Proof. Let $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}} \in L_2(\Gamma_2)$ be a solution to the integral equation (4.7). From the results of Theorem 3.2 and Lemma 3.3, it follows directly that the free field $\mathring{\boldsymbol{v}} = \boldsymbol{E}\boldsymbol{h}$ and the induced scattered field $\tilde{\boldsymbol{v}} = \boldsymbol{G}\boldsymbol{h}$ are both radiating solutions in Ω^-. In addition, the single-layer potential (3.13) satisfies the homogeneous Navier equation in Ω_{C}, owing to the fact that $\Gamma_2 \cap \Omega_{\mathrm{C}} = \emptyset$. Accordingly, (4.8) is obtained from (4.7), the Holmgren's uniqueness theorem [17], and the Neumann boundary conditions (2.5) on Γ. Conversely let $\mathring{\boldsymbol{v}} = \boldsymbol{E}\boldsymbol{h}$, which solves the interior Neumann problem (4.8), be taken as a free field for the scattering by a cavity Ω_{C}. By virtue of Lemma 3.3 and the fact that $\boldsymbol{z} \in \Omega_{\mathrm{C}}$, both the (induced) scattered field $\tilde{\boldsymbol{v}}$ and the Green's function $\widehat{\boldsymbol{U}}(\cdot, \boldsymbol{z}) \cdot \boldsymbol{d}$ are radiating solutions in Ω^- satisfying the homogeneous Navier equation. Owing to (2.5), (4.8b), and the uniqueness of the solution to the scattering problem (2.4)–(2.6) (see [27]), the induced scattered field $(\boldsymbol{G}\boldsymbol{h})(\boldsymbol{x}) = \widehat{\boldsymbol{U}}(\boldsymbol{x}) \cdot \boldsymbol{d}$ in Ω^- and (4.7) follows in the limit as $\boldsymbol{x} \to \boldsymbol{y} \in \Gamma_1$. ∎

Unfortunately, the solution of the interior Neumann problem (4.8) may not permit representation $\mathring{\boldsymbol{v}} = \boldsymbol{E}\boldsymbol{h}$ with $\boldsymbol{h} \in L_2(\Gamma_2)$ in many situations. To examine the approximating characteristics of (3.13), assume that $D \subset \Omega$ is a bounded domain with boundary ∂D of class $C^{1,\alpha}$, and let $H^1(D)$ be a Sobolev space of vector fields equipped with the inner product

$$(\boldsymbol{v}, \boldsymbol{u})_{H^1(D)} \;=\; \theta \int_D \overline{\boldsymbol{v}}(\boldsymbol{\xi}) \cdot \boldsymbol{u}(\boldsymbol{\xi})\, dV_{\boldsymbol{\xi}} + \int_D \boldsymbol{\nabla}\overline{\boldsymbol{v}}(\boldsymbol{\xi}) \mathbin{:} \mathbf{C} \mathbin{:} \boldsymbol{\nabla}\boldsymbol{u}(\boldsymbol{\xi})\, dV_{\boldsymbol{\xi}}, \tag{4.9}$$

where $\mathbb{R} \ni \theta > 0$. With such definitions, one may introduce $\mathbb{H}(D)$ as a set of classical solutions to the homogeneous Navier equation

$$\mathbb{H}(D) = \big\{ \boldsymbol{u} \in C^2(D) \cap C^1(\overline{D}) : \boldsymbol{L}\boldsymbol{u} + \rho\omega^2 \boldsymbol{u} = \boldsymbol{0} \ \text{ in } D \big\},$$

whose closure, $\overline{\mathbb{H}(D)}$, is defined with respect to the norm $\|\boldsymbol{u}\|_{H^1(D)} = \sqrt{(\boldsymbol{u},\boldsymbol{u})_{H^1(D)}}$. Next, consider the single-layer integral operator $\boldsymbol{S} : L_2(\Gamma_2) \to \overline{\mathbb{H}(D)}$ given by

$$(\boldsymbol{S}\boldsymbol{h})(\boldsymbol{\xi}) := \int_{\Gamma_2} [\widehat{\boldsymbol{U}}(\boldsymbol{x},\boldsymbol{\xi})]^{\mathrm{T}} \cdot \boldsymbol{h}(\boldsymbol{x})\, dS_{\boldsymbol{x}}, \quad \boldsymbol{\xi} \in D. \tag{4.10}$$

For $\Gamma_2 \cap \overline{D} = \emptyset$, assumed in this study, $\boldsymbol{S}\boldsymbol{h} \in C^\infty\left(\overline{D}\right) \subset \{C^2(D) \cap C^1(\overline{D})\}$. By virtue of this result and the fact that $\boldsymbol{S}\boldsymbol{h}$ satisfies the homogeneous Navier equation in D according to Theorem 3.2, it immediately follows that $\boldsymbol{S}\boldsymbol{h} \in \mathbb{H}(D)$.

THEOREM 4.3 (range denseness). *The space of single-layer potentials* $\{\boldsymbol{S}\boldsymbol{h}, \boldsymbol{h} \in L_2(\Gamma_2)\}$ *given by* (4.10) *is dense in the space of classical solutions to the homogeneous Navier equation:* $\boldsymbol{L}\boldsymbol{u} + \rho\omega^2\boldsymbol{u} = \boldsymbol{0}$ *in* D *with respect to the* $H^1(D)$ *norm.*

Proof. By establishing the elements of the proof as in [32], it can be shown that $(\boldsymbol{S}\boldsymbol{h}, \boldsymbol{u})_{H^1(D)} = 0$ for all $\boldsymbol{h} \in L_2(\Gamma_2)$ requires $\boldsymbol{u} \equiv \boldsymbol{0}$ in D. ∎

As examined earlier, the adjoint variant of the linear sampling method revolves around the equation of the first kind (4.7), whose reciprocal solution norm can be used as a characteristic function of the scatterer. The key hypotheses in this approach, however, are that (i) (4.7) can be solved uniquely when $\widehat{\boldsymbol{U}} \cdot \boldsymbol{d} \in \text{Range}(\boldsymbol{G})$, (ii) (4.7) can be solved approximately (with arbitrary accuracy) when $\widehat{\boldsymbol{U}} \cdot \boldsymbol{d} \notin \text{Range}(\boldsymbol{G})$, and (iii) the solution $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}$ behaves such that $\lim_{\boldsymbol{z} \to \boldsymbol{y} \in \Gamma} \|\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}\|_{L_2(\Gamma_2)} = \infty$. These requirements are established next.

THEOREM 4.4 (injectivity, approximation, and solution unboundedness). *Assume that* (i) $\boldsymbol{z} \in \Omega_C$ *is fixed and* $\boldsymbol{d} \in \mathbb{R}^3$ *with* $\|\boldsymbol{d}\| = 1$, (ii) Γ *is of class* $C^{1,\alpha}$, *and* (iii) $\rho\omega^2$ *is not a Neumann eigenvalue of* $-\boldsymbol{L}$ *in* Ω_C *with eigenfunction* $\boldsymbol{S}\boldsymbol{h}$ *given by* (4.10). *Then* $\boldsymbol{G}$ *is one-to-one, and for every* $\varepsilon > 0$ *there exists* $\boldsymbol{h}^\varepsilon(\cdot;\boldsymbol{z},\boldsymbol{d}) \in L_2(\Gamma_2)$ *such that*

$$\left\| \boldsymbol{G}\boldsymbol{h}^\varepsilon(\cdot;\boldsymbol{z},\boldsymbol{d}) - \widehat{\boldsymbol{U}}(\cdot,\boldsymbol{z}) \cdot \boldsymbol{d} \right\|_{L_2(\Gamma_1)} < \varepsilon. \tag{4.11}$$

For every fixed $\varepsilon > 0$ *and* $\boldsymbol{h}^\varepsilon$ *satisfying* (4.11), *one further has*

$$\lim_{\boldsymbol{z} \to \boldsymbol{y} \in \Gamma} \|\boldsymbol{h}^\varepsilon(\cdot;\boldsymbol{z},\boldsymbol{d})\|_{L_2(\Gamma_2)} = \infty. \tag{4.12}$$

Proof. A detailed proof of (4.11) and (4.12), which builds on the results from Theorems 4.2 and 4.3, is similar to that in [32] established for the treatment of (3.1) and is omitted here for brevity. ∎

5. Computational treatment and regularization. On the basis of the foregoing developments, elastic-wave reconstruction of impenetrable obstacles in a semi-infinite solid can be achieved by solving the integral equation (4.1) with the near-field operator $\boldsymbol{G}$ given by (4.5), a format that may be especially useful in situations involving a limited density of "illuminating" point sources distributed over $\Gamma_1 \subset \Sigma$ (see Figure 2.1). In this approach, the reference semi-infinite solid is sequentially probed in a pointwise fashion by placing a fictitious point source (acting in direction $\boldsymbol{d}$) over an array of sampling points $\boldsymbol{z} \in \mathcal{D} \subset \Omega$, where $\mathcal{D}$ is the subsurface region of interest. With

reference to (4.1), the unknown scatterer Ω_{C} can thus be reconstructed by solving the linear operator equation

$$\boldsymbol{G}\boldsymbol{h} = \boldsymbol{b}, \tag{5.1}$$

where $\boldsymbol{G}$ is given by (4.5), $\boldsymbol{h} = \boldsymbol{h}(\cdot; \boldsymbol{z}, \boldsymbol{d})$, and $\boldsymbol{b} = \widehat{\boldsymbol{U}}(\cdot, \boldsymbol{z}) \cdot \boldsymbol{d}$. As elucidated earlier, Fredholm integral equation of the first kind (5.1) constitutes an ill-posed mathematical problem in the sense of Hadamard [14, 24]. On citing the solvability of (5.1) as examined in section 4.1, a careful numerical treatment must be adopted next to obtain a stable solution in terms of $\boldsymbol{h}$.

5.1. Discretization. In practice the input data, herein synthesized in the form of the scattered tensor $\widetilde{\boldsymbol{U}}$, are monitored over a discrete set of control points located on the measurement surface Γ_2. Likewise, the time-harmonic excitation used to illuminate the obstacle is often provided by a finite number of "point" sources acting sequentially on the source surface Γ_1. To illustrate the physical relevance of the assumed illuminating field, it is worth noting that in quantitative ultrasound imaging, a point-like excitation of soft tissues can be achieved by way of the so-called acoustic radiation force [13, 16].

To consistently deal with such a discrete experimental input, let $\{E_k\}_{k=1}^{K}$ be a system of closed and nonoverlapping subsets of the receiver surface Γ_2 such that $\Gamma_2 = \bigcup_{k=1}^{K} E_k$. On assuming that each subset E_k can be parametrized by a mapping $E \to E_k$ that introduces local coordinates, $\boldsymbol{\eta} = (\eta^1, \eta^2) \in E$, over $E_k \subset \Gamma_2$, where E is a polygonal domain in $\mathbb{R}^2$, the interpolation formula for a Q-noded approximation E_k^a of a generic surface element $E_k \subset \Gamma_2$ can be written as

$$\boldsymbol{\xi}(\boldsymbol{\eta}) \;=\; \sum_{q=1}^{Q} \psi_q(\boldsymbol{\eta})\, \boldsymbol{\xi}^q, \qquad \boldsymbol{\xi} \in E_k^a, \quad \boldsymbol{\xi}^q \in E_k, \quad \boldsymbol{\eta} \in E.$$

Here $\psi_q(\boldsymbol{\eta})$ are the Lagrange interpolation polynomials (shape functions) for the Q-noded element E_k^a with parent domain E, and $\boldsymbol{\xi}^q$ are the nodal points on E_k. Accordingly $\Gamma_2^a = \bigcup_{k=1}^{K} E_k^a$ is an approximation of Γ_2 so that the scattered tensor $\widetilde{\boldsymbol{U}}$ and distribution $\boldsymbol{h}$ featured in (5.1) via (4.5) can be approximated over E_k^a as

$$\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}(\boldsymbol{\eta}), \boldsymbol{x}) = \sum_{p=1}^{Q} \psi_p(\boldsymbol{\eta})\, \widetilde{\boldsymbol{U}}(\boldsymbol{\xi}^p, \boldsymbol{x}), \qquad \boldsymbol{h}_a(\boldsymbol{\xi}(\boldsymbol{\eta})) = \sum_{q=1}^{Q} \psi_q(\boldsymbol{\eta})\, \boldsymbol{h}^q, \qquad \boldsymbol{\xi} \in E_k^a \subset \Gamma_2^a,$$

where $\boldsymbol{h}^q = \boldsymbol{h}(\boldsymbol{\xi}^q)$ and $\boldsymbol{x} \in \Gamma_1$. In what follows, it is assumed that the values of the scattered tensor $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x})$ are sampled over N_{S} source points $\{\boldsymbol{x}^i\}_1^{N_{\mathrm{S}}}$ on Γ_1, and N_{O} observation points $\{\boldsymbol{\xi}^j\}_1^{N_{\mathrm{O}}}$ on Γ_2. In this setting, an approximation of the near-field operator $\boldsymbol{G}$ over Γ_1 can be written as

$$(\boldsymbol{G}_a \boldsymbol{h}_a)(\boldsymbol{x}) = \sum_{k=1}^{K} \sum_{q=1}^{Q} \sum_{p=1}^{Q} [\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}^{p_k}, \boldsymbol{x})]^{\mathrm{T}} \cdot \boldsymbol{h}^{q_k} \int_{E_k^a} \psi_q(\boldsymbol{\eta})\, \psi_p(\boldsymbol{\eta})\, J\, d\eta^1 d\eta^2, \quad \boldsymbol{x} \in \Gamma_1, \tag{5.2}$$

where $J = J(\boldsymbol{\eta})$ is the Jacobian of transformation (5.2), while p_k and q_k are the respective global indices of the pth and qth element nodes on E_k^a. On the basis of (5.2) and a set of collocation points $\{\boldsymbol{x}^i\}_1^{N_{\mathrm{S}}} \subset \Gamma_1$, a discretized form of the near-field integral equation (5.1) can be written as

$$\boldsymbol{G}_a \boldsymbol{h}_a = \boldsymbol{b}_a, \tag{5.3}$$

where $\boldsymbol{h}_a = (\boldsymbol{h}^1, \boldsymbol{h}^2, \ldots, \boldsymbol{h}^{N_{\rm O}})^{\rm T}$ is a vector containing the nodal values of $\boldsymbol{h}$ on Γ_2, $\boldsymbol{b}_a = (\widehat{\boldsymbol{U}}(\boldsymbol{x}^1, \boldsymbol{z}) \cdot \boldsymbol{d}, \widehat{\boldsymbol{U}}(\boldsymbol{x}^2, \boldsymbol{z}) \cdot \boldsymbol{d}, \ldots, \widehat{\boldsymbol{U}}(\boldsymbol{x}^{N_{\rm S}}, \boldsymbol{z}) \cdot \boldsymbol{d})^{\rm T}$, and $\boldsymbol{G}_a \in \mathbb{C}^{3N_{\rm S} \times 3N_{\rm O}}$ is a finite-dimensional approximation of the near-field operator $\boldsymbol{G}$ following (5.2) wherein the surface integrals are approximated via a product Gauss–Legendre quadrature.

In view of the ill-posed nature of (5.1), a suitable regularization is necessary to obtain a stable approximate solution of (5.3). To this end, let ε be an a priori estimate of the measurement and numerical errors characterizing $\boldsymbol{G}_a$ so that

$$\|\boldsymbol{G} - \boldsymbol{G}_a\|_{L_2(\Gamma_1)} \leq \varepsilon, \qquad \varepsilon = \gamma \, \|\boldsymbol{G}_a\|_{L_2(\Gamma_1)}, \qquad \gamma > 0, \tag{5.4}$$

and let the right-hand side $\boldsymbol{b}$, poluted with numerical inaccuracies, be known up to an error δ, whereby

$$\|\boldsymbol{b} - \boldsymbol{b}_a\|_{L_2(\Gamma_1)} \leq \delta, \qquad \delta = \beta \, \|\boldsymbol{b}_a\|_{L_2(\Gamma_1)}, \qquad \beta > 0. \tag{5.5}$$

In the ensuing (regularized) solution of the discrete system (5.3), Euclidean norm $\|\cdot\|$ in $\mathbb{C}^N$ induced by the inner product

$$(\boldsymbol{u}, \boldsymbol{v}) = \sum_{i=1}^{N} \bar{u}_i v_i, \quad \boldsymbol{u}, \boldsymbol{v} \in \mathbb{C}^N, \tag{5.6}$$

will be assumed, where N is an appropriate dimension.

5.2. Tikhonov regularization. The Tikhonov regularization method [14, 41] replaces (5.3) with an equation of the second kind:

$$\boldsymbol{G}_a^* \boldsymbol{G}_a \boldsymbol{h}_a^\alpha + \alpha \boldsymbol{h}_a^\alpha \, = \, \boldsymbol{G}_a^* \boldsymbol{b}_a, \qquad \boldsymbol{h}_a \in \mathbb{C}^{3N_{\rm O}}, \tag{5.7}$$

where $\boldsymbol{G}_a^*$ denotes the conjugate transpose of $\boldsymbol{G}_a$, $\alpha > 0$ is the regularization parameter, and $\boldsymbol{h}_a^\alpha$ defacto minimizes the functional $J_\alpha(\boldsymbol{h}_a) = \|\boldsymbol{G}_a \boldsymbol{h}_a - \boldsymbol{b}_a\|^2 + \alpha \|\boldsymbol{h}_a\|^2$.

On employing the singular value decomposition of $\boldsymbol{G}_a$, it can be shown [10, 24] that the regularized solution $\boldsymbol{h}_a^\alpha$ of (5.7) and its squared norm admit the representation

$$\boldsymbol{h}_a^\alpha = \sum_{\nu_j > 0} \frac{\nu_j}{\alpha + \nu_j^2} \, (\boldsymbol{u}_j, \boldsymbol{b}_a) \, \boldsymbol{v}_j, \qquad \|\boldsymbol{h}_a^\alpha\|^2 = \sum_{\nu_j > 0} \frac{\nu_j^2}{\left(\alpha + \nu_j^2\right)^2} \, |(\boldsymbol{u}_j, \boldsymbol{b}_a)|^2 \, . \tag{5.8}$$

Here $\boldsymbol{u}_i \in \mathbb{C}^{3N_{\rm S}}$ $(i = 1, 2, \ldots, 3N_{\rm S})$ and $\boldsymbol{v}_j \in \mathbb{C}^{3N_{\rm O}}$ $(j = 1, 2, \ldots, 3N_{\rm O})$ denote respectively the left and right singular vectors of $\boldsymbol{G}_a$, and $\nu_k \in \mathbb{R}$, $k = 1, 2, \ldots, p = \min\{3N_{\rm S}, 3N_{\rm O}\}$ are the singular values of $\boldsymbol{G}_a$ ordered so that $\nu_1 \geq \nu_2 \geq \cdots \geq \nu_p \geq 0$.

A method for choosing an optimal regularization parameter $\alpha = \alpha^*$, for which $\boldsymbol{h}_a^\alpha$ "closely" approximates the solution of (5.3), is given by the Morozov's discrepancy principle [14, 24, 29, 41]. In its most general form, the discrepancy principle due to Morozov states that the residual $\|\boldsymbol{G}_a \boldsymbol{h}_a^\alpha - \boldsymbol{b}_a\|$ should be commensurate to the errors characterizing the estimates of $\boldsymbol{G}$ and $\boldsymbol{b}$. With reference to (5.4)–(5.5), this implies

$$\|\boldsymbol{G}_a \boldsymbol{h}_a^\alpha - \boldsymbol{b}_a\| \, = \, \varepsilon \|\boldsymbol{h}_a^\alpha\| + \delta. \tag{5.9}$$

On assuming that $\delta \ll \varepsilon$ (the right-hand side, $\boldsymbol{b} = \widehat{\boldsymbol{U}}(\cdot, \boldsymbol{z}) \cdot \boldsymbol{d}$, is a known analytic function of real variables), one can neglect numerical inaccuracies in the computation of the right-hand side $\boldsymbol{b}$ in (5.9) and define the discrepancy function as

$$\zeta(\alpha) = \|\boldsymbol{G}_a \boldsymbol{h}_a^\alpha - \boldsymbol{b}_a\|^2 - \varepsilon^2 \|\boldsymbol{h}_a^\alpha\|^2, \qquad \alpha > 0. \tag{5.10}$$

On the basis of (5.8) and decomposition $\boldsymbol{b}_a = \sum_{\nu_j>0} \boldsymbol{u}_j\,(\boldsymbol{u}_j, \boldsymbol{b}_a)$, the discrepancy function (5.10) and its derivative can be respectively rewritten as

$$\zeta(\alpha) = \sum_{\nu_j>0} \frac{\alpha^2 - \varepsilon^2\nu_j^2}{\left(\alpha+\nu_j^2\right)^2}\,|(\boldsymbol{u}_j, \boldsymbol{b}_a)|^2\,, \qquad \zeta'(\alpha) = \sum_{\nu_j>0} \frac{2\nu_j^2(\alpha+\varepsilon^2)}{\left(\alpha+\nu_j^2\right)^3}\,|(\boldsymbol{u}_j, \boldsymbol{b}_a)|^2\,.$$

It is readily seen that $\zeta'(\alpha)>0$ for $\alpha\in(0,\infty)$, and hence the discrepancy function $\zeta(\alpha)$ is a monotonically increasing function. By virtue of the limit from above, asymptotic behavior $\lim_{\alpha\downarrow 0}\zeta(\alpha) < 0$, and the monotonicity of ζ, it follows that $\zeta(\alpha)$ has a unique root $\alpha^\star$, satisfying $\zeta(\alpha^\star) = 0$, which can be computed using, e.g., a root-finding Newton method.

5.3. Preconditioned conjugate gradient method. In situations where the singular value decomposition of $\boldsymbol{G}_a$ is not practical, e.g., for "large" systems, the conjugate gradient (CG) method [22, 24] can be alternatively employed to solve (5.3) wherein the regularized iterative solution $\boldsymbol{h}_a^\kappa$ is found by minimizing the functional $J(\boldsymbol{h}_a) = \|\boldsymbol{G}_a\boldsymbol{h}_a - \boldsymbol{b}_a\|^2$. In the iteration procedure of the CG method, iteration number κ plays the role of the regularization parameter; accordingly, its optimal value, $\kappa=\kappa^\star$, is to be chosen by a suitable stopping rule. In this investigation, a preconditioned CG method proposed by Santos [37] for ill-conditioned systems will be used. Rooted in [3], this technique can be briefly described using the decomposition $\boldsymbol{G}_a\boldsymbol{G}_a^* = \boldsymbol{T} + \boldsymbol{D} + \boldsymbol{T}^*$, where $\boldsymbol{T}$ is strictly lower triangular, $\boldsymbol{D} = \mathrm{diag}(d_1, d_2, \ldots, d_{3N_\mathrm{S}})$, and $d_i \in \mathbb{R}$ is the diagonal element of $\boldsymbol{G}_a\boldsymbol{G}_a^* \in \mathbb{C}^{3N_\mathrm{S}\times 3N_\mathrm{S}}$. With such definitions, let

$$\boldsymbol{C}_\tau = (\boldsymbol{D} + \tau\,\boldsymbol{T})\boldsymbol{D}^{-1/2} \tag{5.11}$$

form a basis for the preconditioner, where $\tau\in[0,2]$ is a relaxation parameter. In this setting, the regularized solution $\boldsymbol{h}_a^\kappa$ of (5.3) can be found by minimizing the functional

$$J_C(\boldsymbol{h}_a) = \|\boldsymbol{C}_\tau^{-1}(\boldsymbol{G}_a\boldsymbol{h}_a - \boldsymbol{b}_a)\|^2, \quad \boldsymbol{h}_a\in\mathbb{C}^{3N_\mathrm{O}},$$

i.e., by solving the the normal equation

$$\boldsymbol{G}_a^*\boldsymbol{C}_\tau^{-*}\boldsymbol{C}_\tau^{-1}\boldsymbol{G}_a\boldsymbol{h}_a \;=\; \boldsymbol{G}_a^*\boldsymbol{C}_\tau^{-*}\boldsymbol{C}_\tau^{-1}\boldsymbol{b}_a, \tag{5.12}$$

where $\boldsymbol{C}_\tau^{-*} = (\boldsymbol{C}_\tau^{-1})^*$. A modification of the CG algorithm (PCCGNR) [37] for solving (5.12), wherein the "net" residual $\boldsymbol{\gamma}^\kappa = \boldsymbol{b}_a - \boldsymbol{G}_a\boldsymbol{h}_a^\kappa$ is computed at every iterate κ, can be written as follows

ALGORITHM 5.1.

Given $\boldsymbol{h}_a^0$:

Set $\boldsymbol{\gamma}^0 = \boldsymbol{b}_a - \boldsymbol{G}_a\boldsymbol{h}_a^0, \quad \boldsymbol{r}^0 = \boldsymbol{G}_a^*\boldsymbol{C}_\tau^{-*}\boldsymbol{C}_\tau^{-1}\boldsymbol{\gamma}^0, \quad \boldsymbol{p}^1 = \boldsymbol{r}^0.$

For $\kappa = 1, 2, \ldots$

$$\begin{aligned}
&\boldsymbol{g}^\kappa = \boldsymbol{G}_a\,\boldsymbol{p}^\kappa, \quad \boldsymbol{q}^\kappa = \boldsymbol{C}_\tau^{-1}\boldsymbol{g}^\kappa,\\
&\alpha_\kappa = \frac{\|\boldsymbol{r}^{\kappa-1}\|^2}{\|\boldsymbol{q}^\kappa\|^2},\\
&\boldsymbol{h}_a^\kappa = \boldsymbol{h}_a^{\kappa-1} + \alpha_\kappa\,\boldsymbol{p}^\kappa,\\
&\boldsymbol{\gamma}^\kappa = \boldsymbol{\gamma}^{\kappa-1} - \alpha_\kappa\,\boldsymbol{g}^\kappa, \quad \boldsymbol{r}^\kappa = \boldsymbol{G}_a^*\boldsymbol{C}_\tau^{-*}\boldsymbol{C}_\tau^{-1}\boldsymbol{\gamma}^\kappa,\\
&\beta_{\kappa+1} = \frac{\|\boldsymbol{r}^\kappa\|^2}{\|\boldsymbol{r}^{\kappa-1}\|^2},\\
&\boldsymbol{p}^{\kappa+1} = \boldsymbol{r}^\kappa + \beta_{\kappa+1}\,\boldsymbol{p}^\kappa.
\end{aligned}$$

For situations involving large numbers of sampling points $\boldsymbol{z}$, the inverse of the lower triangular matrix, $\boldsymbol{C}_\tau^{-1}$, and consequently $\boldsymbol{G}_a^*\boldsymbol{C}_\tau^{-*}\boldsymbol{C}_\tau^{-1}$, can be precomputed explicitly, as they are independent of $\boldsymbol{z}$. In the contrary cases involving only a limited number of sampling points, on the other hand, it may be beneficial to compute the products $\boldsymbol{C}_\tau^{-1}\boldsymbol{g}$ and $\boldsymbol{C}_\tau^{-*}\boldsymbol{w}$ without calculating the inverse of (5.11) explicitly. To this end, let $\boldsymbol{f}_i \in \mathbb{C}^{3N_{\rm O}}$ denote the ith row of $\boldsymbol{G}_a$, and let $d_i = (\boldsymbol{f}_i, \boldsymbol{f}_i)$ be the ith diagonal entry of $\boldsymbol{D} = \mathrm{diag}(d_1, d_2, \ldots, d_{3N_{\rm S}})$, where the inner product $(\cdot,\cdot)$ is given by (5.6). With such definitions, the components of $\boldsymbol{q} = \boldsymbol{C}_\tau^{-1}\boldsymbol{g}$ can be computed in a recursive fashion [3, 37] as

$$q_i = d_i^{-1/2}(g_i - \tau\,(\boldsymbol{a}_i, \boldsymbol{f}_i))\,, \qquad \boldsymbol{a}_{i+1} = \boldsymbol{a}_i + d_i^{-1/2}\,\overline{q}_i\,\boldsymbol{f}_i, \qquad i = 1, 2, \ldots, 3N_{\rm S},$$

where $\mathbb{C}^{3N_{\rm O}} \ni \boldsymbol{a}_1 = \boldsymbol{0}$ initializes the procedure. Similarly by letting $\mathbb{C}^{3N_{\rm O}} \ni \boldsymbol{a}_{3N_{\rm S}} = \boldsymbol{0}$, the components of $\boldsymbol{s} = \boldsymbol{C}_\tau^{-*}\boldsymbol{w}$ can be computed as

$$s_i = d_i^{-1/2} w_i - \tau\, d_i^{-1}(\boldsymbol{a}_i, \boldsymbol{f}_i), \qquad \boldsymbol{a}_{i-1} = \boldsymbol{a}_i + \overline{s}_i\,\boldsymbol{f}_i, \qquad i = 3N_{\rm S}, 3N_{\rm S}-1, \ldots, 1.$$

The selection of an optimal iteration number (regularization parameter) $\kappa = \kappa^\star$ in Algorithm 5.1 is rather heuristic. As mentioned in [40], a generalization of the discrepancy principle manifest in (5.10) to CG-type methods is still an open question. Nevertheless one may, by analogy to (5.10), introduce the discrepancy function as

$$\zeta(\kappa) \;=\; \|\boldsymbol{G}_a\,\boldsymbol{h}_a^\kappa - \boldsymbol{b}_a\|^2 - \varepsilon^2\|\boldsymbol{h}_a^\kappa\|^2, \qquad \kappa \in \mathbb{N}\cup\{0\}. \tag{5.13}$$

By virtue of (5.13), one can select the optimal iteration number $\kappa^\star$ as the number κ that corresponds to the minimum of $|\zeta(\kappa)|$, a quantity whose computation at every iterate is facilitated by the computation of the "net" residual $\boldsymbol{\gamma}^\kappa$ in Algorithm 5.1.

6. Results and discussion. On the basis of the foregoing developments, the task of reconstructing an obstacle $\Omega_{\rm C}$ in the semi-infinite solid Ω from near-field elastic waveforms (Figure 2.1) can be achieved by solving either (3.1) or its adjoint counterpart (4.1) over a sampled region $\mathcal{D} \supset \Omega_{\rm C}$ by means of the featured regularization methods. By introducing the grid of sampling points $\boldsymbol{z}^m \in \mathcal{D} \subset \Omega$ $(m = 1, 2, \ldots, M)$ spanning the region of interest, Ω is sequentially excited by the virtual point sources acting at $\boldsymbol{z}^m$ in direction $\boldsymbol{d}$, and $1/\|\boldsymbol{h}(\cdot; \boldsymbol{z}^m, \boldsymbol{d})\|_{L_2(\Gamma_2)}$ is plotted over the selected raster.

6.1. Testing configuration. With reference to Figure 6.1, consider the problem of reconstructing a dual cavity consisting of (i) a sphere of diameter 1.6 centered at $(-2, -2, 3)$, and (ii) an ellipsoid centered at $(2, 1, 3)$ whose axes, of lengths $(3, 1.6, 1.6)$, are aligned with the reference Cartesian frame $\{O; \xi_1, \xi_2, \xi_3\}$. The Lamé parameters and mass density of the elastic solid are taken as $\lambda = \frac{7}{3}$, $\mu = 1$, and $\rho = 1$, corresponding to a Poisson ratio of 0.35. On assuming that the source surface Γ_1 and the observation surface Γ_2 coincide, i.e., $\Gamma_1 = \Gamma_2 = \Pi$, synthetic observations of the scattered tensor $\widetilde{\boldsymbol{U}}$ are generated via an elastodynamic boundary element method [33] by assuming $N_{\rm S} \in \{8, 21, 40, 65, 96\}$ source points and $N_{\rm O} = 96$ receiver points regularly distributed over the square test area (dimensions 10×10). For quadrature purposes, both the source and the receiver grid are each associated with a uniform "mesh" of eight-node surface elements. In this setting, $N_{\rm S} = 8, 21, 40, 65, 96$ correspond respectively to the $k \times k$ mesh of surface elements, $k = 1, 2, 3, 4, 5$. From every source point $\boldsymbol{x}^k$ on the grid $(k = 1, 2, \ldots, N_{\rm S})$, the half-space is sequentially illuminated using time-harmonic force of magnitude $P = \sqrt{3}\mu a^2$ acting along the coordinate directions ξ_1, ξ_2,

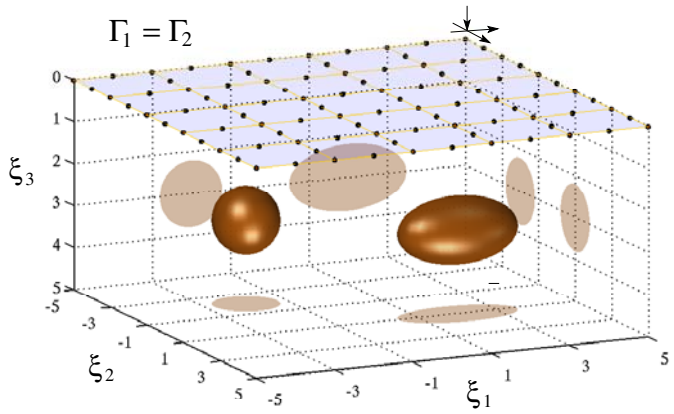

FIG. 6.1. *Dual cavity and testing grid (5×5 surface elements) in a semi-infinite elastic solid with* $N_S = N_O = 96$.

and ξ_3. For each $\boldsymbol{x}^k$, the synthetic data $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}^j, \boldsymbol{x}^k)$ are computed over $N_{\rm O} = 96$ receiver points $\boldsymbol{\xi}^j$, as examined earlier. To examine the effect of measurement uncertainties, synthetic observations $\widetilde{\boldsymbol{U}}$ in selected examples are corrupted as

$$\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}^j, \boldsymbol{x}^k) \;:=\; (1 + \varrho\chi)\, \widetilde{\boldsymbol{U}}(\boldsymbol{\xi}^j, \boldsymbol{x}^k), \qquad \begin{matrix} j = 1, 2, \ldots, N_{\rm O}, \\ k = 1, 2, \ldots, N_{\rm S}, \end{matrix}$$

where ϱ is the noise amplitude and $\chi \in [-1, 1]$ is a uniform random variable.

With the above problem parameters, near-field equations (3.1) and (4.1) are discretized as examined in section 5 and solved, assuming $\boldsymbol{d} = \frac{1}{\sqrt{3}}(1, 1, 1)^{\rm T}$, for the densities $\boldsymbol{g}_{\boldsymbol{z},\boldsymbol{d}}$ and $\boldsymbol{h}_{\boldsymbol{z},\boldsymbol{d}}$, repectively, over a grid of uniformly spaced sampling points in the horizontal plane $\xi_3 = 3$ and vertical planes $\xi_2 = -2, 1$. For completeness, representative numerical results are computed using both Tikhonov regularization (TR) and the preconditioned conjugate gradient (PCG) methods, assuming $\tau = 0.2$ for the relaxation parameter. With reference to the discrepancy functions (5.10) and (5.13), an estimate ε of the "measurement" and numerical errors characterizing the near-field operator is computed as $\varepsilon = \gamma \|\boldsymbol{G}_a\|$, where $\|\boldsymbol{G}_a\|$ is given by the maximum singular value of $\boldsymbol{G}_a$ for the TR method, and by the Frobenius norm of $\boldsymbol{G}_a$ for the PCG method.

To facilitate the comparison of results, each sectional distribution of the reciprocal solution density norm is accompanied by (i) an intersection with the boundary of the "true" obstacle indicated via a dark (red) solid line, and (ii) a white dashed isoline corresponding to a fraction, $\mathcal{R}$, of the peak (maximum) value in the plot. For clarity, the selected threshold level is also featured on the color bar accompanying each graph.

6.2. Adjoint versus direct sampling method. By setting $\gamma = 10^{-7}$ in (5.4) and assuming no extraneous noise on the measurements $\widetilde{\boldsymbol{U}}$ (i.e., $\varrho = 0$), Figures 6.2 and 6.3 depict the contour plots of $1/\|\boldsymbol{g}(\cdot; \boldsymbol{z}, \boldsymbol{d})\|_{L_2(\Pi)}$ (top row) and $1/\|\boldsymbol{h}(\cdot; \boldsymbol{z}, \boldsymbol{d})\|_{L_2(\Pi)}$ (bottom row) computed using the TR method for $\omega = 4$ and $N_{\rm O} = 96$ under the *decreasing number* of source points, namely $N_{\rm S} \in \{96, 65, 40, 21, 8\}$. In particular, the top panels in each figure are computed via direct formulation (3.1), while their bottom companions are associated with the adjoint formula (4.1). In Figure 6.2, which compares the methods for $N_{\rm S} \in \{96, 65, 40\}$, the dashed isolines are computed

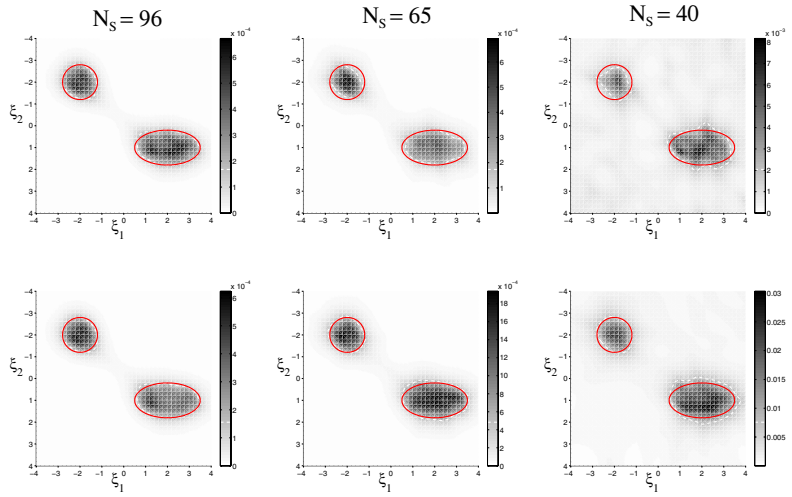

FIG. 6.2. *Images of dual cavity in the $\xi_3 = 3$ plane under decreasing number of source points—$5 \times 5, 4 \times 4$, and 3×3 grids of surface elements: direct (top row) versus adjoint formulation (bottom row) with $N_O = 96$, $\omega = 4$, and $\varrho = 0$.*

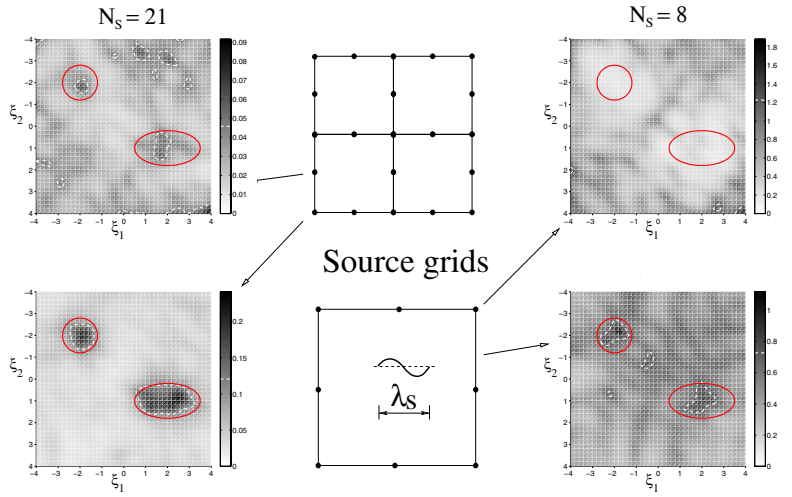

FIG. 6.3. *Images of dual cavity in the $\xi_3 = 3$ plane under decreasing number of source points—2×2 and 1×1 grids of surface elements: direct (top row) versus adjoint formulation (bottom row) with $N_O = 96$, $\omega = 4$, and $\varrho = 0$.*

assuming $\mathcal{R} = 0.25$, a threshold value which was found to perform well (in terms of obstacle reconstruction) when dealing with "high-quality" observations. Owing to the fact that $\Gamma_1 = \Gamma_2$, the images in Figure 6.2 for $N_S = N_O = 96$ resulting respectively from (3.1) and (4.1) should be identical. Indeed, the two distributions are similar, and the apparent (minor) differences reflect the finite accuracy of three-dimensional boundary element simulations used to generate the synthetic measurements. Under reduced N_S, however, the top images stemming from (3.1) became progressively more smeared than their adjoint counterparts. In particular the inspection of results for

$N_S = 40$ indicates that, despite an apparent similarity of the respective isolines, the gray tones are notably more localized inside the support of the defect for the (bottom) "adjoint" image computed from (4.1), indicating higher quality of reconstruction. This trend is further highlighted in Figure 6.3 dealing with "severely limited" obstacle illumination where $N_S \in \{21, 8\}$. As a point of reference, the two sets of results also feature the isolines corresponding respectively to $\mathcal{R} \in \{0.50, 0.65\}$ (applied to compensate for image deterioration), as well as the schematics of respective source grids with the shear wave length plotted to scale. As can be seen from the display, the adjoint formulation of the linear sampling method continues to outperform its "direct" counterpart with the differences becoming more pronounced with decreasing N_S.

With reference to the results in Figures 6.2 and 6.3, it is noted that the rank of the discretized operators $\boldsymbol{F}_a$ in (3.1) and $\boldsymbol{G}_a$ in (4.1) was found, as expected, to be $(3N_S)^2$ for all configurations examined. Here the factor of 3 appears due to the fact that the obstacle is sequentially illuminated by a point force in each coordinate direction from every source location $\boldsymbol{x}^k$, $k = 1, 2, \ldots, N_S$. In this sense both (3.1) and (4.1) operate on the same data set (for a given N_S), and the respective drawbacks of these two methods, when used in the context of limited obstacle illumination, can be described as that of *underintegration* versus *undercollocation*. From the numerical results in Figures 6.2 and 6.3, it follows that the adjoint variant (4.1) of the LSM makes better use of such limited experimental data where the scattered tensor $\widetilde{\boldsymbol{U}}(\boldsymbol{\xi}, \boldsymbol{x})$ is undersampled with respect to its second (i.e., source) argument. This conclusion is uniformly supported by the results from a number of other testing configurations whose results are herein omitted for brevity. From the practical point of view, the above results further indicate that a *comparative* defect reconstruction using *both* direct and adjoint formulation of the LSM may provide an effective tool for exposing an apparent undersampling of the scattered tensor $\widetilde{\boldsymbol{U}}$ with respect to either argument. As an example, such comparative study from Figures 6.2 and 6.3 arguably indicates that, for a given testing aperture as controlled by Γ_1 and Γ_2, the scattered tensor is undersampled with respect to its second argument for $N_S \leq 40$. While a similar conclusion for the configuration of interest (where $\Gamma_1 = \Gamma_2$) could be obtained using an independent argument of spatial aliasing [38], the above heuristic approach for exposing the undersampling of $\widetilde{\boldsymbol{U}}$ could be equally applied to more complex situations where the source and receiver surfaces are associated with distinct "viewing" apertures, i.e., situations where the conventional indicators of undersampling may be insufficient.

6.3. TR versus PCG. To diversify the computational treatment of the LSM, section 5.3 describes an application of the PCG algorithm to ill-conditioned linear systems featured in (5.3). By its nature, such an alternative method of solution, i.e., regularization, may be particularly useful in testing situations involving large numbers of sources and receivers (the issue of their density set aside), as in three-dimensional seismic imaging [38], where an application of the singular value decomposition in terms of TR may lead to substantial computational cost and inaccurate singular values. While the numerical simulation of such "large" sets of experimental data is beyond the scope of this study, one may pose a question as to the relative performance of the PCG and TR methods in the context of "small" experimental data sets such as those in Figures 6.2 and 6.3, where the TR method is expected to have an advantage owing to an explicit knowledge of the singular values of the system.

In the above setting, Figure 6.4 "borrows" the example with $N_S = 40$ from Figure 6.2, where $N_O = 96$, $\omega = 4$, and $\varrho = 0$, as a platform for the comparison between the

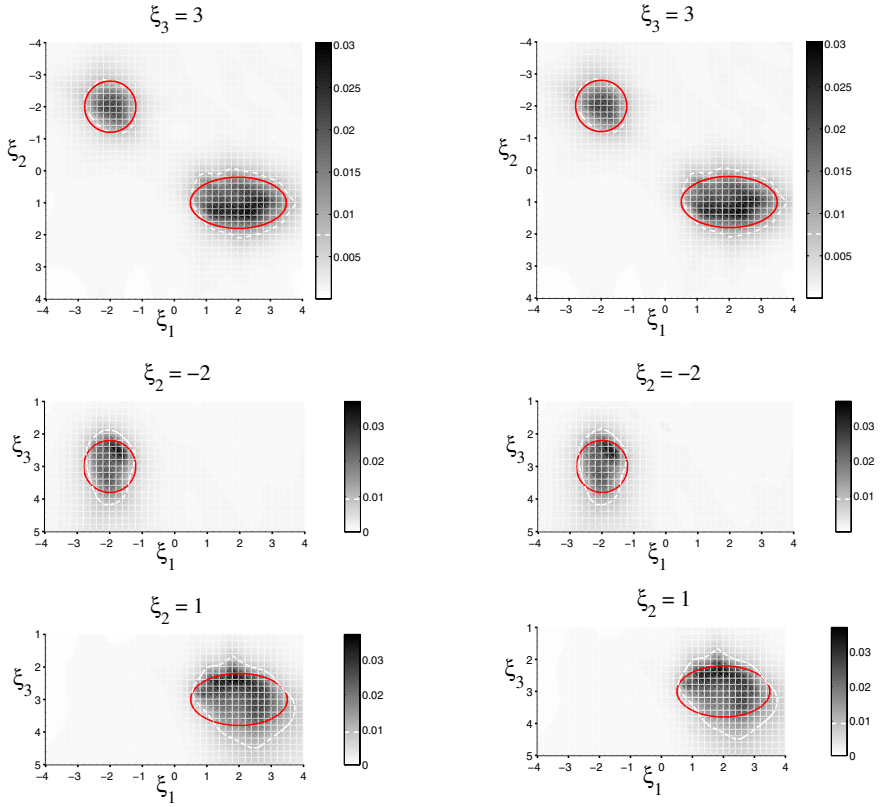

FIG. 6.4. *Images of dual cavity stemming from the adjoint formulation in the horizontal ($\xi_3=3$) and vertical ($\xi_2=-2,1$) planes computed using TR (left panels) and PCG (right panels). Problem parameters: $\omega=4$, $N_S=40$, $N_O=96$, and $\varrho=0$.*

TR method (left panels) and the PCG method (right panels) in terms of the adjoint formulation (4.1). Here the distributions of $1/\|\boldsymbol{h}(\cdot;\boldsymbol{z},\boldsymbol{d})\|_{L_2(\Pi)}$ are plotted both in the horizontal ($\xi_3=3$) and vertical ($\xi_2=-2,1$) sections. For ease of comparison, isolines of $1/\|\boldsymbol{h}\|_{L_2(\Pi)}$ corresponding to $\mathcal{R}=0.25$ are included as before. With reference to the discussion in section 6.2, application of the TR and PCG methods to a "slightly" undercollocated system (5.3) with $N_{\rm S}=40$ and $N_{\rm O}=96$ in Figure 6.4 yields distributions that are barely distinguishable despite the distinct computational treatments. To examine the effect of noise in the measurements, the latter comparison is repeated in Figure 6.5, but this time assuming $\varrho=0.04$, i.e., the 4%-level of experimental errors in (6.1). From the diagram where the isolines are computed for $\mathcal{T}=0.5$, one may observe that (i) the sectional images are relatively stable with respect to the measurement noise, and (ii) the TR and PCG methods still produce comparable results, with the PCG-based image in the $\xi_2=1$ (vertical) section providing a slightly better reconstruction of the "bottom" of the ellipsoid.

As a final illustration, the effect of diminishing $N_{\rm S}$ on the performance of the two regularization methods is illustrated in Figure 6.6 where $N_{\rm S}=21$, $N_{\rm O}=96$, $\varrho=0$, and $\mathcal{T}=0.5$. In this case the edge (as expected) belongs to the TR results, even though the PCG method still performs satisfactorily. In terms of the computational effort, it is noted that for each horizontal section in Figure 6.5 that features $41^2=1681$ sampling

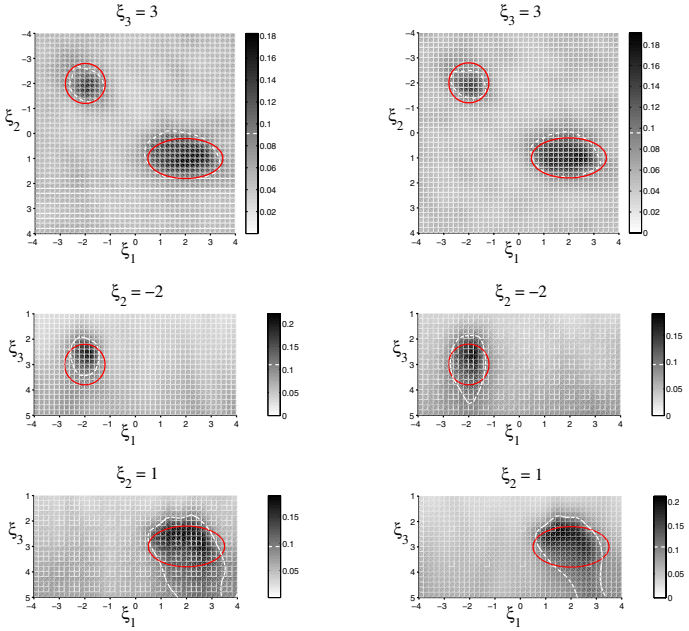

FIG. 6.5. *Images of dual cavity stemming from the adjoint formulation in the horizontal* ($\xi_3 = 3$) *and vertical* ($\xi_2 = -2, 1$) *planes computed using TR (left panels) and PCG (right panels). Problem parameters:* $\omega = 4$, $N_S = 40$, $N_O = 96$, *and* $\varrho = 0.04$.

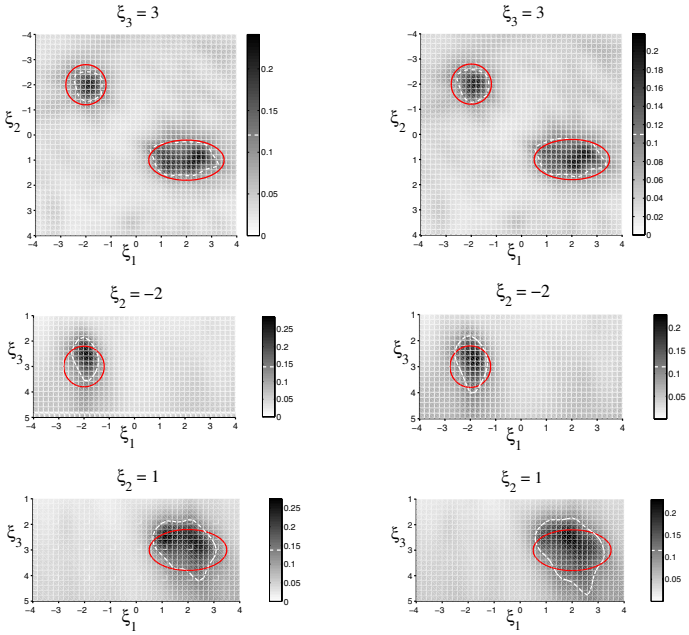

FIG. 6.6. *Images of dual cavity stemming from the adjoint formulation in the horizontal* ($\xi_3 = 3$) *and vertical* ($\xi_2 = -2, 1$) *planes computed using TR (left panels) and PCG (right panels) methods. Problem parameters:* $\omega = 4$, $N_S = 21$, $N_O = 96$, *and* $\varrho = 0$.

points, the computation of $1/\|\boldsymbol{h}\|_{L_2(\Pi)}$ took approximately 19 minutes for the TR method and 21 minutes for the PCG method on a Linux system with a 2.4 GHz Opteron processor. Here one should bear in mind that the majority of computational effort in each case is spent on the calculation of the half-space Green's function [18] featured on the right-hand side of (4.1). For significantly larger experimental systems, however, the computational advantage is naturally expected to shift toward the PCG method.

7. Summary. In this study, three-dimensional inverse scattering problem involving near-field elastodynamic reconstruction of impenetrable obstacles in a semi-infinite solid is examined by way of the linear sampling method (LSM). To cater to active imaging configurations characterized by a limited density of illuminating sources, an adjoint formulation of the near-field LSM is established that features a linear integral equation of the first kind involving integration over the *measurement* (as opposed to the source) surface. To diversify the computational treatment of ill-posed systems involving a significant number of experimental observations, a finite-dimensional approximation of the featured integral equation is solved by alternative means of Tikhonov regularization and a preconditioned conjugate gradient method. Computational details of the imaging technique, including evaluation of the featured integrals as well as the implementation of regularization strategies, are highlighted. Numerical results indicate that the adjoint variant of the LSM outperforms its predecessor (the so-called direct formulation) in situations involving a limited density of illuminating sources. From the practical standpoint, it is also found that a combined defect reconstruction by alternative means of the adjoint and direct sampling methods provides a rational basis for exposing an apparent undersampling of the experimental input, synthesized via the so-called scattered tensor. The results further indicate that the CG method, while designed primarily for the treatment of "large" systems involving a significant amount of experimental observations, may perform satisfactorily even for "small" systems that are characterized by a subpar number of illuminating sources.

INVERSE SOURCE PROBLEM IN NONHOMOGENEOUS BACKGROUND MEDIA*

ANTHONY J. DEVANEY†, EDWIN A. MARENGO†, AND MEI LI†

Abstract. The scalar wave inverse source problem (ISP) of determining an unknown radiating source from knowledge of the field it generates outside its region of localization is investigated for the case in which the source is embedded in a nonhomogeneous medium with known index of refraction profile $n(\mathbf{r})$. It is shown that the solution to the ISP having minimum energy (the so-called minimum energy source) can be obtained via a simple method of constrained optimization. This method is applied to the special case when the nonhomogeneous background is spherically symmetric ($n(\mathbf{r}) = n(r)$), and it yields the minimum energy source in terms of a series of spherical harmonics and radial wave functions that are solutions to a Sturm–Liouville problem. The special case of a source embedded in a spherical region of constant index is treated in detail, and results from computer simulations are presented for this case.

1. Introduction.

We consider in three-dimensional space the fundamental inverse source problem (ISP) of determining an unknown scalar source ρ to the inhomogeneous Helmholtz equation

$$[\nabla^2 + k_0^2 n^2(\mathbf{r})]U(\mathbf{r}) = -\rho(\mathbf{r}) \tag{1.1}$$

(where ∇^2 denotes the Laplacian operator) that radiates a scalar field U which is specified everywhere *outside* the support volume τ of the source. In this equation, k_0 is a constant wavenumber, and $n(\mathbf{r})$ is an index of refraction distribution that depends on position $\mathbf{r} \in R^3$ and that is assumed to go to unity for sufficiently large r. We will assume throughout this paper that the source volume τ is a sphere, centered at the origin and having a radius a. The ISP then consists of computing a source ρ that generates a prescribed *exterior* field U, whose value is specified for $\mathbf{r} \notin \tau$.

There are a number of treatments of the scalar ISP of interest in this work as well as of the full vector electromagnetic inverse problem for the free space case where the index distribution $n(\mathbf{r})$ is constant (equal to unity) throughout space [1, 2, 3, 4, 5, 6, 7, 8, 9, 10]. Most of these treatments make use of the fact that the source's radiation pattern (see below) determines, in principle, the field everywhere outside the source volume [11]. Using this fact, the ISP can be cast in terms of the radiation pattern: determine a source ρ that generates a prescribed radiation pattern. It is also well known [12, 13, 14] that there exist an infinity of sources that radiate fields that vanish identically outside their support volumes so that the ISP does not possess a unique

†Department of Electrical and Computer Engineering, Northeastern University, Boston, MA 02115 (Tonydev2@aol.com, emarengo@ece.neu.edu, mei_li_cdsp@yahoo.com).

solution; i.e., an infinity of solutions can be obtained by adding any one of these *nonradiating sources* to any given solution [15, 16]. Thus, in order to obtain a unique solution to the ISP it is necessary to add constraints that the source must satisfy in addition to yielding a specified radiation pattern. An important and tractable choice of constraint is source energy $\mathcal{E}$, defined to be the L^2 norm of the source over the source volume τ:

$$\mathcal{E} = \int_\tau d^3r \, |\rho(\mathbf{r})|^2. \tag{1.2}$$

The solution to the ISP that minimizes the source energy as defined in (1.2) is usually termed the *minimum energy solution* [2, 3, 6, 7, 8, 9, 10]. It is orthogonal to the nonradiating sources [3] and is the pseudoinverse of the ISP [5, 6]. Physically, this source is also related to the real image field generated by a point-reference hologram of the field recorded on a closed surface completely surrounding the source volume [2, 3, 17].

The source energy as defined in (1.2) is an important measure of the realizability of a source generating a given radiation pattern with the given spatial resource or source volume τ. For the free space case one finds that the energy of the minimum energy source depends critically on the product $x = k_0 a$ of the (free space) wavenumber k_0 and the source radius a [2, 6]. For a given radiation pattern this energy $\mathcal{E}(x)$ is small for $x > l_0$, where l_0 is a parameter that characterizes the radiation pattern and that increases with increasing fine detail in the pattern. However, it is found that $\mathcal{E}(x)$ increases exponentially with decreasing x below the critical value l_0. This exponential increase of source energy indicates that the given radiation pattern cannot be physically realized by *any* source having that specific $k_0 a$ product: it is necessary to either decrease the wavelength (increase k_0) or increase the source radius. This is analogous to the well-known result in antenna theory that states that reactive energy and the quality Q of an antenna increase exponentially with decreasing $k_0 a$ if one attempts to achieve superdirectivity [18, 19]. Furthermore, in the associated full vector treatment the source energy is also a measure of the current levels of the antenna structure, which ideally should be small to cope with ohmic losses in realistic lossy antenna material. In particular, the ability of a source (antenna) to radiate a prescribed field with reduced source energy or "resources" is an indication of efficiency, so that the constraint of minimizing the source energy for a given radiation field is of interest not only for the theoretical treatment of the inverse source problem and of the related field realizability question but also for the practical antenna synthesis problem (see, e.g., the antenna characterizations in [20], the sensitivity factor in [21], and similar factors used in [22, 23, 24]).

As far as the authors of this paper know there are only two treatments of the ISP for the case where the background index distribution $n(\mathbf{r})$ in which the source is embedded is nonhomogeneous [25, 26]. The work in [26] generalizes the main results in [25] to lossy media. Of particular interest to the present research, which focuses on lossless media, is [25], which shows that the minimum energy solution satisfies an integral equation whose kernel is the imaginary part of the outgoing wave Green function of the inhomogeneous Helmholtz equation (1.1). Using this fact, it is shown in [25] that the minimum energy solution can be expanded into a series of eigenfunctions of this integral equation with expansion coefficients that can be determined from the radiation pattern. The paper shows that the formalism reduces to the known theory of the ISP when the index $n = 1$ (homogeneous medium case), but no examples of the general theory were provided.

In this paper we consider the case of a source embedded in a known nonhomogeneous real background index (corresponding to a lossless medium) and solve the minimum energy ISP using a simple method of constrained optimization. Besides providing a simpler formulation of the problem than that used in [25], the method yields a solution that is directly implemented without the need of first computing a Green function for the Helmholtz equation (1.1) and then computing the eigenfunctions of the imaginary part of this quantity. The special case of a spherically symmetric index $n(\mathbf{r}) = n(r)$ is treated in detail, and it is shown that the minimum energy solution to the ISP has exactly the same mathematical form as the solution for the constant index case, but with the spherical Bessel functions replaced by radial wave functions that are solutions to a Sturm–Liouville problem. In particular, these radial wave functions are the radial wave scattering functions obtained in the scattering of an incident plane wave from the spherically symmetric index distribution $n(r)$. This latter problem has been studied extensively in quantum mechanical [27], optical [28], and electromagnetic [29] scattering, and there exist a number of index distributions for which the scattering wave functions have been computed and that can be used to compute the minimum energy solution to the ISP.

Motivation for the research presented in this paper is provided in part by the possibility of optimally selecting the source region index of refraction distribution $n(\mathbf{r})$ to achieve some specified radiation pattern that would otherwise not be realistically possible (due to prohibitive values of required current level, or other engineering constraints) for a source embedded in free space. This possibility has attracted research from time to time in the antenna community, being of interest a variety of antenna-embedding materials or substrates, including plasmas [30], nonmagnetic dielectrics [31, 32, 33, 34, 35, 36], magneto-dielectrics [37, 38, 39, 40], and, more recently, double negative metamaterials, which are receiving much recent attention by a number of groups as antenna performance-enhancing substrates [41, 42, 43, 44, 45, 46, 47, 48, 49]. The envisaged property is miniaturization of antennas by controlling electric size (via larger wavenumber), but other effects are involved, particularly when metamaterials are used.

To arrive from first wave theoretic principles at a non–device specific understanding of the practical possibilities opened by antenna-embedding substrates, we emphasize in the present work the fundamental minimum energy source yielding a given radiation pattern, rather than particular devices, as has been the focus of the aforementioned presentations in this area. Also, the present treatment concerns the scalar inverse problem, which is a simplification of the full vector electromagnetic case. Rigorous treatment of the metamaterials, which are generally bi-anisotropic media, requires the full vector formulation [50, 51] and is left for future work. Thus in the present work attention is restricted to the pertinent properties associated with the index of refraction $n(\mathbf{r}) \geq 0$ of natural "positive" materials whose key aspects can be treated within the scalar formulation, but the general approach can be extended also to the vector case along the lines of, e.g., [52], where both source energy and reactive power constraints have been considered in the formulation of the inverse problem for sources embedded in free space.

The key observation is that, as outlined earlier and as shown in section 3 of this paper, in the free space case the minimum energy source energy increases exponentially with decreasing $x = k_0 a$ below a critical point that is determined by the fine detail that is desired in the radiation pattern. The question then is whether this limitation can be mitigated by embedding the source in a nonhomogeneous background medium. In effect we create a new "effective source" that consists of the actual physi-

cal source interacting with the nonhomogeneous background. In the simplest case we can consider a source embedded in a cavity with partially reflecting walls. This cavity will, of course, have a pronounced effect on the radiated field and, possibly, can aid in achieving desired properties of the radiation pattern.

In this paper we limit our attention, for the most part, to source regions characterized by a spherically symmetric index of refraction distribution $n(\mathbf{r}) = n(r)$, although many of our results can be generalized to sources embedded in cavities and nonspherically symmetric index distributions. The realizability of a given radiation pattern is investigated in some detail by examining the dependence of minimum source energy on the index of refraction profile of the source region. It is found that this energy depends critically on the (weighted) L^2 norm of the radial wave functions taken over the source region. This fact suggests that, by proper choice of the index of refraction profile $n(r)$, the energy can be minimized for any given radiation pattern; i.e., an index distribution can be selected that results in a source having minimum energy for a given prescribed radiation pattern.

The L^2 norms of the radial wave functions are found to be dependent on "resonant" properties of the source index distribution and are also related in a one-to-one fashion with the different angular modes of the radiation pattern. These facts suggest the interesting possibility of exploiting the "resonances" of the source index distribution to selectively control the shape and form of the radiation pattern. This possibility is briefly considered in the computer simulation study.

The final section of the paper treats the simple example of a source embedded in a homogeneous sphere whose constant index of refraction differs from that of the background medium. This is the simplest example of a spherically symmetric index of refraction distribution, and the scattering wave functions are well known (the so-called Mie scattering problem [28, 29]) and easily computed. The minimum energy source is computed for this case, and results from a computer simulation study that examines the dependence of the energy of the minimum energy source on the index of refraction of the source region are presented. The source energy depends in a nonlinear manner on the value of the source region refraction index. The examples considered reveal that, as desired, there are values of the index of refraction for which the improvement of the source-embedded case relative to the free space case is significant for the entire effectively radiating multipole spectrum pertinent to the same source region in free space.

2. Problem formulation. We introduce the scattering potential defined according to the equation

$$V(\mathbf{r}) = k_0^2[1 - n^2(\mathbf{r})]$$

and rewrite (1.1) in a form that we will use in the development to follow. In particular we find that

$$[\nabla^2 + k_0^2 - V(\mathbf{r})]U(\mathbf{r}) = -\rho(\mathbf{r}), \tag{2.1}$$

where here and in the remainder of the paper both the scattering potential V and the source ρ are assumed to vanish outside the source region τ (thus $n(\mathbf{r}) = 1$ for $\mathbf{r} \notin \tau$).

The outgoing wave solution to (2.1) is the unique field radiated by the source obeying Sommerfeld's radiation condition (e.g., see [53, Chapter 2], [54, Chapter 3]), which is the one having the asymptotic behavior of an outgoing spherical wave

$$U(r\mathbf{s}) = f(\mathbf{s})\frac{e^{ik_0 r}}{r} + O\left(\frac{1}{r^2}\right) \tag{2.2}$$

as $k_0 r \to \infty$ uniformly in the direction specified by the unit vector $\mathbf{s}$. In the above equation, the quantity $f(\mathbf{s})$ is the source's far field radiation pattern which is seen to correspond to the limit

$$f(\mathbf{s}) = \lim_{r\to\infty} \left[r e^{-ik_0 r} U(r\mathbf{s}) \right]. \tag{2.3}$$

In the following, we will bear in mind (2.2), (2.3) but will usually express the associated far field asymptotic behavior simply as

$$U(r\mathbf{s}) \sim f(\mathbf{s}) \frac{e^{ik_0 r}}{r} \quad \text{as } k_0 r \to \infty, \tag{2.4}$$

with the understanding that throughout the paper all the far field approximations hold to within $O(1/r^2)$. It is well known that the radiation pattern specified for all directions $\mathbf{s}$ uniquely determines the field U everywhere outside the source region τ [11]; i.e., knowledge of the radiated field everywhere outside τ is equivalent to knowledge of the radiation pattern $f(\mathbf{s})$ specified for all directions $\mathbf{s}$.

The ISP consists of determining a source distribution $\rho(\mathbf{r})$ that radiates a given field U for $\mathbf{r} \notin \tau$. Because the ISP requires that the field radiated by the source be specified only outside τ, the problem does not possess a unique solution, because of the possible presence of nonradiating sources [12, 13, 14] within τ. A nonradiating source generates a field that vanishes identically outside τ and hence can be added to any given solution to the ISP to yield a different solution. Also, because the radiation pattern uniquely determines the field everywhere outside τ, the ISP is equivalent to the problem of determining a source that generates a prescribed radiation pattern $f(\mathbf{s})$ for all observation directions $\mathbf{s}$.

Most treatments of the ISP cast the problem in terms of the radiation pattern but require only that the source generate the radiation pattern to within a given accuracy defined by the integral squared error

$$E = \int_{4\pi} d\Omega_s \, |\hat{f}(\mathbf{s}) - f(\mathbf{s})|^2, \tag{2.5}$$

where f is the prescribed radiation pattern and $\hat{f}$ the radiation pattern actually generated by the source, while $d\Omega_s$ denotes the solid-angular differential element. More precisely, the desired radiation pattern is approximated by a finite series of spherical harmonics $Y_l^m(\mathbf{s})$,

$$f(\mathbf{s}) \approx \hat{f}(\mathbf{s}) = \sum_{l=0}^{L} \sum_{m=-l}^{l} \alpha_{l,m} Y_l^m(\mathbf{s}), \tag{2.6}$$

and the source is required only to generate the approximate radiation pattern $\hat{f}$. Here we have used the unit vector $\mathbf{s}$ having polar angle θ and azimuthal angle ϕ to denote the θ, ϕ arguments of the spherical harmonics. Because the spherical harmonics are orthonormal and complete over the unit sphere, the approximated radiation pattern satisfies (2.5) with an error E given by

$$E = \sum_{l=L+1}^{\infty} \sum_{m=-l}^{l} |\alpha_{l,m}|^2,$$

where the expansion coefficients (multipole moments) $\alpha_{l,m}$, $l > L$, are the higher order (neglected) expansion coefficients of the ideal radiation pattern.

Besides requiring only that the source generate the radiation pattern within a finite error, most treatments of the ISP also require that the source minimize the source energy defined by (cf. (1.2))

$$\mathcal{E} = \int_\tau d^3r\, |\rho(\mathbf{r})|^2. \tag{2.7}$$

We will show (see also [3]) that minimizing the source energy leads to a unique solution of the ISP, namely, the *minimum energy source*, which we designate by ρ_{ME}. This solution has the distinct advantage of being the most efficient source that solves the ISP for a given scattering potential $V(\mathbf{r})$ (corresponding to a given background index of refraction $n(\mathbf{r})$). Since the minimum energy source and, hence, the minimum source energy depend on the scattering potential, an interesting question arises as to the dependence of the source energy on the background index distribution and, in particular, on which index distributions lead to lowest source energies. This question provides much of the motivation for studying the ISP in nonhomogeneous backgrounds, and the derived results shed light onto the possibility of designing very efficient sources (e.g., antennas) that are embedded in such backgrounds.

Our goal in this paper is to develop the formalism for solving the ISP as defined above and to evaluate the formalism in a set of computer simulations. We will first treat the case of a source embedded in free space, and then extend the free space theory to the general case of a source embedded in an inhomogeneous background medium. The free space case is important in that it provides a benchmark of performance as well as a frame of reference for the general theory.

3. Free space case. The minimum energy ISP as defined above has been solved within both the scalar wave formulation under consideration here [1, 2, 3, 4, 5, 7] and the electromagnetic wave formulation [6, 8, 9, 10] in the special case where the scattering potential $V(\mathbf{r})$ vanishes; i.e., when the source is embedded in free space. We will review the scalar wave free space case here, where, however, we will employ a solution methodology to find the minimum energy source somewhat different from the one adopted in earlier work. We will use this same procedure for the general case of nonvanishing scattering potentials later in the paper.

The outgoing wave solution to (2.1) is given in terms of an outgoing wave Green function $G(\mathbf{r}, \mathbf{r}')$ (obeying (2.1) for $\rho(\mathbf{r}) = -\delta(\mathbf{r} - \mathbf{r}')$ and an asymptotic condition of the form (2.4)) by the expression

$$U(\mathbf{r}) = -\int_\tau d^3r'\, \rho(\mathbf{r}')G(\mathbf{r}, \mathbf{r}'), \tag{3.1}$$

where (as indicated earlier) the source volume τ is a sphere of radius a centered at the origin. In the particular free space case where the scattering potential $V = 0$, the outgoing wave Green function G is given by

$$G(\mathbf{r}, \mathbf{r}') = -\frac{1}{4\pi}\frac{e^{ik_0|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r} - \mathbf{r}'|}, \tag{3.2}$$

from which it is easy to show that

$$G(r\mathbf{s}, \mathbf{r}') \sim -\frac{1}{4\pi}e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}\frac{e^{ik_0r}}{r} \tag{3.3}$$

as $k_0r \to \infty$ in the direction $\mathbf{s}$ (which has the required form (2.4)). Using the above result, we conclude from (2.4) and (3.1) that the radiation pattern is given by

$$f(\mathbf{s}) = \frac{1}{4\pi}\int_\tau d^3r'\,\rho(\mathbf{r}')e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}. \tag{3.4}$$

We can obtain an expansion of the radiation pattern in a series of spherical harmonics by using the well-known expansion

$$e^{-ik_0\mathbf{s}\cdot\mathbf{r}'} = 4\pi\sum_{l=0}^{\infty}\sum_{m=-l}^{l}(-i)^l j_l(k_0r')Y_l^{m*}(\hat{\mathbf{r}}')Y_l^m(\mathbf{s}), \tag{3.5}$$

where j_l denotes the spherical Bessel function of the first kind of order l, Y_l^m are the spherical harmonics of degree l and order m, $\hat{\mathbf{r}}'$ denotes the unit vector in the $\mathbf{r}'$ direction, and $*$ denotes the complex conjugate. Upon substituting (3.5) into (3.4), we find that

$$f(\mathbf{s}) = \sum_{l=0}^{\infty}\sum_{m=-l}^{l}\alpha_{l,m}Y_l^m(\mathbf{s}), \tag{3.6}$$

where the expansion coefficients (multipole moments) $\alpha_{l,m}$ are given by

$$\begin{aligned}\alpha_{l,m} &= \int_{4\pi} d\Omega_s\, f(\mathbf{s})Y_l^{m*}(\mathbf{s})\\ &= (-i)^l\int_\tau d^3r'\,\rho(\mathbf{r}')j_l(k_0r')Y_l^{m*}(\hat{\mathbf{r}}').\end{aligned} \tag{3.7}$$

3.1. Minimum energy source. The minimum energy solution to the ISP is required to satisfy (3.7) for some given set of multipole moments $\alpha_{l,m}$, $l = 0, 1, \ldots, L$, and also to minimize the source energy defined according to (2.7). Computing the minimum energy source can be cast as a problem of constrained minimization, where the generalized Lagrangian is given by

$$\mathcal{L} = \mathcal{E} + \sum_{l=0}^{L}\sum_{m=-l}^{l}C_{l,m}\left[\alpha_{l,m}^* - i^l\int_\tau d^3r\,\rho^*(\mathbf{r})j_l(k_0r)Y_l^m(\hat{\mathbf{r}})\right] + \text{c.c.},$$

where $\mathcal{E}$ is the source energy defined in (2.7), c.c. stands for the complex conjugate of the second term on the right-hand side (r.h.s.) of the equation, and the $C_{l,m}$ are a set of Lagrange multipliers to be determined. On expressing the source energy in terms of ρ and ρ^* and taking the first variation of the above Lagrangian, we obtain

$$\delta\mathcal{L} = \int_\tau d^3r\,\delta\rho^*(\mathbf{r})\left[\rho(\mathbf{r}) - \sum_{l=0}^{L}\sum_{m=-l}^{l}C_{l,m}i^l j_l(k_0r)Y_l^m(\hat{\mathbf{r}})\right] + \text{c.c.},$$

which, when set equal to zero, yields the solution

$$\rho_{ME}(\mathbf{r}) = \begin{cases}\sum_{l=0}^{L}\sum_{m=-l}^{l}C_{l,m}i^l j_l(k_0r)Y_l^m(\hat{\mathbf{r}}) & \text{if } r < a,\\ 0 & \text{if } r > a.\end{cases}$$

The Lagrange multipliers $C_{l,m}$ are determined from the condition that the source generate the multipole moments according to (3.7). We find that

$$C_{l,m} = \frac{\alpha_{l,m}}{\sigma_l^2}, \tag{3.8}$$

where

$$\sigma_l^2 = \int_0^a r^2 dr\, j_l^2(k_0 r). \tag{3.9}$$

On making use of the above expression for the Lagrange multipliers, we finally conclude that the minimum energy solution to the free space ISP is given by

$$\rho_{ME}(\mathbf{r}) = \begin{cases} \sum_{l=0}^{L} \sum_{m=-l}^{l} i^l \frac{\alpha_{l,m}}{\sigma_l^2} j_l(k_0 r) Y_l^m(\hat{\mathbf{r}}) & \text{if } r < a, \\ 0 & \text{if } r > a. \end{cases} \tag{3.10}$$

3.2. Source energy. The source energy $\mathcal{E}$ is readily computed using the minimum energy source given in (3.10). We find from (2.7) that

$$\mathcal{E}_{ME} = \int_\tau d^3 r\, |\rho_{ME}(\mathbf{r})|^2 = \sum_{l=0}^{L} \sum_{m=-l}^{l} \frac{|\alpha_{l,m}|^2}{\sigma_l^2}, \tag{3.11}$$

where we have added the subscript "ME" to denote the energy of the minimum energy source. Now, it is easy to show that the quantities σ_l^2 depend critically on the product $k_0 a$ of the free space wavenumber with the source radius a. In particular, these quantities can be shown to be given by

$$\sigma_l^2 = \int_0^a r^2 dr\, |j_l(k_0 r)|^2 = \frac{a^3}{2}[j_l{}^2(k_0 a) - j_{l-1}(k_0 a) j_{l+1}(k_0 a)] \tag{3.12}$$

and to decrease exponentially to zero for $l > k_0 a$. It then follows that the largest value L of the index l allowed in the approximation (2.6) is $L = k_0 a$ if we want to maintain low source energy. Values of $L \gg k_0 a$ will lead to extremely high source energy and unstable source distributions.

To illustrate the remarks made above concerning the behavior of the quantities σ_l^2 on the index l and the product $k_0 a$ we show in Figure 3.1 semilog plots of σ_l^2 as a function the index l for various values of $x = k_0 a$. It is seen from these plots that these quantities decay exponentially to zero for $l \gg x$, so that at wavenumber k_0 a source of radius a can only efficiently radiate a radiation pattern whose maximum l value is $L = k_0 a$. Similar behavior is exhibited in Figure 3.2, which shows semilog plots of $\sigma_l^2(x)$ as a function of x for values of $l = 10$, 20, and 30.

We computed the energy of the minimum energy source for a model radiation pattern $f(\theta)$ having multipole coefficients $\alpha_{l,m}$ given by

$$\alpha_{l,m} = \begin{cases} \frac{1}{\sqrt{L+1}} & \text{if } m = 0 \text{ and } l \le L, \\ 0 & \text{otherwise.} \end{cases} \tag{3.13}$$

This radiation pattern is circularly symmetric about the z axis (is independent of ϕ since the nonzero multipoles correspond to $m = 0$), has an effective beam width inversely related to the cut-off value L, and has unit energy; i.e.,

$$\int_{4\pi} \sin\theta d\theta d\phi\, |f(\theta)|^2 = \sum_{l=0}^{L} \frac{1}{L+1} = 1.$$

We show plots of the model radiation pattern as a function of angle θ in Figure 3.3 for values of the parameter L equal to $L = 10$, $L = 20$, and $L = 30$. It is clear

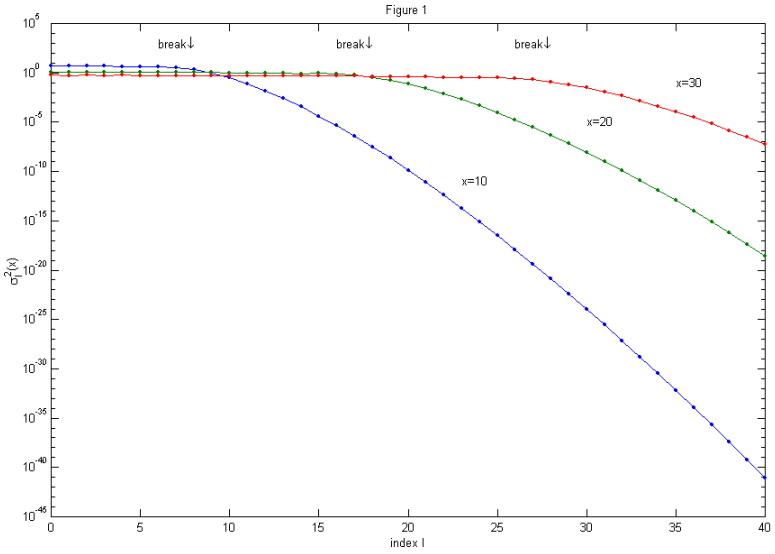

FIG. 3.1. *Behavior of σ_l^2 as a function of index l for three different values of $x = k_0 a$ equal to* 10, 20, *and* 30. *Plots indicate an exponential decay of these quantities for $l \gg x$. The break points are seen to occur when $x \approx l$.*

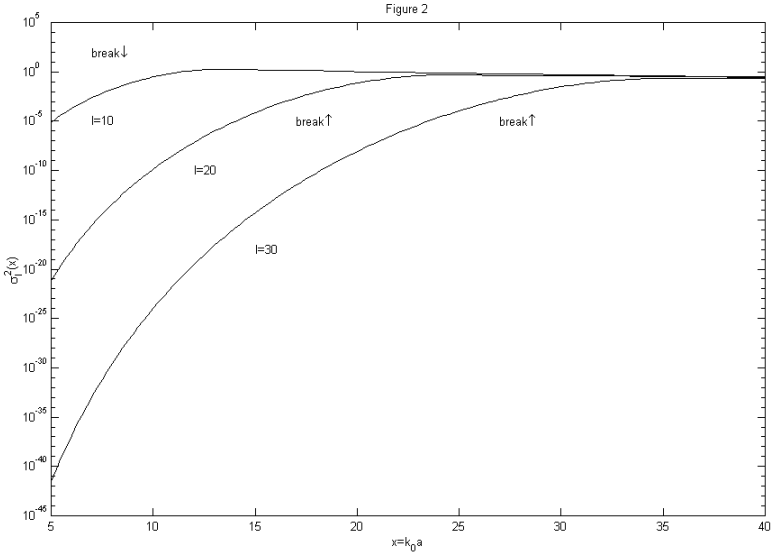

FIG. 3.2. *σ_l^2 as a function of $x = k_0 a$ for values of $l_0 = 10$, $l_0 = 20$, and $l_0 = 30$. Plots indicate an exponential growth of these quantities for $x \ll l_0$. The break points are seen to occur when $x \approx l$.*

from these plots that the larger the value of L, the narrower the radiation pattern and, hence, the higher the directivity of the source. Using the coefficients given in (3.13), we computed the source energy using (3.11) with the σ_l^2 given by (3.12) and

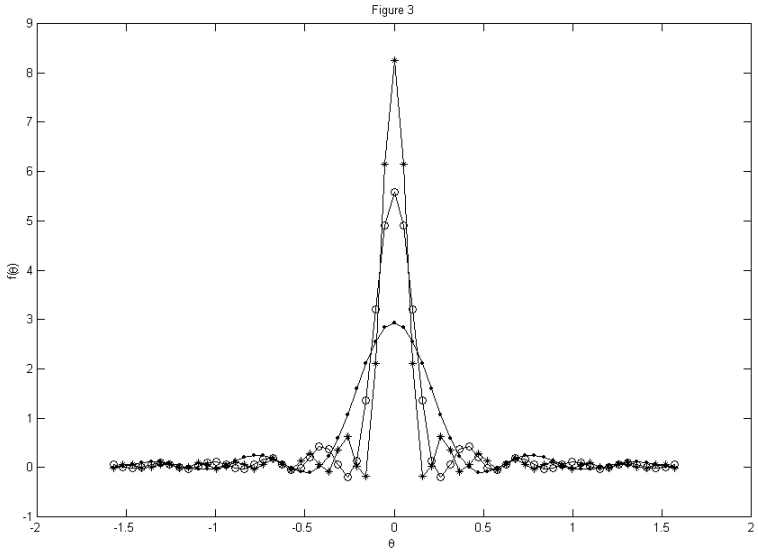

FIG. 3.3. *Plots of the model radiation pattern for* $L = 10$ *(.),* $L = 20$ *(o), and* $L = 30$ *(*).*

with three different L values of $L = 10, 20, 30$. It was found that, as expected, the source energy becomes extremely large if we try to achieve an L value that exceeds the critical value $L = k_0 a$. This is, of course, due to the fact that the quantities σ_l^2 become extremely small when $k_0 a \ll l$, as is indicated in Figure 3.2.

4. Nonhomogeneous backgrounds. The outgoing wave solution of (2.1) for a nonhomogeneous index distribution $n(\mathbf{r})$ of support τ, which behaves as in (2.2), (2.3), (2.4), can be expressed in terms of the outgoing wave Green function for the background medium via (3.1) where, however, the Green function is no longer the free space Green function defined in (3.2), but instead is the total outgoing wave Green function corresponding to the total medium comprised of free space plus the nonhomogeneous index distribution $n(\mathbf{r})$ or its associated scattering potential $V(\mathbf{r})$. In the ISP under consideration in this paper, the field is given outside the source region τ only; that is, the field for a source of support τ is given by (3.1), where $\mathbf{r}' \in \tau$ and $\mathbf{r} \notin \tau$. This particular situation enables us to formulate the forward mapping pertinent here (from a masked source that is confined within τ to an exterior field that is prescribed for $\mathbf{r} \notin \tau$ only) via a conceptually simple and insightful approach which borrows from standard scattering theory and the reciprocity property of the outgoing wave Green function, which can be readily shown for the formally self-adjoint partial differential operator $[\nabla^2 + k_0^2 - V(\mathbf{r})]$ using standard Green function theory (e.g., see [55, Chapters 9 and 10]). Two equivalent versions of the general methodology are outlined next. The main objective is to generalize the statement made in connection with the free space case in the far field mapping equation (3.4) for the more general case of nonhomogeneous backgrounds. The generalization of the derived expression for the far field mapping will be applied to the particular spherically symmetric and piecewise constant background cases later in the paper.

The starting point is provided by the familiar *Lippmann–Schwinger integral equation* (e.g., see [56, eqs. (8.4), (8.5), (10.12), (10.13)], [27, pp. 178–179, 263–265], [53,

p. 5], [57, pp. 60–61]), which in the present formulation and notation yields

$$G(\mathbf{r},\mathbf{r}') = G_0(\mathbf{r},\mathbf{r}') + \int_\tau d^3r''\, G_0(\mathbf{r},\mathbf{r}'')V(\mathbf{r}'')G(\mathbf{r}'',\mathbf{r}'), \tag{4.1}$$

where G denotes the total outgoing wave Green function of the total medium comprised of free space plus the generally nontrivial scattering potential V, and G_0 denotes the free space Green function defined in (3.2) (corresponding to $V = 0$), in particular,

$$G_0(\mathbf{r},\mathbf{r}') = -\frac{1}{4\pi}\frac{e^{ik_0|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|},$$

where (see also (3.3), where, again, the G in (3.3) corresponds to the G_0 of the present section)

$$G_0(r\mathbf{s},\mathbf{r}') = -\frac{1}{4\pi}e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}\frac{e^{ik_0r}}{r} + O\left(\frac{1}{r^2}\right) \quad \text{as } k_0r \to \infty, \tag{4.2}$$

in the direction of the unit vector $\mathbf{s}$, so that from the discussion in (2.2), (2.3), and (2.4) (which holds for a general source ρ) one finds that the far field radiation pattern of a point source $-\delta(\mathbf{r}-\mathbf{r}')$ in free space is $-\frac{1}{4\pi}e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}$. We shall recall this basic result later.

Due to reciprocity, the result (4.1) can be rewritten also as

$$G(\mathbf{r},\mathbf{r}') = G_0(\mathbf{r},\mathbf{r}') + \int_\tau d^3r''\, G(\mathbf{r},\mathbf{r}'')V(\mathbf{r}'')G_0(\mathbf{r}'',\mathbf{r}'). \tag{4.3}$$

We will borrow from both (4.1) and (4.3) in the following.

By making use of the asymptotic result (4.2), it is not difficult to show from (4.1) or its equivalent, (4.3), that the Green function G behaves asymptotically as

$$G(r\mathbf{s},\mathbf{r}') = -\frac{1}{4\pi}\psi^+(\mathbf{r}';-k_0\mathbf{s})\frac{e^{ik_0r}}{r} + O\left(\frac{1}{r^2}\right) \tag{4.4}$$

as $k_0r \to \infty$, where we have introduced the quantity $\psi^+(\mathbf{r};-k_0\mathbf{s})$ defined by

$$\begin{aligned}\psi^+(\mathbf{r};-k_0\mathbf{s}) &= e^{-ik_0\mathbf{s}\cdot\mathbf{r}} + \int_\tau d^3r'\, e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}V(\mathbf{r}')G(\mathbf{r}',\mathbf{r}) \\ &= e^{-ik_0\mathbf{s}\cdot\mathbf{r}} + \int_\tau d^3r'\, G(\mathbf{r},\mathbf{r}')V(\mathbf{r}')e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}.\end{aligned} \tag{4.5}$$

Note from (4.4) that the Green function $G(\mathbf{r},\mathbf{r}')$ does in fact behave as $k_0r \to \infty$, as we have required in (2.2), (2.3), and (2.4). From the same equations one also notes that the far field radiation pattern $f(\mathbf{s})$ in (2.2), (2.3), (2.4), corresponding to the field U obeying (2.1), applies to the *general* source ρ, while, on the other hand, the far field radiation pattern $-\frac{1}{4\pi}\psi^+(\mathbf{r}';-k_0\mathbf{s})$ in (4.4) corresponds to that of the total field produced by the *particular* Dirac-delta point source at $\mathbf{r}'$ in the same medium. In other words, the quantity $-\frac{1}{4\pi}\psi^+(\mathbf{r}';-k_0\mathbf{s})$ is the far field radiation pattern for the particular case of a point source at $\mathbf{r}'$. This quantity is seen from (4.5) to consist of the sum of two terms: the first term, $-\frac{1}{4\pi}e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}$, exists even if $V = 0$ and is the far field radiation pattern for the point source in free space. (It will account for an incident field in the discussion to follow.) This is, in fact, what we have discussed

before in (4.2). On the other hand, the second term, the integral in (4.5), corresponds to a scattered field contribution, as we shall elaborate further next.

The quantity $\psi^+(\mathbf{r}; -k_0\mathbf{s})$ as defined by the formulation above (i.e., (4.4), (4.5)) is customarily termed a *scattering wave function* (e.g., see [56, pp. 3, 4, 164, 172]). This scattering wave function is the unique total (incident plus scattered) field for the scattering potential $V(\mathbf{r})$ under excitation by the incident plane wave $e^{-ik_0\mathbf{s}\cdot\mathbf{r}}$ in the direction defined by the unit vector $-\mathbf{s}$, under Sommerfeld's radiation condition for the scattered field, which translates into the requirement that the respective scattered field, that is, the integral term in (4.5), behaves like an outgoing wave at infinity. Thus the scattering wave function $\psi^+(\mathbf{r}; -k_0\mathbf{s})$ is the solution to the homogeneous Helmholtz equation

$$[\nabla^2 + k_0^2 - V(\mathbf{r})]\psi^+(\mathbf{r}; -k_0\mathbf{s}) = 0, \tag{4.6}$$

which obeys an asymptotic condition of the form

$$\psi^+(r\hat{\mathbf{r}}; -k_0\mathbf{s}) \sim e^{-ik_0\mathbf{s}\cdot\mathbf{r}} + g(\hat{\mathbf{r}}; -k_0\mathbf{s})\frac{e^{ik_0 r}}{r} \tag{4.7}$$

as $k_0 r \to \infty$, where g is the so-called scattering amplitude associated with the scattering potential V whose role in scattering problems is similar to that of the source radiation pattern f (of (2.4)) in radiation problems (e.g., see [56, eq. (10.19)], [58]). Note from (4.4), (4.5) that

$$\psi^+(r\hat{\mathbf{r}}; -k_0\mathbf{s}) \sim e^{-ik_0\mathbf{s}\cdot\mathbf{r}} - \frac{1}{4\pi}\frac{e^{ik_0 r}}{r}\int_\tau d^3r'\, \psi^+(\mathbf{r}'; -k_0\mathbf{s})V(\mathbf{r}')e^{-ik_0\mathbf{s}\cdot\mathbf{r}'} \quad \text{as } k_0 r \to \infty, \tag{4.8}$$

so that from (4.7) the scattering amplitude

$$g(\hat{\mathbf{r}}; -k_0\mathbf{s}) = -\frac{1}{4\pi}\int_\tau d^3r'\, \psi^+(\mathbf{r}'; -k_0\mathbf{s})V(\mathbf{r}')e^{-ik_0\mathbf{s}\cdot\mathbf{r}'}. \tag{4.9}$$

Thus the scattering wave function $\psi^+(\mathbf{r}; -k_0\mathbf{s})$ corresponds to the total (incident plus scattered) field that results when an incident plane wave propagating in the $-\mathbf{s}$ direction scatters off the inhomogeneous index of refraction distribution $n(\mathbf{r})$. Note that in the limit when the scattering potential vanishes this scattering wave function simply reduces to the incident plane wave.

Now, by substituting the asymptotic result (4.4) into (2.2), (2.3), (2.4), and (3.1) we find that the radiation pattern $f(\mathbf{s})$ of a general source ρ embedded in the nonhomogeneous background characterized by index of refraction $n(\mathbf{r})$ or, equivalently, scattering potential $V(\mathbf{r})$, is given by

$$f(\mathbf{s}) = \frac{1}{4\pi}\int_\tau d^3r'\, \rho(\mathbf{r}')\psi^+(\mathbf{r}'; -k_0\mathbf{s}), \tag{4.10}$$

which is simply the free space result (3.3) with the plane wave $\exp(-ik_0\mathbf{s}\cdot\mathbf{r}')$ replaced by the scattering wave function $\psi^+(\mathbf{r}'; -k_0\mathbf{s})$. For a given V, this scattering wave function can be obtained by solving the scattering problem posed by (4.6), (4.7). The ISP for given nonhomogeneous background media then reduces to determining a source ρ that satisfies (4.10) for all observation directions $\mathbf{s}$, and where the scattering wave functions ψ^+ are to be determined a priori for the pertinent scattering potential V by addressing the scattering problem in (4.6), (4.7). Clearly, in the special case

when $V = 0$ the scattering wave function reduces to the plane wave (refer to (4.5)), and (4.10) reduces to the free space result (3.4), as expected.

Prior to engaging in the particular cases of spherically symmetric and piecewise constant backgrounds, we wish to outline an alternative description of the formulation above based on reciprocity; that is, for the total Green function in the total medium characterized by the scattering potential V, $G(\mathbf{r}, \mathbf{r}') = G(\mathbf{r}', \mathbf{r})$. Such a description is very useful in elucidating the connection between radiation and scattering problems (e.g., see [59]), and may thus facilitate application of the present ISP research to other areas, such as scattering and inverse scattering problems. Without loss of generality, in the rest of this paragraph the point $\mathbf{r}'$ will be taken to lie in the spherical volume τ of radius a centered about the origin (the source region). Also, take $\mathbf{r}$ to be a point in a spherical surface of radius $R > a$ centered about the origin. The idea is that the problem of computing the far field produced at the field point $R\mathbf{s}$ (for large $k_0 R$, and where $\mathbf{s}$ is a unit vector) by a point source at the point $\mathbf{r}'$ in the source region τ is, due to reciprocity considerations, equivalent to the problem of computing the (near) field produced at point $\mathbf{r}'$ due to a far zone point source at $R\mathbf{s}$, in particular, $G(R\mathbf{s}, \mathbf{r}') = G(\mathbf{r}', R\mathbf{s})$. Conveniently, the latter problem essentially reduces to the familiar scattering problem under plane wave excitation, and this is the basis of the preceding formulation as well as of the complementary analysis to be given next. The field generated by a given point source at $\mathbf{r}' \in \tau$ at the field point $\mathbf{r} = R\mathbf{s}$ in the far field direction defined by the unit vector $\mathbf{s}$ obeys, from (2.2), (2.3), (2.4), the asymptotic form

$$G(R\mathbf{s}, \mathbf{r}') = f(\mathbf{s}; \mathbf{r}') \frac{e^{ik_0 R}}{R} + O\left(\frac{1}{R^2}\right) \tag{4.11}$$

as $k_0 R \to \infty$, where the respective radiation pattern $f(\mathbf{s}; \mathbf{r}')$ of the total field radiated by the point source at $\mathbf{r}'$ depends on $\mathbf{r}'$ in a way to be clarified in the following (again, note that the radiation pattern in (4.11) is, apart from a factor $-\frac{1}{4\pi}$, the scattering wave function $\psi^+(\mathbf{r}'; -k_0\mathbf{s})$ of the preceding development). On the other hand, the total field produced at the point $\mathbf{r}' \in \tau$ due to a point source at $R\mathbf{s}$ can be decomposed into the sum of an incident field, corresponding to the radiation in free space, that is, the free space Green function component $G_0(\mathbf{r}', R\mathbf{s})$, plus a scattered field corresponding to scattering of that incident field by the medium characterized by scattering potential V. This can be expressed formally by borrowing from (4.1), (4.3), in particular,

$$\begin{aligned} G(\mathbf{r}', R\mathbf{s}) &= G_0(\mathbf{r}', R\mathbf{s}) + \int_\tau d^3 r\, G_0(\mathbf{r}', \mathbf{r}) V(\mathbf{r}) G(\mathbf{r}, R\mathbf{s}) \\ &= G_0(\mathbf{r}', R\mathbf{s}) + \int_\tau d^3 r\, G(\mathbf{r}', \mathbf{r}) V(\mathbf{r}) G_0(\mathbf{r}, R\mathbf{s}), \end{aligned} \tag{4.12}$$

where the integrals define the scattered field component, and where from the outgoing wave nature of both G_0 and G,

$$G(\mathbf{r}', R\mathbf{s}) = -\frac{1}{4\pi} e^{-ik_0 \mathbf{s}\cdot\mathbf{r}'} \frac{e^{ik_0 R}}{R} + \frac{e^{ik_0 R}}{R} \int_\tau d^3 r\, G_0(\mathbf{r}', \mathbf{r}) V(\mathbf{r}) f(\mathbf{s}; \mathbf{r}) + O\left(\frac{1}{R^2}\right) \tag{4.13}$$

as $k_0 R \to \infty$ (where we have used (4.11) and $G(\mathbf{r}', R\mathbf{s}) = G(R\mathbf{s}, \mathbf{r}')$), or, equivalently (from the second of the equations in (4.12)), as

$$G(\mathbf{r}', R\mathbf{s}) = -\frac{1}{4\pi} e^{-ik_0 \mathbf{s}\cdot\mathbf{r}'} \frac{e^{ik_0 R}}{R} - \frac{1}{4\pi} \frac{e^{ik_0 R}}{R} \int_\tau d^3 r\, G(\mathbf{r}', \mathbf{r}) V(\mathbf{r}) e^{-ik_0 \mathbf{s}\cdot\mathbf{r}} + O\left(\frac{1}{R^2}\right) \tag{4.14}$$

as $k_0 R \to \infty$; furthermore, using $G(\mathbf{r}', R\mathbf{s}) = G(R\mathbf{s}, \mathbf{r}')$, one recovers from these developments (4.11), where $f(\mathbf{s}; \mathbf{r}') = -\frac{1}{4\pi}\psi^+(\mathbf{r}'; -k_0\mathbf{s})$ obeys

(4.15)
$$f(\mathbf{s}; \mathbf{r}') = -\frac{1}{4\pi}\psi^+(\mathbf{r}'; -k_0\mathbf{s}) = -\frac{1}{4\pi}\left[e^{-ik_0\mathbf{s}\cdot\mathbf{r}'} + \int_\tau d^3r\, G_0(\mathbf{r}', \mathbf{r})V(\mathbf{r})\psi^+(\mathbf{r}; -k_0\mathbf{s})\right]$$

or, equivalently,

$$f(\mathbf{s}; \mathbf{r}') = -\frac{1}{4\pi}\psi^+(\mathbf{r}'; -k_0\mathbf{s}) = -\frac{1}{4\pi}\left[e^{-ik_0\mathbf{s}\cdot\mathbf{r}'} + \int_\tau d^3r\, G(\mathbf{r}', \mathbf{r})V(\mathbf{r})e^{-ik_0\mathbf{s}\cdot\mathbf{r}}\right], \tag{4.16}$$

which agrees with the previous formulation ((4.4), (4.5), (4.6), (4.7)). It follows that, as explained in connection with those results, the scattering wave function $\psi^+(\mathbf{r}', -k_0\mathbf{s})$ is the total (incident plus scattered) field at $\mathbf{r}'$ due to the interaction of an incident plane wave in the direction $-\mathbf{s}$ with the scattering potential V. Finally, an alternative way of arriving at these results is via the so-called mixed reciprocity relation [57, pp. 61–62, particularly eq. (2.2.6); see also p. 42], which states that the value at $\mathbf{s}$ of the far field radiation pattern corresponding to the *scattered field* component of the field generated in the nonhomogeneous medium due to a point source excitation at $\mathbf{r}'$ is, apart from a multiplicative factor $(-\frac{1}{4\pi})$, equal to the value at $\mathbf{r}'$ of the field that is scattered by the same medium due to an incident plane wave traveling in the direction $-\mathbf{s}$. In the notation of this paper, the far field radiation pattern of the scattered field component of the field generated in the nonhomogeneous medium due to a point source at $\mathbf{r}'$ is, as has been discussed before (see (4.1), (4.2), (4.3), (4.4), (4.5)), precisely the integration term in (4.5), (4.15), and (4.16), which is the field scattered by a plane wave traveling in the direction $-\mathbf{s}$, as expected. Thus our findings are consistent with this standard relation from the literature [57]. Yet, we must point out a difference in notation between [57] and the present paper. In our notation (and without loss of generality), the Green function or fundamental solution applicable to free space,

$$G_0(\mathbf{r}, \mathbf{r}') = -\frac{1}{4\pi}\frac{e^{ik_0|\mathbf{r}-\mathbf{r}'|}}{|\mathbf{r}-\mathbf{r}'|},$$

has a negative sign since we define the Green function (or fundamental solution) for a point source $-\delta(\mathbf{r}-\mathbf{r}')$, while [57] considers the fundamental solution for a point source $\delta(\mathbf{r}-\mathbf{r}')$. (This is explained in [57, p. 8]; see also [53, p. 16], [54, Chapter 3].) Our entire formulation incorporates with no loss of generality this particular choice, as is obvious in our form of the Green function integral (3.1). Thus the result (2.2.6) in [57, p. 61] involves the factor $\gamma_3 = \frac{1}{4\pi}$ (refer to [57, p. 42]), which is equivalent, in the present usage for the fundamental solution (with the added negative sign), to our factor $-\frac{1}{4\pi}$, and this completes the picture (the two theories yield the same final result, as desired). Let us consider special cases next.

4.1. Spherically symmetric backgrounds. In the remainder of the paper we will restrict our attention to the case of spherically symmetric index distributions $n(\mathbf{r}) = n(r)$. The scattering wave functions then satisfy (cf. (4.6))

$$[\nabla^2 + k_0^2 - V(r)]\psi^+(\mathbf{r}; -k_0\mathbf{s}) = 0, \tag{4.17}$$

where the eigenfunctions ψ^+ are required to satisfy the boundary condition (4.7). Because of the spherical symmetry of the scattering potential V, the wavefield ψ^+

can depend only on the magnitude r of the field point vector $\mathbf{r}$ and the polar angle γ formed between the direction of propagation $-\mathbf{s}$ of the incident plane wave and $\mathbf{r}$. If we then take the incident wave direction to be the positive z axis and express the Helmholtz operator in spherical polar coordinates, (4.17) can be written in the form

$$\left[\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial}{\partial r}\right)+\frac{1}{r^2\sin\gamma}\frac{\partial}{\partial\gamma}\left(\sin\gamma\frac{\partial}{\partial\gamma}\right)-V(r)+k_0^2\right]\psi^+(r,\gamma)=0, \tag{4.18}$$

where γ is the polar angle formed between the positive z axis and the field point vector $\mathbf{r}$ and where we have used the fact that the field must be independent of the azimuthal angle ϕ. The boundary condition (4.7) becomes

$$\psi^+(r,\gamma)\sim e^{ik_0r\cos\gamma}+g(\gamma)\frac{e^{ik_0r}}{r}, \tag{4.19}$$

where we have set $-k_0\mathbf{s}\cdot\mathbf{r}=k_0z=k_0r\cos\gamma$ and where $g(\gamma)$ is the scattering amplitude.

We can expand the scattering wave function $\psi^+(r,\gamma)$, the incident plane wave $\exp(ik_0r\cos\gamma)$, and the scattering amplitude $g(\gamma)$ into a series of Legendre polynomials as follows [55, 60]:

$$\begin{aligned}\psi^+(r,\gamma)&=\sum_l i^l(2l+1)\psi_l(r)P_l(\cos\gamma),\\ e^{ik_0r\cos\gamma}&=\sum_l i^l(2l+1)j_l(k_0r)P_l(\cos\gamma),\\ g(\gamma)&=\sum_l i^l(2l+1)A_lP_l(\cos\gamma),\end{aligned}$$

where we have introduced the factors $i^l(2l+1)$ into the expansions for the scattering wave function and the scattering amplitude for later notational convenience. In these equations j_l is the spherical Bessel function of the first kind of order l, and the A_l are expansion coefficients of the scattering amplitude that depend on the specific form of the scattering potential $V(r)$. On substituting the first of these equations into (4.18), we find that the radially dependent coefficients $\psi_l(r)$ satisfy the equation

$$\left[\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d}{dr}\right)-\frac{l(l+1)}{r^2}-V(r)+k_0^2\right]\psi_l(r)=0, \tag{4.20}$$

where we have used the fact that

$$\frac{1}{\sin\gamma}\frac{\partial}{\partial\gamma}\left(\sin\gamma\frac{\partial}{\partial\gamma}\right)P_l(\cos\gamma)=-l(l+1)P_l(\cos\gamma).$$

The asymptotic behavior of the radial functions $\psi_l(r)$ is obtained by substituting the expansions for the scattering wave function, the incident plane wave, and the scattering amplitude into (4.19). We find that

$$\psi_l(r)\sim j_l(k_0r)+A_l\frac{e^{ik_0r}}{r}. \tag{4.21}$$

Besides satisfying the boundary condition (4.21), we also require that the radial functions be everywhere continuous with continuous first derivatives.

Once the radial functions $\psi_l(r)$ are computed, the scattering wave function $\psi^+(r,\gamma)$ corresponding to an incident plane wave propagating along the z axis is given by the expansion in Legendre polynomials above. However, the defining equation for the radiation pattern (4.10) requires that we have the scattering wave functions for all directions $-\mathbf{s}$ of the incident plane wave. This can be easily accomplished by using the addition theorem for spherical harmonics [55, 60],

$$P_l(\cos\gamma) = \frac{4\pi}{2l+1}\sum_{m=-l}^{l}(-1)^l Y_l^{m*}(\hat{\mathbf{r}})Y_l^m(\mathbf{s}),$$

where now γ is the angle formed between the *arbitrary* incident wave direction $-\mathbf{s}$ and the field direction $\hat{\mathbf{r}}$. On using the addition theorem, we obtain

$$\psi^+(\mathbf{r};-k_0\mathbf{s}) = 4\pi\sum_{l=0}^{\infty}\sum_{m=-l}^{l}(-i)^l\psi_l(r)Y_l^{m*}(\hat{\mathbf{r}})Y_l^m(\mathbf{s}), \tag{4.22}$$

which is the generalization of (3.5) to spherically symmetric nonhomogeneous index of refraction distributions.

4.2. Minimum energy source. Upon substituting the expansion (4.22) into (4.10), we obtain (3.6) where, however, the multipole moments are now given by

$$\begin{aligned}\alpha_{l,m} &= \int_{4\pi} d\Omega_s\, f(\mathbf{s})Y_l^{m*}(\mathbf{s})\\ &= (-i)^l\int_\tau d^3r\,\rho(\mathbf{r})\psi_l(r)Y_l^{m*}(\hat{\mathbf{r}}),\end{aligned} \tag{4.23}$$

which is the generalization of (3.7) to the case where the source is embedded in a nonhomogeneous but spherically symmetric index of refraction profile. The generalized equation (4.23) is seen to result from (3.7) under the replacement of the spherical Bessel functions j_l by the radial functions ψ_l. The minimum energy solution to the ISP is required to satisfy (4.23) for some given set of multipole moments $\alpha_{l,m}$, $l = 0, 1, \ldots, L$, and also to minimize the source energy defined according to (2.7).

As in the free space case, the problem of computing the minimum energy source can be cast as one of constrained minimization, where the generalized Lagrangian is now given by

$$\mathcal{L} = \mathcal{E} + \sum_{l=0}^{L}\sum_{m=-l}^{l} C_{l,m}\left[\alpha_{l,m}^* - i^l\int_\tau d^3r\,\rho^*(\mathbf{r})\psi_l^*(r)Y_l^m(\hat{\mathbf{r}})\right] + \text{c.c.},$$

where, as before, $\mathcal{E}$ is the source energy defined in (2.7), c.c. stands for the complex conjugate of the second term on the r.h.s. of the equation, and the $C_{l,m}$ are a set of Lagrange multipliers to be determined. On expressing the source energy in terms of ρ and ρ^* and taking the first variation of the above Lagrangian, we obtain

$$\delta\mathcal{L} = \int_\tau d^3r\,\delta\rho^*(\mathbf{r})\left[\rho(\mathbf{r}) - \sum_{l=0}^{L}\sum_{m=-l}^{l} C_{l,m}i^l\psi_l^*(r)Y_l^m(\hat{\mathbf{r}})\right] + \text{c.c.},$$

which, when set equal to zero, yields the solution

$$\rho_{ME}(\mathbf{r}) = \begin{cases} \sum_{l=0}^{L}\sum_{m=-l}^{l} C_{l,m}i^l\psi_l^*(r)Y_l^m(\hat{\mathbf{r}}) & \text{if } r < a,\\ 0 & \text{if } r > a.\end{cases}$$

The Lagrange multipliers $C_{l,m}$ are determined from the condition that the source generate the multipole moments according to (4.23). We find that

$$C_{l,m} = \frac{\alpha_{l,m}}{\Sigma_l^2}, \tag{4.24}$$

where

$$\Sigma_l^2 = \int_0^a r^2 dr\, |\psi_l(r)|^2. \tag{4.25}$$

On making use of the above expression for the Lagrange multipliers, we finally conclude that the minimum energy solution to the ISP for spherically symmetric background index distributions is given by

$$\rho_{ME}(\mathbf{r}) = \begin{cases} \sum_{l=0}^{L} \sum_{m=-l}^{l} (i)^l \frac{\alpha_{l,m}}{\Sigma_l^2} \psi_l^*(r) Y_l^m(\hat{\mathbf{r}}) & \text{if } r < a, \\ 0 & \text{if } r > a. \end{cases} \tag{4.26}$$

The source energy is found to be given by the free space formula (3.11), where, however, the σ_l^2 are replaced by the Σ_l^2 defined in (4.25). As in the free space case, the source energy is seen to depend inversely on the Σ_l^2. Although these quantities are strictly positive they can become extremely small, leading to extremely high source energy and associated instability in the minimum energy source. Thus, it is of interest to maximize these quantities especially for large values of the index l, which is associated with fine detail (high resolution) in the radiation pattern.

The energy of the minimum energy source is obtained by substituting (4.26) into the source energy definition given in (1.2). We obtain the same expression as was obtained in the free space case (3.11), where, however, the σ_l^2 are replaced by the Σ_l^2. It is clear that the source energy is minimized by maximizing the Σ_l^2, which, in turn, is equivalent to maximizing the weighted L^2 norm of the radial functions ψ_l over the interval $[0, a]$. Since the radial functions ψ_l are solutions to a Sturm–Liouville problem, the energy minimization problem reduces to finding scattering potentials $V(r)$ whose corresponding Sturm–Liouville problem has solutions with maximum norm over this interval. This problem, although simple to state, appears to be nontrivial, and the authors offer no simple recipe for computing optimum potentials at this time. However, in the following section we will treat a simple class of potentials that illustrates the dependence of source energy on selection of V.

5. Piecewise constant backgrounds. In this section we consider the special case where the scattering potential $V(r)$ is constant throughout the source region; i.e.,

$$V(r) = \begin{cases} k_0^2 - k^2 & \text{if } r < a, \\ 0 & \text{if } r > a. \end{cases} \tag{5.1}$$

This is certainly a spherically symmetric scattering potential, so that the scattering wave functions can be expanded in the form of (4.22), where the radial functions $\psi_l(r)$ satisfy (4.20) with $V(r)$ given in (5.1) above. Thus we find that

$$\left[\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d}{dr}\right) - \frac{l(l+1)}{r^2} + k^2\right]\psi_l(r) = 0 \quad \text{if } 0 < r < a,$$
$$\left[\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d}{dr}\right) - \frac{l(l+1)}{r^2} + k_0^2\right]\psi_l(r) = 0 \quad \text{if } a < r < \infty,$$

together with the boundary condition from (4.21):

$$\psi_l(r) \sim j_l(k_0 r) + A_l \frac{e^{ik_0 r}}{r} \quad \text{if } r > a. \tag{5.2}$$

We also require that the radial functions be finite and continuous with a continuous first derivative. The set of differential equations together with the boundary and continuity conditions allow us to obtain a unique solution for the radial function.

5.0.1. Radial function. The radial function has the general form

$$\psi_l(r) = Aj_l(kr) + Bh_l(kr) \quad \text{if } 0 < r < a,$$
$$\psi_l(r) = Cj_l(k_0 r) + Dh_l(k_0 r) \quad \text{if } a < r < \infty,$$

where j_l is the spherical Bessel function of the first kind and h_l the spherical Hankel function of the first kind. The requirement that the radial function be finite at the origin $r = 0$ requires that $B = 0$, while the boundary condition (5.2) requires that the constant $C = 1$. The remaining constants A and D are determined by the continuity requirements applied at the boundary $r = a$. These conditions are

$$Aj_l(ka) = j_l(k_0 a) + Dh_l(k_0 a),$$
$$Aj_l{}'(ka) = \frac{k_0}{k}[j_l{}'(k_0 a) + Dh_l{}'(k_0 a)],$$

from which we obtain the solution

$$A = \frac{k_0}{k} \frac{j_l{}'(k_0 a)h_l(k_0 a) - j_l(k_0 a)h_l{}'(k_0 a)}{j_l{}'(ka)h_l(k_0 a) - \frac{k_0}{k} j_l(ka)h_l{}'(k_0 a)},$$
$$D = -\frac{j_l{}'(ka)j_l(k_0 a) - \frac{k_0}{k} j_l(ka)j_l{}'(k_0 a)}{j_l{}'(ka)h_l(k_0 a) - \frac{k_0}{k} j_l(ka)h_l{}'(k_0 a)}.$$

The expression for the constant A can be further simplified by using the Wronskian relation for spherical Bessel functions

$$j_l'(k_0 a)h_l(k_0 a) - j_l(k_0 a)h_l'(k_0 a) = \frac{-i}{k_0^2 a^2}.$$

We find that

$$A = \frac{\frac{-i}{k_0 k a^2}}{j_l{}'(ka)h_l(k_0 a) - \frac{k_0}{k} j_l(ka)h_l{}'(k_0 a)}. \tag{5.3}$$

5.1. Source energy. The quantities Σ_l^2 are found using (4.25) to be given by

$$\begin{aligned} {\Sigma_l}^2 &= \int_0^a r^2 dr\, |\psi_l(r)|^2 \\ &= |A|^2 \int_0^a r^2 dr\, |j_l(kr)|^2 \\ &= T_l(k, k_0)\sigma_l^2(k), \end{aligned} \tag{5.4}$$

where $\sigma_l^2(k)$ is the free space quantity defined in (3.12) *but with* k_0 *replaced by* k and

$$T_l(k, k_0) = |A|^2 = \frac{1}{k_0^2 a^4 |k j_l'(ka)h_l(k_0 a) - k_0 j_l(ka)h_l'(k_0 a)|^2}. \tag{5.5}$$

In the limit when $k \to k_0$ we have that

$$T_l(k, k_0) \to T(k_0, k_0) = \frac{1}{k_0^4 a^4 |j_l'(k_0 a) h_l(k_0 a) - j_l(k_0 a) h_l'(k_0 a)|^2} = 1,$$

where we have used the Wronskian between the spherical Bessel and spherical Hankel functions. It then follows that $\Sigma_l^2 \to \sigma_l^2(k_0)$ in this limit, as required.

The quantities $T_l(k, k_0)$ appearing in the expression for the Σ_l^2 have a simple interpretation: they are the magnitude square of the transmission coefficients relating the amplitudes of the outgoing multipole fields radiated by the source ρ evaluated on the exterior of the source region to the amplitude of the outgoing wave multipole fields radiated by the source on the interior of the source region. In particular, at the interior of the boundary at $r = a$ we can express the field radiated by the source in the form of a superposition of outgoing and standing wave solutions to the homogeneous Helmholtz equation with wavenumber $k = nk_0$, while outside this sphere the field is a superposition of outgoing wave solutions to the Helmholtz equation with wavenumber k_0. Because the total field and normal derivative must be continuous across the boundary, we find that for each multipole mode we require

$$\begin{aligned} h_l(ka) + r_l j_l(ka) &= t_l h_l(k_0 a), \\ h_l'(ka) + r_l j_l'(ka) &= \frac{k_0}{k} t_l h_l'(k_0 a), \end{aligned}$$

where r_l and t_l are reflection and transmission coefficients and the primes denote derivatives. Solving for the transmission coefficients t_l, we find that

$$\begin{aligned} t_l &= \frac{j_l'(ka) h_l(ka) - j_l(ka) h_l'(ka)}{j_l'(ka) h_l(k_0 a) - \frac{k_0}{k} j_l(ka) h_l'(k_0 a)} \\ &= \frac{\frac{-i}{k^2 a^2}}{j_l'(ka) h_l(k_0 a) - \frac{k_0}{k} j_l(ka) h_l'(k_0 a)}, \end{aligned} \tag{5.6}$$

which is seen to be identical to the coefficient A obtained earlier so that $|t_l|^2 = |A|^2 = T_l$, as indicated.

The interpretation of the quantities T_l as being the magnitude square of the transmission coefficients from the field modes in the interior of the source region to the field modes outside this region makes perfect sense in view of the formula (5.4) for the quantities Σ_l^2. In particular, to minimize source energy $\mathcal{E}$ (i.e., to obtain an efficient source) we wish to maximize the Σ_l^2, which, in turn, requires us to maximize the T_l or, equivalently, maximize the amount of energy transmitted from the source interior to the source exterior. As we will find in our simulations presented below, the $T_l(k, k_0)$ vary *inversely* with index value n, so that low source energy is obtained by selecting n to be small. On the other hand, the Σ_l^2 and hence the source energy also depend on the free space quantities σ_l^2 evaluated at the source region wavenumber k, and, as is easily confirmed from the results presented in section 3, the free space quantities $\sigma_l^2(k)$ *increase* with k and, hence, index n, at fixed source radius a. Thus, the two quantities entering into the expression (5.4) for Σ_l^2 have opposite dependencies on source index n, and it is necessary to carefully evaluate the relative importance of each quantity in order to select an index value that leads to small source energy.

To illustrate, we show in Figures 5.1–5.3 plots of the free space quantities $\sigma_l^2(k)$, the modulus square of the transmission coefficient $T_l(k, k_0)$, and finally the $\Sigma_l^2 =$

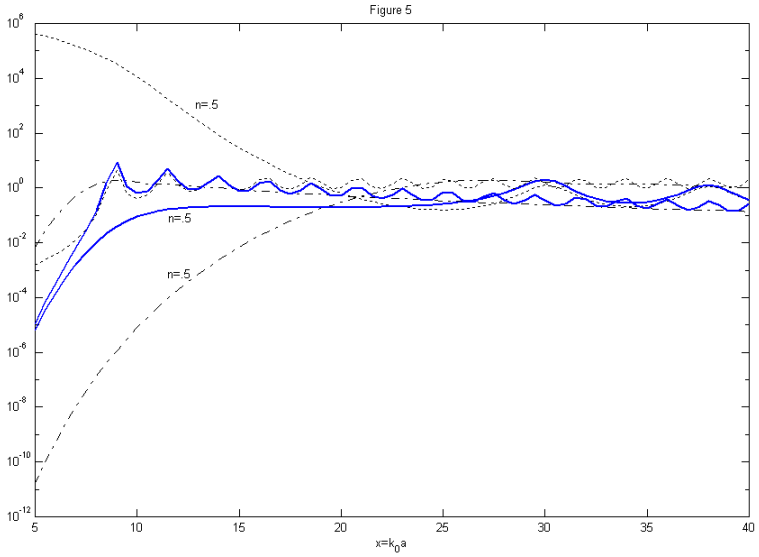

FIG. 5.1. *Plots of* $\sigma_l^2(k = nk_0)$ *(dash-dot),* $T_l(k = nk_0, k_0)$ *(dotted), and* $\Sigma_l^2 = T_l\sigma_l^2$ *(solid) for* $l = 10$ *and* $n = .5$ *and* $n = 1.5$. *It is seen from the plots that the larger* n *value yields larger* Σ_l^2 *around and below the critical point.*

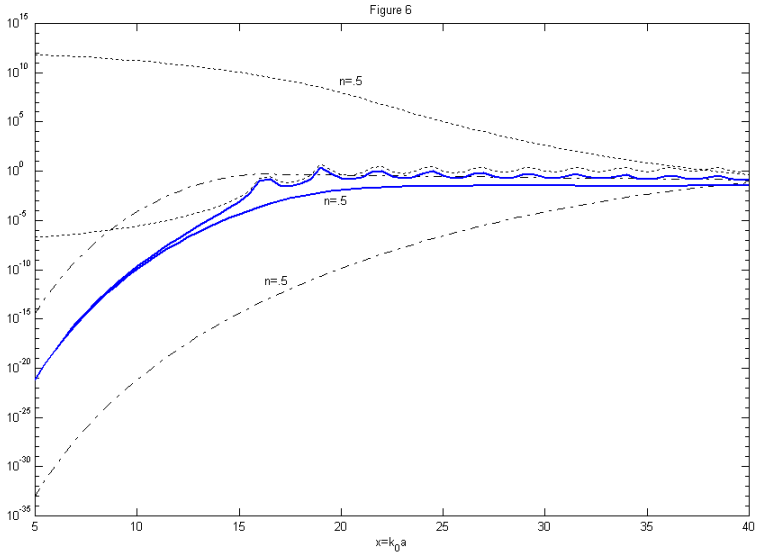

FIG. 5.2. *Plots of* $\sigma_l^2(k = nk_0)$ *(dash-dot),* $T_l(k = nk_0, k_0)$ *(dotted), and* $\Sigma_l^2 = T_l\sigma_l^2$ *(solid) for* $l = 20$ *and* $n = .5$ *and* $n = 1.5$. *It is seen from the plots that the larger* n *value yields larger* Σ_l^2.

$T_l(k, k_0)\sigma_l^2(k)$ plotted as a function of the product $x = k_0a$ of the free space wavenumber with the source radius $a = 10$ and for two values of the source region index n ($n = .5$, $n = 1.5$), for l values of $l = 10, 20, 30$. The following conclusions can be

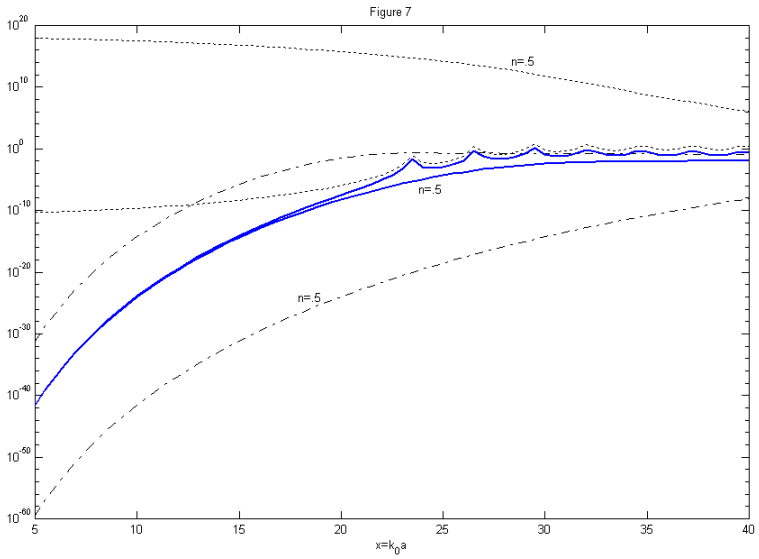

FIG. 5.3. *Plots of* $\sigma_l^2(k = nk_0)$ *(dash-dot),* $T_l(k = nk_0, k_0)$ *(dotted), and* $\Sigma_l^2 = T_l\sigma_l^2$ *(solid) for* $l = 30$ *and* $n = .5$ *and* $n = 1.5$. *It is seen from the plots that the larger* n *value yields larger* Σ_l^2.

drawn from these plots:

- For fixed a and fixed l the free space quantities $\sigma_l^2(k = nk_0)$ *increase* with increasing index n for any given free space wavenumber k_0.
- For fixed a and fixed l the quantities $T_l(k = nk_0, k_0)$ oscillate with k_0. The oscillations indicate the presence of resonances of the scattering functions within the source volume. The T_l are *decreasing* functions of index n at any given free space wavenumber k_0.
- The $\Sigma_l^2 = T_l\sigma_l^2$ oscillate with respect to k_0 due to the resonances of the scattering states in the source region and are also dependent on the source region index n. *For* k_0 *values below the critical point* $k_0a = l$, *the growth of the free space quantity* $\sigma_l^2(k = nk_0)$ *with respect to index* n *tends to outweigh the decay of* $T_l(k = nk_0, k_0)$ *with respect to* n, *with the result that the product* Σ_l^2 *is an increasing function of* n.

A more in-depth look at the behavior of the Σ_l^2 as a function of k_0, n, and l can be obtained from Figures 5.4–5.6. These figures show composite plots of Σ_l^2 for $n = .5, 1, 1.5$ for three different l values ($l = 10, 20, 30$). It is clear from these plots that by making the source region index $n > 1$ it is possible to increase the Σ_l^2 beyond their free space values $\sigma_l^2(k_0)$ and thereby obtain sources which have lower energy than those embedded in free space.

We conclude from the above results that, like the free space quantities $\sigma_l^2(k_0)$, the Σ_l^2 decay exponentially to zero for $l \gg k_0a$. However, by proper selection of the index n of the source region it is possible to obtain higher values of these quantities around and below the critical point $k_0a = l$ and, hence, lower source energy than can be obtained in the free space case for the same radiation pattern. This result follows from the fact that the radiation pattern expansion coefficients $\alpha_{l,m}$ *are independent of the source region index distribution* so that minimum source energy is obtained by

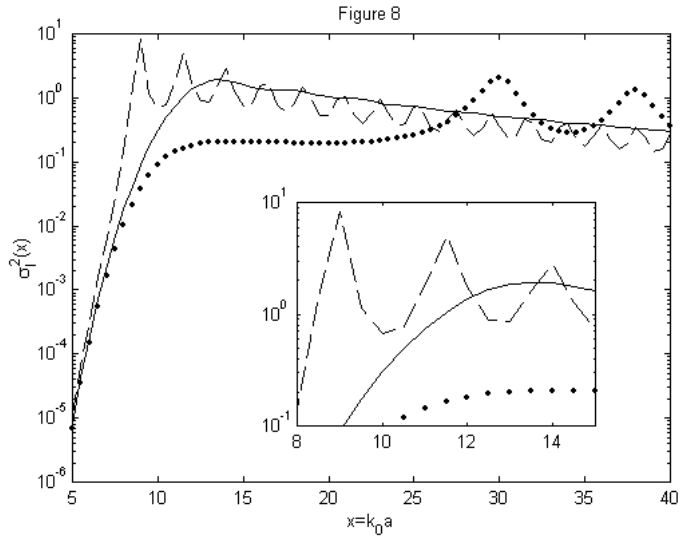

FIG. 5.4. *Plots of* $\Sigma_l^2 = T_l\sigma_l^2$ *for* $l = 10$ *and* $n = .5$ *(dotted),* $n = 1$ *(solid), and* $n = 1.5$ *(dashed). It is seen from the plots that the larger n value yields larger* Σ_l^2 *around and below the critical point* $k_0a = l$.

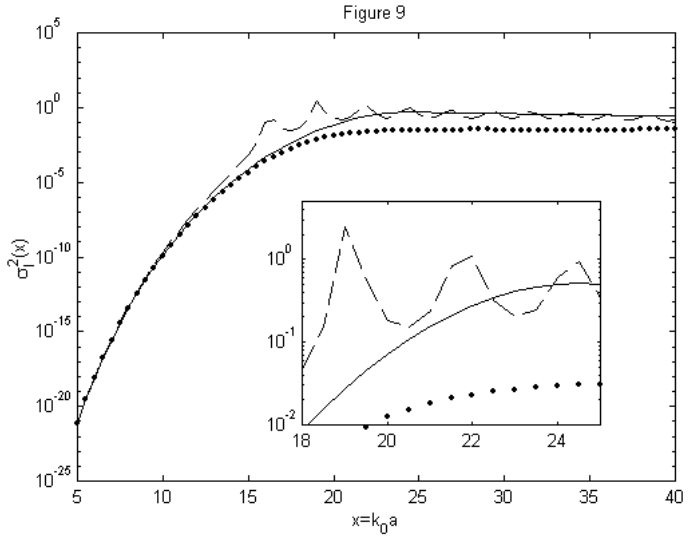

FIG. 5.5. *Plots of* $\Sigma_l^2 = T_l\sigma_l^2$ *for* $l = 20$ *and* $n = .5$ *(dotted),* $n = 1$ *(solid), and* $n = 1.5$ *(dashed). It is seen from the plots that the larger n value yields larger* Σ_l^2 *around and below the critical point* $k_0a = l$.

simply maximizing the Σ_l^2.

We computed the source energy for the model radiation pattern employed in the free space examples of section 3.2. Using the coefficients given in (3.13), we computed the source energy using (3.11) with the Σ_l^2 given by (5.4). We show in Figure 5.7 plots of the source energies as a function of $x = k_0a$ for three different values of the

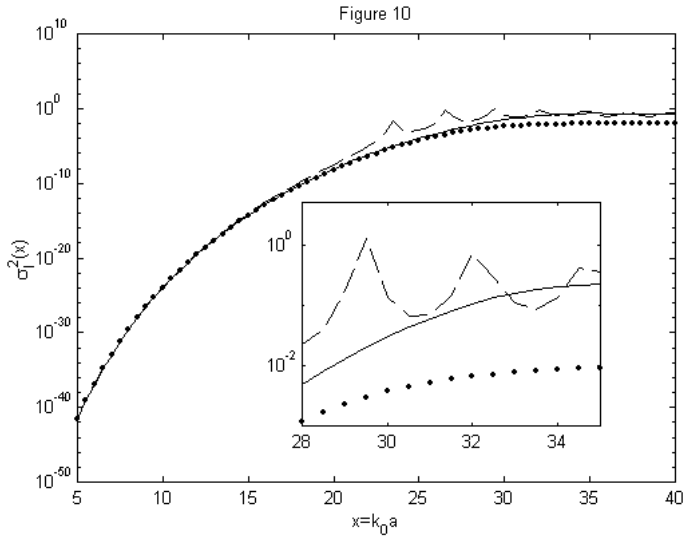

FIG. 5.6. *Plots of* $\Sigma_l^2 = T_l\sigma_l^2$ *for* $l = 30$ *and* $n = .5$ *(dotted),* $n = 1$ *(solid), and* $n = 1.5$ *(dashed). It is seen from the plots that the larger* n *value yields larger* Σ_l^2 *around and below the critical point* $k_0a = l$.

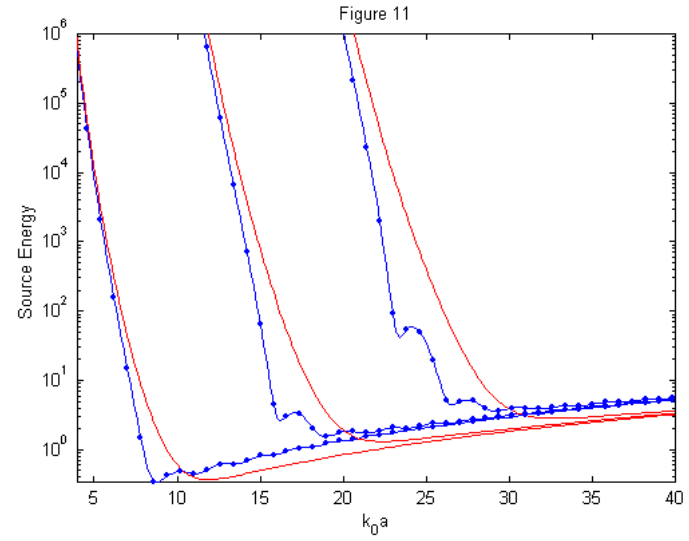

FIG. 5.7. *Plots of source energy for* $a = 10$, $n = 1$ *(solid), and* $n = 1.5$ *(with asterisks) and for* $L = 10, 20, 30$. *It is seen from the plots that the larger* n *value yields smaller energy and, hence, a more efficient source up to the critical point* $k_0a = L$.

cut-off parameter L and for a source radius of $a = 10$ and index value of $n = 1.5$. We also show for comparison the plots of the source energy for a source embedded in free space. It is seen that, as expected, the source energy becomes extremely large if we try to achieve an L value that exceeds the critical value $L = k_0a$. This is, of course, due to the fact that the quantities Σ_l^2 become extremely small when $l > k_0a$.

6. Summary and conclusions. We have developed the basic theory of the inverse source problem for compactly supported sources embedded in an inhomogeneous index profile $n(\mathbf{r})$. Most of our results pertain, in particular, to spherically symmetric index distributions $n(\mathbf{r}) = n(r)$, although the underlying formalism is applicable to general nonsymmetric distributions. For the class of spherically symmetric index profiles we showed how to construct the so-called minimum energy source that generates a given radiation pattern subject to the constraint that the source's L^2 norm over the source region is minimum. It was found that the energy of the minimum energy source depended on the index profile $n(r)$, and we examined this dependence using computer simulations for the case of piecewise constant valued profiles that are unity outside the (spherical) source volume and constant within the source volume and for a "model" radiation pattern characterized by a "resolution parameter" L that was inversely related to the effective angular width of the radiation pattern. The simulations showed that, in general, the source energy increases exponentially when the wavenumber source radius product $k_0 a \gg L$, independent of whether or not the source is embedded in a background medium. However, it was found that by embedding the source in a spherical region having constant index $n > 1$, the source energy can be made smaller than that obtained for a source in vacuum over moderate ranges of the wavenumber source radius product $k_0 a$ in the immediate vicinity of the critical value $k_0 a = L$. We conclude that embedding sources in "designer" background distributions may lead to significant improvement in source efficiency, particularly for resonant antennas. This conclusion has been established here from a new source-inversion point of view, which serves as a theoretical framework of reference for ongoing efforts in this direction within the antenna and optical communities, particularly in connection with novel magneto-dielectrics and metamaterials for enhanced radiation. Currently we are working on the generalization of the research reported in this work to the full vector electromagnetic case including the practical reactive power constraints. We plan to report this ongoing research elsewhere.

GLOBAL DYNAMICS OF A PREDATOR-PREY MODEL WITH STAGE STRUCTURE FOR THE PREDATOR*

PAUL GEORGESCU† AND YING-HEN HSIEH‡

Abstract. The global properties of a predator-prey model with nonlinear functional response and stage structure for the predator are studied using Lyapunov functions and LaSalle's invariance principle. It is found that, under hypotheses which ensure the uniform persistence of the system and the existence of a unique positive steady state, a feasible a priori lower bound condition on the abundance of the prey population ensures the global asymptotic stability of the positive steady state. A condition which leads to the extinction of the predators is indicated. We also obtain results on the existence and stability of periodic solutions. In particular, when (4.2) fails to hold and the unique positive steady state E^* becomes unstable, the coexistence of prey and predator populations is ensured for initial populations not on the one-dimensional stable manifold of E^*, albeit with fluctuating population sizes.

Key words. predator-prey model, stage structure, global stability, uniform persistence, Lyapunov function

1. Introduction.

In classical models of Lotka–Volterra type it is assumed that all individuals of a single species have largely similar capabilities to hunt or reproduce. However, the life cycle of most, if not all, animals and insects consists of at least two stages, immature and mature, and the individuals in the first stage often can neither hunt nor reproduce, being raised by their mature parents. Furthermore, immediately recognizable morphological and behavioral differences may exist between these stages and other adaptive stages, such as dormancy stages for immediate survival purposes.

To study this situation theoretically, stage-structured models have attracted much attention in recent decades. Fundamental work towards a systematic approach to stage-structured model formulation has been made by Gurney, Nisbet, and Blythe [7], Nisbet and Gurney [27], and Nisbet, Gurney, and Metz [28]. Further progress has been made by Aiello and Freedman, who proposed and studied in their often quoted work [1] a single species model with stage structure and discrete delay, predicting the global attractivity of the positive steady state and thereby suggesting that the stage structure does not generate sustained oscillations, at least for a single species model. General consistency criteria to be satisfied by models which describe stage-structured ecological interactions have been laid out in Kuang [18] or Arditi and Michalski [2]. See also Liu, Chen, and Agarwal [24] for a recent survey on the dynamics of stage-structured population models with an emphasis on modeling issues.

Predator-prey models with stage structure for the predator have received considerable attention in recent years. See Wang [35] and Xiao and Chen [38] for global

stability and persistence analysis of a stage-structured predator-prey model without delay terms. See also Wang and Chen [36], Wang et al. [37], and Gourley and Kuang [9] for stability analyses of staged predator-prey models with time delays due to gestation of the predator and crowding of the prey.

Apart from analyzing the stability of their delayed model, Gourley and Kuang [9] also discussed its oscillatory dynamics for a linear functional response of the mature predator and observed that sustained oscillations took place only for a limited interval of maturation delays. This happens since, for small delays, their model inherits the properties of the nondelayed (of Lotka–Volterra type) system. However, if the maturation delay is too long, then the highest possible recruitment rate to adulthood drops below the adult death rate and the predator population dies out.

As far as the asymptotic behavior of predator-prey systems is concerned, it is known from Poincaré–Bendixson theory that two-dimensional continuous time models can approach either an equilibrium state or a limit cycle with any type of chaotic behavior being excluded, while three- and higher-dimensional models can exhibit more complex behavior. In this regard, staged models may provide in some situations a richer dynamics which leads to a better understanding of the interactions within the biological system under consideration. Such models may also incorporate meaningful biological parameters, such as different death rates for mature and immature predators and various delay effects.

In [36], [35], [38] the following predator-prey model with stage structure for the predator has been considered:

$$\begin{cases} x'(t) = x(t)\,(r - ax(t)) - \dfrac{bx(t)}{1+mx(t)}y_2(t), \\ y_1'(t) = k\dfrac{bx(t)}{1+mx(t)}y_2(t) - (D+d_1)y_1(t), \\ y_2'(t) = Dy_1(t) - d_2y_2(t). \end{cases} \tag{1.1}$$

Here $x(t)$, $y_1(t)$, $y_2(t)$ are the densities of prey, respectively of immature and mature predators at time t. It is assumed that in the absence of the predators the prey grows according to a logistic law with intrinsic growth rate r and carrying capacity r/a, while predators feed on prey only and do not count towards the carrying capacity. It is also assumed that the immature predators are either raised by their parents or consume a resource which is available in abundance and for which they do not have to compete. As a consequence, neither crowding nor intraspecies competition terms are added into the equation which models the growth of the immature predator class. The function $x \mapsto bx/(1+mx)$ represents the Holling type 2 functional (behavioral) response of the mature predator, which describes how the consumption rate of the predator depends on prey density, b being the search rate and m being the search rate multiplied by the handling time; while the function $x \mapsto kbx/(1+mx)$ is the associated numerical (reproductive) response of the mature predator which quantifies the relation between the numerical growth of the predator class and the prey consumption, with k representing the conversion coefficient under the assumption that the reproduction rate of the mature predators is directly proportional to the amount of prey consumed. The constants d_1 and d_2 represent the death rates of immature and mature predators, and D denotes the rate at which immature predators become mature predators.

It was proved in Wang [35] that if the condition

$$d_2(D+d_1) < \frac{kbrD}{a+mr} \tag{1.2}$$

holds, then the system (1.1) is uniformly persistent and a unique positive steady state $E^* = (x^*, y_1^*, y_2^*)$ exists. Moreover, it is shown that if, in addition to (1.2), conditions

$$x^*(D+d_1+d_2)(a+2max^*-mr)\left(D+d_1+d_2+\frac{x^*(a+2max^*-mr)}{1+mx^*}\right) > \frac{by_2^*d_2(D+d_1)}{1+mx^*}, \tag{1.3}$$

$$a > b+\frac{bmy_2^*}{1+mx^*}, \quad D+d_1 > \frac{kbr}{a+mr}+\frac{kby_2^*}{1+mx^*}, \quad d_2 > D, \tag{1.4}$$

are also satisfied, then the positive steady state $E^* = (x^*, y_1^*, y_2^*)$ is globally asymptotically stable. The proof uses the theory of competitive systems as developed in Smith [33], with condition (1.3) being used to establish the local stability of E^*.

More recently, Xiao and Chen [38] noted that condition (1.4) contradicts condition (1.2), and showed that the positive steady state E^* is globally asymptotically stable if (1.2) and (1.3) hold, in addition to one of the following two conditions:

$$\text{(H1) } D+d_1 > r \text{ and } \underline{x} > \frac{r}{2a}; \quad \text{(H2) } D+d_1 < r \text{ and } \underline{x} > \frac{r+D+d_1}{2a}.$$

Here $\underline{x} > 0$ is the persistency constant for x, which satisfies $\underline{x} \le \liminf_{t\to\infty} x(t)$. The proof is again based on the theory of competitive systems and uses a result given by Li and Muldowney in [23], which amounts to the fact that for competitive and permanent systems which are defined on convex and bounded sets and have the property of stability of periodic orbits, the local asymptotic stability of a unique positive steady state implies its global asymptotic stability. Essentially, the proof in [38] amounts to showing that the system (1.1) has the property of the stability of periodic orbits under either (H1) or (H2), a fact which is established using a criterion of Muldowney [26] and the theory of additive compound matrices.

Consider the conditions (1.3), (H1), and (H2). It is clear that if the inequality $\underline{x} > (r+D+d_1)/(2a)$, which is required in (H2), can be weakened to $\underline{x} > r/(2a)$ and either (H1) or (H2) can be modified to cover the case $D+d_1 = r$, then (H1) and (H2) can be combined into a single condition $\underline{x} > r/(2a)$, where $r/(2a)$ is the prey population size at the inflection point of the logistic curve in a prey-only system. Moreover, condition (1.3), which a priori ensures the local stability of the positive steady state, was motivated by specifics of the method used for the proof, which roughly inputs local asymptotic stability and outputs global asymptotic stability under certain assumptions.

However, it is clear that once the global asymptotic stability of the positive steady state is proved, then its local asymptotic stability is superseded anyway. Moreover, we shall indicate in section 4 that in fact (1.3) is satisfied if $x^* > r/(2a)$ (and consequently if $\underline{x} > r/(2a)$), and so there is no need to assume (1.3) separately.

In this article, we will study the global dynamics of (1.1) by constructing a suitable Lyapunov function and using LaSalle's invariance principle rather than by using the theory of competitive systems, as has been done in [35] and [38]. This will enable us to obtain the global asymptotic stability of the positive steady state under weaker hypotheses than those used in Xiao and Chen [38] and by a simpler method. In our setting, the persistence condition $\underline{x} > r/(2a)$ used in [38] will appear in a natural way as a monotonicity condition. We will also discuss in section 4 the existence of periodic solutions, together with their stability. Finally, we will discuss the biological significance of our results and indicate possible extensions to the study of more comprehensive models in section 5.

2. The model and its well-posedness. In this section we analyze the global existence of the solutions of (1.1) and their positivity properties.

Let us define $n : [0,\infty) \to \mathbb{R}$ and $f : [0,\infty) \to [0,\infty)$ by $n(x) = x(r - ax)$ and $f(x) = bx/(1 + mx)$ for all $x \in [0,\infty)$. Using the newly defined functions n and f we can rewrite (1.1) as

$$\begin{cases} x' = n(x) - f(x)y_2, \\ y_1' = kf(x)y_2 - (D + d_1)y_1, \\ y_2' = Dy_1 - d_2y_2. \end{cases} \tag{2.1}$$

Note that n is strictly decreasing on $[r/(2a), +\infty)$, while f is strictly increasing on $[0,\infty)$.

First, it is easy to see that if $x(0)$, $y_1(0)$, $y_2(0) \geq 0$, then $x(t), y_1(t), y_2(t) \geq 0$ on their respective intervals of existence. For this purpose, we observe that the vector (R_1, R_2, R_3) points inside the closed set $Q_1 = [0,\infty)^3$ at all points of ∂Q_1, where R_1, R_2, R_3 are the right-hand sides appearing in (1.1), and so Nagumo's tangency conditions are satisfied and Q_1 is a positively invariant set for (1.1). See Pavel [29] for further reference on flow invariance problems for ODEs and abstract ODEs.

To prove that $Q_2 = (0,\infty)^3$ is also a positively invariant set for (1.1), suppose that $x(0), y_1(0), y_2(0) > 0$ and note first that $\frac{d}{dt}(y_2e^{d_2t}) = Dy_1e^{d_2t} \geq 0$, and so $t \mapsto y_2(t)e^{d_2t}$ is increasing. It follows that $y_2(t) \geq y_2(0)e^{-d_2t}$ for all t for which $y_2(t)$ is well defined, and hence y_2 remains strictly positive. Also, $\frac{d}{dt}(y_1e^{(D+d_1)t}) \geq 0$, consequently, $y_1(t) \geq y_1(0)e^{-(D+d_1)t}$ and y_1 remains strictly positive. To prove that x also remains strictly positive, suppose that $x(t_0) = 0$ for some $t_0 > 0$. Then one may find $\tilde{y_1}(0)$ and $\tilde{y_2}(0) > 0$ such that the solution which starts at $t = 0$ from $(0, \tilde{y_1}(0), \tilde{y_2}(0))$ also reaches $(0, y_1(t_0), y_2(t_0))$ at $t = t_0$. By the uniqueness property of (1.1), this solution should coincide with the solution which starts at $t = 0$ from $(x(0), y_1(0), y_2(0))$, which is an obvious contradiction.

We shall now show that x, y_1, y_2 are bounded on their intervals of existence, which in turn will imply by a standard continuability argument that they are defined on $[0,\infty)$. Denote $M_1 = \max(r/a, x(0))$ and $d = \min(d_1, d_2)$. Since $x' \leq x(r - ax)$, it follows that $x(t) \leq M_1$ for all t. That is, x is bounded and consequently defined on $[0,\infty)$. Let us consider the Lyapunov function

$$U(x, y_1, y_2) = x + (1/k)y_1 + (1/k)y_2.$$

We now compute the time derivative of U along the solutions of (1.1). One then has

$$\dot{U} = n(x) - \frac{d_1}{k}y_1 - \frac{d_2}{k}y_2,$$

which implies

$$\dot{U} + dU \leq (r + d)x.$$

Consequently,

$$U(x(t), y_1(t), y_2(t)) \leq U(x(0), y(0), z(0))e^{-dt} + \frac{M_1(r + d)}{d}\left(1 - e^{-dt}\right) \quad \text{for all } t.$$

This implies that y_1, y_2 are also bounded and consequently defined on $[0,\infty)$. Finally, we analyze the behavior of solutions which start with initial data (x_i, y_{1i}, y_{2i}) on the boundary of $(0,\infty)^3$.

If $x_i = 0$, then $(x(t), y_1(t), y_2(t)) \to (0,0,0)$ irrespective of the initial values $y_{1i}, y_{2i} \geq 0$. If $x_i > 0$, then $(x(t), y_1(t), y_2(t)) \to (r/a, 0, 0)$ for $y_{1i} = y_{2i} = 0$, while $(x(t), y_1(t), y_2(t))$ enters $(0,\infty)^3$ (and stays there) otherwise.

3. Global dynamics of the model. In this section we perform a global stability analysis for the system (1.1) regarding both the stability of the boundary equilibrium $(r/a, 0, 0)$ (i.e., the case in which the predator classes tend to extinction) and of the positive steady state (x^*, y_1^*, y_2^*) (i.e., the case in which the coexistence of both species is assured for all future time). As a result, we find sufficient conditions for the stability of the equilibria and establish the existence of a threshold parameter.

Let us denote $T = d_2(D + d_1)/D$ and $x_0 = r/a$. First, we give a condition for the extinction of the predators.

THEOREM 3.1. *Suppose that $T \geq kf(x_0)$. Then $(x_0, 0, 0)$ is globally asymptotically stable on $(0,\infty)^3$.*

Proof. Let us consider the Lyapunov function

$$U_1(x, y_1, y_2) = \int_{x_0}^{x} \frac{f(\tau) - f(x_0)}{f(\tau)} d\tau + \frac{1}{k} y_1 + \frac{1}{k} \frac{D + d_1}{D} y_2.$$

We now compute the time derivative of U_1 along the solutions of (1.1). One then has

$$\begin{aligned} \dot{U_1} &= \frac{f(x) - f(x_0)}{f(x)} (n(x) - f(x)y_2) + \frac{1}{k} (kf(x)y_2 - (D + d_1)y_1) \\ &\quad + \frac{1}{k} \frac{D + d_1}{D} (Dy_1 - d_2 y_2) \\ &= \frac{f(x) - f(x_0)}{f(x)} n(x) + \frac{1}{k} \left(kf(x_0) - \frac{(D + d_1)d_2}{D} \right) y_2. \end{aligned}$$

Since c is strictly increasing on $[0,\infty)$ and $\operatorname{sgn} n(x) = \operatorname{sgn}(x_0 - x)$ for $x \in (0,\infty)$, it is seen that $\dot{U_1} \leq 0$, with equality if and only if $x = x_0$ and either $y_2 = 0$ or $T = kf(x_0)$. In both cases, the only invariant subset $\tilde{M}$ within the set $M = \{(x, y_1, y_2); x = x_0\}$ is $\tilde{M} = \{(x_0, 0, 0)\}$.

Since $\dot{U_1} \leq 0$ on $(0,\infty)^3$ and the only possible ω-limit sets of $(x(t), y_1(t), y_2(t))$ on the boundary of $(0,\infty)^3$ are $\{(x_0, 0, 0)\}$ and $\{(0, 0, 0)\}$, our conclusion follows from LaSalle's invariance principle (see [22]). □

We now attempt to analyze the existence of the positive steady state E^* and the uniform persistence of the system (1.1). We recall that the system (1.1) is said to be *uniformly persistent* if there is $\varepsilon_0 > 0$ such that any solution of (1.1) which starts with $x(0), y_1(0), y_2(0) > 0$ satisfies

$$\liminf_{t\to\infty} x(t) \geq \varepsilon_0, \quad \liminf_{t\to\infty} y_1(t) \geq \varepsilon_0, \quad \liminf_{t\to\infty} y_2(t) \geq \varepsilon_0.$$

For other (weaker) types of persistence and criteria to establish the persistence of a given system, see Butler, Freedman, and Waltman [4], Freedman, Ruan, and Tang [6], and Hofbauer and So [11].

THEOREM 3.2. *Suppose that $T < kf(x_0)$. Then the positive steady state E^* exists, is unique, and the system (1.1) is uniformly persistent.*

Proof. Let us consider the Lyapunov function

$$U_2(x, y_1, y_2) = \frac{1}{k} y_1 + \frac{1}{k} \frac{D + d_1}{D} y_2.$$

We now compute the time derivative of U_2 along the solutions of (1.1). One then has

$$\begin{aligned}\dot{U_2} &= \frac{1}{k}(kf(x)y_2 - (D+d_1)y_1) + \frac{1}{k}\frac{D+d_1}{D}(Dy_1 - d_2y_2)\\ &= \left(f(x) - \frac{(D+d_1)d_2}{kD}\right)y_2.\end{aligned}$$

If $T < kf(x_0)$, then $\dot{U_2}$ is positive in all strictly positive points of a vicinity of $(x_0, 0, 0)$, and so $(x_0, 0, 0)$ is unstable. Since the only invariant subsets on the boundary of $(0,\infty)^3$ are $\{(x_0, 0, 0)\}$ and $\{(0, 0, 0)\}$ and their stable manifolds are also contained in the boundary of $(0,\infty)^3$, it follows from a result of Hofbauer and So [11] that the system (1.1) is uniformly persistent. Also see Margheri and Rebelo [25] for a slightly different approach towards showing the persistence of dynamical systems based on a result of Fonda [5], which establishes necessary and sufficient conditions for a given compact set S to be a uniform repeller.

To show the existence of E^*, we need to find positive solutions for the system

$$\begin{cases} x^*\,(r - ax^*) - \dfrac{bx^*}{1+mx^*}y_2^* = 0,\\ k\dfrac{bx^*}{1+mx^*}y_2^* - (D+d_1)y_1^* = 0,\\ Dy_1^* - d_2y_2^* = 0.\end{cases} \tag{3.1}$$

After some algebraic manipulations, one obtains

$$x^* = \frac{(D+d_1)d_2}{bkD - m(D+d_1)d_2}, \quad y_1^* = \frac{x^*(r-ax^*)k}{(D+d_1)}, \quad y_2^* = \frac{x^*(r-ax^*)kD}{(D+d_1)d_2}. \tag{3.2}$$

Since $d_2(D+d_1)/D < kbr/(a+mr)$, it follows that $bkD/((D+d_1)d_2) > (a+mr)/r$, and so $x^* < r/a$. From the above, it also follows that $bkD/((D+d_1)d_2) > m$, and hence $x^* > 0$. Consequently, x^*, y_1^*, y_2^* are all well defined and positive. We also remark that since the system (1.1) is uniformly persistent, it follows that there is an $\underline{x} > 0$ such that $\liminf_{t\to\infty} x(t) \geq \underline{x}$. □

From Theorems 3.1 and 3.2, combined with the remark about the behavior of the solutions starting on the boundary of $[0,\infty)^3$ which was made at the end of section 2, it also follows that $(0, 0, 0)$ is an unstable equilibrium and its stable manifold consists of the positive quadrant $\{(0, y_{1i}, y_{2i}); y_{1i}, y_{2i} \geq 0\}$. That is, our model predicts that the predator and the prey cannot simultaneously face extinction, with the sole exception of the case in which the size of the initial prey populations equals zero, justified by the fact that the predators feed on prey only and do not consume other resource, and therefore in the absence of prey they are condemned to extinction.

Having established the existence and uniqueness of the positive steady state E^*, we now turn our attention to its stability. For this purpose, we employ a condition on the persistence constant $\underline{x}$, which ensures that the size of the prey population remains ultimately higher than a certain value.

THEOREM 3.3. *Suppose that $T < kf(x_0)$ and $\underline{x} > r/(2a)$. Then the positive steady state E^* is globally asymptotically stable on $(0,\infty)^3$.*

Proof. Since $\underline{x} > r/(2a)$, it is seen that there is $t_0 \geq 0$ such that $x(t) > r/(2a)$ for all $t \geq t_0$ and also that $x^* > r/(2a)$. Let us consider the Lyapunov function

$$U_3(x, y_1, y_2) = \int_{x^*}^{x} \frac{f(\tau) - f(x^*)}{f(\tau)}d\tau + \frac{1}{k}\int_{y_1^*}^{y_1} \frac{\tau - y_1^*}{\tau}d\tau + \frac{1}{k}\frac{D+d_1}{D}\int_{y_2^*}^{y_2} \frac{\tau - y_2^*}{\tau}d\tau.$$

It is easily seen that $U_3(x, y_1, y_2) \geq 0$ and $U_3(x, y_1, y_2) = 0$ if and only if $x = x^*$, $y_1 = y_1^*$, $y_2 = y_2^*$. We now compute the time derivative of U_3 along the solutions of (1.1). One obtains that

$$\begin{aligned}\dot{U_3} &= \frac{f(x) - f(x^*)}{f(x)}\,(n(x) - f(x)y_2) + \frac{1}{k}\frac{y_1 - y_1^*}{y_1}\,(kf(x)y_2 - (D + d_1)y_1) \\ &\quad + \frac{1}{k}\frac{D + d_1}{D}\frac{y_2 - y_2^*}{y_2}\,(Dy_1 - d_2y_2) \\ &= n(x)\frac{f(x) - f(x^*)}{f(x)} + f(x^*)y_2 - \frac{D + d_1}{k}y_1^*\left(\frac{f(x)}{f(x^*)}\frac{y_2}{y_2^*}\frac{y_1^*}{y_1} + \frac{y_2^*}{y_2}\frac{y_1}{y_1^*} + \frac{f(x^*)}{f(x)} - 3\right) \\ &\quad + \frac{D + d_1}{k}y_1^*\frac{f(x^*)}{f(x)} - \frac{D + d_1}{k}y_1^* - \frac{D + d_1}{kD}d_2y_2.\end{aligned}$$

Since $f(x^*) = (D + d_1)d_2/(kD)$, this yields

$$\begin{aligned}\dot{U_3} &= n(x)\frac{f(x) - f(x^*)}{f(x)} - \frac{D + d_1}{k}y_1^*\left(\frac{f(x)}{f(x^*)}\frac{y_2}{y_2^*}\frac{y_1^*}{y_1} + \frac{y_2^*}{y_2}\frac{y_1}{y_1^*} + \frac{f(x^*)}{f(x)} - 3\right) \\ &\quad + \frac{D + d_1}{k}y_1^*\left(\frac{f(x^*)}{f(x)} - 1\right) \\ &= \frac{1}{f(x)}(n(x) - n(x^*))(f(x) - f(x^*)) \\ &\quad - \frac{D + d_1}{k}y_1^*\left(\frac{f(x)}{f(x^*)}\frac{y_2}{y_2^*}\frac{y_1^*}{y_1} + \frac{y_2^*}{y_2}\frac{y_1}{y_1^*} + \frac{f(x^*)}{f(x)} - 3\right).\end{aligned}$$

From the *AM-GM* inequality, it is clear that

$$\frac{f(x)}{f(x^*)}\frac{y_2}{y_2^*}\frac{y_1^*}{y_1} + \frac{y_2^*}{y_2}\frac{y_1}{y_1^*} + \frac{f(x^*)}{f(x)} \geq 3,$$

with equality if and only if

$$\frac{f(x)}{f(x^*)}\frac{y_2}{y_2^*}\frac{y_1^*}{y_1} = \frac{y_2^*}{y_2}\frac{y_1}{y_1^*} = \frac{f(x^*)}{f(x)} = 1,$$

that is, $x = x^*$ and $y_1/y_1^* = y_2/y_2^*$.

