takes place in the early stage of infection before an infected T cell produces virus particles, we divide the infected cells into two subclasses. One subclass represents the cells that have been infected by the virus but in which reverse transcription has not been completed. The other subclass contains infected cells that have finished the reverse transcription process and are capable of producing new virions. Our stability analysis is performed for a general form of both the viral production rate and the mortality rate of infected cells. The stability of the infection-free or the infected steady state is shown to depend on the reproductive ratio $\mathcal{R}$ being

smaller or greater than 1. The formulation of this reproductive ratio also provides an appropriate measure for the within-host viral fitness, which can be used to explore the optimal viral production rate for which $\mathcal{R}$ is maximized.

We also discuss the possible influence of treatment for drug-sensitive strains of HIV-1 on the development of drug-resistant strains of the pathogen. Clinical studies have suggested that prolonged treatment with a single antiretroviral drug may be associated with the emergence of resistant virus [20, 26, 27, 28, 39]. The impact of drug treatment on the dynamics of resistant stains of pathogens has been studied using age-independent mathematical models (see, for example, [11, 26, 55]). We show that if viral production is linked to resistance, then higher treatment efficacy with antiretroviral agents (such as protease inhibitors) may lead to the establishment of multiple viral strains with a wider range of resistance levels.

The organization of the remaining part is as follows. In section 2, we formulate a mathematical model for HIV-1 infection that generalizes the age-structured model proposed in [34] by incorporating an RT inhibitor and a protease inhibitor. Section 3 is devoted to the analysis of our model, including the existence and stability of both the infection-free and the infected steady states. In section 4, another model including therapy with a new class of drugs, fusion/entry inhibitors, is developed. Stability properties of the steady states are also obtained in this section. In section 5, we derive a criterion for invasion by drug-resistant strains and explore how drug treatment may affect the optimal viral fitness of resistant strains. Some numerical simulations are presented in section 6 to illustrate/extend our analytical results. We also compare the treatment effects of these two combination antiretroviral therapies. Section 7 contains concluding remarks.

2. The model with RT and protease inhibitors. HIV infection begins by the attachment of a virus to a $CD4^+$ cell. Inside the cell, the HIV-1 enzyme RT makes a DNA copy of the virus's RNA genome. During this process, if an RT inhibitor is present, then the viral genome will not be copied into DNA, and therefore the host cell will not produce new virus. When the virus replicates, its DNA is read out to produce viral proteins. A large polyprotein is made, and a viral protease is needed to cut the long polypeptide chain into individual components that are needed to produce infectious virus particles. If the HIV-1 protease is inhibited, the newly produced virus will be noninfectious.

From the above description of the HIV life cycle and the roles of various inhibitors, it is clear that the infection age of an infected cell can be important for the study of HIV dynamics under the influence of antiretroviral drug treatment. In [34] the following age-structured model of HIV infection (without drug treatment) was proposed:

$$
\begin{aligned}
&\frac{d}{dt}T(t) = s - dT - kVT,\\
&\frac{\partial}{\partial t}T^*(a,t) + \frac{\partial}{\partial a}T^*(a,t) = -\delta(a)T^*(a,t),\\
&\frac{d}{dt}V(t) = \int_0^\infty p(a)T^*(a,t)da - cV,\\
&T^*(0,t) = kVT,
\end{aligned}
\tag{2.1}
$$

where $T(t)$ denotes the concentration of uninfected target T cells at time t, $T^*(a,t)$

denotes the concentration of infected T cells of infection age a (i.e., the time that has elapsed since an HIV virion has penetrated the cell) at time t, and $V(t)$ denotes the concentration of infectious virus at t. s is the recruitment rate of healthy T cells, d is the per capita death rate of uninfected cells, $\delta(a)$ is the age-dependent per capita death rate of infected cells, c is the clearance rate of virions, k is the rate at which an uninfected cell becomes infected by an infectious virus, and $p(a)$ is the viral production rate of an infected cell with age a.

The functional forms of the viral production kernel, $p(a)$, and the death rate of infected cells, $\delta(a)$, need to be determined experimentally [21, 34]. In [34], the authors choose the following function for the production rate:

$$p(a) = \begin{cases} p^* \left(1 - e^{-\theta(a-a_1)}\right) & \text{if } a \geq a_1, \\ 0 & \text{else,} \end{cases} \tag{2.2}$$

where θ determines how quickly $p(a)$ reaches the saturation level p^*, and a_1 is the age at which reverse transcription is completed.

To incorporate the two types of treatments mentioned above, we divide the class of infected cells, $T^*(a,t)$, into two subclasses: $T^*_{preRT}(a,t)$ and $T^*_{postRT}(a,t)$. $T^*_{preRT}(a,t)$ represents the density of cells that have been "infected" by an HIV virion but in which reverse transcription has not been completed at infection age a. An RT inhibitor could allow a preRT cell to revert back to an uninfected cell (because if reverse transcription fails to complete, cellular nucleases will degrade the HIV RNA that entered the cell) or reduce the probability that a preRT cell progresses to the postRT state [9]. $T^*_{postRT}(a,t)$ represents the density of infected cells that have progressed to the postRT phase at infection age a. The densities of the preRT and postRT cells are related by a function $\beta(a)$ $(0 \leq \beta(a) \leq 1)$ that describes the proportion of infected cells that have not completed reverse transcription, i.e.,

$$T^*_{preRT}(a,t) = \beta(a)T^*(a,t), \qquad T^*_{postRT}(a,t) = (1-\beta(a))T^*(a,t). \tag{2.3}$$

We assume that $\beta(a) \in L^1[0,\infty)$ is a nonincreasing function with the following properties: $0 \leq \beta(a) \leq 1$; $\beta(0) = 1$; $\beta(a) = 0$ for $a \geq a_1$; $\beta'(a) \leq 0$ a.e.

Let ϵ_{RT} and ϵ_{PI} denote the efficacy of the therapy with RT inhibitors and protease inhibitors, respectively $(0 \leq \epsilon_{RT},\ \epsilon_{PI} < 1)$. The efficacy is scaled such that zero represents complete ineffectiveness and unity represents 100% effectiveness. To study the effect of protease inhibitor, we divide the newly produced virus particles into two classes: infectious virions with concentration $V_I(t)$ and noninfectious virions with concentration $V_{NI}(t)$. New infectious virus particles are produced at the rate $\int_0^\infty (1-\epsilon_{PI})p(a)T^*_{postRT}(a,t)da$.

Let $\eta(\epsilon_{RT})$ denote the rate at which preRT cells revert to the uninfected state due to the failure of reverse transcription. The rate at which preRT cells of all ages become uninfected is then given by $\int_0^\infty \eta(\epsilon_{RT})T^*_{preRT}(a,t)da$.

The reversion rate $\eta(\epsilon_{RT})$ is an increasing function of drug efficacy ϵ_{RT}. In the absence of drug therapy, we assume there are no infected cells going back to the uninfected class, i.e., $\eta(0) = 0$. As the limit case, when RT inhibitors are 100% effective $(\epsilon_{RT} \to 1)$, $\eta(\epsilon_{RT})$ should be very large. We shall discuss the functional form of $\eta(\epsilon_{RT})$ more in the simulation section. Our analytical results are obtained for a general reversion rate function.

Incorporating these drugs into the equations for T, T^*, and V in model (2.1), we have

$$\begin{aligned}
&\frac{d}{dt}T(t) = s - dT - kV_IT + \int_0^\infty \eta(\epsilon_{RT})T^*_{preRT}(a,t)da,\\
&\frac{\partial}{\partial t}T^*(a,t) + \frac{\partial}{\partial a}T^*(a,t) = -\delta(a)T^*(a,t) - \eta(\epsilon_{RT})T^*_{preRT}(a,t)da,\\
&\frac{d}{dt}V_I(t) = \int_0^\infty (1-\epsilon_{PI})p(a)T^*_{postRT}(a,t)da - cV_I,\\
&\frac{d}{dt}V_{NI}(t) = \int_0^\infty \epsilon_{PI}p(a)T^*_{postRT}(a,t)da - cV_{NI},\\
&T^*(0,t) = kV_IT.
\end{aligned} \tag{2.4}$$

Notice that the variable V_{NI} does not appear in equations for other variables. Thus, we can ignore the V_{NI} equation when studying the dynamics of infection. Using the relation (2.3), we have the following system:

$$\begin{aligned}
&\frac{d}{dt}T(t) = s - dT - kV_IT + \int_0^\infty \eta(\epsilon_{RT})\beta(a)T^*(a,t)da,\\
&\frac{\partial}{\partial t}T^*(a,t) + \frac{\partial}{\partial a}T^*(a,t) = -\delta(a)T^*(a,t) - \eta(\epsilon_{RT})\beta(a)T^*(a,t),\\
&\frac{d}{dt}V_I(t) = \int_0^\infty (1-\epsilon_{PI})(1-\beta(a))p(a)T^*(a,t)da - cV_I,\\
&T^*(0,t) = kV_IT.
\end{aligned} \tag{2.5}$$

In our analysis, we allow the viral production rate $p(a)$ to be an arbitrary function that is bounded (e.g., it does not have to be a monotone function). $\delta(a)$ is also assumed to be a bounded function.

Since we are interested in the effect of combination therapy on virus dynamics, we assume that the patients are initially at steady state and the combination of drugs is administered at time 0. We choose the initial conditions to be $T(0) = T_0$, $V_I(0) = V_{I0}$, $V_{NI}(0) = 0$, and $T^*(a,0) = T^*_0(a)$, where T_0 and V_{I0} are the steady state levels of target cells and infectious virions, respectively. $T^*_0(a)$ is the age distribution of infected cells at the initial time $t = 0$, and $\int_0^\infty T^*_0(a)da$ represents the steady state level of infected cells before the onset of drug therapy.

System (2.5) can be reformulated as a system of Volterra integral equations. To simplify expressions, we introduce the following notations:

$$\begin{aligned}
&K_0(a) = e^{-\int_0^a(\delta(s)+\eta(\epsilon_{RT})\beta(s))ds}, \quad K_1(a) = \eta(\epsilon_{RT})\beta(a)K_0(a),\\
&K_2(a) = (1-\epsilon_{PI})(1-\beta(a))p(a)K_0(a), \quad \mathcal{K}_i = \int_0^\infty K_i(a)da, \quad i = 1,2.
\end{aligned} \tag{2.6}$$

$K_0(a)$ is the probability of an infected cell remaining infected at age a, hereafter the age-specific survival probability of an infected cell. $K_2(a)$ is the product of the age-specific survival probability of an infected cell and the rate at which infectious virus particles are produced by an infected cell of age a. Thus, the integral of $K_2(a)$ over all ages, i.e., $\mathcal{K}_2 = \int_0^\infty (1-\epsilon_{PI})(1-\beta(a))p(a)K_0(a)da$, gives the total number of infectious virus particles produced by one infected cell over its lifespan. For convenience, we call $\mathcal{K}_2$ the infectious virus burst size.

For mathematical convenience, we introduce a new variable, $B(t)$, to describe the rate at which an uninfected T cell becomes infected at time t,

$$B(t) = kV_I(t)T(t). \tag{2.7}$$

Integrating the T^* equation in system (2.5) along the characteristic lines, $t - a =$ constant, we get the following formula:

$$T^*(a,t) = \begin{cases} B(t-a)K_0(a) & \text{for } a < t, \\ T_0^*(a-t)\dfrac{K_0(a)}{K_0(a-t)} & \text{for } a \geq t. \end{cases} \tag{2.8}$$

Substituting (2.8) into the T and V_I equations in (2.5),

$$\begin{aligned} \frac{d}{dt}T(t) &= s - dT - B(t) + \int_0^t K_1(a)B(t-a)da + \tilde{F}_1(t), \\ \frac{d}{dt}V_I(t) &= \int_0^t K_2(a)B(t-a)da - cV_I + \tilde{F}_2(t), \end{aligned} \tag{2.9}$$

where

$$\begin{aligned} \tilde{F}_1(t) &= \int_t^\infty \eta(\epsilon_{RT})\beta(a)T_0^*(a-t)\frac{K_0(a)}{K_0(a-t)}da, \\ \tilde{F}_2(t) &= \int_t^\infty (1-\epsilon_{PI})(1-\beta(a))p(a)T_0^*(a-t)\frac{K_0(a)}{K_0(a-t)}da. \end{aligned} \tag{2.10}$$

Clearly, $\tilde{F}_i(t) \to 0$ as $t \to \infty$, $i = 1, 2$. Integrating the T equation in (2.9) and changing the order of integration, we have

$$\begin{aligned} T(t) &= T_0e^{-dt} + \int_0^t e^{-d(t-u)}\left[s - B(u) + \int_0^u B(u-\tau)K_1(\tau)d\tau + \tilde{F}_1(u)\right]du \\ &= \int_0^t \left[e^{-d(t-u)}\left(s - B(u)\right) + B(u)H_1(t-u)\right]du + F_1(t), \end{aligned} \tag{2.11}$$

where

$$H_1(t) = e^{-dt}\int_0^t e^{d\tau}K_1(\tau)d\tau, \quad F_1(t) = T_0e^{-dt} + \int_0^t e^{-d(t-u)}\tilde{F}_1(u)du. \tag{2.12}$$

Similarly, by integrating the V_I equation in (2.9), we get

$$\begin{aligned} V_I(t) &= V_{I0}e^{-ct} + \int_0^t e^{-c(t-u)}\left[\int_0^u B(u-\tau)K_2(\tau)d\tau + \tilde{F}_2(u)\right]du \\ &= \int_0^t B(u)H_2(t-u)du + F_2(t), \end{aligned} \tag{2.13}$$

where

$$H_2(t) = e^{-ct}\int_0^t e^{c\tau}K_2(\tau)d\tau, \quad F_2(t) = T_0e^{-ct} + \int_0^t e^{-c(t-u)}\tilde{F}_2(u)du. \tag{2.14}$$

Equations (2.11) and (2.13), with $B(t)$ replaced by $kV_I(t)T(t)$, form a system of Volterra integral equations that are equivalent to the original system (2.5). Hence,

for determining the existence and uniqueness of the solutions we need only consider the following system:

$$\begin{aligned} T(t) &= \int_0^t \left[e^{-d(t-u)}(s - kV_I(u)T(u)) + kV_I(u)T(u)H_1(t-u)\right]du + F_1(t), \\ V_I(t) &= \int_0^t kV_I(u)T(u)H_2(t-u)du + F_2(t), \end{aligned} \tag{2.15}$$

where H_i and F_i $(i = 1, 2)$ are given in (2.12) and (2.14).

3. Analysis of the system (2.5). In this section, we provide analytic results on the existence of positive solutions as well as possible steady states and their stability for the system (2.5) or the equivalent system (2.15).

3.1. Existence of positive solutions. Let $x(t) = (T(t), V_I(t))^\top$, where $\top$ denotes the transpose of the vector. System (2.15) can be written in the form $x(t) = \int_0^t \kappa(t-u)g(x(u))du + f(t)$, where $f(t) = (F_1(t), F_2(t))^\top$ is a continuous function from $[0,\infty)$ to $[0,\infty)^2$, κ is the 2×2 matrix with entries being locally integrable functions on $[0,\infty)$,

$$\kappa(t) = \begin{pmatrix} se^{-dt} & H_1(t) - e^{-dt} \\ 0 & H_2(t) \end{pmatrix},$$

and g is defined by $g(x) = (1, kV_IT)^\top$. Obviously, $f \in C([0,\infty); \mathbf{R}^2)$, $g \in C(\mathbf{R}^2, \mathbf{R}^2)$, and $\kappa \in L^1_{loc}([0,\infty); \mathbf{R}^{2\times 2})$. Theorem 1.1 in Gripenberg, Londen, and Staffans [17, section 12.1], shows that a continuous solution exists on a maximal interval such that the solution goes to infinity if this maximal interval is finite.

To see that all solutions will remain nonnegative for positive initial data, we use the following system (see (2.7) and (2.9)) that is also equivalent to system (2.5):

$$\begin{aligned} \frac{d}{dt}T(t) &= s - dT - B(t) + \int_0^t K_1(a)B(t-a)da + \tilde{F}_1(t), \\ \frac{d}{dt}V_I(t) &= \int_0^t K_2(a)B(t-a)da - cV_I + \tilde{F}_2(t), \\ B(t) &= kV_I(t)T(t), \end{aligned} \tag{3.1}$$

where $\tilde{F}_i$ is given in (2.10) and $\tilde{F}_i(t) > 0$, $\lim_{t\to\infty}\tilde{F}_i(t) = 0$ for $i = 1, 2$.

Suppose that there exists a $\bar{t} > 0$ such that $T(\bar{t}) = 0$ and $T(t), V_I(t) > 0$ for $0 \le t < \bar{t}$. Then $B(\bar{t}) = kV_I(\bar{t})T(\bar{t}) = 0$, $B(t) = kV_I(t)T(t) > 0$ for $0 \le t < \bar{t}$, and thus from the T equation in (3.1) we have $\frac{d}{dt}T(\bar{t}) = s + \int_0^{\bar{t}} K_1(a)B(\bar{t}-a)da + \tilde{F}_1(\bar{t}) > 0$. Hence, $T(t) \ge 0$ for all $t \ge 0$. Similarly, we can show that $V_I(t) \ge 0$ and $B(t) \ge 0$ for all $t \ge 0$ and for all positive initial data.

3.2. Steady states and their stability. We use the system (3.1) for our stability analysis. According to [30], any equilibrium of system (3.1), if it exists, must be a constant solution of the following limiting system:

$$\begin{aligned} \frac{d}{dt}T(t) &= s - dT(t) - B(t) + \int_0^\infty K_1(a)B(t-a)da, \\ \frac{d}{dt}V_I(t) &= \int_0^\infty K_2(a)B(t-a)da - cV_I, \\ B(t) &= kV_I(t)T(t). \end{aligned} \tag{3.2}$$

We mention that the introduction of the variable $B(t)$ is just for mathematical convenience. If we substitute $kV_I(t)T(t)$ for $B(t)$ in the first two equations of (3.2), then we will obtain the same stability results.

System (3.2) has two constant solutions, the infection-free steady state $\bar{E} = (\bar{T}, \bar{V}_I, \bar{B}) = (s/d, 0, 0)$, and the infected steady state $E^\diamond = (T^\diamond, V_I^\diamond, B^\diamond)$, where

$$T^\diamond = \frac{c}{k\mathcal{K}_2}, \quad V_I^\diamond = \frac{sk\mathcal{K}_2 - dc}{kc(1-\mathcal{K}_1)}, \quad B^\diamond = kT^\diamond V_I^\diamond, \tag{3.3}$$

with $\mathcal{K}_1$ and $\mathcal{K}_2$ given in (2.6). Notice that $\mathcal{K}_1$ is less than 1. Thus, $V^\diamond > 0$ if and only if $sk\mathcal{K}_2 - dc > 0$, or $\mathcal{R}_1 > 1$, where

$$\mathcal{R}_1 = \frac{sk\mathcal{K}_2}{dc}. \tag{3.4}$$

Clearly, the infected steady state (3.3) is feasible if and only if $\mathcal{R}_1 > 1$. Notice that s/d is the cell density in the absence of infection, and k and c are the cell infection and viral clearance rate, respectively. Recall that $\mathcal{K}_2$, the infectious virus burst size, gives the number of infectious virus particles produced by one infected cell over its lifespan. Therefore, $\mathcal{R}_1$ gives the reproductive ratio of the virus under the impact of drugs.

We now consider the stability of steady states. Let us first consider the infection-free steady state $\bar{E}$. The following result suggests that the population sizes of virus and infected cells will go to zero if the reproductive ratio is less than 1.

THEOREM 1. *The noninfected steady state $\bar{E}$ is locally asymptotically stable (l.a.s) if $\mathcal{R}_1 < 1$, and it is unstable if $\mathcal{R}_1 > 1$.*

Proof. The Jacobian matrix of (3.2) at the steady state $\bar{E}$ is

$$J = \begin{bmatrix} -d-\lambda & -ks/d & \hat{K}_1(\lambda) \\ 0 & -c-\lambda & \hat{K}_2(\lambda) \\ 0 & ks/d & -1 \end{bmatrix},$$

where λ is an eigenvalue and $\hat{K}_i(\lambda)$ denotes the Laplace transform of $K_i(a)$, i.e., $\hat{K}_i(\lambda) = \int_0^\infty K_i(a)e^{-\lambda a}da,\ i = 1, 2$. The corresponding characteristic equation is

$$(\lambda + d)\left(\lambda + c - \frac{sk}{d}\hat{K}_2(\lambda)\right) = 0. \tag{3.5}$$

One negative root of equation (3.5) is $\lambda = -d$, and all other roots are given by the equation

$$\lambda + c = \frac{sk}{d}\hat{K}_2(\lambda), \tag{3.6}$$

which can be rewritten as

$$\frac{\lambda}{c} + 1 = \mathcal{R}_1 \frac{\hat{K}_2(\lambda)}{\mathcal{K}_2}. \tag{3.7}$$

Notice that $|\hat{K}_2(\lambda)| \le \mathcal{K}_2$ for all complex roots λ with nonnegative real parts (i.e., $\Re\lambda \ge 0$). Hence, the modulus of the right-hand side of (3.7) is less than 1, provided that $\mathcal{R}_1 < 1$. Since the modulus of the left-hand side of (3.7) is always greater than

or equal to 1 if $\Re\lambda \geq 0$, we conclude that all roots of (3.6) have negative real parts if $\mathcal{R}_1 < 1$. It follows that $\bar{E}$ is l.a.s. when $\mathcal{R}_1 < 1$.

In the case of $\mathcal{R}_1 > 1$, let $\psi(\lambda) = \frac{\lambda}{c} + 1 - \mathcal{R}_1 \frac{\hat{\mathcal{K}}_2(\lambda)}{\mathcal{K}_2}$. Thus, any real roots of $\psi(\lambda) = 0$ are also roots of (3.6). Recognizing that $\psi(0) = 1 - \mathcal{R}_1 < 0$ and $\lim_{\lambda\to\infty} \psi(\lambda) = \infty$, we know that $\psi(\lambda) = 0$ has at least one positive root $\lambda^* > 0$, which is a positive eigenvalue of the characteristic equation (3.5). This shows that the infection-free steady state is unstable when $\mathcal{R}_1 > 1$. □

The following theorem deals with the global stability of the noninfected steady state $\bar{E}$.

THEOREM 2. *For $\mathcal{R}_1 < 1$, the noninfected steady state $\bar{E}$ is a global attractor, i.e.,* $\lim_{t\to\infty}(T(t), V_I(t), B(t)) = (s/d, 0, 0)$.

In order to prove Theorem 2, we need the following lemma, in which the following notations are used: $\varphi_\infty = \liminf_{t\to\infty} \varphi(t)$, $\varphi^\infty = \limsup_{t\to\infty} \varphi(t)$, where φ is a real-valued function on $[0, \infty)$.

LEMMA 1 (see [51]). *Let φ: $[0, \infty) \to \mathbf{R}$ be bounded and continuously differentiable. Then there exist sequences $s_n, t_n \to \infty$ as $n \to \infty$ such that $\varphi(s_n) \to \varphi_\infty$, $\varphi'(s_n) \to 0$ and $\varphi(t_n) \to \varphi^\infty$, $\varphi'(t_n) \to 0$.*

Proof of Theorem 2. It is difficult to apply Lemma 1 to the T equation of (2.5) directly. We introduce a new variable, $W(t) = T(t) + \mathcal{T}^*(t)$, where $\mathcal{T}^*(t)$ denotes the total number of infected cells at t. Notice from the T^* equation in (2.5) that $\mathcal{T}^*$ satisfies the equation $\frac{d\mathcal{T}^*}{dt} = kV_I T - \int_0^\infty \big[\delta(a) + \eta(\epsilon_{RT})\beta(a)\big] T^*(a,t)da$. Then we get $\frac{dW}{dt} = s - d(W - \mathcal{T}^*) - \int_0^\infty \delta(a)T^*(a,t)da = s - dW - \int_0^\infty (\delta(a) - d)T^*(a,t)da \leq s - dW$. The last inequality holds because of the fact that $\delta(a) \geq d$ (i.e., the death rate of infected cells $\delta(a)$ is equal to the natural death rate d plus an extra death rate due to the infection). By Lemma 1, we can choose a sequence $t_n \to \infty$ such that $W(t_n) \to W^\infty$, $W'(t_n) \to 0$. From $\frac{dW}{dt} \leq s - dW$, we have $W^\infty \leq s/d$.

Rewrite the V_I equation in (2.15) as $V_I(t) = \int_0^t kV_I(t-u)T(t-u)H_2(u)du + F_2(t)$. We use Lemma 1 to choose a sequence $s_n \to \infty$ such that $V_I(s_n) \to V_I^\infty$ as $n \to \infty$. Taking supremum limit on both sides of the above V_I equation for $t = s_n \to \infty$, we have $V_I^\infty \leq kV_I^\infty T^\infty \int_0^\infty H_2(u)du$. Noticing that $T^\infty \leq W^\infty \leq s/d$ and that $\int_0^\infty H_2(u)du = \mathcal{K}_2/c$, we get $V_I^\infty \leq ks\mathcal{K}_2 V_I^\infty/(cd) = \mathcal{R}_1 V_I^\infty$. Since $\mathcal{R}_1 < 1$, we see that $V_I^\infty = 0$. Thus, $V_I(t) \to 0$ as $t \to \infty$. It also follows that $B(t) \to 0$ since $B(t) = kV_I(t)T(t)$ and $T \leq W \leq s/d$. We use Lemma 1 again to choose a sequence $s_n \to \infty$ such that $T(s_n) \to T_\infty$ and $T'(s_n) \to 0$. Using the T equation in (3.2) we get $T_\infty \geq s/d$. But $T^\infty \leq W^\infty \leq s/d$. This shows that $T(t) \to s/d$ as $t \to \infty$, which finishes the proof of Theorem 2. □

Next, we consider the stability of the infected steady state $E^\diamond$. As noted earlier, this steady state exists if and only if $\mathcal{R}_1 > 1$. The following result suggests that the virus population will be established if the reproductive ratio is greater than 1.

THEOREM 3. *The infected steady state $E^\diamond$ is l.a.s if $\mathcal{R}_1 > 1$.*

Proof. The Jacobian at the steady state $E^\diamond$ is

$$J = \begin{bmatrix} -d - kV_I^\diamond - \lambda & -kT^\diamond & \hat{K}_1(\lambda) \\ 0 & -c - \lambda & \hat{K}_2(\lambda) \\ kV_I^\diamond & kT^\diamond & -1 \end{bmatrix}.$$

Using the notation $\mathcal{R}_1 = sk\mathcal{K}_2/dc$, the corresponding characteristic equation can be

written as

$$\begin{aligned}\Big((1-\mathcal{K}_1)\lambda + d(\mathcal{R}_1-\mathcal{K}_1)\Big)\Big(\lambda + c - c\tfrac{\hat{K}_2(\lambda)}{\mathcal{K}_2}\Big)\\ = d(\mathcal{R}_1-1)\Big((\lambda+c)\hat{K}_1(\lambda) - c\tfrac{\hat{K}_2(\lambda)}{\mathcal{K}_2}\Big),\end{aligned} \tag{3.8}$$

or

$$\Big(1+\frac{\lambda}{c}\Big)\Big(A(\lambda+d)+1-\hat{K}_1(\lambda)\Big) = \frac{\hat{K}_2(\lambda)}{\mathcal{K}_2}A\big(\lambda+d\big), \tag{3.9}$$

where $A = (1-\mathcal{K}_1)/(d(\mathcal{R}_1-1))$.

We can exclude the possibility of a nonnegative real root of (3.9) as follows. Suppose $\lambda \geq 0$. Then $\hat{K}_1(\lambda) \leq \hat{K}_1(0) = \mathcal{K}_1 < 1$. It follows that $A > 0$ and $(1+\frac{\lambda}{c})(A(\lambda+d)+1-\hat{K}_1(\lambda)) > A(\lambda+d)$. Hence, (3.9) yields $\hat{K}_2(\lambda)/\mathcal{K}_2 > 1$. However, since $\lambda \geq 0$, we have $\hat{K}_2(\lambda) \leq \hat{K}_2(0) = \mathcal{K}_2$, which leads to a contradiction. Thus, (3.9) has no nonnegative real roots.

In the next step, we will exclude the possibility that (3.9) has a complex root λ with a nonnegative real part. We prove this by contradiction. Suppose that $\lambda = x_0 + iy_0$ is a root with $x_0 \geq 0$ and $y_0 > 0$. From (3.8), we have

$$(\lambda+d)\Big(\lambda + c - c\frac{\hat{K}_2(\lambda)}{\mathcal{K}_2}\Big) \to 0 \quad \text{as} \quad \mathcal{R}_1 \to 1. \tag{3.10}$$

It follows from a similar argument as in Theorem 1 that $\lambda = x_0 + iy_0$ cannot be a root if $x_0 > 0$. Now we let $x_0 = 0$ and $y_0 > 0$. In this case, (3.10) has a negative root $-d$, and all other roots are determined by the equation $(1+\frac{\lambda}{c}) = \frac{\hat{K}_2(\lambda)}{\mathcal{K}_2}$ or

$$1 + \frac{y_0}{c}i = \frac{\int_0^\infty K_2(a)\cos(ya)da}{\mathcal{K}_2} - \frac{\int_0^\infty K_2(a)\sin(ya)da}{\mathcal{K}_2}i. \tag{3.11}$$

Comparison of the real parts of both sides yields $\cos(ya) = 1$. Thus, $\sin(ya) = 0$, which implies that (3.11) cannot hold. Therefore, (3.8) has no roots with nonnegative real parts when $\mathcal{R}_1 \to 1$.

By the continuous dependence of roots of the characteristic equation on $\mathcal{R}_1$, we know that the curve determined by the roots must cross the imaginary axis as $\mathcal{R}_1$ decreases close to 1. That is, the characteristic equation (3.8) or (3.9) has a pure imaginary root, say, iy, with $y > 0$. Replacing λ in (3.9) with iy, we see that the modulus of the left-hand side of (3.9) satisfies

$$|LHS| > \left|Ad + 1 - \int_0^\infty K_1(a)\cos(ya)da + i\left(Ay + \int_0^\infty K_1(a)\sin(ya)da\right)\right|. \tag{3.12}$$

We claim that $\int_0^\infty K_1(a)\sin(ya)da \geq 0$. In fact, notice that $\int_0^\infty K_1(a)\sin(ya)da = \int_0^{a_1} K_1(a)\sin(ya)da$, where a_1 is the age at which reverse transcription is complete. Notice also that $K_1(0) = \eta(\epsilon_{RT})$ and $K_1'(a) = \eta(\epsilon_{RT})[\beta'(a)K_0(a) + \beta(a)K_0'(a)] \leq 0$ a.e. on $[0,\infty)$. Integrating $\int_0^{a_1} K_1(a)\sin(ya)da$ by parts, we get

$$\begin{aligned}\int_0^{a_1} K_1(a)\sin(ya)da &= \frac{\eta(\epsilon_{RT})}{y} - \frac{1}{y}K_1(a_1)\cos(ya_1) + \frac{1}{y}\int_0^{a_1} K_1'(a)\cos(ya)da\\ &\geq \frac{\eta(\epsilon_{RT})}{y} - \frac{1}{y}K_1(a_1)\cos(ya_1) + \frac{1}{y}\int_0^{a_1} K_1'(a)da\\ &= \frac{1}{y}K_1(a_1)(1-\cos(ya_1)) \geq 0.\end{aligned}$$

Thus, we have $\int_0^\infty K_1(a)\sin(ya)da \geq 0$. We also observe that $1-\int_0^\infty K_1(a)\cos(ya)da \geq 1-\mathcal{K}_1 > 0$. It follows from (3.12) that $|LHS| > A|d+iy|$. On the other hand, the modulus of the right-hand side of (3.9) satisfies $|RHS| \leq A|d+iy|$. This leads to a contradiction. We conclude that the characteristic equation (3.9) has no roots with nonnegative real parts. Therefore, Theorem 3 is proved. □

4. The model with entry and protease inhibitors. Since the discovery of RT inhibitors and protease inhibitors, significant progress in drug development has been made. Recently, a new class of drugs, entry/fusion inhibitors, has been introduced [10, 18]. These compounds can block the fusion of the viral envelope to the target cell membrane and interfere with continued infection. They became available with the FDA approval of enfuvirtide (Fuzeon) in 2003.

In this section, we develop an age-structured model that takes into account the effects of both entry inhibitors and protease inhibitors. The model can be described by the following equations:

$$\begin{aligned}
&\frac{d}{dt}T(t) = s - dT - (1-\epsilon_{EI})kV_IT,\\
&\frac{\partial}{\partial t}T^*(a,t) + \frac{\partial}{\partial a}T^*(a,t) = -\delta(a)T^*(a,t),\\
&\frac{d}{dt}V_I(t) = \int_0^\infty (1-\epsilon_{PI})(1-\beta(a))p(a)T^*(a,t)da - cV_I,\\
&\frac{d}{dt}V_{NI}(t) = \int_0^\infty \epsilon_{PI}(1-\beta(a))p(a)T^*(a,t)da - cV_{NI},\\
&T^*(0,t) = (1-\epsilon_{EI})kV_IT,
\end{aligned} \tag{4.1}$$

where ϵ_{EI} represents the efficacy of the entry inhibitor. The other parameters and variables have the same meaning as in the model (2.4). We remark that the model in [34] is a special case of our model (4.1) when $\epsilon_{EI} = \epsilon_{PI} = \beta(a) = 0$. Our result applies to a general form of the viral production rate $p(a)$ and the death rate $\delta(a)$.

The existence and uniqueness of (nonnegative) solutions for the system (4.1) can be proved in a similar way as for the system (2.4). Here we present only the stability analysis. The following notations are used throughout the rest of this section:

$$K_3(a) = e^{-\int_0^a \delta(s)ds}, \quad K_4(a) = (1-\epsilon_{PI})(1-\beta(a))p(a)K_3(a), \quad \mathcal{K}_4 = \int_0^\infty K_4(a)da.$$

The following limiting system is used to derive stability results:

$$\begin{aligned}
&\frac{d}{dt}T(t) = s - dT(t) - Y(t),\\
&\frac{d}{dt}V_I(t) = \int_0^\infty K_4(a)Y(t-a)da - cV_I,\\
&Y(t) = (1-\epsilon_{EI})kV_I(t)T(t),
\end{aligned} \tag{4.2}$$

where the variable $Y(t)$ is introduced for mathematical convenience.

System (4.2) has two constant solutions (steady states): the noninfected steady state $\bar{E} = (\bar{T}, \bar{V}_I, \bar{Y}) = (s/d, 0, 0)$, and the infected steady state $E^\circ = (T^\circ, V_I^\circ, Y^\circ)$, where

$$T^\circ = \frac{c}{k(1-\epsilon_{EI})\mathcal{K}_4}, \quad V_I^\circ = \frac{sk(1-\epsilon_{EI})\mathcal{K}_4 - dc}{kc(1-\epsilon_{EI})}, \quad Y^\circ = (1-\epsilon_{EI})kT^\circ V_I^\circ.$$

Clearly, $V_I^\circ > 0$ if and only if $\mathcal{R}_2 > 1$, where $\mathcal{R}_2 = sk(1-\epsilon_{EI})\mathcal{K}_4/(dc)$ is the reproductive ratio for model (4.1). Hence, E° exists if and only if $\mathcal{R}_2 > 1$. The stability results are given in the following theorem. It can be proved similarly by previous arguments. Here we omit the proof due to the space limit.

THEOREM 4. (a) *The noninfected steady state $\bar{E}$ is a global attractor if $\mathcal{R}_2 < 1$; and it is unstable if $\mathcal{R}_2 > 1$.*

(b) *When $\mathcal{R}_2 > 1$, the infected steady state E° is l.a.s.*

Results obtained in this section and in the previous section will be used in the next section to explore the impact of drug treatment on the evolution of HIV-1.

5. Influence of drug therapy on the invasion of resistant strains. In the previous sections, we have shown that a virus population can establish itself if and only if its reproductive ratio exceeds 1. Consider an environment in which the drug-sensitive strain of HIV-1 infection is at the infected steady state $E^\diamond = (T^\diamond, V_I^\diamond, B^\diamond)$ (see (3.3)), and a small number of drug-resistant virions has been introduced into the virus population. Denote the reproductive ratio of the sensitive strain by $\mathcal{R}_s$, which is the same as $\mathcal{R}_1$ defined in (3.4). We can rewrite the population size of uninfected cells in terms of $\mathcal{R}_s$, i.e., $T^\diamond = s/(d\mathcal{R}_s)$. Assume that $\mathcal{R}_s$ is greater than 1.

Let $\tilde{\epsilon}_{RT}$ and $\tilde{\epsilon}_{PI}$ denote the efficacies of the two types of drugs for the resistant strain, respectively, and let $\tilde{p}(a)$ denote the viral production rate of the resistant strain. We can define the corresponding $\tilde{K}_0(a)$ as the age-specific survival probability of T cells infected with the resistant strain (an equivalent quantity for the sensitive strain is given in (2.6)). For ease of illustration, we assume that all other parameters are the same for both strains. We derive an invasion criterion for a resistant strain by using a heuristic argument, as is done in [16]. This criterion will be applied to different scenarios of antiretroviral therapy, such as single-drug therapy (e.g., $\epsilon_{PI} > 0$ and $\epsilon_{RT} = 0$) or combination therapy (i.e., $\epsilon_{PI} > 0$ and $\epsilon_{RT} > 0$).

Notice that $1/c$ is the average lifespan of a free virus. Thus a single resistant virus can infect on average $kT^\diamond/c$ cells in its whole life. Each of these infected cells can produce a total of

$$N_r = \int_0^\infty (1-\tilde{\epsilon}_{PI})(1-\beta(a))\tilde{p}(a)\tilde{K}_0(a)da$$

infectious drug-resistant virus particles during its lifespan (burst size). Thus, the reproductive ratio of the resistant strain at the resident equilibrium density $T^\diamond$ is

$$\mathcal{R}_r^\diamond = \frac{kT^\diamond}{c}\int_0^\infty (1-\tilde{\epsilon}_{PI})(1-\beta(a))\tilde{p}(a)\tilde{K}_0(a)da,$$

and the invasion criterion is $\mathcal{R}_r^\diamond > 1$. Substituting $s/(d\mathcal{R}_s)$ for $T^\diamond$, we obtain that the condition for the resistant strain to invade the sensitive strain is $\mathcal{R}_r > \mathcal{R}_s$, where the quantity

$$\mathcal{R}_r = \frac{s}{d}\frac{k}{c}\int_0^\infty (1-\tilde{\epsilon}_{PI})(1-\beta(a))\tilde{p}(a)\tilde{K}_0(a)da \tag{5.1}$$

represents the reproductive ratio of the resistant strain when the equilibrium density of uninfected cells is s/d (which is the value of T at the infection-free steady state).

Viral fitness is often used to describe the relative replication competence of a virus in a given environment. $\mathcal{R}_r$ can be regarded as a good measure of the fitness of a resistant virus. Thus the inequality $\mathcal{R}_r > \mathcal{R}_s$ implies that natural selection within a host favors the virus strain that maximizes its reproductive ratio.

In order to calculate the reproductive ratio, we consider the case when the viral production rate for the resistant strain has the form given in (2.2). That is,

$$\tilde{p}(a) = \begin{cases} \tilde{p}^* \left(1 - e^{-\theta(a-a_1)}\right) & \text{if } a \geq a_1, \\ 0 & \text{else,} \end{cases} \tag{5.2}$$

where $\tilde{p}^*$ is the saturation level for production of the resistant strain. Accordingly, we choose $\beta(a)$ to be

$$\beta(a) = \begin{cases} 1, & 0 \leq a < a_1, \\ 0, & a \geq a_1. \end{cases} \tag{5.3}$$

The death rate of cells is assumed to be the same for both strains with the form

$$\delta(a) = \begin{cases} \delta_0, & 0 \leq a < a_1, \\ \delta_0 + \mu, & a \geq a_1, \end{cases} \tag{5.4}$$

where δ_0 and μ are positive constants with δ_0 representing a background death rate of cells and μ representing an extra death rate for productively infected cells due to either viral cytopathicity or cell-mediated immune responses.

Drug resistance is incorporated by assuming that the efficacy of antiretroviral therapy for the resistant strain is lower than that for the drug sensitive strain by a factor between 0 and 1, i.e., $\tilde{\epsilon}_{RT} = \sigma_{RT}\epsilon_{RT}$, $\tilde{\epsilon}_{PI} = \sigma_{PI}\epsilon_{PI}$. For ease of demonstration, we assume that $\sigma_{RT} = \sigma_{PI} = \sigma$. $\sigma = 0$ corresponds to the completely resistant strain, while $\sigma = 1$ corresponds to the completely sensitive strain. Other strains have an intermediate value $0 < \sigma < 1$. Many drug-resistant HIV variants display some extent of resistance-associated loss of fitness as the resistant viral strains propagate at a reduced rate when compared to sensitive strains [2]. Therefore, there is a trade-off between drug resistance and viral production rate $\tilde{p}(a)$. We choose two types of functional forms for the cost by which the saturation level p^* is reduced in resistant strains, using the following formulas:

$$\text{Type I}: \quad \tilde{p}(a) = \sigma p^* \left(1 - e^{-\theta(a-a_1)}\right), \tag{5.5}$$

$$\text{Type II}: \quad \tilde{p}(a) = e^{-\phi\left(\frac{1}{\sigma}-1\right)} p^* \left(1 - e^{-\theta(a-a_1)}\right), \tag{5.6}$$

where ϕ is a measure for the level of cost. We provide analytic results for the Type I cost and illustrate that the qualitative properties of the two types of costs are similar. Using (5.2)–(5.5), we have the following relationship between $\mathcal{R}_r$ and $\mathcal{R}_s$ (see [13]):

$$\mathcal{R}_r = \frac{\sigma(1 - \sigma\epsilon_{PI}) e^{-\eta(\epsilon_{RT})(1-\sigma)a_1}}{1 - \epsilon_{PI}} \mathcal{R}_s. \tag{5.7}$$

We consider $\mathcal{R}_r = \mathcal{R}_r(\sigma)$ as a function of σ. A drug-resistant strain with resistance σ can invade the sensitive strain if $\mathcal{R}_r(\sigma) > \mathcal{R}_s$. Obviously, it is not easy to draw conclusions from this condition. We first derive some analytic understanding for a simpler case in which only single-drug therapy with a protease inhibitor is considered, i.e., $\epsilon_{PI} > 0$ and $\epsilon_{RT} = 0$. The case of combined therapy will be explored numerically.

(a) Single-drug therapy. In this case, since $\epsilon_{PI} > 0$ and $\epsilon_{RT} = 0$, (5.7) simplifies to $\mathcal{R}_r(\sigma) = \frac{\sigma(1-\sigma\epsilon_{PI})}{1-\epsilon_{PI}} \mathcal{R}_s$. It is easy to check that in order to have $\mathcal{R}_r(\sigma) \geq \mathcal{R}_s$ for some $\sigma \in (0, 1)$ it is necessary that $\epsilon_{PI} > \frac{1}{2}$. In fact, there exists a maximum

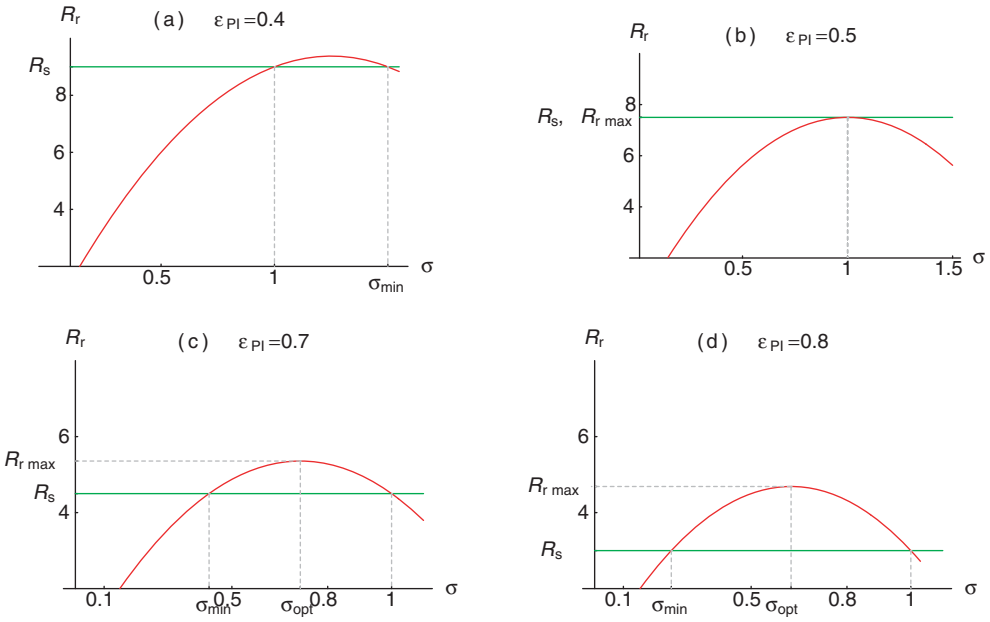

FIG. 1. *Plots of the reproductive ratio $\mathcal{R}_r$ of a resistant strain vs. the resistance σ for different treatment efficacy ϵ_{PI} (ϵ_{RT} is chosen to be 0). In* (a) *and* (b)*, it is shown that $\mathcal{R}_r < \mathcal{R}_s$ for all $\sigma < 1$. Therefore, no resistant strains can invade. In* (c) *and* (d)*, resistant strains with resistance σ in $(\sigma_{\min}, 1)$ can invade. The optimal resistance is σ_{opt} at which $\mathcal{R}_r$ reaches its maximum $\mathcal{R}_{r\max}$.*

level of resistance (corresponding to the smallest value of σ), $\sigma_{\min} = \frac{1-\epsilon_{PI}}{\epsilon_{PI}} < 1$, such that $\mathcal{R}_r(\sigma) > \mathcal{R}_s$ if and only if $\sigma_{\min} < \sigma < 1$ (see Figure 1). Clearly, if $\epsilon_{PI} < \frac{1}{2}$, then $\sigma_{\min} > 1$, and hence $\mathcal{R}_r < \mathcal{R}_s$ for all σ. This indicates that when the drug efficacy is very low, the sensitive strain is favored. The intuitive reason for this is that if the cost of resistance is high, one would not expect resistance when there is little selection pressure from the drugs. Other nonresistant strains would outcompete it under these conditions. Resistant strains can increase in frequency only when the selection pressure (drug efficacy) is high.

We can also determine an optimal resistance, σ_{opt}, which maximizes the reproductive ratio. In fact, we can easily check that $\mathcal{R}_r(\sigma)$ has only one critical point in the interval $(\sigma_{\min}, 1)$, $\sigma = \frac{1}{2\epsilon_{PI}}$, at which $\frac{d\mathcal{R}_r(\sigma)}{d\sigma} = 0$ (see Figure 1). Hence, $\sigma_{opt} = 1/(2\epsilon_{PI})$.

We summarize the following results for the case of single-drug therapy. Recall that a resistant strain with resistance σ can invade the sensitive strain if and only if $\mathcal{R}_r(\sigma) > \mathcal{R}_s$.

(i) There exists a threshold drug efficacy ϵ^*_{PI} ($\epsilon^*_{PI} = 1/2$ for Type I cost) below which no resistant strains can invade (see Figure 1(a)–(b)). Analytically, this is due to the fact that $\sigma_{\min} \geq 1$ when $\epsilon_{PI} < \epsilon^*_{PI}$. Hence, $\mathcal{R}_r(\sigma) < \mathcal{R}_s$ for all $\sigma < 1$.

(ii) When the drug efficacy is above the threshold ϵ^*_{PI}, there is a range of resistance levels for which the resistant strains are able to invade. This is because, analytically, $\sigma_{\min} < 1$ when $\epsilon_{PI} > \epsilon^*_{PI}$, and $\mathcal{R}_r(\sigma) > \mathcal{R}_s$ for all σ in $(\sigma_{\min}, 1)$.

(iii) When $\sigma_{\min} < 1$, the range of invasion strains, $(\sigma_{\min}, 1)$, increases with the drug efficacy ϵ_{PI}. The optimal resistance, σ_{opt}, decreases with the drug efficacy ϵ_{PI} (a more resistant strain corresponds to a smaller σ value; see Figure 1(c)–(d)).

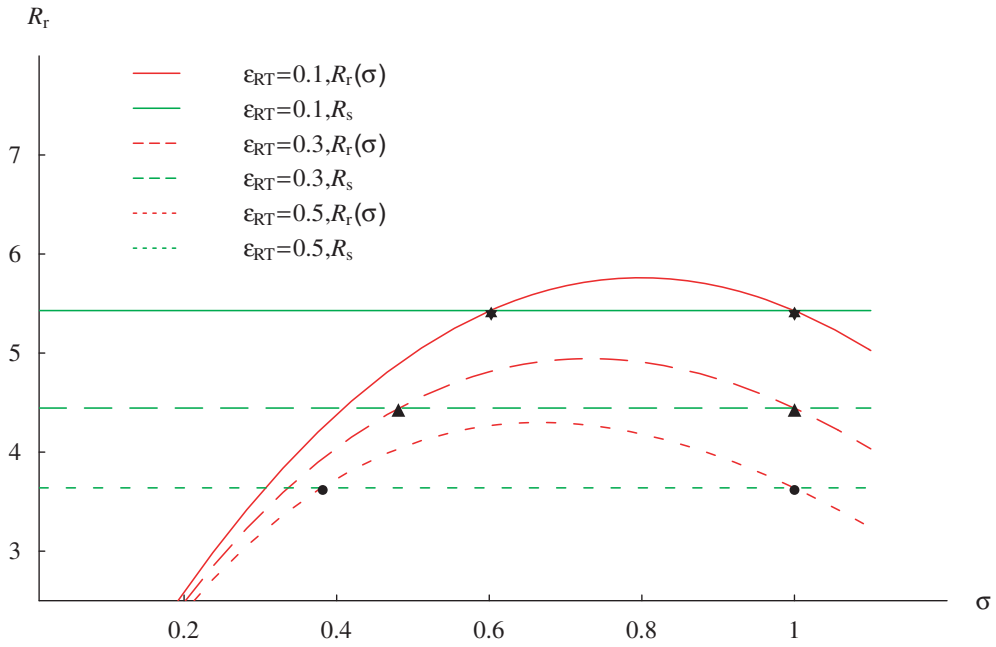

FIG. 2. *Plots of the reproductive ratio $\mathcal{R}_r$ vs. resistance σ for $\epsilon_{RT} = 0.1$ (solid), $\epsilon_{RT} = 0.3$ (long dashed), $\epsilon_{RT} = 0.5$ (short dashed). The value of ϵ_{PI} is fixed at $\epsilon_{PI} = 0.6$ for which invasion is possible in the absence of the an RT drug (i.e., if $\epsilon_{RT} = 0$). For each given ϵ_{RT}, the values of σ for which $\mathcal{R}_r(\sigma) > \mathcal{R}_s$ give the range for resistance invasion, which is the range between the two intersection points of the $\mathcal{R}_r$ curve and the $\mathcal{R}_s$ horizontal line.*

This increasing property is also clear from the formulas $\sigma_{\min} = (1 - \epsilon_{PI})/\epsilon_{PI}$ and $\sigma_{opt} = 1/(2\epsilon_{PI})$.

(iv) As the drug efficacy increases, the optimal viral fitness, $\mathcal{R}_r(\sigma_{opt})$, decreases (see Figure 1(c)–(d)).

(b) Combination therapy. We now consider the case of combination therapy, i.e., $\epsilon_{PI} > 0$ and $\epsilon_{RT} > 0$. Again, we consider $\mathcal{R}_r = \mathcal{R}_r(\sigma)$ in (5.7) as a function of σ. Then $\mathcal{R}_r(\sigma) > \mathcal{R}_s$ if and only if σ satisfies the inequality

$$\frac{\sigma(1 - \sigma\epsilon_{PI})e^{-\eta(\epsilon_{RT})(1-\sigma)a_1}}{1 - \epsilon_{PI}} > 1. \tag{5.8}$$

To explore the role of ϵ_{RT}, we fix ϵ_{PI} (e.g., $\epsilon_{PI} = 0.6$ in Figure 2). Because the numerical simulations appear qualitatively similar for different increasing reversion rate functions, we choose $\eta(\epsilon_{RT}) = \epsilon_{RT}$ for simplicity here. We will discuss the selection of the function $\eta(\epsilon_{RT})$ in the next section. Equation (5.8) cannot be solved analytically for σ. However, plots of $\mathcal{R}_r(\sigma)$ for different values of ϵ_{RT} suggest that, as ϵ_{RT} increases, the range for $\mathcal{R}_r(\sigma) > \mathcal{R}_s$ also increases (see Figure 2). Figure 3 illustrates the joint effect of ϵ_{RT} and ϵ_{PI} on the reproductive ratios $\mathcal{R}_s$ and $\mathcal{R}_r$. From the contour plot (see Figure 3(c)), we see that when the drug efficacy is low (the region in the lower-left corner in which $\mathcal{R}_s > \mathcal{R}_r > 1$) the resistant strain cannot invade. Neither strain can survive when the drug efficacy is high (the top-right region in which $\mathcal{R}_s < 1$ and $\mathcal{R}_r < 1$). In the middle region, the invasion of resistant strains is possible as $\mathcal{R}_r > \mathcal{R}_s$.

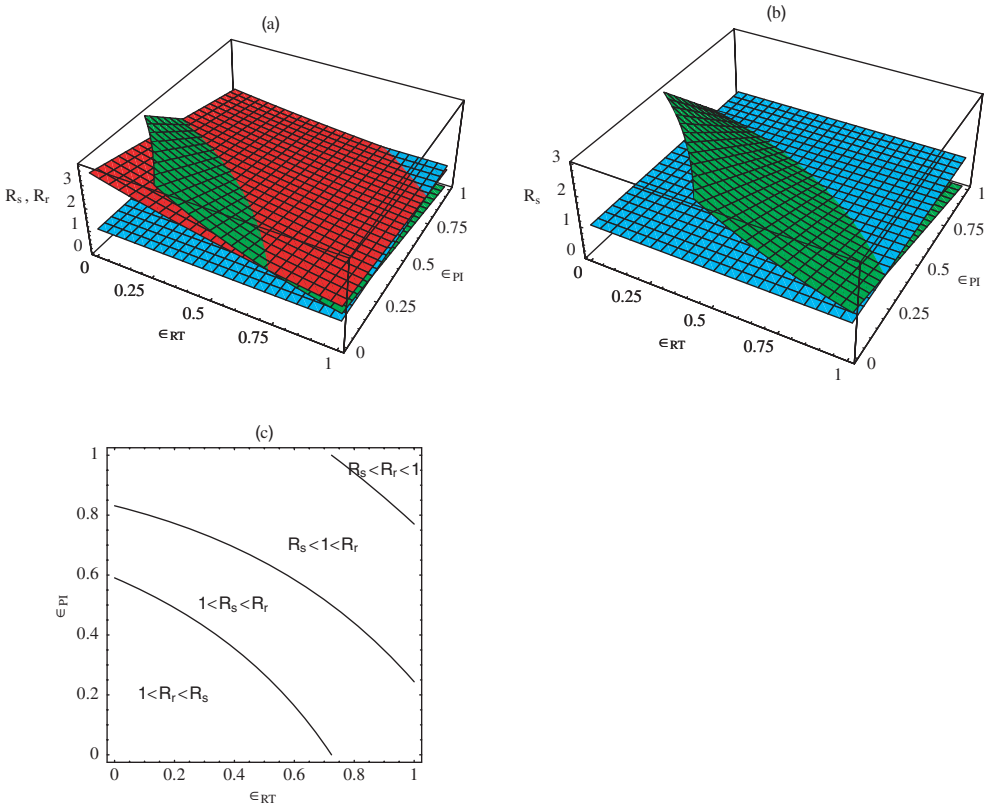

FIG. 3. *Plots of the reproductive ratios $\mathcal{R}_s$ and $\mathcal{R}_r$ as functions of ϵ_{RT} and ϵ_{PI}. Three surfaces are plotted in* (a): *$\mathcal{R}_r(\epsilon_{RT}, \epsilon_{PI})$ (the top surface near the origin), $\mathcal{R}_s(\epsilon_{RT}, \epsilon_{PI})$ (middle surface), and the constant* 1 *(the bottom surface). The intersection of the top two surfaces is the curve on which $\mathcal{R}_r = \mathcal{R}_s$. In* (b), *two surfaces, $\mathcal{R}_s(\epsilon_{RT}, \epsilon_{PI})$ and the constant* 1, *are plotted to show the curve on which $\mathcal{R}_s = 1$.* (c) *is a contour plot of the surfaces $\mathcal{R}_r(\epsilon_{RT}, \epsilon_{PI})$ and $\mathcal{R}_s(\epsilon_{RT}, \epsilon_{PI})$.*

Figure 4 shows that when the Type II cost is used, the qualitative property of the reproductive ratio $\mathcal{R}_r$ as a function of σ is very similar to that when the Type I cost is used. For example, the function $\mathcal{R}_r(\sigma)$ admits a unique $\sigma_{\min}$ and a unique σ_{opt} for sufficiently small values of ϕ.

6. Numerical results. In this section, we provide numerical simulations to confirm and/or extend our analytical results. Backward Euler and the linearized finite difference method are used to discretize the ODE and PDE, respectively, and the integral is evaluated using Simpson's rule. For all simulations, we choose the viral production rate $p(a)$ as (2.2) and $\beta(a)$ as (5.3) with $a_1 = 0.25$ days [24]. The death rate of infected cells $\delta(a)$ is assumed to be constant $\delta = 1$ day^{-1} [29], and the virion clearance rate is set to our best estimate $c = 23$ day^{-1} [45]. The other model parameters are chosen as follows [8]: $s = 10^4$ ml^{-1} day^{-1}, $d = 0.01$ day^{-1}, $k = 2.4 \times 10^{-8}$ ml day^{-1}, and the burst size is $N = 2500$.

The reversion rate function, $\eta(\epsilon_{RT})$, remains to be determined. We know $\eta(0) = 0$, and when $\epsilon_{RT} \to 1$, $\eta(\epsilon_{RT})$ should be sufficiently large such that all the preRT cells will revert back to the uninfected class. In our simulation, we assume the reversion rate function takes the following form: $\eta(\epsilon_{RT}) = -\rho \ln(1 - \epsilon_{RT})$, where the constant

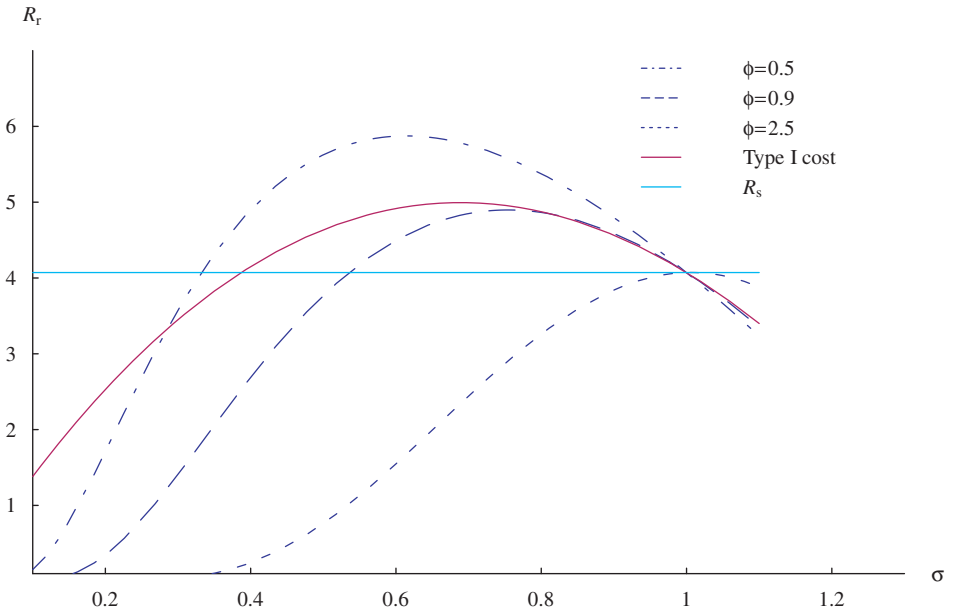

FIG. 4. *Plots of the reproductive ratio $\mathcal{R}_r$ vs. resistance σ when Type* II *cost is considered. The value of ϕ measures the cost of resistance. Invasion is possible for σ in the range between the two intersection points at which $\mathcal{R}_r = \mathcal{R}_s$. It also shows that invasion is impossible if the cost is too high (e.g., $\phi = 2.5$).*

ρ controls the steepness of the function. From the standard model in which there are only short-lived infected cells (see [44]), the viral level will be theoretically suppressed to be below the limit of viral detection (50 RNA copies ml^{-1} in the blood) in 10.2 days if RT inhibitors are assumed to be 100% effective (we assume the same parameters as above and choose the initial viral load to be 6.7038×10^5 ml^{-1}).[1] In our model (2.4), under the same initial conditions and parameters, if we choose $\rho = 2$ day^{-1}, then the viral load can reach the same limit in 10.2 days when the drug efficacy of RT inhibitors is very close to 1. Therefore, we will use the value $\rho = 2$ day^{-1} in our simulation to study the RT inhibitor's effects on the dynamics of viral load. The abilities of RT inhibitors with different ρ to suppress the viral load will be discussed later.

Figures 5 and 6 show numerical simulations of the first model (2.4) and the second model (4.1), respectively. For the calculations underlying Figure 5, the maximum age of infected cells a_{max} is chosen to be 10 days [34]. In (2.2), we choose $p^* = 6.4201 \times 10^3$ and $\theta = 1$ to guarantee the burst size is 2500 [8]. To see the influence of antiretroviral drug therapy on the viral dynamics, we choose the initial conditions to be the steady states of the standard model [44] in the absence of drug treatment. We use $T(0) = 10^6$ ml^{-1} [42] and $V(0) = 10^{-6}$ ml^{-1} [50] in the standard model to get the following steady state values: $T = 3.8333 \times 10^5$ ml^{-1}, $T^* = 6.1675 \times 10^3$ ml^{-1}, $V = 6.7038 \times 10^5$ ml^{-1}, which are used as the initial values of our models (2.4) and (4.1). The value for the efficacy of the protease inhibitor is fixed at $\epsilon_{PI} = 0.50$. Figures 5(a)–(b) and (c)–(d) are for different values of ϵ_{RT} that increase from $\epsilon_{RT} = 0.2$ (Figure 5(a)–(b)) to $\epsilon_{RT} = 0.5$ (Figure 5(c)–(d)). We observe that, when ϵ_{RT} is increased, the infection

[1] In reality, the time to reach this limit is much longer, probably due to the existence of long-lived infected cells and latently infected cells [40, 41].

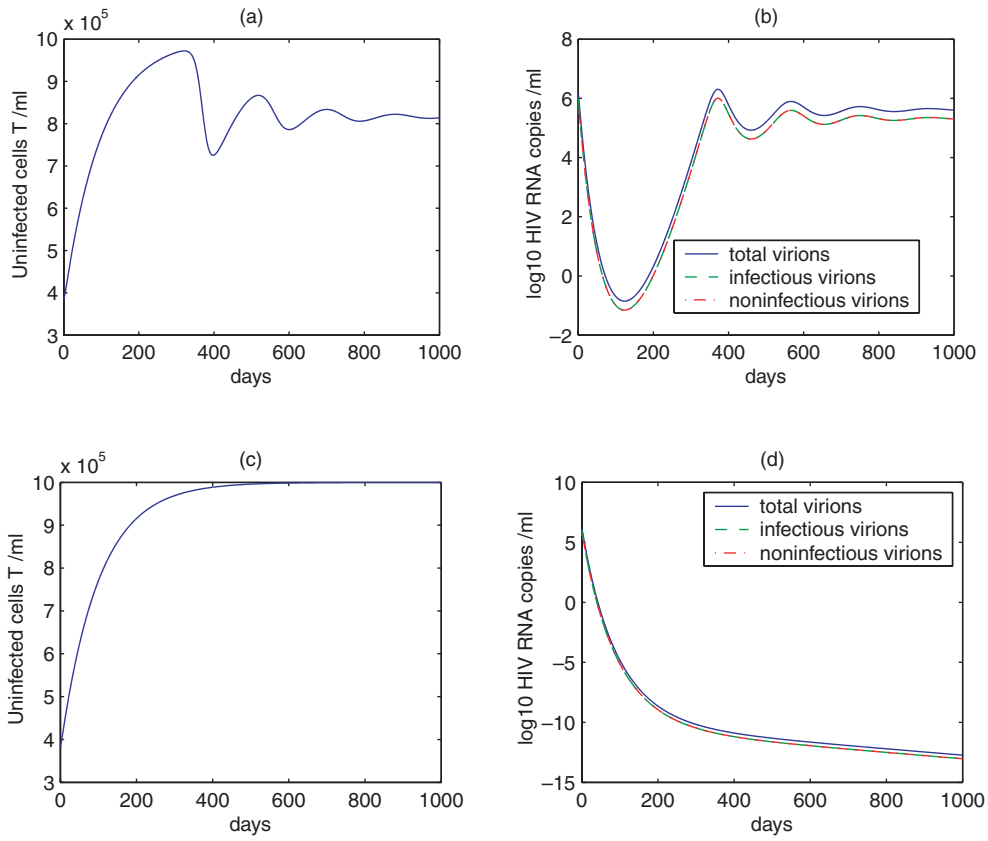

FIG. 5. *Simulation of model* (2.4) *with* $\epsilon_{PI} = 0.50$. *The upper panel:* $\epsilon_{RT} = 0.20$*; the lower panel:* $\epsilon_{RT} = 0.50$. *The other parameters for each panel are the same:* $s = 10^4\ ml^{-1}\ day^{-1}$, $d = 0.01\ day^{-1}$, $c = 23\ day^{-1}$, $k = 2.4 \times 10^{-8}\ ml\ day^{-1}$, $\delta = 1\ day^{-1}$, $p^* = 6.4201 \times 10^3\ day^{-1}$, $\theta = 1$, $T_0 = 3.8333 \times 10^5\ ml^{-1}$, $V_{I0} = 6.7038 \times 10^5\ ml^{-1}$, $V_{NI0} = 0$, $T_0^* = 6.1675 \times 10^3\ ml^{-1}$ *(see text for description). The reproductive numbers of the upper and lower panel are* 1.1666 *and* 0.9223*, respectively. The upper panel shows that the virus population stabilizes at a steady state and uninfected T cell concentration remains at* 800 μl^{-1}*, and the lower panel shows that the virus dies out and the T cell count reaches* 1000 μl^{-1}.

level at which the system stabilizes is decreased as expected. When ϵ_{RT} is greater than a threshold value ($\epsilon_{RT} = 0.41$; see also Figure 8(c)), the virus population will die out. Figure 6 shows a similar qualitative behavior of the viral load, although the efficacy of entry inhibitors has a different threshold value, $\epsilon_{EI} = 0.23$ (Figure 8(c)). The virus population persists when $\epsilon_{EI} < 0.23$ and dies out when $\epsilon_{EI} > 0.23$. This is consistent with our analytic results, as the calculation of the reproductive ratio for this set of parameters shows that $\mathcal{R}_2 > 1$ when $\epsilon_{EI} < 0.23$ and $\mathcal{R}_2 < 1$ when $\epsilon_{EI} > 0.23$. The different behaviors of the models shown in Figures 5 and 6 indicate that the entry inhibitor appears more effective than the RT inhibitor under given conditions. However, this comparison of effectiveness depends heavily on the choice of parameter ρ. If ρ is increased to 5, then the RT inhibitors can suppress viral load more effectively than entry inhibitors (see more discussion in Figure 8).

Figure 7 demonstrates how the viral load can be affected by the virion production rate $p(a)$. Each drug efficacy has a fixed value: $\epsilon_{EI} = 0.20$, $\epsilon_{PI} = 0.40$. We compare

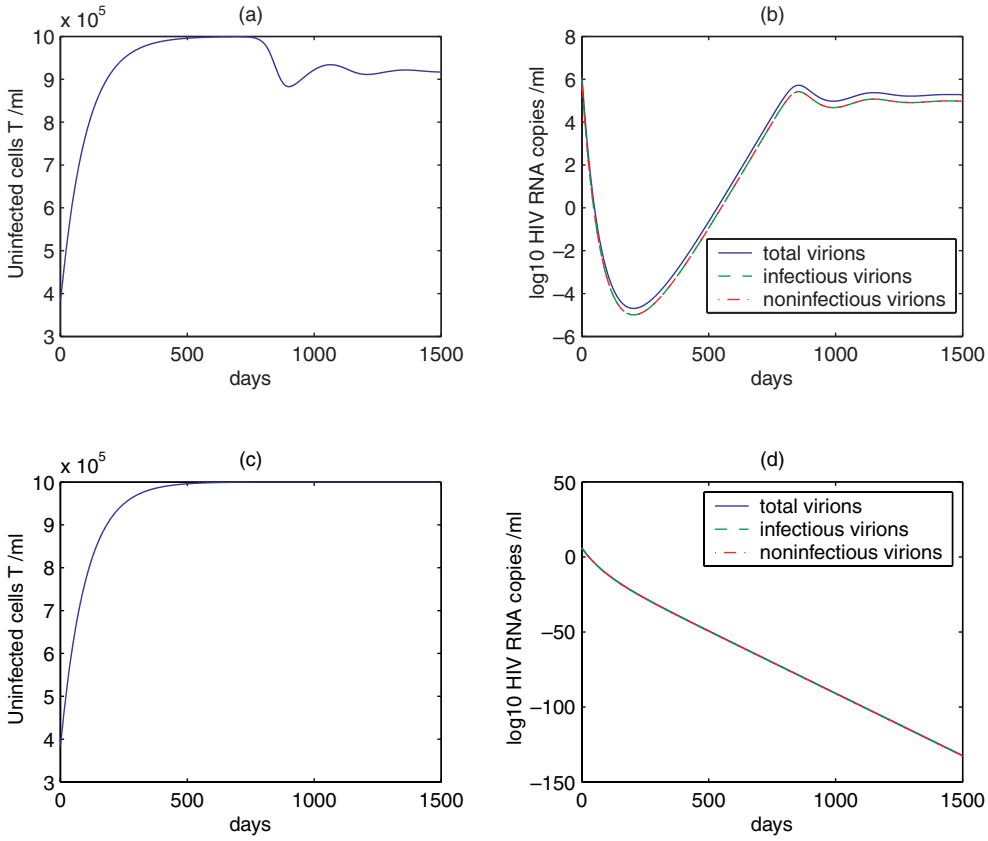

FIG. 6. *Simulation of model* (4.1) *with* $\epsilon_{PI} = 0.50$. *The upper panel:* $\epsilon_{EI} = 0.20$*; the lower panel:* $\epsilon_{EI} = 0.50$. *The other parameters are the same as those in Figure* 5. *The reproductive numbers of the upper and lower panel are* 1.0435 *and* 0.6522*, respectively. The upper panel shows that the virus population stabilizes at a lower steady state than in Figure* 5(b) *(the graphs do not show this clearly, but the numerical values show the difference) and the uninfected T cell concentration remains more than* $900\mu l^{-1}$. *The lower panel shows that the virus dies out and the T cell count reaches* $1000\mu l^{-1}$. *This implies that the entry inhibitor appears more effective than the RT inhibitor in the given conditions.*

two sets of parameters $p^* = 6.4201 \times 10^3$, $\theta = 1$ (Figure 7(a)–(b)) and $p^* = 3.5311 \times 10^3$, $\theta = 10$ (Figure 7(c)–(d)) in the viral production function (2.2), which generate the same burst size, $N = 2500$ [8]. However, the viral production rate in Figure 7(a)–(b) ramps up more slowly to the saturation level than in Figure 7(c)–(d). We observe that there is not much difference in the T cell dynamics, the viral peak, the time needed to reach the peak level, and the steady state viral load, although the nadir of the viral load in panel (d) is less than that of panel (b). This implies that varying the viral production function does not play an important role, at least in the long-term virus dynamics, given the same burst size.

Comparing Figure 7(a)–(b) with Figure 6(a)–(b), we observe that when the drug treatment becomes more effective (ϵ_{PI} increases from 0.4 to 0.5, $\epsilon_{EI} = 0.20$), the amplitude of the viral peak and the steady state viral load are decreased. However, it takes longer for the viral load to reach its peak level when the drug efficacy is higher. A possible explanation for this phenomenon is the following. Because a more effective

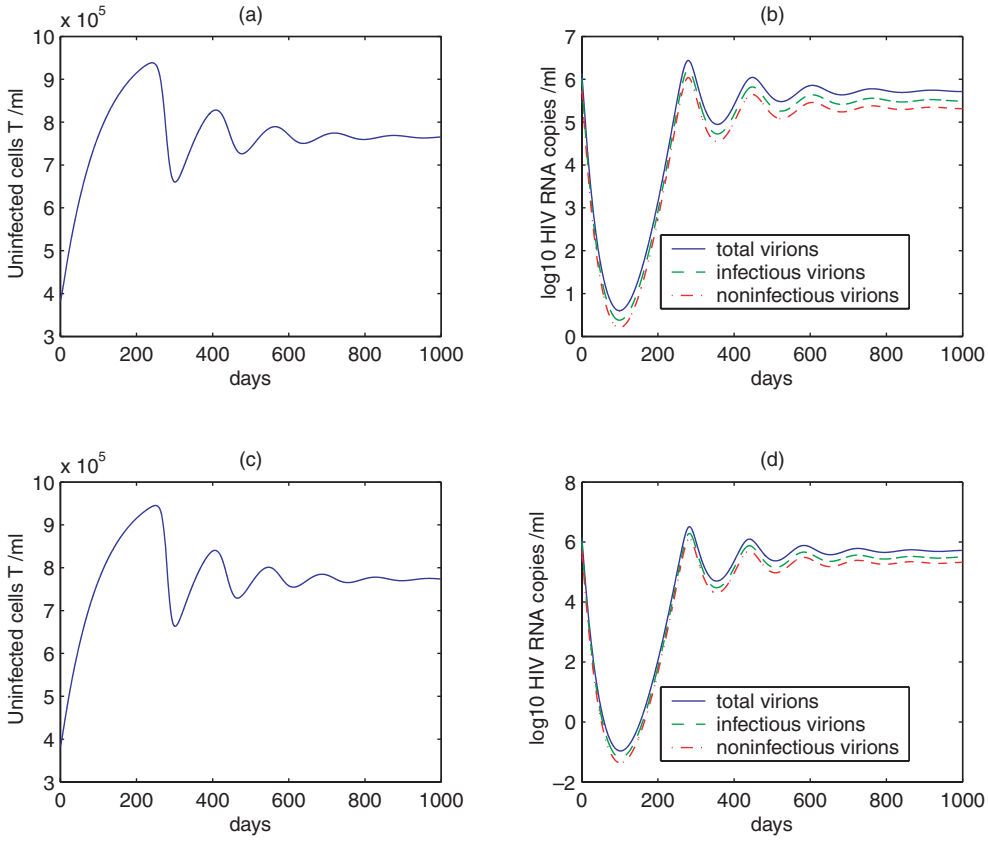

FIG. 7. *Simulation of model* (4.1) *with* $\epsilon_{EI} = 0.20, \epsilon_{PI} = 0.40$. *The upper panel:* $p^* = 6.4201 \times 10^3, \theta = 1$*; the lower panel:* $p^* = 3.5311 \times 10^3, \theta = 10$. *(The burst size of each panel is the same:* $N = 2500$*.) The other parameters are the same as those in Figure* 5. *The viral production of the lower panel ramps up more quickly to the saturation level than that of the upper panel. There is almost no difference in the viral peak, the time to reach the peak level, and the steady state viral load. This shows that the viral production function does not play an important role in the long-term viral dynamics given the same burst size.*

drug treatment (assuming that it is not potent enough to eliminate the virus) can suppress the virus more substantially, the nadir that the viral load can reach is much lower than when the treatment is more effective. Thus the time for the viral load to reach its peak level is prolonged.

In Figure 8, we compare the effects of two combination therapies on reducing the viral load. With the choice of $p(a)$ and $\beta(a)$ given in (2.2) and (5.3), we have the following reproductive numbers:

$$\mathcal{R}_1 = e^{-a_1\eta(\epsilon_{RT})}M_0, \quad \mathcal{R}_2 = (1-\epsilon_{EI})M_0, \tag{6.1}$$

where $M_0 = \frac{sk\theta}{cd\delta(\theta+\delta)}(1-\epsilon_{PI})p^*e^{-\delta a_1}$. Let $V_I^{(1)}$ and $V_I^{(2)}$ denote the viral steady states of models 1 and 2, respectively. Then $V_I^{(1)} = \frac{d(\mathcal{R}_1-1)}{k(1-\mathcal{K}_1)}$, $V_I^{(2)} = \frac{d(\mathcal{R}_2-1)}{k(1-\epsilon_{EI})}$, where $\mathcal{K}_1 = \frac{\eta(\epsilon_{RT})}{\delta+\eta(\epsilon_{RT})}(1-e^{-(\delta+\eta(\epsilon_{RT}))a_1})$. If we assume the reversion rate takes the

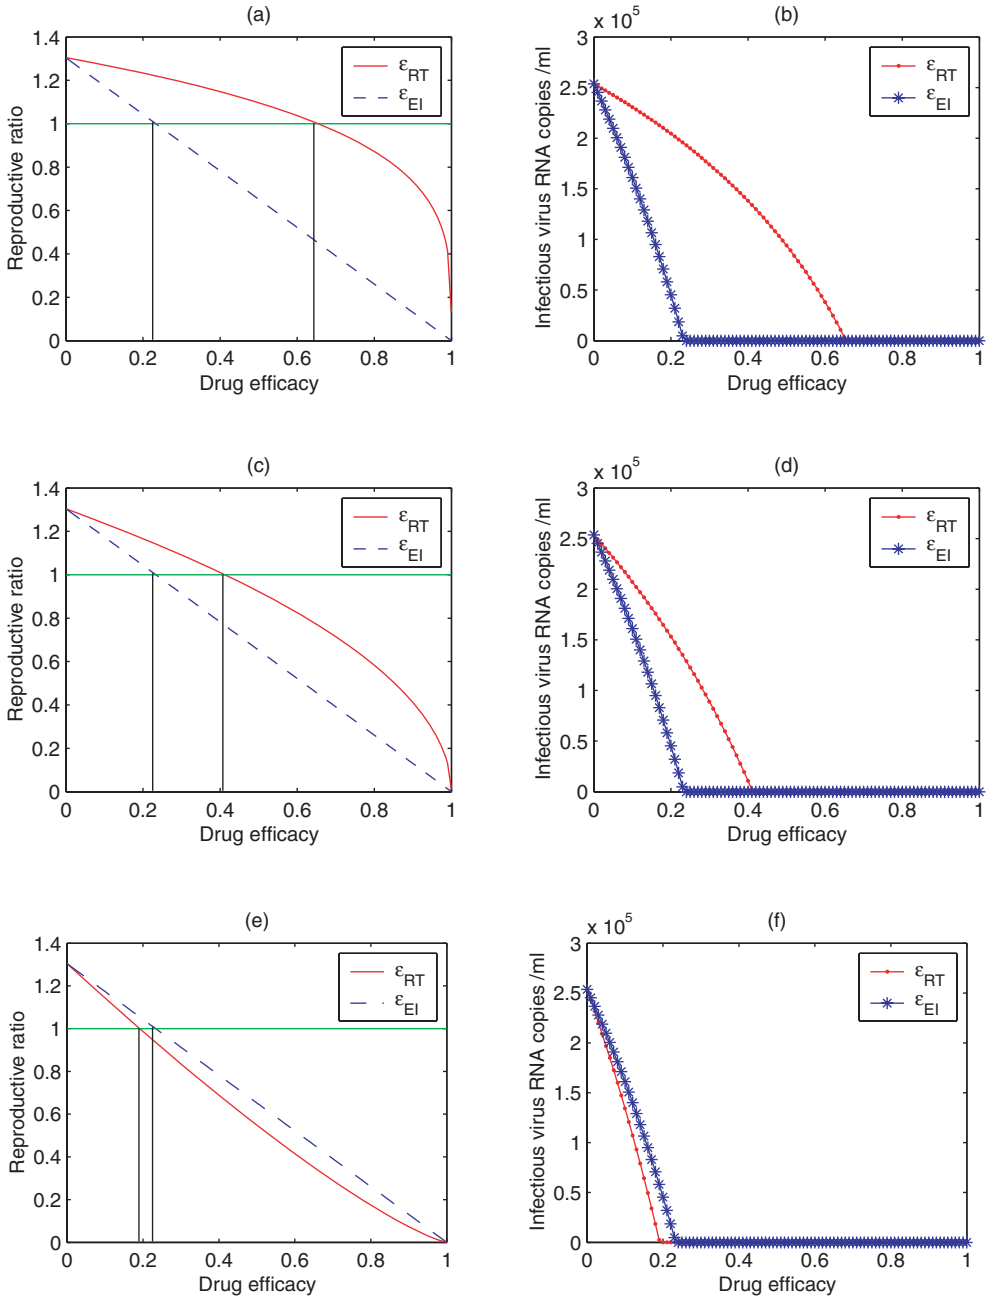

FIG. 8. *Comparison of the two combination therapies with fixed protease inhibitor drug efficacy* $\epsilon_{PI} = 0.50$. *The other parameters are the same as those in Figure* 5. *Left column: reproductive numbers* $\mathcal{R}_1$ *and* $\mathcal{R}_2$ *as the function of* ϵ_{RT} *and* ϵ_{EI}, *respectively. If* $\epsilon_{EI} > 0.23$, *then* $\mathcal{R}_2 < 1$, *and hence virus will die out. Right column: steady state* V_I *of models* (2.4) *and* (4.1) *as the function of* ϵ_{RT} *and* ϵ_{EI}, *respectively. The upper panel:* $\rho = 1$, *the threshold for* $\mathcal{R}_1 < 1$ *is* $\epsilon_{RT} > 0.65$; *the middle panel:* $\rho = 2$, *the threshold for* ϵ_{RT} *is* 0.41; *the bottom panel:* $\rho = 5$, *the threshold for* ϵ_{RT} *is* 0.19. *For a small* ρ *(*$\rho < 4$*), the entry inhibitors appear more effective than the RT inhibitors; for a large* ρ *(*$\rho > 4$*), we have the contrary result.*

form $\eta(\epsilon_{RT}) = -\rho \ln(1-\epsilon_{RT})$, then $\mathcal{R}_1$ can be simplified, and (6.1) reduces to

$$\mathcal{R}_1 = (1-\epsilon_{RT})^{a_1\rho} M_0, \quad \mathcal{R}_2 = (1-\epsilon_{EI}) M_0. \tag{6.2}$$

In Figure 8(c), we let $\epsilon_{PI} = 0.50$ and plot $\mathcal{R}_1(\epsilon_{RT})$ and $\mathcal{R}_2(\epsilon_{EI})$ as functions of ϵ_{RT} and ϵ_{EI}, respectively. We observe that there is a threshold value, $\epsilon_{RT} = 0.41$, such that $\mathcal{R}_1 > 1$ when $\epsilon_{RT} < 0.41$ and $\mathcal{R}_1 < 1$ when $\epsilon_{RT} > 0.41$. By comparison, the threshold value for entry inhibitors is $\epsilon_{EI} = 0.23$, which implies that the virus population will die out when $\epsilon_{EI} > 0.23$ (see also Figures 5 and 6). In Figure 8(d), $V_I^{(1)}(\epsilon_{RT})$ and $V_I^{(2)}(\epsilon_{EI})$ are plotted as functions of ϵ_{RT} and ϵ_{EI}, respectively. Given the same efficacy, the value of steady state $V_I^{(2)}(\epsilon_{EI})$ is less than $V_I^{(1)}(\epsilon_{RT})$. This indicates that the entry inhibitor appears more effective in reducing the viral load than the RT inhibitor in this scenario ($\rho = 2$). In fact, more information can be obtained by looking at the slopes of $\mathcal{R}_1(\epsilon_{RT})$ and $\mathcal{R}_2(\epsilon_{EI})$ in Figure 8(c) since the slope characterizes the effectiveness of drug treatment in infection control when drug efficacy is increased. From (6.2), we see that $\mathcal{R}_1$ decreases nonlinearly as ϵ_{RT} increases and the decay rate is $(1-\epsilon_{RT})^{a_1\rho}$, while $\mathcal{R}_2$ decreases linearly with the decay rate $(1-\epsilon_{EI})$ as ϵ_{EI} increases. This implies that the effectiveness of RT inhibitors depends heavily upon the reversion constant ρ. In our simulation, we choose $\rho = 2$ day^{-1} and find that the entry inhibitor is more likely able to annihilate the virus population than the RT inhibitor when the efficacy is increased by the same percentage (see Figures 5, 6, and 8(c)–(d)). However, we obtain the contrary result when ρ is chosen to be greater than $1/a_1$ (Figure 8(e)–(f)).

7. Concluding remarks. We have formulated two age-structured models for HIV-1 infection with drug treatments to study the influence of antiretroviral therapy on viral dynamics. We considered two types of combination therapies. One is the standard combination of RT inhibitors and protease inhibitors, and the other is a combination of an entry inhibitor with protease inhibitors. For each of these cases, we have calculated the reproductive ratio $\mathcal{R}_i$ ($i = 1, 2$), which is shown to determine the asymptotic stability of the infection-free steady state (when $\mathcal{R}_i < 1$) and the infected steady state (when $\mathcal{R}_i > 1$). In simple nonage-structured models, both RT and entry inhibitors are modeled in the same way, i.e., as a factor that reduces the rate of infection. Here, by considering the details of the viral life cycle, we model these inhibitors differently and explicitly. When an RT inhibitor is administered, some infected cells may have already completed reverse transcription (postRT cells). For these cells, the RT inhibitor will have no effect. For infected cells that have not completed reverse transcription (preRT cells), the RT inhibitor will prevent completion of reverse transcription and allow, under the influence of enzymes that degrade the HIV-1, a reversion of infected cells back into an uninfected state. These features of our model are novel. An entry inhibitor, enfuvirtide, has been used in a combination of RT and protease inhibitors [1, 33]. The addition of enfuvirtide to the regimen was reported to increase the antiretroviral potency in one study [33] but not the other [1]. Thus the impact of entry inhibitor use needs further evaluation, and mathematical modeling may be able to help in this regard.

We studied the impact of combination therapy using RT and protease inhibitors on the emergence of drug-resistant HIV-1 strains. The cost of resistance was assumed to be a reduced viral production rate. We calculated the reproductive ratio for the resistant strain $\mathcal{R}_r(\sigma)$ with a resistance level σ and provided a criterion for the potential invasion of resistant strains, i.e., $\mathcal{R}_r(\sigma) > \mathcal{R}_s$, in an environment where the

wild-type strain was already established. We argue that natural selection within a host favors virions that maximize the reproductive ratio, which is consistent with earlier findings (see, for example, [16]). Consequently, we show that natural selection should favor viral strains that have an intermediate level of resistance and that the optimal resistance level (σ_{opt}) decreases with increasing drug efficacy (see Figures 1 and 2). Mathematically, increasing the values of ϵ_{PI} and ϵ_{RT} results in (1) a reduction in the reproductive ratio $\mathcal{R}_s$ of the drug sensitive strain (see Figure 4) and hence a reduction in the equilibrium level of infection (see $T^\diamond = s/(dcR_s)$ and $V^\diamond = (d/k)(\mathcal{R}_s - 1)/(1 - \mathcal{K}_1)$ in (3.3)); and (2) a decrease in the optimal viral fitness $\mathcal{R}_{r\max}$ of the resistant strain and a decrease in the optimal resistance σ_{opt} (see Figures 1 and 3), and an increase in the range of resistance ($\sigma_{\min} < \sigma < 1$) for which $\mathcal{R}_r > \mathcal{R}_s$ ($\sigma_{\min}$ decreases with both ϵ_{PI} and ϵ_{RT}; see Figures 1 and 2). These are strains that are able to invade a host population. On the other hand, if ϵ_{PI} and ϵ_{RT} are small such that $\sigma_{\min}$ is greater than 1, then $\mathcal{R}_r < \mathcal{R}_s$ for all resistance σ. These strains will not be maintained in a population. It should be noted that the condition under which drug-resistant virus variants are selected in the presence of drug pressure is very complex due to various factors [48], e.g., drug potency [46], adherence to combination antiretroviral medications [14, 15], spatial heterogeneity [23], and the increasing levels of transmitted resistant virus [4]. The management of HIV-infected patients requires a better understanding of the mechanisms underlying the emergence of drug resistance. HIV resistance testing has proved helpful in clinical practice and is rapidly being incorporated into standard HIV care [47, 49].

We have also examined the effect of drug efficacy on viral dynamics by numerical simulations. As the drug efficacy increases, the steady state of viral load as well as the amplitude of the damped oscillations that characterize the approach to equilibrium decrease, which shows that an effective drug treatment will detectably lower the plasma viral load after the administration (see Figures 5, 6, and 8(c)–(d)). Moreover, the age-dependent virion production rate can also have an effect on the viral dynamics (see Figure 7).

We compared the effects of various treatments on reducing the viral population in plasma. The effectiveness of an RT inhibitor was proved to rely heavily on the reversion rate, $\eta(\epsilon_{RT})$, at which preRT cells revert back to an uninfected state because of the inhibitor. In fact, the reproductive ratio in the presence of an RT inhibitor, $\mathcal{R}_1$, is proportional to the factor $e^{-a_1\eta(\epsilon_{RT})}$ (a_1 is the age at which reverse transcription is complete), while the reproductive ratio in the presence of an entry inhibitor, $\mathcal{R}_2$, is proportional to the factor $(1 - \epsilon_{EI})$. Thus the comparison of the effectiveness of RT and entry inhibitors depends on a_1 and the functional form of $\eta(\epsilon_{RT})$. We chose a specific function $-\rho\ln(1-\epsilon_{RT})$ for $\eta(\epsilon_{RT})$ in our simulations. Then the reproductive ratio $\mathcal{R}_1$ is proportional to $(1 - \epsilon_{RT})^{a_1\rho}$. Given the same drug efficacy, an entry inhibitor appears to be more effective in reducing viral load than an RT inhibitor (see Figures 5, 6, and 8(c)–(d)) if ρ is chosen to be 2 day^{-1}. We get the contrary result if we choose ρ such that $\rho > 1/a_1$ ($\rho = 5$ day^{-1} in Figure 8(e)–(f)).

Another comparison of the effectiveness of RT inhibitors is between that obtained here using our age-structured model and the previous results in the literature based on the nonage-structured "standard model" (see [37, 44]). The reproductive ratio in the presence of an RT inhibitor for the standard model is $\mathcal{R} = (1-\epsilon_{RT})kps/(dc\delta)$ [5], where p is the constant production rate and δ is the constant death rate of productively infected cells. Thus $\mathcal{R}$ decreases linearly as the drug efficacy increases, and the decay rate is $(1-\epsilon_{RT})$. A similar comparison follows for the drug effect of RT inhibitors on suppressing the viral load between our model and the standard model. The functional

form of the reversion rate $\eta(\epsilon_{RT})$ awaits future studies. These findings might be helpful in designing treatment for the control of HIV infections. In the current model, we have not included both the wild-type and drug-resistant strains explicitly [54]. This will be done in the future work.

ANALYSIS OF A MODEL OF THE GLUCOSE-INSULIN REGULATORY SYSTEM WITH TWO DELAYS*

JIAXU LI† AND YANG KUANG‡

Abstract. We continue a recent attempt to better understand the glucose-insulin regulatory system via a mathematical model of delay differential equations with two discrete time delays. With explicit delays, the model is more realistic in physiology, more accurate in mathematics, and more robust in applications. We study this model analytically and perform carefully designed numerical simulations by allowing two parameters to vary. Our analytical and numerical results confirm most current existing physiological observations and reveal more insightful information. The following factors are critical for ensuring the sustained oscillatory regulation and insulin secretion: (1) the time lag for insulin secretion stimulated by glucose and the newly synthesized insulin becoming *"remote insulin"* (Theorem 4.2 (b) and Theorem 5.6); (2) the delayed effect of hepatic glucose production (Theorem 4.2 (c) and Theorem 5.6); (3) moderate insulin clearance rate (Theorem 5.6 and simulations in section 6.4); and (4) nonoverwhelming glucose infusion (simulations in section 6.2, 6.3, and 6.4).

Key words. glucose-insulin regulatory system, insulin secretion, ultradian oscillation, time delay

1. Introduction.

Beginning with the pioneering work of Bolie [5] in the 1960s, several attempts at modeling the glucose-insulin regulatory system have been proposed in recent decades [2], [17], [25], [26]. These studies are, at least partially, motivated by the fact that diabetes mellitus is one of the worst diseases in the world due to the large size of the diabetic population, especially among Native Americans [14], as well as severe complications [10] and high health expenses (http://www.diabetes.org). Providing more efficient, effective, and economic treatments is the ultimate goal of these efforts (see [2], [3], [4], [5], [17], [18], [25], [26], and the references therein). The minimal model [3] and its siblings [9], [16], [19] study the insulin sensitivity, while the mathematical models proposed in [2], [5], [17], [25], [26] aim to better understand the glucose-insulin regulatory system.

In the glucose-insulin endocrine metabolic regulatory system, the pancreatic hormone insulin and glucagon are the two key players. Both in-vivo and in-vitro experiments have revealed that the insulin is secreted from the pancreas in oscillatory manners in two time scales. It is widely believed that the rapid pulsatile oscillation is caused by the insulin secretory bursts from the millions of Langerhans islets in hundreds of β-cells in the pancreas at a periodicity of 5–15 minutes [20]. The much slower ultradian oscillation refers to the oscillation of insulin secretion with period in the range of 50–150 minutes [23], [25]. The amplitude of the ultradian oscillation dominates that of the rapid pulsatile oscillation. There exist two time delays in this

system. One naturally occurring time delay is the time needed for the insulin to release from the β-cells stimulated by elevated glucose concentration and the newly synthesized insulin to cross the endothelial barriers and become the so-called *remote insulin*, now known as interstitial insulin. The remote insulin helps the cells, e.g., muscle and adipose, to uptake glucose. The other time delay refers to the delayed effect of hepatic glucose production. Applying the standard compartment transition technique to mimic the time delays, Sturis et al. [25] formulated a model consisting of six ordinary differential equations (ODEs) that successfully captured some of the basic features (oscillations with periods and amplitudes comparable to experiment observations) of ultradian oscillation. Recently, Li, Kuang, and Mason [17] proposed an alternative model of the glucose-insulin regulatory system consisting of two delay differential equations with two naturally explicit discrete time delays. This two-delay model uses only physiologically meaningful and measurable parameters. It is shown that this two-delay model provides the best overall fit among five plausible model systems with the experimental data given in [2], [17], and [25]. It is also shown [17] that the two-time-delay model is more robust compared to the model proposed in [25]. The authors of [17] concluded that the time delay of insulin responding to glucose stimulation plays a key role in generating the oscillatory behavior of insulin secretion.

This paper attempts to provide a systematical study of the two-delay model of [17] with focuses on analytical studies, bifurcation analysis, and carefully designed numerical simulations. In the following sections, we first introduce the model proposed in [17], then present some preliminary results on positivity, boundedness, and persistence of solutions. Local stability analyses are carried out in details whenever feasible. These analytical results are complemented and confirmed by the bifurcation diagrams produced from our extensive and carefully designed simulations. This paper ends with a discussion section containing a list of observations.

2. The two-delay model. By applying the mass conservation law, the approach used in [27], Li, Kuang, and Mason [17] proposed a glucose-insulin regulatory system model with two explicit time delays based on a set of well-known observations [1], [6], [13], [17], [21], [25], [26], [27]. The model can be expressed by the following word equations.

Glucose change rate = glucose production rate − glucose utilization rate.
Insulin change rate = insulin production rate − insulin removal rate.

Throughout this paper, we use $G(t)$ to represent the plasma glucose concentration and $I(t)$ to represent the plasma insulin concentration at time $t \geq 0$.

In the glucose-insulin endocrine metabolic system, the β-cells, contained in the Langerhans islets in the pancreas, are the only source of insulin production. When the plasma glucose concentration level is elevated, the β-cells secrete insulin after a complex series of cascading physiological processes [1], [17]. The newly synthesized insulin crosses the endothelial barriers to become remote insulin, which readily helps the cells, e.g., muscle and fat cells, to utilize the plasma glucose and convert it to energy [17]. These processes take a total of approximately 5–15 minutes [25], [26]. In the model, this is denoted by $f_1(G(t-\tau_1))$, where $\tau_1 > 0$ represents the time delay of the insulin response to the glucose stimulation and the time needed for the newly synthesized insulin crossing endothelial barrier to become remote insulin.

Insulin is degraded by all insulin sensitive tissues, and the degradation is mediated primarily by the insulin receptor with a smaller contribution from nonspecific

processes. The liver and kidney are the primary sites of portal insulin degradation and peripheral insulin clearance, respectively. Insulin not cleared by the liver and kidneys is ultimately removed mainly by muscle and adipose cells [11], [17]. The function of insulin clearance is to remove and inactivate circulating insulin in order to control insulin action [11]. The degradation is almost linearly proportional to insulin [27]. So the degradation rate is denoted by a constant $d_i > 0$. Since $I(t)$ stands for plasma insulin concentration, it is easier to measure clinically.

In muscle and adipose tissue, insulin facilitates the transport of glucose into cells. The glucose is then metabolized by the cells. This type of glucose consumption is called insulin-dependent glucose utilization. Not all glucose consumption depends on the attendance of insulin. For example, the brain and nerve cells consume the glucose without the aid of insulin. This is referred to as insulin-independent glucose utilization. (See [17] for more details.) Respectively, the insulin-independent and insulin-dependent glucose utilization are represented by $f_2(G(t))$ and $f_3(G(t))f_4(I(t))$.

Glucose enters the circulation in two ways: glucose infusion and hepatic glucose production. Glucose infusion includes meal ingestion, oral glucose intake, continuous enteral nutrition absorption, and constant infusion. Hence the model includes a constant glucose infusion term G_{in} that may model the continuous enteral glucose absorption and constant glucose infusion [17], [25], [27].

Hepatic glucose production is due to glucose dispensation by the liver endogenously. When the plasma glucose concentration level becomes low, the β-cells stop releasing insulin. Instead, the α-cells, also contained in Langerhans islets, start to release glucagon. Glucagon exerts control over pivotal metabolic pathways in the liver and leads the liver to dispense glucose [1]. The liver also converts the previously stored glycogen into glucose. Opposite to the fact that glucagon secretion triggers the liver to dispense glucose, insulin secretion inhibits glucose production by the liver [6], [21]. Thus the hepatic glucose production is primarily controlled by insulin concentration in both inhibitory effect by insulin secretion and recovery effect by insulin suppression. Some time is needed for hepatic glucose production to take significant effect, e.g., half maximal suppression or recovery takes time [17], [21]. However, both the pathways and the length of the delay remain unknown. Nevertheless, this time delay is approximately between a few minutes and a half hour, or even longer [17], [21]. The hepatic glucose production is presented by $f_5(I(t-\tau_2))$, where $\tau_2 > 0$ represents the time taken for a noticeable effect on hepatic glucose production, e.g., half maximal suppression or recovery rate.

Therefore the system [17] can be written as

$$\begin{cases} G'(t) = G_{in} - f_2(G(t)) - f_3(G(t))f_4(I(t)) + f_5(I(t-\tau_2)), \\ I'(t) = f_1(G(t-\tau_1)) - d_i I(t). \end{cases} \tag{2.1}$$

For convenience, the initial conditions of the two-time-delay model (2.1) are assumed to be $I(0) = I_0 > 0$, $G(0) = G_0 > 0, G(t) \equiv G_0$ for all $t \in [-\tau_1, 0]$ and $I(t) \equiv I_0$ for $t \in [-\tau_2, 0]$, $\tau_1, \tau_2 > 0$. In this paper, we assume that the functions f_i, $i = 1, 2, 3, 4, 5$, in model (2.1) satisfy the following conditions:

(i) Notice that β-cells release insulin due to glucose stimulation. We assume that $f_1(x) > 0$ and $f_1'(x) > 0$ for $x > 0$. On the other hand, the capacity of the insulin secretion from β-cells is saturated due to highly increased glucose concentration level, so we assume $\lim_{x\to\infty} f_1(x) = M_1$ and $f_1'(x)$ is bounded by a constant $M_1' > 0$ for $x > 0$. Thus it is reasonable to assume that $f_1(x)$ is in sigmoidal shape. Observing that the insulin can be secreted from the β-cells due to bursting without the glucose stimulation, we assume that $f_1(0) := m_1 > 0$.

(ii) As a term indicating the insulin-independent glucose utilization, it is clear that $f_2(0) = 0$, $f_2(x) > 0$, and $f_2'(x) > 0$ for $x > 0$. On the other hand, the utilization is not unlimited, so we assume that $\lim_{x\to\infty} f_2(x) = M_2$ and there exists a constant M_2' such that $f_2'(x) < M_2'$ for $x > 0$.

(iii) The insulin-dependent glucose utilization $f_3(G(t))f_4(I(t))$ can be depicted as $f_3(0) = 0$, $f_4(0) := m_4 > 0$, $f_3'(x) > 0$, $f_4(x) > 0$, and $f_4'(x) > 0$ for $x > 0$. As suggested by Sturis et al. [25], we also assume that there exist constants $k_3 > 0, M_4 > 0$, and $M_4' > 0$ such that $0 < f_3(x) \le k_3 x$, $\lim_{x\to\infty} f_4(x) = M_4$, and $f_4'(x) < M_4'$ for $x > 0$ and $f_4(x)$ is in sigmoidal shape.

(iv) Low glucose concentration will lead β-cells to stop releasing insulin and α-cells to release glucagon. Thus, when insulin is deficit, liver dispenses glucose caused by glucagon exerting control over pivotal metabolic pathways in the liver, and also converts glycogen into glucose. On the other hand, the liver stops this process when insulin is abundant. Hence we assume $f_5(0) > 0$, $f_5(x) > 0$, and $f_5'(x) < 0$ for $x > 0$, and $\lim_{x\to\infty} f_5(x) = 0$ and f_5 is in inverse sigmoidal shape. Since the amount of glucose converted by the liver is small and the process takes time, we assume $\exists M_5, M_5' > 0$ such that $f_5(x) \le M_5$ and $|f_5'(x)| \le M_5'$ for $x > 0$. We can simply set $M_5 = f_5(0)$.

The shapes of the functions are more important than their forms [13]. Figure 3 of [17] shows the shapes of functions in model (2.1). In section 6, we adopt the functions, (6.1)–(6.5), used in [17], [25], and [26], to perform numerical simulations.

3. Preliminaries. We first present some useful preliminary results of model (2.1). The following fluctuation lemma is elementary and well known [12].

LEMMA 3.1 (fluctuation lemma). *Let $f : \mathbf{R} \to \mathbf{R}$ be a differentiable function. If $l = \liminf_{t\to\infty} f(t) < \limsup_{t\to\infty} f(t) = L$, then there are sequences $\{t_k\} \uparrow \infty$, $\{s_k\} \uparrow \infty$ such that for all k, $f'(t_k) = f'(s_k) = 0, \lim_{k\to\infty} f(t_k) = L$, and $\lim_{k\to\infty} f(s_k) = l$.*

We will apply Lemma 3.1 in the proofs of Proposition 3.2 on solution boundedness and Lemma 3.3 on a set of restrictions for the upper and lower limits of a solution. The proofs are given in Appendices A and B.

PROPOSITION 3.2. *In model (2.1), the following hold:*

(i) *If $\lim_{x\to\infty} f_3(x) > (G_{in} - M_2 + M_5)/m_4$, then model (2.1) has unique positive steady state (G^*, I^*) with $I^* = d_i^{-1} f_1(G^*)$. Furthermore, all solutions exist in $(0, \infty)$, and are positive and bounded.*

(ii) *If $\lim_{x\to\infty} f_3(x) < (G_{in} - M_2)/m_4$, then $\limsup_{t\to\infty} G(t) = \infty$.*

Remark. Condition (i) indicates that the steady state is unique if insulin can help the cells to metabolize enough glucose. Otherwise, if condition (ii) holds, the glucose concentration level will be unbounded.

Remark. If $f_3(x) = k_3 x$, where $k_3 > 0$ is a constant, then

$$\limsup_{t\to\infty} G(t) \le M_G := (G_{in} + M_5)/(m_4 k_3). \tag{3.1}$$

In fact, notice that $m_4 \le f_4(x) \le M_4$ and $f_5(x) \le M_5$ and $f_3(x) = k_3 x$ for $x > 0$. Thus $G'(t) = G_{in} - f_2(G(t)) - f_3(G(t))f_4(I(t)) + f_5(I(t-\tau_2)) \le G_{in} - m_4 k_3 G(t) + M_5$. A standard comparison argument yields (3.1).

Throughout this paper, we assume that condition (i) in Proposition 3.2 holds.

Let $(G(t), I(t))$ be a solution of (2.1). Throughout this paper, we denote

$$\overline{G} = \limsup_{t\to\infty} G(t), \qquad \underline{G} = \liminf_{t\to\infty} G(t), \qquad \overline{I} = \limsup_{t\to\infty} I(t), \qquad \underline{I} = \liminf_{t\to\infty} I(t).$$

Due to Proposition 3.2, it is clear that these limits are finite. Further, we have the following lemma.

LEMMA 3.3. *If* $(G(t), I(t))$ *is a solution of* (2.1)*, then*

$$f_1(\underline{G}) \le d_i \underline{I} \le d_i \bar{I} \le f_1(\bar{G}), \tag{3.2}$$

$$f_2(\bar{G}) + f_3(\bar{G}) f_4(\underline{I}) \le G_{in} + f_5(\underline{I}), \tag{3.3}$$

$$G_{in} + f_5(\bar{I}) \le f_2(\underline{G}) + f_3(\underline{G}) f_4(\bar{I}). \tag{3.4}$$

Remark. Apparently, $\bar{G} = \underline{G}$ implies $\bar{I} = \underline{I}$ due to (3.2). If $\bar{I} = \underline{I}$, then (3.3) and (3.4) together lead to $f_2(\bar{G}) - f_2(\underline{G}) \le f_4(\bar{I})(f_3(\underline{G}) - f_3(\bar{G})) \le 0$. That is, $\bar{G} = \underline{G}$.

PROPOSITION 3.4. *Model* (2.1) *is persistent, that is, the components of all solutions are eventually uniformly bounded from above and away from zero.*

Proof. Notice that $f_2(0) + f_3(0) = 0$ and $f_4(x) < M_4$ for all $x \ge 0$. Then (3.4) implies that $G_{in} \le f_2(\underline{G}) + f_3(\underline{G}) M_4$ for all $t > 0$. Thus $\exists \delta_G > 0, t_G > 0$, such that $G(t) > \delta_G$ for $t > t_G > 0$. Hence $G(t)$ is eventually and uniformly bounded away from zero. Inequality (3.2) implies the same for $I(t)$. The parts of boundedness from above are implied in Proposition 3.2. ∎

4. Local analysis: Case $\tau_1\tau_2 = 0$. We analyze the trivial case $\tau_1\tau_2 = 0$ in this section. The study of the nontrivial case $\tau_1\tau_2 > 0$ will be carried out in the next section.

Clearly the linearized system of model (2.1) about (G^*, I^*) is given by

$$\begin{cases} G'(t) = -AG(t) - BI(t) - CI(t - \tau_2), \\ I'(t) = DG(t - \tau_1) - d_i I_1(t), \end{cases} \tag{4.1}$$

where

$$\begin{cases} A := f_2'(G^*) + f_3'(G^*) f_4(I^*) > 0, \ B := f_3(G^*) f_4'(I^*) > 0, \\ C := -f_5'(I^*) > 0, \ D := f_1'(G^*) > 0. \end{cases} \tag{4.2}$$

The characteristic equation of (4.1) is given by

$$\Delta(\lambda) = \lambda^2 + (A + d_i)\lambda + d_i A + DBe^{-\lambda\tau_1} + DCe^{-\lambda(\tau_1+\tau_2)} = 0. \tag{4.3}$$

Notice that $\Delta(0) = d_i A + DB + DC > 0$. So $\lambda = 0$ is not a solution of the characteristic equation (4.3). Thus, if there is any stability switch of the trivial solution of the linearized system (4.1), there must exist a pair of pure conjugate imaginary roots of the characteristic equation (4.3).

When $\tau_1 = \tau_2 = 0$, the original model (2.1) is an ODE model. The characteristic equation of its linearized equation is given by

$$\Delta(\lambda) = \lambda^2 + (A + d_i)\lambda + d_i A + DB + DC = 0.$$

Then, $A + d_i > 0$ and $d_i A + DB + DC > 0$ imply that (G^*, I^*) is stable.

For the cases of $\tau_1\tau_2 = 0$ and $\tau_1 + \tau_2 > 0$, we need the following lemma, which can be obtained via a standard imaginary root crossing method [8], [15]. The details can be found in [15, pp. 74–77] and [15, Theorem 3.1].

LEMMA 4.1. *Assume* $a, c, d > 0$ *in the following delay differential equation:*

$$x''(t) + ax'(t) + cx(t) + dx(t - \tau) = 0, \ \tau \ge 0. \tag{4.4}$$

Then the number of pairs of pure imaginary roots of the characteristic equation

$$\lambda^2 + a\lambda + c + de^{-\lambda\tau} = 0, \ \tau \ge 0, \tag{4.5}$$

can be zero, one, or two only.

(i) *If* $c > d$ *and* $2c - a^2 < 2\sqrt{c^2 - d^2}$, *then the number of such roots is zero for* $\tau > 0$. *The trivial solution of* (4.4) *is stable for all* $\tau > 0$.

(ii) *If* $c < d$ *or* $d = c$ *and* $2c - a^2 > 0$, *then the number of such roots is one for some* $\tau > 0$. *The trivial solution of* (4.4) *is uniformly asymptotically stable for* $\tau < \tau_0$, *and it becomes unstable for* $\tau > \tau_0$, *where* $\tau_0 > 0$ *is a constant. It undergoes a supercritical Hopf bifurcation at* $\tau = \tau_0$.

(iii) *If* $c > d$ *and* $2c - a^2 > 2\sqrt{c^2 - d^2}$, *then the number of such roots is two for some* $\tau > 0$. *The stability of the trivial solution of* (4.4) *can change (when changing from stable to unstable, the trivial solution undergoes a supercritical Hopf bifurcation) a finite number of times at most as* τ *increases, and eventually it becomes unstable.*

For the case of $\tau_1 > 0$ and $\tau_2 = 0$, the characteristic equation is

$$\Delta(\lambda) = \lambda^2 + (A + d_i)\lambda + d_i A + (DB + DC)e^{-\lambda\tau_1} = 0. \tag{4.6}$$

Notice that, in this case, $2c - a^2 = -A^2 - d_i^2 < 0$ in Lemma 4.1. Then $d_i A > D(B + C)$ implies that the trivial solution of (4.1) is always stable for $\tau_1 > 0$. Also, $d_i A < D(B + C)$ implies that $\exists \tau_{10} > 0$ such that the trivial solution of the linearized system (4.1) is stable when $\tau_1 \in (0, \tau_{10})$ and unstable when $\tau_1 \geq \tau_{10}$.

For the case of $\tau_1 = 0$ and $\tau_2 > 0$, the characteristic equation becomes

$$\Delta(\lambda) = \lambda^2 + (A + d_i)\lambda + (d_i A + DB) + DCe^{-\lambda\tau_2} = 0. \tag{4.7}$$

In Lemma 4.1, $2c - a^2 = 2DB - A^2 - d_i^2$. Thus if $d_i^2 > 2DB - A^2$ and $d_i A > D(C - B)$, the trivial solution of (4.1) is stable for all $\tau_2 > 0$. If $d_i A < D(C - B)$, then the stability of the trivial solution of (4.1) switches from stable to unstable when τ_2 increases through a critical value $\tau_{20} > 0$ and remains unstable for $\tau_2 > \tau_{20}$. If $d_i A > D(C - B)$ and $2DB - A^2 - d_i^2 > 2\sqrt{(d_i A + DB)^2 - D^2C^2}$, then the trivial solution of the linearized system (4.1) has at most a finite number of stability switches and eventually is unstable.

Define

$$H_1(d_i, G_{in}) = D(B + C) - d_i A. \tag{4.8}$$

We summarize the above analysis in the following theorem for model (2.1).

THEOREM 4.2. *Consider model* (2.1).

(a) *If* $\tau_1 = 0$ *and* $\tau_2 = 0$, *then* (G^*, I^*) *is stable.*

(b) *If* $\tau_1 > 0$ *and* $\tau_2 = 0$, *and*

(b.1) *if* $H_1(d_i, G_{in}) < 0$, *then* (G^*, I^*) *is stable for* $\tau_1 > 0$;

(b.2) *if* $H_1(d_i, G_{in}) > 0$, *then* $\exists \tau_{10} > 0$ *such that* (G^*, I^*) *is stable when* $\tau_1 \in (0, \tau_{10})$ *and unstable when* $\tau_1 \geq \tau_{10}$.

(c) *When* $\tau_1 = 0$ *and* $\tau_2 > 0$,

(c.1) *if* $D(C - B) - d_i A < 0$ *and* $d_i^2 > 2DB - A^2$, *then* (G^*, I^*) *is stable;*

(c.2) *if* $D(C - B) - d_i A > 0$, *then* $\exists \tau_{20} > 0$ *such that* (G^*, I^*) *is stable when* $\tau_2 \in (0, \tau_{20})$ *and unstable when* $\tau_1 \geq \tau_{20}$;

(c.3) *if* $D(C - B) - d_i A < 0$ *and* $2DB - A^2 - d_i^2 > 2\sqrt{(d_i A + DB)^2 - D^2C^2}$, *then there are at most a finite number of stability switches and eventually* (G^*, I^*) *is unstable,*

where A, B, C, *and* D *are given in* (4.2).

With the specific functions (6.1)–(6.5) in section 6, Figure 5.1 (right) demonstrates the curve $H_1(d_i, G_{in}) = 0$ in the (G_{in}, d_i)-plane. The curves in Figure 5.1 (right) are

independent of delay τ_1 and τ_2. The steady state is stable when $(G_{in}, d_i) \in R_s$, that is, d_i is small. Our computations show that conditions (b.1) and (c.3) in Theorem 4.2 do not hold. Condition (c.1) holds for some values (G_{in}, d_i), and thus the sustained oscillations would not occur.

When condition (b.2) ($\tau_2 = 0$) or (c.2) ($\tau_1 = 0$) holds, the sustained oscillation takes place if $\tau_1 > \tau_{10}$ or $\tau_2 > \tau_{20}$. Based on the arguments (3.12)–(3.17) from [15, pp. 74–76], we have

$$\tau_{10} = \theta_1/\omega_{1+},$$

where ω_{1+} is the root of (4.6) given by

$$\omega_{1+}^2 = \frac{1}{2}\Big\{ -(A^2 + d_i^2) + \Big[(A^2 - d_i^2)^2 + 4D^2(B + C)^2\Big]^{-\frac{1}{2}}\Big\},$$

and $0 \le \theta_1 < 2\pi$, satisfying

$$\begin{cases} \cos\theta_1 = (\omega_{1+}^2 - d_i A)/(DB + DC), \\ \sin\theta_1 = \omega_{1+}(A + d_i)/(DB + DC). \end{cases}$$

Similarly, we have

$$\tau_{20} = \theta_2/\omega_{2+},$$

where ω_{2+} is the root of (4.7) given by

$$\omega_{2+}^2 = \frac{1}{2}\Big\{2DB - (A^2 + di^2) + \Big[(A^2 - d_i^2)^2 - 4DB(A + d_i)^2 + 4D^2C^2\Big]^{-\frac{1}{2}}\Big\},$$

and $0 \le \theta_1 < 2\pi$, satisfying

$$\begin{cases} \cos\theta_2 = (\omega_{2+}^2 - d_i A - DB)/(DC), \\ \sin\theta_2 = \omega_{2+}(A + d_i)/(DC). \end{cases}$$

When condition (b.2) ($\tau_2 = 0$) holds, our computations show that no sustained oscillation occurs when $\tau_1 < 9$. Similarly, when (c.2) ($\tau_1 = 0$) holds, $\tau_{20} > 12$ for $G_{in} < 0.15$ or $G_{in} > 0.85$, and $d_i = 0.06$. Specifically, if $G_{in} = 1.35, d_i = 0.06$, then the Hopf bifurcation point $\tau_{20} > 40$. These observations, with Theorem 4.2 (a), suggest that both delay τ_1 and τ_2 are critical for sustained oscillations in physiologically meaningful ranges. In addition, notice that condition (b.2) automatically holds if (c.2) holds. This seems to suggest that the role of delay τ_1 is more critical than the role of delay τ_2 to ensure the sustained oscillations of the glucose-insulin regulatory system.

5. Local analysis: Case $\tau_1\tau_2 > 0$. Now assume both $\tau_1 > 0$ and $\tau_2 > 0$. Let $\lambda = \omega i$, $\omega > 0$, be such an eigenvalue in (4.3); then we have

$$\begin{aligned}\Delta(\omega i) = {} & [-\omega^2 + d_i A + DB\cos\omega\tau_1 + DC\cos\omega(\tau_1 + \tau_2)] \\ & + i[(A + d_i)\omega - DB\sin\omega\tau_1 - DC\sin\omega(\tau_1 + \tau_2)] = 0.\end{aligned}$$

That is,

$$\begin{cases} -\omega^2 + d_i A + DB\cos\omega\tau_1 + DC\cos\omega(\tau_1 + \tau_2) = 0, \\ (A + d_i)\omega - DB\sin\omega\tau_1 - DC\sin\omega(\tau_1 + \tau_2) = 0. \end{cases} \tag{5.1}$$

This leads to

$$\omega^4 + (A^2 + d_i^2)\omega^2 + d_i^2 A^2 = D^2(B^2 + C^2 + 2BC\cos\omega\tau_2). \tag{5.2}$$

5.1. Stability of the steady state. We shall consider the stability of the steady state first. From (5.2),

$$\omega^4 + (A^2 + d_i^2)\omega^2 + d_i^2 A^2 \le D^2(B^2 + C^2 + 2BC) = D^2(B + C)^2.$$

It is impossible if $d_i A \ge D(B + C)$. So, by definition of $H_1(G_{in}, d_i)$ in (4.8), we have the following proposition.

PROPOSITION 5.1. *In the linearized system* (4.1)*, when* $\tau_1 > 0$ *and* $\tau_2 > 0$*, if* $H_1(G_{in}, d_i) \le 0$*, then the steady state of the linearized system* (4.1) *is stable.*

Therefore we have the following theorem.

THEOREM 5.2. *In model* (2.1)*, if* $\tau_1 > 0$*,* $\tau_2 > 0$ *and*

$$H_1(d_i, G_{in}) = D(B + C) - d_i A \le 0, \tag{5.3}$$

then the steady state (G^*, I^*) *of system* (2.1) *is stable.*

Remark. When $\tau_1 > 0$, the same condition $H_1(d_i, G_{in}) = D(B + C) - d_i A < 0$ ensures the steady state of system (2.1) to be stable regardless of whether $\tau_2 = 0$ or $\tau_2 > 0$.

5.2. Instability of the steady state. We now study the instability of the steady state (G^*, I^*). We will apply *Rouchè's theorem* [7, pp. 125–126] to identify the case that the characteristic equation (4.3) has roots with positive real part.

ROUCHÈ'S THEOREM. *Given two functions* $f(z)$ *and* $g(z)$ *analytic in a simple connected region* $\mathcal{A} \subset \mathbf{C}$ *with boundary* γ*, a simple loop homotopic to a point in* $\mathcal{A}$*, if* $|f(z)| > |g(z)|$ *on* γ*, then* $f(z)$ *and* $f(z) + g(z)$ *have the same number of zeros in* $\mathcal{A}$*.*

Let

$$S_1 = \left\{ \frac{2m}{2n-1} : m, n \in \mathbf{Z}^+, m, n \ge 1 \right\} \text{ and } S_2 = \left\{ \frac{2m-1}{2n} : m, n \in \mathbf{Z}^+, m, n \ge 1 \right\}.$$

Clearly $\mathbf{Q}^+ = S_1 \cup S_2$ and $S_1 \cap S_2 = \emptyset$. Furthermore, S_1 and S_2 are dense in $\mathbf{Q}^+$, and thus in $\mathbf{R}^+$.

In fact, given $r \in \mathbf{Q}^+ \setminus S_1, \exists p, q \in \mathbf{Z}^+$ such that $r = \frac{2p-1}{2q}$. Thus

$$r_k = \frac{2p - 1 - \frac{2}{2k}}{2q - \frac{1}{2k}} = \frac{(4kp - 2k - 2)/2k}{(4kq - 1)/2k} = \frac{2(2kp - 2k - 1)}{2(2kq) - 1} \in S_1 \quad \forall k = 1, 2, 3, \ldots$$

and $\lim_{k \to \infty} r_k = (2p - 1)/2q = r$. That is, $\overline{S}_1 \supseteq \mathbf{Q}^+$. Similarly, $\overline{S}_2 \supseteq \mathbf{Q}^+$.

PROPOSITION 5.3. *For characteristic equation*

$$\lambda^k + \sum_{j=1}^{k-1} a_j \lambda^j + b + ce^{-\lambda\sigma_1} + de^{-\lambda\sigma_2} = 0, \quad k \ge 2,\ \sigma_1, \sigma_2 > 0, \tag{5.4}$$

where $b, c, d > 0, a_j \in \mathbf{R}, j = 1, 2, 3, \ldots, k$*, if* $b < d - c$ *or* $b < c - d$*, then* $\exists \sigma_{10} > 0$ *and* $\sigma_{20} > 0$ *such that the characteristic equation* (5.4) *has at least one root with positive real part for* $\sigma_1 > \sigma_{10}$ *and* $\sigma_2 > \sigma_{20}$ *provided* $\sigma_1/\sigma_2 \in S_1$ *or* $\sigma_1/\sigma_2 \in S_2$*.*

We need the following lemma to prove Proposition 5.3.

LEMMA 5.4. *For the equation*

$$\epsilon^k z^k + \sum_{j=1}^{k-1} a_j \epsilon^j z^j + b + ce^{-p_1 z} + de^{-p_2 z} = 0, \quad k \ge 2,\ p_1, p_2 > 0,\ z \in \mathbf{C}, \tag{5.5}$$

where $b, c, d > 0, a_j \in \mathbf{R}, j = 1, 2, 3, \ldots, k - 1$*, assume*

(i) $b < d - c$ *and* $p_1/p_2 \in S_1$, *or*
(ii) $b < c - d$ *and* $p_1/p_2 \in S_2$.

Then, $\exists \epsilon_0 > 0$ *such that for all* $\epsilon, 0 < \epsilon < \epsilon_0$, *equation* (5.5) *has at least one root with positive real part.*

The proof of Lemma 5.4 is given in Appendix C. Now we prove Proposition 5.3.

Proof. Assume $b < d - c$ and $\sigma_1/\sigma_2 \in S_1$ (or $b < c - d$ and $\sigma_1/\sigma_2 \in S_2$). In Lemma 5.4, choose p_{10} and p_{20} such that $p_{10}/p_{20} \in S_1$ (or $p_{10}/p_{20} \in S_2$). Suppose ϵ_0 is given by inequality (C.2) in the proof of Lemma 5.4. Let $\sigma_{10} = p_{10}/\epsilon_0$ and $\sigma_{20} = p_{20}/\epsilon_0$. Then given $\sigma_1 > \sigma_{10}$, $\sigma_2 > \sigma_{20}$, and $\sigma_1/\sigma_2 \in S_1$ (or $\sigma_1/\sigma_2 \in S_2$), $\exists \epsilon$, $0 < \epsilon < \epsilon_0$, such that

$$\sigma_1 = p_1/\epsilon > \sigma_{10} \quad \text{and} \quad \sigma_2 = p_2/\epsilon > \sigma_{20}.$$

Let $\lambda = \epsilon z$. Then (5.4) becomes (5.5) in Lemma 5.4 and the conclusion follows. ∎

Remark. In Lemma 5.4, given p_1 and p_2, $p_1/p_2 \in S_1$ in case (i) or $p_1/p_2 \in S_2$ in case (ii), if we carefully choose ϵ_0 in the proof of Lemma 5.4, an estimate of unstable region of σ_1 and σ_2 can be given. For the special case $k = 2$, r_0 and ϵ_0 can be chosen as

$$r_0 = \sqrt{K^2 x_0^2 + q^2 \pi^2} \quad \text{and} \quad \epsilon_0 = \left(\sqrt{a_1^2 + 4\eta_0'} - a_1 \right) / 2r_0.$$

Let $k = 2$ and apply Proposition 5.3 to the linearized system (4.1). We have the following.

PROPOSITION 5.5. *If* $d_i A < D|C - B|$, *then there exist* $\tau_{10} > 0$ *and* $\tau_{20} > 0$ *such that the characteristic equation of system* (4.1) *has at least one root with positive real part if*

(i) $d_i A < D(C - B)$, $\tau_1 > \tau_{10}$, $\tau_1 + \tau_2 > \tau_{20}$, *and* $\tau_1/(\tau_1 + \tau_2) \in S_1$, *or*
(ii) $d_i A < D(B - C)$, $\tau_1 > \tau_{10}$, $\tau_1 + \tau_2 > \tau_{20}$, *and* $\tau_1/(\tau_1 + \tau_2) \in S_2$.

Proof. This is straightforward if in Proposition 5.3 we choose $k = 2, a_1 = A + d_i, b = d_i A, c = DB, d = DC, \sigma_1 = \tau_1$, and $\sigma_2 = \tau_1 + \tau_2$. ∎

Therefore, we have the following theorem.

THEOREM 5.6. *In model* (2.1), *let*

$$H_2(d_i, G_{in}) := D|C - B| - d_i A. \tag{5.6}$$

If $\tau_1 > 0$, $\tau_2 > 0$, *and* $H_2(d_i, G_{in}) > 0$, *then there exist* $\tau_{10} > 0$ *and* $\tau_{20} > 0$ *such that the steady state* (G^*, I^*) *is unstable when* $\tau_1 > \tau_{10}$, $\tau_1 + \tau_2 > \tau_{20}$ *and*

(i) $\tau_1/(\tau_1 + \tau_2) \in S_1$ *and* $d_i A < D(C - B)$, *or*
(ii) $\tau_1/(\tau_1 + \tau_2) \in S_2$ *and* $d_i A < D(B - C)$.

Remark. Using the function (6.1)–(6.5), if $G_{in} = 1.35$ and $d_i = 0.06$, then $H_2(d_i, G_{in}) > 0$ and $H_1(d_i, G_{in}) < 0$. According to Theorem 5.6, the steady state will lose its stability as the delays increase. Let $\tau_1 = 7$ and $\tau_2 = 30$. The simulation result is shown in Figure 5.1 (left). There exists a periodic solution bifurcating from the steady state. This periodic solution can be regarded as the sustained oscillation of the insulin and glucose concentration. The period of the periodic solution is approximately 149 minutes. In each cycle, the glucose concentration peaks about 18 minutes ahead of the insulin concentration peaks. The varying range of glucose concentration is within physiological meaningful scope [70, 109].

Remark. It is clear that $H_2(d_i, G_{in}) \leq H_1(d_i, G_{in})$. When $H_1(d_i, G_{in}) \leq 0$, the steady state of model (2.1) is stable due to Theorem 5.2. On the other hand, when $H_2(d_i, G_{in}) > 0$, according to Theorem 5.6, the steady state is unstable for appropriate delay values given in Theorem 5.6. With specific function (6.1)–(6.5), Figure 5.1

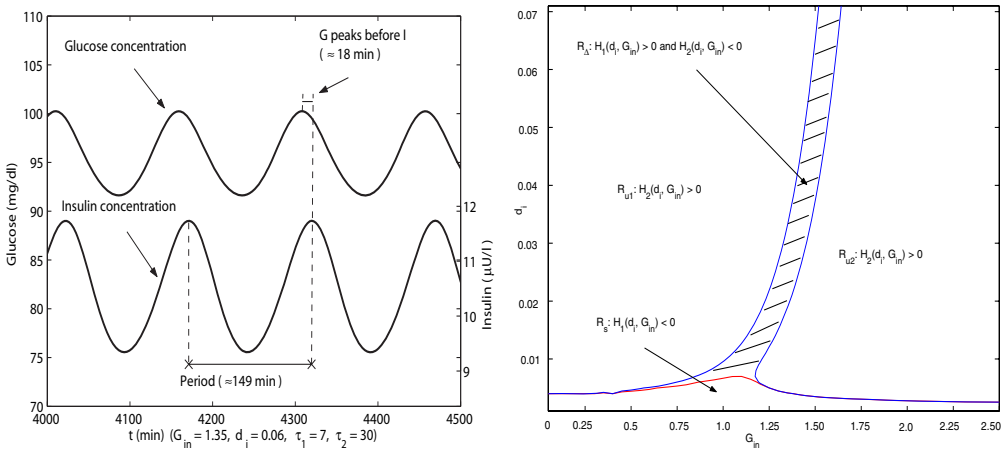

FIG. 5.1. *Left: The periodic solution of model* (2.1) *when* $G_{in} = 1.35, d_i = 0.06, \tau_1 = 7$, *and* $\tau_2 = 30$. *The period is approximately* 149 *minutes and the glucose concentration peaks about* 18 *minutes before the insulin concentration peaks. Right: Regions in the* (G_{in}, d_i)*-plane divided by curves* $H_1(d_i, G_{in}) = 0$ *and* $H_2(d_i, G_{in}) = 0$. *When* $d_i \in R_s$, *the steady state of model* (2.1) *is stable; when* $d_i \in R_{u1} \cup R_{u2}$, *the steady state is unstable.*

(right) shows the delay-independent stable region R_s and delay-dependent unstable region R_{u1} and R_{u2} in the (d_i, G_{in})-plane determined by Theorems 5.2 and 5.6, respectively. The shaded region R_Δ is where $H_1(d_i, G_{in}) > 0$ and $H_2(d_i, G_{in}) \le 0$. The local stability problem of (G^*, I^*) is open when $(d_i, G_{in}) \in R_\Delta$. Our intensive numerical simulations reveal that R_Δ is also a delay-dependent unstable region, that is, with appropriate delay parameters, the steady state is unstable. For example, when $d_i = 0.051$ and $G_{in} = 1.50$, $H_1(0.051, 1.50) = 0.0019$ and $H_2(0.051, 1.50) = -0.00042570$. The steady state is unstable when $\tau_1 \ge 15$ and $\tau_2 \ge 32$. When $d_i = 0.0320$ and $G_{in} = 1.40$, $H_1(0.0320, 1.40) = 0.00099732$ and $H_2(0.051, 1.50) = -0.00026753$. The steady state is unstable when $\tau_1 \ge 18$ and $\tau_2 \ge 36$. Periodic solutions are also observed in these cases.

5.3. Hopf bifurcation. We show below that a local Hopf bifurcation takes place when delay parameter τ_1 or τ_2 varies. It has been shown that when $\tau_1 = 0$ ($\tau_2 = 0$), the steady state of system (2.1) is stable provided that τ_2 (τ_1) is small enough (see Theorem 4.2). To show this system undergoes a unique local Hopf bifurcation at some $\bar\tau_1 > 0$ ($\bar\tau_2 > 0$) as τ_1 (τ_2) increases from 0 and within a physiologically meaningful range, we prove that the characteristic equation (4.3) has a pair of pure conjugate imaginary simple roots at $\tau_1 = \bar\tau_1 > 0$ ($\tau_2 = \bar\tau_2 > 0$) and all such roots cross the imaginary axis from left to right. This indicates that a periodic solution is generated from this stability switch. Our numerical simulations show that the bifurcation is indeed supercritical.

Consider equation

$$\omega^4 + (A^2 + d_i^2)\omega^2 + d_i^2 A^2 = D^2(B^2 + C^2 + 2BC). \tag{5.7}$$

Clearly, (5.7) has a unique positive root $\hat\omega$ when $d_i A < D(B + C)$, where

$$\hat\omega^2 = \frac{1}{2}\Big[-(A^2 + d_i^2) + \sqrt{(A^2 + d_i^2) - 4(d_i^2 A^2 - D^2(B + C)^2)}\Big]. \tag{5.8}$$

Let $g(\omega) = \omega^4 + (A^2 + d_i^2)\omega^2 + d_i^2 A^2 - D^2(B^2 + C^2 + 2BC\cos\omega\tau_2)$. Then (5.2) can be written as $g(\omega) = 0$. If $\omega < \hat{\omega} < \frac{\pi}{2\tau_2}$, then $g(0) = d_i^2 A^2 - D^2(B + C)^2 < 0$ and $g(\hat{\omega}) = 2D^2BC(1 - \cos\omega\tau_2) \geq 0$. Further, $g'(\omega) = 4\omega^3 + 2(A^2 + d_i^2)\omega + 2D^2BC\sin\omega\tau_2 > 0$ for $0 < \omega < \hat{\omega} \leq \frac{\pi}{2\tau_2}$. Therefore we have the following lemma.

LEMMA 5.7. *If $d_iA < D(B + C)$ and $\tau_2 < \frac{\pi}{2\hat{\omega}}$, then (5.2) has a unique root ω_0 with $0 < \omega_0 \leq \hat{\omega}$.*

The following propositions establish sufficient conditions for the existence of Hopf bifurcation when τ_1 or τ_2 varies. We leave the proofs in Appendices D and E.

PROPOSITION 5.8. *If $H_1(G_{in}, d_i) = D(B + C) - d_iA > 0$ and $\tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$, then (4.1) undergoes a Hopf bifurcation when τ_1 increases from 0 to $\frac{\pi}{2\hat{\omega}} - \tau_2$ for given τ_2.*

PROPOSITION 5.9. *If $H_1(G_{in}, d_i) = D(B + C) - d_iA > 0, \tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$, and $\tau_1 < \frac{A+d_i}{DB}$, then (4.1) undergoes a Hopf bifurcation when τ_2 increases from 0 to $\frac{\pi}{2\hat{\omega}} - \tau_1$ for given τ_1.*

Remark. Using the specific functions (6.1)–(6.5) given in section 6, for $(G_{in}, d_i) \in [0, 150] \times [0.001, 0.07]$, approximately, $47.2665 < \frac{\pi}{2\hat{\omega}} < 214.3462$ and $19.6857 < \frac{A+d_i}{DB} < 6361.7$. Thus τ_1 varies within its physiological range under the condition $\tau_1 < \frac{A+d_i}{DB}$. Under the condition $\tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$, both τ_1 and τ_2 are within their physiological meaningful ranges in most situations for $(G_{in}, d_i) \in [0, 150] \times [0.001, 0.07]$. When $\tau_1 + \tau_2$ could be larger than 47.2665, our simulations show that the Hopf bifurcation does exist and it is supercritical.

We summarize the above results in the following theorem.

THEOREM 5.10. *For model (2.1), assume $H_1(G_{in}, d_i) = D(B + C) - d_iA > 0$ and $\tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$.*

(a) *Then there exists a $\bar{\tau}_1 > 0$ such that the steady state (G^*, I^*) is stable when $\tau_1 < \bar{\tau}_1$, and unstable when $\tau_1 \geq \bar{\tau}_1$. The system undergoes a Hopf bifurcation at $\bar{\tau}_1$ and generates a periodic solution.*

(b) *Further, assume $\tau_1 < \frac{A+d_i}{DB}$. Then there exists a $\bar{\tau}_2 > 0$ such that the steady state (G^*, I^*) is stable when $\tau_2 < \bar{\tau}_2$, and unstable when $\tau_2 \geq \bar{\tau}_2$. The system undergoes a Hopf bifurcation at $\bar{\tau}_2$ and generates a periodic solution.*

Remark. With the specific functions (6.1)–(6.5) in the next section, our intensive numerical simulations show that the Hopf bifurcations determined by Theorem 5.10 are supercritical. Moreover, with $G_{in} = 1.35$ and $d_i = 0.06$, $\bar{\tau}_1$ and $\bar{\tau}_2$ approximately satisfy $33.9\bar{\tau}_1 + 17.3\bar{\tau}_2 \approx 36.9$ for $0 \leq \bar{\tau}_1 \leq 20$ and $0 \leq \bar{\tau}_2 \leq 60$.

6. Numerical simulations. In this section, we present numerical analysis on model (2.1) using DDE23 [22] in MATLAB 6.5. We use the same functions $f_i, i = 1, 2, 3, 4, 5$, as [2], [17], [25], and [26] given in (6.1)–(6.5). The parameters, listed in Table 6.1, were generated from experiments [25], [26].

$$f_1(G) = R_m/(1 + \exp((C_1 - G/V_g)/a_1)), \tag{6.1}$$

$$f_2(G) = U_b(1 - \exp(-G/(C_2V_g))), \tag{6.2}$$

$$f_3(G) = G/(C_3V_g), \tag{6.3}$$

$$f_4(I) = U_0 + (U_m - U_0)/(1 + \exp(-\beta\ln(I/C_4(1/V_i + 1/Et_i)))), \tag{6.4}$$

$$f_5(I) = R_g/(1 + \exp(\alpha(I/V_p - C_5))). \tag{6.5}$$

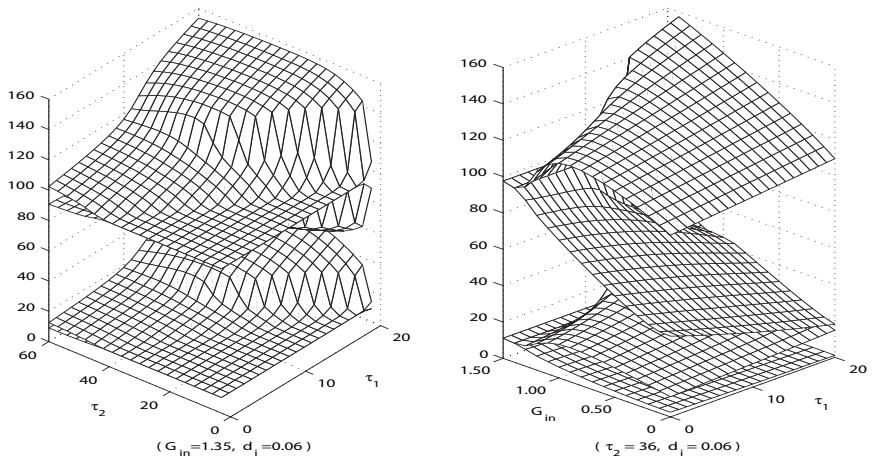

FIG. 6.1. *Limiting values or amplitudes of glucose (top) and insulin (bottom) concentrations when τ_1 and τ_2 vary (left) or G_{in} and τ_1 vary (right).*

The simulations in [17] focused on the bifurcation when a single parameter varies while other parameters are fixed. The detected bifurcation points of the varying parameters can determine when the sustained oscillations occur. In this section, we carry out a sequence of two-parameter bifurcation analyses and depict their quantitative behaviors in three-dimensional meshes or two-dimensional curves formed by transversal points.

For a specific subject, the insulin response time delay, the delayed effect of hepatic glucose production, and the insulin degradation rate are intrinsic. But the exogenous glucose infusion rate is controllable by diet, fasting, and so on. So, in addition to the simulation on the two-delay parameters, we numerically analyze the relationships of the glucose infusion rate G_{in} vs. the insulin response time delay τ_1, the hepatic glucose production time delay τ_2, and the insulin degradation rate d_i, respectively. We end this section by showing the significant impact of the two delays on generating insulin ultradian oscillation.

6.1. Insulin response delay τ_1 vs. hepatic glucose production delay τ_2. We analyzed the relationship between the insulin response delay τ_1 and the hepatic glucose production delay τ_2 while $G_{in} = 1.35$ and $d_i = 0.06$ are fixed. Figure 6.1 (left) shows that a simple curve ($33.9\tau_1 + 17.3\tau_2 \approx 36.9$ for $0 \le \tau_1 \le 20$ and $0 \le \tau_2 \le 60$)

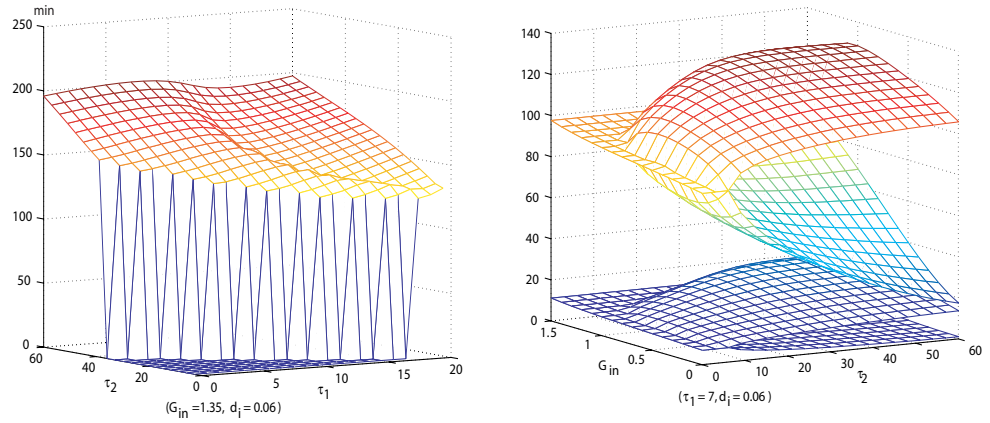

FIG. 6.2. *Left: Mesh of the periods of periodic solutions when* $(\tau_1, \tau_2) \in [0, 20] \times [0, 60]$*, where* $G_{in} = 1.35$ *and* $d_i = 0.06$ *are fixed. Right: Meshes of the amplitudes of glucose and insulin concentrations when* $(G_{in}, \tau_2) \in [0, 1.5] \times [0, 60]$*, where* $\tau_1 = 7$ *and* $d_i = 0.06$ *are fixed.*

divides $[0, 20] \times [0, 60]$ in the (τ_1, τ_2)-plane into two regions. The steady state is stable in one region and unstable in the other. The sustained oscillations occur in the unstable region which requires both $\tau_1 > 0$ and $\tau_2 > 0$ to be sufficiently large. The top and bottom meshes in Figure 6.1 (left) demonstrate the amplitudes of glucose and insulin concentrations, respectively. The periods of periodic solutions are shown in Figure 6.2 (left). According to Figure 6.1 (left) and Figure 6.2 (left), the amplitudes of glucose concentration are between 70 and 109 and the periods of periodic solutions are approximately within 90 and 150 when $\tau_1 \in (5, 15)$ and $\tau_2 \in (25, 50)$. There is a sudden jump of amplitudes of glucose and insulin concentrations when $\tau_1 > 10$ approximately. Also, in such cases, the periods of periodic solutions decrease.

6.2. Glucose infusion rate G_{in} vs. insulin response time delay τ_1. Taking both insulin response delay τ_1 and glucose infusion rate G_{in} as bifurcation parameters, we try to identify the stability regions when $(\tau_1, G_{in}) \in [0, 20] \times [0, 1.5]$. Let $d_i = 0.06$ and $\tau_2 = 36$ be fixed. The computation results are shown in Figure 6.1 (right). The bifurcation point value $\bar{\tau}_1 \approx 1.0429 G_{in} - 1.3740 > 0$ exists for $1.3175 \leq G_{in} \leq 1.50$. The meshes are the amplitudes of glucose (top) and insulin (bottom) concentrations when $(\tau_1, G_{in}) \in [0, 20] \times [0, 1.5]$. It can be seen that a simple curve $(\tau_1 \approx 1.0429 G_{in} - 1.3740 > 0$ for $1.3175 \leq G_{in} \leq 1.50)$ divides the rectangular $[0, 20] \times [0, 1.5]$ in the (τ_1, G_{in})-plane into two regions. The sustained oscillations of model (2.1) occur in the unstable region. The exogenous glucose infusion rate can be larger when τ_1 increases from [5, 15] for sustained regulatory oscillations to occur.

6.3. Glucose infusion rate G_{in} vs. hepatic glucose production delay τ_2. As shown in Figure 6.2 (right), our simulation results indicate that when $\tau_1 = 7$ and $d_i = 0.06$, the rectangular $[0, 60] \times [0, 1.50]$ in the (τ_2, G_{in})-plane is divided by a simple curve into two regions. The steady state of model (2.1) is unstable in the unstable region and the oscillations are sustained. The periods of periodic solutions are in a range of 80 and 195 minutes (not shown). The simple curve is determined by the Hopf bifurcation point values $\bar{\tau}_2(G_{in})$ as G_{in} varies from 0 to 150. The relationship between G_{in} and $\bar{\tau}_2$ is nonlinear. For example, $\bar{\tau}_2 \approx 6.1, 2.8, 6.1, 9, 12, 18, 33$ when

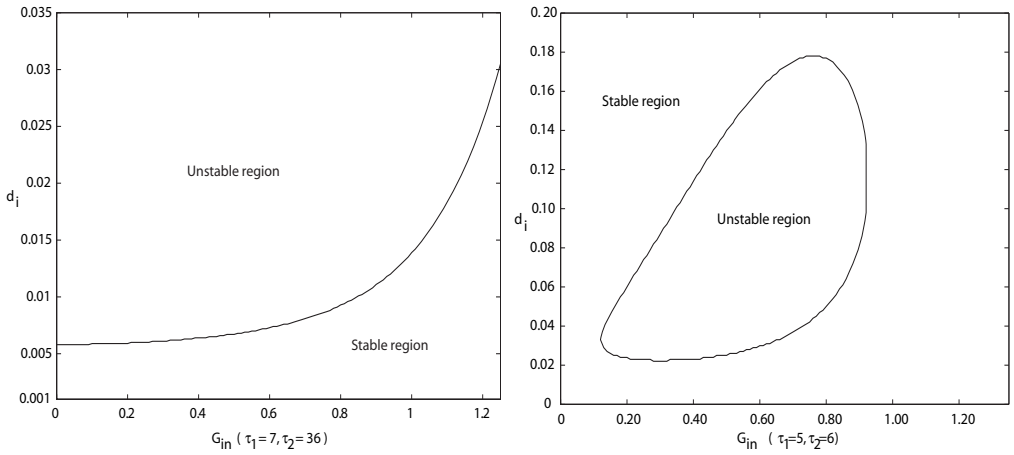

FIG. 6.3. *Left: Insulin degradation rate d_i vs. glucose infusion rate G_{in} while $\tau_1 = 7$ and $\tau_2 = 36$. The steady state of model (2.1) is stable in one region and unstable in the other. Right: Stable and unstable regions of the steady state when $\tau_1 = 5$ and $\tau_2 = 6$.*

$G_{in} = 0, 0.60, 0.80, 1.10, 1.20, 1.30, 1.40$, respectively. Similar to the case of G_{in} vs. τ_1, the exogenous glucose infusion rate can be larger when τ_2 increases from 10 to 60 minutes for sustained regulatory oscillations to occur. When $\tau_2 < 2$, the steady state is stable and no sustained oscillation will occur regardless of what value G_{in} assumes.

6.4. Glucose infusion rate G_{in} vs. insulin degradation rate d_i. Similarly, taking both glucose infusion rate G_{in} and insulin degradation rate d_i as bifurcation parameters while $\tau_1 = 7$ and $\tau_2 = 36$ are fixed, we identified the stability regions in $(G_{in}, d_i) \in [0, 1.35] \times [0.001, 0.20]$. Figure 6.3 shows that a simple curve divides the rectangular $(G_{in}, d_i) \in [0, 1.35] \times [0.001, 0.20]$ into two regions (the figure shows the part of $[0, 1.35] \times [0.001, 0.035]$ only). The steady state of model (2.1) is stable in one region and unstable in the other region. It is clear that larger insulin degradation rate d_i facilitates the oscillatory regulation. However, if $d_i = 1.75$ is large, then no self-sustained oscillation occurs. This suggests that d_i needs to be in moderate range for oscillations to be sustained. Let $\tau_1 = 5$ and $\tau_2 = 6$ be smaller. Figure 6.3 (right) shows that the sustained oscillation occurs in a region surrounded by a closed curve, which requires both d_i and G_{in} to be in moderate ranges. Our simulation shows that the amplitudes of the sustained oscillations are very small ($G \in (80, 100)$ and $I \in (10, 12)$) with periods from 58 to 105 minutes. This shows that when the delays τ_1 and τ_2 are smaller, both the insulin clearance rate and the glucose infusion rate have to be in a moderate range to ensure the oscillatory behavior of insulin secretion.

7. Discussions. In this paper, we studied the glucose-insulin regulatory system model (2.1) analytically and numerically. Compared with the observations obtained in [2], [17], [25], and [26], our work confirms most of the known observations and yields additional insightful information. Using the notation in [17], we refer to the observations in [25] and [26] as [STx] ([ST1]–[ST4]), the observations in [2] as [BGx] ([BG1] and [BG2]), and the observations in [17] as [Ax] ([A1]–[A9]). We conclude this paper with a list of remarks and new observations (denoted by [Bx]).

[B1] Theorem 4.2 reveals that the delays in the glucose-insulin regulatory system are critical for ensuring the sustained oscillations of regulation and

insulin secretions. Particularly, the role of delay of insulin secretion and the newly synthesized insulin becoming remote insulin is more critical than the role of delay of hepatic glucose production.

[B2] If the insulin secretion responds to elevated glucose instantaneously, that is, $\tau_1 = 0$, Theorem 4.2 (c.1) and (c.2) reveal that the insulin degradation rate for sustaining oscillation is likely to be lower than that in the case of $\tau_1 > 0$ and $\tau_2 = 0$ (Theorem 4.2 (b.1) and (b.2)). This suggests that the oscillatory behavior of the glucose-insulin regulation requires the insulin removal rate to be large enough ($H_2(d_i, G_{in}) > 0$) and the delayed effect of hepatic glucose production to be long enough ($\tau_2 > \tau_{20}$).

[B1] and [B2] analytically confirm the numerical observation of [ST3]. It demonstrates that the effort of dividing insulin into two compartments in the model can be and shall be naturally and explicitly replaced by the delay parameter τ_1.

[B3] According to Theorem 4.2 (b.1) for $\tau_1 = 0$, and Theorem 5.2 for $\tau_2 > 0$, the insulin degradation rate d_i has to be "large" enough for sustained oscillatory regulation of the glucose-insulin metabolic system. Here the meaning of "large" refers to the numerical simulation demonstrated in Figure 5.1 (right) that $H_1(d_i, G_{in}) > 0$. This confirms the observation [BG1] in [2].

[B4] When $\tau_1\tau_2 > 0$, Theorem 5.6, Theorem 5.10, and simulations in Figure 5.1 (right) reveal the intrinsic relationship among d_i, G_{in}, τ_1, and τ_2 to secure the oscillatory behavior of the metabolic system. That is, for a subject, the oscillatory regulation occurs if one's insulin degradation rate and the glucose infusion rate satisfy $H_2(d_i, G_{in}) > 0$, and the time delays in the system are long enough ($\tau_1 > \tau_{10}$ and $\tau_1 + \tau_2 > \tau_{20}$). The numerical observations in Figure 6.3 (left) indicate that if the insulin degradation rate is sufficiently small ($H_1(d_i, G_{in}) < 0$), the oscillations cannot be sustained. Small d_i causes the insulin concentration level to remain high in plasma, which prohibits the glucose concentration level to rise. In such cases, the oscillatory regulation does not occur. This provides more insightful information than the general statements in [BG1] and [A7]. On the other hand, Figure 6.3 (right) indicates that both the glucose infusion rate and the insulin clearance rate are sensitive to the delays τ_1 and τ_2. Both rates are required to be in moderate ranges for sustained oscillations when the delayed effects are shorter.

[B5] Figures 6.1 (right), 6.2 (right), and 6.3 (left) show that when the glucose infusion rate is high, the oscillation of insulin secretion is unlikely to persist. This is possibly due to the fact that the β-cells cannot produce and secrete enough insulin to uptake the large amount of glucose infused into plasma. Thus the glucose concentration remains at a high level. The result is that the ultradian oscillations of insulin secretion and the oscillatory regulation of the glucose-insulin metabolic system cannot be sustained. This may help to explain the observed steady state behavior in models of the intravenous glucose tolerance test (IVGTT) where initial glucose infusion values are high [3], [9], [16], [19].

[B6] In the IVGTT, the initial glucose infusion is large. Compared to such large exogenous glucose infusion, the hepatic glucose production is negligible. For this reason, IVGTT models are justified not to include the hepatic glucose production term explicitly (set $f_5 \equiv 0$ thus $\tau_2 = 0$) [3], [9], [16], and [19]. The main goal of these models is to accurately monitor the dynamical behavior of the glucose level, which must return to its basal level after the biphasic insulin secretions have been triggered. Thus the insulin sensitivity can be

tested. The simulations (Figures 1 and 2) in [16] reveal that the delay τ_1 has to be extremely large (> 400 minutes) to produce any sustainable oscillations. Such a huge delay τ_1 clearly falls out of the normal physiological range.

Since we normally eat three meals per day, it is more plausible to consider periodic exogenous glucose infusion. That is, the constant glucose infusion rate G_{in} in model (2.1) shall be replaced by a periodic function $G_{in}(t)$ with a positive period ω between 180 and 300 minutes. Our simulation results reveal that there exists a harmonic solution in such a system. For more details, interested readers can refer to [24].

Appendix A. Proof of Proposition 3.2. For the first part of (i), let

$$H(x) = G_{in} - f_2(x) - f_3(x)f_4(d_i^{-1}f_1(x)) + f_5(d_i^{-1}f_1(x)) = 0, \quad x \geq 0. \tag{A.1}$$

We shall show that (A.1) has a unique root in $[0, \infty)$. Observing that $f_1'(x) > 0$, $f_2'(x) > 0$, $f_4'(x) > 0$, $f_3'(x) > 0$, and $f_5'(x) < 0$, we have $H'(x) < 0$. Notice that $H(0) = G_{in} - f_2(0) - f_3(0)f_4(d_i^{-1}f_1(0)) + f_5(d_i^{-1}f_1(0)) = G_{in} + f_5(d_i^{-1}f_1(0)) > 0$, and

$$\begin{aligned}
\lim_{x\to\infty} H(x) &= G_{in} - \lim_{x\to\infty} f_2(x) - \lim_{x\to\infty} f_3(x)f_4(d_i^{-1} \lim_{x\to\infty} f_1(x)) + f_5(d_i^{-1} \lim_{x\to\infty} f_1(x)) \\
&= G_{in} - M_2 - f_4(d_i^{-1}M_1) \lim_{x\to\infty} f_3(x) + f_5(d_i^{-1}M_1) \\
&< G_{in} - M_2 - m_4 \lim_{x\to\infty} f_3(x) + M_5 < 0.
\end{aligned}$$

In addition, $f_1(x)$ is strictly monotone increasing, so the proof is complete. It is obvious that G^* is the root of (A.1) and $I^* = d_i^{-1}f_1(G^*)$.

For the second part of (i), observing that $|f_i'(x)|$, $i = 1, 2, 3, 4, 5$, are bounded, $f_i(x), i = 2, 3, 4$, and $f_j(x_t), j = 1, 5$, are *Lipschitzian* and completely continuous in $x \geq 0$ and $x_t \in \mathbf{C}([-\max\{\tau_1, \tau_2\}, 0])$, respectively. Then by Theorems 2.1, 2.2, and 2.4 on pp. 19 and 20 in [15], the solution of (2.1) with given initial condition exists and is unique for all $t \geq 0$. If there exists a $t_0 > 0$ such that $G(t_0) = 0$ and $G(t) > 0$ for $0 < t < t_0$, then $G'(t_0) \leq 0$. So

$$\begin{aligned}
0 \geq G'(t_0) &= G_{in} - f_2(G(t_0)) - f_3(G(t_0))f_4(I(t_0)) + f_5(I(t_0 - \tau_2)) \\
&= G_{in} - f_2(0) - f_3(0)f_4(I(t_0)) + f_5(I(t_0 - \tau_2)) \\
&= G_{in} + f_5(I(t - \tau_2)) > 0.
\end{aligned}$$

This contradiction implies that $G(t) > 0$ for all $t > 0$. If $\exists t_0' > 0$ such that $I(t_0') = 0$ and $I(t) > 0$ for all $0 < t < t_0'$, then $I(t_0^{'}) < 0$. Therefore, $0 > I(t_0') = f_1(G(t_0^{'}) - d_i I(t_0' - \tau_1) \geq f_1(G(t_0')) > 0$. This implies that $I(t) > 0$ for all $t > 0$.

Now we show that any given solution $(G(t), I(t))$ of model (2.1) is bounded for $t > 0$. In fact, if $\limsup_{t\to\infty} G(t) = \infty$, there exists a sequence $\{t_n\}_{n=1}^{\infty} \uparrow \infty$ such that $\lim_{n\to\infty} G(t_n) = \infty$ and $G'(t_n) \geq 0$. Thus $0 < G'(t_n) = G_{in} - f_2(G(t_n)) - f_3(G(t_n))f_4(I(t_n)) + f_5(I(t_n - \tau_2)) \leq G_{in} - f_2(G(t_n)) - f_3(G(t_n))m_4 + M_5$, and therefore

$$\begin{aligned}
0 \leq \lim_{n\to\infty} G'(t_n) &\leq G_{in} - \lim_{n\to\infty} f_2(G(t_n)) - m_4 \lim_{n\to\infty} f_3(G(t_n)) + M_5 \\
&\leq G_{in} - M_2 - m_4 \lim_{x\to\infty} f_3(x) + M_5 < 0.
\end{aligned}$$

This contradiction shows that there is an $M_G > 0$ such that $G(t) < M_G$ for all $t > 0$. From the second equation in (2.1), since $|f_1(x)| \leq M_1$, for all $\epsilon > 0$, $I'(t) \leq f_1(M_G +$

$\epsilon) - d_i I(t)$ for sufficiently large $t > 0$. Then we have $\limsup_{t\to\infty} I(t) \le d_i^{-1} f_1(M_G+\epsilon)$. Since $\epsilon > 0$ is arbitrary, $\limsup_{t\to\infty} I(t) \le d_i^{-1} f_1(M_G) := M_I$.

If (ii) is not true, assume $\limsup_{t\to\infty} G(t) = M_G < \infty$. Then $\exists\{t_n\}_{n=1}^{\infty} \uparrow \infty$ such that $G'(t_n) = 0, n = 1, 2, 3, \ldots$, and $\lim_{n\to\infty} G(t_n) = M_G$ according to Lemma 3.1. Thus $G'(t_n) = G_{in} - f_2(G(t_n)) - f_3(G(t_n))f_4(I(t_n)) + f_5(I(t_n - \tau_2)) \ge G_{in} - f_2(G(t_n)) - f_3(G(t_n))m_4$. Let $n \to \infty$; then $0 \ge G_{in} - f_2(M_G) - f_3(M_G)m_4$, that is, $f_3(M_G) \ge (G_{in} - f_2(M_G))/m_4$. On the other hand, $f_3(M_G) \le \lim_{x\to\infty} f_3(x) < (G_{in} - M_2)/m_4 \le (G_{in} - f_2(M_G))/m_4$.

Appendix B. Proof of Lemma 3.3. First we show that (3.2) holds. Due to Lemma 3.1 and part (i) of Proposition 3.2, there exists a sequence $\{t_k\}_{k=1}^{\infty} \uparrow \infty$, such that $I'(t_k) = 0, \lim_{k\to\infty} I(t_k) = \overline{I}$. Thus, $0 = I'(t_k) = f_1(G(t_k - \tau_1)) - d_i I(t_k)$ for all $k = 1, 2, 3, \ldots$. Therefore, $f_1(\overline{G}) - d_i I(t_k) \ge f_1(\overline{G}(t_k - \tau_1)) - d_i I(t_k)$ for $k = 1, 2, 3, \ldots$. Thus, $f_1(\overline{G}) - d_i \overline{I} \ge 0$. On the other hand, there exists a sequence $\{s_k\}_{k=1}^{\infty} \uparrow \infty$ such that $\lim_{k\to\infty} I(s_k) = \underline{I}$ and $I'(s_k) = 0$ for all $k > 0$. Hence, $f_1(\underline{G}) - d_i I(s_k) \le f_1(\underline{G}(s_k - \tau_1)) - d_i I(s_k)$ for $k = 1, 2, 3, \ldots$. Thus, $f_1(\underline{G}) - d_i \underline{I} \le 0$.

Now we show that (3.3) holds. Again, due to Proposition 3.2 and Lemma 3.1, there exists a sequence $\{t_k'\}_{k=1}^{\infty} \uparrow \infty$ as $k \to \infty$ such that $\lim_{k\to\infty} G(t_k') = \overline{G}$ and $0 = G'(t_k') = G_{in} - f_2(G(t_k')) - f_3(G(t_k'))f_4(I(t_k')) + f_5(I(t_k' - \tau_2))$, $k = 1, 2, 3, \ldots$. Notice that $f_5 \downarrow 0$ and f_4 is monotone increasing and bounded from above by M_4; thus $0 = G_{in} - f_2(G(t_k')) - f_3(G(t_k'))f_4(I(t_k')) + f_5(I(t_k' - \tau_2)) \le G_{in} - f_2(G(t_k')) - f_3(G(t_k'))f_4(\underline{I}) + f_5(\underline{I}), k = 1, 2, 3, \ldots$, and thus $G_{in} - f_2(\overline{G}) - f_3(\overline{G})f_4(\underline{I}) + f_5(\underline{I}) \ge 0$.

Similarly we can show that (3.4) is true. According to part (i) of Proposition 3.2 and Lemma 3.1, there exists a sequence $\{s_k'\}_{k=1}^{\infty} \uparrow \infty$ as $k \to \infty$ such that $\lim_{k\to\infty} G(s_k') = \overline{G}$ and $0 = G'(s_k') = G_{in} - f_2(G(s_k')) - f_3(G(s_k'))f_4(I(s_k')) + f_5(I(s_k' - \tau_2)), k = 1, 2, 3, \ldots$. Notice that $f_5 \downarrow 0$ and f_4 is monotone increasing and bounded from above by M_4; thus $0 = G_{in} - f_2(G(s_k')) - f_3(G(s_k'))f_4(I(s_k')) + f_5(I(s_k' - \tau_2)) \ge G_{in} - f_2(G(s_k')) - f_3(G(s_k'))f_4(\overline{I}) + f_5(\overline{I}), k = 1, 2, 3, \ldots$. This leads to $G_{in} - f_2(\underline{G}) - f_3(\underline{G})f_4(\overline{I}) + f_5(\overline{I}) \le 0$.

Appendix C. Proof of Lemma 5.4. Let $f(z) = b + ce^{-p_1 z} + de^{-p_2 z}$. We show that $f(z)$ has a zero with positive real part. Since $p_1/p_2 \in S_1$ in case (i) ($p_1/p_2 \in S_2$ in case (ii)), there exist integers $m, n \ge 1$ such that $\frac{p_1}{p_2} = \frac{2m}{2n-1}$ for case (i), or $\frac{p_1}{p_2} = \frac{2m-1}{2n}$ for case (ii). Let $z = x + q\pi i$, where $q = 2m/p_1 = (2n-1)/p_2$ for case (i) or $q = (2m-1)/p_1 = 2n/p_2$ for case (ii). Then

$$\begin{aligned} f(z) &= b + ce^{-p_1 x}e^{-p_1 q\pi i} + de^{-p_2 x}e^{-p_2 q\pi i} \\ &= b + ce^{-p_1 x}\cos 2m\pi + de^{-p_2 x}\cos(2n-1)\pi \\ &\qquad (= b + ce^{-p_1 x}\cos(2m-1)\pi + de^{-p_2 x}\cos 2n\pi \text{ for case (ii)}) \\ &= b + ce^{-p_1 x} - de^{-p_2 x} \qquad (= b - ce^{-p_1 x} + de^{-p_2 x} \text{ for case (ii)}) \\ &:= H(x). \end{aligned}$$

Notice that $H(0) = b + c - d < 0$ ($H(0) = b - c + d < 0$ for case (ii)) and $\lim_{x\to\infty} H(x) = b > 0$; therefore $H(x)$ has at least one zero $x_0 \in (0, \infty)$. So $f(z)$ has at least one zero $z_0 = x_0 + q\pi i$ with $x_0 > 0$.

We perturb $f(z)$ by $g_\epsilon(z)$ given by

$$g_\epsilon(z) = \epsilon^k z^k + \sum_{j=1}^{k-1} a_j \epsilon^j z^j, \quad \epsilon > 0, \tag{C.1}$$

with small $\epsilon > 0$ and show that $f(z) + g_\epsilon(z)$ has the same number of zeros as $f(z)$ if ϵ is small. To this end, we first construct a simple loop γ homotopic to a point and then show $|f(z)| > |g_\epsilon(z)|$ on γ. Let $z = x$, $x \in (-\infty, \infty)$; then $|f(z)| = b + ce^{-p_1 x} + de^{-p_2 x} > b$. Let $z = x + 2q\pi i$, $x \in (-\infty, \infty)$; then

$$\begin{aligned}|f(z)| &= |b + ce^{-p_1 x} e^{2qp_1\pi i} + de^{-p_2 x} e^{2qp_2\pi i}| \\ &= |b + ce^{-p_1 x} \cos 4m\pi + de^{-p_2 x} \cos 2(2n-1)\pi| \\ &\qquad (= |b + ce^{-p_1 x} \cos 2(2m-1)\pi + de^{-p_2 x} \cos 4n\pi| \text{ for case (ii)}) \\ &= b + ce^{-p_1 x} + de^{-p_2 x} > b.\end{aligned}$$

Let $z = Kx_0 + yi$, $y \in [0, 2q\pi]$, where $K > 1$ such that $b - ce^{-p_1 K x_0} - de^{-p_2 K x_0} > b/2$. Then

$$\begin{aligned}|f(z)| &= |b + ce^{-p_1 K x_0} e^{-p_1 yi} + de^{-p_2 K x_0} e^{-p_2 yi}| \\ &\geq b - ce^{-p_1 K x_0} - de^{-p_2 K x_0} > b/2.\end{aligned}$$

Let $z = yi$, $y \in [0, 2q\pi]$; then

$$\begin{aligned}|f(z)| &= |b + ce^{-p_1 yi} + de^{-p_2 yi}| \geq \begin{cases} d - c - b & \text{for case (i)}, \\ c - d - b & \text{for case (ii)} \end{cases} \\ &:= \eta_0 > 0.\end{aligned}$$

Let $\eta_0' := \min\{\eta_0, b/2\}$. Denote

$$\begin{aligned}\gamma := \{z = x + yi \in \mathbf{C} : z = x \text{ or } z = x \pm 2q\pi i, \quad x \in [0, Kx_0], \\ \text{or } z = yi \text{ or } z = Kx_0 + yi, \quad y \in [0, 2q\pi].\end{aligned}$$

$$\gamma^\circ := \{z = x + yi \in \mathbf{C} : 0 < x < Kx_0, \ -2q\pi < y < 2q\pi\}.$$

Clearly, γ is a simple loop homotopic to the original, $z_0 = x_0 + q\pi i \in \gamma^\circ$ and $|f(z)| > \eta_0'$ on γ. Choose $r_0 > 0$ such that $\gamma \subset \mathcal{A} := \{z \in \mathbf{C} : |z| < r_0\}$. Denote $\partial\mathcal{A} := \{z \in \mathbf{C} : |z| = r_0\}$. Thus for all $z \in \partial\mathcal{A}$, $z = r_0 e^{\theta i}$, $\theta \in [0, 2\pi]$, we have

$$|g_\epsilon(z)| = |\epsilon^k z^k + \sum_{j=1}^{k-1} a_j \epsilon^j z^j| \leq \epsilon^k r_0^k + \sum_{j=1}^{k-1} |a_j| \epsilon^j r_0^j. \tag{C.2}$$

Obviously $\exists \epsilon_0 > 0$ such that for all $\epsilon, 0 < \epsilon < \epsilon_0$, $|g_\epsilon(z)| < \eta_0', z \in \partial\mathcal{A}$. For all $z \in \mathcal{A}, z = re^{\theta i}$; then $r < r_0$, and

$$|g_\epsilon(z)| = |\epsilon^k z^k + \sum_{j=1}^{k-1} a_j \epsilon^j z^j| \leq \epsilon^k r^k + \sum_{j=1}^{k-1} |a_j| \epsilon^j r^j < \epsilon^k r_0^k + \sum_{j=1}^{k-1} |a_j| \epsilon^j r_0^j.$$

Thus $|g_\epsilon(z)| < \eta_0'$ for all $z \in \gamma$. Therefore $|f(z)| > |g_\epsilon(z)|$ on γ. By Rouchè's theorem [7, pp. 125–126], $f(z)$ and $f(z) + g_\epsilon(z)$ have the same number of zeros in γ°. That is, $f(z) + g_\epsilon(z) = 0$ has at least one root $\hat{z}_\epsilon \in \gamma^\circ$.

Appendix D. Proof of Proposition 5.8. We need only show that the conjugate roots of (4.3) cross the imaginary axis from left to right. Assume $\tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$. From (4.3), we have

$$\begin{aligned}&\Big[2\lambda + (A + d_i) - DBe^{-\lambda\tau_1}\tau_1 - DCe^{-\lambda(\tau_1+\tau_2)}(\tau_1 + \tau_2)\Big]\frac{d\lambda}{d\tau_1} \\ &= \Big(DBe^{-\lambda\tau_1} + DCe^{-\lambda(\tau_1+\tau_2)}\Big)\lambda.\end{aligned}$$

If the root $\lambda(\bar{\tau}_1) = i\omega$ is not simple for some $\bar{\tau}_1 > 0$, then $\frac{d\lambda}{d\tau_1}\big|_{\tau_1=\bar{\tau}_1} = 0$. Thus,

$$-DBe^{-i\omega\bar{\tau}_1} - DCe^{-i\omega\bar{\tau}_1+\tau_2}i\omega = 0 \quad \text{and} \quad (B + C\cos\omega\tau_2) - i\sin\omega\tau_2 = 0.$$

This is impossible since $\tau_2 < \frac{\pi}{2\hat{\omega}}$. Therefore,

$$\Big(\frac{d\lambda}{d\tau_1}\Big)^{-1} = \frac{[2\lambda + (A + d_i)]e^{\lambda(\tau_1+\tau_2)} - \tau_2 DC}{(DBe^{\lambda\tau_2} + DC)\lambda} - \frac{\tau_1}{\lambda}.$$

Notice that at $\lambda = i\omega$,

$$\begin{aligned}
&\operatorname{sign}\Big\{\frac{d\mathrm{Re}(\lambda)}{d\tau_1}\Big\} = \operatorname{sign}\Big\{\mathrm{Re}\Big(\Big(\frac{d\lambda}{d\tau_1}\Big)^{-1}\Big)\Big\} \\
&= \operatorname{sign}\Big\{\mathrm{Re}\Big(\frac{(i(A + d_i) - 2\omega)(\cos\omega(\tau_1 + \tau_2) + i\sin\omega(\tau_1 + \tau_2)) - \tau_2 DCi}{-(DB\cos\omega\tau_2 + iDB\sin\omega\tau_2)\omega}\Big)\Big\} \\
&= \operatorname{sign}\Big\{(DB\cos\omega\tau_2 + DC)2\omega\cos\omega(\tau_1 + \tau_2) + DB\sin\omega\tau_2(2\omega\sin\omega(\tau_1 + \tau_2) + \tau_2 DC) \\
&\qquad + DB(A + d_i)\sin\omega\tau_1\Big\} = 1.
\end{aligned}$$

Appendix E. Proof of Proposition 5.9. Similar to the proof of Proposition 5.8 in Appendix D, assume $\tau_1 + \tau_2 < \frac{\pi}{2\hat{\omega}}$. From (4.3), we have

$$\Big[2\lambda + (A + d_i) - \tau_1 DBe^{\lambda\tau_1} - DC(\tau_1 + \tau_2)e^{-\lambda(\tau_1+\tau_2)}\Big]\frac{d\lambda}{d\tau_2} = DC\lambda e^{-\lambda(\tau_1+\tau_2)}.$$

If $\lambda(\bar{\tau}_2) = i\omega$ is a root of (4.3) for some $\bar{\tau}_2 > 0$ with $\omega > 0$, then it must be simple. Otherwise, $\frac{d\lambda}{d\tau_2}\big|_{\tau_2=\bar{\tau}_2} = 0$ and leads to a contradiction, $DC\omega\cos\tau_1 + \bar{\tau}_2 = 0$. We show that if a root of (4.3) crosses the imaginary axis while τ_2 increases, it must cross from left to right. Obviously,

$$\Big(\frac{d\lambda}{d\tau_2}\Big)^{-1} = \frac{(2\lambda + (A + d_i))e^{\lambda(\tau_1+\tau_2)} - \tau_1 DBe^{-\lambda\tau_2}}{DC\lambda} - \frac{\tau_1 + \tau_2}{\lambda}.$$

Thus, at $\lambda = i\omega$,

$$\Big(\frac{d\lambda}{d\tau_2}\Big)^{-1} = \frac{2\omega\cos\omega(\tau_1 + \tau_2) + (A + d_i)\sin\omega(\tau_1 + \tau_2) - \tau_1 DB\sin\omega\tau_2}{DC\omega}.$$

Then, if $\tau_1 DB < A + d_i$,

$$\begin{aligned}
&\operatorname{sign}\Big\{\frac{d\mathrm{Re}(\lambda)}{d\tau_2}\Big\} = \operatorname{sign}\Big\{\mathrm{Re}\Big(\Big(\frac{d\lambda}{d\tau_2}\Big)^{-1}\Big)\Big\} \\
&= \operatorname{sign}\Big\{2\omega\cos\omega(\tau_1 + \tau_2) + (A + d_i)\sin\omega(\tau_1 + \tau_2) - \tau_1 DB\sin\omega\tau_2\Big\} = 1.
\end{aligned}$$

Acknowledgments. We would like to thank the referees and the associate editor for their valuable suggestions that enabled us to improve the presentation of this paper. The first author thanks Prof. Carlos Castillo-Chavez for his encouragement for the analysis of the characteristic equation when $\tau_1\tau_2 > 0$.

NUMERICAL SIMULATION OF ACOUSTIC TIME REVERSAL MIRRORS*

CHOKRI BEN AMAR†, NABIL GMATI†, CHRISTOPHE HAZARD‡, AND KARIM RAMDANI§

Abstract. We study the time reversal phenomenon in a homogeneous and nondissipative medium containing sound-hard obstacles. We propose two mathematical models of time reversal mirrors in the frequency domain. The first one takes into account the interactions between the mirror and the obstacles. The second one provides an approximation of these interactions. We prove, in both cases, that the time reversal operator T is self-adjoint and compact. The DORT method (French acronym for decomposition of the time reversal operator) is explored numerically. In particular, we show that selective focusing, which is known to occur for small and distant enough scatterers, holds when the wavelength and the size of these scatterers are of the same order of magnitude (medium frequency situation). Moreover, we present the behavior of the eigenvalues of T according to the frequency, and we show their oscillations due to the interactions between the mirror and the obstacles and between the obstacles themselves.

Key words. time reversal, frequency domain, acoustic scattering, selective focusing

1. Introduction. During the last decade, time reversal techniques have been extensively studied, in particular for detection, localization, and identification of scatterers in propagative media. In the present paper, we are concerned with one of these techniques, usually referred to as the DORT method (French acronym for decomposition of the time reversal operator). This method was first developed by Prada and Fink [17] in the context of ultrasonics (see [18] for an overview). It consists in determining the invariants of a time reversal process which can be described as follows. A time reversal mirror (TRM), composed of an array of transducers, first emits an incident wave corresponding to a given distribution of signals sent to the transducers. This wave is then scattered by the presence of obstacles in the propagative medium. In a second step, the TRM measures the scattered field and time-reverses the measure, which furnishes a new distribution of signals used to reemit a new incident wave. In short, one cycle of the process corresponds to the succession of steps: emission, scattering, measure, time reversal. The so-called time reversal operator T is obtained by iterating this cycle twice. The DORT method deals with the eigenvalues of T and the associated eigenvectors for a fixed frequency, that is, when time-harmonic waves are considered. In this case, time reversal simply amounts to a phase conjugation. It was shown [17, 19] and confirmed by experiments that for ideally resolved or pointlike and distant enough scatterers with different reflectivities, each eigenvector corresponding to a nonzero eigenvalue of T provides the signals to be sent to the transducers in

order to focus on one scatterer. A mathematical justification of these selective focusing properties is given in [8] for a far field approach, i.e., for an ideal TRM which reverses the asymptotic behavior at large distance of the wave scattered by the obstacles (in this case, the time reversal operator is related with the far field operator [13] well known in scattering theory). Other applications of the DORT method, which concern this question of focusing on a selected target, have been developed: acoustic waveguides [10, 15], electromagnetic scattering [22, 14], or propagation in random media [4].

The focusing properties of the eigenvectors of the time reversal operator are known to occur for small enough scatterers, i.e., when the diameters of the scatterers are small compared to the wavelength. Such a situation corresponds to a low frequency case. The object of the present paper is to explore the medium frequency case by a numerical approach, i.e., when the diameters and the wavelength have the same order of magnitude. The model considered here differs from commonly used models in the fact that the TRM is intrusive: instead of an array of pointlike transducers, the TRM consists of a volumic and nonpenetrable object which perturbs the acoustic field. For the sake of simplicity, we consider the usual simplified model of linear electroacoustic transducers (see, e.g., [16]): the inner behavior of the TRM is modeled by a Robin condition on its boundary.

The paper is organized as follows. In section 2, we present a mathematical model of a nonpenetrable intrusive TRM, which is closely related to the active sonar problem dealt with, for instance, in [20]. In this first model, the interactions between the scatterers and the TRM are taken into account, so that we can deal with the case where they are close to each other. Instead of the symmetric matrix obtained for a finite number of pointlike transducers, the time reversal operator then appears, like in the far field approach [8], as an operator acting in an L^2 space representing the finite energy space of possible excitations. The basic properties of this operator, namely self-adjointness and compactness, are proved in section 3. They essentially tell us that its spectrum is that of a symmetric matrix completed by an infinite number of nonsignificant eigenvalues. In section 4, we propose a nonpenetrable intrusive model of a TRM in which the interactions between the obstacles and the TRM are approximated. We briefly show how to adapt the proofs of section 3. Finally, we present some numerical results in section 5. We show that the expected selective focusing properties hold in the medium frequency case. Moreover, we point out the modulations of the eigenvalues of T with respect to the frequency. These oscillations are due to the interactions between the scatterers and the TRM, and between the scatterers themselves.

The main result of this paper, namely the properties of the time reversal operator (Theorem 2.1), holds in many other situations which can be dealt with by similar integral techniques. For instance, here we consider sound-hard obstacles, but we could have chosen a Dirichlet or Robin boundary condition on $\partial\mathcal{O}$ instead of the Neumann condition. Penetrable scatterers, i.e., inhomogeneities of the medium, can also be considered.

2. A model of nonpenetrable intrusive mirror. We consider a homogeneous medium filling the space $\mathbb{R}^n$ ($n = 2$ or 3) and containing a nonpenetrable mirror M and some nonpenetrable obstacles $\mathcal{O}$.

We study the case of an impedance condition on the boundary ∂M of the mirror and a Neumann condition on the boundary $\partial\mathcal{O}$ of the obstacles (sound-hard obstacles). Let $\Omega_M = \mathbb{R}^n\backslash\overline{M}$, $\Omega_{\mathcal{O}} = \mathbb{R}^n\backslash\overline{\mathcal{O}}$, and $\Omega_{M,\mathcal{O}} = \mathbb{R}^n\backslash(\overline{M} \cup \overline{\mathcal{O}})$. We suppose that the

boundary of the mirror is excited by a signal g (proportional to the current which flows through each transducer). So, in the presence of the obstacles, we observe the total field φ_T satisfying the problem

$$\begin{cases} \Delta\varphi_T + k^2\varphi_T = 0 \quad \text{in } \Omega_{M,\mathcal{O}}, \\ \dfrac{\partial\varphi_T}{\partial n} + \mu\varphi_T = g \quad \text{on } \partial M, \\ \dfrac{\partial\varphi_T}{\partial n} = 0 \quad \text{on } \partial\mathcal{O}, \\ \text{RC} \quad \text{at } \infty, \end{cases} \tag{2.1}$$

where n denotes the unit normal vector directed into the interior of the domain $\Omega_{M,\mathcal{O}}$. The wave number k is defined by $k = \omega/c$, where ω is the frequency and c is the speed of sound in the homogeneous medium, μ is a real parameter which represents the inverse of the open-circuit acoustic impedance of the TRM [16], and RC is the outgoing Sommerfeld "radiation condition" which, for φ_T, is

$$\lim_{r\to+\infty} r^{\frac{n-1}{2}} \left(\frac{\partial\varphi_T}{\partial r}(x) - ik\varphi_T(x) \right) = 0, \quad r = |x|, \tag{2.2}$$

where $\partial\varphi_T/\partial r$ denotes the radial derivative of φ_T.

In the absence of obstacles, we should observe an incident field φ_I solution to

$$\begin{cases} \Delta\varphi_I + k^2\varphi_I = 0 \quad \text{in } \Omega_M, \\ \dfrac{\partial\varphi_I}{\partial n} + \mu\varphi_I = g \quad \text{on } \partial M, \\ \text{RC} \quad \text{at } \infty. \end{cases} \tag{2.3}$$

The perturbation due to the presence of the obstacles is the diffracted field $\varphi_D = \varphi_T - \varphi_I$ satisfying the problem

$$\begin{cases} \Delta\varphi_D + k^2\varphi_D = 0 \quad \text{in } \Omega_{M,\mathcal{O}}, \\ \dfrac{\partial\varphi_D}{\partial n} + \mu\varphi_D = 0 \quad \text{on } \partial M, \\ \dfrac{\partial\varphi_D}{\partial n} = h \quad \text{on } \partial\mathcal{O}, \\ \text{RC} \quad \text{at } \infty, \end{cases} \tag{2.4}$$

where $h = -\partial\varphi_I/\partial n$.

We suppose that the signal measured by the mirror is equal to $\varphi_{D_{/\partial M}}$, the value of the diffracted field on ∂M. The measured signal is then conjugated and used to generate the incident and the total fields in the next iteration.

Time reversal operator. Let R denote the operator describing the response of the medium, that is, the three successive steps: emission, diffraction, measure. It is defined by

$$Rg = \varphi_{D_{/\partial M}}.$$

The time reversal operator is obtained by iterating the time reversal process (emission, diffraction, measure, conjugation) twice. Therefore, T is given by

$$Tg = \overline{R\overline{Rg}}, \quad \text{that is,} \quad T = \overline{R}R,$$

where the operator $\overline{R}$ is defined by

$$\overline{R}g = \overline{R\,\overline{g}}.$$

THEOREM 2.1. *T is a self-adjoint positive and compact operator in $L^2(\partial M)$.*

These properties are proved below by an integral approach based on the use of several Green's functions.

3. Proof of Theorem 2.1. This section is devoted to the proof of the following result, from which Theorem 2.1 derives.

PROPOSITION 3.1. *For every $g \in L^2(\partial M)$, the response $Rg \in L^2(\partial M)$ of the medium is given by*

$$(Rg)(x) = \int_{\partial M} G_R(x,y)g(y)d\sigma(y), \tag{3.1}$$

where $G_R \in L^2(\partial M \times \partial M)$ is symmetric, i.e., $G_R(x,y) = G_R(y,x)$.

This proposition shows that R is a Hilbert–Schmidt operator in $L^2(\partial M)$ such that $R^* = \overline{R}$ since

$$(R^*g)(x) = \int_{\partial M} \overline{G_R(y,x)}g(y)d\sigma(y) \quad \text{and} \quad (\overline{R}g)(x) = \int_{\partial M} \overline{G_R(x,y)}g(y)d\sigma(y).$$

Hence $T = R^*R$ is self-adjoint positive and compact in $L^2(\partial M)$. It is actually a Hilbert–Schmidt operator in $L^2(\partial M)$ whose kernel $G \in L^2(\partial M \times \partial M)$ is given by

$$G(x,y) = \int_{\partial M} \overline{G_R(z,x)}G_R(z,y)d\sigma(z).$$

The spectral properties of T follow. On one hand, the eigenvalues of T form a decreasing sequence of positive numbers $(\lambda_n)_{n\in\mathbb{N}^*}$ such that $\sum_{n\in\mathbb{N}^*} \lambda_n^2$ is finite. On the other hand, one can choose an orthonormal basis of $L^2(\partial M)$ composed of eigenvectors of T, and T becomes diagonal in this basis.

Integral representations. To prove Proposition 3.1, first recall that problems (2.1), (2.3), and (2.4) are well-posed [6] in a proper functional framework which is made precise later. Consider then the operators

$$\begin{aligned} S_T &: g \mapsto \varphi_T \quad \text{solution to (2.1)},\\ S_I &: g \mapsto \varphi_I \quad \text{solution to (2.3)},\\ S_D &: h \mapsto \varphi_D \quad \text{solution to (2.4)}, \end{aligned}$$

as well as the Green's functions G_T, G_I, and G_D, which are, respectively, outgoing solutions (in the sense that they satisfy the outgoing radiation condition (2.2)) to

$$\begin{cases} \Delta G_T(x,.) + k^2 G_T(x,.) = \delta_x & \text{in } \Omega_{M,\mathcal{O}},\\ \Theta_M G_T(x,.) = 0 & \text{on } \partial M,\\ \Theta_{\mathcal{O}} G_T(x,.) = 0 & \text{on } \partial\mathcal{O}, \end{cases} \tag{3.2}$$

$$\begin{cases} \Delta G_I(x,.) + k^2 G_I(x,.) = \delta_x & \text{in } \Omega_M, \\ \Theta_M G_I(x,.) = 0 & \text{on } \partial M, \end{cases} \tag{3.3}$$

$$\begin{cases} \Delta G_D(x,.) + k^2 G_D(x,.) = 0 & \text{in } \Omega_{M,\mathcal{O}}, \\ \Theta_M G_D(x,.) = 0 & \text{on } \partial M, \\ \Theta_{\mathcal{O}} G_D(x,.) = -\Theta_{\mathcal{O}} G_I(x,.) & \text{on } \partial\mathcal{O}, \end{cases} \tag{3.4}$$

where δ_x stands for the Dirac measure at point x, $\Theta_M = (\partial/\partial n + \mu)_{/\partial M}$, and $\Theta_{\mathcal{O}} = (\partial/\partial n)_{/\partial\mathcal{O}}$. By construction, we have $G_T = G_I + G_D$.

These functions can be expressed by means of the usual Green's function G_0 of the Helmholtz operator in the free space, i.e., the outgoing solution in $\mathbb{R}^n$ to $\Delta G_0(x,.) + k^2 G_0(x,.) = \delta_x$, which is given by

$$G_0(x,y) = \begin{cases} -\dfrac{e^{ik|x-y|}}{4\pi|x-y|} & \text{if } n = 3, \\ \dfrac{1}{4i} H_0^{(1)}(k|x-y|) & \text{if } n = 2. \end{cases}$$

Indeed, we have

$$\begin{aligned} &G_I(x,.) = G_0(x,.) + \widetilde{G}_I(x,.), \quad \text{where } \widetilde{G}_I(x,.) = -S_I \Theta_M G_0(x,.), \\ &G_D(x,.) = -S_D \Theta_{\mathcal{O}} G_I(x,.). \end{aligned} \tag{3.5}$$

LEMMA 3.2. *Let Ω_i stand for Ω_M if $i = I$, and for $\Omega_{M,\mathcal{O}}$ if $i = T$ or D. Then $\varphi_T = S_T g$, $\varphi_I = S_I g$, and $\varphi_D = -S_D \Theta_{\mathcal{O}} \varphi_I$ are given by*

$$\varphi_i(x) = \int_{\partial M} G_i(x,y) g(y) d\sigma(y) \quad \forall x \in \Omega_i,\ i \in \{T, I, D\}, \tag{3.6}$$

where the kernels G_i are symmetric: $G_i(x,y) = G_i(y,x)$.

Proof. Formulas (3.6) are classical. For the sake of clarity, we recall briefly how to derive them from the usual integral representation [5]

$$\varphi_i(x) = \int_{\partial\Omega_i} \left\{ G_0(x,y) \frac{\partial \varphi_i}{\partial n}(y) - \frac{\partial G_0}{\partial n_y}(x,y) \varphi_i(y) \right\} d\sigma(y) \quad \forall x \in \Omega_i. \tag{3.7}$$

We use the fact that if two functions φ and ψ satisfy the Helmholtz equation either inside a bounded domain Λ, or outside Λ together with the radiation condition (2.2), then we have the reciprocity relation [5]

$$\int_{\partial\Lambda} \left\{ \psi \frac{\partial \varphi}{\partial n} - \frac{\partial \psi}{\partial n} \varphi \right\} d\sigma = 0, \tag{3.8}$$

where the normal derivative can obviously be replaced by $(\partial/\partial n + \mu)$.

For φ_I, we replace G_0 in (3.7) by $G_I - \widetilde{G}_I$, which yields two similar integral terms on ∂M. Thanks to (3.8), the term involving $\widetilde{G}_I$ vanishes. The other one reduces to the single layer potential (3.6) by virtue of the boundary conditions satisfied by φ_I and $G_I(x,.)$ (see (2.3) and (3.3)).

For φ_T, the same idea applies. The integral terms are now set on $\partial M \cup \partial\mathcal{O}$. The term which involves $\widetilde{G}_T = G_T - G_0$ again vanishes by (3.8). Split the other

one, which involves G_T, into two integrals, respectively, on ∂M and $\partial\mathcal{O}$. Thanks to the boundary conditions in (2.1) and (3.2), the former simplifies as above to (3.6), whereas the latter vanishes.

Finally, subtracting the previous representations yields (3.6) for $\varphi_D = \varphi_T - \varphi_I$.

The symmetry of G_I is easily deduced from that of G_0 by proving that the perturbation term $\widetilde{G}_I$ is also symmetric. The integral representation (3.7) of $\widetilde{G}_I(x,.)$ reads

$$\widetilde{G}_I(x,y) = \int_{\partial M} \left\{ \Theta_M G_0(y,z) \widetilde{G}_I(x,z) - G_0(y,z) \Theta_M \widetilde{G}_I(x,z) \right\} d\sigma(z),$$

where the operator Θ_M is understood with respect to z. The boundary conditions satisfied by $\widetilde{G}_I(x,.)$ and $\widetilde{G}_I(y,.)$ then yield

$$\widetilde{G}_I(x,y) = -\int_{\partial M} \Theta_M \widetilde{G}_I(y,z) \widetilde{G}_I(x,z) d\sigma(z) + \int_{\partial M} G_0(y,z) \Theta_M G_0(x,z) d\sigma(z).$$

Thanks to the reciprocity relation (3.8) applied in Ω_M for the first integral, and in M for the second one, we see that both integrals are symmetric for $(x,y) \in \Omega_M \times \Omega_M$, and hence so is $\widetilde{G}_I$.

The symmetry of G_D is proved similarly, and that of G_T follows. ∎

Functional details. It is now clear that (3.1) follows from the integral representation (3.6) of φ_D simply by taking its restriction on ∂M:

$$G_R(x,y) = G_D(x,y) \text{ for } (x,y) \in \partial M \times \partial M.$$

Hence Proposition 3.1 will be proved if we are able to justify that this double restriction actually yields a function of $L^2(\partial M \times \partial M)$. We thus have to make precise the function spaces in which the kernels G_i are defined: the appropriate tool to do so is the notion of tensor product of Hilbert spaces [1].

All the domains considered are assumed to have Lipschitz boundaries (for instance, ∂M and $\partial\mathcal{O}$ may be piecewise smooth). For a bounded domain $\Lambda \subset \mathbb{R}^n$, we denote

$$\mathbf{H}(\Lambda) = \left\{ \varphi \in H^1(\Lambda);\ \Delta\varphi \in L^2(\Lambda) \right\}.$$

Recall that, on one hand, the trace operator $\gamma_{\partial\Lambda}\varphi = \varphi_{/\partial\Lambda}$ is continuous from $\mathbf{H}(\Lambda)$ to $H^{1/2}(\partial\Lambda)$, and, on the other hand, the normal derivative $(\partial\varphi/\partial n)_{/\partial\Lambda}$ is continuous from $\mathbf{H}(\Lambda)$ to $H^{-1/2}(\partial\Lambda)$. Moreover, for all bounded sets $\Lambda_M \subset \Omega_M$ and $\Lambda_{\mathcal{O}} \subset \Omega_{M,\mathcal{O}}$, the operators S_I and S_D are continuous from $H^{-1/2}(\partial M)$ to $\mathbf{H}(\Lambda_M)$ and from $H^{-1/2}(\partial\mathcal{O})$ to $\mathbf{H}(\Lambda_{\mathcal{O}})$ (see [6]).

LEMMA 3.3. *Let $\Lambda_M \subset \Omega_M$ and $\Lambda_{\mathcal{O}} \subset \Omega_{M,\mathcal{O}}$ be two bounded sets such that $\partial M \subset \partial\Lambda_M$, $\partial\mathcal{O} \subset \partial\Lambda_{\mathcal{O}}$, and $\overline{\Lambda_M} \cap \overline{\Lambda_{\mathcal{O}}} = \emptyset$. Then*

$$G_I \in \mathbf{H}(\Lambda_M) \widehat{\otimes} \mathbf{H}(\Lambda_{\mathcal{O}}) \quad \textit{and} \quad G_D \in \mathbf{H}(\Lambda_M) \widehat{\otimes} \mathbf{H}(\Lambda_M).$$

Proof. Formulas (3.5), which involve operators acting on the second variable y, can be rewritten in terms of tensor products of operators as

$$G_I = G_0 - (Id \otimes S_I \Theta_M) G_0,$$
$$G_D = -(Id \otimes S_D \Theta_{\mathcal{O}})\, G_I.$$

Let us first deal with G_I. Thanks to its symmetry, the announced property amounts to showing that $G_I \in \mathbf{H}(\Lambda_{\mathcal{O}})\widehat{\otimes}\mathbf{H}(\Lambda_M)$. This clearly holds for G_0 since it is infinitely differentiable outside the diagonal $x = y$. Moreover, the above-mentioned properties of S_I and traces show that $S_I\Theta_M$ is continuous from $\mathbf{H}(\Lambda_M)$ to $\mathbf{H}(\Lambda_M)$. As a consequence [1], $Id \otimes S_I\Theta_M$ is continuous from $\mathbf{H}(\Lambda_{\mathcal{O}})\widehat{\otimes}\mathbf{H}(\Lambda_M)$ to itself. The conclusion follows.

For G_D, we use the previous result and the fact that $Id \otimes S_D\Theta_{\mathcal{O}}$ is continuous from $\mathbf{H}(\Lambda_M)\widehat{\otimes}\mathbf{H}(\Lambda_{\mathcal{O}})$ to $\mathbf{H}(\Lambda_M)\widehat{\otimes}\mathbf{H}(\Lambda_M)$. □

We finally have to notice that since $\gamma_{\partial M}$ is continuous from $\mathbf{H}(\Lambda_M)$ to $L^2(\partial M) \supset H^{1/2}(\partial M)$, the "double trace" $\gamma_{\partial M} \otimes \gamma_{\partial M}$ is continuous from $\mathbf{H}(\Lambda_M)\widehat{\otimes}\mathbf{H}(\Lambda_M)$ to $L^2(\partial M)\widehat{\otimes}L^2(\partial M) = L^2(\partial M \times \partial M)$. Hence the above lemma yields

$$G_R = (\gamma_{\partial M} \otimes \gamma_{\partial M})G_D \in L^2(\partial M \times \partial M),$$

which is obviously symmetric. This completes the proof of Proposition 3.1 and thus of Theorem 2.1.

4. An approximate model. The model we consider in this section is an approximation of the model introduced in section 2. Although more intricate in its presentation, it leads to a reduction of the computational cost of the time reversal operator, for it separates the respective roles of the TRM and the scatterers. It can be seen as the first step of an iterative method used in the context of multiple scattering problems (see, e.g., [7, 21] and [3, 2] for a rigorous justification of the method and [12] for an overview). The coupled problem of section 2 is solved by considering the successive reflections between the TRM and the scatterers. Here only specular waves, i.e., the first reflections, are taken into account. Comparing this model with that of section 2 will help us in section 5 to understand the influence of multiple scattering between the obstacles and the TRM upon the eigenelements of the time reversal operator.

Considering the same incident wave $\varphi_I = S_I g$ as in section 2, the diffracted field is now approximated near the TRM by a superposition of two waves: $\varphi_D = \varphi_D^{(1)} + \varphi_D^{(2)}$. The first one $\varphi_D^{(1)}$ represents the result of the diffraction of φ_I by the scatterers alone, i.e., the outgoing solution to

$$\begin{cases} \Delta\varphi_D^{(1)} + k^2\varphi_D^{(1)} = 0 & \text{in } \Omega_{\mathcal{O}}, \\ \Theta_{\mathcal{O}}\varphi_D^{(1)} = -\Theta_{\mathcal{O}}\varphi_I & \text{on } \partial\mathcal{O}. \end{cases} \tag{4.1}$$

The second one is the result of the diffraction of the latter by the TRM alone, i.e., the outgoing solution to

$$\begin{cases} \Delta\varphi_D^{(2)} + k^2\varphi_D^{(2)} = 0 & \text{in } \Omega_M, \\ \Theta_M\varphi_D^{(2)} = -\Theta_M\varphi_D^{(1)} & \text{on } \partial M. \end{cases} \tag{4.2}$$

We assume again that the TRM measures the trace of φ_D on ∂M. Hence the response of the medium is now described by the operator

$$Rg = \varphi_{D/\partial M} = (\varphi_D^{(1)} + \varphi_D^{(2)})_{/\partial M}.$$

Theorem 2.1 holds in this case: the time reversal operator $T = \overline{R}R$ is positive, self-adjoint, and compact in $L^2(\partial M)$.

The proof is similar to that of section 3. We simply have to replace the Green's function G_D by $G_D = G_D^{(1)} + G_D^{(2)}$, where $G_D^{(1)}$ and $G_D^{(2)}$ are, respectively, the outgoing solutions to

$$\begin{cases} \Delta G_D^{(1)}(x,.) + k^2 G_D^{(1)}(x,.) = 0 & \text{in } \Omega_{\mathcal{O}}, \\ \Theta_{\mathcal{O}} G_D^{(1)}(x,.) = -\Theta_{\mathcal{O}} G_I(x,.) & \text{on } \partial\mathcal{O} \end{cases}$$

and

$$\begin{cases} \Delta G_D^{(2)}(x,.) + k^2 G_D^{(2)}(x,.) = 0 & \text{in } \Omega_M, \\ \Theta_M G_D^{(2)}(x,.) = -\Theta_M G_D^{(1)}(x,.) & \text{on } \partial M. \end{cases}$$

LEMMA 4.1. *The following integral representation holds:*

$$\forall x \in \Omega_{M,\mathcal{O}}, \quad \varphi_D(x) = \int_{\partial M} G_D(x,y) g(y) d\sigma(y),$$

where G_D is symmetric in $\Omega_{M,\mathcal{O}} \times \Omega_{M,\mathcal{O}}$.

Proof. Contrary to Lemma 3.2, we are not able to give an intrinsic definition of the total field $\varphi_I + \varphi_D$ by means of a problem such as (2.1), which would depend only on the incident field. We thus give a direct proof of the above integral representation, starting from the classical formula (3.7) applied to $\varphi_D^{(1)}$ in $\Omega_{\mathcal{O}}$.

Using (3.5) and (3.8) applied to $\widetilde{G}_I(x,.)$ and $\varphi_D^{(1)}$ in $\Omega_{M,\mathcal{O}}$, formula (3.7) becomes

$$\forall x \in \Omega_{M,\mathcal{O}}, \quad \varphi_D^{(1)}(x) = \int_{\partial M \cup \partial\mathcal{O}} \left\{ -\Theta_\bullet G_I(x,y) \varphi_D^{(1)}(y) + G_I(x,y) \Theta_\bullet \varphi_D^{(1)}(y) \right\} d\sigma(y),$$

where $\Theta_\bullet$ stands for Θ_M or $\Theta_{\mathcal{O}}$. Thanks to the boundary conditions satisfied by $G_I(x,.)$ and $\varphi_D^{(2)}$, the contribution on ∂M is nothing but $S_I \Theta_M \varphi_D^{(1)} = -\varphi_D^{(2)}$ by Lemma 3.2, and so the contribution on $\partial\mathcal{O}$ is exactly $\varphi_D(x)$. We thus have

$$\begin{aligned} \varphi_D(x) &= \int_{\partial\mathcal{O}} \left\{ \Theta_{\mathcal{O}} G_D^{(1)}(x,y) \varphi_D^{(1)}(y) - G_I(x,y) \Theta_{\mathcal{O}} \varphi_I(y) \right\} d\sigma(y) \\ &= \int_{\partial\mathcal{O}} \left\{ G_D^{(1)}(x,y) \Theta_{\mathcal{O}} \varphi_D^{(1)}(y) - \Theta_{\mathcal{O}} G_I(x,y) \varphi_I(y) \right\} d\sigma(y) \\ &= \int_{\partial\mathcal{O}} \left\{ -G_D^{(1)}(x,y) \Theta_{\mathcal{O}} \varphi_I(y) + \Theta_{\mathcal{O}} G_D^{(1)}(x,y) \varphi_I(y) \right\} d\sigma(y) \\ &= \int_{\partial M} \left\{ G_D^{(1)}(x,y) \Theta_M \varphi_I(y) - \Theta_M G_D^{(1)}(x,y) \varphi_I(y) \right\} d\sigma(y). \end{aligned} \tag{4.3}$$

The first and third equalities result from the boundary conditions satisfied by $G_D^{(1)}(x,.)$ and $\varphi_D^{(1)}$. The second one derives from the reciprocity relation (3.8) applied, on one hand, to $G_D^{(1)}(x,.)$ and $\varphi_D^{(1)}$ in $\Omega_{\mathcal{O}}$ and, on the other hand, to $G_I(x,.)$ and φ_I in $\mathcal{O}$. The last one again results from (3.8) applied to $G_D^{(1)}(x,.)$ and φ_I in $\Omega_{M,\mathcal{O}}$. Noticing finally that $\Theta_M G_D^{(2)}(x,.) = -\Theta_M G_D^{(1)}(x,.)$, we have

$$\int_{\partial M} \Theta_M G_D^{(1)}(x,y) \varphi_I(y) d\sigma(y) = -\int_{\partial M} G_D^{(2)}(x,y) \Theta_M \varphi_I(y) d\sigma(y),$$

thanks to (3.8) applied to $G_D^{(2)}(x,.)$ and φ_I in Ω_M. Since $g = \Theta_M \varphi_I$, the integral representation of φ_D follows.

The symmetry of $G_D(x,.)$ is proved by the same argument as in Lemma 3.2. Since $G_D^{(1)}(x,.)$ and $G_D^{(2)}(x,.)$ play the same role as $\varphi_D^{(1)}$ and $\varphi_D^{(2)}$, we obtain for $G_D(x,y)$ a formula similar to (4.3):

$$G_D(x,y) = \int_{\partial\mathcal{O}} \left\{ \Theta_{\mathcal{O}} G_D^{(1)}(y,z) G_D^{(1)}(x,z) - G_I(y,z) \Theta_{\mathcal{O}} G_I(x,z) \right\} d\sigma(z),$$

where both terms are symmetric by (3.8). □

5. Two-dimensional numerical simulation. To solve numerically problems (2.3), (2.4), (4.1), and (4.2), we formulate them in bounded domains to apply a finite element method. We use the so-called coupling method between integral representation and finite elements, which is a nonsingular alternative to the well-known integral equation techniques. This method has been introduced by Jami and Lenoir [9] in hydrodynamics and then extended to many other wave propagation problems.

5.1. Bounded domain formulation. We describe the method only for problem (4.1), but the same technique is also applied for the other ones. We consider a bounded domain Ω' surrounding $\mathcal{O}$ and included in Ω_O (see Figure 5.1), and we introduce the following problem set in the domain Ω':

$$\begin{cases} \Delta\varphi' + k^2\varphi' = 0 & \text{in } \Omega', \\ \dfrac{\partial\varphi'}{\partial n} = h & \text{on } \partial\mathcal{O}, \\ \Theta_\Sigma \varphi' = \Theta_\Sigma \displaystyle\int_{\partial\mathcal{O}} \left\{ G_0(.,y) \frac{\partial\varphi'}{\partial n}(y) - \frac{\partial G_0}{\partial n_y}(.,y)\varphi'(y) \right\} d\sigma(y) & \text{on } \Sigma, \end{cases} \tag{5.1}$$

where $\Sigma = \partial\Omega' \backslash \partial\mathcal{O}$ and $\Theta_\Sigma = (\partial/\partial n + \beta)$, β being an arbitrary complex parameter.

It is clear that if $\varphi_D^{(1)}$ is a solution of (4.1), then $\varphi' = \varphi^{(1)}_{D_{/\Omega'}}$ is a solution of problem (5.1). Similarly, provided $\mathrm{Im}(\beta) \neq 0$, every solution φ' of (5.1) can be uniquely extended to a solution $\varphi_D^{(1)}$ of (4.1) by the integral representation formula on $\partial\mathcal{O}$:

$$\forall x \in \Omega_{\mathcal{O}}, \quad \varphi_D^{(1)}(x) = \int_{\partial\mathcal{O}} \left\{ G_0(x,y) \frac{\partial\varphi'}{\partial n}(y) - \frac{\partial G_0}{\partial n_y}(x,y)\varphi'(y) \right\} d\sigma(y). \tag{5.2}$$

The variational formulation of the problem (5.1) is the following:

$$\begin{cases} \text{Find } \varphi' \in H^1(\Omega') \text{ such that } \forall \psi \in H^1(\Omega'), \text{ we have} \\ \displaystyle\int_{\Omega'} \nabla\varphi'.\overline{\nabla\psi} - k^2 \int_{\Omega'} \varphi'\overline{\psi} - \beta \int_\Sigma \varphi'\overline{\psi} \\ \displaystyle + \int_\Sigma \overline{\psi(x)} \int_{\partial\mathcal{O}} \varphi'(y) \left(\frac{\partial}{\partial n_x} + \beta \right) \frac{\partial G_0}{\partial n_y}(x,y) d\sigma(y) d\sigma(x) \\ \displaystyle = -\int_{\partial\mathcal{O}} h\overline{\psi} + \int_\Sigma \overline{\psi(x)} \int_{\partial\mathcal{O}} h(y) \left(\frac{\partial}{\partial n_x} + \beta \right) G_0(x,y) d\sigma(y) d\sigma(x). \end{cases} \tag{5.3}$$

Finally, we discretize problem (5.3) to obtain a linear system that we solve numerically.

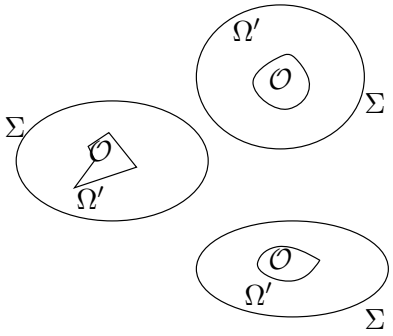

FIG. 5.1. *Bounded domain* Ω'.

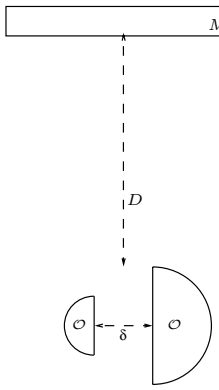

FIG. 5.2. *Geometry of the problem.*

5.2. Numerical results. All the numerical results are obtained by the code MELINA [11]. We consider an oblong mirror of width 8 and height 1 and two half-disk obstacles of diameters 4 and 2 (see Figure 5.2). We denote by D the distance between the mirror and the obstacles. The distance between the scatterers is $\delta = 2$. We investigate two cases: $D = 3$ and $D = 8$. We consider here a Neumann condition on the boundary of the mirror ∂M ($\mu = 0$, that is, the case of a large acoustic impedance of the transducers).

Figure 5.3 (respectively, Figure 5.4) shows the amplitude of the total field corresponding to the emission of the first (respectively, second) eigenvector associated with $\lambda_1 = 0.0499$ if $D = 8$ and $\lambda_1 = 0.2211$ if $D = 3$ (respectively, $\lambda_2 = 0.0191$ if $D = 8$ and $\lambda_2 = 0.0534$ if $D = 3$) in the case of the first model presented in section 2 and where $k = 3.14$ (the wavelength $l_w = 2\pi/k = 2$ is then equal to the distance between the obstacles δ). We observe that the wave is focused on the biggest obstacle (respectively, the smallest). When emitting the third eigenvector associated with $\lambda_3 = 0.0002$ if $D = 8$ and $\lambda_3 = 0.0085$ if $D = 3$, we see in Figure 5.5 that the wave again focuses on the biggest scatterer, although it seems less concentrated in its vicinity than for the first eigenvector. These results essentially show that selective focusing, which is known to occur for small and distant enough scatterers [8], is achieved even though the size of the obstacles, the distance between them, and the wavelength are of the same order.

Figure 5.10 shows the first four eigenvalues of the time reversal operator T ac-

cording to the wave number k in the case of the first model presented in section 2, where the interactions between the mirror and the obstacles are taken into account and where the distance D between them is, respectively, 8 or 3. Figure 5.11 shows the same results in the case of the second model, where these interactions are approximated by only the first reflections.

We can first notice in these figures that there is only one significant eigenvalue λ_1 at low frequencies, which follows from the fact that the wavelength l_w is large compared to the distance δ between the two obstacles, so that the mirror cannot distinguish between them and see them as only one. For $k = 0.325$ (that is, $l_w \simeq 19$), this is illustrated by Figure 5.6 (respectively, Figure 5.7), which shows the amplitude of the total field corresponding to the emission of the first (respectively, second) eigenvector associated with $\lambda_1 = 0.6994$ if $D = 8$ and $\lambda_1 = 3.2717$ if $D = 3$ (respectively,

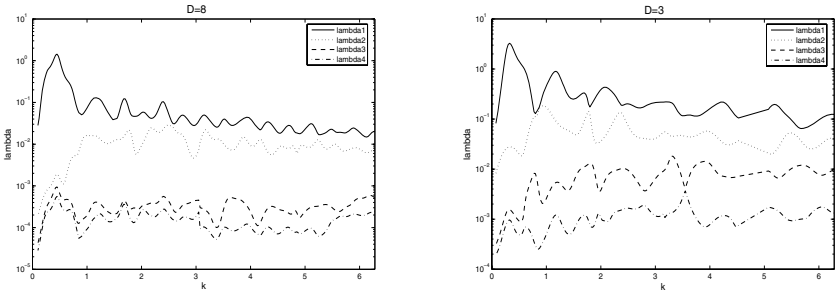

FIG. 5.10. *First model: four largest eigenvalues of T according to k.*

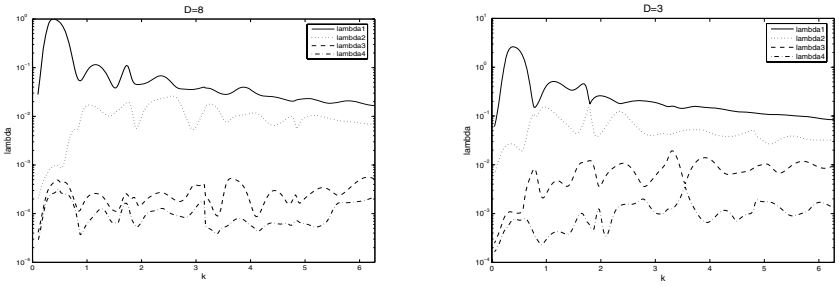

FIG. 5.11. *Second model: four largest eigenvalues of T according to k.*

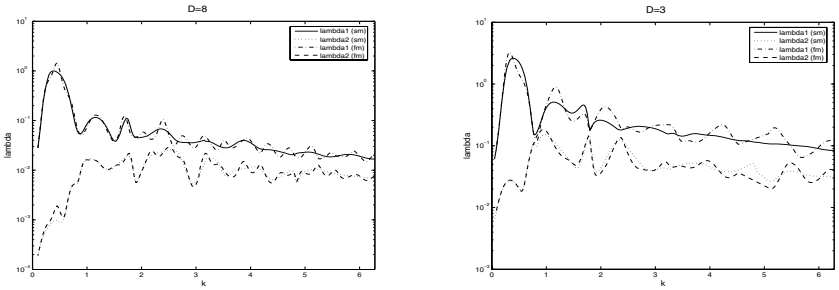

FIG. 5.12. *The first two eigenvalues for the two models.*

$\lambda_2 = 0.0006$ if $D = 8$ and $\lambda_2 = 0.0265$ if $D = 3$) in the case of the first model presented in section 2.

When k increases, Figures 5.10 and 5.11 show that there are two significant eigenvalues: the gap with the third eigenvalue is pronounced when $D = 8$ and becomes smaller when $D = 3$. This confirms a well-known effect: this gap increases when the angular aperture under which the TRM is seen from the obstacles decreases.

We note the presence of oscillations of the first two eigenvalues of T in the case of the first model (Figure 5.10) contrary to the case of the second model (Figure 5.11). To understand this, we show in Figure 5.12 the first two eigenvalues of the two models where, respectively, $D = 3$ and $D = 8$. We remark that the eigenvalues for the first model oscillate around the corresponding eigenvalues for the second model. This can be explained by the fact that the interactions between the mirror and the obstacles can be constructive or destructive according to the distance between the mirror and

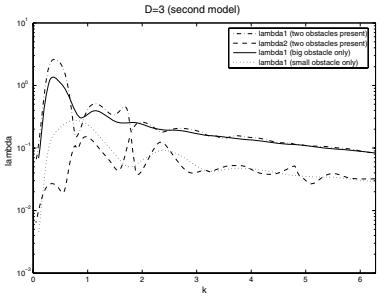

FIG. 5.13. *Analysis of the interactions between obstacles.*

the obstacles. For the greatest eigenvalue, we note the dependence of the period of oscillations on the distance between the mirror and the obstacles: $\Delta k \simeq \pi/D$. More precisely, the interactions between the mirror and the obstacles are constructive for the wave numbers $k_n \simeq n\pi/D$, $n \in \mathbb{N}^*$ (which correspond to local maxima of λ_1), and destructive for $k_n \simeq ((n-1/2)\pi)/D$, $n \in \mathbb{N}^*$. This can be explained by the fact that the wave numbers $n\pi/D$, $n \in \mathbb{N}^*$, represent the eigenvalues of the operator $-\Delta$ with Neumann conditions on the boundaries in the one-dimensional domain $[0, D]$, and the corresponding eigenfunctions are $\varphi_n(y) = \cos(k_n y)$, $y \in [0, D]$.

To study the interactions between the obstacles, we now show in Figure 5.13 the first and second eigenvalues of T for the approximate model and for $D = 3$, together with the first eigenvalue of T for the same model but with a new geometrical configuration in which only the biggest or the smallest obstacle is present. We observe that, at medium frequencies, there is a good coincidence between the first eigenvalue of T corresponding to the case where the two obstacles are present and the one where there is only the biggest obstacle, which explains that the interactions due to the smallest obstacle are negligible. Meanwhile, the second eigenvalue of T corresponding to the case where the two obstacles are present oscillates smoothly around the first eigenvalue where there is only the smallest obstacle, which proves that the interactions due to the biggest obstacle are important.

Figure 5.10 shows that the two greatest eigenvalues become very close near particular values of k. When the time reversal operator has a double eigenvalue, which occurs, for instance, in the case of two identical targets, one generally requires additional information to identify the selective focusing fields within the two-dimensional eigenspace. Here the slight distance between both eigenvalues seems sufficient to identify these fields. Consider, for example, the case $D = 3$ and $k = 0.875$, where $\lambda_1 = 0.1760$ and $\lambda_2 = 0.1637$. The associated eigenvectors generate the fields represented in Figures 5.8 and 5.9 (right). Although both targets are separated by less than one-third of a wavelength, the TRM clearly distinguishes them, contrary to the low frequency situation of Figure 5.6. This effect results from the proximity of the TRM which acts in the near field. Indeed, if the TRM is moved away to $D = 8$ with the same wave number (Figures 5.8 and 5.9 (left)), both targets are seen as a single one, as in the above-mentioned low frequency case.

ON STEP-FUNCTION REACTION KINETICS MODEL IN THE ABSENCE OF MATERIAL DIFFUSION*

DMITRY GOLOVATY†

Abstract. We propose a precise definition of the step-function kinetics suitable for approximating diffuse propagating reaction fronts in one-dimensional gasless-combustion-type models when a Lewis number is large. We investigate this kinetics in the context of free-radical frontal polymerization (FP) in which a monomer-initiator mixture is converted into a polymer via a propagating self-sustaining reaction front. The notion of step-function kinetics has been extensively used in studies of the frontal dynamics both in FP and in combustion problems when the material diffusion is negligible. However, the models have always been effectively reduced to their point-source approximations without defining exactly what the step-function kinetics is for diffuse reaction fronts. We demonstrate numerically that dynamics of diffuse fronts in systems modeled with step-function kinetics and in systems modeled with Arrhenius kinetics are qualitatively the same at time scales at which the bulk reaction ahead of the front can be ignored. We perform stability analysis for the traveling reaction wave and show that the stability threshold is in close agreement with numerical simulations as well as with other existing kinetics approximations. The benefits of using step-function kinetics are two-fold. The reaction dynamics predicted by the step-function kinetics approximates the dynamics predicted by the Arrhenius kinetics over a wider range of system parameters than the point-source approximation. Second, the systems governed by the step-function kinetics can be analyzed both analytically and numerically within the framework of a single model.

1. Introduction.

1.1. Physical background and existing modeling approaches.

In this paper we give a precise definition of the step-function kinetics in the absence of material diffusion and study it in the context of free-radical *frontal polymerization* (FP).

Frontal polymerization is a process in which a monomer converts into a polymer via a self-propagating localized reaction wave [4], [5]. A typical frontal polymerization experiment is performed in a glass tube filled with reagents. An external heat source, when applied at the top of the tube, initiates a descending front that appears as a moving region of polymer formation. Depending on the choice of reactants and the conditions of the experiment, the front either may or may not propagate with a constant speed. Various nonuniform propagation scenarios can occur, even if it is assumed that the front always remains flat—the situation considered in this paper.

There are several conditions necessary for the existence of the frontal mode. First, the ignition temperature must be high enough to generate and initially sustain the reaction front. Further, the reaction rate must be extremely small at the initial (ambient) temperature but very large at the front temperature. The high reaction

†Department of Theoretical and Applied Mathematics, University of Akron, Akron, OH 44325 (dmitry@math.uakron.edu).

rate coupled with the exothermicity of the reaction must be sufficient to overcome heat losses into the reactants and product zones [5].

Note that an alternative to frontal polymerization is *bulk polymerization*, in which a mixture of reagents is heated uniformly and polymer formation occurs simultaneously throughout the mixture.

A more extensively studied chemical process with a frontal reaction mechanism is self-propagating high-temperature synthesis (SHS)—a combustion process characterized by a heat release large enough to propagate a combustion front through a powder compact while consuming the reactant powders [6], [13]. The simplest models and front propagation mechanisms for FP and SHS are essentially the same, except for the magnitudes of the model parameters.

Both steady and unsteady front propagation have been observed in FP [18] as well as in SHS [14]. Unsteady front propagation is usually undesirable, as it leads to nonuniform "layered" structure of the final product. One of the goals of our modeling is to determine the range of material parameters within which the stability of a uniformly propagating polymerization front is guaranteed. The analysis of the full model is, however, too complicated because it requires solving a system of coupled nonlinear partial differential equations describing multiple reactions and energy transport. In order to make analytical predictions, numerous simplifications are usually introduced by employing asymptotics in terms of small parameters, considering effective kinetics, etc.

In the presence of an appropriate small nondimensional parameter, the reaction zone can be replaced by a propagating front with the chemical reaction approximated by a heat source attached to the front (point-source kinetics [12]). With the removal of a nonlinear reaction term, the governing equations become significantly simpler, but, because the location of the front is not known a priori, the reduced problem is of a free-boundary type. The approximate problem is easier to study analytically, especially from the point of view of stability analysis for the traveling wave solutions.

Even though sharp-front approximation is not usually derived via a rigorous asymptotic method, it has been shown to be an effective tool to study SHS and FP problems, yielding qualitatively plausible results. On the negative side, the problems with point-source kinetics are difficult to treat numerically [9]; further, for certain regimes of FP, *the main reaction zone does not always remain narrow even in the presence of a small parameter*, resulting in nonnegligible bulk reactions that are ignored by default within point-source kinetics approximation. Indeed, for oscillating reaction waves, the concentration of the monomer does not evolve via the frontal mode alone [3], as the width of the main reaction zone varies periodically by several orders of magnitude, leaving regions of unreacted monomer behind the polymerization front. The monomer in these regions subsequently converts to polymer via bulk (nonfrontal) polymerization.

Another approach that has been successfully applied in a number of combustion and polymerization studies is to introduce simplified distributed kinetics [1], [10], which is usually combined with narrow reaction zone approximation [11], [16], [20]. Within this approach, the Arrhenius temperature dependence is replaced by a step-function with height equal to the value of the Arrhenius function at a solution-dependent characteristic temperature. The exact choice of characteristic temperature is determined by the physics of the problem. Although the kinetics function in this setup is very simple, the strong nonlinearity of the Arrhenius kinetics is preserved by making the characteristic temperature dependent on the solution.

The advantage of the step-function kinetics is that the traveling wave solution can

generally be found analytically. The stability analysis for this solution is, however, very tedious, and researchers have resorted to additional simplifications, in particular via narrow-reaction-zone-type asymptotics that essentially lead back to point-source kinetics.

Typically, the front is postulated to have a width that is determined by a small nondimensional parameter ϵ (cf. (1.11)) [11], [16], [20]. Then the characteristic temperature is set as a limit of the temperature in an outer solution instead of prescribing the explicit formula for the characteristic temperature for a diffuse front and using a rigorous asymptotic procedure. Since the characteristic temperature for the traveling wave solution is indeed the same as the appropriate outer temperature limit at the interface, this approach successfully captures the stability threshold for the fronts propagating with a constant speed. On the other hand, narrow reaction zone approximations of step-function kinetics suffer from the same limitations as those of point-source kinetics.

To our knowledge, *there is no self-consistent distributed step-function kinetics formulation appropriate for modeling of diffuse fronts in the absence of material diffusion.* In this paper, we introduce a version of such kinetics in the context of one-dimensional FP/SHS. The benefits of using step-function kinetics are two-fold. The solution profiles for the (distributed) step-function kinetics closely resemble the solution profiles for the Arrhenius kinetics models over a wider range of system parameters than do the solution profiles for the point-source models. In particular, possible departures from the purely frontal reaction mechanism can be studied by using distributed step-function kinetics but not point-source kinetics. Second, the systems governed by step-function kinetics can be analyzed both analytically and numerically within the framework of a single model.

We perform the stability analysis for the traveling reaction wave in a diffuse-front setting and determine the stability boundary. In order to make the analysis tractable, we assume that the nondimensional parameter ϵ defined in (1.11) is small. This assumption appears in a number of other works [11], [16], [20] as a justification for considering sharp-front asymptotics of the step-function kinetics. The analysis of [3] indicates that there is no clear relationship between the value of ϵ and the width of the reaction zone, especially for pulsating fronts. Hence *we do not consider the reaction zone to be narrow* in our calculations.

Because the algebra involved in handling perturbations of the ground state and the resulting form of the dispersion relation are very complex, we handle some of the symbolic calculations and solve the dispersion relation in Maple. We obtain the stability threshold and show that it is in excellent agreement with numerical predictions and the existing sharp-front approximations. The combination of analytical computations and Maple has a clear advantage over the full numerical simulations in that it does not require numerical solution of a system of partial differential equations. Also the former requires a significantly shorter computational time (minutes versus hours) even for a single simulation run.

The computational costs are considerably lower for the step-function kinetics model than for the point-source kinetics model since the position of the front is not one of the unknowns in the problem. The numerically determined behavior of the front for the step-function kinetics is qualitatively similar to that under the Arrhenius kinetics [7], [18], as it shows a similar hierarchy of dynamics and similar solution features, including those that result from the nonfrontal mode of polymerization. The same spectrum of system behaviors has also been demonstrated for the point-source kinetics [9]; however, all bulk (nonfrontal) reactions are ignored in this setting.

1.2. Mathematical model. Although the mechanism of free-radical polymerization involves three steps—initiation, propagation, and termination—and five reagents—an initiator, an active initiator radical, an active polymer radical, a monomer, and a complete polymer chain [18]—we will make a number of simplifying assumptions that reduce the complexity of the underlying mathematical model. Hence we will assume [16], [18], [19] the following:

- The rates of reactions between the initiator radicals and the monomer and between the polymer radicals and the monomer are the same.
- The rate of change of total radical concentration is much smaller than the rates of their production and consumption.
- The initial concentration of the initiator is so large that it is not appreciably consumed during the polymerization process.
- Material diffusion is negligible compared to thermal diffusion.
- Both reagents and the final product are viscous enough to ignore convective effects and bubble formation.
- The test tube is sufficiently thin with the adiabatic boundary conditions on sidewalls so that the spatial dependence of the solution can be restricted to the axial variable.

Suppose that a test tube containing the monomer-initiator mixture occupies a region $\Omega \in \mathbf{R}^3$, and denote by $M(x,t)$ the monomer concentration and by $T(x,t)$ the temperature of the mixture at the point $x \in \Omega$ and the time $t > 0$. Then the process of free-radical polymerizations can be described [16] by what is known as a single-step effective kinetics model of monomer-to-polymer conversion:

$$\frac{\partial M}{\partial t} = -kMe^{\frac{E}{R_g T_b}\left(1-\frac{T_b}{T}\right)}, \tag{1.1}$$

$$\frac{\partial T}{\partial t} = \operatorname{div}(\kappa \nabla T) + kqMe^{\frac{E}{R_g T_b}\left(1-\frac{T_b}{T}\right)}, \tag{1.2}$$

where κ is a thermal diffusivity of the mixture/final product, k is the effective pre-exponential factor in the Arrhenius kinetics, R_g is the gas constant, E is the effective activation energy, and T_b is a reference temperature that will be specified below. The constant parameter q is $-\frac{\Delta H}{c\rho}$, where ΔH is the reaction enthalpy; c and ρ are the specific heat and the mixture density, respectively.

Throughout this paper we will assume that the test tube is one-dimensional, $\Omega = [-L\,, L]$, and that the thermal diffusivity κ is constant. (We ignore possible dependence of κ on temperature and degree of conversion $1 - M/M_0$.) Then the problem (1.1)–(1.2) reduces to

$$\frac{\partial M}{\partial t} = -kMe^{\frac{E}{R_g T_b}\left(1-\frac{T_b}{T}\right)}, \tag{1.3}$$

$$\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial x^2} + kqMe^{\frac{E}{R_g T_b}\left(1-\frac{T_b}{T}\right)}. \tag{1.4}$$

We will assume that T and M satisfy the constant initial conditions

$$T(x,0) = T_0, \quad M(x,0) = M_0, \quad x \in [-L\,, L]\,. \tag{1.5}$$

In order to initiate the reaction, heat must be supplied to the system; hence for the first t_0 seconds we will use the following boundary conditions

$$T_x(-L\,, t) = 0\,, \quad M_x(\pm L\,, t) = 0\,, \quad T(L\,, t) = T_b\,, \quad t \in (0\,, t_0)\,. \tag{1.6}$$

During the front propagation regime, we will impose the adiabatic and impenetrability boundary conditions on the temperature and the monomer concentration, respectively, by setting

$$T_x(\pm L\,,t) = 0\,, \quad M_x(\pm L\,,t) = 0\,, \quad t \geq t_0\,. \tag{1.7}$$

Multiplying (1.3) by q, adding the resulting equation to (1.4), integrating with respect to x, applying the adiabatic boundary conditions in (1.7), and setting

$$H := \int_{-L}^{L} (T + qM)\,dx \tag{1.8}$$

yields

$$\frac{dH}{dt} = 0\,, \tag{1.9}$$

expressing conservation of enthalpy in the system when $t > t_0$. Thermodynamics of the problem dictates that the temperature of the reaction products away from the front is given by

$$T_b \;=\; T_0 + qM_0\,, \tag{1.10}$$

where T_0 and M_0 are the initial temperature and concentration, respectively, in (1.5).

We introduce dimensionless parameters

$$\epsilon = \frac{R_g T_b}{E}\,, \quad Z = \frac{qM_0E}{R_g T_b^2}\,, \tag{1.11}$$

$$\tilde{t} = \frac{kt}{Z}\,, \quad \tilde{x} = \sqrt{\frac{k}{Z\kappa}}x\,, \quad \tilde{M} = \frac{M}{M_0}\,, \quad \tilde{T} = \frac{T - T_0}{T_b - T_0}\,.$$

Here T_b is as defined in (1.10), and the Zeldovich number Z is a nondimensionalized activation energy [15] constructed as a ratio of the diffusion temperature scale $T_b - T_0$ to the reaction temperature scale $\frac{R_g T_b^2}{E}$. Also, note that $Z\epsilon < 1$ in order to insure that the initial temperature of the mixture is greater than absolute zero. Then (after dropping tildes) we obtain

$$\frac{\partial M}{\partial t} = -ZM \exp\left(\frac{Z(T-1)}{\epsilon Z(T-1)+1}\right), \tag{1.12}$$

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + ZM \exp\left(\frac{Z(T-1)}{\epsilon Z(T-1)+1}\right). \tag{1.13}$$

From (1.5)–(1.7), the nondimensional temperature T and concentration M satisfy the following initial and boundary conditions:

$$T(x,0) = 0, \quad M(x,0) = 1, \quad x \in [-l\,,l]\,, \tag{1.14}$$

$$M_x(\pm l\,,t) = 0\,, \quad T_x(-l\,,t) = 0\,, \quad T(l\,,t) = 1\,, \quad t \in (0\,,\tau_0)\,, \tag{1.15}$$

$$M_x(\pm l\,,t) = 0\,, \quad T_x(\pm l\,,t) = 0\,, \quad t \geq \tau_0\,, \tag{1.16}$$

where $l = \sqrt{k/Z\kappa}L$ and $\tau_0 = k\,t_0/Z$.

2. Step-function kinetics. Stability analysis and numerical results.

2.1. Motivation. The essential, Arrhenius-like dependence of the reaction rate on temperature is a common feature of the full Arrhenius kinetics model, the point-source model, and the step-function kinetics model introduced below. As a consequence, all three models demonstrate similar sequences of frontal propagation modes, albeit at different threshold values of the bifurcation parameters. The advantage of the approximate models lies mainly with the simplicity of their analytical treatment.

The relatively simple point-source model is a formal asymptotic reduction of the Arrhenius kinetics model in which the reaction is restricted to a propagating interface between the fresh mixture of reagents and the final product. The rigorous proof of this reduction does not exist. In fact, in [3] we demonstrated for oscillating reaction waves corresponding to large values of the Zeldovich number that the concentration of the monomer does not evolve via the frontal mode alone. Numerical simulations in [3] have shown that the width of the main reaction zone periodically varies in time by several orders of magnitude, and there are always instances when the reaction zone is not narrow. Further, the propagation does not occur purely in the frontal regime, as the "pockets" of unreacted monomer are periodically left behind the reaction front. These pockets then slowly convert into the polymer via a nonfrontal mechanism.

Clearly, the nonfrontal reactions cannot be modeled within the point-source model. The purpose of distributed step-function-kinetics is to model diffuse interfaces and nonlocalized reactions while retaining the relative simplicity of an analytical treatment characteristic of the point-source models. In [3], we showed that the step-function-kinetics model introduced in the present paper reproduces all features of reaction dynamics observed for the Arrhenius kinetics models—including the monomer pockets and the oscillating width of the main reaction zone. That is, step-function kinetics is capable of capturing not only the sequence of bifurcations between the different modes of frontal propagation, but the solution features as well.

From now on, we will assume that ϵ is small; then the system of equations (1.12)–(1.13) reduces to

$$\frac{\partial M}{\partial t} = -ZMe^{Z(T-1)}\,, \tag{2.1}$$

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + ZMe^{Z(T-1)}\,. \tag{2.2}$$

When the second nondimensional parameter Z is large, this model has been approximated by using the step-function kinetics [2], [16] in a sharp-front limit as $Z \to \infty$. In this limit the model is identical to the sharp-front model of solid combustion with point-source kinetics at the interface considered in [12]. Here we introduce and investigate the behavior and the stability of solutions of the (distributed) step-function kinetics model and compare the results to both Arrhenius kinetics and point-source kinetics. The step-function kinetics can be thought of as an intermediate approximation between point-source kinetics and Arrhenius kinetics in that it yields to relatively straightforward analytical as well as numerical analyses. As is well known, although the systems modeled with Arrhenius kinetics can be studied numerically, the stability analysis for such systems is very difficult, as no analytical expressions are available for traveling wave solutions. On the contrary, for point-source kinetics (sharp-interface approach) the stability analysis is straightforward, while the numerical computations are difficult, as one has to track a free boundary.

A similar model was considered in [1] for a more general case when the Lewis number Le (the ratio of thermal and material diffusivities) is *not* necessarily large. This work has served as a basis for numerous studies in FP and combustion. As will be explained shortly, the straightforward reduction of the treatment in [1] to (2.1)–(2.2) cannot be considered a priori within an asymptotic procedure as $Le \to \infty$, as it requires additional assumptions. These assumptions will be introduced below and studied both analytically and numerically in order to verify their validity.

In the step-function kinetics model, the reaction is assumed to occur in the temperature range $[T_i\,, T_p]$, and the Arrhenius term $Z\,e^{Z(T-1)}$ in (2.1)–(2.2) is replaced by the step-function

$$K(T) := \begin{cases} 0\,, & T < T_i\,, \\ A(T_p)\,, & T \geq T_i\,. \end{cases} \tag{2.3}$$

Here T_p is the burnout temperature of the mixture immediately upon the completion of the reaction (or, analogously, the temperature at the product end of the reaction zone), and T_i is the ignition temperature. The temperature T_p is, generally, the highest temperature of the mixture, and, unless the front is a steadily propagating wave, both temperatures T_p and T_i as well as the kinetic function $K(T)$ depend on time.

The step-function-type and Arrhenius-type source terms have two important common features—the reactions at both the low-temperature and the product zones are either absent or negligible and the speed of propagation of the reaction wave is temperature-dependent. By selecting a proper height $A(T_p)$ and a jump location T_i in the definition of the step-function, we can obtain the "best" qualitative match between the properties of solutions of the Arrhenius and step-function kinetics models.

Note that the dependence of A on T_p can be arbitrary, and T_i and T_p are essentially "fitting" parameters—we claim neither that the step-function approximation of Arrhenius kinetics is mathematically rigorous nor that step-function kinetics can be obtained from Arrhenius kinetics as a result of a limiting procedure. Rather, we observe that the behavior of solutions of two respective systems is in a qualitative agreement over a wide range of the system characteristics.

Even though the temperatures T_i and T_p have a clear physical interpretation as the temperatures at which the (Arrhenius-type) reaction initiates and completes, respectively, the values of T_i and T_p are not unique, since the monomer concentration in the Arrhenius model is a continuous nonvanishing function of space and time. Instead, we identify the valid ranges for the ignition and burnout temperatures and show that the results are not sensitive to the exact choices of T_i and T_p.

The downside of this approach is that it can lead to a number of different step-function-type kinetics models. On the other hand, the flexibility of choosing A, T_i, and T_p allows for different step-function kinetics for systems that occupy well-separated regions in the parameter space. In the present paper, we concentrate on the case when $\epsilon \ll 1/Z \ll 1$—and the reaction is usually understood as being purely frontal. For this relationship between the nondimensional parameters, it is our experience that, as long as T_i and T_p are "reasonable" (e.g., the concentration of the monomer at the burnout temperature is small, but not too small), the solutions remain qualitatively similar.

2.2. Formulation and traveling wave solution. Here we follow formal arguments along the lines of [21] to examine the relationship between the temperatures

T_i and T_p and to establish the expression for A. Then we discuss the proper choice of T_p.

The main idea is to preserve the dependence between the temperature and the speed of the reaction front when replacing the full kinetics by an approximate kinetics. Formally, for Arrhenius kinetics, the fast reaction occurs in a narrow temperature interval $[T_p - 1/Z\,, T_p]$, where $1/Z \ll 1$ [21]; therefore we set

$$T_i = T_p - \frac{1}{Z}\,.$$

The energy equation for the steady reaction wave propagation (in front-attached coordinates, $x \to x - vt$) is

$$-vT_x = (T_x)_x + M\,\Phi(T)\,, \tag{2.4}$$

where v is the velocity of the front and $\Phi(T)$ is the rate of heat release due to the reaction. The heat released is used to heat up the reacting mixture and to preheat the fresh reagents to the reaction temperature; the terms responsible for these processes are $-\,v\,T_x$ and $(T_x)_x$, respectively. Since $1/Z \ll 1$, we can neglect the right-hand side (RHS) of (2.4) to obtain that

$$(T_x)_x + M\,\Phi(T) = 0\,,\ \text{where } T_p - \frac{1}{Z} < T < T_p\,,$$

in the main reaction zone. Then, multiplying by T_x and integrating, we have

$$\left|T_x^-\right| \approx \left(2\int_{T_p-\frac{1}{Z}}^{T_p} M\,\Phi(T)\,dT\right)^{\frac{1}{2}}\,,$$

where $|T_x^-| = vQ$ is the net flux from the main reaction zone toward the fresh mixture of reagents and Q is the (nondimensional) heat generated by the reaction per unit volume. Here we assume that the heat flux toward the (cold) mixture of reagents is significantly larger than the flux toward the products of the reaction. Further, we assume that both M and T are monotone in the main reaction zone so that we can interpret M as a function of T in the integral above. We conclude that

$$Q\,v \approx \left(2\int_{T_p-\frac{1}{Z}}^{T_p} M\,\Phi(T)\,dT\right)^{\frac{1}{2}}\,, \tag{2.5}$$

where the integral in temperature is taken over the whole temperature region where the reaction is not negligible [21]. Since the temperature zone $[T_p - 1/Z\,, T_p]$ is narrow, we approximate the Arrhenius term $\Phi(T)$ by its maximum value $\Phi(T) \approx \Phi(T_p) = Ze^{Z(T_p-1)}$. Then (cf. [8])

$$Q\,v \approx \left(2\int_{T_p-\frac{1}{Z}}^{T_p} M\,Z\,e^{Z(T_p-1)}\right)^{\frac{1}{2}}\,. \tag{2.6}$$

If we assume that $\Phi(T) = K(T)$ in (2.5), where $K(T)$ is given by (2.3), we obtain an expression of the same form as (2.6) once we set

$$A(T_p) = Z\,e^{Z(T_p-1)}\,. \tag{2.7}$$

Hence, given the similar profiles for M, the speed of front propagation is approximately the same for both Arrhenius and step-function kinetics with A given by (2.7).

Note that, when Z is large, the integral value of the kinetic function over the interval from the initial to the burnout temperature is approximately the same for both step-function kinetics and Arrhenius kinetics. Indeed,

$$\int_0^{T_p} K(T)\,dT = e^{Z(T_p-1)}\,,$$

while

$$\int_0^{T_p} Z\,e^{Z(T-1)}\,dT = e^{Z(T_p-1)} - e^{-Z}\,.$$

Now, to fix ideas, we need a rigorous definition of the burnout temperature T_p. In [1] this quantity is defined as the temperature at the end of the reaction zone on the boundary $x_b(t)$ separating the reacting mixture and the products of the reaction. Since the reaction is negligible in the products zone, it was assumed in [1] that the concentration of the reagent vanishes at $x_b(t)$ and, hence, $T_p(t) = T(x_b(t), t)$. Both T_p and x_b are unknown and are determined as a part of the solution procedure.

The spatial domain in [1] was separated into three zones: preheating zone, reaction zone, and products zone. When traveling-wave solutions are sought subject to boundary conditions at infinity, the problem within each zone consists of two second order ordinary differential equations with solutions that are "glued" together so that the temperature, the reagent concentration, and their derivatives are continuous across all interfaces.

Consider now the same model when the inverse of the Lewis number is equal to zero. Because monomer diffusion is neglected, the concentration equation becomes a first order ordinary differential equation, reducing the number of boundary conditions within each zone—either we have to consider a singularly perturbed problem in terms of the Lewis number, or we can no longer define x_b as a point at which the concentration of the monomer will vanish. Indeed, either it will cause the concentration to vanish everywhere in the domain, or $x_b \to \infty$ as $Le \to \infty$.

As has been already noted, the step-function kinetics approach has been widely applied in a number polymerization studies. Step-function kinetics was used to investigate polymerization waves for two-species [11] and four-species models [19] as well as for two-step and one-step polymerization models in the nonadiabatic case [10]. The problem of defining the temperature of the reaction cutoff has generally been circumvented by assuming that the reaction zone remains narrow. In [10], for example, it was assumed that the heat losses lead to a temperature profile with a maximum T_m within the reaction zone. The reaction is then cut off below the ignition temperature T_f, which itself depends on T_m. The value of T_m is not known in advance and has to be determined as a part of the solution procedure. Even in the simplest case, the solution to this problem is quite complicated and requires additional assumptions; in [10] it was assumed that the reaction zone had a small width of order $0 < \epsilon \ll 1$.

Subsequently, the step-function kinetics was used in conjunction with the narrow reaction zone assumption to study the stability of a uniformly propagating front in various polymerization models in the presence [20] and in the absence [16] of heat losses. The width of the front in both instances was assumed to be of order ϵ, and T_f was set to be equal to $T_p(1-\epsilon)$. Then $T_f = T_p$ in the limit $\epsilon \to 0$, thus reducing the reaction term to a jump condition on the gradient of the temperature on the interface.

Here, instead of either considering asymptotics in terms of the Lewis number or assuming that the reaction zone is narrow, we will set $T_p(t) = T(x_b(t), t)$, where $x_b(t)$ is a point at which the monomer concentration falls below a small prescribed threshold value $M(x_b(t), t) = \beta > 0$.

Given this definition of the burnout temperature, $K(T)$ is actually a functional $K[M, T]$, and the dependence of K on T is nonlocal. The methodology for choosing the parameter β will be discussed below. Essentially, β can be interpreted as the concentration of monomer in the transitional layer between the inner region adjacent to the reaction front and the outer product region. Since the temperature in this layer is approximately constant in spatial variables, the exact value of β should not have a significant influence on the predictions of our model. This is indeed the case, as will be demonstrated below. The range of reasonable values of β appears to be "robust" in the sense that it is independent of the other parameters of the problem. The magnitude of β is of order $10^{-2} \approx 1/Z^2 \ll \frac{1}{Z}$ for the parameter regimes that we have considered.

The formal justification for our choice of $x_b(t)$ is that the burnout temperature T_p is defined as the maximum temperature in the main reaction zone that is reached at the point of full monomer conversion. Due to the exponential character of the model, the concentration of monomer never vanishes, and we have to choose a threshold concentration below which we can assume that the reaction has terminated. If we set this threshold too low, then the temperature at $x_b(t)$ will be measured far away from the front and deep in the product zone. In this case, $T_p \approx const = 1$ and the dependence of the front velocity on temperature will be lost. On the other hand, if the threshold concentration of the monomer is set to be too high, then T_p will be too low and the front will fail to propagate.

Similar to, e.g., [16], we imposed the condition that $\epsilon \ll 1$. Although, typically $1/Z$ and ϵ are roughly of the same order of magnitude—$1/Z\epsilon \approx 3$ in this paper—*the width of the main reaction zone is not determined by* ϵ alone and does not have to be small.

Given our choice of $K(T)$ in (2.3), the step-function approximation of the model (2.1)–(2.2) is

$$\frac{\partial M}{\partial t} = -MK(T)\,, \tag{2.8}$$

$$\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + MK(T)\,. \tag{2.9}$$

Since we assume that the reaction begins when the temperature reaches the threshold value of $T_p - \frac{1}{Z}$, we will associate with this temperature the position $\psi(t)$ of the *reaction front* by defining $\psi(t)$ implicitly through the relation

$$T(\psi(t), t) = T_p(t) - \frac{1}{Z}\,.$$

In order to obtain traveling-wave solutions and study their stability, we introduce the front-attached spatial coordinate $y = x - \psi(t)$. Then the system of equations (2.8)–(2.9) can be written as

$$\frac{\partial M}{\partial t} - \psi'(t)\frac{\partial M}{\partial y} = -ZMe^{Z(T_p-1)}\eta(y)\,, \tag{2.10}$$

$$\frac{\partial T}{\partial t} - \psi'(t)\frac{\partial T}{\partial y} = \frac{\partial^2 T}{\partial y^2} + ZMe^{Z(T_p-1)}\eta(y)\,, \tag{2.11}$$

where

$$\eta(y) = \begin{cases} 0\,, & \text{if } y < 0\,, \\ 1\,, & \text{if } y \geq 0\,, \end{cases}$$

is the Heaviside function.

We will assume that $y \in \mathbf{R}$ and that the following boundary conditions at infinity (cf. dimensional boundary conditions (1.5)–(1.7) on a finite domain) are satisfied:

$$T(-\infty, t) = 0\,, \qquad T_y(\infty, t) = 0\,, \tag{2.12}$$

$$M(-\infty, t) = 1\,, \qquad M(\infty, t) = 0\,. \tag{2.13}$$

These must be supplemented by the conditions on M and T when $y = 0$. By the definition of $\psi(t)$, we immediately have that

$$T(0, t) = T_p(t) - \frac{1}{Z}\,. \tag{2.14}$$

We will require that both monomer concentration and the derivative of the temperature are continuous across the polymerization front, that is,

$$[T_y]_{y=0} = [M]_{y=0} = 0\,, \tag{2.15}$$

where $[f]_{y=a} = f(a^+) - f(a^-)$ denotes the jump of the function f at $y = a$.

Further, by the definition of T_p, an additional condition

$$T\left(x_b(t)\,, t\right) = T_p\,, \quad \text{where } M\left(x_b(t), t\right) = \beta\,, \tag{2.16}$$

must be satisfied. Here we assume that the monomer concentration is a monotone function of x for all $t > 0$. In general, as has been pointed out in [3], this assumption may not be correct for a nonuniformly propagating reacting front. This complication can be easily circumvented, however, by assuming that $x_b(t)$ is the leftmost point in the reaction zone satisfying the condition $M\left(x_b(t), t\right) = \beta$.

First, we seek traveling-wave solutions of (2.10)–(2.11) propagating in the negative y-direction. We set $\psi'(t) = -v$, where v is a positive constant, and suppose that $\frac{\partial M}{\partial t} \equiv \frac{\partial T}{\partial t} \equiv 0$. Then (2.10)–(2.11) reduce to the system of the ordinary differential equations

$$v\frac{d\bar{M}}{dy} = -Z\bar{M}e^{Z(T_p-1)}\eta(y)\,, \tag{2.17}$$

$$v\frac{d\bar{T}}{dy} = \frac{d^2\bar{T}}{dy^2} + Z\bar{M}e^{Z(T_p-1)}\eta(y)\,, \tag{2.18}$$

where $\bar{M}$ and $\bar{T}$ are time-independent solutions of (2.10)–(2.11).

Fix Z and β. Denote the temperature at the reaction front, as in (2.14), by

$$T_f := \bar{T}(0) = T_p - \frac{1}{Z}\,, \tag{2.19}$$

and set

$$A := Z\,e^{Z(T_p-1)} = Z\,e^{Z(T_f-1)+1}\,, \tag{2.20}$$

to be the strength of the kinetics term. The problem (2.17)–(2.18), (2.12)–(2.16) admits the following set of solutions:

$$\bar{M}(y) = \begin{cases} 1\,, & y < 0\,, \\ e^{-\frac{A\,y}{v}}\,, & y \geq 0\,, \end{cases} \qquad \bar{T}(y) = \begin{cases} \dfrac{(1-\beta)Z-1}{(1-\beta)Z} e^{v\,y}\,, & y < 0\,, \\ 1 - \dfrac{1}{(1-\beta)Z} e^{-\frac{A\,y}{v}}\,, & y \geq 0\,, \end{cases} \tag{2.21}$$

where

$$A = Ze^{-\frac{\beta}{1-\beta}}\,, \quad v = \sqrt{\frac{Ze^{-\frac{\beta}{1-\beta}}}{Z(1-\beta)-1}}\,, \quad \bar{T}_f = 1 - \frac{1}{(1-\beta)Z}\,. \tag{2.22}$$

Furthermore, because of the constraint (2.16), the reaction zone extends from $y = 0$ to $y = \bar{y}_b$, where

$$\bar{y}_b := -\frac{v \ln \beta}{A} = -\ln \beta \sqrt{\frac{e^{\frac{\beta}{1-\beta}}}{Z\left(Z(1-\beta)-1\right)}}\,, \tag{2.23}$$

so that

$$\bar{M}\left(\bar{y}_b\right) = \beta\,, \qquad \bar{T}\left(\bar{y}_b\right) = \bar{T}_f + \frac{1}{Z}\,. \tag{2.24}$$

Our choice of β is dictated by the requirement that the reaction zone have a width of order Z^{-1}. Then $\ln \beta$ should be an order-$O(1)$ quantity, independent of Z. As we demonstrate below, choosing β in this range leads to solution behavior that closely resembles what is observed for the Arrhenius kinetics and its point-source approximation.

2.3. Stability analysis. Next, we consider the following perturbations of the base state (2.21)–(2.23):

$$\begin{aligned} M(y\,,t) &= \bar{M}(y) + \delta\, e^{\omega\, t} \mu(y)\,, \\ T(y\,,t) &= \bar{T}(y) + \delta\, e^{\omega\, t} \tau(y)\,, \\ T_f(t) &= \bar{T}_f + \delta\, e^{\omega\, t} \xi\,, \\ \psi(t) &= -vt + \delta\, e^{\omega\, t}\,, \\ y_b(t) &= \bar{y}_b + \delta\, e^{\omega\, t} \zeta\,, \end{aligned}$$

where $0 < \delta \ll 1$ and $\omega \in \mathbf{C}$.

First, we linearize the condition (2.16). To the first order in δ we have

$$\begin{aligned} \beta = M\left(y_b(t)\,,t\right) &= \bar{M}\left(y_b(t)\right) + \delta\, e^{\omega\, t} \mu\left(y_b(t)\right) \\ &\sim \bar{M}\left(\bar{y}_b\right) + \delta\, e^{\omega\, t} \left(\bar{M}'(\bar{y}_b)\zeta + \mu\left(\bar{y}_b\right)\right) \end{aligned}$$

and

$$\begin{aligned} T_f(t) = T\left(y_b(t)\,,t\right) &= \bar{T}\left(y_b(t)\right) + \delta\, e^{\omega\, t} \tau\left(y_b(t)\right) \\ &\sim \bar{T}\left(\bar{y}_b\right) + \delta\, e^{\omega\, t} \left(\bar{T}'(\bar{y}_b)\zeta + \tau\left(\bar{y}_b\right)\right). \end{aligned}$$

Then, using the perturbation of $T_f(t)$ and (2.23), we obtain

$$\bar{M}'(\bar{y}_b)\zeta + \mu\,(\bar{y}_b) = 0\,, \qquad \bar{T}'(\bar{y}_b)\zeta + \tau\,(\bar{y}_b) = \xi\,. \tag{2.25}$$

It follows from (2.21), (2.24), and (2.25) that

$$\xi = \tau\,(\bar{y}_b) - \frac{\bar{T}'(\bar{y}_b)}{\bar{M}'(\bar{y}_b)}\mu\,(\bar{y}_b) = \tau\,(\bar{y}_b) + \frac{1}{(1-\beta)Z}\mu\,(\bar{y}_b)\,. \tag{2.26}$$

Linearization of (2.10)–(2.15) yields the following problems:

$$\begin{cases} v\mu' + \omega\mu = \omega\bar{M}'\,, & y < 0\,, \\ v\mu' + (\omega + Z)\,\mu = \omega\bar{M}' - Z^2\xi\bar{M}\,, & y \geq 0\,, \end{cases} \tag{2.27}$$

and

$$\begin{cases} \tau'' - v\tau' - \omega\tau = -\omega\bar{T}'\,, & y < 0\,, \\ \tau'' - v\tau' - \omega\tau = -\omega\bar{T}' - Z\left(\mu + Z\xi\bar{M}\right)\,, & y \geq 0\,, \end{cases} \tag{2.28}$$

subject to the boundary conditions

$$\tau(-\infty) = \tau'(\infty) = [\tau']_{y=0} = 0\,, \qquad \tau(0) = \xi\,, \tag{2.29}$$

$$\mu(-\infty) = \mu(\infty) = [\mu]_{y=0} = 0\,, \tag{2.30}$$

and (2.26).

As has already been pointed out, $\beta \ll \frac{1}{Z}$; however, the value of $\ln\beta$ that enters into $\bar{y}_b$ is large. We simplify the computations by keeping $\ln\beta$ as a parameter in our calculations, and otherwise restrict our analysis to the $O(1)$-approximation of (2.26)–(2.30) in β by setting $\beta = 0$. Then the base state can be written as

$$\bar{M}(y) = \begin{cases} 1\,, & y < 0\,, \\ e^{-\frac{Z\,y}{v}}\,, & y \geq 0\,, \end{cases} \qquad \bar{T}(y) = \begin{cases} \dfrac{1}{v^2}e^{v\,y}\,, & y < 0\,, \\ 1 - \dfrac{1}{Z}e^{-\frac{Z\,y}{v}}\,, & y \geq 0\,, \end{cases} \tag{2.31}$$

where

$$v = \sqrt{\frac{Z}{Z-1}}\,, \quad \bar{T}_f = 1 - \frac{1}{Z}\,, \quad \bar{y}_b = -\frac{\ln\beta}{\sqrt{Z(Z-1)}}\,. \tag{2.32}$$

The solution to (2.26)–(2.30) and the dispersion relation satisfied by the parameters Z and ω is very complicated, in particular due to the coupling (2.26), and was obtained using the Maple computer algebra system. In order to find the stability boundary, the real part of ω was set equal to zero, $\omega = i\phi$, and the resulting system of equations was solved in Maple for Z and ϕ.

The dependence on $\ln\beta$ of the critical value of the Zeldovich number Z and the dimensional period of front velocity oscillations $\lambda = \frac{2\pi Z}{k\phi}$ at the critical Z are shown in Figure 2.1. Note that the stability boundary is in remarkable agreement with the sharp-front stability boundary obtained in [12] ($Z = 2\left(2 + \sqrt{5}\right) \approx 8.47$) when the reaction kinetics is approximated by the point-source on the front. The same critical value of the Zeldovich number Z as in [12] has been obtained by using the sharp-front limit $Z \to \infty$ of the model with step-function kinetics. This result may be related to the fact that the reductions of Arrhenius kinetics to point-source kinetics and to

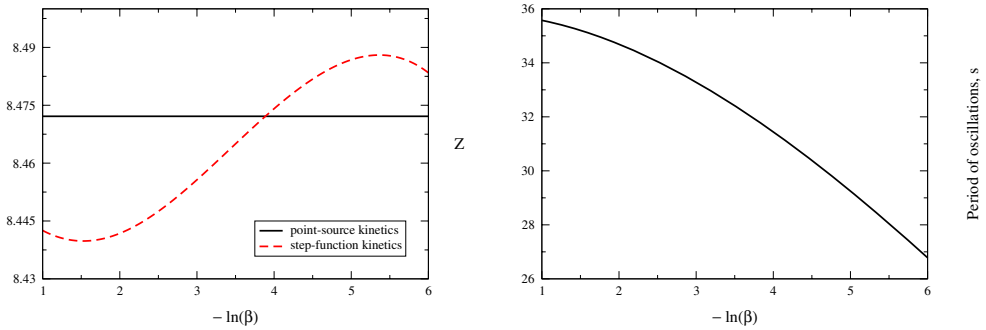

FIG. 2.1. *Dependence of the critical value of the Zeldovich number Z and the dimensional period of velocity oscillations λ on β.*

step-function kinetics are based on similar arguments that enforce the same speed of front propagation for both approximate kinetics and Arrhenius kinetics.

Analysis analogous to that in [16] leads to the same value of the stability boundary as in point-source kinetics, once the jump condition for the balance of heat on the front is imposed in place of the similar one-sided condition employed in [16]. The latter condition was derived on the basis of generalized matched asymptotic expansions [15] and leads to a stability threshold of $Z = 6$. This value disagrees with predictions of other models.

The value of the artificial parameter β can be "tuned" so that the stability threshold coincides with that obtained in [12]. Further, the dependence of the period of oscillations on β is much stronger than that for the critical Zeldovich number.

Although the stability boundaries for the approximate models discussed here are essentially the same ($Z \approx 8.47$), the stability boundary for the model with full Arrhenius kinetics [17] and small ϵ is slightly higher ($Z \approx 9.1$).

2.4. Numerical results. To verify these conclusions, we conducted numerical experiments with the model (2.8)–(2.9), with the Arrhenius kinetic function replaced by the step function.

The system of equations was solved numerically using a finite difference method with semi-implicit time integration. The physical model has no-flow homogeneous Neumann boundary conditions at both ends of the domain. For some parameter combinations, however, we found it necessary to apply Dirichlet boundary condition $T(L, t) = T_b$, where T_b is defined in (1.10), at the ignition end of the domain for a short period of time to initiate the reaction, and then switch to the homogeneous Neumann boundary condition. Numerical experiments have demonstrated that the long-term behavior of the reaction-diffusion equation system studied in this paper is not affected by the application of the Dirichlet boundary condition during the initiation stage.

At each time step, the location of the reaction front was defined as the first grid point, going from left to right, at which the concentration of the monomer drops below 50% of the initial value. The average velocity of the front was calculated by

$$v = a\frac{\Delta x}{\Delta t},$$

where Δx is the distance between grid points, Δt is the size of the time step, and

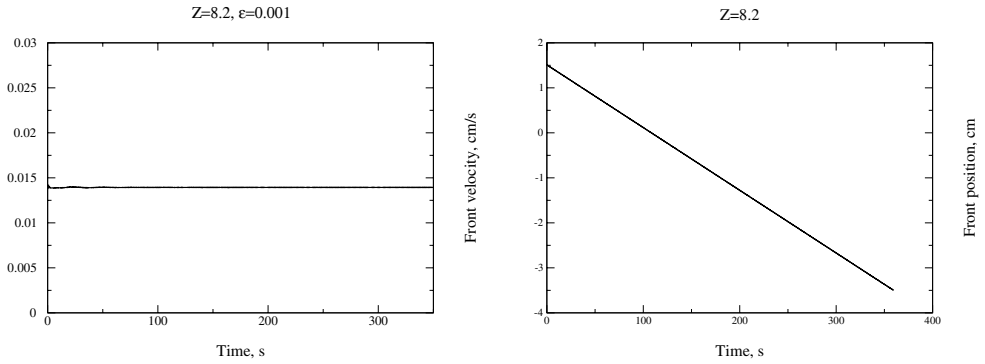

FIG. 2.2. *Reaction front velocity and position when* $Z = 8.2$ *and* $\epsilon = 10^{-3}$.

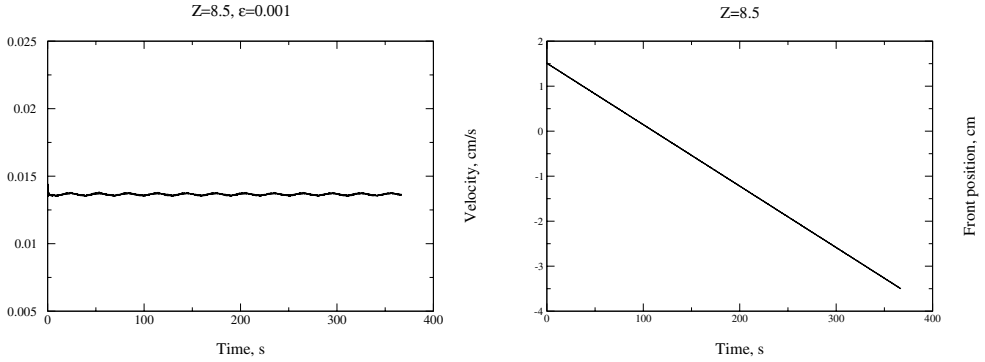

FIG. 2.3. *Reaction front velocity and position when* $Z = 8.5$ *and* $\epsilon = 10^{-3}$.

a is the number of grid intervals that the front travels through in Δt seconds. Note that it may take multiple, say m, time steps for the front to travel through one grid interval. In that case, we have $a = \frac{1}{m}$.

Since we do not use an adaptive scheme, we used uniform grid refinement technique, which clearly indicated numerical convergence and demonstrated that all sharp features are resolved and grid-independent.

We will assume that the parameters

$$q = 33.24 \text{ KL/mol}\,, \quad \kappa = 0.0014 \text{ cm}^2/\text{s}\,, \quad k = 1 \text{ s}^{-1}\,, \quad T_b = 500 \text{ K}$$

are fixed; then the state of the system is completely determined once the values of Z and ϵ are specified. The length of the spatial domain (test tube) in our computations varies from 6 cm to 10 cm, depending on the characteristic time scale of the process of interest.

Using this choice of system parameters, we varied Z while keeping $\epsilon = 1 \cdot \text{E-3}$ and $\beta = 2 \cdot \text{E-2}$ fixed. Since $\ln 0.02 \approx -3.92$, the analytical stability threshold is almost the same (Figure 2.1) as the one predicted by the stability analysis for the point-source kinetics [12].

Our simulations predict that the stability threshold is $Z \approx 8.5$. The typical velocity and the front position profiles are presented in Figures 2.2–2.5. The front

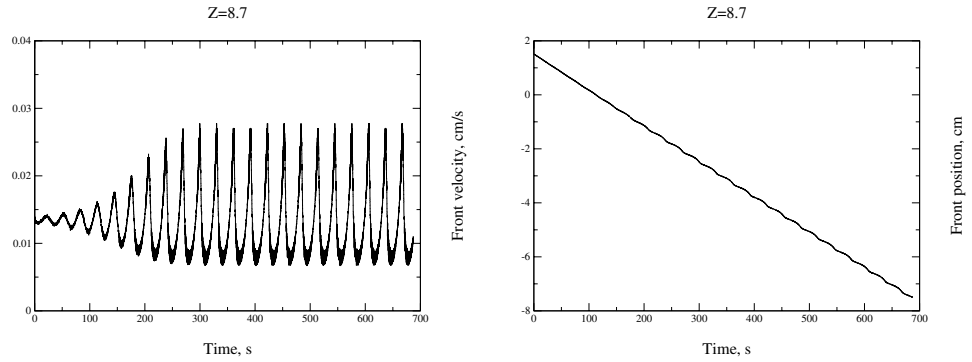

FIG. 2.4. *Reaction front velocity and position when* $Z = 8.7$ *and* $\epsilon = 10^{-3}$.

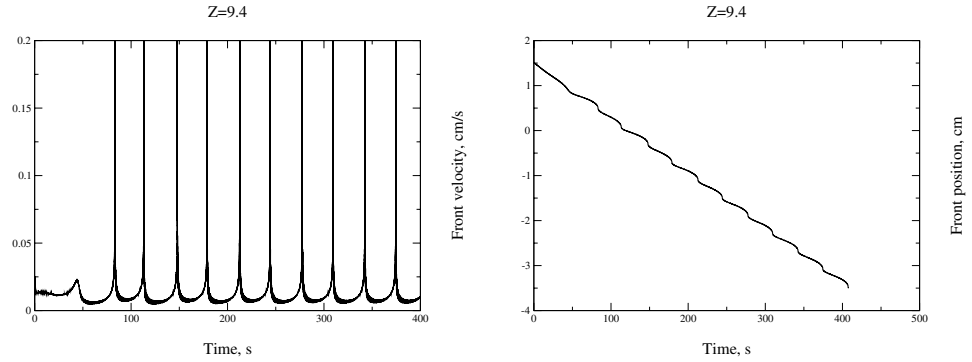

FIG. 2.5. *Reaction front velocity and position when* $Z = 9.4$ *and* $\epsilon = 10^{-3}$.

propagates with the constant velocity when $Z = 8.2$; the velocity oscillations appear when $Z = 8.5$ and become more pronounced once Z is increased ($Z = 8.7$). Further increase in Zeldovich number shows that the behavior of the system is similar to the behavior of a system reacting via Arrhenius kinetics—for instance, the "period doubling" can be observed for $Z = 9.4$.

Another similarity with Arrhenius kinetics was demonstrated in [3], where we showed that pulsating fronts in systems governed both by Arrhenius kinetics and by the step-function kinetics evolve via a combination of bulk and frontal modes. There we showed that, in fact, combustion can be considered to be purely frontal only for uniformly propagating reaction waves in systems governed by kinetics that ignore low-temperature bulk reactions. That is, for Zeldovich numbers beyond the first critical threshold (pulsating mode) there *always* exists a nonfrontal component of the dynamics. In particular, we showed that the monomer profile periodically becomes nonmonotone in regions experiencing high front acceleration, and pockets of unreacted monomer form behind the rapidly advancing front. These pockets later disappear via bulk polymerization. Note that both bulk contribution and the related solution features are *always absent* from the sharp-front–based models, since the reaction is limited to the front.

The numerically determined period of velocity oscillations for $Z = 8.5$ near the threshold of instability is approximately $\lambda \approx 31$ s. This value is almost identical

to the value obtained through the stability analysis (Figure 2.1). We conclude that the predictions of the stability analysis are in very close agreement with numerical simulations.

3. Conclusions. In the context of FP, we introduced a precise definition of distributed step-function kinetics without resorting to a sharp-front approximation. This kinetics is appropriate for simulating the behavior of one-dimensional large-Lewis-number reaction systems governed by Arrhenius kinetics. Among the interesting features of the distributed step-function kinetics is the numerical and analytical tractability of the corresponding model that takes into account possible bulk reactions behind the advancing front.

We demonstrated numerically that dynamics of fronts in systems modeled with distributed step-function kinetics and in systems modeled with Arrhenius kinetics are qualitatively the same for the time scales at which bulk reactions ahead of the front can be neglected. Further, we showed that the stability threshold of the traveling wave solution for the step-function kinetics is in excellent agreement with its numerically determined value as well as with other existing kinetics approximations.

Acknowledgments. The author would like to express his gratitude to L. K. Gross, V. A. Volpert, and J. Zhu for valuable discussions.

STATICS OF POINT JOSEPHSON JUNCTIONS IN A MICROSTRIP LINE*

J. G. CAPUTO†‡ AND L. LOUKITCH†

Abstract. We model the static behavior of point Josephson junctions in a microstrip line using a one-dimensional linear differential equation with delta distributed sine nonlinearities. We analyze the maximum current γ_{max} crossing the microstrip for a given magnetic field H. In particular, we establish its periodicity and analyze how it is affected by the geometry, length, type of current feed, position, and area of the junctions. For the common situation of small currents, we show that γ_{max} can be obtained by a simple formula, the magnetic approximation. This model is in excellent agreement with measurements obtained for real devices.

Key words. Josephson junctions, sine Gordon equation, Dirac delta function, optimization

1. Introduction.

The coupling of two low T_c superconductors across a thin oxide layer is described by the Josephson equations [13]

$$V = \Phi_0 \frac{d\phi}{dt}, \quad I = sJ_c \sin(\phi), \tag{1.1}$$

where V and I are, respectively, the voltage and current across the barrier; s is the contact surface; J_c is the critical current density; and $\Phi_0 = \hbar/2e$ is the reduced quantum flux. These two Josephson relations together with Maxwell's equations imply the modulation of DC current by an external magnetic field in the static regime and the conversion of AC current into microwave radiation [1, 14]. Other applications include rapid single flux quantum logic electronics [14] and microwave signal mixers used in integrated receivers for radio-astronomy [17, 4]. In all these systems there is a characteristic length which reduces to the Josephson length, λ_J, the ratio of the electromagnetic flux to the quantum flux Φ_0 for standard junctions.

For many applications and in order to protect the junction, Josephson junctions are embedded in a so-called microstrip line which is the capacitor made by the overlap of the two superconducting layers. This is the "window geometry" where the phase difference between the top and bottom layer satisfies an inhomogeneous two-dimensional (2D) damped driven sine Gordon equation [9] resulting from Maxwell's equations and the Josephson constitutive relations (1.1). The damping is due to the normal electrons, and the driving is through the boundary conditions with an external current or magnetic field applied to the device.

Even in the static regime ($V \equiv 0$) the 2D problem is complicated because of the multiplicity of solutions due to the sine term. However, flux penetration occurs along the direction of the magnetic field, so one direction dominates the other. A quantity measured by experimentalists is the maximum (static) current $I_{\max}(H)$, which can cross the device for a given magnetic field H. This gives information

on the quality of the junctions. An important issue is how defects in the coupling will affect this maximum current. In particular, high T_c superconductors can be described as Josephson junctions where the critical current density is a rapidly varying function of the position, due to grain boundaries. Fehrenbacher, Geshkenbein, and Blatter [10] calculated $I_{\max}(H)$ for such disordered long Josephson junctions and for a periodic array of defects. Experiments were also done by Itzler and Tinkham on large 2D disordered junctions [11, 12]. However, the overall picture is complex, and it is difficult to obtain geometric information on the junction from the curve $I_{\max}(H)$. The analysis of such a 2D problem [8] provided bounds on the gradient of the solution that were independent of the area of the junctions, so that little information could be obtained on $I_{\max}(H)$. However, the study [8] proved the existence of solutions and the convergence of the Picard iteration to obtain them.

Small junctions of length $w_i < \lambda_J$ are easier to study and lead to the well-known $I_{\max}(H) = \sin(Hw_i)/H$ [1]. Two such junctions are commonly associated to form a superconducting quantum interference device (SQUID), now routinely used to measure magnetic fields. More junctions can be used to form arrays [18] that can bear more critical current and are more flexible than a long junction because the area of the junction components and their position can be varied. When the junctions are closer than λ_J, such arrays behave as a long junction and could be used as microwave generators. Almost all models are discrete lumped models where the effect of the space between junctions is neglected. In particular, the interaction of the junctions through this passive region has always been neglected. This makes it difficult to describe junctions of different areas, placed nonuniformly in the microstrip. This is why up to now mostly equidistant and identical junctions have been considered. To overcome these difficulties we recently introduced a continuous/discrete model that preserves the continuity of the phase and its normal gradient across the junction interface and where the phase is assumed constant in the junctions. The 1D dynamics [6] of one junction in a cavity revealed that the junction could stop waves across the cavity or enhance them throughout. In [5] this model was used to calculate $I_{\max}(H)$ for a misaligned SQUID in a 2D cavity. Nonuniform arrays of junctions that are generalized SQUIDs have been produced and analyzed in particular by Salez and coworkers at the Observatory of Paris [17, 4], and our analysis is in excellent agreement with the measured $I_{\max}(H)$.

In this article we will concentrate on the 1D static problem. We justify our continuous/discrete model and show that it allows an in-depth analysis that was out of reach in the general 2D case. In particular, we will show the properties of $I_{\max}(H)$, its periodicity, its regularity, the relation between different types of current feeds, and how it is affected by the position of the array in the microstrip. In addition, we introduce and justify the "magnetic approximation" in which many details of $I_{\max}(H)$ can be controlled. Specifically in section 2 we introduce our model, and we give preliminary analytical results in section 3. Section 4 details the intrinsic properties of the maximal current as a function of the magnetic field: its periodicity, the relation between the inline and overlap current feed, and the simple magnetic approximation. Section 5 introduces two numerical ways to solve the problem. In section 6, we study a SQUID and examine the effect of a little difference between the junction parameters, and we compare this to the experiment. Section 7 deals with devices with more junctions; there we analyze the effect of separating one junction from the others and show the agreement with the experimental results. After concluding in section 8, we give details of the proofs in section 9.

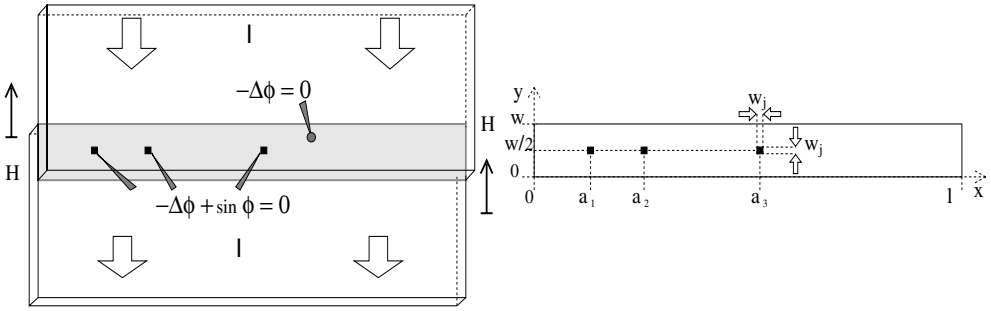

FIG. 2.1. *The left panel shows the top view of a superconducting microstrip line containing three Josephson junctions; H, I, and ϕ are respectively the applied magnetic field, current, and phase difference between the two superconducting layers. Here the current feed is of the overlap type. The phase difference ϕ between the two superconducting layers satisfies $-\Delta\phi = 0$ in the linear part and $-\Delta\phi + \sin(\phi) = 0$ in the Josephson junctions. The right panel shows the associated $2D$ domain of size $l \times w$ containing $n = 3$ junctions placed at the positions $y = w/2$ and $x = a_i$, $i = 1, n$.*

2. The model. The device we model, shown in Figure 2.1, is a so-called microstrip cavity (the grey area in Figure 2.1) between two superconducting layers. Inside this microstrip there are regions where the oxide layer is very thin (~ 10 Angstrom), enabling Josephson coupling between the top and bottom superconductors. The dimensions of the microstrip are about 100 μm in length and 20 μm in width. The phase difference between the top and bottom superconducting layers obeys in the static regime the following semilinear elliptic partial differential equation [9]:

$$-\Delta\varphi + g(x,y)\sin\varphi = 0, \tag{2.1}$$

where $g(x,y)$ is 1 in the Josephson junctions and 0 outside. This formulation guarantees the continuity of the normal gradient of φ, the electrical current on the junction interface. The unit of space is the Josephson length λ_J, the ratio of the flux formed with the critical current density and the surface inductance to the flux quantum Φ_0.

The boundary conditions representing an external current input I or an applied magnetic field H (along the y axis) are

$$\begin{aligned} \left.\frac{\partial\varphi}{\partial y}\right|_{y=0} &= -\frac{I}{2l}\nu, \qquad \left.\frac{\partial\varphi}{\partial y}\right|_{y=w} = \frac{I}{2l}\nu, \\ \left.\frac{\partial\varphi}{\partial x}\right|_{x=0} &= H - \frac{I}{2w}(1-\nu), \quad \left.\frac{\partial\varphi}{\partial x}\right|_{x=l} = H + \frac{I}{2w}(1-\nu), \end{aligned} \tag{2.2}$$

where $0 \le \nu \le 1$ gives the type of current feed. The case $\nu = 1$ shown in Figure 2.1, where the current is applied only to the long boundaries $y = 0, w$, is called overlap feed, while $\nu = 0$ corresponds to the inline feed.

We consider long and narrow strips containing a few small junctions of size $w_j \times w_j$ placed on the line $y = w/2$ and centered on $x = a_i$, $i = 1, n$, as shown in Figure 2.1. We then search for φ in the form

$$\varphi(x,y) = \frac{\nu I}{2L}\left(y - \frac{\omega}{2}\right)^2 + \sum_{n=0}^{+\infty} \phi_n(x)\cos\left(\frac{n\pi y}{w}\right), \tag{2.3}$$

where the first term takes care of the y boundary condition. For narrow strips $w < \pi$, only the first transverse mode needs to be taken into account [7, 2] because the

curvature of φ due to current remains small. Inserting (2.3) into (2.1) and projecting on the zero mode, we obtain the following equation for ϕ_0, where the 0's have been dropped for simplicity:

$$-\phi'' + g\left(x, \frac{w}{2}\right)\frac{w_j}{w}\sin\phi = \nu\frac{\gamma}{l}, \tag{2.4}$$

where $\gamma = I/w$ and the boundary conditions are $\phi'(0) = H - (1-\nu)\gamma/2$ and $\phi'(l) = H + (1-\nu)\gamma/2$.

As the area of the junction is reduced, the total Josephson current is reduced and tends to zero. To describe small junctions where the phase variation can be neglected but that can carry a significant current, we introduce the following function g_h,

$$g_h(x) = \frac{w_j}{2h} \quad \text{for } a_i - h < x < a_i + h, \quad g_h(x) = 0 \quad \text{elsewhere,} \tag{2.5}$$

where $i = 1, \dots n$. In the limit $h \to 0$ we obtain our final delta function model [6],

$$-\phi'' + \sum_{i=1}^{n} d_i\delta(x - a_i)\sin\phi = \nu j, \tag{2.6}$$

where

$$d_i = \frac{w_j^2}{w}, \quad j = \frac{\gamma}{l}, \tag{2.7}$$

and the boundary conditions are

$$\phi'(0) = H - \frac{(1-\nu)\gamma}{2}, \quad \phi'(l) = H + \frac{(1-\nu)\gamma}{2}. \tag{2.8}$$

This is our continuous/discrete 1D model of a parallel array of many point Josephson junctions embedded in a microstrip cavity. It preserves the spatial degrees of freedom in the linear cavity and the matching conditions at the junction interfaces.

3. General properties. The delta function seems to be a theoretical way to approach the problem. Nevertheless we will show that it provides an excellent agreement with experiments, in addition to allowing analytical solutions. We have the following properties:

1. Integrating twice, (2.6) shows that the solution ϕ is continuous at the junctions $x = a_i$, $i = 1, \dots, n$.

2. Let ϕ be a solution of (2.6); then $\phi + 2k\pi$ is also a solution.

3. Almost everywhere, $-\phi''(x) = \nu\gamma/l$, so that outside the junctions, ϕ is a second degree polynomial by parts,

$$\phi(x) = -\frac{\nu j}{2}x^2 + B_i x + C_i \qquad \forall x \in]a_i, a_{i+1}[. \tag{3.1}$$

4. At each junction ($x = a_i$), ϕ' is not defined, but choosing $\epsilon_1 > 0$ and $\epsilon_2 > 0$, we get

$$\lim_{\epsilon_1\to 0}\lim_{\epsilon_2\to 0}\int_{a_i-\epsilon_1}^{a_i+\epsilon_2}\phi''(x)dx = \int_{a_i^-}^{a_i^+}\phi''(x)dx = [\phi'(x)]_{a_i^-}^{a_i^+}.$$

Since the phase is continuous at the junction $x = a_i$, we obtain

$$[\phi'(x)]_{a_i^-}^{a_i^+} = d_i\sin(\phi_i), \tag{3.2}$$

with $\phi_i \equiv \phi(a_i)$.

5. Integrating (2.6) over the whole domain,

$$[\phi']_0^l = \int_0^l \phi'' dx = \sum_{i=1}^{n} d_i \sin(\phi_i) - \nu\gamma,$$

and taking into account the boundary conditions, we obtain

$$\gamma = \sum_{i=1}^{n} d_i \sin(\phi_i), \tag{3.3}$$

which indicates the conservation of current. Note that the total current is equal to the sum of the jumps of ϕ'.

3.1. The solution as a piecewise polynomial. Let ϕ be a solution of (2.6) and $\phi_1 = \phi(a_1)$. From remark (3.1), ϕ is a polynomial by parts. We define $P_{i+1}(x)$ as the second degree polynomial such that $P_{i+1}(x) = \phi(x)$ for $a_i \le x \le a_{i+1}$. Using the left boundary condition, we can specify ϕ on $[0, a_1]$:

$$P_1(x) = -\frac{\nu j}{2}\left(x^2 - a_1^2\right) + \left(H - \frac{1-\nu}{2}\gamma\right)(x - a_1) + \phi_1. \tag{3.4}$$

At the junctions, (3.2) tells us that $\forall k \in \{1, \dots, n\}$,

$$P'_{k+1}(a_k) - P'_k(a_k) = d_k \sin(P_k(a_k)). \tag{3.5}$$

Considering that $\phi'' = -\nu j$ on each interval, the previous relation, and the continuity of the phase at the junction, we can give a first expression for P_{k+1},

$$P_{k+1}(x) = -\frac{\nu j}{2}(x - a_k)^2 + \left[P'_k(a_k) + d_k \sin P_k(a_k)\right](x - a_k) + P_k(a_k). \tag{3.6}$$

Notice that $P_{k+1}(x)$ depends on $P_k(x)$, ν, j, and H. The parameters ν and l are fixed by the geometry of the device. So by recurrence we see that ϕ is entirely determined by the values of ϕ_1, γ, and H.

From (3.5) we can obtain another expression for P_{k+1},

$$P_{k+1}(x) - P_k(x) = d_k \sin(P_k(a_k))(x - a_k). \tag{3.7}$$

Summing all these relations yields

$$P_{k+1}(x) = P_1(x) + \sum_{i=1}^{k} d_i \sin(P_i(a_i))(x - a_i). \tag{3.8}$$

Polynomials (3.4) and (3.6) show by construction that the constants H, j, and ϕ_1 determine completely the solution of (2.6) if one exists. In the same way, we can show that the three other constants, j, $\phi'(a_1)$, and ϕ_1, fix ϕ. From (3.8), we give an expression of ϕ:

$$\phi(x) = P_1(x) + \sum_{i=1}^{n} \mathcal{H}_{\{x \ge a_i\}} d_i \sin(\phi_i)(x - a_i),$$

where

$$\mathcal{H}_{\{x \ge a_i\}} = \begin{cases} 1, & x \ge a_i, \\ 0, & x < a_i, \end{cases}$$

is the Heaviside function.

3.2. An *n*th order transcendental system. Another way to solve (2.6) for ϕ is to write it as a coupled system of n transcendental equations. For that, we first eliminate the constant term by introducing ψ such that

$$\phi = \psi - \nu\frac{\gamma}{l}\frac{x^2}{2} \equiv \psi - f(x)$$

and obtain

$$-\psi'' + \sum_{i=1}^{n} d_i \delta(x - a_i)\sin(\psi - f(a_i)) = 0, \tag{3.9}$$

with the boundary conditions

$$\psi'(0) = H - \frac{(1-\nu)\gamma}{2}, \quad \psi'(l) = H + \frac{(1+\nu)\gamma}{2}.$$

To simplify the notation we will write $f_i \equiv f(a_i)$ and $\psi_i \equiv \psi(a_i)$. Integrating (3.9) over the intervals $[0, a_2^-]$, $[a_1^+, a_3^-]$, ..., we obtain the relations

$$\begin{aligned}
-[\psi']_0^{a_2^-} + d_1\sin(\psi_1 - f_1) &= 0,\\
-[\psi']_{a_1^+}^{a_3^-} + d_2\sin(\psi_2 - f_2) &= 0,\\
-[\psi']_{a_2^+}^{a_4^-} + d_3\sin(\psi_3 - f_3) &= 0,\\
-[\psi']_{a_3^+}^{a_5^-} + d_4\sin(\psi_4 - f_4) &= 0,\\
-[\psi']_{a_4^+}^{l} + d_5\sin(\psi_5 - f_5) &= 0,
\end{aligned} \tag{3.10}$$

where we have assumed $n = 5$ as an example. Now we can use the fact that $\psi'' = 0$ in the intervals between the junctions and the boundary conditions to obtain the final system

$$\begin{aligned}
H - (1-\nu)\frac{\gamma}{2} - \frac{\psi_2 - \psi_1}{a_2 - a_1} + d_1\sin(\psi_1 - f_1) &= 0,\\
-\frac{\psi_3 - \psi_2}{a_3 - a_2} + \frac{\psi_2 - \psi_1}{a_2 - a_1} + d_2\sin(\psi_2 - f_2) &= 0,\\
-\frac{\psi_4 - \psi_3}{a_4 - a_3} + \frac{\psi_3 - \psi_2}{a_3 - a_2} + d_3\sin(\psi_3 - f_3) &= 0,\\
-\frac{\psi_5 - \psi_4}{a_5 - a_4} + \frac{\psi_4 - \psi_3}{a_4 - a_3} + d_4\sin(\psi_4 - f_4) &= 0,\\
-H - (1+\nu)\frac{\gamma}{2} + \frac{\psi_5 - \psi_4}{a_5 - a_4} + d_5\sin(\psi_5 - f_5) &= 0.
\end{aligned} \tag{3.11}$$

We will use this formulation as well as the one in the previous subsection to establish properties of the solutions and solve the problem numerically using Newton's method.

4. General properties of $\gamma_{max}(H)$ for an n junction array. The general problem is

$$-\phi''(x) + \sum_{i=1}^{n} d_i \delta(x - a_i)\sin(\phi) = \nu j, \tag{4.1}$$

with the boundary conditions

$$\phi'(0) = H - \frac{(1-\nu)\gamma}{2}, \quad \phi'(l) = H + \frac{(1-\nu)\gamma}{2}.$$

Experimentalists measure the maximum current γ for a given magnetic field H and plot this as a curve $\gamma_{max}(H)$. To compare with real data it is therefore important to compute and analyze this quantity. In this section, we give some properties of the $\gamma_{max}(H)$ curve. In the appendix some analytical estimates on the influence of the geometry on the maximal current will be presented.

4.1. Periodicity. We introduce

$$l_j \equiv a_{j+1} - a_j,$$

the distance between two consecutive junctions. Let l_{min} be the smallest distance l_j. We define the array as harmonic if l_i is a multiple of l_{min} $\forall\, i$.

PROPOSITION 4.1 (periodicity of the device). *For a harmonic array, the $\gamma_{max}(H)$ curve is periodic with a period $2\pi/l_{min}$.*

Proof. Let ϕ be a solution of (4.1) for a current γ and a magnetic field H. We introduce $f(x) = (2\pi/l_{min})(x - a_1)$ and $\psi(x) = \phi(x) + f(x)$. So ψ verifies

$$-\psi''(x) + \sum_{i=1}^{n} \delta(x - a_i) \sin(\psi - f) = \nu j, \tag{4.2}$$

with $\psi'(0) = H + 2\pi/l_i - (1-\nu)\gamma/2$ and $\psi'(l) = H + 2\pi/l_i + (1-\nu)\gamma/2$. Since $f(a_j) = 2k\pi$ $\forall i \in \{1, \ldots, n\}$, then ψ is a solution of (4.1) for $H + H_p \equiv H + 2\pi/l_{min}$ and the same γ, and so $\gamma_{max}(H + H_p) \geq \gamma_{max}(H)$.

Conversely, by subtracting f from a solution associated with $H + H_p$ and a current γ, we obtain a solution for H and the same current γ, and so $\gamma_{max}(H + H_p) \leq \gamma_{max}(H)$. From the two inequalities we get

$$\gamma_{max}(H + H_p) = \gamma_{max}(H) \tag{4.3}$$

with $H_p = 2\pi/l_{min}$. ∎

In the nonharmonic case, if the junctions are set such that $l_j = p_j/q_j$, where p_j and q_j are integers, prime with each other, then γ_{max} is periodic with period H_p such that

$$H_p = 2\pi \frac{LCM(q_1, \ldots, q_{n-1})}{HCF(p_1, \ldots, p_{n-1})} \tag{4.4}$$

(see Figure 4.1), where LCM is the lowest common multiple and HCF the highest common factor. To prove this write $f(x) = p(x - a_1)$ and use again the previous argument. In Figure 4.1 we show the $\gamma_{max}(H)$ curve for a three-junction unit such that $l_1 = 3/2$ and $l_2 = 5/3$, so that the period of $\gamma_{max}(H)$ is $H_p = 2\pi LCM(2,3)/HCF(3,5) = 12\pi$. In the following plots we will show only one period of $\gamma_{max}(H)$.

In the general case, we have only an approximate periodicity of $\gamma_{max}(H)$, which can be estimated using (4.4). Also, real junctions have a finite size, which causes $\gamma_{max}(H) \to 0$ when $H \to +\infty$. Our model is thus valid as long as the dimensionless magnetic field H is not larger than $1/w_j$.

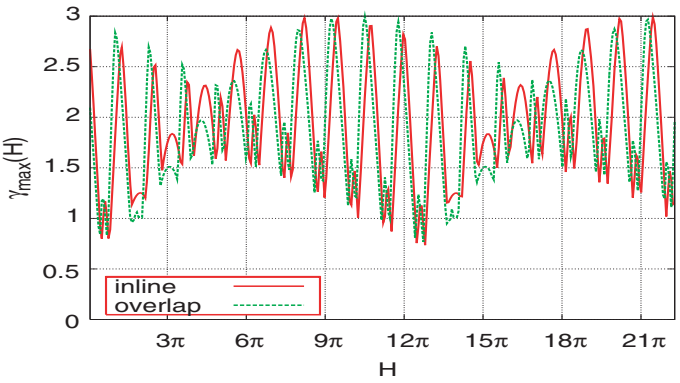

FIG. 4.1. *$\gamma_{max}(H)$ curve for an inline current feed, $\nu = 0$ (solid line), and overlap feed, $\nu = 1$ (dotted line), for a three-junction unit $\{1, 5/2, 5/2 + 5/3\}$, with $d_1 = d_2 = d_3 = 1$. Thus $l_1 = 3/2$ and $l_2 = 5/3$.*

4.2. Influence of the position of the junction unit. In this section, we examine how the position of the set of junctions in the microstrip (linear domain) will affect the $\gamma_{max}(H)$ curve. For an array of junctions placed at the distances $\{a_i, i = 1, n\}$, we define a junction unit as the set $\{l_i, i = 1, n-1\}$. Then the array where the junctions are at $\{a_1 + c, a_2 + c, \ldots, a_n + c\}$ is the same junction unit. We define a_1 as the position of the junction unit. The length of the junction unit is $l_b = a_n - a_1$. The array is centered if $(a_n + a_1)/2 = l/2$.

Inline current feed: $(\nu = 0)$. Then the boundary conditions at the edge of the junction unit are $\phi'(a_1^-) = \phi'(0) = H - \gamma/2$ and $\phi'(a_n^+) = \phi'(l) = H + \gamma/2$, independent of the position of the junction unit.

PROPOSITION 4.2 (inline junction unit). *For inline current feed, $\gamma_{max}(H)$ is independent of a_1 (the position of the junction unit) and of the length l of the cavity.*

Proof. Let $\phi_1(x)$ be a solution of (4.1) for given γ, H. Let us change the position of the junction unit to $a_1 + c$ so that the junctions are now placed at $\{a_1 + c, a_2 + c, \ldots, a_n + c\}$. It is easy to see that $\phi_2(x) = \phi_1(x - c)$ satisfies the boundary conditions and is a solution. This one-to-one map between ϕ_1 and ϕ_2 exists $\forall\, c$, H, and γ, and so the two junction units have the same $\gamma_{\max}(H)$. ∎

Then the $\gamma_{max}(H)$ curve is independent of the position of junction unit when $\nu = 0$. By the same argument, we can show that $\gamma_{max}(H)$ is independent of the length l of the circuit (see Figure 4.3). This curve depends only on the junction unit.

General current feed: $(0 < \nu \leq 1)$. In this case the boundary conditions at the edge of the junction unit are

$$\phi'(a_1^-) = -\nu j a_1 + H + (1 - \nu)\gamma/2, \quad \phi'(a_n^+) = H - (1 - \nu)\gamma/2 + \nu j(l - a_n).$$

Contrary to the inline feed, we cannot shift the phase to find a solution when the junction unit has been shifted, because now the boundary conditions depend on the position of the junction unit. Consider the derivative ϕ' at the boundaries of the junction unit. We will compare the curves $\gamma_{max}(H)$ for a centered unit and for a noncentered unit. For a centered unit, $a_n - a_1 = l/2$ so that

$$\phi'(a_1^-) - H = -\left(\phi'(a_n^+) - H\right),$$

but this equality is false for a noncentered unit. It is possible to choose a correction

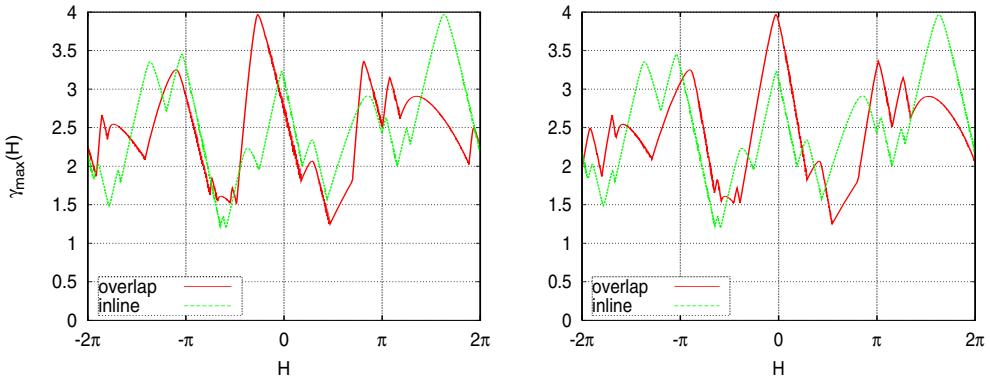

FIG. 4.2. *Plot of $\gamma_{max}(H)$ for a four-junction device ($l = 10$, $d_i = 1$) such that $l_1 = 1.5$, $l_2 = 2.5$, $l_3 = 2$. The left panel shows a noncentered junction unit with $a_1 = 0.1$, and the right panel a centered unit with $a_1 = 2$. Notice the current-dependent shift* (4.5) *for the overlap solution as one goes from a centered junction unit (right panel) to an off-centered junction unit (right panel). The junction unit was moved to the left.*

H_ν to the magnetic field H in order to obtain the equality

$$\begin{aligned} \phi'(a_1^-) - H + H_\nu &= -\left(\phi'(a_n^+) - H + H_\nu\right), \\ -\nu j a_1 + (1-\nu)\frac{\gamma}{2} + H_\nu &= -\left[\nu j(l - a_n) - (1-\nu)\frac{\gamma}{2} + H_\nu\right], \\ H_\nu &= \nu j\left(\frac{l_b - l}{2} + a_1\right). \end{aligned} \tag{4.5}$$

Let us consider two arrays, circuit 1 with a centered junction unit and circuit 2 with the same junction unit but noncentered.

PROPOSITION 4.3 (magnetic shift). *Let (H, γ_{max}) be the coordinates of a point of the $\gamma_{max}(H)$ curve for the circuit* 1. *Then $(H + H_\nu, \gamma_{max})$ is a point of the curve for the circuit* 2.

Thus, moving a junction unit translates the γ_{max} curve by $\nu j a_1$. Figure 4.2 shows a $\gamma_{max}(H)$ for a four-junction device with a noncentered junction unit in the left panel and a centered junction unit in the right panel. Both inline and overlap current feeds are presented. Notice the unchanged behavior for the inline current feed and the effect of H_ν ($= -4.1\gamma/10$) from (4.5) in the overlap case.

Proof. Let $\phi_{\{H,\gamma,a_1\}}$ be a solution for an array $A_1 \equiv \{a_1, \ldots, a_n\}$ with a centered junction unit with γ and H given. Consider another array A_2 with the same junction unit moved by s, $A_2 \equiv \{a_1 + s, \ldots, a_n + s\} \equiv A_1 + s$, the coefficients $d_1, \ldots, d_n$ being equal for the two circuits. From the solution $\phi_{\{H,\gamma,a_1\}}$ for A_1 we can deduce a solution $\psi_{\{H+H_\nu,\gamma,a_1+s\}}$ for A_2. From (4.5) we have

$$\psi'_{\{H+H_\nu,\gamma,a_1+s\}}(a_1^- + s) = \phi'_{\{H,j,a_1\}}(a_1^-).$$

Taking

$$\psi_{\{H+H_\nu,\gamma,a_1+s\}}(a_1^- + s) = \phi_{\{H,\gamma,a_1\}}(a_1^-),$$

and from the unicity of the solution, we obtain $\phi \equiv \psi$ in the two junction units. Thus, if ϕ is a solution for $\{H, \gamma\}$ given for A_1, then ψ is a solution for $\{H + H_\nu, \gamma\}$ for A_2, and vice versa.

Let $\gamma_{max,1}$ and $\gamma_{max,2}$ be the γ_{max} curves for the arrays A_1 and A_2. From the solutions obtained for A_1 we build solutions for A_2. As a consequence, $\gamma_{max,1}(H + H_\nu) \leq \gamma_{max,2}(H)$. On the other side, from solutions of A_2 we build solutions for A_1, then $\gamma_{max,1}(H + H_\nu) \geq \gamma_{max,2}(H)$. So, we obtain the equality

$$\gamma_{max,1}(H + H_\nu) = \gamma_{max,2}(H) \ . \qquad \square$$

Notice that this equality is independent of the number of junctions.

4.3. Comparison between inline and overlap current feeds. We now compare the γ_{max} curves for inline and overlap current feed. For one junction, the problem can be solved exactly using polynomials by parts (see remark (3.1)). We obtain $\gamma_{max}(H) = d_1 \ \forall \nu$. For two junctions there is the possibility of $d_1 \neq d_2$, and this will change $\gamma_{max}(H)$ qualitatively. Let us study the phase difference between two junctions. We use remark (3.1) and the boundary conditions to get

$$\begin{aligned} &\phi_2 - \phi_1 = -\frac{\nu j}{2}(a_2 - a_1)^2 + (P'(a_1) + d_1 \sin(\phi_1))\,(a_2 - a_1), \\ &\frac{\phi_2 - \phi_1}{a_2 - a_1} = -\nu j \frac{a_2 + a_1}{2} + H - \frac{1-\nu}{2}\gamma + d_1 \sin(\phi_1). \end{aligned} \tag{4.6}$$

If $(a_2 + a_1)/2 = l/2$ (the junction unit is also centered), as $\gamma = jl$, (4.6) becomes

$$\frac{\phi_2 - \phi_1}{a_2 - a_1} = H - \frac{\gamma}{2} + d_1 \sin(\phi_1). \tag{4.7}$$

Note that we can obtain (4.7) from (4.6) with $\nu = 0$. We have shown the following result.

PROPOSITION 4.4 (equivalence of all current feeds for a centered SQUID). *For a centered two-junction device, all current feeds give the same γ_{max} curve.*

For an inline current feed, $\nu = 0$, so that the phase difference $\phi_2 - \phi_1$ is independent of the position of the junction unit. This is not true for the overlap feed, where moving the junction unit causes a "magnetic shift" as seen above in H_ν equation (4.5). When the number of the junctions $n \geq 3$, the γ_{max} curve depends on ν. The effect of moving the junction unit on the γ_{max} curve was shown above. Thus, we can reduce the study to a centered junction unit. In this case, we have $a_1 = (l - l_b)/2$, and

$$\begin{aligned} \phi'(a_1^-) &= \phi'(0) + \int_0^{a_1^-} -\nu \frac{\gamma}{l} dx \\ &= H - (1-\nu)\frac{\gamma}{2} - \nu\frac{\gamma}{2} + \frac{\nu l_b}{l}\frac{\gamma}{2} = H - \left(1 - \frac{\nu l_b}{l}\right)\frac{\gamma}{2}, \\ \phi'(a_n^+) &= H + \left(1 - \frac{\nu l_b}{l}\right)\frac{\gamma}{2}, \end{aligned} \tag{4.8}$$

with $l_b = a_n - a_1$. We can write $\nu j = (\nu l_b/l)(\gamma/l_b)$ and $\nu l_b/l = \mu$. Thus, (4.1) is equivalent to the system

$$-\phi''(x) + \sum_{i=1}^{n} d_i \delta(x - a_i)\sin(\phi) = \mu \frac{\gamma}{l_b} \ , \tag{4.9}$$

with

$$\phi'(a_1^-) = H - \frac{(1-\mu)\gamma}{2}, \quad \phi'(a_n^+) = H + \frac{(1-\mu)\gamma}{2}.$$

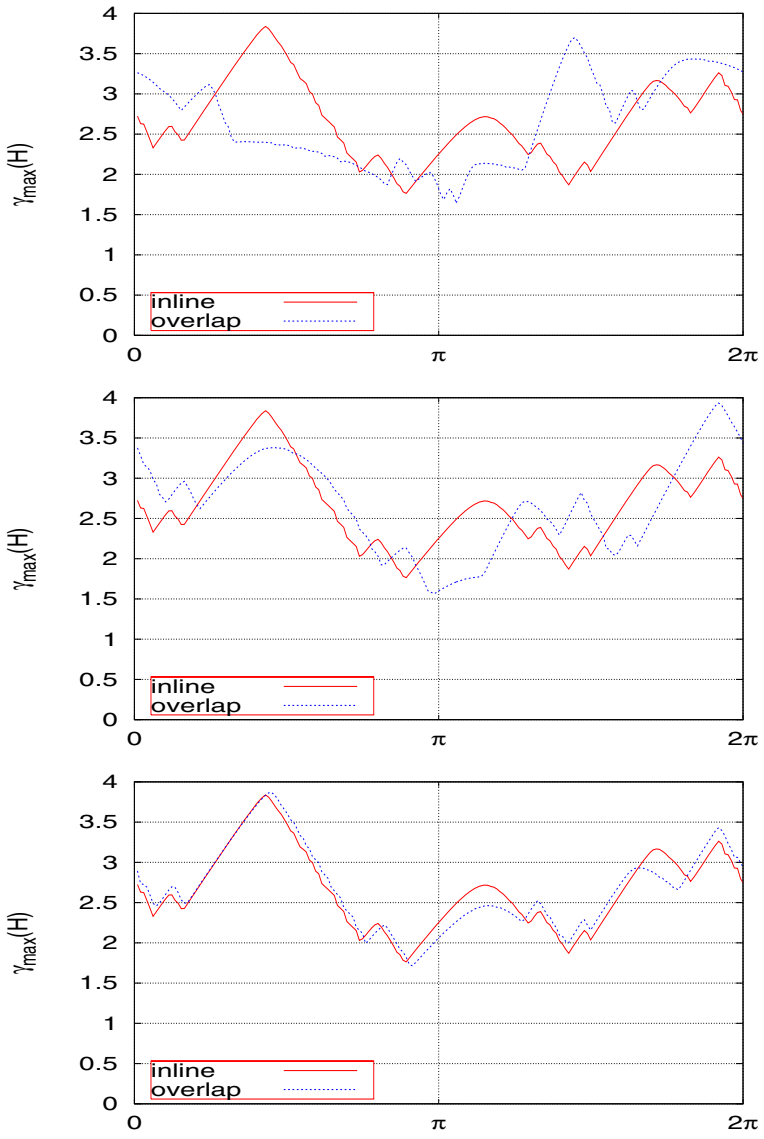

FIG. 4.3. *Plot of $\gamma_{max}(H)$ for the same centered junction unit $l_1 = 1$, $l_2 = 4$, $l_3 = 3$, $d_1 = d_2 = d_3 = d_4 = 1$ and different lengths l of the microstrip; from top to bottom, $l = 8$, 16, and 64. Notice how the overlap solution tends to the inline solution as one increases l.*

As $0 \le \nu \le 1$, $0 \le \mu \le l_b/l$. Note that l_b can be considered as the reference length of the device. Also note that if $l \to +\infty$, then $\mu \to 0$ and (4.9) and boundary conditions tend to the situation of inline current feed. Figure 4.3 illustrates this convergence when we increase the microstrip length l for a centered junction unit. Notice that the solution for the inline feed is not modified by the variation of length. With $l = 8$, we have a maximum difference between the solutions for the overlap and inline current feeds. As l increases, the solution for the overlap current feed tends to the solution for the inline current feed. We prove this in section 9.3.

Conclusion. In the appendix, we show that when $\nu\gamma/l$ tends to 0 the solution

tends to the one for inline current feed. We can get this by increasing the length l or shrinking the junction area. (See section 9.3.) We have three parameters: ν, l, and γ_{max}. l is determined by the circuit. ν comes from the 2D model, and depends on the width of the circuit. The third parameter can be bounded from above: $0 \leq \gamma \leq \sum_i d_i$. We will see in the next section what the limit of $\gamma_{max}(H)$ is for inline and overlap feeds when d_i are small.

4.4. The relation between inline and magnetic approximation. The size of the junctions $w_i < 1 < w$ so that $d_i \ll 1$; therefore the jump of the gradient of the phase across the junctions can be neglected. This is the magnetic approximation where only H fixes the phase gradient. In the previous section, we have shown that the solutions for inline and overlap current feeds converge to the same $\gamma_{max}(H)$ curve for small d_i. We will show that this limit is the magnetic approximation.

Since $[\phi']_{a_i^-}^{a_i^+} = d_i \sin(\phi_i)$ (remark (3.2)) and $j \leq \sum_i d_i/l$, then for small d_i, ϕ tends to the linear function $\phi(x) = Hx + c$. This magnetic approximation seems crude, but we show that it approaches the solution for inline feed; see section 9.4. There we bound the difference between the γ curves for the inline feed and the magnetic approximation. Figure 4.4 illustrates this convergence as d_i decreases.

This approximation gives very good results because we work on very small junctions and the corresponding $d_i \approx 10^{-2}$ (compared with the values taken in Figure 4.4).

4.5. Magnetic approximation. The magnetic approximation is very interesting because it gives an analytic expression of $\gamma_{max}(H)$ and is independent of the value of the current and of the scale of the circuit. Here we consider that $\phi(x) = Hx + c$, and from (3.3),

$$\gamma = \sum_{i=1}^{n} d_i \sin(Ha_i + c) \ .$$

Notice that c is the only parameter which can be adjusted to reach the maximum.

To find the $\gamma_{max}(H)$ curve of the magnetic approximation, we take the derivative

$$\frac{\partial \gamma}{\partial c} = -\sin(c) \left(\sum_{i=1}^{n} d_i \sin(Ha_i) \right) + \cos(c) \left(\sum_{i=1}^{n} d_i \cos(Ha_i) \right) . \tag{4.10}$$

The values of c canceling $\partial\gamma/\partial c$ are

$$c_{max}(H) = \arctan \left(\frac{\sum_{i=1}^{n} d_i \cos(Ha_i)}{\sum_{i=1}^{n} d_i \sin(Ha_i)} \right) , \tag{4.11}$$

and using (4.10), we have the solution:

$$\gamma_{max}(H) = \left| \sum_{i=1}^{n} d_i \sin(Ha_i + c_{max}(H)) \right| . \tag{4.12}$$

This γ_{max} curve is a function of H. A similar expression was given by Miller et al. [16] for homogeneous arrays. Here we generalize this approach to nonhomogeneous arrays and justify it rigorously.

Remark. If $d_i = d \ \forall i \in \{1, \ldots, n\}$, we can simplify:

$$c_{max} = \arctan \left(\frac{\sum_{i=1}^{n} \cos(Ha_i)}{\sum_{i=1}^{n} \sin(Ha_i)} \right) .$$

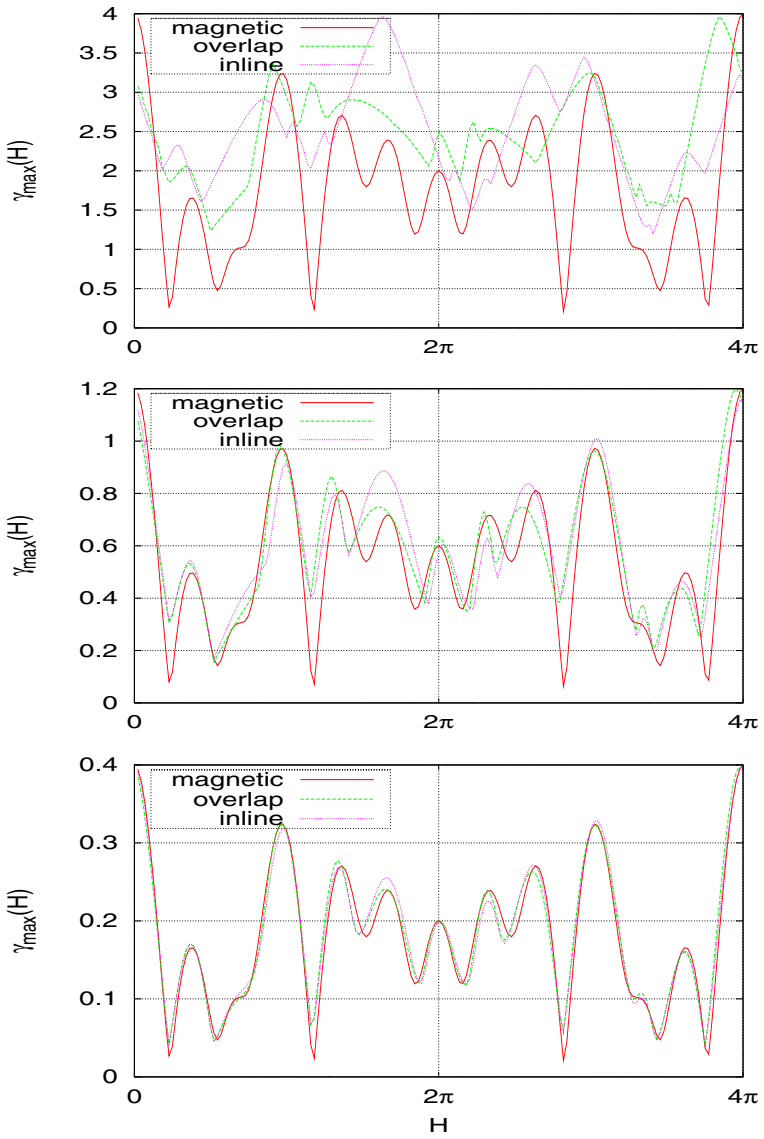

FIG. 4.4. *Plot of $\gamma_{max}(H)$ for the same junction unit and different coefficients d_i, which are all equal; from top to bottom, $d_i = 1$, 0.3, and 0.1. The distances between the junctions are $l_1 = 1.5$, $l_2 = 2.5$, $l_3 = 2$, $l = 10$.*

The maximum current (4.12) is then

$$\gamma_{max}(H) = d \left| \sum_{i=1}^{n} \sin(Ha_i + c_{max}(H)) \right|.$$

Here changing the value of d will change linearly the amplitude of the γ_{max} curve; this is not the case for the solutions of the boundary value problem (2.6). We can notice, too, that the $\gamma_{max}(H)$ obtained from this approximation is invariant by the

transformation

$$\forall t \in \Re, \ \begin{cases} a_i & \to & t a_i, \\ H & \to & H/t. \end{cases}$$

We will show in the next sections that when $d_i \ll 1$, (4.12) provides a good estimate of the $\gamma_{max}(H)$ curve of a circuit. In addition, from its invariant properties we can compare different models and estimate the parameters of the circuit. A cooperation has begun with Boussaha and Salez from the Observatoire de Paris to match theory and design for this type of circuit with specific properties [3].

5. Numerical solutions. We used two different methods, a stepping in the (H, γ) plane using a Newton iteration, and what we call the method of implicit curves to find the maximal current of (4.1) for H given.

5.1. Newton's method. We start from the system of nonlinear transcendental equations (3.11), which is written for $n = 5$. Introducing the vector $X = (\phi_1, \phi_2, \ldots, \phi_n)$, (3.11) can be written as $F(X) = 0$, where F is a nonlinear map from R^n to R^n. To solve this equation numerically, we use the Newton method:

$$X_{k+1} = X_k - (\nabla F(X_k))^{-1} F(X_k),$$

where $\nabla F(X_k)$ is the gradient of F evaluated at $X = X_k$. A first problem is to choose the initial vector X_0. For that consider $H = 0$; there we expect a solution such that $\gamma \approx \sum_i^n d_i$ and consequently $\phi_i \approx \pi/2\,[2\pi]$. We have our initial vector. After finding the solution, we step in H and take as an initial guess the previous solution found, which for a small step in magnetic field is assumed to be close to the one we are looking for. In this way, we obtain a solution with a magnetic field $H + dH$ and a current γ. We can then increase γ until the method does not converge, and this gives the maximum current $\gamma_{\max}(H + dH)$ for increasing H. Similarly we can compute $\gamma_{max}(H)$ by starting with a large magnetic field and decreasing H to 0. This curve will in general be different from the one obtained when increasing H due to hysteresis. The two curves need to be overlapped to find $\gamma_{max}(H)$. So, we introduce another method to be sure to obtain the γ_{max} curve directly.

5.2. Implicit curves method. The polynomials (3.4) and (3.6) establish the existence and value of ϕ at the junctions. This function should satisfy the boundary conditions. The first one,

$$\phi'(0) = P_1'(0) = H - (1 - \nu)\gamma/2,$$

is true by construction; the second (for n junction circuit),

$$P_{n+1}'(l) = H + (1 - \nu)\frac{\gamma}{2}, \tag{5.1}$$

is true only for the solutions of (4.1). As we have remarked in section 3.1, "The solution as a piecewise polynomial," ϕ is entirely determined by ϕ_1, γ, and H. For H given, the solutions of (5.1) define a relation between ϕ_1 and γ. Thus, the maximal current solution depends on ϕ_1 and γ, and (5.1) is the constraint it should satisfy. As the solutions ϕ are defined modulo 2π from (3.1), we can assume $\phi_1 \in [-\pi, \pi]$. On the other hand, because of (3.3), $\gamma \in [0, \sum_i d_i]$. To solve this problem using the software

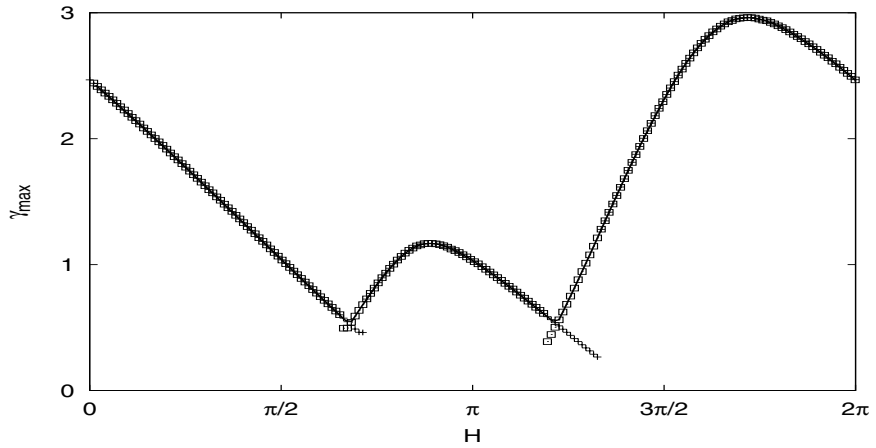

FIG. 5.1. *Comparison between the Newton method and the implicit curve method for the γ_{max} curve for a three-junction unit; $a_1 = 1$, $a_2 = 2$, $a_3 = 3$, $d_1 = d_2 = d_3 = 1$, $\nu = 1$, and $l = 10$. The square (resp., the +) symbols correspond to the Newton results for decreasing (resp., increasing) H, and the continuous line corresponds to the results of the implicit curve method.*

package Maple [15], we plot the implicit function (the constraint) of the two variables ϕ_1 and γ with H and ν fixed, defined by

$$P'_{n+1}\big|_{x=l}(\phi_1, \gamma, \nu, H) - H - \frac{1-\nu}{2}\gamma = 0, \tag{5.2}$$

with $(\phi_1, \gamma) \in [-\pi, \pi] \times [0, \sum_i d_i]$. The program searches, in an exhaustive way, the biggest value of γ of this implicit curve. Incrementing H, we obtain the relation $\gamma_{max}(H)$. We give an expression of P'_{n+1} for two and three junctions, in the appendix (section 9.1).

Compared to the Newton method detailed in the previous section, this method has the advantage of converging to a global maximum γ_{max}, as long as we give enough points to plot the implicit curve. Figure 5.1 compares $\gamma_{max}(H)$ using the two methods for a three-junction unit. The solution given by the implicit curve method is shown as a continuous line and superposes exactly with the other two plots. With the Newton method we can get trapped in local maxima, while the implicit curve method always gives the global maximum. On the other hand, the Newton method is much faster.

6. Two junctions. We have seen two methods to solve the problem numerically and established general properties. Now let us use these results for an array with a few junctions.

6.1. Same junction strength ($d = d_1 = d_2$). In Figure 6.1 we plot in the left panel $\gamma_{max}(H)$ of a two-junction unit. We find the expected periodicity $H_p = 2\pi/(a_2 - a_1)$, with a maximum for $H = 0$ in the inline case ($\nu = 0$). For the overlap feed, we have exactly the inline curve plus a magnetic shift. Notice that for the inline feed the amplitude of the γ_{max} curve is not proportional to d_i, contrary to the magnetic approximation. The larger the d_i, the further away the $\gamma_{max}(H)$ curves are from the ones given by the magnetic approximation. This is expected because the magnetic approximation neglects the effect of d_i on the phase. In this section, to simplify the discussion we will restrict ourselves to the inline current feed. However, the results will be valid for the general case. The maximum of γ_{max} corresponding

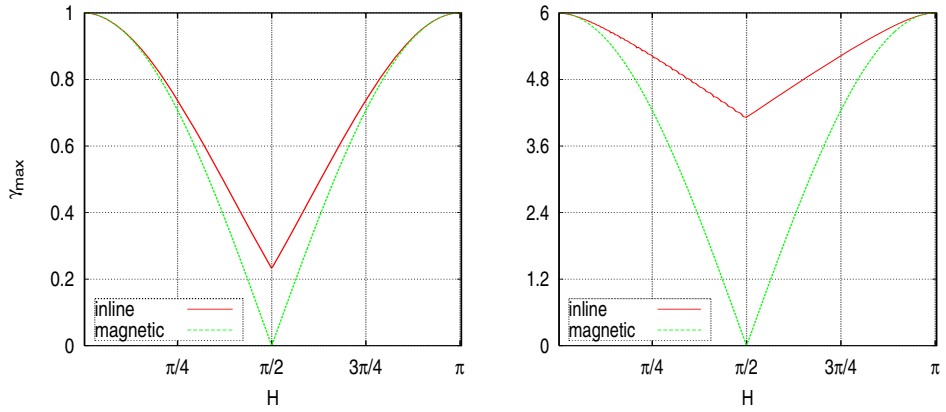

FIG. 6.1. *Plot of the γ_{max} curve for a two-junction unit such that $l_1 = 2$. In the left panel, $d_1 = d_2 = 0.5$, while in the right panel, $d_1 = d_2 = 3$.*

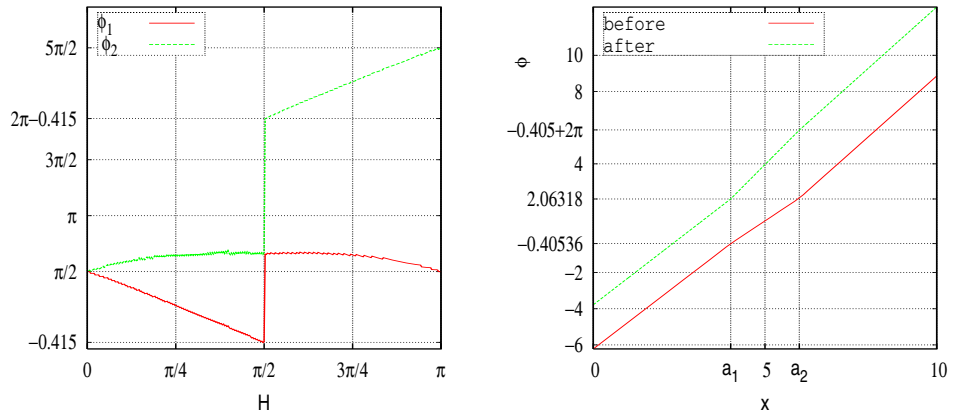

FIG. 6.2. *Left panel: plot of the phases ϕ_1 and ϕ_2 as a function of the magnetic field H for the same junction unit as the one shown in the left panel of Figure* 6.1 *Right panel: plot of $\phi(x)$ for the same device for $H < \pi/(a_2 - a_1)$ (solid line) and $H > \pi/(a_2 - a_1)$ (dashed line).*

to $H \equiv 0(H_p)$ is the only case where $(\phi_2 - \phi_1)/(a_2 - a_1) = H$. On the other hand, by construction, in the magnetic approximation $(\phi_2 - \phi_1)/(a_2 - a_1) = H \; \forall H$. In the general case, the closer H is to $\pi/(a_2 - a_1)$, the further $(\phi_2 - \phi_1)/(a_2 - a_1)$ is from H. This can be seen in the right panel of Figure 6.2. Thus, there will be more tunneling current in one junction than in the other. This phenomenon increases as H increases from 0 to $\pi/(a_2 - a_1)$. For that value, we have two possible solutions for γ_{max}, as shown in the left panel of Figure 6.2 for $H = \pi/2$. As the field crosses $\pi/(a_2 - a_1)$ the two junctions behave in the opposite fashion, as shown by the switch of the jumps in ϕ_x at the junctions; see the right-hand panel of Figure 6.2. These two solutions or reversing behavior of the junction cause a jump in the derivative $\gamma'_{max}(H)$ of $\gamma_{max}(H)$. As long as the evolution of ϕ_1 (or ϕ_2) is continuous there is no jump in γ'_{max}. To summarize, the smaller d is, the closer $(\phi_2 - \phi_1)/(a_2 - a_1)$ is to H. Another way of relaxing this constraint on $(\phi_2 - \phi_1)/(a_2 - a_1)$ for a constant d is to separate the junctions and, we can show that if $l_b = a_2 - a_1 \to +\infty$, then $\gamma_{max}(H) \to d_1 + d_2$.

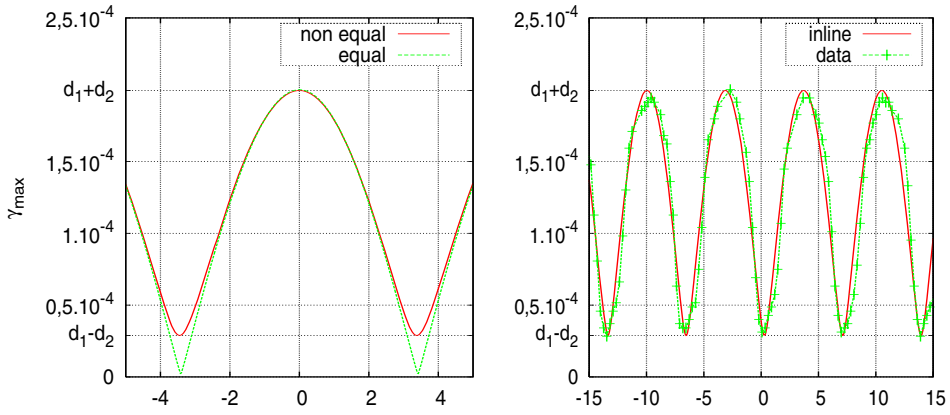

FIG. 6.3. *Plot of $\gamma_{max}(H)$ curves for two two-junction units with inline current feed. Left panel: comparison of $\gamma_{max}(H)$ given by the model for the cases $d_1 = d_2$ and $d_1 \neq d_2$. Right panel: the fit of the experimental data from a two-junction unit of the Observatory of Paris (reproduced from* [3] *with permission of Morvan Salez).*

6.2. Regularity of $\gamma_{max}(H)$. Junctions are never perfectly similar, and small differences in their areas or their critical currents will affect γ_{max}. In the left panel of Figure 6.3, showing $\gamma_{max}(H)$ for a two-junction device, there is no discontinuity of the slope of the curve $\gamma_{max}(H)$ labeled "nonequal"; $\partial\gamma_{max}/\partial H$ exists everywhere. In this case, the values of $\phi_1(H)$ and $\phi_2(H)$ associated with $\gamma_{max}(H)$ vary continuously.

To show this, consider a circuit such that $d_1 > d_2$. If $\phi_1 = \pi/2$, remark (3.3) implies $d_1 - d_2 \leq \gamma_{max} \leq d_1 + d_2$. Now let us find the values of H for which these bounds can be reached. From (3.3) and (3.6) we have

$$\begin{aligned} \gamma &= d_1 \sin(\phi_1) + d_2 \sin(\phi_2), \\ \phi_2 &= -\frac{\nu j}{2} l_1^2 + \left(H - \left(\nu a_1 + \frac{1-\nu}{2} l \right) j + d_1 \sin\phi_1 \right) l_1 + \phi_1, \end{aligned} \tag{6.1}$$

with $l_1 = a_2 - a_1$. By substituting the second equality into the first and taking the derivative with respect to ϕ_1, we obtain

$$\frac{\partial\gamma}{\partial\phi_1} = d_1 \cos\phi_1 + d_2 \left[\left(- \left(\nu \frac{a_2 + a_1}{2l} + \frac{1-\nu}{2} \right) \frac{\partial\gamma}{\partial\phi_1} + d_1 \cos\phi_1 \right) l_1 + 1 \right] \cos\phi_2.$$

Since we search for the maximum of γ, then $\partial\gamma/\partial\phi_1 = 0$, so that

$$d_1 \cos\phi_1 = -d_2 \left(d_1 l_1 \cos(\phi_1) + 1 \right) \cos\phi_2. \tag{6.2}$$

When $\phi_1 = \pi/2$, this condition gives $\phi_2 = \pi/2[\pi]$. Now, inserting these solutions into (6.1), we obtain the values of H for which these solutions are possible:

$\gamma_{max}(H)$	H
$d_1 + d_2$	$2k\pi/l_1 + [\nu(a_1 + l_1/2) + (1-\nu)l/2](d_1 + d_2)/l - d_1$
$d_1 - d_2$	$(2k+1)\pi/l_1 + [\nu(a_1 + l_1/2) + (1-\nu)l/2](d_1 - d_2)/l - d_1$

This enables us to estimate d_1 and d_2 from the curve $\gamma_{max}(H)$.

We now proceed to give the conditions that d_1 and d_2 should satisfy in order to have an angular or smooth $\gamma_{max}(H)$. Since $\phi_2(H)$ varies continuously, $\cos(\phi_2)$ takes

all the values between -1 and 1. We assume that $\forall\phi_1$, $d_1 l_1 \cos(\phi_1) + 1 \geq 0$, where $l_1 = a_2 - a_1$.[1] We consider the following two cases:

1. $\cos\phi_1 \leq 0$: as $\cos\phi_1 \geq -1$ from (6.2), we obtain

$$d_2 \cos(\phi_2) \leq \frac{d_1}{1 - d_1 l_1} \ .$$

Since $\cos(\phi_2)$ must take all values between -1 and 1 and $d_2 > 0$,

$$d_2 \leq \frac{d_1}{1 - d_1 l_1} \ . \tag{6.3}$$

This is the maximal value that d_2 can take compared to d_1.

2. $\cos\phi_1 \geq 0$: as $\cos\phi_1 \leq 1$, for the same reason we obtain

$$d_2 \geq \frac{d_1}{1 + d_1 l_1} \ . \tag{6.4}$$

To summarize, $d\gamma_{max}(H)/dH$ does not vary continuously if

$$\frac{d_1}{1 - d_1 l_1} \leq d_2 \leq \frac{d_1}{1 + d_1 l_1}. \tag{6.5}$$

To illustrate this effect we consider the configuration of a a microstrip with inline current feed with two Josephson junctions built by Salez and Boussaha at the Observatoire de Paris [17, 4]. The results are shown in Figure 6.3. The square junctions have an area of $w_j^2 \approx 1\mu m^2$, the Josephson length is $\lambda_J = 5.6\mu m$, and $l_1 = a_2 - a_1 = 13\mu m$ (using the junction centers). This gives $d_1 = d_2 \approx 0.0357$, $l_1 \approx 2.32$ if the areas are equal. However, the experimental data does not go to 0, and so the junctions are probably slightly different than expected from (6.3) and (6.4),

$$0.032969 \leq d_2 \leq 0.038923.$$

Only a 10% difference in area is enough to give a regular $\gamma_{max}(H)$. From the fit of the experimental data (right panel of Figure 6.3) we can estimate the areas of the junctions as $w_1^2 = 0.85255\mu m^2$ and $w_2^2 = 1.1417\mu m^2$.

As we have seen in the previous section, when the γ_{max} curve does not show any spike, it is bounded by $d_1 + d_2$ and $|d_1 - d_2|$. From this we can obtain the characteristics of the two junctions, their critical current density, and area, except that we do not know which junction corresponds to d_1 and which to d_2. However, if the γ_{max} does not have any spikes, then we can give the exact area of the junctions, assuming that the critical density current is known.

7. Many junctions. A two-junction circuit behaves as a simple SQUID and shows a regular $\gamma_{max}(H)$. To obtain specific properties for advanced detectors, experimentalists make devices with more junctions.

7.1. 3-device junction. When we add a new junction to a circuit with two junctions, new oscillations appear on $\gamma_{max}(H)$. We cannot predict the amplitude of the oscillations, but we can have an idea of their number in one period, i.e., the interval $[0, H_p]$. We introduce the phase difference for $H = 0$, $\delta\phi_i = \phi_i - \phi_1$. Using

[1] For small junctions this is not a strong constraint, because since $d_i = w_i^2/w \ll 1$, w_i, $w \ll 1$, and $l_i \ll 1$ are about 10^{-2}.

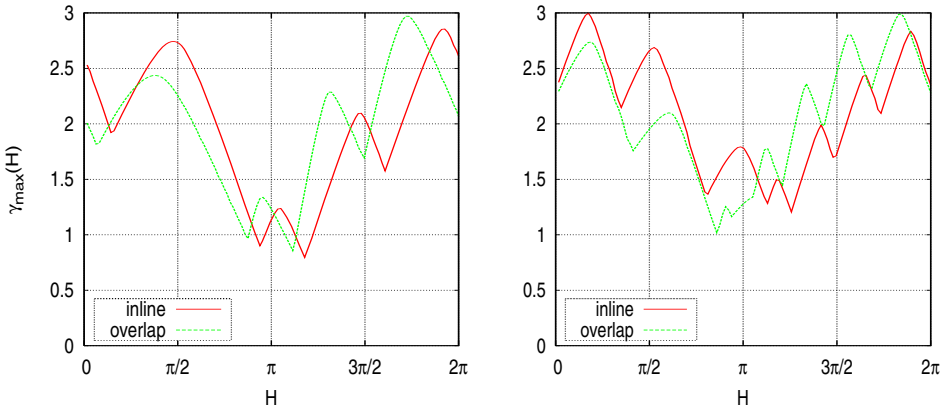

FIG. 7.1. *Plot of $\gamma_{max}(H)$ curves for a two-junction unit $a_1 = 1$, $a_2 = 2$ ($l_1 = 1$) and a third junction placed at $a_3 = 5$, $l_2 = 3$ (left panel) and $a_3 = 8$, $l_2 = 6$ (right panel). All the junctions have the coefficient $d_i = 1$.*

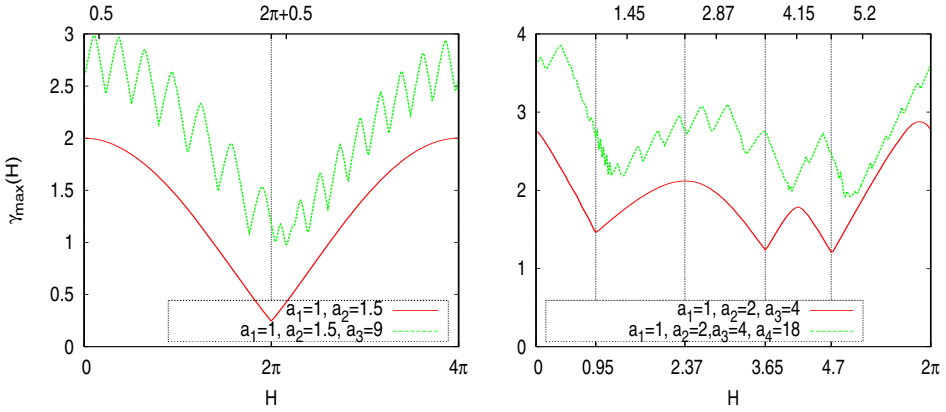

FIG. 7.2. *$\gamma_{max}(H)$ curves for all devices $d_i = 1$. Left panel: we compare a circuit of two junctions with one of three junctions: same junction unit plus one. Right panel: a three- and a four-junction circuit. We report on top of the box the expected shift to the left given by $d_{n+1}/2 = 0.5$.*

Proposition 4.1, we can state that as H goes from 0 to H_p, $\phi_2 - \phi_1$ goes from $\delta\phi_2$ to $\delta\phi_2 + 2\pi l_1/l_1 = \delta\phi_2 + 2\pi$. Similarly $\phi_3 - \phi_1$ goes from $\delta\phi_3$ to $\delta\phi_3 + 2\pi(l_2 + l_1)/l_1 = \delta\phi_3 + 2\pi(l_2/l_1 + 1)$, which becomes $\delta\phi_3 + 2\pi(k + 1)$ if the junctions are placed harmonically so that $l_2 = kl_1$. In that case we expect the $\gamma_{max}(H)$ curve to present $k + 1$ bumps within one period. In Figure 7.1, the junctions are placed in a harmonic way $a_3 - a_2 = k(a_2 - a_1)$, where $k = 3$ (left panel) and $k = 6$ (right panel). As expected, we see the four intermediate "bumps" in the $\gamma_{max}(H)$ curve in the left panel and seven bumps in the curve of the right panel. We can see the periodicity given by $H_p = 2\pi/(a_2 - a_1) \equiv 2\pi/l_1$, which adds new oscillations. This picture shows that the closer the third junction is to the junction unit, the fewer oscillations there are. These estimations hold approximately in the case of an array with more junctions.

In other words, when $a_3 - a_1$ is large, as in the right panel of Figure 7.1 and the left panel of Figure 7.2, the shape of the γ_{max} curve tends to that for a two-junction circuit. We explain this below.

7.2. Influence of a faraway single junction for the inline current feed. In Figure 7.2, for each panel we plot a γ_{max} curve, for an n-junction unit and another with the same junction unit plus a distanced junction. $(n+1)$-junction γ_{max} curves look like n-junction curves to which a shift has been added. We want to evaluate this shift.

Note that for the junction n, using the notation of (3.4) and (3.6), we know that ϕ_{n+1} is determined by P_{n+1}. If we increase P'_{n+1} of ϵ, then ϕ_{n+1} increases by $\epsilon(a_{n+1} - a_n)$. Thus, a variation at ϕ_n of $\epsilon = \pm\pi/(a_{n+1} - a_n)$ is enough to obtain $\sin\phi_{n+1} = 1$. The farther the last junction, the smaller ϵ, and consequently this junction has the smallest action on the junction unit. So, in the search of γ_{max}, the value of $\sin\phi_{n+1}$ is near 1. The γ^{n+1}_{max} curve of a circuit with $n+1$ junctions is close to $\gamma^n_{max} + d_{n+1}$, i.e., the curve for the n-junction circuit with n junctions plus the maximal contribution of the last junction.

Now let us assume that $\sin\phi_{n+1} = 1$. We must not forget the boundary conditions of our problem: $\phi'|_{\{0,l\}} = H \mp \gamma/2$. But boundary conditions at the junction unit are $\phi'(0) = H - \gamma/2$ and $a_n < x_0 < a_{n+1}$, $\phi'(x_0) = H + \gamma/2 - d_{n+1}$. We cannot compare this junction unit with the n-junction problem because of different boundary conditions. As we have done in section 5.2, let $H' = H - d_{n+1}/2$. The previous boundary conditions become

$$\phi'|_{\{0,a_n^+\}} = H' \mp \frac{\gamma}{2} \ .$$

We find wanted boundary values. Finally we show that

$$\lim_{a_{n+1}-a_n\to+\infty} \gamma^{n+1}_{max}\left(H + \frac{d_{n+1}}{2}\right) = \gamma^n_{max}(H) + d_{n+1}. \tag{7.1}$$

Figure 7.2 illustrates this convergence.

This argument cannot be extended simply to the overlap or general current feed, for two reasons. First, introducing or taking out the last junction a_{n+1} induces a variation of the magnetic shift H_ν given by (4.5). We could estimate it, but we have the problem that the curvature of ϕ for an n-junction device is $\nu j/2$, where j depends on the number of the junctions. This will affect the shift between the junctions and consequently the curve $\gamma_{\max}$.

However, numerical simulation shows that (7.1) remains a good approximation for the general case, even with a small number of junctions. The general feed and inline feed problems coincide when $d_{n+1}/\sum_1^n d_i$ tends to zero. Going back to the physical device, this means that the forces of the junctions are very small, $d_i \approx 10^{-2}$, and for these values the inline and overlap results are practically indiscernible from the magnetic approximation. Then (7.1) can be used.

7.3. A real device with five Josephson junctions. We have compared our theory to the experimental results for a device with two Josephson junctions. The same team at the Observatoire de Paris has made a device with five junctions. Here the γ_{max} curve obtained is totally different from the one for a simple SQUID. The parameters are $l_1 = 20$, $l_2 = 42$, $l_3 = 12$, and $l_4 = 6$. Figure 7.3 shows the γ_{max} curve where the current and magnetic field have been scaled using approximately the same factors as for the SQUID of Figure 6.2. Our modeling approach also gives excellent agreement for experimental uniform arrays of 5, 10, and 20 junctions.

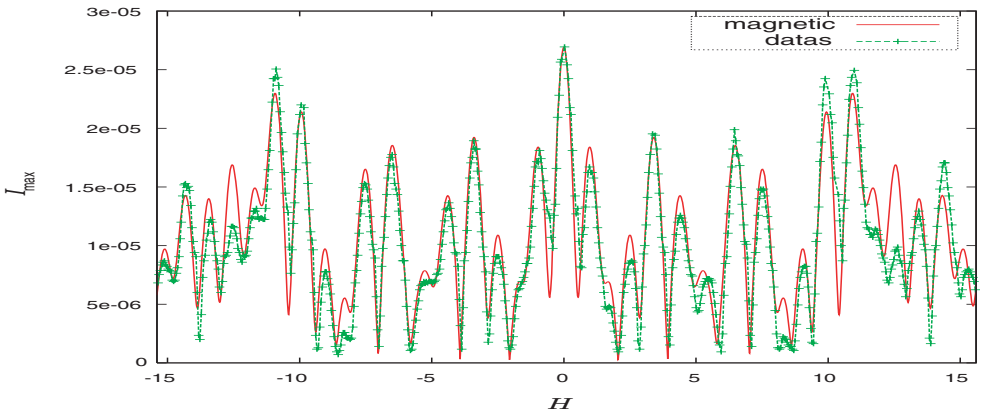

FIG. 7.3. *Experimental $I_{\max}(H)$ for an array of five junctions in a 2D microstrip line built by Salez and Boussaha of the Observatory of Paris (reproduced with their permission). The measured data is presented by the + symbols, and the magnetic approximation result is shown with a solid line.*

8. Conclusion. We have mathematically analyzed a new continuous/discrete model for describing arrays of small Josephson junctions. Compared to standard "lumped" approaches we do not approximate the equations, except for neglecting the phase variation in the junction. In particular, our approach preserves the matching at the interface.

We establish the periodicity of the $\gamma_{max}(H)$ curve and show how it depends on the position of the array with respect to the microstrip. This is particularly interesting for estimating the proportion of inline current feed versus overlap feed. We show how separating a junction from an array will influence $\gamma_{max}(H)$.

We introduce a numerical method for estimating $\gamma_{max}(H)$ which is more reliable than the standard Newton method used up to now.

The relative simplicity of the model allows in-depth analysis that is out of reach for the 2D model. In particular, we show that solutions for general current feed tend to the solutions of inline feed when $\nu j/l \to 0$. All models reduce to what we call the magnetic approximation for small d_i.

Our global model gives a very good agreement with experimental curves obtained for arrays of up to five junctions. The simplicity of the magnetic approximation allows us to address the inverse problem of determining features of the array from $\gamma_{max}(H)$.

9. Appendix.

9.1. Implicit curves. In this part, we give an example of $P'_{n+1}(x)$ for systems with three junctions. We define the following:

$$\begin{cases} \sin_1 &= \sin(\phi_1), \\ C_1 &= \left(d_1 \sin(\phi_1) - \dfrac{\nu\gamma a_1}{l} + H - (1-\nu)\,\dfrac{\gamma}{2}\right)(a_2 - a_1) + \phi_1, \\ D_j &= \dfrac{\nu\gamma(a_{j+1} - a_j)^2}{2l}. \end{cases}$$

Then (3.4) and (3.6) give

$$P_3'(x) = -\frac{\nu\gamma x}{l} + d_2\sin(-D_1 + C_1) + d_1\sin_1 + H - (1-\nu)\frac{\gamma}{2}, \tag{9.1}$$

$$\begin{aligned} P_4'(x) = -\frac{\nu\gamma x}{l} + d_3\sin\Big[-D_2 + \Big\{-d_2\sin(D_1 - C_1) - \frac{\nu\gamma a_2}{l} \\ + d_1\sin_1 + H - (1-\nu)\frac{\gamma}{2}\Big\}(a_3 - a_2) - D_1 + C_1\Big] \\ + d_2\sin(-D_1 + C_1) + d_1\sin_1 + H - (1-\nu)\frac{\gamma}{2}. \end{aligned} \tag{9.2}$$

This example shows that $P_k'(x)$ is C^∞ in the variables $(\gamma, \phi_1, \nu, H, x)$. In particular, $P_n'(l)$ is C^∞ in the variables (γ, ϕ_1, ν, H).

9.2. The current feed factor ν: Analytical estimates. Equation (4.9) shows that we tend to an inline current feed when l is large. However, we should show that the γ_{max} curve tends to that for the inline feed.

LEMMA 9.1 (solution). *$\forall\,\phi_1$ and H $\exists$ a γ such that* (4.1) *has a solution.*

Proof. As we have seen in section 5.2, it is sufficient to solve (5.1), $P_{n+1}'(l) = H + (1-\nu)\gamma/2$, to find a solution. Let us fix a value for ϕ_1 with ν, H, l given. If $\gamma < -\sum_{i=1}^n d_i$, then $P_{n+1}'(l) < H + (1-\nu)\gamma/2$. Conversely when $\gamma > \sum_{i=1}^n d_i$, we obtain $P_{n+1}'(l) > H + (1-\nu)\gamma/2$. But by construction, $P_{n+1}'(l)$ is a function continuous in all its variables, in particular γ. Thus we have at least one value of γ in $[-\sum_{i=1}^n d_i, \sum_{i=1}^n d_i]$ such that $P_{n+1}'(l) = H + (1-\nu)\gamma/2$, and thus it is a solution for that value of ϕ_1. ∎

We want to study the variation of $\gamma(H)$ versus the current feed ν. At this point, we do not consider the γ_{max} curve. Let us fix ϕ_1. Using the previous property, we know that there exists at least one solution of (4.1), and particularly almost one γ. Without changing ϕ_1 or H, we plot all the possible γ versus ν in Figure 9.1. We call this curve the $\gamma(\nu)$ curve. To plot this $\gamma(\nu)$ curve, we use the same parameter as in Figure 4.3, with $H = 1.3617$ (see the top panel; we choose this H because there is a big difference between the solution for inline and overlap current feeds). We choose for ϕ_1 the value found with Maple, giving the maximum γ_{max} for the inline feed. Figure 9.1 (top panel), for $\nu = 0$, confirms the γ_{max} value found in Figure 4.3. But for overlap the maximum current we can obtain is near 0. Thus, there is another value of ϕ_1 for γ_{max} of overlap current feed ($\phi_1 \approx 0.252$).

Let us study the curve $\gamma(\nu)$. By definition, $\gamma = \sum_{i=1}^n d_i\sin(\phi_i)$. Let ϕ_1 be a value such that $\partial\gamma/\partial\nu$ exists; then

$$\begin{aligned} \frac{\partial\gamma}{\partial\nu} &= \sum_{i=1}^n d_i\frac{\partial\phi_i}{\partial\nu}\cos(\phi_i), \\ \left|\frac{\partial\gamma}{\partial\nu}\right| &\le \sum_{i=1}^n d_i\left|\frac{\partial\phi_i}{\partial\nu}\right|. \end{aligned} \tag{9.3}$$

With $\phi_i = \phi(a_i)$, we note in the following: $\phi_i' = \lim_{\epsilon\to 0}\phi'(a_i - \epsilon)$ (the left derivative of ϕ). Let us make some remarks: as ϕ_1 is fixed,

$$\left.\frac{\partial\phi_1}{\partial\nu}\right|_{\nu=0} = 0,$$

$$\frac{\partial\phi_1'}{\partial\nu} = \frac{\partial}{\partial\nu}\left\{H - \left(\frac{1}{2} - \frac{\nu l_b}{2l}\right)\frac{\gamma}{2}\right\} = -\left(\frac{1}{2} - \frac{\nu l_b}{2l}\right)\frac{\partial\gamma}{\partial\nu} + \frac{l_b\gamma}{4l};$$

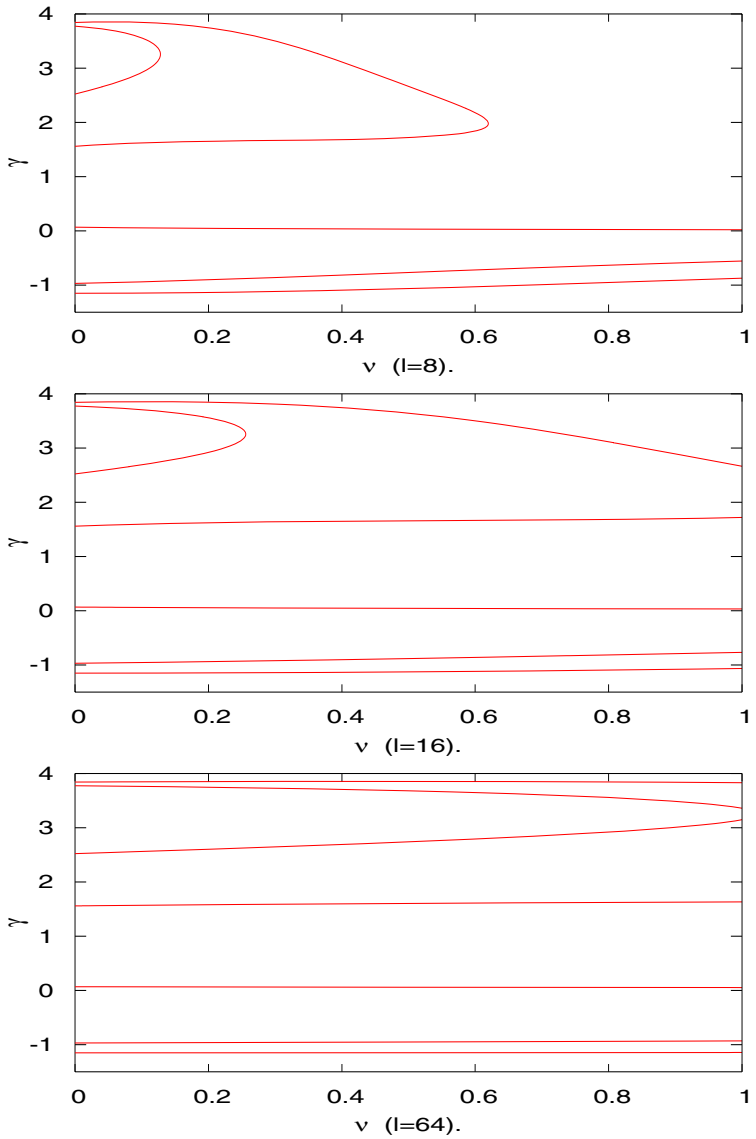

FIG. 9.1. *Each panel corresponds to the devices studied in the panels of Figure* 4.3. *We plot the implicit curve* $\gamma(\nu)$ *curve for* $H = 1.3617$, $\phi_1 = 1.3897$, *corresponding to field* H *giving the maximum current* $\gamma_{max}(H)$ *for the inline feed. From top to bottom we increase the length of the device and notice the stretching of the* $\gamma(\nu)$ *curve (with the coefficient found in* (4.9): l_b/l*).*

using (3.4) and (3.6) we can begin iteration,

$$\frac{\partial \phi_i}{\partial \nu} = -\left(\nu \frac{\partial \gamma}{\partial \nu} + \gamma\right) \frac{l_{i-1}^2}{2l} + l_{i-1} \frac{\partial \phi'_{i-1}}{\partial \nu} + \frac{\partial \phi_{i-1}}{\partial \nu}(d_{i-1} l_{i-1} \cos(\phi_{i-1}) + 1),$$

$$\frac{\partial \phi'_i}{\partial \nu} = -\left(\nu \frac{\partial \gamma}{\partial \nu} + \gamma\right) \frac{l_{i-1}}{l} + d_{i-1} \frac{\partial \phi_{i-1}}{\partial \nu} \cos(\phi_{i-1}) + \frac{\partial \phi'_{i-1}}{\partial \nu},$$

with $l_i = a_{i+1} - a_i$. This last equation can be written, for $i \geq 3$,

$$\left.\frac{\partial \phi_i'}{\partial \nu}\right|_{\nu=0} = -\left(\nu \frac{\partial \gamma}{\partial \nu} + \gamma\right) \frac{a_i - a_1}{l} + \left.\frac{\partial \phi_1'}{\partial \nu}\right|_{\nu=0} + \sum_{k=2}^{k-1} d_k \frac{\partial \phi_k}{\partial \nu} \cos(\phi_k).$$

We obtain

$$\begin{aligned}
\frac{\partial \phi_{i+1}}{\partial \nu} &= -K_1^i \frac{\partial \gamma}{\partial \nu} - K_2^i \gamma + \frac{\partial \phi_i}{\partial \nu} + l_i \sum_{k=2}^{i} d_k \frac{\partial \phi_k}{\partial \nu} \cos(\phi_k), \\
K_1^i &= l_i \left[\frac{\nu l_i}{2l} + \nu \frac{a_{i+1} - a_1}{l} + \frac{1}{2} - \frac{\nu l_b}{2l}\right], \\
K_2^i &= l_i \left[\frac{l_i}{2l} + \frac{a_{i+1} - a_1}{l} - \frac{l_b}{2l}\right].
\end{aligned}$$

Applying absolute values, we obtain

$$\left|\frac{\partial \phi_{i+1}}{\partial \nu}\right| \leq K_1^i \left|\frac{\partial \gamma}{\partial \nu}\right| + K_2^i |\gamma| + \left|\frac{\partial \phi_i}{\partial \nu}\right| + l_i \sum_{k=2}^{i} d_k \left|\frac{\partial \phi_k}{\partial \nu}\right|. \tag{9.4}$$

We do not need to find the exact expression of $|\partial \phi_{i+1}/\partial \nu|$; we know that it is a linear combination of $|\partial \gamma/\partial \nu|$ and $|\gamma|$ and so is $|\partial \phi_2/\partial \nu|$. Using (9.4), we can show by iteration that $|\partial \phi_i/\partial \nu|$ is a linear combination of $|\partial \gamma/\partial \nu|$ and $|\gamma|$. Applying this last remark to inequality (9.3), we obtain that there exist two constants, C_1 and C_2, such that

$$\left|\frac{\partial \gamma}{\partial \nu}\right| \leq C_1 \left|\frac{\partial \gamma}{\partial \nu}\right| + C_2 |\gamma|;$$

C_1 and C_2 are a combination of d_i, l_i, K_1^i, and K_2^i. For ν and d_i sufficiently small, $|C_1| < 1$; then

$$\left|\frac{\partial \gamma}{\partial \nu}\right| \leq \frac{C_2}{1 - C_1} |\gamma|. \tag{9.5}$$

This last equation implies local continuity of the γ curve as a function of ν. As we have seen in section 4.3, increasing l is equivalent to decreasing the range of ν (given by μ). $\forall \epsilon$, $\exists L /\ l \geq L \Rightarrow \mu \leq \epsilon$. This shows the convergence of the γ_{max} $(0 \leq \nu \leq 1)$ curve to the one for inline current feed when $l \to +\infty$.

9.3. Convergence by the junction coefficient d_i. We want to show that the solution for the general case converges to the solution of the inline case, for small d_i. We have shown in Lemma 9.1 that for H and ϕ_1 given, we can find at least one solution, whatever ν. This shows that for the same ϕ_1, we can find a general and an inline solution. Let us define the following:

1. $P_n^i(x)$, $\forall x \in]a_n, a_{n+1}[$, a solution of inline problem ($\nu = 0$) of this circuit, γ^i the maximal current associated to the value ϕ_1.

2. $P_n^g(x)$, $\forall x \in]a_n, a_{n+1}[$, a general solution ($\nu \neq 0$, same l, and same junction unit), γ^g the maximal current associated with the value ϕ_1.

3. α_j and β_j by

$$\begin{cases} \alpha_j = P_j^{g'}(a_j) - P_j^{i'}(a_j), \\ \beta_j = P_j^g(a_j) - P_j^i(a_j). \end{cases}$$

As $P_1^g(a_1) = \phi_1 = P_1^i(a_,)$, we have $\beta_1 = 0$. We can calculate α_1 using (4.8),

$$\alpha_1 = P_1^{g'}(a_1) - P_1^{i'}(a_1) = -\frac{\gamma^i - \gamma^g}{2} + \frac{\nu l_b}{2l}\gamma^g.$$

However, γ^i and γ^g are positive, and so

$$|\alpha_1| \leq \left(\frac{1}{2} + \frac{\nu l_b}{2l}\right) \sum_{i=1}^{n} d_i. \tag{9.6}$$

The aim of the following is to give an upper bound for β_i. We proceed by iteration. We recall that $l_k = a_{k+1} - a_k$. Using (3.6), we estimate β_{k+1}:

$$\beta_{k+1} = \frac{-\nu\gamma^g}{2l} l_k^2 + \left[d_k(\sin(P_k^g(a_k)) - \sin(P_k^i(a_k))) + \alpha_k\right] l_k + \beta_k. \tag{9.7}$$

Let us focus on the sine terms,

$$\begin{aligned}
\sin(P_k^g(a_k)) - \sin(P_k^i(a_k)) &= \sin(P_k^i(a_k) + \beta_k) - \sin(P_k^i(a_k)) \\
&= \sin(P_k^i(a_k))\left[\cos(\beta_k) - 1\right] + \sin(\beta_k)\cos(P_k^i(a_k)) \\
&\leq |\beta_k|^2 + |\beta_k|.
\end{aligned}$$

We assume $\beta_k \gg 1$, and thus we obtain the equivalences $\beta_k \approx \sin(\beta_k)$ and $-\beta_k^2 \approx \cos(\beta_k) - 1$, but we cannot predict the sign of $\sin(P_k^i(a_k))$ or $\cos(P_k^i(a_k))$. We neglect $|\beta_k|^2$. From (9.7),

$$\begin{aligned}
|\beta_{n+1}| &\leq \left|\frac{\nu\gamma^g}{2l} l_n^2\right| + (d_n|\beta_n| + |\alpha_n|)\, l_n + |\beta_n|, \\
|\alpha_{n+1}| &\leq \left|\frac{\nu\gamma^g}{l} l_n\right| + d_n|\beta_n| + |\alpha_n|.
\end{aligned}$$

Let us note $G = \nu \sum_{i=1}^{n} d_i/l$; we then obtain a simple system

$$\zeta_{n+1} \leq M_n \zeta_n + G V_n, \tag{9.8}$$

with, $\zeta_n = \begin{pmatrix} c|\beta_n| \\ |\alpha_n| \end{pmatrix}$, $M_n = \begin{pmatrix} cc d_n l_n + 1 & l_n \\ d_n & 1 \end{pmatrix}$, and $V_n = \begin{pmatrix} c l_n^2/2 \\ l_n \end{pmatrix}$. So, we bound $|\beta_n|$ and $|\alpha_n|$ from above, with $|\beta_1|$ and $|\alpha_1|$:

$$\zeta_n \leq M_{n-1}(\dots(M_2(M_1\zeta_1 + GV_1) + GV_2)\dots) + GV_{n-1}\ . \tag{9.9}$$

When $d_i \to 0$,

1. $G \to 0$; then equation (9.9) tends to $\zeta_n \leq M_{n-1} \dots M_2 M_1 \zeta_1$.
2. $M_k \to \begin{pmatrix} cc1 & l_k \\ 0 & 1 \end{pmatrix}$; then, $M_k \dots M_2 M_1 \to \begin{pmatrix} cc1 & \sum_{i=1}^{k-1} l_i \\ 0 & 1 \end{pmatrix}$.

From the two previous points, we obtain that

$$|\beta_i| \leq |\beta_1| + |\alpha_1|(a_i - a_1) + O\left(\sum_{i=1}^{n} d_i\right).$$

Using (9.6), we have $|\alpha_1|(a_i - a_1) \leq \left(l_b/2 + \nu l_b^2/(2l)\right) \sum_{i=1}^{n} d_i$, and the previous inequality becomes, $\forall i \in \{1, \dots, n\}$,

$$|\beta_i| \leq |\beta_1| + O\left(\sum_{i=1}^{n} d_i\right). \tag{9.10}$$

Remember that $\beta_1 = 0$. Then (9.10) shows that γ^g tends to γ^i. Since this convergence occurs independently of ϕ_1, we obtain the convergence of the γ_{max} curve.

9.4. Inline—Magnetic convergence. We show in this section the convergence of an inline solution to the magnetic approximation when $d_i \ll 1$. We already know that in this case the γ_{max} curve in overlap (or in general case) and inline tend to the same behavior. So, in this way, we show that $\forall\, \nu$ the γ_{max} curve of (4.1) tends to the magnetic approximation when $d_i \ll 1$.

We know that the magnetic approximation is given by $f(x) = Hx + c_{max}(H)$. Notice that c_{max} does not depend on the γ value (see (4.11)). We are going to compare the magnetic approximation and the inline current feed solution for the same geometry. We proceed as in the previous part, choosing $\phi_1 = Ha_1 + c_{max}$. Remember that in the inline case, ϕ is piecewise linear. Then $\forall x \in]a_i, a_{i+1}[$,

$$P_{i+1}(x) = (d_i \sin(P_i(a_i)) + P_i'(a_i))(x - a_i) + P_i(a_i).$$

Let us define

$$\begin{aligned} \alpha_i &= P_i'(a_i) - f'(a_i) = P_i'(a_i) - H, \\ \beta_i &= P_i(a_i) - f(a_i). \end{aligned}$$

We obtain that $\alpha_1 = -\gamma/2$, $\beta_1 = 0$ and, for an n-junction circuit, $\alpha_{n+1} = \gamma/2$. We estimate α_{i+1}:

$$\alpha_{i+1} = d_i \sin(P_i(a_i)) + P_i'(a_i) - H = d_i \sin(P_i(a_i)) + \alpha_i.$$

We obtain $\alpha_{i+1} = \sum_{j=1}^{i} d_j \sin(P_j(a_j)) + \alpha_1$, and thus

$$|\alpha_{i+1}| \le \sum_{k=1}^{n} d_k \ . \tag{9.11}$$

We write β_{i+1}:

$$\begin{aligned} \beta_{i+1} &= (d_i \sin(P_i(a_i)) + P_i'(a_i))(a_{i+1} - a_i) + P_i(a_i) - Ha_{i+1} + b \\ &= (d_i \sin(P_i(a_i)) + P_i'(a_i) - H)(a_{i+1} - a_i) + P_i(a_i) - Ha_i + b \\ &= \alpha_{i+1}(a_{i+1} - a_i) + \beta_i. \end{aligned}$$

Thus if $\beta_1 = 0$, then

$$\beta_i = \sum_{k=1}^{i-1} \alpha_{k+1}(a_{k+1} - a_k) \ . \tag{9.12}$$

Now using the bounds on the α's and bounding the l_i's, we get

$$|\beta_i| \le n l_b \sum_{k=1}^{n} d_k \ . \tag{9.13}$$

This shows that γ_{max} of (4.1) tends to the magnetic approximation when $\sum_{k=1}^{n} d_k$ tends to 0.

Acknowledgments. Both authors wish to thank Faouzi Boussaha and Morvan Salez for helpful discussions and for their experimental results. The authors also thank Yuri Gaididei for useful suggestions. The computations were done at the Centre de Ressources Informatiques de Haute-Normandie (CRIHAN).

FIRST-ORDER CONTINUOUS MODELS OF OPINION FORMATION*

GIACOMO ALETTI†, GIOVANNI NALDI†, AND GIUSEPPE TOSCANI‡

Abstract. We study certain nonlinear continuous models of opinion formation derived from a kinetic description involving exchanges of opinion between individual agents. These models imply that the only possible final opinions are the extremal ones, and they are similar to models of pure drift in magnetization. Both analytical and numerical methods allow us to recover the final distribution of opinion between the two extremal ones.

Key words. nonlinear nonlocal hyperbolic equation, sociophysics, opinion formation, magnetization

1. Introduction.

This paper is devoted to the analysis and large-time behavior of solutions of the equation

$$\frac{\partial f}{\partial t} = \gamma \frac{\partial}{\partial x}\left((1-x^2)(x-m(t))f\right), \tag{1.1}$$

where the unknown $f(x,t)$ is a time-dependent probability density which may represent the density of opinion in a community of agents. This opinion varies between the two extremal opinions represented by ± 1, so that $x \in \mathcal{I} = [-1,1]$. The constant γ is linked to the spreading ($\gamma = -1$) or to the concentration ($\gamma = +1$) of opinions. In (1.1) $m(t)$ represents the mean value of $f(\cdot,t)$,

$$m(t) = \int_{\mathcal{I}} x\, f(x,t)\, dx, \tag{1.2}$$

and its presence introduces a nonlinear effect into its evolution.

When $\gamma = -1$, the related linear equation

$$\frac{\partial f}{\partial t} = -\frac{\partial}{\partial x}\left(x(1-x^2)f\right) \tag{1.3}$$

has been introduced recently by Slanina in [15] to analyze the evolution of density opinions in the voter model on a complete graph. There, the equation was derived as the mean field limit of the Sznajd model [20] in the case of two opinions. Because of linearity, (1.3) allows for an analytical treatment, and it is possible (see, e.g., [1, 15]) both to obtain the exact solution and to control the rate of decay towards the equilibrium for all values of γ (see also, e.g., [3]). Equation (1.1) was introduced in [22], in

connection with the asymptotic limit of a Boltzmann equation for the kinetic description of opinion formation involving binary exchange of opinion between individual agents. This kinetic description is based on two-body interactions involving both compromise and diffusion properties in exchanges between individuals. Compromise and diffusion were quantified in [22] by two parameters, which are mainly responsible of the behavior of the model, and allow for a rigorous asymptotic analysis in which the limiting model is a Fokker–Planck-type equation, where the second-order term is related to diffusion, while the drift term is due to compromise. In a compromise-dominated regime, the resulting equation is exactly (1.1). We point out that, contrary to (1.3), the presence of the mean value $m(t)$ in (1.1) takes into account the influence of the mean opinion on the compromise-dominated dynamics.

Microscopic models of both social and political phenomena describing collective behaviors and self-organization in a society have been recently introduced and analyzed by several authors (see, e.g., [2, 6, 7, 8, 11, 12, 14, 16, 17, 18, 20, 25, 26]). The leading idea is that collective behaviors of a society composed of a sufficiently large number of individuals (agents) can be hopefully described using the laws of statistical mechanics as it happens in a physical system composed of many interacting particles. The details of the social interactions between agents then characterize the emerging statistical phenomena.

Equation (1.3), or in general (1.1) with $\gamma = -1$, can also describe a pure drift in magnetization (see, e.g., [19] and the references therein), where the two extremal points of $\mathcal{I}$ represent the opposite attraction poles. In the kinetic picture of [22], it simply means that the compromise in the binary interaction is substituted by magnetic repulsion between agents. Moreover, the case $\gamma = +1$ is related to models of one-dimensional nonlinear friction equations considered in the study of granular flows (see, e.g., [13, 21]), in connection with the quasi-elastic limit of a Boltzmann equation for rigid spheres with dissipative collisions and variable coefficient of restitution.

The paper is organized as follows. In the next section we introduce the main properties of the model, which justify the treatment in terms of a suitable weak formulation. The qualitative analysis is given in section 3. The large-time behavior is considered in sections 4–6. It is shown that the problem can be solved in sufficiently high generality only in the case of concentration ($\gamma = +1$). This lack of generality in the analytical treatment of the large-time behavior of the solution in the spreading of opinion justifies the numerical treatment of the equation. The numerical approximation is included in section 7, where both the explicit solution of (1.3) and the knowledge of the steady state in the concentration case ($\gamma = +1$) are used as benchmark tests for the numerical scheme. Finally, we note that the mathematical methods used here are close to the recent framework considered in the context of kinetic theory of nonlinear friction equations [10] and made popular by the mass transportation community [24].

2. Main properties and weak description. As briefly described in the introduction, (1.1) describes the evolution of a probability density which represents the density of opinions in a community. For all values of the constant γ, we will show that the time-evolution driven by this equation leads the density towards a equilibrium state that is described in terms of two Dirac masses ($\gamma = -1$) or to a unique Dirac mass ($\gamma = 1$). Having in mind that the equilibrium solution to equation (1.1) is given by Dirac masses, any convergence result towards equilibrium holds in a weak*-measure sense. The recent analysis of [10] of the nonlinear friction equation introduced by McNamara and Young [13] suggests that a suitable way of treating

(1.1) is based on a rewriting of this equation in terms of pseudoinverse functions. It is immediate to show that the drift operator on the right-hand side of (1.1) preserves positivity and mass,

$$\int_{\mathcal{I}} f(x,t)\,dx = \int_{\mathcal{I}} f_0(x)\,dx. \tag{2.1}$$

Then, given a initial datum which is a probability density (nonnegative and with unit mass), the solution remains a probability density at any subsequent time. Let $F(x)$ denote the probability distribution induced by the density $f(x)$,

$$F(x) = \int_{(-\infty,x]} f(y)\,dy \tag{2.2}$$

and let μ denote the distribution on $\mathbb{R}$ associated to F. Since $F(\cdot)$ is not decreasing, we can define its pseudoinverse function (also called quantile function) by setting, for $\rho \in (0,1)$,

$$X^{\mu}(\rho) = X^{F}(\rho) = \inf\{x : F(x) \geq \rho\}.$$

Equation (1.1) for $f(x,t)$ takes a simple form if written in terms of its pseudoinverse $X(\rho,t)$. Theorem 3.1 shows in fact that the evolution equation for $X(\rho,t)$ reads

$$\frac{\partial X(\rho,t)}{\partial t} = -\gamma\,(X(\rho,t) - m(t))\,(1 - X^2(\rho,t)), \tag{2.3}$$

where now $\rho \in (0,1)$. Note that if we assume F to be absolutely continuous with respect to x and strictly increasing, then Theorem 3.1 reduces to elementary computations. In (2.3)

$$m(t) = \int_0^1 X(\rho,t)\,d\rho. \tag{2.4}$$

Let us set $\gamma = -1$ (spreading). Then the weak form (2.3) clarifies the evolution of $X(\rho,t)$ and the role of $m(t)$. In fact, if $X(\rho,t) > m(t)$, $X(\rho,t)$ increases towards 1, while $X(\rho,t) < m(t)$ implies that $X(\rho,t)$ decreases towards -1. Hence, the mean opinion $m(t)$ represent a barrier for the density of opinions to move towards one of the two extremal opinions. The fact that the mean opinion varies with time makes the nonlinear problem harder to handle with respect to the linear problem considered in [15] where the barrier is fixed equal to zero.

Among the metrics which can be defined on the space of probability measures, which metricize the weak convergence of measures [27], one can consider the L^p-distance ($1 \leq p < \infty$) of the pseudoinverse functions

$$d_p(X,Y) = \Big(\int_0^1 |X(\rho) - Y(\rho)|^p\,d\rho\Big)^{1/p}. \tag{2.5}$$

In what follows, we'll use the usual identifications

$$d_p(X,Y) = d_p(f_X,f_Y) = d_p(F_X,F_Y) = d_p(\mu_X,\mu_Y)\,,$$

where μ_X (μ_Y), F_X (F_Y), and f_X (f_Y) denote the distribution, the cumulative function, and the density associated to X (Y), respectively. By this identification, as one can see [10, 23, 24], $d_2(F,G)$ is nothing but the Wasserstein metric [23].

In addition to nonlinear friction equations arising in the modeling of granular gases [10], the strategy of passing to pseudoinverse functions has been recently applied to nonlinear diffusion equations of porous medium type [5] and to degenerate convection–diffusion equations [4]. This rewriting of nonlinear diffusion equations has been shown to be useful in order to obtain simple explicit numerical schemes that satisfy a contraction property with respect to the Wasserstein metric [9].

3. Existence, uniqueness, and well-posedness of the problem. In this section we will study the initial value problem for (1.1), with initial density

$$f(x, t = 0) = f_0(x), \quad x \in \mathcal{I}. \tag{3.1}$$

As before, we will denote by $X_0(\rho)$ the quantile function corresponding to f_0, so that

$$X(\rho, t = 0) = X_0(\rho) = \inf\{x : F_0(x) \geq \rho\}, \quad \rho \in [0, 1]. \tag{3.2}$$

The equivalence between (1.1) and (2.3) is contained in the following.

THEOREM 3.1. *There exists a weak solution of* (1.1)–(3.1) *if and only if there exists a solution of* (2.3)–(3.2).

Proof. Suppose first that there exists $f(x, t)$ which solves (1.1)–(3.1). Then $m(t)$ is a differentiable function of time. Let $y(t)$ be the maximal C^1 solution of the Abel differential equation:

$$\begin{cases} y' = -\gamma(1 - y^2)(y - m(t)), \\ y(0) = \bar{y}_0, \end{cases} \tag{3.3}$$

where, for any $y_0 \in [-1, 1]$, we denoted by $\bar{y}_0$ a C^1-extension of y_0 to $\mathbb{R}$. We have, in weak sense,

$$\begin{aligned} \frac{d}{dt} \int_{(-\infty, y(t)]} f(x, t)\, dx &= \int_{\mathbb{R}} \Big[\frac{\partial}{\partial t} \Big(\mathbb{1}_{(-\infty, y(t)]}(x) \Big) f(x, t) + \mathbb{1}_{(-\infty, y(t)]}(x) \frac{\partial}{\partial t} f(x, t) \Big]\, dx \\ &= \int_{\mathbb{R}} \big(y'(t) \delta_{y(t)}(x) + \gamma[\delta_{y(t)}(x)(1 - x^2)(x - m(t))] \big) f(x, t)\, dx \\ &= 0\,. \end{aligned} \tag{3.4}$$

Since $X(\rho, t) \leq x \iff \rho \leq \int_{-\infty}^{x} f(y, t)\, dy$, the first part of the proof has been shown.

Now, let $X(\rho, t)$ be a solution of (2.3)–(3.2). As a consequence of the properties of the solution to Abel's equation (3.3), given any initial datum $X(\rho, 0)$ satisfying

- $X(\rho, 0) \in [-1, 1]$;
- $X(\rho, 0)$ is nondecreasing;
- $X(\rho, 0)$ is left-continuous,

the same properties are preserved at any subsequent time $t > 0$. Hence, for any t, $\{X(\rho, t),\ \rho \in (0, 1)\}$ is the quantile function of a unique probability measure on $[-1, 1]$. We have only to prove that (1.1) holds. This is a consequence of the change

of variables formula. In fact, if h is a test function,

$$\begin{aligned}\int_{\mathbb{R}} h(x)\frac{\partial}{\partial t}f(x,t)\,dx &= \frac{\partial}{\partial t}\int_{\mathbb{R}} h(x)f(x,t)\,dx\\ &= \frac{\partial}{\partial t}\int_0^1 h(X_\rho(t))\,d\rho\\ &= \int_0^1 \frac{\partial}{\partial t}h(X_\rho(t))\,d\rho\\ &= \int_0^1 h'(X_\rho(t))\Big(-\gamma\left(X(\rho,t)-m(t)\right)\left(1-X^2(\rho,t)\right)\Big)\,d\rho\\ &= \int_{\mathbb{R}} h'(x)\big(-\gamma\left(x-m(t)\right)\left(1-x^2\right)\big)f(x,t)\,dx\\ &= \int_{\mathbb{R}} h(x)\frac{\partial}{\partial x}\Big(\gamma\left(x-m(t)\right)\left(1-x^2\right)f(x,t)\Big)\,dx\,. \qquad \square\end{aligned}$$

We call $(\mathcal{K},p)$ the (compact) set of probability distributions on $[-1,1]$ equipped with the p-Wasserstein distance. Note that all the p-Wasserstein distances on $(\mathcal{K},d)$ are equivalent. In fact, if $q\geq p\geq 1$,

$$\|X^{\mu_1}-X^{\mu_2}\|_p \leq \|X^{\mu_1}-X^{\mu_2}\|_q \leq 2^{1-p/q}\|X^{\mu_1}-X^{\mu_2}\|_p^{p/q}\,. \tag{3.5}$$

We will refer to $\mathcal{K}$ as the topological space of probability distributions on $[-1,1]$ induced by any of this metric: the weak*-topology. Before searching for a continuous solution of (1.1) in $\mathcal{K}$, we state the following trivial lemma.

LEMMA 3.2 (solution Abel). *Let $\phi(x,y)=-\gamma(1-x^2)(x-y)$. Then*

$$|\phi(x_1,y_1)-\phi(x_2,y_2)|\leq 4|x_1-x_2|+|y_1-y_2|\,.$$

Moreover, if f is a solution of $f'(t)=\phi(f(t),g(t))$ with $\sup|g(t)|\leq 1$ and $f(0)\in[-1,1]$,

$$|f(s)-f(t)|\leq 2|s-t|\,.$$

We call any function $\mu\in C^0(\mathbb{R},\mathcal{K})$ s.t. (1.1)–(3.1) holds a *solution of* (1.1)–(3.1). We have the following theorem.

THEOREM 3.3. *For any probability density $f_0(x)$ in* (3.1)*, there exists a unique function $\mu\in C^0(\mathbb{R},\mathcal{K})$ such that if $f(x,t)$ denotes the weak derivative of the probability distribution $\mu(t)$, $f(x,t)$ satisfies* (1.1) *with initial value* (3.1)*. Moreover, for any $t\in\mathbb{R}$, the solution depends in a continuous way on the initial datum: the problem* (1.1)–(3.1) *is well-posed in $C^0(\mathbb{R},\mathcal{K})$.*

Proof. [Existence] We prove the existence of a solution of the equivalent problem (2.3)–(3.2) (see Theorem 3.1) in a constructive way. More precisely,

(A) we construct a sequence $\{X_n,\, n\in\mathbb{N}\}$ which approximates a target solution;
(B) by compactness arguments, we find a convergent subsequence $X_{n_l}\to X$;
(C) the limit X satisfies (2.3)–(3.2).

Let $[-T,T]$ be fixed. For any $n\in\mathbb{N}$, we subdivide $[-T,T]$ into disjoint intervals of length $R/2^N$. Then we proceed as follows:

(A1) we compute $m_0^{(n)}=\int_0^1 X_0(\rho)\,d\rho$;
(A2) we solve (2.3) on $[-T/2^n,T/2^n]$ with $m^{(n)}(t)=m_0$, finding $X^{(n)}(\rho,t)$, $t\in[-T/2^n,T/2^n]$;

(A3) for any $k = 1, \dots, 2^n - 1$,

- we compute
$$m^{(n)}_{\pm k} = \int_0^1 X^{(n)}(\rho, \pm kT/2^n)\, d\rho;$$
- we solve (2.3) on $(kT/2^n, (k+1)T/2^n]$ with $m^{(n)}(t) = m^{(n)}_k$ and initial data $X^{(n)}(\rho, kT/2^n)$, finding $X^{(n)}(\rho, t)$, $t \in (kT/2^n, (k+1)T/2^n]$;
- we solve (2.3) on $[-(k+1)T/2^n, -kT/2^n)$ with $m^{(n)}(t) = m^{(n)}_{-k}$ and initial data $X^{(n)}(\rho, -kT/2^n)$, finding $X^{(n)}(\rho, t)$, $t \in [-(k+1)T/2^n, -kT/2^n)$.

We call $\mu^{(n)} : [-T, T] \to \mathcal{K}$ the sequence of function with value in $\mathcal{K}$ associated to $X^{(n)}$.

(B) For any $n \in \mathbb{N}$, it is possible to prove (by induction on k) that for any $t \in [-T, T]$, $X^{(n)}(\rho, t) \in [-1, 1]$ and $m^{(n)}(t) \in [-1, 1]$. As a consequence of Lemma 3.2, we have

$$\left|X^{(n)}(\rho, s) - X^{(n)}(\rho, t)\right| \le 2|t - s|, \tag{3.6}$$

i.e., for any $\rho \in (0, 1)$, $\{X^{(n)}(\rho, \cdot) : [-T, T] \to [-1, 1]\}_{n\in\mathbb{N}}$ is a uniformly equicontinuous sequence. A diagonal argument together with the Ascoli–Arzelà theorem ensure the existence of a subsequence n_l s.t. $\{X^{(n_l)}(\rho, \cdot) : [-T, T] \to [-1, 1]\}_{l\in\mathbb{N}}$ converges uniformly on $[-T, T]$ for each $\rho \in (0, 1) \cap \mathbb{Q}$.

Now, (3.6) implies

$$\int_0^1 |X^{(n)}(\rho, s) - X^{(n)}(\rho, t)|\, d\rho \le 2|t - s|\,, \tag{3.7}$$

i.e., $\mu^{(n)}$ is a equicontinuous sequence with respect to the distance d_1 on $\mathcal{K}$. Then the Ascoli–Arzelà theorem again ensures the existence of a subsection of n_l (we call it n_l again) such that

$$\sup_{t\in[-T,T]} d_1(\mu^{(n_k)}(t), \mu^{(n_l)}(t)) \le M(k \wedge l) \underset{k\wedge l\to\infty}{\longrightarrow} 0, \tag{3.8}$$

$$\sup_{t\in[-T,T]} |X^{(n_k)}(\rho, t) - X^{(n_l)}(\rho, t)| \le N_\rho(k \wedge l) \underset{k\wedge l\to\infty}{\longrightarrow} 0 \qquad \forall \rho \in \mathbb{Q} \cap (0, 1). \tag{3.9}$$

Now, let $\rho \in (0, 1) \cap \mathbb{Q}$ be fixed. $\{X^{(n_l)}(\rho, \cdot)\}_{l\in\mathbb{N}}$ is a uniform convergent sequence of derivable functions converging to $X(\rho, t) = \lim_l X^{(n_l)}(\rho, t))$. Left-continuity and monotonicity of $\{X(\rho, t),\ \rho \in (0, 1) \cap \mathbb{Q}\}$ extend the definition of $X(\rho, t)$ to all $\rho \in (0, 1)$.

(C) What remains to prove is

- $\lim_l m^{(n_l)}(t) = \int_0^1 X(\rho, t)\, d\rho =: m(t)$;
- $X(\rho, t)$ is differentiable, and (2.3) holds.

Note that, from (3.8), it follows immediately that $|\int_0^1 X^{(n_k)}(\rho, t)\, d\rho - \int_0^1 X^{(n_l)}(\rho, t)\, d\rho| \le M(k \wedge h)$ and hence

$$\left|\int_0^1 X(\rho, t)\, d\rho - \int_0^1 X^{(n_l)}(\rho, t)\, d\rho\right| \le M(h)\,. \tag{3.10}$$

By definition of $m^{(n)}$,

$$m^{(n)}(t) = m^{(n)}(\llbracket 2^n t \rrbracket/2^n) = \int_0^1 X^{(n)}(\rho, \llbracket 2^n t \rrbracket/2^n)\, d\rho,$$

where $[\![\cdot]\!]$ is the integer part of $\cdot$ closer to 0. Therefore,

$$\left|m^{(n)}(t) - \int_0^1 X^{(n)}(\rho,t)\,d\rho\right| \le 2^{-n+1} \tag{3.11}$$

and hence $m^{(n_l)}(t)$ is a Cauchy sequence on $[-1,1]$. Thus, there exists $\widehat{m}(t) = \lim_h m^{(n_l)}(t)$. By (3.10) and (3.11) it follows that $\widehat{m}(t) = m(t)$ since

$$\left|\widehat{m}(t) - \int_0^1 X(\rho,t)\,d\rho\right| \le \left|\widehat{m}(t) - m^{(n_l)}(t)\right| + 2^{-n_l+1} + M(h)\,.$$

Now, let $\rho \in (0,1)\cap\mathbb{Q}$ be fixed. For simplicity of notation, define $H(n,\rho,t) := \frac{\partial}{\partial s}X^{(n)}(\rho,s)\big|_{s=t}$. Moreover, we define

$$H(\rho,t) := \lim_{l\to\infty} H(n_l,\rho,t) = -\gamma(1-X(\rho,t)^2)(X(\rho,t)-m(t)).$$

The uniform convergence theorem states that $\frac{\partial}{\partial s}X(\rho,s)\big|_{s=t} = H(\rho,t)$ if $\{H(n_l,\rho,t)\}_{l\in\mathbb{N}}$ is a uniform converging sequence on $(-T,T)$. To prove this, let $k \ge l$. The triangular inequality

$$\begin{aligned}\left|H(n_k,\rho,t) - H(n_l,\rho,t)\right| &\le \left|H(n_k,\rho,t) - H(n_k,\rho,[\![2^{n_l}t]\!]/2^{n_l})\right| \\ &\quad + \left|H(n_k,\rho,[\![2^{n_l}t]\!]/2^{n_l}) - H(n_l,\rho,[\![2^{n_l}t]\!]/2^{n_l})\right| \\ &\quad + \left|H(n_l,\rho,[\![2^{n_l}t]\!]/2^{n_l}) - H(n_l,\rho,t)\right| \\ &= A_\rho(k,l,t) + B_\rho(l,k,t) + A_\rho(l,l,t)\end{aligned}$$

shows that we may prove that $\sup_{t\in[-T,T]} A_\rho(l,k,t) + B_\rho(l,k,t) + A_\rho(l,l,t) \underset{l\wedge k\to\infty}{\longrightarrow} 0$. As a consequence of (3.7) and (3.11), we have $|m^{(n)}(s) - m^{(n)}(t)| \le 2^{-n+2} + 2|t-s|$, which implies (see Lemma 3.2 and (3.6))

$$\begin{aligned}|H(n,\rho,s) - H(n,\rho,t)| &= \Big|(1-X^{(n)}(\rho,s)^2)(X^{(n)}(\rho,s) - m^{(n)}(s)) \\ &\qquad - (1-X^{(n)}(\rho,t)^2)(X^{(n)}(\rho,t) - m^{(n)}(t))\Big| \\ &\le 4|X^{(n)}(\rho,s) - X^{(n)}(\rho,t)| + |m^{(n)}(s) - m^{(n)}(t)| \\ &\le 10|t-s| + 2^{-n+2},\end{aligned}$$

and hence $A_\rho(k,l,t) \le 10\cdot 2^{-n_l} + 2^{-n_k+2}$. Now, let $k \ge l$ and $l \in \{-2^{n_l}+1,\dots,2^{n_l}-1\}$. Again, Lemma 3.2, (3.8), and (3.9) imply

$$\left|H(n_k,\rho,l/2^{n_l}) - H(n_l,\rho,l/2^{n_l})\right| \le 4N_\rho(l) + M(l),$$

and hence $B_\rho(k,l,t) \le 4N_\rho(l) + M(l)$. This completes the proof for $\rho \in (0,1)\cap\mathbb{Q}$. Now, fixing $y_0 \in [-1,1]$, let $y(t)$ be the maximal C^1 solution of the Abel differential equation (3.3). Since $X(\rho,t) \ge y(t) \iff X(\rho,0) \ge y(0)$ for all $\rho \in (0,1)\cap\mathbb{Q}$, left-continuity and monotonicity of $\{X_\rho(t),\ \rho\in(0,1)\}$ extend the proof to $\rho \in (0,1)$.

[Uniqueness and well-posedness] Let $Y(\rho,t), X(\rho,t)$ be two solutions of (1.1)–(1.2). Denote by $m_X(t)$ and $m_Y(t)$ the mean values of X and Y, respectively, at time

t. Since $|m_Y(t) - m_X(t)| \le d_1(X,Y)$ we have (by Lemma 3.2 and (3.5))

$$\begin{aligned}(3.12)\quad \frac{d}{dt} d_2(\mu_X(t),\mu_Y(t)) &= \frac{d}{dt}\int_0^1 \big(Y(\rho,t)-X(\rho,t)\big)^2\,d\rho \\ &\le 2\int_0^1 \big|Y(\rho,t)-X(\rho,t)\big|\Big(4\big|Y(\rho,t)-X(\rho,t)\big| + \big|m_Y(t)-m_X(t)\big|\Big)\,d\rho \\ &\le 10\cdot d_2(\mu_X(t),\mu_Y(t))\,.\end{aligned}$$

Gronwall's lemma completes the proof. ∎

4. Large-time behavior of solutions. Thanks to the uniqueness of solutions of Abel's equation, we obtain the following lemma.

LEMMA 4.1. *For any $t \ne s \in \mathbb{R}$ and $\rho \ne \rho' \in (0,1)$, we have*

$$X(\rho,t) = X(\rho',t) \iff X(\rho,s) = X(\rho',s)\,,$$

i.e., (1.1) *does not create or destroy delta masses in finite time.*

A direct consequence of the previous lemma is that the initial masses in $+1$, -1, and $(-1,1)$ remain unchanged in time. Let us call them p_{+1}, p_{-1}, and $1-(p_{+1}+p_{-1})$, respectively.

An important argument linked to the large-time behavior of solutions to nonlinear equations is the study both of conservation laws and of Lyapunov functionals. In addition to mass conservation, a second conserved quantity (when defined) is furnished by

$$(4.1)\qquad T(t) := \int_0^1 \log\Big(\frac{1+X(\rho,t)}{1-X(\rho,t)}\Big)\,d\rho\,.$$

In addition to the conservation of both mass and $T(t)$, equation (1.1) possesses a Lyapunov functional, simply given by the variance of the solution

$$(4.2)\qquad V(t) := \int_0^1 (X(\rho,t))^2\,d\rho - \Big(\int_0^1 X(\rho,t)\,d\rho\Big)^2.$$

We give below an easy-to-check condition which ensure both the the boundedness and the conservation in time of the functional (4.1).

LEMMA 4.2. *Let $\log\big((1+X(\rho,0))/(1-X(\rho,0))\big) \in L^1(0,1)$. Then for all $t \in \mathbb{R}$*

$$T(t) := \int_0^1 \log\Big(\frac{1+X(\rho,t)}{1-X(\rho,t)}\Big)\,d\rho$$

is well-defined. Moreover, $T(t)$ is differentiable and $T'(t) = 0$.

Proof. Since $\log\big((1+X(\rho,0))/(1-X(\rho,0))\big) \in L^1(0,1)$, then $X(\rho,0) \in (-1,1)$ for all $\rho \in (0,1)$. Now $(1-x^2)(x-1) \le (1-x^2)(x-m(t)) \le (1-x^2)(x-1)$, and hence the uniqueness of solutions of the Abel equations imply

$$X(\rho,t) \in (-1,1) \qquad \forall \rho \in (0,1)\,, \quad \forall t \in \mathbb{R}\,.$$

Let $G(\rho,t) = \log\big((1+X(\rho,t))/(1-X(\rho,t))\big)$. Since $|G_t(\rho,t)| \le 2$, we have

- $\exists G_t$ for all $\rho \in (-1,1)$, for all $t \in [-T,T]$;
- $|G(\rho,t)| \le |G(\rho,0)| + 2T$ and hence $T(t)$ exists;
- $|G_t(\rho,t)| \le 2$ and $2 \in L^1(0,1)$;

and hence it is possible to differentiate under the integral sign, obtaining $T'(t) = 0$. ∎

The following lemma shows that the variance is a Lyapunov functional for (1.1).

LEMMA 4.3. *The variance $V(t)$ of $\mu(t)$ is a monotone differentiable function with values in $[0,1]$.*

Proof. $V(t)$ is clearly differentiable, and

$$V'(t) = \frac{d}{dt}\int_0^1 (X_t(\rho) - m(t))^2\, d\rho = -2\gamma \int_0^1 (1 - X_t(\rho)^2)(X_t(\rho) - m(t))^2\, d\rho\,.$$

In the case $\gamma = -1$, $V(t)$ is monotonically increasing while bounded from above by 1. In fact, the maximum value of V is attained for $\mu = (\delta_1 + \delta_{-1})/2$. If, on the contrary, $\gamma = 1$, $V(t)$ is monotonically decreasing while bounded from below by 0. In this second case, the minimum value of V is attained for $\mu = \delta_a$, $a \in [-1,1]$. ∎

The most difficult problem linked to (1.1) is the study of the evolution of the mean $m(t)$ and to the exact evaluation of its limit value $\bar{m} = \lim_{t\to\infty} m(t)$. The knowledge of $\bar{m}$ is of primary importance, since in consequence of the structure of the limit state of the solution to (2.3), this value is enough to characterize completely the steady state.

Remark. The difficulty comes out from the evolution of the mean $m(t)$, which is given by the "nonclosed" equation

$$m'(t) = -\gamma m(t)\int_0^1 X^2(\rho)\, dr + \gamma \int_0^1 X^3(\rho)\, dr. \tag{4.3}$$

In what follows, we make use of the previous results to extract information on the behavior of the mean $m(t)$.

LEMMA 4.4. *For any t, $m(t) \in [-\sqrt{1 - V(t)}, \sqrt{1 - V(t)}]$.*

Proof. Since $V(t) = \int x^2 f(x,t)dx - (m(t))^2$, then $V(t) \le 1 - (m(t))^2$. ∎

LEMMA 4.5. *The function $m' : \mathbb{R} \to [-1,1]$ belongs to $L^2(\mathbb{R})$. Moreover, $\exists \lim_{t\to\infty} m'(t) = 0$.*

Proof. It is sufficient to note that

$$(m'(t))^2 \le \int \left(1 - X_\rho(t)^2\right)^2 (X_\rho(t) - m(t))^2\, d\rho \le V'(t),$$

and hence $m' \in L^2(\mathbb{R})$ by Lemma 4.3. Moreover, since m' is a Lipschitz function (in fact it is differentiable and $m'' \le 10$; cf. (4.3)), it follows that $\lim_{t\to\infty} m'(t) = 0$. ∎

5. Spreading of opinions. In this section we study the large behavior of (1.1) when $\gamma = -1$, leaving the opposite case $\gamma = 1$ to the following section.

Remark. If $X(\rho,0) = -X(1-\rho,0)$ (i.e., the initial distribution is symmetric), then from (4.3) it follows that $m(t) = 0$ for any subsequent time $t > 0$. If, in addition, $X(\rho_1,0) = X(\rho_1 + \delta, 0) = 0$, then $X(\rho_1,t) = X(\rho_1+\delta,t) = 0$ for all $t > 0$ (i.e., any initial mass in 0 is not moved away in time if the initial distribution is symmetric). In order to avoid these situations we will allow delta masses only in ± 1: $X(\rho_1,0) = X(\rho_2,0) \iff \rho_1 = \rho_2$ or $(X(\rho_1,0))^2 = 1$.

THEOREM 5.1. *Assume $X(\rho_1,0) = X(\rho_2,0) \iff \rho_1 = \rho_2$ or $(X(\rho_1,0))^2 = 1$. Then the limit distribution exists and is given by two masses located in -1 and $+1$.*

Proof. By Lemmas 4.3 and 4.4, $m(t) \in [-\sqrt{1 - V(0)}, \sqrt{1 - V(0)}]$ for all $t \ge 0$. Thus, if $(X(\rho,t_0)^2 > 1 - V(0)$, then $(X(\rho,t)^2 > 1 - V(0)$ for all $t \ge t_0$. Since

$X(\rho,t) < -\sqrt{1-V(0)} \Rightarrow \frac{\partial}{\partial t}X(\rho,t) \le 0$ and $X(\rho,t) > \sqrt{1-V(0)} \Rightarrow \frac{\partial}{\partial t}X(\rho,t) \ge 0$ by Lemmas 4.3 and 4.4, the two functions

$$p^h_{-1}(t) = \sup\{\rho \in (0,1)\colon X(\rho,t) < -\sqrt{1-V(0)}\} = \int_{[-1,-\sqrt{1-V(0)})} f(x,t)\,dx,$$
$$p^h_{1}(t) = \inf\{\rho \in (0,1)\colon X(\rho,t) > \sqrt{1-V(0)}\} = \int_{(\sqrt{1-V(0)},1]} f(x,t)\,dx$$

are monotone. We call $p^h_{\pm 1} = \lim_{t\to\infty} p^h_{\pm 1}(t)$. Equation (2.3) and monotonicity of Abel's solutions allow us to state that

$$\forall \rho \in [0, p^h_{-1}), \quad \lim_{t\to\infty} X(\rho,t) = -1, \tag{5.1}$$

$$\forall \rho \in (p^h_{+1}, 1], \quad \lim_{t\to\infty} X(\rho,t) = 1. \tag{5.2}$$

Hence the limit distribution has two masses in -1 and $+1$. It remains to characterize what happens for the remaining $p^h_{+1} - p^h_{-1}$ mass. Let us recall that

$$X(\rho,t) \in \big[-\sqrt{1-V(0)}, \sqrt{1-V(0)}\big] \qquad \forall \rho \in (p^h_{-1}, p^h_{+1}). \tag{5.3}$$

By Lemma 4.5, there exists $T > 0$ such that $|m'(t)| \le (V(0)/2)^2$ for all $t > T$. By contradiction, suppose that there exist $t_0 \ge T$ and $\rho \in (p^h_{-1}, p^h_1)$ such that $\big|X(\rho,t_0) - m(t_0)\big| > V(0)/4$.

Since $|\frac{\partial}{\partial t}X(\rho,t_0)| > |m'(t_0)|$, it follows that $\big|X(\rho,t) - m(t)\big| > V(0)/4$ for all $t \ge t_0$. Thus, (5.3) shows the contradiction:

- $\frac{\partial}{\partial t}X(\rho,t)$ is continuous;
- $|\frac{\partial}{\partial t}X(\rho,t)| > (V(0)/2)^2$ if $t \ge t_0$;
- $X(\rho,t)$ is bounded.

Therefore,

$$\big|X(\rho,t) - m(t)\big| \le \frac{V(0)}{4} \qquad \forall \rho \in (p^h_{-1}, p^h_{+1}), \quad t > T\,. \tag{5.4}$$

Now, let $F(x,y) = (1-x^2)(x-y)$ as in Lemma 3.2. Since F is differentiable, when $x_1 \ge x_2$, Lagrange theorem states that we can find $\xi \in (x_1, x_2)$ such that

$$F(x_1,y) - F(x_2,y) = (x_1 - x_2)\frac{\partial}{\partial x}F(x,y)\Big|_{x=\xi}.$$

Now, if $1 - x^2 \ge V(0)$ and $|x-y| \le V(0)/4$, we have

$$\frac{\partial}{\partial x}F(x,y) = 1 - 3x^2 + 2xy \ge V(0) + 2x(y-x) \ge \frac{V(0)}{2},$$

that is,

$$F(x_1,y) - F(x_2,y) \ge (x_1 - x_2)\frac{V(0)}{2}\,, \qquad x_i^2 \le 1 - V(0) \text{ and } |x_i - y| \le \frac{V(0)}{4}\,. \tag{5.5}$$

Let $p^h_{-1} < \rho_2 \le \rho_1 < p^h_{+1}$. Then both (5.3) and (5.4) are satisfied for all $t > T$, (5.5) holds, and

$$\frac{\partial}{\partial t}\Big(X(\rho_1,t) - X(\rho_2,t)\Big) \ge \big(X(\rho_1,t) - X(\rho_2,t)\big)\frac{V(0)}{2} \qquad \forall t > T\,.$$

Since the two solutions are bounded, the only possibility is that $X(\rho_1,t)=X(\rho_2,t)$ for all $t>T$ and for all (ρ_1,ρ_2): $p^h_{-1}<\rho_2\le\rho_1<p^h_{+1}$, which implies $p^h_{-1}=p^h_1$ by Lemma 4.1 and hypothesis. □

Remark. Theorem 5.1 may be read in terms of weak*-measure convergence:

$$f(x,t)\underset{t\to\infty}{\rightharpoonup} p^h_{-1}\delta_{-1}(x)+(1-p^h_{-1})\delta_1(x)\,.$$

In particular, since the support is compact, all the moments exist and will converge. We have the following

COROLLARY 5.2. *Assume* $X(\rho_1,0)=X(\rho_2,0)\iff\rho_1=\rho_2$ *or* $(X(\rho_1,0))^2=1$. *Then there exists* $\lim_{t\to+\infty}m(t)=m_\infty=1-2p^h_{-1}$.

6. Concentration of opinions. Let us recall that the stochastic partial order is naturally given on $\mathcal{K}$. Let $F(x),G(x)$ denote two probability distributions and X_F,X_G their pseudoinverse functions, respectively. We say that $F\preceq G$ if $F(x)\ge G(x)$ for all (x) or, equivalently, if $X_F(\rho)\le X_G(\rho)$ for all $\rho\in(0,1)$.

LEMMA 6.1. *The operator*

$$\phi(X)=-(X-m(X))(1-X^2)$$

is a monotone operator with respect to the stochastic ordering.

Proof. Assume that $X_1(\rho,s)\le X_2(\rho,s)$ for all $\rho\in(0,1)$. Then $m_1(s)\le m_2(s)$ (they are equal if and only if the distributions coincide). Let $\rho\in(0,1)$ be fixed. If $X_1(\rho,s)=X_2(\rho,s)$, then $X_1'(\rho,s)\le X_2'(\rho,s)$. The continuity of X' is sufficient for the remaining part of the proof. □

LEMMA 6.2. *Let* X_0 *in* (3.2) *be given. Then there exists* $\lim_{t\to+\infty}m(t)=m_\infty$.

Proof. Let $[a,b]$ be the class limit of $m(t)$. Suppose $a=-1$, i.e., $\liminf_t m(t)=-1$. Markov inequality then shows that the limit distribution is a mass concentrated in -1, and hence $b=-1$. Otherwise, we may assume that $m(t)\in[-1+\delta,\,1-\delta]$ for all $t\ge t_0$ and let p_0 be the mass not concentrated in ±1 at each time (recall Lemma 4.1). For all $\epsilon>0$, $p_0-\epsilon$ mass is in $[-1+\epsilon,\,1-\epsilon]$ at $t=t_0$. Therefore, for all $\rho\in(0,1)$, $X(\rho,t_0)\in[-1+\epsilon,\,1-\epsilon]$, and $X(\rho,t)$ decays exponentially to $m(t)$ with rate not less than $(\min(\delta,\epsilon))^2$. The large behavior of this process shows three delta masses: the initial two in ±1 and the remaining one in $m(t)$. Stationary arguments imply the existence of m_∞. □

The steady state of the process can now be defined by the following theorem.

THEOREM 6.3. *If* $(1-p_1)(1-p_{-1})<1$ *(i.e., if there are masses in* ±1 *at time* $t=0$*), then* $m_\infty=p_1-p_{-1}$. *Otherwise, if* $\log\big((1+X(\rho,0))/(1-X(\rho,0))\big)\in L^1(0,1)$, *then*

$$m_\infty=\frac{\exp\{T(0)\}-1}{\exp\{T(0)\}+1}. \tag{6.1}$$

Proof. The first part is a consequence of Lemma 6.2 and stationary arguments. The second part is a consequence of Lemma 4.2, since

$$\int_0^1\log\Big(\frac{1+X(\rho,0)}{1-X(\rho,0)}\Big)\,d\rho=\int_0^1\log\Big(\frac{1+X(\rho,t)}{1-X(\rho,t)}\Big)\,d\rho\underset{t\to\infty}{\longrightarrow}\log\Big(\frac{1+m_\infty}{1-m_\infty}\Big)\,,$$

the last limit being true by Lemma 6.2. □

Remark. Lemma 6.1 allows us to extend the previous result to cases where at least one of the two functions $\log(1\pm X(\rho,0))$ is integrable. If, for example,

$\log(1+X(\rho,0)) \in L^1(0,1)$ and $\log(1-X(\rho,0)) \notin L^1(0,1)$, if we take $X^{(n)}(\rho,0) = \min\{X(\rho,0), 1-1/n\}$, then $X^{(n)}(\rho,t) \le X(\rho,t)$ for all $t \ge 0$, for all $\rho \in (0,1)$. The monotone convergence theorem states that $\lim_n T^{(n)}(0) = +\infty$, i.e., $\lim_n m_\infty^{(n)} = 1$. Thus, by the monotonicity argument of Lemma 6.1, $m_\infty = 1$.

With this remark in mind, we now show a "counterintuitive" example. Let

$$f_0(x) = \begin{cases} \frac{1-\epsilon}{\epsilon} & \text{if } -1 < x < -1+\epsilon, \\ \frac{1}{1-x}\left(\frac{\epsilon}{1-\epsilon\log(1-x)}\right)^2 & \text{if } 0 < x < 1, \end{cases}$$

and hence

$$F_0(x) = \begin{cases} 0 & \text{if } x < -1, \\ \frac{1-\epsilon}{\epsilon}(1+x) & \text{if } -1 \le x < -1+\epsilon, \\ 1-\epsilon & \text{if } -1+\epsilon \le x < 0, \\ 1 - \frac{\epsilon}{1-\epsilon\log(1-x)} & \text{if } 0 \le x < 1, \\ 1 & \text{if } 1 \le x, \end{cases}$$

which corresponds to

$$X_0(\rho) = \begin{cases} -1 + \frac{\epsilon}{1-\epsilon}\rho & \text{if } 0 < \rho \le 1-\epsilon, \\ 1 - \exp(-\frac{1}{1-\rho} + \frac{1}{\epsilon}) & \text{if } 1-\epsilon < \rho < 1. \end{cases}$$

With this data, $\log(1+X(\rho,0)) \in L^1(0,1)$ but $\log(1-X(\rho,0)) \notin L^1(0,1)$; the $1-\epsilon$ initial mass is close to -1, while the asymptotic solution is δ_1.

7. Numerical examples. The analysis of the previous section left open the problem of the identification of the steady state in the case of the spreading of opinions. Here results can be achieved only by numerical simulation of the spreading process. To test the numerical method, we will first derive the (explicit) solution to the pure drift linear equation of spreading considered in [15] as the mean field limit of the Sznajd model [20]. This equation reads

$$\frac{\partial f}{\partial t} = \gamma \frac{\partial}{\partial x}\left(x(1-x^2)f\right), \tag{7.1}$$

namely, (1.1) without the presence of the mean $m(t)$. In terms of the quantile function $X(\rho,t)$, equation (7.1) takes the form

$$\frac{\partial X(\rho,t)}{\partial t} = -\gamma X(\rho,t)(1-X^2(\rho,t)). \tag{7.2}$$

Let us set $\gamma = -1$ (spreading), and let $X_0(\rho)$ denote the initial datum. For any given $\rho \in [0,1]$, equation (7.2) is an ordinary differential equation which can be easily integrated to give

$$X(\rho,t) = \frac{X_0(\rho)e^t}{\left(1 - X_0^2(\rho) + X_0^2(\rho)e^{2t}\right)^{1/2}}. \tag{7.3}$$

The asymptotic behavior of (7.2) can be easily deduced from the explicit solution. In fact, the solution converges exponentially in time to -1 if $X_0(\rho) < 0$, while it converges

to $+1$ if $X_0(\rho) > 0$. Solution (7.3) can be inverted by using the definition of $X(\rho, t)$. Let $F_0(x)$ $x \in \mathcal{I}$ be the initial distribution function; then, since $X_0(F_0(x)) = x$,

$$X(F_0(x), t) = \frac{xe^t}{(1 - x^2 + x^2 e^{2t})^{1/2}}. \tag{7.4}$$

Thus, since the function on the right of (7.4) is increasing with respect to the variable x, we can invert it to obtain

$$X\left(F_0\left(\frac{y}{((1-y^2)e^{2t} + y^2)^{1/2}}\right), t\right) = y. \tag{7.5}$$

Finally, (7.5) implies

$$F(y, t) = F_0\left(\frac{y}{((1-y^2)e^{2t} + y^2)^{1/2}}\right). \tag{7.6}$$

Differentiating with respect to y, we conclude that if $f_0(x)$, $x \in \mathcal{I}$, is an initial density for (7.1), the solution in time is given by

$$f(x, t) = \frac{e^{2t}}{((1-x^2)e^{2t} + x^2)^{3/2}} f_0\left(\frac{x}{((1-x^2)e^{2t} + x^2)^{1/2}}\right). \tag{7.7}$$

The behavior of (7.7) shows the formation of two peaks in correspondence to the extremal points ± 1, while in all other points of the interval $\mathcal{I}$ there is exponential decay to zero.

Using the same procedure as above, we can easily solve the problem in the opposite case of concentration, where $\gamma = 1$. In this case, if $X_0(\rho)$ denote the initial datum,

$$X(\rho, t) = \frac{X_0(\rho)e^{-t}}{(1 - X_0^2(\rho) + X_0^2(\rho)e^{-2t})^{1/2}}. \tag{7.8}$$

The solution now converges exponentially in time to zero, except for ρ values for which $X_0(\rho) = \pm 1$, where it remains constant. In the original formulation, the solution $f(x, t)$ corresponding to the initial density $f_0(x)$, $x \in \mathcal{I}$, is

$$f(x, t) = \frac{e^{-2t}}{((1-x^2)e^{-2t} + x^2)^{3/2}} f_0\left(\frac{x}{((1-x^2)e^{-2t} + x^2)^{1/2}}\right). \tag{7.9}$$

Note that except for $x = 0$, $f(x, t)$ converges exponentially to zero. If $f_0(0) > 0$, the solution shows the formation of a peak in $x = 0$.

We perform numerical simulation for different initial data in the general nonlinear case. First, we assume an initial symmetric datum as a benchmark (see Figure 7.1), where

$$f_0(x) = \begin{cases} c_0(1 - x^2)(0.64 - x^2)^{1.3} & \text{if } |x| < 0.8; \\ 0 & \text{otherwise.} \end{cases}$$

In this case we have $m(t) = 0$ for all time t. Then we know the exact solution in order to perform a comparison with numerical results. In Figure 7.1 we show the behavior

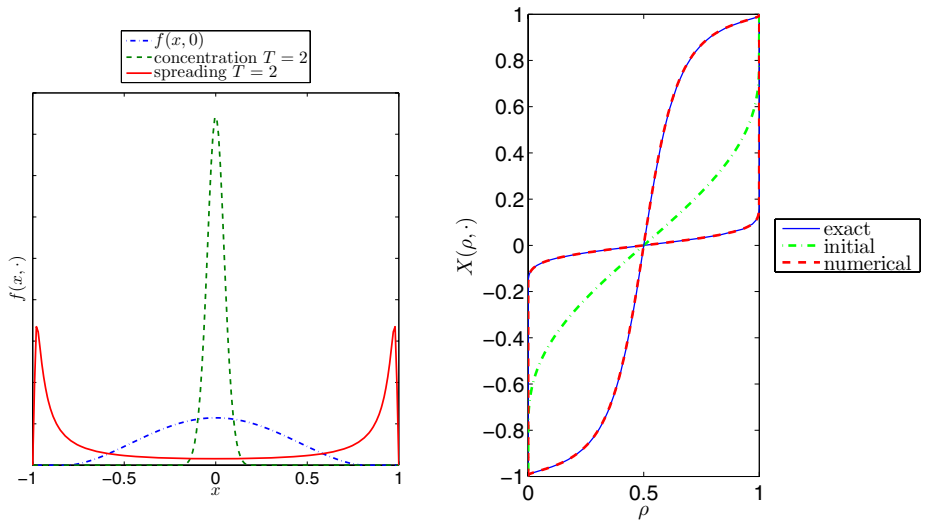

FIG. 7.1. *Benchmark case: evolution of density function (left) and comparison between analytical and numerical solutions for the quantile function (right).*

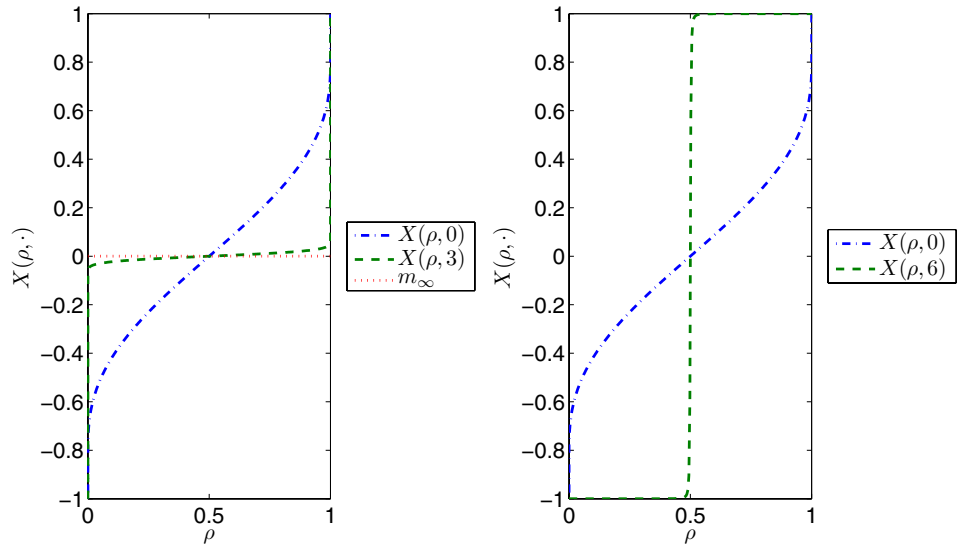

FIG. 7.2. *Plots of the behavior of a numerical solution with symmetric initial data for the concentration case (left) and for the spreading case (right).*

of an exact solution and a numerical one. The last one is obtained by using standard stiff Runge–Kutta methods, which is justified by our theoretical constructive result stated in the proof of Theorem 3.3. As one can see in Figure 7.1 we have a good agreement between the analytical and numerical solutions.

In Figure 7.2 we sketch the plot of the quantile function $X(\rho,t)$ for different times t in both the concentration and the spreading case with the same initial symmetrical data. As expected, in the concentration case, the limit values of all quantiles numerically converge to $m_\infty = 0$, while in the spreading case the quantiles converge to -1

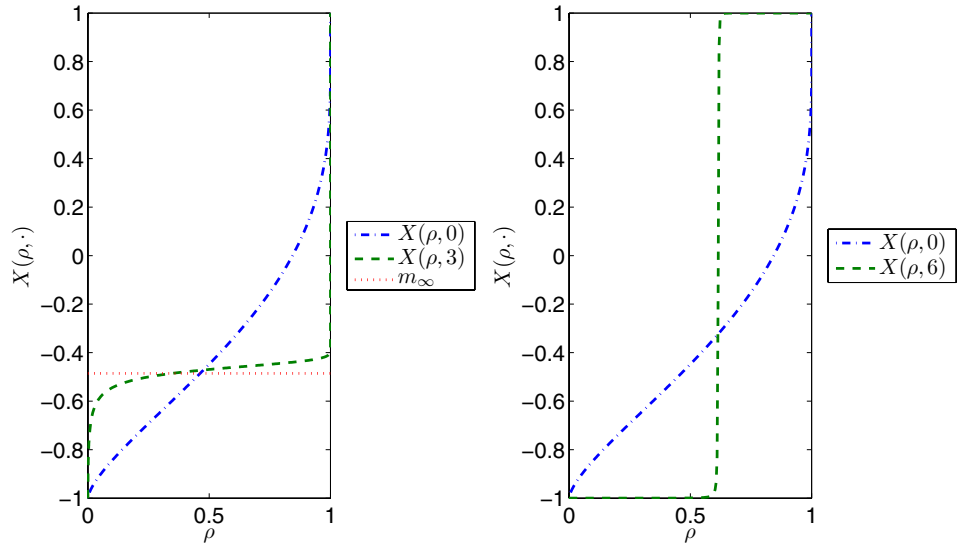

FIG. 7.3. *Plots of the behavior of a numerical solution with nonsymmetric initial data for the concentration case (left) and for the spreading case (right).*

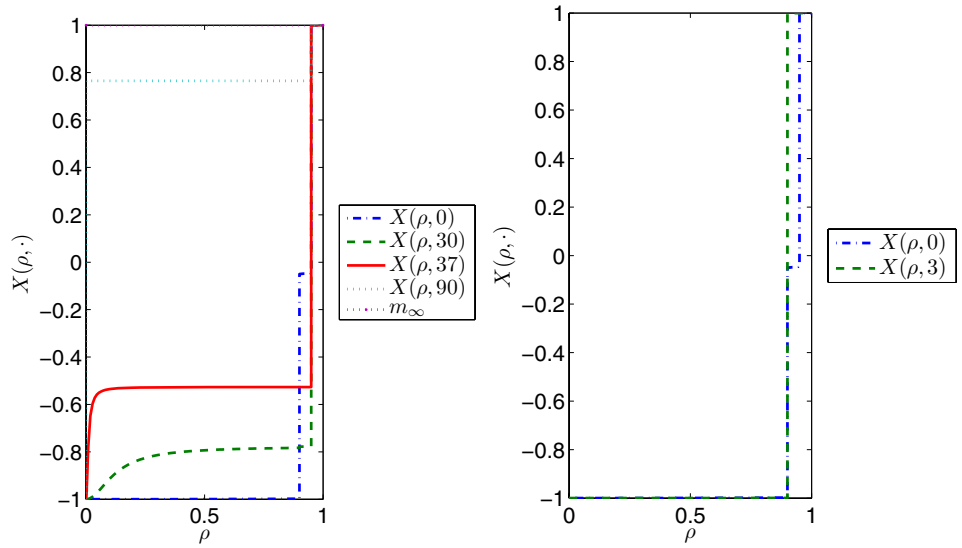

FIG. 7.4. *Plots of the behavior of a numerical "counterintuitive" solution: the concentration case tends to δ_1 (left), while the $1-2\epsilon$ mass goes to -1 in the spreading case (right).*

if $\rho < .5$, and to 1 if $\rho > .5$.

In Figure 7.3 we show an asymmetric case. Now, in the concentration case $m_\infty \neq 0$ given in (6.1) and quantiles converge to it. In the spreading case we can numerically estimate the value p^h_{-1} (see (5.1)) for which $\rho < p^h_{-1}$ implies $X(\rho,t) \to -1$, $\rho > p^h_{-1}$ implies $X(\rho,t) \to 1$.

Finally, in Figure 7.4 we show a numerical "counterintuitive example" analogous to the example given at the end of the previous section. Here, the initial datum con-

sists of the $(1-2\epsilon)$ mass very close to -1, the ϵ mass close to 0, and the remaining ϵ mass concentrated in $+1$. In the concentration case, $\gamma = 1$, the mass goes asymptotically to $+1$, while in the spreading case, $\gamma = -1$, only 2ϵ goes asymptotically to $+1$. We point out that the spreading case is really counterintuitive. In fact, if we take $X(\rho, T)$, with $T \gg 1$, as solution of the concentration case as initial data for the spreading one, the dynamic is as follows. Initially, the $(1-\epsilon)$ mass decays; then it splits into two parts: the right one goes to $+1$, the left one goes to -1. The initial data can be chosen as close as we want to the distribution δ_1. Then, starting from this data (for which $T(t) = +\infty$; see (6.1)), a $(1-2\epsilon)$ mass will reach -1. We note that the asymptotic state for spreading phenomena seems unpredictable for such concentrated initial data.

Remark. The method we used to solve (7.1) represents in various cases a possible alternative to better known methods (like the method of characteristics) able to reckon the solution to one-dimensional first-order partial differential equations of the form

$$\frac{\partial f}{\partial t} = \frac{\partial}{\partial x}\left(\phi(x) f\right). \tag{7.10}$$

Our analysis is possible in all cases where the ordinary differential equation

$$\frac{dX}{dt} = -\phi(X)$$

is explicitly solvable.

8. Conclusions. We investigated in this paper the spreading and/or the concentration of opinion in an organized society by means of a first-order nonlinear partial differential equation recently introduced in [22]. The presence of the nonlinearity renders it difficult to treat the spreading case analytically, and suitable numerical methods were discussed that are able to capture the large-time behavior of the solution in this case. This work represents a first attempt for a continuous approach to the formation of opinion in a community of agents. More complete models can be obtained by considering in addition the (linear or nonlinear) diffusion, which allows for a continuous steady state distribution function. Related problems in the presence of diffusion are presently under study.

ON A MODEL OF FLAME BALL WITH RADIATIVE TRANSFER*

VINCENT GUYONNE† AND PASCAL NOBLE‡

Abstract. In this paper, we derive an equation for the growth of a flame ball for a free boundary combustion model with radiative transfer. The equation for the radiative field is given by the linearized Eddington equation. We then study the mathematical properties of this equation of growth and carry out numerical computations in order to discuss the stability or instability of steady flame balls.

Key words. flame ball, radiative transfer, integro-differential equation, numerical quenching

1. Introduction.

Spherical flame balls have been found to exist as stable objects for small enough Lewis number during some experiments carried out at microgravity [13, 14]. Since the work of Zeldovich [19], "adiabatic" flame balls are unstable to one-dimensional radial perturbations; a stabilizing effect has to be identified. It has been argued [12] that radiation is physically important in near limit combustion at low gravity. Then, it is natural to consider a heat loss mechanism through radiation as a stabilizing effect. Moreover, it is worth noting that halon (CF_3Br) is added to experimental mixtures (to increase the luminosity of flame balls), which augments the radiation through soot formation.

Buckmaster, Joulin, and Ronney [5, 6] proposed different models to take into account the heat loss through radiation. They first considered constant heat losses in the burnt gases [5]: when the heat losses are not too large, they proved the existence of two possible steady flame balls, a small one and a large one. It was proved that they have different linear stability properties: the small flame ball, similar to the Zeldovich flame, is unstable under radial perturbations, whereas the large flame ball is stable under radial perturbations but unstable under three-dimensional perturbation if its radius is too large. Similar results have been obtained for a refined version of the previous model where linear far field heat loss is considered [6]. Using matched asymptotic expansions for large activation energy, Buckmaster, Joulin, and Ronney [5, 6] derived an integro-differential model for the nonlinear radial motion of the flame when $Le < 1$:

$$\partial_{1/2} R(\tau) = \log R(\tau) - \lambda R(\tau)^2 + \frac{Eq(\tau)}{R(\tau)}, \quad R(0) = 0,$$

with $\partial_{1/2} R = \frac{d}{dt} \int_0^t \frac{R(s)}{\sqrt{\pi(t-s)}} ds$ and $Eq(\tau)$ representing the amount of energy injected into the system. Numerical simulations of this model suggested that the small flame

ball is unstable and the large one is stable. Recently, Rouzaud [15] carried out a rigorous study of the long time behavior of flame balls for this equation, which confirms the qualitative behavior. Moreover, Audounet, Roquejoffre, and Rouzaud developed numerical schemes adapted for this kind of equation, which possess similar mathematical properties and exhibit the same type of asymptotic behavior [2].

More refined models have been considered with reaction taking place within an unbounded medium that contains a small volume fraction of porous solid that only exchanges heat with the gas [17]. Heat losses through radiation are modeled in two different ways: either they are constant in the burnt gas and linear in the unburnt gas (similar to the Buckmaster et al. studies), or they are a continuous dimensionless form of Stefan's law having a linear part that dominates close to ambient temperatures and a fourth power that dominates at higher temperatures. Similarly, two branches of solutions are found, the branch of large flame balls being linearly stable and the smaller one being unstable.

Recently, Guyonne, Hulshof, and Van den Berg [18] proposed another mechanism to take into account the radiation, considering a model of flame with *radiative transfer*. Indeed, the presence of particles in the mixture generates a radiation field approximated by the well-known Eddington equation

$$-\nabla\nabla\cdot q + 3\alpha^2 q + \alpha\nabla\theta^4 = 0,$$

where q represents the radiative flux, θ the temperature, and α the opacity of the medium. This system is coupled with a classical free boundary combustion model with simple chemistry $F \to B$, where F is the fresh gas and B the burnt gas. This model is derived in the high activation limit, the reaction occurring in a reaction sheet located at $r = R(t)$, and can be written

$$\partial_t Y - \frac{1}{Le}\Delta Y = 0, \quad r > R(t); \quad Y = 0, \quad r < R(t); \quad \partial_t\theta - \Delta\theta = -\beta\nabla\cdot q, \quad r \neq R(t),$$

with the jump conditions at $r = R(t)$

$$[\theta] = [y] = 0, \qquad \frac{1}{Le}[Y_r] = -[\theta_r] = F_\epsilon(\theta(R(t))),$$

where $F_\epsilon(\theta)$ is the reaction rate modeled by an Arrhenius law. It is proved that there exist steady flame balls for this model. Moreover, numerical simulations with numerical continuation software show that for the same set of parameters there exist several steady flames. Then the question of their stability arises. Even in the simpler case where a linearized Eddington law is considered,

$$-\nabla\nabla\cdot q + 3\alpha^2 q + \alpha\nabla\theta = 0,$$

the question of the linear and nonlinear stability of steady flame balls is far from being understood: we shall mention here the works of Guyonne, Hulshof, and Van den Berg [9] on the numerical analysis of the Evans function for the linear and nonlinear Eddington law, and the paper of Guyonne and Lorenzi [8], which proves that spectral instability implies nonlinear instability with semigroup techniques. Getting nonlinear stability within this framework is quite a hard problem and remains open.

The purpose of this paper is to analyze the stabilizing effect of *radiative transfer* with the viewpoint developed by Buckmaster, Joulin, and Ronney [5, 6]. Indeed, to study the nonlinear growth of radial solutions, they derived an integro-differential

equation using matched asymptotic expansions. This approach has been justified rigorously by Lederman, Roquejoffre, and Wolansky [11] for the adiabatic model with a direct derivation from the reaction diffusion system. Moreover, the asymptotic behavior of this kind of integro-differential equations is now well understood, and efficient numerical schemes are available. The aim of this paper is twofold: through the formal derivation of the same type of integro-differential equations for flame ball growth, and the mathematical and numerical analysis of this model, we want, on the one hand, to study the stabilizing effect of the *radiative transfer* in the formation of flame balls. On the other hand, for this particular model of radiative transfer (the linearized Eddington equation), we want to discuss directly the dynamic of flame balls and the stability of steady flame balls *under radial perturbations* obtained in [18]. We are not concerned here with the stability of flame balls under three-dimensional perturbations. It is worth noting that the approach proposed is very complementary to the indirect approach, which consists of studying the linear stability and then getting information for the full nonlinear free boundary problem. Moreover, if it is possible to rigorously justify this formal derivation, similarly to the paper of Lederman, Roquejoffre, and Wolansky [11], this should give a complete answer on the nonlinear stability of flame balls *under radial perturbations* in the presence of radiative transfer, but this justification is a hard issue.

The paper is organized as follows. In section 2, we derive an integro-differential equation for the nonlinear radial motion of a flame ball using matched asymptotic expansions:

$$\partial_{1/2} R(\tau) = \log R(\tau) - \lambda R(\tau) + \frac{Eq(\tau)}{R(\tau)}\,. \tag{1.1}$$

The dynamic is articulated around the two steady flame balls with radius $R_1 < R_2$ solutions of $\log R = \lambda R$, provided that $\lambda < \frac{1}{e}$. In section 3 we study mathematically the asymptotic behavior of the solutions of (1.1) and discuss the stability of the "large" flame ball with radius R_2 and instability of the "small" flame ball with radius R_1. In section 4, we carry out numerical computations on (1.1) using the numerical schemes designed by Audounet, Roquejoffre, and Rouzaud [2].

2. Growth model for the radius of the flame balls. We consider the following model of combustion with simple chemistry coupled with the *linearized* Eddington equation:

$$\begin{aligned} &\partial_t y - \frac{1}{Le}\Delta y = 0, \quad r > R(t), \qquad y = 0, \quad r < R(t), \\ &\partial_t \theta - \Delta\theta = \beta u, \quad -\Delta u + 3\alpha^2 u = \alpha\Delta\theta, \quad r \neq R(t), \end{aligned} \tag{2.1}$$

where u denotes $u = -\nabla \cdot q$, supplemented with the jump conditions at $r = R(t)$

$$\begin{aligned} &[u] = [\theta] = [y] = 0, \\ &[u_r] = -\alpha[\theta_r], \qquad \frac{1}{Le}[y_r] = -[\theta_r] = F_\epsilon(\theta(R(t))). \end{aligned} \tag{2.2}$$

Moreover, the functions (y, θ, u) must satisfy the conditions at infinity

$$\lim_{r\to\infty} (y(r), \theta(r), u(r)) = (1, 0, 0). \tag{2.3}$$

The reaction rate F_ϵ is given by an Arrhenius law $F_\epsilon(\theta) = A \exp -\frac{1}{\epsilon\theta}$: the constant A is a preexponential factor, and ϵ^{-1} is the activation energy, which is assumed to

be large ($0 < \epsilon \ll 1$). In order to derive an equation for the growth a flame ball, we follow the methodology introduced by Joulin [4] and divide the space into two concentric regions: a quasi-stationary zone, where time derivatives are neglected, in which the combustion occurs, and a far field zone, where the only phenomena that are taken into account are diffusion of the reactant and the temperature. The radiative effects are considered both in the reaction zone and the far field zone. We then obtain an equation for the radius by matching the derivatives of the inner quasi-stationary solution and the outer solution.

2.1. Steady solutions. Before computing quasi-steady solutions, let us first compute the steady solutions of (2.1), (2.2), (2.3). Let us fix the radius $R > 0$ and define η as $\eta = \eta_{\alpha\beta} = \sqrt{3\alpha^2 + \alpha\beta}$. Then there exists a unique steady solution with the following analytic expression:

$$u(r) = \begin{cases} -\dfrac{B_1\eta^2}{\beta r}\sinh(\eta r) & \text{for } r \le R, \\ -\dfrac{B_2\eta^2}{\beta r}\exp(-\eta r) & \text{for } r > R, \end{cases} \tag{2.4}$$

where the constants are given by

$$B_1 = \frac{\alpha\beta Y_f}{\mathrm{Le}\eta^3}\exp(-\eta R), \qquad B_2 = \frac{\alpha\beta Y_f}{\mathrm{Le}\eta^3}\sinh(\eta R), \qquad B_3 = \frac{3\alpha^2 Y_f}{\mathrm{Le}\eta^2}.$$

The expression for θ is

$$\theta(r) = \begin{cases} \dfrac{B_1}{r}\sinh(\eta r) + B_3 & \text{for } r \le R, \\ \dfrac{B_2}{r}\exp(-\eta r) + \dfrac{B_3 R}{r} & \text{for } r > R. \end{cases} \tag{2.5}$$

Finally the solution for the mass fraction variable is expressed by

$$y(r) = \max\left(0, 1 - \frac{R}{r}\right). \tag{2.6}$$

Then the temperature at the front is given by

$$Le\theta(R) = 1 + \frac{\alpha\beta}{\eta^2}\left(\frac{1 - \exp(-2\eta R)}{2\eta R} - 1\right).$$

Note that the dependence of the temperature at the front on the flame radius in the case where radiative transfer is taken into account is different from the case where heat loss radiative terms are considered. In the latter case, the dependence is *parabolic* [5].

It is easily seen via (2.6) that $[y_r]_{|r=R} = \frac{1}{R}$. Then the steady flame balls are the steady solutions (y, θ, u) defined by (2.4), (2.5), (2.6) such that R is the solution of

$$F_\epsilon(\theta(R)) = \frac{1}{RLe}. \tag{2.7}$$

The case where $\alpha, \beta \to 0$ as $\epsilon \to 0$ is of particular interest: as a matter of fact, Buckmaster, Joulin, and Ronney [5, 6] also considered vanishing heat loss terms as $\epsilon \to 0$. As a consequence, in some asymptotic parameter regimes, it is possible to

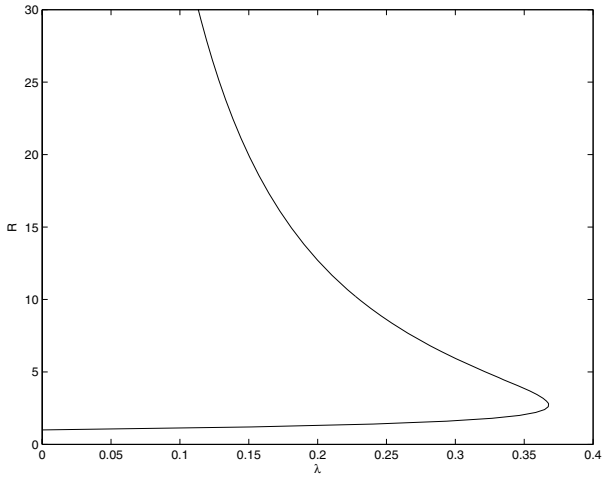

FIG. 2.1. *Diagram of the bifurcation of* (2.8) *in the* $(\lambda = \frac{\overline{\beta} Le}{\sqrt{3}}, R)$ *plane.*

simplify (2.7). Under the scaling $\beta = \overline{\beta}\epsilon$, $\alpha \gg \beta$ (we can choose $\alpha = O(\epsilon^\mu)$ with $0 < \mu < 1$), and $0 < \epsilon \ll 1$, we find that

$$\theta(R) = \frac{1}{Le} - \frac{\overline{\beta}\epsilon}{Le\sqrt{3}} R + O(\epsilon^2).$$

Inserting this relation into (2.7) and letting $\epsilon \to 0$, one finds

$$\log \frac{R}{R_{ad}} = \frac{\overline{\beta} Le}{\sqrt{3}} R, \tag{2.8}$$

where R_{ad} denotes the adiabatic radius. The set of solutions of (2.8) is plotted in Figure 2.1 in the (R, λ) plane, where $\lambda = \frac{\overline{\beta} Le}{\sqrt{3}}$.

We can see that for $\lambda > \lambda_{cr} = \frac{1}{R_{ad} e}$ no solution exists, and for $\lambda < \lambda_{cr}$ there exist two solutions $R_1 < R_2$, which correspond to steady flame balls. The smaller flame ball converges to the flame ball constructed by Zeldovich in the limit $\lambda \to 0$.

It is important to note the difference between the equation for steady flame balls (2.8) when *radiative transfer* is taken into account and the equation for steady flame balls when *radiative heat losses* are considered (which are constant in the burnt phase of order $O(\epsilon)$, linear in the fresh phase and of order $O(\epsilon^2)$). In that case, the equation for steady flame balls reads

$$\log\left(\frac{R}{R_{ad}}\right) = \Lambda R^2,$$

where Λ is a constant depending on heat loss terms. The difference between the two equations is that, considering the *constant heat loss term* in the burnt gas, the temperature at the front $\theta(R)$ is a *parabolic* function of the flame radius, whereas in the case of radiative transfer, the temperature at the front is a *linear* function of the flame radius (in the parameter regime considered previously).

2.2. Inner solutions. Now we consider the nonstationary case, and we suppose that the flame has a spherical symmetry with a flame radius at $r = R(t)$. The purpose is to compute an equation satisfied by $R(t)$. Let us denote (Y, Θ, U) the steady solution computed at the previous section and fix $\nu \in (0,1)$. We are first going to compute an approximation of the solution (y, θ, u) on $B(0, \epsilon^{-\nu})$, considering that it is a quasi-steady solution with a flame radius $r = R(t) \ll \epsilon^{-\nu}$. We write the solution (y, θ, u) as

$$(y, \theta, u) = (1 + \epsilon v(t))\big(Y, \Theta, U\big) + (0, \epsilon w(t), 0).$$

This solution satisfies the steady equations and the jump conditions, provided that

$$\frac{1 + \epsilon v(t)}{RLe} = F_\epsilon\big(\Theta(R) + \epsilon(\Theta(R)v + w)\big).$$

This equation reads, up to order $O(\epsilon)$,

$$v + \frac{w}{\Theta(R)} = -\log(RLe) - \log\Big(F_\epsilon\big(\Theta(R)\big)\Big).$$

The boundary conditions at $r = \epsilon^{-\nu}$ are given by

$$\begin{aligned}
\theta(t, \epsilon^{-\nu}) &= \frac{3\alpha^2}{Le(3\alpha^2 + \alpha\beta)} R\epsilon^\nu + \epsilon w(t) + O(\epsilon^{\nu+1}),\\
y(t, \epsilon^{-\nu}) &= 1 - \epsilon^\nu R(t) + \epsilon v(t) + O(\epsilon^{\nu+1}),\\
u(t, \epsilon^{-\nu}) &= -\frac{\alpha(1 + \epsilon v(t))\epsilon^\nu}{Le\sqrt{3\alpha^2 + \alpha\beta}} \sinh(R\sqrt{3\alpha^2 + \alpha\beta}) \exp\left(-\frac{\sqrt{3\alpha^2 + \alpha\beta}}{\epsilon^\nu}\right)\\
&= O(\epsilon^{\nu+3}).
\end{aligned} \tag{2.9}$$

The last estimate on u is valid, provided that $\sqrt{3\alpha^2 + \alpha\beta} = O(\epsilon^\mu)$ with $\mu < \nu$.

2.3. Outer solution. We compute an approximate solution (y, θ, u) outside $B(0, \epsilon^{-\nu})$ of

$$\partial_t y - \frac{1}{Le}\Delta y = 0, \quad \partial_t \theta - \Delta\theta = \beta u, \quad -\Delta u + 3\alpha^2 u = \alpha\Delta\theta,$$

supplemented with the boundary conditions (2.9); the conditions at infinity are given by $\lim_{r\to\infty}(y, \theta, u) = (1, 0, 0)$, and the initial conditions will be specified later. Following the derivation of Joulin [4], we rescale time and space—$\tau = \epsilon^2 t, \rho = \epsilon r$—and define

$$(\overline{y}, \overline{\theta}, \overline{u})(\tau, \rho) = \left(\frac{y(t,r) - 1}{\epsilon}, \frac{\theta(t,r)}{\epsilon}, \frac{u(t,r)}{\epsilon^3}\right), \qquad \overline{R}(\tau) = R(t).$$

Then $(\overline{y}, \overline{\theta}, \overline{u})$ satisfies the rescaled system

$$\partial_\tau \overline{y} - \frac{1}{Le}\Delta\overline{y} = 0, \quad \partial_\tau\overline{\theta} - \Delta\overline{\theta} = \beta\overline{u}, \quad -\epsilon^2\Delta\overline{u} + 3\alpha^2\overline{u} = \alpha\Delta\overline{\theta},$$

with the boundary conditions

$$\begin{aligned}
\overline{y}(\tau, \epsilon^{1-\nu}) &= -\epsilon^{\nu-1}\overline{R}(\tau) + \overline{v}(\tau) + O(\epsilon^\nu),\\
\overline{\theta}(\tau, \epsilon^{1-\nu}) &= \epsilon^{\nu-1}\frac{3\alpha^2}{Le(3\alpha^2 + \alpha\beta)}\overline{R}(\tau) + \overline{w}(\tau) + O(\epsilon^\nu),\\
\overline{u}(\tau, \epsilon^{1-\nu}) &= O(\epsilon^\nu).
\end{aligned}$$

We are interested only in the jumps of the radial derivatives, namely, $(\rho\overline{y})_\rho$, $(\rho\overline{\theta})_\rho$ evaluated at the point $\rho = \epsilon^{1-\nu}$. Let us start with $\frac{\partial}{\partial\rho}(\rho\overline{y})_{|\rho=\epsilon^{1-\nu}_+}$ and define $Y = \rho\overline{y}$ for all $\rho > \epsilon^{1-\nu}$. Then extend Y on $\mathbb{R}$ by an odd function $\overline{Y}$ so that

$$\overline{Y}(\tau,\rho) = \begin{cases} Y\left(\tau, \frac{1}{\sqrt{Le}}\rho + \epsilon^{1-\nu}\right) - Y(\tau,\epsilon^{1-\nu}) & \text{for } \rho > 0, \\ -Y\left(\tau, -\frac{1}{\sqrt{Le}}\rho + \epsilon^{1-\nu}\right) + Y(\tau,\epsilon^{1-\nu}) & \text{for } \rho < 0. \end{cases}$$

Define $\psi(\tau) = Y(\tau,\epsilon^{1-\nu}) = -\overline{R}(\tau) + O(\epsilon^{1-\nu})$: $\overline{Y}$ satisfies the equation

$$\overline{Y}_\tau - \overline{Y}_{\rho\rho} = \dot{\psi}(\tau)\big(1_{]-\infty,0[}(\rho) - 1_{]0,\infty[}(\rho)\big),$$

with initial condition

$$\overline{Y}(0,\rho) = \begin{cases} Y\left(0, \frac{1}{\sqrt{Le}}\rho + \epsilon^{1-\nu}\right) - \psi(0) & \text{for } \rho > 0, \\ -Y\left(0, -\frac{1}{\sqrt{Le}}\rho + \epsilon^{1-\nu}\right) + \psi(0) & \text{for } \rho < 0. \end{cases}$$

Then we find that

$$\overline{Y}(\tau,\rho) = \frac{1}{\sqrt{4\pi\tau}}\int_0^\infty \left(Y\left(0, \frac{x}{\sqrt{Le}} + \epsilon^{1-\nu}\right) - \psi(0)\right)\left(e^{-\frac{|x-\rho|^2}{4\tau}} - e^{-\frac{|x+\rho|^2}{4\tau}}\right)dx$$
$$- \int_0^\tau\int_0^\infty \dot{\psi}(s)\frac{e^{-\frac{|x-\rho|^2}{4(\tau-s)}} - e^{-\frac{|x+\rho|^2}{4(\tau-s)}}}{\sqrt{4\pi(\tau-s)}}dxds.$$

Derive $\overline{Y}$ with respect to ρ and take the value at point $\rho = 0$:

$$\frac{\partial}{\partial\rho}(\rho\overline{y})_{|\rho=\epsilon^{1-\nu}} = \sqrt{Le}\frac{\partial\overline{Y}}{\partial\rho}_{|\rho=0} = -\sqrt{Le}\partial_{1/2}\psi(\tau) + \phi_y(\tau),$$

where ϕ_y is a function of only the initial data $y(0,x)$, given by

$$\phi_y(\tau) = \frac{Le^{\frac{3}{2}}}{\sqrt{4\pi\tau}}\int_{\epsilon^{1-\nu}}^\infty \big(x\overline{y}(0,x) - \epsilon^{1-\nu}\overline{y}(0,\epsilon^{1-\nu})\big)\frac{x-\epsilon^{1-\nu}}{\tau}e^{-Le\frac{(x-\epsilon^{1-\nu})^2}{4\tau}},$$

and the fractional derivative $\partial_{1/2}\psi(\tau)$ is the function

$$\partial_{1/2}\psi(\tau) = \frac{d}{dt}\int_0^t \frac{\psi(s)}{\sqrt{\pi(t-s)}}ds.$$

As a conclusion, we find that

$$\frac{\partial}{\partial\rho}(\rho\overline{y})^+_{|\rho=\epsilon^{1-\nu}} = \sqrt{Le}\partial_{1/2}\overline{R} + \phi_y(\tau) + O(\epsilon^{1-\nu}).$$

We compute the derivative of $\rho\overline{\theta}$ at point $\rho = \epsilon^{1-\nu}$: following the analysis made previously, one introduces the functions $T = \rho\overline{\theta}$, $V = \rho\overline{u}$ and defines

$$\overline{T}(\tau,\rho) = \begin{cases} T(\tau,\rho+\epsilon^{1-\nu}) - T(\tau,\epsilon^{1-\nu}) & \text{for } \rho > 0, \\ -T(\tau,-\rho+\epsilon^{1-\nu}) + T(\tau,\epsilon^{1-\nu}) & \text{for } \rho < 0, \end{cases}$$

and

$$\overline{V}(\tau,\rho)=\begin{cases} V(\tau,\rho+\epsilon^{1-\nu})-V(\tau,\epsilon^{1-\nu}) & \text{for } \rho>0,\\ -V(\tau,-\rho+\epsilon^{1-\nu})+V(\tau,\epsilon^{1-\nu}) & \text{for } \rho<0.\end{cases}$$

The functions $\overline{T},\overline{V}$ satisfy the system

$$\begin{aligned}\partial_\tau\overline{T}-\overline{T}_{\rho\rho}&=\beta\overline{V}+\dot{\overline{T}}_\epsilon H(\rho)-\beta\overline{V}_\epsilon(\tau)H(\rho),\\ -\epsilon^2\overline{V}_{\rho\rho}+3\alpha^2\overline{V}&=\alpha\overline{T}_{\rho\rho}+3\alpha^2\overline{V}_\epsilon(\tau)H(\rho),\end{aligned}\tag{2.10}$$

with $H(\rho)=1_{]-\infty,0[}(\rho)-1_{]0,\infty[}$ and $(\overline{T}_\epsilon,\overline{V}_\epsilon)=\epsilon^{1-\nu}(\overline{\theta},\overline{u})(\tau,\epsilon^{1-\nu})$. Take the Fourier transform of the system (2.10): this yields

$$\begin{aligned}\partial_\tau\hat{\overline{T}}+\xi^2\hat{\overline{T}}&=\beta\hat{\overline{V}}+\dot{\overline{T}}_\epsilon(\tau)\hat{H}(\xi)-\beta\overline{V}_\epsilon(\tau)\hat{H}(\xi),\\ (3\alpha^2+\epsilon^2\xi^2)\hat{\overline{V}}&=-\alpha\xi^2\hat{\overline{T}}+3\alpha^2\overline{V}_\epsilon(\tau)\hat{H}(\xi).\end{aligned}\tag{2.11}$$

Eliminating $\hat{\overline{V}}$ from (2.11) yields the equation on $\hat{\overline{T}}$:

$$\partial_\tau\hat{\overline{T}}+\xi^2\left(1+\frac{\alpha\beta}{3\alpha^2+\epsilon^2\xi^2}\right)\hat{\overline{T}}=\dot{\overline{T}}_\epsilon\hat{H}(\xi)+\beta\overline{V}_\epsilon(\tau)\left(\frac{3\alpha^2}{3\alpha^2+\epsilon^2\xi^2}-1\right)\hat{H}(\xi).$$

The function $\hat{\overline{T}}$ is given by

$$\begin{aligned}\hat{\overline{T}}(\tau,\xi)=&\,e^{-(1+\frac{\alpha\beta}{3\alpha^2+\epsilon^2\xi^2}\xi^2\tau)}\hat{\overline{T}}(0,\xi)+\int_0^\tau e^{-(1+\frac{\alpha\beta}{3\alpha^2+\epsilon^2\xi^2})\xi^2(\tau-s)}\hat{H}(\xi)\dot{\overline{T}}_\epsilon(s)ds\\ &-\int_0^\tau\overline{V}_\epsilon(s)\frac{\beta\epsilon^2\xi^2}{3\alpha^2+\epsilon^2\xi^2}\hat{H}(\xi)e^{-(1+\frac{\alpha\beta}{3\alpha^2+\epsilon^2\xi^2})\xi^2(\tau-s)}ds.\end{aligned}$$

The analysis is now completely similar to the case treated previously for the derivative of $\rho\overline{y}$ at the boundary: take the inverse Fourier transform of $\hat{\overline{T}}$ and derive $\overline{T}$ with respect to ρ. There exists ϕ_θ which is a function only of $\theta(0,.)$ such that

$$\frac{\partial}{\partial\rho}(\rho\overline{\theta})_{|\rho=\epsilon^{1-\nu}}=-\frac{1}{Le(1+\frac{\alpha\beta}{3\alpha^2})^{\frac{3}{2}}}\partial_{1/2}\overline{R}+\phi_\theta(\tau)+O(\epsilon^{1-\nu}).$$

2.4. Matching of the derivatives. Recall that the analysis of the outer solution yields

$$\begin{aligned}\frac{\partial}{\partial\rho}(\rho\overline{\theta})^+_{|\rho=\epsilon^{1-\nu}}&=-\frac{1}{Le(1+\frac{\alpha\beta}{3\alpha^2})^{\frac{3}{2}}}\partial_{1/2}\overline{R}+\phi_\theta(\tau)+O(\epsilon^{1-\nu}),\\ \frac{\partial}{\partial\rho}(\rho\overline{y})^+_{|\rho=\epsilon^{1-\nu}}&=\sqrt{Le}\partial_{1/2}\overline{R}+\phi_y(\tau)+O(\epsilon^{1-\nu}).\end{aligned}\tag{2.12}$$

Moreover, it is easily proved using the expression of the inner solution that

$$\frac{\partial}{\partial\rho}(\rho\overline{\theta})^-_{|\rho=\epsilon^{1-\nu}}=w(\tau),\qquad\frac{\partial}{\partial\rho}(\rho\overline{y})^-_{|\rho=\epsilon^{1-\nu}}=v(\tau).\tag{2.13}$$

The jump conditions at the free boundary are given by

$$v(\tau)+\frac{w}{\Theta(R)}=-\log(RLe)-\log\Big(F_\epsilon\big(\Theta(R)\big)\Big).\tag{2.14}$$

Eliminating v, w from (2.12), (2.13), (2.14) and up to order $O(\epsilon^{1-\nu})$, we find the equation for the radius $\overline{R}$ of the flame ball:

$$\left(\frac{(Le\Theta(\overline{R}))^{-1}}{(1+\frac{\alpha\beta}{3\alpha^2})^{\frac{3}{2}}}-\sqrt{Le}\right)\partial_{1/2}\overline{R}=\log(RLe)+\log(F_\epsilon(\Theta(\overline{R})))+\frac{\phi_\theta(\tau)}{\Theta(\overline{R})}+\phi_y(\tau).$$

This expansion is valid, provided that we have chosen $\sqrt{3\alpha^2+\alpha\beta}=O(\epsilon^\mu)$ with $\mu<\nu$. This condition is satisfied when β,α are $O(\epsilon^\mu)$.

Let us choose the scaling $\alpha=\overline{\alpha}\epsilon^\mu$ and $\beta=\overline{\beta}\epsilon$, which clearly satisfies the hypothesis $\beta,\alpha=O(\epsilon^\mu)$. In this case, we can simplify the equation of growth. The front temperature is given by

$$\Theta(R)=\frac{1}{Le}-\frac{\overline{\beta}\epsilon}{Le\sqrt{3}}R+(\text{h.o.t.}),$$

where h.o.t. stands for higher order terms. Then the equation for the radius growth can be written

$$(1-\sqrt{Le})\partial_{1/2}\overline{R}=\log\left(\frac{\overline{R}}{R_{ad}}\right)-\frac{Le\overline{\beta}}{\sqrt{3}}R+\Phi(\tau),$$

where R_{ad} is the adiabatic radius. The function Φ is a function of only the initial data $y(0,.)$ and $\theta(0,.)$.

It is remarkable to see the influence of the radiative transfer through the term $-\lambda R$ instead of the heat loss term of radiation $-\lambda R^2$ derived in other analysis [5, 6].

Now if we consider a reaction initiated by the input of energy of order $O(\epsilon)$ at the origin, we choose initial conditions so that $\Phi(\tau)=0$, and the only difference comes from the near field equations: we have to solve the quasi-stationary equations

$$\begin{aligned}-\Delta\,\theta&=\beta\,u+\epsilon\,\mathcal{Q}(t)\delta(r=0),\\ -\Delta\,u+3\alpha^2\,u&=\alpha\Delta\,\theta,\end{aligned}\tag{2.15}$$

where $\mathcal{Q}$ represents the amount of energy input into the system at the origin (see [10] for more details). This system is completed with jump conditions detailed in section 2.2. The stationary solution of (2.15) with jump conditions is the sum of the stationary solution computed in section 2.2 and a particular solution (u_p,θ_p) which is smooth at point $r=R(t)$. It is a Fourier transform exercise to prove that a particular solution (u_p,θ_p) of this system is given by

$$u_p=\alpha\epsilon\mathcal{Q}(t)\frac{\mathrm{sh}(\sqrt{3\alpha^2+\alpha\beta})r}{4\pi\,r},\qquad \theta_p=\frac{\epsilon\mathcal{Q}(t)}{4\pi\,r}-\frac{\alpha\beta\epsilon\mathcal{Q}(t)}{4\pi(3\alpha^2+\alpha\beta)}\frac{\mathrm{sh}\sqrt{3\alpha^2+\alpha\beta}r}{r}.$$

Thus in the asymptotic $\alpha=O(\epsilon^\mu)$ with $0<\mu<1$ and $\beta=\overline{\beta}\epsilon$, the temperature at the front is given by

$$\Theta(R)=\frac{1}{Le}-\frac{\overline{\beta}\epsilon}{Le\sqrt{3}}R+\frac{\epsilon\mathcal{Q}(t)}{4\pi\,R}+(\text{h.o.t}).\tag{2.16}$$

As a consequence, we find the growth equation

$$(1-\sqrt{Le})\partial_{1/2}\overline{R}=\log\frac{\overline{R}}{R_{ad}}-\frac{Le\overline{\beta}}{\sqrt{3}}\overline{R}+\frac{Le^2}{4\pi}\frac{\mathcal{Q}(\tau)}{\overline{R}}.$$

In what follows, we put the last term concerning the energy input at the origin in the form $\frac{Eq(\tau)}{\overline{R}}$. Here E represents the intensity of the energy input and $q(\tau)$ corresponds to the time fluctuations of this energy input. In the next sections, we are going to analyze mathematically and numerically

$$(1-\sqrt{Le})\partial_{1/2}\overline{R} = \log\frac{\overline{R}}{R_{ad}} - \frac{Le\overline{\beta}}{\sqrt{3}}\overline{R} + \frac{Eq(\tau)}{\overline{R}}.$$

3. Mathematical results. In this section, we consider the more generalized equation,

$$\mu R\partial_{1/2}R = R\log R + Eq - \lambda R, \quad t\in\mathbb{R}^+,\ R(0)=0, \tag{3.1}$$

where $\mu>0$, $\lambda>0$ and

$$\partial_{1/2}R = \frac{1}{\sqrt{\pi}}\int_0^t \frac{\dot{R}(s)}{\sqrt{t-s}}\,ds = \frac{1}{\sqrt{\pi}}\frac{d}{dt}\int_0^t \frac{R(s)}{\sqrt{t-s}}\,ds. \tag{3.2}$$

This describes the evolution of a spherical flame, initiated by a point source energy input $Eq(t)$, at which are applied heat losses of radiative nature, represented by the parameter λ. The intensity of this energy input is measured by the positive constant E, and its time evolution is described by the function q. This one is a smooth, nonnegative function, with connected support and unit total mass; its initial values satisfy the assumption

$$q(t)\sim q_0 t^{\beta} \quad \text{as } t\to 0 \quad \text{with } 0\le\beta<\frac{1}{2}, \tag{3.3}$$

and as $t\to+\infty$, q tends to 0. Finally, the parameter μ can be viewed as a time rescaling (see section 4) and is assumed, in this section, to be a positive real number, fixed to 1.

Mathematical results of (3.1) are, according to minor modifications in the proofs, similar to the ones written in [1, 15]. Therefore proofs are omitted; only comments are mentioned when necessary.

Let us begin to state existence results for the Cauchy problem.

PROPOSITION 3.1. *Let us assume q positive on $[0,t_0]$, $q(0)=q_0$. Then there exists $t_1\in\,]0,t_0]$ such that* (3.1) *admits a solution in $C^{3/2}([0,t_1])$ satisfying*

$$R(t)\sim R_0 t^{1/4}, \qquad \textit{with } R_0^2 = \frac{Eq_0}{\sqrt{\pi}}\int_0^1 t^{-\frac{1}{4}}(1-t)^{-\frac{1}{2}}dt.$$

In order to prove the existence of a unique maximal solution, the flame radius is expressed as the trace at $x=0$ of a function $u(t,x)$, solution of the following parabolic equation:

$$\begin{cases} u_t - u_{xx} = 2\delta_{x=0}\left(\log u + \dfrac{Eq}{u} - \lambda u\right) & \text{for } x\in\mathbb{R}.\\ u(0,\cdot)=0. \end{cases} \tag{3.4}$$

This formulation is essential to characterizing the long time behavior of the flame. Then we consider more general Cauchy problems, such as

$$\begin{cases} u_t - u_{xx} = 2\delta_{x=0}\left(\log u + \dfrac{Eq}{u} - \lambda u\right) & \text{for } x\in\mathbb{R},\\ u(0,\cdot)=u_0(x), \end{cases} \tag{3.5}$$

where u_0 is an even, Lipschitz, square-integrable, nonnegative function. This is equivalent to solving

$$\begin{cases} u_t - u_{xx} = 0, \quad x > 0, \\ u_x(t,0) = -\left(\log u + \dfrac{Eq}{u} - \lambda u\right) \quad \text{for } x \in \mathbb{R}, \\ u(0,\cdot) = u_0(x). \end{cases}$$

Such a formulation allows us to prove the following result.

THEOREM 3.2. *Let q satisfy condition* (3.3). *We suppose there exists $t_0 > 0$ such that $q(t) > 0$ on $]0, t_0[$ and $q(t) = 0$ if $t \geq t_0$; then the following hold*:

(i) *If $t_0 = +\infty$,* (3.5) *has a unique global positive solution, except at $t = 0$. Moreover, u is C^∞ on $\mathbb{R}_+^* \times \mathbb{R}^*$ and $t \mapsto u(t,0)$ is C^∞ on $\mathbb{R}_+^*$.*

(ii) *If $t_0 < +\infty$,* (3.5) *has a unique maximal solution u defined on an interval $[0, t_{max}[$, positive, except at $t = 0$. Moreover, u is C^∞ on $]0, t_{max}[$. If $t_{max} < +\infty$, there exists $t_n \to t_{max}$ such that $\lim_{n\to+\infty} u(t_n, 0) = 0$.*

In particular, a consequence of this theorem is the existence of a solution of (3.1). The uniqueness of u is based on a comparison principle (see [15] for more details).

These results now recalled, we may discuss different cases where either quenching or stabilization of the flame occurs. For this purpose, we denote by u_E the solution of (3.4) and by $R_E(t) := u_E(t,0)$ the corresponding radius of the flame. Let us turn to the asymptotic behavior of the radius. In order to prove the following results, monotonicity methods (cf. [16]) are of major importance. Indeed, sub- or supersolutions are computed and create, therefore, an admissible range for the solutions. At this stage, a comparison principle coupled to a relevant choice of the bounds reveals to us either quenching or stabilization of the flame.

Before going further, we make a remark on the role played by the parameter λ. The stationary solutions of

$$u_t - u_{xx} = 2\delta_{x=0}(\log u - \lambda u)$$

are the constants R satisfying

$$\log R = \lambda R;$$

hence the values of λ_{cr} and the distinction we have to make between the cases $\lambda < \lambda_{cr}$ and $\lambda > \lambda_{cr}$. Please note that we do not consider the case $\lambda = \lambda_{cr}$, the study being identical to [15]. Moreover, λ is assumed nonnegative in what follows, so that u_E, the solution of (3.5), is a bounded function.

We first consider the supercritical case, $\lambda > \lambda_{cr}$, corresponding to high radiative heat losses. Then the loss of energy is too important and the flame quenches. We state the following proposition.

PROPOSITION 3.3. *Assume $\lambda > \lambda_{cr}$.*

(i) *If $q > 0$ on $\mathbb{R}_+^*$, then the solution of* (3.4) *is global and $\lim_{t\to+\infty} R_E(t) = 0$.*

(ii) *If q is compactly supported, R_E quenches in finite time.*

We now consider the subcritical case, $\lambda < \lambda_{cr}$. This situation leads to different properties, more complex because they depend on the quantities E and q, i.e., the amount of energy we input into the system and the time length of this injection. We have the following claim.

THEOREM 3.4. *Assume $\lambda < \lambda_{cr}$ and $q > 0$ on $\mathbb{R}_+^*$. Then* (3.1) *has a unique global solution $R_E(t)$ and there exists $E_{cr}(q) > 0$ such that*

(i) *if* $E < E_{cr}(q)$, $\lim_{t\to+\infty} R_E(t) = 0$,
(ii) *if* $E > E_{cr}(q)$, $\lim_{t\to+\infty} R_E(t) = R_2$,
(iii) *if* $E = E_{cr}(q)$, $\lim_{t\to+\infty} R_E(t) = R_1$.

If q *is compactly supported, with support* $]0, t_0[$, *then* (3.1) *has a unique solution* $R_E(t)$ *and there exists* $E_{cr}(q) > 0$ *such that*

(a) *if* $E < E_{cr}(q)$, R_E *quenches in finite time,*
(b) *if* $E \geq E_{cr}(q)$, *the previous result holds again.*

This theorem can be proved with minor changes in the sub- and supersolutions in the proofs developed in [15]. For more details on the theoretical study of this type of equations, we refer the reader to [1, 15].

As a conclusion, we have verified that the equation derived in section 2,

$$(1 - \sqrt{Le})\partial_{1/2}\overline{R} = \log \frac{\overline{R}}{R_{ad}} - \frac{Le\overline{\beta}}{\sqrt{3}}\overline{R} + \frac{Eq(\tau)}{\overline{R}}, \tag{3.6}$$

is well posed, provided that $Le < 1$, and the flame ball quenches if $Le\overline{\beta}$ exceed a threshold. When $Le\overline{\beta}$ is small enough, there exist two steady flame balls. The small one is unstable, and the large one is stable under radial perturbations. Since we have computed nonlinear evolutions of radial perturbations, these results shall be understood as nonlinear stability properties of the steady flame balls.

There are different explanations to justify the assumption Le < 1. From a mathematical point of view, (3.6) is ill posed for Lewis numbers greater than one. Indeed, in this case, we face a backward parabolic equation in which instabilities can occur (see, for example, [4, 3]). The special case Le $= 1$ with high activation energy has been studied in [7]. From a physical point of view, as the Lewis number is the ratio between thermal and molecular diffusion, the condition $Le < 1$ is equivalent, saying that gas molecules diffuse faster than heat. In this configuration, flame balls are able to exist, whereas for Lewis numbers greater than one, flames vanish. Considering the experiments performed by Ronney and coworkers (see, for example, [14]), flame balls are observed only for lean reactant mixtures, for which the Lewis number is between 0.06 and 0.5. Thus the restriction Le < 1 is reasonable and, in fact, is a necessary condition for stationary flame balls to exist.

4. Numerics. In this section, we follow the methods developed in [2]. We first present the numerical scheme and then turn to numerical investigations.

4.1. Presentation of the scheme. We recall that the radius R can be seen as the trace on the axis $x = 0$ of the solution $u(x, t)$ of the diffusive problem (3.5). A suitable scheme for studying long time behavior of such equations is an implicit Euler scheme in time. The scheme reads

$$\begin{cases} \dfrac{u^{n+1} - u^n}{\tau} - u_{xx}^{n+1} = 0 \quad \text{for } x > 0, \\ u_x^{n+1}(0) = -\log u^{n+1}(0) - \dfrac{Eq^{n+1}}{u^{n+1}(0)} + \lambda u^{n+1}(0), \\ u^0 = 0, \end{cases} \tag{4.1}$$

where τ denotes the time step and $q^n = q(n\tau)$. The discretized heat equations can be solved explicitly using Fourier transform, so that system (4.1) determines explicitly the quantity in which we are really interested, i.e., the sequence $R^n := u^n(0)$. Moreover, by induction and because of the maximum principle, we have $u^n \geq 0$.

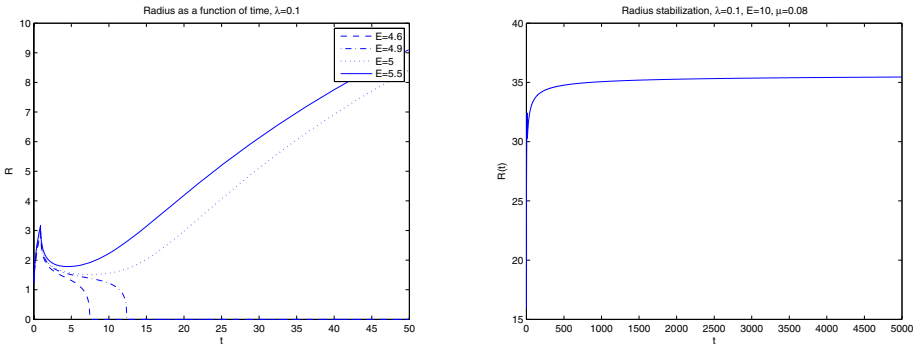

FIG. 4.1. *Evolution of the radius when $\lambda < \lambda_{cr}$ and E is variable; from extinction to stabilization.*

Before going further, we define two quantities needed later on by

$$\begin{cases} \alpha^n = \displaystyle\int_{\mathbb{R}} \frac{\hat{u}^{n-1}(\xi)d\xi}{1+4\pi^2\xi^2\tau} = \sqrt{\tau}\sum_{k=1}^{n-1}\theta_{n-k+1}g^k, \quad \hat{u}^0 = 0, \\ g^n = f^n(\alpha^n + \sqrt{\tau}g^n), \quad n \geq 1, \end{cases}$$

where

$$\theta_{p+1} = \int_{\mathbb{R}} \frac{2\sqrt{\tau}}{(1+4\pi^2\xi^2\tau)^{p+1}}d\xi = \frac{2p-1}{2p}\theta_p = \frac{C^p_{2p-1}}{2^{2p-1}}\theta_1, \qquad \text{with } \theta_1 = 1.$$

The radius R is then expressed in term of these quantities, namely $R^n = \alpha^n + \sqrt{\tau}g^n > 0$. The unknown g^n is determined by successive resolutions of the following implicit equation:

$$\Phi(g^n) := g^n - \log(\alpha^n + \sqrt{\tau}g^n) - \frac{Eq(n\tau)}{\alpha^n + \sqrt{\tau}g^n} + \lambda(\alpha^n + \sqrt{\tau}g^n) = 0. \tag{4.2}$$

In order to be consistent with (3.1), we need to introduce the parameter μ different from 1. It enters (4.2) as

$$\Phi(g^n) := \mu g^n - \log(\alpha^n + \sqrt{\tau}g^n) - \frac{Eq(n\tau)}{\alpha^n + \sqrt{\tau}g^n} + \lambda(\alpha^n + \sqrt{\tau}g^n) = 0. \tag{4.3}$$

This implicit equation is solved by a Newton method with initial data g^{n-1}.

The properties of this scheme remain unchanged so that by [2], the convergence and comparison properties still hold. The numerical scheme also sustained qualitative properties similar to those of the continuous model of flame ball growth (see [2] for more details).

4.2. Numerical results. We now turn to the numerical investigation of the problem. For this purpose, we consider an input energy $q = \chi_{[0,1]}$. In Figure 4.1, we fix a value for the parameter λ, namely $\lambda = 0.1 < \lambda_{cr} = 1/e$, and plot the different radius evolution possibilities for different energy inputs. We note that (see Figure 4.1 (left)) we recover the expected behavior of the radius: when E is small, the flame quenches, whereas when it is larger, the behavior cannot be guessed with this time scale, and numerical simulations have to be performed for longer times. For this

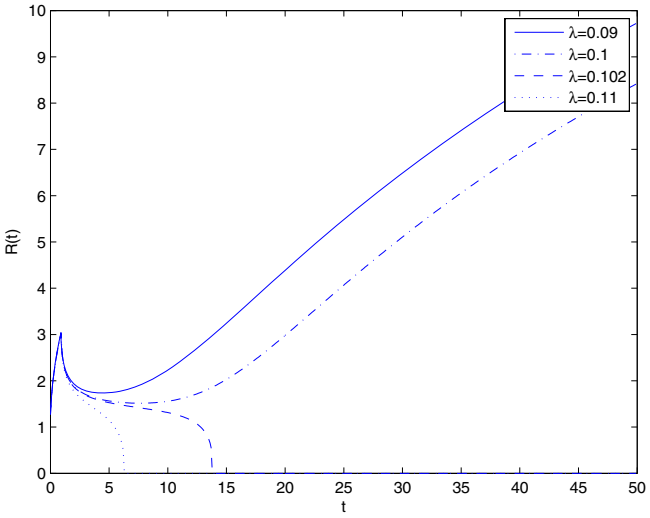

FIG. 4.2. *Evolution of the radius when E fixed and λ variable.*

purpose, we perform a time rescaling. Writing $t = \tau/\epsilon$ in formula (3.1) and dividing by R implies a new expression $\tilde{\mu}\partial_{1/2}R$, where $\tilde{\mu} = \sqrt{\epsilon}\mu$. Dropping the tilde, we are able to simulate a large time scale t via a smaller time scale τ only by taking values of μ less than one. Figure 4.1(right) shows the stabilization towards the radius R_2 in the time coordinate τ.

Finally, in Figure 4.2, the energy E is fixed, and we consider different values for λ. For important radiative heat losses, the flame quenches, whereas it can stabilize to the corresponding critical radius, depending on the value of λ.

5. Conclusion. In this paper, we have studied the stabilizing effect of *radiative transfer* on the formation of flame balls. In the formation of flame balls, radiation is an important physical effect. Instead of considering radiative heat loss, just as Buckmaster, Joulin, and Ronney did in [5, 6] through simplified versions of Stefan's law, we have considered radiative transfer using the well-known (linearized) Eddington law. In some asymptotic parameter regime, we obtain the existence of two steady flame balls. In our study, the asymptotic equation for the radius of the steady flame ball is $\log R = \lambda R$, and that is different from the one obtained in [5, 6], $\log R = \Lambda R^2$. The difference in the power of R comes from the fact that the dependence of the front temperature on R is different depending on whether we consider heat loss terms (in that case, the dependence is parabolic) or radiative transfer (in that case, it is linear). This has an influence on the size of the steady flame balls.

For the linearized Eddington equation of radiative transfer, we have derived, using an approach initiated by Buckmaster, Joulin, and Ronney, an integro-differential equation for the growth of a flame ball. This equation differs again from the one obtained by Buckmaster, Joulin, and Ronney with a loss term proportional to R instead of R^2. The equation obtained in this paper describes the *nonlinear evolution* of *radial perturbation* of steady flame balls and falls into a class of integro-differential equations that are mathematically and numerically well understood [1, 2, 15]; we have used this framework to study mathematically and numerically the asymptotic

behavior of this equation. When two steady flame balls exist, the smaller one is unstable (except for particular values of the parameters), and the larger one is stable, similar to the results obtained in [5, 6]. This gives a partial answer to the stability properties of flame balls obtained in [18] since the perturbations considered in this paper have the *radial* symmetry. Finally, we shall mention that the derivation carried out in this paper is only formal, and it would be interesting to make this derivation rigorously: for that purpose, instead of starting from the free boundary problem, we shall consider the reaction diffusion system with a singular reaction term and follow the method developed by Lederman, Roquejoffre, and Wolansky in the adiabatic case [11].

THE MINIMUM FREE ENERGY FOR CONTINUOUS SPECTRUM MATERIALS*

L. DESERI† AND J. M. GOLDEN‡

Abstract. A general closed expression is given for the isothermal minimum free energy of a linear viscoelastic material with continuous spectrum response. Two quite distinct approaches are adopted, which give the same final result. The first involves expressing a positive quantity, closely related to the loss modulus of the material, defined on the frequency domain, as a product of two factors with specified analyticity properties. The second is the continuous spectrum version of a method used in [S. Breuer and E. T. Onat, *Z. Angew. Math. Phys.*, 15 (1964), pp. 13–21] for materials with relaxation function given by sums of exponentials. It is further shown that minimal energy states are uniquely related to histories and that the work function is the maximum free energy with the property that it is a function of state.

Key words. minimum free energy, linear viscoelasticity, continuous spectrum materials, materials with memory, factorization, complex frequency plane

1. Introduction.

A general expression for the minimum free energy of a linear viscoelastic material under isothermal conditions was given in [1]. This was for a scalar constitutive relation. A generalization to the full tensor case has also been presented [2]. Detailed, explicit expressions for the minimum free energy and related quantities were given in [1, 2] for discrete spectrum materials, namely those for which the relaxation function is a sum of exponentials. The minimum free energy of compressible viscoelastic fluids was determined in [3], while materials with finite memory were considered in [4]. These results are used in the context of the viscoelastic Saint-Venant problem in [5].

A definition of a viscoelastic state, based on the ideas of Noll [6], has been given and explored in [7, 8, 9]. Such a state has been termed a minimal state in [10]. Further related ideas and applications are explored in [11].

Also, a formalism has been developed [10] for the scalar case, which allows expressions for a family of free energies related to a particular minimal state to be derived for discrete spectrum models, including minimum and maximum free energies. Generalization of this work to the full tensor, nonisothermal case was presented in [12]. A generalization of the formalism in [10] has been used recently to propose a closed formula for the physical free energy and rate of dissipation.

It is not clear how the formulae emerging from the the methodology developed in [1, 2] apply to materials other than those exhibiting a discrete spectrum response, in particular for materials with a continuous spectrum response, i.e., those for which

the relaxation function is given by an integral of a density function multiplying a decaying exponential. The object of the present work is to address this issue. We will confine the treatment to the scalar case. There is no great loss of generality in doing so because, in the general tensor case, explicit solutions have been given only if the eigenspaces of the relaxation tensor derivative are time-independent, and on each such eigenspace the explicit results are precisely those of the scalar case [2, 12].

All the above papers are based on the same methodology, which involves factorizing a quantity closely related to the loss modulus of the material, in order to solve the relevant Wiener–Hopf equation (or equivalent variational problem) for the optimal future continuation required to determine the minimum free energy. Another method was used in [13] for the discrete spectrum case. This involved making a very natural assumption on the form of the optimal future continuation and solving algebraic equations for the various parameters. The need for factorization did not arise. This method is also developed in the present work for continuous spectrum materials. The assumption involved in this case is also a very natural one, namely that the optimal future continuation has a singularity structure determined only by that of the Fourier transform of the relaxation function derivative. This is analogous to the method in [13], i.e., to restrict the class of candidate functions when seeking to maximize the recoverable work.

The layout of the paper is as follows. In section 2, fundamental relationships are written down and the basic factorization property is introduced. The Wiener–Hopf equation relating to the maximum recoverable work is derived in section 3. The factorization procedure is discussed in depth for the continuous spectrum case in section 4, and some related formulae are considered in section 5. The minimum free energy is discussed in section 6. The alternative approach referred to in the previous paragraph is discussed in detail in section 7. The concept of a minimal state for continuous spectrum materials is explored in section 8. Some examples are presented in section 9.

2. Basic relationships. We consider a linear viscoelastic solid, subject to stress in such a way that there is only one nonzero component of stress $T(t)$ and strain $E(t)$ related by

$$\begin{aligned} T(t) &= G_0 E(t) + \int_0^\infty G'(s) E^t(s)\,ds, \qquad E^t(s) = E(t-s), \quad s \in \mathcal{R}, \\ &= G_\infty E(t) + \int_0^\infty G'(s) E_r^t(s)\,ds, \quad E_r^t(s) = E^t(s) - E(t), \end{aligned} \tag{2.1}$$

where $E^t \in L^1(\mathcal{R}^+) \cap L^2(\mathcal{R}^+) \cap C^1(\mathcal{R}^+)$ and $G' \in L^1(\mathcal{R}^+) \cap L^2(\mathcal{R}^+)$, using the following notation here and below: $\mathcal{R}$ is the set of reals, $\mathcal{R}^+$ the positive reals, and $\mathcal{R}^{++}$ the strictly positive reals; similarly $\mathcal{R}^-$, $\mathcal{R}^{--}$ are the negative and strictly negative reals. The relative history E_r^t will be used extensively later.[1] The relaxation function

$$G(s) = G_0 + \int_0^s G'(u)\,du \tag{2.2}$$

is well defined, along with $G_\infty = \lim_{s\to\infty} G(s)$. We take

$$G_\infty > 0, \tag{2.3}$$

[1] Note that this notation differs from that in [1].

so that the body is a solid.

A viscoelastic state is defined in general by the current value of strain and the history $(E(t), E^t)$. The concept of a minimal state ([10], based on ideas introduced in [6, 7, 9, 8, 2, 14]) can be expressed as follows: two viscoelastic states $(E_1(t), E_1^t)$, $(E_2(t), E_2^t)$ are equivalent or in the same minimal state if

$$E_1(t) = E_2(t), \qquad \int_0^\infty G'(s+\tau)\left[E_1^t(s) - E_2^t(s)\right] ds = 0 \quad \forall\, \tau \geq 0. \tag{2.4}$$

Let Ω be the complex ω plane and

$$\begin{aligned} \Omega^+ &= \{\omega \in \Omega \mid Im(\omega) \in \mathcal{R}^+\}, \\ \Omega^{(+)} &= \{\omega \in \Omega \mid Im(\omega) \in \mathcal{R}^{++}\}. \end{aligned} \tag{2.5}$$

These define the upper half-plane including and excluding the real axis, respectively. Similarly, Ω^-, $\Omega^{(-)}$ are the lower half-planes including and excluding the real axis, respectively.

For any $f \in L^2(\mathcal{R})$, its Fourier transform $f_F \in L^2(\mathcal{R})$ is given by

$$f_F(\omega) = \int_{-\infty}^{\infty} f(\xi) e^{-i\omega\xi} d\xi. \tag{2.6}$$

If f is a real-valued function in the time domain—which will be the case for all functions of interest here—then

$$\overline{f}_F(\omega) = f_F(-\omega), \tag{2.7}$$

where the bar denotes complex conjugate.

We have

$$\begin{aligned} f_F(\omega) &= f_+(\omega) + f_-(\omega), \\ f_+(\omega) &= \int_0^\infty f(\xi) e^{-i\omega\xi} d\xi, \\ f_-(\omega) &= \int_{-\infty}^0 f(\xi) e^{-i\omega\xi} d\xi, \qquad f_\pm \in L^2(\mathcal{R}), \end{aligned} \tag{2.8}$$

where f_+ has an analytic extension to $\Omega^{(-)}$, by virtue of the unique differentiability of its definition $(2.8)_2$ in terms of an integral. For the cases of interest in the present work, we also assume that it is analytic on an open set including Ω^-, so that we include $\mathcal{R}$ in the region of analyticity. Similarly, f_- is analytic on an open set which includes Ω^+. We will abbreviate these statements in what follows as "$f_\pm$ is analytic in $\Omega^\mp$."

The fact that the singularities of $f_\pm$ are restricted to $\Omega^{(\pm)}$, which is required for the derivation of the free energy [1], means that $f(\xi)$ decays exponentially at large $|\xi|$. This is a limitation in that it excludes, for example, power law decay. However, as we will discuss later, it is in many cases possible to extrapolate final results continuously up to the real axis, thereby removing the limitation to exponential decay.

We have

$$\lim_{\omega\to\infty} i\omega f_+(\omega) = f(0^+), \qquad \lim_{\omega\to\infty} i\omega f_-(\omega) = -f(0^-). \tag{2.9}$$

Functions on $\mathcal{R}$ which vanish identically on $\mathcal{R}^{--}$ are defined as functions on $\mathcal{R}^{+}$. For such quantities, $f_F = f_c - if_s$, where f_c, f_s are the Fourier cosine and sine transforms

$$\begin{aligned} f_c(\omega) &= \int_0^\infty f(\xi)\cos\omega\xi d\xi = f_c(-\omega), \\ f_s(\omega) &= \int_0^\infty f(\xi)\sin\omega\xi d\xi = -f_s(-\omega). \end{aligned} \tag{2.10}$$

Thus

$$F(\omega) = G'_F(\omega) = \int_0^\infty G'(s)e^{-i\omega s}ds = G'_c(\omega) - iG'_s(\omega). \tag{2.11}$$

The notation F is introduced to simplify later formulae. We shall require the property of F that

$$\lim_{\omega\to\infty} i\omega F(\omega) = G'(0^+) = G'(0), \tag{2.12}$$

which is a special case of $(2.9)_1$, with the added assumption that G' is continuous from the right, at the origin. Properties of $G'_s(\omega)$ include (see [15])

$$\begin{aligned} G'_s(\omega) &\le 0 \qquad \forall\, \omega \in \mathcal{R}^{++}, \\ G'_s(-\omega) &= -G'_s(\omega) \qquad \forall\, \omega \in \mathcal{R}, \end{aligned} \tag{2.13}$$

the first relation being a consequence of the second law of thermodynamics and the second being a particular case of (2.10). It follows that $G'_s(0) = 0$. We also have [15]

$$G_\infty - G_0 = \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{G'_s(\omega)}{\omega} d\omega < 0, \tag{2.14}$$

so that $G'_s(\omega)/\omega \in L^1(\mathcal{R})$. It follows from (2.3) and (2.14) that G_0 is positive.

The function F is analytic on $\Omega^{(-)}$. This is a consequence of the fact that G' vanishes on $\mathcal{R}^{--}$, which is essentially the requirement of causality [16]. As noted above, it is assumed that F is analytic in Ω^{-}. Relation $(2.11)_1$ can be used to define $F(\omega)$ where the integral converges, namely Ω^{-} and possibly a strip of $\Omega^{(+)}$. Elsewhere, it is defined by analytic continuation from the region in which the integral exists. In fact, such continuation will generally be possible to all of $\Omega^{(+)}$, excluding singular points.

We let the bar denote complex conjugate. The quantity $\overline{F}(\omega)$ is the complex conjugate of the function, leaving the argument unchanged. For $\omega \in \mathcal{R}$, we have $F(-\omega) = \overline{F}(\omega)$. The quantity $\overline{F}$ is analytic in Ω^{+}, with a mirror image, in the real axis, of the singularity structure of $F(\omega)$. Thus, $G'_s(\omega)$ has singularities in both $\Omega^{(+)}$ and $\Omega^{(-)}$, which are mirror images of one another. Similarly, its zeros will be mirror images of each other. We will be interested in the singularity structure of

$$\begin{aligned} H(\omega) &= \frac{\omega}{2i}\left(F(\omega) - \overline{F}(\omega)\right) \\ &= -\omega G'_s(\omega) = H(-\omega) \ge 0 \qquad \forall\, \omega \in \mathcal{R}, \\ H(\omega) &= H_1(\omega^2), \end{aligned} \tag{2.15}$$

where H_1 is the function H expressed in terms of ω^2. This last relation is a consequence of the analyticity of $H(\omega)$ on the real axis and its evenness property. It follows

that $H(\omega)$ goes to zero at least quadratically at the origin. It is assumed that the behavior is in fact quadratic; i.e., $H(\omega)/\omega^2$ tends to a finite nonzero quantity as ω tends to zero. Note that $H(\omega)$ is nonnegative on the real axis. For ω off the real axis, it is defined by analytic continuation from (2.15) and is in general a complex quantity. Its singularities are the same as those of F in $\Omega^{(+)}$ and of $\overline{F}$ in $\Omega^{(-)}$. We will need the following relationship:

$$\int_{-\infty}^{\infty} \frac{d}{ds} G(|s|) e^{-i\omega s} ds = -2iG'_s(\omega) = 2i\frac{H(\omega)}{\omega}, \tag{2.16}$$

giving the Fourier transform of the odd extension of G' to $\mathcal{R}$.

It will be required in later developments that $H(\omega)$ can be written in the form

$$H(\omega) = H_+(\omega) H_-(\omega), \tag{2.17}$$

where $H_+(\omega)$ has no singularities or zeros in $\Omega^{(-)}$ and is thus analytic in Ω^-. Similarly, $H_-(\omega)$ is analytic in Ω^+ with no zeros in $\Omega^{(+)}$. Therefore the singularities of F must all occur in H_+ and those of $\overline{F}$ in H_-. There may be other singularities in $H_\pm$ which cancel on multiplication. That such a factorization is always possible is shown for general tensor constitutive relations in [2].

Using (2.12) and (2.15), one can show that

$$H_\infty = \lim_{|\omega|\to\infty} H(\omega) = -G'(0) \geq 0. \tag{2.18}$$

The sign of $G'(0)$ has been deduced by various authors from thermodynamic constraints in the general three-dimensional case [17, 18, 15]. We assume for present purposes that $G'(0)$ is nonzero, so that H_∞ is a finite positive number. Then $H(\omega) \in \mathcal{R}^{++}$ $\forall\, \omega \in \mathcal{R}$, $\omega \neq 0$.

The factorization (2.17) is unique up to a constant phase factor. We set [1]

$$\begin{aligned} H_\pm(\omega) &= H_\mp(-\omega) = \overline{H}_\mp(\omega), \\ H(\omega) &= |H_\pm(\omega)|^2, \end{aligned} \tag{2.19}$$

one consequence of which is that the factorization is now unique up to a change of sign.

A general method is outlined in [1] for determining the factors of H. A modification of this method is presented here, which is more convenient for the present application. Consider the function $T(\omega)H(\omega)$ [1], where[2]

$$T(\omega) = \frac{\omega^2 + \omega_0^2}{H_\infty \omega^2}. \tag{2.20}$$

This product is nonnegative on $\mathcal{R}$, is nonsingular at the origin, and approaches unity for large ω. The frequency $\omega_0 \in \mathcal{R}^{++}$ may be chosen arbitrarily. Therefore, the function $\log(T(\omega)H(\omega))$ is well defined on $\mathcal{R}$ and approaches zero for large ω. Let [1]

$$\begin{aligned} H_+(\omega) &= \frac{\omega h_\infty}{\omega - i\omega_0} e^{-M^+(\omega)}, \\ h_\infty &= H_\infty^{1/2}, \end{aligned} \tag{2.21}$$

[2]The introduction of the parameter ω_0 represents a slight modification (improvement) of the formula in [1].

where M^+ is given by[3]

$$
\begin{aligned}
M^+(\omega) &= \lim_{\beta\to 0^-} M(\omega + i\beta), \\
M(z) &= \frac{1}{2\pi i}\int_{-\infty}^{\infty} \frac{\log[T(\omega')H(\omega')]}{\omega' - z} d\omega', \quad z \in \Omega \setminus \mathcal{R}.
\end{aligned} \tag{2.22}
$$

Using (2.15), we can write

$$
\begin{aligned}
\log\left(T(\omega)H(\omega)\right) &= \log\left[-i\frac{\omega - i\omega_0}{H_\infty}F(\omega)\right] + \log U(\omega), \\
U(\omega) &= \frac{1}{2}\left[1 - \frac{\overline{F}(\omega)}{F(\omega)}\right]\left[\frac{\omega + i\omega_0}{\omega}\right].
\end{aligned} \tag{2.23}
$$

The standard branch of the logarithm function is chosen, namely that which vanishes for argument unity. The function U is complex but nonzero on the real line and approaches unity for large ω, by virtue of (2.12). Similarly for the argument of the first term on the right of $(2.23)_1$. This term has all its singularities in $\Omega^{(+)}$ so that if we close on $\Omega^{(-)}$ for $Im\, z < 0$ then, by Cauchy's theorem, its contribution to $M(z)$ is simply the negative of itself. Thus, we have

$$
\begin{aligned}
H_+(\omega) &= \frac{-i\omega}{h_\infty}F(\omega)e^{-N^+(\omega)}, \quad \omega \in \mathcal{R}, \\
N^+(\omega) &= \lim_{\beta\to 0^-} N(\omega + i\beta), \\
N(z) &= \frac{1}{2\pi i}\int_{-\infty}^{\infty} \frac{\log U(\omega')}{\omega' - z} d\omega', \quad z \in \Omega \setminus \mathcal{R}.
\end{aligned} \tag{2.24}
$$

Using the relation $(2.19)_1$, we deduce that

$$
\begin{aligned}
H_-(\omega) &= \frac{i\omega}{h_\infty}\overline{F}(\omega)e^{-N^-(\omega)}, \quad \omega \in \mathcal{R}, \\
N^-(\omega) &= \lim_{\beta\to 0^-} \overline{N}(\omega - i\beta), \\
\overline{N}(z) &= -\frac{1}{2\pi i}\int_{-\infty}^{\infty} \frac{\log \overline{U}(\omega')}{\omega' - z} d\omega', \quad z \in \Omega \setminus \mathcal{R}.
\end{aligned} \tag{2.25}
$$

The extraction of the factor F in (2.24) and $\overline{F}$ in (2.25) has the advantage that the correct behavior of $H_\pm$ at small and large ω is assured. This is of course true of (2.21), but the apparent singularity at $\omega = i\omega_0$ must be eliminated, and the procedures for doing this after the transformations described in section 4 have been carried out is not straightforward. Using (2.24), (2.25), the parameter ω_0 drops out of the formulae in a simple manner, as we shall see later. Furthermore, the singularities of F in $\Omega^{(+)}$ must occur also in H_+ (though, in fact, H_+ may have other singularities), while a similar statement applies to H_- and $\overline{F}$. If the transformation carried out on N^+ in section 4 were instead carried out on M^+ (and this is the natural first approach), it is in fact rather difficult to ensure that the singularity structures of $H_\pm$ in $\Omega^\pm$ are correct. This is particularly true of logarithmic singularities which can, as we shall see, occur at the end points of the branch cuts.

[3]The quantity $M^+(\omega)$ was denoted by $M^-(\omega)$ in [1] and vice versa. The present usage is more consistent with the rest of the paper.

Consider now the strain history E^t. Define

$$E_+^t(\omega) = \int_0^\infty E^t(s)e^{-i\omega s}ds, \quad E_+^t \in L^2(\mathcal{R}^+). \tag{2.26}$$

It is analytic in $\Omega^{(-)}$, a property which will be assumed to extend to Ω^-. This region can be extended to include $\Omega^{(+)}$, excluding singular points, by analytic continuation. From $(2.9)_1$, it follows that

$$\lim_{\omega\to\infty} i\omega E_+^t(\omega) = E^t(0^+) = E(t). \tag{2.27}$$

We also require the Fourier transform of the relative history,

$$\begin{aligned} E_{r+}^t(\omega) &= E_+^t(\omega) - E(t)\int_0^\infty e^{-i\omega s}ds \\ &= E_+^t(\omega) - \frac{E(t)}{i\omega^-}, \qquad \omega^- = \lim_{\alpha\to 0^+}(\omega - i\alpha), \end{aligned} \tag{2.28}$$

where the limit is taken after any integration involving the quantity $(\omega^-)^{-1}$ has been carried out; for purposes of such an integration, ω^- is in $\Omega^{(-)}$. Under an assumption similar to that for E_+^t, we have that E_{r+}^t is analytic on Ω^-. Note that, by virtue of $(2.9)_1$, E_{r+}^t goes to zero at large ω as ω^{-2}.

Let us also define

$$E_-^t(\omega) = \int_{-\infty}^0 E^t(s)e^{-i\omega s}ds, \quad E_-^t \in L^2(\mathcal{R}^-). \tag{2.29}$$

It is analytic in $\Omega^{(+)}$, a property which will be assumed to extend to Ω^+. It is defined on $\Omega^{(-)}$, excluding singular points, by analytic continuation. From (2.9), it follows that

$$\lim_{\omega\to\infty} i\omega E_-^t(\omega) = -E^t(0^-) = -E(t^+). \tag{2.30}$$

We also require the Fourier transform of the relative history,

$$\begin{aligned} E_{r-}^t(\omega) &= E_-^t(\omega) - E(t)\int_{-\infty}^0 e^{-i\omega s}ds \\ &= E_-^t(\omega) + \frac{E(t^+)}{i\omega^+}, \qquad \omega^+ = \lim_{\alpha\to 0^+}(\omega + i\alpha), \end{aligned} \tag{2.31}$$

where for any integration involving the quantity $(\omega^+)^{-1}$ the singularity is in $\Omega^{(+)}$. The limit to the real axis is taken after any such integration has been carried out. Under an assumption similar to that for E_-^t, we have that E_{r-}^t is analytic in Ω^+ and E_{r+}^t goes to zero at large ω as ω^{-2}.

3. The maximum recoverable work and the Wiener–Hopf equation. The total work done on the material up to time t is given by [2]

$$\begin{aligned} W(t) &= \int_{-\infty}^t T(s)\dot{E}(s)ds = \phi(t) + \frac{1}{2}\int_0^\infty\int_0^\infty E_r^t(s)G_{12}(|s-u|)E_r^t(u)dsdu \\ &= \phi(t) + \frac{1}{2\pi}\int_{-\infty}^\infty H(\omega)\left|E_{r+}^t(\omega)\right|^2 d\omega, \end{aligned} \tag{3.1}$$

where ϕ has the form

$$\phi(t) = \frac{1}{2} G_\infty E^2(t). \tag{3.2}$$

This quantity is the equilibrium free energy. Also [19]

$$G_{12}(|s-u|) = \frac{\partial^2}{\partial s \partial u} G(|s-u|) = -2\delta(s-u)G'(|s-u|) - G''(|s-u|), \tag{3.3}$$

in terms of the singular delta function. The form $(3.1)_3$ follows from (2.16) and the convolution theorem.

The maximum recoverable work from a given state of a material with memory is equal to the minimum free energy of that state, as can be shown under very general conditions (e.g., [20] and references therein). Thus, we seek to maximize the integral

$$W_r(t) = -\int_t^\infty T(s)\dot{E}(s)ds, \tag{3.4}$$

or to minimize

$$W(\infty) = \int_{-\infty}^\infty T(s)\dot{E}(s)ds, \tag{3.5}$$

where E is varied only on $[t, \infty)$. When taking the variation, we can assume that $E(\infty)$ vanishes [2]. It follows from (3.1), on changing the integration range to $(-\infty, t]$, that

$$W(\infty) = \frac{1}{2}\int_{-\infty}^\infty \int_{-\infty}^\infty E(s)G_{12}(|s-u|)E(u)dsdu. \tag{3.6}$$

It is easily deduced that the optimization condition is

$$\int_{-\infty}^\infty G_{12}(|s-u|)E(u)du = \int_{-\infty}^\infty G_{12}(|s-u|)E_r^t(u)du = 0, \qquad s \in \mathcal{R}^-. \tag{3.7}$$

We can remove the derivative with respect to s since G_2 tends to zero as s tends to infinity. Also, the derivative with respect to u can be replaced by a derivative with respect to s. Thus, we obtain the relation

$$\int_{-\infty}^\infty \frac{\partial}{\partial s} G(|s-u|)E_r^t(u)du = 0, \qquad s \in \mathcal{R}^-, \tag{3.8}$$

or

$$\int_{-\infty}^0 \frac{\partial}{\partial s} G(|s-u|)E_o^t(u)du = \int_0^\infty G'(u-s)E_r^t(u)du, \qquad s \in \mathcal{R}^-, \tag{3.9}$$

where $E_o^t : \mathcal{R}^- \mapsto \mathcal{R}$ is the future continuation which yields the maximum recoverable work.

4. Factorization of H for continuous spectrum materials. We adopt the following continuous spectrum form for the relaxation function derivative:

$$G'(t) = \int_a^b k(\alpha)e^{-\alpha t}d\alpha, \quad t \in \mathcal{R}^+, \quad b > a > 0. \tag{4.1}$$

It is assumed that $k \in L^1([a,b])$. The upper limit b may be infinite. We take $a > 0$ because of the need to avoid singularities on the real axis. The limit $a \to 0$ is discussed in section 6. We take the Fourier transform of (4.1) to obtain

$$F(\omega) = \int_a^b \frac{k(\alpha)}{\alpha + i\omega} d\alpha, \quad \omega \in \mathcal{R}. \tag{4.2}$$

This formula can be extended by analytic continuation to Ω, excluding singular points. We restrict the density function k to be Hölder continuous on (a,b). It may be singular at the end points with a power less than unity. It is assumed that

$$k(\alpha) \leq 0, \quad \alpha \in [a,b]. \tag{4.3}$$

This assumption is not essential but is the simplest which ensures compatibility with thermodynamic constraint $(2.13)_1$. Note that it renders G completely monotonic in the sense discussed in [9]. Also, it is easily shown that F has no zeros on the finite part of $\Omega \setminus [ia, ib]$. Taking the complex conjugate of (4.2), we have

$$\overline{F}(\omega) = \int_a^b \frac{k(\alpha)}{\alpha - i\omega} d\alpha, \quad \omega \in \mathcal{R}, \tag{4.4}$$

which can similarly be continued into the complex plane.

The quantity F has a branch cut on $[ia, ib]$ and $\overline{F}$ on $[-ia, -ib]$. As ω tends to $i\alpha$, where $\alpha \in \mathcal{R} \setminus [-a, -b]$,

$$\overline{F}(i\alpha) = F(-i\alpha) = \int_a^b \frac{k(\beta)}{\beta + \alpha} d\beta = K(\alpha), \tag{4.5}$$

while if $\alpha \in (a,b)$, we have, by virtue of the Plemelj formulae [21],

$$\begin{aligned} F_R(i\alpha) &= R(\alpha) + iI(\alpha), \\ F_L(i\alpha) &= R(\alpha) - iI(\alpha), \end{aligned} \tag{4.6}$$

with

$$R(\alpha) = P \int_a^b \frac{k(\beta)}{\beta - \alpha} d\beta, \qquad I(\alpha) = -\pi k(\alpha) \geq 0, \tag{4.7}$$

where $F_R(i\alpha)$, $F_L(i\alpha)$ are the limiting values of $F(\omega)$, approaching from the right and the left, respectively, as one moves from ia to ib. Similarly,

$$\begin{aligned} \overline{F}_R(-i\alpha) &= R(\alpha) + iI(\alpha), \\ \overline{F}_L(-i\alpha) &= R(\alpha) - iI(\alpha), \end{aligned} \tag{4.8}$$

for $\alpha \in (a,b)$, where $\overline{F}_R(-i\alpha)$, $\overline{F}_L(-i\alpha)$ are the limiting values of $\overline{F}(\omega)$ from the right and left, respectively, as one moves from $-ia$ to $-ib$. The symbol P in (4.7) indicates a principal value.

From (2.15), we have

$$H(\omega) = -\omega^2 \int_a^b \frac{k(\alpha)}{\alpha^2 + \omega^2} d\alpha. \tag{4.9}$$

Let us consider the behavior of $F(\omega)$ at the end points ia and ib for various limiting behaviors of $k(\alpha)$ as α approaches a or b [21]. If $k(a) = 0$, then $F(\omega)$ has a definite finite nonzero limit as $\omega \to ia$. A similar statement applies to the limit $\omega \to ib$ if $k(b) = 0$.

If

$$k(a) = k_a < 0 \tag{4.10}$$

and k is Hölder continuous near and at a, then $F(\omega)$ has a logarithmic singularity at $\omega = ia$. As ω approaches this end point along any path off $[ia, ib]$, then

$$F(\omega) = k_a \log \frac{1}{a + i\omega} + F_1(\omega), \tag{4.11}$$

where $F_1(a)$ is well defined. Similarly, if

$$k(b) = k_b < 0 \tag{4.12}$$

and k is Hölder continuous near and at b, then, as ω approaches ib, not along $[ia, ib]$, we have

$$F(\omega) = -k_b \log \frac{1}{b + i\omega} + F_2(\omega), \tag{4.13}$$

where $F_2(b)$ is well defined. For points on (ia, ib), relations (4.11) and (4.13) are replaced by

$$\begin{aligned} R(\alpha) &\underset{\alpha \to ia^+}{\longrightarrow} k_a \log \frac{1}{\alpha - a} \\ &\underset{\alpha \to ib^-}{\longrightarrow} -k_b \log \frac{1}{b - \alpha}, \end{aligned} \tag{4.14}$$

where $R(\alpha)$ is given by (4.7). If $k(\alpha)$ has dominant behavior as $\alpha \to a^+$ along (a, b) of the form

$$k(\alpha) \underset{\alpha \to a^+}{\longrightarrow} \frac{k_1}{(\alpha - a)^\gamma}, \quad 0 < \gamma < 1, \quad k_1 < 0, \tag{4.15}$$

then for $\omega \notin (ia, ib)$

$$F(\omega) \underset{\omega \to ia}{\longrightarrow} \frac{Ak_1}{(a + i\omega)^\gamma}. \tag{4.16}$$

The detailed form of A is given in [21]. A similar observation applies to the case where k has such behavior at b. For points on (ia, ib), relation (4.16) is replaced by

$$R(\alpha) \underset{\alpha \to a^+}{\longrightarrow} \frac{A_1 k_1}{(\alpha - a)^\gamma}, \tag{4.17}$$

where again the form of A_1 may be found in [21]. A similar observation applies at b.

We return our attention to (2.24). The function $U(i\alpha)$, $\alpha > 0$, is real for $\alpha \notin [a, b]$. It is discontinuous across $[a, b]$. We define, for $\alpha \in [a, b]$,

$$\begin{aligned} U_R(i\alpha) &= \lim_{\omega \to \omega_R} U(\omega), \qquad \omega_R = \alpha e^{\frac{i\pi}{2}}, \\ U_L(i\alpha) &= \lim_{\omega \to \omega_L} U(\omega), \qquad \omega_L = \alpha e^{\frac{-3i\pi}{2}}. \end{aligned} \tag{4.18}$$

As noted earlier, the function $U(\omega)$ is nonzero on $\Omega^{(+)}$ and approaches unity as $\omega \to \infty$. Thus, $\log U(\omega)$ has a branch cut on $[ia, ib]$ and no other singularity in $\Omega^{(+)}$. The factor $\log\left[\frac{\omega+i\omega_0}{\omega}\right]$ is assigned a branch cut on $[0, -i\omega_0]$. Moving the line of integration in $(2.24)_3$ to the infinite half-circle in $\Omega^{(+)}$ while going around the branch cut, we obtain

$$\begin{aligned} N(z) &= \frac{1}{2\pi i}\int_a^b \frac{\Delta(\alpha)}{\alpha + iz} d\alpha, \\ \Delta(\alpha) &= \log U_R(i\alpha) - \log U_L(i\alpha), \end{aligned} \tag{4.19}$$

where the branch of the logarithm function is as specified earlier. Its imaginary part lies in $[-\pi, \pi]$. Note that the factor $\left[\frac{\omega+i\omega}{\omega}\right]$ in $U(\omega)$ cancels out of $\Delta(\alpha)$; it can henceforth be omitted. Thus, we set

$$\begin{aligned} Y(\omega) &= \frac{1}{2}\left(1 - \frac{\overline{F}(\omega)}{F(\omega)}\right), \\ \Delta(\alpha) &= \log Y_R(i\alpha) - \log Y_L(i\alpha), \end{aligned} \tag{4.20}$$

where, from (4.5) and (4.6),

$$\begin{aligned} Y_R(i\alpha) &= \frac{1}{2}\left[1 - \frac{K(\alpha)}{R(\alpha) + iI(\alpha)}\right], \\ Y_L(i\alpha) &= \frac{1}{2}\left[1 - \frac{K(\alpha)}{R(\alpha) - iI(\alpha)}\right] = \overline{Y_R(i\alpha)}. \end{aligned} \tag{4.21}$$

We can write

$$\Delta(\alpha) = 2iA(\alpha), \quad A(\alpha) = \arg Y_R(\alpha), \quad -\pi \le A(\alpha) \le \pi, \tag{4.22}$$

and

$$\begin{aligned} H_+(\omega) &= -\frac{i\omega}{h_\infty} F(\omega) e^{-N^+(\omega)}, \\ N^+(\omega) &= \frac{1}{\pi}\int_a^b \frac{A(\alpha)}{\alpha + i\omega} d\alpha, \end{aligned} \tag{4.23}$$

while

$$\begin{aligned} H_-(\omega) &= \frac{i\omega}{h_\infty} \overline{F}(\omega) e^{-N^-(\omega)}, \\ N^-(\omega) &= \frac{1}{\pi}\int_a^b \frac{A(\alpha)}{\alpha - i\omega} d\alpha. \end{aligned} \tag{4.24}$$

In the notation of (4.7), we have

$$V(\alpha) = 2[R(\alpha)^2 + I(\alpha)^2] Re Y_R(i\alpha) = R(\alpha)^2 + I(\alpha)^2 - K(\alpha)R(\alpha), \tag{4.25}$$

where $K(\alpha)$, given by (4.5), is real and negative for $\alpha > -a$. Also,

$$W(\alpha) = 2[R(\alpha)^2 + I(\alpha)^2] Im Y_R(i\alpha) = K(\alpha)I(\alpha) \le 0, \tag{4.26}$$

from which it follows that $-\pi \le A(\alpha) \le 0$. Then

$$\begin{aligned} A(\alpha) &= -B(\alpha), \quad V(\alpha) \ge 0, \\ &= -\pi + B(\alpha), \quad V(\alpha) < 0; \\ B(\alpha) &= \arctan\left|\frac{W(\alpha)}{V(\alpha)}\right|, \quad 0 \le B(\alpha) \le \frac{\pi}{2}. \end{aligned} \tag{4.27}$$

Note the following result.

PROPOSITION 4.1. *The quantity*

$$V(\alpha) = R(\alpha)^2 + I(\alpha)^2 - K(\alpha)R(\alpha), \quad \alpha \in (a,b), \tag{4.28}$$

is nonnegative in the vicinity of the end points a and b. It is also nonnegative when $R(\alpha) \in \mathcal{R}^+$.

Proof. The latter statement follows immediately from the fact that $K(\alpha) \le 0$ for $\alpha \in (a,b)$. The statement is trivially true when $R(\alpha)$ vanishes. Nonnegativity near a given end point is manifestly true if R is unbounded at that end point, which is true even if k is finite but nonzero at the end points (see (4.14)). Thus, we must consider only the case where the density function k vanishes at the end point. Consider first the lower end point a. We have

$$R(a) = P\int_a^b \frac{k(\beta)}{\beta - a}d\beta \le 0. \tag{4.29}$$

Then

$$V(a) \ge R(a)^2 - K(a)R(a) \ge 0 \tag{4.30}$$

if

$$-R(a) \ge -K(a). \tag{4.31}$$

Observing that

$$K(a) = \int_a^b \frac{k(\beta)}{\beta + a}d\beta, \tag{4.32}$$

we see that (4.31) is true. Also,

$$R(b) = \int_a^b \frac{k(\beta)}{\beta - b}d\beta \ge 0, \tag{4.33}$$

so that $V(b) \ge 0$. □

If $V \ge 0$ on (a,b), then

$$\begin{aligned} H_+(\omega) &= -\frac{i\omega}{h_\infty}F(\omega)\exp\left\{\frac{1}{\pi}\int_a^b \frac{B(\alpha)d\alpha}{\alpha + i\omega}\right\}, \\ H_-(\omega) &= \frac{i\omega}{h_\infty}\overline{F}(\omega)\exp\left\{\frac{1}{\pi}\int_a^b \frac{B(\alpha)d\alpha}{\alpha - i\omega}\right\}, \end{aligned} \tag{4.34}$$

where B is defined by $(4.27)_3$.

5. Some consequences of the factorization formulae. It is of interest to consider the limits of $H_{\pm}$, given by (4.23) and (4.24), as ω approaches the branch cuts on $[ia, ib]$ and $[-ia, -ib]$. Consider (4.24) as $\omega \to -i\alpha$, $\alpha \in (a, b)$, from the left, i.e., from the fourth quadrant. Noting (4.8), we obtain

$$\begin{aligned} H_{-L}(-i\alpha) &= \frac{\alpha}{h_\infty}(R(\alpha) - iI(\alpha))P(\alpha)e^{-iA(\alpha)}, \\ P(\alpha) &= \exp\left\{-\frac{1}{\pi}P\int_a^b \frac{A(\beta)}{\beta - \alpha}d\beta\right\}, \end{aligned} \tag{5.1}$$

where the Plemelj formulae have been used. Also, from (4.5) and (4.23),

$$\begin{aligned} H_{+L}(-i\alpha) &= -\frac{\alpha}{h_\infty}K(\alpha)Q(\alpha) = H_{+R}(-i\alpha), \\ Q(\alpha) &= \exp\left\{-\frac{1}{\pi}\int_a^b \frac{A(\beta)}{\beta + \alpha}d\beta\right\}. \end{aligned} \tag{5.2}$$

Multiplying $H_{\pm L}$ together, we obtain the limit of $H(\omega)$ as $\omega \to -i\alpha$, $\alpha \in (a, b)$, namely

$$H_L(-i\alpha) = -\frac{\alpha^2}{H_\infty}(R(\alpha) - iI(\alpha))K(\alpha)P(\alpha)Q(\alpha)e^{-iA(\alpha)}. \tag{5.3}$$

Also, from (2.15), we have

$$H_L(-i\alpha) = \frac{\alpha}{2}(R(\alpha) - K(\alpha) - iI(\alpha)). \tag{5.4}$$

Equating the arguments of these two expressions for $H_L(-i\alpha)$ gives

$$\arg(R(\alpha) - K(\alpha) - iI(\alpha)) = -A(\alpha) + \arg(R(\alpha) - iI(\alpha)), \tag{5.5}$$

or, taking complex conjugates,

$$A(\alpha) = \arg\left[1 - \frac{K\alpha)}{R(\alpha) + iI(\alpha)}\right], \tag{5.6}$$

which is, of course, simply $(4.22)_2$. Equating the magnitudes of the two expressions given by (5.3) and (5.4), we obtain

$$-2\alpha K(\alpha)P(\alpha)Q(\alpha) = H_\infty\sqrt{\frac{(R(\alpha) - K(\alpha))^2 + I^2(\alpha)}{R^2(\alpha) + I^2(\alpha)}}. \tag{5.7}$$

With the aid of (5.5), we can write (5.1) in the form

$$\begin{aligned} H_{-L}(-i\alpha) &= \frac{\alpha}{h_\infty}(R(\alpha) - K(\alpha) - iI(\alpha))\sqrt{\frac{R^2(\alpha) + I^2(\alpha)}{(R(\alpha) - K(\alpha))^2 + I^2(\alpha)}}P(\alpha) \\ &= -\frac{h_\infty}{2}\frac{(R(\alpha) - K(\alpha) - iI(\alpha))}{K(\alpha)Q(\alpha)}. \end{aligned} \tag{5.8}$$

The second form follows from (5.7).