If $x(t) > r/(2a)$ for $t \geq t_0$, then since n is strictly decreasing on $[r/(2a), \infty)$ and f is strictly increasing on $[0, \infty)$, it follows that

$$\frac{1}{f(x)}(n(x) - n(x^*))(f(x) - f(x^*)) \leq 0,$$

with equality if and only if $x = x^*$. This implies that $\dot{U_3} \leq 0$, with equality if and only if $x = x^*$ and $y_1/y_1^* = y_2/y_2^*$. We now find the invariant subsets $\tilde{M}$ within the set

$$M = \left\{(x, y_1, y_2); x = x^*, \frac{y_1}{y_1^*} = \frac{y_2}{y_2^*}\right\}.$$

Since $x = x^*$ on $\tilde{M}$ and consequently $x' = n(x^*) - f(x^*)y_2$, it follows that $x' = f(x^*)(y_2 - y_2^*)$, and so $y_2 = y_2^*$. This implies $y_1 = y_1^*$, and consequently the only invariant set in M is $\tilde{M} = \{(x, y_1^*, y_2^*)\}$. From LaSalle's invariance principle one then obtains the desired conclusion. □

4. The local stability of the positive steady state and the existence of the periodic solutions. Suppose now that $T < kf(x_0)$ and consequently that the system (1.1) is persistent and the positive steady state E^* exists and is unique. As seen in Wang [35] and Xiao and Chen [38], it is possible to study the local stability of the positive steady state and the existence of the periodic solutions together with their orbital stability by using a result on the behavior of three-dimensional competitive systems established by Zhu and Smith in [39].

It is easy to see that the Jacobian of the system (1.1) at (x, y_1, y_2) is given by

$$J_{(1.1)}(x, y_1, y_2) = \begin{pmatrix} r - 2ax - \frac{b}{(1+mx)^2} y_2 & 0 & -\frac{bx}{1+mx} \\ k\frac{b}{(1+mx)^2} y_2 & -(D + d_1) & \frac{kbx}{1+mx} \\ 0 & D & -d_2 \end{pmatrix}.$$

Using the equilibrium relations (3.1), one finds that the characteristic equation of the system (1.1) at E^* is given by

$$\lambda^3 + \left[D + d_1 + d_2 + x^* \left(2a - \frac{rm + a}{1 + mx^*}\right)\right] \lambda^2 + x^* \left(2a - \frac{rm + a}{1 + mx^*}\right) (D + d_1 + d_2)\lambda + \frac{r - ax^*}{1 + mx^*} d_2(D + d_1) = 0. \tag{4.1}$$

Consequently, by the classical Routh–Hurwitz theorem, all roots of (4.1) have negative real parts if

$$\left[D + d_1 + d_2 + x^* \left(2a - \frac{rm + a}{1 + mx^*}\right)\right] x^* \left(2a - \frac{rm + a}{1 + mx^*}\right) (D + d_1 + d_2) > \frac{r - ax^*}{1 + mx^*} d_2(D + d_1), \tag{4.2}$$

and if the reverse of the above inequality is satisfied, then two of the characteristic roots have positive real parts. Note that since $(r - ax^*)/(1 + mx^*)d_2(D + d_1) > 0$, there is always a negative real root of (4.1). It is also important to note that (4.2) is satisfied if $x^* > r/(2a)$. Toward this goal, we remark that if $x^* > r/(2a)$, one has

$$x^*(2a(1 + mx^*) - (rm + a)) = x^* \left(2am \left(x^* - \frac{r}{2a}\right) + a\right) \geq ax^* \geq r - ax^*$$

and

$$\left[D + d_1 + d_2 + x^* \left(2a - \frac{rm + a}{1 + mx^*}\right)\right] (D + d_1 + d_2) > 4d_2(D + d_1),$$

from which (4.2) results immediately. It then follows that all equilibria E^* with $x^* > r/(2a)$ are locally asymptotically stable. Moreover, a quick inspection of our argument shows that E^* is also stable for some $x^* < r/(2a)$, provided that $x^* > r/(2a) - \tilde{c}/(2m)$, where

$$\tilde{c} = \left(1 + \frac{a}{mr} - \sqrt{1 - \left(1 - \frac{a}{mr}\right)^2 + 4\frac{a}{mr}\frac{d_2\,(D + d_1)}{(D + d_1 + d_2)^2}}\right) \frac{mr}{2a}. \tag{4.3}$$

In particular, this shows that the inequality (4.2), which has been a priori assumed in Xiao and Chen [38] (stated under the equivalent form (1.3)), does actually follow if

either (H1) or (H2) are assumed, since $\underline{x} > r/(2a)$ implies $x^* > r/(2a)$, and so there is no need to assume (4.2) separately. Also, it is perhaps interesting to remark that while the inequality $\underline{x} > r/(2a)$ ensures the global stability of E^*, a somewhat similar but weaker estimate $x^* > r/(2a)$ ensures its local stability. We do not know, however, whether or not the inequality $\underline{x} > r/(2a)$ is sharp, that is, if $r/(2a)$ is the smallest constant C with the property that $\underline{x} > C$ ensures the converge of the respective solution of (1.1) to E^*, under the condition $kf(r/a) > T$.

Consider now

$$C = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \quad S = [0,\infty) \times (-\infty, 0] \times [0,\infty).$$

One then has

$$CJ_{(1.1)}(x, y_1, y_2)C = \begin{pmatrix} r - 2ax - \frac{b}{(1+mx)^2} y_2 & 0 & -\frac{bx}{1+mx} \\ -k\frac{b}{(1+mx)^2} y_2 & -(D + d_1) & -\frac{kbx}{1+mx} \\ 0 & -D & -d_2 \end{pmatrix}.$$

It is then seen that the matrix $CJ_{(1.1)}(x, y_1, y_2)C$ has negative off-diagonal entries for $(x, y_1, y_2) \in S$, and so the system (1.1) is competitive on S. By the previously established persistence and boundedness results, it follows that (1.1) is point dissipative. It is also easy to see that (1.1) is irreducible in S.

Since (1.1) has a unique equilibrium point $E^* = (x^*, y_1^*, y_2^*)$ and

$$\det J_{(1.1)}(x^*, y_1^*, y_2^*) = -\frac{r - ax^*}{1 + mx^*} d_2(D + d_1) < 0,$$

it follows from Theorem 1.2 in Zhu and Smith [39] that either E^* is stable, or, if it is unstable, there is at least one but no more than finitely many periodic orbits and at least one of these is orbitally asymptotically stable. Also, if E^* is stable but not globally stable, then since (1.1) is a three-dimensional competitive system, it follows from Theorem 4.1 in Smith [34, Chapter 3] that (1.1) has a periodic orbit which is necessarily orbitally unstable. Moreover, if E^* is hyperbolic and unstable with a two-dimensional unstable manifold, it follows from Theorem 4.2 in Smith [34, Chapter 3] that the ω-limit of any orbit of (1.1) which does not start on the stable manifold of E^* is a nontrivial periodic orbit. Summarizing the above discussion, one obtains the following result.

THEOREM 4.1. *Suppose that $T < kf(x_0)$ and that E^* is not globally asymptotically stable.*

1. *If either* (4.2) *or its reverse is satisfied, then E^* is hyperbolic and there is at least a nontrivial periodic orbit. The ω-limit of any orbit with positive initial data is either E^* or a nontrivial periodic orbit.*
2. *If* (4.2) *is satisfied (which happens in particular when $x^* > r/(2a)$), then the positive equilibrium E^* is locally asymptotically stable and there is at least a periodic orbit which is necessarily orbitally unstable.*
3. *If the reverse of* (4.2) *is satisfied, then the positive equilibrium E^* is unstable with a two-dimensional unstable manifold and there is at least one but no more than finitely many periodic orbits and at least one of these is orbitally asymptotically stable. Any solution which does not start on the one-dimensional stable manifold of E^* converges to a nontrivial periodic orbit.*

Unfortunately, we are not able to study analytically whether or not the periodic solutions mentioned in parts 2 and 3 above are unique.

5. Concluding remarks. First, we discuss the biological significance of our results. From the above results, we know that $T = d_2(D + d_1)/D$ is a threshold parameter for the stability of the system and that the numerical response of the mature predator plays a major role in the long-term behavior of the system (1.1). More precisely, Theorem 3.1 indicates that if the numerical response of the mature predator for the prey at carrying capacity is lower than the threshold value T, i.e., if few mature predators introduced in a predator-free ambient with prey at carrying capacity cannot reproduce fast enough, the predator classes tend to extinction. Moreover, we can define the basic reproduction number of the system by $R_0 = kf(x_0)\frac{D}{D+d_1}\frac{1}{d_2}$, and then the condition $T \geq kf(x_0)$ is equivalent to $R_0 \leq 1$. This basic reproduction number has a clear biological interpretation: the first term in R_0, $kf(x_0)$, gives the mean number of newborn predators per mature predator; the second term, $\frac{D}{D+d_1}$, gives the probability that an immature predator will survive to adulthood; and the third term, $\frac{1}{d_2}$, is simply the average lifespan of a mature predator. Subsequently, the product of these three terms yields the mean number of offspring by every predator, which is precisely the biological meaning of a basic reproduction number. A similar threshold condition for the coexistence of a predator-prey system had previously been formulated and explained by Pielou [30], among others, but had not been termed a "basic reproduction number" to the best of our knowledge.

Furthermore, if the numerical response of the mature predator for the prey at carrying capacity is higher than the threshold value T and also the prey population ultimately remains higher than another value $\underline{x} > r/(2a)$, that is, if the prey is always abundant enough, it is seen from Theorem 3.3 that the system tends to a positive steady state. We also note that if the death rate d_1 of the immature predator is negligible compared to the rate D at which the immature predators become mature predators, then the inequality $T < kf(x_0)$ becomes a very simple comparison between the death rate of the mature predators and their reproductive rate. Moreover, the stage structure affects the capability of the predator species to survive and become persistent, since it is now $(D + d_1)/D$ times easier for the predator species to become extinct, as can be seen from Theorem 3.1. This means that if it takes too much for the immature predators to mature, or the through-stage death rate of the immature predator is high (that is, D is small compared to d_1), then the total number of offspring produced during the adult stage will not be enough to compensate the total loss of immature predators and the predator classes will tend to extinction.

However, the situation where $R_0 > 1$ (or $T < kf(x_0)$) but $\underline{x} \leq r/(2a)$ is more complicated. When $x^* > r/(2a)$, we know that E^* is locally asymptotically stable, but we do not know of its global properties. This is similar for the case $x^* \leq r/(2a)$, and (4.2) holds (see Theorem 4.1). Moreover, the precise conditions for the existence and uniqueness of the periodic orbits, namely when E^* is not globally stable, are unknown under part 3 of Theorem 4.1. Therefore, we proceed to investigate further by using numerical simulations.

We use the following parameter values for all numerical simulations below: $k = 1$, $b = 1$, $m = 1$, $D = 1$, $d_1 = 0.1$, and $d_2 = 0.2$. For case 1 (see Figure 5.1), we let $r = 1$ and $a = 2$, and subsequently $x_0 = \frac{r}{a} = 0.5$, $R_0 = \frac{kbx_0}{1+mx_0}\frac{D}{d_2(D+d_1)} = 1.515 > 1$, and $x^* > \frac{r}{2a}$. Since $x^* > r/(2a)$, the positive steady state E^* is locally asymptotically stable. Numerical simulations of trajectories starting at various initial populations seem to indicate that the stability is also global for the parameter values we used. Note that, in all the figures below, the black dot located on the x-axis is E_0^*, while the other black dot is E^*. For case 2 (see Figure 5.2), we let $r = 1$ and $a = 1$ so

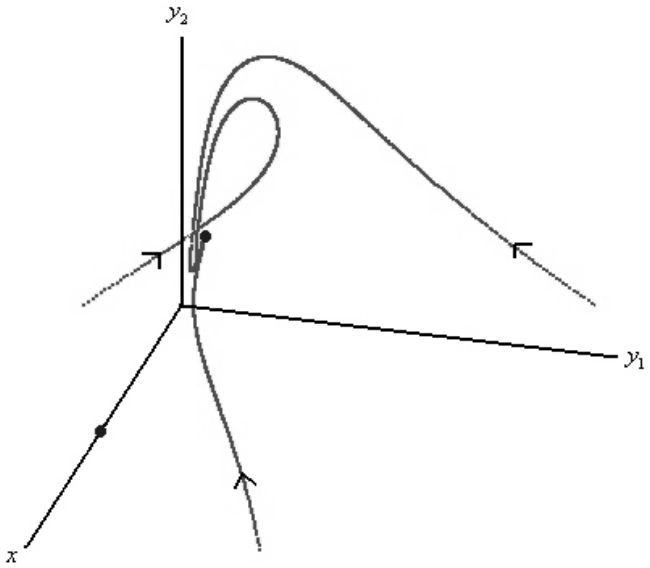

FIG. 5.1. *Simulation for case* 1 *with* $R_0 = 1.515 > 1$ *and* $x^* > \frac{r}{2a}$. *All trajectories approach* E^*.

that $x_0 = \frac{r}{a} = 1$, $R_0 = 2.273 > 1$, $x^* < \frac{r}{2a}$, and (4.2) holds. Since (4.2) holds, we know that the positive equilibrium E^* is locally asymptotically stable. Numerical simulations indicate that its stability is global. It is interesting to note that we are unable to find parameter values under which E^* satisfies (4.2), and hence it is locally asymptotically stable but not globally stable.

We also consider case 3 (see Figure 5.3), where $r = 3$ and $a = 2$, and subsequently $x_0 = \frac{r}{a} = 1.5$, $R_0 = 2.727 > 1$, and $x^* < \frac{r}{2a}$, but (4.2) does not hold. From part 3 of Theorem 4.1, we know the positive equilibrium E^* is unstable and there exists an orbitally asymptotically stable periodic orbit. Our simulation shows that this orbitally stable periodic orbit is unique and its orbital stability appears to be global. We summarize our stability results in Table 5.1. The three cases described by the last three rows of the table are illustrated with Figures 5.1–5.3, respectively. We note that, biologically, when (4.2) fails to hold and E^* becomes unstable, the coexistence of prey and predator populations is still ensured for initial populations not on the one-dimensional stable manifold of E^*, albeit with fluctuating population sizes.

We now continue with a few comments regarding the a priori estimate $\underline{x} > r/(2a)$, which was used to establish the global asymptotic stability of the positive steady state.

Let $0 < l < r/a$. It is seen that

$$x^* > l \Leftrightarrow bkDl < (1 + ml)(D + d_1)d_2,$$

from which it is easy to infer that

$$x^* > l \Leftrightarrow kf(l) < T.$$

Since $\underline{x} > l$ necessarily implies that $x^* > l$ (though this condition is only necessary and is not sufficient), it is seen that in order to have the inequality $\underline{x} > l$ satisfied, it

TABLE 5.1

Asymptotic states of the system. "NE" denotes nonexistent, "NA" denotes not applicable, "NI" denotes no influence, "OASLC" denotes orbitally asymptotically stable limit cycle, "GAS" and "LAS" denote globally and locally asymptotically stable, respectively, and "(1)" denotes the conclusion from the simulation result.

R_0	E_0	x^*	$\underline{x}$	(4.2)	E^*	$(x, y_1, y_2) \to$
≤ 1	GAS	NE	NI	NA	NE	E_0
> 1	unstable	$> \frac{r}{2a}$	$> \frac{r}{2a}$	YES	GAS	E^*
		$> \frac{r}{2a}$	$\leq \frac{r}{2a}$	YES	LAS	$E^{*(1)}$
		$\leq \frac{r}{2a}$	$\leq \frac{r}{2a}$	YES	LAS	$E^{*(1)}$
		$\leq \frac{r}{2a}$	$\leq \frac{r}{2a}$	NO	unstable	OASLC$^{(1)}$

is necessary that $kf(l) < T$. Note that this inequality alone does not suffice to establish that $\underline{x} > l$. Again, this inequality has a certain biological interpretation. In order to have the prey population ultimately staying above a certain level l, one needs as a prerequisite that the numerical response of the predator for prey at density l be lesser than the threshold value T. Particularizing $l = r/(2a)$, it is seen that in order to obtain that $\underline{x} > r/(2a)$, one needs the inequality $kf(r/(2a)) < T$ satisfied.

Also, it is perhaps fitting to give sufficient conditions here which ensure the validity of our boundedness estimate $\underline{x} > r/(2a)$. From the first equation in (1.1), one obtains

$$(1 + mx)x'(t) = x(t)\left[(r - ax(t))(1 + mx(t)) - by_2(t)\right],$$

which implies

$$(1 + mx)x' \geq x\left[(r - b(\bar{M} + \varepsilon)) + x(rm - a) - amx^2\right]$$

for t large enough, where $\bar{M}$ is an ultimate upper bound for y_2 and $\varepsilon > 0$ is an arbitrary constant. If $r - b(\bar{M} + \varepsilon) > 0$, it follows that $\liminf_{t\to\infty} x(t) \geq x_2$, where x_2 is the positive root of

$$(r - b(\bar{M} + \varepsilon)) + x(rm - a) - amx^2 = 0.$$

From the above relations, one may deduce that $\underline{x} > r/(2a)$ whenever the following conditions are satisfied:

$$r - b(\bar{M} + \varepsilon) > 0, \quad a + \sqrt{(a - rm)^2 + 4(r - b(\bar{M} + \varepsilon))am} > 2mr.$$

Since $\varepsilon > 0$ was arbitrary, a set of conditions which ensures that $\underline{x} > r/(2a)$ is therefore

$$r > b\bar{M}, \quad a + \sqrt{(a - rm)^2 + 4(r - b\bar{M})am} > 2mr. \tag{5.1}$$

However, it is difficult to give a clear biological interpretation of the inequalities (5.1), and we would like to point out that our a priori estimate $\underline{x} > r/(2a)$ is easier to interpret and represents a theoretical device readily adaptable for the study of other systems of a certain structure, in connection with monotonicity properties. For explicit estimations of type (5.1), this sort of adjustment may not be transparent. Note that, from the discussions in section 2 on the boundedness of the solutions of

system (1.1), an ultimate upper bound for y_2 is $\bar{M} = k \max(r/a, x(0))(r+d)/d$, where $d = \min(d_1, d_2)$. See also [38] for a numerical example regarding the feasibility of the condition $\underline{x} > r/(2a)$.

Since the mature predator functional response f depends only on the size of the prey population x, our model (1.1) may be called, following the terminology given in Huisman and DeBoer [13], prey-dependent. By the same terminology, a system in which the mature predator functional response f is a function of the prey-to-predator ratio x/y is called ratio-dependent (or, more generally, predator-dependent). It is also easy to see that our model can be thought as a stage-structured version of the classical predator-prey model given below:

$$\begin{cases} x' = rx\left(1 - \dfrac{x}{K}\right) - \dfrac{bx}{1+mx}y, \\ y' = k\dfrac{bx}{1+mx}y - dy. \end{cases} \tag{5.2}$$

It is therefore not surprising that, as is easily seen from (3.2), our model inherits the structure which generates the so-called paradox of enrichment, formulated by Hairston, Smith, and Slobodkin [10] and by Rosenzweig [32], which states that increasing the carrying capacity of the environment will cause an increase in the sizes of the predator classes at equilibrium but not in that of prey. Also, since the left-hand side of (4.2) is a decreasing function of the carrying capacity r/a while the right-hand side of (4.2) is an increasing function of the same variable, it is seen that an increase in the carrying capacity may destabilize an otherwise stable positive equilibrium.

It has already been noted that all prey equilibria x^* for which $x^* > r/(2a)$ are locally asymptotically stable; that is, high prey equilibrium densities are stable. Moreover, it can also be observed that low prey equilibrium densities are unstable, since the limit of the left-hand side of (4.2) as x^* tends to 0 is also 0, while the same limit of the right-hand side of (4.2) is positive.

Note that, by the Rosenzweig–MacArthur graphical stability criterion, any equilibrium of (5.2) with $x^* > r/(2a) - 1/(2m)$ is stable, while any equilibrium of (5.2) with $x^* < r/(2a) - 1/(2m)$ is unstable. Furthermore, by Theorem 3.2 in Kuang [20], one may prove that if $\underline{x} > r/(2a)$, then (x^*, y^*) is globally asymptotically stable. One may then expect a stability threshold for (1.1) which is sharper than $r/(2a)$. Unfortunately, this result does not carry out nicely for our system (1.1) (see (4.3)). Note also that the equilibria of (1.1) with x^* close to $r/(2a) - 1/(2m)$ are unstable, as the left-hand side of (4.2) becomes arbitrarily small, while the right-hand side remains above a strictly positive lower bound.

It has also been observed in this study that, for the most part of the parameter space, the dynamical outcome does not depend on the initial population sizes and the prey and predator species cannot face extinction simultaneously. These are hallmarks of prey-dependent models, as opposed to ratio-dependent models; as seen, for instance, in Jost, Arino, and Arditi [14] or in Beretta and Kuang [3], mutual extinction may occur for ratio-dependent models, together with other rich dynamics, and the behavior of the system may depend on the initial population sizes (see also Kuang [19]). In this regard, it is believed that prey-dependent predator-prey models are more appropriate for situations in which predation involves a random or no search process, while ratio-dependent predator-prey models are more appropriate for situations in which predation involves a thorough search process. See, for instance, Kuang and Beretta [21].

Our considerations may be easily extended to systems of the form

$$\begin{cases} x' = n(x) - f(x)g(y_2), \\ y_1' = kf(x)g(y_2) - c_1 h(y_1), \\ y_2' = c_2 h(y_1) - c_3 r(y_2), \end{cases} \tag{5.3}$$

to encompass different types of functional responses from the mature predator and possible nonlinearities in the behavior of species, including nonlinearity in the predation process, under appropriate monotonicity assumptions on the functions f, g, h, r. Some examples of f and n which fit into our framework are $f(x) = mx^c$, $0 < c \leq 1$, $f(x) = m(1 - e^{-cx})$, $m, c > 0$, $f(x) = bx^p/(1 + mx^p)$, $0 < p \leq 1$ and $n(x) = x(r - ax)/(1 + \varepsilon x)$, $\varepsilon > 0$, $n(x) = rx(1 - (x/(r/a))^c)$, $0 < c \leq 1$, provided that the threshold value T and the minimal value $r/(2a)$ for $\underline{x}$ are modified accordingly. Another simple extension is to a model in which predators pass through $p > 2$ life stages, as long as the consumption of prey occurs only in the last stage. Note that the last form of $n(x)$ given above is the Richards model, a generalized logistic-type model (which simplifies to the logistic model when $c = 1$) often used to model growth of biological populations [31] or severity of disease outbreak [12].

The function n need not be monotone on its whole domain but only on $[\tilde{\underline{x}}, +\infty)$, $\tilde{\underline{x}}$ being the persistency constant of the prey for the system under consideration. In this situation, condition $\liminf_{t\to\infty} x(t) \geq \tilde{\underline{x}}$ is used to restrict n to its monotonicity domain. See Georgescu and Hsieh [8] for a related argument concerning the global stability of the endemic equilibrium for the propagation of a virus in vivo, with the remark that in [8] there is no need to impose any a priori lower bound condition, since the function which corresponds to n is monotone on the whole feasibility domain. Finally, regarding our construction of a Lyapunov function, we mention that functions of type $V(x_1, x_2, x_3, x_4) = \sum_{i=1}^{4} a_i(x_i - x_i^* \ln x_i)$, to which our function U_3 relates, have also been found useful for the study of SEIR epidemiological models. See Korobeinikov [15] and Korobeinikov and Maini [16] for details. In this regard, global stability results for models which incorporate nonlinear incidence rates of a very general form have recently been obtained by Korobeinikov and Maini in [17].

SPATIOTEMPORAL SYMMETRIES IN THE DISYNAPTIC CANAL-NECK PROJECTION*

MARTIN GOLUBITSKY†, LIEJUNE SHIAU‡, AND IAN STEWART§

Abstract. The vestibular system in almost all vertebrates, and in particular in humans, controls balance by employing a set of six semicircular canals, three in each inner ear, to detect angular accelerations of the head in three mutually orthogonal coordinate planes. Signals from the canals are transmitted to eight (groups of) neck motoneurons, which activate the eight corresponding muscle groups. These signals may be either excitatory or inhibitory, depending on the direction of head acceleration. McCollum and Boyle have observed that in the cat the relevant network of neurons possesses octahedral symmetry, a structure that they deduce from the known innervation patterns (connections) from canals to muscles. We rederive the octahedral symmetry from mathematical features of the probable network architecture, and model the movement of the head in response to the activation patterns of the muscles concerned. We assume that connections between neck muscles can be modeled by a "coupled cell network," a system of coupled ODEs whose variables correspond to the eight muscles, and that this network also has octahedral symmetry. The network and its symmetries imply that these ODEs must be equivariant under a suitable action of the octahedral group. It is observed that muscle motoneurons form natural "push-pull pairs" in which, for given movements of the head, one neuron produces an excitatory signal, whereas the other produces an inhibitory signal. By incorporating this feature into the mathematics in a natural way, we are led to a model in which the octahedral group acts by signed permutations on muscle motoneurons. We show that with the appropriate group actions, there are six possible spatiotemporal patterns of time-periodic states that can arise by Hopf bifurcation from an equilibrium representing an immobile head. Here we use results of Ashwin and Podvigina. Counting conjugate states, whose physiological interpretations can have significantly different features, there are 15 patterns of periodic oscillation, not counting left-right reflections or time-reversals as being different. We interpret these patterns as motions of the head, and note that all six types of pattern appear to correspond to natural head motions.

Key words. vestibular system, Hopf bifurcation, spatiotemporal symmetries, coupled cell systems

1. Introduction.

The human vestibular system is a system of tubes that contain sensors for motion and orientation in space, yielding the sense of balance. There are two main components: the otolith organs, which sense linear acceleration of the head (translation), and the semicircular canals, which sense angular acceleration of the head (rotation). Each ear contains three semicircular canals (henceforth "canals") arranged in three approximately mutually orthogonal planes; see Figure 1 below. A similar arrangement occurs in most vertebrates. We do not discuss the otolith system or other physiological features of the sense of balance.

In this paper we focus on two points. First, we rederive the symmetry group Γ of the network of neurons that conveys signals from the six canals to eight principal

muscle groups that control the position of the neck. McCollum and Boyle [12] analyzed experimental work of Shinoda et al. [13, 14, 15] and Wilson and Maeda [16] to discover these symmetries. Our derivation makes transparent the fact that Γ is the 48-element symmetry group of the cube, which is called the *octahedral* group. This network of connections is known as the *canal-neck projection*.

Second, we assume that the octahedral group Γ is also the symmetry group of the internal dynamics of the muscles and associated neural connections, and we use these symmetries to discuss natural rhythmic head motions. We look only for small amplitude periodic head motions that can be sustained by the neck muscles alone. In particular, we assume that the sensory inputs from the canals are not relevant, except to prescribe the symmetries of the system. A similar approach has been applied previously to spatiotemporal patterns in animal locomotion; see Buono and Golubitsky [3], Collins and Stewart [4, 5], and Golubitsky et al. [10, 11]. However, in those papers the patterns of locomotion were used to infer the symmetry of the network of neurons (central pattern generator) that produced them, whereas here we infer the patterns of movement from the known symmetries of the canal-neck projection.

Our approach is straightforward but not completely standard. The work of McCollum and Boyle [12] suggests a simplest network for the motoneurons of the eight muscle groups. Although we do not know (and perhaps cannot know) an accurate differential equation model for the (abstracted) muscle motoneurons, we can presume the form that such a model will take. We use the symmetries and the network structure to answer the question: What are the spatiotemporal symmetries of small amplitude periodic solutions that can be obtained by Hopf bifurcation from a group invariant equilibrium in this class of possible models? (These periodic solutions are the ones that can most naturally exist in models near a position where the head is held fixed and upright. A more general classification of the spatiotemporal symmetries of periodic solutions, whose amplitudes are not necessarily small, can be made using the H/K Theorem [3, 9]. However, we choose to begin our classification with the more restricted problem of small amplitude periodic solutions near an upright head.)

Using a caricature of the physical actions of the muscle groups, we observe that a group invariant equilibrium corresponds to one in which the head is held fixed. Using this caricature, we can also interpret the form that the head motions will take based only on the spatiotemporal symmetries of the associated periodic solutions. In this sense our approach is model-independent; it does not depend on the particular system of ODEs. Our results provide a list, or menu, of the possible head motion types; specific models and specific parameters in the models choose from this menu and determine which solution types exist and which are stable. We do not discuss such model-dependent issues here.

In order to relate these spatiotemporal symmetries to characteristic head motions, we need to make assumptions about how the eight muscle groups move the head. For physiological and mathematical reasons we are led to classify the eight muscle groups into four opposing pairs. When both muscles in a pair are equally activated the head will not move. Indeed, to move the head, one muscle group must pull harder than the opposing one; we classify only those periodic states that satisfy this constraint.

To analyze the possible dynamics we employ the theory of dynamical systems with symmetry, which has implications for the dynamics of such a network. We restrict ourselves to classifying those types of head motions that can be described by small amplitude periodic states near a group invariant equilibrium. The mathematical tool for performing this classification is the equivariant Hopf bifurcation theorem [8, 9]. In particular, we use the results of Ashwin and Podvigina [1] on Hopf bifurcation with

octahedral symmetry.

This classification is "model-independent" in the sense that it does not depend upon the detailed structure of the network of neurons concerned, or on the precise equations used to model neurons, provided that the symmetry constraints are respected. Since all model equations in current use are primarily phenomenological, and the precise architecture of the muscle group network is unknown (even in the cat), model-independent results have a potential advantage: they depend only on the known symmetries of the network. Any specific choice of network architecture and model neuron dynamics (associated, for example, with particular vertebrate species) will generate a list of spatiotemporal patterns taken from the general classification, but with extra model-dependent restrictions on existence and stability. The model-independent features of the problem can also help to structure existence and stability calculations in specific models; see [9].

In order to create this menu and to make predictions about head motions, we must determine the appropriate "phase space" variables upon which the group Γ acts, and also specify the appropriate group action. Our approach, as in the gaits work, is to use the network structure. We assume that each of the eight motoneurons (or more precisely, sets of motoneurons) is identified with variables in $\mathbf{R}^\ell$ so that the phase space of the muscle motoneurons is $Y = (\mathbf{R}^\ell)^8$. We also assume that the octahedral group acts on Y by permuting the coordinates, just as that group permutes the vertices of the cube. Next we assume that the differential equations that describe the time evolution of this coupled system of neck motoneurons have octahedral symmetry. Using this symmetry, we can then classify the types of spatiotemporal symmetries that periodic states of such systems may have.

Specifically we find that there are six types of spatiotemporal symmetries for small amplitude periodic solutions that can bifurcate from a Γ-invariant equilibrium. Each of these symmetry types includes a reasonable pattern of periodic head motion. They are: shaking the head (saying "no" in many cultures), which occurs in two different ways; nodding the head (saying "yes" in those same cultures); a rotating wave in which the head rolls in an approximate horizontal circle; a combination of "yes" and "no," in which the head nods alternately to left and right; and a side-to-side motion with the head rotating to move the nose in the opposite direction (so that the nose always points at a fixed point in the distance).

Organization of the paper. In section 2 we give a brief description of salient features of the physiology of the vestibular system and rederive the octahedral symmetry of the canal-neck projection. We relate the associated network architecture to a graph drawn on a cube and describe a simple caricature of the effects of the eight muscle groups. Section 3 describes the octahedral group in more detail and motivates the choice of action of this group on muscle space. This section also provides an explicit description of the permutation action of the octahedral group on muscle space, lists the relevant subgroups, and classifies the isotropy subgroups—basic data for the application of symmetric dynamics.

The equivariant Hopf theorem is described in section 4, and a discussion of the irreducible representations of the octahedral group, the basic information needed for application of the Hopf theorem, is given. (Proofs, which use character theory, are postponed to the appendix.) Section 5 presents a classification of the possible small amplitude spatiotemporal symmetry patterns for time-periodic motions of the head, determined by the canal-neck projection. We find six distinct (conjugacy classes of) patterns, or 15 distinct patterns (not distinguishing time-reversals or left-right

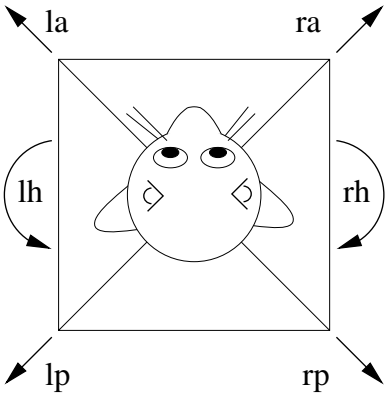

FIG. 1. *Location of the three planes relative to the head, and direction of rotational motion to which canals respond. Canals are drawn schematically near the ears.*

reflections in physical space). These patterns are interpreted as motions of the head in section 6, assuming that the muscle groups act according to our caricature. We pay attention to distinctions arising from conjugate states.

We end with a short conclusions section.

2. Symmetries in the disynaptic canal-neck projection. In this section we rederive the symmetries in the disynaptic canal-neck projection discussed by McCollum and Boyle [12], stating the results in terms of a group of permutations acting on the associated network of neurons. In this aspect of the vestibular system there are six canals (three in each ear) that are connected to eight muscle groups in the neck.

The three canals located in each ear are called *horizontal* h, *anterior* a, and *posterior* p. We denote the six canals by lh, la, lp, rh, ra, rp, where l stands for *left* and r for *right*. Neurons associated with canal hairs have a base firing rate. These hairs are arranged so that fluid flow in one direction in the canal increases the firing rate, and fluid flow in the opposite direction decreases that firing rate. Moreover, the canals are paired ({lh,rh}, {la,rp}, {lp,ra}), so that when one member of a pair transmits an elevated signal, then the other member of that pair transmits a reduced one. These pairs are called *polarity pairs*.

The spatial arrangement of the canals is shown in Figure 1. There are three (approximately) mutually orthogonal planes. One of these planes is horizontal; the other two are vertical, at an angle of 45° to the plane of left-right symmetry of the head. Each polarity pair consists of two canals that are parallel to one of these planes: one canal in the left ear, one in the right. These two canals are oriented in opposite directions in that plane and detect rotations (actually angular accelerations) of the head about an axis perpendicular to that plane. One member of the polarity pair detects acceleration in one orientation (clockwise or counterclockwise), and the other member detects the opposite orientation, as illustrated by the arrows in Figure 1. The four arrows at the corners represent rotations in the direction "along the arrow and down." For example, ra responds to motion in which the nose and right ear move forward to the left and down, while lp responds to motion in which the nose and right ear move backward to the right and up.

Connections from canals to muscles. Experiments show that each of the six canals can transmit signals to each of the eight muscle groups. The muscles also form

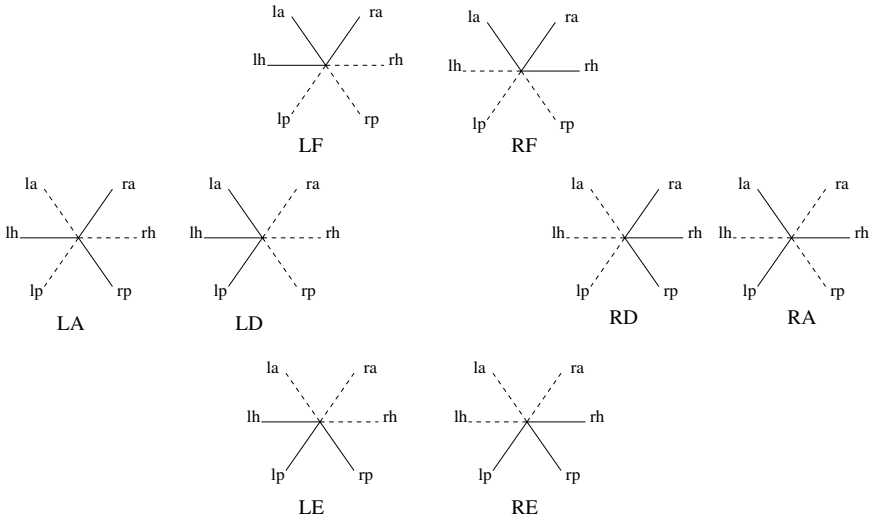

FIG. 2. *Innervation patterns corresponding to eight muscle groups. Dashed lines represent excitatory connections and solid lines inhibitory ones.*

four polarity pairs; if a canal is activated by the motion of the head, then it sends an excitatory signal to one member of each pair and an inhibitory signal to the other member. Physiological investigations (Wilson and Maeda [16], Shinoda *et al.* [13, 14, 15]) suggest that each muscle group is excited by a set of three mutually orthogonal canals (that is, one from each polarity pair) and inhibited by the complementary set of canals (the other members of the polarity pairs).

We describe the details of this arrangement, following McCollum and Boyle, who depict the list of signals transmitted to a given muscle group by an "asterisk," (Figure 2). Each asterisk has three solid lines (inhibitory connections) and three dotted lines (excitatory connections), and diametrically opposite lines have opposite polarity. There are eight possible arrangements of this type. Because the asterisks are drawn in 2-dimensional projection, in a conventional orientation with lh between la and lp, there appear to be two kinds of asterisks: two alternating (with excitation and inhibition alternating) and six nonalternating (with three contiguous excitatory canals). We will shortly see that under a suitable action of the octahedral group, all eight asterisks are equivalent.

The eight neck muscles consist of two flexors in the front (LF, RF), two extensors in the back (LE, RE), and four side (shoulder) muscles. The side muscles are alternating (LA, RA) or directed (LD, RD). McCollum and Boyle [12] discuss the innervation patterns between canal neurons and muscle motoneurons—how the six canal neurons connect to the eight muscle motoneurons, and whether the connection occurs via an excitatory synapse or an inhibitory one. The pattern of connections to each muscle is specified by Figure 2. Each asterisk in Figure 2 is a list of the connections from all six canals to one muscle group, and the type of signal that is transmitted along each connection. Observe that the muscle groups also partition into four polarity pairs:

$$\{LA, RA\}, \quad \{LF, RE\}, \quad \{LE, RF\}, \quad \{LD, RD\}.$$

If one muscle in a polarity pair has an excitatory connection from a canal, then the other muscle in that polarity pair has an inhibitory connection from that canal.

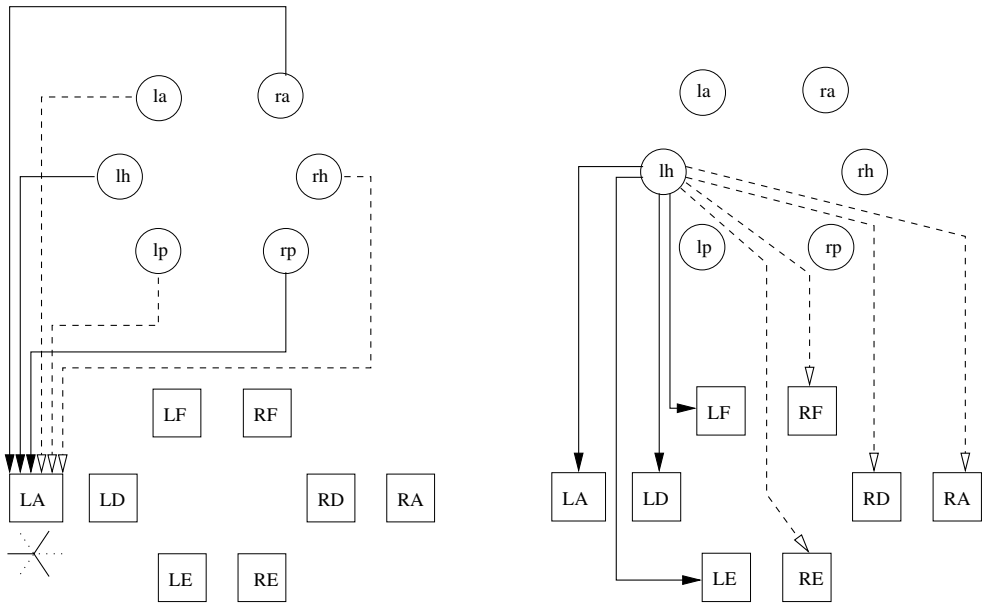

FIG. 3. *Schematic of connections from vestibular nerve afferent to neck motoneuron. Solid line shows inhibitory synapse, dotted line shows excitatory synapse. Left: Connections to a given neck motoneuron, here LA. Right: Connections from a given vestibular nerve afferent, here lh.*

It is useful to display the same information in two other ways. McCollum and Boyle [12] consider only the *disynaptic pathway* from the six vestibular nerve afferents ("canal nerves") to the eight neck motoneurons (by way of the corresponding vestibulospinal neurons). They remark that almost always "the motoneurons of each tested muscle responded to stimulation of all six canal nerves." The responses were classified as either inhibitory or excitatory, as indicated by solid or dotted lines for the relevant arm of the asterisk. This description makes it clear that their Figure 3 (and our Figure 2) is a diagram determining these *connections*.

We make the connection pattern explicit. Figure 3(left) shows connections to a given neck motoneuron, here LA. The associated asterisk is drawn, and the six connections correspond to the six arms. Figure 3(right) shows connections from a given vestibular nerve afferent, here lh. These connections correspond to the eight lh arms in the different asterisks, and connect to the corresponding neck motoneurons.

We do not attempt to draw the complete network since it would contain 48 lines, 24 solid and 24 dotted, and it would be too complicated to convey useful information. However, it is convenient to employ a geometric image in which the canals are identified with the six faces of a cube, and the muscles with the eight vertices. We will describe the network connectivity using the cube.

Octahedral symmetry of canals and muscles. The cube arises naturally from the results of McCollum and Boyle [12], identifying the symmetry group of the canal-neck projection as the 48-element octahedral group. To understand their observation, we identify the canals with faces of a cube, so that polarity pairs of canals are identified with pairs of opposite faces. Up to symmetry there is only one way to make this identification.

To identify the muscles, we observe that every vertex of the cube is in the inter-

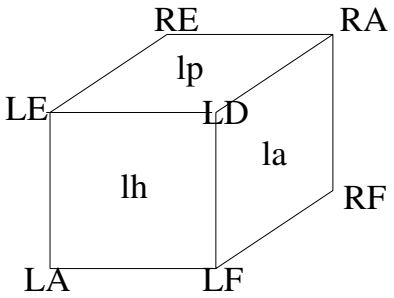

FIG. 4. *Identification of polarity pairs and muscle groups to the cube.*

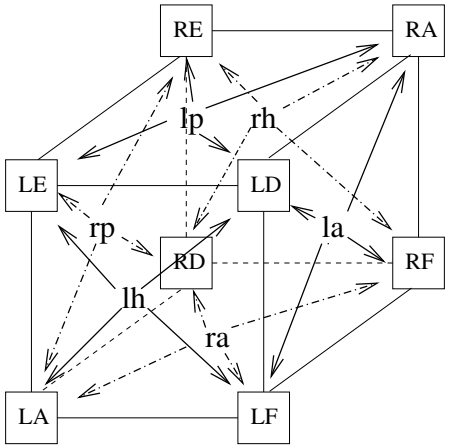

FIG. 5. *Schematic of inhibitory connections from canals to muscles drawn on the cube. Solid lines show connections on "visible" faces, and dot/dashed lines show connections on "hidden" faces. Canals are at centers of faces, muscles at vertices. Connections run to each vertex from the three adjacent faces. The octahedral symmetry of the network is obvious geometrically.*

section of exactly three faces. We identify a given vertex with that muscle that has inhibitory connections from canals corresponding to the three faces adjacent to that vertex. For example, there is a unique vertex that is in the intersection of the three faces corresponding to the left canals lh, lp, la (see Figure 4). We identify this vertex with the left direct muscle LD in Figure 2, since that muscle responds to inhibitory signals from the three left canals.

In Figure 5 we show the 24 inhibitory connections on the cube diagram. The complementary set of connections from canal neurons to muscle motoneurons consists of excitatory connections but is omitted for clarity. The octahedral symmetry of the network is apparent in this figure. The elements of the octahedral group act on the full network by permuting canals, permuting muscles, and permuting the corresponding connections.

Muscle group action: A caricature. What effect do the eight muscle groups have on the head? For purposes of interpretation, we adopt a caricature of the anatomy of the muscle groups, illustrated in Figure 6. Here we assume that the principal effect of a muscle group being activated is to pull the head in the indicated direction. Six muscle groups LF, LD, LE, RF, RD, RE effectively form a "hexagon," and their effect is to tilt the head in various directions. The other two, LA and RA,

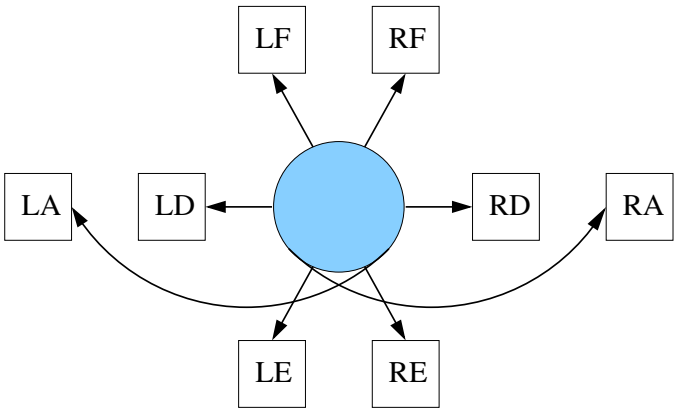

FIG. 6. *Caricature of effect of activation of muscle groups.*

rotate the head about the vertical axis (as sensed by the horizontal canals lh, rh). There is some redundancy here: the hexagon includes three pairs of muscle groups, but the three associated directions are linearly dependent. However, the use of six muscles makes the head position more stable, so there may be physiological reasons for this redundancy. McCollum and Boyle [12] call this hexagon the "central dial." This caricature exhibits the four pairs of opposing muscles (LD, RD), (LE, RF), (LF, RE), (LA, RA), which are just the four polarity pairs.

We stress that this picture of the anatomy is a caricature. At this stage we make no attempt to formulate a more realistic model of the physiology and the mechanics of head movement. However, further detail of this kind could be developed without changing the classification of possible symmetry types of time-periodic motion. What would change would be the fine detail of the corresponding head motions and the precise manner in which each muscle group contributes to that motion.

3. The octahedral group and its actions. We now discuss mathematical features of the octahedral group and various actions of that group that occur in this analysis. In particular, we introduce variables that model the state of the eight muscle groups and discuss how the octahedral group acts on those variables.

The geometry of Figure 5, together with the corresponding figure for excitatory connections (which has the same symmetry), shows that the network of neurons forming the canal-neck projection has octahedral symmetry, where now the octahedral group acts by permuting the eight muscle groups, the six canal neurons, and the connections between them. These permutation actions are distinct from, but induced naturally by, the "standard" action as isometries of $\mathbf{R}^3$ that preserve the cube.

Suppose we fix the cube so that it is centered at the origin. Then the symmetries of the cube have the form R or $-R$, where R is a rotation. It follows that the octahedral group is the direct sum of the group $\mathbb{O}$ of rotation symmetries of the cube and the two-element group $\mathbf{Z}_2^c$ generated by the inversion $-I$. That is, the octahedral group is $\mathbb{O} \oplus \mathbf{Z}_2^c$. The "$c$" in the notation $\mathbf{Z}_2^c$ indicates that this group is the center of the octahedral group.

We are modeling the canal-neck projection by a network of interconnecting neurons, following Figures 3 and 5. This network has symmetry group $\mathbb{O} \oplus \mathbf{Z}_2^c$, which acts on the network by permuting the set of cells and the set of arrows. This permutation action preserves the type of the cell (canal neuron, shown as a circle, or muscle

motoneuron, shown as a square), and it preserves the type of arrow (inhibitory or excitatory).

Phase space for muscles. This permutation action can be transferred to the dynamical variables representing the states of the cells, that is, the phase space of the network. We now describe the effect of this action on the 8 muscle cells. In order to do this we order the eight vertices as in (3.1). The ordering is shown on the cube in Figure 7.

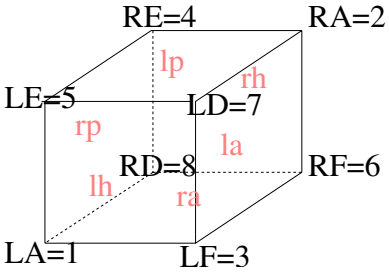

FIG. 7. *Ordering of vertices.*

The simplest model for a state of the eight muscle motoneurons is a point in $\mathbf{R}^8$, with coordinates

$$(y_{\mathrm{LA}}, y_{\mathrm{RA}}, y_{\mathrm{LF}}, y_{\mathrm{RE}}, y_{\mathrm{LE}}, y_{\mathrm{RF}}, y_{\mathrm{LD}}, y_{\mathrm{RD}}). \tag{3.1}$$

Each element of $\mathbb{O} \oplus \mathbf{Z}_2^c$ permutes the eight subscripts LA, RA, LF, RE, LE, RF, LD, RD according to the associated transformation of the vertices of the cube in Figure 7. The overall phase space for any system of ODEs representing the dynamics of the network, consistent with the $\mathbb{O} \oplus \mathbf{Z}_2^c$ symmetry, is therefore equivariant for the permutation action of $\mathbb{O} \oplus \mathbf{Z}_2^c$ on the space $\mathbf{R}^8$.

Our goal is to determine the spatiotemporal symmetries of small amplitude periodic solutions that can be obtained from a synchronous equilibrium by Hopf bifurcation. An important step in this analysis is the computation of the irreducible representations of the symmetry group $\mathbb{O} \oplus \mathbf{Z}_2^c$ on $(\mathbf{R}^\ell)^8$. However, up to isomorphism the answer for general ℓ is identical to the case when $\ell = 1$, for the following reason. Because the group acts by permutations (see the next subsection), the action on $(\mathbf{R}^\ell)^8$ consists of ℓ isomorphic copies of the action on $\mathbf{R}^8$. So the isomorphism types of the irreducible components are the same for all ℓ. However, their multiplicities depend on ℓ. We return to this point in section 4.

The action of $\mathbb{O} \oplus \mathbf{Z}_2^c$ is determined by that of $\mathbb{O}$ and that of $\mathbf{Z}_2^c$. A crucial feature of the "cube" structure is that the action of $-I$ preserves polarity pairs {LA, RA}, {LF, RE}, {LE, RF}, and {LD, RD}, because they label pairs of opposite vertices. Their entries are interchanged by $-I$. That is, $-I$ acts as the permutation

$$(1\ 2)(3\ 4)(5\ 6)(7\ 8).$$

Permutation action of $\mathbb{O}$ on muscle space. It remains to analyze the action of $\mathbb{O}$. We begin the discussion of the action of $\mathbb{O}$ on $\mathbf{R}^8$ by describing how it acts by rotations on $\mathbf{R}^3$ in the "cube" picture. There are three types of rotation: rotations about axes connecting centers of opposite faces, rotations about axes connecting midpoints of opposite edges, and rotations about axes containing opposite vertices. There

are nine rotations corresponding to faces, since there are three pairs of faces and each pair determines three nonidentity rotations. There are six rotations corresponding to edges, since there are six pairs of edges and each pair determines just one nonidentity rotation. There are eight rotations corresponding to vertices, since there are four pairs of vertices and each pair determines two nonidentity rotations.

Denote by V_j the clockwise rotation of 120° about the axis through vertex j for $j = 1, \ldots, 8$ ("clockwise" when viewed with vertex j nearest to the eye). Note that $V_1^2 = V_2$, $V_3^2 = V_4$, $V_5^2 = V_6$, $V_1^7 = V_8$. Denote by F_j the clockwise rotation of 90° about the axis perpendicular to face j for $j = 1, \ldots, 6$. Note that $F_1^3 = F_2$, $F_3^3 = F_4$, $F_5^3 = F_6$. Let $A_i = F_{2i-1}^2$ for $i = 1, 2, 3$. Then the F_j and the A_i are the nine rotations about axes connecting midpoints of opposite faces. Finally, note that each edge is uniquely the intersection of two faces. Denote by E_{ij} the rotation by 180° about the edge in the intersection of faces i and j, where $i < j$. There are six possibilities.

In Table 1 we list the 24 rotations and their permutation actions on $\mathbf{R}^8$. The entries can be read off easily from Figure 7.

Subgroups of $\mathbb{O}$. We use the following notation for groups: $\mathbf{Z}_k$ is the cyclic group of order k, $\mathbf{D}_k$ is the dihedral group of order k, $\mathbf{S}_k$ is the symmetric group of degree k, and $\mathbb{T}$ is the tetrahedral group. This is the unique subgroup of $\mathbb{O}$ that has order 12, and it fixes a tetrahedron inscribed in the cube. Table 2 lists the 11 conjugacy classes of subgroups of $\mathbb{O}$. This calculation was done using the algebra program GAP.

4. Types of Hopf bifurcation. Hopf bifurcation is the tool for finding small amplitude periodic states near an equilibrium. Equivariant Hopf theory [8, 9] states that there is a different type of Hopf bifurcation from a group-invariant equilibrium for each irreducible representation of the group. The equivariant Hopf theorem helps classify the types of spatiotemporal symmetries of periodic states that emanate from a given Hopf bifurcation. We apply this theory in the case of $\mathbb{O}\oplus\mathbf{Z}_2^c$ acting on muscle space $(\mathbf{R}^\ell)^8$, where the equilibrium is $\mathbb{O}\oplus\mathbf{Z}_2^c$-invariant. At such an equilibrium opposing muscles act with equal strength, so that the head is fixed and upright.

As noted previously, the types of irreducible representation of $\mathbb{O}\oplus\mathbf{Z}_2^c$ acting on $(\mathbf{R}^\ell)^8$ are identical with those of $\mathbb{O}\oplus\mathbf{Z}_2^c$ acting on $\mathbf{R}^8$. So the first step is to find the irreducible representations of $\mathbb{O}\oplus\mathbf{Z}_2^c$ acting on $\mathbf{R}^8$. We will show that there are four different irreducible representations, only two of which can lead to periodic states corresponding to nontrivial head motions. One of the associated Hopf bifurcations is simple to analyze, and the other was analyzed previously by Ashwin and Podvigina [1].

Decomposition of $\mathbf{R^8}$ into "push-pull" and "pull-pull" subspaces. The irreducible representations are intimately associated with the action of the inversion $-I$, which plays a key role because it swaps the members of each pair of opposing muscle motoneurons.

We can decompose $\mathbf{R}^8 = Y^+ \oplus Y^-$ into two 4-dimensional $\mathbb{O}\oplus\mathbf{Z}_2^c$-invariant subspaces, so that $-I$ acts trivially on one subspace and changes sign on the other. To do so, define

$$Y^\pm = \{y \in \mathbf{R}^8 : y_{\mathrm{LA}} = \pm y_{\mathrm{RA}}, y_{\mathrm{LF}} = \pm y_{\mathrm{RE}}, y_{\mathrm{LE}} = \pm y_{\mathrm{RF}}, y_{\mathrm{LD}} = \pm y_{\mathrm{RD}}\}.$$

Note that the coordinates corresponding to opposing muscle pairs in Y^+ are equal, and the coordinates corresponding to opposing muscle pairs in Y^- are equal in magnitude but opposite in sign.

As noted previously, three polarity pairs of muscles (the central dial) pull the head in opposite directions, and the muscles of the fourth pair (the alternating muscles) twist the head in opposite directions. In states in Y^+ polarity pairs of muscles act as pull-pull pairs, whereas in states in Y^- these polarity pairs act as push-pull pairs. In fact, all muscles must be under tension; thus push-pull pairs really operate with one muscle group pulling harder than usual while the other pulls less hard. Phenomenologically, we can identify the difference between the tensions of two muscles in a polarity pair with the deviation of the tension (of either muscle, subject to sign) from the rest tension in which the head remains upright.

Next we observe that Hopf bifurcation corresponding to an irreducible representation in Y^+ can only lead to periodic states in which the head is immobile. The reason is simple: $Y^+ = \mathrm{Fix}(-I)$, which is flow-invariant. Thus, in the nonlinear theory, any periodic state emanating from such a bifurcation must itself be fixed by $-I$; consequently, the opposing muscles in each polarity pair are always pulling with the same strength, creating a net motion of zero. As well as being inefficient, this space of motions has no visible effect on the head. In contrast, on the space Y^-, opposing pairs of muscles cooperate to move the head in exactly the same manner, so the muscle actions reinforce each other.

In fact, neither subspace Y^+ or Y^- is irreducible; each subspace decomposes into a 1-dimensional and a 3-dimensional irreducible representation. The previous remark implies that we need focus only on the subspace $Y^- \cong \mathbf{R}^4$.

Decomposition of $\boldsymbol{Y^-}$ into irreducible subspaces. As we have seen, the inversion $-I$ interchanges the muscles in each polarity pair, and the states in Y^- are

TABLE 3
Action of elements in $\mathbb{O}$ on muscle "push-pull" polarity pair space Y^-.

E_{16}	$(\ y_3,\ y_1, -y_5, -y_7)$
E_{35}	$(-y_7, -y_3, -y_5, -y_1)$
E_{45}	$(-y_1, -y_5, -y_3, -y_7)$

ones of the form

$$(y_{\mathrm{LA}}, -y_{\mathrm{LA}}, y_{\mathrm{LF}}, -y_{\mathrm{LF}}, y_{\mathrm{LE}}, -y_{\mathrm{LE}}, y_{\mathrm{LD}}, -y_{\mathrm{LD}}); \tag{4.1}$$

that is, we can parametrize Y^- by the strengths of the four left muscle groups, which correspond to the muscle groups numbered $1, 3, 5, 7$. Thus we can rewrite (4.1) as

$$(y_1, -y_1, y_3, -y_3, y_5, -y_5, y_7, -y_7),$$

which we parametrize by (y_1, y_3, y_5, y_7).

On Y^- the action of $\mathbb{O} \oplus \mathbf{Z}_2^c$ can now be written using signed permutations, since this action preserves polarity pairs and introduces a minus sign when members of a polarity pair are swapped. In particular, we can identify the action of $-I$ on Y^- with the signed permutation $(-y_1, -y_3, -y_5, -y_7)$; that is, $-I$ acts by multiplication by -1 on Y^-, as expected. The signed permutation action of $\mathbb{O}$ on Y^- is given in Table 3.

The subspace Y^- contains the 1-dimensional (hence irreducible) subspace

$$Y_0^- = \mathbf{R}\{(1, -1, -1, 1, -1, 1, 1, -1)\}$$

upon which the elements A_3 and V_4, the generators of the tetrahedral group, act trivially. In addition, $(\mathbb{O} \setminus \mathbb{T}, -I)$ acts trivially, since both $\mathbb{O} \setminus \mathbb{T}$ and $-I$ act as multiplication by -1.

Let Y_1^- be the 3-dimensional invariant complement of Y_0^- in Y^-; so $Y^- = Y_0^- \oplus Y_1^-$. It can be shown that Y_1^- is irreducible, and the action of $\mathbb{O}$ on Y_1^- is isomorphic to the standard action of the cube on $\mathbf{R}^3$. We do this using character theory in the appendix.

Recall that for modeling purposes we assume that the muscle state space Y^- consists of ℓ variables for each polarity pair of muscles. Thus $Y^- \cong (\mathbf{R}^\ell)^4$. As noted previously, the minimal phase space for any of our models occurs when $\ell = 1$. Although the analysis of possible spatiotemporal patterns reduces to the case $\ell = 1$, when we come to consider Hopf bifurcation, it turns out that we must require $\ell \geq 2$. (Reason: equivariant Hopf bifurcation requires certain representations to appear twice, namely, the absolutely irreducible ones, and that multiplicity occurs only when $\ell \geq 2$. See [8, 9].) Since all neurons, and in particular muscle motoneurons, have high-dimensional internal dynamics, this condition poses no difficulties.

5. Symmetry types of periodic state. At a Γ-invariant equilibrium for a Γ-equivariant system of ODEs, the equivariant Hopf theorem [8, 9] states (under several genericity hypotheses) that there exists a branch of small amplitude periodic states corresponding to every $\mathbf{C}$-axial subgroup of $\Gamma \times \mathbf{S}^1$ acting on the center subspace at that equilibrium. Moreover, these periodic states have spatiotemporal symmetries given by the $\mathbf{C}$-axial subgroup. A subgroup of $\Gamma \times \mathbf{S}^1$ is $\mathbf{C}$-*axial* if it is an isotropy subgroup, and its fixed-point subspace, within the eigenspace corresponding to the purely imaginary eigenvalues, has dimension 2.

A complete discussion of equivariant Hopf theory is beyond the scope of this paper; details can be found in [8, 9]. To simplify the remarks we make here, we assume that all periodic solutions have period 1. Then $\mathbf{S}^1$, the group of phase shift symmetries, is parameterized from 0 to 1. We now recall two general points from Hopf theory. First, the phase shift by $\frac{1}{2}$ acts as multiplication by -1 on the center subspace. Second, the kernel of the action of $\Gamma \times \mathbf{S}^1$ on the center subspace is contained in every $\mathbf{C}$-axial subgroup.

In the case at hand, we saw that $-I$ acts as multiplication by -1 on Y^-. Thus the element $(-I, \frac{1}{2})$ in $\mathbf{Z}_2^c \times \mathbf{S}^1$ acts trivially in any Hopf bifurcation with center subspace in Y^-. It follows that every periodic state emanating from such a bifurcation has the property that interchanging polarity pairs is the same as making a half period phase shift. That is,

$$\begin{aligned} y_2(t+\tfrac{1}{2}) &= y_1(t), \qquad & y_4(t+\tfrac{1}{2}) &= y_3(t), \\ y_6(t+\tfrac{1}{2}) &= y_5(t), \qquad & y_8(t+\tfrac{1}{2}) &= y_7(t). \end{aligned} \tag{5.1}$$

Dividing by the subgroup $\mathbf{Z}_2(-I, \frac{1}{2})$ leads to the standard action of $\mathbb{O} \times \mathbf{S}^1$ on the center subspace. To see this, consider the epimorphism $\varphi : (\mathbb{O} \oplus \mathbf{Z}_2^c) \times \mathbf{S}^1 \to \mathbb{O} \times \mathbf{S}^1$ defined by

$$\varphi(\gamma, I, \theta) = (\gamma, \theta) \quad \text{and} \quad \varphi(\gamma, -I, \theta) = (\gamma, \theta + \tfrac{1}{2}).$$

The kernel of φ is $\mathbf{Z}_2(-I, \frac{1}{2})$, and the quotient group is $\mathbb{O} \times \mathbf{S}^1$ with its standard action on Y^-, since $\varphi(\gamma, I, \theta) = (\gamma, \theta)$. It follows that to classify the relevant types of periodic solutions, we need analyze only those periodic solutions that occur in Hopf bifurcations associated to $\mathbb{O}$ acting on Y^- and then add in the constraints (5.1), if needed.

Using the decomposition of phase space into Y^+ and Y^- components, we can write any periodic state in the form $y(t) = y^+(t) + y^-(t)$. When we come to interpret the motions associated with the periodic states, factoring out the Y^+ component will not change these motions in any important manner since, as discussed previously, $y^+(t)$ by itself leaves the head immobile. Moreover, near these Hopf bifurcations the Y^+ components will be small compared to the Y^- components. More precisely, suppose that a Hopf bifurcation supported in Y^- leads to a periodic state of amplitude ε. Then the theory implies that generically $y^-(t)$ will be of order ε, while $y^+(t)$ will be of order ε^2. Finally, coupling (5.1) with the definitions of Y^- and Y^+ leads to the conclusion that $y^+(t)$ oscillates with twice the frequency of $y^-(t)$ and that

$$\begin{aligned} y_1^-(t+\tfrac{1}{2}) &= -y_1^-(t), \qquad & y_3^-(t+\tfrac{1}{2}) &= -y_3^-(t), \\ y_5^-(t+\tfrac{1}{2}) &= -y_5^-(t), \qquad & y_7^-(t+\tfrac{1}{2}) &= -y_7^-(t). \end{aligned} \tag{5.2}$$

In short, when discussing small amplitude periodic solutions of the nonlinear ODEs on muscle phase space, the system can effectively be reduced to an $\mathbb{O}$-equivariant

system of ODEs on the reduced phase space Y^- whose periodic solutions also satisfy (5.2). It is this reduced system that we study for the remainder of this paper.

Spatiotemporal symmetries defined by H and K. In Γ-equivariant systems we can associate two subgroups H and K of Γ to each periodic state $y(t)$. Elements of the subgroup K fix the periodic trajectory pointwise, whereas elements of the subgroup H fix the periodic trajectory setwise. Uniqueness of solutions with a given initial condition implies that each element of H couples with a phase shift to fix the periodic state.

When $\ell \geq 2$, periodic states can have spatiotemporal symmetry group pairs (H, K) only if H/K is cyclic and K is an isotropy subgroup [9]. We describe the symmetries associated with periodic states obtained by Hopf bifurcation in terms of these (H, K) pairs.

Hopf bifurcation in Y^-. Next we classify the types of periodic state that can arise as a small amplitude motion near the steady state (in which there is no head motion). Such states can be found using the equivariant Hopf theorem [8, 9]. This theorem states that there is a possible Hopf bifurcation corresponding to each irreducible representation of $\mathbb{O}$ acting on phase space. Now, the decomposition of Y^- into irreducibles can be viewed as a decomposition $\mathbf{R}^4 = W_0 \oplus W_1$, where

$$W_0 = \mathbf{R}\{(1,-1,-1,1)\} \quad \text{and} \quad W_1 = \mathbf{R}\{(1,1,1,1),(1,1,-1,-1),(1,-1,1,-1)\}.$$

Here W_0 corresponds to Y_0^-, and W_1 corresponds to Y_1^-. Both are irreducible. The kernel of the action of $\mathbb{O}$ on W_0 is $\mathbb{T}$; the representation on W_1 is the standard 3-dimensional irreducible representation, in which $\mathbb{O}$ acts as isometries that preserve the cube.

Hopf bifurcation via W_0 leads to periodic states with $H = \mathbb{O}$ and $K = \mathbb{T}$. Ashwin and Podvigina [1] classify the periodic states that arise from the standard irreducible representation of $\mathbb{O}$. This is the difficult case for Hopf bifurcation. There are five types of periodic state, whose (H, K) pairs are $(\mathbf{D}_4, \mathbf{Z}_4)$, $(\mathbf{D}_2^E, \mathbf{Z}_2^E)$, $(\mathbf{Z}_4, \mathbf{1})$, $(\mathbf{S}_3, \mathbf{Z}_3)$, and $(\mathbf{Z}_3, \mathbf{1})$. Table 4 lists these pairs, together with associated information.

We sketch the derivation of the "muscle oscillation" column of this table. Consider the pair $(H, K) = (\mathbb{O}, \mathbb{T})$ in the first row. Here $\mathbb{T}$ fixes the state of each muscle group at each time. By Table 2, the group $\mathbb{T}$ is generated by A_3 and V_4. Therefore, by Table 3, any state $y(t)$ with the symmetry pair $(\mathbb{O}, \mathbb{T})$ must satisfy

$$y_1(t) \equiv -y_5(t), \qquad y_3(t) \equiv -y_7(t), \qquad y_1(t) \equiv y_7(t),$$

so that

$$y(t) = (u(t), -u(t), -u(t), u(t))$$

for a time-periodic function u. The quotient H/K is isomorphic to $\mathbf{Z}_2$ and is generated (modulo K) by the element $(F_5, \frac{1}{2}) \in \mathbb{O} \times \mathbf{S}^1$. This imposes the same condition $u(t + \frac{1}{2}) = -u(t)$ that was previously noted using the symmetry $(-I, \frac{1}{2})$.

For a more complicated example, consider the pair $(H, K) = (\mathbf{Z}_3, \mathbf{1})$. Since K is trivial, no components of $y(t)$ are forced to be synchronous. The subgroup $\mathbf{Z}_3$ is generated by V_1, whose action on $\mathbf{R}^4$ fixes y_1 and cycles $(y_3, y_5, -y_7)$. The only possible pattern of phase shifts here is $(0, \frac{1}{3}\delta, \frac{2}{3}\delta)$, where $\delta = \pm 1$. So

$$(y_3(t), y_5(t), y_7(t)) = (u(t), u(t + \tfrac{1}{3}\delta), -u(t + \tfrac{2}{3}\delta)),$$

TABLE 4

Conjugacy classes of Hopf-type states, and the associated patterns of muscle activation, where $\delta = \pm 1$, $u(t+\frac{1}{2}) = -u(t)$, $z(t+\frac{1}{2}) = -z(t)$, $v(t+\frac{1}{6}) = -v(t)$. *Column "#" gives a series of reference numbers used for identification in the text.*

Type	H generators	K generators	Muscle oscillation	#

$(\mathbf{Z}_3, \mathbf{1})$	V_1	I	$(v(t), u(t), u(t+\frac{1}{3}\delta), -u(t+\frac{2}{3}\delta))$	11
	V_3	I	$(u(t), v(t), -u(t+\frac{1}{3}\delta), u(t+\frac{2}{3}\delta))$	12
	V_5	I	$(u(t), -u(t+\frac{2}{3}\delta), v(t), u(t+\frac{1}{3}\delta))$	
	V_7	I	$(u(t), -u(t+\frac{1}{3}\delta), -u(t+\frac{2}{3}\delta), v(t))$	13
$(\mathbf{D}_4, \mathbf{Z}_4)$	F_1, A_2	F_1	$(u(t), u(t), u(t), u(t))$	14
	F_3, A_3	F_3	$(u(t), -u(t), u(t), -u(t))$	15
	F_5, A_1	F_5	$(u(t), u(t), -u(t), -u(t))$	

while $y_1(t) = v(t)$ is independent of these. However, the same phase shifts apply to y_1, so we must have $v(t) \equiv v(t + \frac{1}{3}\delta)$. Moreover, like every periodic state arising by Hopf bifurcation, v also satisfies $v(t + \frac{1}{2}) = -v(t)$. These observations lead to the condition $v(t + \frac{1}{6}) = -v(t)$ in the table.

Note that for phase shifts other than $0, \frac{1}{2}$ the states come in pairs, with plus or minus the stated phase shift. These pairs are identical except for time-reversal. For a given imaginary eigenspace, either one of these states occurs, or the other does, but not both. See [9, pp. 112–114]. (When $H/K \cong Z_m$ with $m = 5$ or $m \geq 7$ the same pair H/K can correspond to several distinct phase shifts, even taking the sign into account. For example, the $\mathbf{Z}_5$ case can have phase shift $\frac{2}{5}$ as well as $\frac{1}{5}$. However, these cases do not occur in the group $\mathbb{O}$.)

Table 4 lists (up to conjugacy) five small amplitude periodic state types that can occur by Hopf bifurcation supported by the standard 3-dimensional irreducible representation of $\mathbb{O}$, plus a sixth supported by the 1-dimensional representation. We interpret these motions in terms of our caricature of the muscle groups. We will see that all six cases lead to repetitive motions that seem quite reasonable.

Conjugate states are determined by $\mathbb{O}/(\boldsymbol{N}(\boldsymbol{H}) \cap \boldsymbol{N}(\boldsymbol{K}))$. We briefly discuss the technical issue: states whose associated subgroups are conjugate.

Suppose that $x(t)$ is a periodic state with spatiotemporal symmetry group pair (H, K). Let $\gamma \in \Gamma$. Then $\gamma x(t)$ is a periodic state with spatiotemporal symmetry group pair (H', K'), where

$$H' = \gamma H \gamma^{-1} \quad \text{and} \quad K' = \gamma K \gamma^{-1}.$$

Thus the symmetry group pairs are identical if and only if $\gamma \in N(H) \cap N(K)$. The number of conjugate periodic states with different spatiotemporal symmetries is

$$\frac{|\Gamma|}{|N(H) \cap N(K)|}. \tag{5.3}$$

When we specialize to $\Gamma = \mathbb{O}$, the number of conjugates can be found by computing the normalizers of the appropriate subgroups. The normalizers are found in Table 2. In particular, $N(\mathbb{O}) \cap N(\mathbb{T}) = \mathbb{O}$, $N(\mathbf{S}_3) \cap N(\mathbf{Z}_3) = \mathbf{S}_3$, $N(\mathbf{D}_2^E) \cap N(\mathbf{Z}_2^E) = \mathbf{D}_2^E$, $N(\mathbf{Z}_4) = \mathbf{D}_4$, $N(\mathbf{Z}_3) = \mathbf{S}_3$, and $N(\mathbf{D}_4) \cap N(\mathbf{Z}_4) = \mathbf{D}_4$. It follows that the number of conjugacies of the six solution types are 1, 4, 6, 3, 4, 3, respectively, yielding 21 possibilities.

6. Head motions. The standard equivariant theory classifies solution types up to conjugacy by a symmetry element. However, conjugate states are important here, because, with one exception, the action of $\mathbb{O}$ on the muscle space network does not relate directly to motions of the head in physical space $\mathbf{R}^3$, and that exception is the bilateral (left-right) symmetry of the body, which is realized in our network by E_{45}. So, in general, conjugate symmetry groups can correspond to head motions that are substantially different. Counting conjugates, as we have in Table 4, leads to 21 motions to describe—28 if we include time-reversals for $\pm$ phase shifts. If we consider solution types up to time-reversibility and bilateral symmetry, then there are 15 types to consider. The final column (#) in Table 4 is a reference number which we will use to identify the various patterns of oscillation.

Description of motions listed in Table 4. To explain the derivation of Table 4, we take each conjugacy class in turn and visualize the corresponding periodic state in the following manner. We assume, for simplicity, a 2-dimensional description in which the head is modeled by a circle, as in Figure 6. The position of the neck is identified with the center of this circle. The orientation of the nose (under rotation about the neck axis) is specified by a vector based at the center of the circle with the appropriate orientation.

We decompose the head motion into two distinct components. The spatial motion of the head is obtained by summing the six vectors representing the muscle groups of the central dial. As time t varies through a cycle, the resultant vector describes a closed curve in the horizontal plane, schematically representing the motion of the center of the circle that represents the head position.

Rotations of the neck (caused by muscle groups LA, RA) are represented as rotations of the circle about its instantaneous center. These rotations are assumed to act independently of the translations of the circle. This assumption is invalid in genuine 3-dimensional motion, but it provides an adequate visualization of small amplitude motions, bearing in mind that Figure 6 is itself a caricature.

Next, we choose specific periodic functions u, z, v with the correct symmetry properties. For the figures drawn here we take

$$\begin{aligned} u(t) &= \sin(2\pi t) + 0.2\sin(10\pi t), \\ z(t) &= 0.75\sin(2\pi t) + 0.03\sin(10\pi t), \\ v(t) &= 0.3\sin(6\pi t). \end{aligned}$$

Then we use Table 4 to compute the six vectors of the central dial and the rotation angle of the nose. We denote the center of the circle (head) as a function of time t by

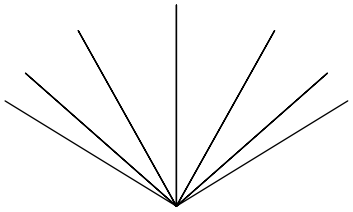

FIG. 8. *Motion for pattern* 1 $(\mathbb{O}, \mathbb{T})$.

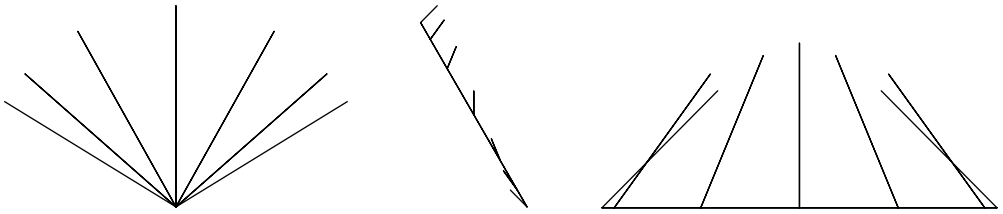

FIG. 9. *Motion for patterns* 2–4 $(\mathbf{S}_3, \mathbf{Z}_3)$.

the curve $\mathcal{C}(t)$. For a periodic state $y(t) = (y_1(t), y_3(t), y_5(t), y_7(t))$ the closed curve $\mathcal{C}(t)$ has the form

$$\begin{aligned} \mathcal{C}_1(t) &= -2y_7(t) - y_3(t) - y_5(t), \\ \mathcal{C}_2(t) &= \sqrt{3}(y_3(t) - y_5(t)). \end{aligned} \tag{6.1}$$

The term $\sin(10\pi t)$ is included to remove some artificial regularities from the pictures, such as motions of the head in a perfect circle. The vector representing the orientation of the nose is drawn at times $\frac{n}{12}$ for $0 \le n \le 11$, as a vector based on the appropriate point of the curve $\mathcal{C}$, of fixed length.

This representation involves some arbitrary choices, but is adequate for our present needs. When interpreting the figures, note that $\mathcal{C}$ may reduce to a line segment (described twice) or even a single point. Also, the segments representing the nose may overlap each other or overlap $\mathcal{C}$. These ambiguities can be resolved by creating a movie.

$(\mathbb{O}, \mathbb{T})$*:*. Here the muscles of the central dial follow the pattern $y_3(t) = y_{\mathrm{LF}}(t) = -u(t)$, $y_5(t) = y_{\mathrm{LE}}(t) = -u(t)$, $y_7(t) = y_{\mathrm{LD}}(t) = u(t)$. From (6.1) we see that the curve $\mathcal{C}$ is a single point, and the center of the head does not move. The nontrivial head motion comes from y_{LA} and y_{RA}, which swivel the head about its vertical axis. The overall invariance under $(-I, \frac{1}{2})$ implies that this swivel motion is the same as its left-right reflection, up to a half-period phase shift. This description corresponds exactly, under the assumptions of the model, to the usual "shake the head" motion indicating the word "no." The schematic visualization of this motion is shown in Figure 8. Here the nose vector oscillates from left to right to form the fan shape illustrated.

$(\mathbf{S}_3, \mathbf{Z}_3)$*:*. If we take $H = \langle V_1, E_{15} \rangle$ and $K = \langle V_1 \rangle$, then this case turns out to be exactly like the previous one, except that the time series of the direct muscled motoneurons $u(t)$ is unequal to the time series of the central dial muscle motoneurons $z(t)$. (Here angle brackets indicate the subgroup generated by their contents.) Since the $z(t)$ motions cancel out, the motion again looks like "no" and is reproduced as the first image in Figure 9.

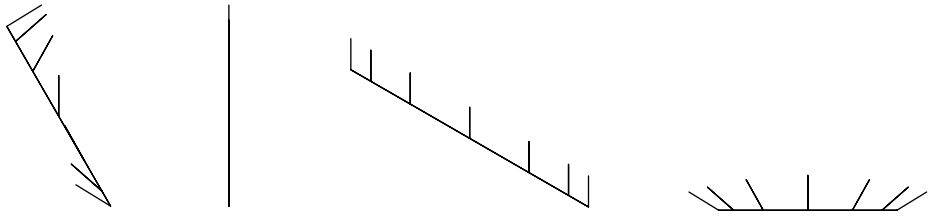

FIG. 10. *Motion for oscillation patterns* 5–8 $(\mathbf{D}_2^E, \mathbf{Z}_2^E)$.

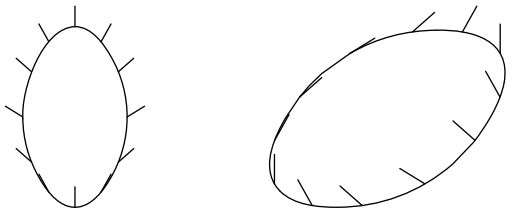

FIG. 11. *Motion for patterns* 9–10 $(\mathbf{Z}_4, \mathbf{1})$.

The patterns for the other two conjugates of this motion can be deduced in a similar manner and are visualized in Figure 9. In pattern 3 the head is inclined alternately down to the left and up to the right, while the nose oscillates from side to side. In pattern 4, the head tilts alternately to left and right while the nose oscillates from side to side.

$(\mathbf{D}_2^E, \mathbf{Z}_2^E)$*:*. First, we consider the conjugate state pattern 5, for which $K = \langle E_{16} \rangle$, $H = \langle E_{16}, E_{15} \rangle$, and $y(t) = (u(t), u(t), 0, 0)$. The phase shift action of H/K implies that $u(t + \frac{1}{2}) = -u(t)$. Now the muscle groups LD, RD, LE, RF are inactive, LA and LF are in phase with each other, and RA and RE are half a period out of phase with LA and LF. The head "nods" down and to the left, then up and to the right, in roughly the direction of the muscle pair LF, RE, with a twist to the right as the head moves down, a twist to the left as it moves up. Another conjugate state has $K = \langle E_{14} \rangle$ and $H = \langle E_{14}, E_{13} \rangle$. This state is just the left/right image of the previous one.

Second, we consider pattern 6, where $K = \langle E_{45} \rangle$ and $H = \langle E_{45}, E_{35} \rangle$. Such a state has $y_{\mathrm{LA}} = y_{\mathrm{RA}} = y_{\mathrm{LD}} = y_{\mathrm{RD}} = 0$. The variables y_{LF} and y_{LE} are half a period out of phase, and the push-pull constraint implies that y_{RF} is in synchrony with y_{LF}, and similarly y_{RE} is in synchrony with y_{LE}. There is thus an overall left-right symmetry, and also a front-back symmetry when combined with a half period phase shift. This is precisely the pattern of movement observed when nodding the head (indicating "yes"). Motions associated with patterns 7 and 8 are found similarly. Note that pattern 8 also corresponds to a standard head motion: one where the head rotates left as it tilts left and then rotates right as it tilts right. See Figure 10 for diagrams of patterns 5–8.

$(\mathbf{Z}_4, \mathbf{1})$*:*. We take $H = \langle F_1 \rangle$. From Table 3, and noting that F_1 induces a phase shift of $\pm\frac{1}{4}$, we obtain the pattern listed in Table 4. (We also use the $(-I, \frac{1}{2})$ symmetry of all periodic states.) The motions are visualized in Figure 11.

In pattern 9, the head moves in an ellipse with long axis pointing towards the front. The nose oscillates from side to side, moving outwards at the front and inwards at the back. There are two conjugates in pattern 10 that are mirror images of each

other. The motion is much as above, but the ellipse is oriented along a different axis.

$(\mathbf{Z}_3, \mathbf{1})$∴ Take $H = \langle V_1 \rangle$. This leads to the pattern stated in Table 4. Bearing in mind the $(-I, \frac{1}{2})$ symmetry, successive phases around the central dial differ by $\frac{1}{6}$. The head rotates in a "circle" (strictly, a closed loop with hexagonal symmetry), combined with a swivel. Choice of plus or minus phase shifts produce clockwise or counterclockwise rotations. Conjugates here replace V_1 by V_3, V_5, V_7, noting that V_3 and V_5 are mirror images. The motions are visualized in Figure 12. In pattern 11 the head rotates in a rounded hexagonal curve, while the nose oscillates slightly. The other two patterns are more complicated and best described using the figure.

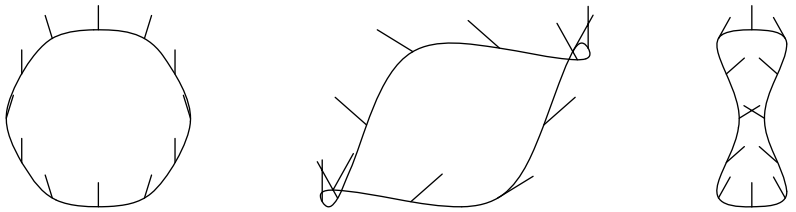

FIG. 12. *Motion for patterns* 11–13 $(\mathbf{Z}_3, \mathbf{1})$.

$(\mathbf{D}_4, \mathbf{Z}_4)$∴ We choose $H = \langle F_3, A_3 \rangle$, $K = \langle F_3 \rangle$, and $y(t) = (u(t), -u(t), u(t), -u(t))$. The conjugates are as shown in Table 4. The motions are visualized in Figure 13. In each case the head moves in one of three planes (so that $\mathcal{C}$ reduces to a line segment), while the nose oscillates from side to side. In pattern 14 the head moves left and right while the nose aims at a fixed central point.

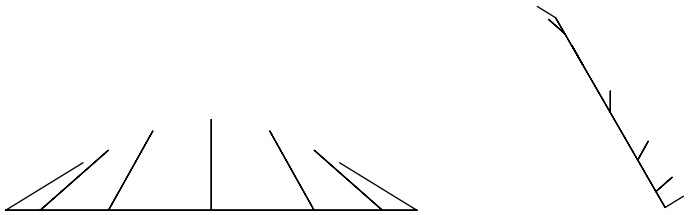

FIG. 13. *Motion for patterns* 14–15 $(\mathbf{D}_4, \mathbf{Z}_4)$.

7. Conclusions. In sections 2–4 we derived the octahedral symmetry of the canal-neck projection first discovered by McCollum and Boyle [12]. After conjecturing that the symmetry of the network of neck muscle motoneurons also has octahedral symmetry, we classified the spatiotemporal symmetry types of small amplitude periodic solutions that can be obtained by Hopf bifurcation. Finally, in section 6, we used the caricature of muscle group actions developed in section 2 to suggest the form that head motions might take.

On a cautionary note, the symmetries of neuronal networks need not reflect symmetries in the physical world. This mismatch in symmetry happens in the network associated with orientation-tuned neurons in the primary visual cortex [2] and is also the case in the vestibular system. Thus, periodic solutions that are symmetrically related in the network need not be (obviously) related in physical space (actual head movements). We believe that the issue of network structure not being directly related to physical world structure will be an important issue in many applications.

The next steps in the program we have described are to include in the model the (symmetry) structure of other projections in the vestibular system, for example the uvula-nodulus [7], to include the semicircular canals, and to make more direct contact with the biology. Two questions arise in this last step: Do the head motions we describe play some special role in the context of general periodic head motions (that is, do these motions appear frequently in animals), and can the classification of spatiotemporal symmetries of small amplitude motions near an upright head give a method for classifying types of head tremor? Our classification, which is based on the symmetries of a network that has been abstracted from the neurobiology of the cat, provides a prediction for likely types of periodic head motions, much like the predictions that were implicit in our previous work on animal gaits [10, 11].

There may exist periodic states that emanate from many types of bifurcation; however, in this study we classify only those types that emanate from a Hopf bifurcation.

Appendix: Characters of the octahedral group. The most efficient way to decompose the space Y^- into irreducible representations of $\mathbb{O}$ or $\mathbb{O} \oplus \mathbf{Z}_2^c$ is to use character theory; see, for example, Curtis and Reiner [6]. Recall that for a given representation of a group Γ, the corresponding *character* χ is the function $\chi : \Gamma \to \mathbf{C}$ for which $\chi(\gamma)$ is the trace of the matrix that represents the action of $\gamma \in \Gamma$. We assume familiarity with character theory.

First, observe that any representation (space) U for $\mathbb{O}$ naturally determines two distinct representations U^+, U^- of $\mathbb{O} \oplus \mathbf{Z}_2^c$ with the same underlying vector space. In both, the elements of $\mathbb{O}$ have the same action as they do on U. The action of $-I$ on U^+ is by the identity, whereas that on U^- is by minus the identity. If U is irreducible for the action of $\mathbb{O}$, then the $U^\pm$ are irreducible for the action of $\mathbb{O} \oplus \mathbf{Z}_2^c$.

It is easy to prove that every irreducible for $\mathbb{O} \oplus \mathbf{Z}_2^c$ arises in this manner, as follows. Every irreducible representation of $\mathbb{O}$ is absolutely irreducible, so by Schur's lemma the only commuting linear maps are scalar multiples of the identity. Since $-I$ commutes with $\mathbb{O}$ and $(-I)^2 = I$, it follows that $-I$ must act as plus or minus the identity. The rest is straightforward.

Therefore we can read off the irreducible representations of $\mathbb{O} \oplus \mathbf{Z}_2^c$ from those of $\mathbb{O}$. It is well known (see, for example, Curtis and Reiner [6, pp. 331–333]) that $\mathbb{O}$ has five distinct irreducible representations: two of dimension 1, one of dimension 2, and two of dimension 3.

We can describe the irreducible representations of $\mathbb{O}$ as follows:

- ρ_0: dimension 1; trivial action.
- ρ_1: dimension 1; $\mathbb{T}$ acts trivially, $\mathbb{O} \setminus \mathbb{T}$ acts by -1.
- ρ_2: dimension 2; kernel is the Klein four-group $\mathbf{D}_2^A$, modulo which $\mathbb{O}$ acts in the standard representation of $\mathbf{D}_3$ on $\mathbf{R}^2$.
- ρ_3: dimension 3; standard action of $\mathbb{O}$ as isometries of $\mathbf{R}^3$ preserving the cube.
- ρ_4: dimension 3; nonstandard action on $\mathbf{R}^3$ in which $\mathbb{T}$ acts as rotations but $\mathbb{O}\setminus\mathbb{T}$ acts as rotations composed with minus the identity. In fact, $\rho_4 = \rho_1 \otimes \rho_3$. This representation is also isomorphic to the standard action of $\mathbf{S}_4$ on the subspace of $\mathbf{R}^4$ consisting of points whose coordinates sum to 0.

The conjugacy classes of $\mathbb{O}$ are also five in number. In the notation of Table 3 they are

$$\{I\}, \quad \{A_j\}, \quad \{V_j\}, \quad \{F_j\}, \quad \{E_j\}.$$

The character table for $\mathbb{O}$ is shown in Table 5, and is derived in Curtis and Reiner [6, pp. 332–333]. It is easy to compute the character χ of the $\mathbb{O}$-action described in Table 3, which is shown in Table 5 in the same format. In particular, we see that $\chi = \rho_1 + \rho_3$. Since characters determine representations uniquely, and direct sums of representations correspond to sums of characters, we see that Y^- decomposes into two irreducible components, the nontrivial 1-dimensional representation and the standard 3-dimensional representation. This is what we claimed in section 4.

TABLE 5
Character table for representations of $\mathbb{O}$.

	$\{I\}$	$\{A_j\}$	$\{V_j\}$	$\{F_j\}$	$\{E_j\}$

A METHOD TO COMPUTE STATISTICS OF LARGE, NOISE-INDUCED PERTURBATIONS OF NONLINEAR SCHRÖDINGER SOLITONS*

R. O. MOORE†, G. BIONDINI‡, AND W. L. KATH§

Abstract. We demonstrate in detail the application of importance sampling to the numerical simulation of large noise-induced perturbations in soliton-based optical transmission systems governed by the nonlinear Schrödinger equation. The method allows one to concentrate numerical Monte Carlo simulations around the noise realizations that are most likely to produce the large pulse deformations connected with errors, and yields computational speedups of several orders of magnitude over standard Monte Carlo simulations. We demonstrate the method by using it to calculate the probability density functions associated with pulse amplitude, frequency, and timing fluctuations in a prototypical soliton-based communication system.

Key words. nonlinear Schrödinger equation, optical fibers, solitons, noise, Monte Carlo simulations, importance sampling

1. Introduction.

The development of high-bit-rate data transmission over optical fibers is one of the major technological achievements of the late 20th century. The information-carrying capacity of such systems has increased by several orders of magnitude over the past quarter-century. There are limits imposed on capacities, however, by various transmission impairments that distort and degrade the signal in a number of ways [1, 2]. One common source of impairments in lightwave communication systems is the amplified spontaneous emission (ASE) noise generated by the erbium-doped fiber amplifiers (EDFAs) used to compensate loss in the fiber [1, 2]. This additive noise perturbs the propagating pulses, producing amplitude, frequency, timing, and phase jitter, which can then lead to bit errors [3, 4, 5].

Since ASE noise is a stochastic phenomenon, Monte Carlo simulations can be used to determine its effects on a system. The direct calculation of bit error rates with standard Monte Carlo simulations is impossible, however. Because data transmission rates are so high (currently, 10 Gb/s or more per channel, with tens of channels usually present per fiber) and errors must be handled by much slower electronic equipment, error rates are required to be very small, typically one error per trillion bits or lower. As a result, an exceedingly large number of Monte Carlo realizations would be needed to observe even a single transmission error, and even more would be required to obtain reliable error estimates.

To overcome this limitation, one approximation is to calculate numerically the variances of pulse amplitude and/or timing and then to extrapolate the results into the tails of the probability density function (pdf) by assuming it to be Gaussian. It is clear, however, that this procedure is inadequate, since nonlinearity and pulse interactions can both contribute to make the resulting distributions non-Gaussian [6, 7, 8]. Nonlinearity arises from several sources, such as self-phase modulation due to the fiber's nonlinear refractive index [9, 10] as well as the nonlinear conversion of optical energy into electrical energy by the photodetector [8].

Various techniques have recently been proposed to address the difficulty in calculating accurate statistics for rare events [8, 11, 12, 13, 14, 15, 16]. One promising approach is a technique known as importance sampling (IS) [17, 18]. In general, IS works by concentrating Monte Carlo samples on those configurations that are most likely to lead to transmission errors, thus significantly speeding up the simulations. Previously, we have successfully applied this technique to the direct simulation of transmission impairments caused by polarization-mode dispersion [14, 15]. More recently, we have presented numerical results demonstrating that IS can also be applied to simulations of ASE-induced transmission impairments [16]. The purpose of this paper is to describe in detail the methods used to produce these numerical simulations. For simplicity, we consider the case of a soliton-based transmission system (where, in the absence of noise, the pulse shape remains fixed), but it is anticipated that the technique can be extended to more realistic systems and more general transmission formats. The advantages of the method are substantial, allowing an increase in efficiency of several orders of magnitude over standard Monte Carlo simulations.

2. Solitons and amplifier noise. The propagation of pulses in an optical fiber with periodically spaced amplification is governed by the nonlinear Schrödinger (NLS) equation [9, 10, 16], which in dimensionless units is

$$i\frac{\partial u}{\partial z} + \frac{1}{2}\frac{\partial^2 u}{\partial t^2} + |u|^2 u = i\sum_{n=1}^{N_a} \delta(z - nz_a) f_n(t). \tag{2.1}$$

Here z and t are distance and retarded time, u is the pulse's electromagnetic field envelope, N_a is the number of amplifiers, and z_a is the amplifier spacing. (The nondimensionalization and our choice of units are described in detail in Appendix A.) In this equation, the periodic power variations due to fiber loss and amplification have been averaged out [9].

The term $f_n(t)$ is the noise added at each amplifier; when the pulse reaches an amplifier at $z = nz_a$ (where z_a is the dimensionless amplifier spacing and $n = 1, 2, \ldots, N_a$, with N_a being the total number of amplifiers in the transmission line), a small amount of noise $f_n(t)$ is added to u: $u(nz_a^+, t) = u(nz_a^-, t) + f_n(t)$, as seen by integrating (2.1) across $z = nz_a$. (Recall that we have averaged out loss and gain; this means that the noise is the only effect remaining at the amplifiers.) The amplifier noise $f_n(t)$ can be modeled as classical zero-mean white noise:

$$\langle f_n(t) \rangle = 0, \tag{2.2a}$$

$$\langle f_m(t) f_n(t') \rangle = 0, \tag{2.2b}$$

$$\langle f_m(t) f_n^\dagger(t') \rangle = \sigma^2 \delta_{mn} \delta(t - t'), \tag{2.2c}$$

where $\langle \cdot \rangle$ denotes ensemble average, the superscript † denotes the complex conjugate, δ_{mn} and $\delta(t-t')$ are the Kronecker and Dirac deltas, respectively, and σ^2 is a parameter describing the noise power. Technically speaking, (2.2c) is not mathematically

correct, since as written it implies an infinite noise bandwidth and thus produces infinite noise power. Any physical system (or any numerical computation) necessarily has a finite noise bandwidth [19]. When calculating amplitude, frequency, and timing fluctuations, however, the specific value of the noise bandwidth is unimportant if it is larger than the soliton bandwidth (this is the case in practice), because only those components of the noise within the same spectral range as the soliton will affect these soliton parameters.

Without the noise term, (2.1) admits the well-known soliton solution

$$u_s(z,t) = u_0(z,t)\, e^{i\Theta(z,t)}, \tag{2.3a}$$

with

$$u_0(z,t) = A\,\mathrm{sech}[A(t-T(z))], \qquad \Theta(z,t) = \Omega\, t + \Phi(z), \tag{2.3b}$$

where $T(z) = T_0 + \Omega z$ and $\Phi(z) = \Phi_0 + \frac{1}{2}(A^2 - \Omega^2)z$ and where the four soliton parameters A, Ω, T_0, and Φ_0 are constant. When noise is added at each amplifier, part of the noise is incorporated into the soliton, where it produces small changes of the soliton parameters [9, 10]. The rest of the noise propagates along with the perturbed soliton. This process is repeated at each amplifier, resulting in a random walk of the four quantities A, Ω, T, and Φ [4, 5]. For typical system configurations, the noise amplitude at each amplifier is small, and thus the noise-induced changes of the soliton parameters at each individual amplifier are also usually small. In rare cases, however, these individual contributions combine to produce large deviations, resulting in potential transmission errors. Because these large pulse deformations are rare, estimating their probability is difficult.

2.1. Soliton perturbation theory. Soliton perturbation theory (SPT) is a standard method that has been used to approximate the effect of noise upon propagating pulses (e.g., see [9, 20, 21, 22, 23]). Rather than using it directly to obtain an analytical approximation to the perturbed pulse, however, here we will use it only as a tool to guide numerical simulations. The key information that is needed to do this comes from the dependence of the soliton solution, equation (2.3), upon the parameters A, Ω, T_0, and Φ_0. Since any value of these parameters is permitted, no resistance is encountered if the noise at an amplifier changes one of them. This lack of resistance allows large variations to build up after many amplifiers. Furthermore, frequency fluctuations change the group velocity of the pulse, and subsequent propagation integrates this velocity shift to produce a large timing shift (as reflected in the dependence of T on Ω).

The small noise-induced changes of the soliton parameters at a single amplifier can be estimated by decomposing $u(z,t)$ into its soliton and radiative (nonsoliton) components,

$$u(z,t) = [u_0(z,t) + v(z,t)]\, e^{i\Theta}, \tag{2.4}$$

and by linearizing the NLS equation (2.1) around the soliton solution (2.3):

$$\frac{\partial v}{\partial z} = L\, v, \qquad L\, v := \frac{i}{2}\frac{\partial^2 v}{\partial t^2} - \frac{i}{2}A^2 v + 2i|u_0|^2 v + i u_0^2\, v^\dagger. \tag{2.5}$$

Importantly, the linearized NLS operator L is non–self-adjoint and nonnormal, and its generalized nullspace admits four modes (localized eigenfunctions) $v_k(z,t)$ ($k = A, \Omega, T, \Phi$) satisfying [9, 10, 24]

$$L\, v_A = A\, v_\Phi, \qquad L\, v_\Omega = v_T, \qquad L\, v_T = 0, \qquad L\, v_\Phi = 0. \tag{2.6}$$

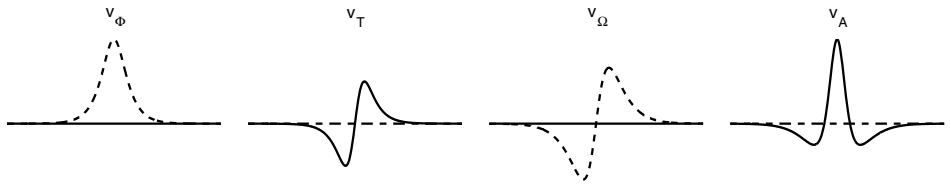

FIG. 1. *The real (solid) and imaginary (dashed) parts of the four neutral modes of the linearized NLS equation associated with the soliton solution* (2.3).

Explicitly, these four modes are

$$v_A(z,t) = \frac{1}{A}\frac{\partial}{\partial t}[(t-T)u_0], \tag{2.7a}$$

$$v_\Omega(z,t) = i(t-T)\,u_0, \tag{2.7b}$$

$$v_T(z,t) = -\frac{\partial u_0}{\partial t}, \tag{2.7c}$$

$$v_\Phi(z,t) = iu_0. \tag{2.7d}$$

Each of these linear modes is associated with a continuous symmetry of the NLS equation [23]: invariance with respect to scaling, Galilean boosts, translations, and phase rotations, respectively. Note also from (2.6) that the timing and phase modes are actual eigenfunctions, whereas the amplitude and frequency modes are generalized eigenfunctions. This is related to two of these symmetries giving rise to modified conservation laws, which are directly related to a change of the pulse frequency producing a subsequent change in its velocity or a change of the pulse amplitude producing a change in its phase upon propagation [23]. These four modes, shown in Figure 1, are also associated with changes of the soliton parameters:[1]

$$\frac{\partial u_s}{\partial A} = v_A\, e^{i\Theta}, \tag{2.8a}$$

$$\frac{\partial u_s}{\partial \Omega} = v_\Omega\, e^{i\Theta} + T v_\Phi\, e^{i\Theta}, \tag{2.8b}$$

$$\frac{\partial u_s}{\partial T} = v_T\, e^{i\Theta}, \tag{2.8c}$$

$$\frac{\partial u_s}{\partial \Phi} = v_\Phi\, e^{i\Theta}. \tag{2.8d}$$

In fact, removing secular terms from the forced linearized NLS equation obtained by adding the right-hand side of (2.1) to (2.5), one finds the local changes of the soliton parameters at the nth amplifier produced by the noise $f_n(t)$ [9, 10]:

$$\Delta A_n = \mathrm{Re}\int \underline{v}_A^\dagger(z,t)e^{-i\Theta} f_n(t)\,dt, \tag{2.9a}$$

$$\Delta \Omega_n = \mathrm{Re}\int \underline{v}_\Omega^\dagger(z,t)e^{-i\Theta} f_n(t)\,dt, \tag{2.9b}$$

$$\Delta T_n = \mathrm{Re}\int \underline{v}_T^\dagger(z,t)e^{-i\Theta} f_n(t)\,dt, \tag{2.9c}$$

$$\Delta \Phi_n = \mathrm{Re}\int (\underline{v}_\Phi(z,t) - T\,\underline{v}_\Omega(z,t))^\dagger e^{-i\Theta} f_n(t)\,dt, \tag{2.9d}$$

[1] Note that the derivatives on the left-hand side of (2.8) are taken with respect to the variables A, Ω, T, and Φ, with the other three variables kept constant. A different choice of parametrization for the soliton solution in (2.3) would lead to different results.

where the integrals are from $-\infty$ to ∞. The functions $\underline{v}_k(z,t)$ are the modes of the *adjoint* linearized NLS operator, defined by $L^{\mathrm{adj}}\underline{v} = -\frac{i}{2}\partial_t^2\underline{v} + \frac{i}{2}A^2\underline{v} - 2i|u_0|^2\underline{v} + iu_0^2\,\underline{v}^\dagger$ and the inner product $\langle \underline{v}, v\rangle = \mathrm{Re}\int \underline{v}^\dagger v\,dt$ [10]. They are

$$\underline{v}_A = -iv_\Phi, \qquad \underline{v}_\Omega = iv_T/A, \qquad \underline{v}_T = iv_\Omega/A, \qquad \underline{v}_\Phi = iv_A. \tag{2.10}$$

(The adjoint modes are easily obtained from those in (2.7), noting that $L^{\mathrm{adj}}(\underline{v}) = iL(i\underline{v})$.) Together, the modes of L and L^{adj} form a biorthonormal basis of the tangent space corresponding to infinitesimal changes in the soliton parameters at a given amplifier,[2] and the source terms in (2.9) represent the projection of the noise onto this basis.

2.2. Noise-induced amplitude, frequency, timing, and phase jitter. Equations (2.9) establish a direct projection from the infinite-dimensional noise which is added at each amplifier to a discrete random walk for the four soliton parameters. In particular, the equations can be easily integrated, including the unperturbed evolution in between amplifiers, to obtain the final values of amplitude A, frequency Ω, timing T, and phase Φ:

$$A_{\mathrm{out}} = A_0 + \sum_{n=1}^{N_a} \Delta A_n, \tag{2.11a}$$

$$\Omega_{\mathrm{out}} = \Omega_0 + \sum_{n=1}^{N_a} \Delta\Omega_n, \tag{2.11b}$$

$$T_{\mathrm{out}} = T_0 + N_a z_a \Omega_0 + \sum_{n=1}^{N_a} \Delta T_n + \sum_{n=1}^{N_a} (N_a + 1 - n)\, z_a \Delta\Omega_n, \tag{2.11c}$$

$$\begin{aligned}\Phi_{\mathrm{out}} = \Phi_0 + \frac{1}{2}N_a z_a (A_0^2 - \Omega_0^2) + \sum_{n=1}^{N_a}\Delta\Phi_n + \sum_{n=1}^{N_a}(N_a+1-n) z_a (A_0\Delta A_n - \Omega_0\Delta\Omega_n) \\ + \frac{1}{2}\sum_{n=1}^{N_a}\sum_{m=1}^{N_a}[N_a - \max(n,m)] z_a (\Delta A_n \Delta A_m - \Delta\Omega_n\Delta\Omega_m).\end{aligned} \tag{2.11d}$$

The fourth term in (2.11c) and the fourth and fifth terms in (2.11d) arise from the above-mentioned Galilean invariance of the NLS equation. Whereas amplitude and timing jitter are the most important failure mechanisms for communication lines using standard on-off keying receivers, phase fluctuations are of critical importance when the receivers are phase-sensitive, as is the case for phase-shift or differential phase-shift keying [25].

Owing to (2.2) and (2.9), ΔA_n, ΔT_n, $\Delta\Omega_n$, and $\Delta\Phi_n$ are Gaussian-distributed random variables at each amplifier, with variances

$$\langle \Delta A_{n+1}^2\rangle = A_n\sigma^2, \tag{2.12a}$$

$$\langle \Delta\Omega_{n+1}^2\rangle = \sigma^2 A_n/3, \tag{2.12b}$$

$$\langle \Delta T_{n+1}^2\rangle = \pi^2\sigma^2/(12A_n^3), \tag{2.12c}$$

$$\langle \Delta\Phi_{n+1}^2\rangle = (1 + \pi^2/12 + T_n^2)\sigma^2/3A_n, \tag{2.12d}$$

[2]Note that, as usual, a true linear mode of the linearized NLS operator corresponds to a generalized mode of the adjoint operator, and vice-versa.

respectively. Note that all of these variances depend on the value of the soliton amplitude immediately prior to arrival at the amplifier, and that the phase variance depends on the soliton position; this is because the time-dependent term in the phase in (2.3b) is not defined to be zero at $t = T(z)$. For small deviations of amplitude and position, one can approximate these variances with their initial values (assuming without loss of generality that the initial position is zero):

(2.13)
$$\sigma_A^2 := A_0\sigma^2, \quad \sigma_\Omega^2 := \sigma^2 A_0/3, \quad \sigma_T^2 := \pi^2\sigma^2/(12A_0^3), \quad \sigma_\Phi^2 := (1+\pi^2/12)\sigma^2/3A_0.$$

The variances of the final soliton amplitude, frequency, and position timing are then easily computed to be

$$\langle A_{\text{out}}^2\rangle \simeq N_a\sigma_A^2, \tag{2.14a}$$

$$\langle \Omega_{\text{out}}^2\rangle \simeq N_a\sigma_\Omega^2, \tag{2.14b}$$

$$\langle T_{\text{out}}^2\rangle \simeq N_a\sigma_T^2 + N_a(N_a+1)(2N_a+1)\,\sigma_\Omega^2\, z_a^2/6, \tag{2.14c}$$

$$\langle \Phi_{\text{out}}^2\rangle \simeq N_a\sigma_\Phi^2 + N_a(N_a+1)(2N_a+1)\,\sigma_A^2\, z_a^2/6, \tag{2.14d}$$

respectively. The cubic dependence on N_a of the growth of $\langle T_{\text{out}}^2\rangle$ and $\langle \Phi_{\text{out}}^2\rangle$ is a discrete analogue to the cubic dependence on distance in a distributed noise approximation, used by Gordon and Haus and by Gordon and Mollenauer, respectively, to derive upper limits for the error-free propagation distance of a soliton transmission system [4, 5].

These calculations, however, are not sufficient to give an accurate estimate of noise-induced transmission penalties, for several reasons. First, the variances in (2.14) are correct only for small deviations of the pulse amplitude. Second, even though the noise is Gaussian-distributed, the full noise-induced changes of the soliton parameters are not necessarily Gaussian. In particular, the variance of each amplitude shift depends on the previous value of the amplitude, which causes the distribution of A to deviate significantly from Gaussian. A Gaussian approximation will therefore be valid only in the limit of exceedingly small amplitude shifts, and quite possibly only in the core region of the pdf and not in the tails. The timing T and frequency Ω also deviate very slightly from Gaussian due to the local dependence of their variances on A (cf. (2.12); see also [13]). Since T, Ω, and Φ have no influence on the random walk of A (or on T, in the case of the phase), however, their statistical behavior is expected to be dominated by the mean value of A. Finally, even if the noise-induced changes of the soliton parameters were approximately Gaussian-distributed, calculating the probability densities in the tails from the (analytically or numerically obtained) variances would require an exponential extrapolation, and any errors or uncertainties would be magnified correspondingly.

3. Importance sampling. The main idea behind importance sampling is to bias the probability distribution functions used to generate the random Monte Carlo samples so that errors occur more frequently than would be the case otherwise [17, 18]. Before we delve into the implementation of importance sampling for amplifier noise, let us briefly present the basic ideas in a general setting.

Let X denote a collection of random variables (RVs) identifying a particular system realization. (In our case, X will be a vector or matrix which determines the noise at all the amplifiers.) Consider a measurable quantity $y(X)$ associated with each system configuration and, therefore, with each value of X. (In our case, $y(X)$ will be the final pulse amplitude or timing.) Suppose that we are interested in calculating

the probability P that $y(X)$ falls in some prescribed range. This probability can be represented as the expectation value of an *indicator function* $I(y(X))$ such that $I(y) = 1$ if the random variable y falls in the prescribed range and $I(y) = 0$ otherwise. That is, the probability P is represented by the multidimensional integral

$$P = \int I(y(x))p_X(x)\,dx = \mathbb{E}[I(y(X))], \tag{3.1}$$

where $p_X(x)$ is the joint pdf of the RVs X, $\mathbb{E}[\,\cdot\,]$ denotes the expectation value with respect to the distribution $p_X(x)$, and the integral is over the entire configuration space. In many cases of interest, a direct evaluation of the integral in (3.1) is impossible. One can then resort to Monte Carlo simulations and write an estimator $\hat{P}$ for P, replacing the integral in (3.1) by

$$\hat{P}_{\rm mc} = \frac{1}{M}\sum_{m=1}^{M} I(y(X_m)), \tag{3.2}$$

where M is the total number of Monte Carlo samples, and where each X_m is a random sample drawn from $p_X(x)$. Equation (3.2) simply expresses the relative number of samples falling in the range of interest. If one is interested in low probability events, however (that is, if $P \ll 1$), an impractically large number of samples is usually necessary in order to see even a single event, and an even larger number is required in order to obtain an accurate estimate.

When the main contribution to P comes from regions of sample space where $p_X(x)$ is small, IS can be used to speed up the simulations. The idea is first to rewrite the the probability P in (3.1) as

$$P = \int I(y(X))\,r(x)p^*(x)\,dx = \mathbb{E}^*[I(y(X))r(X)], \tag{3.3}$$

where $\mathbb{E}^*[\,\cdot\,]$ denotes the expectation value with respect to the *biasing distribution* $p^*(x)$, and where $r(x) = p_X(x)/p^*(x)$ is called the *likelihood ratio* [17]. As before, we then estimate the corresponding integral via Monte Carlo simulations; that is, we write an importance-sampled Monte Carlo estimate for P as

$$\hat{P}_{\rm is} = \frac{1}{M}\sum_{m=1}^{M} I(y(X_m^*))r(X_m^*), \tag{3.4}$$

where now the samples X_m^* are drawn according to the distribution $p^*(x)$. By design, the estimator $\hat{P}_{\rm is}$ is unbiased; i.e., $\mathbb{E}^*[\hat{P}_{\rm is}] = P$. If $p^*(x) \equiv p_X(x)$ (unbiased simulations), $r(x) = 1$ and (3.4) agrees with (3.2) (i.e., one recovers the standard Monte Carlo method). The use of a biasing pdf, however, allows the desired regions of sample space to be visited much more frequently. At the same time, the likelihood ratio automatically adjusts each contribution so that all of the different realizations add properly to give a correct final estimate.

The crucial step when trying to apply IS is to determine a proper choice of the biasing distribution $p^*(x)$ in order to reduce the variance of the estimator $\hat{P}_{\rm is}$. Naturally, not all biasing distributions are appropriate for accomplishing this. One might think that the simplest choice is to increase the overall noise variance, in an attempt to increase the probability of generating errors. It is well-known, however, that this biasing method (which is usually referred to as *variance scaling*) is effective

only in low-dimensional systems [17]. In general, in order for IS to be effective, $p^*(x)$ should concentrate the Monte Carlo samples near the regions that are *most likely* to generate rare events of interest, which in our case means determining the most likely noise instantiations at each amplifier which produce large pulse amplitude or timing variations at the fiber output. The proper choice of biasing distributions when one is interested in amplitude and timing jitter will be discussed in the next section.

If one seeks to reconstruct a broad region of the pdf for the quantity of interest, no single choice of biasing distribution can be expected to capture efficiently all the regions of sample space that give rise to the events of interest. In this case, several different biasing distributions $p_q^*(x)$ can be used and their results combined using a method known as *multiple importance sampling* [26, 27, 28]. With this technique, a weight $w_q(x)$ is associated with each biasing distribution. An importance-sampled estimator for P is then written as

$$\hat{P}_{\text{mis}} = \frac{1}{Q}\sum_{q=1}^{Q}\frac{1}{M_q}\sum_{m=1}^{M_q} w_q(X_{mq}^*)I(y(X_{mq}^*))r_q(X_{mq}^*), \tag{3.5a}$$

where Q is the total number of biasing distributions, M_q is the number of samples drawn from $p_q^*(x)$, X_{mq}^* is the mth such sample, and $r_q(x) = p_X(x)/p_q^*(x)$. Several strategies are possible for selecting the weights; the estimator $\hat{P}$ will be unbiased as long as $\sum_{q=1}^{Q} w_q(x) = 1$ for all x. A particularly simple and effective choice is the *balance heuristic* [26]:

$$w_q(x) = \frac{M_q p_q^*(x)}{\sum_{q'=1}^{Q} M_{q'} p_{q'}^*(x)}. \tag{3.5b}$$

Note that $M_q p_q^*(x)$ is proportional to the expected number of hits from the qth distribution. Thus, the weight of a sample with the balance heuristic is given by the likelihood of realizing that sample with the qth distribution relative to the total likelihood of realizing the same sample with all distributions.

4. IS for amplitude, frequency, timing, and phase jitter. We now turn our attention to the application of IS to Monte Carlo simulations of noise-induced amplitude, frequency, timing, and phase jitter. As explained earlier, in order for IS to be effective we need to bias the simulations towards the events that are most likely to produce the rare events of interest. Therefore, the strategy to bias the simulations toward predetermined target values of each soliton parameter consists of two logically distinct steps: First, we must determine how to bias the noise at each amplifier in order to obtain a specified change of amplitude, frequency, timing, and/or phase. Second, we must determine how to select the individual changes at each amplifier to obtain the desired total change at the end of the transmission line. To accomplish these goals, we need to (i) find the most likely noise configurations that result in a specified soliton parameter change at each amplifier, and (ii) find the most likely combination of individual amplitude, frequency, timing, and phase changes at all of the amplifiers that result in the desired value at the end of the transmission line. The fact that so much is known about NLS solitons greatly simplifies these tasks. The key information comes from the dependence of the soliton solution upon the parameters A, Ω, T_0, and Φ_0. The noise-induced changes in these soliton parameters can be calculated using SPT, as explained in section 2.1. In turn this knowledge can be used to bias the noise at each amplifier to induce larger-than-normal changes of the soliton parameters at the fiber output.

To make these ideas more definite, suppose that we are interested in large deviations of a quantity Y. Later on, this quantity will be identified with the amplitude A, frequency Ω, timing T, or phase Φ of the soliton. For now, let $Y_{\rm in}$ denote the value of Y at the fiber input, and suppose that we want to direct the simulations towards a target value $Y_{\rm out}$. As explained above, we need to (i) find the most likely noise realization at each amplifier to produce a given shift $C_n = Y_n - Y_{n-1}$, and (ii) find the most likely combination of individual contributions $\{C_n\}_{n=1}^{N_a}$ such that the final value of Y is $Y_{\rm out}$. We address these two issues separately.

To solve problem (i), at each amplifier we need to find the noise instantiation that maximizes the probability of realizing a prescribed shift in one of the soliton parameters. In any numerical implementation of (2.1), noise is added to the propagating signal by adding one independent Gaussian random variable to the real part of the optical field, and one to the imaginary part, at each discretized time point (when split-step spectral methods are used to solve (2.1), one can alternatively add an independent Gaussian random variable to the real part and to the imaginary part of every Fourier mode; this is equivalent to the above procedure in the time domain). Maximizing the probability of this Gaussian perturbation amounts to minimizing the sum of the squares of all of the random variables (one for the real part and one for the imaginary part at each time point), and in a continuous-time limit this corresponds to seeking a noise-produced perturbation $f(t)$ that minimizes the L^2-norm

$$\|f\|^2 = \int |f(t)|^2\, dt. \tag{4.1}$$

There is no weighting of the noise because every perturbation of comparable size is equally probable. Of course, we are interested in the noise perturbation that produces not just the most probable change, but rather the most probable change in one of the soliton parameters. This means that the minimization should be performed subject to the constraint

$$\Delta Y_n = \mathrm{Re} \int \underline{v}_Y^\dagger(z_n, t) f(t)\, dt = C_n, \tag{4.2}$$

where $\underline{v}_Y(z_n, t)$ is one of the adjoint linear modes evaluated at $z_n = nz_a$, consistent with (2.9), and C_n is for now an arbitrary constant. This constrained minimization problem can be expressed in Lagrange multiplier form by defining the functional

$$M_n = \int |f(t)|^2\, dt + \lambda \left[\int \underline{v}_Y^\dagger(z_n, t) f(t)\, dt + \int \underline{v}_Y(z_n, t) f^\dagger(t)\, dt - 2C_n \right]. \tag{4.3}$$

The solution to this problem, which is easily obtained using the calculus of variations, is

$$f(t) = C_n \, \frac{\underline{v}_Y(z_n, t)}{\|\underline{v}_Y(z_n, \cdot)\|^2}. \tag{4.4}$$

Here it should be noted that, even though a noise perturbation proportional to one of the linear modes produces a "clean" change in the soliton parameters (that is, a change without additional radiative components), (4.4) implies that the most likely way to realize the same parameter change occurs when the noise is proportional to the corresponding *adjoint* mode, a result which is not evident a priori.

Once the maximum likelihood noise configurations at each amplifier are known, it remains to solve problem (ii), namely to find the coefficients $\{C_1, \ldots, C_{N_a}\}$ that lead

with maximum probability to a prescribed change in the soliton parameter Y over N_a amplifiers. From (2.3), it is immediately apparent that (if one neglects the dependence of the variances in (2.12) on the amplitude) the soliton amplitude A and frequency Ω are not affected by changes to the other parameters, while the soliton timing T and phase Φ are affected both by direct perturbations to T and Φ, respectively, and by integrated changes to the frequency Ω and amplitude A, respectively. We therefore consider these problems separately.

4.1. Amplitude and frequency shifts. In the case of amplitude shifts, the problem is to find the most likely noise realization that produces a prescribed total change in the soliton amplitude, $\Delta A_{\rm tot} = A_{\rm out} - A_{\rm in}$. This amounts to another constrained minimization problem, where we now need to choose the set of individual amplitude shifts at each amplifier, $\{\Delta A_n\}_{n=1}^{N_a}$, in order to minimize the cumulative L^2-norm

$$\sum_{n=1}^{N_a} \|f_n\|^2 = \sum_{n=1}^{N_a} \frac{\Delta A_n^2}{\|\underline{v}_A(z_n,\cdot)\|^2} \tag{4.5}$$

(where (4.4) was used) under the constraint

$$\sum_{n=1}^{N_a} \Delta A_n = \Delta A_{\rm tot}. \tag{4.6}$$

Evaluating the norm of $\underline{v}_A$ using (2.9a), we can also rewrite this optimization problem in Lagrange multiplier form as

$$M = \sum_{n=1}^{N_a} \frac{\Delta A_n^2}{A_n} + \lambda \left[\Delta A_{\rm tot} - \sum_{n=1}^{N_a} \Delta A_n \right], \tag{4.7}$$

where, obviously, at each amplifier $A_n = A_{\rm in} + \sum_{n'=1}^{n} \Delta A_{n'}$. To find the minimum of M we then look for zeros of the gradient of M with respect to all the individual amplitude changes ΔA_n. If the total amplitude change over the N_a amplifiers is not too large, we can write $\Delta A_{\rm tot} = \epsilon\,\Delta$ and employ a perturbation expansion of ΔA_n and λ in powers of ϵ, namely, $\Delta A_n = \epsilon a_n^{(1)} + \epsilon^2 a_n^{(2)} + \cdots$ and of $\lambda = \epsilon\lambda_0 + \epsilon^2\lambda_2 + \cdots$. Minimizing and then matching orders of ϵ gives

$$a_n^{(1)} = \frac{\Delta}{N_a}, \tag{4.8a}$$

$$a_n^{(2)} = -\frac{1}{4}\frac{\Delta^2}{N_a^2}\,(N_a - 2n + 1), \tag{4.8b}$$

and so on. These constants determine the appropriate biasing for amplitude jitter at leading order and up to second order. Note that, at leading order, the desired average change in amplitude over the entire span of amplifiers is simply divided evenly among the individual amplifiers. In practice, this leading order approximation has been found to be adequate for all cases considered, even when the actual amplitude shifts computed were reasonably large.

The optimal biasing problem for the frequency Ω is similar but simpler, in that the L^2-norm of the associated linear mode is independent of Ω. In particular, we seek to minimize

$$\sum_{n=1}^{N_a} \|f_n\|^2 = \sum_{n=1}^{N_a} \frac{\Delta\Omega_n^2}{\|\underline{v}_\Omega(z_n,\cdot)\|^2} \tag{4.9}$$

under the constraint

$$\sum_{n=1}^{N_a} \Delta\Omega_n = \Delta\Omega_{\text{tot}}. \tag{4.10}$$

This leads to

$$M = \sum_{n=1}^{N_a} \frac{\Delta\Omega_n^2}{A_n} + \lambda \left[\Delta\Omega_{\text{tot}} - \sum_{n=1}^{N_a} \Delta\Omega_n \right], \tag{4.11}$$

where, due to the orthogonality of $\underline{v}_\Omega$ and $\underline{v}_A$, the amplitude remains unaffected by the biasing applied to Ω. For this reason, we assume $A_n = 1 \ \forall \ n = 1, \ldots, N_a$, which simply gives

$$\Delta\Omega_n = \frac{\Delta\Omega_{\text{tot}}}{N_a}. \tag{4.12}$$

Note that this assumption would need to be modified if one wished to compute the joint distribution of amplitude and frequency (or amplitude and timing), however.

4.2. Timing and phase shifts. We next look at the most likely noise realization resulting in a prescribed timing shift of the soliton at the fiber output. Because of the Galilean invariance of the NLS equation, in this case we need to consider frequency shifts as well as timing shifts. In other words, we seek to find the most likely set of frequency and timing shifts at each amplifier, $\{\Delta\Omega_n, \Delta T_n\}_{n=1}^{N_a}$, that produce a final value $T_{\text{out}} = T_{\text{in}} + \Delta T_{\text{tot}}$ of timing. Because of the orthogonality of $\underline{v}_T$ and $\underline{v}_\Omega$, this amounts to choosing ΔT_n and $\Delta\Omega_n$ in order to minimize the cumulative L^2-norm

$$\sum_{n=1}^{N_a} \frac{\Delta T_n^2}{\|\underline{v}_T(z_n, \cdot)\|^2} + \sum_{n=1}^{N_a} \frac{\Delta\Omega_n^2}{\|\underline{v}_\Omega(z_n, \cdot)\|^2} \tag{4.13}$$

under the constraint

$$\Delta T_{\text{tot}} = N_a z_a \Omega_{\text{in}} + \sum_{n=1}^{N_a} \Delta T_n + \sum_{n=1}^{N_a} (N_a + 1 - n) \Delta\Omega_n z_a \tag{4.14}$$

for a prescribed value of ΔT_{tot}. Again, we can evaluate the norms in (4.13) and rewrite the above problem in Lagrange multiplier form:

$$M = \frac{6}{\pi^2} \sum_{n=1}^{N_a} A_n^3 \Delta T_n^2 + \frac{3}{2} \sum_{n=1}^{N_a} \frac{\Delta\Omega_n^2}{A_n} + \lambda \left[\sum_{n=1}^{N_a} \Delta T_n + \sum_{n=1}^{N_a} (N + 1 - n) \, \Delta\Omega_n z_a - \Delta T_{\text{tot}} \right]. \tag{4.15}$$

If the noise has components only along $\underline{v}_T$ and $\underline{v}_\Omega$, the soliton amplitude again remains unaffected, so that minimizing the action M gives

$$\Delta T_n = \frac{\pi^2}{12\sigma_{T,\text{tot}}^2} \Delta T_{\text{tot}}, \tag{4.16a}$$

$$\Delta\Omega_n = \frac{(N_a + 1 - n) z_a}{3\sigma_{T,\text{tot}}^2} \Delta T_{\text{tot}}, \tag{4.16b}$$

where

$$\sigma_{T,\mathrm{tot}}^2 = N_a \left[\frac{\pi^2}{12} + \frac{z_a^2}{18} (N_a + 1)(2N_a + 1) \right]. \tag{4.16c}$$

Note that the rule for biasing the frequency given by (4.16b) is rather different from the rule given by (4.12). Whereas the former is designed to produce a given total change in *frequency* with highest likelihood, the latter is designed to produce a given total change in *timing* with highest likelihood, so that frequency shifts occurring earlier in the propagation are weighted much more heavily. In fact, comparing (2.10), (4.14), and (4.16), it can easily be seen that the relative weight of each term is proportional to the variance of its term in the final result. In other words, the most probable way of obtaining a given timing shift at the end of the fiber is to perform relatively larger frequency shifts at the beginning of the fiber, since these are the ones that can accumulate over the longest distances and therefore produce larger deviations for the same "effort" (i.e., for the same contribution to the cumulative L^2-norm of (4.1)).

Just as the optimal noise instantiation to obtain a given total timing shift depends on both frequency and timing shifts at each amplifier, the most probable way of obtaining a prescribed total phase shift requires shifting *three* parameters at each amplifier: phase, amplitude, and frequency. Under the conditions that $\Omega_0 = 0$ and that the individual amplitude shifts are kept small, however, the terms in (2.11d) involving Ω_0 and those involving products of shifts can be neglected, leaving as the action

$$\begin{aligned} M = &\sum_{n=1}^{N_a} \frac{A_n \Delta\Phi_n^2}{\pi^2/18 + 2/3} + \sum_{n=1}^{N_a} \frac{\Delta A_n^2}{2A_n} \\ &+ \lambda \left[\sum_{n=1}^{N_a} \Delta\Phi_n + \sum_{n=1}^{N_a} (N + 1 - n) A_0 \Delta A_n z_a - \left(\Phi_{\mathrm{out}} - \frac{1}{2} N_a z_a A_0^2 \right) \right]. \end{aligned} \tag{4.17}$$

This action has markedly similar form to (4.15) and demonstrates again that the effect of amplitude shifts on phase through self-phase modulation is completely analogous to the effect of frequency shifts on position through Galilean invariance. Here, however, the fact that amplitude appears in the summations is problematic, as amplitude is one of the parameters being shifted in our biasing scheme. To resolve this, we take an approach similar to that for direct amplitude shifting; i.e., we use a perturbation expansion in ΔA_{tot}. At leading order, the optimal phase and amplitude shifts take the same form as the above optimal timing and frequency shifts:

$$\Delta\Phi_n = \frac{\pi^2/36 + 1/3}{\sigma_{\Phi,\mathrm{tot}}^2} \left(\Delta\Phi_{\mathrm{tot}} - \frac{1}{2} N_a z_a \right), \tag{4.18a}$$

$$\Delta A_n = \frac{(N_a + 1 - n) z_a}{\sigma_{\Phi,\mathrm{tot}}^2} \left(\Delta\Phi_{\mathrm{tot}} - \frac{1}{2} N_a z_a \right), \tag{4.18b}$$

where

$$\sigma_{\Phi,\mathrm{tot}}^2 = N_a \left[\frac{\pi^2}{36} + \frac{1}{3} + \frac{z_a^2}{6} (N_a + 1)(2N_a + 1) \right]. \tag{4.18c}$$

4.3. Implementation issues. Having found the most probable configurations that produce given values of amplitude, frequency, timing, and phase shifts, we now

discuss how to use them to guide the biasing of the importance-sampled Monte Carlo simulations.

For concreteness, suppose that we are numerically solving a discretized version of the NLS equation (2.1). As explained earlier, at each amplifier we add random noise f_n. If J is the total number of discrete time points in the computational domain (or, equivalently, the total number of complex Fourier modes), the noise is represented by a vector $\mathbf{x}_n = (x_1, \ldots, x_{2J})^T$ giving the real and imaginary noise components at each discretized time location. In the unbiased case, the x_j are independent identically distributed (i.i.d.) normal RVs with mean zero and variance $\sigma_a^2 = \sigma^2/(2\Delta t)$; explicitly, the probability distribution is $p_{\mathbf{x}}(\mathbf{x}) = \exp[-\mathbf{x}^T\mathbf{x}/2\sigma_a^2]/(2\pi\sigma_a^2)^J$. Let $X = (\mathbf{x}_1, \ldots, \mathbf{x}_N)$ be the $2J \times N$ matrix that denotes all of the noise components at all of the amplifiers, and suppose that we are interested in reconstructing the pdf of a variable $y(X)$. (Here, y will be the amplitude A, the frequency Ω, the timing T, or the phase Φ.)

At each amplifier, we will perform the biasing by selecting a *deterministic* biasing vector $\mathbf{b}_n$ that will be added to the noise vector $\mathbf{x}_n$ drawn from the unbiased distribution. That is, we will form a biased noise realization as $\mathbf{x}_n^* = \mathbf{x}_n + \mathbf{b}_n$. This corresponds to choosing, at each amplifier, the biasing pdf $p_{\mathbf{x}}^*(\mathbf{x}_n^*) = p_{\mathbf{x}}(\mathbf{x}_n^* - \mathbf{b}_n) = p_{\mathbf{x}}(\mathbf{x}_n)$, which therefore gives a likelihood ratio of $r_{\mathbf{x}}(\mathbf{x}_n^*) = p_{\mathbf{x}}(\mathbf{x}_n + \mathbf{b}_n)/p_{\mathbf{x}}(\mathbf{x}_n)$. One can then obtain the overall likelihood ratio of the noise over N_a amplifiers[3] as

$$r(X^*) = \prod_{n=1}^{N_a} \frac{p_{\mathbf{x}}(\mathbf{x}_n^*)}{p_{\mathbf{x}}(\mathbf{x}_n)},$$

where $X^* = (\mathbf{x}_1^*, \ldots, \mathbf{x}_{N_a}^*)$ and $\mathbf{x}_n^* = \mathbf{x}_n + \mathbf{b}_n$, as before. Of course, in order for this strategy to be effective, the choice of the biasing vectors $\mathbf{b}_n$ is crucial. The means by which we choose these biasing vectors in the case of amplitude, frequency, timing, and phase jitter is discussed next.

In order to perform the biasing, at each amplifier we first need to find the soliton parameters associated with the solution immediately before amplification (i.e., the addition of noise). We do this either by solving the Zakharov–Shabat eigenvalue problem [9, 29] or by using the moment integrals for the soliton parameters [10]. (A more detailed discussion of this soliton reconstruction process is contained in Appendices B and C.) The soliton parameters uniquely determine the soliton solution, which in turn determines the linear modes. Since the deterministic biasing term is expressed in the form of a linear combination of modes (as determined in the previous subsection), knowing the soliton parameters allows us to select the proper biasing of the Monte Carlo simulations as given by (4.4) and the determination of C_n in subsections 4.1 and 4.2.

In particular, if one wants to bias the amplitude, one chooses a shift in the mean of the noise $f(t)$ equal to

$$\Delta A_n \frac{\underline{v}_A(z_n, t)}{\|\underline{v}_A(z_n, \cdot)\|^2} = \Delta A_n \frac{\underline{v}_A(z_n, t)}{2A_n}, \tag{4.19}$$

[3]Note that the biased noise realizations at each amplifier are not statistically independent, since at each amplifier the choice of the biasing vector $\mathbf{b}_n$ depends on the current state of the soliton and therefore on the accumulated effect of the noise from the previous amplifiers. Nevertheless, it is easy to show that the overall likelihood ratio for such a Markov process can still be written as a product of the individual likelihood ratios (e.g., see [28]).

where ΔA_n is given by (4.8). Similarly, if one wants to bias the pulse frequency, one chooses a shift in the mean of the noise equal to

$$\Delta\Omega_n \frac{\underline{v}_\Omega(z_n,t)}{\|\underline{v}_\Omega(z_n,\cdot)\|^2} = \Delta\Omega_n \frac{3\,\underline{v}_\Omega(z_n,t)}{2A_n}, \tag{4.20}$$

where $\Delta\Omega_n$ is given by (4.12). To bias the soliton position, however, one must also bias the frequency, and in this case one chooses a shift in the mean of the noise equal to

$$\Delta T_n \frac{\underline{v}_T(z_n,t)}{\|\underline{v}_T(z_n,\cdot)\|^2} + \Delta\Omega_n \frac{\underline{v}_\Omega(z_n,t)}{\|\underline{v}_\Omega(z_n,\cdot)\|^2} = \Delta T_n \frac{6A_n^3\,\underline{v}_T(z_n,t)}{\pi^2} + \Delta\Omega_n \frac{3\,\underline{v}_\Omega(z_n,t)}{2A_n}, \tag{4.21}$$

where ΔT_n and $\Delta\Omega_n$ are now given by (4.16). Finally, to bias the phase one must also bias the amplitude, giving a mean noise shift of

$$\Delta\Phi_n \frac{\underline{v}_\Phi(z_n,t)}{\|\underline{v}_\Phi(z_n,\cdot)\|^2} + \Delta A_n \frac{\underline{v}_A(z_n,t)}{\|\underline{v}_A(z_n,\cdot)\|^2} = \Delta\Phi_n \frac{A_n\,\underline{v}_\Phi(z_n,t)}{\pi^2/18+2/3} + \Delta A_n \frac{\underline{v}_A(z_n,t)}{2A_n}. \tag{4.22}$$

In the discretized version of the problem, this biasing term, i.e., the shift of the mean of the noise $f(t)$, can also be represented as a vector, $\mathbf{b}_n$. Once the biasing direction and strength have been chosen, the actual biasing is straightforward: an unbiased noise realization $\mathbf{x}_n$ is generated, and the biased noise realization $\mathbf{x}_n^*$ is obtained by simply adding $\mathbf{b}_n$ to $\mathbf{x}_n$; that is, $\mathbf{x}_n^* = \mathbf{x}_n + \mathbf{b}_n$, as explained above.

5. Numerical results. To demonstrate the effectiveness of applying IS to Monte Carlo simulations of amplitude, frequency, timing, and phase jitter, we have performed simulations using the procedure described above. In dimensionless units, we took an amplifier spacing of $z_a = 0.1$, a total propagation distance of $N_a z_a = 20$, and a dimensionless noise strength of $\sigma^2 = 6.3 \times 10^{-5}$. The physical parameters generating these values are given in Appendix A. In the simulations, we extracted the soliton parameters at the intermediate amplifiers using moments (see Appendix C), but computed the values at the final distance using the more accurate Zakharov–Shabat eigenvalue problem (see Appendix B).

Figure 2 shows the results of 50,000 importance-sampled Monte Carlo simulations, selectively targeting amplitude fluctuations. Five biasing targets with 10,000 samples per target were used. Different choices of biasing generate the different regions of the pdfs shown in Figure 3, and the results from all Monte Carlo realizations are combined using the balance heuristic described in section 3. Even with a relatively small number of Monte Carlo samples, the method produces values of amplitude and timing jitter far down into the tails of the probability distributions. As shown in Figure 2, these results agree with unbiased Monte Carlo simulations in the main portion of the pdf (the only region that can be reconstructed with unbiased simulations). For smaller probability values, however, the deviations from Gaussian are evident.

A simple model of amplitude fluctuations can be obtained via soliton perturbation theory [10]: $A_{n+1} = A_n + \sqrt{A_n}\, s_{n+1}$, where the s_n are i.i.d. normal RVs with mean zero and variance σ^2. (Of course, this model cannot be correct when the noise is not a small perturbation of the soliton; an obvious erroneous result of this is that there is a very slight probability for negative A_n's to occur. Fortunately, it will be seen that such unphysical cases occur with extremely small probability, and therefore can be ignored.) Note that this model reflects a prepoint approximation of the jump conditions in (2.1). While this approach is closer in spirit to the Markov process created

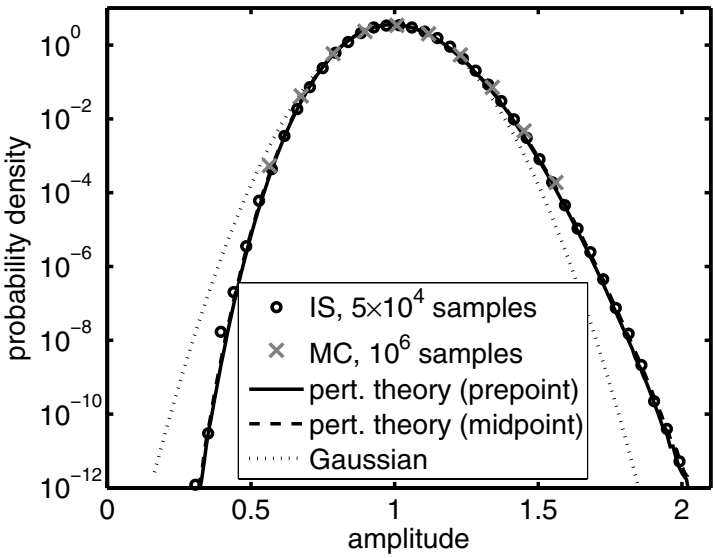

FIG. 2. *The pdf of amplitude jitter in a soliton-based transmission system, obtained from* 50,000 *importance-sampled Monte Carlo simulations. Results from a simple model from perturbation theory and an approximate Gaussian curve are also shown.*

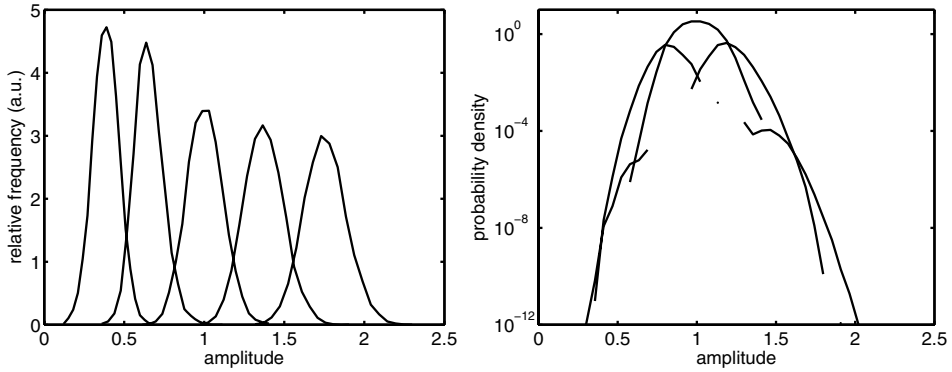

FIG. 3. *(left) Relative frequency plots showing the different ranges of amplitude generated by biasing distributions with five different targets. From left to right, the targets are* $\Delta A_{\rm tot} = \{-0.8, -0.4, 0, 0.4, 0.8\}$. *(right) The relative contribution of each biasing distribution to the final result of Figure* 2 *when weighted by the balance heuristic.*

by the biased Monte Carlo simulations, it is unclear whether the physical process is more accurately represented by this approximation or by a midpoint approximation, given by $A_{n+1} = A_n + (\sqrt{A_{n+1}} + \sqrt{A_n})\, s_{n+1}/2$. (For example, in one interpretation of a quantum-mechanical analysis of noise induced by loss and gain in a periodically amplified system, half of the noise is contributed in a distributed manner by the loss [30].) For comparison, in Figure 2 we show the pdfs obtained from both models, using importance-sampled numerical simulations for the prepoint approximation and simple analysis (see Appendix D) for the midpoint approximation. Although agreement with the importance-sampled simulations of the full NLS equation (2.1) is very

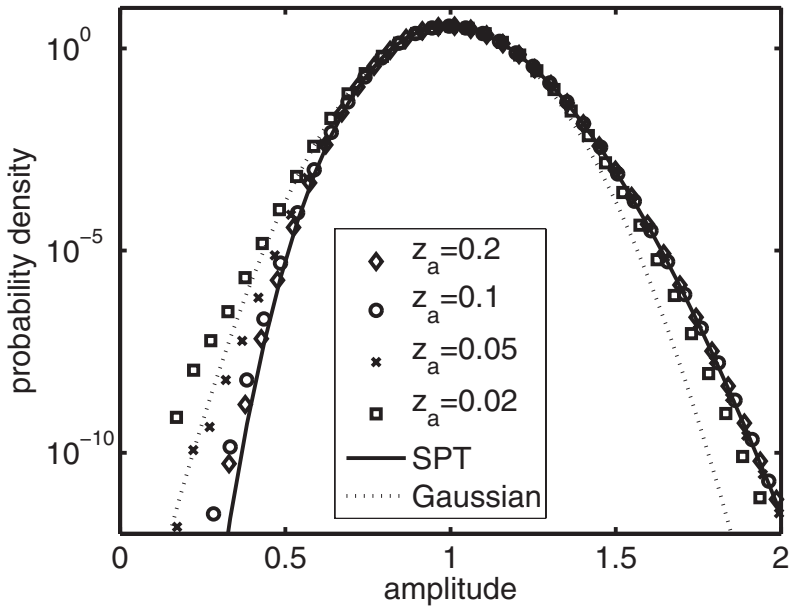

FIG. 4. *The pdf of amplitude jitter when the amplifier separation z_a is varied while the number of amplifiers N_a and the noise strength at each amplifier are held fixed. Even though SPT predicts the solid curve for each of these runs, the agreement with PDE numerics appears to be good only for sufficiently large z_a. Each of the numerical runs was obtained using 5×10^5 simulations.*

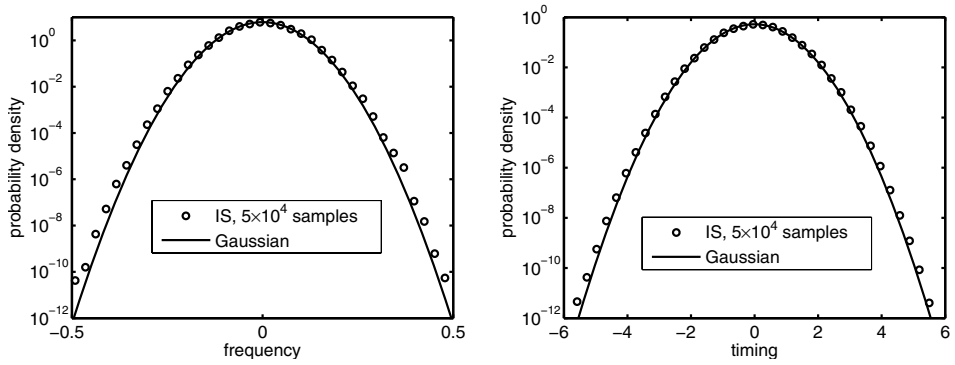

FIG. 5. *The pdfs of frequency (left) and timing jitter (right) in a soliton-based transmission system, each obtained from* 50,000 *importance-sampled Monte Carlo simulations.*

good throughout the range of amplitude values considered, with a slight deviation at small amplitudes, this agreement deteriorates significantly at both small and large amplitudes when the amplifier spacing z_a is decreased, as shown in Figure 4. As z_a is increased, the agreement appears to improve. It is not clear why the numerical results disagree with SPT here; nevertheless, the biasing obtained using SPT is sufficiently close to the correct biasing that the IS simulations accurately capture the pdf.

Figure 5 shows results similar to those of Figure 2, but for importance-sampled Monte Carlo simulations targeting frequency and timing fluctuations. The distributions of frequency and timing jitter agree well over a larger range of probability values with Gaussian curves whose variances are calculated from the theoretical results,

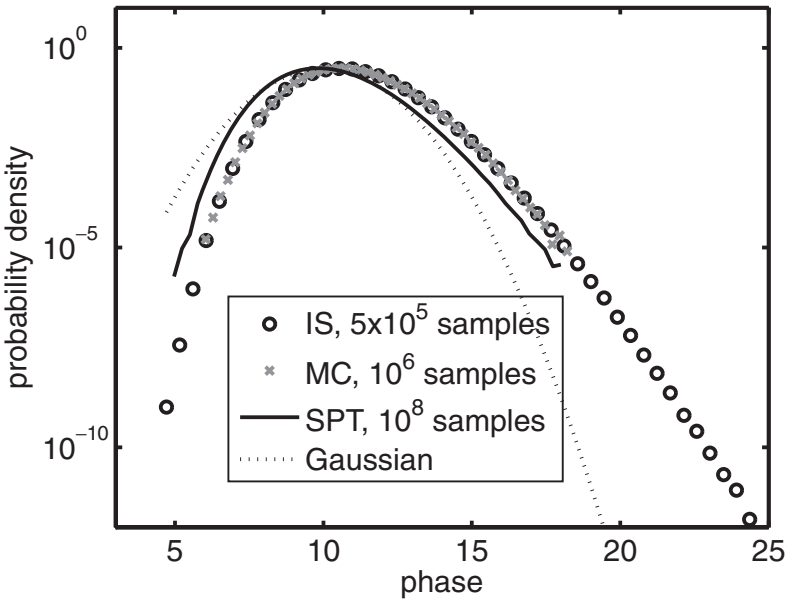

FIG. 6. *Comparison of the pdf of phase jitter with the Gaussian obtained from the linearized equations from SPT and with Monte Carlo simulations of the full PDE and of the nonlinear SPT equations. In this case, the last two results disagree significantly.*

(2.14b) and (2.14c). Note, however, that both for frequency and for timing jitter small deviations from Gaussian behavior are observed in the tails, where the numerically reconstructed pdfs are slightly but systematically larger than the predicted Gaussians. This discrepancy is due to the amplitude dependence of the variances of frequency and timing fluctuations [13]. Such dependence was neglected when the deterministic biasing choices were determined. Nevertheless, because random sampling is used, the numerical simulations access not only the deterministic biasing directions, but also nearby points in sample space around them. If errors in the deterministic biasing directions are not too large, a reasonably large number of random samples will find the correct regions in sample space that contribute most significantly to the pdf.

Finally, the pdf of phase jitter obtained using 5×10^5 IS trials is shown in Figure 6, along with 10^6 Monte Carlo runs to demonstrate the accuracy of the biased runs. We have unwrapped the phase to better illustrate deviations in the pdf tails. As expected, the pdf disagrees with the Gaussian obtained by linearizing the soliton perturbation equations. Somewhat surprising, however, is the fact that it also disagrees with 10^8 Monte Carlo simulations of the full nonlinear SPT equations. This suggests that dispersive radiation plays an important role in the case of phase jitter, rendering the (first-order) SPT equations ineffective in reproducing the correct jitter statistics. These equations are nevertheless still sufficiently accurate to provide effective biasing for the IS runs.

6. Conclusion. In summary, we have presented the application of importance sampling to numerical simulations of large noise-induced perturbations of nonlinear Schrödinger solitons, and we have demonstrated the method by calculating the pdfs of amplitude, frequency, timing, and phase jitter in a soliton-based transmission system. These results show that IS can be an effective tool for assessing the impact of noise in such systems.

Appendix A. NLS nondimensionalization and units. Here we describe the nondimensionalization procedure and the choice of units. The NLS equation is written in dimensional units as

$$i\frac{\partial E}{\partial Z} + \frac{|\beta''|}{2}\frac{\partial^2 E}{\partial T^2} + \gamma|E|^2E = i\sum_{n=1}^{N_a}\delta(Z - nZ_a)F_n(T), \tag{A.1}$$

where $|E|^2$ is optical power in watts, Z and T are dimensional distance in km and retarded time in ps, Z_a is the amplifier spacing, and β'' is the group velocity dispersion parameter in ps^2/km. The nonlinear coefficient is $\gamma = \omega_0 n_2/cA_{\text{eff}}$, where ω_0 is the carrier frequency, n_2 is the Kerr nonlinear-index coefficient, c is the vacuum speed of light, and A_{eff} is the effective area of the fiber core. The periodic cycle of loss and gain introduced by the chain of amplifiers has already been averaged out of (A.1); for details, see [30]. The delta-correlated white noise added at each amplifier then has noise strength

$$\langle F_m(T)F_n^\dagger(T')\rangle = \frac{\hbar\omega_0\eta_{\text{sp}}(G-1)^2}{G\ln G}\delta_{mn}\delta(T-T'), \tag{A.2}$$

where G is the power gain at each amplifier and η_{sp} is the spontaneous emission factor.

We then let $z = Z/L$, $t = T/T_0$, and $u = E/E_0$, where $L = T_0^2/|\beta''|$ is the dispersion length, $T_0 = T_{\text{FWHM}}/1.76$ is the soliton (sech) width, and $E_0 = 1/\sqrt{L\gamma}$ is the characteristic optical power for critical balance between nonlinearity and group velocity dispersion. This reduces (A.1) and (A.2) to (2.1) and (2.2), with

$$\sigma^2 = \frac{\hbar\omega_0\eta_{\text{sp}}\gamma T_0}{|\beta''|}\frac{(G-1)^2}{G\ln G}. \tag{A.3}$$

In the simulations we used a pulse full width at half maximum (FWHM) of 17.6 ps (i.e., a sech width of $T_0 = 10$ ps), an amplifier spacing of $Z_a = 50$ km and a fiber loss of 0.2 dB/km (yielding a power gain of $G = 10$), a spontaneous emission factor of η_{sp} of 1.4, a fiber dispersion $\beta'' = -0.2$ ps^2/km, and a total transmission distance of 10,000 km. The nonlinear coefficient of the fiber was taken to be 2.0 km^{-1}W^{-1}. The dimensionless parameters corresponding to these values are given in section 5.

Appendix B. Soliton extraction via Zakharov–Shabat eigenvalue problem. As discussed in the main text, the first step in implementing importance sampling is to find the soliton part of the solution at each amplifier. One way to do this is to solve the Zakharov–Shabat (Z-S) eigenvalue problem [31, 32]. Given a solution u of the NLS equation at a particular value of z, one can discretize the Z-S eigenvalue problem and solve it numerically [29, 33]. In the case of noisy solutions, which may not be smooth, it may be more robust to use a completely integrable discrete version, such as the Ablowitz–Ladik eigenvalue problem [29].

Unfortunately, an eigenvalue of the Z-S problem (or its discrete equivalent, the Ablowitz–Ladik problem) gives only two of the soliton parameters, the amplitude and the frequency, and there is apparently no way to determine the *exact* values of the soliton's position and phase. One can, however, obtain values that are relatively unaffected by noise, even when this perturbation is large.

To do this, one makes use of the trace formula for the NLS equation [34],

$$u = 2i\sum_{k=1}^{N}\frac{b_k}{a_k'}\psi_1^2 - 2i\sum_{k=1}^{N}\frac{b_k^\dagger}{a_k'^\dagger}\psi_2^{\dagger 2} - \frac{1}{\pi}\int_{-\infty}^{\infty}\left\{\frac{b}{a}(\xi)\psi_1^2(t,\xi) + \frac{b^\dagger}{a^\dagger}(\xi)\psi_2^{\dagger 2}(t,\xi)\right\}d\xi.$$

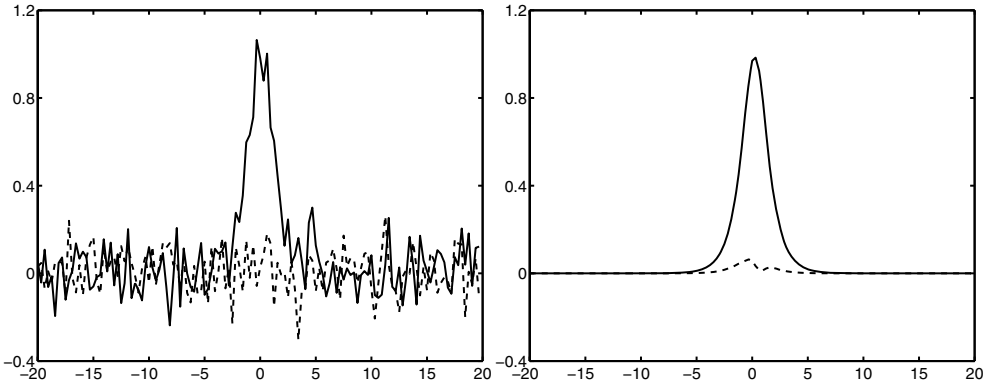

FIG. 7. *A noisy soliton (left) and the "clean" soliton (right) recovered from the Jost functions of the Z-S eigenproblem. Apart from a small ripple in the imaginary component, the Jost functions are seen to produce a reconstructed soliton that is largely free of radiation.*

Essentially, this shows that one can break the solution up into two contributions, one from the eigenfunctions of the Z-S scattering problem and the other from the continuous spectrum. Here, $\psi_1(x,\zeta)$ and $\psi_2(t,\zeta)$ are the components of one set of *Jost functions*, i.e., solutions of the Z-S scattering problem satisfying special boundary conditions, namely,

$$\begin{pmatrix} \psi_1 \\ \psi_2 \end{pmatrix} \sim \begin{pmatrix} 0 \\ 1 \end{pmatrix} e^{i\zeta t} \quad \text{as } t \to +\infty \quad \text{or} \quad \begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix} \sim \begin{pmatrix} 1 \\ 0 \end{pmatrix} e^{-i\zeta t} \quad \text{as } t \to -\infty.$$

The coefficients b_k, a'_k, $b(\xi)$, and $a(\xi)$ are determined by the connection between these two sets of functions,

$$\begin{pmatrix} \phi_1(t,\zeta) \\ \phi_2(t,\zeta) \end{pmatrix} = a(\zeta) \begin{pmatrix} \psi_2^\dagger(t,\zeta^\dagger) \\ -\psi_1^\dagger(t,\zeta^\dagger) \end{pmatrix} + b(\zeta) \begin{pmatrix} \psi_1(t,\zeta) \\ \psi_2(t,\zeta) \end{pmatrix}.$$

At an eigenvalue ζ_k of the Z-S scattering problem (with $\operatorname{Im}\zeta_k > 0$), one has $a(\zeta_k) = 0$. At such an eigenvalue, $a'_k = a'(\zeta_k)$ and $b_k = b(\zeta_k)$.

In order to extract the position and phase from a noisy soliton in a robust way, the idea is to discard the contribution from the continuous spectrum and use only the discrete part of the trace formula. Because of the exponential decay of the eigenfunctions, this "reconstructed" or "nonlinearly filtered" solution will be smooth, and thus definitions of position and phase using moments will not have any difficulties caused by long noisy tails present in the solution. Of course, one must recognize that the trace formula does not precisely partition the solution into "soliton" and "dispersive radiation" components, as the discrete part of the trace formula does not produce solutions which are exactly hyperbolic-secant shaped. Nevertheless, the solutions appear very much like solitons, as shown in Figure 7.

As written, the trace formula is a little difficult to use, as one still needs the coefficients b_k and a'_k. Fortunately, the ratio of these coefficients can be computed more conveniently. From the orthogonality relation [32, equation A6.6e], one has

$$\int_{-\infty}^{\infty} (\psi_{2k}\phi_{1k} + \psi_{1k}\phi_{2k})\, dt = ia'_k \quad \Rightarrow \quad 2b_k \int_{-\infty}^{\infty} \psi_{1k}\psi_{2k}\, dt = ia'_k,$$

since $\phi_{1k} = b_k\psi_{1k}$ and $\phi_{2k} = b_k\psi_{2k}$. Thus, the discrete part of the trace formula becomes

$$u = -\sum_{k=1}^{N}\left(\frac{\psi_{1k}^2}{\int_{-\infty}^{\infty}\psi_{1k}\psi_{2k}\,dt} + \frac{{\psi_{2k}^{\dagger}}^2}{\int_{-\infty}^{\infty}\psi_{1k}^{\dagger}\psi_{2k}^{\dagger}\,dt}\right).$$

Because the numerator and denominator in this expression are both quadratic in ψ_k, this means that one does not need to normalize the Jost eigenfunctions when computing their contribution to the solution.

Appendix C. Soliton extraction via moments. The method of obtaining the soliton parameters described above is very effective but computationally intensive, requiring the numerical determination of selected eigenvalues and eigenfunctions of a large matrix. The resolution afforded by this method is critical for the final calculation of the soliton parameters in order to determine correct statistics; the formulation of the biasing vectors, however, does not require the same degree of precision. In particular, if the applied biasing vector differs from the optimal biasing vector by a small random amount (caused, for example, by sensitivity of the parameter measurement technique to the presence of radiation), this can be expected to produce only a small reduction in the efficiency of generating an accurate and unbiased estimate through IS. As long as the biased Monte Carlo simulations sample a large enough region around the deterministic biasing direction, the method will remain efficient. Another way to interpret this is that the Monte Carlo sampling corrects for slight inaccuracies in the determination of the optimal biasing direction.