Finally, we observe that $(2.15)_1$, (2.17), (4.23), and (4.24) give

$$Z(\omega) = \frac{H_\infty}{2i\omega}\left(\frac{1}{\overline{F}(\omega)} - \frac{1}{F(\omega)}\right) = \exp\left\{-\frac{1}{\pi}\int_a^b \frac{A(\alpha)d\alpha}{\alpha + i\omega} - \frac{1}{\pi}\int_a^b \frac{A(\alpha)d\alpha}{\alpha - i\omega}\right\}. \tag{5.9}$$

Let us show this directly, noting that the left-hand side does not vanish at the origin and is unity at infinity. Consider the contour C, taken clockwise at infinity except that it excludes the positive imaginary axis above ia and the negative imaginary axis below $-ia$. The quantity Z is finite and nonzero within C. Then we see that

$$Z(\omega) = \exp\left\{-\frac{1}{2\pi i}\int_C \frac{\log(Z(u))du}{u - \omega}\right\}, \tag{5.10}$$

where ω is in the interior of C. Invoking an argument similar to that leading to (4.19) and (4.20), the result follows on noting that

$$\log Z_R(i\alpha) - \log Z_L(i\alpha) = \log Y_R(i\alpha) - \log Y_L(i\alpha) \tag{5.11}$$

for $\alpha \in (a, b)$, since real positive factors in the arguments of the logarithms cancel.

6. The minimum free energy. First, we derive the expression for the continuation that yields the maximum recoverable work—which is equal to the minimum free energy—when F is given by (4.2), from the Wiener–Hopf equation (3.8) or (3.9). The unique factorization of H is given by (4.23), (4.24), and (4.27). We shall use the formalism for relative histories, defined by $(2.1)_2$, as in [3, 4, 12, 5] rather than in [1, 2]. Let us replace the right-hand side of (3.8) by $R^t(s)$, where this function vanishes on $\mathcal{R}^-$. Taking the Fourier transform of (3.8) yields

$$\frac{2i}{\omega}H(\omega)(E^t_{r+}(\omega) + E^t_m(\omega)) = R^t_+(\omega), \tag{6.1}$$

where E^t_m is the Fourier transform of the optimum relative continuation E^t_o in (3.9) and R^t_+ is an unknown function, analytic in Ω^-. Equation (6.1) is an immediate consequence of (2.16) and (2.15). Using the factorization property of H, we can write (6.1) as

$$H_-(\omega)E^t_{r+}(\omega) + H_-(\omega)E^t_m(\omega) = \frac{\omega R^t_+(\omega)}{2iH_+(\omega)}. \tag{6.2}$$

Let us define

$$\begin{aligned} p^t(z) &= \frac{1}{2\pi i}\int_{-\infty}^{\infty} d\omega' \frac{H_-(\omega')E^t_{r+}(\omega')}{\omega' - z}, \\ p^t_\pm(\omega) &= \lim_{\alpha \to 0^+} p^t(\omega \mp i\alpha). \end{aligned} \tag{6.3}$$

By the Plemelj formulae [21],

$$H_-(\omega)E^t_{r+}(\omega) = p^t_-(\omega) - p^t_+(\omega). \tag{6.4}$$

Then (6.2) can be written in the form

$$p^t_-(\omega) + H_-(\omega)E^t_m(\omega) = p^t_+(\omega) + \frac{\omega R^t_+(\omega)}{2iH_+(\omega)}. \tag{6.5}$$

Recalling that E_m^t is analytic in Ω^+ (see after (2.29)), we see that the left-hand side of this relation is analytic in Ω^+ and the right-hand side is analytic in Ω^-. Also, the left-hand side goes to zero as ω^{-1}, as we see by applying (2.30) to E_m^t. Thus, both sides are analytic in Ω and vanish at infinity, and are therefore individually zero. Therefore

$$E_m^t(\omega) = -\frac{p_-^t(\omega)}{H_-(\omega)}, \tag{6.6}$$

and the minimum free energy is given by (see [1, 2, 4], for example)

$$\begin{aligned} \psi_m(t) &= \phi(t) + \frac{1}{2\pi}\int_{-\infty}^{\infty} H(\omega)\left|E_m^t(\omega)\right|^2 d\omega \\ &= \phi(t) + \frac{1}{2\pi}\int_{-\infty}^{\infty} \left|p_-^t(\omega)\right|^2 d\omega, \end{aligned} \tag{6.7}$$

where ϕ is given by (3.2). The quantity $\psi_m(t)$ was shown in [1, 2] to be a free energy by the Graffi definition [22, 23] and in [2] by the Coleman–Owen definition [24, 25] for the general tensor case.

From $(3.1)_3$ and (6.4) we have

$$\begin{aligned} W(t) &= \phi(t) + \frac{1}{2\pi}\int_{-\infty}^{\infty} \left[\left|p_+^t(\omega)\right|^2 + \left|p_-^t(\omega)\right|^2\right] d\omega \\ &= \psi_m(t) + \frac{1}{2\pi}\int_{-\infty}^{\infty} \left|p_+^t(\omega)\right|^2 d\omega, \end{aligned} \tag{6.8}$$

where the orthogonality property [1]

$$\int_{-\infty}^{\infty} p_-^t(\omega)\bar{p}_+^t(\omega)d\omega = \int_{-\infty}^{\infty} p_+^t(\omega)\bar{p}_-^t(\omega)d\omega \tag{6.9}$$

was used in writing $(6.8)_1$. This follows from Cauchy's theorem, since $\bar{p}_\pm^t$ are analytic in $\Omega^\pm$ and go to zero as ω^{-1} at large ω.

Note that p_-^t can be written in the form

$$\begin{aligned} p_-^t(\omega) &= \frac{1}{2\pi}\int_a^b \frac{\Delta_h(\alpha)E_{r+}^t(-i\alpha)}{\alpha - i\omega}d\alpha, \\ \Delta_h(\alpha) &= -i(H_{-L}(-i\alpha) - H_{-R}(-i\alpha)), \end{aligned} \tag{6.10}$$

by closing the contour on $\Omega^{(-)}$ around the branch cut and changing variables. The quantity H_{-L} is given by (5.8), while H_{-R} is its complex conjugate. Thus, we have

$$\begin{aligned} \Delta_h(\alpha) &= -\frac{2\alpha}{h_\infty} I(\alpha)P(\alpha)\sqrt{\frac{R^2(\alpha) + I^2(\alpha)}{(R(\alpha) - K(\alpha))^2 + I^2(\alpha)}} \\ &= h_\infty \frac{I(\alpha)}{K(\alpha)Q(\alpha)} \le 0, \qquad \alpha \in [a, b]. \end{aligned} \tag{6.11}$$

The second form has the advantage that the need to evaluate a principal value integral is avoided. The quantities involved are also free of end point singularities.

The definitions of the various quantities in these relationships are summarized for convenience in Table 1.

TABLE 1
Definitions of the various quantities in the formula (6.11).

Formula	Equation reference
$F(\omega) = \int_a^b \frac{k(\alpha)}{\alpha + i\omega} d\alpha, \quad \omega \in \mathcal{R}$	(4.2)
$K(\alpha) = \int_a^b \frac{k(\beta)}{\beta + \alpha} d\beta, \quad \alpha \in \mathcal{R} \backslash [-a, -b]$	(4.5)
$R(\alpha) = P\int_a^b \frac{k(\beta)}{\beta - \alpha} d\beta, \quad I(\alpha) = -\pi k(\alpha), \quad \alpha \in (a, b)$	(4.7)
$A(\alpha) = \arg\left[1 - \frac{K(\alpha)}{R(\alpha) + iI(\alpha)}\right], \quad -\pi \le A(\alpha) \le 0$	(4.21), (4.22), (4.27)
$P(\alpha) = \exp\left\{-\frac{1}{\pi} P\int_a^b \frac{A(\beta)}{\beta - \alpha} d\beta\right\}$	(5.1)
$Q(\alpha) = \exp\left\{-\frac{1}{\pi} \int_a^b \frac{A(\beta)}{\beta + \alpha} d\beta\right\}$	(5.2)

Using (6.7) and (6.10), we can write the minimum free energy in the form (cf. (3.1))

$$\psi_m(t) = \phi(t) + \frac{1}{2}\int_0^\infty \int_0^\infty E_r^t(s) G_{12}(s,u) E_r^t(u) ds du, \tag{6.12}$$

where

$$G_{12}(s,u) = \frac{1}{2\pi^2}\int_a^b \int_a^b \frac{\Delta_h(\alpha) e^{-\alpha s} \Delta_h(\beta) e^{-\beta u}}{\alpha + \beta} d\alpha d\beta, \tag{6.13}$$

and we understand the subscripts to mean differentiation with respect to the first and second variable. It follows that

$$G(s,u) = G(\infty,\infty) + \frac{1}{2\pi^2}\int_a^b \int_a^b \frac{\Delta_h(\alpha) e^{-\alpha s} \Delta_h(\beta) e^{-\beta u}}{(\alpha + \beta)\alpha\beta} d\alpha d\beta \tag{6.14}$$

if we require that [1]

$$G(\infty,\infty) = G(s,\infty) = G(\infty,s), \quad s \in \mathcal{R}^+, \tag{6.15}$$

yielding $G_1(s,\infty) = G_2(\infty,s) = 0$. It is also required that [1]

$$G(s,0) = G(0,s) = G(s), \quad s \in \mathcal{R}^+, \tag{6.16}$$

where $G(s)$ is defined by (2.2). We deduce from (6.15) and (6.16) that

$$G(\infty,\infty) = G(\infty) = G_\infty \tag{6.17}$$

in the notation of (2.1). To show that (6.16) holds, observe that for $z \in \Omega^-$,

$$\frac{1}{2\pi i}\int_{-\infty}^\infty \frac{H_-(\omega')}{(\omega' - z)\omega'} d\omega' = -\frac{H_-(z)}{z} = \frac{i}{2\pi}\int_a^b \frac{\Delta_h(\beta)}{(\beta - iz)\beta} d\beta, \tag{6.18}$$

where the first relation follows by closing the contour in $\Omega^{(-)}$, and the second results in the same manner as (6.10). It follows from (5.2) and $H_-(i\alpha) = H_+(-i\alpha)$ that

$$\frac{1}{2\pi}\int_a^b \frac{\Delta_h(\beta)}{(\beta+\alpha)\beta}d\beta = \frac{1}{h_\infty}K(\alpha)Q(\alpha). \tag{6.19}$$

Noting that

$$G(s) = G_\infty - \int_a^b \frac{k(\alpha)}{\alpha}e^{-\alpha s}d\alpha, \tag{6.20}$$

we deduce from $(6.11)_2$ that (6.16) holds. Observe that both G and G_{12} are positive quantities.

The isothermal energy balance equation can be written as

$$\dot{\psi}_m(t) + D_m(t) = T(t)\dot{E}(t), \tag{6.21}$$

where D_m is the rate of dissipation associated with the minimum free energy. This quantity must be nonnegative by the second law. It is given by [1]

$$\begin{aligned} D_m(t) &= \left\{\frac{1}{2\pi}\int_{-\infty}^{\infty} H_-(\omega)E_{r+}^t(\omega)d\omega\right\}^2 \\ &= \left\{\frac{1}{2\pi}\int_a^b \Delta_h(\alpha)E_{r+}^t(-i\alpha)d\alpha\right\}^2 \\ &= \left\{\frac{1}{2\pi}\int_0^\infty\int_a^b \Delta_h(\alpha)E_r^t(u)e^{-\alpha u}d\alpha du\right\}^2 \geq 0. \end{aligned} \tag{6.22}$$

Integrating (6.21), we obtain the relation

$$\psi_m(t) + \mathcal{D}_m(t) = W(t), \tag{6.23}$$

where $\mathcal{D}_m$ is the total dissipation, defined by

$$\mathcal{D}_m(t) = \int_{-\infty}^t D(s)ds. \tag{6.24}$$

This quantity is assumed to be finite.

It is through the rate of dissipation and the total dissipation that we make the most direct connection with measurable physical quantities. In particular, $\mathcal{D}_m(t)$ is the least upper bound on the total dissipation, under isothermal conditions, which actually occurs in the material. This is clear from (6.23), since $\psi_m(t)$ is the greatest lower bound on the physical free energy.

It follows from (6.8), (6.23) that

$$\mathcal{D}_m(t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \left|p_+^t(\omega)\right|^2 d\omega. \tag{6.25}$$

This is not, however, particularly convenient for deriving a useful formula for $\mathcal{D}_m$. Instead, we take another, more direct approach. From (3.1), $(3.3)_2$, (4.1), and (6.12),

we see that

$$\begin{aligned}\mathcal{D}_m(t) = W(t) - \psi_m(t) &= -G'(0)\int_0^\infty [E_r^t(s)]^2 ds \\ &\quad - \frac{1}{2}\int_0^\infty\int_0^\infty E_r^t(s)L(s,u)E_r^t(u)dsdu,\\ L(s,u) &= -\int_a^b \alpha k(\alpha)e^{-\alpha|s-u|}d\alpha \\ &\quad + \frac{1}{2\pi^2}\int_a^b\int_a^b \frac{\Delta_h(\alpha)e^{-\alpha s}\Delta_h(\beta)e^{-\beta u}}{\alpha+\beta}d\alpha d\beta.\end{aligned} \tag{6.26}$$

A point of interest is whether we can take the limit $a \to 0$ in the above formulae, which would extend the class of relaxation functions beyond those with exponential decay at large times. In light of (4.11), we see that if $k(0) = 0$, then there is no singularity at the real axis, and it should always be possible to do so. In all other cases considered in section 4, there will be an integrable singularity. However, the form $(6.11)_2$ is free of these singularities (see Table 1), and the integrals in (6.13), (6.22), and (6.26) exist, so the formulae may be accepted as valid in the limit $a \to 0$.

7. An alternative approach. Another approach to finding the minimum free energy of a continuous spectrum material is outlined in this section. Its most remarkable feature is that it does not require explicit factorization of the function H. It was motivated initially by the method of Breuer and Onat [13] who propose an ansatz for the optimal continuation in the discrete spectrum case and solve the problem by this means. A similar ansatz can be written down without difficulty for the continuous spectrum case. However, it turns out that no such explicit assumption is required.

We start from the form (6.1) of the Wiener–Hopf equation, absorbing the factor $2i$ in R_+ and seeking not $E_m^t(\omega)$ but

$$\Xi_m^t(\omega) = i\omega\overline{F}(\omega)E_m^t(\omega), \tag{7.1}$$

which is also analytic in Ω^+. The reason for this change of unknown is so that we end up with formulae that are directly comparable with earlier results, in particular (6.6), based on the factorization of H with factors F and $\overline{F}$ extracted, as in (2.24), (2.25), and later formulae. The quantity Ξ_m^t is related to the memory-dependent part of the Fourier transform of the stress associated with the optimal continuation E_m^t and a zero history before time t.

Thus, recalling (2.15), we consider the relation

$$H(\omega)\left[E_{r+}^t(\omega) + \frac{\Xi_m^t(\omega)}{i\omega\overline{F}(\omega)}\right] = H(\omega)E_{r+}^t(\omega) + \overline{Y}(\omega)\Xi_m^t(\omega) = R_+(\omega), \tag{7.2}$$

where Y is defined by (4.20). We consider the discontinuity of both sides across the cut $(-ia, -ib)$. The quantities E_{r+}^t and R_+ are analytic in Ω^- and therefore have no discontinuity across the cut. Using (5.4) and its complex conjugate which gives $H_{-R}(-i\alpha)$, we obtain

$$\begin{aligned}\overline{Y}_L(-i\alpha)\Xi_L^t(-i\alpha) - \overline{Y}_R(-i\alpha)\Xi_R^t(-i\alpha) &= i\alpha I(\alpha)E_{r+}^t(-i\alpha), \quad \alpha \in (a,b),\\ &= 0, \quad \alpha \notin (a,b),\end{aligned} \tag{7.3}$$

where Ξ_L^t, Ξ_R^t are the limits of Ξ_m^t on $[-ia, -ib]$ from the left and right, respectively. If it were assumed that Ξ_m^t could be written as a Cauchy integral over $[-ia, -ib]$, which

amounts to the continuous version of the Breuer–Onat ansatz, then (7.3) could be put in the form of a singular integral equation. As remarked earlier, this is unnecessary. The only and very natural assumption needed is that the only singularity of E_m^t is a branch cut on $[-ia, -ib]$. Note that

$$\Xi_m^t(\omega) \approx \frac{1}{\omega} \tag{7.4}$$

for large frequencies, which follows from (2.9) and (7.1). Relation (7.3) is a Hilbert problem, which we can write in the form

$$\begin{aligned} &\Xi^{t+}(\alpha) = C_1(\alpha)\Xi^{t-}(\alpha) + C_2(\alpha), \\ &\Xi^{t+}(\alpha) = \Xi_L^t(-i\alpha), \qquad \Xi^{t-}(\alpha) = \Xi_R^t(-i\alpha), \\ &C_1(\alpha) = \frac{\overline{Y}_R(-i\alpha)}{\overline{Y}_L(-i\alpha)}, \qquad C_2(\alpha) = \frac{i\alpha I(\alpha) E_{r+}(-i\alpha)}{\overline{Y}_L(-i\alpha)}. \end{aligned} \tag{7.5}$$

Note that, from the complex conjugate of (4.21),

$$C_1(a) = C_1(b) = 1. \tag{7.6}$$

This is clear for singular end points as given by (4.14) and (4.17). For the nonsingular case, $I(a)$ and $I(b)$ vanish.

Equation (7.5) will now be solved for $\Xi^t(z) = \Xi_m^t(-iz)$, which has a branch cut on $[a, b]$ and where $\Xi^{t\pm}(\alpha)$ are the limits of this function from the left and the right of the cut. The solution is subject to (7.4) and to the condition that it is bounded except possibly at a or b, where it may diverge logarithmically or as a power less than unity. This latter property reflects the assumptions made relating to the density function k. The general solution is (see [21, p. 237])

$$\begin{aligned} \Xi^t(z) &= \frac{X(z)}{2\pi i} \int_a^b \frac{C_2(\beta)}{X^+(\beta)(\beta - z)} d\beta + X(z)P(z), \\ X(z) &= \Pi(z) e^{N(iz)}, \\ N(iz) &= \frac{1}{2\pi i} \int_a^b \frac{\log C_1(\lambda)}{\lambda - z} d\lambda, \\ \Pi(z) &= (z-a)^{\lambda_1}(z-b)^{\lambda_2}, \end{aligned} \tag{7.7}$$

where λ_1, λ_2 are integers and $P(z)$ is an arbitrary polynomial of degree not less than $\kappa - 1$ with

$$\kappa = -\lambda_1 - \lambda_2.$$

Observe that $N(iz)$ is the quantity defined by (4.19) and (4.20) since

$$\overline{Y}_R(-i\alpha) = Y_R(i\alpha), \qquad \overline{Y}_L(-i\alpha) = Y_L(i\alpha), \tag{7.8}$$

by virtue of (4.6) and (4.8). The quantity $X^+(\beta)$ is the limit of $X(z)$ as $z \to \beta \in (a, b)$ from the positive half-plane. Near $z = a, b$ the quantity N is finite because of (7.6), so that

$$\begin{aligned} X(z)) \underset{z \to a}{\approx} K_1(z-a)^{\lambda_1} \\ \underset{z \to b}{\approx} K_2(z-b)^{\lambda_2}, \end{aligned} \tag{7.9}$$

where K_1, K_2 are constants. To ensure no divergence in Ξ of order unity or stronger, we must have $\lambda_1, \lambda_2 \geq 0$ and $\kappa \leq 0$. For $\kappa < 0$, solutions vanishing at infinity are possible only if restrictions are placed on C_2, which depends only on given physical parameters [21]. Thus, we must have $\kappa = 0$ and $\lambda_1 = \lambda_2 = 0$. The polynomial P is zero. Therefore

$$X(z) = e^{N(iz)}$$

and

$$\Xi^t(i\omega) = \Xi^t_m(\omega) = \frac{X(i\omega)}{2\pi i} \int_a^b \frac{C_2(\beta)}{X^+(\beta)(\beta - i\omega)} d\beta. \tag{7.10}$$

Observe that, from (4.24),

$$X(i\omega) = \frac{i\omega \overline{F}(\omega)}{h_\infty H_-(\omega)} \tag{7.11}$$

and

$$X^+(\beta) = \frac{\beta \overline{F}_L(-i\beta)}{h_\infty H_{-L}(-i\beta)} = \frac{1}{P(\beta)} e^{iA(\beta)}, \qquad \beta \in (a, b), \tag{7.12}$$

where (4.8) and (5.1) have been used. Now, from (4.21) and (7.8),

$$\overline{Y}_L(-i\beta) = \frac{1}{2}\left[1 - \frac{K(\beta)}{R(\beta) - iI(\beta)}\right] = \frac{1}{2}\sqrt{\frac{(R(\beta) - K(\beta))^2 + I^2(\beta)}{R^2(\beta) + I^2(\beta)}} e^{-iA(\beta)}, \tag{7.13}$$

by virtue of (5.5). Thus

$$\frac{C_2(\beta)}{X^+(\beta)} = 2i\beta P(\beta) I(\beta) \sqrt{\frac{R^2(\beta) + I^2(\beta)}{(R(\beta) - K(\beta))^2 + I^2(\beta)}} E^t_{r+}(-i\beta) = -ih_\infty \Delta_h(\beta) E^t_{r+}(-i\beta) \tag{7.14}$$

in the notation of (6.11). Then, we finally obtain from (7.1), (7.10), and (7.14)

$$E^t_m(\omega) = -\frac{1}{2\pi H_-(\omega)} \int_a^b \frac{\Delta_h(\beta) E^t_{r+}(-i\beta)}{\beta - i\omega} d\beta,$$

which agrees with (6.6) and (6.10).

Note that the quantity X, given by (7.11), is closely related to the factor H_-. This is how the factors of H enter the formulae. The quantity X is the solution of the homogeneous part of the Hilbert problem (7.5). We note that the factorization problem of H can be expressed as a homogeneous Hilbert problem on the real axis:

$$H_-(w) = H(\omega) \left[H_+(w)\right]^{-1}.$$

It is straightforward to show that this is equivalent to the homogeneous problem associated with $(7.5)_1$ by taking the limit of this relation on both sides of the branch cut on $[-ia, -ib]$ in H_- and H, and using (7.11).

8. Minimal states. Finally, let us explore the concept of minimal states, defined by (2.4), in the context of continuous spectrum materials.

PROPOSITION 8.1. *For the relaxation function derivative given by* (4.1)*, where* k *is negative on* (a,b)*, except possibly at a finite number of isolated points, and for histories with* E^t_+ *analytic on* $\mathcal{R}$ *(see the remark after* (2.26)*) the minimal states are singletons. In other words,* $(E(t),E^t)$ *is the minimal state.*

Proof. We define $(E_d(t),E^t_d)$ as

$$\begin{aligned} E_d(t) &= E_1(t)-E_2(t),\\ E^t_d(s) &= E^t_1(s)-E^t_2(s), \quad s\in\mathcal{R}^+. \end{aligned} \tag{8.1}$$

Then (2.4) becomes

$$\begin{aligned} &E_d(t)=0,\\ &\int_0^\infty G'(s+\tau)E^t_d(s)ds=\int_a^b k(\alpha)e^{-\alpha\tau}E^t_{d+}(-i\alpha)d\alpha=0 \quad \forall\,\tau\ge 0. \end{aligned} \tag{8.2}$$

The function

$$Z(\tau)=\int_a^b k(\alpha)e^{-\alpha\tau}E^t_{d+}(-i\alpha)d\alpha \tag{8.3}$$

can be extended to the complex τ plane. It is analytic (and therefore zero) for $Re\ \tau>0$. Taking the inverse Laplace transform, we deduce that $k(\alpha)E^t_+(-i\alpha)$ vanishes for $\alpha\in\mathcal{R}^+$. Thus, since $k(\alpha)$ does not vanish for $\alpha\in(a,b)$, except at most at a finite number of isolated points, we have

$$E^t_{d+}(-i\alpha)=0, \tag{8.4}$$

over (a,b) or some open subinterval of this region, which in turn implies that $E^t_{d+}(\omega)$ vanishes in the region of analyticity connected to $(-ia,-ib)$. This certainly includes Ω^- and in particular the real axis. We conclude that

$$E_d(t)=0, \qquad E^t_d(s)=0, \quad s\in\mathcal{R}^{++}. \qquad \square \tag{8.5}$$

This result is in sharp contrast with the situation prevailing for discrete spectrum materials [10, 26].

It follows from Proposition 8.1 that the work function is a function of state and is the maximum free energy, for relaxation functions obeying a strong dissipativity condition [8].

A generalization of Proposition 8.1 is given in [26, 11]. Also, it follows from a more general result proved in [9, Proposition 7.3].

9. Particular cases and approximations. Explicit expressions for $F(\omega)$, $R(\alpha)$, $K(\alpha)$, and $G'(0)=-h^2_\infty$ corresponding to a number of choices of $k(\alpha)$ are presented in Table 2. These are the quantities required to determine $H_\pm$ in (4.23) and (4.24) or indeed the free energy functional (6.12). A multiplying positive constant may of course be included in k in all cases. In addition, we note the following formulae which allow simple generalizations of those tabulated. If $k(\alpha)$ yields $F(\omega)$, then $\alpha k(\alpha)$ yields $F_1(\omega)$, where

$$\begin{aligned} F_1(\omega) &= G'(0)-i\omega F(\omega),\\ G'(0) &= \int_a^b k(\alpha)d\alpha. \end{aligned} \tag{9.1}$$

TABLE 2

The quantities F, K, R, and $G'(0)$ required to determine the factors of H and the minimum free energy for various choices of the density function k. The function $I(\alpha) = -\pi k(\alpha)$. The quantity $c = (a+b)/2$. The function Ei *is the exponential-integral function. The fourth and fifth rows are, of course, special cases ($\theta = 1/2$) of the sixth and seventh rows. The branch of $[(a-z)(b-z)]^{1/2}$ is chosen to be the one that approaches $-z$ as $|z|$ becomes large; similarly for $(a-z)^{\theta}(b-z)^{1-\theta}$. The quantity $\theta \in (0,1)$.*

	$k(\alpha),\ \alpha \in (a,b)$	$F(\omega)$	$K(\alpha),\ \alpha > -a$	$R(\alpha),\ \alpha \in (a,b)$	$G'(0)$
(1)	-1	$\log\left(\dfrac{\omega - ia}{\omega - ib}\right)$	$\log\left(\dfrac{\alpha + a}{\alpha + b}\right)$	$\log\left(\dfrac{\alpha - a}{b - \alpha}\right)$	$-(b-a)$
(2)	$-(\alpha - a)(b - \alpha)$	$-(b-a)(c+i\omega)$ $+ (a+i\omega)(b+i\omega)\log\left(\dfrac{b+i\omega}{a+i\omega}\right)$	$-(b-a)(c+\alpha)$ $+ (a+\alpha)(b+\alpha)\log\left(\dfrac{b+\alpha}{a+\alpha}\right)$	$-(b-a)(c-\alpha)$ $+ (\alpha-a)(b-\alpha)\log\left(\dfrac{\alpha-a}{b-\alpha}\right)$	$-\dfrac{(b-a)^3}{6}$
(3)	$-e^{-\alpha t_0},\quad \alpha \geq a > 0$	$e^{i\omega t_0}\,\mathrm{Ei}(-(a+i\omega)t_0)$	$e^{\alpha t_0}\,\mathrm{Ei}(-(a+\alpha)t_0)$	$e^{-\alpha t_0}\,\mathrm{Ei}((\alpha-a)t_0)$	$-\dfrac{e^{-at_0}}{t_0}$
(4)	$-\dfrac{1}{\sqrt{(\alpha-a)(b-\alpha)}}$	$-\dfrac{\pi}{[(a+i\omega)(b+i\omega)]^{1/2}}$	$-\dfrac{\pi}{\sqrt{(a+\alpha)(b+\alpha)}}$	0	$-\pi$
(5)	$-\sqrt{(\alpha-a)(b-\alpha)}$	$-\pi\left\{c+i\omega - [(a+i\omega)(b+i\omega)]^{1/2}\right\}$	$-\pi\left\{c+\alpha - \sqrt{(a+\alpha)(b+\alpha)}\right\}$	$-\pi(c-\alpha)$	$-\dfrac{\pi(b-a)^2}{8}$
(6)	$-\dfrac{1}{(\alpha-a)^{1-\theta}(b-\alpha)^{\theta}}$	$-\dfrac{\pi}{\sin\pi\theta}\dfrac{1}{(a+i\omega)^{1-\theta}(b+i\omega)^{\theta}}$	$-\dfrac{\pi}{\sin\pi\theta}\dfrac{1}{(a+\alpha)^{1-\theta}(b+\alpha)^{\theta}}$	$\dfrac{\pi\cot\pi\theta}{(\alpha-a)^{1-\theta}(b-\alpha)^{\theta}}$	$-\dfrac{\pi}{\sin\pi\theta}$
(7)	$-(\alpha-a)^{1-\theta}(b-\alpha)^{\theta}$	$-\dfrac{\pi}{\sin\pi\theta}\{a(1-\theta)+b\theta+i\omega$ $-(a+i\omega)^{1-\theta}(b+i\omega)^{\theta}\}$	$-\dfrac{\pi}{\sin\pi\theta}\{a(1-\theta)+b\theta+\alpha$ $-(a+\alpha)^{1-\theta}(b+\alpha)^{\theta}\}$	$-\dfrac{\pi}{\sin\pi\theta}\{a(1-\theta)+b\theta-\alpha$ $+\cos\pi\theta(\alpha-a)^{1-\theta}(b-\alpha)^{\theta}\}$	$-\dfrac{\pi(b-a)^2\theta(1-\theta)}{2\sin\pi\theta}$

Also

$$
\begin{aligned}
R_1(\alpha) &= G'(0) + \alpha R(\alpha), \\
K_1(\alpha) &= G'(0) - \alpha K(\alpha), \\
G_1'(0) &= \int_a^b \alpha k(\alpha) d\alpha,
\end{aligned}
\tag{9.2}
$$

where the subscript "1" indicates the various quantities corresponding to $\alpha k(\alpha)$. Furthermore, all quantities are linear in k, so that formulae for linear combinations of density functions may be constructed without difficulty.

A choice of k which is of some physical interest is (see [27])

$$
k(\alpha) = -A\alpha^{\lambda}, \quad 0 < \lambda \leq 1, \quad 0 < \alpha < \infty, \quad A > 0,
\tag{9.3}
$$

particularly for $\lambda = 0.5$. However, $G'(0)$ is infinite for this relaxation spectrum, a problem that is easily remedied in principle by taking the range of integrations to be finite. In this case, it would probably be simpler to evaluate all the quantities of interest by numerical methods. Note, however, that the seventh and fifth rows of Table 2 provide a good approximation to (9.3) if a is set equal to zero and b is taken to be large. In any case, the relevance of (9.3) is weakened by the fact that the power λ may depend on the value of α.

Note that the behavior of $H_{\pm}$, given by (4.23) and (4.24), for large ω, is approximated by

$$
\begin{aligned}
H_+(\omega) &\approx -\frac{i\omega}{h_\infty} F(\omega), \\
H_-(\omega) &\approx \frac{i\omega}{h_\infty} \overline{F}(\omega).
\end{aligned}
\tag{9.4}
$$

At small ω, they are approximately given by a real constant times the quantities on the right-hand side of (9.4).

This suggests that (9.4), perhaps with multiplying constants, may provide a reasonable approximation for the factors at all frequencies. However, the functional (6.7) has the properties of a free energy (see [1]) only approximately, if (9.4) is used.

D-BAR METHOD FOR ELECTRICAL IMPEDANCE TOMOGRAPHY WITH DISCONTINUOUS CONDUCTIVITIES*

KIM KNUDSEN†, MATTI LASSAS‡, JENNIFER L. MUELLER§, AND SAMULI SILTANEN¶

Abstract. The effects of truncating the (approximate) scattering transform in the D-bar reconstruction method for two-dimensional electrical impedance tomography are studied. The method is based on the uniqueness proof of Nachman [*Ann. of Math.* (2), 143 (1996), pp. 71–96] that applies to twice differentiable conductivities. However, the reconstruction algorithm has been successfully applied to experimental data, which can be characterized as piecewise smooth conductivities. The truncation is shown to stabilize the method against measurement noise and to have a smoothing effect on the reconstructed conductivity. Thus the truncation can be interpreted as regularization of the D-bar method. Numerical reconstructions are presented demonstrating that features of discontinuous high contrast conductivities can be recovered using the D-bar method. Further, a new connection between Calderón's linearization method and the D-bar method is established, and the two methods are compared numerically and analytically.

1. Introduction.

The two-dimensional (2-D) inverse conductivity problem is to determine and reconstruct an unknown conductivity distribution γ in an open, bounded, and smooth domain $\Omega \subset \mathbb{R}^2$ from voltage-to-current measurements on the boundary $\partial\Omega$. We assume that there is a $C > 0$ such that

$$C^{-1} < \gamma(x) < C, \quad x \in \Omega. \tag{1}$$

The boundary measurements are modeled by the Dirichlet-to-Neumann (DN) map

$$\Lambda_\gamma f = \gamma \frac{\partial u}{\partial \nu}\Big|_{\partial\Omega},$$

where u is the solution to the generalized Laplace equation

$$\nabla \cdot \gamma \nabla u = 0 \quad \text{in } \Omega, \quad u|_{\partial\Omega} = f. \tag{2}$$

Mathematically, the problem is to show that the map $\gamma \mapsto \Lambda_\gamma$ is injective and find an algorithm for the inversion of the map. Physically, u is the electric potential in Ω, and Λ_γ represents knowledge of the current flux through $\partial\Omega$ resulting from the voltage distribution f applied on $\partial\Omega$.

The inverse conductivity problem has applications in subsurface flow monitoring and remediation [30, 31], underground contaminant detection [10, 17], geophysics [9, 27], nondestructive evaluation [11, 36, 39, 37], and a medical imaging technique known as electrical impedance tomography (EIT) (see [8, 5] for a review article on EIT). Conductivity distributions appearing in applications are typically piecewise continuous. This is the case, for example, in medical EIT, since various tissues in the body have different conductivities, and there are discontinuities at organ boundaries. Here we consider 2-D reconstructions. These can be used to image cross-sections of a three-dimensional (3-D) region, such as a patient's torso. In the case of patients receiving mechanical ventilation, for example, 2-D cross-sections are useful for obtaining regional ventilation information in the lungs, which is valuable for setting and controlling the airflow and pressure settings on the ventilator [34, 1]. Real-time imaging of cross-sectional lung activity can also be used for diagnostic purposes, such as detecting a lung collapse, a pulmonary embolism, pulmonary edema, or a pneumothorax.

Let us briefly outline the history of D-bar solution methods for EIT. Recently, Astala and Päivärinta [2] showed that knowledge of the DN map uniquely determines the conductivity $\gamma(x) \in L^\infty(\Omega)$, $0 < c \le \gamma$. This result has been generalized to anisotropic conductivities in [3]. In this work, we will refer to the 2-D uniqueness result by Nachman [25] for $\gamma \in W^{2,p}(\Omega)$, $p > 1$, and by Brown and Uhlmann [6] for $\gamma \in W^{1,p}(\Omega)$, $p > 2$. The proof in [25] is constructive; that is, it outlines a direct method for reconstructing the conductivity γ from knowledge of Λ_γ. This method was realized as a numerical algorithm for C^2 conductivities in [29, 24, 15]. The uniqueness result of Brown and Uhlmann in [6] was formulated as a reconstruction algorithm in [20], which has been implemented in [18, 19]. There are many similarities between the two methods. In fact, it was shown in [18] using the Brown–Uhlmann approach that the reconstruction method of Nachman [25] can be extended to the class of conductivities $\gamma \in W^{1+\epsilon,p}(\Omega)$, $p > 2$, $\epsilon > 0$. We refer the reader to [24, 5, 38] for discussions of uniqueness results for γ in other spaces and $\Omega \subset \mathbb{R}^n$, $n \ge 2$.

Nachman's D-bar approach in [25] is based on the evaluation of the scattering transform $\mathbf{t}(k)$ by the formula

$$\mathbf{t}(k) = \int_{\partial\Omega} e^{i\overline{k}\bar{x}}(\Lambda_\gamma - \Lambda_1)\psi(\cdot,k)d\sigma(x), \quad k \in \mathbb{C},\ x = x_1 + ix_2, \tag{3}$$

where Λ_1 denotes the DN map corresponding to the homogeneous conductivity 1. Then γ can be recovered by solving a D-bar equation containing $\mathbf{t}(k)$. The functions $\psi(\cdot,k)$ in (3) are traces of certain exponentially growing solutions to (2), i.e., solutions that behave like e^{ikx} asymptotically as either $|x|$ or $|k|$ tends to infinity. These traces can, in principle, be found by solving a particular boundary integral equation. However, as solving such an equation is quite sensitive to measurement noise, the following approximation to $\mathbf{t}(k)$ was introduced in [29]:

$$\mathbf{t}^{\exp}(k) = \int_{\partial\Omega} e^{i\overline{k}\bar{x}}(\Lambda_\gamma - \Lambda_1)e^{ikx}d\sigma(x). \tag{4}$$

This approximation can be viewed as a linearizing assumption, since the approximation $\psi|_{\partial\Omega} \approx e^{ikx}$ is used instead of solving for ψ on the boundary using the nonlinear equation (7).

Formula (4) allows the evaluation of $\mathbf{t}^{\exp}(k)$ for L^∞ conductivities, and the D-bar method is found to be effective even when the conductivity does not satisfy the assumptions of the original reconstruction theorem. In [15], quite accurate reconstructions are computed from experimental data collected on a phantom chest consisting

of agar heart and lungs in a saline-filled tank. They are the first reconstructions using the D-bar method on a discontinuous conductivity and on measured data. In [16], the D-bar algorithm with a differencing $\mathbf{t}^{\exp}$ approximation is used to reconstruct conductivity changes in a human chest, particularly pulmonary perfusion.

Our aim is to better understand the reconstruction of realistic conductivities from noisy EIT data using the D-bar method by studying its application to piecewise smooth conductivities. Section 2 gives necessary background on the method and its variants. In section 3, we prove that reconstructions from any truncated scattering data are smooth. In section 4, we show that the reconstructions from noisy data using truncated $\mathbf{t}^{\exp}$ are stable. We remark that previous work [23, 4] shows that the exact reconstruction algorithm is stable in a restricted sense, i.e., as a map defined on the range of the forward operator $\Lambda\colon \gamma \mapsto \Lambda_\gamma$. In contrast, we show that the approximate reconstruction is continuously defined on the entire data space $\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))$. As an application of the stability, we consider in section 5 mollified versions γ_λ of a piecewise continuous conductivity distribution γ and show that reconstructions of γ_λ converge to reconstructions of γ as $\lambda \to 0$. This means that no systematic artifacts are introduced when the reconstruction method is applied to conductivities outside the assumptions of the theory.

In section 6, a connection between the linearization method of Calderón [7] and the D-bar method is established. Calderón's method is written in terms of $\mathbf{t}^{\exp}$ and is revealed to be a low-order approximation to the D-bar method. The simple example of the unit disk containing one concentric ring of constant conductivity with a discontinuity at the interface is studied in depth in section 7. We write $\mathbf{t}^{\exp}$ as a series showing the asymptotic growth rate. Reconstructions by Calderón's method and the D-bar method with the $\mathbf{t}^{\exp}$ approximation are expressed in explicit formulas.

In section 8, we illustrate our theoretical findings by numerical examples. We find that both the D-bar method and Calderón's method can approximately recover the location of a discontinuity. Also, both methods yield good reconstructions of low-contrast conductivities but have difficulties in recovering the actual conductivity values in the presence of high contrast features near the boundary.

2. The D-bar reconstruction method. In this section, we briefly review the reconstruction method based on the proof by Nachman [25]. We will describe both the exact mathematical algorithm and an approximate numerical algorithm.

2.1. Exact reconstruction from infinite precision data. The reconstruction method uses exponentially growing solutions to the conductivity equation. Suppose $\gamma - 1 \in W^{1+\epsilon,p}(\mathbb{R}^2)$ with $p > 2$ and $\gamma \equiv 1$ in $\mathbb{R}^2 \setminus \overline{\Omega}$. Then the equation

$$\nabla \cdot \gamma \nabla u = 0 \text{ in } \mathbb{R}^2 \tag{5}$$

has a unique exponentially growing solution u that behaves like e^{ixk}, where x is understood as $x = x_1 + ix_2 \in \mathbb{C}$ and the parameter $k = k_1 + ik_2 \in \mathbb{C}$. The construction of exponentially growing solutions is done by reducing the conductivity equation to either a Schrödinger equation (requires two derivatives on the conductivity) or a first-order system (requires one derivative). Consider $\psi := u\sqrt{\gamma}$ satisfying $(e^{-ixk}\psi(x,k) - 1) \in W^{1,p}(\mathbb{R}^2)$ with $p > 2$, and note that since $\gamma = 1$ at $\partial\Omega$ we have $u|_{\partial\Omega} = \psi|_{\partial\Omega}$. The intermediate object in the reconstruction method is the scattering transform defined in terms of the DN map by (3).

The reconstruction algorithm consists of the two steps

$$\Lambda_\gamma \to \mathbf{t} \to \gamma. \tag{6}$$

In order to compute $\mathbf{t}$ from Λ_γ by (3), one needs to find the trace of $\psi(\cdot,k)$ on $\partial\Omega$. It turns out that $\psi|_{\partial\Omega}$ satisfies

$$\psi(\cdot,k)|_{\partial\Omega} = e^{ikx} - S_k(\Lambda_\gamma - \Lambda_1)\psi(\cdot,k). \tag{7}$$

Here S_k is the single-layer operator

$$(S_k\phi)(x) := \int_{\partial\Omega} G_k(x-y)\phi(y)d\sigma(y), \quad k \in \mathbb{C}\setminus 0, \tag{8}$$

where the Faddeev's Green's function G_k is defined by

$$G_k(x) := \frac{e^{ikx}}{(2\pi)^2}\int_{\mathbb{R}^2} \frac{e^{ix\cdot\xi}}{|\xi|^2 + 2k(\xi_1 + i\xi_2)}d\xi, \quad -\Delta G_k = \delta. \tag{9}$$

Here the dot product is computed with real vectors $x = (x_1, x_2)$ and $\xi = (\xi_1, \xi_2)$. The Fredholm equation (7) is uniquely solvable in $H^{1/2}(\partial\Omega)$; see [25].

To compute γ from $\mathbf{t}$, the key observation is that with respect to the parameter k, the function $\mu(x,k) = e^{-ixk}\psi(x,k)$ satisfies a differential equation where $\mathbf{t}$ enters as a coefficient. More precisely, μ satisfies for fixed $x \in \mathbb{C}$ the D-bar equation

$$\overline{\partial}_k\mu(x,k) = \frac{1}{4\pi\overline{k}}\mathbf{t}(k)e_{-x}(k)\overline{\mu(x,k)}, \quad k \in \mathbb{C}, \tag{10}$$

where the unimodular function e_k is defined by

$$e_x(k) := e^{i(kx+\overline{k}\bar{x})} = e^{-i(-2k_1,2k_2)\cdot x}. \tag{11}$$

It is shown in [25] (see also [6, 20]) that $\mu(x,\cdot)$ is, in fact, the unique solution to (10) defined by the asymptotic condition $\mu(x,\cdot) - 1 \in L^r(\mathbb{R}^2), r > 2/\epsilon$. Moreover, the solution belongs to $C^\alpha(\mathbb{R}^2)$ with $\alpha < 1$; see section 3. Hence $\mu(x,k)$ can be computed from $\mathbf{t}$ by solving (10) or, equivalently, the Fredholm integral equation

$$\mu(x,s) = 1 + \frac{1}{(2\pi)^2}\int_{\mathbb{R}^2} \frac{\mathbf{t}(k)}{(s-k)\overline{k}}e_{-x}(k)\overline{\mu(x,k)}dk_1dk_2. \tag{12}$$

Finally, the conductivity can be recovered from μ using the formula

$$\gamma(x) = \mu(x,0)^2, \quad x \in \Omega. \tag{13}$$

2.2. Truncation of scattering transform. Note that in (12) the integral is over the whole plane. We will define a regularized D-bar algorithm by truncating the scattering transform to a disk of radius R. Then

$$\mathbf{t}_{\mathrm{R}}(k) \equiv \begin{cases} \mathbf{t}(k) & \text{for } |k| \le R, \\ 0 & \text{for } |k| > R, \end{cases} \tag{14}$$

and $\mu_{\mathrm{R}}(x,k)$ is the solution of

$$\mu_{\mathrm{R}}(x,s) = 1 + \frac{1}{(2\pi)^2}\int_{|k|\le R} \frac{\mathbf{t}_{\mathrm{R}}(k)}{(s-k)\overline{k}}e_{-x}(k)\overline{\mu_{\mathrm{R}}(x,k)}dk_1dk_2. \tag{15}$$

This defines a modified D-bar algorithm consisting of the following steps:

1. Solve (7) for $\psi|_{\partial\Omega}$.
2. Compute $\mathbf{t}_{\mathrm{R}}$ by (3) and (14).
3. Solve the integral equation (15) for μ_{R}.
4. Compute the reconstruction $\gamma_{\mathrm{R}}(x) = \mu_{\mathrm{R}}(x,0)^2$.

According to [24], this algorithm gives correct results at the asymptotic limit $R \to \infty$.

2.3. Approximate reconstruction from finite precision data. In the presence of noise in the data, solving (7) is difficult, and therefore the approximate scattering transform $\mathbf{t}^{\exp}(k)$ defined by (4) was introduced. An advantage of $\mathbf{t}^{\exp}(k)$ is that the definition applies just as well to discontinuous conductivities as to smooth ones. However, it can be shown in certain cases that $\mathbf{t}^{\exp}(k)$ grows so fast as $|k|$ tends to infinity (see (64) below) that the corresponding D-bar equation is not solvable. In addition, the practical computation is stable only for $|k| \le R$, where the radius R depends on the noise level. Thus the scattering transform needs to be truncated. Set

$$\mathbf{t}_{\mathrm{R}}^{\exp}(k) = \begin{cases} \mathbf{t}^{\exp}(k) & \text{for } |k| \le R, \\ 0 & \text{for } |k| > R, \end{cases} \tag{16}$$

and write the corresponding D-bar equation:

$$\mu_{\mathrm{R}}^{\exp}(x,s) = 1 + \frac{1}{(2\pi)^2} \int_{|k|\le R} \frac{\mathbf{t}_{\mathrm{R}}^{\exp}(k)}{(s-k)\overline{k}} e_{-x}(k) \overline{\mu_{\mathrm{R}}^{\exp}(x,k)} dk_1 dk_2. \tag{17}$$

We arrive at the following reconstruction algorithm:

1. Compute $\mathbf{t}_{\mathrm{R}}^{\exp}$ by (4) and (16).
2. Solve (17) for $\mu_{\mathrm{R}}^{\exp}$.
3. Compute $\gamma_{\mathrm{R}}^{\exp}(x) = \mu_{\mathrm{R}}^{\exp}(x,0)^2$.

We will show in section 4 that this reconstruction algorithm is robust against noise. In the numerical implementation, the challenge is to solve (17); see [29, 21].

3. Smoothness of reconstructions from truncated scattering data. We first investigate the x-smoothness of the solution to the D-bar equation

$$\mu(x,s) = 1 + \frac{1}{\pi} \int_{\mathbb{R}^2} \frac{\phi(k)}{s-k} e_{-x}(k) \overline{\mu(x,k)} dk_1 dk_2 \tag{18}$$

under various assumptions on the coefficient ϕ. Then we will show that the reconstructions γ_{R} and $\gamma_{\mathrm{R}}^{\exp}$ computed from truncated scattering data are smooth functions.

The analysis of (18) makes heavy use of the solid Cauchy transform

$$\mathcal{C}f(s) := \frac{1}{\pi} \int_{\mathbb{R}^2} \frac{f(k)}{s-k} dk_1 dk_2. \tag{19}$$

The following result is essentially [25, Lemma 1.2] and [35, Theorem 1.21].

LEMMA 3.1. *Suppose $f \in L^{p_1}(\mathbb{R}^2)$, where $1 < p_1 < 2$. Then*

$$\|\mathcal{C}f\|_{L^{\tilde{p}_1}(\mathbb{R}^2)} \le C \|f\|_{L^{p_1}(\mathbb{R}^2)}, \quad \frac{1}{\tilde{p}_1} = \frac{1}{p_1} - \frac{1}{2}. \tag{20}$$

Suppose further that $f \in L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2)$, where $1 < p_1 < 2 < p_2 < \infty$. Then

$$\|\mathcal{C}f\|_{C^\alpha(\mathbb{R}^2)} \le C(\|f\|_{L^{p_1}(\mathbb{R}^2)} + \|f\|_{L^{p_2}(\mathbb{R}^2)}), \quad \alpha = 1 - \frac{2}{p_2}. \tag{21}$$

In the next lemma, we consider the continuity of the Cauchy transform applied to functions depending on a parameter. To simplify notation, we introduce for $x \in \mathbb{R}^2$ the real-linear operator Φ_x by $\Phi_x f = \phi(k) e_{-k}(x) \overline{f(k)}$.

LEMMA 3.2. *Let $\phi \in L^{p_1} \cap L^{p_2}(\mathbb{R}^2)$ with $1 < p_1 < 2 < p_2 < \infty$. Then the map*

$$x \mapsto \mathcal{C}(\phi e_{-x}) \tag{22}$$

is continuous from $\mathbb{R}^2$ *into* $L^{\widetilde{p}_1}(\mathbb{R}^2) \cap C^\alpha(\mathbb{R}^2)$, $\alpha = 1 - 2/p_2$. *Further,* $\mathcal{C}\Phi_x$ *is bounded on* $L^r(\mathbb{R}^2)$, $r > 2$, *and the map* $x \mapsto \mathcal{C}\Phi_x$ *is continuous from* $\mathbb{R}^2$ *into* $\mathcal{L}(L^r(\mathbb{R}^2))$.

Proof. Using the Lebesgue dominated convergence theorem, it is straightforward to see that the map $x \mapsto \phi e_{-x}$ is continuous from $\mathbb{R}^2$ into $L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2)$. The continuity of the map (22) then follows from the linearity of $\mathcal{C}$ and (20)–(21).

The assumption on ϕ implies by the Hölder inequality that $\phi(k)e_{-k}(x) \in L^2(\mathbb{R}^2)$, and, as before, we can argue that $\phi(k)e_{-k}(x)$ is continuous with respect to $x \in \mathbb{R}^2$. It follows then by the Hölder inequality that $\Phi_x \in \mathcal{L}(L^r(\mathbb{R}^2), L^{2r/(2+r)}(\mathbb{R}^2))$. Moreover, Φ_x is continuous with respect to $x \in \mathbb{R}^2$. The claim for $\mathcal{C}\Phi_x$ then follows from (20). ∎

We are now ready to prove the unique solvability of (18) in the case where ϕ is in certain L^p-spaces and analyze how the solution depends on the parameter x.

LEMMA 3.3. *Let* $\phi \in L^{p_1} \cap L^{p_2}(\mathbb{R}^2)$ *with* $1 < p_1 < 2 < p_2 < \infty$. *Then* (18) *has a unique solution* μ *with* $\mu(x,\cdot) - 1 \in L^r \cap C^\alpha(\mathbb{R}^2)$ *for any* $r \geq \widetilde{p}_1$ *and* $\alpha < 1 - 2/p_2$. *Moreover, the map*

$$x \mapsto \mu(x,\cdot) \tag{23}$$

is continuous from $\mathbb{R}^2$ *into* $L^r \cap C^\alpha(\mathbb{R}^2)$.

Proof. Equation (18) is equivalent to the integral equation

$$(I - \mathcal{C}\Phi_x)(\mu - 1) = \mathcal{C}\Phi_x(1). \tag{24}$$

Note that $\mathcal{C}\Phi_x(1) \in L^r(\mathbb{R}^2)$ for any $r \geq \widetilde{p}_1$. Now, from Lemma 3.2, we know that $\mathcal{C}\Phi_x$ is bounded on $L^r(\mathbb{R}^2)$, $r > 2$. Moreover, the operator is compact (see [26, Lemma 4.2]), and hence (24) is a Fredholm equation of the second kind. Since the associated homogeneous equation has only the trivial solution (see, for instance, [6]), we can define

$$\mu - 1 = [I - \mathcal{C}\Phi_x]^{-1}(\mathcal{C}\Phi_x(1)) \in L^r(\mathbb{R}^2), \quad r \geq \widetilde{p}_1. \tag{25}$$

By (21),

$$\mathcal{C}\Phi_x(1) \in C^\alpha(\mathbb{R}^2), \quad \alpha = 1 - \frac{2}{p_2}, \tag{26}$$

$$\mathcal{C}\Phi_x(\mu - 1) \in C^\alpha(\mathbb{R}^2), \quad \alpha < 1 - \frac{2}{p_2}, \tag{27}$$

and then the Hölder regularity of $\mu - 1$ is obtained from (24).

Next, we show continuity of the map $x \mapsto (\mu(x,\cdot) - 1)$ from $\mathbb{R}^2$ into $L^r(\mathbb{R}) \cap C^\alpha(\mathbb{R}^2)$. By Lemma 3.2, we know that $\mathcal{C}\Phi_x 1 \in L^r(\mathbb{R}^2) \cap C^\alpha(\mathbb{R}^2)$ depends continuously on x.

Also, by Lemma 3.2, the map $x \mapsto \mathcal{C}\Phi_x$ is continuous from $\mathbb{R}^2$ to $\mathcal{L}(L^r(\mathbb{R}^2))$. Since the operator $I - \mathcal{C}\Phi_x$ is invertible for all $x \in \mathbb{R}^2$, the map $x \mapsto [I - \mathcal{C}\Phi_x]^{-1}$ is continuous from $\mathbb{R}^2$ to $\mathcal{L}(L^r(\mathbb{R}^2))$ as well. Hence the right-hand side of (25) depends continuously on x as a map from $\mathbb{R}^2$ into $L^r(\mathbb{R}^2)$. The continuity into $C^\alpha(\mathbb{R}^2)$ now follows as before from (21) and (24). ∎

Next, we consider the solvability of (18) in the case where ϕ is compactly supported.

LEMMA 3.4. *Suppose* $\phi \in L^p(\mathbb{R}^2)$, $p > 2$, *is compactly supported. Then* (18) *has a unique solution* μ *with* $\mu - 1 \in L^r \cap C^\alpha(\mathbb{R}^2), r > 2, \alpha < 1 - 2/p$. *Moreover, the map*

$$x \mapsto \mu(x,\cdot) - 1 \tag{28}$$

is smooth from $\mathbb{R}^2$ *into* $L^r \cap C^\alpha(\mathbb{R}^2)$.

Proof. Since $\phi \in L^{p_1} \cap L^p(\mathbb{R}^2)$ for $1 < p_1 < 2$, by Lemma 3.3, (18) has a unique solution μ with $\mu - 1 \in L^r \cap C^\alpha(\mathbb{R}^2), r > 2, \alpha < 1 - 2/p$, depending continuously on x.

To prove that μ is smooth, we will show first that $\partial_{x_1}\mu$ is continuous. By applying the differential operator ∂_{x_1} to (18), it follows that ∂_{x_1} satisfies the equation

$$\overline{\partial}_k \partial_{x_1}\mu = \phi(k)e_{-k}\overline{\partial_{x_1}\mu} - \phi(k)k_1 e_{-k}\overline{\mu}. \tag{29}$$

Since $\mu - 1 \in L^r(\mathbb{R}^2)$ for any $r > 2$, we have $\phi(k)k_1 e_{-k}\overline{\mu} \in L^q(\mathbb{R}^2)$ for any $q < p$. Hence $\mathcal{C}(\phi(k)k_1 e_{-k}\overline{\mu}) \in L^r(\mathbb{R}^2)$ for any $r > 2$. Equation (29) then has the unique solution

$$\partial_{x_1}\mu = -(I - \mathcal{C}\Phi_x)^{-1}(\phi(k)k_1 e_{-k}\overline{\mu}) \in L^r(\mathbb{R}^2) \cap C^\alpha(\mathbb{R}^2), \quad r > 2, \quad \alpha < 1 - 2/p.$$

Since $(\phi(k)k_1 e_{-k}\overline{\mu})$ and $(I - \mathcal{C}\Phi_x)^{-1}$ are continuous with respect to x, so is $\partial_{x_1}\mu$. Using induction, this argument can easily be extended to show that all x-derivatives of μ are continuous, i.e., that μ is smooth. ∎

We can now show using Lemma 3.3 that (12) admits a unique solution. Moreover, by using Lemma 3.4, we can show that (15) and (17) are uniquely solvable and that the solutions are smooth functions of the x-variable.

PROPOSITION 3.5. *Let* $\Omega \subset \mathbb{R}^2$ *be the unit disc, and suppose* γ *satisfies* (1) *with* $\gamma = 1$ *near* $\partial\Omega$.

(a) *Suppose further that* $\gamma \in W^{1+\epsilon,p}(\Omega)$ *with* $2 < p$. *Then for each* $x \in \mathbb{R}^2$ *and* $R > 0$, (12) *and* (15) *have unique solutions* μ, μ_R, *respectively, which satisfy* $\mu(x, \cdot) - 1 \in L^r \cap \mathbb{C}^\alpha(\mathbb{R}^2), r > 2/\epsilon, \alpha < 1$, *and* $(\mu_R(x, \cdot) - 1) \in L^r \cap C^\alpha(\mathbb{R}^2), r > 2, \alpha < 1$. *Furthermore,* $\mu_R(x, \cdot)$ *is smooth with respect to* x.

(b) *For* $x \in \mathbb{R}^2$ *and* $R > 0$, (17) *has a unique solution* $\mu_R^{\exp}(x, \cdot)$ *with* $\mu_R^{\exp}(x, \cdot) - 1 \in L^r \cap C^\alpha(\mathbb{R}^2), r > 2, \alpha < 1$, *which is smooth with respect to* x.

Proof. To prove (a), we use the fact from [18, 20] that $\mathbf{t}(k)/\overline{k} \in L^p(\mathbb{R}^2), 2 - \epsilon < p < \infty$. Hence $\phi(k) = \mathbf{t}(k)/(4\pi\overline{k})$ satisfies the assumptions in Lemma 3.3, and the claim follows. Furthermore, $\phi = \mathbf{t}_{\mathrm{R}}/(4\pi\overline{k})$ satisfies the assumptions in Lemma 3.4. It follows that (15) has a unique solution μ_{R} with the indicated properties.

To prove (b), we note that $\mathbf{t}_{\mathrm{R}}^{\exp}$ is a bounded function with compact support. Then again we use Lemma 3.4. ∎

As a consequence of this proposition, it follows that the reconstructions $\gamma_{\mathrm{R}}(x) = (\mu_{\mathrm{R}}(x, 0))^2$ and $\gamma_{\mathrm{R}}^{\exp} = (\mu_{\mathrm{R}}^{\exp}(x, 0))^2$ based on truncated scattering data are smooth functions.

4. Stability of the approximate reconstruction method. In this section, we show that the reconstruction method using the truncated $\mathbf{t}^{\exp}$ is stable. We will start by formulating the reconstruction procedure as an operator. Let $L_c^p(\mathbb{R}^2)$ denote the space of $L^p(\mathbb{R}^2)$ functions with compact support, and define for $k \in \mathbb{C}$ the linear operator $\mathcal{T}_{\mathrm{R}}^{\exp} : \mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega)) \to L_c^\infty(\mathbb{R}^2)$ by

$$(\mathcal{T}_{\mathrm{R}}^{\exp} L)(k) = \chi_{|k|<R} \frac{1}{4\pi\overline{k}} \int_{\partial\Omega} (e^{i\overline{kx}} - 1)L(e^{ikx} - 1)d\sigma(x). \tag{30}$$

Define further for $p > 2$ the nonlinear operator

$$\mathcal{S} : L_c^p(\mathbb{R}^2) \to C^\infty(\overline{\Omega}), \quad \phi \mapsto \mu(x, 0),$$

where $\mu(x,\cdot)$ is the unique solution to (10) (see Lemma 3.4). By composition, we then define $\mathcal{M}_{\mathrm{R}}^{\exp} : \mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega)) \to C^\infty(\overline{\Omega})$ by

$$\mathcal{M}_{\mathrm{R}}^{\exp} = \mathcal{S} \circ \mathcal{T}_{\mathrm{R}}^{\exp}. \tag{31}$$

Using this notation, it is clear that

$$(\gamma_{\mathrm{R}}^{\exp}(x))^{1/2} = \mu_{\mathrm{R}}^{\exp}(x,0) = \mathcal{M}_{\mathrm{R}}^{\exp}(\Lambda_\gamma - \Lambda_1), \tag{32}$$

since $(\Lambda_\gamma - \Lambda_1)1 = 0$ and $\int_{\partial\Omega}(\Lambda_\gamma - \Lambda_1) f d\sigma(x) = 0$ for all $f \in H^{1/2}(\partial\Omega)$. Thus $\mathcal{M}_{\mathrm{R}}^{\exp}$ is an operator that implements the reconstruction algorithm based on the truncated approximate scattering data.

The main goal of this section is to show that $\mathcal{M}_{\mathrm{R}}^{\exp}$ is continuous as an operator from $\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))$ into $C^\infty(\overline{\Omega})$. This will show that the reconstruction algorithm using $\mathbf{t}_{\mathrm{R}}^{\exp}$ is stable.

LEMMA 4.1. *The operator $\mathcal{T}_R^{\exp}$ is bounded from $\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))$ into $L_c^\infty(\mathbb{R}^2)$ and satisfies*

$$\|\mathcal{T}_{\mathrm{R}}^{\exp} L\|_{L^\infty(\mathbb{R}^2)} \le C e^{2R} \|L\|_{\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))}. \tag{33}$$

Proof. For $|k| < R$, it is straightforward to obtain the estimate

$$|\mathcal{T}_{\mathrm{R}}^{\exp} L(k)| \le C \frac{1}{|k|} \|e^{ikx} - 1\|^2_{H^{1/2}(\partial\Omega)} \|L\|_{\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))}.$$

Hence (33) follows from the uniform estimate $\|e^{ikx} - 1\|_{H^{1/2}(\partial\Omega)} \le C|k|^{1/2} e^{|k|}$. ∎

Next, we consider the solution operator $\mathcal{S}$. A stability estimate for this operator was given in [18, Lemma 3.1.5]; we will generalize this result slightly. The aim is to show that the solution μ to (18) depends continuously on the coefficient ϕ. Let $\mu_j, j = 1, 2$, be the solution to

$$\begin{aligned} \mu_j(x,s) - 1 = {} & \frac{1}{\pi} \int_{\mathbb{R}^2} \frac{\phi_j(k)}{s-k} e_{-x}(k) (\overline{\mu_j(x,k)} - 1) dk_1 dk_2 \\ & + \frac{1}{\pi} \int_{\mathbb{R}^2} \frac{\phi_j(k)}{s-k} e_{-x}(k) dk_1 dk_2, \quad j = 1, 2. \end{aligned} \tag{34}$$

Then we have the following result.

LEMMA 4.2. *Let $1 < p_1 < 2 < p_2 < \infty$ with $0 < 1/p_1 + 1/p_2 - 1/2 < 1/2$, and suppose $\phi_j \in L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2)$, $j = 1, 2$. Further, let $x \in \overline{\Omega}$. Then, for the solution $\mu_j(x,\cdot)$ to (34), we have the estimate*

$$\|\mu_1(x,\cdot) - \mu_2(x,\cdot)\|_{C^\alpha(\mathbb{R}^2)} \le C K_1 K_2 \|\phi_1 - \phi_2\|_{L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2) \cap L^2(\mathbb{R}^2) \cap L^q(\mathbb{R}^2)}, \tag{35}$$

where $\alpha < 1 - 2/q$, $1/q = 1/p_2 + 1/p_1 - 1/2$, and $K_j = \exp(C\|\phi_j\|_{L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2)})$. If $\phi_1, \phi_2 \in L_c^p(\mathbb{R}^2)$, $p > 2$, we have the estimate

$$\|\mu_1(x,\cdot) - \mu_2(x,\cdot)\|_{C^\alpha(\mathbb{R}^2)} \le C K_1 K_2 \|\phi_1 - \phi_2\|_{L^p(\mathbb{R}^2)} \tag{36}$$

for $\alpha < 1 - 2/p$.

Proof. From [4, Lemma 2.6], we know that if $a \in L^{p_1}(\mathbb{R}^2) \cap L^{p_2}(\mathbb{R}^2)$ for $1 < p_1 < 2 < p_2 < \infty$ and $b \in L^p(^2)$ for $1 < p < 2$, then the solution to the integral equation

$$m = \mathcal{C}(a\overline{m}) + \mathcal{C}(b)$$

satisfies the estimate

$$\|m\|_{L^{\tilde{p}}(\mathbb{R}^2)} \le C\exp(C\|a\|_{L^{p_1}(\mathbb{R}^2)\cap L^{p_2}(\mathbb{R}^2)})\|b\|_{L^p(\mathbb{R}^2)}. \tag{37}$$

Applied to (34), the estimate reads

$$\|\mu_1(x,\cdot)-1\|_{L^{\widetilde{p_1}}(\mathbb{R}^2)} \le CK_1\|\phi_1\|_{L^{p_1}(\mathbb{R}^2)}. \tag{38}$$

Since

$$\begin{aligned}\mu_1(x,s)-\mu_2(x,s) &= \frac{1}{\pi}\int_{\mathbb{R}^2}\frac{\phi_2(k)}{s-k}e_{-x}(k)(\overline{\mu_1-\mu_2})dk_1dk_2\\ &\quad+\frac{1}{\pi}\int_{\mathbb{R}^2}\frac{\phi_1(k)-\phi_2(k)}{s-k}e_{-x}(k)\overline{\mu_1(x,k)}dk_1dk_2,\end{aligned} \tag{39}$$

the estimate (37) applied to $\mu_1-\mu_2$ then gives

$$\begin{aligned}\|\mu_1-\mu_2\|_{L^{\widetilde{p_1}}(\mathbb{R}^2)} &\le CK_2\|(\phi_1-\phi_2)\mu_1\|_{L^{p_1}(\mathbb{R}^2)}\\ &\le CK_2\big(\|\phi_1-\phi_2\|_{L^{p_1}(\mathbb{R}^2)}+\|\phi_1-\phi_2\|_{L^2(\mathbb{R}^2)}\|\mu_1-1\|_{L^{\widetilde{p_1}}(\mathbb{R}^2)}\big)\\ &\le CK_2\left(\|\phi_1-\phi_2\|_{L^{p_1}(\mathbb{R}^2)}+\|\phi_1-\phi_2\|_{L^2(\mathbb{R}^2)}\Phi_1\|\phi_1\|_{L^{p_1}(\mathbb{R}^2)}\right),\end{aligned} \tag{40}$$

where we have used (38). To get the Hölder estimate, we use (39) and (21) to obtain

$$\|\mu_1-\mu_2\|_{C^\alpha(\mathbb{R}^2)} \le \|\phi_2(\mu_1-\mu_2)\|_{L^q(\mathbb{R}^2)}+\|(\phi_1-\phi_2)\mu_1\|_{L^q(\mathbb{R}^2)} \tag{41}$$

for $q>2$ and $\alpha=1-2/q$. By choosing $1/q=1/p_2+1/\widetilde{p_1}$ ($<1/2$ by assumption), we have by (40) and (38)

$$\begin{aligned}\|\phi_2(\mu_1-\mu_2)\|_{L^q(\mathbb{R}^2)} &\le \|\phi_2\|_{L^{p_2}(\mathbb{R}^2)}\|\mu_1-\mu_2\|_{L^{\widetilde{p_1}}(\mathbb{R}^2)}\\ &\le \|\phi_2\|_{L^{p_2}(\mathbb{R}^2)}CK_2\big(\|\phi_1-\phi_2\|_{L^{p_1}(\mathbb{R}^2)}\\ &\quad+\|\phi_1-\phi_2\|_{L^2(\mathbb{R}^2)}K_1\|\phi_1\|_{L^{p_1}(\mathbb{R}^2)}\big)\end{aligned} \tag{42}$$

$$\begin{aligned}\|(\phi_1-\phi_2)\mu_1\|_{L^q(\mathbb{R}^2)} &\le \|\phi_1-\phi_2\|_{L^{p_2}(\mathbb{R}^2)}\|\mu_1-1\|_{L^{\widetilde{p_1}}(\mathbb{R}^2)}+\|\phi_1-\phi_2\|_{L^q(\mathbb{R}^2)}\\ &\le \|\phi_1-\phi_2\|_{L^{p_2}(\mathbb{R}^2)}CK_1\|\phi_1\|_{L^{p_1}(\mathbb{R}^2)}+\|\phi_1-\phi_2\|_{L^q(\mathbb{R}^2)}.\end{aligned} \tag{43}$$

Combining (41) with (42) and (43) gives (35).

Finally, (36) follows from (35) by using the compact support of ϕ_1,ϕ_2. ∎

As a direct consequence of the lemma, we obtain the following result.

COROLLARY 4.3. *The operator $\mathcal{S}$ is bounded from $L^p_c(\mathbb{R}^2)$, $p>2$, into $L^\infty(\Omega)$ and*

$$\|\mathcal{S}(\phi_1)-\mathcal{S}(\phi_2)\|_{L^\infty(\Omega)} \le C\|\phi_1-\phi_2\|_{L^p(\mathbb{R}^2)}, \tag{44}$$

where C depends on p, the support of ϕ_1,ϕ_2, and $\|\phi_1\|_{L^p(\mathbb{R}^2)},\|\phi_2\|_{L^p(\mathbb{R}^2)}$.

Proof. For fixed $x\in\overline{\Omega}$, (36) implies that

$$|\mathcal{S}(\phi_1)-\mathcal{S}(\phi_2)| = |\mu_1(x,0)-\mu_2(x,0)| \le C\Phi_1\Phi_2\|\phi_1-\phi_2\|_{L^p(\mathbb{R}^2)}.$$

This proves the result. ∎

We have now seen that the linear operator $\mathcal{T}_{\mathrm{R}}^{\exp}$ is bounded and the operator $\mathcal{S}$ is continuous. This enables us to conclude that $\mathcal{M}_{\mathrm{R}}^{\exp}=\mathcal{S}\circ\mathcal{T}_{\mathrm{R}}^{\exp}$ is continuous.

5. Convergence of reconstructions of mollified conductivities. Conductivities in practical applications of EIT are often piecewise smooth, but the theory of D-bar method covers only differentiable conductivities. We exclude the possibility of systematic artifacts introduced by discontinuities by proving the following: smooth approximations to nonsmooth conductivities yield almost the same reconstructions.

Let $\Omega = B(0,1)$. Let $c_0 > 0$ and $0 < R < 1$, and define $X = X(c_0, R) \subset L^\infty(\Omega)$ by

$$X = \{\gamma \in L^\infty(\Omega) \mid c_0^{-1} \le \gamma \le c_0,\ \mathrm{supp}(\gamma - 1) \subset B(0,R)\}.$$

The following lemma contains a continuity result for the operator $\gamma \mapsto \Lambda_\gamma$.

LEMMA 5.1. *Let $\gamma, \gamma_j \in X, j \in \mathbb{N}$, and suppose $\gamma_j \to \gamma$ a.e. Then, for any $s \in \mathbb{R}$, $\Lambda_{\gamma_j} - \Lambda_\gamma \longrightarrow 0$ in the strong topology of $\mathcal{L}(H^{1/2}(\partial\Omega), H^s(\partial\Omega))$.*

Proof. Let $f \in H^{1/2}(\partial\Omega)$. Let $\gamma_0 = \gamma$, and define $u_j, j = 0, 1, 2, \ldots$, as the unique solution to $\nabla \cdot \gamma_j \nabla u_j = 0$ in Ω, $u_j|_{\partial\Omega} = f$. Then

$$\|u_0\|_{H^1(\Omega)} \le C_2 \|f\|_{H^{1/2}}, \tag{45}$$

where the constant C_2 depends only on the uniform ellipticity constant c_0. Since

$$\nabla \cdot \gamma_j \nabla (u_j - u_0) = \nabla \cdot (\gamma - \gamma_j) \nabla u_0, \quad (u_j - u_0)|_{\partial\Omega} = 0,$$

there is a constant C_3 (depending only on c_0) such that the estimate

$$\|(u_j - u_0)\|_{H^1(\Omega)} \le C_3 \|(\gamma - \gamma_j)\nabla u_0\|_{L^2(\Omega)} \tag{46}$$

holds. Furthermore, $\Delta(u_j - u_0) = 0$ and $\partial_\nu (u_j - u_0)|_{\partial\Omega} = 0$ in the region $\Omega \setminus B(0,R)$. Therefore we can extend (46) to

$$\|(u_j - u_0)\|_{H^s(\Omega \setminus B(0,R_1))} \le C_4 \|(\gamma - \gamma_j)\nabla u_0\|_{L^2(\Omega)},$$

for any $s \in \mathbb{R}$, where C_4 depends on s, c_0, and $R_1 \in (R, 1)$. By taking normal derivative at the boundary, we then obtain, for any $s \in \mathbb{R}$,

$$\|(\Lambda_{\gamma_j} - \Lambda_\gamma) f\|_{H^s(\partial\Omega)} \le C_5 \|(\gamma - \gamma_j)\nabla u_0\|_{L^2(\Omega)}, \tag{47}$$

where C_5 depends on s, c_0, and R.

To consider convergence in the strong topology, let us fix f and γ, implying that u_0 can be considered as a fixed function. Then using Lebesgue dominated convergence, it follows that $\lim_{j\to\infty} \|(\gamma - \gamma_j)\nabla u_0\|_{L^2(\Omega)} = 0$. By (47), this implies the claim. ∎

The next lemma shows that a strongly convergent sequence of operators is norm convergent when composed with a compact operator defined on a Hilbert space.

LEMMA 5.2. *Let X, Y be Banach spaces and H be a separable Hilbert space. Suppose $T, T_j \in \mathcal{L}(X,Y)$, $j = 1, 2, \ldots$, and $K \in \mathcal{L}(H,X)$ is compact. If $T_j \to T$ as $j \to \infty$ in the strong topology of $\mathcal{L}(X,Y)$, then $T_j K \to TK$ as $j \to \infty$ in the norm topology of $\mathcal{L}(H,Y)$.*

Proof. By the principle of uniform boundedness, there is a constant C_0 such that $\|T\|_{\mathcal{L}(X,Y)} < C_0$ and $\|T_j\|_{\mathcal{L}(X,Y)} < C_0$ for all j.

Since the compact operator K maps from a separable Hilbert space into a Banach space, there is a sequence of finite rank operators $K_n, n \in \mathbb{N}$, with $\mathrm{rank}(K_n) = n$ that converges in norm to K (see [28, Theorem 6.13] for a proof of this fact in the Hilbert space case; the proof is the same in our case). Fix $\epsilon > 0$, and take n such that

$$\|K - K_n\|_{\mathcal{L}(H,X)} < \epsilon.$$

Further, since K_n has finite rank, there is a $J = J(\epsilon) \geq 0$ such that, for $j \geq J$,

$$\|(T_j - T)K_n\|_{\mathcal{L}(H,Y)} \leq \epsilon.$$

Hence, for $j \geq J$,

$$\|(T_j - T)K\|_{\mathcal{L}(H,Y)} \leq \|T_j(K - K_n) + (T_j - T)K_n + T(K_n - K)\|_{\mathcal{L}(H,Y)} = 3C_0\epsilon.$$

This proves the result. ∎

We will now use the preceding lemma to prove norm convergence of the sequence of DN maps in Lemma 5.1.

LEMMA 5.3. *Let γ and γ_j be as in Lemma* 5.1. *Then*

$$\lim_{j\to\infty} \|\Lambda_{\gamma_j} - \Lambda_\gamma\|_{\mathcal{L}(H^{1/2}(\partial\Omega),H^{-1/2}(\partial\Omega))} = 0.$$

Proof. Since the inclusion operator $J\colon H^{1/2+r}(\partial\Omega) \to H^{1/2}(\partial\Omega)$ is compact for any $r > 0$, it follows from Lemmas 5.1 and 5.2 that

$$\lim_{j\to\infty} \|\Lambda_{\gamma_j} - \Lambda_\gamma\|_{\mathcal{L}(H^{\frac{1}{2}+r}(\partial\Omega),H^s(\partial\Omega))} = \lim_{j\to\infty} \|(\Lambda_{\gamma_j} - \Lambda_\gamma)J\|_{\mathcal{L}(H^{\frac{1}{2}+r}(\partial\Omega),H^s(\partial\Omega))} = 0 \tag{48}$$

for $r > 0, s \in \mathbb{R}$. Further, since $\gamma = \gamma_j = 1$ near $\partial\Omega$, $\Lambda_{\gamma_j} - \Lambda_\gamma$ is a smoothing pseudo-differential operator that can be extended to an operator $\mathcal{D}'(\partial\Omega) \to C^\infty(\partial\Omega)$. An application of Green's formula implies that the operator $\Lambda_{\gamma_j} - \Lambda_\gamma : \mathcal{D}'(\partial\Omega) \to C^\infty(\partial\Omega)$ and its transpose $(\Lambda_{\gamma_j} - \Lambda_\gamma)' : \mathcal{D}'(\partial\Omega) \to C^\infty(\partial\Omega)$ coincide. Thus (48) implies

$$\lim_{j\to\infty} \|\Lambda_{\gamma_j} - \Lambda_\gamma\|_{\mathcal{L}(H^{-s'}(\partial\Omega),H^{-1/2-r'}(\partial\Omega))} = 0 \tag{49}$$

for $r' > 0, s' \in \mathbb{R}$. Interpolation of (48) and (49) gives the result; see, for example, Theorem 5.1 and section 7.3 of [22] or formula (3.2) on p. 282 of [33]. ∎

Let $\gamma \in X(c_0, R)$ for some $c_0, R > 0$, and suppose that γ is continuous a.e. Let $\eta \in C_0^\infty(D(0, \alpha/2))$ be nonnegative and $\int_{\mathbb{R}^2} \eta = 1$. Define $\eta_\lambda(x) := \lambda^{-2}\eta(x/\lambda)$ for any $0 < \lambda < 1$, and set $\gamma_\lambda := \eta_\lambda * \gamma$. We then have the following result.

THEOREM 5.4. *Let $\gamma \in X(c_0, R)$ for some $c_0, R > 0$, and let γ_λ be defined as above. Let $\mathcal{M}_R^{\exp}$ be defined as in* (31). *Then we have*

$$\lim_{\lambda\to 0} \|\mathcal{M}_{\mathrm{R}}^{\exp}(\Lambda_{\gamma_\lambda} - \Lambda_\gamma)\|_{\mathcal{L}(L^\infty(\Omega),L^\infty(\Omega))} = 0.$$

Proof. As a consequence of the definition, there exist $\widetilde{c}_0, \widetilde{R} > 0$ such that $\gamma, \gamma_\lambda \in X(\widetilde{c}_0, \widetilde{R})$ for λ sufficiently small. Also $\gamma_\lambda \to \gamma$ a.e. Using Lemma 5.3, it follows that Λ_{γ_λ} converges to Λ_γ in the norm topology of $\mathcal{L}(H^{1/2}(\partial\Omega), H^{-1/2}(\partial\Omega))$. Finally, using the continuity of $\mathcal{M}_{\mathrm{R}}^{\exp}$ (see section 4), we conclude that the reconstruction $\mathcal{M}_{\mathrm{R}}^{\exp}(\Lambda_{\gamma_\lambda} - \Lambda_1)$ of $\gamma_\lambda^{1/2}$ converges to $\mathcal{M}_{\mathrm{R}}^{\exp}(\Lambda_\gamma - \Lambda_1)$. ∎

6. Connection to Calderón's linearization method. In the seminal paper [7], Calderón gave an algorithm for the reconstruction of conductivities close to constant (see also [38]). We write Calderón's method in the context of the approximate scattering transform $\mathbf{t}^{\exp}$ and compare it to the D-bar method.

6.1. Calderón's linearization method. Integrating by parts in (4) gives

$$\mathbf{t}^{\exp}(k) = \int_\Omega (\gamma - 1)\nabla u(x,k) \cdot \nabla(e^{i\overline{kx}})dx, \tag{50}$$

where

$$\nabla \cdot (\gamma - 1)\nabla u = 0 \text{ in } \Omega, \quad u|_{\partial\Omega} = e^{ikx}.$$

When $\|\gamma - 1\|_{L^\infty(\Omega)}$ is small, then u is close to e^{ikx} inside Ω. Indeed, if we write $u = e^{ikx} + \delta u$ for $\delta u \in H_0^1(\Omega)$ satisfying $\nabla \cdot \gamma \nabla \delta u = -\nabla \cdot (\gamma - 1)\nabla(e^{ikx})$, we have the estimate

$$\|\delta u\|_{H^1(\Omega)} \leq C\|\gamma - 1\|_{L^\infty(\Omega)} e^{|k|r}, \tag{51}$$

where r is the radius of the smallest ball containing Ω. Substituting $u = e^{ikx} + \delta u$ into (50) and dividing by $-2|k|^2$, we obtain

$$\begin{aligned} -\frac{\mathbf{t}^{\exp}(k)}{2|k|^2} &= -\frac{1}{2|k|^2}\int_\Omega (\gamma - 1)\nabla(e^{ikx} + \delta u) \cdot \nabla(e^{i\overline{kx}})dx \\ &= \int_\Omega (\gamma - 1)e_k(x)dx + R(k) \\ &= 2\pi \mathcal{F}(\chi_\Omega(\gamma - 1))(-2k_1, 2k_2) + R(k), \end{aligned} \tag{52}$$

where $\mathcal{F}$ denotes the Fourier transform and

$$R(k) = -\frac{1}{2|k|^2}\int_\Omega (\gamma - 1)\nabla \delta u \cdot \nabla(e^{i\overline{kx}})dx.$$

Using (51), it is not hard to obtain

$$|R(k)| \leq C\|\gamma - 1\|^2_{L^\infty(\Omega)} e^{2|k|r}. \tag{53}$$

The idea behind Calderón's method is to multiply (52) by a smooth cut-off function and then apply the inverse Fourier transform. Let $\hat{\eta} \in C_0^\infty(\mathbb{R}^2)$ be a nonnegative function supported in the unit ball with $\hat{\eta} = 1$ near $x = 0$, and let σ be a positive parameter determining the cut-off radius. Then from (52) we obtain

$$\mathcal{F}(\chi_\Omega(\gamma - 1))(-2k_1, 2k_2)\hat{\eta}\left(\frac{k}{\sigma}\right) = -\frac{\mathbf{t}^{\exp}(k)}{4\pi|k|^2}\hat{\eta}(k/\sigma) - R(k)\hat{\eta}\left(\frac{k}{\sigma}\right).$$

Changing variables $s = (s_1, s_2) = 2(-k_1, k_2)$ gives

$$\begin{aligned} &\mathcal{F}(\chi_\Omega(\gamma - 1))(s_1, s_2)\hat{\eta}\left(\frac{(-s_1, s_2)}{(2\sigma)}\right) \\ &= -\frac{\mathbf{t}^{\exp}((-s_1, s_2)/2)}{\pi|s|^2}\hat{\eta}\left(\frac{(-s_1, s_2)}{(2\sigma)}\right) - R\left(\frac{(-s_1, s_2)}{2}\right)\hat{\eta}\left(\frac{(-s_1, s_2)}{(2\sigma)}\right). \end{aligned} \tag{54}$$

Inverting $\mathcal{F}$ and neglecting the second term in (54) yields an approximation to γ:

$$\gamma^{\text{app}}(x) - 1 = -\frac{1}{2\pi}\int_{\mathbb{R}^2} e^{ix\cdot s}\frac{\mathbf{t}^{\exp}((-s_1, s_2)/2)}{\pi|s|^2}\hat{\eta}\left(\frac{(-s_1, s_2)}{(2\sigma)}\right)ds_1 ds_2.$$

Changing back the variables in the integral to $(k_1, k_2) = (-s_1, s_2)/2$ yields the formula

$$\begin{aligned}\gamma^{\text{app}}(x) - 1 &= -\frac{1}{2\pi^2}\int_{\mathbb{R}^2} e^{2i(-x_1k_1+x_2k_2)}\frac{\mathbf{t}^{\exp}(k)}{4|k|^2}\hat{\eta}\left(\frac{k}{\sigma}\right)4dk_1dk_2 \\ &= -\frac{2}{(2\pi)^2}\int_{\mathbb{R}^2} e_{-x}(k)\frac{\mathbf{t}^{\exp}(k)}{|k|^2}\hat{\eta}\left(\frac{k}{\sigma}\right)dk_1dk_2. \qquad (55)\end{aligned}$$

The reconstruction γ^{app} is an approximation of a low-pass filtered version of γ. Choosing the parameter σ as in [7] with $0 < \alpha < 1$ to be

$$\sigma = \frac{1-\alpha}{2r}\log\frac{1}{\|\gamma - 1\|_{L^\infty(\Omega)}} \qquad (56)$$

yields due to (53) the error estimate

$$\|\gamma^{\text{app}}(x) - \eta_\sigma * \gamma\|_{L^\infty} \le \|R(k)\hat{\eta}(k/\sigma)\|_{L^1(\mathbb{R}^2)} \le C\|\gamma - 1\|^{1+\alpha}_{L^\infty(\Omega)}(\log(\|\gamma - 1\|_{L^\infty(\Omega)}))^2.$$

Note that when $\|\gamma - 1\|_{L^\infty(\Omega)}$ is sufficiently small this error is much smaller than $\|\gamma - 1\|_{L^\infty(\Omega)}$. Since in most applications the approximate magnitudes of the conductivities comprising $\gamma(x)$ are known, an estimate to σ in (56) can be computed.

In summary, the algorithm proposed in [7] is tantamount to the following:

1. Compute $\mathbf{t}^{\exp}(k)$ by (4).
2. Construct a low-pass filter $\hat{\eta}(k/\sigma)$.
3. Compute the approximation γ^{app} by (55).

6.2. Calderón's method as an approximation of the D-bar method. Calderón's method using (55) can be seen as a three-step approximation of the D-bar method using (3) and (12)–(13):

1. In (12), $\mathbf{t}(k)$ is approximated by $\mathbf{t}^{\exp}(k)\hat{\eta}(k/\sigma)$, where $\hat{\eta}(k/\sigma)$ is a smooth cut-off function.
2. The function μ in the integral in the right-hand side of (12) is approximated by its asymptotic value $\mu \sim 1$.
3. The square function in (13) is linearized: $(1-h)^2 \sim 1 - 2h$.

In contrast, the D-bar method using $\mathbf{t}^{\exp}_{\text{R}}$ makes only the first approximation (with sharp cut-off).

7. Analysis of a simple radial conductivity distribution. In this section, we consider the simple example of a piecewise constant radial conductivity defined in the unit disc Ω. We will show that in this case $\mathbf{t}^{\exp}$ can be expanded conveniently using Bessel functions. Furthermore, such an expansion leads to a result concerning the asymptotic behavior of $\mathbf{t}^{\exp}(k)$ as $|k|$ tends to infinity. We will write out explicit formulas for γ^{app}, the Calderón reconstruction, and $\gamma^{\exp}$, the D-bar reconstruction of γ with the $\mathbf{t}^{\exp}$ approximation.

Consider the radial conductivity

$$\gamma(x) = \begin{cases} \sigma & \text{for } |x| \le r, \\ 1 & \text{for } |x| > r, \end{cases} \qquad (57)$$

where $0 < r < 1$ and $\sigma > 0, \sigma \ne 1$. Define

$$\alpha = \frac{\sigma - 1}{\sigma + 1}. \qquad (58)$$

According to [32], trigonometric basis functions are eigenfunctions for Λ_γ when γ is radial. More precisely, $\Lambda_\gamma \varphi_n = \lambda_n \varphi_n$ with $\varphi_n(\alpha) := (2\pi)^{-1/2} e^{in\alpha}$ for $n \in \mathbb{Z}$. It is well known [12] that the eigenvalues of Λ_γ corresponding to (57) are given by

$$\lambda_n = n\left(1 + \frac{2\alpha r^{2n}}{1-\alpha r^{2n}}\right), \quad n = 1, 2, 3, \ldots. \tag{59}$$

Hence $\delta\Lambda \equiv \Lambda_\gamma - \Lambda_1$ has eigenvalues

$$\delta\lambda_n = \frac{2n\alpha r^{2n}}{1-\alpha r^{2n}}, \quad n = 1, 2, 3, \ldots. \tag{60}$$

As in [29], one can derive a series representation of $\mathbf{t}^{\exp}(k)$. For the case of the conductivity distribution (57), this leads to a particularly simple representation of $\mathbf{t}^{\exp}$ in terms of Bessel functions, which we derive here. Expanding e^{ikx} in a Fourier series on the circle $x = e^{i\theta}$ yields [13]

$$e^{ikx} = \sum_{n=-\infty}^{\infty} a_n(k) e^{in\theta} \quad \text{with} \quad a_n(k) = \begin{cases} \frac{(ik)^n}{n!}, & n \geq 0, \\ 0, & n < 0. \end{cases}$$

Substituting this series into formula (4) and using (59) gives a series for $\mathbf{t}^{\exp}(k)$:

$$\mathbf{t}^{\exp}(k) = 2\pi \sum_{n=1}^{\infty} (\lambda_n - n) \frac{(-1)^n |k|^{2n}}{(n!)^2} = 4\pi\alpha \sum_{n=1}^{\infty} \frac{n r^{2n}}{1-\alpha r^{2n}} \frac{(-1)^n |k|^{2n}}{(n!)^2}. \tag{61}$$

Write $(1-\alpha r^{2n})^{-1} = \sum_{m=0}^{\infty} (\alpha r^{2n})^m$ so that

$$\mathbf{t}^{\exp}(k) = 4\pi\alpha \sum_{m=0}^{\infty} \alpha^m \sum_{n=1}^{\infty} \frac{n(-1)^n}{(n!)^2} (|k| r^{m+1})^{2n}. \tag{62}$$

Note that the Bessel function $J_1(t) = -J_0'(t) = -(2/t) \sum_{j=1}^{\infty} j(-1)^j (j!)^{-2} (t/2)^{2j}$. Thus, with $t = 2r^{m+1}|k|$,

$$\mathbf{t}^{\exp}(k) = -4\pi\alpha |k| r \sum_{m=0}^{\infty} (\alpha r)^m J_1(2r^{m+1}|k|). \tag{63}$$

This formula gives an accurate way for computing $\mathbf{t}^{\exp}$ numerically. Furthermore, we can derive the asymptotic behavior of $\mathbf{t}^{\exp}$ from (63).

For small z, $J_1(z) \sim z/2$. So using $\sum_{m=0}^{\infty} (\alpha r^2)^m = 1/(1-\alpha r^2)$ yields

$$\mathbf{t}^{\exp}(k) \sim -4\pi\alpha |k|^2 r \sum_{m=0}^{\infty} \alpha^m r^{2m+1} = \frac{-4\pi\alpha (|k| r)^2}{1-\alpha r^2} = O(|k|^2) \quad \text{for small } |k|.$$

For large $|z|$, we have $J_1(z) \sim (2/(\pi z))^{1/2} \cos(z - 3\pi/4) + e^{|\mathrm{Im}\, z|} O(1/|z|)$, and so

$$\mathbf{t}^{\exp}(k) \sim -4\pi\alpha |k| r \sum_{m=0}^{\infty} (\alpha r)^m \sqrt{\frac{1}{\pi r^{m+1} |k|}} \cos\left(2r^{m+1}|k| - \frac{3\pi}{4}\right)$$

for large $|k|$. After some simplification, this results in the asymptotic formula

$$\mathbf{t}^{\exp}(k) \sim \frac{-4\pi\alpha |k|^{1/2} r^{1/2}}{\sqrt{\pi}} \sum_{m=0}^{\infty} (\alpha)^m r^{m/2} \cos\left(2r^{m+1}|k| - \frac{3\pi}{4}\right) = O(|k|^{1/2}). \tag{64}$$

Note that (64) shows the importance of truncation of $\mathbf{t}^{\exp}$: the solvability of the D-bar equation is not proven for $\mathbf{t}^{\exp}$ with asymptotic behavior (64).

7.1. Calderón's method for a simple radial conductivity. Let γ be of the form (57). Note from [14], for example, that the Fourier transform of the characteristic function χ_r is given by

$$\begin{aligned}\mathcal{F}^{-1}(\chi_r)(k) = \check{\chi}_r(k) &= \frac{1}{2\pi}\int_{\mathbb{R}^2}\chi_r(p)e^{ik\cdot p}dp = \frac{1}{2\pi}\int_0^r\int_0^{2\pi} e^{i|k|\rho\cos(\theta)}\rho d\rho d\theta\\ &= \frac{1}{2\pi}\sum_{j=0}^{\infty}\frac{(i|k|)^j}{j!}\int_0^r\rho^{j+1}d\rho\int_0^{2\pi}\cos^j(\theta)d\theta\\ &= \begin{cases}\sum_{j=0}^{\infty}\frac{(i|k|)^j}{j!}\frac{r^{j+2}}{j+2}\frac{1\cdot3\cdot5\cdots(j-1)}{2\cdot4\cdot6\cdots j}, & j \text{ even},\\ 0, & j \text{ odd}\end{cases}\\ &= \sum_{m=0}^{\infty}\frac{(m+1)(-1)^m}{((m+1)!)^2}\left(\frac{r|k|}{2}\right)^{2m}\frac{r^2}{2}\\ &= -\frac{2}{|k|^2}\sum_{n=1}^{\infty}\frac{n(-1)^n}{(n!)^2}\left(\frac{r|k|}{2}\right)^{2n}.\end{aligned}$$

Thus, from (62),

$$\mathbf{t}^{\exp}(k) = -8\pi|k|^2\alpha\sum_{m=0}^{\infty}\alpha^m\check{\chi}_{r^{m+1}}(2k). \tag{65}$$

For this simple case, we can substitute $\mathbf{t}^{\exp}$ directly into (55) and compute explicitly without multiplying by the cut-off function $\hat{\eta}$ (or, equivalently, take $\sigma=\infty$, implying $\hat{\eta}\equiv 1$). Thus Calderón's reconstruction γ^{app} is given by

$$\begin{aligned}\gamma^{\text{app}}(x) &= 1 - \frac{8}{(2\pi)^2}\int_{\mathbb{R}^2}e_{-x}(k)\frac{\mathbf{t}^{\exp}(k)}{|k|^2}dk_1dk_2\\ &= 1 + \frac{4}{\pi}\int_{\mathbb{R}^2}e_{-x}(k)\alpha\sum_{m=0}^{\infty}\alpha^m\check{\chi}_{r^{m+1}}(2|k|)dk_1dk_2\\ &= 1 + 2\alpha\sum_{m=0}^{\infty}\alpha^m\frac{1}{2\pi}\int_{\mathbb{R}^2}e^{-i(x_1w_1-x_2w_2)}\check{\chi}_{r^{m+1}}(|w|)dw_1dw_2\\ &= 1 + 2\alpha\sum_{m=0}^{\infty}\alpha^m\frac{1}{2\pi}\int_{\mathbb{R}^2}e^{-ix\cdot\bar{w}}\check{\chi}_{r^{m+1}}(|w|)dw_1dw_2\\ &= 1 + 2\alpha\sum_{m=0}^{\infty}\alpha^m\mathcal{F}(\check{\chi}_{r^{m+1}}(|s|)) \qquad (66)\\ &= 1 + 2\alpha\sum_{m=0}^{\infty}\alpha^m\chi_{r^{m+1}}(x). \qquad (67)\end{aligned}$$

Note that (67) preserves the location of the jump in the actual conductivity distribution γ. Furthermore, elementary calculations show $\gamma^{\text{app}}(0)=\sigma$; i.e., the correct value of the conductivity is attained at $x=0$.

Similar computations were done in [14] (see also [13]), where the starting point, however, was the Neumann-to-Dirichlet (ND) map. They found the approximation

$$\gamma(x) \approx 1 + 2\alpha\sum_{m=0}^{\infty}(-\alpha)^m\chi_{r^{m+1}}(x). \tag{68}$$

7.2. The D-bar method for a simple radial conductivity. The series (65) can be used in the analysis of the truncated D-bar method. We have

$$\begin{aligned}
\gamma_{\mathrm{R}}^{\exp}(x)^{1/2} \equiv \mu_{\mathrm{R}}^{\exp}(x,0) &= 1 - \frac{1}{4\pi^2}\int_{\mathbb{R}^2} \frac{\mathbf{t}^{\exp}(k)}{|k|^2} e_{-x}(k)\chi_R(|k|)\overline{\mu_{\mathrm{R}}^{\exp}(x,k)}dk_1dk_2 \\
&= 1 + \frac{2\alpha}{\pi}\sum_{m=0}^{\infty}\alpha^m \int_{\mathbb{R}^2} \check{\chi}_{r^{m+1}}(2|k|)e_{-x}(k)\chi_R(|k|)\overline{\mu_{\mathrm{R}}^{\exp}(x,k)}dk_1dk_2 \\
&= 1 + \frac{\alpha}{2\pi}\sum_{m=0}^{\infty}\alpha^m \int_{\mathbb{R}^2} \check{\chi}_{r^{m+1}}(|w|)e^{-ix\cdot\overline{w}}\chi_R(2|w|)\overline{\mu_{\mathrm{R}}^{\exp}\left(x,\frac{w}{2}\right)}dw_1dw_2 \\
&= 1 + \frac{\alpha}{2\pi}\sum_{m=0}^{\infty}\alpha^m \int_{\mathbb{R}^2} \check{\chi}_{r^{m+1}}(|s|)e^{-ix\cdot s}\chi_R(2|s|)\overline{\mu_{\mathrm{R}}^{\exp}\left(x,\frac{\overline{s}}{2}\right)}ds_1ds_2 \\
&= 1 + \alpha\sum_{m=0}^{\infty}\alpha^m \mathcal{F}\left(\check{\chi}_{r^{m+1}}(|\cdot|)\chi_R(2\cdot)\overline{\mu_{\mathrm{R}}^{\exp}\left(x,\frac{\cdot}{2}\right)}\right)(x) \\
&= 1 + \frac{\alpha}{2\pi}\sum_{m=0}^{\infty}\alpha^m \left(\chi_{r^{m+1}}(\cdot) * \mathcal{F}\left(\chi_R(2\cdot)\overline{\mu_{\mathrm{R}}^{\exp}\left(x,\frac{\cdot}{2}\right)}\right)\right)(x). \qquad (69)
\end{aligned}$$

It is evident from this formula that a ringing effect will appear in the reconstruction, but the effect will be somewhat blurred by the convolution of the characteristic functions with the Fourier transform of $\overline{\mu^{\exp}}$.

8. Numerical experiments. In this section, numerical examples are computed that offer intuition and illustrate the results of the previous sections.

8.1. Example conductivities. We consider discontinuous conductivities defined by (57) with all nine possible combinations of the choices $r \in \{0.2, 0.55, 0.9\}$ and $\sigma \in \{1.1, 2, 8\}$. See Figure 8.2 for profiles of the conductivities.

Radially symmetric examples are chosen for their ease of computation and display (it is sufficient to display profiles of the reconstructed conductivities and scattering transforms, which are real-valued and radially symmetric for radially symmetric examples), as well as to illustrate the results of sections 6 and 7.1. However, all of our computational methods apply equally well to nonsymmetric conductivities.

8.2. Results. The computed scattering transform is denoted by $\mathbf{t}_R^{\exp}$, where R indicates the truncation radius. We compute $\mathbf{t}_R^{\exp}$ from the Bessel-series formula (63) with 10 terms in the expansion, which was verified to be in very good agreement with computations of (61) with 45 eigenvalues. Figure 8.1 contains plots of the approximate scattering transforms $\mathbf{t}_R^{\exp}$ with constant multiples of $\sqrt{|k|}$ superimposed to illustrate the growth of $\mathbf{t}^{\exp}(k)$ as demonstrated in (64).

Plots of the reconstructed conductivities are found in Figures 8.2, 8.3, 8.4, and 8.5. Figure 8.2 contains plots of the reconstructed conductivities from the approximate scattering transform $\mathbf{t}_R^{\exp}$ with truncation radius $R = 15$ for rows 1 and 2 and $R = 12$ for row 3. Figure 8.3 illustrates the dependence of the reconstructions $\gamma_{\mathrm{R}}^{\exp}$ on R. Profiles of the reconstructed discontinuous conductivities with contrast 0.1 and a jump at $|x| = 0.2, 0.55$, and 0.9 are plotted for $R = 4, 5, 6, 7, 8$, and 15. The reconstructions from Calderón's linearization method are found in Figure 8.4. Finally, 2-D plots of three conductivities are included in Figure 8.5.

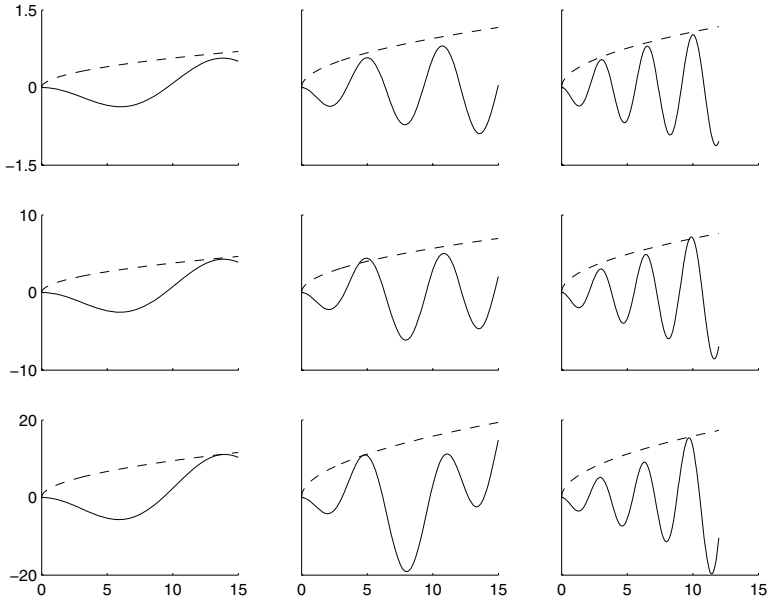

FIG. 8.1. *Profiles of approximate scattering transforms* $\mathbf{t}^{\exp}$ *(solid) for the discontinuous conductivity distributions given by* (57) *with constant multiples of* $\sqrt{|k|}$ *superimposed (dashed) to illustrate the growth of* $\mathbf{t}^{\exp}$*. Note that the vertical axis limits are the same in each row of plots.*

8.3. Discussion. From Figure 8.1, we see that the scattering transforms demonstrate the expected asymptotic growth $\mathbf{t}^{\exp} \sim O(|k|^{1/2})$. The magnitude of the scattering transform increases with the amplitude of γ, and $\mathbf{t}^{\exp}$ becomes more oscillatory as $\operatorname{supp}(\gamma - 1)$ increases. This implies that conductivity distributions with high contrast near the boundary should be particularly difficult to reconstruct, because such a scattering transform is more sensitive to errors in $\partial\Lambda_\gamma$ and more difficult to represent on a discrete mesh.

We see from the corresponding reconstructions in Figure 8.2 that in all cases the location of the jump is reconstructed equally well, but a loss in accuracy in the amplitude becomes apparent as the contrast increases and as the support of $\gamma -$

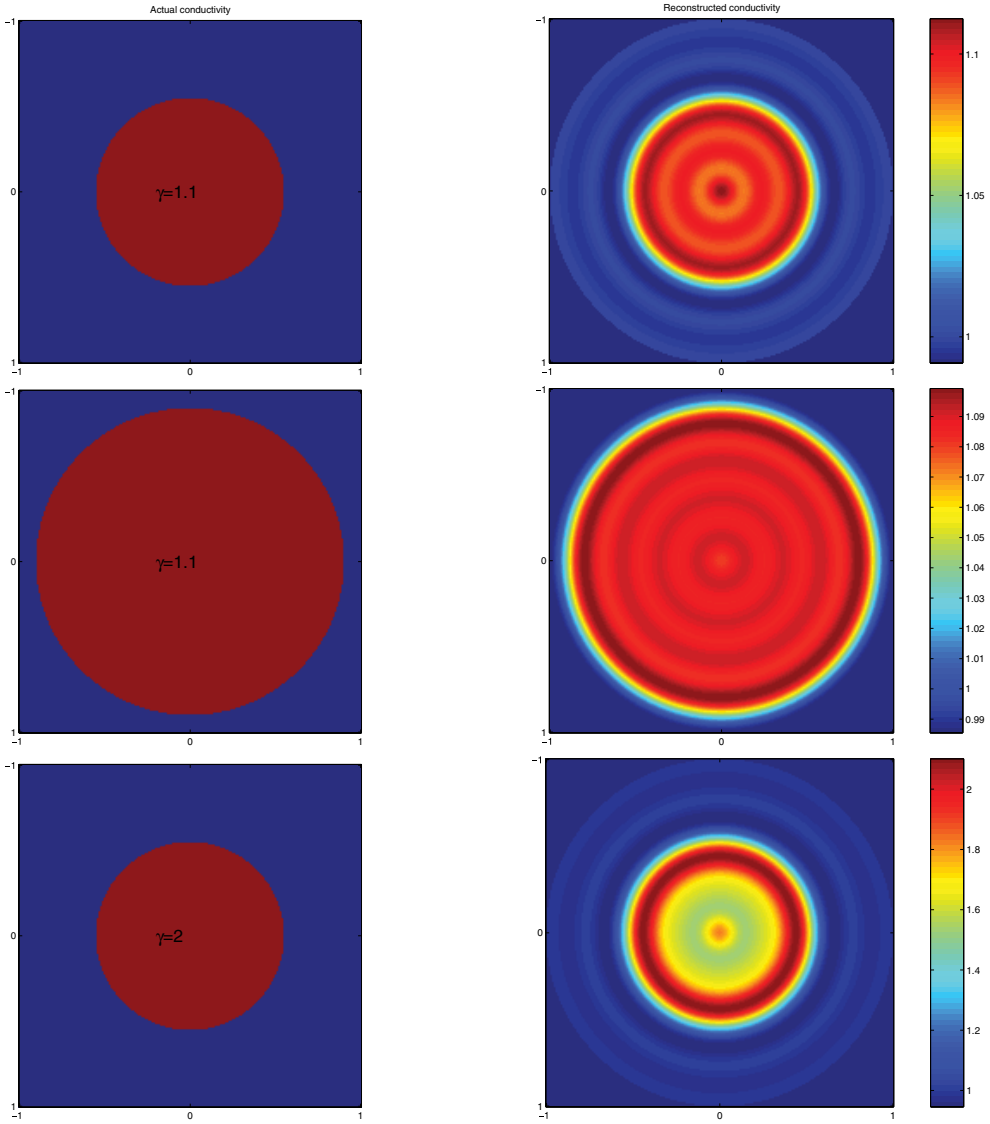

FIG. 8.5. *Three discontinuous conductivity distributions (left) reconstructed (right) from* $\mathbf{t}_R^{\exp}$ *with truncation radius* $R = 15$.

1 widens. This corresponds to the fact that the approximation $\psi|_{\partial\Omega} = e^{izk}|_{\partial\Omega}$ is better the smaller the contrast and the smaller the support of $\gamma - 1$. We see that the reconstructions tend to underestimate the actual amplitude of the conductivity more markedly as the support of $\gamma - 1$ widens and as the magnitude of γ increases. Also note that the reconstructions of the discontinuous conductivities are smooth, as predicted by Proposition 3.5. In Figure 8.3, the nature of the dependence of the smooth approximations on R can be observed. A Gibbs-type phenomenon is indeed present, as suggested by formula (69). Also, the support of $\gamma - 1$ is reconstructed with reasonable accuracy even for very small truncation radii, while the general shape and amplitude of γ is reconstructed with increasing accuracy as R increases. Thus, in

practice one should choose R as large as possible before blow-up of $\mathbf{t}^{\exp}$ is evident. In [29, 24, 15, 16], R was chosen by inspection.

The reconstructions from Calderón's linearization method are found in Figure 8.4. It is interesting to note that the linearized reconstruction from the DN map (67) achieves a more accurate approximation to the amplitude of the conductivity than the linearized reconstruction from the ND map (68). This result also holds for conductivities whose jump is negative ($0 < \sigma < 1$) in $|x| < r$. Note that the linearization formula (67) actually achieves the amplitude of the actual conductivity (albeit only at a single point in some cases), while the D-bar reconstruction $\gamma^{\exp}$ does not. This is presumably due to the damping effect of the convolution with the Fourier transform of $\overline{\mu^{\exp}}$ in (69).

Finally, in Figure 8.5 we display three reconstructions in the typical 2-D display mode for reconstructions from experimental data. This figure further illustrates the ringing effect in the reconstructions of the discontinuous conductivities.

Acknowledgments. The authors thank David Isaacson for helpful discussions and the anonymous reviewers for their suggestions.

MODELING CYCLIC WAVES OF CIRCULATING T CELLS IN AUTOIMMUNE DIABETES*

JOSEPH M. MAHAFFY† AND LEAH EDELSTEIN-KESHET‡

Abstract. Type 1 diabetes (T1D) is an autoimmune disease in which immune cells, notably T lymphocytes, target and kill the insulin-secreting pancreatic beta cells. Elevated blood-sugar levels and full-blown diabetes result once a large enough fraction of these beta cells has been destroyed. Recent investigation of T1D in animals, namely nonobese diabetic (NOD) mice, has revealed large cyclic fluctuations in the levels of T cells circulating in the blood, weeks before the onset of diabetes [J. D. Trudeau, C. Kelly-Smith, C. B. Verchere, J. F. Elliott, J. P. Dutz, D. T. Finegood, P. Santamaria, and R. Tan, *J. Clin. Invest.*, 111 (2003), pp. 217–223], but the mechanism for these oscillations is unclear. We here describe a mathematical model for the immune response that suggests a possible explanation for the cyclic pattern of behavior. We show that cycles similar to those observed experimentally can occur when activation of T cells is an increasing function of self-antigen level, whereas the production of memory cells declines with that level. Our model extends previous theoretical work on T-cell dynamics in T1D [A. F. M. Marée, P. Santamaria, and L. Edelstein-Keshet, *Int. Immunol.*, 18 (2006), pp. 1067–1077], and leads to interesting nonlinear dynamics, including Hopf and homoclinic bifurcations in biologically reasonable regimes of parameters. The model leads to the following explanation for cycles: High rates of beta-cell death, and corresponding elevation of self-antigen, shut off memory-cell production, leading to a gap in the population of activated T cells. Once peptide has been cleared by nonspecific mechanisms, the memory pool is renewed, and the cyclic behavior results.

Key words. autoimmune diabetes, type 1 diabetes, $CD8^+$ T cells, cycles, homoclinic bifurcation, mathematical model

1. Introduction.

Type 1 diabetes (T1D) is an autoimmune disease in which pancreatic beta cells are killed by the immune system, shutting off insulin secretion, and resulting in elevated blood glucose. The disease affects young people, severely impacting their health, and requiring perpetual insulin injection. Finding cures and/or treatment to replace the beta cells (e.g., by transplanting islets from organ donors) remains problematic, mainly because the damage is caused by the body's own immune system, which also attacks the transplant.

Studying autoimmune diabetes in humans presents ethical and clinical challenges. Therefore, animals with diabetic tendency, including *nonobese diabetic* (NOD) mice, are used to gain a basic scientific understanding of the disease. In NOD mice, T1D arises when populations of immune cells called T cells become primed to specifically target and kill beta cells. Such cytotoxic T cells belong to a class of lymphocytes displaying a surface marker called CD8. (Hence, they are denoted $CD8^+$ T cells.) We first briefly describe the background immunology and then present the detailed aspects specific to diabetes, the data on circulating T cells, and our model.

1.1. Immunology primer. For an excellent survey of immunology, see [9]. T cells mature in the thymus, where those that cross-react with self-proteins are normally eliminated to prevent autoimmunity. After this period of development, they are released, circulate, and migrate to lymph nodes. In the lymph nodes, T cells interact with antigen-presenting cells (APCs) that display stimuli, consisting of a small fragment of antigen protein (i.e., a peptide of about nine amino acids in length) held inside a cleft of a larger protein (named major histocompatibility complex, or MHC, for historical reasons) [4]. The peptide-MHC complex (p-MHC for short) interacts with specific receptors on the surface of the T cells ("T-cell receptors," abbreviated TCRs). The strength, duration, and number of such interactions experienced by a given T cell determines its subsequent fate [24, 26, 15, 27, 21]. Within the right range of affinity to and quantity of p-MHC encountered, T cells with the appropriate specificity undergo activation, and the immune response is initiated.

Under normal conditions, APCs display antigens that are derived from foreign proteins such as viral or bacterial coat proteins. Then appropriately specific T cells are primed to form a large battalion of effector cells to combat the infection. Activated T cells proliferate, undergoing about six cell divisions. Their daughters are mostly effector cells (also called cytotoxic T lymphocytes, or CTLs), efficient and specific killers that seek out and destroy targeted cells. These effector cells, though deadly, are relatively short-lived [5]. A few daughters of activated T cells are memory cells that retain the same specificity but have no immediate effect [8, 25]. However, when the stimulus (e.g., the same foreign antigen) is encountered for a second time, memory cells can be activated rapidly to mount a faster immune response.

In autoimmune diseases such as T1D, the antigen peptide derives from normal proteins in the host. Infection or other injury can expose such proteins and initiate the disease, but once in progress, successive killing of targeted cells, and consequent release and exposure of more self-antigen, can sustain the inappropriate immune response. As the immune system is a complex web of nonlinear interactions between cells, chemicals, and tissues, rich dynamical behavior can be expected and indeed does occur. Our first goal in this paper is to point out interesting immunological dynamics to an audience of applied mathematicians. Our second goal is to present a plausible explanation of the cycles in autoimmune diabetes observed by [23], based on an established set of known and hypothesized interactions.

1.2. Autoimmunity in T1D. It has been shown that normal development of NOD mice includes a wave of programmed cell death (apoptosis) of pancreatic beta cells shortly after birth [18, 19]. In these same experiments, it was also determined that clearance of the apoptotic cells (by macrophages, nonspecific cells of the innate immune system) is reduced in NOD mice, leading to the conjecture that material from these dead beta cells forms self-antigen that triggers the autoimmune response. Previous modeling efforts have focused on such early initiation events [12, 13], but here we are mainly concerned with later stages in which the adaptive immune system is involved.

A number of proteins, including insulin, have been implicated as self-antigens in T1D. Most recently, experimental collaborators in Calgary (in the laboratory of P. Santamaria) have identified a new dominant self-antigen, IGRP (glucose-6-phosphatase catalytic subunit-related protein), a protein of beta cells whose normal function is yet to be determined. A fragment of this protein (consisting of amino acids 206–214) is the "peptide" to which most $CD8^+$ T cells in T1D react [10]. The discovery of this specific self-antigen in NOD mice followed years of experiments in which

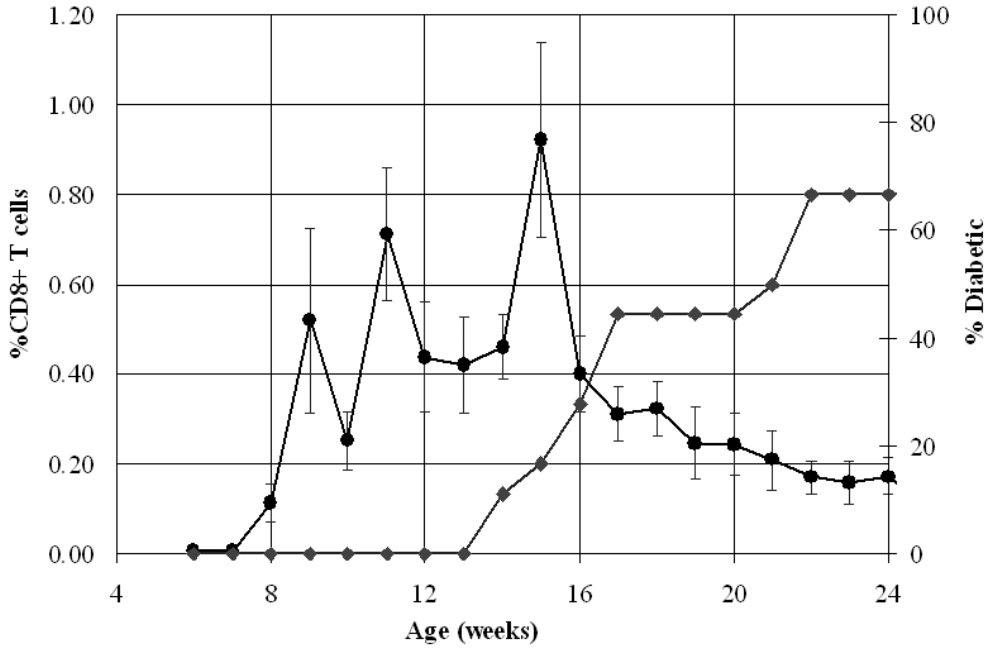

FIG. 1.1. *Periodic waves of circulating T cells occur in mice prone to diabetes (NOD mice) in the weeks before the onset of the disease. Data courtesy of the authors of* [23]. *Dark line, circles: T-cell level. Grey line, squares: percentage of the animals that became diabetic. Our model accounts for the cyclic waves but not for the period of initialization in weeks* 0–5, *the time when other processes prime the adaptive immune system.*

libraries of artificially synthesized peptides were used to identify and label T cells [2, 1, 6]. Use of tetramer probes (constructed of four copies of peptide-MHC with a fluorescent tag) allowed careful investigation of the levels and dynamics of these cells by enhancing the ability to label cells that were previously undetectable.

Using such tetramer staining experiments, it was shown by Trudeau et al. [23] that the level of autoreactive $CD8^+$ T cells is detectable in the pancreatic islets in 4–5-week-old NOD mice and at elevated levels by weeks 11–14. Correlated with this rise, populations of T cells circulating in the blood are also noticeably elevated over weeks 4–16 of age, before the high blood-sugar symptoms of diabetes occur. Surprisingly, the levels of these cells do not simply rise monotonically as the disease progresses but, rather, undergo dramatic fluctuations over this time frame, as shown in Figure 1.1.

Not all NOD mice develop diabetes, but the presence of these cyclic T-cell waves in a given animal predicts that it will become diabetic. Data for each one of the mice were aligned at the time of onset of high blood-sugar symptoms, so that the time axis could be "normalized" before combining and averaging. These pooled data show three peaks in the level of T cells starting at about 8 weeks of age and declining from about 16 weeks. The amplitude of the cycles increases over this time, and a slight increase in the period is also visible. The fact that Figure 1.1 was produced experimentally as an average of data for many mice suggests that there is some robustness in the cycling (as well as in its period) in NOD mice. These mice are all genetically identical, which means that parameters typical of their physiological and immunological processes are likely very similar (with some possible exceptions due to environmental effects).

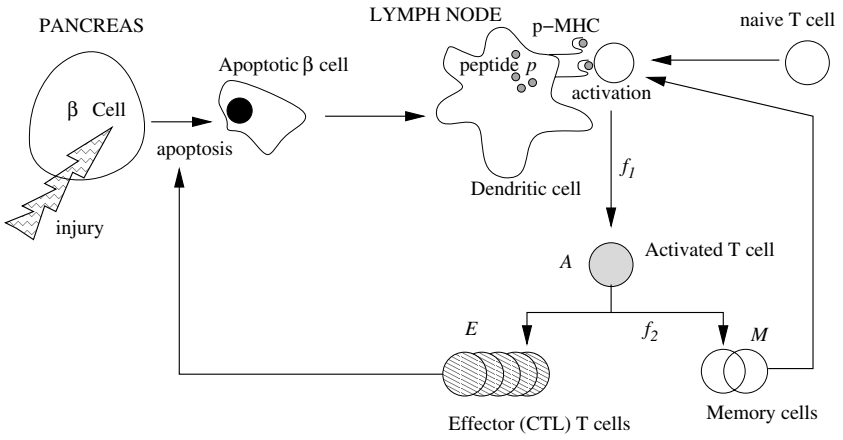

FIG. 2.1. *Scheme of the model. Programmed cell death (apoptosis) of pancreatic (insulin-producing) beta cells generates self-antigen peptide (p). In the pancreatic lymph nodes, this peptide is presented as part of cell-surface complexes (peptide-MHC, or p-MHC) on APCs called dendritic cells. The amount of p-MHC presented affects the activation and the differentiation of naive T cells into memory cells (for self-renewal) and into effector cells (CTLs) that seek and kill beta cells. This leads to more peptide exposure and results in positive feedback that eventually culminates in autoimmunity and T1D.*

Trudeau et al. speculated that each of these cycles represents "a round of proliferation of autoreactive T cells undergoing avidity maturation" [23], but the details of the underlying mechanism were not explored. This exploration is the subject of our paper.

2. Background for the model. Our main hypotheses stem from a recent model by Marée, Santamaria, and Edelstein-Keshet [14] that addressed the dynamics of T cells and peptide. In the latter paper, the focus was on artificial peptide used to treat the disease in a therapy similar to vaccination. It was shown that the competition of T-cell clones during peptide treatment could explain some of the puzzling dose-response behavior of the treatment and predict its success or failure. In their discussion, Marée, Santamaria, and Edelstein-Keshet [14] speculated that the increase in level of peptide antigen that results from beta-cell killing could be a feedback that explains the periodic waves of T cells observed by [23]. However, this idea has not yet been tested rigorously in a mathematical setting. We use some of the formalism and lessons learned in that model to investigate cyclic dynamics seen in [23]. We will show that an explanation for such dynamics is already inherent in the framework of the model of [14], or slight variations thereof.

Figure 2.1 summarizes the essential ingredients of our model. As shown, the process might be initiated by some injury or infection of beta cells, or by the normal wave of programmed cell death (apoptosis), not shown. Fragments of apoptotic cells are processed and presented as p-MHC on dendritic cells in the lymph nodes, and naive T cells interact with these complexes. It is known that the level of peptide presentation (i.e., amount of p-MHC) and the affinity of the T-cell receptors for the peptide determine whether a T cell encountering the APC will become activated to proliferate [4, 6, 16]. When naive T cells are activated, they proliferate to produce about 60 effector cells and about 1–4 memory cells [8]. Memory cells have a low turnover rate. They are able to undergo reactivation in response to antigen and to proliferate again, replenishing the pool of T cells. By killing beta cells, the effector T cells lead to a positive feedback on the amount of peptide produced and hence

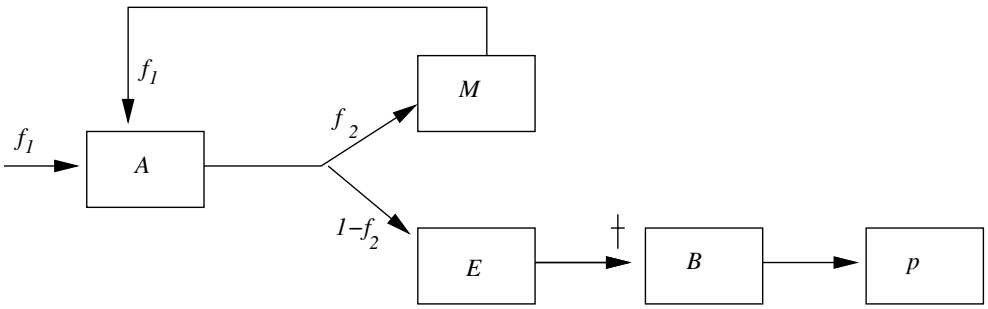

FIG. 2.2. *Simplified model scheme showing the main variables considered: A, E, and M are the number of activated, effector, and memory T cells. B denotes beta cells, and p is peptide. The two peptide-dependent functions are the fraction of T cells activated, f_1, and the fraction of memory cells produced, f_2. (The feedback from peptide to these has been omitted in the diagram for clarity.) The † represents the killing of beta cells by effector T cells.*

on further activation of T cells. The lifetime of the effector T cells is about 3 days [5, 7, 22] versus about 100 days for memory cells.

The level of peptide influences two important aspects of the process described above. First, the rate of activation of T cells depends on peptide level. Second, the fraction of daughter cells that are memory cells versus those that are effector cells is also peptide-dependent. Experimental evidence [11, 17] points to the fact that, at high-peptide doses, too few memory cells are produced. (This is termed "clonal exhaustion.") Following [14], we assume that the fraction of naive and memory T cells activated is given by a sigmoidal increasing function, $f_1(p)$, whereas the fraction, f_2, of daughter cells of activated T cells that become memory cells decreases sigmoidally as peptide increases. We also chose f_1 and f_2 to be Hill functions, i.e., rational functions with powers of degree > 1 (the degree is called the Hill coefficient; see section 3.2.)

In Figure 2.2, we show a simplified scheme, outlining our basic assumptions for the model: A fraction f_1 of incoming naive T cells becomes activated, (A); a fraction, f_2, of their offspring is memory cells, (M), and the rest, $1 - f_2$, are effector cells, (E). Memory cells can be reactivated (same peptide-dependent fraction, f_1, as incoming naive T cells). The effector cells cause the death of beta cells, (B), which, in turn, creates the peptide, (p). The peptide level affects both f_1 and f_2.

3. The model.

3.1. Assumptions. The following assumptions enter the model:

1. We do not consider the distinct compartments of blood, pancreas, and lymph nodes at this stage. Since the dynamics of interest take place over many weeks, whereas the trafficking between these compartments takes place on the time scale of hours, we approximate all variables as densities or concentrations in a single, well-mixed compartment.
2. We do not model the pathogenesis of the disease over the first 4–5 weeks. At this early stage, it is likely that the innate immune system (e.g., macrophages) may set up conditions that eventually give rise to the priming of T cells. See [13] for an analysis of that stage.
3. We assume that effector cells are terminal. (Some controversy exists about whether they give rise to some memory cells.) We also investigated a model in which memory cells are a progeny of effector cells and found essentially similar results.

4. We do not discuss the competition of many distinct "clones" of T cells for sites on ACPs or for p-MHC [14]. We model only the development of one dominant clone.
5. We assume that material from dead beta cells produces self-antigen peptide at a linear rate and that this peptide is presented proportionally as p-MHC on the dendritic cells. In [14], this p-MHC level was denoted m_t and modeled as a quantity in a quasi-steady state (QSS) with peptide and MHC molecules. Here we simplify such details.
6. We assume that once beta cells are gone, the production of the autoantigen ceases, and the immune response stops, since T-cell activation does not occur in the absence of peptide.

3.2. Model equations. Our full model consists of the following set of ordinary differential equations (ODEs):

$$\frac{dA}{dt} = (\sigma + \alpha M) f_1(p) - (\beta + \delta_A) A - \epsilon A^2, \tag{3.1}$$

$$\frac{dM}{dt} = \beta 2^{m_1} f_2(p) A - f_1(p) \alpha M - \delta_M M, \tag{3.2}$$

$$\frac{dE}{dt} = \beta 2^{m_2} (1 - f_2(p)) A - \delta_E E, \tag{3.3}$$

$$\frac{dp}{dt} = REB - \delta_p p, \tag{3.4}$$

$$\frac{dB}{dt} = -\kappa EB, \tag{3.5}$$

where $A(t), M(t)$, and $E(t)$ are the population levels of activated, memory, and effector T cells at time t, $p(t)$ is the peptide level, and $B(t)$ is the population of remaining beta cells. For the peptide-dependent functions, we take Hill functions,

$$f_1(p) = \frac{p^n}{k_1^n + p^n}, \tag{3.6}$$

$$f_2(p) = \frac{a {k_2}^m}{k_2^m + p^m}, \tag{3.7}$$

with $m, n > 1$. The parameters $k_1 > 0$ and $k_2 > 0$ in (3.6) and (3.7) denote typical levels of peptide at which the response of these functions is half-maximal, and $0 < a < 1$ is the maximal value of $f_2(p)$. Note that $f_1(p)$ is monotonic increasing whereas $f_2(p)$ is monotonic decreasing with p. In (3.1)–(3.3), all T cells represent members of clones whose specificity to beta-cell peptide is high. In (3.1), σ is the rate that naive T cells enter the circulation from the thymus. The fraction of incoming naive and memory cells that become activated is governed by the peptide-dependent sigmoidal function, $f_1(p)$ (α is a factor that represents the higher rate of activation of memory cells relative to naive cells). The rate of decay of A, δ_A, is augmented by a term for competition, ϵA^2, as discussed in [14]. Activated cells progress to a differentiated stage at rate β. They then proliferate by a series of cell doublings to produce $2^{m_2} \approx 60$ effector cells and $2^{m_1} \approx 3$–4 memory cells. The commitment to development into these two types of daughter cells depends on peptide according to the decreasing sigmoidal function $f_2(p)$. Effector cells are terminal and have a shorter half-life than memory cells ($\delta_M < \delta_E$).

Equation (3.4) depicts our simple assumption about production and clearance of peptide: the level of "peptide," p, is produced with mass-action kinetics when effector cells kill beta cells (at rate R per effector per beta cell) and cleared with linear kinetics at rate δ_p. Recall that clearance of dead beta cells and their fragments by macrophages is defective in NOD mice [12, 18, 19], and this defect can theoretically lead to the early chronic inflammation that initiates the priming of T cells [13]. Therefore, it is of interest to ask whether this same defect can also account partly for the dynamics of T cells at this later stage of the disease. We investigate this later.

We use the simplest possible model for decay of beta cells due to killing by effector T cells in (3.5). The parameter κ denotes the rate of killing per effector cell. We ignore the (limited) ability of beta cells to regenerate and the very slow aging and turnover rate of beta cells in the healthy individual. Currently, the extent to which beta cells can self-renew after immune attack is still under investigation, and this process is likely to occur on a slow time scale. For this reason, we did not explicitly include this in the model at this stage.

3.3. Model equations for a reduced QSS system. Our analysis begins with a reduction of the full system of equations (3.1)–(3.5) to a simpler model using separation of time scales. First, we argue that the time scale of peptide dynamics—hours—is faster than any of the time scales of cell dynamics—days and weeks—justifying a QSS assumption on the peptide. Hence, we set $dp/dt = 0$ in the model, so that $p = (RB/\delta_p)E$.

The model then consists of (3.1), (3.2), (3.3), and (3.5). The functions f_1, f_2 now depend on E and B via the QSS peptide expression. We refer to this as the *reduced QSS model*. Our first step was to explore this model computationally. To do so, we had to estimate parameters and consider appropriate scaling. Our steps and results are described below.

3.4. Parameter estimates, scaling arguments, and computations. Based on nonlinearities (in the functions f_1, f_2), the model consisting of (3.1)–(3.5) can have a range of interesting behaviors. As we are interested in the possible biological and medical applications of this model, it is essential to study its behavior within a biologically reasonable range of parameter values. Almost all parameters in the model were based on experimental information previously compiled by Marée, Santamaria, and Edelstein-Keshet [14]. Some exceptions include parameters associated with beta-cell killing and peptide production, as these were not considered in the previous treatment. To avoid lengthy diversion into the details, we concentrate all details of the parameter estimates in the appendices. The meanings, units, and values of the parameters are presented in Table B.1. The level of cells of type A, E, M varies on a range of several orders of magnitude. As we wanted to present these all on the same plot, we scaled these population densities by the appropriate powers of ten. Scaling arguments are also given in the appendices. We left the time variable in units of days to emphasize the period and timing of the cycles that we obtained.

Simulations of the dynamics were carried out in MATLAB. Initial conditions were chosen to depict some (preexisting) stimulus to the immune system stemming from earlier stages of the disease (e.g., as speculated in [13]). Bifurcation diagrams were composed with the AUTO feature of XPP, freely available software written by G. Bard Ermentrout.[1] Unless otherwise indicated, all simulations use the basic core set of parameter values, as shown in Table B.1.

[1] www.math.pitt.edu/∼bard/xpp/xpp.html.

4. Results. Starting any simulation with the healthy state as initial condition, i.e., $A = M = E = 0$, $B = 1$ (and thus also $p = 0$), clearly results in continued health, since this point is a steady state of the system. Moreover, the stability of this equilibrium implies that even some (sufficiently small) perturbation rapidly returns to this state. Hence to get any immune dynamics of interest in our model, the system should be initiated with some T cells already "primed." Typically, we start simulations with $A = 0.5, M = 0$, and $E = 1$. This state ensures that effector cells are present to lead to peptide production and that activated T cells are available to renew that pool of effectors. Other initiation values are possible, depending on parameter settings (discussed later). This prototypical set of values represents the outcome of earlier events that our model is not describing (but see, e.g., [13] for a possible description.)

Not all NOD mice develop diabetes. Therefore, any model for this disease also has to account for the fact that some initial stimuli will be resolved without full-blown autoimmunity. We first discuss this baseline control for the model. Running the reduced QSS model from an initially "primed" state with default parameter values gives rise to the behavior shown in Figure 4.1; that is, an initial elevated level of effector and memory T cells is resolved, after some time, and the immune response ceases. This corresponds to resolution of the immune attack with no autoimmunity even though the immune system has been provoked to respond. The beta-cell population decreases by 40% during the immune attack. Since our model does not address replenishment of the beta cells by reproduction or stem-cell differentiation, the beta-cell mass remains constant after this isolated immune response.

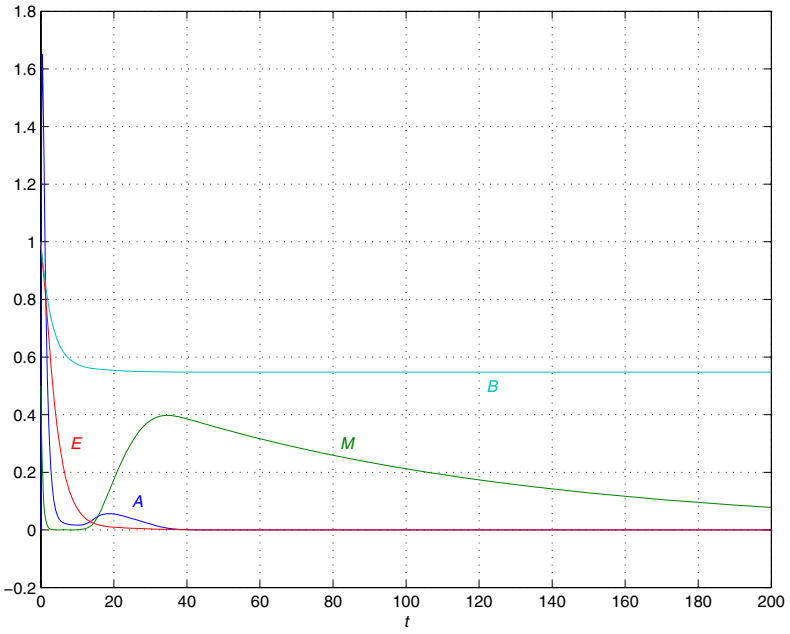

FIG. 4.1. *(color online). Simulation of the model for NOD mice that* do not *become diabetic. Number of circulating cells (scaled) versus time (days). Dark blue: A* ($\times 10^3$ *cells), green: M* ($\times 10^4$ *cells), red: E* ($\times 10^6$ *cells), light blue: B (fraction of beta-cell mass remaining). Simulation uses default ("NOD") parameter values given in Tables B.2 and B.1. For the initial conditions* $A = 0, M = 0.5, E = 1, B = 1$*, the immune response is resolved without chronic disease or cyclic waves.*

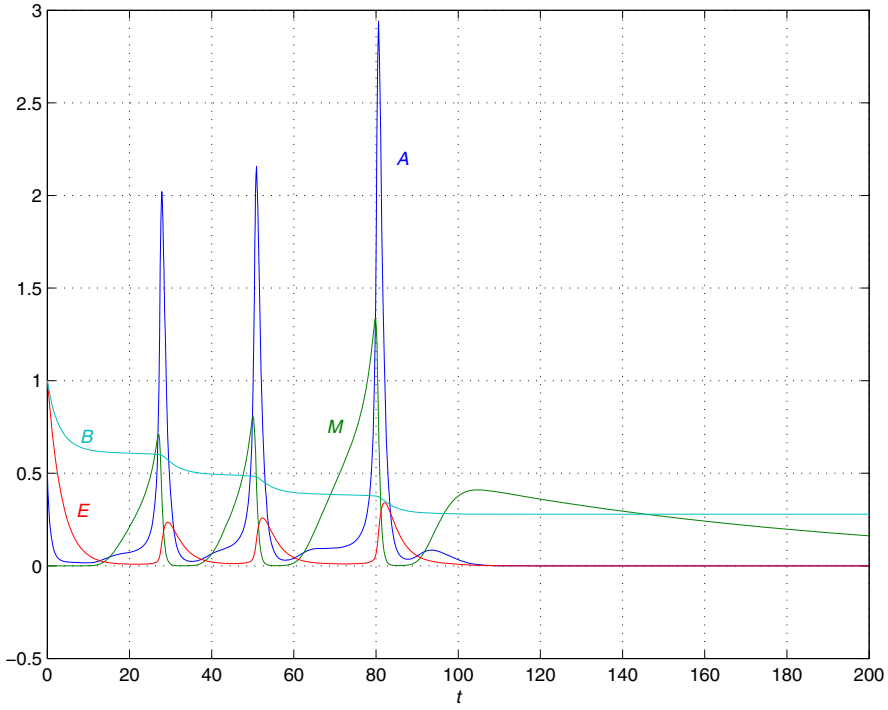

FIG. 4.2. *(color online). Simulation of the model for NOD mice that* do *become diabetic (by* 80–90 *days of age). Default ("NOD") parameter values and scaling are as in Figure* 4.1 *but with initial conditions* $A = 0.5, M = 0, E = 1, B = 1$ *that evoke the elevated periodic immune response. Dark blue: A, green: M, red: E, light blue: B. The disease progresses with cycles of T cells that cause waves of beta-cell killing, as predicted by the model.*

When the initial conditions include more elevated levels of activated T cells (with all other parameters left as is), oscillations can appear, as shown in Figure 4.2. As in Trudeau et al. [23], three peaks with increasing amplitude of effector T cells occur over days 30–80 at the period of approximately 3–4 weeks, as in the experimental data. This run is in close agreement with the data for mice that develop full-blown diabetes, as shown in Figure 1.1.

We can understand intuitively how such cycles occur by reasoning as follows: In our model, (3.5) leads to the decay of beta cells whenever effector cells are present. Due to the assault on beta cells by the T cells (specified by our choice of initial conditions), peptide level increases, T cells are activated, and effector cells are formed. However, once peptide rises to a high level, memory-cell production is turned off (as f_2 decreases with p). Thus, replenishment of activated T cells drops, and subsequently E also declines and is not renewed. Once the effector cells decline, new peptide is hardly produced. It is gradually cleared and eventually reaches a low level that is then consistent with memory-cell production. This then stimulates production of new activated T cells, and the cycle repeats. Periodic peaks and troughs continue until beta cells are depleted, and then no more peptide is formed, and T cell activation stops altogether. At this stage, since beta cells are gone, full-blown diabetes sets in, and the immune response decays to its trivial equilibrium. This reasoning is plausible but relies on an appropriate combination of parameters governing rates of depletion and renewal of the various cell types.

It is noteworthy that merely by increasing the rate of clearance of the peptide, δ_p, we end the tendency of the system to cycle. We ran simulations with elevated values of δ_p and found behavior similar to that of Figure 4.1 for much broader ranges of initial conditions (results not shown). These results can be taken as indications that in "control" mice whose peptide clearance rate is normal, immune response is less likely to lead to prolonged cycling attack. These results are discussed in more detail later.

5. Analysis of a reduced model with B as a parameter. To gain a clearer understanding of the behavior described above, we reduce the four-dimensional model simulated above further yet by considering the level of beta cells, B, to be a parameter. The onset of diabetes in NOD mice requires about 16 weeks, at which time there are very few remaining beta cells in the pancreas. This indicates that the variable B in the full model acts more like a slowly varying parameter compared to the other variables in the model. We therefore consider a reduction to three variables (A, M, E) and analyze the model behavior. We then discuss how the gradual decrease of B influences the dynamics of the whole system. The model to be analyzed now consists of the three equations

$$\frac{dA}{dt} = (\sigma + \alpha M) f_1(p) - (\beta + \delta_A) A - \epsilon A^2, \tag{5.1}$$

$$\frac{dM}{dt} = \beta 2^{m_1} f_2(p) A - f_1(p) \alpha M - \delta_M M, \tag{5.2}$$

$$\frac{dE}{dt} = \beta 2^{m_2} (1 - f_2(p)) A - \delta_E E, \tag{5.3}$$

together with (3.6) and (3.7) and the QSS peptide expression

$$p \approx (RB/\delta_p) E. \tag{5.4}$$

This three-dimensional system of differential equations permits a more complete analysis.

5.1. Steady states and stability properties. The three-dimensional system of differential equations given by (5.1)–(5.3) has several types of feedback. Peptide level (and therefore effector cell level) leads to positive feedback on T-cell activation via f_1. Simultaneously, these levels produce negative feedback on the memory-cell production via f_2. When combined, these nonlinear feedbacks lead to the possibility of multiple steady states, depending on the parameters. Numerical experiments suggest that this mixed feedback system can have from one up to five equilibria.

In the biologically relevant regime of parameters (discussed in the appendices), we find that there are three equilibria. One of these is clearly the trivial equilibrium $A = M = E = 0$. This follows immediately from the fact that $f_1(0) = 0$. This equilibrium corresponds to a disease-free state and is easily shown to be a stable node. The fact that the origin is an attractor means that a small disturbance that provokes the immune system should be resolved, provided it is sufficiently weak.

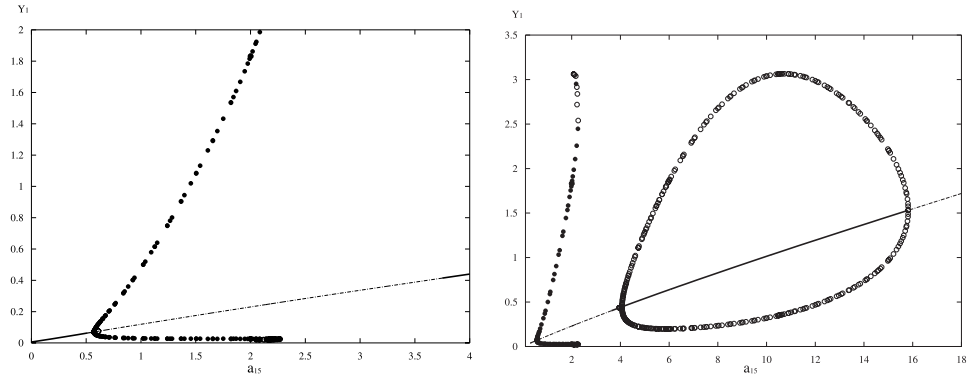
There also exists a positive equilibrium that corresponds to a state of elevated immune cell levels. In that state, effector T cells are continuously killing beta cells, and this corresponds to an autoimmune attack that eventually leads to diabetes. This equilibrium has various stability properties that depend on the parameters. We discuss this in more detail below. A third equilibrium is a saddle with a two-dimensional

stable manifold, which for some parameters separates the "healthy" and diseased equilibria. For these parameters, stimuli that fall on the wrong side of this separatrix will be attracted to the diseased equilibrium. For other parameter values, the unstable manifold of the diseased state connects to the stable manifold of the saddle point. In this case, almost all positive initial conditions asymptotically approach the "healthy" state.

As a specific example of the local analysis, we considered the system of equations (5.1)–(5.3) with the parameters given in Table B.1 and $B = 1$. Due to the nonlinearities in the functions f_1 and f_2, it is not possible to solve explicitly for equilibria. Therefore, we determined steady states, eigenvalues, and eigenvectors numerically using the software program Maple. We found the following results: The disease-free equilibrium, $(\bar{A}_0, \bar{M}_0, \bar{E}_0) = (0, 0, 0)$, is a stable node with the three eigenvalues $\lambda = -1, -0.3, -0.01$. A saddle node at $(\bar{A}_s, \bar{M}_s, \bar{E}_s) = (0.0116, 0.696, 0.00116)$ has a two-dimensional stable manifold (eigenvalues $\lambda_1 = -1.52, \lambda_2 = -0.0188$ and associated eigenvectors $v_1 = [1, 0.495, 0.0245]$, $v_2 = [1, -68.5, 0.107]$) and an unstable manifold (eigenvalue $\lambda_3 = 0.210$ with eigenvector $v_3 = [1, 2.62, 0.0589]$). Finally, the diseased equilibrium, $(\bar{A}_d, \bar{M}_d, \bar{E}_d) = (0.119, 0.0141, 0.0356)$, has a stable manifold (with eigenvalue $\lambda_1 = -2.37$ and associated eigenvector $v_1 = [1, -0.108, -0.0414]$). It also has a two-dimensional unstable manifold (eigenvalues $\lambda = 0.0129 \pm 0.553i$) that spirals outward toward a limit cycle. From this local analysis, we could see that at each equilibrium, one eigenvalue is significantly more negative than the others. This suggests that there is a globally attracting two-dimensional manifold containing the three equilibria, where the interesting dynamic behavior occurs.

5.2. Bifurcations. We first discuss bifurcations with respect to a relevant parameter and later assemble the sequence of dynamical behaviors in Figure 6.2. In the model given by (5.1)–(5.3), we have assumed that the destruction of beta cells occurs on a slow time scale. Thus, the level of beta cells, B, makes a natural bifurcation parameter to consider. At the beginning of our simulations, we normalize $B = 1$ and set $\delta_p = 1$. By the QSS assumption for peptide, a gradual loss of beta cells in this model variant is dynamically equivalent to a gradual increase in the peptide clearance rate δ_p. (Both parameter variations essentially describe the decreasing QSS value, $p = (RB/\delta_p)E$.) We explored this parameter variation using the AUTO option of the software XPP. Figure 5.1 shows the result obtained thereby.

The diagram given in Figure 5.1(a) shows the basic bifurcation behavior of the model (and uses the default parameter values given in Tables B.2 and B.1). Moving across this diagram from left to right along the horizontal axis represents increasing values of the peptide decay rate δ_p or, equivalently, a decreasing level of beta cells, B. Close to the leftmost edge (high B, or low peptide clearance rate), we find a stable diseased state (solid line with shallow slope). The "healthy" state, also stable, and the saddle node are not indicated in the diagram. Moving towards the right leads to a supercritical Hopf bifurcation at $a_{15} = \delta_p = 0.571$, spawning a stable limit cycle. Here we enter the regime of cyclic behavior evidenced in Figure 4.2. The diseased equilibrium is then an unstable spiral, as predicted by the local analysis described above. The limit cycle persists, and its amplitude increases as the parameter increases (respectively, as the beta-cell level decreases) up to a homoclinic bifurcation at $\delta_p = 2.268$ (equivalently at $B = 0.441$, i.e., when only about 44% of beta-cell mass remains). As seen in our runs and in the upper branch of this bifurcation line on the zoomed out diagram of Figure 5.1(b), AUTO has difficulty resolving this global bifurcation. We discuss the nature of this dynamical shift later.



(a) (b)

FIG. 5.1. *Bifurcation diagram for the peptide decay rate, $a_{15} = \delta_p$, with all other parameters set at their default values, as in Tables B.2 and B.1. The vertical axis is A in units of 10^3 cells.* (a) *A portion of the diagram, enlarged, showing the typical bifurcation: a Hopf bifurcation occurs at $a_{15} = 0.5707$, spawning a stable limit cycle. A homoclinic bifurcation occurs at $a_{15} = 2.268$.* (b) *Further bifurcations on an expanded scale: another Hopf bifurcation (to an unstable limit cycle) occurs at $a_{15} = 4.063$. This limit cycle vanishes at $a_{15} = 20.28$.*

Following the homoclinic bifurcation, the diseased state remains unstable, and the origin is the only global attractor for some range of the bifurcation parameter. Interpreting this bifurcation diagram in terms of normal and reduced levels of (peptide) clearance rates (by control versus NOD macrophages) suggests why the clearance defect itself could make the difference between healthy (control) mice versus diabetes-prone (NOD) mice: for example, as seen in Figure 5.1(a), a "control" peptide clearance rate of $\delta_p = 3$ per day leads to dynamics that always resolve any initial stimulus (returning to the baseline where no immune cells persist, since the limit cycle does not occur, and the disease state is unstable), whereas a factor of two decrease to $\delta_p = 1.5$ per day (representing reduced clearance in NOD mice) puts the same system into the regime of cyclic T-cell waves and autoimmunity.

Reinterpreting this diagram in terms of the gradual decrease of beta-cell mass (from left to right starting from $B = 1$) explains the following features shared by the data of Figure 1.1 and the simulation of Figure 4.2: (1) the increase in the amplitude of the cycles, (2) the fact that the cyclic behavior stops abruptly (e.g., around days 80–90 in the simulation of Figure 4.2) when the homoclinic bifurcation occurs, and (3) the slight lengthening of the period just before this transition. It also explains why (4) the immune cells then decay to the baseline state $A = M = E = 0$. Thus, the bifurcation diagram can help to provide a plausible scenario for a mechanism underlying these dynamics.

As previously noted, immunological systems present a menagerie of curious dynamical behaviors that can be an enticing invitation to the applied mathematician. As our model is nonlinear, other interesting behavior is to be anticipated. In Figure 5.1(b), we show an expanded scale, with much higher values of the peptide turnover parameter. As seen here, at $\delta_p = 4.063$ per day, a second subcritical Hopf bifurcation takes place. Thus, for a range of values of $4.063 < \delta_p < 20.28$ per day, the diseased state becomes (locally) stable once more, with a domain of attraction bounded by an unstable limit cycle. All solutions inside this domain will evolve towards the diseased state, whereas outside this domain of attraction, solutions eventually lead to the origin. Aside from purely mathematical interest, this diagram suggests

that there are as yet other unexplored behaviors in this and other immunological models. On one hand, biologically, this result could be interpreted to mean that increased removal of peptide is not always advantageous (since it can reinstate the stability of the diseased state). On the other hand, the dynamics shown in this expanded parameter regime might be more of a mathematical curiosity than a result that is directly relevant to diabetes in NOD mice.

We investigated a number of other parameter variations and bifurcations (diagrams omitted), starting from the default parameter set. For example, we varied the parameter $a = a_4 < 1$ of the function f_2. This parameter specifies the maximal fraction of memory cells produced (when $p = 0$). We found that decreasing a from 1 leads to the homoclinic bifurcation at $a = 0.45$. Similarly, for the T-cell competition parameter, the range $0 \leq \epsilon \leq 2.17$ lies within the stable limit cycle regime. A Hopf bifurcation occurs at $\epsilon = 2.173$, leading to stability of the diseased state. No homoclinic bifurcation was obtained by varying this parameter. Finally, changing k_2, the peptide level that corresponds to the half-maximal value of f_2, gave a stable diseased state when $k_2 = 2$, a Hopf bifurcation at $k_2 = 1.112$, and a homoclinic bifurcation when $k_2 = 0.825$. Due to space constraints, these bifurcation diagrams are not shown.

6. Geometry of the solutions. Figure 6.1 shows two stereograms of the three-dimensional AME system in the regime of parameters consistent with the stability

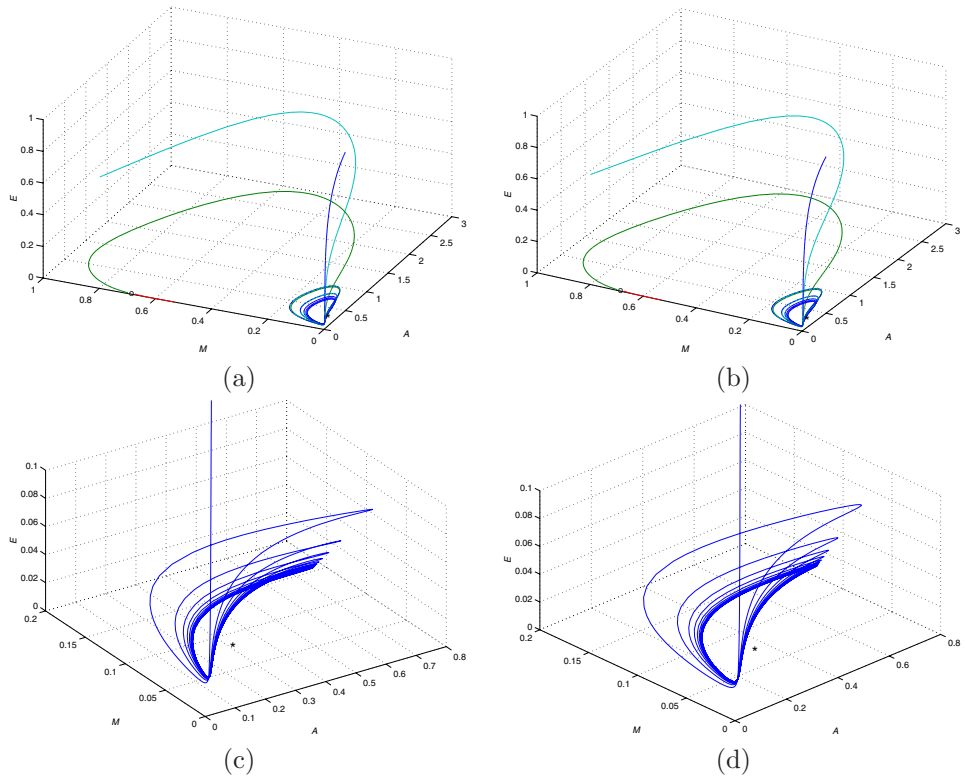


FIG. 6.1. *(color online). Two stereograms showing in* (a) *and* (b) *the limit cycle and location of the saddle point (marked ∘) and in* (c) *and* (d) *the limit cycle and its unstable diseased equilibrium (denoted by ∗). Both diagrams were made for the basic model with default parameter values but with beta-cell mass treated as a (constant) parameter.*

of the limit cycle oscillations. In (a) and (b), we show the position of the saddle node (close to the M-axis) with unstable manifolds in green and red. One branch of the unstable manifold (in red) flows towards the stable disease-free state, while the other branch (in green) spirals towards the limit cycle about the disease state. (The two-dimensional stable manifold is not indicated in this figure.) The limit cycle and two trajectories attracted to it are also shown. In (c) and (d), a zoomed-in view of the limit cycle is shown. The location of the (unstable spiral equilibrium) diseased state is indicated by a small star.

Figure 6.2(a)–(d) shows a sequence of diagrams that illustrates the bifurcations and dynamics described in the previous section. We show two-dimensional "cartoons" that give the overall picture (although our AME system is three-dimensional), since it is difficult to numerically simulate the precise parameter set that leads to the homoclinic connection and equally challenging to represent all stable and unstable manifolds in a three-dimensional plot. As shown in this figure, the origin (heavy dot labeled H for "healthy") retains its stability and is a local attractor in all cases, but its basin of attraction can vary greatly. In (a) and (b), a separatrix (one branch of the stable manifold of the saddle node S) defines the boundary between those states attracted to H and others that remain in the positive orthant. In (a), these other

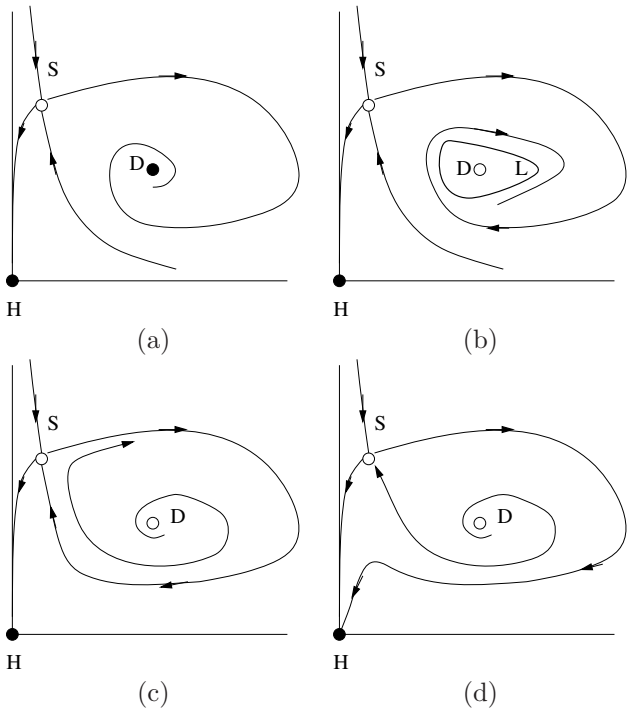

FIG. 6.2. *This sequence of four sketches illustrates the essential geometry of the dynamics and bifurcations. H: "healthy" state in which there are no circulating immune cells, D: diseased equilibrium; S: saddle node, L: stable limit cycle. Heavy dots indicate stable equilibria, and open dots indicate unstable ones. In* (a)*, an unstable manifold of S winds into the stable spiral at D. In* (b)*, just past a Hopf bifurcation, there is a stable limit cycle to which this manifold is attracted.* (c) *represents the homoclinic bifurcation. In* (d)*, the unstable manifold of S makes a detour past the unstable D, ending at H. The state H is always stable. However, the boundary of its basin of attraction is formed by the stable manifold of S. In* (d)*, every initial condition will eventually evolve towards the origin.*

points are attracted to the stable diseased state (heavy dot at D), whereas in (b), past a Hopf bifurcation, the limit cycle is attracting. A homoclinic connection (which exists for one specific set of values of the parameters) is illustrated in (c). In (d), states close to the unstable point D may take an "excursion" towards S but eventually arrive at H. In this case, all solutions of (5.1)–(5.3), except for a set of measure zero (on the stable manifold of the saddle node), would eventually converge to the disease-free state $(\bar{A}, \bar{M}, \bar{E}) = (0, 0, 0)$.

7. Parameter sensitivity. The hallmark of autoimmune diabetes in NOD mice is that many small perturbations and treatments can "cure" the disease, delay its onset, or prevent it from occurring. Thus, the actual (biological) system is sensitive to relatively small changes in essential parameters of the system. In order to explore the sensitivity of the model, we tested how increases and decreases in each of the parameters in (3.1)–(3.5) affect the dynamics. We used the values of parameters that generated Figure 4.2 as a basic set and varied each in turn by 10% up and down. The results are shown in Table B.2.

Recall that the original parameter set is consistent with a stable limit cycle for $B = 1$. In Table B.2, we note whether the dynamics obtained by a given parameter change has moved the system in the direction of the homoclinic ($\rightarrow$) or the Hopf bifurcation ($\leftarrow$) or, in some cases, beyond those bifurcations. (Arrows are indications of shifts along the type of bifurcation shown in Figure 5.1(a).) We also indicate the number of peaks observed between $t = 0$ and the time at which the homoclinic bifurcation occurs. It can be seen that changing some parameters (e.g., n, m, k_2, k_1 of the peptide-dependent response functions f_1, f_2) has a large effect on the number of cycles that occur, increasing the number of peaks up to 9–10. These parameters control the location of the "activation switch" and the switch in commitment to memory versus effector cells with respect to peptide level. The parameter β and the number of memory cells produced, 2^{m_1}, also has a dramatic effect on the behavior. Other variations, e.g., δ_M, a, ϵ, have a very minor effect.

It is interesting to note that certain slight parameter shifts place the system beyond the homoclinic bifurcation, leading to global stability of the origin (as in Figure 6.2(d)). This includes a 10% decrease in the rate of memory-cell reactivation, α, or memory-cell production, a, or a 10% increase in the peptide clearance rate, δ_p, or the effector T cell death rate, δ_E (entries in Table B.2 marked with S, $\rightarrow$). Making these adjustments takes the system out of the cyclic regime and restores global stability of the "healthy" state at the origin.

Here we venture to speculate on implications to the disease itself and possible treatments. One can envision medical interventions that are designed to affect one or another of the parameters mentioned above in patients with a known genetic tendency to autoimmunity. If any of these parameter change(s) could be made before beta-cell mass is destroyed, the immune attack could be resolved or prevented. Alternately, if cycles of circulating T cells are observed, treatments could be applied to knock the system out of its destructive cyclic regime, back to the baseline state. The most effective treatment would be one that targets any of the more sensitive parameters in our model. Because our model is fairly simplistic, it is premature to draw firm conclusions about optimal therapeutic strategies. However, studying parameter sensitivity and bifurcations of more detailed and more realistic models for this disease (or other autoimmune disorders) could possibly lead to new therapeutic strategies. Clearly, in the context of a mathematical model, one can also identify and possibly avoid unforeseen complications (e.g., the unstable limit cycle regime in Figure 5.1(b),

where the disease state regains stability in another range of the parameter(s)).

8. Other variants of the model. We considered several variants of the model that incorporated other features or relaxed certain assumptions. First, we considered a model in which memory cells are offspring (rather than sisters) of effector cells. (In that model, a function like f_2 represented the probability that an effector cell differentiates into a memory cell.) Similar behavior was obtained in a narrower range of parameters. As this scheme of differentiation is less widely accepted, here we omit the details.

The immune response has several inherent delays. After beta cells die, it takes around 8 hours to 1 day for their fragments to be collected, transported to the pancreatic lymph node, processed, and presented by APCs. Once T cells are activated, it take a further 2–3 days for proliferation and production of effector cells. This means that an immune response can take 4–6 days from the time of stimulus. We explored some of the effects of delay in the system by investigating variants of the model that had one or two delays. We found similar dynamics within a slightly shifted set of parameter regimes. Results were similar to figures previously displayed and here are omitted.

We briefly explored competition of various T-cell clones to determine how competition between different peptide-dependent cells could affect the dynamics. We found that similar clones tend to cycle together and that competition was not a major force in the cyclic dynamics. The details are omitted.

9. Experimental tests of the model. This model has been informed by previous theory [13, 14], supplemented by experimental observations. In turn, it suggests new experiments that can be used to verify or refute its conclusions.

First, the model predicts a specific sequence of events, with peaks in memory cells preceding peaks in activated T cells and preceding peaks in effector cells (as shown in Figure 4.2). Further, the model predicts that during these cycles, one should be able to observe cycles of apoptotic beta cells in the pancreas (since killing by effector cells occurs via apoptosis). If the presence or sequence of cell types follows some other trend, our model would have to be revised.

Second, the model predicts outcomes of specific interventions. For example, once NOD T-cell cycles are observed, poisoning some fraction of their macrophages by administering silica, a known poison for such cells (i.e., reducing the innate ability to clear dead beta-cell material and hence reducing δ_p) should decrease the amplitude of the cycles as well as the period of the cycles (see parameter sensitivity, Table B.2). A dose response of this "macrophage poison" versus dynamical behavior would show successively decreased cycle amplitude (see also Figure 5.1(a) for the dependence of cycle amplitude on $a_{15} = \delta_p$). Alternately, treatments that enhance macrophage clearance of apoptotic material (if possible) could, at sufficient dose, stop the cycles and retard the development of the disease. A number of similar interventions are predicted by parameter sensitivity. While we cannot expect that we have captured all NOD parameters accurately in this preliminary model, general trends "towards" or "away from" the Hopf or homoclinic bifurcation predicted by the various changes in basic parameters should be indicative of the accuracy or fallibility of the assumptions on which the model is based. Some (but not all of these) are experimentally feasible. Future work with experimental colleagues will address such issues in an experimental setting.

10. Discussion. Our main conclusion in this paper is that cyclic dynamics can arise spontaneously in the immune response leading up to T1D, at least under conditions typical of the susceptible (NOD) mice. This fact was conjectured in [14] as a possible outcome of the interplay between the effector T cells killing the insulin-producing beta cells and the feedback from self-antigen produced when those cells are killed. We confirmed this conclusion by extending the model in [14] to include the death of beta cells and the accumulation of the antigen that results. Our cyclic dynamics (Figure 4.2) are similar to the experimentally observed cycles (Figure 1.1) in three important ways: (1) it shows cycles of increasing amplitudes; (2) the interpeak time length increases slightly; and (3) the cycles stop, and the levels of T cells drop around 16–18 weeks. (At this point, the mouse becomes diabetic in the experimental system.) This behavior was obtained in a regime of parameters that is based mainly on values assembled from the experimental literature in [14].

We showed that one explanation for these oscillations, illustrated by our model, is as follows: beta-cell killing produces large quantities of self-antigen peptide, expanding the population of effector cells at the expense of memory cells. This creates a gap in self-renewal of the T cells that leads to a pause in their reproduction and reduced effector levels for killing. After a suitable interval, when peptide is cleared, the memory-cell production is reinstated, and the cycle begins once more. The gradual loss of beta-cell mass limits the number of cycles that can occur (to three in the case of NOD mice). The cyclic dynamics are found for a wide range of parameter values, provided the peptide-dependent functions that control T-cell activation, f_1, and memory-cell production, f_2, ramp up (respectively, down) as peptide level increases. Since the immune system is highly complex, with many feedbacks between cells, chemicals, and tissues, it is possible that other explanations for cycles can be equally compelling. For example, recent work by an experimental collaborator (P. Santamaria, U. Calgary) has focused on the role of regulatory T cells and their cytokine IL-2. Positive and negative feedback that is emerging in these experimental investigations will provide future opportunities for modeling and analysis using the tools of nonlinear dynamics.

The main contribution of our study is to explain the mechanism underlying the observed cycles by studying the nonlinear dynamics of the extended model and uncovering its bifurcations. This aspect of our work is particularly apt for readers of SIAM, some of whom may not yet be aware of rich dynamics in immunology. We showed that all three of the observations listed above can be explained as the gradual shift of a parameter (the mass of beta cells remaining) during the course of the immune attack by effector T cells. This gradual shift moves the system from a regime in which there is a stable limit cycle towards a homoclinic bifurcation. The amplitude of the limit cycle expands very quickly just before this bifurcation, and its period increases (theoretically up to infinity) at the homoclinic connection itself. Beyond that, all points are attracted towards the origin; i.e., the levels of T cells drop.

We found that the number of peaks that occur in the model shifts when certain parameters are changed (by 10%). The most sensitive parameters are those appearing in the functions f_1 and f_2, but it is unlikely that these are easy to manipulate in an experimental system. As our model is the simplest possible variant of [14] that produces cycles, this sensitivity to parameters may be a price paid for omitting other regulatory features of the immune system. On the other hand, the sensitivity to parameters also suggests numerous experimental tests of our predictions that could, in principle, validate or falsify the model. Such tests will be under consideration in

future work on this problem. In the original model of [14], competition between various clones of T cells for sites on APCs was considered as an important determinant of dynamics. Here, in preliminary investigations of competition of two clones, we found that clones tended to cycle synchronously. Future work will also address the effect of competition in greater detail.

Our model did not address any of the spatial or compartmental aspects of the immune response. For example, we also did not consider the details of trafficking of T cells between blood, lymph nodes, and tissue. Some of the detailed movement and interactions of T cells with dendritic cells in lymph nodes is currently being modeled in conjunction with experimental observations by the group of R. J. de Boer and A. F. M. Marée (Utrecht, The Netherlands). These insights will inform future models in immunology, including extended models of autoimmune diabetes.

Finally, our model suggests that there are two distinct outcomes in an autoimmune attack typical of T1D: (1) The immune attack clearly subsides once the beta cells have been depleted, but here the outcome is full-blown diabetes. This explains observations in NOD mice, but, therapeutically, it is an outcome to be prevented. (2) More intriguing, any parameter change that shifts the system beyond its homoclinic bifurcation would also end the immune attack. This can happen through the process of "clonal exhaustion"; i.e, so much peptide is presented that memory-cell production is turned off completely. It could also happen through arrest of activation, where so little peptide is presented that T cells no longer become activated. In either case, if this happens before a significant fraction of the beta cells have been killed, it could provide a "cure" that resolves the autoimmunity without diabetes. Here we have hinted at several parameters that could have precisely this type of effect. This suggests that studying more detailed and hence more realistic variants of this model could indicate possible therapeutic strategies by highlighting which parameters give promising leads for medical targets.

Appendix A. Estimation of parameter values. We explain our procedure for estimating parameters below and summarize the values we used in Table B.1.

A.1. Cell turnover rates. The death rate of memory cells is estimated as $\delta_M = 0.01$ day^{-1} versus $\delta_E = 0.3$ day^{-1} for effector cells. We here assumed that activated cells have a relatively low death rate, as most are converted into differentiated cells. Consequently, we assumed that $\delta_A \approx 0.02$ day^{-1}.

A.2. Cell-division rates and numbers. We approximated an 8-hour cell cycle for the immune cells and thereby obtained $\beta \approx 1$–6 day^{-1}. The number of memory and effector cells produced per activated T cell is 0–8 versus 60, respectively, according to [14], leading to values for the factors 2^{m_i}.

A.3. Circulating cell levels. According to [14], around 1–10 naive T cells produced by the thymus per day will have the correct specificity. Consequently, $\sigma \approx$ 1–10 cells day^{-1}. To then determine the competition parameter, ϵ, we first considered the possibility of a QSS for activated T cells of the form $\sigma - \delta_A A - \epsilon A^2 = 0$. We found that this cannot be a correct approximation, because the reactivation of memory cells plays a much greater role in sustaining the level of A than the (limited) entry of new naive T cells from the thymus.

In our subsequent approach, we approximated $M \approx (\beta 2^{m_1} f_2/\delta_M)A \approx 10^4$ circulating memory cells and $E \approx (\beta 2^{m_2}(1-f_2)/\delta_E)A \approx 10^6$ circulating effector cells. The first of these implies that $\beta f_2 A \approx 10$, whereas the second implies that $\beta(1-f_2)A \approx 5 \times 10^3$. These approximations lead to $f_2 \approx 0.002$, and $A \approx 1 - 3 \times 10^3$.

Now considering the situation at a high-peptide level, near the peak of activated T-cell levels, we have $dA/dt \approx 0$, i.e., $\sigma + \alpha M f_1 - (\beta + \delta_A)A - \epsilon A^2 \approx 0$. The relative magnitudes of terms in this equation are as follows: σ is very small and can be neglected in the high-peptide scenario. If $\alpha \approx 1 - 5$ day^{-1} (which means that on average, a memory cell takes a few hours to be reactivated), and $f_1 \approx 1$ at high peptide, then $\alpha M f_1 \approx 1{-}5{\times}10^4$. From the above estimates, $(\beta{+}\delta_A)A \approx \beta A \approx 5{\times}10^3$ is of lower order, and $A^2 \approx 1 - 4 \times 10^6$. The balance is mainly between the terms $\alpha M f_1$ and ϵA^2. We can use these figures to estimate the size of the competition parameter, ϵ, from

$$\epsilon \approx \frac{\alpha M f_1}{A^2} \approx \frac{1 - 5 \times 10^4}{1 - 4 \times 10^6} \approx 1 - 5 \times 10^{-2}.$$

The units of ϵ are day^{-1}cell^{-1}.

A.4. Peptide and beta-cell levels. Because peptide level is not directly observed experimentally, its level in the model is on a relative, rather than absolute, scale. The important relation is the relative magnitude of k_1, k_2, the parameters that represent the level of peptide at which memory-cell production falls off and T-cell activation turns on, respectively. We arbitrarily chose $k_2 = 1$ and $k_1 = 2$. This means that a reasonable scale of peptide level is 0–10 "peptide units." Since peptide time scale is fast, and the peptide variable is assumed to be on QSS, only the ratio of the turnover rate, δ_p, and the production rate, R, of the peptide influence the dynamics. Based on the estimated levels of circulating effector T cells, we used $R \approx 10^{-5}$ per cell per day and $\delta_p = 1$ per day to give the QSS value of peptide in the range of 0–10. We also use a relative scale for the level of remaining beta cells; i.e., B represents the fraction of beta cells still remaining, and so $0 \le B \le 1$.

The removal of peptide by macrophages, by diffusion, and by other influences is assumed to be in the range of $\delta_p \approx 1$day^{-1}. When effector cell levels are high, $E \approx 10^6$ cells, this leads to the approximation $p \approx 10 \approx RBE/\delta_4 \approx R \times 10^6$. This leads to an estimate $R \approx 10^{-5}$ peptide units day^{-1}cell^{-1}.

A.5. Typical values of variables. The results of above ballpark estimates lead to the following ranges of the variables concerned:

$$A \approx 1 - 2 \times 10^3, \quad M \approx 1 - 5 \times 10^4, \quad E \approx 1 - 6 \times 10^6, \quad p \approx 1 - 10, \quad B \approx 1.$$

The populations of the three types of T cells differ by many orders of magnitude. We therefore scaled each variable in terms of some power of 10 for convenient graphics. The scaling considerations are discussed in the next section.

Appendix B. Scaling the equations. Let $A = A^*\bar{A}$, $M = M^*\bar{M}$, $E = E^*\bar{E}$, etc., where stars denote numerical values and overbars denote quantities carrying units. We keep time in units of days; i.e., time is not scaled. Equations (3.1)–(3.7) can be rewritten as follows:

$$\frac{dA^*}{dt} = \left(\frac{\sigma}{\bar{A}} + \left(\frac{\alpha\bar{M}}{\bar{A}}\right) M^*\right) f_1(p) - (\beta + \delta_A)A^* - (\epsilon\bar{A})(A^*)^2, \tag{B.1}$$

$$\frac{dM^*}{dt} = \left(\beta 2^{m_1}\frac{\bar{A}}{\bar{M}}\right) f_2(p)A^* - f_1(p)\alpha M^* - \delta_M M^*, \tag{B.2}$$

$$\frac{dE^*}{dt} = \left(\beta 2^{m_2}\frac{\bar{A}}{\bar{E}}\right)(1 - f_2(p))A^* - \delta_E E^*, \tag{B.3}$$

$$\frac{dB^*}{dt} = -(\kappa \bar{E}) E^* B^*, \tag{B.4}$$

$$\text{QSS}: \qquad p = \left(\frac{R \bar{E} \bar{B}}{\delta_p} \right) E^* B^*. \tag{B.5}$$

Since peptide is already in arbitrary units, we did not rescale the peptide or the functions f_1, f_2. Dropping the *'s, we thus obtained a new system of (scaled) equations,

$$\frac{dA}{dt} = (a_6 + a_7 M)\, f_1(p) - a_8 A - a_9 A^2, \tag{B.6}$$

$$\frac{dM}{dt} = a_{10} f_2(p) A - f_1(p) a_7 a_{16} M - a_{11} M, \tag{B.7}$$

$$\frac{dE}{dt} = a_{12}(1 - f_2(p)) A - a_{13} E, \tag{B.8}$$

$$\frac{dB}{dt} = -a_{17} E B, \tag{B.9}$$

$$\text{QSS}: \qquad p = (a_{14}/a_{15}) E B, \tag{B.10}$$

where the new parameters so defined are as follows:

TABLE B.1

Default "NOD mouse" parameter values used to simulate the model. See Appendix A *for a description of how these values were estimated.*

Par.	Meaning	Default value	Units	Ref.
σ	influx naive T cells from thymus	1–10	cell day^{-1}	[3, 14]
α	rate of production of A per M	1–5	day^{-1}	estimated
β	rate of cell division	1–6	day^{-1}	typical
δ_A	death rate, activated T cells	≈0.01	day^{-1}	[22, 7]
δ_M	death rate, memory T cells	≈0.01	day^{-1}	[22, 7, 14]
δ_E	death rate, effector T cells	0.3	day^{-1}	[5, 14]
δ_p	peptide turnover rate	0-1	day^{-1}	estimated
ϵ	T-cell competition parameter	$1 - 5 \times 10^{-2}$	(cell day)$^{-1}$	estimated
k_1	peptide level for $\frac{1}{2}$ max activation	2	peptide units	arbitrary
k_2	peptide level for $\frac{1}{2}$ max memory cells	1	peptide units	arbitrary
m	Hill coeff. for memory-cell production	2	-	[14]
n	Hill coeff. for T cell activation	3	-	[14]
2^{m_1}	maximum number of memory cells produced per proliferating T cell	8	-	[27, 20, 25]
2^{m_2}	number of effector cells produced per proliferating T cell	60	-	[20, 25]
a	maximal fraction of memory cells produced	< 1	-	fitted
R	peptide accumulation rate	10^{-5}	day^{-1}cell^{-1}	estimated
κ	beta-cell killing per effector T cell	0.14×10^{-6}	day^{-1}cell^{-1}	fitted

TABLE B.2

Parameter sensitivity. The default value of each (scaled) parameter is shown, and the effect of a 10% *increase and decrease is recorded. (See Appendix* C *for the definition of scaled parameters.) Original parameter values produce a stable limit cycle (i.e., dynamics between the Hopf and the homoclinic bifurcations).* $\rightarrow$ *denotes a shift towards the homoclinic bifurcation,* $\leftarrow$ *denotes a shift towards the Hopf bifurcation, or even beyond it, i.e., toward the stable steady state.* S *denotes the return to healthy state, and* P *signifies how many peaks (cycles) are seen before the homoclinic bifurcation occurs.* NC *means little or no change.*

Scaled parameter	Original parameter	Default value	Increase +10%	Decrease −10%
a_1	n	2	$S, \rightarrow$	10P, $\leftarrow$
a_2	k_1	2	S, $\rightarrow$	10P, $\leftarrow$
a_3	m	3	S, $\rightarrow$	9P, $\leftarrow$
a_4	a	0.7	NC, 3P	S, $\rightarrow$

a_6	σ	0.02	4P$\leftarrow$	S, $\rightarrow$
a_7	α	20	7P$\leftarrow$	S, $\rightarrow$
a_8	$\beta + \delta_A$	1	S$\rightarrow$	9P, $\leftarrow$
a_9	ϵ	1	NC, 3P	NC, 3P
a_{10}	$\beta 2^{m_1}$	1	8P$\leftarrow$	S, $\rightarrow$
a_{11}	δ_M	0.01	NC, 3P	NC,3P
a_{12}	$\beta 2^{m_2}$	0.1	4P$\leftarrow$	S, $\rightarrow$
a_{13}	δ_E	0.3	S$\rightarrow$	7P, $\leftarrow$
a_{14}	R	50	4P$\leftarrow$	S, $\rightarrow$
a_{15}	δ_p	1	S, $\rightarrow$	4P, $\leftarrow$
a_{16}	scale	0.1	S, $\rightarrow$	5P, $\leftarrow$
a_{17}	κ	0.14	1P, $\rightarrow$	4P, $\leftarrow$

$$a_6 = \frac{\sigma}{\bar{A}}, \quad a_7 = \frac{\alpha \bar{M}}{\bar{A}}, \quad a_8 = \beta + \delta_A, \quad a_9 = \epsilon \bar{A},$$

$$a_{10} = \beta 2^{m_1} \frac{\bar{A}}{\bar{M}}, \quad a_{11} = \delta_M, \quad a_{16} = \frac{\bar{A}}{\bar{M}},$$

$$a_{12} = \beta 2^{m_2} \frac{\bar{A}}{\bar{E}}, \quad a_{13} = \delta_E, \quad a_{17} = \kappa \bar{E}, \quad a_{14} = R \bar{E} \bar{B}, \quad a_{15} = \delta_p.$$

The original variables, A, M, E, differ by six orders of magnitude. We therefore selected a scaling of the main variables in various powers of 10, so as to display all results on a common coordinate system within the range of 1–10 units. To do so, we scaled variables by selecting the following reference scales:

$$\bar{A} = 10^3, \quad \bar{M} = 10^4, \quad \bar{E} = 10^6, \quad \bar{p} = 10, \quad \bar{B} = 1.$$

Appendix C. XPP code. Below is a typical file used for figures in this paper.

```
#XPP file for simulating AME system
#y1=A, y2=M, y3=E, y4=p, y5=B

y4 = a14*y3*y5/a15
f1 = y4^a1/(a2^a1+y4^a1)
f2 = a4*a5^a3/(a5^a3+y4^a3)
y1' = f1*(a6+a7*y2)-a8*y1-a9*y1^2
y2'= a10*f2*y1-f1*a16*a7*y2-a11*y2

Appendix D. List of abbreviations. We used the following abbreviations.

APC: antigen-presenting cell
CTL: cytotoxic T-lymphocyte
IGRP: islet-specific glucose-6-phosphatase catalytic subunit-related protein
MHC: major histocompatibility complex
NOD: nonobese diabetic mouse
ODE: ordinary differential equation
T1D: type 1 diabetes
TCR: T-cell receptor
QSS: quasi-steady state

Acknowledgments. We thank A. F. M. Marée, Eric Cytrynbaum, and members of Beta-CAAN (P. Santamaria, D. Finegood, B. Verchere, J. Dutz, D. Coombs, A. Khadra) for helpful discussions and comments.

WAVE SCATTERING AT THE SEA-ICE/ICE-SHELF TRANSITION WITH OTHER APPLICATIONS*

TIMOTHY D. WILLIAMS† AND VERNON A. SQUIRE†

Abstract. We present a mathematical model that describes how ice-coupled (flexural-gravity) waves traveling beneath a uniform, floating sea-ice sheet, defined over $(-\infty, 0)$, propagate into a second ice sheet (l, ∞) of different thickness by way of an arbitrarily defined transition region of finite width $(0, l)$. Each ice sheet is represented as an Euler–Bernoulli thin plate with a prescribed thickness and material properties, either or both of which vary across the transition. The most familiar application of this geometry is to sea-ice abutting an ice-shelf—a common occurrence found in the waters around Antarctica and parts of the Arctic or to sea-ice skirting *sikussak*—the band of extremely thick coastal fast ice that can form when local ice is sheltered from destructive storms. Another application is to breakwaters, and this is also discussed. By using Green's theorem two coupled integral equations are derived: one defined over $(0, l)$ and the second of the Wiener–Hopf type, defined over (l, ∞). The latter is solved analytically, allowing the integral equations to be decoupled and the first equation to be solved numerically. Results are presented for the geophysical and engineering examples referred to above.

Key words. Wiener–Hopf method, scattering, sea-ice/ice-shelf transition, flexible breakwaters

1. Introduction.

In a recent paper [19] the authors consider a related geophysical problem, namely, how flexural-gravity waves propagating at the plate/water interface move between three floating elastic plates of different uniform thickness. That work enables several phenomena commonly observed in the polar regions to be modeled, e.g., wave propagation in the marginal ice zone—exploiting a feature of the model that allows any of the plate thicknesses to be zero, and wave scattering by open or refrozen leads and the abrupt thickness changes encountered at the edges of floes. It does not permit the two exterior sheets, defined over $(-\infty, 0)$ and (l, ∞), to be joined smoothly (or otherwise) through a transition region $(0, l)$ of prescribed variable thickness, as the thickness in each outer region is required to be constant. In this paper we relax that requirement, thereby expanding the range of both geophysical and marine engineering problems that can be modeled.

Of particular interest is what occurs when waves impinge on an ice-shelf of significantly greater thickness than the adjoining sea-ice sheet via a transition ramp that may stretch for tens or hundreds of meters or, in some cases, several kilometers. While it might be reasonably assumed that a typical ice-shelf would resist waves, in the Southern Ocean waves can be very long because of the immense fetches involved, and the passage of these waves is effectively unhindered by the sea-ice encountered en route. Waves of a somewhat shorter period—but still of sizable wavelength can also reach the transition depending on the nature of the sea-ice they encounter during their journey, as a cover of sea-ice acts to "attenuate" such waves through

†Department of Mathematics and Statistics, University of Otago, P.O. Box 56, Dunedin, New Zealand (vernon.squire@otago.ac.nz, twilliams@maths.otago.ac.nz).

hysteresis, scattering, mechanical impacts and fracture, and hydrodynamical turbulence in the water column. Given sufficient amplitude ice-coupled waves of this type have the capacity to destroy an ice-shelf; this is a motivating interest of the current study.

Taken in the context of global warming this is of immediate topical significance, as temporal adjustments in pack ice serve as a proxy of climate change [14, 16, 4] and, especially in the vicinity of the Antarctic peninsula, there has been an increased incidence of breakup of ice-shelves with a concomitant recession in their fronts [20]. This paper addresses the complex relationship between an ice-shelf and its sea-ice shield in the context of how incident waves are scattered at the transition and, accordingly, are or are not allowed to progress into the shelf with reduced amplitude. It is found that reflection coefficients are oscillatory but that, because conservation of energy acts to suppress their fine structure, the amplitude transmission coefficient curves are less complicated and with increasing period simply decrease slightly from their low period values to a minimum before increasing monotonically towards perfect transmission at long periods (see Figure 7). In principle, the magnitudes of the waves within the ice-shelf, while reduced from their sea-ice amplitude, are still sufficient to cause the ice-shelf to flex and possibly to fracture and create an iceberg, although in practice, because the wavelength in the ice-shelf is much longer than in the neighbouring sea-ice, the associated strains will be modest. It is also possible that the finite geometry of the ice-shelf will cause certain wave modes to be favored at the expense of others, i.e., resonance [7, 15], but this is not modeled here as we have assumed the ice-shelf is semi-infinite in extent (l, ∞).

2. Equations and boundary conditions. Figure 1 illustrates schematically the situation that we are modeling: A plane wave with unit amplitude and radial frequency ω travels from the left-hand region through a central transition—where it is partially reflected and partially transmitted, into the right-hand region. The plates to the left and right are, respectively, of constant thickness h_0 and h_2, while the thickness across the transition varies according to $h_1(x)$. Throughout the paper

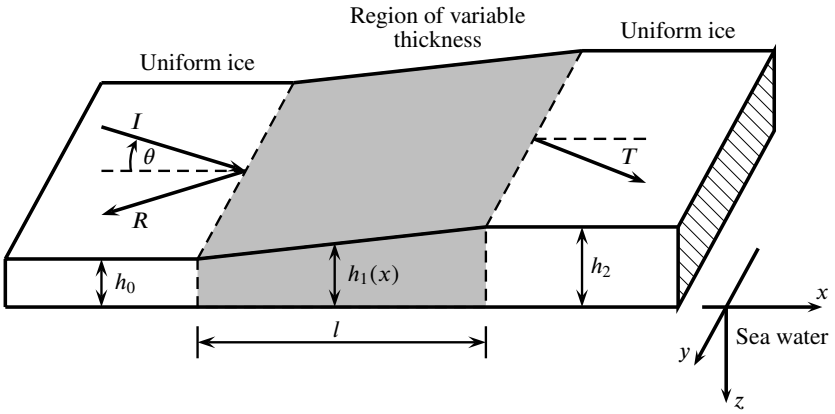

FIG. 1. *A plane flexural-gravity wave arrives from the left-hand region at an angle θ to normal incidence and is partially reflected and partially transmitted through a central transition of width l into the region beneath the right-hand plate. The thicknesses of the three plates are denoted by $h_0, h_1(x), h_2$, as shown, and each is modeled using a Euler–Bernoulli thin plate. Submergence is neglected, so the bottom of each plate is taken to be in the $z = 0$ plane. The left-hand edge of the central plate is located at $x = 0$ (the coordinate axes are displaced to the right to avoid clutter), and the sea water has a finite depth of H.*

subscripts of $j = 0$, 1, or 2 will be used to denote quantities referring to the different plates in the same way that they are in the h_j.

The amplitudes of the reflected and transmitted waves are denoted by R and T, respectively; hereafter referred to as the reflection and transmission coefficients. The determination of their values is the main purpose of our solution.

If we assume that the sea water beneath the ice is inviscid and of constant density and that the fluid flow is irrotational, then there exists a potential function $\Phi(x, y, z, t)$ such that the velocity of a fluid particle is given by $\boldsymbol{\nabla}\Phi$. Since the forcing from the incident wave is periodic in time and since the geometry of the problem is shift-invariant in the y direction, we assume that Φ has the following form:

$$\Phi(x, y, z, t) = \mathrm{Re}\big[\phi(x, z)e^{i(\alpha_y y - \omega t)}\big]. \tag{2.1}$$

This reduces the dimension of the problem from four to two. The wave number α_y will be related to the incoming wave's angle of incidence.

For each plate, define the flexural rigidity D_j, the mass per unit area m_j, and the characteristic length and time L_j and τ_j, as follows:

$$D_j = \frac{E_j h_j^3}{12(1-\nu_j)^2}, \quad m_j = \rho_j h_j, \quad L_j = \sqrt[4]{\frac{D_j}{\rho g}}, \quad \tau_j = \sqrt{\frac{L_j}{g}}.$$

E_j, ν_j, and ρ_j are the Young's modulus, Poisson's ratio, and density of the plate in the j^{th} region, respectively, while ρ is the water density and g is the acceleration due to gravity.

We now denote by the index m the region with the largest flexural rigidity and define the natural length that we will nondimensionalize lengths with respect to, L, as $L = (D_m/\rho\omega^2)^{1/5}$. If we also scale times by a factor of τ_m, then we have

$$(\bar{x}, \bar{y}, \bar{z}) = (x, y, z)/L, \quad \bar{t} = t/\tau_m, \quad \bar{\phi}(\bar{x}, \bar{z}) = \frac{\tau_m}{L^2}\phi(x, z), \quad \bar{\alpha}_y = \alpha_y L.$$

The other two significant lengths, l and H, are also scaled by L, so that $\bar{l} = l/L$ and $\overline{H} = H/L$. Further quantities that we will refer to are

$$\overline{D}_j = D_j/D_m, \quad \overline{m}_j = m_j/m_m, \quad \lambda = \frac{g}{L\omega^2} - i\varepsilon, \quad \mu = \frac{m_m}{\rho L},$$

where ε is an infinitesimal quantity introduced to force the reflected and transmitted waves to decay exponentially as they travel away from the central ice strip. The limit as it becomes zero will be taken once the solution has been completed.

Dropping the overbars to avoid clutter, $\phi(x, z)$ will satisfy the following system of equations:

$$(\nabla^2 - \alpha_y^2)\phi(x, z) = 0, \tag{2.2a}$$

$$\boldsymbol{\mathcal{L}}(x, \partial_x)\phi_z(x, 0) + \phi(x, 0) = 0, \tag{2.2b}$$

$$\phi_x(x^+, z) - \phi_x(x^-, z) = \phi(x^+, z) - \phi(x^-, z) = 0, \tag{2.2c}$$

$$\phi_z(x, H) = 0, \tag{2.2d}$$

where $\boldsymbol{\mathcal{L}}(x, \partial_x) = (\partial_x^2 - \alpha_y^2)D(x)(\partial_x^2 - \alpha_y^2) + (1-\nu)\alpha_y^2 D''(x) + \lambda - m(x)\mu$. The function $D(x)$ is defined piecewise, as follows:

$$D(x) = \begin{cases} D_0 & \text{for } x < 0, \\ D_1(x) & \text{for } 0 < x < l, \\ D_2 & \text{for } x > l, \end{cases}$$

and $m(x)$ is defined analogously in terms of the m_j.

As well as applying the above equations and the required radiation conditions (see section 3.2 below), the full solution must also satisfy some conditions at the two edges $x_e = 0$ and $x_e = l$. If two adjacent plates are joined or frozen together at a given edge, then we must apply what we shall subsequently call the fixed edge conditions:

$$\phi_z(x_e^+, 0) = \phi_z(x_e^-, 0), \tag{2.3a}$$

$$\phi_{zx}(x_e^+, 0) = \phi_{zx}(x_e^-, 0), \tag{2.3b}$$

$$\boldsymbol{\mathcal{M}}(x_e^+, \partial_x)\phi_z(x_e^+, 0) = \boldsymbol{\mathcal{M}}(x_e^-, \partial_x)\phi_z(x_e^-, 0), \tag{2.3c}$$

$$\boldsymbol{\mathcal{S}}(x_e^+, \partial_x)\phi_z(x_e^+, 0) = \boldsymbol{\mathcal{S}}(x_e^-, \partial_x)\phi_z(x_e^-, 0), \tag{2.3d}$$

where

$$\begin{aligned}\boldsymbol{\mathcal{M}}(x, \partial_x) &= D(x)\boldsymbol{\mathcal{L}}_-(\partial_x),\\ \boldsymbol{\mathcal{S}}(x, \partial_x) &= D(x)\boldsymbol{\mathcal{L}}_+(\partial_x) + D'(x)\boldsymbol{\mathcal{L}}_-(\partial_x),\\ \boldsymbol{\mathcal{L}}_\pm(\partial_x) &= (\partial_x^2 - \alpha_y^2) \mp (1-\nu)\alpha_y^2.\end{aligned}$$

If, on the other hand, the two plates are free to move independently, we must apply the free edge conditions:

$$\boldsymbol{\mathcal{M}}(x_e^\pm, \partial_x)\phi_z(x_e^\pm, 0) = 0, \tag{2.4a}$$

$$\boldsymbol{\mathcal{S}}(x_e^\pm, \partial_x)\phi_z(x_e^\pm, 0) = 0. \tag{2.4b}$$

Both sets of conditions imply that energy is conserved at each edge (i.e., no translational or rotational work is done by any of the edges). Note that even if the free edge conditions (2.4) are applied, (2.3c) and (2.3d) are still satisfied.

3. Solution method. To begin we use Green's theorem to derive a pair of coupled IEs (integral equations). The first depends on $\phi_z(x, 0)$ over the finite interval $(0, l)$, and the second is an integral of the Wiener–Hopf type [13] over the semi-infinite interval (l, ∞). The latter IE may be solved analytically using the Wiener–Hopf technique, allowing the two IEs to be decoupled. The IE over $(0, l)$ may then be solved numerically and, once the appropriate edge conditions have been applied, R and T can be calculated.

3.1. Green's function. We use a Green's function that satisfies the following set of equations:

$$\left(\partial_\xi^2 + \partial_\zeta^2 - \alpha_y^2\right)G(x-\xi, z, \zeta) = \delta(x-\xi, z-\zeta), \tag{3.1a}$$

$$\boldsymbol{\mathcal{L}}_0(\partial_\xi)G_\zeta(x-\xi, z, 0) + G(x-\xi, z, 0) = 0, \tag{3.1b}$$

$$G_\zeta(x-\xi, z, H) = 0, \tag{3.1c}$$

where $\boldsymbol{\mathcal{L}}_j(\partial_x) = D_j(\partial_x^2 - \alpha_y^2)^2 + \lambda - m_j\mu$ $(j = 0, 2)$.

This Green's function depends on the dispersion function for the left-hand region $f_0(\gamma)$, where $f_j(\gamma) = \coth(\gamma H)/\gamma - \Lambda_j(\gamma)$, $\Lambda_j(\gamma) = \boldsymbol{\mathcal{L}}_j(i\alpha) = D_j\gamma^4 + \lambda - m_j\mu$ $(j = 0, 2)$, and $\gamma(\alpha) = (\alpha^2 + \alpha_y^2)^{1/2}$. G is presented in [5] in terms of its Fourier transform with respect to $x - \xi$, $\hat{G}(\alpha, z, \zeta)$, which is given by

$$\hat{G}(\alpha, z, \zeta) = \frac{1}{2\pi}\int_{-\infty}^{\infty} G(x-\xi, z, \zeta)e^{i\alpha(x-\xi)}d(x-\xi) = \chi(z_-, \gamma)\frac{\varphi(z_+, \gamma)}{f_0(\gamma)}, \tag{3.2}$$

where $z_+ = \max\{z, \zeta\}$, $z_- = \min\{z, \zeta\}$, and

$$\chi(z,\gamma) = \frac{\Lambda_1(\gamma)\gamma\cosh(\gamma z) - \sinh(\gamma z)}{\gamma^2 \tanh(\gamma H)}, \quad \varphi(z,\gamma) = \frac{\cosh\gamma(z-H)}{\cosh(\gamma H)}.$$

The derivative of G that is most relevant to this problem is $G_{z\zeta}(x-\xi,0,0)$, which we write as $g(x-\xi)$. It is given by

$$g(x-\xi) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{1}{f_0(\gamma)} e^{-i\alpha(x-\xi)} d\alpha = i \sum_{\alpha\in S_0} A_0(\alpha) e^{i\alpha|x-\xi|}, \tag{3.3}$$

where, for $j = 0, 2$, $S_j = \{\alpha \,|\, f_j(\gamma) = 0 \ \&\ \mathrm{Im}(\alpha) > 0\}$ and

$$A_j(\alpha) = \gamma/\alpha f'(\gamma) = -\big(\gamma^2/\alpha\big)\big/\big(H(\Lambda_j^2(\gamma)\gamma^2 - 1) + 5D_j\gamma^4 + \lambda - m_j\mu\big).$$

In the limit as ε becomes zero in the definition of λ, the roots γ of each dispersion relation $f_j(\gamma) = 0$ are distributed throughout the complex plane as illustrated by Fox and Squire [6]. There is one positive real root that we shall label γ_j, a complex conjugate pair in the right-hand half-plane, an infinity of pure imaginary roots in the upper half-plane, and the negatives of the previously mentioned roots. The effect of the ε on the location of the roots is to produce an infinitesimal counterclockwise rotation. In particular, each γ_j is moved slightly off the real line into the upper half-plane.

The elements of each set S_j are given by $\alpha = \sqrt{\gamma^2 - \alpha_y^2}$, taking the square root from the upper half-plane. If $\varepsilon = 0$ and $\alpha_y < \gamma_j$, S_j also contains a real root α_j that moves into the upper half-plane as ε is increased. This forces the sum in (3.3) to decay exponentially as $|x-\xi| \to \infty$. The other members of S_j are two complex roots with the same imaginary parts and an infinity of pure imaginary roots.

If $\alpha_y < \gamma_0$, then $\alpha_y = \gamma_0 \sin\theta$, where θ is the angle of incidence. If $\alpha_y \geq \gamma_0$, then no propagating waves can exist in the left-hand region—in that case waves may travel parallel to the central transition but decay exponentially with distance in the perpendicular direction [5].

One further property of g that we will need to be aware of later is that it has a delta function type singularity in its fourth derivative. This can be seen by noting that

$$\frac{\Lambda_0(\gamma)}{f_0(\gamma)} = -1 + \frac{\coth\gamma H}{\gamma f_0(\gamma)}, \tag{3.4}$$

which is the Fourier transform of the equation

$$\boldsymbol{\mathcal{L}}_0(\partial_x) g(x) = -\delta(x) - G_\zeta(x,0,0). \tag{3.5}$$

3.2. Green's theorem. The radiation conditions alluded to above require that in the limit as $\varepsilon \to 0$ the potential corresponds to an incident wave arriving from the left and being either reflected or transmitted, i.e.,

$$\phi(x,z) \sim \begin{cases} \big(e^{i\alpha_0 x} + Re^{-i\alpha_0 x}\big)\varphi_0(z) & \text{as } x \to -\infty, \\ Te^{i\alpha_2 x}\varphi_2(z) & \text{as } x \to \infty, \end{cases} \tag{3.6}$$

where $\varphi_j(z) = \varphi(z, \gamma_j)$ for $j = 0, 1, 2$.

For $\varepsilon > 0$, $|\phi|$ will become infinite as $x \to -\infty$ due to the incident wave potential $\phi_0(x,z) = e^{i\alpha_0 x}\varphi_0(z)$. To circumvent this we solve for the function $\psi(x,z) = \phi(x,z) - \phi_0(x,z)$ instead, which decays exponentially as $|x| \to \infty$.

We begin the solution by using Green's theorem to derive a pair of coupled IEs. Using (2.2) and (3.1), ψ can be written

$$\psi(x,z) = \iint_\Omega \big(\nabla^2_{\xi\zeta} G\psi - G\nabla^2_{\xi\zeta}\psi\big)\,d\xi\,d\zeta = \oint_{\partial\Omega} \big(\partial_n G - G\partial_n\psi\big)\,ds \tag{3.7a}$$

$$= -\int_{-\infty}^{\infty} \big(G_\zeta(x-\xi,z,0)\psi(\xi,0) - G(x-\xi,z,0)\psi_z(\xi,0)\big)\,d\xi, \tag{3.7b}$$

where Ω is the fluid region, $\{\,(\xi,\zeta)\,|\,-\infty < \xi < \infty \;\&\; 0 < \zeta < H\}$, $\partial\Omega$ is the positively oriented boundary of Ω, s is the arc length as we travel around $\partial\Omega$, and ∂_n is the derivative with respect to the outward normal to $\partial\Omega$. (3.7b) follows from (3.7a) because the exponential decay of G and ψ as $|\xi| \to \infty$, along with the sea floor conditions (2.2d) and (3.1c), forces the other line integrals to vanish. If we eliminate G and ψ from (3.7b) using (2.2b) and (3.1b), integrate by parts, and simplify the resulting expression, we can write ψ entirely in terms of $\phi_z(x,0)$ for $x > 0$:

$$\psi(x,0) = \sum_{x_e \in X_e} \boldsymbol{P}^T_{x_e} \boldsymbol{\mathcal{L}}_{\text{edge}}(\partial_x) G_\zeta(x - x_e, z, 0) + \int_0^\infty \big(\boldsymbol{\mathcal{L}}(\xi,\partial_\xi) - \boldsymbol{\mathcal{L}}_0(\partial_\xi)\big) G_\zeta(x-\xi,z,0)\,\phi_{0,z}(\xi,0)\,d\xi, \tag{3.8}$$

where $\boldsymbol{P}_{x_e} = \boldsymbol{P}^+_{x_e} - \boldsymbol{P}^-_{x_e}$ are vectors containing four unknown constants that must be determined from the edge conditions. If $\boldsymbol{\mathcal{P}}(x,\partial_x) = D(x)\partial_x - D'(x)$, then the $\boldsymbol{P}^\pm_{x_e}$ and the operator $\boldsymbol{\mathcal{L}}_{\text{edge}}$ are

$$\boldsymbol{\mathcal{L}}_{\text{edge}}(\partial_x) = -\begin{pmatrix} \boldsymbol{\mathcal{L}}_+(\partial_x)\,\partial_x \\ \boldsymbol{\mathcal{L}}_-(\partial_x) \\ \partial_x \\ 1 \end{pmatrix}, \quad \boldsymbol{P}^\pm_{x_e} = \begin{pmatrix} D(x_e^\pm) \\ \boldsymbol{\mathcal{P}}(x_e^\pm,\partial_x) \\ \boldsymbol{\mathcal{M}}(x_e^\pm,\partial_x) \\ \boldsymbol{\mathcal{S}}(x_e^\pm,\partial_x) \end{pmatrix} \phi_z(x_e^\pm,0).$$

3.3. Integral equations. We now differentiate (3.8) with respect to z and let $z \to 0$ to give an IE in $\phi_z(x,0)$. We will solve it by splitting it into two different equations, corresponding to regions 0 and 2. The first equation, defined for $0 < x < l$, is

$$\phi_z(x,0) = e^{i\alpha_0 x}\varphi_0'(0) + \sum_{x_e \in X_e} \boldsymbol{P}^T_{x_e}\boldsymbol{\psi}(x - x_e) + \sum_{\alpha\in S_0} \beta_+(\alpha)e^{i\alpha x} + \int_0^l K(x,\xi)\phi_z(\xi,0)\,d\xi, \tag{3.9}$$

where $\boldsymbol{\psi}(x) = \boldsymbol{\mathcal{L}}_{\text{edge}} g(x)$ and

$$\beta_+(\alpha) = -iA_0(\alpha) f_2(\gamma)\Phi^+(\alpha), \tag{3.10a}$$

$$\Phi^+(\alpha) = \int_0^l \phi_z(\xi,0)e^{i\alpha\xi}\,d\xi, \tag{3.10b}$$

arise from differentiating the integral from l to ∞ in (3.8), letting $z \to 0$, and substituting (3.3) into the result.

The kernel $K(x,\xi)$ in (3.9) is given by

$$K(x,\xi) = \big(\boldsymbol{\mathcal{L}}(\xi,\partial_\xi) - \boldsymbol{\mathcal{L}}(\partial_\xi)\big)g(x-\xi) = \sum_{j=1}^{4} d_j(\xi)\boldsymbol{\mathcal{L}}_{1j}(\partial_\xi)g(x-\xi), \tag{3.11}$$

where if $d_0(x) = D_1(x)/D_0$, $d_1(x) = D_0\big(d_0(x)-1\big)$, $d_2(x) = 2D_1'(x)$, $d_3(x) = D_1''(x)$, and $d_4(x) = m_1(x) - m_0$. The four $\boldsymbol{\mathcal{L}}_{1j}$ operators are $\boldsymbol{\mathcal{L}}_{11}(\partial_x) = (\partial_x^2 - \alpha_y^2)^2$, $\boldsymbol{\mathcal{L}}_{12}(\partial_x) = (\partial_x^2 - \alpha_y^2)\partial_x$, $\boldsymbol{\mathcal{L}}_{13}(\partial_x) = \boldsymbol{\mathcal{L}}_{-}(\partial_x)$, and $\boldsymbol{\mathcal{L}}_{14}(\partial_x) = -\mu$.

Now, we know from (3.5) that $\boldsymbol{\mathcal{L}}_{11}(\partial_\xi)g(x-\xi)$ has a delta function type singularity. (This also implies that $\boldsymbol{\mathcal{L}}_{12}\,g$ will have a jump discontinuity.) When this is integrated out, it produces a $\big(1-d_0(\xi)\big)\phi_z(x,0)$ term on the right-hand side of (3.9). Hence, that equation becomes

$$\begin{aligned} d_0(x)\phi_z(x,0) = e^{i\alpha_0 x}\varphi_0'(0) &+ \sum_{x_e\in X_e} \boldsymbol{\psi}^T(x-x_e)\boldsymbol{P}_{x_e} \\ &+ \sum_{\alpha\in S_0} \beta_+(\alpha)e^{i\alpha x} + \sum_{j=1}^{4} \fint_0^l d_j(\xi)\boldsymbol{\mathcal{L}}_{1j}(\partial_\xi)g(x-\xi)\phi_z(\xi,0)d\xi, \end{aligned} \tag{3.12}$$

which can now be solved using numerical quadrature in terms of the unknown $\beta_+(\alpha)$ ($\alpha\in S_0$) coefficients. The Cauchy principal value symbol

$$\fint_0^l = \lim_{\varepsilon'\to 0}\left(\int_0^{x-\varepsilon'} + \int_{x+\varepsilon'}^{l}\right)$$

is used to show that any delta function singularities have been integrated out (as they are identically zero outside the interval $x-\varepsilon' < \xi < x+\varepsilon'$) and none of the integrands are actually Cauchy singular. The above limit can be taken analytically. The next step in the solution is to set up an IE that will facilitate the elimination of β_+ from (3.12) and allow us to solve for $\phi_z(x,0)$ within the ramp independently of its value in region 2.

The equation over $x\in(l,\infty)$ is obtained in the same way that (3.9) was found from (3.8), only this time we assume that $x > l$. Doing this gives us

$$\phi_z(x,0) - \sum_{\alpha\in S_0}\beta_-(\alpha)e^{i\alpha(x-l)} = \int_l^\infty \big(\boldsymbol{\mathcal{L}}_2(\partial_\xi) - \boldsymbol{\mathcal{L}}_0(\partial_\xi)\big)g(x-\xi,z,0)\,\phi_z(\xi,0)d\xi, \tag{3.13}$$

where if $\boldsymbol{p}^T(\alpha) = \boldsymbol{\mathcal{L}}_{\text{edge}}(-i\alpha)$, then

$$\begin{aligned} \beta_-(\alpha) = e^{-i\alpha l}\varphi_0'(0)\delta_{\alpha,\alpha_0} &+ iA_0(\alpha)\sum_{x_e\in X_e}\boldsymbol{p}^T(-\alpha)\boldsymbol{P}_{x_e}e^{i\alpha(l-x_e)} \\ &+ iA_0(\alpha)\boldsymbol{\mathcal{L}}_{1j}(-i\alpha)\sum_{j=1}^{4}\int_0^l d_j(\xi)\phi_z(\xi,0)e^{i\alpha(l-\xi)}d\xi. \end{aligned} \tag{3.14}$$

Equation (3.13) is an IE of the Wiener–Hopf type and thus may be solved analytically in terms of the β_- coefficients. We now proceed to show how this is done.

3.4. Solution of Wiener–Hopf integral equation. Let

$$\Phi^-(\alpha) = -\int_{-\infty}^{l}\int_{l}^{\infty} \big(\boldsymbol{\mathcal{L}}_2(\partial_\xi) - \boldsymbol{\mathcal{L}}_0(\partial_\xi)\big) g(x-\xi,z,0)\,\phi_z(\xi,0) e^{i\alpha(x-l)} d\xi\, d(x-l),$$

and let $\mathbb{C}^+$ and $\mathbb{C}^-$ be the upper and lower complex half-planes, respectively. Φ^- is analytic in $\mathbb{C}^-$ and, in the following, all functions with a "$-$" superscript will be analytic in $\mathbb{C}^-$ and will be termed "minus functions," and all functions with a "$+$" superscript will be analytic in $\mathbb{C}^+$ and will be termed "plus functions."

Assuming that the left-hand side of (3.13) is zero for $x < l$, taking its Fourier transform with respect to $x - l$ gives

$$\Phi^+(\alpha) - i\sum_{k\in S_0} \frac{\beta_-(k)}{\alpha+k} = \Phi^-(\alpha) + \left(1 - \frac{f_2(\gamma)}{f_0(\gamma)}\right)\Phi^+(\alpha), \tag{3.15}$$

so that

$$\frac{f_2(\gamma)}{f_0(\gamma)}\Phi^+(\alpha) - i\sum_{k\in S_0} \frac{\beta_-(k)}{\alpha+k} = \Phi^-(\alpha). \tag{3.16}$$

From [3], the quotient f_2/f_0 can be written as the product of a plus function $K^+(\alpha)$ and a minus function $K^-(\alpha) = K^+(-\alpha)$, where

$$K^+(\alpha) = \prod_{k\in S_2} \frac{\alpha+k}{\gamma(k)} \Big/ \prod_{k'\in S_0} \frac{\alpha+k'}{\gamma(k')}. \tag{3.17}$$

Consequently, we can rearrange (3.16) to give

$$\begin{aligned} K^+(\alpha)\Phi^+(\alpha) - i\sum_{k\in S_0} \frac{\beta_-(k)/K^+(k)}{\alpha+k} \\ = \frac{\Phi^-(\alpha)}{K^-(\alpha)} + i\sum_{k\in S_0} \frac{\beta_-(k)}{\alpha+k}\left(\frac{1}{K^-(\alpha)} - \frac{1}{K^+(k)}\right). \end{aligned} \tag{3.18}$$

Now the above equation states that its left-hand side, which is a plus function, agrees with its right-hand side, a minus function, on the real line. By the Riemann principle both sides must therefore be equal to a single entire function $J(\alpha)$. If $h_2 > 0$, then $K^\pm(\alpha) \sim O(1)$ as $\alpha \to \infty$, so it is clear that both sides of (3.18) are $O(\alpha^{-1})$. Hence $J(\alpha) = 0$ by Liouville's theorem, and we can write

$$\Phi^+(\alpha) = i\sum_{k\in S_0} \frac{\beta_-(k)/K^+(k)}{K^+(\alpha)(\alpha+k)}. \tag{3.19}$$

If $h_2 = 0$, $K^\pm(\alpha) \sim O(\alpha^{-2})$, so the right-hand side of (3.18) is potentially linear as $a \to \infty$. However, the left-hand side is again $O(\alpha^{-1})$, so $J = 0$ again and Φ^+ is still given by (3.19).

Substituting this formula for Φ^+ into (3.10a), we can now eliminate the β_+ coefficients from (3.9), putting them in terms of integrals involving $\phi_z(x,0)$ over $(0,l)$. These integrals may be approximated by quadrature, and (3.9) can be solved as a standard Fredholm IE over a finite interval. (We use the same method of doing this as [18].)

3.5. Scattering coefficients and application of the edge conditions. $\phi_z(x,0)$ can be calculated for $x<0$ from (3.8) and for $x>l$ from (3.19), giving the following eigenfunction expansions:

$$\phi_z(x,0)=\begin{cases} e^{i\alpha_0 x}+\sum_{\alpha\in S_0} a(\alpha)e^{-i\alpha x} & \text{for } x<0,\\ \sum_{\alpha\in S_2} b(\alpha)e^{i\alpha(x-l)} & \text{for } x>l,\end{cases} \tag{3.20}$$

where

$$a(\alpha)=iA_0(\alpha)\sum_{x_e\in X_e}\boldsymbol{p}^T(\alpha)\boldsymbol{P}_{x_e}e^{i\alpha x_e}+\beta_+(\alpha)e^{i\alpha l} + iA_0(\alpha)\sum_{j=1}^{4}\boldsymbol{\mathcal{L}}_{1j}(i\alpha)\int_0^l d_j(\xi)\phi_z(\xi,0)e^{i\alpha\xi}d\xi, \tag{3.21a}$$

$$b(\alpha)=A_2(\alpha)f_0(\gamma)\sum_{k\in S_0}\frac{K^+(\alpha)\beta_-(k)}{K^+(k)(\alpha-k)}. \tag{3.21b}$$

Once the unknowns in the $\boldsymbol{P}_{x_e}$ vectors have been found (by applying the edge conditions), R and T are given by $R=a(\alpha_0)/\varphi_0'(0)$ and $T=b(\alpha_2)e^{-i\alpha_2 l}/\varphi_2'(0)$, respectively.

The edge conditions (2.3c) and (2.3d) are applied by simply setting $\big[\boldsymbol{P}_{x_e}\big]_3$ and $\big[\boldsymbol{P}_{x_e}\big]_4$ to zero. If $X_e=\{0,l\}$, then the remaining two frozen edge conditions can be applied by substituting (3.20) into (2.3a) and (2.3b). However, if X_e has other elements, this is not possible. In that case (2.3a) is most easily applied by observing that, when it holds,

$$\big[\boldsymbol{P}_{x_e}\big]_1=\big(D(x_e^+)-D(x_e^-)\big)\phi_z(x_e^\pm,0)$$

(note that this is zero if D is continuous at x_e), while (2.3b) is best applied by requiring that

$$D(x_e^\pm)\big[\boldsymbol{P}_{x_e}\big]_2=\big(D(x_e^+)-D(x_e^-)\big)\boldsymbol{\mathcal{P}}(x_e^\pm,\partial_x)\phi_z(x_e^\pm,0) +\big(D(x_e^+)D'(x_e^-)-D(x_e^-)D'(x_e^+)\big)\phi_z(x_e^\pm,0). \tag{3.22}$$

The quantity $\boldsymbol{\mathcal{P}}(x_e^\pm,\partial_x)\phi_z(x_e^\pm,0)$ can be calculated without the necessity of numerical differentiation from the formula

$$\frac{1}{D_0}\boldsymbol{\mathcal{P}}(x_e^\pm,\partial_x)\phi_z(x_e^\pm,0)=i\alpha_0e^{i\alpha_0x}\varphi_0'(0)+\sum_{x_f\in X_e}\boldsymbol{P}_{x_f}^T\boldsymbol{\psi}'(x_e^\pm-x_f) +\sum_{j=1}^{4}\int_0^l d_j(\xi)\boldsymbol{\mathcal{L}}_{1j}(\partial_\xi)g'(x_e^\pm-\xi)\phi_z(\xi,0)d\xi, \tag{3.23}$$

which is obtained by differentiating (3.9) with respect to x and integrating out the delta function singularities produced.

When D is continuous, the continuous-slope condition simplifies to

$$\big[\boldsymbol{P}_{x_e}\big]_2=\big(D'(x_e^+)-D'(x_e^-)\big)\phi_z(x_e^\pm,0),$$

the right-hand side of which vanishes when D' is also continuous.

The free edge conditions can usually be applied by substituting (3.20) into (2.4). However, when $h_2 = 0$, or when there are free edges inside $(0, l)$, we must adjust our procedure. Applying $\boldsymbol{\mathcal{L}}_-(\partial_x)$ and $\boldsymbol{\mathcal{L}}_+(\partial_x)\partial_x$ to (3.9) and again allowing for delta function singularities gives the following formulae for the bending moment and the transverse edge force:

(3.24a)
$$\frac{1}{D_0}\boldsymbol{\mathcal{M}}(x_e^{\pm}, \partial_x)\phi_z(x,0) = \boldsymbol{\mathcal{L}}_-(\alpha_0)e^{i\alpha_0 x}\varphi_0'(0) + \sum_{x_f \in X_e} \boldsymbol{P}_{x_f}^T \boldsymbol{\mathcal{L}}_-(\partial_x)\boldsymbol{\psi}(x_e^{\pm} - x_f) + \sum_{j=1}^{4} \int_0^l \boldsymbol{\mathcal{L}}_{1j}(\partial_\xi)\boldsymbol{\mathcal{L}}_-(\partial_x) g(x_e^{\pm} - \xi) d_j(\xi)\phi_z(\xi, 0) d\xi,$$

(3.24b)
$$\frac{1}{D_0}\boldsymbol{\mathcal{S}}(x_e^{\pm}, \partial_x)\phi_z(x,0) = i\alpha_0\boldsymbol{\mathcal{L}}_+(\alpha_0)e^{i\alpha_0 x}\varphi_0'(0) + \sum_{x_f \in X_e} \boldsymbol{P}_{x_f}^T \boldsymbol{\mathcal{L}}_+(\partial_x)\boldsymbol{\psi}'(x_e^{\pm} - x_f) + \sum_{j=1}^{4} \int_0^l \boldsymbol{\mathcal{L}}_{1j}(\partial_\xi)\boldsymbol{\mathcal{L}}_+(\partial_x) g'(x_e^{\pm} - \xi) d_j(\xi)\phi_z(\xi, 0) d\xi.$$

Setting these to zero, choosing whether to apply them at x_e^+ or x_e^- since we have already applied (2.3c) and (2.3d), allows us to find $\left[\boldsymbol{P}_{x_e}\right]_1$ and $\left[\boldsymbol{P}_{x_e}\right]_2$.

4. Results. We begin this section by documenting the different types of transition profiles that can be used, classified in terms of the continuity properties of $D(x)$ and $D'(x)$ at the ends of the variable region (section 4.1). This is followed in section 4.2 by some results that aim to validate the theory and its numerical implementation.

After those two sections we describe two applications. Section 4.3 models a sea-ice/ice-shelf transition, such as occurs where the Ross Sea sea-ice meets the Ross ice-shelf, while section 4.4 presents a discussion on the effectiveness of breakwaters with different widths and thickness profiles. In principle the latter results could be used to protect a very large floating structure (VLFS) of pontoon-type such as a floating airport from incoming ocean waves.

4.1. Types of transition profiles. Transition profiles are classed as either type 0, type 1, or type 2. Type 0 transitions have the property that $D(x)$ and $D'(x)$ are continuous at their edges, and thus no edge conditions are required there (assuming frozen edge conditions are applied, one must always apply two conditions at each free edge); for type 1 transitions $D(x)$ is continuous but $D'(x)$ is not, and so one edge condition must be applied; for type 2 transitions $D(x)$ and/or $D'(x)$ are discontinuous, so that two edge conditions must be applied. Examples of each type are plotted in Figures 2(a), 2(d), and 2(g), and the scattering behavior of each is plotted in the two graphs that appear to their right. The middle column of plots (2(b), 2(e), and 2(h)) shows the scattering of normally incident waves, while the right-hand column (2(c), 2(f), and 2(i)) shows the scattering of obliquely incident waves for a number of periods.

All three profiles have the same average thickness and consequently produce similar amounts of reflection at normal incidence. The type 2 scattering curve, however, has the most structure at low periods, although we observe that the linear (type 1) transition also has a zero in $|R|$ at about 0.3 s. We attribute structure to the greater coherence of the shorter, uniform wavelengths in the intermediate 1.5-m-thick ice

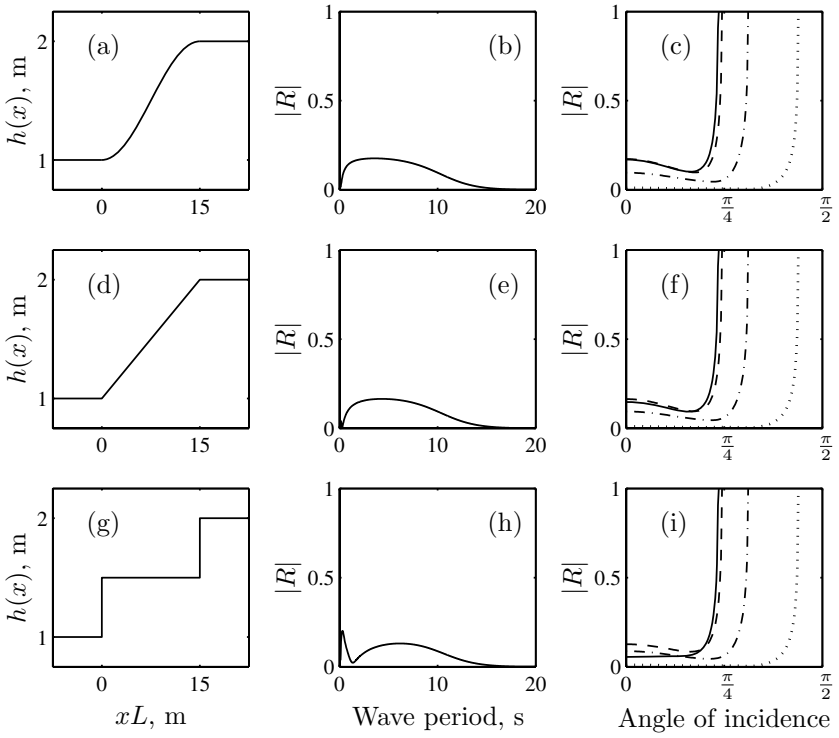

FIG. 2. *The scattering of waves incident on three different types of transition—a smooth type* 0 *transition with profile shown in* (a)*, a linear type 1 transition* (d)*, and a double step type* 2 *transition* (g)*. Scattering results for each different type of transition are shown in the two plots to the right of the corresponding thickness profile—figures in the second column* (b)*,* (e)*, and* (h) *illustrate the variation in the amount of reflection of normally incident waves with wave period, while figures in the right-hand column* (c)*,* (f)*, and* (i) *show the behavior of* $|R|$ *with the angle of incidence at a number of different wave periods. The periods used are* 2 *s (solid curves),* 5 *s (dashed curves),* 10 *s (dashed-dotted curves), and* 15 *s (dotted curves). The water depth is infinite.*

compared to the varying dispersion of the type 0 and type 1 cases. The more complicated the thickness profile is in a functional sense, the less the fine structure in the scattering curve and the more the reflection. This is also found for smooth ridges, which seem to produce more reflection than linear ones [18].

There are two main differences between the scattering of obliquely incident waves by transition zones and by ridges—both arising because $h_0 \neq h_2$. The first is that zeros in $|R|$ occur only when the period exceeds a certain value, e.g., in the three 15 s curves (dotted) of Figures 2(c), 2(f), and 2(i). Curves corresponding to lower periods either have minima or increase monotonically (see the 2 s curve in 2(i)). The second is that each period has a critical angle, less than $\pi/2$, above which any incident waves will be completely reflected. This is due to the wave number in the thinner sea-ice to the left (γ_0) being less than that in the thicker shelf ice on the right (γ_2). If α_y, the component of the wave number in the y direction, exceeds γ_2, no wave is able to propagate into the right-hand region in the x direction. (This corresponds to α_2 either vanishing or becoming imaginary.)

Figure 3 plots this critical angle as a function of period for a series of values of the ratio h_2/h_0. The two smallest values of h_2/h_0 show that as the ratio becomes smaller and smaller there is a "critical period" at which the critical angle reaches $\pi/2$ that

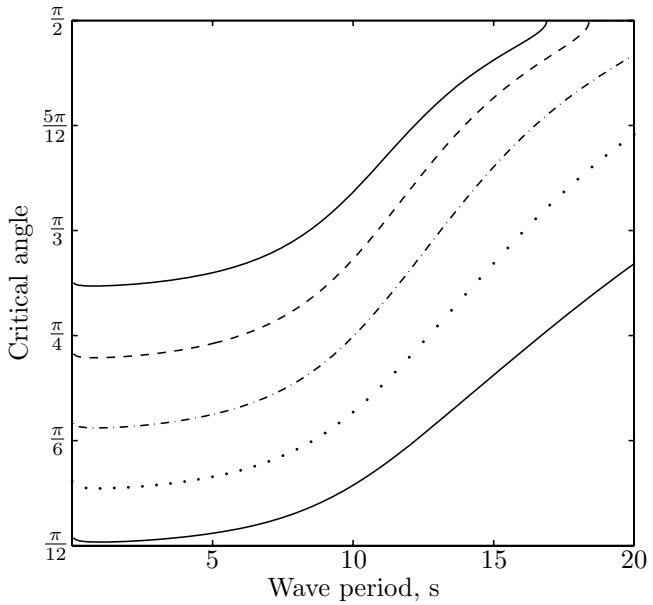

FIG. 3. *The variation of the critical angle of reflection with the period for different values of* h_2/h_0*:* 1.5 *(upper solid curve),* 2 *(dashed curve),* 3 *(dashed-dotted curve),* 5 *(dotted curve), and* 10 *(lower solid curve). The water depth is infinite.*

moves closer to the vertical axis. In the limit, when h_2 reaches h_0, the critical angle is constantly $\pi/2$ since the wave numbers on both sides of the transition are equal (cf. Figure 2). This critical period moves to larger periods as h_2 increases relative to h_0 and has moved out of the plotted range for the three curves corresponding to $h_2/h_0 = 3$, 5, and 10. A result of this is that the critical angle curves move downward as h_2/h_0 increases so that very little transmission of obliquely incident waves can occur when an ice-shelf is very thick.

4.2. Validation of results. The figures in this section are mostly intended to establish that the theory described in sections 2 and 3 produces results that converge to ones that can be independently verified by alternative solutions. Before this is done, however, in Figure 4 we attempt to reproduce Figure 5(a) of the paper by Porter and Porter [12]. These authors develop a variational solution for the spatially inhomogeneous floating plate and then invoke a mild slope approximation to enable results to be computed; zero submergence is not required.

Figure 4(a) plots the thickness profiles of the linear ramps that Porter and Porter use, and 4(b) plots the corresponding scattering calculated by our method as a function of incident wave number. The two methods agree well, although they diverge in the long wave limit. As $\alpha_0 \to 0$, Figure 4(b) predicts that $|R|$ will vanish for all three profiles, while the figure in [12] shows it tending towards a small finite value that decreases as h_2 decreases. This value is predicted in [9] and is the result of narrowing of the right-hand fluid region due to the increased submergence of the ice on that side. This example shows that the no-submergence assumption is unsuited to small finite depths.

Figure 5 illustrates how the scattering for a series of increasingly steep type 1 linear ramps converges to the scattering by a step. Results for a step can be checked

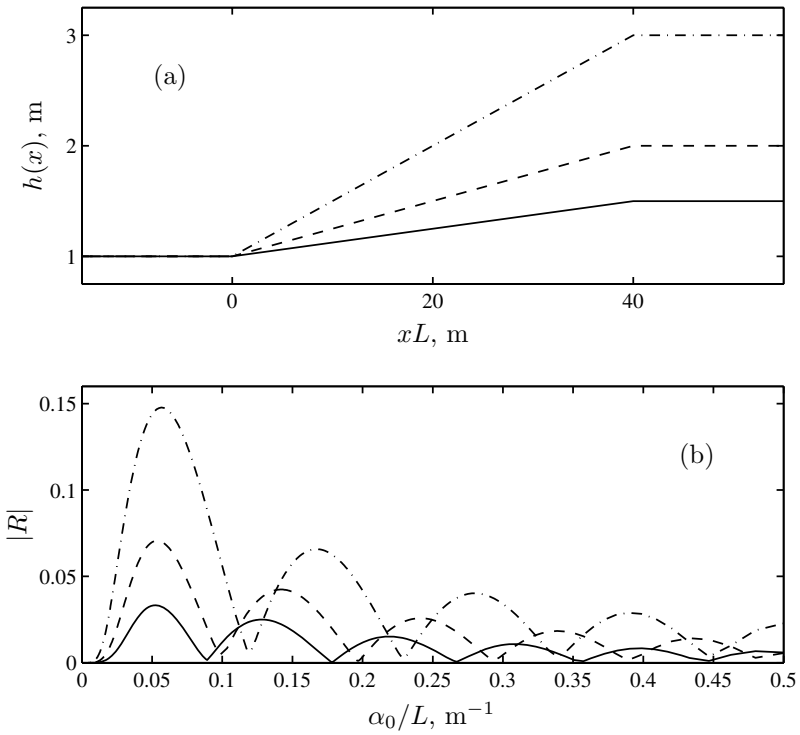

FIG. 4. *Verification of linear ramp results. The plot shown is a reproduction of Figure* 5(a) *of* [12]. *The upper plot* (a) *shows three different thickness profiles that ramp up linearly from* 1 *m to either* 1.5, 2, *or* 3 *m. The scattering by each ramp is plotted in* (b) *using the same line style used for its profile's line style in* (a). *In that figure* $|R|$ *is plotted against its dimensional wave number for the left-hand region,* α_0/L. *The incident waves are normally incident, and the water depth is* 20 *m.*

by comparing them to Figure 8 in [1], where $|R|$ displays a monotonic decrease from about 0.22 as the period is increased. As the steepness of the ramps is increased the progression of their reflection coefficient curves towards the step's scattering behavior can be seen, especially at large periods. It can also be seen in the period below which each ramp curve starts to significantly depart from the step curve. For the 100-m-wide ramp this happens at about 14 s, while the 25-m-wide ramp's reflection is still quite close to that for the step for periods above about 10.5 s. After each curve drops away, it has a maximum followed by either a minimum or a zero. The height of this maximum increases towards the step curve as steepness increases, while the period at which the zero occurs marches to the left. It has almost moved out of the plotted range by the time the ramp width has dropped to 25 m. These results are consistent with those of [18], which shows that the larger a feature's width in relation to the incident wavelength, the more opportunity there is for resonance and the more fine structure that is observed in the corresponding scattering curves.

An analogous computation for type 0 transition can also be done. The smooth transition curves display less fine structure than their linear equivalents, although their reflection is similar to that of the step for larger period ranges. That is, $|R|$ for each smooth transition begins to depart from $|R|$ for the step at a period about

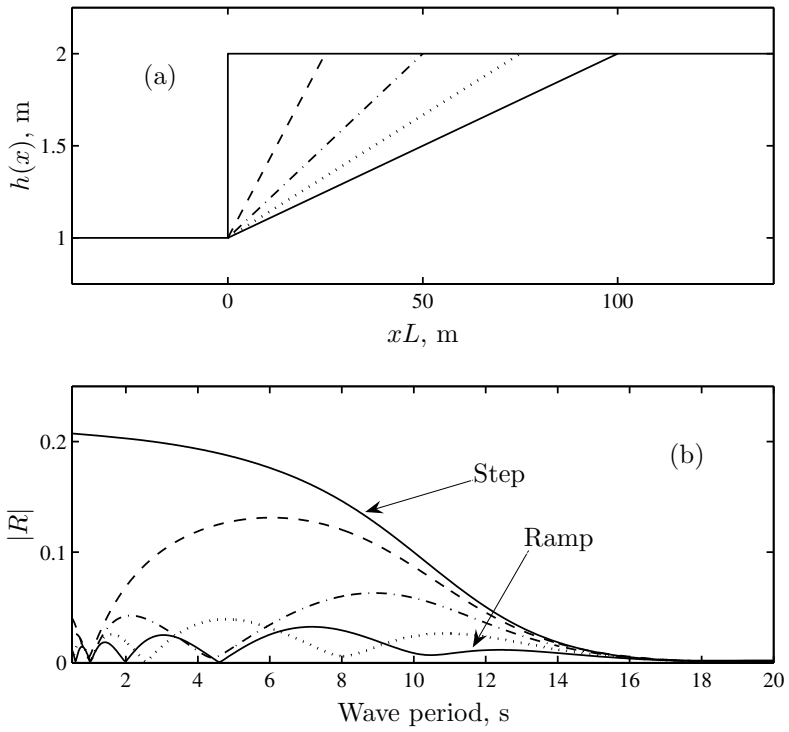

FIG. 5. *Convergence of the scattering by a series of increasingly steep type* 1 *linear ramps to the scattering by a step, which may be considered as an infinitely steep ramp. The curve corresponding to the step is pointed out in* (b)*, as is the curve corresponding to the ramp profile plotted in* (a) *with a solid line; the scattering curves for the other ramps are also plotted using the line style used for their profile in* (a)*. The incident waves are normally incident, and the water depth is infinite.*

1 s lower than the equivalent period for the linear ramp of the same width. Likewise the scattering by a sequence of smooth transitions as their profiles become more and more similar to a double step can be modeled. These examples and more are provided in [17].

We finish this section by reminding the reader that all of the results provided in [17] and in this paper assume that submergence is negligible. Comparing Figure 4 with the equivalent figure of [12] showed that this makes a slight difference for long waves. While this should be borne in mind at small depths, it will not cause problems for deeper water and especially not in the infinite depth limit.

4.3. The sea-ice/ice-shelf transition. The configurations modeled in sections 4.1 and 4.2 of one ice thickness ramping up to a different thickness over a given distance lend themselves well to modeling a ramp connecting relatively thin sea-ice to a much thicker, fresh water ice-shelf. Such a situation is found in the Ross Sea, where the transition from the sea-ice up to the Ross ice-shelf is gentle enough that one can easily walk up it.

Figure 6 plots the scattering by such a transition when the sea-ice has thickness $h_0 = 1\,\text{m}$ and the thickness of the ice-shelf, h_2, is (a) 5 m, (b) 10 m, (c) 15 m, and (d) 20 m. Results are plotted for transition widths of 250, 500, and 750 m.

A typical sea-ice/ice-shelf transition would ramp up from 1 to 15 m over about

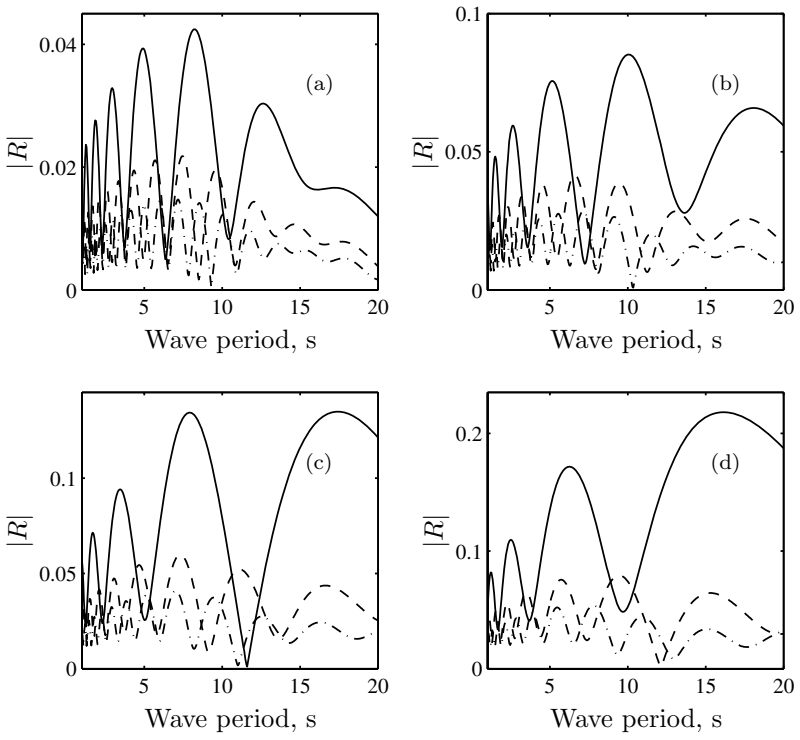

FIG. 6. *The reflection of normally incident waves produced by a sea-ice/ice-shelf transition. The sea-ice has thickness* $h_0 = 1\,m$*, and the thickness then increases linearly to values for* h_2 *of* (a) $5\,m$, (b) $10\,m$, (c) $15\,m$, *and* (d) $20\,m$. *The widths of the ramps are* $250\,m$ *(solid curves),* $500\,m$ *(dashed curves), and* $750\,m$ *(dashed-dotted curves), and the water depth is infinite.*

500 m (cf. the dashed curve in Figure 6(c)), but the other plots are included to give the reader more of an idea about the effect of changing the different dimensions.

Clearly, increasing the width of the ramp produces more complicated reflection patterns due to the occurrence of more resonances when several wavelengths repeat within the transition. In addition, increased width without a concomitant change in thickness lowers the slope of the ramp, making the overall change in the thickness less abrupt and in turn reducing the amount of reflection. In contrast, increasing the thickness h_2 while keeping the width constant increases the slope and thus causes more reflection. The next most noticeable effect of an increase in h_2 is that the scale over which the $|R|$ curves change increases: The spacings between successive maxima and minima become wider, and $|R|$ takes a lot longer to begin dropping to zero. The increase in spacings is attributed to the fact that as the ice becomes thicker the waves in the transition become much longer in comparison to its width. The slow decay in reflection is due to the overall size of the features taking longer to become insignificant in relation to the incident wavelength.

In general it appears that sea-ice/ice-shelf transitions of this type have the most marked effect on the longer waves (in comparison to other features in sea-ice). A value of $|R| = 0.19$ is the largest reflection of a 20 s wave produced by any feature modeled in the previous figures, and none of the features to be discussed later will produce such a large reflection for so long a wave. On the other hand, waves at smaller periods are not unaffected by the considerable increase in thickness as they travel into the region

beneath the ice-shelf. We have already mentioned how the wavelength of a wave of a given period increases with thickness. This increase is actually quite dramatic. For example, when the wave period is 5 s, the wavelength increases from 85 to 205 m as thickness increases from 1 to 5 m. When $h_2 = 20$ m, the wavelength becomes 450 m.

Before leaving Figure 6 we return again to the matter of submergence, as we wish to reassure the reader that the effects we are reporting would not be dwarfed by its assimilation into the model. To do this we invoke results from new work that allows both smooth and abrupt changes of property with submergence correctly incorporated [2]. Reassuringly the results are very similar to those reported herein [21] for the most challenging configuration, namely, the solid curve of Figure 6(b) where the thickness change is largest over the shortest horizontal distance. Differences between the current paper and [2] for no submergence are small (and explainable), giving us further confidence that the present theory is correct because the methods employed are mathematically independent, and the change when submergence is introduced is no more than 10% at worst. Of interest, the separation of the no-submergence and submergence results is negligible at short periods and for very long waves, with an intermediate range of periods where the curves deviate most (up to the 10% figure mentioned previously). It is argued that this occurs because at short periods the slope is so mild that the submergence is not noticed. As the period is gradually increased, the wavelength becomes longer with the result that the slope of the feature above and below the water line appears more abrupt. However, at very long periods the submergence is inconsequential compared to the wavelength. The validation of our results using [2] reassures us that the inclusion of submergence will not significantly alter our conclusions.

The wave amplitude is less under thicker ice due to its greater rigidity and, to a lesser extent, its greater mass. Accordingly, if an incident wave of amplitude A was perfectly transmitted into the region under the ice-shelf, its amplitude would drop to σA, where $\sigma = \varphi_2'(0)/\varphi_0'(0) < 1$. Figure 7 plots σ as a function of period for the four different values of h_2 used in Figure 6. It can be seen that the drop in amplitude is greatest at lower periods but that, as the period increases, the difference diminishes. As might have been expected, σ takes longer to climb to 1 as the ice-shelf becomes thicker. Figure 7 also plots the modulus of $\mathcal{T} = \sigma T$, the amplitude transmission coefficient, for the twelve ramps featured in Figure 6. Allowing for imperfect transmission, therefore, the final amplitude of a wave that initially has amplitude A is $A\mathcal{T}$.

We can see immediately that the width of the sea-ice/ice-shelf transition has only a negligible effect on the amplitude transmission coefficient. The most divergence is in Figure 7(d) when $h_2 = 20$ m, where the three curves separate very slightly around 19 s. In addition, the longer scale over which the curves for the thicker ice-shelves take to reach perfect transmission (the dotted curve) is also apparent.

A final point to make on comparison of Figure 7 with Figure 6 is that the $|\mathcal{T}|$ curves show no evidence at all of the oscillatory maxima and minima that were evident in the $|R|$ curves. This is expected and is a consequence of conservation of energy, i.e., $s|T|^2 = 1 - |R|^2$, where $s = \sigma^2 A_0(\alpha_0)/A_2(\alpha_2)$ is the intrinsic admittance [17]: If two values of $|R|$ are both quite small, their squares will be even smaller and the corresponding values of $|T|$ will both be very close to $1/\sqrt{s}$.

4.4. A flexible breakwater. Another physical application of the method described in this paper is to a breakwater shielding a VLFS from waves arriving from the open ocean. While it would be unusual for such structures to be made from ice,

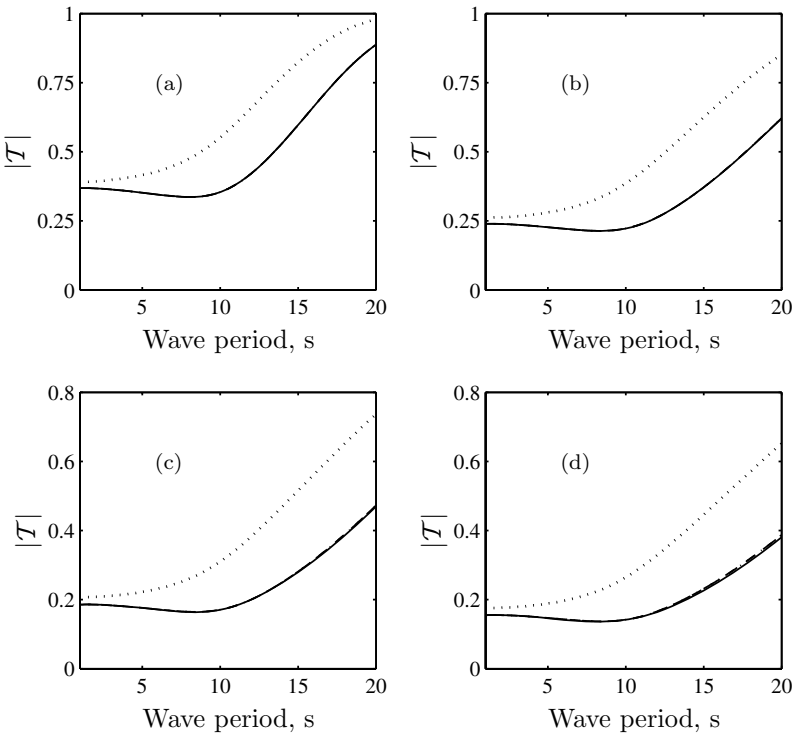

FIG. 7. *The relative amplitudes of normally incident waves transmitted by a sea-ice/ice-shelf transition. If a wave has amplitude A in the sea-ice region, its amplitude when it reaches the ice-shelf will be AT, where* $\mathcal{T} = \sigma T$, *and* $\sigma = \varphi_2'(0)/\varphi_0'(0)$ *is the relative amplitude of a perfectly transmitted wave.* σ *is plotted for reference as a dotted line when* $h_0 = 1\,m$ *and* h_2 *takes values of* (a) $5\,m$, (b) $10\,m$, (c) $15\,m$, *and* (d) $20\,m$. *In each figure, i.e., for each value of* h_2, $|\mathcal{T}|$ *is actually plotted when the widths of the transition regions are* $250\,m$ *(solid curve),* $500\,m$ *(dashed curve), and* $750\,m$ *(dashed-dotted curve) but the latter two curves are almost indistinguishable from the solid ones. The water depth is infinite.*

for convenience we shall take the building material to have the same density, Young's modulus and Poisson's ratio as sea-ice. As an aside the reader may be interested to know that there was actually a plan by the British during World War II to construct an aircraft carrier out of ice for use against German U-boats in the mid-Atlantic. Known as Project Habbakuk (an Admiralty clerk's misspelling of the biblical name Habakkuk), it was proposed that a 4000×600 ft VLFS with 40-ft-thick walls and a displacement of 2 million tons or more would be constructed in Canada from 280,000 blocks of ice. The building material was changed later to a mixture of ice and wood pulp known as pykrete but, because of the immense cost, the project was eventually scrapped.

Figure 8 shows the amounts of reflection produced by three different profiles for three different widths: 5 m (b), 15 m (c), and 30 m (d). The solid, dashed, and dashed-dotted curves correspond to the profiles in Figure 8(a) plotted in the same line style. The outer thicknesses are $h_0 = 1$ m and $h_2 = 0$, and the incident wave arrives normally from the right.

The differences in widths are not great enough for huge variations in the scattering patterns, but we can see that the maxima in $|R|$ at about 4 s in Figure 8(b) moves

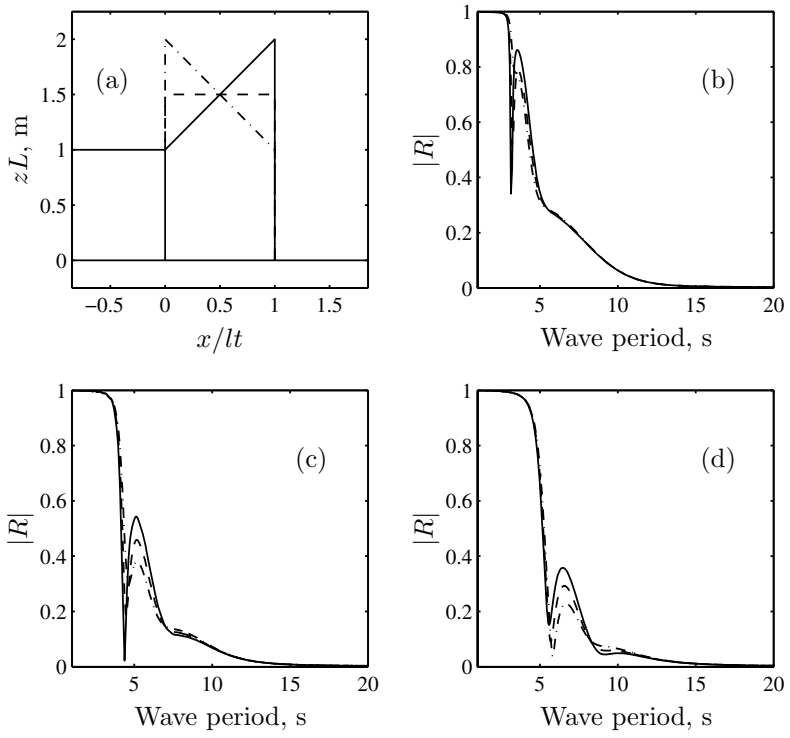

FIG. 8. *Wave scattering by a breakwater.* (a) *shows the three different shapes used. The incident wave arrives at a normal angle from the open water region to the right, and the breakwater is located between the* $x = 0$ *and* $x = l$ *planes and is separated by a free edge from the floating structure to the left that it shields. The reflection that each different shape produces is plotted in the same line style used for its profile in* (a) *when the width of the breakwater is either* (b) 5 *m,* (c) 15 *m, or* (d) 30 *m wide. The water depth is infinite.*

to the right and drops in height as l increases. The region of very high reflection at low periods also moves to the right. The breakwater that is sloping away from the open water (plotted as a solid curve) gives noticeably more reflection than the other breakwaters in the intermediate period range (about 5 to 10 s), although the size of this interval depends on the breakwater's width. When l is larger, it takes longer to become small in comparison to the incident wavelength, at which point the reflection by the three shapes converges. However, when we consider transmission into the region under the VLFS, the differences between the three different widths and shapes become less significant. This is demonstrated by Figure 9, which investigates the effect of a breakwater on a common open water wave spectrum.

The spectral density function (SDF) we use corresponds to a Pierson–Moskowitz wave spectrum [11], given by

$$\vec{f}_{\mathrm{sd}}(\tau) = \beta(\tau_0\tau)^3 \times \exp\big(-\eta(\tau_0\tau)^4\big), \tag{4.1}$$

where $\tau_0\tau$ is the dimensional wave period (τ is nondimensional), $\beta = 7.4\times10^{-4}\,\mathrm{m^2\,s^{-4}}$, and $\eta = 3.0 \times 10^{-4}\,\mathrm{s^{-4}}$. The arrow over the f is intended to indicate that this is the incident wave spectrum. In open water, this density function is very similar in shape to the dotted curves, climbing from zero in the short wave limit to a peak period at

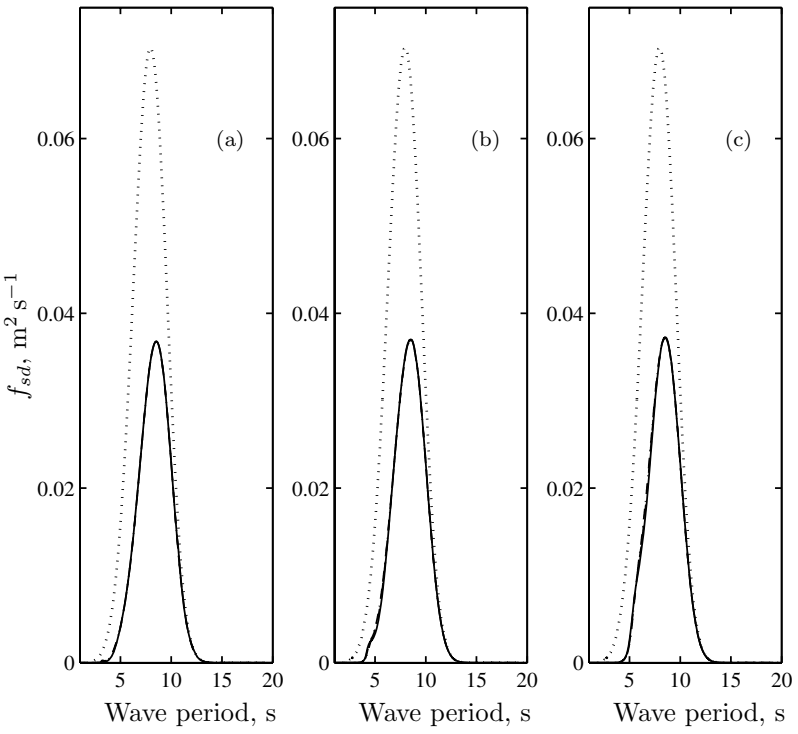

FIG. 9. *The effect of a breakwater on a Pierson–Moskowitz incident wave spectrum. The dotted lines in each figure are reference lines plotting the spectrum that would result if the Pierson–Moskowitz spectrum was transmitted perfectly from the open water region into the VLFS. If* $\vec{f}_{\rm sd}$ *is the SDF for the incident wave spectrum, this reference SDF is given by* $f_{\rm sd} = \sigma^2 \vec{f}_{\rm sd}$. *The dotted, dashed, and dashed-dotted curves show the SDFs resulting from the breakwater profiles plotted in Figure* 8 *in the same line styles, and their widths are either* (a) 5 *m,* (b) 15 *m, or* (c) 30 *m. (Note that the dashed and dashed-dotted curves are very hard to distinguish from the solid curves.) Their SDFs are given by* $f_{\rm sd} = \vec{f}_{\rm sd} \times |\mathcal{T}|^2$. *The incident waves are all taken to arrive normally, and the water depth is infinite.*

8 s, before dropping to zero again as the period increases further.

The dotted lines in Figure 9 actually plot $\sigma^2 \vec{f}_{\rm sd}(\tau)$, which is intended as a reference to show what the wave spectrum beneath the VLFS would look like if the breakwater did not produce any reflection. The solid, dashed, and dashed-dotted curves plot the spectra resulting from the different shaped breakwaters plotted in Figure 8(a), while the different subplots, Figures 9(a), 9(b), and 9(c), correspond to the three different widths used in Figure 8(b), 8(c), and 8(d), respectively.

The spectra are calculated by $f_{\rm sd}(\tau) = \vec{f}_{\rm sd}(\tau) \times |\mathcal{T}|^2$, and it can be seen that the different breakwater shapes produce a negligible difference in the wave spectra underneath the VLFS. The width does not seem to make a large amount of difference either, although the 5-m-wide breakwaters seem to filter out a little more wave amplitude.

Similarly, Figure 10 shows that using a breakwater with a larger average thickness does not affect the transmitted wave spectrum markedly, although in general it does increase $|R|$. Figures 10(a) and 10(c) show $|R|$ and $f_{\rm sd}$ for three 5-m-wide breakwaters: 1 m thick (solid curve), 2 m thick (dashed curve), and 3 m thick (dashed-dotted curve).

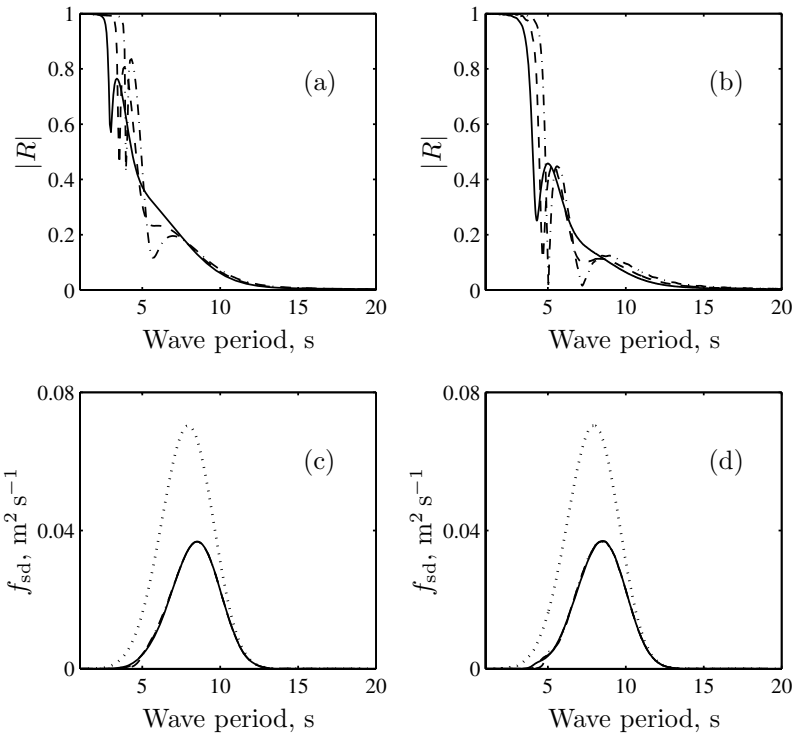

FIG. 10. *Further investigations of the reflection and transmission produced by a breakwater.* (a) *and* (c) *show* $|R|$ *and* f_{sd} *for three* 5*-m-wide breakwaters of* 1 *m thickness (solid curve),* 2 *m thickness (dashed curve), and* 3 *m thickness (dashed-dotted curve), and* (b) *and* (d) *show the analogous results for* 15*-m-wide breakwaters. The waves are normally incident, and the water depth is infinite.*

Figures 10(b) and 10(d) show the analogous results for 15-m-wide breakwaters.

The results of this section lead one to conclude that, should one be required to construct a flexible breakwater to protect a VLFS, the extra expense and effort needed to make it wider and/or thicker would not filter out a significant proportion of the incoming wave amplitude. Of course, if the thickness was reduced too much, reflection would start to decrease, but keeping it at 1 m would seem to be sufficient.

The most economical approach to improving the amount of protection that is afforded the VLFS would probably be to have several smaller breakwaters side by side—possibly separating them by small expanses of open water. Increasing the number of abrupt changes in surface properties that the incident waves must cross would help to produce greater reflection.

5. Conclusions. We have considered wave scattering arising from a change of physical properties—referred to as the transition, across two floating, Euler–Bernoulli, elastic plates. A new model is reported that utilizes Green's theorem to construct two coupled IEs, defined over $(0, l)$ and (l, ∞), respectively, and invokes the Wiener–Hopf method to decouple the system by first solving the IE in (l, ∞). After validating the model two applications are discussed.

1. Wave scattering at the sea-ice/ice-shelf transition, whereby ocean waves incident from the open ocean enter an extended region of sea-ice that may be shore-fast

or separated from the coast by a lead, i.e., a "river" in the ice, before impinging on the ice-shelf itself. This geophysical application of the theory has topical relevance because climate warming is known to be inducing ice-shelf melting in specific regions of Antarctic, e.g., the Antarctic Peninsula alongside the Weddell Sea, and is contributing to a reduction in pack ice and shore-fast ice that would formerly have protected ice-shelves from severe storms. The model described herein replicates this important marine system mathematically, potentially allowing anthropogenically assisted changes in the coastal ice masses to be utilized as a proxy of global change. By way of example it is proposed that in concert with surface-meltwater-enhanced fracture involved in the breakup of the 200–300 m-thick Larson B ice-shelf [10, 8], the removal of the sea-ice barrier and temperature-induced weakening of the ice were precursors that preconditioned the ice-shelf for breakup. An opportunity to test this hypothesis using the current model to compute the flexural waves that energize the ice-shelf with and without the sea-ice barrier in place has arisen and will be the focus of a separate paper directed at the geophysics as opposed to the mathematical development. While nothing in polar geophysics is ever straightforward, the mechanisms we have suggested are worthy of consideration, especially when the possibility of standing waves created by waves reflected at the hingeline and geometric resonance are also incorporated as contributing factors [7, 15].

2. Floating, flexible breakwaters are also considered as an application of the current model. Here, for mathematical convenience the configuration is reversed so that waves travel towards the transition from the right. Concomitantly, the *ice-shelf* is allowed to become vanishingly thin, i.e., open water. Waves then propagate through the transition region into a floating plate of uniform prescribed thickness. This is an effective model of a VLFS, e.g., a floating airport, shielded by a skirt of specified geometry, and the question becomes "how should the skirt be designed to minimize the amount of wave energy reaching the VLFS?" This is not outrageously futuristic. A six-year plan launched in 1995 to research and develop Megafloat, a floating airport in Yokosuka Bay, Japan, involved the construction of a 1,000 m by 60–121 m model that successfully passed takeoff and landing tests. A detailed evaluation of the tests on the 1000 m Megafloat and the 4000 m-class test design concluded that a Megafloat airport with a scale of up to 4000 m was more than feasible. Breakwaters of some type will be necessary to avoid significant wave-induced flexure of the VLFS, so it is fitting that we investigate their design using the tools we have developed. Of significance, we find that the effect of thickness and width of the transition is secondary once a certain thickness is reached, so a simple cost-benefit analysis needs to be done to decide the optimum configuration for a particular VLFS.

Acknowledgment. The authors are grateful to Luke Bennetts, who helped us to quantify the effect of assuming zero submergence.

INVERSE PROBLEMS RELATED TO ION CHANNEL SELECTIVITY*

MARTIN BURGER†, ROBERT S. EISENBERG‡, AND HEINZ W. ENGL§

Abstract. Ion channels control many biological processes in cells, and, consequently, a large amount of research is devoted to this topic. Great progress in the understanding of channel function has been made recently using advanced mathematical modeling and simulation. This paper investigates another interesting mathematical topic, namely inverse problems, in connection with ion channels. We concentrate on problems that arise when we try to determine ("identify") one of the structural features of a channel—its permanent charge—from measurements of its function, namely current-voltage curves in many solutions. We also try to design channels with desirable properties—for example with particular selectivity properties—using the methods of inverse problems. The use of mathematical methods of identification will help in the design of efficient experiments to determine the properties of ion channels. Closely related mathematical methods will allow the rational design of ion channels useful in many applications, technological and medical. We also discuss certain mathematical issues arising in these inverse problems, such as their ill-posedness and the choice of regularization techniques, as well as challenges in their numerical solution. The L-type Ca channel is studied with the methods of inverse problems to see how mathematics can aid in the analysis of existing ion channels and the design of new ones.

Key words. ion channels, Poisson–Nernst–Planck equations, identification, optimal design, permanent charge, current-voltage relations

1. Introduction.

Ion channels are proteins with a hole down their middle that allow ions to move through otherwise impermeable cell membranes, thereby controlling many biological processes of great importance in health and disease. Interest in channels has grown rapidly because of their general role as controllers of biological function in health and disease. A quick glance at the literature through a search on the Internet will find hundreds of papers on channelopathies, diseases of channels (cf. [As99, LHJR00]). Specifically, channels are proteins akin to enzymes (cf. [Ei90]) that control the flow of ions through membranes and thus control a wide range of biological functions (cf. [Aletal94, Hi01]).

Channels generate the action potential which conducts all information in the nervous system and coordinates contraction, including the contraction which allows the heart to function as a pump. Channels are involved in nearly all sensory function, in the secretion of hormones, and in the function of the kidney and intestine. There is hardly a biological function that is not controlled by channels or transporters in an important way.

The enormous importance of channels has generated enormous amounts of experimental work. Literally hundreds of laboratories and thousands of scientists measure channel properties every day with remarkable resolution, often studying the properties of just one protein molecule. Molecular genetics and molecular biology allow routine (although tedious) engineering of channel proteins nearly one atom at a time (cf. [Mietal06]). Few areas of biology are so well explored at such resolution.

Channels also are much simpler than enzymes. Channel function does not involve changes in covalent bonds or chemistry in that sense. Channels perform many of their functions without changing structure (on the biological time scale of msec). Ions move through channels driven by concentration gradients and electrical potential at room temperature. Channels form an unusual nearly unique system because they are both physically simple and biologically very important. The daunting complexity of the structure of many biological systems is not found in single molecules of channel proteins [TBSS01, Ei98, Maetal03].

One of the defining characteristics of proteins is their selectivity. Most proteins bind specific organic chemicals with great specificity even at very low concentrations, 10^{-5} times smaller than concentrations of ions always associated with proteins, e.g., K^+, Na^+, and Cl^-, which are typically found at 0.2 M concentration. These organic molecules often control the biological function of the protein with great specificity even at these very low concentrations. Ion channels (for example) conduct ions of one type much better than ions of another type, and this selectivity among ions is essential for their role in signaling in the nervous system, and coordination of muscle contraction, particularly in the heart. If the selectivity of ion channels is understood, and a physical theory is available showing how channel structure produces channel function, channel proteins can be designed to specification and built using the well-developed techniques of molecular engineering, e.g., by site-directed mutagenesis.

The design of ion channels to specification can also be seen as an application of the mathematical theory of inverse problems ("reverse engineering"). Design requires specialized mathematics because of the complexity and sensitivity (with respect to perturbations) of the system and the mutual dependence of various design goals: improving some properties can make others worse, and so mathematics is needed to find a good compromise. In this paper, we show how iterative and variational regularization methods developed for inverse problems can be applied to design or identify the function—in particular the selectivity—of ion channels using the physical chemistry of crowded charge, which is modeled through the Poisson–Nernst–Planck equations, a system of nonlinear partial differential equations combined with a density functional theory of excess chemical potential. The main idea of this approach is to formulate the design or identification of permanent charge as an abstract operator equation or optimization problem involving Poisson–Nernst–Planck (or related) models for the flow of electrical charge through the channel and to regularize it either by using an iterative method with appropriate stopping criterion and/or additional penalization of the objective functional. This regularization is necessary to compute numerical solutions in a stable and robust way, since the inverse problem is ill-posed in the sense that small differences in the electrical current can correspond to arbitrarily large differences in the permanent charge. In the context of identification, regularization methods allow computation of a stable approximation to the permanent charge in the channel. In the context of design, they also allow us to introduce a priori ideas of suitable designs.

Inverse problems arise whenever one searches for causes of desired or observed effects. Two problems are called inverse to each other if the formulation of one problem involves the solution of the other one. At first sight, it might seem arbitrary which of

these problems is called direct and which is called inverse. Usually, the direct problem is the more classical one. But there is an intrinsic mathematical reason to call one problem "inverse," namely the fact that it is usually ill-posed (cf. [EHN96]). When dealing with partial differential equations, the direct problem usually predicts the evolution of the described system from knowledge of its present state and the governing physical laws including information on all physically relevant parameters. A possible inverse problem would be to compute (some of) the parameters from observations of the evolution of the system; this particular inverse problem is called "parameter identification" and is usually ill-posed (cf. [CER90, EHN96, ER95, IS05, Na06]). We shall highlight the ill-posedness of the inverse problem in a simplified setup, which we nonetheless expect to capture the essential features of the problem, and we also discuss *identifiability*, i.e., the question of whether the unknowns in the inverse problem are determined uniquely from the data.

Regularization methods are needed to overcome these instabilities and to design solution techniques that are robust (i.e., that are stable with respect to data and numerical errors). In general terms, regularization methods replace an ill-posed problem by a family of neighboring well-posed problems. We perform this task for design and identification problems in ion channels. In addition to the stable approximation, the regularization methods are also used to introduce a priori knowledge about the ion channel structure. In a case study of an L-type Ca channel, we present various numerical results, which demonstrate the feasibility of our approach and highlight some particular issues that are likely to appear in channel and protein problems.

2. Modeling ion channels. In the following, we give a brief overview of continuum models of ion transport through channels. Such models need to incorporate the electrostatic interaction between the charged particles, the change of charge density by the mobile ions and a consequent change of the electric field, the generation of ion flux by the electric field, and the direct electrochemical interactions between the ions. Here we shall detail and use Poisson–Nernst–Planck (PNP) models, where the unknowns are the electric potential V and the densities ρ_k of the various (ionic) species present in the channel. Continuum models of this sort have received much attention in the literature (cf. [CE93, GNE02, GNE03, IR02a, IR02b, Maetal03, NCE00]) as well as criticism, mostly because they neglect correlations produced by the small number of ions that can fit into a single channel. Correlations can be included in the derivation of PNP (cf. [SNE01, NHE03]), and certain types of correlations can be analyzed and included in generalizations of PNP with some success (cf. [GNE02, GNE03, Maetal03, SNE01, XWGM06]). Much more work is needed in this regard, and it remains to be seen how well extensions of PNP can deal with the entire set of correlations present in particle-based simulations. Despite similar limitations, continuum models are used very widely in many fields: For example, in computational electronics, continuum models are widely used because they are typically much faster than particle-based simulations (cf. [Se84, JaLu89]).

In our work, we use the extended form of PNP as found in [GNE02, GNE03], understanding that we will need to refine and replace this model as it is improved. The following sections show how our inversion approach can easily be updated to possibly improved forward models.

We assume that the total number of different species is M, but we distinguish between the free species and the species confined to the channel, which create the permanent charge of the channel. For simplicity, we restrict ourselves to a single confined species, denoted with index M, but extensions to multiple confined species

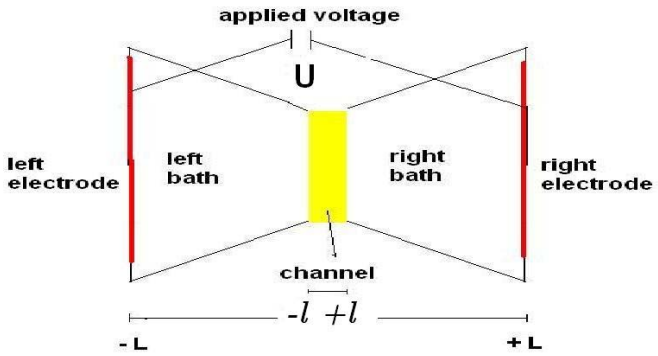

FIG. 1. *Two-dimensional sketch of the computational domain* Ω *modelling the bath-channel system.*

are possible. We mention that selectivity in an ion channel can occur only if $M \geq 4$, since one needs at least two free species with charges of the same sign in order to have selectivity of one over the other, as well as a confined species (permanent charge) and a free species of opposite sign to achieve charge neutrality in the bath. Since the bath and channel in practice always includes water, the number of densities should satisfy $M \geq 5$. Indeed, in the case of an L-type Ca channel we study in further detail below, the number of species is exactly equal to five.

The concentrations have to be computed in a domain Ω that describes the bath and channel. A schematic setup of Ω is depicted in Figure 1.

The electric potential is computed from the Poisson equation with a source term equal to the charge generated by the ions, including the permanent charge. For the continuum description of ion transport, the Nernst–Planck (NP) equations are used, which involve a diffusion term as well as a drift term caused by the electric field (ideal electrostatic potential), an external confining potential, and the excess electrochemical potential. A computational model is a coupled system of the form (after suitable scaling)

$$-\lambda^2 \Delta V = \sum_k z_k \rho_k, \tag{2.1}$$

$$-\nabla \cdot (m_j \rho_j \nabla \mu_j[\rho_1, \ldots, \rho_M; V]) = 0, \qquad j = 1, \ldots, M. \tag{2.2}$$

Here z_k denotes a relative charge of the kth species, m_j is the mobility, and λ is a scaled variable depending on the dielectric coefficient, elementary charge, and typical values of the concentrations ρ_k. The potentials μ_k are computed as variations of an energy functional, i.e.,

$$\mu_k = \frac{\partial}{\partial \rho_k} E[\rho_1, \ldots, \rho_M; V], \tag{2.3}$$

which is of the form

$$E[\rho_1,\dots,\rho_M;V] = \int_\Omega \left(-\lambda^2|\nabla V|^2 + \sum_k (z_k V\rho_k + c_k\rho_k \log\rho_k + \mu_k^0\rho_k) \right) dx + E^{ex}[\rho_1,\dots,\rho_M]. \tag{2.4}$$

The functional E includes electrostatic interaction via the electric field (the first two terms), diffusion (the logarithmic term), external forces via potentials μ_k^0, and direct electric and chemical interactions. Note that the Poisson equation (2.1) can be seen as an equilibrium condition for this energy, i.e.,

$$0 = \frac{\partial}{\partial V} E[\rho_1,\dots,\rho_M,V]. \tag{2.5}$$

Besides the specific exchange terms in energy and potentials, the PNP equations (2.1), (2.2) are a standard model for electrodiffusion of charged species (cf. [Ru90]), which has well-known applications to semiconductors (cf. [VR50, MRS90]). A major difference between electrodiffusion of ions and semiconductors is that it is easy to control the concentrations of the different species in the bath independently of the applied potential, while it is not easy (or even usually possible) to control the concentration of holes or electrons independent of the contact potential. Boundary conditions for the ion channel problem are of the form

$$\begin{aligned}
&V = U && \text{on } \Gamma_D, && \\
&\rho_j = \eta_j && \text{on } \Gamma_D, && j = 1,\dots,M-1, \\
&\frac{\partial \mu_M}{\partial n} = 0 && \text{on } \Gamma_D, && \\
&\frac{\partial V}{\partial n} = 0 && \text{on } \Gamma_N, && \\
&\frac{\partial \mu_j}{\partial n} = 0 && \text{on } \Gamma_N, && j = 1,\dots,M.
\end{aligned} \tag{2.6}$$

Here the boundary is split into $\partial\Omega = \Gamma_D \cup \Gamma_N$, where Γ_N is the insulated part and $\frac{\partial .}{\partial n}$ denotes the normal derivative. Since there are usually two baths, Γ_D will consist of two separated components, and the boundary values are typically constant on each component. The potential U (or, rather, the difference of U between the left and right bath) denotes an applied voltage, and η_j are the bath concentrations of the free species, which are constrained by the charge neutrality condition

$$\sum_{j=1}^{M-1} z_j\eta_j = 0. \tag{2.7}$$

Note that the confined species is usually modeled at equilibrium, which is equivalent to the zero flux boundary condition (for the constrained ions) on the whole boundary. The total number of confined particles N_M needs to be specified to determine ρ_M, giving

$$\int_\Omega \rho_M \, dx = N_M. \tag{2.8}$$

The (measured) output of a channel is the current flowing out on one side, given by

$$I = \sum_{k=1}^{M-1} \int_{\Gamma_0} z_k J_k \cdot dn, \tag{2.9}$$

where $\Gamma_0 \subset \Gamma_D$ is one of the connected components of Γ_D and J_k denotes the flux of species k given by

$$J_k = -\rho_k \nabla \mu_k = -c_k \nabla \rho_k - z_k \rho_k \nabla V - \rho_k \nabla \mu_k^0 - \rho_k \nabla \mu_k^{ex}, \tag{2.10}$$

where the excess potential is defined as $\mu_k^{ex} = \frac{\partial E^{ex}}{\partial \rho_k}$. The current can also be measured and computed from the charge induced on surrounding (Dirichlet) boundaries using the Shockley–Ramo theorem (cf. [NPGE04]).

We mention that the nondimensionalization and scaling of (2.1), (2.2), (2.6) can be performed in an analogous way to the drift-diffusion model for semiconductors (cf. [MRS90]), and for typical values one also has to expect that λ is small; i.e., the Poisson equation (2.1) becomes a singularly perturbed problem.

The system just described has to be coupled to some model for the excess potentials. The excess electrochemical potentials (obtained as variations of the excess energy with respect to the particle densities) include the direct interactions between the ions, usually obtained from hard-sphere or Lennard-Jones models. The external confining potential describes the external forces produced by the structure of the channel on the ionic groups of the protein that make up the permanent charge. This confined permanent charge produces the selectivity of the channel. For our test computations detailed below, we use a specific model of the other components of the excess potential based on density-functional theory (DFT), as described in [GNE02, GNE03, NCE00]. Other models of the excess electrochemical potential require similar computational schemes and lead to the same kind of inverse problems. For a detailed statement of all equations used in the computation of the excess potentials we refer to the appendix of [BEE06].

3. Inverse problems in ion channels. As in many inverse problems, we consider two classes of inverse problems in ion channels, which have different practical motivations:

- *Identification problems* consist in determining properties of a "real" channel (permanent charge and structure), given measurements of the channel output (the total current, in a standard experimental setting) at various different conditions (applied voltages, bath concentrations of the ions).
- *Design problems* consist in determining properties of a "synthetic" channel—either a modification of a natural channel (cf. [Mietal06]) or an abiotic analogue of a biological channel (cf. [Sietal06])—such that optimal characteristics are obtained with respect to some criterion (e.g., selectivity with respect to certain ion species). The medical and technological effects of improved selectivity can be very important. For example, improving Ca selectivity in the L-type Ca channel (by using a drug that changes permanent charge in a way mathematics suggests, if such a drug can be made) would be medically relevant.

The unknowns to be identified or designed are related to the permanent charge, i.e., the ion species confined to the channel. First, an important number is the total

amount of permanent charge, i.e., the number N_M of charged particles confined to the channel. A second important quantity determining the permanent charge is the external confining potential μ_M^0, which represents the forces acting on the permanent charge and encodes the channel structure. In the absence of an electrical field and of electrochemical interaction with other ions, the permanent charge density is given by

$$\rho_M = \gamma_M N_M \exp\left(-\mu_M^0 / z_k\right) \tag{3.1}$$

with a constant γ_M determined from the condition (2.8). Hence, the number N_M and the confining potential μ_M^0 determine the permanent charge density and, subsequently, the selectivity properties of the channel. If the sensitivity of the permanent charge density ρ_M with respect to voltages and bath concentrations in the measured range appears to be negligible, one can also try to directly infer ρ_M from the measurements, ignoring the NP equation for ρ_M. The total charge N_M is a single positive number for which a lower bound (zero) and an upper bound (since too large permanent charges would destroy the channel) are available, and thus it could even be determined by sampling all its possible values. The ill-posedness plays no significant role in the determination of N_M. The confining potential μ_M^0 (and also the density ρ_M as an alternative) is a function of space, so that the inverse problem of determining the confining potential is infinite-dimensional. Since ill-posedness in the sense of discontinuous dependence on data arises only for infinite-dimensional problems and numerical instability becomes more severe as the number of unknowns/design parameters in the inverse problems increases (cf. [EHN96]), instability effects are expected to be more significant for determining the confining potential than for determining the total charge. As a consequence of the ill-posedness, suitable regularization methods have to be used to compute stable approximations of the confining potential, as explained in the previous sections. In the following, we will describe the computational solution of the inverse problems of determining total charge and confining potential in detail, both in the cases of identification and of design.

3.1. Identification. The aim of the identification problem is to find the total charge and/or the confining potential from measurements of the outflow current I taken at different bath concentrations η_j (boundary values of the densities ρ_j) and at different applied voltages U (boundary values of the electric potential V). The measured current I is one real number for each combination of voltage and bath concentrations. In general, I can be seen as a functional of voltage and bath concentrations. The underlying forward model creates a relation between the input P and the output I, which can be modeled via a nonlinear operator $F : P \mapsto I$ between function spaces. Note that the evaluation of the operator F for a specific value of P involves the solution of forward problems with given P for each combination of voltage and bath concentrations (in the idealized setting an infinite number of forward problems). In this setup, the identification problem can be formulated as the operator equation

$$F(P) = I^\delta, \tag{3.2}$$

where I^δ denotes the noisy version of the current obtained from measurements.

We mention that this identification problem has many similarities to the identification of *doping profiles* (i.e., permanent charges) in semiconductor devices from electrical measurements, a problem which has been investigated in detail previously (cf. [BEMP01, BEM02, BELM04, LMZ06, Wo06, WB06]). Since the underlying differential operators appearing in the forward model are exactly the same, one may

expect similar mapping properties of the forward operator F. In particular, this analogy suggests that the identification problem in ion channels (concerning the permanent charge density or the associated constraining potential) is severely ill-posed, as was found in some cases for semiconductors (cf. [BEMP01]). Below we shall also provide analytical arguments for a simplified model and numerical ones for the full model confirming the severe ill-posedness.

We also want to highlight some important differences between the identification problem for the permanent charge of ion channels and the already known identification of doping profiles in semiconductors. First, the forward models include additional effects such as the higher number of species, the excess electrochemical potentials, the different boundary conditions, and the model for the permanent charge density depending on the constraining potential. The second and most important difference is the amount of data that can be used. For semiconductors, only the voltage can be varied, but the boundary concentrations (of electrons and holes) are fixed. As a consequence, the amount of data is not enough to produce a unique solution of the inverse problem using current measurements (cf. [BEM02, Wo06]). On the other hand, one can also measure capacitances in the case of semiconductors (i.e., variations of the total charge with respect voltage change), which can significantly improve the quality of reconstructions in the case of unipolar devices (cf. [Wo06]), but measurements of nonlinear capacitance in biological systems are not analogous (cf. [BeSt98]). However, even with additional capacitance measurements, there are examples of nonuniqueness for the identification of doping profiles in bipolar devices due to an inherent antisymmetry caused by the special boundary values in semiconductors (cf. [Wo06]). Boundary values cover a wide range in an ion channel, and so this antisymmetry is broken, and uniqueness in the identification becomes more likely.

For semiconductors, it has already been shown that very demanding problems such as the inverse conductivity problem with a measured Dirichlet-to-Neumann map arise as special cases, and the full inverse dopant profiling is even more complex (cf. [BEMP01]). Since the measured currents and capacitances are functions of a single variable—the voltage—in semiconductors, the evaluation of the corresponding forward map F involves significantly fewer numerical solutions ("solves") than in the case of ion channels, where the PNP system (2.1), (2.2) has to be solved for varying bath concentrations as well as voltage. Consequently, the computational complexity of the identification problem is even higher for ion channels and seems to be one of the most challenging inverse problems with respect to this issue. Because of the high number of solves of the PNP system, it is of fundamental importance to use efficient numerical schemes for the forward problem. Here we use a mixed finite element scheme with a novel symmetric linearization, which allows an efficient and robust solution of PNP systems with input parameters that cover a wide range of values (cf. [BW07]). The fact that currents are measured for many different setups in ion channel experiments is of crucial importance for the quality of reconstructions. Since the data set is richer than for semiconductors, one can actually achieve more ambitious goals in the inverse problem, e.g., unique reconstruction of the permanent charge density as a function of space (as we shall see below).

3.2. Design. The general remarks and notation of section 3.1 are also valid here. However, in the case of (optimal) design, there is an objective to be achieved instead of an object to be determined. In the applications to ion channels we have in mind, the primary objective is always to increase selectivity of one species over another. As discussed in detail in [GE02], selectivity has to be defined by experimental

results, and several different selectivity measures are available. A selectivity measure S_j of a species can be defined as a functional of ion densities and fluxes (possibly at varying voltage; cf. [GE02]). Since the densities and fluxes depend implicitly on the unknowns P related to the permanent charge (total number of charges or the constraining potential), the selectivity measure can also be rewritten as a functional $S_j = S_j(P)$ of these parameters. If the aim is to increase selectivity of species a over b, then one can minimize a relative selectivity measure

$$Q(S_a(P), S_b(P)) \to \min_P. \tag{3.3}$$

A simple widely used choice which we also use in our computational experiments is the selectivity quotient $Q(S_a, S_b) = -\frac{S_a}{S_b}$ (note that minimizing the negative quotient is equivalent to the original aim of maximizing the relative sensitivity). Analogous treatment is possible for other choices of Q, e.g., $Q(S_a, S_b) = \frac{S_b}{S_a}$ or $Q(S_a, S_b) = -S_a + S_b$.

In practice, to achieve a design task does not mean to actually maximize the functional Q, but usually one is satisfied if a significant improvement with respect to the criterion described by Q, e.g., the channel selectivity, is achieved.

The optimal design problem shares many of the problems of instability and ill-posedness with the identification problem. In the optimal design problem, however, there are no input data, but only a goal to be achieved, so that noise in the input data is not relevant. However, if one minimizes a functional Q as part of the solution of the design problem, as was done previously in the identification problem, then first of all the minimizer might not exist, which means that the norm of P tends to infinity in the associated minimization algorithm. Even if a minimizer exists, it might not be robust with respect to small perturbations of the problem (modeling errors, numerical errors, small changes of applied voltage and concentrations, etc.), so that a computed solution becomes useless in practice. Due to these instabilities, we have used regularization approaches to solve the design problem similar to those used for the identification problem (section 5).

We finally mention that optimal design problems for PNP systems have also been investigated before in semiconductor applications (cf. [HP02a, HP02b, BP03]), but again there are many significant differences in applications to ion channels. Besides all the differences in the forward problem, the optimal design of semiconductors (and, in particular, the objective functional) is always related to currents. In semiconductors, only holes and electrons carry charge, and so there is no analogue to selectivity measures of ion channels. Hence, the optimal design task for ion channels is a quite new problem that connects only loosely to previous literature.

4. Analysis of a simplified model. In order to obtain further insight into the structure of the inverse problems, we study a simplified model case for a spatially one-dimensional setup, i.e., $\Omega = (-L, L)$, with the channel being the subregion $(-\ell, \ell)$. We ignore all direct interactions; i.e., we set $E^{ex} \equiv 0$, and, moreover, we set $\mu_k^0 \equiv 0$. Hence, we arrive at the one-dimensional PNP model

$$-\lambda^2 V'' - \sum_{j=1}^{M} z_j \rho_j = 0, \tag{4.1}$$

$$J_k' = 0, \qquad k = 1, \dots, M-1, \tag{4.2}$$

$$J_k - \rho_k z_k V' - c_k {\rho_k}' = 0, \qquad k = 1, \dots, M-1, \tag{4.3}$$

with boundary conditions

$$V(-L) = 0, \qquad V(L) = U, \qquad \rho_k(\pm L) = \eta_k^{\pm}, \qquad k = 1, \dots, M-1.$$

The equations simplify after an exponential transform to a new set of variables (also called *Slotboom variables*; cf. [MRS90]) $u_k = e^{-\beta_k V}\rho_k$, where $\beta_k = -\frac{z_k}{c_k}$. We obtain

$$-\lambda^2 V'' - \sum_{j=1}^{M-1} z_j e^{\beta_j V} u_k = z_M \rho_M, \tag{4.4}$$

$$J_k' = 0, \qquad k = 1, \dots, M-1, \tag{4.5}$$

$$J_k - c_k e^{\beta_k V} u_k' = 0, \qquad k = 1, \dots, M-1, \tag{4.6}$$

with boundary values $V(-L) = 0$, $V(L) = U$, $u_k(-L) = \eta_k^-$, and $u_k(L) = e^{-\beta_k U}\eta_k^+$. Starting from this transformation, (4.5) and (4.6) can be integrated to obtain the solution

$$\rho_k(x) = \left(\eta_k^- + (e^{-\beta_k U}\eta_k^+ - \eta_k^-)\frac{G_k(x)}{G_k(L)}\right) e^{\beta_k V(x)} \tag{4.7}$$

with the function

$$G_k(y) := \int_{-L}^{y} e^{-\beta_k V(x)}\, \mathrm{d}x.$$

Inserting the explicit solution for the concentrations from the NP equations into the Poisson equation, we obtain a single nonlinear integro-differential equation for the electric potential as

$$-\lambda^2 V'' - \sum_{k=1}^{M-1} \mathcal{R}_k[V] = z_M \rho_M \tag{4.8}$$

with the nonlinear operators $\mathcal{R}_k$ given by

$$\mathcal{R}_k[V](x) = z_k \left(\eta_k^- + (e^{-\beta_k U}\eta_k^+ - \eta_k^-)\frac{G_k(x)}{G_k(L)}\right) e^{\beta_k V(x)}. \tag{4.9}$$

The fluxes J_k can be computed as

$$J_k = \frac{(e^{-\beta_k U}\eta_k^+ - \eta_k^-)}{\int_{-L}^{L} e^{-\beta_k V(x)}\, \mathrm{d}x}. \tag{4.10}$$

Since the fluxes J_k are constant in spatial dimension one (and $J_M = 0$), we obtain the current globally as

$$I = \sum_{k=1}^{M-1} z_k J_k. \tag{4.11}$$

From a computational viewpoint, it seems attractive to consider a setup around (thermodynamic) equilibrium, since the solution of the forward model can be approximated by the simpler linearization around the equilibrium state. An equilibrium situation is obtained if the fluxes of all species vanish, which means in the one-dimensional

setting that $\eta_k^- = e^{-\beta_k U}\eta_k^+$, since the flux of every ionic species vanishes in this case. Note that one can always find suitable combinations of the bath concentrations that satisfy the above equilibrium condition as well as charge neutrality (e.g., vanishing bath concentration will always be an equilibrium case), so that we obtain a family of equilibria, still freely parameterized by the voltage U. This is an important particular feature of PNP systems in channels and will allow us to study some new effects. On the other hand, this also highlights possible redundancy in the data, since there are several parameter combinations that produce zero fluxes and even more that produce zero current, i.e., data without information content for the inverse problem.

The equilibrium electric potential parameterized by U will satisfy

$$-\lambda^2 V_{0,U}'' - \sum_{k=1}^{M-1} z_k \eta_k^- e^{\beta_k V_{0,U}} = z_M \rho_M, \qquad V_{0,U}(-L) = 0, V_{0,U}(L) = U. \tag{4.12}$$

Since β_k and $-z_k$ have the same sign and since η_k^- is nonnegative, the nonlinear terms $z_k\eta_k^- e^{\beta_k V_{0,U}}$ in the Poisson equation depend monotonically on $V_{0,U}$, so that the existence and uniqueness of the solution can be seen easily, as well as the stable dependence on ρ_M.

Now consider the linearization of the problem around the equilibrium values of $\eta_k^\pm$, i.e., the first-order change (in ϵ) of the output I with respect to perturbations of the form $\eta_k^\pm + \epsilon\hat{\eta}_k^\pm$ that still satisfy charge neutrality. The first-order expansion of the integral term in (4.10) disappears, since the numerator vanishes at equilibrium, and hence the linearized output is given by

$$\hat{I}(U) = \sum_{k=1}^{M-1} z_k \frac{(e^{-\beta_k U}\hat{\eta}_k^+ - \hat{\eta}_k^-)}{\int_{-L}^{L} e^{-\beta_k V_{0,U}(x)}\,\mathrm{d}x}.$$

We mention that the use of $\hat{I}_U$ instead of I produces only a restriction of the data set. It is not a simplifying assumption because $\hat{I}_U$ can be computed from the measurements of currents I in a full range of parameters around their equilibrium values.

Now assume that $M \geq 4$, so that we have at least three different mobile species. Then one can always find values $\hat{\eta}_k^\pm$ satisfying charge neutrality such that $\hat{\eta}_k^- = e^{-\beta_k U}\hat{\eta}_k^+$, $k \neq m$, and $\hat{\eta}_m^- \neq e^{-\beta_m U}\hat{\eta}_m^+$ for some $m \in 1, \ldots, M-1$. Hence, for this choice,

$$\hat{I}(U) = z_m \frac{(e^{-\beta_m U}\hat{\eta}_m^+ - \hat{\eta}_m^-)}{\int_{-L}^{L} e^{-\beta_m V_{0,U}(x)}\,\mathrm{d}x},$$

and therefore one can directly infer the knowledge of $M(U) = \int_{-L}^{L} e^{-\beta_m V_{0,U}(x)}\,\mathrm{d}x$ from the knowledge of $\hat{I}_U$. Since the equilibrium Poisson equation can be solved uniquely for fixed U and given ρ_M, the forward map can be related to a (nonlinear) integral operator, and the identification of the permanent charge density corresponds to a nonlinear integral equation of the first kind (the unknown appears only under the integral sign), which is a classical ill-posed problem (cf. [En97, Gr84]).

The analysis particularly simplifies for the equilibrium case of small bath concentrations, i.e., a perturbation of $\eta_k^\pm \equiv 0$. In this situation, we can compute $V_{0,U} = V_{0,0} + \frac{x+L}{2L}U$, where $V_{0,0}$ solves

$$-\lambda^2 V_{0,0}'' = z_M \rho_M, \qquad V_{0,0}(\pm L) = 0.$$

Noticing that there is a one-to-one dependence between ρ_M and the function $f := e^{-\beta_m V_{0,0}}$, we can rephrase the integral equation as

$$\tilde{M}(\sigma) = \int_{-L}^{L} e^{-\sigma x} f(x)\, \mathrm{d}x$$

with $\tilde{M}(\sigma) = e^{\frac{\beta_m U}{2}} M(U)$ and $\sigma = -\frac{\beta_m}{2L} U$. Varying the voltage U in an interval $(-U_{max}, U_{\max})$ is then equivalent to varying $\sigma \in (-\sigma_{max}, \sigma_{max})$. Hence, we arrive at a Fredholm integral equation of the first kind for f, with an analytic kernel, a problem which is known to be severely ill-posed (see the analysis below). The standard classification of ill-posedness we refer to divides into mildly ill-posed problems with an error amplification that grows like a polynomial with increasing frequency and severely ill-posed problems with faster growing error amplification (usually exponentially). The remaining step of computing ρ_M from f is another nonlinear ill-posed problem, which involves the application of a logarithm and two differentiations to compute

$$\rho_M = \frac{\lambda^2}{z_M \beta_m} (\log f)''$$

and is therefore mildly ill-posed.

Identifiability, i.e., uniqueness of the reconstruction from the given data set, can be guaranteed in this case independent of the size of U_{max} (respectively, σ_{max}). Assume that $M(\sigma)$ is known in an arbitrarily small interval around $\sigma = 0$; then, in particular, all derivatives

$$(-1)^p \frac{d^p}{d\sigma^p} \tilde{M}(0) = \int_{-L}^{L} x^p f(x)\, \mathrm{d}x, \qquad p = 0, 1, \ldots,$$

and hence all moments of f are known. Since a function is uniquely determined from its moments, we conclude the uniqueness of the reconstruction of f and subsequently of ρ_M. Note that we have used only a subset of the data to show identifiability, and so one might argue that the full inverse problem is actually overdetermined.

In order to gain some quantitative information about the instability present in the identification problem, we investigate the singular values of the operator

$$K : L^2([-L, L]) \to L^2([-\sigma_{max}, \sigma_{max}]), \qquad f \mapsto \int_{-L}^{L} e^{-\sigma x} f(x)\, \mathrm{d}x.$$

Note that K is a symmetric positive semidefinite operator, and hence the singular values and eigenvalues are equal. As mentioned above, the fact that the integral kernel is analytic implies that the eigenvalues decay faster than any polynomial (cf. [We68]). One actually expects exponential decay. This is confirmed by a numerical computation of the spectrum (with 1025 grid points) displayed in Figure 2, where we plot the singular values (rescaled so that the leading one is equal to one) for different values of σ_{max} and $L = 1$ fixed. (We do not consider the change of L, since its change can be related to the change of σ_{max} by a simple rescaling.) Since the error amplification factor at each frequency equals the inverse of the singular value, this problem is indeed severely ill-posed. The influence of the maximal value σ_{max} is seen by comparing the four results in the figure. For a smaller value of σ_{max}, the decay of singular values is faster, which implies a more significant loss of information. Since σ_{max} is proportional to the maximal value of the applied voltage U, this result shows that one should make measurements at as large a voltage as possible to reduce the instability in the reconstruction as much as possible.

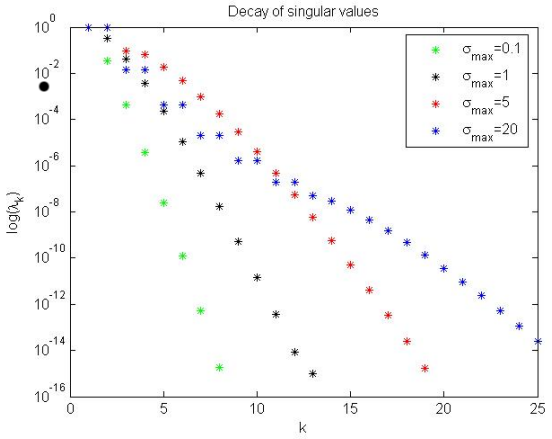

FIG. 2. *Leading singular values of the linear operators K for different values of σ_{max}.*

5. The full inverse problems. In the following, we shall discuss the *forward problem*, namely the solution of the PNP-DFT model for given data, and the map F to the output, namely current-voltage curves for different bath concentrations. This map will be of fundamental use in the mathematical formulation and solution of the inverse problems. As a first step, we analyze the existence and uniqueness of solutions, which hold at least for small bath concentrations of the free species.

5.1. Properties of the forward operators. In the following, we provide an analysis of the PNP model, including the excess free energy. We mention that an extensive analysis of PNP systems is available for applications to semiconductor devices (cf. [MRS90] and the references therein), but the inclusion of the excess free energy in the ion channel model prevents a direct extension of these available results. We shall consider only a particular case of small bath concentrations in the following, in order to make sure that the forward operator can indeed be well-defined at least in some parameter range. To clarify, we state the system we consider, namely the solution of (2.1), (2.10) and, as an equivalent statement of (2.2),

$$\nabla \cdot J_k = 0, \qquad k = 1, \dots, M, \tag{5.1}$$

together with (2.6) and (2.8). In order to show the specific dependence on the applied voltage U, the vector of bath concentrations $\eta = (\eta_k)_{k=1,\dots,M-1}$, the number N_M of confined particles, and the confining potential μ_M^0, we introduce the following nomenclature:

> We denote by $\mathcal{P}(U, \eta; N_M, \mu_M^0)$ the problem of solving (2.1), (2.10), (5.1), (2.6), (2.8) for the unknowns $(V, \rho_1, \dots, \rho_M)$.

We shall assume that $U \in H^{\frac{1}{2}}(\partial\Omega_D) \cap L^\infty(\Omega_D)$ and that E^{ex} is twice continuously differentiable on $H^1(\Omega)^M \cap L^\infty(\Omega)^M$. For the sake of simplicity, we also assume that $E^{ex}(\rho_1, \dots, \rho_{M-1}, \cdot)$ is a convex functional of the last variable if ρ_k, $k = 1, \dots, M-1$, is sufficiently small. Consequently, the map between the density ρ_M and the confining potential μ_M^0 is monotone in this range.

We start our analysis in the case of zero bath concentrations, i.e., $\eta_k = 0$, for $k = 1, \dots, M-1$. In this case, there is obviously no flow, and we can easily construct a solution.

LEMMA 5.1. *Under the above assumptions, there exists a solution*

$$(V, \rho_1, \dots, \rho_M) \in H^1(\Omega)^{M+1} \cap L^\infty(\Omega)^{M+1}$$

of problem $\mathcal{P}(U, 0; N_M, \mu_M^0)$*, which satisfies* $\rho_k \equiv 0$ *for* $k = 1, \dots, M-1$.

Proof. The functions $\rho_k \equiv 0$ satisfy the boundary conditions as well as (2.10), (5.1). We now look for a solution of the remaining problem

$$-\lambda^2 \Delta V = z_M \rho_M, \qquad \rho_M = \gamma_M N_M \exp\left(-\frac{z_M V + \mu_M^0 + \mu_M^{ex}}{c_M}\right),$$

with the boundary conditions remaining for ρ_M and V. Using the monotone dependence of μ_M^{ex} on ρ_M it is straightforward to show that for each $V \in H^1(\Omega) \cap L^\infty(\Omega)$ there exists a unique solution $\rho_M \in H^1(\Omega) \cap L^\infty(\Omega)$ of the second equation. Moreover, the specific exponential dependence on V implies that the map $\mathcal{F} : V \mapsto -z_M \rho_M$ is monotone and continuously Fréchet-differentiable, too. Hence, we can perform a further reduction to a problem of the form

$$-\lambda^2 \Delta V + \mathcal{F}(V) = 0 \quad \text{in } \Omega$$

with Neumann and Dirichlet boundary conditions on the respective parts of $\partial\Omega$. Finally, a standard result for elliptic equations with monotone operators implies existence and uniqueness of this remaining problem (cf. [Sh96]). ∎

In order to proceed to small positive bath concentrations, we shall perform a linearization around zero concentrations. The formal linearization of the PNP system around a given state $(V, \rho_1, \dots, \rho_M)$ is given by

$$-\lambda^2 \Delta \hat{V} - \sum z_k \hat{\rho}_k = f_0, \tag{5.2}$$

$$\nabla \cdot \left(c_k \nabla \hat{\rho}_k + z_k \rho_k \nabla \hat{V} + z_k \rho_k \nabla \left(\sum_j \frac{\partial \mu_k^{ex}}{\partial \rho_j} \hat{\rho}_j \right) + z_k \hat{\rho}_k \nabla (V + \mu_k^0 + \mu_k^{ex}) \right) = \nabla \cdot (\rho_k \nabla f_k), \tag{5.3}$$

$$c_M \frac{\hat{\rho}_M}{\rho_M} + \hat{V} + \sum_j \frac{\partial \mu_M^{ex}}{\partial \rho_j} \hat{\rho}_j = f_M \tag{5.4}$$

with right-hand sides $f_j \in L^\infty(\Omega) \cap H^1(\Omega)$, $j = 0, \dots, M$, to be solved for $\hat{V}$ and $\hat{\rho}_k$. The left-hand side of (5.2), (5.3) is indeed a Fréchet derivative of the left-hand side in the PNP system. We are going to prove that this linearization defines a continuously invertible linear operator $(f_0, \dots, f_M) \mapsto (\hat{V}, \hat{\rho}_1, \dots, \hat{\rho}_M)$ around zero bath concentrations, i.e., for $(V, \rho_1, \dots, \rho_M)$ being the solution of problem $\mathcal{P}(U, 0; N_M, \mu_M^0)$ from Lemma 5.1. The implicit function theorem in Banach spaces (cf. [De85, Theorem 15.1]) then yields the local existence and uniqueness of solutions as well as the well-posedness of the linearized problems for small bath concentrations.

LEMMA 5.2. *Let* $(V, \rho_1, \dots, \rho_M)$ *be the solution of problem* $\mathcal{P}(U, 0; N_M, \mu_M^0)$*, as in Lemma* 5.1*. Then, for any* $f_j \in L^\infty(\Omega) \cap H^1(\Omega), \dots$*, there exists a unique solution*

$$(\hat{V}, \hat{\rho}_1, \dots, \hat{\rho}_M) \in H^1(\Omega)^{M+1} \cap L^\infty(\Omega)^{M+1}$$

of (5.2)*,* (5.3)*, which depends continuously on the data.*

Proof. Due to $\rho_k \equiv 0$ for $k = 1, \dots, M-1$, the NP equations (2.2) simplify to

$$\nabla \cdot \left(c_k \nabla \hat{\rho}_k + z_k \hat{\rho}_k \nabla (V + \mu_k^0 + \mu_k^{ex}) \right) = 0$$

and, in particular, become scalar equations decoupled from the other variables. After a change of variables to $u_k := \hat{\rho}_k \exp(-\beta_k(V + \mu_k^0 + \mu_k^{ex}))$, with $\beta_k = -\frac{z_k}{c_k}$, we obtain the equation

$$\nabla \cdot \left(c_k \exp(-\beta_k(V + \mu_k^0 + \mu_k^{ex}))\nabla u_k\right) = 0,$$

whose well-posedness can be analyzed by standard techniques for elliptic equations due to the absence of convective terms. Using also the equilibrium boundary conditions for $\hat{\rho}_M$, we obtain the remaining problem

$$-\lambda^2 \Delta \hat{V} - z_M \hat{\rho}_M = \tilde{f}_0, \qquad c_M \frac{\hat{\rho}_M}{\rho_M} + \hat{V} + \frac{\partial \mu_M^{ex}}{\partial \rho_M}\hat{\rho}_M = \tilde{f}_M,$$

now with the given right-hand sides $\tilde{f}_0 = \sum_{k=1}^{M-1} z_k \hat{\rho}_k + f_0$ and $\tilde{f}_M = \sum_{k=1}^{M-1}(f_k - \frac{\partial \mu_M^{ex}}{\partial \rho_k}\hat{\rho}_k)$. For the remaining problem to compute $\hat{V}$ and $\hat{\rho}_M$, exactly the same arguments as in Lemma 5.1 apply, so that we can conclude the well-posedness of the linearization. ∎

We now have collected the necessary prerequisites to prove the well-posedness of the problem for small bath concentrations.

THEOREM 5.3. *Let $\|\eta_k\|_{H^{1/2}(\Gamma_D)}$ and $\|\eta_k\|_{L^\infty(\Gamma_D)}$ be sufficiently small. Then, for each $U \in H^{1/2}(\Gamma_D)$, there exists a locally unique solution*

$$(V, \rho_1, \ldots, \rho_M) \in H^1(\Omega)^{M+1} \cap L^\infty(\Omega)^{M+1}$$

of problem $\mathcal{P}(U, \eta; N_M, \mu_M^0)$, and the linearized problem (5.2), (5.3) is well-posed.

Proof. In the lemmas above, we have shown that the problem for $\eta \equiv 0$ is well-posed and its Fréchet-derivative exists with continuous inverse in the respective function spaces. Moreover, the equation operator is Fréchet differentiable, so that we can apply the implicit function theorem in Banach spaces (cf. [De85, Theorem 15.1]) to conclude that a locally unique solution of problem $\mathcal{P}(U, \eta; N_M, \mu_M^0)$ exists around $\eta \equiv 0$ and that the linearized problems are well-posed for small η. ∎

As a direct consequence of the above result, we can verify the well-definedness and even differentiability of the map from the relevant input data related to the permanent charge to the output current.

COROLLARY 5.4. *Let $\|\eta_k\|_{H^{1/2}(\Gamma_D)}$ and $\|\eta_k\|_{L^\infty(\Gamma_D)}$ be sufficiently small. Then, for each $U \in H^{1/2}(\Gamma_D)$, the map*

$$\begin{aligned} G(\cdot; U, \eta): \quad \mathbb{R}^+ \times (H^1(\Omega) \cap L^\infty(\Omega)) &\to \mathbb{R}, \\ (N_M, \mu_M^0) &\mapsto I(U, \eta) = \int_{\Gamma_D} \sum z_k J_k \, d\sigma \end{aligned} \tag{5.5}$$

is well-defined, compact, and continuously Fréchet differentiable.

5.2. Regularization. In practice, one has to discretize the function I of the bath concentrations and voltages, so that one computes only a finite number K of function evaluations, denoted by $I_1, \ldots, I_K$, and the operator F can be written in the form $F = (F_1, \ldots, F_K)$. The evaluation of a single part F_j amounts to a single solution of the forward problem for a specific combination of the bath concentrations and the applied voltage and the subsequent computation of the outflow current from the solution. The linearization is then of the form $F' = (F_1', \ldots, F_K')$, and its adjoint is of the form $F'(P)^* = \sum_{j=1}^K F_j'(P)^*$. Note that the operators F_j are of the form $F_j(P) =$

$G(H(P); U^j, \eta^j)$, where H is the affine linear operator mapping the parameter P to the pair (N_M, μ_0^M). If both N_M and μ_0^M are the unknowns in the inverse problem, then H is just the identity. If one of them is known, then H is the operator mapping the other one to the pair (N_M, μ_0^M). The well-definedness and compactness of the operators F_j and subsequently of F can directly be inferred from Corollary 5.4, and one can even conclude the existence of Fréchet derivatives of F.

Due to the instability of the inverse problems, regularization methods should be used for their solution. One of the most frequently used classes of regularization methods for nonlinear problems is variational methods (cf. [EHN96, EKN89, SV89]), where the inverse problem (3.2) is approximated by the variational problem

$$J_\alpha(P) := \|F(P) - I^\delta\|^2 + \alpha R(P) \to \min_P \tag{5.6}$$

with a suitable regularization functional R (e.g., $R(P) = \|P - P^*\|^2$ for Tikhonov regularization) and a positive real regularization parameter α. An alternative is iterative regularization methods (cf. [KNS06, ES00, OBGXY05]), based on an iteration procedure of the form

$$P_{n+1} = P_n - G_n(F(P_n) - I^\delta) \tag{5.7}$$

with a linear or even nonlinear operator G_n (depending on P_n in general). Such an iterative scheme becomes a regularization method with the appropriate choice of a stopping index n_* at which the iteration is stopped. A common choice of stopping rule—due to its computational simplicity—is the discrepancy principle; i.e., the iteration is stopped when the residual reaches the order of the noise level. We mention that with the properties of the operator F and its linearization F' derived above, the existing theory of variational and iterative regularization methods can be applied (cf. [EHN96, EKN89, KNS06, ES00]) to our case. We can then guarantee the regularizing properties and convergence of the methods we apply to inverse problems in ion channels.

We mention that an analogous iteration method to (5.7) can (and should) be used to solve the variational problem appearing in variational methods. In our test examples detailed below, we carried out a gradient-based method, which is an iteration procedure of the form

$$P_{n+1} = P_n - \tau_n \left[F'(P_n)^*(F(P_n) - I^\delta) + \alpha R'(P_n)\right] = P_n - \tau_n J'_\alpha(P_n) \tag{5.8}$$

which can be interpreted as a minimization method for the variational problem (5.6) or, with $\alpha = 0$ and an appropriate choice of the stopping index, as an iterative regularization method of the form (5.7). Here F', R' denote the derivatives of the operator F and the functional R, respectively, in the appropriate function spaces. Moreover, $F'(P_n)^*$ is the adjoint of the derivative (which is a linear operator between these function spaces).

The simplest, but already quite significant, inverse problem to be solved in this context is to determine the number N_M, characterizing the total permanent charge (i.e., $P = N_M$ in the above setting). As noticed above, this problem is one-dimensional as an inverse problem (although, of course, the direct problem is still a system of partial differential equations), and hence the instability does not appear. Also, this problem is *not* very challenging with respect to the optimization algorithm, which is fortunate because this problem is particularly important biologically. The main issue in the optimization is the evaluation of the functional J_α (respectively, the operator

F) and its derivative, which involves the solution of several forward problems. The derivatives can be computed via the adjoint operator $F_j'(P_n)^*$ or approximated simply by finite differencing, which typically creates a higher computational effort but needs no further implementations than those already used to evaluate the forward operator. Since the aim is to identify a single real number only, it seems reasonable that this is possible for rather low values of K, and indeed our computational experiments indicate that this is possible with high accuracy already for $K = 10$ and even for $K = 5$.

The next level of complexity is the identification of the confining potential μ_M^0 or the identification of the permanent charge ρ_M. By analogy to the simplified problems considered above, we have to expect that these identifications are severely ill-posed so that regularization is of fundamental importance. The computational complexity of this inverse problem is much higher also because a much higher number K of different setups is needed in order to obtain a reasonable reconstruction of the confining potential or the permanent charge density. It is interesting that numerical exploration of the forward problem suggests that the details of the distribution of permanent charge, and thus the details of the constraining potential, are much less important for biological function than the total amount of that charge as long as the charge is of one sign and also is not too small.

Also for the design tasks introduced above, one can define variational regularization methods by just changing the objective functional to $Q + \alpha R$. In our computational tests, we specifically use a variational method of the form

$$Q(S_a(P), S_b(P)) + \alpha \|P - P^*\|^2 \to \min_P, \tag{5.9}$$

where P^* is a favored initial design. In a synthetic ion channel, this a priori guess could introduce additional criteria into the minimization; e.g., P^* can represent a total charge or a confining potential that is easy to manufacture, so that the regularization term would introduce a criterion for the minimizer to be close to easily manufacturable states. In this way, robustness is introduced in the problem, which can also be observed in the results of our computational experiments.

From a computational viewpoint, the minimization of the regularized variational problem (5.9) is an analogous task to the one appearing in identification problems. The main steps are the evaluation of the objective functional (by solving forward problems and subsequently evaluating selectivity measures) and the computations of gradients of the objective functional with respect to P. The latter task can again be carried out by finite differencing, which reduces to additional solves of the forward problem and creates a high computational effort, or by solving appropriate adjoint problems. The total computational effort for solving optimal design problems is usually much less than for solving identification problems, since the selectivity measure is computed only for very few different combinations of bath concentrations and voltages. Significantly fewer forward problems have to be solved for evaluating the objective functional than in the case of identification.

6. Case study: An L-type Ca channel. In this section, we report on a case study performed for an L-type Ca channel (LCC), for which we performed the identification and design tasks as described above. A sketch of the LCC is provided in Figure 3.

We choose the LCC because it is of enormous importance as the regulator of the contraction of skeletal and cardiac muscle, and it has received extensive attention in

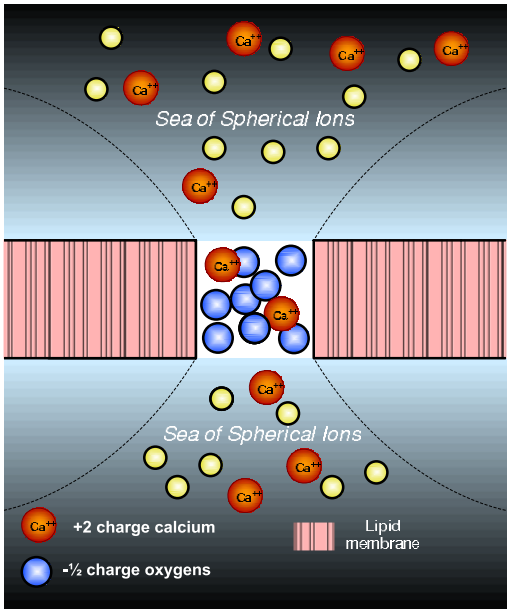

FIG. 3. *Illustration of the LCC when filled with Ca.*

TABLE 1
Parameter settings for the LCC example, using elementary charge $e = 1.602 \times 10^{-19}\,C$.

k	1	2	3	4	5

$\rho_k(-L)$	var	var	var	55 M	0 M

the biophysics literature for that reason (cf., e.g., [KMS83, Hetal92, SMC03]). Recent work shows quite clearly that many properties of two types of calcium channels can be quantitatively described by extended versions of the PNP model (cf. [Betal06, GNE02, Mietal06, Mietal04, Waetal05, XWGM06]). Given the importance of calcium channels and the demonstrated ability of PNP-type models to explain current voltage relations and selectivity over large ranges of concentration of many types of ions, it is natural to use this system in our investigation of inverse problems.

6.1. Forward model. The forward model of the LCC involves the electrical potential V and five densities ρ_k modeling the three mobile ion species Ca^{2+}, Na^{+}, Cl^{-}, a neutral mobile species H_2O, and half-charged oxygens $O^{-1/2}$ corresponding to the permanent charge. This means that each forward problem consists of a coupled system of six partial differential equations, the Poisson equation (2.1) and five NP equations (2.2) for the densities $\rho_1, \ldots, \rho_5$ (see Table 1 for the assignment of densities to the species).

The channel is modeled as cylindrical with diameter 0.4 nm ($y - z$ plane) and length $2\ell = 1$ nm (x-direction), embedded in two baths both of length 1.7 nm. This yields a total length of 4.4 nm for the system, and therefore the computational domain is chosen as $(-L, L)$ with $L = 2.2$ nm.

From the geometry of the system, it is rather obvious that the flow arises in

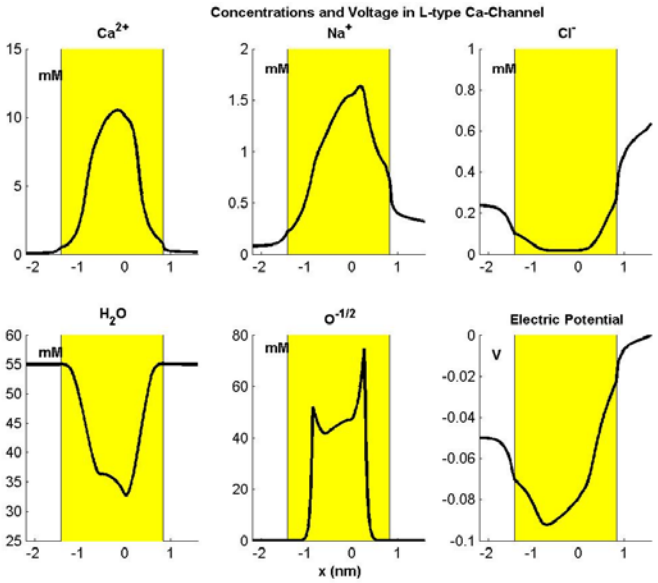

FIG. 4. *Plot of ion densities and electr potential as functions of spatial location for an LCC with applied voltage* 50 *mV. The illuminated region is the channel which is scaled in the* x*-direction by a factor five compared to the bath regions.*

the x-direction, and the model can be reduced by averaging in the $y-z$ plane to a one-dimensional problem with single spatial variable x; but note that our procedures are in no way restricted to the one-dimensional case. In this averaging procedure, the shape of the channel has to be taken into account, which yields some spatially dependent coefficients in the reduced system of one-dimensional differential equations. The details of the averaging and an exact statement of the equations to be solved for the LCC can be found in [GNE02, GNE03, NCE00, BEE06].

We solve the forward problem on a grid with $n = 1251$ (for data generation) and $n = 1000$ cells (for the inverse problem) with a standard conforming finite element discretization of the electric potential and the Poisson equation and a mixed finite element discretization of the continuity equations for the ions. Since we have the electric potential and five different species (Ca^{2+}, Na^+, Cl^-, H_2O, and $O^{-1/2}$), this yields $1252 + 5 \times 1251 = 7507$ degrees of freedom (for data generation), respectively, $1001 + 5 \times 1000 = 6001$ (for the inverse problem) degrees of freedom, in the forward problem.

The measurements are the currents, taken as functions of the voltage and of the left bath concentrations $\rho_k(-L)$ for $k = 1, 2$, whereas the right bath concentrations $\rho_k(L)$ are kept fixed. The water concentration ("osmolarity") is fixed in both baths, and $\rho_5(\pm L) = 0$, because of the confinement of permanent charge to the channel. The concentrations $\rho_3(\pm L)$ are finally determined from the charge neutrality $\sum_k z_k \rho_k(\pm L) = 0$. The parameter settings for the boundary values are given in Table 1, where var means that the values are varied in the identification process.

The solution of the forward model for an LCC with the above settings—applied voltage $U = 50$ mV, $N_M = 8$ confined oxygens, and confining potential μ_M^0 plotted as the exact value in Figure 8—is illustrated in Figure 4. The illuminated region corre-

sponds to the channel, while the white region to the left and right correspond to the bath. In this example, one observes many typical effects, in particular the selectivity properties of the channel. Due to the negative permanent charge (oxygens), there is an attractive electrical force on the positively charged ions (Na and Ca) and a repulsive force on the negatively charged ions (Cl). Moreover, the additional "chemical" forces arising from the finite volume of the ions produce an additional decrease of the densities in the channel region. These excluded volume forces are particularly important because of the narrow cross section of the channel. This decrease in densities can be observed in particular in the plot of the water density, since it is the only force acting on this species. (There are no electrical interactions with water in our system due to neutrality of our model of water.)

6.2. Identification I: Reconstruction of the total charge. In this case, one assumes that the structure of the channel is known, but the total charge of the crowded elements in the selectivity filter is unknown. The inverse identification problem consists of identifying the total charge based on measurements of the total current for different bath concentrations of the ions. As noticed before, the reconstruction of the total charge is the simplest case of an inverse problem for ion channels, so that we expect more accurate results than for the more complicated inverse problems in the sections below.

This inverse problem is a finite-dimensional one. We try only to identify a single real number from a finite number of measurements. As mentioned above, this inverse problem is not ill-posed in the classical sense of inverse problems theory, cf. [EHN96], because of the low dimension. The only possible instability is due to nonlinearity effects, but such effects seemed not to appear in the various computational tests.

For a test of the inverse problem technique, we generated synthetic data for the setup as used in the LCC [GNE03], i.e., a crowded charge consisting of eight half-charged oxygens. This means we solve the forward problem with the finer grid and then compute the resulting currents. Subsequently, we perturb the synthetic measurements by noise and use them as data to solve the inverse problem. (The same technique is also used for the other inverse problems below.) In this way, we have a known reference solution, and we can check to see if the algorithm yields reasonable reconstructions in a stable way.

The reconstructions are carried out by a gradient method for the associated least-squares functional describing the residual. The gradients are approximated by finite differences. This is for illustration only. More efficient ways are possible to approximate the gradient for this and related problems, e.g., via adjoint problems.

In this case, one obtains very accurate reconstructions of the exact total charge even for noisy data and even for a rather low number of measurements, allowing us to deal effectively with this quite significant biological problem. The pessimism of early analysis can be removed if the problem is posed with PNP equations and solved with the methods of inverse problems (cf. [At79, AJ78]); see below. A typical setup consists of three different applied voltages (0.1V, 0V, -0.1 V) and two different concentrations for Na and Ca (2 mM and 4 mM) in the left bath. With all combinations, this gives $3 \times 2 \times 2 = 12$ measured values; i.e., the problem is already overdetermined. An illustration of the reconstruction process in this situation is given in Figure 5. Here the reconstructed mass of the crowded particles (scaled by the mass of the eight half-charged oxygens in the real structure) are plotted versus the number of iterations in the optimization method. In this case, a standard stopping criterion would stop the calculation after some 90 to 100 iterations. (The reconstruction does not change

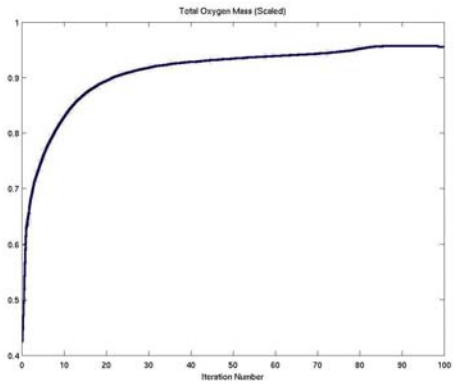

FIG. 5. *Plot of the total charge (relative to the exact value) during the iterations of the gradient method.*

significantly with more computation.) The difference between the scaled mass of the real total charge and the reconstructed one is less than 5%, although the initial value is quite far away from the solution. Similar behavior was found also in other tests with different initial values and parameter settings.

6.3. Identification II: Reconstruction of the structure. The second inverse problem is related to the reconstruction of the structure of the channel. This is done indirectly by identifying the confining potential acting on the crowded ions (oxygens in our example), which models the way the structure interacts with the channel. More specifically, the confining potential models the forces that keep the charged oxygens of the channel inside the selectivity filter.

The unknown in the above setting is given by $P = \mu_5^0$. Now the inverse problem is to find a space-dependent function on the channel region, which is really an infinite-dimensional problem. In an idealized setting, the unique reconstruction of the confining potential (as a function of space) would require an infinite number of measurements. Therefore, any measurement realized in practice (where, of course, only a finite number of measurements can be taken) has to be interpreted as a discretization of the problem with an infinite number of measurements. It therefore seems obvious that a higher number of measurements yields better reconstruction, and this is also confirmed by all our tests. On the other hand, a much higher number of measurements forces an extremely high computational effort.

The variation of the confining potential μ_5^0 has a significant influence only in the channel region, since outside it will just take some very large values that cause the confinement of the permanent charge species. In the solution of the identification problem, we use this a priori knowledge and approximate μ_5^0 by a constant function in the baths. Note that due to the large values of μ_5^0 in the bath regions, the concentration ρ_5 is almost zero there in any case.

As representative examples of the behavior of the reconstructions, we illustrate the results for

(a) four applied voltages and different left bath concentrations for Na and Cl, for a total of $4 \times 2 \times 2 = 16$ measurements (voltages ± 10 mV, ± 5 mV and concentrations 2 mM, 4 mM),
(b) six applied voltages and different left bath concentrations for Na and Cl, for

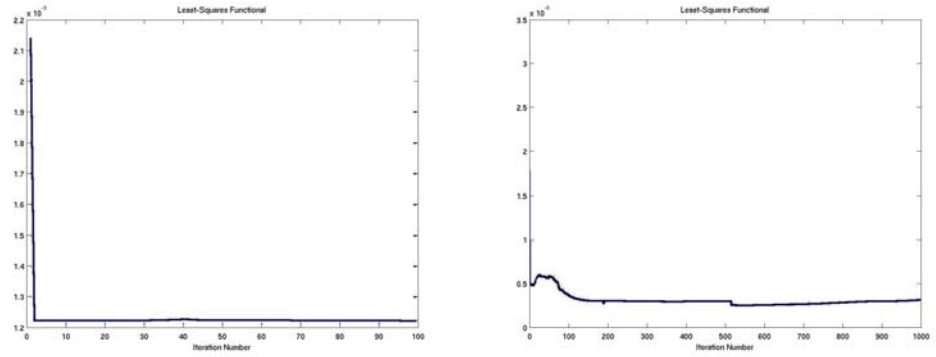

FIG. 6. *Plot of the squared residual* $\|F(P_n) - I^\delta\|2$ *as a function of the iteration number for* $4 \times 2 \times 2$ *measurements (left) and* $6 \times 3 \times 3$ *measurements (right).*

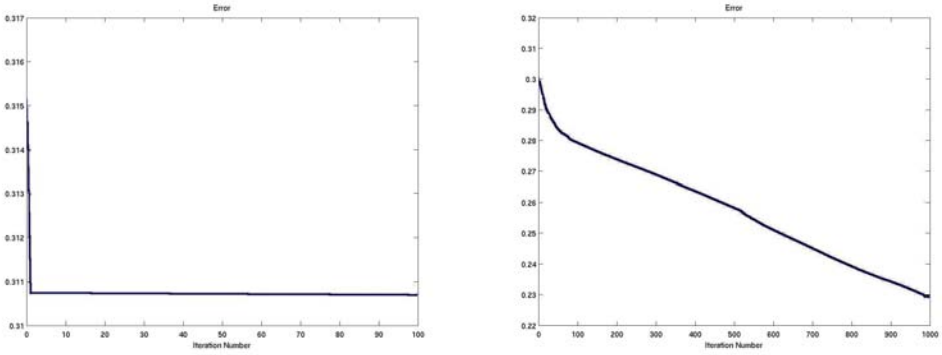

FIG. 7. *Plot of the identification error* $\|P_n - P^\dagger\|$ *as a function of the iteration number for* $4 \times 2 \times 2$ *measurements (left) and* $6 \times 3 \times 3$ *measurements (right).*

a total of $6 \times 3 \times 3 = 54$ measurements (voltages ± 10 mV, ± 6.6 mV, ± 3.3 mV and concentrations 2 mM, 4 mM, 6 mM),

obtained with 0.1% noise. The resulting evolution of the least-squares functional during the iteration is plotted in Figure 6 (left for case (a) and right for case (b))—one observes that they are quite similar in the two cases, and the residual decreases to some value around the size of the noise level. As has to be expected for iterative regularization methods (cf. [EHN96, KNS06]), the evolution of the reconstruction error, however, is completely different, as one can see in the plots of Figure 7 (left for case (a) and right for case (b)). In the first case (16 measurements), the reconstruction error is hardly reduced, while in the second case, one already obtains a very significant decrease before the noise level is reached. This can also be seen from the final reconstructions obtained with a stopping of the iteration dependent on the noise, which are shown (here plotting the negative potentials for illustration purpose) in Figure 8 (left for case (a) and right for case (b)). The initial guess used in both cases is shown in Figure 9. One observes that the second reconstruction is already rather close to the real potential, in particular in the left part of the channel. The reason for the better reconstruction in the left part is that the concentrations are varied in the left bath, and so there is more sensitivity with respect to the data in this region.

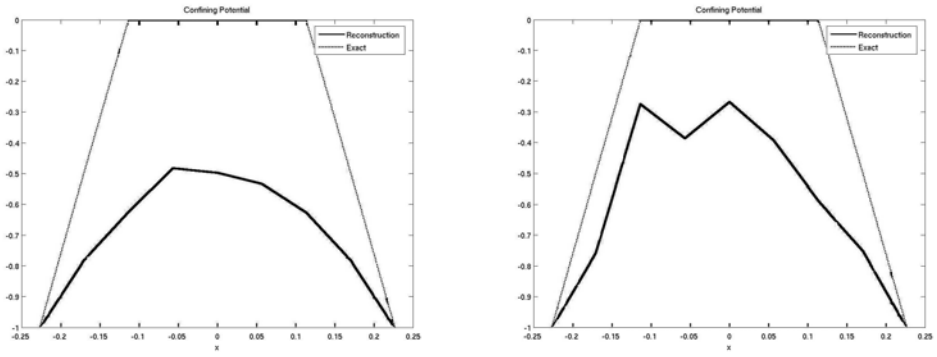

FIG. 8. *Final reconstructions P_{n_*} obtained at the stopping index determined by the discrepancy principle for $4 \times 2 \times 2$ measurements (left) and $6 \times 3 \times 3$ measurements (right).*

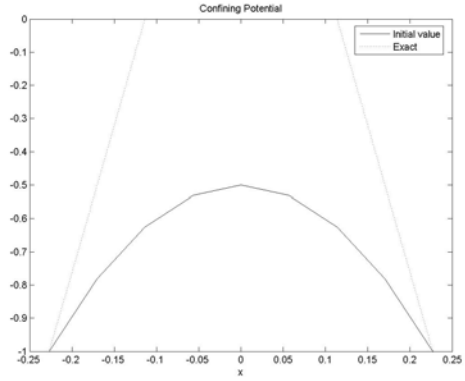

FIG. 9. *Initial value P_0 used for all reconstructions of potentials.*

These results clearly indicate that the reconstructions will improve for an increasing number of measurements. For a very high number of measurements, the computational complexity of the inverse problem dramatically increases and will be necessary to implement very efficient methods to compute reconstructions, including faster forward solvers (cf. [BW07]), adjoint methods for computing derivatives (cf. [GP00]), and multiscale versions of the regularization methods (cf. [Sch98, BM02]).

The instability of the identification problem in this case is illustrated in the plots of Figure 10. Here we use the same setup as before ($6 \times 3 \times 3$ measurements) but a slightly higher noise level (1%). We start with an initial guess where the residual is in the order of the noise level; in such a situation, a stopping rule for an iterative regularization such as the discrepancy principle would immediately stop the iteration. If one iterates further (which one would do when using a standard optimization stopping criterion based on the gradient of the residual), then the error starts to increase (and then possibly oscillates), although the residual is still decreasing. This situation is illustrated in Figure 10, where the least-squares functional and the error are plotted as functions of the iteration number. One observes that in this case the least-squares functional is still decreasing, but the error between the reconstruction and the exact solution can increase, which demonstrates the ill-posedness of the problem. Note that

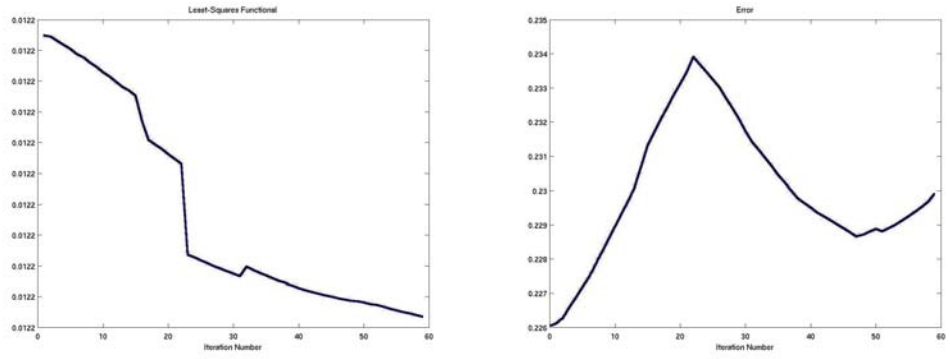

FIG. 10. *Plot of the residual (left) and identification error* $\|P_n - P^\dagger\|$ *(right) as a function of the iteration number without regularizing stopping criterion.*

this effect did not appear in the examples with a stopping criterion based on regularization theory as described in section 5, which again illustrates the importance of regularization.

6.4. Identification III: Reconstruction of the permanent charge density for PNP. As a final step in our study of identification problems, we consider the reconstruction of the permanent charge density ρ_M in a pure PNP model; i.e., the forward model consists in solving (2.1), (2.2), and (2.6) for $k = 1, \dots, M-1$ with given ρ_M and $E^{ex} \equiv 0$. Apart from the elimination of the equation for ρ_M, the discretization and numerical schemes used to solve the PNP system are the same as in the previous section; in particular, we use the Landweber iteration as a regularization method.

In this case, we numerically implemented adjoint solvers to compute derivatives, which results in improved accuracy and lower computational effort even for finer discretizations (in this case, we use 21 grid points) of the unknown in the inverse problem. We refer the reader to [GP00] for a general overview of adjoint methodology and to [BEMP01, Wo06] for the derivation of adjoint problems in related semiconductor applications.

For the reconstruction, we used five different values of the voltage U and eight different bath concentrations of Na and Ca, which results in a total number of $5 \times 16 \times 16 = 1280$ measured values. With this amount of data, very reasonable reconstructions can be obtained even in the presence of noise. The development of the residual and error $\|P_n - P^\dagger\|$ are illustrated in Figures 11 (without noise) and 12 (with noise level 3%). One observes that the residual and error both decrease in a monotone way in the noiseless case, whereas a minimum of the error is reached after some iteration number in the presence of noise. However, at this iteration number the relative residual is already very close to the noise level, so that a stopping rule like the discrepancy principle would stop already slightly earlier. These results have been obtained with an initial value $P_0 \equiv 3$ and an exact value $P^\dagger \equiv 5$, but qualitatively similar results have been computed also with other choices of P_0 and $P^\dagger$.

The quality of the reconstructions is illustrated in Figure 13 for permanent charge $P^\dagger$ being constant (left) and of a sinusoidal shape (right). In both cases, the starting value P_0 is dashed, the exact solution $P^\dagger$ is dotted, and the reconstruction is the solid line. One observes that with the amount of data we use, it is possible to reconstruct the constant solution very accurately, while there remains some visible deviation for

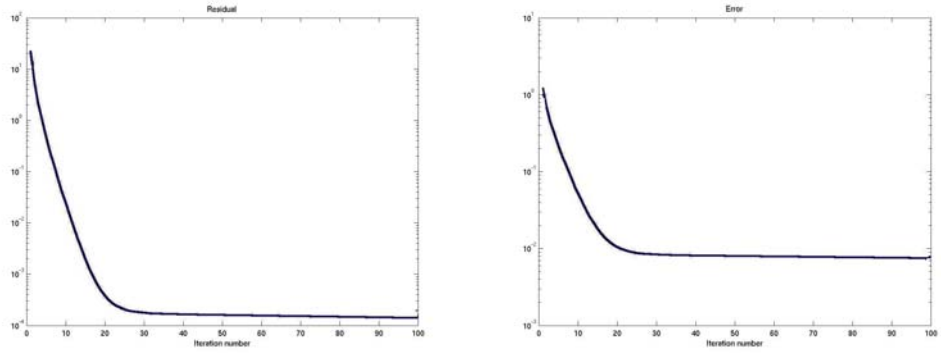

FIG. 11. *Plot of the residual (left) and identification error* $\|P_n - P^\dagger\|$ *(right) as a function of the iteration number in the absence of noise.*

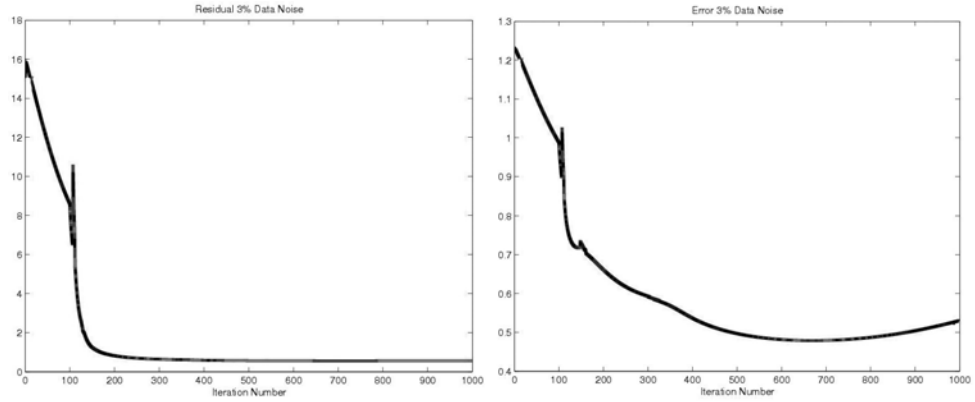

FIG. 12. *Plot of the residual (left) and identification error* $\|P_n - P^\dagger\|$ *(right) as a function of the iteration number for* 3% *data noise.*

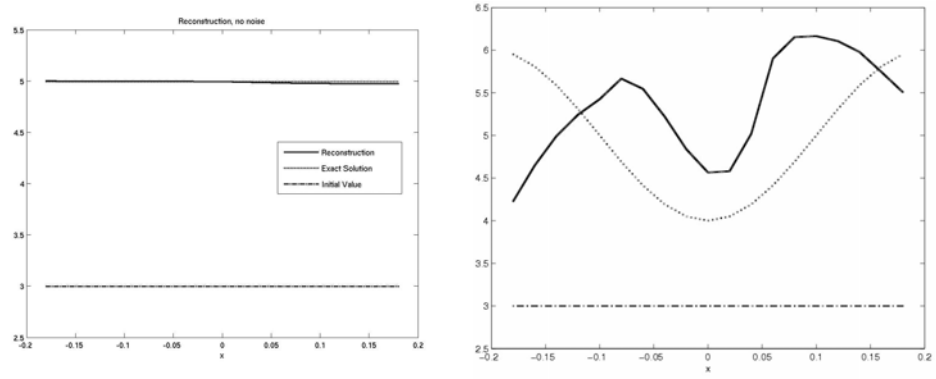

FIG. 13. *Plot of reconstructions in the absence of noise for a spatially constant permanent charge (left) and a spatially varying permanent charge (right).*

the more complicated shape. However, the magnitude of values as well as the principal shape (a valley in the middle) could also be reconstructed in the more difficult sinusoidal second case. Reconstructions of this moderate quality have to be expected in a severely ill-posed problem even for a larger number of measurements, and even these are quite tricky to achieve. Situations in which the permanent charge changes sign or reaches nearly zero are likely to pose even more problems.

6.5. Design: Maximizing selectivity. The final inverse problem we consider is an optimal design problem, which aims at designing in silico channels with optimal sensitivity properties (or at least improved sensitivity compared to a given initial design but possibly also close to this one, which can be used as a constraining criterion).

As a test case, we use one of the three selectivity measures from [GE02], the so-called permeability ratio, at equal concentrations for all ions in the left and right bath. (For this sake, we use the bath concentrations $\rho_k(\pm L) = 20$ mM for $k = 1, 2$ and $\rho_3(\pm L) = 60$ mM.) More precisely, the selectivity measure is the permeability ratio for Na and Ca, where the permeabilities on the right side of the channel are computed (detailed formulas for the computations of the permeabilities S_a are given in the appendix of [BEE06] and in [GE02]). The unknown to be designed is again related to the structure of the channel; i.e., we set $P = \mu_5^0$ and use the same discretization as in the previous section. Since our design goal is to maximize or at least significantly increase the selectivity, we should minimize the negative permeability ratio. It turns out that formulating the negative permeability ratio $-\frac{S_{Na}(P)}{S_{Ca}(P)}$ as the objective functional for selectivity, one ends up with a very unstable problem (which is also expected from the arguments in section 3.2). Moreover, the computed designs seem not really useful for practical construction due to various oscillations. Therefore, we use an additional regularization term as proposed in (5.9),

$$J_\alpha(P) := -\frac{S_{Na}(P)}{S_{Ca}(P)} + \alpha\|P - P^*\|2 \to \min_P, \tag{6.1}$$

where $P = \mu_5^0$ is the confining potential to be optimized and P^* is the favored initial design of the confining potential (the one used in the simulations in [GE02]). Besides its regularizing effect, the second term in the objective functional favors solutions as close as possible to the initial design, which helps to obtain potentials that can be realized in practice.

The objective functional is then minimized with a gradient method and suitable step-size selection to guarantee decrease of the objective, and the gradients are again approximated by finite differences (see above for a discussion of this point).

A special design case (with parameter $\alpha = 200$) is illustrated in the plot in Figure 14 (left), which shows the evolution of the objective functional (black) as well as its first part, the negative permeability (i.e., selectivity) ratio $-\frac{S_{Na}(P)}{S_{Ca}(P)}$, during the iteration until convergence. One observes that an increase in the selectivity measure of more than 100% is achieved by the optimization. The initial value used for the optimization and the final result are plotted in Figure 15. One observes that the two potentials are still very close, and so the structure has not been changed completely.

For comparison (and illustration of instabilities), the classical approach of just minimizing the negative permeability (i.e., selectivity) ratio is also illustrated with the same initial value and parameter settings but with the objective functional $J(P) := -\frac{S_{Na}(P)}{S_{Ca}(P)}$. Again, the right plot in Figure 14 displays the objective functional during the iterations; the optimal solution is plotted in Figure 16. One observes that in this

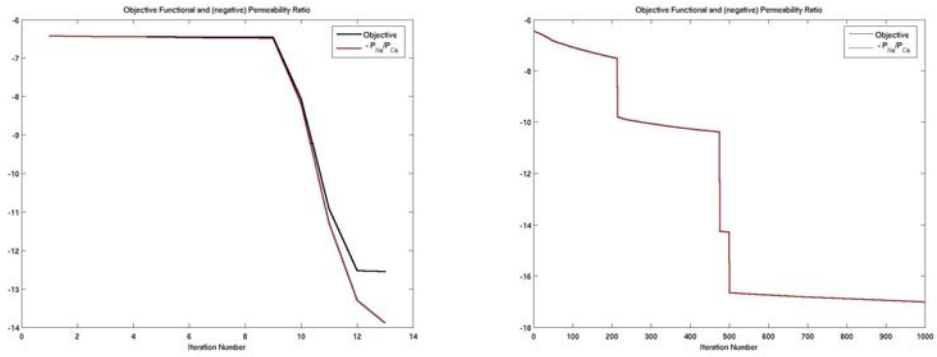

FIG. 14. *Objective functional $J_\alpha(P_n)$ (black) and negative permeability ratio (grey; red online) as a function of the iteration number for $\alpha = 200$ (left) and $\alpha = 0$ (right).*

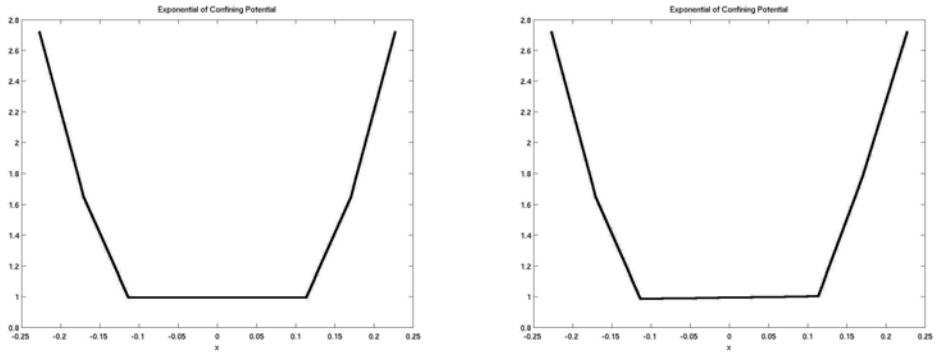

FIG. 15. *Initial value (left) and computed optimal confining potential (right) for the functional J_α with $\alpha = 200$.*

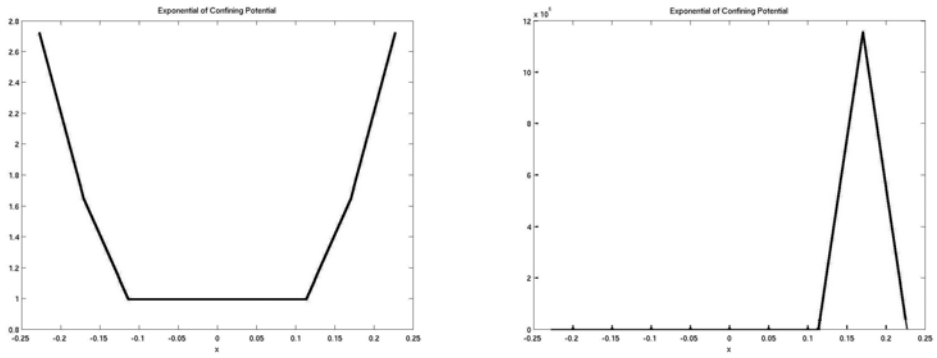

FIG. 16. *Initial value (left) and computed optimal confining potential (right) for the functional J.*

case, the gradient method needs many more iterations than with penalization but does not yield a dramatic increase of selectivity ratio (around 17 instead of 14 for the penalized case). However, just one look at the optimal confining potential in the

unpenalized case (Figure 16) shows that the (small) increase in the ratio is caused by a blowup in the confining potential (notice the vertical scale of 10^6!). Obviously, such extremely high forces will not be easy to realize, and the resulting channel will not be useful in practice, which is another point in favor of our regularization approach. The regularization parameter α can control the balance between increasing the selectivity and "practicability," namely, remaining close enough to the initial design that the new channel can actually be built. If α is very large, then the minimizer of J_α will remain close to the initial guess. For $\alpha \to 0$, the permeability ratio can be increased further, but also the optimal confining potential will increase more and more (until it reaches the one computed for J in the limit). So, regularization gives (in addition to the advantages discussed) even more flexibility in finding a compromise between different design goals.

We summarize by stating that our examples show that both the identification and the design goals can be achieved in a stable and efficient way by our approach based on regularization, as illustrated by the special case using Tikhonov regularization with an iterative minimization of the Tikhonov functional, and that such results are not possible by standard approaches due the ill-posed nature of the inverse problems considered. It will be interesting to see how regularization methods help in the solution of a range of problems in ion channels and proteins.

THE METHOD OF MOMENTS FOR NONLINEAR SCHRÖDINGER EQUATIONS: THEORY AND APPLICATIONS*

VÍCTOR M. PÉREZ-GARCÍA†, PEDRO J. TORRES‡, AND GASPAR D. MONTESINOS§

Abstract. The method of moments in the context of nonlinear Schrödinger equations relies on defining a set of integral quantities, which characterize the solution of this partial differential equation and whose evolution can be obtained from a set of ordinary differential equations. In this paper we find all cases in which the method of moments leads to closed evolution equations, thus extending and unifying previous works in the field of applications. For some cases in which the method fails to provide rigorous information we also develop approximate methods based on it, which allow us to get some approximate information on the dynamics of the solutions of the nonlinear Schrödinger equation.

Key words. nonlinear Schrödinger equations, methods of moments, nonlinear optics, Bose–Einstein condensates

1. Introduction.

Nonlinear Schrödinger (NLS) equations appear in a great array of contexts [1] as, for example, in semiconductor electronics [2, 3], optics in nonlinear media [4], photonics [5], plasmas [6], fundamentation of quantum mechanics [7], dynamics of accelerators [8], mean-field theory of Bose–Einstein condensates [9], or biomolecule dynamics [10]. In some of these fields and many others, the NLS equation appears as an asymptotic limit for a slowly varying dispersive wave envelope propagating in a nonlinear medium [11].

The study of these equations has served as the catalyst for the development of new ideas or even mathematical concepts such as solitons [12] or singularities in partial differential equations [13, 14].

One of the most general ways to express an NLS equation is

$$i\frac{\partial u}{\partial t} = -\frac{1}{2}\Delta u + V(x,t)u + g(|u|^2,t)u - i\sigma(t)u, \tag{1.1}$$

where $\Delta = \partial^2/\partial x_1^2 + \cdots + \partial^2/\partial x_n^2$ and u is a complex function which describes some physical wave. We shall consider here the solution of (1.1) on $\mathbb{R}^n$ and therefore $u : \mathbb{R}^n \times [0,T] \to \mathbb{C}$, with initial values $u(x,0) = u_0(x) \in X$, X being an appropriate functional space ensuring finiteness of certain integral quantities to be defined later.

The family of NLS equations (1.1) contains many particular cases, depending on the specific choices of the nonlinear terms $g(|u|^2,t)$, the potentials $V(x,t)$, the

dissipation $\sigma(t)$, and the dimension of the space n. The best known cases are those of power type, $g(|u|^2) = \alpha|u|^p$, or polynomial, $g(|u|^2) = \alpha_1|u|^{p_1} + \alpha_2|u|^{p_2}$, nonlinearities.

The potential term $V(x,t)$ models the action of an external force acting upon the system and may have many forms. Finally, we include in (1.1) a simple loss term arising in different applications [15, 16]. In many cases these losses are negligible, i.e., $\sigma = 0$.

The description of the dynamics of initial data ruled by this equation is of great interest for applications. Nevertheless, gathering information about the solutions of a partial differential equation that is nonlinear like (1.1) constitutes a problem that is a priori nearly unapproachable. For this reason, most studies about the dynamics of this type of equation are exclusively numerical. The rigorous studies carried out to date concentrate on (i) properties of stationary solutions [17], (ii) particular results on the existence of solutions [18, 19], and (iii) asymptotic properties [13, 14].

Only when $n = 1$, $g(|u|^2, t) = |u|^2$, $V(x,t) = 0$, $\sigma = 0$ it is possible to arrive at a solution of the initial value problem by using the inverse scattering transform method [12]. In this paper we develop the so-called method of moments, which tries to provide qualitative information about the behavior of the solutions of NLS equations. Instead of tackling the Cauchy problem (1.1) directly, the method studies the evolution of several integral quantities (the so-called *moments*) of the solution $u(x,t)$. In some cases the method allows one to reduce the problem to the study of systems of coupled ordinary nonlinear differential equations. In other cases the method provides a foundation for making approximations in a more systematic (and simpler) way than other procedures used in physics, such as those involving finite-dimensional reductions of the original problem, namely, the averaged Lagrangian, collective coordinates, or variational methods [20, 21]. In any case the method of moments provides information which is very useful for the applied scientist, who is usually interested in obtaining as much information as possible characterizing the *dynamics* of the solutions of the problem.

It seems that the first application of the method of moments was performed by Talanov [22] in order to find a formal condition of sufficiency for the blowup of solutions of the NLS equation with $g(|u|^2) = -|u|^2$ and $n = 2$. Since then, the method has been applied to different particular cases (mainly solutions of radial symmetry in two spatial dimensions), especially in the context of optics, where many equations of NLS type arise [23].

In previous research, the method of moments has been studied in a range of specific situations, but in all such cases the success of the method is unrelated to a more general study. In this paper we try to consider the method systematically and solve a number of open questions: (i) to find the most general type of nonlinear term and potentials in (1.1) for which the method of moments allows us to get conclusions, and (ii) to develop approximate methods based on it for situations in which the moment equations do not allow us to obtain exact results.

2. Preliminary considerations. Let us define the functional space $Q(H)$ as the space of functions for which the so-called energy functional,

$$E(u) = (u, Hu)_{L^2(\mathbb{R}^n)} + \int_{\mathbb{R}^n} G(|u|^2, t)dx, \tag{2.1}$$

is finite, G being a function such that $\partial G(|u|^2,t)/\partial|u|^2 = g(|u|^2,t)$, $(\cdot,\cdot)_{L^2(\mathbb{R}^n)}$ denoting the usual scalar product in $L^2(\mathbb{R}^n)$, and $H = -\frac{1}{2}\Delta + V(x,t)$. For the case

$V(x,t) = 0$ and g independent of time, several results on existence and uniqueness were given by Velo [18].

As regards the case $V \neq 0$, which is the one in which we are mainly interested in our work, the best documented case in the literature is that of potentials with $|D^\alpha V|$ bounded in $\mathbb{R}^n$ for every $|\alpha| \geq 2$; that is, potentials with at most quadratic growth. Oh [24] proved the local existence of solutions in $L^2(\mathbb{R}^n)$ and in $Q(H)$ for nonlinearities of the type $g(u) = -|u|^p$, $0 \leq p < 4/n$. However, the procedure used allows one to substitute this nonlinearity with other more general ones. It also seems possible to extend the results to the case in which the potential depends on t.

Therefore, from now on we shall suppose that the nonlinear term satisfies the conditions set by Velo and that $|D^\alpha V|$ is bounded in space for all $|\alpha| \geq 2$. Under these conditions it is possible to guarantee at least local existence of solutions of (1.1) in appropriate functional spaces.

2.1. Formal elimination of the loss term. In the first place we carry out the transformation [15]

$$\hat{u}(x,t) = u(x,t)e^{\int_0^t \sigma(\tau)d\tau}, \tag{2.2}$$

which is well defined for any bounded function $\sigma(t)$ (this includes all known realistic cases arising in the applications). The equation satisfied by $\hat{u}(x,t)$ is obtained from the following direct calculation:

$$\begin{aligned} i\frac{\partial \hat{u}}{\partial t} &= i\frac{\partial u}{\partial t}e^{\int_0^t \sigma(\tau)d\tau} + i\sigma(t)ue^{\int_0^t \sigma(\tau)d\tau} \\ &= \left[-\frac{1}{2}\Delta u + V(x,t)u + g(|u|^2,t)u - i\sigma(t)u\right] e^{\int_0^t \sigma(\tau)d\tau} + i\sigma(t)ue^{\int_0^t \sigma(\tau)d\tau} \\ &= -\frac{1}{2}\Delta\hat{u} + V(x,t)\hat{u} + \hat{g}(|\hat{u}|^2,t)\hat{u}, \end{aligned}$$

where

$$\hat{g}(|\hat{u}|^2,t) = g(|u|^2,t) = g(e^{-2\int_0^t \sigma(\tau)d\tau}|\hat{u}|^2,t). \tag{2.3}$$

From here on we shall consider, with no loss of generality, that $\sigma(t) = 0$ in (1.1), assuming that this choice might add an extra time-dependence to the nonlinear term.

3. The method of moments: Generalities.

3.1. Definition of the moments. Let us define the following quantities:

$$I_{k,j}(t) = \int x_j^k |u(x,t)|^2 dx = \left\| x_j^{k/2} u \right\|^2_{L^2(\mathbb{R}^n)}, \tag{3.1a}$$

$$V_{k,j}(t) = 2^{k-1} i \int x_j^k \left(u(x,t)\frac{\partial u(\bar{x},t)}{\partial x_j} - \bar{u}\frac{\partial u(x,t)}{\partial x_j} \right) dx, \tag{3.1b}$$

$$K_j(t) = \frac{1}{2}\int \left|\frac{\partial u(x,t)}{\partial x_j}\right|^2 dx = \frac{1}{2}\left\|\frac{\partial u}{\partial x_j}\right\|^2_{L^2(\mathbb{R}^n)} \tag{3.1c}$$

$$J(t) = \int G(|u(x,t)|^2,t)dx, \tag{3.1d}$$

with $j = 1,\ldots,n$ and $k = 0,1,2,\ldots$, which we will call *moments* of $u(x,t)$ in analogy with the moments of a distribution. From now on and also in (3.1) it is understood

that all integrals and norms refer to the spatial variables $x \in \mathbb{R}^n$ unless otherwise stated. In (3.1) we denote by $\bar{u}$ the complex conjugate of u.

In some cases we will make specific reference to which solution u of (1.1) is used to calculate the moments by means of the notation: $I^u_{k,j}$, etc.

The moments are quantities that have to do with *intuitive* properties of the solution $u(x,t)$. For example, the moment $I_{0,0}$ is the squared $L^2(\mathbb{R}^n)$-norm of the solution and therefore measures the *magnitude*, *quantity*, or *mass* thereof. Depending on the particular application context, this moment is denominated mass, charge, intensity, energy, number of particles, etc. The moments $I_{1,j}(t)$ are the coordinates of the *center* of the distribution u, giving us an idea of the overall position thereof. The quantities $I_{2,j}$ are related to the *width* of the distribution defined as $W_j = (\int_{\mathbb{R}^n}(x_j - I_{1,j})^2|u|^2dx)^{1/2} = (I_{2,j} + I^2_{1,j}I_{0,0} - 2I^2_{1,j})^{1/2}$, which is also a quantity with an evident meaning.

The evolution of the moments is determined by that of the function $u(x,t)$. From now on we will assume that the initial datum $u_0(x)$ and the properties of the equation guarantee that the moments are well defined for all time. This excludes explicitly certain classes of initial data such as plane waves, etc., which do not decay at infinity. Thus our results will be relevant for studying the evolution of initially localized and regular enough initial data.

3.2. First *conservation law*. It is easy to prove formally that the moment $I_{0,0}$ is invariant during the temporal evolution by just calculating

$$\begin{aligned}
\frac{d}{dt}I_{0,0}(t) &= \int_{\mathbb{R}^n}\left(\frac{d}{dt}|u|^2\right)dx = \int_{\mathbb{R}^n}\left(\bar{u}\frac{\partial}{\partial t}u + u\frac{\partial}{\partial t}\bar{u}\right)dx \\
&= \int_{\mathbb{R}^n} i\left(\frac{1}{2}\bar{u}\Delta u - V(x,t)|u|^2 - g(|u|^2,t)|u|^2\right)dx \\
&\quad + \int_{\mathbb{R}^n} i\left(-\frac{1}{2}u\Delta\bar{u} + V(x,t)|u|^2 + g(|u|^2,t)|u|^2\right)dx \\
&= \int_{\mathbb{R}^n}\frac{i}{2}\left(\bar{u}\Delta u - u\Delta\bar{u}\right)dx \\
&= \frac{i}{2}\left(\int_{\mathbb{R}^n}|\nabla u|^2dx - \int_{\mathbb{R}^n}|\nabla u|^2dx\right) = 0, \qquad (3.2)
\end{aligned}$$

where we have performed integration by parts and used that the function u and its derivatives vanish at infinity.

Obviously the above *demonstration* is formal in the sense that a regularity, which we do not know for certain, has been used for u. Nevertheless, this type of proof can be formalized by making a convolution of the function u with a regularizing function. The details of these methodologies can be seen in [18] or [24, 25]. In this paper we will limit ourselves to formal calculations.

4. General results for harmonic potentials.

4.1. Introduction. From this point onward we will focus on the particular case of interest for this study when $V(x,t)$ is a harmonic potential of the type $V(x,t) = \frac{1}{2}(x, \Lambda(t)x)$, where Λ is a real matrix of the form $\Lambda_{ij}(t) = \lambda_i^2(t)\delta_{ij}$, with $\lambda_i \geq 0$ for $i = 1, \ldots, n$, and δ_{ij} is the Kronecker delta. Bearing in mind the results of section 2.1,

the NLS equation under study is then

$$i\frac{\partial u}{\partial t} = -\frac{1}{2}\Delta u + \frac{1}{2}\left(\sum_{j=1}^{n}\lambda_j^2 x_j^2\right)u + g(|u|^2,t)u. \tag{4.1}$$

This equation appears in a wide variety of applications such as propagation of waves through optical transmission lines with online modulators [26, 27, 28, 29], propagation of light beams in nonlinear media with a gradient of the refraction index [30, 31], or dynamics of Bose–Einstein condensates [9]. Generically it can provide a model for studying some properties of the solutions of NLS equations localized near a minimum of a general potential $V(x)$.

4.2. First moment equations. If we differentiate the definitions of the moments $I_{1,j}$ and $V_{0,j}$, we obtain, after some calculations, the evolution equations

$$\frac{dI_{1,j}}{dt} = V_{0,j}, \tag{4.2a}$$

$$\frac{dV_{0,j}}{dt} = -\lambda_j^2 I_{1,j}, \tag{4.2b}$$

so that $I_{1,j}$, $j = 1,\dots,n$, satisfy

$$\frac{d^2 I_{1,j}}{dt^2} + \lambda_j^2 I_{1,j} = 0 \tag{4.3}$$

with initial data $I_{1,j}(0), \dot{I}_{1,j}(0) = V_{0,j}(0)$. These expressions are a generalization of the Ehrenfest theorem of linear quantum mechanics to the NLS equation and particularized for the potential that concerns us [24, 32].

This result has been discussed previously in many papers and is physically very interesting. It indicates that the evolution of the center of the solution is independent of the nonlinear effects and of the evolution of the rest of the moments and depends only on the potential parameters.

4.3. Reduction of the general problem to the case $I_{1,j} = V_{0,j} = 0$. We shall begin by stating the following lemma [33].

LEMMA 4.1. *Let $u(x,t)$ be a solution of* (4.1) *with the initial datum $u(x,0) = u_0(x)$. Then the functions*

$$u_R(x,t) = u(x - R(t),t)e^{i\theta(x,t)}, \tag{4.4a}$$

where

$$\theta(x,t) = \left(x,\dot{R}\right) + \int_0^t \left[(\dot{R}(t'),\dot{R}(t')) - (R(t'),\Lambda(t')R(t'))\right]dt' \tag{4.4b}$$

and

$$\frac{d^2 R}{dt^2} + \Lambda R = 0 \tag{4.4c}$$

for any set of initial data $R(0), \dot{R}(0) \in \mathbb{R}^n$, are also solutions of (4.1).

Proof. All we have to do is substitute (4.4a), (4.4b), and (4.4c) into (4.1). ∎

One noteworthy conclusion is that, given a solution of (4.1), we can *translate* it initially by a constant vector and obtain another solution. In the case of stationary states, defined as solutions of the form

$$u(x,t) = \varphi_\mu(x) e^{i\mu t}, \tag{4.5}$$

which exist in the autonomous case (i.e., $d\lambda/dt = 0$) and whose dynamics is trivial, this result implies that under displacements the only dynamics acquired is one of the movement of the center given by (4.4c). The coincidence of the evolution laws (4.3) and (4.4c) allows us to state the following theorem, which is an immediate consequence of the above lemma.

THEOREM 4.2. *If $\psi(x,t)$ is a solution of (4.1) with nonzero $I^\psi_{1,j}$ or $V^\psi_{0,j}$, then there exists a unique solution $u(x,t) = \psi(x + \{I^\psi_{1,j}(t)\}_j, t) e^{i\theta(x,t)}$ with*

$$\theta(x,t) = -\sum_j x_j V^\psi_{0,j} + \sum_j \left[\int_0^t V^\psi_{0,j}(t')^2 - \lambda_j(t')^2 I^\psi_{1,j}(t')^2 \right] dt'$$

such that $I^u_{1,j} = 0$ and $V^u_{0,j} = 0$.

The important conclusion of this theorem is that it suffices to study solutions with $I_{1,j}$ and $V_{0,j}$ equal to zero, as those that have one of these coefficients different from zero can be obtained from previous ones, by means of translation and multiplication by a linear phase in x. From a practical standpoint, what is most important is that $I_{1,j}$ be null without any loss of generality, as then we can establish a direct link between the widths and the moments $I_{2,j}$ (see the discussion in the third paragraph of section 3).

4.4. Moment equations. Assuming that all of the moments can be defined at any time t, we can calculate their evolution equations by means of direct differentiation. The results are gathered in the next theorem.

THEOREM 4.3. *Let $u_0(x)$ be an initial datum such that the moments $I_{2,j}$, $V_{1,j}$, K_j, and J are well defined at $t = 0$. Then*

$$\frac{dI_{2,j}}{dt} = V_{1,j}, \tag{4.6a}$$

$$\frac{dV_{1,j}}{dt} = 4K_j - 2\lambda_j^2 I_{2,j} - 2\int_{\mathbb{R}^n} D(\rho,t)dx, \tag{4.6b}$$

$$\frac{dK_j}{dt} = -\frac{1}{2}\lambda_j^2 V_{1,j} - \int_{\mathbb{R}^n} D(\rho,t)\frac{\partial^2 \phi}{\partial x_j^2}\, dx, \tag{4.6c}$$

$$\frac{dJ}{dt} = \int_{\mathbb{R}^n} D(\rho,t)\Delta\phi\, dx + \int_{\mathbb{R}^n} \frac{\partial G(\rho,t)}{\partial t} dx, \tag{4.6d}$$

where $D(\rho,t) = G(\rho,t) - \rho g(\rho,t)$, $\rho = |u(x,t)|^2$.

Proof. The demonstration of the validity of (4.6) can be carried out from direct calculations, performing integration by parts, and using the decay of u and ∇u at infinity.

To demonstrate (4.6a) it is easier to work with the modulus-phase representation

of u, $u=\rho^{1/2}e^{i\phi}$ (with $\rho>0$). Then

$$\begin{aligned}\frac{dI_{2,j}}{dt}&=\int x_j^2\dot{\rho}=-\int x_j^2(\nabla\rho\cdot\nabla\phi+\rho\Delta\cdot\phi)\\&=-\int x_j^2\nabla\rho\cdot\nabla\phi+\int\nabla(x_j^2\rho)\cdot\nabla\phi\\&=-\int x_j^2\nabla\rho\cdot\nabla\phi+\int x_j^2\nabla\rho\cdot\nabla\phi+\int\nabla(x_j^2)\rho\cdot\nabla\phi\\&=2\int x_j\rho\frac{\partial\phi}{\partial x_j}=V_{1,j}.\end{aligned}$$

We can also prove (4.6b) as follows:

$$\begin{aligned}\frac{dV_{1,j}}{dt}&=i\int x_j\left(u_t\frac{\partial\bar{u}}{\partial x_j}+u\frac{\partial\bar{u_t}}{\partial x_j}-\bar{u_t}\frac{\partial u}{\partial x_j}-\bar{u}\frac{\partial u_t}{\partial x_j}\right)\\&=\int x_j\left[-\frac{1}{2}\Delta u\frac{\partial\bar{u}}{\partial x_j}+\frac{1}{2}\left(\sum\lambda_k^2x_k^2\right)u\frac{\partial\bar{u}}{\partial x_j}+gu\frac{\partial\bar{u}}{\partial x_j}+u\frac{1}{2}\frac{\partial\Delta\bar{u}}{\partial x_j}\right.\\&\qquad\left.-\lambda_j^2x_j|u|^2-\frac{1}{2}\left(\sum\lambda_k^2x_k^2\right)u\frac{\partial\bar{u}}{\partial x_j}-\frac{\partial g}{\partial x_j}|u|^2-gu\frac{\partial\bar{u}}{\partial x_j}+\text{c.c.}\right]\\&=-2\lambda_j^2\int x_j^2|u|^2-2\int x_j|u|^2\frac{\partial g}{\partial x_j}\\&\qquad-\frac{1}{2}\int x_j\left(\Delta u\frac{\partial\bar{u}}{\partial x_j}+\Delta\bar{u}\frac{\partial u}{\partial x_j}-u\frac{\partial\Delta\bar{u}}{\partial x_j}+\bar{u}\frac{\partial\Delta u}{\partial x_j}\right),\end{aligned}\tag{4.7}$$

where c.c. indicates the complex conjugate. Operating on the above integrals, we have

$$\begin{aligned}&\int x_j\left(\Delta u\frac{\partial\bar{u}}{\partial x_j}+\Delta\bar{u}\frac{\partial u}{\partial x_j}-u\frac{\partial\Delta\bar{u}}{\partial x_j}-\bar{u}\frac{\partial\Delta u}{\partial x_j}\right)\\&=-2\int x_j\left(\nabla u\cdot\frac{\partial\nabla\bar{u}}{\partial x_j}+\nabla\bar{u}\cdot\frac{\partial\nabla u}{\partial x_j}\right)-4\int\left|\frac{\partial u}{\partial x_j}\right|^2-2\int|\nabla u|^2\\&=2\int|\nabla u|^2-4\int\left|\frac{\partial u}{\partial x_j}\right|^2-2\int|\nabla u|^2=-4\int\left|\frac{\partial u}{\partial x_j}\right|^2\end{aligned}$$

and

$$\int x_j\frac{\partial g}{\partial x_j}\rho=-\int g\rho-\int x_j\frac{\partial G}{\partial x_j}=-\int g\rho+\int G=\int D.$$

By substitution into (4.7), we arrive at the desired result:

$$\begin{aligned}\frac{dV_{1,j}}{dt}&=-2\lambda_j^2\int x_j^2|u|^2+2\int\left|\frac{\partial u}{\partial x_j}\right|^2-2\int D\\&=-2\lambda_j^2I_{2,j}+4K_j-2\int D.\end{aligned}$$

Let us now prove (4.6c):

$$\begin{aligned}\frac{dK_j}{dt}&=\frac{1}{2}\int\frac{d}{dt}\left(\frac{\partial u}{\partial x_j}\frac{\partial\bar{u}}{\partial x_j}\right)=\frac{1}{2}\int\left(\frac{\partial u_t}{\partial x_j}\frac{\partial\bar{u}}{\partial x_j}+\frac{\partial u}{\partial x_j}\frac{\partial\bar{u_t}}{\partial x_j}\right)\\&=\frac{1}{2}\int\frac{\partial}{\partial x_j}\left[\frac{i}{2}\Delta u-\frac{i}{2}\left(\sum_{k=1}^n\lambda_k^2x_k^2\right)u-igu\right]\frac{\partial\bar{u}}{\partial x_j}+\text{c.c.};\end{aligned}$$

then

$$\frac{dK_j}{dt} = -\frac{i}{2}\lambda_j^2 \int x_j \left(u\frac{\partial \bar{u}}{\partial x_j} - \bar{u}\frac{\partial u}{\partial x_j}\right) - \frac{i}{2}\int \frac{\partial g}{\partial x_j}\left(u\frac{\partial \bar{u}}{\partial x_j} - \bar{u}\frac{\partial u}{\partial x_j}\right)$$
$$+ \frac{i}{4}\int \left(\frac{\partial \Delta u}{\partial x_j}\frac{\partial \bar{u}}{\partial x_j} - \frac{\partial u}{\partial x_j}\frac{\partial \Delta \bar{u}}{\partial x_j}\right) = -\frac{1}{2}\lambda_j^2 V_{1,j} + \int g\frac{\partial}{\partial x_j}\left(\rho\frac{\partial \phi}{\partial x_j}\right)$$
$$= -\frac{1}{2}\lambda_j^2 V_{1,j} + \int g\left(\rho\frac{\partial^2 \phi}{\partial x_j^2} + \frac{\partial \rho}{\partial x_j}\frac{\partial \phi}{\partial x_j}\right),$$

and, using the definition of G, we obtain

$$\frac{dK_j}{dt} = -\frac{1}{2}\lambda_j^2 V_{1,j} + \int g\rho\frac{\partial^2 \phi}{\partial x_j^2} + \int \frac{\partial G}{\partial x_j}\frac{\partial \phi}{\partial x_j}$$
$$= -\frac{1}{2}\lambda_j^2 V_{1,j} + \int g\rho\frac{\partial^2 \phi}{\partial x_j^2} - \int G\frac{\partial^2 \phi}{\partial x_j^2}$$
$$= -\frac{1}{2}\lambda_j^2 V_{1,j} - \int (G - \rho g)\frac{\partial^2 \phi}{\partial x_j^2} = -\frac{1}{2}\lambda_j^2 V_{1,j} - \int D\frac{\partial^2 \phi}{\partial x_j^2}.$$

Finally, to demonstrate (4.6d) we proceed as follows:

$$\frac{dJ}{dt} = \int \frac{dG(\rho,t)}{dt} = \int \left[\frac{\partial G}{\partial \rho}\left(\frac{\partial \rho}{\partial u}u_t + \frac{\partial \rho}{\partial \bar{u}}\bar{u}_t\right) + \frac{\partial G}{\partial t}\right]$$
$$= \int \left[\frac{\partial G}{\partial \rho}\left(\bar{u}u_t + u\bar{u}_t\right) + \frac{\partial G}{\partial t}\right] = \frac{i}{2}\int \left[g\left(\bar{u}\Delta u - u\Delta \bar{u}\right) + \frac{\partial G}{\partial t}\right]$$
$$= \int \left[-g\nabla\cdot(\rho\nabla\phi) + \frac{\partial G}{\partial t}\right] = \int \left[-g\nabla\rho\cdot\nabla\phi - g\rho\Delta\phi + \frac{\partial G}{\partial t}\right]$$
$$= \int \left[-\nabla G\cdot\nabla\phi - g\rho\Delta\phi + \frac{\partial G}{\partial t}\right] = \int (G - g\rho)\,\Delta\phi + \int \frac{\partial G}{\partial t}$$
$$= \int D\Delta\phi + \int \frac{\partial G}{\partial t}. \qquad \square$$

A direct consequence of the theorem is the following.

COROLLARY 4.4. *Let $u(x,t)$ be a stationary solution of* (4.1). *Then*

$$K_j = \frac{1}{2}\lambda_j^2 I_{2,j} + \frac{1}{2}\int D(\rho)dx. \tag{4.8}$$

5. Solvable cases of the method of moments. In this section we will study several particular situations of practical relevance in which the method of moments thoroughly provides exact results.

5.1. The linear case $g(\rho,t) = 0$. In this case, (3.1d) and (4.6d) tell us that $J(t) = 0$ for all t, and then the moment equations (4.6) become

$$\frac{dI_{2,j}}{dt} = V_{1,j}, \tag{5.1a}$$

$$\frac{dV_{1,j}}{dt} = 4K_j - 2\lambda_j^2 I_{2,j}, \tag{5.1b}$$

$$\frac{dK_j}{dt} = -\frac{1}{2}\lambda_j^2 V_{1,j}. \tag{5.1c}$$

That is, in the linear case the equations for the moments along each direction j of the physical space $\mathbb{R}^n$ are uncoupled. This property was known in the context of optics for $n = 2$ and constant λ_j [34]. Here we see that this property holds for any number of spatial dimensions, time dependence $\lambda(t)$, and even for nonsymmetric initial data.

5.2. Condition of closure of the moment equations in the general case. Equations (4.6) do not form a closed set, and therefore to obtain, in general, their evolution we would need to continue obtaining moments of a higher order, which would provide us with an infinite hierarchy of differential equations. Given the similarity among the terms that involve second derivatives of the phase of the solution in (4.6), it is natural to wonder whether it would be possible to somehow close the system and thus obtain information about the solutions.

From this point on, and for the rest of the section, we will limit ourselves to the case $\lambda_j(t) = \lambda(t)$, $j = 1, \dots, n$, which is the most realistic one, and which includes as a particular case the situation without external potentials $\lambda_j = 0$. Let us define the following quantities:

$$\mathcal{I} = \sum_{j=1}^{n} I_{2,j}, \quad \mathcal{V} = \sum_{j=1}^{n} V_{1,j}, \quad \mathcal{K} = \sum_{j=1}^{n} K_j. \tag{5.2}$$

Differentiating (5.2) and using (4.6), we have

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{5.3a}$$

$$\frac{d\mathcal{V}}{dt} = 4\mathcal{K} - 2\lambda^2\mathcal{I} - 2n\int_{\mathbb{R}^n} D(\rho,t)dx, \tag{5.3b}$$

$$\frac{d\mathcal{K}}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} - \int_{\mathbb{R}^n} D(\rho,t)\Delta\phi dx, \tag{5.3c}$$

$$\frac{dJ}{dt} = \int_{\mathbb{R}^n} D(\rho,t)\Delta\phi + \int_{\mathbb{R}^n} \frac{\partial G(\rho,t)}{\partial t}dx. \tag{5.3d}$$

If we add up (5.3c) and (5.3d), we arrive at

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{5.4a}$$

$$\frac{d\mathcal{V}}{dt} = 4\left[\mathcal{K} - \frac{n}{2}\int_{\mathbb{R}^n} D(\rho,t)dx\right] - 2\lambda^2\mathcal{I}, \tag{5.4b}$$

$$\frac{d\left(\mathcal{K}+J\right)}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} + \int_{\mathbb{R}^n} \frac{\partial G}{\partial t}dx. \tag{5.4c}$$

In order that equations (5.4) form a closed system, they must fulfill $-\frac{n}{2}\int_{\mathbb{R}^n} D(\rho,t)dx = J = \int_{\mathbb{R}^n} G(\rho,t)dx$ and that $\int_{\mathbb{R}^n} \frac{\partial G(\rho,t)}{\partial t}dx$ can be expressed in terms of the other known quantities. The former condition requires that

$$0 = \int_{\mathbb{R}^n}\left[\frac{n}{2}D(\rho,t) + G(\rho,t)\right]dx = \int_{\mathbb{R}^n}\left[\left(1+\frac{n}{2}\right)G(\rho,t) - \frac{n}{2}\frac{\partial G(\rho,t}{\partial\rho}\rho\right]dx.$$

As $G(\rho,t)$ does not depend explicitly on x, this condition is verified when

$$\frac{\partial G(\rho,t)}{\partial\rho} = \left(1+\frac{2}{n}\right)\frac{G(\rho,t)}{\rho}, \tag{5.5}$$

that is, if

$$G(\rho,t) = g_0(t)\rho^{1+2/n}, \tag{5.6}$$

or, equivalently, if

$$g(\rho,t) = g_0(t)\rho^{2/n}, \tag{5.7}$$

where $g_0(t)$ is an arbitrary function that indicates the temporal variation of the nonlinear term. Then

$$\int_{\mathbb{R}^n} \frac{\partial G(\rho,t)}{\partial t}dx = \frac{1}{g_0}\frac{dg_0}{dt}\int_{\mathbb{R}^n} G(\rho,t)dx = \frac{1}{g_0}\frac{dg_0}{dt}J(t). \tag{5.8}$$

To close the equations it is necessary that $g_0(t)$ be constant in order to cancel the last term of this expression. Then, the nonlinearities for which it is possible to find closed results are

$$g(\rho) = g_0\rho^{2/n} = g_0|u|^{4/n}, \tag{5.9}$$

with $g_0 \in \mathbb{R}$, remembering that in the case $g_0 < 0$ there may be problems of blowup in finite time. Fortunately, these nonlinearities for $n = 1, 2, 3$ correspond to cases of practical interest. For instance, the case $n = 1$ with quintic nonlinearity has been studied in [35, 36, 37] and the case $n = 2$, with cubic nonlinearity, corresponds probably to the most relevant instance of the NLS equation, i.e., the cubic one in two spatial dimensions [30, 31]. For $n = 3$ the nonlinearity given by (5.9) appears in the context of the Hartree–Fock theory of atoms.

5.3. Simplification of the moment equations. Defining a new quantity $\mathcal{E} = \mathcal{K} + J$, (5.4) becomes

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{5.10a}$$

$$\frac{d\mathcal{V}}{dt} = 4\mathcal{E} - 2\lambda^2(t)\mathcal{I}, \tag{5.10b}$$

$$\frac{d\mathcal{E}}{dt} = -\frac{1}{2}\lambda^2(t)\mathcal{V}. \tag{5.10c}$$

These equations form a set of nonautonomous linear equations for the three averaged moments: $\mathcal{E}(t)$, $\mathcal{V}(t)$, and $\mathcal{I}(t)$. To continue our analysis, we note that

$$\mathcal{Q} = 2\mathcal{E}\mathcal{I} - \frac{1}{4}\mathcal{V}^2 \tag{5.11}$$

is a dynamical invariant of (5.10). We finally define $X = |\mathcal{Q}|^{-1/4}\mathcal{I}^{1/2}$, which is proportional to the *mean width* of u. A simple calculation allows us to corroborate that the equation that $X(t)$ satisfies is

$$\frac{d^2X}{dt^2} + \lambda^2(t)X = \frac{\operatorname{sgn}(\mathcal{Q})}{X^3}. \tag{5.12}$$

Solving (5.12) allows us to calculate $\mathcal{V}$ and $\mathcal{E}$ by simple substitution in (5.10). This equation is similar to that obtained in [30] for solutions of radial symmetry in the case $n = 2$ and $g(u) = |u|^2$. Here we find that it is possible to obtain a more general

result for solutions without specific symmetry requirements, and for any combination of dimension and nonlinearity $g(u) = |u|^p$ satisfying the condition $np = 4$. The case with $\mathrm{sgn}(\mathcal{Q}) = -1$ corresponds to collapsing situations [13, 38]. In what follows we consider mostly the case $\mathcal{Q} > 0$.

Equation (5.12) was studied by Ermakov in 1880 [39], although since then it has been *rediscovered* many times (see, e.g., [40]). It is a particular case of the so-called Ermakov systems [41, 42, 43], for which it is possible to give fairly complete results. Especially easy, though tedious to demonstrate, is the following claim.

THEOREM 5.1 (Ermakov, 1880). *Let $X(t)$ be the solution of* (5.12) *with initial data $X(0) = X_0$, $\dot{X}(0) = \dot{X}_0$. Then, if $\chi_1(t)$ and $\chi_2(t)$ are solutions of the differential equation*

$$\frac{d^2\chi}{dt^2} + \lambda^2(t)\chi = 0 \tag{5.13a}$$

satisfying the initial data $\chi_1(0) = X_0$, $\dot{\chi}_1(0) = \dot{X}_0$ and $\chi_2(0) = 0$, $\dot{\chi}_2(0) \neq 0$, then

$$X(t) = \sqrt{\chi_1^2(t) + \frac{1}{w^2}\chi_2^2(t)}, \tag{5.13b}$$

where w is the constant $w = \chi_1\dot{\chi}_2 - \chi_2\dot{\chi}_1$.

Equation (5.13b) is often called *the principle of nonlinear superposition*. Equation (5.13a) is the well-known Hill's equation [44] which models a parametrically forced oscillator and which has been studied in depth. In the following, we shall study a couple of special situations in view of their physical interest.

It is remarkable that the complex dynamics of a family of nonlinear partial differential equations can be understood in terms of a simple equation such as Hill's.

If we suppose that the function $\lambda^2(t)$ depends on a parameter ε in the way $\lambda^2(t) = 1+\tilde{\lambda}_\varepsilon(t)$, $\tilde{\lambda}_\varepsilon(t)$ being a periodic function with maximum value ε (not necessarily small), there exists a complete theory that describes the intervals of values of ε for which the solutions of (5.13a) are bounded (intervals of stability) and the intervals for which the solutions are unbounded (intervals of instability) [44].

5.4. Connection of the method of moments with variational methods. In the physical literature devoted to the study of applications of the NLS equations there is a widely used method which receives different names depending on the specific field of application: time-dependent variational method, collective coordinates method, or method of averaged Lagrangians. There is a huge literature on the applications of this method to different problems (see, e.g., the reviews [20] and [21] for two specific application fields).

The idea of the method is to write the Lagrangian density corresponding to the NLS equation

$$\mathcal{L} = \frac{i}{2}\left(u\frac{\partial\bar{u}}{\partial t} - \bar{u}\frac{\partial u}{\partial t}\right) - \frac{1}{2}|\nabla u|^2 + V(x,t)|u|^2 + G(|u|), \tag{5.14}$$

and to transform the problem of solving the NLS equation into the problem of finding $u(x,t)$ such that the action

$$S(u,\bar{u}) = \int \mathcal{L}(x,t)dx\,dt \tag{5.15}$$

has an extremum.

This new problem is as difficult to handle as the equation itself. The idea of the heuristic method of averaged Lagrangians (or variational method or collective coordinates method) is to restrict the analysis of this variational problem to a particular family of trial functions *which are not the true solutions*, i.e., finding the extremum over a prescribed family of trial functions. Taking a particular form of the trial function depending on a few parameters $u(x,t) = \varphi(x, p_1(t), \dots, p_S(t))$ leads to an averaged finite-dimensional Lagrangian

$$L(t) = \int_{\mathbb{R}^n} \mathcal{L}(x,t)dx. \tag{5.16}$$

From (5.16), using the Euler–Lagrange equations

$$\frac{d}{dt}\left(\frac{\partial L}{\partial \dot{p_j}}\right) - \frac{\partial L}{\partial p_j} = 0, \tag{5.17}$$

one obtains evolution equations for the parameters $p_j(t)$.

Since the trial functions (sometimes called "solutions") must be incorporated from the very beginning in the treatment (i.e., one must choose their specific form to be either Gaussian, sech, etc.), the information provided by this method is the "approximate" evolution of the parameters $p_j(t)$, and since nobody knows how far the solution is from the trial function, it is not clear what the word "approximate" means in that context. Usually one can choose φ based on experience or qualitative considerations.

In this sense the moment method, when it works, provides a much more convenient and rigorous way to obtain the evolution of the relevant parameters without assuming an (incorrect) specific form of the solution. Moreover, since there are no error bounds for the estimates of the method of averaged Lagrangians, one must at the end simulate numerically the full NLS equation in order to validate the predictions of the time-dependent variational method. Within the framework of the method of moments these simulations are not necessary, since the equations are exact.

6. Applications.

6.1. Dynamics of laser beams in GRIN media. When a laser beam propagates in a medium with a gradex refraction index (GRIN medium) with a specific profile quadratic in the transverse coordinates, the distribution of intensity $u(x,y,z)$ in the permanent regime is ruled by (4.1) with $g(\rho) = \rho$ and $n = 2$ (in the optical version of the equation $t \leftrightarrow z$), so that we are dealing with the critical case that we know how to solve. Although in principle it would be possible to design fibers with arbitrary profiles, technically the simplest way is to join fibers with different uniform indexes in each section.

In this case, the phenomenon can be modeled by

$$\lambda^2(t) = \begin{cases} a^2, & t \in [0, T_a], \\ b^2, & t \in (T_a, T_a + T_b = T]. \end{cases} \tag{6.1}$$

Equation (5.13a) with $\lambda(t)$ given by (6.1) is known as the Meissner equation, whose solution is trivial, given in each segment by a combination of trigonometric functions.

The solutions to the Meissner equation can be bounded (periodical or quasi-periodical) or unbounded (resonant oscillations). In Figure 6.1 the two types of solutions are shown for a particular choice of parameters.

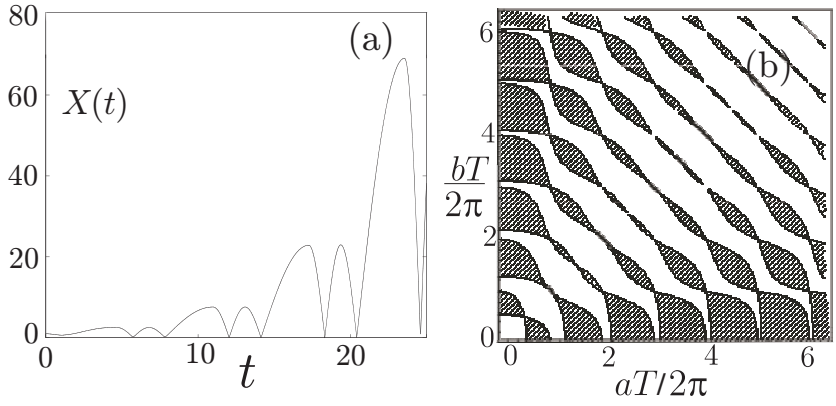

FIG. 6.1. *Solutions of* (5.13a) *with* $\lambda(t)$ *given by* (6.1). (a) *Resonant solution for* $T_a = 10\pi$, $T = 20\pi$, $a = 0.05$, $b = 0.15$ *and* (b) *regions of resonance for* $T_a = T_b = T/2$.

As far as the regions of stability in the space of parameters are concerned, they can be obtained by studying the discriminant of (5.13a), defined as the trace of the monodromy matrix, that is,

$$D(a, b, T_a, T_b) := \phi_1(T) + \phi_2'(T), \tag{6.2}$$

where ϕ_1, ϕ_2 are the solutions of (5.13a) satisfying the initial data $\phi_1(0) = 1$, $\phi_1'(0) = 0$ and $\phi_2(0) = 0$, $\phi_2'(0) = 1$, respectively.

In our case it is easy to arrive at

$$\phi_1(T) = \cos(aT_a)\cos(bT_b) - \frac{a}{b}\operatorname{sen}(aT_a)\operatorname{sen}(bT_b), \tag{6.3a}$$

$$\phi_2'(T) = \cos(aT_a)\cos(bT_b) - \frac{b}{a}\operatorname{sen}(aT_a)\operatorname{sen}(bT_b). \tag{6.3b}$$

Finally, the form of the discriminant is

$$D(a, b, T_a, T_b) = 2\cos(aT_a + bT_b) - \frac{(a-b)^2}{ab}\operatorname{sen}(aT_a)\operatorname{sen}(bT_b). \tag{6.4}$$

The Floquet theory for linear equations with periodical coefficients connects the stability of the solutions of (5.13a) with the value of the discriminant. The regions of resonance correspond to values of the parameters for which $|D| > 2$, whereas if $|D| < 2$, the solutions are bounded [44]. The equations $D(a, b, T_a, T_b) = 2$ and $D(a, b, T_a, T_b) = -2$ are the manifolds that limit the regions of stability in the four-dimensional space of parameters. In reality, defining $\alpha = aT$, $\beta = bT$, $T_a = \gamma T$, $T_b = (1-\gamma)T$, the number of parameters is reduced to three:

$$D(\gamma, \alpha, \beta) = 2\cos(\alpha\gamma + \beta(1-\gamma)) - \frac{(\alpha-\beta)^2}{\alpha\beta}\operatorname{sen}(\alpha\gamma)\operatorname{sen}(\beta(1-\gamma)). \tag{6.5}$$

Therefore, the isosurfaces $D(\gamma, \alpha, \beta) = 2$ and $D(\gamma, \alpha, \beta) = -2$ can be visualized in three dimensions, as is shown in Figure 6.2.

The general study of the regions that appear in Figure 6.2 is complex, which leads us to focus on a few particular cases below.

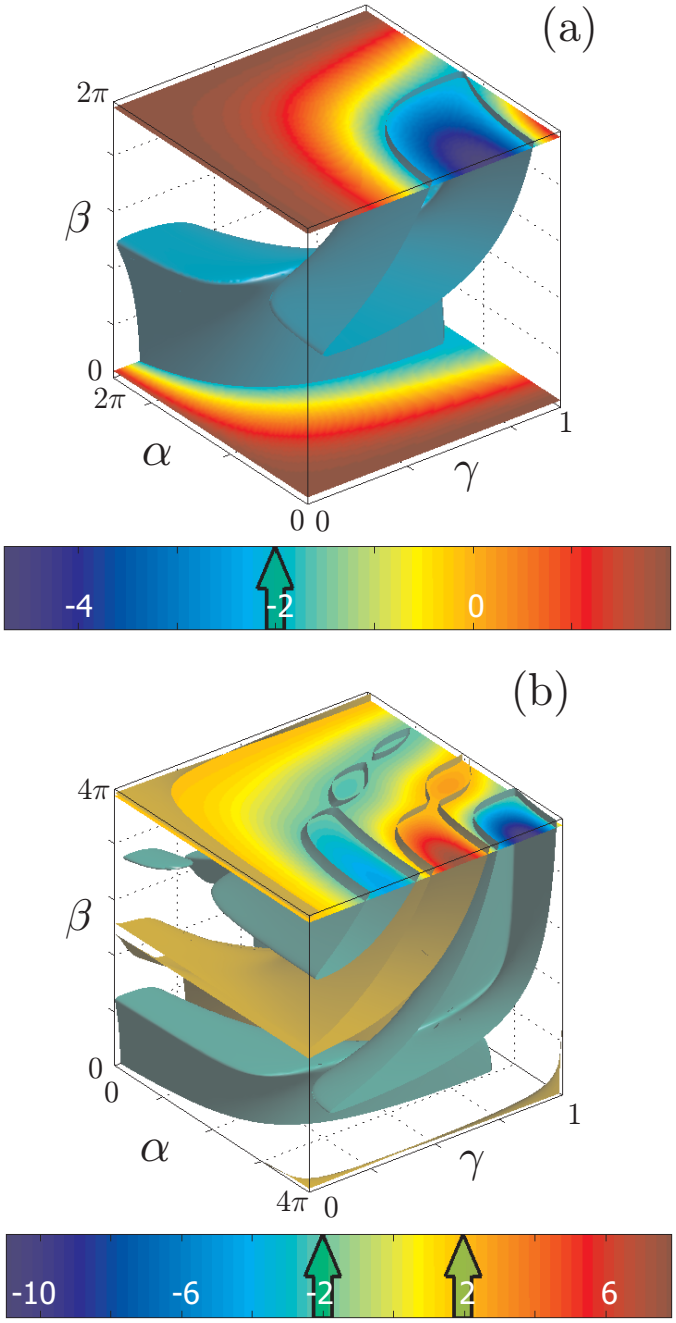

FIG. 6.2. (a) *Isosurfaces corresponding to* $D = -2$ *(in this range of values* $D \leq 2$*) for a limited range of parameters. The regions between the gray surface and the planes limiting the drawing are regions of resonance. Sections are shown for two particular values of* β*, where the bluish tones correspond to the regions of resonance. The color bar indicates the color corresponding to each level of* $D(\gamma, \alpha, \beta)$*, and the arrow indicates the color assigned to the isosurface* $D = -2$*.* (b) *The same as* (a) *but for a larger range of parameters. Isosurfaces* $D = 2$ *and* $D = -2$ *are shown in brown and green, respectively. A section is shown for a particular value of* β *with bluish and reddish tones corresponding to regions of resonances with* $D < -2$ *and* $D > 2$*, respectively. In this case the two values* $D = 2$ *and* $D = -2$ *are indicated by arrows on the color bar.*

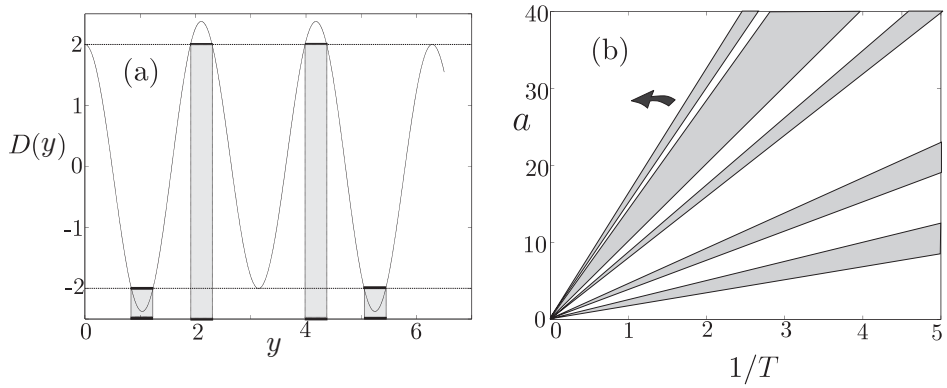

FIG. 6.3. (a) *First four regions of resonance in* y *(shaded) for* $T_a = T/2$, $b = 2a$, *as a function of* $y = aT/2$. (b) *First five regions of resonance in the plane* $a - 1/T$.

For example, in the case in which the two sections have the same length $T_a = T_b$, the discriminant depends only on aT, bT and it is

$$D(a,b) = 2\cos\left(\frac{(a+b)T}{2}\right) - \frac{(aT-bT)^2}{abT^2}\operatorname{sen}\left(\frac{aT}{2}\right)\operatorname{sen}\left(\frac{bT}{2}\right), \tag{6.6}$$

so that now the condition $|D| = 2$ determines curves such as those of Figure 6.1(b).

The structure of the regions of resonance can be explored in more detail, fixing the relative values of the coefficients; for example, taking $b = 2a$,

$$D(a,T) = 2\cos\left(\frac{3aT}{2}\right) - \frac{1}{2}\operatorname{sen}\left(\frac{aT}{2}\right)\operatorname{sen}(aT). \tag{6.7}$$

Defining the variable $y = aT/2$, the discriminant is a function $D(y)$; see Figure 6.3. The so-called characteristic curves are hyperbolas of the form $2y_{\pm}^{(n)} = aT$ with $y_{+}^{(n)}$ and $y_{-}^{(n)}$ being respectively the solutions of the algebraic equations $f_{\pm}(y) = 2\cos 3y - \frac{1}{2}\operatorname{sen} y \operatorname{sen} 2y \mp 2 = 0$. It is easy to demonstrate that the regions of resonance are contained between two consecutive zeros of f_+ or f_- that can be obtained using any elementary numerical method. If we draw a as a function of $1/T$, the regions of resonance are the shaded portions in Figure 6.3(b). Obviously the image is repeated due to the periodicity 2π of $D(y)$, and there are only four basic regions of resonance (together with its harmonics) contained in the intervals (roots of f_+ and f_-): $y \in [0.84, 1.23] \cup [1.91, 2.3] \cup [3.98, 4.37] \cup [5.05, 5.44]$ (see Figure 6.3(a)).

Another case of possible interest is that in which one of the fibers is not of GRIN type, that is, $b = 0$. Then the discriminant is given by the limit of (6.4) when $b \to 0$:

$$D(a,T) = -aT\operatorname{sen}\left(\frac{aT}{2}\right) + 2\cos\left(\frac{aT}{2}\right). \tag{6.8}$$

As in the previous case, the only relevant parameter is $y = aT/2$, the regions of resonance on the plane $a - T$ are hyperbolas, and the relevant quantities are the zeros of f_+ and f_-, which are given by

$$f_{\pm}(y) = -y\operatorname{sen} y + 2\cos y \mp 2 = 0. \tag{6.9}$$

Now there is no exact periodicity in the positions of the zeros any more, but at least it is possible to estimate the location of those of high order. To do this we must bear in mind that for y big enough the dominating term in both cases is $f_\pm(y) \simeq -y \operatorname{sen} y$, so that the zeros will be given by $y = n\pi$. It can be seen with a perturbative argument that the convergence ratio is of the order of $\mathcal{O}(1/n)$. Writing $y_\pm^{(n)} = n\pi + \varepsilon_\pm^{(n)}$ and substituting it into (6.9), it is found that

$$\varepsilon_\pm^{(n)} \simeq (-1)^{n+1} \frac{1 \pm 2}{n\pi}. \tag{6.10}$$

This type of analysis can be extended to any restricted set of parameters.

6.2. Dynamics of Bose–Einstein condensates. There has recently been great interest in the study of the dynamics of Bose–Einstein condensates in a parametrically oscillating potential. Recent experiments (see, e.g., [45, 46]) have motivated a series of qualitative theoretical analyses (the pioneer works on this subject can be seen in [47, 48, 49], although there is a great deal of subsequent literature).

In the models to which we refer, the trap is modified harmonically in time; that is,

$$\lambda^2(t) = 1 + \varepsilon \cos \omega t \tag{6.11}$$

with $\varepsilon > -1$. Equation (5.13a) with $\lambda(t)$ given by (6.11) is called the Mathieu equation. For this equation it is possible, as in the case of the Meissner equation, to carry out the study of the regions of the space of parameters in which resonances occur. In the first place, for any fixed ε, there exist two successions $\{\omega_n\}, \{\omega_n'\}$ with $\omega_n, \omega_n' \overset{n\to\infty}{\longrightarrow} 0$ such that if we take $\omega \in (\omega_n, \omega_n')$, (5.13a) possesses a resonance. In the second place, for fixed ω, the resonances appear when ε is large enough. The boundaries of those regions are the so-called characteristic curves that cannot be obtained explicitly but whose existence can be demonstrated analytically, as in the previous section, by using the discriminant. In the case of the Mathieu equation, it can be proven that the regions of instability begin in frequencies $\omega = 2, 1, 1/2, \ldots, 2/n^2, \ldots$ [44].

As in the previous case, the resonant behavior depends only on the parameters and not on the initial data. With respect to stability, the Massera theorem implies that if (ε, ω) is in a region of stability, then there exists a periodic solution of (5.13a), and by the nonlinear superposition principle, such a solution is stable in the sense of Lyapunov.

7. Approximate methods I: Quadratic phase approximation (QPA).

7.1. Introduction and justification of the QPA. Up to now, the results we have shown for the evolution of the solution moments are exact and in some sense rigorous. Unfortunately, in many situations of practical interest it is not possible to obtain closed evolution equations for the moments. In this section we will deal with an approximate method which is based on the method of moments.

The idea of this method is to approximate the phase of the solution u by a quadratic function of the coordinates, that is,

$$u(x,t) = U(x,t) \exp\left(i \sum_{j=1}^{n} \beta_j x_j^2 \right), \tag{7.1}$$

where $U(x,t)$ is a *real* function.

Why use a quadratic phase? Although there is not a formal justification and we do not know of any rigorous error bounds for the method to be presented here, there are several reasons which can heuristically support the use of this ansatz for the phase for situations where there are no essential shape changes of the solutions during the evolution. First of all, when (4.1) has self-similar solutions, they have exactly a quadratic phase [50]. Second, the dynamics of the phase close to stationary solutions of the classical cubic NLS equation in two spatial dimensions (critical case) is known to be approximated by quadratic phases [14, 16]. Finally, to capture the dynamics of the phase of solutions close to the stationary ones, which have a constant phase, by means of a polynomial fit, the terms of lowest order are quadratic since the linear terms in the phase may be eliminated by using Theorem 4.2.

For NLS equations all commonly used ansatzes in the framework of the previously mentioned variational methods have a quadratic phase, e.g., in applications related to dispersion management [51, 52], Bose–Einstein condensation, etc. Our systematic method provides a more general framework in which other methods can be systematized and understood.

As we will see in what follows, the choice (7.1) allows us to obtain explicit evolution equations and solves the problem of calculating the integrals of the phase derivatives in (4.6).

7.2. Modulated power-type nonlinear terms. Under the QPA, for modulated power-type nonlinearities $g(\rho,t) = g_0(t)\rho^{p/2}$, $p \in \mathbb{R}$, for which $\int_{\mathbb{R}^n} D(\rho)dx = -pJ/2$, the moment equations (4.6) are

$$\frac{dI_{2,j}}{dt} = V_{1,j}, \tag{7.2a}$$

$$\frac{dV_{1,j}}{dt} = 4K_j - 2\lambda_j^2 I_{2,j} + pJ, \tag{7.2b}$$

$$\frac{dK_j}{dt} = -\frac{1}{2}\lambda_j^2 V_{1,j} + p\beta_j J, \tag{7.2c}$$

$$\frac{dJ}{dt} = -p\left(\sum_{j=1}^{n}\beta_j\right)J + \frac{1}{g_0}\frac{dg_0}{dt}J. \tag{7.2d}$$

To these equations we must add the identity $V_{1,j} = 4\beta_j I_{2,j}$, which is directly obtained by calculating $V_{1,j}$. Or, expressed otherwise,

$$\beta_j = \frac{\dot{I}_{2,j}}{4I_{2,j}}. \tag{7.3}$$

Let us now consider the simplest case of solutions with spherical symmetry with $\lambda_j = \lambda(t)$, $j = 1,\dots,n$, for which $\phi(x_1,\dots,x_n) = \beta(t)\left(x_1^2 + \cdots + x_n^2\right)$. Using the same notation as in (5.2), the moment equations become

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{7.4a}$$

$$\frac{d\mathcal{V}}{dt} = 4\left(\mathcal{K} + \frac{np}{4}J\right) - 2\lambda^2\mathcal{I}, \tag{7.4b}$$

$$\frac{d\mathcal{K}}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} + np\beta J, \tag{7.4c}$$

$$\frac{dJ}{dt} = -np\beta J + \frac{1}{g_0}\frac{dg_0}{dt}J \tag{7.4d}$$

with $\mathcal{V} = 4\beta\mathcal{I}$. Despite the complexity of the system of equations (7.4) it is possible to find two positive invariants,

$$\mathcal{Q}_1 = 2\mathcal{K}\mathcal{I} - \mathcal{V}^2/4, \tag{7.5a}$$

$$\mathcal{Q}_2 = \frac{np}{2g_0}\mathcal{I}^{np/4}J. \tag{7.5b}$$

The existence of these invariants provides J as a function of $\mathcal{I}$, which allows us to arrive at an equation for $X = \mathcal{I}^{1/2}$,

$$\frac{d^2X}{dt^2} + \lambda^2(t)X = \frac{\mathcal{Q}_1}{X^3} + g_0(t)\frac{\mathcal{Q}_2}{X^{np/2+1}}. \tag{7.6}$$

Again we obtain a Hill's equation with a singular term. Note that in the case $n = 3$, $p = 2$ we have a quartic term in the denominator, which corresponds with the type of powers that appear in the equations which are obtained in the framework of averaged Lagrangian methods [20].

The quadratic phase method provides reasonably precise results that at least describe the qualitative behavior of the solutions of the partial differential equation. Using several numerical methods, we have carried out different tests especially in the most realistic case $np = 6$ in (4.1). For example, in Figure 7.1 we present the results of a simulation of (4.1) with $n = 3$, $p = 2$, $\lambda^2(t) = 1 + 0.1\sin(2.8t)$, and $g_0 = 10$ for an initial datum $u_0(x) = e^{-x^2/2}/\pi^{3/4}$. In this case the simplified equation (7.6) predicts quasi-periodic solutions, which is what we obtain when resolving the complete problem.

In Figure 7.2 we show the results for $\lambda^2(t) = 1 + 0.1\sin(2.1t)$, for which (7.6) predicts resonant solutions. Again, the results of the two models are in good agreement.

Another interesting application of the quadratic phase approximation method is the case of cubic nonlinearity, $g(\rho, t) = g_0(t)\rho = g_0(t)|u|^2$, without potential $\lambda(t) = 0$. In this situation (7.6) becomes

$$\frac{d^2X}{dt^2} = \frac{\mathcal{Q}_1}{X^3} + g_0(t)\frac{\mathcal{Q}_2}{X^{n+1}}, \tag{7.7}$$

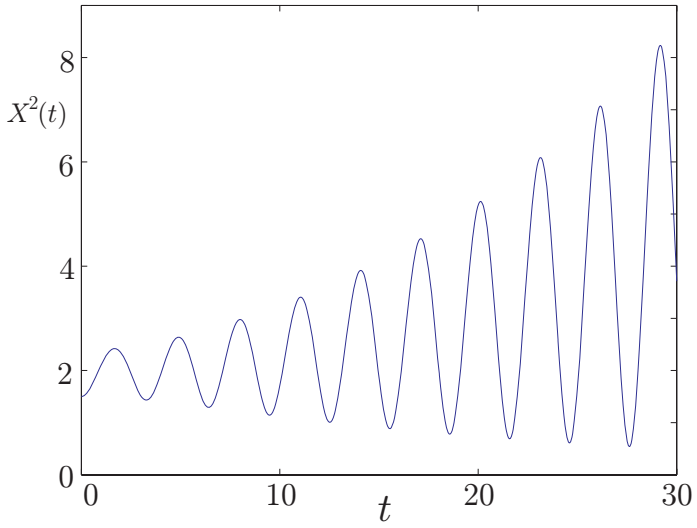

FIG. 7.2. *Results of the simulation of* (4.1) *in three dimensions on a grid of* $64 \times 64 \times 64$ *with* $\Delta t = 0.005$ *for* $p = 2$, $\lambda^2(t) = 1 + 0.1\sin(2.1t)$. $X^2(t)$ *obtained numerically from the solutions on the* $3D$ *grid is shown.*

where the conserved quantities are

$$\mathcal{Q}_1 = 2\mathcal{K}\mathcal{I} - \frac{\mathcal{V}^2}{4}, \tag{7.8a}$$

$$\mathcal{Q}_2 = \frac{n}{g_0}\mathcal{I}^{n/2}J. \tag{7.8b}$$

This model describes the propagation of light in nonlinear Kerr media as well as the dynamics of trapless Bose–Einstein condensates. In this situation the previous equations are used to study the possibility of stabilizing unstable solutions of the NLS equation by means of an appropriate temporal modulation of the nonlinear term, that is, by choosing a suitable function $g_0(t)$, thus providing an alternative to more heuristic treatments [53, 54, 55]. More details can be seen in [56].

7.3. Closure of the equations in other cases. We have just seen that the quadratic phase approximation method allows us to close the moment equations in the case of power-type nonlinear terms. Following those ideas, we have managed to close the equations in more general cases.

We start from the evolution equations for the mean moments (5.4), that after performing the quadratic phase approximation become

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{7.9a}$$

$$\frac{d\mathcal{V}}{dt} = 4\mathcal{K} - 2\lambda^2\mathcal{I} - 2n\int_{\mathbb{R}^n} D(\rho,t), \tag{7.9b}$$

$$\frac{d\mathcal{K}}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} - 2n\beta\int_{\mathbb{R}^n} D(\rho,t), \tag{7.9c}$$

$$\frac{dJ}{dt} = 2n\beta\int_{\mathbb{R}^n} D(\rho,t) + \int_{\mathbb{R}^n}\frac{\partial G(\rho,t)}{\partial t}, \tag{7.9d}$$

and $\mathcal{V} = 4\beta\mathcal{I}$.

The idea to close the previous equations is to calculate the evolution of $\int_{\mathbb{R}^n} D(\rho,t)dx$, which is the term that prevents us from closing the equations, and try to write this evolution in terms of the moments. Let us define a new moment $\mathcal{F}$ as

$$\mathcal{F}(t) = \int_{\mathbb{R}^n} D(\rho,t)dx = J - \int_{\mathbb{R}^n} \rho \frac{\partial G(\rho,t)}{\partial \rho} dx. \tag{7.10}$$

Then, the evolution equations are

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{7.11a}$$

$$\frac{d\mathcal{V}}{dt} = 4\mathcal{K} - 2\lambda^2\mathcal{I} - 2n\mathcal{F}, \tag{7.11b}$$

$$\frac{d\mathcal{K}}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} - 2n\beta\mathcal{F}, \tag{7.11c}$$

$$\frac{dJ}{dt} = 2n\beta\mathcal{F} + \int_{\mathbb{R}^n} \frac{\partial G}{\partial t} dx, \tag{7.11d}$$

together with the evolution of $\mathcal{F}$

$$\frac{d\mathcal{F}}{dt} = 2n\beta F + 2n\beta \int_{\mathbb{R}^n} \rho^2 \frac{\partial^2 G}{\partial \rho^2} dx + \int_{\mathbb{R}^n} \frac{\partial G}{\partial t} dx - \int_{\mathbb{R}^n} \rho \frac{\partial}{\partial t}\frac{\partial G}{\partial \rho} dx. \tag{7.12}$$

To try to close the system of equations (7.11)–(7.12) we impose that $\int_{\mathbb{R}^n} \rho^2 \frac{\partial^2 G}{\partial \rho^2} dx$ is a linear combination of $\mathcal{F}$ and J

$$\int_{\mathbb{R}^n} \rho^2 \frac{\partial^2 G}{\partial \rho^2} dx = a_{\mathcal{F}}\mathcal{F} + a_J J = (a_{\mathcal{F}} + a_J)\int_{\mathbb{R}^n} G dx - a_{\mathcal{F}} \int_{\mathbb{R}^n} \rho \frac{\partial G}{\partial \rho} dx, \tag{7.13}$$

where $a_{\mathcal{F}}$ and a_J are two arbitrary constants. Then G must verify

$$\int_{\mathbb{R}^n} \left[\rho^2 \frac{\partial^2 G}{\partial \rho^2} + a_{\mathcal{F}} \rho \frac{\partial G}{\partial \rho} - (a_{\mathcal{F}} + a_J) G \right] = 0.$$

Therefore, if the nonlinear term $g(\rho)$ in the NLS equation is such that $G(\rho)$ verifies Euler's equation

$$\rho^2 \frac{\partial^2 G}{\partial \rho^2} + a_{\mathcal{F}} \rho \frac{\partial G}{\partial \rho} - (a_{\mathcal{F}} + a_J) G = 0, \tag{7.14}$$

the evolution equations will close. In that case we can write $G(\rho,t) = g_0(t)G_1(\rho)$, where $g_0(t)$ is an arbitrary function which indicates the temporal variation of the nonlinear term and $G_1(\rho)$ satisfies (7.14). So

$$\int_{\mathbb{R}^n} \frac{\partial G}{\partial t} dx = \frac{dg_0}{dt} \int_{\mathbb{R}^n} G_1(\rho) dx = \frac{1}{g_0}\frac{dg_0}{dt} J(t),$$
$$\int_{\mathbb{R}^n} \rho \frac{\partial}{\partial t}\frac{\partial G}{\partial \rho} dx = \frac{dg_0}{dt} \int_{\mathbb{R}^n} \rho \frac{dG_1}{d\rho} = \frac{1}{g_0}\frac{dg_0}{dt}[J(t) - \mathcal{F}(t)],$$

and the moment equations are written as

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{7.15a}$$

$$\frac{d\mathcal{V}}{dt} = 4\mathcal{K} - 2\lambda^2\mathcal{I} - 2n\mathcal{F}, \tag{7.15b}$$

$$\frac{d\mathcal{K}}{dt} = -\frac{1}{2}\lambda^2\mathcal{V} - 2n\beta\mathcal{F}, \tag{7.15c}$$

$$\frac{dJ}{dt} = 2n\beta\mathcal{F} + \frac{1}{g_0}\frac{dg_0}{dt}J, \tag{7.15d}$$

$$\frac{d\mathcal{F}}{dt} = 2n\beta(1+a_{\mathcal{F}})\mathcal{F} + 2n\beta a_J J + \frac{1}{g_0}\frac{dg_0}{dt}\mathcal{F}. \tag{7.15e}$$

By solving (7.14), we obtain specific nonlinear terms for which the quadratic phase approximation allows us to write closed equations for the moments. Depending on the parameter $\delta = (1+a_{\mathcal{F}})^2 + 4a_J$, there exist three families of solutions

$$G_1(\rho) = \begin{cases} C_1\rho^{p_+} + C_2\rho^{p_-}, & \delta > 0, \\ C_1\rho^R + C_2\rho^R\log\rho, & \delta = 0, \\ C_1\rho^R\cos(I\log\rho) + C_2\rho^R\sin(I\log\rho), & \delta < 0, \end{cases} \tag{7.16}$$

where $p_\pm = \left((1-a_{\mathcal{F}}) \pm \delta^{1/2}\right)/2$, $R = (1-a_{\mathcal{F}})/2$, $I = |\delta|^{\frac{1}{2}}/2$.

The most interesting case for applications is $\delta > 0$, the nonlinear term being of the form

$$g_1(\rho) = k_1\rho^{p_+-1} + k_2\rho^{p_--1}, \tag{7.17}$$

where k_1 and k_2 are arbitrary constants and p_+ and p_- are defined through the relations

$$a_{\mathcal{F}} = 1 - p_+ - p_-, \tag{7.18a}$$

$$a_J = -(p_+ - 1)(p_- - 1). \tag{7.18b}$$

Equation (7.17) implies that the quadratic phase approximation allows us to close the moment equations for nonlinear terms, which can be written as a linear combination of two arbitrary powers of $|u|$.

As in the previous subsection, it is possible to find some invariant quantities, namely,

$$Q_1 = 2\mathcal{K}\mathcal{I} - \frac{\mathcal{V}^2}{4}, \tag{7.19a}$$

$$Q_+ = C\frac{n}{f_+}\frac{\mathcal{I}^{a+n}}{g_0}(J + f_+\mathcal{F}), \tag{7.19b}$$

$$Q_- = C\frac{n}{f_+}\frac{\mathcal{I}^{a-n}}{g_0}(J + f_-\mathcal{F}), \tag{7.19c}$$

where

$$a_\pm = \frac{p_\pm - 1}{2}, \quad f_\pm = \frac{1}{p_\mp - 1}, \quad C = \left(1 - \frac{f_-}{f_+}\right)^{-1} = \left(1 - \frac{p_- - 1}{p_+ - 1}\right)^{-1}. \tag{7.20}$$

These conserved quantities allow us to write a differential equation for the dynamical width $X(t) = \mathcal{I}^{1/2}$:

$$\frac{d^2X}{dt^2} + \lambda^2(t)X = \frac{\mathcal{Q}_1}{X^3} + g_0(t)\left(\frac{\mathcal{Q}_-}{X^{2a_-n+1}} - \frac{\mathcal{Q}_+}{X^{2a_+n+1}}\right). \tag{7.21}$$

The most interesting kind of nonlinearity in the form of (7.17) is the so-called cubic-quintic nonlinearity, for which $g_0(t) = 1$, $g_1(\rho) = k_1\rho + k_2\rho^2 = k_1|u|^2 + k_2|u|^4$. Then we have $p_+ - 1 = 2$, $p_- - 1 = 1$, $a_{\mathcal{F}} = -4$, $a_J = -2$, $a_+ = 1$, $f_+ = 1$, $a_- = 1/2$, $f_- = 1/2$, $C = 2$. The invariant quantities are

$$\mathcal{Q}_1 = 2\mathcal{K}\mathcal{I} - \frac{\mathcal{V}^2}{4}, \tag{7.22a}$$

$$\mathcal{Q}_+ = 2n\mathcal{I}^n(J + \mathcal{F}), \tag{7.22b}$$

$$\mathcal{Q}_- = 2n\mathcal{I}^{n/2}\left(J + \frac{\mathcal{F}}{2}\right), \tag{7.22c}$$

and the equation for the width is

$$\frac{d^2X}{dt^2} + \lambda^2(t)X = \frac{\mathcal{Q}_1}{X^3} + \frac{\mathcal{Q}_-}{X^{n+1}} - \frac{\mathcal{Q}_+}{X^{2n+1}}. \tag{7.23}$$

These equations contain a finite-dimensional description of the dynamics of localized solutions of the model and are similar to those found under specific assumptions for the profile $u(x,t)$ (see, e.g., [57, 58, 59]). The main difference is that the method of moments allows us to obtain the equations under minimal assumptions on the phase of the solutions and that depend on general integral quantities related to the initial data $\mathcal{Q}_1, \mathcal{Q}_+, \mathcal{Q}_-$. This is an essential advantage over the averaged Lagrangian methods used in the literature for which the specific shape of the solution must be chosen a priori (see also [20, 50]).

8. Approximate methods II: The Thomas–Fermi limit.

8.1. Concept. In the framework of the application of the NLS equations to Bose–Einstein condensation problems (and thus for nonlinearities of the form $g(\rho) = g_0\rho$), the Thomas–Fermi limit corresponds to the case $g_0 \gg 1$. (Note that this is only one of the many different meanings of "Thomas–Fermi" limit in physics.)

Usually, what is pursued in this context is to characterize the ground state, defined as the stationary solution of the NLS equation given by (4.5) with fixed L^2-norm having minimal energy E. It is also interesting to find the dynamics of the solutions under small perturbations of the ground state solution.

8.2. Physical treatment. Let us consider the problem of characterizing the ground state of (4.1). The usual "physical" way of dealing with this problem consists of assuming that if the nonlinear term is very large, then it would be possible to neglect the Laplacian term in (4.1) (!) and to obtain the ground state solution as

$$\varphi_{TF}(x) = \sqrt{\left(\frac{\mu - \frac{1}{2}\sum \lambda_j^2 x_j^2}{g_0}\right)_+}. \tag{8.1}$$

The value of μ is obtained from the condition of normalization $\|\varphi_{TF}\|_2 = 1$. This procedure provides a solution without nodes, which is then argued to be an approximation to the ground state.

This method is used in many applied works, but unfortunately it is not even self-consistent. Near the zero of the radicand of (8.1) the approximation obtained has divergent derivatives, which contradicts the initial hypothesis of "smallness" of the Laplacian term. Although several numerical results can be obtained using this approximation, its foundation is very weak.

In order to understand the problem better, we rewrite (4.1) making the change of variables $\kappa = \mu/g_0$, $\eta = x/\sqrt{g_0}$, $\psi(\eta) = \varphi\left(x/\sqrt{g_0}\right)$, to give us the equation

$$-\frac{1}{2}\epsilon^2\Delta\psi + \frac{1}{2}\left(\sum_j \lambda_j^2\eta_j^2\right)\psi + |\psi|^2\psi = -\kappa\psi, \tag{8.2}$$

with $\epsilon = 1/g_0$. It is evident that $\epsilon^2\Delta\psi$ is a singular perturbation whose effect may not be trivial.

8.3. The method of moments and the Thomas–Fermi limit. What can be said for the case of power-type nonlinearities in the limit $g \gg 1$ on the basis of the method of moments? Before making any approximations we write an evolution equation for $\mathcal{I}$ as follows. For the sake of simplicity, though it is not strictly necessary, we will consider the case of $\lambda_j = \lambda$ for $j = 1, \ldots, n$ and study the equations for the mean values (5.2).

First, we write (5.3a) and (5.3b) as

$$\frac{d\mathcal{I}}{dt} = \mathcal{V}, \tag{8.3a}$$

$$\frac{d\mathcal{V}}{dt} = 4\left(\mathcal{K} + \frac{np}{4}J\right) - 2\lambda^2\mathcal{I} = (4-np)\mathcal{K} + np\mathcal{H} - \left(2+\frac{np}{2}\right)\lambda^2\mathcal{I}, \tag{8.3b}$$

where $\mathcal{H}$ is the conserved energy. Combining (8.3a) and (8.3b), we arrive at

$$\frac{d^2\mathcal{I}}{dt^2} + \left(2+\frac{np}{2}\right)\lambda^2\mathcal{I} = (4-np)\mathcal{K} + np\mathcal{H}. \tag{8.4}$$

Equation (8.4) is exact.

The fact that the energy functional E reaches a minimum over φ_0 implies, by Lyapunov stability, that initial data $u_0(x) = \varphi_0(x) + \varepsilon\delta(x)$ close to the ground state must remain proximal for sufficiently small values of ε.

The only approximation needed to complete our analysis is to assume that when $g \gg 1$, then $J \gg \mathcal{K}$ for the ground state. Notice that this is a much more reasonable assumption than the direct elimination of the second derivative in the evolution equation. Thus, the energy conservation and the previous considerations allow us to affirm that $J(t) \gg \mathcal{K}(t)$ for all times.

Although these facts can be used to write explicit bounds for $\mathcal{K}$, as a first approximation and just in order to show the power of these ideas we can simply take $\mathcal{K} \simeq 0$. Under this approximation we have

$$\frac{d^2\mathcal{I}}{dt^2} + \left(2+\frac{np}{2}\right)\lambda^2\mathcal{I} \approx np\mathcal{H}, \tag{8.5}$$

whose solutions can be obtained explicitly as

$$\mathcal{I}(t) \simeq \frac{np\mathcal{H}}{\lambda^2\left(2+\frac{np}{2}\right)} + A\cos\left(\lambda t\sqrt{2+\frac{np}{2}}\right) + B\,\mathrm{sen}\left(\lambda t\sqrt{2+\frac{np}{2}}\right). \tag{8.6}$$

The equilibrium point of (8.4) (corresponding to $A = B = 0$) gives us the "size" of the ground state as a function of the physical parameters. Also the frequency of the oscillations around the equilibrium point is immediately obtained from (8.6):

$$\Omega = \lambda\sqrt{2 + \frac{np}{2}}. \tag{8.7}$$

We have performed numerical simulations of the partial differential equations (4.1) to verify this prediction. Specifically, taking $g = 5000, 20000$, $\lambda = 1$, and initial data of the form $u_0(x) = \varphi_0((1+\varepsilon)x)/\sqrt{1+\varepsilon}$ for $\varepsilon = 0.01$ and $\varepsilon = 0.02$, we find a numerical frequency of $\Omega_{\rm num} = 2.26$, which is in excellent agreement with the value provided by our Thomas–Fermi formula $\Omega_{\rm TF} = \sqrt{8} = 2.24$.

9. Summary and conclusions. In this paper we have developed the method of moments for nonlinear Schödinger equations. First we have found the general expressions of the method and classified the nonlinearities for which it allows a closed explicit solution of the evolution of the moments. We have also discussed several applications of the method such as the dynamics of Kerr beams in nonlinear stratified media and the dynamics of parametrically forced Bose–Einstein condensates.

Approximate techniques based on the method of moments have also been discussed in this paper. In particular, the quadratic phase approximation was developed here and applied to different problems, such as the writing of simple equations describing the stabilization of solitonic structures by control of the nonlinear terms and the dynamics of localized structures in cubic-quintic media. Finally, we have also studied the moment equations in the so-called Thomas–Fermi limit.

THE FORMATION OF RIVER CHANNELS*

A. C. FOWLER†, NATALIA KOPTEVA‡, AND CHARLES OAKLEY†

Abstract. We consider a deterministic model of landscape evolution through the mechanism of overland flow over an erodible substrate, using the St. Venant equations of hydraulics together with the Exner equation for hillslope erosion. A novelty in the model is the allowance for a nonzero bedload layer thickness, which is necessary to distinguish between transport limited and detachment limited sediment removal. It has long been known that transport limited uniform flow is unstable when the hillslope topography is geomorphologically concave (i.e., the center of curvature is above ground). In this paper, we show how finite amplitude development of the consequent channel flow leads to an evolution equation for its depth h of the form $h_t = h^{3/2} + (h^{3/2})_{YY}$, where Y is the cross-stream space variable. We show that solutions of compact support exist but that, despite appearances, blow up does not occur because of an associated integral constraint, and the channel equation admits a unique and apparently globally stable steady state. The consequences for hillslope evolution models are discussed.

Key words. river networks, mathematical geomorphology, channel formation, nonlinear diffusion

1. Introduction.

The formation of river networks is one of a class of morphological problems in which fractal structures are generated by an instability in the medium. Other familiar examples are the lungs, blood capillary beds, and underground limestone cave systems. Two questions immediately present themselves in connection with such structures. The first is whether it is possible to explain quantitatively the basic mechanisms which are involved in causing them to form. The second is the consequent deeper issue of whether it is possible to explain and predict the fractal structures which are observed in nature, given that the model will originate as a deterministic set of differential equations. In this paper, we will be concerned with the first of these questions.

The basic way in which landscape evolves under fluvial erosion is this. Tectonic processes cause uplift of mountain belts, and as the mountains are raised, erosion due to rainfall and runoff causes a gradual lowering of the topography. Other processes, such as glacial erosion and landslides, contribute more dramatically: glaciation at high altitudes, and landslides in regions of higher relief. As is evident from Figure 1, this balance between uplift and erosion is unstable, and the runoff is concentrated into small river channels which drain the catchment.

In attempting to formulate a model to describe this process, we identify two variables of importance; these are the surface elevation s and the water depth h (Figure 2). These will be described by evolution equations representing conservation

of sediment and water, respectively.

Smith and Bretherton (1972) presented such a model and found that while there is a uniform steady state solution, it is unstable to the formation of channel-like features. In particular, they associated instability with concavity of the hillslope, i.e., $s_{xx} > 0$, where x is the downslope direction of flow.

The particular way in which this instability is manifested is curious. The physical mechanism is plain enough, that increasing depth causes increased water flow, which in turn causes increased erosion and thus channel deepening. In their linear stability analysis, Smith and Bretherton found that the mathematical cause of instability was an effective lateral diffusion coefficient for hillslope which was negative. This naturally produces instability, but the resulting growth rate is unbounded at short wavelength, and their model is consequently ill-posed. Unsurprisingly, properly resolved numerical solutions of the Smith–Bretherton model are not available.

Another consequence of this ill-posedness is a suspicious absence of wavelength selection. Loewenherz (1991) addressed this issue by carrying out a formal linear stability analysis using normal modes (something Smith and Bretherton did not do), and she extended this to convex/concave slopes using the asymptotic technique of WKB theory (Carrier, Krook, and Pearson (1966)) at high wave number k. She also considered the problem of regularization as $k \to \infty$, by introduction of a (fairly arbitrary) modification to the sediment transport law.

Later (Loewenherz-Lawrence (1994)), she treated the whole problem again, but now starting from the hydrodynamic theory, which is also the starting point for the model we present below. In this way, she was able to identify the cause of the ill-posedness of the Smith–Bretherton theory, which lies in the assumption of equal water and land surface slopes. The small mismatch between these two allows regularization at high wave number, and therefore also wavelength selection.

A different approach to the issue of wavelength selection was taken by Izumi and Parker (1995, 2000), who used a St. Venant overland flow model together with a finite

threshold stress for the onset of erosion to show that there is a preferred wavelength for instability. Their estimate in the earlier paper was 33 m, comparable to observed headwater spacings of order 100 m. A formal stability analysis in the second paper (of a slightly different problem) yielded plausibly similar values.

The next logical steps in the development of this theory are a nonlinear theory for finite depth channel development, and full numerical solution of the governing equations. Progress in the first of these aims was made by Kramer and Marder (1992), who developed a nonlinear evolution equation for channel depth by seeking particular solutions of their hillslope model, which was similar, but by no means identical to, the Smith–Bretherton model. The main difference between their result and that of the present paper is that their model is partially empirical, and the derivation of the channel model is not placed in the context of a formal asymptotic approximation to the full model. This leads to important differences in the way the channel evolution equation is posed.

Kramer and Marder also sought to implement a direct numerical simulation, but here, in common with other authors, they were stymied. The apparent reason for this is that the governing partial differential equations are very stiff in both space and time. Water flow in channels occurs on much shorter space and time scales than hillslope evolution, and such numerical computational studies as there have been have not been able to overcome this difficulty.

In response to this, they adopted a cellular lattice model, with physically motivated rules at the lattice points determining the evolution of water depth and land surface elevation. Such cellular models do produce networks but evidently lack a theoretically based predictive capacity. To a large extent, they provide the computational model of choice for other researchers also (e.g., Howard (1994), Tucker and Slingerland (1994)).

A variant on this was the model developed by Willgoose, Bras, and Rodríguez-Iturbe (1991), which combined physically based erosion and water flow equations with an artificial equation for an indicator function Y. Essentially, Y would switch from $Y = 0$ (hillslope) to $Y = 1$ (channel) when water flow increased beyond a critical threshold. In this way, Willgoose et al. could simulate network formation but again without a physically based predictive criterion.

In a sequence of papers, Smith and his coworkers have developed a semianalytic theory of hillslope and channel evolution. Their work is actually orthogonal to the present paper but will be discussed in some detail here because of the apparent parallelism with our work. Smith, Birnir, and Merchant (1997a) consider a simplified version of the Smith–Bretherton model, and use it to suggest that large time solutions have separable form, which they are able to characterize in terms of a variational principle. Smith, Birnir, and Merchant (1997b) elaborate this description by suggesting that an initially smooth hillslope develops channels on a small scale through the Smith–Bretherton instability; the channels saturate via nonlinearity and then evolve into the long time separable solutions described earlier. These results are obtained numerically. In order to obtain numerical results for the ill-posed Smith–Bretherton model, Smith, Birnir, and Merchant (1997b) used a coarse grid on a small plot (100 m by 100 m with grid spacing 1 m), together with enough numerical diffusion to stabilize the results. Smith, Merchant, and Birnir (2000) develop a theory for the time evolution of the grade line of both alluvial and bedrock channels; the former is modelled by a nonlinear diffusion equation, and the latter is modelled by a nonlinear first-order wave equation. Both theories ignore hillslope evolution and make heuristic assumptions in order to derive the models. Birnir, Smith, and Merchant (2001) develop the

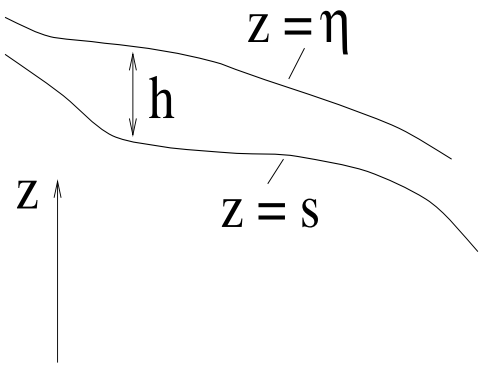

FIG. 2. *Geometry of overland flow.*

ideas originated in the earlier papers by Smith, Birnir, and Merchant (1997a, 1997b). They paint a fairly compelling picture of landscape evolution, which hinges on the twin hypotheses that small scale shock formation in overland flow acts as a seed for white noise to drive the slower hillslope evolution towards a self-similar (separable in time) mature landscape. Crucial to this notion is the assumption that the numerical results are sufficiently detailed to support it. The numerical procedures are improved over those of Smith, Birnir, and Merchant (1997b), but apparently retain the small plot and coarse grid of the earlier calculations, and are therefore open to the same objection, that the coarse grid in particular allows only mildly unstable results by suppressing the high wave number instabilities. The paper by Welsh, Birnir, and Bertozzi (2006) is similar to that of Smith, Merchant, and Birnir (2000), insofar as it uses the Smith–Bretherton model to assess the evolution of the long profile of a river channel. To do this, it assumes a purely one-dimensional model, so that the channel evolves in isolation from the surrounding hillslope.

Our purpose in this paper is to show that a hydrodynamic model similar to those of Loewenherz-Lawrence (1994) and Tucker and Slingerland (1994) leads formally to the derivation of an evolution equation for channel depth (which resembles that of Kramer and Marder). The solution properties of this equation are studied, and it is shown that, despite a similarity of the channel equation to partial differential equations having blow-up properties, there is a unique steady state solution which is stable. This solution may provide an ingredient for future direct numerical simulations of hillslope evolution.

2. A model for sediment and water transport. The geometric situation we consider is portrayed in Figure 2. The vertical coordinate is z, while x and y are horizontal coordinates. The simplest situation is where overland flow occurs down a plane slope, and in this case we take x in the downstream direction and y across stream. The land surface is $z = s(x, y, t)$, the water surface is $z = \eta(x, y, t)$, and the water depth is h, and thus $h = \eta - s$. This relationship is not exact, because the sedimentary surface is further subdivided into a mobile part and a stationary part. A precise statement is given below in (2.9).

The St. Venant equations of hydraulic flow can be written in the form

$$\begin{aligned} &h_t + \boldsymbol{\nabla}.(h\mathbf{u}) = r, \\ &\mathbf{u}_t + (\mathbf{u}.\boldsymbol{\nabla})\mathbf{u} = -g\boldsymbol{\nabla}\eta - \frac{f|\mathbf{u}|\mathbf{u}}{h}. \end{aligned} \tag{2.1}$$