We have therefore used the following filtered moments to generate approximate values for the soliton parameters at each amplifier. We first obtain an estimate for the soliton frequency

$$\Omega_{\text{est}} = \frac{\int \omega\,|\tilde{u}|^2\,d\omega}{\int |\tilde{u}|^2\,d\omega}, \tag{C.1}$$

where $\tilde{u}$ is the Fourier transform of u. We then use this to band-pass filter the soliton to reduce the noise,

$$\tilde{u}_{\text{filt}} = \tilde{u}\,e^{-(\omega-\Omega_{\text{est}})^2/2W_{\text{filt}}^2}. \tag{C.2}$$

This filtered image of the noisy soliton is used to obtain the final parameter estimates,

$$A = \frac{1}{2}\int |u_{\text{filt}}|^2\,dt, \qquad \Omega = \frac{\int \omega|\tilde{u}_{\text{filt}}|^2\,d\omega}{\int |\tilde{u}_{\text{filt}}|^2\,d\omega}, \tag{C.3}$$

$$T = \frac{\int t|u_{\text{filt}}|^2\,dt}{\int |u_{\text{filt}}|^2\,dt}, \qquad \Phi = \frac{\int \arctan(\operatorname{Im} u_{\text{filt}}/\operatorname{Re} u_{\text{filt}})|u_{\text{filt}}|^2\,dt}{\int |u_{\text{filt}}|^2\,dt}. \tag{C.4}$$

Appendix D. Pdf for the midpoint model. The model of the soliton amplitude's random walk obtained by applying first-order SPT and a particular midpoint approximation to (2.1) was given in section 5 as

$$A_{n+1} = A_n + \frac{1}{2}\left(\sqrt{A_{n+1}} + \sqrt{A_n}\right)s_{n+1}, \tag{D.1}$$

where the s_n are i.i.d. normal RVs with mean zero and variance σ^2. To obtain the pdf for this process, it is convenient to introduce $a_n = \sqrt{A_n}$ and to collect terms, noting

that one can then complete the square by adding $s_n^2/16$ to both sides of the resulting equation:

$$\left(a_{n+1} - \frac{1}{4}s_{n+1}\right)^2 = \left(a_n + \frac{1}{4}s_{n+1}\right)^2. \tag{D.2}$$

Taking the positive branch of this square root then gives the much simpler process $a_{n+1} = a_n + s_{n+1}/2$, which is seen immediately to result in a Gaussian distribution for a_n with mean a_0 and variance $\sigma_a^2 = n\sigma^2/4$. Finally, a simple transformation yields the pdf for A_n:

$$p(A_n) = \frac{1}{2}\frac{1}{\sqrt{2\pi A_n \sigma_a^2}} \exp\left(-\frac{(\sqrt{A_n} - \sqrt{A_0})^2}{2\sigma_a^2}\right). \tag{D.3}$$

THE INVERSE CONDUCTIVITY PROBLEM WITH AN IMPERFECTLY KNOWN BOUNDARY IN THREE DIMENSIONS*

VILLE KOLEHMAINEN†, MATTI LASSAS‡, AND PETRI OLA§

Abstract. We consider the inverse conductivity problem in a strictly convex domain whose boundary is not known. Usually the numerical reconstruction from the measured current and voltage data is done assuming that the domain has a known fixed geometry. However, in practical applications the geometry of the domain is usually not known. This introduces an error, and effectively changes the problem into an anisotropic one. The main result of this paper is a uniqueness result characterizing the isotropic conductivities on convex domains in terms of measurements done on a different domain, which we call the model domain, up to an affine isometry. As data for the inverse problem, we assume the Robin-to-Neumann map and the contact impedance function on the boundary of the model domain to be given. Also, we present a minimization algorithm based on the use of Cotton–York tensor, which finds the push forward of the isotropic conductivity to our model domain and also finds the boundary of the original domain up to an affine isometry. This algorithm works also in dimensions higher than three, but then the Cotton–York tensor has to replaced with the Weyl tensor.

Key words. inverse conductivity problem, electrical impedance tomography, unknown boundary, Cotton–York tensor

1. Introduction.

We consider the electrical impedance tomography problem (EIT for short), i.e. the determination of the unknown isotropic conductivity distribution inside a domain in $\mathbb{R}^3$, for example the human thorax, from voltage and current measurements made on the boundary. Mathematically this is formulated as follows: Let Ω be the measurement domain, and denote by γ the bounded and strictly positive function describing the conductivity in Ω. The voltage potential u satisfies in Ω the equation

$$\nabla \cdot \gamma \nabla u = 0. \tag{1.1}$$

To uniquely fix the solution u it is enough to give its value on the boundary. Let this be f. In the idealized case, when the contact impedance of the measurement device is zero, one measures for all voltage distributions $u|_{\partial M} = f$ on the boundary the corresponding current flux through the boundary, $\gamma \partial y / \partial \nu$, where ν is the exterior unit normal to $\partial\Omega$. Mathematically this amounts to the knowledge of the Dirichlet–Neumann map Λ corresponding to γ, i.e., the map taking the Dirichlet boundary values to the corresponding Neumann boundary values of the solution to (1.1),

$$\Lambda : \quad u|_{\partial M} \mapsto \gamma \frac{\partial u}{\partial \nu}.$$

The Calderón inverse problem is then to to reconstruct γ from Λ. The problem was originally proposed by Calderón [5] in 1980 and then solved in dimensions three and higher for isotropic conductivities which are C^∞-smooth in [31] and [22]. The smoothness requirements have been since relaxed, and currently the best known result is [25] with unique determination of conductivities in $W^{3/2,\infty}$; see also [10] for a somewhat different approach to the lack of smoothness. In two dimensions the first global result is due to Nachman [23], and later Astala and Päivärinta showed in [4] that uniqueness holds also for general isotropic L^∞-conductivities. For the corresponding anisotropic case, see [3, 17, 18, 19], and for numerical implementations of the methods with simulated and real data, see [13, 28, 21].

Assuming that the measured Dirichlet-to-Neumann map Λ_{meas} is given, an often used method to solve the EIT problem is to minimize

$$\|\Lambda_{\text{meas}} - \Lambda_\sigma\|^2 + \alpha\|\sigma\|_X^2$$

for σ defined in terms of some triangulation of Ω and $\|\cdot\|_X$ some regularization norm; here Λ_σ is the Dirichlet–Neumann map corresponding to the conductivity σ. One then also fixes the geometry of Ω by assuming that it is, for example, a ball or an ellipsoid. Now, if our measurements have no error, a Bayesian interpretation of this problem as a search of a maximum a posteriori (MAP) estimate suggests that $\alpha = 0$. Usually, the given data Λ_{meas} does not correspond to any isotropic conductivity in the model domain. The reason for this is that there is no conformal map deforming the original domain to the model domain. Therefore, in solving the minimization problem we obtain an incorrect solution σ. This means that a systematic error in modeling causes a systematic error in the reconstruction. In particular, if we consider linearization $\gamma = \gamma_0 + \varepsilon\gamma_1$, where γ_0 is a given known background conductivity and ε is small, it seems that a localized perturbation γ_1 gives a reconstruction $\sigma = \gamma_0 + \varepsilon\sigma_1$, where the reconstructed perturbation σ_1 is not localized. This is clearly seen in brain-activity measurements; see [9] and [14].

This work is continuation of [15], where the corresponding question in two dimensions was studied: We proved that on the model domain there is a unique (anisotropic) conductivity with minimal anisotropy. This follows from a result of Strebel saying that among all quasi-conformal self-maps of the unit disk with a fixed boundary value there is a unique one with minimal complex dilation. In higher dimensions there are several new issues. First, the nonuniqueness due to anisotropy is not understood, except in the case when both the domain and the conductivity function are the real analytic [19, 20]. Also, as we already mentioned, in the plane case one could use the theory of quasi-conformal maps to break the nonuniqueness. The higher dimensional analogue of this is unknown. Finally, there is no analogue of the Riemann mapping theorem that we could use.

The structure of this paper is the following. In the first part, consisting of sections 2–4, we present the uniqueness results that we have on the problem. It is worth noting that we choose to work with the Robin-to-Neumann (RN) map instead of the Dirichlet-to-Neumann (DN) map described above. Mathematically they are equivalent, as we will show, but the RN map is a better model for the actual measurement configuration, since it takes into account the contact impedances at $\partial\Omega$ [29]. Also, we assume that the function modeling the contact impedances of the electrodes is known. This means that we have measured the contact impedance, e.g., using a reference body. There are two key ideas to compensate for our lack of understanding of the full anisotropic problem. The first is to note that if an isotropic conductivity is pushed forward by

a diffeomorphism, the resulting conductivity is still conformally flat, and in three dimensions this is equivalent to the vanishing of the Cotton–York tensor. Second, we assume that our original domain is strictly convex, and then the Cohn–Vossen theorem (see [27]) can be used to determine the original boundary $\partial\Omega$ up to rigid motions.

In the second part we develop an algorithm for finding the shape of the domain Ω and the conductivity inside using a minimization technique. An important feature is that we do not have to construct an embedding of the boundary to the Euclidean space. We plan to report on the numerical implementation of our algorithm in a separate article.

2. Measurements. Let $\Omega \subset \mathbb{R}^n$, $n \geq 3$, be a strictly convex domain, and denote by $\gamma = (\gamma^{ij}(x))_{i,j=1}^n$ the symmetric real valued matrix describing the conductivity in Ω. We assume that the matrix is bounded from above and from below; that is, for some $C, c > 0$ we have

$$c\|\xi\|^2 \leq \langle \xi, \gamma(x)\xi \rangle \leq C\|\xi\|^2 \quad \text{for all } x \in \Omega. \tag{2.1}$$

We will state the precise smoothness of γ later. We start by considering the EIT problem with continuous boundary data. Instead of the DN map we will use the RN map defined below, which corresponds better to the measurements done in practice. We discuss later in this section the relation of the continuous model and the electrode measurements made in practice.

For the electrical potential u we write the model

$$\nabla \cdot \gamma \nabla u = 0, \qquad x \in \Omega, \tag{2.2}$$

$$(z\nu \cdot \gamma \nabla u + u)|_{\partial\Omega} = h, \tag{2.3}$$

where h is the Robin-boundary value of the potential and z is a function describing the contact impedance on the boundary. The contact impedance models the impedance that is caused by electro-chemical phenomena at the interface of the skin and the measurement electrodes in practical measurements [6].

In mathematical terms, the perfect boundary measurements are modeled by the RN map $R = R_{z,\gamma}$ given by

$$R : h \mapsto \nu \cdot \gamma \nabla u|_{\partial\Omega},$$

which maps the potential on the boundary to the current across the boundary. Next we relate this continuous model to measurements done in practice.

The physically realistic measurements are usually modeled by the following *complete electrode model* (see [6, 29]): Let $e_j \subset \partial\Omega$, $j = 1, \ldots, J$, be disjoint open sets of the boundary modeling the electrodes that are used for the measurements. Let u solve the equation

$$\nabla \cdot \gamma \nabla v = 0 \qquad \text{in } \Omega, \tag{2.4}$$

$$z_j \nu \cdot \gamma \nabla v + v|_{e_j} = V_j, \tag{2.5}$$

$$\nu \cdot \gamma \nabla v|_{\partial\Omega \setminus \cup_{j=1}^J e_j} = 0, \tag{2.6}$$

where V_j are constants representing electric potentials on electrode e_j. Then, one measures the currents observed on the electrodes, given by

$$I_j = \frac{1}{|e_j|} \int_{e_j} \nu \cdot \gamma \nabla v(x)\, ds(x), \quad j = 1, \ldots, J.$$

Thus the electrode measurements are given by map $E : \mathbb{R}^J \to \mathbb{R}^J$, $E(V_1, \dots, V_J) = (I_1, \dots, I_J)$. We say that E is the electrode measurement matrix for $(\partial\Omega, \gamma, e_1, \dots, e_J, z_1, \dots, z_J)$.

The complete electrode model can alternatively be defined as follows: The RN map R_η is given by $R_\eta f = \nu \cdot \gamma \nabla u|_{\partial\Omega}$, where u is the solution of

$$\begin{aligned} \nabla \cdot \gamma \nabla u &= 0 \qquad \text{in } \Omega, \\ z\nu \cdot \gamma \nabla v + \eta v|_{\partial\Omega} &= h, \end{aligned} \tag{2.7}$$

where $z \in C^\infty(\partial\Omega)$ is such that its restriction to the electrode e_j is equal to the constant z_j and $\eta = \sum_{j=1}^J \chi_{e_j}$, where χ_{e_j} is the characteristic function of electrode e_j.

We associate with the electrode measurement matrix and with the complete electrode model also the corresponding quadratic forms $E : \mathbb{R}^J \times \mathbb{R}^J \to \mathbb{R}$ and $R_\eta : H^{-1/2}(\partial\Omega) \times H^{-1/2}(\partial\Omega) \to \mathbb{R}$ given by

$$E[V, \widetilde{V}] = \sum_{j=1}^J (EV)_j \widetilde{V}_j |e_j|, \quad R_\eta[h, \widetilde{h}] = \int_{\partial\Omega} (R_\eta h)\, \widetilde{h}\, ds. \tag{2.8}$$

These have the following simple relation to each other: Let $S = \operatorname{span}(\chi_{e_j} : j = 1, \dots, J) \subset H^{-1/2}(\partial\Omega)$ and define $M : V = (V_j)_{j=1}^J \mapsto \sum_{j=1}^J V_j \chi_{e_j}$ to be a map $M : \mathbb{R}^J \to S$. Then

$$E[V, \widetilde{V}] = R_\eta[MV, M\widetilde{V}]. \tag{2.9}$$

By (2.9), the electrode measurement matrix can be viewed as the discretization of the form R_η. By increasing the number of the electrodes and making the gaps between them smaller, we can assume that $\eta \to 1$. In this case R_η approximates the RN map $R_{\gamma,z}$. Note that $E(V, V)$ corresponds to the power needed to maintain the voltages V in electrodes.

In practical EIT experiments, one places a set of measurement electrodes on the boundary $\partial\Omega$, e.g., around the chest of the patient. All the traditional approaches to numerical EIT reconstruction assume that the shape of the domain Ω is known and that the only unknown is the conductivity γ. However, in most EIT experiments the boundary of the body Ω is not known accurately, and since there are no practically reliable measurement methods available for the determination of the boundary, the EIT image reconstruction problem is typically solved using an approximate model domain $\widetilde{\Omega}$, which represents our best guess for the shape of the true body Ω. However, it has been noticed that the use of a slightly incorrect model for the body Ω in the numerical reconstruction can lead to serious artifacts in reconstructed images [14, 1, 9]. This situation is our paradigm for the EIT problem when the boundary is unknown. Next we analyze how the deformation of the domain affects measurements.

3. Deformations of the domain. In this section we analyze the behavior of the electrode models under a diffeomorphism. Let's consider first the RN map R. The corresponding quadratic form, which we still denote by R, is given on the diagonal by

$$R[h, h] = \int_{\partial\Omega} (u + z\nu \cdot \gamma \nabla u) \nu \cdot \gamma \nabla u \, dS_E = \int_\Omega \gamma \nabla u \cdot \nabla u \, dx + \int_{\partial\Omega} z \, |\nu \cdot \gamma \nabla u|^2 \, dS_E, \tag{3.1}$$

where $h \in H^{-1/2}(\partial\Omega)$, u solves (2.7), and dS_E is the Euclidean volume form (or area) of $\partial\Omega$. The value $R[h, h]$ corresponds to the power needed to maintain the current

h on the boundary. From the mathematical viewpoint, using the (incorrect) model domain $\widetilde{\Omega}$ instead of the original domain Ω can be viewed as a deformation of the original domain. Thus, let us next consider what happens to the conductivity equation when the domain Ω is deformed to $\widetilde{\Omega}$. Assume that $F : \Omega \to \widetilde{\Omega}$ is a sufficiently smooth orientation-preserving map with sufficiently smooth inverse $F^{-1} : \widetilde{\Omega} \to \Omega$. Let $f : \partial\Omega \to \partial\widetilde{\Omega}$ be the restriction of F on the boundary. When u is a solution of $\nabla\cdot\gamma\nabla u = 0$ in Ω, then $\widetilde{u}(\widetilde{x}) = u(F^{-1}(\widetilde{x}))$ and $\widetilde{h}(x) = h(f^{-1}(x))$ satisfy the conductivity equation

$$\begin{aligned} &\nabla\cdot\widetilde{\gamma}\nabla\widetilde{u} = 0 \quad \text{in } \widetilde{\Omega}, \\ &\widetilde{z}\widetilde{\nu}\cdot\widetilde{\gamma}\nabla\widetilde{u} + \widetilde{u}|_{\partial\widetilde{\Omega}} = \widetilde{h}, \end{aligned} \tag{3.2}$$

where $\widetilde{\nu}$ is the unit normal vector of $\partial\widetilde{\Omega}$, $\widetilde{z}$ is the deformed contact impedance, and $\widetilde{\gamma}$ is the conductivity

$$\widetilde{\gamma}(x) = \left.\frac{F'(y)\,\gamma(y)\,(F'(y))^{\mathrm{T}}}{|\det F'(y)|}\right|_{y=F^{-1}(x)}, \tag{3.3}$$

where $F' = DF$ is the Jacobian of the map F. This transformation formula can be seen from the weak definition of $\nabla\cdot\gamma\nabla u = 0$ in Ω; i.e., for all $\phi \in C_0^\infty(\Omega)$

$$\begin{aligned} 0 &= \int_\Omega \gamma\nabla u\cdot\nabla\phi\,dx = \int_{\widetilde{\Omega}} \gamma(F^{-1}(y))(F'(y)^T\nabla(u(F^{-1}(y))))\cdot F'(y)^T\nabla(\phi(F^{-1}(y)))\,dy \\ &= \int_{\widetilde{\Omega}} \widetilde{\gamma}\nabla\widetilde{u}\cdot\nabla\widetilde{\phi}\,dy, \end{aligned}$$

where $\widetilde{\phi}(y) = \phi(F^{-1}(y))$; see also [30], for more on the transformation rule (3.3) and its relations to inverse problems. Note that even if γ is isotropic, i.e., scalar valued, the deformed conductivity $\widetilde{\gamma}$ can be anisotropic, i.e., matrix valued.

To determine the deformed contact impedance $\widetilde{z}$, we consider the corresponding invariant $(n-1)$-form

$$J := \nu\cdot\gamma\nabla u\,dS_E \in \Omega^{n-1}(\partial\Omega)$$

corresponding to the current flux through the boundary. Next we denote $\widetilde{x} = F(x)$. A straightforward application of the chain rule gives that

$$\widetilde{\nu}\cdot\widetilde{\gamma}\nabla\widetilde{u}|_{\partial\widetilde{\Omega}} = \big((\det DF)^{-1}\nu\cdot\nabla u\big)\circ f^{-1}|_{\partial\widetilde{\Omega}}$$

since F was orientation preserving and DF is the Jacobian of F in boundary normal coordinates associated with the surface $\partial\Omega \subset \mathbb{R}^n$. In these coordinates $\det DF|_{\partial\Omega} = \det Df$, where $\det Df$ is the determinant of the differential of the the boundary map $f : \partial\Omega \to \partial\widetilde{\Omega}$. We note that $(\det Df\circ f^{-1})f_*(dS_E) = d\widetilde{S}_E$, where dS_E and $d\widetilde{S}_E$ are Euclidean volume forms of $\partial\Omega$ and $\partial\widetilde{\Omega}$, respectively. Hence, $z\nu\cdot\nabla u$ transforms as an invariantly defined function when the contact impedance is interpreted as a density, i.e.,

$$\widetilde{z}(\widetilde{x}) = (\det Df(x))z(x), \tag{3.4}$$

where $f(x) = \widetilde{x}$. Now we see that the boundary measurements are invariant: When $f : \partial\Omega \to \partial\widetilde{\Omega}$ is the restriction of $F : \Omega \to \widetilde{\Omega}$, we say that the map $\widetilde{R} = f_*R_{z,\gamma}$, defined by

$$((f_*R_{z,\gamma})h)(x) = (R_{z,\gamma}(h\circ f))(y)|_{y=f^{-1}(x)}, \quad h \in H^{1/2}(\partial\widetilde{\Omega}),$$

has the property that $\widetilde{R} = R_{\widetilde{z},\widetilde{\gamma}}$. We call $\widetilde{R}$ the push forward of $R_{z,\gamma}$ by f.

Is is also worth noting that in formula (3.1) the integral over Ω as well as the integral over the boundary are invariant because of the deformation rule (3.4) for the contact impedance z; that is, we have

$$R[h, h'] = \widetilde{R}[h \circ f^{-1}, h' \circ f^{-1}]$$

for $h, h' \in H^{-1/2}(\partial\Omega)$.

4. Uniqueness results. Now we are ready to give the exact set-up of the problem we consider: We want to recover an image of the unknown conductivity γ in Ω from the measurements of the RN map, and we assume a priori that γ is isotropic. We assume that z, $\partial\Omega$, and R are not known. Instead, let $\widetilde{\Omega}$, called the model domain, be our best guess for the domain, and let $f_m : \partial\Omega \to \partial\Omega_m$ be a diffeomorphism modeling the approximate knowledge of the boundary.

As the data for the inverse problem, we assume that we are given the boundary of the model domain $\partial\widetilde{\Omega}$, the function $z \circ f^{-1}$ corresponding to the contact impedance of electrodes, and the RN map $\widetilde{R} = (f_m)_* R$. Note that the discrete analogue of this data is to know the voltage-to-power form $V \mapsto E(V, V)$ and the contact impedances of the electrodes, but not the location of the electrodes or the boundary of the domain. It is reasonable to assume that the contact impedance $z \circ f_m^{-1}$ on the boundary of the model domain is known since we can observe and set up the contact impedances of the electrodes the way we want. Hence we have on the boundary of our model domain $\partial\widetilde{\Omega}$ a boundary map $\widetilde{R}$ that does not generally correspond to any isotropic conductivity. Furthermore, we saw above that there are many anisotropic conductivities for which the RN map is the given map $\widetilde{R}$. Next we show that the existence of the "underlying" isotropic conductivity in Ω gives the uniqueness in $\widetilde{\Omega}$ up to a diffeomorphism and that the domain Ω and the isotropic conductivity on it can be uniquely determined.

THEOREM 4.1. *Let $\Omega \subset \mathbb{R}^n$, $n \geq 3$, be a bounded strictly convex C^∞-domain. Assume that $\gamma \in C^\infty(\overline{\Omega})$ is an isotropic conductivity, $z \in C^\infty(\partial\Omega)$, $z > 0$ a contact impedance, and $R_{\gamma,z}$ the corresponding RN map. Let $\widetilde{\Omega}$ be a model of the domain satisfying the same regularity assumptions as Ω, and $f_m : \partial\Omega \to \partial\widetilde{\Omega}$ be a C^∞-smooth orientation-preserving diffeomorphism.*

Assume that we are given $\partial\widetilde{\Omega}$, the values of the contact impedance $z(f_m^{-1}(\widetilde{x}))$, $\widetilde{x} \in \partial\widetilde{\Omega}$, and the map $\widetilde{R} = (f_m)_* R_{\gamma,z}$. Then we can determine Ω up to a rigid motion T and the conductivity $\gamma \circ T^{-1}$ on the reconstructed domain $T(\Omega)$.

We recall also that rigid motion is an affine isometry $T : \mathbb{R}^n \to \mathbb{R}^n$.

Proof. Assume that we are given $\widetilde{R}$ and the values of the contact impedance, that is, the function $z(f_m^{-1}(\widetilde{x}))$. Let $F_m : \Omega \to \widetilde{\Omega}$ be an orientation-preserving diffeomorphism satisfying $F_m|_{\partial\Omega} = f_m$. As noted before, $\widetilde{R} = R_{\widetilde{z},\widetilde{\gamma}}$, where $\widetilde{z}(x) = \det(Df_m) z(f_m^{-1}(x))$ is the contact impedance on $\partial\widetilde{\Omega}$ and $\widetilde{\gamma} = (F_m)_* \gamma$ is the push forward of γ in F_m. The RN map is a classical pseudodifferential operator of order zero, with principal symbol $1/\widetilde{z}$, and hence $\widetilde{R}$ determines $\widetilde{z}$. Since we also assume $z \circ f^{-1}$ known, we can determine the determinant $\det Df_m$; note that this gives the change of boundary area under deformation f_m. For the rest of the proof denote $\beta = \det Df_m$. Also, this implies that we can find the DN map $\Lambda_{\widetilde{\gamma}} = (\widetilde{R}^{-1} - \widetilde{z} I)^{-1}$ on $\partial\widetilde{\Omega}$, that is, the map taking the Dirichlet boundary values to Neumann boundary values. In terms of electrostatics, this means that the impedance given by Λ_γ^{-1} and the contact impedance z are connected in series; i.e., the total impedance is the sum of Λ_γ^{-1} and z.

The Riemannian metric corresponding to the isotropic conductivity $\gamma = \gamma(x)I$ in Ω is given by

$$g_{ij}(x) = \det(\gamma(x)I)^{1/(2-n)}\,(\gamma(x)I)^{-1} = \gamma(x)^{2/(n-2)}\delta_{ij}.$$

Then, if Δ_g is the Laplace–Beltrami operator corresponding to the metric g, we have $\Delta_g = |g|^{-1/2}\nabla\cdot\gamma\nabla$, where $|g| = \det(g_{ij})$. This metric is an invariant object, and in the deformation F_m it is transformed to the metric $\widetilde{g} = (F_m)_* g$ in $\widetilde{\Omega}$. By [19], the DN map $\Lambda_{\widetilde{\gamma}}$ determines the restriction of the n-dimensional metric tensor $\widetilde{g}_{jk}$ on the boundary in the boundary normal coordinates, and since in these coordinates

$$[\widetilde{g}_{jk}]_{j,k=1}^{n} = \begin{pmatrix} \widetilde{g}_{\partial\widetilde{\Omega}} & 0 \\ 0 & 1 \end{pmatrix},$$

where $\widetilde{g}_{\partial\widetilde{\Omega}} = \widetilde{h}$ is the induced metric on $\partial\widetilde{\Omega}$, we can also recover $\widetilde{h}$.

In particular, if we consider $\partial\widetilde{\Omega}$ as a submanifold of $\mathbb{R}^n$ with the metric $\widetilde{h} = \widetilde{i}^*(\widetilde{g})$ inherited from $(\widetilde{\Omega}, \widetilde{g})$ where $\widetilde{i}: \partial\Omega \to \Omega$ is the identity map, we see that our boundary data determines the metric $\widetilde{h}$ on $\partial\widetilde{\Omega}$. Now let metric $h = i^*(g)$ be the corresponding metric on $\partial\Omega$, where $i: \partial\Omega \to \Omega$ is the identical embedding. Then we have

$$\widetilde{h} = (f_m)_* h, \quad h = \gamma^{2/(n-2)} h^E, \tag{4.1}$$

where h^E is the Euclidean metric of $\partial\Omega$. Denote by $\widetilde{h}^E = (f_m)_* h^E$ the metric tensor on $\partial\widetilde{\Omega}$, i.e., the push forward of the Euclidean metric of $\partial\Omega$ by f_m. Recall that dS_E and $d\widetilde{S}_E$ are the Euclidean volume forms of $\partial\Omega$ and $\partial\widetilde{\Omega}$, respectively. Then the Riemannian volume forms $dS_{\widetilde{h}}$ and dS_h of the metrics $\widetilde{h}$ and h, respectively, satisfy

$$dS_{\widetilde{h}} = (f_m)_*(dS_h) = \gamma(f_m^{-1}(\widetilde{x}))(f_m)_*(dS_E) = (\gamma\beta)\circ f_m^{-1}(\widetilde{x})\, d\widetilde{S}_E$$

on $\widetilde{\partial}\Omega$. As β was already determined, this shows that we can find $\gamma(f_m^{-1}(\widetilde{x}))$, $\widetilde{x} \in \partial\widetilde{\Omega}$, and hence by (4.1) we can determine the metric

$$\widetilde{h}^E = \gamma(f_m^{-1}(\widetilde{x}))^{-2/(n-2)}\widetilde{h}.$$

In other words, if we consider $\partial\widetilde{\Omega}$ as an abstract manifold that can be embedded to $\partial\Omega \subset \mathbb{R}^n$, we have found the metric tensor on $\partial\widetilde{\Omega}$ corresponding to the Euclidean metric of $\partial\Omega$. By the Cohn–Vossen rigidity theorem, intrinsically isometric C^2-smooth surfaces that are boundaries of a strictly convex body are congruent in a rigid motion. For uniqueness, see, e.g., [27, Theorems V and VI] and also [11, 12]. This means that the boundary data uniquely determines the map $T \circ f_m^{-1}$, where T is a rigid motion. Hence we can find the surface $T(\partial\Omega)$ and on it the map $T_*\Lambda_{\widetilde{\gamma}} = T_*\Lambda_\gamma$. Using the uniqueness of of the isotropic inverse problem [31, 22], we see that the boundary data determines $\gamma \circ T^{-1}$. ∎

Note that the construction of the surface $\partial\Omega \subset \mathbb{R}^3$ from the intrinsic metric h^E is a more delicate issue (see [24, 26]); hence we take care to avoid it.

5. A reconstruction algorithm and the use of conformal flatness. In this section we consider the case $n = 3$, even though the considerations could be generalized for $n \geq 4$ by changing the Cotton–York tensor to a Weyl tensor in our considerations (see the appendix). As noted before, an actual construction of the

isometric embedding of an abstract manifold to Euclidean space is complicated, and thus we try to avoid it.

We want to find an anisotropic conductivity η such that $R_{\widetilde{z},\eta} = \widetilde{R}$ assuming that $\widetilde{R} = (f_m)_* R_{z,\gamma}$, where γ is an isotropic conductivity. Clearly, when $F_m : \Omega \to \widetilde{\Omega}$ is diffeomorphism satisfying $F_m|_{\partial\Omega} = f_m$, the anisotropic conductivity $(F_m)_*\gamma$ is a solution of the inverse problem, but it is not unique. However, we also know that $(F_m)_*\gamma$ has a conformally flat structure, and this fact will help in solving the inverse problem as we will see. Note that in principle, one could start to solve the inverse problem by minimizing over all pairs (Ω, σ) of smooth domains $\Omega \subset \mathbb{R}^n$ and all isotropic conductivities σ in Ω. However, the minimization over domains is complicated, and our objective is to find a reasonably simple minimization algorithm where we minimize over conductivities in the fixed model domain $\widetilde{\Omega}$ with an appropriately chosen cost function.

Let $\eta = (F_m)_*\gamma$ be a possibly anisotropic conductivity in $\widetilde{\Omega}$ such that γ is isotropic. As already noted, it defines a Riemannian metric g on $\widetilde{\Omega}$, given by

$$[g_{jk}]_{j,k=1}^n = ([g^{jk}]_{j,k=1}^n)^{-1}, \quad g^{jk} = \det(\eta)^{1/(n-2)}\eta^{jk}.$$

From now on we will use the Einstein summation convention and omit the summation symbols. As $F_m^{-1} : \widetilde{\Omega} \to \Omega$ can be considered as coordinates, we see that in proper coordinates the metric g is a scalar function times a Euclidean metric; that is, g is conformally flat. This means that

$$g_{ij}(x) = e^{-2\sigma(x)}\overline{g}_{ij}(x),$$

where $\overline{g}_{ij}(x)$ is a metric with zero curvature tensor (i.e., flat metric) and $\sigma(x) \in \mathbb{R}$. By [8] (for original work, see [7]), the conformal flatness of the metric g in three dimensions is equivalent to the vanishing of the Cotton–York tensor $\mathrm{C} = \mathrm{C}_{ij}$ corresponding to g (see the appendix). Note that we can choose $\sigma = \frac{1}{2-n}\log\gamma$ and $\overline{g} = (F_m)_*(\delta_{ij})$. By [8, formulae (28.18) and (14.1)], σ satisfies a differential equation (with $n = 3$)

$$\sigma_{ij} = -\frac{1}{n-2}\,\mathrm{Ric}_{ij} + \frac{1}{2(n-1)(n-2)}\,g_{ij}\mathrm{R} - \frac{1}{2}\,g_{ij}g^{lm}\sigma_l\sigma_k, \quad i,j = 1,\dots,n, \tag{5.1}$$

where Ric_{ij} is the Ricci curvature tensor of g, R is the scalar curvature of g, and

$$\sigma_k = \frac{\partial\sigma}{\partial x^k}, \quad \sigma_{ij} = \nabla_{e_i}\sigma_j - \sigma_i\sigma_j, \quad \text{where} \quad e_i = \frac{\partial}{\partial x^i},$$

where ∇_{e_i} is the covariant derivative with respect to metric g. Thus if g is given, (5.1) is a second order nonlinear differential equation for σ. By [8, p. 92], the equations (5.1) satisfy the sufficient integrability conditions to be locally solvable if and only if the Cotton–York tensor vanishes. Note that the existence of the isotropic conductivity γ in Ω gives a solution for these equations.

Consider now the following algorithm.

Data: Assume that we are given $\partial\Omega_m$, $\widetilde{R} = (f_m)_* R_{\gamma,z}$, and $z \circ f_m^{-1}$ on $\partial\Omega_m$.

Aim: We look for a metric $\widetilde{g}$ corresponding to the conductivity $\widetilde{\gamma}$ and $\widetilde{z}$ such that on $\partial\Omega_m$, $\widetilde{R} = R_{\widetilde{\gamma},\widetilde{z}}$ and $\widetilde{z} = (f_m)_* z$.

Algorithm.

1. Determine the two leading terms in the symbolic expansion of $\widetilde{R}$. They determine a contact impedance $\widehat{z}$ and a metric $\widehat{g}$ on $\partial\widetilde{\Omega}$ such that if $\widetilde{R} = R_{\widetilde{\gamma},\widetilde{z}}$, then $\widetilde{z} = \widehat{z}$ and $\widetilde{i}^*(\widetilde{g}) = \widehat{g}$.

2. Form the ratio of the given contact impedance, $\widetilde{z}$, and the reconstructed contact impedance, $\widehat{z}$, that is,

$$\widehat{r}(\widetilde{x}) := \frac{z(f_m^{-1}(\widetilde{x}))}{\widehat{z}(\widetilde{x})}, \quad \widetilde{x} \in \partial\widetilde{\Omega}.$$

Note that then

$$\widehat{r}(\widetilde{x})(f_m)_*(dS_E) = d\widetilde{S}_E$$

since the contact impedances transformed as densities.

3. Let $dS_{\widehat{g}}$ be the volume form of $\widehat{g}$ on $\partial\widetilde{\Omega}$. Then

$$dS_{\widehat{g}} = (\det \widehat{g})^{1/2}\, d\widetilde{S}_E.$$

Define

$$\widehat{\gamma} = (\det \widehat{g})^{1/2}\, \widehat{r}.$$

With this choice $\widehat{\gamma}$ will satisfy $\widehat{\gamma}(\widetilde{x}) = \gamma(f_m^{-1}(\widetilde{x}))$ for $\widetilde{x} \in \partial\widetilde{\Omega}$.

4. Define the boundary value $\widehat{\sigma}$ for the function σ by

$$\widehat{\sigma}(\widetilde{x}) = \frac{1}{2-n} \log\left(\widehat{\gamma}(\widetilde{x})\right), \quad \widetilde{x} \in \partial\widetilde{\Omega}.$$

5. Solve the minimization problem

$$\min F_\tau(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma}) + \alpha\, H(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma}),$$

where $H(\widetilde{z}, \widetilde{\gamma})$ is a regularization functional, say,

$$H(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma}) = \|\widetilde{z}\|^2_{H^8(\widetilde{\Omega})} + \|\widetilde{\gamma}\|^2_{H^8(\widetilde{\Omega})} + \|\widetilde{\sigma}\|^2_{H^8(\widetilde{\Omega})};$$

$\alpha \geq 0$ is a regularization parameter; and

$$\begin{aligned} &F_\tau(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma}) \\ &= \left\| \widetilde{R} - R_{\widetilde{\gamma},\widetilde{z}} \right\|^2_{L(H^{-1/2}(\partial\widetilde{\Omega}))} + \| \frac{\widetilde{z}(\widetilde{x})}{z(f_m^{-1}(\widetilde{x}))} - \widehat{r}(\widetilde{x}) \|^2_{L^2(\partial\widetilde{\Omega})} + \|\widetilde{\sigma}|_{\partial\widetilde{\Omega}} - \widehat{\sigma}\|^2_{L^2(\partial\widetilde{\Omega})} \\ &\quad + \tau \|\mathrm{C}\|^2_{L^2(\widetilde{\Omega})} \\ &\quad + \sum_{i,j=1}^{n} \left\| \widetilde{\sigma}_{ij} - \left(-\frac{1}{n-2}\mathrm{Ric}_{ij} + \frac{1}{2(n-1)(n-2)} \widetilde{g}_{ij}\mathrm{R} - \frac{1}{2}\widetilde{g}_{ij}\widetilde{g}^{lm}\sigma_l\sigma_k \right) \right\|^2_{L^2(\widetilde{\Omega})}, \end{aligned}$$

where $\tau \geq 0$, $\widetilde{g}$ is the metric tensor corresponding to $\widetilde{\gamma}$, $\mathrm{C} = \mathrm{C}_{ij}$ is the Cotton–York tensor of $\widetilde{g}$, and finally Ric and R are the Ricci curvature and scalar curvature tensors, respectively, of $\widetilde{g}$.

Note that step 1 above requires the use of highly oscillating boundary data, and hence very small values of z might cause problems in practice. Also, the value of the Cotton–York tensor at $x \in \Omega$, $\mathrm{C}_{ij}(x)$, the Ricci curvature tensors $R_{ij}(x)$, and the scalar curvature $R(x)$ depend on the values of the conductivity η and its three first derivatives at x.

PROPOSITION 5.1. *Let $\Omega \subset \mathbb{R}^3$ be a bounded strictly convex C^∞-domain. Assume that $\gamma \in C^\infty(\overline{\Omega})$ is an isotropic conductivity, $z \in C^\infty(\partial\Omega)$, $z > 0$ a contact*

impedance, and $R_{\gamma,z}$ the corresponding RN map. Let $\widetilde{\Omega}$ be a model of the domain satisfying the same regularity assumptions as Ω, and $f_m : \partial\Omega \to \partial\widetilde{\Omega}$ be a C^∞-smooth diffeomorphism.

Assume that we are given $\partial\widetilde{\Omega}$, the values of the contact impedance $z(f_m^{-1}(\widetilde{x}))$, $\widetilde{x} \in \partial\widetilde{\Omega}$, and the map $\widetilde{R} = (f_m)_* R_{\gamma,z}$.

Let $\tau \geq 0$. Then the minimum of $F_\tau(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma})$ is zero; any minimizers $\widetilde{z}$, $\widetilde{\sigma}$, and $\widetilde{\gamma}$ of $F_\tau(\widetilde{z}, \widetilde{\sigma}, \widetilde{\gamma})$ satisfy $\widetilde{z} = (f_m)_* z$; and there is a diffeomorphism $\widetilde{F} : \Omega \to \widetilde{\Omega}$ such that $\widetilde{F}|_{\partial\Omega} = f_m$, $\widetilde{\gamma} = \widetilde{F}_* \gamma$, and $\widetilde{\sigma} = -\log \widetilde{\gamma}$.

Proof. Assume first that $\tau > 0$. The minimizer exists because of the existence of Ω, γ, z, and σ, and the minimum is zero. Let $\widetilde{z}$, $\widetilde{\sigma}$, and $\widetilde{g}$ be some minimizers of F_τ. As then the Cotton–York tensor is zero and the equations (5.1) are valid, it follows from [8] that the metric $\overline{g}_{ij} = \exp(2\sigma(\widetilde{x}))g_{ij}(\widetilde{x})$, $x \in \widetilde{\Omega}$, is flat. Since $R_{\widetilde{z},\widetilde{\gamma}} = \widetilde{R}$, we have $\widetilde{z} = (f_m)_* z$, and the metric $\widetilde{g}$ corresponding to $\widetilde{\gamma}$ has to satisfy $i^*\widetilde{g} = \widehat{g}$ on the boundary. This and the vanishing of F_τ imply that

$$\begin{aligned} i^*\overline{g} &= \exp(2\widehat{\sigma}) i^*\widetilde{g} = \exp(2\widehat{\sigma})\widehat{g} = \exp(2\widehat{\sigma})(f_m)_*(\gamma h_E) \\ &= \exp(2\widehat{\sigma})\,\widehat{\gamma}\,(f_m)_*(h_E) = (f_m)_*(h_E). \end{aligned}$$

Consider now $(\widetilde{\Omega}, \overline{g})$ as a Riemannian manifold. As $\overline{g}$ is flat, we know that $(\widetilde{\Omega}, \overline{g})$ can be embedded isometrically to domain $\Omega_0 \subset \mathbb{R}^n$. Let $k : \widetilde{\Omega} \to \Omega_0$ be this embedding. Since $i^*\overline{g} = (f_m)_*(h_E)$, it follows from the Cohn–Vossen rigidity theorem that the boundaries $\partial\Omega_0$ and $\partial\Omega$ are congruent in a rigid motion T and $k \circ f_m = T|_{\partial\Omega}$. Then $(T^{-1} \circ k)_* \widetilde{\gamma}$ is an isotropic conductivity, the contact impedances of $(T^{-1} \circ k)_* \widetilde{z}$ and z coincide, and the RN maps of $(T^{-1} \circ k)_* \widetilde{\sigma}$ and σ coincide. By the uniqueness of the isotropic inverse conductivity problem [31], $(T^{-1} \circ k)_* \widetilde{\gamma} = \gamma$. This proves the claim in the case $\tau > 0$.

Next, consider the case $\tau = 0$. Again, a minimizer exists because of the existence of Ω, γ, z, and σ, and the minimum is zero. Let $\widetilde{z}$, $\widetilde{\sigma}$, and $\widetilde{g}$ be some minimizers. As the minimum of F_τ is zero, the equations (5.1) are valid. By [8, p. 92], the solutions σ satisfy the integrability conditions

$$\nabla_k \sigma_{ij} - \nabla_j \sigma_{ik} = \sigma_l \mathrm{R}^l_{ijk}, \quad i, j, k = 1, \ldots, n, \tag{5.2}$$

which imply that the conformal covariant satisfying R_{ijk} vanishes. Thus the Cotton–York tensor C_{ij} is zero. This means that the minimizers $\widetilde{z}$, $\widetilde{\sigma}$, and $\widetilde{g}$ of F_τ with $\tau = 0$ are also minimizers of F_τ with any $\tau > 0$. □

One can think of τ as a regularization parameter: In general the solvability properties of (5.1) are sensitive to the compatibility conditions, i.e., the vanishing of the Cotton–York (or the Weyl tensor in higher dimensions).

To find the domain Ω, we can continue the above algorithm by applying the fact that conformally Euclidean manifold of dimension n can be a conformally embedded to $\mathbb{R}^n$ in a constructive way (cf. [16]).

6. In steps 1–5 we have found metric tensors $\widetilde{g}$ and $\overline{g} = e^{2\widetilde{\sigma}}\widetilde{g}$ on $\widetilde{\Omega}$ such that $\widetilde{g} = F_*(g)$ and $\overline{g} = F_*(g^E)$, where g is the metric corresponding to the metric γ on Ω, g^E is the Euclidean metric on Ω, and $F : \Omega \to \widetilde{\Omega}$ is some diffeomorphism.

   Let $y \in \widetilde{\Omega}$ and find geodesics $\overline{\mu}_{y,\xi}(s)$ starting from y with respect to the metric $\overline{g}$. We parametrize these geodesics in such a way that $\overline{\mu}_{y,\xi}(0) = y$ and $\partial_s \overline{\mu}_{y,\xi}(0) = \xi$ is a unit tangent vector of the tangent space $(T_y\widetilde{\Omega}, \overline{g})$. These

geodesics correspond to the half-lines in $\mathbb{R}^3$ starting from some point $y_0 \in \Omega$. Let $J : (T_y\widetilde{\Omega}, \overline{g}) \to \mathbb{R}^3$ be a linear isometry, and define a map $\kappa : \widetilde{\Omega} \to \mathbb{R}^3$ by setting

$$\kappa(\overline{\mu}_{y,\xi}(s)) \,=\, s\, J\xi, \quad s \geq 0.$$

Then $\kappa \circ F : \Omega \to \mathbb{R}^3$ is an affine isometry that extends to a rigid motion $T : \mathbb{R}^3 \to \mathbb{R}^3$ with $T(y) = 0$. Thus we can find $\kappa(\widetilde{\Omega}) = T(\Omega)$, $\kappa_*(\widetilde{\sigma}) = T_*\gamma$, and $\kappa_*(\widetilde{z}) = T_*z$

Thus we have shown the following reconstruction result.

COROLLARY 5.2. *Let Ω, γ, z, $\widetilde{\Omega}$, and f_m be as in Proposition* 5.1. *Assume that we are given $\partial\widetilde{\Omega}$, the contact impedance $z(f_m^{-1}(\widetilde{x}))$, $\widetilde{x} \in \partial\widetilde{\Omega}$, and the RN map $\widetilde{R} = (f_m)_* R_{\gamma,z}$. Then the algorithm* 1–6 *determines Ω, γ, and z up to a rigid motion $T : \mathbb{R}^3 \to \mathbb{R}^3$.*

We intend to investigate the numerical implementation of the method and give numerical test results in part II of this paper.

Appendix. Here we define the conformal curvature tensors. We say that a metric g_{ij} in a domain $\Omega \subset \mathbb{R}^n$ is conformally flat if there is a scalar function $a(x) > 0$ such that the curvature of tensor of $a(x)g_{ij}(x)$ is identically zero.

First, let γ be an isotropic conductivity, i.e., a smooth positive function in Ω, and let $F : \Omega \to \widetilde{\Omega}$ be a diffeomorphism. Let $\eta = F_*\gamma$ be a possibly anisotropic conductivity in $\widetilde{\Omega}$. It defines a Riemannian metric $\widetilde{g}$ on $\widetilde{\Omega}$, given by

$$[\widetilde{g}_{jk}]_{j,k=1}^n = ([\widetilde{g}^{jk}]_{j,k=1}^n)^{-1}, \quad \widetilde{g}^{jk} = \det(\eta)^{1/(n-2)}\eta^{jk}.$$

As $F^{-1} : \widetilde{\Omega} \to \Omega$ can be considered as coordinates, we see that in proper coordinates the metric $\widetilde{g}$ is a scalar function times a Euclidean metric; that is, $\widetilde{g}$ is conformally flat.

Next we consider a general metric tensor g_{ij} and recall facts concerning its conformal flatness. Note that below we use the Einstein summation convention and omit the summation symbols when possible. The following tensors are related to conformal flatness:

(a) Assume that $n = 3$. Then the conformal covariant, given in terms of curvature tensors (see the explanation on notation below) is

$$R_{ijk} = \nabla_k R_{ij} - \nabla_j R_{ik} + \frac{1}{2(n-1)}(g_{ik}\nabla_j R - g_{ij}\nabla_k R).$$

In the three dimensional case, R_{ijk} defines a tensor that can be considered as a vector valued 2-form $R_{ijk}dx^j \wedge dx^k$. Operating with the Hodge operator $*$ on this 2-form, we obtain the Cotton–York tensor,

$$\mathrm{C}_{ij} = g^{kp}g^{lq}\nabla_k \left(R_{li} - \frac{1}{4} R\, g_{li} \right) \epsilon_{pqj},$$

where ϵ_{pqj} is the Levi–Civita permutation symbol.

(b) Assume that $n \geq 4$. Then the Weyl tensor is

$$W_{ijkl} = R_{ijkl} + \frac{1}{n-2}(g_{il}R_{kj} + g_{jk}R_{kj} - g_{ik}R_{lj} - g_{jl}R_{ki}) + \frac{1}{(n-1)(n-2)}(g_{ik}g_{lj} - g_{il}g_{kj})R.$$

The crucial fact related to our considerations is that the metric g is conformally flat if and only if in the dimension $n = 3$ the Cotton–York tensor vanishes and in the dimension $n = 4$ the Weyl tensor vanishes; see [8, p. 92] or [7, 32, 2].

Above, R_{ijkl} is the Riemannian curvature tensor,

$$R_{ijkl} = \frac{\partial}{\partial x^k}\Gamma^i_{jl} - \frac{\partial}{\partial x^l}\Gamma^i_{jk} + \Gamma^p_{jl}\Gamma^i_{pk} - \Gamma^p_{jk}\Gamma^i_{pl}, \quad R^p_{jkl} = g^{pi}R_{ijkl},$$

where Γ^i_{jk} are Christoffel symbols,

$$\Gamma^i_{jk} = \frac{1}{2}g^{pi}\left(\frac{\partial g_{jp}}{\partial x^k} + \frac{\partial g_{kp}}{\partial x^j} - \frac{\partial g_{jk}}{\partial x^p}\right),$$

R_{ij} is the Ricci curvature tensor, $R_{ij} = R^k_{ijk}$, and R is the scalar curvature $R = g^{ij}R_{ij}$. Finally, ∇_k is the covariant derivative that is defined for a (0,2)-tensor A_{il} and a (0,1)-tensor B_l by

$$\nabla_k A_{li} = \frac{\partial}{\partial x^k}A_{li} - \Gamma^p_{kl}A_{pi} - \Gamma^p_{ki}A_{lp}, \qquad \nabla_k B_l = \frac{\partial}{\partial x^k}B_l - \Gamma^p_{kl}B_p.$$

Acknowledgment. The authors wish to thank the anonymous referees for their valuable comments.

HETEROCLINIC BIFURCATION IN THE MICHAELIS–MENTEN-TYPE RATIO-DEPENDENT PREDATOR-PREY SYSTEM*

BINGTUAN LI† AND YANG KUANG‡

Abstract. The existence of a heteroclinic bifurcation for the Michaelis–Menten-type ratio-dependent predator-prey system is rigorously established. Limit cycles related to the heteroclinic bifurcation are also discussed. It is shown that the heteroclinic bifurcation is characterized by the collision of a stable limit cycle with the origin, and the bifurcation triggers a catastrophic shift from the state of large oscillations of predator and prey populations to the state of extinction of both populations. It is also shown that the limit cycles related to the heteroclinic bifurcation originally bifurcate from the Hopf bifurcation.

Key words. ratio-dependent predator-prey model, heteroclinic cycle, bifurcation

1. Introduction.

In studying the interaction between predators and their prey, it is crucial to determine what specific form of the functional response that describes the amount of prey consumed per predator per unit of time is biologically plausible and provides a sound basis for theoretical development. Traditionally, dependence on prey density has been the starting point, giving a functional response function of the form $p(x)$. In the simplest case, such a function is a linear function of x, which is incorporated into the classical Lotka–Volterra predator-prey model. The linear functional response is a limiting case of the more general and useful Michaelis–Menten or Holling type II response function of the form $p(x) = \frac{cx}{m+x}$. Because $p(x)$ varies solely with prey density, it is usually labeled as "prey-dependence."

Sole dependence of the functional response on prey density has been questioned by several biologists (e.g., DeAngelis, Goldstein, and O'Neill [10], Arditi and Ginzburg [4], Arditi, Ginzburg, and Akcakaya [5], Akcakaya [1], Gutierrez [12]). It has been recognized that predators might interfere with each other's foraging, requiring the functional response to depend on densities of both predators and prey (DeAngelis, Goldstein, and O'Neill [10], Arditi and Akcakaya [2], Beddington [6]). Arditi and Ginzburg [4] have argued that a functional response depending on the ratio of prey to predator abundance is a suitable representation of some of these phenomena. With the Michaelis–Menten or Holling type II-type ratio-dependence functional response $p(x/y)$ and logistic prey growth, the predator-prey system takes the form of

$$\begin{aligned} x'(t) &= rx\left(1-\frac{x}{K}\right)-\frac{cxy}{x+my}, \\ y'(t) &= y\left(\frac{fx}{x+my}-d\right), \end{aligned} \tag{1.1}$$

where $x(t)$, $y(t)$ represent population densities of prey and predator, respectively, and r, K, c, m, f, d are positive constants that stand for prey intrinsic growth rate, carrying capacity, capturing rate, half saturation constant, maximal predator growth rate, and predator mortality rate, respectively.

The ratio-dependent predator-prey system (1.1) exhibits original dynamic properties that have never been observed in the early prey-dependent predator-prey systems. Specifically, the ratio-dependent predator-prey system (1.1) does not produce the so-called paradox of enrichment (Hairston, Smith, and Slobodkin [13], Rosenzweig [19]) or the paradox of biological control (Arditi and Berryman [3]). It also allows the predator population or both populations to either become extinct or coexist, depending on the initial population values. These are realistic features of predator-prey models that have been observed experimentally (Huffaker [14], Luckinbill [17]).

The dynamics of the ratio-dependent predator-prey system (1.1) has been systematically studied by Kuang and Beretta [16], Hsu, Hwang, and Kuang [15], Berezovskaya, Karev, and Arditi [7], and Xiao and Ruan [22]. These authors have shown that system (1.1) has very rich dynamics. In particular, the origin is a complicated equilibrium point whose characteristics determine some important properties of the system (see [7, 22]), the limit cycle exists and is unique and stable (see [15]), and the heteroclinic bifurcation plays an important role in understanding the dynamics of the system (see [7, 15]). Berezovskaya, Karev, and Arditi [7] have found numerically the heteroclinic cycle in (1.1) that corresponds to the disappearance of the limit cycle. It is thus interesting to rigorously establish the existence of heteroclinic bifurcation and to study the properties associated with the bifurcation. In a recent paper [20], Tang and Zhang reduced the system to a perturbed Hamiltonian system with a Delta-shape heteroclinic loop and computed Melnikov's function by eliminating some complicated terms in establishing the heteroclinic bifurcation. This is a valid and novel approach, yet its implementation is subtle since it involves intensive steps of variable manipulations and computations. The analysis presented in [20] contains a flaw that failed to ensure a proper application of Melnikov's method.

The objective of this paper is to rigorously establish the existence of heteroclinic bifurcation and determine the associated dynamics in system (1.1). This paper is organized as follows. The main results of the paper are provided in section 2. In this section, we use Melnikov's method to determine the existence of heteroclinic bifurcation. It is shown that the heteroclinic bifurcation is characterized by the collision of a stable limit cycle with the origin, and the bifurcation triggers a catastrophic shift from the state of large oscillations of predator and prey populations to the state of extinction of both populations. We also employ Melnikov's method to study limit cycles related to the heteroclinic bifurcation. It is shown that the limit cycles related the heteroclinic bifurcation originally bifurcate from the Hopf bifurcation. The biological interpretations of the theoretical results are also provided. Some concluding remarks are given in section 3.

2. Bifurcations.

2.1. Heteroclinic bifurcation. For simplicity, we nondimensionalize system (1.1) as in Tang and Zhang [20] with the following scaling:

$$x \to Kx, \quad y \to Ky/m, \quad t \to mt/c.$$

(Throughout this paper the variable on the left-hand side of $\to$ always represents the old variable.) With this scaling, system (1.1) takes the form

$$\begin{aligned} x'(t) &= \alpha x(1-x) - \frac{xy}{x+y}, \\ y'(t) &= -\beta y + \frac{\kappa xy}{x+y}, \end{aligned} \tag{2.1}$$

where

$$\alpha = \frac{rm}{c}, \beta = \frac{dm}{c}, \kappa = \frac{fm}{c}. \tag{2.2}$$

As shown in [7, 20, 22], system (2.1) in the first quadrant is equivalent to the polynomial system

$$\begin{aligned} x'(t) &= \alpha x(1-x)(x+y) - xy \\ y'(t) &= -\beta y(x+y) + \kappa xy \end{aligned} \tag{2.3}$$

obtained from (2.1) by a change of the independent variable

$$t \to (x+y)t.$$

As in [7, 20, 22], one can then use Briot–Bouquet's transformation

$$x \to x, \quad y \to yx, \quad t \to t/x \tag{2.4}$$

to convert (2.3) to

$$\begin{aligned} x'(t) &= x[\alpha - \alpha x - (1-\alpha)y - \alpha xy], \\ y'(t) &= y[(\kappa - \alpha - \beta) + \alpha x + (1-\alpha-\beta)y + \alpha xy]. \end{aligned} \tag{2.5}$$

Transformation (2.4) is a homomorphism in the first quadrant, and its inverse maps the y axis to the point $(0,0)$.

Tang and Zhang [20] used variable changes to transform (2.5) to

$$\begin{aligned} v_1'(t) &= v_1\left[\mu_1 + v_1^2 + \frac{1-\alpha}{1-\alpha-\beta}v_2^2\right] + \delta v_1\left(\mu_2 + \frac{1}{1-\alpha-\beta}v_1^2v_2^2\right), \\ v_2'(t) &= v_2\left[\frac{-2(1-\alpha-\beta)}{2-2\alpha-\beta}\mu_1 - v_1^2 - v_2^2\right] + \delta v_2\left(\mu_2 - \frac{1}{1-\alpha-\beta}v_1^2v_2^2\right), \end{aligned} \tag{2.6}$$

where δ, μ_1, and μ_2 are related to α and $\alpha+\beta-\kappa$, and in particular $\alpha = -(\delta\mu_1 + \delta^2\mu_2)$. In [20] the coefficient term $(1-\alpha)/(1-\alpha-\beta)$ is treated as a constant when Melnikov's method is used to carry out bifurcation analysis with respect to parameters δ, μ_1, μ_2. This is not appropriate. One needs to split this coefficient term into a term independent of bifurcation parameters and a perturbation term in applying Melnikov's method.

Instead of working on (2.6), we study the following simpler system

$$\begin{aligned} x'(t) &= x[\alpha - x - (1-\alpha)y - xy], \\ y'(t) &= y[(\kappa - \alpha - \beta) + x + (1-\alpha-\beta)y + xy], \end{aligned} \tag{2.7}$$

obtained from (2.5) by the change of variable

$$x \to x/\alpha.$$

We simply use α and $\nu = \kappa - \alpha - \beta$ (or equivalently α and κ) as our unfolding parameters while fixing β. In (2.7) there are two second order terms whose coefficients depend on α. We decompose these terms and rewrite (2.7) as

$$\begin{aligned} x'(t) &= x(\alpha - x - y) + x(\alpha y - xy), \\ y'(t) &= y(\nu + x + (1-\beta)y) + y(-\alpha y + xy). \end{aligned} \tag{2.8}$$

This system can then be viewed as a perturbation of the system

$$\begin{aligned} x'(t) &= x(\alpha - x - y), \\ y'(t) &= y(\nu + x + (1-\beta)y), \end{aligned} \tag{2.9}$$

as α, ν, x, and y are all small. Note that the coefficients of second order terms in (2.9) do not depend on α and ν.

We shall assume that

$$\beta < 1.$$

System (2.9) is integrable if

$$\nu = -\frac{2(1-\beta)}{2-\beta}\alpha < 0, \tag{2.10}$$

and in this case the function

$$F_\alpha(x,y) = \frac{1}{b}x^a y^b \left(\alpha - x - \frac{2-\beta}{2}y\right), \tag{2.11}$$

where

$$a = 2\frac{1-\beta}{\beta}, \qquad b = \frac{2-\beta}{\beta}, \tag{2.12}$$

is constant along solution curves. In fact, when (2.10) holds, along any solution curve $(x(t), y(t))$ of (2.9), $\frac{dF_\alpha(x,y)}{dt} = \frac{\partial F_\alpha}{\partial x}x'(t) + \frac{\partial F_\alpha}{\partial y}y'(t) = \frac{1}{b}[\alpha a x^{a-1}y^b - (a+1)x^a y^b - \frac{2-\beta}{2}a x^{a-1}y^{b+1}]x(\alpha - x - y) + \frac{1}{b}[\alpha b x^a y^{b-1} - b x^{a+1}y^{b-1} - \frac{2-\beta}{2}(b+1)x^a y^b]y(\nu + x + (1-\beta)y) = 0$. The level curves of F_α take the form shown in Figure 1. Here we have a family of periodic orbits encircling the center at $(\bar{x}, \bar{y}) = (\frac{(1-\beta)\alpha}{2-\beta}, \frac{\alpha}{2-\beta})$ and limiting on the heteroclinic cycle $F_\alpha(x,y) = 0$, which is a triangle connecting the saddles at $(0,0)$, $(\alpha, 0)$, and $(0, \frac{2\alpha}{2-\beta})$.

Using the transformations

$$x \to \epsilon x, \quad y \to \epsilon y, \quad \alpha = \epsilon\nu_1, \quad \nu = -\frac{2(1-\beta)}{2-\beta}\epsilon\nu_1 + \nu_2\epsilon^2$$

and rescaling time $t \to t/\epsilon$, we convert system (2.8) into

$$\begin{aligned} x'(t) &= x[\nu_1 - x - y] + \epsilon(\nu_1 xy - x^2 y), \\ y'(t) &= y\left[-\frac{2(1-\beta)}{2-\beta}\nu_1 + x + (1-\beta)y\right] + \epsilon(\nu_2 y - \nu_1 y^2 + xy^2). \end{aligned} \tag{2.13}$$

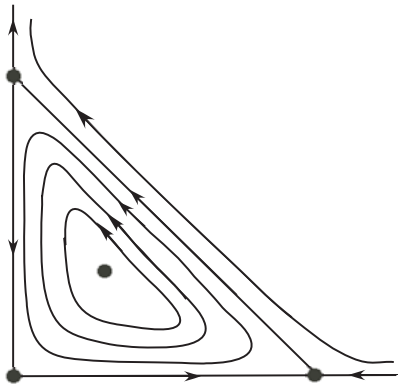

FIG. 1. *The level curves of* $F_\alpha(x,y)$.

Multiplying (2.13) by the integrating factor $x^{a-1}y^{b-1}$, we obtain the "equivalent" perturbed Hamiltonian system:

$$\begin{aligned} x'(t) &= x^a y^{b-1}\{[\nu_1 - x - y] + \epsilon(\nu_1 y - xy)\} \\ y'(t) &= x^{a-1}y^b \left\{ \left[-\frac{2(1-\beta)}{2-\beta}\nu_1 + x + (1-\beta)y \right] + \epsilon(\nu_2 - \nu_1 y + xy) \right\}. \end{aligned} \tag{2.14}$$

One can check that

$$F_{\nu_1}(x,y) = \frac{1}{b}x^a y^b \left(\nu_1 - x - \frac{2-\beta}{2}y \right) \tag{2.15}$$

is the Hamiltonian function for (2.14) when $\epsilon = 0$, where a and b are given in (2.12).

We use the Melnikov theory [9, 11, 21] to locate parameter values that produce a heteroclinic cycle for (2.14) in the case $\epsilon \neq 0$. The analysis that we perform here is similar to what is carried out in section 7.5 of [11] and section 4.7 of [9]. We can set $\nu_1 = 1$ without loss of generality. The heteroclinic cycle for $\epsilon = 0$ lies on the level curve $F_1(x,y) = 0$, denoted by Γ_0, which corresponds to a triangle formed by the three line segments determined by $x = 0$, $y = 0$, and $x + \frac{2-\beta}{2}y = 1$. Let

$$\mathbf{G}(x,y) = (x^a y^{b-1}(y - xy), x^{a-1}y^b(\nu_2 - y + xy)).$$

The Melnikov function is

$$\begin{aligned} M(\nu_2) &= \int\int_{\text{int}\Gamma_0} \text{trace} D\mathbf{G}(x,y)dxdy \\ &= \int\int_{\text{int}\Gamma_0} [(a-b-1)x^{a-1}y^b + (b-a)x^a y^b + bx^{a-1}y^{b-1}\nu_2]dxdy, \end{aligned} \tag{2.16}$$

where $\text{int}\Gamma_0$ denotes the region bounded by Γ_0. $M(\nu_2) = 0$ has a unique solution

$$\nu_2 = -\frac{(a-b-1)I(a-1,b) + (b-a)I(a,b)}{bI(a-1,b-1)}, \tag{2.17}$$

where

$$I(u,v) = \int\int_{\text{int}\Gamma_0} x^u y^v dxdy, \qquad u > -1, v > -1.$$

It is easy to see that

$$I(u,v)=\int_0^1 x^u\int_0^{\frac{(1-x)}{s}} y^v dydx=\frac{1}{(v+1)s^{v+1}}\int_0^1 x^u(1-x)^{v+1}dx,$$

where $s=\frac{2-\beta}{2}$.

We have

$$\begin{aligned} I(u+1,v)&=\frac{1}{(v+1)s^{v+1}}\int_0^1 x^{u+1}(1-x)^{v+1}dx\\ &=\frac{1}{(v+1)s^{v+1}}\int_0^1 x^u(1-x)^{v+1}(x-1+1)dx\\ &=-\frac{1}{(v+1)s^{v+1}}\int_0^1 x^u(1-x)^{v+2}dx+I(u,v)\\ &=-\frac{v+2}{v+1}sI(u,v+1)+I(u,v). \end{aligned} \tag{2.18}$$

Using integration by parts, we obtain

$$\begin{aligned} I(u,v+1)&=\frac{1}{(v+2)s^{v+2}}\int_0^1 x^u(1-x)^{v+2}dx\\ &=\frac{1}{(v+2)s^{v+2}}\left[\frac{x^{u+1}(1-x)^{v+2}}{u+1}\Big|_0^1-\int_0^1\frac{x^{u+1}}{u+1}(-1)(v+2)(1-x)^{v+1}dx\right]\\ &=\frac{v+1}{(u+1)s}I(u+1,v). \end{aligned} \tag{2.19}$$

Using (2.18) and (2.19), we find

$$I(u+1,v)=\frac{u+1}{u+v+3}I(u,v),\qquad I(u,v+1)=\frac{v+1}{(u+v+3)s}I(u,v). \tag{2.20}$$

It follows from (2.12), (2.17), and (2.20) that

$$\begin{aligned} \nu_2&=-\left[\frac{a-b-1}{b}\frac{I(a-1,b)}{I(a-1,b-1)}+\frac{b-a}{b}\frac{I(a,b)}{I(a,b-1)}\frac{I(a,b-1)}{I(a-1,b-1)}\right]\\ &=-\left[\frac{a-b-1}{(a+b+1)s}+\frac{a(b-a)}{(a+b+1)(a+b+2)s}\right]\\ &=\frac{6\beta}{(4-\beta)(2-\beta)^2}. \end{aligned}$$

The Melnikov theory [11] shows that if

$$\nu=-\frac{2(1-\beta)}{2-\beta}\alpha+\frac{6\beta}{(4-\beta)(2-\beta)^2}\alpha^2+O(\alpha^3), \tag{2.21}$$

then system (2.8) has a heteroclinic cycle. It is shown in [7] that the heteroclinic cycle is stable.

Condition (2.21) is equivalent to

$$\kappa=\beta+\frac{\beta}{2-\beta}\alpha+\frac{6\beta}{(4-\beta)(2-\beta)^2}\alpha^2+O(\alpha^3). \tag{2.22}$$

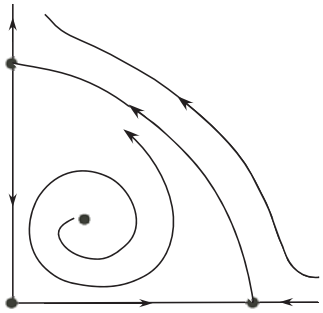

FIG. 2. *Dynamics of system* (2.7) *if the conditions of Lemma* 1 *hold.*

We have obtained the following result.

LEMMA 1. *Assume that* β *is fixed and* $\beta < 1$. *For small* α, *if condition* (2.22) *holds, then system* (2.7) *has a stable heteroclinic cycle connecting saddles at* $(0,0)$, $(\alpha,0)$, *and* $(0, \frac{-(\kappa-\alpha-\beta)}{1-\alpha-\beta})$.

The dynamics of the system in the case that there exists a stable heteroclinic cycle was discussed by Tang and Zhang [20]. For the sake of completeness, we describe the dynamics in this case based on our analytical results. The positive coexistence equilibrium $(\frac{\beta+\alpha\kappa-\kappa}{\kappa}, \frac{\kappa-\beta}{\beta})$ lies inside the heteroclinic cycle. One can check that it is a spiral source. Conditions of Lemma 1 show that for small α

$$\beta < \kappa < \alpha + \beta < 1, \qquad \beta + \alpha\kappa - \kappa > 0, \tag{2.23}$$

which implies that the condition (2.9) in Hsu, Hwang, and Kuang [15] holds. Theorem 2.7 in [15] shows that in this case a limit cycle in the system is always stable and unique once it exists. We therefore conclude that there is no limit cycle inside the heteroclinic cycle since it is attracting. The dynamics of the system in this case is depicted in Figure 2.

Lemma 1 and the transformations used to convert (2.1) to (2.7) imply the following result.

THEOREM 1. *Assume that* β *is fixed and* $\beta < 1$. *If for small* α *condition* (2.22) *holds, then system* (2.1) *has a stable heteroclinic cycle connecting saddles at* $(0,0)$ *and* $(1,0)$.

The conditions of Theorem 1 imply that

$$c - rm - dm > 0, \quad f - r - d < 0, \quad d < f < \frac{cd}{c - rm} \tag{2.24}$$

in the original system (1.1). In view of the properties of the heteroclinic cycle described in Lemma 1, and after Theorem 2.3 and Theorem 2.5 of Xiao and Ruan [22], we see that the heteroclinic cycle in Theorem 1 approaches the origin in the characteristic direction $\theta = \arctan((\kappa - \alpha - \beta)/(\alpha + \beta - 1))$, and the topological structure of the origin consists of a hyperbolic sector and a parabolic sector; see Figure 3.

2.2. Limit cycles near the heteroclinic bifurcation. We have used Melnikov's method to show the persistence of the heteroclinic cycle of the integrable system (2.13) when $\epsilon = 0$ under the perturbation described by (2.22). This method can also be used to study the survival of each periodic cycle in (2.13) under an appropriate perturbation (see section 7.5 of Guckenheimer and Holmes [11] and section 4.7

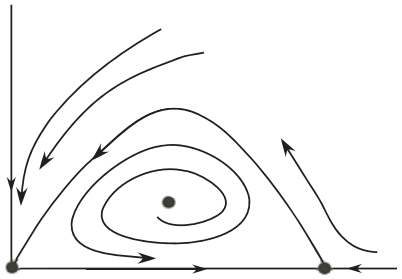

FIG. 3. *Dynamics of system* (2.1) *when a stable heteroclinic cycle exists.*

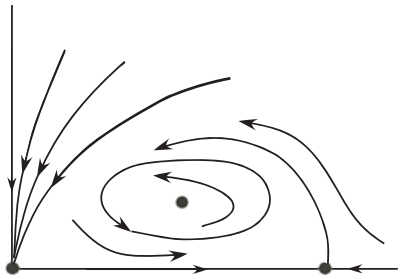

FIG. 4. *Dynamics of system* (2.1) *when* $0 < \nu_2 < \frac{6\beta}{(4-\beta)(2-\beta)^2}$, $\beta < 1$, *and* κ *is given by* (2.25).

of Chow, Li, and Wang [9]). Let Γ_γ be a periodic cycle in Figure 1 that represents the level curves of F_1; then this cycle survives in system (2.1) if

$$\kappa = \beta + \frac{\beta}{2-\beta}\alpha + \nu_2\alpha^2 + O(\alpha^3) \tag{2.25}$$

with

$$\nu_2 = -\frac{\int\int_{\text{int}\Gamma_\gamma} [(a-b-1)x^{a-1}y^b + (b-a)x^a y^b]dxdy}{\int\int_{\text{int}\Gamma_\gamma} bx^{a-1}y^{b-1}dxdy}, \tag{2.26}$$

where $\text{int}\Gamma_\gamma$ denotes the region bounded by Γ_γ. In (2.26), ν_2 represents the solution of $M(\nu_2) = 0$, where $M(\nu_2)$ is given by (2.16) with Γ_0 replaced by Γ_γ. We first study small cycles near the equilibrium. As Γ_γ shrinks to the equilibrium $(\bar{x}, \bar{y}) = (\frac{(1-\beta)\alpha}{2-\beta}, \frac{\alpha}{2-\beta})$, the right-hand side of (2.26) approaches $-\frac{(a-b-1)\bar{x}^{a-1}\bar{y}^b + (b-a)\bar{x}^a\bar{y}^b}{b\bar{x}^{a-1}\bar{y}^{b-1}} = 0 + O(\alpha)$, which shows $\nu_2 = 0$ in (2.25). In this case, standard Hopf bifurcation analysis shows that a supercritical Hopf bifurcation occurs in (2.1). Since (2.25) implies the condition (2.9) in [15], Theorem 2.7 in [15] shows that system (2.1) has at most one limit cycle. Due to this fact and continuity, as Γ_γ moves from a circle near the equilibrium to a circle near the heteroclinic cycle, ν_2 increases from a number near 0 to a number near $\frac{6\beta}{(4-\beta)(2-\beta)^2}$. This shows that as ν_2 increases from 0 to $\frac{6\beta}{(4-\beta)(2-\beta)^2}$, system (2.1) has a unique limit cycle whose size increases from 0 to the size of the heteroclinic cycle.

One can easily check that condition (2.25) and the assumption $\beta < 1$ imply (2.24). Using Theorem 2.3 and Theorem 2.5 of Xiao and Ruan [22] and the properties associated with the heteroclinic cycle discussed above, we depict the dynamics of (2.1) before and after the heteroclinic bifurcation occurs as in Figures 4 and 5.

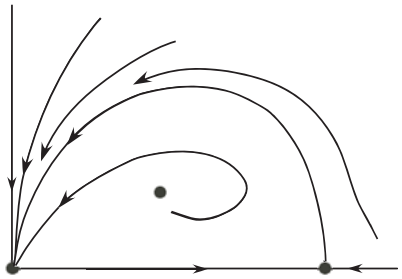

FIG. 5. *Dynamics of system* (2.1) *when* $\nu_2 > \frac{6\beta}{(4-\beta)(2-\beta)^2}$, $\beta < 1$, *and* κ *is given by* (2.25).

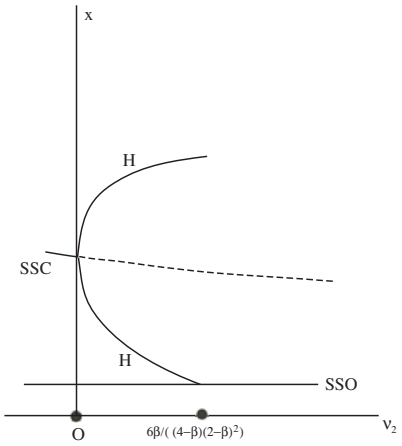

FIG. 6. *Bifurcation diagram of the prey population.*

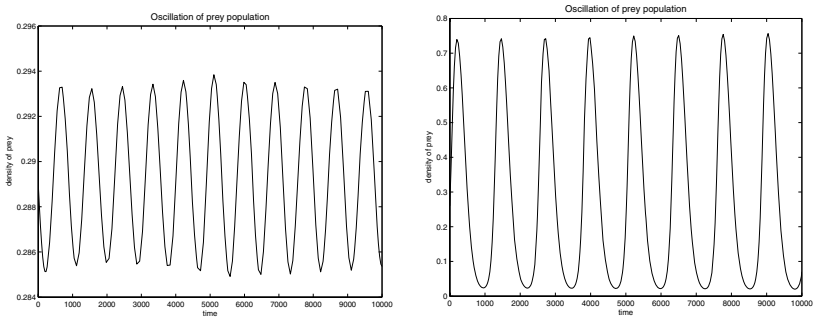
2.3. Interpretation of the theoretical results. Based on the above results, the bifurcation diagram of the prey population x of system (2.1) is depicted in Figure 6. (The bifurcation diagram of the predator population y is similar.) 0 is the first critical value for ν_2 at which the Hopf bifurcation occurs. If ν_2 is slightly less than 0, both prey and predator populations either tend to the origin (solid line labeled SS0), becoming extinct eventually, or tend toward a stable coexistence equilibrium (solid line labeled SSC), depending on the initial values. If ν_2 is greater than 0, both prey and predator populations either tend toward the origin or tend to a limit cycle (solid line labeled H). In this case, the coexistence equilibrium (dashed line) is unstable. The Hopf bifurcation marks a critical condition at which the coexistence equilibrium becomes unstable and the prey and predator populations near the equilibrium starts oscillating periodically. If ν_2 increases from 0 to $\frac{6\beta}{(4-\beta)(2-\beta)^2}$, the amplitude of the oscillating population becomes larger. $\frac{6\beta}{(4-\beta)(2-\beta)^2}$ is the second critical value for ν_2 at which heteroclinic bifurcation occurs. It represents the collision of a large stable limit cycle with the origin. If ν_2 is slightly greater than $\frac{6\beta}{(4-\beta)(2-\beta)^2}$, the limit cycle attractor does not exist anymore, and both prey and predator populations become "unconditionally extinct"; i.e., the origin attracts all solutions (except the coexistence equilibrium solution). Thus starting in the oscillating state, a small increase in ν_2 may lead to a shift to the attractor—the origin. This heteroclinic bifurcation leading to the collapse of large oscillations of populations and extinction of populations is usually



(a) (b)

FIG. 7. *Small and large periodic oscillations of prey population.* (a) $\nu_2 = 0.2$, (b) $\nu_2 = 0.54$.

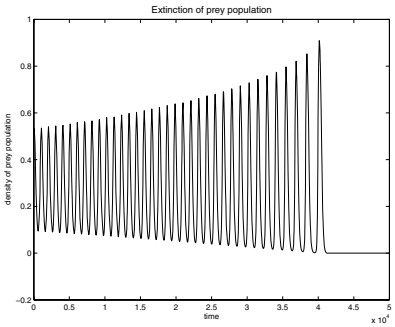


FIG. 8. *Extinction of prey population accompanied with oscillations when* $\nu_2 = 0.56$.

called a "catastrophic bifurcation" (Rinaldi and Scheffer [18]).

We carry out numerical simulations to demonstrate the dynamics of (2.1) described in the bifurcation diagram of Figure 6. We choose $\beta = 0.6$ and $\alpha = 0.02$ (a relatively small number). In this case $\frac{6\beta}{(4-\beta)(2-\beta)^2} = 0.5402$. Figure 7 shows periodic oscillations of the prey population when $\nu_2 = 0.2$ and $\nu_2 = 0.54$. Note that the amplitude of the periodic solution for $\nu_2 = 0.54$ is large, whereas the amplitude of the periodic solution for $\nu_2 = 0.2$ is very small. Figure 8 shows extinction of the population accompanied with oscillations when $\nu_2 = 0.56$, which is slightly greater than the critical value near 0.5402

Recall that α, β, and κ in terms of the parameters in the original system (1.1) are given by

$$\alpha = \frac{rm}{c}, \quad \beta = \frac{dm}{c}, \quad \kappa = \frac{fm}{c}.$$

Our assumption $\beta < 1$ implies $dm < c$. This shows that the capturing rate is relatively large. We fix $\frac{m}{c}$ so that if the prey intrinsic growth rate r is small, then α is small. We rewrite (2.25) in the form that the maximal predator growth rate f is a function of other parameters in (1.1) for small r. The resulting expression can then be used to study the dynamics of (1.1) including the Hopf bifurcation and heteroclinic bifurcation by varying f, based on the dynamics of the equivalent system (2.1). One can see that for relatively large c and f both predator and prey populations become extinct.

3. Concluding remarks. We have rigorously established the existence of a heteroclinic bifurcation and studied the related dynamics for the Michaelis–Menten-type ratio-dependent system by using Melnikov's method. This method is often used to obtain "small" heteroclinic cycles or limit cycles in studying local bifurcations (see Guckenheimer and Holmes [11], Wiggins [21], and Chow, Li, and Wang [9]). The heteroclinic cycle described in Lemma 1 is such a small heteroclinic cycle near the origin. However, the heteroclinic cycle described in Theorem 1 that connects the origin and the equilibrium $(1, 0)$ is not a small one. This is essentially due to the variable change $x \to x/\alpha$ for small α that we have used, which together with other variable changes converts the former heteroclinic cycle into the latter one.

Our results show that near the Hopf bifurcation, depending on the initial conditions, populations of predators and prey either coexist or become extinct. These features have not been described by early prey-dependent predator-prey systems. The heteroclinic bifurcation triggers a shift from the state of periodic coexistence of populations to the state of extinction of both populations, resulting in a "catastrophe" to the predator-prey system.

Rinaldi and Scheffer [18] gave many interesting bifurcation examples in ecological models. They pointed out that a heteroclinic bifurcation is due to the collision of a stable limit cycle and a unstable saddle equilibrium. This is similar to what happens in system (1.1). However, the origin, an unstable point involved in the heteroclinic bifurcation for (1.1), is always an attractor. It is very interesting to note that the heteroclinic bifurcation results in the global attractivity of the origin.

Acknowledgments. We would like to thank the two referees for helpful suggestions for improving the paper. We also want to thank Professor Weinian Zhang for valuable discussions.

LIFT ON SLENDER BODIES WITH ELLIPTICAL CROSS SECTION EVALUATED BY USING AN OSEEN FLOW MODEL*

EDMUND CHADWICK† AND NINA FISHWICK†

Abstract. Consider uniform, incompressible flow past a slender body with an elliptical cross section such that the major axis of the body is inclined slightly to the flow direction. Assume that the flow is inviscid everywhere except in a thin boundary layer region and in the vortex core of trailing line vortices that emanate from the body into the vortex wake. Hence, the flow is quasi-inviscid, and so the slip (impermeability) boundary condition is applied. Further assume that outside the boundary layer the velocity is to first order the uniform stream velocity. Then the Oseen approximation can be applied. The resulting solution, up to the slender body approximation, is given, and the lift over the slender body is determined. This solution is then compared with the theoretical and experimental results for flow past a delta wing, the viscous cross-flow method and experimental results for flow past a body with a circular cross section, and Newtonian impact theory and experimental results for flow past a body with an elliptical cross section.

Key words. oseen flow, slender body theory

1. Introduction. Slender body theories are used to provide efficient and accurate algorithms to important fluid maneuvering applications, in particular in missile guidance [24] and ship maneuverability [23]. The historical development began with Munk [22] to calculate the moment on an airship. Munk used the inviscid flow model, and for the lift on a slender delta wing Jones [15] demonstrated a high degree of agreement with experiment. However, for bodies that do not have trailing edges or wings, there are significant discrepancies in the lift calculation from the inviscid formulation. Newman [23] notes an almost factor two increase in the experimental lift over the theoretical result for the lift on a slender ship.

Allen and Perkins [1] modify the inviscid result for missiles with a circular cross section by including a viscous cross-flow contribution. The lift is obtained by considering the cross-flow drag along the body, and the results agree well with experiment. However, the moment calculation is not as accurate. Fishwick [10] has determined the center of moment for the viscous lift for a comprehensive set of National Advisory Committee for Aeronautics (NACA) experiments on various slender missile shapes with Reynolds number $Re = 10^3 - 10^6$, aspect ratio, and slenderness parameter of order $O(10^{-1})$. All of the subsequent experimental results referred to in this paper are in this range. For flows less than or equal to 4°, Fishwick demonstrates that the viscous force acts at the end section. This result has also been observed by Clarke [9], who divides a variety of ship hulls into sections along the length and then determines the forces on each section. The results show a large viscous lift (on top of the inviscid lift from the pressure distribution) at the end section only. In contrast, the Allen and Perkins method assumes a viscous cross-flow at each section along the body length, and consequently the viscous force acts close to the midsection. Furthermore, the

Allen and Perkins method does not work as well for bodies not having a circular cross section, and modifications to the general theory are required.

Jorgensen modifies the viscous cross-flow method to overcome this deficiency by using Newtonian impact theory [16]. For the case of a body with an elliptical cross section, as the semiminor axis of the body is reduced the lift also reduces relative to a body with a circular cross section. Jorgensen's result gives good first order agreement with experiment, and Jorgensen argues that the reduction in lift determined by this theory is justified from experimental observations relating to the change in the position and therefore the lifting effect of trailing line vortices over the slender body.

Trailing vortices emanating from the leading edge of a delta wing are known to generate uplift at a high angle of attack [27] but not at small angles of attack. However, for slender ships the vortex strength and position of the trailing line vortices along the length of the body have been determined experimentally, and these results were fed into an inviscid flow model [13]. This approach gives good agreement with experiment, but the calculation of the vortex strength and position has been determined experimentally rather than from the theoretical model.

Chadwick [6] considers a slender body in Oseen flow. The theory is applicable to large Reynolds number flows (but aerodynamically low-speed) of around $Re = kL = 10^3 - 10^6$, where $k = \rho U/2\mu$ and $d = L\delta$. (Here, the free stream velocity is given by U; ρ and μ are the fluid density and the dynamical coefficient of viscosity, respectively; a typical cross-sectional length is given by d; L is the body length; and δ is the slenderness parameter.) So near the slender body, viscous forces are negligible, and the flow is very nearly inviscid up to a small thickness boundary layer. This means that the slip/impermeability boundary condition can be applied to the inviscid velocity potential. However, in the far-field downstream wake, viscous forces cannot be neglected. Batchelor [2] states that the effect of viscosity, although small, gives the appropriate leading order solution. To obtain the far-field representation of the trailing vortex, Batchelor [3] retains the viscous component and linearizes about the uniform stream, yielding the Oseen equations. Chadwick [8] determines the line vortex in Oseen flow and demonstrates the importance of the viscous term in the calculation of the lift force. Outside the wake, the velocity is given by the Oseen velocity potential. The near-field inviscid potential and far-field Oseen potential are matched. (It is further noted that the near-field inviscid flow region assumes a small perturbation flow [18] such that the perturbed velocity is much smaller than the uniform stream velocity. This is the Oseen approximation, and so to this level of approximation the near-field inviscid potential is identically the Oseen potential.) In the matching a coupled viscous term arises in the Oseen flow field which provides an additional viscous force. In this way, the additional viscous force contribution of Allen and Perkins is obtained without the requirement of employing a semiempirical procedure. For flow past a slender body with a circular cross section, Chadwick [6] demonstrates that the additional viscous lifting force is equal to, and on top of, the inviscid lifting force from the pressure. This agrees with the experimental findings of Newman [23], Clarke [9], and Allen and Perkins [1]. Applied to the problem of flow past a slender delta wing [7], the theory gives a lifting force the same as that given by the inviscid flow theory and experiment detailed by Jones [15].

In the present paper, we shall apply the slender body theory in Oseen flow presented in [6] for the case of a slender body with an elliptical cross section and in particular derive the formula that determines the lift. This is obtained by representing the body by a far-field distribution of Oseen lifting elements over an area bounded by the focii of each elliptical cross section. The potential velocity part of this distribu-

tion in turn approximates to a near-field inviscid flow distribution of normal dipoles. The two velocity potentials can be matched, and by using elliptical coordinates the slip (impermeability) boundary condition is satisfied. This theory then enables us to determine the lift for a delta wing which is compared with Jones's theory and experimental results, bodies of a circular cross section which is compared with Allen's and Perkins's viscous cross-flow method and experimental results, and bodies of an elliptical cross section which is compared with Jorgensen's Newtonian impact theory and experimental results. The results of the comparisons are then discussed.

2. Statement of the problem. We start with the Navier–Stokes equations [20, p. 577]

$$\rho(\mathbf{u}^\dagger.\nabla)\mathbf{u}^\dagger = -\nabla p^\dagger + \mu\nabla^2\mathbf{u}^\dagger\ , \quad \nabla.\mathbf{u}^\dagger = 0. \tag{2.1}$$

$\mathbf{u}^\dagger$ and $p^\dagger$ are the Navier–Stokes velocity and pressure, respectively. ρ and μ are the fluid density and the dynamical coefficient of viscosity, respectively, and are both assumed to be constant. ∇ denotes the gradient operator and ∇^2 the Laplacian operator.

The Navier–Stokes equations are linearized to a uniform stream U by assuming that

$$\mathbf{u}^\dagger = U\hat{\mathbf{x_1}} + \mathbf{u} + O(U\delta_{Oseen}^2)\ , \quad p^\dagger = p_\infty + p + O(\rho U^2\delta_{Oseen}^2), \tag{2.2}$$

where "O" means "of the order of." The ratio of the perturbed velocity to the uniform stream velocity is given by δ_{Oseen} and is much less than 1: $|\mathbf{u}/U| = O(\delta_{Oseen}) << 1$. $\hat{\mathbf{x_1}}$ is the unit vector in the x_1-direction for the Cartesian coordinates (x_1, x_2, x_3). p_∞ is the far-field pressure upstream from the body and so from Bernoulli's equation is of order $\mathrm{O}(\rho U^2)$. As the value is a constant, it is often taken to be zero. $\mathbf{u}$ and p are the Oseen velocity and pressure, respectively. In the linearization about the parameter δ_{Oseen}, $\mathbf{u}$ is of order $\mathrm{O}(U\delta_{Oseen})$, and p is of order $\mathrm{O}(\rho U^2\delta_{Oseen})$. We note that δ_{Oseen} is independent of the Reynolds number Re, so the linearization does not imply any restrictions on Re [2], [3], [4]. For the lifting problem at a small angle of attack, $\alpha \sim V/U$, where V is the uniform stream in the cross-flow direction. The order for the velocity $\mathbf{u}$ is given by the cross-flow order $\mathrm{O}(V)$, which is $\mathrm{O}(U\alpha)$. So, δ_{Oseen} is given by the angle of attack α, unless $\delta > \alpha$, where δ is the slenderness parameter. In this case, like the nonlifting problem, the order of the perturbed velocity is given by the outflow at a cross section, and so δ_{Oseen} is given by δ. The order of the error in the velocity and pressure using this approximation is then given from (2.2). (We note that this error is much larger than the error associated with that due to the boundary layer thickness for this Reynolds number range, slenderness ratio, and angle of attack range.) This yields the Oseen equations [25, pp. 30–38]

$$\rho U\frac{\partial\mathbf{u}}{\partial x_1} = -\nabla p + (\mu\nabla^2)\mathbf{u}\ , \quad \nabla.\mathbf{u} = 0, \tag{2.3}$$

$$\nabla^2 p = 0. \tag{2.4}$$

As $R = \sqrt{x_1^2 + x_2^2 + x_3^2} \to \infty$, then $\mathbf{u}$, $p \to 0$.

The force on the body is represented by a surface integral enclosing the body [5] such that

$$\mathbf{F}^\dagger = \int\int_S -p^\dagger\mathbf{n} + \mu(\mathbf{n}.\nabla)\mathbf{u}^\dagger - \rho\mathbf{u}^\dagger\mathbf{u}^\dagger.\mathbf{n}\mathrm{d}s. \tag{2.5}$$

$\mathbf{n} = (n_1, n_2, n_3)$ denotes the normal vector to the surface, and $\mathbf{F}^\dagger$ is the force integral in terms of the Navier–Stokes velocity and pressure. Therefore

$$\mathbf{F} = \int\int_S -p\mathbf{n} + \mu(\mathbf{n}.\nabla)\mathbf{u} - \rho U\mathbf{u}n_1 \mathrm{d}s, \tag{2.6}$$

where $\mathbf{F}$ is the force integral in terms of the Oseen velocity and pressure. The singular force solutions are then obtained by decomposing the fluid velocity into a potential velocity and a wake velocity [20], [11], [12], [25] such that

$$\mathbf{u} = \nabla\Phi + \mathbf{w}\ , \quad p = -\rho U\frac{\partial\Phi}{\partial x_1}. \tag{2.7}$$

The wake velocity $\mathbf{w}$ is obtained from the wake velocity potential χ defined separately for the drag and lift Oseenlet in the following sections 2.1 and 2.2, and the two potentials satisfy

$$\nabla^2\Phi = 0\ , \quad \left(\nabla^2 - 2k\frac{\partial}{\partial x_1}\right)\chi = 0. \tag{2.8}$$

2.1. Drag Oseenlet. This gives the unit drag [25], [19], where

$$\mathbf{u^d} = \nabla\phi^d + \nabla\chi^d - 2k\chi^d\mathbf{\hat{x}_1}\ , \quad p^d = -\rho U\frac{\partial\phi^d}{\partial x_1}, \tag{2.9}$$

$$\phi^d = \frac{1}{4\pi\rho U}\frac{\partial}{\partial x_1}\log(R - x_1)\ , \quad \chi^d = -\frac{1}{4\pi\rho U}e^{-k(R-x_1)}\frac{\partial}{\partial x_1}\log(R - x_1). \tag{2.10}$$

2.2. Lift Oseenlet. This gives the unit lift [25], [19], where

$$\mathbf{u^l} = \nabla\phi^l + \nabla\chi^l - 2k\chi^{*l}\mathbf{\hat{x}_2}\ , \quad p^l = -\rho U\frac{\partial\phi^l}{\partial x_1}, \tag{2.11}$$

$$\phi^l = \frac{1}{4\pi\rho U}\frac{\partial}{\partial x_2}\log(R - x_1)\ , \quad \chi^l = -\frac{1}{4\pi\rho U}e^{-k(R-x_1)}\frac{\partial}{\partial x_2}\log(R - x_1) \tag{2.12}$$

and where $\frac{\partial\chi^{*l}}{\partial x_2} = \frac{\partial\chi^l}{\partial x_1}$.

Consider the limit as the Reynolds number tends to infinity, such that outside of the boundary layer there is inviscid flow everywhere except in the core of the viscous wake comprising of trailing line vortices in which the viscous wake velocity term is present and such that the fluid velocity is finite there. Such a wake can be constructed from a distribution of singular lifting solutions over an area A. This results in a distribution of bound and free vortex lines, and the inviscid part is given by the velocity potential for quasi-inviscid flow

$$\phi(x_1, x_2, x_3) = \int\int_A \frac{l(y_1, y_3)}{4\pi\rho U}\frac{\partial}{\partial x_2}\ln(R_{13} - x_{11})\mathrm{d}y_1\mathrm{d}y_3. \tag{2.13}$$

A point in space is given by (x_1, x_2, x_3); a point on the area A is given by (y_1, y_2, y_3); $R_{13} = \sqrt{(x_1 - y_1)^2 + x_2^2 + (x_3 - y_3)^2}$; and $x_{11} = x_1 - y_1$.

The total lift is given by

$$L = \int\int_A l(y_1, y_3)\mathrm{d}y_1\mathrm{d}y_3. \tag{2.14}$$

For a slender body such that $0 \leq x_1 \leq x_e$, we can define a measure of the lift contribution from the singularities up to the station x_1 by

$$\begin{aligned} L(x_1) &= \int_0^{x_1} \int_{y_3} l(y_1, y_3) \mathrm{d}y_3 \mathrm{d}y_1 \\ &= \int_{y_3} l_1(x_1, y_3) \mathrm{d}y_3, \end{aligned} \tag{2.15}$$

where the double integration is such that it is over the area A, and so the total lift is

$$L = L(x_e), \tag{2.16}$$

where x_e is the end section of the body. The slip body boundary condition for inviscid flow is

$$\mathbf{u}.\mathbf{n} = \frac{\partial \Phi}{\partial n} = 0 \tag{2.17}$$

on the body surface, where Φ is the total velocity potential given by

$$\Phi = \phi^{(symm)} + \phi + Ux_1 + Vx_2 \tag{2.18}$$

for a uniform stream velocity $(U, V, 0)$; $\phi^{(symm)}$ is related to terms symmetric about the x_2 axis, and ϕ is related to terms antisymmetric about the x_2 axis. The boundary condition is satisfied by letting

$$\begin{aligned} \nabla \phi^{(symm)}.\mathbf{n} &= -U\mathbf{x_1}.\mathbf{n}, \\ \nabla \phi.\mathbf{n} &= -V\mathbf{x_2}.\mathbf{n}, \end{aligned}$$

where the solution for the potential ϕ, which is related to the lift, is of primary concern.

3. Inviscid flow theory. Inviscid flow theory gives the lift L^p determined from the pressure distribution over the body surface. Assume at each two-dimensional (2-D) cross section the 2-D Laplacian holds for the potential ϕ such that

$$\nabla^2 \phi = 0. \tag{3.1}$$

The boundary condition is then given by

$$\frac{\partial \phi}{\partial n} = -V\mathbf{x_2}.\mathbf{n}. \tag{3.2}$$

Consider a body with an elliptical cross section described by Figure 1. The ellipse is described by $\xi = \xi_0$, where (ξ, η) are the elliptic coordinates

$$\begin{aligned} x_2 &= c \cos \eta \sinh \xi, \\ x_3 &= c \sin \eta \cosh \xi. \end{aligned}$$

In elliptic coordinates, the uniform stream incident potential is then

$$\phi^{inc} = Vy = Vc \cos \eta \sinh \xi, \tag{3.3}$$

and the boundary condition is

$$\left. \frac{\partial \phi^{tot}}{\partial \xi} \right|_{\xi = \xi_0} = 0, \tag{3.4}$$

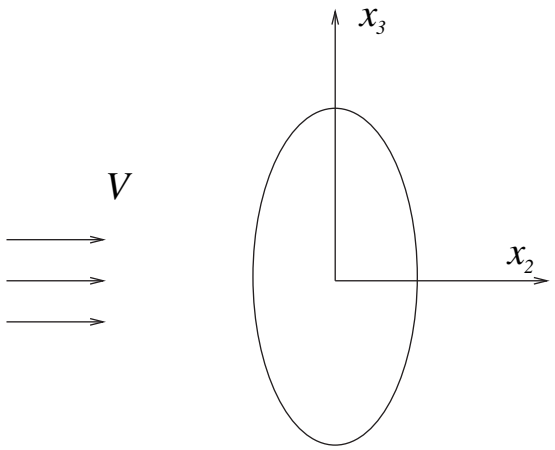

FIG. 1. *Elliptical cross section.*

where $\phi^{tot} = \phi^{inc} + \phi$. The total solution for the velocity potential is the sum of the uniform potential and a perturbation potential that exists due to the presence of the body in the uniform stream. This (perturbation) potential then satisfies

$$\phi = Vc\cos\eta\cosh\xi_0 e^{-(\xi-\xi_0)}. \tag{3.5}$$

3.1. Lift force. The lift force at the station x_1 from the pressure distribution alone, which in general is a different value from the lift measure $L(x_1)$, is given by the integral

$$\begin{aligned} L^p &= -\int\int_{S_B} p\mathbf{n}.\hat{\mathbf{y}}_\mathbf{2}\mathrm{d}S \\ &= \rho U\int_0^{x_e}\int_{ellipse}\frac{\partial\phi}{\partial y_1}\mathbf{n}.\hat{\mathbf{y}}_\mathbf{2}\mathrm{d}q\mathrm{d}y_1, \end{aligned} \tag{3.6}$$

where $\hat{\mathbf{y}}_\mathbf{2}$ is the unit vector in the y_2 direction, $\mathrm{d}q$ is an element of length along the ellipse boundary at this section, $y_1 = x_e$ is the position of the end section, and $\int_{ellipse}$ is the integral along the ellipse closed contour boundary. We then have

$$L^p(y_1) = \rho U\int_{ellipse}\phi\mathbf{n}.\hat{\mathbf{y}}_\mathbf{2}\mathrm{d}q. \tag{3.7}$$

Changing to elliptic coordinates, we have

$$L^p(y_1) = \rho U\int_0^{2\pi} Vc(y_1)\cos\eta\cosh\xi_0 e^{-(\xi-\xi_0)}c\cos\eta\cosh\xi\mathrm{d}\eta\Big|_{\xi=\xi_0}, \tag{3.8}$$

since $\mathbf{n} = (0, \frac{\partial y_2}{\partial\xi}, \frac{\partial y_3}{\partial\xi})/\sqrt{(\frac{\partial y_2}{\partial\xi})^2 + (\frac{\partial y_3}{\partial\xi})^2}$, $\mathrm{d}q = \sqrt{(\frac{\partial y_2}{\partial\eta})^2 + (\frac{\partial y_3}{\partial\eta})^2}\mathrm{d}\eta$, and $(\frac{\partial y_2}{\partial\xi})^2 + (\frac{\partial y_3}{\partial\xi})^2 = (\frac{\partial y_2}{\partial\eta})^2 + (\frac{\partial y_3}{\partial\eta})^2$, where the distance of the two focii of the ellipse from the coordinate origin is c. This gives the standard result

$$L^p(y_1) = \rho UV(\pi s(y_1)^2), \tag{3.9}$$

where $s(y_1)$ is the semispan of the ellipse $s(x_1) = c(x_1)\cosh\xi_0$ and determined using different methods from this one in different contexts by Lighthill [21], Jones [15], and Nielsen [24]. However, this method does not calculate the additional lift due to viscous terms. To determine this, we consider Oseen flow and use matched asymptotics rather than apply the Allen and Perkins method.

4. Lift from Oseen flow slender body theory. By continuing the approximate 2-D near-field flow into the slender body and onto a singular sheet, we can represent the flow by an integral distribution of normal 2-D dipoles; see the appendix. Similarly, by using the slender body approximation, the flow near the same singular sheet can be approximated from the integral representation of lifting elements. This approximation is also given in terms of an integral distribution of normal 2-D dipoles, and in this way the two flows are matched.

First, from Green's integral theorem it can be shown that ϕ can be represented by (see the appendix)

$$\begin{aligned}\phi(x_1,x_2,x_3) &= \int_{-c(x_1)}^{c(x_1)} \frac{f(y_1,y_3)}{2\pi}\frac{\partial}{\partial y_2}\ln r_{23}\mathrm{d}y_3\bigg|_{y_2=0}\\ &= -\int_{-c(x_1)}^{c(x_1)} \frac{f(y_1,y_3)}{2\pi}\frac{x_2}{x_2^2+(x_3-y_3)^2}\mathrm{d}y_3,\end{aligned} \tag{4.1}$$

where $r_{23} = \sqrt{(x_2-y_2)^2+(x_3-y_3)^2}$, $c(x_1)$ is the x_3 position of the focii of the ellipse boundary at section x_1, and $f(x_1,x_3)$ is the dipole strength along the singularity sheet area A. The singular sheet is defined within the above integral limits. Therefore the discontinuity in ϕ across the singular sheet is given by

$$\begin{aligned}\phi(x_1,x_2\to 0_\pm,x_3) &= \lim_{x_2\to 0}\left\{\mp\frac{f(x_1,x_3)}{2\pi}\left[\tan^{-1}\frac{c(x_1)-x_3}{|x_2|}-\tan^{-1}\frac{-c(x_1)-x_3}{|x_2|}\right]\right\}\\ &= \mp\frac{f(x_1,x_3)}{2}\end{aligned} \tag{4.2}$$

for $0\le x_1\le x_e$, $-c(x_1)\le x_3\le c(x_1)$. So $f(x_1,x_3) = \phi(x_1,x_2\to 0_-,x_3)-\phi(x_1,x_2\to 0_+,x_3)$ as shown in (A.9).

4.1. Normal dipole representation of the near-field 2-D flow representation. The near-field 2-D inviscid flow has been obtained in section 3 and is given by the potential (3.5). This potential represents a distribution of singularities along the line between the ellipse focii. Hence, we can continue (analytically in this case) the potential up to this line, replacing the body boundary by a region of fluid. In this way, the type and strength of the singularities that generate this flow can be determined. From the appendix, it is demonstrated that the flow can be represented by a distribution of dipoles normal to the line connecting the ellipse focii. The appendix also enables us to find the strength of the distribution. Continuing the flow into the ellipse such that $\xi\to 0$, then

$$\begin{aligned}\phi &= Vc(x_1)\cos\eta\cosh\xi_0 e^{-(\xi-\xi_0)}\\ &\sim \pm V\sqrt{c(x_1)^2-x_3^2}\cosh\xi_0 e^{\xi_0}\end{aligned} \tag{4.3}$$

since $\xi(x_1,x_2\to 0_\pm)\sim\pm\frac{x_2}{\sqrt{c(x_1)^2-x_3^2}}$. Hence, from (4.2) and (A.9), the strength is given by

$$f(x_1,x_3) = -2V\sqrt{c(x_1)^2-x_3^2}\cosh\xi_0 e^{\xi_0}. \tag{4.4}$$

4.2. Normal dipole representation of the 3-D flow representation. We use the slender body approximation given by Chadwick [6] relating a line distribution of lifting elements to a near-field approximate distribution of normal dipoles. This gives, using (2.13),

$$\begin{aligned}\phi &= \int\int_A \frac{l(y_1,y_3)}{4\pi\rho U}\frac{\partial}{\partial x_2}\ln(R_{13}-x_{11})\mathrm{d}y_1\mathrm{d}y_3 \\ &\sim \int_{-c(x_1)}^{c(x_1)} \frac{l_1(y_1,y_3)}{2\pi\rho U}\frac{x_2}{x_2^2+(x_3-y_3)^2}\mathrm{d}y_3,\end{aligned} \tag{4.5}$$

where $\frac{\partial}{\partial y_1}l_1(y_1,y_3)=l(y_1,y_3)$. Hence

$$f(y_1,y_3) = -\frac{l_1(y_1,y_3)}{\rho U}. \tag{4.6}$$

4.3. Matching the two flows to find the lift force. Matching the two flows gives

$$\frac{l_1(y_1,y_3)}{\rho U} = 2V\sqrt{c(y_1)^2-y_3^2}\cosh\xi_0 e^{\xi_0};$$

therefore,

$$\begin{aligned}L(y_1) &= 2\rho UV\cosh\xi_0 e^{\xi_0}\int_{-c(y_1)}^{c(y_1)}\sqrt{c(y_1)^2-y_3^2}\mathrm{d}y_3 \\ &= \pi\rho UVc(y_1)^2\cosh\xi_0 e^{\xi_0}.\end{aligned} \tag{4.7}$$

Relating the potential ϕ to the Oseen potential then gives $L(y_1)=\int_{-c(y_1)}^{c(y_1)} l_1(y_1,y_3)\mathrm{d}y_3$, which is the lift generated at each section. So,

$$L(y_1) = \pi s(y_1)^2\rho UV\left(\frac{e^{\xi_0}}{\cosh\xi_0}\right), \tag{4.8}$$

where $s(y_1)$ is the semispan of the major axis of the ellipse at station y_1, and so $s(y_1)=c(y_1)\cosh\xi_0$.

Hence, the total lift is given by

$$\begin{aligned}L &= (\pi s_e^2)\rho UV\left(\frac{e^{\xi_0}}{\cosh\xi_0}\right) \\ &= (\pi s_e^2)\rho UV\left(\frac{s_e^{min}+s_e}{s_e}\right),\end{aligned} \tag{4.9}$$

where the end of the slender body is at station y_e, and $s_e = s(y_e)$. s_e^{min} is the semispan of the minor axis of the ellipse at station y_e.

Alternatively, the total lift can be found by considering the end section only, in the following way.

4.4. Alternative calculation for lift at the end section. We follow the method given in [6] to find a general formula for the lift of a slender body with an elliptical cross section.

In the far field, the elliptic coordinates tend to $\eta \sim \theta$ and $e^{-\xi} \sim \frac{c}{2r}$ according to Batchelor [4, p. 465].

Hence, the potential at the end section becomes

$$\begin{aligned}\phi &= Vc(x_1)\cos\eta\cosh\xi_0 e^{-(\xi-\xi_0)}\Big|_{x_1=x_e} \\ &\sim \left(\frac{\cos\theta}{r}\right)\left(\frac{1}{2}c(x_1)^2 V\cosh\xi_0 e^{\xi_0}\right)\Big|_{x_1=x_e}. \end{aligned} \tag{4.10}$$

Using [6, equation (4.3)], the lift is then given by

$$\begin{aligned} L &= \pi\rho UVc(x_1)^2\cosh\xi_0 e^{\xi_0}\big|_{x_1=x_e} \\ &= (\pi s(x_1)^2)\,\rho UV\left(\frac{e^{\xi_0}}{\cosh\xi_0}\right)\Big|_{x_1=x_e} \\ &= (\pi s_e^2)\rho UV\left(\frac{s_e^{min}+s_e}{s_e}\right). \end{aligned} \tag{4.11}$$

Therefore, the lift on the body L is not given by the lift calculation over the slender body surface $L^p(x_e)$ calculated from the surface pressure. This is because, in order to find the total lift, the contribution from the viscous term must also be included in the lift calculation.

5. Lift on a delta wing. For a delta wing, with rounded leading edges such that flow separation is avoided, the lift over its surface between the ends is given by

$$L^p = (\pi s_e^2)\rho UV. \tag{5.1}$$

The Oseen lift on the body is given by

$$L = (\pi s_e^2)\rho UV. \tag{5.2}$$

Hence the two lift evaluations agree with each other and also with the lift expression given by Jones [15], who then verifies it by experiment.

6. Lift on a slender body with a circular cross section. The lift from inviscid flow theory due to pressure over the surface of a body with a circular cross section between the ends is given by

$$L^p = (\pi s_e^2)\rho UV. \tag{6.1}$$

This is in contrast to the lift on the body due to the Oseen theory, which is given by

$$L = 2(\pi s_e^2)\rho UV. \tag{6.2}$$

So there is a doubling of the lift force due to the viscous terms within the Oseen representation. This is similar to the motivation of the viscous cross-flow method of Allen and Perkins [1], who assume an additional contribution to the lift from viscous forces. However, they determine this from empirical data related to cross-flow drag past a circular cylinder applied at each body section. In Figure 2, we compare the Oseen theory with the viscous cross-flow method of Allen and Perkins against the two experiments given in their report. We see that both theories give good first order approximations to the experiments, unlike the inviscid lift calculation from the pressure field. Small angles only have been taken because a linear variation in the angle of attack is assumed. Many other NACA reports give similar results, and these are detailed in [10]. However, Figure 3 shows that, for a less conventional missile profile, results were obtained by Jack [14] which show that the Allen-Perkins method compares far less favorably.

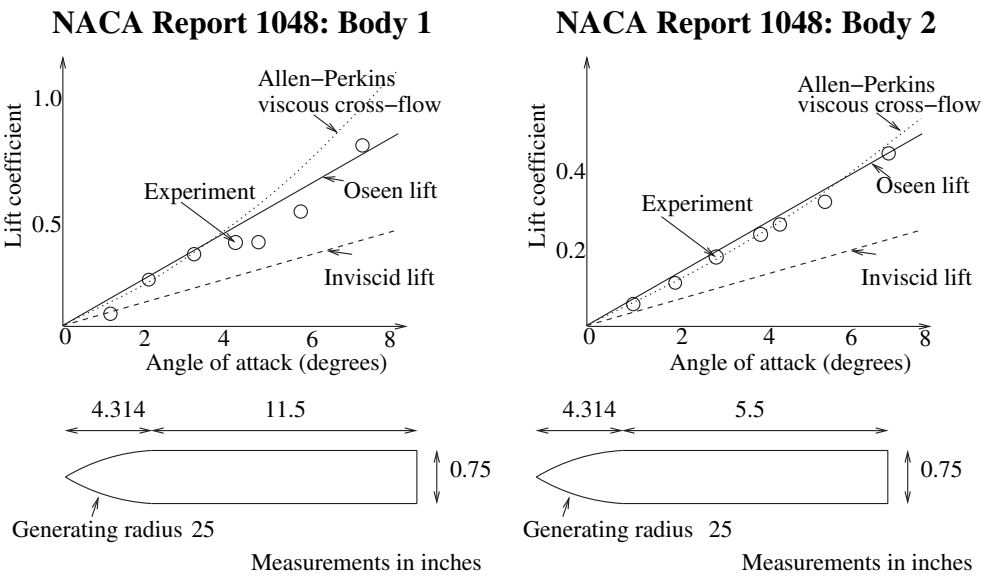

FIG. 2. *Lift of slender bodies with a circular cross section.*

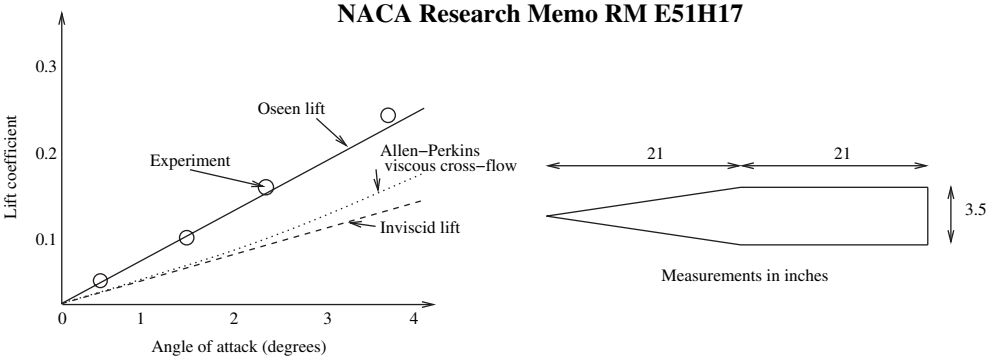

FIG. 3. *Lift of slender bodies with a circular cross section.*

7. Comparison with experiment and other theories for slender bodies with an elliptical cross section. Consider a slender body of an elliptical cross section with a fixed ellipticity. In Figure 4, we plot on the y-axis the ratio of the lift coefficient with the lift coefficent of an equivalent slender body with a circular cross section such that the semimajor axis b equals the circular cylinder radius r. On the x-axis we plot the ellipticity given by the ratio of the semiminor axis to the semimajor axis a/b. A variety of such slender bodies with varying ellipticity from 0 to 1 is considered. For an ellipticity of 0, the slender body is a slender wing, and the result of Jones [15] applies. The horizontal inviscid lift line also goes through this point, since Lighthill's result [21] states that the inviscid lift is dependent upon the maximum span of the slender body only; for slender bodies with an elliptical cross section, this result is also given by (3.9). The Oseen lift line is also plotted in the figure from the result of (4.9). We see that, for a slender body with a circular cross section, the total lift is twice that for a slender wing with the same maximum span. Also plotted in the figure

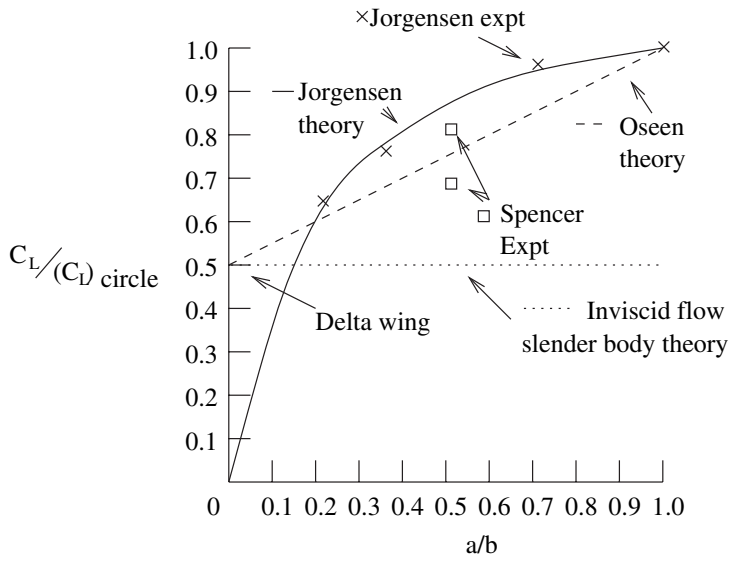

FIG. 4. *Ratio of lift coefficient to lift coefficient of a circular cross section slender body plotted against ellipticity.*

are the expected results from Jorgensen's Newtonian impact theory [16]. In [17], Jorgensen gives the percentage reduction from the viscous cross-flow method of Allen and Perkins (which is applied to a slender body with a circular cross section) for a slender body with a particular ellipticity. Jorgensen's theoretical results match well with his experimental results and better than the Oseen theory presented here. However, consider two experimental results denoted by squares plotted in the figure given by Sigal [26] quoting the results of Spencer and Phillips [28]. Sigal gives the percentage reduction in lift force evaluated from experiment for a slender body with an elliptical cross section compared to a slender body with a circular cross section having the same span. Two results for ellipticity 0.5 but with different fineness ratio are plotted, and the Oseen theory fits these experimental results better than Jorgensen's theory.

8. Discussion. The slender body theory in Oseen flow given by Chadwick [6] is applied to bodies with an elliptical cross section and compared with various other theories and methods and with experimental results. In particular, the lift on a slender body with an elliptical cross section is given in Oseen flow by representing the flow field by a distribution of lift Oseenlets between the focii of the ellipse at each cross section. The potential part of this solution is then matched to the expected two-dimensional near-field solution given in elliptic coordinates such that the slip (impermeability) boundary condition is satisfied. This lift formula is compared against other theories and experiment, such as Jones's results for a delta wing [15], the Allen and Perkins viscous cross-flow method [1], and Jorgensen's Newtonian impact theory [16]. For a delta wing with zero ellipticity, the Oseen theory predicts that the additional viscous force is zero and so reduces to the standard inviscid result given by Jones [15]. In contrast, the viscous cross-flow method of Jorgensen cannot be applied to this problem and gives zero total force (see Figure 4). The moment depends upon the distribution of lift, and the experimental results suggest that the additional viscous lift force (over and above the lift force from inviscid potential flow theory) is distributed towards the

rear of the slender body rather than close to the middle as predicted by the Allen and Perkins viscous cross-flow method. So, for the moment calculation at angles at or below 4°, the experimental results agree better with the Oseen flow method. These results are detailed extensively by Fishwick [10].

Appendix A. We start with Green's integral theorem for 2-D potential flow in the $x_2 - x_3$ plane, which defines the flow as an integral distribution of sources and dipoles over a closed contour C_y such that

$$\phi(x_2, x_3) = -\frac{1}{2\pi} \int_{C_y} \left(\phi(y_2, y_3) \frac{\partial}{\partial n} \ln r_{23} - \frac{\partial}{\partial n} \phi(y_2, y_3) \ln r_{23} \right) \mathrm{d}y_C, \tag{A.1}$$

where (x_2, x_3) is a point in the fluid, (y_2, y_3) is a point on the contour, a length element along the contour C_y is given by $\mathrm{d}y_C$, and $r_{23} = \{(x_2 - y_2)^2 + (x_3 - y_3)^2\}^{1/2}$. Consider ϕ such that it can be continued onto the line $x_3 = 0$, $-c \le x_2 \le c$. Let the closed contour C include the two lines $y_3 = \delta$, $-c \le y_2 \le c$ and $y_3 = -\delta$, $-c \le y_2 \le c$ and also include the two semicircular arcs $r_\delta^- = \delta$, $0 \le \theta^- \le \pi$, $y_2 + c = r_\delta^- \cos\theta^-$, $y_3 = r_\delta^- \sin\theta^-$ and $r_\delta^+ = \delta$, $-\pi \le \theta^+ \le 0$, $y_2 - c = r_\delta^+ \cos\theta^+$, $y_3 = r_\delta^+ \sin\theta^+$.

We go around the contour in the clockwise sense, and the contour is described pictorially in Figure 5. Letting $\delta \to 0$, we then get the expression for ϕ:

$$\begin{aligned} \phi = &-\frac{1}{2\pi} \int_{-c}^{c} \left\{ (\phi^+ - \phi^-) \frac{\partial}{\partial y_2} \ln r_{23} - \left(\frac{\partial}{\partial y_2} \phi^+ - \frac{\partial}{\partial y_2} \phi^- \right) \ln r_{23} \right\} \mathrm{d}y_3 \\ &+ I^+ + I^-, \end{aligned} \tag{A.2}$$

where $\phi^\pm = \lim_{y \to 0^\pm} \phi$ and $\frac{\partial \phi^\pm}{\partial y_2} = \lim_{y \to 0^\pm} \frac{\partial \phi}{\partial y_2}$ are assumed to exist, and

$$\begin{aligned} I^+ &= \lim_{r_\delta^+ \to 0} \left\{ \frac{1}{2\pi} \int_0^{\pi} \left(\phi \frac{\partial}{\partial r_\delta^+} \ln r_{23} - \ln r_{23} \frac{\partial}{\partial r_\delta^+} \phi \right) r_\delta^+ \mathrm{d}\theta^+ \right\}, \\ I^- &= \lim_{r_\delta^- \to 0} \left\{ \frac{1}{2\pi} \int_0^{-\pi} \left(\phi \frac{\partial}{\partial r_\delta^-} \ln r_{23} - \ln r_{23} \frac{\partial}{\partial r_\delta^-} \phi \right) r_\delta^- \mathrm{d}\theta^- \right\}. \end{aligned} \tag{A.3}$$

In particular, consider the solution (3.5) $\phi = A \cos\eta e^{-\xi}$, where $A = Vc \cosh\xi_0 e^{\xi_0}$. Then $\phi^\pm$ and $\frac{\partial \phi^\pm}{\partial y_2}$ exist. Furthermore, $\frac{\partial \phi^+}{\partial y_2} = \frac{\partial \phi^-}{\partial y_2}$.

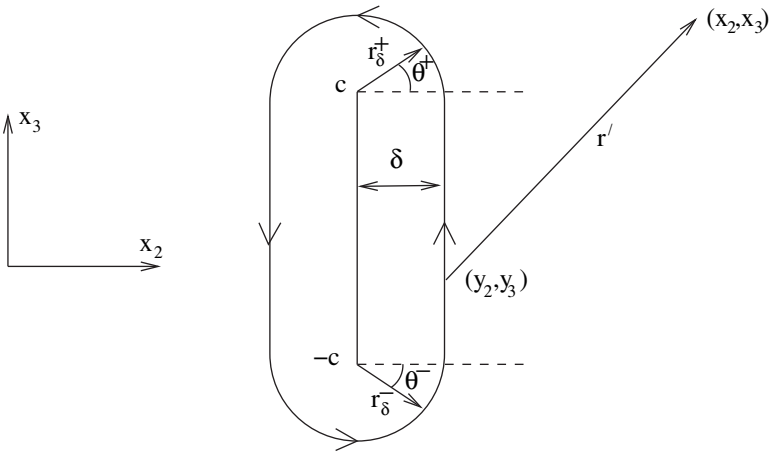

FIG. 5. *The closed contour C.*

We will now show that the integrals $I^{\pm}$ are zero. Consider the first terms in the integral expressions given for $I^{\pm}$. The first factor in the term is ϕ. In the limit as $r_{\delta}^{\pm} \to 0$, $\xi \to 0$ and $\eta \to \pm\pi/2$. So,

$$\lim_{r_{\delta}^{\pm} \to 0} \phi = 0. \tag{A.4}$$

The second factor in the first term is $\frac{\partial \ln r_{23}}{\partial r_{\delta\pm}}$. This is

$$\begin{aligned} \frac{\partial \ln r_{23}}{\partial r_{\delta\pm}} &= \frac{1}{r_{23}} \frac{\partial r_{23}}{\partial r_{\delta\pm}} = \frac{1}{r_{23}} \left\{ \frac{\partial y_2}{\partial r_{\delta\pm}} \frac{\partial r_{23}}{\partial y_2} + \frac{\partial y_3}{\partial r_{\delta\pm}} \frac{\partial r_{23}}{\partial y_3} \right\} \\ &= O(1/r_{23}). \end{aligned} \tag{A.5}$$

So the first term in the integrands of the integral expressions for $I^{\pm}$ give integral contributions $O(|\phi| r_{\delta}^{\pm}/r_{23})$, and in the limit as $r_{\delta}^{\pm} \to 0$, these tend to zero.

The first factor in the second term of the integrand of $I^{\pm}$ is $\frac{\partial \phi}{\partial r_{\delta}^{\pm}}$. We find the order of magnitude of this term by considering

$$\left| \frac{\partial \phi}{\partial r_{\delta\pm}} \right| \leq \left| \frac{\partial \phi}{\partial \xi} \right| \left| \frac{\partial \xi}{\partial r_{\delta\pm}} \right| + \left| \frac{\partial \phi}{\partial \eta} \right| \left| \frac{\partial \eta}{\partial r_{\delta\pm}} \right| \tag{A.6}$$

as $r_{\delta}^{\pm} \to 0$. Similarly,

$$\begin{aligned} \left| \frac{\partial \xi}{\partial r_{\delta\pm}} \right| &\leq \left| \frac{\partial \xi}{\partial y_2} \frac{\partial y_2}{\partial r_{\delta\pm}} \right| + \left| \frac{\partial \xi}{\partial y_3} \frac{\partial y_3}{\partial r_{\delta\pm}} \right| \\ &\leq \frac{1}{c} \end{aligned} \tag{A.7}$$

since $\frac{\partial \xi}{\partial y_2} \sim \frac{1}{c}$, $\frac{\partial \xi}{\partial y_3} \sim 0$, $\frac{\partial \eta}{\partial y_2} \sim 0$, and $\frac{\partial \eta}{\partial y_3} \sim \frac{1}{c}$ as $r_{\delta}^{\pm} \to 0$. Furthermore, $\frac{\partial \phi}{\partial \xi} \sim A$ and $\frac{\partial \phi}{\partial \eta} \sim 0$ as $r_{\delta}^{\pm} \to 0$, since $\phi = A \cos \eta e^{-\xi}$. So the second term in the integrands of $I^{\pm}$ gives the integral contributions of order $O(A|\ln r_{23}| r_{\delta}^{\pm}/c)$. So as $r_{\delta}^{\pm} \to 0$, then the integral contributions tend to zero. Hence in the limit $I^{+} = I^{-} = 0$. So

$$\phi = -\frac{1}{2\pi} \int_{-c}^{c} \left\{ (\phi^{+} - \phi^{-}) \frac{\partial}{\partial y_2} \ln r_{23} - \left(\frac{\partial}{\partial y_2} \phi^{+} - \frac{\partial}{\partial y_2} \phi^{-} \right) \ln r_{23} \right\} \mathrm{d}y_3. \tag{A.8}$$

From the symmetry of the problem, $\frac{\partial \phi^{+}}{\partial y_2} = \frac{\partial \phi^{-}}{\partial y_2}$, and so

$$\phi = -\frac{1}{2\pi} \int_{-c}^{c} \left\{ (\phi^{+} - \phi^{-}) \frac{\partial}{\partial y_2} \ln r_{23} \right\} \mathrm{d}y_3. \tag{A.9}$$

STATIONARY PATTERN OF A RATIO-DEPENDENT FOOD CHAIN MODEL WITH DIFFUSION*

RUI PENG†, JUNPING SHI‡, AND MINGXIN WANG§

Abstract. In the paper, we investigate a three-species food chain model with diffusion and ratio-dependent predation functional response. We mainly focus on the coexistence of the three species. For this coupled reaction-diffusion system, we study the persistent property of the solution, the stability of the constant positive steady state solution, and the existence and nonexistence of nonconstant positive steady state solutions. Both the general stationary pattern and Turing pattern are observed as a result of diffusion. Our results also exhibit some interesting effects of diffusion and functional responses on pattern formation.

Key words. food chain model, diffusion, ratio-dependent functional response, stationary pattern, Turing pattern, steady state solution

1. Introduction.

Understanding of spatial and temporal behaviors of interacting species in ecological systems is a central issue in population ecology. One aspect of great interest for a model with multispecies interactions is whether the involved species can persist or even stabilize at a coexistence steady state. In the case where the species are homogeneously distributed, this would be indicated by a constant positive solution of an ordinary differential equation (ODE) system. In the spatially inhomogeneous case, the existence of a nonconstant time-independent positive solution, also called stationary pattern, is an indication of the richness of the corresponding partial differential equation (PDE) dynamics. In recent years, stationary pattern induced by diffusion has been studied extensively, and many important phenomena have been observed.

In particular, starting with Turing's seminal 1952 paper [34], diffusion has been regarded as the driving force of the spontaneous emergence of spatiotemporal structure in a variety of nonequilibrium situations. To verify the influence of diffusion on this aspect, in the past decades, biologists and applied mathematicians have proposed a number of models, and much work has been devoted to the investigation of the existence of stationary pattern in chemical and biological dynamics theoretically as well as numerically. For example, chemical models include the activator-inhibitor Gierer–Meinhardt model [10, 23], the Sel'kov model [7, 35], the Gray–Scott model [32, 37], the Brusselator model [3, 30], the Noyes–Field model for Belousov–Zhabotinskii

reaction [29], and the chemotactic diffusion model [4, 18, 19, 22, 24, 37], and biological models include the competition model [14, 20] and the predator-prey model [8, 15, 16, 27, 28, 31, 36] (see also the references therein).

In his original paper [34], Turing proposed the notion of diffusion-driven instability (also called Turing instability) in his attempt at modeling, among other things, the regeneration phenomenon of hydra—one of the earliest examples of morphogenesis. That is, Turing claimed that the formation of spatial pattern during morphogenesis could be explained in terms of the instability of a homogeneous steady state solution to a reaction-diffusion network describing the growth and movement of a set of morphogens. Turing's original work was primarily concerned with the stability analysis of the uniform steady state solution of the system for the interacting morphogens.

In biology and chemistry, the more interesting question, however, is whether the spatially inhomogeneous solution may be generated by such instability. Strikingly, in some cases, Turing instability can indeed lead to stationary pattern (also called Turing pattern), a fascinating phenomenon in nonlinear science, which has been found in various mechanisms [4, 18, 26, 27, 28, 30, 35, 36, 37]. While linear stability analysis of the homogeneous steady state is a straightforward method for calculating conditions for the onset of Turing instability, the analysis of the existence of resulting nonhomogeneous steady states is mathematically challenging. In this paper, it is the question of the existence of nonhomogeneous steady states that we focus on.

In the present work, we will investigate a coupled reaction-diffusion food chain model with ratio-dependent functional response and analyze the coexistence of the three species. We attempt to further understand the influences of diffusion and functional responses on pattern formation. As a consequence, the existence and nonexistence results for nonconstant positive steady state solutions to this system indicate that stationary pattern arises as the diffusion coefficients enter into certain regions. In other words, diffusion does help to create stationary pattern. For this model, we also show that Turing instability occurs and prove the generation of Turing pattern in some cases.

On the other hand, our results also demonstrate that diffusion and functional response can become determining factors in the formation of pattern. Although our model is very different from the one considered by Lou, Martinez, and Ni in [20], their interesting observation that the introduction of a new species may qualitatively change the pattern structure of the original system is again present in our study. At the same time, our work corroborates recent numerical results implemented by Alonso, Bartumeus, and Catalan in [2]. We refer the reader to more detailed discussions in section 6.

Our paper is organized as follows. In section 2, we propose our mathematical model. In section 3, we discuss the persistence and stability of the unique constant positive steady state for the ODE and PDE systems. In section 4, we consider the nonexistence of nonconstant positive steady state solutions, while section 5 is devoted to the existence of nonconstant positive steady state solutions. In section 6, from the biological viewpoint we make some comments on our studies, indicating some interesting influences of diffusion and functional responses on pattern formation. Finally, in the appendix, we analyze some conditions, which are imposed in section 5 to obtain the nonconstant positive steady state solutions to the PDE system.

2. The derivation of the mathematical model. Numerous examples from biological control indicate that the classical prey-dependent predator-prey model is often contrary to actual observations, such as the well-known paradox of enrichment formulated by Rosenzweig [33]. The theory of Rosenzweig states that enriching a

predator-prey system (increasing the prey's carrying capacity) will cause an increase in the equilibrium density of the predator but not in that of the prey; it will destabilize the positive equilibrium as the prey's carrying capacity increases, and thus will increase the possibility of stochastic extinction of the predator. Recently there is growing evidence that in some situations, especially when predators have to search, share, and compete for food, a more suitable general predator-prey model should be a so-called ratio-dependent one (namely, the functional responses are ratio-dependent). Roughly speaking, this model states that the per capita predator growth rate should be a function of the ratio of prey to predator abundance (see, e.g., [1]).

In the case of multiple species interaction, the prey-dependent models such as those studied in [5, 9, 11, 17], while mathematically interesting, inherit the mechanism that generates the factitious paradox of enrichment and fail to produce the often observed extinction dynamics resulting in the collapse of the system. Consequently, a ratio-dependent food chain model, which is an ODE system with three equations whose species are hence assumed to be spatially homogeneous, was proposed by Hsu, Hwang, and Kuang in [13] to describe the growth of plant, pest, and top predator.

More precisely, the authors of [13] considered the following three–trophic-level food chain system with ratio-dependent functional response:

$$\begin{cases} \dfrac{\mathrm{d}u_1}{\mathrm{d}t} = ru_1\left(1-\dfrac{u_1}{k}\right) - \dfrac{1}{\eta_1}\dfrac{m_1u_1u_2}{u_1+c_1u_2}, & t>0,\\ \dfrac{\mathrm{d}u_2}{\mathrm{d}t} = \dfrac{m_1u_1u_2}{u_1+c_1u_2} - b_1u_2 - \dfrac{1}{\eta_2}\dfrac{m_2u_2u_3}{u_2+c_2u_3}, & t>0,\\ \dfrac{\mathrm{d}u_3}{\mathrm{d}t} = \dfrac{m_2u_2u_3}{u_2+c_2u_3} - b_2u_3, & t>0,\\ u_1(0)>0, \quad u_2(0)>0, \quad u_3(0)>0, \end{cases} \tag{2.1}$$

where u_i $(i=1,2,3)$ are the respective population densities of prey, predator, and top predator. For $i=1,2$, η_i, m_i, c_i, and b_i represent the yield constants, maximal predator growth rates, half-saturation constants, and predator's death rates, respectively. Constants r and k are the prey intrinsic growth rate and carrying capacity, respectively. As observed in [13], u_3 preys on u_2 and only on u_2, and u_2 preys on u_1 and nutrient recycling is not accounted for, which produces the so-called simple food chain. A distinct feature of the simple food chain is the domino effect: if one species dies out, all the species at higher trophic levels die out as well.

As in [13], for simplicity, we use the following scaling to (2.1):

$$\begin{array}{cccc} t\to rt, & u_1\to u_1/k, & u_2\to c_1u_2/k, & u_3\to c_1c_2u_3/k,\\ m_1\to m_1/r, & b_1\to b_1/r, & m_2\to m_2/r, & b_2\to b_2/r, \end{array}$$

and (2.1) becomes the form

$$\begin{cases} \dfrac{\mathrm{d}u_1}{\mathrm{d}t} = u_1\left(1-u_1\right) - \dfrac{a_1u_1u_2}{u_1+u_2}, & t>0,\\ \dfrac{\mathrm{d}u_2}{\mathrm{d}t} = \dfrac{m_1u_1u_2}{u_1+u_2} - b_1u_2 - \dfrac{a_2u_2u_3}{u_2+u_3}, & t>0,\\ \dfrac{\mathrm{d}u_3}{\mathrm{d}t} = \dfrac{m_2u_2u_3}{u_2+u_3} - b_2u_3, & t>0,\\ u_1(0)>0, \quad u_2(0)>0, \quad u_3(0)>0, \end{cases} \tag{2.2}$$

where $a_i = m_i/(\eta_i c_i r)$ $(i = 1, 2)$, can be regarded as the respective predation rate of u_2 and u_3.

From [13], it is easily shown that (2.2) has a unique positive steady state solution if and only if the following are satisfied:

$$m_2 > b_2, \quad A > 1 \quad \text{and} \quad 0 < a_1 < A/(A-1), \tag{2.3}$$

where

$$A \equiv m_1/(a_2(m_2 - b_2)/m_2 + b_1).$$

Moreover, the unique positive steady state $(u_1, u_2, u_3) = (\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$ can be expressed as

$$\tilde{u}_1 = [a_1 + A(1 - a_1)]/A, \quad \tilde{u}_2 = (A-1)\tilde{u}_1, \quad \text{and} \quad \tilde{u}_3 = (m_2 - b_2)\tilde{u}_2/b_2.$$

We also note that $m_2 > b_2$ and $A > 1$ imply $m_1 > b_1$.

In [13], the authors dealt with (2.2). In particular, they obtained the extinction conditions of certain species and discussed the local asymptotical stability of $(\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$ and various scenarios where distinct solutions can be attracted to the origin, the pest-free steady state, and the positive steady state $(\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$. For more detail, we refer the reader to [13]. From their results, the authors pointed out that this ODE system is very rich in dynamics.

To take into account the inhomogeneous distribution of the predators and the prey in different spatial locations within a fixed bounded domain Ω in $\mathbf{R}^N$ with smooth boundary at any given time, and the natural tendency of each species to diffuse to a smaller population concentration, instead of (2.2), we need to consider the following reaction-diffusion (PDE) system:

$$\begin{cases} u_{1t} - d_1\Delta u_1 = u_1(1 - u_1) - \dfrac{a_1 u_1 u_2}{u_1 + u_2} & \text{in } \Omega \times (0, \infty), \\ u_{2t} - d_2\Delta u_2 = \dfrac{m_1 u_1 u_2}{u_1 + u_2} - b_1 u_2 - \dfrac{a_2 u_2 u_3}{u_2 + u_3} & \text{in } \Omega \times (0, \infty), \\ u_{3t} - d_3\Delta u_3 = \dfrac{m_2 u_2 u_3}{u_2 + u_3} - b_2 u_3 & \text{in } \Omega \times (0, \infty), \\ \partial_\nu u_i = 0, \quad i = 1,\ 2,\ 3, & \text{on } \partial\Omega \times (0, \infty), \\ u_i(x, 0) = u_{i0}(x) \geq 0, \not\equiv 0,\ i = 1, 2, 3, & \text{in } \Omega. \end{cases} \tag{2.4}$$

Here ν is the outward unit normal vector on the boundary $\partial\Omega$ and $\partial_\nu = \partial/\partial\nu$, and d_i $(i = 1, 2, 3)$ are called the diffusion coefficients of the corresponding species u_i and hence are assumed to be positive constants. The initial data u_{i0} $(i = 1, 2, 3)$ are continuous functions, and the homogeneous Neumann boundary condition means that model (2.4) is self-contained and has no population flux across the boundary $\partial\Omega$.

In our work here, we are mainly concerned with the effect of diffusion on stationary pattern generated by (2.4). Hence, this leads us to study the steady state problem of

(2.4), which satisfies

$$
(2.5)\qquad \begin{cases} -d_1\Delta u_1 = u_1(1-u_1) - \dfrac{a_1u_1u_2}{u_1+u_2} & \text{in } \Omega,\\ -d_2\Delta u_2 = \dfrac{m_1u_1u_2}{u_1+u_2} - b_1u_2 - \dfrac{a_2u_2u_3}{u_2+u_3} & \text{in } \Omega,\\ -d_3\Delta u_3 = \dfrac{m_2u_2u_3}{u_2+u_3} - b_2u_3 & \text{in } \Omega,\\ \partial_\nu u_i = 0,\ i=1,2,3, & \text{on } \partial\Omega. \end{cases}
$$

It is evident that only nonnegative solutions of (2.5) are of real interest. The positive solution (u_1, u_2, u_3) of (2.5) to be mentioned throughout this paper always refers to a classical solution with $u_i > 0$ $(i = 1, 2, 3)$ on $\bar{\Omega}$. It should also be noted that the well-known maximum principle ensures that a nonnegative classical solution of (2.5) with $u_i \not\equiv 0$ $(i = 1, 2, 3)$ must be a positive one.

For (2.4) and the steady state problem (2.5), we will mainly concentrate on the coexistence of the three species and consider the case of $a_1 < 1$. In particular, some results for the existence and nonexistence of nonconstant positive solutions to (2.5) are derived. In establishing the existence of nonconstant positive solutions, due to the lack of variational structure for (2.5), our mathematical tool is the topology degree theory incorporated with the calculation of the fixed point index.

3. Persistence and stability. For simplicity of presentation, we introduce some notation. Throughout this section, let

$$
\mathbf{u}(t) = (u_1(t), u_2(t), u_3(t))^T \quad \text{and} \quad \mathbf{u}(x,t) = (u_1(x,t), u_2(x,t), u_3(x,t))^T
$$

be the respective solutions of (2.2) and (2.4). Denote $\mathbf{u} = (u_1, u_2, u_3)^T$, $\tilde{\mathbf{u}} = (\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)^T$. From classical theories of ODEs and parabolic equations, $\mathbf{u}(t)$ and $\mathbf{u}(x,t)$ exist globally and are positive; namely, $u_i(t),\ u_i(x,t) > 0$ $(i = 1, 2, 3)$ for all $t > 0$ and $x \in \bar{\Omega}$.

First we state some simple facts about the asymptotical behavior of solutions to (2.4). The proof is similar to that of Theorem 2.5 in [28] and so is omitted here.

PROPOSITION 3.1. *The solution* $(u_1(x,t), u_2(x,t), u_3(x,t))$ *of* (2.4) *satisfies the following:*

(i) *If* $m_1 \le b_1$, *then* $(u_2(x,t), u_3(x,t)) \to (0,0)$ *uniformly on* $\bar{\Omega}$ *as* $t \to \infty$.

(ii) *If* $m_2 \le b_2$, *then* $u_3(x,t) \to 0$ *uniformly on* $\bar{\Omega}$ *as* $t \to \infty$.

(iii) *If* $a_1 \le 1$ *and* $m_1 \le b_1$, *then* $u_1(x,t) \to 1$ *and* $(u_2(x,t), u_3(x,t)) \to (0,0)$ *uniformly on* $\bar{\Omega}$ *as* $t \to \infty$. *As a consequence, if* $m_1 \le b_1$ *or* $m_2 \le b_2$, *problem* (2.5) *has no positive solutions.*

As shown in Proposition 3.1, if $m_1 \le b_1$ or $m_2 \le b_2$, the two predators or the top predator will become extinct, respectively. Moreover, if $a_1 \le 1$ and $m_1 \le b_1$, then only the plant will exist eventually.

In this paper, since our main goal is to analyze the coexistence of the three species, from now on, unless otherwise specified, it is always assumed that $(\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$ exists, which implies that $m_1 > b_1$ and $m_2 > b_2$ as indicated in section 2.

We have the following basic persistence property of the solutions $\mathbf{u}(t)$ and $\mathbf{u}(x,t)$, which shows that the three species always coexist at any time and any location of the habitat domain, no matter how fast or slowly they diffuse, under certain conditions on parameters. This result is even new for the ODE system (2.2).

PROPOSITION 3.2. *Assume that* $a_1 < 1$, $a_2 + b_1 < m_1$ *hold. Then, for any* $0 < \varepsilon \ll 1$, *there exists* $T \gg 1$ *such that* $\mathbf{u}(t)$ *and* $\mathbf{u}(x,t)$ *satisfy*

$$K - \varepsilon < u_1(t), \quad u_1(x,t) < 1 + \varepsilon,$$
$$\frac{K(m_1 - (a_2 + b_1))}{a_2 + b_1} - \varepsilon < u_2(t), \quad u_2(x,t) < \frac{m_1 - b_1}{b_1} + \varepsilon,$$
$$\frac{K(m_1 - (a_2 + b_1))(m_2 - b_2)}{(a_2 + b_1)b_2} - \varepsilon < u_3(t), \quad u_3(x,t) < \frac{(m_1 - b_1)(m_2 - b_2)}{b_1 b_2} + \varepsilon$$

for all $x \in \bar{\Omega}$ *and* $t > T$. *Here,* K *is given by*

$$K = \frac{1}{2}\left\{ 2 - \frac{m_1}{b_1} + \sqrt{\Big(2 - \frac{m_1}{b_1}\Big)^2 + 4(1 - a_1)\Big(\frac{m_1}{b_1} - 1\Big)} \ \right\}.$$

Proof. The proof is based on comparison principles. We first prove that the estimates hold for $\mathbf{u}(t)$. For $0 < \varepsilon \ll 1$ and $t \gg 1$, from the first equation in (2.2) it is clear that $u_1(t) < 1 + \varepsilon$ by the comparison principle for ODEs.

In the following, we always consider that $0 < \varepsilon \ll 1$ and $t \geq T \gg 1$, and the values of ε and T may be different from line to line. Since $u_2(t)$ satisfies

$$u_2'(t) < \frac{(m_1 - b_1)(1 + \varepsilon) - b_1 u_2}{1 + \varepsilon + u_2} u_2,$$

by the comparison principle for ODEs again, we have that

$$u_2(t) < \frac{(m_1 - b_1)(1 + \varepsilon)}{b_1} + \varepsilon = \frac{m_1 - b_1}{b_1} + \frac{m_1}{b_1}\varepsilon.$$

Thus we can assume the following holds:

$$u_2(t) < \frac{m_1 - b_1}{b_1} + \varepsilon. \tag{3.1}$$

Combining (3.1) and the first equation in (2.2), we deduce that

$$u_1'(t) > \frac{-u_1^2 + (2 - m_1/b_1 - \varepsilon)u_1 + (1 - a_1)[(m_1 - b_1)/b_1 + \varepsilon]}{(m_1 - b_1)/b_1 + \varepsilon + u_1} u_1.$$

Therefore

$$u_1(t) > \frac{1}{2}\left\{ 2 - \frac{m_1}{b_1} - \varepsilon + \sqrt{\Big(2 - \frac{m_1}{b_1} - \varepsilon\Big)^2 + 4(1 - a_1)\Big(\frac{m_1}{b_1} - 1 + \varepsilon\Big)} \ \right\} \tag{3.2}$$
$$-\varepsilon > K - \varepsilon.$$

Similarly, applying (3.2) to the second equation in (2.2), we obtain

$$u_2(t) > \frac{K(m_1 - (a_2 + b_1))}{a_2 + b_1} - \varepsilon. \tag{3.3}$$

Together with (3.1) and (3.3), the third equation in (2.2) results in

$$\frac{K[m_1 - (a_2 + b_1)](m_2 - b_2)}{(a_2 + b_1)b_2} - \varepsilon < u_3(t) < \frac{(m_1 - b_1)(m_2 - b_2)}{b_1 b_2} + \varepsilon. \tag{3.4}$$

To sum up, (3.1)–(3.4) deduce our result for $\mathbf{u}(t)$. In a similar manner, by the comparison principle for parabolic equations, one can establish the desired estimates for $\mathbf{u}(x,t)$. □

In particular Proposition 3.2 and the maximum principle imply a priori upper and lower bounds for the positive solutions of (2.5), which will play crucial roles in the later sections. To prove that we recall the following maximum principle (for example, Lemma 2.1 in [21]).

LEMMA 3.1. *Suppose that* $g \in C(\bar{\Omega} \times \mathbf{R})$.

(i) *Assume that* $w \in C^2(\Omega) \cap C^1(\bar{\Omega})$ *and satisfies*

$$\Delta w(x) + g(x, w(x)) \geq 0 \quad \text{in } \Omega, \quad \partial_\nu w \leq 0 \quad \text{on } \partial\Omega.$$

If $w(x_0) = \max_{\bar{\Omega}} w$, *then* $g(x_0, w(x_0)) \geq 0$.

(ii) *Assume that* $w \in C^2(\Omega) \cap C^1(\bar{\Omega})$ *and satisfies*

$$\Delta w(x) + g(x, w(x)) \leq 0 \quad \text{in } \Omega, \quad \partial_\nu w \geq 0 \quad \text{on } \partial\Omega.$$

If $w(x_0) = \min_{\bar{\Omega}} w$, *then* $g(x_0, w(x_0)) \leq 0$.

Now we have the following a priori estimates for steady state solutions.

THEOREM 3.1. *Assume that* $a_1 < 1$ *and* $a_2 + b_1 < m_1$ *hold. Let* K *be defined as in Proposition* 3.2. *Then any positive solution* (u_1, u_2, u_3) *of* (2.5) *satisfies the following: for all* $x \in \bar{\Omega}$,

$$K < u_1(x) < 1,$$

$$\frac{K(m_1 - (a_2 + b_1))}{a_2 + b_1} < u_2(x) < \frac{m_1 - b_1}{b_1},$$

$$\frac{K(m_1 - (a_2 + b_1))(m_2 - b_2)}{(a_2 + b_1)b_2} < u_3(x) < \frac{(m_1 - b_1)(m_2 - b_2)}{b_1 b_2}.$$

Proof. From Proposition 3.2, stated results hold if strict inequalities are replaced by nonstrict inequalities. Thus we only need to show the strict inequalities. Let (u_1, u_2, u_3) be a positive solution of (2.5) and set

$$u_i(x_i) = \max_{\bar{\Omega}} u_i \quad \text{and} \quad u_i(y_i) = \min_{\bar{\Omega}} u_i, \quad i = 1, 2, 3.$$

Applying Lemma 3.1 to the first equation in (2.5), we find that

$$1 - u_1(x_1) - \frac{a_1 u_2(x_1)}{u_1(x_1) + u_2(x_1)} \geq 0.$$

Thus when $a_1 < 1$, it follows that $u_1(y_1) < 1$. Following the same order in the proof of Proposition 3.2, we can show that the stated results with strict inequalities hold. □

When the population persistence holds for the food chain, the constant steady state $\tilde{\mathbf{u}}$ is always in the attracting region given in Proposition 3.2 and Theorem 3.1. Next we discuss the stability of $\tilde{\mathbf{u}}$ with respect to (2.4). To this end, we need to collect some known facts from [13]. For sake of simplicity, we denote

$$\mathbf{G}(\mathbf{u}) = \begin{pmatrix} u_1(1 - u_1) - \dfrac{a_1 u_1 u_2}{u_1 + u_2} \\ \dfrac{m_1 u_1 u_2}{u_1 + u_2} - b_1 u_2 - \dfrac{a_2 u_2 u_3}{u_2 + u_3} \\ \dfrac{m_2 u_2 u_3}{u_2 + u_3} - b_2 u_3 \end{pmatrix} \quad \text{and} \quad \mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}}) = \begin{pmatrix} a_{11} & a_{12} & 0 \\ a_{21} & a_{22} & a_{23} \\ 0 & a_{32} & a_{33} \end{pmatrix},$$

where

$$\begin{cases} a_{11} = \tilde{u}_1\Big[-1+\dfrac{a_1\tilde{u}_2}{(\tilde{u}_1+\tilde{u}_2)^2}\Big], \quad a_{22} = \tilde{u}_2\Big[-\dfrac{m_1\tilde{u}_1}{(\tilde{u}_1+\tilde{u}_2)^2}+\dfrac{a_2\tilde{u}_3}{(\tilde{u}_2+\tilde{u}_3)^2}\Big], \\ a_{33} = -\dfrac{m_2\tilde{u}_2\tilde{u}_3}{(\tilde{u}_2+\tilde{u}_3)^2} < 0, \quad a_{12} = -\dfrac{a_1\tilde{u}_1^2}{(\tilde{u}_1+\tilde{u}_2)^2} < 0, \quad a_{21} = \dfrac{m_1\tilde{u}_2^2}{(\tilde{u}_1+\tilde{u}_2)^2} > 0, \\ a_{23} = -a_2\tilde{u}_2^2/(\tilde{u}_2+\tilde{u}_3)^2 < 0, \quad a_{32} = m_2\tilde{u}_3^2/(\tilde{u}_2+\tilde{u}_3)^2 > 0. \end{cases}$$

In Proposition 3.1 in [13], it was proved that if $a_{11} \le 0$ and $a_{22} \le 0$, $\tilde{\mathbf{u}}$ is locally asymptotically stable for (2.2). Indeed even with the presence of the diffusion, $\tilde{\mathbf{u}}$ is uniformly asymptotically stable for (2.4) under the same conditions. More precisely, we have the following theorem.

THEOREM 3.2. *Assume that $a_{11} \le 0$ and $a_{22} \le 0$ hold; then $\tilde{\mathbf{u}}$ is locally uniformly asymptotically stable for* (2.4) *in the sense of* [12]. *As a consequence*, (2.5) *has no nonconstant positive solution in a neighborhood of $\tilde{\mathbf{u}}$. Moreover, if $a_1 < 1$ and $a_2 + b_1 < m_1$, then $a_{11} < 0$ and $a_{22} < 0$; hence $\tilde{\mathbf{u}}$ is locally uniformly asymptotically stable.*

Proof. The proof of stability when $a_{11} \le 0$ and $a_{22} \le 0$ is similar to that of Theorem 2 in [36], and we omit the details here. We note that if $a_1 < 1$, then $a_{11} < 0$. Moreover, the inequality $a_{22} \le 0$ is equivalent to

$$m_1 \ge \Big(b_1 + a_2\frac{m_2-b_2}{m_2}\Big)^2 \Big/ \Big(b_1 + a_2\Big(\frac{m_2-b_2}{m_2}\Big)^2\Big). \tag{3.5}$$

It is also noted that

$$\Big(b_1 + a_2\frac{m_2-b_2}{m_2}\Big)^2 \Big/ \Big(b_1 + a_2\Big(\frac{m_2-b_2}{m_2}\Big)^2\Big) < a_2 + b_1.$$

Hence if $a_1 < 1$ and $a_2 + b_1 < m_1$, we have a_{11}, $a_{22} < 0$ by (3.5). ∎

Remark 3.1. Theorem 3.2 and the previous arguments show that no Turing instability or diffusion-driven instability phenomenon occurs when $a_{11} \le 0$ and $a_{22} \le 0$ hold. On the other hand, if we take $m_1 = (b_1 + a_2(m_2-b_2)/m_2)^2/(b_1 + a_2(m_2-b_2)^2/m_2^2) - o(b_1)$, and $b_1 \to 0$, a_2, b_2, m_2 are properly chosen and either $a_1 \to 1/2$ or $a_1 \to 1$, as in Proposition 3.1 in [13], together with some meticulous computations, the well-known Roth–Hurwitz criterion ensures that $\tilde{\mathbf{u}}$ is still stable for the ODE system (2.2). However, by fixing these parameters including d_1 and d_2, and then letting the diffusion d_3 be large enough, similar to the proof of Theorem 2 in [36], one can show that $\tilde{\mathbf{u}}$ is unstable with respect to the PDE system (2.4). Thus Turing instability could occur when the conditions of Theorem 3.2 are not satisfied.

From Theorem 3.2, $\tilde{\mathbf{u}}$ is locally uniformly asymptotically stable when $a_1 < 1$ and $a_2 + b_1 < m_1$. In this case it is unlikely that nonconstant positive solutions (stationary pattern) of (2.5) exist. Indeed with more restrictive conditions on the parameters, we can show the global stability of $\tilde{\mathbf{u}}$ for systems (2.2) and (2.4). Our result below is independent of the diffusion rates d_i; that is, the constant coexistence state $\tilde{\mathbf{u}}$ is globally asymptotically stable. Hence when the conditions on the parameters are satisfied, $\tilde{\mathbf{u}}$ is stabilized under arbitrary spatially inhomogeneous perturbation.

THEOREM 3.3. *Let K be defined as in Proposition* 3.2. *Assume that the following hold*:

(i) $a_1 < 1$ *and* $a_2 + b_1 < m_1$;
(ii) $a_1(A-1)/A < m_1K/(a_2+b_1)$;

(iii) $a_2b_2m_1(m_2-b_2)(a_2+b_1) < b_1m_2K[m_1-(a_2+b_1)][b_1m_2+a_2(m_2-b_2)]$.
Then the constant positive steady state $\tilde{\mathbf{u}}$ *is globally asymptotically stable for systems* (2.2) *and* (2.4) *for all initial nonnegative conditions which are not steady states. In particular*, (2.5) *has no nonconstant positive solution if conditions* (i)–(iii) *hold.*

Proof. We use Lyapunov functionals for the proof. First, we verify the result for system (2.2). For our purpose, we first recall the following basic Lyapunov functionals:

$$E(u_i) = u_i - \tilde{u}_i - \tilde{u}_i \ln \frac{u_i}{\tilde{u}_i}, \qquad i = 1,\ 2,\ 3.$$

Note that $E(u_i(t))$ are nonnegative, and $E(u_i(t)) = 0$ $(i = 1, 2, 3)$ if and only if $(u_1(t), u_2(t), u_3(t)) = (\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$. Hence, letting

$$E(t) = E(u_1(t)) + \frac{a_1\tilde{u}_1}{m_1\tilde{u}_2}E(u_2(t)) + \frac{a_1a_2\tilde{u}_1}{m_1m_2\tilde{u}_3}E(u_3(t)),$$

we have

$$\begin{aligned}\frac{dE}{dt} = {} & \left\{ -1 + \frac{a_1\tilde{u}_2}{(\tilde{u}_1+\tilde{u}_2)(u_1+u_2)} \right\}(u_1-\tilde{u}_1)^2 + \frac{a_1\tilde{u}_1}{m_1\tilde{u}_2}\left\{ -\frac{m_1\tilde{u}_1}{(\tilde{u}_1+\tilde{u}_2)(u_1+u_2)} \right. \\ & \left. + \frac{a_2\tilde{u}_3}{(\tilde{u}_2+\tilde{u}_3)(u_2+u_3)} \right\}(u_2-\tilde{u}_2)^2 - \frac{a_1a_2\tilde{u}_1\tilde{u}_2}{m_1\tilde{u}_3(\tilde{u}_2+\tilde{u}_3)(u_2+u_3)}(u_3-\tilde{u}_3)^2. \end{aligned} \tag{3.6}$$

Under our assumptions (i)–(iii), we can claim that for $t \gg 1$ the following hold:

$$\frac{a_1\tilde{u}_2}{(\tilde{u}_1+\tilde{u}_2)(u_1+u_2)} \le 1 \quad \text{and} \quad \frac{a_2\tilde{u}_3}{(\tilde{u}_2+\tilde{u}_3)(u_2+u_3)} \le \frac{m_1\tilde{u}_1}{(\tilde{u}_1+\tilde{u}_2)(u_1+u_2)}. \tag{3.7}$$

In fact, by Proposition 3.2, to satisfy (3.7), for $t \gg 1$ it is sufficient to require

$$\frac{a_1\tilde{u}_2}{(\tilde{u}_1+\tilde{u}_2)} < \frac{m_1K}{a_2+b_1} \quad \text{and} \quad \frac{a_2\tilde{u}_3}{(\tilde{u}_2+\tilde{u}_3)} \cdot \frac{m_1}{b_1} < \frac{m_1\tilde{u}_1}{(\tilde{u}_1+\tilde{u}_2)} \cdot \frac{Km_2(m_1-(a_2+b_1))}{(a_2+b_1)b_2}.$$

Therefore by the definition of $(\tilde{u}_1, \tilde{u}_2, \tilde{u}_3)$, we easily see that the above two inequalities are equivalent to assumptions (ii) and (iii), respectively. Thus (3.6) implies that $E'(t) < 0$ for $t \gg 1$. Now for $t \gg 1$, $E(t)$ is a Lyapunov functional for system (2.2); namely, for $t \gg 1$, $E'(t) < 0$ along trajectories and $E(t) > 0$ except at $\tilde{\mathbf{u}}$. Hence $\tilde{\mathbf{u}}$ is globally asymptotically stable for (2.2) following the well-known theorem of Lyapunov stability.

Based on the proof of Theorem 3.3, by Proposition 3.2, it is not hard to see that for $t \gg 1$

$$E^*(t) = \int_\Omega \left\{ E(u_1(x,t)) + \frac{a_1\tilde{u}_1}{m_1\tilde{u}_2}E(u_2(x,t)) + \frac{a_1a_2\tilde{u}_1}{m_1m_2\tilde{u}_3}E(u_3(x,t)) \right\} \mathrm{d}x$$

is a Lyapunov functional for system (2.4) and $\tilde{\mathbf{u}}$ is globally asymptotically stable for system (2.4) under our assumptions. ∎

Remark 3.2. Simple analysis shows that Theorem 3.3 holds if one of the following holds: (1) $a_1 \to 0$, $a_2 \to 0$; (2) $a_1 < 1$, m_1 is large and $m_2 \to b_2$; or (3) $a_1 < 1$, m_1 is large, and $a_2b_2(m_2-b_2)(a_2+b_1) < (1-a_1)b_1m_2[b_1m_2+a_2(m_2-b_2)]$. Indeed in case (1), K defined in Proposition 3.2 tends to 1 as $a_1 \to 0$, and the lower and upper bounds in Proposition 3.2 and Theorem 3.1 tend to the same value as $a_2 \to 0$.

This shows that the a priori estimate in Proposition 3.2 and Theorem 3.1 are sharp when a_1 and a_2 are small.

Results in this section have interesting and significant biological implications. Regarding the impact of the diffusion, all results in this section (Propositions 3.1 and 3.2 and Theorems 3.1, 3.2, and 3.3) are independent of diffusion coefficients d_i, $i = 1, 2, 3$. In these parameter ranges, diffusion usually enhances the stability of the constant steady states. Proposition 3.1 gives conditions of total extinction of all three species and conditions of the extinction of both middle and top predators. Comparison can be made with results in section 2 of [13], where the ODE system is studied in more detail.