These represent conservation of water mass and momentum and can be derived from the vertically integrated point forms of the equations. r is the source due to rainfall, $\mathbf{u}$ is the mean velocity, and f is a friction factor in a term which represents the bed stress exerted by the flow, assuming this is turbulent. While this is a good parameterization of the bed friction in channelized flow, it is less obviously appropriate for the very thin films which characterize overland flow. We shall comment further on this below, but for the moment we note that consideration of laminar flow at low flow rates would simply have the effect in the model of changing the term $f|\mathbf{u}|$ in $(2.1)_2$ to a constant k, making quantitative but not conceptual difference to the discussion.

Sediment transport. Sediment transport in rivers occurs, for noncohesive sediments with little clay content, when an appropriately dimensionless shear stress (called the Shields stress) delivered by the river exceeds a certain critical value. The turbulent shear stress is taken to be

$$\boldsymbol{\tau} = f\rho_w|\mathbf{u}|\mathbf{u}, \tag{2.2}$$

where ρ_w is water density. If the sediment particles are of diameter D_s (supposed uniform, for simplicity) at the bed, the streamflow exerts a force of approximately $\boldsymbol{\tau}D_s^2$ on it, and it is this force which causes motion. On a slope, there is an additional force due to gravity, approximately $-\Delta\rho g D_s \boldsymbol{\nabla} s$, where $\Delta\rho = \rho_s - \rho_w$ is the density difference between sediment and water, and g is gravitational acceleration. Thus the net effective stress causing motion is actually

$$\boldsymbol{\tau}_e = \boldsymbol{\tau} - \Delta\rho g D_s \boldsymbol{\nabla} s. \tag{2.3}$$

The Shields stress is

$$\mu = \frac{\tau_e}{\Delta\rho g D_s}, \tag{2.4}$$

and particle motion occurs if $\mu \gtrsim \mu_c \approx 0.05$; the critical value depends to some extent on particle size via the particle Reynolds number.

Particle motion occurs in two ways. Larger particles bounce and roll along the bed, and the resultant transport is called bedload transport. Finer particles are lifted up and carried in suspension. In this paper, we will suppose that only bedload transport is relevant. This assumption is made partly for convenience, partly because it corresponds to the choice of Smith and Bretherton (1972), and partly because it may be an unnecessary elaboration to consider suspended load instead or as well.

Various empirical formulae for bedload transport q_b have been proposed. A popular one is that due to Meyer-Peter and Müller (1948), which takes the form

$$q_b = \left(\frac{\rho_s K}{\rho_w^{1/2}\Delta\rho\, g}\right)(\tau_e - \tau_c)_+^{3/2}, \tag{2.5}$$

where Meyer-Peter and Müller chose values of $K = 8$ and $\mu_c = 0.047$, and the critical stress τ_c is defined by

$$\tau_c = \mu_c \Delta\rho g D_s. \tag{2.6}$$

The units of q_b are kg m^{-1} s^{-1}, i.e., mass per unit stream width per unit time.

It is commonly the case that bedload transport is conceived to occur in a layer of zero thickness, if this is considered at all. Although the moving bedload layer

thickness may indeed be small, it is essential to include it in the model (as did Tucker and Slingerland (1994)), because otherwise a relationship such as (2.5) implies that transport occurs even if the substrate is inerodible bedrock. In fact, we must modify (2.5) so that the bedload transport is zero if the bedload layer thickness is equal to zero.

To be specific, we now suppose that $z = s$ describes the interface between stationary bed and moving bedload, and we suppose that the moving bedload layer has thickness a. If the (constant) porosity of the bed (both mobile and immobile) is ϕ and the bedload transport is $\mathbf{q}_b$, then conservation of mobile sediment implies that

$$\rho_s(1-\phi)a_t + \boldsymbol{\nabla}.\mathbf{q}_b = \rho_s(1-\phi)v_A, \tag{2.7}$$

where v_A is the abrasion or entrainment rate of the immobile bed, measured as a velocity.

The Exner equation which describes land surface evolution can now be written in the form

$$\rho_s(1-\phi)s_t = -\rho_s(1-\phi)v_A \ + \ \rho_s(1-\phi)U, \tag{2.8}$$

where U is the velocity of tectonic uplift, or more generally, baselevel fall. The geometric relation between the various depths is seen to be

$$\eta = s + a + h. \tag{2.9}$$

Equations (2.1), (2.7), (2.8), and (2.9) provide five equations for the five variables η, s, a, h, and $\mathbf{u}$; the abrasion rate v_A and bedload transport $\mathbf{q}_b$ need to be prescribed in constitutive relations.

Abrasion and transport rates. It is a fact of observation that the thickness a of the moving bedload layer in a stream is commonly quite small, perhaps only one or two grain thicknesses (Slingerland, Harbaugh, and Furlong (1994, pp. 80–81)). If the stream flow is very rapid, we might expect the consequently rapidly moving grains to mobilize the grains below them. These considerations suggest that the abrasion rate v_A should be a (nonnegative) decreasing function of a which tends to zero at large a and that it should depend on stream flow. With little to guide us, we make the simplest assumption that $v_A = 0$ for a larger than some constant threshold a_0, although it is not difficult to modify this assumption. When $a \geq a_0$, we have conditions of transport limitation, and when $a < a_0$, we have detachment limitation.

We define a bedload velocity (when $a = a_0$)

$$v_b = \frac{q_b}{\rho_s(1-\phi)a_0}, \tag{2.10}$$

and v_b is a function of τ_e. For example, the Meyer-Peter–Müller law (2.5) gives

$$v_b = \left(\frac{K}{\rho_w^{1/2}\Delta\rho\, g(1-\phi)a_0}\right)(\tau_e - \tau_c)_+^{3/2}. \tag{2.11}$$

The constitutive assumptions we will then make for transport and abrasion rates are

$$\begin{aligned} \mathbf{q}_b &= \rho_s(1-\phi)a v_b\,(\tau_e)\,\mathbf{N}, \\ v_A &= k v_b\,(\tau_e)\left[1 - \frac{a}{a_0}\right]_+; \end{aligned} \tag{2.12}$$

the dimensionless constant k would be expected to be extremely small. The direction of bedload transport is given by the unit vector

$$\mathbf{N} = \frac{\boldsymbol{\tau}_e}{\tau_e}. \tag{2.13}$$

Equations (2.7) and (2.8), for mobile and immobile bed surface, respectively, can now be written in the form

$$\begin{aligned} a_t + \boldsymbol{\nabla}.[av_b\mathbf{N}] &= v_A, \\ s_t &= -v_A + U. \end{aligned} \tag{2.14}$$

Nondimensionalization. We choose scales for the variables h, $\mathbf{u}$, η, s, a, τ_e, as well as $\mathbf{x}$ and t, by balancing suitable terms in the governing equations. Suppose that d is a suitable hillslope height scale and l is a suitable horizontal length scale; then we choose

$$\begin{aligned} &r \sim r_D, \quad U \sim U_D, \quad v_b \sim v_D, \quad v_A \sim U_D, \\ &\eta,\ s \sim d, \quad \mathbf{x} \sim l, \quad t \sim [t] = \frac{d}{U_D}, \quad \tau_e \sim [\tau] = f\rho_w\,[u]^2, \\ &\mathbf{u} \sim [u] = \left(\frac{gr_D d}{f}\right)^{1/3}, \quad a \sim a_0, \quad h \sim [h] = l\left(\frac{fr_D^2}{gd}\right)^{1/3}, \end{aligned} \tag{2.15}$$

where square-bracketed terms indicate scales, r_D and U_D are typical precipitation and uplift rates, and for the Meyer-Peter–Müller law (2.11) we would define

$$v_D = \left(\frac{K[\tau]^{3/2}}{\rho_w^{1/2}\Delta\rho\, g(1-\phi)a_0}\right). \tag{2.16}$$

The choice of l is determined by the implied tectonic setting. The simplest conceptual idea is the continuing uplift of an island (or mountain belt), with sea level fixed at prescribed boundaries, and this determines a natural length scale l, the scale of the island. Similarly, crustal folding determines l via the folding wave length. The other length scale d is fixed by the balance of uplift rate with hillslope denudation, which requires (since $v_A \sim U_D$ and also $v_A \sim kv_D$) that

$$U_D = kv_D. \tag{2.17}$$

This determines d through the dependence of v_D on $[\tau]$ and thus $[u]$. For example, if we take v_D to be given by (2.16), then we find

$$d = \left(\frac{\Delta\rho(1-\phi)}{Kf^{1/2}\rho_w}\right)\frac{a_0U_D}{kr_D}. \tag{2.18}$$

The first bracketed term is a constant of $O(1)$, and so we see that the depth scale $d \sim \frac{a_0U_D}{kr_D}$; high mountains are (in this theory) a consequence of high uplift rate and low rainfall, which makes intuitive sense. In addition, the thickness (a_0) and abrasiveness (k) of the bedload layer are crucial in determining d. In practice, we will actually use observed estimates for d to infer suitable values for k.

Using the scaled variables in the model equations (2.1), (2.9), (2.7), and (2.8), we obtain the dimensionless set (where now all the variables refer to the dimensionless

quantities)

$$\begin{aligned} \delta\varepsilon h_t + \boldsymbol{\nabla}.(h\mathbf{u}) &= r, \\ \delta F^2[\,\delta\varepsilon\mathbf{u}_t + (\mathbf{u}.\boldsymbol{\nabla})\mathbf{u}] &= -\boldsymbol{\nabla}\eta - \frac{|\mathbf{u}|\mathbf{u}}{h}, \\ \eta &= s + \delta h + \delta\nu a, \\ \delta\nu\alpha a_t + \boldsymbol{\nabla}.[aV\mathbf{N}] &= \alpha A, \\ s_t &= -A + U, \\ \boldsymbol{\tau}_e &= |\mathbf{u}|\mathbf{u} - \beta\boldsymbol{\nabla}s, \end{aligned} \tag{2.19}$$

where the dimensionless bedload velocity V and abrasion rate A are given, from (2.11) and $(2.12)_2$, by

$$V = [\tau_e - \tau_c^*]_+^{3/2}, \quad A = [1-a]_+ V, \tag{2.20}$$

and the parameters are given by

$$F = \frac{[u]}{(g[h])^{1/2}}, \quad \varepsilon = \frac{U_D}{r_D}, \quad \delta = \frac{[h]}{d},$$

$$\nu = \frac{a_0}{[h]}, \quad \alpha = \frac{kl}{a_0} = \frac{lU_D}{a_0 v_D}, \quad \beta = \frac{\Delta\rho\, D_s}{\rho_w [h]}. \tag{2.21}$$

The dimensionless critical stress can be written in the form

$$\tau_c^* = \frac{\Delta\rho}{\rho_w}\frac{D_s}{[h]}\frac{\mu_c l}{d}, \tag{2.22}$$

which sets out simply how the size of this parameter is determined by the hillslope aspect ratio and by the ratio of water film depth to grain size. μ_c is the dimensionless critical Shields stress, defined in (2.6), and differs from τ_c^* because of the way in which we have nondimensionalized the bed stress.

Parameter estimation. Typical values of precipitation and uplift are $r_D \sim 1$ m y^{-1}, $U_D \sim 10^{-3}$ m y^{-1} (1 km per million years). There is some flexibility in the choice of length scales l and d. Let us suppose that $d \sim 10^3$ m, $l \sim 10^5$ m (i.e., one kilometer uplift over a distance of 100 km) and that $f \sim 0.1$ and $g \sim 10$ m s^{-2}. From these, we find

$$[u] \sim 0.15 \text{ m s}^{-1}, \quad [h] \sim 2.2 \text{ cm}. \tag{2.23}$$

Let us additionally suppose that $a_0 \sim D_s \sim 1$ mm, $\Delta\rho/\rho_w = 2$. It then follows that

$$\begin{gathered} F^2 \sim 0.1, \quad \varepsilon \sim 10^{-3}, \quad \delta \sim 10^{-5}, \\ \alpha \sim 0.1, \quad \beta \sim 0.1, \quad \nu \sim 0.05, \quad \tau_c^* \sim 0.5. \end{gathered} \tag{2.24}$$

It should be emphasized that there is some flexibility in the values of these parameters, but they are all less than one, and in particular ε and δ are very small. It is then legitimate to neglect all the terms proportional to δ in the model. We shall find later that this is a singular approximation, and in order to regularize it we will need at least some of the δ terms to be retained. Apparently, the largest such term is δh in the definition of η, and we therefore choose to retain this term only. It will be easy

to check a posteriori that the neglected terms indeed remain small when the δh term becomes significant.

With the neglect of the terms in δ excluding this excepted term, we derive the reduced model

$$\begin{aligned} \boldsymbol{\nabla}.(h\mathbf{u}) &= r, \\ \mathbf{0} &= -\boldsymbol{\nabla}\eta - \frac{|\mathbf{u}|\mathbf{u}}{h}, \\ \eta &= s + \delta h, \\ \boldsymbol{\nabla}.[aV\mathbf{N}] &= \alpha A, \\ s_t &= -A + U, \\ \boldsymbol{\tau}_e &= |\mathbf{u}|\mathbf{u} - \beta\boldsymbol{\nabla}s. \end{aligned} \tag{2.25}$$

The downslope normal $\mathbf{N}$ is still defined by (2.13).

In order to prescribe boundary conditions for (2.25), consider the uplift of an island continent D with a boundary ∂D; the natural conditions to apply are then

$$\eta = 0 \quad \text{and} \quad \frac{\partial \eta}{\partial n} = 0 \quad \text{on} \quad \partial D. \tag{2.26}$$

These represent the idea that the water surface gradient becomes equal to the ocean gradient (zero) at the coastline. Because the equation for η is essentially elliptic (see the first two equations in (2.25)), the extra condition in (2.26) locates the precise position of the shoreline. Because δ is small, the shoreline position ∂D is essentially known. It will be seen that these conditions are sufficient, together with an initial condition for s, to determine the solution.

A comment on bedload transport. For a given water flow and depth, and thus constant V, the solution for a is $a = 1-\exp(-\alpha x)$, where x is the direction of flow, and assuming that $a = 0$ initially. Thus when $\alpha \gg 1$, we have conditions of transport limitation, and when $\alpha \ll 1$, the transport is detachment limited. The parameter α is the ratio of two small numbers (see (2.21)): k, the ratio of abrasion velocity to bedload velocity (see (2.12)), and a_0/l, the ratio of bedload layer thickness to regional length scale. Its size therefore depends critically on our assumptions about abrasion and bedload. It is plausible that $\alpha \ll 1$ is the more appropriate condition in a regional context over long geological time scales, as suggested by Howard (1994), but this will depend on the friability of the underlying rock. In the laboratory, however, α can be much larger than one because the abrasion coefficient k is likely to be close to one for noncohesive sediments. Simply, noncohesive sediment is eroded and removed rapidly in the field, and over longer time scales, detachment limitation is more appropriate.

A comment on time scales. Although the model and the associated parameter values derived above are consistent with observation, it is unrealistic in the sense that, for example, rainfall is not continuous, and there is no continual overland flow. Rather, erosion actually occurs during severe storms and is virtually absent between them. In a sense, time is not a continuous variable, and it may be more appropriate to switch on the erosional part of the model only during storms. The consequence of this would be a much higher value of r_D, with consequent changes in the parameter values. Despite this, it is still robustly the case that $\delta \ll 1$, and so it seems that the model may be suitable in any case; this, at least, is our assumption.

3. Linear stability. In this section, we review the stability results of Smith and Bretherton (1972) and Loewenherz-Lawrence (1994). We define the downstream flow direction by

$$\mathbf{n} = -\frac{\boldsymbol{\nabla}\eta}{|\boldsymbol{\nabla}\eta|}, \tag{3.1}$$

the stream slope as

$$S = |\boldsymbol{\nabla}\eta|, \tag{3.2}$$

and the water flux as

$$q = h|\mathbf{u}|. \tag{3.3}$$

From (2.25), we then have

$$\boldsymbol{\nabla}.[q\mathbf{n}] = r,$$

$$q = h^{3/2}S^{1/2}, \tag{3.4}$$

and the effective stress is

$$\boldsymbol{\tau}_e = -(h+\beta)\boldsymbol{\nabla}\eta + \delta\beta\boldsymbol{\nabla}h. \tag{3.5}$$

In order to relate our model to those of previous authors, we begin by making corresponding assumptions about bed abrasion and transport. In essence, the prescription of the abrasion rate A in (2.25) is replaced by an assumption that the bedload layer thickness a is constant, $a = 1$. In this case, A is determined by the model, and the bed evolution equation is

$$s_t = U - \frac{1}{\alpha}\boldsymbol{\nabla}.[V\mathbf{N}]. \tag{3.6}$$

This form of the equation is in fact what is obtained in transport limiting conditions when A is prescribed and $\alpha \gg 1$. If A is not prescribed, then the constant k is undefined, so that (2.17) cannot be used to define d. Instead, we define d by choosing $\alpha = 1$, which leads (via (2.21)) to

$$d = \left(\frac{\Delta\rho(1-\phi)}{Kf^{1/2}\rho_w}\right)\frac{lU_D}{r_D}, \tag{3.7}$$

which can be compared with (2.18). For the time being, we assume this to be the case.

Now let us consider the evolution of (one side of) a unidirectional hillslope as shown in Figure 3; that is, we suppose the equations (2.25) are to be solved in the domain $0 < x < 1$, $-L < y < L$, where x is the downslope direction. Suitable boundary conditions are for there to be zero normal flux of sediment and water at the ridge and the two sides, and $\eta = 0$ at $x = 1$. (The extra condition $\eta_x = 0$ at the shoreline is used to locate its precise position near $x = 1$.)

If we take r and U to be constant (more generally, they could be functions of x), then there is a steady state solution for hillslope and water flux; we denote the

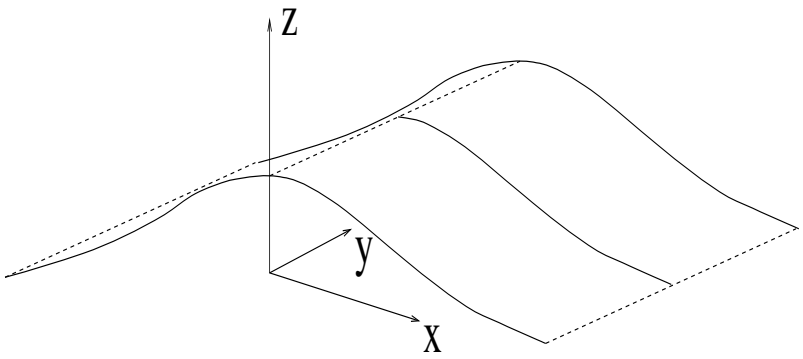

FIG. 3. *One-dimensional hillslope geometry.*

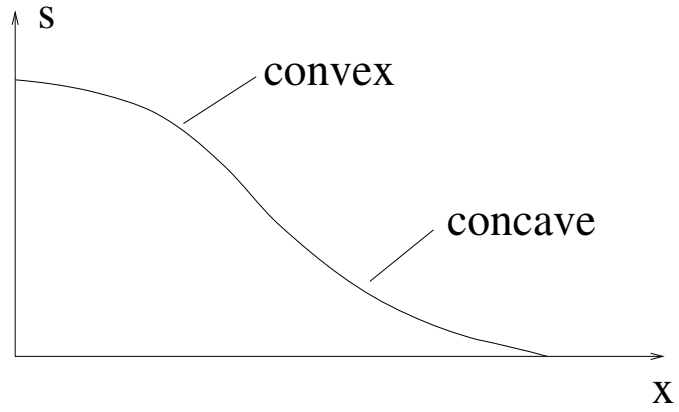

FIG. 4. *Convexity and concavity.*

steady hillslope profile by $\eta = \eta_0(x)$. Smith and Bretherton (1972) showed that for this steady state

$$x\frac{\partial V}{\partial S}S' = V - q\frac{\partial V}{\partial q}, \tag{3.8}$$

where the bedload transport function V is taken to be a function of q and S. (This can be done only if the term in δ is ignored.) Somewhat confusingly, geomorphologists term a slope with $S' < 0$ concave (see Figure 4) or, better, concave upwards, and we shall follow this practice.

As we expect, $\partial V/\partial S > 0$, and this implies that a slope is geomorphologically concave if $\partial V/\partial q > V/q$, and in particular for mathematically convex functions V. We shall find that geomorphologically concave slopes are unstable to channel formation. To leading order in δ, (3.4) and (3.5) imply

$$\tau_e = (qS)^{2/3} + \beta S, \tag{3.9}$$

and so the dimensionless Meyer-Peter–Müller relationship in (2.20), for example, can be written in the form

$$V = [(qS)^{2/3} + \beta S - \tau_c^*]_+^{3/2}. \tag{3.10}$$

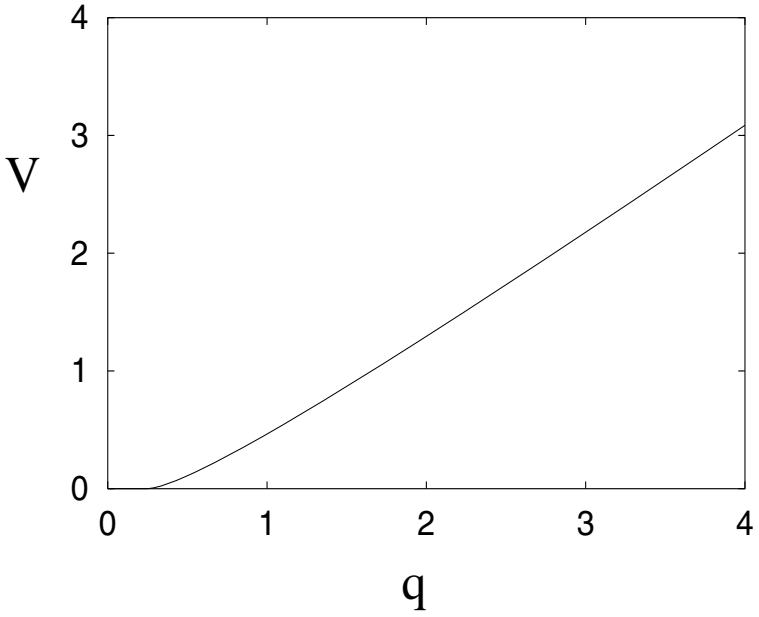

FIG. 5. $V(q,S)$ *given by* (3.10) *for* $\beta = 0.1$, $\tau_c^* = 0.5$.

Figure 5 shows that this relation typically produces a (weakly) mathematically convex function and hence a weakly concave upward hillslope.

Our aim is study perturbations to the steady state $\eta = \eta_0(x)$. Even if the water depth perturbations are large, we can still linearize the geometry of the directions $\mathbf{n}$ and $\mathbf{N}$ by expanding in terms of δ. We do this first. In the one-dimensional steady state, $\mathbf{N} = \mathbf{n} = \mathbf{i}$. We put

$$\eta = \eta_0 + \tilde{\eta}, \tag{3.11}$$

and suppose that $\tilde{\eta}$ is small. We then find

$$\begin{aligned} \boldsymbol{\nabla}\eta &= \eta_0'\mathbf{i} + \boldsymbol{\nabla}\tilde{\eta}, \\ |\boldsymbol{\nabla}\eta| = S &= S_0 - \tilde{\eta}_x + \cdots, \end{aligned} \tag{3.12}$$

where the steady state slope is

$$S_0 = |\eta_0'|. \tag{3.13}$$

Thus

$$\begin{aligned} \mathbf{n} &= \mathbf{i} - \frac{\tilde{\eta}_y}{S_0}\mathbf{j} + \cdots, \\ q &= h^{3/2}S^{1/2}, \end{aligned} \tag{3.14}$$

and in a similar way we find (if also δh is small)

$$\begin{aligned} \tau_e &= (h+\beta)S + \delta\beta h_x + \cdots, \\ \mathbf{N} &= \mathbf{i} - \frac{1}{S_0}\left\{\tilde{\eta}_y - \frac{\delta\beta}{h+\beta}h_y\right\}\mathbf{j} + \cdots. \end{aligned} \tag{3.15}$$

Adopting for the moment only these approximations (that is, we linearize the geometry only), we derive from (3.4) and (3.6) the following approximate model:

$$\frac{\partial q}{\partial x} - \frac{\partial}{\partial y}\left[\frac{q}{S_0}\frac{\partial \tilde{\eta}}{\partial y}\right] = r,$$

$$\frac{\partial \tilde{\eta}}{\partial t} - \delta\frac{\partial h}{\partial t} = U - \frac{\partial V}{\partial x} + \frac{\partial}{\partial y}\left[\frac{V}{S_0}\left\{\frac{\partial \tilde{\eta}}{\partial y} - \frac{\beta\delta}{h+\beta}\frac{\partial h}{\partial y}\right\}\right], \tag{3.16}$$

with q and τ_e defined in (3.14) and (3.15). Notice that this model is still nonlinear.

If the steady solution in which $q_0 = rx$ and $V_0 = Ux$ of this pair of equations is linearized, then what we find is the following. If we put $\delta = 0$ (and thus $V = V(q, S)$), instability occurs if $\partial V/\partial q > V/q$ at any point, as stated above, and the growth rate is unbounded ($\propto k^2$) as the lateral wave number k of modes $\propto e^{iky}$ increases. This implies ill-posedness of the model with $\delta = 0$. If $\delta > 0$ but is small, then the system is stabilized at high wave number. More detailed consideration of the linear eigenvalue problem suggests that instability occurs for k in the range $O\left(\frac{1}{\delta^{1/2}}\right) < k < O\left(\frac{1}{\delta}\right)$, and that maximal growth occurs for $k = O\left(\frac{1}{\delta^{3/4}}\right)$. Oscillations in the x direction are stabilizing.

In dimensional terms, the range of unstable wavelengths l_u is thus in the range

$$\frac{[h]l}{d} < l_u < \frac{[h]^{1/2}l}{d^{1/2}}, \tag{3.17}$$

and thus it bears no simple relation to any of the three geometric length scales of the problem but involves them all.

Because $\delta \ll 1$, i.e., $[h] \ll l$, the result in (3.17) suggests that a nonlinear theory for channel formation can be based on the fact that the lateral length scale for growing perturbations is much smaller than the downstream length scale; in other words, we now turn to a direct asymptotic solution of (3.16) when h is large.

4. An evolution equation for channel formation. The discussion above of linear stability when $\delta \ll 1$ suggests that a distinguished lateral length scale of order $\lesssim \delta^{1/2}$ may serve to delineate the unstable growth of rills. Let us now focus on this growth by defining

$$y = \delta^{1/2}Y, \quad \tilde{\eta} = \delta Z, \quad t = \delta\tilde{t}; \tag{4.1}$$

the rescaling of $\tilde{\eta}$ and t is motivated by the linear stability result of Loewenherz-Lawrence (1994), which suggests that when $y \sim 1/k \ll 1$, then $\tilde{\eta} \sim \tilde{q}/k^2$, or more generally $\tilde{\eta} \sim h^{3/2}/k^2$, and $t \sim 1/k^2$. For $k \sim 1/\delta^{1/2}$ and $h \sim O(1)$, we obtain (4.1). Note that if the original time scale $\sim d/U_D$ was 10^6 years, then this new time scale is $[h]/U_D$ (film thickness divided by uplift or erosion rate), of order 10 years.

The equations (3.16) retain their validity based on geometric linearity, and take the form

$$\frac{\partial q}{\partial x} - \frac{\partial}{\partial Y}\left[\frac{q}{S}\frac{\partial Z}{\partial Y}\right] = r,$$

$$\frac{\partial Z}{\partial \tilde{t}} - \frac{\partial h}{\partial \tilde{t}} = U - \frac{\partial V}{\partial x} + \frac{\partial}{\partial Y}\left[\frac{V}{S}\left\{\frac{\partial Z}{\partial Y} - \frac{\beta}{h+\beta}\frac{\partial h}{\partial Y}\right\}\right], \tag{4.2}$$

in which $S(x)$ is the steady slope (i.e., such that $Z = 0$ is a solution of (4.2)), and the water flux q and effective driving stress for sediment transport τ_e are given by

$$\tau_e \approx (h+\beta)S, \quad q = h^{3/2}S^{1/2}. \tag{4.3}$$

To be specific, we pose these equations on a rectangular domain $-L < y < L$ (thus $-L/\delta^{1/2} < Y < L/\delta^{1/2}$) and $0 < x < 1$. In terms of x and y, the no flux and shoreline boundary conditions require

$$\begin{aligned} \frac{\partial h}{\partial y} = \frac{\partial Z}{\partial y} = 0 \quad &\text{on} \quad y = \pm L, \\ q = V = 0 \quad &\text{on} \quad x = 0, \\ Z = 0 \quad &\text{on} \quad x = 1. \end{aligned} \tag{4.4}$$

These equations enclose the linear instability of the steady state (on a lateral space scale $Y = O(1)$, and time scale $\tilde{t} = O(1)$); but they are fully nonlinear equations and may provide a vehicle to understand the nonlinear development of the linear rill instability we have found before.

One possibility is that stable finite amplitude solutions (rills) exist for this model, with $h \sim O(1)$. Such rills have depths of order millimeters or centimeters, and do not correspond to larger river channels, which presumably evolve over longer geological time scales, possibly by coarsening and scale evolution.

We make the supposition that larger channels can evolve in this model, and therefore we seek solutions representing such large channels in which the depth $h \gg 1$, and where it is a function of the short length scale $Y \sim O(1)$. Note that a consequence of $(4.2)_1$ is that

$$\int_{-L/\delta^{1/2}}^{L/\delta^{1/2}} q \, dY = 2Lrx/\delta^{1/2}, \tag{4.5}$$

which serves as a constraint on the channel depth. In particular, (4.3) suggests a distinguished limit $h \sim 1/\delta^{1/3}$ when most of the rainfall finds its way into the channel. Thus we rescale the variables as

$$h = \frac{H}{\delta^{1/3}}, \quad q = \frac{Q}{\delta^{1/2}}, \quad V = \frac{F}{\delta^{1/2}}, \quad \tau_e = \frac{T_e}{\delta^{1/3}}, \quad \tilde{t} = \delta^{1/6} T. \tag{4.6}$$

(This assumes that $V \sim \tau_e^{3/2}$ for large τ_e, as is the case for the Meyer-Peter relation in (2.20).) With $\delta \approx 10^{-5}$, then $1/\delta^{1/3} \approx 46$, and the new depth scale is of the order of a meter, sensible for a developed stream. The choice of time scale (corresponding dimensionally to a year) is so that the time derivative of h in $(4.2)_2$ is balanced. On the other hand, we expect the water surface to remain flat, so that we do not seek to rescale Z: as we will see, this is consistent with the model equations.

Introducing (4.6) into (4.2) and (4.3), we obtain

$$\begin{aligned} \frac{\partial Q}{\partial x} - \frac{\partial}{\partial Y}\left[\frac{Q}{S}\frac{\partial Z}{\partial Y}\right] &= \delta^{1/2} r, \\ \delta^{1/2}\frac{\partial Z}{\partial T} - \frac{\partial H}{\partial T} &= \delta^{1/2} U - \frac{\partial F}{\partial x} + \frac{\partial}{\partial Y}\left[\frac{F}{S}\left\{\frac{\partial Z}{\partial Y} - \frac{\beta}{H + \delta^{1/3}\beta}\frac{\partial H}{\partial Y}\right\}\right], \end{aligned} \tag{4.7}$$

$$T_e \approx (H + \delta^{1/3}\beta)S, \quad Q = H^{3/2} S^{1/2}. \tag{4.8}$$

The rescaled sediment transport function F is only $O(1)$ with this rescaling if $F \sim \tau_e^{3/2}$, which is of course precisely true for the Meyer-Peter–Müller law:

$$F = \left[T_e - \delta^{1/3}\tau_c^*\right]_+^{3/2}. \tag{4.9}$$

Any other choice of transport law would require a more contorted rescaling.

We can use (4.8) to write (4.9) in the form

$$F = QS + \tfrac{3}{2}(\delta QS)^{1/3}(\beta S - \tau_c^*) + \cdots . \tag{4.10}$$

Simplification of $(4.7)_2$ now yields

$$-\delta^{1/2}\frac{\partial Z}{\partial T} + \frac{\partial H}{\partial T} = S'S^{1/2}H^{3/2} + S^{1/2}\frac{\partial}{\partial Y}\left[\beta H^{1/2}\frac{\partial H}{\partial Y}\right] + C\frac{\partial^2 Z}{\partial Y^2}, \tag{4.11}$$

with inessential error terms of $O(\delta^{1/3})$. The instability parameter C is given by

$$C = \frac{Q}{S}\left(F_Q - \frac{F}{Q}\right) \approx -\delta^{1/3}(\beta S - \tau_c^*)\left(\frac{H}{S}\right)^{1/2}. \tag{4.12}$$

It is a peculiarity of the Meyer-Peter–Müller law that $C = 0$ to leading order, so that the steady state is approximately neutrally linearly stable (at these large stresses). This is because at leading order F is linear in Q, and the function is neither mathematically convex nor concave

Equation (4.11) reveals the essence of linear instability and its nonlinear development. Linear instability is associated with the negative diffusion coefficient of Z if $C > 0$, i.e.,

$$S < S_c = \frac{\tau_c^*}{\beta} = \frac{\mu_c l}{d}, \tag{4.13}$$

using (2.21) and (2.22). In dimensional terms, this suggests instability if the slope is less than μ_c, which occurs at the shoreline. If the resulting rills are able to grow to significant depth, then the nonlinear evolution of H is described approximately by

$$\frac{\partial H}{\partial T} = S'S^{1/2}H^{3/2} + S^{1/2}\frac{\partial}{\partial Y}\left[\beta H^{1/2}\frac{\partial H}{\partial Y}\right], \tag{4.14}$$

and Z then follows from (4.7) by quadrature. Equation (4.14) is a degenerate nonlinear diffusion equation, about which a good deal is known. The source term is suggestive (if $S' > 0$, i.e., on the (upper) convex portion of the hillslope) of blow up and the possibility that H could reach ∞ at a finite time. The degenerate diffusion coefficient is suggestive of solutions of compact support.

The integral constraint (4.5) can be written in the limiting form (as $\delta \to 0$)

$$\int_{-\infty}^{\infty} H^{3/2}\, dY = \frac{2Lrx}{S^{1/2}}. \tag{4.15}$$

Note that this constraint is independent of (4.14), which is derived from sediment conservation, whereas (4.15) is a condition of water mass flow.

Suitable boundary conditions for (4.14) follow from matching to an outer film flow, where $Y \sim 1/\delta^{1/2}$ and $H \sim \delta^{1/3}$. Consequently, we require

$$H \to 0 \quad \text{as} \quad Y \to \pm\infty. \tag{4.16}$$

The initial condition is that H is initially small (since we suppose it arises from an instability of the steady state $H \sim \delta^{1/3}$), i.e.,

$$H \to 0 \quad \text{as} \quad T \to 0. \tag{4.17}$$

The precise behavior of H for small T is less easy to describe. The reason for this is that we have omitted an intermediate discussion of the nonlinear stability of the uniform steady state. The long time evolution of an arbitrary (infinitesimal) perturbation to the steady state can be described by consideration of a Fourier integral over normal modes of wave number k. The upshot of such a consideration is that the emerging linear solution is a monochromatic oscillation whose wave number is that with maximum growth rate, and this would serve as a suitable initial condition for the resulting nonlinear equations in (4.2). However, to obtain an appropriate initial condition for (4.14), we really need to know how solutions to (4.2) behave. We suppose that the nonlinear equations (4.2) do not (always) have stable bounded solutions for H and that (for example) they may exhibit some kind of blow up. In that case, one might expect to obtain a suitable form for the initial behavior of H by matching to the large amplitude solution of (4.2). This is similar to the procedure adopted by Stewartson and Stuart (1971).

In directly seeking solutions at larger amplitude, we are motivated by the fact that developed river channels do indeed attain depths on the order of a meter, and this is consistent with the scale of the solutions described by (4.14).

5. Solution properties. The problem (4.14) with the integral constraint, boundary, and initial conditions (4.15)–(4.17) can be written in normalized form by defining new variables u, t, η (note this is unrelated to the use of η for the water surface in sections 2 and 3) via

$$H = \left(\frac{6}{\beta}\right)^{1/3} (Lrx)^{2/3} u, \quad T = \left(\frac{\beta}{6}\right)^{1/6} \frac{S^{1/2} S'}{(Lrx)^{1/3}} t, \quad Y = \left(\frac{2\beta}{3S'}\right)^{1/2} \eta, \tag{5.1}$$

whence we find

$$u_t = u^{3/2} + \left(u^{3/2}\right)_{\eta\eta},$$

$$\int_{-\infty}^{\infty} u^{3/2}\, d\eta = 1, \quad u \to 0 \quad \text{as} \quad \eta \to \pm\infty, \quad t \to 0. \tag{5.2}$$

This equation has been much studied by pure mathematicians, and it features prominently in the book by Samarskii et al. (1995), where numerous results concerning blow up and localization (i.e., attainment of compact support) are proved. The results in this book are, however, concerned with smooth solutions, for which blow up is essentially obvious; that is, for solutions of compact support, it is assumed that the derivative of u is zero at the boundary of the support. The derivation of the same equation here from a real physical model is clearly of some interest, but it is clearly incorrect to suppose that solutions will necessarily have zero derivative at the support margin. In general, the derivatives are finite at the margins, and in fact blow up does not occur (which, physically, is an appropriate behavior).

In our investigation of the solutions of (5.2), we are led to assert the following. A solution of the problem exists, and there is a unique steady state which is globally stable and of compact support. Starting from an initial condition of infinite support, the solution attains finite support immediately (i.e., for all $t > 0$). We have not proved these results, but we show why we think they are true in the following subsections.

Steady state and linear stability. We will limit our attention to symmetric solutions, so that u is even, and $u_\eta = 0$ on $\eta = 0$. It is convenient to define

$$v = u^{3/2}, \tag{5.3}$$

and we note that for symmetric solutions, we have

$$\int_0^\infty v\,d\eta = \tfrac{1}{2}. \tag{5.4}$$

It is trivial to see that there is a unique steady state $v_s(\eta)$, given by

$$v = \tfrac{1}{2}\cos\eta, \quad 0 < \eta < \pi/2,$$
$$v = 0, \quad \eta > \pi/2. \tag{5.5}$$

To examine linear stability, we put

$$v = \tfrac{1}{2}\cos\eta + V, \tag{5.6}$$

and linearize the equations, to obtain

$$\frac{2}{3v_s^{1/3}} V_t = V_{\eta\eta} + V, \tag{5.7}$$

subject to

$$\int_0^{\pi/2} V\,d\eta = 0, \quad V_\eta = 0 \quad \text{at} \quad \eta = 0. \tag{5.8}$$

(The condition on v at the margin determines the motion of the margin.) Separable solutions to this of the form $V = W(\eta)e^{\sigma t}$ exist, and W then satisfies a nonstandard eigenvalue problem. It is convenient to define

$$\phi = W + W_\eta|_{\pi/2}\cos\eta; \tag{5.9}$$

it follows that ϕ satisfies the nonstandard eigenvalue problem

$$\phi'' + \phi = \frac{2\sigma}{3v_s^{1/3}}\left[\phi - v_s\int_0^{\pi/2}\phi\,d\eta\right], \tag{5.10}$$

subject to

$$\phi'(0) = \phi'(\pi/2) = 0. \tag{5.11}$$

Consider for a moment the equation

$$\psi'' + \psi = \lambda\psi, \tag{5.12}$$

subject to

$$\psi'(0) = \psi'(\pi/2) = 0. \tag{5.13}$$

This is a standard eigenvalue problem with eigenfunctions $\cos 2n\eta$ and eigenvalues $\lambda = 1 - 4n^2$, $n \in \mathbf{N}$, and direct integration shows that

$$\lambda = \frac{\displaystyle\int_0^{\pi/2}(\psi^2 - \psi'^2)\,d\eta}{\displaystyle\int_0^{\pi/2}\psi^2\,d\eta}. \tag{5.14}$$

The standard variational formulation for Sturm–Liouville problems then implies that the functional $\lambda(\psi)$ defined by (5.14) is maximized by the principal eigenfunction $\cos 2\eta$, for which $\lambda = -3$. It follows from this that for all functions ϕ satisfying (5.10) and (5.11) (and thus not proportional to this eigenfunction), we have

$$\int_0^{\pi/2} (\phi^2 - \phi'^2)\, d\eta < -3 \int_0^{\pi/2} \phi^2\, d\eta. \tag{5.15}$$

Multiplying (5.10) by ϕ and integrating from 0 to $\pi/2$, we thus have

$$\frac{2\sigma}{3}\left[\int_0^{\pi/2} \frac{\phi^2}{v_s^{1/3}}\, d\eta - \int_0^{\pi/2} v_s^{2/3}\phi\, d\eta \int_0^{\pi/2} \phi\, d\eta\right] = \int_0^{\pi/2} (\phi^2 - \phi'^2)\, d\eta < 0. \tag{5.16}$$

We are assuming for convenience in this exposition that σ is real. The problem (5.10) is not self-adjoint, and so σ may be complex. We leave it as an exercise to show that the proof below that $\sigma < 0$ can be straightforwardly generalized to the result $\operatorname{Re}\sigma < 0$.

From the Cauchy–Schwarz inequality, we have

$$\int_0^{\pi/2} v_s^{2/3}\phi\, d\eta \le \left(\int_0^{\pi/2} v_s^{5/3}\, d\eta\right)^{1/2} \left(\int_0^{\pi/2} \frac{\phi^2}{v_s^{1/3}}\, d\eta\right)^{1/2},$$

$$\int_0^{\pi/2} \phi\, d\eta \le \left(\int_0^{\pi/2} v_s^{1/3}\, d\eta\right)^{1/2} \left(\int_0^{\pi/2} \frac{\phi^2}{v_s^{1/3}}\, d\eta\right)^{1/2}, \tag{5.17}$$

and thus

$$\begin{aligned}\int_0^{\pi/2} v_s^{2/3}\phi\, d\eta \int_0^{\pi/2} \phi\, d\eta &\le \left(\int_0^{\pi/2} v_s^{5/3}\, d\eta \int_0^{\pi/2} v_s^{1/3}\, d\eta\right)^{1/2} \int_0^{\pi/2} \frac{\phi^2}{v_s^{1/3}}\, d\eta \\ &< \frac{\pi}{4} \int_0^{\pi/2} \frac{\phi^2}{v_s^{1/3}}\, d\eta, \end{aligned} \tag{5.18}$$

since $v_s \le \frac{1}{2}$. It follows from this and (5.16) that $\sigma < 0$. More generally, we can prove $\operatorname{Re}\sigma < 0$, so that the steady state is linearly stable as far as the discrete spectrum is concerned.

Front motion. The degeneracy of (5.2) suggests that solutions will be of compact support and that the fronts where $u = 0$ will move at finite speed. The fronts correspond to the location of the margins of the channel. Even if the initial support is unbounded, we suggest below that the solution support instantly becomes finite. It is then of interest to know how the front moves.

We write (5.2) in terms of $v = u^{3/2}$, and thus

$$\frac{2}{3v^{1/3}} v_t = v_{\eta\eta} + v, \tag{5.19}$$

and if the front position is $\eta_m(t)$ (thus $v > 0$ for $\eta < \eta_m$), we assume that near the front,

$$v \sim c(\eta_m - \eta)^\nu + d(\eta_m - \eta)^\mu + \cdots, \tag{5.20}$$

where $\mu > \nu > 0$. Substituting this into (5.19) and balancing the leading-order terms, we obtain $\nu = 3$, $\dot\eta_m = \frac{3}{2}(\nu - 1)c^{1/3}$, and thus

$$v \sim c(\eta_m - \eta)^3, \quad \dot\eta_m \sim 3c^{1/3}. \tag{5.21}$$

In terms of u, this implies

$$u \sim \alpha(\eta_m - \eta)^2, \quad \dot\eta_m \sim 3\sqrt{\alpha}, \tag{5.22}$$

and we see that such solutions are possible only for front advance. In particular, they do not describe the evolution of a channel from the initial conditions in (5.2).

Another balance is possible if $\nu = 1$, when the second-order term in (5.20) comes into play. Balancing of terms then implies $\mu = \frac{5}{3}$, and then

$$v \sim c(\eta_m - \eta) + d(\eta_m - \eta)^{5/3} + \cdots, \quad \dot\eta_m \sim \frac{5d}{3c^{2/3}}. \tag{5.23}$$

In terms of u, this yields

$$u \sim \alpha(\eta_m - \eta)^{2/3} + \beta(\eta_m - \eta)^{4/3} + \cdots, \quad \dot\eta_m \sim \frac{5\beta}{2\sqrt{\alpha}}; \tag{5.24}$$

the slope is infinite at the front, and the direction of motion depends on the coefficient of the higher-order corrective term. Fatter fronts advance, and thinner ones retreat.

Small time solution. We have mentioned above that numerical results are consistent with the idea that the solution immediately becomes of finite support. To examine how this occurs, we study the form of the solution for small t.

It is convenient for the analysis (and also for the numerical solution of the problem) to transform the domain to a fixed interval. A smart way to do this is to define the independent variable

$$s = \int_0^\eta v \, d\eta. \tag{5.25}$$

Changing variables from η, t to s, t leads to the pair of equations for v and η (which now becomes a function of s and t):

$$\begin{gathered} v\eta_s = 1, \\ \frac{2}{3v^{1/3}}[v_t - \eta_t v v_s] = v + v[v v_s]_s, \end{gathered} \tag{5.26}$$

subject to the conditions

$$\begin{aligned} \eta \;=\; & v_s = 0 \quad \text{on} \quad s = 0, \\ & v = 0 \quad \text{on} \quad s = \tfrac{1}{2}, \\ & v = v_0(s) \quad \text{at} \quad t = 0. \end{aligned} \tag{5.27}$$

The front position is then found a posteriori from the equation

$$\eta_m(t) = \eta(\tfrac{1}{2}, t). \tag{5.28}$$

If we take $v_0'(\frac{1}{2})$ to be finite, then the initial support is infinite, $\eta_m(0) = \infty$, and the solution has a singularity at $t = 0$, $s = \frac{1}{2}$. In expanding the solution for small

t, we therefore make use of the method of strained coordinates in order to ensure a uniform expansion. This will enable us to determine the initial position of the front η_m. We define new variables T, ζ via

$$t = \varepsilon T, \quad s = \zeta + \varepsilon s_1(\zeta) + \cdots, \tag{5.29}$$

in terms of which the equations become

$$\begin{aligned} v(1 - \varepsilon s_{1\zeta} \dots)\eta_\zeta &= 1, \\ v_T - \varepsilon s_{1T} v_\zeta \dots - (\eta_T - \varepsilon s_{1T}\eta_\zeta \dots)v(1 - \varepsilon s_{1\zeta} \dots)v_\zeta & \\ = \frac{3}{2}\varepsilon v^{4/3}\left[1 + (1 - \varepsilon s_{1\zeta} \dots)\frac{\partial}{\partial \zeta}\{v(1 - \varepsilon s_{1\zeta} \dots)v_\zeta\}\right]. & \end{aligned} \tag{5.30}$$

Now we seek solutions in the form

$$v \sim v_0 + \varepsilon v_1 \dots, \quad \eta \sim \eta_0 + \varepsilon \eta_1 \dots, \tag{5.31}$$

anticipating that the leading-order solution v_0 is given by the initial function $v_0(\zeta)$. The function s_1 is to be chosen in order to ensure that the expansions in (5.31) are uniformly valid.

Equating powers of ε, we find that at $O(1)$,

$$\begin{aligned} v_0\eta_{0\zeta} &= 1, \\ v_{0T} - \eta_{0T}v_0v_{0\zeta} &= 0. \end{aligned} \tag{5.32}$$

We take the solution of this to be

$$v_0 = v_0(s), \quad \eta_0 = \int_0^\zeta \frac{d\zeta'}{v_0(\zeta')}. \tag{5.33}$$

Then at $O(\varepsilon)$, we find (since $\eta_{0T} = 0$)

$$\begin{aligned} v_0\eta_{1\zeta} + \eta_{0\zeta}v_1 &= s_{1\zeta}, \\ v_{1T} - v_0v_{0\zeta}\eta_{1T} &= \tfrac{3}{2}v_0^{4/3}[1 + (v_0v_{0\zeta})_\zeta]. \end{aligned} \tag{5.34}$$

The conditions we require to be satisfied for the functions η_1, v_1, and s_1 are

$$\begin{aligned} \eta_1 = v_{1\zeta} = s_1 = 0 \quad &\text{on} \quad \zeta = 0, \\ s_1 = v_1 = 0 \quad &\text{at} \quad T = 0. \end{aligned} \tag{5.35}$$

The choice of $s_1 = 0$ ensures that $s = 0$ when $\zeta = 0$ and seems feasible because of the term $s_{1\zeta}$ in $(5.34)_1$; it is less obvious that we will be able to choose $s_1 = 0$ at $T = 0$, but if so, then $s = \zeta$ initially, which allows us to prescribe $v_1 = 0$ initially. Note that there is no boundary condition at the front, as its location in terms of ζ is not known: we do not expect to be able to prescribe $s_1 = 0$ at $\zeta = \frac{1}{2}$.

The solution can be found by eliminating v_1 in (5.34), and we find

$$\begin{aligned} \eta_1 &= \frac{s_1}{v_0} - \frac{3TI(\zeta)}{2v_0}, \\ v_1 &= v_0s_{1\zeta} - v_0^2\eta_{1\zeta}, \end{aligned} \tag{5.36}$$

taking into account the boundary and initial conditions. The function $I(\zeta)$ is defined by

$$I(\zeta) = \int_0^\zeta v_0^{1/3}[1 + (v_0 v_{0\zeta})_\zeta]\, d\zeta'. \tag{5.37}$$

We compute $v_{1\zeta}$ at $\zeta = 0$ and find

$$v_{1\zeta}|_{\zeta=0} = s_1|_{\zeta=0} + \tfrac{3}{2} T v_0^{7/3} v_0'''. \tag{5.38}$$

Because of our assumption of a symmetric solution, v_0 is even, and therefore $v_0'''(0) = 0$. It is because of this that we can consistently choose $s_1 = 0$ at $\zeta = 0$.

Finally, we must specify s_1. This is done by examining the behavior of the solution as $\zeta \to \frac{1}{2}$. We define

$$a = -v_0'(\tfrac{1}{2}). \tag{5.39}$$

Then as $\zeta \to \frac{1}{2}$,

$$v_0 \sim aX, \quad \eta_0 \sim -\frac{1}{a} \ln X + O(1), \tag{5.40}$$

where we write $X = \frac{1}{2} - \zeta$. We thus require s_1 to be such that $v_1 \le O(X)$ and $\eta_1 \le O(\ln X)$. Expanding v_1 and η_1 for small X, we find

$$\begin{aligned} \eta_1 &\sim \frac{s_1}{aX} - \frac{3 I_m T}{2aX} + O(1), \\ v_1 &\sim -a s_1 + \frac{3 I_m a T}{2} \ldots, \end{aligned} \tag{5.41}$$

where

$$I_m = I(\tfrac{1}{2}) = \int_0^{1/2} v_0^{1/3}[1 + (v_0 v_{0\zeta})_\zeta]\, d\zeta'. \tag{5.42}$$

In order to suppress the singular terms, a simple choice of s_1 which also satisfies the requested initial and boundary conditions is

$$s_1 = \tfrac{3}{2} I_m T (1 - 2X). \tag{5.43}$$

Of principal interest is the margin position, which is given implicitly by the pair of equations

$$\begin{aligned} \eta_m &= \eta_0(\zeta) + \varepsilon \eta_1(\zeta, T) + \cdots, \\ \tfrac{1}{2} &= \zeta + \varepsilon s_1(\zeta, T) + \cdots. \end{aligned} \tag{5.44}$$

Using the definitions of η_1 and s_1 and expanding for small ε, we find that the margin position is given in terms of t by the expression

$$\eta_m \approx \frac{1}{a} \ln\left\{\frac{1}{3 I_m t}\right\} + \int_0^{1/2} \left[\frac{1}{v_0(\zeta)} - \frac{1}{a(\frac{1}{2} - \zeta)}\right] d\zeta + O(t). \tag{5.45}$$

This result suggests (but does not prove) that the solution is of compact support for all $t > 0$. The asymptotic form of the front position is consistent with a numerical solution of the problem, as we now describe.

Numerical solution. To solve the system (5.26) and (5.27) numerically, we discretize the equations on uniform meshes. To avoid a sparse mesh in the neighborhood of the endpoint $\eta = \eta_m$, which would occur because of the slow change of s there, we reformulate our problem once again by defining a new positive space variable ξ as

$$(1 - \xi) = \sqrt{1 - 2s}. \tag{5.46}$$

The model can then be written in the form

$$\begin{aligned}
u_t &= \eta_t w u_\xi + w(w v_\xi)_\xi + v \quad \text{for } \xi \in (0,1), \quad t > 0,\\
v &= u^{3/2}, \qquad w = \frac{v}{1-\xi},\\
u_\xi(0,t) &= 0, \qquad u(1,t) = 0,\\
v(\xi,0) &= v_0[s(\xi)],\\
\eta_\xi &= \frac{1-\xi}{v} \quad \text{for } \xi \in (0,1], \quad \eta(0,t) = 0, \quad t \geq 0,
\end{aligned} \tag{5.47}$$

where now $u = u(\xi,t)$, $v = v(\xi,t)$, and $\eta = \eta(\xi,t)$. Furthermore, we now have

$$\eta_m(t) = \eta(1,t).$$

We discretize in time using the first-order explicit Euler method and in space using second-order finite differences on uniform meshes. Hence the time step τ is chosen much smaller than the space mesh size N^{-1}.

Approximations of η are computed at each time level by numerical integration of $(5.47)_5$ and thus will be $O(N^{-2})$-accurate. If we evaluated η_t in $(5.47)_1$ using these computed approximations of η, we would introduce huge errors of order N^{-2}/τ in the discretization of $(5.47)_1$ and fail to get accurate computed solutions. More accurate approximations of η_t are obtained by differentiating $(5.47)_5$ with respect to t, eliminating v_t from the right-hand side by $(5.47)_1$, and solving the resulting differential equation for η_t numerically. This is equivalent to replacing $(5.47)_1$ by

$$\begin{aligned}
\chi_\xi &= -\frac{3(1-\xi)}{2u}\,[w(w v_\xi)_\xi + v], \qquad \chi(0,t) = 0,\\
u_t &= \frac{\chi}{1-\xi}\,u_\xi + w(w v_\xi)_\xi + v,
\end{aligned} \tag{5.48}$$

where χ replaces $v\eta_t$. The convective term u_ξ in $(5.48)_2$ was discretized using second-order upwinding that depends on the sign of χ; for details see, e.g., Kopteva (1996).

In our computations, we used the initial condition

$$v \propto \exp\left\{-\frac{a\eta^2}{\eta+1}\right\} \quad \text{at} \quad t = 0, \tag{5.49}$$

since it follows from (5.26) that if $v_0'(s = \frac{1}{2}) = -a$, then $v \sim \exp(-a\eta)$ as $\eta \to \infty$. Figure 6 shows snapshots of the relaxation of the solution towards the steady state, while Figure 7 shows the margin evolution. We have checked the initial evolution of the margin against the asymptotic formula (5.45) and found excellent agreement. The results support the conjecture that the steady state solution is globally stable.

6. Conclusions. Beginning with a physics-based model of hillslope evolution and hydraulic drainage, we have shown how one can obtain a rational model for the local evolution of a stream or drainage channel. This model takes the form of a nonlinear diffusion equation with a nonlinear source term, similar to equations which have been much studied by analysts, but with the novelty of an additional integral constraint. The evidence we have gathered appears to indicate that this model is well-posed, and that its solution evolves to a unique steady state, with a width which is self-determining. This observation is interesting in view of the continuing difficulty in finding models of stream flow which can describe the stream width (see, for example, Parker (1978)).

A question of concern (but which is not addressed here) is that of putting our channel model within the context of the large scale evolution of hillslope topography. The way this can be done is as follows. As a river channel evolves, sediment is transported from the adjoining hillslope which is thus lowered. In a maturing hillslope, the channel thus eats its way down into the valley. In terms of the mathematical model, the channel will act as a thin, "shock-like" transition region between regions of hillslope with different gradients; it is a boundary layer connecting the different parts of the outer hillslope solution. Thus the results of the present paper can be used to provide a parameterization of the local channel dynamics in terms of the fluxes of sediment and water delivered from the surrounding hillslope, which evolves essentially via the Smith–Bretherton model. In this description, the hillslope evolves smoothly until it becomes concave, at which point a new channel will form. Specifically, this occurs where the characteristics of the water flow equation intersect, and the evolution of the head of the channel up the hillslope is determined by the point of shock formation. This is similar in tone but not in application to the discussion by Birnir, Smith, and Merchant (2001).

There are a number of interesting mathematical questions which deserve further study: the nonstandard eigenvalue problem (5.10) and (5.11), and the selection of front advance rate between (5.22) and (5.24), are two obvious ones. Of most concern in the application of the model to river system development is the fact that these channels grow (see (4.14)) when $S' > 0$; i.e., the hillslope is convex (upwards, in the sense of Figure 3). This is precisely the Smith–Bretherton condition which ensures that a uniform overland flow is stable. We thus have the paradoxical result that finite amplitude channels exist and are stable when the uniform steady state is also stable.

This observation is suggestive of bistability. We have not yet performed a study of the "rill" scaled model (4.2), but it is reasonable to expect it to have finite amplitude steady solutions, and these might plausibly connect to the uniform state branch at the linear stability, and "become" the channel branch as S' increases. It has to be said that it is not at all obvious how such a bifurcation diagram should be constructed. As with the other problems described above, this problem also awaits study.

Two other practical considerations deserve mention on this point. One is that our model assumes an unlimited sediment supply. In mature landscapes, erosion may become detachment limited (Howard 1994), and the form of the channel equation is somewhat changed. In essence, it appears that a similar equation may be appropriate in that case also but with a source term $H^{3/2}S^{3/2}$ which is independent of hillslope curvature.

The other comment is that in mature landscapes, such as that of Figure 1, it is evident that there will be flux of water and sediment to the channel; the hillslope is essentially three-dimensional, and it is possible that in such an altered geometry, the

conditions for channel formation are simply slope (and not curvature) dependent.

CHANNEL FLOW OF A BINARY MIXTURE OF RIGID SPHERES DESCRIBED BY THE LINEARIZED BOLTZMANN EQUATION AND DRIVEN BY TEMPERATURE, PRESSURE, AND CONCENTRATION GRADIENTS*

R. D. M. GARCIA† AND C. E. SIEWERT‡

Abstract. An analytical version of the discrete-ordinates method (the ADO method) is used with recently established analytical expressions for the rigid-sphere scattering kernels in a study devoted to the flow of a binary gas mixture in a plane channel. In particular, concise and accurate solutions to basic flow problems in a plane channel driven by temperature, pressure, and concentration gradients and described by the linearized Boltzmann equation are established for the case of Maxwell boundary conditions for each of the two species. The velocity, heat-flow, and shear-stress profiles, as well as the mass- and heat-flow rates, are established for each species of particles, and numerical results are reported for two binary mixtures (Ne-Ar and He-Xe).

Key words. rarefied gas dynamics, binary mixtures, rigid spheres, channel flow, linearized Boltzmann equation

1. Introduction.

While the classical problems of Poiseuille flow and thermal-creep flow in a plane channel in the general field of rarefied gas dynamics [24, 3, 5, 4] have been extensively studied for the case of a single-species gas (see, for example, [1, 25, 20, 22, 21, 14, 17] and the references therein), there are relatively few works (for example, [23, 16, 13]) devoted to these problems for gas mixtures. While [23] and [16] are based on the McCormack kinetic model [15], the work of Kosuge et al. [13] is carried out in terms of the linearized Boltzmann equation (LBE). It can be noted that the paper by Siewert and Valougeorgis [23] reports (in terms of the McCormack model) concise and accurate solutions to the problems of channel flow driven by pressure, temperature, and concentration gradients. While the approach used in [16], also based on the McCormack model, is purely numerical, that work does investigate flow in a two-dimensional channel. Most closely related to this work is [13], where purely numerical methods are used to establish some results for channel-flow problems based on the LBE.

In this work, we develop and evaluate concise and accurate solutions for flow problems in a plane-parallel channel driven by pressure, temperature, and concentration gradients. We make use of an analytical discrete-ordinates method (ADO method, [2]), and we use (in the LBE) explicit forms of the rigid-sphere collision kernels for binary gas mixtures [12, 6, 8]. The developed solutions depend (aside from some normalizations) only on the mass and diameter ratios and the relative equilibrium concentration of the two species of particles. We allow a free choice of the accommodation coefficients for each species at the confining surfaces of the channel. Our

approach relies on a continuous treatment of both the space and speed variables that has proved to be particularly efficient and accurate for other classical problems for binary gas mixtures [7, 9, 10].

2. Basic formulation. The flow problems considered in this work are driven by a temperature gradient, a pressure gradient, or concentration gradients (or any linear combination of these effects), and so we base our linearizations of the particle distribution functions about local rather than absolute conditions, as was done in [9], for example. We use x to measure distance in the direction (parallel to the confining walls of the plane-parallel channel) of the mentioned gradients, and so we write the local Maxwellians (for the two species of particles identified by the subscripts $\alpha = 1$ and 2) as

$$f_{\alpha,0}(x,v) = n_\alpha(x)\left[\frac{m_\alpha}{2\pi kT(x)}\right]^{3/2}\exp\left\{-\frac{m_\alpha v^2}{2kT(x)}\right\}, \quad \alpha = 1,2, \tag{2.1}$$

where v is the magnitude of the velocity $\boldsymbol{v}$. If we now express the considered linear variations in the number densities and the temperature as

$$n_\alpha(x) = n_\alpha(1 + R_\alpha x), \quad \alpha = 1,2, \tag{2.2}$$

and

$$T(x) = T_0(1 + K_T x), \tag{2.3}$$

where R_α and K_T are considered to be given (small) constants, we can linearize (2.1) to obtain the approximations

$$f^*_{\alpha,0}(x,v) = f_{\alpha,0}(v)[1 + f_\alpha(v)x], \quad \alpha = 1,2, \tag{2.4}$$

where

$$f_{\alpha,0}(v) = n_\alpha(\lambda_\alpha/\pi)^{3/2}\mathrm{e}^{-\lambda_\alpha v^2}, \quad \lambda_\alpha = m_\alpha/(2kT_0), \tag{2.5}$$

is the absolute Maxwellian distribution for n_α particles of mass m_α in equilibrium at temperature T_0. Here k is the Boltzmann constant, and the $f_\alpha(v)$ are to be determined. If we express the pressure distribution as

$$p(x) = p_0(1 + K_P x), \tag{2.6}$$

where $p_0 = nkT_0$, $n = n_1 + n_2$, and K_P is a given (small) constant, then using the perfect gas law

$$p(x) = n(x)kT(x), \tag{2.7}$$

where

$$n(x) = n_1(x) + n_2(x), \tag{2.8}$$

we find, after neglecting second-order effects,

$$c_1R_1 + c_2R_2 = K_P - K_T, \tag{2.9}$$

where $c_\alpha = n_\alpha/n$, $\alpha = 1,2$. And so, making use of (2.9), we find that we can use

$$f_1(v) = [m_1v^2/(2kT_0) - 5/2]K_T + K_P + c_2K_C \tag{2.10a}$$

and

$$f_2(v) = [m_2 v^2/(2kT_0) - 5/2]K_T + K_P - c_1 K_C, \tag{2.10b}$$

with $K_C = R_1 - R_2$, to complete (2.4). Using the variable $z \in [-z_0, z_0]$ to measure the transverse or cross-channel direction, we now write the true velocity distributions as

$$f_\alpha(x, z, \boldsymbol{v}) = f_{\alpha,0}(v)\{1 + f_\alpha(v)x + h_\alpha(z, \lambda_\alpha^{1/2}\boldsymbol{v})\}, \tag{2.11}$$

where the perturbations $h_\alpha(z, \lambda_\alpha^{1/2}\boldsymbol{v})$ are to be determined from a form of the LBE used in [12, 6, 8, 7, 10] that has an added inhomogeneous driving term due to the x variation in (2.11).

And so we proceed with an inhomogeneous form of the LBE, for a binary mixture of rigid spheres, written as

$$\boldsymbol{S}(\boldsymbol{c}) + c\mu\frac{\partial}{\partial z}\boldsymbol{H}(z, \boldsymbol{c}) + \varepsilon_0 \boldsymbol{V}(c)\boldsymbol{H}(z, \boldsymbol{c}) = \varepsilon_0 \int \mathrm{e}^{-c'^2}\boldsymbol{\mathcal{K}}(\boldsymbol{c}' : \boldsymbol{c})\boldsymbol{H}(z, \boldsymbol{c}')\mathrm{d}^3 c', \tag{2.12}$$

where ε_0 is, at this point, an arbitrary parameter that we will soon use to define a dimensionless spatial variable,

$$\boldsymbol{H}(z, \boldsymbol{c}) = \begin{bmatrix} h_1(z, \boldsymbol{c}) \\ h_2(z, \boldsymbol{c}) \end{bmatrix}, \tag{2.13}$$

and

$$\boldsymbol{S}(\boldsymbol{c}) = c(1-\mu^2)^{1/2}\cos\phi \left\{ (c^2 - 5/2)K_T \begin{bmatrix} 1 \\ 1 \end{bmatrix} + K_P \begin{bmatrix} 1 \\ 1 \end{bmatrix} + K_C \begin{bmatrix} c_2 \\ -c_1 \end{bmatrix} \right\}. \tag{2.14}$$

Considering that the driving term in (2.12) is given by (2.14), we note that (i) the case of flow driven by a temperature gradient corresponds to $K_P = 0$, $K_C = 0$, and $K_T \neq 0$, (ii) the case of flow driven by a pressure gradient corresponds to $K_T = 0$, $K_C = 0$, and $K_P \neq 0$, and (iii) the case of flow driven by concentration gradients corresponds to $K_P = 0$, $K_T = 0$, and $K_C \neq 0$. Furthermore, we note that in writing (2.12), we have introduced the variable changes

$$h_\alpha(z, \boldsymbol{c}) = h_\alpha(z, \lambda_\alpha^{1/2}\boldsymbol{v}), \quad \alpha = 1, 2, \tag{2.15}$$

in order to work with the dimensionless velocity variable $\boldsymbol{c}$. Continuing, we note that we use spherical coordinates $\{c, \theta, \phi\}$, with $\mu = \cos\theta$, to describe the dimensionless velocity vector, so that

$$\boldsymbol{H}(z, \boldsymbol{c}) \Leftrightarrow \boldsymbol{H}(z, c, \mu, \phi).$$

In our notation, $c\mu$ is the component of the (dimensionless) velocity vector in the positive z direction, and

$$c_x = c(1 - \mu^2)^{1/2}\cos\phi \tag{2.16}$$

is the component of velocity in the direction x (parallel to the confining surfaces) of the flow.

In regard to the homogeneous version of (2.12), we note that all of the defining elements have been developed in a recent series of papers [12, 6, 8]. We consider

that these works [12, 6, 8] can be consulted if a complete understanding of all of the required elements is desired. And so at this point we simply quote from our previous work [12, 6, 8] and list without additional comments the required definitions. First,

$$\boldsymbol{V}(c) = (1/\varepsilon_0)\boldsymbol{\Sigma}(c) \tag{2.17}$$

and

$$\boldsymbol{\mathcal{K}}(\boldsymbol{c}' : \boldsymbol{c}) = (1/\varepsilon_0)\boldsymbol{K}(\boldsymbol{c}' : \boldsymbol{c}), \tag{2.18}$$

where

$$\boldsymbol{\Sigma}(c) = \begin{bmatrix} \varpi_1(c) & 0 \\ 0 & \varpi_2(c) \end{bmatrix}, \tag{2.19}$$

with

$$\varpi_\alpha(c) = \varpi_\alpha^{(1)}(c) + \varpi_\alpha^{(2)}(c) \tag{2.20}$$

and

$$\varpi_\alpha^{(\beta)}(c) = 4\pi^{1/2} n_\beta \sigma_{\alpha,\beta} a_{\beta,\alpha} \nu(a_{\alpha,\beta} c). \tag{2.21}$$

Here

$$\nu(c) = \frac{2c^2 + 1}{c} \int_0^c \mathrm{e}^{-x^2} \mathrm{d}x + \mathrm{e}^{-c^2} \tag{2.22}$$

and

$$a_{\alpha,\beta} = (m_\beta/m_\alpha)^{1/2}, \quad \alpha, \beta = 1, 2. \tag{2.23}$$

We use $\sigma_{\alpha,\beta}$ to denote the differential-scattering cross section, which (for the case of rigid-sphere scattering that is isotropic in the center-of-mass system) we write as [4]

$$\sigma_{\alpha,\beta} = \frac{1}{4}\left(\frac{d_\alpha + d_\beta}{2}\right)^2, \quad \alpha, \beta = 1, 2, \tag{2.24}$$

where d_1 and d_2 are the atomic diameters of the two types of gas particles. We continue to follow [12, 6, 8] and write

$$\boldsymbol{K}(\boldsymbol{c}' : \boldsymbol{c}) = \begin{bmatrix} K_{1,1}(\boldsymbol{c}' : \boldsymbol{c}) & K_{1,2}(\boldsymbol{c}' : \boldsymbol{c}) \\ K_{2,1}(\boldsymbol{c}' : \boldsymbol{c}) & K_{2,2}(\boldsymbol{c}' : \boldsymbol{c}) \end{bmatrix}, \tag{2.25}$$

where

$$K_{1,1}(\boldsymbol{c}' : \boldsymbol{c}) = 4n_1\sigma_{1,1}\pi^{1/2}\mathcal{P}(\boldsymbol{c}' : \boldsymbol{c}) + n_2\sigma_{1,2}\pi^{1/2}\mathcal{F}_{1,2}(\boldsymbol{c}' : \boldsymbol{c}), \tag{2.26}$$

$$K_{1,2}(\boldsymbol{c}' : \boldsymbol{c}) = 4n_2\sigma_{1,2}\pi^{1/2}\mathcal{G}_{1,2}(\boldsymbol{c}' : \boldsymbol{c}), \tag{2.27}$$

$$K_{2,1}(\boldsymbol{c}' : \boldsymbol{c}) = 4n_1\sigma_{2,1}\pi^{1/2}\mathcal{G}_{2,1}(\boldsymbol{c}' : \boldsymbol{c}), \tag{2.28}$$

and

$$K_{2,2}(\boldsymbol{c}' : \boldsymbol{c}) = 4n_2\sigma_{2,2}\pi^{1/2}\mathcal{P}(\boldsymbol{c}' : \boldsymbol{c}) + n_1\sigma_{2,1}\pi^{1/2}\mathcal{F}_{2,1}(\boldsymbol{c}' : \boldsymbol{c}). \tag{2.29}$$

Here

$$\mathcal{P}(\boldsymbol{c}' : \boldsymbol{c}) = \frac{1}{\pi}\left(\frac{2}{|\boldsymbol{c}' - \boldsymbol{c}|}\exp\left\{\frac{|\boldsymbol{c}' \times \boldsymbol{c}|^2}{|\boldsymbol{c}' - \boldsymbol{c}|^2}\right\} - |\boldsymbol{c}' - \boldsymbol{c}|\right) \tag{2.30}$$

is the basic kernel for a single-species gas used by Pekeris [18]. In addition,

$$\mathcal{F}_{\alpha,\beta}(\boldsymbol{c}' : \boldsymbol{c}) = \mathcal{F}(a_{\alpha,\beta}; \boldsymbol{c}' : \boldsymbol{c}) \tag{2.31}$$

and

$$\mathcal{G}_{\alpha,\beta}(\boldsymbol{c}' : \boldsymbol{c}) = \mathcal{G}(a_{\alpha,\beta}; \boldsymbol{c}' : \boldsymbol{c}), \tag{2.32}$$

where

$$\mathcal{F}(a; \boldsymbol{c}' : \boldsymbol{c}) = \frac{(a^2+1)^2}{a^3\pi|\boldsymbol{c}' - \boldsymbol{c}|}\exp\left\{a^2\frac{|\boldsymbol{c}' \times \boldsymbol{c}|^2}{|\boldsymbol{c}' - \boldsymbol{c}|^2} - \frac{(1-a^2)^2({c'}^2 + c^2)}{4a^2} - \frac{(a^4-1)\boldsymbol{c}' \cdot \boldsymbol{c}}{2a^2}\right\} \tag{2.33}$$

and

$$\mathcal{G}(a; \boldsymbol{c}' : \boldsymbol{c}) = \frac{1}{a\pi}\big|\boldsymbol{c}' - a\boldsymbol{c}\big|[J(a; \boldsymbol{c}' : \boldsymbol{c}) - 1], \tag{2.34}$$

with

$$J(a; \boldsymbol{c}' : \boldsymbol{c}) = \frac{(a + 1/a)^2}{2\Delta(a; \boldsymbol{c}' : \boldsymbol{c})}\exp\left\{\frac{-2C(a; \boldsymbol{c}' : \boldsymbol{c})}{(a - 1/a)^2}\right\}\sinh\left\{\frac{2\Delta(a; \boldsymbol{c}' : \boldsymbol{c})}{(a - 1/a)^2}\right\}, \quad a \neq 1, \tag{2.35a}$$

or

$$J(a; \boldsymbol{c}' : \boldsymbol{c}) = \frac{1}{|\boldsymbol{c}' - \boldsymbol{c}|^2}\exp\left\{\frac{|\boldsymbol{c}' \times \boldsymbol{c}|^2}{|\boldsymbol{c}' - \boldsymbol{c}|^2}\right\}, \quad a = 1. \tag{2.35b}$$

We have used the definitions [12, 6, 8]

$$\Delta(a; \boldsymbol{c}' : \boldsymbol{c}) = \left\{C^2(a; \boldsymbol{c}' : \boldsymbol{c}) + (a - 1/a)^2|\boldsymbol{c}' \times \boldsymbol{c}|^2\right\}^{1/2} \tag{2.36}$$

and

$$C(a; \boldsymbol{c}' : \boldsymbol{c}) = {c'}^2 + c^2 - (a + 1/a)\boldsymbol{c}' \cdot \boldsymbol{c}. \tag{2.37}$$

In this work, we intend to compute the velocity, the shear-stress, and the heat-flow profiles which we express as

$$\boldsymbol{U}(z) = \frac{1}{\pi^{3/2}}\int_0^\infty\int_{-1}^1\int_0^{2\pi} \mathrm{e}^{-c^2}\boldsymbol{H}(z, \boldsymbol{c})c^3(1-\mu^2)^{1/2}\cos\phi \mathrm{d}c\mathrm{d}\phi\mathrm{d}\mu\mathrm{d}c, \tag{2.38}$$

$$\boldsymbol{P}(z) = \frac{2}{\pi^{3/2}}\int_0^\infty\int_{-1}^1\int_0^{2\pi} \mathrm{e}^{-c^2}\boldsymbol{H}(z, \boldsymbol{c})c^4\mu(1-\mu^2)^{1/2}\cos\phi \mathrm{d}c\mathrm{d}\phi\mathrm{d}\mu\mathrm{d}c, \tag{2.39}$$

and

$$\boldsymbol{Q}(z) = \frac{1}{\pi^{3/2}}\int_0^\infty\int_{-1}^1\int_0^{2\pi} \mathrm{e}^{-c^2}\boldsymbol{H}(z, \boldsymbol{c})\left(c^2 - \frac{5}{2}\right)c^3(1-\mu^2)^{1/2}\cos\phi \mathrm{d}c\mathrm{d}\phi\mathrm{d}\mu\mathrm{d}c, \tag{2.40}$$

where the components of $\boldsymbol{U}(z)$, $\boldsymbol{P}(z)$, and $\boldsymbol{Q}(z)$ are the functions $U_\alpha(z)$, $P_\alpha(z)$, and $Q_\alpha(z)$, for $\alpha = 1, 2$, that can be used, as mentioned in Appendix A of [9], to define the macroscopic quantities for a binary mixture.

As in [9], it is clear (for the specific flow problems considered here) that an expansion of $\boldsymbol{H}(z, \boldsymbol{c})$ in a Fourier series (in the angle ϕ) requires only one term—that is, one proportional to $\cos\phi$. And so we follow [8] and introduce the dimensionless spatial variable

$$\tau = z\varepsilon_0, \tag{2.41}$$

where

$$\varepsilon_0 = (n_1 + n_2)\pi^{1/2}\left(\frac{n_1 d_1 + n_2 d_2}{n_1 + n_2}\right)^2, \tag{2.42}$$

and write

$$\boldsymbol{H}(\tau/\varepsilon_0, \boldsymbol{c}) = \boldsymbol{\Psi}(\tau, c, \mu)(1 - \mu^2)^{1/2}\cos\phi, \tag{2.43}$$

where $\boldsymbol{\Psi}(\tau, c, \mu)$ is the (vector-valued) function to be determined. We now let $z = \tau/\varepsilon_0$ in (2.38)–(2.40) and consider that

$$\boldsymbol{U}(\tau) = \frac{1}{\pi^{1/2}}\int_0^\infty\int_{-1}^1 \mathrm{e}^{-c^2}\boldsymbol{\Psi}(\tau, c, \mu)c^3(1 - \mu^2)\mathrm{d}\mu\mathrm{d}c, \tag{2.44}$$

$$\boldsymbol{P}(\tau) = \frac{2}{\pi^{1/2}}\int_0^\infty\int_{-1}^1 \mathrm{e}^{-c^2}\boldsymbol{\Psi}(\tau, c, \mu)c^4(1 - \mu^2)\mu\mathrm{d}\mu\mathrm{d}c, \tag{2.45}$$

and

$$\boldsymbol{Q}(\tau) = \frac{1}{\pi^{1/2}}\int_0^\infty\int_{-1}^1 \mathrm{e}^{-c^2}\boldsymbol{\Psi}(\tau, c, \mu)\left(c^2 - \frac{5}{2}\right)c^3(1 - \mu^2)\mathrm{d}\mu\mathrm{d}c \tag{2.46}$$

are the quantities to be computed. It should be noted that to avoid excessive notation, we have, in writing (2.44)–(2.46), followed the (often-used) procedure of not always introducing new labels for dependent quantities (in this case $\boldsymbol{U}$, $\boldsymbol{P}$, and $\boldsymbol{Q}$) when the independent variable is changed.

We can now use (2.43) in (2.12), multiply the resulting equation by $\cos\phi$, integrate over all ϕ, and use the Legendre expansion of the scattering kernel $\boldsymbol{\mathcal{K}}(\boldsymbol{c}' : \boldsymbol{c})$ that was introduced in a previous work—see equations (26) and (65) of [8]—to find

$$\begin{aligned}\boldsymbol{\Upsilon}(c) + c\mu\frac{\partial}{\partial\tau}\boldsymbol{\Psi}(\tau, c, \mu) + \boldsymbol{V}(c)\boldsymbol{\Psi}(\tau, c, \mu)\\ = \int_0^\infty\int_{-1}^1 \mathrm{e}^{-c'^2} f(\mu', \mu)\boldsymbol{\mathcal{K}}(c', \mu' : c, \mu)\boldsymbol{\Psi}(\tau, c', \mu')c'^2\mathrm{d}\mu'\mathrm{d}c',\end{aligned} \tag{2.47}$$

where

$$f(\mu', \mu) = \left(\frac{1 - \mu'^2}{1 - \mu^2}\right)^{1/2}. \tag{2.48}$$

In addition,

$$\boldsymbol{\mathcal{K}}(c', \mu' : c, \mu)\cos\phi' = \int_0^{2\pi}\boldsymbol{\mathcal{K}}(\boldsymbol{c}' : \boldsymbol{c})\cos\phi\mathrm{d}\phi, \tag{2.49}$$

which we can express, in the notation of [8], as

$$\boldsymbol{\mathcal{K}}(c',\mu':c,\mu)=(1/2)\sum_{n=1}^{\infty}(2n+1)P_n^1(\mu')P_n^1(\mu)\boldsymbol{\mathcal{K}}_n(c',c), \tag{2.50}$$

where $P_n^1(x)$ is used to denote one of the normalized associated Legendre functions. More explicitly,

$$P_l^m(\mu)=\left[\frac{(l-m)!}{(l+m)!}\right]^{1/2}(1-\mu^2)^{m/2}\frac{\mathrm{d}^m}{\mathrm{d}\mu^m}P_l(\mu), \tag{2.51}$$

where $P_l(\mu)$ is the Legendre polynomial. In addition,

$$\boldsymbol{\mathcal{K}}_n(c',c)=\begin{bmatrix}\mathcal{K}_n^{(1,1)}(c',c) & \mathcal{K}_n^{(1,2)}(c',c)\\ \mathcal{K}_n^{(2,1)}(c',c) & \mathcal{K}_n^{(2,2)}(c',c)\end{bmatrix}, \tag{2.52}$$

with

$$\mathcal{K}_n^{(1,1)}(c',c)=p_1\mathcal{P}^{(n)}(c',c)+(g_2/4)\mathcal{F}^{(n)}(a_{1,2};c',c), \tag{2.53a}$$

$$\mathcal{K}_n^{(1,2)}(c',c)=g_2\mathcal{G}^{(n)}(a_{1,2};c',c), \tag{2.53b}$$

$$\mathcal{K}_n^{(2,1)}(c',c)=g_1\mathcal{G}^{(n)}(a_{2,1};c',c), \tag{2.53c}$$

and

$$\mathcal{K}_n^{(2,2)}(c',c)=p_2\mathcal{P}^{(n)}(c',c)+(g_1/4)\mathcal{F}^{(n)}(a_{2,1};c',c). \tag{2.53d}$$

We also can write

$$\boldsymbol{V}(c)=\begin{bmatrix}v_1(c) & 0\\ 0 & v_2(c)\end{bmatrix}, \tag{2.54}$$

where now

$$v_1(c)=p_1\nu(c)+g_2a_{2,1}\nu(a_{1,2}c) \tag{2.55a}$$

and

$$v_2(c)=p_2\nu(c)+g_1a_{1,2}\nu(a_{2,1}c). \tag{2.55b}$$

In writing (2.53) and (2.55), we have used

$$p_\alpha=c_\alpha\left(\frac{nd_\alpha}{n_1d_1+n_2d_2}\right)^2,\quad \alpha=1,2, \tag{2.56a}$$

and

$$g_\alpha=c_\alpha\left(\frac{nd_{\mathrm{avg}}}{n_1d_1+n_2d_2}\right)^2,\quad \alpha=1,2, \tag{2.56b}$$

where

$$d_{\mathrm{avg}}=(d_1+d_2)/2. \tag{2.57}$$

In order to avoid too much repetition, we do not list here our expressions for the Legendre moments

$$\mathcal{P}^{(n)}(c',c), \quad \mathcal{F}^{(n)}(a;c',c), \quad \text{and} \quad \mathcal{G}^{(n)}(a;c',c),$$

since they are explicitly given in Appendix A of [8]. To complete (2.47), we note that the inhomogeneous driving term is

$$\boldsymbol{\Upsilon}(c) = (c/\varepsilon_0) \left[\begin{array}{c} (c^2 - 5/2)K_T + K_P + c_2 K_C \\ (c^2 - 5/2)K_T + K_P - c_1 K_C \end{array} \right]. \tag{2.58}$$

At the walls located at $\tau = -a$ and $\tau = a$, we use a combination of specular and diffuse reflection, and so, in regard to (2.12), we write the boundary conditions as

$$\boldsymbol{H}(-a,c,\mu,\phi) - (\boldsymbol{I} - \boldsymbol{\alpha})\boldsymbol{H}(-a,c,-\mu,\phi) - \boldsymbol{\alpha}\boldsymbol{\mathcal{I}}_-\{\boldsymbol{H}\}(-a) = \boldsymbol{0} \tag{2.59a}$$

and

$$\boldsymbol{H}(a,c,-\mu,\phi) - (\boldsymbol{I} - \boldsymbol{\beta})\boldsymbol{H}(a,c,\mu,\phi) - \boldsymbol{\beta}\boldsymbol{\mathcal{I}}_+\{\boldsymbol{H}\}(a) = \boldsymbol{0} \tag{2.59b}$$

for $\mu \in (0,1]$ and all c and all ϕ. Here

$$\boldsymbol{\mathcal{I}}_\mp\{\boldsymbol{H}\}(z) = \frac{2}{\pi}\int_0^\infty \int_0^1 \int_0^{2\pi} \mathrm{e}^{-c'^2} \boldsymbol{H}(z,c',\mp\mu',\phi')\mu' c'^3 \mathrm{d}\phi' \mathrm{d}\mu' \mathrm{d}c', \tag{2.60}$$

$$\boldsymbol{\alpha} = \mathrm{diag}\{\alpha_1, \alpha_2\}, \tag{2.61a}$$

and

$$\boldsymbol{\beta} = \mathrm{diag}\{\beta_1, \beta_2\}, \tag{2.61b}$$

where α_1, α_2, β_1, and β_2 are the accommodation coefficients to be used for the two species of gas particles at the confining surfaces. Taking note of (2.43), we find from (2.59) the boundary conditions subject to which we must solve (2.47), that is,

$$\boldsymbol{\Psi}(-a,c,\mu) - (\boldsymbol{I} - \boldsymbol{\alpha})\boldsymbol{\Psi}(-a,c,-\mu) = \boldsymbol{0} \tag{2.62a}$$

and

$$\boldsymbol{\Psi}(a,c,-\mu) - (\boldsymbol{I} - \boldsymbol{\beta})\boldsymbol{\Psi}(a,c,\mu) = \boldsymbol{0}, \tag{2.62b}$$

for $\mu \in (0,1]$ and all c. We use $\boldsymbol{I}$ to denote the 2×2 identity matrix.

3. Solutions. Following our previous work as reported in [9, 11], we express our solution (evaluated at the N pairs of discrete ordinates $\pm\mu_i$) of (2.47) in the form

$$\boldsymbol{\Psi}(\tau,c,\pm\mu_i) = \boldsymbol{\Psi}_{ps}(\tau,c,\pm\mu_i) + \boldsymbol{\Psi}_{*}(\tau,c,\pm\mu_i) + \boldsymbol{\Psi}_{app}(\tau,c,\pm\mu_i) \tag{3.1}$$

for $i = 1,2,\ldots,N$. We note that $\boldsymbol{\Psi}_*(\tau,c,\mu)$ is defined in terms of two of the exact elementary solutions we reported in a previous work [8], that is,

$$\boldsymbol{\Psi}_*(\tau,c,\mu) = A_1 c\boldsymbol{\Phi} + B_1\big[c\tau\boldsymbol{\Phi} - \mu\boldsymbol{B}(c)\big], \tag{3.2}$$

where

$$\boldsymbol{\Phi} = \left[\begin{array}{c} 1 \\ a_{1,2} \end{array} \right], \tag{3.3}$$

and where $\boldsymbol{B}(c)$ is one of the generalized Chapman–Enskog (vector-valued) functions discussed in [8]. In addition,

(3.4)
$$\boldsymbol{\Psi}_{app}(\tau, c, \pm\mu_i) = \boldsymbol{\Pi}(c) \sum_{j=2}^{J} \left[A_j \boldsymbol{\Phi}(\nu_j, \pm\mu_i) \mathrm{e}^{-(a+\tau)/\nu_j} + B_j \boldsymbol{\Phi}(\nu_j, \mp\mu_i) \mathrm{e}^{-(a-\tau)/\nu_j} \right].$$

For our computations, we use the $2 \times 2(K+1)$ matrix

$$\boldsymbol{\Pi}(c) = \left[P_0(2\mathrm{e}^{-c} - 1)\boldsymbol{I} \;\; P_1(2\mathrm{e}^{-c} - 1)\boldsymbol{I} \cdots P_K(2\mathrm{e}^{-c} - 1)\boldsymbol{I} \right], \tag{3.5}$$

where $K+1$ is the number of basis functions used to represent the speed dependence of the approximate part of our solution. We note that [9] can be consulted if a complete understanding of the eigenvalue spectrum $\{\nu_j\}$ and the elementary solutions $\{\boldsymbol{\Phi}(\nu_j, \pm\mu_i)\}$ is desired. Since (2.47) has the inhomogeneous driving term $\boldsymbol{\Upsilon}(c)$, we have included in (3.1) the particular solution

$$\boldsymbol{\Psi}_{ps}(\tau, c, \mu) = \boldsymbol{\Psi}_P(\tau, c, \mu) + \boldsymbol{\Psi}_T(\tau, c, \mu) + \boldsymbol{\Psi}_C(\tau, c, \mu), \tag{3.6}$$

the elements of which were developed and reported in [11]. We repeat from [11]:

(3.7)
$$\boldsymbol{\Psi}_P(\tau, c, \mu) = [1/(\varepsilon_0 \varepsilon_p)] \{ c\tau^2 \boldsymbol{\Phi} - 2\mu\tau \boldsymbol{B}(c) + (1/5)\boldsymbol{D}(c) + [(5\mu^2 - 1)/5]\boldsymbol{E}(c) \} K_P,$$

$$\boldsymbol{\Psi}_T(\tau, c, \mu) = -(1/\varepsilon_0)[\boldsymbol{A}^{(1)}(c) + \boldsymbol{A}^{(2)}(c)] K_T, \tag{3.8}$$

and

$$\boldsymbol{\Psi}_C(\tau, c, \mu) = (1/\varepsilon_0)[c_2 \boldsymbol{A}^{(1)}(c) - c_1 \boldsymbol{A}^{(2)}(c)] K_C. \tag{3.9}$$

In [8] and [11], we have defined and computed, for selected cases, the generalized Chapman–Enskog and Burnett (vector-valued) functions $\boldsymbol{A}^{(1)}(c)$, $\boldsymbol{A}^{(2)}(c)$, $\boldsymbol{B}(c)$, $\boldsymbol{D}(c)$, and $\boldsymbol{E}(c)$ that appear in (3.7)–(3.9). In addition, the constant ε_p is expressed in [11] as

$$\varepsilon_p = \begin{bmatrix} c_1 & c_2 \end{bmatrix} \boldsymbol{\varepsilon}_p, \tag{3.10}$$

where

$$\boldsymbol{\varepsilon}_p = \frac{16}{15\pi^{1/2}} \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{B}(c) c^4 \mathrm{d}c. \tag{3.11}$$

We note that the components $\varepsilon_{p,1}$ and $\varepsilon_{p,2}$ of $\boldsymbol{\varepsilon}_p$ have been evaluated (for several data sets) in [8].

Finally, to complete our discussion of (3.1), we note that the arbitrary constants $\{A_j, B_j\}$ are to be determined from boundary conditions to be applied at $\tau = \pm a$. For this purpose, we substitute (3.1) into discrete-ordinates versions of (2.62), multiply the resulting equations by

$$c^2 \exp\{-c^2\} \boldsymbol{\Pi}^T(c),$$

where the superscript T is used to denote the transpose operation, and integrate over all c to define a system of $2J$ linear algebraic equations for the $2J$ unspecified constants. We note that only the right-hand-side vector of such system is problem-dependent.

4. Quantities of interest. Considering that we have solved the system of linear algebraic equations to establish the arbitrary constants $\{A_j, B_j\}$, we can use (3.1) to find our final expressions for the quantities of interest here, that is, the velocity, heat-flow, and shear-stress profiles. And so, using (3.1) in discrete-ordinates versions of (2.44)–(2.46), we find

(4.1a)

$$\boldsymbol{U}(\tau) = \boldsymbol{U}_{ps}(\tau) + (1/2)(A_1 + B_1\tau)\boldsymbol{\Phi} + \sum_{j=2}^{J} \left[A_j \mathrm{e}^{-(a+\tau)/\nu_j} + B_j \mathrm{e}^{-(a-\tau)/\nu_j}\right]\boldsymbol{\mathcal{U}}_j,$$

(4.1b)

$$\boldsymbol{Q}(\tau) = \boldsymbol{Q}_{ps}(\tau) + \sum_{j=2}^{J} \left[A_j \mathrm{e}^{-(a+\tau)/\nu_j} + B_j \mathrm{e}^{-(a-\tau)/\nu_j}\right]\boldsymbol{\mathcal{Q}}_j,$$

and

(4.1c)

$$\boldsymbol{P}(\tau) = \boldsymbol{P}_{ps}(\tau) - (1/2)B_1\boldsymbol{\varepsilon}_p + \sum_{j=2}^{J} \left[A_j \mathrm{e}^{-(a+\tau)/\nu_j} - B_j \mathrm{e}^{-(a-\tau)/\nu_j}\right]\boldsymbol{\mathcal{P}}_j.$$

In writing (4.1), we have used the definitions

(4.2a)

$$\boldsymbol{\mathcal{U}}_j = \boldsymbol{\Pi}_1 \boldsymbol{X}_j,$$

(4.2b)

$$\boldsymbol{\mathcal{P}}_j = 2\boldsymbol{\Pi}_2 \boldsymbol{Y}_j,$$

and

(4.2c)

$$\boldsymbol{\mathcal{Q}}_j = [\boldsymbol{\Pi}_3 - (5/2)\boldsymbol{\Pi}_1]\boldsymbol{X}_j,$$

where

(4.3a)

$$\boldsymbol{X}_j = \frac{1}{\pi^{1/2}} \sum_{k=1}^{N} w_k(1-\mu_k^2)[\boldsymbol{\Phi}(\nu_j, \mu_k) + \boldsymbol{\Phi}(\nu_j, -\mu_k)],$$

(4.3b)

$$\boldsymbol{Y}_j = \frac{1}{\pi^{1/2}} \sum_{k=1}^{N} w_k\mu_k(1-\mu_k^2)[\boldsymbol{\Phi}(\nu_j, \mu_k) - \boldsymbol{\Phi}(\nu_j, -\mu_k)],$$

and

(4.4)

$$\boldsymbol{\Pi}_n = \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{\Pi}(c) c^{n+2} \mathrm{d}c.$$

In (4.3), we use the weights $\{w_k\}$, along with the nodes $\{\mu_k\}$, to complete the definition of our N-point, half-range quadrature scheme. Finally, to complete (4.1), we must compute

(4.5)

$$\boldsymbol{U}_{ps}(\tau) = \frac{1}{\pi^{1/2}} \int_0^\infty \int_{-1}^1 \mathrm{e}^{-c^2} \boldsymbol{\Psi}_{ps}(\tau, c, \mu) c^3 (1-\mu^2) \mathrm{d}\mu \mathrm{d}c,$$

(4.6)

$$\boldsymbol{Q}_{ps}(\tau) = \frac{1}{\pi^{1/2}} \int_0^\infty \int_{-1}^1 \mathrm{e}^{-c^2} \boldsymbol{\Psi}_{ps}(\tau, c, \mu) \left(c^2 - \frac{5}{2}\right) c^3 (1-\mu^2) \mathrm{d}\mu \mathrm{d}c,$$

and

$$\boldsymbol{P}_{ps}(\tau) = \frac{2}{\pi^{1/2}} \int_0^\infty \int_{-1}^1 \mathrm{e}^{-c^2} \boldsymbol{\Psi}_{ps}(\tau, c, \mu) c^4 (1-\mu^2) \mu \mathrm{d}\mu \mathrm{d}c. \tag{4.7}$$

Using (3.6)–(3.9), we find

$$\boldsymbol{U}_{ps}(\tau) = (1/\varepsilon_0)\{(1/\varepsilon_p)[(1/2)\tau^2 \boldsymbol{\Phi} + \boldsymbol{D}_U] K_p - [\boldsymbol{A}_U^{(1)} + \boldsymbol{A}_U^{(2)}] K_T + [c_2 \boldsymbol{A}_U^{(1)} - c_1 \boldsymbol{A}_U^{(2)}] K_C\}, \tag{4.8}$$

$$\boldsymbol{Q}_{ps}(\tau) = (1/\varepsilon_0)\{(1/\varepsilon_p) \boldsymbol{D}_Q K_p - [\boldsymbol{A}_Q^{(1)} + \boldsymbol{A}_Q^{(2)}] K_T + [c_2 \boldsymbol{A}_Q^{(1)} - c_1 \boldsymbol{A}_Q^{(2)}] K_C\}, \tag{4.9}$$

and

$$\boldsymbol{P}_{ps}(\tau) = -[\tau/(\varepsilon_0 \varepsilon_p)] \boldsymbol{\varepsilon}_p K_p, \tag{4.10}$$

where

$$\boldsymbol{D}_U = \frac{4}{15\pi^{1/2}} \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{D}(c) c^3 \mathrm{d}c, \tag{4.11a}$$

$$\boldsymbol{A}_U^{(\alpha)} = \frac{4}{3\pi^{1/2}} \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{A}^{(\alpha)}(c) c^3 \mathrm{d}c, \quad \alpha = 1, 2, \tag{4.11b}$$

$$\boldsymbol{D}_Q = \frac{4}{15\pi^{1/2}} \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{D}(c) \left(c^2 - \frac{5}{2}\right) c^3 \mathrm{d}c, \tag{4.11c}$$

and

$$\boldsymbol{A}_Q^{(\alpha)} = \frac{4}{3\pi^{1/2}} \int_0^\infty \mathrm{e}^{-c^2} \boldsymbol{A}^{(\alpha)}(c) \left(c^2 - \frac{5}{2}\right) c^3 \mathrm{d}c, \quad \alpha = 1, 2. \tag{4.11d}$$

Since the expressions listed as (4.1a), (4.1b), (4.8), and (4.9) are analytical and continuous in the space variable, we can immediately find results for the normalized mass- and heat-flow rates

$$\boldsymbol{U} = \frac{1}{2a^2} \int_{-a}^a \boldsymbol{U}(\tau) \mathrm{d}\tau \tag{4.12}$$

and

$$\boldsymbol{Q} = \frac{1}{2a^2} \int_{-a}^a \boldsymbol{Q}(\tau) \mathrm{d}\tau, \tag{4.13}$$

where the factor $1/(2a^2)$ is included in order to be consistent with definitions adopted in other works and to facilitate comparisons with numerical results reported in these works. We find

$$\boldsymbol{U} = \frac{1}{2a^2} \left[\boldsymbol{U}_{ps} + a A_1 \boldsymbol{\Phi} + \sum_{j=2}^J \nu_j (A_j + B_j)(1 - \mathrm{e}^{-2a/\nu_j}) \boldsymbol{\mathcal{U}}_j \right] \tag{4.14}$$

and

$$\boldsymbol{Q} = \frac{1}{2a^2} \left[\boldsymbol{Q}_{ps} + \sum_{j=2}^J \nu_j (A_j + B_j)(1 - \mathrm{e}^{-2a/\nu_j}) \boldsymbol{\mathcal{Q}}_j \right], \tag{4.15}$$

As our solutions are now complete, we are ready for some numerical results.

5. Numerical results. The sample cases for which we report numerical results in this work are defined in terms of two binary mixtures: Ne-Ar and He-Xe. We note that only the mass ratio m_1/m_2, the diameter ratio d_1/d_2, and the density ratio n_1/n_2 are needed to define the LBE for rigid-sphere interactions, and so we use the basic data:

$$m_2 = 39.948, \quad m_1 = 20.183, \quad d_2/d_1 = 1.406, \quad n_1/n_2 = 2/3$$

for the Ne-Ar mixture and

$$m_2 = 131.30, \quad m_1 = 4.0026, \quad d_2/d_1 = 2.226, \quad n_1/n_2 = 2/3$$

for the He-Xe mixture. It should be noted here that the values of the masses of these gas species were taken from [23] and those of the diameter ratios from [19].

We report in Tables 1–12 the velocity, heat-flow, and shear-stress profiles computed for the three considered problems of pressure-driven, temperature-driven, and concentration-driven flow, using as additional input data the accommodation coefficients $\alpha_1 = 0.2$, $\alpha_2 = 0.4$, $\beta_1 = 0.6$, and $\beta_2 = 0.8$ and two different values of the channel width ($2a = 0.1$ and 1.0). The numerical results reported in Tables 1–12 are thought to be correct to within ± 1 in the last reported digit and were obtained by increasing the values of the approximation parameters $\{L, M, K, N, K_s\}$ of our method in steps, until numerical convergence was observed. Here L is the kernel truncation parameter (the maximum value of n considered in the summation of (2.50)), M is the order of the Gaussian quadrature used to evaluate numerically integrals over the

rates, as defined by (4.14)–(4.17), for several values of the channel width. We note that the composition and the wall interaction data used to generate Tables 13–15 were the same as those used for Tables 1–12, and that the numerical results for the flow rates are also thought to be correct to within ± 1 in the last reported digit.

While an implementation of our solutions for the three considered problems requires, in general, some hours of computer time to establish the high-quality results we are reporting in our tables, solutions good enough for graphical presentation require very modest computational expense. To have an idea of the CPU time for what we might consider "practical results," we found, for example, that all of the He-Xe results given in Tables 1–15 could be obtained with essentially three figures of accuracy in less than one minute on an Apple MacBook running at 2 GHz.

Finally, we note that we have (for the three considered problems) compared numerical results from our approach based on the LBE for binary mixtures with those of the McCormack model, as developed and implemented in [23]. Due to different ways of the defining the dimensionless space variables in [23] and in this work, we have used the relationship

$$a = \xi_M a_M,$$

where ξ_M is the conversion factor defined by equation (7.19) of [9], to relate the channel half-width a used in this work with the a_M used in [23]. For the mass- and heat-flow rates, this is the only conversion that is required; for the profiles, in addition to the channel half-width conversion, the LBE results must be divided by ξ_M, in order to be properly compared to the results of [23]. Thus, concerning the mass-

flow rates reported in Tables 1–9 of [23], we have found maximum relative deviations (with respect to our LBE results) of 33%, 62%, and 33% for the problems driven by pressure, temperature, and concentration gradients, respectively. For the heat-flow rates reported in these same tables of [23], we have found maximum relative deviations of 40%, 34%, and 300%, respectively, for the pressure-, temperature-, and concentration-driven problems. In all cases but one, the maximum deviations were found to occur for the following input parameters considered in [23]: the heaviest gas particle (Xe), the widest channel ($2a_M = 100$), and the largest concentration of the lighter species ($c_1 = 0.9$). Large maximum relative deviations between the McCormack profiles reported in Tables 10–18 of [23] and those computed with our current (LBE) approach were also observed.

6. Onsager relationships. In [23], Siewert and Valougeorgis established three independent (generalized) Onsager relationships relevant to the flow of binary gas mixtures in a plane-parallel channel driven by pressure, temperature, and concentration gradients. While the derivations reported in [23] were based on the McCormack kinetic model [15], little work is required to establish those same relationships [23] for the LBE (for rigid-sphere interactions) used in this work. For that purpose, we follow here a procedure described in detail for half-space flow problems in [9]. However, before starting our derivation, we should mention that, to denote the solutions and the driving terms of two different problems (among the three that can be defined by considering separately pressure, temperature, and concentration gradients), we attach subscripts X and Y to $\boldsymbol{\Psi}(\tau, c, \mu)$ and to $\boldsymbol{\Upsilon}(c)$.

In short, using the fact that the kernel defined by (2.25) is such that

$$\boldsymbol{S}\boldsymbol{K}^T(\boldsymbol{c} : \boldsymbol{c}') = \boldsymbol{K}(\boldsymbol{c}' : \boldsymbol{c})\boldsymbol{S}, \tag{6.1}$$

where

$$\boldsymbol{S} = \begin{bmatrix} c_2 & 0 \\ 0 & c_1 a_{1,2} \end{bmatrix} \tag{6.2}$$

and $a_{1,2}$ is given by (2.23), we can multiply (2.47) with μ changed to $-\mu$ and subscript Y added to $\boldsymbol{\Psi}(\tau, c, \mu)$ and $\boldsymbol{\Upsilon}(c)$ by

$$c^2(1-\mu^2)\mathrm{e}^{-c^2}\boldsymbol{\Psi}_X^T(\tau, c, \mu)\boldsymbol{S}^{-1},$$

multiply (2.47) with subscript X added to $\boldsymbol{\Psi}(\tau, c, \mu)$ and $\boldsymbol{\Upsilon}(c)$ by

$$c^2(1-\mu^2)\mathrm{e}^{-c^2}\boldsymbol{\Psi}_Y^T(\tau, c, -\mu)\boldsymbol{S}^{-1},$$

subtract the resulting equations, one from the other, and integrate the result of this operation over all μ, over all c, and over τ from $-a$ to a to find, after using (2.62),

$$\int_{-a}^{a}\int_{0}^{\infty}\int_{-1}^{1} \mathrm{e}^{-c^2}c^2(1-\mu^2)\big[\boldsymbol{\Psi}_X^T(\tau, c, \mu)\boldsymbol{S}^{-1}\boldsymbol{\Upsilon}_Y(c) - \boldsymbol{\Psi}_Y^T(\tau, c, -\mu)\boldsymbol{S}^{-1}\boldsymbol{\Upsilon}_X(c)\big]\mathrm{d}\mu\mathrm{d}c\mathrm{d}\tau = 0. \tag{6.3}$$

Taking all possible combinations of X and Y (with the restriction that $X \neq Y$) when these subscripts are set equal to P, T, and C in (6.3) and using the forms of the driving terms appropriate to each problem, we find the relationships

$$K_T\,[c_1 a_{1,2} \quad c_2]\,\boldsymbol{Q}_P = K_P\,[c_1 a_{1,2} \quad c_2]\,\boldsymbol{U}_T, \tag{6.4a}$$

$$K_T\,[c_1 a_{1,2} \quad c_2]\,\boldsymbol{Q}_C = c_1 c_2 K_C\,[a_{1,2} \quad -1]\,\boldsymbol{U}_T, \tag{6.4b}$$

and

$$c_1 c_2 K_C\,[a_{1,2} \quad -1]\,\boldsymbol{U}_P = K_P\,[c_1 a_{1,2} \quad c_2]\,\boldsymbol{U}_C, \tag{6.4c}$$

where we have added subscripts P, T, C to the quantities defined by (4.14) and (4.15) as tags for the problems driven, respectively, by pressure, temperature, and concentration gradients. As a (minor) test of our computations, we have confirmed the three identities listed as (6.4) for the data sets used to define the numerical results reported in this work. Moreover, since Kosuge et al. [13] have tabulated numerical results related to our (6.4), we include in Table 16 our numerical results for the quantities used in [13] to express the (generalized) Onsager relationships. We note that the results listed in Table 16 are relevant to the special case [13] of strictly diffuse reflection at both walls, equal-diameter particles, mass ratio $m_2/m_1 = 2$, and density ratio $n_2/n_1 = 1$ at equilibrium. In order to compare with [13], we used the channel half-width

$$a = \left(\frac{1}{k}\right)\left[\frac{(c_1 + c_2 d_2/d_1)^2}{4(2^{1/2})c_1 + c_2(1 + d_1/d_2)^2(1 + m_1/m_2)^{1/2}}\right], \tag{6.5}$$

where k is the Knudsen number used in [13], and the following expressions (valid for

TABLE 16
The quantities Λ_{XY}, $X \neq Y$, $X, Y = P, T, C$ as defined in [13] *for various values of k with $\alpha_1 = 1.0$, $\alpha_2 = 1.0$, $\beta_1 = 1.0$, $\beta_2 = 1.0$, $m_2/m_1 = 2$, $d_2/d_1 = 1$, and $n_2/n_1 = 1$.*

10.0	7.076139(−1)	7.076139(−1)	2.785816(−1)	2.785816(−1)	1.472278(−1)	1.472278(−1)
20.0	8.340453(−1)	8.340453(−1)	3.317800(−1)	3.317800(−1)	1.717606(−1)	1.717606(−1)

K_P, K_T, and K_C set equal to ε_0) for the quantities defined in [13]:

$$\Lambda_{PT} = \frac{1}{2c_1} a_{2,1} \begin{bmatrix} c_1 a_{1,2} & c_2 \end{bmatrix} \boldsymbol{U}_T, \tag{6.6a}$$

$$\Lambda_{PC} = \frac{1}{2c_1 c_2} a_{2,1} \begin{bmatrix} c_1 a_{1,2} & c_2 \end{bmatrix} \boldsymbol{U}_C, \tag{6.6b}$$

$$\Lambda_{TP} = \frac{1}{2c_1} a_{2,1} \begin{bmatrix} c_1 a_{1,2} & c_2 \end{bmatrix} \boldsymbol{Q}_P, \tag{6.6c}$$

$$\Lambda_{TC} = \frac{1}{2c_1 c_2} a_{2,1} \begin{bmatrix} c_1 a_{1,2} & c_2 \end{bmatrix} \boldsymbol{Q}_C, \tag{6.6d}$$

$$\Lambda_{CP} = \frac{1}{2} a_{2,1} \begin{bmatrix} a_{1,2} & -1 \end{bmatrix} \boldsymbol{U}_P, \tag{6.6e}$$

and

$$\Lambda_{CT} = \frac{1}{2} a_{2,1} \begin{bmatrix} a_{1,2} & -1 \end{bmatrix} \boldsymbol{U}_T. \tag{6.6f}$$

Note that subscript D is used in [13] with the same meaning as subscript C in this work (i.e., a tag for the concentration-driven problem). To be clear, we have listed identical results in various columns of Table 16 in order to emphasize that all quantities were computed as defined.

Finally, we note that we have also confirmed that

$$p_* = \begin{bmatrix} c_1 & c_2 \end{bmatrix} \boldsymbol{P}(\tau) + (K_P/\varepsilon_0)\tau,$$

where the second term on the right-hand side should not be taken into account for the cases of temperature and concentration gradients, is a (problem-dependent) constant.

7. Concluding remarks. We have reported in this work what we believe to be a compact, fast, and accurate method of solving channel-flow problems driven by pressure, temperature, and concentration gradients and described by the (vector) LBE for a binary mixture of rigid spheres. Accurate numerical results were given for the velocity, heat-flow, and shear-stress profiles, as well as for the mass- and heat-flow rates, for selected cases based on Ne-Ar and He-Xe mixtures.

10.0	7.9139(−2)	8.4299(−2)	8.9950(−2)	3.7488(−1)	3.6167(−1)	3.4674(−1)

In addition to the comparisons with the numerical results of the McCormack model that are discussed in section 5, we have also performed comparisons with the single-gas LBE results of [21], using three different ways of achieving the single-gas limit in our formulation:

$$\text{(i) } c_1 = 0, \quad \text{(ii) } c_2 = 0, \quad \text{or} \quad \text{(iii) } m_1 = m_2,\ d_1 = d_2,\ \alpha_1 = \alpha_2, \text{ and } \beta_1 = \beta_2.$$

We note that to convert our results to the same spatial units used in [21] we made use of the factor

$$\xi_{S,p} = 0.449027806\ldots,$$

which (for a single-species case) is the ratio between our dimensionless spatial variable, as defined by (2.41) and (2.42), and that used in [21] for channel-flow problems. Doing this, we found good but not perfect agreement with the five-figure results for the mass- and heat-flow rates and for the velocity and heat-flow profiles that are tabulated in [21]. In regard to the flow rates, while we found at most a difference of one unit in the fifth digit listed in Table 10 of [21], where the accommodation coefficients are taken to be equal to 0.1, we did find a maximum difference of 7 units in the fifth digit listed in Table 11 of [21] (case with accommodation coefficients equal to 0.5) and a maximum difference of 4 units in the fourth digit listed in Table 12 of [21] (case with accommodation coefficients equal to 1.0). The largest differences always occurred for the smallest channel width considered in Tables 10–12 of [21]. For the velocity and heat-flow profiles listed in Tables 13 and 14 of [21], we have observed, respectively, maximum differences of 5 and 3 units in the fifth digit listed in these tables. The maximum differences for the profiles were found to always occur at the channel walls. We have confirmed that the loss of accuracy in Tables 10–14 of [21] was due to using $L = 8$ in those computations, and so we list in Tables 17–19 our improved results (based on $L = 30$) for the cases studied in Tables 10–14 of [21].

Finally, we should like to mention that, considering the large deviations between the numerical results from the LBE and those from the McCormack model that were observed in this and other [9, 10] works, we are of the opinion that the McCormack model has a limited value as an economical alternative to the LBE for gas mixtures.

PATTERN SELECTION FOR FARADAY WAVES IN AN INCOMPRESSIBLE VISCOUS FLUID*

A. C. SKELDON† AND G. GUIDOBONI‡

Abstract. When a layer of fluid is oscillated up and down with a sufficiently large amplitude, patterns form on the surface, a phenomenon first observed by Faraday. A wide variety of such patterns have been observed from regular squares and hexagons to superlattice and quasipatterns and more exotic patterns such as oscillons. Previous work has investigated the mechanisms of pattern selection using the tools of symmetry and bifurcation theory. The hypotheses produced by these generic arguments have been tested against an equation derived by Zhang and Viñals in the weakly viscous and large depth limit. However, in contrast, many of the experiments use shallow viscous layers of fluid to counteract the presence of high frequency weakly damped modes that can make patterns hard to observe. Here we develop a weakly nonlinear analysis of the full Navier–Stokes equations for the two-frequency excitation Faraday experiment. The problem is formulated for general depth, although results are presented only for the infinite depth limit. We focus on a few particular cases where detailed experimental results exist and compare our analytical results with the experimental observations. Good agreement with the experimental results is found.

Key words. Faraday waves, superlattice patterns, weakly nonlinear analysis

1. Introduction.

Waves on the surface of a fluid excited by a vertical oscillation were first observed by Faraday [1]. Subsequently, in the 1980's, the so-called Faraday crispation experiment became one of the first fluid experiments where mode interactions and chaos were observed [2]. Over the last decade, this experiment has become a testbed for ideas of pattern selection in systems under parametric excitation, and a large variety of patterns have been observed including not just regular patterns of squares and hexagons but many more exotic patterns such as superlattice patterns, quasipatterns, and oscillons. These more recent studies were initiated by the results of Edwards and Fauve [3], who used a two-frequency, rather than a single-frequency, excitation, thereby increasing the number of parameters in the problem and breaking the subharmonic time symmetry. Further two-frequency experiments have been performed by Kudrolli, Pier, and Gollub [4] and Arbell and Fineberg [5, 6, 7]. Subsequently, many of the patterns have been observed in experiments with only a single frequency of excitation [8]. Meanwhile, in practical applications of Faraday waves, the phenomenon has been investigated as a tool to produce patterns on films [9, 10], investigated as a mechanism for transporting gas across an air/water boundary [11], and seen as oscillations on the surface of bubbles [12].

In a container, if the amplitude of the vertical excitation is not too large, then no waves form on the surface of the fluid and the fluid is merely translated up and down. As the amplitude of the excitation is increased, waves appear at a critical amplitude of excitation. This onset of waves was first described theoretically by Benjamin and

Ursell [13], who showed that for an inviscid infinite layer of fluid the problem reduces to a Mathieu equation. Kumar and Tuckerman [14] developed a method for solving the linear stability problem for the viscous, finite depth fluid problem for a single frequency of excitation. This work was extended to two-frequency excitation [15] and gives excellent agreement with experimental measurements of the onset of patterns.

Understanding not just the onset of patterns but the type of patterns is challenging. The full mathematical description of the fluid problem involves the Navier–Stokes equations in a domain with a free surface, and the excitation makes the problem nonautonomous. Symmetry arguments along with the notion of resonant trial interactions have been used to uncover some of the pattern selection mechanisms [18]. This showed that weakly damped harmonic modes play a key role, with the wavenumber of the weakly damped mode relative to the critical wavenumber being an indicator of what patterns are likely to be seen. Since the wavenumbers of weakly damped modes are determined by the particular forcing function, this in turn has led to theoretical work in the nearly Hamiltonian limit on controlling pattern selection [19, 20]. In this work, they showed how multiple frequency components in the forcing can be used to enhance particular resonant triad interactions that in turn promote the stability of particular superlattice patterns. The theoretical ideas in [18, 19, 20] were all tested by calculating the coefficients of the relevant amplitude equations for a two-coupled scalar partial differential equation model derived and analyzed by Zhang and Viñals describing the Faraday problem in a weakly viscous and large depth limit [16, 17]. While the theory and the results calculated from the Zhang–Viñals equation agree well, it is harder to establish to what degree these pattern selection mechanisms can be used to explain experimental findings. This is because many of the experimental studies use a fluid that is either moderately viscous or a container that is shallow, neither of which is within the range of validity of the Zhang–Viñals model. The reason that experiments tend to focus on these cases is because of the presence of long wavelength modes that can make it difficult to observe regular patterns: these modes can be damped either by increasing the viscosity or by increasing the dissipation from the lower boundary by making the container shallower [21]. The large viscosity also minimizes the impact of the lateral boundaries on the patterns and the effect of patterns formed by meniscus waves emitted from the sidewalls.

Weakly nonlinear analysis from the full fluid equations for single-frequency excitation in an infinite fluid layer has been carried out by Chen and Viñals [22]. In this paper, we extend the formulation of the weakly nonlinear problem to two-frequency excitation and to finite fluid depth. The former involves a significantly different approach to the derivation of a solvability condition: for a single frequency of excitation, the form of the linear problem may be written as a recursion relation, and an adjoint to this recursion relation may be defined. This works because, in the linear Faraday problem, modes with different frequencies are coupled only through the excitation. Specifically, a frequency component $\cos\omega t$ in the excitation couples the nth Fourier mode to the $n-1$ and the $n+1$ mode. When an N mode truncation is taken, then the equation for the Nth mode is coupled only to the $(N-1)$th mode. Consequently, one can solve for the Nth mode in terms of the $(N-1)$th mode. In turn, this then allows one to solve for the $(N-1)$th mode and, recursively, for all modes. If instead multiple frequency forcing, for example, $\cos\chi\cos M_1\omega t+\sin\chi\cos M_2\omega t$, is used, then the nth Fourier mode is coupled to four other modes, $n-M_1$, $n-M_2$, $n+M_1$, $n+M_2$. Truncating at N modes leaves the Nth mode coupled to both $N-M_1$ and $N-M_2$, and so a recursion relation cannot readily be defined.

In the future, we will investigate the effect of depth on the coefficients of the

amplitude equations; however, for the purposes of this paper, we have focused on carrying out the calculations and detailed results for infinite depth only.

The pattern selection problem is further complicated by several issues. First, above onset not just a single wavenumber but a band of wavenumbers is unstable. Allowing for variation of the spatial scale to account for this typically leads to Ginzburg–Landau-type amplitude equations. Second, in the viscous Faraday problem, there are weakly damped long wavelength modes. These are coupled to the free surface deformation so that the larger the amplitude of the Faraday waves the more significant the effect. Both of these effects are discussed in [23] for Faraday waves in two space dimensions, but as yet there has been no attempt to include these effects in three space dimensions. Note that since the weakly damped long wavelength modes are coupled to the surface deformation, they do not effect the pattern selection at onset but could have an effect thereafter. Finally, at onset the wavenumber specifies the magnitude but not the direction of the associated wavevector. The spatial scale is therefore determined but not the particular pattern. Typically, a finite number of wavevectors are considered and amplitude equations derived for the amplitude associated with each wavevector. Two approaches are taken. In the first, an integer number of eigenvectors corresponding to modes that are equispaced around a circle are considered. Depending on the number of modes used, this leads to an amplitude equation describing squares, hexagons, or quasipatterns. The amplitude equations are of gradient form, and a Lyapunov function can be written down. The relative stability of the different patterns is then inferred from the relative value of the energy for the different states. A clear discussion of some of the issues involved in using amplitude equations to describe quasipatterns is given in [24]. Alternatively, eigenvectors that generate different spatially periodic lattices are considered. Amplitude equations may again be derived, but this time the eigenvalues indicating the relative stability for different patterns that are supported by the same lattice are considered. The methods are closely related, as discussed further in sections 4 and 6. In their single-frequency study, Chen and Vinãls [22] focus on squares, hexagons, and quasipatterns. Here in our two-frequency approach we, at least initially, consider spatially periodic patterns on a lattice. We apply our results to the particular two-frequency experimental results of Kudrolli, Pier, and Gollub [4] and find good agreement with their observations.

The layout of this paper is as follows. In section 2, we set up the mathematical problem. In section 3, a weakly nonlinear expansion about the critical wavenumber is carried out and the weakly nonlinear equations at each order derived. In section 4, we briefly discuss the pattern formation context within which we work and specify the general form of the solutions in the horizontal direction. This leads to a sequence of problems for the surface height and the vertical dependence of the velocity. These equations are solved in section 5, leading to the evaluation of the coefficients for the amplitude equations describing the weakly nonlinear pattern formation. The problem contains a number of physical parameters, and the coefficients are calculated for a range of values relevant to the experimental results in [4]. The calculations in section 5 are performed only in the case of infinite depth, although all early sections are not restricted in this way. The justification for this and the implications of the values of the coefficients for the pattern selection are discussed in section 6. Our conclusions are drawn in section 7.

2. Mathematical model. We consider an infinite horizontal layer of viscous incompressible fluid of finite depth that is subjected to gravity g and to a vertical periodic acceleration of amplitude a. At the lower boundary the fluid is in contact

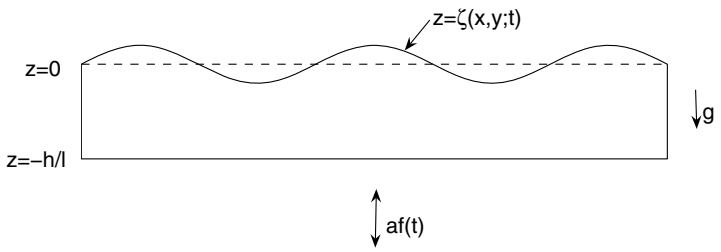

FIG. 2.1. *Sketch of a cross-section through the layer of fluid.*

with a rigid plane, while at the upper boundary the surface is open to the external ambient conditions. This means that the upper surface is a free boundary whose shape and evolution is an unknown of the problem.

We consider a frame of reference which is moving with the periodic excitation whose z-axis is perpendicular to the rigid plane at the bottom at $z = -h/l$, where h/l is the nondimensional depth of the layer. A sketch of the geometry is shown in Figure 2.1. We suppose the free surface is regular enough to be written in the Cartesian representation $z = \zeta(x, y; t)$; then the fluid motion is described by the dimensionless Navier–Stokes equations

$$\begin{aligned} \nabla \cdot \mathbf{u} &= 0, \\ \partial_t \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} &= -\nabla \mathcal{P} + C\Delta \mathbf{u} - (1 + af(t))\mathbf{e}_3, \end{aligned} \tag{2.1}$$

where $\mathbf{u} = (u, v, w)$ is the velocity field, $\mathcal{P}$ the pressure, and

$$f(t) \equiv f_1(t) = \cos(\omega t) \tag{2.2}$$

for single-frequency excitation and

$$f(t) = f_2(t) = \cos(\chi)\cos(M_1\omega t) + \sin(\chi)\cos(M_2\omega t + \phi) \tag{2.3}$$

for two-frequency excitation, where M_1 and M_2 are integers and χ and ϕ are real. The units of length, time, velocity, and pressure have been taken as l, $\sqrt{l/g}$, $\sqrt{gl}$, and ϱgl, respectively. The amplitude of the acceleration due to the excitation, a, is measured in units of g. Here l is taken as k_c^{-1}, where k_c is the wavenumber of the pattern at onset. The parameter $C = \nu/(gl^3)^{1/2}$ is the square of the inverse of the Galileo number, where ν is the kinematic viscosity of the fluid. We have used the notation $\nabla = (\nabla_H, \partial_z)$, with $\nabla_H = (\partial_x, \partial_y)$. Equations (2.1) apply in a domain $\Omega = \Sigma \times (-h/l, \zeta(x, y; t))$, where Σ is the horizontal periodicity cell. The bottom of the container, at $z = -h/l$, is rigid, and therefore we take no-slip boundary conditions here:

$$u = v = w = 0. \tag{2.4}$$

At the free surface $z = \zeta(x, y; t)$ we have the kinematic condition, which says that the surface is advected by the fluid, and two further conditions, one for the balance of the tangential stresses and one for the balance of normal stresses. This leads to three conditions at $z = \zeta(x, y; t)$, namely

$$\begin{aligned} \partial_t \zeta + u\partial_x \zeta + v\partial_y \zeta &= w, \\ \mathbf{t}_1 \cdot \mathbf{T}\mathbf{n} = \mathbf{t}_2 \cdot \mathbf{T}\mathbf{n} &= 0, \\ -\mathcal{P} + 2C\mathbf{n}\mathbf{D}(\mathbf{u})\mathbf{n} &= B\mathcal{H} - p_e, \end{aligned} \tag{2.5}$$

where $\mathbf{T} = -\mathcal{P}\mathbf{I} + 2C\mathbf{D}(\mathbf{u})$ is the stress tensor, $\mathbf{D}(\mathbf{u}) = (\nabla\mathbf{u} + \nabla^T\mathbf{u})/2$ is the rate-of-strain tensor, $\mathcal{H} = \nabla_H \cdot (\nabla_H\zeta/\sqrt{1+|\nabla_H\zeta|^2})$ is the double mean curvature, and the unit normal and tangent vectors are defined as

$$\mathbf{n}(x,y;t) = \left(-\frac{\partial_x\zeta}{\sqrt{1+|\nabla_H\zeta|^2}}, -\frac{\partial_y\zeta}{\sqrt{1+|\nabla_H\zeta|^2}}, \frac{1}{\sqrt{1+|\nabla_H\zeta|^2}}\right),$$
$$\mathbf{t}_1(x,y;t) = \left(\frac{1}{\sqrt{1+|\partial_x\zeta|^2}}, 0, \frac{\partial_x\zeta}{\sqrt{1+|\partial_x\zeta|^2}}\right),$$
$$\mathbf{t}_2(x,y;t) = \left(0, \frac{1}{\sqrt{1+|\partial_y\zeta|^2}}, \frac{\partial_y\zeta}{\sqrt{1+|\partial_y\zeta|^2}}\right).$$

Here p_e is the dimensionless pressure of the external ambient fluid and is assumed known. The parameter $B = \sigma/\varrho g l^2$, where σ is the surface tension and ϱ the density of the fluid, is the inverse Bond number and is a nondimensional measure of the relative importance of surface tension and gravity.

It is convenient to define a new pressure,

$$p = \mathcal{P} + (1 + af(t))z, \tag{2.6}$$

and this has the effect of shifting the acceleration term from the momentum equation to the normal stress condition. In addition, we eliminate the pressure from the momentum equation by taking $-(\nabla\times\nabla\times)$. Using the relation $\nabla\times\nabla\times\mathbf{u} = \nabla(\nabla\cdot\mathbf{u}) - \Delta\mathbf{u}$ and the fact that $\nabla\cdot\mathbf{u} = 0$, the problem then becomes

$$\begin{aligned} \nabla\cdot\mathbf{u} &= 0, \\ \partial_t\Delta\mathbf{u} - C\Delta\Delta\mathbf{u} &= \nabla\times\nabla\times(\mathbf{u}\cdot\nabla\mathbf{u}), \end{aligned} \tag{2.7}$$

with boundary conditions on $z = -h/l$,

$$u = v = w = 0, \tag{2.8}$$

and on $z = \zeta$,

$$\begin{aligned} \partial_t\zeta + u\partial_x\zeta + v\partial_y\zeta &= w, \\ \mathbf{t}_1\cdot\mathbf{T}\mathbf{n} = \mathbf{t}_2\cdot\mathbf{T}\mathbf{n} &= 0, \\ 2C\mathbf{n}\mathbf{D}(\mathbf{u})\mathbf{n} &= B\mathcal{H} + p - p_e - (1+af(t))\zeta. \end{aligned} \tag{2.9}$$

Equations (2.7) with boundary conditions (2.8) and (2.9) have a trivial solution,

$$\mathbf{u} = \mathbf{0}, \quad p = p_e, \quad \zeta = 0. \tag{2.10}$$

This solution corresponds to a flat-surface state where there is no relative motion of the fluid with respect to the moving frame.

3. Weakly nonlinear analysis. The flat-surface state loses stability at a critical amplitude of the excitation frequency to regular patterns of standing waves. We use a multiple timescale approach to derive equations describing the amplitude of these standing waves near threshold. In order to do this, the governing equations and the boundary conditions are expanded in a power series of the dimensionless distance

away from the threshold, ε, and solved order by order in ε. So for the driving dimensionless amplitude a, we let $a = a_0 + \varepsilon a_1 + \varepsilon^2 a_2$ and expand the flow variables as

$$\begin{aligned}
\mathbf{u} &= \varepsilon \mathbf{u}_1 + \varepsilon^2 \mathbf{u}_2 + \varepsilon^3 \mathbf{u}_3 + \cdots, \\
p &= p_e + \varepsilon p_1 + \varepsilon^2 p_2 + \varepsilon^3 p_3 + \cdots, \\
\zeta &= \varepsilon \zeta_1 + \varepsilon^2 \zeta_2 + \varepsilon^3 \zeta_3 + \cdots.
\end{aligned}$$

At each order in ε the solution is defined in a different domain since each ζ_i is different. In order to overcome this difficulty, Chen and Vinãls [22] take a Taylor expansion of the boundary conditions at the free surface around the flat surface state $z = 0$, so that they consider the solution in $\Sigma \times [-h/l, 0]$ at each order. We follow the same approach here. Near threshold, $\varepsilon \ll 1$, we separate fast and slow timescales: $t = \tau + T_1/\varepsilon + T_2/\varepsilon^2$ such that $\partial_t = \partial_\tau + \varepsilon \partial_{T_1} + \varepsilon^2 \partial_{T_2}$. The fast timescale is the timescale of the excitation, while the slower timescales describe the evolution of the amplitude of the patterns over many periods of the excitation. In sections 3.1, 3.2, and 3.3, we list the problem for each of the first three orders in ε. These agree with those used in the computations of [22], although note that there is a typographical error in their paper for the normal stress boundary condition at third order. In section 3.4, we derive the linear adjoint problem that is needed in order to find the solvability conditions that lead to the amplitude equations. The general form for the solvability conditions themselves are given in section 3.5. As found in [14] for the linear problem, the linear operator on the left-hand side of the hierarchy of problems for different ε depends only on the vertical velocity w and on the height of surface ζ. The horizontal components of the velocity, u and v, and the pressure, p, are needed to evaluate the nonlinear terms that appear on the right-hand side. These may be computed from w and ζ: details are given in the appendices.

3.1. Linear problem (first order problem).

$$\partial_\tau \Delta w_1 - C \Delta \Delta w_1 = 0, \tag{3.1}$$

with boundary conditions on $z = -h/l$,

$$w_1 = \partial_z w_1 = 0, \tag{3.2}$$

and on $z = 0$,

$$\begin{aligned}
\partial_\tau \zeta_1 - w_1 &= 0, \\
\Delta_H w_1 - \partial_z^2 w_1 &= 0, \\
-\partial_\tau \partial_z w_1 + C \partial_z^3 w_1 + 3C \Delta_H \partial_z w_1 & \\
-B \Delta_H \Delta_H \zeta_1 + (1 + a_0 f(\tau)) \Delta_H \zeta_1 &= 0.
\end{aligned}$$

Here $\Delta_H = \partial_x^2 + \partial_y^2$.

3.2. Second order problem.

$$\partial_\tau \Delta w_2 - C \Delta \Delta w_2 = N_{eq}^{(2)}, \tag{3.3}$$

with boundary conditions on $z = -h/l$,

$$w_2 = \partial_z w_2 = 0, \tag{3.4}$$

and on $z = 0$,

$$\begin{aligned}\partial_\tau \zeta_2 - w_2 &= N_{kc}^{(2)},\\ \Delta_H w_2 - \partial_z^2 w_2 &= N_{ts}^{(2)},\\ -\partial_\tau \partial_z w_2 + C\partial_z^3 w_2 + 3C\Delta_H \partial_z w_2 &\\ -B\Delta_H \Delta_H \zeta_2 + (1 + a_0 f(\tau))\Delta_H \zeta_2 &= N_{ns}^{(2)}.\end{aligned}$$

Here

$$\begin{aligned}N_{eq}^{(2)} &= [\nabla \times \nabla \times (\mathbf{u}_1 \cdot \nabla)\mathbf{u}_1] \cdot \mathbf{e}_3 - \partial_{T_1} \Delta w_1,\\ N_{kc}^{(2)} &= -\partial_{T_1}\zeta_1 - u_1\partial_x\zeta_1 - v_1\partial_y\zeta_1 + \partial_z w_1 \zeta_1,\\ N_{ts}^{(2)} &= \partial_x\Big[-\partial_{zz}u_1\zeta_1 - \partial_{xz}w_1\zeta_1 + 2(\partial_x u_1 - \partial_z w_1)\partial_x\zeta_1 + (\partial_y u_1 + \partial_x v_1)\partial_y\zeta_1\Big]\\ &\quad +\partial_y\Big[-\partial_{zz}v_1\zeta_1 - \partial_{yz}w_1\zeta_1 + 2(\partial_y v_1 - \partial_z w_1)\partial_y\zeta_1 + (\partial_y u_1 + \partial_x v_1)\partial_x\zeta_1\Big],\\ N_{ns}^{(2)} &= \partial_{T_1}\partial_z w_1 - \nabla_H \cdot (\mathbf{u}_1 \cdot \nabla)\mathbf{u}_1 + \Delta_H(-2C\partial_{zz}w_1\zeta_1 + \partial_z p_1 \zeta_1) - a_1 f(\tau)\Delta_H\zeta_1.\end{aligned}$$

3.3. Third order problem.

$$\partial_\tau \Delta w_3 - C\Delta\Delta w_3 = N_{eq}^{(3)}, \tag{3.5}$$

with boundary conditions on $z = -h/l$,

$$w_3 = \partial_z w_3 = 0, \tag{3.6}$$

and on $z = 0$,

$$\begin{aligned}\partial_\tau \zeta_3 - w_3 &= N_{kc}^{(3)},\\ \Delta_H w_3 - \partial_z^2 w_3 &= N_{ts}^{(3)},\\ -\partial_\tau \partial_z w_3 + C\partial_z^3 w_3 + 3C\Delta_H \partial_z w_3 &\\ -B\Delta_H \Delta_H \zeta_3 + (1 + a_0 f(\tau))\Delta_H \zeta_3 &= N_{ns}^{(3)}.\end{aligned}$$

Here

$$\begin{aligned}N_{eq}^{(3)} &= [\nabla \times \nabla \times (\mathbf{u}_1 \cdot \nabla)\mathbf{u}_2] \cdot \mathbf{e}_3 + [\nabla \times \nabla \times (\mathbf{u}_2 \cdot \nabla)\mathbf{u}_1] \cdot \mathbf{e}_3 - \partial_{T_2}\Delta w_1 - \partial_{T_1}\Delta w_2,\\ N_{kc}^{(3)} &= -\partial_{T_2}\zeta_1 - \partial_{T_1}\zeta_2 + \partial_z w_1 \zeta_2 + \partial_z w_2 \zeta_1 + \frac{1}{2}\partial_{zz} w_1 \zeta_1^2\\ &\quad -u_1\partial_x\zeta_2 - u_2\partial_x\zeta_1 - \partial_z u_1 \zeta_1 \partial_x \zeta_1 - v_1\partial_y\zeta_2 - v_2\partial_y\zeta_1 - \partial_z v_1 \zeta_1 \partial_y \zeta_1,\\ N_{ts}^{(3)} &= \partial_x\Big[-\partial_{zz}u_2\zeta_1 - \partial_{zz}u_1\zeta_2 - \frac{1}{2}\partial_{zzz}u_1\zeta_1^2 - \partial_{xz}w_2\zeta_1 - \partial_{xz}w_1\zeta_2 - \frac{1}{2}\partial_{xzz}w_1\zeta_1^2\\ &\quad -2(\partial_z w_2 - \partial_x u_2)\partial_x\zeta_1 - 2(\partial_z w_1 - \partial_x u_1)\partial_x\zeta_2 - 2\partial_z(\partial_z w_1 - \partial_x u_1)\zeta_1\partial_x\zeta_1\\ &\quad +(\partial_y u_2 + \partial_x v_2)\partial_y\zeta_1 + (\partial_y u_1 + \partial_x v_1)\partial_y\zeta_2 + \partial_z(\partial_y u_1 + \partial_x v_1)\zeta_1\partial_y\zeta_1\Big]\\ &\quad +\partial_y\Big[-\partial_{zz}v_2\zeta_1 - \partial_{zz}v_1\zeta_2 - \frac{1}{2}\partial_{zzz}v_1\zeta_1^2 - \partial_{yz}w_2\zeta_1 - \partial_{yz}w_1\zeta_2 - \frac{1}{2}\partial_{yzz}w_1\zeta_1^2\\ &\quad -2(\partial_z w_2 - \partial_y v_2)\partial_y\zeta_1 - 2(\partial_z w_1 - \partial_y v_1)\partial_y\zeta_2 - 2\partial_z(\partial_z w_1 - \partial_y v_1)\zeta_1\partial_y\zeta_1\\ &\quad +(\partial_y u_2 + \partial_x v_2)\partial_x\zeta_1 + (\partial_y u_1 + \partial_x v_1)\partial_x\zeta_2 + \partial_z(\partial_y u_1 + \partial_x v_1)\zeta_1\partial_x\zeta_1\Big],\end{aligned}$$

$$
\begin{aligned}
N_{ns}^{(3)} = {} & \partial_{T_2}\partial_z w_1 + \partial_{T_1}\partial_z w_2 - a_2 f(\tau)\Delta_H \zeta_1 - a_1 f(\tau)\Delta_H \zeta_2 - \nabla_H \cdot [\mathbf{u}_1 \cdot \nabla \mathbf{u}_2 + \mathbf{u}_2 \cdot \nabla \mathbf{u}_1] \\
& + \Delta_H \Big[\partial_z p_2 \zeta_1 + \partial_z p_1 \zeta_2 + \frac{1}{2}\partial_{zz} p_1 \zeta_1^2 - 2C\partial_{zz} w_1 \zeta_2 - 2C\partial_{zz} w_2 \zeta_1 - C\partial_{zzz} w_1 \zeta_1^2 \\
& + 2C(\partial_z u_2 + \partial_x w_2)\partial_x \zeta_1 + 2C(\partial_z w_1 - \partial_x u_1)(\partial_x \zeta_1)^2 + 2C(\partial_z v_2 + \partial_y w_2)\partial_y \zeta_1 \\
& + 2C\partial_z(\partial_x w_1 + \partial_z u_1)\partial_x \zeta_1 \zeta_1 + 2C\partial_z(\partial_y w_1 + \partial_z v_1)\partial_y \zeta_1 \zeta_1 \\
& + 2C(\partial_z w_1 - \partial_y v_1)(\partial_y \zeta_1)^2 - 2C(\partial_y u_1 + \partial_x v_1)\partial_x \zeta_1 \partial_y \zeta_1 - \frac{3}{2}B\partial_{xx}\zeta_1(\partial_x \zeta_1)^2 \\
& - \frac{3}{2}B\partial_{yy}\zeta_1(\partial_y \zeta_1)^2 - \frac{1}{2}B\partial_{xx}\zeta_1(\partial_y \zeta_1)^2 - \frac{1}{2}B\partial_{yy}\zeta_1(\partial_x \zeta_1)^2 - 2B\partial_x \zeta_1 \partial_y \zeta_1 \partial_{xy}\zeta_1 \Big].
\end{aligned}
$$

3.4. Linear adjoint problem. In order to use the Fredholm alternative and derive a solvability condition, the solution to the linear adjoint problem is needed. We suppose that $S_1 = (w_1, \zeta_1)$ is the solution of the linear problem and denote by $S^* = (w^*, \zeta^*)$ the solution of the linear adjoint problem. Then S_1 and S^* satisfy

$$
(S^*, \mathcal{L}S_1) = 0 = (\mathcal{L}^* S^*, S_1), \tag{3.7}
$$

where $\mathcal{L}$ and $\mathcal{L}^*$ are the linear and the linear adjoint operators, respectively, and $(\cdot, \cdot)$ means the following scalar product:

$$
\int_0^{2\pi/\omega} \int_\Omega w^* \Big(\partial_\tau \Delta w_1 - C\Delta\Delta w_1 \Big) d\Omega d\tau + \int_0^{2\pi/\omega} \int_\Sigma \zeta_* \Big[\partial_\tau \zeta_1 - w_1 \Big]_{z=0} d\Sigma d\tau = 0, \tag{3.8}
$$

where $\Omega = \Sigma \times (-h/l, 0)$ and Σ is the horizontal periodicity cell.

3.5. Solvability conditions. From the Fredholm alternative theorem it follows that at second order the solvability condition takes the form of

$$
\begin{aligned}
& \int_0^{2\pi/\omega} \int_\Omega w^* (\partial_\tau \Delta w_2 - C\Delta\Delta w_2 - N_{eq}^{(2)}) d\Omega d\tau \\
& \quad + \int_0^{2\pi/\omega} \int_\Sigma [\zeta^* (\partial_\tau \zeta_2 - w_2 - N_{kc}^{(2)})]_{z=0} d\Sigma d\tau = 0.
\end{aligned} \tag{3.9}
$$

This implies that

$$
\begin{aligned}
& \int_0^{2\pi/\omega} \int_\Omega w^* N_{eq}^{(2)} d\Omega d\tau + \int_0^{2\pi/\omega} \int_\Sigma [\zeta^* N_{kc}^{(2)}]_{z=0} d\Sigma d\tau \\
& + \int_0^{2\pi/\omega} \int_\Sigma [w^* N_{ns}^{(2)}]_{z=0} d\Sigma d\tau + C \int_0^{2\pi/\omega} \int_\Sigma [\partial_z w^* N_{ts}^{(2)}]_{z=0} d\Sigma d\tau = 0.
\end{aligned}
$$

Similarly at third order, we have

$$\int_0^{2\pi/\omega}\int_\Omega w^* N_{eq}^{(3)} d\Omega d\tau + \int_0^{2\pi/\omega}\int_\Sigma [\zeta^* N_{kc}^{(3)}]_{z=0} d\Sigma d\tau$$
$$+ \int_0^{2\pi/\omega}\int_\Sigma [w^* N_{ns}^{(3)}]_{z=0} d\Sigma d\tau + C\int_0^{2\pi/\omega}\int_\Sigma [\partial_z w^* N_{ts}^{(3)}]_{z=0} d\Sigma d\tau = 0.$$

4. Patterns. In order to proceed further, we need to first solve the linear problem set out in section 3.1. However, in an unbounded horizontal domain, while the linear problem predicts the onset of spatially periodic patterns at a given excitation frequency and excitation amplitude with a wavenumber k_c, it does not uniquely determine the pattern that is produced. This is related to the fact that, in an unbounded horizontal domain, the Faraday problem is isotropic so that no particular direction is preferred: any wavevector with wavenumber k_c would give an allowable solution; for example, stripes with any orientation would be possible. Furthermore, within the linear problem, linear superposition of different wavevectors with the critical wavenumber also give solutions. In this way, solutions such as squares, hexagons, superlattice patterns, and quasipatterns may be constructed by adding together stripe solutions of the appropriate orientation. However, the fact that these are solutions to the linear problem does not guarantee their existence or stability for the nonlinear problem. Indeed, only particular combinations of patterns are observed in experiments. Here we consider patterns that are spatially periodic, and this is implicit in our choice of domain in sections 2 and 3.

For patterns that are spatially periodic in two space dimensions, previous work has used equivariant bifurcation theory to find the generic types of solutions that exist [25], the generic amplitude equations that these patterns satisfy, and the stability of each pattern in terms of the coefficients of these amplitude equations [26]. For example, on the family of lattices with hexagonal symmetry, the generic amplitude equations are

$$\begin{aligned}
\dot{z}_1 &= \lambda z_1 + \epsilon \bar{z}_2 \bar{z}_3 \\

&\quad + (b_6|z_1|^2 + b_5|z_2|^2 + b_4|z_3|^2 + b_2|z_4|^2 + b_2|z_5|^2 + b_1|z_6|^2) z_6 + \mathcal{O}(|\mathbf{z}|^4),
\end{aligned} \tag{4.1}$$

where the z_i are complex amplitudes and λ, ϵ, and b_i are real. An example of one of the family of such lattices is shown in Figure 4.1, where $\mathbf{K_{i_h}}$ is the mode with amplitude z_i. Different lattices correspond to different choices for θ. In terms of the Faraday problem considered in this paper, these equations arise by representing the horizontal spatial dependence of the linear problem for the surface height ζ_1 and the

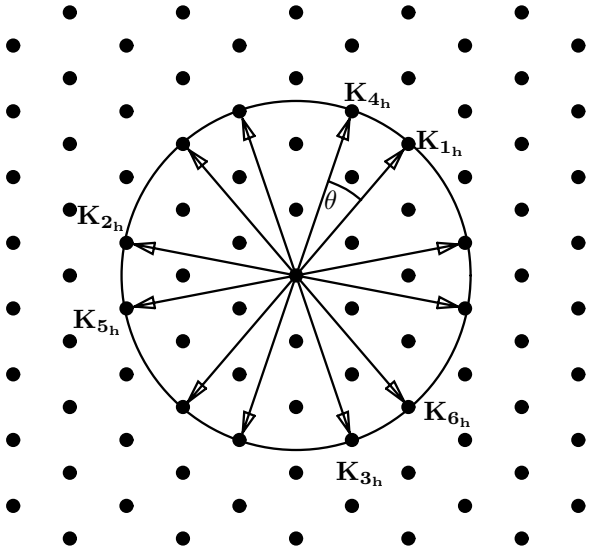

FIG. 4.1. *Hexagonal lattice generated by* 12 *wavevectors on the critical circle.*

vertical velocity w_1 as a sum of six modes where the ith mode has amplitude z_i and wavevector K_{i_h}.

For each hexagonal lattice, the equivariant branching lemma gives six patterns that bifurcate from the trivial state, and these are listed in Table 4.1 along with their branching equations and stability assignments. A further pattern has been found to exist and bifurcate from the trivial solution as discussed in [27]. We have not included this in Table 4.1 since its eigenvalues are indistinguishable from those for superhexagons at cubic order. We refer to both the superhexagons and the patterns discussed in [27] as superlattice patterns.

Similar results exist for families of square lattices.

Previously, the coefficients of the amplitude equations have been calculated for a long wavelength scalar partial differential equation describing a range of convection problems [28], for Turing patterns [29], and more recently for the Zhang–Viñals model of the Faraday problem [18]. These calculations allow inferences on the relative stability of different spatially periodic patterns to be made.

The cubic truncation of the amplitude equations (4.1) can be written in gradient form:

$$\dot{z}_i = -\frac{\partial \mathcal{F}}{\partial \bar{z}_i}, \tag{4.2}$$

where the Lyapunov function is given by

$$\begin{aligned}\mathcal{F} = &-\sum_{i=1..6}\left[\lambda|z_i|^2 - \frac{1}{2}b_1|z_i|^4\right]\\ &-\epsilon(z_1z_2z_3 + z_4z_5z_6 + \bar{z}_1\bar{z}_2\bar{z}_3 + \bar{z}_4\bar{z}_5\bar{z}_6)\\ &-b_2\left(|z_1|^2|z_2|^2 + |z_1|^2|z_3|^2 + |z_4|^2|z_5|^2 + |z_4|^2|z_6|^2 + |z_5|^2|z_6|^2\right)\\ &-b_4\left(|z_1|^2|z_4|^2 + |z_2|^2|z_5|^2 + |z_3|^2|z_6|^2\right) - b_5\left(|z_1|^2|z_5|^2 + |z_2|^2|z_6|^2 + |z_3|^2|z_4|^2\right)\\ &-b_6\left(|z_1|^2|z_6|^2 + |z_2|^2|z_4|^2 + |z_3|^2|z_5|^2\right).\end{aligned} \tag{4.3}$$

TABLE 4.1

Branching equations and signs of eigenvalues for primary bifurcation branches on the hexagonal lattice; $\epsilon, b_1, \ldots, b_6$ are coefficients in the bifurcation equation (4.1).

Branching equation	Signs of nonzero eigenvalues
Stripes (S) $\mathbf{z} = (A_S, 0, 0, 0, 0, 0)$ $0 = \lambda A_S + b_1 A_S^3 + \mathcal{O}(A_S^5)$	$\mathrm{sgn}(b_1)$, $\mathrm{sgn}(\tilde{\epsilon} A_S + (b_2 - b_1) A_S^2)$, $\mathrm{sgn}(-\tilde{\epsilon} A_S + (b_2 - b_1) A_S^2)$, $\mathrm{sgn}(b_4 - b_1)$, $\mathrm{sgn}(b_5 - b_1)$, $\mathrm{sgn}(b_6 - b_1)$.
Simple hexagons ($\mathrm{H}^{\pm}$) $\mathbf{z} = (A_H, A_H, A_H, 0, 0, 0)$ $0 = \lambda A_H + \tilde{\epsilon} A_H^2$ $+(b_1 + 2b_2) A_H^3 + \mathcal{O}(A_H^4)$	$\mathrm{sgn}(\tilde{\epsilon} A_H + 2(b_1 + 2b_2) A_H^2)$, $\mathrm{sgn}(-\tilde{\epsilon} A_H + (b_1 - b_2) A_H^2)$, $\mathrm{sgn}(-\tilde{\epsilon} A_H + (b_4 + b_5 + b_6 - b_1 - 2b_2) A_H^2)$, $\mathrm{sgn}(-\tilde{\epsilon} A_H + \mathcal{O}(A_H^3))$.
Rectangles ($\mathrm{R}_{h1,m,n}$) $\mathbf{z} = (A_R, 0, 0, A_R, 0, 0)$ $0 = \lambda A_R + (b_1 + b_4) A_R^3 + \mathcal{O}(A_R^5)$	$\mathrm{sgn}(b_1 + b_4)$, $\mathrm{sgn}(b_1 - b_4)$, $\mathrm{sgn}(\mu_1)$, $\mathrm{sgn}(\mu_2)$, where $\mu_1 + \mu_2 = (-2b_1 - 2b_4 + 2b_2 + b_5 + b_6) A_R^2$, $\mu_1 \mu_2 = -\tilde{\epsilon}^2 A_R^2 + (b_1 + b_4 - b_2 - b_5)$ $(b_1 + b_4 - b_2 - b_6) A_R^4$.
Rectangles ($\mathrm{R}_{h2,m,n}$) $\mathbf{z} = (A_R, 0, 0, 0, A_R, 0)$ $0 = \lambda A_R + (b_1 + b_5) A_R^3 + \mathcal{O}(A_R^5)$	$\mathrm{sgn}(b_1 + b_5)$, $\mathrm{sgn}(b_1 - b_5)$, $\mathrm{sgn}(\mu_1)$, $\mathrm{sgn}(\mu_2)$, where $\mu_1 + \mu_2 = (-2b_1 - 2b_5 + 2b_2 + b_4 + b_6) A_R^2$, $\mu_1 \mu_2 = -\tilde{\epsilon}^2 A_R^2 + (b_1 + b_5 - b_2 - b_4)$ $(b_1 + b_5 - b_2 - b_6) A_R^4$.
Rectangles ($\mathrm{R}_{h3,m,n}$) $\mathbf{z} = (A_R, 0, 0, 0, 0, A_R)$ $0 = \lambda A_R + (b_1 + b_6) A_R^3 + \mathcal{O}(A_R^5)$	$\mathrm{sgn}(b_1 + b_6)$, $\mathrm{sgn}(b_1 - b_6)$, $\mathrm{sgn}(\mu_1)$, $\mathrm{sgn}(\mu_2)$, where $\mu_1 + \mu_2 = (-2b_1 - 2b_6 + 2b_2 + b_4 + b_5) A_R^2$, $\mu_1 \mu_2 = -\tilde{\epsilon}^2 A_R^2 + (b_1 + b_6 - b_2 - b_4)$ $(b_1 + b_6 - b_2 - b_5) A_R^4$.
Superhexagons ($\mathrm{SH}^{\pm}_{m,n}$) $\mathbf{z} = (A_{SH}, A_{SH}, A_{SH},$ $A_{SH}, A_{SH}, A_{SH})$ $0 = \lambda A_{SH} + \tilde{\epsilon} A_{SH}^2 + (b_1 + 2b_2) A_{SH}^3$ $+(b_4 + b_5 + b_6) A_{SH}^3 + \mathcal{O}(A_{SH}^4)$	$\mathrm{sgn}(\tilde{\epsilon} A_{SH} + 2(b_1 + 2b_2 + b_4 + b_5 + b_6) A_{SH}^2)$, $\mathrm{sgn}(\tilde{\epsilon} A_{SH} + 2(b_1 + 2b_2 - b_4 - b_5 - b_6) A_{SH}^2)$, $\mathrm{sgn}(-\tilde{\epsilon} A_{SH} + \mathcal{O}(A_{SH}^3))$, $\mathrm{sgn}(-\tilde{\epsilon} A_{SH} + \mathcal{O}(A_{SH}^3))$,* $\mathrm{sgn}(\mu_1)$, $\mathrm{sgn}(\mu_2)$, where $\mu_1 + \mu_2 = -4\tilde{\epsilon} A_{SH} + 4(b_1 - b_2) A_{SH}^2$, $\mu_1 \mu_2 = 4(\tilde{\epsilon} A_{SH} - (b_1 - b_2) A_{SH}^2)^2$ $-2((b_4 - b_5)^2 + (b_4 - b_6)^2$ $+(b_5 - b_6)^2)) A_{SH}^4$, $\mathrm{sgn}(\mu_0)$, where $\mu_0 = \mathcal{O}(A_{SH}^{2(m-1)})$.

*These two eigenvalues differ at $\mathcal{O}(A_{SH}^3)$.

The different planforms then correspond to minima of the Lyapunov functional, and an "energy" for each state may be computed. In Table 4.2, we list the different planforms and the corresponding value of the Lyapunov function (4.3). The information given by the eigenvalues of the amplitude equations given in Table 4.1 and that given by the energy of the different states as given in Table 4.2 is complementary. Below we calculate the coefficients for the amplitude equations (4.1) from the full Navier–Stokes equation formulation of the Faraday problem. We then calculate the eigenvalues to examine relative stability. For those states that are relatively stable, we calculate the value of the Lyapunov function to find which have the lowest energy.

The coefficients of the amplitude equations are found by focusing on three calculations: one for stripes, one for rectangular patterns, and one for hexagons; these correspond to considering the three subspaces, $\mathbf{z} = (A_S, 0, 0, 0, 0, 0)$, $\mathbf{z} = (A_R, 0, 0, A_R, 0, 0)$,

TABLE 4.2

Value of the Lyapunov function $\mathcal{F}$ for each of the primary bifurcation branches on the hexagonal lattice; $\epsilon, b_1, \ldots, b_6$ are coefficients in the bifurcation equation (4.1). Only one of the rectangular states has been included: the other two may be obtained by cyclic permutation.

Planform	$\mathcal{F}$
Stripes (S) $\mathbf{z} = (A_S, 0, 0, 0, 0, 0)$	$\frac{\lambda^2}{b_1}$
Simple hexagons ($H^{\pm}$) $\mathbf{z} = (A_H, A_H, A_H, 0, 0, 0)$	$-\left(3\lambda A_H^2 + 2\epsilon A_H^3 + \frac{3}{2}(b_1 + 2b_2)A_H^4\right)$, where $0 = \lambda + \epsilon A_H + (b_1 + 2b_2)A_H^2$
Rectangles ($R_{h1,m,n}$) $\mathbf{z} = (A_R, 0, 0, A_R, 0, 0)$	$\frac{\lambda^2}{(b_1+b_4)}$
Superhexagons ($SH^{\pm}_{m,n}$) $\mathbf{z} = (A_{SH}, A_{SH}, A_{SH}, A_{SH}, A_{SH}, A_{SH})$	$-\left(6\lambda A_{SH}^2 + 4\epsilon A_{SH}^3 + 3(b_1 + 2b_2 + b_4 + b_5 + b_6)A_{SH}^4\right)$, where $0 = \lambda + \tilde{\epsilon} A_{SH} + (b_1 + 2b_2 + b_4 + b_5 + b_6)A_{SH}^2$

and $\mathbf{z} = (A_H, A_H, A_H, 0, 0, 0)$, respectively. Focusing on a particular pattern means that we make an assumption about the particular form of the horizontal behavior of the fluid variables. We can use this to reformulate the weakly nonlinear analysis in section 3 that is in terms of functions of x, y, and z to a simpler set of problems for sets of functions that depend only on z. It is this reformulation of the problem that is carried out in this section for each of the stripes, rectangles, and hexagons. Since stripes and rectangles arise through a symmetry-breaking bifurcation, there are no quadratic terms in the amplitude equations for these patterns. A result of this is that the solvability condition at second order necessarily leads to $a_1 = 0$. This fact can be included from the beginning of the analysis, and then we need only scale on two timescales; that is, we let $t = \tau + T/\varepsilon^2$ so that $\partial_t = \partial_\tau + \varepsilon^2 \partial_T$. (The more general formulation on three timescales is needed for hexagons.)

For stripes, we consider a solution to the first order problem given in section 3.1 of the form

$$w_1(x, z, \tau, T) = A_S(T)(e^{ikx} + e^{-ikx}) \sum_n W_{1,n}(z) e^{i(n\omega+\alpha)\tau},$$
$$\zeta_1(x, \tau, T) = A_S(T)(e^{ikx} + e^{-ikx}) \sum_n Z_{1,n} e^{i(n\omega+\alpha)\tau},$$

and for rectangular patterns, we consider

$$w_1(x, y, z, \tau, T) = A_R(T)[e^{ikx} + e^{ik(cx+sy)} + c.c.] \sum_n W_{1,n}(z) e^{i(n\omega+\alpha)\tau},$$
$$\zeta_1(x, y, \tau, T) = A_R(T)[e^{ikx} + e^{ik(cx+sy)} + c.c.] \sum_n Z_{1,n} e^{i(n\omega+\alpha)\tau}, \tag{4.4}$$

where $s = \sin\theta$ and $c = \cos\theta$ and θ is the angle between the wavevectors that make up the rectangular pattern. Here k is the wavenumber of the pattern, and a Floquet expansion in the basic frequency ω has been used as in [14]. When $\alpha = 0$, the expansion gives a harmonic solution, and when $\alpha = \omega/2$, the expansion gives a subharmonic

solution. Here and below we sum from $n = -\infty$ to $n = +\infty$. Consequently, since both the w_1 and ζ_1 are real, we have in addition

$$\begin{aligned} W_{1,n} &= \bar{W}_{1,-n}, \quad \alpha = 0, \\ W_{1,n} &= \bar{W}_{1,-n-1}, \quad \alpha = \omega/2. \end{aligned} \tag{4.5}$$

Although we do not list them, there are analogous reality conditions for the velocity components and surface height at each order. Similar choices for the expansion are made for the behavior of the horizontal velocity components u_1 and v_1, and these are listed in Appendix A. Since the results for stripes can be obtained by setting $\theta = 0$ and careful consideration of some factors of two, in what follows we include stripes as a special case in our formulation of the problem for rectangles. In order to proceed, the general form (4.4) for the pattern is substituted into the first order problem given in section 3.1. The result is a homogeneous fourth order linear differential equation for the vertical dependence of the vertical velocity component $W_{1,n}(z)$ along with the appropriate boundary conditions at $z = 0$ and $z = -h/l$. This is given in section 4.1.

At second order, as for the first order problem, assuming that we are interested in particular patterns means that we know the form for the horizontal behavior of the fluid. Specifically, we take the general form of the second order solution for rectangles as

$$\begin{aligned} w_2(x,y,z,\tau,T) = {} & A_R^2(T)[e^{2ikx} + e^{2ik(cx+sy)} + c.c.] \sum_n W_{2,1,n}(z) e^{i(n\omega+2\alpha)\tau} \\ & + A_R^2(T)[e^{ik[(1+c)x+sy]} + c.c.] \sum_n W_{2,2,n}(z) e^{i(n\omega+2\alpha)\tau} \\ & + A_R^2(T)[e^{ik[(1-c)x-sy]} + c.c.] \sum_n W_{2,3,n}(z) e^{i(n\omega+2\alpha)\tau}, \\ \zeta_2(x,y,\tau,T) = {} & A_R^2(T)[e^{2ikx} + e^{2ik(cx+sy)} + c.c.] \sum_n Z_{2,1,n} e^{i(n\omega+2\alpha)\tau} \\ & + A_R^2(T)[e^{ik[(1+c)x+sy]} + c.c.] \sum_n Z_{2,2,n} e^{i(n\omega+2\alpha)\tau} \\ & + A_R^2(T)[e^{ik[(1-c)x-sy]} + c.c.] \sum_n Z_{2,3,n} e^{i(n\omega+2\alpha)\tau}. \end{aligned} \tag{4.6}$$

The forms that are taken for the velocity components u_2 and v_2 are given in Appendix A. The expressions for the velocity components are substituted into the equations and boundary conditions at second order given in section 3.2, and this leads to an inhomogeneous fourth order ordinary differential equation for $W_{2,i,n}(z)$ along with boundary conditions. These are given in section 4.2.

As discussed above, if we take $a_1 = 0$, then there is no solvability condition at second order for rectangles. However, at third order there is a solvability condition. In order to derive this, the general form for the adjoint problem is needed. In section 4.3, we give the formulation for the adjoint problem, derived from the adjoint problem given in (3.8) along with the assumption that patterns to the adjoint problem take the general form

$$\begin{aligned} w^*(x,z,\tau,T) &= A^*(T)(e^{ikx} + e^{-ikx}) \sum_n W_n^*(z) e^{i(n\omega+\alpha)\tau}, \\ \zeta^*(x,\tau,T) &= A^*(T)(e^{ikx} + e^{-ikx}) \sum_n Z_n^* e^{i(n\omega+\alpha)\tau}. \end{aligned}$$

This then allows us to formulate the solvability condition at third order in section 4.4. The result is an amplitude equation for rectangles whose coefficients may be determined from $W_{1,n}(z), Z_{1,n}, W_{2,i,n}(z), Z_{2,i,n}$ and their derivatives along with the adjoint eigenfunctions $W^*_{1,n}(z)$ and $Z^*_{1,n}$ and their derivatives.

In the case of hexagons, we consider a first order solution of the form

$$\begin{aligned} &w_1(x,y,z,\tau,T_1,T_2) \\ &\quad = A_H(T_1,T_2)[e^{ikx} + e^{ik(-x+\sqrt{3}y)/2} + e^{ik(-x-\sqrt{3}y)/2} + c.c.] \sum_n W_{1,n}(z) e^{i(n\omega+\alpha)\tau}, \\ &\zeta_1(x,y,z,\tau,T_1,T_2) \\ &\quad = A_H(T_1,T_2)[e^{ikx} + e^{ik(-x+\sqrt{3}y)/2} + e^{ik(-x-\sqrt{3}y)/2} + c.c.] \sum_n Z_{1,n} e^{i(n\omega+\alpha)\tau} \end{aligned} \tag{4.7}$$

with similar choices for u_1 and v_1 that are listed in Appendix A. This leads to the same first order problem as for stripes and rectangles, as given in section 4.1 below.

At second order hexagons differ from rectangles. Generically, in problems that have E(2) symmetry, hexagons arise in a transcritical bifurcation and are necessarily locally unstable. In the weakly nonlinear analysis, this appears as a quadratic amplitude equation that results from the solvability condition for the second order problem. Two cases of interest arise that can result in stable hexagonal solutions: first, when there is an extra symmetry in the problem that removes the quadratic term, and second, when the coefficient of the quadratic term is sufficiently small so that the quadratic terms may formally be included at cubic order [30]. The Faraday problem is an example of a system that has E(2) symmetry. As we shall see below, for some values of the parameter χ in the drive (2.3), the response is subharmonic, and for some values it is harmonic. When the response is subharmonic, then there is an extra time symmetry in the problem and there are no quadratic terms in the amplitude equations. When $\chi = 0$, the response is harmonic, but since there is no M_2 component in the drive, there is again an extra symmetry in the problem, and again there are no quadratic terms in the amplitude equations. However, as the parameter χ is increased from 0, this extra symmetry is broken, and there is a gradual increase from zero in the size of the coefficient of the quadratic term. There is therefore at least some range in parameter space where it is reasonable to include the quadratic terms at cubic order. The way we proceed with the hexagon calculation is therefore as follows. First, we consider three timescales and formulate the solvability condition at second order. This is done using the solvability condition given in (3.9) and the specific form for the hexagonal pattern at first order (4.7); the result is given in section 4.5. This gives us a quadratic amplitude equation and enables us to compute the size of the quadratic term.

Next, we make the assumption that the coefficient of the quadratic term is either zero or sufficiently small ($O(\varepsilon)$) so that we may formally include the terms at cubic order. We therefore set $a_1 = 0$, rescale the problem on two timescales, and formulate the problem for the solution at second order by taking as a general form for the second order problem

$$\begin{aligned} w_2(x,y,z,\tau,T) &= A_H^2[e^{2ikx} + e^{ik(-x+\sqrt{3}y)} + e^{ik(-x-\sqrt{3}y)} + c.c.] \sum_n W_{2,1,n}(z) e^{i(n\omega+2\alpha)\tau} \\ &\quad + A_H^2[e^{ik\sqrt{3}y} + e^{ik(3x+\sqrt{3}y)/2} + e^{ik(3x-\sqrt{3}y)/2} + c.c.] \sum_n W_{2,2,n}(z) e^{i(n\omega+2\alpha)\tau}, \end{aligned}$$

$$\zeta_2(x,y,\tau,T) = A_H^2[e^{2ikx} + e^{ik(-x+\sqrt{3}y)} + e^{ik(-x-\sqrt{3}y)} + c.c.]\sum_n Z_{2,1,n}e^{i(n\omega+2\alpha)\tau}$$

$$+A_H^2[e^{ik\sqrt{3}y} + e^{ik(3x+\sqrt{3}y)/2} + e^{ik(3x-\sqrt{3}y)/2} + c.c.]\sum_n Z_{2,2,n}e^{i(n\omega+2\alpha)\tau}. \tag{4.8}$$

Expressions for u_2 and v_2 are listed in Appendix A. Substitution of these expressions into the second order equation and boundary conditions given in section 3.2 leads to an inhomogeneous fourth order ordinary differential equation for $W_{2,i,n}$ along with boundary conditions. These are given in section 4.6. Finally, including the quadratic terms at cubic order, we formulate the solvability condition for the third order hexagonal problem in section 4.7.

4.1. The linear problem. The linear problem is the same for all periodic patterns and is given by

$$[i(n\omega+\alpha) - C(D^2-k^2)](D^2-k^2)W_{1,n}(z) = 0, \tag{4.9}$$

where D indicates the derivative with respect to z, with boundary conditions

$$W_{1,n} = DW_{1,n} = 0, \tag{4.10}$$

on $z = -h/l$, and on $z = 0$,

$$i(n\omega+\alpha)Z_{1,n} - W_{1,n} = 0, \tag{4.11}$$

$$(D^2+k^2)W_{1,n} = 0, \tag{4.12}$$

$$\Big(i(n\omega+\alpha) + 3Ck^2\Big)DW_{1,n} - CD^3W_{1,n} + k^2(Bk^2+1)Z_{1,n} = -\frac{1}{2}a_0k^2Z_{1,f,n}. \tag{4.13}$$

For a single frequency of excitation,

$$Z_{1,f,n} = Z_{1,n-1} + Z_{1,n+1}, \tag{4.14}$$

and for two frequencies,

$$Z_{1,f,n} = \cos(\chi)(Z_{1,n-M_1} + Z_{1,n+M_1}) + \sin(\chi)(e^{i\phi}Z_{1,n-M_2} + e^{-i\phi}Z_{1,n+M_2}). \tag{4.15}$$

These equations are supplemented by the reality conditions

$$W_{1,-n}(0) = \bar{W}_{1,n}(0), \quad Z_{1,-n} = \bar{Z}_{1,n}$$

for harmonic modes and

$$W_{1,-n}(0) = \bar{W}_{1,n-1}(0), \quad Z_{1,-n} = \bar{Z}_{1,n-1}$$

for subharmonic modes, where the bar indicates complex conjugation.

4.2. Second order problem for rectangles and stripes. The functions $W_{2,i,n}$ and $Z_{2,i,n}$, $i = 1,2,3$, can all be found from the same system of equations with different choices made for the parameters θ and d. For $i = 1$, we take $\theta = 0$ and $d = 1/2$: this would be the same as solving for stripes. For $i = 2$, we take $\theta = \tilde{\theta}$ and $d = 1$. For $i = 3$, we take $\theta = \pi + \tilde{\theta}$ and $d = 1$, where $\tilde{\theta} \in (0, \pi/2]$. The solutions $W_{2,i,n}$ satisfy

$$\begin{aligned}[i(n\omega+2\alpha) - C(D^2-2k^2(1+c))](D^2-2k^2(1+c))W_{2,i,n}(z) \\ = d\sum_{l+m=n}\big[4k^2s^2DW_{1,l}(z)W_{1,m}(z) - 2(1+c)D^3W_{1,l}(z)W_{1,m}(z) \\ +2(-1+c+2c^2)D^2W_{1,l}(z)DW_{1,m}(z)\big]\end{aligned} \tag{4.16}$$

at $z = -h/l$,

$$W_{2,i,n} = DW_{2,i,n} = 0, \tag{4.17}$$

while at $z = 0$ we have the kinematic condition and the tangential stress condition,

$$i(n\omega + 2\alpha)Z_{2,i,n} - W_{2,i,n} = 2d(1+c)\sum_{l+m=n} DW_{1,l}Z_{1,m}, \tag{4.18}$$

$$\begin{aligned}(D^2 + 2k^2(1+c))W_{2,i,n} = -d\sum_{l+m=n}\big[&2(1+c)Z_{1,l}D^3W_{1,m}\\ &+2(3+2c)(1+c)k^2Z_{1,l}DW_{1,m}\big],\end{aligned} \tag{4.19}$$

and the normal stress condition,

$$\begin{aligned}&\left[i(n\omega+2\alpha) + 6(1+c)Ck^2\right]DW_{2,i,n} - CD^3W_{2,i,n}\\ &\qquad +2k^2(1+c)(2B(1+c)k^2+1)Z_{2,i,n} = S_{1,i,n} - a_0k^2(1+c)Z_{2,f,i,n},\end{aligned} \tag{4.20}$$

where

$$\begin{aligned}S_{1,i,n} = d\sum_{l+m=n}\big[&2c(1+c)DW_{1,l}DW_{1,m}\\ &+4(1+c)k^2Z_{1,l}DP_{1,m} - 8(1+c)Ck^2Z_{1,l}D^2W_{1,m} - 2(1+c)W_{1,l}D^2W_{1,m}\big].\end{aligned}$$

For a single frequency,

$$Z_{2,f,i,n} = Z_{2,i,n-1} + Z_{2,i,n+1},$$

and for two frequencies,

$$Z_{2,f,i,n} = \cos(\chi)(Z_{2,i,n-M_1} + Z_{2,i,n+M_1}) + \sin(\chi)(e^{i\phi}Z_{2,i,n-M_2} + e^{-i\phi}Z_{2,i,n+M_2}). \tag{4.21}$$

Note that if there is no extra symmetry that suppresses it, then the resonant triad interaction at second order causes this calculation to blow up at $\theta = \pi/3$.

4.3. Linear adjoint problem. The adjoint problem is

$$\left[i(n\omega+\alpha) + C(D^2-k^2)\right](D^2-k^2)W_n^*(z) = 0, \tag{4.22}$$

with boundary conditions

$$W_n^* = DW_n^* = 0,$$

on $z = -h/l$, and on $z = 0$,

$$\left[i(n\omega+\alpha) - 3Ck^2\right]DW_n^* + CD^3W_n^* = Z_n^*, \tag{4.23}$$

$$(D^2+k^2)W_n^* = 0, \tag{4.24}$$

$$i(n\omega+\alpha)Z_n^* + k^2(Bk^2+1)W_n^* = -\frac{1}{2}a_0k^2W_{f,n}^*. \tag{4.25}$$

For a single frequency,

$$W_{f,n}^* = W_{n-1}^* + W_{n+1}^*,$$

and for two frequencies,

$$W_{f,n}^* = \cos(\chi)(W_{n-M_1}^* + W_{n+M_1}^*) + \sin(\chi)(e^{i\phi}W_{n-M_2}^* + e^{-i\phi}W_{n+M_2}^*).$$

4.4. Solvability condition for rectangles and stripes. The solvability condition is

$$\delta \frac{dA}{dT} = a_2 \beta A + \gamma A^3, \tag{4.26}$$

where $A \equiv A_S$ in Table 4.1 for stripes and $A \equiv A_R$ in Table 4.1 for rectangles and

$$\begin{aligned} \delta = \sum_{l,m}^{(1)} \Bigg[& -2 Z_l^* Z_{1,m} + 2 W_l^*(0) D W_{1,m}(0) \\ & + 2 \int_{-h/l}^{0} W_l^*(z) \Big(-D^2 W_{1,m}(z) + k^2 W_{1,m}(z) \Big) dz \Bigg]. \end{aligned} \tag{4.27}$$

For one frequency,

$$\beta = -k^2 \left[\sum_{l,m}^{(4)} W_l^*(0) Z_{1,m} + \sum_{l,m}^{(5)} W_l^*(0) Z_{1,m} \right], \tag{4.28}$$

and for two frequencies,

$$\begin{aligned} \beta = -k^2 \Bigg[& \cos(\chi) \left(\sum_{l,m}^{(6)} W_l^*(0) Z_{1,m} + \sum_{l,m}^{(7)} W_l^*(0) Z_{1,m} \right) \\ & + \sin(\chi) \left(\sum_{l,m}^{(8)} W_l^*(0) e^{i\psi} Z_{1,m} + \sum_{l,m}^{(9)} W_l^*(0) e^{-i\psi} Z_{1,m} \right) \Bigg]. \end{aligned} \tag{4.29}$$

The coefficient γ is given by the sum of three separate components corresponding to contributions from each of $W_{2,i,n}$ and $Z_{2,i,n}$. They may each be calculated from a single function $\gamma_i(\theta_s, d)$ by taking each of the three functions in turn and different θ_s and d. Specifically,

$$\gamma(\theta_s, d) = \gamma_1 \left(0, \frac{1}{2} \right) + \gamma_2(\theta_s, 1) + \gamma_3(\pi + \theta_s, 1).$$

The function γ_i is given in Appendix B.

4.5. Second order solvability condition for hexagons. The second order solvability condition for hexagons leads to the amplitude equation

$$\delta \frac{dA_H}{dT_1} = a_1 \beta A_H + \gamma_2 A_H^2, \tag{4.30}$$

and γ_2 is given by

$$\begin{aligned} \gamma_2 = & -2 \sum_{l,m,n}^{(2)} Z_l^* Z_{1,m} D W_{1,n}(0) \\ & - \sum_{l,m,n}^{(2)} W_l^*(0) \left[D W_{1,m}(0) D W_{1,n}(0) + 8 C k^2 Z_{1,m} D^2 W_{1,n}(0) \right] \\ & + \sum_{l,m,n}^{(2)} W_l^*(0) \left[4 k^2 Z_{1,m} D P_{1,n}(0) - 2 W_{1,m}(0) D^2 W_{1,n}(0) \right] \end{aligned}$$

$$-C\sum_{l,m,n}^{(2)} DW_l^*(0)Z_{1,m}\left[2D^3W_{1,n}(0)+4k^2DW_{1,n}(0)\right]$$
$$-\sum_{l,m,n}^{(2)}\int_{-h/l}^{0} W_l^*(z)\Big[W_{1,m}(z)(6k^2DW_{1,n}(z)-2D^3W_{1,n}(z))$$
$$-4DW_{1,m}(z)D^2W_{1,n}(z)\Big]\,dz. \tag{4.31}$$

4.6. Second order problem for hexagons. The second order problem for hexagons consists of $W_{2,1,n}(z) = W_{2,n}(z)$, which solves the same problem as that obtained for stripes, and $W_{2,2,n}$, which satisfies

$$[i(n\omega+2\alpha)-C(D^2-3k^2)](D^2-3k^2)W_{2,2,n}(z)$$
$$=\sum_{l+m=n}(3k^2W_{1,l}(z)DW_{1,m}(z)-3D^3W_{1,l}(z)W_{1,m}(z)).$$

At $z=-h/l$ we have $W_{2,2,n}=DW_{2,2,n}=0$, while at $z=0$ we have the kinematic condition and the tangential stress conditions, namely,

$$i(n\omega+2\alpha)Z_{2,2,n}-W_{2,2,n}=3\sum_{l+m=n}Z_{1,l}DW_{1,m},$$
$$(3k^2+D^2)W_{2,2,n}=-\sum_{l+m=n}\Big[3Z_{1,l}D^3W_{1,m}+12k^2Z_{1,l}DW_{1,m}\Big],$$

and the normal stress condition,

$$(i(n\omega+2\alpha)+9Ck^2)DW_{2,2,n}-CD^3W_{2,2,n}+3k^2(3Bk^2+1)Z_{2,2,n}$$
$$=S_{1,h,n}-\frac{3}{2}a_0k^2Z_{2,f,n},$$

where

$$S_{1,h,n}=\sum_{l+m=n}\left(\frac{3}{2}DW_{1,l}DW_{1,m}-12Ck^2Z_{1,l}D^2W_{1,m}\right.$$
$$\left.+6k^2Z_{1,l}DP_{1,m}-3W_{1,l}D^2W_{1,m}\right).$$

For a single frequency of excitation,

$$Z_{2,f,n}=Z_{2,2,n-1}+Z_{2,2,n+1},$$

and for two frequencies,

$$Z_{2,f,n}=\cos(\chi)(Z_{2,2,n-M_1}+Z_{2,2,n+M_1})+\sin(\chi)(e^{i\phi}Z_{2,2,n-M_2}+e^{-i\phi}Z_{2,2,n+M_2}).$$

4.7. Solvability condition for hexagons at third order. The solvability condition at third order problem takes the form

$$\delta\frac{dA_H}{dT}=a_2\beta A_H+\gamma_2A_H^2+(\gamma_1+\gamma_3)A_H^3, \tag{4.32}$$

where δ, β, and γ_1 are the same as for stripes, γ_2 is given by (4.31), and γ_3 is given in Appendix C.

5. Calculation of the coefficients of the amplitude equations. In section 4, we formulated a hierarchy of problems for the z dependence of the fluid parameters. In this section, we outline how we solve this sequence of problems and calculate the coefficients of the amplitude equations. We focus on the harmonic case, $\alpha = 0$, but the calculations for the subharmonic case are similar. We also note that using the transformation $\omega \to \omega/2$, $M_1 \to 2M_1$, $M_2 \to 2M_2$, the subharmonic case can be incorporated into the formulation for the harmonic problem. As explained in section 5.1, the calculations are substantially simpler in the specific case of an infinite layer, and while we have solved the linear problem for both the finite and infinite cases, we have calculated the coefficients of the amplitude equations only for infinite depth. We justify why this is a reasonable approximation for the specific fluid parameter choices we use when we discuss the results in section 6.

5.1. Linear problem. The general solution for $W_{1,n}(z)$ that satisfies (4.9) is

$$\begin{aligned} W_{1,0}(z) &= (a_{1,0} + zc_{1,0})e^{kz} + (b_{1,0} + zd_{1,0})e^{-kz}, \\ W_{1,n}(z) &= a_{1,n}e^{kz} + b_{1,n}e^{-kz} + c_{1,n}e^{q_{1,n}z} + d_{1,n}e^{-q_{1,n}z}, \qquad n \neq 0, \end{aligned} \tag{5.1}$$

where

$$q_{1,n}^2 = \frac{in\omega}{C} + k^2.$$

Applying the boundary conditions allows values for the coefficients $a_{1,n}$, $b_{1,n}$, $c_{1,n}$, and $d_{1,n}$ to be found. However, the subsequent analysis is substantially easier in the particular case of an infinite layer, where the lower boundary conditions are replaced with the requirement that the solution be bounded as $z \to -\infty$. In this case, $b_{1,n} = d_{1,n} = 0$, and it is this case we discuss below.

In order to find $a_{1,n}$ and $c_{1,n}$, they are expressed first in terms of $Z_{1,n}$ using the kinematic condition (4.11) and the tangential stress condition (4.12) to give

$$\begin{aligned} a_{1,0} &= 0, \\ a_{1,n} &= (in\omega + 2Ck^2)Z_{1,n}, \qquad n \neq 0, \\ c_{1,0} &= 0, \\ c_{1,n} &= -2Ck^2 Z_{1,n}, \qquad n \neq 0. \end{aligned} \tag{5.2}$$

Then the normal stress condition (4.13) is used to eliminate $W_{1,n}$ to give

$$\begin{aligned} k^2\left(Bk^2+1\right)Z_{1,0} &= -\frac{1}{2}a_0k^2Z_{1,f,0}, \qquad n = 0, \\ \left[k(2Ck^2+in\omega)^2 - 4C^2k^4q_{1,n} + k^2\left(Bk^2+1\right)\right]Z_{1,n} &= -\frac{1}{2}a_0k^2Z_{1,f,n}, \qquad n \neq 0. \end{aligned} \tag{5.3}$$

This is a generalized eigenvalue problem for a_0 of the form

$$\mathbf{AZ} = a_0\mathbf{BZ},$$

where $\mathbf{Z} = (Z_{1,0}, Z_{1,1}, \ldots, Z_{1,N})^T$. This generalized eigenvalue problem is the same as that solved in [15]. The minimum real positive eigenvalue a_0 gives the critical amplitude of onset of patterns, and the corresponding eigenvector gives the values for $Z_{1,n}$. Hence $W_{1,n}$ can be found from (5.2) and (5.1). These calculations and those that follow were carried out using MATLAB. For the majority of the harmonic calculations, we take $N = 20$, and for the subharmonic calculations, we take $N = 40$. Doubling the number of modes typically changed the results by less than 0.2%.

5.2. Linear adjoint problem. The general solution for the linear adjoint problem (4.22) for a fluid of infinite depth is

$$W_0^*(z) = (a_0^* + zc_0^*)e^{kz},$$
$$W_n^*(z) = a_n^* e^{kz} + c_n^* e^{q_n^* z}, \qquad n \neq 0,$$

where

$$q_n^{*\,2} = -\frac{in\omega}{C} + k^2.$$

Note that q_n^* is the complex conjugate of $q_{1,n}$. This can be solved analytically in terms of Z_n^* using the adjoint equivalents to the kinematic condition (4.23) and the tangential stress condition (4.24), and after some manipulation we find

$$Z_0^* = -2Ck^3 W_0^*(0),$$
$$Z_n^* = \frac{1}{ind_n\omega} W_n^*(0), \qquad n \neq 0, \tag{5.4}$$

where

$$d_n = \left(k(2Ck^2 - in\omega)^2 - 4C^2k^4 q_n^*\right)^{-1}.$$

Substitution of these expressions for Z_n^* into the normal stress condition (4.25) gives

$$k^2(Bk^2+1)W_0^*(0) = -\frac{1}{2}a_0^* k^2 W_{f,0}^*(0), \tag{5.5}$$
$$\left[k(2Ck^2 - in\omega)^2 - 4C^2k^4 q_n^* + k^2(Bk^2+1)\right] W_n^*(0) = -\frac{1}{2}a_0^* k^2 W_{f,n}^*(0), \qquad n \neq 0.$$

This results in a second generalized eigenvalue problem of the form

$$\mathbf{A}^*\mathbf{W}^* = a_0^*\mathbf{B}^*\mathbf{W}^*.$$

As expected, when we solve this, we find $a_0 = a_0^*$, and $W_n^*(0)$ is the complex conjugate of $Z_{1,n}$. Once W_n^* has been found, then Z_n^* follows from (5.4).

5.3. Second order problem for stripes and rectangles. Next, we consider the problem for $W_{2,i,n}(z)$, (4.16). The homogeneous equation has the solution

$$W_{2,i,0}(z) = (a_{2,i,0} + zc_{2,i,0})e^{\tilde{k}z},$$
$$W_{2,i,n}(z) = a_{2,i,n}e^{\tilde{k}z} + c_{2,i,n}e^{q_{2,i,n}z}, \qquad n \neq 0,$$

where

$$\tilde{k}^2 = 2(1+c)k^2,$$
$$q_{2,i,n}^2 = \frac{in\omega}{C} + \tilde{k}^2.$$

In the inhomogeneous equation (4.16), the right-hand side generates terms of the form $\alpha_{l,m}e^{Q_{l,m}z}$. Each of these contributes to the solution a term $\delta_{l,m}e^{Q_{l,m}z}$, where

$$\delta_{l,m} = \frac{\alpha_{l,m}}{\left(in\omega - C\left(Q_{l,m}^2 - \tilde{k}^2\right)\right)\left(Q_{l,m}^2 - \tilde{k}^2\right)}.$$

The general solution to (4.16) is therefore

$$W_{2,i,0}(z) = (a_{2,i,0} + c_{2,i,0}z)e^{\tilde{k}z} + \sum_{l+m=0} \delta_{l,m} e^{Q_{l,m}z},$$
$$W_{2,i,n}(z) = a_{2,i,n}e^{\tilde{k}z} + c_{2,i,n}e^{q_{2,i,n}z} + \sum_{l+m=n} \delta_{l,m} e^{Q_{l,m}z}, \qquad n \neq 0. \tag{5.6}$$

The coefficients $a_{2,i,n}$ and $c_{2,i,n}$ can be found in terms of $Z_{2,i,n}$, using the tangential stress condition (4.19) and the kinematic condition (4.18), to give

$$\begin{aligned} a_{2,i,n} &= \gamma_{1,i,n} Z_{2,i,n} + v_{1,i,n}, \\ c_{2,i,n} &= \gamma_{2,i,n} Z_{2,i,n} + v_{2,i,n}, \end{aligned} \tag{5.7}$$

where

$$\begin{aligned} &\gamma_{1,i,0} = 0, \\ &\gamma_{1,i,n} = (in\omega + 2C\tilde{k}^2), \qquad n \neq 0, \\ &\gamma_{2,i,0} = 0, \\ &\gamma_{2,i,n} = -2C\tilde{k}^2, \qquad n \neq 0, \end{aligned}$$

and

$$\begin{aligned} v_{1,i,0} &= S_{2,i,0}, \\ v_{1,i,n} &= \frac{C}{in\omega}\left(\left(\frac{in\omega}{C} + 2\tilde{k}^2\right) S_{2,i,n} - S_{3,i,n}\right), \qquad n \neq 0, \\ v_{2,i,0} &= \frac{1}{2\tilde{k}}\left(S_{3,i,0} - 2\tilde{k}^2 S_{2,i,0}\right), \\ v_{2,i,n} &= \frac{C}{in\omega}\left(-2\tilde{k}^2 S_{2,i,n} + S_{3,i,n}\right), \qquad n \neq 0, \end{aligned}$$

and

$$\begin{aligned} S_{2,i,n} &= -2(1+c)d \sum_{l+m=n} Z_{1,l} D W_{1,m} - \sum_{l+m=n} \delta_{l,m}, \\ S_{3,i,n} &= -d \sum_{l+m=n} \left(2(1+c) Z_{1,l} D^3 W_{1,m} + (3+2c)\tilde{k}^2 Z_{1,l} D W_{1,m}\right) \\ &\quad - \sum_{l+m=n} Q_{l,m}^2 \delta_{l,m} - \tilde{k}^2 \sum_{l+m=n} \delta_{l,m}. \end{aligned}$$

Substitution of the general solution (5.6) into the normal stress condition, (4.20), gives

$$\begin{aligned} \tilde{k}^2\left(B\tilde{k}^2 + 1\right) Z_{2,i,0} + \frac{1}{2} a_0 \tilde{k}^2 Z_{2,f,i,0} &= -2C\tilde{k}^3 S_{2,i,0} + S_{1,i,0} \\ &\quad -3C\tilde{k}^2 \sum_{l+m=0} Q_{l,m}\delta_{l,m} + C \sum_{l+m=0} Q_{l,m}^3 \delta_{l,m}, \end{aligned}$$

$$\Big(\tilde{k}(in\omega + 2C\tilde{k}^2)\gamma_{1,i,n} + 2C\tilde{k}^2 q_{2,i,n}\gamma_{2,i,n}$$
$$+\tilde{k}^2\left(B\tilde{k}^2+1\right)\Big) Z_{2,i,n} + \frac{1}{2}a_0\tilde{k}^2 Z_{2,f,i,n} = -\tilde{k}(in\omega + 2C\tilde{k}^2)v_{1,i,n} - 2C\tilde{k}^2 q_{2,i,n}v_{2,i,n}$$
$$+S_{1,i,n} - (in\omega + 3C\tilde{k}^2)\sum_{l+m=n} Q_{l,m}\delta_{l,m}$$
$$+C\sum_{l+m=n} Q^3_{l,m}\delta_{l,m}, \qquad n \neq 0.$$

This is of the form

$$\mathbf{A}\mathbf{Z}_2 = \mathbf{b},$$

where $\mathbf{Z}_2 = (Z_{2,i,0}, Z_{2,i,1}, \ldots, Z_{2,i,N})$. This can be solved for $Z_{2,i,n}$, and hence $W_{2,i,n}$ can be found from (5.7) and (5.6).

5.4. Solvability condition for stripes and rectangles. Once the calculations for the linear, linear adjoint, and second order problem have been completed, the coefficients for the solvability condition are calculated from (4.27), (4.28), (4.29), and (B.1).

5.5. Second order problem and solvability condition for hexagons. The linear and linear adjoint problems for hexagons are the same as for stripes and rectangles. Once Z_1, W_1, Z^*, and W^* are known, the size of the quadratic coefficient in the amplitude equation for hexagons may be computed from (4.31). The calculations of the second order solution and solvability condition at third order then follow in a very similar fashion to the calculation for rectangles: the same products appear but with different coefficients.

5.6. Evaluating the coefficients of the amplitude equations. In order to compute the stability of the patterns as given in Table 4.1, we need to calculate each of the cubic coefficients b_i that appear in the generic amplitude equations (4.1) along with the value of the quadratic coefficient $\tilde{\epsilon}$. From the calculations for rectangles, stripes, and hexagons this may be done as follows. The solvability condition for rectangles and stripes takes the form given in (4.26), that is,

$$\delta\frac{dA}{dT} = a_2\beta A + \gamma A^3. \tag{5.8}$$

The values of δ and β are independent of the type of pattern considered, but the value of γ is not. By comparing the amplitude equations with the equations given for each state given in Table 4.1, we see that when γ is computed in the case of stripes, it gives us the value for b_1. If the solvability condition is calculated for rectangles, then γ gives us $b_1 + b_4$, and hence the value of b_4 (and similarly b_5 and b_6) may be found. In the case of hexagons, the solvability condition takes the form

$$\delta\frac{\partial A_H}{\partial T} = a_2\beta A_H + \gamma_2 A_H^2 + (\gamma_1 + \gamma_3)A_H^3, \tag{5.9}$$

where δ, β, and γ_1 are the same as for stripes and γ_2 is given by (4.31) and γ_3 comes from (C.1). By comparing with the amplitude equation for hexagons given in Table 4.1, we see that γ_3 gives the value of $2b_2$. Note that while b_1 and b_2 are fixed for a given set of fluid parameters, the values of b_4, b_5, and b_6 depend on the lattice angle θ.

In the results we present in the next section, we rescale the amplitude equations by letting $A \mapsto \sqrt{|\beta/b_1|}A$, $A_H \mapsto \sqrt{|\beta/b_1|}A_H$, and $T \mapsto |\delta/\beta|$ so that the cubic coefficient for stripes b_1 in the rescaled equations is always ± 1.

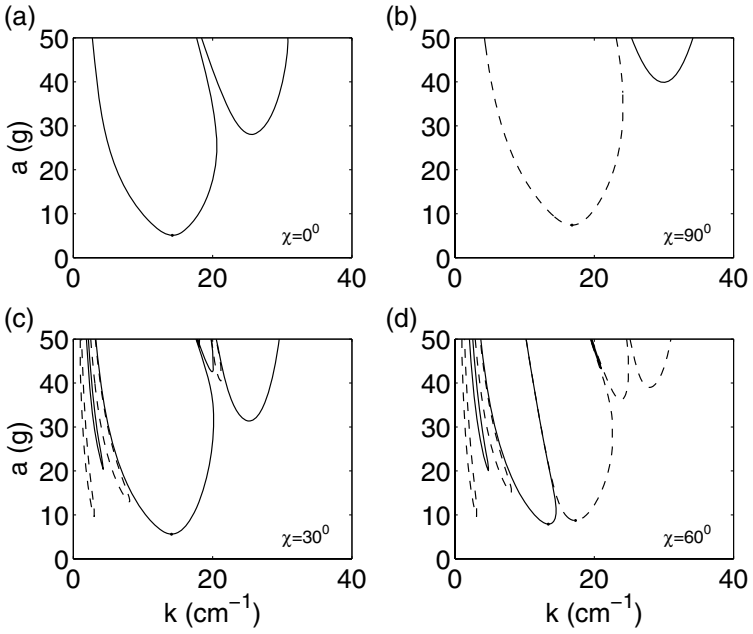

FIG. 6.1. *Linear stability curves for different values of* χ. $\rho = 0.95cm^{-3}$, $\nu = 20.9cS$, $\sigma = 20.6dyn/cm$. *Excitation is* $a(\cos\chi\cos M_1\omega t + \sin\chi\cos M_2\omega t)$ *with* $(M_1, M_2) = (4, 5)$, $\omega = 44\pi$. *Harmonic tongues are marked with solid lines and subharmonic tongues with dashed lines.*

6. Results. Here we present the results of our calculations for the particular fluid parameters used in the experimental results given in [4].

6.1. Linear stability results. First, the generalized eigenvalue problem (5.3) is solved, and this gives the critical amplitude as a function of k. Typical curves are shown in Figure 6.1. These are analogous to those computed by Besson, Edwards, and Tuckerman [15] but focus on the particular parameter values that are used by Kudrolli, Pier, and Gollub [4], namely $\rho = 0.95\text{cm}^{-3}$, $\nu = 20.9$cS, and $\sigma = 20.6$dyn/cm. Curves that have a subharmonic response with the excitation are indicated with dotted lines, and those that are harmonic are marked with a solid line. The critical onset occurs at the minimum value of a, and this occurs at a critical wavenumber k_c. For ease of comparison with the experimental results, the curves are plotted in dimensional rather than nondimensional units: with our choice of nondimensionalization, the value of k_c is always 1. The minimum value point is indicated by a dot. The richness of the dynamics that is seen with two-frequency forcing is partly due to the fact that the parameter χ allows one to tune between the critical value for a occurring for either a harmonic tongue, as is the case for $0^\circ < \chi < 60^\circ$, or a subharmonic tongue, as is the case for $60^\circ < \chi < 90^\circ$. There is a bicritical point that occurs when χ is approximately 60°. The phase ϕ has little impact on the position of the minimum value of the lowest tongue and therefore in the position of the bicritical point (changes in the position of the mimima are typically less than 0.001%). The phase does, however, alter the position of the tongues for some of the other harmonics.

Experimentally, it is the onset of patterns as a function of χ that is observed rather than the linear stability curves directly. In Figure 6.2, we show how the minimum of the linear stability curves varies with the relative importance of the amplitude of

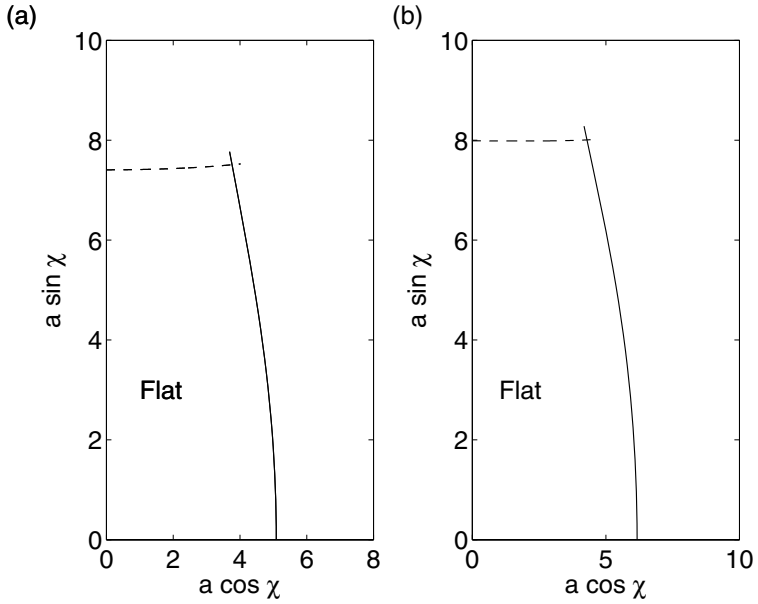

FIG. 6.2. *Path of a_0 as a function of χ.* (a) $(M_1, M_2) = (4, 5)$, $\phi = 16°$, *and* $\omega = 44\pi$; (b) $(M_1, M_2) = (6, 7)$, $\phi = 20°$, *and* $\omega = 32.88\pi$.

the two components of the excitation as given by $a\cos\chi$ and $a\sin\chi$. Two cases are shown: Figure 6.2(a) is for the same parameter values as for Figure 6.1. Figure 6.2(b) is for the same fluid parameters but different excitation parameters. These two cases correspond to the two cases considered in detail in Kudrolli, Pier, and Gollub, and the linear stability boundaries compare well with the corresponding experimental results shown in Figures 1 and 6 of their paper [4]. The bicritical point occurs for $\chi = 63.4$ in the case $(M_1, M_2) = (4, 5)$ and $\chi = 61.8$ when $(M_1, M_2) = (6, 7)$. These compare well with the value quoted by Kudrolli, Pier, and Gollub of $\chi = 61.5$.

As discussed in the introduction, high viscosity or shallow depth are used to damp modes with a small wavenumber that can make regular patterns hard to observe. The fluid used by Kudrolli, Pier, and Gollub was of moderate viscosity ($C \approx 0.4$ rather than $C \ll 1$). How "shallow" a container is depends on the product $k_c h$, in particular whether $e^{-k_c h}$ is negligible when compared with $e^{k_c h}$. For the Kudrolli–Pier–Gollub experiments, $h = 0.3$cm, giving $k_c \approx 14$ and $e^{-k_c h}/e^{k_c h} \approx 0.0002$. In the weakly nonlinear calculations, we shall see that it is not just the main harmonic tongue that is of importance but the weakly damped harmonic tongue that has a minimum at $k \approx 6\text{cm}^{-1}$. For this tongue, $e^{-k_c h}/e^{k_c h} \approx 0.03$. Since this is also small, we believe that an infinite depth approximation is reasonable. Consequently, in the nonlinear results that we present below, the calculations are performed only for infinite depth.

6.2. Single-frequency results ($\chi = 0°$ and $\chi = 90°$). The two-frequency excitation term we are interested in is of the form

$$f(t) = f_2(t) = \cos(\chi)\cos(M_1\omega t) + \sin(\chi)\cos(M_2\omega t + \phi).$$

When $\chi = 0°$ or $90°$, this reduces to a single-frequency excitation. When $\chi = 0°$, this corresponds to a pure M_1 excitation, and when $\chi = 90°$, this is a pure M_2 excitation.

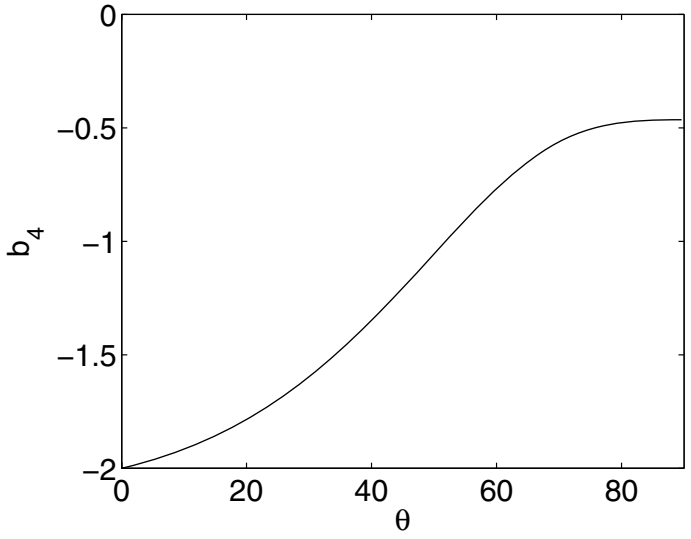

FIG. 6.3. *For* $(M_1, M_2) = (4, 5)$ *and* $\chi = 0°$ *the value of the coefficient* b_4 *as a function of the lattice angle* θ.

Since the two cases we consider have M_1 even and M_2 odd, the pure M_1 response is harmonic and the pure M_2 response is subharmonic. In each case, the overall picture is similar. The quadratic term in the amplitude equations is zero and we find the following:

- All the eigenvalues for hexagons given in Table 4.1 are negative for all values of the lattice angle θ. This suggests that hexagons are a stable state.
- Stripes and superlattice patterns have at least one unstable eigenvalue.
- Rectangular patterns are stable, on the lattice on which they occur, if they are "sufficiently square."

This last point may be seen by considering the eigenvalues of the family of rectangles $R_{h1,m,n}$ listed in Table 4.1. The eigenvalues $b_1 + b_4$, μ_1, and μ_2 are all negative. The remaining eigenvalue, $b_1 - b_4$, is negative only if the lattice angle θ is sufficiently large. In the case $(M_1, M_2) = (4, 5)$ and $\chi = 0°$ in Figure 6.3, we plot the scaled value of b_4 as a function of the lattice angle θ. Since in the scaled units $b_1 = -1$, $b_1 - b_4 < 0$ only if $\theta > 52°$. The aspect ratio of the rectangles is given by $\sqrt{(1 - \cos\theta)/(1 + \cos\theta)}$ so that stability for rectangles with $\theta > 52°$ means that rectangles with an aspect ratio between 0.48 and 1 are stable (on the lattice on which they occur).

By considering the eigenvalues on spatially periodic lattices alone, we find that both hexagons and rectangles are possible stable states. If we find the values of the Lyapunov function $\mathcal{F}$ (see Table 4.2) for hexagons and rectangles, then we find that those rectangles with an aspect ratio closest to 1 have the lowest value.

The results are similar for the three other single frequency cases that are relevant to the bifurcation sets shown in Figure 6.2, namely $(M_1, M_2) = (4, 5)$ and $\chi = 90°$ and $(M_1, M_2) = (6, 7)$ and $\chi = 0°$ or $\chi = 90°$. The conclusion is that the calculations for solutions on periodic lattices show that stripe patterns are unstable. Hexagons and "sufficiently square" rectangular patterns are relatively stable states with square patterns having the lowest value of the Lyapunov function. This suggests that square patterns will be observed at the points where $\chi = 0°$ and $\chi = 90°$. These square

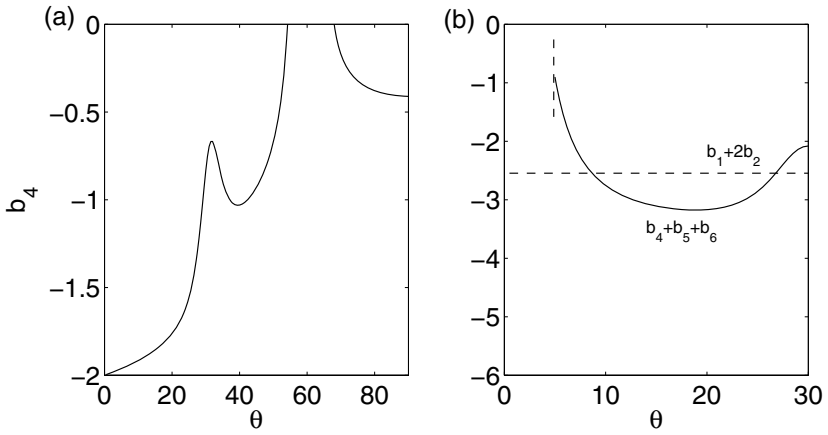

FIG. 6.4. $(M_1, M_2) = (4, 5)$ *and* $\chi = 60°$, $\phi = 20°$*:* (a) *The value of the coefficient* b_4 *as a function of the lattice angle* θ*. At* $\theta = 60°$ *quadratic resonance occurs, and the calculation for* b_4 *is not valid. For this reason, this point has been excluded from the calculation.* (b) *The value of the coefficient* $b_4 + b_5 + b_6$ *compared with* $b_1 + 2b_2$ *as a function of the lattice angle* θ*. Just as* b_4 *has a singularity at* $60°$*,* b_5 *has a singularity at* $0°$*, and so the region around* $0°$ *has been excluded.*

patterns will be harmonic when $\chi = 0°$ and subharmonic when $\chi = 90°$. This agrees with the experimental findings of Kudrolli, Pier, and Gollub.

Note that if we use the same parameter values as used by Chen and Viñals in [22] in their single-frequency study, then we get excellent agreement with their work.

6.3. Two-frequency results ($0 < \chi < 90°$). For two-frequency excitation, we have performed a systematic study of the coefficients $\tilde{\epsilon}$, b_1, b_2, b_3, b_4, b_5, and b_6 as a function of χ and the lattice angle θ for the same fluid parameters as used above and for the two cases $(M_1, M_2) = (4, 5)$ and $(M_1, M_2) = (6, 7)$. In the first case, most results are presented for $\phi = 16°$ and in the second case for $\phi = 20°$: these are the values for which the majority of the results in [4] are presented. We focus on the onset of harmonic patterns since along the subharmonic branch squares the absence of the quadratic term means that hexagons and rectangles remain the only stable states, with squares having the lowest energy.

From the values of the coefficients we have computed the stability of the different planforms based on the eigenvalues for each state given in Table 4.1 as a function of the lattice angle. If the eigenvalues indicate that the state is relatively stable, then we compute the value of the Lyapunov function, as given in Table 4.2.

When χ is zero, b_4 increases monotonically with θ, as shown in Figure 6.3. However, this changes as χ is increased and peaks develop. In Figure 6.4(a), we plot $b_4(\theta)$ for $(M_1, M_2) = (4, 5)$ and for $\chi = 60°$, $\phi = 16°$. The angle $\theta = 60°$ has been excluded because this corresponds to the quadratic resonance point, and the calculation for rectangles breaks down here. From Table 4.1 it can be seen that for superlattice patterns to become stable, one needs $b_4 + b_5 + b_6 - b_1 - 2b_2 > 0$. This same quantity causes the destabilization of hexagons. In Figure 6.4(b), we plot $b_4 + b_5 + b_6$ along with $b_1 + 2b_2$. For most values of θ, and so on most lattices, $b_4 + b_5 + b_6 - b_1 - 2b_2 < 0$, and superlattice patterns are unstable. However, the peak in $b_4(\theta)$ at $31.8°$ leads to a small region centered at $30°$ for which $b_4 + b_5 + b_6 - b_1 - 2b_2 > 0$, and it is possible for superlattice patterns to be stable.

The corresponding graphs of b_4 and $b_4 + b_5 + b_6$ for $(M_1, M_2) = (6, 7)$ are

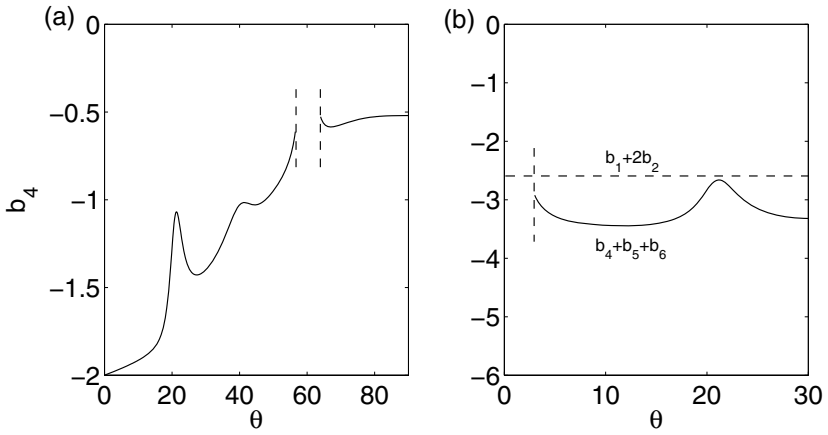

FIG. 6.5. $(M_1, M_2) = (6, 7)$ *and* $\chi = 60°$*:* (a) *The value of the coefficient* b_4 *as a function of the lattice angle* θ*;* (b) *the value of the coefficient* $b_4 + b_5 + b_6$ *compared with* $b_1 + 2b_2$ *as a function of the lattice angle* θ*.*

shown in Figure 6.5. In this case, there is a peak in b_4 at 21.2°, and this leads to a peak in $b_4 + b_5 + b_6$ with a maximum at 21.2°. Note that even at $\chi = 60°$, $b_4 + b_5 + b_6 - b_1 - 2b_2 < 0$, and all superlattice patterns are unstable. It is only once, $\chi > 61°$, that stable superlattice patterns occur, the first to stabilize being those that occur on a lattice with lattice angle $\theta = 21.2°$.

We have shown for $\chi = 0°$ that both hexagons and rectangles may be stable with rectangles having the lowest value of the Lyapunov function. Figure 6.4 suggests that in the case $(M_1, M_2) = (4, 5)$, stable superlattice patterns may occur for $\chi = 60°$. In Figure 6.6(a), we show a bifurcation set that summarizes the regions where different states are stable for the λ, χ plane. Note that hexagons are a planform that exists on all the hexagonal lattices and so that where hexagons are shown as stable they are stable to perturbations on all hexagonal lattices. Where they are unstable, there is at least one lattice on which they are unstable. The peak in $b_4(\theta)$ at 30° means that the maximal region of instability for hexagons occurs as $\theta_h \to 30°$. For rectangles and superlattices, the story is more complicated. Different lattices support different superlattice patterns and different rectangles. Since it is on lattices with $\theta \to 30°$ that hexagons become unstable first (and superlattices onset first), we plot the regions for the stability of rectangles and superlattice patterns for the specific case $\theta = 30°$.

At the actual value of $\theta = 30°$ the center manifold reduction that leads to the amplitude equations is not formally valid, as discussed in [24], and the "superlattice patterns" are in fact quasipatterns. However, in practical terms, there is little real difference between taking a periodic lattice that has a lattice angle close to 30° and taking 30° itself: although on the periodic lattice the amplitude equations may be formally justified, the spectral gap between critical and noncritical eigenvalues will be small, and thus the formal region of validity for the center manifold is likely to be small. Visually, it is impossible to distinguish between a quasipattern and a superlattice pattern with a very large lengthscale. Similarly, the regions of stability would be indistinguishable whether we took $\theta = 30°$ or a value of θ close to 30° that results in a spatially periodic lattice.

As shown in Figure 6.6(a), for most values of λ and χ, there is bistability where more than one pattern is stable. In Figure 6.6(b), we show which of the stable

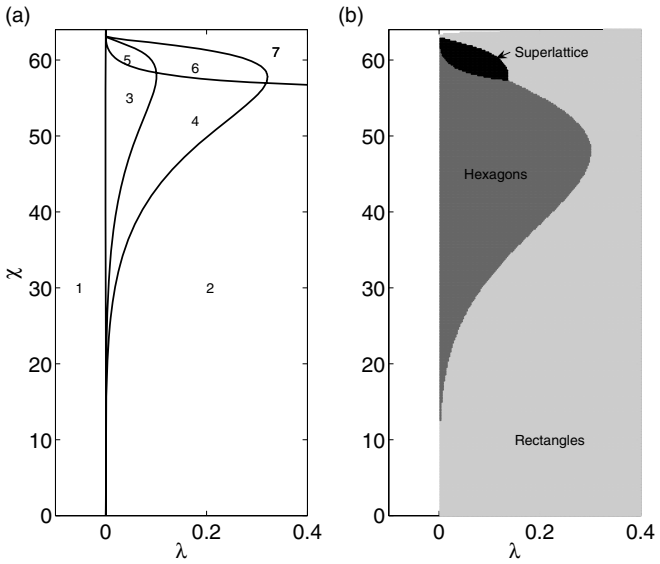

FIG. 6.6. *Results in the λ, χ plane for $(M_1, M_2) = (4, 5)$ and $\phi = 16°$.* (a) *Eigenvalue results. Black: superlattice patterns. Dark grey: hexagons. Light grey: rectangles.*

patterns has the lowest value of the Lyapunov function. What we find is that, for small values of χ, rectangles and hexagons are both stable, with rectangles being the most stable state. Note that it is the $R_{h3,m,n}$ rectangles that are stable, and as $\theta \to 30°$, the aspect ratio of these particular rectangles tends to 1. As χ increases, the value of $\tilde{\epsilon}$ increases from zero, and this results in the destabilization of the rectangles so that hexagons become the preferred state at onset. Near the bicritical point, hexagons are themselves destabilized to superlattice patterns, and there are regions where superlattice patterns are the only stable state. A typical bifurcation diagram for $(M_1, M_2) = (4, 5)$ at $\chi = 60°$ is shown in Figure 6.7. Note that the values of $\tilde{\epsilon}$ are small so that higher order correction terms for the position of the secondary bifurcation points are unlikely to affect the overall qualitative bifurcation sequence.

The analogous bifurcation set and energy diagram for the case $(M_1, M_2) = (6, 7)$ are shown in Figure 6.8. In this case, the lattice angle $\theta = 21.2°$ has been used since in the case $(6, 7)$, it is on this lattice that hexagons are destabilized first. On this lattice, the stable rectangles have aspect ratio 0.86. The overall picture is similar to that for $(4, 5)$ but with the transitions from rectangle to hexagon and hexagon to superlattice pattern occurring for larger values of χ.

Figures 6.6 and 6.8 compare well with the experimental results of Kudrolli, Pier, and Gollub. As is suggested by our results, they find that rectangles are stable for low values of χ giving way to hexagons as χ is increased. As for our theoretical results, the transition from rectangles to hexagons occurs for higher values of χ in the $(6, 7)$ case than in the $(4, 5)$ case. In both cases, there are superlattice/quasipatterns near the bicritical point.

Kudrolli, Pier, and Gollub also investigated the dependence of their results on the

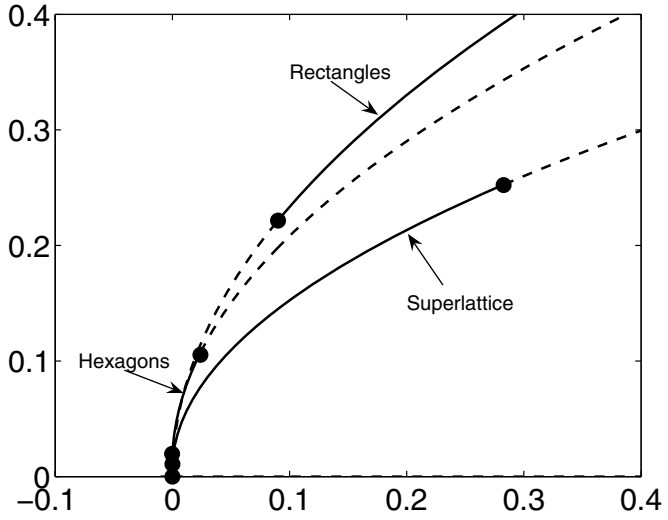

FIG. 6.7. *Bifurcation diagram for* $(M_1, M_2) = (4, 5)$ *and* $\chi = 60°$, $\phi = 16°$. *Stable branches are shown by a solid line and unstable lines by a dotted line. Only branches where some part is stable are shown.*

phase ϕ for $\chi = 61°$. In the $(6, 7)$ case, they found relatively little phase dependence. In the $(4, 5)$ case, they found that the largest region of superlattice patterns was for angles of ϕ close to $16°$, but they also found that for some values of ϕ there were

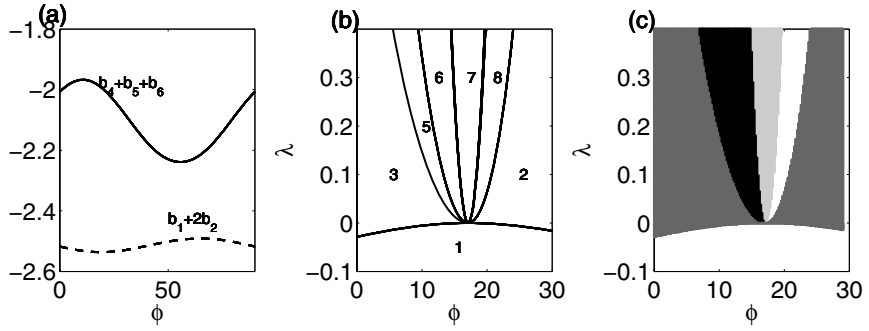

FIG. 6.9. $(M_1, M_2) = (4, 5)$, $\chi = 61°$, $\theta = 30°$: (a) *Dependence of* $b_1 + 2b_2$ *and* $b_4 + b_5 + b_6$ *on* ϕ. no stable states near onset and for others the hexagons bifurcated to a pattern they called superlattice II. We cannot hope to capture this latter transition in our study since these patterns are time periodic and our amplitude equations have a gradient structure. A theoretical explanation for these patterns was given in [31]. Nevertheless, we illustrate how the phase does effect our results in Figure 6.9 for $(4, 5)$ and $\chi = 61°$. First, in Figure 6.9(a), the quantities $b_1 + 2b_2$ and $b_4 + b_5 + b_6$ are shown. These are $\pi/2$ periodic functions of ϕ. The consequence is that the regions of stability of different patterns depend on ϕ, as shown by the bifurcation set in Figure 6.9(b) and the corresponding plot of the Lyapunov function in Figure 6.9(c) for the angle $\theta = 30°$. These show that it is for phases close to 16° that stable superlattice patterns occur closest to onset. We also find values of the phase for which there are no stable spatially periodic pattern near onset (the white wedge region in Figure 6.9).

Overall, the results of Figures 6.4 through 6.8 show that the cases $(M_1, M_2) = (4, 5)$ and $(M_1, M_2) = (6, 7)$ are broadly similar. The experimental results show similar bifurcation sequences in both cases but very different forms for the planforms: in the case $(6, 7)$, superlattice patterns are observed with an easily visible regular periodic structure with two wavelengths. In [4], these are referred to as superlattice-I patterns. In the $(4, 5)$ case, quasipatterns are observed. The key difference in the two cases is the lattice angle for which stable superlattice patterns are possible. In [18], it was argued that the stabilization of the superlattice-I patterns followed from a resonant triad formed by the harmonic tongue with one of the weakly damped harmonic tongues. This was supported by a peak in the value of the rhombic coefficient (b_4 here) at around 22° for the Zhang–Vinãls model. In Figures 6.5 and 6.8, we have seen that the same mechanism operates in the full Navier–Stokes equations. Furthermore, it is the same fundamental mechanism that is at play in the $(4, 5)$ case, as shown in Figures 6.4 and 6.6, where now it is a peak in b_4 at 32.8° which is significant. This peak can again be traced to a resonant triad between the main harmonic mode and the first (that is, smallest k) weakly damped harmonic mode. The consequence is that while the analysis for the $(6, 7)$ case suggests that a superlattice pattern with angle close to 21.2°, such as that shown in Figure 6.10(a), will occur, for the $(4, 5)$ case a superlattice pattern/quasipattern with angle close to 30°, such as that shown in Figure 6.10(b), will occur.

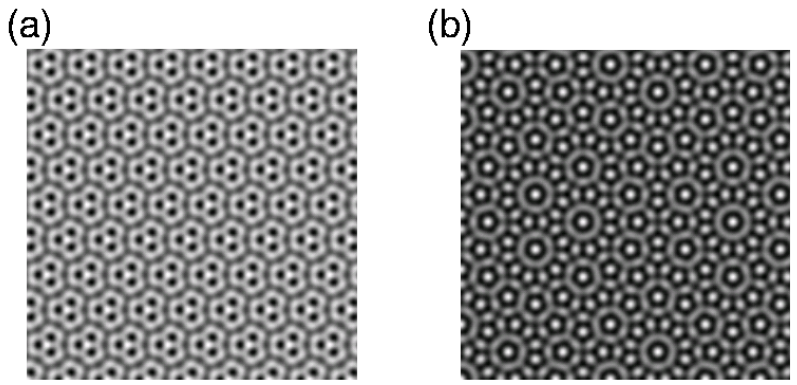

FIG. 6.10. *Typical superlattice patterns. Superlattice patterns have the form* $\mathbf{z} = (A_{SH}, A_{SH}, A_{SH}, A_{SH}, A_{SH}, A_{SH})$*; the associated planform has the form* $A_{SH}(\cos(\mathbf{K_{1_h}} \cdot \mathbf{r} + \psi) + \cos(\mathbf{K_{2_h}} \cdot \mathbf{r} + \psi) + \cos(\mathbf{K_{3_h}} \cdot \mathbf{r} + \psi) + \cos(\mathbf{K_{4_h}} \cdot \mathbf{r} + \psi) + \cos(\mathbf{K_{5_h}} \cdot \mathbf{r} + \psi) + \cos(\mathbf{K_{6_h}} \cdot \mathbf{r} + \psi))$*, where* $\mathbf{r} = (x, y)$*.* (a) *For* $\theta \approx 21.2^\circ$*,* $\psi = 2\pi/3$*.* (b) *For* $\theta \approx 30^\circ$*,* $\psi = 0$*. The superlattice pattern for* $\psi = 0$ *has a hexagonal rather than a triangular symmetry. Of these two states, only one is stable, but which one is not determined at cubic order. The experimental patterns for the* $(6, 7)$ *case clearly show a triangular structure, and it was this that motivated the theoretical work of* [27] *on the* $\psi = 2\pi/3$ *superlattice pattern.*

Note that there is a peak in the value of the coefficient b_4 for values of χ far from the bicritical point. For example, there is still a distinct peak in b_4 at approximately 21° for $\chi = 30^\circ$ in the $(4, 5)$ case. This can be related to the fact that the weakly damped harmonic tongue involved in the triad resonance is still prominent, as seen in Figure 6.1(c). However, it is only near the bicritical point that $b_4 + b_5 + b_6 - b_1 - 2b_2$ becomes positive, allowing superlattice patterns to stabilize.

7. Conclusion. In this paper, we have derived the form of the weakly nonlinear problem for a finite depth of fluid that is subject to a vertical oscillation from the full Navier–Stokes equations. Using the ideas of symmetry for patterns that tessellate the plane, we have found the coefficients of the amplitude equations and calculated the consequences for stability of different spatially periodic patterns in the infinite depth case. We have focused on the particular parameters that were used in experimental results presented in [4]. Good agreement has been found between the predictions of the weakly nonlinear analysis and the experimental results, without the use of any fitted parameters.

In the future, there are many interesting questions relating to regular patterns in the Faraday problem that we plan to use our method to explore. Our current code will allow us to perform a careful comparison between the Zhang–Viñals equations and the full Navier–Stokes equations for varying viscosity. We will also be able to investigate how the coefficients of the amplitude equations scale with the different parameters and compare with the scaling arguments given in [20] for multiple frequency forcing. This will enable us to see the degree to which the arguments for the control of patterns through multiple frequency in the weak viscosity case carry over to moderate and large viscosity. (With our formulation, it is straightforward to include more than two frequency components.)

The solvability condition is valid for both finite and infinite depth, although our subsequent calculations were carried out only for infinite depth. Our future plans also include coding up the finite depth case. This will allow us to explore how the coef-

ficients vary with depth and enable comparison with experimental results in shallow containers to be made.

Meanwhile, the Faraday wave experiment continues to be a rich source for striking and intriguing patterns, as shown by the recent results of Epstein and Fineberg [32].

Appendix A. Form for the horizontal components of the velocity. The form of the horizontal velocity components can be derived from the form of the vertical velocity and equations (2.1). Hence, the horizontal velocity components for rectangles at first order are

$$u_1 = \frac{iA_R}{k}[e^{ikx} + ce^{ik(cx+sy)} - c.c.]\sum_n DW_{1,n}(z)e^{i(n\omega+\alpha)\tau},$$
$$v_1 = \frac{isA_R}{k}[e^{ik(cx+sy)} - c.c.]\sum_n DW_{1,n}(z)e^{i(n\omega+\alpha)\tau}.$$

Horizontal velocity components for rectangles at second order are

$$\begin{aligned}
u_2 = {} & \frac{i}{2k}A_R^2[e^{2ikx} + ce^{2ik(cx+sy)} - c.c.]\sum_n DW_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& + \frac{i}{2k}A_R^2[e^{ik[(1+c)x+sy]} - c.c.]\sum_n DW_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& + \frac{i}{2k}A_R^2[e^{ik[(1-c)x-sy]} - c.c.]\sum_n DW_{2,3,n}(z)e^{i(n\omega+2\alpha)\tau}, \\
v_2 = {} & \frac{is}{2k}A_R^2[e^{2ik(cx+sy)} - c.c.]\sum_n DW_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& + \frac{is}{2k(1+c)}A_R^2[e^{ik[(1+c)x+sy]} - c.c.]\sum_n DW_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& - \frac{is}{2k(1-c)}A_R^2[e^{ik[(1-c)x-sy]} - c.c.]\sum_n DW_{2,3,n}(z)e^{i(n\omega+2\alpha)\tau}.
\end{aligned}$$

Horizontal velocity components for hexagons at first order are

$$u_1 = \frac{iA_H}{k}\left[e^{ikx} - \frac{1}{2}e^{ik(-x+\sqrt{3}y)/2} - \frac{1}{2}e^{ik(-x-\sqrt{3}y)/2} - c.c.\right]\sum_n DW_{1,n}(z)e^{i(n\omega+\alpha)\tau},$$
$$v_1 = \frac{i\sqrt{3}A_H}{2k}[e^{ik(-x+\sqrt{3}y)/2} - e^{ik(-x-\sqrt{3}y)/2} - c.c.]\sum_n DW_{1,n}(z)e^{i(n\omega+\alpha)\tau}.$$

Horizontal velocity components for hexagons at second order are

$$\begin{aligned}
u_2 = {} & \frac{iA_H^2}{2k}\left[e^{2ikx} - \frac{1}{2}e^{ik(-x+\sqrt{3}y)} - \frac{1}{2}e^{ik(-x-\sqrt{3}y)} - c.c.\right]\sum_n DW_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& + \frac{iA_H^2}{2k}[e^{ik(3x+\sqrt{3}y)/2} + e^{ik(3x-\sqrt{3}y)/2} - c.c.]\sum_n DW_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau}, \\
v_2 = {} & \frac{i\sqrt{3}A_H^2}{4k}[e^{ik(-x+\sqrt{3}y)} - e^{ik(-x-\sqrt{3}y)} - c.c.]\sum_n DW_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau} \\
& + \frac{iA_H^2}{\sqrt{3}k}\left[e^{ik\sqrt{3}y} + \frac{1}{2}e^{ik(3x+\sqrt{3}y)/2} - \frac{1}{2}e^{ik(3x-\sqrt{3}y)/2} - c.c.\right]\sum_n DW_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau}.
\end{aligned}$$

$$\sum_{l,m}^{(6)} = \begin{cases} l+m+M_1=0 \quad (\alpha=0), \\ l+m+M_1+1=0 \quad (\alpha=\omega/2), \end{cases}$$

$$\sum_{l,m}^{(7)} = \begin{cases} l+m-M_1=0 \quad (\alpha=0), \\ l+m-M_1+1=0 \quad (\alpha=\omega/2), \end{cases}$$

$$\sum_{l,m}^{(8)} = \begin{cases} l+m+M_2=0 \quad (\alpha=0), \\ l+m+M_2+1=0 \quad (\alpha=\omega/2), \end{cases}$$

$$\sum_{l,m}^{(9)} = \begin{cases} l+m-M_2=0 \quad (\alpha=0), \\ l+m-M_2+1=0 \quad (\alpha=\omega/2). \end{cases}$$

Note that terms involving the derivative of the pressure with respect to z appear in the solvability condition. These may be computed from the flow variables, as discussed in Appendix D.

Appendix C. Cubic coefficient for hexagons.

$$\begin{aligned}
\gamma_3 = &\sum_{l,m,n}^{(2)} Z_l^* \left(2DW_{1,m}(0)Z_{2,2,n} - 2Z_{1,m}DW_{2,2,n}(0)\right) \\

&\qquad\qquad \left. +6Bk^4Z_{1,j}\right)
\end{aligned}$$

$$
\begin{aligned}
&-C\sum_{l,m,n,j}^{(3)} DW_l^*(0)Z_{1,m}Z_{1,n}\left(24k^2D^2W_{1,j}(0)+4D^4W_{1,j}(0)\right)\\
&-\sum_{l,m,n}^{(2)}\int_{-h/l}^{0} W_l^*(z)\left(10k^2DW_{1,m}(z)W_{2,2,n}(z)+6k^2W_{1,m}(z)DW_{2,2,n}(z)\right)\\
&+4\sum_{l,m,n}^{(2)}\int_{-h/l}^{0} W_l^*(z)DW_{1,m}(z)D^2W_{2,2,n}(z)\\
&+\sum_{l,m,n}^{(2)}\int_{-h/l}^{0} W_l^*(z)\left(2W_{1,m}(z)D^3W_{2,2,n}(z)-2D^3W_{1,m}(0)W_{2,2,n}(z)\right). \qquad \text{(C.1)}
\end{aligned}
$$

Appendix D. A posteriori computation of the pressure. We compute the pressure from the Navier–Stokes equations. As we need only the derivative of the pressure with respect to z, we need only consider the third component of the Navier–Stokes equations:

$$\partial_z p = -\partial_t w + C\Delta w - \mathbf{u}\cdot\nabla w. \qquad \text{(D.1)}$$

At the first order this reduces to

$$\partial_z p_1 = -\partial_\tau w_1 + C\Delta w_1, \qquad \text{(D.2)}$$

and then we can take $\partial_z p_1$ in the form

$$\partial_z p_1 = A_S(e^{ikx}+e^{-ikx})\sum_n DP_{1,n}(z)e^{i(n\omega+\alpha)\tau}, \qquad \text{(D.3)}$$

or the equivalent form for rectangles and hexagons, where $DP_{1,n}(z)$ solves

$$DP_{1,n}(z) = [-i(n\omega+\alpha)+C(D^2-k^2)]W_{1,n}(z). \qquad \text{(D.4)}$$

At the second order we have

$$\partial_z p_2 = -\partial_\tau w_2 + C\Delta w_2 - \mathbf{u}_1\cdot\nabla w_1 - \partial_{T_1} w_1. \qquad \text{(D.5)}$$

The solution for the rectangular pattern does not depend on T_1. Here we take $\partial_z p_2$ in the form

$$
\begin{aligned}
\partial_z p_2 = {}& A_R^2[e^{2ikx}+e^{2ik(cx+sy)}+c.c.]\sum_n DP_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&+A_R^2[e^{ik[(1+c)x+sy]}+c.c.]\sum_n DP_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&+A_R^2[e^{ik[(1-c)x-sy]}+c.c.]\sum_n DP_{2,3,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&+A_R^2\sum_n DP_{2,4,n}(z)e^{i(n\omega+2\alpha)\tau},
\end{aligned}
$$

where

$$DP_{2,1,n}(z) = [-i(n\omega+2\alpha)+C(D^2-4k^2)]W_{2,1,n}(z),$$

$$
\begin{aligned}
DP_{2,2,n}(z) &= [-i(n\omega+2\alpha)+C(D^2-2(1+c)k^2)]W_{2,2,n}(z)\\
&\quad -2(1-c)\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z),\\
DP_{2,3,n}(z) &= [-i(n\omega+2\alpha)+C(D^2-2(1-c)k^2)]W_{2,3,n}(z)\\
&\quad -2(1+c)\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z),\\
DP_{2,4,n}(z) &= -8\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z).
\end{aligned}
$$

In the hexagonal pattern, the solution depends on both T_1 and T_2. We take the pressure as the sum of two terms:

$$\partial_z p_2 = \partial_z \hat{p}_2 + \partial_z \tilde{p}_2,$$

where $\hat{p}_z$ solves

$$\partial_z \hat{p}_2 = -\partial_\tau w_2 + C\Delta w_2 - \mathbf{u}_1\cdot\nabla w_1, \tag{D.6}$$

while $\tilde{p}_z = -\partial_{T_1} w_1$. We take $\hat{p}_z$ in the form of a hexagonal pattern:

$$
\begin{aligned}
\partial_z \hat{p}_2 &= A_H^2[e^{ikx}+e^{ik(-x+\sqrt{3}y)/2}+e^{ik(-x-\sqrt{3}y)/2}+c.c.]\sum_n DP_{2,0,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&\quad +A_H^2[e^{2ikx}+e^{ik(-x+\sqrt{3}y)}+e^{ik(-x-\sqrt{3}y)}+c.c.]\sum_n DP_{2,1,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&\quad +A_H^2[e^{ik\sqrt{3}y}+e^{ik(3x+\sqrt{3}y)/2}+e^{ik(3x-\sqrt{3}y)/2}+c.c.]\sum_n DP_{2,2,n}(z)e^{i(n\omega+2\alpha)\tau}\\
&\quad +A_H^2\sum_n DP_{2,3,n}(z)e^{i(n\omega+2\alpha)\tau},
\end{aligned}
$$

where

$$
\begin{aligned}
DP_{2,0,n}(z) &= -3\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z),\\
DP_{2,1,n}(z) &= [-i(n\omega+2\alpha)+C(D^2-4k^2)]W_{2,1,n}(z),\\
DP_{2,2,n}(z) &= [-i(n\omega+2\alpha)+C(D^2-3k^2)]W_{2,2,n}(z)\\
&\quad -\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z),\\
DP_{2,3,n}(z) &= -12\sum_{(l+m=n)} W_{1,l}(z)DW_{1,m}(z).
\end{aligned}
$$

Acknowledgments. We have benefited from discussions with a number of people during the course of writing this paper, including Paul Matthews, Alastair Rucklidge, and José Vega. We are very grateful to Peilong Chen for letting us use his code to compare our work with his and to the anonymous referees, who made a number of helpful suggestions.

LOCATING TRANSPARENT REGIONS IN OPTICAL ABSORPTION AND SCATTERING TOMOGRAPHY*

NUUTTI HYVÖNEN†

Abstract. The aim of optical absorption and scattering tomography is to reconstruct the optical properties inside a physical body, e.g., a neonatal head, by illuminating it with near-infrared light and measuring the outward flux of photons on the object boundary. Because brain consists of strongly scattering tissue with imbedded cavities filled by weakly scattering cerebrospinal fluid, propagation of near-infrared photons in the human head can be treated by combining the diffusion approximation of the radiative transfer equation with geometrical optics to obtain the radiosity-diffusion forward model of optical tomography. Currently, a disadvantage with the radiosity-diffusion model is that the locations of the transparent cavities must be known in advance in order to be able to reconstruct the physiologically interesting quantities, i.e., the absorption and the scatterer in the strongly scattering brain tissue. In this work we show, both theoretically and numerically, that under suitable conditions the factorization method of Andreas Kirsch can be used for locating the transparent cavities through the boundary measurements of optical tomography if the background optical properties of the strongly scattering tissue are known.

1. Introduction.

In optical absorption and scattering tomography (OAST), a physical body is illuminated with a flux of near-infrared (NIR) photons and the outward flux is measured on the surface of the body. The idea is to reconstruct the optical properties, such as absorption and scatter, inside the body by using the measured pairs of input and output fluxes. OAST has a few possible clinical applications, the most important of which are, arguably, screening for breast cancer and the development of a cerebral imaging modality for mapping structure and function in newborn infants, and possibly adults too. For more medical and instrumental details we refer to the articles [2, 3, 5, 14, 16].

In a strongly scattering medium, e.g., brain tissue, propagation of NIR photons can be modeled to a good extent by the diffusion approximation of the radiative transfer equation (RTE) [2]. Since the diffusion approximation is not valid in weakly scattering regions [4, 11], e.g., in cavities that are filled with nearly transparent cerebrospinal fluid, some other approximation of the RTE is also needed when building up the forward model of OAST for the human head. By combining the diffusion approximation with geometrical optics, one obtains the radiosity-diffusion forward model [19, 29], which takes into account the effect of the weakly scattering regions.

As noted in [14], a disadvantage with the current implementation of the radiosity-diffusion model is that the boundaries of the transparent cavities must be known in advance when solving the actual inverse problem of OAST, i.e., reconstructing the absorption and the scatter in the strongly scattering tissue. If an anatomical

magnetic resonance image is available, it is possible to segment the head into diffusive and transparent regions and proceed by reconstructing the optical properties in the diffusive region within the framework of the radiosity-diffusion model [14]. However, if there is no such a priori information on the locations of the transparent cavities, the natural way to solve the inverse problem of OAST is to locate the cavities and reconstruct the optical properties of the diffusive region simultaneously. In this work we tackle a preliminary simplified version of this inverse problem: We assume that the absorption and the scatter in the diffusive region of the examined body are known and try locate the transparent regions through boundary measurements. Notice that this is not an easy task for a state-of-the-art iterative Newton-type algorithm based on the output least squares formulation of the inverse problem (cf. [2, 14]) since differentiating the measurement mappings with respect to the shape of the transparent region is difficult (cf. [19, 29]).

The factorization method, introduced originally within inverse obstacle scattering by Kirsch [25], provides a tool that can be used for locating inhomogeneities in a diffusive background in noniterative fashion. The factorization technique has already been applied to electrical impedance tomography in [7, 8, 20] and to OAST with strongly scattering inclusions in [21, 23] and with thin transparent layers in [6] (see also [13]). In this work, we will use the factorization method to obtain a conditional characterization of the transparent cavities via boundary measurements. Based on this theoretical work, we will formulate a reconstruction algorithm and test it numerically with two-dimensional simulated data.

This text is organized as follows. In section 2, we introduce the radiosity-diffusion model. Since our formulation differs slightly from the material in some of the references, we do not use mere citations but provide the most essential details, as well. Section 3 introduces and proves the conditional characterization result. In section 4, we interpret the theoretical work of section 3 as a reconstruction algorithm and test it numerically with simulated data. Section 5 contains some concluding remarks.

2. Radiosity-diffusion model. Propagation of electromagnetic radiation in a medium is governed by Maxwell's equations. In particular, this holds for the case of interest to us, namely, NIR light traveling through some biological tissue. However, since the radiation within a strongly scattering medium is completely incoherent and the wavelength of NIR light is small compared to the characteristic distances of human tissue, the exact models are totally useless. Therefore, we will model light propagation by using approximations of the radiative transfer equation, also known as the Boltzmann equation. Because the human brain consists of strongly scattering tissue with weakly scattering cavities filled by cerebrospinal fluid [3, 28], our aim is to treat these two extremes separately and then bundle the models together to obtain the so-called radiosity-diffusion forward problem [3, 11, 12].

We begin our work with a short glance at transport theory. Let $\Omega \subset \mathbb{R}^n$, $n = 2, 3$, be a bounded body with a smooth enough boundary. The radiation flux density at $x \in \Omega$ at time $t \in \mathbb{R}$ to the infinitesimal solid angle ds in direction $\hat{\theta} \in S^{n-1}$ is written as

$$d\vec{J}(x, t, \hat{\theta}) = I(x, t, \hat{\theta})\hat{\theta} ds(\hat{\theta}),$$

where the amplitude $I(x, t, \hat{\theta})$ is called the radiance. In the framework of transport theory, this scalar function satisfies the RTE

$$\frac{1}{c}I_t(x,t,\hat{\theta}) + \hat{\theta}\cdot\nabla I(x,t,\hat{\theta}) + (\mu_a(x)+\mu_s(x))I(x,t,\hat{\theta}) - \mu_s(x)\int_{S^{n-1}} f(x,\hat{\theta},\hat{\omega})I(x,t,\hat{\omega})ds(\hat{\omega}) = q(x,t,\hat{\theta}), \tag{2.1}$$

where c is the speed of light (assumed to be constant), the positive scalar functions μ_a and μ_s are the absorption and scattering coefficients, respectively, and q denotes the source term, which is assumed to vanish in this discussion. The kernel f is the scattering phase function, satisfying the following three conditions:

$$\int_{S^{n-1}} f(x,\hat{\theta},\hat{\omega})ds(\hat{\theta}) = \int_{S^{n-1}} f(x,\hat{\theta},\hat{\omega})ds(\hat{\omega}) = 1,$$
$$f(x,\hat{\theta},\hat{\omega}) \geq 0, \qquad x\in\mathbb{R}^n, \quad \hat{\theta},\hat{\omega}\in S^{n-1},$$
$$f(x,\hat{\theta},\hat{\omega}) = f(x,-\hat{\omega},-\hat{\theta}), \quad \hat{\theta},\hat{\omega}\in S^{n-1}.$$

Due to the first two conditions, for fixed x, f may be regarded as a probability distribution on S^{n-1} with respect to either of the variables $\hat{\theta}$ and $\hat{\omega}$.

The net photon flux through an infinitesimal oriented surface patch $\nu(x)dS(x)$ is obtained by integrating the flux density over all radiation directions,

$$d\Phi(x,t) = \left(\int_{S^{n-1}} d\vec{J}(x,t,\hat{\theta})\right)\cdot\nu(x)dS(x) = \vec{J}(x,t)\cdot\nu(x)dS(x), \tag{2.2}$$

where the vector field $\vec{J}$ is the energy current density. In a similar manner, the outward $d\Phi_+$ and the inward flux $d\Phi_-$ through νdS can be computed by choosing the domain of integration in (2.2) to be the positive $\{\hat{\theta}\in S^{n-1} \mid \hat{\theta}\cdot\nu > 0\}$ or the negative hemisphere $\{\hat{\theta}\in S^{n-1} \mid \hat{\theta}\cdot\nu < 0\}$, respectively. Furthermore, the scalar function

$$\varphi(x,t) = \int_{S^{n-1}} I(x,t,\hat{\theta})ds(\hat{\theta})$$

is the photon density. Note that $\varphi(x,t)$ and $\vec{J}(x,t)$ are essentially the coefficients of the zeroth- and first order terms for the linearization of $I(x,t,\hat{\theta})$ with respect to $\hat{\theta}$. For more transport theory the reader may consult, e.g., [9].

2.1. Strong scattering. Being an integro-differential equation, the radiative transfer equation, as discussed above, can easily lead to numerical problems of prohibitive size if no simplifications are made. The commonly used simplification is called the diffusion approximation, which has been shown to be justified for materials that are much more scattering than absorbing [14, 17].

Let $P : L^2(S^{n-1}) \to \text{span}\{1,\theta_1,\ldots,\theta_n\}$ be an orthogonal projection which linearizes the dependence on the components of the scattering direction. Denoting the integro-differential operator induced by the left-hand side of (2.1) by $\mathcal{B}$, we define the diffusion approximation of the radiative transfer equation as

$$P\mathcal{B}PI = 0, \tag{2.3}$$

where I denotes the radiance. Due to the way that the projection P is defined, one should be able to write the diffusion approximation using only the photon density φ and the energy current density $\vec{J}$ defined above. Indeed, by a straightforward

calculation [3, 18], one sees that (2.3) is equivalent to the coupled system

$$\frac{1}{c}\varphi_t = -\nabla \cdot \vec{J} - \mu_a \varphi, \tag{2.4}$$

$$\frac{1}{c}\vec{J}_t = -\frac{1}{n}\nabla\varphi - (\mu_a I + (I-B)\mu_s)\vec{J}, \tag{2.5}$$

where $I \in \mathbb{R}^{n\times n}$ is the identity matrix and the symmetric matrix $B \in \mathbb{R}^{n\times n}$ is defined by

$$B_{jk} = \frac{n}{|S^{n-1}|}\int_{S^{n-1}}\int_{S^{n-1}} \theta_j \omega_k f(x,\hat{\theta},\hat{\omega}) ds(\hat{\theta}) ds(\hat{\omega}).$$

In order to be able to handle the boundary conditions corresponding to the diffusion approximation, we write out the total flux inwards ($-$) and outwards ($+$) on the boundary $\partial\Omega$ when the dependence on the scattering direction is linearized [18]:

$$\Phi_\pm = \left(\pm\gamma\varphi + \frac{1}{2}\nu\cdot\vec{J}\right)\Big|_{\partial\Omega}, \tag{2.6}$$

where $\nu = \nu(x)$ is the exterior unit normal of $\partial\Omega$, in two dimensions $\gamma = 1/\pi$ and in three dimensions $\gamma = 1/4$. Note that the expression for the fluxes $\Phi_\pm$ differs somewhat from the one given in most references (cf. [29]). However, it is carefully deduced from the mathematical model described above, and so it is one reasonable choice.

2.2. Transparent regions. In weakly scattering regions, the diffusion approximation ceases to be valid [11, 12], and so we will have to come up with something different. Let $D \subset \Omega$, with $\partial D \cap \partial\Omega = \emptyset$, be a nonscattering region with a C^2-boundary. Because in a nonscattering, or transparent, region all radiation is in the forward direction, in D equation (2.1) yields the relation

$$\frac{1}{c}I_t(x,t,\hat{\theta}) + \hat{\theta}\cdot\nabla I(x,t,\hat{\theta}) + \tilde{\mu}_a I(x,t,\hat{\theta}) = 0,$$

where $\tilde{\mu}_a > 0$ is the absorption coefficient that is assumed to be constant in D. For the time-harmonic case $I(x,t,\hat{\theta}) = \hat{I}(x,\hat{\theta})e^{-i\omega t}$, we have

$$(\tilde{\mu}_a - ik)\hat{I} + \hat{\theta}\cdot\nabla\hat{I} = 0,$$

yielding an attenuated plane wave solution

$$\hat{I} \sim e^{-(\tilde{\mu}_a - ik)\hat{\theta}\cdot x},$$

where $k = \omega/c$.

Let $x \in \partial D$ be a boundary point of the nonscattering region. Denote the unit normal vector of ∂D pointing into D by $\nu = \nu(x)$, and let $\hat{\theta} \in S^{n-1}$ satisfy $\hat{\theta}\cdot\nu(x) < 0$. Let $y(\hat{\theta}) \in \partial D$ be the first boundary point where the line emanating from x into direction $-\hat{\theta}$ hits the boundary ∂D. Since the radiation propagates with no scattering, the contribution from the direction $-\hat{\theta}$ to the time-harmonic amplitude of the radiation flux density at x is

$$d\vec{J}(x,\hat{\theta}) = \hat{\theta}\hat{I}(y,\hat{\theta})e^{-(\tilde{\mu}_a - ik)\hat{\theta}\cdot(x-y)} ds(\hat{\theta}).$$

Using this expression and assuming that the total flux into the nonscattering region distributes uniformly to all directions, i.e., $\hat{I}(y,\hat{\theta}) = \hat{I}_0(y)$, through a straightforward

geometrical consideration one obtains the following dependence between the time-harmonic amplitudes of the total fluxes in (+) and out (−) of the nonscattering region (for details, see [19]):

$$\begin{aligned}\Phi_-(x) &= \frac{n-1}{|S^{n-2}|}\int_{\partial D} v(x,y)\frac{(\nu(x)\cdot(x-y))(\nu(y)\cdot(x-y))}{|x-y|^{n+1}}\\ &\quad\times e^{-(\tilde{\mu}_a - ik)|x-y|}\Phi_+(y)dS(y)\\ &= (\mathcal{G}\Phi_+)(x),\end{aligned} \tag{2.7}$$

where $v(\cdot,\cdot)$ is a visibility function,

$$v(x,y) = \begin{cases} 1 & \text{if } tx+(1-t)y \in D \text{ for } 0<t<1,\\ 0 & \text{otherwise.}\end{cases} \tag{2.8}$$

Thus, we have obtained a relation between the inward and outward fluxes on the boundary of the nonscattering region, which gives us the means to handle the transparent regions using nonlocal boundary conditions.

The following lemma summarizes a few essential properties of $\mathcal{G}$ [19, 22].

LEMMA 2.1. *The linear integral operator $\mathcal{G} : L^2(\partial D) \to L^2(\partial D)$ is compact and*

$$\|\mathcal{G}\|_{L^2(\partial D)\to L^2(\partial D)} < 1.$$

In particular, $I - \mathcal{G} : L^2(\partial D) \to L^2(\partial D)$ is invertible. Furthermore, if $k = 0$, $\mathcal{G}$ is self-adjoint.

2.3. Forward problem. Let us consider the time-harmonic radiosity-diffusion forward problem of optical tomography in a bounded domain Ω consisting of a nonscattering open region D, with $\partial\Omega \cap \partial D = \emptyset$, and a strongly scattering region $\Omega \setminus \overline{D}$. Assume that the time-harmonic flux $\Phi_{\text{in}}(x)e^{-i\omega t}$ is conducted through the object boundary $\partial\Omega$. By solving (2.5) for the time-harmonic amplitude of the energy current density and substituting into (2.4), we see that the time-harmonic amplitude of the photon density (still denoted by φ) satisfies the equation

$$\nabla\cdot\kappa\nabla\varphi + (ik - \mu_a)\varphi = 0 \quad \text{in } \Omega\setminus\overline{D}, \tag{2.9}$$

where $k = \omega/c$ and

$$\kappa = \frac{1}{n}((\mu_a - ik)I + (I-B)\mu_s)^{-1}.$$

Further, by using identity (2.6), together with (2.5) and (2.7), one obtains the outer boundary condition

$$\gamma\varphi + \frac{1}{2}\nu\cdot\kappa\nabla\varphi = \Phi_{\text{in}} \quad \text{on } \partial\Omega, \tag{2.10}$$

where the sign of Φ_{in} is inverted for convenience, and the nonlocal inner boundary condition

$$G\varphi + \nu\cdot\kappa\nabla\varphi = 0 \quad \text{on } \partial D. \tag{2.11}$$

In (2.11), we have used the shorthand notation

$$G = 2\gamma(I-\mathcal{G})^{-1}(I+\mathcal{G}), \tag{2.12}$$

where $(I-\mathcal{G})^{-1}: L^2(\partial D) \to L^2(\partial D)$ denotes the $L^2(\partial D)$-inverse of $I-\mathcal{G}$. Notice that $G: L^2(\partial D) \to L^2(\partial D)$ is self-adjoint if $k=0$; this can be seen, for example, by expanding $(I-\mathcal{G})^{-1}$ as a Neumann series and using the self-adjointness of $\mathcal{G}$. In all above formulae and in what follows, the normal vectors point out of the strongly scattering region $\Omega \setminus \overline{D}$.

In [19] and [22], it has been shown that the radiosity-diffusion forward problem, obtained as a combination of (2.9), (2.10), and (2.11), has a unique solution under physically reasonable conditions, as follows.

THEOREM 2.2. *Assume that* $0 < c_a \le \mu_a \le C_a$, $0 \le \mu_s \le C_s$, $\tilde{\mu}_a > 0$, *and that* $\partial\Omega$ *and* ∂D *are smooth enough. Then* κ *is well defined and positive definite, and the time-harmonic radiosity-diffusion forward problem has a unique weak solution* $\varphi \in H^1(\Omega \setminus \overline{D})$ *for any input flux* $\Phi_{\text{in}} \in H^{-1/2}(\partial\Omega)$.

2.4. Inverse problem. According to the above derived mathematical model and under the assumption of time-harmonicity, to know all pairs of inward and outward photon fluxes on the object boundary $\partial\Omega$ is equivalent to knowing the Robin-to-Robin boundary map

$$\Upsilon : \Phi_{\text{in}} \mapsto \left(\gamma\varphi - \frac{1}{2}\nu \cdot \kappa\nabla\varphi\right)\Big|_{\partial\Omega},$$

where φ is the solution of (2.9) with the boundary conditions (2.10) and (2.11). If the assumptions of Theorem 2.2 hold, it is easy to see that Υ is a bounded linear operator from $H^{-1/2}(\partial\Omega)$ to itself (cf. [21]). The idealized time-harmonic inverse problem of OAST is to determine μ_a and κ from the knowledge of Υ.

Since collecting all Robin–Robin boundary value pairs is in a pure mathematical sense equivalent to collecting all Neumann–Dirichlet pairs, besides Υ we may assume to know the Neumann-to-Dirichlet boundary map

$$\Lambda : f \mapsto \varphi|_{\partial\Omega},$$

where $\varphi \in H^1(\Omega \setminus \overline{D})$ is the solution of (2.9) with the boundary conditions (2.11) and

$$\nu \cdot \kappa\nabla\varphi = f \quad \text{on } \partial\Omega.$$

It is easy to see that Λ is an isomorphism from $H^{-1/2}(\partial\Omega)$ to $H^{1/2}(\partial\Omega)$. When implementing the factorization method to the framework of OAST and transparent inclusions, we will work with Λ instead of Υ for the sake of convenience and readability.

In earlier work [11], it has been demonstrated that reconstructing the optical parameters inside $\Omega \setminus \overline{D}$ is practically impossible if the shape of the nonscattering region D is not known in advance. On the other hand, locating ∂D via boundary measurements by using some Newton-type iterative algorithm seems far-fetched due to the difficulties encountered when differentiating the boundary operator $\mathcal{G}$ with respect to the shape of D: It is easy to see that the differentiation results in awkward formulae even if the effect of the irregular visibility function (2.8) is not taken into account. In consequence, introducing noniterative algorithms for finding D is of great importance for the further development of OAST.

In the following section, we will assume that the absorption coefficient μ_a and the diffusion tensor κ inside Ω are known but the whereabouts of the possible nonscattering region D is unknown. We will show that under such circumstances there is reason to believe that the factorization method of Kirsch [25] can be used for locating D via boundary measurements. To be more precise, we will formulate and prove a

conditional characterization result. In section 4, the functionality of the method will be confirmed through numerical studies.

3. Factorization method and transparent regions. We begin by summarizing our framework. Let $\Omega \subset \mathbb{R}^n$, $n = 2, 3$, be a bounded body with a connected complement and $D \subset \Omega$, with $\partial D \cap \partial\Omega = \emptyset$, a nonscattering region for which $\Omega \setminus \overline{D}$ is connected. For simplicity, we assume that the measurements are static in time, i.e., $k = 0$ in the formulae of the preceding section. Furthermore, assume that the a priori known absorption coefficient $\mu_a : \Omega \to \mathbb{R}$ and symmetric diffusion tensor $\kappa : \Omega \to \mathbb{R}^{n\times n}$ are smooth enough and satisfy the the following conditions:

$$c_a \le \mu_a \le C_a, \quad c_\kappa I \le \kappa \le C_\kappa I, \tag{3.1}$$

where c_a, c_κ, C_a, and C_κ are positive constants and the latter inequality is to be understood in the sense of positive definiteness.

We denote the Neumann-to-Dirichlet map corresponding to the object containing the transparent region by Λ, i.e.,

$$\Lambda : f \mapsto \varphi|_{\partial\Omega}, \quad H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial\Omega), \tag{3.2}$$

where the photon density $\varphi \in H^1(\Omega \setminus \overline{D})$ satisfies the elliptic boundary value problem

$$\begin{aligned} \nabla \cdot \kappa\nabla\varphi - \mu_a\varphi &= 0 && \text{in } \Omega \setminus \overline{D}, \\ \nu \cdot \kappa\nabla\varphi &= f && \text{on } \partial\Omega, \\ G\varphi + \nu \cdot \kappa\nabla\varphi &= 0 && \text{on } \partial D, \end{aligned} \tag{3.3}$$

and the operators G and $\mathcal{G}$ are defined by (2.12) and (2.7), respectively, with $k = 0$ and a constant $\tilde{\mu}_a > 0$. Moreover, let Λ_0 be the Neumann-to-Dirichlet map corresponding to the same object without any nonscattering regions, meaning that Λ_0 is also defined by (3.2) but this time the first equation of (3.3) is satisfied everywhere in Ω and the inner boundary condition of (3.3) is deleted. Since μ_a and κ are assumed to be known in advance, Λ_0 can be computed and Λ—or at least a noisy incomplete version of Λ—can be measured. Notice that both Λ and Λ_0 are self-adjoint (cf. [7, 19]), i.e.,

$$\langle f_1, \Lambda f_2\rangle_{L^2(\partial\Omega)} = \overline{\langle f_2, \Lambda f_1\rangle}_{L^2(\partial\Omega)} \quad \text{and} \quad \langle f_1, \Lambda_0 f_2\rangle_{L^2(\partial\Omega)} = \overline{\langle f_2, \Lambda_0 f_1\rangle}_{L^2(\partial\Omega)}$$

for all $f_1, f_2 \in H^{-1/2}(\partial\Omega)$. Here and in what follows, we denote by $\langle f, g\rangle_{L^2(\partial\Omega)} = \int_{\partial\Omega} f\bar{g}dS$ the inner product of $L^2(\partial\Omega)$ as well as its extension to the dual system $\langle H^{-1/2}(\partial\Omega), H^{1/2}(\partial\Omega)\rangle$.

Before we can formulate the conditional characterization result, a couple of auxiliary concepts need to be introduced. Let h_y be the photon density corresponding to a point source at $y \in \Omega$, no transparent region, and a homogeneous Neumann condition on $\partial\Omega$; i.e., h_y is the solution of

$$\begin{aligned} \nabla \cdot \kappa\nabla h_y(x) - \mu_a h_y(x) &= \delta(x - y) && \text{in } \Omega, \\ \nu \cdot \kappa\nabla h_y &= 0 && \text{on } \partial\Omega, \end{aligned} \tag{3.4}$$

where δ is the delta distribution. Furthermore, let $\Lambda_D^{-1} : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ be the Dirichlet-to-Neumann boundary map corresponding to D and the diffusion equation. To be more precise,

$$\Lambda_D^{-1} g = \nu \cdot \kappa\nabla u|_{\partial D},$$

where ν is the unit normal pointing into D and u satisfies the Dirichlet boundary value problem

$$\begin{aligned} \nabla \cdot \kappa \nabla u - \mu_a u &= 0 \qquad \text{in } D, \\ u &= g \qquad \text{on } \partial D. \end{aligned} \tag{3.5}$$

THEOREM 3.1. *Assume that $\Lambda_D^{-1} + G : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is injective. Then, $h_y|_{\partial\Omega}$ belongs to the range of $|\Lambda - \Lambda_0|^{1/2}$ if and only if $y \in D$. Here, $\Lambda - \Lambda_0$ is interpreted as a compact operator from $L^2(\partial\Omega)$ to itself and $|\Lambda - \Lambda_0| = \{(\Lambda - \Lambda_0)^2\}^{1/2}$.*

The proof of Theorem 3.1 will be presented in the following subsection. Meanwhile, we will concentrate on the implications of the theorem itself. Since Λ can be measured and Λ_0 and $h_y|_{\partial\Omega}$ can be computed, Theorem 3.1 provides an explicit way to locate D through boundary measurements, assuming that $\Lambda_D^{-1} + G : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is injective. This injectivity condition can be interpreted in an intuitive way: If D is strongly scattering and characterized by the optical parameters κ and μ_a, Λ_D^{-1} maps the Dirichlet boundary value of the photon density on ∂D onto the Neumann boundary value of the photon density on ∂D. On the other hand, as indicated by (2.11), $-G$ does the same job if D is a transparent region. Consequently, $\Lambda_D^{-1} + G$ is injective if and only if one can determine whether D is transparent or diffusive by any single nontrivial measurement of the Dirichlet and Neumann boundary values of the photon density on ∂D.

Since $\Lambda_D^{-1} : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is an isomorphism [10], $G : H^{1/2}(\partial D) \to L^2(\partial D)$ is bounded, and the imbedding $L^2(\partial D) \hookrightarrow H^{-1/2}(\partial D)$ is compact [10], $\Lambda_D^{-1} + G : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is a Fredholm operator of index zero, and so its null space is in any case finite dimensional. Hence, the condition of Theorem 3.1 does not seem totally unrealistic, although there is in general no guarantee that $\Lambda_D^{-1} + G$ is injective: One can quite easily find physically reasonable parameters μ_a, κ, and $\tilde{\mu}_a$ for which the injectivity is lost. Luckily, the odds of meeting such parameters in practice seem quite low, but unfortunately the algorithmic implementation of Theorem 3.1 may run into trouble also if the optical properties inside Ω are just close to those causing noninjectivity. These statements are clarified by the following examples and the numerical studies of section 4.

Example 3.1. Let D be an isotropic unit disc, and assume that κ and μ_a are constant within D. Solving the problem (3.5) explicitly in polar coordinates $x = r(\cos(\theta), \sin(\theta))$ yields the spectral decomposition

$$\Lambda_D^{-1} : e^{ij\theta} \mapsto -\lambda_j e^{ij\theta}, \quad j \in \mathbb{Z},$$

where λ_j is given by

$$\lambda_j = \sqrt{\mu_a \kappa} \frac{I_{j-1}\left(\sqrt{\mu_a/\kappa}\right) + I_{j+1}\left(\sqrt{\mu_a/\kappa}\right)}{2I_j\left(\sqrt{\mu_a/\kappa}\right)} \tag{3.6}$$

and I_j is the modified Bessel function of the first kind. In this simple geometry the integral operator G obeys a similar representation. Indeed, by denoting $y = (\cos(\phi), \sin(\phi))$ in (2.7), one easily sees that

$$(\mathcal{G}\Phi)(\theta) = -\frac{1}{4\sqrt{2}} \int_{-\pi}^{\pi} (1 - \cos(\phi - \theta))^{1/2} e^{-\sqrt{2}\tilde{\mu}_a (1 - \cos(\phi - \theta))^{1/2}} \Phi(\phi) d\phi. \tag{3.7}$$

By substituting $e^{ij\phi}$ into (3.7), making a suitable change of variables, bearing (2.12) in mind, and using the even parity of the kernel in (3.7), it is straightforward to deduce that

$$G : e^{ij\theta} \mapsto \frac{2}{\pi}\frac{1+\eta_j}{1-\eta_j}e^{ij\theta}, \quad j \in \mathbb{Z},$$

where $\{\eta_j\}$ are the eigenvalues of $\mathcal{G}$:

$$\eta_j = -\frac{1}{4\sqrt{2}}\int_{-\pi}^{\pi}\cos(j\upsilon)(1-\cos(\upsilon))^{1/2}e^{-\sqrt{2}\tilde{\mu}_a(1-\cos(\upsilon))^{1/2}}d\upsilon. \tag{3.8}$$

These spectral decompositions indicate that the injectivity of $\Lambda_D^{-1}+G$ is lost if and only if the identity

$$\lambda_j = \frac{2}{\pi}\frac{1+\eta_j}{1-\eta_j} \tag{3.9}$$

holds for some $j \in \mathbb{Z}$.

Let us assume that $\tilde{\mu}_a > 0$ and $\kappa > 0$ are fixed and consider how $\mu_a > 0$ should be chosen in order to make $\Lambda_D^{-1}+G$ noninjective. It is easy to check that

$$\lim_{\mu_a\to 0}\lambda_j = |j|\kappa, \quad \lim_{\mu_a\to\infty}\lambda_j = \infty, \quad \text{and} \quad \frac{\partial}{\partial\mu_a}\lambda_j > 0 \quad \text{for all } j \in \mathbb{Z} \text{ and } \mu_a > 0,$$

where the equalities follow from the basic properties of the modified Bessel functions [1] and the inequality is a consequence of the monotonicity of $\langle\Lambda_D^{-1}g, g\rangle_{L^2(\partial D)}$ with respect to μ_a for any $g \in H^{1/2}(\partial D)$ (cf. [7]). Notice also that due to Lemma 2.1, $|\eta_j| < 1$ for all $j \in \mathbb{Z}$ and η_j converges to zero as $|j|$ goes to infinity. Hence, there exists a finite $J = J(\tilde{\mu}_a, \kappa) > 0$ such that for $0 \le j \le J$, equality (3.9) is satisfied by at most one value of μ_a, whereas no μ_a solves (3.9) for any $j > J$. To put it all together, in our simplified framework there are only finitely many values of μ_a that make $\Lambda_D^{-1}+G$ noninjective for fixed κ and $\tilde{\mu}_a$. □