When the constant coexistence steady state $\tilde{\mathbf{u}}$ exists, our main persistence and stability results are proved under the assumptions

$$a_1 < 1 \quad \text{and } a_2 + b_1 < m_1. \tag{3.8}$$

These conditions are evidently stronger than the conditions (2.3) under which $\tilde{\mathbf{u}}$ exists. But with (3.8) satisfied, persistence holds for the whole food chain, and all three species coexist regardless of initial conditions (see Proposition 3.2). The persistence question is even open for the same ODE system, and here we prove it for the more general reaction-diffusion system with no-flux boundary condition. This answers an open question raised in [13] (see discussion on p. 80). Moreover, under (3.8), $\tilde{\mathbf{u}}$ is also locally uniformly asymptotically stable with respect to (2.4), and under strong conditions in Theorem 3.3, $\tilde{\mathbf{u}}$ is globally asymptotically stable. For the ODE systems, these results complement those in [13] in which the main concern is successful biological control. Indeed our results show that under (3.8), biological control of the pest cannot be achieved.

4. Nonexistence of nonconstant positive solutions of (2.5). In Theorem 3.3, the global stability of the constant coexistence steady state implies the nonexistence of nonconstant positive solutions of (2.5) regardless of diffusions. Several nonexistence results of nonconstant positive solutions to (2.5) will be presented in this section, and in these results, the diffusion coefficients do play important roles. The mathematical techniques to be employed are the implicit function theorem method and the energy method, respectively. From now on, let $0 = \mu_0 < \mu_1 \le \mu_2 \le \cdots$ be the eigenvalues of the operator $-\Delta$ on Ω with the homogeneous Neumann boundary condition.

4.1. The energy method. In this subsection, we apply the energy method to establish some results on the nonexistence of nonconstant positive solutions of (2.5). For convenience, let us denote the constants a_i, b_i, m_i $(i = 1, 2)$ collectively by Λ.

THEOREM 4.1. *Assume that* $a_1 < 1$ *and* $a_2 + b_1 < m_1$.

(i) *There exists* $\hat{D}_{1,2} = \hat{D}_{1,2}(\Lambda)$ *which is independent of* d_3 *and* Ω, *such that* (2.5) *has no nonconstant positive solution provided that* $\min\{\mu_1 d_1,\ \mu_1 d_2\} \ge \hat{D}_{1,2}$.

(ii) *If, in addition,* $a_1(a_2 + b_1)^2(m_1 - b_1) \le (1 - a_1)^2 b_1 m_1^2$, *then there exists* $\hat{D}_2 = \hat{D}_2(\Lambda)$ *which is independent of* d_1, d_3, *and* Ω, *such that* (2.5) *has no nonconstant positive solution provided that* $\mu_1 d_2 \ge \hat{D}_2$.

(iii) *If, in addition,* $a_2(a_2 + b_1)^2 b_2 m_1(m_1 - b_1)(m_2 - b_2) \le (1 - a_1)^3 b_1^3 m_2^2(m_1 - (a_2 + b_1))^2$, *then there exists* $\hat{D}_{1,3} = \hat{D}_{1,3}(\Lambda)$ *which is independent of* d_2 *and* Ω, *such that* (2.5) *has no nonconstant positive solution provided that* $\min\{\mu_1 d_1,\ \mu_1 d_3\} \ge \hat{D}_{1,3}$.

Proof. Let (u_1, u_2, u_3) be a positive solution of (2.5) and let $\bar{g} = |\Omega|^{-1}\int_\Omega g\,\mathrm{d}x$. Then, multiplying the corresponding equation in (2.5) by $\frac{1}{u_i}(u_i - \bar{u}_i)$, $i = 1, 2, 3$, integrating over Ω, and adding the results, we get

$$\begin{aligned}
&\int_\Omega \left\{ \sum_{i=1}^{3} \frac{d_i \bar{u}_i |\nabla(u_i - \bar{u}_i)|^2}{u_i^2} \right\} \mathrm{d}x \\
&\quad = \int_\Omega \Bigg\{ (u_1 - \bar{u}_1)^2 \Big(-1 + \frac{a_1 \bar{u}_2}{(u_1 + u_2)(\bar{u}_1 + \bar{u}_2)} \Big) \\
&\qquad + (u_1 - \bar{u}_1)(u_2 - \bar{u}_2) \frac{-a_1 \bar{u}_1 + m_1 \bar{u}_2}{(u_1 + u_2)(\bar{u}_1 + \bar{u}_2)} \\
&\qquad + (u_2 - \bar{u}_2)^2 \Big(\frac{-m_1 \bar{u}_1}{(u_1 + u_2)(\bar{u}_1 + \bar{u}_2)} + \frac{a_2 \bar{u}_3}{(u_2 + u_3)(\bar{u}_2 + \bar{u}_3)} \Big) \\
&\qquad + (u_2 - \bar{u}_2)(u_3 - \bar{u}_3) \frac{-a_2 \bar{u}_2 + m_2 \bar{u}_3}{(u_2 + u_3)(\bar{u}_2 + \bar{u}_3)} - (u_3 - \bar{u}_3)^2 \frac{m_2 \bar{u}_2}{(u_2 + u_3)(\bar{u}_2 + \bar{u}_3)} \Bigg\} \mathrm{d}x. \qquad (4.1)
\end{aligned}$$

By Theorem 3.1 and the Young inequality, from (4.1) it follows that

$$\begin{aligned}
\int_\Omega \sum_{i=1}^{3} d_i |\nabla(u_i - \bar{u}_i)|^2 \,\mathrm{d}x \le C \int_\Omega \Bigg\{ & (u_1 - \bar{u}_1)^2 \left(-1 + \frac{a_1 \bar{u}_2}{(u_1 + u_2)(\bar{u}_1 + \bar{u}_2)} + \varepsilon \right) \\
& + C(\varepsilon)(u_2 - \bar{u}_2)^2 \\
& + (u_3 - \bar{u}_3)^2 \left(- \frac{m_2 \bar{u}_2}{(u_2 + u_3)(\bar{u}_2 + \bar{u}_3)} + \varepsilon \right) \Bigg\} \mathrm{d}x. \qquad (4.2)
\end{aligned}$$

Here, C depends only on Λ, and $C(\varepsilon)$ depends only on Λ and ε. By Theorem 3.1 again, we can choose $0 < \varepsilon \ll 1$ which depends only on Λ such that

$$- \frac{m_2 \bar{u}_2}{(u_2 + u_3)(\bar{u}_2 + \bar{u}_3)} + \varepsilon < 0.$$

Thus, with (4.2) and the Poincaré inequality,

$$\mu_1 \int_\Omega (g - \bar{g})^2 \,\mathrm{d}x \le \int_\Omega |\nabla(g - \bar{g})|^2 \,\mathrm{d}x,$$

we find that

$$\mu_1 \int_\Omega \sum_{i=1}^{3} d_i (u_i - \bar{u}_i)^2 \,\mathrm{d}x \le C(\varepsilon) \int_\Omega \sum_{i=1}^{2} (u_i - \bar{u}_i)^2 \,\mathrm{d}x.$$

By the above inequality, it is clear that there exists $\hat{D}_{1,2}$ depending only on Λ, such that when $\min\{\mu_1 d_1,\ \mu_1 d_2\} \ge \hat{D}_{1,2}$, $u_i \equiv \bar{u}_i = \text{constant}$, $i = 1, 2, 3$, which asserts our result (i).

If, in addition, we assume $a_1(a_2 + b_1)^2(m_1 - b_1) \le (1 - a_1)^2 b_1 m_1^2$, then Theorem 3.1 implies

$$-1 + \frac{a_1 \bar{u}_2}{(u_1 + u_2)(\bar{u}_1 + \bar{u}_2)} < 0.$$

Therefore, for $0 < \varepsilon \ll 1$ satisfying

$$-1 + \frac{a_1\bar{u}_2}{(u_1+u_2)(\bar{u}_1+\bar{u}_2)} + \varepsilon < 0 \quad \text{and} \quad -\frac{m_2\bar{u}_2}{(u_2+u_3)(\bar{u}_2+\bar{u}_3)} + \varepsilon < 0,$$

as before, (4.2) implies

$$\int_\Omega \sum_{i=1}^{3} d_i |\nabla(u_i - \bar{u}_i)|^2 \, \mathrm{d}x \le C(\varepsilon) \int_\Omega (u_2 - \bar{u}_2)^2 \, \mathrm{d}x. \tag{4.3}$$

Similar to arguments above, from (4.3) and the Poincaré inequality, there exists $\hat{D}_2 = \hat{D}_2(\Lambda)$ such that (2.5) has no nonconstant positive solution if $\mu_1 d_2 > \hat{D}_2$. Thus (ii) holds.

To prove (iii), as in the arguments above, it is enough to verify that

$$a_2\bar{u}_3(u_1+u_2)(\bar{u}_1+\bar{u}_2) < m_1\bar{u}_1(u_2+u_3)(\bar{u}_2+\bar{u}_3). \tag{4.4}$$

By Theorem 3.1 again, to ensure (4.4), it suffices to require that the third condition in (iii) holds. This completes our proof. ∎

THEOREM 4.2.

(i) *Let d_1^*, d_3^* be fixed positive constants satisfying $\mu_1 d_1^* > 1$ and $\mu_1 d_3^* > m_2 - b_2$. Then there exists a positive constant $D_2^* = D_2^*(d_1^*, d_3^*, \Lambda)$ such that (2.5) has no nonconstant positive solution provided that $\mu_1 d_2 \ge D_2^*$, $d_1 \ge d_1^*$, and $d_3 \ge d_3^*$.*

(ii) *Let d_2^* be a fixed positive constant satisfying $\mu_1 d_2^* > m_1 - b_1$. Then there exists a positive constant $D_{1,3}^* = D_{1,3}^*(d_2^*, \Lambda)$ such that (2.5) has no nonconstant positive solution provided that $\min\{\mu_1 d_1, \mu_1 d_3\} \ge D_{1,3}^*$ and $d_2 \ge d_2^*$.*

Proof. We prove only (i), and the verification of (ii) is similar. Suppose that (u_1, u_2, u_3) and $(\bar{u}_1, \bar{u}_2, \bar{u}_3)$ are the same as in the proof of Theorem 4.1. Multiplying the corresponding equation of (2.5) by $u_i - \bar{u}_i$, $i = 1, 2, 3$, the analysis similar to the proof of Theorem 4.1 deduces

$$\mu_1 \sum_{i=1}^{3} \int_\Omega d_i (u_i - \bar{u}_i)^2 \mathrm{d}x \le \int_\Omega \{(1+\varepsilon)(u_1 - \bar{u}_1)^2 + C(u_2 - \bar{u}_2)^2 + (m_2 - b_2 + \varepsilon)(u_3 - \bar{u}_3)^2\} \mathrm{d}x$$

for some positive constant $C = C(\Lambda, \varepsilon)$. Choose $\varepsilon > 0$ to be so small that $d_1\mu_1 \ge 1 + \varepsilon$, $d_3\mu_1 \ge m_2 - b_2 + \varepsilon$; then there exists D_2^* such that $(u_1, u_2, u_3) = (\bar{u}_1, \bar{u}_2, \bar{u}_3)$ must hold if $d_2 \ge D_2^*$, and so our conclusion holds. ∎

The results in this subsection demonstrate such a phenomenon: when all diffusion coefficients are large, no patterns exist. Here either d_1, d_3, or d_2 has a lower bound (see Theorem 4.2). If, in addition, the conditions (3.8) are satisfied, then the patterns do not exist even if only one or two diffusion coefficients are large. Such results for general reaction-diffusion systems appeared in [6], and our results here show more delicate dependence on the diffusion coefficients only for the food chain system (2.4) and (2.5).

4.2. The implicit function theorem method. In this subsection, we use the implicit function theorem to obtain some further results for the nonexistence of nonconstant positive solutions of (2.5). We will need the following a priori estimate.

THEOREM 4.3. *Let $a_1 < 1$ and let d be a fixed positive number. Assume that for any positive constants $\tilde{d}_2$ and $\tilde{d}_3$, the boundary value problem*

$$\begin{cases} -\tilde{d}_2\Delta w_2 = (m_1 - b_1)w_2 - \dfrac{a_2 w_2 w_3}{w_2 + w_3} & \text{in } \Omega, \\ -\tilde{d}_3\Delta w_3 = \dfrac{m_2 w_2 w_3}{w_2 + w_3} - b_2 w_3 & \text{in } \Omega, \\ \partial_\nu w_2 = \partial_\nu w_3 = 0 & \text{on } \partial\Omega \end{cases} \tag{4.5}$$

has no positive solution satisfying $|w_2|_\infty + |w_3|_\infty = 1$. Then there exist positive constants $C_1(\Lambda, \Omega, d)$ and $C_2(\Lambda, \Omega, d)$ such that any positive solution (u_1, u_2, u_3) of (2.5) satisfies

$$C_1(\Lambda, \Omega, d) \le u_i \le C_2(\Lambda, \Omega, d), \quad i = 1, 2, 3,$$

provided that d_1, d_2, $d_3 \ge d$.

Proof. Since $a_1 < 1$, from the proof of Theorem 3.1, we see that

$$1 - a_1 < u_1 < 1, \quad u_2 < (m_1 - b_1)/b_1, \quad \text{and } u_3 < (m_1 - b_1)(m_2 - b_2)/(b_1 b_2), \tag{4.6}$$

so $C_2(\Lambda, \Omega, d)$ has been found. Similarly to the proof of Theorem 3.4 in [28], from the second and third equations in (2.5), the desired $C_1(\Lambda, \Omega, d)$ can be obtained. □

The assumption that (4.5) has no positive solution is satisfied in some important parameter ranges.

LEMMA 4.1. *Problem (4.5) has no positive solution if one of the following holds*:

(i) $a_2 + b_1 \le m_1$; *or*

(ii) $a_2 + b_1 > m_1$ *and* $\sqrt{a_2 + m_2} < \sqrt{m_1 - b_1} + \sqrt{b_2}$.

In particular, if $a_1 < 1$ and either (i) *or* (ii) *holds, the a priori estimate in Theorem 4.3 holds.*

Proof. If condition (i) holds, our conclusion is derived from (ii) of Lemma 3.1; if condition (ii) is satisfied, the proof is the same as that of Corollary 3.5 in [28]. □

In this subsection, we will prove a result which considerably improves Theorem 4.2 if the estimates in Theorem 4.3 hold. We note that the conditions (i) and (ii) include (3.8); thus the results are along the same lines as those in the last subsection. To prove our result, we first prepare two lemmas.

LEMMA 4.2. *Assume that $f(u)$ is a continuous function in $[0, \infty)$ and for some positive constant a, $f(u) > 0$ in $(0, a)$ and $f(u) < 0$ in (a, ∞). Then the problem*

$$-\Delta u = u f(u) \quad \text{in } \Omega, \qquad \partial_\nu u = 0 \quad \text{on } \partial\Omega$$

has a unique positive solution $u(x) \equiv a$.

Proof. The above result is easily obtained by the direct application of Lemma 3.1. □

LEMMA 4.3. (i) *Assume that $a_1 < 1$ and that assumptions in Theorem 4.3 hold. Let (u_{1i}, u_{2i}, u_{3i}) be a sequence of positive solutions of (2.5) with $d_2 = d_{2i}$ and $d_{2i} \to \infty$ as $i \to \infty$. Then (u_{1i}, u_{2i}, u_{3i}) converges to $\tilde{\mathbf{u}}$ in $[C(\bar{\Omega})]^3$ as $i \to \infty$.*

(ii) *Assume that $a_1 < 1$ and that assumptions in Theorem 4.3 hold. Let (u_{1i}, u_{2i}, u_{3i}) be a sequence of positive solutions of (2.5) with $(d_1, d_3) = (d_{1i}, d_{3i})$ and $d_{1i}, d_{3i} \to \infty$ as $i \to \infty$. Then (u_{1i}, u_{2i}, u_{3i}) converges to $\tilde{\mathbf{u}}$ in $[C(\bar{\Omega})]^3$ as $i \to \infty$.*

Proof. We prove only (i), and (ii) can be proved similarly by using Theorem 3.1 and Lemma 3.1.

From Theorem 4.3, the sequence $\{(u_{1i}, u_{2i}, u_{3i})\}$ is bounded in $[C(\bar{\Omega})]^3$ with the bound independent of d_2. Then some standard arguments show that there is a subsequence of (u_{1i}, u_{2i}, u_{3i}) (still labelled by itself), such that $(u_{1i}, u_{2i}, u_{3i}) \to (u_1, u_2, u_3)$ in $[C(\bar{\Omega})]^3$ as $i \to \infty$. Furthermore, $u_2 \equiv c$, which is a positive constant; $u_1, u_3 > 0$ on $\bar{\Omega}$; and (u_1, c, u_3) solves

$$
\begin{cases}
-d_1\Delta u_1 = u_1(1-u_1) - \dfrac{a_1 c u_1}{u_1 + c} & \text{in } \Omega, \quad \partial_\nu u_1 = 0 \ \text{ on } \partial\Omega, \\
\displaystyle\int_\Omega \left\{ \frac{m_1 u_1}{u_1 + c} - b_1 - \frac{a_2 u_3}{c + u_3} \right\} \mathrm{d}x = 0, & \\
-d_3\Delta u_3 = \dfrac{c m_2 u_3}{c + u_3} - b_2 u_3 & \text{in } \Omega, \quad \partial_\nu u_3 = 0 \ \text{ on } \partial\Omega.
\end{cases} \tag{4.7}
$$

By Lemma 4.2, from the first and third equations in (4.7), we find that u_1 and u_3 are both constants:

$$
u_1 \equiv \frac{1}{2}\Big\{ 1 - c + \sqrt{(1-c)^2 + 4c(1-a_1)} \Big\} \ \text{ and } \ u_3 \equiv \frac{m_2 - b_2}{b_2} c. \tag{4.8}
$$

Substituting (4.8) into the second equation in (4.7), we find that $(u_1, c, u_3) = \tilde{\mathbf{u}}$. This verifies that the convergence holds for a subsequence of (u_{1i}, u_{2i}, u_{3i}). But the limit is a fixed point; thus the convergence holds for the whole sequence (u_{1i}, u_{2i}, u_{3i}). ∎

Now we state our main result in this subsection.

THEOREM 4.4. *Assume that $a_1 < 1$ and that assumptions in Theorem 4.3 hold.*

(i) *Let ϵ_1 be an arbitrary positive constant. Then there exists $D_2 = D_2(\epsilon_1, \Lambda, \Omega)$ such that (2.5) has no nonconstant positive solution provided that $\min\{d_1, d_3\} \geq \epsilon_1$ and $d_2 \geq D_2$.*

(ii) *Let ϵ_2 be an arbitrary positive constant. Then there exists $D_{1,3} = D_{1,3}(\epsilon_2, \Lambda, \Omega)$ such that (2.5) has no nonconstant positive solution provided that $d_2 \geq \epsilon_2$ and $\min\{d_1, d_3\} \geq D_{1,3}$.*

Proof. We first prove (i). By (i) of Theorem 4.2, for a fixed large constant $D_{1,3}$ depending only on Λ and Ω, there exists $D_2^* = D_2^*(\Lambda, \Omega)$ such that (2.1) has no positive nonconstant solution when $d_1, d_3 \geq D_{1,3}$ and $d_2 \geq D_2^*$. As a result, it suffices to consider the case $d_1, d_3 \in [\epsilon_1/2, D_{1,3}]$.

We make a decomposition: $u_2 = w_2 + \xi$ with $\int_\Omega w_2 = 0$ and $\xi \in \mathbf{R}^+$. We observe that finding the positive solution of (2.5) is equivalent to solving the following problem:

$$
\begin{cases}
d_1\Delta u_1 + u_1(1-u_1) - \dfrac{a_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi} = 0 & \text{in } \Omega,\ \partial_\nu u_1 = 0 \text{ on } \partial\Omega, \\
\Delta w_2 + \rho \left\{ \dfrac{m_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi} \right. & \\
\qquad \left. - b_1(w_2 + \xi) - \dfrac{a_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} \right\} = 0 & \text{in } \Omega,\ \partial_\nu w_2 = 0 \text{ on } \partial\Omega, \\
\displaystyle\int_\Omega \left\{ \frac{m_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi} - b_1(w_2 + \xi) \right. & \\
\qquad \left. - \frac{a_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} \right\} \mathrm{d}x = 0, & \\
d_3\Delta u_3 + \dfrac{m_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} - b_2 u_3 = 0 & \text{in } \Omega,\ \partial_\nu u_3 = 0 \text{ on } \partial\Omega, \\
\xi > 0, u_1, u_3 > 0 & \text{in } \Omega,
\end{cases} \tag{4.9}
$$

where $\rho = d_2^{-1}$. Clearly, $(u_1, w_2, \xi, u_3) = (\tilde{u}_1,\, 0, \tilde{u}_2, \tilde{u}_3)$ is a solution of (4.9) for $\rho > 0$.

To prove our theorem, by the finite covering argument, it is sufficient to prove that, for any fixed $\tilde{d}_1,\, \tilde{d}_3 \in [\epsilon_1/2, D_{1,3}]$, there exists $\delta_0 > 0$ such that if $\rho \in (0, \delta_0)$, $(d_1, d_3) \in (\tilde{d}_1 - \delta_0, \tilde{d}_1 + \delta_0) \times (\tilde{d}_3 - \delta_0, \tilde{d}_3 + \delta_0)$, then $(\tilde{u}_1, 0, \tilde{u}_2, \tilde{u}_3)$ is the unique solution of (4.9). To this end, we define the following Banach spaces:

$$W_\nu^{2,2}(\Omega) = \{g \in W^{2,2}(\Omega) \,\big|\, \partial_\nu g = 0 \ \text{ on } \ \partial\Omega\}, \quad L_0^2(\Omega) = \left\{ g \in L^2(\Omega) \,\Big|\, \int_\Omega g \,\mathrm{d}x = 0 \right\},$$

and denote

$$F(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3) = (f_1,\, f_2,\, f_3,\, f_4)(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3)$$

with

$$f_1(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3) = d_1 \Delta u_1 + u_1\,(1 - u_1) - \frac{a_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi},$$

$$f_2(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3) = \Delta w_2 + \rho \left\{ \frac{m_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi} - b_1 (w_2 + \xi) - \frac{a_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} \right\},$$

$$f_3(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3) = \int_\Omega \left\{ \frac{m_1 u_1 (w_2 + \xi)}{u_1 + w_2 + \xi} - b_1 (w_2 + \xi) - \frac{a_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} \right\} \mathrm{d}x,$$

$$f_4(d_1,\, d_3,\, \rho,\, u_1,\, w_2,\, \xi,\, u_3) = d_3 \Delta u_3 + \frac{m_2 (w_2 + \xi) u_3}{w_2 + \xi + u_3} - b_2 u_3.$$

Then

$$F : \mathbf{R}^+ \times \mathbf{R}^+ \times \mathbf{R}^+ \times W_\nu^{2,2}(\Omega) \times (L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega)) \times \mathbf{R}^+ \times W_\nu^{2,2}(\Omega) \to L^2(\Omega) \times L_0^2(\Omega) \times \mathbf{R} \times L^2(\Omega)$$

is a well-defined mapping. It is clear that the solutions of (4.9) satisfy $F(d_1, d_3, \rho, u_1, w_2, \xi, u_3) = 0$. Moreover, (4.9) has a unique solution $(u_1,\, w_2,\, \xi,\, u_3) = (\tilde{u}_1,\, 0,\, \tilde{u}_2,\, \tilde{u}_3)$ when $\rho = 0$ and $(d_1,\, d_3) = (\tilde{d}_1,\, \tilde{d}_3)$ from the proof of (i) of Lemma 4.3. Obviously, F is a differentiable mapping, and its partial derivative with respect to the last four arguments is

$$\Psi \equiv D_{(u_1,\, w_2,\, \xi,\, u_3)} F(\tilde{d}_1,\, \tilde{d}_3,\, 0,\, \tilde{u}_1,\, 0,\, \tilde{u}_2,\, \tilde{u}_3),$$

$$\Psi : W_\nu^{2,2}(\Omega) \times (L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega)) \times \mathbf{R} \times W_\nu^{2,2}(\Omega) \to L^2(\Omega) \times L_0^2(\Omega) \times \mathbf{R} \times L^2(\Omega)$$

with

$$\Psi(v_1, v_2, \tau, v_3) = \begin{pmatrix} \tilde{d}_1 \Delta v_1 + a_{11} v_1 + a_{12}(v_2 + \tau) \\ \Delta v_2 \\ \int_\Omega \{a_{21} v_1 + a_{22}(v_2 + \tau) + a_{23} v_3\} \,\mathrm{d}x \\ \tilde{d}_3 \Delta v_3 + a_{32}(v_2 + \tau) + a_{33} v_3 \end{pmatrix},$$

where a_{ij} are given in section 3.

We claim that Ψ is an isomorphism operator. Assume that $\Psi(v_1, v_2, \tau, v_3) = (0, 0, 0, 0)$; then $v_2 = 0$. Note that $a_1 < 1$ implies $a_{11} < 0$. Then from the equation of v_1, it follows that $v_1 \equiv -a_{12}\tau/a_{11}$. Similarly, $v_3 \equiv -a_{32}\tau/a_{33}$ since $a_{33} < 0$ and $\tau \in \mathbf{R}$. We substitute these results into the integral equations satisfied by (v_1, v_2, τ, v_3) and obtain that

$$\left(-\frac{a_{12}a_{21}}{a_{11}} + a_{22} - \frac{a_{23}a_{32}}{a_{33}}\right)\tau = 0.$$

This is equivalent to $\det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\}\tau = 0$, where

$$\det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} = -(a_{12}a_{21}a_{33} + a_{11}a_{23}a_{32} - a_{11}a_{22}a_{33}) = -\frac{m_1 m_2 \tilde{u}_1^2 \tilde{u}_2^2 \tilde{u}_3}{(\tilde{u}_1 + \tilde{u}_2)^2(\tilde{u}_2 + \tilde{u}_3)^2} < 0$$

by some basic computations. Therefore $\tau = 0$, which implies that $(v_1, v_2, \tau, v_3) = (0, 0, 0, 0)$ and Ψ is injective. On the other hand, for a given $h_2 \in L_0^2(\Omega)$, the problem

$$-\Delta u_2 = h_2 \ \text{ in } \ \Omega, \qquad u \in L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega)$$

has a unique solution. By using $\det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} < 0$ again, one can also check that Ψ is also surjective. Consequently Ψ is an isomorphism.

By the implicit function theorem, there exist positive constants ρ_0 and δ_0 such that, for each $\rho \in [0, \rho_0]$ and $(d_1, d_3) \in (\tilde{d_1} - \delta_0, \tilde{d_1} + \delta_0) \times (\tilde{d_3} - \delta_0, \tilde{d_3} + \delta_0)$, $(\tilde{u}_1, 0, \tilde{u}_2, \tilde{u}_3)$ is the unique solution of $F(d_1, d_3, \rho, u_1, w_2, \xi, u_3) = 0$ in $B_{\delta_0}(\tilde{u}_1, 0, \tilde{u}_2, \tilde{u}_3)$, where $B_{\delta_0}(\tilde{u}_1, 0, \tilde{u}_2, \tilde{u}_3)$ is the ball in $W_\nu^{2,2}(\Omega) \times (L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega)) \times \mathbf{R} \times W_\nu^{2,2}(\Omega)$ centered at $(\tilde{u}_1, 0, \tilde{u}_2, \tilde{u}_3)$ with radius δ_0. Taking smaller ρ_0 and δ_0 if necessary, we can conclude (i) by use of Lemma 4.3(i).

In a similar manner, (ii) can be proved. In fact, we write $u_i = w_i + \xi_i$ with $\int_\Omega w_i = 0$ and $\xi_i \in \mathbf{R}^+$ $(i = 1, 3)$ and construct analogous operator

$$F(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = (f_1, f_2, f_3, f_4, f_5)(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3)$$

with

$$f_1(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = \Delta w_1 + \rho_1 \left\{(w_1 + \xi_1)(1 - w_1 - \xi_1) - \frac{a_1(w_1 + \xi_1)u_2}{w_1 + \xi_1 + u_2}\right\},$$

$$f_2(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = \int_\Omega \left\{(w_1 + \xi_1)(1 - w_1 - \xi_1) - \frac{a_1(w_1 + \xi_1)u_2}{w_1 + \xi_1 + u_2}\right\} \mathrm{d}x,$$

$$f_3(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = d_2\Delta u_2 + \frac{m_1(w_1 + \xi_1)u_2}{w_1 + \xi_1 + u_2} - b_1 u_2 - \frac{a_2(w_3 + \xi_3)u_2}{w_3 + \xi_3 + u_2},$$

$$f_4(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = \Delta w_3 + \rho_3 \left\{\frac{m_2(w_3 + \xi_3)u_2}{w_3 + \xi_3 + u_2} - b_2(w_3 + \xi_3)\right\},$$

$$f_5(d_2, \rho_1, \rho_3, w_1, \xi_1, u_2, w_3, \xi_3) = \int_\Omega \left\{\frac{m_2(w_3 + \xi_3)u_2}{w_3 + \xi_3 + u_2} - b_2(w_3 + \xi_3)\right\} \mathrm{d}x,$$

where $\rho_i = d_i^{-1}$ (i=1, 3). For fixed $\tilde{d}_2 > 0$, we can verify that

$$D_{(w_1,\xi_1,u_2,w_3,\xi_3)}F(\tilde{d}_2, 0, 0, 0, \tilde{u}_1, \tilde{u}_2, 0, \tilde{u}_3) :$$
$$(L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega)) \times \mathbf{R} \times W_\nu^{2,2}(\Omega) \times (L_0^2(\Omega) \cap W_\nu^{2,2}(\Omega))$$
$$\times \mathbf{R} \to L_0^2(\Omega) \times \mathbf{R} \times L^2(\Omega) \times L_0^2(\Omega) \times \mathbf{R}$$

is an isomorphism. As in the discussion of (i), by the implicit function theorem, Lemma 4.3(ii) and Theorem 4.2(ii), our result is obtained. The proof of Theorem 4.4 is complete. □

5. Existence of nonconstant positive solutions of (2.5). This section is devoted to the existence of nonconstant positive solutions of (2.5) for certain values of diffusion coefficients d_1 and d_3, respectively, while the other parameters are fixed. Our results will show that, if the parameters are properly chosen, both the general stationary pattern and more interesting Turing pattern can arise as a result of diffusion.

For our purposes, we start with some preliminary results. First we study the linearization of (2.5) at $\tilde{\mathbf{u}}$. We denote

$$\mathbf{X} = \{\mathbf{u} \in [C^2(\bar{\Omega})]^3 \mid \partial_\nu \mathbf{u} = 0 \ \text{ on } \partial\Omega\}$$

and

$$\mathbf{X}^+ = \{\mathbf{u} \in \mathbf{X} \mid u_i > 0 \ \text{ on } \ \bar{\Omega}, \ \ i = 1, 2, 3\},$$
$$B(C) = \{\mathbf{u} \in \mathbf{X} \mid C^{-1} < u_i < C \ \text{ on } \ \bar{\Omega}, \ \ i = 1, 2, 3\}, \ \ C > 0.$$

With the diffusion matrix $\mathcal{D} = \text{diag}(d_1, d_2, d_3)$, (2.5) can be written as

$$\begin{cases} -\mathcal{D}\Delta\mathbf{u} = \mathbf{G}(\mathbf{u}) & \text{in } \ \Omega, \\ \partial_\nu \mathbf{u} = 0 & \text{on } \ \partial\Omega, \end{cases} \tag{5.1}$$

and $\mathbf{u}$ is a positive solution to (5.1) if and only if

$$\mathbf{F}(\mathbf{u}) \equiv \mathbf{u} - (\mathbf{I} - \Delta)^{-1}\{\mathcal{D}^{-1}\mathbf{G}(\mathbf{u}) + \mathbf{u}\} = 0 \ \text{ for } \ \mathbf{u} \in \mathbf{X}^+,$$

where $(\mathbf{I} - \Delta)^{-1}$ is the inverse of $\mathbf{I} - \Delta$ in $\mathbf{X}$. As $\mathbf{F}(\cdot)$ is a compact perturbation of the identity operator, for any $B = B(C)$, the Leray–Schauder degree $\deg(\mathbf{F}(\cdot), 0, B)$ is well defined if $\mathbf{F}(\mathbf{u}) \neq 0$ on ∂B.

We also note that

$$D_{\mathbf{u}}\mathbf{F}(\tilde{\mathbf{u}}) = \mathbf{I} - (\mathbf{I} - \Delta)^{-1}\{\mathcal{D}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}}) + \mathbf{I}\},$$

and recall that if $D_{\mathbf{u}}\mathbf{F}(\tilde{\mathbf{u}})$ is invertible, the index of $\mathbf{F}$ at $\tilde{\mathbf{u}}$ is defined as $\text{index}(\mathbf{F}(\cdot), \tilde{\mathbf{u}}) = (-1)^\gamma$, where γ is the multiplicity of negative eigenvalues of $D_{\mathbf{u}}\mathbf{F}(\tilde{\mathbf{u}})$ [25, Theorem 2.8.1].

For the sake of convenience, we denote

$$H(d_1, d_2, d_3; \mu) \equiv \det\{\mu\mathbf{I} - \mathcal{D}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} = \frac{1}{d_1 d_2 d_3}\det\{\mu\mathcal{D} - \mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\}, \tag{5.2}$$

By arguments similar to those in [28], it can be shown that the following proposition holds.

PROPOSITION 5.1. *Suppose that, for all* $n \geq 0$, *the matrix* $\mu_n \mathbf{I} - \mathcal{D}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})$ *is nonsingular. Then*

$$\text{index}(\mathbf{F}(\cdot),\, \tilde{\mathbf{u}}) = (-1)^{\gamma}, \quad \textit{where} \;\; \gamma = \sum_{n\geq 0,\, H(d_1,d_2,d_3;\mu_n)<0} \dim E(\mu_n).$$

To compute $\text{index}(\mathbf{F}(\cdot),\, \tilde{\mathbf{u}})$, we have to consider the sign of $H(d_1, d_2, d_3; \mu)$. Direct calculation gives

$$\begin{aligned} \det\{\mu\mathcal{D} - \mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} &= A_3(d_1,d_3)\mu^3 + A_2(d_1,d_3)\mu^2 + A_1(d_1,d_3)\mu \\ &\quad - \det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} \equiv \mathcal{A}(d_1, d_3;\, \mu), \end{aligned} \tag{5.3}$$

with

$$\begin{cases} A_3(d_1,d_3) = d_1d_2d_3, \quad A_2(d_1,d_3) = -\{a_{33}d_1d_2 + (a_{11}d_2 + a_{22}d_1)d_3\}, \\ A_1(d_1,d_3) = a_{11}a_{33}d_2 + (a_{22}a_{33} - a_{23}a_{32})d_1 + (a_{11}a_{22} - a_{12}a_{21})d_3, \end{cases}$$

where a_{ij} are defined in section 3.

We first consider the dependence of $\mathcal{A}$ on d_1. Let $\tilde{\mu}_i(d_1;\, d_2, d_3)$, $i = 1, 2, 3$, be the three roots of $\mathcal{A}(d_1, d_3;\, \mu) = 0$ satisfying $\text{Re}\{\tilde{\mu}_1(d_1;\, d_2, d_3)\} \leq \text{Re}\{\tilde{\mu}_2(d_1;\, d_2, d_3)\} \leq \text{Re}\{\tilde{\mu}_3(d_1;\, d_2, d_3)\}$. Since $\det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} < 0$ and $A_3(d_1, d_3) > 0$, one of $\tilde{\mu}_i(d_1;\, d_2, d_3)$ is real and negative, and the product of the other two is positive.

In addition, we have

$$\lim_{d_1\to\infty} \mathcal{A}(d_1, d_3;\, \mu)/d_1 = \mu[d_2d_3\mu^2 - (a_{33}d_2 + a_{22}d_3)\mu + a_{22}a_{33} - a_{23}a_{32}].$$

Note that $a_{22}a_{33} - a_{23}a_{32} > 0$. If $a_{22} > 0$ or the reverse inequality of (3.5),

$$m_1 < \Big(b_1 + a_2\frac{m_2 - b_2}{m_2}\Big)^2 \Big/ \Big(b_1 + a_2\Big(\frac{m_2 - b_2}{m_2}\Big)^2\Big), \tag{5.4}$$

holds, and the parameters d_2 and d_3 satisfy

$$a_{33}d_2 + a_{22}d_3 > 0, \quad \Delta_1 \equiv (a_{33}d_2 + a_{22}d_3)^2 - 4d_2d_3(a_{22}a_{33} - a_{23}a_{32}) > 0, \tag{5.5}$$

we can establish the following proposition.

PROPOSITION 5.2. *Assume that* (5.4) *holds and that* d_2 *and* d_3 *satisfy* (5.5). *Then there exists a positive constant* D_1^* *such that when* $d_1 \geq D_1^*$, *the three roots* $\tilde{\mu}_i(d_1;\, d_2,\, d_3)$, $i = 1, 2, 3$, *of* $\mathcal{A}(d_1, d_3;\, \mu) = 0$ *are all real and satisfy*

$$\begin{cases} \lim\limits_{d_1\to\infty} \tilde{\mu}_1(d_1;\, d_2, d_3) = 0, \\ \lim\limits_{d_1\to\infty} \tilde{\mu}_2(d_1;\, d_2, d_3) = \dfrac{1}{2d_2d_3}\Big\{a_{33}d_2 + a_{22}d_3 - \sqrt{\Delta_1}\Big\} \equiv \mu_2^*(d_2, d_3) > 0, \\ \lim\limits_{d_1\to\infty} \tilde{\mu}_3(d_1;\, d_2, d_3) = \dfrac{1}{2d_2d_3}\Big\{a_{33}d_2 + a_{22}d_3 + \sqrt{\Delta_1}\Big\} \equiv \mu_3^*(d_2, d_3) > 0. \end{cases} \tag{5.6}$$

Moreover, when $d_1 \geq D_1^*$,

$$\begin{cases} -\infty < \tilde{\mu}_1(d_1; d_2, d_3) < 0 < \tilde{\mu}_2(d_1; d_2, d_3) < \tilde{\mu}_3(d_1; d_2, d_3), \\ \mathcal{A}(d_1, d_3; \mu) < 0 \;\; \textit{if} \;\; \mu \in (-\infty, \tilde{\mu}_1(d_1; d_2, d_3)) \cup (\tilde{\mu}_2(d_1; d_2, d_3), \tilde{\mu}_3(d_1; d_2, d_3)), \\ \mathcal{A}(d_1, d_3;\, \mu) > 0 \;\; \textit{if} \;\; \mu \in (\tilde{\mu}_1(d_1; d_2, d_3), \tilde{\mu}_2(d_1; d_2, d_3)) \cup (\tilde{\mu}_3(d_1; d_2, d_3), \infty). \end{cases} \tag{5.7}$$

Similarly, we consider d_3 as the parameter, and d_1 and d_2 satisfy

$$a_{11}d_2 + a_{22}d_1 > 0, \quad \Delta_2 \equiv (a_{11}d_2 + a_{22}d_1)^2 - 4d_1d_2(a_{11}a_{22} - a_{12}a_{21}) > 0; \tag{5.8}$$

then we have the following proposition.

PROPOSITION 5.3. *Assume that* (5.4) *holds and that* d_1 *and* d_2 *satisfy* (5.8). *Then there exists a positive constant* D_3^* *such that when* $d_3 \geq D_3^*$, *the three roots* $\tilde{\mu}_1(d_3; d_1, d_2)$, $i = 1, 2, 3$, *of* $\mathcal{A}(d_1, d_3; \mu) = 0$ *are all real and satisfy*

$$\begin{cases} \lim_{d_3\to\infty} \tilde{\mu}_1(d_3;\, d_1, d_2) \leq 0, \\ \lim\limits_{d_3\to\infty} \tilde{\mu}_2(d_3;\, d_1, d_2) = \dfrac{1}{2d_1d_2}\Big\{a_{11}d_2 + a_{22}d_1 - \sqrt{\Delta_2}\Big\} \equiv \mu_2^*(d_1, d_2) \geq 0, \\ \lim\limits_{d_3\to\infty} \tilde{\mu}_3(d_3;\, d_1, d_2) = \dfrac{1}{2d_1d_2}\Big\{a_{11}d_2 + a_{22}d_1 + \sqrt{\Delta_2}\Big\} \equiv \mu_3^*(d_1, d_2) > 0. \end{cases}$$

Moreover, when $d_3 \geq D_3^*$,

$$\begin{cases} -\infty < \tilde{\mu}_1(d_3;\, d_1, d_2) < 0 < \tilde{\mu}_2(d_3;\, d_1, d_2) < \tilde{\mu}_3(d_3;\, d_1, d_2), \\ \mathcal{A}(d_1, d_3;\, \mu) < 0 \quad \textit{if} \quad \mu \in (-\infty,\, \tilde{\mu}_1(d_3;\, d_1, d_2)) \cup (\tilde{\mu}_2(d_3;\, d_1, d_2),\, \tilde{\mu}_3(d_3;\, d_1, d_2)), \\ \mathcal{A}(d_1, d_3;\, \mu) > 0 \quad \textit{if} \quad \mu \in (\tilde{\mu}_1(d_3;\, d_1, d_2),\, \tilde{\mu}_2(d_3;\, d_1, d_2)) \cup (\tilde{\mu}_3(d_3;\, d_1, d_2),\, \infty). \end{cases}$$

Remark 5.1. Simple computations show that $\mu_2^*(d_1, d_2) = 0$ if and only if $a_{11}a_{22} - a_{12}a_{21} \leq 0$.

In virtue of Theorems 4.3 and 4.2 and Propositions 5.1 and 5.2, the first result of the existence of nonconstant positive solutions of (2.5) can be stated as follows.

THEOREM 5.1. *Assume that* $a_1 < 1$, (5.4), (5.5), *and assumptions in Theorem* 4.3 *hold. If* $\mu_2^*(d_2, d_3) \in (\mu_i,\, \mu_{i+1})$ *and* $\mu_3^*(d_2, d_3) \in (\mu_j,\, \mu_{j+1})$ *for some* $j > i \geq 0$, *where* $\mu_2^*(d_2, d_3)$, $\mu_3^*(d_2, d_3)$ *are defined in Proposition* 5.2, *and the sum* $\sum_{n=i+1}^{j} \dim E(\mu_n)$ *is odd, then there exists a positive constant* $\tilde{D}_1$ *such that, if* $d_1 \geq \tilde{D}_1$, (2.5) *admits at least one nonconstant positive solution.*

Proof. By Proposition 5.2 and our assumptions, there exists a positive constant $\tilde{D}_1$, such that when $d_1 \geq \tilde{D}_1$, (5.7) holds and

$$\mu_i < \tilde{\mu}_2(d_1;\, d_2, d_3) < \mu_{i+1}, \quad \mu_j < \tilde{\mu}_3(d_1;\, d_2, d_3) < \mu_{j+1}. \tag{5.9}$$

According to Theorem 4.2, for $\hat{d}_1$ and $\hat{d}_3$ satisfying $\mu_1\hat{d}_1 > 1$, $\mu_1\hat{d}_3 > m_2 - b_2$, there exists a large $\hat{d}_2$ such that (2.5) has no constant positive solutions when $d_1 \geq \hat{d}_1$, $\mu_1 d_2 \geq \hat{d}_2$, and $d_3 \geq \hat{d}_3$. In addition, since $\det\{\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})\} < 0$ and $\lim_{n\to\infty} \mu_n = \infty$, from (5.3), we can further choose $\hat{d}_1$, $\hat{d}_2$, and $\hat{d}_3$ to be so large that

$$H(\hat{d}_1,\, \hat{d}_2,\, \hat{d}_3;\, \mu_n) > 0 \quad \text{for all} \quad n \geq 0. \tag{5.10}$$

Now we show that for any $d_1 \geq \tilde{D}_1$, (2.5) has at least one nonconstant positive solution. The proof, which is accomplished by a contradiction argument, is based on the homotopy invariance of the topological degree. Suppose on the contrary that the assertion is not true for some $d_1 = \tilde{d}_1 \geq \tilde{D}_1$.

We fix $d_1 = \tilde{d}_1$. Let $d_i(t) = td_i + (1 - t)\hat{d}_i$, $i = 1, 2, 3$, and define $\mathcal{D}(t) = \operatorname{diag}(d_1(t), d_2(t), d_3(t))$. Now we consider the problem

$$\begin{cases} -\mathcal{D}(t)\Delta\mathbf{u} = \mathbf{G}(\mathbf{u}) & \text{in} \quad \Omega, \\ \partial_\nu \mathbf{u} = 0 & \text{on} \quad \partial\Omega. \end{cases} \tag{5.11}$$

Then $\mathbf{u}$ is a positive solution of (2.5) if and only if it is a positive solution of (5.11) for $t = 1$. It is obvious that $\tilde{\mathbf{u}}$ is the unique constant positive solution of (5.11) for any $0 \le t \le 1$. For any $0 \le t \le 1$, $\mathbf{u}$ is a positive solution of (5.11) if and only if

$$\mathbf{F}(t;\, \mathbf{u}) \equiv \mathbf{u} - (\mathbf{I} - \Delta)^{-1}\Big\{\mathcal{D}^{-1}(t)\mathbf{G}(\mathbf{u}) + \mathbf{u}\Big\} = 0 \quad \text{for} \quad \mathbf{u} \in \mathbf{X}^{+}.$$

Clearly, $\mathbf{F}(1;\, \mathbf{u}) = \mathbf{F}(\mathbf{u})$. Theorem 4.2 shows that the only positive solution of $\mathbf{F}(0;\, \mathbf{u}) = 0$ is $\tilde{\mathbf{u}}$. From direct calculation,

$$D_{\mathbf{u}}\mathbf{F}(t;\, \tilde{\mathbf{u}}) = \mathbf{I} - (\mathbf{I} - \Delta)^{-1}\{\mathcal{D}^{-1}(t)\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}}) + \mathbf{I}\}.$$

In particular,

$$\begin{aligned} D_{\mathbf{u}}\mathbf{F}(0;\, \tilde{\mathbf{u}}) &= \mathbf{I} - (\mathbf{I} - \Delta)^{-1}\{\hat{\mathcal{D}}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}}) + \mathbf{I}\}, \\ D_{\mathbf{u}}\mathbf{F}(1;\, \tilde{\mathbf{u}}) &= \mathbf{I} - (\mathbf{I} - \Delta)^{-1}\{\mathcal{D}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}}) + \mathbf{I}\} = D_{\mathbf{u}}\mathbf{F}(\tilde{\mathbf{u}}), \end{aligned}$$

where $\hat{\mathcal{D}} = \mathrm{diag}(\hat{d}_1,\, \hat{d}_2,\, \hat{d}_3)$. From (5.2) and (5.3) we see that

$$H(d_1, d_2, d_3;\, \mu) = \frac{1}{d_1 d_2 d_3}\mathcal{A}(d_1, d_3;\, \mu). \tag{5.12}$$

In view of (5.7) and (5.9), it follows from (5.12) that

$$\begin{cases} H(d_1, d_2, d_3;\, \mu_0) = H(0) > 0, \\ H(d_1, d_2, d_3;\, \mu_n) < 0, \quad i+1 \le n \le j, \\ H(d_1, d_2, d_3;\, \mu_n) > 0, \quad 1 \le n \le i \ \text{ and } \ n \ge j+1. \end{cases}$$

Therefore, zero is not an eigenvalue of the matrix $\mu_i\mathbf{I} - \mathcal{D}^{-1}\mathbf{G}_{\mathbf{u}}(\tilde{\mathbf{u}})$ for all $n \ge 0$, and

$$\sum_{n\ge 0, H(d_1,d_2,d_3;\,\mu_n)<0} \dim E(\mu_n) = \sum_{n=i+1}^{j} \dim E(\mu_n) = \text{an odd number}.$$

Then Proposition 5.1 shows that

$$\mathrm{index}(\mathbf{F}(1;\, \cdot),\, \tilde{\mathbf{u}}) = (-1)^{\gamma} = -1. \tag{5.13}$$

On the other hand, by (5.10) and Proposition 5.1 again, we obtain that

$$\mathrm{index}(\mathbf{F}(0;\, \cdot),\, \tilde{\mathbf{u}}) = (-1)^{0} = 1. \tag{5.14}$$

In view of $\tilde{d}_1 > \tilde{D}_1$, by Theorem 4.3, there exists a positive constant $C = C(\tilde{D}_1, d_2, d_3, \hat{d}_1, \hat{d}_2, \hat{d}_3, \Lambda)$ such that, for all $0 \le t \le 1$, the positive solutions of (5.11) satisfy $1/C < u_1,\, u_2,\, u_3 < C$. Therefore, $\mathbf{F}(t;\, \mathbf{u}) \ne 0$ on $\partial B(C)$ for all $0 \le t \le 1$. By the homotopy invariance of the topological degree,

$$\deg\left(\mathbf{F}(1;\, \cdot),\, 0,\, B(C)\right) = \deg\left(\mathbf{F}(0;\, \cdot),\, 0,\, B(C)\right). \tag{5.15}$$

Moreover, under our assumptions, the only positive solution of both $\mathbf{F}(1;\mathbf{u}) = 0$ and $\mathbf{F}(0;\, \mathbf{u}) = 0$ in $B(C)$ is $\tilde{\mathbf{u}}$, and hence, by (5.13) and (5.14),

$$\deg\left(\mathbf{F}(0;\, \cdot),\, 0,\, B(C)\right) = \mathrm{index}(\mathbf{F}(0;\, \cdot),\, \tilde{\mathbf{u}}) = 1$$

and

$$\deg\left(\mathbf{F}(1;\, \cdot),\, 0,\, B(C)\right) = \mathrm{index}(\mathbf{F}(1;\, \cdot),\, \tilde{\mathbf{u}}) = -1.$$

This contradicts (5.15), and the proof is complete. □

Remark 5.2. When d_3 is fixed, we note that $\lim_{d_2\to 0}\mu_2^*(d_2,d_3) = (a_{22}a_{33} - a_{23}a_{32})/(a_{22}d_3)$, $\lim_{d_2\to 0}\mu_3^*(d_2,d_3)=\infty$, and (5.5) is automatically fulfilled for small d_2. Therefore, if for all $i=0,1,2,\dots,\mu_i$ are simple and $(a_{22}a_{33}-a_{23}a_{32})/(a_{22}d_3)\neq\mu_i$, by Theorem 5.1, when $a_1<1$ and the assertion of Theorem 4.3 hold, there exist two sequences of intervals $\{(\theta_n^1,\theta_n^2)\}_{n=1}^\infty$ and $\{(\Theta_n^1,\Theta_n^2)\}_{n=1}^\infty$ satisfying $\theta_{n+1}^2<\theta_n^1$, $\Theta_n^2<\Theta_{n+1}^1$, and $\theta_n^1,\ \theta_n^2\to 0^+$ while $\Theta_n^1,\ \Theta_n^2\to\infty$ as $n\to\infty$ such that (2.5) admits at least one nonconstant positive solution for all $d_1\in(\Theta_n^1,\Theta_n^2)$ and $d_2\in(\theta_n^1,\theta_n^2)$, $n=1,2,3,\dots$. Recall that Theorem 4.3 holds when condition (i) or (ii) in Lemma 4.1 holds. When (i) (same as (3.8)) holds, (5.4) is not satisfied. But when (ii) in Lemma 4.1 holds, conditions in Theorem 5.1 can be satisfied.

Similarly, let us consider the case of large d_3. By Proposition 5.3 and Remark 5.1, we have the following theorem.

THEOREM 5.2. *Assume that* $a_1<1$, (5.4), (5.8), *and Theorem* 4.3 *hold.*

(i) *If* $a_{11}a_{22}-a_{12}a_{21}>0$, *then* $\mu_2^*(d_1,d_2)\in(\mu_i,\mu_{i+1})$, $\mu_3^*(d_1,d_2)\in(\mu_j,\mu_{j+1})$ *for some* $j>i\geq 0$, *and* $\sum_{n=i+1}^{j}\dim E(\mu_n)$ *is odd.*

(ii) *If* $a_{11}a_{22}-a_{12}a_{21}\leq 0$, $\mu_3^*(d_1,d_2)\in(\mu_j,\mu_{j+1})$ *for some* $j>0$, *and* $\sum_{n=1}^{j}\dim E(\mu_n)$ *is odd, where* $\mu_2^*(d_1,d_2)$, $\mu_3^*(d_1,d_2)$ *are defined in Proposition* 5.3, *then there exists a positive constant* $\tilde{D}_3$ *such that, if* $d_3\geq\tilde{D}_3$, (2.5) *admits at least one nonconstant positive solution.*

Remark 5.3. By Proposition 5.3, regardless of the sign of $a_{11}a_{22}-a_{12}a_{21}$, we have a conclusion similar to that in Remark 5.2. In addition, we mention that the sign of $a_{11}a_{22}-a_{12}a_{21}$ is indefinite when $a_1<1$, $a_{22}>0$, $\tilde{\mathbf{u}}$ exists, and the assertion of Theorem 4.3 holds (note that, if $\sqrt{a_2+m_2}<\sqrt{m_1-b_1}+\sqrt{b_2}$, then Theorem 4.3 is true by Lemma 4.1). The detailed analysis on this claim is left to the appendix.

Remark 5.4. Fix d_1 and d_2; by Remark 3.1, if $m_1=(b_1+a_2(m_2-b_2)/m_2)^2/(b_1+a_2(m_2-b_2)^2/m_2^2)-o(b_1)$, and $b_1\to 0$, a_2, b_2, m_2 are properly chosen and either $a_1\to 1/2$ or $a_1\to 1$, and d_3 is sufficiently large, Turing instability actually happens. Furthermore, combined with the analysis of the appendix, Proposition A.2(i) also holds for such chosen parameters. With proper choices of d_1 and d_2, we can find certain parameter ranges guaranteeing the existence of both Turing instability and the nonconstant positive solution to (2.5) by Theorem 5.2(i). As a consequence, Turing patterns exist for these parameter ranges.

6. Conclusions. In this paper, we analyze a reaction-diffusion food chain model with ratio-dependent functional response. We are mainly concerned with the coexistence of the three species and focus on the case of a weak predation rate for the pest species (i.e., $a_1<1$). In particular, the existence and nonexistence of nonconstant positive steady states have been established. The existence results provide a theoretical support for pattern formation caused by diffusion.

We summarize our investigation here and hope to reveal some interesting phenomena of pattern formation in population ecology. We always assume the existence of a constant coexistence. The main results of sections 3 and 4 show that this constant coexistence steady state $\tilde{\mathbf{u}}$ is the only steady state if (a) both of the predation rates a_1 and a_2 are small; (b) a_1 is small while a_2 is suitably chosen, and either the pest or the other two species diffuse quickly (Theorem 4.4). In the former case, we are also able to find a more restrictive parameter range so that $\tilde{\mathbf{u}}$ is globally asymptotically stable (Theorem 3.3). This can also be seen from a bifurcation point of view. Here if we assume that a_1 is small, then stronger stability results of $\tilde{\mathbf{u}}$ can be proved when a_2 is smaller. When a_2 is close to zero, then $\tilde{\mathbf{u}}$ is globally asymptotically stable; when a_2

increases, $\tilde{\mathbf{u}}$ is still locally asymptotically stable but may not be globally asymptotically stable, and it is still the only steady state; and when a_2 further increases, $\tilde{\mathbf{u}}$ becomes unstable for both the ODE and the reaction-diffusion system, and nonconstant patterns exist in this case. In the latter case, the diffusion of the first or third species must be large enough (see Theorems 5.1 and 5.2). Thus for small a_1 and suitable a_2, the quick migration of the plant or top predator enhances the formation of spatial pattern for the system. In contrast, the quick migration of the pest or both the plant and top predators tends to prevent the system from generating pattern. It is well known that fast diffusion of all species in a biological system will not lead to spatial inhomogeneous patterns; see [6]. Our result shows the importance of the diffusion rate of the middle species in a food chain. The large diffusion rate of the pest (middle species) alone can lead to the nonexistence of spatial patterns, but if the pest diffusion rate is not large, then all other diffusion rates must be large to prevent the occurrence of patterns. On the other hand, a large diffusion rate of the top species or bottom species will help the generation of patterns. This demonstrates that, in an ecological model, different diffusions may play essentially different roles in developing spatial patterns. In addition, taking into account the close relationship between the time-dependent solutions to a reaction-diffusion system and the corresponding steady state solutions, to a great extent, the dynamical behaviors of (2.4) will be determined by the diffusions of the three species.

These conclusions can also be compared with those in [28] and [36]. In the absence of u_3, (2.4) becomes the prey-predator model studied by Pang and Wang in [28]. The results of the existence and nonexistence of nonconstant positive solutions there indicate that large d_2 contributes to the evolution of heterogeneousness for the dynamics, while large d_1 tends to increase the possibility of spatial uniform distribution. Therefore, combined with the our conclusions for (2.5), this suggests that the structure of solutions to the model in [28] will be significantly different due to the emergence of the top predator, which in turn leads to the qualitative change of the biological mechanism of the system. Such a phenomenon was also discussed by Lou, Martinez, and Ni for the classical Lotka–Volterra competition model in [20].

In [36], Wang investigated a three-species prey-predator model. In that model, the interaction between the lower and middle species is described by Holling II-type functional response (prey-dependent), while the functional response between the middle and top species is ratio-dependent (predator-dependent). It was proved that Turing pattern may appear if both d_1 and d_3 are large, but will not if d_2 is large. Therefore the results of the present paper and [36] show that the formation of Turing pattern in the biological models with the same degree of complexity depends on the choices of functional responses. In other words, the feeding strategy of predators may be one of the determining factors in producing Turing pattern. In a very recent work [2], Alonso, Bartumeus, and Catalan performed some numerical calculations indicating that predator-dependent models are sometimes capable of generating Turing pattern, while similar prey-dependent models are not. Hence our theoretical analysis for the food chain model rigorously confirms the outcome of computer simulation in [2].

Finally we point out that some of our mathematical techniques in sections 4 and 5 can be applied to deal with the prey-predator model proposed by Pang and Wang in [28] and derive some new a priori estimates for positive steady state solutions and nonexistence results for nonconstant positive steady state solutions.

Appendix A. In section 6, to prove the existence of nonconstant positive solutions to (2.5), we have made some hypotheses, namely, $a_1 < 1,\ a_{22} > 0$, $\tilde{\mathbf{u}}$ exists, and The-

orem 4.3 holds (in particular, $\sqrt{a_2+m_2} < \sqrt{m_1-b_1}+\sqrt{b_2}$ means that Theorem 4.3 is true). We list these conditions as follows:

$$\text{(A.1)}\quad \begin{cases} a_1 < 1, \quad m_2 > b_2, \quad A > 1 \Longleftrightarrow a_2(m_2-b_2)/m_2 + b_1 < m_1, \\ \sqrt{a_2+m_2} < \sqrt{m_1-b_1}+\sqrt{b_2} \Longleftrightarrow (\sqrt{a_2+m_2}-\sqrt{b_2}\,)^2 + b_1 < m_1, \\ a_{22} > 0 \Longleftrightarrow m_1 < (b_1 + a_2(m_2-b_2)/m_2)^2/(b_1 + a_2(m_2-b_2)^2/m_2^2). \end{cases}$$

In the following, we will verify the claim made in Remark 5.3, which says that $a_{11}a_{22} - a_{12}a_{21}$ is indefinite when (A.1) holds. First of all, by the definitions of a_{11}, a_{22}, a_{12}, a_{21}, the direct computations yield the following proposition.

PROPOSITION A.1. *Define*

$$\begin{aligned} Q \equiv {} & -(1-a_1)a_2b_2(m_2-b_2)A^3 + (1-a_1)m_1m_2^2A^2 \\ & + [(2a_1-1)m_1m_2^2 - a_1a_2b_2(m_2-b_2)]A - a_1m_1m_2^2; \end{aligned}$$

then $a_{11}a_{22} - a_{12}a_{21} > 0 \Longleftrightarrow Q > 0$. *Moreover, we note that*

(i) *as* $a_1 \to 0$, $Q \to (m_1m_2^2(A-1) - a_2b_2(m_2-b_2)A^2)A$;

(ii) *as* $a_1 \to 1/2$, $Q \to -\frac{1}{2}a_2b_2(m_2-b_2)A^3 - \frac{1}{2}a_2b_2(m_2-b_2)A + \frac{1}{2}m_1m_2^2(A+1)(A-1)$;

(iii) *as* $a_1 \to 1$, $Q \to m_1m_2^2(A-1) - a_2b_2(m_2-b_2)A$.

PROPOSITION A.2. *The following results hold*:

(i) *If we take* $m_1 = (b_1 + a_2(m_2-b_2)/m_2)^2/(b_1 + a_2(m_2-b_2)^2/m_2^2) - o(b_1)$, *then* (A.1) *can be satisfied and* $Q > 0$ *if* $b_1 \to 0$, a_2, b_2, m_2 *are properly chosen and either* $a_1 \to 1/2$ *or* $a_1 \to 1$.

(ii) *If we take* $m_1 = b_1 + 1$, *then* (A.1) *can be satisfied and* $Q < 0$ *if* $b_1 \to \infty$, $a_2 > 1$, b_2, m_2 *are properly chosen and either* $a_1 \to 0$ *or* $a_1 \to 1/2$ *or* $a_1 \to 1$.

Proof. (i) As $b_1 \to 0$, $m_1 \to a_2$, and $A \to m_2/(m_2-b_2)$, it is clear that $Q > 0$ provided that $b_1 \to 0$ and either $a_1 \to 1/2$ or $a_1 \to 1$ by Proposition A.1. On the other hand, it is clear that there are a_2, b_2, m_2 such that (i) holds.

Now, we verify (ii). If $a_1 \to 1$, $Q \to m_1m_2^2(A-1) - a_2b_2(m_2-b_2)A$. Choosing $m_1 = b_1+1$ and letting $b_1 \to \infty$, we note that $A \to 1$ and $m_1(A-1) \to 1 - a_2(m_2-b_2)/m_2$. Therefore,

$$\text{(A.2)}\qquad Q < 0 \Longleftrightarrow 1 - a_2(m_2-b_2)/m_2 < a_2b_2(1-b_2/m_2)/m_2.$$

By the above choice, (A.1) becomes equivalent to

$$\text{(A.3)}\qquad \begin{aligned} a_2(m_2-b_2)/m_2 &< 1, \\ 1 + a_2(m_2-b_2)^2/m_2^2 &< 2a_2(m_2-b_2)/m_2, \\ \sqrt{a_2+m_2} &< 1 + \sqrt{b_2}. \end{aligned}$$

Claim. There exist a_2, b_2, m_2, and $b_2 < m_2$ such that (A.2) and (A.3) are true. In fact, let $b_2 = \alpha m_2$, where $\alpha \in (0,1)$ will be determined later. If $a_2 > 1$, solving (A.3), we have

$$(a_2-1)/a_2 < \alpha < \sqrt{(a_2-1)/a_2} \quad \text{and} \quad \alpha > \left(\sqrt{1+a_2/m_2} - \sqrt{1/m_2}\,\right)^2.$$

It is evident that if

$$\sqrt{(a_2-1)/a_2} > \left(\sqrt{1+a_2/m_2} - \sqrt{1/m_2}\right)^2, \tag{A.4}$$

there is α such that (A.3) holds. We verify that there exist a_2 and m_2 such that (A.4) is valid. Let $a_2 = \beta m_2$, where $\beta \in (0,\infty)$ will be determined later, and denote

$$f(\beta) = \sqrt[4]{1-1/a_2} + \sqrt{\beta/a_2} - \sqrt{1+\beta}.$$

So, for some $\beta > 0$, $f(\beta) > 0 \Longleftrightarrow$ (A.4) holds for some a_2 and m_2. Simple analysis shows that $f(\beta)$ attains its maximal value at $\beta = 1/(a_2-1)$ and $f(1/(a_2-1)) > 0$. Take $\beta = 1/(a_2-1)$. According to our notation, (A.2) becomes equivalent to $a_2(1-\alpha^2) - 1 > 0$. If $\alpha = \sqrt{(a_2-1)/a_2}$, $a_2(1-\alpha^2) - 1 = 0$. Hence, we can find α which is close to but less than $\sqrt{(a_2-1)/a_2}$ such that (A.2) is valid. Consequently, our claim holds.

For $a_1 \to 0$ or $a_1 \to 1/2$, as above, similar analysis can be done. Therefore, from these arguments, it can follow that (ii) is also true under our requirements. □

Acknowledgment. The authors wish to thank the referees for their constructive comments, which led to a significant improvement of the original manuscript.

A SIMPLE ILLUSTRATION OF A WEAK SPECTRAL CASCADE*

DAVID J. MURAKI†

Abstract. The textbook first encounter with nonlinearity in a partial differential equation (PDE) is the first-order wave equation: $u_t + uu_x = 0$. Often referred to as the inviscid Burgers equation, this equation is familiar to many in the theoretical contexts of characteristics, wavebreaking, or shock propagation. Another canonical behavior contained within this simplest of PDEs is the *spectral cascade*. Surprisingly, buried in a little-known 1964 article by G.W. Platzman is an elegant example of an exact Fourier series solution associated with a purely sinusoidal initial condition. This Fourier representation, valid prior to wavebreaking, is generalized to arbitrary continuous initial conditions on both the periodic and infinite domains. For the specific example of Platzman's original problem, the Fourier coefficients decay exponentially with increasing wavenumber, and the decay rate flattens to zero precisely at the time of wavebreaking. It is demonstrated that two simplified descriptions, a downscale truncation and a linearization from initial conditions, also produce an exponential spectral cascade uniformly to large wavenumbers. This weak cascade is responsible for the initial generation of Fourier harmonics in the viscous Burgers equation.

Key words. spectral cascade, nonlinear wave, inviscid Burgers equation

1. Introduction.

One of the first nonlinear partial differential equations (PDEs) typically encountered in the applied mathematical canon is the wave equation

$$u_t + uu_x = 0, \tag{1.1}$$

which, though elementary, provides a rich introduction to nonlinearity. As a first-order PDE, it provides an example with exact representations for the quasi-linear characteristics. Convergence of these characteristics leads to wavebreaking, multivaluedness, and the development of shock structures. Subsequent propagation of discontinuities is governed by Rankine–Hugoniot conditions obtained from conservation law properties of weak solutions. Beyond this, there is a vast literature associated with this equation whose early references include the simple wave of advection in one-dimensional fluid flow [7], the inviscid limit of the Burgers equation [2], and the kinematic wavespeed equation [21].

Without the advantages of linearity, the usual applications of Fourier methods do not generate modal solutions to (1.1). Rather the opposite occurs, as the forward time evolution from a sinusoidal initial condition, via the wave steepening process, immediately generates a solution with nonzero Fourier amplitudes at all scales. This is an example of a spectral cascade, whereby the nonlinear interaction of Fourier modes leads to an increase in the Fourier amplitudes at shorter spatial scales (higher wavenumbers). While this imagery of the downscale cascade is quite intuitive, as the textbook Fourier methods do not apply to nonlinear PDEs, the absence of illustrative examples is one barrier to elementary-level analysis of this process. It is relatively

unknown, however, that a Fourier series solution, whose coefficients are expressed as Bessel functions, can be elegantly derived for the evolution of (1.1) in the special case of a sinusoidal initial condition. This surprising result, by Platzman in 1964, appeared in *Tellus*, a journal for dynamic meteorology and oceanography [15].

In this article, we generalize this result to obtain an integral representation of the Fourier coefficients for arbitrary periodic initial conditions, which is valid up to the time of first wavebreaking. This gives an exact formula for each Fourier amplitude as a function of wavenumber and time, which requires only a spatial quadrature over the initial condition. For the wave equation (1.1), the Fourier spectrum is characterized by an exponential decay with wavenumber [18]. The increase in the decay rate with time is a convenient measure of the developing cascade. The weak cascade process is further investigated from the perspectives of spectral dynamics and linearized PDE dynamics about small amplitude initial conditions. For the specific case of sinusoidal initial conditions, both these perspectives on the cascade dynamics also produce short-time approximations where the exponential decay of the Fourier spectrum is uniform to large wavenumbers. The inviscid cascade is shown to be consistent with initial growth of the exponential spectra observed for the viscous Burgers equation. Finally, the Fourier solution of the wave equation is extended to the infinite line, where it is applied to the downscale cascade from a Gaussian initial condition.

The primary intent here is the presentation of explicit PDE solutions which illustrate the downscale cascade. First, we examine an exact integral formula for obtaining the Fourier coefficients of solutions to the nonlinear wave initial value problem (1.1). Additionally, the special Platzman solution, whose Fourier coefficients are expressible using Bessel functions, provides a benchmark against which we can compare various approximate descriptions of the cascade process. As it happens, the concepts required to relate this particular story nearly read as an introductory syllabus of applied mathematics: characteristics, Fourier representations, special functions, perturbation series, contour integration, and integral asymptotics. So, in keeping with the illustrative nature of this problem, these calculations have been presented in a manner to emphasize its more expository aspects.

2. From characteristics to Fourier series. Consider the general initial value problem of the nonlinear wave equation

$$u_t + uu_x = 0, \qquad u(x,0) = f(x), \tag{2.1}$$

periodic on a domain $-\pi \le x \le \pi$. The characteristics are curves in x-t space which are defined by the ordinary differential equation (ODE)

$$\frac{dx}{dt} = u, \qquad x(0) = x_0, \tag{2.2}$$

where x_0 labels the originating initial point at $(x,t) = (x_0, 0)$. Along this characteristic, the PDE (2.1) is now seen to be the perfect derivative

$$\frac{du}{dt} = 0, \qquad u(0) = f(x_0), \tag{2.3}$$

which shows that u maintains the constant value established at its initial point $(x_0, 0)$. Solutions to the ODEs (2.2) and (2.3) produce the wave solution

$$u = f(x_0), \qquad x = ut + x_0, \tag{2.4}$$

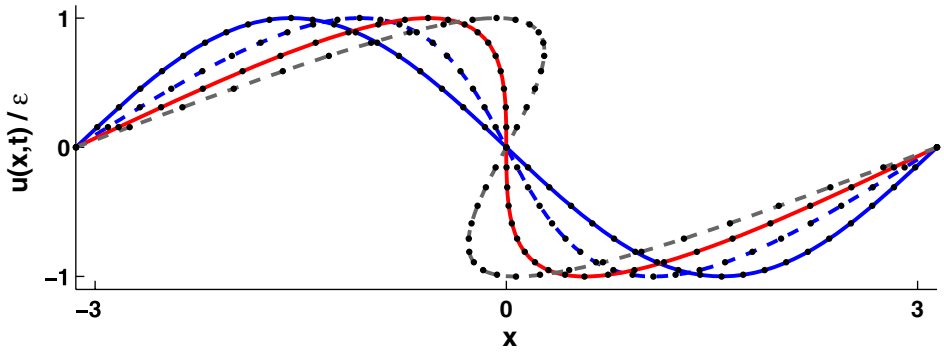

FIG. 2.1. *Wavebreaking evolution of $u(x,t)/\epsilon$ beginning from a sinusoidal initial condition* (2.6). *Shown are scaled times $\epsilon t = 0, 1/2, 1, 3/2$ with the initial and critical wavebreaking profiles in solid and an overturning profile in gray dashed. Obtained from the parametric solution* (2.4), *the dots track values of $u = f(x_0)$ corresponding to characteristics labeled by x_0 at intervals of $\pi/20$.*

expressed as a parametrization on x_0. Eliminating the parameter immediately produces the well-known implicit general solution for $u(x,t)$:

$$u = f(x - ut). \tag{2.5}$$

It is a consequence of the nonlinearity in (1.1) that (nontrivial) solutions beginning from smooth initial conditions will eventually develop a finite-time derivative singularity. Figure 2.1 shows the solution $u(x,t)$ beginning from the sinusoidal initial condition

$$f(x) = -\epsilon \sin x \tag{2.6}$$

at times $\epsilon t = 0, 1/2, 1, 3/2$, where the critical wavebreaking event occurs at $\epsilon t_c = 1$. Although the ϵ can be removed by rescaling, it is retained for future convenience in the short-time analyses in later sections.

At first glance, construction of a Fourier series solution directly from the PDE (1.1) seems unlikely since nonlinearity precludes the usual application of Fourier transforms. It is a truly remarkable consequence from Platzman's original analysis that the Fourier series representation of $u(x,t)$,

$$u(x,t) = \frac{a_0}{2} + \sum_{n=1}^{\infty} [a_n(t) \cos nx + b_n(t) \sin nx], \tag{2.7}$$

$$a_n(t) = \frac{1}{\pi} \int_{-\pi}^{+\pi} u(x,t) \cos nx \, dx, \tag{2.8}$$

$$b_n(t) = \frac{1}{\pi} \int_{-\pi}^{+\pi} u(x,t) \sin nx \, dx, \tag{2.9}$$

has coefficients $a_n(t)$ and $b_n(t)$, which can be manipulated into integrals completely determined by the given initial profile $f(x)$. For the sine coefficient $b_n(t)$, this reformulation begins from an integration by parts of (2.9), followed by a replacement of u_x using the parametrized form of the characteristic $x = ut + x_0$ (2.4),

$$b_n(t) = \frac{1}{\pi n}\int_{-\pi}^{+\pi} u_x(x,t)\cos nx\,dx$$
$$= \frac{1}{\pi nt}\int_{-\pi}^{+\pi}\left(1-\frac{dx_0}{dx}\right)\cos nx\,dx. \tag{2.10}$$

Noting that only the dx_0/dx-term contributes to the full-period integration, changing the variable of integration to x_0 gives

$$b_n(t) = -\frac{1}{\pi nt}\int_{-\pi}^{+\pi}\cos[nx_0 + nt\,f(x_0)]dx_0 \tag{2.11}$$

and achieves a final integral which involves only the initial condition (2.1). Analogous operations obtain the cosine coefficients for $n \geq 0$:

$$a_n(t) = \begin{cases} \dfrac{1}{\pi}\displaystyle\int_{-\pi}^{+\pi} f(x_0)dx_0 & \text{for } n = 0, \\ \dfrac{1}{\pi nt}\displaystyle\int_{-\pi}^{+\pi}\sin[nx_0 + nt\,f(x_0)]dx_0 & \text{for } n > 0, \end{cases} \tag{2.12}$$

where the exceptional $n = 0$ case is simply the conservation of the mean by the PDE (1.1). It is important to note that the use of integration by parts assumes that the solution remains continuous and hence is not valid after wavebreaking.

A further step can be taken by substituting the Fourier coefficients (2.12) and (2.11) back into the series (2.7). First, the Fourier sine and cosine sums collapse into a single sum

$$u(x,t) = \frac{a_0}{2} + \sum_{n=1}^{\infty}\frac{1}{\pi nt}\int_{-\pi}^{+\pi}\sin n[x - x_0 - tf(x_0)]dx_0$$
$$= \frac{a_0}{2} + \frac{1}{t}\int_{-\pi}^{+\pi}\left[\left(\frac{x - x_0 - t\,f(x_0)}{2\pi}\mathrm{mod}1\right) - \frac{1}{2}\right]dx_0; \tag{2.13}$$

then an interchange of sum and integral yields what seems to be a quadrature solution for (2.1). Prior to crossing of characteristics, however, $u(x,t)$ cannot depend globally on the initial condition, but is determined exactly by one value of the initial condition. The resolution of this apparent nonlocality is the presence of the modulus in (2.13), which produces a discontinuous integrand. The discontinuity occurs precisely at the unique value of x_0 parametrizing the characteristic (2.4) that determines $u(x,t)$. Shifting the integration domain to the periodic interval $x_0 - 2\pi \leq y \leq x_0$ allows the removal of the modulus

$$u(x,t) = \frac{a_0}{2} + \frac{1}{t}\int_{x_0-2\pi}^{x_0}\left[\frac{x - y - t\,f(y)}{2\pi} - \frac{1}{2}\right]dy$$
$$= \left[\frac{a_0}{2} - \frac{1}{2\pi}\int_{x_0-2\pi}^{x_0} f(y)\;dy\right] + \int_{x_0-2\pi}^{x_0}\left[\frac{x - x_0}{2\pi t} - \frac{y - (x_0 - \pi)}{2\pi t}\right]dy$$
$$= \frac{x - x_0}{t} = f(x_0) \tag{2.14}$$

and, after some grouping of terms, reduces the integral to the local value $f(x_0)$. Similarly, for the case when several characteristics are involved, the integral then

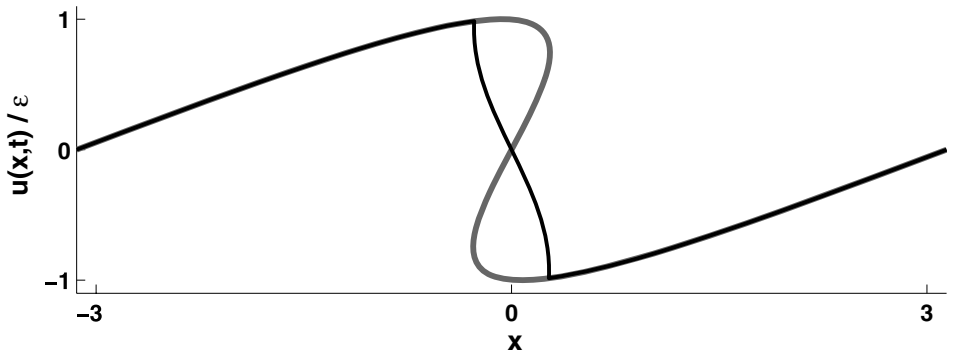

FIG. 2.2. *The characteristic solution* (2.4) *from Figure* 2.1 *(thick, light curve) beyond the wave-breaking time* ($\epsilon t = 3/2$) *compared with the Fourier series representation* (3.2)*, which is single-valued and continuous (thin, dark curve). The two solutions differ only in regions where the characteristic solution is multivalued.*

becomes a weighted sum over all such characteristic values $\pm f(x_0)$, where the sign matches that of dx/dx_0. For instance, when the characteristic solution becomes triple-valued ($u_b < u_m < u_t$), the series adopts the value $u_b - u_m + u_t$. This averaging effect within the Fourier series is illustrated by the thin dark curve in Figure 2.2, in comparison to the multivalued characteristic solution ($\epsilon t = 3/2$) as replicated from Figure 2.1. Thus, although the Fourier series defined by (2.11) and (2.12) no longer satisfies the original PDE (1.1) after wavebreaking, the series retains a meaning related to the multivaluedness of the characteristic solution (2.4), but not one connected with any of the usual entropy solutions [8].

3. Platzman's solution and its downscale cascade. The specific example considered by Platzman [15] was based upon the sinusoidal initial condition (2.6), whose forward evolution is shown as Figure 2.1. It is this solution for which Platzman essentially realized that the Fourier coefficient (2.11),

$$b_n(t) = -\frac{1}{\pi nt}\int_{-\pi}^{+\pi} \cos(nx_0 - nt\epsilon \sin x_0)dx_0 = -2\frac{J_n(\epsilon nt)}{nt}, \tag{3.1}$$

resulted in a standard integral representation of the Bessel function of order n [1]. This produced a solution to the nonlinear wave equation (1.1) having an exact expression for its Fourier sine series

$$u(x,t) = -2\sum_{n=1}^{\infty} \frac{J_n(\epsilon nt)}{nt} \sin nx, \tag{3.2}$$

where, in the $t \to 0^+$ limit, only the $n = 1$ term is nonzero and the initial condition (2.6) is satisfied. In classical analysis, summations whose terms involve Bessel functions of increasing indices and arguments are known as Kapteyn series [19]. As a historical aside, Platzman also recognized that the identical series also appears in the analysis of the Keplerian orbital problem.

It is clear from the coefficients (3.1) that all modes become activated for $t > 0$. This is an illustration of a *downscale spectral cascade* whereby the nonlinear evolution from a single initial Fourier mode leads to the immediate appearance of all smaller

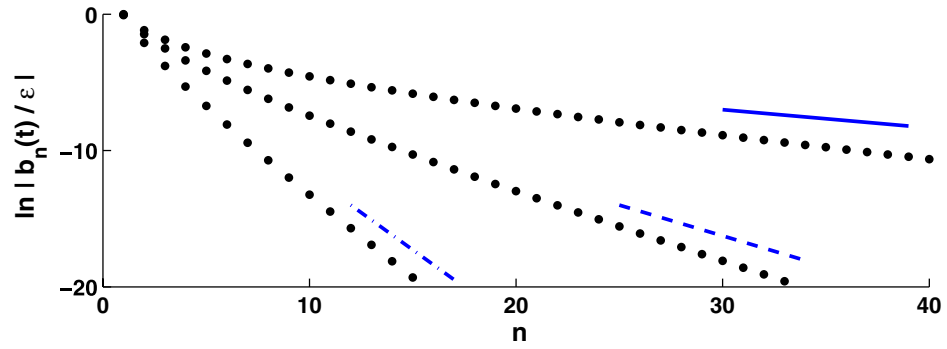

FIG. 3.1. *Semilog plot of spectral amplitudes $b_n(t)/\epsilon$ for Platzman's Fourier series solution* (3.2) *showing the growth of the $n > 1$ modes at scaled times $\epsilon t = 1/4, 1/2, 3/4$. The exponential spectrum is indicated by linear asymptotes* (3.5), *which are becoming flatter with time (dash-dot, dash, solid), and thus illustrates a downscale spectral cascade. The decrease in the fundamental $n = 1$ mode is not discernable on this semilog axis.*

scales. A Bessel recurrence identity [1] gives an alternate expression for (3.1),

$$b_n(t) = -\epsilon \frac{J_{n+1}(\epsilon n t) + J_{n-1}(\epsilon n t)}{n}, \tag{3.3}$$

from which it follows that the $n \geq 2$ amplitudes $|b_n(t)|$ are strictly increasing up to the time of wavebreaking, since $J_n'(z) > 0$ in the interval $0 < z < n$ [19]. The exception is the fundamental amplitude $|b_1(t)|$, the source of the cascade, which decreases steadily and is roughly 88% of its original amplitude at the time of critical wavebreaking. Figure 3.1 shows a semilog plot of the Fourier amplitudes against wavenumber for the times $\epsilon t = 1/4, 1/2, 3/4$.

Also shown in Figure 3.1 are lines indicating the large-n asymptotic slopes of the semilog spectral amplitudes. These are evident from the Debye expansions for the Bessel functions of large index and argument [1],

$$|b_n| \sim \sqrt{\frac{2}{\pi t^2 \tanh\alpha}}\, n^{-3/2} e^{n(-\alpha + \tanh\alpha)} \quad \text{as } n \to \infty, \tag{3.4}$$

where $\cosh\alpha = 1/\epsilon t$. This wavenumber-dependence of the Fourier coefficient reflects the (real) analytic nature of the solution $u(x,t)$ [3]. The spectral slope, $-\alpha + \tanh\alpha$, represents the exponential decay rate with wavenumber and can be explicitly written in terms of ϵt:

$$\frac{\ln|b_n|}{n} \sim \ln\left(\frac{\epsilon t}{2}\right) + \sqrt{1-\epsilon^2 t^2} - \ln\left(\frac{1+\sqrt{1-\epsilon^2 t^2}}{2}\right) \quad \text{as } n \to \infty. \tag{3.5}$$

This expression is equivalent to that deduced by Sulem, Sulem, and Frisch [18] from the pole singularities of the analytic continuation of $u(x,t)$ to the complex x-plane.[1] The early cascade has a spectral slope whose growth is logarithmic in time and corresponds to a geometric decay of the Fourier amplitudes by the factor ϵt (as illustrated

[1] Also in [18] is the identification of a narrow $n^{-4/3}$ spectral regime which occurs just prior to the critical wavebreaking time. This corresponds to a special case of the Bessel asymptotics [1].

later in (5.3)). However, as the wavebreaking $\epsilon t = 1$ is approached, the spectral slope flattens to zero. After this time, the decay becomes algebraic following the development of the derivative singularities such as those shown in Figure 2.2.

The connection of (3.1) to a known integral identity appears to be unique to the Platzman initial condition. More generally, however, the form of (2.12) and (2.11) is such that when the integrands are analytic, extraction of the exponential cascade can be approached by deforming the path of integration into the complex x-plane. For entire $f(x)$, the method of steepest descent applies, as the integration path can be deformed such that the large n contribution is localized to a saddle point. This approach can also be used to obtain (3.4). The saddle-point method is illustrated by the example for the infinite line formulation in section 7.

4. Spectral dynamics and the short-time cascade. A conventional approach for analyzing the cascade is by direct substitution of the series (2.7) into the PDE (1.1). For the special case of a Fourier sine series, the terms involved in the $\sin nx$-mode are

$$\begin{aligned} \cdots + b_n' \sin nx + \cdots & \\ + \sum_{1}^{n-1} \quad & k b_k b_{n-k} \cos kx \sin(n-k)x \\ + \sum_{1}^{\infty} \quad & k b_k b_{n+k} \cos kx \sin(n+k)x \\ + \sum_{1}^{\infty} \quad & (n+k) b_{n+k} b_k \cos(n+k)x \sin kx \quad + \cdots = 0. \end{aligned} \tag{4.1}$$

After applying a trigonometric product identity and reorganizing the terms, a description of the spectral dynamics is obtained as coupled ODEs:

$$b_n' = -\frac{n}{4} \sum_{1}^{n-1} b_k b_{n-k} + \frac{n}{2} \sum_{1}^{n-1} b_k b_{n+k} + \frac{n}{2} \sum_{n}^{\infty} b_k b_{n+k} \tag{4.2}$$

for the amplitudes $b_n(t)$ over wavenumbers n. The first of the three sums corresponds to downscale transfer involving longer waves with wavenumbers from below, $k < n$ and $(n-k) < n$. The second corresponds to mixing transfer involving straddling wavenumbers, $k < n < n+k$, while the third corresponds to upscale transfer involving only shorter waves, $n \le k < n+k$. These last two summations can be combined into a single sum. It is quite unclear as to how the Bessel amplitudes (3.1) could possibly have been directly obtained beginning only from the spectral ODEs (4.2) and the initial conditions $\{b_n(0)\} = \{-\epsilon, 0, 0, \ldots\}$.

Analytical progress is possible, however, in the limit of small ϵ. At $O(1)$ times, the assumption of small amplitude initial condition leads to a wavenumber scaling of the Fourier amplitudes $b_n(t) = O(\epsilon^n)$ and allows a natural truncation of the spectral dynamics (4.2) to involve only the downscale transfer summation

$$\tilde{b}_n' = \begin{cases} 0 & \text{for } n = 1, \\ -\dfrac{n}{4} \displaystyle\sum_{1}^{n-1} \tilde{b}_k \tilde{b}_{n-k} & \text{for } n \ge 2. \end{cases} \tag{4.3}$$

This will be referred to as the downscale cascade truncation. The exact solution to the above truncation must therefore be the small ϵ limit of Platzman's solution (3.1),

$$\tilde{b}_n(t) = -\epsilon \frac{n^{n-1}}{n!} \left(\frac{\epsilon t}{2}\right)^{n-1}, \tag{4.4}$$

which derives from the first nonzero term of the Taylor expansion for the Bessel function [1]. Verification of this, by direct substitution of (4.4) into (4.3), yields a combinatorial identity of uncommon origin—one such instance is found in graph theory as an elementary counting of trees [10]. A direct approach for arriving at expression (4.4) is via a generating function

$$B(z,t) = \sum_{n=1}^{\infty} \tilde{b}_n(t) \frac{e^{inz}}{2i}. \tag{4.5}$$

By virtue of the downscale spectral dynamics (4.3), $B(z,t)$ also satisfies the same nonlinear wave equation (1.1),

$$B_t + BB_z = 0, \qquad B(z,0) = \epsilon \frac{e^{iz}}{2i}, \tag{4.6}$$

but now with a complex-valued initial condition that is exactly the restriction of the original sinusoid to the positive wavenumber modes. Solution by characteristics leads to the implicit relation

$$iBte^{iBt} = \frac{\epsilon t}{2} e^{iz}, \tag{4.7}$$

whose inversion can be expressed in terms of Lambert's transcendental equation (see also [20]), and otherwise designated by the *W-function* [6],

$$B(z,t) = -\frac{i}{t} W\left(\frac{\epsilon t}{2} e^{iz}\right). \tag{4.8}$$

However, explicit recovery of the formula for the coefficients (4.4) follows more directly from (4.7) with the application of the Lagrange inversion theorem. Using the Stirling approximation for the factorial in (4.4) gives the large wavenumber behavior

$$\tilde{b}_n \sim -\sqrt{\frac{2}{\pi t^2}} n^{-3/2}\, e^n \left(\frac{\epsilon t}{2}\right)^n \quad \text{for } n \to \infty \tag{4.9}$$

and implies the downscale spectral slope

$$\frac{\ln|\tilde{b}_n|}{n} \sim \ln\left(\frac{\epsilon t}{2}\right) + 1 \quad \text{as } n \to \infty \text{ for } \epsilon t \ll 1. \tag{4.10}$$

The difference here from the full cascade (3.5) is that the slope from the downscale cascade truncation (4.10) is less steep, as the exclusion of any upscale transfers results in a more rapid generation of a smaller-scale spectrum. Hence, at short times ($\epsilon t \ll 1$), the spectral slope (3.5) for Platzman's example is well described by the downscale cascade approximation (4.3).

5. A linearized description of the weak cascade. One conclusion from the previous section is that even the truncation of the spectral dynamics to the downscale transfer requires the solution of a fully nonlinear problem. As such, the results relied upon considerable good karma in there being an exact solution (4.4) to a system of nonlinear equations (4.3). In this section, a linear approach is investigated for constructing an approximate solution to the PDE (2.1) that involves the full spectrum of wavenumbers.

Consider a weakly nonlinear analysis which seeks the form of a perturbation expansion

$$u(x,t) \sim f(x) + u_2(x,t) + u_3(x,t) + \cdots, \tag{5.1}$$

where the first term is a small amplitude initial condition $f(x) = O(\epsilon) \gg u_2(x,t) \gg u_3(x,t)\ldots$ for $\epsilon \ll 1$. The simplest such expansion assumes that the corrections $u_n(x,t) = O(\epsilon^n)$. Substituting (5.1) into the PDE and collecting on powers of ϵ gives the sequence of equations

$$\frac{\partial u_n}{\partial t} = -\sum_1^{n-1} u_{n-k}\frac{\partial u_k}{\partial x}, \qquad u_n(x,0) = 0, \tag{5.2}$$

which can be solved iteratively for $n \geq 2$ by direct integration for $t > 0$. For the sinusoidal initial conditions, the first two corrections are

$$\begin{aligned} u_2(x,t) &= -\epsilon \left(\frac{\epsilon t}{2}\right) \quad \sin 2x, \\ u_3(x,t) &= -\epsilon \left(\frac{\epsilon t}{2}\right)^2 \quad \left\{\frac{3}{2}\sin 3x - \sin x\right\}; \end{aligned} \tag{5.3}$$

subsequent terms $u_n(x,t)$ contain only $O(\epsilon^n)$ expressions, which include not only the short-time harmonic $\tilde{b}_n(t)\sin nx$ from the downscale transfer (4.4), but also smaller harmonics due to contributions from the straddling and upscale transfers (4.2). Finite application of this method thus produces an $O(\epsilon^n)$ series expansion limited to the first n harmonics. Such a finite expansion is not a uniform approximation over wavenumbers, since for the sinusoidal initial condition the extent to which the spectral cascade is realized is limited by the number of terms in the expansion (5.1).

To develop an approach which involves all harmonics, consider the solution as a disturbance from a small amplitude initial condition

$$u(x,t) = f(x) + \tilde{u}(x,t), \tag{5.4}$$

so that $\tilde{u}(x,t) \ll f(x) = O(\epsilon)$. This results in the exact disturbance equation

$$\tilde{u}_t = -ff_x - (f\tilde{u})_x - \tilde{u}\tilde{u}_x, \quad \tilde{u}(x,0) = 0, \tag{5.5}$$

where the right-hand side terms are nominally $O(\epsilon^2), O(\epsilon^3)$, and $O(\epsilon^4)$. If (5.5) is approximated by keeping only the ff_x-term, then the disturbance $\tilde{u}(x,t)$ is $O(\epsilon^2)$-correct and would be identical to $u_2(x,t)$ as determined by (5.2). Alternatively, an additional order in $\tilde{u}(x,t)$ is achieved if only the last and nonlinear disturbance term is neglected. This truncation can be interpreted as a first Newton iterate, since the $\tilde{u}$-correction is obtained by a linearized solve against a residual error (in the form of the ff_x-term). Thus we consider the linearized problem

$$U_t + (fU)_x = -ff_x, \quad U(x,0) = 0, \tag{5.6}$$

so that $u(x,t) \sim f(x)+U(x,t)$ constitutes an $O(\epsilon^3)$-correct asymptotic representation. Multiplying the equation though by $f(x)$ and defining $v(x,t) = f(x)\,U(x,t)$ gives

$$v_t + f v_x = -\frac{1}{2} f (f^2)_x, \quad v(x,0) = 0, \tag{5.7}$$

which is a first-order but nonconstant coefficient and inhomogeneous PDE. Unlike the original PDE (1.1), the characteristics for the linearization (5.6) do not depend on the solution, but only on the initial condition, via

$$\frac{dx}{dt} = f(x), \quad x(0) = x_0, \tag{5.8}$$

where again x_0 labels the originating initial point at $(x,t) = (x_0, 0)$. Along this characteristic, the PDE (5.8) now becomes the perfect derivative

$$\frac{dv}{dt} = -\frac{1}{2}\frac{dx}{dt}(f^2)_x = -\frac{1}{2}\frac{d(f^2)}{dt}, \quad v(x_0,0) = 0, \tag{5.9}$$

which relies upon the t-independence of f^2. Direct integration from a zero initial condition gives the solutions

$$\begin{aligned} v(x,t) &= -\frac{1}{2}\left(f^2(x) - f^2(x_0)\right), \\ U(x,t) &= -\frac{1}{2}\left(\frac{1 - f^2(x_0)}{f^2(x)}\right) f(x), \end{aligned} \tag{5.10}$$

where the label $x_0 = x_0(x,t)$ is obtained by inverting the solution of the characteristic ODE (5.8). Specifically for Platzman's initial condition, it is shown next that this correction term is no longer spectrally limited to a few harmonics but embodies a cascade across all wavenumbers.

For the case of $f(x) = -\epsilon \sin x$, the characteristic ODE (5.8) is a nonlinear but separable equation; hence

$$\ln\left(\frac{\tan x/2}{\tan x_0/2}\right) = \int_{x_0}^{x} \frac{dx}{\sin x} = -\epsilon \int_0^t dt = -\epsilon t, \tag{5.11}$$

from which the trigonometric relation $\tan(x_0/2) = e^{\epsilon t}\tan(x/2)$ follows. Using this and a half-angle identity gives

$$\sin x_0 = \frac{2\tan(x_0/2)}{1+\tan^2(x_0/2)} = \frac{2e^{\epsilon t}\tan(x/2)}{1+e^{2\epsilon t}\tan^2(x/2)} = \frac{\operatorname{sech}\epsilon t}{1-\tanh\epsilon t\cos x}\sin x, \tag{5.12}$$

which, in the Platzman case, effects the inversion of the characteristic label x_0 into the original x,t-coordinates. Thus, the linearized solution (5.10) leads to the asymptotic approximation

$$u(x,t) \sim -\epsilon \sin x + \frac{\epsilon}{2}\left(1 - \frac{\operatorname{sech}^2\epsilon t}{(1-\tanh\epsilon t\cos x)^2}\right)\sin x + O(\epsilon^4), \tag{5.13}$$

where the second term is actually $O(\epsilon^2)$ with the vanishing of the bracketed factor when $\epsilon = 0$.

Obtaining the spectral cascade requires finding the Fourier series representation of (5.13). The obvious problematic term is the second term in the correction whose Fourier-sine coefficient is the imaginary part of

$$-\frac{\epsilon}{2\pi}\operatorname{sech}^2\epsilon t\int_{-\pi}^{+\pi}\frac{e^{inx}\sin x}{(1-\tanh\epsilon t\cos x)^2}\,dx. \tag{5.14}$$

This expression can be evaluated via complex contour integration around a rectangle whose corners are $\{-\pi,+\pi,+\pi+iY,-\pi+iY\}$. Contributions from the sides parallel to the imaginary axis cancel by the periodicity of the integrand, and the contribution from the side with $\operatorname{Im}(z)=Y$ tends to zero as $Y\to+\infty$ by the decay of the integrand. The closed contour contains only a double pole at z_p, where

$$\begin{aligned}\cos z_p=\cosh iz_p&=\frac{\tanh(\epsilon t2)+\coth(\epsilon t2)}{2}=\coth\epsilon t\\ \Rightarrow\qquad e^{iz_p}&=\tanh(\epsilon t2),\end{aligned} \tag{5.15}$$

and thus is located along the positive imaginary axis for $\epsilon t>0$. The end result of this residue calculation is the series representation for (5.13):

$$u(x,t)\sim-\frac{\epsilon}{2}\left(\sin x+\operatorname{sech}^2(\epsilon t2)\sum_1^\infty n\tanh^{n-1}(\epsilon t2)\sin nx\right), \tag{5.16}$$

which reveals that again the spectrum has exponential decay, whose spectral slope is

$$\text{slope}\ \sim\ \ln\left|\tanh\frac{\epsilon t}{2}\right|\quad\text{as } n\to\infty\ \text{ for } \epsilon t\ll 1. \tag{5.17}$$

Thus the logarithmic part of the $\epsilon t\ll 1$ spectral slope is obtained. It is emphasized that this is really just a scaling result on the amplitudes, indicating only that harmonics decay as powers of ϵt. This limited result is not too surprising since the downscale cascade within the short-time and linear approximation is still a fully nonlinear process (4.3). Nonetheless, for the sinusoidal initial condition, the linearization (5.6) does produce, after just one perturbative calculation, an explicit short-time correction (5.13) that is asymptotically valid only to $O(\epsilon^3)$ yet captures the exponential decay of the spectrum uniformly to large wavenumbers.

More generally, the linearization generates Fourier harmonics through the action of the nonconstant coefficient (5.7), as the Fourier harmonics are no longer the linear modes. In essence, this allows a coupling between Fourier coefficients, but one where the strength of the interaction is determined by the nonconstant coefficient and hence is fixed in time by the initialized state. The above example shows that even when the coupling is established by an initial condition consisting only of a single initial sinusoid, the cascade described by (5.6) captures the downscale cascade with an exponential decay in wavenumber. A second example of a linearized cascade based on a spectrally richer initial Gaussian is computed for the infinite line case of section 7.

6. The weak cascade of the Burgers equation. The exponential spectrum appears in the wave equation (1.1) as a consequence of pole singularities associated with the analytic continuation of the inversion (2.5) over complex x [18]. An exponential spectrum is also common to solutions of the Burgers equation [16, 18], and it includes the effect of viscous, linear dissipation into the nonlinear wave equation [2]:

$$u_t+uu_x=\sigma u_{xx},\qquad u(x,0)=f(x). \tag{6.1}$$

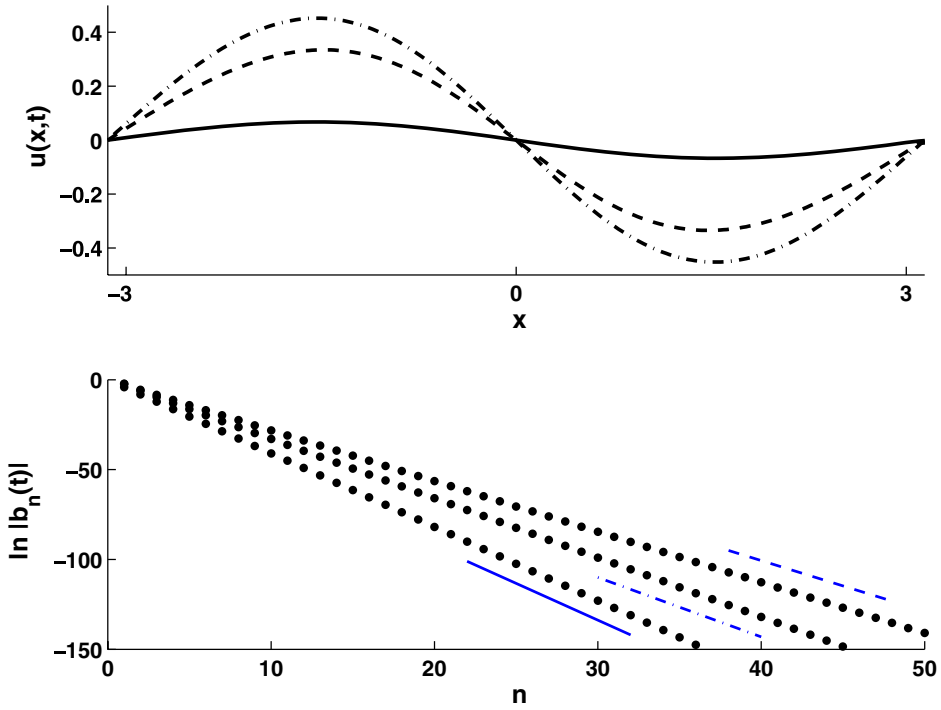

FIG. 6.1. *Top panel shows a Burgers solution beginning from a sinusoidal initial condition for* $\epsilon = 0.5$, $\sigma = 1.0$ *at times* $t = 0.1, 0.4, 2.0$ *(dash-dot, dashed, solid). Bottom panel shows the corresponding semilog Fourier spectra with the asymptotic slopes indicated. The spectral slope initially increases until roughly* $t = 0.4$*, and then decreases linearly in time.*

A familiar spectral result [2, 18, 4] is the exponential spectrum for the steady-state tanh-solution. It is also well known that the Burgers dynamics is equivalent to the linear diffusion equation via the Hopf–Cole transformation [21],

$$u = -2\sigma \frac{\psi_x}{\psi}, \qquad \psi_t = \sigma \psi_{xx}. \tag{6.2}$$

For Hopf–Cole functions $\psi(x,t)$ which are meromorphic over complex x, the evaluation of Fourier coefficients

$$b_n(t) = -\frac{2\sigma}{\pi} \mathrm{Imag} \int_{-\pi}^{+\pi} \frac{\psi_x(x,t)}{\psi(x,t)} e^{inx} dx \tag{6.3}$$

by a contour integration of the type used to obtain (5.14) involves only simple poles. The residue of the pole with smallest imaginary part determines the spectral slope of the exponential spectrum [18].

The upper panel of Figure 6.1 shows the decay of the Burgers solution beginning from an initial sinusoid (2.6) of small amplitude ($\epsilon = 0.5$, $\sigma = 1.0$) as computed by a fully spectral code. Clearly apparent in the lower panel of Figure 6.1 are the linear asymptotes in the corresponding semilog plots of Fourier amplitudes. Inspection of the chronology of the spectra (dash-dot, dashed, solid) reveals that the spectral slopes initially increase in time, and subsequently decrease through the action of viscous dissipation. Figure 6.2 (solid) shows the best-fit spectral slopes, as a function of

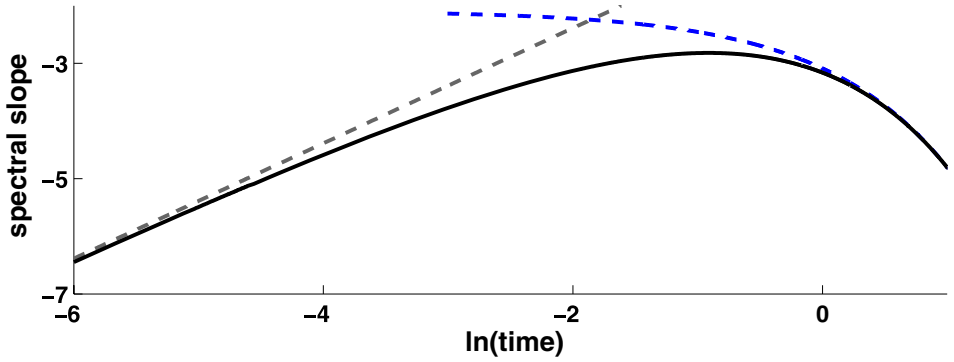

FIG. 6.2. *The semilog spectral slope as a function of log-time for the evolution of Figure* 6.1 *as obtained by the best-fit line over modes* $n = 80$–100 *(solid). At short times, the Platzman spectral slope* (4.10) *illustrates that the growth of the initial cascade scales similarly as the inviscid dynamics (gray dashed). At long times, the slope follows the asymptote as obtained from the Hopf–Cole solution* (6.8) *and shows the erosion of the spectrum by the viscous decay (dashed).*

log-time, for the evolution of Figure 6.1. In terms of the spectral slope, the Burgers cascade exhibits the same growth as the inviscid cascade (4.10) at very early times (gray dashed). At later times, when the amplitudes are decaying, the spectral slope approaches a linear-in-time asymptote (dashed). It is not apparent how to obtain the early-time spectral growth directly from the Hopf–Cole solution, but the long-time behavior is easily extracted.

The initial Hopf–Cole function is given by

$$\psi(x,0) = \exp\Big(-\frac{\epsilon}{2\sigma}\cos x\Big) = I_0\Big(\frac{\epsilon}{2\sigma}\Big) + 2\sum_1^\infty I_n\Big(-\frac{\epsilon}{2\sigma}\Big)\cos nx, \tag{6.4}$$

where the series representation [1] involves a modified Bessel identity which is closely related to that used in the Platzman cascade (3.1). The time-dependent evolution thus has the exact Fourier solution

$$\psi(x,t) = I_0\Big(\frac{\epsilon}{2\sigma}\Big) + 2\sum_1^\infty I_n\Big(-\frac{\epsilon}{2\sigma}\Big)\, e^{-\sigma n^2 t}\cos nx. \tag{6.5}$$

After sufficiently long times (regardless of the values of ϵ and σ), the Hopf–Cole dynamics is dominated by the slowest decaying $n = 1$ mode,

$$\psi(x,t) \sim I_0\Big(\frac{\epsilon}{2\sigma}\Big) - 2I_1\Big(\frac{\epsilon}{2\sigma}\Big)\, e^{-\sigma t}\cos x. \tag{6.6}$$

The corresponding Burgers solution then has the form

$$\begin{aligned} u(x,t) &\sim -4\sigma \frac{I_1(\epsilon/2\sigma)e^{-\sigma t}\sin x}{I_0(\epsilon/2\sigma) - 2I_1(\epsilon/2\sigma)e^{-\sigma t}\cos x} \\ &= -4\sigma\sum_1^\infty e^{n\rho}\sin nx, \end{aligned} \tag{6.7}$$

where the spectral slope, ρ, calculated using the same contour used to obtain (5.14), is given by

$$\rho = -\cosh^{-1}\left(\frac{I_0(\epsilon/2\sigma)}{2I_1(\epsilon/2\sigma)}e^{\sigma t}\right) \sim -\sigma t + \ln\left(\frac{I_1(\epsilon/2\sigma)}{I_0(\epsilon/2\sigma)}\right) \quad \text{for } t \gg 1. \tag{6.8}$$

This is the long-time asymptote (dashed) shown in Figure 6.2 and is the generic spectral behavior once the Burgers evolution is dominated by a largest scale mode.

The special case of the sinusoidal initial condition illustrates that the initial downscale cascade evolves on the inviscid timescale, ϵt, despite the fact that the advective term is a weakly nonlinear effect. The cascade then transitions to dissipation on the viscous timescale, σt, as the solution comes to be dominated by the slowest decaying mode $u(x,t) \sim e^{-\sigma t} \sin x$. The modal dissipation is then driven by weak nonlinearity, as harmonics decay as $e^{-n\sigma t}$, in contrast to the $e^{-n^2\sigma t}$ decay of linear diffusion.

7. Fourier solution on the infinite line. The derivation of the periodic Fourier coefficients (2.11), (2.12) is easily modified to obtain an analogous integral for the Fourier transform solution on the infinite line. Defining the Fourier transform representation of continuous solutions to (1.1) by

$$u(x,t) = \int_{-\infty}^{+\infty} c(k,t) e^{-ikx} dk, \tag{7.1}$$

the coefficients $c(k,t)$ can also be shown to derive from the initial profile $u(x,0) = f(x)$. Beginning from the Fourier integral, an integration by parts is performed,

$$c(k,t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} u(x,t) e^{ikx} dx = \frac{i}{2\pi k} \int_{-\infty}^{+\infty} u_x(x,t) e^{ikx} dx, \tag{7.2}$$

which again assumes continuity as well as sufficiently fast decay of the solution at $x \to \pm\infty$. In a slight departure from the periodic case, the next step introduces the parametric solution $u = f(x_0)$,

$$\begin{aligned} c(k,t) &= \frac{i}{2\pi k} \int_{-\infty}^{+\infty} f'(x_0) \frac{dx_0}{dx} e^{ikx} dx \\ &= \frac{i}{2\pi k} \int_{-\infty}^{+\infty} f'(x_0) \exp[ik(x_0 + t f(x_0))] dx_0, \end{aligned} \tag{7.3}$$

where decay of the integrand is ensured through the initial profile. (Note that an analogous formula can also be derived for the periodic case.)

For example, the solution from an initial Gaussian profile $f(x) = e^{-x^2/2}$ remains single-valued up until the breaking time of $t_c = \sqrt{e}$ (Figure 7.1). In the limit of large wavenumber k, the Fourier integral (7.3) can be approximated by the method of steepest descent. The complex plane for the phase function $\phi(z) = i(z + te^{-z^2/2})$ is shown as Figure 7.2. The saddle points of the phase are determined by the stationary points $\phi'(z_s) = 0$, which for the Gaussian profile can be expressed as the condition

$$(-z_s^2) e^{(-z_s^2)} = -\frac{1}{t^2}. \tag{7.4}$$

Thus the saddle points are complex-valued solutions to Lambert's transcendental equation $z_s^2 = -W(-1/t^2)$. Figure 7.2 shows the four saddle points closest to the real z-axis at time $t/t_c = 3/4$. The integration along the real axis (7.3) can be deformed into a scalloped contour (solid curve in Figure 7.2) in the upper half-plane, so that the dominant contribution will be localized to the saddle point with the maximum $\mathrm{Re}(\phi(z_s))$. The quadratic Taylor expansion of the phase function at a saddle point simplifies to

$$\phi(z) \sim i \left(z_s + \frac{1}{z_s} \right) + \frac{i}{2} \left(z_s - \frac{1}{z_s} \right) (z - z_s)^2 \tag{7.5}$$

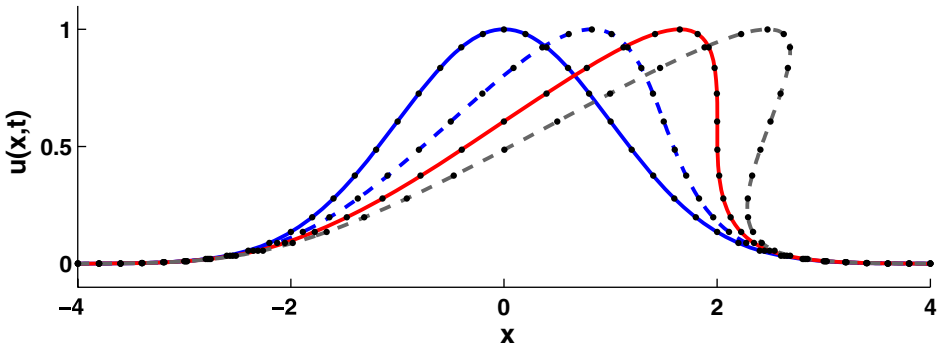

FIG. 7.1. *Wavebreaking evolution of $u(x,t)/\epsilon$ beginning from a Gaussian initial condition. Shown are scaled times $t/t_c = 0, 1/2, 1, 3/2$ with the initial and critical wavebreaking profiles in solid and an overturning profile in gray dashed. Obtained from the parametric solution (2.4), the dots track values of $u = f(x_0)$ corresponding to characteristics labeled by x_0 at intervals of $1/5$.*

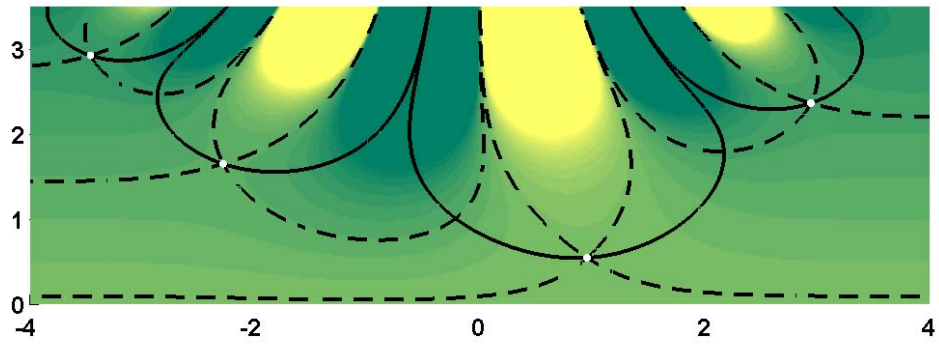

FIG. 7.2. *Complex plane for the phase function $\phi(z;t)$ for $t/t_c = 3/4$. The grayscale indicates $Re(\phi(z;t))$, where darker regions correspond to exponential smallness of the integrand. The contours shown are associated with the four saddle points closest to the real axis (closest $z_s \approx 0.95 + 0.55i$). Solid contours are paths of steepest descent to regions of exponentially small integrand. Dashed contours are level curves of the magnitude.*

and gives the steepest descent contribution

$$\sqrt{\frac{1}{2\pi i(z_s - 1/z_s)t^2}}\, k^{-3/2} e^{i(z_s + 1/z_s)k}, \tag{7.6}$$

where additional time-dependence lies in the location of the saddle point (7.4). Using only the dominant saddle point, this gives an expression for the spectral slope:

$$\frac{\ln|c(k,t)|}{k} \sim -\operatorname{Im}\left(z_s + \frac{1}{z_s}\right) \text{ as } k \to \infty, \tag{7.7}$$

which is verified by the lines in Figure 7.3. As expected, the breaking time $t_c = \sqrt{e}$ coincides with the first real root of the saddle-point condition (7.4), where the spectral decay changes from exponential to algebraic. Thus, at finite times $0 < t < t_c$, the spectrum decays exponentially despite its beginning from more rapid quadratic Gaussian decay (light curve).

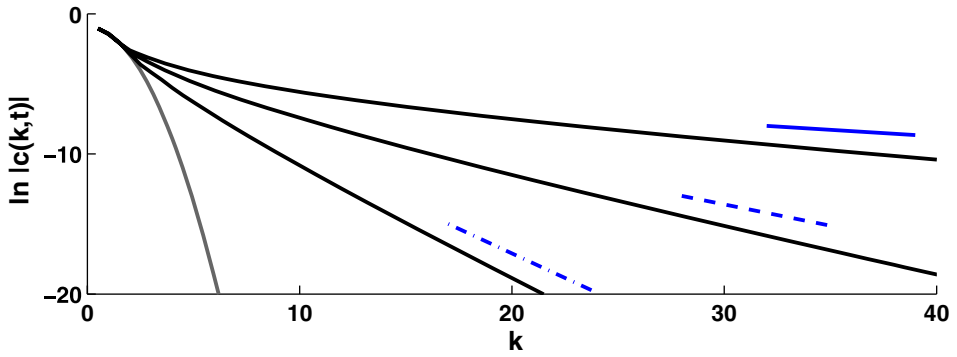

FIG. 7.3. *Semilog plot of spectral amplitudes $c_n(t)/\epsilon$ of a pseudospectral computation (de-aliased to 2048 modes on a 4π-periodic domain) from a Gaussian initial condition (leftmost curve). The downscale spectral cascade is illustrated by the growth of the Fourier amplitudes (other dark solid) over times $t/t_c = 1/4, 1/2, 3/4$. The flattening of the exponential spectrum is indicated by the linear asymptotes (dash-dot, dash, solid) as calculated from the steepest descent contribution* (7.7) *from the saddle point nearest the real axis.*

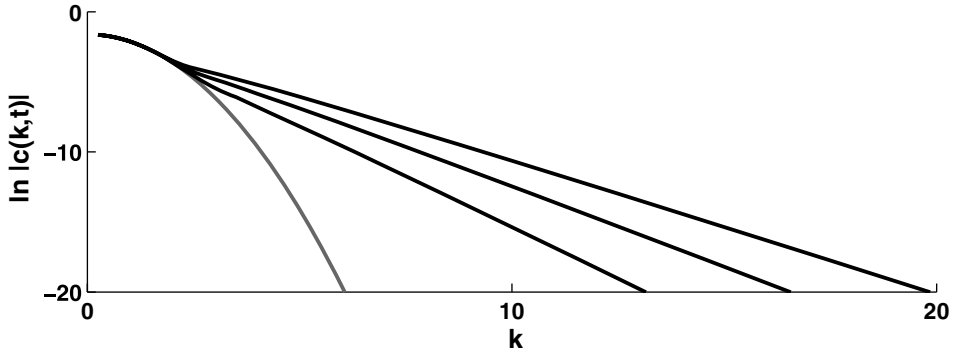

FIG. 7.4. *Semilog plot of spectral amplitudes $c_n(t)/\epsilon$ for the linearized evolution* (5.6) *from an initial Gaussian (gray solid) shows that its cascade also develops an exponential spectrum. The numerical parameters are the same as those of the nonlinear computation of Figure* 7.3. *The flattening of the spectrum is shown for earlier times $t/t_c = 1/12, 1/6, 1/4$, based on the breaking time of the nonlinear evolution. The slope of the linearized cascade at $t = t_c/4$ lags just behind the fully nonlinear cascade shown in Figure* 7.3.

The development of the linearized spectrum from the Gaussian initial condition is shown in Figure 7.4. Although the communication between the Fourier modes is fixed by the spectral characteristics at the initial time in (5.6), the linear evolution still generates a downscale cascade with an exponential decay with wavenumber.

8. Closing thoughts. The Fourier results presented here are spectral identities which follow from Platzman's observation that u_x is simply related to the change of variable dx_0/dx via the parametric solution (2.4) for (1.1). This is a rather unusual situation that does not readily apply beyond the characteristic wave equation. Nonetheless, one generalization for which such spectral formulas can be stated is

$$u_t + g(u,x)u_x = h'(t)u, \quad u(x,0) = f(x). \tag{8.1}$$

On the infinite line, the Fourier transform is expressible as the integral

$$c(k,t) = \frac{i}{2\pi k} e^{h(t)-h(0)} \int_{-\infty}^{+\infty} f'(x_0) e^{ik\,x(x_0,t)} dx_0, \tag{8.2}$$

where $x(x_0,t)$ is determined by the characteristic ODE

$$\frac{dx}{dt} = g(f(x_0)e^{h(t)-h(0)}, x), \quad x(0) = x_0. \tag{8.3}$$

The occurrence of nontrivial examples where the formulas (8.2), (8.3) allow further analysis is a rare event. However, a decaying version of Platzman's example with the additional effect $h' = -\alpha$, a constant value, yields

$$b_n(t) = \frac{2\alpha}{n(1-e^{\alpha t})} J_n\left(\frac{\epsilon n(1-e^{-\alpha t})}{\alpha}\right), \tag{8.4}$$

an exercise that reveals a suppression of the wavebreaking when $\alpha > \epsilon$.

As an explicit Fourier analysis of the inviscid Burgers equation, the spectral formulas (2.12), (2.11), (7.3) can be used to investigate cascades from other initial conditions. Although Platzman's example highlighted the downscale cascade, the dynamics of upscale transfers to large scales from smaller scales can also be addressed by initial sums of sinusoids. For real analytic initial conditions, the method of steepest descent generally applies for obtaining the asymptotic exponential spectrum. In contrast, compactly supported (but piecewise continuous) initial conditions yield simple examples whose spectra have algebraic decay.

The Burgers equation, and its inviscid limit, have long been used as a pedagogical introduction to the nonlinearity of fluid motions [2, 5, 9]. This generalization of Platzman's result provides explicit formulas for one-dimensional, deterministic, and continuous realizations of the spectral cascade — hence the qualification to a *weak* cascade. Large wavenumber asymptotics for the integral formula allow direct calculation of the exponential decay of the Fourier spectrum. The inviscid cascade is observed to characterize the early development of the spectrum in the viscous Burgers equation. The examples shown here are direct spectral illustrations of the nonlinear cascade but are far from those required to understand the multidimensional, statistical nature of fluid turbulence. Nonetheless, they are a clear demonstration of a nonlinear process by which advection can sustain an exponential spectrum in the dissipation range, the scales at which the fields are smooth [17, 12]. The turbulence question aside, these results provide an elementary contribution to the broader effort to understand the spectral signatures of singularities in nonlinear PDEs [14, 18, 16].

Although the existence of an exact solution (2.5) would seemingly render (1.1) as fully understood, recent revisitations in the research literature remind that this textbook equation still serves as a source of inspiration for investigations in nonlinearity. Weideman [20] used complex-valued solutions as tests for a method for tracking singularities using numerical analytical continuation. In particular, the dynamics of the logarithmic branch point was computed for the initial condition $u(x,0) = e^{ix}$. The sinusoidal initial condition has also been used by Majda and Timofeyev [11] to initiate postbreaking ergodic dynamics among the Fourier modes for a Galerkin truncation of the spectral dynamics. The truncated dynamics exhibits a chaos which is shown to have a well-defined statistical equilibrium. Finally, the linearization result is very closely related to some current investigations of Mattingly, Soudian, and Vanden-Eijnden [13], who are constructing linear spectral cascade models with exact solutions.

These models have spectral dynamics which are limited to linear coupling of nearest neighbors (in wavenumber), of which (5.6) is an inviscid example. Their analyses involve an unexpected generalization of the generating function method that is based on orthogonal eigenfunction expansions.

In these investigations the wave equation (1.1) is utilized as a testbed for furthering our understanding of nonlinearity. It is in a similar spirit that these one-dimensional Fourier results, although limited to continuous solutions, are communicated for their novelty as an exact spectral viewpoint.

Acknowledgments. The author acknowledges Ed Spiegel, who recommended the Platzman article some years ago. Special thanks to colleagues Ralf Wittenberg, J. F. Williams, and Youngsuk Lee for their enthusiastic discussions during the course of this work, and for their careful readings of the manuscript. Finally, the author is very grateful to Jim Colliander [18], Elef Gkioulekas [12], and Mike Siegel [14] for alerting me to related works.

P MATRIX PROPERTIES, INJECTIVITY, AND STABILITY IN CHEMICAL REACTION SYSTEMS*

MURAD BANAJI†, PETE DONNELL†, AND STEPHEN BAIGENT‡

Abstract. In this paper we examine matrices which arise naturally as Jacobians in chemical dynamics. We are particularly interested in when these Jacobians are P matrices (up to a sign change), ensuring certain bounds on their eigenvalues, precluding certain behavior such as multiple equilibria, and sometimes implying stability. We first explore reaction systems and derive results which provide a deep connection between system structure and the P matrix property. We then examine a class of systems consisting of reactions coupled to an external rate-dependent negative feedback process and characterize conditions which ensure that the P matrix property survives the negative feedback. The techniques presented are applied to examples published in the mathematical and biological literature.

Key words. chemical reactions, P matrices, injectivity, stability, mass action

1. Introduction.

In this paper we will study chemical reaction systems and systems derived from them. Chemical reaction systems have Jacobians with more structure than those of arbitrary dynamical systems. Under mild assumptions we derive a condition on the reaction structure which ensures that a reaction system has Jacobians in a particular class, $P_0^{(-)}$ matrices, to be defined below. This condition is algorithmically easy to check, and immediately implies the absence of multiple equilibria as long as there are appropriate outflow conditions. A weaker condition is then derived specifically for mass action reaction systems, which ensures that they have Jacobians in this class and hence, under appropriate outflow conditions, cannot have multiple equilibria. These conditions are shown to be not only sufficient to preclude multiple equilibria, but also necessary to ensure that the Jacobians can never be singular. Finally a class of systems of particular importance in biochemistry is examined. These systems involve reactions interacting with some external quantity giving rise to a negative feedback process. Necessary and sufficient conditions are derived which ensure that the P matrix properties of the system without feedback persist with the feedback.

2. Basic material.

We start with some basic definitions and observations.

2.1. Chemical reaction systems.

A chemical reaction system in which n reactants participate in m reactions has dynamics governed by the ordinary differential equation

$$\dot{x} = Sv(x). \tag{2.1}$$

Here $x = [x_1, \ldots, x_n]^T$ is the nonnegative n-vector of reactant concentrations, $v = [v_1, \ldots, v_m]^T$ is the m-vector of reaction rates, and S is the $n \times m$ stoichiometric matrix. Equation (2.1) defines a dynamical system on $\mathbb{R}^n_+$ (the nonnegative orthant in $\mathbb{R}^n$). The entries in S are constants—generally integers—with $|S_{ij}|$ describing how many molecules of substrate i are involved in reaction j. The sign of S_{ij} reflects an arbitrary choice of direction for the reaction, with no implication of reversibility or irreversibility. We will generally assume that substrates occur only on one side of a reaction (more on this later), and if $S_{ij} < 0$, we will say that substrate i occurs on the "left-hand side" of reaction j, and on the "right-hand side" if $S_{ij} > 0$.

The same form (2.1) can represent either a closed reaction system, where there is no inflow or outflow of reactants, or an open system. For an open system we simply allow some of the reactions to have empty left- or right-hand sides. We will refer to reactions not involving any inflow or outflow as "true" reactions. S describes a linear mapping between the reaction rates and the time derivatives of the concentrations, and any steady states of (2.1) must correspond to reaction rates lying in the kernel of S. Thus a nontrivial kernel means that there are steady states corresponding to nonzero reaction rates.

The $m \times n$ matrix $V(x)$ defined by $V_{ij}(x) \equiv \frac{\partial v_i}{\partial x_j}$ describes the dependence of the reaction rates on the concentrations. For later notational convenience we will write V instead of $V(x)$. The Jacobian of (2.1) is then just SV.

To make progress, we need to narrow the class of reactions a little. We call a reaction system *nonautocatalytic* (*NAC*) if the stoichiometric matrix S and the matrix V^T have opposite sign structures in the following sense: $S_{ij}V_{ji} \leq 0$ for all i and j, and $S_{ij} = 0 \Rightarrow V_{ji} = 0$. These assumptions are quite general—they mean that if a substrate is used up (created) in a reaction, then increasing the concentration of this substrate, while holding all others constant, cannot cause the reaction rate to decrease (increase). Further, if a substrate does not participate in a reaction, then it is not allowed to influence the reaction rate. As we allow $S_{ij}V_{ji} = 0$, even when $S_{ij} \neq 0$, irreversible reactions are implicitly allowed by this definition.

The assumption that the system is NAC holds for mass action systems, Michaelis–Menten systems, etc., provided that a reactant occurs only on one side of a reaction. It is possible to violate this condition, for example with reactions such as $\mathrm{A}+\mathrm{B} \rightleftharpoons 2\mathrm{A}$, where perhaps for small concentrations of A net flux is to the right, while for large concentrations it is to the left. Sometimes, in practice, such reactions actually represent the amalgamation of several NAC reactions. For example, the above system might actually represent $\mathrm{A} + \mathrm{B} \rightleftharpoons \mathrm{C}$, $\mathrm{C} \rightleftharpoons 2\mathrm{A}$, where C is some short-lived intermediate complex. If a reaction can be rewritten in this way, then it becomes amenable to the analysis presented here.

Most results in this paper are independent of the functional forms chosen for the reaction dynamics, apart from the assumption that reactions are NAC, as just described. However, some of the results which motivated this work are those of Craciun and Feinberg [5, 6] on the possibility of multiple equilibria in *mass action systems*, and the techniques they present to deduce the absence of multiple equilibria from the reaction network structure alone. Since we have included some results on mass action systems, we define these here. Let ν_j be the set of indices of the reactants on the left-hand side of the jth reaction, and ρ_j be the set of indices of the reactants on the right-hand side of the jth reaction. Further, let L_{ij} be the number of molecules of substrate i occurring on the left-hand side of the jth reaction, and R_{ij} be the number of molecules of substrate i occurring on the right-hand side of the jth reaction. Then,

for a mass action system, the reaction rate v_j for the jth reaction takes the form

$$v_j = k_j \prod_{i \in \nu_j} x_i^{L_{ij}} - k_{-j} \prod_{i \in \rho_j} x_i^{R_{ij}},$$

where k_j and k_{-j} are nonnegative constants, known as the forward and backward rate constant for the jth reaction. When the reaction is NAC, this can be rewritten in terms of entries in the stoichiometric matrix to get

$$v_j = k_j \prod_{i \in \nu_j} x_i^{-S_{ij}} - k_{-j} \prod_{i \in \rho_j} x_i^{S_{ij}}.$$

We can clearly write a single reversible reaction as two irreversible reactions.

2.2. *P* matrices and related classes. For some matrix A, $A(\alpha|\gamma)$ will refer to the submatrix of A with rows indexed by the set α and columns indexed by the set γ. A *principal submatrix* of A is a submatrix containing columns and rows from the same index set, i.e., of the form $A(\alpha|\alpha)$, which we will abbreviate to $A(\alpha)$. A *minor* is the determinant of a square submatrix. If $A(\alpha|\gamma)$ is a square submatrix of A (i.e., $|\alpha| = |\gamma|$), then $A[\alpha|\gamma]$ will refer to the corresponding minor, i.e., $A[\alpha|\gamma] = \det(A(\alpha|\gamma))$. A *principal minor* of a matrix is the determinant of a principal submatrix. $A[\alpha]$ will refer to the principal minor corresponding to submatrix $A(\alpha)$.

P matrices are square matrices all of whose principal minors are positive. They are nonsingular, and their eigenvalues are excluded from a certain wedge around the negative real axis [15]. If $-A$ is a P matrix, then we will say that A is a $P^{(-)}$ matrix. These matrices were originally called $N-P$ matrices in [17]. Throughout this paper, when A is a matrix such that $-A$ belongs to some class $\mathcal{C}$, then we will say that A belongs to the class $\mathcal{C}^{(-)}$. If A is a $P^{(-)}$ matrix, this means that each $k \times k$ principal minor of A has sign $(-1)^k$. The problem of checking whether a given matrix is a P matrix is in general NP hard [19].

Another important characterization of P matrices is that a matrix A is a P matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i > 0$ [3]. It follows immediately that a matrix A is a $P^{(-)}$ matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i < 0$. In other words a $P^{(-)}$ matrix maps each nonzero vector y out of any orthants in which it lies. (As orthants share boundaries, y may lie in several orthants at once.)

P matrices contain other important classes of matrices, such as positive definite matrices and also so-called nonsingular M matrices. As these will be mentioned again later, we define them here. Z matrices are square matrices all of whose off-diagonal entries are less than or equal to zero. Nonsingular M matrices are precisely those matrices which are both Z matrices and P matrices, i.e., matrices whose off-diagonal elements are nonpositive and all of whose principal minors are positive. Using the notational convention defined above, $M^{(-)}$ matrices are matrices which are both $Z^{(-)}$ matrices and $P^{(-)}$ matrices.

A related class of matrices are P_0 matrices consisting of the closure of the set of P matrices. These are matrices all of whose principal minors are nonnegative [14]. Similarly A is a $P_0^{(-)}$ matrix if $-A$ is a P_0 matrix. A matrix A is a P_0 matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i \geq 0$, and similarly it is a $P_0^{(-)}$ matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i \leq 0$. By definition, P_0 and $P_0^{(-)}$ matrices can be singular.

2.3. Implications of a $P^{(-)}$ Jacobian: Injectivity and stability. In the work of Craciun and Feinberg [5, 6] global injectivity, and hence the absence of multiple equilibria, follows from the nonsingularity of the Jacobian. This is not true for general functions—it is well known that nonsingularity of the Jacobian alone does not imply global injectivity of arbitrary polynomial functions [18]. In this direction there are several results connecting properties of functions with injectivity. A well-known theorem of Hadamard [12] states that nonsingularity of the Jacobian ensures global injectivity, provided that the function is *proper*—i.e., the preimage of any compact set is compact. Recent elegant work such as that in [9] and [20] provides conditions (not all spectral) which ensure that a function is globally injective.

Regarding P matrices, there is a result stating that if the Jacobian of a function is a P matrix (or equivalently a $P^{(-)}$ matrix), this guarantees injectivity of the function on any rectangular region of $\mathbb{R}^n$ [10]. The result for all of $\mathbb{R}^n$ also follows from the geometric fact mentioned in section 2.2 that $P^{(-)}$ matrices map vectors out of the orthants in which they lie. Thus, for a fixed nonzero vector y, every $P^{(-)}$ matrix must rotate y by at least some angle $\theta > \theta_y > 0$, where θ_y is the infimum of the angular distance from y to an orthant to which y does not belong; thus for any unit vector y and any set of $P^{(-)}$ matrices $A(x)$,

$$\sup_x \left\langle y, \frac{A(x)\,y}{|A(x)\,y|} \right\rangle < \cos\theta_y < 1.$$

From Theorem 2 in [20], this condition on the Jacobian guarantees global injectivity of the function.

[10] also contains the following strengthened result, which weakens the condition needed for injectivity: If the Jacobian of a function is a nonsingular P_0 matrix (termed a "weak P matrix" in this reference), this guarantees injectivity of the function on any rectangular region of $\mathbb{R}^n$. The result obviously holds for a nonsingular $P_0^{(-)}$ matrix as well.

While the ruling out of multiple equilibria is the first and perhaps most important consequence of finding that a particular dynamical system gives rise to $P^{(-)}$ matrix Jacobians, sometimes stronger conclusions can be drawn. In particular, if a matrix J is a $P^{(-)}$ matrix, then Hurwitz stability of J may follow from additional observations. We list three of these:

1. If J is similar to a symmetric matrix, and thus has real eigenvalues, then it must be Hurwitz stable.
2. If all off-diagonal elements of J are nonnegative, then it is in fact a nonsingular $M^{(-)}$ matrix [3] and hence Hurwitz stable.
3. A weaker condition is when J is "sign-symmetric," meaning that all symmetrically placed pairs of minors have the same sign: Then it is stable because sign-symmetric $P^{(-)}$ matrices are Hurwitz stable [14]. Certain physical assumptions can give rise to Jacobians which are sign-symmetric.

In this paper we will refer to a reaction system whose Jacobians are always $P^{(-)}$ matrices as $P^{(-)}$ systems, and ones whose Jacobians are always $P_0^{(-)}$ matrices as $P_0^{(-)}$ systems.

2.4. Rate-dependent negative feedback processes. The assumption that a reaction is NAC means, roughly speaking, that every substrate interacts with the reactions in which it participates in the following way: If it is produced by a reaction, then it inhibits the reaction. If it is used up by a reaction, then it activates the

reaction. Physically any scalar quantity ψ which behaves like this participates in *rate-dependent negative feedback*, and adding such a quantity to a system adds a rate-dependent negative feedback process to the system. Although ψ might be the concentration of a chemical, this need not be the case—for example, ψ may take negative values. In an example of biological importance discussed in [1] and used to illustrate our results below, ψ is in fact a chemical and electrical *gradient* with which some of the reactions interact because they pump material across a membrane. This is a frequent occurrence in biochemistry: Quite generally where reactions involve the build-up of gradients between compartments, we get such systems.

Adding a rate-dependent negative feedback process, whether a reactant or not, to a reaction system involves choosing two vectors $x_1, x_2 \in \mathbb{R}^m$ and adding a row x_1^T to S and a column x_2 to V to get augmented versions, S_{aug} and V_{aug}, of these matrices. The negative feedback assumption means that x_1 and x_2 lie in opposite orthants, so that $x_{1,i}x_{2,i} \leq 0$. In general, if if $x_{1,i} = 0$, then $x_{2,i} = 0$, but it is convenient to ignore this and ask the more general question: Given that SV is a $P^{(-)}$ matrix, when will $S_{aug}V_{aug}$ be a $P_0^{(-)}$ matrix for all possible $x_1, x_2 \in \mathbb{R}^m$ lying in (specified) opposite orthants? Given particular orthants, it is possible to state necessary and sufficient conditions on S and V which answer this question, and with appropriate outflow conditions to replace $P_0^{(-)}$ with $P^{(-)}$ in the above statement.

3. $P^{(-)}$ matrices and general reaction systems. We now examine the close connection between $P^{(-)}$ matrices and reaction systems of the form (2.1). After some preliminaries we present a structural result giving a sufficient condition on the stoichiometric matrix S, which will ensure that the Jacobian will be a $P_0^{(-)}$ matrix. In a sense to be made precise this condition is also a necessary condition.

We need some definitions first. A real matrix S determines a *qualitative class* [4] of all matrices with the same sign pattern as S, which we will refer to as $\mathcal{Q}(S)$. It is helpful to think of $\mathcal{Q}(S)$ as a matrix with entries consisting of zeroes and variables of fixed sign, and $\det(\mathcal{Q}(S))$ is then a polynomial in these variables. If $\det(\mathcal{Q}(S))$ is not identically zero, then it is a sum of monomials, each of which is either positive or negative. It also makes sense to refer to $\overline{\mathcal{Q}(S)}$ as the closure of $\mathcal{Q}(S)$ (regarded as a set of matrices), and $\det(\overline{\mathcal{Q}(S)})$ as the same polynomial as $\det(\mathcal{Q}(S))$, with variables now allowed to take the value zero. In this terminology a reaction system is NAC if $V \in \overline{\mathcal{Q}(-S^T)}$.

A square matrix is *sign-nonsingular* (*SNS*) [4] if the sign of its determinant is nonzero and can be determined from the signs of its entries. In other words, it is SNS if the sign of the determinant is the same for every matrix in its qualitative class. For example, any 2-by-2 matrix with a single negative, positive, or zero entry is SNS. On the other hand, a 2-by-2 matrix with two positive and two negative entries is not SNS. If any square matrix T is SNS, then it makes sense to talk about $\text{sign}(\det(\mathcal{Q}(T)))$.

A (not necessarily square) matrix S will be termed *strongly sign determined* (*SSD*) if all square submatrices of S are either SNS or singular. SSD matrices intersect various classes of matrices discussed in [4], for example the so-called totally L-matrices and the S^2NS matrices, and the SSD property is algorithmically quick and easy to check. Some results concerning SSD matrices are collected in Appendix A. These properties show among other things that alternative notational choices in chemical dynamics—for example, the choice to represent one reversible reaction as two irreversible ones, which side of a reaction to consider as the left-hand side, how to order the set of substrates, or how to order the set of reactions—never change whether the stoichiometric matrix is SSD or not.

For the proofs which follow in this section, it is convenient to set up the following notational conventions. S will always refer to some particular, but unspecified, stoichiometric matrix. Since we are interested in NAC, but otherwise unspecified, reaction systems in this section, given a matrix S, it is convenient for V to refer to the closure of a whole class $\overline{\mathcal{Q}(-S^T)}$. Similarly $V(\gamma|\alpha)$ will refer to $\overline{\mathcal{Q}(-S(\alpha|\gamma))}$, and $V[\gamma|\alpha]$ will refer to the polynomial $\det(\overline{\mathcal{Q}(-S(\alpha|\gamma))})$. If we refer to a "choice of V," then this means some particular matrix in $\overline{\mathcal{Q}(-S^T)}$. Objects defined as products will take the appropriate meanings; for example, an object such as $S[\alpha|\gamma]V[\gamma|\alpha]$ is again a polynomial.

It helps to note a few obvious, but important, *preliminaries* about SSD matrices:

1. If a matrix S is SSD, then so is $-S$. In particular, given any square submatrix $S(\alpha|\gamma)$ which is SNS,

$$\operatorname{sign}(\det(-S(\alpha|\gamma))) = (-1)^{|\alpha|}\operatorname{sign}(\det(S(\alpha|\gamma))).$$

   On the other hand, if $S(\alpha|\gamma)$ is singular, then so is $-S(\alpha|\gamma)$.
2. If a stoichiometric matrix S is not SSD, then there is some square submatrix $S(\alpha|\gamma)$ such that $\det(\mathcal{Q}(S(\alpha|\gamma)))$—and hence $V[\gamma|\alpha]$—contains both a positive and a negative term.

We can now state our first theorem.

THEOREM 3.1. *If the stoichiometric matrix S of an NAC reaction system is SSD, then the Jacobian $J = SV$ is a $P_0^{(-)}$ matrix.*

Proof. Let $J[\alpha]$ be the principal minor of J corresponding to the submatrix with rows and columns indexed by a set $\alpha \subset \{1, \dots, n\}$. By the Cauchy–Binet formula (see [11], for example) we get

$$J[\alpha] = (SV)[\alpha] = \sum_{\substack{\gamma \subset \{1,\dots,m\} \\ |\gamma| = |\alpha|}} S[\alpha|\gamma]V[\gamma|\alpha].$$

The sum is over all subsets of $\{1, \dots, m\}$ of size $|\alpha|$, if any such subsets exist. Since the reaction system is NAC and S is SSD, for each γ, either $S[\alpha|\gamma]$ is zero or $S(\alpha|\gamma)$ is SNS, in which case

$$\operatorname{sign}(V[\gamma|\alpha]) = (-1)^{|\alpha|}\operatorname{sign}(S[\alpha|\gamma])$$

by preliminary 1 above. So $J[\alpha]$ is a sum of terms each of which is either zero or has sign $(-1)^{|\alpha|}$, and thus either $J[\alpha] = 0$ or $\operatorname{sign}(J[\alpha]) = (-1)^{|\alpha|}$. ∎

A natural question which arises is whether there is any kind of converse to Theorem 3.1 or, equivalently, whether there could be a weaker condition on the stoichiometric matrix which would still always ensure a $P_0^{(-)}$ Jacobian. The answer, provided in the next theorem, is that there is no weaker condition guaranteeing a $P_0^{(-)}$ Jacobian.

THEOREM 3.2. *Assume that the stoichiometric matrix S of an NAC system is not SSD. Then there is some choice of V for which SV is not a $P_0^{(-)}$ matrix.*

Proof. Since S is not SSD, there are sets $\alpha_0 \subset \{1, \dots, n\}$, $\gamma_0 \subset \{1, \dots, m\}$ with $|\alpha_0| = |\gamma_0|$ such that $S(\alpha_0|\gamma_0)$ is neither SNS nor singular. Consider

$$J[\alpha_0] = \sum_{\substack{\gamma \subset \{1,\dots,m\} \\ |\gamma| = |\alpha_0|}} S[\alpha_0|\gamma]V[\gamma|\alpha_0].$$

Since $S(\alpha_0|\gamma_0)$ is not SNS, $V[\gamma_0|\alpha_0]$ contains a term t such that $S[\alpha_0|\gamma_0]t$ is of the "wrong" sign: $(-1)^{|\alpha_0|+1}$. This follows because, as noted in preliminary 2 earlier, since $S(\alpha_0|\gamma_0)$ is not SNS, $V[\gamma_0|\alpha_0]$ contains both positive and negative terms. However, t is just a term in the determinant of a submatrix of V, i.e., a product of entries of V. Set all entries in V which do not figure in t to 0. Since determinants are homogeneous polynomials in the entries of a matrix, and since no entry has power higher than 1, all terms in $J[\alpha_0]$ other than $S[\alpha_0|\gamma_0]t$ become zero, so that $J[\alpha_0] = S[\alpha_0|\gamma_0]t$, which has sign $(-1)^{|\alpha_0|+1}$. Hence J is not a $P_0^{(-)}$ matrix. By continuity, since the set of matrices which are not $P_0^{(-)}$ matrices is open, the argument still holds if entries in V not occurring in t are sufficiently small but nonzero. □

Incidentally we could phrase the above two results together as the following corollary, possibly of broad interest.

COROLLARY 3.3. *Consider an $n \times m$ matrix A. Then A is SSD iff AB is a P_0 matrix for every $m \times n$ matrix B which satisfies $A_{ij}B_{ji} \geq 0$ and $A_{ij} = 0 \Rightarrow B_{ji} = 0$.*

Proof. The proof is immediate from the previous two results. □

Although the discussion so far has been of $P_0^{(-)}$ matrices, it is clear from the proofs that if, in addition to S being SSD, for $\alpha = \{1, \ldots, n\}$ there is some γ such that $S[\alpha|\gamma]$ and $V[\gamma|\alpha]$ are both nonzero, then J is in fact nonsingular $P_0^{(-)}$, and the function is injective. And if, for every α, there is some γ such that $S[\alpha|\gamma]$ and $V[\gamma|\alpha]$ are both nonzero, then J is in fact a $P^{(-)}$ matrix (and injective). This often arises in practice because there are inflow and outflow processes contributing terms on the diagonal of SV. For example, continuous flow stirred tank reactors (CFSTRs) as presented in [5] have properties which ensure that for nonzero flow rate any Jacobian which is a $P_0^{(-)}$ matrix is in fact a $P^{(-)}$ matrix. Using S to refer to the stoichiometric matrix of the "true" reactions in a CFSTR (excluding the inflow and outflow processes), a CFSTR system can be written as

$$\dot{x} = q(x_{in} - x) + Sv(x), \tag{3.1}$$

where q is a positive scalar representing the flow rate through the reactor and x_{in} is a nonnegative vector representing the "feed" concentration. We then have the following result.

THEOREM 3.4. *Assume that all the reactions in a CFSTR are NAC. If the stoichiometric matrix S is SSD, then the Jacobian of the system is a $P^{(-)}$ matrix.*

Proof. The full stoichiometric matrix S_f of a CFSTR system can be written in block form,

$$S_f = [S| -I_n],$$

where S is the matrix of true reactions and I_n is the $n \times n$ unit matrix. Similarly define V_f by

$$V_f = \left[\frac{V}{qI_n}\right].$$

The Jacobian of the system is

$$J \equiv S_f V_f = -qI + SV,$$

where I is the identity matrix. Since the reactions are NAC and S is SSD this means, by Theorem 3.1, that SV is a $P_0^{(-)}$ matrix. As mentioned in section 2.2, a matrix A

is a P_0 matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i \geq 0$, and similarly it is a P matrix iff for any nonzero vector y there is some index i such that $y_i(Ay)_i > 0$. So any P_0 matrix plus a positive diagonal matrix is a P matrix. It follows that a $P_0^{(-)}$ matrix plus a negative diagonal matrix is a $P^{(-)}$ matrix. Thus J is a $P^{(-)}$ matrix. □

Combined with the result of Gale and Nikaido [10], this can be stated as the following corollary.

COROLLARY 3.5. *If the reactions in a CFSTR are NAC, and the stoichiometric matrix S is SSD, then the system does not admit multiple equilibria.*

This result is independent of the nature of the reactions (mass action, Michaelis–Menten, etc.).

For CFSTR systems the result presented in Theorem 3.2 can be strengthened. If the stoichiometric matrix of true reactions in a CFSTR system is not SSD, and hence the Jacobian can fail to be a $P^{(-)}$ matrix, then it can in fact be singular.

THEOREM 3.6. *Assume that all the reactions in a CFSTR are NAC, and that the stoichiometric matrix of true reactions, S, is not SSD. Then there is some choice of entries in V for which* $\det(J)$ *has sign* $(-1)^{n+1}$ *(i.e., the "wrong" sign).*

Proof. The result follows as long as there is a term of the wrong sign in the expansion of the determinant, and this term can be made to dominate all other terms in the expansion.

As in the proof of Theorem 3.2, when S is not SSD, this implies the existence of sets $\alpha_0 \subset \{1, \ldots, n\}$, $\gamma_0 \subset \{1, \ldots, m\}$ with $|\alpha_0| = |\gamma_0|$ such that $V[\gamma_0|\alpha_0]$ contains a term t such that $S[\alpha_0|\gamma_0]t$ has sign $(-1)^{|\alpha_0|+1}$.

Let S_f and V_f be defined as in the proof of Theorem 3.4. The structure of S_f and V_f means that there is a term in $\det(S_f V_f)$ of the form $(-q)^{n-|\alpha_0|}S[\alpha_0|\gamma_0]t$, which is clearly of sign $(-1)^{n+1}$. As the determinant of any submatrix of V_f is a homogeneous polynomial in the entries of V_f, and no entry from V can occur more than once in any term, setting all entries in V other than those which occur in t to zero ensures that

$$\det(S_f V_f) = (-q)^{n-|\alpha_0|}S[\alpha_0|\gamma_0]t \ + \ \text{higher order terms in } q.$$

Choosing any fixed values for entries in t, then for small enough q, the lowest order term $(-q)^{n-|\alpha_0|}S[\alpha_0|\gamma_0]t$ is the dominant term in this expression, and hence $\det(S_f V_f)$ has sign $(-1)^{n+1}$. As in the proof of Theorem 3.2, by continuity, the argument remains true for small nonzero entries in V_f. □

This last theorem is more important than it may at first seem. It implies that if S is not SSD, then the Jacobian can be made singular by choosing entries in V appropriately. Thus finding that a particular reaction system has a stoichiometric matrix which is SSD is a *necessary* condition to ensure that under arbitrary choice of dynamics the Jacobian of the CFSTR system can never be singular.

The astute reader will have noticed that combination of the previous theorems implies that, for a CFSTR system, nonsingularity of the Jacobian (for all entries in V) is equivalent to injectivity of the system. This implies that when checking whether a system is necessarily injective, rather than checking whether S is SSD, one could instead check whether all $n \times n$ submatrices of S_f are either SNS or singular. Although at first glance the second strategy appears easier, the two problems are computationally equivalent, as computing the determinants of all $n \times n$ submatrices of S_f requires computation of the determinants of all square submatrices of S.

4. $P^{(-)}$ matrices and mass action systems. In this section we present some results on mass action systems. It is possible to prove stronger results about mass action systems than arbitrary reaction systems because the matrix V has additional structure beyond its sign structure. Our concern now is with the question of when a reaction system, as a result of its structure combined with the assumption of mass action dynamics, generates a $P_0^{(-)}$ matrix Jacobian (or, in the case of CFSTR systems, a $P^{(-)}$ matrix Jacobian). Of course, if a substrate never occurs on both sides of any reaction, then the mass action form guarantees that all reactions are NAC, and so if the stoichiometric matrix S is SSD, this will ensure a $P_0^{(-)}$ Jacobian. We show, however, that in the case of mass action systems it is possible to weaken the condition that S must be SSD and still get a $P_0^{(-)}$ Jacobian.

It is important at the outset to highlight the close relationship between results in this section and results in [5]. The techniques given in [5] for confirming whether a reaction system is injective are more general than ours in that they apply to autocatalytic reactions as well. We are unable to make claims about injectivity of autocatalytic reactions using our techniques because the stoichiometric matrix "loses information" about reactions which have the same substrate occurring on both sides of the equation—it encodes only net production or loss of a substrate in a reaction, rather than absolute quantities on each side of a reaction. There is some overlap in our methods of proof, although there are also important differences. We will return to this theme at the end of the section.

To formulate the results to follow we need to note that any mass action system can be written as a system of irreversible reactions by considering any reversible reaction as two irreversible reactions. From Lemma A.2 in Appendix A, rewriting the system in this way does not affect whether the stoichiometric matrix is SSD.

We now define a property of stoichiometric matrices weaker than the property of being SSD. Given a matrix S, define S_- to be the matrix S with all positive entries replaced with zeroes. Let a constant matrix S be *weakly sign determined* (*WSD*) if every square submatrix $\tilde{S}$ of S satisfies $\det(\tilde{S})\det(\tilde{S}_-) \geq 0$. In Lemma A.3 of Appendix A it is shown that every SSD matrix is WSD. The two are not equivalent, however—for example, the matrix

$$\tilde{S} = \begin{bmatrix} 1 & -1 \\ -2 & 1 \end{bmatrix}$$

is neither SNS nor singular, but it does satisfy $\det(\tilde{S})\det(\tilde{S}_-) \geq 0$. Results in Appendix A also show that the choice of how to order the set of substrates or reactions does not affect whether the stoichiometric matrix is WSD or not. However, as we shall see later, the choice to represent one reversible reaction as two irreversible ones *can* affect whether the stoichiometric matrix is WSD or not.

We can now restate Theorem 3.1 for mass action systems.

THEOREM 4.1. *Consider the stoichiometric matrix S of an NAC mass action reaction system written as a system of irreversible reactions. If S is WSD, then the Jacobian J is a $P_0^{(-)}$ matrix.*

Proof. The reaction rate for the ith reaction takes the form

$$v_i = k_i \prod_{j \in \nu_i} x_j^{-S_{ji}},$$

where k_i is the rate constant for the ith reaction and ν_i is the set of indices of the reactants on the left-hand side of the ith reaction. Thus the entries in V take the

form

$$V_{ij} = \frac{\partial v_i}{\partial x_j} = \begin{cases} \frac{-S_{ji}}{x_j} v_i & (j \in \nu_i), \\ 0 & (j \notin \nu_i). \end{cases}$$

As above, define S_- to be the matrix S with all positive entries replaced with zeroes. Further, let D_x be the $n \times n$ positive diagonal matrix with entries $\frac{1}{x_j}$ on the diagonal (defined when $x_j > 0$ for all j). Finally, let D_v be the $m \times m$ positive diagonal matrix with entries v_i on the diagonal. With this notation the matrix V can be written

$$V = -D_v S_-^T D_x$$

(again formally defined only when all $x_j > 0$, although of course V exists in the limit as well). Now consider an arbitrary minor of V, $V[\gamma|\alpha]$ with $\alpha \subset \{1, \ldots, n\}$ and $\gamma \subset \{1, \ldots, m\}$, and $|\alpha| = |\gamma|$. Application of the Cauchy–Binet formula combined with the fact that only principal minors of a diagonal matrix are nonzero gives

$$V[\gamma|\alpha] = (-1)^{|\alpha|} D_v[\gamma] S_-^T[\gamma|\alpha] D_x[\alpha].$$

Thus a principal minor of the Jacobian takes the form

$$\begin{aligned} J[\alpha] = (SV)[\alpha] &= \sum_{\substack{\gamma \subset \{1,\ldots,m\} \\ |\gamma| = |\alpha|}} S[\alpha|\gamma] V[\gamma|\alpha] \\ &= (-1)^{|\alpha|} \sum_{\substack{\gamma \subset \{1,\ldots,m\} \\ |\gamma| = |\alpha|}} S[\alpha|\gamma] D_v[\gamma] S_-^T[\gamma|\alpha] D_x[\alpha] \\ &= (-1)^{|\alpha|} D_x[\alpha] \sum_{\substack{\gamma \subset \{1,\ldots,m\} \\ |\gamma| = |\alpha|}} S[\alpha|\gamma] S_-[\alpha|\gamma] D_v[\gamma]. \end{aligned}$$

Since D_x and D_v are positive diagonal matrices, $D_x[\alpha]$ and $D_v[\gamma]$ are positive. Thus $J[\alpha]$ has sign $(-1)^{|\alpha|}$ or is zero, provided that every $S[\alpha|\gamma]$ and $S_-[\alpha|\gamma]$ have the same sign (or one of them is zero).

The argument presented above shows that if S is WSD, then the Jacobian of a mass action system is a $P_0^{(-)}$ matrix in the interior of the positive orthant. However, the set of $P_0^{(-)}$ matrices is closed, and since the Jacobian depends continuously on the values of x_i, it must be $P_0^{(-)}$ everywhere in the closed positive orthant. ∎

The following corollary is immediate.

COROLLARY 4.2. *Assume that all the reactions in a CFSTR are NAC mass action reactions. If the stoichiometric matrix S of the system written as a set of irreversible reactions is WSD, then the Jacobian of the system is a $P^{(-)}$ matrix.*

Proof. The proof is identical to that of Theorem 3.4: A $P_0^{(-)}$ matrix plus a negative diagonal matrix is a $P^{(-)}$ matrix. ∎

There is a kind of converse to Theorem 4.1 showing that the condition of being WSD is *necessary* to guarantee that the Jacobian of a mass action system will be a $P_0^{(-)}$ matrix.

THEOREM 4.3. *Assume that the stoichiometric matrix S of an NAC mass action system written as a set of irreversible reactions is not WSD. Then there is some choice of rate constants k_i for which SV is not a $P_0^{(-)}$ matrix.*

Proof. If S is not WSD, then $S[\alpha_0|\gamma_0]S_-[\alpha_0|\gamma_0] < 0$ for some $\alpha_0 \subset \{1,\dots,n\}$, $\gamma_0 \subset \{1,\dots,m\}$ with $|\alpha_0| = |\gamma_0|$. We have from above

$$J[\alpha_0] = (-1)^{|\alpha_0|} D_x[\alpha_0] \sum_{\substack{\gamma\subset\{1,\dots,m\}\\ |\gamma|=|\alpha_0|}} S[\alpha_0|\gamma]S_-[\alpha_0|\gamma]D_v[\gamma].$$

Since $D_v[\gamma] = \prod_{j\in\gamma} v_j$, choosing $k_j = 0$ for all $j \notin \gamma_0$ and $k_j \neq 0$ for all $j \in \gamma_0$ sets all $D_v[\gamma] = 0$ for $\gamma \not\subseteq \gamma_0$. So with this choice

$$J[\alpha_0] = (-1)^{|\alpha_0|} D_x[\alpha_0]S[\alpha_0|\gamma_0]S_-[\alpha_0|\gamma_0]D_v[\gamma_0],$$

which has sign $(-1)^{|\alpha_0|+1}$ everywhere in the interior of the positive orthant. By continuity, $J[\alpha_0]$ continues to have sign $(-1)^{|\alpha_0|+1}$ in some region of the positive orthant when k_j, $j \notin \gamma_0$, are small but nonzero. ∎

For mass action systems, the condition of being WSD is thus *necessary* to guarantee that the Jacobian will be a $P_0^{(-)}$ matrix. In fact, in the case of CFSTR mass action systems there is an analogue of the general result in Theorem 3.6: The property of S being WSD is necessary to guarantee that the Jacobian will be nonsingular.

THEOREM 4.4. *Assume that the stoichiometric matrix S of the true reactions in an NAC mass action CFSTR system written as a set of irreversible reactions is not WSD. Then there is some choice of flow rate q, rate constants k_i, and concentrations x_i for which* $\det(SV)$ *has sign* $(-1)^{n+1}$ *(i.e., the "wrong" sign).*

Proof. The proof is a little harder than the equivalent proof for general systems, but again, the result follows as long as there is a term of the wrong sign in the expansion of the determinant, and this term can be made to dominate all other terms in the expansion.