Example 3.2. Let us continue working with the simple framework of Example 3.1 and assume that $\tilde{\mu}_a = \mu_a \ll \min\{1, \kappa\}$. Under such circumstances, the exponential term in (3.8) can be approximated fairly well by its linearization:

$$e^{-\sqrt{2}\mu_a(1-\cos(\upsilon))^{1/2}} \approx 1 - \sqrt{2}\mu_a(1-\cos(\upsilon))^{1/2}.$$

By substituting this into (3.8) and calculating the resulting integral with the help of Lemma 3.5 of [19], one sees that

$$\frac{2}{\pi}\frac{1+\eta_0}{1-\eta_0} \approx \frac{2\mu_a}{4-\pi\mu_a} \approx \frac{\mu_a}{2}.$$

On the other hand, since $\sqrt{\mu_a/\kappa}$ is small, the modified Bessel functions in (3.6) can be approximated by the constant and linear terms of their series representations [1], yielding

$$\lambda_0 \approx \sqrt{\mu_a\kappa}\frac{\sqrt{\mu_a/\kappa}}{2} = \frac{\mu_a}{2}.$$

In consequence, (3.9) is satisfied approximately for $j = 0$.

According to the above result, it is difficult to distinguish between a nonscattering disc and a homogeneous isotropic strongly scattering disc by a single rotationally symmetric measurement if both discs are characterized by the same negligible absorption. From the point of view of the factorization method, this observation is troublesome since the algorithmic implementation of Theorem 3.1 may fail if the transparent inclusion is as absorbing as its strongly scattering surroundings. This drawback is studied numerically in section 4. □

3.1. Proof of the characterization result. Theorem 3.1 follows with some work from the following result, which is a simplified version of Theorem 3.3 in [26].

THEOREM 3.2. *Let $X \subset U \subset X^*$ be a Gelfand triple with Hilbert space U and reflexive Banach space X such that the imbeddings are dense. Furthermore, let H be another Hilbert space, $T : X^* \to H$ linear, compact, and injective with dense range, $R : X \to X^*$ linear and self-adjoint, and*

$$A = TRT^*. \tag{3.10}$$

Assume that $R : X \to X^*$ is an isomorphism that can be written as $R = E + K$, where $K : X \to X^*$ is self-adjoint and compact and $E : X \to X^*$ is self-adjoint and coercive, i.e.,

$$\langle E\psi, \psi \rangle \geq C \|\psi\|_X^2 \quad \text{for all } \psi \in X.$$

Then, the ranges of $T : X^* \to H$ and $|A|^{1/2} = (A^2)^{1/4} : H \to H$ coincide.

In order to utilize Theorem 3.2, we need to show that $\Lambda - \Lambda_0$ obeys a factorization of the type (3.10). To this end, let us introduce a few auxiliary operators. We define the mapping $L : H^{-1/2}(\partial D) \to H^{1/2}(\partial\Omega)$ through

$$L : \phi \mapsto v|_{\partial\Omega}, \tag{3.11}$$

where $v \in H^1(\Omega \setminus \overline{D})$ is the weak solution of

$$\begin{aligned} \nabla \cdot \kappa \nabla v - \mu_a v &= 0 && \text{in } \Omega \setminus \overline{D}, \\ \nu \cdot \kappa \nabla v &= 0 && \text{on } \partial\Omega, \\ \nu \cdot \kappa \nabla v &= \phi && \text{on } \partial D. \end{aligned}$$

In what follows, L plays the role of T in Theorem 3.2. The adjoint $L^* : H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial D)$ is defined by (cf. [7])

$$L^* : \phi' \mapsto v'|_{\partial D}, \tag{3.12}$$

where $v' \in H^1(\Omega \setminus \overline{D})$ is the weak solution of

$$\begin{aligned} \nabla \cdot \kappa \nabla v' - \mu_a v' &= 0 && \text{in } \Omega \setminus \overline{D}, \\ \nu \cdot \kappa \nabla v' &= \phi' && \text{on } \partial\Omega, \\ \nu \cdot \kappa \nabla v' &= 0 && \text{on } \partial D. \end{aligned}$$

Next, we will introduce two mappings that constitute the intermediate operator R of Theorem 3.2. For $\psi \in H^{1/2}(\partial D)$, let $w_0 \in H^1(\Omega \setminus \partial D)$ be the weak solution of the transmission problem

$$\begin{aligned} \nabla \cdot \kappa \nabla w_0 - \mu_a w_0 &= 0 && \text{in } \Omega \setminus \partial D, \\ \nu \cdot \kappa \nabla w_0 &= 0 && \text{on } \partial\Omega, \\ w_0^+ - w_0^- &= \psi && \text{on } \partial D, \\ \nu \cdot \kappa \nabla w_0^+ - \nu \cdot \kappa \nabla w_0^- &= 0 && \text{on } \partial D. \end{aligned} \tag{3.13}$$

Here and in what follows, we denote by $w_0^{\pm}$ the trace from the exterior and from the interior of $\Omega \setminus \overline{D}$, respectively; the superscripts will often be left out if the direction of approach is clear from the context or if it does not affect the value of the trace. Moreover, assume that $w \in H^1(\Omega \setminus \overline{D})$ is the weak solution of

$$\begin{aligned} \nabla \cdot \kappa \nabla w - \mu_a w &= 0 \qquad \text{in } \Omega \setminus \overline{D}, \\ \nu \cdot \kappa \nabla w &= 0 \qquad \text{on } \partial\Omega, \\ G(w+\psi) + \nu \cdot \kappa \nabla w &= 0 \qquad \text{on } \partial D. \end{aligned} \tag{3.14}$$

We define the operators $F_0, F : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ through

$$F_0 : \psi \mapsto \nu \cdot \kappa \nabla w_0|_{\partial D}, \quad F : \psi \mapsto \nu \cdot \kappa \nabla w|_{\partial D}. \tag{3.15}$$

The following lemma lists some essential properties of the above introduced operators.

LEMMA 3.3. *The operators $L : H^{-1/2}(\partial D) \to H^{1/2}(\partial\Omega)$, $L^* : H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial D)$, and $F_0, F : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ defined by* (3.11), (3.12), *and* (3.15), *respectively, are linear and bounded. Furthermore, L is injective and compact, and its range is dense in $H^{1/2}(\partial\Omega)$; $-F_0$ is a coercive and self-adjoint isomorphism, and F is compact and self-adjoint.*

Proof. The fact that $L : H^{-1/2}(\partial D) \to H^{1/2}(\partial\Omega)$ and $L^* : H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial D)$ are linear and bounded follows from the standard theory of elliptic partial differential equations [10]. Furthermore, both L and L^* are injective and compact due to the unique continuation principle and the regularity theory for elliptic partial differential equations (cf. [26]). In particular, $\overline{\mathcal{R}(L)} = \mathcal{N}(L^*)^{\perp} = H^{1/2}(\partial\Omega)$; i.e., the range of L is dense in $H^{1/2}(\partial D)$.

The unique solvability of (3.13) in $H^1(\Omega \setminus \partial D)$ and the solution's continuous dependence on the data $\psi \in H^{1/2}(\partial D)$ follow, for example, from the material in [27] (see also [26]). Since $\nabla \cdot \kappa \nabla w_0 = \mu_a w_0 \in L^2(\Omega \setminus \partial D)$, $F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is bounded according to a slight modification of [10, Lemma 1, p. 381]. Furthermore, the self-adjointness of F_0 follows by modifying the proof of Lemma 3.3 of [7] in an obvious way. In addition, $-F_0$ can be shown to be coercive by estimating as follows:

$$\begin{aligned} \langle -F_0\psi, \psi \rangle_{L^2(\partial D)} &= \langle \nu \cdot \kappa \nabla w_0, w_0^- \rangle_{L^2(\partial D)} - \langle \nu \cdot \kappa \nabla w_0, w_0^+ \rangle_{L^2(\partial D)} \\ &= \int_{\Omega \setminus \overline{D}} \left(\kappa \nabla w_0 \cdot \nabla \overline{w}_0 + \mu_a |w_0|^2 \right) dx \\ &\quad + \int_D \left(\kappa \nabla w_0 \cdot \nabla \overline{w}_0 + \mu_a |w_0|^2 \right) dx \\ &\geq C \left\{ \|w_0\|^2_{H^1(\Omega \setminus \overline{D})} + \|w_0\|^2_{H^1(D)} \right\} \\ &\geq C \left\{ \left\|w_0^-\right\|^2_{H^{1/2}(\partial D)} + \left\|w_0^+\right\|^2_{H^{1/2}(\partial D)} \right\} \\ &\geq C \left\|\psi\right\|^2_{H^{1/2}(\partial D)}, \end{aligned}$$

where we used Green's formula [10], the symmetry of $\kappa : \Omega \to \mathbb{R}^{n \times n}$, (3.1), and the trace theorem. Since $-F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is coercive and self-adjoint, it is injective and its range is closed and dense. In other words, F_0 is an isomorphism.

To finish the proof, let us consider F. The variational formulation of (3.14) is to find $w \in H^1(\Omega \setminus \overline{D})$ such that

$$\int_{\Omega \setminus \overline{D}} \left(\kappa \nabla w \cdot \nabla \overline{v} + \mu_a w \overline{v} \right) dx + \int_{\partial D} G w \overline{v} dS = -\langle G\psi, v \rangle_{L^2(\partial D)} \tag{3.16}$$

for all $v \in H^1(\Omega \setminus \overline{D})$. Because of (3.1), Lemma 2.1, the trace theorem, and the nonnegativeness of $G : L^2(\partial D) \to L^2(\partial D)$ indicated by Theorem 3.12 of [19], the left-hand side of (3.16) defines a coercive and bounded sesquilinear form from $H^1(\Omega \setminus \overline{D}) \times H^1(\Omega \setminus \overline{D})$ to $\mathbb{C}$, and the right-hand side induces a bounded antilinear functional from $H^1(\Omega \setminus \overline{D})$ to $\mathbb{C}$. In consequence, due to the Lax–Milgram lemma, (3.16) has a unique solution $w \in H^1(\Omega \setminus \overline{D})$ which depends continuously on the data:

$$\|w\|_{H^1(\Omega\setminus\overline{D})} \leq C \|G\psi\|_{H^{-1/2}(\partial D)} \leq C \|\psi\|_{L^2(\partial D)}.$$

In particular, by the trace theorem and Lemma 2.1,

$$\|F\psi\|_{L^2(\partial D)} = \|G(w+\psi)\|_{L^2(\partial D)} \leq C \left\{ \|w\|_{L^2(\partial D)} + \|\psi\|_{L^2(\partial D)} \right\} \leq C \|\psi\|_{L^2(\partial D)};$$

i.e., F is bounded from $L^2(\partial D)$ to itself. Hence, due to the compactness of the imbeddings $H^{1/2}(\partial D) \hookrightarrow L^2(\partial D)$ and $L^2(\partial D) \hookrightarrow H^{-1/2}(\partial D)$ [10], $F : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is bounded and compact.

In order to prove that F is self-adjoint, let $w_1, w_2 \in H^1(\Omega \setminus \overline{D})$ be the solutions of (3.14) corresponding to the inputs $\psi_1, \psi_2 \in H^{1/2}(\partial D)$, respectively. By using the self-adjointness of $G : L^2(\partial D) \to L^2(\partial D)$ and the inner boundary condition of (3.14), it follows that

$$\begin{aligned} \langle F\psi_1, \psi_2 \rangle_{L^2(\partial D)} &= -\int_{\partial D} G(\psi_1 + w_1)\overline{\psi}_2 dS \\ &= \int_{\partial D} \psi_1(\nu \cdot \kappa \nabla \overline{w}_2 + \overline{Gw_2}) dS - \int_{\partial D} w_1 \overline{G\psi}_2 dS \\ &= \overline{\langle F\psi_2, \psi_1 \rangle}_{L^2(\partial D)} + \int_{\partial D} (G\psi_1 \overline{w}_2 - w_1 \overline{G\psi}_2) dS. \end{aligned} \tag{3.17}$$

Thus, by showing that the latter term on the last line of (3.17) vanishes, the proof is complete:

$$\begin{aligned} \int_{\partial D} (G\psi_1 \overline{w}_2 - w_1 \overline{G\psi}_2) dS &= \int_{\partial D} (\nu \cdot \kappa \nabla \overline{w}_2 w_1 - \nu \cdot \kappa \nabla w_1 \overline{w}_2) dS \\ &\quad + \int_{\partial D} (w_1 \overline{Gw}_2 - G w_1 \overline{w}_2) dS \\ &= \int_{\partial\Omega} (\nu \cdot \kappa \nabla w_1 \overline{w}_2 - \nu \cdot \kappa \nabla \overline{w}_2 w_1) dS = 0, \end{aligned}$$

where we used the boundary conditions of (3.14), the self-adjointness of G, the symmetry of κ, and Green's formula. ∎

Next, we will provide the needed factorization.

LEMMA 3.4. *The difference of the operators $\Lambda, \Lambda_0 : H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial\Omega)$ can be factorized as $\Lambda - \Lambda_0 = L(F - F_0)L^*$, where $L : H^{-1/2}(\partial D) \to H^{1/2}(\partial\Omega)$, $L^* : H^{-1/2}(\partial\Omega) \to H^{1/2}(\partial D)$, and $F_0, F : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ are defined by* (3.11), (3.12), *and* (3.15), *respectively.*

Proof. Let $\varphi \in H^1(\Omega\setminus\overline{D})$ be the solution of (3.3) corresponding to $f \in H^{-1/2}(\partial\Omega)$, and let $\varphi_0 \in H^1(\Omega)$ be the solution of

$$\nabla \cdot \kappa \nabla \varphi_0 - \mu_a \varphi_0 = 0 \quad \text{in } \Omega, \qquad \nu \cdot \kappa \nabla \varphi_0 = f \quad \text{on } \partial\Omega. \tag{3.18}$$

Clearly,

$$L\left(\nu \cdot \kappa \nabla(\varphi - \varphi_0)|_{\partial D}\right) = (\varphi - \varphi_0)|_{\partial\Omega} = (\Lambda - \Lambda_0) f.$$

By defining the operators

$$\begin{aligned} B: &\quad f \mapsto \nu \cdot \kappa \nabla \varphi|_{\partial D}, \quad H^{-1/2}(\partial\Omega) \to H^{-1/2}(\partial D), \\ B_0: &\quad f \mapsto \nu \cdot \kappa \nabla \varphi_0|_{\partial D}, \quad H^{-1/2}(\partial\Omega) \to H^{-1/2}(\partial D), \end{aligned}$$

we have thus far obtained the factorization

$$\Lambda - \Lambda_0 = L(B - B_0). \tag{3.19}$$

Notice that B is bounded (from $H^{-1/2}(\partial\Omega)$ to $L^2(\partial D)$) due to the trace theorem and Lemma 2.1, and the boundedness of B_0 follows from the fact that $\nabla \cdot \kappa \nabla \varphi_0 = \mu_a \varphi_0 \in L^2(\Omega)$ [10].

By following the line of reasoning used in the proof of Lemma 3.2 in [7], one easily sees that the adjoint operator of $B_0 : H^{-1/2}(\partial\Omega) \to H^{-1/2}(\partial D)$ is defined through

$$B_0^* : \psi \mapsto w_0|_{\partial\Omega}, \quad H^{1/2}(\partial D) \to H^{1/2}(\partial\Omega),$$

where $w_0 \in H^1(\Omega \setminus \partial D)$ is the solution of (3.13). Similarly, the adjoint of $B : H^{-1/2}(\partial\Omega) \to H^{-1/2}(\partial D)$ can be defined through

$$B^* : \psi \mapsto w|_{\partial\Omega}, \quad H^{1/2}(\partial D) \to H^{1/2}(\partial\Omega),$$

where $w \in H^1(\Omega \setminus \overline{D})$ is the solution of (3.14). Indeed, by using the self-adjointness of $G : L^2(\partial D) \to L^2(\partial D)$, Green's formula, and the boundary conditions of (3.3) and (3.14), we obtain that

$$\begin{aligned} \langle Bf, \psi \rangle_{L^2(\partial D)} &= -\int_{\partial D} G\varphi\overline{\psi} dS \\ &= \int_{\partial D} \varphi(\overline{Gw} + \nu \cdot \kappa \nabla \overline{w}) dS \\ &= \int_{\partial D} \nu \cdot \kappa \nabla \overline{w} \varphi dS - \int_{\partial D} \nu \cdot \kappa \nabla \varphi \overline{w} dS \\ &= \int_{\partial\Omega} \nu \cdot \kappa \nabla \varphi \overline{w} dS - \int_{\partial\Omega} \nu \cdot \kappa \nabla \overline{w} \varphi dS \\ &= \langle f, w \rangle_{L^2(\partial\Omega)}. \end{aligned}$$

Bearing in mind how $F, F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ and $L : H^{-1/2}(\partial D) \to H^{1/2}(\partial\Omega)$ were defined, it is straightforward to deduce that

$$L(F - F_0) = B^* - B_0^*. \tag{3.20}$$

By taking the adjoint of (3.20), plugging it into (3.19), and using the self-adjointness of F and F_0, we finally obtain that

$$\Lambda - \Lambda_0 = L(F - F_0)L^*,$$

which completes the proof. □

Now the proof of Theorem 3.1 follows by combining Theorem 3.2 with Lemma 3.4 and showing that $F - F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is an isomorphism if $\Lambda_D^{-1} + G : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is injective.

Proof of Theorem 3.1. Inspired by Theorem 3.2, let us make the choices $X = H^{1/2}(\partial D)$, $U = L^2(\partial D)$, $H = L^2(\partial\Omega)$, $R = F - F_0$, $A = (\Lambda - \Lambda_0)|_{L^2(\partial\Omega)} : L^2(\partial\Omega) \to$

$L^2(\partial\Omega)$, and $T = L$ with $\mathcal{R}(L)$ interpreted as a subspace $L^2(\partial\Omega)$. Clearly, $X \subset U \subset X^*$ is now a Gelfand triple, and T is compact and injective with dense range in H because of Lemma 3.3 and since the imbedding $H^{1/2}(\partial\Omega) \hookrightarrow L^2(\partial\Omega)$ is compact and dense [10]. Furthermore, by making the choices $E = -F_0$ and $K = F$, $R : X \to X^*$ is given as a sum of two self-adjoint operators, one of which is coercive and the other one compact. Hence, to be able to use Theorem 3.2, the only thing we still need to prove is that $F - F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is an isomorphism.

Since $F - F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is a sum of a compact and an isomorphic operator, it is a Fredholm operator of index zero, and so it is bijective if and only if it is injective. Assume that $\psi \in H^{1/2}(\partial D)$ belongs to the null space of $F - F_0$, meaning that the solutions of (3.14) and (3.13), namely $w \in H^1(\Omega \setminus \overline{D})$ and $w_0 \in H^1(\Omega \setminus \partial D)$, satisfy the equality

$$\nu \cdot \kappa \nabla w = \nu \cdot \kappa \nabla w_0 \quad \text{on } \partial D. \tag{3.21}$$

In consequence, w and $w_0|_{\Omega\setminus\overline{D}}$ satisfy the diffusion equation with the same Neumann boundary values in $\Omega \setminus \overline{D}$. Due to (3.1), such a Neumann boundary value problem is uniquely solvable in $H^1(\Omega\setminus\overline{D})$ [10], and so $w_0|_{\Omega\setminus\overline{D}} = w$. In particular, $w_0^-|_{\partial D} = w|_{\partial D}$.

Clearly, $w_0|_D \in H^1(D)$ satisfies (3.5) with $g = w_0^+|_{\partial D} = w|_{\partial D} + \psi$, from which it follows that

$$\Lambda_D^{-1}(w|_{\partial D} + \psi) = \nu \cdot \kappa \nabla w_0.$$

By using (3.21) and the inner boundary condition of (3.14), we deduce that

$$\left(\Lambda_D^{-1} + G\right)(w|_{\partial D} + \psi) = 0,$$

i.e., $w|_{\partial D} + \psi = 0$ since $\Lambda_D^{-1} + G$ is injective by assumption. In consequence, (3.14) transforms into a homogeneous Neumann problem, and so $w_0|_{\Omega\setminus\overline{D}} = w = 0$. In particular, $\nu \cdot \kappa \nabla w_0|_{\partial D} = 0$, or in other words, $F_0\psi = 0$. Since $F_0 : H^{1/2}(\partial D) \to H^{-1/2}(\partial D)$ is an isomorphism, we deduce that $\psi = 0$. Thus, $\mathcal{N}(F - F_0) = \{0\}$ and $F - F_0$ is a linear isomorphism.

Now Theorem 3.2 tells us that

$$\mathcal{R}\left(\left|(\Lambda - \Lambda_0)\,|_{L^2(\partial\Omega)}\right|^{1/2}\right) = \mathcal{R}(L).$$

Bearing this equality in mind, the claim finally follows by using the same line of reasoning as in the proof of Lemma 3.5 in [7]. □

4. Numerical examples. In this section, the performance of the introduced method is evaluated by simulated test cases. In subsection 4.1, we discuss the algorithmic implementation of Theorem 3.1. Subsection 4.2 considers briefly the computational methods for finding forward solutions to the radiosity-diffusion model. The reconstruction results are presented in subsection 4.3.

4.1. Algorithmic implementation. Assume that $f_y^\alpha \in L^2(\partial\Omega)$ is the unique minimizer of the Tikhonov functional

$$\left\| |\Lambda - \Lambda_0|^{1/2} f - h_y \right\|_{L^2(\partial\Omega)}^2 + \alpha \|f\|_{L^2(\partial\Omega)}^2, \quad f \in L^2(\partial\Omega), \tag{4.1}$$

where $\alpha > 0$ is a regularization parameter and $h_y \in C^\infty(\overline{\Omega} \setminus \{y\})$ is the singular solution of (3.4). Let us examine how f_y^α behaves as α goes to zero. It is well known

that f_y^α converges to the minimum norm solution of the equation

$$|\Lambda - \Lambda_0|^{1/2} f = h_y|_{\partial\Omega}$$

if $h_y|_{\partial\Omega}$ belongs to the range of $|\Lambda - \Lambda_0|^{1/2} : L^2(\partial\Omega) \to L^2(\partial\Omega)$ [24]. On the other hand, if $h_y|_{\partial\Omega} \notin \mathcal{R}(|\Lambda - \Lambda_0|^{1/2})$ and the injectivity condition of Theorem 3.1 is satisfied, in which case $\mathcal{R}(|\Lambda - \Lambda_0|^{1/2})$ is dense in $L^2(\partial\Omega)$, the $L^2(\partial\Omega)$-norm of f_y^α goes to infinity as α goes to zero. In consequence, provided that the assumptions of Theorem 3.1 are valid, y belongs to D if and only if

$$\limsup_{\alpha\to 0^+} \left\| f_y^\alpha \right\|_{L^2(\partial\Omega)} < \infty.$$

In practical computations we choose an $L^2(\partial\Omega)$-orthonormal set of input patterns $\{f_l\}_{l=-m}^m$, denote the orthogonal projector onto the span of $\{f_l\}$ by P, and replace (4.1) by

$$\left\| |P(\Lambda - \Lambda_0)P|^{1/2} f - \frac{Ph_y}{\|Ph_y\| L^2(\partial\Omega)} \right\| L^2(\partial\Omega)^2 + \alpha_\delta(y) \|f\|^2_{L^2(\partial\Omega)} . \tag{4.2}$$

Furthermore, instead of examining how the norm of the minimizer for (4.2) behaves as y moves around in Ω, we take a slightly different approach that gives better contrast. We choose $\alpha_\delta : \Omega \to \mathbb{R}_+$, $0 < \delta < 1$, in such a way that the minimizer $f_y^\delta \in L^2(\partial\Omega)$ of the Tikhonov functional (4.2) satisfies the discrepancy condition

$$\left\| |P(\Lambda - \Lambda_0)P|^{1/2} f_y^\delta - \frac{Ph_y}{\|Ph_y\| L^2(\partial\Omega)} \right\|_{L^2(\partial\Omega)} = \delta \tag{4.3}$$

for every $y \in \Omega$. If this condition cannot be met for some $y \in \Omega$, we set $\alpha_\delta(y) = 0$; not taking into account possible numerical restrictions, such a situation can occur only if the injectivity condition of Theorem 3.1 does not hold true.

Let us explain why the graph of $\alpha_\delta : \Omega \to \mathbb{R}_+$ contains information on the location of D, provided that the injectivity condition of Theorem 3.1 is satisfied. The above considerations suggest that if (4.3) is satisfied for a small $0 < \delta < 1$ and $y \in \Omega \setminus D$, the corresponding minimizer $f_y^\delta \in L^2(\partial\Omega)$ probably has a large norm. Since the norm of the minimizer of (4.2) is monotonically decreasing with respect to the regularization parameter [24], $\alpha_\delta(y)$ is likely to be small if $y \in \Omega \setminus D$. Conversely, if $y \in D$, the minimizer of (4.2) satisfying (4.3) is probably smallish in norm, and so $\alpha_\delta(y)$ is presumably large compared to the case $y \in \Omega \setminus D$. In consequence, the graph of $\alpha_\delta : \Omega \to \mathbb{R}_+$ should be flat apart from an elevation over the inclusion D.

In the practical algorithm, we have chosen to work with $Ph_y / \|Ph_y\|_{L^2(\partial\Omega)}$ instead of Ph_y because one is ultimately interested in the shape of the singular solution on $\partial\Omega$, not in its magnitude; it is trivial to check that Theorem 3.1 remains valid if $h_y|_{\partial\Omega}$ is replaced by $h_y|_{\partial\Omega} / \|h_y\|_{L^2(\partial\Omega)}$.

4.2. Numerical implementation. To be able to test the algorithm introduced in subsection 4.1 numerically, one needs to simulate $\{\Lambda f_l\}$ and $\{\Lambda_0 f_l\}$, compute $P(h_y|_{\partial\Omega})$ for numerous $y \in \Omega$, and introduce a procedure aiming at satisfying (4.3). In what follows, we will discuss each of these steps briefly.

4.2.1. Simulation of the measurement data. The numerical solution of (3.3) is based on the finite element method with piecewise linear basis functions. The

domain $\Omega \setminus \overline{D}$ is divided into T triangles joined at N vertex nodes, and the solution is sought in the form

$$\varphi^N = \sum_{k=1}^{N} a_k \phi_k,$$

where $a_k \in \mathbb{C}$ and the basis function ϕ_k is continuous, piecewise linear, smooth in each triangle, has value one at the kth node, and vanishes at all the other nodes. The coefficient vector $a = (a_1, \ldots, a_N)^T$ is solved from the matrix equation

$$(K + M + A)a = F,$$

which is obtained from the variational formulation of problem (3.3) in standard finite element style (cf. [19]):

$$\begin{aligned} K_{jk} &= \int_{\Omega\setminus\overline{D}} \kappa \nabla\phi_k \cdot \nabla\phi_j dx, \\ M_{jk} &= \int_{\Omega\setminus\overline{D}} \mu_a \phi_k \phi_j dx, \\ A_{jk} &= \int_{\partial D} G\phi_k \phi_j dS, \\ F_j &= \int_{\partial\Omega} f\phi_j dS. \end{aligned} \tag{4.4}$$

These matrix elements are approximated by integrals over the finite element triangulation; an approximative way to compute $\mathcal{G}\phi_k$, needed in the evaluation of (4.4), is given in [4]. After $a \in \mathbb{C}^N$ corresponding to the input f_l has been solved, Λf_l is approximated by the Dirichlet boundary value of φ^N on $\partial\Omega$.

The elliptic boundary value problem corresponding to Λ_0, i.e., (3.18), could be solved in a similar manner. However, in the numerical studies presented in subsection 4.3, Ω is the unit disc, μ_a and κ are constant and scalar in Ω, and $f_l = e^{il\theta}$ with θ being the polar angle. This simplifies the situation considerably as Λ_0 obeys the spectral representation (see Example 3.1)

$$\Lambda_0 : e^{il\theta} \mapsto \frac{2}{\sqrt{\mu_a \kappa}} \frac{I_l\left(\sqrt{\mu_a/\kappa}\right)}{I_{l-1}\left(\sqrt{\mu_a/\kappa}\right) + I_{l+1}\left(\sqrt{\mu_a/\kappa}\right)} e^{il\theta}, \quad l = \mathbb{Z}, \tag{4.5}$$

where I_l is the modified Bessel function of the first kind. In what follows, $\{\Lambda_0 f_l\}$ are computed using (4.5).

4.2.2. Computation of the singular photon density. Let us assume that μ_a and κ are scalar and constant in Ω. In this case, the solution of (3.4) can be computed with the help of the modified Bessel function of the second kind because

$$\tilde{h}_y = -\frac{1}{2\pi\kappa} K_0\left(\sqrt{\frac{\mu_a}{\kappa}}|x-y|\right)$$

satisfies the first equation of (3.4) [1]. Hence, the solution of (3.4) can be given as

$$h_y = \tilde{h}_y - v_y,$$

where v_y is the solution of the boundary value problem

$$\nabla \cdot \kappa \nabla v - \mu_a v = 0 \quad \text{in } \Omega, \qquad \nu \cdot \kappa \nabla v = \nu \cdot \kappa \nabla \tilde{h}_y \quad \text{on } \partial\Omega. \tag{4.6}$$

In consequence, for each probe location $y \in \Omega$ we must, in general, solve one elliptic Neumann boundary value problem using, for example, the finite element method.

The numerical studies of subsection 4.3 are conducted in the unit disc with the Fourier input patterns $\{e^{il\theta}\}$. Since only the projection $P(h_y|_{\partial\Omega})$ is explicitly needed in (4.2) and (4.3), in this simple framework the algorithm of subsection 4.1 can be implemented without having to solve (4.6). Indeed, by using the spectral decomposition (4.5), it is easy to see that

$$P\left(h_y|_{\partial\Omega}\right) = P\left(\tilde{h}_y|_{\partial\Omega}\right) - P\Lambda_0\left(\nu \cdot \kappa \nabla \tilde{h}_y|_{\partial\Omega}\right) = P\left(\tilde{h}_y|_{\partial\Omega}\right) - \Lambda_0 P\left(\nu \cdot \kappa \nabla \tilde{h}_y|_{\partial\Omega}\right),$$

which can be computed efficiently with the help of (4.5).

4.2.3. Computation of the indicator function. Let us consider finding the regularization parameter $\alpha_\delta(y)$ satisfying (4.3) for a fixed $y \in \Omega$. It is well known that the minimizer of the functional (4.2), with $\alpha_\delta(y)$ replaced by a generic regularization parameter $\alpha > 0$, is given by [24]

$$f_y^\alpha = \frac{1}{\|Ph_y\|_{L^2(\partial\Omega)}} \left\{|P(\Lambda - \Lambda_0)P| + \alpha I\right\}^{-1} |P(\Lambda - \Lambda_0)P|^{1/2} Ph_y,$$

where we have used the self-adjointness of Λ, Λ_0, and P. Furthermore, the derivative of the discrepancy function

$$e(\alpha) = \left\| |P(\Lambda - \Lambda_0)P|^{1/2} f_y^\alpha - \frac{Ph_y}{\|Ph_y\|\, L^2(\partial\Omega)} \right\|^2_{L^2(\partial\Omega)}$$

can be written as [24]

$$e'(\alpha) = 2\alpha \left\langle f_y^\alpha, \left\{|P(\Lambda - \Lambda_0)P| + \alpha I\right\}^{-1} f_y^\alpha \right\rangle_{L^2(\partial\Omega)}.$$

By using these formulae, $\alpha_\delta(y)$ can be computed efficiently by Newton's method; if the discrepancy condition (4.3) cannot be achieved within the working precision, $\alpha_\delta(y)$ is set to zero. Notice that the number of orthogonal input patterns used is typically quite low—in our studies, nine—and so computing the inverse operators needed above is relatively cheap.

4.3. Results. In this subsection, we evaluate the performance of the proposed method with four test cases. In the first test case, we try to locate a nonconvex transparent inclusion inside an object that is far less scattering and absorbing than the tissues encountered in practical applications. The idea is to set up an upper bound on the performance of the algorithm: When performing measurements with an object characterized by smaller absorption and scattering coefficients, there are more photons that travel through the inner parts of the object without being absorbed before arriving at the object boundary. As a consequence, the measurements contain more information on the inner parts of the object and the inverse problem becomes less ill-posed. The second test case considers a circular nonscattering inhomogeneity and optical parameter values that are chosen so that the injectivity condition of

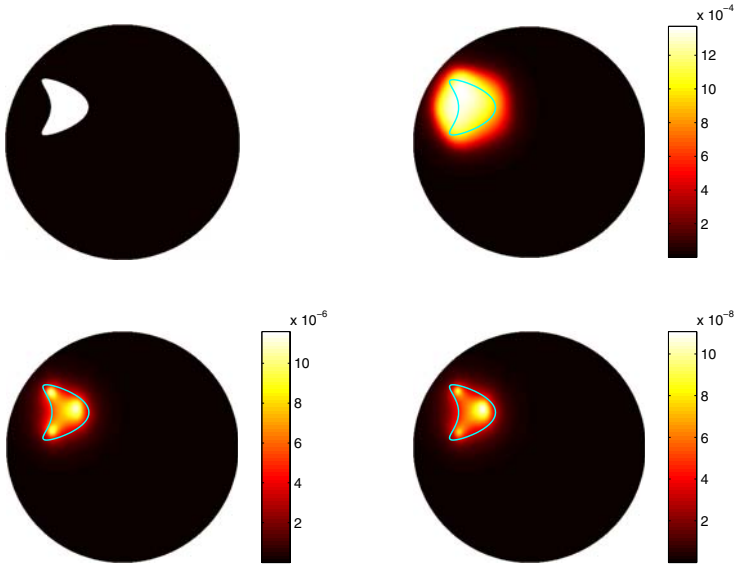

FIG. 4.1. *The first test case with the optical parameters* $\kappa = 0.5$, $\mu_a = 0.05$, *and* $\tilde{\mu}_a = 0.005$. *The graph of the indicator function* α_δ *is compared with the original kite-shaped transparent cavity for different* $\delta > 0$. *Top left: The original cavity. Top right:* $\delta = 10^{-3}$. *Bottom left:* $\delta = 10^{-5}$. *Bottom right:* $\delta = 10^{-7}$.

Theorem 3.1 is not satisfied. The third and fourth cases work with realistic optical parameters and noisy data. In the third test, the object is contaminated by a nonconvex transparent inclusion, and in the fourth one we have two circular inclusions.

The computations were conducted in two dimensions, and the object of interest Ω was an isotropic unit disc with constant background diffusion and absorption coefficients. In all studies, we worked with full aperture data and used nine L^2-orthogonal input patterns $\{e^{il\theta}\}_{l=-4}^{l=4}$, where θ is the polar angle. By following the line of reasoning introduced in [15] for electrical impedance tomography, the algorithm could also be implemented with limited aperture data, but the resulting reconstructions would be worse than those presented in this work. The reason behind the low number of inputs is twofold: First, the higher spatial frequencies penetrate the object so poorly that their outputs contain more numerical noise than information on the location of the transparent region. Second, because of the limitations of the real-life measurement setting [16], one cannot assume the object to be exposed on arbitrarily high spatial frequencies in a controlled manner. The outputs $\{(\Lambda e^{il\cdot})(\theta)\}$ and $\{(\Lambda_0 e^{il\cdot})(\theta)\}$ were simulated by the finite element method, with approximately five hundred thousand nodal points, and by formula (4.5), respectively. In the computations, we used two types of inclusion shapes:

$$D_1 = \{x \in \Omega \mid |x - x_0| < R\}, \quad x_0 \in \Omega,\ |x_0| + R < 1,$$

and D_2 is the celebrated nonconvex kite-shaped inclusion; i.e., D_2 is the interior of the region bounded by the curve

$$z(t) = x_0 + R(\cos t + 0.65 \cos 2t - 0.65, 1.5 \sin t), \quad t \in (-\pi, \pi],$$

where x_0 and R are such that Ω contains the curve.

The results for the first test case are illustrated in Figures 4.1 and 4.2. The original transparent inclusion, namely D_2 with $x_0 = (-0.45, 0.3)$ and $R = 0.16$, is shown in the

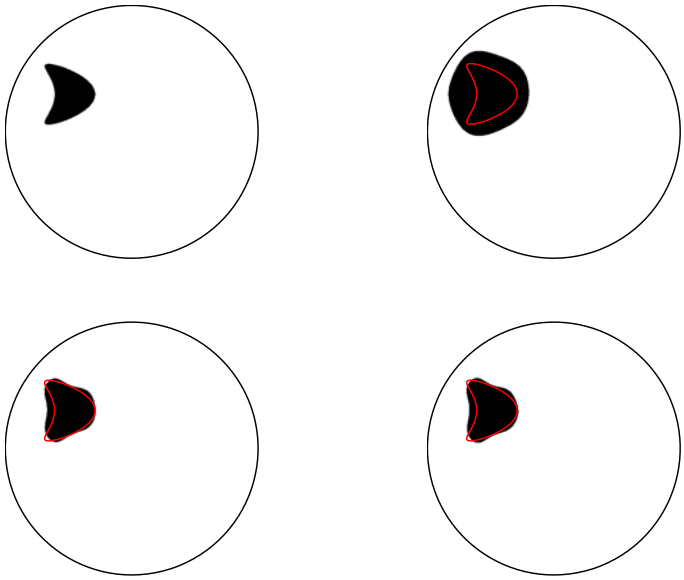

FIG. 4.2. *The first test case. The inclusion supports obtained by approximating the indicator functions in the sense of least squares are compared with the original kite-shaped transparent cavity. Top left: The original inclusion. Top right:* $\delta = 10^{-3}$. *Bottom left:* $\delta = 10^{-5}$. *Bottom right:* $\delta = 10^{-7}$.

top left image of Figure 4.1. The a priori known background optical parameters were $\kappa = 0.5$ and $\mu_a = 0.05$, and the absorption in the nonscattering region was $\tilde{\mu}_a = 0.005$; these parameter values correspond to absorption and scattering that are less than a tenth of the values that would be used if one modeled the neonatal head [2]. The other three images of Figure 4.1 show the graphs of the indicator function $\alpha_\delta : \Omega \to \mathbb{R}$ on a rectangular grid with three different discrepancy parameter values: $\delta = 10^{-3}$, 10^{-5}, and 10^{-7}. The reconstructed inclusion supports presented in Figure 4.2 were obtained by approximating the indicator functions in the sense of least squares by piecewise constant functions that take at most two distinct values. As Figures 4.1 and 4.2 demonstrate, the algorithm finds the approximate location of the inclusion with all three discrepancy parameters, whereas only the smallest two parameter values result in reconstructions that represent some characteristics of the inclusion shape. Although the reconstructed inclusion supports illustrated on the bottom row of Figure 4.2 are slightly concave on the side that corresponds to the nonconvex face of the original kite-shaped cavity, one cannot claim that the convexity properties of the inclusion are reconstructed correctly since there is also some concavity on the two originally convex sides. In fact, by testing the method with transparent cavities that are more concave than the one used here, it can be demonstrated that the proposed method is not accurate enough to capture nonconvexity reliably.

Figure 4.3 shows the findings of the second test case, where the transparent inclusion was D_1 with $x_0 = (-0.4, -0.5)$ and $R = 0.2$. In this test, we used three different sets of optical parameters: $\kappa = 0.5$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.005$; $\kappa = 0.5$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.05$; $\kappa = 0.254$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.005$. By using the same line of reasoning as in Examples 3.1 and 3.2, it is easy to see that the latter two parameter sets make $\Lambda_{D_1}^{-1} + G$ nearly noninjective. To be more precise, with the second set of parameters

$$(\Lambda_{D_1}^{-1} + G)(e^{ij\theta}) \approx 0$$

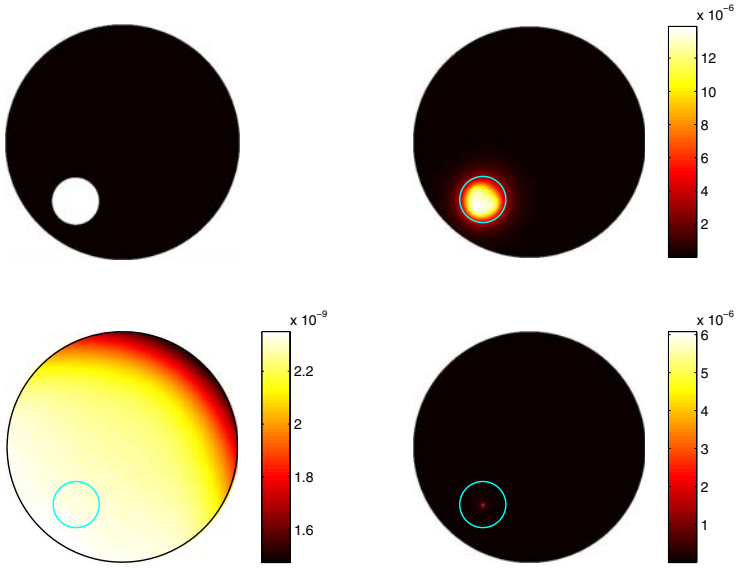

FIG. 4.3. *The second test case. The graph of the indicator function α_δ, with $\delta = 10^{-5}$, is compared with the original circular inclusion. Three different sets of optical parameters were used. Top left: The original inclusion. Top right: $\kappa = 0.5$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.005$. Bottom left: $\kappa = 0.5$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.05$. Bottom right: $\kappa = 0.254$, $\mu_a = 0.05$, and $\tilde{\mu}_a = 0.005$.*

for $j = 0$, and with the third set the same equation holds for $j = \pm 1$. Here, θ denotes the polar angle with respect to the center of the inclusion. The graphs of the indicator functions corresponding to the three parameter sets and $\delta = 10^{-5}$ are shown in Figure 4.3. The reconstruction corresponding to the first set of parameters is good, but the reconstructions with the latter two parameter sets have their shortcomings as expected: The indicator function corresponding to the second set of parameters contains almost no information on the location of the inclusion, whereas the indicator function corresponding to the last set of parameters finds the location correctly but contains little information on the size of the inhomogeneity.

The inclusion geometry of the third test case was the same as in the first test, as shown in the top left image of Figure 4.4. This time, the optical parameters were chosen so that the unit disc could model a neonatal head of radius 25 mm [2]: $\kappa = 0.05$, $\mu_a = 0.5$, and $\mu_a = 0.05$. The noisy measurements were simulated by adding Gaussian random noise with standard deviation $\epsilon \geq 0$ times the maximum element of $P\Lambda P \in \mathbb{R}^{9\times 9}$ to each element of the matrix $P(\Lambda - \Lambda_0)P \in \mathbb{R}^{9\times 9}$. The results are illustrated in Figure 4.4, where the top right image shows the indicator function α_δ for $\epsilon = 0$ and $\delta = 0.01$, the bottom left for $\epsilon = 10^{-4}$ and $\delta = 0.03$, and the bottom right for $\epsilon = 10^{-3}$ and $\delta = 0.1$. As Figure 4.4 demonstrates, the shape of the inclusion is not reconstructed correctly even if the data contains no noise. Compared to the first test case, this shortcoming is probably due to the higher level of ill-posedness caused by the introduction of the realistic optical parameters. However, one cannot rule out the possibility that the injectivity condition of Theorem 3.1 also plays a role in the relatively poor quality of the reconstructions. On the positive side, the graph of the indicator function contains information on the location of the inclusion with all three noise levels. The amount of additive noise used in the computations can be put into perspective by noticing that the maximal absolute value of the elements of

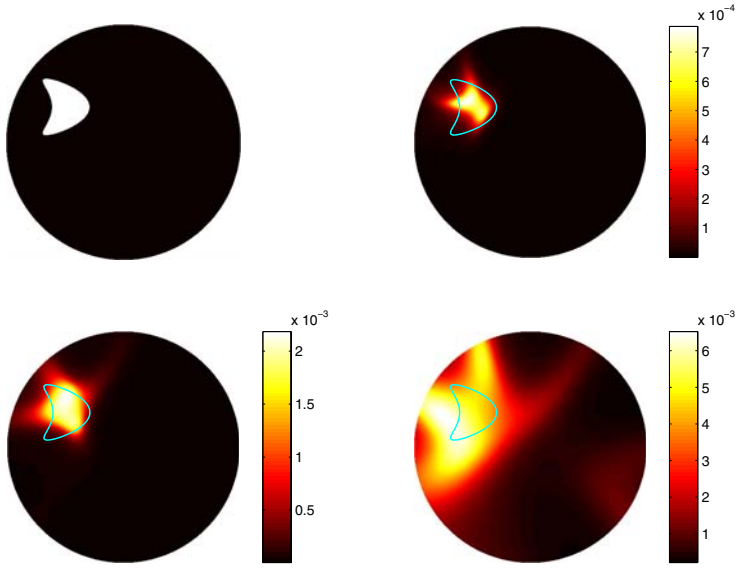

FIG. 4.4. *The third test case with the optical parameters* $\kappa = 0.05$, $\mu_a = 0.5$, *and* $\mu_a = 0.05$. *The graph of the indicator function* α_δ *is compared with the original kite-shaped transparent cavity for three different noise levels. Top left: The original inclusion. Top right:* $\epsilon = 0$ *and* $\delta = 0.01$. *Bottom left:* $\epsilon = 10^{-4}$ *and* $\delta = 0.03$. *Bottom right:* $\epsilon = 10^{-3}$ *and* $\delta = 0.1$.

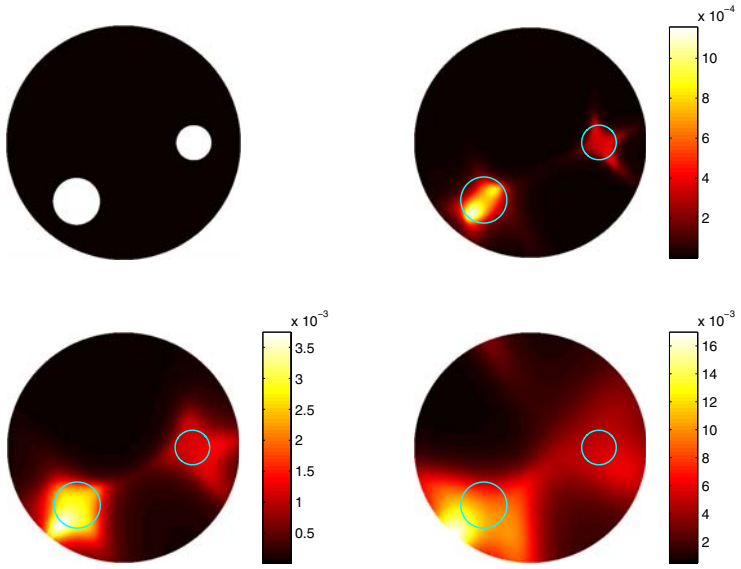

FIG. 4.5. *The fourth test case with the optical parameters* $\kappa = 0.05$, $\mu_a = 0.5$, *and* $\mu_a = 0.05$. *The graph of the indicator function* α_δ *is compared with the original circular transparent cavities for three different noise levels. Top left: The original inclusions. Top right:* $\epsilon = 0$ *and* $\delta = 0.01$. *Bottom left:* $\epsilon = 10^{-4}$ *and* $\delta = 0.03$. *Bottom right:* $\epsilon = 10^{-3}$ *and* $\delta = 0.1$.

$P\Lambda P$ is 7.7, whereas the maximal absolute value of the elements of $P(\Lambda - \Lambda_0)P$ is only 0.048.

Figure 4.5 illustrates the results of the fourth and final test case, where we used

the same optical parameters as in the third test. The top left image of Figure 4.5 shows the original nonscattering region that consists of two distinct circular inclusions of the type D_1. The top right image of Figure 4.5 shows the indicator function α_δ for $\epsilon = 0$ and $\delta = 0.01$, the bottom left for $\epsilon = 10^{-4}$ and $\delta = 0.03$, and the bottom right for $\epsilon = 10^{-3}$ and $\delta = 0.1$. Both inclusions are visible but malformed in all three reconstructions.

5. Conclusions. We have shown that, within the framework of the radiosity-diffusion model of OAST, the factorization method provides means to extract information on the transparent cavities embedded in known strongly scattering background from boundary measurements. Although the quality of the obtained reconstructions is quite sensitive to noise and depends strongly on the optical properties of the diffusive background and the absorption inside the nonscattering cavities, the results are quite promising because using sampling-type techniques, as is the factorization method, to locate the transparent regions seems straightforward compared to implementing Newton-type methods that search for the optimal inclusion shape iteratively.

In this work, we considered only the situation where the optical properties of the diffusive region surrounding the cavities are known in advance. However, in practice one is ultimately interested in locating absorbing inhomogeneities in the strongly scattering tissue. In consequence, to make the factorization method more useful for the further development of OAST, the possibility of characterizing transparent and absorbing inclusions simultaneously should be considered. This observation and the testing of the proposed method with measured data provide interesting subjects for future studies.

RECONSTRUCTION OF THE SHAPE AND SURFACE IMPEDANCE FROM ACOUSTIC SCATTERING DATA FOR AN ARBITRARY CYLINDER*

J. J. LIU†, G. NAKAMURA‡, AND M. SINI§

Abstract. The inverse scattering for an obstacle $D \subset R^2$ with mixed boundary condition can be considered as a prototype for radar detection of complex obstacles with coated and noncoated parts of the boundary. We construct some indicator functions for this inverse problem using the far-field pattern directly, without the necessity of transforming the far field to the near field. Based on careful singularity analysis, these indicator functions enable us to reconstruct the shape of the obstacle and distinguish the coated from the noncoated part of the boundary. Moreover, an explicit representation formula for the surface impedance in the coated part of the boundary is also given. Our reconstruction scheme reveals that the coated part of the obstacle is less visible than the noncoated one, which corresponds to the physical fact that the coated boundary absorbs some part of the scattered wave. Numerics are presented for the reconstruction formulas, which show that both the boundary shape and the surface impedance in the coated part of the boundary can be reconstructed accurately. The theoretical reconstruction techniques proposed in this work can be applied in the practical 3-dimensional electromagnetic inverse scattering problems with promising numerical performance. Such problems are of great importance in the design of nondetectable obstacles.

Introduction and examples. Inverse scattering problems aim to identify some properties of an obstacle such as the boundary shape and type from the information contained in the scattered wave for given incident waves. Optimization techniques are well known for reconstructing the obstacle, up to some accuracy, by minimizing the objective functional for an unknown obstacle from given inversion input data by iteration procedures. However, it seems that a good initial guess is needed.

In recent years, some new inversion methods for the reconstruction of obstacle boundaries have been proposed. The common idea of these methods is the construction of some indicator functions from given inversion input data, which depend on some detecting point (a parameter) varying inside or outside the obstacle. When this point approaches the obstacle, these indicator functions blowup. The linear sampling method [7], the factorization method [16], and the singular sources method [21] construct the indicator functions from the far-field pattern directly, while the probe method [13, 14] constructs the indicator in terms of the near field. The near field

can be obtained from the far field by some regularization procedures [21]. However, we can also state the natural version of the probe method directly from the far-field data, without reducing the far field to the near field; see [11]. For a review of these methods, the readers are referred to [22, 23], and for some relations between them, to [11, 20].

If the scattering is caused by multiple obstacles with different types of boundary or with mixed boundary condition, one should identify both the boundary shape, boundary type, and surface impedance. These kinds of problems come from some industry designs such as radar detection by electromagnetic wave scattering; see [10]. The obstacle is illuminated by an electromagnetic wave coming from an antenna. The wave is scattered by the obstacle and received by an antenna located in a different place. One of the objectives is to design the shape of the obstacle such that a reflected wave can be avoided or minimized in some directions. One possible approach to this goal is to introduce a coating on the surface of the obstacle or on some of its parts. This is motivated by the fact that reflections are minimized by applying such a surface coating. The surface coating is modeled by introducing an impedance boundary condition on a part or on the whole surface of the scatterer, which gives a relation between the electric and the magnetic field through a coefficient called surface impedance.

Due to this practical importance, the reconstruction of boundary impedance has been addressed by many authors. In [1], the authors construct the inhomogeneous boundary impedance for a cylinder obstacle with known shape using only one incident wave, assuming that the surface impedance is distributed along the whole boundary of the obstacle. In this case, the scattering of electromagnetic waves can be described by the 2-dimensional Helmholtz equation. We also refer to [17], where an optimization method is applied. After reducing the far field to the near field, a moment method is suggested in [6] to reconstruct the surface impedance approximately in the case of a completely coated obstacle, and the identification of different types of multiple obstacles is given in [5] in the case where on each obstacle we have one type of boundary condition.

The problem of whether a part of the surface of the obstacle is coated or not is important. Answering this question and reconstructing the surface impedance, in case of coating, from far-field measurements is our main object. In this work, we restrict ourselves to the acoustic wave scattering governed by a 2-dimensional Helmholtz equation, noticing that the 3-dimensional electromagnetic wave scattering in the cylinder case can be modeled by the 2-dimensional Helmholtz equation [8]. These issues were first considered in [2, 3] by the linear sampling method, where the authors simultaneously reconstruct the obstacle and compute the L^∞-norm of the surface impedance. This can be used to answer the question of existence or absence of coating and to give the value of the surface impedance in case it is known to be constant.

Motivated by these last works, our aim is to give another way to consider these issues and give further information on the obstacle. We proceed by constructing some indicator functions giving a direct link between the far-field pattern and the physical parameters of the obstacle. More precisely, we establish pointwise formulas which enable us to detect the boundary of the scatterer and distinguish and recognize the coated and the noncoated parts of the obstacle surface. In addition, on the coated part of the obstacle, the indicator functions give explicitly the pointwise values of this surface impedance as a functional of the far fields. These types of results have been initiated in [19], where the theoretical justification of these formulas in

3-dimensional acoustic scattering is given. Since we need more singularity analysis in the 2-dimensional case than in 3-dimensional case, which is due to the use of a more singular point source, we give the theoretical justification of the steps where it is necessary, and refer to [19] for the rest of the proof. We would like to emphasize that we are reconstructing the obstacle, localizing the eventual coated part and reconstructing the surface impedance in one step, i.e., simultaneously; compare with [1, 2, 3, 5, 6, 17]. Also, since the analysis is done pointwise, we can also consider multiple obstacles and give similar results.

The validity of the theoretical reconstruction formula presented in this paper is also checked by numerical tests with satisfactory performances. We would like to mention the following observations from the numerics. The coated part of an obstacle with larger impedance is less visible than the other part in terms of the value of the indicator. This explains the practical motivation for introducing the coating, i.e., to avoid or perturb the detection of an obstacle by applying an absorbing boundary layer. On the other hand, for nonconvex obstacles with mixed boundary conditions, the inversion formulas proposed in this paper also generate a satisfactory reconstruction by combining different blowing-up criterion together. These reconstruction performances are supported by our numerical implementations given in the last section of this paper.

The rest of the paper is organized as follows. In section 1, we state the problem mathematically. In section 2, we present the results, which we prove in section 3. Section 4 is devoted to the numerical tests.

1. Statement of the problem. Let D be a bounded domain of R^2 such that $R^2 \setminus \overline{D}$ is connected. We assume that its boundary ∂D is of class C^2 and has the following form:

$$\partial D = \overline{\partial D_I} \cup \overline{\partial D_D}, \quad \partial D_I \cap \partial D_D = \emptyset,$$

where ∂D_D and ∂D_I are open surfaces in ∂D.

The propagation of time-harmonic acoustic fields in homogeneous cylinder media can be modeled by the Helmholtz equation

$$\Delta u + \kappa^2 u = 0 \quad \text{in} \quad R^2 \setminus \overline{D}, \tag{1.1}$$

where $\kappa > 0$ is the wave number. At the part ∂D_I of the obstacle boundary, we assume the total field u that satisfies the impedance boundary condition, while the part ∂D_D satisfies the Dirichlet boundary condition. That is,

$$\frac{\partial u}{\partial \nu} + i\kappa\sigma u = 0 \text{ on } \partial D_I \tag{1.2}$$

with some impedance function σ and

$$u = 0 \text{ on } \partial D_D, \tag{1.3}$$

where ν is the outward unit normal of ∂D. We assume that σ is a real valued Holder continuous function of order $\beta \in (0, 1]$ and has a uniform lower bound $\sigma_- > 0$ on ∂D_I. The part ∂D_I is referred to by the coated part of ∂D, and ∂D_D is the noncoated part.

For a given incident plane wave $u^i(x, d) = e^{i\kappa d \cdot x}$ with incident direction $d \in S^1$, where S^1 is a unit circle in R^2, we look for a solution $u := u^i + u^s$ of (1.1), (1.2), and (1.3), where the scattered field u^s satisfies the Sommerfeld radiation condition

$$\lim_{r\to\infty} \sqrt{r} \left(\frac{\partial u^s}{\partial r} - i\kappa u^s \right) = 0 \tag{1.4}$$

with $r = |x|$ and the limit is uniform for all directions $\hat{x} \in S^1$.

The mixed problem (1.1)–(1.4) is well posed. More generally, for $f \in H^{\frac{1}{2}}(\partial D_D)$ and $h \in H^{-\frac{1}{2}}(\partial D_I)$, there exists a unique solution of the mixed problem

$$\begin{cases} (\Delta + \kappa^2)u = 0 \quad \text{in } R^2 \setminus \overline{D}, \\ u = f \quad \text{on } \partial D_D, \\ \frac{\partial u}{\partial \nu} + i\kappa\sigma u = h \quad \text{on } \partial D_I, \\ \lim_{r\to\infty} \sqrt{r}(\frac{\partial u}{\partial r} - i\kappa u) = 0, \end{cases} \tag{1.5}$$

and the solution satisfies

$$\|u\|_{H^1(\Omega_R \cap (R^2 \setminus \overline{D}))} \le C_R(\|f\|_{H^{1/2}(\partial D_D)} + \|h\|_{H^{-\frac{1}{2}}(\partial D_I)}), \tag{1.6}$$

where Ω_R is a disk of radius R and C_R is positive constant depending on R; see [4] for more details.

It is well known (see [8]) that the scattered wave has the asymptotic behavior

$$u^s(x,d) = \frac{e^{i\kappa r}}{\sqrt{r}} u^\infty(\hat{x},d) + O(r^{-3/2}), \quad r := |x| \to \infty, \tag{1.7}$$

where the function $u^\infty(\cdot, d)$ defined on S^1 is called the far field of the scattered wave u^s corresponding to incident direction d. We introduce a constant $\gamma_2 := \frac{e^{i\pi/4}}{\sqrt{8\pi\kappa}}$ and

$$\Phi(x,y) := \frac{i}{4} H_0^{(1)}(\kappa|x-y|), \quad x \neq y, x, y \in R^2,$$

the fundamental solution to the Helmholtz equation in R^2, where $H_0^{(1)}$ is the Hankel function of the first kind of order zero. In this paper, we will consider the following.

Inverse scattering problem for an obstacle with mixed boundary type. Given $u^\infty(\cdot,\cdot)$ on $S^1 \times S^1$ for the scattering problem (1.1)–(1.4), reconstruct the shape of obstacle D, identify ∂D_I and ∂D_D, and reconstruct the surface impedance $\sigma(x)$ on ∂D_I.

2. Presentation of the results. It is well known also (see [8]) that the scattered field associated with the Herglotz incident field $v_g^i := v_g$ defined by

$$v_g(x) := \int_{S^1} e^{i\kappa x\cdot d} g(d)\, ds(d), \quad x \in R^2, \tag{2.1}$$

with $g \in L^2(S^1)$ is given by

$$v_g^s(x) := \int_{S^1} u^s(x,d) g(d)\, ds(d), \quad x \in R^2 \setminus D, \tag{2.2}$$

and its far field is

$$v_g^\infty(\hat{x}) := \int_{S^1} u^\infty(\hat{x},d) g(d)\, ds(d), \quad \hat{x} \in S^1. \tag{2.3}$$

We will need the identity (see [8])

$$u^\infty(\hat{x},d) = -\gamma_2 \int_{\partial D} \left\{ \frac{\partial u^s(y,d)}{\partial \nu} e^{-i\kappa\hat{x}\cdot y} - \frac{\partial e^{-i\kappa\hat{x}\cdot y}}{\partial \nu} u^s(y,d) \right\} ds(y) \tag{2.4}$$

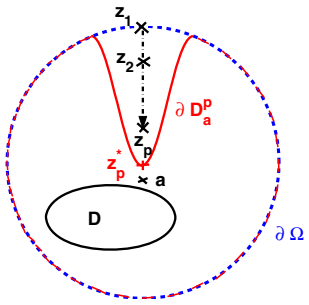

FIG. 2.1. *Geometric configuration.*

and the representation formula for the scattered wave $\Phi^s(\cdot, z)$ in $R^2 \setminus \overline{D}$ for the point source $\Phi(\cdot, z)$,

(2.5)
$$\Phi^s(x,z) = -\int_{\partial D} \left\{ \frac{\partial \Phi^s(y,z)}{\partial \nu(y)} \Phi(x,y) - \Phi^s(y,z) \frac{\partial \Phi(x,y)}{\partial \nu(y)} \right\} ds(y), \quad x, z \in R^2 \setminus \overline{D}.$$

Assume that $\overline{D} \subset\subset \Omega$ for some known Ω with smooth boundary. For $a \in \Omega \setminus D$, denote by $\{z_p\} \subset \Omega \setminus \overline{D}$ a sequence tending to a. For any z_p, set D_a^p a C^2-regular domain such that $\overline{D} \subset D_a^p$ with $z_q \in \Omega \setminus \overline{D_a^p}$ for every $q = 1, 2, \ldots, p$ and such that the Dirichlet interior problem on D_a^p for the Helmholtz equation is uniquely solvable; see Figure 2.1 for the configuration. In this case, the Herglotz wave operator $\mathbb{H}$ defined from $L^2(S^1)$ to $L^2(\partial D_a^p)$ by

$$\mathbb{H}[g](x) := v_g(x) = \int_{S^1} e^{i\kappa x \cdot d} g(d)\, ds(d) \tag{2.6}$$

is injective compact with dense range; see [8]. Let z_p^* be a point on ∂D_a^p near z_p such that $z_p^* \to a$ as $z_p \to a$, as chosen in Figure 2.1. Denote by $\nu(z_p^*)$ the outward normal of ∂D_a^p at z_p^*. Now we consider the sequence of point sources $\Phi(\cdot, z_p)$. For every p fixed, we construct two density sequences $\{g_n^p\}$ and $\{f_m^p\}$ in $L^2(S^1)$ by the Tikhonov regularization such that

$$\|v_{g_n^p} - \Phi(\cdot, z_p)\|_{L^2(\partial D_a^p)} \to 0, \quad n \to \infty, \tag{2.7}$$

$$\left\| v_{f_m^p} - \frac{\partial}{\partial \nu(z_p^*)} \Phi(\cdot, z_p) \right\|_{L^2(\partial D_a^p)} \to 0, \quad m \to \infty, \tag{2.8}$$

where $\partial_{\nu(z_p^*)} \Phi(\cdot, z_p) := \nabla_x \Phi(x, z_p) \cdot \nu(z_p^*)$. Since both $v_{g_n^p}$ and $\Phi(\cdot, z_p)$ satisfy the same Helmholtz equation in D_a^p, (2.7) implies that

$$\|v_{g_n^p} - \Phi(\cdot, z_p)\|_{H^{\frac{1}{2}}(\partial D)} \to 0, \quad n \to \infty, \tag{2.9}$$

and

$$\left\| \frac{\partial}{\partial \nu} v_{g_n^p} - \frac{\partial}{\partial \nu} \Phi(\cdot, z_p) \right\|_{H^{-\frac{1}{2}}(\partial D)} \to 0, \quad n \to \infty. \tag{2.10}$$

Similarly, it follows from (2.8) that

$$\left\| v_{f_m^p} - \frac{\partial}{\partial \nu(z_p^*)} \Phi(\cdot, z_p) \right\|_{H^{\frac{1}{2}}(\partial D)} \to 0, \quad m \to \infty, \tag{2.11}$$

and

$$\left\| \frac{\partial}{\partial \nu} v_{f_m^p} - \frac{\partial}{\partial \nu} \left(\frac{\partial}{\partial \nu(z_p^*)} \Phi(\cdot, z_p) \right) \right\|_{H^{-\frac{1}{2}}(\partial D)} \to 0, \quad m \to \infty. \tag{2.12}$$

Multiplying (2.4) by $f_m^p(d) g_n^p(\hat{x})$ and integrating over $S^1 \times S^1$, we have

$$\begin{aligned} & - \int_{S^1} \int_{S^1} u^\infty(-\hat{x}, d) f_m^p(d) g_n^p(\hat{x}) \, ds(\hat{x}) ds(d) \\ &= \gamma_2 \int_{\partial D} \left\{ \int_{S^1} \frac{\partial u^s(y,d)}{\partial \nu} f_m^p(d) \, ds(d) \cdot \int_{S^1} e^{i\kappa \hat{x} \cdot y} g_n^p(\hat{x}) \, ds(\hat{x}) \right. \\ &\qquad \left. - \int_{S^1} \frac{\partial e^{i\kappa \hat{x} \cdot y}}{\partial \nu} g_n^p(\hat{x}) \, ds(\hat{x}) \cdot \int_{S^1} u^s(y,d) f_m^p(d) \, ds(d) \right\} ds(y) \\ &= \gamma_2 \int_{\partial D} \left\{ \frac{\partial v^s_{f_m^p}}{\partial \nu}(y) v^i_{g_n^p}(y) - \frac{\partial v^i_{g_n^p}}{\partial \nu}(y) v^s_{f_m^p}(y) \right\} ds(y). \end{aligned} \tag{2.13}$$

From (2.9), (2.10), and (2.13), we have

$$\begin{aligned} & \lim_{n \to \infty} \int_{S^1} \int_{S^1} u^\infty(-\hat{x}, d) \, f_m^p(d) \, g_n^p(\hat{x}) \, ds(\hat{x}) ds(d) \\ &= \gamma_2 \int_{\partial D} \left\{ v^s_{f_m^p} \frac{\partial \Phi(y, z_p)}{\partial \nu(y)} - \frac{\partial v^s_{f_m^p}}{\partial \nu(y)} \Phi(y, z_p) \right\} ds(y) \\ &= \gamma_2 v^s_{f_m^p}(z_p) \end{aligned} \tag{2.14}$$

from the Green formula, where $v^s_{f_m^p}(\cdot)$ is the scattered wave corresponding to incident wave $v^i_{f_m^p}(x) = \mathbb{H}[f_m^p](x)$.

Denote by $E^s(x, z_p)$ the scattered wave corresponding to the incident wave $\frac{\partial \Phi(x, z_p)}{\partial \nu(z_p^*)}$, which is well defined for every $x \in R^2 \setminus \overline{D}$. Then it follows from (2.11), (2.12), the well-posedness of the direct scattering problem, and the use of interior estimate that

$$E^s(x, z_p) = \lim_{m \to \infty} v^s_{f_m^p}(x), \quad x \in R^2 \setminus \overline{D}. \tag{2.15}$$

Finally, it follows from (2.14) that

$$\lim_{m \to \infty} \lim_{n \to \infty} \int_{S^1} \int_{S^1} u^\infty(-\hat{x}, d) \, f_m^p(d) \, g_n^p(\hat{x}) \, ds(\hat{x}) ds(d) = \gamma_2 E^s(z_p, z_p). \tag{2.16}$$

The reconstruction of ∂D as well as its surface impedance in the coating part can be established based on (2.16). For this purpose, an analysis of $E^s(x, z)$ near ∂D is the key point. We need the natural C^2 smoothness assumption on the regularity of ∂D. Precisely, for every point $a \in \partial D$, there exists a rigid transformation of coordinates under which the image of a is $\mathbf{0}$ and a function $f \in C^2(-r, r)$ such that

$$f(0) = \frac{df}{dx}(0) = 0, \quad D \cap B(\mathbf{0}, r) = \{(x, y) \in B(\mathbf{0}, r); y > f(x)\} \tag{2.17}$$

in terms of the new coordinates, where $B(\mathbf{0}, r)$ is the 2-dimensional ball of center $\mathbf{0}$ with radius r.

For the points $a \in \partial D$, we choose the sequence $\{z_p\}_{p \in \mathbb{N}}$ included in $C_{a,\theta}$, where $C_{a,\theta}$ is a cone with center a, angle $\theta \in [0, \frac{\pi}{2})$, and axis $\nu(a)$. The main theoretical result of this paper is as follows.

THEOREM 2.1. *Assume that the boundary ∂D is of class C^2 and that σ is a real valued Holder continuous function with positive lower bound. Then the boundary properties of the obstacle D can be identified by the following indicator functions:*

1. *The obstacle boundary ∂D can be constructed from the following property:*

$$\lim_{p\to\infty}\lim_{m,n\to\infty}\left|\mathrm{Re}\left[\gamma_2^{-1}\int_{S^1}\int_{S^1}u^\infty(-\hat{x},d)f_m^p(d)g_n^p(\hat{x})\,ds(\hat{x})ds(d)\right]\right| = \begin{cases} +\infty, a\in\partial D,\\ <+\infty, \qquad a\in\Omega\setminus\overline{D}.\end{cases} \tag{2.18}$$

Precisely, we have the blowup rate

$$\lim_{m,n\to\infty}\mathrm{Re}\left[\gamma_2^{-1}\int_{S^1}\int_{S^1}u^\infty(-\hat{x},d)f_m^p(d)g_n^p(\hat{x})\,ds(\hat{x})ds(d)\right] = \frac{\pm 1}{4\pi|(z_p-a)\cdot\nu(a)|} + O(|\ln|z_p-a||^2), \tag{2.19}$$

where $z_p := (z_{p,1}, z_{p,2})$ and $a = (a_1, a_2)$. The sign $(+)$ is for $a\in\partial D_D$, while the sign $(-)$ is for $a\in\partial D_I$.

2. *The coated and the noncoated parts of ∂D can also be distinguished from the following properties*

$$\lim_{p\to\infty}\lim_{m,n\to\infty}\frac{\mathrm{Im}\left[\gamma_2^{-1}\int_{S^1}\int_{S^1}u^\infty(-\hat{x},d)f_m^p(d)g_n^p(\hat{x})\,ds(\hat{x})ds(d)\right]}{|\ln|(z_p-a)\cdot\nu(a)||^s} = \begin{cases}+\infty, & a\in\partial D_I,\\ 0, & a\in\partial D_D,\end{cases} \tag{2.20}$$

by choosing any fixed $s\in(0,1)$.

3. *The impedance coefficient on ∂D_I can be detected by the following formula:*

$$\lim_{p\to\infty}\lim_{m,n\to\infty}\frac{\mathrm{Im}\left[\gamma_2^{-1}\int_{S^1}\int_{S^1}u^\infty(-\hat{x},d)f_m^p(d)g_n^p(\hat{x})\,ds(\hat{x})ds(d)\right]}{|\ln|(z_p-a)\cdot\nu(a)||} = \frac{\kappa}{\pi}\sigma(a), \quad a\in\partial D_I. \tag{2.21}$$

REMARK 2.2. *The formula* (2.18) *is also true if f_m^p is replaced by g_n^p. That is, the singularity of $\Phi(x,z_p)$ is theoretically enough for identifying ∂D. However, as the blowup rate in this 2-dimensional case is of logarithmic order, it is not suitable to localize the obstacle clearly in the numerical experiments. For this reason, we introduced the density f_m^p, which is related to a stronger singularity $\frac{\partial}{\partial\nu(z_p^*)}\Phi(\cdot,z_p)$, to get a blowup rate of order $|z_p-a|^{-1}$. For the formulas* (2.20) *and* (2.21)*, the stronger singularity of $\frac{\partial}{\partial\nu(z_p^*)}\Phi(\cdot,z_p)$ is necessary. Moreover, we can in fact use $\nu(a)$ instead of $\nu(z_p^*)$, since ∂D has been determined in terms of* (2.18)*. The formula* (2.19) *can also be used to distinguish the coated part ∂D_I from the noncoated ∂D_I.*

REMARK 2.3. *Theorem* 2.1 *is stated for the case of a single obstacle. However, these results are still true for the multiple obstacle case with coated and noncoated parts.*

REMARK 2.4. *If $a\in D$, then the limit in* (2.18) *is conjectured to be ∞; see* [11]*. However, up to now, we do not have the full answer. The approach in* [15] *can be used to justify it in the case where the frequency κ is small enough.*

3. Proof of Theorem 2.1. For any given point $a\in\partial D$, we first take the rotation R_a and the translation M_a such that

$$R_a(\nu(a)) = (0,1), \quad R_a(a) + M_a = \mathbf{0}$$

in the new coordinate system $\tilde{x}$. Under the transform $\tilde{x} := \mathbb{T}(x) := R_a(x) + M_a$, it follows that

$$\mathbb{T}(\nu(a)) = (0,1), \quad \mathbb{T}(a) = \mathbf{0}.$$

Define $\tilde{\sigma}(\tilde{x}) := \sigma(x)$ and consider the following two problems in the coordinate $\tilde{x} = (\tilde{x}_1, \tilde{x}_2)$ for any given $\tilde{z} = (\tilde{z}_1, \tilde{z}_2) \in R^2_+$. We set $\tilde{w}^+_{\tilde{\sigma}(\mathbf{0})}(\tilde{x}, \tilde{z})$ and $\tilde{w}^+_D(\tilde{x}, \tilde{z})$ to be two functions satisfying

$$\text{(3.1)} \quad \begin{cases} \Delta \tilde{w}^+_{\tilde{\sigma}(\mathbf{0})} = 0, \quad \tilde{x} \in R^2_+, \\ (\frac{\partial}{\partial \tilde{x}_2} \tilde{w}^+_{\tilde{\sigma}(\mathbf{0})} + i\kappa\tilde{\sigma}(\mathbf{0}) \tilde{w}^+_{\tilde{\sigma}(\mathbf{0})})(\tilde{x}, \tilde{z})|_{\tilde{x}_2=0} = -(\frac{\partial}{\partial \tilde{x}_2} + i\kappa\tilde{\sigma}(\mathbf{0})) \frac{\partial}{\partial x_2} \Gamma(\tilde{x}, \tilde{z})|_{\tilde{x}_2=0}, \end{cases}$$

$$\text{(3.2)} \quad \begin{cases} \Delta \tilde{w}^+_D = 0, \quad \tilde{x} \in R^2_+, \\ \tilde{w}^+_D(\tilde{x}, \tilde{z})|_{\tilde{x}_2=0} = -\frac{\partial}{\partial x_2} \Gamma(\tilde{x}, \tilde{z})|_{\tilde{x}_2=0}, \end{cases}$$

respectively, where $\Gamma(\tilde{x}, \tilde{z}) = \frac{1}{2\pi} \ln \frac{1}{|\tilde{x} - \tilde{z}|}$ and the subscript D in $\tilde{w}^+_D(\tilde{x}, \tilde{z})$ refers to the Dirichlet boundary condition in (3.2).

We give explicit solutions to these two problems in the following proposition.

PROPOSITION 3.1. *We have the explicit form of* $w^+_{\tilde{\sigma}(\mathbf{0})}(\tilde{x}, \tilde{z})$,

$$\text{(3.3)} \quad \tilde{w}^+_{\tilde{\sigma}(\mathbf{0})}(\tilde{x}, \tilde{z}) = \frac{1}{4\pi} \int_R e^{i(\tilde{x}_1 - \tilde{z}_1)\xi_1} e^{-(\tilde{x}_2 + \tilde{z}_2)|\xi_1|} \frac{|\xi_1| + i\kappa\tilde{\sigma}(\mathbf{0})}{|\xi_1| - i\kappa\tilde{\sigma}(\mathbf{0})} d\xi_1,$$

while $\tilde{w}^+_D(\tilde{x}, \tilde{z})$ *has the form*

$$\text{(3.4)} \quad \tilde{w}^+_D(\tilde{x}, \tilde{z}) = -\frac{1}{4\pi} \int_R e^{i(\tilde{x}_1 - \tilde{z}_1)\xi_1} e^{-(\tilde{x}_2 + \tilde{z}_2)|\xi_1|} d\xi_1.$$

This proposition can be proven by expressing

$$\tilde{w}^+_{\tilde{\sigma}(\mathbf{0})}(\tilde{x}, \tilde{z}) = (U_+[\tilde{x}_2]\phi_+)(\tilde{x}_1), \quad \tilde{w}^+_D(\tilde{x}, \tilde{z}) = (U_+[\tilde{x}_2]\phi_-)(\tilde{x}_1)$$

in R^2_+ with $(U_\pm[\tilde{x}_2]\phi)(\tilde{x}_1) := \frac{1}{2\pi} \int_R e^{i\tilde{x}_1\xi_1 \mp \tilde{x}_2|\xi_1|} \hat{\phi}(\xi_1, \tilde{z}) d\xi_1$ and computing the density functions $\phi_\pm$ from the boundary value problems (3.1), (3.2), where $\hat{\phi}$ is the 1-dimensional Fourier transform of ϕ; see [19] for explicit computations.

Define

$$w^+_{\sigma(a)}(x, z) = \tilde{w}^+_{\tilde{\sigma}(\mathbf{0})}(\mathbb{T}x, \mathbb{T}z), \quad w^+_D(x, z) = \tilde{w}^+_D(\mathbb{T}x, \mathbb{T}z)$$

for $x, z \in R^2 \setminus \overline{D}$ near a, which is well defined by the definition of $\mathbb{T}$.

The next proposition gives the relation between $E^s(x, z)$ and $w^+_{\sigma(a)}(x, z), w^+_D(x, z)$ near the point a.

PROPOSITION 3.2. *If* $a \in \partial D_I$, *then there exist* $\delta(a) > 0$ *and* $C > 0$ *such that*

$$\text{(3.5)} \quad |\text{Im } E^s(x, z) - \text{Im } w^+_{\sigma(a)}(x, z)| \le C \qquad \textit{for } (x, z) \in B_+(a, \delta(a)) \cap C_{a,\theta},$$

$$\text{(3.6)} \quad |\text{Re } E^s(x, z) - \text{Re } w^+_{\sigma(a)}(x, z)| \le C |\ln |x - a|| \cdot |\ln |z_p - a|| \qquad \textit{for } (x, z) \in B_+(a, \delta(a)) \cap C_{a,\theta},$$

where $B_+(a, \delta(a)) := B(a, \delta(a)) \cap (R^2 \setminus D)$ *and* $B(a, \delta(a))$ *is the ball of center* a *and radius* $\delta(a)$.

Similarly, if $a \in \partial D_D$, we obtain (3.5) *and* (3.6) *by replacing $w^+_{\sigma(a)}$ by w^+_D.*

REMARK 3.3. *The estimate of* $|\text{Re } E^s(x,z) - \text{Re } w^+_{\sigma(a)}(x,z)|$ *is not optimal. We do not need the term* $|\ln|x-a||$. *The upper bound in* (3.6) *can be replaced by* $C_\alpha|z-a|^{-\alpha}$ *for any* $\alpha > 0$, *where* C_α *depends on* α. *But to prove Theorem* 2.1 *the estimate given in* (3.6) *is enough.*

Now we can prove Theorem 2.1 based on these propositions.

Proof of Theorem 2.1.

Step A: It follows from Proposition 3.2 that

$$|\text{Re } E^s(x,z_p) - \text{Re } w^+(x,z_p)| \le C \ln \frac{1}{|z_p - a|} \tag{3.7}$$

uniformly for all x, z_p near any fixed point $a \in \partial D$, where $w^+(z_p,z_p)$ may be $w^+_{\sigma(a)}(z_p,z_p)$ or $w^+_D(z_p,z_p)$, depending on the position of a. For $w^+(z_p,z_p) = w^+_D(z_p,z_p)$, it follows from (3.4) that

$$\text{Re } w^+(z_p,z_p) = -\frac{1}{4\pi}\int_R e^{-2|z_{p,2}-a_2||\xi_1|}d\xi_1 = \frac{1}{4\pi|z_{p,2}-a_2|},$$

while for $w^+(z_p,z_p) = w^+_{\sigma(a)}(z_p,z_p)$ it holds from (3.3) that

$$\text{Re } w^+(z_p,z_p) = \frac{1}{4\pi}\int_R e^{-2|z_{p,2}-a_2||\xi_1|}\frac{|\xi_1|^2 - \kappa^2\sigma^2(a)}{|\xi_1|^2+\kappa^2\sigma^2(a)}d\xi_1 = -\frac{1}{4\pi|z_{p,2}-a_2|} + O(1),$$

where $z_p = (z_{p,1}, z_{p,2}) \to a = (a_1,a_2) \in \partial D$ as $p \to \infty$. The application of the above relations in (3.7) leads to (2.19) and then $\lim_{p\to\infty}|\text{Re } E^s(z_p,z_p)| = +\infty$. Now (2.18) is proven for $a \in \partial D$.

Suppose that a is outside $\overline{D}$. We can construct z_p^*, z_p tending to a as we did for $a \in \partial D$. Recall that $E^s(x,z_p)$ satisfies

$$\begin{cases} (\Delta+\kappa^2)E^s(x,z_p) = 0 \text{ in } R^2 \setminus \overline{D}, \\ E^s(\cdot,z_p) = -\frac{\partial\Phi}{\partial\nu(z_p^*)}(x,z_p) \text{ on } \partial D_D, \\ (\frac{\partial}{\partial\nu} + i\kappa\sigma(x))E^s(x,z_p) = -(\partial_\nu + i\kappa\sigma(x))\frac{\partial\Phi}{\partial\nu(z_p^*)}(x,z_p) \text{ on } \partial D_I, \\ E^s(\cdot,z_p) \text{ satisfies the Sommerfeld radiation conditions,} \end{cases}$$

where $\nu(z_p^*)$ is the unit outward normal on ∂D_a^p at the point z_p^*. Hence the boundary condition is bounded with respect to x in $H^{1/2}(\partial D_D)$ and $H^{-\frac{1}{2}}(\partial D_I)$, respectively, for z_p^*, z_p near a. It follows from the well-posedness of the direct problem and interior estimates near a (i.e., away from ∂D) that $E^s(x,z_p)$, and then $E^s(z_p,z_p)$, is bounded.

Step B. Let $a \in \partial D_I$. From (3.3) we have

$$\tilde{w}^+_{\tilde{\sigma}(\mathbf{0})}(\tilde{z},\tilde{z}) = \frac{1}{4\pi}\int_R e^{-2\tilde{z}_2|\xi_1|}\frac{|\xi_1| + i\kappa\tilde{\sigma}(\mathbf{0})}{|\xi_1| - i\kappa\tilde{\sigma}(\mathbf{0})}d\xi_1. \tag{3.8}$$

By taking the imaginary part and setting $\tilde{z} = (\tilde{z}_1,\tilde{z}_2) = R_a(z) + M_a$ for $z \in C(a,\theta)$, we get

$$\begin{aligned} \text{Im}(4\pi w^+_{\sigma(a)}(z,z)) &= 4\kappa\sigma(a)\int_0^{+\infty}\frac{e^{-2(z-a)\cdot\nu(a)r}}{r^2+\kappa^2\sigma(a)^2}r\,dr \\ &= 4\kappa\sigma(a)\Big[-\ln(\kappa\sigma(a)) - \ln((z-a)\cdot\nu(a)) \\ &\qquad + 2\int_0^{+\infty}\ln(r^2+\kappa^2|(z-a)\cdot\nu(a)|^2\sigma^2(a))e^{-2r}dr\Big], \end{aligned} \tag{3.9}$$

which leads to the first relation in (2.20) by dividing by $|\ln((z-a)\cdot\nu(a))|^s$ for $0<(z-a)\cdot\nu(a)<1$ with $0<s<1$ using (3.5) and (2.16). The representation (2.21) for $\sigma(a)$ can be gotten from the above relation by dividing by $|\ln((z-a)\cdot\nu(a))|$ for $0<(z-a)\cdot\nu(a)<1$.

Step C. Let $a\in\partial D_D$. Proposition 3.2 for $w_D^+(x,z)$ and (2.14) imply the second relation in (2.20), noticing the fact that $\mathrm{Im}w_D^+(z,z)=0$. □

The rest of this section is devoted to the proof of Proposition 3.2. As we said in the introduction, in the 2-dimensional case, we need more singularity analysis than in [19]. This is due to the use of the more singular point source $\frac{\partial}{\partial\nu(z_p^*)}\Phi(\cdot,z_p)$. We give the detailed analysis and refer to [19] for the steps which do not need important changes.

3.1. Proof of Proposition 3.2. We give the proof for $a\in\partial D_I$. The proof for $a\in\partial D_D$ is similar.

Let $\tilde{E}^s(x,z_p)$ be the solution of

$$\text{(3.10)}\qquad \begin{cases} (\Delta+\kappa^2)\tilde{E}^s(x,z_p)=0 \quad \text{in } R^2\setminus\overline{D},\\ (\frac{\partial}{\partial\nu}+i\kappa\sigma(x))\tilde{E}^s(x,z_p)=-(\partial_\nu+i\sigma(x))\frac{\partial}{\partial\nu(z_p^*)}\Phi(x,z_p) \quad \text{on } \partial D,\\ \tilde{E}^s(\cdot,z) \text{ satisfies the Sommerfeld radiation condition.}\end{cases}$$

Hence $(E^s-\tilde{E}^s)(x,z_p)$ satisfies

$$\text{(3.11)}\qquad \begin{cases} (\Delta+\kappa^2)(E^s-\tilde{E}^s)(x,z_p)=0 \quad \text{in } R^2\setminus\overline{D},\\ (\frac{\partial}{\partial\nu}+i\kappa\sigma(x))(E^s-\tilde{E}^s)(x,z_p)=0 \quad \text{on } \partial D_I,\\ (E^s-\tilde{E}^s)(\cdot,z_p)=-\frac{\partial}{\partial\nu(z_p^*)}\Phi(x,z_p)-\tilde{E}^s \quad \text{on } \partial D_D,\\ (E^s-\tilde{E}^s)(\cdot,z) \text{ satisfies the Sommerfeld radiation condition.}\end{cases}$$

We state $H_\sigma(x,z):=\tilde{E}(x,z)+\partial_{\nu(z_p^*)}\Phi(x,z)$. Hence H satisfies

$$\text{(3.12)}\qquad \begin{cases} (\Delta+\kappa^2)H_\sigma(x,z)=-\nabla\delta(x,z)\cdot\nu(z_p^*) \quad \text{in } R^2\setminus\overline{D},\\ (\frac{\partial}{\partial\nu}+i\kappa\sigma(x))H_\sigma(x,z)=0 \quad \text{on } \partial D,\\ H_\sigma(\cdot,z) \text{ satisfies the Sommerfeld radiation condition.}\end{cases}$$

We have the following estimates:

$$\text{(3.13)}\qquad \begin{cases} |G_\sigma(x,z)|\le c|\ln|x-z||\\ |\nabla G_\sigma(x,z)|\le c|x-z|^{-1}\\ |H_\sigma(x,z)|\le c|x-z|^{-1}\\ |\nabla H_\sigma(x,z)|\le c|x-z|^{-2}\end{cases} \quad \text{in } R^2\setminus D, \text{ where } c \text{ is a positive constant.}$$

The justification of these properties can be derived following, for instance, the approach of [24] and [25] since an explicit form of a local fundamental solution for the half-space case can be derived as we did in Proposition 3.1. See also [18] and [12] for the case of elliptic problems with rough coefficients.

From these estimates, we deduce that $\tilde{E}(\cdot,z_p)$ and its derivatives are bounded for $x\in\partial D_D$ and z_p near $a\in\partial D_I$. The well-posedness of (3.11) implies that $(E^s-\tilde{E}^s)(\cdot,z_p)$ is bounded in $H^1_{loc}(R^2\setminus\overline{D})$ for z_p near a. Introducing a cutoff function near the point a and using (3.11), we deduce that $(E^s-\tilde{E}^s)(\cdot,z_p)$ is bounded for x near ∂D_I and z_p near a.

This means that we can replace E^s by $\tilde{E}^s$ in Proposition 3.2.

We introduce $w^s_\sigma(\cdot, z_p)$ as the solution of

$$\begin{cases} (\Delta + \kappa^2) w^s_\sigma(x, z_p) = 0 \quad \text{in } R^2 \setminus \overline{D}, \\ (\frac{\partial}{\partial \nu} + i\kappa\sigma(x)) w^s_\sigma(x, z_p) = -(\partial_\nu + i\sigma(x)) \frac{\partial}{\partial \nu(a)} \Phi(\cdot, z_p) \quad \text{on } \partial D, \\ w^s_\sigma(\cdot, z) \text{ satisfies the Sommerfeld radiation condition,} \end{cases} \tag{3.14}$$

and denote by $w^s_{\sigma(a)}(\cdot, z_p)$ the solution of (3.14) replacing $\sigma(x)$ by $\sigma(a)$. Then we have the following result.

LEMMA 3.4. *There exist $\delta(a) > 0$ and $C(R) > 0$ such that*

$$|(\tilde{E}^s - w^s_\sigma)(x, z_p)| \le C(R) |\ln d(x, \partial D)| \cdot |\ln d(z_p, \partial D)|,$$

$$|\mathrm{Im}(\tilde{E}^s - w^s_\sigma)(x, z_p)| \le C(R), \quad |(w^s_\sigma - w^s_{\sigma(a)})(x, z_p)| \le C(R)$$

for $z_p \in B(a, \delta(a)) \cap C_{a,\theta}$ and $x \in (R^2 \setminus D) \cap B(0, R)$, for any $R > 0$ fixed.

Let $w^s_{\sigma(a),\Phi}(\cdot, z)$ be the solution of

$$\begin{cases} (\Delta + \kappa^2) w^s_{\sigma(a),\Phi}(x, z) = 0 \quad \text{in } \Omega \setminus \overline{D}, \\ (\frac{\partial}{\partial \nu} + i\kappa\sigma(a)) w^s_{\sigma(a),\Phi}(x, z) = -(\frac{\partial}{\partial \nu} + i\kappa\sigma(a)) \frac{\partial}{\partial \nu(a)} \Phi(x, z_p) \quad \text{on } \partial D, \\ w^s_{\sigma(a),\Phi}(\cdot, z) = -\frac{\partial}{\partial \nu(a)} \Phi(x, z_p) \quad \text{on } \partial\Omega \end{cases} \tag{3.15}$$

and $w^s_{\sigma(a),\Gamma}(\cdot, z)$ be the solution of (3.15) replacing Φ by Γ. Then we have the following claim.

LEMMA 3.5. *There exists $C > 0$ such that*

$$|(w^s_{\sigma(a)} - w^s_{\sigma(a),\Phi})(x, z)| \le C, \quad |(w^s_{\sigma(a),\Phi} - w^s_{\sigma(a),\Gamma})(x, z)| \le C$$

for $z \in \Omega \setminus D$ near D and $x \in \Omega \setminus D$.

We define $w^{s,0}_{\sigma(a)}$ to be the solution of (3.15) replacing Φ by Γ and the Helmholtz equation by the Laplace equation. Then we have the next claim.

LEMMA 3.6. *There exists $C > 0$ such that $|(w^s_{\sigma(a),\Gamma} - w^{s,0}_{\sigma(a)})(x, z)| \le C$, for $z \in \Omega \setminus D$ near D and $x \in \Omega \setminus D$.*

Finally, we have the next claim.

LEMMA 3.7. *There exist $C > 0$, $\delta(a) > 0$ such that*

1. $|(\mathrm{Im}\, w^{s,0}_{\sigma(a)} - \mathrm{Im}\, w^+_{\sigma(a)})(x, z)| \le C$ *for* $(x, z) \in B(a, \delta(a)) \cap C_{a,\theta}$;
2. $|(\mathrm{Re} w^{s,0}_{\sigma(a)} - \mathrm{Re} w^+_{\sigma(a)})(x, z)| \le C |\ln d(z_p, \partial D)|$ *for* $(x, z) \in B(a, \delta(a)) \cap C_{a,\theta}$.

By combining all the lemmas stated above, we end the proof of Proposition 3.2. □

In the proofs of these lemmas we do not, in general, specify the interdependency of the constants appearing in the estimates. However, we distinguish the constants that do or do not depend on the angle θ.

Proof of Lemma 3.4. The function $\tilde{E}^s(x, z_p) - w^s_\sigma(x, z_p)$ satisfies

$$\begin{cases} (\Delta + \kappa^2)(\tilde{E}^s - w^s_\sigma)(x, z_p) = 0 \quad \text{in } R^2 \setminus \overline{D}, \\ (\frac{\partial}{\partial \nu} + i\kappa\sigma)(\tilde{E}^s - w^s_\sigma)(x, z_p) = -(\frac{\partial}{\partial \nu} + i\kappa\sigma) \nabla\Phi \cdot [\nu(z^*_p) - \nu(a)] \quad \text{on } \partial D, \\ (\tilde{E}^s - w^s_\sigma)(\cdot, z_p) \text{ satisfies the Sommerfeld radiation condition.} \end{cases} \tag{3.16}$$

We need the following lemma.

LEMMA 3.8. *We have the estimate*

$$|\nu(z^*_p) - \nu(a)| \le C |z^*_p - a|$$

for z_p^* near a, where C is a positive constant.

Proof of Lemma 3.8. Take a point $b \in \partial\Omega$ and connect it to a by a C^3 smooth curve l such that $l(0) = a$, $l(1) = b$, $l(s) \in \Omega \setminus \overline{D}$ $(s \in (0,1))$. By Theorem 7.1 of [11], there is a C^2 strict deformation family $\{D_a^{l(s)}\}$ of a and $\partial\Omega$. That is, each $\partial D_a^{l(s)}$ is C^2 diffeomorphic to the unit circle and $\{D_a^{l(s)}\}$ satisfies the following properties:

(i) $a \in \partial D_a^{l(0)}$, $D \subset D_a^{l(0)} \subset \Omega$.

(ii) $\partial D_a^{l(1)} = \partial\Omega$, $\overline{D_a^{l(s)}} \subset D_a^{l(s')}$ $(0 \le s < s' \le 1)$.

(iii) l intersects $\partial D_a^{l(s)}$ at $l(s)$.

(iv) $\partial D_a^{l(s)}$ depends C^2 smoothly on $s \in [0,1]$.

For every $s \in [0,1]$ we define $\nu(l(s))$ to be the unit normal of $\partial D_a^{l(s)}$ at $l(s)$. From (iv), the map $s \in [0,1] \to \nu(l(s))$ is C^1. Choosing l to be a one-to-one curve near a, we deduce that the map $l(s) \in l([0,1]) \to \nu(l(s))$ is also C^1 near $l(0)$. Now let $\{s_p\} \subset [0,1]$ be such that $s_p \to 0$ $(p \to \infty)$ and let l be a C^3 smooth curve such that $z_p^* := l(s_p)$ and $\{z_p\}_{p\in\mathbb{N}} \subset l([0,1])$. Since for every p, z_p and z_p^* are in $\Omega \setminus \overline{D}$, then we can always choose l such that $l(s) \in \Omega \setminus \overline{D}$, $(s \in [0,1])$. We set $D_a^p := D_a^{l(s_p)}$. Hence the sequence $\nu(z_p^*)$ satisfies Lemma 3.8. □

The function $\mathrm{Im}(\tilde{E}^s - w_\sigma^s)$ satisfies

(3.17)
$$\begin{cases} (\Delta + \kappa^2)\mathrm{Im}(\tilde{E}^s - w_\sigma^s)(x,z) = 0 \quad \text{in } R^2 \setminus \overline{D}, \\ \frac{\partial}{\partial\nu}\mathrm{Im}(\tilde{E}^- w_\sigma^s)(x,z) = [\kappa\sigma\mathrm{Re}(\tilde{E}^s - w_\sigma^s) - [\frac{\partial}{\partial\nu}\mathrm{Im}\nabla\Phi + \kappa\sigma\mathrm{Re}\nabla\Phi] \cdot [\nu(z_p^*) - \nu(a)]](x,z) \\ \qquad \text{on } \partial D. \end{cases}$$

Hence we have

$$-\mathrm{Im}(\tilde{E}^s - w_\sigma^s)(x,z_p) = \int_{\partial D} F(y,z_p) G_N(y,x) ds(y) + \int_{\partial B_R} \mathrm{Im}(\tilde{E}^s - w_\sigma^s)(y,z_p) \frac{\partial}{\partial\nu} G_N(y,x) ds(y), \tag{3.18}$$

where

$$F(x,z_p) := \kappa\sigma(x)\mathrm{Re}(\tilde{E}^s - w_\sigma^s)(x,z) + \left[-\frac{\partial}{\partial\nu}\mathrm{Im}\nabla\Phi - \kappa\sigma(x)\mathrm{Re}\nabla\Phi\right](x,z) \cdot [\nu(z_p^*) - \nu(a)],$$

and $G_N(x,y)$ is the Green's function of the problem given by the Helmholtz equation in $B_R \setminus \overline{D}$ with Neumann boundary condition on ∂D and Dirichlet boundary condition on ∂B_R. The normal ν is oriented outside $B \setminus \overline{D}$.

From (3.16), we have

$$-(\tilde{E}^s - w_\sigma^s)(x,z_p) = \int_{\partial D} G_\sigma(x,y) \left(\frac{\partial}{\partial\nu} + i\kappa\sigma(y)\right) [\nabla\Phi \cdot (\nu(z_p^*) - \nu(a))](y,z_p) ds(y).$$

Hence

$$|(\tilde{E}^s - w_\sigma^s)(x,z_p)| \le c \int_{\partial D} (\ln|x-y|)|y-z_p|^{-2}|z_p^* - a| ds(y).$$

For $y \in \partial D$ and $z_p \in C_{a,\theta}$ we have the inequality $|z_p - a| \le C(\theta)|z_p - y|$. Applying this inequality to z_p^*, enlarging θ if necessary, we have

$$|(\tilde{E}^s - w_\sigma^s)(x,z_p)| \le c \int_{\partial D} (\ln|x-y|)|y-z_p|^{-1} ds(y) \tag{3.19}$$

since $|z_p^* - y| \le |z_p - y|$, for $y \in \partial D$ and z_p near a. Hence for every $\alpha > 0$ there exists $C_\alpha > 0$ such that

$$|(\tilde{E}^s - w_\sigma^s)(x, z_p)| \le C_\alpha |x - z_p|^{-\alpha}.$$

From the explicit form of Φ, we have $|\frac{\partial}{\partial \nu} \mathrm{Im} \nabla \Phi(x, z_p)| \cdot |\nu(z_p^*) - \nu(a)| \le c|x - z_p|^{-1} \cdot |z_p^* - a|$ and $\mathrm{Re} \nabla \Phi(x, z_p)| \cdot |\nu(z_p^*) - \nu(a)| \le c|x - z_p|^{-1} |z_p^* - a|$. Hence $F(y, z_p) \le C_\alpha |y - z_p|^{-\alpha}$ for $y \in \partial D$. Using the estimate $|G_N(x, y)| \le C_\alpha \ln |x - y|$ and choosing $\alpha < 1$, we deduce from (3.18) that

$$|\mathrm{Im}(\tilde{E}^s - w_\sigma^s)(x, z_p)| \le C_\alpha.$$

We have the first estimate of Lemma 3.4 from (3.19), i.e.,

$$|(\tilde{E}^s - w_\sigma^s)(x, z_p)| \le C \ln d(x, \partial D)| \cdot |\ln d(z_p, \partial D)|.$$

Now consider the third estimate of Lemma 3.4. We set $R(x, z) := w_\sigma^s(x, z) - w_{\sigma(a)}^s(x, z)$. Then it satisfies

(3.20)
$$\begin{cases} (\Delta + \kappa^2) R(x, z) = 0 \quad \text{in } R^2 \setminus \overline{D}, \\ \frac{\partial R(x,z)}{\partial \nu} + i\kappa\sigma(a) R(x, z) = -i\kappa(\sigma(x) - \sigma(a))(w_\lambda^s(x, z) + \frac{\partial}{\partial \nu(a)} \Phi(x, z)) \quad \text{on } \partial D, \\ R(\cdot, z) \text{ satisfies the Sommerfeld radiation condition.} \end{cases}$$

From (3.20), we have the representation

$$R(x, z) = -\int_{\partial D} i\kappa(\sigma(y) - \sigma(a)) G_{\sigma(a)}(y, x) \left(w_\sigma^s + \frac{\partial}{\partial \nu(a)} \Phi \right)(y, z) ds(y) \quad \text{for } (x, z) \in R^2 \setminus \overline{D}. \tag{3.21}$$

We define $K(x, z) := -(\frac{\partial}{\partial \nu} + i\kappa\sigma(x)) \frac{\partial}{\partial \nu(a)} \Phi(x, z)$. From (3.14) we have the representation

$$w_\sigma^s(x, z) = \int_{\partial D} G_{\sigma(a)}(y, x) K(y, z) ds(y);$$

hence, due to the estimates of the Green's function $G_{\sigma(a)}(x, y)$ and $\Phi(x, y)$, we have

$$|w_\sigma^s(x, z)| \le \int_{\partial D} |\ln(|y - x|)||z - y|^{-2} ds(y) \le \frac{c}{|x - z|}.$$

From (3.21) and the Holder regularity of $\sigma(x)$, we deduce that

$$|R(x, z)| \le c \int_{\partial D} |y - a|^\beta \ln(|y - x|)||z - y|^{-1} ds(y).$$

From the inequality $|y - a| \le c(\theta)|y - z|$ for $y \in \partial D$ and $z \in C_{a,\theta} \cap B(a, \delta(a))$ we have

$$\frac{|y - a|^\beta}{|y - z|} \le \frac{c(\theta)^\beta C}{|y - z|^{1-\beta}},$$

which implies

$$|R(x, z)| \le \int_{\partial D} \frac{c(\theta)^\beta C |\ln |y - x||}{|y - z|^{1-\beta}} dy$$

and therefore $|R(x,z)| = O(1)$ for $x \in R^2 \setminus D$ and $z \in C_{a,\theta} \cap B(0,R)$. ∎

Proof of Lemmas 3.5 *and* 3.6. Similarly to the proof of Lemma 3.4, these proofs are based on the use of integral representations and the pointwise estimates of the Green's functions of the corresponding problems. We omit the details. ∎

Proof of Lemma 3.7. Since $w^{s,0}_{\sigma(a)}$ satisfies

$$\begin{cases} \Delta w^{s,0}_{\sigma(a)}(x,z) = 0 \quad \text{in } \Omega \setminus \overline{D}, \\ (\frac{\partial}{\partial \nu} + i\kappa\sigma(a))(w^{s,0}_{\sigma(a)}(\cdot,z)) = -(\frac{\partial}{\partial \nu} + i\kappa\sigma(a))\frac{\partial}{\partial \nu(a)}\Gamma \quad \text{on } \partial D, \\ w^{s,0}_{\sigma(a)}(\cdot,z) = -\frac{\partial}{\partial \nu(a)}(\Gamma) \quad \text{on } \partial\Omega, \end{cases} \tag{3.22}$$

then it is clear that $G^0_{\sigma(a)} := w^{s,0}_{\sigma(a)}(x,y) + \partial_{\nu(a)}\Gamma(x,y)$ satisfies

$$\begin{cases} \Delta(G^0_{\sigma(a)})(x,z) = -\frac{\partial}{\partial \nu(a)}\delta(x-y) \quad \text{in } \Omega \setminus \overline{D}, \\ (\frac{\partial}{\partial \nu} + i\kappa\sigma(a))(G^0_{\sigma(a)})(\cdot,z) = 0 \quad \text{on } \partial D, \\ (G^0_{\sigma(a)})(\cdot,z) = 0 \quad \text{on } \partial\Omega. \end{cases} \tag{3.23}$$

We can assume without loss of generality that $a = (0,0)$ and $\nu(a) = (0,1)$ by using the rigid transformation of coordinates $[R_a(\nu(a)) + M_a]$. Let $\xi = F(x)$ be the local change of variables

$$\xi_1 = x_1, \quad \xi_2 = x_2 - f(x_1), \tag{3.24}$$

where f is the function defined in the introduction. We have the following properties:

$$\begin{cases} c_1|x-z| \le |F(x) - F(z)| \le c_2|x-z|, \\ |F(x) - x| \le c_3|x|^2, \\ |DF(x) - I| \le c_4|x| \end{cases} \tag{3.25}$$

for x, z near the point a, where c_i $(i = 1,2,3,4)$ are positive constants, which is due to hypothesis on the regularity of ∂D.

Let x, z be points near a. From (3.23), we deduce that $\tilde{G}^0_{\sigma(a)}(\xi,\eta) = G^0_{\sigma(a)}(x,z)$ satisfies

$$\begin{cases} \nabla_\xi \cdot B(\xi)\nabla_\xi \tilde{G}^0_{\sigma(a)} = -J^T(\xi)\nabla_\xi\delta(\xi-\eta)\cdot(0,1) \quad \text{near } F(a), \\ |J^{-T}\nu|B(\xi)\nabla_\xi\tilde{G}^0_{\sigma(a)}\cdot\tilde{\nu} + i\kappa\sigma(a)\tilde{G}^0_{\sigma(a)} = 0 \quad \text{on } \partial R^2_+ \text{ near } F(a), \end{cases} \tag{3.26}$$

where $\xi := F(x)$ and $\eta := F(z)$, $B := JJ^T$ and $J := \frac{\partial \xi}{\partial x}(F^{-1}(\xi))$, and $\tilde{\nu} := (0,1)$ is the unit normal to ∂R^2_+. We denoted by J^{-T} the adjoint of J^{-1}. We have from (3.25) that

$$|J^T(\xi) - J^T(0)| \le c|\xi|, \quad |B(\xi) - B(0)| \le c|\xi|$$

and $J(0) = B(0) = I$.

We set $\Gamma_{\sigma(a)}(x,z) := (w^+_{\sigma(a)} + \frac{\partial}{\partial x_2}\Gamma)(x,z)$ and write $\tilde{R}(\xi,\eta) := \tilde{G}^0_{\sigma(a)}(\xi,\eta) - \Gamma_{\sigma(a)}(\xi,\eta)$. Then the function $\tilde{R}(\cdot,\eta)$ satisfies

$$\begin{cases} \nabla_\xi \cdot B(\xi)\nabla_\xi\tilde{R} = \nabla_\xi\cdot(I-B)\nabla_\xi\Gamma_{\sigma(a)} + (I - J^T(\xi))\nabla_\xi\delta(\xi-\eta)\cdot(0,1), \\ B(\xi)\nabla_\xi\tilde{R}\cdot\tilde{\nu} + i\kappa\sigma(a)\tilde{R} = (I-B)\nabla_\xi\Gamma_{\sigma(a)}\cdot\tilde{\nu} + i\kappa\sigma(a)(1 - |J^{-T}\nu|^{-1})\tilde{R}, \end{cases} \tag{3.27}$$

where the first relation holds in R^2_+ near $F(a)$, while the second one is satisfied on ∂R^2_+ near $F(a)$.

We remark that $(I - J^T(\xi))$ is equal to the matrix given by the two line vectors $(0, -f(\xi))$ and $(0, 0)$. Hence we have

$$(I - J^T(\xi))\nabla_\xi \mathrm{Im}\Gamma_{\sigma(a)}(\xi, \eta) \cdot (0, 1) = 0.$$

With this remark, the problem (3.27) is exactly the one studied in [19]. We write $\partial B_r^+ = S_r \cup S_r^c$ with $S_r := \partial B_r^+ \cap \partial F(D)$. Arguing as in [19], we obtain the estimate

$$|\mathrm{Im}\ \tilde{R}(\xi, \eta)| < c \quad \text{for } \xi \in S_r \text{ and } \eta \in C_{F(a),\theta}$$

and

$$|\mathrm{Re}\ \tilde{R}(\xi, \eta)| < c|\ln|\xi - \eta|| \quad \text{for } \xi \in S_r \text{ and } \eta \in C_{F(a),\theta}.$$

We go back to $R(x, z) := G^0_{\sigma(a)}(x, z) - \Gamma_{\sigma(a)}(x, z)$. We have

$$R(x, z) = G^0_{\sigma(a)}(x, z) - \Gamma_{\sigma(a)}(F(x), F(z)) + \Gamma_{\sigma(a)}(F(x), F(z)) - \Gamma_{\sigma(a)}(x, z),$$

which can be rewritten as

$$\begin{aligned} R(x, z) = \tilde{R}(F(x), F(z)) &+ [\Gamma_{\sigma(a)}(F(x), F(z)) - \Gamma_{\sigma(a)}(F(x), z)] \\ &+ [\Gamma_{\sigma(a)}(F(x), z) - \Gamma_{\sigma(a)}(x, z)]. \end{aligned} \tag{3.28}$$

By the same argument as in [19], we end up with the estimate

$$|\mathrm{Im}\ R(x, z)| \le c(\theta) \tag{3.29}$$

for $x \in B(a, \delta(a))$ such that $F(x) \in S_r$ and $z \in C_{a,\theta} \cap B(a, \delta(a))$.

For $z \in C_{a,\theta} \cap B(a, \frac{\delta(a)}{2})$ and $x \in [\partial B(a, \delta(a))] \cap R^2 \setminus \overline{D}$, we have

$$|\mathrm{Im}\ R(x, z)| \le c \tag{3.30}$$

with some positive constant c, because $C_{a,\theta} \cap B(a, \frac{\delta(a)}{2})$ and $[\partial B(a, \delta(a))] \cap R^2 \setminus \overline{D}$ are separated sets. Since in $B(a, \delta(a)) \cap (R^2 \setminus \overline{D})$, we have $\Delta_x \mathrm{Im}\ R(x, z) = 0$; then, using (3.29) and (3.30), we have $|\mathrm{Im}\ R(x, z)| \le c(\theta)$ for $x \in [R^2 \setminus D] \cap B(a, \delta(a))$ and $z \in C_{a,\theta} \cap B(a, \frac{\delta(a)}{2})$, by the maximum principle.

Similarly we have $|\mathrm{Re}R(x, z)| \le C|\ln|x - z||$ for $x \in B(a, \delta(a))$ such that $F(x) \in S_r$ and $z \in C_{a,\theta} \cap B(a, \delta(a))$. Hence $|\mathrm{Re}R(x, z)| \le C|\ln d(z, \partial D)|$ for $x \in B(a, \delta(a))$ such that $F(x) \in S_r$ and $z \in C_{a,\theta} \cap B(a, \delta(a))$, which is the counterpart of (3.30) for $\mathrm{Re}\tilde{R}$. The rest of the proof is the same as that for the imaginary part. ∎

4. Numerical tests. In this section, we consider two reconstruction model problems for numerical tests based on Theorem 2.1. In the first model we take the obstacle to be a disc, and on its whole boundary we impose the impedance boundary condition. The purpose of considering such a model is to show the influence of wave number κ and singularity strength on the inversion scheme. In the second model, we consider a nonconvex obstacle with mixed boundary conditions. We check our inversion formulas fully, especially for the identification of a different type of boundary. Also we show the effect of the nonconvex part on the inversion performance.

In the reconstruction scheme, the approximation of $\Phi(x, z_p)$ and $\Phi_{\nu(a)}(x, z_p)$ by the Herglotz wave function plays a key role. To do this, we need to construct the approximate domain D_a^p in the way mentioned in section 2. Then its density functions

can be determined by the standard argument of a minimum norm solution of the integral equation of the first kind. In this way the numerators in (2.18), (2.20), and (2.21) can be computed for every sequence of points $(z_p)_{p\in\mathbb{N}}$ approaching ∂D in terms of the far-field pattern.

In testing our inversion scheme, we simulate the inversion input data (far-field pattern) by solving the direct problem using the combined single- and double-layer potential method; see [8] and [9].

In subsections 4.1 and 4.2, we consider the first model, while subsection 4.3 is dedicated to a nonconvex obstacle with mixed boundary conditions, from which we can test our theoretical results.

4.1. Reconstruction of ∂D. For the numerical test we take $\partial D = \{x = (x_1(t), x_2(t)) = 1.2(\cos t, \sin t) : t \in [0, 2\pi]\}$. We can construct D_a^p in a special way by

$$\partial D_a^p = \{(\tilde{x}_1(t), \tilde{x}_2(t)) = (1.2 + \delta_0(p))(\cos t, \sin t) : t \in [0, 2\pi]\}$$

and take $z_p = (\tilde{x}_1(t_0), \tilde{x}_2(t_0)) + \delta_1(p)(\cos t_0, \sin t_0)$ outside of $\overline{D}_a^p$ for $a = 1.2(\cos t_0, \sin t_0)$ in ∂D. The smallness of $\delta_1(p)$ determines the singularity of $\Phi(x, z_p), \Phi_{\nu(a)}(x, z_p)$ on ∂D_a^p near z_p.

Example 1. Construction of ∂D with unknown impedance $\sigma(x)$ for given far-field data.

It follows from the first point of Theorem 2.1 that the boundary ∂D can be reconstructed from the blowup behavior of the approximate values of the indicator function:

$$I_{m,n}(z_p) :\approx \left(\frac{\pi}{N}\right)^2 \left| \sum_{i,j=1}^{2N-1} \mathrm{Re}\left(\gamma_2^{-1} U^\infty(i,j) F_m^p(j) G_m^p(i)\right) \right| \tag{4.1}$$

for large m, n, where $G_n^p(i) := g_n^p(\hat{x}_i)$, $F_m^p(j) := f_m^p(\hat{d}_j)$, and $U^\infty(i,j)$ represents $u^\infty(-\hat{x}_i, d_j)$.

Therefore, we can test the numerical performance of this formula by taking z_p approaching ∂D. If $I_{m,n}(z_p)$ is greater than some a priori given large value, for fixed m, n large enough, we consider z_p to be almost in ∂D. Notice that only the singularity in $\Phi_{\nu(\tilde{z}_p)}(x, z_p)$ is needed in this procedure; we do not need the boundary ∂D.

In our numerical implementations, we take $\kappa = 0.6$, $N = 32$ and keep the singularity of $\Phi(\cdot, z_p)$ unchanged near ∂D_a^p by fixing $\delta_1 = 0.015$. When z_p approaches ∂D by decreasing δ_0 from different directions t_0, we get different values of $I_{m,n}(z_p)$. We choose the same constant CB as the criterion for the blowing-up of the indicator $I_{m,n}(z_p(t_0))$ at different direction t_0. That is, we choose $z_p(t_0)$ as the approximation of the point $a \in \partial D$ in the direction t_0 when $I_{m,n}(z_p(t_0))$ is larger than CB. Then the constructed approximate position of ∂D is given by interpolating those points. In this way, we can draw the approximate shape of ∂D by choosing all directions t_0 using the same given CB. As obtained in the theoretical result, the larger the value CB is, the better the approximation of ∂D should be.

Consider the boundary reconstruction problem with nonconstant impedance

$$\sigma(x) = \frac{2 + x_1 x_2}{(3 + x_2)^2}, \quad x \in \partial D.$$

Under this configuration, the reconstructions for different blowup criteria are shown in Figure 4.1(left), while the distribution of indicator value is given in the right panel.

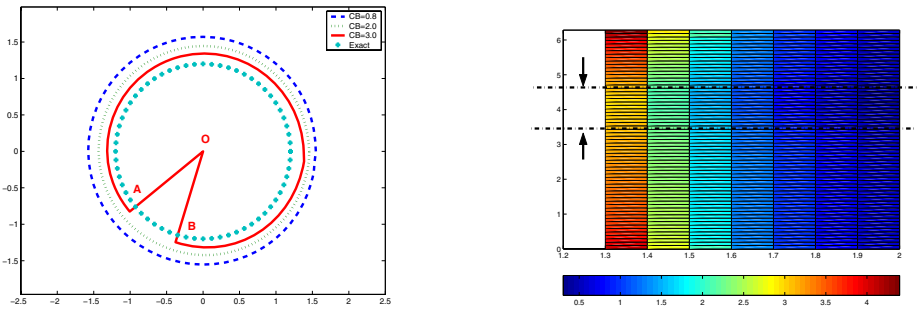

FIG. 4.1. *Reconstruction of ∂D for variable impedance with $\kappa = 0.6$ with different blowup constants CB; the values of the indicator are small in the directions corresponding to large impedance.*

There is an interesting phenomenon in the numerics. For a reasonable indicator value $CB = 2$, we can see the whole rough shape of ∂D. However, for larger values, i.e., $CB = 3$, most of the part of ∂D can be seen with more satisfactory accuracy, but some part, i.e., $(\widehat{AB})$, is not visible. In this part the indicator value is less than 3 (but, of course, bigger than 2). This numerical performance is closely related to the impedance distribution in ∂D. It can be seen from the right-hand part of Figure 4.1 that the indicator value is obviously smaller in the narrow domain at each radius layer. Therefore as r decreases, the part of ∂D related to these angles cannot be detected with the same accuracy. Considering the distribution of boundary impedance, this part corresponds to $\sigma(x)$ with large value, so it cannot be seen as clearly as the other part by using the same criterion values CB. This may be explained by the fact that the scattered wave along these directions will be much absorbed. Another, but related, reason is the property (2.19), i.e.,

$$\lim_{m,n\to\infty} \mathrm{Re}\left[\gamma_2^{-1}\int_{S^1}\int_{S^1} u^\infty(-\hat{x},d) f_m^p(d) g_n^p(\hat{x})\, ds(\hat{x}) ds(d)\right] = \frac{\pm 1}{4\pi|(z_p-a)\cdot\nu(a)|} + O(|\ln|z_p-a||),$$

where $O(|\ln|z_p-a||)$ may be large if σ is large near the point a. Hence numerically the second term can weaken the blowup of the first term.

Physically, this is the reason why we introduce the coated part of an obstacle, i.e., to avoid or perturb the detection of the obstacle.

The other special property of this example is that the whole boundary shape can be reconstructed well using only one blowup criterion CB. This comes from the special geometric shape and the fact that we have a complete impedance boundary condition. However, in the case of general problems, as for a nonconvex obstacle, with a mixed boundary condition we need to use multiple blowup values to get a satisfactory reconstruction; see subsection 4.3.

4.2. Reconstruction of $\sigma(x)$ for known ∂D. For a given $a \in \partial D$, we take $z_p \in R^2 \setminus \overline{D}_a^p$ with $D \subset\subset D_a^p$.

By the theoretical result given in (2.21), the approximate formula for $\sigma(a)$ is

$$\frac{\kappa}{\pi}\sigma(a) \approx \frac{1}{|\ln((z_p-a)\cdot\nu(a))|}\left(\frac{\pi}{n}\right)^2 \sum_{i,j=1}^{2n-1} \mathrm{Im}\,\left(\gamma_2^{-1} U^\infty(i,j) F_m^p(j) G_n^p(i)\right) \tag{4.2}$$

for large m, n and small $|z_p - a|$.

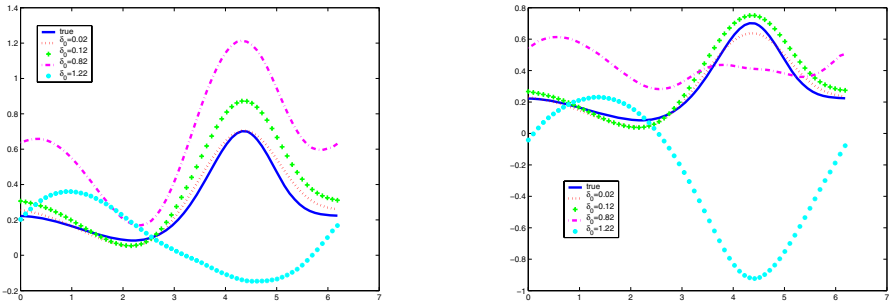

FIG. 4.2. *Reconstruction of* $\sigma(x) = \frac{2+x_1x_2}{(3+x_2)^2}$ *for* $\delta_0 = 1.22, 0.82, 0.12, 0.02$ *with two different wave numbers* $\kappa = 0.6$ *(left) and* $\kappa = 0.7$ *(right), where we fix* $\delta_1 = 0.015$.

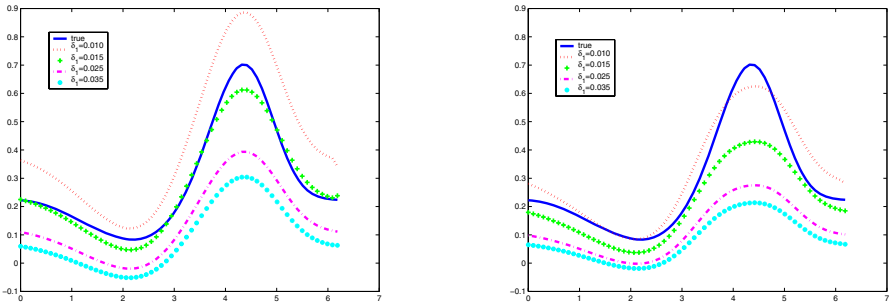

FIG. 4.3. *Reconstruction of* $\sigma(x) = \frac{2+x_1x_2}{(3+x_2)^2}$ *for* $\delta_1 = 0.010, 0.015, 0.025, 0.035$ *with two different wave numbers* $\kappa = 0.6$ *(left) and* $\kappa = 1.0$ *(right), where we fix* $\delta_0 = 0.002$.

Example 2. Consider the variable impedance distribution given in Example 1.

We take $n = 32$. First, let us keep the singularity unchanged by fixing δ_1 and shrink the radius of ∂D_a^p such that $z_p \to a \in \partial D$. The computed values of $\sigma(x(t))$ with fixed $\delta_1 = 0.015$ and different $\delta_0 = 1.22, 0.82, 0.12, 0.02$ for two wave numbers $\kappa = 0.6, \kappa = 0.7$ are shown in Figure 4.2. It can be seen from this figure that when $\delta_0 \to 0$ ($\delta_0 = 0.02$), the reconstruction results are satisfactory for both wave numbers.

It is interesting to see that when δ_0 is large enough ($\delta_0 = 1.22$), the reconstruction is invalid, even if here we use a strong singularity $\delta_1 = 0.015$. This is reasonable since the approximation to the strong singularity of the fundamental solution contains much error.

Finally, we fix ∂D_a^p near ∂D and take z_p tending to ∂D_a^p. In our configuration, this means $\delta_1 \to 0$ for fixed small δ_0. The tests with $\delta_0 = 0.002$ for two wave numbers $\kappa = 0.6, 1.0$ at different $\delta_1 = 0.025, 0.020, 0.015, 0.010$ are given in Figure 4.3, which shows the influence of the singularity. It can be seen that the approximation is sensitive to the wave number κ. The reason is that we ignore the remaining term $C/|\ln|(z_p - a)\cdot\nu(a)||$, where the constant C comes from (3.5). Theoretically, this term tends to 0 as $z_p \to a$. However, this procedure causes a difficulty in approximating the fundamental solution. We expect that the constant C becomes large as κ becomes small. This is naturally related to the following relation, in the 2-dimensional case, between the fundamental solution to the Helmholtz and Laplace equations:

$$H_0^{(1)}(\kappa|x-y|) = -\frac{1}{2\pi}\ln(|x-y|) - \ln\kappa + O(1)$$

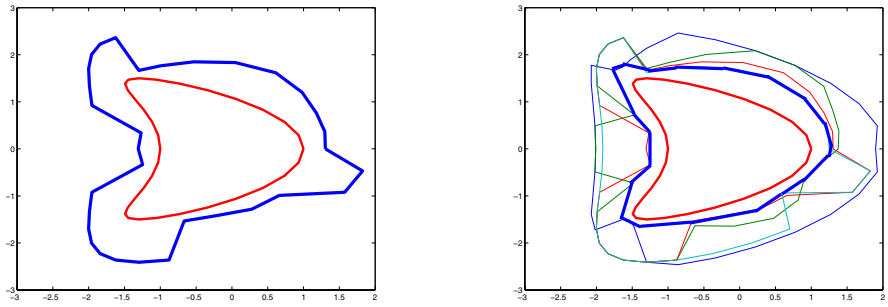

FIG. 4.4. *Reconstruction of ∂D with $CB = 3.0$ (left) and four CBs (right) by concave-hull.*

locally for $x, y \in R^2$ and κ small enough; see [8]. This implies that the difference between the fundamental solution behaves as $\ln \kappa$. So the constant C should have a similar behavior with respect to κ. These remarks on the dependency on wave number κ are also observed in the tests for detecting ∂D. However, we think that this is just a 2-dimensional phenomenon.

4.3. Reconstruction of an obstacle with mixed-type boundary. Since the main advantage of our inversion method is its ability to identify the full complex obstacle simultaneously, here we consider the numerical behavior of our inversion method acting on a nonconvex obstacle with mixed boundary condition.

Example 3. Consider a nonconvex obstacle D with the boundary

$$\partial D = \{x : x(t) = (x_1(t), x_2(t)) = (\cos t + 0.65 \cos 2t - 0.65, 1.5 \sin t), t \in [0, 2\pi]\}.$$

Let ∂D be composed of sound-soft part ∂D_D for $t \in [0, 1.42\pi]$, and impedance part ∂D_I for $t \in [1.42\pi, 2\pi]$. In ∂D_I, we assume the impedance coefficient $\sigma(x(t)) \equiv 3$.

We also choose ∂D_a^p and z_p in a special way. For two small constants $\delta_0, \delta_1 > 0$, we take

$$\begin{cases} \partial D_a^p = \{y(t) := x(t) + \delta_0 \times (\cos t, \sin t) : x(t) \in \partial D, t \in [0, 2\pi]\}, \\ z_p(t) = y(t) + \delta_1 \times (\cos t, \sin t) \quad \text{for } t \in [0, 2\pi]. \end{cases} \tag{4.3}$$

In terms of Theorem 2.1, the inversion schemes contain the following three steps:

Step 1. Identify the location of ∂D using (2.18);

Step 2. Distinguish the different parts of ∂D in terms of (2.20);

Step 3. Reconstruct $\sigma(x)$ in ∂D_I from (2.21).

We present the numerical results with fixed wave number $\kappa = 0.9$ and $\delta_1 = 0.01$.

Step 1. we take $n = 16$ and decrease $\delta_0 = l \times 0.05$ by taking l from 20 to 2. The indicator values in (2.18) for ∂D are computed for $z_p(t)$ and ∂D_a^p specified here for every direction t_j and different δ_0. Then we draw the contour line to obtain an approximation of ∂D. As for Examples 1 and 2, we choose some appropriate value CB for the stopping rule of l. In the case when the indicator is always less than CB in some direction, we take z_p for the initial guess (the largest l) as an approximate location of points in ∂D.

In this case, the situation is different from the examples given in the previous subsections; the reconstruction of the boundary using only one blowup value CB is not sufficient. See the left-hand picture in Figure 4.4 for the reconstruction of $CB = 3.0$, where the kite-shape in red color is the exact obstacle. Enlarging CB

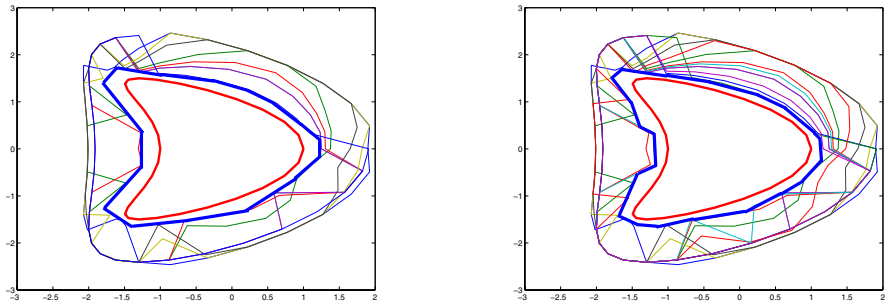

FIG. 4.5. *Reconstruction of ∂D by concave-hull using eight CBs (left) and twelve CBs (right).*

can improve the reconstruction along some directions, but the approximation to the whole boundary is still not satisfactory. The reason for this phenomenon is that our theoretical results do not guarantee the uniform blowup property for all directions.

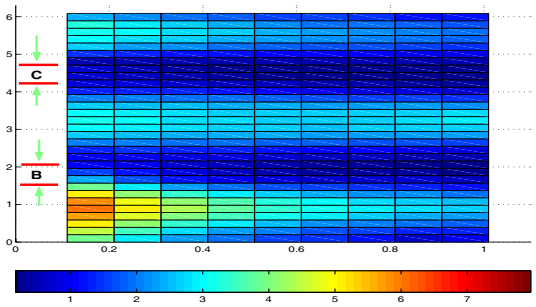

FIG. 4.6. *The indicator values for boundary shape.*

To overcome this difficulty and apply our reconstruction formula, we propose to combine the reconstruction results for different CB together and take the concave hull. Then ∂D can be approximated very well; see Figure 4.4, where we compare the shape given by using one CB only and the one obtained by using four CB values. In Figure 4.5, we show the reconstruction results by using eight and twelve CB values. Precisely, the reconstructions in Figures 4.4 and 4.5 correspond to the following CB values:

Figure 4.4 (right): four values–$CB = 0.8, 2.5, 3.0, 3.5$;

Figure 4.5 (left): eight values–$CB = 0.8, 2.5, 3.0, 3.5, 1.2, 1.5, 5.5, 6.5$;

Figure 4.5 (right): twelve values–$CB = 0.8, 2.5, 3.0, 3.5, 1.2, 1.5, 5.5, , 6.5, 2.0, 3.2, 4.5, 6.0$.

It can be seen that the reconstruction is satisfactory. This means that, using the technique of combining several CB's, the theoretical formulas provide good reconstructions.

We give the indicator value distribution in Figure 4.6 for all directions t with different l at each direction. We can see how the indicator near $t = 0.58\pi, \pi, 1.42\pi$ has some special property, which explains the difficulty of reconstructing these parts shown in Figures 4.4 and 4.5.

Next we consider Steps 2 and 3 by using (2.20) and (2.21), that is, we test the numerical behavior in distinguishing the boundary type and impedance in ∂D_I. Different from the formula (2.18), these two formulas need the boundary shape ∂D,

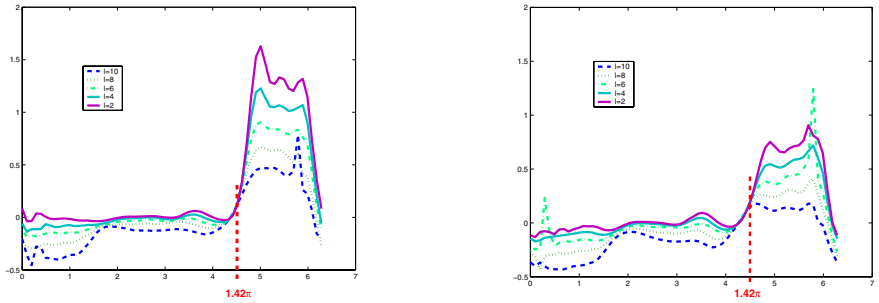

FIG. 4.7. *Indicator values for different parts of the boundary using exact ∂D (left) and $\partial\tilde{D}$ with $\delta^* = 0.1$ (right).*

which is theoretically obtained from (2.18). Since we can get some approximation to ∂D only numerically in terms of (2.18), it is necessary to check the approximate versions of (2.20) and (2.21) for distinguishing the boundary type and recovering $\sigma(x)$ on the coating part.

Step 2. We express the quantitative behavior for distinguishing ∂D_D and ∂D_I by giving the indicator distribution. As explained in Step 1, by using different blowup criteria in the shape reconstruction, we can get a good approximation to ∂D. In this step, we specify $\partial\tilde{D} \approx \partial D$ with an explicit expression given by

$$\partial\tilde{D} = \begin{pmatrix} \cos\delta^* & -\sin\delta^* \\ \sin\delta^* & \cos\delta^* \end{pmatrix} [\partial D + \{\delta^* \times (\cos t, \sin t) : t \in [0, 2\pi]\}] \tag{4.4}$$

with small constant $\delta^* > 0$, for simplicity. In this way, $\tilde{D}$ is no longer symmetric with respect to x_1, and the location for the corner part also differs from that of ∂D. To check the effect of this domain approximation on (2.20) and (2.21), we also evaluate them using the exact ∂D.

We generate $(\partial\tilde{D}_a^p, \partial D_a^p)$ from $(\partial\tilde{D}, \partial D)$ and therefore the sequences $(\{\tilde{z}_p\}, \{z_p\})$ as in (4.3). In this way, we have $\tilde{z}_p \to \tilde{a} \in \partial\tilde{D}$, $z_p \to a \in \partial D$, and $\delta_0, \delta_1 \to 0$. In the computation, we take $n = 32$ and decrease $\delta_0 = l \times 0.05 \to 0$ by taking l from 10 to 2. The indicator behavior using the same far-field pattern for ∂D and $\partial\tilde{D}$ with $\delta^* = 0.05$ is given in Figure 4.7.

Noticing the fact that the sound-soft part corresponds to the parameter $t \in [0, 1.42\pi]$, while the impedance part is related to $t \in [1.42\pi, 2\pi]$, the above numerical behavior supports (2.21) strongly with a large difference in $[0, 1.42\pi]$ and $[1.42\pi, 2\pi]$; that is, we can distinguish the boundary type in terms of the obvious difference of indicator values when z_p approaches the boundary (for small l), even if the boundary shape is known with a relative error.

Step 3. We compute the impedance coefficient on ∂D_I by applying the formulas for ∂D and also for its approximation $\partial\tilde{D}$. The reconstruction behavior for exact ∂D as well as its approximation $\partial\tilde{D}$ with $\delta^* = 0.05$ is shown in Figure 4.8. It can be seen that, for a given exact boundary shape ∂D, the theoretical result (2.21) for the impedance is valid (left figure), except near the end points of ∂D_I. The rough approximation in this part is reasonable, since this part is near to the sound-soft boundary. Using the approximate domain $\partial\tilde{D}$, the impedance can still be captured (right figure). Of course, the reconstruction is less accurate. Due to the nonconvex property of the obstacle and the mixed boundary condition, we think these results are satisfactory.

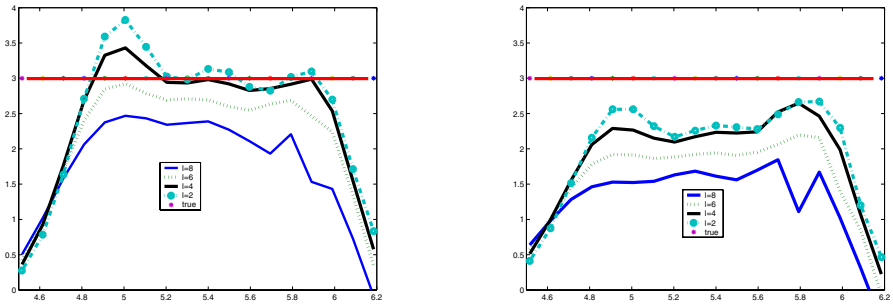

FIG. 4.8. *Recovery of σ using exact ∂D (left) and approximate $\partial\tilde{D}$ with $\delta^* = 0.05$ (right).*

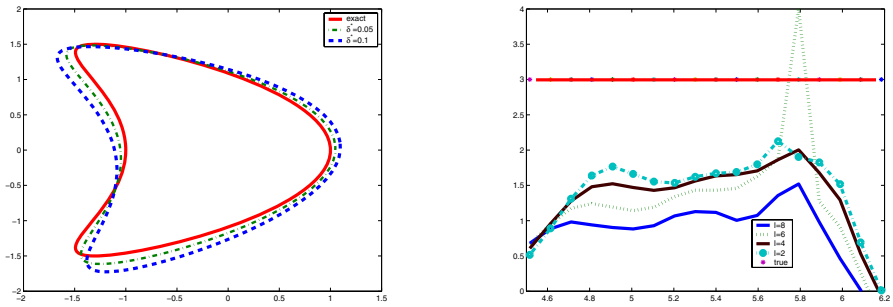

FIG. 4.9. *Approximate $\partial\tilde{D}$ with $\delta^* = 0.05, 0.1$ (left) and reconstruction of σ for different l from approximate $\partial\tilde{D}$ with $\delta^* = 0.1$ (right).*

However, if the perturbation for ∂D is very large, then the reconstruction of $\sigma(x(t))$ is much contaminated. This is due to the sensitivity of the approximate reconstruction to the boundary shape, especially for the corner part of the nonconvex domain, noticing that in the formula (2.21), the normal direction $\nu(a)$ appears. The perturbation scheme (4.4) moves the position of the corner part by rotation. An inversion result for the impedance with $\delta^* = 0.1$ is shown in Figure 4.9. From the left picture of this figure, we see how the corner part of $\partial\tilde{D}$ with $\delta^* = 0.1$ has been much moved from that of ∂D with a relative error almost 10%.

We conclude that the theoretical results (2.20) and (2.21) are well supported by our numerical tests even for nonconvex domains. If the approximate domain $\partial\tilde{D}$ is used in these two formulas, then we can still distinguish the boundary type in terms of the obvious blowup property of the indicator. However, the quantitative identification of impedance depends on the error level of ∂D.

Acknowledgments. The authors thank the anonymous referees for their valuable comments and suggestions, which led to a modified version of this paper.

DIFFUSION LIMITED REACTIONS*

BYRON GOLDSTEIN†, HAROLD LEVINE‡, AND DAVID TORNEY†§

Abstract. Changes to the relative separation of molecules or other interacting species on account of diffusion accompany their associative or dissociative reaction. The molecules are symbolized, for two distinct types, A, B, by the relations $A + B \quad AB$, and, if $[A]$, $[B]$, and $[AB]$ denote the corresponding densities, the equation $\frac{d}{dt}[AB] = k_+[A][B]$ specifies an associative process with *forward rate constant* k_+. An approximate version of the preceding takes the form of a linear differential equation, which can be employed to obtain significant estimates for both k_+ and the flux function $d[AB]/dt$. Such estimates are presented in different circumstances, including the localization of A, B on a common planar surface or their distribution in space, and also when the domain of A is a half space whereas that of B is a bounding planar surface. It proves advantageous to reformulate the last, a mixed boundary value problem, in terms of a linear integral equation. Biological applications are discussed, including the mechanism for the observed phosphorylation of proteins in resting cells and the incipience of phototransduction in rod photoreceptors.

1. Introduction.

1.1. Diffusion limited reaction. Recall that diffusion limited reactions are those in which diffusion transports the reactants to "reaction range," where reaction takes place instantaneously. Diffusion and reaction introduce spatial correlations between molecules, which influence the rate of reaction. Nonequilibrium thermodynamics has been applied to the irreversible diffusion limited kinetics $A + B \to AB$ (cf. [8]); here the latter is encompassed as a special case of the following reversible reaction:

$$A + B \underset{k_-}{\overset{k_+}{\rightleftharpoons}} AB,$$

where k_+ and k_- denote the intrinsic *forward* and *reverse rate constants* associated, respectively, with molecular association, for which $d[AB]/dt$ equals $k_+[A][B]$, with reaction occurring at range $r = a$, and molecular dissociation, for which $d[AB]/dt = -k_-[AB]$, with dissociation occurring at range $r = d$ $(> a)$. (The $[A]$, $[B]$, etc., notations denote respective macroscopic concentrations, i.e., expected numbers of molecules inside a "unit measure.")

Note that at equilibrium, $k_+[A][B] = k_-[AB]$. The obvious advantage of considering a system at equilibrium is that time is expunged from consideration. The cost is the introduction of the parameter d, but the latter will be seen to be advantageous in applications.

k_+ is expressible primarily in terms of the range parameters a and d and the diffusion coefficients, denoted D_A and D_B, respectively, with the sum $D_A + D_B$ hereafter denoted D. As will be seen, k_+ is obtainable from a pair density function, $\varrho(r)$: the density of A times the density of B at an arbitrary pair of respective points, lying at range r from one another. Differential equations for $\varrho(r)$ comprise triple-density functions [21]. However, using the independent-pairs approximation for triple densities, these equations become effectively linear in $\varrho(r)$, with dissociation modeled by a Dirac delta-function source.

$\varrho(r)$ is obtained for reactions occurring in $\mathbb{R}^2$ and in $\mathbb{R}^3$ (see sections 2 and 3). The inclusion of triple densities affords improvement upon the Smoluchowski theory [13]. This pioneering theory is based on an oversimplified model, but its shortcomings obtrude only when the theory is applied in challenging settings. The theory yields, for instance, the quandary that $k_+ = 0$ for reactions in $\mathbb{R}^2$. Our approach affords direct resolution thereof (cf. [8]) and, furthermore, yields two (or more) terms of asymptotic virial expansions for k_+. Section 4 addresses an interfacial reaction, combining aspects of reactions in $\mathbb{R}^2$ and $\mathbb{R}^3$. Biological applications of our results are described in section 5, and section 6 collects the k_+'s derived herein.

1.2. Biological motivations. Mobile receptors diffusing over the surface of a biological cell allow the cell to sense its environment and to respond to it. For many types of receptors, including growth-factor receptors, cytokine receptors, and immune recognition receptors, the aggregation of these receptors is required for the turning on or off of a cellular response. Therefore, for these receptors, the binding of the ligand to the receptor is insufficient to trigger a cellular response. Instead, the ligand induces the receptors to aggregate, holding the receptors in proximity for times long enough for various chemical modifications to occur on their cytoplasmic domains.

For example, growth-factor receptors are protein tyrosine kinases (PTKs), enzymes that can add a phosphate group to tyrosine residues. Growth-factor receptors also contain tyrosines in their cytoplasmic domains—whose phosphorylation induces specific functions, such as controlling the PTK's enzymatic activity and determining which cytoplasmic proteins (adapters and other participating enzymes) it can associate with. When a growth factor induces two receptors to aggregate, a change occurs inside the cell: the cytoplasmic domains of the receptors become phosphorylated, creating binding sites for proteins participating in the chemical cascade that leads to a cellular response. This is the mechanism for conveying to the inside of the cell the information that a hormone is present outside the cell, initiating what is referred to as cell signalling.

Quantitative insights into the kinetics of the primary events in receptor-initiated cell signalling require estimates for the forward and reverse rate constants for the steps that lead to receptor aggregation. Here, by means of a straightforward theory, we obtain the diffusion limited forward rate constant for a reaction between two species diffusing in a plane: a model applicable to reactions in cell membranes. This constant, which is related to the mean first passage time for two reactants to approach within a given distance, puts an upper bound on the rate at which (irreversible) receptor aggregation can occur. Furthermore, in section 5.1 we point out the importance of this rate constant, and of the corresponding reverse rate constant, for understanding

the background phosphorylation of receptors that is observed in the absence of any ligand-induced receptor aggregation.

Many cellular responses to hormones, e.g., growth factors, are mediated by cyclic nucleotides. Somewhat analogously, in photoreceptors, photons substitute for hormones as the effectors. Diffusion limited reactions taking place on phospholipid membranes—the discs of photoreceptors—are involved in phototransduction, and, in section 5.2, we quantitatively analyze the kinetics of its first reaction, the activation of the protein transducin, via the theoretical rate constant.

Although our main motivation is reactions on cell surfaces, we also present results for diffusion limited reactions in three space to verify that our theory reproduces an expression previously obtained by other means [3] and to intimate the range of applicability of our approach. Also, in section 4, we generalize a result concerning the diffusion limited forward rate constant for an interfacial reaction with ligands in solution binding to stationary receptors on a planar surface [2]. By means of a PDE with mixed boundary conditions, the receptors are also allowed to diffuse; we obtain the dependence of the diffusion limited forward rate constant upon both the diffusion coefficient of ligands in solution and the diffusion coefficient of receptors in the plane.

1.3. Fundamentals. For the present aims, the desideratum is the "reaction flux," Φ, whose dimensions are those of a concentration divided by time, and whose interpretation is the rate of creation of $[AB]$; whence, from the foregoing kinetic formulae,

$$\Phi = k_+[A][B].$$

As will be seen, Φ is obtained from the A B pair-density $\varrho(r)$, $r = a$. The latter function satisfies an equation comprising triple-density functions $\tau_\alpha(r, s, \theta)$ and $\tau_\beta(r, s, \theta)$ [21], having dimensions of the cube of a concentration. These subscripts distinguish two types of triples—B A B and A B A, respectively. These triples are viewed as being spatially centered on the sandwiched molecule, with their subscript connoting the latter, i.e., α for A and β for B. Furthermore, r and s denote the distances between the (centers of the) first and middle and between the middle and last molecules of the foregoing triples, and θ denotes the angle, at the central molecule, between the displacement vectors to the first and last, $0 \le \theta \le \pi$.

Similarly, an equation for τ includes quadruple-density functions, etc. However, as will be seen, the (unformulated) hierarchy may be pruned back by using the "independent-pairs" approximation for triple densities, yielding an equation involving only $\varrho(r)$ [21]. The additional natural assumption of constant pair densities for like-molecule pairs yields the following expressions for the τ's as a product of two ϱ's divided by a concentration:

$$\tau_\alpha(r, s, \theta) \doteq \varrho(r)\varrho(s)/[A], \quad \tau_\beta(r, s, \theta) \doteq \varrho(r)\varrho(s)/[B], \quad a \le r, s. \tag{1}$$

These constitute our *independent-pairs* approximations.

2. Reactions in planar surfaces. Here molecular trajectories are restricted to a plane. $\varrho(r)$ has the dimensions of L^{-4} and satisfies the following equation. For $a \le r < \infty$,

$$\frac{D}{r}\frac{d}{dr}r\frac{d}{dr}\varrho(r) + \left[2Da\int_0^\pi \left\{\frac{\partial}{\partial s}\tau_\alpha(R, s, \theta)\bigg|_{s=a} + \frac{\partial}{\partial s}\tau_\beta(R, s, \theta)\bigg|_{s=a}\right\} d\theta\right]\bigg|_{R=r}^{R=\infty} = -\frac{\Phi\delta(r-d)}{2\pi d}, \tag{2}$$

with boundary conditions $\varrho(a) = 0$ and $\varrho(\infty) = [A][B]$, and where Φ, with the dimensions of $L^{-2}T^{-1}$, is given by

$$\Phi = 2\pi a D \left.\frac{d\varrho(r)}{dr}\right|_{r=a}. \tag{3}$$

The foregoing equation is exact, which may be seen as follows.

The rate at which A B pairs react, at $R = a$, given in (3), is balanced by a dissociative flux, at $R = b$, which is the rate of creation of such pairs at range d, implementing microscopic balance. (For a physical interpretation of delta-function sources, see [11, p. 6]). Triples may be used to model the reaction of either molecule of such pairs with a suitable third molecule [21]. Thus, triple densities contribute an inhomogeneous term: the one contained in square brackets. The $R = r$ term reproduces the (net) rate of diminution of $\varrho(r)$ due to reaction of either member of the corresponding pair with appropriate third molecules, and the corresponding $R = \infty$ term is a constant, included so that the Laplacian of $\varrho(r)$ vanishes as $r \to \infty$, to reproduce the Smoluchowski theory at long range.

Thus, spatial correlations among triples of molecules influence $\varrho(r)$ and thereby Φ. Substituting the independent-pairs approximations (1) and performing the integrals in (2), using (3), gives

$$\frac{D}{r}\frac{d}{dr}r\frac{d}{dr}\varrho(r) + \Phi([A][B] - \varrho(r))\left(\frac{1}{[A]} + \frac{1}{[B]}\right) = -\frac{\Phi\delta(r-d)}{2\pi d}. \tag{4}$$

The leftmost term is the cylindrically symmetric Laplacian. The boundary conditions are as above. The weak nonlinearity of (4) poses no impediment to its solution.

Let $\chi(r) = [A][B] - \varrho(r)$; let $\bar{a} = a/\ell$, $\bar{d} = d/\ell$, and $\bar{r} = r/\ell$, where

$$\ell \stackrel{\text{def}}{=} \left[\frac{\Phi}{D}\left(\frac{1}{[A]} + \frac{1}{[B]}\right)\right]^{-1/2}. \tag{5}$$

Adopting these notations, (4) becomes

$$\frac{1}{\bar{r}}\frac{d}{d\bar{r}}\bar{r}\frac{d}{d\bar{r}}\chi(\bar{r}) - \chi(\bar{r}) = \frac{\Phi\delta(\bar{r}-\bar{d})}{2\pi D\bar{d}}, \tag{6}$$

with $\chi(\bar{a}) = [A][B]$ and $\chi(\infty) = 0$. Thus,

$$\chi(\bar{r}) = \begin{cases} C_1 I_0(\bar{r}) + C_2 K_0(\bar{r}), & \bar{a} \le \bar{r} \le \bar{d}, \\ C_3 K_0(\bar{r}), & \bar{d} \le \bar{r}, \end{cases}$$

where I_0 and K_0 denote modified Bessel functions of index zero. The constants C_1, C_2, and C_3 are to be obtained using three conditions, namely, $\chi(\bar{a}) = [A][B]$, the continuity of χ at $\bar{r} = \bar{d}$, and the jump condition required by (6), namely,

$$\bar{r}\left.\frac{d\chi}{d\bar{r}}\right|_{\bar{d}-0}^{\bar{d}+0} = \frac{\Phi}{2\pi D}.$$

These conditions yield

$$C_1 = -\frac{\Phi K_0(\bar{d})}{2\pi D},$$

$$C_2 = \frac{[A][B]}{K_0(\bar{a})} + \frac{\Phi I_0(\bar{a})K_0(\bar{d})}{2\pi D K_0(\bar{a})}, \qquad \text{and}$$

$$C_3 = \frac{[A][B]}{K_0(\bar{a})} + \frac{\Phi(I_0(\bar{a})K_0(\bar{d}) - I_0(\bar{d})K_0(\bar{a}))}{2\pi D K_0(\bar{a})}.$$

Thus, from (3),

$$\Phi = -2\pi D\bar{a}\,\frac{d\chi(\bar{r})}{d\bar{r}}\bigg|_{\bar{r}=\bar{a}} = 2\pi D\left\{\frac{\bar{a}K_1(\bar{a})[A][B]}{K_0(\bar{a})} + \frac{\Phi K_0(\bar{d})}{2\pi D K_0(\bar{a})}\right\}$$

or

$$\Phi = \frac{2\pi D\bar{a}K_1(\bar{a})[A][B]}{K_0(\bar{a}) - K_0(\bar{d})}. \tag{7}$$

With reference to (5), the foregoing may be regarded as implicit equations in Φ, but it simplifies matters and suffices for the present aims to focus on two limiting cases, (i) $\bar{a} < \bar{d} \to 0$ and (ii) $\bar{a} \to 0$, $\bar{d} \to \infty$, germane to irreversible reactions. Successive approximations yield, for (i),

$$\Phi \sim \frac{2\pi D[A][B]}{\log d/a},$$

where the omitted terms are $\mathcal{O}(\bar{a}^2 \log \bar{a} + \bar{d}^2 \log \bar{d})$, establishing that corrections to Φ are substantially smaller than the given term. Similarly, for (ii), these approximations yield

$$\Phi \sim \frac{2\pi D[A][B]}{-\log\sqrt{\psi}}\left(1 + \frac{\log\sqrt{-\log\sqrt{\psi}} + \frac{1}{2}\log 2 - \gamma}{\log\sqrt{\psi}} + \cdots\right), \tag{8}$$

where ψ is the expected number of A molecules plus B molecules within a circle of radius a, $\psi = \pi a^2([A] + [B]) \ll 1$, and where $\gamma \doteq 0.577\ldots$ denotes the Euler–Mascheroni constant. One may note, to leading order, that the functional dependence of k_+ upon a (via ψ) was previously obtained from nonequilibrium thermodynamics [8, (121)–(122)].

3. Bulk reactions. Here the molecular trajectories are in Euclidean three space, and the notations and definitions of section 2 are also adopted. In analogy to (4), the differential equation is

$$\frac{D}{r^2}\frac{d}{dr}r^2\frac{d}{dr}\varrho(r) + \Phi([A][B] - \varrho(r))\left(\frac{1}{[A]} + \frac{1}{[B]}\right) = -\frac{\Phi\delta(r-d)}{4\pi d^2}, \tag{9}$$

with the previous boundary conditions. This $\varrho(r)$ has the dimensions of L^{-6}. The left-hand term of (9) is the spherically symmetric Laplacian. Here Φ, with the dimensions of $L^{-3}T^{-1}$, is given by

$$\Phi = 4\pi a^2 D\,\frac{d\varrho(r)}{dr}\bigg|_{r=a}. \tag{10}$$

As above, (9) may be written

$$\frac{1}{\bar{r}^2}\frac{d}{d\bar{r}}\bar{r}^2\frac{d}{d\bar{r}}\chi(\bar{r}) - \chi(\bar{r}) = \frac{\Phi\delta(\bar{r}-\bar{d})}{4\pi D\bar{d}^2\ell},$$

with $\chi(\bar{a}) = [A][B]$ and $\chi(\infty) = 0$. Thus,

$$\chi(\bar{r}) = \begin{cases} C_1 \dfrac{e^{\bar{r}}}{\bar{r}} + C_2 \dfrac{e^{-\bar{r}}}{\bar{r}}, & \bar{a} \le \bar{r} \le \bar{d}, \\ C_3 \dfrac{e^{-\bar{r}}}{\bar{r}}, & \bar{d} \le \bar{r}. \end{cases}$$

C_1, C_2, and C_3 are obtainable as before; here the jump condition is

$$\bar{r}^2 \left. \frac{d\chi}{d\bar{r}} \right|_{\bar{d}-0}^{\bar{d}+0} = \frac{\Phi}{4\pi D\ell} \stackrel{\text{def}}{=} \Phi^{3/2}\Gamma,$$

where reference to (5) yields

$$\Gamma = \frac{1}{4\pi D\ell\sqrt{\Phi}} = \frac{1}{4\pi D^{3/2}} \sqrt{\frac{1}{[A]} + \frac{1}{[B]}}. \tag{11}$$

It follows that

$$C_1 = -\frac{\Phi^{3/2}\Gamma e^{-\bar{d}}}{2\bar{d}},$$

$$C_2 = \bar{a}e^{\bar{a}}[A][B] + \frac{\Phi^{3/2}\Gamma e^{2\bar{a}-\bar{d}}}{2\bar{d}}, \qquad \text{and}$$

$$C_3 = \bar{a}e^{\bar{a}}[A][B] + \frac{\Phi^{3/2}\Gamma(e^{2\bar{a}-\bar{d}} - e^{\bar{d}})}{2\bar{d}}.$$

Thus, from (10), using (11),

$$\Phi = -\frac{4\pi Da^2}{\ell} \left. \frac{d\chi(\bar{r})}{d\bar{r}} \right|_{\bar{r}=\bar{a}} = 4\pi Da \left\{ [A][B](1+\bar{a}) + \frac{\Phi e^{\bar{a}-\bar{d}}}{4\pi Dd} \right\}.$$

As before, we address the limits (i) $\bar{a} < \bar{d} \to 0$ and (ii) $\bar{a} \to 0$, $\bar{d} \to \infty$. For (i),

$$\Phi \sim \frac{4\pi Da[A][B](1 + o(\sqrt{\phi}))}{1 - a/d};$$

i.e., the first correction is $\mathcal{O}(\phi)$, where ϕ is the expected number of A molecules plus B molecules within a sphere of radius a: $\phi = \frac{4}{3}\pi a^3([A] + [B]) \ll 1$. Similarly, for (ii),

$$\Phi \sim 4\pi Da[A][B](1 + \sqrt{3\phi} + \cdots).$$

The leading-order behavior reproduces the Smoluchowski rate, and the first-order correction agrees, for the case $[A] \ll [B]$, with that of [3, (1.3)].

4. Reaction on an interface. Here the B's and the AB's diffuse in the plane $z = 0$, whereas the A's diffuse in the half space $z \ge 0$. Alternative interfacial diffusion limited reactions have been considered (cf. [2, 5]).

4.1. Partial differential equation. The A B pair density is denoted $\varrho(r,z)$, with $r=\sqrt{x^2+y^2}$ and with r and z denoting the magnitudes of perpendicular components of displacement. This density is the product of the concentrations of A and B. Thus, $\varrho(r,z)$ has the dimensions of L^{-5}. Here it is taken to be the solution of the Smoluchowski differential equation

$$\left(\frac{D}{r}\frac{\partial}{\partial r}r\frac{\partial}{\partial r}+\frac{D_A\partial^2}{\partial z^2}\right)\varrho(r,z)=-\frac{\Phi\delta(z)\delta(r-d)}{2\pi d}, \tag{12}$$

with boundary conditions $\varrho(r,0)=0$; $0<r<a$, $\partial\varrho(r,0)/\partial z=0$; $a<r<\infty$, $\varrho(r,z)\to[A][B]$ as $r^2+z^2\to\infty$. Here

$$\Phi=2\pi D_A\int_0^a\frac{\partial\varrho(r,0)}{\partial z}rdr. \tag{13}$$

Note that Φ has the dimensions of $L^{-2}T^{-1}$: the rate of generation of $[AB]$, in the plane $z=0$. As before, the source term of (12) is distinguished from one which characterizes a fixed-source Green's function of potential theory by the appearance of the factor Φ, a quantity related to $\varrho(r,z)$ via (13).

The simplifications leading to (12) include planar sources and sinks, furnishing a half-space problem with mixed boundary conditions. Furthermore, because the current aim is exploratory, the term derived from triple densities and (1),

$$\Phi([A][B]-\varrho(r,z))\left(\frac{\delta(z)}{[A]}+\frac{1}{[B]}\right), \tag{14}$$

is omitted from the left-hand side of (12). We conjecture that the k_+ obtained from the solution of (12) is nevertheless correct to leading order (in the concentrations). (Note that (14) might require modification, for instance, at $r=a$, $z=0$, for well-posedness.)

Let

$$r=\sqrt{D}R,\qquad z=\sqrt{D_A}Z; \tag{15}$$

then (12) takes the form

$$\left(\frac{1}{R}\frac{\partial}{\partial R}R\frac{\partial}{\partial R}+\frac{\partial^2}{\partial Z^2}\right)\varrho(R,Z)=-\frac{\Phi\delta(Z)\delta(R-d/\sqrt{D})}{2\pi d\sqrt{D_AD}}.$$

Let

$$\varrho(R,Z)=[A][B]-\beta(R,Z),$$

and the system defining $\beta(R,Z)$ comprises

$$\nabla^2\beta(R,Z)=\left(\frac{1}{R}\frac{\partial}{\partial R}R\frac{\partial}{\partial R}+\frac{\partial^2}{\partial Z^2}\right)\beta(R,Z)=\frac{\Phi\delta(Z)\delta(R-d/\sqrt{D})}{2\pi d\sqrt{D_AD}}, \tag{16}$$

$$\beta(R,0)=[A][B],\qquad 0<R\le a/\sqrt{D}, \tag{17}$$

$$\frac{\partial}{\partial Z}\beta(R,0)=0,\qquad a/\sqrt{D}<R, \tag{18}$$

$$\beta\to 0,\qquad R^2+Z^2\to\infty. \tag{19}$$

4.2. An associated integral equation. To recast the boundary value problem defined by (16)–(19) in terms of an integral equation, introduce a Green's function $G(R, Z; R', Z')$ specified by

$$\nabla^2 G = \left(\frac{1}{R}\frac{\partial}{\partial R} R \frac{\partial}{\partial R} + \frac{\partial^2}{\partial Z^2}\right) G = -\frac{\delta(R-R')\delta(Z-Z')}{2\pi R}, \qquad 0 < R, R', Z, Z' < \infty, \tag{20}$$

$$\frac{\partial}{\partial Z} G = 0, \quad Z = 0, \quad R > 0, \quad \text{and} \quad G \to 0, \quad R^2 + Z^2 \to \infty.$$

If

$$\bar{G}(\zeta, Z; R', Z') = \int_0^\infty R J_0(\zeta R) G(R, Z; R', Z') dR, \tag{21}$$

where J_0 denotes the Bessel function of the first kind of order zero, then it follows from (20) that

$$\left(\frac{\partial^2}{\partial Z^2} - \zeta^2\right) \bar{G}(\zeta, Z; R', Z') = -\frac{J_0(\zeta R')\delta(Z-Z')}{2\pi},$$

and explicitly

$$\bar{G}(\zeta, Z; R', Z') = \frac{J_0(\zeta R')}{2\pi|\zeta|} \cosh \zeta Z_< \exp^{-|\zeta| Z_>},$$

with $Z_<$ and $Z_>$ denoting the smaller and larger of Z and Z', respectively. The inverse of the transform (21) thus yields the Green's function representation

$$G(R, Z; R', Z') = \int_0^\infty \zeta J_0(\zeta R) \bar{G}(\zeta, Z; R', Z') d\zeta = \frac{1}{2\pi} \int_0^\infty J_0(\zeta R) J_0(\zeta R') \cosh \zeta Z_< \exp^{-\zeta Z_>} d\zeta. \tag{22}$$

Apply Green's integral relation

$$\int (G \nabla^2 \beta - \beta \nabla^2 G) dV = \int \left(G \frac{\partial}{\partial n}\beta - \beta \frac{\partial}{\partial n} G\right) dS$$

in the half space $Z \geq 0$, where the surface integral consists of a hemispherical portion and a plane circular domain where $Z = 0$. Invoking the various conditions obeyed by β and G, it follows that

$$\frac{\Phi}{D\sqrt{D_A}} G(d/\sqrt{D}, 0; R', Z') + \beta(R', Z') = \int_0^{a/\sqrt{D}} G(R, 0; R', Z') 2\pi R \sigma(R) dR, \tag{23}$$

with

$$\sigma(R) = -\left.\frac{\partial \beta}{\partial Z}\right|_{Z=0}, \qquad 0 < R < a/\sqrt{D}. \tag{24}$$

After changing variables in (23) (with regard for the argument symmetry of G), one obtains, for $Z \geq 0$,

$$\begin{aligned}\beta(R,Z) &= -\frac{\Phi}{D\sqrt{D_A}}G(R,Z;d/\sqrt{D},0) + 2\pi\int_0^{a/\sqrt{D}} G(R,Z;R',0)\sigma(R')R'dR' \\ &= -\frac{\Phi}{2\pi D\sqrt{D_A}}\int_0^\infty J_0(\zeta R)J_0(\zeta d/\sqrt{D})\exp^{-\zeta Z}\,d\zeta \\ &\quad + \int_0^{a/\sqrt{D}} R'\sigma(R')dR'\int_0^\infty J_0(\zeta R)J_0(\zeta R')\exp^{-\zeta Z}\,d\zeta. \qquad (25)\end{aligned}$$

The representation (25) for $\beta(R,Z)$ implies [11, (6.3.62)] that

$$\frac{\partial}{\partial Z}\beta(R,Z)\bigg|_{Z=0} = -\sigma(R), \qquad R < a/\sqrt{D}, \qquad (26)$$

and

$$\frac{\partial}{\partial Z}\beta(R,Z)\bigg|_{Z=0} = 0, \qquad a/\sqrt{D} < R \ \ (\neq d/\sqrt{D}),$$

in accord with (24).

An integral equation for $\sigma(R)$ is next secured on imposing the condition (17), namely, for $R < a/\sqrt{D}$,

$$\begin{aligned}[A][B] &= -\frac{\Phi}{2\pi D\sqrt{D_A}}\int_0^\infty J_0(\zeta R)J_0(\zeta d/\sqrt{D})d\zeta \\ &\quad + \int_0^{a/\sqrt{D}} \sigma(R')R'dR'\int_0^\infty J_0(\zeta R)J_0(\zeta R')d\zeta. \qquad (27)\end{aligned}$$

From (13), (15), and (26),

$$\Phi = 2\pi D\sqrt{D_A}F, \qquad F \stackrel{\text{def}}{=} \int_0^{a/\sqrt{D}} \sigma(R)RdR, \qquad (28)$$

enabling (27) to be rewritten in the forms

$$\begin{aligned}&[A][B] + F\int_0^\infty J_0(\zeta R)J_0(\zeta d/\sqrt{D})d\zeta \\ &\quad = \int_0^{a/\sqrt{D}} \sigma(R')R'dR'\int_0^\infty J_0(\zeta R)J_0(\zeta R')d\zeta, \qquad R \leq a/\sqrt{D}, \qquad (29)\end{aligned}$$

or

$$\begin{aligned}V(R) &= \int_0^{a/\sqrt{D}} \sigma(R')R'dR'\int_0^\infty J_0(\zeta R)J_0(\zeta R')d\zeta \\ &= \int_0^\infty J_0(\zeta R)\varphi(\zeta)d\zeta, \qquad R < a/\sqrt{D},\end{aligned}$$

where

$$V(R) = [A][B] + F\int_0^\infty J_0(\eta R)J_0(\eta d/\sqrt{D})d\eta \qquad (30)$$

and

$$\varphi(\zeta) = \int_0^\infty R'\sigma(R')J_0(\zeta R')dR',$$

$$\sigma(R) = 0, \qquad R > a/\sqrt{D},$$

$$\sigma(R) = \int_0^\infty \zeta\varphi(\zeta)J_0(\zeta R)d\zeta. \tag{31}$$

Beltrami established the representation

$$\varphi(\zeta) = \frac{2}{\pi}V(0)\frac{\sin\zeta a/\sqrt{D}}{\zeta} + \frac{2}{\pi}\int_0^{a/\sqrt{D}} \bar{R}\cos\zeta\bar{R}d\bar{R}\int_0^{\bar{R}} \frac{V'(R')}{\sqrt{\bar{R}^2 - R'^2}}dR' \tag{32}$$

(cf. [1, 12]). In accordance with (30),

$$\frac{dV}{dR} = V'(R) = -F\int_0^\infty \eta J_1(\eta R)J_0(\eta d/\sqrt{D})d\eta,$$

whence

$$\begin{aligned}\int_0^{\bar{R}} \frac{V'(R')}{\sqrt{\bar{R}^2 - R'^2}}dR' &= -F\int_0^\infty \eta J_0(\eta d/\sqrt{D})d\eta \int_0^{\bar{R}} \frac{J_1(\eta R')}{\sqrt{\bar{R}^2 - R'^2}}dR' \\ &= -\frac{F}{\bar{R}}\int_0^\infty J_0(\eta d/\sqrt{D})(1 - \cos\eta\bar{R})d\eta \\ &= -\frac{F}{\bar{R}}\left\{\frac{\sqrt{D}}{d} - \frac{1}{\sqrt{d^2/D - \bar{R}^2}}\right\}, \qquad \bar{R} < d/\sqrt{D}. \end{aligned} \tag{33}$$

Also,

$$V(0) = [A][B] + F\frac{\sqrt{D}}{d}. \tag{34}$$

Thus, inasmuch as $\varphi(0) = F$, (32) implies

$$\begin{aligned} F &= \frac{2a}{\pi\sqrt{D}}\left[[A][B] + F\frac{\sqrt{D}}{d}\right] - \frac{2F}{\pi}\int_0^{a/\sqrt{D}} \left(\frac{\sqrt{D}}{d} - \frac{1}{\sqrt{d^2/D - \bar{R}^2}}\right)d\bar{R} \\ &= \frac{2a}{\pi}\frac{[A][B]}{\sqrt{D}} + \frac{2F}{\pi}\sin^{-1}\frac{a}{d} \end{aligned}$$

or

$$F\left\{1 - \frac{2}{\pi}\sin^{-1}\frac{a}{d}\right\} = \frac{2a}{\pi}\frac{[A][B]}{\sqrt{D}}. \tag{35}$$

From (28) and (35), taken together, the specification

$$\Phi = \frac{4a\sqrt{DD_A}[A][B]}{1 - \frac{2}{\pi}\sin^{-1}\frac{a}{d}} \tag{36}$$

follows.

4.3. Explicit form for $\sigma(R)$. From (32), via (31), there follows

$$\sigma(R) = \frac{2}{\pi}\int_0^\infty \zeta J_0(\zeta R)\left\{V(0)\frac{\sin\zeta a/\sqrt{D}}{\zeta} + \int_0^{a/\sqrt{D}} \bar{R}\cos\zeta\bar{R}d\bar{R}\int_0^{\bar{R}}\frac{V'(R')}{\sqrt{\bar{R}^2-R'^2}}dR'\right\}d\zeta.$$

Using (33) and (34), it is found that

$$\begin{aligned}\int_0^\infty \zeta J_0(\zeta R)\frac{2}{\pi}V(0)\frac{\sin\zeta a/\sqrt{D}}{\zeta}d\zeta &= \frac{2}{\pi}\left([A][B]+F\frac{\sqrt{D}}{d}\right)\int_0^\infty J_0(\zeta R)\sin\zeta a/\sqrt{D}d\zeta \\ &= \frac{2}{\pi}\left([A][B]+F\frac{\sqrt{D}}{d}\right)\frac{1}{\sqrt{a^2/D-R^2}}, \qquad R<a/\sqrt{D}.\end{aligned}$$

Further,

$$\begin{aligned}&\frac{2}{\pi}\int_0^{a/\sqrt{D}}\bar{R}\cos\zeta\bar{R}\int_0^{\bar{R}}\frac{V'(R')}{\sqrt{\bar{R}^2-R'^2}}dR'd\bar{R} \\ &\quad= -\frac{2F}{\pi}\int_0^{a/\sqrt{D}}\cos\zeta\bar{R}\left\{\frac{\sqrt{D}}{d}-\frac{1}{\sqrt{d^2/D-\bar{R}^2}}\right\}d\bar{R} \\ &\quad= \frac{2F}{\pi}\left\{-\frac{\sqrt{D}}{d}\frac{\sin\zeta a/\sqrt{D}}{\zeta}+\int_0^{a/\sqrt{D}}\frac{\cos\zeta\bar{R}}{\sqrt{d^2/D-\bar{R}^2}}d\bar{R}\right\},\end{aligned}$$

and thus

$$\begin{aligned}\sigma(R) = \frac{2}{\pi}\int_0^\infty \zeta J_0(\zeta R)\Bigg\{&\left([A][B]+F\frac{\sqrt{D}}{d}\right)\frac{\sin\zeta a/\sqrt{D}}{\zeta}-F\frac{\sqrt{D}}{d}\frac{\sin\zeta a/\sqrt{D}}{\zeta} \\ &+F\int_0^{a/\sqrt{D}}\frac{\cos\zeta\bar{R}}{\sqrt{d^2/D-\bar{R}^2}}d\bar{R}\Bigg\}d\zeta \\ = \frac{2}{\pi}\frac{[A][B]}{\sqrt{a^2/D-R^2}}&+\frac{2F}{\pi}\int_0^\infty\zeta J_0(\zeta R)\int_0^{a/\sqrt{D}}\frac{\cos\zeta\bar{R}}{\sqrt{d^2/D-\bar{R}^2}}d\bar{R}d\zeta, \qquad R<a/\sqrt{D}.\end{aligned}$$

Write

$$\begin{aligned}\int_0^{a/\sqrt{D}}\frac{\cos\zeta\bar{R}}{(d^2/D-\bar{R}^2)^{1/2}}d\bar{R} &= \int_0^{a/\sqrt{D}}\frac{1}{(d^2/D-\bar{R}^2)^{1/2}}d_{\bar{R}}\left(\frac{\sin\zeta\bar{R}}{\zeta}\right) \\ &= \frac{\sin\zeta a/\sqrt{D}}{\zeta\sqrt{(d^2-a^2)/D}}-\frac{1}{\zeta}\int_0^{a/\sqrt{D}}\frac{\bar{R}\sin\zeta\bar{R}}{(d^2/D-\bar{R}^2)^{3/2}}d\bar{R},\end{aligned}$$

and then

(37)
$$\sigma(R) = \frac{2}{\pi}\frac{[A][B]}{\sqrt{a^2/D - R^2}} + \frac{2F}{\pi}\left\{\frac{1}{\sqrt{(d^2-a^2)/D}\sqrt{a^2/D-R^2}} - \int_R^{a/\sqrt{D}} \frac{\bar{R}d\bar{R}}{(d^2/D-\bar{R}^2)^{3/2}(\bar{R}^2-R^2)^{1/2}}\right\}.$$

In accordance with the appendix,

(38)
$$\int_R^{a/\sqrt{D}} \frac{\bar{R}d\bar{R}}{(d^2/D-\bar{R}^2)^{3/2}(\bar{R}^2-R^2)^{1/2}} = \frac{1}{(d^2/D-R^2)}\sqrt{\frac{a^2-DR^2}{d^2-a^2}}$$

(a result which can be checked by considering $R = 0$), it follows from (37) that

$$\sigma(R) = \frac{2}{\pi}\frac{[A][B]}{\sqrt{a^2/D - R^2}} + \frac{2F}{\pi}\left\{\frac{1}{\sqrt{(d^2-a^2)/D}\sqrt{a^2/D-R^2}} - \frac{1}{(d^2/D-R^2)}\sqrt{\frac{a^2-DR^2}{d^2-a^2}}\right\},$$

whence the explicit determination

(39)
$$\sigma(R) = \frac{2}{\pi}\frac{[A][B]}{\sqrt{a^2/D-R^2}} + \frac{2F}{\pi\sqrt{D}}\frac{\sqrt{d^2-a^2}}{\sqrt{a^2/D-R^2}}\frac{1}{(d^2/D-R^2)}, \qquad 0 < R < a/\sqrt{D} < d/\sqrt{D},$$

follows.

A final check is called for: multiply by R in (39) and integrate over $0 < R < a/\sqrt{D}$, which yields

$$F = \frac{2}{\pi}[A][B]\frac{a}{\sqrt{D}} + \frac{2F}{\pi}\sqrt{\frac{d^2-a^2}{D}}\int_0^{a/\sqrt{D}} \frac{RdR}{\sqrt{a^2/D-R^2}(d^2/D-R^2)}.$$

Since

$$\int_0^{a/\sqrt{D}} \frac{RdR}{\sqrt{a^2/D-R^2}(d^2/D-R^2)} = \frac{a}{2\sqrt{D}}\int_0^1 \frac{dx}{\sqrt{1-x}(d^2/D-a^2x/D)}$$
$$= \frac{a\sqrt{D}}{2d^2}\int_0^1 \frac{dx}{\sqrt{1-x}(1-\frac{a^2}{d^2}x)} = \frac{a\sqrt{D}}{2d^2}\frac{2}{\frac{a}{d}\sqrt{1-\frac{a^2}{d^2}}}\tan^{-1}\left(\frac{-\frac{a^2}{d^2}\sqrt{1-x}}{\frac{a}{d}\sqrt{1-\frac{a^2}{d^2}}}\right)\Bigg|_{x=0}^{x=1}$$
$$= \frac{\sqrt{D}}{\sqrt{d^2-a^2}}\tan^{-1}\left(\frac{a}{d}\frac{1}{\sqrt{1-\frac{a^2}{d^2}}}\right) = \frac{\sqrt{D}}{\sqrt{d^2-a^2}}\sin^{-1}\frac{a}{d},$$

equation (35) follows.

4.4. Irreversible reaction. One may directly obtain the limit $d \to \infty$ of (36) by omitting the "source" term on the right-hand side of (12). This implies the setting aside of the first term on the left-hand side of (27), yielding the integral equation

$$[A][B] = \int_0^{a/\sqrt{D}} \sigma(R')R'dR' \int_0^\infty J_0(\zeta R)J_0(\zeta R')d\zeta, \qquad R < a/\sqrt{D}.$$

This equation applies to a classical mixed boundary value problem for an axially symmetric potential/harmonic function in the half space $Z > 0$. Write

$$[A][B] = \int_0^\infty J_0(\zeta R)\varphi(\zeta)d\zeta, \qquad R < a/\sqrt{D}, \tag{40}$$

where

$$\varphi(\zeta) = \int_0^\infty R'\sigma(R')J_0(\zeta R')dR',$$

$$\sigma(R) = 0, \qquad R > a/\sqrt{D};$$

then,

$$\sigma(R) = \int_0^\infty \zeta\varphi(\zeta)J_0(\zeta R)d\zeta = 0, \qquad R > a/\sqrt{D}. \tag{41}$$

The dual equations (40), (41) are satisfied with the specification

$$\varphi(\zeta) = \frac{2[A][B]}{\pi}\frac{\sin\zeta a/\sqrt{D}}{\zeta}$$

because

$$\int_0^\infty J_0(\zeta R)\frac{\sin\zeta a/\sqrt{D}}{\zeta}d\zeta = \frac{\pi}{2}, \qquad R < a/\sqrt{D},$$

and

$$\sigma(R) \propto \int_0^\infty J_0(\zeta R)\sin(\zeta a/\sqrt{D})d\zeta = 0, \qquad R > a/\sqrt{D}.$$

Furthermore,

$$\sigma(R) = \frac{2}{\pi}[A][B]\int_0^\infty J_0(\zeta R)\sin(\zeta a/\sqrt{D})d\zeta = \frac{2}{\pi}\frac{[A][B]}{\sqrt{a^2/D - R^2}}, \qquad R < a/\sqrt{D},$$

the limit $d \to \infty$ of (39). From (28), one obtains

$$\Phi = 4a\sqrt{DD_A}[A][B],$$

the corresponding limit of (36).

5. Applications to biological cell signalling.

5.1. Basal level of receptor phosphorylation. As described in the introduction, for a number of receptor families, ligand-induced receptor aggregation is rapidly followed by phosphorylation of sites on cytoplasmic and membrane-associated proteins. Even in the absence of an outside stimulus, cells show basal levels of protein phosphorylation (e.g., [15, 18]). In the cell there is a constant competition between enzymes that phosphorylate their substrates (kinases) and enzymes that reverse this phosphorylation and dephosphorylate their substrates (phosphatases). In the absence of a ligand which binds to receptors and induces them to aggregate, diffusion

will nonetheless bring them into proximity, although these aggregates will be short-lived, as diffusion will also lead to their separation. If these receptors are kinases (growth-factor receptors) or are associated with kinases (immune recognition and cytokine receptors), then they may phosphorylate their neighbor, leading to the observed basal phosphorylation.

These adjacent pairs, referred to as dimers, are modeled by the homogeneous reaction $A + A \rightleftharpoons A_2$. Linearization of a corresponding formula suggests that, subject to the following proviso, the forward rate constants derived for the heterogeneous reaction analyzed herein are also applicable to the homogeneous reaction (at least to leading order): based on combinatorial considerations, the forward rate constant for the homogeneous reaction is taken to be half that of the heterogeneous reaction, given by (8).

Given k_+, the easiest way to obtain an expression for k_-, the reverse rate constant governing dissociation of these dimers, is from the diffusion limited equilibrium constant

$$K = \frac{k_+}{k_-}.$$

For the situation of interest, the dilute limit where the typical distance between receptors is much larger than a, $K \doteq \pi a^2$, provided that the receptors are treated as point particles [4]. When the receptors are treated instead as hard discs of diameter b, so that their centers must be at least a distance b apart, then [22]

$$K = \pi a^2(1 - (b/a)^2). \tag{42}$$

To derive (42), focus on a "reference receptor." Because of the assumption of diluteness, the centers of other receptors are distributed approximately as a spatial Poisson process with density ρ_T outside a disc of diameter b centered on the reference receptor. Recall that the "distance between receptors" is the distance between their centers. Thus, for another receptor to be within a distance a of the reference receptor, its center must lie within an annulus of inner radius b and outer radius a. From the Poisson distribution for the number of points in a given area in a spatial Poisson process, the probability P_0 that the reference receptor has no other receptors within a, and the probability P_1 that there is exactly one other receptor, are given by

$$P_0 = e^{-\rho_T \pi (a^2 - b^2)} = e^{-\psi(1-(b/a)^2)},$$

$$P_1 = \rho_T \pi (a^2 - b^2) e^{-\rho_T \pi (a^2 - b^2)} = \rho_T \pi a^2 (1 - (b/a)^2)) e^{-\psi(1-(b/a)^2)}.$$

Multiplying the above equations by ρ_T gives us the equilibrium concentrations of isolated receptors, $[A]$, and dimers, $[D]$. When these equations are expanded, to leading order in ψ

$$[D] \approx [A]^2 \pi a^2 (1 - (b/a)^2), \tag{43}$$

and because $K \approx [D]/[A]^2$, (42) follows. Thus

$$k_- = \frac{k_+}{\pi a^2 (1 - (b/a)^2)}. \tag{44}$$

5.1.1. Estimates for k_+ and k_-. We estimate the values of the rate constants for a well-studied receptor system: the high affinity receptor, FcεRI, that binds IgE antibody on the surface of rat basophilic leukemia (RBL) cells. This receptor plays a central role in allergic reactions, as its activation leads to the release of histamine and other mediators of allergic reactions.

An RBL cell has approximately 3×10^5 FcεRIs on its cell surface and has a surface area of about 5×10^{-6} cm^2, so that $\rho_T = 6 \times 10^{10}$ cm^{-2}. Unlike, for example, growth-factor receptors, FcεRI is not an intrinsic kinase. However, it associates with a tyrosine kinase called Lyn, and when Lyn is bound to a receptor it phosphorylates other receptors in its proximity.

We will take a to be the maximum distance that a receptor associated with Lyn can be from its neighbor and still phosphorylate it. Experiments from another receptor system suggest $a \approx 40$ Å [14]. With this value of a, $\psi = \pi a^2 \rho_T = 0.03$. A reasonable range for b is 10–20 Å. Taking $b = 10$ Å, from (42), $K = 5.4 \times 10^{-13}$ cm^2. The diffusion coefficient of FcεRI on RBL, $D_A = 2$–3×10^{-10} cm^2/s (see [10, 17]). The last parameter requiring estimation is d: the separation distance which two receptors, initially a dimer, must achieve before they are deemed dissociated. We take d to be the average nearest-neighbor distance so that $d = \sqrt{\rho_T}/2 = 2 \times 10^{-6}$ cm. Rather than solving the implicit equation (7) for Φ, since ψ is small, (8) may be used to obtain an estimate for k_+. For the parameters given, $k_+ = 8.7 \times 10^{-10}$ cm^2/s, and from (44), $k_- = 1.85 \times 10^3$ s^{-1}. Thus, the average lifetime of an FcεRI dimer on an RBL cell, which aggregates and dissociates purely by diffusion, is $1/k_- = 5.4 \times 10^{-4}$ s.

The obvious question this result poses is, For such short dimer lifetimes can phosphorylation occur at the levels seen? By using these rate constants in the FcεRI signalling model of [6], this question may be further investigated.

5.2. Phototransduction. Diffusion limited reactions in $\mathbb{R}^2$ are thought to occur in the primary amplification steps of phototransduction, which accrue high levels of photosensitivity in the dark-adapted rod photoreceptor. When a photon is absorbed by the *retinal* moiety of a rhodopsin molecule, R, photoisomerization ensues, inducing a conformational change in rhodopsin: $R \to R^*$. Then R^*, diffusing in the phospholipid membrane of "discs," catalytically activates the G-protein transducin, T. This reaction,

$$R^* + T \to R^* + T^*,$$

is one which is thought to be diffusion limited. In the time scale of interest, the decay $R^* \to R$ may be ignored, and R^* effectively acts as a catalyst. The method of section 2 is readily adapted to encompass this reaction. As before, the reagents, R^* and T, may not coexist at a separation a. The novelty lies in the triple-density terms. Instead of including two terms, there is only the one pertaining to $R^*\,T\,R^*$, because it is not possible for two T's to interfere with one another in reacting with one R^*: this reaction is catalytic. This results in the substitution of $1/[T]$ for the coefficient $(1/[R^*] + 1/[T])$, obtaining a k_+ in the form (8) but with a $\psi = \pi a^2 [R^*]$.

We estimate the parameter a of this k_+, using the stochastic-simulation data of [9], whose parameters arise from experimental data from amphibian rods. We have $D_{R^*} = 0.7 \times 10^{-8}$cm^2/s, $D_T = 1.2 \times 10^{-8}$cm^2/s, and the (initial) concentrations are $[R^*] = 2.5 \times 10^7$/cm^2 and $[T] = 2.5 \times 10^{11}$/cm^2 (molecules/cm^2) [9, Figure 3]. Using $k_+ \sim -2\pi D / \log \sqrt{\psi}$ and the initial rate of concentration change $d[T^*]/dt = k_+[R^*][T] = 1.75 \times 10^{11}$/cm^2 s [9], it follows that

$$\log \sqrt{\psi} \doteq -4\pi \times 6.25/17.5 \doteq -4.5.$$

Whence, from $\psi = \pi a^2[R^*] \doteq e^{-9} \doteq 1.2 \times 10^{-4}$, $a \doteq 100$ Å. Because this is a plausible distance for interaction between the reactants, this result corroborates the hypothesis of diffusion limitation.

This a enters into the pair densities of this reaction. πa^2 is interpretable as a "cross section" for reaction. However, the length scale of this reaction, analogous to ℓ (see (5)) with $1/[T]$ for the parenthetic term, is approximately equal to 2×10^{-4} cm. Because this length is comparable to the linear dimension of a disc, the detailed shape of the latter could influence these kinetics—as would also be expected to be the case when a disc contains a single R^*.

A related analysis could be applied to the subsequent reaction, in which T^* activates cGMP phosphodiesterase, the enzyme which cleaves cGMP. This requires an appropriate treatment for the nonuniform distribution of T^*, which traces the path of R^*s. The latter may best be comprised via Monte Carlo simulations [9].

6. k_+'s. In this section, to facilitate the application of our theoretical results, we collect the rate constants derived herein, derived to be used with "concentrations" given as numbers of molecules per unit volume (or area). In practice, one may employ molar concentrations, obtained by dividing the number of molecules per unit volume (or area) by Avogadro's number $N_0 \doteq 6.02 \times 10^{23}$. Therefore, to obtain a k_+ appropriate for molar concentrations, multiply the following k_+'s by N_0. For reactions in $\mathbb{R}^2$,

$$k_+ \sim \frac{2\pi D}{\log d/a},$$

and correspondingly, in $\mathbb{R}^3$,

$$k_+ \sim \frac{4\pi D a(1 + o(\sqrt{\phi}))}{1 - a/d},$$

where ϕ denotes the expected number of A molecules plus B molecules within a sphere of radius a. For an interfacial reaction, with A's diffusing in a half space and B's (and AB's) diffusing in a plane bounding the half space,

$$k_+ \sim \frac{4a\sqrt{DD_A}}{1 - \frac{2}{\pi}\sin^{-1}\frac{a}{d}}.$$

Letting $d \to \infty$ in the differential equation corresponds to irreversible reaction because, when $a \ll d$, $\varrho(r)$ becomes uninfluenced by dissociation. The related k_+ is therefore obtainable by omitting the "source" term modeling dissociation from the equation (see section 4.4). For irreversible reactions $d[AB]/dt = -d[A]/dt = -d[B]dt = k_+[A][B]$, and, in $\mathbb{R}^2$,

$$k_+ \sim \frac{2\pi D}{-\log\sqrt{\psi}}\left(1 + \frac{\log\sqrt{-\log\sqrt{\psi}} + \frac{1}{2}\log 2 - \gamma}{\log\sqrt{\psi}} + \cdots\right),$$

recalling that $\psi = \pi a^2([A] + [B])$ ($\ll 1$), and where γ denotes Euler's constant. Recall from section 5.2 that for the catalytic reaction $A + B \to A + C$, one needs only substitute $\psi = \pi a^2[A]$ in the foregoing formula for k_+ (with an analogous substitution for spatial reactions). Correspondingly, in $\mathbb{R}^3$,

$$k_+ \sim 4\pi a D(1 + \sqrt{3\phi} + \cdots),$$

recalling that $\phi = \frac{4}{3}\pi a^3([A]+[B])$ ($\ll 1$). Agreement with previous results [3, (1.3)], [8, (121)–(122)] suggests that the independent-pair approximation for the triple density imparts negligible errors to these terms. Furthermore, for irreversible interfacial reactions,

$$k_+ \sim 4a\sqrt{DD_A}.$$

For the latter, when a protein A in solution reacts with a protein B in a cell membrane, $D_A \gg D_B$, and $D \approx D_A$, the above equation reduces to that obtained in [2], under the assumption that $D_B = 0$. Even when a protein in the cytosol, where the viscosity is 1.5 times larger than in solution, reacts with a lipid diffusing in a cell membrane, the required correction to the result of [2] will be negligible for most proteins. In detail, lipids have diffusion coefficients $\sim 10^{-8}\,\mathrm{cm}^2/\mathrm{s}$, two orders of magnitude larger than the coefficient of FCϵR1 on the cell surface. Furthermore, as the enzyme ribonuclease has a diffusion coefficient $\sim 10^{-6}\,\mathrm{cm}^2/\mathrm{s}$ in solution, only for massive proteins would our enhancement be nonnegligible.

7. Discussion. As may be surmised from section 5, the present results are practicable; they constitute extensions to the Smoluchowski theory. The applications presented above required adaptation of our theory, perhaps unsurprisingly, but they kindle the expectation that our approach can facilitate the modeling of a cornucopia of diffusion limited reactions, including irreversible reactions—exclusive of kinetic aberrations such as those attributable to reaction-induced concentration "archipelagoes" of A and B [16, 19, 20]. The forward reaction rate constant may be obtained from abridged solution of the respective differential equation, fostering the analysis of complex reactions [7].

It follows that the types of criticisms that can be leveled at the Smoluchowski theory may also apply to ours. We have sidestepped the complicated problem of estimating the error of our theory. For example, for $A+B \to AB$, although the use of the independent-pairs approximation for triple densities (1) did not, apparently, compromise the accuracy of the given results, the determination of the first decommissioned term (in the virial expansion) remains to be investigated, as do alternative reactions, such as $A + A \to A_2$, for which the independent-pairs approximation is likely to be less propitious. Thus, many challenges lie ahead.

Appendix. Consider the integral

$$\begin{aligned} I(\alpha,\beta) &= \int_R^\alpha \frac{\bar{R}d\bar{R}}{(\beta^2-\bar{R}^2)^{1/2}(\bar{R}^2-R^2)^{1/2}} \\ &= \frac{R}{2}\int_1^{\alpha^2/R^2} \frac{dx}{\sqrt{\beta^2-R^2x}\sqrt{x-1}} = \frac{R}{2}\int_1^{\alpha^2/R^2} \frac{dx}{\sqrt{-\beta^2+(\beta^2+R^2)x-R^2x^2}} \\ &= \frac{R}{2}\left(-\frac{1}{R}\right)\sin^{-1}\frac{-2R^2x+\beta^2+R^2}{\beta^2-R^2}\Bigg|_{x=1}^{x=\alpha^2/R^2} = \frac{\pi}{4}-\frac{1}{2}\sin^{-1}\frac{\beta^2-2\alpha^2+R^2}{\beta^2-R^2}, \\ &\qquad\qquad \alpha<\beta,\ \bar{R}<\alpha, \end{aligned}$$

Now

$$\frac{dI}{d\beta} = -\beta\int_R^\alpha \frac{\bar{R}d\bar{R}}{(\beta^2-\bar{R}^2)^{3/2}(\bar{R}^2-R^2)^{1/2}}$$

$$= -\frac{1}{2}\frac{1}{\sqrt{1-\left(\frac{\beta^2-2\alpha^2+R^2}{\beta^2-R^2}\right)^2}}\left\{\frac{2\beta}{\beta^2-R^2} - \frac{2\beta(\beta^2-2\alpha^2+R^2)}{(\beta^2-R^2)^2}\right\}$$

$$= -\frac{\beta}{\beta^2-R^2}\sqrt{\frac{1-\lambda}{1+\lambda}}, \qquad \lambda = \frac{\beta^2-\alpha^2-(\alpha^2-R^2)}{\beta^2-R^2},$$

$$1-\lambda = 2\frac{\alpha^2-R^2}{\beta^2-R^2}, \quad 1+\lambda = 2\frac{\beta^2-\alpha^2}{\beta^2-R^2}, \quad \sqrt{\frac{1-\lambda}{1+\lambda}} = \sqrt{\frac{\alpha^2-R^2}{\beta^2-\alpha^2}}.$$

Thus,

$$\int_R^\alpha \frac{\bar{R}d\bar{R}}{(\beta^2-\bar{R}^2)^{3/2}(\bar{R}^2-R^2)^{1/2}} = \frac{1}{\beta^2-R^2}\sqrt{\frac{1-\lambda}{1+\lambda}} = \frac{1}{\beta^2-R^2}\sqrt{\frac{\alpha^2-R^2}{\beta^2-\alpha^2}},$$

whence (38).

Acknowledgments. Professor H. M. McConnell, of Stanford University, called attention to the Smoluchowski theory and pointed out its shortcomings for reactions in surfaces. We are indebted to Professor Frits Wiegel, emeritus of Twente University, for sharing his insights.

COMPUTATION OF EXTENSIONAL FALL OF SLENDER VISCOUS DROPS BY A ONE-DIMENSIONAL EULERIAN METHOD*

B. H. BRADSHAW-HAJEK†, Y. M. STOKES†, AND E. O. TUCK†

Abstract. We develop a one-dimensional Eulerian model suitable for analyzing the behavior of viscous fluid drops falling from rest from an upper boundary. The method allows examination of development and behavior from early time, when a drop and filament begin to form, out to large times when the bulk of the fluid forms a drop at the bottom of a long thin filament which connects it with the upper boundary. This model overcomes problems seen in Lagrangian models, caused by excessive stretching of grid elements, and enables a better examination of the thin fluid filament.

Key words. extensional flow, dripping, moving boundary, viscous flow, free surface

DOI. 10.1137/050646743

1. Introduction. Formation of drops via extensional flow and break-off has been much studied (see the review article by Eggers [6]), motivated by a wide range of applications such as ink-jet printing, spinning and drawing of polymer or glass fibers, glass blowing and blow-molding in the manufacture of containers, light bulbs and glass tubing, rheological measurement by fiber extension, and fiber spinning for polymers and glasses [3, 4, 9, 13]. Considerable progress has been made towards an understanding of the breakup of a thin filament into drops, although the exact details of the final stages of breakup are yet to be resolved. However, the evolution of the drop and filament from some initial configuration, and the influence of initial conditions on the final breakup, are still relatively unexplored and have been the focus of our attention for some time [15, 14]. Some work by others on this topic includes [20, 18].

The problem of interest is a drop of very viscous fluid hanging beneath a solid wall/boundary and extending under gravity, similar to honey dripping from an upturned spoon. Analyses with and without inertia have been done and compared by the present authors [15, 14]. Surface tension was neglected in those studies, on the basis that a mean diameter $\ell = \sqrt{R_0 L_0}$ of the drop is large compared to the meniscus scale $\sqrt{\gamma/(\rho g)}$, or equivalently that the Bond number $Bo = \rho g \ell^2/\gamma$ is large. Here g is the gravitational acceleration, ρ, γ are respectively the density and surface tension coefficient of the fluid, R_0 is a length scale for the drop's cross section (e.g., the radius of the drop at the wall), and L_0 is the initial length of the drop. As the fluid filament extends and gets thinner, this neglect of surface tension may become less justifiable, and an examination of the effect of surface tension is desirable.

Because of the slender geometries involved, one-dimensional models are common in analysis of filament breakup [8, 1, 19, 5, 7, 17, 11]. However, the development of a drop and filament may also involve nonslender geometries at early times, requiring numerical solution of the full Navier–Stokes equations. Our previous work [15, 14] has involved both one-dimensional models and numerical solution of the Navier–Stokes

equations for axisymmetric drops and two-dimensional sheets.

For all of our work, a Lagrangian reference frame has been used, with grids that move with moving fluid elements. However, as the filament thins and surface tension potentially becomes important, Lagrangian numerics begin to fail due to the stretching of the grid. For example, in finite-element simulations of the full Navier–Stokes equations [14], mesh elements in and near the filament region become excessively elongated or distorted, leading to loss of accuracy. Similarly, in one-dimensional models the grid points become sparse in the filament region while congregating in the main drop, so that we lose the ability to examine the development of the filament. Hence, if we are to better investigate the filament evolution, including possible effects of surface tension, we must modify our methods.

A number of techniques are available to address the resolution problem in the filament region. First, we can begin with an irregular mesh that has a concentration of grid points in the section of the drop that will develop into the filament region. This, however, will only be successful until that section of the mesh becomes very stretched. Another option is to remesh when grid points become too sparse in the filament. This method becomes difficult (although not impossible) with the inclusion of inertia (see, for example, [18]), as all unknowns and their time derivatives must be interpolated from the old mesh onto the new mesh. In this paper, we wish to present a further alternative in which the congregation of mesh points does not occur.

We have therefore developed a one-dimensional model in an Eulerian reference frame, where the Lagrangian coordinate (a fluid particle label equal to the initial distance ξ from the wall) is sought as a function of time t and that particle's physical distance x from the wall. This model may be derived directly from the Navier–Stokes and continuity equations, as described below. It may also be obtained (in the absence of surface tension) by a transformation of our previous one-dimensional Lagrangian model [14] for the cross-sectional area A as a function of time t and Lagrangian coordinate ξ, which will also be outlined here.

The resulting PDE for $\xi = Z(x,t)$ is formally of higher order in space than the original PDE for $A(\xi,t)$. Also, while the original problem could be solved in a fixed spatial domain $0 < \xi < L_0$, where L_0 is the initial drop length, the transformation results in a moving boundary problem in the domain $0 < x < L(t)$, where the actual drop length $L(t)$ must be determined as part of the problem. Both of these aspects mean that the problem in physical coordinates is considerably harder to solve than that in Lagrangian coordinates, but it has the major benefit that grid elements do not become stretched over time and is therefore worth pursuing in order to better understand the filament behavior.

The increased complexity of the problem is partly a result of the transformation employed, with a further element of difficulty added by the inclusion of surface tension. In the absence of surface tension, the equations may be directly integrated, simplifying the numerical problem. In this paper we explore the new model and its solution in the absence of surface tension, which will be considered in a future paper. We will, however, derive here the equations with surface tension included.

2. A one-dimensional Eulerian model. For an axisymmetric column of incompressible fluid, a one-dimensional lubrication approximation to the Navier–Stokes equations yields (see, for example, [5, 11, 10])

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} = g - \frac{\gamma}{\rho}\frac{\partial K}{\partial x} + \frac{\nu^*}{h^2}\frac{\partial}{\partial x}\left(h^2\frac{\partial u}{\partial x}\right), \tag{2.1}$$

while the continuity equation becomes

$$(h^2)_t + (uh^2)_x = 0, \tag{2.2}$$

where subscripts denote derivatives, $\nu_* = 3\mu/\rho$ is the elongational (Trouton) kinematic viscosity [16] of a fluid with shear viscosity μ and density ρ, g is gravitational acceleration in the downward (positive) direction, γ is the coefficient of surface tension, $u(x,t)$ is the downward velocity of the fluid at position x and time t, $h(x,t)$ is the radius of the drop, and $K(x,t)$ is the curvature of the drop, given by

$$K = \frac{1}{\sqrt{1+(h_x)^2}}\left[\frac{1}{h} - \frac{h_{xx}}{1+(h_x)^2}\right]. \tag{2.3}$$

The cross-sectional area of the drop is given by $A = \pi h^2$, so (2.2) can be rewritten as

$$A_t + uA_x = -Au_x \tag{2.4}$$

and substituted into (2.1) to obtain

$$u_t + uu_x = g - \frac{\gamma}{\rho}K_x - \frac{\nu^*}{A}\frac{\partial}{\partial x}\left(\frac{\partial A}{\partial t} + u\frac{\partial A}{\partial x}\right)$$

or

$$\frac{Du}{Dt} = g - \frac{\gamma}{\rho}K_x - \frac{\nu^*}{A}\frac{\partial}{\partial x}\frac{DA}{Dt}, \tag{2.5}$$

where $D/Dt = \partial/\partial t + u\,\partial/\partial x$ denotes the material time derivative.

In a Lagrangian reference frame [15, 14, 19] we let $x = X(\xi,t)$, where ξ is a fluid-particle label such that $x = \xi$ at $t = 0$. The initial drop geometry is assumed to have a cross-sectional area distribution given by some function $A_0(\xi)$. That is, $A(\xi,0) = A_0(\xi)$, $0 \le \xi \le L_0$, where $A(\xi,t)$ is the cross-sectional area at label ξ and time t, and L_0 is the initial drop length. Conservation of mass demands [14]

$$A\frac{\partial X}{\partial \xi} = A_0$$

or, on integration,

$$X(\xi,t) = \int_0^\xi \frac{A_0(\xi_1)}{A(\xi_1,t)}d\xi_1. \tag{2.6}$$

Now, defining $\xi = Z(x,t)$, we have

$$A = A_0 Z_x, \quad u = X_t = -\frac{Z_t}{Z_x}, \quad \text{and} \quad \frac{\partial A_0}{\partial x} = A_0' Z_x,$$

where primes denote differentiation with respect to ξ. Substituting for A and u in (2.5) gives

$$\begin{aligned} -\frac{D}{Dt}\left(\frac{Z_t}{Z_x}\right) &= g - \frac{\gamma}{\rho}K_x - \frac{\nu^*}{A_0 Z_x}\frac{\partial}{\partial x}\left[A_0\frac{D}{Dt}(Z_x)\right] \\ &= g - \frac{\gamma}{\rho}K_x - \nu^*\left[\frac{A_0'}{A_0}\frac{D}{Dt}(Z_x) + \frac{1}{Z_x}\frac{\partial}{\partial x}\left(\frac{D}{Dt}(Z_x)\right)\right] \\ &= g - \frac{\gamma}{\rho}K_x - \nu^*\frac{D}{Dt}\left(\frac{A_0'}{A_0}Z_x + \frac{Z_{xx}}{Z_x}\right), \end{aligned} \tag{2.7}$$

with

$$\frac{D}{Dt} = \frac{\partial}{\partial t} - \frac{Z_t}{Z_x}\frac{\partial}{\partial x}.$$

The transformation to the dependent variable $Z(x,t)$ has yielded a PDE (2.7) that is second order in time and third order in space, whereas the Navier–Stokes equation (2.1) is first order in time and second order in space. The main reason for this increase in order is that the dependant variable is a position rather than a velocity (as in the Navier–Stokes equations). In order to solve (2.7), we must also solve for the length of the drop $L(t) = X(L_0, t)$, which is increasing with time. Thus, we need two initial conditions and four boundary conditions. One initial condition is obtained from the definition of the Lagrangian coordinate such that $\xi = x$ at $t = 0$, so that

$$Z(x,0) = x. \tag{2.8}$$

The other comes from the condition that the flow starts from rest, so $u(x,0) = 0$ or

$$Z_t(x,0) = 0. \tag{2.9}$$

With respect to boundary conditions, two (one at each end) come from the definition of the Lagrangian coordinate such that $x = 0$ at $\xi = 0$ and $x = L(t)$ at $\xi = L_0$, giving

$$Z(0,t) = 0, \tag{2.10}$$

$$Z(L(t),t) = L_0. \tag{2.11}$$

Since the drop is falling from under a solid plane boundary where the normal velocity is zero for all time, i.e., $u = 0$ at $x = 0$, then $Du/Dt = 0$ at $x = 0$, and hence, from (2.7),

$$0 = g - \frac{\gamma}{\rho}K_x - \nu^* \frac{D}{Dt}\left(\frac{A_0'}{A_0}Z_x + \frac{Z_{xx}}{Z_x}\right) \quad \text{at} \quad x = 0. \tag{2.12}$$

We require a further boundary condition which comes from a balance between viscous stresses and surface tension at the bottom of the drop $x = L(t)$. One-dimensional theory yields

$$\frac{\partial}{\partial x}\left(\frac{Z_t}{Z_x}\right) = -\frac{\gamma}{\rho\nu^*}K, \quad \text{or, equivalently,} \quad \frac{D}{Dt}(Z_x) = -\frac{\gamma}{\rho\nu^*}Z_x K. \tag{2.13}$$

Equation (2.7) subject to initial and boundary conditions (2.8)–(2.13) describes the fall of a drop of viscous fluid from underneath a solid boundary, starting from a known initial configuration. Gravitational, viscous, inertial, and surface tension effects are all included. The model derived involves the fluid-particle label $\xi = Z(x,t)$ as the dependent variable, with the physical space coordinate x and time t as the independent variables.

For zero surface tension ($\gamma = 0$), (2.7) simplifies considerably, by integration with respect to the material time derivative. With nonzero surface tension ($\gamma \neq 0$), such a procedure is computationally problematic due to the necessity of time-integrating the surface-tension term while holding the particle label $\xi = Z(x,t)$ constant. We leave consideration of this matter to a future paper and, from here on, neglect surface

tension (i.e., set $\gamma = 0$). Integration with respect to t at fixed $\xi = Z$, subject to $Z = x$ and $Z_t = 0$ at $t = 0$, then yields

$$-\frac{Z_t}{Z_x} = gt - \nu^* \left(\frac{A_0'}{A_0}(Z_x - 1) + \frac{Z_{xx}}{Z_x} \right)$$

or

$$Z_t = \nu^* Z_{xx} - gtZ_x - \nu^* \frac{A_0'(Z)}{A_0(Z)} Z_x(1 - Z_x). \tag{2.14}$$

Equation (2.14) is in general a nonlinear PDE which, like the Navier–Stokes equation (2.1), is first order in time and second order in space. It is worth noting in passing that in the special case of an initially cylindrical drop where $A_0 =$ constant, it becomes linear, and in the further special case where gravity can be neglected (such as in a liquid bridge problem [2]), it reduces to the ordinary linear heat-conduction equation, with diffusivity ν^*.

The appropriate initial and boundary conditions are

$$\begin{aligned} Z(x,0) &= x \qquad \text{at } t = 0, \\ Z(0,t) &= 0 \qquad \text{at } x = 0, \\ Z(L(t),t) &= L_0 \qquad \text{at } x = L(t), \\ Z_x(L(t),t) &= 1 \qquad \text{at } x = L(t). \end{aligned} \tag{2.15}$$

Note that we no longer need boundary condition (2.12), which in integrated form is equivalent to $u = 0$ at $x = 0$, and which is automatically satisfied by demanding $Z(0,t) = 0$. Also, with $\gamma = 0$, (2.13) can be integrated with respect to the material time derivative to give $Z_x = 1$ at $x = L(t)$ as we have in (2.15).

The Lagrangian equivalent to (2.14) in terms of the cross-sectional area $A(\xi, t)$ as a function of Lagrangian coordinate ξ and time t is readily (by manipulation of (2.14)) shown to be

$$u = gt - \frac{\nu^*}{A_0} \frac{\partial}{\partial \xi}(A - A_0).$$

Differentiating with respect to ξ, using (2.6), and rearranging gives

$$\frac{\partial A}{\partial t} = \nu_* \frac{A^2}{A_0} \frac{\partial}{\partial \xi} \left(\frac{1}{A_0} \frac{\partial}{\partial \xi}(A - A_0) \right), \quad 0 \le \xi \le L_0. \tag{2.16}$$

The corresponding initial and boundary conditions are

$$A(\xi,0) = A_0(\xi), \quad \frac{\partial}{\partial \xi}(A - A_0)(0,t) = \frac{gt}{\nu^*} A_0(0), \quad A(L_0,t) = A_0(L_0). \tag{2.17}$$

The Lagrangian model given by (2.16) and (2.17) was derived directly in [14] by balancing viscous and gravitational forces; the inertialess version was considered in [15]. Comparison between solutions to these models and those for the new Eulerian model of present interest, (2.14) and (2.15), will be given below. We note that the Eulerian model involves gravity explicitly in the PDE (2.14), whereas the Lagrangian model involves gravity only in a boundary condition at $\xi = 0$ (2.17).

3. Eulerian-model solution. For the remainder of this paper, we will be primarily interested in initially paraboloidal slender drops, given in Lagrangian coordinates by $A_0(\xi) = A_0(0)(1 - \xi/L_0)$ with small aspect ratio $\alpha_r = \sqrt{A_0(0)}/L_0 \ll 1$, as considered in [14].

Defining dimensionless variables (denoted by bars)

$$\overline{A}_0(\overline{\xi}) = \frac{A_0(\xi)}{A_0(0)}, \quad \overline{\xi} = \overline{Z} = \frac{\xi}{L_0} = \frac{Z}{L_0}, \quad \overline{x} = \frac{x}{L_0}, \quad \overline{t} = \frac{gL_0}{\nu^*}t, \tag{3.1}$$

the dimensionless form of (2.14) for the initially paraboloidal drop $\overline{A}_0(\overline{Z}) = 1 - \overline{Z}$ is (after removing the bars)

$$Re\, Z_t = Z_{xx} - tZ_x + \frac{Z_x}{1 - Z}[1 - Z_x], \tag{3.2}$$

with the Reynolds number Re given by

$$Re = \frac{gL_0^3}{\nu^{*2}}.$$

The initial and boundary conditions (2.15) become

$$Z(x,0) = x, \quad Z(0,t) = 0, \quad Z(L(t),t) = 1, \quad \text{and} \quad Z_x(L(t),t) = 1. \tag{3.3}$$

Equation (3.2) subject to (3.3) is most easily solved using the explicit forward-time-centered-space finite difference method. Setting the time step Δt and spatial step Δx, we approximate (3.2) in the usual manner by

$$\begin{aligned} Re\frac{Z_i^{j+1} - Z_i^j}{\Delta t} &= \frac{Z_{i+1}^j - 2Z_i^j + Z_{i-1}^j}{\Delta x^2} - t\frac{Z_{i+1}^j - Z_{i-1}^j}{2\Delta x} \\ &\quad + \frac{1}{1 - Z_i^j}\frac{Z_{i+1}^j - Z_{i-1}^j}{2\Delta x}\left[1 - \frac{Z_{i+1}^j - Z_{i-1}^j}{2\Delta x}\right], \end{aligned} \tag{3.4}$$

where $Z_i^j = Z(x_i, t_j)$ is the value of $Z(x,t)$ at the jth time step and the ith grid point. For numerical stability, we must ensure that the diffusion number $\Delta t/Re(\Delta x)^2 < 0.5$.

The initial and wall boundary conditions are easily specified by setting $Z_i^0 = i\Delta x$ and $Z_0^j = 0$. However, the boundary conditions at the free end are not quite so straightforward to implement, due to the moving boundary. At each time step, the drop becomes longer and some of the drop (at the bottom) will move beyond the current computational domain. Hence we need to extend the grid to the new position of the bottom of the drop.

Specifically, having computed Z_i^{j+1}, $i = 1, \ldots, N_j - 1$, using (3.4), we seek an extrapolation procedure that approximates the bottom of the drop, satisfying the boundary conditions $Z = Z_x = 1$ at the (as yet unknown) drop bottom $x = L(t_{j+1})$, and that matches our already computed solution above the bottom. The most obvious choice is a linear polynomial extrapolation, but this can only be first order accurate, and we prefer to preserve the second order accuracy of the finite difference scheme. To achieve this, we could seek a quadratic polynomial extrapolation

$$Z(x, t_{j+1}) = a_{j+1}(x - x_{N_j - 1})^2 + b_{j+1}(x - x_{N_j - 1}) + c_{j+1},$$

where the unknown coefficients $a_{j+1}, b_{j+1}, c_{j+1}$ and the unknown length $L(t_{j+1})$ of the drop are determined by satisfying the two boundary conditions at $x = L(t)$ and

matching the already computed solution at x_{N_j-2} and x_{N_j-1}. An equally good second order extrapolation is to use the exponential approximation

$$Z(x,t_{j+1}) = e^{x-L(t_{j+1})}, \quad \text{where} \quad e^{-L(t_{j+1})} = Z_{N_j-1}^{j+1} e^{-x_{N_j-1}}. \tag{3.5}$$

In fact, (3.5) is just the local form of the solution from the corresponding Lagrangian model neglecting inertia as in [15], and hence has a stronger physical motivation than the quadratic extrapolant.

Earlier work [15, 14] has shown that, with neglect of surface tension, the drop shape very near to the bottom is given quite accurately by the inertialess solution. This is because at early times, accelerations are very small and Stokes flow solutions are applicable; at later times, the main drop is essentially in free fall and (with neglect of surface tension) does not change in shape. Furthermore, for some initial configurations, including the initially paraboloidal drop considered here, we can obtain an exact analytic solution to the Lagrangian model neglecting inertia and use this to assign appropriate values of $Z(x,t)$ to the new grid points. Specifically, using (3.1), the dimensionless form of the Lagrangian PDE (2.16) is (after removing the bars)

$$Re\frac{\partial A}{\partial t} = \frac{A^2}{A_0}\frac{\partial}{\partial \xi}\left(\frac{1}{A_0}\frac{\partial}{\partial \xi}(A - A_0)\right), \quad 0 \le \xi \le 1, \tag{3.6}$$

with initial and boundary conditions

$$A(\xi,0) = A_0(\xi), \quad \frac{\partial}{\partial \xi}(A - A_0)(0,t) = t, \quad A(1,t) = A_0(1,t). \tag{3.7}$$

In the inertialess limit ($Re = 0$) this has the explicit solution

$$A(\xi,t) = A_0(\xi) - tV(\xi), \quad V(\xi) = \int_\xi^1 A_0(\xi_1)\, \mathrm{d}\xi_1. \tag{3.8}$$

As discussed by Stokes, Tuck, and Schwartz [15], the cross-sectional area of the drop vanishes at the position $\xi = \xi_*$ such that $t = t_* = A_0(\xi_*)/V(\xi_*)$ is a minimum, so that the drop formally breaks with $A(\xi_*, t_*) = 0$. The time t_* is the "crisis" time; at this time the length of the drop, given by (2.6) with $\xi = 1$, formally becomes infinite in this inertialess approximation. No solution exists for $t > t_*$; i.e., we have a finite-time blow up at the crisis time t_*. However, for larger times $t > t_*$ the main drop is effectively falling as a solid body, and in the absence of surface tension it retains the same shape given by (3.8) with $t = t_*$.

For the initially paraboloidal drop $A_0(\xi) = 1 - \xi$, (3.8) becomes

$$A(\xi,t) = (1-\xi)\left(1 - \frac{1}{2}t(1-\xi)\right), \tag{3.9}$$

from which we see that $\xi_* = 0$ and $t_* = 2$; i.e., the drop breaks at the wall at the crisis time $t = 2$. Hence, for all $t \ge 2$,

$$A(\xi) = \xi(1-\xi), \tag{3.10}$$

which is a solution to (3.6). It is readily verified using $Z_x = A/A_0$ that (3.9) satisfies the condition $Z_x = 1$ at $x = L(t)$ (i.e., $\xi = 1$) for all $t \le 2$.

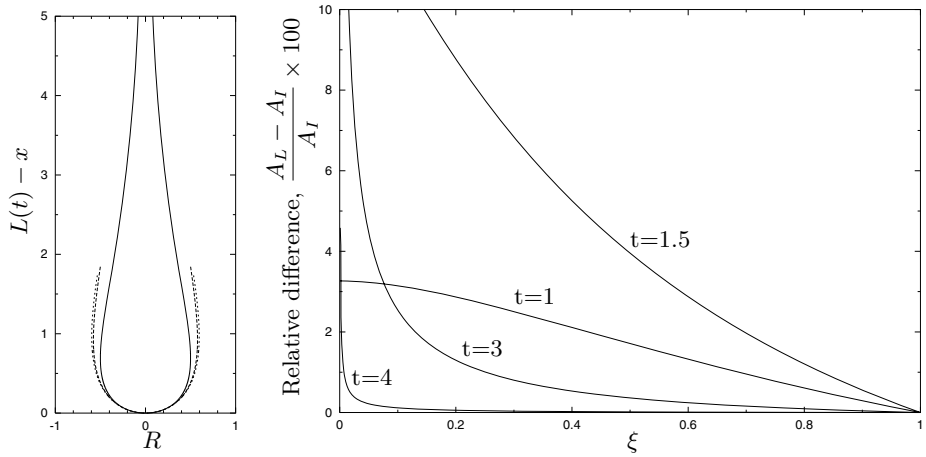

FIG. 3.1. (a) *Drop shape as a function of distance* $L(t) - x$ *from the bottom of the drop. Inertialess solution* (3.9) *at* $t = 1.5$ *(solid); solution to the Lagrangian PDE* (3.6) *at* $t = 1.5$ *(dotted) and* $t = 4.0$ *(dashed); the inertialess large-time solution* (3.10) *is indistinguishable from the dashed curve.* (b) *Percentage relative difference between the solution to the Lagrangian PDE* (3.6) *and the inertialess solution* (3.9) *for* $t < 2$ *or* (3.10) *for* $t \geq 2$. *The percentage relative difference is calculated as* $100 \times (A_L - A_I)/A_I$, *where* A_L *is the calculated solution to* (3.6) *and* A_I *is the inertialess solution* (3.9) *or* (3.10). *Here* (3.6) *was solved using implicit backward differencing with* $Re = 0.1$, $\Delta\xi = 10^{-3}$, $\Delta t = 10^{-3}$.

The extrapolant for $Z(x,t)$ is obtained by substituting $A_0 = 1 - Z$, and $A(Z,t)$ given by (3.9) for $t < 2$ or (3.10) for $t \geq 2$, into $Z_x = A/A_0$. Integrating then yields

$$Z(x,t) = \begin{cases} 1 - \dfrac{2}{t} + c(t)\,\mathrm{e}^{xt/2} & \text{for } \ 0 < t < 2, \\ c(t)\,\mathrm{e}^{x} & \text{for } \ t \geq 2. \end{cases} \tag{3.11}$$

We solve for the value of the unknown function of time $c(t)$ at time t_{j+1} using the already computed value of Z at x_{N_j-1}. The expression so obtained for $t \geq 2$ is (3.5) exactly. It is also readily seen that the expression obtained for $t < 2$ is second-order accurate. Thus, we use (3.11) to calculate values of $Z^{j+1}_{N_j+k}$, $k = 0, 1, \ldots$, stopping when $Z^{j+1}_{N_j+k} > 1$, and thus extending the computational domain to N_{j+1} grid points. The actual position of the bottom of the drop is given by solving $Z(L(t_{j+1}), t_{j+1}) = 1$.

The accuracy of this procedure is demonstrated for $Re = 0.1$ in Figure 3.1. Figure 3.1(a) compares the drop shape at $t = 1.5$ given by the inertialess solution (3.9) and as found by solving (3.6); also shown is the large- (i.e., crisis) time inertialess solution (3.10), which is indistinguishable from the solution to (3.6) at $Re = 0.1$, $t = 4$. Figure 3.1(b) shows the percentage relative difference between solutions to (3.6) at Reynolds number $Re = 0.1$ and the inertialess solution at different times. At the very bottom of the drop, the relative difference is much less than 1%. As the Reynolds number increases, the inertialess solution becomes less accurate as a global approximation for the drop shape, but each (dimensionless) time step represents a decreasing physical time interval so that still only very few grid points are extrapolated. Even for Reynolds numbers as high as $Re = 10$, it gives a good approximation for the local region near the bottom of the drop. Thus the method remains (second-order) accurate. In fact, because only a very few grid points are ever extrapolated, the choice of extrapolation procedure has only a minor effect on the solution.

Having determined the Lagrangian coordinate $Z(x,t)$ over the new, extended, computational domain, the actual shape of the drop can be calculated via $R = \sqrt{A} = \sqrt{A_0 Z_x}$.

4. Results and comparison between Eulerian and Lagrangian models. The numerical solution to (3.2) for the particle label $Z(x,t)$ as a function of physical space and time is shown, for Reynolds number $Re = 0.1$, in Figure 4.1. The growth of the computational domain as a result of the moving boundary at $Z = 1$ can be clearly seen.

The axisymmetric drop shape is shown in Figure 4.2(a), alongside drop shapes from the numerical solution to the Lagrangian equation (3.6), in Figure 4.2(b). The solution to (3.6) was calculated using the implicit backward-time-centered-space finite difference method. The two different models produce the same drop shapes with the same overall length; however, there are some differences to be highlighted.

First, for times $t \gtrsim 2.6$ the computed solutions to the Lagrangian model (Figure 4.2(b)) appear to move away from the wall. This is due to stretching of the grid and a consequent loss of grid points in the filament region and accumulation of grid points in the main drop below the filament, as seen in Figure 4.3(b). The fluid particle that is initially a distance $x = \Delta\xi$ from the wall (i.e., the closest point to the wall for which we calculate $A(\xi,t)$) falls ever downwards, so that there is a continually lengthening region in physical space, which is essentially the fluid filament connecting the drop to the wall, about which we know virtually nothing. Unfortunately, it is in this filament region that our greatest interest lies, since this is where the drop will eventually break. While decreasing the grid spacing near the wall will extend the time over which we have near complete information, there will always come a time (soon after the crisis time t_* of the inertialess theory, when accelerations approach gravitational acceleration) when the grid becomes too stretched in the filament region. This loss of information in the filament region is completely overcome with the Eulerian model (Figure 4.2) because gridpoints are fixed in space and the grid constantly extended as the drop length increases. This leads to a uniform spacing of grid points over the full

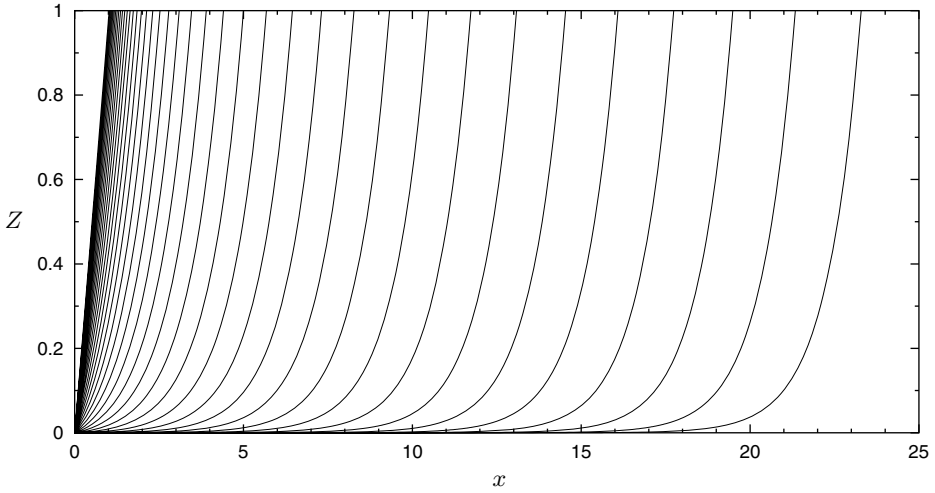

FIG. 4.1. *Solution to PDE* (3.2) *for* $Z(x,t)$*, with* $Re = 0.1$*, at times* $t = 0, 0.1, \ldots, 3.9, 4.0$*. Here* $\Delta x = 10^{-2}$*,* $\Delta t = 4 \times 10^{-6}$*.*

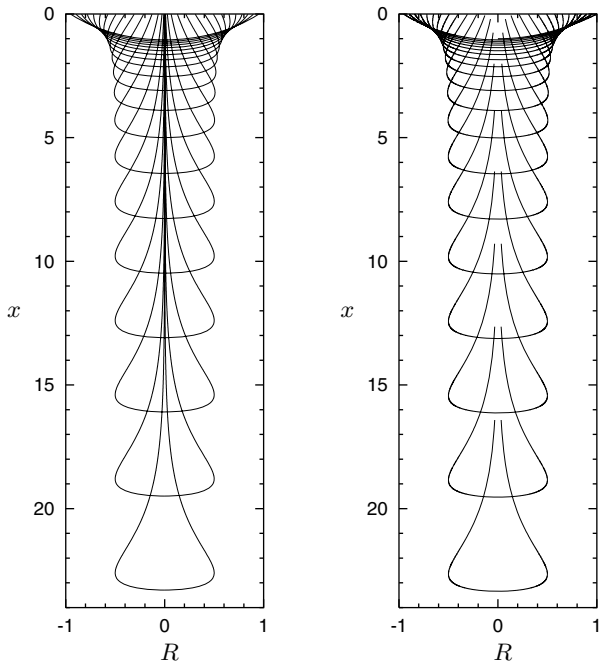

FIG. 4.2. *Drop shapes for* $Re = 0.1$ *at times* $t = 0, 0.2, \ldots, 3.8, 4.0$. (a) *Shape calculated using Eulerian framework* (3.2) *(*$\Delta x = 10^{-2}$, $\Delta t = 4. \times 10^{-6}$*).* (b) *Shape calculated using Lagrangian framework* (3.6) *(*$\Delta\xi = 10^{-3}$, $\Delta t = 10^{-3}$*).*

length of the drop, as seen in Figure 4.3(a). The greater knowledge of the filament region that results from the Eulerian model will better enable a future study of the effect of surface tension on filament breakup and drop pinch-off.

A second point of difference between the Eulerian and Lagrangian models is with respect to the behavior near the wall boundary at $x = \xi = 0$. At this boundary, the Lagrangian boundary condition (3.7) for the initially paraboloidal drop is

$$\frac{\partial A}{\partial \xi}(0,t) + 1 = t. \tag{4.1}$$

For the Lagrangian model it is a simple matter to check that this boundary condition is indeed satisfied, by computing $A_\xi(0,t)$ using the forward-space finite difference formula, i.e.,

$$A_\xi(0,t) = \frac{A(\Delta\xi, t) - A(0,t)}{\Delta\xi}.$$

The value of $A_\xi(0,t) + 1$ so computed is plotted against time t in Figure 4.4 (solid curve). The wall boundary condition is satisfied until $t \approx 2.0$ and then $A_\xi(i,t)$ begins to move away from t. At $t \approx 2.4$ there is a rapid deviation from the correct solution as the value of $A_\xi(0,t)$ decreases and appears to approach a constant unit value. This highlights the fact that the Lagrangian solution cannot be relied upon at large times when the grid becomes excessively stretched in physical space.

The equivalent condition on $A_\xi(0,t)$ for the Eulerian model is obtained by differ-

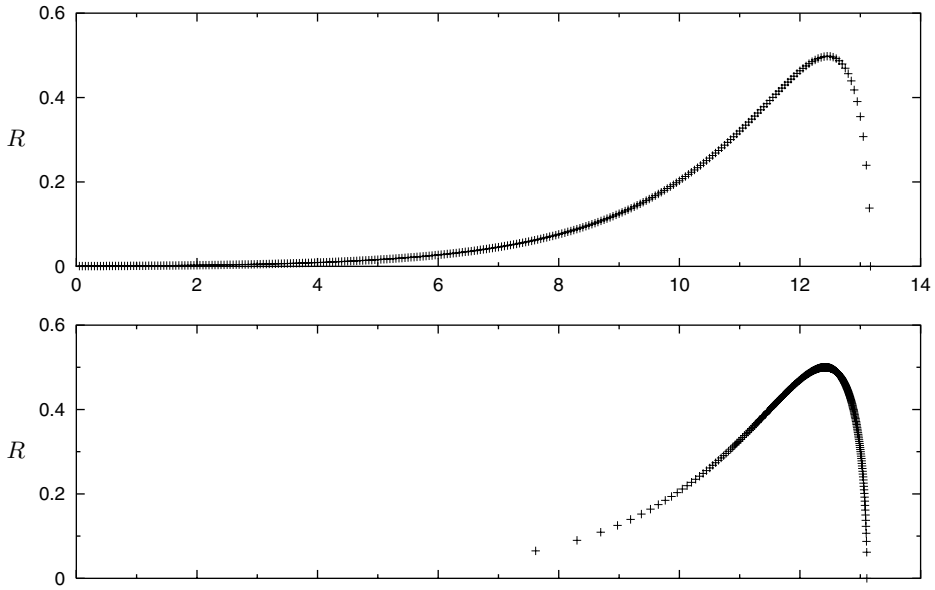

FIG. 4.3. *Comparison of Lagrangian and Eulerian solution methods at* $t = 3.4$. *Each figure has approximately* 260 *grid points.* (a) *Drop shape calculated using the Eulerian model* (3.2), (3.3) *(*$\Delta x = 5 \times 10^{-2}$, $\Delta t = 10^{-4}$*).* (b) *Drop shape calculated using the Lagrangian model* (3.6), (3.7) *(*$\Delta x = 1/260$, $\Delta t = 10^{-3}$*). The extra grid points in the filament region of the Eulerian model can be clearly seen.*

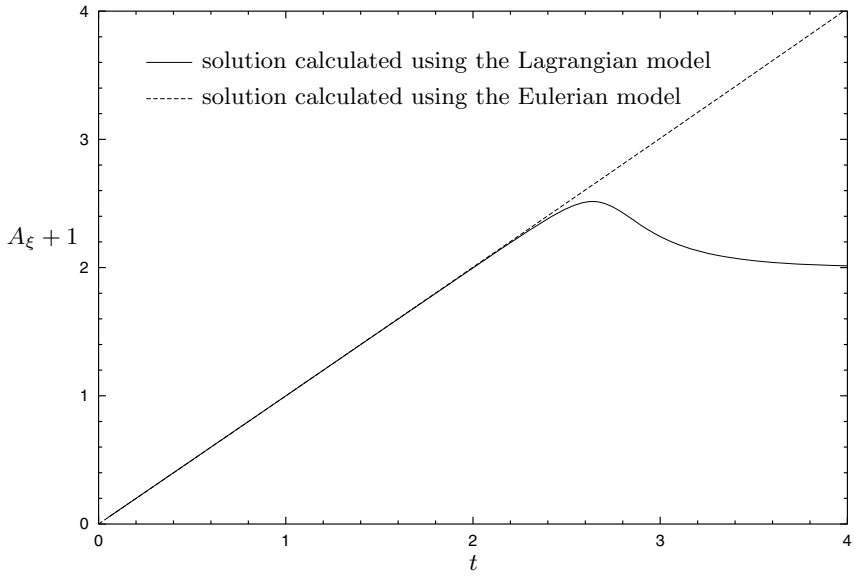

FIG. 4.4. *The accuracy of the Lagrangian and Eulerian models as indicated by the wall boundary condition* $(3.7)_2$. *For an initially paraboloidal drop we require* $A_\xi + 1 \sim t$. *This condition is satisfied by the Eulerian model but not the Lagrangian model.*

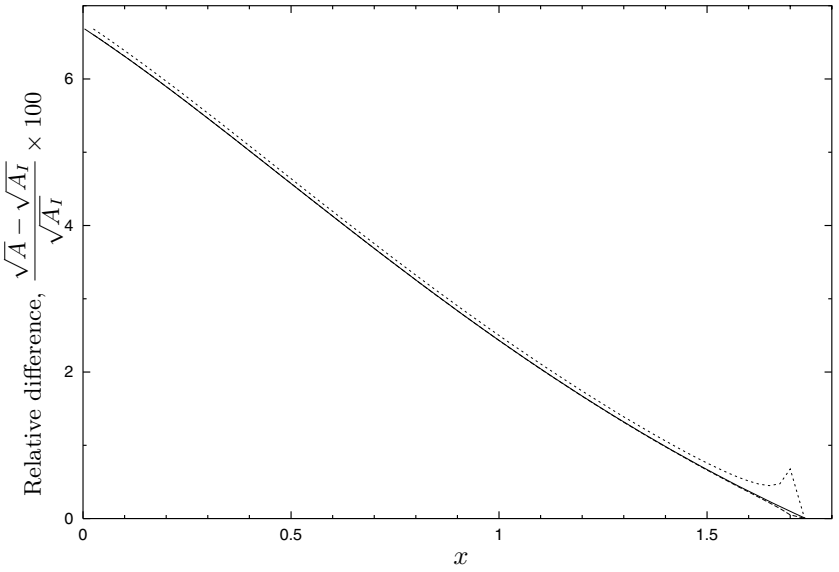

FIG. 4.5. *Percentage relative differences at $t = 1.5$ between the inertialess radius $\sqrt{A_I}$ with A_I given by (3.9), and Lagrangian and Eulerian solutions with $Re = 0.1$. The difference is given by $100 \times (\sqrt{A} - \sqrt{A_I})/\sqrt{A_I}$, where A denotes the Lagrangian solution (solid), the Eulerian solution with extension of the computational domain using the inertialess solution at crisis time (dashed), and the Eulerian solution with extension of the computational domain using the forward-difference representation of $Z_x(L(t), t) = 1$ (dotted).*

entiating $A = A_0 Z_x$ with respect to ξ, i.e. (for the initially paraboloidal drop),

$$\begin{aligned} A_\xi &= A_0' Z_x + \frac{A_0 Z_{xx}}{Z_x} \\ &= -Z_x + (1 - Z)\frac{Z_{xx}}{Z_x}. \end{aligned}$$

The slope, A_ξ at the wall can thus be found from the calculated values of $Z(0, t)$, $Z(\Delta x, t)$, and $Z(2\Delta x, t)$ using first order forward-space finite difference formulae for Z_x and Z_{xx}, i.e.,

$$Z_x(0, t) = \frac{Z(\Delta x, t) - Z(0, t)}{\Delta x} \quad \text{and} \quad Z_{xx}(0, t) = \frac{Z(2\Delta x, t) - 2Z(\Delta x, t) + Z(0, t)}{\Delta x^2}.$$

Figure 4.4 (dashed line) shows that $A_\xi + 1 \sim t$ for times well beyond $t = 2.4$; i.e., the wall boundary condition (4.1) is satisfied. Thus, we see that, for large times, the solution obtained from the Eulerian model is more reliable than that obtained from the Lagrangian model, especially in the filament region.

This is also shown by Figures 4.5 and 4.6. Figure 4.5 shows the relative differences between the inertialess prediction (3.9) of the drop/filament radius ($R = \sqrt{A}$) and solutions at $Re = 0.1$ to the Lagrangian and Eulerian models, as a function of physical distance x from the upper wall boundary, at time $t = 1.5$ before the crisis time of inertialess theory. There is excellent agreement between the Lagrangian and Eulerian models at this time, with a difference visible only at the very bottom of the drop. Figure 4.6 gives the same comparisons but at time $t = 4$, well after the crisis time of inertialess theory. Now we see considerably more difference between the Lagrangian

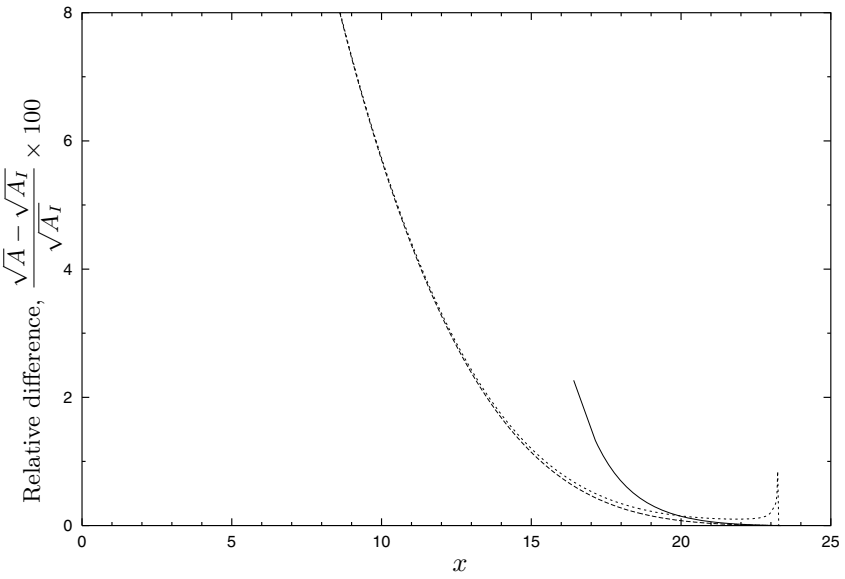

FIG. 4.6. *As for Figure* 4.5 *but at time* $t = 4$*, with* A_I *given by the inertialess large-time solution* (3.10).

and Eulerian solutions, which is due to error in the Lagrangian solution resulting from an excessively stretched grid. Note also that grid stretching limits our comparison to the bottom third of the drop where the Lagrangian solution is available; in the region $0 \leq x < 16$ no information is available from the Lagrangian solution due to a lack of grid points.

For interest, Figures 4.5 and 4.6 also show results for the Eulerian solution obtained using the finite difference approximation to the boundary condition $Z_x = 1$ at $x = L(t)$, discussed earlier as an alternative to pasting of the inertialess solution to the bottom of the drop. This differs from the other curves by only about 0.1% over most of the drop length, with the difference increasing to about 1% at the very bottom; note that the overall drop length is slightly less, as mentioned earlier, although it is not noticable with the grid size used here or at the scales shown.

It is interesting to note that at small Reynolds number the time at which the numerical solution to (3.6) begins to become inaccurate in the filament region (as indicated by Figure 4.4) is approximately equal to the crisis time of inertialess theory, as predicted in [15] ($t_* = 2$), when accelerations increase rapidly up to gravitational acceleration. This correlation between the inertialess crisis time and the time at which the small-Reynolds-number Lagrangian solution becomes inaccurate is also observed with other initial drop shapes.

5. Discussion and conclusions. The major benefit of reformulating the extensional flow problem using an Eulerian framework is that, in contrast to other one-dimensional Lagrangian models, we now include many grid points in the filament region. The Eulerian scheme is computationally more costly, as there is a rapid increase in the number of grid points as the computational domain extends with the falling drop. However, this method provides us with information about the filament region which we cannot obtain using a Lagrangian method. Accuracies such as those achieved in Figure 4.2 can still be obtained in a matter of minutes. This greater res-

olution in the filament region enables us to better study the dynamics and behavior of the developing filament. In particular we are now much better equipped to investigate the effects of surface tension on the filament, the drop shape, and pinch-off of the main drop by solving (2.7) with $\gamma \neq 0$. This will be considered in a future paper.

Meanwhile, reformulating the problem also enables us to address a question previously posed in Stokes and Tuck [14]. In that paper, we saw that at small Reynolds numbers and large times, the main part of the drop is indistinguishable from a solid object that fell from rest at an apparent time t_0. Identification of this apparent time with the crisis time of inertialess theory leads to the conclusion that the large-time drop shape is the drop shape obtained at the crisis time when neglecting inertia. Conversely, it can be shown that equating the large-time drop shape at small Reynolds numbers with the drop shape at the crisis time of inertialess theory, which is strongly supported by the numerical solutions (both here and in [14]), implies that the apparent time t_0 and the crisis time t_* are identical. This relationship between the inertialess theory and the large-time limit of the flow with inertia implies the expected large-time shape for an initially paraboloidal drop [14]

$$A(x,t) = \mathrm{e}^{-(L-x)}\left[1 - \mathrm{e}^{-(L-x)}\right], \tag{5.1}$$

where $L = L(t)$ is the length of the drop at time t. However, the asymptotic theory described in [14] did not provide an estimate of the actual length $L(t)$ of the drop. We can now supply that estimate.

In the physical coordinate system, the cross-sectional area of the drop is given by $A(x,t) = A_0 Z_x$. The expected large-time drop shape obtained from the inertialess theory, for the initially paraboloidal drop, is given by $(3.11)_2$ as $Z(x,t) = c(t)\mathrm{e}^x$, so that

$$\begin{aligned} A(x,t) &= (1 - Z)Z_x \\ &= (1 - c(t)\,\mathrm{e}^x)c(t)\,\mathrm{e}^x. \end{aligned} \tag{5.2}$$

Comparing this with (5.1), we see that

$$c(t) = \mathrm{e}^{-L(t)} \quad \text{or} \quad L(t) = -\ln c(t). \tag{5.3}$$

Furthermore, since $(3.11)_2$ must be a solution to the PDE in physical coordinates, we may substitute it into (3.2) to obtain a first order differential equation for $c(t)$. Upon solving this, we find

$$c(t) = \exp\left[-\frac{1}{2Re}(t-2)^2 - \widetilde{L}_0\right], \tag{5.4}$$

where $\widetilde{L}_0$ is a constant. The length of the drop at large times is then given by

$$L(t) = \frac{1}{2Re}(t-2)^2 + \widetilde{L}_0, \tag{5.5}$$

and the velocity of the bottom of the drop can be found by differentiating to get

$$L'(t) = \frac{1}{Re}(t-2). \tag{5.6}$$

The constant $\widetilde{L}_0$ is seen to be the apparent initial length of the drop at the crisis time $t_* = 2$ of inertialess theory when the main drop essentially enters free fall from rest. That is, at later times, the bottom of the drop falls as if it were dropped from rest at time t_* with apparent initial length $\widetilde{L}_0$.

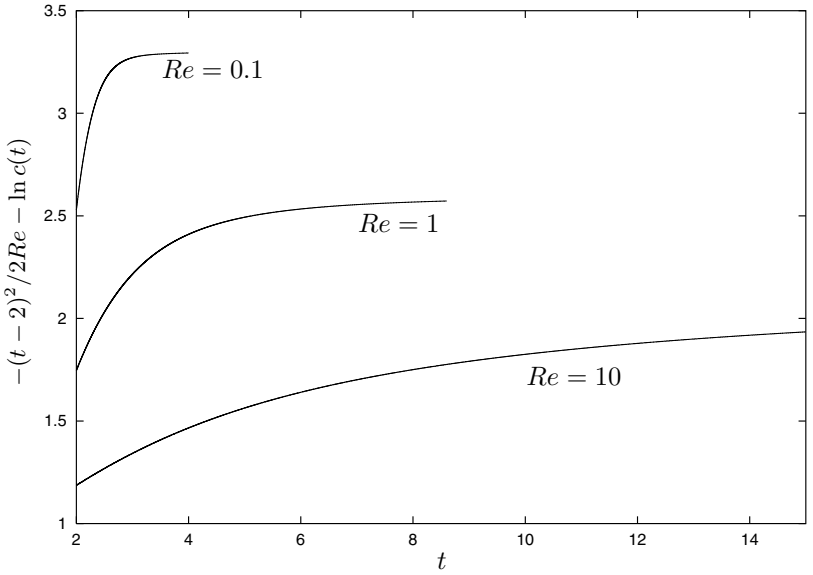

FIG. 5.1. *Plot of the function* $-(t-2)^2/(2Re) - \ln c(t)$ *for* $Re = 0.1, 1.0, 10$, *which at large time* t *gives the apparent initial length* $\widetilde{L}_0$ *of an initially paraboloidal drop. We obtain* $\widetilde{L}_0 \approx 3.3$ *for* $Re = 0.1$, $\widetilde{L}_0 \approx 2.6$ *for* $Re = 1.0$, *and* $\widetilde{L}_0 \approx 2.0$ *for* $Re = 10$.

Our solution of the Eulerian model for initially paraboloidal slender drops involves computation of the function $c(t)$ for extension of the computational domain. Then, at large time, an approximate value for the apparent initial length is given by

$$\widetilde{L}_0 = -\frac{1}{2Re}(t-2)^2 - \ln c(t).$$

With Reynolds numbers $Re = 0.1, 1.0, 10$, we find $\widetilde{L}_0 \approx 3.3, 2.6, 2.0$ (see Figure 5.1). As the Reynolds number increases we must compute to (dimensionless) times well beyond the crisis time $t_* = 2$ of inertialess theory to determine $\widetilde{L}_0$. Figure 5.2 shows $Re\left(L(t) - \widetilde{L}_0\right)$, $Re = 0.1, 1, 10$, versus time t, where $L(t)$ is the length of the drop found by solving (3.2) as described above. At large time this approaches $(t-2)^2/2$, as predicted by (5.5), although, again, as the Reynolds number increases we must compute to times increasingly larger than the crisis time of the inertialess limit to see the agreement.

Another point of interest is that the large-time drop (5.1) (Lagrangian coordinates) or (5.2) (Eulerian coordinates), which derives from the inertialess large-time drop shape (3.10) is observed to be a good representation for the main body of the drop and the lower portion of the filament, as seen by a comparison of Figures 4.6 and 4.2(a); the inertialess large- (crisis) time solution is accurate to within 1% over $x > 15$ (see Figure 4.6), which we see from Figure 4.2(a) is over the bottom third of the drop and filament at this time. The inertialess solution is less accurate in the upper filament region, which is to be expected since inertia and viscous fluid flow are significant in this region of transition from rigid body motion (at increasing velocity) back to zero velocity at the wall; the inertialess solution can be justified only at early time when accelerations are much smaller than gravity, or at larger times in the main drop region which is falling as a rigid body.

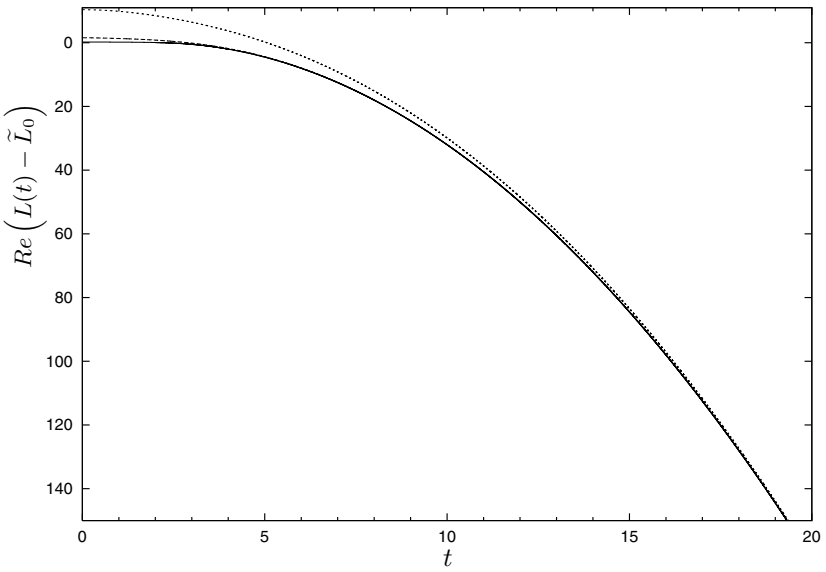

FIG. 5.2. *Plot of* $Re(L(t) - \widetilde{L}_0)$ *with* $L(t)$ *found by solving* (3.2) *for* $Re = 0.1$ *(solid),* 1.0 *(dashed), and* 10 *(dotted), and as predicted at large times* $t > 2$ *by* (5.5), $(t-2)^2/2$ *(solid).*

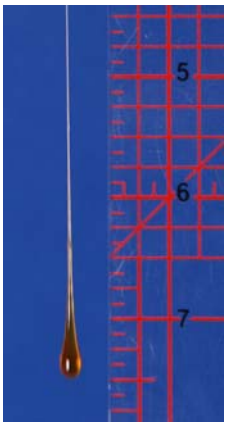

FIG. 5.3. *Dripping golden syrup from a knife. The drop shape is paraboloidal, in contrast to the globular shape of glycerine dripping from a capillary tube as in* [12]. *Note that the scale is in inches.*

Finally we consider the extent to which our computed drop shapes agree with observation. Typically, photographs of viscous fluid drops in the literature (e.g., as in [12]) are of liquids like glycerine dripping from a capillary tube. These drops appear to be considerably more globular in shape than those computed here, but this is essentially a matter of initial conditions. For glycerine-like drops, the initial drop shape is determined by (essentially static) capillarity, as the drop forms slowly at the bottom of the capillary, so that it begins its fall with an already quite globular shape. On the other hand, in the present paper we are assuming an initial shape which is paraboloidal, which is quite like that seen for larger and more viscous drops of liquids like honey falling from a knife or upturned spoon (Figure 5.3). The initial

shape of such rapidly formed drops is influenced very little by surface tension, and their subsequent shape in fall is then quite like those presented here.

Acknowledgments. We gratefully acknowledge valuable discussions with Prof. P. Broadbridge and Dr. Michael Teubner. We are also grateful to an anonymous referee whose helpful comments have resulted in an improved paper.

ON THE SHOCKLEY–READ–HALL MODEL: GENERATION-RECOMBINATION IN SEMICONDUCTORS*

THIERRY GOUDON†, VERA MILJANOVIĆ‡, AND CHRISTIAN SCHMEISER§

Abstract. The Shockley–Read–Hall model for generation-recombination of electron-hole pairs in semiconductors based on a quasi-stationary approximation for electrons in a trapped state is generalized to distributed trapped states in the forbidden band and to kinetic transport models for electrons and holes. The quasi-stationary limit is rigorously justified both for the drift-diffusion and for the kinetic model.

Key words. semiconductor, generation, recombination, drift-diffusion, kinetic model

1. Introduction.

The Shockley–Read–Hall (SRH) model was introduced in 1952 [15], [9] to describe the statistics of recombination and generation of holes and electrons in semiconductors occurring through the mechanism of trapping.

The transfer of electrons from the valence band to the conduction band is referred to as the generation of electron-hole pairs (or pair-generation process), since not only is a free electron created in the conduction band, but also a hole in the valence band which can contribute to the charge current. The inverse process is termed recombination of electron-hole pairs. The bandgap between the upper edge of the valence band and the lower edge of the conduction band is very large in semiconductors, which means that a big amount of energy is needed for a direct band-to-band generation event. The presence of trap levels within the forbidden band caused by crystal impurities facilitates this process, since the jump can be split into two parts, each of them "cheaper" in terms of energy. The basic mechanisms are illustrated in Figure 1: (a) hole emission (an electron jumps from the valence band to the trapped level), (b) hole capture (an electron moves from an occupied trap to the valence band, and a hole disappears), (c) electron emission (an electron jumps from the trapped level to the conduction band), (d) electron capture (an electron moves from the conduction band to an unoccupied trap).

Models for this process involve equations for the densities of electrons in the conduction band, holes in the valence band, and trapped electrons. Basic for the SRH model are the drift-diffusion assumption for the transport of electrons and holes, the assumption of one trap level in the forbidden band, and the assumption that

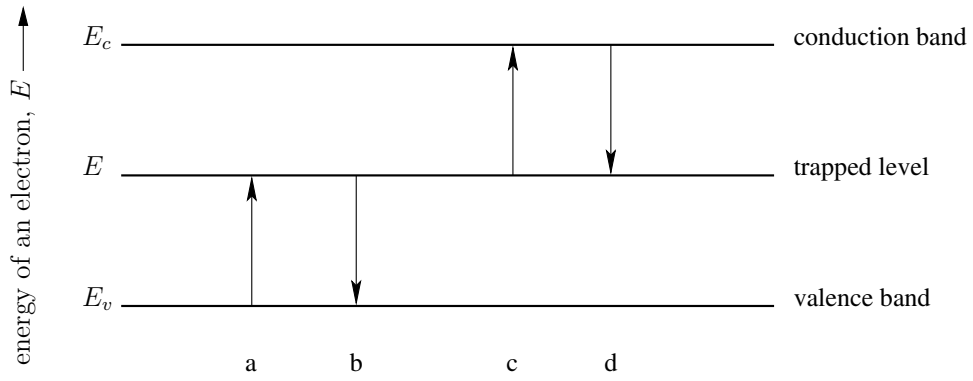

FIG. 1. *The four basic processes of electron-hole recombination.*

the dynamics of the trapped electrons is quasi-stationary, which can be motivated by the smallness of the density of trapped states compared to typical carrier densities. This last assumption leads to the elimination of the density of trapped electrons from the system and to a nonlinear effective recombination-generation rate, reminiscent of Michaelis–Menten kinetics in chemistry. This model is an important ingredient of simulation models for semiconductor devices (see, e.g., [10], [14]).

In this work, two generalizations of the classical SRH model are considered: Instead of a single trapped state, a distribution of trapped states across the forbidden band is allowed, and, in a second step, a semiclassical kinetic model including the fermion nature of the charge carriers is introduced. Although direct band-to-band recombination-generation (see, e.g., [13]) and impact ionization (e.g., [2], [3]) have been modelled on the kinetic level before, this is (to the best of the authors' knowledge) the first attempt to derive a "kinetic SRH model." (We also mention the modelling discussions and numerical simulations in [7], [8].)

For both the drift-diffusion and the kinetic models with self-consistent electric fields existence results and rigorous results concerning the quasi-stationary limit are proven. For the drift-diffusion problem, the essential estimate is derived similarly to [6], where the quasi-neutral limit has been carried out. For the kinetic model Degond's approach [4] for the existence of solutions of the Vlasov–Poisson problem is extended. Actually, the existence theory already provides the uniform estimates necessary for passing to the quasi-stationary limit.

In the following section, the drift-diffusion based model is formulated and nondimensionalized, and the SRH model is formally derived. Section 3 contains the rigorous justification of the passage to the quasi-stationary limit. Section 4 corresponds to section 2, dealing with the kinetic model, and in section 5 existence of global solutions for the kinetic model is proven, and the quasi-stationary limit is justified.

2. The drift-diffusion Shockley–Read–Hall model. We consider a semiconductor crystal with a forbidden band represented by the energy interval (E_v, E_c) with the valence band edge E_v and the conduction band edge E_c. The constant (in space) number density N_{tr} of trapped states is obtained by summing up contributions across the forbidden band:

$$N_{tr} = \int_{E_v}^{E_c} M_{tr}(E)\, dE.$$

Here $M_{tr}(E)$ is the energy dependent density of available trapped states. The position density of occupied traps is given by

$$n_{tr}(f_{tr})(x,t) = \int_{E_v}^{E_c} M_{tr}(E) f_{tr}(x,E,t)\, dE,$$

where $f_{tr}(x,E,t)$ is the fraction of occupied trapped states at position $x \in \Omega$, energy $E \in (E_v, E_c)$, and time $t \geq 0$. Note that $0 \leq f_{tr} \leq 1$ should hold from a physical point of view.

The evolution of f_{tr} is coupled to those of the density of electrons in the conduction band, denoted by $n(x,t) \geq 0$, and the density of holes in the valence band, denoted by $p(x,t) \geq 0$. Electrons and holes are oppositely charged. The coupling is expressed through the following quantities:

$$S_n = \frac{1}{\tau_n N_{tr}}\big[n_0 f_{tr} - n(1-f_{tr})\big], \qquad S_p = \frac{1}{\tau_p N_{tr}}\big[p_0(1-f_{tr}) - p f_{tr}\big], \tag{1}$$

$$R_n = \int_{E_v}^{E_c} S_n M_{tr}\, dE, \qquad R_p = \int_{E_v}^{E_c} S_p M_{tr}\, dE. \tag{2}$$

Indeed, the governing equations are given by

$$\partial_t f_{tr} = S_p - S_n = \frac{p_0}{\tau_p N_{tr}} + \frac{n}{\tau_n N_{tr}} - f_{tr}\left(\frac{p_0+p}{\tau_p N_{tr}} + \frac{n_0+n}{\tau_n N_{tr}}\right), \tag{3}$$

$$\partial_t n = \nabla \cdot J_n + R_n, \quad J_n = \mu_n(U_T \nabla n - n \nabla V), \tag{4}$$

$$\partial_t p = -\nabla \cdot J_p + R_p, \quad J_p = -\mu_p(U_T \nabla p + p \nabla V), \tag{5}$$

$$\varepsilon_s \Delta V = q(n + n_{tr}(f_{tr}) - p - C). \tag{6}$$

For the current densities J_n, J_p we use the simplest possible model, the drift diffusion ansatz, with constant mobilities μ_n, μ_p, and with thermal voltage U_T. Moreover, since the trapped states have fixed positions, no flux appears in (3).

By R_n and R_p we denote the recombination-generation rates for n and p, respectively. The rate constants are $\tau_n(E)$, $\tau_p(E)$, $n_0(E)$, $p_0(E)$, where $n_0(E)p_0(E) = {n_i}^2$ with the energy independent intrinsic density n_i.

Integration of (3) yields

$$\partial_t n_{tr} = R_p - R_n. \tag{7}$$

By adding (4), (5), (7), we obtain the continuity equation

$$\partial_t(p - n - n_{tr}) + \nabla \cdot (J_n + J_p) = 0, \tag{8}$$

with the total charge density $p - n - n_{tr}$ and the total current density $J_n + J_p$.

In the Poisson equation (6), $V(x,t)$ is the electrostatic potential, ε_s the permittivity of the semiconductor material, q the elementary charge, and $C = C(x)$ the given doping profile.

Note that if τ_n, τ_p, n_0, p_0 are independent of E, or if there exists only one trap level E_{tr} with $M_{tr}(E) = N_{tr}\delta(E - E_{tr})$, then $R_n = \frac{1}{\tau_n}[n_0 \frac{n_{tr}}{N_{tr}} - n(1 - \frac{n_{tr}}{N_{tr}})]$, $R_p = \frac{1}{\tau_p}[p_0(1 - \frac{n_{tr}}{N_{tr}}) - p\frac{n_{tr}}{N_{tr}}]$, and (4), (5) together with (7) are a closed system governing the evolution of n, p, and n_{tr}.

We now introduce a scaling of n, p, and f_{tr} in order to render (4)–(6) dimensionless:

Scaling of parameters:

i. $M_{tr} \to \frac{N_{tr}}{E_c - E_v} M_{tr}$.

ii. $\tau_{n,p} \to \bar{\tau}\tau_{n,p}$, where $\bar{\tau}$ is a typical value for τ_n and τ_p.

iii. $\mu_{n,p} \to \bar{\mu}\mu_{n,p}$, where $\bar{\mu}$ is a typical value for $\mu_{n,p}$.

iv. $(n_0, p_0, n_i, C) \to \bar{C}(n_0, p_0, n_i, C)$, where $\bar{C}$ is a typical value of C.

Scaling of unknowns:

v. $(n, p) \to \bar{C}(n, p)$.

vi. $n_{tr} \to N_{tr} n_{tr}$.

vii. $V \to U_T V$.

viii. $f_{tr} \to f_{tr}$.

Scaling of independent variables:

ix. $E \to E_v + (E_c - E_v)E$.

x. $x \to \sqrt{\bar{\mu} U_T \bar{\tau}}\, x$, where the reference length is a typical diffusion length before recombination.

xi. $t \to \bar{\tau} t$, where the reference time is a typical carrier life time.

Dimensionless parameters:

xii. $\lambda = \sqrt{\frac{\varepsilon_s}{q\bar{C}\bar{\mu}\bar{\tau}}} = \frac{1}{\bar{x}}\sqrt{\frac{\varepsilon_s U_T}{q\bar{C}}}$ is the scaled Debye length.

xiii. $\varepsilon = \frac{N_{tr}}{\bar{C}}$ is the ratio of the density of traps to the typical doping density, and will be assumed to be small: $\varepsilon \ll 1$.

The scaled system reads as follows:

(9)
$$\varepsilon \partial_t f_{tr} = S_p(p, f_{tr}) - S_n(n, f_{tr}), \quad S_p = \frac{1}{\tau_p}\big[p_0(1 - f_{tr}) - p f_{tr}\big],$$
$$S_n = \frac{1}{\tau_n}\big[n_0 f_{tr} - n(1 - f_{tr})\big],$$

(10)
$$\partial_t n = \nabla \cdot J_n + R_n(n, f_{tr}), \quad J_n = \mu_n(\nabla n - n\nabla V), \quad R_n = \int_0^1 S_n M_{tr}\, dE,$$

(11)
$$\partial_t p = -\nabla \cdot J_p + R_p(p, f_{tr}), \quad J_p = -\mu_p(\nabla p + p\nabla V), \quad R_p = \int_0^1 S_p M_{tr}\, dE,$$

(12)
$$\lambda^2 \Delta V = n + \varepsilon n_{tr} - p - C, \quad n_{tr}(f_{tr}) = \int_0^1 f_{tr} M_{tr}\, dE,$$

with $n_0(E)p_0(E) = n_i^2$ and $\int_0^1 M_{tr}\, dE = 1$.

By letting $\varepsilon \to 0$ in (9) formally, we obtain $f_{tr} = \frac{\tau_n p_0 + \tau_p n}{\tau_n(p + p_0) + \tau_p(n + n_0)}$, and the reduced system has the following form:

(13) $$\partial_t n = \nabla \cdot J_n + R(n, p),$$

(14) $$\partial_t p = -\nabla \cdot J_p + R(n, p),$$

(15) $$R(n, p) = ({n_i}^2 - np) \int_0^1 \frac{M_{tr}(E)}{\tau_n(E)(p + p_0(E)) + \tau_p(E)(n + n_0(E))\, dE},$$

(16) $$\lambda^2 \Delta V = n - p - C.$$

Note that if τ_n, τ_p, n_0, p_0 are independent of E or if there exists only one trap level, then we would have the standard SRH model, with $R = \frac{{n_i}^2 - np}{\tau_n(p+p_0)+\tau_p(n+n_0)}$. Existence and uniqueness of solutions of the limiting system (13)–(16) under assumptions (21)–(25) stated below is a standard result in semiconductor modelling. A proof can be found in, e.g., [10].

3. Rigorous derivation of the drift-diffusion Shockley–Read–Hall model. We consider the system (9)–(12) with the position x varying in a bounded domain $\Omega \in \mathbb{R}^3$ (all our results are easily extended to the one- and two-dimensional situations), the energy $E \in (0,1)$, and time $t > 0$, subject to initial conditions

$$n(x,0) = n_I(x), \quad p(x,0) = p_I(x), \quad f_{tr}(x,E,0) = f_{tr,I}(x,E) \tag{17}$$

and mixed Dirichlet–Neumann boundary conditions

$$n(x,t) = n_D(x,t), \quad p(x,t) = p_D(x,t), \quad V(x,t) = V_D(x,t), \quad x \in \partial\Omega_D \subset \partial\Omega, \tag{18}$$

and

$$\frac{\partial n}{\partial \nu}(x,t) = \frac{\partial p}{\partial \nu}(x,t) = \frac{\partial V}{\partial \nu}(x,t) = 0, \quad x \in \partial\Omega_N := \partial\Omega \setminus \partial\Omega_D, \tag{19}$$

where ν is the unit outward normal vector along $\partial\Omega_N$. We permit the special case that either $\partial\Omega_D$ or $\partial\Omega_N$ is empty. More precisely, we assume that either $\partial\Omega_D$ has positive $(d-1)$-dimensional measure, or it is empty. In the second situation ($\partial\Omega_D$ empty) we have to assume total charge neutrality; i.e.,

$$\int_\Omega (n + \varepsilon n_{tr} - p - C)\, dx = 0 \qquad \text{if } \partial\Omega = \partial\Omega_N. \tag{20}$$

The potential is then determined only up to a (physically irrelevant) additive constant.

The following assumptions on the data will be used: For the boundary data, given any $0 < T < \infty$,

$$n_D, p_D \in W^{1,\infty}(0,T; W^{1,\infty}_{loc}(\Omega)), \quad V_D \in L^\infty(0,T; W^{1,6}(\Omega)); \tag{21}$$

for the initial data

$$n_I, p_I \in H^1(\Omega) \cap L^\infty(\Omega), \quad 0 \le f_{tr,I} \le 1, \tag{22}$$

$$\int_\Omega (n_I + \varepsilon n_{tr}(f_{tr,I}) - p_I - C)\, dx = 0 \qquad \text{if } \partial\Omega = \partial\Omega_N; \tag{23}$$

for the doping profile

$$C \in L^\infty(\Omega); \tag{24}$$

and for the recombination-generation rate constants

$$n_0, p_0, \tau_n, \tau_p \in L^\infty((0,1)), \quad \tau_n, \tau_p \ge \tau_{min} > 0. \tag{25}$$

With these assumptions, a local existence and uniqueness result for the problem (9)–(12), (17)–(19) for fixed positive ε can be proven by a straightforward extension of the approach in [5] (see also [10]). In the following, local existence will be assumed, and we shall concentrate on obtaining bounds which guarantee global existence and

which are uniform in ε as $\varepsilon \to 0$. For the sake of simplicity, we consider that the data in (21), (22), and (24) do not depend on ε; of course, our strategy works when dealing with sequences of data bounded in the mentioned spaces.

The following result is a generalization of [6, Lemma 3.1], where the case of homogeneous Neumann boundary conditions and vanishing recombination was treated. Our proof uses a similar approach.

LEMMA 3.1. *Let the assumptions* (21)–(25) *be satisfied. Then, the solution of* (9)–(12), (17)–(19) *exists for all times and satisfies* $n, p \in L^\infty(0,T;L^\infty(\Omega)) \cap L^2(0,T;H^1(\Omega))$ *uniformly in* ε *as* $\varepsilon \to 0$ *as well as* $0 \le f_{tr} \le 1$.

Proof. Global existence will be a consequence of the following estimates. Introducing the new variables $\widetilde{n} = n - n_D$, $\widetilde{p} = p - p_D$, $\widetilde{C} = C - \varepsilon n_{tr} - n_D + p_D$, (10)–(12) take the following form:

$$\partial_t \widetilde{n} = \nabla \cdot J_n + R_n - \partial_t n_D, \quad J_n = \mu_n\big[\nabla\widetilde{n} + \nabla n_D - (\widetilde{n} + n_D)\nabla V\big], \tag{26}$$

$$\partial_t \widetilde{p} = -\nabla J_p + R_p - \partial_t p_D, \quad J_p = -\mu_p\big[\nabla\widetilde{p} + \nabla p_D + (\widetilde{p} + p_D)\nabla V\big], \tag{27}$$

$$\lambda^2 \Delta V = \widetilde{n} - \widetilde{p} - \widetilde{C}. \tag{28}$$

As a consequence of $0 \le f_{tr} \le 1$, $\widetilde{C} \in L^\infty((0,\infty)\times\Omega)$ holds. For $q \ge 2$ and even, we multiply (26) by $\widetilde{n}^{q-1}/\mu_n$ and (27) by $\widetilde{p}^{q-1}/\mu_p$, and add:

$$\begin{aligned}
\frac{d}{dt}\int_\Omega \left[\frac{\widetilde{n}^q}{q\mu_n} + \frac{\widetilde{p}^q}{q\mu_p}\right] dx \;=\; & -(q-1)\int_\Omega \widetilde{n}^{q-2}\nabla\widetilde{n}\nabla n\,dx - (q-1)\int_\Omega \widetilde{p}^{q-2}\nabla\widetilde{p}\nabla p\,dx \\
& + (q-1)\int_\Omega \left[\widetilde{n}^{q-2} n\nabla\widetilde{n} - \widetilde{p}^{q-2} p\nabla\widetilde{p}\right]\nabla V\,dx \\
& + \int_\Omega \frac{\widetilde{n}^{q-1}}{\mu_n}(R_n - \partial_t n_D) + \int_\Omega \frac{\widetilde{p}^{q-1}}{\mu_p}(R_p - \partial_t p_D) \\
=:\; & I_1 + I_2 + I_3 + I_4 + I_5.
\end{aligned} \tag{29}$$

Using the assumptions on n_D, p_D and $|R_n| \le C(n+1)$, $|R_p| \le C(p+1)$, we estimate

$$I_4 \le C\int_\Omega |\widetilde{n}|^{q-1}(n+1)\,dx \le C\left(\int_\Omega \widetilde{n}^q\,dx + 1\right), \quad I_5 \le C\left(\int_\Omega \widetilde{p}^q\,dx + 1\right).$$

The term I_3 can be rewritten as follows:

$$\begin{aligned}
I_3 = & \int_\Omega \left[\widetilde{n}^{q-1}\nabla\widetilde{n} - \widetilde{p}^{q-1}\nabla\widetilde{p}\right]\nabla V\,dx \\
& + \int_\Omega \left[\widetilde{n}^{q-2}\nabla\widetilde{n}\right](n_D\nabla V)\,dx - \int_\Omega \left[\widetilde{p}^{q-2}\nabla\widetilde{p}\right](p_D\nabla V)\,dx \\
= & -\frac{1}{\lambda^2 q}\int_\Omega \left[\widetilde{n}^q - \widetilde{p}^q\right](\widetilde{n} - \widetilde{p} - \widetilde{C})\,dx \\
& - \frac{1}{\lambda^2(q-1)}\int_\Omega \widetilde{n}^{q-1}\left(\nabla n_D\nabla V + n_D(\widetilde{n} - \widetilde{p} - \widetilde{C})\right)dx \\
& + \frac{1}{\lambda^2(q-1)}\int_\Omega \widetilde{p}^{q-1}\left(\nabla p_D\nabla V + p_D(\widetilde{n} - \widetilde{p} - \widetilde{C})\right)dx.
\end{aligned}$$

The second equality uses integration by parts and (28). The first term on the right-hand side is the only term of degree $q+1$. It reflects the quadratic nonlinearity of

the problem. Fortunately, it can be written as the sum of a term of degree q and a nonnegative term. By estimation of the terms of degree q using the assumptions on n_D and p_D as well as $\|\nabla V\|_{L^q(\Omega)} \le C(\|\widetilde{n}\|_{L^q(\Omega)} + \|\widetilde{p}\|_{L^q(\Omega)} + \|\widetilde{C}\|_{L^q(\Omega)})$, we obtain

$$\begin{aligned} I_3 &\le -\frac{1}{\lambda^2 q}\int_\Omega [\widetilde{n}^q - \widetilde{p}^q]\,(\widetilde{n}-\widetilde{p})\,dx + C\left(\int_\Omega (\widetilde{n}^q + \widetilde{p}^q)\,dx + 1\right) \\ &\le C\left(\int_\Omega (\widetilde{n}^q + \widetilde{p}^q)\,dx + 1\right). \end{aligned}$$

The integral I_1 can be written as

$$I_1 = -\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx + \int_\Omega \widetilde{n}^{q-2}\nabla n_D \nabla n\,dx. \tag{30}$$

By rewriting the integrand in the second integral as

$$\widetilde{n}^{q-2}\nabla n_D \nabla n = \widetilde{n}^{\frac{q-2}{2}}\nabla n \widetilde{n}^{\frac{q-2}{2}}\nabla n_D$$

and applying the Cauchy–Schwarz inequality, we have the following estimate for (30):

$$\begin{aligned} I_1 &\le -\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx + \sqrt{\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx \int_\Omega \widetilde{n}^{q-2}|\nabla n_D|^2\,dx} \\ &\le -\frac{1}{2}\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx + C\|\widetilde{n}\|_{L^q}^{q-2} \le -\frac{1}{2}\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx + C\left(\int_\Omega \widetilde{n}^q\,dx + 1\right). \end{aligned}$$

For I_2, the same reasoning (with n and n_D replaced by p and p_D, respectively) yields an analogous estimate. Collecting our results, we obtain

$$\begin{aligned} \frac{d}{dt}\int_\Omega \left[\frac{\widetilde{n}^q}{q\mu_n} + \frac{\widetilde{p}^q}{q\mu_p}\right]dx &\le -\frac{1}{2}\int_\Omega \widetilde{n}^{q-2}|\nabla n|^2\,dx - \frac{1}{2}\int_\Omega \widetilde{p}^{q-2}|\nabla p|^2\,dx \\ &\quad + C\left(\int_\Omega (\widetilde{n}^q + \widetilde{p}^q)\,dx + 1\right). \end{aligned} \tag{31}$$

Since $q \ge 2$ is even, the first two terms on the right-hand side are nonpositive, and the Gronwall lemma gives

$$\int_\Omega (\widetilde{n}^q + \widetilde{p}^q)\,dx \le e^{qCt}\left(\int_\Omega (\widetilde{n}(t=0)^q + \widetilde{p}(t=0)^q)\,dx + 1\right).$$

A uniform-in-q-and-ε estimate for $\|n\|_{L^q}$, $\|p\|_{L^q}$ follows, and the uniform-in-ε bound in $L^\infty(0,T;L^\infty(\Omega))$ is obtained in the limit $q \to \infty$. The estimate in $L^2(0,T;H^1(\Omega))$ is then derived by returning to (31) with $q = 2$. ∎

Now we are ready to prove the main result of this section.

THEOREM 3.2. *Let the assumptions of Theorem* 3.1 *be satisfied. Then, as $\varepsilon \to 0$, for every $T > 0$, the solution (f_{tr}, n, p, V) of* (9)–(12), (17)–(19) *converges with convergence of f_{tr} in $L^\infty((0,T)\times\Omega\times(0,1))$ weak*, n and p in $L^2((0,T)\times\Omega)$, and V in $L^2(0,T;H^1(\Omega))$. The limits of n, p, and V satisfy* (13)–(19).

Proof. The L^∞-bounds for f_{tr}, n, and p, which are uniform with respect to ε, and the Poisson equation (12) imply ∇V is bounded in $L^2((0,T)\times\Omega)$. From the definition of J_n, J_p (see (4), (5)), it then follows that $J_n, J_p \in L^2((0,T)\times\Omega)$. Then (10) and (11) together with $R_n, R_p \in L^\infty((0,T)\times\Omega)$ imply $\partial_t n, \partial_t p \in L^2(0,T;H^{-1}(\Omega))$.

The previous result and the Aubin lemma (see, e.g., Simon [16, Corollary 4, p. 85]) give compactness of n and p in $L^2((0,T)\times\Omega)$.

We already know from the Poisson equation that $\nabla V \in L^\infty(0,T;H^1(\Omega))$. By taking the time derivative of (12), one obtains

$$\partial_t \Delta V = \nabla\cdot(J_n + J_p),$$

with the consequence that $\partial_t \nabla V$ is bounded (uniformly with respect to ε) in $L^2((0,T)\times\Omega)$. Therefore, the Aubin lemma can again be applied as above to prove compactness of ∇V in $L^2((0,T)\times\Omega)$.

These results and the weak compactness of f_{tr} are sufficient for passing to the limit in the nonlinear terms $n\nabla V$, $p\nabla V$, nf_{tr}, and pf_{tr}. Let us also remark that $\partial_t n$ and $\partial_t p$ are bounded in $L^2(0,T;H^{-1}(\Omega))$, so that n,p are compact in $C^0([0,T];L^2(\Omega)$ weak). With this remark the initial data for the limit equation make sense. By the uniqueness result for the limiting problem (mentioned at the end of section 2), the convergence is not restricted to subsequences. ∎

4. A kinetic Shockley–Read–Hall model. In this section we replace the drift-diffusion model for electrons and holes by a semiclassical kinetic transport model. It is governed by the system

$$\partial_t f_n + v_n(k)\cdot\nabla_x f_n + \frac{q}{\hbar}\nabla_x V\cdot\nabla_k f_n = Q_n(f_n) + Q_{n,r}(f_n,f_{tr}), \tag{32}$$

$$\partial_t f_p + v_p(k)\cdot\nabla_x f_p - \frac{q}{\hbar}\nabla_x V\cdot\nabla_k f_p = Q_p(f_p) + Q_{p,r}(f_p,f_{tr}), \tag{33}$$

$$\partial_t f_{tr} = S_p(f_p,f_{tr}) - S_n(f_n,f_{tr}), \tag{34}$$

$$\varepsilon_s\Delta_x V = q(n + n_{tr} - p - C), \tag{35}$$

where $f_i(x,k,t)$ represents the particle distribution function (with $i=n$ for electrons and $i=p$ for holes) at time $t\ge 0$, at the position $x\in\mathbb{R}^3$, and at the wave vector (or generalized momentum) $k\in\mathbb{R}^3$. All functions of k have the periodicity of the reciprocal lattice of the semiconductor crystal. Equivalently, we shall consider only $k\in B$, where B is the Brillouin zone, i.e., the set of all k which are closer to the origin than to any other lattice point, with periodic boundary conditions on ∂B.

The coefficient functions $v_n(k)$ and $v_p(k)$ denote the electron and hole velocities, respectively, which are related to the electron and hole band diagrams by

$$v_n(k) = \nabla_k\varepsilon_n(k)/\hbar, \quad v_p(k) = -\nabla_k\varepsilon_p(k)/\hbar,$$

where $\hbar$ is the reduced Planck constant. The elementary charge is still denoted by q.

The collision operators Q_n and Q_p describe the interactions between the particles and the crystal lattice. They involve several physical phenomena and can be written in the general form

$$Q_n(f_n) = \int_B \widetilde{\Phi}_n(k,k')[M_n f_n'(1-f_n) - M_n' f_n(1-f_n')]\,dk', \tag{36}$$

$$Q_p(f_p) = \int_B \widetilde{\Phi}_p(k,k')[M_p f_p'(1-f_p) - M_p' f_p(1-f_p')]\,dk', \tag{37}$$

with the primes denoting evaluation at k', with the nonnegative, symmetric scattering cross sections $\widetilde{\Phi}_n(k,k')$ and $\widetilde{\Phi}_p(k,k')$, and with the Maxwellians

$$M_n(k) = c_n\exp(-\varepsilon_n(k)/k_BT), \quad M_p(k) = c_p\exp(-\varepsilon_p(k)/k_BT),$$

where k_BT is the thermal energy of the semiconductor crystal lattice and the constants c_n, c_p are chosen such that

$$\int_B M_n \, dk = \int_B M_p \, dk = 1.$$

The remaining collision operators $Q_{n,r}(f_n, f_{tr})$ and $Q_{p,r}(f_p, f_{tr})$ model the generation and recombination processes and are given by

$$Q_{n,r}(f_n, f_{tr}) = \int_{E_v}^{E_c} \hat{S}_n(f_n, f_{tr}) M_{tr} \, dE, \tag{38}$$

with

$$\hat{S}_n(f_n, f_{tr}) = \frac{\Phi_n(k, E)}{N_{tr}} \left[n_0 M_n f_{tr}(1 - f_n) - f_n(1 - f_{tr}) \right],$$

and

$$Q_{p,r}(f_p, f_{tr}) = \int_{E_v}^{E_c} \hat{S}_p(f_p, f_{tr}) M_{tr} \, dE, \tag{39}$$

with

$$\hat{S}_p(f_p, f_{tr}) = \frac{\Phi_p(k, E)}{N_{tr}} \left[p_0 M_p(1 - f_p)(1 - f_{tr}) - f_p f_{tr} \right],$$

and where $\Phi_{n,p}$ are nonnegative and $M_{tr}(x, E)$ is the same density of available trapped states as for the drift-diffusion model, except that we allow for a position dependence now. This will be commented on below. The parameter N_{tr} is now determined as $N_{tr} = \sup_{x \in \mathbb{R}^3} \int_0^1 M_{tr}(x, E) \, dE$.

The right-hand side in the equation for the occupancy $f_{tr}(x, E, t)$ of the trapped states is defined by

$$S_n(f_n, f_{tr}) = \int_B \hat{S}_n \, dk = \lambda_n[n_0 M_n(1 - f_n)] f_{tr} - \lambda_n[f_n](1 - f_{tr}), \tag{40}$$

with $\lambda_n[g] = \int_B \Phi_n g \, dk$, and

$$S_p(f_p, f_{tr}) = \int_B \hat{S}_p \, dk = \lambda_p[p_0 M_p(1 - f_p)](1 - f_{tr}) - \lambda_p[f_p] f_{tr}, \tag{41}$$

with $\lambda_p[g] = \int_B \Phi_p g \, dk$.

The factors $(1 - f_n)$ and $(1 - f_p)$ take into account the Pauli exclusion principle, which therefore manifests itself in the requirement that the values of the distribution function have to respect the bounds $0 \le f_n, f_p \le 1$.

The position densities on the right-hand side of the Poisson equation (35) are given by

$$n(x, t) = \int_B f_n \, dk, \quad p(x, t) = \int_B f_p \, dk, \quad n_{tr}(x, t) = \int_{E_v}^{E_c} f_{tr} M_{tr} \, dE.$$

The following scaling, which is strongly related to the one used for the drift-diffusion model, will render (32)–(35) dimensionless:

Scaling of parameters:

i. $M_{tr} \to \frac{N_{tr}}{E_v - E_c} M_{tr}$.
ii. $(\varepsilon_n, \varepsilon_p) \to k_B T(\varepsilon_n, \varepsilon_p)$, with the thermal energy $k_B T$.
iii. $(\Phi_n, \Phi_p) \to \tau_{rg}^{-1}(\Phi_n, \Phi_p)$, where τ_{rg} is a typical carrier life time.
iv. $(\widetilde{\Phi}_n, \widetilde{\Phi}_p) \to \tau_{coll}^{-1}(\widetilde{\Phi}_n, \widetilde{\Phi}_p)$.
v. $(n_0, p_0, C) \to \overline{C}(n_0, p_0, C)$, where $\overline{C}$ is a typical value of $|C|$.
vi. $(M_n, M_p) \to \overline{C}^{-1}(M_n, M_p)$.

Scaling of independent variables:

vii. $x \to k_B T \sqrt{\tau_{rg}\tau_{coll}}\overline{C}^{-1/3}\hbar^{-1}\, x$.
viii. $t \to \tau_{rg} t$.
ix. $k \to \overline{C}^{1/3} k$.
x. $E \to E_v + (E_c - E_v)E$.

Scaling of unknowns:

xi. $(f_n, f_p, f_{tr}) \to (f_n, f_p, f_{tr})$.
xii. $V \to U_T V$, with the thermal voltage $U_T = k_B T/q$.

Dimensionless parameters:

xiii. $\alpha^2 = \frac{\tau_{coll}}{\tau_{rg}}$.
xiv. $\lambda = \frac{\hbar}{q\sqrt{\tau_{rg}\tau_{coll}}\overline{C}^{1/6}} \sqrt{\frac{\varepsilon_s}{k_B T}}$.
xv. $\varepsilon = \frac{N_{tr}}{\overline{C}}$, where again we shall study the situation $\varepsilon \ll 1$.

Finally, the scaled system reads as follows:

$$\alpha^2 \partial_t f_n + \alpha v_n(k) \cdot \nabla_x f_n + \alpha \nabla_x V \cdot \nabla_k f_n = Q_n(f_n) + \alpha^2 Q_{n,r}(f_n, f_{tr}), \tag{42}$$

$$\alpha^2 \partial_t f_p + \alpha v_p(k) \cdot \nabla_x f_p - \alpha \nabla_x V \cdot \nabla_k f_p = Q_p(f_p) + \alpha^2 Q_{p,r}(f_p, f_{tr}), \tag{43}$$

$$\varepsilon \partial_t f_{tr} = S_p(f_p, f_{tr}) - S_n(f_n, f_{tr}), \tag{44}$$

$$\lambda^2 \Delta_x V = n + \varepsilon n_{tr} - p - C = -\rho, \tag{45}$$

with $v_n = \nabla_k \varepsilon_n$, $v_p = -\nabla_k \varepsilon_p$, with Q_n and Q_p still having the form (36) and (37), respectively, with the scaled Maxwellians

$$M_n(k) = c_n \exp(-\varepsilon_n(k)), \qquad M_p(k) = c_p \exp(-\varepsilon_p(k)), \tag{46}$$

and with the recombination-generation terms

$$Q_{n,r}(f_n, f_{tr}) = \int_0^1 \hat{S}_n M_{tr}\, dE, \qquad Q_{p,r}(f_p, f_{tr}) = \int_0^1 \hat{S}_p M_{tr}\, dE, \tag{47}$$

with

$$\hat{S}_n = \Phi_n[n_0 M_n f_{tr}(1-f_n) - f_n(1-f_{tr})], \quad \hat{S}_p = \Phi_p[p_0 M_p(1-f_{tr})(1-f_p) - f_p f_{tr}]. \tag{48}$$

The right-hand side of (44) still has the form (40), (41). The position densities are given by

$$n = \int_B f_n\, dk, \qquad p = \int_B f_p\, dk, \qquad n_{tr} = \int_0^1 f_{tr} M_{tr}\, dE. \tag{49}$$

The system (42)–(44) conserves the total charge $\rho = p + C - n - \varepsilon n_{tr}$. With the definition

$$J_n = -\frac{1}{\alpha} \int_B v_n f_n\, dk, \quad J_p = \frac{1}{\alpha} \int_B v_p f_p\, dk$$

of the current densities, the following continuity equation holds formally:

$$\partial_t \rho + \nabla_x \cdot (J_n + J_p) = 0.$$

Formally setting $\varepsilon = 0$ in (44), we obtain

$$\overline{f}_{tr}(f_n, f_p) = \frac{p_0 \lambda_p[M_p(1-f_p)] + \lambda_n[f_n]}{p_0 \lambda_p[M_p(1-f_p)] + \lambda_p[f_p] + \lambda_n[f_n] + n_0 \lambda_n[M_n(1-f_n)]}.$$

Substituting $\overline{f}_{tr}$ into (47) leads to the kinetic SRH recombination-generation operators

$$\begin{aligned} \overline{Q}_{n,r}(f_n, f_p) &= \overline{g}_n[f_n, f_p](1-f_n) - \overline{r}_n[f_n, f_p] f_n, \\ \overline{Q}_{p,r}(f_n, f_p) &= \overline{g}_p[f_n, f_p](1-f_p) - \overline{r}_p[f_n, f_p] f_p, \end{aligned} \tag{50}$$

with

$$\begin{aligned} \overline{g}_n &= \int_0^1 \frac{\Phi_n M_n n_0 \Big(p_0 \lambda_p[M_p(1-f_p)] + \lambda_n[f_n] \Big) M_{tr}}{p_0 \lambda_p[M_p(1-f_p)] + \lambda_p[f_p] + \lambda_n[f_n] + n_0 \lambda_n[M_n(1-f_n)]}\, dE, \\ \overline{r}_n &= \int_0^1 \frac{\Phi_n \Big(\lambda_p[f_p] + n_0 \lambda_n[M_n(1-f_n)] \Big) M_{tr}}{p_0 \lambda_p[M_p(1-f_p)] + \lambda_p[f_p] + \lambda_n[f_n] + n_0 \lambda_n[M_n(1-f_n)]}\, dE, \\ \overline{g}_p &= \int_0^1 \frac{\Phi_p M_p p_0 \Big(n_0 \lambda_n[M_n(1-f_n)] + \lambda_p[f_p] \Big) M_{tr}}{p_0 \lambda_p[M_p(1-f_p)] + \lambda_p[f_p] + \lambda_n[f_n] + n_0 \lambda_n[M_n(1-f_n)]}\, dE, \\ \overline{r}_p &= \int_0^1 \frac{\Phi_p \Big(\lambda_n[f_n] + p_0 \lambda_p[M_p(1-f_p)] \Big) M_{tr}}{p_0 \lambda_p[M_p(1-f_p)] + \lambda_p[f_p] + \lambda_n[f_n] + n_0 \lambda_n[M_n(1-f_n)]}\, dE. \end{aligned}$$

Of course, the limiting model still conserves charge, which is expressed by the identity

$$\int_B \overline{Q}_{n,r}\, dk = \int_B \overline{Q}_{p,r}\, dk.$$

Pairs of electrons and holes are generated or recombine, however, generally not with the same wave vector. This absence of momentum conservation is reasonable since the process involves an interaction with the trapped states fixed within the crystal lattice.

5. Rigorous derivation of the kinetic Shockley–Read–Hall model. The limit $\varepsilon \to 0$ will be carried out rigorously in an initial value problem for the kinetic model: From now on we work with $x \in \mathbb{R}^3$ (and we avoid any discussion on boundary conditions and possible boundary layers). Concerning the behavior for $|x| \to \infty$, we shall require the densities to be in L^1 and use the Newtonian potential solution of the Poisson equation; i.e., (45) will be replaced by

$$\mathcal{E}(x,t) = -\nabla_x V = \lambda^{-2} \int_{\mathbb{R}^3} \frac{x-y}{|x-y|^3} \rho(y,t)\, dy. \tag{51}$$

We define Problem (K) as the system (42)–(44), (51) with (36), (37), (47)–(49), (40), and (41), subject to the initial conditions

$$f_n(x,k,0) = f_{n,I}(x,k), \quad f_p(x,k,0) = f_{p,I}(x,k), \quad f_{tr}(x,E,0) = f_{tr,I}(x,E).$$

We start by stating our assumptions on the data. For the velocities we assume

$$v_n, v_p \in W^{1,\infty}_{per}(B), \tag{52}$$

where here and in the following, the subscript *per* denotes Sobolev spaces of functions of k satisfying periodic boundary conditions on ∂B. Further we assume that the cross sections satisfy

$$\widetilde{\Phi}_n, \widetilde{\Phi}_p \geq 0, \quad \widetilde{\Phi}_n, \widetilde{\Phi}_p \in W^{1,\infty}_{per}(B \times B), \tag{53}$$

and

$$\Phi_n, \Phi_p \geq 0, \quad \Phi_n, \Phi_p \in W^{1,\infty}_{per}(B \times (0,1)). \tag{54}$$

A finite total number of trapped states is assumed:

$$M_{tr} \geq 0, \quad M_{tr} \in W^{1,\infty}(\mathbb{R}^3 \times (0,1)) \cap W^{1,1}(\mathbb{R}^3 \times (0,1)).$$

The L^1-assumption with respect to x is needed for controlling the total number of generated particles. For the initial data we assume

$$\begin{aligned} &0 \leq f_{n,I}, f_{p,I} \leq 1, \quad f_{n,I}, f_{p,I} \in W^{1,\infty}_{per}(\mathbb{R}^3 \times B) \cap W^{1,1}_{per}(\mathbb{R}^3 \times B), \\ &0 \leq f_{tr,I} \leq 1, \quad f_{tr,I} \in W^{1,\infty}_{per}(\mathbb{R}^3 \times (0,1)). \end{aligned} \tag{55}$$

We also assume

$$n_0, p_0 \in L^\infty((0,1)), \qquad C \in W^{1,\infty}(\mathbb{R}^3) \cap W^{1,1}(\mathbb{R}^3). \tag{56}$$

Finally, we need an upper bound for the life time of trapped electrons:

$$\int_B (\Phi_n \min\{1, n_0 M_n\} + \Phi_p \min\{1, p_0 M_p\})\, dk \geq \gamma > 0. \tag{57}$$

The reason for the various differentiability assumptions above is that we shall construct smooth solutions by an approach along the lines of [13], which goes back to [4].

An essential tool relies on the following potential theory estimates:

$$\|\mathcal{E}\|_{L^\infty(\mathbb{R}^3)} \leq C \|\rho\|^{1/2}_{L^1(\mathbb{R}^3)} \|\rho\|^{1/2}_{L^\infty(\mathbb{R}^3)}, \tag{58}$$

$$\|\nabla_x \mathcal{E}\|_{L^\infty(\mathbb{R}^3)} \leq C\big(1 + \|\rho\|_{L^1(\mathbb{R}^3)} + \|\rho\|_{L^\infty(\mathbb{R}^3)} \big[1 + \log(1 + \|\nabla_x \rho\|_{L^\infty(\mathbb{R}^3)})\big]\big). \tag{59}$$

This kind of estimate was already crucial in [17]; for the sake of completeness, we recall the proof in the appendix. We start by rewriting the collision and recombination-generation operators as

$$Q_i(f_i) = a_i[f_i](1 - f_i) - b_i[f_i] f_i, \quad i = n, p,$$

and

$$Q_{i,r}(f_i, f_{tr}) = g_i[f_{tr}](1 - f_i) - r_i[f_{tr}] f_i, \quad i = n, p,$$

with

$$\begin{aligned} a_i[f_i] &= \int_B \widetilde{\Phi}_i M_i f_i'\, dk', \quad b_i[f_i] = \int_B \widetilde{\Phi}_i M_i' (1 - f_i')\, dk', \quad i = n, p, \\ g_n[f_{tr}] &= \int_0^1 \Phi_n n_0 M_n f_{tr} M_{tr}\, dE, \quad g_p[f_{tr}] = \int_0^1 \Phi_p p_0 M_p (1 - f_{tr}) M_{tr}\, dE, \\ r_n[f_{tr}] &= \int_0^1 \Phi_n (1 - f_{tr}) M_{tr}\, dE, \quad r_p[f_{tr}] = \int_0^1 \Phi_p f_{tr} M_{tr}\, dE. \end{aligned}$$

In order to construct an approximating sequence $(f_n^j, f_p^j, f_{tr}^j, \mathcal{E}^j)$ we begin with

$$f_i^0(x,k,t) = f_{i,I}(x,k), \quad i = n,p, \quad f_{tr}^0(x,E,t) = f_{tr,I}(x,E). \tag{60}$$

The field always satisfies

$$\mathcal{E}^j(x,t) = \int_{\mathbb{R}^3} \frac{x-y}{|x-y|^3} \rho^j(y,t)\, dy. \tag{61}$$

Let $(f_n^j, f_p^j, f_{tr}^j, \mathcal{E}^j)$ be given. Then the ${f_i}^{j+1}$ are defined as the solutions of the following problem:

(62)
$$\begin{aligned}
&\alpha^2 \partial_t f_n^{j+1} + \alpha v_n(k) \cdot \nabla_x f_n^{j+1} - \alpha \mathcal{E}^j \cdot \nabla_k f_n^{j+1} \\
&\qquad = (a_n[f_n^j] + \alpha^2 g_n[f_{tr}^j])(1 - f_n^{j+1}) - (b_n[f_n^j] + \alpha^2 r_n[f_{tr}^j]) f_n^{j+1}, \\
&\alpha^2 \partial_t f_p^{j+1} + \alpha v_p(k) \cdot \nabla_x f_p^{j+1} + \alpha \mathcal{E}^j \cdot \nabla_k f_p^{j+1} \\
&\qquad = (a_p[f_p^j] + \alpha^2 g_p[f_{tr}^j])(1 - f_p^{j+1}) - (b_p[f_p^j] + \alpha^2 r_p[f_{tr}^j]) f_p^{j+1}, \\
&\varepsilon \partial_t f_{tr}^{j+1} = (p_0 \lambda_p[M_p(1 - f_p^j)] + \lambda_n[f_n^j])(1 - f_{tr}^{j+1}) - (n_0 \lambda_n[M_n(1 - f_n^j)] + \lambda_p[f_p^j]) f_{tr}^{j+1},
\end{aligned}$$

subject to the initial conditions

(63)
$$f_n^{j+1}(x,k,0) = f_{n,I}(x,k), \quad f_p^{j+1}(x,k,0) = f_{p,I}(x,k), \quad f_{tr}^{j+1}(x,E,0) = f_{tr,I}(x,E).$$

For the iterative sequence we state the following lemma, which is very similar to Proposition 3.1 from [13].

LEMMA 5.1. *Let the assumptions* (52)–(56) *be satisfied. Then the sequence* $(f_n^j, f_p^j, f_{tr}^j, \mathcal{E}^j)$ *defined by* (60)–(63) *satisfies the following for any time* $T > 0$:

(a) $0 \le {f_i}^j \le 1$, $i = n,p,tr$.

(b) f_n^j *and* f_p^j *are uniformly bounded with respect to* $j \to \infty$ *and* $\varepsilon \to 0$ *in* $L^\infty(0,T; L^1(\mathbb{R}^3 \times B))$.

(c) $\mathcal{E}^j$ *is uniformly bounded with respect to* j *and* ε *in* $L^\infty((0,T) \times \mathbb{R}^3)$.

Proof. The first two equations in (62) are standard linear transport equations, and the third equation is a linear ODE. Existence and uniqueness for the initial value problems is therefore a standard result.

Note that the a_i, b_i, g_i, r_i, and λ_i in (62) are nonnegative if we assume that (a) holds for j. Then (a) for $j+1$ is an immediate consequence of the maximum principle.

To estimate the L^1-norms of the distributions, we integrate the first equation in (62) and obtain

$$\|f_n^{j+1}\|_{L^1(\mathbb{R}^3 \times B)} \le \|f_{n,I}\|_{L^1(\mathbb{R}^3 \times B)} + \int_0^t \left\| a_n[f_n^j] \frac{1}{\alpha^2} + g_n[f_{tr}^j] \right\|_{L^1(\mathbb{R}^3 \times B)} (s)\, ds. \tag{64}$$

The boundedness of $\widetilde{\Phi}_n$, Φ_n, and f_{tr}^j and the integrability of M_{tr} imply

$$\|a_n[f_n^j]\|_{L^1(\mathbb{R}^3 \times B)} \le C \|f_n^j\|_{L^1(\mathbb{R}^3 \times B)}, \quad \|g_n[f_{tr}^j]\|_{L^1(\mathbb{R}^3 \times B)} \le C. \tag{65}$$

This is now used in (64). Then an estimate is derived for f_n^j by replacing $j+1$ by j and using the Gronwall inequality. Finally, it is easily seen that this estimate is passed from j to $j+1$ by (64). An analogous argument for f_p^j completes the proof of (b).

A uniform-in-ε ($L^1 \cap L^\infty$)-bound for the total charge density $\rho^j = n^j + \varepsilon n_{tr}^j - p^j - C$ follows from (b) and from the integrability of M_{tr}. Statement (c) of the lemma is now a consequence of (58). ∎

For passing to the limit in the nonlinear terms some compactness is needed. Therefore we prove uniform smoothness of the approximating sequence.

LEMMA 5.2. *Let the assumptions* (52)–(57) *be satisfied. Then for any time* $T > 0$ *the following hold:*

(a) f_n^j *and* f_p^j *are uniformly bounded with respect to* j *and* ε *in* $L^\infty(0,T; W^{1,1}_{per}(\mathbb{R}^3 \times B) \cap W^{1,\infty}_{per}(\mathbb{R}^3 \times B))$.

(b) f_{tr}^j *is uniformly bounded with respect to* j *and* ε *in* $L^\infty(0,T; W^{1,\infty}(\mathbb{R}^3 \times (0,1)))$.

(c) $\mathcal{E}^j$ *is uniformly bounded with respect to* j *and* ε *in* $L^\infty(0,T; W^{1,\infty}(\mathbb{R}^3))$.

Proof. We start by introducing $\nu^j = \nabla_{x,k} f_n^j = (\nu_x^j, \nu_k^j)$, $\pi^j = \nabla_{x,k} f_p^j = (\pi_x^j, \pi_k^j)$, $\phi^j = \nabla_x f_{tr}^j$, and by differentiating the last equation in (62) with respect to x:

$$\begin{aligned}\varepsilon \partial_t \phi^{j+1} = {} & (-p_0 \lambda_p[M_p \pi_x^j] + \lambda_n[\nu_x^j])(1 - f_{tr}^{j+1}) - (-n_0 \lambda_n[M_n \nu_x^j] + \lambda_p[\pi_x^j]) f_{tr}^{j+1} \\ & - (p_0 \lambda_p[M_p(1 - f_p^j)] + \lambda_n[f_n^j] + n_0 \lambda_n[M_n(1 - f_n^j)] + \lambda_p[f_p^j])\phi^{j+1}.\end{aligned}$$

The coefficient of ϕ^{j+1} on the right-hand side is bounded from below by the term appearing in assumption (57) and, thus, bounded away from zero. The maximum principle implies

$$\sup_{(0,t)} \|\phi^{j+1}\|_\infty \le C \left(\sup_{(0,t)} \|\nu_x^j\|_\infty + \sup_{(0,t)} \|\pi_x^j\|_\infty + 1 \right),$$

where here and in the following we use the symbol $\|\cdot\|_\infty$ for the L^∞-norm on $\mathbb{R}^3$, on $\mathbb{R}^3 \times B$, and on $\mathbb{R}^3 \times (0,1)$. The gradient of the first equation in (62) with respect to x and k can be written as

$$\alpha^2 \partial_t \nu^{j+1} + \alpha v_n \cdot \nabla_x \nu^{j+1} - \alpha \mathcal{E}^j \cdot \nabla_k \nu^{j+1} + (a_n + b_n + \alpha^2 g_n + \alpha^2 r_n)\nu^{j+1} = S_n^j,$$

where it is easily seen that, using our assumptions,

$$\|S_n^j\|_\infty \le C \left(1 + \|\nu^j\|_\infty + \|\phi^j\|_\infty + \|\nu^{j+1}\|_\infty (1 + \|\nabla_x \mathcal{E}^j\|_\infty)\right)$$

holds. The analogous treatment of the second equation in (62), the potential theory inequality (59), and the definition

$$\gamma^j(t) = \sup_{(0,t)} (\|\nu^j\|_\infty + \|\pi^j\|_\infty + \|\phi^j\|_\infty)$$

lead to

$$\gamma^{j+1} \le C \left(1 + \int_0^t (\gamma^j + \gamma^{j+1}(1 + \log(1 + \gamma^j)))\, ds \right),$$

implying boundedness of γ^j on arbitrary bounded time intervals (as in [4]). This proves (c) and the L^∞-part of (a). The equation for $\partial_E f_{tr}^{j+1}$ can be treated as above, completing the proof of (b).

By $\int_{\mathbb{R}^3} n_{tr}\, dx \le \int_{\mathbb{R}^3} M_{tr}\, dx$, it is trivial that the total number of trapped electrons is bounded. Therefore, the L^1-estimates in (a) follow the line of [13] since no coupling with the equation for the trapped electrons is necessary. ∎

With the previous results, the first two equations in (62) also give uniform bounds for the time derivatives of f_n^j and f_p^j. Thus, subsequences converge strongly locally in x and t. In the same way, the right-hand side of the time derivative of the Poisson equation is bounded in L^1 and in L^∞, and (58) implies boundedness of the time derivative of the field. So the field also converges strongly. This and the (obvious) weak convergence of f_{tr}^j are sufficient for passing to the limit in the quadratic nonlinearities. Note also that we have enough bounds on the time derivative to define the trace at time $t = 0$. Existence of a global solution of Problem (K) follows. By the same argument, the limit $\varepsilon \to 0$ can be justified, since all estimates are also uniform in ε.

THEOREM 5.3. *Let the assumptions* (52)–(57) *be satisfied. Then Problem* (K) *has a global solution* $(f_n, f_p, f_{tr}, \mathcal{E})$ *with* $f_n, f_p \in L^\infty(0,T; W^{1,\infty}_{per}(\mathbb{R}^3 \times B))$, $f_{tr} \in L^\infty(0,T; W^{1,\infty}(\mathbb{R}^3 \times (0,1)))$, $\mathcal{E} \in L^\infty(0,T; W^{1,\infty}(\mathbb{R}^3))$. *For* $\varepsilon \to 0$, *a subsequence of solutions converges to the formal limit problem. The convergence of* f_n *and* f_p *is in* $L^\infty((0,\infty) \times \mathbb{R}^3 \times B)$, *that of* $\mathcal{E}$ *in* $L^\infty((0,\infty) \times \mathbb{R}^3)$, *and that of* f_{tr} *in* $L^\infty((0,\infty) \times \mathbb{R}^3 \times (0,1))$ *weak*.*

6. Relation between macroscopic and kinetic models. In this section the relation between the two models in sections 2 and 4 is clarified on a formal level. The drift-diffusion model of section 2 can be derived from the kinetic model of section 4 by two simplification steps: a macroscopic and a low density limit.

Starting with the macroscopic limit, i.e., the limit when the Knudsen number α tends to zero in (42), (43), the solutions are expanded in terms of powers of α:

$$f_n = f_n^0 + \alpha f_n^1 + \mathcal{O}(\alpha^2), \qquad f_p = f_p^0 + \alpha f_p^1 + \mathcal{O}(\alpha^2), \tag{66}$$

$$f_{tr} = f_{tr}^0 + \mathcal{O}(\alpha), \qquad V = V^0 + \mathcal{O}(\alpha). \tag{67}$$

The limit of (42), (43) as $\alpha \to 0$ leads to $Q_n(f_n^0) = Q_p(f_p^0) = 0$. With the (frequently used) simplifying assumption that the cross sections $\widetilde{\Phi}_n$ and $\widetilde{\Phi}_p$ are strictly positive, the limiting distributions are of Fermi–Dirac type (see [13]):

$$f_n^0(x,k,t) = \frac{1}{1 + e^{-\mu_n(x,t)}/M_n(k)}, \qquad f_p^0(x,k,t) = \frac{1}{1 + e^{\mu_p(x,t)}/M_p(k)},$$

where the scaled Maxwellians M_n, M_p are given by (46) and the chemical potentials μ_n and μ_p are yet to be specified. Note the one-to-one relations between the chemical potentials and the macroscopic electron and hole densities:

$$n(\mu_n) = \int_B \frac{dk}{1 + e^{-\mu_n}/M_n(k)}, \qquad p(\mu_p) = \int_B \frac{dk}{1 + e^{\mu_p}/M_p(k)}.$$

Now (42) is divided by α, and then again the limit $\alpha \to 0$ is carried out (formally):

$$v_n \cdot \nabla_x f_n^0 + \nabla_x V^0 \cdot \nabla_k f_n^0 = LQ_n(f_n^0) f_n^1, \tag{68}$$

where LQ_n is the linearization of Q_n:

$$LQ_n(f_n^0) f_n^1 = \int_B \widetilde{\Phi}_n \big[(M_n(1 - f_n^0) + M_n' f_n^0) f_n^{1'} - (M_n f_n^{0'} + M_n'(1 - f_n^{0'})) f_n^1 \big] \, dk'.$$

For the following we shall need two facts about the linearized collision operator $LQ_n(f_n^0)$ (see, e.g., [1]): It has a one-dimensional kernel spanned by $f_n^0(1 - f_n^0)$, and

its range consists of functions whose integral with respect to k vanishes. Therefore, for solvability of (68), seen as an equation for f_n^1, the integral with respect to k of the left-hand side has to vanish. This is obvious for the second term $\nabla_x V^0 \cdot \nabla_k f_n^0$ by the periodicity with respect to k. Since the first term can be written as

$$v_n \cdot \nabla_x f_n^0 = \nabla_k \varepsilon_n \cdot \nabla_x \frac{M_n}{M_n + e^{-\mu_n}} = -\nabla_k \cdot \nabla_x \log\left(M_n + e^{-\mu_n}\right),$$

it also satisfies the solvability condition. Now (68) is written as

$$\frac{M_n e^{-\mu_n}}{(M_n + e^{-\mu_n})^2} \nabla_k \varepsilon_n \cdot (\nabla_x V^0 - \nabla_x \mu_n) = LQ_n(f_n^0) f_n^1. \tag{69}$$

Note that the factor in parentheses is independent of k. Thus, choosing a solution $h_n(k, \mu_n)$ of

$$LQ_n(f_n^0) h_n = -\frac{M_n e^{-\mu_n}}{(M_n + e^{-\mu_n})^2} \nabla_k \varepsilon_n, \tag{70}$$

the solution of (69) can be written as

$$f_n^1 = h_n(k, \mu_n) \cdot (\nabla_x V^0 - \nabla_x \mu_n) + \mu_n^1 f_n^0 (1 - f_n^0).$$

Analogously,

$$f_p^1 = h_p(k, \mu_p) \cdot (\nabla_x V^0 + \nabla_x \mu_p) + \mu_p^1 f_p^0 (1 - f_p^0) \tag{71}$$

is obtained (with $\mu_n^1(x,t)$ and $\mu_p^1(x,t)$ not specified, and not needed in the following). Finally, (42), (43) are divided by α^2 and integrated with respect to k, and the limit $\alpha \to 0$ is carried out:

$$\partial_t n + \nabla_x \cdot \int_B v_n f_n^1 \, dk = \int_B Q_{n,r}(f_n^0, f_{tr}^0) \, dk = \int_0^1 S_n(f_n^0, f_{tr}^0) \, dE, \tag{72}$$

$$\partial_t p + \nabla_x \cdot \int_B v_p f_p^1 \, dk = \int_B Q_{p,r}(f_p^0, f_{tr}^0) \, dk = \int_0^1 S_p(f_p^0, f_{tr}^0) \, dE. \tag{73}$$

With the formulas for f_n^1 and f_p^1, we obtain the drift-diffusion fluxes

$$\int_B v_n f_n^1 \, dk = D_n(\mu_n)(\nabla_x V^0 - \nabla_x \mu_n), \qquad \int_B v_p f_p^1 \, dk = D_p(\mu_p)(\nabla_x V^0 + \nabla_x \mu_p),$$

with the diffusion matrices

$$D_n = \int_B v_n \otimes h_n \, dk, \qquad D_p = \int_B v_p \otimes h_p \, dk.$$

For the recombination-generation terms, we obtain

$$S_n(f_n^0, f_{tr}^0) = \lambda_n \left[\frac{e^{-\mu_n}}{1 + e^{-\mu_n}/M_n}\right] (n_0 f_{tr}^0 - e^{\mu_n}(1 - f_{tr}^0)),$$

$$S_p(f_p^0, f_{tr}^0) = \lambda_p \left[\frac{e^{\mu_p}}{1 + e^{\mu_p}/M_p}\right] (p_0(1 - f_{tr}^0) - e^{-\mu_p} f_{tr}^0).$$

Finally, we consider the small densities situation, when μ_n is large and negative and μ_p large and positive. This gives $n(\mu_n) \approx e^{\mu_n}$ and $p(\mu_p) \approx e^{-\mu_p}$. The above recombination-generation terms can then be approximated by the terms in (9) with $1/\tau_n = \lambda_n[M_n]$ and $1/\tau_p = \lambda_p[M_p]$.

Equation (70) for h_n can be approximated by

$$\int_B \widetilde{\Phi}_n \big[M_n h_n' - M_n' h_n\big]\, dk' = -nM_n \nabla_k \varepsilon_n,$$

implying $h_n = n\tilde{h}_n(k)$ and, thus, $D_n = n\tilde{D}_n$. With this and the analogous approximation for holes, the macroscopic model becomes the drift-diffusion model from section 2.

It is worth pointing out that the drift-diffusion SRH model has been obtained from the kinetic model by a two-step approximation procedure: At first, the hydrodynamic limit leads to a more nonlinear system, and we perform additionally the small densities asymptotics. This remark appeals to further mathematical questions:

• It could be interesting to investigate the intermediate macroscopic model that comes directly from the Fermi–Dirac statistics.

• It could be tempting to reverse the limits. Roughly speaking, it means that we do not take into account the Pauli exclusion principle in the kinetic equations, and the collision operator is replaced by a linear Boltzmann operator which relaxes to a Maxwellian (instead of a Fermi–Dirac distribution). Mathematically, this leads to additional difficulties since we lose the natural L^∞-estimate given for free with the exclusion terms. Rigorous derivation of the diffusion regime for the corresponding Boltzmann–Poisson system in a bounded domain, with only one species of charged particles, has been obtained only very recently by using a tricky renormalization argument; see [11] (and [12] for an earlier work on renormalized solutions).

Appendix. Proof of (58) and (59). We recall that the fundamental solution of $-\Delta$ in $\mathbb{R}^N$, $N \geq 3$, reads $E(x) = C_N|x|^{2-N}$. For a given function $\rho : \mathbb{R}^N \to \mathbb{R}^+$, we set

$$\Phi = E * \rho, \qquad \nabla_x \Phi(x) = C_N(2-N) \int_{\mathbb{R}^N} \frac{x-y}{|x-y|}\, \frac{\rho(y)}{|x-y|^{N-1}}\, dy.$$

For any $0 < R < \infty$, we have

$$\int_{\mathbb{R}^N} \frac{\rho(y)}{|x-y|^{N-1}}\, dy = \int_{|x-y|\leq R} \dots\, dy + \int_{|x-y|\geq R} \dots\, dy \leq \|\rho\|_\infty \frac{\Omega_N R^2}{2} + \frac{1}{R^{N-1}} \|\rho\|_1,$$

where Ω_N stands for the surface of the N-dimensional sphere. Optimizing with respect to R yields

$$\|\nabla \Phi\|_\infty \leq K_N \|\rho\|_\infty^{(N-1)/(N+1)} \|\rho\|_1^{2/(N+1)},$$

where K_N is the constant depending only on the dimension.

Since $|x|^{N-1}$ is locally integrable, we compute the second derivatives of the potential as follows. For any $\varphi \in C_c^\infty(\mathbb{R}^N)$, we have

$$\big\langle \partial_{ij}^2 \Phi; \varphi \big\rangle = C_N(2-N) \int_{\mathbb{R}^N} \frac{x_j}{|x|^N}\, \partial_j \varphi(x)\, dx = C_N(2-N) \lim_{\eta \to 0} \int_{|x|\geq \eta} \frac{x_j}{|x|^N}\, \partial_j \varphi(x)\, dx$$

$$= C_N(N-2) \lim_{\eta \to 0} \left(\int_{|x|\geq \eta} \left(\frac{\delta_{ij}}{|x|^N} - N \frac{x_i x_j}{|x|^{N+2}} \right) \varphi(x)\, dx + \int_{|x|=\eta} \frac{x_j}{|x|^N} \frac{x_i}{|x|} \varphi(x)\, d\sigma(x) \right).$$

The second integral in the right-hand side can be recast as

$$\int_{\mathbb{S}^{N-1}} \varphi(\eta\omega)\omega_i\omega_j \, d\omega,$$

and therefore it converges to

$$\frac{\Omega_N}{N}\delta_{ij}\,\varphi(0).$$

Let us introduce the matrix

$$\mathbb{K}_{ij}(x) = C_N \frac{N-2}{|x|^N}\left(\delta_{ij} - N\frac{x_i x_j}{|x|^2}\right).$$

Then, in the sense of distribution the Hessian matrix of E satisfies

$$D^2E(x) = C_N(2-N)\frac{\Omega_N}{N}\mathbb{I}\,\delta(x=0) + \lim_{\eta\to 0}\mathbb{K}(x)\chi_{|x|\geq\eta}.$$

In particular we remark that

$$\int_{\mathbb{S}^{N-1}} \mathbb{K}(r\omega)\, d\omega = 0, \qquad \operatorname{Tr}\mathbb{K} = 0. \tag{74}$$

Accordingly, the Hessian matrix of the potential Φ is given by

$$D^2\Phi(x) = C_N(2-N)\frac{\Omega_N}{N}\mathbb{I}\,\rho(x) + \lim_{\eta\to 0}\int_{|x-y|\geq\eta}\mathbb{K}(x-y)\rho(y)\,dy.$$

Let us discuss the last term. Consider $0<\eta<R_1<R_2<\infty$. Using the notation C to stand for any constant depending only on the dimension, we get

$$\begin{aligned}\left|\int_{|x-y|\geq\eta}\mathbb{K}(x-y)\rho(y)\,dy\right| &\leq C\left(\int_{|x-y|\geq R_2}\frac{\rho(y)}{|x-y|^N}\,dy + \int_{R_1\leq|x-y|\leq R_2}\frac{\rho(y)}{|x-y|^N}\,dy \right.\\ &\qquad \left. + \left|\int_{\eta\leq|x-y|\leq R_1}\mathbb{K}(x-y)\rho(y)\,dy\right|\right)\\ &\leq C\frac{1}{R_2^N}\|\rho\|_1 + C\|\rho\|_\infty \ln\left(\frac{R_2}{R_1}\right) + C\left|\int_{\eta\leq|x-y|\leq R_1}\mathbb{K}(x-y)\big(\rho(y)-\rho(x)\big)\,dy\right|\end{aligned}$$

where we used (74). We deduce the following estimate:

$$\left|\int_{|x-y|\geq\eta}\mathbb{K}(x-y)\rho(y)\,dy\right| \leq C\left(\frac{1}{R_2^N}\|\rho\|_1 + \|\rho\|_\infty\ln\left(\frac{R_2}{R_1}\right) + \|\nabla_x\rho\|_\infty R_1\right).$$

Then, we choose $R_2 = 1 > R_1 = (1+\|\nabla_x\rho\|_\infty)^{-1}$ and conclude that

$$|D^2\Phi(x)| \leq C\Big(1 + \|\rho\|_1 + \|\rho\|_\infty\big(1+\ln(1+\|\nabla_x\rho\|_\infty)\big)\Big)$$

holds. A similar analysis can be done in dimension two; see [17].

ROLL-WAVES IN GENERAL HYPERBOLIC SYSTEMS WITH SOURCE TERMS*

PASCAL NOBLE†

Abstract. The purpose of this article is to prove the existence of particular nonlinear waves, so-called roll-waves, in general hyperbolic systems with a source term: these are periodic and discontinuous traveling waves, the discontinuities satisfying entropy conditions. We show that roll-wave solutions can be seen as zeros of a suitably chosen map. In the vanishing amplitude limit, a particular solution exists, and we prove that this solution persists to small amplitudes, which yields the existence of small amplitude roll-waves. The shock conditions (Rankine–Hugoniot conditions and Lax entropy conditions) are treated as nonlinear boundary conditions.

Key words. nonlinear waves, hyperbolic systems, roll-waves, relaxation

1. Introduction.

Roll-waves are hydrodynamic instabilities appearing in shallow water flows downstream from an open inclined channel. This type of flow is described by the Saint Venant equation, which reads in its adimensional form as:

$$\begin{aligned} &h_t + (hu)_x = 0, \\ &(hu)_t + \left(\frac{h^2}{2F} + hu^2\right)_x = h - u^2, \end{aligned} \tag{1}$$

where h is the height of the water, u its velocity, and F is the Froude number. This system is *hyperbolic*, the hyperbolic part being similar to the isentropic Euler equations, with a *source term* taking into account the gravity effects and the rugosity of the channel (through the friction term $-u^2$). When the uniform flow is unstable $F > 4$, it is proved that roll-waves appear as mathematical solutions of (1). More precisely, Dressler [4] proved the existence of periodic traveling waves, which are necessarily discontinuous. The discontinuities satisfy the Rankine–Hugoniot jump conditions and a Lax entropy condition.

In this paper, we consider a general hyperbolic system with a source term

$$u_t + Df(u)\,u_x = g(u), \quad u \in \mathbb{R}^n,\ n \geq 2. \tag{2}$$

For this general class of equations, we study the existence of roll-wave solutions, i.e., discontinuous periodic traveling waves, the discontinuities satisfying the Rankine–Hugoniot jump conditions and the Lax shock conditions.

There are many mathematical studies of the system (2) in the *relaxation case*, where equation (2) has the particular form

$$u_t + Df(u)\,u_x = \frac{1}{\epsilon}\,g(u), \tag{3}$$

with $\epsilon \ll 1$, and the set of equilibrium $g(u) = 0$ forms a j-dimensional manifold, $j < n$. This type of system appears in many physical situations, for example, in kinetic theory [2], gases not in local equilibrium [7], multiphase and phase transition [17], or linear and nonlinear waves [19]. Let us mention a few mathematical results out of a huge literature on the topic. For relaxation equations, reduced systems, inviscid and viscous local conservation laws, and weakly nonlinear limits can be computed through asymptotic expansions. These computations can be justified rigorously for 2×2 systems [3], and in the general case an entropy condition on the full system ensures the hyperbolicity of the reduced inviscid system. For 2×2 systems, this condition is nothing but the stability condition of the equilibrium states. In that case, the first order correction is shown to be dissipative. More recently, the existence and the stability of relaxation shocks have been established in general hyperbolic systems with relaxation [18, 15].

Less studied is the system (2) when the uniform flow is *unstable*: let us just mention the paper of Jin and Katsoulakis [6], where 2×2 hyperbolic systems with supercharacteristic relaxations are considered: a weakly nonlinear limit is identified which is a Burgers equation with a source term, and this equation possesses roll-wave solutions. Such a limit is justified in the presence of artificial viscosity, using the energy method [6]. For the Saint Venant system (1), when the uniform flow is unstable $F > 4$, roll-waves appear and are proved to be stable. This is done formally in [1] for roll-waves of large spatial period, and rigorously in [10], where it is proved that roll-waves are spectrally stable. The nonlinear stability of roll-waves shall be treated in a forthcoming paper [11]. The notion of nonlinear stability of solutions of hyperbolic equations that contain shocks means that for any initial data close to the solution and with the same structure of shocks, the solution of the Cauchy problem exists on a sufficiently small interval and keeps the structure of the initial data; see [14, 16] and the references therein for more details.

In this paper we are going to prove that under suitable conditions system (2) possesses small amplitude roll-wave solutions. For that purpose, we follow the approach of Dressler and search for discontinuous periodic traveling waves, the discontinuities satisfying the Rankine–Hugoniot conditions and the Lax shock entropy condition. We shall see that this is equivalent to proving the existence of a special regular solution of the differential system

$$\big(Df(u) - c\big)u' = g(u) \quad \forall x \in (0, L),$$

where c is the wave speed and L the wavelength of the roll-wave, satisfying nonlinear boundary conditions. This approach has already been used successfully to prove the existence of pulsating roll-waves in Saint Venant equations with a periodic bottom [12].

In order to prove the existence of roll-waves, we show that they are zeros of a suitably chosen map. Then, searching for small amplitude roll-waves, we introduce the scaling used by Jin and Katsoulakis to derive a Burgers equation from 2×2 hyperbolic systems with supercharacteristic relaxation [6]. In the vanishing amplitude limit $\epsilon \to 0$ and $L = 2\epsilon\tau \to 0$, we prove that the map considered has a zero. Then we show that the differential of this map is invertible and, using the implicit function theorem, deduce the existence of small amplitude roll-waves. The plan of the paper is as follows. In section 2, we reduce the problem of finding roll-waves to finding zeros of a particular map. These zeros satisfy a differential system and the Rankine–Hugoniot conditions. The Lax shock condition is treated separately. In section 3, we show that the map has a zero in the limit $\epsilon \to 0$ and $L = 2\epsilon\tau \to 0$. In section 4, we prove that

under suitable conditions, this particular solution persists when $0 < \epsilon \ll 1$. We shall separate two cases. We first consider the "artificial" case where $dg(\overline{u}_0)$ is invertible, $\overline{u}_0$ being a stationary solution of (2) (i.e., such that $g(\overline{u}_0) = 0$): we obtain a family of roll-waves parametrized by the rescaled wavelength $2\tau > 0$. Then we consider the "real" case where $g(u) =^t (0, h(u))$ with $h : \mathbb{R}^n \to \mathbb{R}^{n-j}$. Then assuming that $dh(u_0)$ is surjective, we can prove that the particular solution persists when $\epsilon \neq 0$ and, if the rescaled period is fixed, belongs to a j-dimensional manifold. Under suitable conditions, we show that this family can be parametrized by j-conserved quantities of the motion. Then we draw a conclusion and present some perspectives on this paper.

2. Formulation of the problem. Let us consider the first order system of partial differential equations

$$u_t + Df(u)\,u_x = g(u). \tag{4}$$

The left-hand side of system (4) is supposed to be hyperbolic in a neighborhood $\mathcal{V}(\overline{u}_0)$ of a constant solution $u = \overline{u}_0$ of (4), i.e., so that $g(\overline{u}_0) = 0$. That is, $Df(u)$ has n real eigenvalues $\big(\lambda_k(u)\big)_{k=1,\dots,n}$ so that

$$\lambda_1(u) < \cdots < \lambda_k(u) < \cdots < \lambda_n(u) \qquad \forall u \in \mathcal{V}(\overline{u}_0). \tag{5}$$

We shall consider in what follows that f and g both have a power series expansion at the point $u = \overline{u}_0$ with a domain of convergence $\mathbb{D}$ containing $B(\overline{u}_0, r),\ r > 0$.

The purpose of the paper is to prove the existence of periodic traveling waves with admissible discontinuities given by the Rankine–Hugoniot conditions and a Lax entropy shock condition. Following the approach developed by Dressler [4], we search for a periodic traveling wave with wave speed c and wavelength $2L$ in the form $u(x,t) = U(x - ct)$, with U a $2L$ periodic function with discontinuities at points $x_j = (2j + 1)L$, $j \in \mathbb{Z}$, which satisfies the differential system

$$\big(Df(U(x)) - c\big)U' = g(U(x)) \qquad \forall x \in (-L, L). \tag{6}$$

The discontinuities verify the admissible conditions

$$\begin{aligned} &[f(U)]_{(2j+1)L} = c[U]_{(2j+1)L} \quad \forall j \in \mathbb{Z}, \\ &\lambda_k(U_j^+) < c < \lambda_k(U_j^-), \qquad \lambda_{k-1}(U_j^-) < c < \lambda_{k+1}(U_j^+), \end{aligned} \tag{7}$$

for some k, $1 \le k \le n$, and $U_j^\pm$ denotes $U((2j+1)L)^\pm$ $\forall j \in \mathbb{Z}$. Due to the translational invariance of (6), the problem (6)–(7) is equivalent to finding a smooth solution U defined on $(-L, L)$ satisfying the system (6) with the nonlinear boundary conditions

$$\begin{aligned} &f\big(U(L)\big) - f\big(U(-L)\big) = c\big(U(L) - U(-L)\big), \\ &\lambda_k\big(U(-L)\big) < c < \lambda_k\big(U(L)\big), \qquad \lambda_{k-1}\big(U(L)\big) < c < \lambda_{k+1}\big(U(-L)\big), \end{aligned} \tag{8}$$

for some k, $1 \le k \le n$. Now let us take U as the solution of (6) and integrate this system on $(-L, L)$: this yields

$$f\big(U(L)\big) - f\big(U(-L)\big) - c\big(U(L) - U(-L)\big) = \int_{-L}^{L} g(U(x))dx. \tag{9}$$

As a consequence, the Rankine–Hugoniot jump conditions for solutions in the class of roll-waves are satisfied if and only if

$$\int_{-L}^{L} g(U(x))dx = 0.$$

In what follows we are going to prove the existence of a *small amplitude* roll-wave with a *small spatial period*. For that purpose, we use the scaling introduced by Jin and Katsoulakis to derive a Burgers equation from 2×2 hyperbolic systems with supercharacteristic relaxation [6]. Denote by ϵ the amplitude of the roll-wave and by $L = 2\epsilon\tau$, with $\tau > 0$, its spatial wavelength. Let us write u in the form

$$u(x) = \overline{u} + \epsilon v\left(\frac{x - ct}{2\epsilon\tau}\right), \tag{10}$$

with v a smooth function defined on $(-1, 1)$. The resulting roll-wave is a traveling wave with wave speed c and spatial period $2\epsilon\tau$ for some $\tau > 0$. Note that the amplitude of the roll-wave and its spatial period are of the same order. Inserting (10) into (6), (8) yields

$$\big(Df(u + \epsilon v(x)) - c\big)v'(x) = \tau\, g(u + \epsilon v(x)) \qquad \forall x \in (-1, 1). \tag{11}$$

The nonlinear boundary conditions are given by

$$\begin{aligned} &\frac{f(\overline{u} + \epsilon v(1) - f(\overline{u} + \epsilon v(-1))}{\epsilon} = c(v(1) - v(-1), \\ &\lambda_k(\overline{u} + \epsilon v(-1)) < c < \lambda_k(\overline{u} + \epsilon v(1)), \\ &\lambda_{k-1}(\overline{u} + \epsilon v(1)) < c < \lambda_{k+1}(\overline{u} + \epsilon v(-1)), \end{aligned} \tag{12}$$

for some k, $1 \le k \le n$. It is a classical result that the Lax entropy shock conditions for small amplitude shocks reduce to the single condition

$$\lambda_k(\overline{u} + \epsilon v(-1)) < c < \lambda_k(\overline{u} + \epsilon v(1)), \tag{13}$$

the other condition being automatically satisfied when ϵ is sufficiently small. Moreover, letting $\epsilon \to 0$ in the shock conditions yields

$$Df(\overline{u})\big(v(1) - v(-1)\big) = c(v(1) - v(-1)).$$

Thus $c = \lambda_k(\overline{u})$ is necessarily one of the eigenvalues of $Df(\overline{u})$. In what follows, we suppose that $c = \lambda_k(\overline{u})$.

We are going to prove that there exists a solution $(\overline{u}, v)$ of (11,12) for $0 < \epsilon \ll 1$. For that purpose, let us consider the map $\mathcal{F}_{\epsilon,\tau}$ defined by

$$\begin{aligned} \mathcal{F}_{\epsilon,\tau} &: \mathbb{X} \times \mathbb{R}^n \to \mathbb{Y} \times \mathbb{R}^n, \\ \mathcal{F}_{\epsilon,\tau}(v, \overline{u})_1 &= \Pi_k(\overline{u})\left(\frac{Df(u + \epsilon v) - Df(\overline{u})}{\epsilon}v' - \tau\frac{g(\overline{u} + \epsilon v) - \langle g(u + \epsilon v)\rangle}{\epsilon}\right) \\ &\quad + (1 - \Pi_k(\overline{u}))\Big(\big(Df(u + \epsilon v) - \lambda_k(\overline{u})\big)v'\Big) \\ &\quad + \tau(1 - \Pi_k(\overline{u}))\big(\langle g(u + \epsilon v)\rangle - g(u + \epsilon v)\big), \\ \mathcal{F}_{\epsilon,\tau}(v, \overline{u})_2 &= \int_{-1}^{1} g(\overline{u} + \epsilon v(x))\, dx, \end{aligned}$$

where $\langle u\rangle$ denotes the spatial mean $\langle u\rangle = \frac{1}{2}\int_{-1}^{1} u(x)dx$ and $\Pi_k(\overline{u})$ is the projection on the eigenspace $Ker(Df(\overline{u}) - \lambda_k(\overline{u})I)$ with respect to $Im(Df(\overline{u}) - \lambda_k(\overline{u})I)$. The functional spaces $\mathbb{X}, \mathbb{Y}$ are given by

$$\mathbb{X}_0 = \left\{ f \in C^1(-1,1)/\, f(x) = \sum_{n\geq 0} a_n\, x^n,\ \sum_{n\geq 0}(n+1)|a_n| < +\infty \right\},$$

$$\mathbb{X} = \{ f \in \mathbb{X}_0/\, (1 - \Pi_k(\overline{u}_0))\langle f\rangle = 0\}, \tag{14}$$

$$\mathbb{Y} = \left\{ f \in C(-1,1)/\, f(x) = \sum_{n\geq 0} a_n\, x^n,\ \sum_{n\geq 0}|a_n| < +\infty \right\},$$

endowed with the norms $\|f\|_{\mathbb{X}} = \sum_{n\geq 0}(n+1)|a_n|$ and $\|f\|_{\mathbb{X}} = \sum_{n\geq 0}|a_n|$. The mapping $\mathcal{F}_{\epsilon,\tau}$ is well defined, provided that $v, \tau > 0$ are in a bounded subset of $\mathbb{X}\times\mathbb{R}_*^+$, ϵ is sufficiently small, and u is close enough to $\overline{u}_0$. Moreover, the eigenvalue $\lambda_k(\overline{u})$ of $Df(\overline{u})$ is isolated in a sufficiently small neighbourhood $\mathcal{V}(\overline{u}_0)$ of $\overline{u}_0$: it is standard perturbation theory to prove that the application $u \mapsto \Pi_k(\overline{u})$ is C^1 (see [5] for more details). Consequently, since we have supposed that f, g have power series expansions, the map F is C^1 for $\overline{u} \in \mathcal{V}(\overline{u}_0)$, v, and $\tau > 0$ in a bounded subset of $\mathbb{X}\times\mathbb{R}_*^+$ and ϵ sufficiently small. Since $Ker(Df(\overline{u}) - \lambda_k(\overline{u})I)$ is one-dimensional, we can identify, for any $v \in \mathbb{R}^n$, $\Pi_k(\overline{u})v$ with a real number.

The following proposition relates the zeros of $\mathcal{F}_{\epsilon,\tau}$ with the roll-wave solutions.

PROPOSITION 1. *Let $(\overline{u}, v) \in \mathbb{R}^n \times \mathbb{X}$ be a zero of $\mathcal{F}_{\epsilon,\tau}$; then*

$$\begin{aligned} &\big(Df(\overline{u} + \epsilon v(x)) - c\big)v'(x) = \tau\, g(u + \epsilon v(x)) \qquad \forall x \in (-1,1), \\ &\frac{f(\overline{u} + \epsilon v(1) - f(\overline{u} + \epsilon v(-1))}{\epsilon} = c\big(v(1) - v(-1)\big), \end{aligned} \tag{15}$$

with $c = \lambda_k(\overline{u})$.

Then a zero of $\mathcal{F}_{\epsilon,\tau}$ is a solution of (11) and the Rankine–Hugoniot jump conditions. In what follows, given any $\tau_0 > 0$, we are going to prove that $\mathcal{F}_{0,\tau_0}$ has a particular solution $(\overline{u}_0, v^0)$ and that the derivative at this point $D\mathcal{F}_{0,\tau_0}$ is invertible with a bounded inverse. Using the implicit function theorem, this particular solution *persists* as a zero of $\mathcal{F}_{\epsilon,\tau}$, provided that $\epsilon \approx 0$ and $\tau \approx \tau_0$.

Let us deal with the Lax shock condition: this condition is equivalent to

$$\frac{\lambda_k(\overline{u} + \epsilon v(-1)) - \lambda_k(\overline{u})}{\epsilon} < 0 < \frac{\lambda_k(\overline{u} + \epsilon v(1)) - \lambda_k(\overline{u})}{\epsilon}. \tag{16}$$

Let $\epsilon \to 0$; then

$$d\lambda_k(\overline{u}).v(-1) \leq 0 \leq d\lambda_k(\overline{u}).v(1). \tag{17}$$

It is easy to prove the following lemma

LEMMA 1. *Suppose that $(\overline{u}_0, v^0)$ satisfies the "asymptotic" Lax shock condition*

$$d\lambda_k(\overline{u}_0).v^0(-1) < 0 < d\lambda_k(\overline{u}_0).v^0(1); \tag{18}$$

then $(\overline{u}, v)$, a zero of $\mathcal{F}_{\epsilon,\tau}$, which lies in a sufficiently small neighborhood of $(\overline{u}_0, v^0)$, corresponds to a roll-wave solution of (4).

As a conclusion, we clearly see that the task is two-fold: first we have to prove the existence of a particular zero $(\overline{u}_0, v^0)$ of $\mathcal{F}_{0,\tau_0}$, which satisfies the "asymptotic" Lax shock condition (18). Then we show that $D\mathcal{F}_{0,\tau_0}$ is invertible at point $(\overline{u}_0, v^0)$. Shrinking the neighborhood of $(\overline{u}_0, v^0)$ if necessary, the Lax shock conditions will be automatically satisfied, and this will establish the existence of roll-waves.

3. Roll-wave solutions in the limit $\epsilon \to 0$. In this section we are going to compute a zero $(\overline{u}_0, v^0)$ of $\mathcal{F}_{0,\tau_0}$ which satisfies the "asymptotic" Lax shock condition

$$d\lambda_k(\overline{u}).v(-1) < 0 < d\lambda_k(\overline{u}).v(1). \tag{19}$$

It is easy to see that $(\overline{u}, v)$ as a zero of $\mathcal{F}_{0,\tau_0}$ satisfies

$$\begin{array}{l} g(\overline{u}) = 0, \\ \Pi_k(\overline{u}) D^2 f(\overline{u}).v(x).v'(x) - \Pi_k(\overline{u})\, dg(\overline{u})\big(v(x) - \langle v\rangle\big) = 0, \\ (1 - \Pi_k(\overline{u}))(Df(\overline{u}) - \lambda_k(\overline{u}))v'(x) = 0 \qquad \forall x \in (-1,1). \end{array} \tag{20}$$

Let us choose $\overline{u} = \overline{u}_0$: then $g(\overline{u}) = g(\overline{u}_0) = 0$. The last equation of (20) implies that v is given by

$$\begin{array}{l} v(x) = \Pi_k(\overline{u}_0)v(x) + V_k^0 \quad \forall x \in (-1,1), \\ v(x) = \lambda(x) r_k(u0) + V_k^0 \quad \forall x \in (-1,1), \end{array} \tag{21}$$

where $V_k^0 \in (1 - \Pi_k(\overline{u}_0))\mathbb{R}^n$ is a constant vector. Since $v \in \mathbb{X}$, it is clear that necessarily $V_k^0 = 0$. In order to compute λ, insert (21) into the second equation of (20): this yields

$$\lambda'(x) = \frac{\Pi_k(\overline{u}_0) dg(\overline{u}_0).r_k(\overline{u}_0)\big(\lambda(x) - \langle\lambda\rangle\big)}{\Pi_k(\overline{u}_0) D^2 f(\overline{u}_0).r_k(\overline{u}_0).r_k(\overline{u}_0)\lambda(x)} \qquad \forall x \in (-1,1). \tag{22}$$

The equation has a smooth solution if we choose $\langle\lambda\rangle = 0$. In that case, we find that

$$\lambda(x) = \alpha x, \quad \text{with} \quad \alpha = \tau_0 \frac{\Pi_k(\overline{u}_0) dg(\overline{u}_0).r_k(\overline{u}_0)}{\Pi_k(\overline{u}_0) D^2 f(\overline{u}_0).rk(\overline{u}_0).r_k(\overline{u}_0)}. \tag{23}$$

Hence we have proved the following proposition.

PROPOSITION 2. *Assume that*

$$\Pi_k(\overline{u}_0) D^2 f(\overline{u}_0).r_k(\overline{u}_0).r_k(\overline{u}_0) \neq 0, \qquad \Pi_k(\overline{u}_0)\, dg(\overline{u}_0).r_k(\overline{u}_0) \neq 0.$$

Then there exists a zero $(\overline{u}_0, v^0)$ of $\mathcal{F}_{0,\tau_0}$ with v^0 defined by

$$v^0(x) = \alpha\, x\, r_k(\overline{u}_0), \quad \textit{with} \quad \alpha = \tau_0 \frac{\Pi_k(\overline{u}_0) dg(\overline{u}_0).r_k(\overline{u}_0)}{\Pi_k(\overline{u}_0) D^2 f(\overline{u}_0).r_k(\overline{u}_0).r_k(\overline{u}_0)}. \tag{24}$$

Let us check the "asymptotic" Lax shock condition: this is done in the following lemma.

LEMMA 2. *Under the assumption $d\lambda_k(\overline{u}_0).r_k(\overline{u}_0) > 0$, the particular solution $(\overline{u}_0, \alpha\, x\, r_k(\overline{u}_0))$ satisfies the "asymptotic" Lax shock condition.*

Thus we have proved the existence of a zero $(\overline{u}_0, v^0)$ of $\mathcal{F}_{0,\tau_0}$, which satisfies the asymptotic Lax shock condition. Let us prove that the particular solution $(\overline{u}_0, v^0)$ persists for $\epsilon \neq 0$ and $\tau \approx \tau_0$ as an "admissible" zero of $\mathcal{F}_{\epsilon,\tau}$, (in the sense that they satisfy the Lax shock condition and are zeros of $\mathcal{F}_{\epsilon,\tau}$). This is done in the next section.

4. Persistence of the "asymptotic" roll-waves. In this section, we prove that $D\mathcal{F}_{0,\tau_0}$ is invertible at point $(\overline{u}_0, v^0)$. The expression for $D\mathcal{F}_{0,\tau_0}$ is given in the following lemma.

LEMMA 3. *The differential of $\mathcal{F}_{0,\tau_0}$ at the point $(\overline{u}_0, \alpha\, x\, r_k(\overline{u}_0))$ is given by*

$$\begin{aligned} D\mathcal{F}_{0,\tau_0} : \mathbb{X}\times\mathbb{R}^n &\to \mathbb{Y}\times\mathbb{R}^n \\ (v,u) &\mapsto \begin{array}{l} \Pi_k(\overline{u}_0)L_1(x).v + (1-\Pi_k(\overline{u}_0))L_2.v + M(x).\overline{u} \\ dg(\overline{u}_0).\overline{u}, \end{array} \end{aligned}$$

with

$$\begin{aligned} L_1(x).v &= \alpha x D^2 f(\overline{u}_0).r_k(\overline{u}_0).v' + D^2 f(\overline{u}_0).v.r_k(\overline{u}_0) - dg(\overline{u}_0).(v - \langle v\rangle), \\ L_2.v &= \big(Df(\overline{u}_0) - \lambda_k(\overline{u}_0)\big).v', \\ M(x).u &= \alpha^2 x\big(dA(\overline{u}_0).\overline{u}\big).r_k(\overline{u}_0).r_k(\overline{u}_0) \\ &\quad - \alpha x dB(\overline{u}_0).\overline{u}.r_k(\overline{u}_0) + \alpha dC(\overline{u}_0).\overline{u}.r_k(\overline{u}_0) \end{aligned} \tag{25}$$

and

$$\begin{aligned} &A(u) = \Pi_k(u)D^2 f(u), \\ &B(u) = \Pi_k(u)\, dg(u), \qquad\qquad \forall u\in\mathcal{V}(\overline{u}_0). \\ &C(u) = (1-\Pi_k(u))\big(Df(u) - \lambda_k(u)\big), \end{aligned} \tag{26}$$

Now we prove that $D\mathcal{F}_{0,\tau_0}$ is invertible with bounded inverse at the point $(\overline{u}_0, \alpha x r_k(\overline{u}_0))$: choose $(w,f)\in\mathbb{R}^n\times\mathbb{Y}$ and make the following assumption.

HYPOTHESIS 1. *The operator $dg(\overline{u}_0):\mathbb{R}^n\to\mathbb{R}^n$ is invertible.*

As a consequence, there exists a unique $\overline{u}$ so that

$$dg(\overline{u}_0).\overline{u} = w.$$

Now that $\overline{u}$ is determined, we prove that there exists a unique v so that

$$D\mathcal{F}_{0,\tau_0}(\overline{u},v)_1(x) = f(x) \qquad \forall x\in(-1,1). \tag{27}$$

Projecting the system (27) onto $(1-\Pi_k(\overline{u}_0))\mathbb{R}^n$ yields

$$(1-\Pi_k(\overline{u}_0))\Big(\big(Df(\overline{u}_0) - \lambda_k(\overline{u}_0)\big)v' + M(x).\overline{u}\Big) = (1-\Pi_k(\overline{u}_0))f(x). \tag{28}$$

Integrating (28) yields

$$v(x) = \lambda(x) r_k(\overline{u}_0) + V_k^0 + \mathcal{L}(\overline{u},f)(x), \tag{29}$$

with $V_k^0\in(1-\Pi_k(\overline{u}_0))\mathbb{R}^n$ a constant vector, and $\mathcal{L}(u,f)(x)\in(1-\Pi_k(\overline{u}_0))\mathbb{R}^n$ satisfies

$$\big(Df(\overline{u}_0) - \lambda_k(\overline{u}_0)\big)\mathcal{L}(\overline{u},f)(x) = (1-\Pi_k(\overline{u}_0))\int_0^x M(t).u + f(t)dt.$$

Since $M(x).u$ is polynomial in x and f lies in $\mathbb{Y}$, it is easily seen that

$$\mathcal{L}(\overline{u},f)\in\mathbb{X}.$$

Using the fact that $v\in\mathbb{X}$, V_k^0 is uniquely defined and is given by

$$V_k^0 = \langle \mathcal{L}(\overline{u},f)\rangle. \tag{30}$$

Now let us determine λ. Inserting (29) into the system (27) and projecting onto $\Pi_k(\overline{u}_0)\mathbb{R}^n$ yields the equation on λ:

$$x\lambda'(x) + \langle\lambda\rangle = \mathcal{A}(\overline{u}, f)(x) \qquad \forall x \in (-1, 1) \tag{31}$$

with

$$\begin{aligned}\beta\,\mathcal{A}(\overline{u}, f)(x) = {} & \Pi_k(\overline{u}_0)f(x) - \Pi_k(\overline{u}_0)M(x).\overline{u} \\ & + \Pi_k(\overline{u}_0)\Big(dg(\overline{u}_0)\big(\mathcal{L}(\overline{u}, f)(x) - \langle\mathcal{L}(\overline{u}, f)\rangle\big)\Big) \\ & - \alpha\Pi_k(\overline{u}_0)D^2f(\overline{u}_0)\big(\mathcal{L}(\overline{u}, f)(x) - \langle\mathcal{L}(\overline{u}, f)\rangle\big)r_k(\overline{u}_0) \\ & - \alpha x\Pi_k(\overline{u}_0)D^2f(\overline{u}_0).r_k(\overline{u}_0).\mathcal{L}(\overline{u}, f)'(x),\end{aligned} \tag{32}$$

and $\beta = \Pi_k(\overline{u}_0)dg(\overline{u}_0).r_k(\overline{u}_0)$. Clearly $\mathcal{A}(\overline{u}, f)$ lies in $\mathbb{Y}$. We prove that (31) has a *unique* solution in $\mathbb{X}$. Taking $x = 0$ in (31) yields

$$\langle\lambda\rangle = \mathcal{A}(\overline{u}, f)(0).$$

Then we find that

$$\lambda'(x) = \frac{\mathcal{A}(\overline{u}, f)(x) - \mathcal{A}(\overline{u}, f)(0)}{x} \qquad \forall x \in (-, 1). \tag{33}$$

The right-hand side of (33) lies in $\mathbb{Y}$: thus there exists a *unique* $\lambda \in \mathbb{X}$ which satisfies (33) and

$$\langle\lambda\rangle = \mathcal{A}(\overline{u}, f)(0).$$

Thus we have proved that $D\mathcal{F}_{0,\tau_0} : \mathbb{X} \times \mathbb{R}^n \to \mathbb{Y} \times \mathbb{R}^n$ is invertible. It is an easy computation to prove that this inverse is bounded from $\mathbb{R}^n \times \mathbb{Y}$ to $\mathbb{R}^n \times \mathbb{X}$, and we have proved the following proposition.

PROPOSITION 3. *Under the Hypothesis* 1*, the operator $D\mathcal{F}_{0,\tau_0}$ is invertible at the point $(\overline{u}_0, \alpha x r_k(\overline{u}_0))$. This particular solution persists as a zero of $\mathcal{F}_{\epsilon,\tau}$ to $\epsilon \approx 0$ and $\tau \approx \tau_0 > 0$.*

Using Lemma 2, we have proved that there exist roll-wave solutions of (4) in the case of "artificial" source terms for $0 < \epsilon \ll 1$, and they belong to a curve of roll-waves parametrized by the rescaled wavelength $\tau > 0$. Indeed, in most of the applications in physics, "real" source terms have the form

$$g(u) = \begin{pmatrix} 0 \\ h(u) \end{pmatrix}, \tag{34}$$

with $h : \mathbb{R}^n \to \mathbb{R}^{n-j}$ for some $j \geq 1$. We employ here a terminology similar to the one employed in the case of viscous approximation of conservation laws (we then deal with "artificial" and "real" viscosity). In the case of "real" source terms, the hypothesis (1) is not satisfied. Nevertheless, it is still possible to prove the existence of roll-waves. More precisely, we show the next theorem.

THEOREM 1. *Assume that $dh(\overline{u}_0) : \mathbb{R}^n \to \mathbb{R}^{n-j}$ is surjective. Then under the hypothesis*

$$\Pi_k(\overline{u}_0)D^2f(\overline{u}_0).r_k(\overline{u}_0).r_k(\overline{u}_0) \neq 0, \qquad \Pi_k(\overline{u}_0)dg(\overline{u}_0).r_k(\overline{u}_0) \neq 0,$$

and $\alpha d\lambda_k(\overline{u}_0).r_k(\overline{u}_0) > 0$, there exists a family of roll-wave solutions of (4) *which belongs to a j-dimensional manifold.*

Proof. In the case $g(u) =^t (0, h(u))$, we consider the mapping $\mathcal{G}_{\epsilon,\tau}$ defined by

$$\begin{aligned}\mathcal{G}_{\epsilon,\tau} : \mathbb{X} \times \mathbb{R}^n &\to \mathbb{Y} \times \mathbb{R}^{n-j} \\ (v, \overline{u}) &\mapsto \begin{array}{l} \mathcal{F}_{\epsilon,\tau}(u,v)_1, \\ \displaystyle\int_{-1}^{1} h(\overline{u} + \epsilon v(x))dx, \end{array}\end{aligned}$$

Then a zero $(\overline{u}, v)$ of $\mathcal{G}_{\epsilon,\tau}$ clearly satisfies the differential system (11) and the Rankine–Hugoniot conditions (12). Under the assumptions

$$\Pi_k(\overline{u}_0) D^2 f(\overline{u}_0).r_k(\overline{u}_0).r_k(\overline{u}_0) \neq 0, \qquad \Pi_k(\overline{u}_0) dg(\overline{u}_0).r_k(\overline{u}_0) \neq 0,$$

and $\alpha d\lambda_k(\overline{u}_0).r_k(\overline{u}_0) > 0$, we construct a zero $(\overline{u}_0, v^0 = \alpha\, x\, r_k(\overline{u}_0))$ of $\mathcal{G}_{0,\tau_0}$ (for any $\tau_0 > 0$ fixed). Then it is easily proved that $D\mathcal{G}_{0,\tau_0}(\overline{u}_0, v^0)$ is a submersion, and its kernel is j-dimensional with

$$Ker\, D\mathcal{G}_{0,\tau_0}(\overline{u}_0, v^0) = Ker\, dh(\overline{u}_0) \times \{0\}. \tag{35}$$

Consequently, the zeros of $\mathcal{G}_{0,\tau_0}$ form a j-dimensional manifold. Moreover, since $\mathcal{G}_{\epsilon,\tau}$ is a C^1 perturbation of $\mathcal{G}_{0,\tau_0}$, the zero set $\mathcal{G}_{\epsilon,\tau}^{-1}(0)$ is locally a j-dimensional manifold for $0 < \epsilon \ll 1$ and $\tau \approx \tau_0$. This completes the proof of the theorem. ∎

The question is now to find parameters that describes this j-dimensional family of solutions (the rescaled spatial period τ being fixed): indeed, since $g(u) =^t (0, h(u))$, we find that

$$\big(f_i(\overline{u} + \epsilon v(x)) - \lambda_k(\overline{u}) v_i\big)' = 0 \qquad \forall i = 1, \dots, j. \tag{36}$$

Then there exist $q_1, \dots, q_j$ so that

$$f_i(\overline{u} + \epsilon v(x)) - \lambda_k(\overline{u}) v_i(x) = q_i \qquad \forall i = 1, \dots, j. \tag{37}$$

The question arises whether we can use the conserved quantities $(q_i)_{i=1,\dots,j}$ and the adimensioned period τ to parametrize the solution. For that purpose, let us consider the mapping $\mathcal{H}_{\epsilon,\tau,q}$, where $q =^t (q_1, \dots, q_j)$ is defined by

$$\begin{aligned}\mathcal{H}_{\epsilon,\tau,q} : \mathbb{X} \times \mathbb{R}^n &\to \mathbb{Y} \times \mathbb{R}^n \\ (v, \overline{u}) &\mapsto \begin{array}{l} \mathcal{F}_{\epsilon,\tau}(\overline{u}, v)_1 \\ \pi_j\big(f(u + \epsilon v(1)) - \epsilon \lambda_k(\overline{u}) v(1)\big) - q, \\ \displaystyle\int_{-1}^{1} h(\overline{u} + \epsilon v(x))dx, \end{array}\end{aligned}$$

where $\pi_j : \mathbb{R}^n \to \mathbb{R}^j$ denotes the projection on the j first coordinates. Let us make the following assumption.

HYPOTHESIS 2. *The matrix $A_0 \in M_n(\mathbb{R})$ defined by*

$$A_0 = \begin{pmatrix} \pi_j\, df(\overline{u}_0) \\ dh(\overline{u}_0) \end{pmatrix} \tag{38}$$

is invertible.

Then it is easy to prove that at point $(\overline{u}_0, v^0)$ and for $q^0 = \pi_j(f(\overline{u}_0))$, the operator $D\mathcal{H}_{0,\tau_0,q_0}$ is invertible with a bounded inverse. Then applying the implicit function theorem, we see that for any fixed period $\tau \approx \tau_0$ and for $\epsilon \approx 0$, the j-dimensional manifold of roll-wave solutions is parametrized by the j conserved quantities $q \approx q^0$.

5. Conclusion. In this paper we have proved the existence of small amplitude roll-wave solutions for general hyperbolic systems with a "real" or "artificial" source term. These are periodic traveling waves, piecewise regular with discontinuities periodically distributed, which satisfy the Rankine–Hugoniot and a Lax shock condition (the shocks are indeed k-shocks). We have proved that when the zeros of the source term form a $(n-j)$-manifold, the roll-wave solutions, when they exist, form a $(j+1)$-manifold and are parametrized by their spatial period and j conserved quantities of the motion. This result generalizes the existence result obtained by Dressler in [4] for the Saint Venant equations, which reads in its adimensioned form as

$$\begin{aligned} &h_t + (hu)_x = 0, \\ &(hu)_t + \left(\frac{h^2}{2F} + hu^2\right)_x = h - u^2. \end{aligned} \tag{39}$$

In that case, the relative discharge rate $q = h(c-u)$ is a conserved quantity: Dressler proved in that case the existence of roll-waves parametrized by the spatial period $0 < L < \infty$ and the relative discharge rate $q > 0$. The question of the existence of large amplitude roll-waves for a general hyperbolic system with source term is still open.

Similarly to the study of Dressler roll-waves, several questions arise for inviscid roll-waves in hyperbolic systems with source term. On the one hand, considering artificial or real viscous perturbations of the system (4), one could address the question of the existence of continuous roll-waves. For a fixed size of the viscosity, we shall expect that, under suitable assumptions, one can show the existence of small amplitude roll-waves through a Hopf bifurcation argument. A more interesting question would be the "persistence" of inviscid roll-waves under viscous perturbation already addressed in [8] for Dressler roll-waves: given any inviscid roll-wave solution of (4), is there a viscous roll-wave solution if the viscous system in the vanishing viscosity limit converges to the inviscid roll-wave? This problem seems to be out of reach for general systems but should be possible to treat in low-dimensional systems $n = 2, 3$.

On the other hand, one could ask whether this type of solution is stable. In the viscous case, the question of the linear stability of roll-waves in Saint Venant systems has been treated in [9] using the approach initiated by Oh and Zumbrun [13] for periodic traveling waves in viscous conservation laws: it should be possible to prove for "general" viscous roll-waves that spectral stability implies the linear stability of viscous roll-waves. In the inviscid case, the question of the spectral stability is quite a hard problem but is treated in [10] for the Dressler roll-waves. The question of the nonlinear stability of inviscid roll-waves is also an open problem: this task will be completed for Dressler roll-waves in a forthcoming paper [11] using the framework introduced by Majda [14] for multidimensional compact shocks and generalized by Métivier and co workers [16]. In this case we prove the "persistence" result: more precisely, given any initial data which is close to a roll-wave and satisfies suitable compatibility conditions, one can show that the solution of the Cauchy problem exists on a sufficiently small interval and has a structure analogous to the roll-wave. This question shall be also addressed in a multidimensional framework.

MULTIPHASE IMAGE SEGMENTATION VIA MODICA–MORTOLA PHASE TRANSITION*

YOON MO JUNG†, SUNG HA KANG‡, AND JIANHONG SHEN†

Abstract. We propose a novel multiphase segmentation model built upon the celebrated phase transition model of Modica and Mortola in material sciences and a properly synchronized fitting term that complements it. The proposed sine-sinc model outputs a single multiphase distribution from which each individual segment or phase can be easily extracted. Theoretical analysis is developed for the Γ-convergence behavior of the proposed model and the existence of its minimizers. Since the model is not quadratic nor convex, for computation we adopted the convex-concave procedure (CCCP) that has been developed in the literatures of both computational nonlinear PDEs and neural computation. Numerical details and experiments on both synthetic and natural images are presented.

Key words. multiphase, segmentation, variational, partial differential equation, Modica–Mortola model, phase transition, Γ-convergence, convex splitting, convex-concave procedure

1. Introduction.

The literature on segmentation has been the most wealthy and inspiring. From Geman and Geman's mixture random-field models [23] to Mumford and Shah's piecewise smooth variational image models [36], segmentation has been extensively studied by several major stochastic and deterministic machineries of modeling, analysis, and computation. New segmentation models incorporating more complexities or flexibilities have been further proposed by a number of authors in recent years, e.g., the data-driven Monte Carlo Markov chain (DDMCMC) model of Tu and Zhu [52], the graph-cutting and spectral method of Shi and Malik [47], and the variational texture segmentation models by Sandberg, Chan, and Vese [42], and Shen [45] (based on the texture models of Meyer [32] and Osher, Solé, and Vese [40]), just to name a few.

In this paper, we focus on the variational-PDE approach that is closely connected to the Mumford–Shah type of model. Computationally, such models have been implemented in various approaches: the finite-difference or finite-element methods, e.g., by Bourdin and Chambolle [5], Chambolle [8, 9], and Morel and Solimini [35], as well as the influential level-set approach by Chan and Vese [15, 13] (based on the level-set technology of Osher and Fedkiw [38], Osher and Sethian [39], and Sethian [43]). In the level-set approach, in particular, several multiphase computational models have been recently designed by Chan and Vese [16], Chung and Vese [17], as well as Lie, Lysaker, and Tai [26] and Tai and Chan [49]. We emphasize that the current work is more or less related to those ideas explored in [17] and [26], but it is carried out in a completely different framework.

An alternative approach to modeling and computing segmentation is via the theory of Γ-convergence elliptic approximations, as first developed by Ambrosio and Tortorelli [2, 3] for the Mumford–Shah model. This method has been extensively studied and extended for segmentation, inpainting, and several other applications in image analysis and processing (see, e.g., [20, 21, 30, 29, 46]). We propose a new multiphase segmentation model in the framework of Γ-convergence and phase transition, and develop the relevant mathematical analysis and computational strategies. More specifically, we propose to adopt the celebrated phase transition model of Modica and Mortola [33] with a *sinusoidal* potential. The new model is a self-contained segmentation model, and is different from Ambrosio and Tortorelli's formulation [2], which approximates and computes the Mumford–Shah model.

We hereby emphasize that the similarities are inherent between image segmentation and the phase transition problem in material sciences and fluid mechanics. First, different phases in material sciences are characterized by densities and tensions (e.g., ice versus water), while in image and vision analysis, distinct "object" segments are similarly characterized by some *visual features* such as intensities, orientations, or more general Gabor features (e.g., in texture segmentation [42, 14]). Second, the difficulties in dealing with sharp interfaces emerging from both material phase transitions and image segmentation share the very same roots—the characteristic complexities in handling free boundaries and their geometry. Under such observations, it is beneficial for the imaging community to borrow the successful ideas in contemporary material sciences, e.g., the diffuse-interface model of Cahn and Hilliard [7], and its rigorous mathematical analysis in the framework of Γ-convergence approximation by Modica and Mortola [33] (as initially conjectured by De Giorgi).

Finally, as for all the major segmentation efforts in existence, the phase field based segmentation model proposed herein is also nonlinear and nonconvex, and its robust computation (for local minima) is nontrivial. In the current work, we employ the so-called convex-concave (splitting) procedure (CCCP) as in the literatures of both computational nonlinear PDEs [4, 22, 54] and neural computation [55], and develop the corresponding computational schemes for the proposed energy functional.

The paper has been organized as follows. The new model is developed in section 2. The relevant Mumford–Shah segmentation model and its related literature are briefly reviewed in subsection 2.1, and the proposed Modica–Mortola sine-sinc model is established in subsection 2.2. We analyze the major mathematical properties of the model in section 3, including the Γ-convergence behavior in subsection 3.2 and the existence and compactness theorems in subsection 3.3. Computational schemes are presented in section 4, where we develop the convex-splitting or the CCCP algorithm in subsection 4.2, and demonstrate the numerical performance on generic image examples in subsection 4.3. The conclusion is drawn in section 5.

2. Multiphase segmentation via Modica–Mortola phase transition. In this section, we first motivate and develop the new model based upon the phase transition model of Modica and Mortola in material sciences and fluid dynamics [33], and discuss its connections to the Mumford–Shah segmentation model and some related works. Mathematical analysis will be further developed in the next section.

Let Ω be a bounded Lipschitz domain, and $u_o : \Omega \longrightarrow \mathbb{R}_+ \cup \{0\}$ be a given image. Recall that the classical Mumford–Shah segmentation is to minimize

$$\mathcal{E}_{ms}[u, \Gamma | u_o] = \mathcal{H}^1(\Gamma) + \alpha \int_{\Omega \setminus \Gamma} |\nabla u|^2 dx + \lambda \int_{\Omega} (u - u_o)^2 dx, \tag{2.1}$$

where $\Gamma \in \Omega$ denotes the *edge set* of the ideal image u, and $\mathcal{H}^1$ represents the 1-dimensional Hausdorff measure. This functional is well defined on

$$\mathcal{A}_{ms} = \{(u, \Gamma) \ : \ u \in H^1(\Omega \setminus \Gamma), \mathcal{H}^1(\Gamma) < \infty, \Gamma \text{ is relatively closed in } \Omega\},$$

provided that the given image $u_o \in L^2(\Omega)$. In machine learning [18, 41], $\mathcal{A}_{ms}$ represents the *hypothesis* space (*model* space) of all piecewise smooth functions on Ω.

2.1. Piecewise constant segmentation model. In order to identify individual objects, conceptually one has to carry out a postprocessing step after the Mumford–Shah model outputs the edge set Γ. That is, one has to identify the individual connected components Ω_i's of $\Omega \setminus \Gamma$. If each patch Ω_i is to be called a *phase*, then segmentation automatically bears the nature of *multiple* phases, since a generic image often contains *multiple* objects projected from the 3-dimensional world.

On the other hand, there also exist attempts to *directly* represent and compute different phases. Normally phase separation or identification relies upon the clustering of certain visual features such as frequency, local orientation, and local density, etc. A simple but commonly adopted phase feature is the image intensity value of a pixel. In the Mumford–Shah setting (2.1), this leads to the piecewise constant reduced Mumford–Shah (RMS) model,

$$\mathcal{E}_{rms}[u, \Gamma | u_o] = \mathcal{H}^1(\Gamma) + \lambda \int_\Omega (u - u_o)^2 dx,$$

defined on the following admissible space:

$$\mathcal{A}_{rms} = \{(u, \Gamma) \ : \ Du\big|_{\Omega \setminus \Gamma} = 0, \ \mathcal{H}^1(\Gamma) < \infty, \ \Gamma \text{ is relatively closed in } \Omega\} \subseteq \mathcal{A}_{ms}.$$

Here Du denotes the vectorial Radon measure of the total variation (TV) of u.

The TV constraint requires any admissible u to be constant on any connected component of $\Omega \setminus \Gamma$. For practical convenience, we assume that there are finitely many such patches, say K number of different patches. Then the entire image domain is partitioned into

$$\Omega \setminus \Gamma = \bigcup_{k=0}^{K-1} \Omega_k.$$

On each patch Ω_k, one must have $u|_{\Omega_k} := C_k, \ k = 0, \ldots, K-1$, for a set of distinct intensity values $\mathbf{C} = (C_0, \ldots, C_{K-1})$. Then the RMS energy can be rewritten as

$$\mathcal{E}_{rms}[\mathbf{C}, \Gamma | u_o] = \frac{1}{2} \sum_{k=0}^{K-1} \mathcal{H}^1(\partial \Omega_k) + \lambda \sum_{k=0}^{K-1} \int_{\Omega_k} (C_k - u_o)^2 dx.$$

Notice that the factor $\frac{1}{2}$ is due to the double counting of any two adjacent patches. With successful level-set implementation, the RMS model is also frequently referred to as the *Chan–Vese model* for two phases, honoring its rediscovery from the viewpoint of robust active contours [15]. This particular multiphase model was first used in [26] and has shown that it can keep symmetry for triple junctions.

The main mechanism of the proposed model is to identify *multiple phases* by piecewise constant values, similar to those considered in [17, 26, 49]. However, there are two major differences:

(i) All the aforementioned prior works are in essence still built upon the framework of Mumford and Shah (or its reduced form as discussed above), while our proposed model is not strictly a Mumford–Shah-type model (though some equivalence will be established immediately below).

(ii) All the aforementioned prior works have employed the celebrated level-set technology of Osher and Sethian [39], while our new model adopts the phase field framework in material sciences and fluid mechanics. A level-set function offers remarkable efficiency and robustness for representing and computing free boundaries, yet (strictly speaking) does not participate in the modeling process, while a phase field function is indispensably part of the model itself.

To proceed, we label each phase component with an integer and define a *signature* function z by

$$z(x) = k \ \text{ if } \ x \in \Omega_k, \qquad k = 0, \dots, K-1.$$

In practice, phase extraction is of course the very opposite process from getting the signature function z. That is, one has to first obtain the signature function z before different phase patches Ω_k can be identified and extracted. For convenience, we shall also call z a *phase field*. We then propose the multiphase segmentation model *in this ideal scenario* by minimizing

$$E[\mathbf{C}, z|u_o] = \int_\Omega |Dz(x)| + \lambda \sum_{k=0}^{K-1} \int_\Omega (C_k - u_o)^2 \chi_{\{z=k\}} dx.$$

As in the RMS or the Chan–Vese model [13, 36], the intensity distribution variable $\mathbf{C}$ can be conditionally solved by the following: from any given phase field z,

$$C_k = \langle u_o \rangle_{\Omega_k} = \frac{1}{|\Omega_k|} \int_{\Omega_k} u_o(x)\, dx, \qquad i = 0, \dots, K-1. \tag{2.2}$$

Then the *ideal* model depends only on the phase field z:

$$E[z|u_o] = \int_\Omega |Dz(x)| + \lambda \sum_{k=0}^{K-1} \int_\Omega (C_k - u_o)^2 \chi_{\{z=k\}} dx. \tag{2.3}$$

The admissible class is simply $\mathcal{A} = \{z \in BV(\Omega) : z(x) \in \mathbb{Z} \text{ a.e.}\}$.

The main challenge of the proposed model arises from its mixture of the *continuous* TV Radon measure and the *discrete* constraint. Thus in the next subsection, this *ideal* model will be further polished in the framework of phase transitions and Γ-convergence.

Here we first emphasize that this ideal energy is somewhat equivalent to the piecewise constant Mumford–Shah functional. With the help of the signature function and the formulae for C_k's, $\mathcal{E}_{rms}$ depends only on Γ or z and can be rewritten as

$$\mathcal{E}_{rms}[\Gamma|u_o] = \frac{1}{2} \sum_{k=0}^{K-1} \mathcal{H}^1(\partial\{z = k\}) + \lambda \sum_{k=0}^{K-1} \int_\Omega (C_k - u_o)^2 \chi_{\{z=k\}} dx. \tag{2.4}$$

For any fixed number of phases K, the two functionals (2.3) and (2.4) are then equivalent, in the sense of

$$\mathcal{E}_{rms}[\Gamma|u_o] \le E[z|u_o] \le K\mathcal{E}_{rms}[\Gamma|u_o],$$

since

$$\int_\Omega |Dz| = \int_\Gamma \big|[z]\big| d\mathcal{H}^1 \quad \text{and} \quad 1 \le \big|[z]\big| < K.$$

In most applications (especially in medical imaging), for instance, $K \le 5$.

The difference between the two functionals (2.3) and (2.4) is also obvious, since the former weighs the jumps, while the latter does not. For example, consider a rectangular domain Ω and two disjoint disks Ω_1, Ω_2 in Ω with radius $1/2$. If we assign $z = 0$ on $\Omega_0 = \Omega \setminus (\Omega_1 \cup \Omega_2)$, $z = 1$ on Ω_1, and $z = 2$ on Ω_2, then $\sum_{k=0}^2 \mathcal{H}^1(\partial\Omega_k) = \frac{1}{2}\sum_{k=0}^2 \mathcal{H}^1(\partial\{z = k\}) = \frac{1}{2}(2\pi + \pi + \pi) = 2\pi$, but $\int_\Omega |Dz(x)| = 1\pi + 2\pi = 3\pi$. Thus, $\int_\Omega |Dz|$ is a *weighted length* of Γ. Recall that the TV Radon measure can be decomposed into

$$Dz = \nabla z + [z]\Big|_{S_z} \mathcal{H}^1 \llcorner S_z + \mathcal{C}_z,$$

corresponding to the Lebesgue continuous gradient, the jump set $S_z = \Gamma$ (or reduced boundary) with $[z] = z^+ - z^-$, and the singular Cantor measure. Now if the signature z is ideally piecewise constant, both the Lebesgue and Cantor components must vanish,

$$\int_\Omega |Dz| = \int_{S_z} \big|[z]\big| d\mathcal{H}^1,$$

which clearly shows the weighing nature of $\int_\Omega |Dz|$.

Weighing the object boundaries certainly makes the proposed *ideal* model depending upon the labels. But for a fixed number K of phases, the energies are more or less equivalent as just discussed. More importantly, it allows us to invoke the celebrated phase transition approach in material sciences and fluid dynamics, in order to successfully overcome the major challenge in reconciling the two very opposite characteristics of the segmentation problem: continuum vs. discreteness.

2.2. The sine-sinc model via Modica–Mortola phase transition. The objective functional (2.3)

$$E[z|u_o] = \int_\Omega |Dz(x)| + \lambda \sum_{k=0}^{K-1} \int_\Omega (C_k - u_o)^2 \chi_{\{z=k\}} dx$$

itself does not appear too complicated but becomes immensely baffling under the discrete constraint $z \in \mathbb{Z}$. *This is a very common scenario in integer or discrete programming.* For example, it is difficult to minimize this functional by any ordinary PDE approaches such as Euler–Lagrange equations or gradient-descent time marching.

We thus introduce its relaxed version via the celebrated model of Modica and Mortola [33] on phase transitions in material sciences and fluid mechanics. Recall that in the classical literature on phase transitions, the mixture of two immiscible and incompressible fluids are often modelled so that in equilibrium they separate into two phases with a minimal interface area. Cahn and Hilliard [7] first proposed to use a thin layer of continuous interface (i.e., *diffuse interface*) to model this separation. Later on Modica [34] proved that the Cahn–Hilliard model Γ-converges to the classical model. In another well-known paper [33], Modica and Mortola established that the diffuse-interface energy

$$F_\epsilon[z] = \int_\Omega \left[\epsilon |\nabla z|^2 + \frac{1}{\epsilon}\sin^2 \pi z\right] dx \quad \Gamma\text{-converges to} \quad \frac{4}{\pi}\int_\Omega |Dz(x)|$$

for phase fields that ultimately take only integer values.

Notice that in the Modica–Mortola model, the *discrete* constraint $z \in \mathbb{Z}$ has been *softly* enforced due to the sine potential regulated by the transition bandwidth ϵ in the denominator. In the present work, we adopt this Modica–Mortola diffuse-interface energy F_ϵ to approximate the ideal TV energy in $E[z|u_o]$. This model thus well integrates both the TV regularity and the integer constraint $z \in \mathbb{Z}$.

For the data-fitting term, instead of the ideal indicator $\chi_{\{z=k\}}$ or Kronecker's delta, we also propose to use a properly relaxed version to facilitate model analysis and computing. More specifically, we choose $\mathrm{sinc}^2(z-k)$ to match the sine potential in Modica and Mortola's phase transition energy,

$$G[z|u_o] = \sum_{k=0}^{K-1} \int_\Omega |C_k - u_o|^2 \mathrm{sinc}^2(z-k)\, dx.$$

Recall that the sinc function is defined as $\mathrm{sinc}(z) = \frac{\sin \pi z}{\pi z}$ for $z \in \mathbb{R}$. For a phase field z that takes almost only integer values, sinc leads to desirable approximations to the indicator functions of integer phases and is more appealing computationally. This is because (i) $\mathrm{sinc}(k) = \delta_k$ (Kronecker's delta) for $k \in \mathbb{Z}$, the so-called interpolating property in the celebrated theorem of Shannon interpolation [11, 19, 48]; and (ii) $\mathrm{sinc}(z)$ is an *entire* function for $z \in \mathbb{C}$, and when $z \in \mathbb{R}$,

$$\frac{d}{dz}\mathrm{sinc}(z) = \mathrm{O}\left(\frac{1}{|z|}\right) \quad \text{as } z \to \pm\infty.$$

Thus in particular, $\mathrm{sinc}\,(z) \in W^{1,\infty}(\mathbb{R})$ and is Lipschitz continuous. As a result, the sinc-approximation will facilitate both analysis and computation later on.

In combination, we have arrived at the *relaxed* version of the *ideal* multiphase segmentation model (2.3) with a given number K of phases:

$$\begin{aligned} E_\epsilon[z|u_o] &= F_\epsilon[z] + \lambda G[z|u_o] \\ &= \int_\Omega \left[\epsilon|\nabla z|^2 + \frac{1}{\epsilon}\sin^2 \pi z\right] dx + \lambda \sum_{k=0}^{K-1} \int_\Omega |C_k - u_o|^2 \mathrm{sinc}^2(z-k)\, dx. \end{aligned} \tag{2.5}$$

Here the values C_k's have been conditionally optimized by the following equation with any given phase field z (under the least-square principle):

$$C_k = C_k[z] = \begin{cases} \dfrac{\int_\Omega u_o \,\mathrm{sinc}^2(z-k)\, dx}{\int_\Omega \mathrm{sinc}^2(z-k)\, dx} & \text{if } \displaystyle\int_\Omega \mathrm{sinc}^2(z-k)\, dx > 0, \\ 0 & \text{otherwise.} \end{cases} \tag{2.6}$$

When $z(x)$ takes only integer values, this C_k indeed reproduces the value introduced in (2.2). If the denominator in (2.6) vanishes, since

$$\int_\Omega \mathrm{sinc}^2(z-k)\, dx = 0 \iff \mathrm{sinc}(z(x)-k) = 0 \text{ a.e } x \in \Omega \iff z(x) \in \mathbb{Z} \setminus \{k\},$$

we observe that the phase k is empty and redundant. Also in this case the particular value of $C_k[z]$ is unimportant, since the integral $\int_\Omega |u - C_k|^2 \mathrm{sinc}^2(z-k)\, dx$ vanishes.

This relaxed functional (2.5) is our proposed model, and there are essential differences between our model and the closely related work by Lie, Lysaker, and Tai [26] on the piecewise constant level-set method (PCLSM).

- We utilize $\sin(z(x)\pi) = 0$ as our constraints, while, in [26], $\Pi_{i=1}^{k}(z-i) = 0$ is used to get integer value. In our model, we do not need to predetermine the number of phase k, and $\sin(z)$ synchronizes well with $\mathrm{sinc}(z)$ function. The $\mathrm{sinc}(z)$ function is used in place of the usual Heaviside and delta functions.
- The PCLSM gives sharp edges by directly using $\int |\nabla u|$, while one may have to resolve singular layer issues related to renormalization of level sets. This proposed relaxed functional does not have any singular layer issues, and the boundary is identified as a transition band determined by the size of ϵ.

3. Γ-convergence of the model and existence of minimizers. In this section, we develop the necessary analysis of the proposed model. Following a brief review of the Γ-convergence theory, we first show that the relaxed model (2.5) converges to the original piecewise constant model (2.3) and then prove that optimal segmentation does exist for any fixed ϵ. Compactness of the minimizers for all ϵ's is also discussed in the end.

3.1. Brief review of Γ-convergence. Γ-convergence was first introduced by De Giorgi and Franzoni in [24] to facilitate analysis and approximation of PDEs and variational problems. Since then it has been widely applied to phase transition models in material sciences, the modeling of thin films or plates, homogenization of variational problems, and free discontinuity problems (see, e.g., [6, 31]). In image processing, the most influential application is Ambrosio–Tortorelli's Γ-convergence approximation to the Mumford–Shah functional [2]. The definition of Γ-convergence is as follows.

DEFINITION 3.1 (Γ-convergence). *Let X be a metric space and $\mathcal{F}_\epsilon : X \to \bar{\mathbb{R}}$ for $\epsilon > 0$. We say that $\mathcal{F}_\epsilon$ Γ-converges to $\mathcal{F}$ in X as $\epsilon \to 0$ and write $\mathcal{F}_\epsilon \xrightarrow{\Gamma} \mathcal{F}$ if the following two conditions hold for all $u \in X$:*

(i) *(liminf inequality) for every sequence (u_ϵ) converging to u,*

$$\mathcal{F}(u) \le \liminf_{\epsilon \to 0} \mathcal{F}_\epsilon(u_\epsilon);$$

(ii) *(limsup inequality) there exists a sequence (u_ϵ) converging to u such that*

$$\mathcal{F}(u) \ge \limsup_{\epsilon \to 0} \mathcal{F}_\epsilon(u_\epsilon).$$

The most important properties of Γ-convergence are summarized by the following theorem. We refer the reader to [1, 6, 31] for further discussion.

THEOREM 3.2. Γ*-convergence has the following properties:*

(i) *(spatial stability of the limit) the* Γ*-limit $\mathcal{F}$ is lower semicontinuous;*

(ii) *(stability under continuous perturbations) if $\mathcal{F}_\epsilon \xrightarrow{\Gamma} \mathcal{F}$ and $\mathcal{G}$ is continuous, then $\mathcal{F}_\epsilon + \mathcal{G} \xrightarrow{\Gamma} \mathcal{F} + \mathcal{G}$;*

(iii) *(stability of minimizing sequences) if $\mathcal{F}_\epsilon \xrightarrow{\Gamma} \mathcal{F}$ and v_ϵ minimizes $\mathcal{F}_\epsilon$, then every cluster point of (v_ϵ) minimizes $\mathcal{F}$.*

Let us briefly comment on these three properties. Property (i) reveals the necessary condition for designing Γ-convergence approximation to a target functional. Property (ii) paves the way to extending existing Γ-convergence schemes, which is particularly helpful in the current work. Property (iii) reveals the real essence of the entire machinery of Γ-convergence, by which the minimization of a touchy objective $\mathcal{F}$ is tamed or relaxed by a family of better behaved objectives $\mathcal{F}_\epsilon$.

Directly benefiting the current work is the following remarkable theorem in the original paper of Modica and Mortola [33], which historically has played significant roles in the theories of Γ-convergence, phase transitions, and the Cahn–Hilliard model.

THEOREM 3.3 (Modica and Mortola [33]). *Define* $\mathcal{S} = \{z \in BV(\mathbb{R}^n) : z(x) \in \mathbb{Z}$ *a.e.* $x\}$, *and*

$$F_\epsilon(z) := \begin{cases} \displaystyle\int_{\mathbb{R}^n} \left[\epsilon|\nabla z(x)|^2 + \frac{1}{\epsilon}\sin^2(\pi z(x))\right] dx & \text{for } z \in H^1(\mathbb{R}^n) \cap L^1(\mathbb{R}^n), \\ +\infty & \text{for } z \in L^1(\mathbb{R}^n) \setminus H^1(\mathbb{R}^n), \end{cases}$$

$$F(z) := \begin{cases} \displaystyle\frac{4}{\pi}\int_{\mathbb{R}^n} |Dz(x)| & \text{for } z \in S(\mathbb{R}^n), \\ +\infty & \text{for } z \in L^1(\mathbb{R}^n), \text{ but } z \notin S(\mathbb{R}^n). \end{cases}$$

Then the functional F_ϵ Γ*-converges to* F *as* $\epsilon \to 0$ *in* $L^1(\mathbb{R}^n)$.

We note that the domain $\mathbb{R}^n$ can be replaced by any regular open bounded domain Ω, which is the case in the current application. Theorem 3.3 was originally conjectured by De Giorgi and then proven by Modica and Mortola [33] in 1977, shortly after the notion of Γ-convergence was introduced in [24]. The connection with the Cahn–Hilliard model was established in Modica [34].

3.2. Γ-convergence of the sine-sinc model. In image processing, the image range is often bounded by $u_o \in [0, 1]$ in the analog setting and $u_o \in [0, 255]$ in the digital setting with 8 bits. Therefore, we assume $u_o \in L^\infty(\Omega)$ for technical clarity.

In the Modica–Mortola sine-sinc model proposed in (2.5),

$$\begin{aligned} E_\epsilon[z|u_o] &= F_\epsilon[z] + \lambda G[z|u_o] \\ &= \int_\Omega \left[\epsilon|\nabla z|^2 + \frac{1}{\epsilon}\sin^2 \pi z\right] dx + \lambda \sum_{k=0}^{K-1} \int_\Omega |C_k - u_o|^2 \operatorname{sinc}^2(z-k)\, dx, \end{aligned}$$

the first term F_ϵ has already been proven to Γ-converge to F in [33]. In this subsection, we show that the fitting term G is continuous in $L^1(\Omega)$.

In what follows, we shall use the notation $\omega(x|z)$ to denote a spatial function $\omega(\cdot|z)$ that depends on the given phase field $z = z(x)$. Such dependence could be *local* in the form of $g(x, z(x))$, or *global* in the form of $g(x, J[z])$, where $J[z]$ is a functional on z. The following general theorem gives a unified foundation for the proof of Γ-convergence of the proposed model.

THEOREM 3.4. *Suppose that*

(i) $\varphi : \mathbb{R} \to \mathbb{R}$ *is Lipschitz continuous with* $|\varphi(x) - \varphi(y)| \le L|x - y|$,

(ii) $\|w(\cdot|z_n) - w(\cdot|z)\|_{L^\infty(\Omega)} \to 0$ *as* $\|z_n - z\|_{L^1(\Omega)} \to 0$,

(iii) $\|w(\cdot|z)\|_{L^\infty(\Omega)} \le M$ *for some positive* M *and for all* $z \in L^1(\Omega)$;

then $g[z] = \int_\Omega w(x|z)\varphi(z)\, dx$ *is continuous for* $z \in L^1(\Omega)$.

Proof. Let $\{z_n\}$ be a sequence converging to z: $z_n \to z$ in $L^1(\Omega)$. Then

$$\begin{aligned} |g[z_n] - g[z]| &\le \left|\int_\Omega w(x|z_n)\varphi(z_n) - w(x|z)\varphi(z_n) dx\right| + \left|\int_\Omega w(x|z)\varphi(z_n) - w(x|z)\varphi(z) dx\right| \\ &\le \|w(x|z_n) - w(x|z)\|_{L^\infty(\Omega)} \|\varphi(z_n)\|_{L^1(\Omega)} + M\int_\Omega |\varphi(z_n) - \varphi(z)| dx \\ &\le L\|z_n\|_{L^1(\Omega)} \|\omega(x|z_n) - w(x|z)\|_{L^\infty(\Omega)} + ML\|z_n - z\|_{L^1(\Omega)}. \end{aligned}$$

Both terms tend to zero as $\|z_n - z\|_{L^1(\Omega)} \to 0$ by assumption (ii). ∎

This theorem can be applied to establish that $C_k[z]$'s are continuous, and eventually that $G[z|u_o]$ is continuous as well.

COROLLARY 3.5. *Suppose $z_n \to z$ in L^1 and $\int_\Omega \operatorname{sinc}^2(z(x)-k)dx \neq 0$. Then $C_k(z)$ defined in (2.6) is continuous in z, i.e., $C_k[z_n] \to C_k[z]$.*

This is directly proven by Theorem 3.4 with $w(x) = u_o(x)$ (for the denominator) and $w(x) = 1$ (for the numerator), as well as $\varphi(z) = \sin^2(z(x)-k)$.

COROLLARY 3.6 (degenerate case). *If $\varphi(z(x)) = 0$ a.e., then $g[z] = 0$ and condition* (ii) *in Theorem* 3.4 *can be dropped.*

It simply comes from the definition of $g[z]$ and conditions (i) and (iii):

$$|g[z_n]| \le M \int_\Omega |\varphi(z_n)| = M \int_\Omega |\varphi(z_n) - \varphi(z)|dx \le ML \int_\Omega |z_n - z|dx \to 0.$$

PROPOSITION 3.7. *The fitting functional G is continuous in $L^1(\Omega)$:*

$$G[z|u_o] = \sum_{k=0}^{K-1} \int_\Omega |C_k - u_o|^2 \operatorname{sinc}^2(z-k)\,dx$$

with

$$C_k = C_k[z] = \begin{cases} \frac{\int_\Omega u_o \operatorname{sinc}^2(z-k)\,dx}{\int_\Omega \operatorname{sinc}^2(z-k)\,dx} & \text{if } \int_\Omega \operatorname{sinc}^2(z-k)\,dx > 0, \\ 0 & \text{otherwise.} \end{cases}$$

Proof. Let $w(x|z) = (u_o(x) - C_k[z])^2$ and $\varphi(z) = \operatorname{sinc}^2(z-k)$ for $z \in L^1(\Omega)$. We now show that $G[z|u_o]$ indeed satisfies all three conditions of Theorem 3.4. Condition (i) is clear, since φ is Lipschitz continuous. For (ii), let $\{z_n\}$ be a converging sequence $z_n \to z$ in $L^1(\Omega)$. Then

$$\begin{aligned} |w(x|z_n) - w(x|z)| &= |(C_k[z_n] - u_o(x))^2 - (C_k[z] - u_o(x))^2| \\ &\le |C_k[z_n] + C_k[z] - 2u_o(x)||C_k[z_n] - C_k[z]| \\ &\le 4\|u_o\|_{L^\infty(\Omega)}|C_k[z_n] - C_k[z]|, \end{aligned}$$

and $|C_k[z_n] - C_k[z]| \to 0$ from the continuity of C_k in Corollary 3.5. Thus $|w(x|z_n) - w(x|z)| \to 0$. For (iii), notice that $|C_k[z]| \le \|u_o\|_{L^\infty(\Omega)}$ for all z. Then

$$w(x|z) \le (\|u\|_{L^\infty(\Omega)} + |C_k[z]|)^2 \le (2\|u_o\|_{L^\infty(\Omega)})^2 \quad \text{for all } x \in \Omega.$$

Therefore, by Theorem 3.4, $G[z|u_o]$ is continuous in $L^1(\Omega)$. ∎

Finally, the Γ-convergence of the Modica–Mortola sine-sinc model becomes evident from the combination of Proposition 3.7, Theorem 3.3, and Theorem 3.2.

THEOREM 3.8 (Γ-convergence). *E_ϵ Γ-converges to E w.r.t. $L^1(\Omega)$ topology.*

3.3. Existence of minimizers of E_ϵ. In this subsection we show that for each ϵ, a minimizer to E_ϵ does exist. We shall also briefly discuss the compactness of a sequence of minimizers for all ϵ's.

THEOREM 3.9 (existence of minimizers). *Suppose the given image $u_o \in L^2(\Omega)$ and denote the admissible space for K-phase segmentation by*

$$\mathcal{A}_K = \{z \in H^1(\Omega) : -1/2 < z < K - 1/2\}.$$

Then for each $\epsilon > 0$, there exists a minimizer of E_ϵ in $\mathcal{A}_K$.

Proof. We first show that the infimum is finite. Consider the uniform phase $z \equiv 0 \in \mathcal{A}_K$. Then the Modica–Mortola energy $F_\epsilon[z] = 0$, and $C_0 = \frac{1}{|\Omega|}\int_\Omega u_o(x)dx < \infty$, while $C_k = 0$ for $k = 1, \dots, K-1$. Therefore,

$$E_\epsilon[0|u_o] = \lambda \int_\Omega |C_0 - u_o(x)|^2 \, dx < \infty, \tag{3.1}$$

and since $E_\epsilon[\,\cdot\,|u_o] \geq 0$, the claim is proved.

Let $\{z_n\}$ be a minimizing sequence for E_ϵ in $\mathcal{A}_K$. Since $\sup_n \int_\Omega |\nabla z_n|^2 \, dx < \infty$ from the Modica–Mortola energy, as well as $-1/2 < z_n < K - 1/2$, the sequence $\{z_n\}$ must be precompact in $L^1(\Omega)$ by Rellich and Kondrachov's compactness theorem. There thus exists a subsequence of $\{z_n\}$, which is still denoted by $\{z_n\}$ after relabelling to simplify notations, such that

$$z_n \to z^* \text{ in } L^2(\Omega) \text{ for some } z^* \in L^2(\Omega).$$

As a result, one has the weak convergence for the gradient fields:

$$\nabla z_n \to \nabla z^* \text{ weakly in } L^2(\Omega).$$

Then, by the lower semicontinuity of the L^2-norm under the weak topology,

$$\int_\Omega |\nabla z^*|^2 \, dx \leq \liminf_{n\to\infty} \int_\Omega |\nabla z_n|^2 \, dx. \tag{3.2}$$

For the other two terms with sine and sinc functions, convergence follows from Lebesgue's dominated convergence theorem (LDCT) as shown below. First, possibly with another round of subsequence refinement and relabelling, one can further assume that $z_n \to z^*$ a.e. Then $\sin^2 \pi z_n \to \sin^2 \pi z^*$ a.e., and by LDCT,

$$\int_\Omega \sin^2 \pi z_n \, dx \to \int_\Omega \sin^2 \pi z^* \, dx. \tag{3.3}$$

Similarly, $\mathrm{sinc}^2\pi(z_n - k) \to \mathrm{sinc}^2\pi(z^* - k)$ a.e. for $k = 0, \dots, K-1$. By LDCT, one has $\int_\Omega \mathrm{sinc}^2\pi(z_n - k)\, dx \to \int_\Omega \mathrm{sinc}^2\pi(z^* - k)\, dx$, and

$$\int_\Omega u_o(x)\mathrm{sinc}^2\pi(z_n - k)\, dx \to \int_\Omega u_o(x)\mathrm{sinc}^2\pi(z^* - k)\, dx,$$

since $u_o \in L^2(\Omega) \subset L^1(\Omega)$. Consequently, if $\int_\Omega \mathrm{sinc}^2\pi(z^* - k)\, dx > 0$ for kth phase, then $(C_k[z_n])_n$ must be a bounded sequence. Since $u_o \in L^2(\Omega)$, by LDCT, as $n \to \infty$,

$$\int_\Omega |u_o - C_k[z_n]|^2 \mathrm{sinc}^2\pi(z_n - k)\, dx \to \int_\Omega |u_o - C_k[z^*]|^2 \mathrm{sinc}^2\pi(z^* - k)\, dx. \tag{3.4}$$

If, on the other hand, $\mathrm{sinc}^2\pi(z^* - k) = 0$ a.e., then

$$\int_\Omega |u_o - C_k[z^*]|^2 \mathrm{sinc}^2(z^* - k)\, dx = 0 \leq \liminf_{n\to\infty} \int_\Omega |u_o - C_k[z_n]|^2 \mathrm{sinc}^2(z^* - k)\, dx. \tag{3.5}$$

Finally, in combination of (3.2), (3.3), (3.4), and (3.5), we have

$$E_\epsilon[z^*|u_o] \leq \liminf_{n\to\infty} E_\epsilon[z_n|u_o] \leq \inf_{z\in\mathcal{A}_K} E_\epsilon[z|u_o],$$

and the limit z^* has to be a minimizer of E_ϵ. This completes the proof. ∎

Notice that in this theorem, we have even allowed the given image $u_o \in L^2(\Omega)$, instead of $u_o \in L^\infty(\Omega)$, which is the default assumption throughout the work.

Finally, we briefly comment on the compactness or stability of the sequence of minimizers from the Γ-convergence approximation.

THEOREM 3.10 (compactness of the sequence of minimizers). *Let z_ϵ minimize E_ϵ for each $\epsilon > 0$. Then there exist a subsequence $(z_{\epsilon'})$ of (z_ϵ) and some $z \in L^1(\Omega)$ such that $z_{\epsilon'} \longrightarrow z$ in $L^1(\Omega)$ as $\epsilon' \to 0$, and z minimizes E.*

Proof. By the Cauchy–Schwarz inequality,

$$\begin{aligned} E_\epsilon[z|u_o] \geq F_\epsilon[z] &= \int_\Omega \left[\epsilon|\nabla z|^2 + \frac{1}{\epsilon}\sin^2 \pi z\right] dx \\ &\geq 2\int_\Omega |\nabla z||\sin \pi z| dx = \int_\Omega |\nabla(H(z))| dx. \end{aligned} \tag{3.6}$$

Here $H : (-\frac{1}{2}, K - \frac{1}{2}) \to \mathbb{R}$ satisfies $H'(r) = 2|\sin \pi r|$ and $H(0) = 0$. By (3.1), there exists $M > 0$ such that $E_\epsilon[z_\epsilon|u_o] \leq M$ for all ϵ. By (3.6), the sequence of functions $(h_\epsilon(x) = H(z_\epsilon(x)))_\epsilon$ must be bounded in $BV(\Omega)$, and thus precompact in $L^1(\Omega)$. By subsequence refinement, one can assume that there exists a subsequence $h_{\epsilon'} \to h$ a.e. for some $h \in L^1(\Omega)$. Since $H(r)$ is continuous and strictly monotone, it admits a continuous inverse. Thus one has $z_{\epsilon'}(x) \longrightarrow z(x) = H^{-1}(h(x))$ a.e. Since $z_\epsilon \in (-\frac{1}{2}, K - \frac{1}{2})$ is uniformly bounded for ϵ, one must have $z_{\epsilon'} \to z$ in $L^1(\Omega)$ by LDCT. Then the rest of the theorem follows from Theorem 3.2. ∎

4. Computation and experiments. In this section, we develop the computational schemes for the proposed model. The major difficulty arises from the fact that the Modica–Mortola sine-sinc functional is nonconvex. In this paper, we apply the method of convex splitting or the concave-convex procedure (CCCP) for robustly computing the local minima of the model. After a brief review on the CCCP method, we detail our computational strategies, and test the schemes on some generic examples involving both synthetic and natural images.

4.1. Review of the CCCP. There are growing interests in how to solve nonconvex functions efficiently. In [22] in the setting of gradient flows, Eyre proposed to split nonconvex functions into two functions, contractive and expansive. It included computational examples of the Cahn–Hilliard equation with different time steps. More analysis on the numerical algorithms for the Cahn–Hilliard or Allen–Cahn equations were studied by Vollmayr-Lee and Rutenberg in [54], where unconditionally stable time step was explored. The idea of convex splitting is also applied to the Cahn–Hilliard inpainting by Bertozzi, Esedoglu, and Gilette [4].

Independent of the computational PDE literature, on the other hand, the similar idea of convex splitting was also explored by Yuille and Rangarajan [55] in a more general setting of neural computation, where the method has been termed the CCCP. The method has found many important applications in computer vision and neural computation.

THEOREM 4.1 (Yuille and Rangarajan [55]). *Let $\mathcal{E}(\vec{x})$ with $\vec{x} \in \mathbb{R}^n$ be an energy function with a bounded Hessian. Then it can be decomposed into the sum of a convex function and a concave function.*

THEOREM 4.2 (Yuille and Rangarajan [55]). *Consider an energy function which is bounded below and is an addition of convex and concave functions:*

$$\mathcal{E}(\vec{x}) = \mathcal{E}_{convex}(\vec{x}) + \mathcal{E}_{concave}(\vec{x}).$$

Then the discrete iterative CCCP algorithm given by

$$\nabla \mathcal{E}_{convex}(\vec{x}^{n+1}) = -\nabla \mathcal{E}_{concave}(\vec{x}^{n}), \qquad n = 0, 1, \ldots, \tag{4.1}$$

is guaranteed to monotonically decrease the energy $\mathcal{E}(\vec{x})$ as a function of time and to converge to a local minimum or a saddle point of $\mathcal{E}(\vec{x})$.

We briefly comment on these results for our application. First, notice that (4.1) is solvable only when

$$\text{Range}(-\nabla \mathcal{E}_{concave}) \subseteq \text{Range}(\nabla \mathcal{E}_{convex}). \tag{4.2}$$

In particular, the condition holds when $\text{Range}(\mathcal{E}_{convex}) = \mathbb{R}^n$, the entire space. The solvability condition (4.2) implies that, in some sense, the convex part must be *stronger* than or *dominant* over the concave part, which is often (practically) true for energy minimization problems when the function f is bounded below and $f \to \infty$ as $|\vec{x}| \to \infty$.

Second, in the present context, the CCCP should be applied to the functional setting instead of the function in $\mathbb{R}^n$. Therefore, the gradients in (4.1) should be naturally replaced by the Fréchet derivatives of the functionals. In our application, the functional is indeed Fréchet differentiable. (In general, the CCCP iteration (4.1) can also be based upon the subgradients of convex function(al)s, since the splitting yields convex components.)

4.2. Details of the computational scheme. To numerically solve (2.5),

$$\begin{aligned} E_\epsilon[z|u_o] &= F_\epsilon[z] + \lambda G[z|u_o] \\ &= \int_\Omega \left[\epsilon |\nabla z|^2 + \frac{1}{\epsilon} \sin^2 \pi z \right] dx + \lambda \sum_{k=0}^{K-1} \int_\Omega |C_k - u_o|^2 \text{sinc}^2(z-k)\, dx, \end{aligned}$$

we compute $E_\epsilon[z, \mathbf{C}|u_o]$ regarding z and $\mathbf{C}$ as independent variables. This allows the application of the alternating minimization (AM) scheme, i.e., to alternatingly optimize the two conditional energies $E_\epsilon[z|\mathbf{C}, u_o]$ and $E_\epsilon[\mathbf{C}|z, u_o]$, under the iterations of $z^n \to \mathbf{C}^n \to z^{n+1}$ given by

$$\mathbf{C}^n = \text{argmin}\, E_\epsilon[\mathbf{C}|z^n, u_o], \tag{4.3}$$

$$z^{n+1} = \text{argmin}\, E_\epsilon[z|\mathbf{C}^n, u_o]. \tag{4.4}$$

It is well known (i.e., Vogel [53] or Shen [44]) that the AM scheme is monotone:

$$E_\epsilon[z^{n+1}, \mathbf{C}^{n+1}|u_o] \le E_\epsilon[z^n, \mathbf{C}^n|u_o].$$

To minimize (4.3), one simply computes at the pixel level,

$$C_k = \frac{\sum_i \sum_j u_{i,j} \text{sinc}^2(z^n_{i,j} - k)}{\sum_i \sum_j \text{sinc}^2(z^n_{i,j} - k)}, \qquad k = 0, \ldots, K-1, \tag{4.5}$$

where $z^n_{i,j}$ denotes computational phase field on the Cartesian image domain. There is a study on treating C_k as an independent variable in image segmentation [50]. However, we update C_k in every alternating step, as in any usual AM schemes.

We apply the CCCP to minimize $E_\epsilon[z|\mathbf{C}^n, u_o]$ in (4.4). For convenience, we shall omit the superscript n of $\mathbf{C}^n$ hereafter. First, we add simple convex functionals to express E_ϵ as the difference of two convex functionals. By noticing that if f is a

convex function from $\mathbb{R}$ to $\mathbb{R}$, then the functional $F(u) = \int_\Omega f(u(x))dx$ is a convex functional, we have the following proposition.

PROPOSITION 4.3. *Let $F(u) = \int_\Omega f(u(x))dx$, where $f \in C^2(\mathbb{R})$ and $f'' \geq -\gamma$ for some $\gamma \geq 0$. Define the splitting*

$$F(u) = \int_\Omega \left(f(u) + \frac{\gamma}{2}u^2\right) dx - \int_\Omega \frac{\gamma}{2}u^2 dx := F^1(u) - F^2(u).$$

Then both F^1 and F^2 are convex.

The proof is trivial, since $f_1''(u) \geq 0$ if $f_1(u) = f(u) + \frac{\gamma}{2}u^2$. We now apply this splitting technique to the proposed model E_ϵ in (2.5).

We shall add two sets of terms, one for the nonconvex Modica–Mortola functional F_ϵ and the other for the nonconvex fitting term G. For the functional F_ϵ, we add $\frac{\pi^2}{\epsilon}\int_\Omega |z|^2\,dx$ by noticing that $\frac{d^2}{dz^2}\sin^2 \pi z \geq -2\pi^2$:

$$F_\epsilon[z] = \left(F_\epsilon[z] + \frac{\pi^2}{\epsilon}\int_\Omega |z|^2\,dx\right) - \frac{\pi^2}{\epsilon}\int_\Omega |z|^2\,dx := F_\epsilon^1[z] - F_\epsilon^2[z].$$

Similarly, the fitting term G in (2.5) can be split into $G[z|\mathbf{C}, u_o] = G^1[z|\mathbf{C}, u_o] - G^2[z|\mathbf{C}, u_o]$, where

$$G^1[z|\mathbf{C}, u_o] = G[z|\mathbf{C}, u_o] + \frac{\pi^2}{3}\sum_{k=0}^{K-1}\int_\Omega |u_o - C_k|^2|z-k|^2\,dx,$$
$$G^2[z|\mathbf{C}, u_o] = \frac{\pi^2}{3}\sum_{k=0}^{K-1}\int_\Omega |u_o - C_k|^2|z-k|^2\,dx,$$

since $\frac{d^2}{dz^2}\mathrm{sinc}^2 z \geq \frac{-2\pi^2}{3}$.

Thus, the functional (2.5) becomes $E_\epsilon = E_\epsilon^1 - E_\epsilon^2 = (F_\epsilon^1 + \lambda G^1) - (F_\epsilon^2 + \lambda G^2)$. We then apply the CCCP algorithm (4.1) via the Fréchet derivative:

$$(F_\epsilon^1 + \lambda G^1)'(z^{n+1}) = (F_\epsilon^2 + \lambda G^2)'(z^n). \tag{4.6}$$

Under integration by parts, (4.6) is equivalent to the PDE

(4.7)
$$\left[-2\epsilon\Delta z^{n+1} + \frac{\pi}{\epsilon}\sin 2\pi z^{n+1}\right] + \frac{2\pi^2}{\epsilon}z^{n+1}$$
$$+ \left[\lambda\sum_{k=0}^{K-1}|u_o - C_k|^2\frac{d}{dz}\mathrm{sinc}^2(z^{n+1}-k)\right] + \lambda\sum_{k=0}^{K-1}|u_o - C_k|^2\frac{2\pi^2}{3}(z^{n+1}-k)$$
$$= \frac{2\pi^2}{\epsilon}z^n + \lambda\sum_{k=0}^{K-1}|u_o - C_k|^2\frac{2\pi^2}{3}(z^n - k).$$

Here the terms in the square brackets come from the Euler–Lagrange equation of E_ϵ.

Numerically, the Laplacian term Δz^{n+1} is computed by the standard 5-pixel stencil, i.e., with h denoting the grid size,

$$h^2\Delta z = z_{i-1,j} + z_{i,j-1} + z_{i+1,j} + z_{i,j+1} - 4z_{i,j}.$$

This could further lead to the Jacobi-type iteration when the central pixel $z_{i,j}$ is assigned to the time step $n+1$, while the other four neighbors still stay at the step n.

We now elaborate on how to develop proper *linearization* schemes for the nonlinear terms that involve sine and sinc. For the second term with $\sin 2\pi z_{i,j}^{n+1}$, we use $\frac{\sin 2\pi z_{i,j}^n}{z^n} z_{i,j}^{n+1} = 2\pi z_{i,j}^{n+1} \mathrm{sinc}(2z_{i,j}^n)$ for linearization. This is inspired by the closely related problem of finding a solution to the nonlinear equation $\sin x = a$ for a given $a \in (0,1)$ and on $[0, \pi/2]$. An effective iteration scheme is given by the same linearization technique:

$$\frac{\sin x^n}{x^n} x^{n+1} = a, \quad \text{or equivalently,} \quad x^{n+1} = a\frac{x^n}{\sin x^n} = \Phi(x^n),$$

where $\Phi(x) = \frac{ax}{\sin x}$. A remarkable property is that for $x \in [0, \pi/2]$ and any given $a \in (0,1)$, Φ is a contractive mapping, i.e., $\max_{x\in[0,\pi/2]} |\Phi'(x)| \le a < 1$. In particular, the linearization iteration indeed leads to a unique fixed point x^*, $\frac{ax^*}{\sin x^*} = x^*$, by Picard's fixed point theorem. In addition, to avoid singularities in the denominators, small value δ, $\delta \ll 1$ (e.g., $\delta = 10^{-16}$, the MATLAB constant), is often added for numerical robustness.

For the fourth term on the left that involves the derivative of the sinc function, we similarly linearize it to

$$\frac{d}{dz}\mathrm{sinc}^2(z_{i,j}^{n+1} - k) = 2\,\mathrm{sinc}(z_{i,j}^n - k) \left[\frac{\pi z \cos \pi z - \sin \pi z}{\pi z^3}\right]_{z=z_{i,j}^n - k} (z_{i,j}^{n+1} - k).$$

Combining all the above steps of finite-difference discretization and function linearization, in the case when the Jacobi iteration is adopted for the Laplacian, we attain the following iteration scheme: at each step n,

$$\begin{aligned} &\left\{ 8\epsilon + \frac{\pi}{\epsilon}\left(\frac{\sin 2\pi z_{i,j}^n}{z_{i,j}^n} + 2\pi\right) \right. \\ &\quad \left. + \lambda \sum_{k=0}^{K-1} |u_{i,j} - C_k|^2 \left(\frac{2\pi^2}{3} + 2\mathrm{sinc}(z_{i,j}^n - k)\frac{\frac{d}{dz}\mathrm{sinc}(z_{i,j}^n - k)}{z_{i,j}^n - k}\right) \right\} z_{i,j}^{n+1} \\ &= 2\epsilon(z_{i-1,j}^n + z_{i,j-1}^n + z_{i+1,j}^n + z_{i,j+1}^n) + \frac{2\pi^2}{\epsilon} z_{i,j}^n \\ &\quad + \lambda \sum_{k=0}^{K-1} |u_{i,j} - C_k|^2 \left(\frac{2\pi^2}{3} z_{i,j}^n + 2k\mathrm{sinc}(z_{i,j}^n - k)\frac{\frac{d}{dz}\mathrm{sinc}(z_{i,j}^n - k)}{z_{i,j}^n - k}\right). \end{aligned} \tag{4.8}$$

The Neumann natural boundary condition is imposed along the boundary of the image domain. The detailed numerical analysis on the CCCP method augmented with all the above linearization techniques is interesting but foreseeably involved. This offers an intriguing open problem to the numerical analysis community.

Finally, once the phase field z is solved from the system, in order to extract each phase or segment, we apply the hard thresholding decision rule: $k - \frac{1}{2} \le z < k + \frac{1}{2}$ for each individual kth phase. A simple morphological transformation (opening) is also employed to remove any spurious dots due to the hard thresholding. Instead of hard thresholding, it is also possible to adopt a slightly more complex local decision rule based on windowing, which will then make the morphological operation obsolete.

4.3. Numerical experiments. In this subsection, we present some generic experimental results based on the theories and computational schemes developed above. In all the experiments, a given image is always normalized to the canonical gray interval $[0,1]$, and the bandwidth parameter (or the diffuse scale) ϵ is in the order of a

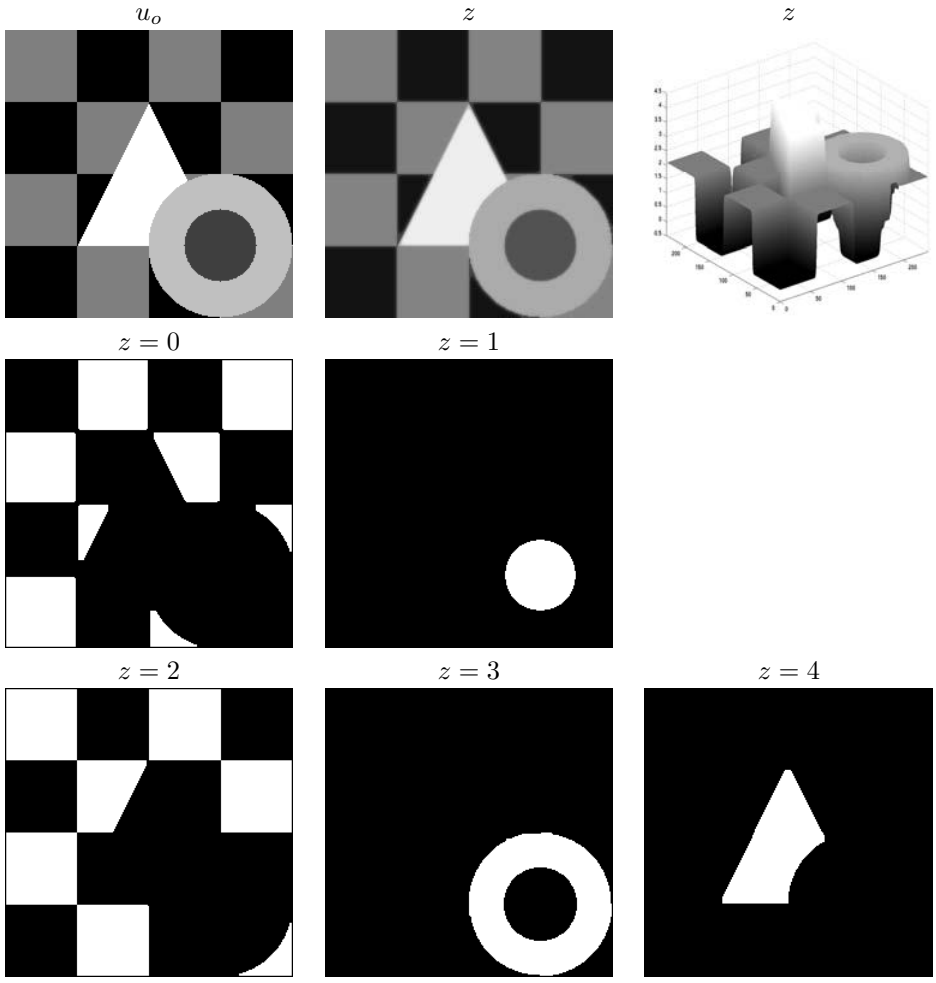

FIG. 4.1. *A complex synthetic image u_o with multiple objects and several generic visual structures. Image size is 240×240, $\epsilon = 2$ (pixels), and $\lambda = 15$ (scaled by the grid size). The calculated C_k values are $0, 0.16, 0.50, 0.74, 0.97$, respectively.*

few pixels. Furthermore, inspired by the simulated annealing technique in stochastic image processing (see, e.g., Geman and Geman [23]) and Gibbs' random fields, we have also experimented with dynamically decreasing ϵ's to speed up convergence, for example, adopting ϵ_1 in the first 50 iterations, while $\epsilon_2 = \epsilon_1/2$ for the rest.

Regarding the initial guess for the phase field z, we have typically adopted random values between -0.5 to $K + 0.5$ as mentioned in the theory (the set $\mathcal{A}_K$). For complex images with large variances in homogeneous regions or with many phases, weak supervision can be used for the initial values; i.e., initial C_k values can be estimated from the assigned supervised "seed" regions. For more discussion on weak supervision and automated stochastic supervision (based on patch statistics), we refer the reader to the recent works of Shen [46], Li et al. [28], and Li and Perona [27].

The first example, Figure 4.1, shows a complex synthetic image that contains several generic visual structures, including an internal hole, occlusion and stacked objects, T-junctions, singular junctions where multiple objects (or phases) meet, as

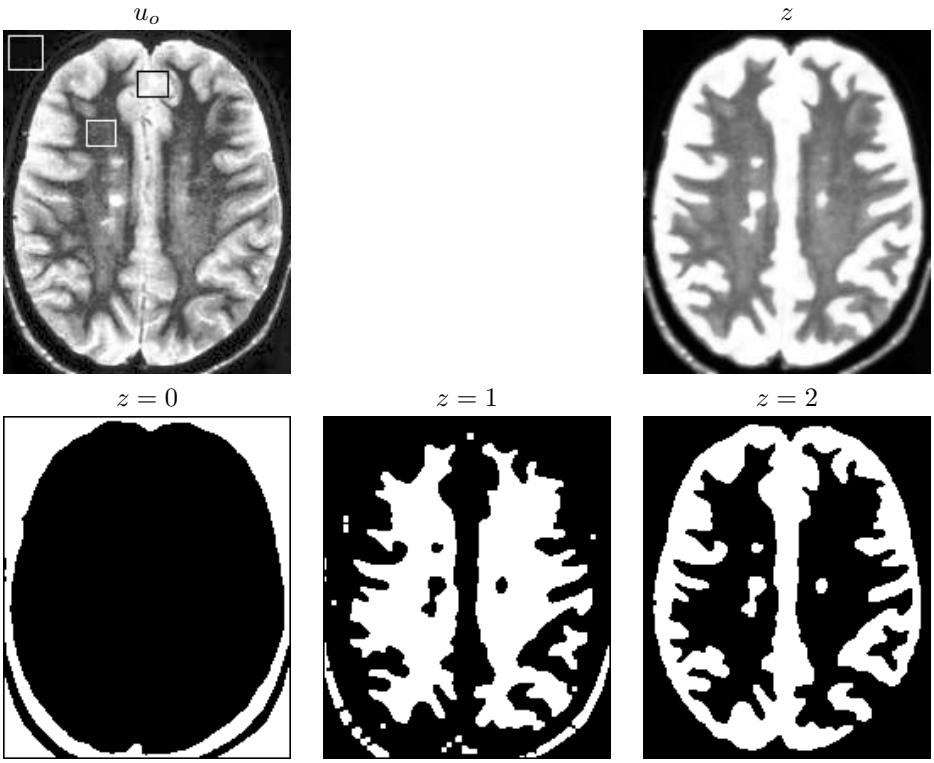

FIG. 4.2. *The performance of the proposed Modica–Mortola sine-sinc model to the segmentation of an MRI brain image. Shown on top of the original image (upper left) are the three "seed" phase patches which are often easily supervised by a radiologist. The resolution details in the segmented phases depend upon the bandwidth parameter* ϵ *(*$\epsilon = 2$ *(pixels) for this particular output).*

well as thin passages that reveal the bottleneck effect (see the recent work of Kohn and Slastikov [25] in material sciences for asymptotic bottleneck analysis in phase transitions). In this case, with $K = 5$ phases, initial condition is weakly supervised.

Figure 4.2 shows the application of the proposed model to an MRI brain image. Even though the intensities fluctuate severely and the boundaries are complex, the proposed method has done a satisfactory job in separating the major different phases. Shown on top of the original image are the three small patches that are in practice easily supervised by a radiologist.

In Figure 4.3, it is shown that the proposed model works well with a noisy image containing a generic T-junction, a universal singular structure crucial in visual perception (see, e.g., Nitzberg, Mumford, and Shiota [37]). The level of noise is exaggerated to show the stability of the proposed method.

The next couple of examples, Figures 4.4 and 4.5, involve color images for which the RGB color space has been employed. We have adopted the Euclidean metric of three color channels as in [51]:

$$|u_o^R - C_k^R|^2 + |u_o^G - C_k^G|^2 + |u_o^B - C_k^B|^2,$$

where u_o^R, u_o^G, u_o^B correspond to the red, green, and blue channels of the given color image u_o. (This may not be optimal for color perception; see, e.g., [10, 12]). In addition, the following two examples deal with either blurry edges or the absence of

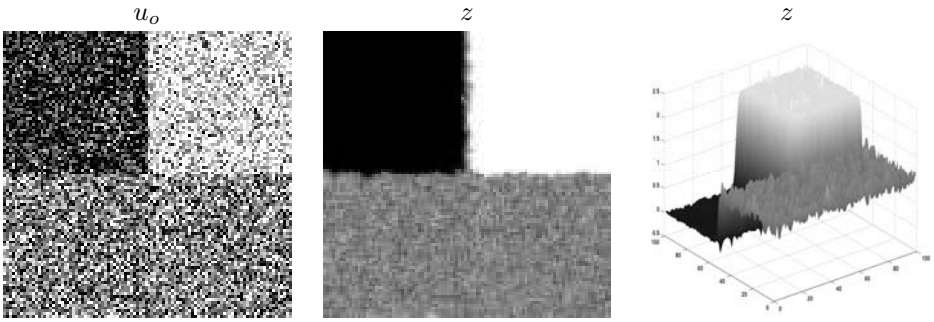

FIG. 4.3. *A noisy synthetic image u_o containing a generic T-junction (left); the phase field z computed by the proposed sine-sinc model (middle and right). The example shows that the model is robust to noise and reconstructs well the geometry.*

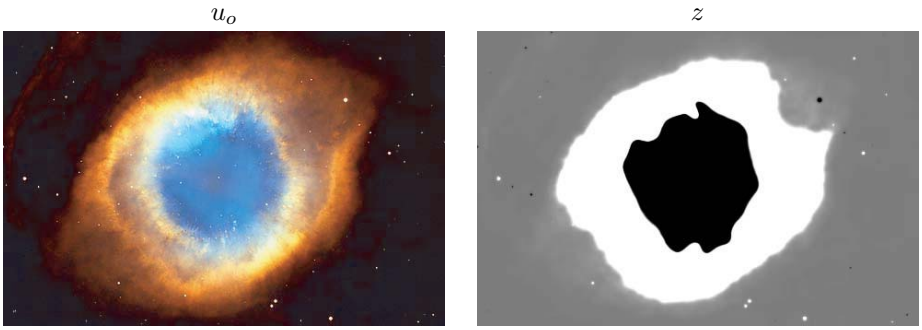

FIG. 4.4. *Example of image with blurry edges. The image of Helix nebula has blurry edges, and the proposed model captures each different level clearly: three phases $z = 0$, 1, and 2.*

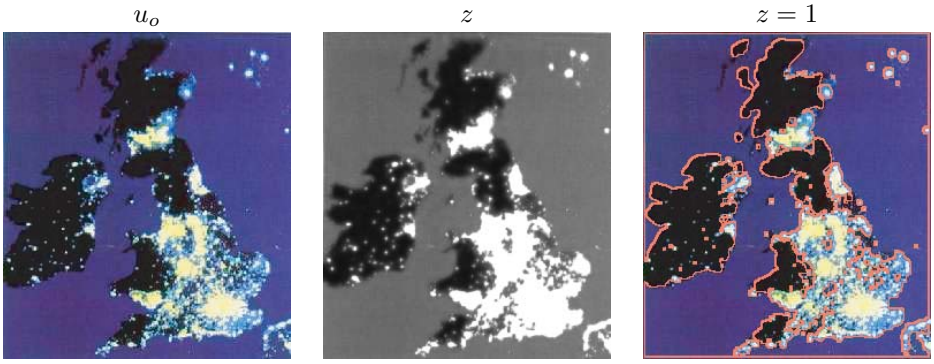

FIG. 4.5. *Example of cluster segmentation. The original (left) and z with three phases (middle) are shown. The $z = 1$ contour is superposed over the original to show the accuracy (right).*

edges. Figure 4.4 is an example of blurring image. The edges are not clearly defined; however, the proposed Modica–Mortola sine-sinc model captures each different level clearly. Figure 4.5 shows an example of cluster segmentation. It is an image of the night light of England and correctly segments three different phases. These two examples further demonstrate the flexibility of the proposed model and its computational algorithm.

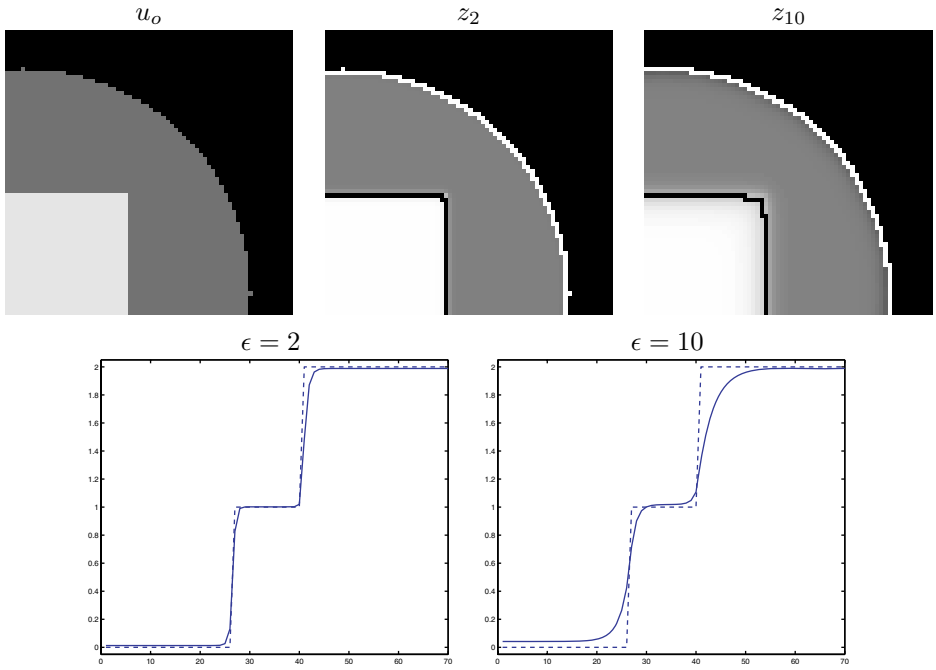

FIG. 4.6. *Effect of different ϵ values. From the same original image u_o, two different ϵ values are used to show the effect of ϵ. In the top row, segmented results z_2 and z_{10} are superposed with black and white contours identifying each segment's $z = 0$, $z = 1$, and $z = 2$. The second row plots show the profile (solid) of the diagonal of z_2 and z_{10} compared to the ideal segmentation (dotted).*

As a final example, we present the effect of using different ϵ in Figure 4.6. From the original image u_o, two different ϵ values are used to show the effect of having different transition bands: as ϵ gets bigger, the transition band gets wider. In Figure 4.6, except for the sharp corner, z_2 and z_{10} show little differences.

5. Conclusion. In this paper, we propose a new multiphase segmentation model based on the celebrated phase transition model of Modica and Mortola [33] in material sciences, fluid mechanics, and the Γ-convergence theory. The sine-sinc model properly synchronizes the fitting term for the given image with the regularity term for the diffuse interfaces. Mathematical analysis is developed for the Γ-convergence behavior of the model and the existence of its minimizers. We also develop in detail the convex-splitting or the CCCP algorithm for minimizing the nonconvex energy functional. Several numerical experiments on both generic synthetic and natural images demonstrate the satisfying performance of the proposed model and its algorithm.

It is our belief that the interplay and integration between physics and information technologies will further blossom in the near future. The current work is a typical example that has substantially benefited from numerous existing contributions in these two fields.

Acknowledgments. Jung is grateful to Prof. Jin Keun Seo for his support and encouragement. Kang would like to thank IMA for supporting a long term visit during the thematic year on imaging which has made this collaboration possible. Shen would like to thank his dear teacher and friend Riccardo March for kindly educating him on the Γ-convergence theory with fun and joy through all these years, and also dear

friends Alan Yuille and Andrea Bertozzi for the enlightenment on the convex splitting or the CCCP algorithm.

SCATTERING BY A SEMI-INFINITE PERIODIC ARRAY AND THE EXCITATION OF SURFACE WAVES*

C. M. LINTON†, R. PORTER‡, AND I. THOMPSON†

Abstract. The two-dimensional problem of acoustic scattering of an incident plane wave by a semi-infinite array of either rigid or soft circular scatterers is solved. Solutions to the corresponding infinite array problems are used, together with a novel filtering approach, to enable accurate solutions to be computed efficiently. Particular attention is focused on the determination of the amplitude of the Rayleigh–Bloch waves that can be excited along the array. In general, the far field away from the array consists of the sum of a finite number of plane waves propagating in different directions (the number depending on the observation angle) and a circular wave emanating from the edge of the array. In certain *resonant* cases (characterized by one of the scattered plane waves propagating parallel to the array), a different far field pattern occurs, involving contributions that are neither circular waves nor plane waves. Uniform asymptotic expansions that vary continuously across all of the shadow boundaries that exist are given for both cases.

Key words. acoustic scattering, semi-infinite array, surface wave

1. Introduction.

Large array scattering problems are of considerable current interest in many different areas and present significant theoretical and computational challenges. Whereas wave scattering by a small number of scatterers, or by an infinite periodic array, is fairly well understood, scattering by large but finite arrays has received much less attention. Scattering by large finite arrays is of considerable importance in the theory of array antennas and the fabrication of electromagnetic band gap materials [1], [2], [3]; in water waves [4], [5], where offshore structures supported by thousands of cylindrical columns are being designed; and in acoustics, where large periodic arrays continue to be the subject of numerous studies—applications include acoustic filters, noise control, and the design of transducers.

It has long been recognized that one way to approach large finite array scattering is to analyze the effects of each edge of the array in isolation—in other words, to study arrays with just one edge—and this leads to problems formulated on semi-infinite arrays. On the assumption that opposite edges of a finite array are well separated, results from analyses of semi-infinite arrays can then be combined to provide results for finite arrays. Unfortunately, such problems are difficult to analyze and little work has been done on the subject since the pioneering studies of Hills and Karp [6] and Millar [7].

For the case of a semi-infinite periodic array of isotropic point scatterers, it has been shown [8] that progress can be made if the problem is formulated for the difference between unknowns relevant to the infinite and semi-infinite array problems. The situation considered was appropriate to acoustic diffraction by sound-soft scatterers

in the limit as the ratio of wavelength to body size tends to infinity and also to the scattering of an E-polarized electromagnetic wave by an array of perfectly conducting wires. Important as these applications are, they do not cover many of the cases in which large array scattering is a serious issue.

As a significant extension we consider here two-dimensional scattering by a semi-infinite row of periodically spaced, identical circular cylinders and show how the diffracted field can be efficiently computed. We extend the techniques developed in [8] so as to investigate the effects of the size of scatterers and the boundary conditions applied on them. Neumann boundary conditions appropriate for rigid bodies give rise to a major complication since diffraction gratings of rigid structures are known to support pure Rayleigh–Bloch surface waves at low frequencies [9], [10] and these may be excited by the edge of the array.

The excitation of surface waves by array edges is a virtually unexplored area, partly because there are very few geometries for which the range of possible Rayleigh–Bloch modes (also called array guided surface waves) is completely understood. They have been observed numerically in arrays of dipoles [2] and are akin to the edge waves that can be excited by the edge of a semi-infinite crack in a thin plate [11]. It is common practice in many applications to assume that the behavior of a large finite array can be approximated well by an infinite array, at least away from the edges. One of the consequences of the presence of Rayleigh–Bloch surface waves is that this is no longer valid. For example, Maniar and Newman [12] showed that the effect of these modes (especially those which are close to standing modes) can be extremely important, giving rise to enormous amplification of the wave field close to the center of a large array. It is thus important to have a good understanding of when and to what extent array guided surface waves are excited.

The structure of the paper is as follows. We begin in section 2 by formulating the scattering problems for both an infinite and a semi-infinite array of circular scatterers using separation of variables. Details of the Rayleigh–Bloch surface waves that can be supported by an infinite array are given. In section 3 the solution to the infinite array problem is used to reformulate the semi-infinite array problem in such a way that the unknown coefficients associated with each cylinder decay to zero as one moves away from the array edge. A number of different approaches are considered, and they are used to compute the amplitude of the Rayleigh–Bloch waves that are excited. The nature of the far field is analyzed in section 4, and a uniform asymptotic approximation is derived. A special treatment is required when the parameters correspond to resonance in the infinite array (when one of the scattered waves propagates along the array), and this is given in section 5. In particular, this allows us to solve the semi-infinite problem in the case of head-on incidence.

2. Formulation. We consider a two-dimensional scattering problem which has application in a number of physical contexts. We will refer primarily to the acoustic setting in which we look for time-harmonic solutions $\mathrm{Re}[\phi(x,y)\exp(-\mathrm{i}\omega t)]$ so that the acoustic potential ϕ satisfies the two-dimensional Helmholtz equation $(\nabla^2+k^2)\phi=0$ in the region exterior to the scatterers, where $k=\omega/c$ and c is the speed of sound. The scatterers can be taken as either rigid (in which case the normal derivative of ϕ must vanish on the boundary; we call this the Neumann problem) or acoustically soft (in which case the appropriate boundary condition is $\phi=0$; we call this the Dirichlet problem). Exactly the same boundary-value problem can be used to study electromagnetic diffraction by an array of perfect conductors or, once the depth variation has been factored out, the scattering of water waves by vertical circular cylinders. In

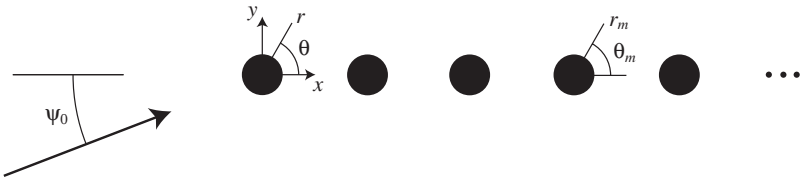

FIG. 2.1. *Definition sketch.*

the latter case, k is the positive solution to the dispersion relation $k \tanh kh = \omega^2/g$, h being the water depth and g the acceleration due to gravity; the appropriate boundary condition is $\partial\phi/\partial n = 0$. The geometry under consideration is sketched in Figure 2.1.

We are concerned with the scattering of a plane wave

$$\phi_{\text{inc}} = \mathrm{e}^{\mathrm{i}(\lambda x + \mu y)}, \tag{2.1}$$

where $\mu = k \sin\psi_0$ and $\lambda = k \cos\psi_0$, by a semi-infinite row of identical circular cylinders of radius a, located at $(x, y) = (j, 0)$, $j = 0, 1, 2, \ldots$. The spacing between the cylinders has been set to unity for convenience, and hence $0 < a \leq 0.5$. We will use polar coordinates (r_j, θ_j), centered on the jth scatterer and defined by

$$x - j = r_j \cos\theta_j, \qquad y = r_j \sin\theta_j, \tag{2.2}$$

and we will usually write (r, θ) for (r_0, θ_0). In terms of (r_j, θ_j) the incident wave is given by

$$\phi_{\text{inc}} = \mathrm{e}^{\mathrm{i}\lambda j} \mathrm{e}^{\mathrm{i}kr_j \cos(\theta_j - \psi_0)}. \tag{2.3}$$

This problem can be formulated using separation of variables. If we write the total field as $\phi = \phi_{\text{inc}} + \phi_{\text{sc}}$ with

$$\phi_{\text{sc}} = \sum_{j=0}^{\infty} \sum_{n=-\infty}^{\infty} A_n^j Z_n \, H_n(kr_j) \mathrm{e}^{\mathrm{i}n\theta_j}, \tag{2.4}$$

where $H_n(\cdot)$ is a Hankel function of the first kind and $Z_n = J_n(ka)/\, H_n(ka)$ if the Dirichlet problem is being studied, or $Z_n = J_n'(ka)/\, H_n'(ka)$ for the Neumann problem, then the unknowns A_n^j are solutions to ([13, eq. (2.11)])

$$A_m^p + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0 \\ \neq p}}^{\infty} A_n^j X_{n-m}^{jp} \, H_{n-m}(k|j-p|) = -\mathrm{e}^{\mathrm{i}\lambda p} \mathrm{e}^{\mathrm{i}m(\frac{1}{2}\pi - \psi_0)}, \tag{2.5}$$

$p = 0, 1, 2, \ldots, m \in \mathbb{Z}$, where $X_n^{jp} = 1$ if $p > j$ and $X_n^{jp} = (-1)^n$ if $p < j$.

This system of equations could, in principle, be solved numerically by truncation, but the infinite spatial sum (over j) converges extremely slowly. (The coefficients A_n^j do not decay to zero as $j \to \infty$, and so the terms in this sum decay like $j^{-1/2} \exp(\mathrm{i}j\delta)$ for some δ.) By contrast, the order summation (over n) converges exponentially. The strategy that is followed here is to make use of known properties of the diffraction problem when the array extends to both plus and minus infinity to allow us to sum up the slowly convergent spatial series analytically.

2.1. The infinite array. For the infinite grating problem, with cylinders at $(j,0)$, $j\in\mathbb{Z}$, we can seek a solution of the form

$$\phi_{\rm sc}^{\rm inf}=\sum_{j=-\infty}^{\infty}\sum_{n=-\infty}^{\infty}B_n^jZ_n\,H_n(kr_j)\mathrm{e}^{\mathrm{i}n\theta_j}. \tag{2.6}$$

The periodicity of the geometry and of the incident wave allows us to look for a solution which satisfies

$$B_n^j=\mathrm{e}^{\mathrm{i}\lambda j}B_n^0=\mathrm{e}^{\mathrm{i}\lambda j}B_n, \tag{2.7}$$

say, and then we need only solve for B_n. These coefficients are solutions to the infinite system of equations

$$B_m+\sum_{n=-\infty}^{\infty}B_nZ_n\sigma_{n-m}(\lambda)=-\mathrm{e}^{\mathrm{i}m(\frac12\pi-\psi_0)},\qquad m\in\mathbb{Z}, \tag{2.8}$$

where

$$\sigma_n(\lambda)=\sum_{j=1}^{\infty}\left[(-1)^n\mathrm{e}^{\mathrm{i}\lambda j}+\mathrm{e}^{-\mathrm{i}\lambda j}\right]H_n(kj). \tag{2.9}$$

The quantities σ_n are easily evaluated (though not from the above expression); see [14], [15]. The system (2.8) is straightforward to solve numerically by truncation, the convergence of B_n with $|n|$ being exponential.

The far field for the infinite array problem can be determined as follows. First we define the scattering angles $\psi_m(\lambda)$ by

$$\psi_m=\arccos(\lambda_m/k),\qquad \lambda_m=\lambda+2m\pi. \tag{2.10}$$

If $|\lambda_m|<k$, i.e.,

$$-1<\cos\psi_0+\frac{2m\pi}{k}<1, \tag{2.11}$$

then we say that $m\in\mathcal{M}$ and we have $0<\psi_m<\pi$. If $|\lambda_m|>k$, then ψ_m is no longer real and the appropriate branch of the arccos function is given by

$$\arccos t=\begin{cases}\mathrm{i}\,\mathrm{arccosh}\,t, & t>1,\\ \pi-\mathrm{i}\,\mathrm{arccosh}(-t), & t<-1,\end{cases} \tag{2.12}$$

with $\mathrm{arccosh}\,t=\ln\left(t+\sqrt{t^2-1}\right)$ for $t>1$. Next we use the integral representation

$$H_n(kr)\,\mathrm{e}^{\mathrm{i}n\theta}=\frac{(-\mathrm{i})^{n+1}}{\pi}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)}\,\mathrm{e}^{\mathrm{i}kxt}\,(t-\gamma(t))^{n\,\mathrm{sgn}(y)}\,\mathrm{d}t, \tag{2.13}$$

in which $\gamma(t)=(t^2-1)^{1/2}$ with $\gamma(0)=-\mathrm{i}$ and the path of integration is indented so as to pass above the branch point at $t=-1$ and below that at $t=1$ (for $n=0$, see [8, Appendix A]; for the extension to all n we use [16, Theorem 2.7]). If this is inserted into (2.6), we can apply the Poisson summation formula to obtain

$$\phi_{\rm sc}^{\rm inf}=\sum_{m=-\infty}^{\infty}\mathcal{F}_m^{\pm}\mathrm{e}^{\mathrm{i}kr\cos(\theta\mp\psi_m)}, \tag{2.14}$$

in which

$$\mathcal{F}_m^{\pm} = \frac{2}{k} \sum_{n=-\infty}^{\infty} (-\mathrm{i})^n B_n Z_n \frac{\mathrm{e}^{\pm \mathrm{i}n\psi_m}}{\sin \psi_m} \tag{2.15}$$

and the superscripts + and − correspond to $y > 0$ and $y < 0$, respectively. The integral representation (2.13) with $n \neq 0$ is valid except on $y = 0$, and thus this expression for the field is valid everywhere outside the scatterers except on $y = 0$, provided that $\sin \psi_m \neq 0$ for any m. If there is a value of m for which $\sin \psi_m = 0$, then the scattering problem is described as resonant and requires a separate treatment. This is discussed elsewhere [17]. As $y \to \pm\infty$, the only contribution comes from those m for which ψ_m is real, i.e., $m \in \mathcal{M}$. Hence the far field consists of a set of plane waves propagating in the directions $\theta = \psi_m$ and $\theta = 2\pi - \psi_m$:

$$\phi_{\mathrm{sc}}^{\mathrm{inf}} \sim \sum_{m \in \mathcal{M}} \mathcal{F}_m^{\pm} \mathrm{e}^{\mathrm{i}kr\cos(\theta \mp \psi_m)} \quad \text{as} \quad y \to \pm\infty. \tag{2.16}$$

2.2. Rayleigh–Bloch surface waves. Crucial to what follows is the fact that in the Neumann problem the solution to the scattering problem described above may not be unique. If we relax the quasi-periodicity condition (2.7) and replace it with another with a different phase, it may be possible to find a value β (maybe more than one), dependent on k, such that the homogeneous infinite system

$$B_m + \sum_{n=-\infty}^{\infty} B_n Z_n \sigma_{n-m}(\beta) = 0, \qquad m \in \mathbb{Z}, \tag{2.17}$$

has a nontrivial solution. The resulting potential

$$\phi^{\mathrm{rb}} = \sum_{j=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} \mathrm{e}^{\mathrm{i}\beta j} B_n Z_n \, H_n(kr_j) \mathrm{e}^{\mathrm{i}n\theta_j} \tag{2.18}$$

does not share the same periodicity as the incident wave, but nevertheless satisfies all the boundary conditions of the full problem. Such potentials are referred to as Rayleigh–Bloch surface waves (or array guided surface waves), and for the geometry under consideration here the dispersion relation connecting β and k has been computed in [18] and [19] (the existence of these surface waves was proved in [10]). Since $\exp(\mathrm{i}\beta m) = \exp(\mathrm{i}(\beta + 2\pi)m)$, we can restrict our attention to $0 \leq \beta < 2\pi$. It follows from (2.17) that if there is a solution for a given β, then there is also a solution with β replaced by $2\pi - \beta$ (representing a wave whose energy is travelling in the opposite direction). If we insist that energy is propagating in the positive x-direction, as it will be in the semi-infinite array problem considered below, then we can restrict attention to $0 < \beta < \pi$. The numerical results in [18] and [19] show that Rayleigh–Bloch surface waves exist at discrete values of k for any $\beta < \pi$ and that they satisfy $k < \beta$. The fact that no such modes exist in the Dirichlet problem is proved in [20].

Computations show that a mode which is symmetric about $y = 0$ (for which $B_{-n} = (-1)^n B_n$) exists for all scatterer sizes, and a mode antisymmetric about $y = 0$ (for which $B_{-n} = -(-1)^n B_n$, with $B_0 = 0$) exists for $0.403 \lesssim a \leq 0.5$. For a given value of a, Rayleigh–Bloch waves exist only for a range of values of k: symmetric modes in the range $0 < k < k_{\mathrm{max}}^{\mathrm{s}} < \pi$ and antisymmetric modes in the range $k_{\mathrm{min}}^{\mathrm{a}} < k < k_{\mathrm{max}}^{\mathrm{a}} < \pi$. It turns out that there are three distinct regimes:

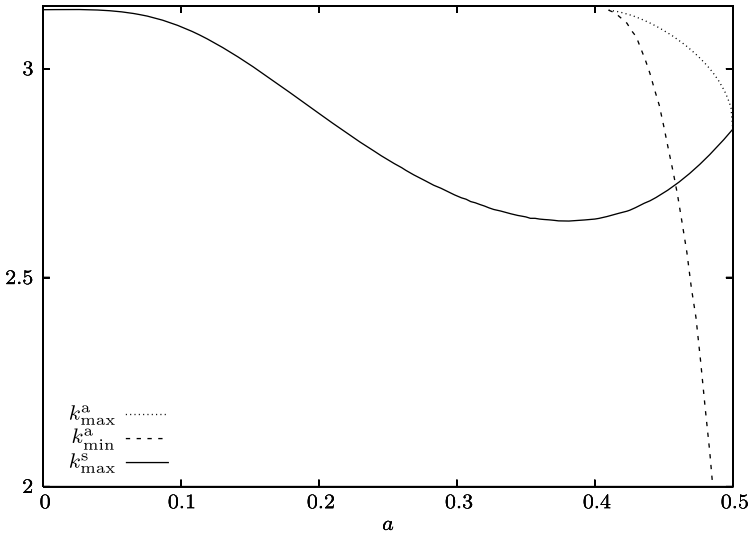

FIG. 2.2. $k_{\rm min}$ *and* $k_{\rm max}$ *for symmetric and antisymmetric Rayleigh–Bloch modes.*

for $a \lesssim 0.403$, only symmetric modes are possible; for $0.403 \lesssim a \lesssim 0.459$, we have $k^{\rm s}_{\rm max} < k^{\rm a}_{\rm min}$, and thus it is possible to have symmetric and antisymmetric modes, but not for the same value of k; and finally, when $0.459 \lesssim a < 0.5$, we have $k^{\rm s}_{\rm max} > k^{\rm a}_{\rm min}$, and hence it is only in this parameter range that it is possible to excite both symmetric and antisymmetric modes at the same time. Figure 2.2 shows values of $k^{\rm s}_{\rm max}$, $k^{\rm a}_{\rm min}$, and $k^{\rm a}_{\rm max}$ for varying scatterer radius a. When $a = 0.5$, the symmetric and antisymmetric Rayleigh–Bloch modes are essentially the same since the cylinders are touching and there is no connection between the two sides of the array.

3. Infinite array subtraction. We will formulate the problem allowing for the excitation of a single Rayleigh–Bloch mode. If both symmetric and antisymmetric modes are present, then this is easily accommodated by first splitting the problem into parts symmetric and antisymmetric about $y = 0$ and treating each of them separately. In fact it is numerically efficient to make this decomposition irrespective of the parameter values, and this was done in all the computations presented below. For the semi-infinite grating we would like to construct an infinite system of equations in which, unlike in (2.5), the unknowns decay to zero as one moves along the array. To this end we first introduce new unknowns which are the differences between the solutions to the infinite and semi-infinite array problems (as in [8], [21]). There are then a number of different ways in which the Rayleigh–Bloch waves can be handled. These fall into two broad categories: filtering methods, in which knowledge about the phase of the unknown coefficients is used to filter out unwanted terms (used for a simpler quasi–one-dimensional scattering problem in [22]), and explicit methods, where the amplitude of the Rayleigh–Bloch waves that are excited is introduced as an extra unknown and an extra equation is therefore required. We will consider the latter type first.

3.1. Explicit methods. We define a new set of unknowns, $\hat{C}^p_m$, as follows:

$$A^p_m = \hat{C}^p_m + {\rm e}^{{\rm i}\lambda p} B_m + \alpha\, {\rm e}^{{\rm i}\widetilde{\beta} p} \widetilde{B}_m. \tag{3.1}$$

Here B_m is the solution to the infinite array problem (2.8), $\widetilde{B}_m$ is a solution to the homogeneous system (2.17) with $\beta \equiv \widetilde{\beta}$, normalized so that

$$\sum_{m=-\infty}^{\infty} |Z_m \widetilde{B}_m|^2 = 1, \tag{3.2}$$

and α is an unknown constant representing the (complex) amplitude of the Rayleigh–Bloch mode. We expect that as $p \to \infty$ (i.e., as we move away from the edge) the coefficients A_m^p will tend to the values appropriate to a fully infinite array, plus possibly the effect of any Rayleigh–Bloch waves, and hence that $\hat{C}_m^p \to 0$ as $p \to \infty$ provided that α is chosen appropriately.

If we substitute from (3.1) into (2.5) and use (2.8) and (2.17), we get a system of equations for the coefficients $\hat{C}_m^p$ which is the same as (2.5) except with a different right-hand side:

$$\begin{aligned} &\hat{C}_m^p + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0 \\ \neq p}}^{\infty} \hat{C}_n^j X_{n-m}^{jp} H_{n-m}(k|j-p|) \\ &\qquad = \sum_{n=-\infty}^{\infty} Z_n \left(B_n S_{n-m}^p(\lambda) + \alpha \widetilde{B}_n S_{n-m}^p(\widetilde{\beta}) \right), \qquad p = 0, 1, 2, \ldots, m \in \mathbb{Z}, \end{aligned} \tag{3.3}$$

where

$$S_n^p(\beta) = \sum_{j=p+1}^{\infty} \mathrm{e}^{\mathrm{i}\beta(p-j)} H_n(kj). \tag{3.4}$$

The slowly convergent series (3.4) does not contain unknown coefficients and thus can be treated analytically and computed efficiently; see [23]. It can be shown that (see [8, Appendix D] for the method though the final result in that paper is in error), provided that θ is not an integer multiple of 2π,

$$\sum_{j=p+1}^{\infty} \frac{\mathrm{e}^{\mathrm{i}j\theta}}{j^{1/2}} \sim \frac{-p^{-1/2}\mathrm{e}^{\mathrm{i}\theta p}}{1 - \mathrm{e}^{-\mathrm{i}\theta}} \quad \text{as} \quad p \to \infty. \tag{3.5}$$

Hence

$$S_n^p(\beta) \sim -\sqrt{\frac{2}{\pi k p}} \frac{(-\mathrm{i})^n \, \mathrm{e}^{-\frac{1}{4}\mathrm{i}\pi} \, \mathrm{e}^{\mathrm{i}kp}}{\left(1 - \mathrm{e}^{-\mathrm{i}(k-\beta)}\right)}. \tag{3.6}$$

It follows that the right-hand side of (3.3) decays as $p \to \infty$; therefore the behavior of the coefficients $\hat{C}_n^p$ in this limit must be such that the sum on the left-hand side converges. In fact, it turns out that (see section 4), as $p \to \infty$,

$$\hat{C}_n^p \sim C_n p^{-3/2} \mathrm{e}^{\mathrm{i}kp}. \tag{3.7}$$

The simplest way to determine α is to set $\hat{C}_N^P = 0$, treat α as an unknown, and solve (3.3) for $\hat{C}_n^0, \ldots, \hat{C}_n^P$, $|n| \le N$, by truncation, a procedure which was used for a related problem in [24]. This works, in that as P gets large, the value obtained for α converges, but the convergence is slow, and very large values of P are therefore required in order to obtain accurate results. We will refer to this approach to the

determination of α as the direct method. We can also make use of a subsequent result from the analysis of the far field as a means of obtaining an additional equation. Thus, the asymptotic behavior of the coefficients $\hat{C}_n^p$ given by (3.7) means that we must take $g(0) = 0$ in (4.7) (see section 4.2), and thus

$$\sum_{n=-\infty}^{\infty} (-\mathrm{i})^n Z_n \left(\frac{B_n}{1 - \mathrm{e}^{\mathrm{i}(\lambda - k)}} + \frac{\alpha \widetilde{B}_n}{1 - \mathrm{e}^{\mathrm{i}(\tilde{\beta} - k)}} + \sum_{j=0}^{\infty} \hat{C}_n^j \mathrm{e}^{-\mathrm{i}kj} \right) = 0. \tag{3.8}$$

Note that this is not an explicit formula for α since the coefficients $\hat{C}_n^j$ are the solutions to (3.3), which contains α on the right-hand side. For the antisymmetric part of the field this identity is trivially satisfied; thus it is of use only for the symmetric part. The use of (3.3) combined with (3.8) will be referred to as the far field method for the determination of α. Unfortunately, the sum involving $\hat{C}_n^j$ converges too slowly for this approach to work well. In cases where there is no Rayleigh–Bloch wave (i.e., in the Neumann problem with $k > k_{\max}^{\mathrm{s}}$ or in the Dirichlet case), $\alpha = 0$, and equation (3.8) is an identity that can be used as a check on the results. It can also be used as a numerical check in cases where Rayleigh–Bloch waves do exist if α is calculated by some other means.

In order to make the best use of (3.8) we use a simple acceleration procedure. This procedure has been used wherever possible in what follows and we will refer to it as asymptotic acceleration. Thus, we substitute the asymptotic form for the coefficients $\hat{C}_n^j$ for all values of j greater than the truncation parameter $j = J$, giving

$$\sum_{j=0}^{\infty} \hat{C}_n^j \mathrm{e}^{-\mathrm{i}kj} = \sum_{j=0}^{J} \hat{C}_n^j \mathrm{e}^{-\mathrm{i}kj} + C_n \sum_{j=J+1}^{\infty} j^{-3/2}, \tag{3.9}$$

the coefficient C_n being determined from the computed value of $\hat{C}_n^J \approx C_n J^{-3/2} \exp(\mathrm{i}kJ)$ and the final sum being a generalized zeta function which can easily be computed from standard packages.

3.2. Filtering. We have found that filtering methods yield the best results in terms of accuracy and efficiency, and these are described next. This time we define new unknowns C_m^p via

$$A_m^p = C_m^p + \mathrm{e}^{\mathrm{i}\lambda p} B_m \tag{3.10}$$

(so that $C_m^p = \hat{C}_m^p + \alpha\, \mathrm{e}^{\mathrm{i}\tilde{\beta}p} \widetilde{B}_m$). Instead of (3.3) we now have

$$C_m^p + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0 \\ \neq p}}^{\infty} C_n^j X_{n-m}^{jp}\, H_{n-m}(k|j-p|) = \Gamma_m^p, \tag{3.11}$$

$p = 0, 1, 2, \ldots, m \in \mathbb{Z}$, where for future convenience we have defined

$$\Gamma_m^p = \sum_{n=-\infty}^{\infty} Z_n B_n S_{n-m}^p(\lambda). \tag{3.12}$$

If Rayleigh–Bloch modes are excited, then the coefficients C_m^p will not decay to zero as $p \to \infty$. Instead, we expect that $C_m^p \sim \mathrm{e}^{\mathrm{i}\tilde{\beta}} C_m^{p-1}$ in this limit. We thus introduce

$$D_m^p = \begin{cases} C_m^p - \mathrm{e}^{\mathrm{i}\tilde{\beta}} C_m^{p-1}, & p = 1, 2, \ldots, \\ C_m^0, & p = 0, \end{cases} \tag{3.13}$$

so that D_m^p decays to zero as $p \to \infty$. This recurrence relation can be solved for C_m^p to give

$$C_m^p = \sum_{j=0}^{p} \mathrm{e}^{\mathrm{i}\tilde{\beta}(p-j)} D_m^j, \qquad p = 0, 1, 2, \ldots. \tag{3.14}$$

A system of equations for D_m^p can then be derived in more than one way. If (3.14) is substituted into (3.11), we get

$$\sum_{j=0}^{p} \mathrm{e}^{\mathrm{i}\tilde{\beta}(p-j)} D_m^j + \sum_{n=-\infty}^{\infty} Z_n \sum_{j=0}^{\infty} D_n^j \sum_{\substack{l=j \\ \neq p}}^{\infty} \mathrm{e}^{\mathrm{i}\tilde{\beta}(l-j)} X_{n-m}^{lp} H_{n-m}(k|l-p|) = \Gamma_m^p, \tag{3.15}$$

$p = 0, 1, 2, \ldots, m \in \mathbb{Z}$. Alternatively we can combine equations in (3.11) in the obvious way so that

$$D_m^p + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0 \\ \neq p}}^{\infty} D_n^j X_{n-m}^{jp} H_{n-m}(k|j-p|) = \Gamma_m^p - \mathrm{e}^{\mathrm{i}\tilde{\beta}} \Gamma_m^{p-1}, \tag{3.16}$$

$p = 1, 2, \ldots, m \in \mathbb{Z}$. The system (3.16) then needs to be supplemented by an equation for D_m^0 which can be obtained from (3.11) with $p = 0$ by substituting for C_n^j from (3.14). This yields

$$D_m^0 + \sum_{n=-\infty}^{\infty} (-1)^{n-m} Z_n \sum_{j=0}^{\infty} D_n^j \sum_{l=\max(j,1)}^{\infty} \mathrm{e}^{\mathrm{i}\tilde{\beta}(l-j)} H_{n-m}(kl) = \Gamma_m^0. \tag{3.17}$$

The sums over l in either of the formulations can be expressed in terms of the sums S_n^p defined in (3.4) and can be computed efficiently and accurately using results from [23]. The two formulations are equivalent, but we have found that the second (i.e., using (3.16) and (3.17)) is easier to implement. In either case, the finite sum in (3.14) has been interchanged with the (infinite) spatial sum in (3.11). This crucial step has the effect of continuing the filtered term (in this case the Rayleigh–Bloch mode) to infinity, so that it is unaffected by spatial truncation. This is the essence and great advantage of infinite array subtraction and filtering methods: only the part of the solution which decays as one moves along the array is subject to errors caused by spatial truncation.

Once the coefficients D_m^p have been computed via truncation, the coefficients C_m^p can be reconstructed from (3.14). If we truncate at $p = P$, a value for α can then be deduced from

$$C_m^P \mathrm{e}^{-\mathrm{i}\tilde{\beta}P} = \sum_{p=0}^{P} \mathrm{e}^{-\mathrm{i}\tilde{\beta}p} D_m^p \to \alpha \widetilde{B}_m \quad \text{as} \quad P \to \infty. \tag{3.18}$$

The coefficients D_m^p have the asymptotic behavior $D_m^p \sim D_m p^{-3/2} \exp(\mathrm{i}kp)$ exactly as for $\hat{C}_m^p$ because they both model the behavior of the scattered field once the Rayleigh–Bloch wave has been removed. Thus asymptotic acceleration can be used in (3.18).

It is possible to use the known asymptotic behavior of D_m^p to create a set of coefficients which decay like $p^{-5/2}$ by filtering again. In other words we define a new

TABLE 3.1

Convergence of different methods for the determination of $|\alpha|$ for the symmetric Rayleigh–Bloch mode that is excited when $a = 0.25$, $\psi_0 = \pi/10$, and $k = 2$. The numbers in parentheses are the results when asymptotic acceleration is not used (note that this is not available when using the direct method). Eleven modes have been used in the order summations.

set of coefficients via

$$E_m^p = \begin{cases} D_m^p - \mathrm{e}^{\mathrm{i}k} D_m^{p-1}, & p = 1, 2, \ldots, \\ D_m^0, & p = 0. \end{cases} \tag{3.19}$$

Details of the resulting equations can be found in the appendix. In most situations there is very limited gain from this second filtering. However, there are certain situations (which we will mention below) where it is absolutely essential.

3.3. Numerical results. We have described four methods which can be used to determine α: the direct method, the far field method, single filtering, and double filtering. The final three can all be improved via asymptotic acceleration. Table 3.1 shows the relative performance of these different approaches for a typical, rather than an extreme, case. We have taken $a = 0.25$, $\psi_0 = \pi/10$, and $k = 2$. For these parameters, there is a symmetric Rayleigh–Bloch mode with $\widetilde{\beta} \approx 2.0268$. The table, which lists values of $|\alpha|$, clearly demonstrates the superiority of the filtering methods, and also the increased convergence that results from using asymptotic acceleration. An important caveat to note is that double filtering does not work well when k and $\widetilde{\beta}$ are too close together. This happens for symmetric Rayleigh–Bloch waves when k is small. However, this is mitigated against by the fact that in long waves smaller truncations in the order summations are necessary for a given accuracy, and hence large spatial truncations can easily be used.

When antisymmetric surface waves are excited, computing α accurately is more of a challenge. One factor is that such modes exist only for large values of a when the cylinders are close together, and this entails the use of many more terms in the order summations so as to accurately model the interactions. The second is that the problematic case $k \approx \widetilde{\beta}$ occurs not for very long waves but when k is near $k^{\mathrm{a}}_{\mathrm{min}}$. Table 3.2 shows the relative performance of the different approaches for computing α for the case $a = 0.49$, $\psi_0 = \pi/10$, and $k = 2.5$. For these parameters, there is an antisymmetric Rayleigh–Bloch mode with $\widetilde{\beta} \approx 2.5096$. (There is also a symmetric mode excited with $\widetilde{\beta} \approx 2.5644$, and thus the problem must be decomposed into its symmetric and antisymmetric parts before the Rayleigh–Bloch amplitudes are calculated.) Note that the far field method cannot be used in the antisymmetric case. Again, the filtering methods are seen to converge fastest as the spatial truncation is increased. It is also evident that the convergence is not as good as in the symmetric case presented in Table 3.1.

TABLE 3.2

Convergence of different methods for the determination of $|\alpha|$ for the antisymmetric Rayleigh–Bloch mode that is excited when $a = 0.49$, $\psi_0 = \pi/10$, and $k = 2.5$. The numbers in parentheses are the results when asymptotic acceleration is not used (note that this is not available when using the direct method). Twenty-one modes have been used in the order summations.

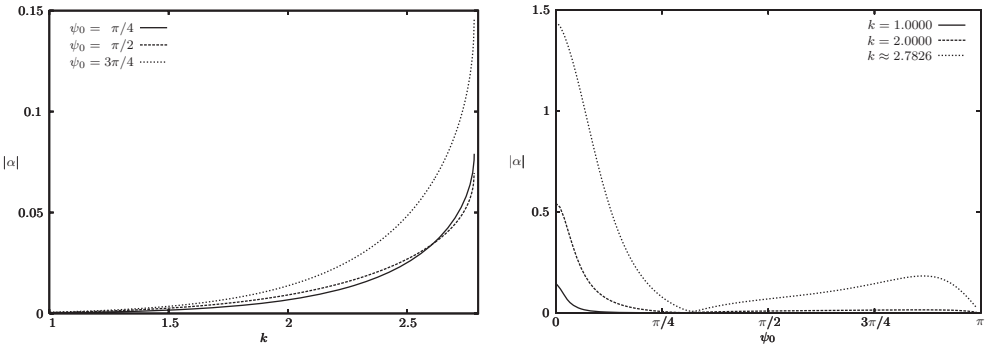

FIG. 3.1. *Left: variation with k of $|\alpha|$ for the excited symmetric surface wave, for three different angles of incidence, when $a = 0.25$. Right: variation with ψ_0 of $|\alpha|$ for the excited symmetric surface wave, for three different values of k, when $a = 0.25$.*

Figure 3.1 shows the variation in the amplitude of the excited symmetric surface wave with k for three different angles of incidence and with ψ_0, for three different wavenumbers, when $a = 0.25$. For this value of a, symmetric Rayleigh–Bloch waves are excited for all k in the range $0 < k < k^{\mathrm{s}}_{\max} \approx 2.783$ (and antisymmetric Rayleigh–Bloch waves are never excited). For $0 < k < 1$ (not shown in the figure), $|\alpha|$ is essentially zero. This corresponds to wavelength-to-spacing ratios greater than 2π. As k increases so the amplitude increases, reaching a maximum at $k^{\mathrm{s}}_{\max}$ (at which point $\widetilde{\beta} = \pi$). The variation in $|\alpha|$ with ψ_0 is not monotonic, and this is illustrated clearly in Figure 3.1. For a given k, the amplitude is greatest at head-on incidence (note that this case requires special treatment as described in section 5 below). It then reduces to approximately zero at an angle somewhere near $\pi/3$ (independently of the value of k) before increasing and then getting smaller again as the incident wave grazes the array.

Figure 3.2 shows the variation in the amplitude of the excited antisymmetric surface wave with k for three different angles of incidence and with ψ_0, for three different wavenumbers, when $a = 0.49$. For this value of a, antisymmetric Rayleigh–Bloch waves are excited for all k in the range $1.796 \lesssim k \lesssim 2.969$ (and symmetric Rayleigh–Bloch waves are also excited). For k just above 1.796 we have problems computing α accurately caused by the closeness of k and $\widetilde{\beta}$. The qualitative behavior of the amplitude as a function of k is very similar to that for the symmetric mode shown in Figure 3.1. At head-on incidence the problem is entirely symmetric about

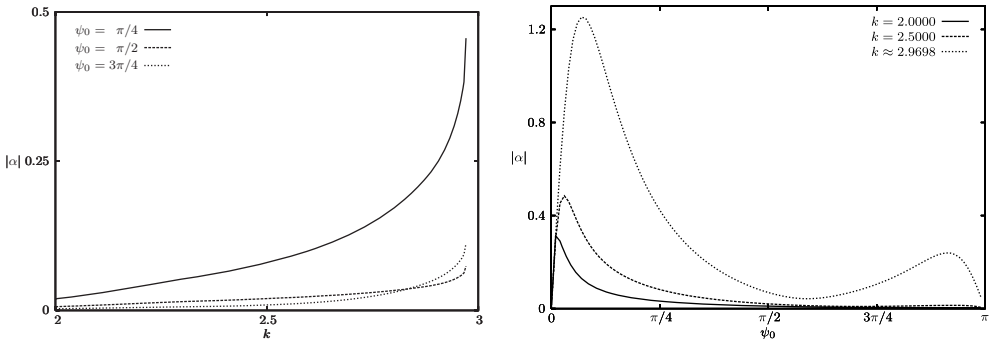

FIG. 3.2. *Left: variation with k of $|\alpha|$ for the excited antisymmetric surface wave, for three different angles of incidence, when $a = 0.49$. Right: variation with ψ_0 of $|\alpha|$ for the excited antisymmetric surface wave, for three different values of k, when $a = 0.49$.*

the line of the array, and thus the amplitude of the antisymmetric mode tends to zero as the incidence angle tends to zero. The amplitude rises sharply as ψ_0 increases from zero, and the maximum amplitude occurs for quite small angles.

Figures 3.1–3.2 clearly show that the amplitude of the surface waves that are excited are greatest when the frequency parameter k is close to its maximum possible value for the modes to exist. When k is just less than $k_{\max}$, $\widetilde{\beta}$ is just less than π, and as $\widetilde{\beta} \to \pi$ from below, the Rayleigh–Bloch mode approaches a standing wave and its group velocity, $c_{\rm g}$, tends to zero. The energy in the Rayleigh–Bloch wave is proportional to $|\alpha|^2$, and thus the rate of energy transport is proportional to $|\alpha|^2 c_{\rm g}$, which tends to zero as $k \to k_{\max}$. Hence the large amplitudes correspond to situations where the energy is transported slowly away from the array edge.

4. The far field. From (2.4), (2.13), and (3.1), the scattered field can be written as

$$\phi_{\rm sc} = \sum_{j=0}^{\infty}\sum_{n=-\infty}^{\infty}\left(\mathrm{e}^{\mathrm{i}\lambda j}B_n + \alpha\,\mathrm{e}^{\mathrm{i}\widetilde{\beta}j}\widetilde{B}_n + \hat{C}_n^j\right)Z_n \times \frac{(-\mathrm{i})^{n+1}}{\pi}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{-k\gamma(t)|y|}}{\gamma(t)}\,\mathrm{e}^{\mathrm{i}k(x-j)t}\,(t-\gamma(t))^{n\,\mathrm{sgn}(y)}\,\mathrm{d}t. \tag{4.1}$$

The spatial sums involving B_n and $\widetilde{B}_n$ can be evaluated using the result

$$\sum_{j=0}^{\infty}\int_{-\infty}^{\infty} f(u)\,\mathrm{e}^{-\mathrm{i}ju}\,\mathrm{d}u = \int_{-\infty}^{\infty}\frac{f(u)}{1-\mathrm{e}^{-\mathrm{i}u}}\,\mathrm{d}u \tag{4.2}$$

(see [8], [25]). Thus

$$\phi_{\rm sc} = \sum_{n=-\infty}^{\infty} Z_n\frac{(-\mathrm{i})^{n+1}}{\pi}\int_{-\infty}^{\infty}\left[b_n(t)+\tilde{b}_n(t)+\hat{c}_n(t)\right](t-\gamma(t))^{n\,\mathrm{sgn}(y)}\,\mathrm{e}^{-k\gamma(t)|y|+\mathrm{i}kxt}\frac{\mathrm{d}t}{\gamma(t)}, \tag{4.3}$$

in which

$$b_n(t) = \frac{B_n}{1 - \mathrm{e}^{\mathrm{i}(\lambda - kt)}}, \qquad \tilde{b}_n(t) = \frac{\alpha \tilde{B}_n}{1 - \mathrm{e}^{\mathrm{i}(\tilde{\beta} - kt)}}, \tag{4.4}$$

$$\hat{c}_n(t) = \sum_{j=0}^{\infty} \hat{C}_n^j \mathrm{e}^{-\mathrm{i}kjt}, \quad \mathrm{Im}(t) \leq 0. \tag{4.5}$$

The path of integration passes below all of the singularities, apart from the branch point at $t = -1$.

In general the far field asymptotics of (4.3) can be obtained via a straightforward application of the method of steepest descents, provided that the point of observation is not close to the array. The function $\hat{c}_n(t)$ is analytic in $\mathrm{Im}(t) < 0$ by definition, and from (3.7) and [26, section 3.4] the only singularities on $\mathbb{R}$ are branch points, on approach to which $\hat{c}_n(t)$ remains bounded; these do not contribute to the leading order far field behavior of ϕ_{sc}. For $\mathrm{Im}(t) > 0$, $\hat{c}_n(t)$ represents the meromorphic continuation of (4.5) into some cut upper half-plane. While $\hat{c}_n(t)$ may possess singularities in this region, these will yield an exponentially small contribution to the far field should they be encountered in the process of making the steepest descents deformation. Also, the poles of $\tilde{b}_n(t)$ lie outside the interval $[-1, 1]$, so that their contribution is also exponentially small. Thus, only the term involving $b_n(t)$ requires special treatment. First, assume that the saddle point $t = \cos\theta$ does not coincide with any of the poles of $b_n(t)$. Ignoring evanescent contributions, we find that as $kr \to \infty$ with $\theta \in (0, 2\pi)$ (provided $\psi_m \neq 0$ for any m),

$$\phi_{\mathrm{sc}} \sim \widetilde{H}(kr) g(\theta) + \sum_{\substack{m \in \mathcal{M} \\ \psi_m > \theta}} \mathcal{F}_m^+ \mathrm{e}^{\mathrm{i}kr\cos(\theta - \psi_m)} + \sum_{\substack{m \in \mathcal{M} \\ 2\pi - \psi_m < \theta}} \mathcal{F}_m^- \mathrm{e}^{\mathrm{i}kr\cos(\theta + \psi_m)}. \tag{4.6}$$

Here, $\mathcal{F}_m^{\pm}$ is defined in (2.15), $\widetilde{H}(kr) = \sqrt{\frac{2}{\pi kr}}\, \exp(\mathrm{i}(kr - \frac{1}{4}\pi))$, and

$$g(\theta) = \sum_{n=-\infty}^{\infty} (-\mathrm{i})^n \mathrm{e}^{\mathrm{i}n\theta} Z_n\big(b_n(\cos\theta) + \tilde{b}_n(\cos\theta) + \hat{c}_n(\cos\theta)\big). \tag{4.7}$$

The diffracted field takes the form of a circular wave of directivity $g(\theta)$ plus a sum of plane waves which propagate in the same directions as in the infinite grating case. However, unlike in the grating problem, the plane waves do not exist everywhere, and the wave making an angle ψ_m (resp., $-\psi_m$) with the x-axis is found only in the sector $0 < \theta < \psi_m$ (resp., $2\pi > \theta > 2\pi - \psi_m$). Crucially, the coefficients $\hat{C}_n^m$ affect only the circular wave. The plane wave field is determined entirely from the solution to the infinite grating problem; in fact, where the plane waves exist, their amplitude is precisely as in the infinite grating problem. Thus it is only the circular wave which causes any computational difficulties.

4.1. Uniform asymptotics. The approximation (4.6) is nonuniform in the sense that $b_n(\cos\theta)$ is singular at the shadow boundaries where $\theta = \psi_p$ or $\theta = 2\pi - \psi_p$ (a case which corresponds to a pole of $b_n(t)$ coinciding with the saddle point). This limitation can be overcome by adding correction terms, each of which includes an error function which rapidly but continuously activates and deactivates the appropriate plane wave as the shadow boundary is crossed. These correction terms have appeared in the literature in numerous forms and with various regions of validity. The appropriate form for use here is that given by Thompson [27], since this accounts for limits

in which a shadow boundary in $y > 0$ approaches its counterpart in $y < 0$. Thus, the uniform approximation to $\phi_{\rm sc}$ is

$$\phi_{\rm sc} \sim \widetilde{H}(kr)g(\theta) + \tfrac{1}{2}\mathrm{e}^{\mathrm{i}kr} \sum_{m\in\mathcal{M}} \left[\mathcal{F}_m^+ \left(w\left(\zeta_m^- \mathrm{e}^{\mathrm{i}\pi/4}\right) - \frac{\mathrm{e}^{\mathrm{i}\pi/4}}{\zeta_m^- \sqrt{\pi}} \right) + \mathcal{F}_m^- \left(w\left(\zeta_m^+ \mathrm{e}^{\mathrm{i}\pi/4}\right) - \frac{\mathrm{e}^{\mathrm{i}\pi/4}}{\zeta_m^+ \sqrt{\pi}} \right) \right], \tag{4.8}$$

where $\zeta_m^\pm = \sqrt{2kr}\sin\frac{1}{2}(\theta \pm \psi_m)$ and $w(z) = \exp(-z^2)\operatorname{erfc}(-\mathrm{i}z)$ is the scaled complex error function. It is not difficult to show that (4.8) is continuous at all of the shadow boundaries, as the singularities in $\widetilde{H}(kr)g(\theta)$ are cancelled by those in the series (note that $w(0) = 1$). Now, if $\zeta_m^\pm > 0$, we can use the result [28, equation (7.1.23)]

$$w(z) \sim \mathrm{i}/(z\sqrt{\pi}) + O(z^{-3/2}), \quad z \to \infty, \quad -\pi/4 < \arg(z) < 5\pi/4, \tag{4.9}$$

to show that the correction term vanishes to leading order as $kr \to \infty$. On the other hand, for $\zeta_p < 0$, we must first apply the identity

$$w(z) + w(-z) = 2\mathrm{e}^{-z^2} \tag{4.10}$$

and then use (4.9) to deduce that

$$\frac{\mathrm{e}^{\mathrm{i}kr}}{2}\left(w\left(\zeta_p^\pm \mathrm{e}^{\mathrm{i}\pi/4}\right) - \frac{\mathrm{e}^{\mathrm{i}\pi/4}}{\zeta_p^\pm \sqrt{\pi}} \right) \sim \mathrm{e}^{\mathrm{i}kr\cos(\theta\pm\psi_p)} + O((kr)^{-3/2}) \tag{4.11}$$

as $kr \to \infty$. Thus each error function term in (4.8) (which is an exact solution to the Helmholtz equation) includes a plane wave in the appropriate region.

Note that the limit $y \to 0$ of (4.3) can be taken directly, provided that $x < 0$, since then convergence can be maintained by deforming the path of integration into the lower half-plane. The value taken for $\operatorname{sgn}(0)$ is immaterial. To see this, subtract (4.3) with $y = 0^+$ from the same equation with $y = 0^-$. The resulting integrand has no branch point at $t = -1$, in view of the identity $(t - \gamma(t))^n = (t + \gamma(t))^{-n}$, and therefore evaluates to zero. This shows that (4.6) and (4.8) are valid at $\theta = \pi$. For $x > 0$, the required upwards deformation cannot be performed since the sums of residues from $b(t)$ and $\tilde{b}(t)$ and of branch point contributions from $\hat{c}_n(t)$ all diverge when $y = 0$. Consequently, (4.8) represents only a part of the far field at $\theta = 0$ and $\theta = 2\pi$, and not necessarily the most significant.

Figure 4.1 shows a contour plot of the real part of the scattered field, with $a = 0.25$, $\psi_0 = 0.25\pi$, and $k = 5.0$, using Dirichlet boundary conditions. Table 4.1 contains the amplitudes of the propagating modes for this case, and the real part of the leading order contribution to the far field given by (4.8) is plotted in Figure 4.2, with $r = 5$. The imaginary part exhibits qualitatively similar behavior and is not shown. The black disks indicate the locations of the shadow boundaries. The data from which the dashed line is plotted includes contributions from plane waves and is therefore continuous. The solid line represents the same uniform approximation, but with the plane waves removed via (4.10). The two lines coincide in the region $0.69\pi < \theta < 1.25\pi$ where no plane waves exist; here the circular wave is clearly visible in Figure 4.1. The sizes of the discontinuities in the solid line are consistent with the mode amplitudes in Table 4.1; all of the associated shadow boundaries are clearly evident in Figure 4.1.

4.2. Behavior of $\hat{C}_n^p$ as $p \to \infty$. Finally, we give some justification for (3.7), though this will not amount to a rigorous proof. The total field in the region $r_p < 1/2$ (i.e., local to scatterer p) can be written in the form [13]

$$\phi = \sum_{n=-\infty}^{\infty} A_n^p \left[Z_n H_n(kr_p) - J_n(kr_p) \right] \mathrm{e}^{\mathrm{i}n\theta_p}. \tag{4.12}$$

If we write similar expressions for $\phi^{\rm inf}$ and $\phi^{\rm rb}$ (see section 2) and introduce $\hat{\phi} = \phi - (\phi^{\rm inf} + \phi^{\rm rb})$, then from (3.1) we have

$$\hat{\phi} = \sum_{n=-\infty}^{\infty} \hat{C}_n^p \left[Z_n \, H_n(kr_p) - J_n(kr_p) \right] \mathrm{e}^{\mathrm{i}n\theta_p}. \tag{4.13}$$

For sufficiently large p, $\hat{\phi}$ represents the field due to end effects other than the Rayleigh–Bloch wave, and its asymptotic behavior is evidently determined by that of $\hat{C}_n^p$. It is not difficult to show that $\hat{\phi}$ can also be represented by (4.3), but with the path of integration now passing above the poles. Nevertheless, we cannot set $y = 0$, since then the sum of contributions from the branch points of $\hat{c}_n(t)$ would diverge. Instead, we can impose the restriction $y < a$, so that letting $x \to \infty$ causes θ to approach zero. Then, we deform the contour into the upper half-plane and deduce the leading order behavior of $\hat{\phi}$ as $x \to \infty$. The phase dependence and rate of decay of $\hat{C}_n^p$ as $p \to \infty$ must be such that the result of this calculation is consistent with (4.13). Now we introduce the ansatz

$$\hat{C}_n^p \sim C_n \mathrm{e}^{\mathrm{i}p\xi} p^{-u}, \tag{4.14}$$

in which C_n is a constant, $u > 0$, and $\xi > 0$, and substitute this into (4.5). Clearly, the critical points will be those at which the phase disappears; therefore we define

$$t_m = (\xi + 2m\pi)/k. \tag{4.15}$$

The behavior of $\hat{c}_n(t)$ in the vicinity of $t = t_m$ now follows from [26, section 3.4]. Thus, as $(t_m - t) \to 0^+$, we have

$$\hat{c}_n(t) = C_n \Gamma(1-u) \mathrm{e}^{\mathrm{i}\pi(1-u)/2} \xi^{u-1} (t_m - t)^{u-1} + f_n(t), \quad u \neq 1, \tag{4.16}$$

where $f_n(t)$ is regular at $t = t_m$ and the terms with exponent $u - 1$ are positive real. If $u = 1$, then the integrand in (4.3) possesses logarithmic singularities whose contribution cannot be consistent with (4.13). There are now two cases to consider. If $\xi \neq k$, then the leading order behavior must be due to a singularity of the function $\hat{c}_n(t)$, since the contribution from the branch point at $t = 1$ (which in general is $O((kr)^{-1/2})$) has the wrong phase, according to (4.13). Consequently, we must have $u < 1/2$ in this case. On the other hand, if $\xi = k$, then the singularity at $t = 1$ yields a contribution whose rate of decay is slower than that predicted by (4.13), unless a sufficient number of terms vanish as $\theta \to 0$ (or 2π) so as to achieve consistency. Note that we must have $u > 1/2$, or else the sum from $j = 0$ to $j = p - 1$ on the left-hand side of (3.3) would diverge as $p \to \infty$ due to phase cancellation. If $u = 3/2$, only the leading order term must disappear, that is, $g(0) = g(2\pi) = 0$, and now both (4.3) and (4.13) predict that the leading order far field behavior of $\hat{\phi}$ on the array is $O((kr)^{-3/2})$. This is borne out by numerical computations and is also the behavior proved in [8] using the discrete Wiener–Hopf technique for a semi-infinite array of point scatterers (which is equivalent to taking only the monopole terms in the Dirichlet problem here).

5. Resonance. Resonance occurs when one of the modes in (4.6) propagates in a direction parallel to the array. This requires that either $\psi_m = 0$ or $\psi_m = \pi$ for some m; see (2.10). In general, resonances can occur only if $k > \pi$, thereby precluding the possibility of simultaneous occurrence with Rayleigh–Bloch waves. The special case of head-on incidence ($\psi_0 = 0$) is resonant for *all* k; symmetric Rayleigh–Bloch waves

may be excited if $k < \pi$. We will take (3.11) as the starting point for solving resonant problems. Now, in order to use the infinite array subtraction technique we must first compute the coefficients B_n in the resonant case; this is complicated by the fact that the Schlömilch series in (2.9) are now divergent. However, it can be achieved using the method developed in [17]. The form for the mode amplitude $\mathcal{F}_m^{\pm}$ in the limit $\sin\psi_m \to 0$ is also given in [17]. It was noted in [6, 29] that for point scatterers all the nonresonant scattered modes disappear at resonance. To see this, one need only note that the solution for point scatterers is retrieved by truncating all order summations at zero. Then, at a resonance, the divergence of the Schlömilch series in (2.8) requires that $B_0 = 0$, which in turn implies that $\mathcal{F}_p^{\pm} = 0$, unless mode p is resonant in which case we have $\mathcal{F}_p^{\pm} = -1$; see [17]. For finite size scatterers, however, singular behavior in the Schlömilch series requires that the coefficients B_n satisfy a modified system of equations which permits nonzero values (except in the case of head-on incidence), and thus all the modes are present in the scattered field.

5.1. Outward resonance. The case in which $\psi_m = \pi$ is known as outward resonance, since now mode m has the form $\mathcal{F}_m^{\pm}\mathrm{e}^{-\mathrm{i}kx}$. This can occur only if $k > \pi$; therefore no Rayleigh–Bloch waves are excited. Outward resonant modes exist in all space; however, in general they have different amplitudes in regions $y < 0$ and $y > 0$. Once the resonant solution to the infinite array problem has been obtained, no further special treatment is required, and the coefficients C_m^p can be computed from (3.11). Note that, in the case of point scatterers, in which $B_0 = 0$, the right-hand side of (3.11) vanishes, so that $C_0^p = 0$ for all p, and therefore the circular wave term in (4.6) also disappears. For finite sized scatterers, this is not the case, since $B_n \neq 0$ in general.

Figure 5.1 shows a contour plot of the real part of the scattered field, with $a = 0.25$, $\psi_0 = 0.6\pi$, and the wavenumber chosen so that mode -1 is outward resonant ($k \approx 9.1$). Including the resonant mode, there are three propagating plane waves; the amplitudes above and below the array are shown in Table 5.1. Since the amplitude of mode 1 is relatively small, its shadow boundaries are not visible in Figure 5.1; however, those at $\theta = 0.6\pi$, $\theta = \pi$, and $\theta = 1.4\pi$ are clearly evident. The presence of mode 0 when $\theta < 0.6\pi$ and $\theta > 1.4\pi$ accounts for the interference in this region. The real part of the leading order contribution to the far field given by (4.8) is plotted in Figure 5.2, with $r = 5$. As before, the black disks indicate the locations of the shadow boundaries, and the dashed line includes contributions from plane waves, whereas the solid line does not. Notice in particular the smooth transition that occurs in the amplitude of the resonant mode across $\theta = \pi$. This effect is due to the coincidence of two shadow boundaries directly opposite the array; thus, as the observer moves from the region where $\theta < \pi$ to that where $\theta > \pi$, the mode $\mathcal{F}^{+}\mathrm{e}^{-\mathrm{i}kx}$ is deactivated, and $\mathcal{F}^{-}\mathrm{e}^{-\mathrm{i}kx}$ is activated in its place. The sizes of the discontinuities that occur at the shadow boundaries are consistent with the mode amplitudes shown in Table 5.1. Note that the plane wave terms are, in general, of greater amplitude than the circular wave; this is why the latter is not particularly visible in Figure 5.1.

5.2. Inward resonance. The inward resonance case in which $\psi_m = 0$ is more interesting and presents more of a challenge. The extra difficulty in handling inward resonance was noted by Hills [29], who attempted to analyze this case for a semi-infinite array of isotropic point scatterers. As before, we require the coefficients B_n from the infinite array problem, and these can be obtained using the method in [17]. There is now an additional obstacle, caused by the divergence of the series in the

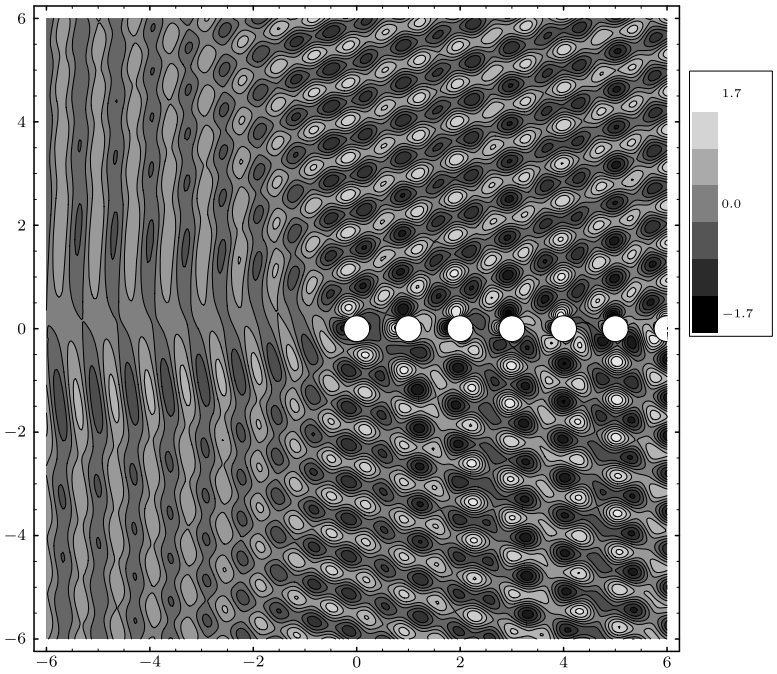

FIG. 5.1. *Contour plot of* $\mathrm{Re}[\phi_{\mathrm{sc}}]$*, with* $a = 0.25$*,* $\psi_0 = 0.6\pi$*, and the wavenumber chosen so that mode* -1 *is (outward) resonant (*$k \approx 9.1$*).*

TABLE 5.1

right-hand side of (3.11). In fact, it can be deduced from equations in [23] that

$$S_n^p(\lambda) = \hat{S}_n^p(\lambda) + 2(-\mathrm{i})^n \mathrm{e}^{\mathrm{i}pk}/(k\psi_m), \tag{5.1}$$

where $\hat{S}_n^p(\lambda)$ remains bounded as $\psi_m \to 0$, and we have used the fact that, since mode m is resonant, $\cos\psi_0 = (1 - 2m\pi)/k$. In order for the solution to remain bounded,

we must have

$$\frac{2}{k}\sum_{n=-\infty}^{\infty}(-\mathrm{i})^n Z_n B_n = a_1\psi_m + O(\psi_m^2), \tag{5.2}$$

and the value of the constant a_1 is obtained as a by-product of the procedure used in computing B_n; see [17]. Equation (3.11) now becomes

$$C_m^p + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0\\ \neq p}}^{\infty} C_n^j X_{n-m}^{jp}\, H_{n-m}(k|j-p|) = a_1 \mathrm{i}^m \mathrm{e}^{\mathrm{i}pk} + \sum_{n=-\infty}^{\infty} Z_n B_n \hat{S}_{n-m}^p(\lambda). \tag{5.3}$$

The solution to this linear system for an inward resonant case is composed of a sum of two components, each corresponding to one of the terms on the right-hand side of (5.3). The first component is a constant multiple of the solution to the head-on incidence problem; therefore the case where $\psi_0 = 0$ is canonical to all inward resonances at the same frequency. In particular, this means that the most interesting features of the scattered field at inward resonance are purely symmetric, and this is a significant simplification, as we shall see. The second component is akin to the solution of an ordinary (nonresonant) scattering problem; its computation presents no special difficulty beyond those already discussed.

5.3. Head-on incidence ($\psi_0 = 0$). We now consider the head-on incidence case in detail. Note that subtraction of the infinite array solution is not required here, since $B_n = 0$ for all n [17]. Indeed, we also have $a_1 = -1$; therefore (5.3) is identical to (2.5). Also, the integrand in (4.3) no longer has poles at the points $t = \cos\psi_m$, $m \neq 0$, and therefore the scattered plane waves disappear in this case.

It turns out that the coefficients $\hat{C}_n^p$ decay more slowly as p increases than in the nonresonant cases discussed above. To see this, we must consider the boundary condition on the surface of the scatterers for large p. Therefore, we may leave aside for the present the possibility of Rayleigh–Bloch waves, since these independently satisfy the boundary conditions in the far field. Next, we impose the restriction $y < a$ and take the limit $x \to \infty$. Since the incident wave $\mathrm{e}^{\mathrm{i}kx}$ is present everywhere, it follows that there must be a simple pole above the path of integration in (4.3); otherwise $\phi_{\mathrm{sc}} \to 0$ and the boundary condition cannot be satisfied. In order for its contribution to possess the correct x dependence, this singularity must be located at $t = 1$. Indeed, from (4.14)–(4.16), we must have

$$\hat{C}_n^p = C_n^p \sim C_n p^{-1/2}\mathrm{e}^{\mathrm{i}kp} \tag{5.4}$$

as $p \to \infty$, so that $\hat{c}_n(t)$ has a branch point at $t = 1$ and the ratio $\hat{c}_n(t)/\gamma(t)$ has the required simple pole. The residue can also be deduced; thus from (4.3), (4.16), and (5.4),

$$\sum_{n=-\infty}^{\infty}(-\mathrm{i})^n Z_n C_n = -\sqrt{k/(2\pi)}\mathrm{e}^{\mathrm{i}\pi/4}, \tag{5.5}$$

so that

$$\phi \sim \mathrm{e}^{\mathrm{i}kx} - \mathrm{e}^{\mathrm{i}kr\cos\theta} \to 0 \tag{5.6}$$

as $x \to \infty$.

If the frequency is sufficiently low to permit the excitation of Rayleigh–Bloch waves, double filtering can be applied to (5.3); only the right-hand side differs from (3.11). Indeed, of the methods described in section 3, only double filtering yields accurate results in the head-on incidence case. This is due to the rate of decay of the coefficients $\hat{C}_n^p$ as $p \to \infty$ given by (5.4) being slower than that which occurs in other cases (cf. (3.7)).

Results in the appendix show that the coefficients C_n can be approximated via

$$C_n = \lim_{p\to\infty} \mathrm{e}^{-\mathrm{i}kp} C_n^p; \tag{5.7}$$

the computed values can then be checked using (5.5). At higher frequencies, i.e., for $k > \pi$, single filtering can be used with k in place of $\tilde{\beta}$. The values for C_n can then be approximated using the limit

$$C_n = \lim_{p\to\infty} \sqrt{p} \sum_{j=0}^{p} \mathrm{e}^{-\mathrm{i}kj} D_n^j. \tag{5.8}$$

Since $\hat{c}_n(t)$ is $2\pi/k$ periodic, it is evident that there are now branch points located at

$$t = \cos\psi_m = 1 + 2m\pi/k, \quad m \neq 0. \tag{5.9}$$

The path of integration in (4.3) is indented so as to pass below these singularities. We can deduce from (4.16) and (5.4) that

$$\hat{c}_n(t) = \frac{C_n \mathrm{e}^{-\mathrm{i}\pi/4}\sqrt{\pi/k}}{(t-\cos\psi_m)^{1/2}} + f_n(t), \tag{5.10}$$

where $f_n(t)$ is regular in the vicinity of the point $t = \cos\psi_m$ and the branch of the fractional power is chosen so that $(t-\cos\psi_m)^{1/2} = \sqrt{t-\cos\psi_m}$ for $t > \cos\psi_m$. Now the asymptotic behavior of an integral with branch points (that are not branch points of the exponent) is far more complicated than that of an integral with poles. The essential reason for this is that a rational function can easily be split into partial fractions, whereas a product of square roots cannot. Therefore we make the assumption that the neighborhood of the point $t = \cos\psi_m$ in which $f_n(t)$ is analytic is of sufficient size to permit the branch points of $\hat{c}_n(t)$ to be treated separately. This is valid if k is not too large. Of course, if $k < \pi$, the branch points of $\hat{c}_n(t)$ given by (5.9) lie outside the interval $[-1, 1]$ and are of no concern since their contribution to the far field is evanescent. Otherwise, if $\cos\psi_m \in (-1, 1)$, then we shall write $m \in \mathcal{M}$, as before. Note that this requires $m < 0$ and $k > -m\pi$.

When the saddle point in (4.3) lies to the right of a branch point (other than $t = -1$), then the steepest descent path is diverted in a counterclockwise loop around the cut, and an extra contribution must be included in the far field. The contribution from $t = \cos\psi_m$ is therefore present only in the regions where $\theta < \psi_m$ and $\theta > 2\pi - \psi_m$, which is the behavior exhibited by the scattered plane waves in the nonresonant case. Since the field is symmetric at head-on incidence, we give results for $y \geq 0$ only. Provided that we are not close to the array, we have, from (4.3) and (5.10),

$$\phi_{\mathrm{sc}} \sim \sqrt{\frac{2}{\pi kr}} \mathrm{e}^{-\mathrm{i}\pi/4} \left[h(\theta)\mathrm{e}^{\mathrm{i}kr} + \sum_{\substack{m\in\mathcal{M} \\ \psi_m > \theta}} \frac{\mathcal{G}(\psi_m)\mathrm{e}^{\mathrm{i}kr\cos(\theta-\psi_m)}}{\sqrt{\sin(\psi_m - \theta)}} \right], \tag{5.11}$$

in which

$$h(\theta) = \sum_{n=-\infty}^{\infty} (-\mathrm{i})^n Z_n \hat{c}_n(\cos\theta)\mathrm{e}^{\mathrm{i}n\theta}, \tag{5.12}$$

and

$$\mathcal{G}(\psi) = \sqrt{\frac{2\pi}{k\sin\psi}}\mathrm{e}^{\mathrm{i}\pi/4} \sum_{n=-\infty}^{\infty} Z_n C_n (-\mathrm{i})^n \mathrm{e}^{\mathrm{i}n\psi}. \tag{5.13}$$

Thus, the branch point contribution is not a circular wave, as its crests are linear, perpendicular to the line $\theta = \psi_m$. Noting from (5.9) that $\mathrm{e}^{\mathrm{i}n\psi_m} = 1 + O(k^{-1})$, it then follows from (5.5) that a multiplicative factor $\mathcal{G}(\psi_m)$ has no bearing on the asymptotic dependence upon k, to leading order.

5.4. Uniform asymptotics. The approximation (5.11) is nonuniform in the sense that it is singular at the shadow boundaries, where $\psi_m = \theta$. The uniform counterpart to (5.11) is given by

$$\begin{aligned}\phi_{\mathrm{sc}} \sim \mathrm{e}^{\mathrm{i}kr}\Bigg\{ & \mathrm{e}^{-\mathrm{i}\pi/4}\sqrt{\frac{2}{\pi kr}}h(\theta) - w\left(\mathrm{e}^{\mathrm{i}\pi/4}\zeta_0\right) + \frac{\mathrm{e}^{\mathrm{i}\pi/4}}{\zeta_0\sqrt{\pi}} - \sum_{m\in\mathcal{M}} \frac{\mathcal{G}(\psi_m)\mathrm{e}^{\mathrm{i}\pi/4}}{\sqrt{\pi}\sqrt[4]{kr}}\sqrt{\sec\frac{\psi_m-\theta}{2}} \\ & \times \left[\mathrm{e}^{\mathrm{i}(3\pi/8-\zeta_m^2/2)} D_{-1/2}\left(\sqrt{2}\mathrm{e}^{-\mathrm{i}\pi/4}\zeta_m\right) - \frac{1}{\sqrt[4]{2}(-\zeta_m)^{1/2}}\right]\Bigg\},\end{aligned} \tag{5.14}$$

in which $\zeta_m = \sqrt{2kr}\sin(\frac{1}{2}(\theta - \psi_m))$. Here, the term involving ζ_0 removes the singularity at $\theta = 0$. Note that the resonant mode actually has *no* region of existence, since $\zeta_0 \geq 0$. Nevertheless, its influence can be felt as $\theta \to 0$, since for small z, $w(z) = \mathrm{e}^{-z^2}[1 + O(z)]$. As in the nonresonant case, in the limit $\theta \to 0$, (5.14) accurately represents a contribution to the far field, though this is not necessarily the most significant. The final term involves the parabolic cylinder function $D_{-1/2}(\cdot)$ and can be obtained using methods outlined in [30], although this is by no means an easy procedure. However, it is relatively straightforward to check that (5.14) is correct. First, it is continuous across all of the shadow boundaries. To see this, we use (5.10) and (5.12) to show that the singular behavior of the term involving $h(\theta)$ at $\theta = \psi_m$ is cancelled by the series. Also, for large $|\zeta|$, we have from [31, section 9.246]

$$\mathrm{e}^{\mathrm{i}(3\pi/8-\zeta^2/2)} D_{-1/2}(\sqrt{2}\mathrm{e}^{-\mathrm{i}\pi/4}\zeta) = \frac{1 + \mathrm{i}\sqrt{2}\,\mathrm{H}(-\zeta)\mathrm{e}^{-\mathrm{i}\zeta^2}}{\sqrt[4]{2}(-\zeta)^{1/2}} + O(\zeta^{-5/2}), \tag{5.15}$$

where $\mathrm{H}(\cdot)$ is the Heaviside unit function and $(-\zeta_m)^{1/2}$ is either positive real or negative imaginary. If we now use this expansion, along with (4.9), in (5.14), we retrieve (5.11), as we should expect. Note that $D_{-1/2}(0) \approx 1.216$; therefore in the vicinity of the shadow boundary, the scattered field is $O((kr)^{-1/4})$, as in the case of point scatterers [29].

Figure 5.3 shows a contour plot of the real part of the total field, at head-on incidence with $a = 0.25$ and $k = 2.0$. The cancellation of the incident field close to the array is clearly apparent, so that the symmetric Rayleigh–Bloch wave (for which $|\alpha| \approx 0.542$) is clearly visible.

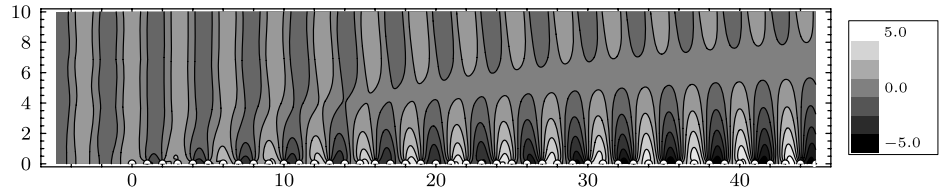

FIG. 5.3. *Contour plot of the real part of the total field,* $\mathrm{Re}[\phi]$ *at head-on incidence with* $a = 0.25$ *and* $k = 2.0$.

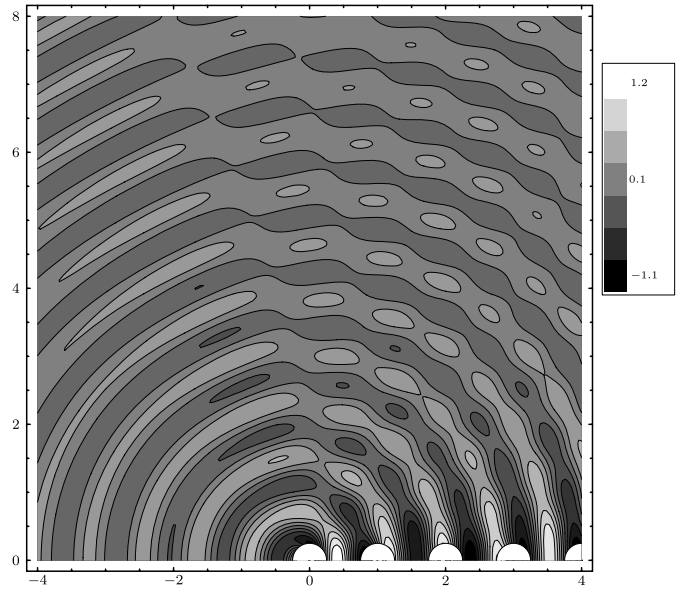

FIG. 5.4. *Contour plot of* $\mathrm{Re}[\phi_{\mathrm{sc}}]$*, at head-on incidence with* $a = 0.25$ *and* $k = 8.0$*, using Dirichlet boundary conditions.*

The branch point contributions that are significant at higher frequencies can most easily be observed in a plot of the scattered field. Thus, Figure 5.4 shows a contour plot of $\mathrm{Re}[\phi_{\mathrm{sc}}]$, with $a = 0.25$ and $k = 8.0$, using Dirichlet boundary conditions. Values of ψ_m for which $m \in \mathcal{M}$ and the associated values of $|\mathcal{G}(\psi_m)|$ are shown in Table 5.2. Far field plots with $r = 8$ are shown in Figure 5.5, with shadow boundaries indicated by black disks. The dashed line is computed from (5.14), whereas for the solid line, $D_{-1/2}(\sqrt{2}\mathrm{e}^{-\mathrm{i}\pi/4}\zeta)$ is replaced by $-\mathrm{i}D_{-1/2}(\sqrt{2}\mathrm{e}^{-\mathrm{i}\pi/4}|\zeta|)$ for $\zeta < 0$ so as to deactivate the branch point contributions. This plot is therefore discontinuous at the shadow boundaries, and the sizes of the discontinuities are consistent with the values of $|\mathcal{G}(\psi_m)|$ in Table 5.2. There are three regions to consider. For $\theta \gtrsim 0.69\pi$, no branch point contributions are present in the field, and the circular wave dominates. For smaller observation angles, a branch point contribution is activated, causing interference. Notice in particular the strong field close to the shadow boundary, where (5.14) predicts $O((kr)^{-1/4})$ behavior. A second branch point contribution is active when $\theta \lesssim 0.43\pi$. This is somewhat weaker and has a more limited effect on the field pattern.

TABLE 5.2
Shadow boundary locations and values of $\mathcal{G}(\psi_m)$ for the plot shown in Figure 5.1.

m	ψ_m	$\lvert\mathcal{G}(\psi_m)\rvert$
-2	0.69π	0.39
-1	0.43π	0.12

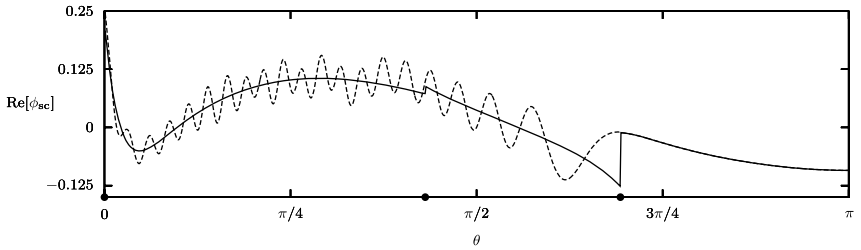

FIG. 5.5. *Far field plots for the parameters used in Figure* 5.4*, with $r = 8$. Correction terms are included for both shadow boundaries; the dashed line includes branch point contributions, whereas the solid line does not.*

A final possibility is that of *double resonance*, which requires that $k = n\pi$, $n \in \mathbb{N}$. In this case, if $\cos\psi_m = 1$, then $\cos\psi_{m-n} = -1$, so that modes m and $m - n$ are inward and outward resonant, respectively. Once the coefficients B_n for the infinite array problem have been obtained using the method in [17], the computation of the coefficients C_m^p for this case presents no special difficulty beyond those already discussed. However, the determination of the far field pattern involves a significant additional complication and will therefore appear in a future paper.

6. Conclusion. Problems involving semi-infinite arrays are notoriously difficult to solve accurately because the inevitable spatial truncation that has to be made can introduce significant errors. We have shown how infinite array subtraction, together with a novel filtering approach, can be used to obtain accurate solutions which can be computed efficiently for two-dimensional acoustic scattering of a plane wave by a semi-infinite array of rigid or soft circles. Unlike the case of isotropic point scatterers solved previously by one of the authors [8], this case is made considerably more complicated by the presence of Rayleigh–Bloch surface waves which can be excited along the array. We have presented methods which enable the amplitude of these modes to be computed accurately for the first time.

In nonresonant and outward resonant cases, the far field away from the array has been shown to be composed of the sum of a finite number of plane waves propagating in different directions and a circular wave emanating from the edge of the array. At inward resonance, the field can include additional terms that are neither circular waves nor plane waves. Uniform asymptotic expansions that vary continuously across all shadow boundaries have been derived.

If the incident field is generated by a line source rather than a plane wave, then the problem is much easier from a computational point of view. There is now no need to subtract an infinite array solution, since the decay of the source potential with distance means that the errors introduced by spatial truncation are small, and there is no need for double filtering because there are no resonances. Once the Rayleigh–Bloch waves are removed by single filtering, the remaining contribution in the coefficients D_n^p will decay like $p^{-3/2}$ as $p \to \infty$. The solution to the source-excitation problem has been

implemented by the authors; the results offer no extra insight, though the problem may be important for practical applications.

One of the main reasons for studying semi-infinite arrays is that they provide a tool with which to analyze large finite arrays. Thus we intend to use the techniques presented in this paper to study scattering by a long finite array under the assumption that the ends of the array are far enough apart to be treated separately.

Appendix. If we define

$$\Delta^p_m = \Gamma^p_m - \mathrm{e}^{\mathrm{i}\tilde{\beta}}\Gamma^{p-1}_m, \qquad p = 2, 3, \ldots, \tag{A.1}$$

then from (3.16) and (3.19) we obtain

$$E^p_m + \sum_{n=-\infty}^{\infty} Z_n \sum_{\substack{j=0\\ \neq p}}^{\infty} E^j_n X^{jp}_{n-m}\, H_{n-m}(k|j-p|) = \Delta^p_m - \mathrm{e}^{\mathrm{i}k}\Delta^{p-1}_m, \tag{A.2}$$

$p = 2, 3, \ldots, m \in \mathbb{Z}$. The equations in which $p = 0$ and $p = 1$ now require special treatment. From (3.19), we have

$$D^p_m = \sum_{j=0}^{p} \mathrm{e}^{\mathrm{i}(p-j)k} E^j_m, \qquad p = 0, 1, 2, \ldots. \tag{A.3}$$

Setting $p = 1$ in (3.16) we find that

$$\begin{aligned} \mathrm{e}^{\mathrm{i}k}E^0_m + E^1_m + \sum_{n=-\infty}^{\infty} E^0_n Z_n\, H_{n-m}(k) \\ + \sum_{n=-\infty}^{\infty} (-1)^{n-m} Z_n \sum_{j=0}^{\infty} E^j_n\, \mathrm{e}^{\mathrm{i}(1-j)k} \sum_{l=\max(j-1,1)}^{\infty} \mathrm{e}^{\mathrm{i}kl}\, H_{n-m}(kl) = \Delta^1_m. \end{aligned} \tag{A.4}$$

Finally from (3.17), for $p = 0$,

$$E^0_m + \sum_{n=-\infty}^{\infty} Z_n (-1)^{n-m} T_{nm} = \Gamma^0_m, \tag{A.5}$$

where

$$T_{nm} = \sum_{j=0}^{\infty}\sum_{q=0}^{j} E^q_n \mathrm{e}^{\mathrm{i}(j-q)k} \sum_{l=\max(j,1)}^{\infty} \mathrm{e}^{\mathrm{i}\tilde{\beta}(l-j)}\, H_{n-m}(kl). \tag{A.6}$$

This expression can be rearranged so that the sum over j becomes innermost. After evaluating the finite geometric series that appears, we obtain

$$T_{nm} = \frac{1}{\mathrm{e}^{\mathrm{i}\tilde{\beta}} - \mathrm{e}^{\mathrm{i}k}} \sum_{q=0}^{\infty} E^q_n \sum_{l=\max(q,1)}^{\infty} \left(\mathrm{e}^{\mathrm{i}\tilde{\beta}(1+l-q)} - \mathrm{e}^{\mathrm{i}k(1+l-q)}\right) H_{n-m}(kl). \tag{A.7}$$

The sum over l is again easily expressed in terms of the sums S^p_n defined in (3.4).

To reconstruct the coefficients C_m^p, we substitute (A.3) into (3.14), reverse the order of the summations, and evaluate the resulting geometric series to obtain

$$C_m^p = \frac{\mathrm{e}^{\mathrm{i}p\tilde{\beta}}}{1-\mathrm{e}^{\mathrm{i}(k-\tilde{\beta})}} \sum_{q=0}^{p} E_m^q \mathrm{e}^{-\mathrm{i}q\tilde{\beta}} + \frac{\mathrm{e}^{\mathrm{i}pk}}{1-\mathrm{e}^{-\mathrm{i}(k-\tilde{\beta})}} \sum_{q=0}^{p} E_m^q \mathrm{e}^{-\mathrm{i}qk} \tag{A.8}$$

$$= \frac{\mathrm{e}^{\mathrm{i}p\tilde{\beta}}}{1-\mathrm{e}^{\mathrm{i}(k-\tilde{\beta})}} \sum_{q=0}^{p} E_m^q \mathrm{e}^{-\mathrm{i}q\tilde{\beta}} + \frac{D_m^p}{1-\mathrm{e}^{-\mathrm{i}(k-\tilde{\beta})}}, \tag{A.9}$$

where we have used (3.19) to evaluate the second (telescopic) series.

The Rayleigh–Bloch amplitude α can then be retrieved by letting $p \to \infty$ and using (3.18):

$$\alpha \widetilde{B}_m = \frac{1}{1-\mathrm{e}^{\mathrm{i}(k-\tilde{\beta})}} \sum_{q=0}^{\infty} E_m^q \mathrm{e}^{-\mathrm{i}q\tilde{\beta}}. \tag{A.10}$$

Once again, asymptotic acceleration can be used in the approximate evaluation of this series, once spatial truncation has been applied.

ON THE CONVERGENCE OF THE HARMONIC B_Z ALGORITHM IN MAGNETIC RESONANCE ELECTRICAL IMPEDANCE TOMOGRAPHY*

J. J. LIU†, J. K. SEO‡, M. SINI§, AND E. J. WOO¶

Abstract. Magnetic resonance electrical impedance tomography (MREIT) is a new medical imaging technique that aims to provide electrical conductivity images with sufficiently high spatial resolution and accuracy. A new MREIT image reconstruction method called the harmonic B_z algorithm was proposed in 2002, and it is based on the measurement of B_z that is a single component of an induced magnetic flux density $\mathbf{B} = (B_x, B_y, B_z)$ subject to an injection current. Since then, MREIT imaging techniques have made significant progress, and recent published numerical simulations and phantom experiments show that we can produce high-quality conductivity images when the conductivity contrast is not very high. Though numerical simulations can explain why we could successfully distinguish different tissues with small conductivity differences, a rigorous mathematical analysis is required to better understand the underlying physical and mathematical principle. The purpose of this paper is to provide such a mathematical analysis of those numerical simulations and experimental results. By using a uniform a priori estimate for the solution of the elliptic equation in the divergent form and an induction argument, we show that, for a relatively small contrast of the target conductivity, the iterative harmonic B_z algorithm with a good initial guess is stable and exponentially convergent in the continuous norm. Both two- and three-dimensional versions of the algorithm are considered, and the difference in the convergence property of these two cases is analyzed. Some numerical results are also given to show the expected exponential convergence behavior.

1. Introduction.

Magnetic resonance electrical impedance tomography (MREIT) is an electrical conductivity imaging technique using a magnetic resonance imaging (MRI) scanner with a current injection apparatus. Since the early 1980s, there have been significant efforts to produce cross-sectional images of a conductivity distribution σ inside a three-dimensional body Ω using boundary measurements of current-voltage data (Neumann-to-Dirichlet data) satisfying the elliptic equation $\nabla \cdot (\sigma \nabla u) = 0$ in Ω, and this technique has been called electrical impedance tomography (EIT) [4, 14, 21]. Here u denotes the electric potential inside Ω. It is well known that EIT has suffered from the ill-posedness of the corresponding inverse problem related with the insensitivity of Cauchy data on the boundary $\partial\Omega$ to any internal local change of σ. Acquisition of accurate Cauchy data on $\partial\Omega$ requires a sophisticated EIT instrument and a large number of surface electrodes. In practice, however, the cum-

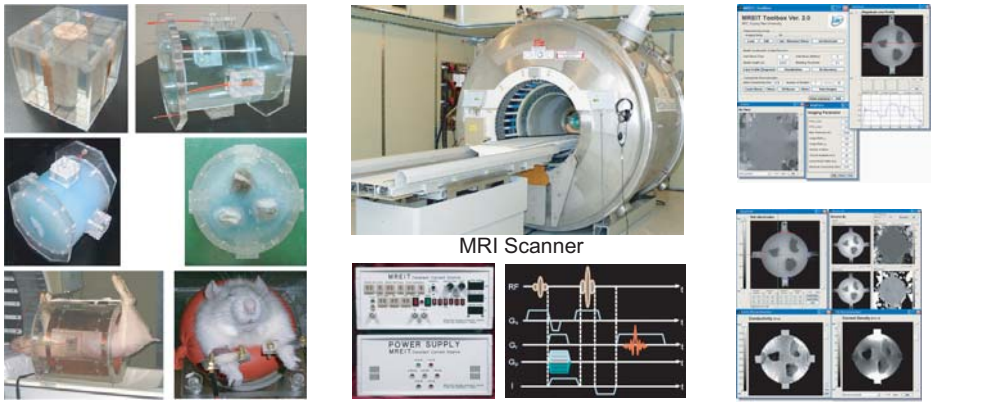

FIG. 1. *MREIT system at Impedance Imaging Research Center in Korea and image reconstruction software.*

bersome procedure to attach many electrodes is prone to increase measurement errors in addition to electronic noise and various artifacts. Furthermore, there exist uncertainties in terms of electrode positions and boundary shape of an imaging subject. Due to the ill-posedness and the errors originating from these practical difficulties, the spatial resolution and accuracy of EIT images are relatively poor, and therefore its applicability has been limited in the clinical environment.

On the other hand, MREIT takes advantage of the internal information of B_z, the z-component of the magnetic flux density distribution $\mathbf{B} = (B_x, B_y, B_z)$ induced by the internal current density $\mathbf{J} = -\sigma \nabla u$ subject to an injection current through a pair of surface electrodes. The B_z data can be measured by using an MRI scanner as illustrated in Figure 1. Here the z-axis is the direction of the main magnetic field of the MRI scanner. MREIT utilizes the fact that the data B_z convey the information about any local change of σ via the Biot–Savart law:

$$B_z(x,y,z) = \frac{\mu_0}{4\pi} \int_\Omega \frac{\sigma(\mathbf{r}) \left[(x-x') \frac{\partial u}{\partial y}(\mathbf{r}') - (y-y') \frac{\partial u}{\partial x}(\mathbf{r}') \right]}{|\mathbf{r}-\mathbf{r}'|^3} \, d\mathbf{r}', \ \mathbf{r} = (x,y,z) \in \Omega.$$

This supplementary use of the internal B_z data enables MREIT to bypass the ill-posedness problem in EIT. In early 2002, the first constructive B_z-based MREIT algorithm called the harmonic B_z algorithm was proposed in [18]. Since then, MREIT has advanced rapidly and now is at the stage of animal experiments [13].

The harmonic B_z algorithm is based on the following curl of the Ampere law:

$$\frac{1}{\mu_0} \Delta B_z = \left\langle \nabla \sigma \, , \, \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix} \nabla u \right\rangle, \tag{1.1}$$

where μ_0 is the magnetic permeability of the free space, $\langle \cdot, \cdot \rangle$ is the inner product, and Δ denotes the Laplacian. Recent published numerical simulations and phantom experiments show that conductivity images with high spatial resolution are achievable [9, 10, 15, 16, 17, 19]. Figure 2 shows a schematic diagram of the harmonic B_z algorithm and typical MREIT images of a conductivity phantom including three chunks of biological tissues having different conductivity values inside a cylindrical container Ω.

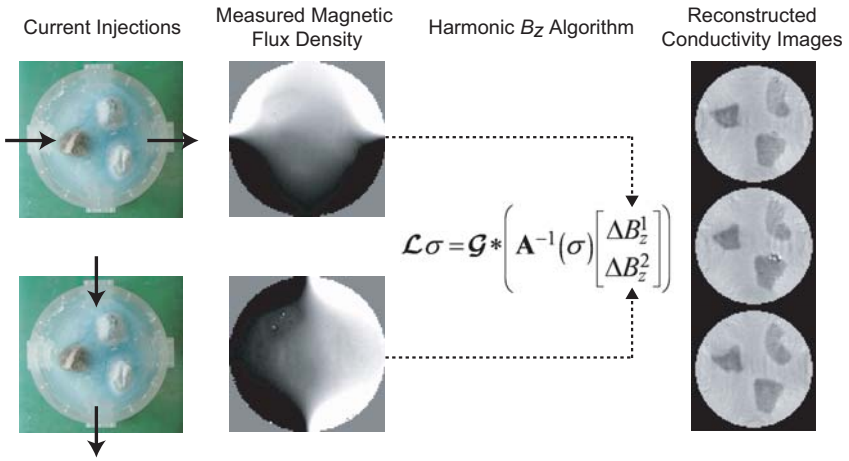

FIG. 2. *Overview of the harmonic B_z algorithm.*

Although the harmonic B_z algorithm shows a remarkable performance in various numerical simulations and phantom experiments, rigorous mathematical theories regarding its convergence behavior have not been supported yet. The purpose of this paper is to deal with this convergence analysis rigorously. For a suitably constructed admissible iteration set in terms of a priori information about the target conductivity, we can prove that the sequence $\{\sigma^n\}$ is uniformly bounded by a uniform estimate on the solution to the elliptic equation in the divergent form. Using this a priori estimate and an induction argument, we show that, in both two- and three-dimensional cases, the harmonic B_z algorithm is stable and exponentially convergent, provided that the contrast of the target conductivity distribution is not very high. It is impossible to get the C^1 convergence in the three-dimensional problem even when the harmonic B_z algorithm is applied to a target conductivity distribution with a small contrast. This mathematical difficulty comes from the algorithm itself. With this theoretical result, we partially answer the question on the applicable scope of the harmonic B_z algorithm and explain the fast convergent phenomena arising in numerical tests. We refer to our recent article [12], which briefly discusses this convergence issue using special examples of two-dimensional conductivity distributions.

It seems that the small contrast in the target conductivity is necessary for the convergence of the harmonic B_z iteration scheme, provided that the input current is not so large. This phenomenon can be explained physically. For a given input current from the boundary, if the conductivity has a large jump inside the medium, then the current going through will be small, and therefore the magnetic flux density will also be weak. For a relatively high contrast of the conductivity distribution, the algorithm needs to be adapted to control the representation of this contrast in the iteration process. This issue should be considered in the future.

2. Exact mathematical model of MREIT. Since our goal is to use the MREIT technique in practical clinical applications, we must set up an exact mathematical model of MREIT that agrees with a planned medical imaging system. To simplify our study, let us make several assumptions which should not go astray from the practical model. Let the subject to be imaged occupy a three-dimensional bounded domain $\Omega \subset \mathbb{R}^3$ with a smooth connected boundary $\partial\Omega$, and each $\Omega_{z_0} := \Omega \cap \{z =$

$z_0\} \subset \mathbb{R}^2$, the slice of Ω cut by the plane $\{z = z_0\}$, has a smooth connected boundary. We assume that the conductivity distribution σ of the subject Ω is isotropic, $C^1(\overline{\Omega})$, and $0 < \sigma_- < \sigma < \sigma_+$ with two known constants $\sigma_\pm$. Though σ is usually piecewise-smooth in practice, this can be approximated by the $C^1(\overline{\Omega})$ function, and so it is a matter of how big $\|\sigma\|_{C^1(\Omega)}$ is. We attach a pair of copper electrodes $\mathcal{E}^+$ and $\mathcal{E}^-$ on $\partial\Omega$ in order to inject current, and let $\mathcal{E}^+ \cup \mathcal{E}^-$ be the portion of the surface $\partial\Omega$ where electrodes are attached; see Figure 2.

The injection current I produces an internal current density $\mathbf{J} = (J_x, J_y, J_z)$ inside the subject Ω satisfying the following problem:

$$\begin{cases} \nabla \cdot \mathbf{J} = 0 \quad \text{in } \Omega, \\ I = -\displaystyle\int_{\mathcal{E}^+} \mathbf{J} \cdot \mathbf{n} ds = \int_{\mathcal{E}^-} \mathbf{J} \cdot \mathbf{n} ds, \quad \mathbf{J} \times \mathbf{n} = 0 \ \text{ on } \mathcal{E}^+ \cup \mathcal{E}^-, \\ \mathbf{J} \cdot \mathbf{n} = 0 \quad \text{on } \partial\Omega \setminus \overline{\mathcal{E}^+ \cup \mathcal{E}^-}, \end{cases} \tag{2.1}$$

where $\mathbf{n}$ is the outward unit normal vector on $\partial\Omega$ and ds the surface area element. The condition of $\mathbf{J} \times \mathbf{n} = 0$ on $\mathcal{E}^+ \cup \mathcal{E}^-$ comes from the fact that copper electrodes are considered as perfect conductors. Since $\mathbf{J}$ is expressed as $\mathbf{J} = -\sigma\nabla u$, where u is the corresponding electrical potential, (2.1) can be converted to

$$\begin{cases} \nabla \cdot (\sigma \nabla u) = 0 \quad \text{in } \Omega, \\ I = \displaystyle\int_{\mathcal{E}^+} \sigma \frac{\partial u}{\partial \mathbf{n}} \, ds = -\int_{\mathcal{E}^-} \sigma \frac{\partial u}{\partial \mathbf{n}} ds, \quad \nabla u \times \mathbf{n} = 0 \ \text{ on } \mathcal{E}^+ \cup \mathcal{E}^-, \\ \sigma \dfrac{\partial u}{\partial \mathbf{n}} = 0 \quad \text{on } \partial\Omega \setminus \overline{\mathcal{E}^+ \cup \mathcal{E}^-}, \end{cases} \tag{2.2}$$

where $\frac{\partial u}{\partial \mathbf{n}} = \nabla u \cdot \mathbf{n}$. The above nonstandard boundary value problem (2.2) is well-posed and has a unique solution up to a constant. We omit the proof of the uniqueness (up to a constant) within the class $W^{1,2}(\Omega)$ since it follows from the standard argument in the PDE.

Let us briefly discuss the boundary conditions that are essentially related with the size of electrodes. The condition $\nabla u \times \mathbf{n}|_{\mathcal{E}^\pm} = 0$ ensures that each of $u|_{\mathcal{E}^+}$ and $u|_{\mathcal{E}^-}$ is a constant, since ∇u is normal to its level surface. The term $\pm I = \int_{\mathcal{E}^\pm} \sigma \frac{\partial u}{\partial \mathbf{n}} \, ds$ means that the total amount of injection current through the electrodes is I mA. Let us denote $g := -\sigma \frac{\partial u}{\partial \mathbf{n}}|_{\partial\Omega}$. In practice, it is difficult to specify the Neumann data g in a pointwise sense because only the total amount of injection current I is known. It should be noticed that the boundary condition in (2.2) leads to $|g| = \infty$ on $\partial\mathcal{E}^\pm$, singularity along the boundary of electrodes, and $g \notin L^2(\partial\Omega)$. But fortunately $g \in H^{-1/2}(\partial\Omega)$, which also can be proven by the standard regularity theory in the PDE.

The exact model (2.2) can be converted into the following standard problem of an elliptic equation with mixed boundary conditions.

LEMMA 2.1. *Assume that $\tilde{u}$ solves*

$$\begin{cases} \nabla \cdot (\sigma \nabla \tilde{u}) = 0 \quad \textit{in} \quad \Omega, \\ \tilde{u}|_{\mathcal{E}^+} = 1, \ \tilde{u}|_{\mathcal{E}^-} = 0, \\ -\sigma \dfrac{\partial \tilde{u}}{\partial \mathbf{n}} = 0 \quad \textit{on} \quad \partial\Omega \setminus (\mathcal{E}^+ \bigcup \mathcal{E}^-). \end{cases} \tag{2.3}$$

If u is a solution of the mixed boundary value problem (2.2)*, then*

$$u = \frac{I}{\int_{\partial\mathcal{E}^+} \sigma \frac{\partial \tilde{u}}{\partial \mathbf{n}}\, ds}\tilde{u} \quad \text{in } \Omega \qquad \textit{(up to a constant).} \tag{2.4}$$

Proof. The proof is elementary by looking at the energy of $w = u - c\tilde{u}$ for a constant c:

$$\begin{aligned}\int_\Omega \sigma|\nabla w|^2\, d\mathbf{r} &= \int_{\partial\Omega} \sigma \frac{\partial w}{\partial \mathbf{n}}\, w\, ds \\ &= \int_{\mathcal{E}^+} \sigma \frac{\partial w}{\partial \mathbf{n}}\, ds\, (u|_{\mathcal{E}^+} - c) + \left(\int_{\mathcal{E}^-} \sigma \frac{\partial w}{\partial \mathbf{n}}\, ds\right) u|_{\mathcal{E}^-} \\ &= (u|_{\mathcal{E}^+} - u|_{\mathcal{E}^-} - c)\left(I - c\int_{\partial\mathcal{E}^+} \sigma \frac{\partial \tilde{u}}{\partial \mathbf{n}} ds\right).\end{aligned}$$

Hence, for $c = \frac{I}{\int_{\partial\mathcal{E}^+} \sigma \frac{\partial \tilde{u}}{\partial \mathbf{n}}\, ds}$, the above relation generates $|\nabla w| = 0$ in Ω, which means w is a constant in Ω. ∎

Now we explain the inverse problem for the MREIT model, in which we try to reconstruct σ. The presence of the internal current density $\mathbf{J} = -\sigma\nabla u$ generates a magnetic flux density $\mathbf{B} = (B_x, B_y, B_z)$ such that the Ampere law $\mathbf{J} = \nabla \times \mathbf{B}/\mu_0$ holds in Ω. With the z-axis pointing to the direction of the main magnetic field of the MRI scanner, the relation between the measurable quantity B_z and the unknown σ is governed by the Biot–Savart law:

$$B_z(\mathbf{r}) = \frac{\mu_0}{4\pi}\int_\Omega \frac{\langle \mathbf{r} - \mathbf{r}',\ \sigma(\mathbf{r}')\mathbb{L}\nabla u(\mathbf{r}')\rangle}{|\mathbf{r} - \mathbf{r}'|^3}\, d\mathbf{r}' \qquad \text{for } \mathbf{r} \in \Omega, \tag{2.5}$$

where

$$\mathbb{L} = \begin{pmatrix} 0 & 1 & 0 \\ -1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}.$$

Here we must read u as a nonlinear function of σ. The following lemma is crucial to understand why we need at least two injection currents with the requirement (2.11) in what follows.

LEMMA 2.2. *Suppose u is a solution of* (2.2) *and the pair (σ, u) satisfies* (2.5)*. Then B_z in* (2.5) *can be expressed as*

$$B_z = \frac{\mu_0}{4\pi}\int_\Omega \frac{-1}{|\mathbf{r} - \mathbf{r}'|}\begin{vmatrix} \frac{\partial\sigma}{\partial x} & \frac{\partial\sigma}{\partial y} \\ \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} \end{vmatrix} d\mathbf{r}' + \frac{\mu_0}{4\pi}\int_{\partial\Omega} \frac{1}{|\mathbf{r} - \mathbf{r}'|}\, \mathbf{n}\cdot(\sigma\mathbb{L}\nabla u)\, ds. \tag{2.6}$$

Moreover, there exist infinitely many pairs $(\tilde{\sigma}, \tilde{u})$ such that

$$\begin{vmatrix} \frac{\partial\sigma}{\partial x} & \frac{\partial\sigma}{\partial y} \\ \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} \end{vmatrix} = \begin{vmatrix} \frac{\partial\tilde{\sigma}}{\partial x} & \frac{\partial\tilde{\sigma}}{\partial y} \\ \frac{\partial\tilde{u}}{\partial x} & \frac{\partial\tilde{u}}{\partial y} \end{vmatrix}$$

in Ω and $\mathbf{n}\cdot(\sigma\mathbb{L}\nabla u) = \mathbf{n}\cdot(\tilde{\sigma}\mathbb{L}\nabla\tilde{u})$ on $\partial\Omega$.

Proof. From (2.5), we have

$$\begin{aligned} B_z &= \frac{\mu_0}{4\pi}\int_\Omega \nabla_{\mathbf{r}'}\frac{1}{|\mathbf{r} - \mathbf{r}'|}\cdot(\sigma(\mathbf{r}')\mathbb{L}\nabla u(\mathbf{r}'))\, d\mathbf{r}' \\ &= \frac{\mu_0}{4\pi}\int_\Omega \frac{-1}{|\mathbf{r} - \mathbf{r}'|}\nabla\cdot(\sigma\mathbb{L}\nabla u)\, d\mathbf{r}' + \frac{\mu_0}{4\pi}\int_{\partial\Omega}\frac{1}{|\mathbf{r} - \mathbf{r}'|}\, \mathbf{n}\cdot(\sigma\mathbb{L}\nabla u)\, ds.\end{aligned}$$

Then (2.6) follows from

$$\nabla \cdot (\sigma \mathbb{L} \nabla u) = \mathbf{e}_z \cdot [\nabla \sigma \times \nabla u] = \begin{vmatrix} \frac{\partial \sigma}{\partial x} & \frac{\partial \sigma}{\partial y} \\ \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} \end{vmatrix},$$

where $\mathbf{e}_z = (0, 0, 1)$.

Now we will show that there are infinitely many pairs $(\tilde{\sigma}, \tilde{u})$ such that $\mathbf{e}_z \cdot [\nabla \sigma \times \nabla u] = \mathbf{e}_z \cdot [\nabla \tilde{\sigma} \times \nabla \tilde{u}]$ and $\tilde{u}$ is a solution of (2.2) with σ replaced by $\tilde{\sigma}$. Indeed, we can construct infinitely many pairs $(\tilde{\sigma}, \tilde{u})$ satisfying the much stronger condition $\sigma \nabla u = \tilde{\sigma} \nabla \tilde{u}$. From the maximum-minimum principle for an elliptic equation, $u|_{\mathcal{E}^+}$ and $u|_{\mathcal{E}^-}$ are the maximum and minimum values of u in $\overline{\Omega}$, respectively. Choose a and b such that $\inf_\Omega u = u|_{\mathcal{E}^-} < a < b < u|_{\mathcal{E}^+} = \sup_\Omega u$. For any increasing function $\phi \in C^2([a, b])$ satisfying

$$\phi'(a) = \phi'(b) = 1, \quad \phi''(a) = \phi''(b) = 0, \quad \phi(a) = a, \ \phi(b) = b, \tag{2.7}$$

we define

$$\tilde{u}(\mathbf{r}) = \begin{cases} \phi(u(\mathbf{r})) & \text{if } \mathbf{r} \in \hat{\Omega}, \\ u(\mathbf{r}) & \text{if } \mathbf{r} \in \Omega \setminus \hat{\Omega}, \end{cases} \qquad \tilde{\sigma}(\mathbf{r}) = \begin{cases} \frac{\sigma(\mathbf{r})}{\phi'(u(\mathbf{r}))} & \text{if } \mathbf{r} \in \hat{\Omega}, \\ \sigma(\mathbf{r}) & \text{if } \mathbf{r} \in \Omega \setminus \hat{\Omega}, \end{cases}$$

where $\hat{\Omega} := \{\mathbf{r} \in \Omega \ : \ a \le u(\mathbf{r}) \le b\}$. The conditions of ϕ guarantee $\tilde{\sigma} \in C^1(\Omega)$ and $\tilde{\sigma} > 0$ in Ω. Since $\nabla \tilde{u} = \phi'(u) \nabla u$, we have $\tilde{\sigma} \nabla \tilde{u} = \frac{\sigma}{\phi'(u)} \nabla \hat{u} = \sigma \nabla u$. So it is clear that

$$\begin{vmatrix} \frac{\partial \sigma}{\partial x} & \frac{\partial \sigma}{\partial y} \\ \frac{\partial u}{\partial x} & \frac{\partial u}{\partial y} \end{vmatrix} = \begin{vmatrix} \frac{\partial \hat{\sigma}}{\partial x} & \frac{\partial \hat{\sigma}}{\partial y} \\ \frac{\partial \hat{u}}{\partial x} & \frac{\partial \hat{u}}{\partial y} \end{vmatrix}$$

and $\mathbf{n} \cdot (\sigma \mathbb{L} \nabla u) = \mathbf{n} \cdot (\tilde{\sigma} \mathbb{L} \nabla \tilde{u})$ on $\partial\Omega$. Since $\tilde{u} = u$ near the electrodes $\mathcal{E}^+$ and $\mathcal{E}^-$, $\tilde{u}$ has the same boundary condition on the electrodes as u. Therefore, $\tilde{u}$ is a solution of (2.2) with σ replaced by $\tilde{\sigma}$. This completes the proof since ϕ can be chosen arbitrarily under the constraint (2.7). ∎

According to Lemma 2.2, the unique determination of σ requires us to inject at least two input currents I_1 and I_2. Now we are ready to explain the exact MREIT model. We inject electrical currents I_1 and I_2 through two pairs of surface electrodes $\mathcal{E}_1^\pm$ and $\mathcal{E}_2^\pm$, respectively. Let u_j and B_z^j be the potential and magnetic flux density, respectively, corresponding to I_j, with $j = 1, 2$.

For the measured data B_z^1, B_z^2 corresponding to two input currents I_1, I_2 and a given constant $\alpha > 0$, we try to reconstruct σ satisfying the following conditions for $j = 1, 2$:

$$\begin{cases} \nabla \cdot (\sigma \nabla u_j) = 0 \quad \text{in } \Omega, \\ I_j = \displaystyle\int_{\mathcal{E}_j^+} \sigma \frac{\partial u_j}{\partial \mathbf{n}} \, ds = -\int_{\mathcal{E}_j^-} \sigma \frac{\partial u_j}{\partial \mathbf{n}}, \quad \nabla u_j \times \mathbf{n}|_{\mathcal{E}_j^+ \cup \mathcal{E}_j^-} = 0, \\ \sigma \dfrac{\partial u_j}{\partial \mathbf{n}} = 0 \quad \text{on } \partial\Omega \setminus \overline{\mathcal{E}_j^+ \cup \mathcal{E}_j^-}, \\ B_z^j(\mathbf{r}) = \dfrac{\mu_0}{4\pi} \displaystyle\int_\Omega \frac{\langle \mathbf{r} - \mathbf{r}' \, , \, \sigma \mathbb{L} \nabla u_j \rangle}{|\mathbf{r} - \mathbf{r}'|^3} \, d\mathbf{r}', \quad \mathbf{r} \in \Omega, \\ \left| u_1|_{\mathcal{E}_2^+} - u_1|_{\mathcal{E}_2^-} \right| = \alpha. \end{cases} \tag{2.8}$$

Remark 2.3. The last condition regarding α is necessary for fixing the scaling uncertainty of σ. Without this condition, whenever σ and u_j satisfy the other four relations in (2.8), so do $c\sigma$ and $\frac{u_j}{c}$ for any positive constant c. Here we should avoid measuring the voltage difference between the pair of electrodes used for current injection since any electrode contact impedance may cause measurement errors. Therefore, in practice, we usually use the other pair of electrodes for the voltage measurement.

To explain the MREIT image reconstruction algorithm, we define

$$\mathcal{L}_{z_0}\sigma(x,y) := \sigma(x,y,z_0) + \frac{1}{2\pi}\int_{\partial\Omega_{z_0}} \frac{(x-x',\ y-y')\ \cdot\ \nu(x',y')}{|x-x'|^2+|y-y'|^2}\ \sigma(x',y',z_0)\ dl, \tag{2.9}$$

where ν is the unit outward normal vector to $\partial\Omega_{z_0}$ and $\Omega_{z_0} := \Omega \cap \{z = z_0\} \subset \mathbb{R}^2$. For a vector-valued function $F = (F_1, F_2)$ defined on Ω, we define

$$\mathcal{G}_{z_0} * F(x,y) := \frac{1}{2\pi\mu_0}\int_{\Omega_{z_0}} \frac{(x-x',\ y-y')}{|x-x'|^2+|y-y'|^2}\cdot F(x',y',z_0)\ dx'dy'. \tag{2.10}$$

Let each $u_j[\sigma]$ be a solution to the direct problem (2.2) corresponding to I_j satisfying

$$\begin{vmatrix} \frac{\partial u_1}{\partial x} & \frac{\partial u_1}{\partial y} \\ \frac{\partial u_2}{\partial x} & \frac{\partial u_2}{\partial y} \end{vmatrix} \neq 0 \quad \text{in } \Omega, \tag{2.11}$$

and set

$$\mathbb{A}[\sigma] := \begin{bmatrix} \frac{\partial u_1[\sigma]}{\partial y} & -\frac{\partial u_1[\sigma]}{\partial x} \\ \frac{\partial u_2[\sigma]}{\partial y} & -\frac{\partial u_2[\sigma]}{\partial x} \end{bmatrix}. \tag{2.12}$$

Now let us state the implicit relation between σ and B_z^j, on which the harmonic B_z algorithm is based.

LEMMA 2.4. *Suppose that $|\nabla\sigma|$ is compactly supported in Ω and $u_j[\sigma]$ for $j = 1, 2$ satisfy* (2.11). *Then the following identity:*

$$\mathcal{L}_z\sigma(x,y) = \mathcal{G}_z * \left(\mathbb{A}[\sigma]^{-1}\begin{bmatrix} \nabla^2 B_z^1 \\ \nabla^2 B_z^2 \end{bmatrix}\right)(x,y), \qquad (x,y)\in\Omega_z \tag{2.13}$$

holds for each z. Moreover, $\mathcal{L}_z : H_*^{1/2}(\Omega_z) \to H_*^{1/2}(\Omega_z)$ is invertible where $H_*^{1/2}(\Omega_z) := \{\eta \in H^{1/2}(\Omega_z) : \int_{\partial\Omega_z}\eta = 0\}$.

Proof. The proof of (2.13) is based on the fact that $\nabla\cdot\mathbf{B} = 0$ and the Ampere law $\mathbf{J} = \frac{1}{\mu_0}\nabla\times\mathbf{B}$. Direct computation yields $\nabla u_j \times \nabla\sigma = \frac{1}{\mu_0}\Delta\mathbf{B}^j$, and we have

$$\begin{bmatrix} \frac{\partial\sigma}{\partial x} \\ \frac{\partial\sigma}{\partial y} \end{bmatrix} = \frac{1}{\mu_0}\mathbb{A}[\sigma]^{-1}\begin{bmatrix} \Delta B_z^1 \\ \Delta B_z^2 \end{bmatrix}. \tag{2.14}$$

Since $\nabla\sigma = 0$ near $\partial\Omega$, so does $\Delta B_z = 0$. Hence, the right-hand side of (2.13) is well defined. Now the result follows from the formal identity

$$\sigma(x,y,z) = \int_{\Omega_z}\frac{1}{2\pi}\left(\frac{\partial^2}{\partial x^2}+\frac{\partial^2}{\partial y^2}\right)\log\sqrt{(x-x')^2+(y-y')^2}\,\sigma(x',y',z)dx'dy'$$

and integration by parts.

The invertibility of $\mathcal{L}$ can be proved by the standard layer potential theory [7, 20]. Let $w \in H_*^{1/2}(\Omega_z)$. We will find $v \in H_*^{1/2}(\Omega_z)$ such that $\mathcal{L}_z v = w$. Note that $w|_{\partial\Omega_z} \in L_*^2(\partial\Omega_z) := \{\phi \in L^2(\Omega_z) : \int_{\partial\Omega_z} \phi = 0\}$. It is well known that there exists a unique $\psi \in L_*^2(\partial\Omega_z)$ such that $\frac{1}{2}\psi - \mathcal{K}\psi = w|_{\partial\Omega_z}$ on $\partial\Omega_z$, where $\mathcal{K}\psi(x,y) = \frac{-1}{2\pi}\int_{\partial\Omega_{z_0}} \frac{(x-x',\, y-y')\cdot\nu}{|x-x'|^2+|y-y'|^2}\,\psi(x',y')\,dl$ for $(x,y) \in \partial\Omega_z$. Now we define

$$v(x,y) = w(x,y) - \frac{1}{2\pi}\int_{\partial\Omega_{z_0}} \frac{(x-x',\, y-y')\,\cdot\,\nu(x',y')}{|x-x'|^2+|y-y'|^2}\,\psi(x',y')\,dl \tag{2.15}$$

for $(x,y) \in \Omega_z$. Due to the trace formula of the double layer potential, $v = \psi$ on $\partial\Omega_z$. By replacing ψ in (2.15) with v, we have $w = \mathcal{L}_z v$, and this completes the proof. ∎

Remark 2.5. The condition (2.11) is necessary for the harmonic B_z algorithm. However, we still do not have a rigorous theory for the issue related to (2.11) in a three-dimensional domain. In the two-dimensional case, the validity of condition (2.11), under suitably chosen boundary data, is proved in [2] when σ is smooth. When σ is just measurable, (2.11) holds in the a.e. sense [1]. In the three-dimensional case, there are examples [3, 11] which suggest that it may be difficult, if not impossible, to find boundary data such that (2.11) holds independently of σ, even assuming smoothness of σ.

In this paper, we will consider the convergence result for the harmonic B_z method based on the governing problem (2.3), since the solution u to the standard governing problem (2.2) can be expressed as a constant multiple in terms of Lemma 2.1. Let σ^* be the target conductivity to be determined. Based on Lemma 2.4, the harmonic B_z algorithm approximating σ^* at each slice Ω_{z_0}, for given σ^* on $\partial\Omega_{z_0}$, can be stated as follows. Notice here that we also use σ^* to represent the known boundary value of unknown conductivity σ^* defined in the whole domain, which can be distinguished from the context. Given an initial guess $\sigma^0(x,y,z)$ in Ω with exact boundary values, the harmonic B_z iteration algorithm constructs an approximation sequence $\{\sigma^n(x,y,z_0)\}$ by

$$\begin{cases} \nabla\sigma^{n+1}(x,y,z_0) := \dfrac{1}{\mu_0}\mathbb{A}[\sigma^n]^{-1}\begin{bmatrix} \Delta B_z^1 \\ \Delta B_z^2 \end{bmatrix}, \\ \sigma^{n+1}(x,y,z_0) := H(\sigma^*) - \dfrac{1}{2\pi}\displaystyle\int_{\Omega_{z_0}} \frac{(x-x',\, y-y')}{|x-x'|^2+|y-y'|^2}\cdot\nabla\sigma^{n+1}(x',y',z_0)dx'dy' \end{cases} \tag{2.16}$$

for $n = 0, 1, 2, \ldots$ at each slice Ω_{z_0}, where $\mathbb{A}[\sigma]$ is defined in (2.12) and

$$H(\sigma^*) := \frac{1}{2\pi}\int_{\partial\Omega_{z_0}} \frac{(x-x',\, y-y')\,\cdot\,\nu(x',y')}{|x-x'|^2+|y-y'|^2}\,\sigma^*(x',y',z_0)\,dl.$$

Notice that, to compute $\mathbb{A}[\sigma^n]^{-1}$ at each slice $\Omega_{z_0} \subset \mathbb{R}^2$, we need the value σ^n in the whole domain $\Omega \subset \mathbb{R}^3$. This fact will cause some difficulties when we do the iteration for the full three-dimensional model (see the convergence proof in subsection 3.2 of this paper). On the other hand, in the above scheme, the value of σ^n on the boundary of the slice Ω_{z_0} is specified as the exact value $\sigma^*(x,y,z_0)$ for all n.

3. Convergence for the harmonic B_z algorithm. It should be noticed that $\mathbb{A}[\sigma^n]^{-1}(x,y,z)$ may be large near $\partial\Omega$ due to the fact that two induced current densities $\sigma^n\nabla u_1^n, \sigma^n\nabla u_2^n$ are probably almost parallel for some configuration. To avoid

this case, let us assume that σ^* is constant in $\Omega \setminus \tilde{\Omega}$ for some interior domain $\tilde{\Omega}$. Then it is easy to show that $\nabla^2 B_z^1 \equiv \nabla^2 B_z^2 \equiv 0$ in $\Omega \setminus \tilde{\Omega}$. So the original iteration scheme (2.16) at each slice becomes

(3.1)
$$\begin{cases} \nabla\sigma^{n+1}(x,y,z_0) := \dfrac{1}{\mu_0}\mathbb{A}[\sigma^n]^{-1}\begin{bmatrix} \Delta B_z^1 \\ \Delta B_z^2 \end{bmatrix}, \\ \sigma^{n+1}(x,y,z_0) := \tilde{H}(\sigma^*) - \dfrac{1}{2\pi}\displaystyle\int_{\tilde{\Omega}_{z_0}} \frac{(x-x',\, y-y')}{|x-x'|^2+|y-y'|^2} \cdot \nabla\sigma^{n+1}(x',y',z_0)dx'dy' \end{cases}$$

for $(x,y) \in \tilde{\Omega}_{z_0}$, where $\tilde{\Omega}_{z_0} = \tilde{\Omega} \bigcap \{(x,y,z) : z = z_0\} \subset \mathbb{R}^2$ and $\tilde{H}(\sigma^*)$ is $H(\sigma^*)$ with $\partial\Omega_{z_0}$ replaced by $\partial\tilde{\Omega}_{z_0}$. For $(x,y) \in \Omega_{z_0} \setminus \tilde{\Omega}_{z_0}$, it is obvious that $\sigma^n(x,y,z_0) \equiv \sigma^*(x,y,z_0)$ from this iteration since $\nabla\sigma^n \equiv 0$ in $\Omega_{z_0} \setminus \tilde{\Omega}_{z_0}$.

The major difficulty dealing with the convergence comes from the uniform upper bound of the inverse matrix $\mathbb{A}[\sigma^n]^{-1}$ in the iteration procedure. Without some uniform bound on the iteration conductivity σ^n, it is quite difficult to estimate $\mathbb{A}[\sigma^n]^{-1}$. The key ideas taken in this paper to overcome this difficulty are some assumptions on the target conductivity and the initial guess. With these conditions, we can establish the convergence. Rather than the general way of the convergence proof, which sets the uniform bound for the sequence $\{\sigma^n\}$ and then obtains the convergence of the sequence, we should establish the uniform bound on σ^n and estimate the error $\|\sigma^n - \sigma^*\|$ at each step simultaneously by the induction argument.

We first give the following estimates, which will be used in the convergence proof.

LEMMA 3.1. *Denote by $\mathcal{E}$ any regular open subsurface of the boundary $\partial\Omega$ of $\Omega \subset \mathbb{R}^m$, with $m = 2, 3$. Then for the boundary value problem*

$$\begin{cases} \nabla \cdot (\sigma\nabla u) = \nabla \cdot f & \text{in } \Omega, \\ u|_{\mathcal{E}} = h & \text{on } \mathcal{E}, \\ -\sigma\nabla u \cdot \mathbf{n} = g & \text{on } \partial\Omega \setminus \overline{\mathcal{E}}, \end{cases} \tag{3.2}$$

with $\sigma \in L^\infty(\Omega)$ satisfying $\inf_\Omega \sigma > 0$, $h \in H^{1/2}(\mathcal{E})$, and $g \in H^{-1/2}(\partial\Omega \setminus \overline{\mathcal{E}})$, the following estimates hold:

If $f \in (L^2(\Omega))^m$ and $\sigma \in C(\Omega)$, then $u \in H^1(\Omega)$ and

$$\|u\|_{H^1(\Omega)} \le C_1(\sigma)[\|f\|_{L^2(\Omega)} + \|h\|_{H^{1/2}(\mathcal{E})} + \|g\|_{H^{-1/2}(\partial\Omega\setminus\overline{\mathcal{E}})}]; \tag{3.3}$$

if $f \in (H^1(\Omega))^m$ and $\sigma \in C^1(\Omega)$, then $u \in H^2(\tilde{\Omega})$ and

$$\|u\|_{H^2(\tilde{\Omega})} \le C_2(\sigma)[\|u\|_{H^1(\Omega)} + \|\nabla \cdot f\|_{L^2(\Omega)}]; \tag{3.4}$$

if $f \in (C^{0,\alpha}(\Omega))^m$, with $\alpha \in (0,1)$ and $\sigma \in C^1(\Omega)$, then $u \in C^{1,\alpha}(\tilde{\tilde{\Omega}})$ and

$$\|\nabla u\|_{C^{0,\alpha}(\tilde{\Omega})} \le C_3(\sigma)[\|u\|_{C^{0,\alpha}(\tilde{\tilde{\Omega}})} + \|f\|_{C^{0,\alpha}(\tilde{\tilde{\Omega}})}]; \tag{3.5}$$

if $f \in (L^p(\Omega))^m$, with $p > 1$ and $\sigma \in C(\Omega)$, then $u \in W^{1,p}(\tilde{\tilde{\Omega}})$ and

$$\|\nabla u\|_{L^p(\tilde{\Omega})} \le C_4(\sigma)[\|u\|_{L^p(\tilde{\tilde{\Omega}})} + \|f\|_{L^p(\tilde{\tilde{\Omega}})}], \tag{3.6}$$