Since S is not WSD, $S[\alpha_0|\gamma_0]S_-[\alpha_0|\gamma_0] < 0$ for some sets $\alpha_0 \subset \{1,\dots,n\}$, $\gamma_0 \subset \{1,\dots,m\}$ with $|\alpha_0| = |\gamma_0|$.

The Jacobian $J = SV - qI$, and the determinant of the Jacobian is $\det(SV - qI)$. Expanding this, we get

$$\begin{aligned}
\det(SV - qI) &= \sum_{j=0}^{n} (-1)^j q^j \sum_{\substack{\alpha\subset\{1,\dots,n\}\\ |\alpha|=n-j}} SV[\alpha] \\
&= \sum_{j=0}^{n} (-1)^j q^j \sum_{\substack{\alpha\subset\{1,\dots,n\}\\ |\alpha|=n-j}} (-1)^{n-j} D_x[\alpha] \sum_{\substack{\gamma\subset\{1,\dots,m\}\\ |\gamma|=|\alpha|}} S[\alpha|\gamma]S_-[\alpha|\gamma]D_v[\gamma] \\
&= (-1)^n \sum_{j=0}^{n} q^j \sum_{\substack{\alpha\subset\{1,\dots,n\}\\ |\alpha|=n-j}} D_x[\alpha] \sum_{\substack{\gamma\subset\{1,\dots,m\}\\ |\gamma|=|\alpha|}} S[\alpha|\gamma]S_-[\alpha|\gamma]D_v[\gamma].
\end{aligned}$$

Setting all $k_i \notin \gamma_0$ equal to zero, we get

$$\begin{aligned}
\det(SV - qI) = (-1)^n q^{n-|\gamma_0|} D_v[\gamma_0] &\sum_{\substack{\alpha\subset\{1,\dots,n\}\\ |\alpha|=|\gamma_0|}} D_x[\alpha]S[\alpha|\gamma_0]S_-[\alpha|\gamma_0] \\
&+ \text{higher order terms in } q.
\end{aligned}$$

We know that $S[\alpha_0|\gamma_0]S_-[\alpha_0|\gamma_0] < 0$. Since $D_x[\alpha] = \prod_{i\in\alpha} x_i^{-1}$, by fixing values of x_i for $i \in \alpha_0$ and increasing the values of x_i for $i \notin \alpha_0$ we can make $D_x[\alpha_0]$ much

larger than $D_x[\alpha]$ for any $\alpha \neq \alpha_0$ in the sum above, thus ensuring that the term

$$D_v[\gamma_0]D_x[\alpha_0]S[\alpha_0|\gamma_0]S_-[\alpha_0|\gamma_0]$$

is the dominant term in the coefficient of $q^{n-|\gamma_0|}$ and thus that this coefficient has sign $(-1)^{n+1}$. (Note that increasing the values of $x_i \notin \alpha_0$ affects, but can never decrease, the size of $D_x[\alpha_0]D_v[\gamma_0]$.)

Once we have ensured that the coefficient of $q^{n-|\gamma_0|}$ has sign $(-1)^{n+1}$, we can choose q small so that the term of order $q^{n-|\gamma_0|}$ is the dominant term in $\det(SV - qI)$. Thus for small q, small $x_i \in \alpha_0$ (and all other x_i sufficiently large), large $k_i \in \gamma_0$ (and all other k_i sufficiently small) we can ensure that $\det(SV - qI)$ has sign $(-1)^{n+1}$. ∎

This final result shows that if S is not WSD, then for some choices of rate constants and flow rate the Jacobian of a CFSTR system will be singular. Thus the property of S being WSD is both sufficient and *necessary* to ensure that the Jacobian of an NAC mass action CFSTR system is always nonsingular. It is also sufficient and *necessary* to ensure that the Jacobian is always a $P^{(-)}$ matrix and hence that the system is injective. Together these facts imply that nonsingularity of the Jacobian of an NAC mass action CFSTR system is equivalent to injectivity for these systems. This theorem overlaps with Theorem 3.3 in [5]: Both theorems rely on the fact that for the polynomials which define the determinants in CFSTR systems positivity of the numerical coefficients is necessary to ensure positivity of the polynomial.

There are further close relationships between the theorems here and those in [5]. In Theorem 3.1 of [5] it is proved directly that mass action systems are injective iff their Jacobians are nonsingular for all positive values of the rate constants and concentrations. As just related, we come to the same conclusion for NAC systems via a different route: We have proved that the condition that S is WSD is equivalent both to injectivity and to nonsingularity of the Jacobian in the CFSTR case, and thus that these two are themselves equivalent. This in turn implies that the condition that the stoichiometric matrix of true reactions must be WSD and the requirement that the quantity in (3.4) of [5] must be positive are equivalent for NAC mass action systems embedded in a CFSTR.

One apparent difference between the results here and those in [5] lies in the fact that, in Theorem 3.2 of [5], only determinants of $n \times n$ submatrices of the *full* stoichiometric matrix are needed, whereas when checking the WSD condition we have to check all square submatrices of the stoichiometric matrix. However, this difference is only apparent, and the remark that we made about general systems applies again here: Checking whether S is WSD is computationally equivalent to checking whether all $n \times n$ submatrices T of $S_f = [S| - I_n]$ satisfy $\det(\tilde{T})\det(\tilde{T}_-) \geq 0$.

5. Examples. We present some examples to illustrate the theoretical points in the previous sections.

5.1. Examples from [5]. The phenomenon of S being SSD is more common than it might at first seem. We first examined the reaction system (1.1) in [5] and examples (i) to (viii) presented in Table 1.1 of that reference. Of these, examples (vi), (vii), and (viii) have reactants on both sides of the reactions, and are discussed below in section 5.4. Our analysis of the other examples is presented in Table 5.1. In all cases, we found that whether or not the system had the capacity for multiple equilibria corresponded precisely to whether or not the stoichiometric matrix was SSD. We can thus state for the three systems in which multiple equilibria were ruled out—system (1.1) and systems (ii) and (iv) in Table 1.1—that this remains true if we violate the mass action assumption.

TABLE 5.1

Behavior of some reaction systems presented in [5]. *In all the examples where the systems are WSD, the systems are also in fact SSD, and thus multiple equilibria are ruled out in a CFSTR under arbitrary dynamics.*

	Reaction system	SSD	WSD
(i)	$A + B \rightleftharpoons P$ $B + C \rightleftharpoons Q$ $C \rightleftharpoons 2A$	not SSD	not WSD
(ii)	$A + B \rightleftharpoons P$ $B + C \rightleftharpoons Q$ $C + D \rightleftharpoons R$ $D \rightleftharpoons 2A$	SSD	WSD
(iii)	$A + B \rightleftharpoons P$ $B + C \rightleftharpoons Q$ $C + D \rightleftharpoons R$ $D + E \rightleftharpoons S$ $E \rightleftharpoons 2A$	not SSD	not WSD
(iv)	$A + B \rightleftharpoons P$ $B + C \rightleftharpoons Q$ $C \rightleftharpoons A$	SSD	WSD
(v)	$A + B \rightleftharpoons F$ $A + C \rightleftharpoons G$ $C + D \rightleftharpoons B$ $C + E \rightleftharpoons D$	not SSD	not WSD
Ex. 1.1	$A + B \rightleftharpoons C$ $X \rightleftharpoons 2A + D$ $2A + D \rightleftharpoons Y$ $D \rightleftharpoons C + W$ $B + D \rightleftharpoons Z$	SSD	WSD

It is no surprise that the NAC systems which were proved to be injective in [5] proved to be WSD since, as shown in the previous section, the stoichiometric matrix being WSD is necessary for injectivity of the Jacobian for all values of the rate constants. What is surprising is that all of these examples turned out also to be SSD, and thus that the conclusions about these systems in [5] turn out to be more generally true.

5.2. Systems which are WSD but not SSD. Although the examples taken from [5] and presented in Table 5.1 are all either both SSD and WSD or neither, it is possible to construct examples of systems which are WSD but not SSD. Consider the reaction system

$$A + B \rightleftharpoons C, \qquad 2A + B \rightleftharpoons D,$$

which has stoichiometric matrix, in reversible and irreversible forms,

$$S_r = \begin{bmatrix} -1 & -2 \\ -1 & -1 \\ 1 & 0 \\ 0 & 1 \end{bmatrix}, \qquad S_{ir} = \begin{bmatrix} -1 & 1 & -2 & 2 \\ -1 & 1 & -1 & 1 \\ 1 & -1 & 0 & 0 \\ 0 & 0 & 1 & -1 \end{bmatrix}.$$

It is quick to check that S_r (and hence S_{ir}) is not SSD. On the other hand S_{ir} is WSD. Thus if these reactions are embedded in a CFSTR, multiple equilibria can be ruled out as long as the dynamics are mass action dynamics, but not in the general case.

5.3. The reaction system as a reversible/irreversible system. To illustrate that it is essential to consider a system as a set of irreversible reactions when checking whether a stoichiometric matrix is WSD or not, consider the following reaction system:

$$2A \rightleftharpoons B + C, \qquad A \rightleftharpoons B,$$

which has stoichiometric matrix, in reversible and irreversible forms,

$$S_r = \begin{bmatrix} -2 & -1 \\ 1 & 1 \\ 1 & 0 \end{bmatrix}, \qquad S_{ir} = \begin{bmatrix} -2 & 2 & -1 & 1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & 0 & 0 \end{bmatrix}.$$

Here S_r is WSD, but S_{ir} is not. Thus examining S_r alone could give rise to the wrong conclusion that multiple equilibria can be ruled out in the mass action case.

This example also illustrates the importance of reversibility in the mass action case. Consider the above system with one reaction now irreversible:

$$2A \rightleftharpoons B + C, \qquad B \to A.$$

This has stoichiometric matrix, in irreversible form

$$S_{ir} = \begin{bmatrix} -2 & 2 & 1 \\ 1 & -1 & -1 \\ 1 & -1 & 0 \end{bmatrix},$$

which is in fact WSD. Thus with mass action dynamics this system does not admit multiple equilibria when embedded in a CFSTR. It is perhaps surprising that if the reaction $B \to A$ were replaced with $A \to B$, then the system would no longer be WSD, and the conclusion would no longer hold. Instead, for certain choices of the rate constants, the system would cease to be injective, and multiple equilibria, while not guaranteed, can no longer be ruled out by this method.

5.4. Autocatalytic reactions. Consider the reactions in [5] of the form

$$m_1 A + m_2 B \rightleftharpoons (m_1 + m_2)A$$

for some positive integers m_1 and m_2. Recasting these as

$$m_1 A + m_2 B \rightleftharpoons C, \qquad C \rightleftharpoons (m_1 + m_2)A$$

and assuming NAC dynamics gives rise to stoichiometric matrices, in reversible and irreversible forms,

$$S_r = \begin{bmatrix} -m_1 & (m_1+m_2) \\ -m_2 & 0 \\ 1 & -1 \end{bmatrix}, \qquad S_{ir} = \begin{bmatrix} -m_1 & m_1 & (m_1+m_2) & -(m_1+m_2) \\ -m_2 & m_2 & 0 & 0 \\ 1 & -1 & -1 & 1 \end{bmatrix}.$$

Barring the trivial possibilities that $m_1 = 0$ or $m_2 = 0$, S_r is never SSD and S_{ir} is never WSD. Thus multiple equilibria cannot be ruled out in general or for mass action systems. However, for mass action dynamics in the cases $m_1 = 1$, $m_2 = 1$ and $m_1 = 1$, $m_2 = 2$, it is known that multiple equilibria cannot exist [5], illustrating that singularity of the Jacobian is not sufficient to guarantee multiple equilibria. This is

because, although a function in some class may fail to be injective, the class may not allow this failure to occur near its zeroes.

In fact it is easy to show that when a reactant occurs on both sides of a reaction with different stoichiometries, and we rewrite the system as two NAC reactions with an intermediate complex, the system cannot be SSD or WSD. Consider the reaction system

$$nA + \cdots \rightleftharpoons C, \qquad C \rightleftharpoons mA + \cdots,$$

which might result from such a rewriting. Assume for definiteness that $m > n$. Then the irreversible stoichiometric matrix S_{ir} has a 2×2 submatrix of the form

$$T = \begin{bmatrix} -n & m \\ 1 & -1 \end{bmatrix},$$

which is clearly not SNS, not singular, and does not satisfy $\det(T)\det(T_-) \geq 0$ either.

5.5. Computational considerations. Although it is easy to write down algorithms to check whether a given matrix is SSD or WSD, the actual computation involves checking a large number of submatrices, and can be lengthy if the reaction network is large. Since large stoichiometric matrices are in general highly sparse, considerable speed-up can be achieved by using algorithms to identify submatrices which have (identically) zero determinant without actually attempting to compute the determinant. Similarly, intelligent algorithms should avoid recomputation of the determinants of matrices when they occur as submatrices in larger matrices.

Another technique which can speed up the classification of a matrix as SSD or WSD relies on the fact that it is possible to ignore all substrates which occur in only one reaction, as shown in Lemmas A.4–A.6 in Appendix A. This greatly shortens the calculations in many real examples. Consider example (i) in Table 5.1:

$$A + B \rightleftharpoons P, \qquad B + C \rightleftharpoons Q, \qquad C \rightleftharpoons 2A,$$

which has stoichiometric matrix, in reversible and irreversible forms,

$$S_r = \begin{bmatrix} -1 & 0 & 2 \\ -1 & -1 & 0 \\ 0 & -1 & -1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{bmatrix}, \qquad S_{ir} = \begin{bmatrix} -1 & 1 & 0 & 0 & 2 & -2 \\ -1 & 1 & -1 & 1 & 0 & 0 \\ 0 & 0 & -1 & 1 & -1 & 1 \\ 1 & -1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & -1 & 0 & 0 \end{bmatrix}.$$

Since P and Q each occur only in a single reaction, when checking whether the system is SSD and WSD, respectively, it suffices to check the reduced matrices

$$\tilde{S}_r = \begin{bmatrix} -1 & 0 & 2 \\ -1 & -1 & 0 \\ 0 & -1 & -1 \end{bmatrix}, \qquad \tilde{S}_{ir} = \begin{bmatrix} -1 & 1 & 0 & 0 & 2 & -2 \\ -1 & 1 & -1 & 1 & 0 & 0 \\ 0 & 0 & -1 & 1 & -1 & 1 \end{bmatrix},$$

which considerably reduces the computational effort.

6. Rate-dependent negative feedback processes. Having seen that NAC reaction systems often give rise to Jacobians which are $P_0^{(-)}$ or $P^{(-)}$ matrices, and how this property is deeply associated with *reaction structure* rather than reaction details, we now examine the process of adding a rate-dependent negative feedback

process to a given system—i.e., adding a scalar quantity ψ (perhaps the concentration of another reactant) which inhibits or activates reactions according to whether it is produced or used up in them. We also allow ψ to be subject to an outflow/degradation process.

The full system becomes

$$\dot{x} = Sv(x,\psi), \qquad \dot{\psi} = C(v(x,\psi)) - L(\psi). \tag{6.1}$$

The function $C(v)$ represents the reaction-rate-dependent creation of ψ, while $L(\psi)$ represents its level-dependent outflow or degradation.

We define the following quantities:

1. $F \equiv \frac{\partial v}{\partial \psi}$. This m vector describes the dependence of the reaction rates on ψ.
2. $P \equiv \left(\frac{\partial C}{\partial v}\right)^T$. This m vector describes the way that the production of ψ depends on the reaction rates.
3. $u \equiv \frac{\partial L}{\partial \psi}$. This scalar describes the rate of decay of ψ.

The most general mathematical meaning of the negative feedback assumption is that the vectors F and P lie in opposite cones generated by some set of m orthogonal vectors. Thus for some orthogonal transformation U,

$$P \in K \equiv U(\mathbb{R}^m_+) \quad \text{and} \quad F \in -K.$$

The case generally encountered in examples is where K is a particular orthant so that U is a so-called signature matrix (a diagonal matrix with diagonal entries ± 1) and we know the signs of the elements of P and F, but not their values. In fact we will initially assume that $U = I$, the identity matrix, i.e., $P \in \mathbb{R}^m_+$ and $F \in \mathbb{R}^m_-$, showing later how the results can be extended to the general case.

The Jacobian of (6.1) is now the key object of interest. It can be written in block form:

$$J = \begin{bmatrix} SV & SF \\ P^T V & P^T F - u \end{bmatrix}. \tag{6.2}$$

We will prove all the results in this section by examining matrices (and submatrices) of the form J above. In order to discuss the negative feedback assumption, we adopt the following standard notation (see [3], for example): Given a vector $y \in \mathbb{R}^n$,

- $y \geq 0$ will mean that $y_i \geq 0$ for all i,
- $y > 0$ will mean that $y \geq 0$ and $y \neq 0$,
- $y \gg 0$ will mean that $y_i > 0$ for all i,
- $y \leq 0$, $y < 0$, and $y \ll 0$ will have analogous meanings.

With this notation, the negative feedback assumption can be rephrased as $F < 0$ and $P > 0$. We will assume that $u > 0$ and make claims about when J is a $P^{(-)}$ matrix—the extension to $u = 0$ and the $P_0^{(-)}$ case will be automatic, using the continuous dependence of determinants on the entries in a matrix.

Having discussed these preliminaries, we now ask the following question: Assuming that SV is a $P^{(-)}$ matrix, under what conditions will the Jacobian J in (6.2) remain a $P^{(-)}$ matrix for all values of $F < 0$, $P > 0$, and $u > 0$? The complete answer to this question is contained in Theorems 6.2 and 6.3.

In what is to follow, we will make use of the following formula for the determinant of a matrix.

LEMMA 6.1. *Let A be any matrix written in block form as follows:*

$$A = \begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix},$$

where A_{11} and A_{22} are square matrices. Assuming that A_{11} is nonsingular, then

$$\det(A) = \det(A_{22} - A_{21}A_{11}^{-1}A_{12})\det(A_{11}).$$

Proof. See, for example, [16, p. 46]. □

Note that if A_{22} is a scalar, the equation becomes

$$\det(A) = (A_{22} - A_{21}A_{11}^{-1}A_{12})\det(A_{11}).$$

We now state the basic theorem about the determinant of Jacobians of the form in (6.2), from which results on $P^{(-)}$ properties will follow easily.

THEOREM 6.2. *Consider a matrix J of the form in* (6.2). *Define $\mathcal{S} = \ker(S)$ and $\mathcal{V} = \ker(V^T)$. Assume that* $\det(SV)$ *has sign* $(-1)^n$. *Define $Z \equiv V(SV)^{-1}S$. Then the following statements are equivalent:*

(A) *Given any vector $w_1 \in \mathcal{S}$ satisfying $w_1 \not\geq 0$, we can find a vector $w_2 \in \mathcal{V}$ satisfying $w_2 > 0$ such that $\langle w_1, w_2 \rangle < 0$.*

(B) $\det(J)$ *has sign $(-1)^{n+1}$ for any choice of $F < 0$, $P > 0$, and $u > 0$.*

(C) *$I - Z$ is a nonnegative matrix.*

Before we begin the proof of the theorem we discuss a couple of the assumptions. The assumption that $\det(SV)$ is always of sign $(-1)^n$ implies that $\ker(V)$ and $\ker(S^T)$ consist only of 0. The condition that $\ker(S^T)$ consists only of 0 in turn means that there are no conserved quantities in the system [8], certainly true in the CFSTR case. In any case, where there are conserved quantities, the system can generally be redefined with some variables being eliminated to remove these.

A situation in which the theorem is trivially satisfied is when S and hence V are square matrices—i.e., there are the same number of substrates and reactions. Then the condition that SV is nonsingular implies that S and V are both nonsingular and hence both $\mathcal{S}$ and $\mathcal{V}$ consist only of zero, and there are no vectors $w_1 \in \mathcal{S}$ satisfying $w_1 \not\geq 0$. In this case the matrix Z is the identity. As mentioned earlier, if S is a nonsingular square matrix, then any equilibria correspond to all reaction rates being zero.

During the proof, we will see that condition (A) of the theorem has the following geometric interpretation: It means that the projection of any nonnegative vector $y > 0$ along $\mathcal{V}^T$ onto $\mathcal{S}$ is nonnegative. We remark that there is an important special case where condition (A) is immediately satisfied—this is when $\mathcal{S}$ is one dimensional, lying entirely in the nonnegative and nonpositive orthants, and $\mathcal{V}$ contains some strictly positive vectors. Then given $w_1 \in \mathcal{S}$, $w_1 \not\geq 0 \Rightarrow w_1 < 0$, and given any $w_2 \in \mathcal{V}$ satisfying $w_2 \gg 0$, we have $\langle w_1, w_2 \rangle < 0$. In general, however, where $\mathcal{S}$ can intersect other orthants, the existence of the vector w_2 will depend on the structures of $\mathcal{S}$ and $\mathcal{V}$.

Proof of Theorem 6.2. We show that both (A) and (B) are equivalent to (C), starting with (B) $\Leftrightarrow$ (C). Using Lemma 6.1, we get that

$$\begin{aligned}\det(J) &= (P^T F - u - P^T V(SV)^{-1}SF)\det(SV)\\ &= (P^T(I - Z)F - u)\det(SV),\end{aligned}$$

where I is the $m \times m$ unit matrix. Since $\det(SV)$ has sign $(-1)^n$, this means immediately that (6.2) will have determinant of sign $(-1)^{n+1}$ as long as $P^T(I-Z)F - u < 0$. This is true for all $u > 0$ iff $P^T(I - Z)F \leq 0$. This in turn is true for all $P > 0$, and $F < 0$ iff $(I - Z)$ is a nonnegative matrix (i.e., it leaves the nonnegative orthant invariant). Otherwise we can choose F and P appropriately so that $P^T(I - Z)F > 0$. Thus (B) $\Leftrightarrow$ (C).

We now show that (A) $\Rightarrow$ (C). It is easy to see that $Z^2 = Z$—i.e., Z is a projection. As SV is nonsingular, $\ker(Z) = \ker(S) = \mathcal{S}$ and $\ker(Z^T) = \ker(V^T) = \mathcal{V}$. Thus Z acts as a projection along $\mathcal{S}$ onto $\mathcal{V}^\perp$, and $I - Z$ projects along $\mathcal{V}^\perp$ onto $\mathcal{S}$.

Consider an arbitrary vector $y > 0$. Write $y = y_1 + y_2$, where $y_1 \equiv (I - Z)y \in \mathcal{S}$ and $y_2 \equiv Zy \in \mathcal{V}^\perp$. Now if $y_1 \not\geq 0$, then by assumption we can choose a vector $z \in \mathcal{V}$ satisfying $z > 0$ and $\langle z, y_1\rangle < 0$. But then $\langle z, y\rangle = \langle z, y_1\rangle < 0$, contradicting the fact that $z > 0$ and $y > 0$. So $y_1 \geq 0$. Thus $(I - Z)$ leaves the nonnegative orthant invariant and is a nonnegative matrix. Thus (A) $\Rightarrow$ (C).

Finally, (C) $\Rightarrow$ (A): If $(I - Z)$ is a nonnegative matrix, we show that, given any $y_1 \in \mathcal{S}$ satisfying $y_1 \not\geq 0$, there is a $z \in \mathcal{V}$ satisfying $z > 0$ such that $\langle z, y_1\rangle < 0$. Note that if $y_1 \not\geq 0$, then there is some vector $r \gg 0$ such that $\langle r, y_1\rangle < 0$. So

$$0 > \langle r, y_1\rangle = \langle r, (I - Z)y_1\rangle = \langle (I - Z^T)r, y_1\rangle.$$

Now note that $(I - Z^T)r > 0$ because $(I - Z^T) = (I - Z)^T$ is a nonnegative matrix and $r \gg 0$. Moreover, $(I - Z^T)r \in \mathcal{V}$ since $(I - Z^T)$ is a projection along $\mathcal{S}^\perp$ onto $\mathcal{V}$. So $z \equiv (I - Z^T)r$ is a positive vector in $\mathcal{V}$ which satisfies $\langle z, y_1\rangle < 0$. ∎

Theorem 6.2 leads immediately to the following.

THEOREM 6.3. *Let J be a matrix of the form defined in* (6.2). *Let α be some subset of $\{1, \ldots, n\}$, S^α be the matrix S with rows belonging to α deleted, and V^α the matrix V with columns belonging to α deleted. Define $\mathcal{S}^\alpha = \ker(S^\alpha)$ and $\mathcal{V}^\alpha = \ker((V^\alpha)^T)$.*

Assume that SV is a $P^{(-)}$ matrix. Then the following statements are equivalent:

(A) *For every $\alpha \subset \{1, \ldots, n\}$, given any vector $w_1 \in \mathcal{S}^\alpha$ satisfying $w_1 \not\geq 0$, we can find a vector $w_2 \in \mathcal{V}^\alpha$ satisfying $w_2 > 0$ such that $\langle w_1, w_2\rangle < 0$.*

(B) *J is a $P^{(-)}$ matrix for any choice of $F < 0$, $P > 0$, and $u > 0$.*

Proof. Since SV is a $P^{(-)}$ matrix, to prove that J is a $P^{(-)}$ matrix it suffices to treat all the principal submatrices of J obtained by deleting a set of rows/columns *not* including the final row and column. We show that for any $\alpha \subset \{1, \ldots, n\}$ the principal minor corresponding to the deletion of rows and columns from α has sign $(-1)^{n+1-|\alpha|}$.

In the trivial case where $\alpha = \{1, \ldots, n\}$, the principal submatrix corresponding to the removal of rows and columns from α is simply the scalar $P^T F - u$, which we know to be negative. In the case where $\alpha = \emptyset$, the principal submatrix is J itself. In general the principal submatrix corresponding to the removal of rows and columns from α is

$$J^\alpha \equiv \begin{bmatrix} S^\alpha V^\alpha & S^\alpha F \\ P^T V^\alpha & P^T F - u \end{bmatrix}.$$

$S^\alpha V^\alpha$ is a principal submatrix of SV, and since SV is a $P^{(-)}$ matrix, its determinant has sign $(-1)^{n-|\alpha|}$. J^α is of the form in (6.2), and to prove that $\det(J^\alpha)$ has sign $(-1)^{n+1-|\alpha|}$ it suffices by Theorem 6.2 that given any vector $w_1 \in \mathcal{S}^\alpha$ satisfying $w_1 \not\geq 0$, we can find a vector $w_2 \in \mathcal{V}^\alpha$ satisfying $w_2 > 0$ such that $\langle w_1, w_2\rangle < 0$.

The converse result follows because of the sufficiency of the condition set out in Theorem 6.2. ∎

Although the results above are about the $P^{(-)}$ case, they extend to the $P_0^{(-)}$ case, as seen in the next result.

COROLLARY 6.4. *Assume that the conditions of Theorem* 6.3 *are fulfilled and hence that the matrix J in* (6.2) *is a $P^{(-)}$ matrix for all values of $F < 0$, $P > 0$, and $u > 0$. Then J is a $P_0^{(-)}$ matrix for all values of $F \leq 0$, $P \geq 0$, and $u \geq 0$.*

Proof. Given any particular $\tilde{F} \leq 0$, $\tilde{P} \geq 0$, and $\tilde{u} \geq 0$ and J constructed using these, we can construct a sequence of $P^{(-)}$ matrices $\{J_i\}$ converging to J by choosing sequences $\{F_i\} < 0$, $\{P_i\} > 0$, and $\{u_i\} > 0$ converging to $\tilde{F}$, $\tilde{P}$, and $\tilde{u}$, respectively. Thus J lies in the closure of the $P^{(-)}$ matrices and must be a $P_0^{(-)}$ matrix. ∎

6.1. Extension to the general case. We now show briefly how the arguments in Theorems 6.2 and 6.3 extend to the general case where U is some orthogonal transformation, $K = U(\mathbb{R}^m_+)$, $P \in K$, and $F \in -K$. For arbitrary orthogonal U, the statement of Theorem 6.2 modifies to the following.

THEOREM 6.5. *Consider a matrix of the form J in* (6.2)*, and let U be any $m \times m$ orthogonal matrix. Define $K = U(\mathbb{R}^m_+)$, $\mathcal{S} = \ker(SU)$, and $\mathcal{V} = \ker(V^T U)$. Assume that* $\det(SV)$ *has sign* $(-1)^n$*. Define $Z \equiv V(SV)^{-1}S$. Then the following statements are equivalent:*

(A) *Given any vector $w_1 \in \mathcal{S}$ satisfying $w_1 \not\geq 0$, we can find a $w_2 \in \mathcal{V}$ satisfying $w_2 > 0$ such that $\langle w_1, w_2 \rangle < 0$.*

(B) $\det(J)$ *has sign $(-1)^{n+1}$ for any choice of $F \in -K$, $P \in K$, and $u > 0$.*

(C) *$I - U^T Z U$ is a nonnegative matrix*

Proof. The proof is identical to that of Theorem 6.2. In following through the steps the only things to note are that $U^T P \in \mathbb{R}^m_+$ and $U^T F \in \mathbb{R}^m_-$. Further,

$$\begin{aligned} P^T(I - Z)F &= P^T U U^T (I - Z) U U^T F \\ &= P^T U (I - U^T Z U) U^T F, \end{aligned}$$

and $U^T Z U$ is a projection, now projecting along $\ker(SU)$ onto $\ker(V^T U)$. ∎

Similarly, Theorem 6.3 extends to the following.

THEOREM 6.6. *Let J be a matrix of the form defined in* (6.2) *and U be any orthogonal matrix. Define $K = U(\mathbb{R}^m_+)$. Let α be some subset of $\{1, \ldots, n\}$, S^α be the matrix S with rows belonging to α removed, and V^α the matrix V with columns belonging to α removed. Define $\mathcal{S}^\alpha = \ker(S^\alpha U)$ and $\mathcal{V}^\alpha = \ker((V^\alpha)^T U)$.*

Assume that SV is a $P^{(-)}$ matrix. Then the following statements are equivalent:

(A) *For every α, given any vector $w_1 \in \mathcal{S}^\alpha$ satisfying $w_1 \not\geq 0$, we can find a vector $w_2 \in \mathcal{V}^\alpha$ satisfying $w_2 > 0$ such that $\langle w_1, w_2 \rangle < 0$.*

(B) *J is a $P^{(-)}$ matrix for any choice of $P \in K$, $F \in -K$, and $u > 0$.*

Proof. The proof follows directly from that of Theorem 6.5. ∎

6.2. Two examples. The way the above theorems can be used is seen in the two examples to follow. The first is a rather trivial example for illustrative purposes; the second is considerably harder and arises from a real biological system.

It is appropriate to mention that because for NAC reaction systems (see section 3) S and V^T have opposite sign structures, there are certain natural relationships between $\ker(S^\alpha)$ and $\ker((V^T)^\alpha)$. However, this fact alone does not imply that condition (A) of Theorem 6.2 is automatically fulfilled. Our first example illustrates this.

Example 1. Consider an open reaction system in which a single substrate x is involved in three processes, one of which produces a molecule of x, one of which produces two molecules of x, and one of which degrades a molecule of x, so that $S = [1, 2, -1]$. Let $V^T = [-a, -b, c]$, where $a, b, c \geq 0$ and not all are equal to zero. Now $SV = -(a + 2b + c) < 0$, so the Jacobian of the basic system is a negative scalar and hence a $P^{(-)}$ matrix. $\mathcal{S}$ is the plane in $\mathbb{R}^3$ satisfying $x_1 + 2x_2 - x_3 = 0$, while $\mathcal{V}$ is the plane satisfying $ax_1 + bx_2 - cx_3 = 0$.

Now assume that there is a rate-dependent feedback process such that the three reactions all create and are inhibited by some quantity. With P_i and F_i taking their usual meanings, we can check that the Jacobian of the system is

$$J = \begin{bmatrix} -(a+2b+c) & F_1 + 2F_2 - F_3 \\ -aP_1 - bP_2 + cP_3 & P_1F_1 + P_2F_2 + P_3F_3 - u \end{bmatrix}.$$

It is not immediately obvious by inspection that there are indeed choices of $P_i \geq 0$ and $F_i \leq 0$ for which J is not a $P^{(-)}$ matrix, but an easy calculation gives

$$I - V(SV)^{-1}S = \frac{1}{(a+2b+c)} \begin{bmatrix} 2b+c & -2a & a \\ -b & a+c & b \\ c & 2c & a+2b \end{bmatrix},$$

which is clearly not a nonnegative matrix unless a and b are both zero. So, for small $u > 0$ and some choices of P and F, J is indeed not a $P^{(-)}$ matrix, and can in fact be singular. Thus the $P^{(-)}$ matrix property can be destroyed by a rate-dependent negative feedback process for this NAC reaction system.

Example 2. In [1] a model of mitochondrial metabolism was presented consisting of a system of coupled redox reactions, some of which interacted with the proton gradient across the mitochondrial membrane. Without this gradient the Jacobian of the system could be written as the product of a matrix

$$S = \begin{bmatrix} -1 & 1 & 0 & \cdots & 0 & 0 \\ 0 & -1 & 1 & \cdots & 0 & 0 \\ 0 & 0 & -1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & -1 & 1 \end{bmatrix}$$

and a matrix V:

$$V = \begin{bmatrix} f_{11} & 0 & 0 & \cdots & 0 & 0 \\ -F_{21} & f_{22} & 0 & \cdots & 0 & 0 \\ 0 & -F_{32} & f_{33} & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & f_{n-1,n-1} & 0 \\ 0 & 0 & 0 & \cdots & -F_{n-1,n} & f_{nn} \\ 0 & 0 & 0 & \cdots & 0 & -F_{n+1,n} \end{bmatrix}.$$

All quantities of the form F_{ij} and f_{ii} are strictly positive. Note that V is a rectangular $(n+1) \times (n)$ matrix (i.e., $V : \mathbb{R}^n \to \mathbb{R}^{n+1}$), while S is a rectangular $(n) \times (n+1)$ matrix (i.e., $S : \mathbb{R}^{n+1} \to \mathbb{R}^n$), and they have opposite sign structures.

The Jacobian J of the full system with the potential included is an $(n+1)\times(n+1)$ matrix of the form:

$$\begin{bmatrix} -f_{11} - F_{21} & f_{22} & \cdots & 0 & F_2 - F_1 \\ F_{21} & -f_{22} - F_{32} & \cdots & 0 & F_3 - F_2 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & -f_{nn} - F_{n+1,n} & F_{n+1} - F_n \\ P_1f_{11} - P_2F_{21} & P_2f_{22} - P_3F_{32} & \cdots & P_nf_{nn} - P_{n+1}F_{n+1,n} & -u + \sum_{i=1}^{n+1}(P_iF_i) \end{bmatrix}.$$

Elementary physical assumptions imply that $u > 0$, $P \equiv [P_1, P_2, \ldots P_{n+1}]^T > 0$, and $F \equiv [F_1, F_2, \ldots, F_{n+1}]^T < 0$. (Note that in the notation of [1], $P_i = p_i$ and $F_i = -F_{i\psi}$.)

We wish to use Theorem 6.2 to show that J is a $P^{(-)}$ matrix for all $P > 0$, $F < 0$, and $u > 0$. Incidentally this is hard to show by any direct method but becomes almost immediate by Theorem 6.2. Note first that SV is of the form discussed in Appendix B, and thus SV is a nonsingular $M^{(-)}$ matrix and hence a $P^{(-)}$ matrix.

We start by showing that the sign of $\det(J)$ is $(-1)^{n+1}$. Since $\det(SV)$ has sign $(-1)^n$, it suffices to examine $\ker(S)$ and $\ker(V^T)$. We can see that the $\ker(S)$ consists only of multiples of the vector $[1, 1, \ldots, 1]^T$. On the other hand, by inspection or induction, the strictly positive vector defined by

$$y_1 = 1, \tag{6.3}$$

$$y_{i+1} = \frac{f_{i,i}}{F_{i+1,i}} y_i, \quad i = 1, \ldots, n, \tag{6.4}$$

spans $\ker(V^T)$. Thus this situation corresponds to the special case where $\ker(S)$ lies entirely in the nonnegative and nonpositive orthants of $\mathbb{R}^{n+1}$ and $\ker(V^T)$ contains a strictly positive vector, confirming that $\det(J)$ has sign $(-1)^{n+1}$.

We now show that J is a $P^{(-)}$ matrix, using Theorem 6.3. For any $\alpha \subset \{1, \ldots, n\}$, the coordinates of a vector $x \in \ker(S^\alpha)$ are defined by the equations

$$x_{i+1} = x_i, \quad i = 1, \ldots, n, \quad i \notin \alpha.$$

On the other hand, vectors $y \in \ker((V^\alpha)^T)$ satisfy

$$y_{i+1} = \frac{f_{i,i}}{F_{i+1,i}} y_i, \quad i = 1, \ldots, n, \quad i \notin \alpha.$$

Let x be an arbitrary vector in $\ker(S^\alpha)$ with some coordinates $x_j, \ldots, x_{j+k}$ negative. Then, regardless of the sizes of f_{ii} and F_{ij}, we can choose a positive vector $y \in \ker((V^\alpha)^T)$ with $y_j, \ldots, y_{j+k}$ much larger in magnitude than the other coordinates of y so that $\langle x, y \rangle < 0$. Thus the conditions of Theorem 6.3 are satisfied, and the Jacobian is a $P^{(-)}$ matrix.

7. Conclusions and extensions. We have shown that the structure of chemical reaction systems alone can determine whether their Jacobians are $P^{(-)}$ matrices. The property of the stoichiometric matrix being SSD for general reaction systems, and WSD for mass action reactions, has been shown to be fundamentally linked to whether these systems can admit multiple equilibria. A technique has been presented to study when the $P^{(-)}$ matrix property is preserved under rate-dependent negative feedback.

There are several possible extensions to this work. In the discussion on rate-dependent negative feedback processes, an arbitrary row with particular sign structure was added to the stoichiometric matrix S, and a column with opposite sign structure to the matrix V. However, in the case where the extra row in S corresponds to a chemical reactant this row is a constant, and only the column added to V can vary. This situation clearly gives rise to less restrictive conditions on S and V, which would preserve the $P^{(-)}$ property of the Jacobian under the feedback. A related question is to find a *geometric* (rather than a combinatorial) characterization of when adding a row (column) to a given SSD matrix preserves the SSD property. Finding such a

characterization would be helpful in explaining why many real reaction systems have the SSD property.

The reader might have noted that during this paper we have nowhere used the law of atomic balance [7]. Intuitively we know that the two reactions $A \rightleftharpoons B$ and $A \rightleftharpoons 2B$ cannot both be true reactions (with no inflow or outflow involved). Mathematically this corresponds to the fact that the stoichiometric matrix S of the true reactions should have at least one (often more) nonnegative left eigenvectors of zero, corresponding to conserved quantities. This endows S with additional structure, and it would be of interest to examine how this extra structure affects the likelihood of a given stoichiometric matrix being SSD.

We discussed the fact that certain additional assumptions can mean that $P^{(-)}$ matrices are actually Hurwitz. One of the most interesting of these is sign-symmetry, which can be implied by certain physical assumptions. We hope, in future work, to expand on these ideas, as they form an interesting extension to the results in this paper.

On the same theme, when reaction systems have Jacobians with more structure than simply being a $P^{(-)}$ matrix, and can be shown to be Hurwitz, it may sometimes be possible to write down sufficient conditions which guarantee that the system with feedback remains Hurwitz, for example, if the Jacobian of the full system is an H matrix [13], or is similar to one by a transformation preserving the $M^{(-)}$ structure of the original system.

Appendix A. Properties of SSD and WSD matrices. We collect a few easy results on SSD and WSD matrices which are needed for the arguments in this text. Note that, by definition, any submatrix of an SSD (WSD) matrix is SSD (WSD). Note also that swapping rows/columns of a matrix does not alter whether it is SSD (WSD).

The first result is a trivial consequence of the definitions and the properties of determinants.

LEMMA A.1. *Let S be any square matrix. Multiply some column or row in S by a scalar constant to get a new matrix $\tilde{S}$. Then if S is SNS or singular, so is $\tilde{S}$.*

The next result states that it is possible to augment matrices in certain simple ways and preserve the SSD property.

LEMMA A.2. *Let S be an SSD matrix. Augment S with a single column (row) which is a scalar multiple of some column (row) of S to get a new matrix S_{aug}. Then S_{aug} is SSD.*

Proof. Any square submatrix of S_{aug} either

1. occurs in S, in which case it is SNS or singular because S is SSD,
2. is a square submatrix of S with one column/row multiplied by a scalar, in which case it is SNS or singular by Lemma A.1,
3. contains some subset of both the original column/row and its multiple and hence is singular. ∎

Incidentally the above result would not hold if we replaced SSD by WSD: Although by definition any submatrix of a WSD matrix is WSD, the augmented versions of WSD matrices are not necessarily WSD. Thus in the statements of the theorems on mass action systems in section 4 it is essential that the systems be written as sets of irreversible reactions.

The next result shows that the set of WSD matrices contains the set of SSD matrices. (This is also a corollary of Theorem 1.2.5. in [4].)

LEMMA A.3. *Let S be an SNS or singular matrix and S_- be the matrix S with all positive entries set to zero. Then* $\det(S)\det(S_-) \geq 0$.

Proof. If S is singular, the result is trivial, so assume that S is SNS. Consider the family of matrices $S_p = (1-p)S + pS_-$ with $p \in [0,1]$. By the definition of SNS, if S is SNS, then S_p is in the same qualitative class as S for $p \in [0,1)$. By continuity of the determinant, S_- either has the same sign as S or is singular. □

From the previous two results it follows that if the stoichiometric matrix of a system of reactions is SSD, then it is also SSD when written as a system of irreversible reactions, in which case it is WSD when written this way.

The next few results are useful from an algorithmic point of view—they can considerably reduce the computational effort involved in calculating whether a matrix is SSD/WSD or not.

LEMMA A.4. *Let S be an SSD matrix. Let S_{aug} be the matrix S with a row/column containing at most one nonzero element added. Then S_{aug} is SSD.*

Proof. Any square submatrix of S_{aug} is either

1. a submatrix of S, and hence SNS or singular,
2. a single element and hence trivially SNS or singular, or
3. a submatrix of S augmented with an extra row/column containing at most one nonzero element. In this case the determinant is either zero or the product of a nonzero element and the determinant of a submatrix of S which is itself SNS or singular. □

From this the next result follows immediately.

LEMMA A.5. *Let S be a matrix which is not SSD. Let S_{dim} be the matrix S with some rows/columns containing no more than one nonzero element removed. Then S_{dim} is not SSD.*

Proof. Suppose that S_{dim} is SSD. A square submatrix of S is either

1. diagonal,
2. a submatrix of S_{dim},
3. a submatrix of S_{dim} augmented with rows/columns containing no more than one nonzero element.

In the first two cases it is trivial that the square submatrix is SNS or singular. In the third case the result follows from repeated application of Lemma A.4. □

Since any submatrix of an SSD matrix is SSD by definition, it follows that the full stoichiometric matrix of a CFSTR system (termed S_f in the text) is SSD iff the stoichiometric matrix S of the true reactions is SSD. In other words, columns containing a single element (corresponding to inflow/outflow processes) can be ignored when checking whether a matrix is SSD. Lemma A.5 also often considerably reduces the computational effort involved in checking whether a matrix is SSD, by allowing one to ignore rows in S containing a single element (i.e., to ignore reactants which participate in only one reaction).

The above result also extends to WSD matrices and thus reduces the computational effort involved in checking whether a matrix which has been shown not to be SSD is actually WSD. The next lemma, while tedious to state, is actually very useful in practice.

LEMMA A.6. *Let S_r refer to the stoichiometric matrix of a system of reactions, and S_{ir} refer to the stoichiometric matrix of the system written as a set of irreversible reactions. Let α be the set of rows in S_r containing a single element, and γ be the set of columns in S_r containing a single element. Let S_{dim} be the matrix S_{ir} with rows from α and columns from γ deleted. Then S_{ir} is WSD iff S_{dim} is.*

Proof. The "only if" part is trivial, as S_{dim} is a submatrix of S_{ir}. Suppose that S_{ir} is not WSD, and consider a square submatrix T of S_{ir} which does not satisfy $\det(T)\det(T_-) \geq 0$. Any elements of T not in S_{dim} must lie in rows/columns of T containing a single nonzero element, because if they lie in rows containing a single positive and a single negative element, then two columns of T will be multiples of each other and hence T will be singular. Further, any nonzero elements of T not in S_{dim} must be negative, since otherwise T_- would contain a row of zeroes and thus be singular. The only way that $\det(T)$ can be nonzero is if it takes the form of the product of these negative elements with the determinant of a submatrix $\tilde{T}$ of S_{dim}. Similarly $\det(T_-)$ must take the form of the product of these negative elements with the determinant of $\tilde{T}_-$. Thus $\det(T)\det(T_-)$ is a positive multiple of $\det(\tilde{T})\det(\tilde{T}_-)$, implying that $\det(\tilde{T})\det(\tilde{T}_-) < 0$. Thus S_{dim} is not WSD. □

This final lemma means that in checking whether a non-SSD matrix is actually WSD one can first remove rows corresponding to reactants which occur only in one (perhaps reversible) reaction from the stoichiometric matrix before checking the matrix.

Appendix B. Binary reaction systems. We present an important class of systems which give rise to $P^{(-)}$ matrix Jacobians. Consider a set of n reactants A_i, $i = 1, \ldots, n$. Assume that the only reactions taking place are (reversible or irreversible) interconversions between the reactants along with some inflow and outflow processes. It is reasonable to assume that the rates depend on the substrates in a monotone way, so such systems are nonautocatalytic. They have been discussed in some detail in [2], where global stability of a unique equilibrium was shown using techniques connected with logarithmic norms. Each column of the stoichiometric matrix S contains either a $+1$ and a -1 (interconversion) or a single negative entry (outflow). It can be shown inductively that this structure implies that S is SSD and hence that the Jacobian is a $P_0^{(-)}$ matrix.

Here we show that, subject to a weak assumption on the inflow and outflow processes, the Jacobian J is a $P^{(-)}$ matrix and in fact a nonsingular $M^{(-)}$ matrix.

Associated with any such interconversion network is a directed graph $\mathcal{G}$ on $n+1$ nodes. Nodes $i = 1, \ldots, n$ correspond to the n substrates, while the extra node which we term node 0 corresponds to the zero complex, i.e., to the outside of the system. For $i, j \geq 1$, there is an edge from node i to node j ($i \neq j$) iff $J_{ji} > 0$—i.e., A_i can be converted to A_j, or alternatively the rate of conversion of A_j to A_i is inhibited by the concentration of A_i. On the other hand, for $i \geq 1$, there is an edge from node i to node 0 iff A_i is subject either to an outflow process or to an inflow process whose rate is inhibited by an increase in the concentration of i. This has the consequence of ensuring that J is strictly dominant in the ith column.

Our assumption is that *there is a directed path in $\mathcal{G}$ from any node to node* 0. This has the physical interpretation that the concentration of any substrate is affected by the "outside," a considerably weaker condition than insisting on a CFSTR. We refer the reader to [2] for the details, but the above assumptions together imply that the following hold:

1. J has negative diagonal entries.
2. J has nonnegative off-diagonal entries.
3. There is a constant coordinate transformation T such that TJT^{-1} still satisfies conditions 1 and 2 and is also strictly diagonally dominant in every column; hence J is Hurwitz.

These three facts combine to ensure that J is a nonsingular $M^{(-)}$ matrix [3].

Nonsingular $M^{(-)}$ matrices are a subset of $P^{(-)}$ matrices. In fact, all trajectories converge to a unique equilibrium [2].

Note that the basic system of coupled redox reactions presented in [1] gives rise to a Jacobian of the above form, even though in this case electrons are being transferred rather than reactants interconverted.

Acknowledgment. Thanks are due to the reviewer of this manuscript who helped us understand several connections between this work and the work in [5].

WEAK LACUNAE OF ELECTROMAGNETIC WAVES IN DILUTE PLASMA*

S. V. TSYNKOV†

Abstract. The propagation of waves is said to be diffusionless, and the corresponding governing PDE (or system) is said to satisfy Huygens' principle if the waves due to compactly supported sources have sharp aft fronts. The areas of no disturbance behind the aft fronts are called lacunae. Diffusionless propagation of waves is rare, whereas its opposite—diffusive propagation accompanied by aftereffects—is common. Nonetheless, lacunae can still be observed in a number of important applications, including the Maxwell equations in vacuum or in dielectrics with static response. In the framework of these applications, lacunae can be efficiently exploited for the numerical simulation of unsteady waves, and considerable progress has been made toward the development of lacunae-based methods for computational electromagnetism. Maxwell equations in vacuum are Huygens' because they reduce to a set of d'Alembert equations. Besides d'Alembert equations, there are no other scalar Huygens' equations in the standard $3+1$-dimensional Minkowski space-time. In terms of physics, this means that the mechanisms of dissipation and dispersion destroy the lacunae. In fact, all conventional low-frequency electromagnetic models, such as metals with Ohm conductivity, semiconductors, and magnetohydrodynamic media, are diffusive. An important case of the propagation of high-frequency electromagnetic waves in plasma is governed by the Klein–Gordon equation. It does not reduce to the d'Alembert equation either, and therefore the corresponding propagation is diffusive as well. However, one can still identify "weak lacunae" in the solutions of the Klein–Gordon equation, with the aft fronts that can be clearly observed, although they may not be as sharp as in the pure Huygens' case. Moreover, one can show that the "depth" of a weak lacuna is controlled by the dimensionless ratio of the Langmuir frequency to the primary carrying frequency of the waves.

Key words. Huygens' principle, wave diffusion, aftereffects, aft fronts, lacunae, ionospheric propagation, isotropic plasma, Langmuir frequency, cold plasma, transverse waves, Maxwell equations, Klein–Gordon equation, weak dispersion, short waves, external magnetic field, cyclotron frequency, gyrotropy, Faraday rotation

1. Introduction.

1.1. The Huygens' principle.

Consider a three-dimensional Cauchy problem for the wave (d'Alembert) equation:

$$\frac{1}{c^2}\frac{\partial^2\varphi}{\partial t^2}-\Delta\varphi=f(\boldsymbol{x},t),\qquad \varphi(\boldsymbol{x},0)=\varphi_t(\boldsymbol{x},0)=0,\tag{1.1}$$
$$\mathbb{R}^3\ni\boldsymbol{x}=(x_1,x_2,x_3).$$

The fundamental solution of the d'Alembert operator is the expanding spherical wave (single layer)

$$\mathcal{E}(\boldsymbol{x},t)=\frac{\Theta(t)}{4\pi}\frac{\delta(|\boldsymbol{x}|-ct)}{t},\tag{1.2}$$

where $\Theta(t)$ is the Heaviside function, and the solution to the Cauchy problem (1.1) is given by the convolution of the fundamental solution (1.2) with the right-hand side $f(\boldsymbol{x},t)$, i.e., by the Kirchhoff integral

$$\varphi(\boldsymbol{x},t)=\mathcal{E}*f=\frac{1}{4\pi}\iiint\limits_{\varrho\le ct}\frac{f\left(\boldsymbol{\xi},t-\varrho/c\right)}{\varrho}d\boldsymbol{\xi}, \tag{1.3}$$

where $\mathbb{R}^3\ni\boldsymbol{\xi}=(\xi_1,\xi_2,\xi_3)$ and $\varrho=|\boldsymbol{x}-\boldsymbol{\xi}|$.

Assume now that the right-hand side $f(\boldsymbol{x},t)$ is compactly supported in space and in time, i.e., that $\operatorname{supp} f\subseteq Q$, where Q is a bounded region in $\mathbb{R}^3\times[0,+\infty)\equiv\{(\boldsymbol{x},t)\,|\,\boldsymbol{x}\in\mathbb{R}^3,\,0\le t<+\infty\}$. Then, the Kirchhoff formula (1.3) immediately implies that

$$\varphi(\boldsymbol{x},t)\equiv 0\ \text{ for }\ (\boldsymbol{x},t)\in\bigcap_{(\boldsymbol{\xi},\tau)\in Q}\left\{(\boldsymbol{x},t)\big||\boldsymbol{x}-\boldsymbol{\xi}|<c(t-\tau),\ t>\tau\right\}. \tag{1.4}$$

The region of space-time defined by formula (1.4) is known as the *lacuna* of the solution $\varphi(\boldsymbol{x},t)$ of problem (1.1), because the solution vanishes there. This region can be interpreted as the intersection of all the characteristic cones of the d'Alembert equation, once the vertex of the cone sweeps the support Q of the right-hand side.

The presence of lacunae (or lacunas) in the solution is equivalent to the existence of the sharp aft fronts of the waves. In other words, the perturbation due to a compactly supported source first reaches a given fixed location of the observer and then ceases completely once a finite interval of time has elapsed. Subsequently, the solution at this location remains identically zero. Lacunae can then be viewed as areas of "quietness" behind the aft fronts, and the latter, reciprocally, serve as boundaries of the lacunae.

Differential equations, for which lacunae can be identified in their solutions, are said to satisfy *the Huygens' principle*. The most well-known classical example is provided by the foregoing d'Alembert equation. The Huygens' principle should not be confused with another concept that bears the same name and that often appears in the context of wave propagation in optics. Namely, according to *the Huygens' construction,* at every given moment of time the front of the propagating wave can be considered a collection of secondary sources that altogether define the wave field at subsequent moments of time [5].

Existence of the lacunae is a rare and fragile property. Its opposite is known as *the diffusion of waves* and is considered common. The diffusion manifests itself by aftereffects that accompany the propagation of waves governed by non-Huygens' equations. In this case, there are no sharp aft fronts, and once the perturbation has reached a given observation point it will never cease but only decay in amplitude.

A key constraint that distinguishes between the diffusionless and diffusive propagation is that lacunae may exist only *if the number of space dimensions is odd.* In particular, the propagation of waves governed by the d'Alembert equation on the plane ($\mathbb{R}^2$, as opposed to $\mathbb{R}^3$) is already characterized by aftereffects.

Another important consideration is that studying the wave phenomena in the time domain is essential for the analysis and interpretation of the Huygens' principle. Indeed, a standard frequency-domain model is the Helmholtz equation

$$\Delta\hat{\varphi}+k^2\hat{\varphi}=\hat{f}, \tag{1.5}$$

which is obtained from the d'Alembert equation by applying the Fourier transform in time. In (1.5), $k^2=\omega^2/c^2$, and $\hat{\varphi}$ denotes the complex amplitude of the time-harmonic

wave at the frequency ω (i.e., the ω Fourier coefficient). Solutions of the Helmholtz equation (1.5) are known to be analytic in the areas of homogeneity; therefore, they may not turn into zero only on a subdomain.

A review of the facts and publications in the literature pertaining to the Huygens' principle can be found in [3]; see also [10, 11]. The question of describing the hyperbolic differential equations and systems that admit the diffusionless propagation of waves was first formulated by Hadamard [12, 13, 14]. He did not know any other examples besides the classical d'Alembert equation. The notion of lacunae was introduced and studied by Petrowsky in [23]; see also [7, Chapter VI]. He obtained general conditions for the coefficients of hyperbolic equations/systems that guaranteed the presence of lacunae. Subsequent work in this direction was done by Atiyah, Bott, and Gȧrding in [1, 2]. However, no other constructive examples of lacunae in the solutions have been found besides solutions of the wave equation and its equivalents. In fact, Matthisson [20] has shown that in the standard $3+1$-dimensional Minkowski space-time the only scalar hyperbolic equation that satisfies the Huygens' principle is the wave equation. From the standpoint of applications, this result provides one of the most convenient and useful criteria. Namely, the equation may be Huygens' only if it is equivalent to the d'Alembert equation. We will employ this criterion for the analysis in the current paper. In this regard, we also emphasize that the aforementioned equivalence does not have to be global; a given equation may only locally reduce to the d'Alembert equation. An interesting illustration of this fact is provided by Lax and Phillips in [19]—they analyze the waves that propagate on an n-dimensional sphere, where n is odd, and prove that the propagation is diffusionless. The first examples of nontrivial scalar equations (i.e., nonequivalent to the d'Alembert equation) that satisfy the Huygens' principle were built by Stellmacher (see [28, 16, 29]) in the spaces $\mathbb{R}^n$ for odd $n \geq 5$. His examples have the form $c^{-2}\varphi_{tt} - \Delta\varphi + H(\boldsymbol{x}, t)\varphi = 0$, where the function $H(\boldsymbol{x}, t)$ is specially chosen to guarantee the diffusionless propagation, in which case it is called the Huygens' potential [3]. There are also examples of nontrivial diffusionless (i.e., Huygens') systems (as opposed to scalar equations) in the standard Minkowski $3+1$ space-time [26, 3, 10], as well as examples of nontrivial scalar Huygens' equations in a $3+1$-dimensional space-time but equipped with an alternative metric (the so-called plane wave metric); see [3, 10, 9].

1.2. Applications of lacunae. Lacunae of a given differential equation or system can be efficiently exploited for designing advanced numerical integration techniques. Lacunae-based methods have been developed previously for solving the scalar wave equation [25, 24], as well as for the problems of computational acoustics [31] and computational electromagnetism [32, 33, 34]. For the simplest possible setup that involves the radiation of waves by a known source, these methods guarantee that the grid convergence of a given discrete approximation will be *uniform in time.* For a more general setting that involves a sophisticated or potentially unknown mechanism of wave generation confined to a bounded region, lacunae-based methods facilitate construction of highly accurate unsteady artificial boundary conditions (ABCs) with only fixed and limited extent of temporal nonlocality in time. Note that overcoming the nonlocality of the exact unsteady ABCs in time has long been regarded as a challenging numerical issue [30]. From this perspective it is important to emphasize that the bound on temporal nonlocality obtained through the use of lacunae does not come at the expense of any approximation and/or simplification of the model; it is rather an implication of the fundamental properties of the corresponding solutions.

In addition to having the aforementioned computational benefits, lacunae can

also be instrumental in performing a number of tasks other than numerical ones. For example, explicit knowledge of their shape can help in planning of electromagnetic measurements and subsequent interpretation of the results.

In the current paper, we are not going to concentrate on numerical issues, except in section 3.5. Instead, we will focus on the phenomenon of lacunae itself. In particular, we will see that in the context of electromagnetism, only the simplest models that involve the propagation of waves in vacuum or in dielectrics with static response admit lacunae in the classical sense of the word. Many other traditional low-frequency models, such as different types of dielectrics, metals, semiconductors, magnetohydrodynamic media (MHD), turn out to be diffusive. However, for the important case of the propagation of high-frequency electromagnetic waves in dilute plasma, lacunae can still be identified in the solutions of the Maxwell equations in some approximate sense. Moreover, one can show that the quality, or "depth," of these weak lacunae is controlled by the ratio of the Langmuir frequency, which is a key parameter that characterizes temporal responses of the plasma to the primary carrying frequency of the incident wave.

2. Traditional electromagnetic models.

2.1. The Maxwell system of equations. Lacunae in vacuum. The evolution of electromagnetic field in vacuum is governed by the classical Maxwell equations

$$\begin{aligned} &\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} + \operatorname{curl}\boldsymbol{E} = \boldsymbol{0}, && \operatorname{div}\boldsymbol{B} = 0, \\ &\frac{1}{c}\frac{\partial \boldsymbol{E}}{\partial t} - \operatorname{curl}\boldsymbol{B} = -\frac{4\pi}{c}\boldsymbol{j}_{\text{ext}}, && \operatorname{div}\boldsymbol{E} = 4\pi\rho_{\text{ext}}. \end{aligned} \tag{2.1}$$

In system (2.1), $\boldsymbol{E}$ and $\boldsymbol{B}$ are intensities of the electric and magnetic field, respectively, c is the speed of light, $\boldsymbol{j}_{\text{ext}}$ is the density of the extraneous current, and ρ_{ext} is the density of the extraneous electric charge [17]. *A necessary solvability condition* for system (2.1) is continuity of the charges and currents:

$$\frac{\partial \rho_{\text{ext}}}{\partial t} + \operatorname{div}\boldsymbol{j}_{\text{ext}} = 0. \tag{2.2}$$

Equation (2.2) is obtained by taking divergence of the second unsteady equation of (2.1) and then substituting the second steady-state equation of (2.1). From the standpoint of physics, continuity (2.2) implies the conservation of electric charge. The rate of change of the total charge contained in any given region of space is equal to the flux of the charge, i.e., the total current, through the boundary of this region.

By differentiating each unsteady equation of (2.1) with respect to time, taking curl of the other unsteady equation, substituting $\operatorname{curlcurl}[\,\cdot\,] = \operatorname{graddiv}[\,\cdot\,] - \Delta[\,\cdot\,]$, and employing the corresponding steady-state equation of (2.1), we arrive at the following individual equations for the field intensities $\boldsymbol{B}$ and $\boldsymbol{E}$:

$$\begin{aligned} &\frac{1}{c^2}\frac{\partial^2 \boldsymbol{B}}{\partial t^2} - \Delta\boldsymbol{B} = \frac{4\pi}{c}\operatorname{curl}\boldsymbol{j}_{\text{ext}}, \\ &\frac{1}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} - \Delta\boldsymbol{E} = -4\pi\left[\frac{1}{c^2}\frac{\partial \boldsymbol{j}_{\text{ext}}}{\partial t} + \operatorname{grad}\rho_{\text{ext}}\right]. \end{aligned} \tag{2.3}$$

Equations (2.3) are vector d'Alembert equations with the propagation speed c. Each equation of (2.3) is Huygens' in $\mathbb{R}^3$, and hence system (2.1) is also Huygens'. If the

charges ρ_{ext} and currents $\boldsymbol{j}_{\text{ext}}$ are compactly supported, then the solution of (2.1) will have a lacuna of the same structure as determined by the Kirchhoff integral (1.3). Hence, the three-dimensional propagation of electromagnetic waves in vacuum is diffusionless.

Equations (2.1) will also remain a valid model for describing the electromagnetic field in various materials, but *only on the microscopic level.* The macroscopic equations are obtained by averaging; see [18]. In doing so, the impinging electromagnetic field may give rise to the induced charges and currents (see section 2.2), which, in turn, may affect the fields themselves. This range of phenomena is described by introducing the electric induction (or displacement) $\boldsymbol{D}$ and the magnetic field $\boldsymbol{H}$, whereas the "old" quantity $\boldsymbol{B}$ is referred to as the magnetic induction. The macroscopic Maxwell equations in the medium then become

$$\begin{aligned} &\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} + \operatorname{curl}\boldsymbol{E} = \boldsymbol{0}, && \operatorname{div}\boldsymbol{B} = 0, \\ &\frac{1}{c}\frac{\partial \boldsymbol{D}}{\partial t} - \operatorname{curl}\boldsymbol{H} = -\frac{4\pi}{c}\boldsymbol{j}_{\text{ext}}, && \operatorname{div}\boldsymbol{D} = 4\pi\rho_{\text{ext}}. \end{aligned} \tag{2.4}$$

Note that once $\boldsymbol{B}$ is referred to as the induction, and $\boldsymbol{H}$ as the magnetic field, system (2.4) looks mathematically more symmetric. However, as far as the physics is concerned, the true intensity of the magnetic field[1] is $\boldsymbol{B}$ rather than $\boldsymbol{H}$. As for the right-hand sides' $\boldsymbol{j}_{\text{ext}}$ and ρ_{ext} of system (2.4), they may be interpreted differently for different types of media and may sometimes be treated only as formal mathematical source terms.

System (2.4) is underdetermined unless additional relations are specified between the electric quantities $\boldsymbol{E}$ and $\boldsymbol{D}$ and the magnetic quantities $\boldsymbol{H}$ and $\boldsymbol{B}$. These relations are determined by the medium, across which the electromagnetic waves propagate. They are called *the responses.* The responses may vary drastically for different types of media and different regimes of propagation. The simplest response is static.

2.2. Dielectric media with static response. Lacunae. A dielectric medium may not support a constant (i.e., steady-state) electric current. Responses of a dielectric medium can be characterized in terms of the electric polarization $\boldsymbol{P}$, which is the induced electric dipole moment per unit volume, and magnetization $\boldsymbol{M}$, which is the induced magnetic dipole moment per unit volume. Then, by definition,

$$\boldsymbol{D} = \boldsymbol{E} + 4\pi\boldsymbol{P} \quad \text{and} \quad \boldsymbol{B} = \boldsymbol{H} + 4\pi\boldsymbol{M}. \tag{2.5}$$

In an isotropic dielectric with static response, the electric induction $\boldsymbol{D}$ is assumed directly proportional to the electric field $\boldsymbol{E}$, and the magnetic induction $\boldsymbol{B}$ is assumed directly proportional to the magnetic field $\boldsymbol{H}$:

$$\boldsymbol{D} = \epsilon\boldsymbol{E} \quad \text{and} \quad \boldsymbol{B} = \mu\boldsymbol{H}, \tag{2.6}$$

where the dielectric permittivity $\epsilon = \text{const}$ and the magnetic permeability $\mu = \text{const}$. In vacuum, we have $\epsilon = \mu = 1$, so that (2.4), (2.6) transform back to (2.1). In dielectric media other than vacuum, the assumptions of $\epsilon = \text{const}$ and $\mu = \text{const}$ may hold only for static incident fields. They can be used in the case of unsteady fields as well, but only as approximations and provided that *the incident frequencies*

[1] A quantitative characteristic of the field that determines how it affects the moving charged particles.

are low,[2] i.e., considerably lower than the typical frequencies of the molecular or electronic oscillations that are responsible for the onset of electric polarization and/or magnetization of the medium.

Under the assumption of a static response (2.6), the Maxwell equations (2.4) reduce to

$$\begin{aligned} &\frac{\mu}{c}\frac{\partial \boldsymbol{H}}{\partial t} + \operatorname{curl}\boldsymbol{E} = \boldsymbol{0}, && \operatorname{div}\boldsymbol{H} = 0, \\ &\frac{\epsilon}{c}\frac{\partial \boldsymbol{E}}{\partial t} - \operatorname{curl}\boldsymbol{H} = -\frac{4\pi}{c}\boldsymbol{j}_{\text{ext}}, && \operatorname{div}\boldsymbol{E} = \frac{4\pi}{\epsilon}\rho_{\text{ext}}. \end{aligned} \tag{2.7}$$

Then, a procedure identical to the one used when deriving equations (2.3) from (2.1) yields

$$\begin{aligned} &\frac{\epsilon\mu}{c^2}\frac{\partial^2 \boldsymbol{H}}{\partial t^2} - \Delta \boldsymbol{H} = \frac{4\pi}{c}\operatorname{curl}\boldsymbol{j}_{\text{ext}}, \\ &\frac{\epsilon\mu}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} - \Delta \boldsymbol{E} = -4\pi\left[\frac{\mu}{c^2}\frac{\partial \boldsymbol{j}_{\text{ext}}}{\partial t} + \frac{1}{\epsilon}\operatorname{grad}\rho_{\text{ext}}\right]. \end{aligned} \tag{2.8}$$

Thus, equations (2.8) that individually govern the fields $\boldsymbol{H}$ and $\boldsymbol{E}$ in $\mathbb{R}^3$ are Huygens'. As such, so is system (2.7). The corresponding wave speed $c/\sqrt{\epsilon\mu}$ is slower than the speed of light c.

Unfortunately, the propagation in vacuum or in dielectrics with static response is practically the only case of electromagnetic propagation with no aftereffects. In sections 2.3, 2.4, and 2.5, we will see that many conventional electrodynamic models appear diffusive even before the onset of *dispersion,* i.e., for *low frequencies,* when static relations between $\boldsymbol{D}$, $\boldsymbol{B}$ and $\boldsymbol{E}$, $\boldsymbol{H}$ can still be employed for unsteady fields. The propagation remains diffusive in the case of higher incident frequencies as well.[3]

Note also that the description of the responses in terms of the polarization $\boldsymbol{P}$ and magnetization $\boldsymbol{M}$ (see (2.5)) naturally brings along the definition of the induced charge ρ_{ind} and the induced current $\boldsymbol{j}_{\text{ind}}$:

$$\rho_{\text{ind}} = -\operatorname{div}\boldsymbol{P}, \qquad \boldsymbol{j}_{\text{ind}} = \frac{\partial \boldsymbol{P}}{\partial t} + c\operatorname{curl}\boldsymbol{M}. \tag{2.9}$$

Substitution of (2.5) and (2.9) into the Maxwell equations (2.4) yields

$$\begin{aligned} &\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} + \operatorname{curl}\boldsymbol{E} = \boldsymbol{0}, && \operatorname{div}\boldsymbol{B} = 0, \\ &\frac{1}{c}\frac{\partial \boldsymbol{E}}{\partial t} - \operatorname{curl}\boldsymbol{B} = -\frac{4\pi}{c}(\boldsymbol{j}_{\text{ext}} + \boldsymbol{j}_{\text{ind}}), && \operatorname{div}\boldsymbol{E} = 4\pi(\rho_{\text{ext}} + \rho_{\text{ind}}). \end{aligned} \tag{2.10}$$

System (2.10) is identical to (2.1), except that on its right-hand side we have the full current $\boldsymbol{j} = \boldsymbol{j}_{\text{ext}} + \boldsymbol{j}_{\text{ind}}$ and the full charge $\rho = \rho_{\text{ext}} + \rho_{\text{ind}}$ instead of only the extraneous quantities. This is an alternative way of representing the electromagnetic field inside a material—by looking at the actual intensities $\boldsymbol{B}$ and $\boldsymbol{E}$ only, but driven by the induced sources added to the original extraneous sources.[4]

[2]The notion of incident frequency is to be interpreted broadly here as frequency of any external excitation to the field inside the material, whether it be the frequency of the actual impinging wave or the frequency of the extraneous sources.

[3]Incident frequencies on the order of, or higher than, the characteristic microscopic frequencies for a given medium.

[4]Extraneous sources may or may not be present in every particular case.

2.3. Ohm conductivity in metals. In contradistinction to dielectrics, conducting materials can support a constant electric current. The steady-state model of a conductor can be obtained by dropping the displacement current $\frac{\partial \boldsymbol{D}}{\partial t} = \epsilon \frac{\partial \boldsymbol{E}}{\partial t}$ from the second unsteady Maxwell equation (2.4) or (2.7), which yields

$$\operatorname{curl} \boldsymbol{H} = \frac{4\pi}{c} \boldsymbol{j}_{\mathrm{c}}. \tag{2.11}$$

The quantity $\boldsymbol{j}_{\mathrm{c}}$ on the right-hand side of (2.11) is called the conductivity current. In the pure static case it is assumed given, and then (2.11) is solved along with $\operatorname{div} \boldsymbol{B} = 0$ to determine the magnetic field. Note that according to formula (2.11) the conductivity current is solenoidal, $\operatorname{div} \boldsymbol{j}_{\mathrm{c}} = 0$, which is a manifestation of the conservation of charge in this case.

The foregoing static model for conducting materials such as metals can also be applied to the analysis of slowly varying electromagnetic fields. In this case, however, the conductivity current $\boldsymbol{j}_{\mathrm{c}}$ shall no longer be treated as given. It rather becomes an unsteady current induced by the electric field that, in turn, is due to the variation in the magnetic field. Then, one also needs to add the first unsteady equation of the Maxwell system (2.4) or (2.7) to (2.11) and $\operatorname{div} \boldsymbol{B} = 0$. In doing so, the displacement current may still remain omitted from (2.11). The justification for not including it into the unsteady analysis is outlined in section 2.4, where a more comprehensive model is considered that includes semiconductors.

The key relation that one still needs in order to complete the unsteady model is a connection between the conductivity current and the electric field. Often, this connection is provided by the same classical Ohm law of electrostatics that establishes the direct proportionality between $\boldsymbol{j}_{\mathrm{c}}$ and the electric intensity $\boldsymbol{E}$:

$$\boldsymbol{j}_{\mathrm{c}} = \sigma \boldsymbol{E}. \tag{2.12}$$

The quantity σ in formula (2.12) is the electric conductivity; in the isotropic case it is a scalar. The conductivity σ can be assumed constant, and accordingly, static relations (2.11), (2.12) can be used for the unsteady fields in metals, under conditions similar to those discussed in section 2.2. Namely, the frequency of the incident field must be much lower than the characteristic frequencies of the microscopic mechanism of conductivity, which is due to the collisions between the conductivity electrons and atoms of the crystal lattice. Therefore, the incident frequency must be much lower than the collision frequency $\mathcal{O}(v_{\mathrm{e}}/\delta)$, where v_{e} is the electron thermal speed and δ is the mean free path.

By combining the first two equations of (2.4) with relations (2.11) and (2.12), we obtain the following system of equations that governs the unsteady electromagnetic field in metals:

$$\begin{gathered} \frac{1}{c} \frac{\partial \boldsymbol{B}}{\partial t} + \operatorname{curl} \boldsymbol{E} = \boldsymbol{0}, \qquad \operatorname{div} \boldsymbol{B} = 0, \\ \operatorname{curl} \boldsymbol{H} = \frac{4\pi}{c} \sigma \boldsymbol{E}, \end{gathered} \tag{2.13}$$

where we again assume that $\boldsymbol{B} = \mu \boldsymbol{H}$ with $\mu = \mathrm{const}$. From system (2.13) we easily obtain

$$\frac{1}{c} \frac{\partial \boldsymbol{B}}{\partial t} + \operatorname{curl} \frac{c}{4\pi\sigma} \operatorname{curl} \boldsymbol{H} = \boldsymbol{0},$$

which, along with $\mathrm{div}\boldsymbol{B} = \mu \mathrm{div}\boldsymbol{H} = 0$, yields the following parabolic equation for the magnetic field $\boldsymbol{H}$:

$$\frac{\partial \boldsymbol{H}}{\partial t} - \frac{c^2}{4\pi\sigma\mu}\Delta \boldsymbol{H} = \boldsymbol{0}. \tag{2.14}$$

Once (2.14) is solved, the electric field $\boldsymbol{E}$ is determined by the magnetic field through the last equation of (2.13). Equation (2.14) is not equivalent to the d'Alembert equation. Hence, according to the Matthisson criterion [20], it is not Huygens', and there may be no lacunae in its solutions.

We should also notice that (2.14) is homogeneous and therefore may only be driven by the initial and/or boundary conditions, whereas previously we have analyzed lacunae in the solutions due to the compactly supported right-hand sides. Thus, let us see how a source term for (2.14) can be generated.

Let us introduce a nonphysical artificial current $\boldsymbol{j}_{\mathrm{a}}$ that will be included on the right-hand side of (2.11) and as such will be affecting the magnetic field $\boldsymbol{H}$,

$$\mathrm{curl}\boldsymbol{H} = \frac{4\pi}{c}\boldsymbol{j}_{\mathrm{c}} + \frac{4\pi}{c}\boldsymbol{j}_{\mathrm{a}}, \tag{2.15}$$

but will not itself be driven by the induced electric field $\boldsymbol{E}$ through the Ohm law (2.12). Then, we use (2.15) instead of (2.11) and obtain a modified form of system (2.13):

$$\begin{gathered} \frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} + \mathrm{curl}\boldsymbol{E} = \boldsymbol{0}, \qquad \mathrm{div}\boldsymbol{B} = 0, \\ \mathrm{curl}\boldsymbol{H} = \frac{4\pi}{c}\sigma\boldsymbol{E} + \frac{4\pi}{c}\boldsymbol{j}_{\mathrm{a}}. \end{gathered} \tag{2.16}$$

The conservation of charge in the case is expressed as the total current being solenoidal: $\mathrm{div}(\boldsymbol{j}_{\mathrm{c}} + \boldsymbol{j}_{\mathrm{a}}) = 0$. For simplicity, and with no substantial loss of generality (see Theorem 1 in [34]), we can also assume that the artificial current $\boldsymbol{j}_{\mathrm{a}}$ itself is divergence-free, $\mathrm{div}\boldsymbol{j}_{\mathrm{a}} = 0$. In this case, the electric field will remain solenoidal as in system (2.13): $\mathrm{div}\boldsymbol{E} = 0$. From (2.16) we obtain the inhomogeneous counterpart of (2.14):

$$\frac{\partial \boldsymbol{H}}{\partial t} - \frac{c^2}{4\pi\sigma\mu}\Delta \boldsymbol{H} = \frac{1}{\sigma}\mathrm{curl}\boldsymbol{j}_{\mathrm{a}}. \tag{2.17}$$

Solutions of (2.17) do not have lacunae even if $\boldsymbol{j}_{\mathrm{a}}$ is compactly supported. We can therefore conclude that the propagation of electromagnetic waves in the media with Ohm conductivity is diffusive.

2.4. Semiconductors. Let us now look more thoroughly into how one shall actually treat the displacement current for conducting materials. Keeping the unsteady term $\frac{1}{c}\frac{\partial \boldsymbol{D}}{\partial t} = \frac{\epsilon}{c}\frac{\partial \boldsymbol{E}}{\partial t}$, i.e., considering

$$\mathrm{curl}\boldsymbol{H} = \frac{4\pi}{c}\sigma\boldsymbol{E} - \frac{\epsilon}{c}\frac{\partial \boldsymbol{E}}{\partial t} \tag{2.18}$$

instead of (2.11), (2.12), can make sense only under the special circumstances when the second term on the right-hand side of (2.18) is of the same order of magnitude as the first term, or at least not negligibly small compared to the first term. If the field is time-harmonic, then the ratio of these two terms is $\mathcal{O}\left(\frac{\epsilon\omega}{4\pi\sigma}\right)$. In metals, we typically have $\frac{\omega}{\sigma} \ll 1$ for the entire range of frequencies, for which the conductivity σ can still be considered constant [18]. Therefore, (2.18) in metals indeed reduces to (2.13).

In semiconductors, however, because of the low concentration of conductivity electrons, the value of σ could be very small, so that for all those frequencies, for which σ and ϵ can still be regarded as constants, we may already have $\frac{\epsilon\omega}{4\pi\sigma} = \mathcal{O}(1)$. Then, the Maxwell equations become (cf. formulae (2.13) and (2.7))

$$\begin{aligned} &\frac{\mu}{c}\frac{\partial \boldsymbol{H}}{\partial t} + \mathrm{curl}\boldsymbol{E} = \boldsymbol{0}, \quad \mathrm{div}\boldsymbol{H} = 0, \\ &\frac{\epsilon}{c}\frac{\partial \boldsymbol{E}}{\partial t} + \frac{4\pi}{c}\sigma\boldsymbol{E} - \mathrm{curl}\boldsymbol{H} = \boldsymbol{0}, \quad \mathrm{div}\boldsymbol{E} = 0. \end{aligned} \tag{2.19}$$

By differentiating the second unsteady equation of (2.19) with respect to t, taking curl of the first unsteady equation, and then substituting $\mathrm{div}\boldsymbol{E} = 0$, we arrive at the telegrapher's equation for the electric field:

$$\frac{\epsilon\mu}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \frac{4\pi\mu\sigma}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} - \Delta\boldsymbol{E} = \boldsymbol{0}. \tag{2.20}$$

A right-hand side for (2.20) can be built similarly to how it was done in section 2.3 for (2.14). Namely, if we were to formally add the artificial source terms $-\frac{4\pi}{c}\boldsymbol{j}_{\mathrm{a}}$ and $\frac{4\pi}{\epsilon}\rho_{\mathrm{a}}$ to the second pair of the Maxwell equations (2.19), then we would have obtained the following equation instead of (2.20):

$$\frac{\epsilon\mu}{c^2}\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + \frac{4\pi\mu\sigma}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} - \Delta\boldsymbol{E} = -4\pi\left[\frac{\mu}{c^2}\frac{\partial \boldsymbol{j}_{\mathrm{a}}}{\partial t} + \frac{1}{\epsilon}\mathrm{grad}\rho_{\mathrm{a}}\right]. \tag{2.21}$$

The operator on the left-hand side of (2.21) is not equivalent to the d'Alembert operator. Therefore, the Huygens' principle will not hold, and there will be no lacunae. Note also that the larger the ratio $\frac{\epsilon\omega}{4\pi\sigma}$, the more of a standard dielectric behavior will be displayed by the medium governed by (2.18).

2.5. Magnetohydrodynamics. The case of a conducting medium in motion is not very different from the stationary conducting medium analyzed in section 2.3. Instead of the Ohm law (2.12) we now have

$$\boldsymbol{j}_{\mathrm{c}} = \sigma\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{u}\times\boldsymbol{B}\right), \tag{2.22}$$

where $\boldsymbol{u}$ denotes the velocity of the conducting fluid. The second term on the right-hand side of (2.22) is the so-called Lorentz correction that helps obtain the electric field in the frame of reference that moves with the velocity $\boldsymbol{u}$, provided that $|\boldsymbol{u}| \ll c$; see [17]. Accordingly, instead of system (2.13) we obtain

$$\begin{aligned} &\frac{1}{c}\frac{\partial \boldsymbol{B}}{\partial t} + \mathrm{curl}\boldsymbol{E} = \boldsymbol{0}, \qquad \mathrm{div}\boldsymbol{B} = 0, \\ &\mathrm{curl}\boldsymbol{H} = \frac{4\pi}{c}\sigma\left(\boldsymbol{E} + \frac{1}{c}\boldsymbol{u}\times\boldsymbol{B}\right), \end{aligned}$$

and instead of (2.14) we have

$$\frac{\partial \boldsymbol{H}}{\partial t} - \mathrm{curl}(\boldsymbol{u}\times\boldsymbol{H}) - \frac{c^2}{4\pi\sigma\mu}\Delta\boldsymbol{H} = \boldsymbol{0}. \tag{2.23}$$

As before, (2.23) is to be solved under the condition that the magnetic field is solenoidal: $\mathrm{div}\boldsymbol{H} = 0$.

Unlike in section 2.3, in magnetohydrodynamics the electromagnetic equations are not independent. They are coupled to the equations of the fluid flow through the quantity $\boldsymbol{u}$ in (2.23). Moreover, the ponderomotive force $\frac{1}{c}\boldsymbol{j}_{\mathrm{c}} \times \boldsymbol{H}$ is added to the right-hand side of the momentum equation of the fluid, and the Joule heat $\boldsymbol{j}_{\mathrm{c}}^2/\sigma$ is added to the right-hand side of the energy equation of the fluid. Therefore, we cannot directly apply the Matthisson criterion to (2.23); this can only be done if we consider the velocity field $\boldsymbol{u}$ as given. Then, the answer is still negative—(2.23) is not Huygens'.

Of particular interest may be the case of very large (theoretically, infinite) conductivities σ, when the dissipative term $\sim \Delta \boldsymbol{H}$ can be dropped from (2.23). Let us then consider the equations of inviscid compressible flow coupled with (2.23) for the magnetic field with no magnetic viscosity, $\frac{c^2}{4\pi\sigma\mu} = 0$:

$$\begin{aligned} \frac{d\varrho}{dt} + \varrho \mathrm{div}\boldsymbol{u} &= 0, \\ \varrho \frac{d\boldsymbol{u}}{dt} + \mathrm{grad}p &= \frac{1}{4\pi}\mathrm{curl}\boldsymbol{H} \times \boldsymbol{H}, \\ \frac{\partial \boldsymbol{H}}{\partial t} &= \mathrm{curl}(\boldsymbol{u} \times \boldsymbol{H}). \end{aligned} \tag{2.24}$$

In system (2.24), ϱ, p, and T are the density, pressure, and temperature of the fluid, respectively, and $\frac{d}{dt} = \frac{\partial}{\partial t} + (\boldsymbol{u} \cdot \mathrm{grad})$. It is easy to show (see, e.g., [27, Vol. 1]) that infinite conductivity also implies the adiabatic nature of the flow, because the Joule heat $\frac{1}{\sigma}\boldsymbol{j}_{\mathrm{c}}^2$ must be disregarded. Then, instead of the energy equation, system (2.24) can be supplemented by the Poisson adiabatic relation between the pressure and density of a thermodynamically ideal fluid: $p = \mathrm{const} \cdot \varrho^{\gamma}$, where $\gamma = \frac{c_p}{c_v}$ is the ratio of specific heats.

Let us linearize equations (2.24) at the background of an ambient conducting fluid immersed into a constant magnetic field, i.e., at the background of a constant solution: $\varrho = \varrho_0$, $p = p_0$, $\boldsymbol{u} = \boldsymbol{u}_0 = \boldsymbol{0}$, and $\boldsymbol{H} = \boldsymbol{H}_0$. Let $\varrho = \varrho_0 + \tilde{\varrho}$, $p = p_0 + \tilde{p}$, $\boldsymbol{u} = \tilde{\boldsymbol{u}}$, and $\boldsymbol{H} = \boldsymbol{H}_0 + \tilde{\boldsymbol{H}}$, where all the quantities with the tilde are small perturbations. Retaining only the first order terms with respect to these perturbations, we obtain

$$\begin{aligned} \frac{\partial \tilde{\varrho}}{\partial t} + \varrho_0 \mathrm{div}\tilde{\boldsymbol{u}} &= 0, \\ \varrho_0 \frac{\partial \tilde{\boldsymbol{u}}}{\partial t} + \mathrm{grad}\tilde{p} &= \frac{1}{4\pi}\mathrm{curl}\tilde{\boldsymbol{H}} \times \boldsymbol{H}_0, \\ \frac{\partial \tilde{\boldsymbol{H}}}{\partial t} &= \mathrm{curl}(\tilde{\boldsymbol{u}} \times \boldsymbol{H}_0), \\ \tilde{p} &= \frac{\gamma p_0}{\varrho_0}\tilde{\varrho}. \end{aligned}$$

Then, introducing the displacement vector $\boldsymbol{x}$ as $\frac{\partial \boldsymbol{x}}{\partial t} = \tilde{\boldsymbol{u}}$, we can derive the following equation (see [15]):

$$\frac{\partial^2 \boldsymbol{x}}{\partial t^2} = c_{\mathrm{s}}^2 \mathrm{graddiv}\boldsymbol{x} + c_{\mathrm{A}}^2 \mathrm{grad}_{\perp}\mathrm{div}\boldsymbol{x}_{\perp} + c_{\mathrm{A}}^2 \frac{\partial^2 \boldsymbol{x}_{\perp}}{\partial z^2}, \tag{2.25}$$

where $c_{\mathrm{s}} = \sqrt{\gamma p_0/\varrho_0}$ is the conventional speed of sound, $c_{\mathrm{A}} = |\boldsymbol{H}_0|/\sqrt{4\pi\varrho_0}$ is the Alfvén speed, and $\boldsymbol{x}_{\perp}$ and $\mathrm{grad}_{\perp}$ are the components of $\boldsymbol{x}$ and the gradient, respectively, orthogonal to the magnetic field $\boldsymbol{H}_0$.

For a particular class of transverse displacements, $\boldsymbol{x} = \boldsymbol{x}_\perp$ and $\mathrm{div}\boldsymbol{x}_\perp = 0$, we obtain from (2.25)

$$\frac{\partial^2 \boldsymbol{x}_\perp}{\partial t^2} = c_{\mathrm{A}}^2 \frac{\partial^2 \boldsymbol{x}_\perp}{\partial z^2}. \tag{2.26}$$

This is a one-dimensional d'Alembert equation that describes the propagation of the so-called Alfvén waves along the magnetic field with the speed c_{A}. Even though the number of space dimensions in (2.26) is odd, the one-dimensional case is special. Solutions to (2.26) may display the Huygens' behavior only if the equation is driven by some particular classes of initial data, whereas for the general RHS there is wave diffusion.

If the component of $\boldsymbol{x}$ along the magnetic field $\boldsymbol{H}_0$ is not zero, i.e., $x_3 \neq 0$, then (2.25) yields

$$\frac{\partial^2 x_3}{\partial t^2} = c_{\mathrm{s}}^2 \frac{\partial^2 x_3}{\partial z^2} + c_{\mathrm{s}}^2 \frac{\partial}{\partial z} \mathrm{div}\boldsymbol{x}_\perp. \tag{2.27}$$

For $\mathrm{div}\boldsymbol{x}_\perp = 0$, (2.27) governs the propagation of the so-called ion sound along the magnetic field with the speed c_{s}. As in the previous case of the Alfvén waves, the propagation of ion sound is diffusive.

To supplement (2.27), a second equation can be derived from (2.25) that would govern $\mathrm{div}\boldsymbol{x}_\perp$:

$$\begin{aligned} \frac{\partial^2 \mathrm{div}\boldsymbol{x}_\perp}{\partial t^2} &= c_{\mathrm{s}}^2 \mathrm{divgrad}_\perp \underbrace{\mathrm{div}\boldsymbol{x}}_{\mathrm{div}\boldsymbol{x}_\perp + \frac{\partial x_3}{\partial z}} + c_{\mathrm{A}}^2 \underbrace{\left[\mathrm{divgrad}_\perp \mathrm{div}\boldsymbol{x}_\perp + \frac{\partial^2 \mathrm{div}\boldsymbol{x}_\perp}{\partial z^2} \right]}_{\Delta \mathrm{div}\boldsymbol{x}_\perp} \\ &= c_{\mathrm{s}}^2 \mathrm{divgrad}_\perp \mathrm{div}\boldsymbol{x}_\perp + c_{\mathrm{s}}^2 \mathrm{divgrad}_\perp \frac{\partial x_3}{\partial z} + c_{\mathrm{A}}^2 \Delta \mathrm{div}\boldsymbol{x}_\perp. \end{aligned} \tag{2.28}$$

Equations (2.27) and (2.28) form a system with the unknowns x_3 and $\mathrm{div}\boldsymbol{x}_\perp$. These equations decouple only when $c_{\mathrm{s}} \ll c_{\mathrm{A}}$. In this case, the terms $\sim c_{\mathrm{s}}^2$ on the right-hand side of (2.28) can be disregarded, which yields

$$\frac{\partial^2 \mathrm{div}\boldsymbol{x}_\perp}{\partial t^2} = c_{\mathrm{A}}^2 \Delta \mathrm{div}\boldsymbol{x}_\perp. \tag{2.29}$$

Equation (2.29) governs the so-called magnetoacoustic waves that propagate with the Alfvén speed c_{A}. It is a true three-dimensional d'Alembert equation and as such, is Huygens'. The assumption of the speed of sound c_{s} being much slower than the Alfvén speed c_{A} holds when the thermodynamic pressure p_0 is much lower than the quantity $\boldsymbol{H}_0^2/8\pi$, which can be interpreted as pressure of the magnetic field [15].

Hence, lacunae can potentially exist in the solutions for the transverse quantity $\mathrm{div}\boldsymbol{x}_\perp$. However, $\mathrm{div}\boldsymbol{x}_\perp$ is then substituted into (2.27) to find the longitudinal displacement x_3 in magnetoacoustic waves, and the spatially one-dimensional solution for x_3 will, generally speaking, be diffusive. Altogether, the propagation of waves governed by (2.29), (2.27) will be only partially diffusionless.

2.6. Summary on low-frequency models. Having analyzed a number of conventional low-frequency electromagnetic models, we conclude that for most of them the propagation of waves is diffusive; i.e., the Huygens' principle does not hold. The driving frequency in these models is assumed lower than the characteristic microscopic frequencies of the medium, so that the material coefficients can be taken as constants

(permittivity, permeability, and conductivity). The mechanism that destroys the lacunae in all these cases is typically of a dissipative nature, related to the electric conductivity. An exception, for which the Huygens' principle holds, is pure dielectric materials with static response. Another partial exception is magnetoacoustic waves in the medium with infinite conductivity.

When the incident (driving) frequency becomes higher, the material coefficients can no longer be assumed constant. Instead, they become frequency-dependent, and while relations (2.6) can still keep their form, all the quantities involved have to be considered in the frequency domain rather than in the time domain. In other words, relations (2.6) transform into the corresponding relations between the Fourier coefficients of the fields and of material "constants," while in the physical space the medium responses typically appear nonlocal in time (given by convolution-type integrals); see [18]. It is also known that the discrepancy between $\boldsymbol{H}$ and $\boldsymbol{B}$ becomes unimportant/negligible even for relatively low frequencies. Hence, for higher frequencies only the discrepancy between $\boldsymbol{D}$ and $\boldsymbol{E}$ matters.

Hereafter, we will depart from the low-frequency framework and analyze the propagation of high-frequency electromagnetic waves in the dilute ionospheric plasma. We will see that in this case the key mechanism that can destroy the lacunae is of a dispersive nature. We will also see that under certain assumptions lacunae can still be identified in this dispersive medium, but in an approximate sense.

3. High-frequency electromagnetic waves in dilute plasma.

3.1. Characteristics of the medium. Our ultimate goal will be to work out an approximate interpretation of the Huygens' principle as it applies to the propagation of electromagnetic waves through the Earth's ionosphere. The ionosphere is a layer of dilute plasma (weakly ionized rarefied gas which is electrically neutral as a whole) surrounding the Earth at heights roughly between 60 km and 400 km from the surface. The primary source of ionization in the ionosphere is solar radiation. The negatively charged particles in the ionosphere are electrons with the charge of $e = -4.803 \cdot 10^{-10}$ Gaussian units and the mass of $m_{\mathrm{e}} = 9.1 \cdot 10^{-28} g$, and the positively charged particles are ions that are much heavier: $m_{\mathrm{i}}/m_{\mathrm{e}} \gtrsim 2.93 \cdot 10^4$. The ionosphere is, in fact, layered, and its local parameters strongly depend on the altitude; this dependence for key characteristics, such as the concentrations of charged particles, may be nonmonotonic. The parameters of the ionosphere also change between day and night and winter and summer, and depend on the level of solar activity; more detail can be found, e.g., in [8, 6]. In our subsequent considerations, we will be quoting the parameters typical for the so-called F-layer (that starts at about 130 km above the Earth's surface) during the periods of low solar activity. The concentrations of the negatively and positively charged particles are equal, and we will mostly use the electron concentration: $n_{\mathrm{e}} \approx 10^6 cm^{-3}$. Note that the concentration of neutral atoms and molecules in the F-layer could be as high as $n_{\mathrm{m}} = 10^{10}\mathrm{cm}^{-3}$. A typical value of the electron temperature in the F-layer is $T_{\mathrm{e}} \approx 2000K$; the ions are a few times colder.

Several key quantities that depend on the foregoing parameters characterize the properties of the ionospheric plasma. The plasma electron frequency, also known as the Langmuir frequency, is defined as $\omega_{\mathrm{pe}} = \sqrt{\frac{4\pi e^2 n_{\mathrm{e}}}{m_{\mathrm{e}}}}$; it provides a fundamental temporal scale. For the specific parameters of the plasma given above we obtain $\omega_{\mathrm{pe}} \approx 5.64 \cdot 10^7 rad/s \approx 9$ MHz; in the literature, one can find the range of values for the Langmuir frequency in the ionosphere between 3 MHz and 15 MHz. The thermal speed of the electrons, $v_{\mathrm{e}} = \sqrt{3\kappa T_{\mathrm{e}}/2m_{\mathrm{e}}} \approx 3 \cdot 10^7$ cm/s, provides a characteristic

velocity, where $\kappa = 1.38 \cdot 10^{-16} erg/K$ is the Boltzmann constant; the speed v_e is roughly three orders of magnitude slower than the speed of light in vacuum, $c = 3 \cdot 10^{10}$ cm/s. The speed of the waves that propagate through the plasma will subsequently need to be compared to the characteristic velocity v_e. The Debye shielding length, $d = \sqrt{\frac{\kappa T_e}{8\pi e^2 n_e}} \approx 0.22$ cm, provides a characteristic spatial scale for the shielding of a point charge immersed into the plasma by other charges; shielding effectively results in multiplication of the classical Coulomb electrostatic potential by the rapidly decaying function $e^{-r/d}$.

Another important parameter yet to be included in the consideration is the magnetic field of the Earth, $\boldsymbol{B}_0$, $|\boldsymbol{B}_0| \approx 0.3G$. It brings along another characteristic frequency known as the electron cyclotron frequency, $\Omega_e = \frac{e|\boldsymbol{B}_0|}{c \cdot m_e} \approx 0.8$ MHz, which is about an order of magnitude lower than the Langmuir frequency. The presence of $\boldsymbol{B}_0$ implies anisotropy of the plasma and transforms it into a gyrotropic medium; see [18]. The propagation of electromagnetic waves through such a medium is accompanied by interesting effects, e.g., the Faraday rotation. In the literature, these effects are typically studied in the frequency domain (see [18, Chapter XI]); for our analysis we will use the time domain (see section 3.6).

3.2. Cold plasma. In the Maxwell system of equations (2.10), assume that no extraneous charges or currents are present; then take curl of the first unsteady equation and by substitution eliminate the magnetic field from the second unsteady equation, having differentiated it with respect to time. This yields

$$\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + c^2 \mathrm{curlcurl}\boldsymbol{E} = -4\pi \frac{\partial \boldsymbol{j}_{\mathrm{ind}}}{\partial t}. \tag{3.1}$$

Equation (3.1) is the key governing equation for the electric field. However, it still requires that the time derivative of the induced current on the right-hand side be specified. To do so, we will use the approximation known as cold plasma (see, e.g., [8, 21]); the meaning of the term will be explained later.

To obtain the current, let us write Newton's second law of motion for the electrons:

$$m_e \frac{d\boldsymbol{u}}{dt} + m_e \nu_{\mathrm{eff}} \boldsymbol{u} = -e\boldsymbol{E} - \frac{e}{c}\boldsymbol{u} \times \boldsymbol{B}. \tag{3.2}$$

As the ions are much heavier than the electrons, their motion is not taken into account. In (3.2), $\boldsymbol{u}$ denotes the velocity of the electrons due to the applied electromagnetic field (as opposed to the thermal velocity). Equation (3.2) is nonrelativistic because $\kappa T / m_e c^2 \approx 3.37 \cdot 10^{-7} \ll 1$. The quantity ν_{eff} in (3.2) is the effective frequency of collisions between the electrons and other particles (both charged and neutral). Note that the acceleration term in (3.2) is important in the case of high frequencies, whereas in the low-frequency case it is often omitted. Omitting the acceleration term results in (3.2) being transformed into the (generalized) Ohm law; see [15]. In the high-frequency case we can instead drop the collision term $m_e \nu_{\mathrm{eff}} \boldsymbol{u}$ on the left-hand side of (3.2). This term is responsible for the mechanism of Ohm conductivity in the plasma and is dropped because typical collision frequencies ν_{eff} in the ionosphere are low. A thorough analysis of collisions in dilute plasma requires the calculation of cross-sections using the apparatus of quantum mechanics; it goes beyond the scope of this paper, and we refer the reader to [8]. Here we only mention that for the collisions of electrons with either positive ions or neutral molecules in the F-layer we have $\nu_{\mathrm{eff}} \sim 10^2 s^{-1} \ll \omega_{\mathrm{pe}}$, and as we are predominantly interested in high incident frequencies, $\omega \gg \omega_{\mathrm{pe}}$, we can indeed disregard the collisions term in (3.2).

In the isotropic case, when the constant magnetic field $\boldsymbol{B}_0$ is not taken into account, the Lorentz term on the right-hand side of (3.2) can also be neglected. The reason is that unlike, for example, the case of MHD (section 2.5), when plasma is immersed into the magnetic field and the electric field is induced, here we are assuming that both the electric field and the magnetic field have roughly the same magnitude in the impinging wave. Then, the term $-\frac{e}{c}\boldsymbol{u}\times\boldsymbol{B}$ becomes a small relativistic correction, because $|\boldsymbol{u}| \ll c$. The latter relation always holds, because even when the plasma is not at thermal equilibrium, i.e., when the velocity distribution function is not Maxwellian, the speed of systematic motion $|\boldsymbol{u}|$ is still much slower than the average particle speed $\sqrt{2K/m_e e}$ (K is the kinetic energy), which, in turn, is much slower than the speed of light. Altogether, (3.2) then reduces to

$$m_{\mathrm{e}}\frac{d\boldsymbol{u}}{dt} = -e\boldsymbol{E}. \tag{3.3}$$

Next, by expressing the induced current as $\boldsymbol{j}_{\mathrm{ind}} = -en_{\mathrm{e}}\boldsymbol{u}$, we transform (3.3) into

$$\frac{\partial \boldsymbol{j}_{\mathrm{ind}}}{\partial t} = -en_{\mathrm{e}}\frac{\partial \boldsymbol{u}}{\partial t} = \frac{e^2 n_{\mathrm{e}}}{m_{\mathrm{e}}}\boldsymbol{E}. \tag{3.4}$$

In doing so we note that the foregoing expression $\boldsymbol{j}_{\mathrm{ind}} = -en_{\mathrm{e}}\boldsymbol{u}$ corresponds to a simplified framework, whereas, strictly speaking, we should have written $\boldsymbol{j}_{\mathrm{ind}} = -e\int \boldsymbol{v}f(\boldsymbol{v})d\boldsymbol{v}$, where $f(\boldsymbol{v})$ is the probability distribution function for electron velocities. In this paper, however, we employ the elementary approach rather than the full-fledged kinetic considerations.

We would also like to emphasize that the relation (3.4) between the induced current and the electric field is local in space, because (3.3) is an ordinary differential equation. In the frequency domain, when all the variables are interpreted as Fourier components, we immediately have

$$\boldsymbol{j}_{\mathrm{ind}}(\omega) = \frac{\omega_{\mathrm{pe}}}{4\pi}\frac{1}{i\omega}\boldsymbol{E}(\omega),$$

and since $\frac{\partial \boldsymbol{D}}{\partial t} = \frac{\partial \boldsymbol{E}}{\partial t} + 4\pi\frac{\partial \boldsymbol{P}}{\partial t} = \frac{\partial \boldsymbol{E}}{\partial t} + 4\pi\boldsymbol{j}_{\mathrm{ind}}$ (assuming $\mu = 1$; see (2.5), (2.9)), we obtain

$$\boldsymbol{D}(\omega) = \boldsymbol{E}(\omega) - \frac{\omega_{\mathrm{pe}}^2}{\omega^2}\boldsymbol{E}(\omega) \stackrel{\mathrm{def}}{=} \varepsilon\boldsymbol{E}(\omega) \quad \Rightarrow \quad \varepsilon = 1 - \frac{\omega_{\mathrm{pe}}^2}{\omega^2}. \tag{3.5}$$

In other words, the electric permittivity ε depends only on the incident frequency ω and does not depend on the wavenumber $\boldsymbol{k}$. This is equivalent to neglecting the phenomenon of spatial dispersion in the plasma. It can indeed be neglected if $a \ll \lambda$, where a is a characteristic length and λ is the wavelength in the plasma. For the characteristic length we are taking the distance traveled by the electron during one period of fast oscillation, $a = 2\pi v_{\mathrm{e}}/\omega$, and $\lambda = 2\pi v_{\mathrm{ph}}/\omega = 2\pi/k$, where $k = |\boldsymbol{k}|$ and v_{ph} is the phase speed of the waves. Hence, we need to require that the phase speed be much faster than the thermal speed of the electrons:

$$v_{\mathrm{ph}} = \frac{\omega}{k} \gg v_{\mathrm{e}} = \sqrt{\frac{3\kappa T}{2m_{\mathrm{e}}}}, \tag{3.6}$$

which is also equivalent to requiring that $kd \ll \omega/\omega_{\mathrm{pe}}$, where d is the Debye shielding length. The meaning of the term *cold plasma* can be explained with the help of

relation (3.6). Namely, the temperature should be sufficiently low so that the thermal speed is much slower that the phase speed of the waves.

Finally, by substituting expression (3.4) into the right-hand side of (3.1), we obtain

$$\frac{\partial^2 \boldsymbol{E}}{\partial t^2} + c^2 \mathrm{curlcurl}\boldsymbol{E} + \omega_{\mathrm{pe}}^2 \boldsymbol{E} = \boldsymbol{0}. \tag{3.7}$$

Equation (3.7) is a self-contained governing equation for the electric field $\boldsymbol{E}$. It no longer includes any other unknown quantities that need to be determined through additional considerations. Equation (3.7) admits different types of propagating waves that we are going to analyze.

3.3. Longitudinal and transverse waves. According to the Helmholtz theorem (see [22, section 1.5]), any vector field has a unique representation as a sum of its irrotational (longitudinal) and solenoidal (transverse) components. In other words, we can write

$$\boldsymbol{E} = \boldsymbol{E}_{\shortparallel} + \boldsymbol{E}_{\perp}, \quad \text{where} \quad \mathrm{curl}\boldsymbol{E}_{\shortparallel} = \boldsymbol{0} \quad \text{and} \quad \mathrm{div}\boldsymbol{E}_{\perp} = 0. \tag{3.8}$$

Note that calling the curl-free and divergence-free parts of the field by their alternative names—the longitudinal and transverse components, respectively—has a clear physical interpretation. Namely, in the frequency domain a plane wave propagating in an isotropic medium has the form $\boldsymbol{E} \sim e^{i\omega t + i\boldsymbol{k}\cdot\boldsymbol{r}}$, where $\boldsymbol{r}$ is the radius vector. Then, clearly, $\mathrm{curl}\boldsymbol{E} \sim \boldsymbol{k} \times \boldsymbol{E}$ and $\mathrm{div}\boldsymbol{E} \sim \boldsymbol{k} \cdot \boldsymbol{E}$. As such, $\mathrm{curl}\boldsymbol{E}_{\shortparallel} = \boldsymbol{0}$ would mean that $\boldsymbol{k} \times \boldsymbol{E}_{\shortparallel} = \boldsymbol{0}$, or in other words, that $\boldsymbol{E}_{\shortparallel}$ is parallel to the wave vector $\boldsymbol{k}$, which justifies its name of the longitudinal component. Similarly, $\mathrm{div}\boldsymbol{E}_{\perp} = 0$ would imply that $\boldsymbol{k} \cdot \boldsymbol{E}_{\perp} = 0$, or in other words, that $\boldsymbol{E}_{\perp}$ is perpendicular to the wave vector $\boldsymbol{k}$, which justifies its name of the transverse component.

Let us consider the longitudinal waves first. In this case, (3.7) reduces to

$$\frac{\partial^2 \boldsymbol{E}_{\shortparallel}}{\partial t^2} + \omega_{\mathrm{pe}}^2 \boldsymbol{E}_{\shortparallel} = \boldsymbol{0}. \tag{3.9}$$

Equation (3.9) governs the so-called Langmuir waves in plasma. As there is no spatial differentiation in (3.9), the Langmuir waves can basically be interpreted as high-frequency oscillations of the entire volume of plasma. The dispersion relation for the Langmuir waves is straightforward: $\omega^2 = \omega_{\mathrm{pe}}^2$, which means that the oscillations always occur with one and the same frequency $\omega_{\mathrm{pe}} = \sqrt{\frac{4\pi e^2 n_{\mathrm{e}}}{m_{\mathrm{e}}}}$. Accordingly, the group velocity of these waves is zero: $v_{\mathrm{gr}} \overset{\mathrm{def}}{=} \frac{\partial \omega}{\partial k} = 0$, which means that no energy transport is associated with the Langmuir waves.

On the other hand, propagation of the Langmuir waves is accompanied by perturbations of the local electric neutrality of the plasma. Indeed, according to the second steady-state Maxwell equation (2.10), when there are no extraneous charges we have

$$\rho_{\mathrm{ind}} = \frac{1}{4\pi}\mathrm{div}\boldsymbol{E} = \frac{1}{4\pi}\mathrm{div}\boldsymbol{E}_{\shortparallel},$$

and, consequently, the density of the induced charge ρ_{ind} undergoes oscillations with the frequency ω_{pe}, because it is governed by the same differential equation as (3.9):

$$\frac{\partial^2 \rho_{\mathrm{ind}}}{\partial t^2} + \omega_{\mathrm{pe}}^2 \rho_{\mathrm{ind}} = 0.$$

Let us reemphasize that the foregoing considerations are valid only when the phase velocity of the waves is large; see (3.6). By substituting $\omega = \omega_{\mathrm{pe}}$ we obtain $v_{\mathrm{ph}} = \omega_{\mathrm{pe}}/k \gg \omega_{\mathrm{pe}} d = v_{\mathrm{e}}$, which means $kd \ll 1$, or in other words, the wavelength must be much greater than the Debye shielding length: $\lambda \gg d$. If this constraint does not hold, i.e., if $kd \sim 1$, then $v_{\mathrm{ph}} \sim v_{\mathrm{e}}$, and the assumption of cold plasma breaks down. In this case, the dispersion relation of the plasma can be obtained only by solving the kinetic equation. As shown, e.g., in [21, Chapter 13], the Langmuir waves become dispersive for slower phase speeds: $\omega^2 = \omega_{\mathrm{pe}}^2 + 3k^2 v_{\mathrm{e}}^2$. Going even further down in the phase speed, i.e., allowing for $v_{\mathrm{ph}} \ll v_{\mathrm{e}}$, would necessitate taking the ions' motion into account; this leads to the ion sound that has been briefly discussed in section 2.5.

Having provided this very concise account of longitudinal oscillations, we will next turn to the primary subject of our discussion, the transverse high-frequency waves.

3.4. Transverse waves. To study the evolution of the transverse component $\boldsymbol{E}_\perp$ of the electric field, we first notice that $\mathrm{div}\boldsymbol{E}_\perp = 0$ implies $\mathrm{curlcurl}\boldsymbol{E}_\perp = -\Delta \boldsymbol{E}_\perp$, and, consequently, (3.7) transforms into the well-known Klein–Gordon equation

$$\frac{\partial^2 \boldsymbol{E}_\perp}{\partial t^2} - c^2 \Delta \boldsymbol{E}_\perp + \omega_{\mathrm{pe}}^2 \boldsymbol{E}_\perp = \boldsymbol{0}. \tag{3.10}$$

The dispersion relation for the Klein–Gordon equation (3.10) is easy to obtain. It reads

$$\omega^2 = \omega_{\mathrm{pe}}^2 + c^2 k^2, \tag{3.11}$$

which, in particular, means that similarly to the previous longitudinal case (see section 3.3), only high-frequency transverse waves can propagate in the plasma governed by (3.10). The range of allowable frequencies that corresponds to (3.11) is defined as $\omega > \omega_{\mathrm{pe}}$.

From relation (3.11), one can easily obtain the phase speed and the group speeds of the waves:

$$v_{\mathrm{ph}} = c\left(1 + \omega_{\mathrm{pe}}^2/c^2k^2\right)^{\frac{1}{2}} > c, \tag{3.12}$$

$$v_{\mathrm{gr}} = c\left(1 + \omega_{\mathrm{pe}}^2/c^2k^2\right)^{-\frac{1}{2}} < c. \tag{3.13}$$

Unlike in the longitudinal case of section 3.3, the propagation of transverse waves preserves the local electric neutrality of the plasma, because $\mathrm{div}\boldsymbol{E}_\perp = 0$. Moreover, it is possible to show (see [21, Chapter 13]), that even if one employs kinetic considerations for the analysis of transverse waves with a slow phase speed, $\omega/k \ll v_{\mathrm{e}}$, there will, in fact, be no such waves. In other words, there are no thermal transverse modes analogous to the thermal longitudinal modes.

The dispersion properties of high-frequency transverse waves are of particular interest. Let us first assume that $\frac{\omega_{\mathrm{pe}}}{ck} = \frac{v_{\mathrm{e}}}{ckd} \ll 1$, which implies that $kd \gg \frac{v_{\mathrm{e}}}{c} \approx 10^{-3}$, or in other words, that the waves are short: $\lambda \ll 10^3 d$, with the wavelength much shorter than a thousand times the Debye shielding length. These waves exhibit

a weakly dispersive behavior, as substitution of $\frac{\omega_{\rm pe}}{ck} \ll 1$ into (3.12) and (3.13) immediately yields

$$v_{\rm ph} \approx c\left(1+\frac{\omega_{\rm pe}^2}{2c^2k^2}\right), \tag{3.14}$$

$$v_{\rm gr} \approx c\left(1-\frac{\omega_{\rm pe}^2}{2c^2k^2}\right). \tag{3.15}$$

We indeed see that both the phase speed $v_{\rm ph}$ of (3.14) and the group speed $v_{\rm gr}$ of (3.15) are close to the speed of light c, with the former being slightly faster than c and the latter being slightly slower than c. The frequency in this case, according to (3.11), is approximately equal to the speed of light times the wavenumber ($\omega \approx ck \gg \omega_{\rm pe}$), and is also much higher than the Langmuir frequency. Note that the ultimate case of $v_{\rm ph} = v_{\rm gr} = c$, $\omega = ck$, would correspond to the propagation of waves with no dispersion in the framework of a pure d'Alembert equation rather than the Klein–Gordon equation.

In contradistinction to the short waves, the long transverse waves governed by (3.10) are similar to the longitudinal waves. Indeed, let $\frac{\omega_{\rm pe}}{ck} \gg 1$; it means that $\lambda \gg 10^3 d$ and also that $\omega \gtrsim \omega_{\rm pe}$, i.e., that the waves propagate with the frequencies close to the lowest possible frequency $\omega_{\rm pe}$. In this case, $v_{\rm ph} \approx \omega_{\rm pe}/k$, and $v_{\rm gr} = c\cdot\frac{ck}{\omega_{\rm pe}} \ll c$; i.e., the expression for the phase velocity is basically the same as that in the longitudinal case (see section 3.3), while the group velocity is small (in the pure longitudinal case it is equal to zero). This behavior is not surprising because the longer the wave, the less of a spatial variation per unit length it undergoes, and, consequently, the more the corresponding oscillations should resemble the oscillations of the entire plasma volume as a whole, which are characteristic of the longitudinal case.

In general, we should mention that the foregoing dispersion properties, while not completely unparalled, are, perhaps, still less typical than the inverse situation, when the long waves, rather than the short waves, exhibit a weakly dispersive behavior; see [15]. Our primary goal, however, is to see what can be said about the lacunae and the Huygens' principle for the waves governed by (3.10). From the previous considerations we conclude that *it is for the short waves, which are only weakly dispersive, that one can possibly observe some sort of "lacunae"* in the solutions of (3.10). Indeed, in this case the propagation speeds (3.12) and (3.13) (see also (3.14) and (3.15)) are close to the nondispersive propagation velocity c, and therefore one may expect to see relatively few aftereffects behind what would have been the sharp aft fronts in the genuine Huygens' case. To provide a somewhat more accurate yet still qualitative argument, let us consider the waves propagating from an instantaneous point source located at the origin. Given the distance to the source r and the moment of time t, one can easily see that only those waves that have the group velocity $v_{\rm gr} = r/t$ can reach the location r precisely at the moment t. Using expression (3.13) for the group velocity, we obtain a formula for k as it depends on r and t:

$$k = \frac{\omega_{\rm pe}}{c}\left(\frac{c^2t^2}{r^2}-1\right)^{-\frac{1}{2}}. \tag{3.16}$$

We see that the wavenumbers are defined only inside the light cone $r \le ct$. Formula (3.16) also indicates that for a given moment of time t, the larger the r, the larger the k.

In other words, the closer the value of r to ct, the shorter the wave that reaches this location at time t, and ultimately, for the purely nondispersive propagation $r = ct$ the wavelength $\lambda = 2\pi/k$ defined by (3.16) becomes equal to zero.

Let us now fix some large wavenumber $k_1 \gg \frac{\omega_{\rm pe}}{c}$ and consider a wave packet propagating from the origin with the range of wavenumbers $k \geq k_1$. By noticing that the group velocity $v_{\rm gr}$ of (3.13) is a monotone increasing function of k, we conclude that the range of group velocities for this packet will be

$$c\left(1+\omega_{\rm pe}^2/c^2k_1^2\right)^{-\frac{1}{2}} \leq v_{\rm gr} < c.$$

Therefore, at every given moment of time t we can easily estimate how wide this packet is going to be. The width of the packet can be thought of as the spatial extent of the "tail" behind the aft front $r = ct$:

$$\delta_{\rm tail} = (c - \min_k v_{\rm gr})t = c\left[1 - \left(1 + \frac{\omega_{\rm pe}^2}{c^2k_1^2}\right)^{-\frac{1}{2}}\right] t \approx ct \cdot \frac{\omega_{\rm pe}^2}{2c^2k_1^2}. \tag{3.17}$$

We see that the tail expands linearly with time and shrinks quadratically as the minimum borderline wavenumber k_1 for the packet increases. We also note that the short waves, as they are defined above, $k \gg \frac{\omega_{\rm pe}}{c}$, propagate with high frequencies $\omega \approx ck \gg \omega_{\rm pe}$. Therefore, we can equivalently reformulate our general expectation in terms of the frequency rather than the wavelength. Namely, we hope that lacunae could be approximately observed in the solutions of (3.10) for high frequencies $\omega \gg \omega_{\rm pe}$, whereas the overall range of frequencies allowed by the dispersion relation (3.11) is $\omega > \omega_{\rm pe}$. Using the dispersion relation (3.11), we can also recast estimate (3.17) for the width of the aftereffects region (the tail) as

$$\delta_{\rm tail} \approx ct \cdot \frac{\omega_{\rm pe}^2}{2\omega_1^2}, \tag{3.18}$$

where $\omega_1^2 = \omega_{\rm pe}^2 + c^2k_1^2$ is the minimum borderline frequency for the packet we are considering: $\omega \geq \omega_1 \gg \omega_{\rm pe}$. We also note that the ratio of the Langmuir frequency over the driving frequency of the waves that appears in formula (3.18) is going to play a key role in our subsequent analysis.

Let us emphasize, however, that the entire discussion based on the dispersion relation (3.11) is basically conducted in the frequency domain. On the other hand, we have seen in section 1.1 that the frequency domain is inadequate for the analysis of lacunae and the Huygens' principle. A time-domain analysis is needed in order to see how the Huygens' principle can be interpreted for the weakly dispersive transverse waves governed by (3.10).

Consider a three-dimensional Cauchy problem for the inhomogeneous Klein–Gordon equation (cf. (1.1)):

$$\frac{\partial^2\varphi}{\partial t^2} - c^2\Delta\varphi + \omega_{\rm pe}^2\varphi = f(\boldsymbol{x},t), \qquad \varphi(\boldsymbol{x},0) = \varphi_t(\boldsymbol{x},0) = 0, \tag{3.19}$$
$$\mathbb{R}^3 \ni \boldsymbol{x} = (x_1,x_2,x_3).$$

Compared to the vector equation (3.10), the differential equation in (3.19) is scalar and may govern, e.g., one Cartesian component of the total field. The right-hand side $f(\boldsymbol{x},t)$ may be due to the extraneous current.

The Klein–Gordon equation is obviously not equivalent to the d'Alembert equation, and therefore, according to the Matthisson criterion [20], its solutions must be diffusive and may have no lacunae in the classical sense of the word. The discrepancy between the two equations is accounted for by the term $\omega_{\rm pe}^2\varphi$ in (3.10). This term is responsible for the onset of dispersion that ruins the lacunae. We still hope, though, that the behavior of solutions to (3.10) will be close to Huygens' when the dispersion is weak. Therefore, while it is clear that the term $\omega_{\rm pe}^2\varphi$ in the Klein–Gordon equation may not be completely disregarded, we would nonetheless like to see when it can be legitimately classified as "small." Note that it is not as straightforward as simply calling the coefficient $\omega_{\rm pe}^2$ small, because this coefficient is is *not dimensionless.* As such, we would rather need to identify special classes of solutions $\varphi=\varphi(x,t)$, for which the entire term $\omega_{\rm pe}^2\varphi$ can be deemed small. The previous frequency-domain considerations suggest that this may be the case when a high driving frequency $\omega\gg\omega_{\rm pe}$ is brought into the time-domain analysis.

The fundamental solution for the Klein–Gordon operator can be obtained in the closed form (see [4]):

$$\mathcal{E}(\boldsymbol{x},t)=\underbrace{\frac{\Theta(t)}{2\pi c}\delta\left(\beta^2\right)}_{\mathcal{E}_1(\boldsymbol{x},t)}-\underbrace{\frac{\omega_{\rm pe}^2}{4\pi c^3}\Theta(t)\Theta\left(\beta^2\right)\frac{J_1(y)}{y}}_{\mathcal{E}_2(\boldsymbol{x},t)}, \tag{3.20}$$

where $\beta^2=c^2t^2-|\boldsymbol{x}|^2$, $y=\frac{\omega_{\rm pe}}{c}\beta$, $J_1(\,\cdot\,)$ is the Bessel function, and $\Theta(\,\cdot\,)$ denotes the Heaviside function, as before. The first term $\mathcal{E}_1(\boldsymbol{x},t)$ on the right-hand side of formula (3.20) is the same as the fundamental solution of the d'Alembert operator; see (1.2). The second term $\mathcal{E}_2(\boldsymbol{x},t)$ can be interpreted as a correction due to the presence of $\omega_{\rm pe}^2\varphi$ in (3.19). Accordingly, solution $\varphi=\varphi(\boldsymbol{x},t)$ of the Cauchy problem (3.19) is given by the convolution

$$\varphi=\mathcal{E}*f=\mathcal{E}_1*f-\mathcal{E}_2*f=\varphi_1-\varphi_2, \tag{3.21}$$

where the first term $\varphi_1=\mathcal{E}_1*f$ on the right-hand side of (3.21) is the Kirchhoff integral (cf. formula (1.3)), while the second term $\varphi_2=\mathcal{E}_2*f$ is basically what "contaminates" the lacuna. We are going to study the properties of exactly this contaminating term for a particular choice of f.

Namely, we will consider the following point excitation for problem (3.19):

$$f(\boldsymbol{x},t)=\begin{cases}M\cdot\delta(\boldsymbol{x})\cdot\sin(\omega t)\equiv\delta(\boldsymbol{x})\tilde{f}(t), & 0\le t\le T,\\ 0, & t<0 \text{ and } t>T,\end{cases} \tag{3.22}$$

where $M>0$ and $T>0$ are two parameters and ω denotes the driving frequency. We will assume that the source (3.22) undergoes sufficiently many oscillations with frequency ω during the interval $0\le t\le T$. At the same time, this interval still remains finite, which allows us to preserve the time-dependent nature of the problem rather than have it transformed into the frequency domain. Choosing the right-hand side $f(\boldsymbol{x},t)$ of (3.19) in the form (3.22) enables us to perform a sufficiently straightforward analysis on one hand, and, on the other hand, it still allows us to illustrate the key phenomena of interest.

According to the definition of the fundamental solution (see (3.20)), we have

(3.23)
$$\varphi_2 = \frac{\omega_{\rm pe}^2}{4\pi c^3}\int_0^t \iiint_{|\boldsymbol{x}-\boldsymbol{\xi}|\le c|t-\tau|} \frac{f(\boldsymbol{\xi},\tau)J_1\left(\omega_{\rm pe}\sqrt{(t-\tau)^2-|\boldsymbol{x}-\boldsymbol{\xi}|^2/c^2}\right)}{\omega_{\rm pe}\sqrt{(t-\tau)^2-|\boldsymbol{x}-\boldsymbol{\xi}|^2/c^2}}d\boldsymbol{\xi}d\tau$$
$$= \frac{\omega_{\rm pe}^2}{4\pi c^3}\int_0^{T_1} \frac{\tilde f(\tau)J_1\left(\omega_{\rm pe}\sqrt{(t-\tau)^2-|\boldsymbol{x}|^2/c^2}\right)}{\omega_{\rm pe}\sqrt{(t-\tau)^2-|\boldsymbol{x}|^2/c^2}}d\tau = \frac{\omega_{\rm pe}^2}{4\pi c^3}\int_0^{T_1}\frac{\tilde f(\tau)J_1(y)}{y}d\tau,$$

where $T_1 = \min\{(t-|\boldsymbol{x}|/c), T\}$, $y = y(\tau,t,\boldsymbol{x}) = \omega_{\rm pe}\sqrt{(t-\tau)^2-|\boldsymbol{x}|^2/c^2}$, and $\tilde f(\tau)$ denotes the temporal dependence of the source term (3.22): $\tilde f(\tau) = M\sin(\omega\tau)$. We will analyze the cases of small and large arguments y of the Bessel function J_1 in formula (3.24). Let us first note that if y is small, or more precisely, if $0 \le y \le \mu_1^{(2)}$, where $\mu_1^{(2)}$ is the first positive root of the Bessel function $J_2(y)$, then the function

$$G(y) \stackrel{\rm def}{=} \frac{J_1(y)}{y}$$

is a monotone decreasing function of the argument y. Indeed, we have

$$G'(y) = \frac{d}{dy}\left[\frac{J_1(y)}{y}\right] = -\frac{J_2(y)}{y} \le 0 \quad \text{if } y\in[0,\mu_1^{(2)}].$$

The inequality $0 \le y \le \mu_1^{(2)}$ implies a constraint on the maximum value of t. In the worst-case scenario—$\tau = 0$ and $|\boldsymbol{x}| = 0$—this constraint reads

$$t \le \mu_1^{(2)}/\omega_{\rm pe} \equiv T_0, \tag{3.24}$$

and from here on we will require that the most conservative sufficient condition (3.24) hold in order to guarantee that the value of y be sufficiently small.

We also notice that the function $y = y(\tau,\,\cdot\,)$ is a monotone decreasing function of its argument τ on the interval $0 \le \tau \le T_1$. Consequently, the composite function $\tilde G(\tau) = G(y(\tau,\,\cdot\,))$ is a monotone increasing function of τ. We can then apply the Bonnet theorem (second mean value theorem) (see [35]), to the last integral from (3.24) and obtain

$$\varphi_2 = \frac{\omega_{\rm pe}^2}{4\pi c^3}\left[\tilde G(0)\int_0^\eta \tilde f(\tau)d\tau + \tilde G(T_1)\int_\eta^{T_1}\tilde f(\tau)d\tau\right], \tag{3.25}$$

where η is some point of the interval $[0,\,T_1]$.

We note that the contaminating part φ_2 of the solution will eventually need to be compared against its regular part φ_1, which, according to (1.3), is given by

$$\varphi_1(\boldsymbol{x},t) = \frac{1}{4\pi c^2}\frac{\tilde f(t-|\boldsymbol{x}|/c)}{|\boldsymbol{x}|}, \tag{3.26}$$

where, again, $\tilde f(t) = M\sin(\omega t)$ for $t\in[0,T]$; see (3.22). The function φ_1 of (3.26) represents a genuine d'Alembert wave packet due to the source (3.22); it may differ from zero only on the region $c(t-T) \le |\boldsymbol{x}| \le ct$. For $|\boldsymbol{x}| > ct$ we have $\varphi_1(\boldsymbol{x},t) = 0$

because the propagation speed is finite, and for $|\boldsymbol{x}| < c(t-T)$ we have $\varphi_1(\boldsymbol{x},t) = 0$ because this is a lacuna of the wave equation.

Similarly, for $|\boldsymbol{x}| > ct$ we also have $\varphi_2(\boldsymbol{x},t) = 0$. However, otherwise $\varphi_2(\boldsymbol{x},t) \neq 0$ either in the wave packet area $c(t-T) \le |\boldsymbol{x}| \le ct$ or in the lacuna area $|\boldsymbol{x}| < c(t-T)$. The wave packet area corresponds to $T_1 = (t - |\boldsymbol{x}|/c) \le T$; then $y(T_1, \cdot\,) = 0$, and, consequently, $\tilde{G}(T_1) = G(0) = 1/2$ in formula (3.25). In contradistinction to that, the area that would have been a lacuna in the nondispersive case corresponds to $T_1 = T < t - |\boldsymbol{x}|/c$, which means $y(T_1, \cdot\,) = y(T, \cdot\,) > 0$ and $\tilde{G}(T_1) < 1/2$. Altogether, the constants in formula (3.25) can be estimated as follows (recall that $\mu_1^{(2)} \approx 5.13562230$):

$$-6.61397437 \cdot 10^{-2} = G(\mu_1^{(2)}) \le \tilde{G}(0) < \tilde{G}(T_1) \le G(0) = \frac{1}{2}. \tag{3.27}$$

By evaluating the integrals in (3.25), we obtain

$$\begin{aligned} \varphi_2 &= \frac{\omega_{\mathrm{pe}} M}{4\pi c^3} \frac{\omega_{\mathrm{pe}}}{\omega} \Big[\tilde{G}(0)\,(1 - \cos(\omega\eta)) + \tilde{G}(T_1)\,(\cos(\omega\eta) - \cos(\omega T_1)) \Big] \\ &= \frac{\omega_{\mathrm{pe}} M}{4\pi c^3} \frac{\omega_{\mathrm{pe}}}{\omega} \Big[\tilde{G}(0) + (\tilde{G}(T_1) - \tilde{G}(0)) \cos(\omega\eta) - \tilde{G}(T_1) \cos(\omega T_1) \Big], \end{aligned} \tag{3.28}$$

and according to estimates (3.27), the absolute value of the quantity in rectangular brackets in formula (3.28) may never exceed $3/2 - G(\mu_1^{(2)})$.

Let us now compare the dispersionless solution φ_1 of (3.26) with the dispersion-induced correction φ_2 of (3.28). Note that φ_1 is defined only inside the wave packet area, $c(t-T) \le |\boldsymbol{x}| \le ct$, including the aft front $|\boldsymbol{x}| = c(t-T)$. We can then recast formula (3.26) as

$$\varphi_1(\boldsymbol{x},t) = \frac{M}{4\pi c^3} \frac{\sin(\omega T_1)}{t - T_1} \tag{3.29}$$

and thus obtain

$$\frac{\sup\limits_{|\boldsymbol{x}| \le ct} |\varphi_2(\boldsymbol{x},t)|}{\sup\limits_{c(t-T) \le |\boldsymbol{x}| \le ct} |\varphi_1(\boldsymbol{x},t)|} = \Big(\tfrac{3}{2} - G(\mu_1^{(2)}) \Big)\, \omega_{\mathrm{pe}} (t - T_1) \frac{\omega_{\mathrm{pe}}}{\omega}. \tag{3.30}$$

In formula (3.29), we can always consider $\omega_{\mathrm{pe}}(t - T_1) < \mu_1^{(2)}$ because of inequality (3.24). As such,

$$\frac{\sup |\varphi_2|}{\sup |\varphi_1|} = \mathcal{O}\left(\frac{\omega_{\mathrm{pe}}}{\omega} \right). \tag{3.31}$$

Estimate (3.31) is important as it quantifies the previously outlined "tentative" consideration that the higher the driving frequency, the more of a lacuna one might be able to observe in the corresponding solution. It is because of this particular estimate (see (3.31)) that we can call the region $|\boldsymbol{x}| < c(t-T)$ for $t \le T_0$ *a weak lacuna* and also refer to the quantity on the left-hand side of (3.31) as its *"depth."* Indeed, the region $|\boldsymbol{x}| < c(t-T)$ corresponds to the genuine lacuna of the d'Alembert equation. In the dispersive case, there is still a residual field inside this region, but its magnitude relative to the magnitude of the field in the packet (the depth of a weak lacuna) is

small and, quantitatively, is proportional to the ratio of the Langmuir frequency over the driving frequency of the waves.

Next, we will consider the opposite case—that of the large argument y of the Bessel function J_1 in formula (3.24). Our goal will be to justify a relation similar to (3.31) for long propagation times.

Let $y \gg 1$. Then, we will use the asymptotic form of the Bessel function $J_1(y)$,

$$J_1(y) = \sqrt{\frac{2}{\pi y}} \cos\left(y - \frac{3\pi}{4}\right) + \mathcal{O}\left(y^{-\frac{3}{2}}\right), \tag{3.32}$$

which means that by disregarding the higher order terms $\mathcal{O}(y^{-\frac{5}{2}})$ in the integral (3.24) we can recast it as

$$\varphi_2 \approx \frac{\omega_{\rm pe}^2}{4\pi c^3} \sqrt{\frac{2}{\pi}} \int_0^{T_1} \tilde{f}(\tau) y^{-\frac{3}{2}} \cos\left(y - \frac{3\pi}{4}\right) d\tau. \tag{3.33}$$

We would like to estimate the magnitude of $\varphi_2(\boldsymbol{x}, t)$ of (3.33) for $|\boldsymbol{x}| < c(t-T)$, i.e., inside the region that would have been a lacuna in the nondispersive case. This means that the upper integration limit in formula (3.33) can be taken as $T_1 = T$.

Let us first analyze the expression for $y = y(\tau, t, \boldsymbol{x}) = \omega_{\rm pe}\sqrt{(t-\tau)^2 - |\boldsymbol{x}|^2/c^2}$ that enters into formulae (3.32) and (3.33) and see under what conditions it can indeed be regarded as large. Obviously, as $\tau \in [0, T]$, then $\min_\tau y(\tau, t, \boldsymbol{x}) = y(T, t, \boldsymbol{x})$, and it will be sufficient to see when $y(T, t, \boldsymbol{x})$ is large. To begin with, we notice that for a given moment of time t, the quantity $y(T, t, \boldsymbol{x})$ cannot be large all across the lacuna, because on the aft front $|\boldsymbol{x}| = c(t-T)$ we have $y(T, t, c(t-T)) = 0$. Consequently, to be able to legitimately use the asymptotics (3.32) we will need to step inside the lacuna.

Then we introduce the distance δ between a given point inside the lacuna and the aft front at the moment of time, t. For $|\boldsymbol{x}| = c(t-T) - \delta$ we have $y = \frac{\omega_{\rm pe}}{c}\sqrt{2c(t-T)\delta - \delta^2}$. We can therefore conclude that if we consider δ as a function of time, $\delta = \delta(t)$, and require that

$$\lim_{t\to\infty} [2c(t-T)\cdot\delta(t) - \delta^2(t)] = \infty,$$

then the quantity $y = y(T, t, \boldsymbol{x})$ will increase with no bound when $t \longrightarrow \infty$ and $|\boldsymbol{x}| \le c(t-T) - \delta(t)$. Clearly, in so doing the "gap width" δ itself may even decrease as t increases, but only more slowly than $(t-T)^{-1}$. On the other hand, δ may also be a constant or an increasing function of the argument t; in the latter case it may not increase faster than linearly because the lacuna itself expands only linearly with respect to time.

To summarize, we can claim that

$$\lim_{t\to\infty} y(T, t, \boldsymbol{x}) = \infty$$

uniformly for all $\boldsymbol{x}$ such that $|\boldsymbol{x}| \le c(t-T) - \delta(t)$, provided that

$$\frac{\text{const}}{(t-T)\zeta(t)} \le \delta(t) \le (c - c_1)(t-T), \tag{3.34}$$

where $c_1 < c$ and $\zeta(t)$ is an auxiliary function such that $\zeta(t) = o(1)$ as $t \longrightarrow \infty$. Clearly, the most conservative strategy for choosing the gap width, $\delta = (c-c_1)(t-T)$,

where $c_1 < c$, will guarantee the fastest growth of y in a narrower cone $|\boldsymbol{x}| < c_1(t-T)$:

$$\begin{aligned} &\forall \boldsymbol{x}: \ |\boldsymbol{x}| \le c_1(t-T), \ c_1 < c \ \ \& \ \ \forall \tau \in [0,T] \ : \\ &y(\tau,t,\boldsymbol{x}) \ge y(T,t,\boldsymbol{x}) \ge \omega_{\rm pe}\sqrt{1-c_1^2/c^2}(t-T). \end{aligned} \tag{3.35}$$

Estimate (3.35) will allow us to use the asymptotic formulae (3.32) and (3.33) for sufficiently large times t.

Next, we notice that $y^{-\frac{3}{2}}$ is a monotone decreasing function of y for $y > 0$, and as $y = y(\tau,t,\boldsymbol{x})$ is, in turn, a monotone decreasing function of τ for $\tau \in [0,T]$, it follows that $y^{-\frac{3}{2}}$ is a monotone increasing function of τ. Consequently, we can apply the Bonnet theorem again, this time to the integral (3.33), and obtain (recall that $T_1 = T$ for the interior of the lacuna)

$$\begin{aligned} \varphi_2 \approx \frac{\omega_{\rm pe}^2}{4\pi c^3}\sqrt{\frac{2}{\pi}}\Bigg[&(y(0,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_0^{\eta}\tilde{f}(\tau)\cos\left(y(\tau,t,\boldsymbol{x})-\frac{3\pi}{4}\right)d\tau \\ &+(y(T,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_{\eta}^{T}\tilde{f}(\tau)\cos\left(y(\tau,t,\boldsymbol{x})-\frac{3\pi}{4}\right)d\tau\Bigg], \end{aligned} \tag{3.36}$$

where $\eta \in [0,T]$. Let us now substitute $\tilde{f}(\tau) = M\sin(\omega\tau)$ into (3.36):

$$\begin{aligned} \varphi_2 \approx \frac{M\omega_{\rm pe}^2}{8\pi c^3}\sqrt{\frac{2}{\pi}}\Bigg[&(y(0,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_0^{\eta}\left\{\sin\left(\omega\tau+y(\tau,t,\boldsymbol{x})-\frac{3\pi}{4}\right)\right. \\ &\left.-\sin\left(\omega\tau-y(\tau,t,\boldsymbol{x})+\frac{3\pi}{4}\right)\right\}d\tau \\ &+(y(T,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_{\eta}^{T}\left\{\sin\left(\omega\tau+y(\tau,t,\boldsymbol{x})-\frac{3\pi}{4}\right)\right. \\ &\left.-\sin\left(\omega\tau-y(\tau,t,\boldsymbol{x})+\frac{3\pi}{4}\right)\right\}d\tau\Bigg]. \end{aligned}$$

The argument $\left(\omega\tau \pm y(\tau,t,\boldsymbol{x}) \mp \frac{3\pi}{4}\right)$ of the sine functions above can be approximated as follows. Denote $\nu = T-\tau$, $0 \le \nu \le T$, and recast y in the form

$$y(\tau,t,\boldsymbol{x}) = \omega_{\rm pe}\sqrt{(t-T)^2-|\boldsymbol{x}|^2/c^2}\sqrt{1+\frac{2(t-T)\nu+\nu^2}{(t-T)^2-|\boldsymbol{x}|^2/c^2}}. \tag{3.37}$$

Notice that if

$$\frac{2(t-T)\nu}{(t-T)^2-\frac{|\boldsymbol{x}|^2}{c^2}} = \frac{2\nu}{(t-T)\left(1-\frac{|\boldsymbol{x}|^2}{(t-T)^2c^2}\right)} \ll 1,$$

then also

$$\begin{aligned} \frac{\nu^2}{(t-T)^2-\frac{|\boldsymbol{x}|^2}{c^2}} &= \frac{\nu^2}{(t-T)^2\left(1-\frac{|\boldsymbol{x}|^2}{(t-T)^2c^2}\right)} \\ &= \left[\frac{\nu}{(t-T)\left(1-\frac{|\boldsymbol{x}|^2}{(t-T)^2c^2}\right)}\right]^2\left(1-\frac{|\boldsymbol{x}|^2}{(t-T)^2c^2}\right) \ll 1. \end{aligned}$$

Consequently, if the linear term with respect to ν under the second square root in formula (3.37) is indeed small, then the quadratic term can be disregarded, which yields

$$y(\tau,t,\boldsymbol{x}) \approx y(T,t,\boldsymbol{x}) + \frac{\omega_{\rm pe}^2(t-T)\nu}{y(T,t,\boldsymbol{x})} = \underbrace{y(T,t,\boldsymbol{x}) + \frac{\omega_{\rm pe}^2(t-T)T}{y(T,t,\boldsymbol{x})}}_{\text{does not depend on } \tau} - \frac{\omega_{\rm pe}^2(t-T)\tau}{y(T,t,\boldsymbol{x})}.$$

Therefore, we can write

$$\begin{aligned}\varphi_2 \approx \frac{M\omega_{\rm pe}^2}{8\pi c^3}\sqrt{\frac{2}{\pi}}\Bigg[&(y(0,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_0^{\eta}\big\{\sin\left((\omega+\gamma\omega_{\rm pe})\tau-\alpha\right)\\ &\qquad -\sin\left((\omega+\gamma\omega_{\rm pe})\tau-\alpha\right)\big\}d\tau\\ &+(y(T,t,\boldsymbol{x}))^{-\frac{3}{2}}\int_{\eta}^{T}\big\{\sin\left((\omega-\gamma\omega_{\rm pe})\tau+\alpha\right)\\ &\qquad -\sin\left((\omega+\gamma\omega_{\rm pe})\tau-\alpha\right)\big\}d\tau\Bigg],\end{aligned}$$

where $\gamma = \frac{\omega_{\rm pe}(t-T)}{y(T,t,\boldsymbol{x})}$ and $\alpha = y(T,t,\boldsymbol{x}) + \frac{\omega_{\rm pe}^2(t-T)T}{y(T,t,\boldsymbol{x})} - \frac{3\pi}{4}$. The integrals can now be explicitly evaluated:

$$\begin{aligned}\varphi_2 \approx \frac{M\omega_{\rm pe}^2}{8\pi c^3}\sqrt{\frac{2}{\pi}}\Bigg[&(y(0,t,\boldsymbol{x}))^{-\frac{3}{2}}\left\{\frac{\cos\alpha-\cos((\omega-\gamma\omega_{\rm pe})\eta+\alpha)}{\omega-\gamma\omega_{\rm pe}}\right.\\ &\qquad\left.-\frac{\cos\alpha-\cos((\omega+\gamma\omega_{\rm pe})\eta-\alpha)}{\omega+\gamma\omega_{\rm pe}}\right\}\\ &+(y(T,t,\boldsymbol{x}))^{-\frac{3}{2}}\left\{\frac{\cos((\omega-\gamma\omega_{\rm pe})\eta+\alpha)-\cos((\omega-\gamma\omega_{\rm pe})T+\alpha)}{\omega-\gamma\omega_{\rm pe}}\right.\\ &\qquad\left.-\frac{\cos((\omega+\gamma\omega_{\rm pe})\eta-\alpha)-\cos((\omega+\gamma\omega_{\rm pe})T-\alpha)}{\omega+\gamma\omega_{\rm pe}}\right\}\Bigg],\end{aligned}$$

and using (3.35) we obtain

$$\begin{aligned}|\varphi_2(\boldsymbol{x},t)| &\le \frac{M\omega_{\rm pe}^2}{4\pi c^3}\sqrt{\frac{2}{\pi}}\left[(y(0,t,\boldsymbol{x}))^{-\frac{3}{2}}+(y(T,t,\boldsymbol{x}))^{-\frac{3}{2}}\right]\\ &\quad\cdot\left\{\frac{1}{\omega-\gamma\omega_{\rm pe}}+\frac{1}{\omega+\gamma\omega_{\rm pe}}\right\}\\ &\le \frac{M\omega_{\rm pe}^2}{\pi c^3}\sqrt{\frac{2}{\pi}}\omega_{\rm pe}^{-\frac{3}{2}}(t-T)^{-\frac{3}{2}}(1-c_1^2/c^2)^{-\frac{3}{4}}\frac{\omega}{\omega^2-\gamma^2\omega_{\rm pe}^2}.\end{aligned}$$

We also note that, according to (3.35), the quantity γ is bounded: $\gamma = \frac{\omega_{\rm pe}(t-T)}{y(T,t,\boldsymbol{x})} \le \frac{1}{\sqrt{1-c_1^2/c^2}}$. Then, assuming that $\omega \gg \omega_{\rm pe}$, we drop the quadratic term $\mathcal{O}(\frac{\gamma^2\omega_{\rm pe}^2}{\omega^2})$ and get

$$|\varphi_2(\boldsymbol{x},t)| \le \frac{M}{\pi c^3}\sqrt{\frac{2}{\pi}}\omega_{\rm pe}^{-\frac{1}{2}}(t-T)^{-\frac{3}{2}}(1-c_1^2/c^2)^{-\frac{3}{4}}\frac{\omega_{\rm pe}}{\omega}. \tag{3.38}$$

Estimate (3.38) for the correction φ_2 is valid inside the lacuna of the wave equation in a narrower cone $|\boldsymbol{x}| < c(t-T) - \delta(t) = c_1(t-T)$. As before, the magnitude of the correction φ_2 now needs to be compared against the magnitude of the solution φ_1 inside the wave packet. For the purpose of comparison, we will consider φ_1 given by (3.26) on the boundary of the lacuna, i.e., exactly at the aft front $|\boldsymbol{x}| = c(t-T)$:

$$\varphi_1(\boldsymbol{x},t) = \frac{M}{4\pi c^3}\frac{\sin(\omega T)}{t-T}.$$

Using estimate (3.38), we can therefore write (cf. formula (3.31))

$$\frac{\sup|\varphi_2|}{\sup|\varphi_1|} = \mathcal{O}\left(\omega_{\mathrm{pe}}^{-\frac{1}{2}}(t-T)^{-\frac{1}{2}}\frac{\omega_{\mathrm{pe}}}{\omega}\right). \tag{3.39}$$

From estimate (3.39) we see not only that for long propagation times the depth of a weak lacuna is controlled by the ratio $\frac{\omega_{\mathrm{pe}}}{\omega}$ (similar to the case of short times) but that it also decays with the rate proportional to the inverse square root of time. We need to remember, however, that whereas in the previous estimate (3.31) we could use the maximum of the residual field φ_2 all across the lacuna $|\boldsymbol{x}| < c(t-T)$, in estimate (3.39) it can be taken only across a narrower cone $|\boldsymbol{x}| < c(t-T) - \delta(t) = c_1(t-T)$; see formula (3.35).

Let us additionally note that if we were to allow regions wider than the cone $|\boldsymbol{x}| < c_1(t-T)$ when analyzing the rate of growth of y, i.e., if we were to take the gap width $\delta(t)$ increasing more slowly than $(c-c_1)(t-T)$ (see formula (3.34)), then we would still obtain the key quantification of the depth of the weak lacuna by means of $\frac{\omega_{\mathrm{pe}}}{\omega}$, but we could lose the additional decay $\sim \omega_{\mathrm{pe}}^{-\frac{1}{2}}(t-T)^{-\frac{1}{2}}$ for long propagation times. For example, let $\delta(t) = A(t-T)^{\frac{1}{3}}$, where A is an appropriate constant needed to take into account that t is time and δ is distance. Then, for large times t we would obviously have $\delta^2(t) \ll 2c(t-T)\delta(t)$ and, consequently, $y = \frac{\omega_{\mathrm{pe}}}{c}\sqrt{2c(t-T)\delta - \delta^2} \approx \frac{\omega_{\mathrm{pe}}}{c}\sqrt{2cA}(t-T)^{\frac{2}{3}}$. In other words, instead of (3.35) we obtain

$$\begin{gathered}\forall\boldsymbol{x}:\ |\boldsymbol{x}| \le c(t-T) - A(t-T)^{\frac{1}{3}} \ \ \&\ \ \forall\tau\in[0,T]: \\ y(\tau,t,\boldsymbol{x}) \ge y(T,t,\boldsymbol{x}) \gtrsim \frac{\omega_{\mathrm{pe}}}{c}\sqrt{2cA}(t-T)^{\frac{2}{3}}.\end{gathered} \tag{3.40}$$

Accordingly, estimate (3.38) gets replaced by

$$|\varphi_2(\boldsymbol{x},t)| \le \frac{M}{2\pi c^3}\sqrt{\frac{2}{\pi}}\omega_{\mathrm{pe}}^{-\frac{1}{2}}(t-T)^{-1}\left(\frac{2A}{c}\right)^{-\frac{3}{4}}\frac{\omega_{\mathrm{pe}}}{\omega}, \tag{3.41}$$

and instead of (3.39) we obtain a simpler relation (cf. formula (3.31)):

$$\frac{\sup|\varphi_2|}{\sup|\varphi_1|} = \mathcal{O}\left(\frac{\omega_{\mathrm{pe}}}{\omega}\right). \tag{3.42}$$

Clearly, estimate (3.39) guarantees a deeper lacuna for large times t than estimate (3.42) does. However, estimate (3.42) is valid on the region $|\boldsymbol{x}| < c(t-T) - A(t-T)^{\frac{1}{3}}$, which is wider than the cone $|\boldsymbol{x}| < c_1(t-T)$, $c_1 < c$, on which estimate (3.39) holds.

We should reemphasize, however, that both estimates (3.31) and (3.39) (as well as (3.42)) are only asymptotic results, for the small and large values, respectively, of the argument y of the Bessel function J_1 in formula (3.24). To corroborate and further expand the scope of these results, we will evaluate the convolution (3.24) numerically.

TABLE 3.1
The depth of the weak lacuna for different moments of time.

$\frac{\omega_{\mathrm{pe}}}{\omega}$	$\frac{1}{10}$	$\frac{1}{20}$	$\frac{1}{40}$	$\frac{1}{80}$
$t = 0.8$	$1.16 \cdot 10^{-3}$	$4.57 \cdot 10^{-4}$	$1.95 \cdot 10^{-4}$	$1.01 \cdot 10^{-4}$
$t = 4$	$7.64 \cdot 10^{-2}$	$3.96 \cdot 10^{-2}$	$2.0 \cdot 10^{-2}$	$1.04 \cdot 10^{-2}$
$t = 10$	$3.87 \cdot 10^{-1}$	$1.98 \cdot 10^{-1}$	$1.04 \cdot 10^{-1}$	$5.43 \cdot 10^{-2}$
$t = 20$	$1.04 \cdot 10^{0}$	$4.88 \cdot 10^{-1}$	$2.47 \cdot 10^{-1}$	$1.35 \cdot 10^{-1}$

This is done using the Simpson rule on a very fine grid of the argument τ in order to guarantee that the level of the truncation error is far below the magnitude of either φ_1 or φ_2. To provide a most transparent interpretation of the numerical results, we also adopt a slightly different notion of the depth of a weak lacuna, namely, $\frac{\max|\varphi_{\mathrm{lacuna}}|}{\max|\varphi_{\mathrm{packet}}|}$, where $\varphi_{\mathrm{lacuna}} = \varphi_2$ and $\varphi_{\mathrm{packet}} = \varphi_1 + \varphi_2$. This new definition immediately provides a quantitative measure of how big the residual field inside the lacuna is compared to the total field inside the wave packet. For computations, we select $\omega_{\mathrm{pe}} = 1$, $T = 2\pi/10$, and in Table 3.1 present the depth of the weak lacuna for different values of $\omega_{\mathrm{pe}}/\omega$ and different moments of time t.

From Table 3.1, one can clearly see that for all moments of time—small, intermediate (not covered by the asymptotics), and large—the depth of the weak lacuna is indeed proportional to the quantity $\omega_{\mathrm{pe}}/\omega$. However, the maximum of the contaminating field φ_2 is taken in Table 3.1 across the entire lacuna $|\boldsymbol{x}| < c(t-T)$. Therefore, as expected, we do not observe any decay of the depth as the time increases; we rather observe the increase. In fact, this increase is due to the "tail" of the residual field that decays toward the center of the lacuna, as shown in Figure 3.1.

On the other hand, if we were to take a region narrower than the cone $|\boldsymbol{x}| < c(t-T)$ to evaluate the depth of the weak lacuna, then we would be able to actually see its decrease in time, as prescribed previously by the asymptotic estimates. In Table 3.2, we present the same quantity as in Table 3.1, except that $\max|\varphi_{\mathrm{lacuna}}| = \max|\varphi_2|$ is evaluated on a narrower cone $|\boldsymbol{x}| < c_1(t-T)$, where $c_1 = 0.75c$; see formula (3.35). The time range in Table 3.2 covers only intermediate to large intervals. From Table 3.2, one can clearly see not only that the depth of the weak lacuna is inversely proportional to $\omega_{\mathrm{pe}}/\omega$ for every particular moment of time, but that it also decays roughly as the inverse square root of time for every particular value of $\omega_{\mathrm{pe}}/\omega$; see formula (3.39).

An intermediate conclusion that we can draw, based on the combined use of asymptotic arguments and numerical quadratures, is that for high-frequency transverse electromagnetic waves that propagate in a dilute isotropic plasma (with particular pointwise excitation) one can still observe lacunae in the solutions but only in an approximate sense. The depth of these approximate, or weak, lacunae is proportional to the ratio of the Langmuir frequency of the plasma over the primary carrier frequency of the waves.

3.5. Numerical tests. In this section, we report on some results enabled by exploiting the weak lacunae in the computational context. As of yet, these results do not amount to a systematic numerical study. They rather provide a proof-of-concept illustration, whereas a broader and more coherent account of numerical simulations will be reported later.

FIG. 3.1. *Solution of the Klein–Gordon equation inside the lacuna and inside the wave packet.*

TABLE 3.2
The depth of a weak lacuna for $c_1 = 0.75c$ and different moments of time.

$\frac{\omega_{\rm pe}}{\omega}$	$\frac{1}{10}$	$\frac{1}{20}$	$\frac{1}{40}$	$\frac{1}{80}$
$t = 4$	$4.80 \cdot 10^{-2}$	$2.48 \cdot 10^{-2}$	$1.26 \cdot 10^{-2}$	$6.52 \cdot 10^{-3}$
$t = 10$	$3.64 \cdot 10^{-2}$	$1.81 \cdot 10^{-2}$	$9.47 \cdot 10^{-3}$	$4.93 \cdot 10^{-3}$
$t = 20$	$3.14 \cdot 10^{-2}$	$1.33 \cdot 10^{-2}$	$6.56 \cdot 10^{-3}$	$3.56 \cdot 10^{-3}$

We apply the lacunae-based algorithm of [24] to the Klein–Gordon equation (3.19). The algorithm of [24] was originally developed for the d'Alembert equation. It yields nonlocal ABCs that enable the computation of an unsteady wave field on a given finite region of interest. The rest of the space beyond this finite computational region is truncated, and the ABCs provide the required closure at the external artificial boundary so that the outgoing waves can propagate without any nonphysical reflections. Our objective hereafter is to demonstrate that the weak lacunae of section 3.4 can sometimes substitute for the actual lacunae in the numerical framework.

Lacunae-based ABCs for the genuine diffusionless case are constructed in two stages. Below we provide only a very brief description of the method and refer the reader to [24, 25] for details. A key initial assumption is that the overall infinite-domain problem has a unique solution and that (at least) outside of the aforementioned

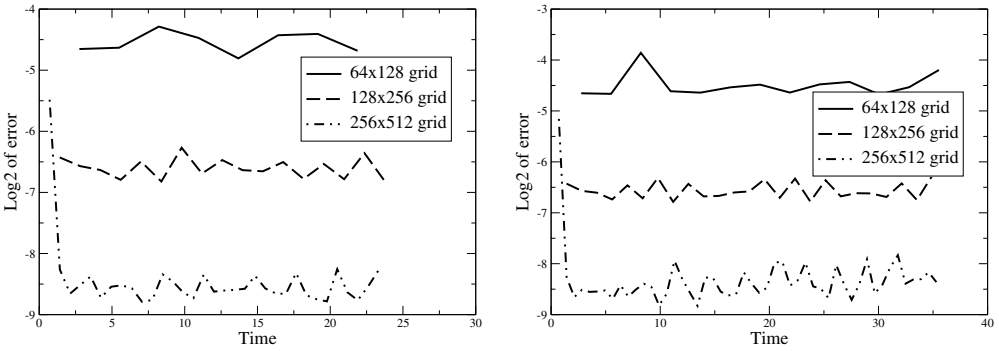
finite region of interest this solution is governed by a linear homogeneous equation, such as the d'Alembert equation. At the first stage, the original problem is decomposed into two subproblems that depend on one another. The interior subproblem is formulated on the bounded computational domain. It inherits all the structure and properties of the original problem on this domain. As the computational domain is obtained by truncation, the interior subproblem obviously requires a closure, i.e., the ABCs, at the outer boundary. The ABCs are to be provided by the solution of the exterior subproblem. The latter, in turn, is formulated on the entire space and is driven by the special auxiliary sources that depend on the solution of the interior problem. The governing equation for the the exterior subproblem on the entire space is the same linear homogeneous equation that governs the solution of the original problem outside the region of interest.

At the second stage, the two problems are integrated concurrently. In doing so, the algorithm for integrating the exterior problem is built around the presence of lacunae. The continuously operating auxiliary sources are partitioned in time into finite fragments. The solution due to each fragment has a lacuna, and the entire domain of interest falls inside this lacuna after a predetermined interval of time. Once this happens, the computation for this particular fragment does not need to be continued any further. Moreover, no wave can travel more than a certain fixed distance away from the source during this interval of time, which implies that the computations can always be conducted on a bounded auxiliary domain of a fixed nonincreasing size. This is the mechanism of transition from an infinite-domain formulation to a finite-domain one. Altogether, one can show that at any given moment of time only a finite fixed number of fragments contribute to the solution of the exterior problem, and each contribution needs to be computed only over a fixed time interval. This yields the exact unsteady ABCs with only fixed and limited extent of nonlocality in time. The performance of these ABCs does not deteriorate when integrating over long time intervals [24].

Replacing genuine lacunae by weak lacunae in the framework of the ABC algorithm basically means that the interior problem is still integrated in its entirety, whereas the dispersive effects for the exterior problem, i.e., for the boundary conditions, are artificially "cut short." Indeed, for each element of the source partition the solution to the exterior problem is computed only until the region of interest falls inside the lacuna. The effect of the corresponding mismatch on the overall numerical performance will be throughly studied in the future. In the meantime, we simply provide some computational examples.

We are solving a model problem of radiation of waves by a known source. The exact solution for this problem is available; it is obtained by reverse engineering, i.e., by picking a function, substituting it under the differential operator, and deriving the right-hand side. For actual computations, we choose the Yee scheme [36], which is a well-known staggered central-difference scheme that has second order accuracy. We also set $\omega_{\mathrm{pe}}/\omega = 1/100$ and select other parameters (grids, geometry, etc.) as in [24]. Namely, the computations are conducted on a uniform grid in the cylindrical coordinates. The methodology does not require that the grid be fitted to the shape of the domain of interest, and we choose the latter spherical. Note that the parameter c_1 (see formulae (3.34) and (3.35)), is not specified explicitly as input for the computational procedure, but other parameters are specified so as to effectively make it $c_1/c \approx 0.9$.

In Figure 3.2, we present the results of the grid convergence study (binary logarithm of the maximum norm of the error as a function of time) for two different values of the diameter of the sphere. The grid dimensions shown in Figure 3.2 pertain to the



(a) Diameter 1.2 (b) Diameter 1.8

FIG. 3.2. *Numerical performance of the ABCs based on weak lacunae.*

auxiliary domain of cylindrical coordinates that has radius π and length 2π. The propagation speed is taken equal to one, and the computations are conducted over the time interval equivalent to 20 times the time required for the waves to travel across the sphere. At least for the particular setup selected, the plots in Figure 3.2 experimentally corroborate the design convergence rate of the scheme (second order) equipped with the ABCs based on the weak lacunae.

3.6. Anisotropic case. As has been mentioned, the primary source of anisotropy in the ionospheric plasma is the magnetic field of the Earth. It may play an important role for the propagation of electromagnetic waves. In particular, it may affect the structure and depth of the weak lacunae. In this section, we outline an approach to analyzing the weak lacunae in the presence of a constant external magnetic field.

Let $\boldsymbol{B}_0 = \text{const}$ be the magnetic field of the Earth. Then, the Lorentz term is to be kept on the right-hand side of (3.2), and instead of (3.3) we obtain

$$m_{\text{e}}\frac{d\boldsymbol{u}}{dt} = -e\boldsymbol{E} - \frac{e}{c}\boldsymbol{u}\times\boldsymbol{B}_0. \tag{3.43}$$

We now need to find the first time derivative of the induced current that provides the excitation for the electric field on the right-hand side of the governing equation (3.1). Substituting $\boldsymbol{j}_{\text{ind}} = -en_{\text{e}}\boldsymbol{u}$ into (3.43), we obtain

$$\boldsymbol{j}'_{\text{ind}} = \frac{\omega_{\text{pe}}^2}{4\pi}\boldsymbol{E} - \Omega_{\text{e}}\boldsymbol{j}_{\text{ind}}\times\frac{\boldsymbol{B}_0}{|\boldsymbol{B}_0|}. \tag{3.44}$$

Equation (3.44) is a first order ordinary differential equation with respect to the unknown current $\boldsymbol{j}_{\text{ind}}$, which is a function of time. It needs to be solved along with (3.1). It is clear that in doing so the dependence of $\boldsymbol{j}'_{\text{ind}}$ on $\boldsymbol{E}$ will be given by a convolution, which means that the responses of the anisotropic medium (3.43) will, generally speaking, be nonlocal in time. Later in the section we will see, however, that under certain assumptions the effect of anisotropy can still be regarded as small.

We begin with providing an elementary frequency-domain analysis. The use of the variable $\boldsymbol{P}$ (polarization), where $\boldsymbol{j}_{\text{ind}} = \frac{\partial\boldsymbol{P}}{\partial t}$, will be more convenient on some occasions, because it has the same dimension as the field $\boldsymbol{E}$. In the frequency domain,

(3.44) can be transformed into

$$\omega^2 \boldsymbol{P}(\omega) + i\omega\Omega_{\mathrm{e}} \boldsymbol{P}(\omega) \times \frac{\boldsymbol{B}_0}{|\boldsymbol{B}_0|} = -\frac{\omega_{\mathrm{pe}}^2}{4\pi} \boldsymbol{E}(\omega). \tag{3.45}$$

Assuming with no loss of generality that the magnetic field $\boldsymbol{B}_0$ is aligned with the Cartesian coordinate z, we solve (3.45) with respect to $\boldsymbol{P}(\omega)$ and obtain

$$\begin{aligned} \boldsymbol{P}(\omega) = -\frac{\omega_{\mathrm{pe}}^2}{4\pi\omega^2} \boldsymbol{E}(\omega) + \frac{\omega_{\mathrm{pe}}^2}{4\pi\omega^2} \frac{i\omega\Omega_{\mathrm{e}}}{\omega^2 - \Omega_{\mathrm{e}}^2} \boldsymbol{E}(\omega) \times \frac{\boldsymbol{B}_0}{|\boldsymbol{B}_0|} \\ - \frac{\omega_{\mathrm{pe}}^2}{4\pi\omega^2} \frac{\Omega_{\mathrm{e}}^2}{\omega^2 - \Omega_{\mathrm{e}}^2} \begin{bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 0 \end{bmatrix} \boldsymbol{E}(\omega). \end{aligned} \tag{3.46}$$

Note that the first term on the right-hand side of (3.46) is exactly the same as we obtained in the isotropic case; see formula (3.5). The second and third terms on the right-hand side of (3.46) are due to the presence of the magnetic field $\boldsymbol{B}_0$. These terms, which are proportional to the first and second power of the cyclotron frequency Ω_{e}, respectively, are known to be responsible for the effects of gyrotropy and Faraday rotation that accompany the propagation of electromagnetic waves in the anisotropic plasma; see [18, 21].

The case of particular interest for us is that of the high-frequency propagation. If $\omega \gg \omega_{\mathrm{pe}}$, then also $\omega \gg \Omega_{\mathrm{e}}$, because according to section 3.1, Ω_{e} is about an order of magnitude lower than ω_{pe} for the typical range of parameters that characterize the ionospheric plasma. Consequently, instead of (3.46) we can write

$$\boldsymbol{P}(\omega) \approx -\frac{\omega_{pe}^2}{4\pi\omega^2} \boldsymbol{E}(\omega) + \frac{\omega_{\mathrm{pe}}^2}{4\pi\omega^2} \frac{i\Omega_{\mathrm{e}}}{\omega} \boldsymbol{E}(\omega) \times \frac{\boldsymbol{B}_0}{|\boldsymbol{B}_0|}. \tag{3.47}$$

Note that $\boldsymbol{B}_0/|\boldsymbol{B}_0|$ on the right-hand side of (3.47) is a dimensionless unit vector in the direction of the magnetic field $\boldsymbol{B}_0$. Then, by comparing the two terms on the right-hand side of (3.47) and by recalling that the effect of the first term on lacunae back in the time domain is $\mathcal{O}(\frac{\omega_{\mathrm{pe}}}{\omega})$ (see estimates (3.31) and (3.39)), we can qualitatively conjecture that the additional effect of anisotropy on lacunae is likely to be $\mathcal{O}(\frac{\omega_{\mathrm{pe}}}{\omega} \cdot \sqrt{\frac{\Omega_{\mathrm{e}}}{\omega}})$. It is expected to be much smaller than the $\mathcal{O}(\frac{\omega_{\mathrm{pe}}}{\omega})$ attributed to the "primary" dispersion, because the extra factor contained in the second term on the right-hand side of (3.47) is $\Omega_{\mathrm{e}}/\omega \ll 1$.

To conduct the analysis in the time domain, we employ the Laplace transform instead of the Fourier transform and, assuming homogeneous initial conditions for the polarization, obtain (cf. formula (3.45))

$$s^2 \boldsymbol{P}(s) + s\Omega_{\mathrm{e}} \boldsymbol{P}(s) \times \frac{\boldsymbol{B}_0}{|\boldsymbol{B}_0|} = \frac{\omega_{\mathrm{pe}}^2}{4\pi} \boldsymbol{E}(s). \tag{3.48}$$

The primary quantity of interest for us is $s^2\boldsymbol{P}$, because $\boldsymbol{j}'_{\mathrm{ind}} = \boldsymbol{P}''$, and we find

$$s^2 \boldsymbol{P}(s) = \frac{\omega_{\mathrm{pe}}^2}{4\pi} \boldsymbol{E}(s) + \frac{\omega_{\mathrm{pe}}^2}{4\pi} \begin{bmatrix} -\frac{\Omega_{\mathrm{e}}^2}{s^2+\Omega_{\mathrm{e}}^2} & -\frac{\Omega_{\mathrm{e}} s}{s^2+\Omega_{\mathrm{e}}^2} & 0 \\ \frac{\Omega_{\mathrm{e}} s}{s^2+\Omega_{\mathrm{e}}^2} & -\frac{\Omega_{\mathrm{e}}^2}{s^2+\Omega_{\mathrm{e}}^2} & 0 \\ 0 & 0 & 0 \end{bmatrix} \boldsymbol{E}(s).$$

Consequently,

$$(j'_{\rm ind})_x = P''_x = \frac{\omega_{\rm pe}^2}{4\pi}E_x + \frac{\omega_{\rm pe}^2\Omega_{\rm e}}{4\pi}\left[-\sin(\Omega_{\rm e}t) * E_x(t) - \cos(\Omega_{\rm e}t) * E_y(t)\right],$$

$$(j'_{\rm ind})_y = P''_y = \frac{\omega_{\rm pe}^2}{4\pi}E_y + \frac{\omega_{\rm pe}^2\Omega_{\rm e}}{4\pi}\left[\cos(\Omega_{\rm e}t) * E_x(t) - \sin(\Omega_{\rm e}t) * E_y(t)\right],$$

$$(j'_{\rm ind})_z = P''_z = \frac{\omega_{\rm pe}^2}{4\pi}E_z.$$

From the previous expressions we see that electromagnetic responses of the anisotropic plasma involve off-diagonal terms, i.e., relate different components of the field and current vectors (as opposed to only respective components). Therefore, we will employ diagonalization by means of the transformation $\mathcal{T}$:

$$\mathcal{T} = \begin{bmatrix} i & -i & 0 \\ 1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \mathcal{T}^{-1} = \begin{bmatrix} -i/2 & 1/2 & 0 \\ i/2 & 1/2 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

Let $\boldsymbol{E} = \mathcal{T}\boldsymbol{G}$ and $\boldsymbol{P} = \mathcal{T}\boldsymbol{Q}$. Then, (3.48) transforms into

$$s^2\boldsymbol{Q}(s) = \frac{\omega_{\rm pe}^2}{4\pi}\boldsymbol{G}(s) + \frac{\omega_{\rm pe}^2}{4\pi}\frac{\Omega_{\rm e}}{s^2+\Omega_{\rm e}^2}\begin{bmatrix} -\Omega_{\rm e}+is & 0 & 0 \\ 0 & -\Omega_{\rm e}-is & 0 \\ 0 & 0 & 0 \end{bmatrix}\boldsymbol{G}(s). \tag{3.49}$$

If we also define $\boldsymbol{j}_{\rm ind} = \mathcal{T}\boldsymbol{q}$, then $s\boldsymbol{q}(s) = s^2\boldsymbol{Q}(s)$, and from (3.49) we find

$$\begin{aligned} q'_x(t) &= \frac{\omega_{\rm pe}^2}{4\pi}G_x(t) + i\frac{\omega_{\rm pe}^2\Omega_{\rm e}}{4\pi}\left[e^{i\Omega_{\rm e}t} * G_x(t)\right], \\ q'_y(t) &= \frac{\omega_{\rm pe}^2}{4\pi}G_y(t) - i\frac{\omega_{\rm pe}^2\Omega_{\rm e}}{4\pi}\left[e^{-i\Omega_{\rm e}t} * G_y(t)\right], \\ q'_z(t) &= \frac{\omega_{\rm pe}^2}{4\pi}G_z(t). \end{aligned} \tag{3.50}$$

To quantify the effect of anisotropy, we will need to analyze the convolutions on the right-hand side of the first two equations (3.50):

$$e^{\pm i\Omega_{\rm e}t} * G_{x,\,y}(t) = \int_0^t e^{\pm i\Omega_{\rm e}(t-v)}G_{x,\,y}(v)dv = e^{\pm i\Omega_{\rm e}t}\int_0^t e^{\mp i\Omega_{\rm e}v}G_{x,\,y}(v)dv.$$

Consider, for example, the component G_x and introduce the following ansatz: $G_x(v) = e^{i\omega t}\tilde{G}_x(v)$, where $\tilde{G}_x(v)$ is assumed to be a slowly varying function. Then, we integrate by parts twice and obtain

$$\begin{aligned} \int_0^t e^{-i\Omega_{\rm e}v}G_x(v)dv &= \frac{1}{i(\omega-\Omega_{\rm e})}\left[G_x(t)e^{-i\Omega_{\rm e}t} - \int_0^t e^{i(\omega-\Omega_{\rm e})v}\tilde{G}'_x(v)dv\right] \\ &= \frac{1}{i(\omega-\Omega_{\rm e})}G_x(t)e^{-i\Omega_{\rm e}t} + \frac{\tilde{G}'_x(t)e^{i(\omega-\Omega_{\rm e})t} - \tilde{G}'_x(0)}{(\omega-\Omega_{\rm e})^2} \\ &\quad - \frac{1}{(\omega-\Omega_{\rm e})^2}\int_0^t e^{i(\omega-\Omega_{\rm e})v}\tilde{G}''_x(v)dv. \end{aligned}$$

Consequently,

$$\begin{aligned}\frac{\partial q_x}{\partial t} &= \frac{\omega_{\rm pe}^2}{4\pi} G_x(t) + \frac{\omega_{\rm pe}^2}{4\pi}\,\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}} G_x(t)\\ &+ e^{i\Omega_{\rm e}t}\,\frac{\omega_{\rm pe}^2}{4\pi}\,\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}}\,\frac{\tilde G_x'(t)e^{i(\omega-\Omega_{\rm e})t} - \tilde G_x'(0)}{\omega-\Omega_{\rm e}}\\ &- e^{i\Omega_{\rm e}t}\,\frac{\omega_{\rm pe}^2}{4\pi}\,\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}}\,\frac{1}{\omega-\Omega_{\rm e}}\int_0^t e^{i(\omega-\Omega_{\rm e})v}\tilde G_x''(v)dv.\end{aligned} \tag{3.51}$$

Slow variation of $\tilde G_x(v)$ means that it is slow on the scale of the high-frequency oscillation ω, and in many cases this slowness is a natural assumption about the field. Under this assumption, the third and fourth terms on the right-hand side of equality (3.51) can be neglected. Indeed, the third term is small compared to the second one because

$$\frac{\max|G_x'|}{\omega-\Omega_{\rm e}} \ll \max|G_x|.$$

As for the fourth term on the right-hand side of (3.51), using the Riemann–Lebesgue lemma we can write

$$\int_0^t e^{i(\omega-\Omega_{\rm e})v}\tilde G_x''(v)dv = o\left(\max|G_x''|\right) \quad \text{as} \quad \omega\to\infty.$$

Therefore, for high carrier frequencies it is also small compared to the second term. Consequently,

$$\frac{\partial q_x}{\partial t} \approx \frac{\omega_{\rm pe}^2}{4\pi}\left(1+\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}}\right) G_x(t), \tag{3.52}$$

and a similar expression can be obtained for q_y'. Hence, when the field is represented as the product of a rapidly oscillating carrier times a slowly varying envelope, the nonlocal responses due to the anisotropy can be approximated by local expressions of the type (3.52).

Finally, let us revisit the governing equation for the field (3.1). We note that when plasma becomes anisotropic, the notion of longitudinal and transverse waves often changes its meaning, and in the literature one would typically consider the waves that propagate along the magnetic field and those that propagate perpendicular to the magnetic field; see, e.g., [8]. Of course, other propagation angles are also possible, and, in general, the split into the longitudinal and transverse components is not always straightforward. We will, however, still consider the transverse field $\boldsymbol{E}_\perp$ in the previous sense of the word, i.e., the one that satisfies $\operatorname{div}\boldsymbol{E}_\perp = 0$. Let also $\boldsymbol{E}_\perp = \mathcal{T}\boldsymbol{G}$; then from (3.1) we obtain

$$\frac{\partial \mathcal{T}\boldsymbol{G}}{\partial t} - c^2\Delta(\mathcal{T}\boldsymbol{G}) + 4\pi\frac{\partial \mathcal{T}\boldsymbol{q}}{\partial t} = \boldsymbol{0}.$$

Since $\mathcal{T}$ is a constant matrix, and the vector Laplacian in the Cartesian coordinates applies independently to individual components, we can use formulae (3.50), (3.52) and write

$$\frac{\partial \boldsymbol{G}}{\partial t} - c^2\Delta\boldsymbol{G} + \omega_{\rm pe}^2\begin{bmatrix} 1+\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}} & 0 & 0\\ 0 & 1+\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}} & 0\\ 0 & 0 & 1\end{bmatrix}\boldsymbol{G} = \boldsymbol{0}.$$

This is a vector equation, which is equivalent to three scalar Klein–Gordon equations. For the first two components the dispersive term is $\sim \omega_{\rm pe}^2(1+\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}})$ as opposed to simply $\sim \omega_{\rm pe}^2$, which was the case in section 3.4. We therefore conclude that the additional effect of anisotropy on weak lacunae of electromagnetic waves in the dilute ionospheric plasma can be approximately measured as $\mathcal{O}(\frac{\omega_{\rm pe}}{\omega}\sqrt{\frac{\Omega_{\rm e}}{\omega-\Omega_{\rm e}}})$.

4. Discussion. Classical lacunae can be observed in the solutions of the Maxwell equations only when the electromagnetic waves propagate in vacuum or in dielectric media with static response. Otherwise, the propagation is accompanied by aftereffects, and there are no sharp aft fronts and no lacunae in the solutions. For low incident frequencies, the mechanism that destroys the lacunae can largely be attributed to dissipation due to the Ohm conductivity. For high incident frequencies, when the material coefficients can no longer be considered constant, the diffusion of waves is basically caused by the physical dispersion. However, for the propagation of transverse electromagnetic waves in dilute plasma, when the incident frequency is much higher than the Langmuir frequency, lacunae can still be identified in the corresponding solutions of the Maxwell equations, although in an approximate sense. The depth of these weak lacunae, i.e., the magnitude of the residual field relative to the magnitude of the field in the primary wave packet, is proportional to the ratio of the Langmuir frequency over the primary carrying frequency of the waves. In the anisotropic case, when the plasma is immersed into the external magnetic field, there is an additional small factor, approximately equal to the square root of the ratio of the cyclotron frequency over the carrier frequency, that affects the depth of the weak lacunae.

An interesting subject for future study could be analysis of the case when anisotropic responses should remain nonlocal in time, as well as a more careful analysis of the conductivity mechanisms in the ionosphere. On the numerical side, the future direction is the ABC algorithm based on the weak lacunae.

ACTIVE CONTROL OF SOUND FOR COMPOSITE REGIONS*

A. W. PETERSON† AND S. V. TSYNKOV‡

Abstract. We present a methodology for the active control of time-harmonic wave fields, e.g., acoustic disturbances, in composite regions. This methodology extends our previous approach developed for the case of arcwise connected regions. The overall objective is to eliminate the effect of all outside field sources on a given domain of interest, i.e., to shield this domain. In this context, active shielding means introducing additional field sources, called active controls, that generate the annihilating signal and cancel out the unwanted component of the field. As such, the problem of active shielding can be interpreted as a special inverse source problem for the governing differential equation or system. For a composite domain, not only do the controls prevent interference from all exterior sources, but they can also enforce a predetermined communication pattern between the individual subdomains (as many as desired). In other words, they either allow the subdomains to communicate freely with one another or otherwise have them shielded from their peers. In the paper, we obtain a general solution for the composite active shielding problem and show that it reduces to solving a collection of auxiliary problems for arcwise connected domains. The general solution is constructed in two stages. Namely, if a particular subdomain is not allowed to hear another subdomain, then the supplementary controls are employed first. They communicate the required data prior to building the final set of controls. The general solution can be obtained with only the knowledge of the acoustic signals propagating through the boundaries of the subdomains. No knowledge of the field sources is required, nor is any knowledge of the properties of the medium needed.

Key words. active shielding, noise control, inverse source problem, time-harmonic acoustic fields, composite domain, communication pattern, the Helmholtz equation, generalized Calderon's potentials, exact volumetric cancellation, general solution, incoming and outgoing waves, wave split

DOI. 10.1137/060662368

1. Introduction.

Active shielding and control of noise is a very rich field with a variety of applications. In the most general terms, exercising active control means introducing additional sources of sound, called controls, to facilitate a specific change in the overall acoustic field. In particular, the desired change may imply canceling all or part of the field on a given region. Referring the reader to other, more detailed sources for a comprehensive review (see [17, 8, 24]), we mention several representative publications in the area. Research by Elliott, Stothers, and Nelson [7] focused on the minimization of noise at pointwise locations. Wright and Vuksanovic expanded the field to include directional noise cancellation in [30, 31]. A large portion of the research done today has been motivated by the airline industry and its desire to control unwanted engine noise in the cabin during flight. There are various methods of dealing with in-flight noise. Damping structural vibrations is one approach to attenuating low frequencies. This is done by placing actuators and sensors throughout the cabin at optimized locations. Kincaid, Laba, and Padula worked extensively on this problem [12, 11]. A comprehensive account of the area, along with many additional references, can be found in [4]. Another method involves placing a series of microphones and

speakers throughout the cabin and uses acoustic excitation to cancel unwanted noise. Passive techniques such as sound insulation are more effective in dealing with high frequencies. Van der Auweraer et al. tackled the problem of aircraft noise in [26] by using a combination of both methods.

In [9], Fuller and von Flotow present an overview of current common practices in active noise control. One of the most popular algorithms used today in the control of noise is based on a least mean squares (LMS) method. It is employed to tune the control filter to reduce unwanted noise near the sensors and was first introduced by Burgess in [1] and by Widrow, Shur, and Shaffer in [29]. This algorithm was later improved upon by Cabell and Fuller in [2]. While LMS methods offer good results near the sensors in small-scale applications such as mobile phones, they do not allow for the exact volumetric cancellation of noise desired in an airline cabin.

In the current paper, we introduce and study a new formulation of active noise control problem. Namely, the overall region of space to be protected from noise is assumed to be composed of a number of simple, i.e., arcwise connected, (sub)domains. The standard part of the formulation involves shielding the overall domain, i.e., the union of all subdomains, from the unwanted noise. In addition, the individual subdomains are selectively allowed to either communicate freely with one another according to a predetermined pattern or else be shielded from their peers. In doing so, no reciprocity is assumed; i.e., for a given pair of subdomains one may be allowed to hear the other, but not vice versa.

The method of analysis used in this paper builds upon the previous research done by Lončarić, Ryaben'kii, and Tsynkov in [13] and by Tsynkov in [25] for the case of a single arcwise connected domain, and subsequently extended in [14, 15, 16] by investigating various optimization formulations. The approach of [13] allows for the exact volumetric cancellation of time-harmonic noise in a given region. In other words, this region is shielded from the unwanted sound that comes from the outside. The shielding is achieved by first splitting the total acoustic field into the incoming and outgoing components. This can be done unambiguously using only the knowledge of the field and its normal derivative measured at the boundary of the region to be protected. Subsequently, the unwanted incoming component of the field is canceled by additional sources that are insensitive to the outgoing component. Other methods, such as those employed by Nelson and Elliott in [17], require that the noise to be canceled be measured at the boundary by itself, and be distinguished from other components of the acoustic field ahead of time. This restriction does not exist in the methodology presented herein. Moreover, our methodology requires knowledge of neither the volumetric properties of the medium nor the location and strength of the noise sources. Decomposition of the overall sound field into incoming and outgoing components, as well as design of the antinoise sources, are accomplished by applying Calderon's potentials and projections [3]; see also [23]. This is a very convenient and powerful apparatus that allows one to describe all appropriate control sources in closed form. In the simplest case of constant coefficients, the Calderon operators can be obtained using boundary integrals of classical potential theory.

There are two types of control sources that can be explored, volumetric and surface. In [13], it is determined that the general solution for volumetric controls $g = g(x)$ is given by

$$g(x) = -Lw$$

outside of the region to be shielded, where w is a special auxiliary function which must satisfy the Sommerfeld radiation condition at infinity, as well as coincide with

the acoustic field u and its normal derivative $\frac{\partial u}{\partial n}$ at the boundary. Here $L = \Delta + k^2 I$ denotes the Helmholtz operator. Since these are fairly loose restrictions, volumetric controls define a very broad class of solutions to the problem.

Surface controls are concentrated at the boundary. They are given by

$$g^{(surf)} = -\left[\frac{\partial w}{\partial n} - \frac{\partial u}{\partial n}\right]_\Gamma \delta(\Gamma) - \frac{\partial}{\partial n}([w-u]_\Gamma \delta(\Gamma)),$$

where the auxiliary function w is additionally required to satisfy the homogeneous Helmholtz equation, $Lw = 0$, outside the boundary but is no longer required to satisfy any boundary conditions at Γ. The general solution to the surface control problem is discussed in [25]. It is to be noted that surface controls have the same fundamental properties as volumetric controls. A universal framework for both volumetric and surface controls is built by Ryaben'kii and Utyuzhnikov in the recent paper [22]; it treats the governing equation for the field in an operator form.

We should also emphasize that the continuous formulation is not practical for implementation. Any realistic implementation would consist only of a finite number of sensors (microphones) and actuators (speakers). This will lead to a discretization of the problem on a grid. Discrete active shielding problems were analyzed, and the corresponding solutions obtained in [14, 15, 16, 25], as well as more recently in [22]. The finite-difference analysis of [14, 15, 16, 22, 25] uses the constructs developed previously in the works by Ryaben'kii [18] and by Veizman and Ryaben'kii [27, 28].

Specific objective of the current paper. We will extend the methodology of [13] to the case of composite regions. This will allow two or more separate subregions to be fully protected from the influence of outside sources. Moreover, according to a predetermined communication pattern, each individual subregion may or may not be allowed to hear any other subregion. As in [13], only the total acoustic field and its normal derivative specified at the boundaries will be needed for the exact volumetric cancellation of the outside noise, as well as for the realization of a given communication pattern. It will not be necessary to distinguish the "adverse," i.e., unwanted, part of the acoustic field from its "friendly," i.e., wanted, part as this is done automatically by the control system. The methodology will provide a closed form general solution for the controls, including the case of an inhomogeneous medium.

2. Two regions. In this section, the formulation for two separate domains will be discussed. In other words, we will distinguish between the two given disjoint regions and the rest of the space. Let it be noted, however, that the forthcoming methodology could be presented in a more general framework. The rest of the space outside of the two given regions can be treated as a third region on equal terms with the first two. This formulation lends itself more naturally to surface controls separating the three regions. A rigorous analysis of this approach for the finite-difference setting can be found in the recent paper [21], which, in turn, builds upon [18]. We, however, choose a simpler form of presentation in order to make it more accessible for applications. Accordingly, the focus will be on volumetric controls, which will allow for more flexibility in their construction.

2.1. Formulation. Let Ω_1 and Ω_2 be given, where $\Omega_i \subseteq \mathbb{R}^2$ or $\mathbb{R}^3$ is either bounded or unbounded. For simplicity we will first assume that Ω_1 and Ω_2 are two separate bounded regions of $\mathbb{R}^n$ (see Figure 2.1), and such that $\operatorname{dist}(\Omega_1, \Omega_2) \geq \epsilon > 0$. Let Γ_1 and Γ_2 be the boundaries of Ω_1 and Ω_2, respectively. Consider the time-

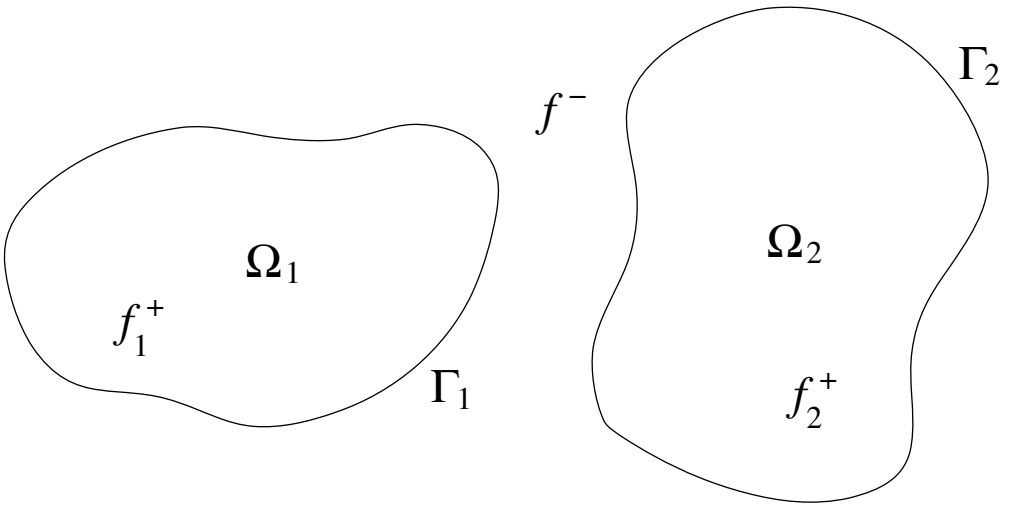

FIG. 2.1. *Two domains.*

harmonic acoustic field $u = u(x)$ governed by the inhomogeneous Helmholtz equation:

$$Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + f^-, \tag{2.1}$$

where for the sources we have $\text{supp} f_1^+ \subset \Omega_1$, $\text{supp} f_2^+ \subset \Omega_2$, and $\text{supp} f^- \subset \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)$. The overall acoustic field can be represented as

$$u = u_1^+ + u_2^+ + u^-, \tag{2.2a}$$

where

$$Lu_1^+ = f_1^+, \tag{2.2b}$$

$$Lu_2^+ = f_2^+, \tag{2.2c}$$

and

$$Lu^- = f^-. \tag{2.2d}$$

Our first goal is to eliminate all sound from the exterior sources f^- inside Ω_1 and Ω_2 while allowing sound from the sources f_1^+ and f_2^+ to propagate freely between Ω_1 and Ω_2. This is to be achieved by introducing a new control source g. After that, the total acoustic field $\tilde{u}$ will be governed by

$$L\tilde{u} = f_1^+ + f_2^+ + f^- + g.$$

We would like to choose the controls g to guarantee

$$\tilde{u}|_{x\in\Omega_1} = (u_1^+ + u_2^+)|_{x\in\Omega_1}$$

and

$$\tilde{u}|_{x\in\Omega_2} = (u_1^+ + u_2^+)|_{x\in\Omega_2}.$$

In other words, the field after the control inside either Ω_1 or Ω_2 should contain no contribution from the sources f^-. Notice that $g = -f^-$ is a solution to the problem, but it can be very difficult to implement and also requires previous knowledge of the sources f^-. Therefore, other, less expensive, solutions that do not require extensive knowledge of the exterior sources are preferable.

Our second goal is to selectively eliminate the sound that propagates between the regions Ω_1 and Ω_2. This is to be done in addition to the cancellation of the common exterior sound. For example, Ω_1 may be allowed to hear Ω_2, but not vice versa.

Note that the problem of active noise control as formulated above is, in fact, a problem of enabling a desired change in the solution of a given differential equation by appropriately modifying its source terms, i.e., by adding new sources. Consequently, it can be interpreted as an inverse source problem for the corresponding differential equation. Inverse source problems have been extensively studied in the literature, both from the standpoint of physics/engineering (see, e.g., [6, 5]), as well as from the standpoint of mathematics (see, e.g., [10]).

2.2. General solution. Let us first recall that in order to guarantee uniqueness of the solution to the Helmholtz equation (2.1) on unbounded regions, we must require that this solution satisfy the Sommerfeld radiation condition at infinity:

$$\frac{\partial v(x)}{\partial |x|} + ikv(x) = o(|x|^{-1/2}), \quad x \in \mathbb{R}^2, \tag{2.3a}$$

or

$$\frac{\partial v(x)}{\partial |x|} + ikv(x) = o(|x|^{-1}), \quad x \in \mathbb{R}^3. \tag{2.3b}$$

In particular, for any sufficiently smooth function $v = v(x)$ that satisfies the Sommerfeld condition we get

$$v(x) = \int_{\mathbb{R}^n} G(x-y) Lv(y) dy, \tag{2.4}$$

where

$$Lv = \Delta v + k^2 v$$

is the Helmholtz operator and $G = G(x)$ is its fundamental solution on $\mathbb{R}^n$. For $\mathbb{R}^2$, the fundamental solution is given by

$$G(x) = -\frac{1}{4i} H_0^{(2)}(k|x|), \tag{2.5}$$

where $H_0^{(2)}(z)$ is the Hankel function of the second kind defined by means of the Bessel functions $J_0(z)$ and $Y_0(z)$ as $H_0^{(2)}(z) = J_0(z) - iY_0(z)$. For $\mathbb{R}^3$, we have

$$G(x) = -\frac{1}{4\pi} \frac{e^{-ik|x|}}{|x|}. \tag{2.6}$$

Note that the fundamental solutions (2.5) and (2.6) satisfy the Sommerfeld radiation condition at infinity (2.3a) and (2.3b), respectively.

2.2.1. Straightforward cancellation. Let $u = u(x)$ be the overall acoustic field (see (2.1)) and n be the exterior normal to the boundary, and introduce an auxiliary function $w = w(x)$ such that

$$w\big|_{\Gamma_1\cup\Gamma_2} = u\big|_{\Gamma_1\cup\Gamma_2}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_1\cup\Gamma_2} = \frac{\partial u}{\partial n}\Big|_{\Gamma_1\cup\Gamma_2}$$

(recall that $\operatorname{dist}(\Gamma_1,\Gamma_2) \geq \epsilon > 0$). We also require that $w(x)$ satisfies the Sommerfeld condition (2.3a) or (2.3b). Next, we define the control sources as follows:

$$g(x) = \begin{cases} -Lw, & x \in \{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)\}, \\ 0, & x \in (\Omega_1 \cup \Omega_2). \end{cases} \tag{2.7}$$

To analyze properties of the controls (2.7), we must determine their output $v = v(x)$ for $x \in \mathbb{R}^n$. Using (2.4), we get[1]

$$\begin{aligned} v(x) &= \int_{\mathbb{R}^n} G g dy = -\int_{\mathbb{R}^n\backslash(\Omega_1\cup\Omega_2)} GLw dy \\ &= -\left(w(x) - \int_{\Omega_1} GLw dy - \int_{\Omega_2} GLw dy \right), \end{aligned}$$

where the individual integrals on the right-hand side are computed by integrating over Ω_1 and Ω_2 and are completely independent. Yet we emphasize that even though the computation of $v(x)$ can be reduced to integration over Ω_1 and Ω_2, the shape of $w(x)$ inside these two domains will not affect the output $v(x)$ since the original controls g are defined outside of $\Omega_1 \cup \Omega_2$; see formula (2.7).

Let us examine the individual terms. By Green's theorem, for $x \in \Omega_1$ we obtain

$$\begin{aligned} w(x) - \int_{\Omega_1} GLw dy &= \int_{\Gamma_1} \left(w \frac{\partial G}{\partial n} - \frac{\partial w}{\partial n} G \right) ds_y \\ &= \int_{\Gamma_1} \left(u \frac{\partial G}{\partial n} - \frac{\partial u}{\partial n} G \right) ds_y \\ &= u^-(x) + u_2^+(x), \qquad x \in \Omega_1, \end{aligned}$$

where n is the normal exterior to Γ_1 and $u^-(x)$ and $u_2^+(x)$ are defined by (2.2d) and (2.2c), respectively. This expression yields the entire incoming component of the field for the domain Ω_1. Next, we need to see what the contribution of $-\int_{\Omega_1} GLw dy$ will be outside of Ω_1. Introduce a smooth auxiliary function $w_1(x)$ such that $w_1(x) = w(x)$ on Ω_1 and $w_1(x)$ is compactly supported on a small neighborhood of Ω_1. Then, for

[1] All integrals hereafter are of the convolution type, as in formula (2.4).

$x \in \mathbb{R}^n \backslash \Omega_1$ we have

$$\begin{aligned} -\int_{\Omega_1} GLwdy &= -\int_{\Omega_1} GLw_1 dy \\ &= -\int_{\Omega_1} GLw_1 dy + w_1 - w_1 \\ &= \int_{\mathbb{R}^n \backslash \Omega_1} GLw_1 dy - w_1 \\ &= \int_{\Gamma_1} \left(w_1 \frac{\partial G}{\partial n} - \frac{\partial w_1}{\partial n} G \right) ds_y \\ &= -u_1^+(x), \qquad x \in \mathbb{R}^n \backslash \Omega_1, \end{aligned}$$

where the third equality in the chain is obtained with the help of formula (2.4) applied to $w_1(x)$. Therefore, we can write

$$-\int_{\Omega_1} GLwdy = \begin{cases} -u_1^+, & x \in \mathbb{R}^n \backslash \Omega_1, \\ -w + u^- + u_2^+, & x \in \Omega_1. \end{cases}$$

We also have a similar output from Ω_2 given by

$$-\int_{\Omega_2} GLwdy = \begin{cases} -u_2^+, & x \in \mathbb{R}^n \backslash \Omega_2, \\ -w + u^- + u_1^+, & x \in \Omega_2. \end{cases}$$

Altogether, the full output of the controls $g(x)$ of (2.7) is as follows:

$$\begin{aligned} v(x) &= -\left(w - \int_{\Omega_1} GLwdy - \int_{\Omega_2} GLwdy \right) \\ &= \begin{cases} -(u^- + u_2^+) + u_2^+ = -u^-, & x \in \Omega_1, \\ -(u^- + u_1^+) + u_1^+ = -u^-, & x \in \Omega_2, \\ -(w - u_1^+ - u_2^+), & x \in \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2). \end{cases} \end{aligned}$$

Consequently, these controls enable the cancellation of sound due to the exterior sources f^- on the domains Ω_1 and Ω_2 regardless of the specific choice of the auxiliary function w. The output of the controls outside $\Omega_1 \cup \Omega_2$ is given by $u_1^+ + u_2^+ - w$. It duplicates the acoustic field generated inside the two regions with the correction $-w$.

Let us elaborate a little further on the structure of the control output $v(x)$. Assume that $x \in \Omega_1$. Then,

$$\begin{aligned} v(x) &= -w(x) + \int_{\Omega_1} GLwdy + \int_{\Omega_2} GLwdy \\ &= -w + \underbrace{w - (u^- + u_2^+)}_{\text{contribution due to } \Omega_1} + \underbrace{u_2^+}_{\text{due to } \Omega_2} \\ &= -u^-(x), \ x \in \Omega_1, \end{aligned}$$

where $-(u^- + u_2^+)$ from the second term above renders cancellation of the entire incoming wave for Ω_1, and u_2^+ is the interior sound from Ω_2 duplicated by the controls. The same is true for Ω_2. Hence we conclude that the controls double the output of the sources interior to a region on the way out and then halve it as it comes into the other region. As such, the overall acoustic field after the control is given by

$$\begin{aligned} u &= u_1^+ + u_2^+ + u^- + v \\ &= \begin{cases} u_1^+ + u_2^+, & x \in \Omega_1, \\ u_1^+ + u_2^+, & x \in \Omega_2, \\ -w + u^- + 2u_1^+ + 2u_2^+, & x \in \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2), \end{cases} \end{aligned} \tag{2.8}$$

allowing the domains Ω_1 and Ω_2 to communicate freely with each other without interference from outside sources.

2.2.2. Selective cancellation. Now suppose that we would like Ω_1 to hear Ω_2 without outside interference, but we do not allow Ω_2 to hear anything from outside its boundary, including Ω_1. To achieve this we must elaborate further on how the split between the incoming and outgoing waves works. Consider just one domain Ω_1 with the boundary Γ_1 and again choose the auxiliary function $w_1 = w_1(x)$. Let

$$w_1\big|_{\Gamma_1} = u\big|_{\Gamma_1} \tag{2.9a}$$

and

$$\frac{\partial w_1}{\partial n}\Big|_{\Gamma_1} = \frac{\partial u}{\partial n}\Big|_{\Gamma_1}, \tag{2.9b}$$

where $u = u_1^- + u_1^+$ is the total acoustic field and $u_1^- = u^- + u_2^+$ is the acoustic field generated outside of Ω_1. Then the surface integral gives us

$$\int_{\Gamma_1} \left(w_1 \frac{\partial G}{\partial n} - \frac{\partial w_1}{\partial n} G \right) ds_y = \begin{cases} u_1^-, & x \in \Omega_1, \\ -u_1^+, & x \in \mathbb{R}^n \backslash \Omega_1. \end{cases}$$

With respect to the domain Ω_1, the field u_1^- is incoming, and u_1^+ is outgoing. Assuming that $w_1(x)$ also satisfies the appropriate Sommerfeld radiation condition (2.3a) or (2.3b), the surface integral can be replaced by the volumetric integral, so that for $x \in \Omega_1$ we have

$$\begin{aligned} \int_{\Gamma_1} \left(w_1 \frac{\partial G}{\partial n} - \frac{\partial w_1}{\partial n} G \right) ds_y &= w_1 - \int_{\Omega_1} GLw_1 dy \Big|_{x \in \Omega_1} \\ &= \int_{\mathbb{R}^n \backslash \Omega_1} G(x-y) Lw_1(y) dy \Big|_{x \in \Omega_1}. \end{aligned}$$

This is precisely why we would choose the controls as $g_1(x) = -Lw_1|_{\mathbb{R}^n \backslash \Omega_1}$ if we were to completely eliminate all of the outside sound on Ω_1—because they produce $-u_1^-$ on Ω_1. At the same time, on the complementary domain $\mathbb{R}^n \backslash \Omega_1$ the output of the

controls $g_1(x)$ is the duplicate of the outgoing field u_1^+ corrected by $-w_1$:

$$\begin{aligned}\int_{\mathbb{R}^n} G(x-y)g_1(y)dy &= -\int_{\mathbb{R}^n\setminus\Omega_1} G(x-y)Lw_1(y)dy \\ &= w_1 - \int_{\mathbb{R}^n\setminus\Omega_1} GLw_1 dy - w_1 \\ &= -\int_{\Gamma_1}\left(w_1\frac{\partial G}{\partial n} - \frac{\partial w_1}{\partial n}G\right)ds_y - w_1 = u_1^+ - w_1.\end{aligned} \tag{2.10}$$

Having described individual controls g_1 for a single domain Ω_1, we are now ready to construct the controls so that Ω_1 will hear Ω_2 without outside interference, but Ω_2 will not hear anything from outside its boundary, including Ω_1. The procedure will consist of two stages. At the first stage, we will use the controls $g_1(x)$ as a supplementary tool. Namely, choose an auxiliary function $w_1(x)$ that satisfies conditions (2.9a) and (2.9b), as well as the Sommerfeld condition at infinity. In addition, require that w_1 be compactly supported near Ω_1, in particular, that $w_1(x) = 0$ near Ω_2. This is clearly possible since the distance between the subdomains Ω_1 and Ω_2 is positive. Then, build the supplementary controls

$$g_1(x) = -Lw_1|_{\mathbb{R}^n\setminus\Omega_1}, \qquad g_1(x) = 0|_{\Omega_1}. \tag{2.11}$$

According to formula (2.10), the output of these controls on $\mathbb{R}^n\setminus\Omega_1$ is

$$v_1 = \int_{\mathbb{R}^n} Gg_1 dy = u_1^+ - w_1, \qquad x \in \mathbb{R}^n\setminus\Omega_1, \tag{2.12}$$

and since w_1 is compactly supported near Ω_1, we have $v_1 = u_1^+$ near Ω_2.

At the second stage of building the controls, we begin as usual with our auxiliary function w. It is still required that w satisfy the Sommerfeld condition at infinity, while on Γ_1 we still impose the same boundary conditions (2.9a) and (2.9b):

$$w\big|_{\Gamma_1} = u\big|_{\Gamma_1}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_1} = \frac{\partial u}{\partial n}\Big|_{\Gamma_1},$$

where u is the given total acoustic field. The difference is in the boundary conditions on Γ_2. Here it is required that

$$w\big|_{\Gamma_2} = (u+v_1)\big|_{\Gamma_2} \equiv (u+u_1^+)\big|_{\Gamma_2}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_2} = \frac{\partial (u+v_1)}{\partial n}\Big|_{\Gamma_2} \equiv \frac{\partial (u+u_1^+)}{\partial n}\Big|_{\Gamma_2},$$

where v_1 was obtained at the first stage; see (2.12). Then, defining the controls as

$$g(x) = -Lw|_{\mathbb{R}^n\setminus(\Omega_1\cup\Omega_2)}, \qquad g(x) = 0|_{(\Omega_1\cup\Omega_2)}$$

yields the output

$$v(x) = -\left(w - \int_{\Omega_1} GLwdy - \int_{\Omega_2} GLwdy\right)$$

$$= \begin{cases} -(u^- + u_2^+) + u_2^+ = -u^-, & x \in \Omega_1, \\ -(u^- + 2u_1^+) + u_1^+ = -(u^- + u_1^+), & x \in \Omega_2, \\ -(w - u_1^+ - u_2^+), & x \in \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2). \end{cases} \tag{2.13}$$

Therefore, we see that Ω_1 hears Ω_2 without outside interference, but Ω_2 does not hear anything from outside its boundary, including Ω_1.

2.2.3. Proofs. We will now prove that what we have obtained is, in fact, a general solution for the controls with the prescribed properties. That is, we will prove that our method of construction gives all possible controls.

THEOREM 2.1. *Suppose that $\Omega_1 \subset \mathbb{R}^n$ and $\Omega_2 \subset \mathbb{R}^n$ are two disjoint regions:* $\operatorname{dist}(\Omega_1, \Omega_2) \geq \epsilon > 0$, *with the boundaries $\partial\Omega_1 = \Gamma_1$ and $\partial\Omega_2 = \Gamma_2$. Assume that the total acoustic field in $\mathbb{R}^n$ is governed by $Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + f^-$, where the sources f are located according to* $\operatorname{supp} f_1^+ \subset \Omega_1$, $\operatorname{supp} f_2^+ \subset \Omega_2$, *and* $\operatorname{supp} f^- \subset \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)$. *Let the overall acoustic field u be represented as $u = u_1^+ + u_2^+ + u^-$.*

Let a control source $g = g(x)$ be added to the other sources $f(x)$ such that the overall field $\tilde{u}$ governed by $L\tilde{u} = f_1^+ + f_2^+ + f^- + g$ satisfies

$$\tilde{u} = \begin{cases} u_1^+ + u_2^+, & x \in \Omega_1, \\ u_1^+ + u_2^+, & x \in \Omega_2. \end{cases} \tag{2.14}$$

Then the general solution for the desired control is given by

$$g = -Lw|_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)}, \qquad g = 0|_{(\Omega_1 \cup \Omega_2)}, \tag{2.15}$$

where w satisfies the Sommerfeld condition (2.3a) *or* (2.3b) *at infinity, as well as the interface conditions*

$$w\big|_{\Gamma_1 \cup \Gamma_2} = u\big|_{\Gamma_1 \cup \Gamma_2} \tag{2.16a}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_1 \cup \Gamma_2} = \frac{\partial u}{\partial n}\Big|_{\Gamma_1 \cup \Gamma_2}. \tag{2.16b}$$

Proof. We need to prove that any control g given by (2.15) is an appropriate control and, conversely, that any appropriate control g can be obtained by using a suitable auxiliary function w. Suppose we have a function $w(x)$ that satisfies (2.16a), (2.16b), and the Sommerfeld condition at infinity. Then, according to formula (2.8), the corresponding control g given by formula (2.15) yields the desired properties by eliminating u^- on $\Omega_1 \cup \Omega_2$.

Conversely, suppose that a control g achieves the desired cancellation; see formula (2.14). Then, substituting $\tilde{u} = \tilde{u}(x)$ into the equation $L\tilde{u} = f_1^+ + f_2^+ + f^- + g$, we immediately obtain that $g(x) = 0$ for $x \in (\Omega_1 \cup \Omega_2)$. In other words, $\operatorname{supp} g \subset \mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2)$. Consequently, the output v of the control g is as follows:

$$v(x) = \int_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)} Ggdy = \begin{cases} -u^-, & x \in \Omega_1, \\ -u^-, & x \in \Omega_2. \end{cases}$$

Consider the equation $-Lw = g - f_1^+ - f_2^+$, where f_1^+ and f_2^+ are the sound sources from Ω_1 and Ω_2, respectively. Its solution, subject to the Sommerfeld condition at infinity (2.3a) or (2.3b), satisfies

$$w = -v + u_1^+ + u_2^+$$
$$= \begin{cases} u^- + u_1^+ + u_2^+ = u, & x \in \Omega_1, \\ u^- + u_1^+ + u_2^+ = u, & x \in \Omega_2. \end{cases}$$

Since $w(x)$ is at least C^1 smooth on $\mathbb{R}^n$, we can claim that it satisfies relations (2.16a) and (2.16b). Therefore, the control $g(x)$ can be obtained by formula (2.15), since $\mathrm{supp} f_1^+ \subset \Omega_1$ and $\mathrm{supp} f_2^+ \subset \Omega_2$. □

THEOREM 2.2. *Suppose that $\Omega_1 \subset \mathbb{R}^n$ and $\Omega_2 \subset \mathbb{R}^n$ are two disjoint regions:* $\mathrm{dist}(\Omega_1, \Omega_2) \geq \epsilon > 0$, *with the boundaries $\partial\Omega_1 = \Gamma_1$ and $\partial\Omega_2 = \Gamma_2$. Assume that the total acoustic field in $\mathbb{R}^n$ is governed by $Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + f^-$, where the sources f are located according to* $\mathrm{supp} f_1^+ \subset \Omega_1$, $\mathrm{supp} f_2^+ \subset \Omega_2$, *and* $\mathrm{supp} f^- \subset \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)$. *Let the overall acoustic field u be represented as $u = u_1^+ + u_2^+ + u^-$.*

Let a control source $g = g(x)$ be added to the other sources $f(x)$ such that the overall field $\tilde{u}$ governed by $L\tilde{u} = f_1^+ + f_2^+ + f^- + g$ satisfies

$$\tilde{u} = \begin{cases} u_1^+ + u_2^+, & x \in \Omega_1, \\ u_2^+, & x \in \Omega_2. \end{cases} \tag{2.17}$$

Then the general solution for the desired control is given by

$$g = -Lw|_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2)}, \qquad g = 0|_{(\Omega_1 \cup \Omega_2)}, \tag{2.18}$$

where $w = w(x)$ satisfies the Sommerfeld condition (2.3a) *or* (2.3b) *at infinity and the following interface conditions:*

$$w\big|_{\Gamma_1} = u\big|_{\Gamma_1}, \quad w\big|_{\Gamma_2} = (u + u_1^+)\big|_{\Gamma_2} \tag{2.19a}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_1} = \frac{\partial u}{\partial n}\Big|_{\Gamma_1}, \quad \frac{\partial w}{\partial n}\Big|_{\Gamma_2} = \frac{\partial (u + u_1^+)}{\partial n}\Big|_{\Gamma_2}. \tag{2.19b}$$

The function u_1^+ on Γ_2 can be obtained as the output v_1 given by formula (2.12) *of the supplementary controls g_1 of* (2.11).

Theorem 2.2 essentially implies that the controls (2.18) are obtained by means of a predictor-corrector procedure. The predictor stage consists of computing v_1 of (2.12) as the output of the control g_1 of (2.11), whereas the corrector stage consists of obtaining the overall composite controls $g(x)$ with the help of the auxiliary function $w(x)$ defined via (2.19).

Proof. We need to prove that any control g given by (2.18) is an appropriate control and, conversely, that any appropriate control g can be obtained by using a suitable auxiliary function w. Suppose we have a function $w(x)$ that satisfies (2.19a), (2.19b), and the Sommerfeld condition at infinity. Then, according to formula (2.13), the corresponding control given by (2.18) provides the desired properties eliminating u^- on $\Omega_1 \cup \Omega_2$ and additionally eliminating u_1^+ on Ω_2.

Conversely, suppose that a control g achieves the desired cancellation; see formula (2.17). Then, $\operatorname{supp} g \in \mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2)$, and the output of the control, v, is as follows:

$$v(x) = \int_{\mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2)} Ggdy = \begin{cases} -u^-, & x \in \Omega_1, \\ -u^- - u_1^+, & x \in \Omega_2. \end{cases}$$

Consider the equation $-Lw = g - f_1^+ - f_2^+$. Its solution, subject to the Sommerfeld condition at infinity (2.3a) or (2.3b), satisfies

$$\begin{aligned} w &= -v + u_1^+ + u_2^+ \\ &= \begin{cases} u^- + u_1^+ + u_2^+ = u, & x \in \Omega_1, \\ u^- + 2u_1^+ + u_2^+ = u + u_1^+, & x \in \Omega_2. \end{cases} \end{aligned}$$

Since $w(x)$ is at least C^1 smooth on $\mathbb{R}^n$, it satisfies relations (2.19a) and (2.19b). Therefore, the control $g(x)$ can be obtained by formula (2.18) since $\operatorname{supp} f_1^+ \subset \Omega_1$ and $\operatorname{supp} f_2^+ \subset \Omega_2$. ∎

3. Multiple regions.

3.1. Formulation. Let $\Omega_1, \Omega_2, \ldots, \Omega_N$ be given, where $\Omega_i \subseteq \mathbb{R}^2$ or $\mathbb{R}^3$ is either bounded or unbounded. For simplicity we will assume that $\Omega_1, \Omega_2, \ldots, \Omega_N$ are separate bounded regions of $\mathbb{R}^n$. Let $\Gamma_1, \Gamma_2, \ldots, \Gamma_N$ be the boundaries of $\Omega_1, \Omega_2, \ldots, \Omega_N$ respectively. Consider the time-harmonic acoustic field u governed by the inhomogeneous Helmholtz equation:

$$Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + \cdots + f_N^+ + f^-,$$

where the sources are $\operatorname{supp} f_1^+ \subset \Omega_1$, $\operatorname{supp} f_2^+ \subset \Omega_2, \ldots, \operatorname{supp} f_n^+ \subset \Omega_N$, and $\operatorname{supp} f^- \subset \mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)$. Therefore, the overall acoustic field can be represented as

$$u = u_1^+ + u_2^+ + \cdots + u_N^+ + u^-,$$

where

$$\begin{aligned} Lu_1^+ &= f_1^+, \\ Lu_2^+ &= f_2^+, \\ &\cdots \\ Lu_N^+ &= f_N^+, \end{aligned}$$

and

$$Lu^- = f^-.$$

Our goal is to eliminate all sound from the sources f^- inside $\Omega_1, \Omega_2, \ldots, \Omega_N$, while allowing sound from the sources $f_1^+, f_2^+, \ldots, f_N^+$ to propagate between $\Omega_1, \Omega_2, \ldots, \Omega_N$ as we see fit. That is, we wish to selectively eliminate unwanted sound from various regions while leaving other regions free to receive predetermined communications. This is done as before by introducing a new control source g. Therefore, the total acoustic field is now governed by the modified equation

$$L\tilde{u} = f_1^+ + f_2^+ + \cdots + f_N^+ + f^- + g.$$

3.2. General solution.

3.2.1. Straightforward cancellation. We will first demonstrate how to eliminate all sound in $\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$ that originates from $\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)$. As before, we introduce an auxiliary function $w = w(x)$, which satisfies the Sommerfeld condition (2.3a) or (2.3b) at infinity, and is such that

$$w\big|_{\Gamma_i} = u\big|_{\Gamma_i}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_i} = \frac{\partial u}{\partial n}\Big|_{\Gamma_i}$$

for all $i = 1, \ldots, N$.

Next, we define the control sources as (cf. formula (2.7))

$$g(x) = \begin{cases} -Lw, & x \in \{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)\}, \\ 0, & x \in (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N), \end{cases}$$

and see that their output $v = v(x)$, $x \in \mathbb{R}^n$, is given by

$$v(x) = \int_{\mathbb{R}^n} G g dy = -\int_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)} GLw dy$$

$$= -\left(w(x) - \int_{\Omega_1} GLw dy - \int_{\Omega_2} GLw dy - \cdots - \int_{\Omega_N} GLw dy \right),$$

where the individual integrals are computed by integrating over $\Omega_1, \Omega_2, \ldots, \Omega_N$ and are completely independent. Again, all integrals are convolutions, as in section 2.

Let us examine the individual terms. By Green's theorem, for $x \in \Omega_i$, where $i \in \{1, 2, \ldots, N\}$, we obtain

$$w(x) - \int_{\Omega_i} GLw dy = \int_{\Gamma_i} \left(w \frac{\partial G}{\partial n} - \frac{\partial w}{\partial n} G \right) ds_y$$

$$= \int_{\Gamma_i} \left(u \frac{\partial G}{\partial n} - \frac{\partial u}{\partial n} G \right) ds_y$$

$$= u^-(x) + \sum_{\substack{j=1,2,\ldots,N \\ j \neq i}} u_j^+(x), \qquad x \in \Omega_i.$$

This is the entire incoming component for the domain Ω_i. Now the effect of the integral $-\int_{\Omega_i} GLw dy$ outside of Ω_i must be examined. To do this, we introduce a smooth auxiliary function $w_i(x)$ such that $w_i(x) = w(x)$ on Ω_i and $w_i(x)$ is compactly

supported on a small neighborhood of Ω_i. Consequently, for $x \in \mathbb{R}^n \backslash \Omega_i$ we have

$$\begin{aligned}
-\int_{\Omega_i} GLwdy &= -\int_{\Omega_i} GLw_i dy \\
&= -\int_{\Omega_i} GLw_i dy + w_i - w_i \\
&= \int_{\mathbb{R}^n \backslash \Omega_i} GLw_i dy - w_i \\
&= \int_{\Gamma_i} \left(w_i \frac{\partial G}{\partial n} - \frac{\partial w_i}{\partial n} G \right) ds_y \\
&= -u_i^+(x), \quad x \in \mathbb{R}^n \backslash \Omega_i.
\end{aligned}$$

Therefore we can write

$$-\int_{\Omega_i} GLwdy = \begin{cases} -u_i^+, & x \in \mathbb{R}^n \backslash \Omega_i, \\ -w + u^- + \displaystyle\sum_{\substack{j=1,2,\ldots,N, \\ j \neq i}} u_j^+, & x \in \Omega_i. \end{cases}$$

Altogether, the full output of the controls $g(x)$ is as follows:

$$\begin{aligned}
v(x) &= -\left(w - \int_{\Omega_i} GLwdy - \sum_{j \neq i} \int_{\Omega_j} GLwdy \right) \\
&= \begin{cases} -u^-, & x \in \Omega_i,\ i = 1, 2, \ldots, N, \\ -\left(w - \displaystyle\sum_{j=1,2,\ldots,N} u_j^+ \right), & x \in \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N). \end{cases}
\end{aligned} \tag{3.1}$$

Consequently, these controls enable the cancellation of sound due to the exterior sources on the domains $\Omega_1, \Omega_2, \ldots, \Omega_N$ regardless of the specific choice of the auxiliary function w. The output of the controls outside $\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$ is given by $\sum_{j=1,2,\ldots,N} u_j^+ - w$. It basically duplicates the acoustic field generated inside the regions with the correction $-w$. More specifically, for any given Ω_i the controls double the output of the sources interior to a region on the way out and then halve the result as it comes into another region. As such, the overall acoustic field is given by

$$\begin{aligned}
u &= u_1^+ + u_2^+ + \cdots + u_N^+ + u^- + v \\
&= \begin{cases} u_1^+ + u_2^+ + \cdots + u_N^+, & x \in \Omega_i,\ i = 1, 2, \ldots, N, \\ -w + u^- + 2u_1^+ + 2u_2^+ + \cdots + 2u_N^+, & x \in \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N), \end{cases}
\end{aligned}$$

which means that the subdomains $\Omega_1, \Omega_2, \ldots, \Omega_N$ can communicate freely with each other without interference from outside sources.

THEOREM 3.1. *Suppose that $\Omega_1, \Omega_2, \ldots, \Omega_N$ are given, where $\Omega_i \subseteq \mathbb{R}^n$ are disjoint regions:* $\operatorname{dist}(\Omega_i, \Omega_j) \geq \epsilon > 0$ *if $i \neq j$, with the boundaries $\partial\Omega_1 = \Gamma_1, \partial\Omega_2 =$*

$\Gamma_2, \ldots, \partial\Omega_n = \Gamma_N$. *Assume that the total acoustic field in* $\mathbb{R}^n$ *is governed by* $Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + \cdots + f_N^+ + f^-$, *where the sources are located according to* $\mathrm{supp} f_1^+ \subset \Omega_1$, $\mathrm{supp} f_2^+ \subset \Omega_2, \ldots, \mathrm{supp} f_n^+ \subset \Omega_N$, *and* $\mathrm{supp} f^- \subset \mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)$. *Let the overall acoustic field* u *be represented as* $u = u_1^+ + u_2^+ + \cdots + u_N^+ + u^-$.

Let a control source $g = g(x)$ *be added to the other sources* $f(x)$ *such that the overall field* $\tilde{u}$ *governed by* $L\tilde{u} = f_1^+ + f_2^+ + \cdots + f_N^+ + f^- + g$ *satisfies*

$$\tilde{u} = \sum_{j=1,2,\ldots,N} u_j^+, x \in \Omega_i, \ i = 1, 2, \ldots, N. \tag{3.2}$$

Then the general solution for the desired control is given by

$$g = -Lw|_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}, \qquad g = 0|_{(\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}, \tag{3.3}$$

where $w = w(x)$ *satisfies the Sommerfeld condition at infinity and the following interface conditions:*

$$w\big|_{\Gamma_i} = u\big|_{\Gamma_i} \tag{3.4a}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_i} = \frac{\partial u}{\partial n}\Big|_{\Gamma_i} \tag{3.4b}$$

for all $i = 1, \ldots, N$.

Proof. We need to prove that any control g given by (3.3) is an appropriate control and, conversely, that any appropriate control g can be obtained by using a suitable auxiliary function w. Suppose we have a function $w(x)$ that satisfies (3.4a), (3.4b), and the Sommerfeld condition (2.3a) or (2.3b) at infinity. Then, formula (3.1) implies that the corresponding control (3.3) provides the desired properties eliminating the exterior sound u^- on $\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$.

Conversely, suppose a control g achieves the desired cancellation, so that equality (3.2) holds. Then, clearly, $g(x) = 0$ for $x \in \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$. Consequently, the output v of the control g is as follows:

$$v(x) = \int_{\mathbb{R}^n \backslash (\Omega_1 \cup \Omega_2 \cup \ldots \Omega_N)} G g dy = -u^-, \quad x \in \Omega_i, \ i = 1, \ldots N.$$

Consider the equation $-Lw = g - f_1^+ - f_2^+ - \cdots - f_N^+$. Its solution, subject to the Sommerfeld condition at infinity (2.3a) or (2.3b), satisfies

$$\begin{aligned} w &= -v + u_1^+ + u_2^+ + \cdots + u_N^+ \\ &= u, \quad x \in \Omega_i, \ i = 1, 2, \ldots, N. \end{aligned}$$

Since $w(x)$ is at least C^1 smooth on $\mathbb{R}^n$, it satisfies relations (3.4a) and (3.4b). Therefore the control $g(x)$ can be obtained by formula (3.3) applied to this particular $w(x)$, since $\mathrm{supp} f_1^+ \subset \Omega_1$, $\mathrm{supp} f_2^+ \subset \Omega_2, \ldots, \mathrm{supp} f_N^+ \subset \Omega_N$. ∎

3.2.2. Selective cancellation. Now suppose that in each subdomain Ω_i, we would like to eliminate all outside interference and, in addition, selectively eliminate sound from some other subdomains. It will be helpful to formulate a convenient way of keeping track of communications between the subdomains. For that purpose, let us

introduce an $N \times N$ matrix $\mathbf{M}$, such that each row i corresponds to a region Ω_i, and the entry (0 or 1) in each column is used to determine whether this Ω_i hears a region corresponding to that column or not. In other words, if the entry at the intersection of row i and column j is 0, then Ω_i hears Ω_j. If this entry is 1, then it does not. Obviously the diagonal of $\mathbf{M}$ is filled with zeros since the regions hear themselves. So, in the case of Theorem 2.1 we have

$$\mathbf{M} = \begin{pmatrix} 0 & 0 \\ 0 & 0 \end{pmatrix}$$

and for Theorem 2.2 we get

$$\mathbf{M} = \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix}.$$

Notice that no reciprocity in the communication pattern is assumed; i.e., the matrix $\mathbf{M}$ is not necessarily symmetric.

For a given matrix $\mathbf{M}$ that corresponds to a specific communication pattern between the regions $\Omega_1, \Omega_2, \ldots, \Omega_N$, we will now build the auxiliary function $w(x)$ and the controls $g(x)$ as before, i.e., in two stages. At the first stage, we take the auxiliary functions $w_i(x)$ for all Ω_i, $i = 1, \ldots, N$, that satisfy

$$w_i\big|_{\Gamma_i} = u\big|_{\Gamma_i}$$

and

$$\frac{\partial w_i}{\partial n}\Big|_{\Gamma_i} = \frac{\partial u}{\partial n}\Big|_{\Gamma_i},$$

as well as the Sommerfeld condition at infinity. We also require that each w_i be compactly supported near the corresponding Ω_i. Then, we build the supplementary controls:

$$g_i(x) = -Lw_i|_{\mathbb{R}^n \setminus \Omega_i}, \qquad g_i(x) = 0|_{\Omega_i}.$$

According to formula (2.10) applied to a given subdomain Ω_i, the output of these controls on $\mathbb{R}^n \setminus \Omega_i$ is

$$v_i = \int_{\mathbb{R}^n} G g_i dy = u_i^+ - w_i, \quad x \in \mathbb{R}^n \setminus \Omega_i, \tag{3.5}$$

and since w_i is taken compactly supported near Ω_i, we have $v_i = u_i^+$ near Ω_j, where $j = 1, 2, \ldots, N$ and $j \neq i$.

At the second stage, we start with introducing the auxiliary function $w(x)$, which satisfies the Sommerfeld radiation condition (2.3a) or (2.3b) at infinity. In addition, on each Γ_i we require that

$$w\big|_{\Gamma_i} = (u + \mathbf{e}_i^T \mathbf{M} \mathbf{v})\big|_{\Gamma_i}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_i} = \frac{\partial (u + \mathbf{e}_i^T \mathbf{M} \mathbf{v})}{\partial n}\Big|_{\Gamma_i}.$$

In these formulae, $\mathbf{e}_i$ is a vector with its ith component equal to 1 and all other components equal to 0, and

$$\mathbf{v} = \begin{pmatrix} v_1 \\ v_2 \\ \vdots \\ v_N \end{pmatrix},$$

where each v_i is obtained at the first stage with the help of the supplementary controls $g_i(x)$ according to formula (3.5).

Next, we define the control sources $g(x)$ as

$$g(x) = -Lw|_{\mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}, \qquad g(x) = 0|_{(\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}.$$

Their output $v = v(x)$, $x \in \mathbb{R}^n$, is given by

$$\begin{aligned} v(x) &= \int_{\mathbb{R}^n} Ggdy \\ &= -\int_{\mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)} GLwdy \\ &= -\left(w(x) - \int_{\Omega_1} GLwdy - \int_{\Omega_2} GLwdy - \cdots - \int_{\Omega_N} GLwdy \right), \\ &= \begin{cases} -(u^- + \mathbf{e}_i^T \mathbf{M} \mathbf{v}), & x \in \Omega_i, \\ -(w - u_1^+ - u_2^+ - \cdots - u_N^+), & x \in \mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N), \end{cases} \end{aligned} \tag{3.6}$$

which obviously enables the desired cancellation.

We now prove that this is in fact the general solution for the controls with the prescribed properties, i.e., that we obtain all possible controls.

THEOREM 3.2. *Suppose that $\Omega_1, \Omega_2, \ldots, \Omega_N$ are given, where $\Omega_i \subseteq \mathbb{R}^n$ are disjoint regions:* $\operatorname{dist}(\Omega_i, \Omega_j) \geq \epsilon > 0$ *if $i \neq j$, with the boundaries $\partial\Omega_1 = \Gamma_1, \partial\Omega_2 = \Gamma_2, \ldots, \partial\Omega_n = \Gamma_N$. Assume that the total acoustic field in $\mathbb{R}^n$ is governed by $Lu \equiv \Delta u + k^2 u = f = f_1^+ + f_2^+ + \cdots + f_N^+ + f^-$, where the sources are located according to* $\operatorname{supp} f_1^+ \subset \Omega_1$, $\operatorname{supp} f_2^+ \subset \Omega_2, \ldots, \operatorname{supp} f_n^+ \subset \Omega_N$, *and* $\operatorname{supp} f^- \subset \mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)$. *Let the overall acoustic field u be represented as $u = u_1^+ + u_2^+ + \cdots + u_N^+ + u^-$.*

Let a control source $g = g(x)$ be added to the other sources $f(x)$ such that the overall field $\tilde{u}$ governed by $L\tilde{u} = f_1^+ + f_2^+ + \cdots + f_N^+ + f^- + g$ satisfies

$$\tilde{u} = \mathbf{e}_i^T (\mathbf{1} - \mathbf{M}) \mathbf{u}, \ x \in \Omega_i, \ i = 1, 2, \ldots, N, \tag{3.7}$$

where $\mathbf{1}$ is an $N \times N$ matrix with all entries equal to 1, *and*

$$\mathbf{u} = \begin{pmatrix} u_1^+ \\ u_2^+ \\ \vdots \\ u_N^+ \end{pmatrix}.$$

Then, the general solution for the desired control is given by

$$g = -Lw|_{\mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}, \qquad g = 0|_{(\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)}, \tag{3.8}$$

where $w = w(x)$ satisfies the Sommerfeld condition at infinity and the following interface conditions:

$$w\big|_{\Gamma_i} = (u + \mathbf{e}_i^T \mathbf{M}\mathbf{v})\big|_{\Gamma_i} \tag{3.9a}$$

and

$$\frac{\partial w}{\partial n}\Big|_{\Gamma_i} = \frac{\partial (u + \mathbf{e}_i^T \mathbf{M}\mathbf{v})}{\partial n}\Big|_{\Gamma_i} \tag{3.9b}$$

for all $i = 1, \ldots, N$. Note that if $\mathbf{M} = \mathbf{0}$, then (3.7) *reduces to* (3.2)*, and the current theorem becomes the same as Theorem* 3.1.

Similarly to Theorem 2.2, Theorem 3.2 implies that the controls (3.8) are built using a predictor-corrector procedure. The predictor stage consists of computing $\mathbf{v}$ of (3.5), whereas the corrector stage consists of obtaining the overall composite controls $g(x)$ by means of the auxiliary function $w(x)$ defined via (3.9).

Proof. We need to prove that any control g given by (3.8) is an appropriate control and, conversely, that any appropriate control g can be obtained by using a suitable auxiliary function w. Suppose we have a function $w(x)$ that satisfies (3.9a), (3.9b), and the Sommerfeld condition at infinity. Then, according to formula (3.6), the corresponding control (3.8) provides the desired properties as it eliminates u^- on $\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$ and selectively allows the sound to propagate between the subdomains following a predetermined pattern $\mathbf{M}$.

Conversely, suppose that a control g achieves the desired cancellation; see formula (3.7). Then, $g(x) = 0$ for $x \in \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$, and the output v of the control g is

$$\begin{aligned} v(x) &= \int_{\mathbb{R}^n \setminus (\Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N)} G g dy \\ &= -(u^- + \mathbf{e}_i^T \mathbf{M}\mathbf{v}),\ x \in \Omega_i,\ i = 1, 2, \ldots, N. \end{aligned}$$

Consider the equation $-Lw = g - f_1^+ - f_2^+ - \cdots - f_N^+$. Its solution, subject to the Sommerfeld condition at infinity (2.3a) or (2.3b), satisfies

$$\begin{aligned} w &= -v + u_1^+ + u_2^+ + \cdots + u_N^+ \\ &= \mathbf{e}_i^T (\mathbf{1} - \mathbf{M})\mathbf{u},\ x \in \Omega_i,\ i = 1, 2, \ldots, N. \end{aligned}$$

Since $w(x)$ is at least C^1 smooth on $\mathbb{R}^n$, it satisfies the interface conditions (3.9a) and (3.9b). Therefore, the control $g(x)$ can be obtained by formula (3.8) applied to this $w(x)$, because $\operatorname{supp} f_1^+ \subset \Omega_1$, $\operatorname{supp} f_2^+ \subset \Omega_2, \ldots, \operatorname{supp} f_N^+ \subset \Omega_N$. ∎

4. Generalized Calderon's potentials. We will now show how the split between $u_1^+, u_2^+, \ldots, u_N^+$, and u^- can be conveniently described in terms of the generalized potentials and boundary projection operators of Calderon's type. For more detail, the reader is referred to the work of Lončarić, Ryaben'kii, and Tsynkov [13].

Consider some function $u(x)$ that satisfies $Lu = 0$, where $x \in \Omega_i$ for a given i. Then the Green's formula yields

$$u(x) = \int_{\Gamma_i} \left(u \frac{\partial G}{\partial n} - \frac{\partial u}{\partial n} G \right) ds_y, \quad x \in \Omega_i. \tag{4.1}$$

Note than the direction of the normal n is fixed to always point outward from a given domain Ω_i. A generalized potential of Calderon's type with vector density $\xi_{\Gamma_i} = (\xi_0, \xi_1)$ specified on Γ_i is defined by the following formula:

$$P_{\Omega_i}\xi_{\Gamma_i}(x) = \int_{\Gamma_i} \left(\xi_0 \frac{\partial G}{\partial n} - \xi_1 G\right) ds_y, \quad x \in \Omega_i, \tag{4.2}$$

which is similar to (4.1) except that we do not require ahead of time that ξ_0 and ξ_1 in (4.2) be the boundary values of some function u that solves $Lu = 0$ on Ω_i and its normal derivative. With the help of (4.2), formula (4.1) can be rewritten as

$$u = P_{\Omega_i}\left(u, \frac{\partial u}{\partial n}\right)\Big|_{\Gamma_i}, \ x \in \Omega_i.$$

Next, for any sufficiently smooth function v specified on Ω_i, we define its vector trace on Γ_i as

$$Tr_i\, v = \left(v, \frac{\partial v}{\partial n}\right)\Big|_{\Gamma_i} \tag{4.3}$$

and then introduce the boundary operator as P_{Γ_i} as a combination of the potential P_{Ω_i} of (4.2) and trace Tr_i of (4.3):

$$P_{\Gamma_i}\xi_{\Gamma_i} = Tr_i\, P_{\Omega_i}\xi_{\Gamma_i}. \tag{4.4}$$

Note that the operator P_{Γ_i} is a projection, $P_{\Gamma_i}^2 = P_{\Gamma_i}$.

The previous construction can easily be changed from the use of surface integrals to that of volume integrals. Given a vector density $\xi_{\Gamma_i} = (\xi_0, \xi_1)$, we take a sufficiently smooth auxiliary function $w(x)$ that is compactly supported near Γ_i and such that

$$Tr_i\, w = \xi_{\Gamma_i}. \tag{4.5}$$

Then, the potential (4.2) can be redefined as follows:

$$\begin{aligned} P_{\Omega_i}\xi_{\Gamma_i}(x) &= w(x) - \int_{\Omega_i} GLw dy \\ &= \int_{\mathbb{R}^n \setminus \Omega_i} GLw dy, \ x \in \Omega_i. \end{aligned} \tag{4.6}$$

Note that $P_{\Omega_i}\xi_{\Gamma_i}(x)$ of (4.6) does not depend on the specific choice of $w(x)$ as long as condition (4.5) is satisfied. We can also define the exterior potential, $Q_{\mathbb{R}^n\setminus\Omega_i}\xi_{\Gamma_i}(x)$, $x \in \mathbb{R}^n\setminus\Omega_i$, for the complementary domain $\mathbb{R}^n\setminus\Omega_i$ as

$$\begin{aligned} Q_{\mathbb{R}^n\setminus\Omega_i}\xi_{\Gamma_i}(x) &= w(x) - \int_{\mathbb{R}^n\setminus\Omega_i} GLw dy \\ &= \int_{\Omega_i} GLw dy, \ x \in \mathbb{R}^n\setminus\Omega_i. \end{aligned} \tag{4.7}$$

The exterior projection operator Q_{Γ_i} will be given by

$$Q_{\Gamma_i}\xi_{\Gamma_i} = Tr_i\, Q_{\mathbb{R}^n\setminus\Omega_i}\xi_{\Gamma_i}. \tag{4.8}$$

Combining (4.2), (4.6), and (4.7), we obtain a scalar function defined on both Ω_i and $\mathbb{R}^n\backslash\Omega_i$:

$$\int_{\Gamma_i}\left(\xi_0\frac{\partial G}{\partial n}-\xi_1 G\right)ds_y=\begin{cases}P_{\Omega_i}\xi_{\Gamma_i}(x), & x\in\Omega_i,\\ -Q_{\mathbb{R}^n\backslash\Omega_i}\xi_{\Gamma_i}(x), & x\in\mathbb{R}^n\backslash\Omega_i.\end{cases}\tag{4.9}$$

As has already been seen, we can calculate each branch of (4.9) using volumetric integrals instead of surface integrals.

Now let $u=u_i^+ + u_i^-$, where u_i^+ originates inside its corresponding Ω_i and u_i^- originates from outside of Ω_i. That is, $u_i^- = u^- + \sum_{j\neq i} u_i^+$ is the entire incoming component for Ω_i. Also denote $\xi_{\Gamma_i}=(u,\frac{\partial u}{\partial n})|_{\Gamma_i}$ and

$$\xi_{\Gamma_i}^+=\left(u_i^+,\frac{\partial u_i^+}{\partial n}\right)\Big|_{\Gamma_i},$$

$$\xi_{\Gamma_i}^-=\left(u_i^-,\frac{\partial u_i^-}{\partial n}\right)\Big|_{\Gamma_i}.$$

According to formula (4.9) and definitions of the projections (4.4) and (4.8), we then have

$$\begin{aligned}P_{\Gamma_i}\xi_{\Gamma_i}&=\xi_{\Gamma_i}^-,\\ Q_{\Gamma_i}\xi_{\Gamma_i}&=\xi_{\Gamma_i}^+.\end{aligned}\tag{4.10}$$

Hence the sum of the two projections is the identity $P_{\Gamma_i}+Q_{\Gamma_i}=I$. Formula (4.10) renders the wave split. The space Ξ_{Γ_i} of all two-dimensional vector functions ξ_{Γ_i} is split into a direct sum of two subspaces: $\Xi_{\Gamma_i}=\Xi_{\Gamma_i}^+\oplus\Xi_{\Gamma_i}^-$, where $\Xi_{\Gamma_i}^-=ImP_{\Gamma_i}\equiv KerQ_{\Gamma_i}$ contains traces of all incoming waves and $\Xi_{\Gamma_i}^+=ImQ_{\Gamma_i}\equiv KerP_{\Gamma_i}$ contains traces of all outgoing waves. The split is done only on the boundary, and no knowledge of the wave sources is needed. Any function ξ_{Γ_i} is represented as $\xi_{\Gamma_i}^-+\xi_{\Gamma_i}^+$, where $\xi_{\Gamma_i}^-$ can be extended to Ω_i and $\xi_{\Gamma_i}^+$ can be extended to $\mathbb{R}^n\backslash\Omega_i$, as solutions of the homogeneous equation $Lu=0$. The extensions are given by the incoming and outgoing branches of the potential:

$$P_{\Omega_i}\xi_{\Gamma_i}=P_{\Omega_i}\xi_{\Gamma_i}^-=u_i^-,\quad x\in\Omega_i,$$

and

$$Q_{\mathbb{R}^n\backslash\Omega_i}\xi_{\Gamma_i}=Q_{\mathbb{R}^n\backslash\Omega_i}\xi_{\Gamma_i}^+=u_i^+,\quad x\in\mathbb{R}^n\backslash\Omega_i,$$

respectively. If a given ξ_{Γ_i} satisfies the boundary equation with projection

$$P_{\Gamma_i}\xi_{\Gamma_i}=\xi_{\Gamma_i},\tag{4.11}$$

then this function is the trace of some u_i^-. That is, it is extendible to Ω_i as a solution of $Lu=0$. In other words, those and only those ξ_{Γ_i} that are traces of solutions to the homogeneous equation $Lu=0$ on Ω_i satisfy the Calderon boundary equation (4.11). A reciprocal result holds for $Q_{\Gamma_i}\xi_{\Gamma_i}=\xi_{\Gamma_i}$.

Having defined the potentials and projections for individual domains Ω_i, we will now extend the definitions to the entire composite domain $\Omega = \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$. Denote $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \cdots \cup \Gamma_N$, and let ξ_Γ be a two-dimensional vector function on this composite boundary. The interior branch of the potential with the density ξ_Γ is defined similarly to (4.6):

$$P_\Omega \xi_\Gamma(x) = \int_{\mathbb{R}^n \setminus \Omega} GLw dy, \quad x \in \Omega,$$

where $w = w(x)$ is an auxiliary function that satisfies the interface conditions

$$Tr\, w = \xi_\Gamma \quad \Longleftrightarrow \quad \left\{ Tr_i\, w = \xi_\Gamma\big|_{\Gamma_i},\ i = 1, 2, \ldots, N \right\}$$

and the appropriate Sommerfeld condition (2.3a) or (2.3b) at infinity. Other than that, $w(x)$ may be arbitrary. Likewise, the exterior branch of the potential is given by

$$Q_{\mathbb{R}^n \setminus \Omega} \xi_\Gamma(x) = \int_\Omega GLw dy, \quad x \in \mathbb{R}^n \setminus \Omega.$$

Using definition (4.7), for the exterior region $\mathbb{R}^n \setminus \Omega$ we can write

$$Q_{\mathbb{R}^n \setminus \Omega} \xi_\Gamma(x) = \sum_{i=1}^N Q_{\mathbb{R}^n \setminus \Omega_i} \xi_{\Gamma_i}(x) = \sum_{i=1}^N u_i^+(x), \quad x \in \mathbb{R}^n \setminus \Omega, \tag{4.12}$$

whereas for the interior of Ω_i, $i = 1, 2, \ldots, N$, we have according to (4.6) and (4.7)

$$\begin{aligned} P_\Omega \xi_\Gamma(x) &= P_{\Omega_i} \xi_{\Gamma_i}(x) - \sum_{\substack{j=1 \\ j \neq i}}^N Q_{\mathbb{R}^n \setminus \Omega_j} \xi_{\Gamma_j}(x) \\ &= u_i^- - \sum_{\substack{j=1 \\ j \neq i}}^N u_j^+(x) = u^-(x), \quad x \in \Omega_i. \end{aligned} \tag{4.13}$$

In formula (4.13), u_i^- denotes the entire incoming field with respect to the domain Ω_i. In other words, u_i^- is composed of u^- and u_j^+ from all Ω_j except $j = i$.

The projections for composite domains are defined as traces of the potentials:

$$\begin{aligned} P_\Gamma \xi_\Gamma &= Tr\, P_\Omega \xi_\Gamma, \\ Q_\Gamma \xi_\Gamma &= Tr\, Q_{\mathbb{R}^n \setminus \Omega} \xi_\Gamma. \end{aligned} \tag{4.14}$$

They possess the same properties as the projections built previously for individual subdomains. Namely, $P_\Gamma + Q_\Gamma = I$, and the projections render the wave split at the interface Γ into incoming waves $\xi_\Gamma^- = P_\Gamma \xi_\Gamma$ and outgoing waves $\xi_\Gamma^+ = Q_\Gamma \xi_\Gamma$.

Now that we have defined the potentials and projections for individual subdomains and for the composite domain, we can once again obtain the controls for composite domains. First, we will investigate the simple case of fully eliminating the exterior noise inside $\Omega = \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$, i.e., eliminating the entire incoming

component of the acoustic field with respect to Ω. Our control function $g = g(x)$ is defined as

$$g(x) = -Lw|_{\mathbb{R}^n\setminus\Omega}, \qquad g(x) = 0|_{\Omega}, \tag{4.15}$$

giving the output $v = v(x)$ in the form

$$v(x) = \begin{cases} -P_\Omega \xi_\Gamma(x), & x \in \Omega, \\ -w(x) + Q_{\mathbb{R}^n\setminus\Omega}\xi_\Gamma(x), & x \in \mathbb{R}^n\setminus\Omega. \end{cases} \tag{4.16}$$

Hence we achieve the desired cancellation on Ω, because for $x \in \Omega$ according to (4.13) we have $v(x) = -P_\Omega\xi_\Gamma(x) = -u^-(x)$. As for the exterior region $\mathbb{R}^n\setminus\Omega$, formulae (4.12), (4.13), and (4.16) indicate that the controls basically duplicate the output of a given Ω_i and subsequently halve it as it enters another subdomain Ω_j.

Next, we will explore the operator interpretation of the selective cancellation for individual subdomains. As before, assume that the $N \times N$ communication matrix $\mathbf{M}$ is given that determines which regions are allowed to hear one another. If the entry m_{ij} of this matrix at the intersection of row i and column j is equal to zero, then Ω_i hears Ω_j; otherwise, if $m_{ij} = 1$, then Ω_i does not hear Ω_j. In doing so, no reciprocity is assumed; i.e., the matrix $\mathbf{M}$ is not necessarily symmetric. At the first stage of building the selective controls, we will modify the boundary trace ξ_Γ with the help of the matrix $\mathbf{M}$.

Let $u = u(x)$ be the overall acoustic field from all original sources, and let $\xi_\Gamma = Tr\, u$. Denote $\xi_{\Gamma_i} = \xi_\Gamma\big|_{\Gamma_i}$ and introduce

$$\tilde{\xi}_\Gamma \stackrel{\text{def}}{=} \left\{ \tilde{\xi}_{\Gamma_i},\ i = 1, 2, \ldots, N \,\middle|\, \tilde{\xi}_{\Gamma_i} = \xi_{\Gamma_i} + \sum_{\substack{j=1 \\ m_{ij}=1}}^{N} Tr_i\, Q_{\mathbb{R}^n\setminus\Omega_j}\xi_{\Gamma_j} \right\}. \tag{4.17}$$

At the second stage, we obtain the controls $\tilde{g}$ according to the same formula (4.15) as we used previously, but substituting a different auxiliary function $\tilde{w} = \tilde{w}(x)$. In addition to the appropriate Sommerfeld condition (2.3a) or (2.3b) at infinity, this new auxiliary function is supposed to satisfy an alternative interface condition at Γ:

$$Tr\, \tilde{w} = \tilde{\xi}_\Gamma, \tag{4.18}$$

where $\tilde{\xi}_\Gamma$ is defined by formula (4.17). The output of the control sources $\tilde{g}(x)$ on the domain $\Omega = \Omega_1 \cup \ldots \cup \Omega_N$ is given by the potential

$$\begin{aligned} v(x) =& -P_\Omega\tilde{\xi}_\Gamma(x) = -P_{\Omega_i}\tilde{\xi}_{\Gamma_i}(x) + \sum_{\substack{j=1 \\ j\neq i}}^{N} Q_{\mathbb{R}^n\setminus\Omega_j}\tilde{\xi}_{\Gamma_j} \\ =& -P_{\Omega_i}\xi_{\Gamma_i}(x) - \sum_{\substack{j=1 \\ m_{ij}=1}}^{N} Q_{\mathbb{R}^n\setminus\Omega_j}\xi_{\Gamma_j} + \sum_{\substack{j=1 \\ j\neq i}}^{N} Q_{\mathbb{R}^n\setminus\Omega_j}\tilde{\xi}_{\Gamma_j} \\ =& -u^- - \sum_{\substack{j=1 \\ j\neq i}}^{N} u_j^+ - \sum_{\substack{j=1 \\ m_{ij}=1}}^{N} u_j^+ + \sum_{\substack{j=1 \\ j\neq i}}^{N} u_j^+ \\ =& -u^- - \sum_{\substack{j=1 \\ m_{ij}=1}}^{N} u_j^+, \quad x \in \Omega_i, \end{aligned}$$

where we have taken into account that $P_{\Omega_i} Tr_i Q_{\mathbb{R}^n \setminus \Omega_j} \xi_{\Gamma_j} = Q_{\mathbb{R}^n \setminus \Omega_j} \xi_{\Gamma_j}$ for $x \in \Omega_i$ if $i \neq j$. Consequently, the overall field on Ω after applying the control $\tilde{g}$ is given by

$$\begin{aligned}\tilde{u}(x) &= u(x) + v(x) \\ &= u^-(x) + \sum_{j=1}^{N} u_j^+(x) - u^-(x) - \sum_{\substack{j=1 \\ m_{ij}=1}}^{N} u_j^+(x) \\ &= \sum_{\substack{j=1 \\ m_{ij}=0}}^{N} u_j^+(x), \quad x \in \Omega_i.\end{aligned}$$

In other words, the unwanted exterior noise $u^-(x)$ gets canceled out on all Ω_i, $i = 1, \ldots, N$, as before. Moreover, the sound field on a given Ω_i contains only the contributions from those Ω_j for which $m_{ij} = 0$, i.e., from those regions that Ω_i is allowed to hear. This is precisely the type of selective cancellation that we strived to achieve. Note also that even though we did not formulate the results in this section as theorems, it is clear that they are equivalent to the theorems of section 3.

5. A more realistic formulation. As of yet, we have only used the Calderon potentials and projections of section 4 to recast the results of section 3 in a more convenient yet equivalent operator form. However, the operator framework introduced in section 4 will also allow us to analyze a more elaborate formulation of the problem compared to that from section 3.

Instead of the Helmholtz equation (2.1), consider a general variable coefficient differential (or operator) equation

$$Lu = f, \tag{5.1}$$

where both the unknown solution $u = u(x)$ and the given right-hand side $f = f(x)$ are defined on some domain Ω_0 that may, but does not have to, coincide with the entire space $\mathbb{R}^n$. In the context of acoustics, (5.1) may, for example, govern the propagation of sound through a nonhomogeneous medium, where the propagation speed depends on the location.

A very important consideration is to define the solvability class for (5.1) on Ω_0. In most generic terms, let us require that $u \in U$, where U is a certain linear subspace of the space of all sufficiently smooth functions on Ω_0. We will assume that the solution $u = u(x)$ of (5.1) exists and is unique in U, provided that the right-hand side f belongs to another appropriate class F. Note that in the context of sections 2, 3, and 4, we had $\Omega_0 = \mathbb{R}^n$ and the class U was defined by the Sommerfeld condition (2.3a) or (2.3b) at infinity.

Since for any $f \in F$ there is a unique solution $u \in U$ of (5.1), we can introduce the inverse operator $G: F \longmapsto U$ that provides the solution for a given right-hand side:

$$u = Gf, \quad u \in U, \quad f \in F. \tag{5.2}$$

Note that previously (in the context of constant coefficients) the operator G was introduced by means of the convolution (2.4) with the fundamental solution (2.5) or (2.6). For variable coefficients, and/or when the domain Ω_0 is smaller than the entire

space $\mathbb{R}^n$, the apparatus of fundamental solutions does not apply. Yet the inverse operator G of (5.2) is well defined. In practice, it can be computed; i.e., problem (5.1) subject to the condition $u \in U$ can be discretized on Ω_0 and solved numerically.

Another very important consideration is the structure of the boundary trace that corresponds to the new operator L of (5.1). For the Laplace and Helmholtz operators, the vector traces on Γ are defined as traces of the solution itself and of the normal derivative; see formula (4.3). In the general theory of Calderon's operators (see [19]), the traces are constructed to guarantee a key property of the potentials (4.6), (4.7) and projections (4.4), (4.8), namely, their independence of the auxiliary function $w(x)$ as long as it has the correct trace, i.e., as long as the interface condition (4.5) is satisfied. For the second order variable coefficient operators L that have the form

$$Lv = \nabla(p\nabla v) + \{\text{lower order terms}\}, \quad p = p(x), \tag{5.3}$$

the Neumann data reduce to the standard normal derivative, and, consequently, the previous definition of the trace (see (4.3)) applies with no change. Hereafter, we will assume for simplicity that this is the case. This assumption does not entail a considerable loss of generality because operators (5.3) cover many important applications.

Having introduced the operator equation (5.1), defined the inverse (5.2), and identified the boundary trace Tr (4.3), we can extend all the operator constructions of section 4 in a straightforward manner, as done in [13] for a single domain. The only thing that will change is that every time a volumetric convolution with the fundamental solution appears in an equation, it ought to be replaced by the operator G of (5.2) applied to the corresponding source function. This way, we define the generalized Calderon potentials (cf. formulae (4.6) and (4.7))

$$P_{\Omega_i}\xi_{\Gamma_i}(x) = G\Big\{ Lw\big|_{\mathbb{R}^n\setminus\Omega_i} \Big\}, \quad x \in \Omega_i, \tag{5.4}$$

$$Q_{\mathbb{R}^n\setminus\Omega_i}\xi_{\Gamma_i}(x) = G\Big\{ Lw\big|_{\Omega_i} \Big\}, \quad x \in \mathbb{R}^n\setminus\Omega_i, \tag{5.5}$$

and the boundary projection operators (cf. formulae (4.4) and (4.8))

$$P_{\Gamma_i}\xi_{\Gamma_i} = Tr_i P_{\Omega_i}\xi_{\Gamma_i}, \tag{5.6}$$

$$Q_{\Gamma_i}\xi_{\Gamma_i} = Tr_i Q_{\mathbb{R}^n\setminus\Omega_i}\xi_{\Gamma_i} \tag{5.7}$$

for all $i = 1, 2, \ldots, N$. Combined operators for the composite domain $\Omega = \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$ are also introduced similarly to section 4, according to formulae (4.12), (4.13), and (4.14), where the individual operators are now given by (5.4)–(5.7).

The fundamental properties of the projections (5.6) and (5.7) are the same as before. Namely, the function $u \in U$ is a solution to the homogeneous equation $Lu = 0$ on the domain Ω_i if and only if its boundary trace $\xi_{\Gamma_i} = Tr_i u$ satisfies the boundary equation with projection,

$$P_{\Gamma_i}\xi_{\Gamma_i} = \xi_{\Gamma_i}. \tag{5.8}$$

Similarly, the function $u \in U$ is a solution to the homogeneous equation $Lu = 0$ on the complementary domain $\Omega_0 \setminus \Omega_i$ if and only if its boundary trace $\xi_{\Gamma_i} = Tr_i u$ satisfies the boundary equation with projection,

$$Q_{\Gamma_i}\xi_{\Gamma_i} = \xi_{\Gamma_i}. \tag{5.9}$$

Accordingly, if the solutions to (5.1) are interpreted as waves, then one can say that the boundary equations with projections (5.8) and (5.9) render the wave split into incoming and outgoing with respect to a given Ω_i. If $u \in U$ and $Tr_i u = \xi_{\Gamma_i}$, then

$$\xi_{\Gamma_i} = P_{\Gamma_i}\xi_{\Gamma_i} + Q_{\Gamma_i}\xi_{\Gamma_i} \stackrel{\text{def}}{=} \xi^-_{\Gamma_i} + \xi^+_{\Gamma_i},$$

where the component $\xi^-_{\Gamma_i}$ is the trace of the incoming field due to the sources outside Ω_i,

$$\xi^-_{\Gamma_i} = Tr_i u_i^-, \quad Lu_i^- = 0 \ \text{ for } \ x \in \Omega_i,$$

and the component $\xi^+_{\Gamma_i}$ is the trace of the outgoing field due to the sources inside Ω_i,

$$\xi^+_{\Gamma_i} = Tr_i u_i^+, \quad Lu_i^+ = 0 \ \text{ for } \ x \in \mathbb{R}^n \setminus \Omega_i.$$

In doing so, the entire space $\Xi_{\Gamma_i} = \{\xi_{\Gamma_i}\}$ can be represented as a direct sum of the traces of incoming waves and those of the outgoing waves:

$$\Xi_{\Gamma_i} = \Xi^-_{\Gamma_i} \oplus \Xi^+_{\Gamma_i}.$$

The exact same results automatically extend to the operators built for the composite domain $\Omega = \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$ as well.

Moreover, all the conclusions of sections 3 and 4 regarding the active control sources are also preserved. Namely, to cancel out the unwanted exterior sound u^- on $\Omega = \Omega_1 \cup \Omega_2 \cup \cdots \cup \Omega_N$, we build the controls according to formula (4.15):

$$g(x) = -Lw|_{\mathbb{R}^n \setminus \Omega}, \qquad g(x) = 0|_{\Omega}, \tag{5.10}$$

where the auxiliary function $w = w(x)$ satisfies $w \in U$ and $Trw = Tru$, and $u = u(x)$ is the overall acoustic field. We emphasize that in order to obtain the controls $g(x)$ of (5.10), we only need to know Tru at the boundary $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \cdots \cup \Gamma_N$. Moreover, the coefficients of the operator L, i.e., the properties of the medium, only need to be known outside Ω on the region where the auxiliary function $w(x) \neq 0$. This region can be a narrow layer outside Γ right next to it. This conclusion seems counterintuitive at first glance, because the controls $g(x)$ of (5.10) are supposed to eliminate the unwanted component of the field inside Ω, and yet it seems that the properties of the medium do not need to be known. The explanation, however, is quite simple. Both the unwanted noise $u^-(x)$ and the output of the controls $v(x) = Gg$ propagate across one and the same medium, and to achieve cancellation we do not necessarily need to know what this medium is inside Ω. Equivalently, one can think that the entire incoming component $u^-(x)$ is canceled by the controls (5.10) right at the entry to Ω so that it does not propagate any further; see [13, sections 4.2 and 4.3].

Active controls $\tilde{g}(x)$ that will render the selective cancellation of sound on the system of subdomains Ω_i, $i = 1, 2, \ldots, N$, according to a predetermined communication pattern $\mathbf{M}$ are also obtained with the help of formula (5.10). The only difference is that as before, the application of this formula requires a preliminary stage. At this preliminary stage, we construct a modified boundary trace $\tilde{\xi}_\Gamma$ according to formula (4.17), where the operators $Q_{\mathbb{R}^n \setminus \Omega_j}$ are defined by (5.5). At the final stage, we take an auxiliary function $\tilde{w} = \tilde{w}(x)$ that satisfies $\tilde{w} \in U$ and $Tr\tilde{w} = \tilde{\xi}_\Gamma$ and substitute it into (5.10), thus obtaining the desired selective controls $\tilde{g}(x)$.

For more detail on the theory of generalized Calderon potentials and projections, as well as their efficient computation by means of the method of difference potentials, we refer the reader to the monograph [19].

6. Conclusions. We have introduced and studied the problem of active control of sound for composite regions. This problem is, in fact, a particular inverse source problem for the differential equation (or system) that governs the sound field. Allowing for composite domains is a key innovation proposed here as compared to our previous work on the subject (see [13] and related references). We obtained a closed form general solution for the control sources. This solution allows all individual subdomains to either communicate freely with one another or else be shielded from their peers. In doing so, no reciprocity is assumed; i.e., for a given pair of subdomains one may be allowed to hear the other but not necessarily vice versa.

If the controls in the composite case are built exactly as in the previously analyzed case of simple, i.e., arcwise connected, domains, then the communications between all subdomains is allowed. In other words, by default all subdomains hear one another. If, however, a particular subdomain is not allowed to hear another given subdomain, then the supplementary controls are employed prior to building the final set of controls. The role of the supplementary controls (one can call it the predictor stage) is to communicate the specific acoustic output of the domain not to be heard to the domain that is not allowed to hear it. Subsequently, the final controls (corrector stage) use these data to render the desired sound cancellation.

Moreover, the general solution requires no information on the original acoustic sources and can be constructed based solely on the knowledge of the field quantities at the boundaries of the subdomains. In practice, those quantities can be obtained by measurements. In doing so, the methodology guarantees the exact volumetric cancellation of the unwanted noise, as opposed to many other techniques available in the literature that would only provide for a pointwise or directional cancellation, and would not even offer an approach to selective cancellation on composite domains.

The problem is solved for a general formulation that allows the propagation of sound across a medium with variable characteristics. In doing so, to cancel out the outside sound on a given domain, no actual knowledge of the medium properties on this domain is required. The explanation of this seemingly counterintuitive behavior is simple—both the original sound and the output of the controls propagate across one and the same medium, and for building the control sources we do not necessarily need to know what this medium is.

It is also important to mention that for every subdomain there is a component of the acoustic field to be canceled out and another component to be left unaffected. Yet the quantities at the boundary that need to be measured in order to build the control system can pertain to the overall field rather than only to its unwanted component, and the methodology will automatically distinguish between the two. Of course, the locations and shapes of the subdomains need to be known ahead of time.

Finally, it is clear that in the context of implementation, obtaining the continuous data, as well as providing a continuous excitation (control sources), along the interface Γ is not practical. Instead, the problem needs to be discretized so that only finite arrays of individual sensors (microphones) and actuators (loudspeakers) are used. A powerful apparatus for the analysis of discrete active shielding problems is provided by the method of difference potentials [19]. This method offers a comprehensive finite-difference theory, which is fully analogous to the continuous theory of Calderon's operators [3, 23] and in many instances even goes beyond it. As mentioned in section 1, discrete active controls have been built, and their properties established, for various settings; see [14, 15, 16, 18, 22, 25, 27, 28]. In particular, the case of a composite region in the discrete framework is analyzed in [21]. A brief account of the method of difference potentials, along with the analysis of discrete active shielding problems, can be found in [20, Chapter 14].

ON THE UPLINK OF A CELLULAR SYSTEM WITH IMPERFECT POWER CONTROL AND MULTIPLE SERVICES*

JOHN A. MORRISON†‡ AND PHIL WHITING†

Abstract. We analyze the reverse link of a single wireless cell in which mobile phones simultaneously transmit to the base station using code division multiple access (CDMA). The mobiles are transmitting data which is delay intolerant, so that scheduling cannot be employed. There is a finite number of data classes, and the users transmit either data or a lower rate synchronizing signal. To overcome the near-far problem, received power control is used, which has a log-normal error. For each class there is an outage probability that the user's signal-to-noise ratio (SNR) will be met (when active and when idle). Refinements of the central limit theorem are used to determine the number of users of each class that can be supported, i.e., the capacity. The approximation can also be used to determine the minimal target powers necessary to meet the outage requirements. Comparison with simulation shows these approximations to be accurate.

1. Introduction.

This paper considers the capacity of the reverse link of a cellular code division multiple access (CDMA) system in which there are multiple circuit-switched data connections, and the minimal target powers when the link is operating within its capacity. Each data connection is drawn from one of a small number of data classes, with its own quality of service (QoS) requirements. The data in all classes is delay *intolerant*, so that scheduling of the data is infeasible. Furthermore, while users are connected, data is transmitted periodically to the base station in "bursts"; otherwise they are "idle," and a synchronization signal is transmitted. Active transmissions are made up of a series of channel encoded frames. The base station makes no attempt to coordinate user transmissions, and so frames will be undecodable when there is excessive interference from other user transmissions. Interference is generated both when users are active and when they are idle.

One way to manage this interference is to endeavor to directly control the received signal-to-noise-ratio (SNR) of the user frames by power control [15],[16]. However, since data transmissions are bursty, of short duration, and difficult to anticipate, management of *user SNR* by such a power control may be difficult to accomplish. Instead we propose a power control with the simpler objective of maintaining received power only. The interference then fluctuates according to the activity of the users themselves and the target powers. Clearly the target powers should depend on the number of users of each class which are connected at any point as well as their QoS. However it is not a priori clear how to set these targets. One possibility is to set them using stochastic approximation, raising and lowering the targets according to user performance. This is not our approach. Instead we propose to set the targets

directly using the statistics of activity for each class, which we suppose known. (In some implementations of the system it may be possible to actually control the degree of activity and so make the usual trade-offs between throughput and the number of users supported.)

Users set their transmit powers in conjunction with a pilot signal measured by the mobile receivers. The base station then compares the user's received power with its target and sends corrections to the mobile phone (henceforward referred to as a mobile) via a feedback link. The feedback link increases the accuracy of the power control. A distributed algorithm for perfect power control, and its convergence, were investigated in [12]. Ideal power control (very small error in the received power) is of course difficult to achieve, however, and we suppose that there is a nonnegligible residual error. The marginal distribution of this error at any instant we take to be log-normal, and the underlying standard deviation is supposed known. It will be convenient to quote relative powers in decibels (dB), which is $10\log_{10}$.

The QoS requirements specify the fraction of packets that is allowed to be undecodable at the receiver. We propose to control this fraction by maintaining the received signals so that the instantaneous probability of an outage is small. An outage occurs when the SNR ratio falls below a predetermined threshold, which we also suppose known. Our approach is thus related to the one described in [3] where outage probabilities are determined by modeling the distribution of users as a spatial Poisson process.

Each class i is thus characterized by requirements both when active and idle and which are in general distinct. These are the users' rate, the SNR thresholds $\alpha_i/W, \beta_i/W$, and the outage probabilities L_i, l_i. Here W is the spread bandwidth. Additionally we suppose that the probability that a user is active is w_i. The standard deviation of power control error may also be taken to depend on whether the user is active as well as on the user's data class. In what follows it will be convenient to work with the bit-energy-to-interference density ratio E_b/I_0, which determines the performance of the base station decoder and is usually quoted in the design of wireless communication links. E_b/I_0 is related to the SNR threshold via the processing gain to be $E_\mathrm{b}/I_0 = \alpha_i/R_i$, where R_i is the class i active bit rate and a similar relationship when the user is idle.

To estimate the number of users that can be supported and determine the minimal target powers when the link is operating within its capacity, we suppose that the system is large-scale and use a central limit approximation. Put crudely, we are relying on the approximately normal behavior of the interference from users in the same cell. The statistics of this interference is a combination of random activity and the user power control errors, as already mentioned. In order to have a satisfactory approximation, it will turn out that estimates involving the density of these statistics will be needed and not just their distribution. Indeed we are led to a model in which the scaled interference converges to a fixed quantity plus a normal error with scale $1/\sqrt{K}$, where K is a scale factor for the number of users in the system. The interference from users in adjacent cells is modeled along the lines in [3], [4], with allowance for skewness and kurtosis.

Before continuing, we would like to discuss some other related references. First it should be noted that the model used in our paper is very similar to Model 2 described in [1] and that we also address similar performance questions. We refer readers to [1] but note that both papers are concerned with received power control and corresponding received power targets, both have more than one class of users, and both are concerned with outage, referred to as the service availability probability

(SAP) in [1]; see our (2.8) and (2.9). Both models also consider imperfect power control with a marginal log-normal error. However, the methods of analysis are very different, with the imperfect power control (SAP) in [1] being approximated using an estimate given in [8], whereas our results are obtained via refined asymptotics based on the central limit theorem, as mentioned earlier. Finally, our results lead to the determination of minimum feasible received power targets themselves as well as explicit constraints for the capacity, as in Propositions 2.1 and 2.2.

Next we would like to mention other papers related to our work. Results for a single cell, two service class system were obtained in [13] where in this case resources were allocated according to a mechanism of dynamically adapting the spreading gain (chip-to-data bit ratio). Second there is the well-known paper [6] which is for a pure voice system but does not consider power control errors. (The influence of power control error on reverse link capacity was the subject of detailed investigation in subsequent studies; see, for example, [2] and [14].) Additionally, in our system, load control might be affected by active rate control (via the vocoder or similar controls for streaming video and other near-real-time applications). A related idea of adaptive control of error correction codes, power, and scheduling of users is considered in [10] for the downlink of a CDMA system. Finally, algorithms for joint load balancing and cell assignment were treated by Hanly [7] as well as Yates and Huang [15], which were indeed devised initially for the reverse link of CDMA networks.

The model is formulated in section 2, and the asymptotic results are stated there. The asymptotic analysis is carried out in section 3, under the assumption that the system is large-scale. The capacity of the system, in terms of the number of mobiles requiring each service, is determined to lowest order in section 4, and correction terms are determined in section 5. Asymptotic approximations to the minimal powers are also determined. Numerical results are presented in section 6. These results are used to illustrate the analysis in the relatively simple setting of distance-based path loss laws. Subsequently, there are detailed discussions as to how to incorporate more involved propagation models with log-normal shadowing as well as how to approximate the multicell interference where the control is being used at each cell in a network. Conclusions are presented in section 7.

2. Model and results. Because of the imperfect power control, we assume that the power received at the base station from an active mobile m of class j is $P_j e_m^{(j)}$, where P_j is the target power, and $e_m^{(j)} = e^{\kappa_j \xi_m^{(j)}}$, where $\xi_m^{(j)}$ is normally distributed, with zero mean and unit variance. Analogously, the power received at the base station from an idle mobile of class j is $p_j \epsilon_m^{(j)}$, where $\epsilon_m^{(j)} = e^{\sigma_j \eta_m^{(j)}}$ and $\eta_m^{(j)}$ is normally distributed, with zero mean and unit variance.

Additionally, let $X_m^{(j)}$ be the activity indicator for mobile m of class j. We assume that

$$w_j = \Pr\left\{X_m^{(j)} = 1\right\} = 1 - \Pr\left\{X_m^{(j)} = 0\right\}, \quad m \in \mathcal{M}_j,\ j = 1, \dots, J, \tag{2.1}$$

where $\mathcal{M}_j$ denotes the set of mobiles of class j. We also assume that the random variables $(\xi_m^{(j)}, \eta_m^{(j)})$ and $X_m^{(j)}$, $m \in \mathcal{M}_j$, $j = 1, \dots, J$, are mutually independent, but we allow for possible correlation between $\xi_m^{(j)}$ and $\eta_m^{(j)}$.

The power $I^{(j)}$ received at the base station due to all the mobiles of class j in the cell under consideration is

$$I^{(j)} = \sum_{m \in \mathcal{M}_j} \left[P_j e_m^{(j)} X_m^{(j)} + p_j \epsilon_m^{(j)} (1 - X_m^{(j)}) \right]. \tag{2.2}$$

The total power I_0 received at the base station, including that from mobiles in other cells, is taken to be

$$I_0 = \sum_{l=1}^{J} I^{(l)} + \eta W + MK_0 + \sqrt{vK_0}\, S\,. \tag{2.3}$$

Here η, M, and v are positive constants, and ηW is the local receiver noise power. Since we are considering a wideband system, W is large. Also, $K_0 \gg 1$ is the total number of users in adjacent cells and, motivated by the results of Chan and Hanly [3], we assume that the density of the random variable S has a truncated Edgeworth-like expansion of the form

$$p(y) = \frac{1}{\sqrt{2\pi}} e^{-y^2/2} \left[1 + \frac{\mu_3}{6} He_3(y) + \frac{\mu_4}{24} He_4(y) + \frac{\mu_3^2}{72} He_6(y)\right], \tag{2.4}$$

where μ_3 and μ_4 are $O(1)$ constants and, in the notation of [11],

$$He_n(y) = (-1)^n e^{y^2/2} \frac{d^n}{dy^n}(e^{-y^2/2}) \tag{2.5}$$

are Hermite polynomials. The mean MK_0 and variance vK_0 of $MK_0 + \sqrt{vK_0}S$ are both $O(K_0)$, and μ_3 is the skewness of S.

We define

$$J_m^{(j)} = \sum_{m' \neq m} \left[P_j e_{m'}^{(j)} X_{m'}^{(j)} + p_j \epsilon_{m'}^{(j)} (1 - X_{m'}^{(j)})\right], \quad m \in \mathcal{M}_j\,. \tag{2.6}$$

Then the interference $I_m^{(j)}$ to the transmission of any mobile of class j is

$$I_m^{(j)} = \sum_{l \neq j} I^{(l)} + J_m^{(j)} + \eta W + MK_0 + \sqrt{vK_0}\, S\,. \tag{2.7}$$

The SNR requirement for an active mobile is

$$\Pr\left\{P_j e_m^{(j)} \geq \frac{\alpha_j}{W} I_m^{(j)}\right\} \geq 1 - L_j, \quad m \in \mathcal{M}_j,\ j = 1, \ldots, J\,, \tag{2.8}$$

and the SNR requirement for an idle mobile is

$$\Pr\left\{p_j \epsilon_m^{(j)} \geq \frac{\beta_j}{W} I_m^{(j)}\right\} \geq 1 - l_j, \quad m \in \mathcal{M}_j,\ j = 1, \ldots, J\,, \tag{2.9}$$

where L_j and l_j are prescribed loss probabilities.

We define the outage quantiles ν_j and ρ_j by

$$1 - L_j = \frac{1}{\sqrt{2\pi}} \int_{-\nu_j}^{\infty} e^{-z^2/2} dz \tag{2.10}$$

and

$$1 - l_j = \frac{1}{\sqrt{2\pi}} \int_{-\rho_j}^{\infty} e^{-x^2/2} dz\,. \tag{2.11}$$

We assume that the target powers are limited, with

$$P_j \le \bar{P}_j, \quad p_j \le \bar{p}_j, \quad j = 1, \dots, J\,, \tag{2.12}$$

and we define

$$\delta_0 = \max_j \max \left(\frac{\alpha_j}{\bar{P}_j} e^{\kappa_j \nu_j}, \ \frac{\beta_j}{\bar{p}_j} e^{\sigma_j \rho_j} \right). \tag{2.13}$$

We suppose that K_j is the large number of mobiles belonging to class j, and we define

$$\tau = \frac{1}{W} \sum_{j=1}^{J} [\alpha_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j + \beta_j e^{\sigma_j \rho_j} e^{\sigma_j^2/2} (1 - w_j)] K_j. \tag{2.14}$$

We first derive the following asymptotic result.

PROPOSITION 2.1. *The first order approximation to the admissible set, which gives a constraint on the number of users of each class that can be supported, is given by*

$$\tau \le 1 - \left(\eta + \frac{MK_0}{W} \right) \delta_0\,. \tag{2.15}$$

The corresponding minimal target powers necessary to meet the outage requirements are

$$P_j^* = \frac{\alpha_j e^{\kappa_j \nu_j}}{(1-\tau)} \left(\eta + \frac{MK_0}{W} \right), \qquad p_j^* = \frac{\beta_j e^{\sigma_j \rho_j}}{(1-\tau)} \left(\eta + \frac{MK_0}{W} \right). \tag{2.16}$$

We remark that, to this order, the approximation does not involve the variance or skewness of the interference from users in adjacent cells. We derive a refined asymptotic approximation which does depend on these quantities. We define

$$f_j = \alpha_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j + \beta_j e^{\sigma_j \rho_j} e^{\sigma_j^2/2} (1 - w_j)\,, \tag{2.17}$$

$$\psi_l = \alpha_l^2 e^{2\kappa_l \nu_l} e^{2\kappa_l^2} w_l + \beta_l^2 e^{2\sigma_l \rho_l} e^{2\sigma_l^2} (1 - w_l) - f_l^2\,, \tag{2.18}$$

$$\psi = vK_0 W \left[\frac{(1-\tau)}{(\eta W + MK_0)} \right]^2, \tag{2.19}$$

and

$$\omega_j = \frac{1}{2} \left(\frac{\nu_j}{\kappa_j} - 1 \right) \left(\frac{1}{W} \sum_{l=1}^{J} \psi_l K_l + \psi \right) - f_j, \tag{2.20}$$

$$\zeta_j = \frac{1}{2} \left(\frac{\rho_j}{\sigma_j} - 1 \right) \left(\frac{1}{W} \sum_{l=1}^{J} \psi_l K_l + \psi \right) - f_j,$$

and

$$m_j = \frac{1}{6} \mu_3 \psi^{3/2} \left[\left(\frac{\nu_j}{\kappa_j} - 1 \right) \left(\frac{\nu_j}{\kappa_j} - 2 \right) - \frac{1}{\kappa_j^2} \right], \tag{2.21}$$

$$q_j = \frac{1}{6} \mu_3 \psi^{3/2} \left[\left(\frac{\rho_j}{\sigma_j} - 1) \right) \left(\frac{\rho_j}{\sigma_j} - 2 \right) - \frac{1}{\sigma_j^2} \right].$$

Also, we let

$$X = \frac{1}{W}\sum_{j=1}^{J}[\alpha_j e^{\kappa_j\nu_j}e^{\kappa_j^2/2}w_j\omega_j + \beta_j e^{\sigma_j\rho_j}e^{\sigma_j^2/2}(1-w_j)\zeta_j]K_j\,, \tag{2.22}$$

$$U = \frac{1}{W}\sum_{j=1}^{J}[\alpha_j e^{\kappa_j\nu_j}e^{\kappa_j^2/2}w_j m_j + \beta_j e^{\sigma_j\rho_j}e^{\sigma_j^2/2}(1-w_j)q_j]K_j\,, \tag{2.23}$$

and

$$\delta = \max_j \max\left[\frac{\alpha_j}{\bar{P}_j}e^{\kappa_j\nu_j}\left(1+\frac{\omega_j}{W}+\frac{m_j}{W^{3/2}}\right),\ \frac{\beta_j}{\bar{p}_j}e^{\sigma_j\rho_j}\left(1+\frac{\zeta_j}{W}+\frac{q_j}{W^{3/2}}\right)\right]. \tag{2.24}$$

We then have the following asymptotic results.

PROPOSITION 2.2. *The refined approximation to the admissible set is given by*

$$\tau + \frac{X}{W} + \frac{U}{W^{3/2}} \le 1 - \left(\eta + \frac{MK_0}{W}\right)\delta\,, \tag{2.25}$$

and the corresponding minimal target powers are

$$P_j^* = \frac{\alpha_j e^{\kappa_j\nu_j}\left(\eta+\frac{MK_0}{W}\right)\left(1+\frac{\omega_j}{W}+\frac{m_j}{W^{3/2}}\right)}{\left(1-\tau-\frac{X}{W}-\frac{U}{W^{3/2}}\right)}\,, \tag{2.26}$$

$$p_j^* = \frac{\beta_j e^{\sigma_j\rho_j}\left(\eta+\frac{MK_0}{W}\right)\left(1+\frac{\zeta_j}{W}+\frac{q_j}{W^{3/2}}\right)}{\left(1-\tau-\frac{X}{W}-\frac{U}{W^{3/2}}\right)}\,.$$

We remark that, to this order, which neglects terms of $O(1/W^2)$, the kurtosis μ_4 in (2.4) *does not appear.*

3. Asymptotic analysis. For $m \in \mathcal{M}_j$, the error terms have first and second moments

$$E(e_m^{(j)}) = e^{\kappa_j^2/2}, \qquad E\left[(e_m^{(j)})^2\right] = e^{2\kappa_j^2} \tag{3.1}$$

and

$$E(\epsilon_m^{(j)}) = e^{\sigma_j^2/2}, \qquad E\left[(\epsilon_m^{(j)})^2\right] = e^{2\sigma_j^2}\,. \tag{3.2}$$

From (2.1), since we have assumed that the activity and error random variables are mutually independent,

$$E\left[P_j e_m^{(j)}X_m^{(j)} + p_j\epsilon_m^{(j)}(1-X_m^{(j)})\right] = P_j e^{\kappa_j^2/2}w_j + p_j e^{\sigma_j^2/2}(1-w_j) \tag{3.3}$$

and

$$E\left\{\left[P_j e_m^{(j)}X_m^{(j)} + p_j\epsilon_m^{(j)}(1-X_m^{(j)})\right]^2\right\} = P_j^2 e^{2\kappa_j^2}w_j + p_j^2 e^{2\sigma_j^2}(1-w_j)\,. \tag{3.4}$$

Hence,

$$\begin{aligned} v_j &\equiv \mathrm{Var}\left[P_j e_m^{(j)}X_m^{(j)} + p_j\epsilon_m^{(j)}(1-X_m^{(j)})\right] \\ &= P_j^2 e^{2\kappa_j^2}w_j + p_j^2 e^{2\sigma_j^2}(1-w_j) - \left[P_j e^{\kappa_j^2/2}w_j + p_j e^{\sigma_j^2/2}(1-w_j)\right]^2. \end{aligned} \tag{3.5}$$

Suppose that K_j is the number of mobiles belonging to class j. From (2.2) and (2.6), since $P_j e_m^{(j)} X_m^{(j)} + p_j \epsilon_m^{(j)}(1 - X_m^{(j)})$, $m \in \mathcal{M}_j$, are independently and identically distributed random variables with finite third moment,

$$I^{(j)} = \left[P_j e^{\kappa_j^2/2} w_j + p_j e^{\sigma_j^2/2}(1 - w_j)\right] K_j + \sqrt{v_j K_j} S^{(j)} \tag{3.6}$$

and

$$J_m^{(j)} = \left[P_j e^{\kappa_j^2/2} w_j + p_j e^{\sigma_j^2/2}(1 - w_j)\right] (K_j - 1) + \sqrt{v_j (K_j - 1)} S_m^{(j)}\,, \tag{3.7}$$

where $S^{(j)}$ and $S_m^{(j)}$ are asymptotically normally distributed with zero mean, unit variance, and error $O(1/\sqrt{K_j})$ as $K_j \to \infty$; see [5, p. 539]. This is an estimate for convergence in distribution, but it is shown in Appendix A that the densities converge as well. The random variables $S^{(l)}$, $l \neq j$, and $S_m^{(j)}$ are mutually independent. We now take the following asymptotic scalings:

$$\eta W = N_0 K,\ K_j = \gamma_j K, \quad j = 0, \ldots, J\,, \tag{3.8}$$

where $N_0 = 0(1)$ in appropriate power units and $\gamma_j = O(1)$ as $K, W \to \infty$. We take $K = \min_j K_j$. If we introduce these scalings into the expression (2.7) for $I_m^{(j)}$, use (3.6) and (3.7), and let

$$N = N_0 + M\gamma_0, \quad V = v\gamma_0, \tag{3.9}$$

we obtain

$$\begin{aligned} \frac{I_m^{(j)}}{K} = {} & \sum_{l=1}^{J} \left[P_l e^{\kappa_l^2/2} w_l + p_l e^{\sigma_l^2/2}(1 - w_l)\right] \gamma_l + N + \sqrt{\frac{V}{K}}\, S \\ & + \frac{1}{\sqrt{K}} \left[\sum_{l \neq j} \sqrt{v_l \gamma_l} S^{(l)} + \sqrt{v_j \left(\gamma_j - \frac{1}{K}\right)} S_m^{(j)}\right] \\ & - \frac{1}{K} \left[P_j e^{\kappa_j^2/2} w_j + p_j e^{\sigma_j^2/2}(1 - w_j)\right]\,. \end{aligned} \tag{3.10}$$

We define

$$G = \sum_{l=1}^{J} \left[P_l e^{\kappa_l^2/2} w_l + p_l e^{\sigma_l^2/2}(1 - w_l)\right] \gamma_l + N\,, \tag{3.11}$$

$$\lambda_j = \frac{P_j}{G}, \quad \theta_j = \frac{p_j}{G}, \quad \Phi = \frac{V}{G^2}\,, \tag{3.12}$$

$$\begin{aligned} \Gamma_j &= \lambda_j e^{\kappa_j^2/2} w_j + \theta_j e^{\sigma_j^2/2}(1 - w_j)\,, \\ \Phi_l &= \lambda_l^2 e^{2\kappa_l^2} w_l + \theta_l^2 e^{2\sigma_l^2}(1 - w_l) - \Gamma_l^2\,, \end{aligned} \tag{3.13}$$

and

$$\Lambda_m^{(j)} = \sum_{l \neq j} \sqrt{\Phi_l \gamma_l} S^{(l)} + \sqrt{\Phi_j \left(\gamma_j - \frac{1}{K}\right)} S_m^{(j)} + \sqrt{\Phi}\, S\,. \tag{3.14}$$

We also introduce the scalings

$$\frac{\alpha_j}{W} = \frac{a_j}{K}, \quad \frac{\beta_j}{W} = \frac{b_j}{K}, \quad j = 1, \ldots, J, \tag{3.15}$$

where $a_j = O(1)$ and $b_j = O(1)$ as $K, W \to \infty$. Then, from (3.5) and (3.10)–(3.15), the inequalities $P_j e_m^{(j)} \geq (\alpha_j/W) I_m^{(j)}$ and $p_j \epsilon_m^{(j)} \geq (\beta_j/W) I_m^{(j)}$ imply that, for $j = 1, \ldots, J$,

$$\frac{\lambda_j}{a_j} e^{\kappa_j \xi_m^{(j)}} \geq 1 + \frac{\Lambda_m^{(j)}}{\sqrt{K}} - \frac{\Gamma_j}{K}, \qquad \frac{\theta_j}{b_j} e^{\sigma_j \eta_m^{(j)}} \geq 1 + \frac{\Lambda_m^{(j)}}{\sqrt{K}} - \frac{\Gamma_j}{K}\,. \tag{3.16}$$

In the next section we consider the implications of these stochastic inequalities.

4. Capacity and minimal powers. We assume that $\kappa_j \geq \kappa > 0$ and $\sigma_j \geq \sigma > 0$, $j = 1, \ldots, J$, and that κ and σ are not small. We define

$$Y_m^{(j)} = \frac{\lambda_j}{a_j} e^{\kappa_j \xi_m^{(j)}} - \frac{\Lambda_m^{(j)}}{\sqrt{K}}, \qquad U_m^{(j)} = \frac{\theta_j}{b_j} e^{\sigma_j \eta_m^{(j)}} - \frac{\Lambda_m^{(j)}}{\sqrt{K}}\,. \tag{4.1}$$

It is shown in Appendix B that the densities of $(\lambda_j/a_j) e^{\kappa_j \xi_m^{(j)}}$ and $(\theta_j/b_j) e^{\sigma_j \eta_m^{(j)}}$ are, respectively,

$$g_j(y) = \frac{1}{\sqrt{2\pi}\kappa_j y} \exp\left\{ -\frac{1}{2} \left[\frac{1}{\kappa_j} \ln\left(\frac{a_j y}{\lambda_j} \right) \right]^2 \right\}, \quad y > 0\,, \tag{4.2}$$

and

$$h_j(y) = \frac{1}{\sqrt{2\pi}\sigma_j y} \exp\left\{ -\frac{1}{2} \left[\frac{1}{\sigma_j} \ln\left(\frac{b_j y}{\theta_j} \right) \right]^2 \right\}, \quad y > 0\,. \tag{4.3}$$

Moreover, it is shown that $Y_m^{(j)}$ and $U_m^{(j)}$ have densities

$$g_j(y) + \frac{1}{2K} \left(\sum_{l=1}^{J} \Phi_l \gamma_l + \Phi \right) \frac{d^2 g_j}{dy^2} + \frac{\mu_3 \Phi^{3/2}}{6K^{3/2}} \frac{d^3 g_j}{dy^3} + O\left(\frac{1}{K^2} \right), \quad y > 0, \tag{4.4}$$

and

$$h_j(y) + \frac{1}{2K} \left(\sum_{l=1}^{J} \Phi_l \gamma_l + \Phi \right) \frac{d^2 h_j}{dy^2} + \frac{\mu_3 \Phi^{3/2}}{6K^{3/2}} \frac{d^3 h_j}{dy^3} + O\left(\frac{1}{K^2} \right), \quad y > 0\,, \tag{4.5}$$

respectively.

From (2.8)–(2.11), (3.16), and (4.1)–(4.3), the QoS requirements are

$$\Pr\left\{ Y_m^{(j)} \geq 1 - \frac{\Gamma_j}{K} \right\} \geq \int_{\frac{\lambda_j}{a_j} e^{-\kappa_j \nu_j}}^{\infty} g_j(y) dy \tag{4.6}$$

and

$$\Pr\left\{ U_m^{(j)} \geq 1 - \frac{\Gamma_j}{K} \right\} \geq \int_{\frac{\theta_j}{b_j} e^{-\sigma_j \rho_j}}^{\infty} h_j(y) dy\,. \tag{4.7}$$

With the densities of $Y_m^{(j)}$ and $U_m^{(j)}$ given by (4.4) and (4.5), these inequalities are asymptotically equivalent to

(4.8)

$$\int_{\frac{\lambda_j}{a_j}e^{-\kappa_j\nu_j}}^{\infty} g_j(y)dy$$
$$\leq \int_{1-\frac{\Gamma_j}{K}}^{\infty} g_j(y)dy - \frac{1}{2K}\left(\sum_{l=1}^{J}\Phi_l\gamma_l+\Phi\right)\frac{dg_j}{dy}(1) - \frac{\mu_3\Phi^{3/2}}{6K^{3/2}}\frac{d^2g_j}{dy^2}(1) + O\left(\frac{1}{K^2}\right)$$

and

(4.9)

$$\int_{\frac{\theta_j}{b_j}e^{-\sigma_j\rho_j}}^{\infty} h_j(y)dy$$
$$\leq \int_{1-\frac{\Gamma_j}{K}}^{\infty} h_j(y)dy - \frac{1}{2K}\left(\sum_{l=1}^{J}\Phi_l\gamma_l+\Phi\right)\frac{dh_j}{dy}(1) - \frac{\mu_3\Phi^{3/2}}{6K^{3/2}}\frac{d^2h_j}{dy^2}(1) + O\left(\frac{1}{K^2}\right).$$

However, from (4.2) and (4.3),

$$\frac{dg_j}{dy}(1) = -\left[1+\frac{1}{\kappa_j^2}\ln\left(\frac{a_j}{\lambda_j}\right)\right]g_j(1), \tag{4.10}$$

$$\frac{d^2g_j}{dy^2}(1) = \left\{\left[1+\frac{1}{\kappa_j^2}\ln\left(\frac{a_j}{\lambda_j}\right)\right]\left[2+\frac{1}{\kappa_j^2}\ln\left(\frac{a_j}{\lambda_j}\right)\right]-\frac{1}{\kappa_j^2}\right\}g_j(1),$$

and

$$\frac{dh_j}{dy}(1) = -\left[1+\frac{1}{\sigma_j^2}\ln\left(\frac{b_j}{\theta_j}\right)\right]h_j(1), \tag{4.11}$$

$$\frac{d^2h_j}{dy^2}(1) = \left\{\left[1+\frac{1}{\sigma_j^2}\ln\left(\frac{b_j}{\theta_j}\right)\right]\left[2+\frac{1}{\sigma_j^2}\ln\left(\frac{b_j}{\theta_j}\right)\right]-\frac{1}{\sigma_j^2}\right\}h_j(1).$$

Also

$$\int_{1-\frac{(\zeta+\xi)}{K}-\frac{\eta}{K^{3/2}}}^{\infty} g_j(y)dy \tag{4.12}$$
$$= \int_{1-\frac{\zeta}{K}}^{\infty} g_j(y)dy + \left(\frac{\xi}{K}+\frac{\eta}{K^{3/2}}\right)g_j(1) + O\left(\frac{1}{K^2}\right)$$

and

$$\int_{1-\frac{(\zeta+\mu)}{K}-\frac{\nu}{K^{3/2}}}^{\infty} h_j(y)dy \tag{4.13}$$
$$= \int_{1-\frac{\zeta}{K}}^{\infty} h_j(y)dy + \left(\frac{\mu}{K}+\frac{\nu}{K^{3/2}}\right)h_j(1) + O\left(\frac{1}{K^2}\right).$$

It follows from (4.8)–(4.13) that, for $j = 1, \ldots, J$,

$$\frac{\lambda_j}{a_j} e^{-\kappa_j \nu_j} \geq 1 - \frac{\Gamma_j}{K} - \frac{1}{2K} \left(\sum_{l=1}^{J} \Phi_l \gamma_l + \Phi \right) \left[1 + \frac{1}{\kappa_j^2} \ln \left(\frac{a_j}{\lambda_j} \right) \right] + \frac{\mu_3 \Phi^{3/2}}{6K^{3/2}} \left\{ \left[1 + \frac{1}{\kappa_j^2} \ln \left(\frac{a_j}{\lambda_j} \right) \right] \left[2 + \frac{1}{\kappa_j^2} \ln \left(\frac{a_j}{\lambda_j} \right) \right] - \frac{1}{\kappa_j^2} \right\} + O\left(\frac{1}{K^2} \right) \tag{4.14}$$

and

$$\frac{\theta_j}{b_j} e^{-\sigma_j \rho_j} \geq 1 - \frac{\Gamma_j}{K} - \frac{1}{2K} \left(\sum_{l=1}^{J} \Phi_l \gamma_l + \Phi \right) \left[1 + \frac{1}{\sigma_j^2} \ln \left(\frac{b_j}{\theta_j} \right) \right] + \frac{\mu_3 \Phi^{3/2}}{6K^{3/2}} \left\{ \left[1 + \frac{1}{\sigma_j^2} \ln \left(\frac{b_j}{\theta_j} \right) \right] \left[2 + \frac{1}{\sigma_j^2} \ln \left(\frac{b_j}{\theta_j} \right) \right] - \frac{1}{\sigma_j^2} \right\} + O\left(\frac{1}{K^2} \right). \tag{4.15}$$

These are the deterministic inequalities implied by the stochastic ones in (3.16).

To lowest order,

$$\lambda_j \geq a_j e^{\kappa_j \nu_j} \left[1 + O\left(\frac{1}{K} \right) \right], \qquad \theta_j \geq b_j e^{\sigma_j \rho_j} \left[1 + O\left(\frac{1}{K} \right) \right]. \tag{4.16}$$

Hence, from (3.12),

$$P_j \geq a_j e^{\kappa_j \nu_j} G \left[1 + O\left(\frac{1}{K} \right) \right], \qquad p_j \geq b_j e^{\sigma_j \rho_j} G \left[1 + O\left(\frac{1}{K} \right) \right]. \tag{4.17}$$

We define

$$\tau = \sum_{j=1}^{J} \left[a_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j + b_j e^{\sigma_j \rho_j} e^{\sigma_j^2/2} (1 - w_j) \right] \gamma_j . \tag{4.18}$$

Then, from (3.11) and (4.17), we obtain

$$\left[1 - \tau + O\left(\frac{1}{K} \right) \right] G \geq N . \tag{4.19}$$

We assume that the target powers are limited, as in (2.12), and we define

$$\Delta_0 = \max_j \max \left(\frac{a_j}{\overline{P}_j} e^{\kappa_j \nu_j}, \ \frac{b_j}{\overline{p}_j} e^{\sigma_j \rho_j} \right) \tag{4.20}$$

and assume that $N \Delta_0 < 1$. It follows from (4.17) that

$$\frac{1}{G} \geq \Delta_0 \left[1 + O\left(\frac{1}{K} \right) \right], \tag{4.21}$$

and (4.19) implies that

$$\tau \leq 1 - N\Delta_0 + O\left(\frac{1}{K}\right), \tag{4.22}$$

which is the lowest-order approximation to the admissible set. Also, from (4.17) and (4.19), the minimal powers are

$$P_j^* = \frac{Na_j e^{\kappa_j \nu_j}\left[1 + O\left(\frac{1}{K}\right)\right]}{\left[1 - \tau + O\left(\frac{1}{K}\right)\right]}, \qquad p_j^* = \frac{Nb_j e^{\sigma_j \rho_j}\left[1 + O\left(\frac{1}{K}\right)\right]}{\left[1 - \tau + O\left(\frac{1}{K}\right)\right]}. \tag{4.23}$$

We investigate correction terms in the next section.

5. Refined approximation. The minimal powers P_j^* and p_j^* correspond to equality in (4.17) and (4.19) and hence, from (3.12),

$$\lambda_j = a_j e^{\kappa_j \nu_j}\left(1 + \frac{n_j}{K}\right), \qquad \theta_j = b_j e^{\sigma_j \rho_j}\left(1 + \frac{r_j}{K}\right), \tag{5.1}$$

where $n_j = O(1)$ and $r_j = O(1)$, and

$$\frac{1}{G} = \frac{(1-\tau)}{N} + O\left(\frac{1}{K}\right). \tag{5.2}$$

Then, from (3.12), (3.13), (5.1), and (5.2),

$$\Gamma_j = \Theta_j + O(1/K), \quad \Phi_l = \Psi_l + O(1/K), \quad \Phi = \Psi + O(1/K), \tag{5.3}$$

where

$$\Theta_j = a_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j + b_j e^{\sigma_j \rho_j} e^{\sigma_j^2/2}(1 - w_j) \tag{5.4}$$

and

$$\Psi_l = a_l^2 e^{2\kappa_l \nu_l} e^{2\kappa_l^2} w_l + b_l^2 e^{2\sigma_l \rho_l} e^{2\sigma_l^2}(1 - w_l) - \Theta_l^2, \ \Psi = V\left(\frac{1-\tau}{N}\right)^2. \tag{5.5}$$

Also, (4.14) and (4.15) imply that

$$n_j \geq \Omega_j + \frac{M_j}{\sqrt{K}} + O\left(\frac{1}{K}\right), \qquad r_j \geq Z_j + \frac{Q_j}{\sqrt{K}} + O\left(\frac{1}{K}\right), \tag{5.6}$$

where

$$\Omega_j = \frac{1}{2}\left(\frac{\nu_j}{\kappa_j} - 1\right)\left(\sum_{l=1}^{J} \Psi_l \gamma_l + \Psi\right) - \Theta_j, \tag{5.7}$$

$$Z_j = \frac{1}{2}\left(\frac{\rho_j}{\sigma_j} - 1\right)\left(\sum_{l=1}^{J} \Psi_l \gamma_l + \Psi\right) - \Theta_j,$$

and

$$M_j = \frac{1}{6}\mu_3 \Psi^{3/2}\left[\left(\frac{\nu_j}{\kappa_j} - 1\right)\left(\frac{\nu_j}{\kappa_j} - 2\right) - \frac{1}{\kappa_j^2}\right], \tag{5.8}$$

$$Q_j = \frac{1}{6}\mu_3 \Psi^{3/2}\left[\left(\frac{\rho_j}{\sigma_j} - 1\right)\left(\frac{\rho_j}{\sigma_j} - 2\right) - \frac{1}{\sigma_j^2}\right].$$

We define

$$\chi = \sum_{j=1}^{J} [a_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j \Omega_j + b_j e^{\sigma_j \rho_j} e^{\sigma_j^2/2} (1 - w_j) Z_j] \gamma_j, \tag{5.9}$$

$$u = \sum_{j=1}^{J} \left[a_j e^{\kappa_j \nu_j} e^{\kappa_j^2/2} w_j M_j + b_j e^{\sigma_j p_j} e^{\sigma_j^2/2} (1 - w_j) Q_j \right] \gamma_j \,.$$

From (3.12), (5.1), and (5.6), we obtain lower bounds on P_j and p_j. If we multiply these expressions by $w_j \gamma_j \exp(\kappa_j^2/2)$ and $(1 - w_j)\gamma_j \exp(\sigma_j^2/2)$, respectively, sum on j, and use the definition of G in (3.11) and those of τ, χ, and u in (4.18) and (5.9), we obtain

$$\left[1 - \tau - \frac{\chi}{K} - \frac{u}{K^{3/2}} + O\left(\frac{1}{K^2}\right) \right] G \geq N \,. \tag{5.10}$$

The minimal powers, corresponding to equality in (5.6) and (5.10), are

$$P_j^* = \frac{N a_j e^{\kappa_j \nu_j} \left[1 + \frac{\Omega_j}{K} + \frac{M_j}{K^{3/2}} + O\left(\frac{1}{K^2}\right) \right]}{\left[1 - \tau - \frac{\chi}{K} - \frac{u}{K^{3/2}} + O\left(\frac{1}{K^2}\right) \right]} \tag{5.11}$$

and

$$p_j^* = \frac{N b_j e^{\sigma_j \rho_j} \left[1 + \frac{Z_j}{K} + \frac{Q_j}{K^{3/2}} + O\left(\frac{1}{K^2}\right) \right]}{\left[1 - \tau - \frac{\chi}{K} - \frac{u}{K^{3/2}} + O\left(\frac{1}{K^2}\right) \right]} \,. \tag{5.12}$$

However, $P_j^* \leq \overline{P}_j$ and $p_j^* \leq \overline{p}_j$, $j = 1, \ldots, J$. We define

$$\Delta = \max_j \max \left[\frac{a_j}{\overline{P}_j} e^{\kappa_j \nu_j} \left(1 + \frac{\Omega_j}{K} + \frac{M_j}{K^{3/2}} \right), \right. \tag{5.13}$$

$$\left. \frac{b_j}{\overline{p}_j} e^{\sigma_j \rho_j} \left(1 + \frac{Z_j}{K} + \frac{Q_j}{K^{3/2}} \right) \right] ,$$

and assume that $N\Delta < 1$. Then, from (3.12), (5.1), and (5.6),

$$\frac{1}{G} \geq \Delta \left[1 + O\left(\frac{1}{K^2}\right) \right] , \tag{5.14}$$

and, from (5.10), the refined approximation to the admissible set is

$$\tau + \frac{\chi}{K} + \frac{u}{K^{3/2}} \leq 1 - N\Delta + O\left(\frac{1}{K^2}\right) . \tag{5.15}$$

We now express the results in terms of the original variables and define

$$f_j = \frac{W}{K} \Theta_j, \qquad \psi_j = \left(\frac{W}{K}\right)^2 \Psi_j, \quad \psi = \frac{W}{K} \Psi \,, \tag{5.16}$$

$$\omega_j = \frac{W}{K} \Omega_j, \qquad \zeta_j = \frac{W}{K} Z_j \,, \tag{5.17}$$

$$m_j = \left(\frac{W}{K}\right)^{3/2} M_j, \qquad q_j = \left(\frac{W}{K}\right)^{3/2} Q_j \,,$$

and

$$\delta_0 = \frac{W}{K}\Delta_0, \quad \delta = \frac{W}{K}\Delta, \quad X = \frac{W}{K}\chi, \quad U = \left(\frac{W}{K}\right)^{3/2} u\,. \tag{5.18}$$

Then, from (3.8), (3.9), (3.15), (5.4), (5.5), (5.7), and (5.8), we obtain (2.17)–(2.21). Also, from (3.8), (3.15), (4.18), and (5.9), we obtain (2.14), (2.22), and (2.23). Finally, from (3.15), (4.20), and (5.13), we obtain (2.13) and (2.24).

To lowest order, from (4.22) and (4.23), ignoring the $O(1/K)$ terms, the admissible set is given by (2.15), and the minimal powers by (2.16). In the refined approximation, from (5.11), (5.12), and (5.15), ignoring the $O(1/K^2)$ terms, we obtain (2.25) and (2.26).

6. Numerical results. The first order approximation is that given by Proposition 2.1. The second order approximation corresponds to setting $\mu_3 = 0$, i.e., to neglecting the effects of skewness, so that, from (2.21) and (2.23), $m_j = 0$, $q_j = 0$, and $U = 0$ in (2.24)–(2.26). The third order approximation retains $\mu_3 \neq 0$.

In the following results the external interference is simulated (as well as analyzed) as being statistically independent of the power control processes which are taking place in the desired or target cell. This is obviously a simplification of what would happen in an actual network. We further suppose that the first three moments (mean, variance, and skewness) of this external interference are known exactly at the desired cell. Thus the impact on capacity of estimation error is neglected. Finally, we neglect background noise, which is supposed to be small in comparison with the interference.

The path loss propagation law is taken to be

$$\gamma_{Loss} \propto R_D^{-\alpha},$$

where γ_{loss} is the absolute path loss, R_D is the distance between the mobile and base, and $\alpha > 0$ is a small positive constant taken to be roughly $2 \leq \alpha \leq 4$ in most wireless network models. The constant of proportionality is neglected for the results presented, as the background noise is not taken into account.

The simulations all use the power settings derived from the preceding analysis for the second order approximation. The sample outages over 100000 trials were then examined for numbers of mobiles varying close to the second order approximation. The largest number of mobiles achieving an outage strictly smaller than the target is given as the result of the simulation. A more thorough trial and error search for the optimal power ratio was not conducted.

In general all three approximations were in complete agreement with the simulation (after rounding down, rather than up, to avoid violating any constraint determined by the asymptotics). However, we did obtain discrepancies between the first order approximation and the simulated results in some cases, and to a lesser extent between the second- and third order approximations and the simulations. The following is an example.

In this example the interference is taken to be normal, with the mean and variance of the interference per mobile being $M = 0.6$ and $v = 0.015$, respectively. There were 6 interfering cells, corresponding to a hexagonal cellular array. The power control error was taken as $10\log_{10}\kappa = 10\log_{10}\rho = 1$ dB. The number K_0 of interfering mobiles and other parameters is given in Table 1. The received power target was set according to the second order approximation.

TABLE 3
Parameters for capacity with normal interference experiment.

K_0	$\overline{P}$	$\overline{p}$	w	L/l	W (MHz)	$\alpha/\beta \times 10^3$
120	1.0 (0 dB)	0.12589 (−9 dB)	0.5	0.1/0.1	5	48/6

Our results are given in Table 2. These show that the first order approximation overestimates the capacity of the desired cell by 2, whereas the second order and simulation results are in agreement. The received power limits were $\overline{P}, \overline{p} = 1, 0.12589$, respectively. Under the second order approximation the actual targets were $1, 0.1070825$ so that the active power target was at constraint.

Since in all of our numerical results the third order approximation, which includes the skewness of the external interference, differed only slightly from the second order, we have omitted any presentation of these results. However, it was imperative to ascertain that the skewness made only a slight difference; see [3].

6.1. Normal interference. Here we examine the impact of the mean interference on capacity. The external interference is modeled as normal, independent of the target cell. The mean and variance of the interference are $K_0 M$ and $K_0 v$, where K_0 is the total number of mobiles in the interfering cells. $v = 0.0025$, and the remaining parameters for the simulation runs are given in Table 3.

Our results are presented in Table 4. Where the first order approximation does not agree with the simulation it underestimates the capacity only by 1. The second order approximation is in complete agreement with the simulation, with one exception due to rounding down.

6.2. Capacity and control error. In this experiment external interference is generated by K_0 mobiles which are placed at random in cells surrounding the desired cell. The positions of these mobiles are fixed throughout the simulation. Since the path loss for each mobile is determined with an exponent of 3.5, this is also fixed.

The other parameters for the experiment are tabulated in Table 5. Note that since both outages and control errors (see Tables 5, 7) are the same, the ratio of the active to idle transmit powers equals the ratio of α to β. Since this also holds for the interfering cells, in this special case, the statistics of the interference are completely determined. Furthermore, as there is no external noise, performance does not depend on the transmitted powers as such. An increase in transmitted powers in the desired cell by any given factor leads to an increase in transmitted power in the interfering cells by the same factor. Thus performance depends only on the active to idle power ratio. (In more general cases, the idle and active transmit powers are not in this ratio and do depend on the external interference.)

Table 6 shows the results for the mean and variance of the interference. These were calculated using the activity and power variables given in Table 5. The activity of the interfering mobiles was simulated and used in determining interference. The mean and variance of this interference was sampled during the simulation, and illustrative results are also tabulated in Table 6, which are consistent with the calculated values. Our results are depicted in Table 7. These results indicate that capacity is significantly affected by power control error. In fact, the capacity diminishes by a factor of roughly 10 as the power control error increases from 0.5 to 5.0 dB. The second order approximation is in complete agreement with the simulation; however, the first order calculation has a small error in the cases of 0.5 dB (overestimate) and 5.0 dB (underestimate).

6.3. Minimal powers. As described earlier, if the system is underloaded, the powers may be reduced, thus restricting the interference caused to adjacent cells. The parameters used are the same as for the previous simulations except that the powers were set according to Table 8 and the power control error was taken as $10 \log_{10} \kappa =$

$10 \log_{10} \rho = 2dB$. The capacity of the system was determined to be 86 mobiles using both the first- and second order approximations.

The results from the simulations are given in Table 9. The left-hand column is the desired number of mobiles to support. The simulation column gives the maximum number of mobiles which achieved an outage strictly smaller than the desired outages. The final columns give the outages achieved for the desired number of mobiles given in the first column. The results show that the actual outages are very close to their desired values and that the simulation and desired number of mobiles are in agreement.

6.4. Two-class example. Table 10 gives the class dependent parameters which were used in the simulation. In addition, $W = 5$ MHz, $M = 0.05$, $v = 0.005, K_0 = 10$. The first- and second order capacity regions were determined in two steps. In the first step the maximum number of users in each class was determined using the asymptotics for a *single* class, yielding $K_1^{\max}, K_2^{\max}$. Then in the second step the maximum number of class 2 users was obtained, with class 1 users fixed at $K_1 = 1, \ldots, K_1^{\max}$. This search was performed by binary chop for both first- and second order approximations. Table 11 shows the results for both the first- and second order capacity regions. The simulation results were also obtained by fixing the number of class 1 users and then the number of class 2 users for an interval centered on the second order approximation. The powers were set for each pair of points (K_1, K_2) according to the second order approximation at the boundary. The largest value of

K_2 so that all outage probabilities were strictly met was given as the result of the simulation. The maximum number of K_1 users was determined by the second order approximation.

As the results show, the first order approximation and to a lesser extent the second order approximation overestimate the capacity region. This latter approximation agreed with simulation at both end points (the results were 28 (28.24095) and 45 (45.447203)).

The reader is cautioned against using the multiclass results when not all classes have a large number of mobiles, and in particular for empty classes. In the latter case, the maxima in the expressions for δ_0 and δ in (5.27) and (5.28), and for Δ_0 and Δ in (4.22) and (5.13), should be taken over nonempty classes.

6.5. Numerical result extensions. So far we have considered networks in which the mean path loss (average over fading) is determined by distance alone. However, more realistic models of networks of mobile phones often suppose that this quantity is determined as the product of the deterministic distance loss and an addi-

tional random log-normal shadowing factor

$$S_F \sim \text{lognormal}(0, \sigma^2).$$

We now discuss how our results can be used to examine the coverage and capacity of networks in which such log-normal shadowing is present. To do so we consider a single class of mobiles in all cells to avoid obscuring the discussion with unnecessary details. We also go in more detail into the question of obtaining numerical results where there are interfering cells.

As far as coverage is concerned, let P_T be the maximum transmit power of the mobile device used in the network. Once shadowing is determined by a random factor such as S_F, it is no longer the case that all mobiles within a distance R_c from the base station can meet the maximum received power requirement $\overline{Q} = \max(\overline{P}, \overline{p})$. (Here

$$R_c = \left(\frac{P_T C}{\overline{Q}} \right)^{\frac{1}{\alpha}},$$

and $\overline{P}, \overline{p}$ are the common active and idle receive power targets.) Instead, only a random fraction are within coverage, and the cell sizes are chosen to ensure that this fraction is suitably high, say f_c. Thus coverage must now be expressed as the maximum distance R_c such that

$$\Pr\left\{ \frac{P_T C}{R_M^{\alpha}} \geq \overline{Q} \right\} \geq f_c.$$

Of course, similar criteria may be used. In any case, whether or not there is log-normal shadowing, there is always in addition a coverage versus capacity trade-off in that the higher the maximum received power target, the higher the system capacity but the smaller the coverage area which can be supported. This trade-off can be explored using our results. See [1] for typical values of transmit power, acceptable path loss, and so on in both voice systems such as IS-95 and data services.

Log-normal shadowing also impinges on the capacity directly, in that it affects the distribution of interference between mobiles. Note that mobiles are usually assigned to the base station offering the lowest degree of path loss, and log-normal shadowing to distinct base stations is usually taken to be independent. Under these assumptions, the shadowing distribution is determined as order statistics of log-normal random variables, with means varying with mobile positions. If coverage is taken into account, then these log-normal random variables are truncated accordingly.

A final but very important general consideration is that the minimal received power targets (the ones likely to be used in practice) depend on the interference from the surrounding base stations, which in turn depend on their own receive power targets. In symmetrical cases it is reasonable to apply common received power targets at each cell and so establish the corresponding cell capacity. By varying the targets, capacity can be optimized. Moreover, this can be done in conjunction with the independent shadowing distribution so that the moments needed for the Edgeworth expansion of a random mobile's interference can be obtained by using, e.g., simulation or some other numerical technique. Obviously other factors, such as the distribution of position of the mobiles within the cells, numbers of interfering cells, etc., also have to be taken into account. Only results for a symmetrical case with mobiles along the cell edges were obtained in [1].

Of course if we fix the maximum received powers as target at each cell, distinct cell loadings may also be treated. Further work is needed to establish estimates for what the minimum feasible targets should be for heterogeneous cell loadings. As this goes into the question of power control interactions between cells, it is beyond the scope of this paper.

7. Conclusions. We have investigated a model of the reverse link of a single wireless cell with imperfect power control. For each class there is a specified small probability that the user's SNR will fall below a prescribed threshold, when active and when idle. We have investigated the capacity of the system, i.e., the number of users of each class that can be supported, and the minimal transmission powers when the link is operating within capacity. We have performed an asymptotic analysis, based on a large number of users in each class. The mean of the interference from users in adjacent cells affects the lowest order asymptotic approximation to the minimal powers and the capacity region, while the variance, and to a lesser extent the skewness, affects the refined approximation. Comparison with simulation illustrates that the refined approximation is good even for only moderately large numbers of users in each class.

The results have significant practical interest for power control in cellular systems. The power available at a mobile device for transmission in the reverse link is limited, so the minimal powers required to achieve the desired outage probabilities are important. It is essential to consider different classes of users, since voice transmission is often acceptable despite a significant error rate, while data transmission at such significant error rates would not be acceptable.

Also our results do carry implications for current commercial CDMA networks (see, e.g., [6]) even though these do not quite work according to our model. In particular, the received power targets (more precisely, E_b/I_0 targets) are determined by using feedback control instead of being determined in advance as here. (For example, in mobile voice this control reacts to the loss of speech frames by increasing the target sharply, and otherwise gradually decrementing it.) Nevertheless, our results show how sensitive the capacity is to fast power control error, and we anticipate that this will remain the case for the commercial systems too. Nor do we expect any significant difference in the capacities of commercial systems from the values which would be predicted by our approximation. Finally, our results concerning the received power targets should provide insight as to how the E_b/I_0 targets should be set in actual systems.

Further research is needed to examine the accuracy of our approach for a network of CDMA cells. In particular, the accuracy of the independence assumption is yet to be fully assessed. To conduct an analysis taking into account such dependence in detail appears difficult. Such a model would involve asymptotics for the joint state of the mobiles across the cells in the network. In particular, the computation of capacity would involve the asymptotics of the eigenvalues for a matrix determining the received power targets and would involve the propagation between desired base stations and interfering mobiles.

Appendix A. Uniform convergence to Gaussian density. We here establish (3.6), where $S^{(j)}$ is asymptotically normally distributed with zero mean, unit variance, and error $O(1/\sqrt{K_j})$ as $K_j \to \infty$. We define

$$\phi(\kappa;T) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{iTe^{\kappa\xi}} e^{-\xi^2/2} d\xi \,. \tag{A.1}$$

Then, from (2.1), since $e_m^{(j)} = e^{\kappa_j \xi_m^{(j)}}$ and $\epsilon_m^{(j)} = e^{\sigma_j \eta_m^{(j)}}$, where $\xi_m^{(j)}$ and $\eta_m^{(j)}$ are normally distributed, with zero mean and unit variance, and $(\xi_m^{(j)}, \eta_m^{(m)})$ and $X_m^{(j)}$ are mutually independent,

$$u_j(t) \equiv E\left(\exp\left\{it[P_j e_m^{(j)} X_m^{(j)} + p_j \epsilon_m^{(j)}(1 - X_m^{(j)})]\right\}\right) = w_j \phi(\kappa_j; P_j t) + (1 - w_j)\phi(\sigma_j; p_j t)\,. \tag{A.2}$$

We first show that $\phi(\kappa; T)$, where $\kappa > 0$, is absolutely integrable for $-\infty < T < \infty$. From (A.1), we have $|\phi(\kappa; T)| \le 1$. If we integrate twice by parts for $T \neq 0$, we obtain

$$\begin{aligned}\phi(\kappa; T) &= -\frac{i}{\sqrt{2\pi}\kappa T}\int_{-\infty}^{\infty} e^{iTe^{\kappa\xi}}(\kappa + \xi)e^{-\kappa\xi}e^{-\xi^2/2}d\xi \\ &= \frac{1}{\sqrt{2\pi}(\kappa T)^2}\int_{-\infty}^{\infty} e^{iTe^{\kappa\xi}}[1 - (\kappa + \xi)(2\kappa + \xi)]e^{-2\kappa\xi}e^{-\xi^2/2}d\xi\,. \end{aligned} \tag{A.3}$$

Hence,

$$|\phi(\kappa; T)| \le \frac{1}{\sqrt{2\pi}(\kappa T)^2}\int_{-\infty}^{\infty} |[1 - (\kappa + \xi)(2\kappa + \xi)]|\, e^{-2\kappa\xi}e^{-\xi^2/2}d\xi \equiv \frac{C(\kappa)}{T^2}\,, \tag{A.4}$$

which shows that $\phi(\kappa; T)$ is absolutely integrable. We assume that $\kappa_j > 0$ and $\sigma_j > 0$, and that $P_j > 0$, $p_j \ge 0$, and $0 < w_j \le 1$. If $p_j > 0$ or $w_j = 1$, then $u_j(t)$ is absolutely integrable, and (3.6) follows from (1.5.9) of [9].

If $p_j = 0$ and $0 < w_j < 1$, then we must modify the estimate (1.5.9) in [9], since $|u_j(t)|^\nu$ is not absolutely integrable for any $\nu \ge 1$ in this case. We now adopt the notation in [9] and, dropping the subscripts and superscripts and rescaling t, we define

$$\gamma(t) = w\phi(\kappa; t) + 1 - w\,. \tag{A.5}$$

To establish our result, we need to estimate

$$R = \left(\int_{\sqrt{n}c_3}^{\sqrt{n}r} + \int_{-\sqrt{n}r}^{-\sqrt{n}c_3}\right)\left[\gamma\left(\frac{t}{\sqrt{n}}\right)\right]^n e^{-i\mu_1\sqrt{n}t}e^{-iyt}dt \tag{A.6}$$

as $n \to \infty$, for real $y = O(1)$ and $r > c_3 > 0$. Here the mean $\mu_1 = we^{\kappa^2/2} > 0$.

Now, for $|x| < \delta$,

$$\begin{aligned}|(1 + x)^n - 1| &= \left|x\sum_{s=1}^{n}\binom{n}{s}x^{s-1}\right| \\ &\le \frac{|x|}{\delta}|(1 + \delta)^n - 1| \le \frac{|x|}{\delta}(1 + \delta)^n\,. \end{aligned} \tag{A.7}$$

However, $|\phi(\kappa; T)| \le \epsilon < 1$ for $|T| \ge c_3$. It follows that

$$|[\gamma(T)]^n - (1 - w)^n| \le \frac{1}{\epsilon}|\phi(\kappa; T)|(1 - w + \epsilon w)^n, \quad |T| \ge c_3\,. \tag{A.8}$$

Hence,

$$\begin{aligned}&\left|\int_{|t|\ge\sqrt{n}c_3}\left\{\left[\gamma\left(\frac{t}{\sqrt{n}}\right)\right]^n - (1 - w)^n\right\}e^{-i\mu_1\sqrt{n}t}e^{-iyt}dt\right| \\ &\le \frac{\sqrt{n}}{\epsilon}(1 - w + \epsilon w)^n\int_{|T|\ge c_3}|\phi(\kappa; T)|dT \to 0\end{aligned} \tag{A.9}$$

as $n \to \infty$, since $0 < 1 - w + \epsilon w < 1$.

Next, for $y = 0(1)$ and $\mu_1\sqrt{n} + y > 0$,

$$\text{(A.10)} \qquad \left| \left(\int_{\sqrt{n}c_3}^{\sqrt{n}r} + \int_{-\sqrt{n}r}^{-\sqrt{n}c_3} \right) e^{-\mu_1\sqrt{n}t} e^{-iyt} dt \right|$$

$$\leq \left| \frac{i}{(\mu_1\sqrt{n} + y)} \left\{ [e^{-i\mu_1\sqrt{n}t} e^{-iyt}]_{\sqrt{n}c_3}^{\sqrt{n}r} + [e^{-i\mu_1\sqrt{n}t} e^{-iyt}]_{-\sqrt{n}r}^{-\sqrt{n}c_3} \right\} \right|$$

$$\leq \frac{4}{(\mu_1\sqrt{n} + y)} .$$

This holds for all $r > c_3$. Hence, from (A.6), (A.9), and (A.10), we obtain

$$\text{(A.11)} \qquad |R| \leq \frac{\sqrt{n}}{\epsilon}(1 - w + \epsilon w)^n \int_{|T| \geq c_3} |\phi(\kappa; T)| dT + \frac{4(1-w)^n}{(\mu_1\sqrt{n} + y)} .$$

With this modification of the estimate in (1.5.9) in [9], the result in (3.6) follows.