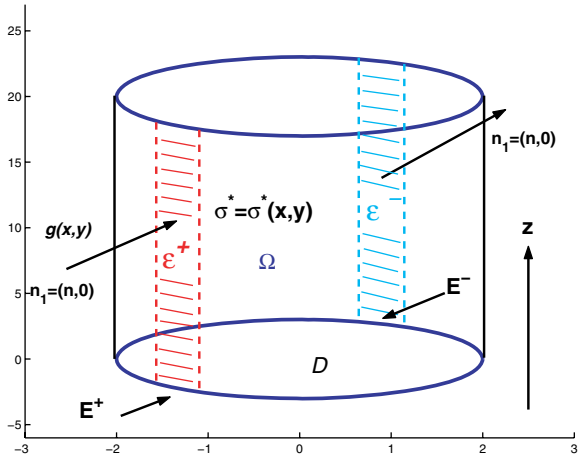

FIG. 3. *Axially symmetric cylindrical configuration.*

where $\tilde{\Omega} \subset\subset \tilde{\tilde{\Omega}} \subset\subset \Omega$ *are regular domains, and the functions* $C_i(\sigma)$ *have the following forms:*

$$C_i(\sigma) = F_i\left(\|\sigma\|_{C(\Omega)}, \|\nabla\sigma\|_{C(\Omega)}, \frac{1}{\inf_\Omega \sigma}\right), \quad i = 2, 3, \tag{3.7}$$

$$C_i(\sigma) = F_i\left(\|\sigma\|_{C(\Omega)}, \frac{1}{\inf_\Omega \sigma}\right), \quad i = 1, 4. \tag{3.8}$$

The functions F_i $(i = 1, 2, 3, 4)$ *are known bounded functions with respect to the arguments.*

For the proof of these estimates, we refer to [6] and Theorems 8.8 and 8.32 and Corollary 8.36 in [8]. The form of the constant $C_i(\sigma)$ is of importance in our convergence proof.

3.1. Convergence in axially symmetric cylindrical sections. Let $\Omega := D \times \mathbb{R}^1 \subset \mathbb{R}^3$ be a cylinder along the z direction with infinite length and the fixed cross section $D \subset \mathbb{R}^2$. We assume that the conductivity σ^* in Ω does not change along the z direction. That is, $\sigma^*(x, y, z) \equiv \sigma^*(x, y)$, $(x, y) \in D$.

Consider the electrodes $\mathcal{E}^{\pm}$ on $\partial\Omega$ where the input currents are specified. For an ideal electrode pair $\mathcal{E}^{\pm}$ parallel to the z direction with infinite length, we assume that the current density is independent of z; see Figure 3. In this case, it follows from (2.2) that the potential u is also independent of z in Ω due to the causality, and $u(x, y)$ meets

$$\begin{cases} \nabla \cdot (\sigma \nabla u) = 0 \quad \text{in } D, \\ \tilde{I} = \displaystyle\int_{E^+} \sigma \frac{\partial u}{\partial \mathbf{n}}\, ds = -\int_{E^-} \sigma \frac{\partial u}{\partial \mathbf{n}} ds, \quad \nabla u \times \mathbf{n} = 0 \ \text{ on } E^+ \cup E^-, \\ \sigma \dfrac{\partial u}{\partial \mathbf{n}} = 0 \quad \text{on } \partial\Omega \setminus \overline{E^+ \cup E^-}, \end{cases} \tag{3.9}$$

where $E^{\pm} := \mathcal{E}^{\pm} \bigcap \overline{D} \subset \partial D$, $\tilde{I}$ is the total input current in $E^{\pm}$, and $\mathbf{n} \in \mathbb{R}^2$ is the outward normal direction of ∂D. The equation (3.9) is the governing model for potential $u(x, y)$, which is in fact defined in the two-dimensional domain D.

To unify the notations in our proof for convergence in both the axially cylindrical case and the three-dimensional case, we will use $\Omega, \mathcal{E}^{\pm}$ to represent the geometry in (3.9) instead of $D, E^{\pm}$ in this subsection. Now we can state our convergence result of the harmonic B_z method based on the model (3.9) for the two-dimensional domain $\Omega \subset \mathbb{R}^2$.

THEOREM 3.2. *Assume that the target conductivity $\sigma^*(x,y) \in C^1(\overline{\Omega})$ meets the following:*

H1. $0 < \sigma_-^* \le \sigma^*(x) \le \sigma_+^*$ *for known constants* $\sigma_\pm^*$;

H2. *there exists* $\tilde{\Omega} \subset\subset \Omega$ *such that* σ^* *is a known constant in* $\Omega \setminus \tilde{\Omega}$;

H3. $|\det A[\sigma^*](x,y)| \ge d_-^* > 0$ *in* $\tilde{\Omega}$, *where* d_-^* *is a known constant.*

Under these hypotheses, there exist constants $\epsilon = \epsilon(\sigma_\pm^*, d_-^*) > 0$ small enough and $\theta = \theta(\epsilon, \sigma_\pm^*, d_-^*) \in (0,1)$ such that if we take the initial guess σ^0 as the constant $\sigma^*|_{\Omega\setminus\tilde{\Omega}}$, then the sequence $\{\sigma^n\}$ given by the harmonic B_z iteration scheme holds for $\|\nabla\sigma^*\|_{C(\tilde{\Omega})} \le \epsilon$ that

$$\sigma^n \equiv \sigma^* \text{ in } \Omega\setminus\tilde{\Omega}, \quad \|\sigma^n - \sigma^*\|_{C^1(\tilde{\Omega})} \le K\theta^n\epsilon, \quad n = 1,2,\ldots, \tag{3.10}$$

where $K := diam(\Omega) + 1$.

Remark 3.3. We obtain a local convergence for the target conductivity σ^* with a small contrast. At the present stage, we do not know how to remove the smallness requirement on ϵ.

Remark 3.4. The convergence property holds only in the interior domain $\tilde{\Omega}$. The reason is as follows. First, the regularity property of an elliptic equation with the mixed boundary condition will fail at the boundary. Second, for some geometry configuration, the induced internal current densities near the boundary should be almost parallel, so it is very hard to get the uniform bound on $\mathbb{A}[\sigma^n]^{-1}$ near the boundary.

Proof. Let us take $0 < \epsilon < \frac{1}{2K}\sigma_-^*$. Denote by u_j^n and u_j^* the solutions of the direct problem

$$\begin{cases} \nabla\cdot(\sigma\nabla u_j) = 0 \quad \text{in} \quad \Omega, \\ u_j|_{\mathcal{E}_j^+} = 1, \qquad u_j|_{\mathcal{E}_j^-} = 0, \\ -\sigma\nabla u_j \cdot \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega \setminus \mathcal{E}_j^+ \cup \mathcal{E}_j^-, \end{cases} \tag{3.11}$$

with $\sigma = \sigma^n$ and σ^*, respectively. This is a special case of (3.2) with $\mathcal{E} := \mathcal{E}_j^+ \bigcup \mathcal{E}_j^-$ in Lemma 3.1. For a given interior domain $\tilde{\Omega}$, there exists a constant $\overline{C}_* = \overline{C}_*(\sigma_\pm^*)$ such that

$$\left\|\nabla u_j^*\right\|_{C(\tilde{\Omega})} + \left\|u_j^*\right\|_{H^2(\tilde{\Omega})} \le \overline{C}_*. \tag{3.12}$$

This fact can be deduced from Lemma 3.1 as follows. Indeed, from the first and second points of this Lemma, we have $\left\|u_j^*\right\|_{H^2(\tilde{\Omega})} \le C_1(\sigma^*)C_2(\sigma^*)$. By the Sobolev imbedding theorem, we have $\left\|u_j^*\right\|_{C^{0,\alpha}(\tilde{\Omega})} \le C_s \left\|u_j^*\right\|_{H^2(\tilde{\Omega})}$ for every $\alpha \in (0,1)$. Finally, combining these last two estimates with the third point of Lemma 3.1, we have

$$\left\|\nabla u_j^*\right\|_{C(\tilde{\Omega})} + \left\|u_j^*\right\|_{H^2(\tilde{\Omega})} \le C_s C_1(\sigma^*)C_2(\sigma^*)C_3(\sigma^*),$$

which leads to (3.12) with

$$\overline{C}_* := C_s \sup_{(t_1,t_2,t_3)\in\mathbb{S}_1} F_1(t_1,t_3)F_2(t_1,t_2,t_3)F_3(t_1,t_2,t_3), \tag{3.13}$$

where $\mathbb{S}_1 := [\sigma_-^*, \sigma_+^*] \times [0, \frac{1}{2K}\sigma_-^*] \times [\frac{1}{\sigma_+^*}, \frac{1}{\sigma_-^*}]$, and each F_i is uniformly bounded with respect to their arguments.

Step 1. Expand the initial guess σ^0 at σ^*.

Expand σ^0 as $\sigma^0 = \sigma^* + e^0$. Since $\|\nabla\sigma^*\|_{C(\Omega)} < \epsilon$ and $\sigma^* = \sigma^0$ in $\Omega \setminus \tilde{\Omega}$,

$$\left\|e^0\right\|_{C(\Omega)} \leq diam(\Omega)| \left\|\nabla e^0\right\|_{C(\Omega)} \leq diam(\Omega)\epsilon.$$

Hence, $\left\|e^0\right\|_{C^1(\Omega)} \leq (diam(\Omega)+1)\epsilon = K\epsilon$. We expand u_j^0 at u_j^* as

$$u_j^0 = u_j^* + \epsilon w_j^0. \tag{3.14}$$

Noticing that $\sigma^0 = \sigma^*$ in $\Omega \setminus \tilde{\Omega}$, ϵw_j^0 meets

$$\begin{cases} \nabla \cdot \left(\sigma^0 \nabla \epsilon w_j^0\right) = -\nabla \cdot (e^0 \nabla u_j^*) \quad \text{in} \quad \Omega, \\ \epsilon w_j^0|_{\mathcal{E}_j^+} = 0, \qquad \epsilon w_j^0|_{\mathcal{E}_j^-} = 0, \\ -\sigma^0 \nabla \epsilon w_j^0 \cdot \ \mathbf{n} = (\sigma^0 - \sigma^*)\nabla u_j^* \cdot \ \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega \setminus \mathcal{E}_j^+ \cup \mathcal{E}_j^-. \end{cases} \tag{3.15}$$

Since $\|e^0\|_{C^1(\tilde{\Omega})} \leq K\epsilon$ and $e^0 = 0$ in $\Omega \setminus \tilde{\Omega}$, it follows from (3.12) that the right-hand side of the first equation in (3.15) satisfies

$$\left\|\nabla \cdot (e^0 \nabla u_j^*)\right\|_{L^2(\Omega)} \leq \overline{C}_* \left\|e^0\right\|_{C^1(\tilde{\Omega})}. \tag{3.16}$$

Therefore it follows from Lemma 3.1 and the Sobolev imbedding theorem that

$$\begin{aligned} \left\|\epsilon w_j^0\right\|_{C(\tilde{\tilde{\Omega}})} &\leq C_s \left\|\epsilon w_j^0\right\|_{H^2(\tilde{\tilde{\Omega}})} \leq C_s C_2(\sigma^0)[\left\|\epsilon w_j^0\right\|_{H^1(\tilde{\Omega})} + \left\|\nabla \cdot e^0 \nabla u_j^*\right\|_{L^2(\tilde{\Omega})}] \\ &\leq C_s C_2(\sigma^0)[C_1(\sigma^0)\left\|e^0 \nabla u_j^*\right\|_{L^2(\Omega)} + \overline{C}_* \left\|e^0\right\|_{C^1(\Omega)}] \\ &\leq C_s C_2(\sigma^0)[C_1(\sigma^0)C_1(\sigma^*) + \overline{C}_*] \left\|e^0\right\|_{C^1(\Omega)}. \end{aligned}$$

Hence

$$\begin{aligned} \left\|\epsilon \nabla w_j^0\right\|_{C(\tilde{\Omega})} &\leq C_3(\sigma^0)[\left\|\epsilon w_j^0\right\|_{C(\tilde{\tilde{\Omega}})} + \left\|e^0 \nabla u_j^*\right\|_{C(\tilde{\Omega})}] \\ &\leq C_3(\sigma^0)[C_s C_2(\sigma^0)[C_1(\sigma^0)C_1(\sigma^*) + \overline{C}_*] + \overline{C}_*] \left\|e^0\right\|_{C^1(\Omega)}. \end{aligned} \tag{3.17}$$

We denote by

$$\overline{F}(\sigma) := C_3(\sigma)\left[C_s C_2(\sigma)\left(C_1(\sigma) \sup_{[\sigma_-^*, \sigma_+^*] \times [\frac{1}{\sigma_+^*}, \frac{1}{\sigma_-^*}]} F_1(t_1, t_3) + \overline{C}_*\right) + \overline{C}_*\right] \tag{3.18}$$

a known function due to the Lemma 3.1. For $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$, we introduce the constant

$$\overline{C}_\epsilon(\sigma^*) := \sup_{\|\sigma - \sigma^*\|_{C^1(\Omega)} \leq K\epsilon} \overline{F}(\sigma), \tag{3.19}$$

which is well defined. Noticing that $\|\sigma - \sigma^*\|_{C^1(\Omega)} \leq K\epsilon$, we have $\sigma > \frac{1}{2}\sigma_-^* > 0$ for $0 < \epsilon < \frac{1}{2K}\sigma_-^*$ due to H1. Moreover, this constant can be estimated by a known constant as

$$\overline{C}_\epsilon(\sigma^*) \leq \sup_{\mathbb{S}_2} \overline{F}(\sigma) =: \overline{G}(\sigma_\pm^*) \tag{3.20}$$

for $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$ from the a priori information about σ^*, where

$$\mathbb{S}_2 := \left\{ \sigma(x,y) : \frac{1}{2}\sigma_-^* < \sigma < \frac{1}{2}\sigma_-^* + \sigma_+^*,\ \|\nabla\sigma\|_C \le \frac{K+1}{2K}\sigma_-^* \right\}.$$

Now it follows from (3.17)–(3.20) that

$$\left\|\epsilon\nabla w_j^0\right\|_{C(\tilde{\Omega})} \le \overline{G}(\sigma_\pm^*)\left\|e^0\right\|_{C^1(\Omega)}. \tag{3.21}$$

Since $\|e^0\|_{C^1(\tilde{\Omega})} \le K\epsilon$, it follows that

$$\left\|\nabla w_j^0\right\|_{C(\tilde{\Omega})} \le K\overline{G}(\sigma_\pm^*). \tag{3.22}$$

Step 2. Estimate $\left\|\sigma^1 - \sigma^*\right\|_{C^1(\tilde{\Omega})}$.

First, $\mathbb{A}[\sigma^*]^{-1}$ exists from H3. From the definition, we know that $\nabla\sigma^1$ satisfies

$$\mathbb{A}[\sigma^0]\nabla\sigma^1 = \frac{1}{\mu_0}\begin{bmatrix} \Delta B_z^1 \\ \Delta B_z^2 \end{bmatrix},$$

which can be written as

$$\left(I + \epsilon\mathbb{A}[\sigma^*]^{-1}\begin{bmatrix} \frac{\partial w_1^0}{\partial y}, & -\frac{\partial w_1^0}{\partial x} \\ \frac{\partial w_2^0}{\partial y}, & -\frac{\partial w_2^0}{\partial x} \end{bmatrix}\right)\nabla\sigma^1 = \frac{1}{\mu_0}\mathbb{A}[\sigma^*]^{-1}\begin{bmatrix} \Delta B_z^1 \\ \Delta B_z^2 \end{bmatrix} = \nabla\sigma^*$$

due to the definition of the matrix $\mathbb{A}[\sigma^0]$ and (3.14). So we have

$$\left(I + \epsilon\mathbb{A}[\sigma^*]^{-1}\begin{bmatrix} \frac{\partial w_1^0}{\partial y}, & -\frac{\partial w_1^0}{\partial x} \\ \frac{\partial w_2^0}{\partial y}, & -\frac{\partial w_2^0}{\partial x} \end{bmatrix}\right)\nabla(\sigma^1 - \sigma^*) = -\epsilon\mathbb{A}[\sigma^*]^{-1}\begin{bmatrix} \frac{\partial w_1^0}{\partial y}, & -\frac{\partial w_1^0}{\partial x} \\ \frac{\partial w_2^0}{\partial y}, & -\frac{\partial w_2^0}{\partial x} \end{bmatrix}\nabla\sigma^*. \tag{3.23}$$

On the other hand, it is obvious from (3.22) that

$$\begin{aligned}\left\|\epsilon\mathbb{A}[\sigma^*]^{-1}\begin{bmatrix} \frac{\partial w_1^0}{\partial y}, & -\frac{\partial w_1^0}{\partial x} \\ \frac{\partial w_2^0}{\partial y}, & -\frac{\partial w_2^0}{\partial x} \end{bmatrix}\right\|_{C(\tilde{\Omega})} &\le \epsilon\left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})}\sqrt{2}\max_{j=1,2}\left\|\nabla w_j^0\right\|_{C(\tilde{\Omega})} \\ &\le \epsilon\left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})}\sqrt{2\overline{G}}(\sigma_\pm^*)K. \end{aligned} \tag{3.24}$$

A direct computation leads to $\left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \le \frac{\sqrt{2}}{d_-^*}\max_{j=1,2}\|\nabla u_j(\sigma^*)\|_{C(\tilde{\Omega})}$, from which we deduce

$$\left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \le \frac{\sqrt{2}}{d_-^*}\overline{C}_* \tag{3.25}$$

due to (3.12). Now we take $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$ small enough such that

$$\epsilon\frac{2}{d_-^*}\overline{G}(\sigma_\pm^*)\overline{C}_*K < \frac{1}{2}; \tag{3.26}$$

then it follows from (3.25) that

$$\epsilon\left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})}\sqrt{2\overline{G}}(\sigma_\pm^*)K < \frac{1}{2}. \tag{3.27}$$

It follows from (3.22), (3.23), and (3.27) that

$$\begin{aligned}\left\|\nabla(\sigma^1-\sigma^*)\right\|_{C(\tilde{\Omega})} &\le 2\epsilon \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \sqrt{2} \max_{j=1,2} \left\|\nabla w_j^0\right\| \|\nabla\sigma^*\|_{C(\tilde{\Omega})} \\ &\le 2\sqrt{2} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \overline{G}(\sigma_\pm^*) K\epsilon^2. \end{aligned} \tag{3.28}$$

This last estimate generates

$$\left\|\sigma^1-\sigma^*\right\|_{C^1(\tilde{\Omega})} \le K \left\|\nabla(\sigma^1-\sigma^*)\right\|_{C(\tilde{\Omega})} \le K2\sqrt{2} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \overline{G}(\sigma_\pm^*) K\epsilon^2.$$

Introducing a new constant

$$\overline{D}_* := K\frac{4}{d_-^*}\overline{C}_*, \tag{3.29}$$

the above estimate becomes

$$\left\|\sigma^1-\sigma^*\right\|_{C^1(\tilde{\Omega})} \le \overline{D}_*\overline{G}(\sigma_\pm^*) K\epsilon^2 \tag{3.30}$$

due to (3.25). For $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$ satisfying (3.26), it follows from the definition of $\overline{D}_*$ that

$$\epsilon\overline{D}_*\overline{G}(\sigma_\pm^*) := \theta \in (0,1) \tag{3.31}$$

and then

$$\left\|\sigma^1-\sigma^*\right\|_{C^1(\tilde{\Omega})} \le K\theta\epsilon, \tag{3.32}$$

which implies via (3.19) that

$$\overline{F}(\sigma^1) \le \overline{C}_\epsilon(\sigma^*). \tag{3.33}$$

From (3.26) and (3.31), we assert that $\epsilon := \epsilon(\sigma_\pm^*, d_-^*)$ and $\theta := \theta(\epsilon, \sigma_\pm^*, d_-^*)$. Since σ^* is constant in $\Omega \setminus \tilde{\Omega}$, we deduce from (2.14) that $\nabla^2 B_z^j = 0$ in $\Omega \setminus \tilde{\Omega}$, $j = 1, 2$. Hence from (2.16) we deduce that $\nabla\sigma^1 = 0$ in $\Omega \setminus \tilde{\Omega}$, and therefore $\sigma^1 = \sigma^*$ in $\Omega \setminus \tilde{\Omega}$, since $\sigma^1 = \sigma^*$ on $\partial\Omega$. Now we can apply the induction argument to prove the theorem. That is, assume that the following properties:

$$\left\|\sigma^k-\sigma^*\right\|_{C^1(\tilde{\Omega})} \le K\theta^k\epsilon \text{ and } \sigma^k = \sigma^* \text{ in } \Omega\setminus\tilde{\Omega} \tag{3.34}$$

are true for $k = n$. We shall prove that it is also true for $k = n + 1$.

Step 3. Expand σ^n at σ^*.

For the expansion $\sigma^n = \sigma^* + e^n$, it follows that

$$\|e^n\|_{C^1(\tilde{\Omega})} \le (\overline{D}_*\overline{G}(\sigma_\pm^*))^n K\epsilon^{n+1} \tag{3.35}$$

from (3.34) with $k = n$. Correspondingly, we expand the solution u_j^n at u_j^* as

$$u_j^n = u_j^* + \epsilon^{n+1} w_j^n. \tag{3.36}$$

Noticing $\sigma^n = \sigma^*$ in $\Omega \setminus \tilde{\Omega}$, it is easy to see that $\epsilon^{n+1}w_j^n$ satisfies

$$\begin{cases} \nabla\cdot\left(\sigma^n\nabla\epsilon^{n+1}w_j^n\right) = -\nabla\cdot(e^n\nabla u_j^*) \quad \text{in} \quad \Omega, \\ \epsilon^{n+1}w_j^n|_{\mathcal{E}_j^+} = 0, \qquad \epsilon^{n+1}w_j^n|_{\mathcal{E}_j^-} = 0, \\ -\sigma^n\nabla\epsilon^{n+1}w_j^n\cdot\ \mathbf{n} = (\sigma^n-\sigma^*)\nabla u_j^*\cdot\ \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega\setminus\mathcal{E}_j^+\cup\mathcal{E}_j^-. \end{cases} \tag{3.37}$$

Similarly as in (3.21), we have

$$\left\|\nabla \epsilon^{n+1} w_j^n\right\|_{C(\tilde{\Omega})} \le \overline{F}(\sigma^n) \left\|e^n\right\|_{C^1(\Omega)} \le \overline{F}(\sigma^n)(\overline{D}_* \overline{G}(\sigma_\pm^*))^n K \epsilon^{n+1}.$$

That is,

$$\left\|\nabla w_j^n\right\|_{C(\tilde{\Omega})} \le \overline{F}(\sigma^n)(\overline{D}_* \overline{G}(\sigma_\pm^*))^n K \le \overline{D}_*^n (\overline{G}(\sigma_\pm^*))^{n+1} K, \tag{3.38}$$

since $\overline{F}(\sigma^n) \le \overline{C}_\epsilon(\sigma^*) \le \overline{G}(\sigma_\pm^*)$ due to the fact that $\|\sigma^n - \sigma^*\|_{C^1(\tilde{\Omega})} \le K\theta^n \epsilon < K\epsilon$.

Step 4. Estimate $\left\|\sigma^{n+1} - \sigma^*\right\|_{C^1}$.

From (2.16) we get $\nabla \sigma^{n+1} = 0$ in $\Omega \setminus \tilde{\Omega}$ and then $\sigma^{n+1} = \sigma^*$ in $\Omega \setminus \tilde{\Omega}$. By the same argument as in Step 2, we have

$$\left(I + \epsilon^{n+1} \mathbb{A}[\sigma^*]^{-1} \begin{bmatrix} \frac{\partial w_1^n}{\partial y} & -\frac{\partial w_1^n}{\partial x} \\ \frac{\partial w_2^n}{\partial y} & -\frac{\partial w_2^n}{\partial x} \end{bmatrix}\right) \nabla(\sigma^{n+1} - \sigma^*) = -\epsilon^{n+1} \mathbb{A}[\sigma^*]^{-1} \begin{bmatrix} \frac{\partial w_1^n}{\partial y} & -\frac{\partial w_1^n}{\partial x} \\ \frac{\partial w_2^n}{\partial y} & -\frac{\partial w_2^n}{\partial x} \end{bmatrix} \nabla \sigma^*. \tag{3.39}$$

With the condition (3.26) for ϵ, we have

$$\begin{aligned} \left\| \epsilon^{n+1} \mathbb{A}[\sigma^*]^{-1} \begin{bmatrix} \frac{\partial w_1^n}{\partial y}, & -\frac{\partial w_1^n}{\partial x} \\ \frac{\partial w_2^n}{\partial y}, & -\frac{\partial w_2^n}{\partial x} \end{bmatrix} \right\|_{C(\tilde{\Omega})} &\le \epsilon^{n+1} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \sqrt{2} \max_{j=1,2} \left\|\nabla w_j^n\right\|_{C(\tilde{\Omega})} \\ &\le \epsilon^{n+1} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\Omega)} \sqrt{2} \overline{D}_*^n (\overline{G}(\sigma_\pm^*))^{n+1} K \\ &\le \frac{1}{2} (\epsilon \overline{D}_* \overline{G}(\sigma_\pm^*))^n < \frac{1}{2} \end{aligned} \tag{3.40}$$

due to (3.26), (3.31), and (3.38). So it follows from (3.38)–(3.40) that

$$\begin{aligned} \left\|\nabla(\sigma^{n+1} - \sigma^*)\right\|_{C(\tilde{\Omega})} &\le 2\epsilon^{n+1} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \sqrt{2} \max_{j=1,2} \left\|\nabla w_j^n\right\|_{C(\tilde{\Omega})} \|\nabla \sigma^*\|_{C(\tilde{\Omega})} \\ &\le 2\sqrt{2} K \epsilon^{n+1} \left\|\mathbb{A}[\sigma^*]^{-1}\right\|_{C(\tilde{\Omega})} \overline{D}_*^n (\overline{G}(\sigma_\pm^*))^{n+1} \epsilon. \end{aligned} \tag{3.41}$$

This estimate together with $\left\|\sigma^{n+1} - \sigma^*\right\|_{C^1(\Omega)} \le K \left\|\nabla \sigma^{n+1} - \nabla \sigma^*\right\|_{C(\Omega)}$ generates

$$\left\|\sigma^{n+1} - \sigma^*\right\|_{C^1(\tilde{\Omega})} \le K2 \left\|\mathbb{A}^{-1}[\sigma^*]\right\|_{C(\tilde{\Omega})} \sqrt{2} \overline{D}_*^n (\overline{G}(\sigma_\pm^*))^{n+1} \epsilon^{n+1} K\epsilon \le (\overline{D}_* \overline{G}(\sigma_\pm^*)\epsilon)^{n+1} K\epsilon$$

from (3.25) and (3.29). Now under (3.31) for ϵ, the above estimate leads to

$$\left\|\sigma^{n+1} - \sigma^*\right\|_{C^1(\tilde{\Omega})} \le \theta^{n+1} K\epsilon. \tag{3.42}$$

It is obvious that $\sigma^{n+1} = \sigma^*$ in $\Omega \setminus \tilde{\Omega}$. So (3.34) is also true for $k = n+1$. The proof is complete. ∎

3.2. Convergence for a three-dimensional medium. Now we consider the convergence in the three-dimensional case. The essence of the proof is almost the same as that in the two-dimensional case, but we need some modifications due to the fact that the harmonic B_z algorithm computes a conductivity distribution in each two-dimensional slice of the three-dimensional medium. More explanations are given in Remark 3.6.

THEOREM 3.5. *Assume the target conductivity $\sigma^* \in C^1(\overline{\Omega})$, with $\Omega \subset \mathbb{R}^3$, which satisfies the following conditions:*

A1. $0 < \sigma_-^* \le \sigma^* \le \sigma_+^*$ *with known constants* $\sigma_\pm^*$*;*

A2. *there exists* $\tilde{\Omega} \subset\subset \Omega$ *such that* σ^* *is a known constant in* $\Omega \setminus \tilde{\Omega}$*;*

A3. $|\det \mathbb{A}[\sigma^*](x,y,z)| \ge d_-^* > 0$ *in* Ω*, where* d_-^* *is a known constant.*

Under these hypotheses, there exist constants $\epsilon = \epsilon(\sigma_\pm^*, d_-^*) > 0$ *small enough and* $\theta = \theta(\epsilon, \sigma_\pm^*, d_-^*) \in (0,1)$ *such that if we take the initial guess* σ^0 *as the constant* $\sigma^*|_{\Omega\setminus\tilde{\Omega}}$*, then it holds that the sequence* $\{\sigma^n := \sigma^n(x,y,z_0)$ *for all* $z_0\}$ *defined in* Ω*, where* $\sigma^n(x,y,z_0)$ *is constructed by the harmonic* B_z *iteration* (2.16) *for every* z_0*, converges to the true conductivity* σ^* *in* Ω *for* σ^* *satisfying*

$$\|\nabla \sigma^*\|_{C(\tilde{\Omega})} \le \epsilon. \tag{3.43}$$

More precisely, it holds that

$$\sigma^n = \sigma^* \text{ in } \Omega \setminus \tilde{\Omega}, \tag{3.44}$$

$$\|\sigma^n - \sigma^*\|_{C(\tilde{\Omega})} \le K\theta^n \epsilon, \quad \|\nabla_{x,y}(\sigma^n - \sigma^*)\|_{C(\tilde{\Omega})} \le K\theta^n \epsilon, \quad n = 1, 2, \dots, \tag{3.45}$$

where $K := diam(\Omega) + 1$.

Remark 3.6. In this three-dimensional setting, the estimate (3.45) is given by the C-norm, while the one in the two-dimensional case in Theorem 3.2 is given by the C^1-norm. We cannot improve the derivative estimate $\nabla_{x,y}(\sigma^n - \sigma^*)$ in (3.45) by $\nabla(\sigma^n - \sigma^*)$ since we do not know $\partial_z(\sigma^n - \sigma^*)$, although we have the full three gradient estimates (3.43) for σ^*. The main difficulty in this case is due to the fact that, in the iteration process (2.16), we get $\nabla_{x,y}\sigma^{n+1}$ at each slice with no information about $\partial_z \sigma^{n+1}$. That is, the harmonic B_z method approximates the three-dimensional conductivity function $\sigma^*(x,y,z)$ in $\Omega \subset \mathbb{R}^3$ at each two-dimensional slice $\Omega_{z_0} := \Omega \bigcap \{(x,y,z) : z = z_0\} \subset \mathbb{R}^2$. Then σ^n in $\Omega \subset \mathbb{R}^3$, at each iteration, is constructed as $\sigma^n := \bigcup_{z_0} \sigma^n(x,y,z_0)$.

Proof. We also take $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$. Similarly to the two-dimensional case, we denote by u_j^n and u_j^* the solutions to

$$\begin{cases} \nabla \cdot (\sigma \nabla u_j) = 0 \quad \text{in} \quad \Omega, \\ u_j|_{\mathcal{E}_j^+} = 1, \qquad u_j|_{\mathcal{E}_j^-} = 0, \\ -\sigma \nabla u_j \cdot \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega \setminus \mathcal{E}_j^+ \cup \mathcal{E}_j^-, \end{cases} \tag{3.46}$$

with $\sigma = \sigma^n$ and σ^*, respectively, and we write σ^0 as $\sigma^0 = \sigma^* + e^0$.

In every slice Ω_{z_0}, we have

$$|e^0(x,y,z_0)| \le diam(\Omega_{z_0}) \left\|\nabla_{x,y} e^0\right\|_{C(\Omega_{z_0})} \le diam(\Omega)\epsilon;$$

hence $\left\|e^0\right\|_{C(\tilde{\Omega})} \le K\epsilon$. Correspondingly, we expand u_j^0 at u_j^* as

$$u_j^0 = u_j^* + \epsilon w_j^0. \tag{3.47}$$

Hence ϵw_j^0 satisfies

$$\begin{cases} \nabla \cdot \left(\sigma^0 \nabla \epsilon w_j^0\right) = -\nabla \cdot (e^0 \nabla u_j^*) \quad \text{in} \quad \Omega, \\ \epsilon w_j^0|_{\mathcal{E}_j^+} = 0, \qquad \epsilon w_j^0|_{\mathcal{E}_j^-} = 0, \\ -\sigma^0 \nabla \epsilon w_j^0 \cdot \mathbf{n} = (\sigma^0 - \sigma^*)\nabla u_j^* \cdot \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega \setminus \mathcal{E}_j^+ \cup \mathcal{E}_j^-. \end{cases} \tag{3.48}$$

In the two-dimensional case, we can estimate the L^2-norm of $(\nabla \cdot e^n \nabla u_j^*)$ by (3.16). This is due to the fact that we can estimate $\|\nabla e^n\|_{C(\Omega)}$. But in the three-dimensional case, it is impossible to estimate $\|\partial_z e^n\|_{C(\Omega)}$. To overcome this difficulty, instead of using the L^2 and the Holder estimates of elliptic problems, we use the L^p estimate with $p > 1$.

First, by applying Lemma 3.1 to (3.46) with $\sigma = \sigma^*$ and the Sobolev imbedding theorem, we deduce that

$$\left\|u_j^*\right\|_{H^2(\tilde{\tilde{\Omega}})} + \left\|\nabla u_j^*\right\|_{C(\tilde{\Omega})} \leq C_* = C_*(\sigma_\pm^*) \tag{3.49}$$

due to (3.43) for $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$, where $\tilde{\Omega} \subset \tilde{\tilde{\Omega}} \subset \Omega$ and C_* in this three-dimensional case is constructed in the same way as constant $\overline{C}_*$ in (3.13), which implies that the right-hand side of the equation in (3.48) satisfies

$$\|e^0 \nabla u_j^*\|_{L^p(\Omega)} \leq C_* \left\|e^0\right\|_{C(\tilde{\Omega})} \quad \forall p > 1 \tag{3.50}$$

due to $\sigma^0 = \sigma^1$ on $\Omega \setminus \tilde{\Omega}$. The L^p interior estimates of the problem (3.48) give

$$\|\nabla \epsilon w_j^0\|_{L^p(\tilde{\tilde{\Omega}})} \leq C_4(\sigma^0)[\|\epsilon w_j^0\|_{L^p(\Omega)} + \|e^0 \nabla u_j^*\|_{L^p(\Omega)}]. \tag{3.51}$$

Again by the Sobolev imbedding theorem $H^1(\Omega) \subset L^p(\Omega)$, with $1 < p \leq 6$, we have

$$\|\epsilon w_j^0\|_{L^p(\Omega)} \leq C_s \|\epsilon w_j^0\|_{H^1(\Omega)} \leq C_s C_1(\sigma^0) \|e^0 \nabla u_j^*\|_{L^2(\Omega)} \leq C_s C_1(\sigma^0) C_* \left\|e^0\right\|_{C(\tilde{\Omega})}.$$

Hence combining this last estimate with (3.49) and (3.51) gives

$$\|\nabla \epsilon w_j^0\|_{L^p(\tilde{\tilde{\Omega}})} \leq C_4(\sigma^0)[C_s C_4(\sigma^0) C_* + C_*] \left\|e^0\right\|_{C(\tilde{\Omega})}. \tag{3.52}$$

Using Nirenberg's difference quotient method with respect to x in (3.48) in $\tilde{\tilde{\Omega}}$ yields

$$\nabla \cdot \sigma^0 \nabla \epsilon D_{x,h} w_j^0 = -\nabla \cdot e^0 \nabla D_{x,h} u_j^* - \nabla \cdot D_{x,h} e^0 \nabla u_{j,x,h}^* - \nabla \cdot D_{x,h} \sigma^0 \nabla \epsilon w_{j,x,h}^0, \tag{3.53}$$

where $D_{x,h} u := \frac{u(x+h,y,z) - u(x,y,z)}{h}$, $u_{x,h}(x,y,z) := u(x+h,y,z)$, with $h < dist(\partial\Omega, \tilde{\tilde{\Omega}})$.

The term in the right-hand side of (3.53) satisfies

$$\begin{cases} \|e^0 \nabla D_{x,h} u_j^*\|_{L^p(\tilde{\tilde{\Omega}})} \leq (1+\epsilon) C_4(\sigma^*) C_* \left\|e^0\right\|_{C(\tilde{\Omega})}, \\ \|D_{x,h} e^0 \nabla u_{j,x,h}^*\|_{L^p(\tilde{\tilde{\Omega}})} \leq C_* \left\|D_{x,h} e^0\right\|_{C(\tilde{\Omega})}, \\ \|D_{x,h} \sigma^0 \nabla \epsilon w_{j,x,h}^0\|_{L^p(\tilde{\tilde{\Omega}})} \leq \left\|D_{x,h} \sigma^0\right\|_{C(\tilde{\tilde{\Omega}})} \|\nabla \epsilon w_j^0\|_{L^p(\tilde{\tilde{\Omega}})}. \end{cases} \tag{3.54}$$

Indeed, $D_{x,h} u_j^*$ satisfies $\nabla \cdot \sigma^* \nabla (D_{x,h} u_j^*) = -\nabla \cdot (D_{x,h} \sigma^*) \nabla u_{j,x,h}^*$ in $\tilde{\tilde{\Omega}}$ from (3.46). Applying point 4 of Lemma 3.1, we deduce

$$\|\nabla (D_{x,h} u_j^*)\|_{L^p(\tilde{\Omega})} \leq C_4(\sigma^*)[\|D_{x,h} u_j^*\|_{L^p(\tilde{\tilde{\Omega}})} + \|(D_{x,h} \sigma^*) u_{j,x,h}^*\|_{L^p(\tilde{\tilde{\Omega}})}].$$

The estimate $\|D_{x,h} u_j^*\|_{L^p(\tilde{\tilde{\Omega}})} \leq \|\nabla u_j^*\|_{L^p(\tilde{\tilde{\Omega}})}$ and (3.50) give

$$\|\nabla (D_{x,h} u_j^*)\|_{L^p(\tilde{\Omega})} \leq (1+\epsilon) C_4(\sigma^*) C_*,$$

which is the first estimate in (3.54). The second term in (3.54) comes from (3.49).

Again from the interior L^p estimates applied for (3.53), we deduce that $D_{x,h}w_j^0$ is in $W^{1,p}_{loc}(\tilde{\Omega})$ and

$$\begin{aligned}\left\|\epsilon D_{x,h}w_j^0\right\|_{W^{1,p}(\tilde{\Omega})} \leq (1+C_4(\sigma^0))[&\left\|\epsilon D_{x,h}w_j^0\right\|_{L^p(\tilde{\tilde{\Omega}})} + \left\|e^0\nabla D_{x,h}u_j^*\right\|_{L^p(\tilde{\tilde{\Omega}})} \\ &+ \left\|D_{x,h}e^0\nabla u^*_{j,x,h}\right\|_{L^p(\tilde{\tilde{\Omega}})} + \left\|D_{x,h}\sigma^0\nabla\epsilon w^0_{j,x,h}\right\|_{L^p(\tilde{\tilde{\Omega}})}].\end{aligned}$$

(3.55)

Notice that $\left\|\epsilon D_{x,h}w_j^0\right\|_{L^p(\tilde{\tilde{\Omega}})} \leq \left\|\nabla\epsilon w_j^0\right\|_{L^p(\tilde{\tilde{\Omega}})}$ and

$$\left\|D_{x,h}\sigma^0\right\|_{C(\tilde{\tilde{\Omega}})} \leq \left\|\partial_x\sigma^0\right\|_{C(\tilde{\tilde{\Omega}})} \leq \left\|\nabla_{x,y}\sigma^0\right\|_{C(\tilde{\Omega})}. \tag{3.56}$$

The estimate (3.56) is trivial for σ^0 since it is a constant. However, we need this kind of estimate for the iterated sequence $\{\sigma^n\}$ with $\nabla_{x,y}\sigma^n$ continuous in $\tilde{\tilde{\Omega}}$. Hence the estimate (3.55) generates from (3.52), (3.54), and (3.56) that

$$\|\epsilon D_{x,h}w_j^0\|_{W^{1,p}(\tilde{\Omega})} \leq G(\sigma^0)[\left\|e^0\right\|_{C(\tilde{\Omega})} + \left\|D_{x,h}e^0\right\|_{C(\tilde{\Omega})}]$$

for $\epsilon \in (0, \frac{1}{2K}\sigma^*_-)$, where

$$G(\sigma) := (1+C_4(\sigma))C_* \times \max\left\{[1+\|\nabla_{x,y}\sigma\|_{C(\tilde{\Omega})}]C_4(\sigma)[C_sC_4(\sigma)+1] + \left(1+\frac{\sigma^*_-}{2K}\right)\sup_{[\sigma^*_-,\sigma^*_+]\times[\frac{1}{\sigma^*_+},\frac{1}{\sigma^*_-}]} F_4(t_1,t_3), 1\right\}. \tag{3.57}$$

Similarly, we know that $D_{y,h}w_j^0 \in W^{1,p}_{loc}(\tilde{\Omega})$ and also have the estimate

$$\|\epsilon D_{y,h}w_j^0\|_{W^{1,p}(\tilde{\Omega})} \leq G(\sigma^0)[\left\|e^0\right\|_{C(\tilde{\Omega})} + \left\|D_{y,h}e^0\right\|_{C(\tilde{\Omega})}].$$

Taking the limit with respect to $h \to 0$, we deduce that $\partial_x w_j^0,\ \partial_y w_j^0 \in W^{1,p}_{loc}(\tilde{\Omega})$ and

$$\|\epsilon\partial_x w_j^0\|_{W^{1,p}(\tilde{\Omega})},\ \ \|\epsilon\partial_y w_j^0\|_{W^{1,p}(\tilde{\Omega})} \leq G(\sigma^0)[\left\|e^0\right\|_{C(\tilde{\Omega})} + \left\|\nabla_{x,y}e^0\right\|_{C(\tilde{\Omega})}],$$

from which the Sobolev imbedding theorem $W^{1,p}(\tilde{\Omega}) \subset C(\tilde{\Omega})$ for $p>3$ implies

$$\|\epsilon\partial_x w_j^0\|_{C(\tilde{\Omega})},\ \ \|\epsilon\partial_y w_j^0\|_{C(\tilde{\Omega})} \leq C_sG(\sigma^0)[\left\|e^0\right\|_{C(\tilde{\Omega})} + \left\|\nabla_{x,y}e^0\right\|_{C(\tilde{\Omega})}].$$

We set $F(\sigma) := C_sG(\sigma)$, with $G(\sigma)$ defined in (3.57) and the constant $C_\epsilon(\sigma^*) := \sup_{\mathbb{S}_3} F(\sigma)$, with

$$\mathbb{S}_3 := \{\sigma(x,y,z) : \|\sigma-\sigma^*\|_{C(\Omega)} \leq K\epsilon,\ \|\nabla_{x,y}\sigma\|_{C(\tilde{\Omega})} \leq (K+1)\epsilon\}.$$

Again, noticing that $F(\sigma)$ contains only F_1 and F_4, the constant $C_\epsilon(\sigma^*)$ can be estimated by

$$C_\epsilon(\sigma^*) \leq \sup_{\mathbb{S}_4} F(\sigma) =: G(\sigma^*_\pm) \tag{3.58}$$

for $\epsilon \in (0, \frac{1}{2K}\sigma^*_-)$, where

$$\mathbb{S}_4 := \left\{\sigma(x,y,z) : \frac{1}{2}\sigma^*_- < \sigma < \frac{1}{2}\sigma^*_- + \sigma^*_+,\ \|\nabla_{x,y}\sigma\|_{C(\tilde{\Omega})} \leq \frac{K+1}{2K}\sigma^*_-\right\}.$$

In particular, we have $C_s G(\sigma^0) \le G(\sigma_\pm^*)$. Then the above estimate reads as

$$\|\epsilon\partial_x w_j^0\|_{C(\tilde\Omega)},\ \|\epsilon\partial_y w_j^0\|_{C(\tilde\Omega)} \le G(\sigma_\pm^*)[\|e^0\|_{C(\tilde\Omega)} + \|\nabla_{x,y} e^0\|_{C(\tilde\Omega)}]. \tag{3.59}$$

Obviously, (3.59) is also true in $\tilde\Omega_{z_0} := \tilde\Omega \bigcap \{(x,y,z) : z = z_0\} \subset \mathbb{R}^2$ for any z_0, that is,

$$\|\epsilon\partial_x w_j^0\|_{C(\tilde\Omega_{z_0})},\ \|\epsilon\partial_y w_j^0\|_{C(\tilde\Omega_{z_0})} \le G(\sigma_\pm^*)[\|e^0\|_{C(\tilde\Omega)} + \|\nabla_{x,y} e^0\|_{C(\tilde\Omega)}],$$

which corresponds to (3.21) in the two-dimensional case. As for (3.25) in the two-dimensional case, we have

$$\|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega_{z_0})} \le \|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega)} \le \frac{\sqrt{2}}{d_-^*} C_* \tag{3.60}$$

for any z_0 due to A2. We choose $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$ small enough such that

$$\epsilon \|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega)} \sqrt{2} G(\sigma_\pm^*) K \le \frac{2\epsilon C_* G(\sigma_\pm^*) K}{d_-^*} < \frac{1}{2}; \tag{3.61}$$

then we get from the same argument as that in subsection 3.1 that

$$\begin{aligned} \|\nabla_{x,y}(\sigma^* - \sigma^1)\|_{C(\tilde\Omega_{z_0})} &\le 2\|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega_{z_0})} \sqrt{2} \|\epsilon \nabla_{x,y} w_j\|_{C(\tilde\Omega_{z_0})} \|\nabla_{x,y}\sigma^*\|_{C(\tilde\Omega_{z_0})} \\ &\le 2\sqrt{2}\|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega)} G(\sigma_\pm^*) K\epsilon^2. \end{aligned} \tag{3.62}$$

As for $\sigma^1 - \sigma^*$, we have the estimate $\|\sigma^1 - \sigma^*\|_{C(\tilde\Omega_{z_0})} \le K \|\nabla_{x,y}(\sigma^1 - \sigma^*)\|_{C(\tilde\Omega_{z_0})}$, and hence

$$\|\sigma^1 - \sigma^*\|_{C(\tilde\Omega)} \le K 2\sqrt{2} \|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega)} G(\sigma_\pm^*) K\epsilon^2. \tag{3.63}$$

For each $\sigma^1(x,y,z_0)$ generated by the harmonic B_z method at each slice $\tilde\Omega_{z_0}$, we generate σ^1 in $\tilde\Omega \subset \mathbb{R}^3$ by $\sigma^1 := \bigcup_{z_0} \sigma^1(x,y,z_0)$. Now for $\epsilon \in (0, \frac{1}{2K}\sigma_-^*)$ satisfying (3.61),

$$K2\sqrt{2}\|\mathbb{A}[\sigma^*]^{-1}\|_{C(\tilde\Omega)} G(\sigma_\pm^*)\epsilon \le \frac{4}{d_-^*} C_* K G(\sigma_\pm^*)\epsilon := D_* G(\sigma_\pm^*)\epsilon := \theta \in (0,1); \tag{3.64}$$

then it follows that

$$\|\nabla_{x,y}(\sigma^1 - \sigma^*)\|_{C(\tilde\Omega)},\ \|\sigma^1 - \sigma^*\|_{C(\tilde\Omega)} \le K\theta\epsilon,$$

which means $F(\sigma^1) \le C_\epsilon(\sigma^*) \le G(\sigma_\pm^*)$. As in the two-dimensional case, we have $\sigma^1 = \sigma^*$ in $\Omega \setminus \tilde\Omega$. So the theorem is true for $n = 1$. It follows from (3.61) and (3.64) that $\epsilon = \epsilon(\sigma_\pm^*, d_-^*), \theta = \theta(\epsilon, \sigma_\pm^*, d_-^*)$.

Now we can apply the induction argument to prove the theorem. That is, assume that $\sigma^k \equiv \sigma^*$ in $\Omega \setminus \tilde\Omega$ and the following estimates:

$$\|\nabla_{x,y}(\sigma^k - \sigma^*)\|_{C(\tilde\Omega)},\ \|\sigma^k - \sigma^*\|_{C(\tilde\Omega)} \le K(D_* G(\sigma_\pm^*)\epsilon)^k \epsilon = K\theta^k\epsilon$$

are true for $k = n$. We shall prove that this is also true for $k = n + 1$.

This can be done by the same way as in the two-dimensional case, with the same modifications for the three-dimensional case as given in the proof of this theorem for the step $n = 1$. Indeed, $\nabla_{x,y}\sigma^n$ is continuous in every slice Ω_{z_0} from its definition (2.16) for $\sigma^* \in C^1$. This fact implies that (3.56) is true with σ^0 replaced by σ^n. Moreover, we have $C_s G(\sigma^n) \le C_\epsilon(\sigma^*) \le G(\sigma_\pm^*)$ from the assumption of the induction argument. So we omit the details. ∎

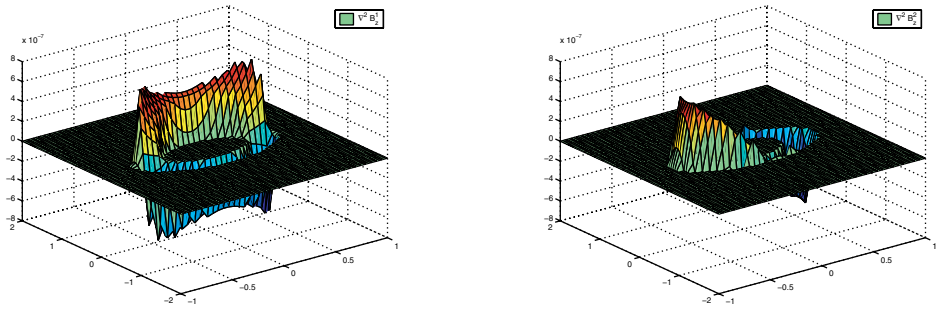

FIG. 4. *Distributions of* $\nabla^2 B_z^1$, $\nabla^2 B_z^2$.

4. Numerical performance. We present some numerics to show our theoretical convergence property. For simplicity, we deal with the axially symmetric case where input current densities in the electrodes are specified. That is, we consider the following two-dimensional problem for potential $u = u(x, y)$:

$$\begin{cases} \nabla \cdot (\sigma \nabla u) = 0 & \text{in } \Omega, \\ -\sigma \nabla u \cdot \mathbf{n} = g(x, y) & \text{on } \partial\Omega, \end{cases} \tag{4.1}$$

with $u(0, 0) = 0$ at the reference point $(0, 0)$. Consider the target conductivity in $\Omega := [-1, 1] \times [-2, 2]$ of the form

$$\sigma^*(r) = \begin{cases} 3 & \text{if} \quad 0 \le r \le 0.4, \\ -10r^2 + 4.6 & \text{if} \quad 0.4 \le r \le 0.6, \\ 1 & \text{otherwise}, \end{cases} \tag{4.2}$$

where $r = \sqrt{x^2 + y^2}$. Electrodes are specified as $\mathcal{E}_1^{\pm} := \{(\pm 1, y) : |y| < 0.1\}$ and $\mathcal{E}_2^{\pm} := \{(x, \pm 2) : |x| < 0.1\}$ on $\partial\Omega$. The input current densities $g^j, j = 1, 2$ are given by

$$g^j|_{\mathcal{E}_j^{\pm}} = \pm 1 \quad \text{and} \quad g^j = 0 \quad \text{on } \partial\Omega \setminus [\mathcal{E}_j^+ \cup \mathcal{E}_j^-]. \tag{4.3}$$

The corresponding $\nabla^2 B_z^j = \mu_0(\sigma_x u_y^{j,*} - \sigma_y u_x^{j,*})$ are shown in Figure 4, where $u^{j,*}$ is the solution corresponding to (σ^*, g_j) for $j = 1, 2$.

We introduce $\Phi(\mathbf{r}, \mathbf{r}') = \frac{1}{2\pi} \ln|\mathbf{r} - \mathbf{r}'|$ and divide Ω into $N \times M$ small rectangles. Denote by $\mathbf{r}_{k,l}$ the center of each rectangle $e(k, l)$. Then a simple computation generates the following discrete iteration formula:

$$\sigma^{n+1}(\mathbf{r}_{k,l}) = f(\mathbf{r}_{k,l}) - \frac{1}{\mu_0} \sum_{i,j=1}^{N,M} \int_{e(i,j)} \nabla\Phi(\mathbf{r}', \mathbf{r}_{k,l}) \cdot \mathbb{A}[\sigma^n]^{-1} \begin{pmatrix} \nabla^2 B_z^1 \\ \nabla^2 B_z^2 \end{pmatrix} (\mathbf{r}') d\mathbf{r}', \tag{4.4}$$

where $f(\mathbf{r}) = \int_{\partial\Omega} \nabla_{\mathbf{r}'}\Phi(\mathbf{r}, \mathbf{r}') \cdot \mathbf{n}_{\mathbf{r}'}\, \sigma^*(\mathbf{r}') ds(\mathbf{r}')$.

For the integrals in the elements, where we take $\mathbb{A}[\sigma^n]^{-1}, \nabla^2 B_z$ as constants at each element, they are zero for $(i, j) = (k, l)$ due to the symmetric property (noticing that $\mathbf{r}_{k,l}$ is the center of $e(k, l)$) and regular for $(i, j) \neq (k, l)$. So we can construct the sequence $\{\sigma^n\}$ inside Ω for a given initial guess $\sigma^0(\mathbf{r})$.

In our numerical test, the finite element method with bilinear base functions $\phi^{i,j}(x, y) = (a + by)(c + dy)$ at each nodal point are used to solve the direct problem

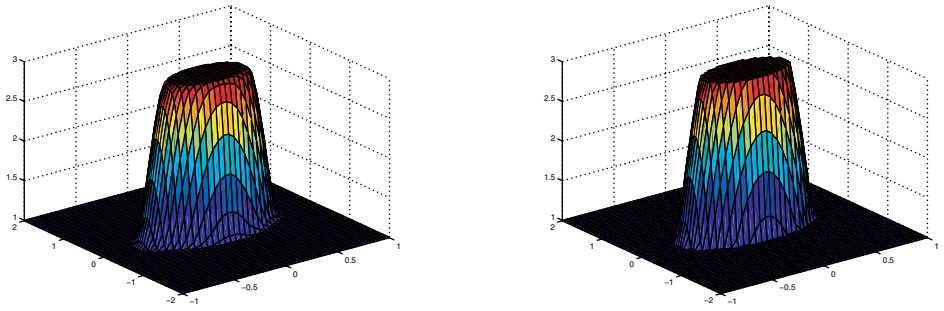

FIG. 5. *Reconstruction after six iterations (left) and the exact one (right).*

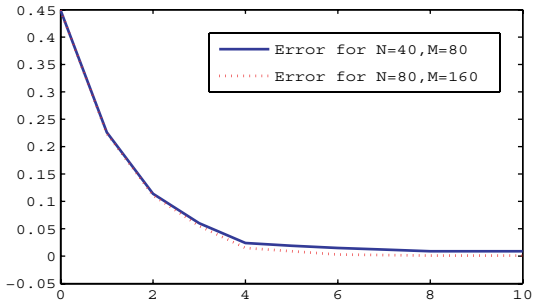

FIG. 6. *$E(n)$ with respect to the iteration number n for two different meshes.*

for $u[\sigma^n]$ at each iteration step. Then $\nabla u[\sigma^n]$ at the center of each element can be computed by the difference method. We also use this scheme to simulate $\nabla^2 B_z$ from (4.1)–(4.3) for our inversion input. To avoid the well-known *inverse crime* in the numerical tests [5], we use different grids in simulating the input data from those used in the inversion algorithm.

First, we take $N = 40, M = 80$ (case 1) and the initial guess function $\sigma_0(x, y) \equiv 1$. The recovering result after six iterations as well as the exact one are shown in Figure 5. Now we choose a finer mesh with $N = 80, M = 160$ (case 2). Denote by $E(n)$ the relative L^2-error between the target conductivity and the reconstructed one after the nth iteration. The numerical values of $E(n)$ in these two cases are given in Table 4.1, while curves are plotted in Figure 6 for a bigger iteration number $n = 10$.

From the error distributions in Figure 6 and Table 4.1, we can observe that the iteration algorithm converges very quickly. In fact, the error is almost unchanged after six iterations. This phenomenon matches very well with our theoretical result, which assumes a convergence rate of the order θ^n, with $\theta \in (0, 1)$. The excellent convergence performance comes from our good initial guess $\sigma^0 \equiv 1$. This means that the error of ϵ for the initial guess is not so large, and θ will be also small for small ϵ. We can also observe that the finer mesh can improve the inversion result at the expense of an increased number of computations.

Now let us consider an inferior initial guess function

$$\sigma^0(x, y) = \frac{4}{5} - \frac{1}{5}\cos\frac{(x^2 + y^2)\pi}{5}, \tag{4.5}$$

TABLE 4.1
Relative L^2-error $E(n)$ in two cases.

n	Case 1	Case 2	n	Case 1	Case 2
0	0.449118	0.449185	4	0.035278	0.028515
1	0.226044	0.224892	5	0.024009	0.015632
2	0.114281	0.111283	6	0.019200	0.009711
3	0.060467	0.055545	7	0.017172	0.007149

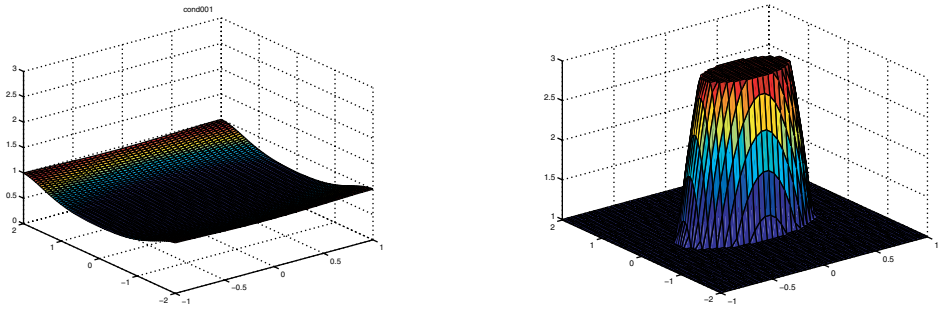

FIG. 7. *Inferior initial guess σ^0 (left) and the exact σ^* (right).*

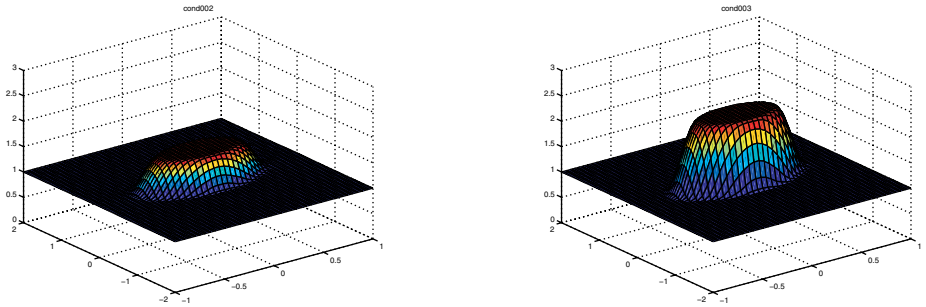

FIG. 8. *Reconstruction for $n = 1$ (left) and $n = 2$ (right) using the inferior initial guess.*

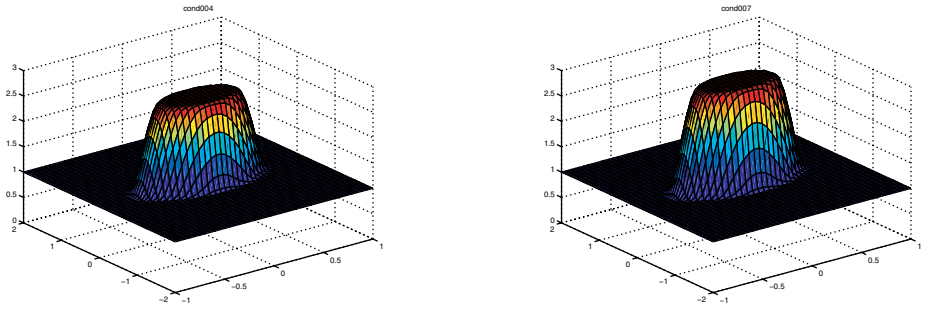

FIG. 9. *Reconstruction for $n = 3$ (left) and $n = 6$ (right) using the inferior initial guess.*

which is quite different from the exact $\sigma^*(x, y)$; see Figure 7. The reconstruction results for $n = 1, 2, 3, 6$ are given in Figures 8 and 9 with its error distribution illustrated in Figure 10. Even for this case with the undesirable initial guess, we can see that the algorithm still catches the target σ^* in the whole domain.

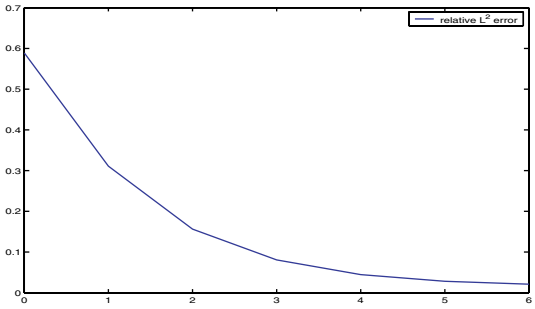

FIG. 10. *Relative error distribution for the inferior initial guess.*

It should be noticed that we used the simulation data $\nabla^2 B_z^j, j = 1, 2$, directly for the harmonic B_z algorithm rather than computing $\nabla^2 B_z^j$ from B_z^j. Obviously, if we use noisy measured B_z data as the inversion input, a suitable denoising technique must be used. Noticing the expression of the iteration (2.16), the harmonic B_z algorithm uses in fact the first derivative of B_z. A similar inversion scheme using the first derivative of B_z named the gradient B_z method can be found in [16, 17].

Acknowledgment. We thank a referee for pointing out results about the condition (2.11) in Remark 2.5.

ASYMPTOTIC PROFILES OF THE STEADY STATES FOR AN SIS EPIDEMIC PATCH MODEL*

L. J. S. ALLEN†, B. M. BOLKER‡, Y. LOU§, AND A. L. NEVAI¶

Abstract. Spatial heterogeneity, habitat connectivity, and rates of movement can have large impacts on the persistence and extinction of infectious diseases. These factors are shown to determine the asymptotic profile of the steady states in a frequency-dependent SIS (susceptible-infected-susceptible) epidemic model with n patches in which susceptible and infected individuals can both move between patches. Patch differences in local disease transmission and recovery rates characterize whether patches are low-risk or high-risk, and these differences collectively determine whether the spatial domain, or habitat, is low-risk or high-risk. The basic reproduction number $\mathcal{R}_0$ for the model is determined. It is then shown that when the disease-free equilibrium is stable ($\mathcal{R}_0 < 1$) it is globally asymptotically stable, and that when the disease-free equilibrium is unstable ($\mathcal{R}_0 > 1$) there exists a unique endemic equilibrium. Two main theorems link spatial heterogeneity, habitat connectivity, and rates of movement to disease persistence and extinction. The first theorem relates the basic reproduction number to the heterogeneity of the spatial domain. For low-risk domains, the disease-free equilibrium is stable ($\mathcal{R}_0 < 1$) if and only if the mobility of infected individuals lies above a threshold value, but for high-risk domains, the disease-free equilibrium is always unstable ($\mathcal{R}_0 > 1$). The second theorem states that when the endemic equilibrium exists, it tends to a spatially inhomogeneous disease-free equilibrium as the mobility of susceptible individuals tends to zero. This limiting disease-free equilibrium has a positive number of susceptible individuals on all low-risk patches and can also have a positive number of susceptible individuals on some, but not all, high-risk patches. Sufficient conditions for whether high-risk patches in the limiting disease-free equilibrium have susceptible individuals or not are given in terms of habitat connectivity, and these conditions are illustrated using numerical examples. These results have important implications for disease control.

Key words. spatial heterogeneity, dispersal, habitat connectivity, basic reproduction number, disease-free equilibrium, endemic equilibrium

1. Introduction.

Spatial heterogeneity, habitat connectivity, and rates of movement play important roles in disease persistence and extinction. Movement of susceptible or infected individuals can enhance or suppress the spread of disease, depending on the heterogeneity and connectivity of the spatial environment (see, e.g., Castillo-Chavez and Yakubu (2001, 2002); Bolker and Grenfell (1995); Hess (1996); Lloyd and May (1996); Salmani and van den Driessche (2006); Ruan (2006); Allen et al. (2007)). For example, the compartmental patch model of Ruan, Wang, and

Levin (2006) demonstrates that diseases such as SARS can be contained by screening for infection at borders and barring residents of disease hot spots from travel. Spatial heterogeneity can also give rise to complex and surprising disease dynamics (Allen, Kirupaharan, and Wilson (2004); Castillo-Chavez and Yakubu (2001, 2002); Hess (1996); Lloyd and Jansen (2004); Wang and Zhao (2004)). In numerical investigations of a discrete-time two-patch SIS (susceptible-infected-susceptible) epidemic model, Allen, Kirupaharan, and Wilson (2004) considered a case where, in the absence of movement, the disease persists in only one of the two patches—a high-risk patch, where the patch reproduction number is greater than one. When the patches are connected by susceptible and infective movement, an endemic equilibrium is reached in both patches. But if the movement pattern is changed so that only infected individuals disperse between the two patches, a surprising result occurs. The disease does not persist in either patch; the high-risk patch becomes empty, and all susceptible individuals eventually reside in the low-risk patch, where the patch reproduction number is less than one. We investigate this latter phenomenon in a continuous-time SIS metapopulation model with n patches that includes both high-risk and low-risk patches.

Disease spread in metapopulation models involving discrete patches has been investigated in a variety of settings (Arino and van den Driessche (2006, 2003a, 2003b); Arino et al. (2005); Jin and Wang (2005); Rvachev and Longini (1985); Salmani and van den Driessche (2006); Sattenspiel and Dietz (1995); Wang and Mulone (2003); Wang and Zhao (2004)). In a review article, Arino and van den Driessche (2006) summarize some known results on disease dynamics in metapopulation models with regard to existence and stability of disease-free and endemic equilibria. They develop a general framework for movement of susceptible, exposed, infected, and recovered individuals (SEIRS model) and define a *mobility matrix*, an irreducible matrix that defines the spatial arrangement of patches and rates of movement between patches (see also Arino and van den Driessche (2003a, 2003b)). Wang and colleagues studied uniform persistence and global stability of disease-free and endemic equilibria in SIS metapopulation models (Jin and Wang (2005); Wang and Mulone (2003); Wang and Zhao (2004)).

Here, we formulate a frequency-dependent SIS metapopulation model consisting of n patches. The spatial arrangement of patches, and rates of movement between patches, are defined by an irreducible matrix. The spatial domain is characterized as *low-risk* or *high-risk* if the spatial average of the patch transmission rates is less than or greater than, respectively, the spatial average of the recovery rates. Individual patches are also characterized as *low-risk* or *high-risk* if the patch transmission rate is less than or greater than the patch recovery rate, which is equivalent to the patch reproduction number being less than or greater than one, respectively. A unique disease-free equilibrium is shown to exist, and a basic reproduction number $\mathcal{R}_0$ is determined. If $\mathcal{R}_0 < 1$, the disease-free equilibrium is shown to be globally asymptotically stable, and if $\mathcal{R}_0 > 1$, a unique endemic equilibrium is shown to exist.

Our two main theorems link spatial heterogeneity, habitat connectivity, and rates of movement to disease persistence and extinction. The first theorem relates the basic reproduction number to the heterogeneity of the spatial domain. It is shown that for low-risk domains, the disease-free equilibrium is stable ($\mathcal{R}_0 < 1$) if and only if the mobility of infected individuals lies above a threshold value. For high-risk domains the disease-free equilibrium is always unstable ($\mathcal{R}_0 > 1$). The second theorem concerns the spatial heterogeneity in the limiting case where the mobility of susceptible individuals approaches zero. We show that if $\mathcal{R}_0 > 1$, then the endemic

equilibrium approaches a spatially inhomogeneous disease-free equilibrium which has a positive number of susceptible individuals on all low-risk patches and no susceptibles on at least one of the high-risk patches. These results have important implications for disease control. If the spatial environment can be modified to include low-risk patches (i.e., low transmission rates or high recovery rates) and if the movement of susceptible individuals can be restricted (e.g., quarantine), then it may be possible to eliminate the disease.

1.1. The model. Let $n \geq 2$ be the number of patches and $\Omega = \{1, 2, \ldots, n\}$. Consider the SIS patch model

$$\frac{d\bar{S}_j}{dt} = d_S \sum_{k\in\Omega}(L_{jk}\bar{S}_k - L_{kj}\bar{S}_j) - \frac{\beta_j \bar{S}_j \bar{I}_j}{\bar{S}_j + \bar{I}_j} + \gamma_j \bar{I}_j, \quad j \in \Omega, \tag{1.1a}$$

$$\frac{d\bar{I}_j}{dt} = d_I \sum_{k\in\Omega}(L_{jk}\bar{I}_k - L_{kj}\bar{I}_j) + \frac{\beta_j \bar{S}_j \bar{I}_j}{\bar{S}_j + \bar{I}_j} - \gamma_j \bar{I}_j, \quad j \in \Omega, \tag{1.1b}$$

where $\bar{S}_j(t)$ and $\bar{I}_j(t)$ denote the number of susceptible and infected individuals in patch j at time $t \geq 0$; d_S and d_I are positive diffusion coefficients for the susceptible and infected subpopulations; L_{jk} represents the degree of movement from patch k into patch j; and β_j and γ_j are nonnegative constants that express the rate of disease transmission and recovery in patch j. Because $\bar{S}_j\bar{I}_j/(\bar{S}_j+\bar{I}_j)$ is a Lipschitz continuous function of $\bar{S}_j$ and $\bar{I}_j$ in the open first quadrant, we extend its definition to the entire first quadrant by defining it to be zero when at least one of $\bar{S}_j = 0$ or $\bar{I}_j = 0$ holds. We assume that

(A1) $\bar{S}_j(0) \geq 0$ and $\bar{I}_j(0) \geq 0$ for $j \in \Omega$, and $\sum_{j\in\Omega}\left[\bar{S}_j(0) + \bar{I}_j(0)\right] > 0$.

Let $\bar{S} = (\bar{S}_j)$ and $\bar{I} = (\bar{I}_j)$. Brauer and Nohel's work (1989) implies that a unique solution $(\bar{S}, \bar{I})$ of (1.1) exists for all time. Let

$$N = \sum_{j\in\Omega}\left[\bar{S}_j(0) + \bar{I}_j(0)\right] \tag{1.2}$$

be the total number of individuals in all patches at $t = 0$. By (A1), N is positive. Summing the $2n$ equations in (1.1) makes it clear that

$$\sum_{j\in\Omega}\left[\bar{S}_j(t) + \bar{I}_j(t)\right] = N, \quad t \geq 0. \tag{1.3}$$

We will assume that the *connectivity matrix* $L = (L_{jk})$ satisfies

(A2) L is nonnegative, irreducible, and symmetric.

We shall say that a matrix $A = (A_{jk})$ is *nonnegative* (or *positive*) if all its elements are nonnegative (or positive), in which case we will write $A \geq 0$ (or $A > 0$). Similar comments apply to vectors $u = (u_j)$. The symmetry assumption ensures that the per capita rates of susceptible and infected individuals entering patch j from patch k ($d_S L_{jk}$ and $d_I L_{jk}$) are equal to the per capita rates of individuals moving in the other direction ($d_S L_{kj}$ and $d_I L_{kj}$). Hence, in (1.1)

$$L_{jk}\bar{S}_k - L_{kj}\bar{S}_j = L_{jk}(\bar{S}_k - \bar{S}_j) \quad \text{and} \quad L_{jk}\bar{I}_k - L_{kj}\bar{I}_j = L_{jk}(\bar{I}_k - \bar{I}_j).$$

The irreducibility assumption implies that the system of patches considered as a directed graph with patches as the vertices is strongly connected (Ortega (1987)).

Other characterizations of irreducibility are given in Appendix A, and we will make use of these additional facts as needed.

We say that in a *low-risk patch* disease transmission occurs at a lower rate than disease recovery when the number of infected individuals in that patch is very small. A *high-risk patch* is defined in a similar manner. Let

$$H^- = \{j \in \Omega : \beta_j < \gamma_j\} \quad \text{and} \quad H^+ = \{j \in \Omega : \beta_j > \gamma_j\}$$

denote the set of these low-risk and high-risk patches, respectively. We assume that

(A3) H^- and H^+ are nonempty and $H^- \cup H^+ = \Omega$.

Let $\mathcal{R}_0^{[j]} = \beta_j/\gamma_j$ be the *patch reproduction number* for patch $j \in \Omega$ (we set $\mathcal{R}_0^{[j]} = \infty$ when $\gamma_j = 0$). Then $\mathcal{R}_0^{[j]} < 1$ for low-risk patches ($j \in H^-$), and $\mathcal{R}_0^{[j]} > 1$ for high-risk patches ($j \in H^+$). It is well known that the disease can persist in isolated high-risk patches but not in isolated low-risk patches.

Let

$$\Sigma_\beta = \sum_{j\in\Omega} \beta_j \quad \text{and} \quad \Sigma_\gamma = \sum_{j\in\Omega} \gamma_j.$$

We say that Ω is a *low-risk domain* if $\Sigma_\beta < \Sigma_\gamma$, but a *high-risk domain* if $\Sigma_\beta \geq \Sigma_\gamma$.

For an arbitrary patch $j \in \Omega$, it will be convenient to define

$$L_j = \sum_{k\in\Omega} L_{jk}, \quad L_j^- = \sum_{k\in H^-} L_{jk}, \quad \text{and} \quad L_j^+ = \sum_{k\in H^+} L_{jk}.$$

These sums denote the connectivity between patch j and all patches, all low-risk patches, and all high-risk patches, respectively. The irreducibility of L implies that $L_j > 0$ for all $j \in \Omega$.

1.2. The equilibrium problem. We will be primarily interested in equilibrium solutions of (1.1), i.e., solutions of

$$d_S \sum_{k\in\Omega} L_{jk}(\tilde{S}_k - \tilde{S}_j) - \frac{\beta_j \tilde{S}_j \tilde{I}_j}{\tilde{S}_j + \tilde{I}_j} + \gamma_j \tilde{I}_j = 0, \quad j \in \Omega, \tag{1.4a}$$

$$d_I \sum_{k\in\Omega} L_{jk}(\tilde{I}_k - \tilde{I}_j) + \frac{\beta_j \tilde{S}_j \tilde{I}_j}{\tilde{S}_j + \tilde{I}_j} - \gamma_j \tilde{I}_j = 0, \quad j \in \Omega, \tag{1.4b}$$

where $\tilde{S}_j$ and $\tilde{I}_j$ denote the number of susceptible and infected individuals, respectively, in patch $j \in \Omega$ at equilibrium. In view of (1.3), we impose the condition

$$\sum_{j\in\Omega} \left(\tilde{S}_j + \tilde{I}_j\right) = N. \tag{1.4c}$$

Let $\tilde{S} = (\tilde{S}_j)$ and $\tilde{I} = (\tilde{I}_j)$. We are interested only in solutions $(\tilde{S}, \tilde{I})$ of (1.4) which satisfy $\tilde{S} \geq 0$ and $\tilde{I} \geq 0$. A *disease-free equilibrium* (DFE) is a solution in which $\tilde{I}_j = 0$ for all $j \in \Omega$. An *endemic equilibrium* (EE) is a solution in which $\tilde{I}_j > 0$ for some $j \in \Omega$. To distinguish between these two types of equilibria, we will for notational convenience denote a DFE by $(\hat{S}, 0)$ and an EE by $(\tilde{S}, \tilde{I})$.

1.3. Statement of the main results. We consider in section 2 properties of the DFE, including its existence, uniqueness, and stability. We first show that there exists a unique DFE $(\hat{S}, 0)$, and it is given by $\hat{S}_j = N/n$ for $j \in \Omega$. We then calculate the basic reproduction number $\mathcal{R}_0$ for (1.1) using the next generation approach (Diekmann, Heesterbeek, and Metz (1990); Diekmann and Heesterbeek (2000); van den Driessche and Watmough (2002)) for which it is known that if $\mathcal{R}_0 < 1$, then the DFE is locally asymptotically stable, but if $\mathcal{R}_0 > 1$, then it is unstable. Our calculation will show that $\mathcal{R}_0$ does not depend on the diffusion coefficient d_S. Finally, we show that if $\mathcal{R}_0 < 1$, then the DFE is globally asymptotically stable.

In section 3, we find an equivalent characterization for the stability of the DFE in terms of d_I rather than $\mathcal{R}_0$. In particular, we show that the DFE in a low-risk domain is stable if and only if the diffusion coefficient for infected individuals lies above a certain threshold value, but in a high-risk domain, the DFE is always unstable. We also show that when the DFE is unstable, then there exists a unique EE. Moreover, the disease persists in every patch.

THEOREM 1. *Suppose that* (A1)–(A3) *hold and N is fixed.*

(a) *In a low-risk domain ($\Sigma_\beta < \Sigma_\gamma$), there exists a threshold value $d_I^* \in (0, \infty)$ such that $\mathcal{R}_0 > 1$ for $d_I < d_I^*$ and $\mathcal{R}_0 < 1$ for $d_I > d_I^*$.*

(b) *In a high-risk domain ($\Sigma_\beta \geq \Sigma_\gamma$), we have $\mathcal{R}_0 > 1$ for all d_I.*

(c) *If $\mathcal{R}_0 > 1$, then an EE exists, it is unique, and $\tilde{I} > 0$.*

Observe from (1.4) that in the limiting case $d_S = 0$ there also exists a family of infinitely many spatially inhomogeneous DFEs $(\hat{S}, 0)$, each of which satisfies

$$\hat{S} \geq 0 \quad \text{and} \quad \sum_{j \in \Omega} \hat{S}_j = N. \tag{1.5}$$

In section 4, we show that if $\mathcal{R}_0 > 1$, then the EE approaches such a spatially inhomogeneous DFE as the mobility of susceptible individuals becomes very small. We write this limiting DFE as $(S^*, 0)$ and also consider the distribution of patches for which S^* is either positive or zero.

THEOREM 2. *Suppose that* (A1)–(A3) *hold, N is fixed, and $\mathcal{R}_0 > 1$.*

(a) *$(\tilde{S}, \tilde{I}) \to (S^*, 0)$ as $d_S \to 0$ for some S^* satisfying* (1.5)*;*

(b) *$S^* > 0$ on H^- and $S_j^* = 0$ for some $j \in H^+$;*

(c) *if*

$$\frac{1}{d_I} > \max_{k \in H^+} \left[\frac{L_k^-}{\beta_k - \gamma_k} \right] + \max_{k \in H^-} \left[\frac{L_k^+}{\beta_k - \gamma_k} \right], \tag{1.6}$$

then $S^* \equiv 0$ on H^+;

(d) *if*

$$\frac{1}{d_I} < \frac{L_j^-}{\beta_j - \gamma_j} + \min_{k \in H^-} \left[\frac{L_k^+}{\beta_k - \gamma_k} \right] \tag{1.7}$$

for some $j \in H^+$, then $S_j^* > 0$.

We now make several remarks concerning Theorem 2, which connects spatial heterogeneity, habitat connectivity, and rates of movement. First, condition (1.6) will be satisfied whenever d_I is sufficiently small.

Second, Theorem 2(c) immediately implies that if

$$\frac{1}{d_I} > \max_{k \in H^+} \left[\frac{L_k^-}{\beta_k - \gamma_k} \right], \tag{1.8}$$

then $S^* \equiv 0$ on H^+ because $L_k^+/(\beta_k - \gamma_k)$ is nonpositive for every $k \in H^-$. Although condition (1.6) is more inclusive than condition (1.8), the latter is usually easier to verify. Furthermore, if some low-risk patch ($k \in H^-$) is not directly connected to any high-risk patches ($L_k^+ = 0$), then conditions (1.6) and (1.8) are in fact equivalent.

Third, Theorem 2(d) implies that if

$$\frac{1}{d_I} < \max_{k\in H^+}\left[\frac{L_k^-}{\beta_k - \gamma_k}\right] + \min_{k\in H^-}\left[\frac{L_k^+}{\beta_k - \gamma_k}\right], \tag{1.9}$$

then $S^* \not\equiv 0$ on H^+.

1.4. Examples. Before proving Theorems 1 and 2, we first illustrate the second theorem with some examples of metapopulations occupying different distributions of low-risk and high-risk patches.

Example 1. If $H^- = \{1, 2, \ldots, n-1\}$ and $H^+ = \{n\}$, then Theorem 2(b) implies that $S^* > 0$ on H^- and $S^* = 0$ on H^+. For this case, condition (1.6) in Theorem 2 (c) may or may not hold, but condition (1.7) in Theorem 2(d) cannot. That is, for this particular configuration of patches, the assumption that $\mathcal{R}_0 > 1$ in Theorem 2 excludes the possibility that condition (1.7) can be satisfied.

Example 2. If $H^- = \{1\}$ and $H^+ = \{2, 3, \ldots, n\}$, then

$$\max_{k\in H^-}\left[\frac{L_k^+}{\beta_k - \gamma_k}\right] = \min_{k\in H^-}\left[\frac{L_k^+}{\beta_k - \gamma_k}\right] = \frac{L_1^+}{\beta_1 - \gamma_1}.$$

Theorem 2(b) implies that $S^* > 0$ on H^-, and Theorem 2(c), (d) provide necessary and sufficient conditions (except in the case of equality) for determining whether $S^* \equiv 0$ or $S^* \not\equiv 0$ on H^+. For example, suppose that there are $n = 3$ patches with $H^- = \{1\}$ and $H^+ = \{2, 3\}$. If

$$\frac{1}{d_I} > \max\left\{\frac{L_{21}}{\beta_2 - \gamma_2}, \frac{L_{31}}{\beta_3 - \gamma_3}\right\} + \frac{L_{12} + L_{13}}{\beta_1 - \gamma_1},$$

then $S^* \equiv 0$ on H^+, but if

$$\frac{1}{d_I} < \max\left\{\frac{L_{21}}{\beta_2 - \gamma_2}, \frac{L_{31}}{\beta_3 - \gamma_3}\right\} + \frac{L_{12} + L_{13}}{\beta_1 - \gamma_1},$$

then either $S_2^* = 0$ and $S_3^* > 0$ or $S_2^* > 0$ and $S_3^* = 0$.

Example 3. Suppose there are $n = 9$ patches arranged and connected as in Figure 1. We assume that $L_{ij} \in \{0, 1\}$ with $L_{ij} = 1$ whenever patches i and j are connected by an arrow. In addition, $\gamma_j = 1$ and $\bar{S}_j(0) + \bar{I}_j(0) = 100$ for $j \in \Omega$, so that $\mathcal{R}_0^{[j]} = \beta_j$ and $N = 900$. Four numerical examples (see Figure 2) illustrate the values of S_j^* for $j \in \Omega$. Low-risk patches ($\mathcal{R}_0^{[j]} < 1$) are gray, and high-risk patches ($\mathcal{R}_0^{[j]} > 1$) are white. For $\mathcal{R}_0 > 1$ ($d_I < d_I^*$), the value of S_j^* was approximated by $\tilde{S}_j$, which was calculated using the iterative method (3.11) with $d_S \le 10^{-5}$, $d_I = 1$, and $\sum_{j\in\Omega} \tilde{I}_j < 0.005$.

For the limiting DFE in Figure 2(a), susceptibles can persist only on low-risk patches. In this case, condition (1.6) of Theorem 2(c) is satisfied:

$$1 = \frac{1}{d_I} > \max_{k\in H^+}\left\{\frac{L_k^-}{\beta_k - \gamma_k}\right\} + \max_{k\in H^-}\left\{\frac{L_k^+}{\beta_k - \gamma_k}\right\} = \frac{2}{0.5} - \frac{2}{0.5} = 0.$$

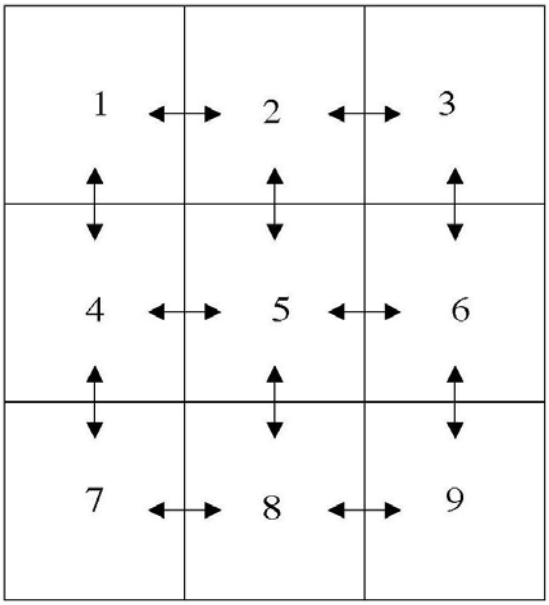

FIG. 1. *Nine patches connected at their boundaries.*

For the limiting DFE in Figure 2(b), susceptibles can persist on several high-risk patches. In this case, condition (1.7) of Theorem 2(d) is satisfied for $j = 2, 5, 6$,

$$1 = \frac{1}{d_I} < \frac{L_j^-}{\beta_j - \gamma_j} + \min_{k \in H^-} \left\{ \frac{L_k^+}{\beta_k - \gamma_k} \right\} = \frac{\{2 \text{ or } 1\}}{0.25} - \frac{1}{0.5} = \{6 \text{ or } 2\},$$

but not for $j = 3$:

$$1 = \frac{1}{d_I} > \frac{L_3^-}{\beta_3 - \gamma_3} + \min_{k \in H^-} \left\{ \frac{L_k^+}{\beta_k - \gamma_k} \right\} = \frac{0}{0.25} - \frac{1}{0.5} = -2.$$

We consider Figure 2(c), (d) in the Discussion.

2. The disease-free equilibrium. Throughout this section, we assume that (A1)–(A3) hold and that N is fixed.

2.1. Existence and uniqueness of the DFE. Equation (1.4) has a unique disease-free solution, and it is spatially homogeneous.

LEMMA 2.1. *A DFE* $(\hat{S}, 0)$ *exists, it is unique, and it is given by* $\hat{S}_j = N/n$ *for* $j \in \Omega$.

Proof. It is clear from (1.4) that $(\hat{S}, 0)$, with $\hat{S}_j = N/n$ for $j \in \Omega$, is a DFE. Now, let $(\tilde{S}, 0)$ be any DFE. Choose $m \in \Omega$ such that $\tilde{S}_m = \min\{\tilde{S}_j : j \in \Omega\}$. Setting $\tilde{I} = 0$ in (1.4a) with $j = m$ leads to $\sum_{k \in \Omega} L_{mk}(\tilde{S}_k - \tilde{S}_m) = 0$. The minimality of $\tilde{S}_m$ implies that $\tilde{S}_k = \tilde{S}_m$ whenever $L_{mk} > 0$. Let $j \in \Omega$ with $j \neq m$. The irreducibility of L implies that there exists a chain from j to m, i.e., a sequence $j_1, j_2, \ldots, j_s \in \Omega$ with $j_1 = j$ and $j_s = m$ such that $L_{j_p j_{p+1}} > 0$ for $1 \leq p \leq s-1$. Thus $\tilde{S}_{j_p} = \tilde{S}_{j_{p+1}}$ for $1 \leq p \leq s-1$. We conclude that $\tilde{S}_j = \tilde{S}_m$. Since j is arbitrary, we must have $\tilde{S}_j = \tilde{S}_m$ for all $j \in \Omega$. In view of (1.4c) with $\tilde{I} = 0$, we obtain $\tilde{S}_j = N/n$ for $j \in \Omega$. ∎

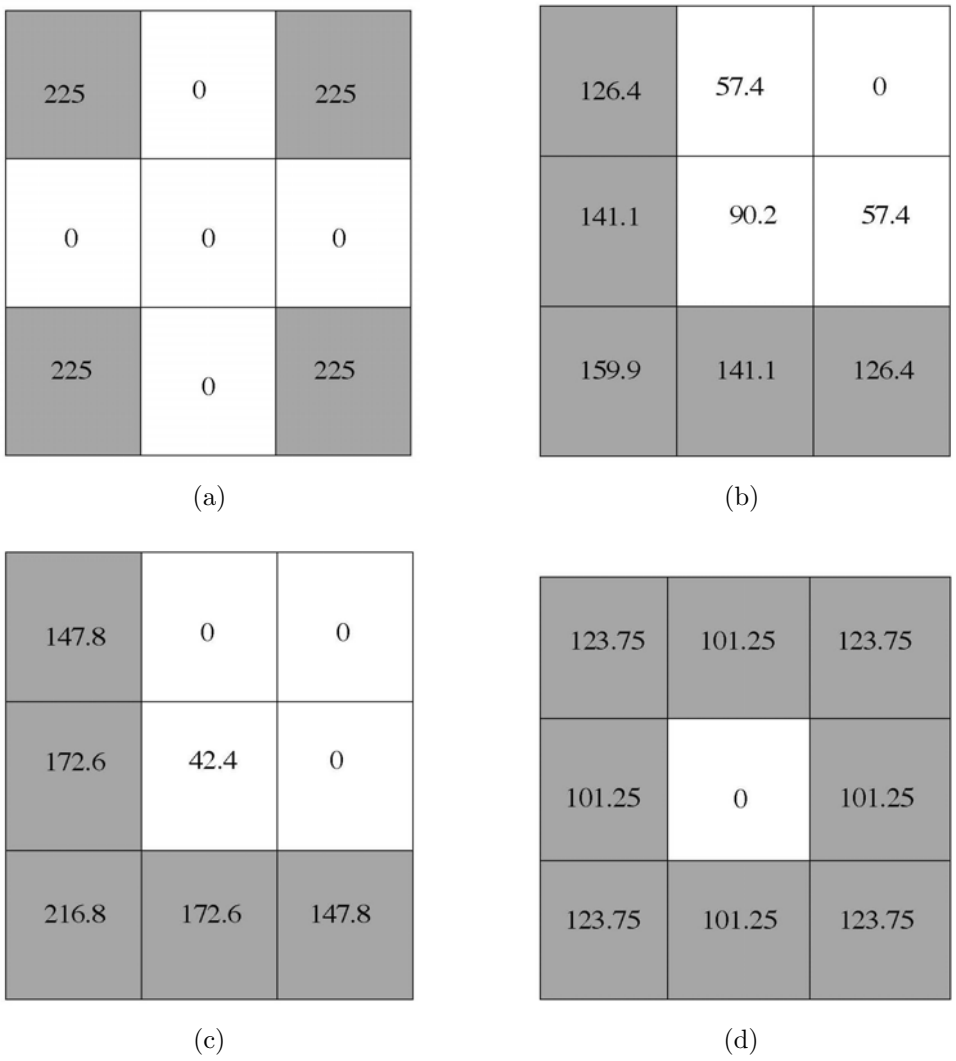

FIG. 2. *The limiting DFE under four parameter conditions.* (a) $\mathcal{R}_0 = 1.20$, $\mathcal{R}_0^{[5]} = 2$, $\mathcal{R}_0^{[j]} = 1.5$, *and* $\mathcal{R}_0^{[k]} = 0.5$ *for* $j = 2, 4, 6, 8$ *and* $k = 1, 3, 7, 9$; (b) $\mathcal{R}_0 = 1.51$, $\mathcal{R}_0^{[3]} = 3$, $\mathcal{R}_0^{[j]} = 1.25$, *and* $\mathcal{R}_0^{[k]} = 0.5$ *for* $j = 2, 5, 6$ *and* $k = 1, 4, 7, 8, 9$; (c) $\mathcal{R}_0 = 1.58$, $\mathcal{R}_0^{[3]} = 3$, $\mathcal{R}_0^{[j]} = 1.5$, *and* $\mathcal{R}_0^{[k]} = 0.5$ *for* $j = 2, 5, 6$ *and* $k = 1, 4, 7, 8, 9$; (d) $\mathcal{R}_0 = 1.03$, $\mathcal{R}_0^{[5]} = 3$, *and* $\mathcal{R}_0^{[j]} = 0.5$ *for* $j \neq 5$.

2.2. Stability of the DFE. Applying Lemma 2.1, we can calculate the basic reproduction number $\mathcal{R}_0$ for (1.1) using the next generation approach (Diekmann, Heesterbeek, and Metz (1990); Diekmann and Heesterbeek (2000); van den Driessche and Watmough (2002)). Since there are n patches, the basic reproduction number will be the spectral radius of an $n \times n$ nonnegative matrix. It is known that if $\mathcal{R}_0 < 1$, then the DFE is locally asymptotically stable, and if $\mathcal{R}_0 > 1$, then the DFE is unstable (van den Driessche and Watmough (2002)).

LEMMA 2.2. *The basic reproduction number for* (1.1) *is the spectral radius of the next generation matrix,*

$$\mathcal{R}_0 = \rho(FV^{-1}),$$

where $F = \operatorname{diag}(\beta_j)$ *and* $V = \operatorname{diag}(\gamma_j + d_I L_j) - d_I L$.

Proof. We can write (1.1b) as

$$\frac{d\bar{I}}{dt} = \mathcal{F} - \mathcal{V},$$

where $\mathcal{F}$ is the vector of new infections and $\mathcal{V}$ is the vector of transitions in the n infected states. Linearization of this system about the DFE yields

$$\frac{dx}{dt} = (F - V)x,$$

where F and V are the Jacobian matrices of $\mathcal{F}$ and $\mathcal{V}$, respectively, evaluated at the DFE. The eigenvalues of $(F - V)$ have negative real part if and only if $\mathcal{R}_0 = \rho(FV^{-1}) < 1$ (van den Driessche and Watmough (2002)). ∎

We now show that if $\mathcal{R}_0 < 1$, then the disease always becomes extinct; i.e., the DFE is globally asymptotically stable.

LEMMA 2.3. *If* $\mathcal{R}_0 < 1$, *then* $(\bar{S}, \bar{I}) \to (\hat{S}, 0)$ *as* $t \to \infty$.

Proof. Suppose that $\mathcal{R}_0 < 1$. We will use the comparison principle to show that $\bar{I}(t) \to 0$ as $t \to \infty$. To begin, observe from (1.1b) that

$$\frac{d\bar{I}_j}{dt} \le d_I \sum_{k\in\Omega} L_{jk}\bar{I}_k + (\beta_j - \gamma_j - d_I L_j)\bar{I}_j, \quad j \in \Omega,$$

or equivalently

$$\frac{d\bar{I}}{dt} \le (F - V)\bar{I},$$

where F and V are as in Lemma 2.2. The linear comparison system

$$\frac{dx}{dt} = (F - V)x, \quad x(0) = \bar{I}(0),$$

which is monotone, has eigenvalues with negative real part because $\mathcal{R}_0 < 1$ (van den Driessche and Watmough (2002)). Consequently, $x(t) \to 0$ as $t \to \infty$. By comparison, $\bar{I}(t) \to 0$ as $t \to \infty$. ∎

The global asymptotic stability of the DFE when $\mathcal{R}_0 < 1$ implies that there can be no EE in this case. In section 3, we consider what happens when $\mathcal{R}_0 > 1$.

3. The endemic equilibrium. Throughout this section, we again assume that (A1)–(A3) hold and that N is fixed.

3.1. Equivalent problems. It will be useful to consider several alternative statements of the equilibrium problem. We present here the first such equivalent problem.

LEMMA 3.1. *The pair* $(\tilde{S}, \tilde{I})$ *is a solution of* (1.4) *if and only if* $(\tilde{S}, \tilde{I})$ *is a solution of*

$$\kappa = d_S\tilde{S}_j + d_I\tilde{I}_j, \qquad j \in \Omega, \tag{3.1a}$$

$$0 = d_I \sum_{k\in\Omega} L_{jk}(\tilde{I}_k - \tilde{I}_j) + \tilde{I}_j\left(\beta_j - \gamma_j - \frac{\beta_j\tilde{I}_j}{\tilde{S}_j + \tilde{I}_j}\right), \quad j \in \Omega, \tag{3.1b}$$

$$N = \sum_{j\in\Omega}\left(\tilde{S}_j + \tilde{I}_j\right), \tag{3.1c}$$

where κ is some positive constant that is independent of $j \in \Omega$.

Proof. Suppose first that $(\tilde{S}, \tilde{I})$ is a solution of (1.4). We will show that there exists some $\kappa > 0$ such that $(\tilde{S}, \tilde{I})$ satisfies (3.1a). Summing (1.4a) and (1.4b) produces the relation

$$d_S \sum_{k\in\Omega} L_{jk}(\tilde{S}_k - \tilde{S}_j) + d_I \sum_{k\in\Omega} L_{jk}(\tilde{I}_k - \tilde{I}_j) = 0, \quad j \in \Omega.$$

We rearrange to get

$$\sum_{k\in\Omega} (L_{jk}/L_j) \left(d_S \tilde{S}_k + d_I \tilde{I}_k \right) = d_S \tilde{S}_j + d_I \tilde{I}_j, \quad j \in \Omega.$$

We can express this system of equations in matrix-vector form as

$$A \left(d_S \tilde{S} + d_I \tilde{I} \right) = d_S \tilde{S} + d_I \tilde{I},$$

where $A = (L_{jk}/L_j)$. Clearly, $A \geq 0$ because $L \geq 0$ and $L_j > 0$ for $j \in \Omega$. Moreover, since A and L are associated with the same adjacency matrix, it follows that A is irreducible. According to the Frobenius theorem (Gantmacher (1960), Theorem 2, p. 53), A has a largest (or *principal*) eigenvalue μ which is real, and μ has a one-dimensional eigenspace $\langle \psi \rangle$ for some positive eigenvector ψ. No other eigenvalue of A has a positive corresponding eigenvector. Since A is a stochastic matrix, the positive vector $x = (1, 1, \ldots, 1)^t$ is an eigenvector for A belonging to the eigenvalue 1. It follows from the remarks above that $\mu = 1$ and we may take $\psi = x$. As the vector $d_S \tilde{S} + d_I \tilde{I}$ is also an eigenvector for A belonging to the eigenvalue 1, we conclude that $d_S \tilde{S} + d_I \tilde{I} = \kappa \psi$ for some $\kappa \in \mathbb{R}$. Since $d_S \tilde{S}_j + d_I \tilde{I}_j > 0$ for at least one $j \in \Omega$ (because $N > 0$) it must be that $\kappa > 0$. Therefore $(\tilde{S}, \tilde{I})$ satisfies (3.1a) for some $\kappa > 0$. The fact that $(\tilde{S}, \tilde{I})$ satisfies (3.1b) and (3.1c) is clear by inspection. If $(\tilde{S}, \tilde{I})$ is a solution of (3.1) for some $\kappa > 0$, then it follows from a direct calculation that $(\tilde{S}, \tilde{I})$ satisfies (1.4). ∎

For our second equivalent formulation of the equilibrium problem, let

$$S_j = \frac{\tilde{S}_j}{\kappa} \quad \text{and} \quad I_j = \frac{d_I \tilde{I}_j}{\kappa}, \tag{3.2}$$

where κ is as in Lemma 3.1. Let $S = (S_j)$, $I = (I_j)$, and

$$f_j(u) = \beta_j \left(1 - \frac{d_S u}{d_I + (d_S - d_I)u} \right) - \gamma_j, \quad u \in [0, 1] \text{ and } j \in \Omega. \tag{3.3}$$

Observe that if $\beta_j > 0$, then f_j decreases from $\beta_j - \gamma_j$ to $-\gamma_j$ as u increases from 0 to 1. The next result follows from a direct calculation.

LEMMA 3.2. *The pair $(\tilde{S}, \tilde{I})$ is a solution of (3.1) if and only if (S, I) is a solution of*

$$1 = d_S S_j + I_j, \qquad j \in \Omega, \tag{3.4a}$$

$$0 = d_I \sum_{k\in\Omega} L_{jk}(I_k - I_j) + I_j f_j(I_j), \quad j \in \Omega, \tag{3.4b}$$

$$\kappa = \frac{d_I N}{\sum_{j\in\Omega} (d_I S_j + I_j)}. \tag{3.4c}$$

The benefit of this second formulation is that (3.4b) depends on I but not S. Thus, once I is determined, it is then a simple matter to determine S from (3.4a) and κ from (3.4c). Observe that κ is in a one-to-one correspondence with N.

3.2. An eigenvalue problem. The linear eigenvalue problem associated with (3.1b) at the DFE is

$$d_I \sum_{k\in\Omega} L_{jk}(\psi_k - \psi_j) + (\beta_j - \gamma_j)\psi_j + \lambda\psi_j = 0, \quad j \in \Omega. \tag{3.5}$$

Observe that (3.5) can be written as

$$d_I \sum_{k\in\Omega} L_{jk}\psi_k + (\beta_j + \theta - \gamma_j - d_I L_j)\psi_j = (\theta - \lambda)\psi_j, \quad j \in \Omega,$$

where $\theta = \max\{\gamma_j + d_I L_j : j \in \Omega\}$, and this equation can be written in the equivalent matrix-vector form $(d_I L + D)\psi = (\theta - \lambda)\psi$, where $D = \mathrm{diag}(\beta_j + \theta - \gamma_j - d_I L_j)$ and $\psi = (\psi_j)$. Thus, (λ, ψ) is a solution of (3.5) if and only if $(\mu, \psi) = (\theta - \lambda, \psi)$ is a solution of

$$Q\psi = \mu\psi, \tag{3.6}$$

where $Q = d_I L + D$.

LEMMA 3.3. *The matrix Q has all real eigenvalues, and it has a largest eigenvalue $\mu^* = \mu^*(d_I)$, which is positive. This eigenvalue μ^* has a one-dimensional eigenspace $\langle\phi\rangle$, where $\phi > 0$. Furthermore, no other eigenvalue of Q has a positive corresponding eigenvector.*

Proof. By construction, $Q_{jk} = d_I L_{jk} \geq 0$ for $j, k \in \Omega$ with $j \neq k$, and $Q_{jj} \geq d_I L_{jj} + \beta_j \geq 0$ for $j \in \Omega$. Therefore, Q is nonnegative. Moreover, Q is irreducible because Q and L are associated with adjacency matrices whose off-diagonal entries are the same. The stated properties of Q now follow from the symmetry of L (which implies that the eigenvalues of Q are real) and the Frobenius theorem (Gantmacher (1960)). ∎

LEMMA 3.4. *Define $\lambda^* = \lambda^*(d_I) = \theta - \mu^*(d_I)$ and let $\phi > 0$ be as in Lemma 3.3. Then*

(a) *λ^* is real and (λ^*, ϕ) satisfies (3.5), i.e.,*

$$d_I \sum_{k\in\Omega} L_{jk}(\phi_k - \phi_j) + (\beta_j - \gamma_j)\phi_j + \lambda^*\phi_j = 0, \quad j \in \Omega. \tag{3.7}$$

Moreover, (λ^*, ψ) satisfies (3.5) if and only if $\psi \in \langle\phi\rangle$. Finally, if (λ, ψ) satisfies (3.5) with $\lambda \neq \lambda^*$, then $\lambda > \lambda^*$ and $\psi_j \leq 0$ for some $j \in \Omega$.

(b) *λ^* is a strictly monotone increasing function of $d_I > 0$.*

(c) *$\lambda^* \to \min\{\gamma_j - \beta_j : j \in \Omega\}$ as $d_I \to 0$.*

(d) *$\lambda^* \to \frac{\Sigma_\gamma - \Sigma_\beta}{n}$ as $d_I \to \infty$.*

(e) *If $\Sigma_\beta \geq \Sigma_\gamma$, then $\lambda^* < 0$ for all $d_I > 0$.*

(f) *If $\Sigma_\beta < \Sigma_\gamma$, then the equation $\lambda^*(d_I) = 0$ has a unique positive root denoted by d_I^*. Furthermore, if $d_I < d_I^*$, then $\lambda^* < 0$, and if $d_I > d_I^*$, then $\lambda^* > 0$.*

The proof of Lemma 3.4 appears in Appendix B. In view of Lemma 3.4(e), (f), let us define $d_I^* = \infty$ when $\Sigma_\beta \geq \Sigma_\gamma$. We now connect λ^* to the basic reproduction number $\mathcal{R}_0$.

LEMMA 3.5. *Let $\mathcal{R}_0$ and λ^* be as in Lemmas 2.2 and 3.4, respectively. Then*

(a) *$\mathcal{R}_0 < 1$ if and only if $\lambda^* > 0$;*

(b) *$\mathcal{R}_0 > 1$ if and only if $\lambda^* < 0$.*

Proof. Observe from (3.7) that

$$(F - V)\phi + \lambda^* \phi = 0, \tag{3.8}$$

where F and V are defined as in Lemma 2.2. Also, since $F - V$ is symmetric, its eigenvalues are all real. Finally, recall from van den Driessche and Watmough (2002) that (i) $\mathcal{R}_0 < 1$ if and only if $F - V$ has all negative eigenvalues, and (ii) $\mathcal{R}_0 > 1$ if and only if $F - V$ has a positive eigenvalue.

(a) Suppose first that $\mathcal{R}_0 < 1$. We see from (3.8) that $(-\lambda^*)$ is an eigenvalue of $F - V$. Since $F - V$ has all negative eigenvalues, we obtain $\lambda^* > 0$. Now suppose that $\lambda^* > 0$. Equation (3.8) and Lemma 3.4(a) imply that $(-\lambda^*)$ is the largest eigenvalue of $F - V$. Thus, all the eigenvalues of $F - V$ are negative, and consequently $\mathcal{R}_0 < 1$.

(b) Suppose first that $\mathcal{R}_0 > 1$. Then $F - V$ has a positive eigenvalue μ. Equation (3.8) and Lemma 3.4(a) imply that $\lambda^* \le -\mu < 0$, i.e., $\lambda^* < 0$. Now suppose that $\lambda^* < 0$. We see from (3.8) that $\mu = -\lambda^*$ is a positive eigenvalue of $F - V$, and hence that $\mathcal{R}_0 > 1$. □

In the next section, we use λ^* and ϕ, rather than $\mathcal{R}_0$, to obtain the existence of an EE when the DFE is unstable.

3.3. Existence of an EE.

LEMMA 3.6. *Suppose that $\mathcal{R}_0 > 1$. Then* (3.4) *has a nonnegative solution (S, I), which can be chosen to satisfy $I \not\equiv 0$. Furthermore, this solution with $I \not\equiv 0$ is unique, $S > 0$, and $0 < I_j < 1$ for every $j \in \Omega$.*

Here we prove the existence of such an (S, I), and in the next section we will demonstrate that it is unique. Suppose that $\mathcal{R}_0 > 1$. In view of (3.4b), consider the related system of differential equations

$$\frac{dI_j}{dt} = G_j(I) \stackrel{\text{def}}{=} d_I \sum_{k \in \Omega} L_{jk}(I_k - I_j) + I_j f_j(I_j), \quad j \in \Omega. \tag{3.9}$$

First, I is a solution of (3.4b) if and only if $G(I) = 0$, where $G = (G_j)$. Second, (3.9) defines a monotone dynamical system because L_{jk} is nonnegative when $j \neq k$. It follows that if $\underline{I}$ and $\overline{I}$ are ordered (i.e., $\underline{I} \le \overline{I}$), and they are sub- and supersolutions of (3.9), respectively, i.e., $G(\underline{I}) \ge 0 \ge G(\overline{I})$, then there must exist some $I \in [\underline{I}, \overline{I}]$ such that $G(I) = 0$, where $[\underline{I}, \overline{I}] = \{I \in \mathbb{R}^n : \underline{I} \le I \le \overline{I}\}$ (Smith (1995)).

With $\phi > 0$ defined as in Lemma 3.3, we now show that $\underline{I} = \epsilon\phi$ and $\overline{I} = (1, 1, \ldots, 1)^t$ can be chosen as sub- and supersolutions for (3.9) if ϵ is chosen to be positive and sufficiently small. We may assume that ϕ is chosen so that $\sum_{j \in \Omega} \phi_j^2 = 1$. Lemma 3.5(b) implies that $\lambda^* < 0$. In view of (3.3), define

$$g(u) = \frac{d_S u}{d_I + (d_S - d_I)u}, \quad u \in [0, 1].$$

We remark that g increases from 0 to 1 as u increases from 0 to 1. Observe from (3.3) and (3.7) that

$$\begin{aligned} G_j(\underline{I}) &= d_I \sum_{k \in \Omega} L_{jk}(\epsilon\phi_k - \epsilon\phi_j) + \epsilon\phi_j f_j(\epsilon\phi_j) \\ &= \epsilon \left[d_I \sum_{k \in \Omega} L_{jk}(\phi_k - \phi_j) + (\beta_j - \gamma_j)\phi_j - \beta_j \phi_j g(\epsilon\phi_j) \right] \\ &= \epsilon\phi_j \left[-\lambda^* - \beta_j g(\epsilon\phi_j) \right] \end{aligned}$$

is positive for $j \in \Omega$ when $0 < \epsilon \ll 1$. Therefore, $\underline{I}$ is a subsolution of (3.9) for ϵ positive and sufficiently small. Next, since $G_j(\overline{I}) = f_j(1) = -\gamma_j$ is nonpositive for $j \in \Omega$, it follows that $\overline{I}$ is a supersolution of (3.9). Also, it is obvious that $\underline{I} \le \overline{I}$ if ϵ is chosen sufficiently small. We conclude from the remarks above that there must be an $I \in [\underline{I}, \overline{I}]$ with $G(I) = 0$. That is, there exists some I satisfying (3.4b) with $0 < I_j \le 1$ for $j \in \Omega$. We argue by contradiction to show that I_j cannot be equal to 1 for any $j \in \Omega$. If $I_j = 1$ for all $j \in \Omega$, then $G_j(I) = -\gamma_j < 0$ for $j \in H^-$, a contradiction. If $I_j = 1$ and $I_m < 1$ for some $j, m \in \Omega$, then there exists a chain from j to m, i.e., a sequence $j_1, j_2, \ldots, j_s \in \Omega$ with $j_1 = j$ and $j_s = m$ such that $L_{j_p j_{p+1}} > 0$ for $1 \le p \le s-1$. Thus, there exists some $k \in \Omega$ for which $I_{j_k} = 1$, $I_{j_{k+1}} < 1$, and $L_{j_k j_{k+1}} > 0$. But then $G_{j_k}(I) \le d_I L_{j_k j_{k+1}}(I_{j_{k+1}} - I_{j_k}) - \gamma_{j_k} < 0$, again a contradiction. We conclude that $0 < I_j < 1$ for $j \in \Omega$. In view of (3.4a), let us define S by $1 = d_S S + I$. Then $S > 0$. Consequently, (S, I) is a positive solution of (3.4) with $I_j < 1$ for $j \in \Omega$.

For sake of completeness, and also for the purpose of proving uniqueness in the next section, we now proceed to construct an iteration algorithm to find I. This algorithm is also used to generate the numerical plots appearing in Figure 2. Equation (3.4b) can be written equivalently as

$$-d_I \sum_{k \in \Omega} L_{jk}(I_k - I_j) = F_j(I_j), \quad j \in \Omega, \tag{3.10}$$

where $F_j(u) = u f_j(u)$. Let $j \in \Omega$. By inspection, the function f_j in (3.3) and its derivative f_j' are bounded for $u \in [0,1]$. We conclude that there exists some $M > 0$ (which can be chosen to be independent of j) such that $|F_j'(u)| < M$ for $u \in [0,1]$. It follows that $F_j'(u) + M > 0$ for $u \in [0,1]$. That is, $F_j(u) + Mu$ is a monotone increasing function of $u \in [0,1]$. Since $F_j'(u) = f_j(u) + u f_j'(u) \le f_j(u)$ for $u \in [0,1]$, it follows that $f_j(u) + M > 0$ for $u \in [0,1]$.

We now add MI_j to both sides of (3.10) to get

$$-d_I \sum_{k \in \Omega} L_{jk}(I_k - I_j) + MI_j = F_j(I_j) + MI_j, \quad j \in \Omega.$$

This equation inspires the vector iteration

$$-d_I \sum_{k \in \Omega} L_{jk}\big(I_k^{(l+1)} - I_j^{(l+1)}\big) + MI_j^{(l+1)} = F_j\big(I_j^{(l)}\big) + MI_j^{(l)}, \quad j \in \Omega, \tag{3.11}$$

with the index $l \ge 0$. This implicit scheme can be made explicit because the left-hand operator, which takes the form $A + M\mathcal{I}_n = M[(1/M)A + \mathcal{I}_n]$, is invertible for M sufficiently large. Let $I^{(l)} = \big(I_j^{(l)}\big)$. For our purposes, we will set $I^{(0)} = \underline{I} = \epsilon\phi$ with ϵ taken to be sufficiently small so that $\underline{I}$ is a subsolution of (3.9) satisfying $\underline{I} < \overline{I} = (1, 1, \ldots, 1)^t$. Similarly, we define the iteration

$$-d_I \sum_{k \in \Omega} L_{jk}\big(I_k^{[l+1]} - I_j^{[l+1]}\big) + MI_j^{[l+1]} = F_j\big(I_j^{[l]}\big) + MI_j^{[l]}, \quad j \in \Omega, \tag{3.12}$$

for $l \ge 0$ with $I^{[0]} = \overline{I}$, a supersolution of (3.9). We want to show that

$$\underline{I} = I^{(0)} \le I^{(1)} \le \cdots \le I^{(n)} \le \cdots \le I^{[n]} \le \cdots \le I^{[1]} \le I^{[0]} = \overline{I},$$

where the symbols surrounding the iteration index indicate the initial condition for the sequence. For convenience, we will refer to the sequences $I^{(l)}$ and $I^{[l]}$ as the *lower* and *upper sequences*, respectively.

It can be shown that all components of both sequences remain within the interval $[0,1]$, that the lower sequence is nondecreasing, that the upper sequence is nonincreasing, and that an iterate of the lower sequence is always less than or equal to the corresponding iterate of the upper sequence. Let $\Delta I^{(l)} = I^{(l+1)} - I^{(l)}$, $\Delta I^{[l]} = I^{[l+1]} - I^{[l]}$, and $\Delta I^{\{l\}} = I^{[l]} - I^{(l)}$.

LEMMA 3.7. *The following statements hold:*

(a) $I_j^{(l)}, I_j^{[l]} \in [0,1]$ *for* $l \geq 0$ *and* $j \in \Omega$*;*

(b) $\Delta I^{(l)} \geq 0$, $\Delta I^{[l]} \leq 0$, *and* $\Delta I^{\{l\}} \geq 0$ *for* $l \geq 0$.

The proof of this result appears in Appendix C. According to Lemma 3.7, the lower and upper sequences are both monotone and bounded. They also satisfy $\underline{I} \leq I^{(l)} \leq I^{[l]} \leq \overline{I}$ for $l \geq 0$. Therefore, there exist $I^{\min}$ and $I^{\max}$ such that $I^{(l)} \to I^{\min}$ and $I^{[l]} \to I^{\max}$ as $l \to \infty$. Clearly, $\underline{I} \leq I^{\min} \leq I^{\max} \leq \overline{I}$. Furthermore, since $I^{\min}$ is a fixed point for (3.11), and $I^{\max}$ is a fixed point for (3.12), each is a solution to (3.4b) with the property that $0 < I_j^{\min} \leq I_j^{\max} \leq 1$ for $j \in \Omega$. By an argument similar to the one given above, we obtain the stronger result that $0 < I_j^{\min} \leq I_j^{\max} < 1$ for $j \in \Omega$. In the next section, we show that $I_j^{\min} = I_j^{\max}$.

3.4. Uniqueness of the EE. Because we are interested only in those (S, I) that satisfy (3.4) with $S \geq 0$ and $I \geq 0$, we will assume throughout this section that if I is a solution to (3.4b), then $0 \leq I_j \leq 1$ for $j \in \Omega$.

LEMMA 3.8. *If* I *is a solution to* (3.4b)*, then either* $I \equiv 0$ *or* $I > 0$.

Proof. We argue by contradiction. Suppose that I is a solution of (3.4b) with $I \not\equiv 0$ and $I \not> 0$. Then there exist nonempty subsets K^- and K^+ of Ω with $I_j = 0$ for $j \in K^-$, $I_j > 0$ for $j \in K^+$, and $K^- \cup K^+ = \Omega$. Equation (3.4b) implies that $\sum_{k\in\Omega} L_{jk} I_k = 0$ for $j \in K^-$. The nonnegativity of L and I implies that $L_{jk} I_k = 0$ for $j \in K^-$ and $k \in \Omega$. Since $I_k > 0$ when $k \in K^+$, we must have $L_{jk} = 0$ when $j \in K^-$ and $k \in K^+$. But this contradicts the irreducibility of L. We conclude that either $I \equiv 0$ or $I > 0$. ∎

The following lemma justifies our referring to $I^{\min}$ and $I^{\max}$ as *minimal* and *maximal* solutions, respectively.

LEMMA 3.9. *If* I *is a positive solution to* (3.4b)*, then* $I \in [I^{\min}, I^{\max}]$.

Proof. Choose ϵ small enough so that $\underline{I} = I^{(0)} \leq I \leq I^{[0]} = \overline{I}$. Arguments similar to the one used in the proof of Lemma 3.7(b) show that $I^{(l)} \leq I \leq I^{[l]}$ for $l \geq 0$. The conclusion follows by letting $l \to \infty$. ∎

We now show that if two positive solutions of (3.4b) are ordered, then they are either strictly ordered or they are equal.

LEMMA 3.10. *If* I^- *and* I^+ *are positive solutions to* (3.4b) *with* $I^- \leq I^+$*, then either* $I^- < I^+$ *or* $I^- \equiv I^+$.

Proof. We argue by contradiction. Suppose that $I^- = (I_j^-)$ and $I^+ = (I_j^+)$ are positive solutions to (3.4b) with $I^- \leq I^+$, and that neither $I^- < I^+$ nor $I^- \equiv I^+$. Then there exist nonempty and disjoint subsets K^- and K^+ of Ω, whose union forms all of Ω, and with the property that $I_j^- < I_j^+$ for $j \in K^-$ and $I_j^- = I_j^+$ for $j \in K^+$. We subtract (3.4b) with $I = I^-$ from (3.4b) with $I = I^+$, and use the fact that $I_j^- = I_j^+$ for $j \in K^+$, to get $\sum_{k\in K^-} L_{jk}(I_k^+ - I_k^-) = 0$ for $j \in K^+$. We sum only over $k \in K^-$ because $I_k^+ = I_k^-$ for $k \in K^+$. By definition, the expression $I_k^+ - I_k^-$ is positive for $k \in K^-$. Consequently, $L_{jk} = 0$ for $j \in K^+$ and $k \in K^-$. But this contradicts the irreducibility of L. We conclude that either $I^- < I^+$ or $I^- \equiv I^+$. ∎

LEMMA 3.11. *If* I^* *and* I^{**} *are positive solutions to* (3.4b)*, then* $I^* \equiv I^{**}$.

Proof. We argue by contradiction. Suppose that I^* and I^{**} are positive solutions to (3.4b) with $I^* \not\equiv I^{**}$. Then $I^*, I^{**} \in [I^{\min}, I^{\max}]$, by Lemma 3.9. Since $I^* \not\equiv I^{**}$, it follows that $I^{\min} \not\equiv I^{\max}$. We conclude from the relation $I^{\min} \le I^{\max}$ and Lemma 3.10 that $I^{\min} < I^{\max}$. So, without loss of generality, we may assume that $I^* < I^{**}$, for otherwise we may replace I^* with $I^{\min}$ and I^{**} with $I^{\max}$. We substitute $I^* = (I_j^*)$ and $I^{**} = (I_j^{**})$ individually into (3.4b) to get

$$d_I \sum_{k\in\Omega} L_{jk}(I_k^* - I_j^*) + I_j^* f_j(I_j^*) = 0, \quad j \in \Omega,$$
$$d_I \sum_{k\in\Omega} L_{jk}(I_k^{**} - I_j^{**}) + I_j^{**} f_j(I_j^{**}) = 0, \quad j \in \Omega.$$

We multiply both sides of the first equation by I_j^{**} and both sides of the second equation by I_j^*, subtract the resulting equations, and then sum over all $j \in \Omega$ to get

$$d_I \sum_{j,k\in\Omega} L_{jk}\left[I_j^{**} I_k^* - I_j^* I_k^{**}\right] + \sum_{j\in\Omega} I_j^* I_j^{**}\left[f_j(I_j^*) - f_j(I_j^{**})\right] = 0.$$

The symmetry of L implies that the first sum vanishes, and the second sum is nonnegative because $I_j^* I_j^{**} > 0$ and $f_j(I_j^*) \ge f_j(I_j^{**})$ for $j \in \Omega$. The fact that $\beta_k > 0$ for $k \in H^+$ implies that $f_k(I_k^*) > f_k(I_k^{**})$, and thus the second sum is in fact positive, a contradiction. We conclude that $I^* \equiv I^{**}$. ∎

Lemmas 3.9 and 3.11 imply that (3.4b) has a unique positive solution given by $I \stackrel{\text{def}}{=} I^{\min} = I^{\max}$. We conclude from Lemma 3.8 that I is the only nonnegative solution of (3.4b) satisfying $I \not\equiv 0$. We have completed the proof of Lemma 3.6. The next result follows from Lemmas 3.2 and 3.6 and (3.2).

LEMMA 3.12. *Suppose that $\mathcal{R}_0 > 1$. Then* (1.4) *has a nonnegative solution $(\tilde{S}, \tilde{I})$ which satisfies $\tilde{I} \not\equiv 0$. Furthermore, this solution is unique; it is given by $(\tilde{S}, \tilde{I}) = (\kappa S, \kappa I/d_I)$, where κ is as in* (3.4c)*; and $\tilde{I} > 0$.*

We have shown that a unique EE exists when $\mathcal{R}_0 > 1$ and that it satisfies $\tilde{I} > 0$. In the next section, we consider the asymptotic behavior of the EE as $d_S \to 0$.

4. Asymptotic behavior of the endemic equilibrium. Throughout this section, we still assume that (A1)–(A3) hold and that N is fixed. We also assume that $\mathcal{R}_0 > 1$, so that Lemma 3.6 for (S, I) and Lemma 3.12 for $(\tilde{S}, \tilde{I})$ always apply.

4.1. The limiting DFE. Observe that $\tilde{S}$, $\tilde{I}$, and κ are all functions of d_S in (1.4) and (3.1). First, we determine the asymptotic behavior of $\tilde{I}$ and κ.

LEMMA 4.1. *As $d_S \to 0$, $\kappa \to 0$ and $\tilde{I} \to 0$.*

Proof. We first show that $\kappa \to 0$ as $d_S \to 0$. Let $j \in H^-$ and $\hat{I}_j$ be a limit point of $\tilde{I}_j$ as $d_S \to 0$. Equation (1.4a) and the nonnegativity of β_j, $\tilde{S}_j$, and $\tilde{I}_j$ imply that

$$d_S \sum_{k\in\Omega} L_{jk}(\tilde{S}_k - \tilde{S}_j) \le \tilde{I}_j\,(\beta_j - \gamma_j)\,.$$

Since $\tilde{S}_k \in [0, N]$ for $k \in \Omega$, it follows that the left-hand side vanishes as $d_S \to 0$. Since $\beta_j < \gamma_j$, it must be that $\hat{I}_j \le 0$. But $\hat{I}_j \ge 0$ because $\tilde{I}_j > 0$ for $d_S > 0$. We conclude that $\hat{I}_j = 0$. Thus, $\tilde{I}_j \to 0$ as $d_S \to 0$ for all $j \in H^-$. Let $k \in H^-$ be fixed. Equation (3.1a) implies that $\kappa = d_S \tilde{S}_k + d_I \tilde{I}_k$. The product $d_S \tilde{S}_k \to 0$ as $d_S \to 0$ because $\tilde{S}_k \in [0, N]$, and $d_I \tilde{I}_k \to 0$ as $d_S \to 0$ by the argument above. Therefore, $\kappa \to 0$ as $d_S \to 0$.

We now show that $\tilde{I} \to 0$. Let $j \in \Omega$. Again, (3.1a) specifies that $\kappa = d_S\tilde{S}_j + d_I\tilde{I}_j$. The left-hand side vanishes as $d_S \to 0$ by part (a). The product $d_S\tilde{S}_j \to 0$ as $d_S \to 0$ because $\tilde{S}_j \in [0, N]$. We conclude that $\tilde{I}_j \to 0$ as $d_S \to 0$. ∎

So that we may determine the asymptotic behavior of $\tilde{S}$, we first consider I in (3.2) as a function of d_S.

LEMMA 4.2. *I_j is a monotone decreasing function of d_S for each $j \in \Omega$.*

Proof. Suppose that $0 < d_{S_1} < d_{S_2}$, and let I^1 and I^2 be corresponding solutions to (3.4b) with $0 < I^1_j, I^2_j < 1$ for $j \in \Omega$. Then

$$d_I \sum_{k\in\Omega} L_{jk}(I^1_k - I^1_j) + I^1_j f_j(I^1_j, d_{S_1}) = 0, \quad j \in \Omega, \tag{4.1a}$$

$$d_I \sum_{k\in\Omega} L_{jk}(I^2_k - I^2_j) + I^2_j f_j(I^2_j, d_{S_2}) = 0, \quad j \in \Omega, \tag{4.1b}$$

where

$$f_j(u, d_S) = \beta_j \left(1 - \frac{d_S u}{d_S u + d_I(1-u)}\right) - \gamma_j, \quad u \in [0,1] \text{ and } j \in \Omega.$$

It is easy to see that $\partial f_j/\partial d_S \le 0$. It follows from this fact and (4.1b), with d_{S_1} in place of d_{S_2}, that

$$d_I \sum_{k\in\Omega} L_{jk}(I^2_k - I^2_j) + I^2_j f_j(I^2_j, d_{S_1}) \ge 0, \quad j \in \Omega.$$

Thus, I^2 is a subsolution of (4.1a). Again, $\overline{I} = (1, 1, \ldots, 1)^t$ is a supersolution of (4.1a). Also, $I^2 < \overline{I}$. By the iteration method presented in sections 3.3 and 3.4, (4.1a) has a unique solution $I^1 \in [I^2, \overline{I}]$. We conclude that $I^1 \ge I^2$. ∎

Recall that $0 < I_j < 1$ for each $j \in \Omega$. The above lemma implies that for every $j \in \Omega$ there exists some I^*_j such that as $d_S \to 0$,

$$I_j \to I^*_j \quad \text{and} \quad 0 < I^*_j \le 1. \tag{4.2}$$

Let $I^* = (I^*_j)$. It remains to establish conditions under which $0 < I^*_j < 1$ or $I^*_j = 1$. Let

$$J^- = \{j \in \Omega : 0 < I^*_j < 1\} \quad \text{and} \quad J^+ = \{j \in \Omega : I^*_j = 1\}.$$

Observe that $J^- \cup J^+ = \Omega$. We will need to know that J^- is nonempty.

LEMMA 4.3. *$H^- \subseteq J^-$.*

Proof. We argue by contradiction. Suppose that there exists some $j \in H^-$ with $j \in J^+$. Then $\beta_j < \gamma_j$ and $I^*_j = 1$. In view of (3.2), we multiply both sides of (3.1b) by d_I/κ and drop the nonnegative term $\beta_j\tilde{I}_j/(\tilde{S}_j + \tilde{I}_j)$ to get

$$d_I \sum_{k\in\Omega} L_{jk}(I_k - I_j) + I_j(\beta_j - \gamma_j) \ge 0.$$

Letting $d_S \to 0$ on both sides yields

$$d_I \sum_{k\in\Omega} L_{jk}(I^*_k - 1) + \beta_j - \gamma_j \ge 0.$$

The negativity of $\beta_j - \gamma_j$ implies that

$$\sum_{k\in\Omega} L_{jk}(I_k^* - 1) > 0.$$

But this inequality contradicts (4.2). We conclude that if $j \in H^-$, then $j \in J^-$. ∎

We are now in a position to determine the asymptotic behavior of $\tilde{S}_j$.

LEMMA 4.4. *The following statements hold:*

(a) $\kappa/d_S \to N^* \stackrel{\text{def}}{=} N/\sum_{j\in\Omega}(1 - I_j^*)$ *as* $d_S \to 0$;

(b) $\tilde{S} \to S^*$ *as* $d_S \to 0$, *where* $S_j^* \stackrel{\text{def}}{=} (1 - I_j^*)N^*$;

(c) $S^* \geq 0$ *and* $\sum_{j\in\Omega} S_j^* = N$.

Proof.

(a) Equations (3.1a), (3.1c), and (3.2) imply that

$$N = \sum_{j\in\Omega}\left(\frac{\kappa - d_I\tilde{I}_j}{d_S}\right) + \sum_{j\in\Omega}\tilde{I}_j = \frac{\kappa}{d_S}\sum_{j\in\Omega}(1 - I_j) + \sum_{j\in\Omega}\tilde{I}_j.$$

Lemma 4.1 and (4.2) imply that

$$\frac{\kappa}{d_S} \to \frac{N}{\sum_{j\in\Omega}(1 - I_j^*)} \quad \text{as} \quad d_S \to 0.$$

This limit is well defined because J^- is nonempty.

(b) Again, (3.1a) and (3.2) imply that

$$\tilde{S}_j = \frac{\kappa - d_I\tilde{I}_j}{d_S} = (1 - I_j)\frac{\kappa}{d_S}.$$

Equation (4.2) and part (a) imply that $\tilde{S}_j \to (1 - I_j^*)N^*$ as $d_S \to 0$.

(c) This part follows immediately from parts (a) and (b), the positivity of N, and (4.2). ∎

4.2. The limiting DFE on high-risk patches. Observe from Lemma 4.4(b) that $S^* > 0$ on J^- and $S^* \equiv 0$ on J^+. We know from Lemma 4.3 that J^- is nonempty because it contains H^-. Next we show that J^+, which is a subset of H^+, is also nonempty.

LEMMA 4.5. J^+ *is nonempty.*

Proof. We argue by contradiction. Suppose that J^+ is empty, i.e., $J^- = \Omega$. Multiply both sides of (3.1b) by d_I/κ to get

$$d_I\sum_{k\in\Omega} L_{jk}(I_k - I_j) + I_j\left(\beta_j - \gamma_j - \frac{\beta_j\tilde{I}_j}{\tilde{S}_j + \tilde{I}_j}\right) = 0, \quad j \in \Omega. \tag{4.3}$$

Since $I_j^* \in (0, 1)$ for $j \in \Omega$, we have from (3.4a) and (4.2) that $S_j = (1 - I_j)/d_S \to \infty$ as $d_S \to 0$ for $j \in \Omega$. It follows from this fact and (3.2) that

$$\frac{\beta_j\tilde{I}_j}{\tilde{S}_j + \tilde{I}_j} = \frac{\beta_j I_j}{d_I S_j + I_j} \to 0$$

as $d_S \to 0$ for $j \in \Omega$. Letting $d_S \to 0$ in (4.3), we get

$$d_I\sum_{k\in\Omega} L_{jk}(I_k^* - I_j^*) + I_j^*(\beta_j - \gamma_j) = 0, \quad j \in \Omega.$$

Thus $(\lambda, \psi) = (0, I^*)$ satisfies (3.5). Since $I^* > 0$, we obtain from Lemma 3.4(a) that $\lambda^* = 0$. But this contradicts Lemma 3.5(a). We conclude that J^+ is nonempty. ∎

Next, we determine a condition under which J^+ is as large as it can be.

LEMMA 4.6. *If condition* (1.6) *holds, then* $J^+ = H^+$.

Proof. Recall that $J^+ \subseteq H^+$. We argue by contradiction to show that if condition (1.6) holds, then $H^+ \subseteq J^+$. Suppose that condition (1.6) holds and that there exists some $j \in H^+$ with the property that $j \in J^-$. Without loss of generality, we may assume that $I_j^* = \min\{I_k^* : k \in H^+\}$. Choose $m \in H^-$ so that $I_m^* = \min\{I_k^* : k \in H^-\}$. Letting $d_S \to 0$ in (3.4b) implies that

$$d_I \sum_{k \in \Omega} L_{jk}(I_k^* - I_j^*) + I_j^*(\beta_j - \gamma_j) = 0.$$

Here we used the fact that $0 < I_j^* < 1$. Since $\Omega = H^- \cup H^+$, we obtain

$$d_I \sum_{k \in H^+} L_{jk}(I_k^* - I_j^*) + d_I \sum_{k \in H^-} L_{jk} I_k^* + I_j^*(\beta_j - \gamma_j - d_I L_j^-) = 0.$$

The minimality of I_j^* over H^+ and I_m^* over H^- implies that

$$(d_I L_j^-) I_m^* \le I_j^*(\gamma_j - \beta_j + d_I L_j^-). \tag{4.4}$$

A similar argument shows that

$$(d_I L_m^+) I_j^* \le I_m^*(\gamma_m - \beta_m + d_I L_m^+). \tag{4.5}$$

We multiply corresponding sides of (4.4) and (4.5) together and simplify to get

$$(\gamma_j - \beta_j)(\gamma_m - \beta_m) + (\gamma_j - \beta_j) d_I L_m^+ + (\gamma_m - \beta_m) d_I L_j^- \ge 0.$$

We divide both sides by $d_I(\gamma_j - \beta_j)(\gamma_m - \beta_m)$, which is negative, and rearrange to get

$$\frac{1}{d_I} \le \frac{L_j^-}{\beta_j - \gamma_j} + \frac{L_m^+}{\beta_m - \gamma_m} \le \max_{j \in H^+} \left[\frac{L_j^-}{\beta_j - \gamma_j} \right] + \max_{k \in H^-} \left[\frac{L_k^+}{\beta_k - \gamma_k} \right].$$

This contradicts (1.6). We conclude that $H^+ \subseteq J^+$, and therefore that $H^+ = J^+$. ∎

Finally, we determine a condition under which J^+ is a proper subset of H^+.

LEMMA 4.7. *If condition* (1.7) *holds for some* $j \in H^+$, *then* $j \in J^-$.

Proof. We argue by contradiction. Suppose that condition (1.7) holds for some $p \in H^+$, and that $p \in J^+$. Choose $m \in H^-$ such that $I_m^* = \max\{I_k^* : k \in H^-\} < 1$. We let $d_S \to 0$ in (3.4b) with $j = m$ to get

$$0 = d_I \sum_{k \in \Omega} L_{mk}(I_k^* - I_m^*) + I_m^*(\beta_m - \gamma_m).$$

We rearrange to get

$$0 = d_I \sum_{k \in H^+} L_{mk} I_k^* + d_I \sum_{k \in H^-} L_{mk} I_k^* + I_m^*(\beta_m - \gamma_m - d_I L_m).$$

The upper bound of 1 on I_k^* and the maximality of I_m^* imply that

$$0 \le d_I L_m^+ + I_m^*(\beta_m - \gamma_m + d_I L_m^- - d_I L_m).$$

The relation $L_m^+ + L_m^- = L_m$ implies that

$$I_m^*(\gamma_m - \beta_m + d_I L_m^+) \le d_I L_m^+.$$

The positivity of $\gamma_m - \beta_m$ implies that

$$I_m^* \le \frac{d_I L_m^+}{\gamma_m - \beta_m + d_I L_m^+}. \tag{4.6}$$

Letting $d_S \to 0$ in (3.4b), we get

$$0 \le d_I \sum_{k\in\Omega} L_{jk}(I_k^* - I_j^*) + I_j^*(\beta_j - \gamma_j), \quad j \in \Omega.$$

Again, we rearrange to get

$$0 \le d_I \sum_{k\in H^+} L_{jk} I_k^* + d_I \sum_{k\in H^-} L_{jk} I_k^* + I_j^*(\beta_j - \gamma_j - d_I L_j), \quad j \in \Omega.$$

In particular, if $j = p$, then

$$0 \le d_I L_p^+ + d_I \sum_{k\in H^-} L_{pk} I_k^* + (\beta_p - \gamma_p - d_I L_p).$$

The relation $L_p^+ + L_p^- = L_p$ and the maximality of I_m^* imply that

$$0 \le d_I(I_m^* - 1)L_p^- + \beta_p - \gamma_p.$$

Equation (4.6) implies that

$$0 \le d_I \left(\frac{d_I L_m^+}{\gamma_m - \beta_m + d_I L_m^+} - 1 \right) L_p^- + \beta_p - \gamma_p.$$

We rearrange to get

$$\frac{\beta_p - \gamma_p}{d_I} \ge \left(\frac{\gamma_m - \beta_m}{\gamma_m - \beta_m + d_I L_m^+} \right) L_p^-.$$

The positivity of $\gamma_m - \beta_m$ and $\beta_p - \gamma_p$ implies that

$$\frac{1}{d_I} \ge \frac{L_p^-}{\beta_p - \gamma_p} + \frac{L_m^+}{\beta_m - \gamma_m} \ge \frac{L_p^-}{\beta_p - \gamma_p} + \min_{k\in H^-} \left[\frac{L_k^+}{\beta_k - \gamma_k} \right].$$

But this contradicts (1.7) with $j = p$. We conclude that if (1.7) holds for some $p \in H^+$, then $p \in J^-$. □

5. Discussion. We first mention some limiting cases for which we can simplify the expression for the basic reproduction number $\mathcal{R}_0$. We next state some open problems that relate to our work, and then finish with some concluding remarks.

5.1. Limiting cases. In the general case, we will not be able to obtain a simple expression for $\mathcal{R}_0$. However, we can compute an explicit expression for $\mathcal{R}_0$ in special cases.

In two limiting cases for n patches, the expression for $\mathcal{R}_0$ can be simplified. The basic reproduction number tends to the maximum ratio of the transmission rate to the recovery rate as infected movement becomes arbitrarily small ($\mathcal{R}_0 \to \max\{\beta_j/\gamma_j : j \in \Omega\}$ as $d_I \to 0$), and it tends to the average transmission rate divided by the average recovery rate as infected movement becomes arbitrarily large ($\mathcal{R}_0 \to \Sigma_\beta/\Sigma_\gamma$ as $d_I \to \infty$). The latter limit can be verified for a given value of n by calculating the limit V_∞^{-1} of V^{-1} as $d_I \to \infty$ (McCormack (2006)). For example, if $n = 2$ patches, then $F = \left(\begin{smallmatrix} \beta_1 & 0 \\ 0 & \beta_2 \end{smallmatrix}\right)$ and $V_\infty^{-1} = \frac{1}{\gamma_1+\gamma_2}\left(\begin{smallmatrix} 1 & 1 \\ 1 & 1 \end{smallmatrix}\right)$, so that the limiting value of $\mathcal{R}_0$ is $\rho(FV_\infty^{-1}) = \frac{\beta_1+\beta_2}{\gamma_1+\gamma_2}$.

In the general case that $n = 2$, then $\mathcal{R}_0$ in Lemma 2.2 becomes

$$\mathcal{R}_0 = \frac{\beta_2\gamma_1 + \beta_1\gamma_2 + d_I\ell(\beta_1+\beta_2) + \sqrt{[\beta_2\gamma_1 - \beta_1\gamma_2 + d_I\ell(\beta_2-\beta_1)]^2 + (2d_I\ell)^2\beta_1\beta_2}}{2[\gamma_1\gamma_2 + d_I\ell(\gamma_1+\gamma_2)]},$$

where $\ell = L_{12} = L_{21}$. In this case, the condition $\mathcal{R}_0 < 1$ is equivalent to the following conditions:

$$(\beta_1 - \gamma_1 - d_I\ell) + (\beta_2 - \gamma_2 - d_I\ell) < 0,$$
$$(\beta_1 - \gamma_1 - d_I\ell)(\beta_2 - \gamma_2 - d_I\ell) - (d_I\ell)^2 > 0.$$

That is, the eigenvalues of $F - V$ are negative if and only if the conditions above are satisfied.

5.2. Open problems. Some open mathematical questions remain in connection with this research.

- We conjecture that the basic reproductive number $\mathcal{R}_0$ is a monotone decreasing function of d_I. The difficulty in showing this directly is that, although V^{-1} is a function of d_I, a general expression for V^{-1} is not simple. If this conjecture is true, then $\max\{\beta_j/\gamma_j : j \in \Omega\}$ and $\Sigma_\beta/\Sigma_\gamma$ are upper and lower bounds, respectively, on $\mathcal{R}_0$.
- We did not prove stability of the EE in Theorem 1. We conjecture that the EE globally attracts all solutions of (1.1) satisfying (1.2), and numerical simulations suggest that this is indeed the case. The uniform persistence of $\bar{I} = (\bar{I}_j)$ in (1.1) when the DFE is unstable has recently been established by Dhirasakdanon, Thieme, and van den Driessche (2007).
- We do not yet fully understand the asymptotic behavior of the EE as $d_S \to 0$. For example, condition (1.6) is not necessary for S_j^* to be zero on a patch. In Figure 2(c) susceptibles can persist on only one of four high-risk patches. In this case, condition (1.7) is satisfied for $j = 5$,

$$1 = \frac{1}{d_I} < \frac{L_5^-}{\beta_5 - \gamma_5} + \min_{k\in H^-}\left\{\frac{L_k^+}{\beta_k - \gamma_k}\right\} = \frac{2}{0.5} - \frac{1}{0.5} = 2,$$

but neither condition (1.6) nor (1.7) is satisfied for $j = 2, 3, 6$. Similarly, condition (1.7) is probably not necessary for S_j^* to be positive on a patch. It is easy to see that if some high-risk patch ($j \in H^+$) is not directly connected to any low-risk patches ($L_j^- = 0$), then condition (1.7) cannot be satisfied because $L_k^+/(\beta_k - \gamma_k)$ is nonpositive for $k \in H^-$. However, this does not rule

out the possibility that $S_j^* > 0$. In general, an open problem is to determine the distribution of high-risk patches for which S^* is either positive or zero when neither condition (1.6) nor (1.7) is satisfied. In Figure 2(d), susceptibles cannot persist on the single high-risk patch, and neither condition (1.6) nor (1.7) is satisfied:

$$\max_{j\in H^+}\left\{\frac{L_j^-}{\beta_j-\gamma_j}\right\} = \frac{L_5^-}{\beta_5-\gamma_5} = \frac{4}{2} = 2,$$

$$\min_{j\in H^-}\left\{\frac{L_j^+}{\beta_j-\gamma_j}\right\} = -\frac{1}{0.5} = -2, \quad \text{and} \quad \max_{j\in H^-}\left\{\frac{L_j^+}{\beta_j-\gamma_j}\right\} = 0.$$

As always, there are biological realities that we did not take into account, but which ecologists have suggested are important determinants of community dynamics.

- We neglect *population dynamics* (births or deaths) within the patches. At a very crude level, we can either ignore these dynamics on the grounds that epidemic dynamics often occur on a faster time scale than host demography, or we can say heuristically that death of an infected individual and subsequent replacement by a susceptible (in the absence of vertical transmission) is equivalent to a recovery event. Of course, either of these claims is an approximation, and it remains to be seen whether the results would be sensitive to such details.
- *Death during movement* may occur, especially if patches are separated by hostile "matrix" habitat. Adding this phenomenon might simply mean that some component of mortality (corresponding to a loss of infective potential, as argued in the previous point) scaled with d_I.
- *Density-dependent movement*—typically increasing rates of movement at higher population density, by organisms seeking to avoid competition—is generally an important factor in determining the behavior of spatial population dynamics models (Amarasekare (2004)).

These factors suggest possible directions for future exploration.

5.3. Mathematical and biological conclusions. Some of the relationships and techniques applied here have been applied by others. The relationship between the high rate of movement for infectives ($d_I > d_I^*$) and the basic reproduction number ($\mathcal{R}_0 < 1$) was noted by Salmani and van den Driessche (2006) in a two-patch SIS epidemic model. In addition, global stability of the DFE using comparison or monotone techniques has been applied by others (Arino et al. (2005); Arino and van den Driessche (2006); Wang and Mulone (2003); Wang and Zhao (2004)).

Our new results relate spatial heterogeneity, habitat connectivity, and rates of movement to disease persistence and extinction. We showed for populations with low mobility of susceptibles ($d_S \approx 0$) and moderate mobility of infectives ($0 \ll d_I < d_I^*$) that disease prevalence is very low ($\tilde{I} \approx 0$) in a spatial environment that includes both low-risk and high-risk patches. These results may have implications for disease control. If the environment is low-risk, but infectives move a lot, the disease may die out; conversely, restricting movement of infectives among patches (e.g., by habitat fragmentation) may allow the disease to persist and/or reemerge. In contrast, if a high-risk spatial environment can be modified to include low-risk patches (i.e., low transmission rates or high recovery rates) and if the mobility of susceptible individuals can be restricted, then it may be possible to eliminate the disease. In epidemiology,

quarantine attempts to prevent infected individuals from moving into a patch with a susceptible population; a *cordon sanitaire* attempts to restrict the movement of infected individuals out of a restricted area. The control strategy suggested by these results most closely resembles the movement restrictions imposed on *all* individuals (susceptible as well as infective) during the 2001 foot-and-mouth disease virus epidemic in Britain.

In a broader sense, these results fall under the ecological rubric of *source-sink dynamics*—population dynamics in heterogeneous environments with both "good" and "bad" patches (in our terminology, high- or low-risk patches, depending on whether we mean "good for the host" or "good for the disease"). The initially counterintuitive result that movement of infectives leads to disease extinction in a high-risk environment, which seems at odds with the idea of preventing disease from spreading between high-risk core groups and the general population (Jacquez, Simon, and Koopman (1995)), or between patches in a metapopulation (Hess (1996)), makes sense when we consider that (unlike in the core-group example), high infection rates are a property of the environment rather than of the individual. Ecologists usually want to prevent the extinction of threatened species; in contrast, epidemiologists want to promote the extinction of disease. However, ecologists have explored a broad range of questions, including evolutionary dynamics (Gomulkiewicz, Holt, and Barfield (1995)) and community structure (Namba and Hashimoto (2004)), in the context of source-sink dynamics. In the long run, linking the mathematical analyses of theoretical epidemiological and ecological models in heterogeneous landscapes can lead to broader mathematical and biological insights.

Appendix A. The irreducibility of L implies that, given any $j, k \in \Omega$ with $j \neq k$, there exists a distinct sequence $j_1, j_2, \ldots, j_s \in \Omega$, with $j_1 = j$ and $j_s = k$, such that $L_{j_p j_{p+1}} > 0$ for $1 \leq p \leq s-1$ (Seneta (1973), Exercise 1.3). We call such a sequence a *chain* from j to k. Second, the irreducibility of L implies that there exists no nonempty proper subset K of Ω with the property that $L_{jk} = 0$ for $j \in K$ and $k \notin K$ (Bapat and Raghavan (1997), Lemma 1.1.1). Finally, L is associated with an adjacency matrix $B = (B_{jk})$ for which $B_{jk} = 1$ if $L_{jk} > 0$ and $B_{jk} = 0$ if $L_{jk} = 0$. If the corresponding adjacency matrix for another nonnegative matrix A has the same off-diagonal entries as B, then A is also irreducible (Ortega (1987)).

Appendix B.

Proof of Lemma 3.4.

(a) As θ and μ^* are both real, so is λ^*. The fact that (μ^*, ϕ) is a solution of (3.6) implies that (λ^*, ϕ) is a solution of (3.5). Since (λ^*, ψ) satisfies (3.5) if and only if (μ^*, ψ) satisfies (3.6), and (μ^*, ψ) is a solution of (3.6) if and only if $\psi \in \langle \phi \rangle$, it follows that (λ^*, ψ) is a solution of (3.5) if and only if $\psi \in \langle \phi \rangle$. Suppose that (λ, ψ) satisfies (3.5) with $\lambda \neq \lambda^*$. Then (μ, ψ) satisfies (3.6) with $\mu = \theta - \lambda \neq \theta - \lambda^* = \mu^*$. Lemma 3.3 implies that $\mu < \mu^*$ and $\psi_j \leq 0$ for some $j \in \Omega$. We conclude that $\lambda = \theta - \mu > \theta - \mu^* = \lambda^*$.

(b) Observe from (3.7) that both ϕ and λ^* are functions of d_I. Both ϕ and λ^* are, in fact, differentiable functions of d_I by the implicit function theorem. We differentiate both sides of (3.7) by d_I to obtain

$$\sum_{k \in \Omega} L_{jk}(\phi_k - \phi_j) + d_I \sum_{k \in \Omega} L_{jk}\left(\phi_k' - \phi_j'\right) + (\beta_j - \gamma_j + \lambda^*)\phi_j' + (\lambda^*)'\phi_j = 0, \qquad j \in \Omega.$$

It suffices to show that $(\lambda^*)' > 0$. We multiply both sides of the equation above by ϕ_j and sum over all $j \in \Omega$ to get

$$\sum_{j,k\in\Omega} L_{jk}(\phi_k - \phi_j)\phi_j + d_I \sum_{j,k\in\Omega} L_{jk}\left(\phi_k' - \phi_j'\right)\phi_j + \sum_{j\in\Omega}(\beta_j - \gamma_j + \lambda^*)\phi_j\phi_j' + (\lambda^*)' \sum_{j\in\Omega}\phi_j^2 = 0.$$

Equation (3.7) and the symmetry of L imply that the second and third sums on the left-hand side cancel:

$$\begin{aligned}\sum_{j\in\Omega}(\beta_j - \gamma_j + \lambda^*)\phi_j\phi_j' &= d_I \sum_{j,k\in\Omega} L_{jk}(\phi_j - \phi_k)\phi_j' \\ &= d_I \sum_{j,k\in\Omega} L_{jk}(\phi_j' - \phi_k')\phi_j.\end{aligned}$$

Therefore,

$$\sum_{j,k\in\Omega} L_{jk}(\phi_k - \phi_j)\phi_j + (\lambda^*)' \sum_{j\in\Omega}\phi_j^2 = 0.$$

The symmetry of L implies that

$$(\lambda^*)' \sum_{j\in\Omega}\phi_j^2 = \frac{1}{2}\sum_{j,k\in\Omega} L_{jk}(\phi_j - \phi_k)^2. \tag{B.1}$$

Clearly, the right-hand side is nonnegative. We now show that it is in fact positive. We argue by contradiction. Suppose that

$$\sum_{j,k\in\Omega} L_{jk}(\phi_j - \phi_k)^2 = 0. \tag{B.2}$$

If $\phi_j = \phi_1$ for all $j \in \Omega$, then (3.7) and the positivity of ϕ imply that $\beta_j - \gamma_j + \lambda^* = 0$ for all $j \in \Omega$. But this is impossible, because H^- and H^+ are both nonempty. Therefore, it must be that $\phi_m \neq \phi_1$ for some $m \in \Omega$. The irreducibility of L implies that there exists a chain from 1 to m, i.e., a sequence $j_1, j_2, \ldots, j_s \in \Omega$ with $j_1 = 1$ and $j_s = m$ such that $L_{j_p j_{p+1}} > 0$ for $1 \le p \le s-1$. Equation (B.2) implies that $\phi_{j_p} = \phi_{j_{p+1}}$ for $1 \le p \le s-1$. Hence, $\phi_1 = \phi_m$, another contradiction. We conclude that the right-hand side of (B.1) is positive, and thus that $(\lambda^*)'$ is also positive.

(c) A variational characterization of λ^* is given by

$$\lambda^* = \inf_{\sum_{j\in\Omega}\varphi_j^2 = 1}\left\{\frac{d_I}{2}\sum_{j,k\in\Omega} L_{jk}(\varphi_j - \varphi_k)^2 + \sum_{j\in\Omega}(\gamma_j - \beta_j)\varphi_j^2\right\}, \tag{B.3}$$

and (3.7) is its corresponding Euler–Lagrange equation. Thus,

$$\lim_{d_I\to 0}\lambda^* = \inf_{\sum_{j\in\Omega}\varphi_j^2 = 1}\left\{\sum_{j\in\Omega}(\gamma_j - \beta_j)\varphi_j^2\right\}.$$

The right-hand side is minimized by setting $\varphi_j = 1$ for a single $j \in \Omega$ with the property that $\gamma_j - \beta_j = \min\{\gamma_k - \beta_k : k \in \Omega\}$ and letting $\varphi_j = 0$ otherwise.

(d) Parts (b) and (c) show that λ^* is a strictly monotone increasing function of $d_I > 0$ that is bounded from below, and substituting $\phi_j = 1/\sqrt{n}$ for $j \in \Omega$ into (B.3) shows that λ^* is bounded from above. Therefore, λ^* has a limit $\lambda^*_\infty \in (\min\{\gamma_k - \beta_k : k \in \Omega\}, \infty)$ as $d_I \to \infty$. We divide both sides of (3.7) by d_I to get

$$\sum_{k\in\Omega} L_{jk}(\phi_k - \phi_j) + \frac{(\beta_j - \gamma_j)\phi_j}{d_I} + \frac{\lambda^*\phi_j}{d_I} = 0, \quad j \in \Omega. \tag{B.4}$$

Without loss of generality, we may assume that $\phi = (\phi_j)$ is a unit vector, i.e., $\sum_{j\in\Omega} \phi_j^2 = 1$. It follows from the positivity of ϕ and compactness that $\phi \to \bar{\phi}$, where $\bar{\phi}_j \geq 0$ for $j \in \Omega$ and $\sum_{j\in\Omega} \bar{\phi}_j^2 = 1$, for some positive sequence of values $d_I \to \infty$. Let this sequence be denoted by $d_I^{(l)}$. Taking such a limit in (B.4) produces

$$\sum_{k\in\Omega} L_{jk}(\bar{\phi}_k - \bar{\phi}_j) = 0, \quad j \in \Omega.$$

We can write this equation in matrix-vector form as $A\bar{\phi} = \bar{\phi}$, where $A = (L_{jk}/L_j)$. The nonnegativity and irreducibility of A implies that $\bar{\phi}$ is proportional to $(1, 1, \ldots, 1)^t$, as both vectors belong to the principal eigenvalue $\mu = 1$. The fact that $\bar{\phi}$ is a nonnegative unit vector implies that $\bar{\phi}_j = 1/\sqrt{n}$ for $j \in \Omega$. Observe from the symmetry of L that $\sum_{j,k\in\Omega} L_{jk}(\phi_k - \phi_j) = 0$. Therefore, summing (3.7) with $d_I = d_I^{(l)}$ over all $j \in \Omega$ yields

$$\sum_{j\in\Omega} (\beta_j - \gamma_j)\phi_j + \lambda^*\big(d_I^{(l)}\big) \sum_{j\in\Omega} \phi_j = 0. \tag{B.5}$$

We let $d_I^{(l)} \to \infty$ to get

$$\sum_{j\in\Omega} (\beta_j - \gamma_j)\bar{\phi}_j + \lambda^*_\infty \sum_{j\in\Omega} \bar{\phi}_j = 0.$$

Since $\bar{\phi}_j = 1/\sqrt{n}$ for $j \in \Omega$, we obtain

$$\lambda^*_\infty = \frac{1}{n} \sum_{j\in\Omega} (\gamma_j - \beta_j) = \frac{\Sigma_\gamma - \Sigma_\beta}{n}.$$

Finally, parts (e) and (f) follow directly from parts (b), (c), and (d) together with the fact that H^+ is nonempty. ∎

Appendix C.

Proof of Lemma 3.7.

(a) We argue by induction on l for $I^{(l)}$. If $l = 0$, then the result is immediate because $I_j^{(0)} = \underline{I}_j = \epsilon\phi_j \in [0, 1]$ for $j \in \Omega$. Suppose now that $I_j^{(l)} \in [0, 1]$ for $0 \leq l \leq s$ and $j \in \Omega$, where $s \geq 0$, but that $I_m^{(s+1)} \notin [0, 1]$ for some $m \in \Omega$. Suppose first that $I_m^{(s+1)} < 0$. Without loss of generality, we may assume that $I_m^{(s+1)} = \min\{I_j^{(s+1)} : j \in \Omega\}$. Equation (3.11) with $l = s$ and $j = m$ implies that

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) + MI_m^{(s+1)} = \Big[f_m\big(I_m^{(s)}\big) + M\Big] I_m^{(s)}.$$

Since $I_m^{(s)} \in [0,1]$, we have, by the properties of M,

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) + MI_m^{(s+1)} \geq 0.$$

Since $MI_m^{(s+1)} < 0$, it follows that

$$d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) < 0.$$

However, this result contradicts the minimality of $I_m^{(s+1)}$. Suppose now that $I_m^{(s+1)} > 1$, and without loss of generality that $I_m^{(s+1)} = \max\{I_j^{(s+1)} : j \in \Omega\}$. Again, (3.11) with $l = s$ and $j = m$ implies that

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) + MI_m^{(s+1)} = F_m\big(I_m^{(s)}\big) + MI_m^{(s)}.$$

Since $I_m^{(s)} \in [0,1]$, and $F_m(u) + Mu$ is a monotone increasing function of $u \in [0,1]$, we have

$$F_m\big(I_m^{(s)}\big) + MI_m^{(s)} \leq F_m(1) + M \leq M,$$

where the last inequality follows from $F_m(1) = f_m(1) = -\gamma_m \leq 0$. Hence

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) + MI_m^{(s+1)} \leq M.$$

Since $I_m^{(s+1)} > 1$, we have

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(s+1)} - I_m^{(s+1)}\big) < 0.$$

However, this result contradicts the maximality of $I_m^{(s+1)}$. We conclude that $I_j^{(s+1)} \in [0,1]$ for all $j \in \Omega$, and, by induction, $I_j^{(l)} \in [0,1]$ for $l \geq 0$ and $j \in \Omega$. The argument for $I^{[l]}$ is similar.

(b) We argue by induction on l for $\Delta I^{(l)}$. To show that $\Delta I^{(0)} \geq 0$, we suppose otherwise and obtain a contradiction. If $\Delta I^{(0)} \not\geq 0$, then there exists some $m \in \Omega$ such that $\Delta I_m^{(0)} < 0$. We may assume that $\Delta I_m^{(0)} = \min\{\Delta I_j^{(0)} : j \in \Omega\}$. Recall that ϵ was chosen so that $G(\underline{I}) = G(\epsilon\phi) \geq 0$. Equation (3.9) with $j = m$ and $I = I^{(0)} = \underline{I}$ implies that

$$G_m\big(I^{(0)}\big) = d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(0)} - I_m^{(0)}\big) + F_m\big(I_m^{(0)}\big) \geq 0.$$

It follows from this inequality and (3.11) with $l = 0$ and $j = m$ that

$$-d_I \sum_{k\in\Omega} L_{mk}\big(I_k^{(1)} - I_m^{(1)}\big) + MI_m^{(1)} \geq d_I \sum_{k\in\Omega} L_{mk}\big(I_m^{(0)} - I_k^{(0)}\big) + MI_m^{(0)}.$$

Therefore,

$$d_I \sum_{k\in\Omega} L_{mk}\big(\Delta I_k^{(0)} - \Delta I_m^{(0)}\big) \leq M\Delta I_m^{(0)} < 0.$$

However, this result contradicts the minimality of $\Delta I_m^{(0)}$. We conclude that $\Delta I^{(0)} \geq 0$.

Suppose now that $\Delta I^{(l)} \geq 0$ for $0 \leq l \leq s$, where $s \geq 0$, but that $\Delta I^{(s+1)} \not\geq 0$. Then there exists some $m \in \Omega$ such that $\Delta I_m^{(s+1)} < 0$. We may assume that $\Delta I_m^{(s+1)} = \min\{\Delta I_j^{(s+1)} : j \in \Omega\}$. We subtract (3.11) with $l = s$ and $j = m$ from (3.11) with $l = s+1$ and $j = m$ to get

$$\begin{aligned} -d_I \sum_{k\in\Omega} L_{mk}\big(\Delta I_k^{(s+1)} - \Delta I_m^{(s+1)}\big) + M\Delta I_m^{(s+1)} \\ = F_m\big(I_m^{(s+1)}\big) - F_m\big(I_m^{(s)}\big) + M\Delta I_m^{(s)}. \end{aligned}$$

Recall from part (a) that $I_m^{(s)}$ and $I_m^{(s+1)}$ both lie within the interval $[0,1]$. There exists ζ between $I_m^{(s)}$ and $I_m^{(s+1)}$ such that

$$-d_I \sum_{k\in\Omega} L_{mk}\big(\Delta I_k^{(s+1)} - \Delta I_m^{(s+1)}\big) + M\Delta I_m^{(s+1)} = \Big[F_m'(\zeta) + M\Big]\Delta I_m^{(s)}.$$

The right-hand side is nonnegative because $F_m'(\zeta) + M > 0$ and $\Delta I_m^{(s)} \geq 0$. Therefore,

$$d_I \sum_{k\in\Omega} L_{mk}\big(\Delta I_k^{(s+1)} - \Delta I_m^{(s+1)}\big) \leq M\Delta I_m^{(s+1)} < 0.$$

However, this result contradicts the minimality of $\Delta I_m^{(s+1)}$. We conclude that $\Delta I^{(s+1)} \geq 0$, and, by induction, $\Delta I^{(l)} \geq 0$ for $l \geq 0$. The arguments for $\Delta I^{[l]}$ and $\Delta I^{\{l\}}$ are similar, except that $\Delta I^{[1]} = I^{[1]} - I^{[0]} \leq 0$ by part (a) and $\Delta I^{\{0\}} = I^{[0]} - I^{(0)} \geq 0$ is immediately clear. ∎

NONLINEAR DYNAMICS OF ELECTRIFIED THIN LIQUID FILMS*

DMITRI TSELUIKO† AND DEMETRIOS T. PAPAGEORGIOU†

Abstract. We study a nonlinear nonlocal evolution equation describing the hydrodynamics of thin films in the presence of normal electric fields. The liquid film is assumed to be perfectly conducting and to completely wet the upper or lower surface of a horizontal flat plate. The flat plate is held at constant voltage, and a vertical electric field is generated by a second parallel electrode kept at a different constant voltage and placed at a large vertical distance from the bottom plate. The fluid is viscous, and gravity and surface tension act. The equation is derived using lubrication theory and contains an additional nonlinear nonlocal term representing the electric field. The electric field is linearly destabilizing and is particularly important in producing nontrivial dynamics in the case when the film rests on the upper side of the plate. We give rigorous results on the global boundedness of positive periodic smooth solutions, using an appropriate energy functional. We also implement a fully implicit numerical scheme and perform extensive numerical experiments. Through a combination of analysis and numerical experiments we present evidence for the global existence of positive smooth solutions. This means, in turn, that the film does not touch the wall in finite time but asymptotically at infinite time. Numerical solutions are presented to support such phenomena, which are also observed in hanging films when electric fields are absent.

1. Introduction.

A viscous liquid film wetting the upper surface of a flat horizontal substrate is expected to be stable, under normal conditions, and eventually returns to its uniform undisturbed value of the film thickness. If the film is hanging (i.e., it wets the underside of the substrate), then gravity is destabilizing. This paper is concerned with the addition of electric fields normal to the substrate. Using experiments and linear theory, Taylor and McEwan [26] observed that a sufficiently strong field can overcome viscous forces in overlying films and induce wavy perturbations. We aim to model and analyze the nonlinear stages of this phenomenon for overlying and hanging films.

In the absence of electric fields the problem was studied by Ehrhard and Davis [9], who considered spreading of viscous drops on smooth horizontal surfaces which are uniformly heated or cooled. Their isothermal evolution equation for the interface coincides with ours when there is no electric field. Yiantsios and Higgins [30] considered the behavior of a viscous film bounded below by a wall and above by an unbounded second heavier immiscible fluid. For the case when the Bond number $B \ll 1$ (it measures the ratio between gravitational and interfacial forces) and the viscosity ratio $m = \mu_1/\mu_2$ is $O(1)$, where μ_2 is the film viscosity, they obtained the same evolution equation for the interface as did Ehrhard and Davis [9]. Ehrhard [8] used the model derived by Erhard and Davis [9] to describe the quasi-steady evolution of a viscous drop hanging on the earth-facing side of a smooth horizontal plate, which is either uni-

formly heated or cooled. Also, other similar equations arising in the modeling of thin liquid films have been derived and studied by Bertozzi [1], Dussan [7], Greenspan [13], Haley and Miksis [14], Hocking [16], Myers [18], and Oron, Davis, and Bankoff [19].

Here we consider the problem of a perfectly conducting liquid film on a horizontal plane with the upper electrode placed far from the grounded substrate. There has been considerable interest in electrically induced instabilities and their use in pattern formation and transfer in photolithographic applications. Demonstrations of such instabilities in this context have been made by Schaffer et al. [23], [24] and Lin et al. [17], for example. Theoretical works have focused on linear theory, as in Pease and Russel [21] and references therein, as well as long wave theories in the thin film and small gap approximation (i.e., the second electrode is placed close to the grounded bottom plate) in Shankar and Sharma [25], and the more recent leaky dielectric study of Craster and Matar [5]. The present work is related to but different from those cited above, but we expect that the mathematical tools developed here can be used in those problems also.

A long wave theory leads to a nonlocal nonlinear evolution equation at the leading order, which by a change of the sign of the gravitational parameter also describes hanging films. (Nonlocal equations have also been derived in related problems by Papageorgiou and Vanden-Broeck [20], Savettaseranee et al. [22], and Tilley, Petropoulos, and Papageorgiou [27].) If $H(x, t)$ denotes the scaled interfacial position, then the equation takes the form

$$H_t + \frac{1}{3}\left[H^3\left(\frac{1}{C}H_{xxx} - GH_x + 2W_e\mathcal{H}[H_{xx}]\right)\right]_x = 0, \quad (x, t) \in \mathbb{R} \times \mathbb{R}_+, \tag{1.1}$$

$$H(x, t) = H(x + 2L, t),$$

where $C > 0$, $W_e > 0$, and G can be positive or negative for overlying or hanging films, respectively. In the absence of an electric field the film is linearly stable or unstable, depending on whether $G > 0$ or $G < 0$. The addition of an electric field can always make the film unstable irrespective of the sign of G.

We prove that positive smooth solutions of (1.1) do not blow up and are uniformly bounded for all time in the Sobolev H^1-norm. This is done by constructing an appropriate energy functional $\mathcal{E}[H]$ having the steady-state solutions as extrema. Our analysis extends that of Bertozzi and Pugh [3] to the nonlocal equation (1.1). We also note that Hocherman and Rosenau [15] considered a class of thin film equations with the coefficients in front of the spatial derivatives being polynomials of higher or lower degree of the unknown function (it is unclear whether such equations arise in physical applications). They were interested in identifying equations whose solutions blow up in finite time, and they made a conjecture regarding this. This possibility was also recently studied by Bertozzi and Pugh [3], [4], and Witelski, Bernoff, and Bertozzi [29] based on both rigorous analysis and numerical computations.

For (1.1) we also establish analytically that for positive solutions the integral $\int_{-L}^{L}(1/H)dx$ is bounded on each time interval. Extensive numerical experiments indicate that $\max|H_{xx}|$ is bounded on each time interval; if we assume this, then we can use the observation on the evolution of $\int_{-L}^{L}(1/H)dx$ to prove global existence of positive smooth solutions (i.e., that the film does not touch down in finite time). A rigorous proof of boundedness of $\max|H_{xx}|$ is under investigation. Results of extensive computations and their relation to the analytical results are also reported.

The outline of the paper is as follows. In section 2 we describe the physical problem and give the governing equations. Section 3 develops the asymptotic long

wave theory that leads to the scaled evolution equation (1.1). Section 4 is devoted to rigorous analytical results, and section 5 describes the numerical method used to solve (1.1). Section 6 contains the numerical results, and finally, in section 7 we give our conclusions.

2. Physical model and governing equations. Consider a viscous liquid film completely wetting a solid horizontal substrate. Two related configurations are of interest: *overlying* two-dimensional films with the liquid layer resting on the substrate, and *overhanging* two-dimensional films with the liquid layer wetting the underside of the horizontal substrate. A schematic is provided in Figure 1 for the overlying film with a normal electric field present.

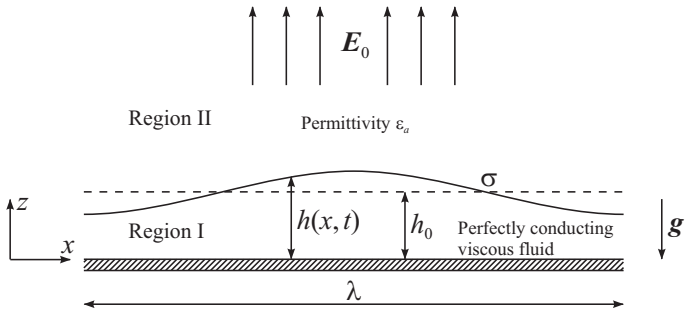

FIG. 1. *Schematic of the problem.*

The fluid is Newtonian of a constant density ρ and dynamic viscosity μ and is assumed to be a perfect conductor. The surface tension coefficient between the liquid and the surrounding medium is σ. We denote by $h(x, t)$ the local film thickness, which is a function of space and time, and the unperturbed thickness of the liquid layer is h_0. The gravitational acceleration $\boldsymbol{g}$ acts in the vertical direction. The plate is a grounded infinite electrode held at zero voltage. Another flat parallel electrode is placed infinitely far from the wetted substrate, so that a uniform vertical electric field is set up at infinity; i.e., at infinity the electric field $\boldsymbol{E}$ approaches a constant value $\boldsymbol{E}_0$ which is normal to the plate. The surrounding medium is assumed to be a perfect dielectric with permittivity ε_a, and the corresponding voltage potential in it is denoted by V. Since the liquid is a perfect electric conductor, the potential is zero on the interface, and there is no electric field inside the liquid layer. We use a rectangular coordinate system (x, z) with the x-axis pointing along the plate and the z-axis pointing up and being perpendicular to the plate. The associated velocity field is denoted by $\boldsymbol{u} = (u, v)$, the liquid layer is denoted by Region I, and the surrounding medium by Region II.

The hydrodynamics in Region I is governed by the Navier–Stokes equations. In Region II the electric field can be written as $\boldsymbol{E} = -\nabla V$, with V satisfying the Laplace equation. The equations are made dimensionless by scaling lengths with h_0, velocities with a typical velocity U_0, time with h_0/U_0, pressure with $\mu U_0/h_0$, and voltages by $E_0 h_0$. This leads to the following equations in Region I:

$$u_t + uu_x + vu_z = \frac{1}{R}(-p_x + u_{xx} + u_{zz}), \tag{2.1}$$

$$v_t + uv_x + vv_z = \frac{1}{R}(-p_z + v_{xx} + v_{zz} - G), \tag{2.2}$$

$$u_x + v_z = 0, \tag{2.3}$$

and in Region II we obtain

$$V_{xx} + V_{zz} = 0. \tag{2.4}$$

The dimensionless boundary conditions of no slip at the wall and the far field condition in Region II for the voltage become

$$u|_{z=0} = 0, \quad v|_{z=0} = 0, \tag{2.5}$$

$$V_x \to 0,\ V_z \to -1 \quad \text{as } z \to \infty. \tag{2.6}$$

At the interface $z = h(x, t)$ we have

$$V = 0, \tag{2.7}$$

$$v = h_t + uh_x, \tag{2.8}$$

$$(1 - h_x^2)(u_z + v_x) + 4h_x v_z = 0, \tag{2.9}$$

$$-\frac{W_e}{2}(1 + h_x^2)V_z^2 + \frac{1 + h_x^2}{1 - h_x^2}v_z + \frac{1}{2}(\bar{p}_{\text{atm}} - p) = \frac{h_{xx}}{2C(1 + h_x^2)^{3/2}}, \tag{2.10}$$

where $\bar{p}_{\text{atm}} = p_{\text{atm}}h_0/\mu U_0$, with p_{atm} a constant, is the nondimensional constant pressure in Region II. The boundary condition (2.7) reflects the fact that $z = h(x, t)$ is an equipotential surface, (2.8) is the kinematic condition, and (2.9) and (2.10) follow from the balance of tangential and normal stresses at the interface. The parameters

$$R = \frac{U_0 h_0}{\nu}, \qquad C = \frac{U_0 \mu}{\sigma}, \qquad W_e = \frac{\varepsilon_a E_0^2 h_0}{2\mu U_0}, \qquad G = \frac{\rho g h_0^2}{\mu U_0} \tag{2.11}$$

are a Reynolds number, a Capillary number measuring the ratio of inertial to capillary forces, an electric Weber number measuring the ratio of electrical to fluid pressures, and a gravity number G measuring the ratio of gravitational to viscous forces.

It is useful to use the following exact solution to (2.1)–(2.10),

$$\bar{u} = 0, \qquad \bar{v} = 0, \qquad \bar{p} = \bar{p}_{\text{atm}} - W_e - G(z - 1), \qquad \overline{V} = 1 - z, \tag{2.12}$$

and introduce new unknown functions $\tilde{u}$, $\tilde{v}$, $\tilde{p}$, $\widetilde{V}$ by $u = \bar{u} + \tilde{u}$, etc., and drop tildes from the transformed equations and boundary conditions. The resulting fully nonlinear dimensionless system is exact and presents a formidable computational and analytical task. In what follows we make analytical progress by studying the physically relevant case of thin films using a long wave nonlinear theory.

3. Long wave asymptotics. In the asymptotic analysis presented next we assume that the typical length λ of the interface deformation is long compared to the undisturbed thickness; that is, $\delta = h_0/\lambda \ll 1$ is a small parameter. In Region I, we introduce the lubrication scalings

$$x = \frac{1}{\delta}\xi, \quad t = \frac{1}{\delta}\tau, \quad v = \delta w, \quad p = \frac{1}{\delta}P. \tag{3.1}$$

The conditions at the interface $z = h(\xi, t)$ become

$$w = h_\tau + uh_\xi, \tag{3.2}$$

$$(1 - \delta^2 h_\xi^2)(u_z + \delta^2 w_\xi) + 4\delta^2 h_\xi w_z = 0, \tag{3.3}$$

$$-\frac{W_e}{2}\left[(V_z-1)^2(1+\delta^2 h_\xi^2)-1\right]+\delta\frac{1+\delta^2 h_x^2}{1-\delta^2 h_x^2}w_z$$
$$-\frac{G}{2}(1-h)-\frac{P}{2\delta}=\frac{\delta^2 h_{\xi\xi}}{2C(1+\delta^2 h_\xi^2)^{3/2}}. \tag{3.4}$$

The last boundary condition contains a nonlocal contribution since V satisfies the Laplace equation in the potential region above the fluid layer. This is obtained by considering the problem in Region II. The analysis is the same as in Tseluiko and Papageorgiou [28] and results in the following expression for V_z in terms of the interfacial position (keeping the $O(\delta)$ term and dropping the higher order terms):

$$V_z(\xi,0)=-\delta\mathcal{H}[h_\xi], \tag{3.5}$$

where $\mathcal{H}$ is the Hilbert transform operator defined by

$$\mathcal{H}[g](\xi)=\frac{1}{\pi}PV\int_{-\infty}^{\infty}\frac{g(\xi')}{\xi-\xi'}d\xi', \tag{3.6}$$

where PV denotes the principal value. Using (3.5) in (3.4) yields

$$-\delta W_e\mathcal{H}[h_\xi]+\delta w_z-\frac{G}{2}(1-h)-\frac{P}{2\delta}=\frac{\delta^2 h_{\xi\xi}}{2C}+O(\delta^2), \tag{3.7}$$

from which we deduce the following canonical scalings that retain the effects of the electric field, gravity, and surface tension (bar quantities are of order one):

$$C=\delta^3\overline{C},\quad W_e=\frac{\overline{W}_e}{\delta^2},\quad G=\frac{1}{\delta}\overline{G}. \tag{3.8}$$

The Reynolds number R is assumed to be $o(\delta^{-1})$ throughout. Expanding in powers of δ, e.g., $u=u_0+\delta u_1+\cdots$, etc., gives the following leading order solutions:

$$u_0=\frac{P_{0\xi}}{2}z^2-P_{0\xi}H_0 z, \tag{3.9}$$

$$w_0=-\frac{P_{0\xi\xi}z^3}{6}+\frac{P_{0\xi\xi}H_0 z^2}{2}+\frac{P_{0\xi}H_{0\xi}z^2}{2}, \tag{3.10}$$

$$P_0=-2\overline{W}_e\mathcal{H}[H_{0\xi}]-\overline{G}(1-H_0)-\frac{1}{\overline{C}}H_{0\xi\xi}. \tag{3.11}$$

Using the velocities (3.9) and (3.10) in the kinematic condition (3.2) gives $H_{0\tau}=\frac{1}{3}[H_0^3P_{0\xi}]_\xi$; using (3.11) for P_0, the evolution equation becomes

$$H_t+\frac{1}{3}\left[H^3\left(\frac{1}{C}H_{xxx}-GH_x+2W_e\mathcal{H}[H_{xx}]\right)\right]_x=0, \tag{3.12}$$

where for simplicity we write t and x for τ and ξ, H for H_0, and drop the bars from $\overline{C}$, $\overline{G}$, $\overline{W}_e$. There are several noteworthy features of (3.12). The electric field enters through a nonlocal term and is destabilizing as in falling films; see Tseluiko and Papageorgiou [28]. Gravity is present, and if we allow G to be negative, we obtain the long wave thin film dynamics of hanging films. In the absence of an electric field ($W_e=0$) and if $G>0$, the flow is linearly stable; instability is possible if $G<0$, as is intuitive for hanging films (this case has been considered by Bertozzi and Pugh [3],

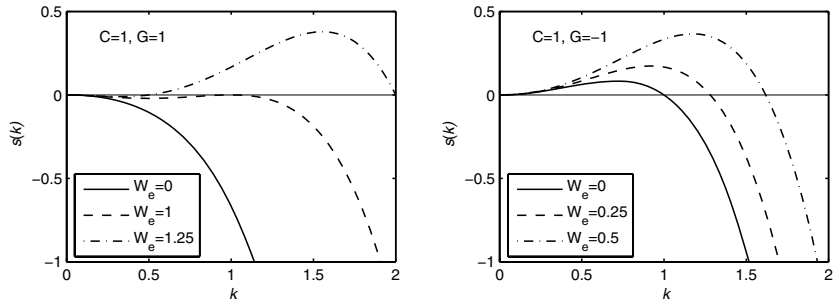

FIG. 2. *The effect of the electric field on linear growth rates $s(k)$. The left panel has $G = 1$ (overlying film) and the right panel $G = -1$ (under-hanging film). In both cases $C = 1$, and the values of W_e are shown in the figures.*

Ehrhard [8], Ehrhard and Davis [9], Yiantsios and Higgins [30], [31]). The electric field, however, can be utilized to destabilize liquid films lying on top of a substrate electrode ($G > 0$), and the novel equation (3.12) enables a quantitative study of such phenomena. To quantify some of these observations we perform a linear stability analysis to identify stable and unstable regimes when $W_e \neq 0$. Writing $H = 1 + \epsilon\eta$, linearizing with respect to ϵ, and seeking solutions proportional to $\eta = \hat{\eta}\exp(st + \mathrm{i}kx)$, where $\hat{\eta}$ is a complex constant, leads to the following linear dispersion relation:

$$s(k) = -\frac{1}{3C}k^4 + \frac{2W_e}{3}k^2|k| - \frac{G}{3}k^2. \tag{3.13}$$

(We have used the Fourier transform property $\mathcal{F}\big[\mathcal{H}[u]\big](k) = -\mathrm{i}\,\mathrm{sign}(\mathrm{Re}k)\hat{u}(k)$.)

When $G > 0$ (the film is resting on a substrate), we see that for $W_e < (G/C)^{1/2}$ all modes are stable; i.e., $s(k) < 0$ for all k. For $W_e > (G/C)^{1/2}$, however, there is a band of unstable waves with wavenumbers extending from $k_L = CW_e - \sqrt{(CW_e)^2 - CG}$ to $k_R = CW_e + \sqrt{(CW_e)^2 - CG}$, and the electric field is destabilizing. The most unstable mode has wavenumber $k = (3CW_e + \sqrt{9(CW_e)^2 - 8CG})/4$. Also, $k_L > 0$ for all W_e, and hence all waves in the immediate vicinity of $k = 0$ are stable—for large W_e, for example, all waves longer that $4\pi W_e/G$ are stable. Typical results are depicted in Figure 2 (the left panel), for the particular values $C = 1$, $G = 1$ for which $W_e > 1$ yields instability, as is clear from the figure.

When $G < 0$, there is always a band of unstable waves extending from $k_L = 0$ to $k_R = CW_e + \sqrt{(CW_e)^2 - CG}$; see Figure 2 (the right panel) for typical results for the case $C = 1$, $G = 1$. For large W_e we have $k_R \sim 2CW_e$, and so increasingly shorter wavelengths become linearly unstable as W_e increases. Damping of sufficiently high wavenumbers (and, hence, well-posedness) is provided by the presence of surface tension which is extremely important in this case.

The linear results set the stage for nonlinear computations and analysis, and we can expect nontrivial behavior in parameter regimes that support unstable linear waves. We concentrate on such calculations next.

4. Analytical results. In this section we prove the global boundedness of positive classical solutions of the evolution equation (3.12). This is achieved by constructing an energy functional whose extrema are steady state solutions of (3.12) and using it to estimate the H^1-norm of the solution and show that it is uniformly bounded.

The main result is Proposition 4.2 in section 4.2. The results extend those of Bertozzi and Pugh [3] to a class of physically meaningful nonlocal equations.

4.1. The energy functional. We consider the generalized equation

$$H_t + \big[f(H)\mathcal{A}[H]_x\big]_x = 0, \tag{4.1}$$

where f is a function which takes positive values for positive arguments and is zero only at zero, and $\mathcal{A}[H]$ is some integro-differential operator, which involves the function H, its first and second spatial derivatives, and the Hilbert transform operator. The additional condition that is satisfied by this operator will be given below. We consider (4.1) on a periodic interval $[-L, L]$ with positive initial data $H(x, 0) = H_0(x)$.

Steady state solutions of (4.1) are found by integrating once to obtain

$$f(H)\mathcal{A}[H]_x = C_1, \tag{4.2}$$

where C_1 is some constant. If H vanishes at some point, then $C_1 = 0$. Otherwise $\mathcal{A}[H]_x = C_1/f(H)$; integration gives $C_1 \int_{-L}^{L}(1/f(H))dx = 0$, which in turn implies that $C_1 = 0$. So, for steady state solutions, $\mathcal{A}[H]_x = 0$, i.e.,

$$\mathcal{A}[H] = C_2, \tag{4.3}$$

where C_2 is some constant.

Let $\mathcal{E}[H]$ be the energy functional having the form

$$\mathcal{E}[H] = \int_{-L}^{L} \mathcal{L}\big(H, H_x, \mathcal{H}[H]\big)dx, \tag{4.4}$$

and whose extrema are the steady state solutions of (4.1). More precisely, we assume that the following generalized Euler–Lagrange equation,

$$\frac{\partial \mathcal{L}}{\partial H} - \frac{d}{dx}\left[\frac{\partial \mathcal{L}}{\partial H_x}\right] - \mathcal{H}\left[\frac{\partial \mathcal{L}}{\partial \mathcal{H}[H]}\right] = 0, \tag{4.5}$$

coincides with the equation $C_2 - \mathcal{A}[H] = 0$. Then

$$\frac{d\mathcal{E}[H]}{dt} = \int_{-L}^{L}\left(\frac{\partial \mathcal{L}}{\partial H}H_t + \frac{\partial \mathcal{L}}{\partial H_x}H_{xt} + \frac{\partial \mathcal{L}}{\partial \mathcal{H}[H]}\mathcal{H}[H_t]\right)dx. \tag{4.6}$$

Integrating the second term by parts and applying the property $\int_I u(x)\mathcal{H}[v](x)dx = -\int_I v(x)\mathcal{H}[u](x)dx$ to the third term gives

$$\frac{d\mathcal{E}[H]}{dt} = \int_{-L}^{L}\left(\frac{\partial \mathcal{L}}{\partial H} - \frac{d}{dx}\left[\frac{\partial \mathcal{L}}{\partial H_x}\right] - \mathcal{H}\left[\frac{\partial \mathcal{L}}{\partial \mathcal{H}[H]}\right]\right)H_t dx \tag{4.7}$$

$$= -\int_{-L}^{L}(C_2 - \mathcal{A}[H])\big[f(H)\mathcal{A}[H]_x\big]_x dx = -\int_{-L}^{L} f(H)\mathcal{A}[H]_x^2 dx. \tag{4.8}$$

Therefore, $d\mathcal{E}[H]/dt \le 0$ for nonnegative H i.e., $\mathcal{E}[H]$ is bounded above.

For (3.12) we have $f(H) = H^3/3$ and $\mathcal{A}[H] = (1/C)H_{xx} - GH + 2W_e\mathcal{H}[H_x]$. The steady state solutions are determined by the equation

$$\frac{1}{C}H_{xx} - GH + 2W_e\mathcal{H}[H_x] = C_2, \tag{4.9}$$

which on integration yields

$$C_2 = -\frac{G}{2L}\int_{-L}^{L} H dx. \tag{4.10}$$

It follows that the functional $\mathcal{L}\big(H,\, H_x,\, \mathcal{H}[H]\big)$ can be chosen in the following form:

$$\mathcal{L}\big(H,\, H_x,\, \mathcal{H}[H]\big) = \frac{1}{2C}H_x^2 + \frac{G}{2}H^2 + W_e H_x \mathcal{H}[H] + C_2 H. \tag{4.11}$$

Thus, the energy functional

$$\mathcal{E}[H] = \int_{-L}^{L}\left(\frac{1}{2C}H_x^2 + \frac{G}{2}H^2 + W_e H_x \mathcal{H}[H] + C_2 H\right)dx \tag{4.12}$$

is a nonincreasing function of time for a nonnegative solution H.

4.2. Uniform boundedness of positive smooth solutions. In the previous section we have shown that the energy functional $\mathcal{E}[H]$ is bounded above by its initial value for a nonnegative solution H of (3.12). In this section we will show uniform boundedness of solutions. We will restrict our consideration to positive solutions, since, given upper and lower bounds for positive solutions, the equation is uniformly parabolic, which implies small time smoothness of the solutions (see Eidelman [10], Friedman [11]).

We begin with the following lemma.

LEMMA 4.1. *Let $\mathcal{E}[H]$ be the functional defined on $H^1(-L,\, L)$ by* (4.12). *Then there exist constants $\alpha > 0$, $\beta > 0$, and γ such that (s.t.)*

$$\|H\|_{H^1}^2 \le \alpha \mathcal{E}[H] + \beta \|H\|_1^2 + \gamma \|H\|_1 \tag{4.13}$$

for all nonnegative $H \in H^1_{\mathrm{per}}$. (Here and everywhere else we denote by L^2_{per}, H^k_{per}, $k = 1, 2, \ldots$, the subspaces of the Sobolev spaces $L^2(-L,\, L)$, $H^k(-L,\, L)$ consisting of periodic functions with period $2L$.)

Proof. First, using the Cauchy–Schwartz and Young's inequalities and the property $\|\mathcal{H}[u]\| = \|u\|$ of the Hilbert transform gives

$$\begin{aligned}\int_{-L}^{L} H_x \mathcal{H}[H] dx &\ge -\|H_x\|_2 \|\mathcal{H}[H]\|_2 = -\|H_x\|_2 \|H\|_2 \\ &\ge -\frac{\varepsilon_1}{2}\|H_x\|_2^2 - \frac{1}{2\varepsilon_1}\|H\|_2^2, \end{aligned} \tag{4.14}$$

where ε_1 is some positive number. Hence,

$$\begin{aligned}\mathcal{E}[H] &\ge \int_{-L}^{L}\left(\frac{1}{2C}H_x^2 + \frac{G}{2}H^2 + C_2 H\right)dx - \frac{\varepsilon_1 W_e}{2}\|H_x\|_2^2 - \frac{W_e}{2\varepsilon_1}\|H\|_2^2 \\ &= \left(\frac{1}{2C} - \frac{\varepsilon_1 W_e}{2}\right)\|H_x\|_2^2 + \left(\frac{G}{2} - \frac{W_e}{2\varepsilon_1}\right)\|H\|_2^2 + C_2\int_{-L}^{L} H dx \\ &= \left(\frac{1}{2C} - \frac{\varepsilon_1 W_e}{2}\right)\|H\|_{H^1}^2 + \left(\frac{G}{2} - \frac{W_e}{2\varepsilon_1} - \frac{1}{2C} + \frac{\varepsilon_1 W_e}{2}\right)\|H\|_2^2 + C_2\int_{-L}^{L} H dx. \end{aligned} \tag{4.15}$$

Note that $\int_{-L}^{L} H dx = \|H\|_1$ for nonnegative H. We define $A = 1/2C - \varepsilon_1 W_e/2$ and $B = -G/2 + W_e/2\varepsilon_1 + 1/2C - \varepsilon_1 W_e/2$. Choosing ε_1 sufficiently small gives $A > 0$, $B > 0$. Also, using the interpolation inequality

$$\|H\|_2 \le C_3 \|H\|_{H^1}^{1/3} \|H\|_1^{2/3} \tag{4.16}$$

and applying Young's inequality for the right-hand side of the expression above gives

$$\|H\|_2 \le C_3 \left(\frac{\varepsilon_2}{3} \|H\|_{H^1} + \frac{2}{3\varepsilon_2^{1/2}} \|H\|_1 \right), \tag{4.17}$$

where ε_2 is some positive number. Therefore,

$$\|H\|_2^2 \le \frac{2\varepsilon_2^2 C_3^2}{9} \|H\|_{H^1}^2 + \frac{8C_3^2}{9\varepsilon_2} \|H\|_1^2, \tag{4.18}$$

and we get

$$\mathcal{E}[H] \ge A\|H\|_{H^1}^2 - B\|H\|_2^2 + C_2\|H\|_1 \tag{4.19}$$

$$\ge A\|H\|_{H^1}^2 - B\left(\frac{2\varepsilon_2^2 C_3^2}{9} \|H\|_{H^1}^2 + \frac{8C_3^2}{9\varepsilon_2} \|H\|_1^2 \right) + C_2\|H\|_1 \tag{4.20}$$

$$= \left(A - \frac{2\varepsilon_2^2 B C_3^2}{9} \right) \|H\|_{H^1}^2 - \frac{8BC_3^2}{9\varepsilon_2} \|H\|_1^2 + C_2\|H\|_1. \tag{4.21}$$

We define $\tilde{A} = A - 2\varepsilon_2^2 B C_3^2/9$ and $\tilde{B} = 8BC_3^2/9\varepsilon_2$. Note that $\tilde{B}$ is positive and choosing ε_2 small enough makes $\tilde{A}$ also positive. Thus,

$$\mathcal{E}[H] \ge \tilde{A}\|H\|_{H^1}^2 - \tilde{B}\|H\|_1^2 + C_2\|H\|_1, \tag{4.22}$$

i.e.,

$$\|H\|_{H^1}^2 \le \alpha \mathcal{E}[H] + \beta\|H\|_1^2 + \gamma\|H\|_1, \tag{4.23}$$

where $\alpha = 1/\tilde{A}$, $\beta = \tilde{B}/\tilde{A}$, $\gamma = -C_2/\tilde{A}$, as required. □

We can now prove uniform boundedness of positive smooth solutions to (3.12).

PROPOSITION 4.2. *Let $H(x, t)$ be a positive smooth solution of* (3.12) *with periodic boundary conditions on some time interval* $[0, T]$. *If $H(x, 0) = H_0(x) \in H^1_{\mathrm{per}}$, then $\|H\|_{H^1}$ is uniformly bounded.*

Proof. First, note that (3.12) is a conservation law. The spatial integral of the solution is conserved. Indeed, integrating over $[-L, L]$ gives $(d/dt)\int_{-L}^{L} H dx = 0$ and hence $\|H\|_1 = \|H_0\|_1$. Also, since $\mathcal{E}[H]$ is a nonincreasing function of time, (4.13) implies

$$\|H\|_{H^1}^2 \le \alpha \mathcal{E}[H] + \beta\|H\|_1^2 + \gamma\|H\|_1 \tag{4.24}$$

$$= \alpha \mathcal{E}[H] + \beta\|H_0\|_1^2 + \gamma\|H_0\|_1 \tag{4.25}$$

$$\le \alpha \mathcal{E}[H_0] + \beta\|H_0\|_1^2 + \gamma\|H_0\|_1, \tag{4.26}$$

which was to be proved. □

Remark. Proposition 4.2 is essentially a no-blow-up theorem for the solution H. The result does not prevent a touchdown (the numerics predicts a touchdown in infinite time—see Figures 3–6).

4.3. Evolution of $\int_{-L}^{L} H^{-1}dx$. In this section we show that the spatial integral of H^{-1} is bounded on each finite time interval. Indeed,

$$\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} = -\int_{-L}^{L}\frac{H_t}{H^2}dx. \tag{4.27}$$

Substituting the expression for H_t from (3.12) into (4.27) gives

$$\begin{aligned}\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} &= \frac{1}{3}\int_{-L}^{L}\frac{1}{H^2}\left[H^3\left(\frac{1}{C}H_{xxx} - GH_x + 2W_e\mathcal{H}[H_{xx}]\right)\right]_x dx\\ &= \frac{1}{3}\int_{-L}^{L}\frac{1}{H^2}(3H^2H_x)\left(\frac{1}{C}H_{xxx} - GH_x + 2W_e\mathcal{H}[H_{xx}]\right)dx\\ &\quad + \frac{1}{3}\int_{-L}^{L}\frac{1}{H^2}H^3\left(\frac{1}{C}H_{xxx} - GH_x + 2W_e\mathcal{H}[H_{xx}]\right)_x dx\\ &= \frac{1}{C}\int_{-L}^{L}H_xH_{xxx}dx - G\int_{-L}^{L}H_x^2dx + 2W_e\int_{-L}^{L}H_x\mathcal{H}[H_{xx}]dx\\ &\quad + \frac{1}{3C}\int_{-L}^{L}HH_{xxxx}dx - \frac{G}{3}\int_{-L}^{L}HH_{xx}dx + \frac{2W_e}{3}\int_{-L}^{L}H\mathcal{H}[H_{xxx}]dx.\end{aligned} \tag{4.28}$$

Integration by parts then gives

$$\begin{aligned}\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} &= -\frac{1}{C}\int_{-L}^{L}H_{xx}^2dx - G\int_{-L}^{L}H_x^2dx + 2W_e\int_{-L}^{L}H_x\mathcal{H}[H_{xx}]dx\\ &\quad + \frac{1}{3C}\int_{-L}^{L}H_{xx}^2dx + \frac{G}{3}\int_{-L}^{L}H_x^2dx - \frac{2W_e}{3}\int_{-L}^{L}H_x\mathcal{H}[H_{xx}]dx.\end{aligned} \tag{4.29}$$

Therefore,

$$\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} = -\frac{2}{3C}\int_{-L}^{L}H_{xx}^2dx - \frac{2G}{3}\int_{-L}^{L}H_x^2dx + \frac{4W_e}{3}\int_{-L}^{L}H_x\mathcal{H}[H_{xx}]dx. \tag{4.30}$$

Using the Cauchy–Schwartz and Young's inequalities and the property $\|\mathcal{H}[u]\| = \|u\|$ gives

$$\begin{aligned}\int_{-L}^{L}H_x\mathcal{H}[H_{xx}]dx &\le \|H_x\|_2\|\mathcal{H}[H_{xx}]\|_2 = \|H_x\|_2\|H_{xx}]\|_2\\ &\le \frac{1}{2\varepsilon}\|H_x\|_2^2 + \frac{\varepsilon}{2}\|H_{xx}\|_2^2,\end{aligned} \tag{4.31}$$

where ε is some positive number. Hence,

$$\begin{aligned}\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} &\le -\frac{2}{3C}\|H_{xx}\|_2^2 - \frac{2G}{3}\|H_x\|_2^2 + \frac{4W_e}{3}\left(\frac{1}{2\varepsilon}\|H_x\|_2^2 + \frac{\varepsilon}{2}\|H_{xx}\|_2^2\right)\\ &= A\|H_{xx}\|_2^2 + B\|H_x\|_2^2,\end{aligned} \tag{4.32}$$

where $A = -2/3C + 2W_e\varepsilon/3$, $B = -2G/3 + 2W_e/3\varepsilon$. Choosing ε small enough (s.t. $A < 0$) implies

$$\frac{d}{dt}\int_{-L}^{L}\frac{dx}{H} \le B\|H_x\|_2^2. \tag{4.33}$$

Since the H^1-norm of the positive solution H is uniformly bounded (as was shown in the previous section), we obtain the desired boundedness result since there exists a constant D s.t. $(d/dt)\int_{-L}^{L}(1/H)dx \le D$.

It was proved in section 4.2 that the H^1-norm of a positive solution is bounded for all time. Due to Agmon's inequality this also implies boundedness of the maximum of the solution. Hence, if the solution is positive for all time, then it is also uniformly bounded above; i.e., it does not blow up in finite or infinite time. In this section we have shown that the spatial integral of $1/H$ is bounded on each finite time interval; i.e., it does not blow up in finite time (though this can happen in infinite time). This result can be used to show that as long as $\max|H_{xx}|$ remains bounded on each finite time interval, an initially positive solution will remain positive for all time; that is, the interface does not touch down in finite time. We prove this below. (The boundedness of $\max|H_{xx}|$ comes from extensive computations (see section 6) and is used as an assumption in what follows. A rigorous proof has not yet been found.)

PROPOSITION 4.3. *Let $H(x, t)$ be a positive smooth solution of* (3.12) *with periodic boundary conditions on some time interval $[0, T)$. In addition, assume that $\max|H_{xx}|$ is bounded above on each finite time interval. Then the solution H remains positive for all time, i.e., $T = \infty$.*

Proof. Suppose that T is finite and the solution becomes zero at some point $x = x_0$ in finite time $t = T$, and seek a contradiction. This means that at $t = T$ the solution obtains a minimum at $x = x_0$. Denote by $\xi(t)$ the point at which the solution has a (local) minimum at a given time t s.t. $\xi(t)$ is a continuous function of t and $\xi(T) = x_0$. Also, let $\max|H_{xx}| = A$, where A is a function of time which is bounded on $[0, T)$. At each time $t < T$ we expand the function H into a Taylor series about $x = \xi(t)$ and use the fact that $H_x(\xi(t), t) = 0$,

$$H(x, t) = H(\xi(t), t) + \frac{1}{2}(x - \xi(t))^2 H_{xx}(\zeta, t), \tag{4.34}$$

where $\zeta = \zeta(x, t)$ is some point between x and $\xi(t)$. We get

$$\begin{aligned}\int_{-L}^{L}\frac{dx}{H(x, t)} &= \int_{-L}^{L}\frac{dx}{H(\xi(t), t) + \frac{1}{2}(x - \xi(t))^2 H_{xx}(\zeta, t)}\\ &\ge \int_{-L}^{L}\frac{dx}{H(\xi(t), t) + \frac{A}{2}(x - \xi(t))^2}\\ &= -\sqrt{\frac{2}{AH(\xi(t), t)}}\tan^{-1}\left(\sqrt{\frac{A}{2H(\xi(t), t)}}(\xi(t) - x)\right)\Bigg|_{-L}^{L}. \qquad (4.35)\end{aligned}$$

It follows that the right-hand side of (4.35) blows up when $t \to T$, since then $H(\xi(t), t) \to 0$ by the assumption. This contradicts the boundedness of $\int_{-L}^{L}(1/H)dx$ on each finite time interval. Thus, if $\max|H_{xx}|$ is bounded on each finite time interval, then the solution cannot become zero in finite time; i.e., it remains positive for all time. ∎

5. Numerical method. We use a fully implicit two-level scheme with Newton iterations for (3.12) on a finite periodic interval $[-L, L]$. The method was developed for the following more general equation (this also includes the falling film equation derived in Tseluiko and Papageorgiou [28]):

$$H_t + \left[f_1(H)H_{xxx}\right]_x + \left[f_2(H)\right]_{xx} + \left[f_3(H)\mathcal{H}[H_{xx}]\right]_x + \left[f_4(H)\right]_x = 0, \tag{5.1}$$

with $f_1, \dots, f_4$ polynomials in H. We incorporate the ideas of Bertozzi and Pugh [2], Diez, Kondic, and Bertozzi [6] into nonlocal problems. The equation is solved on a uniform spatial grid $x_m = (m - M)\Delta x$, $m = 1, 2, \dots, 2M$, where $\Delta x = L/M$, and spatial derivatives are discretized using central differences; H_m denote the values of a $2L$-periodic function H at the mesh points. We also set $H_0 = H_{2M}$, $H_{-1} = H_{2M-1}$, etc., and $H_{2M+1} = H_1$, $H_{2M+2} = H_2$, etc., which follow by the periodicity of H. For $m = 1, 2, \dots, 2M - 1$, we introduce the midpoints $x_{m+1/2} = (x_m + x_{m+1})/2$ with $x_{1/2} = (-L + x_1)/2$ and define $H_{m+1/2} = (H_m + H_{m+1})/2$. Second order accurate central differences are used to approximate odd derivatives at $x_{m+1/2}$ and even derivatives at x_m. To approximate the Hilbert transform of H_{xx} at $x = x_{m+1/2}$ we use trapezoidal quadrature in the periodic representation $\mathcal{H}[g](x) = (1/2L)PV \int_{-L}^{L} g(\xi) \cot\big(\pi(x - \xi)/2L\big) d\xi$,

$$\mathcal{H}[H_{xx}](x_{m+1/2}) \approx \widetilde{\mathcal{H}}[\partial_2(H)]_{m+1/2} \equiv \frac{\Delta x}{2L} \sum_{k=1}^{2M} \partial_2(H)_k \cot\left(\frac{\pi(x_{m+1/2} - x_k)}{2L}\right). \tag{5.2}$$

This leads to the system of ordinary differential equations for $H_1, H_2, \dots, H_{2M}$:

$$\begin{aligned} \frac{dH_m}{dt} = &- \frac{f_1(H_{m+1/2})\partial_3(H)_{m+1/2} - f_1(H_{m-1/2})\partial_3(H)_{m-1/2}}{\Delta x} - \partial_2(f_2(H))_m \\ &- \frac{f_3(H_{m+1/2})\widetilde{\mathcal{H}}[\partial_2(H)]_{m+1/2} - f_3(H_{m-1/2})\widetilde{\mathcal{H}}[\partial_2(H)]_{m-1/2}}{\Delta x} \\ &- \frac{f_4(H_{m+1/2}) - f_4(H_{m-1/2})}{\Delta x}, \end{aligned} \tag{5.3}$$

where the grid operators ∂_2 and ∂_3 correspond to the second- and third order spatial derivatives, respectively. We write (5.3) in the following compact form:

$$\frac{d\boldsymbol{H}}{dt} = \boldsymbol{F}(\boldsymbol{H}), \tag{5.4}$$

where $\boldsymbol{H} = (H_1, H_2, \dots, H_{2M})^T$, $\boldsymbol{F}(\boldsymbol{H}) = (F_1(\boldsymbol{H}), F_2(\boldsymbol{H}), \dots, F_{2M}(\boldsymbol{H}))^T$ are given by the right-hand side of (5.3). Note that, unlike similar thin film problems that have been studied previously, $F_m(\boldsymbol{H})$ depends on all the components of $\boldsymbol{H}$ due to the presence of the nonlocal Hilbert transform.

This semidiscrete scheme preserves the discrete approximation of the volume. We show this by multiplying (5.3) by Δx and summing over $m = 1, 2, \dots, 2M$ to obtain $\sum_{m=1}^{2M} (dH_m/dt)\Delta x = 0$. A time integration yields $\sum_{m=1}^{2M} H_m(t)\Delta x = \sum_{m=1}^{2M} H_m(0)\Delta x$, as desired.

For the time discretization of (5.4) we use the usual implicit two-level scheme,

$$\frac{\boldsymbol{H}^{n+1} - \boldsymbol{H}^n}{\Delta t_n} = \boldsymbol{F}(\theta \boldsymbol{H}^{n+1} + (1 - \theta)\boldsymbol{H}^n), \tag{5.5}$$

where $\boldsymbol{H}^n = (H_1^n, H_2^n, \dots, H_{2M}^n)^T$ is the numerical solution for $\boldsymbol{H}$ at $t = t_n$, $\Delta t_n = t_{n+1} - t_n$, and θ is some real number between 0 and 1 (the scheme is first order accurate in time). To advance from the time level n to the time level $n + 1$, the algebraic system of nonlinear equations (5.5) for $\boldsymbol{H}^{n+1}$ is solved iteratively using Newton's method. The time step is chosen dynamically for each time level by requiring several constraints to be satisfied as described below (see also Bertozzi and Pugh [2] and Diez,

Kondic, and Bertozzi [6]). If the numerical solution violates one of the constraints, then the time step is reduced and the calculation is repeated until all the constraints are met. On the other hand, if all the constraints are met after the first application of Newton's method, the time step is increased at the next time level in order to prevent using unnecessarily small time steps. The constraints are the following: (a) the minimum of the solution should change by no more than 10%, (b) the local relative error should be small (10^{-3}, say). The local relative error e_m approximates $((\Delta t_{n-1})^2/H_m^n)(d^2H_m^n/dt^2)$ and is computed as follows (see [2], [6]):

$$e_m = \frac{2\Delta t_{n-1}}{\Delta t_{n-2}} \frac{\Delta t_{n-2} H_m^{n+1} + \Delta t_{n-1} H_m^{n-1} - (\Delta t_{n-2} + \Delta t_{n-1}) H_m^n}{(\Delta t_{n-2} + \Delta t_{n-1}) H_m^n}. \tag{5.6}$$

In addition, the spatial grid is refined during the calculation to get better resolution of the solution. This is done by doubling the number of mesh points when the magnitude of more than 2/3 of the Fourier modes is larger than a set tolerance of 10^{-13}. (The fast Fourier transform is used as an accuracy diagnostic.)

The numerical method has been described and implemented for solutions without any assumed symmetry. If $f_4 \equiv 0$, however, as is the case here, and the initial condition is an even function, then H remains even for all time. In this case we can consider $2L$-periodic even solutions and discretize the equation on the interval $[0, L]$ alone, thus halving the number of unknowns. The appropriate boundary conditions are

$$H_x(0, t) = H_{xxx}(0, t) = 0, \qquad H_x(L, t) = H_{xxx}(L, t) = 0, \tag{5.7}$$

with periodicity used as needed in calculating difference formulas.

6. Numerical results. The code was validated by reproducing the results of Yiantsios and Higgins [30], who solved (3.12) with $C = 1$, $G = -1$, $W_e = 0$, on periodic intervals of lengths $2\sqrt{2}\pi$, $4\sqrt{2}\pi$, $6\sqrt{2}\pi$, 5π. We also reproduced the results of Bertozzi and Pugh [3]. Part of their work involved the numerical solution of (3.12) on the interval $[-1, 1]$, with $C = 1$, $G = -80$, $W_e = 0$. Our code has reproduced these results with indistinguishable differences at $t = 100$, which is the largest time that Bertozzi and Pugh [3] report.

For the results presented here we take $C = 1$, $G = -1$ or $G = 1$, and increase W_e to enhance the instability. We take $L = 10$ and an initial condition

$$H(x, 0) = 1 + 0.1\cos(\pi x/L). \tag{6.1}$$

Thus, without loss of generality the mean value of $H(x, 0)$ over a period is taken to be 1. If it were $d > 0$, then the change of time scale, $t \to d^{-3}t$, leaves the evolution equation (3.12) unchanged but normalizes the initial condition to have unit mean.

6.1. Films wetting the underside of the plate, $G < 0$. As explained previously, when $G < 0$ the flat film state is long-wave unstable even when $W_e = 0$. We present results for fixed $G = -1$ and $C = 1$ as the electric field parameter W_e increases. For these parameters with $W_e = 0$ and $L = 10$, the first two harmonics are linearly unstable modes of the flat state, as can be seen from the linear result (6.2) below. We aim to systematically quantify the dynamics in the nonlinear regime as W_e increases.

The first set of results is presented in Figure 3 for $W_e = 0$. There are eight panels in the figure depicting the evolution over 1000 time units. The plots of the

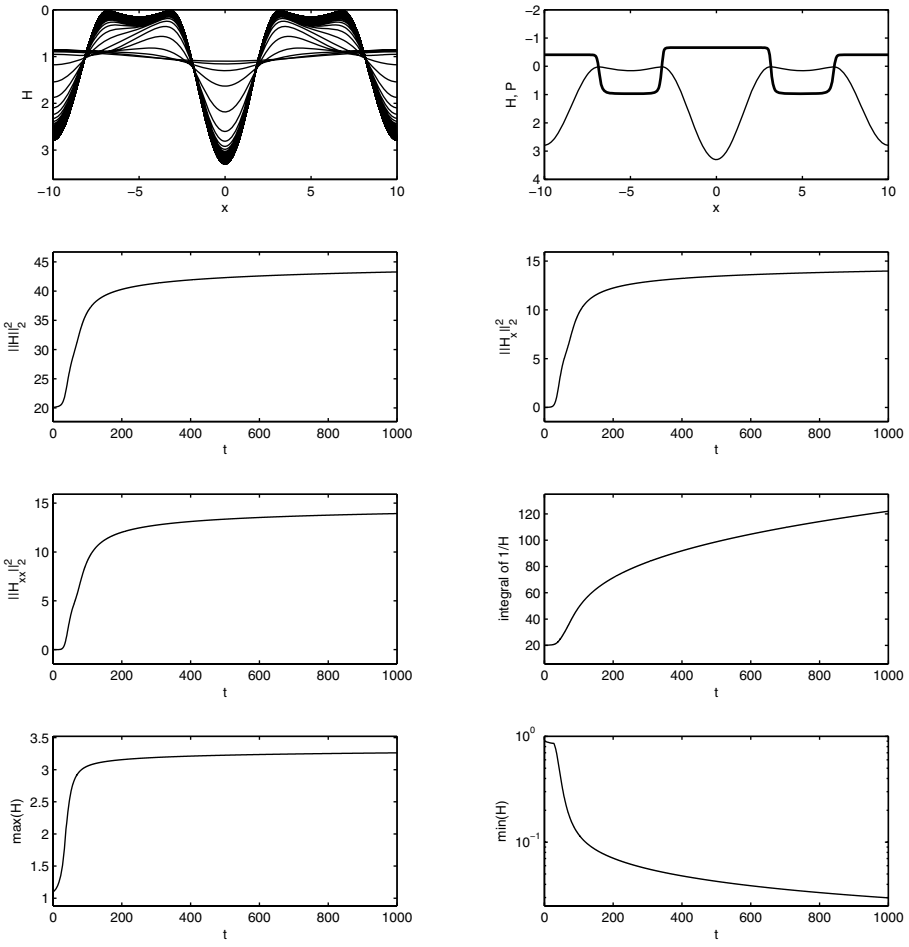

FIG. 3. *Evolution of the spatially periodic interface for* $C = 1$, $G = -1$, $W_e = 0$. *The equation was integrated for* $0 \le t \le 1000$. *The upper-left panel shows the evolution of the profile* H *(the time interval between the plots is* 10*). The upper-right panel shows the profile* H *(thin line) and the pressure* P *given by* (3.11) *(solid line) at* $t = 1000$. *Also, the evolution of* $\|H\|_2^2$, $\|H_x\|_2^2$, $\|H_{xx}\|_2^2$, *as well as the evolution of* $\int_{-10}^{10}(1/H)dx$ *and the maximum and minimum of* H *are shown. (For the minimum we use a log-linear plot.)*

interface are reflected about the x-axis to emphasize that we are dealing with hanging films. The interface evolution is shown in the top-left panel, and the top-right panel shows the solution at the last computed time $t = 1000$; the thin line curve represents the interface $H(x, 1000)$, and the thick line curve the corresponding perturbation pressure distribution $P(x, 1000)$ given by (3.11) (note that the subscript zero has been dropped). It can be seen that the pressure is essentially uniform and negative in the regions where large drops are forming (the pressure has different values in different-sized drops), and uniform and positive in the thinning regions between large drops. The resulting pressure gradient acts to push fluid out of the thinning regions and into the larger drops. This mechanism is at play for all computed results presented here and is responsible for the asymptotic thinning of the regions between the larger

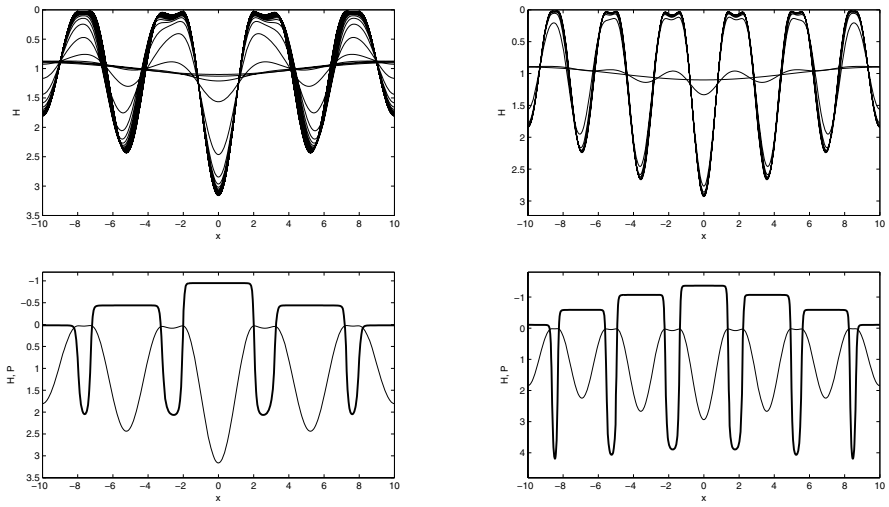

FIG. 4. *Evolution for $C = 1$, $G = -1$. The top row shows the interface evolution for $W_e = 0.5$ (left) and 1 (right); the bottom row shows the corresponding profiles H (thin line) and the pressures P (solid line) at the final times.*

quasi-static drops. The other six panels contain information on the evolution of different norms of H, namely $\|H\|_2^2$, $\|H_x\|_2^2$, and $\|H_{xx}\|_2^2$ (labeled in the figure); the evolution of $\int_{-L}^{L}(1/H)dx$; and the evolution of the maximum and minimum of H over the spatial domain, $\max(H)$ and $\min(H)$, respectively (the latter is plotted using log-linear scales). The boundedness of $\|H\|_2^2$ and $\|H_x\|_2^2$ (equivalently of the L^2- and H^1-norms) is in line with the rigorous results of section 4, as is the at most linear growth of the integral $\int_{-L}^{L}(1/H)dx$. The evolution of $\|H_{xx}\|_2^2$ (equivalently the H^2-norm) indicates that it is bounded (moreover, from numerics it can be seen that $\max|H_{xx}|$ is bounded as well)—this is used as an assumption in producing a proof that the interface cannot touch down in finite time but can do so asymptotically in infinite time (see section 4.3). The log-linear evolution of $\min(H)$ also provides strong evidence of an asymptotic touchdown after infinite time in line with the conjecture in section 4.3. Finally, we note that the profile at large time contains two large drops (see the top-right panel), and this number coincides with the number of linearly unstable modes. Nonlinearity produces small daughter drops between the main mother drops that cannot be predicted by linear theory. This phenomenon is generic and holds when W_e is nonzero also (see Figures 4, 5, 6 also).

Figure 4 contains results for nonzero electric fields with $W_e = 0.5$ and 1. The top row shows the evolution of the interface for $W_e = 0.5$ (left) and $W_e = 1$ (right), and the bottom row shows the corresponding final computed interfacial profiles and pressure distributions. The calculations were carried out to 100 and 30 time units for $W_e = 0.5$ and 1, respectively, and profiles in the top row are depicted at intervals of 4 time units. Once more we see main drops forming at large times with thinning regions between them containing smaller humps. The pressure distribution is uniform in the larger drops with maxima in the thinning regions, producing the draining mechanism discussed earlier. The main difference between the two cases is that for $W_e = 0.5$ we ultimately have four drops forming, while for $W_e = 1$ we have six. This can be explained using linear theory and (3.13). The wavenumber of the maximally unstable

mode on 2π-periodic domains is $k_{max} = (3CW_e + \sqrt{9(CW_e)^2 - 8CG})/4$. Modifying this to $2L$-periodic domains gives

$$k_{max} = \left(\frac{L}{\pi}\right) \frac{3CW_e + \sqrt{9(CW_e)^2 - 8CG}}{4}. \tag{6.2}$$

The value of k_{max} provides a qualitative estimate of the main features of the interface at large times; for example, in the results of Figure 3 we have $k_{max} = 2.25$, which explains the two large drops that form. For the parameters of Figure 4 we have $k_{max} = 3.74$ and $k_{max} = 5.67$, which explain the four and six drops formed. The smaller drops forming in the thinning regions are due to nonlinearity and cannot be explained using a simple linear theory. We have also monitored norms and other diagnostics as in Figure 3 and have found similar behavior. Most notably, $\max |H_{xx}|$ remains bounded in time.

6.2. Films wetting the upper side of the plate, $G > 0$. Here we present results for $G = 1$, $C = 1$, and increasing values of W_e. As noted earlier, if $W_e = 0$, the flat state is stable—the solutions to the initial value problem are damped and produce the uniform trivial state at large times (this has been confirmed numerically also). Support for this is also provided by the linear result (3.13), since $s(k) < 0$ for all $k \neq 0$. If W_e exceeds the critical value $W_{ec} = (G/C)^{1/2}$, instability sets in over a band of wavenumbers $k_L < k < k_R$, using the notation of section 3. For our parameters, $W_{ec} = 1$, and in what follows we present results for increasing $W_e > 1$.

The first set of results has $W_e = 1.02$, which is just above critical. According to (6.2), $k_{max} = 3.37$, and so we may expect three drops to form at large times. The results are shown in Figure 5; the integration was carried out to $t = 5000$. The format of the figure is the same as that of Figure 3, and the results are qualitatively similar. The top-right panel shows an enlargement of the solution and the corresponding pressure distribution in the vicinity of the first thinning region to the left of the origin. Again we see essentially uniform negative pressure in the main drops and a pressure maximum in the thinning region in between, so that the fluid draining mechanism described earlier is seen to operate. The other diagnostics are in agreement with the analytical results.

In Figure 6 we present results for $W_e = 1.1$, 1.5, and 2.0, respectively. The top row shows the time evolution of H as W_e increases from the left to the right, and the bottom row shows the corresponding final computed profiles and pressure distributions (thin and thick solid lines, respectively)—for $W_e = 1.1$ this is enlarged accordingly. The computations were carried out to 1000, 75, and 20 time units for $W_e = 1.1$, 1.5, and 2, respectively, and profiles are plotted every 10, 1, and 1 time units, respectively. The pressure gradient draining mechanism is operational throughout, and uniform but different negative pressures are attained inside the large drops. The number of drops formed at large times is again in excellent agreement with linear theory (linear theory cannot provide the volumes of the drops or the formation of smaller daughter droplets in the thinning regions). For example, the values of k_{max} given by (6.2) are 3.98, 6.37, and 8.99 for $W_e = 1.1$, 1.5, and 2.0, respectively, while the numbers of the main computed drops are 4, 6, and 9, respectively. It can be concluded, therefore, that linear theory can be used in a very simple way to predict how many drops will form at large time. Details, including drop volumes, must be calculated numerically by solving the nonlinear problem.

7. Conclusions. We have derived and studied analytically and numerically a nonlinear nonlocal evolution equation that describes the evolution of thin films wetting

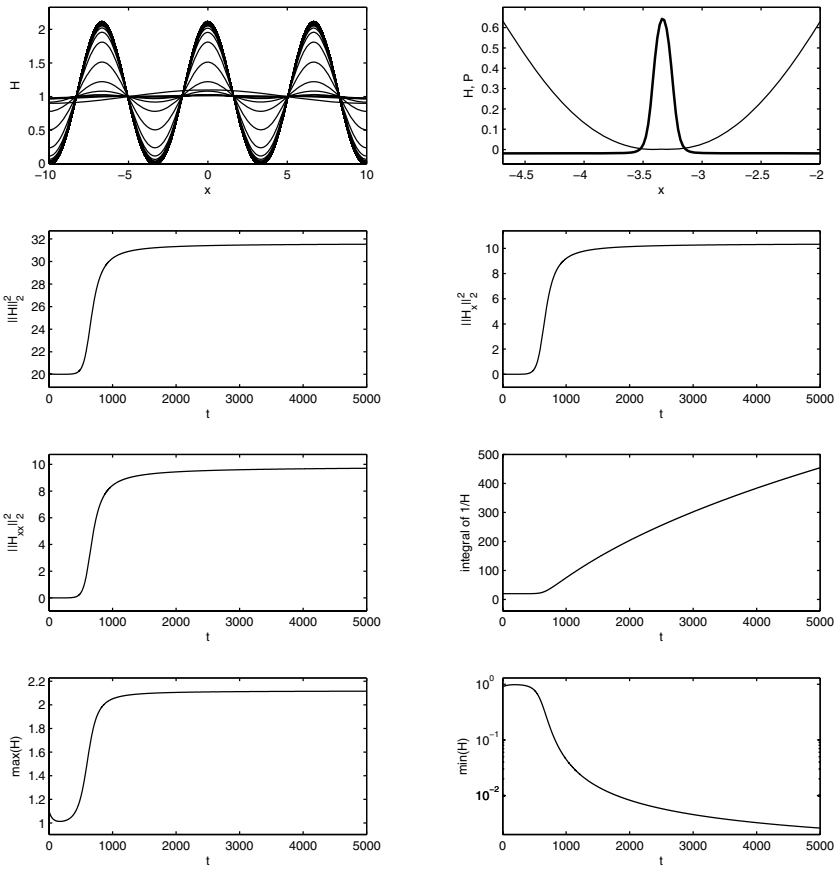

FIG. 5. *Evolution of the spatially periodic interface for* $C = 1$, $G = 1$, $W_e = 1.02$. *The equation was integrated for* $0 \le t \le 5000$. *The upper-left panel shows the evolution of the profile* H *(the time interval between the plots is* 100*). a horizontal plate in the presence of a vertical electric field. The field introduces the instability when $G > 0$ (films wetting the upper side of the plate) and enhances the instability when $G < 0$ (films wetting the underside side of the plate).

By extending previous analytical studies to incorporate nonlocal terms, we have proved a no-blow-up theorem of positive smooth solutions of the evolution equation. Using an estimate of the integral of the reciprocal of the solution and assuming that $\max|H_{xx}|$ is uniformly bounded (this is suggested by extensive numerical work), we have also presented a conjecture that the film cannot touch down in finite time but can do so only asymptotically in infinite time. This also holds in the absence of the field. All rigorous results are seen in the numerical solutions, thus providing additional accuracy checks for the latter.

Extensive numerical experiments have been carried out to describe the salient features of thin electrified film dynamics. Initially, the evolution follows the predictions of linear theory, and the solution grows exponentially. As time increases, higher

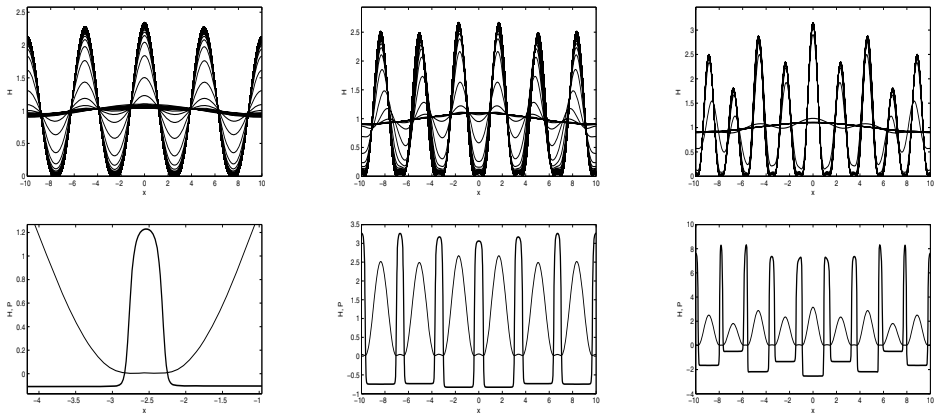

FIG. 6. *Evolution for $C = 1$, $G = 1$. The top row shows the interface evolution for $W_e = 1.1$, 1.5, and 2, from left to right; the bottom row shows the corresponding profiles H (thin line) and the pressures P (solid line) at the final times.*

harmonics are generated due to the nonlinearities, and the most dominant mode appears to be the most unstable mode predicted by linear theory; note that this mode corresponds to the number of the drops which appear at large times. The qualitative features of the solutions for $G < 0$ and W_e zero or nonzero are similar to those with $G > 0$ and $W_e > 0$ (in the latter case a nonzero electric field is required to destabilize the flow and to produce nontrivial dynamics). An increase in W_e for fixed G and C (or equivalently a decrease of a negative G with fixed W_e and C), produces increasingly more drops at large times, whose number is predicted by linear theory. This drop-formation behavior is one of the main features of the dynamics as additional unstable modes enter. In all computed cases, as the time increases the evolution slows down (this can be seen in any of the different computational panels in the figures, but is most clearly evidenced by the evolution of $\min(H)$). The spatial features at large times are also quite intricate: First, as the interface reaches the vicinity of the wall it tends to flatten, and after that the solution tends to bulge near the ends of the flat regions forming a secondary hump in between—see Figure 3, for example. All the results indicate that the solution remains positive—the film does not touch down within finite time. Also, the solution is bounded for all time (this has been proven rigorously), despite the fact that the electric field increases the instability and promotes the process of the formation of the increasingly larger numbers of drops.

Finally, we comment on the possibility of coarsening dynamics, as seen in other thin film studies by Glasner and Witelski [12], for example. Even though it is not clear a priori whether neighboring drops communicate with each other in order to trigger merging and coarsening, the numerical solutions with electric fields present suggest that such dynamics is not seen. Our results suggest that the thinning of the interdrop regions feeds fluid into main drops and that the large time dynamics of the latter remain independent from each other, drops remaining fixed and not moving. It would be interesting to add a disjoining pressure in the manner of Glasner and Witelski [12] that prevents asymptotic thinning and allows communication between main drops. It is also interesting to revisit the calculations of Yiantsios and Higgins [30] for $W_e = 0$, where they do not impose symmetry and see that drops move (slowly) with the larger drop moving more. The calculations failed to see merging, however, due to a critical

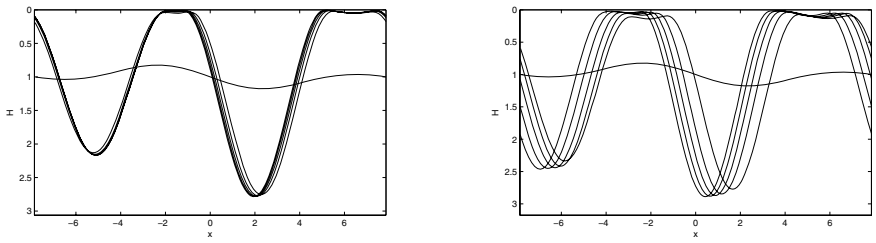

FIG. 7. *Nonsymmetric initial conditions for hanging drops, $C = 1$, $G = -1$. Left panel, $W_e = 0$, and right panel, $W_e = 0.1$. The domain length is 5π, and the initial condition in both runs is $H(x,0) = 1 + 0.1\sin(2x/5) + 0.1\sin(4x/5)$. As time increases, the minimum film thickness decreases.*

slow-down of drop motion as thinning of interdrop regions takes place. Following [30], we take $C = 1$, $G = -1$, and $W_e = 0$ and 0.1 with the length $L = 2.5\pi$ and the initial condition $H(x,0) = 1 + 0.1\sin(2x/5) + 0.1\sin(4x/5)$. The results are shown in Figure 7, with $W_e = 0$ for the left panel and $W_e = 0.1$ for the right panel. For $W_e = 0$ two drops are formed and are approaching each other, with the larger drop being more mobile and moving from the right to the left, while the smaller drop moves from the left to the right. The rate of approach slows down critically (the integration is carried out to 2000 time units, and the profiles are shown every 400 units). For $W_e = 0.1$, two drops are formed but move in the same direction (from the right to the left) with the electric field present. The electric field significantly increases the mobility of the drops. The velocity of the larger drop is slowing down, while the velocity of the smaller drop is increasing with time, and the distance between the drops is decreasing with increasing time. We did not see merging again due to a critical slow-down of drop motion (the integration is carried out to 500 time units, and the profiles are shown every 100 units).

ELASTIC SCATTERER RECONSTRUCTION VIA THE ADJOINT SAMPLING METHOD*

S. NINTCHEU FATA† AND B. B. GUZINA‡

Abstract. An inverse problem dealing with the reconstruction of voids in a uniform semi-infinite solid from near-field elastodynamic waveforms is investigated via the linear sampling method. To cater to active imaging applications that are characterized by a limited density of illuminating sources, existing formulation of the linear sampling method is advanced in terms of its adjoint statement that features integration over the receiver surface rather than its source counterpart. To deal with an ill-posedness of the integral equation that is used to reconstruct the obstacle, the problem is solved by alternative means of Tikhonov regularization and a preconditioned conjugate gradient method. Through a set of numerical examples, it is shown (i) that the adjoint statement elevates the performance of the linear sampling method when dealing with scarce illuminating sources, and (ii) that a combined use of the existing formulation together with its adjoint counterpart represents an effective tool for exposing an undersampling of the experimental input, e.g., in terms of the density of source points used to illuminate the obstacle.

Key words. inverse scattering, elastic waves, near-field waveforms, linear sampling

1. Introduction.

Remote sensing of internal defects or obstacles using elastic waves with "long" wavelengths, i.e., those inside the so-called resonance region [8], is an inverse scattering problem relevant to a variety of applications such as nondestructive material testing, hydrocarbon prospecting, and medical diagnosis. In the context of seismic inversion, such low-frequency waveforms are often interpreted by means of the full waveform tomography [36], which typically couples gradient-based nonlinear minimization with a finite-difference (forward) simulation of elastic wave propagation [4, 35]. For simple (e.g., homogeneous) background media, the waveform tomography approach to seismic imaging can be alternatively established within the framework of elastodynamic boundary integral equation methods, especially when equipped by the analytical sensitivity estimates [2, 19] (see also [6] for acoustic problems). Irrespective of the type of forward model, however, the high resolution of full waveform inversion is commonly balanced by its lack of robustness, manifest in the "trapping" of iterative solution within local minima [31, 36].

Over the past decade, Colton and coworkers [7, 9, 11] introduced an alternative, point-probing technique for solving inverse scattering problems in acoustics and electromagnetism, the so-called linear sampling method (LSM), that circumvents many of the foregoing impediments. This minimization-free approach to waveform tomography makes use of an ill-posed integral equation, written with reference to the obstacle-free domain, whose kernel is constructed from the observed waveforms and whose solution norm (used as an obstacle indicator) remains bounded *only* for sampling points strik-

ing the support of the scatterer. Owing to its computational efficiency and relative robustness (stemming from the circumvention of nonlinear optimization), the LSM has since been adapted to both far-field [1, 5, 34] and near-field [32] elastic scattering problems. Despite its inherent appeal, however, the existing formulation of the LSM for active imaging configurations in near-field elastodynamics [32], which postulates integration over the source region, may not be applicable to testing arrangements that are characterized by a limited density of "illuminating" sources (e.g., magnetic resonance elastography [23, 12, 39]). Beyond the issue of source *density*, the existing algorithm in [32], which makes use of the singular value decomposition, may face an additional set of difficulties related to significant computational cost and inaccurate singular values when dealing with large *amounts* of experimental data (e.g., large numbers of sources and receivers, regardless of their density) as in three-dimensional (3D) seismic imaging [38].

To transcend the foregoing impediments, the focus of this study is two-fold and includes (i) a reformulation of the LSM for near-field elastodynamics, to cater for active imaging configurations with only a limited density of excitation sources, and (ii) computational treatment of ill-conditioned linear systems, which establishes an alternative to singular value decomposition in situations involving significant amounts of experimental data. To this end, an *adjoint statement* of the so-called direct sampling method in [32] is proposed, wherein the inverse problem is formulated as a linear integral equation of the first kind, involving integration over the *measurement* (as opposed to the source) surface, whose solution becomes unbounded in the exterior of a hidden scatterer. A preconditioned conjugate gradient algorithm for solving ill-posed linear systems, established earlier for X-ray computed tomography [37], is adapted to provide an alternative computational treatment of the LSM in dealing with extensive data sets. A set of numerical examples is included to illustrate the performance of the proposed developments.

2. Problem formulation. This investigation deals with time-harmonic elastic wave imaging of an obstacle Ω_C that is strictly embedded in a uniform, isotropic, semi-infinite solid; see Figure 2.1. With reference to the Cartesian frame $\{O;\xi_1,\xi_2,\xi_3\}$ set at the top of the half-space, the background domain $\Omega = \{(\xi_1,\xi_2,\xi_3)|\,\xi_3>0\}$ is characterized by the Lamé constants λ and μ and the mass density ρ; its free surface $\{(\xi_1,\xi_2,\xi_3)|\,\xi_3=0\}$ is denoted by Σ. Adopting further the hypothesis of an "impenetrable" scatterer, Ω_C is taken to be in the form of a *cavity* with smooth boundary Γ of class $C^{1,\alpha}$, $\alpha\in(0,1]$. For further reference, let

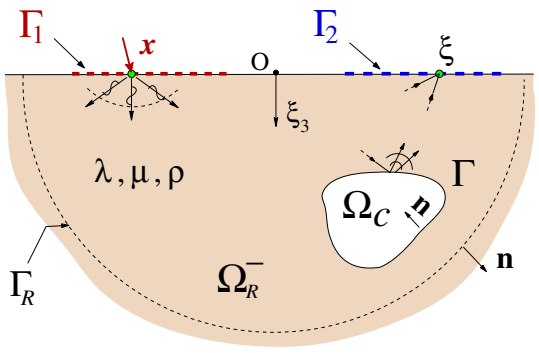

FIG. 2.1. *Illumination of an impenetrable obstacle in the semi-infinite solid by elastic waves.*

$\Omega^- = \Omega \setminus (\Omega_{\rm C} \cup \Gamma)$ denote the unbounded region surrounding the obstacle, and let $\Gamma_{\rm R} \subset \Omega$ be a hemisphere of radius R centered at the origin. The respective subsets of Ω and Ω^- that are bounded by $\Gamma_{\rm R}$ are denoted by $\Omega_{\rm R}$ and $\Omega^-_{\rm R}$, with an implicit assumption that R is sufficiently large such that $\Omega_{\rm C} \subset \Omega^-_{\rm R}$. As implied by the figure, the scatterer $\Omega_{\rm C}$ is exposed by time-harmonic sources acting on the source surface $\Gamma_1 \subset \Sigma$, with the induced solid motion monitored over the measurement area $\Gamma_2 \subset \Sigma$. In what follows, the frequency of excitation is denoted by ω, with the implicit time-harmonic factor $\mathrm{e}^{\mathrm{i}\omega t}$ omitted for brevity.

2.1. Direct scattering problem. In situations where the excitation source used to illuminate the obstacle is a *point force* of unit magnitude acting at $\boldsymbol{x} \in \Gamma_1$ in the kth coordinate direction, the elastodynamic displacement response of the perturbed reference solid Ω^- can be conveniently decomposed as

$$\boldsymbol{u}^k(\boldsymbol{\xi}, \boldsymbol{x}) \,=\, \mathring{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}) + \tilde{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}), \qquad \boldsymbol{\xi} \in \Omega^-, \quad \boldsymbol{x} \in \Gamma_1, \tag{2.1}$$

where $\tilde{\boldsymbol{u}}^k$ represents the scattered field ($\tilde{\boldsymbol{u}}^k \equiv \boldsymbol{0}$ in the absence of a scatterer) and $\mathring{\boldsymbol{u}}^k$ denotes the free field, i.e., the response of the obstacle-free solid Ω due to prescribed excitation. With such definitions, one has

$$\mathring{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}) = \hat{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}), \quad \boldsymbol{\xi} \neq \boldsymbol{x}, \quad \boldsymbol{\xi} \in \Omega, \quad \boldsymbol{x} \in \Gamma_1, \tag{2.2}$$

where $\hat{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x})$ is the elastodynamic (displacement) Green's function for a homogeneous semi-infinite solid [18] at $\boldsymbol{\xi} \in \Omega$ due to a unit time-harmonic point force acting at $\boldsymbol{x} \in \Gamma_1$ in the kth direction.

With reference to any smooth surface $S \subset \Omega$ with unit normal $\boldsymbol{n}$, it is further useful to introduce the traction vector

$$\boldsymbol{t}(\boldsymbol{\xi}; \boldsymbol{u}) = \boldsymbol{n}(\boldsymbol{\xi}) \cdot \mathbf{C} : \boldsymbol{\nabla} \boldsymbol{u}(\boldsymbol{\xi}), \quad \boldsymbol{\xi} \in S, \tag{2.3}$$

associated with the displacement field $\boldsymbol{u}$, where $\mathbf{C} = \lambda\, \mathbf{I}_2 \otimes \mathbf{I}_2 \,+\, 2\,\mu\, \mathbf{I}_4$ denotes the isotropic elasticity tensor and $\mathbf{I}_k$ ($k = 2, 4$) is the symmetric kth order identity tensor.

On the basis of (2.1)–(2.3), the forward problem associated with Figure 2.1 can be specified as a task of resolving the scattered field $\tilde{\boldsymbol{u}}^k$ from the knowledge of the free field $\mathring{\boldsymbol{u}}^k$ and the exact geometry of (impenetrable) scatterer $\Omega_{\rm C}$. More precisely, one is to find a $\tilde{\boldsymbol{u}}^k \in C^2(\Omega^-) \cap C^1(\Omega^- \cup \Gamma \cup \Sigma)$ satisfying the homogeneous Navier equation

$$\boldsymbol{L} \tilde{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}) + \rho \omega^2 \tilde{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}) = \boldsymbol{0}, \quad \boldsymbol{\xi} \in \Omega^-, \quad \boldsymbol{x} \in \Gamma_1, \tag{2.4}$$

and Neumann boundary conditions

$$\tilde{\boldsymbol{t}}^k(\boldsymbol{\xi}, \boldsymbol{x}) = \begin{cases} \boldsymbol{0}, & \boldsymbol{\xi} \in \Sigma, \\ -\mathring{\boldsymbol{t}}^k(\boldsymbol{\xi}, \boldsymbol{x}), & \boldsymbol{\xi} \in \Gamma, \end{cases} \qquad \boldsymbol{x} \in \Gamma_1, \tag{2.5}$$

where $\mathring{\boldsymbol{t}}^k = \boldsymbol{t}(\boldsymbol{\xi}; \mathring{\boldsymbol{u}}^k)$; $\tilde{\boldsymbol{t}}^k = \boldsymbol{t}(\boldsymbol{\xi}; \tilde{\boldsymbol{u}}^k)$ is understood in the sense of the trace [28, 30], and $\boldsymbol{L} = \mu \boldsymbol{\nabla}^2 + (\lambda + \mu) \boldsymbol{\nabla} \boldsymbol{\nabla} \cdot$ is the Lamé operator (see also [15]). To ensure the well-posedness of the forward scattering problem, the scattered field $\tilde{\boldsymbol{u}}^k$ must also satisfy the generalized radiation condition

$$\mathcal{R}(\tilde{\boldsymbol{u}}^k) := \lim_{R \to \infty} \int_{\Gamma_{\rm R}} \left\{ \hat{\boldsymbol{u}}^j(\boldsymbol{\xi}, \boldsymbol{y}) \cdot \tilde{\boldsymbol{t}}^k(\boldsymbol{\xi}, \boldsymbol{x}) - \hat{\boldsymbol{t}}^j(\boldsymbol{\xi}, \boldsymbol{y}) \cdot \tilde{\boldsymbol{u}}^k(\boldsymbol{\xi}, \boldsymbol{x}) \right\} dS_{\boldsymbol{\xi}} = 0, \tag{2.6}$$

$$\boldsymbol{y} \in \Omega, \quad j = 1, 2, 3,$$

common to all radiating solutions in a semi-infinite elastic solid [27]. In (2.6), $\hat{\boldsymbol{t}}^j(\boldsymbol{\xi},\boldsymbol{y}) = \boldsymbol{t}(\boldsymbol{\xi};\hat{\boldsymbol{u}}^j)$ is the traction vector associated with $\hat{\boldsymbol{u}}^j(\boldsymbol{\xi},\boldsymbol{y})$, i.e., the elastodynamic traction Green's function for the reference half-space Ω. As shown in [19], the generalized radiation condition applies equally when $\hat{\boldsymbol{u}}^j$ and $\hat{\boldsymbol{t}}^j$ in (2.6) are superseded by the respective displacements and tractions corresponding to *any radiating* elastodynamic state in Ω^-. To facilitate the ensuing presentation, this result can be applied to establish the equality

$$\lim_{R\to\infty}\int_{\Gamma_R}\left\{\tilde{\boldsymbol{u}}^j(\boldsymbol{\xi},\boldsymbol{y})\cdot\tilde{\boldsymbol{t}}^k(\boldsymbol{\xi},\boldsymbol{x})-\tilde{\boldsymbol{t}}^j(\boldsymbol{\xi},\boldsymbol{y})\cdot\tilde{\boldsymbol{u}}^k(\boldsymbol{\xi},\boldsymbol{x})\right\}dS_{\boldsymbol{\xi}} \;=\; 0, \qquad \boldsymbol{x},\boldsymbol{y}\in\Omega^-. \tag{2.7}$$

For completeness, it is also noted that the Green's functions featured in (2.6) satisfy

$$\begin{aligned} &\boldsymbol{L}\hat{\boldsymbol{u}}^j(\boldsymbol{\xi},\boldsymbol{y})+\rho\omega^2\hat{\boldsymbol{u}}^j(\boldsymbol{\xi},\boldsymbol{y})+\delta(\boldsymbol{\xi}-\boldsymbol{y})\boldsymbol{e}^j=\boldsymbol{0}, \qquad \boldsymbol{\xi},\boldsymbol{y}\in\Omega,\\ &\hat{\boldsymbol{t}}^j(\boldsymbol{\xi},\boldsymbol{y})=\boldsymbol{0}, \qquad \boldsymbol{\xi}\in\Sigma, \quad \boldsymbol{y}\in\Omega,\\ &\mathcal{R}(\hat{\boldsymbol{u}}^j)=0, \qquad \boldsymbol{\xi},\boldsymbol{y}\in\Omega, \end{aligned} \tag{2.8}$$

where $\boldsymbol{e}^j$ is the unit vector in the jth coordinate direction and $\hat{\boldsymbol{t}}^j$ on Σ is understood in the sense of the trace. In this setting, the Green's functions due to a "surface" point load as in (2.2) are interpreted in the limit as $\Omega\ni\boldsymbol{y}\to\Sigma$. Throughout this investigation, it is assumed that the forward scattering problem for the semi-infinite solid Ω^- given by (2.4), (2.5), and (2.6) admits a unique solution $\tilde{\boldsymbol{u}}^k\in H^1_{loc}(\Omega^-)$.

2.2. Inverse scattering problem. To formulate the reconstruction method, it is next instructive to introduce the *Green's tensor* $\widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})$ and the *scattered tensor* $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})$, both associated with a unit point source acting at $\boldsymbol{x}\in\Gamma_1$. In the reference Cartesian frame, the components of $\widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})$ can be arranged in a 3×3 matrix

$$\widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})=\begin{pmatrix}\hat{u}_1^1(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_1^2(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_1^3(\boldsymbol{\xi},\boldsymbol{x})\\ \hat{u}_2^1(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_2^2(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_2^3(\boldsymbol{\xi},\boldsymbol{x})\\ \hat{u}_3^1(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_3^2(\boldsymbol{\xi},\boldsymbol{x}) & \hat{u}_3^3(\boldsymbol{\xi},\boldsymbol{x})\end{pmatrix}, \quad \boldsymbol{\xi}\in\Omega\setminus\{\boldsymbol{x}\}, \quad \boldsymbol{x}\in\Gamma_1, \tag{2.9}$$

where $\hat{\boldsymbol{u}}^k=(\hat{u}_1^k,\hat{u}_2^k,\hat{u}_3^k)$ is the elastodynamic displacement Green's function for the semi-infinite solid Ω as examined before. Here it is useful to note that $\widehat{\boldsymbol{U}}$ is characterized by the reciprocity property [19], i.e., that $\widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})=[\widehat{\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{\xi})]^{\mathrm{T}}$ $(\boldsymbol{x}\neq\boldsymbol{\xi},\boldsymbol{x},\boldsymbol{\xi}\in\Omega)$, where superscript "$_{\mathrm{T}}$" denotes the matrix transpose.

By analogy to (2.9), the perturbation of $\widehat{\boldsymbol{U}}$ due to the presence of an obstacle can be written in the form of the scattered tensor

$$\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})=\begin{pmatrix}\tilde{u}_1^1(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_1^2(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_1^3(\boldsymbol{\xi},\boldsymbol{x})\\ \tilde{u}_2^1(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_2^2(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_2^3(\boldsymbol{\xi},\boldsymbol{x})\\ \tilde{u}_3^1(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_3^2(\boldsymbol{\xi},\boldsymbol{x}) & \tilde{u}_3^3(\boldsymbol{\xi},\boldsymbol{x})\end{pmatrix}, \quad \boldsymbol{\xi}\in\Omega^-, \quad \boldsymbol{x}\in\Gamma_1, \tag{2.10}$$

where $\tilde{u}_j^k$ is the jth Cartesian component of the scattered field at $\boldsymbol{\xi}\in\Omega^-$ due to a unit point source acting at $\boldsymbol{x}\in\Gamma_1$ in the kth coordinate direction so that $\tilde{\boldsymbol{u}}^k=(\tilde{u}_1^k,\tilde{u}_2^k,\tilde{u}_3^k)$. With reference to (2.3) and (2.9), one may further introduce the *traction Green's tensor*

$$\widehat{\boldsymbol{T}}(\boldsymbol{\xi},\boldsymbol{x})=\boldsymbol{n}(\boldsymbol{\xi})\cdot\mathbf{C}:\boldsymbol{\nabla}_{\boldsymbol{\xi}}\widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x}), \quad \boldsymbol{\xi}\in S\setminus\{\boldsymbol{x}\}, \quad \boldsymbol{x}\in\Gamma_1, \tag{2.11}$$

for any smooth surface $S\subset\Omega$ with unit normal $\boldsymbol{n}$.

With the above definitions, the inverse problem of interest can be specified as a task of reconstructing an impenetrable obstacle $\Omega_{\rm C}$ from the knowledge of the scattered tensor $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})$ for *all* observation points $\boldsymbol{\xi}\in\Gamma_2\subset\Sigma$ and *all* source points $\boldsymbol{x}\in\Gamma_1\subset\Sigma$. In what follows, this problem will be solved by generalizing upon the LSM for near-field elastodynamics proposed in [32], which assumes a continuous representation of $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})$ over $\Gamma_1\times\Gamma_2$ as an experimental input. In practice, however, $\widetilde{\boldsymbol{U}}$ is constructed using spatially discrete measurements, which necessitates a sufficient density of the source and observation points. One of the key objectives in this study is to relax the former requirement in terms of the density of excitation sources through a rigorous mathematical reformulation of the existing technique.

3. Preliminaries. Initially developed by Colton and Kirsch [7] in the context of far-field acoustics, the LSM for the *full waveform* (i.e., near-field) obstacle identification in elastodynamics was shown in [32] to revolve around the linear integral equation

$$(\boldsymbol{F}\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}})(\boldsymbol{\xi}) = \widehat{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{z})\cdot\boldsymbol{d},\qquad \boldsymbol{\xi}\in\Gamma_2,\quad \boldsymbol{z}\in\Omega,\quad \boldsymbol{d}\in\mathbb{R}^3, \tag{3.1}$$

of the first kind, where the near-field operator $\boldsymbol{F}\colon L_2(\Gamma_1)\to L_2(\Gamma_2)$ is defined as

$$(\boldsymbol{F}\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}})(\boldsymbol{\xi}) := \int_{\Gamma_1}\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})\cdot\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}(\boldsymbol{x})\,dS_{\boldsymbol{x}},\quad \boldsymbol{\xi}\in\Gamma_2; \tag{3.2}$$

$\widetilde{\boldsymbol{U}}$ synthesizes the experimental observations, $\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}(\cdot)\equiv\boldsymbol{g}(\cdot;\boldsymbol{z},\boldsymbol{d})\in L_2(\Gamma_1)$ is the unknown vector density, and $\boldsymbol{d}$ is a unit vector ($\|\boldsymbol{d}\|=1$) signifying the polarization of a "fictitious" point source on the right-hand side of (3.1) acting at *sampling point* $\boldsymbol{z}$. Here $L_2(S)$ denotes the Hilbert space of square-integrable vector fields equipped with the inner product

$$(\boldsymbol{g},\boldsymbol{h})_{L_2(S)} = \int_S \overline{\boldsymbol{g}}(\boldsymbol{x})\cdot\boldsymbol{h}(\boldsymbol{x})\,dS_{\boldsymbol{x}}, \tag{3.3}$$

the overbar implies complex conjugation, and $S\subset\Sigma$ is a generic planar surface of finite extent. In what follows, it is assumed that $\boldsymbol{d}\in\mathbb{R}^3$ and $\|\boldsymbol{d}\|=1$.

For sampling points inside the support of the obstacle, i.e., $\boldsymbol{z}\in\Omega_{\rm C}$, it can be shown under certain restrictions on ω as in [32] that (i) the near-field operator $\boldsymbol{F}$ is injective, (ii) $\boldsymbol{F}$ has a dense range so that (3.1) can be solved at least approximately, and (iii) the solution norm $\|\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_1)}$ becomes unbounded as the sampling point $\boldsymbol{z}\in\Omega_{\rm C}$ approaches boundary Γ of the scatterer $\Omega_{\rm C}$ from its interior. Using the concept of topological derivative [20], it is also shown that $\|\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_1)}$ can be made arbitrarily large when $\boldsymbol{z}$ lies outside of the support of the scatterer, i.e., $\boldsymbol{z}\in\Omega^-$. This unbounded behavior of $\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}$ has prompted the use of $1/\|\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_1)}$, $\boldsymbol{z}\in\Omega$, as a characteristic function of the hidden obstacle $\Omega_{\rm C}$.

Unfortunately, integral representation (3.2) and thus (3.1) do not make much sense if the density of source points on the source surface Γ_1 is insufficient, a situation that is common to many physical testing configurations. To mitigate the problem, it is useful to consider an alternative statement of the LSM wherein the integrals involved are taken over the observation surface Γ_2 rather than the source surface Γ_1.

For the ensuing developments, it is useful to recall Betti's integral identities of linear elasticity (see [26]). To this end, let D be a finite homogeneous elastic body with boundary ∂D of class $C^{1,\alpha}$, and let $\boldsymbol{n}$ denote the unit outward normal on ∂D.

With such a premise Betti's third formula for vector fields $\boldsymbol{u}, \boldsymbol{v} \in C^2(D) \cap C^1(\overline{D})$ can be written as

$$\int_D [\boldsymbol{v}(\boldsymbol{\xi}) \cdot \boldsymbol{L}\boldsymbol{u}(\boldsymbol{\xi}) - \boldsymbol{u}(\boldsymbol{\xi}) \cdot \boldsymbol{L}\boldsymbol{v}(\boldsymbol{\xi})] dV_{\boldsymbol{\xi}} = \int_{\partial D} [\boldsymbol{v}(\boldsymbol{\xi}) \cdot \boldsymbol{t}(\boldsymbol{\xi}; \boldsymbol{u}) - \boldsymbol{u}(\boldsymbol{\xi}) \cdot \boldsymbol{t}(\boldsymbol{\xi}; \boldsymbol{v})] dS_{\boldsymbol{\xi}}, \tag{3.4}$$

where $\boldsymbol{t}(\boldsymbol{\xi}; \boldsymbol{u})$ is given by (2.3) and $\boldsymbol{L}$ is the Lamé operator as examined before.

To formulate the counterpart of (3.1) in terms of an alternative near-field operator that entails integration over the receiver surface, it is essential to show that the scattered tensor in (2.10) is reciprocal. This result is established next.

THEOREM 3.1 (reciprocity). *For the scattering by a cavity, the following symmetry holds:*

$$\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x}) = [\widetilde{\boldsymbol{U}}(\boldsymbol{x}, \boldsymbol{\xi})]^{\mathrm{T}}, \quad \boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-. \tag{3.5}$$

Proof. Let Ω_{C} be fixed, and let $\tilde{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x})$ and $\tilde{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})$ be the scattered fields at $\boldsymbol{\zeta} \in \Omega^-$ due to point forces acting respectively at $\boldsymbol{x} \in \Omega^-$ in the kth coordinate direction and $\boldsymbol{\xi} \in \Omega^-$ in the jth coordinate direction. Next, select R so that $\boldsymbol{\zeta}, \boldsymbol{x}, \boldsymbol{\xi} \in \Omega_{\mathrm{R}}^-$ as well. On the basis of Betti's third formula (3.4) applied to Ω_{R}^-, homogeneous Navier equations in terms of $\tilde{\boldsymbol{u}}^k$ and $\tilde{\boldsymbol{u}}^j$ over Ω^-, the homogeneous Neumann condition in (2.5), and the radiation condition (2.7), it can be shown in the limit as $R \to \infty$ that

$$\int_\Gamma [\tilde{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) \cdot \tilde{\boldsymbol{t}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) - \tilde{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) \cdot \tilde{\boldsymbol{t}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})] dS_{\boldsymbol{\zeta}} = 0, \quad \boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-. \tag{3.6}$$

Similarly, application of Betti's third formula and the use of the homogeneous Navier equations in terms of Green's functions $\hat{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x})$ and $\hat{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})$ over the interior domain Ω_{C} yield the identity

$$\int_\Gamma [\hat{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) \cdot \hat{\boldsymbol{t}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) - \hat{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) \cdot \hat{\boldsymbol{t}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})] dS_{\boldsymbol{\zeta}} = 0, \quad \boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-, \tag{3.7}$$

where, owing to the vanishing right-hand side, the boundary normal $\boldsymbol{n}$ (implicit to $\hat{\boldsymbol{t}}^j$ and $\hat{\boldsymbol{t}}^k$) can be taken as oriented toward the interior of Ω_{C} for consistency with (3.6). For $\boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-$, one can next write the boundary integral representations

$$\begin{aligned} \tilde{u}_j^k(\boldsymbol{\xi}, \boldsymbol{x}) &= \int_\Gamma [\hat{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) \cdot \tilde{\boldsymbol{t}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) - \hat{\boldsymbol{t}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) \cdot \tilde{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x})] dS_{\boldsymbol{\zeta}}, \\ \tilde{u}_k^j(\boldsymbol{x}, \boldsymbol{\xi}) &= \int_\Gamma [\hat{\boldsymbol{u}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) \cdot \tilde{\boldsymbol{t}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) - \hat{\boldsymbol{t}}^k(\boldsymbol{\zeta}, \boldsymbol{x}) \cdot \tilde{\boldsymbol{u}}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})] dS_{\boldsymbol{\zeta}}, \quad \boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-, \end{aligned} \tag{3.8}$$

of the scattered field; see, e.g., [2]. On subtracting (3.8b) from the sum of (3.6), (3.7), and (3.8a), one finds that

$$\tilde{u}_j^k(\boldsymbol{\xi}, \boldsymbol{x}) - \tilde{u}_k^j(\boldsymbol{x}, \boldsymbol{\xi}) = \int_\Gamma [\boldsymbol{u}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) \cdot \boldsymbol{t}^k(\boldsymbol{\zeta}, \boldsymbol{x}) - \boldsymbol{u}^k(\boldsymbol{\zeta}, \boldsymbol{x}) \cdot \boldsymbol{t}^j(\boldsymbol{\zeta}, \boldsymbol{\xi})] dS_{\boldsymbol{\zeta}}, \quad \boldsymbol{x}, \boldsymbol{\xi} \in \Omega^-, \tag{3.9}$$

where $\boldsymbol{u}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) = \hat{\boldsymbol{u}}^j + \tilde{\boldsymbol{u}}^j$ and $\boldsymbol{t}^j(\boldsymbol{\zeta}, \boldsymbol{\xi}) = \hat{\boldsymbol{t}}^j + \tilde{\boldsymbol{t}}^j$ denote respectively the *total* displacement and traction vectors at $\boldsymbol{\zeta} \in \Gamma$ due to a point source acting at $\boldsymbol{\xi} \in \Omega^-$ in the jth coordinate direction. By virtue of the fact that $\boldsymbol{t}^j(\boldsymbol{\zeta}, \cdot) = \boldsymbol{t}^k(\boldsymbol{\zeta}, \cdot) \equiv \boldsymbol{0}$ for $\boldsymbol{\zeta} \in \Gamma$ according to (2.5), the right-hand side of (3.9) vanishes identically, which, through (2.10), completes the proof. ∎

One of the key steps in establishing the rationale for (3.1) is the proof that (3.2) represents a scattered field in Ω^-. The following theorem and its lemma aim to establish an analogous result for the sought "source-friendly" variant of (3.1).

THEOREM 3.2. *Let $\Gamma_2 \subset \Sigma$ be a surface of finite extent, and let $\boldsymbol{h} \in L_2(\Gamma_2)$. Then the single-layer potential*

$$\boldsymbol{v}(\boldsymbol{x}) = \int_{\Gamma_2} [\widehat{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x})]^{\mathrm{T}} \cdot \boldsymbol{h}(\boldsymbol{\xi})\, dS_{\boldsymbol{\xi}} = \int_{\Gamma_2} \hat{\boldsymbol{u}}^k(\boldsymbol{x}, \boldsymbol{\xi})\, h_k(\boldsymbol{\xi})\, dS_{\boldsymbol{\xi}}, \quad \boldsymbol{x} \in \Omega, \tag{3.10}$$

is a radiating solution of the homogeneous Navier equation in Ω so that

$$\begin{aligned} \boldsymbol{L}\boldsymbol{v}(\boldsymbol{x}) + \rho\omega^2 \boldsymbol{v}(\boldsymbol{x}) &= \boldsymbol{0}, \quad \boldsymbol{x} \in \Omega, \\ \boldsymbol{t}(\boldsymbol{x}; \boldsymbol{v}) = \boldsymbol{0}, \quad \boldsymbol{x} \in \Sigma \backslash \Gamma_2, &\qquad \mathcal{R}(\boldsymbol{v}) = 0, \quad \boldsymbol{x} \in \Omega, \end{aligned} \tag{3.11}$$

where $\boldsymbol{t}(\boldsymbol{x}; \boldsymbol{v}) = \boldsymbol{n}(\boldsymbol{x}) \cdot \mathbf{C} : \boldsymbol{\nabla} \boldsymbol{v}(\boldsymbol{x})$ is the traction vector associated with $\boldsymbol{v}$, understood in the sense of the trace.

Proof. For $\boldsymbol{x} \in \Omega$ and $\boldsymbol{\xi} \in \Gamma_2$, $\boldsymbol{u}^k(\boldsymbol{x}, \boldsymbol{\xi})$ are regular since $\Omega \cap \Gamma_2 = \emptyset$, and (3.10) accordingly permits differentiation under the integral sign. With such a result, (3.11) follows directly from the fact that $\hat{\boldsymbol{u}}^k$ $(k = 1, 2, 3)$ satisfies the homogeneous Navier equation away from the source surface Γ_2. In a similar fashion, the homogeneous Neumann condition in (3.11) can be obtained by means of (3.10) and the limit of (2.8b) when the source point $\boldsymbol{y} \to \Gamma_2$. On the basis of (2.3) and (3.10), on the other hand, one finds that for any $\boldsymbol{y} \in \Omega$

$$\begin{aligned} &\int_{\Gamma_{\mathrm{R}}} \left\{ \hat{\boldsymbol{u}}^j(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{t}(\boldsymbol{x}; \boldsymbol{v}) - \hat{\boldsymbol{t}}^j(\boldsymbol{x}, \boldsymbol{y}) \cdot \boldsymbol{v}(\boldsymbol{x}) \right\} dS_{\boldsymbol{x}} \\ &= \int_{\Gamma_2} h_k(\boldsymbol{\eta}) \int_{\Gamma_{\mathrm{R}}} \left\{ \hat{\boldsymbol{u}}^j(\boldsymbol{x}, \boldsymbol{y}) \cdot \hat{\boldsymbol{t}}^k(\boldsymbol{x}, \boldsymbol{\eta}) - \hat{\boldsymbol{t}}^j(\boldsymbol{x}, \boldsymbol{y}) \cdot \hat{\boldsymbol{u}}^k(\boldsymbol{x}, \boldsymbol{\eta}) \right\} \mathrm{d}S_{\boldsymbol{x}}\, dS_{\boldsymbol{\eta}} \end{aligned} \tag{3.12}$$

over a hemispherical surface Γ_{R}, where R is taken sufficiently large so that $\Gamma_2 \subset \partial\Omega_{\mathrm{R}}$ and $\boldsymbol{y} \in \Omega_{\mathrm{R}}$. By virtue of (3.12), statement $\mathcal{R}(\boldsymbol{v}) = 0$ in (3.11) immediately follows from the fact that the displacement Green's function $\hat{\boldsymbol{u}}^k(\cdot, \boldsymbol{z})$ is a radiating elastodynamic solution in $\Omega \backslash \{\boldsymbol{z}\}$; see [19]. ∎

LEMMA 3.3. *For a given vector density $\boldsymbol{h} \in L_2(\Gamma_2)$, the radiating solution to the scattering problem for a cavity Ω_C in the semi-infinite reference solid Ω illuminated by the free field*

$$\mathring{\boldsymbol{v}}(\boldsymbol{x}) = (\boldsymbol{E}\boldsymbol{h})(\boldsymbol{x}) \equiv \int_{\Gamma_2} [\widehat{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x})]^{\mathrm{T}} \cdot \boldsymbol{h}(\boldsymbol{\xi})\, dS_{\boldsymbol{\xi}}, \quad \boldsymbol{x} \in \Omega, \tag{3.13}$$

is given by the scattered field

$$\tilde{\boldsymbol{v}}(\boldsymbol{x}) = \int_{\Gamma_2} [\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x})]^{\mathrm{T}} \cdot \boldsymbol{h}(\boldsymbol{\xi})\, dS_{\boldsymbol{\xi}}, \quad \boldsymbol{x} \in \Omega^-, \tag{3.14}$$

where $\widehat{\boldsymbol{U}}$ and $\widetilde{\boldsymbol{U}}$ are given respectively by (2.9) *and* (2.10).

Proof. With the aid of (2.10) and the reciprocity property (3.5) established in Theorem 3.1, formula (3.14) can be rewritten as

$$\tilde{v}_j(\boldsymbol{x}) = \int_{\Gamma_2} \tilde{u}_j^k(\boldsymbol{x}, \boldsymbol{\xi})\, h_k(\boldsymbol{\xi})\, dS_{\boldsymbol{\xi}}, \qquad \boldsymbol{x} \in \Omega^-, \quad j = 1, 2, 3. \tag{3.15}$$

By virtue of (2.5), integral representation of the scattered field $\tilde{\boldsymbol{u}}^k$ in Ω^- in terms of the total field $\boldsymbol{u}^k$ over the cavity boundary Γ can be written as

$$\tilde{u}_j^k(\boldsymbol{x},\boldsymbol{\xi}) = -\int_\Gamma \hat{\boldsymbol{t}}^j(\boldsymbol{\eta},\boldsymbol{x})\cdot\boldsymbol{u}^k(\boldsymbol{\eta},\boldsymbol{\xi})\,dS_{\boldsymbol{\eta}}, \quad \boldsymbol{x}\in\Omega^-, \quad \boldsymbol{\xi}\in\Gamma_2; \tag{3.16}$$

see, e.g., [21]. By use of (3.16) in (3.15) and interchanging the order of integration, one finds

$$\tilde{v}_j(\boldsymbol{x}) = -\int_\Gamma \hat{\boldsymbol{t}}^j(\boldsymbol{\eta},\boldsymbol{x})\cdot\boldsymbol{v}(\boldsymbol{\eta})\,dS_{\boldsymbol{\eta}}, \quad \boldsymbol{x}\in\Omega^-, \tag{3.17}$$

where

$$\boldsymbol{v}(\boldsymbol{\eta}) = \int_{\Gamma_2} \boldsymbol{u}^k(\boldsymbol{\eta},\boldsymbol{\xi})\,h_k(\boldsymbol{\xi})\,dS_{\boldsymbol{\xi}}, \quad \boldsymbol{\eta}\in\Gamma. \tag{3.18}$$

From (3.17), it is seen that $\tilde{\boldsymbol{v}}(\boldsymbol{x})$ admits a representation in terms of a double-layer potential similar to that in (3.16). Since $\boldsymbol{x}\in\Omega^-$, it can be shown [27] using the radiating property of $\hat{\boldsymbol{u}}^k$ that the right-hand side of (3.17) is itself a *radiating* solution of the homogeneous Navier equation in Ω^- so that

$$\begin{aligned} \boldsymbol{L}\tilde{\boldsymbol{v}}(\boldsymbol{x}) + \rho\omega^2\tilde{\boldsymbol{v}}(\boldsymbol{x}) &= \boldsymbol{0}, \qquad \boldsymbol{x}\in\Omega^-, \\ \mathcal{R}(\tilde{\boldsymbol{v}}) &= 0, \qquad \boldsymbol{x}\in\Omega^-. \end{aligned} \tag{3.19}$$

On applying (2.3) to (3.13) and (3.15) and interchanging the order of integral and differential operators, one finds from (2.5) that

$$\boldsymbol{t}(\boldsymbol{y};\tilde{\boldsymbol{v}}) \;=\; \int_{\Gamma_2} \tilde{\boldsymbol{t}}^k(\boldsymbol{y},\boldsymbol{\xi})\,h_k(\boldsymbol{\xi})\,dS_{\boldsymbol{\xi}} \;=\; \begin{cases} \boldsymbol{0}, & \boldsymbol{y}\in\Sigma, \\ -\boldsymbol{t}(\boldsymbol{y};\mathring{\boldsymbol{v}}), & \boldsymbol{y}\in\Gamma, \end{cases} \tag{3.20}$$

in the limits as $\boldsymbol{x}\to\boldsymbol{y}\in\Sigma$ and $\boldsymbol{x}\to\boldsymbol{y}\in\Gamma$, respectively. Given the fact that $\Gamma=\partial\Omega_{\rm C}$ and $\Omega^-=\Omega\setminus(\Omega_{\rm C}\cup\Gamma)$, equations (3.19) and (3.20) indeed demonstrate that $\tilde{\boldsymbol{v}}$ is a radiating solution to the scattering problem for a cavity $\Omega_{\rm C}$ due to free field (3.13). ∎

4. Adjoint formulation of the LSM. With the foregoing developments, linear sampling equation (3.1) aiding the full waveform tomography of semi-infinite elastic solids can now be reformulated so that the featured integration is performed over the receiver surface Γ_2 in lieu of Γ_1. To this end, let the sampling point $\boldsymbol{z}\in\Omega$ be fixed. The idea is to establish an alternative near-field operator $\boldsymbol{G}\colon L_2(\Gamma_2)\to L_2(\Gamma_1)$ that synthesizes experimental observations in terms of the scattered tensor $\widetilde{\boldsymbol{U}}$, and to seek the vector density $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}(\cdot)\equiv\boldsymbol{h}(\cdot;\boldsymbol{z},\boldsymbol{d})\in L_2(\Gamma_2)$ as a solution to the integral equation of the first kind

$$(\boldsymbol{G}\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}})(\boldsymbol{x}) \;=\; \widehat{\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{z})\cdot\boldsymbol{d}, \qquad \boldsymbol{x}\in\Gamma_1, \quad \boldsymbol{z}\in\Omega, \quad \boldsymbol{d}\in\mathbb{R}^3, \tag{4.1}$$

where $\boldsymbol{d}$ is a fixed polarization vector ($\|\boldsymbol{d}\|=1$) as examined earlier. Adopting fundamental hypotheses of the LSM, $\boldsymbol{G}$ must be designed so that, under certain restrictions on the excitation frequency ω, the following statements apply:

- For $\boldsymbol{z}\in\Omega_{\rm C}$, operator $\boldsymbol{G}$ is injective and has a dense range. The solution of (4.1) further has the property $\lim_{\boldsymbol{z}\to\boldsymbol{y}\in\Gamma}\|\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_2)}=\infty$.

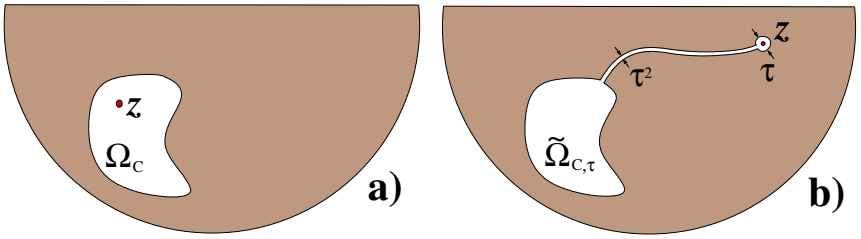

FIG. 4.1. *Sampling cases:* (a) $\boldsymbol{z}\in\Omega_C$, *"true" obstacle;* (b) $\boldsymbol{z}\in\Omega\setminus\overline{\Omega}_C$, *perturbed obstacle.*

- For $\boldsymbol{z}\in\Omega\setminus(\Omega_{\rm C}\cup\Gamma)$, there exists an approximate solution $\boldsymbol{h}^{\tau}_{\boldsymbol{z},\boldsymbol{d}}$ to (4.1) such that $\lim_{\tau\to 0}\|\boldsymbol{h}^{\tau}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_2)}=\infty$, where τ is the approximation parameter. With reference to Figure 4.1, approximate solution $\boldsymbol{h}^{\tau}_{\boldsymbol{z},\boldsymbol{d}}$ is understood in the sense of a perturbed scatterer domain $\widetilde{\Omega}_{{\rm C},\tau}\ni z$ [32].

With such prerequisites, the *unboundedness* property of the sought vector density $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}$ can then be used to reconstruct a hidden cavity $\Omega_{\rm C}$ by probing the subsurface volume of interest through an array of sampling points $\boldsymbol{z}$, and identifying $\Omega_{\rm C}$ via an assembly of points where $\|\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_2)}$ is bounded. As elucidated earlier, such an identification procedure would make sense even when the density of source points on Γ_1, used to illuminate the cavity, is limited.

To facilitate the ensuing developments, it is useful to make reference to the near-field operator $\boldsymbol{F}$ in (3.2) and introduce its adjoint counterpart $\boldsymbol{F}^*: L_2(\Gamma_2)\to L_2(\Gamma_1)$ by the ensuing proposition.

LEMMA 4.1. *For all* $\boldsymbol{g}\in L_2(\Gamma_1)$ *and* $\boldsymbol{e}\in L_2(\Gamma_2)$,

$$(\boldsymbol{F}\boldsymbol{g},\boldsymbol{e})_{L_2(\Gamma_2)} \;=\; (\boldsymbol{g},\boldsymbol{F}^*\boldsymbol{e})_{L_2(\Gamma_1)}, \tag{4.2}$$

where $\boldsymbol{F}$ *is defined by* (3.2) *and*

$$(\boldsymbol{F}^*\boldsymbol{e})(\boldsymbol{x}) := \int_{\Gamma_2}[\overline{\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})}]^{\rm T}\cdot\boldsymbol{e}(\boldsymbol{\xi})\,dS_{\boldsymbol{\xi}},\quad \boldsymbol{x}\in\Gamma_1, \tag{4.3}$$

where an overbar symbol denotes complex conjugation.

Proof. The statement of the lemma in terms of (4.2) and (4.3) can be established using (3.2) and (3.3) and interchanging the order of integration. ∎

To arrive at a form of $\boldsymbol{G}$ that yields the required solvability and unboundedness properties in terms of $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}$, one is tempted to employ the result of Lemma 4.1 and postulate the integral equation

$$\int_{\Gamma_2}[\overline{\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})}]^{\rm T}\cdot\boldsymbol{e}(\boldsymbol{\xi})\,dS_{\boldsymbol{\xi}} \;=\; [\overline{\widehat{\boldsymbol{U}}(\boldsymbol{z},\boldsymbol{x})}]^{\rm T}\cdot\boldsymbol{d},\qquad \boldsymbol{x}\in\Gamma_1,\quad \boldsymbol{z}\in\Omega, \tag{4.4}$$

as a basis for the "source-friendly"alternative to (3.1). On employing the symmetry of the elastodynamic displacement Green's tensor (2.9) and letting $\boldsymbol{h}=\overline{\boldsymbol{e}}$, integral equation (4.4) can be conveniently rewritten as (4.1), where

$$(\boldsymbol{G}\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}})(\boldsymbol{x}) := \int_{\Gamma_2}[\widetilde{\boldsymbol{U}}(\boldsymbol{\xi},\boldsymbol{x})]^{\rm T}\cdot\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}(\boldsymbol{\xi})\,dS_{\boldsymbol{\xi}},\quad \boldsymbol{x}\in\Gamma_1. \tag{4.5}$$

With reference to Lemma 3.3, the conjugation of (4.4) represents a key step in establishing (4.1) that features the near-field operator (4.5) as a *radiating* elastodynamic

field in the sense of (2.6) and thus enables a direct use of the results obtained in section 3. It is also useful to note that, for $\widetilde{\boldsymbol{U}} \in L_2(\Gamma_1 \times \Gamma_2)$, the near-field operator $\boldsymbol{G}$ is well defined, linear, and bounded from $L_2(\Gamma_2)$ into $L_2(\Gamma_1)$. The latter property can be demonstrated via the Cauchy-Schwarz inequality

$$\|\boldsymbol{G}\boldsymbol{h}\|^2_{L_2(\Gamma_1)} \leq \|\boldsymbol{h}\|^2_{L_2(\Gamma_2)} \left(\sum_{k=1}^{3} \sum_{j=1}^{3} \int_{\Gamma_1} \int_{\Gamma_2} \left| \tilde{u}^k_j(\boldsymbol{\xi}, \boldsymbol{x}) \right|^2 dS_{\boldsymbol{x}}\, dS_{\boldsymbol{\xi}} \right), \tag{4.6}$$

where $|\cdot|$ denotes the complex modulus. It can also be shown (see, e.g., [25]) that the linear integral operator $\boldsymbol{G}$ is *compact* from $L_2(\Gamma_2)$ into $L_2(\Gamma_1)$, thus rendering the linear equation (4.1) ill-posed.

4.1. Mathematical justification of the adjoint method. To validate the proposed developments, it is next necessary to establish the injectivity, denseness, and unboundedness theorems characterizing the solution of (4.1). For brevity, attention is herein focused on the "default" case when $\boldsymbol{z} \in \Omega_{\mathrm{C}}$. Following the approach taken in [32], situations with $\boldsymbol{z} \notin \Omega_{\mathrm{C}}$ can be effectively treated by considering the perturbed scatterer $\widetilde{\Omega}_{\mathrm{C},\tau}$ with a vanishing appendage (see Figure 4.1(b)) so that $\boldsymbol{z} \in \widetilde{\Omega}_{\mathrm{C},\tau}$ and investigating the behavior of such perturbed (4.1) as $\tau \to 0$.

THEOREM 4.2 (solvability). *Let Ω_C be a cavity. Then the equation*

$$(\boldsymbol{G}\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}})(\boldsymbol{x}) \;=\; \widehat{\boldsymbol{U}}(\boldsymbol{x}, \boldsymbol{z}) \cdot \boldsymbol{d}, \qquad \boldsymbol{x} \in \Gamma_1, \quad \boldsymbol{z} \in \Omega_C, \tag{4.7}$$

where $\boldsymbol{G}$ is given by (4.5)*, possesses a solution $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}} \in L_2(\Gamma_2)$ if and only if there exists an elastodynamic solution $\mathring{\boldsymbol{v}}$ to the interior Neumann problem*

$$\begin{aligned} \boldsymbol{L}\mathring{\boldsymbol{v}}(\boldsymbol{x}) + \rho\,\omega^2 \mathring{\boldsymbol{v}}(\boldsymbol{x}) &= \boldsymbol{0}, \quad \boldsymbol{x} \in \Omega_C, \\ \boldsymbol{t}(\boldsymbol{x}; \mathring{\boldsymbol{v}}) + \widehat{\boldsymbol{T}}(\boldsymbol{x}, \boldsymbol{z}) \cdot \boldsymbol{d} &= \boldsymbol{0}, \quad \boldsymbol{x} \in \Gamma, \end{aligned} \tag{4.8}$$

that permits a representation in the form of the single-layer potential (3.13).