Appendix B. Density calculations. We here determine the densities of the random variables $Y_m^{(j)}$ and $U_m^{(j)}$ defined in (4.1), where $\Lambda_m^{(j)}$ is given by (3.14). Since $\xi_m^{(j)}$ and $\eta_m^{(j)}$ are normally distributed with zero mean and unit variance, the characteristic functions of $(\lambda_j/a_j)e^{\kappa_j \xi_m^{(j)}}$ and $(\theta_j/b_j)e^{\sigma_j \eta_m^{(j)}}$ are

$$\text{(B.1)} \qquad \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{it(\lambda_j/a_j)e^{\kappa_j \zeta}} e^{-\zeta^2/2} d\zeta = \int_0^{\infty} e^{ity} g_j(y) dy$$

and

$$\text{(B.2)} \qquad \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{it(\theta_j/b_j)e^{\sigma_j \zeta}} e^{-\zeta^2/2} d\zeta = \int_0^{\infty} e^{ity} h_j(y) dy,$$

where the densities are given by (4.2) and (4.3).

The random variables $S^{(l)}$ and $S_m^{(j)}$ are asymptotically normally distributed with zero mean and unit variance and densities. Since $K_l = O(K)$, $l = 1, \ldots, J$, it follows from (1.5.3) of [9] that, for $t = O(1)$,

$$\text{(B.3)} \qquad E\left(e^{it\sqrt{\Phi_l \gamma_l} S^{(l)}/\sqrt{K}}\right) = e^{-\Phi_l \gamma_l t^2/(2K)} \left[1 + O\left(\frac{1}{K^2}\right)\right],$$

$$E\left(e^{it\sqrt{\Phi_j(\gamma_j - \frac{1}{K})} S_m^{(j)}/\sqrt{K}}\right) = e^{-\Phi_j \gamma_j t^2/(2K)} \left[1 + O\left(\frac{1}{K^2}\right)\right].$$

From (2.5), after integration by parts n times,

$$\text{(B.4)} \qquad \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{it\sqrt{\Phi} y/\sqrt{K}} e^{-y^2/2} He_n(y) dy = \left(\frac{it\sqrt{\Phi}}{\sqrt{K}}\right)^n e^{-\Phi t^2/(2K)},$$

and hence, from (2.4),

$$\text{(B.5)} \qquad E\left(e^{it\sqrt{\Phi} S/\sqrt{K}}\right) = e^{-\Phi t^2/(2K)} \left[1 - \frac{i\mu_3 \Phi^{3/2}}{6K^{3/2}} t^3 + O\left(\frac{1}{K^2}\right)\right].$$

Thus, from (3.14), since S, $S^{(l)}$, $l \neq j$, and $S_m^{(j)}$ are mutually independent,

$$\begin{aligned}(\text{B.6}) \qquad & E(e^{it\Lambda_m^{(j)}/\sqrt{K}}) \\ & = \exp\left(-\frac{1}{2K}\left[\sum_{l=1}^{J}\Phi_l\gamma_l + \Phi\right]t^2\right)\left[1 - \frac{i\mu_3\Phi^{3/2}}{6K^{3/2}}t^3 + O\left(\frac{1}{K^2}\right)\right] \\ & = 1 - \frac{1}{2K}\left[\sum_{l=1}^{J}\Phi_l\gamma_l + \Phi\right]t^2 - \frac{i\mu_3\Phi^{3/2}}{6K^{3/2}}t^3 + O\left(\frac{1}{K^2}\right)\end{aligned}$$

for $t = O(1)$.

Since the random variables $(\xi_m^{(j)}, \eta_m^{(j)})$ and $\Lambda_m^{(j)}$ are independent, it follows from (4.1), (B.1), (B.2), and (B.6) that the characteristic functions of $Y_m^{(j)}$ and $U_m^{(j)}$ are

$$(\text{B.7}) \qquad \left[1 - \frac{1}{2K}\left(\sum_{l=1}^{J}\Phi_l\gamma_l + \Phi\right)t^2 + \frac{i\mu_3\Phi^{3/2}}{6K^{3/2}}t^3 + O\left(\frac{1}{K^2}\right)\right]\int_0^\infty e^{ity}g_j(y)dy$$

and

$$(\text{B.8}) \qquad \left[1 - \frac{1}{2K}\left(\sum_{l=1}^{J}\Phi_l\gamma_l + \Phi\right)t^2 + \frac{i\mu_3\Phi^{3/2}}{6K^{3/2}}t^3 + O\left(\frac{1}{K^2}\right)\right]\int_0^\infty e^{ity}h_j(y)dy\,,$$

and hence the densities are given by (4.4) and (4.5), respectively.

Acknowledgments. The authors are grateful to Debasis Mitra for posing the capacity problem. They would also like to thank Sem Borst and Dennis Morgan for many helpful comments on earlier versions of this paper, and the referees for their helpful suggestions for improving the presentation.

CAVITATION ON DEFORMABLE GLACIER BEDS*

CHRISTIAN SCHOOF†

Abstract. The formation of water-filled cavities at the interface between a glacier and its bed can significantly affect the drainage of meltwater along the base of a glacier, which in turn is one of the most important controls on glacier sliding. In this paper, we analyze a mathematical model for cavity formation on deformable glacier beds. By contrast with the case of rigid glacier beds, the cavities described here are the result of an interfacial instability in coupled ice-sediment flow. This instability causes bumps on the ice-sediment interface to grow until normal stress in the lee of bed bumps drops to the local porewater pressure, at which point the ice begins to lose contact with the surface of the sediment. We extend the basic instability model to cover the case of cavity formation, and analyze the corresponding traveling wave problem. This takes the form of a viscous contact problem in which the obstacle on the boundary—the traveling bed bump caused by the initial instability—must be determined as part of the solution. A classical complex variable method allows the traveling wave problem to be cast as an eigenvalue problem which is straightforward to solve numerically. Our results show that solutions for different wavelengths can be obtained from an apparently unique solution to a scaled problem, and that the amplitude of traveling waves increases with wavelength, while their speed decreases with wavelength.

1. Introduction.

The ice contained in many glaciers, especially those in mid-latitude mountain ranges, is close to the melting point, and meltwater generated at the glacier surface can reach the glacier bed through a network of conduits or *moulins* in the ice. The subsequent routing of meltwater via the glacier bed not only affects water discharge from the glacier, but also the dynamics of the glacier itself. The downslope motion of a glacier—which can be treated as a slowly flowing viscous body—consists of shearing in the ice and sliding at its base. High water pressure at the base of a glacier weakens the contact between ice and bed, and consequently reduces the amount of friction generated at the bed by sliding [7, 20, 17].

The presence of water-filled cavities at the interface between a glacier and its bed can play an important role in the drainage of meltwater along the glacier bed. The purpose of this paper is to analyze a model for the formation of such cavities. Previously developed mathematical models for subglacial cavitation [6, 17] deal with the flow of ice over a rigid glacier bed, and are essentially viscous analogues of elastic Signorini-type contact problems [13], although the subtle differences between the elastic and viscous cases appear to preclude a variational formulation for the latter. In contrast, the model considered here describes the spontaneous formation of cavities on a bed composed of deformable sediment. Consequently, the bed no longer represents a fixed "obstacle," but evolves as a result of stresses at the ice-sediment interface.

The instability mechanism which causes the formation of cavities in our model was

first proposed by Hindmarsh [11] and Fowler [8], and is described in detail in Schoof [19]. It relies on the pressure-dependence of the viscosity of subglacial sediment. (More precisely, sediment viscosity is assumed to depend on *effective pressure*, the difference between total pressure and porewater pressure, which controls how hard sediment grains are pressed together.) The mechanism may be summed up as follows: A shallow bump in the interface between ice and sediment causes a perturbation in the flow of ice over the bed, which leads to higher compressive normal stress being exerted on the upstream side of the bump than its lee. In turn, this causes increased effective pressure in the sediment layer upstream of the bump compared with downstream. Moreover, if the viscosity of the sediment is much lower than that of ice, the horizontal velocity of the interface is approximately constant (i.e., independent of position). Then, if the sediment rheology is such that flux in a thin sediment layer increases with effective pressure when the surface velocity of the layer is fixed, this implies that more sediment flows into the bump than out, causing it to grow.

This mechanism can be shown to work for a variety of viscous sediment rheologies, and numerical solutions of a simplified model show that growth of the instability is generally unbounded before the onset of cavitation [16, 19], which occurs when compressive normal stress in the lee of a bed bump drops to the local porewater pressure. In this paper, we will be concerned with the extension of that model to the case of cavitation. Our interest in this problem is largely motivated by the fact that cavity formation introduces a nonlinearity into the model, which may be sufficient to lead to bounded growth of the instability. Due to the complexity of the problem, we do not, however, consider the full time-dependent problem of cavity evolution, but restrict ourselves mostly to the case of traveling wave solutions, in the hope that these represent the fully evolved ice-bed interface.

The paper is structured as follows. In section 2, we describe the extension of the basic instability model to the case of cavitation. Subsequently, we formulate the traveling wave problem in section 3 and present a method of solution based on a classical complex variable approach. Results are discussed in section 4.

2. The model. We consider a simplified two-dimensional model for the spatially periodic flow of ice over a thin layer of water-saturated subglacial sediment in the absence of cavitation, as detailed in Schoof [19]. We set out the full time-dependent model here, first in the absence of cavitation and subsequently with cavitation. The analysis in this paper will, however, deal almost exclusively with the corresponding traveling wave problem, which we describe in the next section.

The basic assumptions of the model derived in [19] are the following. Ice is treated as an incompressible Newtonian fluid, while subglacial sediment is modeled as an incompressible shear-thinning viscous material whose viscosity additionally depends on *effective pressure*, defined as the difference between the ordinary pressure variable (the spherical part of the stress tensor in the language of continuum mechanics) and a prescribed porewater pressure. In particular, the rheology of subglacial sediment may be taken to be of the form

$$D_{ij} = KN^{-n}\tau^{m-1}\tau_{ij}, \tag{2.1}$$

where D_{ij} is strain rate, N is effective pressure, and τ_{ij} is deviatoric stress with second invariant $\tau = \sqrt{\tau_{ij}\tau_{ij}/2}$, while K, m, and n are positive constants. This rheological model has the qualitative features that strain rate increases with stress, as required for a viscous material, while strain rate decreases with effective pressure, corresponding to sediment grains less able to move past each other when pressed

harder together. The model described below makes a further approximation, treating only the parametric limit $n \approx m \gg 1$ in the rheology (2.1). This corresponds to a "nearly plastic" behavior, in which shear stress is only weakly dependent on strain rate [12]. As described in [19, section 7], this greatly simplifies expressions for volume flux in the sediment layer and shear stress at its surface, and leads to a more tractable ice flow problem.

Moreover, the model assumes that unstable waves generated at the ice-sediment interface have wavelengths that are long compared with the thickness of the sediment. Consequently, the sediment layer is treated as thin, with small surface slopes that allow the ice flow domain to be approximated by a half-space. Treating the sediment layer as thin further allows it to be described by a depth-integrated model that appears in the Stokes flow problem for the ice in the form of boundary conditions at the lower boundary. These boundary conditions can be derived essentially by integrating (2.1). For reasons of space, we refer to [19] for a more detailed derivation of the model.

Below, x and y are Cartesian coordinates parallel and perpendicular, respectively, to the mean bed elevation, while t is time and subscripts $_x$, $_y$, and $_t$ denote the corresponding partial derivatives. $\mathbf{u}(x, y, t)$ is a dimensionless velocity perturbation in the ice relative to a mean shearing flow, and $p(x, y, t)$ a dimensionless pressure perturbation about a mean hydrostatic pressure field. If a is the spatial period of the bed, $\mathbf{u} = (u, v)$ and p satisfy Stokes' equations on a semi-infinite strip in the upper half-plane:

$$\nabla^2 \mathbf{u} - \nabla p = \mathbf{0}, \qquad \nabla \cdot \mathbf{u} = 0 \qquad \text{on } (x, y) \in (0, a) \times (0, \infty), \tag{2.2}$$

with periodic boundary conditions applied at $x = 0$ and $x = a$. The interface between ice and sediment remains, at leading order, at $y = 0$ if waves on the bed are shallow. We denote the amplitude of these waves by $h(x, t)$, and sediment flux in the direction of the x-axis by $q(x, t)$. Effective pressure (the difference between confining normal stress and a prescribed porewater pressure) at the sediment surface will be denoted by $N(x, t)$, and shear stress at the ice-sediment interface by $\tau_b(x, t)$. Lastly, the velocity of the ice-sediment interface will be denoted by U. As before, all of these quantities have been scaled as in [19] and are dimensionless. Boundary conditions for the Stokes flow problems (2.2) are then

$$\left.\begin{aligned} u_y + v_x &\to \gamma^{-1}, \\ p &\to 0 \end{aligned}\right\} \qquad \text{as } y \to \infty, \tag{2.3}$$

$$\left.\begin{aligned} \gamma\,(u_y + v_x) &= \tau_b, \\ 1 + p - 2v_y &= N, \\ v &= U h_x + h_t \end{aligned}\right\} \qquad \text{on } y = 0. \tag{2.4}$$

Above, $\gamma > 0$ is the ratio of mean dimensional effective pressure to far-field shear stress. Hence γ^{-1} is a dimensionless far-field shear stress in $(2.3)_1$, while $(2.3)_2$ ensures that the pressure perturbation p vanishes at large distances from the bed. The boundary conditions $(2.4)_{1,2}$ at the bed relate the appropriate stress components in the Stokes problem to interfacial shear stress and effective pressure, while $(2.4)_3$ relates normal velocity at the bed to the evolution of bed wave amplitude h. h itself satisfies the evolution equation

$$h_t + q_x = 0. \tag{2.5}$$

As described at the beginning of this section, interfacial shear stress τ_b and flux q in the boundary conditions (2.4) must be determined through a model for the thin-

film flow of subglacial sediment. With the rheological specifications based on (2.1) described above, we find the appealingly simple (and *linear*) relationships

$$\tau_b(x,t) = N(x,t), \qquad q(x,t) = N(x,t). \tag{2.6}$$

Meanwhile, interface velocity is determined by a large-scale ice flow problem [18, 19], and in scaled terms we can simply set

$$U = 1, \tag{2.7}$$

while the x-component of the velocity $\mathbf{u} = (u, v)$ is subject to $\int_0^a u(x,0)\,\mathrm{d}x = 0$ (this condition being necessary to ensure a unique solution for $\mathbf{u}$).

As described above, the "constitutive relations" (2.6) are appropriate for a sediment layer flowing in simple shear with rheology given by (2.1) in the parametric limit $m \sim n \gg 1$ [19, section 7]. The relations are thus not completely general, though rheological tests support them [12]. As described in [16, 19] more general sediment rheologies can be introduced into the model simply by changing the prescriptions for τ_b and N in (2.6). We persist with (2.6) in part because it is supported by empirical evidence [12], and also because it is the simplest physically motivated choice we can make, yielding a linear relationships between τ_b, q, and N. However, as we point out in section 4, other rheological models for sediment may also be of practical interest, but these introduce the additional complication of nonlinear constitutive relations in (2.6), which are beyond the scope of this paper.

It is straightforward to show that the trivial solution $h(x,t) \equiv 0$ to (2.2)–(2.6) is unstable: The model admits Fourier mode solutions of the form $h(x,t) = \mathrm{Re}(\exp(ikx + \sigma t))$, where $\sigma = 2|k|^3/(1+2ik|k|)$ has a positive real part, and growth of the instability is apparently unbounded. However, this is physical only while effective pressure N is positive everywhere, which ensures that normal stress at the top of the sediment layer exceeds the porewater pressure within. Once $N = 0$ somewhere, compressive normal stress at the top of the sediment layer at that location equals porewater pressure, and porewater starts to leak out of the sediment. The ice loses contact with the sediment, and a water-filled cavity forms, as also happens in glacier sliding over undeformable beds [6, 17].

When a cavity has formed, different boundary conditions apply to (2.2) on those parts of the bed where cavities are present from those in effect where ice is in contact with sediment. Let the cavitated part of the bed at time t be denoted by $C(t)$, and the contact areas by $C'(t)$; the closure of $C \cup C'$ is then the interval $[0, a]$. The boundary conditions (2.4) together with the constraint $N \geq 0$ (which ensures that normal stress in contact areas cannot drop below the porewater pressure) still hold on $y = 0$, $x \in C'$. On cavitated parts of the bed, we require that effective pressure and shear stress vanish, as water pressure equals normal stress in the ice, and the water is assumed to be inviscid. This is tantamount to setting $\tau_b = N = 0$ in (2.4). In addition, the cavity roof must be above the surface of the sediment over cavitated parts of the bed and must satisfy a kinematic boundary condition analogous to $(2.4)_3$. We denote the dimensionless elevation of the cavity roof by $h_C(x,t)$ (see Figure 2.1) and assume that the cavity roof has a low aspect ratio, comparable with that of the sediment layer. Then we have [16, Chapter 6]

$$\left.\begin{aligned} 1 + p - 2v_y &= 0, \\ u_y + v_x &= 0, \\ v &= Uh_{Cx} + h_{Ct} \end{aligned}\right\} \qquad \text{on } y = 0,\ x \in C, \tag{2.8}$$

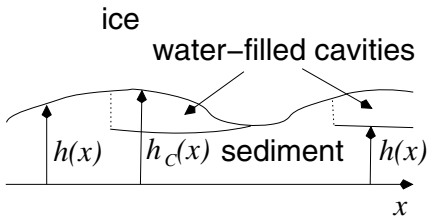

FIG. 2.1. *Illustration of cavity and contact areas, and the definition of h and h_C. The model assumes that bed slopes are small, so that the lower boundary of the ice flow domain can be reduced to $y = 0$ in dimensionless terms. Note that we generally assume discontinuities in h at downstream endpoints of contact areas. These sediment shocks are shown as dotted lines.*

while the absence of traction at the surface of the sediment in the cavities also implies

$$h_t = 0, \qquad q = 0, \qquad \text{on } y = 0,\ x \in C, \tag{2.9}$$

combined with the constraint $h_C > h$.

In addition to the boundary conditions (2.4) and (2.8) for the two-dimensional Stokes equations (2.2) and the evolution equation (2.5), we require jump conditions on h and h_C at the boundary points of C and C'. Based on physical considerations [16], we require that there be no discontinuities in the elevation of the lower boundary of the ice. Defining h_C everywhere as the scaled elevation of the base of the ice, so that $h_C(x) = h(x)$ for $x \in C'$, this implies that h_C is continuous across the endpoints of C and C'. It turns out that the same degree of continuity cannot be imposed on the sediment wave amplitude h, and a discontinuity must be expected at at least one endpoint of each individual contact area. Such discontinuities are not entirely unexpected: For the somewhat similar problem of dune formation in deserts and on river beds [9], the equivalent would be a slip face. The flow of sediment close to a contact point where h is discontinuous cannot be resolved by our thin-film approximation for the sediment. However, instead of attempting to solve an extremely complicated local sediment flow problem, we argue heuristically. We assume that the propagation speed of the contact point is determined by a Rankine–Hugeniot condition which ensures conservation of sediment:

$$V_s = [q]^+_-/[h]^+_-, \tag{2.10}$$

where V_s is the propagation speed of the sediment shock and $[\cdot]^+_-$ denotes the jump in the bracketed quantity across the shock. With $q = N$, it follows from the continuity of h_C and the inequality constraints on h and N that the jump in q must have the same sign as the jump in h, and hence the sediment shock must propagate downstream with $V_s > 0$.

If there were a sediment shock at the upstream end of a contact area, then effective pressure would be positive downstream of the contact point and zero in the cavity. The resulting pressure difference should drive a local sediment flow (not resolved by our thin-film approximation) into the cavity, that is, in the upstream direction and therefore opposite to that required by (2.10). As a consequence, we permit discontinuities in h only at the downstream ends of contact areas and require that h be continuous across the upstream end of each contact area.

As we shall see below, these jump conditions on h and h_C lead to an apparently

well-posed traveling wave problem. Whether or not they can in fact be applied to the general time-dependent problem is a matter for future research.

3. Traveling waves. In what follows, we consider solutions in which h and h_C depend on x and t only through the traveling wave coordinate

$$\eta = x - Vt, \tag{3.1}$$

where $V > 0$ is the unknown pattern speed of the traveling wave. Note that negative pattern speeds are not possible because sediment shocks must propagate downstream, as explained above. Writing $\hat{\nabla} = (\partial/\partial\eta, \partial/\partial y)$, the model can then be cast in the form

$$\hat{\nabla}^2\mathbf{u} - \hat{\nabla}p = \mathbf{0}, \qquad \hat{\nabla}\cdot\mathbf{u} = 0 \qquad \text{on } (\eta, y) \in (0, a) \times (0, \infty), \tag{3.2}$$

$$\left.\begin{aligned} u_y + v_\eta &\to \gamma^{-1}, \\ p &\to 0 \end{aligned}\right\} \qquad \text{as } y \to \infty, \tag{3.3}$$

$$\left.\begin{aligned} \gamma\,(u_y + v_\eta) &= \tau_b, \\ 1 + p - 2v_y &= N, \\ v &= (U - V)h', \\ q' - Vh' &= 0, \\ N &\geq 0 \end{aligned}\right\} \qquad \text{on } \eta \in \hat{C}',\ y = 0, \tag{3.4}$$

$$\left.\begin{aligned} u_y + v_\eta &= 0, \\ 1 + p - 2v_y &= 0, \\ v &= (U - V)h_C', \\ h' &= 0, \\ h_C &> h \end{aligned}\right\} \qquad \text{on } \eta \in \hat{C},\ y = 0, \tag{3.5}$$

$$q = N \qquad \text{on } \eta \in \hat{C}', \tag{3.6}$$

$$q = 0 \qquad \text{on } \eta \in \hat{C}, \tag{3.7}$$

$$\tau_b = N, \qquad U = 1. \tag{3.8}$$

Here primes on h, h_C, and q denote differentiation with respect to η, and $\hat{C}' = C'(0)$ and $\hat{C} = C(0)$ denote contact and cavity areas, respectively, at the bed in the (η, y) coordinate system. In addition, we consider only the case of a single cavity per bed period, and without further loss of generality we can set

$$\hat{C}' = (0, b), \qquad \hat{C} = (b, a), \tag{3.9}$$

where the contact point $\eta = b$ is to be determined as part of the solution. As before, we impose periodic boundary conditions on $\eta = 0$ and $\eta = a$. The continuity requirements on h and h_C at the contact points are

$$h(0^+) = h(a^-) = h_C(a^-), \qquad h(b^-) = h_C(b^+), \tag{3.10}$$

where superscripts $+$ and $-$ indicate limits taken from above and below, respectively (and where, in an abuse of notation, we have replaced the arguments (x, t) by η). Lastly, the jump condition (2.10) for a sediment shock at $\eta = b$ propagating at the pattern speed $V_s = V$ becomes

$$V = -q(b^-)/(h(b^+) - h(b^-)), \tag{3.11}$$

where we recognize that $q(b^+) = 0$ from (3.7).

Some small simplifications are immediately possible. As the model is invariant under changes of h and h_C by the same constant, we can without loss of generality set $h = 0$ in $\hat{C}$ by $(3.5)_4$. $(3.4)_4$ and (3.11) combined then require that

$$q = Vh \qquad \text{on } \hat{C}, \tag{3.12}$$

and the jump conditions on h and h_C become

$$h(0^+) = h_C(a^-) = 0, \qquad h(b^-) = h_C(b^+). \tag{3.13}$$

Equations (3.12) and (3.13) then replace $(3.4)_4$, (3.10), and (3.11) in the subsequent analysis.

The model described above is in many ways similar to the viscous contact problems considered by Fowler [6] and Schoof [17], in the sense that we have a Stokes flow problem with mixed boundary conditions prescribed on parts of the boundary which are not known a priori but must be found as part of the solution so as to satisfy the inequality constraints $(3.4)_5$ and $(3.5)_5$. This introduces an important nonlinearity into the problem which is missing in the original linear evolution problem and, as we shall see, allows for the existence of (nontrivial) traveling wave solutions, which are not possible without cavitation. The crucial difference between the model considered here and that in [6, 17] is that the bed elevation h is not fixed here but forms part of the solution. This renders the problem considerably more complicated.

The remainder of this section will be devoted to constructing a method of solution. Our approach consists of the following steps. First, we represent the solution of the Stokes equations (3.2) in terms of complex potentials. When mapped conformally so as to make use of the periodic boundary conditions at the sides of the domain, the boundary conditions (3.3)–(3.5) lead to a pair of Hilbert problems for these complex potentials, which admit explicit solutions in terms of the unknown functions N and τ_b and the contact point position b. Finally, applying the remaining conditions (3.8), (3.12), and (3.13) allows the problem of finding N and τ_b to be recast as an eigenvalue problem for h (which simultaneously determines the pattern speed V), and b can be determined through an additional integral constraint which ensures that the lower ice surface has no discontinuities.

3.1. Complex variable formulation. We introduce a stream function ψ such that

$$u = \psi_y + y/\gamma, \qquad v = -\psi_\eta, \tag{3.14}$$

where the additional shearing term in the definition of u accounts for the far-field shear stress. Further, we define the complex variables $z = \eta + iy$ and $\overline{z} = \eta - iy$. ψ satisfies the biharmonic equation, which can be written in terms of z and $\overline{z}$ as

$$\hat{\nabla}^4 \psi = 4\psi_{zz\overline{z}\overline{z}} = 0. \tag{3.15}$$

Using standard methods in complex analysis [5], ψ can be shown to take the general form

$$\psi = (\overline{z} - z)\theta(z) + \phi(z) + (z - \overline{z})\overline{\theta(z)} + \overline{\phi(z)} \tag{3.16}$$

for z in the semi-infinite strip $0 < \eta < a$, $0 < y$, where θ and ϕ are analytic functions and an overbar denotes complex conjugation. Furthermore, the Stokes equations (3.2) become

$$\hat{\nabla}^2 \psi_y = p_\eta, \qquad -\hat{\nabla}^2 \psi_\eta = p_y, \tag{3.17}$$

which are the Cauchy–Riemann relations for $p + i\hat{\nabla}^2\psi$ (i.e., pressure p and vorticity $\hat{\nabla}^2\psi$ are harmonic conjugates). Using standard differentiation rules [5], $\hat{\nabla}^2\psi = 4(\theta'(z) + \overline{\theta'(z)}) = 8\mathrm{Im}(i\theta'(z))$, where a prime denotes differentiation. Consequently,

$$p = C_0 + 8\mathrm{Re}(i\theta'(z)) = C_0 + 4i(\theta'(z) - \overline{\theta'(z)}), \tag{3.18}$$

where C_0 is a real constant. The value of this constant can be chosen arbitrarily: If $C_0 \neq 0$, we can add $iC_0 z/8$ to $\theta(z)$ and simultaneously add $iC_0 z^2/8$ to $\phi(z)$ while leaving the stream function ψ in (3.16) unchanged. By redefining θ and ϕ in this way, we ensure that $C_0 = 0$ in (3.18), and we will henceforth assume this to be the case.

In order to satisfy the periodic boundary conditions imposed on the problem, it suffices to ensure that u, v, and p can be extended to sufficiently smooth functions in the half-space $y > 0$, which are periodic in η with period a. Anticipating therefore that p and vorticity $\nabla^2\psi$ can be extended to harmonic functions which are appropriately periodic, we conclude that $\theta'(z)$ can be continued to an analytic function in the upper half-plane which is periodic in $\mathrm{Re}(z)$ with period a. Furthermore, we have for $y > 0$

$$u = 4y\mathrm{Re}\left[\theta'(z)\right] + 2\mathrm{Im}\left[2\theta(z) - \phi'(z)\right], \tag{3.19}$$

$$v = -4y\mathrm{Im}\left[\theta'(z)\right] - 2\mathrm{Re}\left[\phi'(z)\right]. \tag{3.20}$$

Hence, if $\theta'(z)$ can be continued to a periodic analytic function, it suffices to ensure in addition that $\mathrm{Im}[2\theta(z) - \phi'(z)]$ and $\mathrm{Re}[\phi'(z)]$ can be extended to harmonic functions in the upper half-plane with period a in $\mathrm{Re}(z)$. From the periodicity of $\mathrm{Re}[\phi'(z)]$, it follows that $\phi''(z)$ can be continued to an appropriately periodic analytic function in the entire upper half-plane $\mathrm{Im}(z) > 0$. Moreover, the periodicity of $\mathrm{Re}[\phi'(z)]$ and $\mathrm{Im}[2\theta(z) - \phi'(z)]$ are equivalent to

$$\mathrm{Re}\left[\phi'(a+iy) - \phi'(iy)\right] = \mathrm{Re}\left[\int_0^a \phi''(\eta + iy)\,\mathrm{d}\eta\right] = 0, \tag{3.21}$$

$$\mathrm{Im}\left[\int_0^a 2\theta'(\eta + iy) - \phi''(\eta + iy)\,\mathrm{d}\eta\right] = 0 \tag{3.22}$$

for all $y > 0$.

We complete our complex variable formulation by casting the boundary conditions (3.3)–(3.5) in terms of θ and ϕ. At the lower boundary $y = 0$

$$2i(\phi''(\eta) - \overline{\phi''(\eta)}) = \begin{cases} N(\eta) - 1, & \eta \in \hat{C}', \\ -1, & \eta \in \hat{C}, \end{cases} \tag{3.23}$$

$$2(2\theta'(\eta) - \phi''(\eta) + 2\overline{\theta'(\eta)} - \overline{\phi''(\eta)}) = \begin{cases} \gamma^{-1}\left(\tau_b(\eta) - 1\right), & \eta \in \hat{C}', \\ -\gamma^{-1}, & \eta \in \hat{C}, \end{cases} \tag{3.24}$$

$$-(\phi'(\eta) + \overline{\phi'(\eta)}) = \begin{cases} (U - V)h'(\eta), & \eta \in \hat{C}', \\ (U - V)h'_C(\eta), & \eta \in \hat{C}, \end{cases} \tag{3.25}$$

combined with (3.8), (3.12), and (3.13). Naturally, θ', ϕ', and ϕ'' are defined on the real axis as boundary values taken as z approaches the axis from above. As $\mathrm{Im}(z) = y \to \infty$, we have from (3.3)

$$4i\left[\theta'(z) - \overline{\theta'(z)}\right] \to 0, \tag{3.26}$$

$$-2\left[\phi''(z) - 2iy\theta''(z) - 2\theta'(z) + \overline{\phi''(z)} + 2iy\overline{\theta''(z)} - 2\overline{\theta'(z)}\right] \to 0. \tag{3.27}$$

3.2. Reformulation as a Hilbert problem. In order to exploit the periodicity of the problem, and to obtain a straightforwardly solved pair of Hilbert problems for proxies of θ' and ϕ'', we map conformally to the ζ-plane as

$$\zeta = \exp(i2\pi z/a), \qquad \xi = \exp(i2\pi\eta/a), \tag{3.28}$$

where $0 < \eta = \mathrm{Re}(z) < a$. We denote by Γ and Γ' the images of $\hat{C}$ and $\hat{C}'$ under this mapping. Γ and Γ' are then disjoint arcs of the unit circle in the ζ-plane, and the closure of $\Gamma \cup \Gamma'$ is the unit circle itself. We also define $\tilde{N}(\xi) = N(\eta)$, $\tilde{\tau}_b(\xi) = \tau_b(\eta)$, and let

$$\Omega(\zeta) = \begin{cases} \overline{\phi''(\overline{z})}, & |\zeta| > 1, \\ \phi''(z), & 0 < |\zeta| < 1, \end{cases} \tag{3.29}$$

$$\omega(\zeta) = \phi'(z), \qquad 0 < |\zeta| < 1, \tag{3.30}$$

$$\Theta(\zeta) = \begin{cases} \overline{\theta'(\overline{z})}, & |\zeta| > 1, \\ \theta'(z), & 0 < |\zeta| < 1. \end{cases} \tag{3.31}$$

From the Schwarz reflection principle and the periodicity requirements above, it follows that Ω and Θ are analytic in the finite ζ-plane cut along the unit circle and punctured at the origin, while ω is analytic inside the open unit disk cut along the nonnegative part of the real axis in the ζ-plane, where ω may be discontinuous because we know only that $\mathrm{Re}(\phi')$ is periodic. As we shall show later, ω is in fact analytic across that branch cut. Moreover, using $\mathrm{d}/\,\mathrm{d}z = (i2\pi/a)\zeta\,\mathrm{d}/\,\mathrm{d}\zeta$,

$$\Omega(\zeta) = (i2\pi/a)\zeta\omega'(\zeta) \tag{3.32}$$

for $|\zeta| < 1$, except on the branch cut.

The boundary conditions (3.23)–(3.25) become

$$2i\left[\Omega^+(\xi) - \Omega^-(\xi)\right] = \begin{cases} \tilde{N}(\xi) - 1, & \xi \in \Gamma', \\ -1, & \xi \in \Gamma, \end{cases} \tag{3.33}$$

$$2\left[2\Theta^+(\xi) - \Omega^+(\xi) + 2\Theta^-(\xi) - \Omega^-(\xi)\right] = \begin{cases} \gamma^{-1}(\tilde{\tau}_b(\xi) - 1), & \xi \in \Gamma', \\ -\gamma^{-1}, & \xi \in \Gamma, \end{cases} \tag{3.34}$$

$$-2\mathrm{Re}(\omega^+(\xi)) = \begin{cases} (U - V)h'(\eta), & \xi \in \Gamma', \\ (U - V)h'_C(\eta), & \xi \in \Gamma, \end{cases} \tag{3.35}$$

where superscripts + and − denote limits taken as the unit circle is approached from within and without, respectively. The first two of these equations take the form of standard Hilbert problems, whose solutions depend on the behavior of Ω and Θ at infinity. Because of the symmetry inherent in the definitions of Ω and Θ, their behavior at infinity is determined by their behavior at the origin. From (3.27), we have for $\zeta \to 0$

$$4i\left[\Theta(\zeta) - \overline{\Theta(\zeta)}\right] \to 0, \tag{3.36}$$

$$\Omega(\zeta) + \overline{\Omega(\zeta)} - 2\Theta(\zeta) - 2\overline{\Theta(\zeta)} - 2\log|\zeta|\left[\zeta\Theta'(\zeta) + \overline{\zeta\Theta'(\zeta)}\right] \to 0. \tag{3.37}$$

It follows from (3.36) that Θ is analytic at the origin with $\Theta(0) = C_1$, where C_1 is a real constant. Hence $\lim_{\zeta\to 0} \zeta\log|\zeta|\Theta'(\zeta) = 0$, and from (3.37) it follows that Ω is also analytic at the origin with $\Omega(0) = 4C_1 + iC_2$, where C_2 is another real constant.

It can then be shown from the periodicity requirements (3.22) that both C_1 and C_2 vanish. Specifically, (3.22) can be written as

$$\operatorname{Re}\left[\frac{a}{i2\pi}\oint_L \frac{\Omega(\zeta)\,\mathrm{d}\zeta}{\zeta}\right] = \operatorname{Im}\left[\frac{a}{i2\pi}\oint_L \frac{[2\Theta(\zeta)-\Omega(\zeta)]}{\zeta}\,\mathrm{d}\zeta\right] = 0, \tag{3.38}$$

where L is a circular contour about the origin with radius less than 1, traversed anticlockwise. Applying the residue theorem, this implies that $C_1 = C_2 = 0$, and hence

$$\Omega(0) = \Theta(0) = 0. \tag{3.39}$$

From (3.39) and the definitions of Ω and Θ in (3.31) it finally follows that

$$\Omega(\zeta) = \overline{\Omega(1/\bar{\zeta})}, \qquad \Omega(\infty) = 0, \qquad \Theta(\zeta) = \overline{\Theta(1/\bar{\zeta})}, \qquad \Theta(\infty) = 0, \tag{3.40}$$

which taken together also ensure the appropriate behavior at the origin.

We can now solve (3.33), (3.34), and (3.40) explicitly in terms of the as yet unknown effective pressure $N(\eta)$ and shear stress $\tau_b(\eta)$. For the sake of simplicity, define Ξ as a proxy for Θ through

$$\Xi(\zeta) = \begin{cases} 2\Theta(\zeta) - \Omega(\zeta), & |\zeta| < 1, \\ -2\Theta(\zeta) + \Omega(\zeta), & |\zeta| > 1, \end{cases} \tag{3.41}$$

so that (3.34) becomes

$$\Xi^+(\xi) - \Xi^-(\xi) = \begin{cases} \gamma^{-1}(\tilde{\tau}_b(\xi) - 1), & \xi \in \Gamma', \\ -\gamma^{-1}, & \xi \in \Gamma, \end{cases} \tag{3.42}$$

subject to $\Xi(\infty) = 0$, $\Xi(\zeta) = -\overline{\Xi(1/\bar{\zeta})}$. Assuming that $\tilde{N}$ and $\tilde{\tau}_b$ are Hölder continuous and bounded on Γ' (we exclude the possibility of integrable singularities at the endpoints of Γ' because N and τ_b are related to h through (3.8) and (3.12), and h is clearly bounded), (3.33) and (3.42) admit solutions vanishing at infinity of the form (see [14])

$$\Omega(\zeta) = -\frac{1}{4\pi}\int_{\Gamma'} \frac{\tilde{N}(\xi)}{\xi - \zeta}\,\mathrm{d}\xi + \frac{1}{4\pi}\int_{\Gamma\cup\Gamma'} \frac{1}{\xi-\zeta}\,\mathrm{d}\xi, \tag{3.43}$$

$$\Xi(\zeta) = \gamma^{-1}\left[\frac{1}{2\pi i}\int_{\Gamma'} \frac{\tilde{\tau}_b(\xi)}{\xi-\zeta} - \frac{1}{2\pi i}\int_{\Gamma\cup\Gamma'} \frac{1}{\xi-\zeta}\,\mathrm{d}\xi\right], \tag{3.44}$$

where integrals over Γ and Γ' are taken (here and in what follows) as the unit circle is traversed in the anticlockwise direction. Note that the second integral on the right-hand side of each equation may be recognized as $\int_{\Gamma\cup\Gamma'}(\xi-\zeta)^{-1}\,\mathrm{d}\xi = 2\pi i$ if ζ is inside the unit circle, $\int_{\Gamma\cup\Gamma'}(\xi-\zeta)^{-1}\,\mathrm{d}\xi = 0$ for ζ outside the unit circle.

It remains to ensure that Ω and Ξ satisfy $(3.40)_{1,3}$. Using the fact that $\tilde{N}$ is real, while $\bar{\xi} = 1/\xi$ and $\overline{\mathrm{d}\xi} = -1/\xi^2\,\mathrm{d}\xi$, it follows after some manipulation that

$$\overline{\Omega(1/\bar{\zeta})} = -\frac{1}{4\pi}\int_{\Gamma'} \tilde{N}(\xi)\left[\frac{1}{\xi-\zeta} - \frac{1}{\xi}\right]\mathrm{d}\xi + \frac{1}{4\pi}\int_{\Gamma'\cup\Gamma}\left[\frac{1}{\xi-\zeta} - \frac{1}{\xi}\right]\mathrm{d}\xi, \tag{3.45}$$

with a similar expression for $\overline{\Xi(1/\bar{\zeta})}$. In order to satisfy $\Omega(\zeta) = \overline{\Omega(1/\bar{\zeta})}$ and $\Xi(\zeta) = -\overline{\Xi(1/\bar{\zeta})}$, we therefore require

$$\int_{\Gamma'} \frac{\tilde{N}(\xi)}{\xi}\,\mathrm{d}\xi - \int_{\Gamma\cup\Gamma'} \frac{\mathrm{d}\xi}{\xi} = 0, \qquad \int_{\Gamma'} \frac{\tilde{\tau}_b(\xi)}{\xi}\,\mathrm{d}\xi - \int_{\Gamma\cup\Gamma'} \frac{\mathrm{d}\xi}{\xi} = 0. \tag{3.46}$$

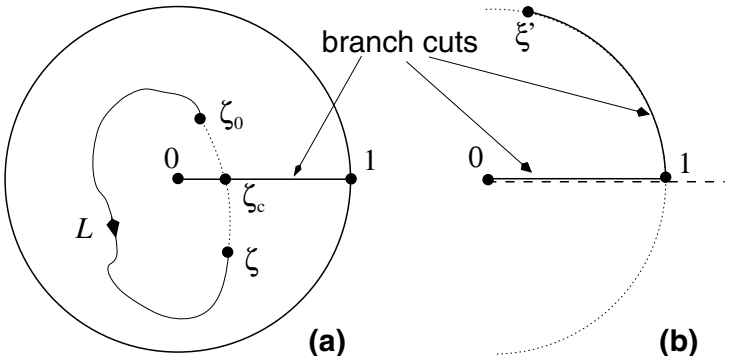

FIG. 3.1. *The contour L in* (3.48) *is shown in panel* (a)*, where solid lines indicate branch cuts in ω. The branch cuts for* $\log(\xi'/\zeta - 1)$ *(solid line) and* $\log(\zeta)$ *(dashed line) are shown in panel* (b).

In real terms, these equations are simply

$$\frac{1}{a}\int_0^b N(\eta)\,\mathrm{d}\eta = 1, \qquad \frac{1}{a}\int_0^b \tau_b(\eta)\,\mathrm{d}\eta = 1, \tag{3.47}$$

which physically state that the mean shear stress at the ice-sediment interface is the far-field shear stress, and that mean effective pressure is fixed by hydrostatic ice overburden and by porewater pressure in the bed (the difference between the two being scaled to unity). With the particular prescription of τ_b in (3.8), the two equations in (3.47) are identical, and we are left with the single constraint $(3.47)_1$, which states that mean effective pressure at the bed is fixed at unity.

The expressions for Ω and Ξ in (3.43) and (3.44) as well as the solvability constraints in (3.47) contain the unknown functions N and τ_b, which depend on sediment thickness h through the constitutive relations (3.6) and (3.8) as well as through (3.12), while h conversely depends on N and τ_b through (3.35). Moreover, the limits of integration appearing in (3.43) and (3.44) are not known a priori, as we have yet to determine the position of the contact point $\eta = b$. In the next section, we show how h (and hence N and τ_b) can be calculated from an eigenvalue problem arising from (3.35), which also determines the pattern speed V as its eigenvalue. Additionally, the continuity requirements in (3.13) allow us to derive an integral constraint which fixes the position of the contact point b.

3.3. Reduction to an eigenvalue problem. We exploit (3.35), (3.32), and (3.43) as well as (3.6), (3.12), (3.13) and the inequality constraints in (3.4) and (3.5) in order to obtain integral equations for h and h_C. Our first task is to calculate ω, which determines the bed slopes h' and h'_C through (3.35). For ζ_0 and ζ in the open unit disk of the ζ-plane cut along the nonnegative half of the real axis, where ω has a branch cut, we have from (3.32)

$$\omega(\zeta) - \omega(\zeta_0) = \frac{a}{i2\pi}\int_L \frac{\Omega(\zeta')}{\zeta'}\,\mathrm{d}\zeta', \tag{3.48}$$

where primes on ζ' indicate a dummy variable, not differentiation. L is any arc connecting ζ_0 to ζ such that L lies entirely in the open unit disk and does not cross the branch cut in ω (see Figure 3.1). It follows from (3.48) that ω is in fact continuous and therefore analytic across that branch cut: Let ζ_c lie on the branch cut, and let

ζ_0 and ζ approach ζ_c from the first and fourth quadrants, respectively. In the limit, L becomes a closed contour encircling the origin (Figure 3.1), and from the residue theorem we have

$$\omega(\zeta) - \omega(\zeta_0) \to a\Omega(0) = 0, \tag{3.49}$$

so $\omega(\zeta_c)$ can be assigned a unique limiting value regardless of which side the real axis is approached from. As a corollary, we can in fact allow the arc L above to cross the positive half of the real axis (which later allows us to establish that $\omega(\zeta)$ has a unique limit when $\zeta \to 1$ from inside the unit circle).

Using (3.43), we can evaluate the integral in (3.48) explicitly:

$$\begin{aligned}\omega(\zeta) - \omega(\zeta_0) = &-\frac{a}{i8\pi^2}\int_{\Gamma'} \tilde{N}(\xi')\left[\log\left(\frac{\xi'}{\zeta_0} - 1\right) - \log\left(\frac{\xi'}{\zeta} - 1\right)\right]\frac{\mathrm{d}\xi'}{\xi'} \\ &+ \frac{a}{4\pi}[\log(\zeta) - \log(\zeta_0)],\end{aligned} \tag{3.50}$$

where for definiteness $\log(\xi'/\zeta_0 - 1)$ and $\log(\xi'/\zeta - 1)$ denote a branch of the logarithm which has a branch cut as indicated in Figure 3.1. Similarly, $\log(\zeta_0)$ and $\log(\zeta)$ denote a branch which has a branch cut along the positive half of the real axis.

Next, we let $\zeta \to \xi$ and $\zeta_0 \to 1$ from inside the unit circle. It is easy to show from (3.48), Cauchy's theorem, and the continuity properties of Ω [14, pp. 53–55 and Chapter 4] that the limit $\omega^+(\xi)$ exists and is continuous as a function of ξ for all ξ on the unit circle. Importantly, this result holds true at both endpoints of Γ', where $\xi = 1$ and $\xi = \exp(i2\pi b/a)$ (with continuity at $\xi = 1$ resulting from the continuity of ω across the real axis). Using (3.35) and (3.50) and taking care with the branches of the logarithms involved, we find after some elementary manipulations that

$$\begin{aligned}-2\mathrm{Re}(\omega^+(\xi) - \omega^+(1)) &= -\frac{1}{2\pi}\int_0^b N(\eta')\log\left|\frac{\sin(\pi(\eta' - \eta)/a)}{\sin(\pi\eta'/a)}\right|\mathrm{d}\eta' \\ &= \begin{cases} (U - V)(h'(\eta) - h'(0^+)), & \eta \in \hat{C}', \\ (U - V)(h'_C(\eta) - h'(0^+)), & \eta \in \hat{C}, \end{cases}\end{aligned} \tag{3.51}$$

where $\xi = \exp(i2\pi\eta/a)$ as before and $\log(\cdot)$ is the ordinary logarithm defined for positive real numbers.

To proceed further, we require $h'(0^+)$. Since ω^+ is continuous at $\xi = 1$, we conclude from (3.35) that $h'_C(a^-) = h'(0^+)$, provided $V \neq U$. In other words, the continuity of the y-component of velocity precludes any breaks in the slope of the lower boundary of the ice. The local behavior of h and h_C near the contact points $\eta = 0$, $\eta = a$ then requires that $h'_C(a^-) = h'(0^+) = 0$ if the inequality constraints $(3.4)_5$ and $(3.5)_5$ on N and h_C are to be satisfied close to the contact points. To see this, note that the cavity roof is above the sediment surface and we have $h_C(\eta) > h(\eta) = 0$ for $b < \eta < a$, while the cavity roof recontacts the bed at $\eta = a$, so that $h_C(a^-) = 0$ and hence $h'(0^+) = h'_C(a^-) \leq 0$. Meanwhile, $h(\eta) \geq 0$ in contact areas $0 < \eta < b$ (as flux $Vh = q = N \geq 0$ and $V > 0$), and sediment thickness is continuous at the downstream cavity endpoint, so that $h(0) = 0$, which implies $h'_C(a^-) = h'(0^+) \geq 0$. These two inequalities on $h'(0^+)$ can be satisfied simultaneously only if bed and cavity roof slope vanish at the downstream cavity endpoint, $h'(0^+) = h'_C(a^-) = 0$.

An integral equation for h is now straightforward to obtain by integrating (3.51)

once more and using $h(0^+) = 0$:

$$\begin{aligned}(U-V)h(\eta) &= \int_0^\eta (U-V)h'(\eta')\,\mathrm{d}\eta' \\ &= -\frac{1}{2\pi}\int_0^\eta \int_0^b N(\eta')\log\left|\frac{\sin(\pi(\eta'-\eta'')/a)}{\sin(\pi\eta'/a)}\right|\,\mathrm{d}\eta'\,\mathrm{d}\eta'' \\ &= -\frac{1}{2\pi}\int_0^b \left[\int_0^\eta \log\left|\frac{\sin(\pi(\eta'-\eta'')/a)}{\sin(\pi\eta'/a)}\right|\,\mathrm{d}\eta''\right] N(\eta')\,\mathrm{d}\eta' \qquad (3.52)\end{aligned}$$

for $\eta \in (0, b)$. As $h_C(a^-) = 0$ from (3.13), the cavity roof similarly satisfies

$$\begin{aligned}(U-V)h_C(\eta) &= -\int_\eta^a (U-V)h_C(\eta')\,\mathrm{d}\eta' \\ &= \frac{1}{2\pi}\int_0^b \left[\int_\eta^a \log\left|\frac{\sin(\pi(\eta'-\eta'')/a)}{\sin(\pi\eta'/a)}\right|\,\mathrm{d}\eta''\right] N(\eta')\,\mathrm{d}\eta' \qquad (3.53)\end{aligned}$$

for $\eta \in (b, a)$. Solutions of these integral equations automatically satisfy $(3.13)_1$. It remains to ensure that $h_C(b^+) = h(b^-)$. Using (3.52) and (3.53), this can be written in the form

$$\frac{1}{2\pi}\int_0^b \left[\int_0^a \log\left|\frac{\sin(\pi(\eta'-\eta'')/a)}{\sin(\pi\eta'/a)}\right|\,\mathrm{d}\eta''\right] N(\eta')\,\mathrm{d}\eta' = 0. \qquad (3.54)$$

This equation ensures that there is no discontinuity in the ice surface at $\eta = b$, but it generally requires a discontinuity in h (in the sense that (3.54) does not ensure $h(b^-) = 0$). This justifies our statement in section 2 that we cannot generally expect sediment thickness to be continuous across all contact points; this is at least true for traveling wave solutions.

Equation (3.54) allows the integrals above to be simplified somewhat. The kernel on the left-hand side of (3.54) can be rewritten as

$$\begin{aligned}&\int_0^a \log\left|\frac{\sin(\pi(\eta'-\eta'')/a)}{\sin(\pi\eta'/a)}\right|\,\mathrm{d}\eta'' \\ &\quad = \int_0^a \frac{1}{2}\left\{\log\left[4\sin^2\left(\frac{\pi(\eta'-\eta'')}{a}\right)\right] - \log\left[4\sin^2\left(\frac{\pi\eta'}{a}\right)\right]\right\}\,\mathrm{d}\eta''. \qquad (3.55)\end{aligned}$$

But, as shown in the appendix,

$$\int_0^a \log\left[4\sin^2(\pi(\eta'-\eta'')/a)\right]\,\mathrm{d}\eta'' = \int_0^a \log\left[4\sin^2(\pi\eta''/a)\right]\,\mathrm{d}\eta'' = 0, \qquad (3.56)$$

and (3.54) becomes more simply

$$\int_0^b \log\left[4\sin^2(\pi\eta/a)\right] N(\eta)\,\mathrm{d}\eta = 0. \qquad (3.57)$$

Similarly rewriting the integral kernel in (3.52) and (3.53) and using (3.56) and (3.57) yields the integral equations

$$(U-V)h(\eta) = -\frac{1}{4\pi}\int_0^b \left\{\int_0^\eta \log\left[4\sin^2\left(\frac{\pi(\eta'-\eta'')}{a}\right)\right]\,\mathrm{d}\eta''\right\} N(\eta')\,\mathrm{d}\eta' \qquad (3.58)$$

for $\eta \in (0, b)$, and

$$(U-V)h_C(\eta) = -\frac{1}{4\pi}\int_0^b \left\{ \int_0^\eta \log\left[4\sin^2\left(\frac{\pi(\eta'-\eta'')}{a}\right)\right] \mathrm{d}\eta'' \right\} N(\eta')\,\mathrm{d}\eta' \tag{3.59}$$

for $\eta \in (b, a)$.

On writing $N = q = Vh$ and setting $U = 1$ from (3.6) and (3.12), the structure of the problem finally becomes apparent: For a given contact point position b, $h(\eta)$ satisfies the eigenvalue problem

$$\lambda h(\eta) + \int_0^b k(\eta, \eta')h(\eta')\,\mathrm{d}\eta' = 0 \tag{3.60}$$

for $\eta \in (0, b)$, where the kernel k is given by

$$k(\eta, \eta') = \frac{1}{4\pi}\int_0^\eta \log\left(4\sin^2\left[\pi(\eta'-\eta'')/a\right]\right)\,\mathrm{d}\eta'', \tag{3.61}$$

and the real eigenvalue λ is a proxy for pattern velocity V, $\lambda = (1-V)/V$. The contact point b is constrained by (3.54), which reads

$$\int_0^b \log\left[4\sin^2(\pi\eta/a)\right] h(\eta)\,\mathrm{d}\eta = 0. \tag{3.62}$$

Finally, the eigenfunction $h(\eta)$ satisfies the normalization condition (3.47), which becomes

$$\frac{1}{a}\int_0^b h(\eta)\,\mathrm{d}\eta = \lambda + 1. \tag{3.63}$$

Once h, λ, and b have been found, the cavity roof shape $h_C(\eta)$ for $\eta \in (b, a)$ can be calculated from (3.53):

$$\lambda h_C(\eta) = -\int_0^b k(\eta, \eta')h(\eta')\,\mathrm{d}\eta'. \tag{3.64}$$

As mentioned previously, we allow only positive pattern speeds $V > 0$, so $\lambda > -1$, and the mean of h is positive by (3.63). A solution h must further satisfy the stronger pointwise constraint $h(\eta) \geq 0$ for $\eta \in (0, b)$, and similarly $h_C(\eta) > 0$ for $\eta \in (b, a)$. It is by no means obvious that this will be the case: We have so far employed the inequality constraints on h and h_C only locally in order to determine the slopes of h and h_C at the contact points $\eta = 0$, $\eta = a$. Compliance with these constraints must therefore be checked *a posteriori* once a solution has been found. Further, our solution of the Hilbert problems (3.33) and (3.42) requires $N(\eta)$ and $\tau_b(\eta)$ to be Hölder continuous on C'; that is, $h(\eta)$ must be Hölder continuous on $(0, b)$ and (to make sense of the jump conditions (3.13)) continuous up to $\eta = 0$ and $\eta = b$ from the left and right, respectively. Moreover, $h(\eta)$ must satisfy the original integrodifferential equation (3.51), rather than simply the integrated version (3.52). In the appendix, we show that any continuous solution $h \in C([0, b])$ of the eigenvalue problem (3.60)–(3.62) does in fact satisfy this equation and is in $C^1([0, b])$, which takes care of the Hölder continuity of h. Hence it is sufficient to look for continuous $h \in C([0, b])$.

3.4. Numerical method. In order to eliminate the arbitrary wavelength a from the eigenvalue problem, we define

$$X = \eta/a, \qquad B = b/a, \qquad \mu = \lambda/a^2 = (1-V)/(a^2V),$$

$$S(X) = h(\eta), \qquad S_C(X) = h_C(\eta). \tag{3.65}$$

The equations we wish to solve are then

$$\mu S(X) + \frac{1}{4\pi}\int_0^B \left[\int_0^X \log\left[4\sin^2(\pi(X'-X''))\right]\,\mathrm{d}X''\right] S(X')\,\mathrm{d}X' = 0, \tag{3.66}$$

$$\int_0^B \log\left[4\sin^2(\pi X)\right] S(X)\,\mathrm{d}X = 0, \tag{3.67}$$

where the eigenfunction S is to be normalized as

$$\int_0^B S(X)\,\mathrm{d}X = 1 + a^2\mu. \tag{3.68}$$

We are not interested in calculating the entire spectrum of the integral operator in (3.66), but merely seek real eigenvalues $\mu > -1/a^2$. To this end, we can exploit the structure of the integral operator by rewriting (3.66) in the form

$$\begin{aligned}\mu S(X) + \frac{1}{4\pi}\int_0^B \left[\int_0^{X-X'} \log\left[4\sin^2(\pi X'')\right]\,\mathrm{d}X''\right] S(X')\,\mathrm{d}X' \\ = -\frac{1}{4\pi}\int_0^B \left[\int_0^{X'} \log\left[4\sin^2(\pi X'')\right]\,\mathrm{d}X''\right] S(X')\,\mathrm{d}X'.\end{aligned} \tag{3.69}$$

The right-hand side of this equation is simply a constant, while the kernel of the convolution-type integral operator on the left-hand side is antisymmetric and therefore has purely imaginary eigenvalues. It follows that the constant on the right-hand side cannot vanish unless we have the trivial solution $S \equiv 0$, which is, however, precluded by the normalization condition (3.68). If we dispense temporarily with this normalization condition by rescaling S—which we are at liberty to do because (3.66) and (3.67) are homogeneous in S—we can therefore fix the constant on the right-hand side of (3.69) at unity. Denoting this rescaled version of S by $\tilde{S}$, we obtain the pair of equations

$$\mu\tilde{S}(X) + \frac{1}{4\pi}\int_0^B \left[\int_0^{X-X'} \log\left[4\sin^2(\pi X'')\right]\,\mathrm{d}X''\right] \tilde{S}(X')\,\mathrm{d}X' = 1, \tag{3.70}$$

$$-\frac{1}{4\pi}\int_0^B \left[\int_0^{X'} \log\left[4\sin^2(\pi X'')\right]\,\mathrm{d}X''\right] \tilde{S}(X')\,\mathrm{d}X' = 1. \tag{3.71}$$

The advantage of (3.70) is precisely that the kernel of the integral operator on the left-hand side is antisymmetric and hence has purely imaginary eigenvalues. By the Fredholm alternative, (3.70) has a unique solution $\tilde{S}(X;\mu,B) \in C([0,B])$ for every

real nonzero μ and every $B \in (0,1]$. We denote this solution by $\tilde{S}(X;\mu,B)$. In terms of $\tilde{S}(X;\mu,B)$, equations (3.71) and (3.67) can then be written in the form

$$f_1(\mu,B) := \frac{1}{4\pi}\int_0^B \left[\int_0^X \log\left[4\sin^2(\pi X')\right]\,\mathrm{d}X'\right]\tilde{S}(X;\mu,B)\,\mathrm{d}X + 1 = 0, \tag{3.72}$$

$$f_2(\mu,B) := \int_0^B \log\left[4\sin^2(\pi X)\right]\tilde{S}(X;\mu,B)\,\mathrm{d}X = 0. \tag{3.73}$$

The task of finding μ and B can therefore be reduced to solving two nonlinear equations, which must be done numerically. Here we use a backtracking line-search modification of Newton's method [4], where the Jacobian is approximated by finite differences.

In order to evaluate the functions $f_1(\mu,B)$ and $f_2(\mu,B)$, $\tilde{S}(X;\mu,B)$ must be calculated from (3.70). We use a degenerate kernel approximation [2, Chapter 2]: As shown in the appendix, the kernel

$$K(X-X') = \frac{1}{4\pi}\int_0^{X-X'} \log\left[4\sin^2(\pi X'')\right]\,\mathrm{d}X'' \tag{3.74}$$

can be approximated uniformly by the truncated Fourier series

$$K_{n_0}(X-X') = \sum_{n=-n_0,\,n\neq 0}^{n_0} \frac{i\exp(i2n\pi X)\exp(-i2n\pi X')}{8\pi^2|n|n} \tag{3.75}$$

as $n_0 \to \infty$. Replacing $K(X-X')$ by $K_{n_0}(X-X')$, the solution of (3.70) follows the standard method for degenerate kernels.

4. Results and discussion. Regardless of the initial guess for μ and B, only a single solution was found numerically, with $\mu = 2.971\times 10^{-3}$ and $B = 0.2285$. Visual inspection of the surfaces generated by f_1 and f_2 also suggests that this solution is unique. In Figure 4.1, we plot the corresponding shape of $S(X)$ and $S_C(X)$, normalized so that $\int_0^B S(X)\,\mathrm{d}X = 1$ (formally, this is (3.68) with $a = 0$, that is, the short-wave limit). The sediment in the traveling wave is confined to a relatively short wedge upstream of an extended cavity, and the vanishing sediment surface and cavity roof slopes at the contact points $X = 0$, 1 are clearly visible. Moreover, the solution appears to satisfy the constraints $S(X) \geq 0$ for $X \in (0,B)$, $S_C(X) > 0$ for $X \in (B,1)$. Note that a solution $S(X)$ for a given wavelength $a \neq 0$ can be obtained from that plotted in Figure 4.1 simply by multiplying it by $1 + a^2\mu$. This ensures that the normalization condition (3.68) is satisfied. Since the amplitude of S varies with wavelength as $1+a^2\mu$, we see that long waves are also taller than short ones. Furthermore, the pattern speed V can be calculated as $V = 1/(1+a^2\mu)$, which states that pattern speed is inversely proportional to amplitude and hence that shorter waves travel faster than longer ones. Moreover, since $\mu > 0$, the pattern speed V is always less than the ice velocity U. If we take a to be given as the fastest growing wavelength in the original instability model in section 2, then $a = 2\pi[2/\sqrt{3}]^{1/2} = 6.752$ and $V = 0.881$. These traveling waves are advected downstream at 88% of the velocity of ice at the bed, and their amplitude is 1.135 times that shown in Figure 4.1.

The existence of a traveling wave solution suggests that cavity formation may be sufficient to lead to bounded growth in the instability mechanism proposed by Hindmarsh [11] and Fowler [8]. However, it also poses some interesting open questions

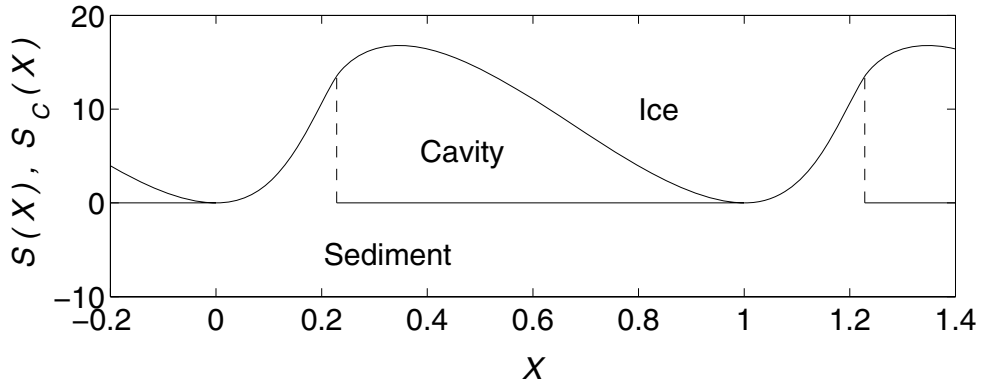

FIG. 4.1. *Solution $S(X)$ for sediment surface elevation and $S_C(X)$ for cavity roof elevation, normalized so that $\int_0^B S(X)\,\mathrm{d}X = 1$ and extended periodically. The sediment shock at $X = B$ is shown as a dashed vertical line.*

regarding the dynamical problem of section 2: First, are the traveling waves described here stable to small perturbation, and if so, does their stability depend on their wavelength? Second, how do waves of different wavelengths interact? Do shorter waves merge with larger ones, and does wavelength coarsening occur? The first of these questions may be amenable to a complex variable approach of the type used above, using an appropriate linearization. The second is much harder and requires an understanding of the fully nonlinear time-dependent problem.

Physically, our results also pose some additional questions. Following [11, 8], our model assumes that porewater pressure in the sediment, and hence mean effective pressure, are fixed by a pre-existing subglacial drainage system, most likely taking the form of channels at the ice-bed interface [15]. However, once cavities have formed, it is likely that they will serve as both storage volume and conduits for water flowing beneath the glacier, and that drainage through these cavities will be instrumental in controlling water pressures at the bed. The simplest way to understand how this type of drainage might work is by considering cavities as a kind of macroscopic pore space, and to consider drainage through cavities at the bed as being a two-dimensional analogue of drainage in ordinary porous media, giving rise to a Biot-type problem [7, 10] for water pressure on an outer length scale associated with the length of the glacier as a whole (which is assumed to be large compared with the instability length scale considered in the model studied in this paper). The problem with applying this approach here is that the size of cavities increases with mean effective pressure (scaled to unity in the dimensionless model), as can be shown from the scalings used in [19]. Specifically, the dimensional scale for h is

$$[h] = \frac{[N]}{(n-2)(1-\phi)(\rho_s - \rho_w)g},$$

where $[N]$ is mean effective pressure at the bed ("mean" being an average taken over the cavity length scale), n is an exponent in the assumed power-law rheology for sediment (which gives rise to the constitutive relations for shear stress τ_b and flux q in (2.6) for $n \gg 1$; see [19]), ϕ is the porosity of the sediment, ρ_s and ρ_w are the densities of sediment grains and of water, and g is acceleration due to gravity. Hence $[h]$ increases linearly with effective pressure, and it follows that cavity size *decreases*

with water pressure. This in turn means that the advocated Biot-type drainage model takes the form of a backward diffusion problem and is therefore ill-posed.

It is unclear to what extent this result is due to the particular rheological model employed for subglacial sediment, and an obvious avenue for further research is to consider alternative prescriptions for τ_b and q from those introduced in (2.6). The eigenvalue problem (3.58) combined with constraints of the form (3.47) and (3.54) generalizes relatively easily to other forms of τ_b and q, though the resulting nonlinear eigenvalue problem is considerably more complicated [16], and we leave a solution as an open problem.

Appendix. Smoothness of solutions. It can be shown in the usual way from the Arzelà–Ascoli theorem that the integral operator in (3.70) is compact on $C([0,B])$, and the antisymmetry of the kernel further ensures that all its eigenvalues are purely imaginary. By the Fredholm alternative [3, Chapter 7.5], the integral equation (3.70) therefore has a unique solution in $C([0,B])$ for every real μ. In what follows, we will show that this solution is in fact in $C^1([0,B])$ and satisfies the integrodifferential equation (3.51). In the process, we will also prove (3.56) and show that the degenerate kernel approximation (3.75) converges uniformly to K in the limit $n_0 \to \infty$.

At issue is thus whether a solution of (3.70) satisfies (3.51), which in view of (3.54), (3.6), (3.12), and the rescaling in (3.65) may be rewritten in the form

$$-\frac{1}{4\pi}\int_0^b \log\left(4\sin^2[\pi(X-X')]\right)\tilde{S}(X)\,\mathrm{d}X' = \mu\tilde{S}'(X) \tag{A.1}$$

for $X \in (0,B)$. If $\tilde{S} \in C([0,B])$ satisfies (A.1), it follows immediately from the properties of convolution integrals that $\tilde{S}' \in C([0,B])$, and $\tilde{S} \in C^1([0,B])$, as required. Equation (A.1) can be obtained by differentiating (3.70) (noting that the right-hand side is simply a constant) and by exchanging the order of differentiation and integration on the integral term. In order to prove that integration and differentiation do commute—which is not obvious because the integrand in (A.1) has a singularity—we approximate the integrand by a sequence of bounded integrands.

A.1. Degenerate kernel approximation. The power series

$$\sum_{n=1}^{\infty}\frac{\zeta^{n-1}}{n} = -\frac{\log(1-\zeta)}{\zeta}$$

has radius of convergence one, and therefore converges everywhere inside the unit circle in the complex ζ-plane. The branch of the logarithm must be continuous on the open unit disk with $\log(1)=0$. Note that the singularity at the origin is removable: We can assign $-\frac{1}{\zeta}\log(1-\zeta)$ its limiting value of 1. The series also converges pointwise on the unit circle except at $\zeta = 1$ [1, p. 409]. For ξ on the unit circle and $r \in (0,1)$, we have

$$\left|\sum_{n=1}^{n_0}\frac{r^{n-1}\xi^n}{n}\right| \le \sum_{n=1}^{n_0}\left|\frac{r^{n-1}\xi^n}{n}\right| = \sum_{n=1}^{n_0}\frac{r^{n-1}}{n} < \frac{\log(1-r)}{r} \tag{A.2}$$

for any finite n_0. Since $\frac{1}{r}\log(1-r)$ is integrable over $r \in (0,1)$, so is

$$\sum_{n=1}^{\infty}\frac{r^{n-1}\xi^n}{n} = -\frac{\log(1-r\xi)}{r\xi}\xi,$$

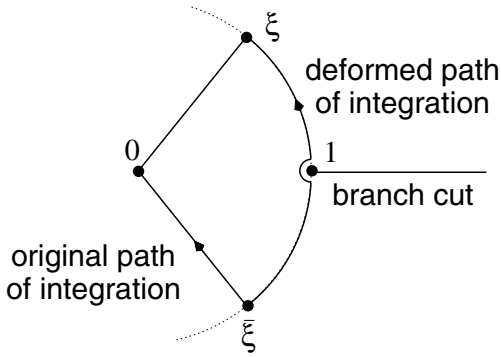

FIG. A.1. *Integration paths in the degenerate kernel approximation of* $K(x)$.

and the order of summation and integration may be interchanged by the dominated convergence theorem, i.e.,

$$\int_0^1 -\frac{\log(1-r\xi)}{r\xi}\xi\,\mathrm{d}r = \sum_{n=1}^{\infty}\int_0^1 \frac{(r\xi)^{n-1}}{n}\xi\,\mathrm{d}r = \sum_{n=1}^{\infty}\frac{\xi^n}{n^2}. \tag{A.3}$$

Similarly,

$$\int_0^1 -\frac{\log(1-r\bar{\xi})}{r\bar{\xi}}\bar{\xi}\,\mathrm{d}r = \sum_{n=1}^{\infty}\frac{\bar{\xi}^n}{n^2}. \tag{A.4}$$

Subtracting the last two expressions and recognizing that $\bar{\xi} = 1/\xi$ yields

$$\sum_{n=-\infty,\, n\neq 0}^{\infty}\frac{\xi^n}{n|n|} = \int_0^1 -\frac{\log(1-r\xi)}{r\xi}\xi\,\mathrm{d}r - \int_0^1 -\frac{\log(1-r\bar{\xi})}{r\bar{\xi}}\bar{\xi}\,\mathrm{d}r. \tag{A.5}$$

However, the right-hand side is just the integral $\int -\frac{1}{\zeta}\log(1-\zeta)\,\mathrm{d}\zeta$ taken along the radial path from $\bar{\xi}$ to ξ via the origin (see Figure A.1). Since the integrand $-\frac{1}{\zeta}\log(1-\zeta)$ can be made holomorphic in the complex plane cut along the interval $[1,\infty)$ on the real line, the curve along which the integral is taken can be deformed to lie on the unit circle, with a small indentation at the branch point $\zeta = 1$ (Figure A.1). The indentation does not contribute to the integral along the deformed curve in the limit where the radius of the indentation tends to zero. Setting $\xi = \exp(i2\pi X)$, the integral may thus be expressed as

$$\begin{aligned}\sum_{n=-\infty,\, n\neq 0}^{\infty}\frac{\xi^n}{n|n|} &= -i2\pi\int_{-X}^{X}\log\left[1-\exp(i2\pi X')\right]\,\mathrm{d}X' \\ &= -i2\pi\int_{0}^{X}\log\left[1-\exp(i2\pi X')\right] + \log\left[1-\exp(-i2\pi X')\right]\,\mathrm{d}X' \\ &= -i2\pi\int_{0}^{X}\log\left[4\sin^2(\pi X')\right]\,\mathrm{d}X'. \end{aligned} \tag{A.6}$$

Consequently, the kernel K defined by (3.74) may be written as

$$K(X) = \frac{1}{4\pi}\int_0^X \log\left[4\sin^2(\pi X')\right]\,\mathrm{d}X' = \sum_{n=-\infty,\, n\neq 0}^{\infty} \frac{i\xi^n}{8\pi^2 n|n|}. \tag{A.7}$$

The argument above has shown that the series on the right converges pointwise to the integral in the middle. By the Weierstrass M-test, it also converges uniformly; that is, $K_{n_0}(X)$ defined in (3.75) converges to $K(X)$ in the $C([0,B])$ norm as $n_0 \to \infty$.

Lastly, it follows immediately that $K(1) = 0$, and (3.56) holds.

A.2. Differentiation under the integral sign. We can use the series representation (A.7) of the kernel K to show that (A.1) holds. Specifically, let

$$\mu\tilde{S}_{n_0}(X) = -\int_0^B K_{n_0}(X - X')\tilde{S}(X')\,\mathrm{d}X' + 1, \tag{A.8}$$

where K_{n_0} is defined in (3.75). It is easy to see that $\tilde{S}_{n_0}$ converges to $\tilde{S}$ in the $C([0,B])$ norm. Since K'_{n_0} is continuous and hence bounded, we can further differentiate directly,

$$\mu\tilde{S}'_{n_0}(X) = -\int_0^B K'_{n_0}(X - X')\tilde{S}(X')\,\mathrm{d}X', \tag{A.9}$$

and $\tilde{S}_{n_0} \in C^1([0,B])$. But $K'_{n_0}(X) = -\sum_{n=-n_0,n\neq 0}^{n_0} \exp(i2\pi X)/(4\pi n)$ converges to $K'(X)$ almost everywhere in $[0,1]$ by the results of section A.1. Moreover, because $\sum_{n=1}^{\infty} 1/|n|^2 < \infty$, $K'_{n_0}(X)$ also converges as a Fourier series to $K'(X)$ in the $L^2([0,1])$-norm, and hence in the $L^1([0,1])$-norm. Hence, for $B \in [0,1]$,

$$\begin{aligned}\sup_{x\in[0,B]} &\left|\int_0^B K'_{n_0}(X - X')\tilde{S}(X')\,\mathrm{d}X' - \int_0^B K'(X - X')\tilde{S}(X')\,\mathrm{d}X'\right| \\ &\leq \sup_{X\in[0,B]} |\tilde{S}(X)| \int_0^1 \left|K'_{n_0}(X') - K'(X')\right|\,\mathrm{d}X' \to 0\end{aligned} \tag{A.10}$$

as $n_0 \to \infty$. By the completeness of $C^1([0,B])$, we therefore have

$$\mu\tilde{S}'(X) = \mu\frac{\mathrm{d}}{\mathrm{d}X}\lim_{n_0\to\infty}\tilde{S}_{n_0}(X) = -\int_0^B K'(X - X')\tilde{S}(X')\,\mathrm{d}X', \tag{A.11}$$

which is (A.1).

ATTRACTORS IN CONFINED SOURCE PROBLEMS FOR COUPLED NONLINEAR DIFFUSION*

D. V. STRUNIN†

Abstract. In processes driven by nonlinear diffusion, a signal from a concentrated source is confined in a finite region. Such solutions can be sought in the form of power series in a spatial coordinate. We use this approach in problems involving coupled agents. To test the method, we consider a single equation with (a) linear and (b) quadratic diffusivity in order to recover the known results. The original set of PDEs is converted into a dynamical system with respect to the time-dependent series coefficients. As an application we consider an expansion of a free turbulent jet. Some example trajectories from the respective dynamical system are presented. The structure of the system hints at the existence of an attracting center manifold. The attractor is explicitly found for a reduced version of the system.

1. Introduction.

A variety of physical processes are described by the nonlinear diffusion equations

$$\partial_t K = (-1)^n \nabla \left(K^m \nabla \, \Delta^n K \right), \tag{1}$$

where $n \geq 0$ is an integer and $m > 0$. In the particular case of $n = 0$, (1) becomes the second-order diffusion equation

$$\partial_t K = \nabla \left(K^m \nabla K \right). \tag{2}$$

An important common property of the nonlinear diffusion (2) and its higher-order generalizations (1) is the finiteness of the speed of a signal propagation. If the signal is initially confined in a finite region so that it is identically equal to zero beyond the region, the signal remains confined during the dynamics. This property distinguishes the nonlinear diffusion from the linear diffusion ($m = 0$), where the signal instantaneously propagates to infinity.

The range of processes described by (1)–(2) is wide. The second-order equations (2) are known as the porous medium equations and appear in models of gas filtration in porous media [1, 2] and thin fluid films in a gravitational field ($m = 3$) [3]. The fourth-order equations ($n = 1$) emerge in lubrication models for thin viscous films ($m = 3$) and Hele–Shaw flows ($m = 1$). The sixth-order models ($n = 2$) are relevant to the process of isolation oxidation of silicon ($m = 3$) [4]. The models with $m = 3$ and different values of n describe thin viscous droplets driven by different factors: gravity ($n = 0$), surface tension ($n = 1$), and an elastic plate ($n = 2$).

Various mathematical aspects of the second-order equation (2) are analyzed in [5, 6, 7]; the fourth-order model is investigated, for example, in [8]. Numerical schemes for

†Department of Mathematics and Computing, University of Southern Queensland, Toowoomba, QLD 4350, Australia (strunin@usq.edu.au).

solving the fourth- and sixth-order equations using finite differences or finite elements are developed in [9, 10, 11].

In this paper we focus on attractors in coupled nonlinear diffusion with confined sources when there are more than one diffusing agent.

To give an example of an attractor in nonlinear diffusion we consider the second-order equation (2) in one dimension, $\partial_t K = \partial_x(K^m \partial_x K)$. Its solution evolving from a confined initial profile is attracted to the universal regime [12, 13],

$$K(x,t) = \frac{\gamma(m)}{t^{1/(m+2)}} \left(\xi_0^2 - \xi^2\right)^{1/m}, \tag{3}$$

where

$$\xi = \frac{x}{t^{1/(m+2)}}, \quad \xi_0 = \left[\frac{\Gamma\left(\frac{1}{m}+\frac{3}{2}\right)}{\gamma(m)\sqrt{\pi}\,\Gamma\left(\frac{1}{m}+1\right)} E\right]^{\frac{m}{m+2}}, \quad \gamma(m) = \left[\frac{m}{2(m+2)}\right]^{\frac{1}{m}},$$

Γ is the gamma-function, and E is the integral

$$E = \int_{-\infty}^{\infty} K(x,t)\,dx,$$

which conserves during the evolution. For our purposes it is convenient to write the attractor (3) in the form

$$K(x,t) = \frac{\alpha}{t^{1/(m+2)}} \left(1 - \frac{\beta}{t^{2/(m+2)}}\, x^2\right)^{1/m}, \tag{4}$$

where α and β are the coefficients depending on m and E.

Similar attractors exist for the higher-order equations (1). For example, in one dimension for $m = 1$ and $n = 1$, i.e., for the fourth-order equation $\partial_t K = \partial_x(K\partial_x^3 K)$, the attractor is [14]

$$K(x,t) = \frac{1}{120\,t^{1/5}} \left(\xi_0^2 - \xi^2\right)^2,$$

where

$$\xi = \frac{x}{t^{1/5}}, \quad \xi_0 = \left(\frac{225E}{2}\right)^{1/5}.$$

Recently in [11], (1) was analyzed numerically for $n = 2$ and $m = 1$, that is, the sixth-order equation $\partial_t K = \partial_x(K\partial_x^5 K)$. It was proved that the solution converges to the attractor found in [14].

Many processes involve more than one diffusing agent. For example, in a free turbulent jet the diffusing turbulent energy is coupled with the diffusing momentum. We analyze this process later in the paper. In the multicomponent problems an important question to answer is whether there exists an attractor.

Another motivation for us to analyze this particular phenomenon stems from fluid mechanics, where an expansion of a jet from a narrow pulse is a natural problem formulation. For other processes, other regimes can be of interest. For example, in the isolation oxidation of silicon, traveling waves are of major interest [10].

In this paper we take an approach in which confined solutions are sought as power-series in a spatial coordinate. The diffusion of the turbulent jet is one of many problems to which this approach is applicable.

Previously [15] we studied the expansion of the turbulent jet using a *nonlocal* version of the K-ℓ model of turbulence (see, e.g., the review [16]).

In the present paper we use the K-ε model [17, 18], which is *local*. The locality enables us to convert the governing PDEs into a set of ODEs. Thus, the problem transforms into a standard dynamical system formulation, in which framework we look for an attractor.

As a first step, in section 2 we test our approach on some standard problems to recover known results. Then, in section 3 the approach is applied to the turbulent jet. In section 4 we analyze in detail its reduced version. The conclusions are given in section 5.

2. Power-series approach. In this section we formulate our approach and test it on simple problems. We consider the nonlinear diffusion with linear and then quadratic diffusivity.

2.1. Diffusion with linear diffusivity. Consider (2) with $m = 1$:

$$\partial_t K = \partial_x (K \partial_x K). \tag{5}$$

The long-term asymptotics (4) of its pulse solution is

$$K = \frac{\alpha}{t^{1/3}} \left(1 - \beta \frac{x^2}{t^{2/3}} \right) \tag{6}$$

or

$$K = a(t) \left[1 - b(t) x^2 \right] \tag{7}$$

with

$$a(t) = \frac{\alpha}{t^{1/3}}, \quad b(t) = \frac{\beta}{t^{2/3}}.$$

For finite times, assuming an initial pulse is symmetric, we seek a solution in the form

$$K(x,t) = A(t) \left[1 - B_2(t) x^2 - B_4(t) x^4 - B_6(t) x^6 - \cdots \right], \tag{8}$$

where $A(t) > 0$ is the value of K at $x = 0$. Expression (8) is acceptable as long as it gives a positive answer. Thus, (8) represents the solution on some interval $0 \le x \le h(t)$, where $h(t)$ is the position of the front in which $K[h(t), t] = 0$. Beyond the front, for $x > h(t)$, formula (8) does not apply; we assume $K(x,t) \equiv 0$ instead. With various initial values $B_k(0)$, $k = 2, 4, \ldots$, the form (8) expresses a wide class of symmetric initial conditions. Apparently $B_k(t)$ are proportional to the Taylor-series coefficients of $K(x,t)$.

Substituting (8) into (5), collecting the terms with the same powers of x, and equating the coefficients gives

$$\begin{aligned} \dot{A} &= -2A^2 B_2, \\ \dot{B}_2 &= -4AB_2^2 + 12AB_4, \\ \dot{B}_4 &= -28AB_2B_4 + 30AB_6, \\ \dot{B}_6 &= -54AB_2B_6 - 28AB_4^2 + 56AB_8, \\ &\ldots. \end{aligned} \tag{9}$$

The system (9) contains no linear terms; however, we can "create" those by modifying time. Divide all the equations in (9) by AB_2 and introduce the new time τ by

$$\frac{d}{AB_2\,dt} = \frac{d}{d\tau} \equiv ()'. \tag{10}$$

Then system (9) transforms into

$$\begin{aligned} A' &= -2A, \\ B_2' &= -4B_2 + 12\frac{B_4}{B_2}, \\ B_4' &= -28B_4 + 30\frac{B_6}{B_2}, \\ B_6' &= -54B_6 - 28\frac{B_4^2}{B_2} + 56\frac{B_8}{B_2}, \\ &\dots. \end{aligned} \tag{11}$$

Looking at the coefficients of the linear terms we notice a considerable spectral gap between the coefficient -4 at B_2 in the equation $B_2' = \dots$ and the coefficient -28 at B_4 in the equation $B_4' = \dots$. Therefore we can expect that B_4 and the subsequent B_k, $k = 6, 8, \dots$, will decay much faster than A and B_2. This is confirmed numerically as demonstrated by Figure 1. The plot shows a family of trajectories for the truncated system formed by the dynamic equations for B_2, B_4, and B_6 in (11) with the term containing B_8 removed. The figure gives three different views of the same trajectories to expose the faster decay of B_4 and B_6 in comparison to B_2.

The numerical results in this paper are obtained with the MATLAB solver DAE2 developed by Roberts [19].

It is interesting to evaluate the contribution of different terms, $(-B_k x^k)$, in the function

$$1 - B_2x^2 - B_4x^4 - B_6x^6 - \cdots \tag{12}$$

defining the shape of $K(x,t)$. Let us compare the terms for the largest value of x inside the signal, that is, the coordinate of the front, $x = h(t)$. Retain the first three terms in (12), presuming that the input of the sixth- and higher-order terms is negligible. On the front the signal vanishes, and therefore approximately

$$1 - B_2h^2 - B_4h^4 = 0.$$

From here

$$h^2 = \left(-B_2 + \sqrt{B_2^2 + 4B_4}\right) \Big/ (2B_4). \tag{13}$$

Further, if we suppose that

$$B_4 \ll B_2/h^2, \tag{14}$$

then the fourth-order term appears to be negligible compared to the quadratic term. Inserting (13) into (14) and rearranging, we obtain

$$B_4 \ll 2B_2^2. \tag{15}$$

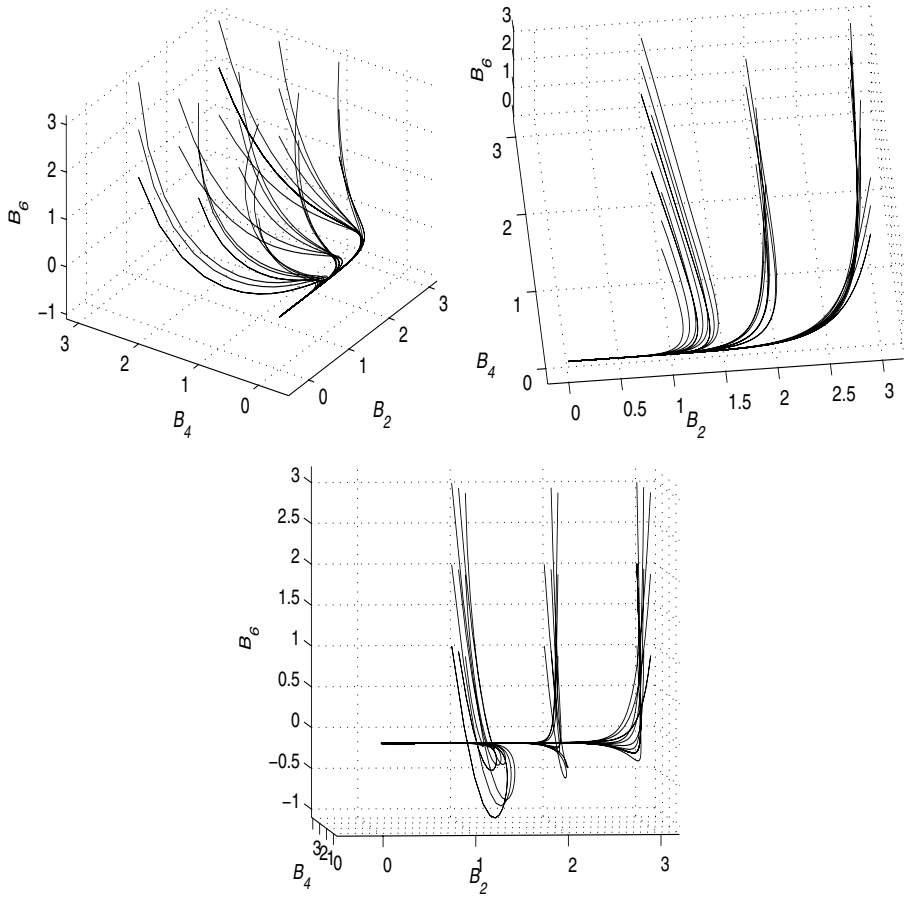

FIG. 1. *Solutions of truncated system* (11).

In the numerical experiments the condition (15) was satisfied several orders over. Tracking the value of $h(t)$ directly from the numerical experiment confirms the negligible contribution of the fourth- and higher-order terms.

Thus, the power-series approach recovered the expected result that (6) is indeed the attractor for the diffusion problem with the linear diffusivity.

2.2. Diffusion with quadratic diffusivity. In this section we consider the diffusion equation with quadratic diffusivity,

$$\partial_t K = \partial_x \left(K^2 \partial_x K \right). \tag{16}$$

Its pulse solution (4) has the form

$$K = \frac{\alpha}{t^{1/4}} \left(1 - \beta \frac{x^2}{t^{1/2}} \right)^{1/2}. \tag{17}$$

Expanding (17) into the Taylor-series, we get

$$K(x,t) = a(t) \left[1 - b_2(t) x^2 - b_4(t) x^4 - b_6(t) x^6 - \cdots \right], \tag{18}$$

where

$$
\begin{aligned}
&b_2(t) = \beta\frac{1}{2\sqrt{t}}, \quad b_4(t) = \beta^2\frac{1}{8t},\\
&b_6(t) = \beta^3\frac{1}{16t^{3/2}}, \quad b_8(t) = \beta^4\frac{5}{128t^2},\\
&\ldots.
\end{aligned}
\tag{19}
$$

It converges for $\beta x^2/t^{1/2} \le 1$, that is, for all x of interest, $0 \le x \le h(t) = t^{1/2}/\beta$. Any b_k in (19) can be expressed through a selected one, for instance, b_2:

$$
b_4 = \frac{1}{2}b_2^2, \quad b_6 = \frac{1}{2}b_2^3, \quad b_8 = \frac{5}{8}b_2^4, \quad \ldots. \tag{20}
$$

Expressions (20) describe the attractor which we intend to reproduce by our approach. As in the previous section, we seek a power-series solution of (16),

$$
K(x,t) = A(t)\,[1 - B_2(t)x^2 - B_4(t)x^4 - B_6(t)x^6 - \cdots]. \tag{21}
$$

Substituting (21) into (16) leads to

$$
\begin{aligned}
&\dot{A} = -2A^3B_2,\\
&\dot{B}_2 = -10A^2B_2^2 + 12A^2B_4,\\
&\dot{B}_4 = -58A^2B_2B_4 + 30A^2B_6 + 10A^2B_2^3,\\
&\dot{B}_6 = -110A^2B_2B_6 + 56A^2B_2^2B_4 - 56A^2B_4^2 + 56A^2B_8,\\
&\dot{B}_8 = -178A^2B_2B_8 + 90A^2B_2^2B_6 + 90A^2B_2B_4^2 - 180A^2B_4B_6 + 90A^2B_{10},\\
&\ldots.
\end{aligned}
\tag{22}
$$

We divide all the equations in (22) by A^2B_2 and introduce the new time τ by

$$
\frac{d}{A^2B_2\,dt} = \frac{d}{d\tau} \equiv ()'. \tag{23}
$$

As a result, system (22) transforms into the following form with linear terms:

$$
\begin{aligned}
&A' = -2A,\\
&B_2' = -10B_2 + \frac{12B_4}{B_2},\\
&B_4' = -58B_4 + \frac{30B_6}{B_2} + 10B_2^2,\\
&B_6' = -110B_6 + 56B_2B_4 - \frac{56B_4^2}{B_2} + \frac{56B_8}{B_2},\\
&B_8' = -178B_8 + 90B_2B_6 + 90B_4^2 - \frac{180B_4B_6}{B_2} + \frac{90B_{10}}{B_2},\\
&\ldots.
\end{aligned}
\tag{24}
$$

Consider only three dynamic equations for B_2, B_2, and B_4 with the term containing B_8 omitted. A set of trajectories for such a system is shown in Figure 2. It is clearly seen from different angles that the trajectories are attracted to a single curve or a one-dimensional manifold. It can be shown that the curve is described by

$$
B_4 = \gamma B_2^3, \quad B_6 = \mu B_2^3, \tag{25}
$$

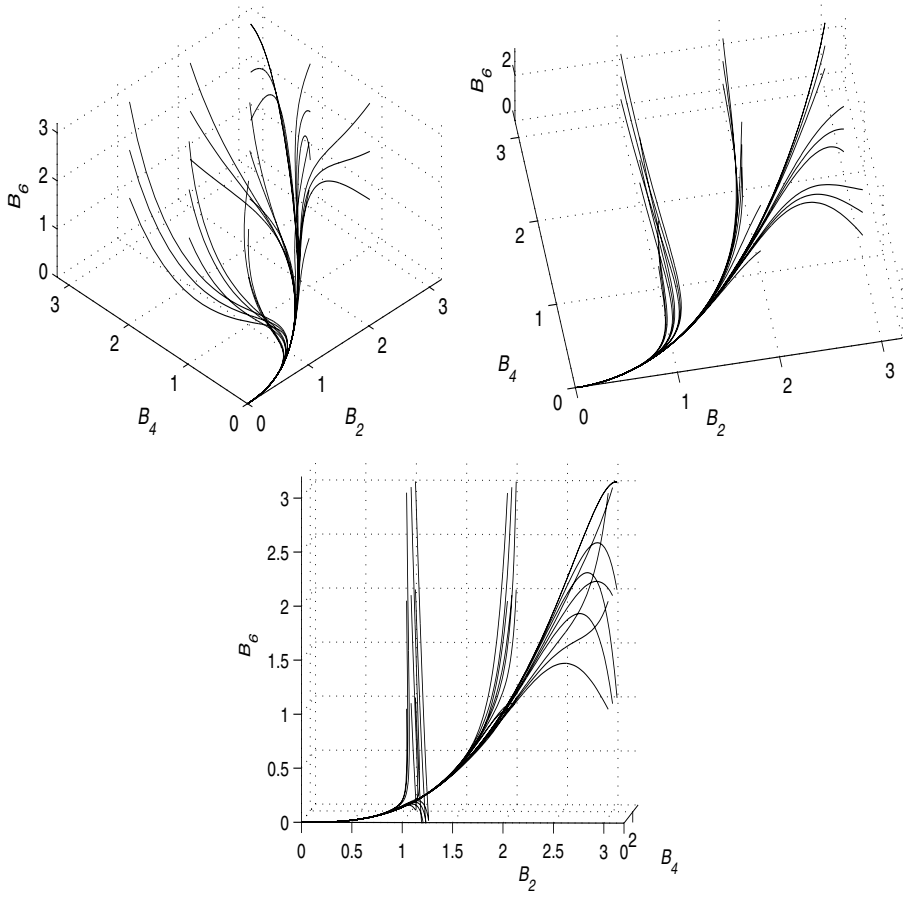

FIG. 2. *Solutions of truncated system* (24).

where γ and μ are parameters. It is interesting to compare them to their values on the attractor defined by (20). We substitute (25) into (24) to obtain

$$\begin{aligned} B_2' &= (-10 + 12\gamma)\, B_2, \\ B_2' &= \left(-29 + \frac{15\mu}{\gamma} + \frac{5}{\gamma}\right) B_2, \\ B_2' &= \left(-\frac{110}{3} + \frac{56\gamma}{3\mu} - \frac{56\gamma^2}{3\mu}\right) B_2. \end{aligned} \tag{26}$$

As each of the equations in (26) describes the motion on the attractor, they all must coincide. So must the coefficients at B_2 in their right-hand sides. This leads to two algebraic equations with respect to γ and μ, giving approximately $\gamma = 0.31$, $\mu = 0.14$. Compare these to the exact values from (20),

$$\gamma_* = 1/2 = 0.5, \quad \mu_* = 1/2 = 0.5.$$

The departure from the exact values can be diminished by involving more equations. For the four-equation system with respect to B_2, B_4, B_6, and B_8, with the term

containing B_{10} excluded, we have

$$B_4 = \gamma B_2^3, \quad B_6 = \mu B_2^3, \quad B_8 = \lambda B_2^4. \tag{27}$$

Inserting (27) into (24) leads to a system of three equations, with respect to γ, μ, and λ, having the approximate solution $\gamma = 0.35$, $\mu = 0.20$, $\lambda = 0.11$. Note that from (20) the exact value for λ is $\lambda_* = 5/8 = 0.62$. To improve the approximation further, more equations have to be involved.

In summary, we reproduced the well-known fact that for the diffusion with quadratic diffusivity the trajectories converge to a one-dimensional manifold representing the similarity regime (17).

3. The K-ε model of a turbulent jet. Consider a turbulent jet created in an unbounded motionless fluid by a quick impulse shaped in space as a narrow flat layer. For instance, some amount of fluid is quickly injected. The velocity shear between the jet and surrounding fluid pumps up the kinetic energy of turbulence. The turbulent region expands and, in the long term, the energy decays due to the geometric effect of expansion and the loss into heat caused by intersections of vortices (we will call this loss simply dissipation).

The expansion is driven by the turbulent diffusion which is essentially nonlinear. As a consequence, the jet has a sharp front similar to the above examples. However, the dynamics is complicated by the coupling between the kinetic energy, dissipation, and momentum. The K-ε model of turbulence [17, 18] is written

$$\begin{aligned}
\partial_t K &= \alpha_1 \partial_x \left(\frac{K^2}{\varepsilon} \partial_x K \right) + \alpha_2 \frac{K^2}{\varepsilon} \left(\partial_x u \right)^2 - \alpha_3 \varepsilon, \\
\partial_t \varepsilon &= \beta_1 \partial_x \left(\frac{K^2}{\varepsilon} \partial_x \varepsilon \right) + \beta_2 K \left(\partial_x u \right)^2 - \beta_3 \frac{\varepsilon^2}{K}, \\
\partial_t u &= \chi \partial_x \left(\frac{K^2}{\varepsilon} \partial_x u \right).
\end{aligned} \tag{28}$$

In (28) the coordinate x is directed across the flat turbulent layer originating in its middle, K stands for the kinetic energy of turbulent pulsations per mass unit, and ε is the dissipation of the turbulent energy; $\alpha_{1,2,3}$, $\beta_{1,2,3}$, and χ are nondimensional coefficients. The system (28) is nondimensional, obtained from dimensional form by using some useful scales, for example, the average initial velocity across the jet, U, as the velocity scale; the initial width of the jet, $2h$, as the length scale; U^2 as the turbulent energy scale; U^3/h as the dissipation rate scale; and h/U as the time scale.

The initial profiles of K, ε, and u across the turbulent layer are assumed to have dome-like forms. We assume that they are symmetric with respect to the middle of the layer. On the edge, or front, of the jet the functions descend to zero and remain zero beyond the front (see the discussion further in this section).

We look for the power-series solutions of (28),

$$\begin{aligned}
K &= A(t) \left[1 - B_2(t) x^2 - B_4(t) x^4 - B_6(t) x^6 - \cdots \right], \\
\varepsilon &= P(t) \left[1 - R_2(t) x^2 - R_4(t) x^4 - R_6(t) x^6 - \cdots \right], \\
u &= M(t) \left[1 - N_2(t) x^2 - N_4(t) x^4 - N_6(t) x^6 - \cdots \right].
\end{aligned} \tag{29}$$

Substituting the series (29) into the dynamic equations (28) leads to

$$
\begin{aligned}
\dot{A} &= -\alpha_1 \frac{2A^3 B_2}{P} - \alpha_3 P,\\
\dot{P} &= -\beta_1 2A^2 R_2 - \beta_3 \frac{P^2}{A},\\
\dot{M} &= -\chi \frac{2A^2 M N_2}{P},\\
\dot{B}_2 &= -\alpha_1 \frac{10A^2 B_2^2}{P} + \alpha_3 \frac{PB_2}{A} + \alpha_1 \frac{6A^2 B_2 R_2}{P} + \alpha_1 \frac{12A^2 B_4}{P}\\
&\quad - \alpha_2 \frac{4AM^2 N_2^2}{P} - \alpha_3 \frac{PR_2}{A},\\
\dot{R}_2 &= -\beta_1 \frac{12A^2 B_2 R_2}{P} + \beta_1 \frac{8A^2 R_2^2}{P} - \beta_3 \frac{PR_2}{A} + \beta_1 \frac{12A^2 R_4}{P}\\
&\quad - \beta_2 \frac{4AM^2 N_2^2}{P} + \beta_3 \frac{PB_2}{A},\\
\dot{N}_2 &= -\chi \frac{12A^2 B_2 N_2}{P} + \chi \frac{2A^2 N_2^2}{P} + \chi \frac{6A^2 N_2 R_2}{P} + \chi \frac{12A^2 N_4}{P},\\
\dot{B}_4 &= -\alpha_1 \frac{58A^2 B_2 B_4}{P} + \alpha_3 \frac{PB_4}{A} + \alpha_1 \frac{10A^2 B_2^3}{P} - \alpha_1 \frac{20A^2 B_2^2 R_2}{P}\\
&\quad + \alpha_1 \frac{10A^2 B_2 R_2^2}{P} + \alpha_1 \frac{10A^2 B_2 R_4}{P} + \alpha_1 \frac{20A^2 B_4 R_2}{P} + \alpha_1 \frac{30A^2 B_6}{P}\\
&\quad + \alpha_2 \frac{8AB_2 M^2 N_2^2}{P} - \alpha_2 \frac{4AM^2 N_2^2 R_2}{P} - \alpha_2 \frac{16AM^2 N_2 N_4}{P} - \alpha_3 \frac{PR_4}{A},\\
\dot{R}_4 &= -\beta_1 \frac{40A^2 B_2 R_4}{P} + \beta_1 \frac{2A^2 R_2 R_4}{P} - \beta_3 \frac{PR_4}{A} + \beta_1 \frac{10A^2 B_2^2 R_2}{P}\\
&\quad - \beta_1 \frac{20A^2 B_2 R_2^2}{P} - \beta_1 \frac{20A^2 B_4 R_2}{P} + \beta_1 \frac{10A^2 R_2^3}{P} + \beta_1 \frac{30A^2 R_2 R_4}{P}\\
&\quad + \beta_1 \frac{30A^2 R_6}{P} + \beta_2 \frac{4AB_2 M^2 N_2^2}{P} - \beta_2 \frac{16AM^2 N_2 N_4}{P} + \beta_3 \frac{PB_2^2}{A}\\
&\quad - \beta_3 \frac{2B_2 PR_2}{A} + \beta_3 \frac{B_4 P}{A} + \beta_3 \frac{PR_2^2}{A},\\
\dot{N}_4 &= -\chi \frac{40A^2 B_2 N_4}{P} + \chi \frac{2A^2 N_2 N_4}{P} + \chi \frac{10A^2 B_2^2 N_2}{P} - \chi \frac{20A^2 B_2 N_2 R_2}{P}\\
&\quad - \chi \frac{20A^2 B_4 N_2}{P} + \chi \frac{10A^2 N_2 R_2^2}{P} + \chi \frac{10A^2 N_2 R_4}{P} + \chi \frac{20A^2 N_4 R_2}{P}\\
&\quad + \chi \frac{30A^2 N_6}{P},\\
&\ldots.
\end{aligned}
\tag{30}
$$

An immediate idea of how to solve (30) could be to truncate the system by removing higher-order variables and solve the resulting closed system under some initial conditions. However, such an approach has a serious flaw since there is no guarantee that the three fronts—the energy front, dissipation front, and velocity front—would coincide during the evolution. By the physics of diffusion, if the fronts do not coincide initially, they must catch up with each other. Suppose, for example, that initially the velocity front is behind the energy and dissipation fronts (suppose that these two coincide). Then the turbulent diffusion will instantaneously transfer the momentum forward up to the energy/dissipation front position. Conversely, if the velocity front

is initially ahead of the energy/dissipation front, it will be motionless for some time, as there is no turbulence in its vicinity. The velocity front would move only when the energy/dissipation front catches up, after which all the fronts move together. The front $x = h(t)$, where the energy, dissipation, and velocity decrease to a zero level, is a special point, yet the system (30) "does not know about it." We should explicitly impose the physical condition that the three profiles (29) must meet at the point $(K = \varepsilon = u = 0,\ x = h)$.

Let us demonstrate with a simple example that the lack of such a condition leads to the growth of the gap between the fronts. Consider a relatively simple model

$$\partial_t K = \partial_x(K\partial_x K),$$
$$\partial_t u = \partial_x(K\partial_x u),$$

without attributing any physical sense to K and u. We look for power-series solutions in the form of (29) and transfer to the new time by using $AB_2\,dt = d\tau$. Retaining only two leading equations for the series coefficients and removing terms with B_4 and N_4, we have

$$\begin{aligned} B_2' &= -4B_2, \\ N_2' &= -6N_2 + \frac{2N_2^2}{B_2}. \end{aligned} \tag{31}$$

Upon solving (31), the front of K can be determined from

$$1 - B_2 h_K^2 = 0,$$

and the front of u can be found from

$$1 - N_2 h_u^2 = 0.$$

Clearly $N_2 = B_2$ satisfies (31), but is this solution stable? Introduce the perturbation s by

$$N_2 = B_2 - s. \tag{32}$$

Substituting (32) into (31) and linearizing, we get

$$s' = -2s.$$

The perturbation decays as $\exp(-2\tau)$, whereas B_2 decays, according to (31), as $\exp(-4\tau)$. Thus, the perturbation goes to zero slower than the function itself. This leads to a large discrepancy between the values of B_2 and N_2, and hence in the front positions, $h_u^2 = 1/N_2$ and $h_K^2 = 1/B_2$. A similar effect occurs with the system (30).

Let us see how the situation changes if we require that the fronts coincide. We augment (31) by two extra equations stating that the functions turn into zero at the same point $x = h(t)$, that is, $K(h,t) = 0$ and $u(h,t) = 0$, where K and u are represented by the truncated series (29). The two extra equations bring one extra unknown, h. Therefore we need to add another unknown to have as many equations as unknowns. Let this new unknown be N_4. We get

$$\begin{aligned} B_2' &= -4B_2, \\ N_2' &= -6N_2 + \frac{12N_4}{B_2} + \frac{2N_2^2}{B_2}, \\ 1 - B_2 h^2 &= 0, \\ 1 - N_2 h^2 - N_4 h^4 &= 0. \end{aligned} \tag{33}$$

Excluding h and N_4 from (33) leads to

$$\begin{aligned} B_2' &= -4B_2, \\ N_2' &= -6N_2 + \frac{2N_2^2}{B_2} + 12(B_2 - N_2). \end{aligned} \tag{34}$$

Substituting (32) into (34) and linearizing gives

$$s' = -14s.$$

Now s decays much faster than B_2 so that, in contrast to the previous case, B_2 and N_2 become closer to each other.

Applying a similar approach to the system (30), we require that K, ε, and u turn into zero at the same location $x = h(t)$. Retaining in the power-series (29) only terms up to the fourth order, we require

$$\begin{aligned} 1 - B_2h^2 - B_4h^4 &= 0, \\ 1 - R_2h^2 - R_4h^4 &= 0, \\ 1 - N_2h^2 - N_4h^4 &= 0. \end{aligned} \tag{35}$$

Equations (35) are complemented by the truncated dynamic equations (30),

$$\begin{aligned} \dot{A} &= -\alpha_1\frac{2A^3B_2}{P} - \alpha_3 P, \\ \dot{P} &= -\beta_1 2A^2R_2 - \beta_3\frac{P^2}{A}, \\ \dot{M} &= -\chi\frac{2A^2MN_2}{P}, \\ \dot{B}_2 &= -\alpha_1\frac{10A^2B_2^2}{P} + \alpha_3\frac{PB_2}{A} + \alpha_1\frac{6A^2B_2R_2}{P} + \alpha_1\frac{12A^2B_4}{P} \\ &\quad - \alpha_2\frac{4AM^2N_2^2}{P} - \alpha_3\frac{PR_2}{A}, \\ \dot{R}_2 &= \beta_1\frac{8A^2R_2^2}{P} - \beta_3\frac{PR_2}{A} - \beta_1\frac{12A^2B_2R_2}{P} + \beta_1\frac{12A^2R_4}{P} \\ &\quad - \beta_2\frac{4AM^2N_2^2}{P} + \beta_3\frac{PB_2}{A}, \\ \dot{N}_2 &= \chi\frac{2A^2N_2^2}{P} - \chi\frac{12A^2B_2N_2}{P} + \chi\frac{6A^2N_2R_2}{P} + \chi\frac{12A^2N_4}{P}, \\ \dot{B}_4 &= -\alpha_1\frac{58A^2B_2B_4}{P} + \alpha_3\frac{PB_4}{A} + \alpha_1\frac{10A^2B_2^3}{P} - \alpha_1\frac{20A^2B_2^2R_2}{P} \\ &\quad + \alpha_1\frac{10A^2B_2R_2^2}{P} + \alpha_1\frac{10A^2B_2R_4}{P} + \alpha_1\frac{20A^2B_4R_2}{P} + \alpha_1\frac{30A^2B_6}{P} \\ &\quad + \alpha_2\frac{8AB_2M^2N_2^2}{P} - \alpha_2\frac{4AM^2N_2^2R_2}{P} - \alpha_2\frac{16AM^2N_2N_4}{P} - \alpha_3\frac{PR_4}{A}. \end{aligned} \tag{36}$$

The system (35)–(36) contains 10 equations with respect to 10 time-dependent functions: A, P, M, B_2, R_2, N_2, B_4, R_4, N_4, and h.

As before, we "create" linear terms by modifying time:

$$\frac{d}{(A^2B_2/P)\,dt} = \frac{d}{d\tau} \equiv ()'. \tag{37}$$

Dividing (36) by A^2B_2/P and converting to τ results in

$$\begin{aligned}
A' &= -\alpha_1 2A - \alpha_3 \frac{P^2}{A^2B_2},\\
P' &= -\beta_1 \frac{2R_2P}{B_2} - \beta_3 \frac{P^3}{A^3B_2},\\
M' &= -\chi \frac{2MN_2}{B_2},\\
B_2' &= -\alpha_1 10B_2 + \alpha_3 \frac{P^2}{A^3} + \alpha_1 6R_2 + \alpha_1 \frac{12B_4}{B_2}\\
&\quad - \alpha_2 \frac{4M^2N_2^2}{AB_2} - \alpha_3 \frac{P^2R_2}{A^3B_2},\\
R_2' &= -\beta_1 12R_2 + \beta_1 \frac{8R_2^2}{B_2} - \beta_3 \frac{P^2R_2}{A^3B_2} + \beta_1 \frac{12R_4}{B_2}\\
&\quad - \beta_2 \frac{4M^2N_2^2}{AB_2} + \beta_3 \frac{P^2}{A^3},\\
N_2' &= -\chi 12N_2 + \chi \frac{2N_2^2}{B_2} + \chi \frac{6N_2R_2}{B_2} + \chi \frac{12N_4}{B_2},\\
B_4' &= -\alpha_1 58B_4 + \alpha_3 \frac{P^2B_4}{A^3B_2} + \alpha_1 10B_2^2 - \alpha_1 20B_2R_2\\
&\quad + \alpha_1 10R_2^2 + \alpha_1 10R_4 + \alpha_1 \frac{20B_4R_2}{B_2} + \alpha_1 \frac{30B_6}{B_2}\\
&\quad + \alpha_2 \frac{8M^2N_2^2}{A} - \alpha_2 \frac{4M^2N_2^2R_2}{AB_2} - \alpha_2 \frac{16M^2N_2N_4}{AB_2} - \alpha_3 \frac{P^2R_4}{A^3B_2}.
\end{aligned} \tag{38}$$

Figures 3, 4, and 5 display some trajectories for the system (35)–(38). We used $\alpha_1 = 0.09$, $\alpha_2 = 0.09$, $\alpha_3 = 1$, $\beta_1 = 0.07$, $\beta_2 = 0.13$, $\beta_3 = 1.92$, $\chi = 0.09$. The initial conditions were chosen to ensure the same position for the three fronts.

Figure 6 shows the front propagation. Note that the seeming acceleration occurs only in terms of the artificial time τ. In terms of the real time t the graph will have opposite curvature showing deceleration.

We notice a considerable spectral gap between the linear decay rates in (36): the coefficient at B_4, $(-58\alpha_1)$, is from 5 to 6 times larger than that of B_2, $(-10\alpha_1)$, of R_2, $(-12\beta_1)$, and of N_2, (-12χ). The numerical data show that the linear terms are the largest in absolute value in each dynamic equation.

The numerical data also show that on the initial sections of the trajectories the velocity terms M, N_2, and N_4 in the equation $B_4' = \ldots$ are much smaller than the terms associated with the energy and dissipation. However, after some period of time the velocity-associated terms become comparable to the other terms.

This points to a mechanism characteristic of center manifolds, where some variables, such as B_4 in our problem, rapidly decay until they are small enough to be comparable with the nonlinear terms which come into play.

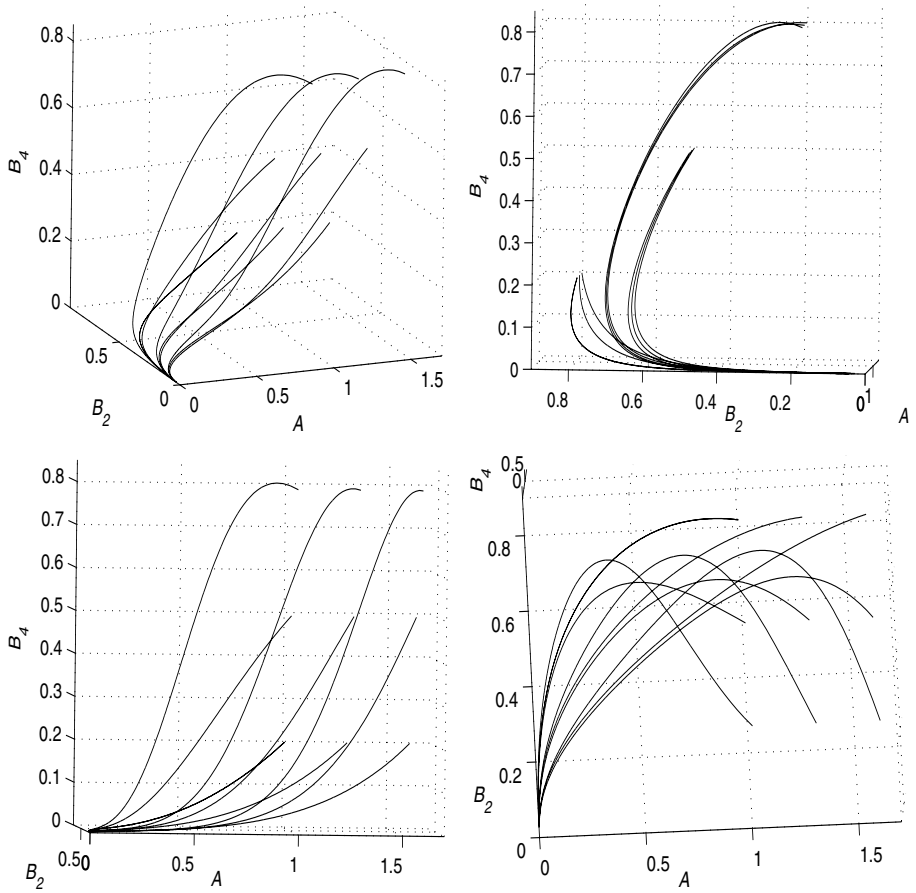

FIG. 3. *Trajectories for the model* (35)–(38) *in the space of the energy variables.*

To illustrate this mechanism we use a simple example from [20]:

$$\begin{aligned} \dot{x} &= -px - xy, \\ \dot{y} &= -y + x^2 - 2y^2. \end{aligned} \tag{39}$$

The linear decay rate p of x is much smaller than that of y, say $p = 0.1 \ll 1$. A set of trajectories for the system (39) is shown in Figure 7. See that the trajectories are attracted to a single curve. It can be shown that in the limit $p = 0$ the attractor is exactly

$$y = x^2, \tag{40}$$

which is called the center manifold. Driven by the linear term $(-y)$ the trajectories quickly drop onto the manifold on which the nonlinear terms $(x^2 - 2y^2)$ are comparable to $(-y)$. On the attractor, in view of (40), the motion is described by $\dot{x} = -xy = -x^3$. The variable y depends on t through x to which it is rigidly linked by (40).

We anticipate that a similar situation takes place in our problem with B_4 being analogous to y in the above example. However, the problem is complicated by a multitude of variables. In this paper we investigate a simplified version of the model.

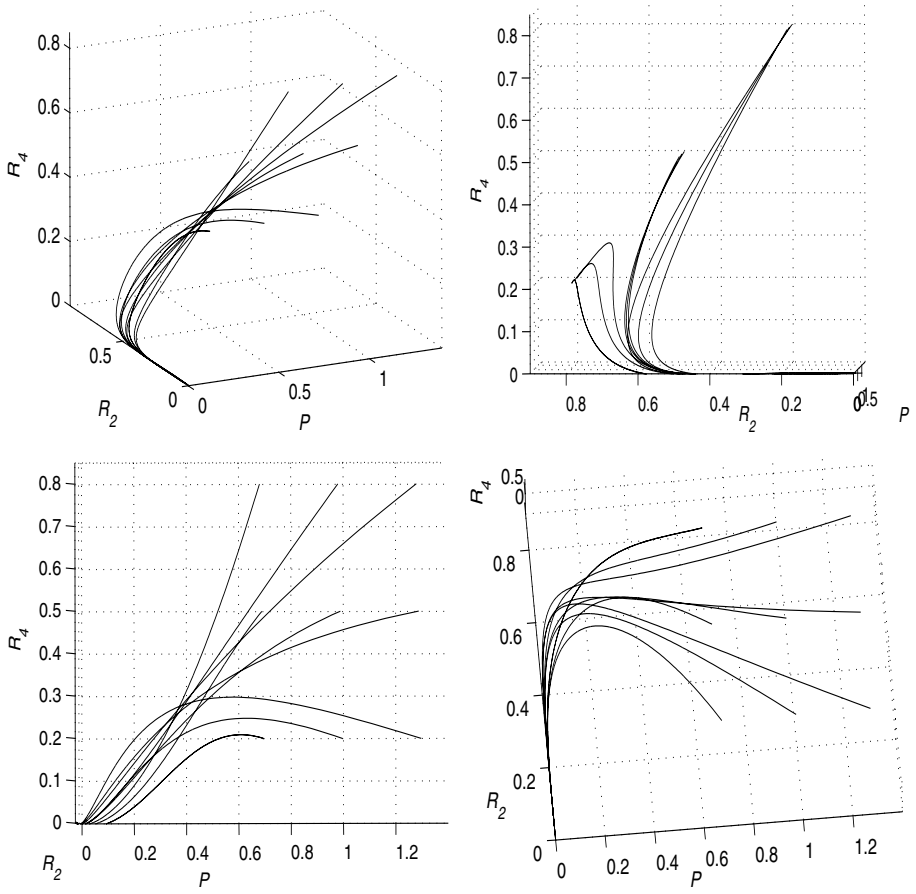

FIG. 4. *Trajectories for the model* (35)–(38) *in the space of the dissipation variables.*

4. Reduced version of the model. In this section we simplify the K-ε model (28) to a great extent, yet make sure that the key physical factors remain. These factors are the nonlinear diffusion and the coupling via the velocity shear. We will keep calling K the energy and u the velocity for consistency with the previous section. However, these terms should not be directly associated with the physical quantities. If we find attractors, our approach will provide a useful basis for studies of more complicated systems.

We assume that (a) $\alpha_3 = \beta_3 = 0$ to remove the dissipation terms, (b) $\alpha_1 = \alpha_2 = \beta_1 = \beta_2 = 1$ for simplicity, and (c) initial conditions for K and ε coincide. Thus, the problem formulations for K and ε become identical; therefore $K \equiv \varepsilon$ at all times, that is, $A(t) \equiv P(t)$ and $B_k(t) \equiv R_k(t)$, $k = 2, 4, \ldots$. As a result, system (28) reduces to the two equations

$$\begin{aligned} \partial_t K &= \partial_x \left(K \partial_x K \right) + K \left(\partial_x u \right)^2 , \\ \partial_t u &= \partial_x \left(K \partial_x u \right) . \end{aligned} \tag{41}$$

The manipulations in section 3 automatically apply to (41). The definition of new time (37) transforms into

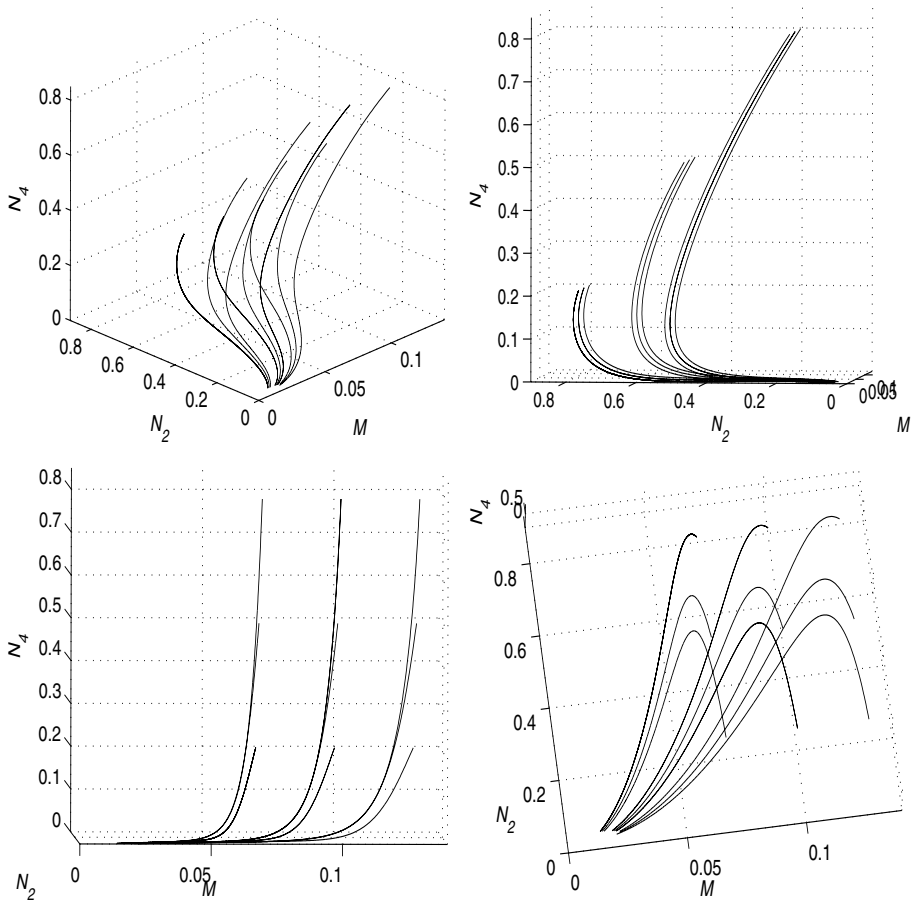

FIG. 5. *Trajectories for the model* (35)–(38) *in the space of the velocity variables.*

$$\frac{d}{(AB_2)\,dt} = \frac{d}{d\tau} \equiv ()'. \tag{42}$$

We introduce the new function

$$T \equiv \frac{M^2}{A}. \tag{43}$$

It turns out that it is possible to derive a dynamic equation for T, where M and A appear in combination (43). This equation will replace the two dynamic equations for A and M. Differentiating (43) gives

$$T' = \left(\frac{M^2}{A}\right)' = \frac{2MM'A - M^2A'}{A^2}. \tag{44}$$

The following expressions for A' and M' are obtained from (38) under conditions (a), (b), and (c): $A' = -2A$ and $M' = -2MN_2/B_2$. Substituting these into (44) gives the equation shown below.

Under assumptions (a), (b), and (c), and in view of (44), system (35)–(38) becomes

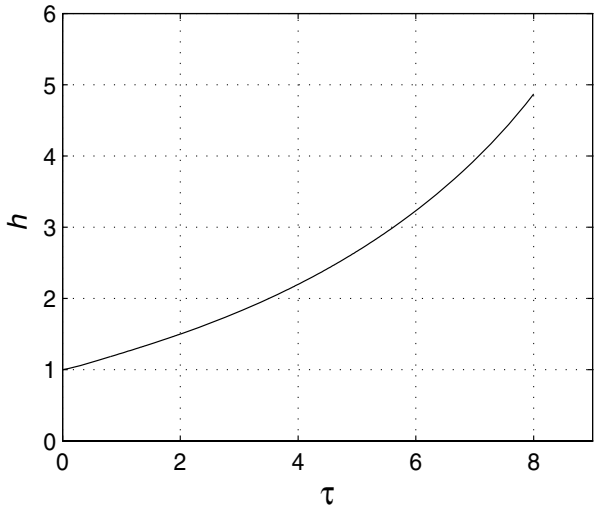

FIG. 6. *Propagation of the turbulent front in the model* (35)–(38).

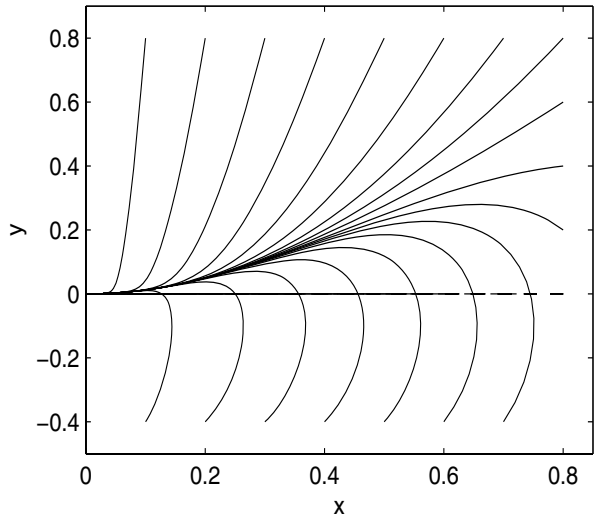

FIG. 7. *Center manifold in model* (39).

$$
\begin{aligned}
&T' = -\frac{4N_2T}{B_2} + 2T,\\
&B_2' = -4B_2 - \frac{4N_2^2T}{B_2} + \frac{12B_4}{B_2},\\
&N_2' = -6N_2 + \frac{2N_2^2}{B_2} + \frac{12N_4}{B_2},\\
&B_4' = -28B_4 + 4N_2^2T - \frac{16N_2N_4T}{B_2},\\
&1 - B_2h^2 - B_4h^4 = 0,\\
&1 - N_2h^2 - N_4h^4 = 0.
\end{aligned}
\tag{45}
$$

System (45) contains six equations with respect to six unknown functions: T, B_2, N_2, B_4, N_4, and h. We solved (45) numerically, making sure that the initial positions of the energy and velocity fronts coincide.

Using the data from the numerical experiments we can deduce results in analytical form. According to the data, at large times some terms in (45) become negligible, namely, $(-16N_2N_4T/B_2)$ in the equation $B_4' = \ldots$, $(12B_4/B_2)$ and $(-4N_2^2T/B_2)$ in the equation $B_2' = \ldots$, and $(12N_4/B_2)$ in the equation $N_2' = \ldots$. Also it is important to note $N_2 \to B_2$. Therefore from (45) we get *asymptotically*

$$T' = -2T, \quad N_2' = -4N_2, \quad B_2 = N_2, \tag{46}$$

from which we get

$$T = T_0 e^{-2(\tau-\tau_0)}, \quad B_2 = N_2 = N_0 e^{-4(\tau-\tau_0)}, \tag{47}$$

where τ_0, T_0, and N_0 are some reference values. Substituting (47) into (45), we get

$$B_4' = -28B_4 + 4N_0^2 T_0 e^{-10(\tau-\tau_0)}. \tag{48}$$

The solution of the homogeneous part of (48), $\sim \exp[-28(\tau-\tau_0)]$, expresses the decay caused by the linear term $(-28B_4)$. This part of the solution is negligible compared to the solution of the nonhomogeneous equation,

$$B_4 = Ce^{-10(\tau-\tau_0)}, \tag{49}$$

expressing the forced dynamics of B_4.

Here we recognize the center manifold mechanism: a rapid decay of a function to a level where the linear term becomes comparable to the nonlinear term. It is easy to find the constant by substituting (49) into (48),

$$C = \frac{2}{9}N_0^2 T_0.$$

Hence, the variable B_4 is attracted to the manifold described by

$$B_4(\tau) = \frac{2}{9}N_0^2 T_0 \exp[-10(\tau-\tau_0)] = \frac{2}{9}N_2^2 T$$

or, using (43),

$$B_4 = \frac{2N_2^2 M^2}{9A}. \tag{50}$$

Let us use the numerical data directly to show that B_4 is indeed attracted to (50). There are many ways to demonstrate the attraction, and below we implement just one of them. A graph B_4 versus N_2^2 and T would be a curved surface. We go over to new variables, in terms of which the surface would be a plane,

$$N_2^2 = \xi + \eta, \quad T = \xi - \eta. \tag{51}$$

The product $N_2^2 T$ is represented by a plane in terms of ξ^2 and η^2:

$$N_2^2 T = \xi^2 - \eta^2. \tag{52}$$

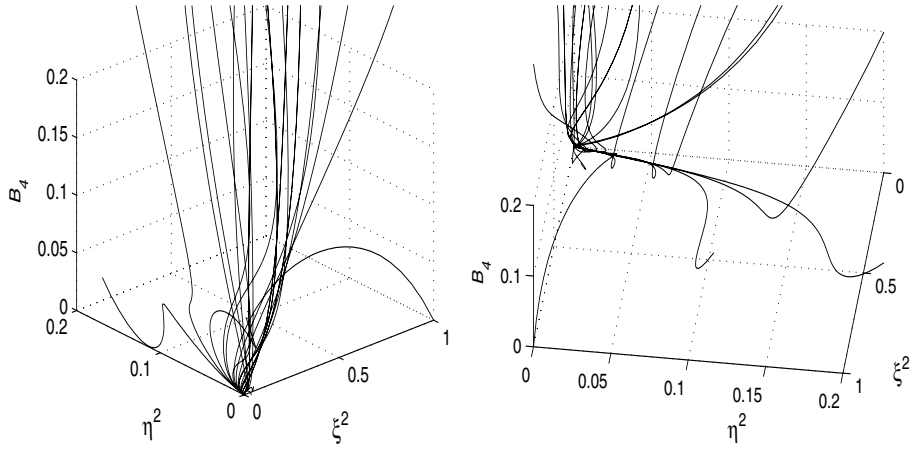

FIG. 8. *Trajectories for the reduced model* (45).

The new variables are defined by (51),

$$\xi = \frac{1}{2}\left(N_2^2 + T\right), \quad \eta = \frac{1}{2}\left(N_2^2 - T\right).$$

Figure 8 gives two views of a set of trajectories in the space (ξ^2, η^2). The right-hand view shows that all the trajectories converge to a surface which, from this particular angle, appears as a straight line. Clearly the surface is a plane.

In order to obtain a closed system from (35)–(38), we removed the term with B_6 from the equation $B_4' = \ldots$ and obtained the dynamics of N_4 from the front equation $1 - N_2h^2 - N_4h^4 = 0$ rather than from the respective dynamic equation.

To let N_4 evolve according to the dynamic law, we add the equation $N_4' = \ldots$. Adding the extra equation makes it necessary to add another unknown to the system, say B_6 (or alternatively, N_6; however, this is not of principle importance):

$$\begin{aligned}
T' &= -\frac{4N_2T}{B_2} + 2T,\\
B_2' &= -4B_2 - \frac{4N_2^2T}{B_2} + \frac{12B_4}{B_2},\\
N_2' &= -6N_2 + \frac{2N_2^2}{B_2} + \frac{12N_4}{B_2},\\
B_4' &= -28B_4 + 4N_2^2T - \frac{16N_2N_4T}{B_2} + \frac{30B_6}{B_2},\\
N_4' &= -20N_4 + \frac{2N_2N_4}{B_2} - \frac{10N_2B_4}{B_2},\\
1 &- B_2h^2 - B_4h^4 - B_6h^6 = 0,\\
1 &- N_2h^2 - N_4h^4 = 0.
\end{aligned} \tag{53}$$

Trajectories for the system (53) are shown in Figure 9. We see the same attractor as for the shorter version (45). In the dynamic equation $B_4' = \ldots$ the new term $(30B_6/B_2)$ and the old term $(-16N_2N_4T/B_2)$ are smaller than the other terms by two orders of magnitude.

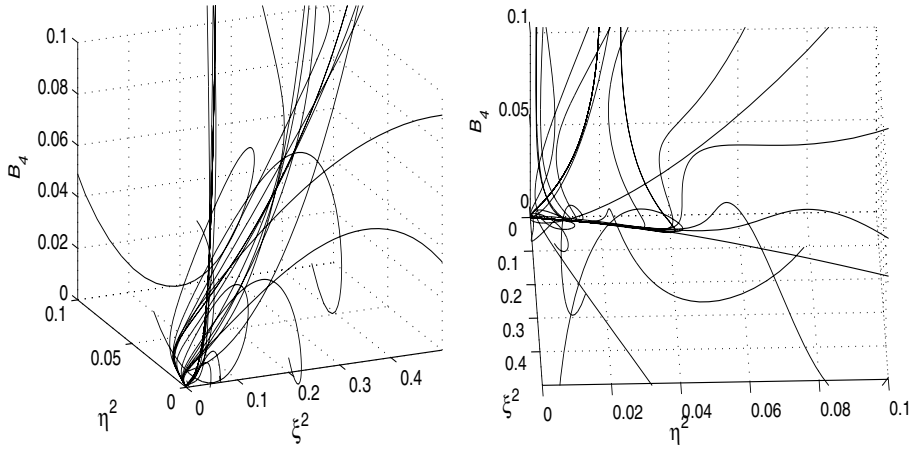

FIG. 9. *Trajectories for the enhanced version* (53) *of the reduced model.*

Now we look for an attractor for N_4. Substituting $N_2 = B_2$ (we emphasize that this relation is asymptotic, not exact) and the expression for B_4, (50), into the equation $N_4' = \dots$ in (53) we get

$$N_4' = -18N_4 - \frac{20}{9}N_0^2 T_0 e^{-10(\tau-\tau_0)}. \tag{54}$$

As in the case for B_4, the solution of the homogeneous part of this equation rapidly decays as $\exp[-18(\tau - \tau_0)]$ so that the solution is virtually the forced one,

$$N_4 = De^{-10(\tau-\tau_0)}. \tag{55}$$

Substituting (55) into (54) gives $D = -5N_0^2 T_0/18$, and therefore the attractor is

$$N_4 = -\frac{5N_2^2 M^2}{18A}. \tag{56}$$

A graph N_4 against ξ^2 and η^2 is again a plane, as is evident from Figure 10.

Remarkably, dividing (50) by (56), we find

$$\frac{B_4}{N_4} = -\frac{4}{5} \tag{57}$$

on the attractor. The dependence B_4/N_4 versus time in the numerical experiments is given in Figure 11. It clearly shows the attraction to the predicted value $(-4/5) = -0.8$.

Further extension of the model can be done by involving the equation $B_6' = \dots$ (without the term with B_8). Accordingly we need to add another unknown, for instance, N_6, to make the front equation $1 - N_2h^2 - N_4h^4 - N_6h^6 = 0$. This process can be continued.

More equations would give a more accurate description; however, the result about the existence of the attractors (50) and (56) holds.

In summary, the solutions of the confined-source problem for the quasi–fluid-dynamical system $\partial_t K = \partial_x (K\partial_x K) + K(\partial_x u)^2$, $\partial_t u = \partial_x (K\partial_x u)$ converge to the

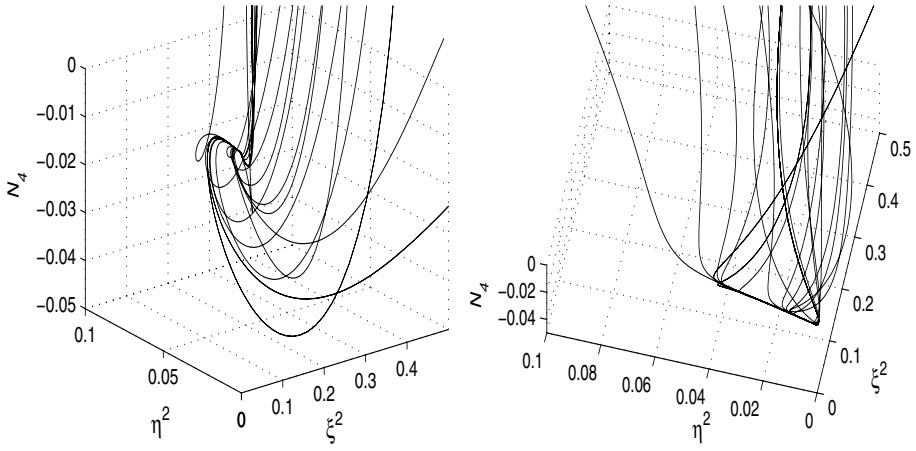

FIG. 10. *Trajectories for the enhanced version* (53) *of the reduced model.*

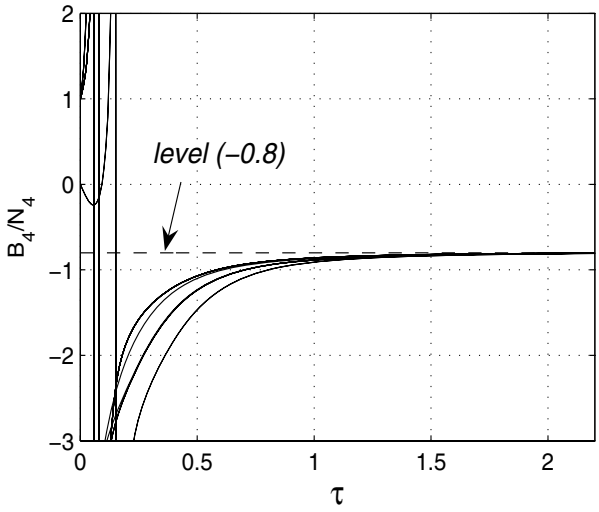

FIG. 11. *The ratio B_4/N_4 versus time.*

attractor

$$K = A\,(1 - B_2x^2 - B_4x^4 - \cdots),$$
$$u = M\,(1 - N_2x^2 - N_4x^4 - \cdots),$$

where

$$B_4 = \frac{2N_2^2M^2}{9A}, \quad N_4 = -\frac{5N_2^2M^2}{18A} \tag{58}$$

and the variables A, M, B_2, and N_2 evolve according to (43), (53). (Note that one should not substitute the asymptotic result (58) into (53) and then solve for A, M, B_2, and N_2. This would break stability, similarly to example (34). If in (34) one replaces $12(B_2 - N_2)$ by its asymptotic value zero, the system becomes unstable; see (31).)

5. Conclusions. We considered a process of an expansion of a turbulent jet driven by turbulent diffusion. The mathematical model essentially involves coupling between the turbulent energy, dissipation, and momentum. Looking for solutions in the form of power-series in a spatial coordinate, we derived dynamical systems with respect to time-dependent series coefficients. The system is essentially nonlinear; however, modifying time allowed us to create linear terms, which dominate during the early dynamics. We analyzed in detail a simplified version of the model with a radically reduced number of variables. The numerical and analytical analyses allowed us to find an attractor in exact form.

NUMERICAL INVESTIGATION OF CAVITATION IN MULTIDIMENSIONAL COMPRESSIBLE FLOWS*

KRISTEN J. DEVAULT†, PIERRE A. GREMAUD†, AND HELGE KRISTIAN JENSSEN‡

Abstract. The compressible Navier–Stokes equations for an ideal polytropic gas are considered in $\mathbb{R}^n$, $n = 2, 3$. The question of possible vacuum formation, an open theoretical problem, is investigated numerically using highly accurate computational methods. The flow is assumed to be symmetric about the origin with a purely radial velocity field. The numerical results indicate that there are weak solutions to the Navier–Stokes system in two and three space dimensions, which display formation of vacuum when the initial data are discontinuous and sufficiently large. The initial density is constant, while the initial velocity field is symmetric, points radially away from the origin, and belongs to H^s_{loc} for all $s < n/2$. In addition, in the one-dimensional case, the numerical solutions are in agreement with known theoretical results.

Key words. Navier–Stokes, Euler, compressible flow, cavitation, pseudospectral

1. Introduction.

A long-standing open problem in the mathematical theory for fluid dynamics is the question of vacuum formation in compressible flow. Roughly stated, the issue is: Do there exist solutions of the Navier–Stokes system (3.1)–(3.3) for viscous compressible flow that exhibit vacuum (vanishing density) in finite time when the initial density is strictly bounded away from zero?

This problem is relevant from a modeling perspective as well as for theoretical results. The underlying assumption in the derivation of the Navier–Stokes equations from physical principles is that the fluid is nondilute and can be described as a continuum. A negative answer to the question above would thus provide self-consistency of the continuum assumption for the Navier–Stokes model. On the other hand, it is known that an a priori estimate of the form

$$\text{for a constant } C = C(T): \quad C^{-1} \le \rho(x,t) \le C \quad \text{for all } (x,t) \in \mathbb{R}^n \times [0,T] \tag{1.1}$$

(where ρ denotes density) implies further estimates and would greatly facilitate existence proofs. For a discussion of this point, see Chapter 3 of [11].

Estimates of the above type are available for one-dimensional (1D) flow [26], even in the case of large and discontinuous data [15]. As reviewed in section 2, large efforts have been invested in searching for similar bounds in the multidimensional (multi-D) case. However, no such results seem to be currently known for the standard Navier–Stokes model with constant transport coefficients.

To gain some insight, it is natural first to make a careful numerical study of the simplest possible scenario where one could expect cavitation in several space dimensions. This is the subject of the present work. In section 3, we consider 2D and 3D flows with symmetry for the full Navier–Stokes equations, as well as for the barotropic case (where pressure is assumed to be a function of density alone). The equations are written in a proper nondimensionalized form, and the problem is completed with appropriate initial and boundary conditions. More is known in the formal limit of infinitely large Reynolds numbers, i.e., in the case of inviscid fluids. The corresponding Euler equations and their solutions are used as a benchmark for the numerics. Various considerations regarding the inviscid case are discussed in section 4.

The above difficulties are mirrored on the numerical side in the form of various challenges regarding stability. The case of 1D flows illustrates this issue. Riemann data with large jumps may lead to vacuum formation for the Euler equations while, at least for Hoff's solutions [15], no vacuum occurs for solutions to the corresponding Navier–Stokes equations. Minimizing the amount of numerical diffusion is thus paramount. A splitting method is used between the convective part, corresponding to the Euler equations, and the diffusive part. The hyperbolic part is solved by computing *local* similarity solutions. Those solutions are then "diffused," and the process is repeated at the next time step. A highly accurate pseudospectral spatial discretization is used; see section 5. The stiffness [1] of the discretized-in-time system increases as the density ρ goes to zero; for $\rho = 0$, the system is infinitely stiff and has degenerated from being purely differential to being differential algebraic. Several numerical schemes, none of them explicit, are known to handle this kind of difficulty [1, 12] (at least for some problems presenting this type of structure). A backward difference formula (BDF)-type method is considered here. This approach has been successfully tested with respect to mass conservation and energy balance. Finally, a test over the magnitude of the density has to be done to determine whether "vacuum" has been reached, an arduous task in finite precision computations! The solution is analyzed both for its magnitude and its behavior in phase space.

The numerical experiments are set up so that vacuum, if any, appears first at a known point (the origin). The calculations do not attempt to track the solution past vacuum formation. The detection of the vacuum itself requires density to be less than 10^{-14} (see criterion (6.1)), i.e., just slightly above what corresponds to machine epsilon for the IEEE double precision machines used in the experiments.

Our detailed numerical study is described in section 6. It indicates that vacuum formation indeed occurs for multi-D symmetric flows for sufficiently large and discontinuous initial data, i.e., in the regime of high Mach number and high Reynolds number. Section 7 contains a brief summary and a conclusion of our findings.

2. Challenges and relation to other works.

2.1. Theoretical issues.

There is a voluminous literature on compressible flow. A short review of work relevant to vacuum formation and a priori estimates follows.

2.1.1. 1D flows.

For 1D flow, i.e., multi-D flow with planar symmetry, much stronger results are known than what is currently available for higher dimensions. A seminal work of Kazhikhov and Shelukhin [26] considers the full 1D Navier–Stokes system for an ideal polytropic gas. Building on earlier work by Kanel [21] and Kazhikhov [25], the global existence and uniqueness of a smooth ($W^{1,2}$) solution is proved in [26] for arbitrarily large and smooth data. In particular, a priori bounds of the type (1.1) are established. Similar results for more general gases can be found

in [4], [5], [24].

Highly relevant to the present work is an extension to large and rough (possibly discontinuous) data established by Hoff [15]. This result pertains to isentropic or isothermal flow with data (ρ_0, u_0) satisfying

$$\rho_0 \in L^\infty(\mathbb{R})\,, \qquad \operatorname{ess\,inf}_{\mathbb{R}} \rho_0 > 0\,,$$

and

$$\rho_0 - \bar{\rho}\,, \quad u_0 - \bar{u} \ \in L^2(\mathbb{R})\,,$$

where $\bar{\rho}, \bar{u}$ are monotone functions that agree outside a bounded interval with the limiting values of ρ and u at $\pm\infty$. Hoff [15] proves that there exists a global weak solution which satisfies (1.1). This result shows that there is at least one solution of the Navier–Stokes equations that does not exhibit cavitation, even for Riemann-type data with arbitrarily large jumps. (For an extension of this result to certain flows for the full Navier–Stokes system see [20].) This is in contrast to the 1D inviscid Euler equations, for which it is well known that vacuum formation can occur [36]. The present numerical study does not contradict Hoff's result. Indeed, while our results clearly indicate the possibility of vacuum formation in higher dimensions, we have not numerically observed cavitation in solutions of the 1D Navier–Stokes system.

A significant result concerning cavitation in 1D flow is given by Hoff and Smoller [19]. They demonstrate that any, everywhere defined, weak solution of the Navier–Stokes (barotropic or full) system which satisfies some natural weak integrability assumptions cannot contain a vacuum in a nonempty open set unless the initial data do so. (For a refinement of this result, see [9].) Xin and Yuan [38] have recently performed a corresponding analysis for spherically symmetric solutions in $\mathbb{R}^2$ and $\mathbb{R}^3$. For everywhere defined solutions they give detailed information on the behavior of vacuum regions (if any), and they also provide sufficient conditions to rule out cavitation.

2.1.2. Multi-D flows. Much less is known about compressible flow in higher dimensions. Global existence of weak solutions is a formidable problem, and the theory is far from complete. Roughly speaking, currently known results are of two types: (A) for large and rough data that possibly contain vacuum states, and (B) for small, rough (discontinuous) data with $\operatorname{ess\,inf} \rho_0 > 0$.

In the former case, Lions [28] has established existence of global weak solutions in the case of compressible barotropic flow. For recent extensions, including results for the full Navier–Stokes system, see [10], [11] and references therein. It is not known if a bound of the type (1.1) holds for these solutions when the data satisfy $\operatorname{ess\,inf} \rho_0 > 0$.

More is known for "small" data, i.e., data close to a constant state in a suitable norm. In particular, small and sufficiently smooth data generate global smooth solutions without cavitation for the full Navier–Stokes system [31], [22], [23]. For a representative result in the case of barotropic flow, see Chapter 9 in [33]. In a series of papers [6], [7], [8], Danchin has established global existence, and also uniqueness, of compressible flows in several space dimensions for solutions in so-called critical spaces. For flows with even less regularity, possibly with discontinuities across hypersurfaces, Hoff [14] has shown that if the data are sufficiently close to a constant state, in a suitable norm, and with initial density and temperature bounded away from zero, then there exists a global weak solution with the same properties at all later times. No corresponding result seems to be known for large data in several space dimensions.

There are somewhat stronger results available for the type of symmetric (quasi-1D) flows that we consider in this paper. For isothermal flow with spherical symmetry, Hoff [13] establishes existence of a global weak solution for large symmetric data. The solution is obtained as the limit of solutions in shells $\{0 < a \leq r \leq b\}$ as $a \downarrow 0$. By rewriting the equations in Lagrangian coordinates and exploiting the energy estimate, certain a priori bounds are obtained that are independent of the inner radius a. However, while guaranteeing existence of a weak solution, the available a priori bounds do not seem strong enough to determine whether the constructed solution contains a vacuum at the center of motion. (For an extension of this result to the full Navier–Stokes system, see [17].)

We note that the higher the dimension of the space, the easier it should be to generate a vacuum, as the fluid is free to move in more directions. This can be quantified for the corresponding inviscid system. Consider the isentropic Euler equations with spherically symmetric Riemann-type data. Let the initial velocity field have constant magnitude $\bar{u}$ and be directed radially away from the origin. In this case, there is a threshold value $\hat{u}(n)$ of $\bar{u}$, depending on the dimension n, above which a vacuum is formed immediately [43]. One can verify that $\hat{u}(1) > \hat{u}(2) > \hat{u}(3)$. For the 1D Navier–Stokes system, we know from Hoff's result [13] that there exists a weak solution without vacuum; i.e., "$\hat{u}(1) = \infty$" for these solutions. However, in higher dimensions it may well be that there are solutions with strictly positive density everywhere at time zero, but which develop a vacuum at later times.[1] There are also technical reasons that seem to prevent a priori bounds on the density in higher dimensions. More precisely, in the 1D analysis of [26], [13] the bounds on the density are derived from the a priori bounds one gets "for free" from the equations themselves. These are integral bounds that are strictly stronger in one dimension than in higher dimensions due to the geometrical factor of r^{n-1} in the space integrals (i.e., $dx = const.r^{n-1}\,dr$).

2.2. Additional remarks.

Cavitation and uniqueness. The issue of cavitation is closely related to the question of uniqueness and to the concept of solution that one works with. To illustrate this consider the 1D Navier–Stokes equations with Riemann-type data:

$$\rho_0(x) \equiv \bar{\rho} > 0\,, \qquad u_0(x) = \begin{cases} -\bar{u} & \text{for } x < 0\,, \\ \bar{u} & \text{for } x > 0\,, \end{cases} \tag{2.1}$$

where $\bar{u} > 0$. One weak solution to this problem is provided by Hoff's result [15], and this solution does not exhibit cavitation. However, a different solution can also be constructed, with the same data, by piecing together solutions of two disjoint flows into surrounding vacuum. More precisely, consider the two sets of initial data

$$\rho_0^-(x) = \begin{cases} \bar{\rho} & \text{for } x < 0\,, \\ 0 & \text{for } x > 0\,, \end{cases} \qquad u_0^-(x) = \begin{cases} -\bar{u} & \text{for } x < 0\,, \\ \emptyset & \text{for } x > 0\,, \end{cases} \tag{2.2}$$

and

$$\rho_0^+(x) = \begin{cases} 0 & \text{for } x < 0\,, \\ \bar{\rho} & \text{for } x > 0\,, \end{cases} \qquad u_0^+(x) = \begin{cases} \emptyset & \text{for } x < 0\,, \\ \bar{u} & \text{for } x > 0\,. \end{cases} \tag{2.3}$$

(Here $\emptyset$ indicates that the velocity is left undefined where there is no matter.) One can now construct solutions (ρ^-, u^-) and (ρ^+, u^+) corresponding to these data, which

[1] Furthermore, the possibility remains that there are other weak solutions exhibiting vacuum even in one dimension (see below for further comments on uniqueness).

in addition satisfy a physical no-traction boundary condition along a vacuum-fluid interface; see [4], [5], [24], [25]. By concatenating the two solutions, a solution to the original problem (2.1) is obtained, and in this solution an open vacuum region is present from time $t = 0+$ (and staying at least for a short time). In the region between the two solutions, one may simply consider the flow to be undefined. Without going into the discussion of which solution is more relevant, we note that Hoff's solution [15] is defined *everywhere* on $\mathbb{R} \times \mathbb{R}_+$, while the second solution is defined only on the support of its density. The issue of nonuniqueness for 1D compressible Navier–Stokes in connection with vacuums is treated in detail by Hoff and Serre [18].

For flow in several space dimensions, the picture is less clear since we do not even know if there is a solution without cavitation in this case. The present work indicates that there is at least one solution where a vacuum forms. Uniqueness of *general* weak solutions, i.e., without any regularity assumptions beyond what is necessary to make sense of a weak formulation, is not known. On the other hand, sufficiently smooth and small solutions are unique (see [31]), as are flows belonging to critical spaces (see Danchin [6], [7], [8]). To the best of our knowledge, the only uniqueness result for flows with possible discontinuities in the density field is given in a recent work by Hoff [16].

Continuum assumption and physical boundary conditions. In view of the 1D examples above, one should be cautious in making claims about the "physicality" of constructed or computed solutions to the standard Navier–Stokes model (3.1)–(3.3) in the low-density regime. Of course, from a modeling point of view, this is not surprising. The Navier–Stokes system is derived under the assumption that the fluid can be described as a continuum with everywhere strictly positive mass density. Issues related to nonuniqueness in the presence of vacuum are therefore not surprising. For a discussion of this point, see [11]. It is also known [37] that the lifespan of smooth, everywhere defined solutions to the Navier–Stokes system (with vanishing heat conductivity) is finite whenever the initial density is compactly supported.

Once a vacuum has developed, one should impose the physical boundary condition of vanishing traction at the vacuum-fluid interface. In other words, the vacuum should not exert a force on the fluid. Note that in the present work we track the *onset* of vacuum formation, not its subsequent evolution.

Well-posedness. In view of both physical arguments as well as the apparent lack of good a priori estimates for the standard Navier–Stokes model, it is natural to ask whether more accurate models would lead to stronger results. In particular, models where the transport coefficients λ, μ, κ depend on the thermodynamical state have been considered.[2] Recent results for such models are given in [2] and [32]. Several issues pertaining to well-posedness in the presence of vacuum have been analyzed in [29], [30], [39], [40], [41], [42]. These results show that the nonuniqueness observed in [18] can be attributed to the unphysical assumption of constant viscosity coefficient. The corresponding problem for the full system appears to require new methods. For results in this direction for the full 1D system, see [4], [5], [24], and see the recent monograph by Feireisl [11] for the multi-D case.

2.3. Precise formulation. After the above remarks, our original question can be formulated precisely as follows. Given the standard multidimensional Navier–Stokes model with constant transport coefficients, let the pressure be that of an ideal

[2] In the isentropic case a relevant assumption is that the viscosity μ depends on the density. In accordance with kinetic theory it is natural to consider the case with $\mu \sim \rho^k$, for a constant $k > 0$.

polytropic gas or, in the case of barotropic flow, of the form $A\rho^\gamma$ with $\gamma \geq 1$. Consider the initial-boundary value problem in a ball centered at the origin, with initial density strictly bounded away from zero and with a possibly discontinuous initial velocity field. Then: *Does there exist an everywhere defined weak solution of the equations with the property that its density reaches zero in finite time?*

3. The full compressible Navier–Stokes equations. Consider the compressible Navier–Stokes equations for a Newtonian fluid in $\mathbb{R}^n$, $n = 1$, $n = 2$, or $n = 3$, with no external forces or heat sources. The invariant form of the equations in spatial (Eulerian) formulation is

$$\rho_t + \operatorname{div}(\rho\vec{u}) = 0, \tag{3.1}$$

$$(\rho\vec{u})_t + \operatorname{div}(\rho\vec{u}\otimes\vec{u}) = \operatorname{grad}(-p + \lambda \operatorname{div}\vec{u}) + \operatorname{div}(2\mu D), \tag{3.2}$$

$$\mathcal{E}_t + \operatorname{div}\big((\mathcal{E}+p)\vec{u}\big) = \operatorname{div}\big(\lambda(\operatorname{div}\vec{u})\vec{u} + 2\mu D\cdot\vec{u} - \vec{q}\big), \tag{3.3}$$

where ρ is the density, $\vec{u} = (u_1, \ldots, u_n)^T$ is the fluid velocity, p is the pressure, $\mathcal{E}$ is the total energy, D is the deformation rate tensor, $\vec{q}$ is the heat flux vector, and λ and μ are the viscosity coefficients. Equations (3.1)–(3.3) are often referred to as the continuity equation, the conservation of momentum equation, and the conservation of energy equation, respectively. We also have

$$\mathcal{E} = \rho(e + |\vec{u}|^2/2), \qquad D_{ij} = (\partial_i u_j + \partial_j u_i)/2, \qquad \vec{q} = -\kappa\nabla\theta,$$

where e stands for the internal energy, κ is the coefficient of heat conductivity, and θ is the temperature. In what follows, we restrict ourselves to the study of ideal and polytropic (perfect) gases such that

$$p = \mathcal{R}\rho\theta, \qquad e = c_v\theta, \tag{3.4}$$

where $\mathcal{R}$ is the gas constant and c_v is the specific heat at constant volume. The local sound speed c is then given by

$$c = \sqrt{\frac{\gamma p}{\rho}},$$

where $\gamma = 1 + \mathcal{R}/c_v$ is the adiabatic exponent. All the transport coefficients $c_v, \lambda, \mu, \kappa$ are assumed to be constant. For the derivation of the equations, see, e.g., [33], [34].

3.1. Equations for symmetric flow. We next consider the case of flow with symmetry; i.e., the velocity is directed (radially when $n = 2, 3$) away from the origin, and all quantities are functions only of the distance to the origin and of time. Let x denote a point in space, and set $r = |x|$. Setting

$$\rho(r,t) = \rho(x,t), \qquad \vec{u}(x,t) = u(r,t)\frac{x}{r}, \quad \text{etc.},$$

leads to the following system of equations:

$$\rho_t + (\rho u)_\xi = 0, \tag{3.5}$$

$$\rho(u_t + uu_r) + p_r = \nu u_{\xi r}, \tag{3.6}$$

$$c_v\rho(\theta_t + u\theta_r) + pu_\xi = \kappa\theta_{r\xi} + \nu(u_\xi)^2 - \frac{2m\mu}{r^m}(r^{m-1}u^2)_r\,, \tag{3.7}$$

where we have used the notation

$$m = n - 1, \qquad \partial_\xi = \partial_r + \frac{m}{r}, \qquad \nu = \mu + 2\lambda\,.$$

(Note that $\partial_{\xi r} \neq \partial_{r\xi}$ for $n = 2$ and $n = 3$.)

We consider spherically symmetric flows (3.5)–(3.7) in the interior of the interval/disk/ball B_b of fixed outer radius b:

$$\rho(r,0)=\rho_0(r), \qquad u(r,0)=u_0(r), \qquad \theta(r,0)=\theta_0(r) \qquad \text{for } r\le b. \tag{3.8}$$

In the 1D case we require that (3.8) hold for all $|r|\le b$. Throughout, we consider only the case where the gas is set in motion in the outward direction; i.e., we assume that u_0 is a nonnegative function in two and three dimensions and is odd with positive values for $r>0$ in one dimension. Suitable boundary conditions are discussed in 3.4.

3.2. Nondimensional form of symmetric equations. Using the initial data, characteristic length, velocity, density, and temperature can be defined as follows:

$$\begin{aligned}\bar r &:= b\,,\\ \bar u &:= \max_{0\le r\le b}|u_0(r)|\,,\\ \bar\rho &:= \max_{0\le r\le b}\rho_0(r)\,,\\ \bar\theta &:= \max_{0\le r\le b}\theta_0(r)\,.\end{aligned}$$

From these we define characteristic time and pressure by

$$\begin{aligned}\bar t &:= \frac{\bar r}{\bar u}\,,\\ \bar p &:= p(\bar\rho,\bar\theta)\,.\end{aligned}$$

The dimensionless independent variables are then

$$R:=\frac{r}{\bar r}, \qquad T:=\frac{t}{\bar t},$$

and the dimensionless dependent variables are

$$D:=\frac{\rho}{\bar\rho}, \qquad U:=\frac{u}{\bar u}, \qquad \Theta:=\frac{\theta}{\bar\theta}, \qquad P:=\frac{p}{\bar p}\,.$$

Regarding D, U, Θ, P as functions of R and T, we obtain the nondimensionalized system

$$\rho_t+(\rho u)_\xi=0, \tag{3.9}$$

$$\rho(u_t+uu_r)+\frac{1}{\gamma M^2}(\rho\theta)_r=\frac{1}{\mathrm{Re}}u_{\xi r}, \tag{3.10}$$

$$\begin{aligned}\rho(\theta_t+u\theta_r)+(\gamma-1)\rho\theta u_\xi &= \frac{1}{\mathrm{Pr}\,\mathrm{Re}}\theta_{r\xi}\\ &\quad+\gamma(\gamma-1)\frac{\mathrm{M}^2}{\mathrm{Re}}\left((u_\xi)^2-\frac{2m\mu}{\nu}\frac{(r^{m-1}u^2)_r}{r^m}\right),\end{aligned} \tag{3.11}$$

where we have reverted to the original symbols and where

$$\begin{aligned}\mathrm{M}&:=\frac{|\bar u|}{\bar c}=\text{ Mach number}, \qquad \bar c=\text{ sound speed }=\sqrt{\frac{\gamma\bar p}{\bar\rho}}\,,\\ \mathrm{Re}&:=\frac{\bar r\bar\rho\bar u}{\nu}=\text{ Reynolds number},\\ \mathrm{Pr}&:=\frac{\nu c_v}{\kappa}=\text{ Prandtl number}.\end{aligned}$$

These equations are valid also for $n=1$ ($m=0$), provided that r is interpreted as the position along the x-axis; in this case $\partial_\xi=\partial_r=\partial_x$.

3.3. Barotropic equations. If the pressure p is considered as a function of the density ρ only, the energy equation (3.7) decouples from the mass and momentum conservation equations (3.5), (3.6). Here, we consider exclusively the isentropic and isothermal cases where

$$p(\rho) = a\rho^\gamma, \qquad \gamma \geq 1\,, \tag{3.12}$$

and where $a > 0$ is a constant. A nondimensional version of the barotropic equations can be derived in very much the same way as (3.9)–(3.11) were derived, except for the characteristic pressure, which is now taken as

$$\bar{p} = p(\bar{\rho}) = a\bar{\rho}^\gamma.$$

This leads to the nondimensionalized system for barotropic flow

$$\rho_t + (\rho u)_\xi = 0, \tag{3.13}$$

$$\rho(u_t + uu_r) + \frac{1}{\gamma \mathrm{M}^2}(\rho^\gamma)_r = \frac{1}{\mathrm{Re}} u_{\xi r}\,, \tag{3.14}$$

where the Mach number at the reference state is now given by

$$M := \frac{|\bar{u}|}{\bar{c}} = \frac{|\bar{u}|}{a\gamma\bar{\rho}^{\gamma-1}}\,.$$

3.4. Initial and boundary conditions: Balance relations. The following initial and boundary conditions are considered throughout:

$$\rho(r,0) = \rho_0(r) = 1 \quad \text{for } r \geq 0, \qquad u(r,0) = u_0(r) = \begin{cases} 1 & \text{if } r > 0, \\ 0 & \text{if } r = 0, \end{cases} \tag{3.15}$$

$$u(1,t) = 1, \qquad t > 0, \tag{3.16}$$

where $r = 1$ corresponds now to the outer boundary of the computational domain. Furthermore, by symmetry, one has

$$u(0,t) = 0, \qquad t > 0. \tag{3.17}$$

A calculation shows that the initial velocity field is in $H^s_{loc}(\mathbb{R}^n)$ for all $s < n/2$.

It may seem more natural to consider a homogeneous condition of the type $u(1,t) = 0$, instead of (3.16), since existence of weak solutions has been established in the former case. However, such a condition leads to steep gradients and unwanted numerical boundary layer effects on the outer boundary of the domain. A vanishing boundary condition at $x = 1$ would thus complicate the numerical resolution of the problem by making it more susceptible to spurious oscillations. In any case, under the above type of initial conditions (3.15), vacuum formation (if any) is expected to be initiated at the origin (see section 6). For short time intervals one would therefore expect that the outer boundary condition does not significantly influence the behavior of the solution near the origin.

4. The isentropic Euler equations. The isentropic Euler equations are easily obtained from (3.13), (3.14) by formally taking the limit $\mathrm{Re} \to \infty$, i.e.,

$$\rho_t + (\rho u)_\xi = 0, \tag{4.1}$$

$$\rho(u_t + uu_r) + \frac{1}{\gamma \mathrm{M}^2}(\rho^\gamma)_r = 0. \tag{4.2}$$

4.1. The 1D case. Let us consider (4.1), (4.2) together with the Riemann data

$$\rho(r,0)=1 \quad \text{for all } r, \qquad u(r,0)=\begin{cases} -1 & \text{if } r<0,\\ 1 & \text{if } r>0. \end{cases} \tag{4.3}$$

As is well known, the above Riemann problem can easily be solved. Interestingly, the isothermal case, $\gamma=1$, and the general isentropic case, $\gamma>1$, are quite different.

The isothermal case $\gamma=1$. For the "symmetric data" (4.3), the solution is found to consist of two rarefaction waves:

$$\begin{bmatrix} \rho \\ u \end{bmatrix}(r,t)=\begin{cases} \begin{bmatrix} 1 \\ -1 \end{bmatrix} & \text{if } \frac{r}{t}<-1-\frac{1}{\mathrm{M}},\\ \begin{bmatrix} e^{-(\mathrm{M}\frac{r}{t}+\mathrm{M}+1)} \\ \frac{r}{t}+\frac{1}{\mathrm{M}} \end{bmatrix} & \text{if } -1-\frac{1}{\mathrm{M}}<\frac{r}{t}<-\frac{1}{\mathrm{M}},\\ \begin{bmatrix} e^{-\mathrm{M}} \\ 0 \end{bmatrix} & \text{if } -\frac{1}{\mathrm{M}}<\frac{r}{t}<\frac{1}{\mathrm{M}},\\ \begin{bmatrix} e^{\mathrm{M}\frac{r}{t}-\mathrm{M}-1} \\ \frac{r}{t}-\frac{1}{\mathrm{M}} \end{bmatrix} & \text{if } \frac{1}{\mathrm{M}}<\frac{r}{t}<1+\frac{1}{\mathrm{M}},\\ \begin{bmatrix} 1 \\ 1 \end{bmatrix} & \text{if } 1+\frac{1}{\mathrm{M}}<\frac{r}{t}. \end{cases}$$

Note that, regardless of the values of the Mach number, M, the above solution does not lead to cavitation. Indeed, the smallest value of the density is found to be $e^{-\mathrm{M}}$.

The case $\gamma>1$. Again, the solution is found to consist of two rarefaction waves for the data (4.3). However, in the present case, cavitation can occur. More precisely, if $M>\frac{2}{\gamma-1}$, the solution $\left[\begin{smallmatrix}\rho\\ u\end{smallmatrix}\right](r,t)$ is given by

$$\begin{cases} \begin{bmatrix} 1 \\ -1 \end{bmatrix} & \text{if } \frac{r}{t}<-1-\frac{1}{\mathrm{M}},\\ \begin{bmatrix} \left(\frac{2}{\gamma+1}-\mathrm{M}\frac{\gamma-1}{\gamma+1}(1+\frac{r}{t})\right)^{2/(\gamma-1)} \\ \frac{1}{\mathrm{M}(\gamma+1)}\left(2+(1-\gamma)\mathrm{M}+2\mathrm{M}\frac{r}{t}\right) \end{bmatrix} & \text{if } -1-\frac{1}{\mathrm{M}}<\frac{r}{t}<-1+\frac{2}{\gamma-1}\frac{1}{\mathrm{M}},\\ \begin{bmatrix} 0 \\ \emptyset \end{bmatrix} & \text{if } -1+\frac{2}{\gamma-1}\frac{1}{\mathrm{M}}<\frac{r}{t}<1-\frac{2}{\gamma-1}\frac{1}{\mathrm{M}},\\ \begin{bmatrix} \left(\frac{2}{\gamma+1}+\mathrm{M}\frac{\gamma-1}{\gamma+1}(-1+\frac{r}{t})\right)^{2/(\gamma-1)} \\ \frac{1}{\mathrm{M}(\gamma+1)}\left(-2+(-1+\gamma)\mathrm{M}+2\mathrm{M}\frac{r}{t}\right) \end{bmatrix} & \text{if } 1-\frac{2}{\gamma-1}\frac{1}{\mathrm{M}}<\frac{r}{t}<1+\frac{1}{\mathrm{M}},\\ \begin{bmatrix} 1 \\ 1 \end{bmatrix} & \text{if } 1+\frac{1}{\mathrm{M}}<\frac{r}{t}. \end{cases}$$

Note that, for this latter solution, no velocity u is specified in the vacuum. If, on the other hand, the fluid is not sheared as hard, i.e., if $0<\mathrm{M}<\frac{2}{\gamma-1}$, then no cavitation

takes place and the solution $\left[\begin{smallmatrix}\rho\\ u\end{smallmatrix}\right](r,t)$ is found to be

$$\begin{cases} \begin{bmatrix} 1 \\ -1 \end{bmatrix} & \text{if } \frac{r}{t} < -1 - \frac{1}{\mathrm{M}}, \\ \begin{bmatrix} \left(\frac{2}{\gamma+1} - \mathrm{M}\,\frac{\gamma-1}{\gamma+1}(1+\frac{r}{t})\right)^{2/(\gamma-1)} \\ \frac{1}{\mathrm{M}(\gamma+1)}\left(2 + (1-\gamma)\mathrm{M} + 2\mathrm{M}\frac{r}{t}\right) \end{bmatrix} & \text{if } -1 - \frac{1}{\mathrm{M}} < \frac{r}{t} < -\frac{1}{\mathrm{M}} + \frac{\gamma-1}{2}, \\ \begin{bmatrix} \left(1 - \frac{\mathrm{M}}{2}(\gamma-1)\right)^{\frac{2}{\gamma-1}} \\ 0 \end{bmatrix} & \text{if } -\frac{1}{\mathrm{M}} + \frac{\gamma-1}{2} < \frac{r}{t} < \frac{1}{\mathrm{M}} - \frac{\gamma-1}{2}, \\ \begin{bmatrix} \left(\frac{2}{\gamma+1} + \mathrm{M}\,\frac{\gamma-1}{\gamma+1}(-1+\frac{r}{t})\right)^{2/(\gamma-1)} \\ \frac{1}{\mathrm{M}(\gamma+1)}\left(-2 + (-1+\gamma)\mathrm{M} + 2\mathrm{M}\frac{r}{t}\right) \end{bmatrix} & \text{if } \frac{1}{\mathrm{M}} - \frac{\gamma-1}{2} < \frac{r}{t} < 1 + \frac{1}{\mathrm{M}}, \\ \begin{bmatrix} 1 \\ 1 \end{bmatrix} & \text{if } 1 + \frac{1}{\mathrm{M}} < \frac{r}{t}. \end{cases}$$

4.2. The multidimensional axisymmetric case. Similarity solutions to the Euler equations have also been considered for the 2D and 3D axisymmetric problems that are studied in this paper. Even though no closed form solutions can be found, the analysis reveals that solutions without swirls may exhibit cavitation if $\gamma > 1$ but not if $\gamma = 1$; see [43, section 7.4].

More precisely, let us concentrate on the case $\gamma > 1$. Following [43], self-similar solutions to (4.1), (4.2) are sought in the form

$$\rho = \rho(s), \qquad u = u(s), \qquad \text{where } s = \frac{t}{r}.$$

This leads to the ODE system

$$\rho_s = m\frac{\rho u(1-su)}{s^2c^2 - (1-su)^2}, \tag{4.4}$$

$$u_s = m\frac{sc^2 u}{s^2c^2 - (1-su)^2}, \tag{4.5}$$

$$\rho(0) = 1, \quad u(0) = 1, \tag{4.6}$$

where $c = \frac{1}{M}\rho^{\frac{\gamma-1}{2}}$. The generalization of the 2D results of [43] to 3D problems is straightforward. It is presented here for the sake of completeness. Introducing the variables

$$I = su \quad \text{and} \quad K = sc,$$

relations (4.4), (4.5) can be written

$$\frac{dI}{d\tau} = I\left((1-I)^2 - (1+m)K^2\right) \equiv I\,\mathcal{F}(I,K), \tag{4.7}$$

$$\frac{dK}{d\tau} = K\left((1-I)^2 - K^2 - \frac{m}{2}(\gamma-1)I(1-I)\right) \equiv K\,\mathcal{G}(I,K), \tag{4.8}$$

$$\frac{ds}{d\tau} = s\left((1-I)^2 - K^2\right), \tag{4.9}$$

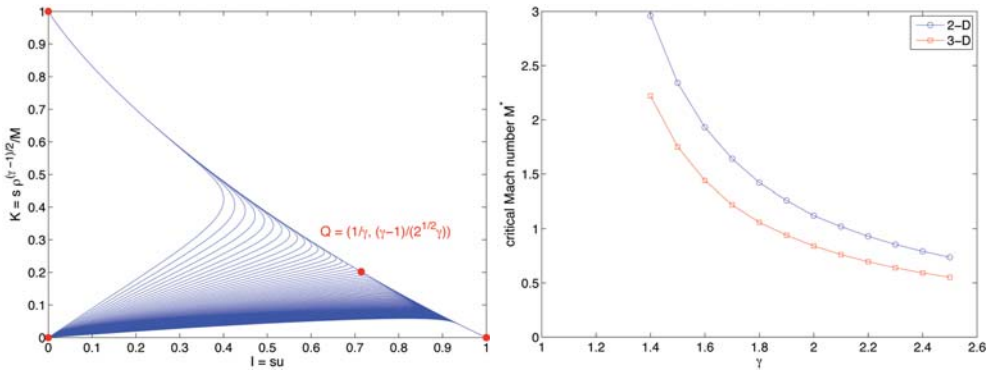

FIG. 4.1. *Left: Phase diagram* ($I = su$, $K = sc$) *of the solutions to* (4.7), (4.8), (4.9) *for* $m = 1$ *(2D) and* $\gamma = 1.4$. *Solutions "leaving"* $(0,0)$ *are represented for values of the Mach number* $M = 1.1, 1.2, 1.3, \ldots, 10$. *Right: Dependency of the critical Mach number* $M^\star$ *on* γ *for* $2D$ *and* $3D$ *problems as obtained through numerical integration of* (4.4), (4.5), (4.6). *Vacuum takes place if and only if* $M > M^\star$.

with the obvious definitions for $\mathcal{F}$ and $\mathcal{G}$ and where τ is a new independent variable defined by (4.9), which is introduced to make (4.7), (4.8) an autonomous system. In the (I, K)-phase plane, the stationary points of (4.7), (4.8) are found to be

$$(0,0), (1,0), (0,1) \quad \text{and} \quad Q = \left(\frac{2}{\gamma(1+m)+1-m}, \frac{1}{\sqrt{1+m}} \frac{\gamma(1+m)-1-m}{\gamma(1+m)+1-m} \right).$$

Let us consider the region $\Omega \subset \mathbb{R}^2$ defined by

$$\Omega = \Big\{ (I,K); I > 0, K > 0, \\ \mathcal{G} > 0 \text{ for } 0 < I \leq \frac{2}{\gamma(1+m)+1-m}, \\ \mathcal{F} > 0 \text{ for } \frac{2}{\gamma(1+m)+1-m} \leq I < 1 \Big\}.$$

A simple sign study along $\partial\Omega$ shows that Ω is invariant under (4.7), (4.8). The system (4.7), (4.8), (4.9) then has integral curves from $(0,0)$ to either $(0,1)$, $(1,0)$ or Q.

LEMMA 1. *Let* $m = 1$ *(two space dimensions) or* 2 *(three space dimensions) and let* $\gamma > 1$. *Then there exists* $M^\star = M^\star(m,\gamma) > 0$ *such that*

- *if* $M = M^\star$, *the solution* (ρ, u) *of* (4.4), (4.5), (4.6) *is defined for* $0 < s < \infty$ *and converges to* $(I,K) = Q$ *as* $s \to \infty$ *(critical case).*

Proof. The proof follows in a straightforward way from [43, section 7.4] ∎

There does not appear to be an explicit formula for the critical value $M^\star$. However, equations (4.4), (4.5), (4.6) can be solved numerically and an approximate value of $M^\star$ inferred from the corresponding results. The feasibility of this approach is illustrated in Figure 4.1(left), which is in exact agreement with the above lemma.

The above observations provide a relatively easy way to numerically investigate vacuum formation for the multidimensional Euler equations. A standard ODE solver can be used to integrate the above equations. It is worth noting that the points $(I, K) = (0, 1)$ or $(1, 0)$ are reached for finite values of s; the solution can then be continuously extended toward $r = 0$. We omit the details. Figure 4.1(right) illustrates the dependency of $M^\star$ on γ for 2D and 3D problems as found through numerical investigation.

5. Discretization and numerical analysis. The numerical approach for solving the Navier–Stokes equations (3.9), (3.10), (3.11) under the specific assumptions considered here is based on a splitting between the Euler equations, on the one hand, and a diffusive equation, on the other hand. This way, one can take advantage of the similarity solutions considered in the previous section (which can be solved to a high degree of accuracy by ODE solvers; see below). At each space/time node, such a solution is locally constructed. This process is akin to numerically solving families of local Riemann problems, as is routinely done in many numerical schemes for hyperbolic conservation laws; see, e.g., [27].

The splitting algorithm is illustrated in the case of the barotropic equations (4.1), (4.2). Let (ρ_n, u_n) be the solution at some time $t_n = n\,\Delta t$, where Δt is the time step. To obtain the solution (ρ_{n+1}, u_{n+1}) at a later time $t_{n+1} = (n+1)\Delta t$, an "Euler step" is first taken; i.e., one solves (4.1), (4.2) from t_n to t_{n+1} with the initial condition

$$\rho(\cdot, t_n) = \rho_n, \qquad u(\cdot, t_n) = u_n.$$

The resulting solution at time t_{n+1} is denoted $(\rho^\star, u^\star)$. The following diffusive step is then taken:

$$\rho^\star u_t = \frac{1}{\mathrm{Re}} u_{\xi r}, \qquad t \in (t_n, t_{n+1}), \tag{5.1}$$

$$u(\cdot, t_n) = u^\star. \tag{5.2}$$

As both steps have to be solved numerically, their respective discretization is now described. For notational convenience, the diffusive step is described first.

5.1. The diffusive step. Equation (5.1) is discretized in space using Chebyshev collocation methods [3]. Such methods deliver high accuracy with a low number of nodes for smooth solutions (which are expected here for $t > 0$). To circumvent the coordinate singularity at $r = 0$ of the 2D and 3D problems, Chebyshev–Gauss–Radau nodes are used instead of the more common Chebyshev–Gauss–Lobatto nodes. In the spatial domain $(0, 1)$ those nodes have location

$$r_j = \frac{1}{2}\left(1 + \cos\left(\frac{2\pi j}{2N-1}\right)\right), \qquad j = 0, \ldots, N-1.$$

In each case, N stands for the number of nodes. For $r \in (0, 1)$ and $t > 0$, we seek an approximation u_N of u of the form

$$u_N(r, t) = \sum_{i=0}^{N-1} U_i(t)\psi_i(r),$$

where $\{\psi_i\}_{i=0}^{N-1}$ are the Lagrange interpolation polynomials at the Chebyshev–Gauss–Lobatto/Radau nodes on $[0, 1]$, i.e., $\psi_i(x_j) = \delta_{ij}$.

Interpolation at one of the above sets of nodes of a function $v = v(r,t)$ simply takes the form

$$I_N v(r,t) = \sum_{j=0}^{N-1} v(r_j,t)\psi_j(r).$$

By definition, the Chebyshev collocation derivative of v with respect to r at those nodes is then

$$\frac{\partial}{\partial r}(I_N v)(r_l,t) = \sum_{j=0}^{N-1} v(r_j,t)\psi_j'(r_l) = \sum_{j=0}^{N-1} D_{lj} v(r_j,t),$$

with $D_{lj} = \psi_j'(r_l)$. The collocation derivative at the nodes can then be obtained through matrix multiplication.

The discrete velocity u_N takes the form

$$u_N(r,t) = \sum_{i=0}^{N-1} U_i(t)\psi_i(r).$$

The semidiscretized in space problem (5.1) has the form

$$Z_U\left((I_N\rho^\star).*U'\right) = \left(D^2 + m\,\mathrm{diag}(1./R)D - m\,\mathrm{diag}\,1./(R.\hat{}\,2)\right)U + B_U, \tag{5.3}$$

with the obvious notation for U and D; the vector R is the node vector, $R_j = r_j$, $j = 0,\ldots,N-1$. The matrix Z_U zeroes the first and/or the last entry(ies) of a vector, and further B_U is a vector related to the boundary conditions (to be specified below). In the above equations, a "dotted operation" (for instance $.*$) refers to that operation being performed elementwise (for instance, $U.*V$ is the vector of ith component U_iV_i, $i = 0,\ldots,N-1$).

The computations are carried out with the boundary condition (3.16). In case the density vanishes (or becomes very small) at some node r_i at time t, i.e., $\mathcal{I}_N\rho^\star(r_i,t) = 0$, then the differential equation for $\mathcal{U}_i(t)$ degenerates into an algebraic equation; in other words, (5.3) becomes differential algebraic. How much of a numerical problem this is depends on the index of the system. The minimum number of times one has to differentiate all or part of (5.3) to recover an ODE system is the index of the differential algebraic equation (DAE) [1]. Here the index is easily found to be equal to 1. Indeed, differentiating the algebraic equation for $\mathcal{U}_i$ leads to an ODE, provided that the operator $D^2 + m\,\mathrm{diag}(1./R)D - m\,\mathrm{diag}\,1./(R.\hat{}\,2)$ with proper side conditions applied to U' is nonsingular. The side conditions are that the velocity is fixed on the outer boundary and thus $U_1'(t) = 0$ and that nonsingular solutions are sought. The above operator can be checked to be nonsingular by direct inspection of the matrices involved. Alternatively, at the continuous level, one can check that the only nonsingular solution to $\partial_{rr}\dot{u} + m/r\partial_r\dot{u} - m\dot{u}/r^2 = 0$ with $\dot{u}(1) = 0$ is the trivial solution $\dot{u} \equiv 0$ (where $\dot{u} = u_t$).

In the presence of vacuum, the system (5.3) is a DAE that is semiexplicit of index 1; as such it is amenable to relatively simple time discretization such as BDF [1]. Here, we used the MATLAB routine ODE15s, which implements a variant of BDF [35].

5.2. The Euler step. Let $(\rho_n(r_j), u_n(r_j))$ be given values for the density and velocity at time t^n at the node r_j, $j = 0,\ldots,N-1$. A family of N similarity solutions

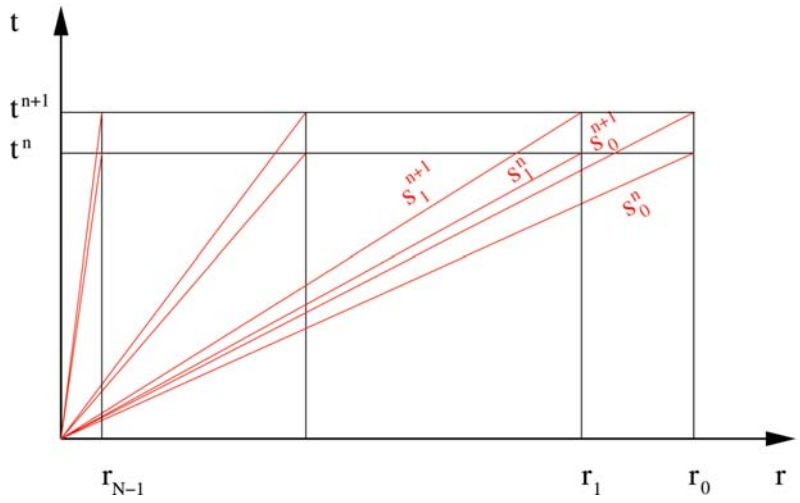

FIG. 5.1. *Meshes used for the diffusive step* $(\{r_j, t^n\}_{j=0,n=0}^{N-1,N_t})$ *and Euler step* $(\{s_j^n\}_{j=0,n=0}^{N-1,N_t})$.

is now defined in the same way as in section 4.1. More precisely, let $s_j^n = \frac{t^n}{r_j}$ be the slopes corresponding to the above data points, and let $s_j^{n+1} = \frac{t^{n+1}}{r_j}$ be the slopes at the next time step; see Figure 5.1. Then, for each $j = 0, \ldots, N-1$, equations (4.4), (4.5) are solved from $s = s_j^n$ to s_j^{n+1} with initial conditions

$$\rho(s_j^n) = \rho_n(r_j), \qquad u(s_j^n) = u_n(r_j). \tag{5.4}$$

5.3. The splitting algorithm. For given Mach and Reynolds numbers, and given spatial and temporal resolutions, i.e., N and Δt being chosen, the following steps are taken for N_t time steps:

- initialize ρ_0 and u_0 according to (3.15),
- for $n = 0$ to $N_t - 1$
  - for $j = N-1$ to 0 by -1
    - EULER: solve (4.4), (4.5), (5.4)
    - set $\rho^\star(r_j) = \rho(s_j^{n+1}) = \rho_{n+1}(r_j)$ and $u^\star(r_j) = u(s_j^{n+1})$
  - end
  - DIFFUSION: solve (5.1), (5.2) through (5.3)
  - set $u_{n+1}(r_j) = u(r_j, t_{n+1})$, $j = 0, \ldots, N-1$
- end

6. Numerical results. The problem (3.13), (3.14) has been solved using the method described in the previous section with various values of the physical parameters (Mach number M, Reynolds number Re, and adiabatic coefficient γ). The initial and boundary conditions are given by (3.15) and (3.16), respectively. The mesh size is fixed at $N = 32$ for all the results given below.

For all our examples, the numerical density ρ_N is an increasing function of r, and thus the numerical solution is probed at the node closest to the origin for vacuum detection. Vacuum formation, if it occurs, is expected to take place during a fast initial transient phase. A comparison with the inviscid case is instructive. If cavitation takes place for the Euler equations, it does so instantaneously (at the origin), i.e., for $t = 0+$. For the 1D case, this fact is obvious from the explicit self-similar solutions given in

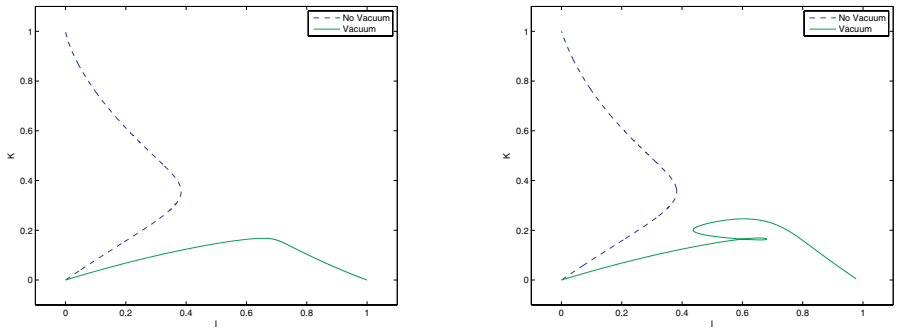

FIG. 6.1. *Phase diagram corresponding to the evolution of the solutions, at the node closest to the origin, of the Euler solution (left) and the Navier–Stokes solution (right) (see section* 4 *for definition of* I *and* K*). The parameters are taken as* $m = 2$ *(3D) and* $\mathrm{M} = 1.2$ *(no vacuum) and* $\mathrm{M} = 2.7$ *(vacuum); for the Navier–Stokes solution (right), the Reynolds number* Re *is* 10^6.

section 4. Regarding the Navier–Stokes equations, our efforts are concentrated on the multidimensional cases for which there is no node at the origin. For the node closest to the origin, phase space trajectories can be used in a way similar to what was done in Figure 4.1(left), giving a clear picture of the evolution of the density there. Using the same notation as in section 4, Figure 6.1 illustrates the difference between the evolution of the Euler solutions (left panel) and Navier–Stokes solutions (right panel).

Based on the above remarks, a specific calculation is said to lead to vacuum formation if for some time t, $0 < t < .005$,

$$\rho_N(r_{N-1}, t) < tol = 10^{-14}, \tag{6.1}$$

where $r_{N-1} = \frac{1}{2}(1 + \cos(\frac{2N-1}{2N-2}\pi))$ is the Chebyshev–Gauss–Radau node closest to the origin. In some cases, the time asymptotic behavior of the solution at r_{N-1} was not clear based on a phase plane analysis. Those cases are reported below as inconclusive, even if the density itself satisfied (6.1).

6.1. The 1D case. The above method cannot be used directly in the 1D case. Using an adapted method (details are omitted), no vacuum formation was numerically observed for the 1D Navier–Stokes solution as is shown in Figure 6.2. The absence of vacuum in the solutions to the 1D Navier–Stokes system is consistent with the solutions found by Hoff [15], who considers discontinuous data of the same type as in the present paper.

6.2. The multi-D barotropic case. The 2D and 3D barotropic flows (3.13), (3.14) with initial and boundary conditions (3.15), (3.16) are solved, for fixed values of the adiabatic coefficient γ, on grids in "Reynolds and Mach number space," i.e., for a collection of values of those two parameters.

Figure 6.3 corresponds to the value $\gamma = 1.4$ for the 2D and 3D cases, in the left and right panels, respectively. As explained above, the gray area corresponds to values of the parameters for which the numerical calculations were inconclusive, for instance due to the absence of a clear asymptotic behavior in phase space during the allotted computational time. It clearly illustrates that for large enough values of M there appears to be vacuum formation. The displayed results are relatively insensitive to

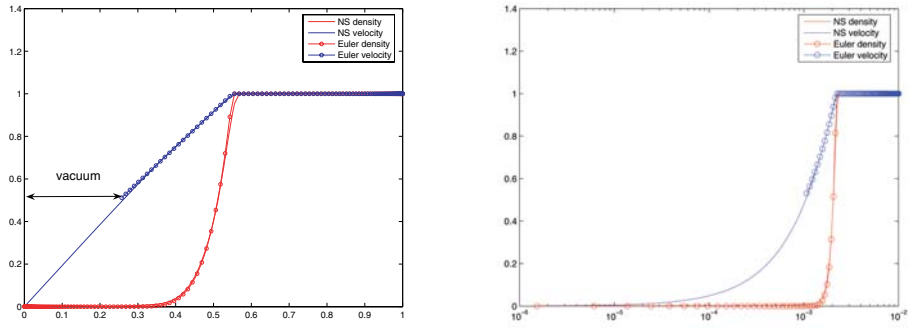

FIG. 6.2. *1D Navier–Stokes and Euler solutions for* $\gamma = 1.4$, $\mathrm{M} = 10$. *Left: Solutions at time* $t = 0.5$ *with* $\mathrm{Re} = 10{,}000$ *(for the Navier–Stokes flow). Right: Solutions at time* $t = .002$ *with* $\mathrm{Re} = 1{,}000{,}000$ *(for the Navier–Stokes flow). For these values, both the 1D Euler solution and the multi-D Navier–Stokes solution exhibit cavitation (see Figure* 6.3 *below), while the 1D Navier–Stokes solution does not.*

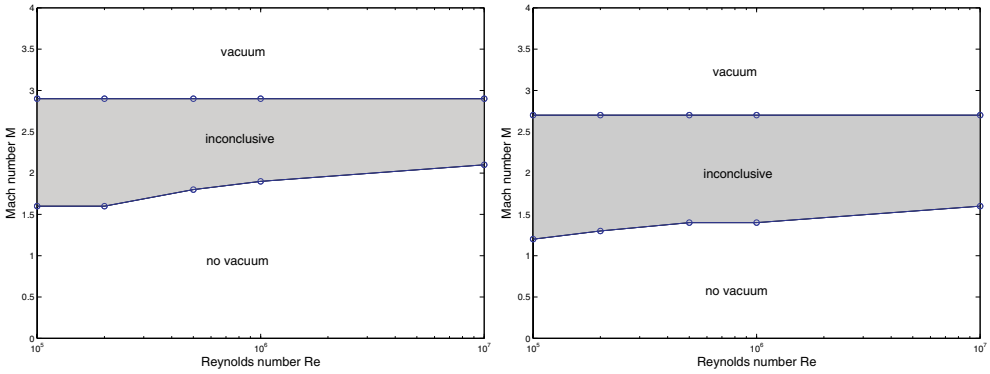

FIG. 6.3. *Vacuum formation for 2D (left) and 3D (right) barotropic flows* (3.13), (3.14) *with initial and boundary conditions* (3.15), (3.16) *and* $\gamma = 1.4$.

the discretization parameters. It is also observed that vacuum is more easily formed in three than in two dimensions, in agreement with the remarks in section 2.1.2.

Similar results were observed for larger values of γ: it gets easier to create vacuum as γ increases.

6.3. The full system. As mentioned in section 4.2, the construction of self-similar solutions for the nonisentropic Euler equations (3.1)–(3.3) appears to be open. Therefore, we do not have the benefit of using this tool as part of the numerical algorithm. While more research is needed, preliminary calculations based on an unsplit algorithm indicate vacuum formation here as well.

7. Conclusion. Our numerical results indicate that vacuum formation is possible in solutions of the multidimensional compressible Navier–Stokes equations. This applies to discontinuous and sufficiently large data where the initial density is uniformly bounded away from zero. The same numerical code gives results for one-dimensional flow that are in agreement with the known analytical results. The conclusions do not contradict the currently known results for multi-D flow.

No attempt was made to follow the solutions *past* vacuum formation. The present study also leaves unanswered the issue of whether vacuum formation is instantaneous, as is the case for the corresponding solutions to the Euler equations.

Acknowledgments. The last author is indebted to David Hoff for several discussions about the vacuum problem in compressible flow. The clarity and accuracy of this article were significantly improved by the criticism of an anonymous referee.

HOPF BIFURCATION IN DIFFERENTIAL EQUATIONS WITH DELAY FOR TUMOR–IMMUNE SYSTEM COMPETITION MODEL*

RADOUANE YAFIA†

Abstract. This paper deals with the qualitative analysis of the solutions to a model that refers to the competition between the immune system and an aggressive host such as a tumor. The model which describes this competition is governed by a system of differential equations with one delay. It is shown that the dynamics depends crucially on the time delay parameter. By using the time delay as a parameter of bifurcation, the analysis is focused on the Hopf bifurcation problem to predict the occurrence of a limit cycle bifurcating from the nontrivial steady state. The obtained results depict the oscillations, given by simulations (see [M. Galach, *Int. J. Appl. Math. Comput. Sci.*, 13 (2003), pp. 395–406]), which are observed in reality (see [D. Kirschner and J. C. Panetta, *J. Math. Biol.*, 37 (1998), pp. 235–252]). It is suggested to examine by laboratory experiments how to employ these results for control of tumor growth.

Key words. tumor–immune system competition, delayed differential equations, Hopf bifurcation, periodic solutions

1. Introduction.

We consider a model concerning the competition of tumor cells with the immune system. The modeling approach, proposed by many authors, uses ordinary and delayed differential equations; see [14, 16, 19, 20, 24, 27]. Other authors use kinetic equations that give a complex description, at the cellular scale, in comparison with other, simpler models. Kinetic models are needed to describe heterogeneity of virulence; see [1, 2, 3, 4, 9, 26].

Modeling in other fields of biology also uses kinetic equations; for instance, [11] develops a kinetic theory approach to describe population dynamics, while [3] deals with the development of suitable general mathematical structures including a large variety of Boltzmann-type models. Other authors use models based on partial differential equations corresponding to population dynamics of cells with internal structure [22] (however, not heterogeneous) or models based on interacting agents [21].

The reader interested in a more complete bibliography about the evolution of a cell, and the pertinent role of cellular phenomena in directing the body toward recovery or toward illness, is referred to [13, 17]. A detailed description of virus, antivirus, and body dynamics can be found in [8, 12, 23, 25].

The mathematical model under consideration was proposed in a recent paper by Galach [16], who proposed a simple model, with one delay, of tumor–immune system competition. The idea is inspired from [20]. He also refers to numerical results in [20] to compare them with those obtained in his paper [16].

The mathematical analysis of this present paper is motivated by experimental and numerical results; see [19, 16], respectively. These results give evidence that the oscillating state of the tumor is more desirable, from the medical point of view, than the monotonically growing state, presumably because oscillations prolong the nonterminal phase of disease. We can ask what are the conditions and feedback loops

which make oscillations possible and whether the tumor can be preserved in such an oscillating state by therapeutic means for an indefinite time. This leads to study of the model in terms of a time delay ordinary differential equation system. We believe that it makes sense to ask qualitative questions about the behavior of the system locally with respect to time, such as questioning the existence and stability of fixed points and the existence of Hopf bifurcation. Being interested in periodic or quasi-periodic behavior of the tumor, we investigate the model with respect to existence of the Hopf point.

This paper is organized as follows. In section 2, we introduce the model. In section 3, we establish some results on the stability of the possible steady states (trivial and nontrivial) of the delayed system (2.4). The existence of a critical value of the delay in which the nontrivial steady state changes stability is investigated. The main result of this paper is given in section 4. Based on the Hopf bifurcation theorem, we show the occurrence of Hopf bifurcation when the delay crosses some critical value. Section 5 is devoted to a numerical application for the parameter values of system (2.4). In section 6, we give short discussions.

2. Mathematical model. When unknown tissues, organisms, or tumor cells appear in a body the immune system tries to identify them and, if successful, attempts to eliminate them. The immune system response consists of two different interacting responses: the cellular response and the humoral response. The cellular response is carried by T lymphocytes. The humoral response is related to the class of cells called B lymphocytes. A dynamics of the antitumor immune response in vivo is complicated and not well understood.

The immune response begins when tumor cells are identified. Then tumor cells are caught by macrophages, which are found in all tissues in the body and circulate in the blood stream. Macrophages absorb tumor cells, destroy them, and release a series of cytokines which activate T helper cells (i.e., a subpopulation of T lymphocytes). These latter cells coordinate the counterattack. T helper cells can also be directly stimulated to interact with antigens. These helper cells cannot kill tumor cells, but they send urgent biochemical signals to a special type of T lymphocytes called natural killers (NKs). T cells begin to multiply and release other cytokines that further stimulate more T cells, B cells, and NK cells. As the number of B cells increases, T helper cells send a signal to start the production of antibodies. Antibodies circulate in the blood and are attached to tumor cells, which implies that the tumor cells are more quickly engulfed by macrophages or killed by NK cells. Like all T cells, NK cells are programmed to recognize one specific type of infected cell or cancer cell. NK cells are lethal and constitute a critical line of the defense.

The model proposed in [20] describes the response of effector cells (ECs) to the growth of tumor cells (abbreviated TCs from here on). This model differs from others because it takes into account the penetration of TCs by ECs, which simultaneously causes the inactivation of ECs. It is assumed that interactions between ECs and TCs in vitro can be described by the kinetic scheme shown in Figure 1, where E, T, C,

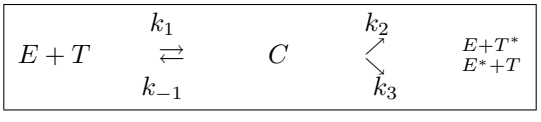

FIG. 1. *Kinetic scheme describing interactions between ECs and TCs* (*see* [16]).

E^*, and T^* are the local concentrations of ECs, TCs, EC–TC complexes, inactivated ECs, and "lethally hit" TCs, respectively. k_1 and k_{-1} denote the rates of bindings of ECs to TCs and the detachment of ECs from TCs without damaging TCs, k_2 is the rate at which EC–TC interactions program TCs for lysis, and k_3 is the rate at which EC–TC interactions inactivate ECs.

Kuznetsov and Taylor's model [20] is as follows:

$$\begin{cases} \frac{dE}{dt} = s + F(C,T) - d_1 E - k_1 ET + (k_{-1} + k_2)C, \\ \frac{dT}{dt} = aT(1 - bT) - k_1 ET + (k_{-1} + k_3)C, \\ \frac{dC}{dt} = k_1 ET - (k_{-1} + k_2 + k_3)C, \\ \frac{dE^*}{dt} = k_3 C - d_2 E^*, \\ \frac{dT^*}{dt} = k_2 C - d_3 T^*, \end{cases} \tag{2.1}$$

where s is the normal (i.e., not increased by the presence of the tumor) rate of the flow of adult ECs into the tumor site. $F(C,T)$ describes the accumulation of ECs in the tumor site; d_1, d_2, and d_3 are the coefficients of the processes of destruction and migration for E, E^*, and T^*, respectively; a is the coefficient of the maximal growth of tumor; and b is the environment capacity.

It is claimed in [20] that experimental observations motivate the approximation $\frac{dC}{dt} \approx 0$. Therefore, it is assumed that $C \approx KET$, where $K = \frac{k_1}{k_2 + k_3 + k_{-1}}$, and the model can be reduced to two equations which describe the behavior of ECs and TCs only. Moreover, in [16] it is suggested that the function F should be in the form $F(C,T) = F(E,T) = \theta ET$. Therefore, the model (2.1) takes the form

$$\begin{cases} \frac{dE}{dt} = s + \alpha_1 ET - dE, \\ \frac{dT}{dt} = aT(1 - bT) - nET, \end{cases} \tag{2.2}$$

where $\alpha_1 = \theta - m$, and a, b, s have the same meanings as $n = Kk_2$, $m = Kk_3$, and $d = d_1$, respectively, in (2.1). All coefficients except α_1 are positive. The sign of α_1 depends on the relation between θ and m. If the stimulation coefficient of the immune system exceeds the neutralization coefficient of ECs during the formation of EC–TC complexes, then $\alpha_1 > 0$. We use the dimensionless form of model (2.2),

$$\begin{cases} \frac{dx}{dt} = \sigma + \omega xy - \delta x, \\ \frac{dy}{dt} = \alpha y(1 - \beta y) - xy, \end{cases} \tag{2.3}$$

where x denotes the dimensionless density of ECs; y stands for the dimensionless density of the population of TCs; $\alpha = \frac{a}{nT_0}$, $\beta = bT_0$, $\delta = \frac{d}{nT_0}$, $\sigma = \frac{s}{nE_0T_0}$, and $\omega = \frac{\alpha_1}{n}$ represent the immune response to the appearance of the tumor cells; and E_0 and T_0 are the initial conditions. The existence, uniqueness, and nonnegativity of solutions are analyzed in [16], and the nonexistence of a nonnegative periodic solution of system (2.3) is proved. The existence and stability of a periodic solution of system (2.3) are studied in [28].

For $\omega > 0$ and $\alpha\delta < \sigma$, system (2.3) has one nonnegative steady state P_0, which is stable, and for $\omega > 0$ and $\alpha\delta > \sigma$ (2.3) has two possible nonnegative steady states P_0 and P_2, where the first is unstable and the second is stable (see [16]).

The delayed mathematical model corresponding to (2.3) is given by the following system [16]:

$$\begin{cases} \frac{dx}{dt} = \sigma + \omega x(t-\tau)y(t-\tau) - \delta x, \\ \frac{dy}{dt} = \alpha y(1-\beta y) - xy, \end{cases} \tag{2.4}$$

where the parameter τ is the time delay which the immune system needs to develop a suitable response after the recognition of nonself cells (see [16]). Time delays in connection with tumor growth also appear in [5, 6, 7, 15].

The existence and uniqueness of solutions of system (2.4) for every $t > 0$ are established in [16], and in the same paper it is shown that

(1) if $\omega \geq 0$, these solutions are nonnegative for any nonnegative initial conditions (biologically realistic case);

(2) if $\omega < 0$, there exist nonnegative initial conditions such that the solution becomes negative in a finite time interval.

The existence and stability of periodic solution of system (2.4) when $\omega < 0$ are studied in [29, 30], respectively.

Our goal in this paper is to consider case (1) when $\omega > 0$ (this case corresponds to the existence of a nonnegative solution), which is the most biologically meaningful one. We study the asymptotic behavior of the possible steady states P_0 and P_2 with respect to the delay τ. We establish that the Hopf bifurcation may occur by using the delay as a parameter of bifurcation. This result is depicted numerically.

3. Steady states and stability for positive delays. Consider the system (2.4), and suppose that $\omega > 0$. We distinguish between two cases, $\alpha\delta < \sigma$ and $\alpha\delta > \sigma$.

Let the following hypotheses hold:

(A_1) $\omega > 0$ and $\alpha\delta < \sigma$.

(A_2) $\omega > 0$ and $\alpha\delta > \sigma$.

Under hypothesis (A_1), system (2.4) has a unique positive equilibrium P_0 given by $P_0 = (\frac{\sigma}{\delta}, 0)$, and the linearized system around P_0 takes the form

$$\begin{cases} \frac{dx}{dt} = \omega\frac{\sigma}{\delta}y(t-\tau) - \delta x, \\ \frac{dy}{dt} = (\alpha - \frac{\sigma}{\delta})y, \end{cases} \tag{3.1}$$

which leads to the characteristic equation

$$W(\lambda) = \left(\lambda + \frac{\sigma}{\delta} - \alpha\right)(\lambda + \delta). \tag{3.2}$$

Therefore, we have the following result.

PROPOSITION 3.1. *Assume* (A_1). *The equilibrium point* P_0 *is asymptotically stable for all* $\tau > 0$.

Proof. The characteristic equation (3.2) has two roots $\lambda_1 = -\frac{\sigma}{\delta} + \alpha$ and $\lambda_2 = -\delta$ which are independent of τ and are negative. From [18], the equilibrium point P_0 is asymptotically stable for all $\tau > 0$. □

Under hypothesis (A_2), system (2.4) has two equilibrium points $P_0 = (\frac{\sigma}{\delta}, 0)$ and $P_2 = (x_2, y_2)$, where

$$x_2 = \frac{-\alpha(\beta\delta - \omega) + \sqrt{\Delta}}{2\omega}, \qquad y_2 = \frac{\alpha(\beta\delta + \omega) - \sqrt{\Delta}}{2\alpha\beta\omega},$$

with $\Delta = \alpha^2(\beta\delta - \omega)^2 + 4\alpha\beta\sigma\omega$.

From the characteristic equation (3.2), we state the following result.

PROPOSITION 3.2. *Assume* (A_2). *Then, the equilibrium point P_0 is unstable for all $\tau > 0$.*

Proof. The characteristic equation (3.2) has two roots $\lambda_1 = -\frac{\sigma}{\delta} + \alpha$ and $\lambda_2 = -\delta$ which are independent of τ. As $\alpha\delta > \sigma$, we have $\lambda_1 > 0$. From [18], the equilibrium point P_0 is unstable for all $\tau > 0$. □

In the next sections, we shall study the stability of the nontrivial equilibrium point P_2.

Let $z(t) = (u(t), v(t)) = (x(t), y(t)) - (x_2, y_2)$; then system (2.4) is written as a functional differential equation in $C := C([-\tau, 0], \mathbb{R}^2)$,

$$\frac{dz(t)}{dt} = L(\tau)z_t + f(z_t, \tau), \tag{3.3}$$

where $L(\tau) : C \longrightarrow \mathbb{R}^2$ (a linear operator) and $f : C \times \mathbb{R} \longrightarrow \mathbb{R}^2$ are given, respectively, by

$$L(\tau)\varphi = \begin{pmatrix} \omega y_2\varphi_1(-\tau) + \omega x_2\varphi_2(-\tau) - \delta\varphi_1(0) \\ -y_2\varphi_1(0) + (\alpha - 2\alpha\beta y_2 - x_2)\varphi_2(0) \end{pmatrix}$$

and

$$f(\varphi, \tau) = \begin{pmatrix} \sigma + \omega\varphi_1(-\tau)\varphi_2(-\tau) + \omega x_2 y_2 - \delta x_2 \\ -\alpha\beta\varphi_2^2(0) + \alpha y_2 - \alpha\beta y_2^2 - \varphi_1(0)\varphi_2(0) - x_2 y_2 \end{pmatrix}$$

for $\varphi = (\varphi_1, \varphi_2) \in C$ and $z_t \in C$, defined by $z_t(\theta) = z(t + \theta)$, for all $\theta \in [-\tau, 0]$.

The characteristic equation of linearized equation

$$\frac{dz(t)}{dt} = L(\tau)z_t \tag{3.4}$$

has the form

$$W(\lambda, \tau) = \lambda^2 + p\lambda + r + (s\lambda + q)e^{-\lambda\tau} = 0, \tag{3.5}$$

where $p = \delta + \alpha\beta y_2 > 0$, $r = \delta\alpha\beta y_2 > 0$, $s = -\omega y_2 < 0$, and $q = \alpha\omega y_2(1 - 2\beta y_2) > 0$.

The stability of the equilibrium point P_2 is a result of the localization of the roots of (3.5); then we have the following theorem.

THEOREM 3.3. *Assume* (A_2) *and $\alpha > \sup(\frac{\omega}{\beta}, \frac{\sigma}{\delta})$. Then, there exist $\beta_1 > 0$ and $\tau_l > 0$ such that, for all $0 < \beta < \beta_1$, the nontrivial steady state P_2 is asymptotically stable for $\tau < \tau_l$ and unstable for $\tau > \tau_l$, where*

$$\tau_l = \frac{1}{\zeta_l} \arccos\left\{ \frac{q(\zeta_l^2 - r) - ps\zeta_l^2}{s^2\zeta_l^2 + q^2} \right\}, \tag{3.6}$$

$$\zeta_l^2 = \frac{1}{2}(s^2 - p^2 + 2r) + \frac{1}{2}[(s^2 - p^2 + 2r)^2 - 4(r^2 - q^2)]^{\frac{1}{2}}, \tag{3.7}$$

$$\beta_1 = \frac{2\omega(2\sigma - \alpha\delta) - \sqrt{\Delta_1}}{2\alpha^2\delta^2} > 0, \tag{3.8}$$

and

$$\Delta_1 = 4\alpha^2\omega^2(4\sigma^2 - 4\alpha\delta\sigma + 2\alpha^2\delta^2) > 0. \tag{3.9}$$

For the proof of Theorem 3.3, we need Lemma 3.4.

Consider the equation

$$\lambda^2 + p\lambda + r + (s\lambda + q)e^{-\lambda\tau} = 0, \tag{3.10}$$

where p, r, q, and s are real numbers.

Let the following hypotheses hold:

(H_1) $p + s > 0$.

(H_2) $q + r > 0$.

(H_3) $r^2 - q^2 < 0$ or ($s^2 - p^2 + 2r > 0$ and $(s^2 - p^2 + 2r)^2 = 4(r^2 - q^2)$).

LEMMA 3.4 (see [10]). *If* (H_1)–(H_3) *hold, then when* $\tau \in [0, \tau_l)$ *all roots of* (3.10) *have negative real parts; when* $\tau = \tau_l$ (3.10) *has a pair of purely imaginary roots* $\pm i\zeta_l$*; and when* $\tau > \tau_l$ (3.10) *has at least one root with positive real part, where* τ_l *and* ζ_l *are defined as in Theorem* 3.3.

Proof of Theorem 3.3. From the hypothesis $\alpha > \sup(\frac{\omega}{\beta}, \frac{\sigma}{\delta})$ and the expressions of p, q, s, and r, we have $p + s > 0$ and $q + r > 0$. Therefore, hypotheses (H_1) and (H_2) are satisfied.

Then, all roots of the characteristic equation (3.5) have negative real parts for $\tau = 0$, and the steady state P_2 is asymptotically stable for $\tau = 0$.

By Rouche's theorem, it follows that the roots of (3.5) have negative real parts for some critical value of the delay τ.

We want to determine if the real part of some root increases to reach zero and eventually becomes positive as τ varies.

If $i\zeta$ is a root of (3.5), then

$$-\zeta^2 + ip\zeta + is\zeta(\cos(\tau\zeta) + i\sin(\tau\zeta)) + r + q(\cos(\tau\zeta) + i\sin(\tau\zeta)) = 0. \tag{3.11}$$

Separating the real and imaginary parts, we have

$$\begin{cases} -\zeta^2 + r = -q\cos(\tau\zeta) + s\zeta\sin(\tau\zeta), \\ p\zeta = -s\zeta\cos(\tau\zeta) - q\sin(\tau\zeta). \end{cases} \tag{3.12}$$

It follows that ζ satisfies

$$\zeta^4 - (s^2 - p^2 + 2r)\zeta^2 + (r^2 - q^2) = 0. \tag{3.13}$$

The two roots of the above equation can be expressed as follows:

$$\zeta^2 = \frac{1}{2}(s^2 - p^2 + 2r) \pm \frac{1}{2}[(s^2 - p^2 + 2r)^2 - 4(r^2 - q^2)]^{\frac{1}{2}}. \tag{3.14}$$

As

$$r^2 - q^2 = \alpha^2 y_2^2(\delta^2\beta^2 - \omega^2(1 - 2\beta y_2)^2),$$

the sign of $r^2 - q^2$ is deduced from the sign of

$$(\delta\beta - \omega(1 - 2\beta y_2)) = \frac{2\alpha\beta\delta - \sqrt{\Delta}}{\alpha}, \tag{3.15}$$

which is negative for $0 < \beta < \beta_1$, where β_1 is given by (3.8). Because the discriminant of (3.15) is positive for all $\alpha > 0$, we have $\delta, \sigma > 0$.

Therefore, we have $r^2 - q^2 < 0$, and hypothesis (H_3) is satisfied, which concludes the proof of Theorem 3.3. □

4. Hopf bifurcation occurrence. We apply the Hopf bifurcation theorem to show the existence of a nontrivial periodic solution of system (3.3), for suitable values of parameter delay, and use the Hopf bifurcation as a bifurcation parameter. Therefore, the periodicity is a result of changing the type of stability from a stable stationary solution to a limit cycle.

In what follows, we recall the formulation of the Hopf bifurcation theorem for retarded differential equations. Let the equation

$$\frac{dx(t)}{dt} = F(\alpha, x_t) \tag{4.1}$$

hold with $F : \mathbb{R} \times C \longrightarrow \mathbb{R}^n$, F of class $\mathcal{C}^k$, $k \geq 2$, $F(\alpha, 0) = 0$ for all $\alpha \in \mathbb{R}$, and $C = C([-r, 0], \mathbb{R}^n)$ the space of continuous functions from $[-r, 0]$ into $\mathbb{R}^n$. As usual, x_t is the function defined from $[-r, 0]$ as $\mathbb{R}^n$ by $x_t(\theta) = x(t + \theta)$, $r \geq 0$, and $n \in \mathbb{N}^*$.

The following assumptions are stated:

(M_0) F is of class $\mathcal{C}^k$, $k \geq 2$, $F(\alpha, 0) = 0$ for all $\alpha \in \mathbb{R}$, and the map $(\alpha, \varphi) \longrightarrow D^k_\varphi F(\alpha, \varphi)$ sends bounded sets into bounded sets.

(M_1) The characteristic equation

$$\Delta(\alpha, \lambda) = \det(\lambda Id - D_\varphi F(\alpha, 0) \exp(\lambda(.)Id)) \tag{4.2}$$

of the linearized equation of (4.1) around the equilibrium $v = 0$,

$$\frac{dv(t)}{dt} = D_\varphi F(\alpha, 0) v_t, \tag{4.3}$$

has in $\alpha = \alpha_0$ a simple imaginary root $\lambda_0 = \lambda(\alpha_0) = i$; all other roots λ satisfy $\lambda \neq m\lambda_0$ for $m \in \mathbb{Z}$.

(M_2) $\lambda(\alpha)$ is the branch of roots passing through λ_0, and we have

$$\frac{\partial}{\partial \alpha} \operatorname{Re} \lambda(\alpha)_{/\alpha=\alpha_0} \neq 0. \tag{4.4}$$

THEOREM 4.1 (see [18]). *Under assumptions* (M_0), (M_1), *and* (M_2), *there exist constants* $\varepsilon_0 > 0$ *and* δ_0, *functions* $\alpha(\varepsilon)$, $T(\varepsilon)$, *and a* $T(\varepsilon)$*-periodic function* $x^*(\varepsilon)$ *such that*

(a) *all of these functions are of class* $\mathcal{C}^{k-1}$ *with respect to* ε, *for* $\varepsilon \in [0, \varepsilon_0[$, $\alpha(0) = \alpha_0$, $T(0) = 2\pi$, $x^*(0) = 0$;

(b) $x^*(\varepsilon)$ *is a* $T(\varepsilon)$*-periodic solution of* (4.1), *for the parameter values equal to* $\alpha(\varepsilon)$;

(c) *for* $|\alpha - \alpha_0| < \delta_0$ *and* $|T - 2\pi| < \delta_0$, *any* T*-periodic solution* p, *with* $\|p\| < \delta_0$, *of* (4.1) *for the parameter value* α, *there exists* $\varepsilon \in [0, \varepsilon_0[$ *such that* $\alpha = \alpha(\varepsilon)$, $T = T(\varepsilon)$, *and* p *is up to a phase shift equal to* $x^*(\varepsilon)$.

We notice that (M_1) implies that the root λ_0 lies on a branch of roots $\lambda = \lambda(\alpha)$ of (4.2) of class $\mathcal{C}^{k-1}$.

The following theorem gives the main result of this paper.

THEOREM 4.2. *Assume* (A_2) *and* $\alpha > \sup(\frac{\omega}{\beta}, \frac{\sigma}{\delta})$. *There exists* $\varepsilon_1 > 0$ *such that, for each* $0 \leq \varepsilon < \varepsilon_1$, (3.3) *has a family of periodic solutions* $p_l(\varepsilon)$, *with period* $T_l = T_l(\varepsilon)$, *for the parameter values* $\tau = \tau(\varepsilon)$ *such that* $p_l(0) = P_2$, $T_l(0) = \frac{2\pi}{\zeta_l}$, *and* $\tau(0) = \tau_l$, *where* τ_l *and* ζ_l *are given, respectively, as in* (3.6) *and* (3.7).

Proof. For the proof of Theorem 4.2, we apply the Hopf bifurcation theorem, Theorem 4.1.

From the expression of f in (3.3), we have

$$f(0,\tau)=0 \text{ for all } \tau>0$$

and

$$\frac{\partial f(0,\tau)}{\partial\varphi}=0 \text{ for all } \tau>0.$$

Then hypothesis (M_0) is satisfied. From (3.5) and Theorem 3.3, the characteristic equation (3.5) has a pair of simple imaginary roots $\lambda_l=i\zeta_l$ and $\overline{\lambda}_l=-i\zeta_l$ at $\tau=\tau_l$.

From (3.5), we have

$$W(\lambda_l,\tau_l)=0,$$

and, by differentiation, we find

$$\frac{\partial}{\partial\lambda}W(\lambda_l,\tau_l)=2i\zeta_l+p+(s-\tau(is\zeta_l+q))e^{-i\zeta_l\tau_l}\neq 0.$$

According to the implicit function theorem, there exist neighborhoods $\mathcal{U}\subset\mathbb{R}$ and $\mathcal{V}\subset\mathbb{C}$ of τ_l and λ_l, respectively, and a complex function $\lambda=\lambda(\tau)$ defined from $\mathcal{U}$ to $\mathcal{V}$, such that

$$\lambda(\tau_l)=\lambda_l,$$

and we have

$$W(\lambda(\tau),\tau)=0 \text{ for } \tau\in\mathcal{U}; \tag{4.5}$$

thus, we find

$$\lambda'(\tau)=-\frac{\partial W(\lambda,\tau)/\partial\tau}{\partial W(\lambda,\tau)/\partial\lambda} \text{ for } \tau\in\mathcal{U}. \tag{4.6}$$

From (3.5), we have

$$\begin{aligned}\frac{\partial}{\partial\tau}W(\lambda,\tau)&=-\lambda(s\lambda+q)e^{-\lambda\tau}\\&=\lambda(\lambda^2+p\lambda+r)\end{aligned}$$

and

$$\begin{aligned}\frac{\partial}{\partial\lambda}W(\lambda,\tau)&=2\lambda+p+(s-\tau s\lambda-\tau q)e^{-\lambda\tau}\\&=2\lambda+p+\tau(\lambda^2+p\lambda+r)-s\left(\frac{\lambda^2+p\lambda+r}{s\lambda+q}\right).\end{aligned}$$

From these expressions, a simple calculation leads to

$$\lambda'(\tau)=\frac{\lambda(s\lambda+q)e^{-\lambda\tau}}{2\lambda+p+(s-\tau s\lambda-\tau q)e^{-\lambda\tau}}. \tag{4.7}$$

From (3.5), (4.5), and (4.7), we obtain the following expression of $\lambda'(\tau)$ for $\tau\in\mathcal{U}$:

$$\lambda'(\tau)=-\lambda\frac{A(\lambda)}{B(\tau,\lambda)}, \tag{4.8}$$

where

$$A(\lambda) = s\lambda^3 + (sp+q)\lambda^2 + (sr+pq)\lambda + qr$$

and

$$B(\tau,\lambda) = \tau s\lambda^3 + (s+\tau(sp+q))\lambda^2 + (2q+\tau(sr+pq))\lambda + pq - sr + \tau qr.$$

Let $\lambda(\tau) = \kappa(\tau) + i\zeta(\tau)$ (where κ and ζ are the real and imaginary parts of λ such that $\kappa(\tau_l) = 0$ and $\zeta(\tau_l) = \zeta_l$, respectively).

From (4.8) and for $\tau = \tau_l$, we have

$$\lambda'(\tau)_{/\tau=\tau_l} = -i\zeta_l \frac{A(i\zeta_l)}{B(\tau_l, i\zeta_l)}. \tag{4.9}$$

By separating the real and imaginary parts in (4.9), we deduce that

$$\begin{aligned}\kappa'(\tau)_{/\tau=\tau_l} &= \frac{\partial}{\partial\tau}\operatorname{Re}\lambda(\tau)_{/\tau=\tau_l} \\ &= \zeta_l^2 \frac{s^2\zeta_l^4 + (sqr(\tau_l - 1) + 2q^2)\zeta_l^2 + sr^2(q - sr)}{A^2 + B^2} \\ &\quad + \frac{pq^2(p+r) - qr(2q + \tau_l(sr+pq))}{A^2 + B^2},\end{aligned}$$

where

$$A = -(s + \tau_l(sp+q))\zeta_l^2 + pq - sr + \tau qr$$

and

$$B = -\tau_l s\zeta_l^3 + (2q + \tau_l(sr+pq))\zeta_l.$$

As ζ_l (which exists for $0 < \beta < \beta_1$) is a root of (3.13), we conclude that

$$\kappa'(\tau)_{/\tau=\tau_l} \neq 0.$$

Then hypotheses (M_1) and (M_2) are satisfied, which completes the proof of Theorem 4.2. ∎

5. Application. Let us fix the parameters of the model as follows: $\alpha = 1.636$, $\beta = 0.002$, $\sigma = 0.1181$, $\delta = 0.3747$, and $0.00184 < \omega < 0.01185$. Moreover, assume $\omega = 0.04$ according to medical experiments (Kuznetsov and Taylor [20]). Therefore, $\alpha\beta = 0.003272 > \omega$ for $\omega = 0.04$. $\alpha\delta = 0.6160372 > \sigma$, $\beta < \beta_1 = 0.04654$.

The nontrivial steady state $P_2 = (x_2, y_2)$ is given by $x_2 = 1.6113$, $y_2 = 7.5352$, $p = 0.3994$, $r = 0.0092$, $s = -0.3014$, and $q = 0.4782$.

It is easy to verify that the conditions of Theorem 4.2 are fulfilled. A limit cycle bifurcation occurs when the time delay parameter τ passes through $\tau = \tau_l = 2.3581$, where the relative eigenvalues are $\lambda_l = i0.2010$. Moreover, we can compute the approximate period of the bifurcating periodic solution by

$$T_l = \frac{2\pi}{|\lambda_l|} = 9.2681 \text{ days}.$$

The bifurcating periodic solution of (2.4) is visualized with the aid of MATLAB software.

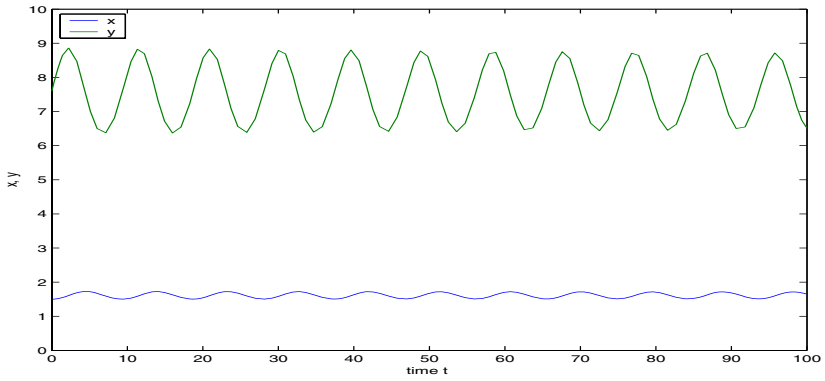

FIG. 2. *The bifurcating periodic solution of* (2.4) *in* (t, x) *and* (t, y) *planes for the delay parameter value* $\tau = \tau_l$.

We can deduce, according to Theorem 4.2, that the nontrivial stationary point P_2 is asymptotically stable when $\tau < \tau_l$. In this case the model allows for the possibility of a small tumor mass. When $\tau > \tau_l$, P_2 becomes unstable and a large tumor mass appears.

After extension of the time delay τ, the stable equilibrium is lost and the tumor starts to oscillate periodically (period equal to 9.2681 days). See Figure 2. Because of those oscillations the tumor can disappear (if the periodic oscillations are stable) or the patient can die (if the periodic oscillations are unstable).

6. Discussions. A numerical investigation, given in [16], shows that the characteristic equation (3.5) of the linearized system (2.4) around the nontrivial steady state P_2 has a purely imaginary root for some $\tau = \tau_0$, and the switching of stability may occur by using the Mikhailov hodograph.

In this paper, we gave an analytical study of stability (with respect to the time delay τ) of the possible steady states P_0 and P_2 for the positive values of the parameter ω.

In section 4 we prove that system (2.4) has a family of periodic solutions bifurcating from the nontrivial steady state.

We hope the results proposed in this paper improve the understanding of the qualitative properties of the description delivered by model (2.4). So far we now have a description of stability properties and Hopf bifurcation with a detailed analysis of the influence of delays terms. As demonstrated, whenever time delay was introduced into the tumor immune model, a Hopf point was found, leading to oscillatory behavior. It seems to us worthwhile to examine these results in the clinical context, that is, to check whether or not one can contain tumor growth by imposing (by use of certain drugs) time delay in tumor immune system competition.

Acknowledgments. I am very grateful to Professor N. Bellomo for improving this paper and I thank the two referees for their valuable suggestions.

A STOCHASTIC MODEL AND ASSOCIATED FOKKER–PLANCK EQUATION FOR THE FIBER LAY-DOWN PROCESS IN NONWOVEN PRODUCTION PROCESSES*

T. GÖTZ†, A. KLAR‡, N. MARHEINEKE†, AND R. WEGENER‡

Abstract. In this paper we present and investigate a stochastic model and its associated Fokker–Planck equation for the lay-down of fibers on a conveyor belt in the production process of nonwoven materials. The model is based on a stochastic differential equation taking into account the motion of the fiber under the influence of turbulence. A reformulation as a stochastic Hamiltonian system and an application of the stochastic averaging theorem lead to further simplifications of the model. Finally, the model is used to compute the distribution of functionals of the process that are important for the quality assessment of industrial fabrics.

Key words. fiber dynamics, stochastic Hamiltonian system, Fokker–Planck equations, stochastic averaging

1. Introduction.

The understanding of the forms generated by the lay-down of flexible fibers onto a moving conveyor belt is of great interest in the production process of nonwovens that find their applications in, e.g., composite materials (filters), textiles, and the hygiene industry [3]. In the melt-spinning process of nonwoven materials, hundreds of individual endless fibers obtained by the continuous extrusion of a melted polymer are stretched and entangled by highly turbulent air flows to finally form a web on the conveyor belt. The quality of this web and the resulting nonwoven material—in terms of homogeneity and load capacity—depends essentially on the dynamics and the deposition of the fibers.

A mathematical model and numerical simulations for the nonwoven production process are presented in [12]. The paper focuses on the fiber spinning and lay-down, where the fiber dynamics in the deposition region close to the conveyor belt is dominated by the turbulent air flow. For the description of the interaction between fibers and turbulent flow, a stochastic force model is derived and analyzed in [18] as well as experimentally validated in [19]. Applying this concept, the fiber fabric can in principle be numerically generated and its quality investigated in the spirit of the multiscale image analysis of [22]. However, these or similar simulations usually lead to excessively large computation times, when all physical details of the production process are considered. Thus, simplified models for the lay-down process are needed. In particular, this is true for optimization and control procedures where many different simulations are needed. Experimental studies on the forms of threads laid on a moving belt as well as a simplified general theory for the buckling of the fibers can be found in [11]. The coiling behavior of flexible rods is investigated in [17].

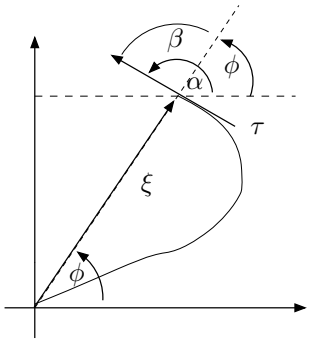

FIG. 1. *Fiber scenario on the conveyor belt.*

Motivated by the research work done in the field of woven textile composites [7], e.g., modeling [15], numerical and asymptotical stress analysis [23], and stiffness/load capacity investigations [6], we focus in this paper on the modeling of nonwoven textiles and the determination of textile properties, e.g., weight distribution, that are important for the quality assessment of industrial nonwoven fabrics. In particular, we present a new simplified stochastic model for the fiber lay-down process, i.e., for the generation of the fiber web on the conveyor belt that is assumed for simplicity to be nonmoving. Taking into account the fiber motion under the influence of turbulence, the process is described by a stochastic differential system in section 2. Its associated Kolmogoroff equation and stationary solution are investigated in section 3. Moreover, we include remarks on the identification of the process parameters. Section 4 contains an investigation of the scaled stochastic Hamiltonian system using stochastic averaging. In section 5 we conclude with the computation of the probability distribution of process functionals.

2. Stochastic model for fiber lay-down. In the industrial application a nonwoven material is generated by the superposition of many elastic, slender, and inextensible fibers. The nonwoven quality is measured by the homogeneity of the fiber mass distribution. Neglecting the interaction of neighboring fibers, we focus here on a single fiber in an isotropic lay-down process. Instead of describing this lay-down process in all physical details, we directly model the resulting fiber on the conveyor belt as an arc-length parameterized curve $\xi : \mathbb{R}_0^+ \to \mathbb{R}^2$ satisfying $\|\partial_t \xi\| = 1$; see Figure 1. Assuming constant cross sections, the curve carries the full information of the mass contribution of this fiber to the mass distribution of the nonwoven material. We prescribe ξ by a dynamical system with respect to the arc-length t that contains the crucial physical characteristics of the lay-down process, i.e., buckling/coiling of the fiber as well as the influence of the turbulent air flow in the deposition region on the fiber. Assuming for simplicity a nonmoving conveyor belt, the dynamical system is modeled by the following stochastic differential equations:

$$\begin{aligned} \mathrm{d}\xi_t &= \tau(\alpha_t)\,\mathrm{d}t, \\ \mathrm{d}\alpha_t &= -b(\|\xi\|)\frac{\xi_t}{\|\xi_t\|}\cdot\tau^{\perp}(\alpha_t)\,\mathrm{d}t + A\,\mathrm{d}W_t, \end{aligned}$$

where $\tau(\alpha) = (\cos\alpha, \sin\alpha)^T$ denotes the normalized tangent on the fiber. Since a curved fiber returns to the reference point of the spinning process determined by the nozzle position according to its coiling behavior, the change of the angle α is assumed

to be proportional to $\xi \cdot \tau^{\perp}(\alpha)$ with $\tau^{\perp}(\alpha) = (-\sin\alpha, \cos\alpha)^T$. The amplitude of this drive is prescribed by a continuously differentiable function $b : \mathbb{R}_0^+ \to \mathbb{R}$ with $b(r) > 0$ for $r > 0$ and $b'(r) \geq 0$ for $r \geq 0$. Let r_0 be the argument that satisfies $b(r_0) = 1/r_0$. The effect of the turbulent flow on the fiber in the deposition region close to the conveyor belt yields a stochastic force in the fiber lay-down process that is modeled here by a Wiener process W_t in $\mathbb{R}$ with amplitude A.

The parameters A and b depend on the specific industrial application and need to be adapted to experimental data. In case of an anisotropic lay-down process the scalar-valued function b has to be replaced by an appropriate matrix-valued one, i.e.,

$$\mathrm{d}\alpha_t = -\frac{\xi_t}{\|\xi_t\|} M(\|\xi_t\|)\tau^{\perp}(\alpha_t)\,\mathrm{d}t + A\,\mathrm{d}W_t,$$

where $M(r) \in \mathbb{R}^{2\times 2}$ denotes a positive definite matrix.

Since length, i.e., fiber (arc-)length t and position ξ, is the only dimension in the lay-down process, the system can be nondimensionalized by scaling it with the typical deposition radius r_0. Then, we have $b^\star(r^\star) = r_0\, b(r_0 r^\star)$ and $A^\star = \sqrt{r_0}A$. Consequently, $b^\star(1) = 1$ holds, and the dimensionless noise amplitude $A^\star$ characterizes the relation between stochastic and deterministic rates in the behavior of the system. Figure 2 shows examples for the pathwise behavior of the solution for varying noise A with constant drive $b(r) = 1$ and fixed fiber length. Physically relevant scenarios typically include parameters ranging from $A = 0.1$ to $A = 5$ depending on the size of the turbulent force exerted on the fiber. Note that for convenience we have skipped the superscript star * denoting the dimensionless quantities. Moreover, we embed our model in the context of dynamical systems and stochastic processes and use in the following the notation and interpretation of time for the arc-length parameter.

Introducing polar coordinates $\xi = (r\cos\phi, r\sin\phi)^T$, $r = \|\xi\|$ and the angle $\beta = \alpha - \phi$ with ϕ in ξ-space (Figure 1), the given stochastic differential system can be rewritten in terms of $(r, \beta) \in [0, \infty) \times [0, 2\pi]$:

$$\mathrm{d}r_t = \cos\beta_t\,\mathrm{d}t, \tag{2.1a}$$

$$\mathrm{d}\beta_t = \left(b(r_t) - \frac{1}{r_t}\right)\sin\beta_t\,\mathrm{d}t + A\,\mathrm{d}W_t, \tag{2.1b}$$

$$\mathrm{d}\phi_t = \frac{\sin\beta_t}{r_t}\,\mathrm{d}t. \tag{2.1c}$$

Due to symmetry, we can restrict ourselves to $\beta \in [0, \pi]$. Since the equation for ϕ_t is decoupled from the remaining (r_t, β_t)-process, this transformation leads to a dimension reduction of the problem. The deterministic (r, β)-system with $A = 0$ moves on closed orbits in the (r, β)-plane, as illustrated in Figure 3. Its fixpoint is $(r, \beta) = (1, \pi/2)$. The periodic orbits are given by level sets $H(r, \beta) = h \in [0, \infty)$ of the Hamiltonian

$$H(r, \beta) = B(r) - \ln r - \ln\sin\beta,$$

where $B(r) = \int_1^r b(r')\,\mathrm{d}r'$. For fixed energy h, the radius r takes values in $[r_{\min}(h), r_{\max}(h)]$ with $0 < r_{\min}(h) < 1 < r_{\max}(h)$.

We can rewrite (2.1) in Hamiltonian coordinates $(r, z) \in [0, \infty) \times (-\infty, \infty)$ with $z = \ln\tan(\beta/2)$, i.e., $\beta = 2\arctan(e^z)$, $z' = 1/\sin\beta$, $\beta' = \sin\beta$. Using Ito's formula

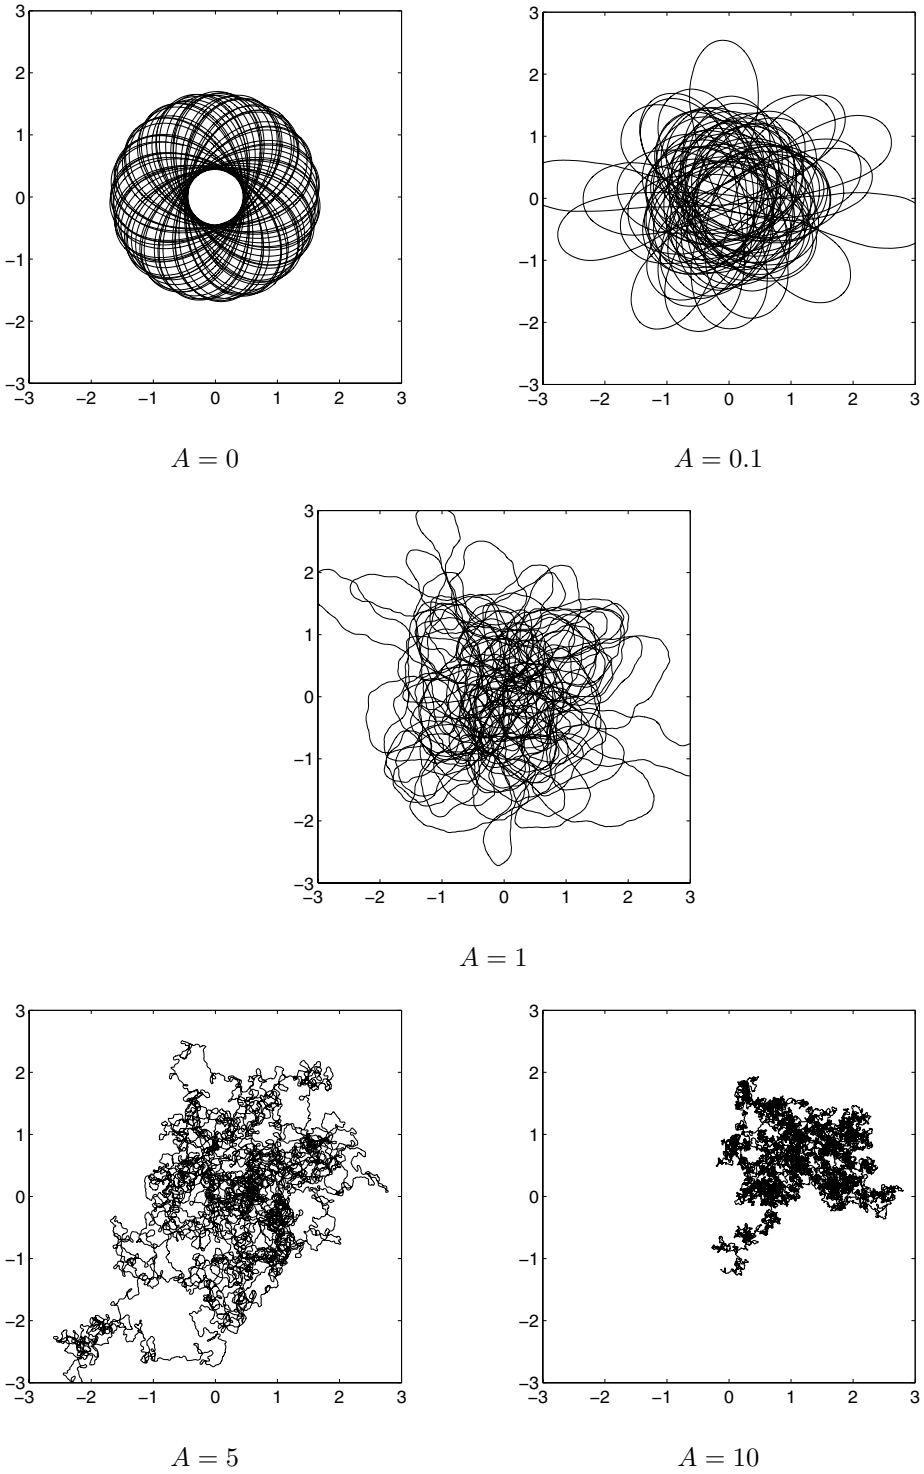

FIG. 2. *Representative path behavior for balanced ($A = 1$) as well as deterministic ($A < 1$) and stochastic ($A > 1$) dominated (ξ, α)-systems.*

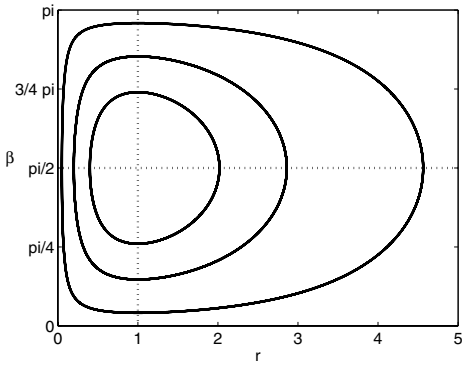

FIG. 3. *Orbits of the deterministic (r, β)-system for different values of h.*

then gives

$$\mathrm{d}r_t = \cos\beta(z_t)\,\mathrm{d}t, \tag{2.2a}$$

$$\mathrm{d}z_t = \left(b(r_t) - \frac{1}{r_t}\right)\mathrm{d}t - \frac{A^2\cos\beta(z_t)}{2\sin^2\beta(z_t)}\,\mathrm{d}t + \frac{A}{\sin\beta(z_t)}\,\mathrm{d}W_t \tag{2.2b}$$

and consequently, with $H(r,z) = B(r) - \ln(r) - \ln\sin(2\arctan(e^z))$,

$$\mathrm{d}r_t = -\partial_z H(r_t, z_t)\,\mathrm{d}t,$$

$$\mathrm{d}z_t = \partial_r H(r_t, z_t)\,\mathrm{d}t - \frac{A^2\cos\beta(z_t)}{2\sin^2\beta(z_t)}\,\mathrm{d}t + \frac{A}{\sin\beta(z_t)}\,\mathrm{d}W_t.$$

Remark 1. Linearizing the system in (2.2) around the fixpoint $(r,z) = (1,0)$, we obtain a Hamiltonian system with the Hamiltonian function

$$H_{lin}(r,z) = \frac{1}{2}\Big(b'(1)+1\Big)(r-1)^2 + \frac{1}{2}z^2$$

being a harmonic oscillator. Its period of motion [4] is $T_{lin} = 2\pi/\sqrt{b'(1)+1}$.

In general, as in the nonlinear case considered above, the period of motion T_H is not constant but depends on the energy h. An integral representation for T_H stated in (3.4) can be derived analytically; see below and [4] for further investigations. For small h, the nonlinear period of motion tends obviously to the linearized one.

Example 1. Considering the linearized system, the period of motion is $T_{lin} = 2\pi$ for $b(r) = 1$ and $T_{lin} = 2\pi/\sqrt{2}$ for $b(r) = r$. For the corresponding nonlinear cases, numerical evaluations of T_H are presented in Figure 4.

3. Kolmogoroff equation and stationary solution. We start the investigation of the fiber lay-down model by considering the associated Fokker–Planck equation and determining its stationary distribution as $t \to \infty$. We use the term "associated Fokker–Planck equation" for the Kolmogoroff forward equation of the stochastic process. The solution of this equation gives the probability density of the stochastic process for a given initial distribution; see, for example, [5].

The Fokker–Planck equation for the density $p_1 : (t, r, \beta) \mapsto p_1(t, r, \beta)$ of system (2.1) with $r \in [0, \infty)$, $\beta \in [0, 2\pi)$ is given by

$$\partial_t p_1 + \cos\beta\,\partial_r p_1 + \left(b(r) - \frac{1}{r}\right)\partial_\beta(\sin\beta\, p_1) = \frac{A^2}{2}\partial_{\beta\beta} p_1, \tag{3.1}$$

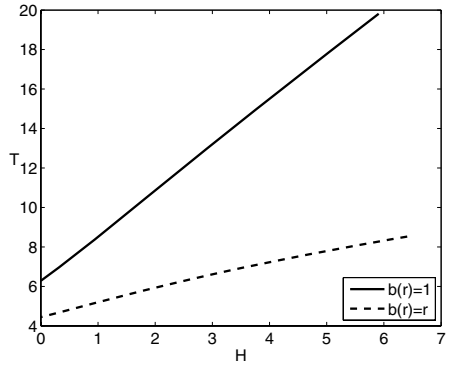

FIG. 4. *Period of motion $T_H(h)$ for $b(r) = 1$ (–) and $b(r) = r$ (- -).*

where the initial condition $p_1(t = 0, r, \beta)$ is prescribed. Moreover, periodic boundary conditions for β and the additional condition

$$\int_0^{2\pi} \int_0^{\infty} p_1(t, r, \beta)\, dr\, d\beta = 1$$

are prescribed. A stationary solution is obviously

$$p_{S_1}(r, \beta) = Cre^{-B(r)} \tag{3.2}$$

with the normalization constant C. In Hamiltonian coordinates (r, $z = \ln \tan(\beta/2)$) of system (2.2) we have

$$p_{S_2}(r, z) = p_{S_1}(r, \beta(z))\, \beta'(z) = Cre^{-B(r)} \sin \beta(z) = Ce^{-H(r,z)}$$

due to the transformation of measures. Note that the subscript of the stationary solution indicates the corresponding system.

Remark 2. In Hamiltonian coordinates the Fokker–Planck equation reads with the Hamiltonian function $H(r, z) = V(r) - W(z)$, where $V(r) = B(r) - \ln(r)$ and $W(z) = \ln \sin \beta(z)$:

$$\partial_t p_2 - \partial_r(p_2 \partial_z H) + \partial_z(p_2 \partial_r H) = \frac{A^2}{2} \partial_z(e^{-2W}(\partial_z p_2 + p_2 \partial_z H)).$$

Obviously, a solution is e^{-H}, as one would expect from physical considerations; see, e.g., Risken [21].

In the energy variable H the stationary distribution reads

$$\begin{aligned} p_{S_H}(h) &= \frac{\mathrm{d}}{\mathrm{d}h} \int_{H(r,z)<h} p_{S_2}(r, z)\, \mathrm{d}r\, \mathrm{d}z = C\, e^{-h} \frac{\mathrm{d}}{\mathrm{d}h} \int_{H(r,z)<h} \mathrm{d}r\, \mathrm{d}z \\ &= C\, e^{-h}\, T_H(h) \end{aligned} \tag{3.3}$$

because the period of motion of the deterministic system is given by

$$T_H(h) = \frac{\mathrm{d}}{\mathrm{d}h} \int_{H(r,z)<h} \mathrm{d}r\, \mathrm{d}z. \tag{3.4}$$

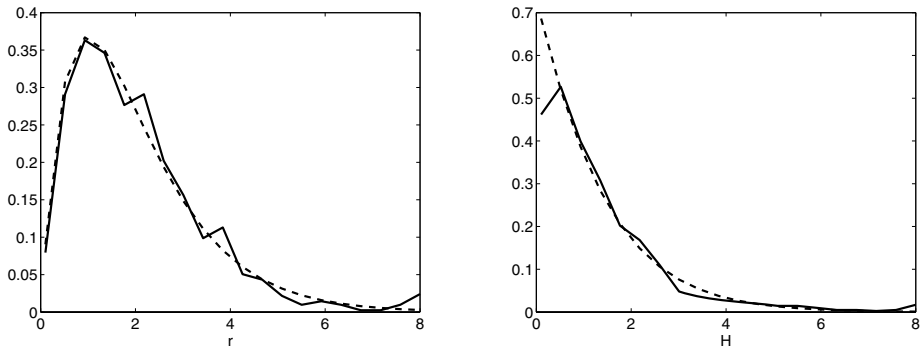

FIG. 5. *Stationary distributions, analytical (- -) versus numerical (–). Left:* p_{S_1}. *Right:* p_{S_H} *for* $b(r) = 1$.

This follows from the following consideration (cf. [4]). Take the reduced one-parametric family of deterministic processes with initial condition $H(r(0), \beta(0)) = h$; then every point (r, z) in the phase-space can be prescribed by h and the first time t to reach this point. As a simple consequence of the conservation of energy and the canonical structure of the Hamiltonian system, the functional determinant of the corresponding transformation is one. Hence, $\int_{H(r,z)<h} \mathrm{d}r\,\mathrm{d}z = \int_0^h \int_0^{T_H(h')} \mathrm{d}t\,\mathrm{d}h'$ which yields (3.4).

A Monte Carlo simulation of the stochastic model (2.1) with $b(r) = 1$ enables the computation of the time development of the solution and the comparison of the analytical stationary distributions p_{S_1} with the stationary distribution of the r_t-process and, respectively, the comparison of p_{S_H} with the numerically computed stationary distribution of the energy process H_t; see Figure 5. For further simulations of the time development of the stochastic model, see the next section.

Remark 3. Alternatively, to obtain the stationary solution and the time evolution of the density one can solve the partial differential equation (3.1) numerically; see [14]. The solutions indicate the convergence to the stationary solution with a rate of convergence depending on A, where the convergence is slow for A small and A large and fast for intermediate A. Compare also Figure 2 showing the paths of the stochastic process for different A.

Remark 4. An analytical investigation of the convergence towards equilibrium and the rate of convergence is complicated due to the degeneracy of the Fokker–Planck equation (3.1) with respect to the variable r. For related problems we refer to [24, 8]. A proof of ergodicity and convergence to the stationary distribution is performed in [10].

Remark 5. The identification of the parameters, i.e., drive b and noise amplitude A, in the lay-down model is important for the realistic description of industrially relevant scenarios. Comparing the stationary distribution p_{S_1} with experimentally available data, we can determine the function B and thus its derivative b. The noise amplitude A can in principle be computed from

$$(\mathrm{d}\alpha_t)^2 = A^2\,\mathrm{d}t$$

or alternatively from

$$\lim_{h\to 0} \frac{\mathbb{E}\left[(\alpha_{t+h} - \alpha_t)^2\right]}{h} = A^2,$$

supposing that the real process is prescribed by white noise. More sophisticated approaches can be found in [16].

4. Stochastic averaging and energy equation. In the following we consider lay-down processes (2.1) with small noise $A = \sqrt{\epsilon}\tilde{A}$ on associated long "time" scales $t = \tilde{t}/\epsilon$ with $0 < \epsilon \ll 1$; see Figure 2 for the pathwise behavior for different noise levels. In this case, a simplified approximation of the dynamics can be given by stochastic averaging. This leads to a reduced system as $\epsilon \to 0$, i.e., a stochastic differential equation for the limit energy process for which we determine the drift and variance coefficients.

Dropping the tildes, the rescaled $(r_t^\epsilon, \beta_t^\epsilon)$-system reads

$$\begin{aligned} \mathrm{d}r_t^\epsilon &= \frac{1}{\epsilon}\cos\beta_t^\epsilon \,\mathrm{d}t, \\ \mathrm{d}\beta_t^\epsilon &= \frac{1}{\epsilon}\left(b(r_t^\epsilon) - \frac{1}{r_t^\epsilon}\right)\sin\beta_t^\epsilon \,\mathrm{d}t + A\,\mathrm{d}W_t. \end{aligned} \tag{4.1}$$

Applying Ito's formula, the resulting energy process $H_t^\epsilon = H(r_t^\epsilon, \beta_t^\epsilon)$ fulfills the equation

$$\begin{aligned} \mathrm{d}H_t^\epsilon &= \partial_r H\,\mathrm{d}r_t^\epsilon + \partial_\beta H\,\mathrm{d}\beta_t^\epsilon + \frac{1}{2}\partial_{\beta\beta}H\,(\mathrm{d}\beta_t^\epsilon)^2 \\ &= \left(b(r_t^\epsilon) - \frac{1}{r_t^\epsilon}\right)\mathrm{d}r_t^\epsilon - \cot\beta_t^\epsilon\,\mathrm{d}\beta_t^\epsilon + \frac{1}{2\sin^2\beta_t^\epsilon}\,(\mathrm{d}\beta_t^\epsilon)^2 \\ &= \frac{A^2}{2\sin^2\beta_t^\epsilon}\,\mathrm{d}t - A\cot\beta_t^\epsilon\,\mathrm{d}W_t. \end{aligned}$$

Using formally the stochastic averaging theorem (see, e.g., [13] or [20] and [1, 2] for an application to stochastic Hamiltonian systems), the limit equation for H_t^ϵ as ϵ tends to 0 is given by

$$\mathrm{d}H_t^0 = a_H(H_t^0)\,\mathrm{d}t + \sigma_H(H_t^0)\,\mathrm{d}W_t$$

with drift and variance

$$a_H(h) = \frac{A^2}{2T_H(h)}\int_0^{T_H(h)} \frac{1}{\sin^2\beta(t)}\,\mathrm{d}t, \quad \sigma_H^2(h) = \frac{A^2}{T_H(h)}\int_0^{T_H(h)} \cot^2\beta(t)\,\mathrm{d}t. \tag{4.2}$$

In these formulas β denotes the solution of the deterministic (r, β)-process for fixed energy h. The expressions for a_H and σ_H^2 can be rewritten in explicit form as

$$a_H(h) = \frac{A^2}{2}\left(1 + \overline{T_H}(h)\right), \qquad \sigma_H^2(h) = A^2\,\overline{T_H}(h), \tag{4.3}$$

with

$$\overline{T_H}(h) = \frac{e^{2h}}{T_H(h)}\int_0^h T_H(h')e^{-2h'}\,\mathrm{d}h'.$$

The derivation of (4.3) is based on two equations for the coefficients a and σ. First, due to their form in (4.2) we have

$$2a_H(h) - \sigma_H^2(h) = A^2. \tag{4.4}$$

The second equation is obtained from the stationary distribution. Consider the Fokker–Planck equation corresponding to H_t^0:

$$\partial_t p_H + \partial_h \left(a_H(h) p_H\right) = \frac{1}{2} \partial_{hh} \left(\sigma_H^2(h) p_H\right).$$

Looking for integrable solutions of the stationary equation, we consider

$$2a_H(h)\, p_{S_H} = \partial_h \left(\sigma_H^2(h)\, p_{S_H}\right).$$

The solution reads

$$p_{S_H}(h) = \tilde{C} \exp\left(-\int^h \frac{(\sigma_H^2)'(h') - 2a_H(h')}{\sigma_H^2(h')}\, dh'\right)$$

with the normalizing constant $\tilde{C}$. On the other hand, the stationary solution for the $(r_t^\epsilon, \beta_t^\epsilon)$-process is independent of ϵ, and according to (3.3),

$$p_{S_H}(h) = Ce^{-h}\, T_H(h)$$

holds for all ϵ and therefore also for the limit process. Hence, from the comparison of the different expressions for p_{S_H}, we obtain

$$\frac{(\sigma_H^2)'(h) - 2a_H(h)}{\sigma_H^2(h)} = 1 - (\ln T_H(h))'. \tag{4.5}$$

Equations (4.4) and (4.5) yield a differential equation for the variance

$$(\sigma_H^2)'(h) = A^2 + 2\sigma_H^2(h) - (\ln T_H(h))'\, \sigma_H^2(h)$$

from which the explicit formulas in (4.3) can be concluded.

Summarizing, the energy equation for the limit process H_t^0 and its associated Fokker–Planck equation read

$$\begin{aligned} \mathrm{d}H_t^0 &= \frac{A^2}{2}(1 + \overline{T_H}(H_t^0))\, \mathrm{d}t + A\sqrt{\overline{T_H}(H_t^0)}\, \mathrm{d}W_t, \\ \partial_t p_H + \frac{A^2}{2} \partial_h \left((1 + \overline{T_H}(h))\, p_H\right) &= \frac{A^2}{2} \partial_{hh} \left(\overline{T_H}(h)\, p_H\right). \end{aligned}$$

The introduction of the alternative energy process

$$G_t^\epsilon = e^{-H_t^\epsilon} = r_t^\epsilon\, e^{-B(r_t^\epsilon)} \sin \beta_t^\epsilon$$

is more suitable for the following numerical simulations since it is restricted on the interval $[0, 1]$. Analogously to the previous averaging procedure or directly from H_t^ϵ by means of the Ito calculus, i.e.,

$$\mathrm{d}G_t^0 = -e^{-H_t^0}\, \mathrm{d}H_t^0 + \frac{1}{2} e^{-H_t^0}\, (\mathrm{d}H_t^0)^2,$$

we determine the limit process G_t^0 as

$$\mathrm{d}G_t^0 = a_G(G_t^0)\, \mathrm{d}t + \sigma_G(G_t^0)\, \mathrm{d}W_t \tag{4.6}$$

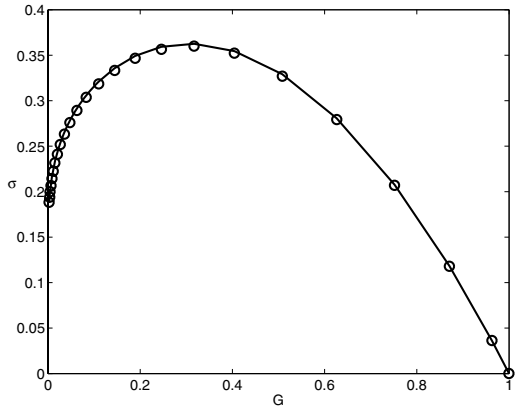

FIG. 6. σ_G *for* $A = 1$, $b(r) = 1$, *computed via* (4.8) *(–), via* (4.7) *(o).*

with drift and variance

$$a_G(g) = -\frac{A^2}{2} g, \qquad \sigma_G^2(g) = \frac{A^2 g^2}{T_G(g)} \int_0^{T_G(g)} \cot^2 \beta(t)\, \mathrm{d}t \tag{4.7}$$

or the explicit version,

$$\begin{aligned} \sigma_G^2(g) &= A^2 \overline{T_G}(g), \\ \overline{T_G}(g) &= \frac{1}{T_G(g)} \int_g^1 T_G(g')\, g'\, \mathrm{d}g'. \end{aligned} \tag{4.8}$$

Here, the period of motion T_G is defined by the associated transformation $T_G(g) = T_H(-\ln g)$. The associated Fokker–Planck equation is

$$\partial_t p_G - \frac{A^2}{2}\, \partial_g (g p_G) = \frac{A^2}{2}\, \partial_{gg} (\overline{T_G}(g) p_G). \tag{4.9}$$

The equation is complemented with an initial condition and conservation of mass

$$\int_0^1 p_G(t, g)\, \mathrm{d}g = 1.$$

The transformed stationary solution of the Fokker–Planck equation is

$$p_{S_G}(g) = C\, T_G(g), \quad g \in [0, 1].$$

Remark 6. Equation (4.9) can be rewritten in the usual form of a Sturm–Liouville problem. For a more detailed treatment of these problems, see, for example, [25]. At least formally it is easily observed that the rate of convergence to equilibrium for this equation is faster as A becomes larger, which is consistent with the statement on the speed of convergence of the full problem (3.1) in Remark 3.

Remark 7. For $T_H(h)$ tending to infinity as $h \to \infty$ (as motivated by Figure 4) and $T_G(g)\, g$ being integrable over $[0, 1]$, we observe from (4.8) that the variance satisfies $\sigma_G^2(g = 0) = 0$ with $\sigma_G^2(g) \sim (T_H(-\ln g))^{-1}$ as $g \to 0$. See Figure 6 for a numerical evaluation of σ_G for $b(r) = 1$ and $A = 1$.

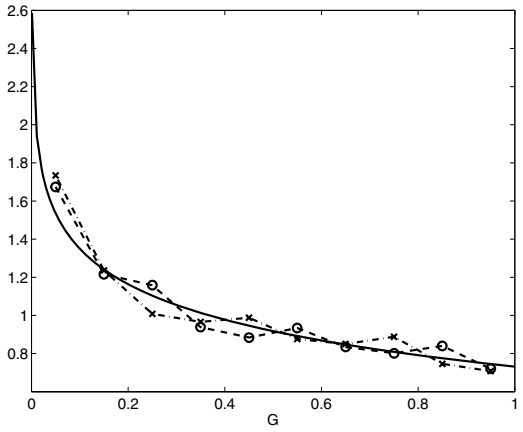

FIG. 7. *Stationary distribution p_{S_G} (–) versus numerical computed distributions for G_t^ϵ, $\epsilon = 1$ (x-.) and G_t^0 (o- -) for $b(r) = 1$.*

A numerical simulation of the corresponding stochastic differential equations (4.1) and (4.6) yields the stationary distributions of the energy process G_t^ϵ, $\epsilon = 1$, and the limit process G_t^0 that are plotted against the theoretical stationary distribution p_{S_G} in Figure 7. The temporal evolution of the mean value and the standard deviation of the two energy processes is visualized in Figure 8, where ϵ is chosen as $\epsilon = 1, 0.1$. The results for smaller ϵ are similar to the case $\epsilon = 0.1$. We observe that for large ϵ the decay in the beginning differs significantly, before the final behavior of the processes is driven by the standard noise of Monte Carlo simulations. For smaller values of ϵ the time evolutions of the full process and the limit process coincide.

5. Distributions of process functionals. An important issue for the quality assessment of fabrics is the distribution of fiber length that lies in a prescribed spatial domain, since this information yields the weight distribution in the physical space and thus gives insight into the structure of the nonwoven material, i.e., holes, thinning, swelling. In the context of stochastic processes the distribution of the length of the fibers laid down in a prescribed domain is associated with the distribution of the time the process stays in this domain. In the following we perform a numerical study of such functionals of the process.

The "time" spent in a domain D of the (r, β)–phase-space is described by the distribution of the random variable $I = \int_{t_0}^T \chi_D(r_t, \beta_t)\,\mathrm{d}t$ for fixed T, where χ_D is the characteristic function of D. Alternatively for domains given by the energy functional $G = e^{-H}$, e.g., $D = D_g = \{(r, \beta) \mid G(r, \beta) < g\}$, we can also use the approximate equations for G_t^0 to determine an approximation I_G for I with $I_G = \int_{t_0}^T \chi_{[0,g]}(G_t^0)\,\mathrm{d}t$.

Remark 8. The distribution of the above functionals can in principle be determined by solving a related partial differential equation to obtain the characteristic function of I. The distribution of I is then computed using the inverse Fourier transform; see [9]. However, for the nonlinear processes considered here there is no explicit solution of these equations, and a direct evaluation of the functionals by a Monte Carlo method is more straightforward.

Figure 9 shows the distribution of the functionals I/T and I_G/T with $D = D_g = \{(r, \beta) \mid G(r, \beta) < g\}$ for initial values $G_0 = 0.53$, $t_0 = 0$, $g = 0.3$ and final time $T = 40, 200, 400$ using the $(r_t^\epsilon, \beta_t^\epsilon)$-process with $\epsilon = 1$ and the G_t^0-process, respectively.

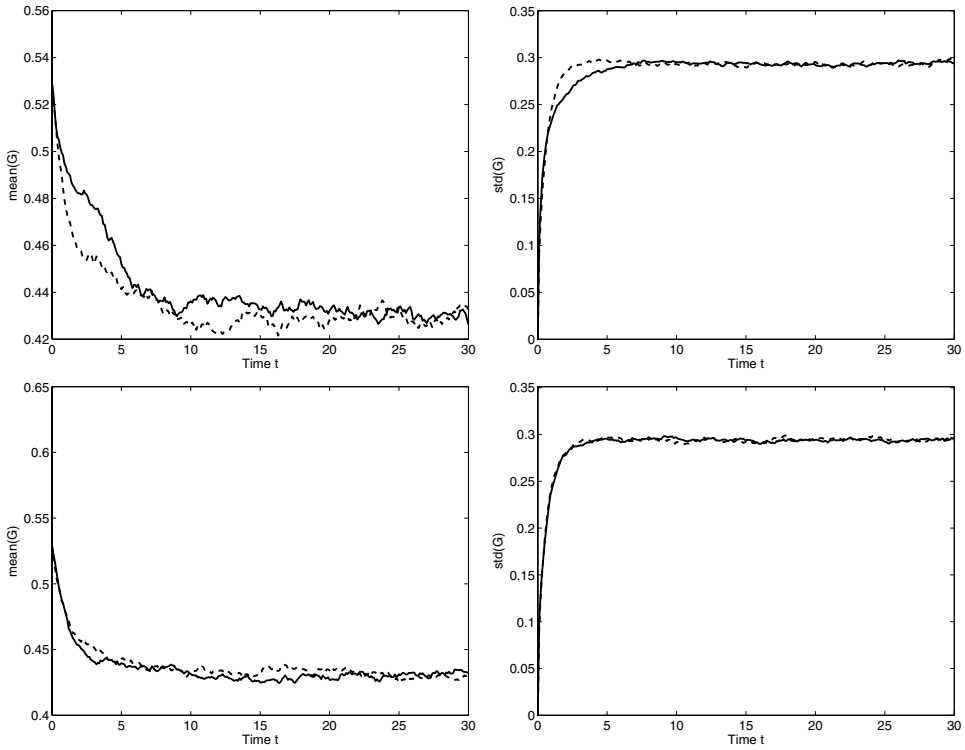

FIG. 8. *Time development of mean values (left) and standard deviations (right) of* G_t^ϵ *(solid) and* G_t^0 *(dashed) for* $\epsilon = 1, 0.1$ *(from top to bottom) for* $b(r) = 1$.

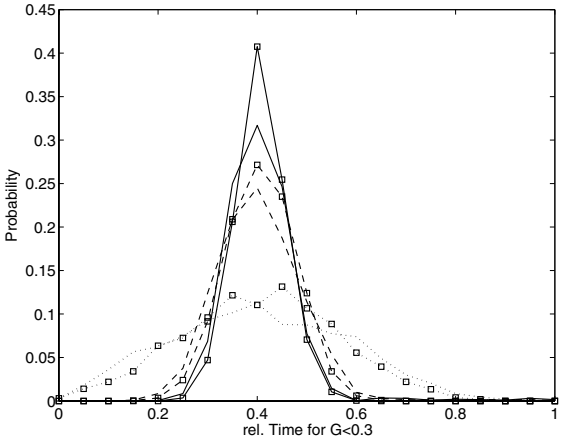

FIG. 9. *Probability distribution of time spent in* D_g, $g = 0.3$, $P(D_g) = 0.39$ *using the* $(r_t^\epsilon, \beta_t^\epsilon)$*-process,* $\epsilon = 1$ *(line), and* G_t^0*-process (line and marker) for* $T = 40$ *(··),* 200 *(- -),* 400 *(–).*

Obviously, in these cases evaluating the functionals with the limit G_t^0-process gives a good approximation of the true value even for $\epsilon = 1$.

Remark 9. For large times T, starting with the stationary distribution, the distribution of I_G tends towards a δ-distribution at the value $P(D_g) := \int_0^g p_{S_G}(g')\,\mathrm{d}g'$:

$$\lim_{T\to\infty} \frac{1}{T} \int_{t_0}^{t_0+T} \chi_{[0,g]}(G_t^0)\,\mathrm{d}t = P(D_g).$$

This means that, at least numerically, the distribution function behaves as predicted by the ergodic theorem.

6. Conclusion and outlook. In this paper we presented a new stochastic model for the lay-down of fibers which can be used as a basis for further investigations of the production process of nonwovens. We have determined the associated Kolmogoroff equation and stationary solution of the model and derived the corresponding energy process with drift and variance coefficients by help of stochastic averaging. The limit energy process enables the simple computation of probability distributions of process functionals, e.g., fiber length distribution, that are helpful for the quality assessment of nonwoven materials. Some points which need to be discussed in further detail are listed below:

- The application of the above results on the industrial process requires the extension of the model with regard to an anisotropic lay-down process and a moving conveyor belt. This generalization will lead to a matrix-valued drive function and an additional drift (transport) term in the (ξ, α)-system. For example, for a moving conveyor belt, we have to distinguish between the fiber curve η on the conveyor belt and the deviation ξ of the fiber from the now moving reference point of the spinning process

$$\eta_t = \xi_t - \kappa t e_1,$$

  where $\kappa \in [0, 1]$ is the speed of the belt moving in direction e_1 relative to the spinning velocity of the fiber. The inextensibility condition holds for η_t; i.e., $\|\partial_t \eta\| = 1$. Hence, in generalization to the presented model ξ_t fulfills

$$\begin{aligned} \mathrm{d}\xi_t &= \tau_t\,\mathrm{d}t + \kappa e_1\,\mathrm{d}t, \\ \mathrm{d}\alpha_t &= -b(\|\xi_t\|)\frac{\xi_t}{\|\xi_t\|}\tau_t^{\perp}\,\mathrm{d}t + A\,\mathrm{d}W_t. \end{aligned}$$

- The practical relevance of the model has to be guaranteed by the identification of the parameters, i.e., drive and noise amplitude. Therefore, appropriate validation data will be generated by the simulation of the complete physical production process as discussed above. Both parameters can be identified from the simulation of the complete production process of nonwovens, according to [12, 18], for different industrially relevant cases.
- The theoretical and numerical analysis of the solution of the degenerate Fokker–Planck equation (3.1) or the associated equation for the (ξ_t, α_t)-process and, in particular, the rates of convergence to equilibrium, gives valuable insight into the behavior of the process. A detailed analytical investigation with explicit rates of convergence for the process is presented in [10]. For a numerical investigation we refer to [14].
- The analytical investigation of the Fokker–Planck equation for the limit energy process G_t^0 is also a point of interest that is left to future work.

PULSE PROPAGATION AND TIME REVERSAL IN RANDOM WAVEGUIDES*

JOSSELIN GARNIER† AND GEORGE PAPANICOLAOU‡

Abstract. Mode coupling in a random waveguide can be analyzed with asymptotic analysis based on separation of scales when the propagation distance is large compared to the size of the random inhomogeneities, which have small variance, and when the wavelength is comparable to the scale of the inhomogeneities. In this paper we study the asymptotic form of the joint distribution of the mode amplitudes at different frequencies. We derive a deterministic system of transport equations that describe the evolution of mode powers. This result is applied to the computations of pulse spreading in a random waveguide. It is also applied to the analysis of time reversal in a random waveguide. We show that randomness enhances spatial refocusing and that diffraction-limited focal spots can be obtained even with small-size time-reversal mirrors. The refocused field is statistically stable for broadband pulses in general. We show here that it is also stable for narrowband pulses, provided that the time-reversal mirror is large enough.

Key words. acoustic waveguides, random media, asymptotic analysis

1. Introduction.

In a perfect waveguide, energy propagates through its guided wave modes, which do not interact with each other. Imperfections in the material or in the geometrical properties of the waveguide induce mode coupling. These imperfections are usually small, but their effects accumulate over large propagation distances and can be significant. In this paper we consider wave propagation in an acoustic waveguide whose bulk modulus is a three-dimensional random function. Using the propagating modes of the unperturbed waveguide, we can reduce the three-dimensional wave propagation problem to the analysis of a system of coupled ordinary differential equations with random coefficients. It is in the frequency domain that the mode amplitudes satisfy these differential equations. We can analyze them as a system of random differential equations in a diffusion approximation, in which the mode amplitudes are a multidimensional diffusion process. This coupled mode asymptotic analysis was considered previously for applications in underwater acoustics [14, 5], fiber optics [17], and quantum mechanics [11].

The main purpose of this paper is to analyze the asymptotic behavior of the coupled mode amplitudes in the time domain. This requires the analysis of the joint distribution of the mode amplitudes at two nearby frequencies, which results in a system of transport equations for the mode powers. This is done in section 6. In section 7 we apply this result to the analysis of pulse spreading in a random waveguide.

In section 8 we consider time reversal in a random waveguide and present the first analysis of the phenomenon of side-lobe suppression, which has been observed in experiments [15] and in numerical simulations [2]. Side-lobe suppression is the main

application of our asymptotic analysis. Time-reversal refocusing has been studied extensively both experimentally and theoretically, in various contexts such as in ultrasound and underwater acoustics, as reviewed in [7, 8]. A time-reversal mirror is an active array of transducers that records a signal, time reverses it, and re-emits it into the medium. The waves generated at the time-reversal mirror propagate back to their source and focus near it, as if wave propagation was run in reverse time. Surprisingly, random inhomogeneities enhance the refocusing of the time-reversed waves near the original source location [4, 8]. Ultrasonic wave propagation and time reversal in homogeneous waveguides is studied experimentally and theoretically in [22]. Time-reversal refocusing was experimentally investigated in underwater acoustics in [15, 23], where the random inhomogeneities in the environment reduce the side-lobes that are seen in refocusing in a homogeneous waveguide.

In addition to enhanced refocusing and side-lobe suppression, statistical stability of the refocused field is critical for applications in communications and detection. Statistical stability means that the refocused field does not depend on the particular realization of the random medium. It has been studied in *broadband* regimes of propagation in one-dimensional random media [3, 10], in three-dimensional randomly layered media [9, 10], and in three-dimensional wave propagation in the paraxial approximation [2, 21]. Stabilization of the refocused field for broadband pulses results from the superposition of its many approximately uncorrelated frequency components. We show in section 8 that in random waveguides we have statistical stability of the refocused field even for *narrowband* pulses, provided that the number of propagating modes and the size of the time-reversal mirror are large enough.

2. Propagation in homogeneous waveguides. In this section we study wave propagation in an acoustic waveguide that supports a finite number of propagating modes. In an ideal waveguide the geometric structure and the medium parameters can have a general form in the transverse directions but must be homogeneous along the waveguide axis. There are two general types of ideal waveguides: those that surround a homogeneous region with a confining boundary, and those in which the confinement is achieved with a transversely varying index of refraction. We will present the analysis of the effects of random perturbations on waveguides of the first type and will illustrate specific results with a planar waveguide. The main difference in working with waveguides of the second type is that the transverse wave mode profiles depend on the frequency, but this does not affect the theory we present here.

2.1. Modeling of the waveguide. We consider linear acoustic waves propagating in three space dimensions modeled by the system of wave equations

$$\rho(\mathbf{r})\frac{\partial \mathbf{u}}{\partial t} + \nabla p = \mathbf{F}\,, \qquad \frac{1}{K(\mathbf{r})}\frac{\partial p}{\partial t} + \nabla \cdot \mathbf{u} = 0\,, \tag{2.1}$$

where p is the acoustic pressure, $\mathbf{u}$ is the acoustic velocity, ρ is the density of the medium, and K is the bulk modulus. The source is modeled by the forcing term $\mathbf{F}(t, \mathbf{r})$. We assume that the transverse profile of the waveguide is a simply connected region $\mathcal{D}$ in two dimensions. The direction of propagation along the waveguide axis is z and the transverse coordinates are denoted by $\mathbf{x} \in \mathcal{D}$. In the interior of the waveguide the medium parameters are homogeneous:

$$\rho(\mathbf{r}) \equiv \bar{\rho}, \qquad K(\mathbf{r}) = \bar{K} \qquad \text{for } \mathbf{x} \in \mathcal{D} \text{ and } z \in \mathbb{R}\,.$$

By differentiating the second equation of (2.1) with respect to time and substituting the first equation into it, we get the standard wave equation for the pressure field,

$$\Delta p - \frac{1}{\bar{c}^2}\frac{\partial^2 p}{\partial t^2} = \nabla \cdot \mathbf{F}\,, \tag{2.2}$$

where $\Delta = \Delta_\perp + \partial_z^2$ and $\Delta_\perp$ is the transverse Laplacian. The sound speed is $\bar{c} = \sqrt{\bar{K}/\bar{\rho}}$. We must now prescribe boundary conditions on the boundary $\partial\mathcal{D}$ of the domain $\mathcal{D}$. In underwater acoustics, or in seismic wave propagation, the density is much smaller outside than inside the waveguide. This means that we must use a pressure release boundary condition since the pressure is very weak outside, and therefore, by continuity, the pressure is zero just inside the waveguide. Motivated by such examples, we will use Dirichlet boundary conditions

$$p(t,\mathbf{x},z) = 0 \qquad \text{for } \mathbf{x} \in \partial\mathcal{D} \text{ and } z \in \mathbb{R}\,. \tag{2.3}$$

We could also consider other types of boundary conditions if, for example, the boundary of the waveguide is a rigid wall, in which case the normal velocity vanishes. By (2.1) we obtain Neumann boundary conditions for the pressure.

2.2. The propagating and evanescent modes. A waveguide mode is a monochromatic wave $p(t,\mathbf{x},z) = \hat{p}(\omega,\mathbf{x},z)e^{-i\omega t}$ with frequency ω, where $\hat{p}(\omega,\mathbf{x},z)$ satisfies the time harmonic form of the wave equation (2.2) without a source term:

$$\partial_z^2\hat{p}(\omega,\mathbf{x},z) + \Delta_\perp\hat{p}(\omega,\mathbf{x},z) + k^2(\omega)\hat{p}(\omega,\mathbf{x},z) = 0\,. \tag{2.4}$$

Here $k = \omega/\bar{c}$ is the wavenumber and we have Dirichlet boundary conditions on $\partial\mathcal{D}$. The transverse Laplacian in $\mathcal{D}$ with Dirichlet boundary conditions on $\partial\mathcal{D}$ is self-adjoint in $L^2(\mathcal{D})$. Its spectrum is an infinite number of discrete eigenvalues

$$-\Delta_\perp\phi_j(\mathbf{x}) = \lambda_j\phi_j(\mathbf{x}),\ \mathbf{x}\in\mathcal{D}, \qquad \phi_j(\mathbf{x}) = 0,\ \mathbf{x}\in\partial\mathcal{D}$$

for $j = 1, 2, \ldots$. The eigenvalues are positive and nondecreasing, and we assume for simplicity that they are simple, so we have $0 < \lambda_1 < \lambda_2 < \cdots$. The eigenmodes are real and form an orthonormal set

$$\int_{\mathcal{D}} \phi_j(\mathbf{x})\phi_l(\mathbf{x})d\mathbf{x} = \delta_{jl}\,,$$

with $\delta_{jl} = 1$ if $j = l$ and 0 otherwise. For a given frequency ω, there exists a unique integer $N(\omega)$ such that $\lambda_{N(\omega)} \le k^2(\omega) < \lambda_{N(\omega)+1}$, with the convention that $N(\omega) = 0$ if $\lambda_1 > k(\omega)$. The modal wavenumbers $\beta_j(\omega) \ge 0$ for $j \le N(\omega)$ are defined by

$$\beta_j^2(\omega) = k^2(\omega) - \lambda_j\,. \tag{2.5}$$

The solutions $\hat{p}_j(\omega,\mathbf{x},z) = \phi_j(\mathbf{x})e^{\pm i\beta_j(\omega)z}$, $j = 1,\ldots,N(\omega)$, of the wave equation (2.4) are the propagating waveguide modes. For $j > N(\omega)$ we define the modal wavenumbers $\beta_j(\omega) > 0$ by $\beta_j^2(\omega) = \lambda_j - k^2(\omega)$, and the corresponding solutions $\hat{q}_j(\omega,\mathbf{x},z) = \phi_j(\mathbf{x})e^{\pm\beta_j(\omega)z}$ of the wave equation (2.4) are the evanescent modes.

In this paper we shall illustrate some results for the planar waveguide. This is the case where $\mathcal{D}$ is $(0,d)\times\mathbb{R}$, and we consider only solutions that depend on $x \in (0,d)$. In this case we have $\lambda_j = \pi^2 j^2/d^2$, $\phi_j(x) = \sqrt{2/d}\sin(\pi jx/d)$, $j \ge 1$, and the number of propagating modes is $N(\omega) = [(\omega d)/(\pi\bar{c})]$, where $[x]$ is the integer part of x.

2.3. Excitation conditions for a source. We consider a point-like source located at $(\mathbf{x}_0, z = 0)$ that emits a signal with orientation in the z-direction:

$$\mathbf{F}(t, \mathbf{x}, z) = f(t)\delta(\mathbf{x} - \mathbf{x}_0)\delta(z)\mathbf{e}_z\,.$$

Here $\mathbf{e}_z$ is the unit vector pointing in the z-direction. By the first equation of (2.1), this source term implies that the pressure satisfies the following jump conditions across the plane $z = 0$:

$$\hat{p}(\omega, \mathbf{x}, z = 0^+) - \hat{p}(\omega, \mathbf{x}, z = 0^-) = \hat{f}(\omega)\delta(\mathbf{x} - \mathbf{x}_0)\,,$$

while the second equation of (2.1) implies that there is no jump in the longitudinal velocity so that the pressure field also satisfies $\partial_z\hat{p}(\omega, \mathbf{x}, z = 0^+) = \partial_z\hat{p}(\omega, \mathbf{x}, z = 0^-)$. Here $\hat{f}$ is the Fourier transform of f with respect to time:

$$\hat{f}(\omega) = \int f(t)e^{i\omega t}dt, \qquad f(t) = \frac{1}{2\pi}\int \hat{f}(\omega)e^{-i\omega t}d\omega\,.$$

The pressure field can be written as a superposition of the complete set of modes,

$$\begin{aligned}\hat{p}(\omega, \mathbf{x}, z) = &\left[\sum_{j=1}^{N} \frac{\hat{a}_j(\omega)}{\sqrt{\beta_j(\omega)}}e^{i\beta_j z}\phi_j(\mathbf{x}) + \sum_{j=N+1}^{\infty} \frac{\hat{c}_j(\omega)}{\sqrt{\beta_j(\omega)}}e^{-\beta_j z}\phi_j(\mathbf{x})\right]\mathbf{1}_{(0,\infty)}(z)\\ &+ \left[\sum_{j=1}^{N} \frac{\hat{b}_j(\omega)}{\sqrt{\beta_j(\omega)}}e^{-i\beta_j z}\phi_j(\mathbf{x}) + \sum_{j=N+1}^{\infty} \frac{\hat{d}_j(\omega)}{\sqrt{\beta_j(\omega)}}e^{\beta_j z}\phi_j(\mathbf{x})\right]\mathbf{1}_{(-\infty,0)}(z)\,,\end{aligned}$$

where $\hat{a}_j$ is the amplitude of the jth right-going mode propagating in the right half-space $z > 0$, $\hat{b}_j$ is the amplitude of the jth left-going mode propagating in the left half-space $z < 0$, and $\hat{c}_j$ (resp., $\hat{d}_j$) is the amplitude of the jth right-going (resp., left-going) evanescent mode. Substituting this expansion into the jump conditions, multiplying by $\phi_j(\mathbf{x})$, integrating with respect to $\mathbf{x}$ over $\mathcal{D}$, and using the orthogonality of the modes, we express the mode amplitudes in terms of the source:

$$\hat{a}_j(\omega) = -\hat{b}_j(\omega) = \frac{\sqrt{\beta_j(\omega)}}{2}\hat{f}(\omega)\phi_j(\mathbf{x}_0)\,, \qquad \hat{c}_j(\omega) = -\hat{d}_j(\omega) = -\frac{\sqrt{\beta_j(\omega)}}{2}\hat{f}(\omega)\phi_j(\mathbf{x}_0)\,.$$

3. Mode coupling in random waveguides. We consider a randomly perturbed waveguide section occupying the region $z \in [0, L/\varepsilon^2]$, with two homogeneous waveguides occupying the two half-spaces $z < 0$ and $z > L/\varepsilon^2$. The bulk modulus and the density have the form

$$\begin{aligned}\frac{1}{K(\mathbf{x}, z)} &= \begin{cases} \frac{1}{\bar{K}}\left(1 + \varepsilon\nu(\mathbf{x}, z)\right) & \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in [0, L/\varepsilon^2],\\ \frac{1}{\bar{K}} & \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in (-\infty, 0) \cup (L/\varepsilon^2, \infty),\end{cases}\\ \rho(\mathbf{x}, z) &= \bar{\rho} \quad \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in (-\infty, \infty)\,,\end{aligned}$$

where ν is a zero-mean, stationary, and ergodic random process with respect to the axis coordinate z. Moreover, it is assumed to possess enough decorrelation; more precisely, it fulfills the condition that "ν is ϕ-mixing, with $\phi \in L^{1/2}(\mathbb{R}^+)$" [16, section 4.6.2].

The perturbed wave equation satisfied by the pressure field is

$$\Delta p - \frac{1+\varepsilon\nu(\mathbf{x},z)}{\bar{c}^2}\frac{\partial^2 p}{\partial t^2} = \nabla\cdot\mathbf{F}\,, \tag{3.1}$$

where the average sound speed is $\bar{c} = \sqrt{\bar{K}/\bar{\rho}}$. The pressure field also satisfies the boundary conditions (2.3). We consider that a point-like source located at $(\mathbf{x}_0, 0)$ emits a pulse $f(t)$ and we denote by $\hat{a}_{j,0}(\omega)$ the initial mode amplitudes as described in the previous section. The weak fluctuations of the medium parameters induce a coupling between the propagating modes, as well as between propagating and evanescent modes, which build up and become of order one after a propagation distance of order ε^{-2}, as expected from the diffusion approximation theory.

3.1. Coupled amplitude equations. We fix the frequency ω and expand the field $\hat{p}$ inside the randomly perturbed waveguide in terms of the transverse eigenmodes,

$$\hat{p}(\omega,\mathbf{x},z) = \sum_{j=1}^{N(\omega)} \phi_j(\mathbf{x})\hat{p}_j(\omega,z) + \sum_{j=N(\omega)+1}^{\infty} \phi_j(\mathbf{x})\hat{q}_j(\omega,z)\,, \tag{3.2}$$

where $\hat{p}_j$ is the amplitude of the jth propagating mode and $\hat{q}_j$ is the amplitude of the jth evanescent mode. We introduce the right-going and left-going mode amplitudes $\hat{a}_j(\omega,z)$ and $\hat{b}_j(\omega,z)$, defined by

$$\hat{p}_j = \frac{1}{\sqrt{\beta_j}}\left(\hat{a}_j e^{i\beta_j z} + \hat{b}_j e^{-i\beta_j z}\right)\,, \qquad \frac{d\hat{p}_j}{dz} = i\sqrt{\beta_j}\left(\hat{a}_j e^{i\beta_j z} - \hat{b}_j e^{-i\beta_j z}\right)$$

for $j \le N(\omega)$. The total field $\hat{p}$ satisfies the time harmonic wave equation

$$\Delta\hat{p}(\omega,\mathbf{x},z) + k^2(\omega)(1+\varepsilon\nu(\mathbf{x},z))\hat{p}(\omega,\mathbf{x},z) = 0\,. \tag{3.3}$$

Using (3.2) in this equation, multiplying it by $\phi_l(\mathbf{x})$, and integrating over $\mathbf{x}\in\mathcal{D}$, we deduce from the orthogonality of the eigenmodes $(\phi_j)_{j\ge1}$ the following system of coupled differential equations for the mode amplitudes:

$$\frac{d\hat{a}_j}{dz} = \frac{i\varepsilon k^2}{2}\sum_{1\le l\le N}\frac{C_{jl}(z)}{\sqrt{\beta_j\beta_l}}\left(\hat{a}_l e^{i(\beta_l-\beta_j)z} + \hat{b}_l e^{-i(\beta_l+\beta_j)z}\right)\,, \tag{3.4}$$

$$\frac{d\hat{b}_j}{dz} = -\frac{i\varepsilon k^2}{2}\sum_{1\le l\le N}\frac{C_{jl}(z)}{\sqrt{\beta_j\beta_l}}\left(\hat{a}_l e^{i(\beta_l+\beta_j)z} + \hat{b}_l e^{i(\beta_j-\beta_l)z}\right)\,, \tag{3.5}$$

where

$$C_{jl}(z) = \int_{\mathcal{D}}\phi_j(\mathbf{x})\phi_l(\mathbf{x})\nu(\mathbf{x},z)d\mathbf{x}\,, \tag{3.6}$$

and we have neglected the evanescent modes. The system (3.4)–(3.5) is complemented with the boundary conditions

$$\hat{a}_j(\omega,0) = \hat{a}_{j,0}(\omega), \qquad \hat{b}_j\left(\omega,\frac{L}{\varepsilon^2}\right) = 0 \tag{3.7}$$

for the propagating modes. The second condition indicates that no wave is incoming from the right.

It is possible to carry out a complete asymptotic analysis, including the coupling with the evanescent modes, in a general context of random ordinary differential equations [20], and specifically for random waveguide problems [13, 12] and shallow water waves [18]. The evanescent modes do affect the propagation statistics in the asymptotic regime considered here. A detailed asymptotic analysis shows, however, that the coupling with evanescent modes does not remove energy from the propagating modes. This coupling changes only the frequency-dependent phases of the propagating mode amplitudes. The overall effect for these modes is an additional dispersive term, which is given in terms of the two-point statistics of the random process ν, in the same asymptotic regime as the one considered here. This effective dispersion affects the operator $\mathcal{L}$ for the statistics of the complex mode amplitudes in (4.1) but not the operator $\mathcal{L}_P$ for their square modulus in (4.10). Therefore, all results that involve the propagation of energy, which includes nearly all results presented here, are not affected by the evanescent modes. We indicate in the following where the results are affected and refer to [12] for their form when full evanescent coupling is included.

3.2. Propagator matrices. We introduce the rescaled propagating mode amplitudes $\hat{a}_j^\varepsilon$, $\hat{b}_j^\varepsilon$, $j = 1, \ldots, N(\omega)$, given by

$$\hat{a}_j^\varepsilon(\omega, z) = \hat{a}_j\left(\omega, \frac{z}{\varepsilon^2}\right), \qquad \hat{b}_j^\varepsilon(\omega, z) = \hat{b}_j\left(\omega, \frac{z}{\varepsilon^2}\right). \tag{3.8}$$

The two-point linear boundary value problem (3.4), (3.5), (3.7) for $(\hat{a}^\varepsilon, \hat{b}^\varepsilon)$ can be solved using propagator matrices. We first put the problem in vector-matrix form:

$$\frac{dX_\omega^\varepsilon}{dz} = \frac{1}{\varepsilon}\mathbf{H}_\omega\left(\frac{z}{\varepsilon^2}\right) X_\omega^\varepsilon. \tag{3.9}$$

Here the $2N(\omega)$-vector X_ω^ε, obtained by concatenating the $N(\omega)$-vectors $\hat{a}^\varepsilon$ and $\hat{b}^\varepsilon$ and the $2N(\omega) \times 2N(\omega)$ matrix $\mathbf{H}_\omega$, is defined by

$$X_\omega^\varepsilon(z) = \begin{bmatrix} \hat{a}^\varepsilon(\omega, z) \\ \hat{b}^\varepsilon(\omega, z) \end{bmatrix}, \qquad \mathbf{H}_\omega(z) = \begin{bmatrix} \mathbf{H}_\omega^{(a)}(z) & \mathbf{H}_\omega^{(b)}(z) \\ \overline{\mathbf{H}_\omega^{(b)}}(z) & \overline{\mathbf{H}_\omega^{(a)}}(z) \end{bmatrix}, \tag{3.10}$$

where the entries of the $N(\omega) \times N(\omega)$ matrices $\mathbf{H}_\omega^{(a)}(z)$ and $\mathbf{H}_\omega^{(b)}(z)$ are given by

$$H_{\omega,jl}^{(a)}(z) = \frac{ik^2}{2}\frac{C_{jl}(z)}{\sqrt{\beta_j\beta_l}} e^{i(\beta_l - \beta_j)z}, \qquad H_{\omega,jl}^{(b)}(z) = \frac{ik^2}{2}\frac{C_{jl}(z)}{\sqrt{\beta_j\beta_l}} e^{-i(\beta_l + \beta_j)z}. \tag{3.11}$$

The propagator matrices $\mathbf{P}_\omega^\varepsilon(z)$ are the $2N(\omega) \times 2N(\omega)$ random matrices solution of the initial value problem

$$\frac{d\mathbf{P}_\omega^\varepsilon}{dz} = \frac{1}{\varepsilon}\mathbf{H}_\omega\left(\frac{z}{\varepsilon^2}\right)\mathbf{P}_\omega^\varepsilon, \tag{3.12}$$

with the initial condition $\mathbf{P}_\omega^\varepsilon(z = 0) = \mathbf{I}$. The solution of (3.4), (3.5), (3.7) satisfies

$$\begin{bmatrix} \hat{a}^\varepsilon(\omega, L) \\ 0 \end{bmatrix} = \mathbf{P}_\omega^\varepsilon(L) \begin{bmatrix} \hat{a}_0(\omega) \\ \hat{b}^\varepsilon(\omega, 0) \end{bmatrix}, \tag{3.13}$$

so that $\hat{a}^\varepsilon(\omega, L)$ can be expressed in terms of the entries of the propagator matrix $\mathbf{P}_\omega^\varepsilon(L)$. The symmetry relation (3.10) satisfied by the matrix $\mathbf{H}_\omega$ imposes the condition that the propagator has the form

$$\mathbf{P}_\omega^\varepsilon(z) = \begin{bmatrix} \mathbf{P}_\omega^{\varepsilon,a}(z) & \mathbf{P}_\omega^{\varepsilon,b}(z) \\ \overline{\mathbf{P}_\omega^{\varepsilon,b}}(z) & \overline{\mathbf{P}_\omega^{\varepsilon,a}}(z) \end{bmatrix}, \tag{3.14}$$

where $\mathbf{P}_\omega^{\varepsilon,a}(z)$ and $\mathbf{P}_\omega^{\varepsilon,b}(z)$ are $N(\omega)\times N(\omega)$ matrices. Note that the matrix $\mathbf{P}_\omega^{\varepsilon,a}$ describes the coupling between different right-going modes, while $\mathbf{P}_\omega^{\varepsilon,b}$ describes the coupling between right-going and left-going modes.

3.3. The forward scattering approximation. The limit as $\varepsilon\to 0$ of $\mathbf{P}_\omega^\varepsilon$ can be obtained and identified as a multidimensional diffusion process, meaning that the entries of the limit matrix satisfy a system of linear stochastic differential equations. This follows from the application of the diffusion-approximation theorem proved in [19]. The stochastic differential equations for the limit entries of $\mathbf{P}_\omega^{\varepsilon,b}(z)$ are coupled to the limit entries of $\mathbf{P}_\omega^{\varepsilon,a}(z)$ through the coefficients

$$\int_0^\infty \mathbb{E}[C_{jl}(0)C_{jl}(z)]\cos((\beta_j(\omega)+\beta_l(\omega))z)\,dz,\qquad j,l=1,\dots,N(\omega)\,.$$

This is because the phase factors present in the matrix $\mathbf{H}_\omega^{(b)}(z)$ are $\pm(\beta_j+\beta_l)z$. On the other hand, the stochastic differential equations for the limit entries of $\mathbf{P}_\omega^{\varepsilon,a}(z)$ are coupled to each other through the coefficients

$$\int_0^\infty \mathbb{E}[C_{jl}(0)C_{jl}(z)]\cos((\beta_j(\omega)-\beta_l(\omega))z)\,dz,\qquad j,l=1,\dots,N(\omega)\,.$$

This is because the phase factors present in the matrix $\mathbf{H}_\omega^{(a)}(z)$ are $\pm(\beta_j-\beta_l)z$. If we assume that the power spectral density of the process ν (i.e., the Fourier transform of its z-autocorrelation function) possesses a cut-off frequency, then it is natural to consider the case where

$$\int_0^\infty \mathbb{E}[C_{jl}(0)C_{jl}(z)]\cos((\beta_j(\omega)+\beta_l(\omega))z)\,dz=0,\qquad j,l=1,\dots,N(\omega),\tag{3.15}$$

while (at least) some of the intracoupling coefficients (those with $|j-l|=1$) are not zero. As a result of this assumption, the asymptotic coupling between $\mathbf{P}_\omega^{\varepsilon,a}(z)$ and $\mathbf{P}_\omega^{\varepsilon,b}(z)$ becomes zero. If we also take into account the initial condition $\mathbf{P}_\omega^{\varepsilon,b}(z=0)=\mathbf{0}$, then the limit of $\mathbf{P}_\omega^{\varepsilon,b}(z)$ is $\mathbf{0}$.

In the forward scattering approximation, we neglect the left-going (backward) propagating modes. As we have just seen, it is valid in the limit $\varepsilon\to 0$ when the condition (3.15) holds. In this case we can consider the simplified coupled mode equation given by

$$\frac{d\hat a^\varepsilon}{dz}=\frac{1}{\varepsilon}\mathbf{H}_\omega^{(a)}\left(\frac{z}{\varepsilon^2}\right)\hat a^\varepsilon\,,\tag{3.16}$$

where $\mathbf{H}_\omega^{(a)}$ is the $N(\omega)\times N(\omega)$ complex matrix given by (3.11). The system (3.16) is provided with the initial condition $\hat a_j^\varepsilon(\omega,z=0)=\hat a_{j,0}(\omega)$. Note that the matrix $\mathbf{H}_\omega^{(a)}$ is skew Hermitian, which implies the conservation relation $\sum_{j=1}^N|\hat a_j^\varepsilon(L)|^2=\sum_{j=1}^N|\hat a_{j,0}|^2$. We finally introduce the *transfer*, or propagator matrix $\mathbf{T}^\varepsilon(\omega,z)$, which is the fundamental solution of (3.16). It is the $N(\omega)\times N(\omega)$ matrix solution of

$$\frac{d}{dz}\mathbf{T}^\varepsilon(\omega,z)=\frac{1}{\varepsilon}\mathbf{H}_\omega^{(a)}\left(\frac{z}{\varepsilon^2}\right)\mathbf{T}^\varepsilon(\omega,z)\,,\tag{3.17}$$

starting from $\mathbf{T}^\varepsilon(\omega,0)=\mathbf{I}$. The (j,l)-entry of the transfer matrix is the transmission coefficient $T_{jl}^\varepsilon(\omega,L)$, i.e., the output amplitude of the mode j when the input wave is a pure l mode with amplitude one. The transfer matrix $\mathbf{T}^\varepsilon(\omega,L)$ is unitary because $\mathbf{H}_\omega^{(a)}$ is skew Hermitian.

4. The time harmonic problem. In this section we consider the system of random differential equations (3.16) for a single frequency ω. Most of the results presented in this section can be found in [14] and are known collectively as the "coupled mode theory." We reproduce this theory because the original two-frequency analysis presented in the next section will give a new point of view on it.

4.1. The coupled mode diffusion process. We now apply the diffusion approximation theorem [19] to the system (3.16). The limit distribution of $\hat{a}^\varepsilon$ as $\varepsilon \to 0$ is a diffusion on $\mathbb{C}^{N(\omega)}$. We will assume that the longitudinal wavenumbers β_j, along with their sums and differences, are distinct. In this case the infinitesimal generator of the limit $\hat{a}$ has a simple form, provided we write it in terms of $\hat{a}$ and $\bar{\hat{a}}$ rather than in terms of the real and imaginary parts of $\hat{a}$. We get the following result.

PROPOSITION 4.1. *The mode amplitudes $(\hat{a}_j^\varepsilon(\omega,z))_{j=1,\dots,N}$ converge in distribution as $\varepsilon \to 0$ to the diffusion process $(\hat{a}_j(\omega,z))_{j=1,\dots,N}$, whose infinitesimal generator is*

$$\mathcal{L} = \frac{1}{4}\sum_{j\neq l}\Gamma_{jl}^{(c)}(\omega)\left(A_{jl}\overline{A_{jl}} + \overline{A_{jl}}A_{jl}\right) + \frac{1}{2}\sum_{j,l}\Gamma_{jl}^{(1)}(\omega)A_{jj}\overline{A_{ll}}$$

$$+\frac{i}{4}\sum_{j\neq l}\Gamma_{jl}^{(s)}(\omega)(A_{ll}-A_{jj})\,, \tag{4.1}$$

$$A_{jl} = \hat{a}_j\frac{\partial}{\partial \hat{a}_l} - \bar{\hat{a}}_l\frac{\partial}{\partial \bar{\hat{a}}_j} = -\overline{A_{lj}}\,. \tag{4.2}$$

Here we have defined the complex derivatives in the standard way: if $z = x + iy$, then $\partial_z = (1/2)(\partial_x - i\partial_y)$ and $\partial_{\bar{z}} = (1/2)(\partial_x + i\partial_y)$. The coefficients $\Gamma^{(c)}$, $\Gamma^{(s)}$, and $\Gamma^{(1)}$ are given by

$$\Gamma_{jl}^{(c)}(\omega) = \frac{\omega^4\gamma_{jl}^{(c)}(\omega)}{4\bar{c}^4\beta_j(\omega)\beta_l(\omega)} \quad \text{if } j\neq l\,, \qquad \Gamma_{jj}^{(c)}(\omega) = -\sum_{n\neq j}\Gamma_{jn}^{(c)}(\omega)\,, \tag{4.3}$$

$$\gamma_{jl}^{(c)}(\omega) = 2\int_0^\infty \cos\left((\beta_j(\omega)-\beta_l(\omega))z\right)\mathbb{E}[C_{jl}(0)C_{jl}(z)]dz\,, \tag{4.4}$$

$$\Gamma_{jl}^{(s)}(\omega) = \frac{\omega^4\gamma_{jl}^{(s)}(\omega)}{4\bar{c}^4\beta_j(\omega)\beta_l(\omega)} \quad \text{if } j\neq l\,, \qquad \Gamma_{jj}^{(s)}(\omega) = -\sum_{n\neq j}\Gamma_{jn}^{(s)}(\omega)\,, \tag{4.5}$$

$$\gamma_{jl}^{(s)}(\omega) = 2\int_0^\infty \sin\left((\beta_j(\omega)-\beta_l(\omega))z\right)\mathbb{E}[C_{jl}(0)C_{jl}(z)]dz\,, \tag{4.6}$$

$$\Gamma_{jl}^{(1)}(\omega) = \frac{\omega^4\gamma_{jl}^{(1)}}{4\bar{c}^4\beta_j(\omega)\beta_l(\omega)} \quad \text{for all } j,l\,, \tag{4.7}$$

$$\gamma_{jl}^{(1)} = 2\int_0^\infty \mathbb{E}[C_{jj}(0)C_{ll}(z)]dz\,. \tag{4.8}$$

Let us discuss some qualitative properties of the diffusion process $\hat{a}$.

(1) The coefficients of the second derivatives of the generator $\mathcal{L}$ are homogeneous of degree two, while the coefficients of the first derivatives are homogeneous of degree one. As a consequence we can write closed differential equations for moments of any order, as we shall see in the next sections.

(2) The coefficients $\gamma_{jl}^{(c)}$, and thus $\Gamma_{jl}^{(c)}$, are proportional to the power spectral densities of the stationary process $C_{jl}(z)$ for $j \neq l$. They are, therefore, nonnegative. In this paper we assume that the off-diagonal entries of the matrix $\Gamma^{(c)}$ are positive.

(3) We have $A_{jn}\big(\sum_{l=1}^N |\hat{a}_l|^2\big) = 0$ for any j, n, so that the infinitesimal generator satisfies $\mathcal{L}\big(\sum_{l=1}^N |\hat{a}_l|^2\big) = 0$. This implies that the diffusion process is supported on a sphere of $\mathbb{C}^N$, whose radius R_0 is determined by the initial condition $R_0^2 = \sum_{l=1}^N |\hat{a}_{l,0}(\omega)|^2$. The operator $\mathcal{L}$ is not self-adjoint on the sphere because of the term $\Gamma^{(s)}$ in (4.1). This means that the process is not reversible. However, the uniform measure on the sphere is invariant, and the generator is strongly elliptic. From the theory of irreducible Markov processes with compact state space, we know that the process is ergodic, which means in particular that for large z, the limit process $\hat{a}(z)$ converges to the uniform distribution over the sphere of radius R_0. This fact can be used to compute the limit distribution of the mode powers $(|\hat{a}_j|^2)_{j=1,\dots,N}$ for large z, which is the uniform distribution over $\mathcal{H}_N$,

$$\mathcal{H}_N = \left\{ (P_j)_{j=1,\dots,N},\, P_j \geq 0,\, \sum_{j=1}^N P_j = R_0^2 \right\}. \tag{4.9}$$

In the next section we carry out a more detailed analysis that is valid for any z.

(4) As noted at the end of section 3.1, coupling to the evanescent modes does affect $\mathcal{L}$ in (4.1). All the coefficients (4.3)–(4.8) remain the same except for $\Gamma_{jl}^{(s)}(\omega)$ in (4.5) which has an additional term [12]. This modification affects (6.1) and (6.7) in the following sections.

4.2. Coupled power equations. The generator of the limit process $\hat{a}$ possesses an important symmetry, which follows from noting that, when applying the generator to a function of $(|\hat{a}_1|^2, \dots, |\hat{a}_N|^2)$, we obtain another function of $(|\hat{a}_1|^2, \dots, |\hat{a}_N|^2)$. This implies that the limit process $(|\hat{a}_1(z)|^2)_{j=1,\dots,N}$ is itself a Markov process.

PROPOSITION 4.2. *The mode powers $(|\hat{a}_j^\varepsilon(\omega, z)|^2)_{j=1,\dots,N}$ converge in distribution as $\varepsilon \to$ to the diffusion process $(P_j(\omega, z))_{j=1,\dots,N}$, whose infinitesimal generator is*

$$\mathcal{L}_P = \sum_{j \neq l} \Gamma_{jl}^{(c)}(\omega) \left[P_l P_j \left(\frac{\partial}{\partial P_j} - \frac{\partial}{\partial P_l} \right) \frac{\partial}{\partial P_j} + (P_l - P_j) \frac{\partial}{\partial P_j} \right]. \tag{4.10}$$

As pointed out above, the diffusion process $(P_j(\omega, z))_{j=1,\dots,N}$ is supported in $\mathcal{H}_N$. As a first application of this result, we compute the mean mode powers:

$$P_j^{(1)}(\omega, z) = \mathbb{E}[P_j(\omega, z)] = \lim_{\varepsilon \to 0} \mathbb{E}[|\hat{a}_j^\varepsilon(\omega, z)|^2].$$

Using the generator $\mathcal{L}_P$ we get the following proposition.

PROPOSITION 4.3. *The mean mode powers $\mathbb{E}[|\hat{a}_j^\varepsilon(\omega, z)|^2]$ converge to $P_j^{(1)}(\omega, z)$, which is the solution of the linear system*

$$\frac{dP_j^{(1)}}{dz} = \sum_{n \neq j} \Gamma_{jn}^{(c)}(\omega) \left(P_n^{(1)} - P_j^{(1)} \right), \tag{4.11}$$

starting from $P_j^{(1)}(\omega, z = 0) = |\hat{a}_{j,0}(\omega)|^2$, $j = 1, \dots, N$.

The solution of this system can be written in terms of the exponential of the matrix $\Gamma^{(c)}(\omega)$. We note that the vector $P^{(1)}(\omega, z)$ has a probabilistic interpretation, which we consider in some detail in section 6.3. We give here some basic properties. First, the matrix $\Gamma^{(c)}(\omega)$ is symmetric and real, its off-diagonal terms are positive, and its diagonal terms are negative. The sums over the rows and columns are all

zero. As a consequence of the Perron–Frobenius theorem, $\Gamma^{(c)}(\omega)$ has zero as a simple eigenvalue, and all other eigenvalues are negative. The eigenvector associated with the zero eigenvalue is the uniform vector $(1,\dots,1)^T$. This shows that

$$\sup_{j=1,\dots,N}\left|P_j^{(1)}(\omega,z)-\frac{1}{N}R_0^2\right|\le Ce^{-z/L_{\mathrm{equip}}(\omega)},$$

where $R_0^2=\sum_{j=1}^N|\hat a_{j,0}(\omega)|^2$ and $L_{\mathrm{equip}}(\omega)$ is the absolute value of the reciprocal of the second eigenvalue of $\Gamma^{(c)}(\omega)$. In other words, the mean mode powers converge exponentially fast to the uniform distribution, which means that we have asymptotic *equipartition* of mode energy. The length $L_{\mathrm{equip}}(\omega)$ is the equipartition distance for the mean mode powers.

4.3. Fluctuations theory. Proposition 4.2 also allows us to study the fluctuations of the mode powers by looking at the fourth-order moments of the mode amplitudes:

$$P_{jl}^{(2)}(\omega,z)=\lim_{\varepsilon\to0}\mathbb{E}\left[|\hat a_j^\varepsilon(\omega,z)|^2|\hat a_l^\varepsilon(\omega,z)|^2\right]=\mathbb{E}[P_j(\omega,z)P_l(\omega,z)]\,.$$

Using the generator $\mathcal{L}_P$ we get a system of ordinary differential equations for limit fourth-order moments $(P_{jl}^{(2)})_{j,l=1,\dots,N}$ of the form

$$\begin{aligned}\frac{dP_{jj}^{(2)}}{dz}&=\sum_{n\ne j}\Gamma_{jn}^{(c)}\left(4P_{jn}^{(2)}-2P_{jj}^{(2)}\right),\\ \frac{dP_{jl}^{(2)}}{dz}&=-2\Gamma_{jl}^{(c)}P_{jl}^{(2)}+\sum_n\Gamma_{ln}^{(c)}\left(P_{jn}^{(2)}-P_{jl}^{(2)}\right)+\sum_n\Gamma_{jn}^{(c)}\left(P_{ln}^{(2)}-P_{jl}^{(2)}\right),\qquad j\ne l\,.\end{aligned}$$

The initial conditions are $P_{jl}^{(2)}(z=0)=|\hat a_{j,0}|^2|\hat a_{l,0}|^2$. This is a system of linear ordinary differential equations with constant coefficients that can be solved by computing the exponent of the evolution matrix.

It is straightforward to check that the function $P_{jl}^{(2)}\equiv1+\delta_{jl}$ is a stationary solution of the fourth-order moment system. Using the positivity of $\Gamma_{jl}^{(c)}$, $j\ne l$, we conclude that this stationary solution is asymptotically stable, which means that the solution $P_{jl}^{(2)}(z)$ starting from $P_{jl}^{(2)}(z=0)=|\hat a_{j,0}|^2|\hat a_{l,0}|^2$ converges as $z\to\infty$ to

$$P_{jl}^{(2)}(z)\overset{z\to\infty}{\longrightarrow}\begin{cases}\dfrac{1}{N(N+1)}R_0^4 & \text{if } j\ne l\,,\\ \dfrac{2}{N(N+1)}R_0^4 & \text{if } j=l\,,\end{cases}$$

where $R_0^2=\sum_{j=1}^N|\hat a_{j,0}|^2$. This implies that the correlation of $P_j(z)$ and $P_l(z)$ converges to $-1/(N-1)$ if $j\ne l$ and to $(N-1)/(N+1)$ if $j=l$ as $z\to\infty$. We see from the $j\ne l$ result that if, in addition, the number of modes N becomes large, then the mode powers become uncorrelated. The $j=l$ result shows that, whatever the number of modes N, the mode powers P_j are not statistically stable quantities.

5. Pulse propagation in waveguides. Bandwidth plays a basic role in the propagation of pulses in a waveguide because of dispersion. We assume that a point

source located inside the waveguide at $(z = 0, \mathbf{x} = \mathbf{x}_0)$ emits a pulse with carrier frequency ω_0 and bandwidth of order ε^2:

$$\mathbf{F}^\varepsilon(t,\mathbf{x},z) = f^\varepsilon(t)\delta(\mathbf{x}-\mathbf{x}_0)\delta(z)\mathbf{e}_z\,, \qquad f^\varepsilon(t) = f(\varepsilon^2 t)e^{i\omega_0 t}\,. \tag{5.1}$$

We have assumed in this model a narrowband source whose duration is of order ε^{-2}, that is, of the same order as the travel time through the waveguide whose length is L/ε^2. This is not the typical situation encountered in ultrasonic and underwater sound experiments in connection with time reversal [22, 15], where broadband pulses are used and, in the notation of this paper, $f^\varepsilon(t) = f(\varepsilon^p t)e^{i\omega_0 t}$ with $0 \le p < 2$. The analysis of these broadband regimes is carried out in [10]. The main results are similar in the two regimes, except for those regarding statistical stability in time reversal. We discuss this issue in sections 8.3 and 8.4, where we show that statistical stability in the narrowband case (5.1) can be achieved by mode diversity rather than by frequency diversity. The latter is typical for time-reversal refocusing of broadband pulses [10]. This is the reason that we consider the narrowband case in this paper.

The point source (5.1) generates left-going propagating modes that we do not need to consider, as they propagate in a homogeneous half-space, and right-going modes that we do analyze. As shown in section 2.3, the interface conditions at $z = 0$, which are initial conditions in the forward scattering approximation, have the form

$$\hat a_j^\varepsilon(\omega,0) = \frac{1}{2}\sqrt{\beta_j(\omega)}\hat f^\varepsilon(\omega)\phi_j(\mathbf{x}_0)\,, \qquad \hat f^\varepsilon(\omega) = \frac{1}{\varepsilon^2}\hat f\left(\frac{\omega-\omega_0}{\varepsilon^2}\right)$$

for $j \le N(\omega)$. The transmitted field observed in the plane $z = L/\varepsilon^2$ and at time t/ε^2 has the form

$$p_{tr}^\varepsilon(t,\mathbf{x},L) := p\left(\frac{t}{\varepsilon^2},\mathbf{x},\frac{L}{\varepsilon^2}\right),$$

$$p_{tr}^\varepsilon(t,\mathbf{x},L) = \frac{1}{4\pi\varepsilon^2}\int\sum_{j,l=1}^{N(\omega)}\frac{\sqrt{\beta_l(\omega)}}{\sqrt{\beta_j(\omega)}}\phi_j(\mathbf{x})\phi_l(\mathbf{x}_0)\hat f\left(\frac{\omega-\omega_0}{\varepsilon^2}\right)T_{jl}^\varepsilon(\omega)e^{i\frac{\beta_j(\omega)L-\omega t}{\varepsilon^2}}d\omega\,.$$

We change variables $\omega = \omega_0 + \varepsilon^2 h$ and expand $\beta_j(\omega_0+\varepsilon^2 h)$ with respect to ε:

$$p_{tr}^\varepsilon(t,\mathbf{x},L) = \frac{1}{4\pi}\int\sum_{j,l=1}^{N}\frac{\sqrt{\beta_l}}{\sqrt{\beta_j}}\phi_j(\mathbf{x})\phi_l(\mathbf{x}_0) \times\hat f(h)T_{jl}^\varepsilon(\omega_0+\varepsilon^2 h)e^{i\frac{\beta_j(\omega_0)L-\omega_0 t}{\varepsilon^2}}e^{i[\beta_j'(\omega_0)L-t]h}dh\,. \tag{5.2}$$

Here $\beta_j'(\omega)$ is the ω-derivative of $\beta_j(\omega)$. We do not show the dependence of N on ω_0 after we approximate $N(\omega_0+\varepsilon^2 h)$ by $N(\omega_0)$.

In a homogeneous waveguide we have that $T_{jl}^\varepsilon = \delta_{jl}$ and

$$p_{tr}^\varepsilon\,(t,\mathbf{x},L) = \frac{1}{2}\sum_{j=1}^{N}\phi_j(\mathbf{x})\phi_j(\mathbf{x}_0)e^{i\frac{\beta_j(\omega_0)L-\omega_0 t}{\varepsilon^2}}f\left(t-\beta_j'(\omega_0)L\right)\,. \tag{5.3}$$

The transmitted field is therefore a superposition of modes, each of which is centered around its travel time $\beta_j'(\omega_0)L$. The modal dispersion makes the overall spreading of the transmitted field linearly increasing with L.

In a random waveguide, the integral representation (5.2) shows that the moments of the transmitted field depend on the joint statistics of the entries of the transfer matrix at different frequencies. The next section will give the needed results.

6. Statistics of the transfer matrix.

6.1. Single frequency statistics of the transfer matrix. Using Proposition 4.1 with the special initial conditions $\hat{a}_j(0) = \delta_{jl}$, we obtain the first moments of the transmission coefficients.

PROPOSITION 6.1. *The expectations of the transmission coefficients* $\mathbb{E}[T^\varepsilon_{jl}(\omega, L)]$ *converge to zero as* $\varepsilon \to 0$ *if* $j \neq l$ *and to* $\bar{T}_j(\omega, L)$ *if* $j = l$*, where*

$$\bar{T}_j(\omega, L) = \exp\left(\frac{\Gamma^{(c)}_{jj}(\omega)L}{2} - \frac{\Gamma^{(1)}_{jj}(\omega)L}{2} + \frac{i\Gamma^{(s)}_{jj}(\omega)L}{2}\right). \tag{6.1}$$

The real part of the exponential factor is $[\Gamma^{(c)}_{jj}(\omega) - \Gamma^{(1)}_{jj}(\omega)]L/2$. The coefficient $\Gamma^{(c)}_{jj}(\omega)$ is negative. The coefficient $\Gamma^{(1)}_{jj}(\omega)$ is nonnegative because it is proportional to the power spectral density of C_{jj} at zero-frequency. As a result, the damping coefficient has a negative real part, and therefore the mean transmission coefficients decay exponentially with propagation distance.

Using Proposition 4.3, we immediately get the following result.

PROPOSITION 6.2. *The mean square moduli of the transmission coefficients have limits as* $\varepsilon \to 0$*,* $\lim_{\varepsilon\to 0} \mathbb{E}[|T^\varepsilon_{jl}(\omega, L)|^2] = \mathcal{T}^{(l)}_j(\omega, L)$*, which are the solutions of the system of linear equations*

$$\frac{d\mathcal{T}^{(l)}_j}{dz} = \sum_{n\neq j} \Gamma^{(c)}_{jn}(\omega)\left(\mathcal{T}^{(l)}_n - \mathcal{T}^{(l)}_j\right), \qquad \mathcal{T}^{(l)}_j(\omega, z = 0) = \delta_{jl}\,. \tag{6.2}$$

The coefficients $\Gamma^{(c)}_{jl}$ *are given by* (4.3)*.*

From the analysis of section 4.2, we know that the mean square moduli of the entries of the transfer matrix converge exponentially fast to the constant $1/N$.

6.2. Transport equations for the autocorrelation of the transfer matrix. In many physically interesting contexts, such as in calculating the mean transmitted intensity or the mean refocused field amplitude, we need two-frequency statistical information. We now introduce a proposition that describes the two-frequency statistical properties that we will need in the applications discussed in this paper.

PROPOSITION 6.3. *The autocorrelation function of the transmission coefficients at two nearby frequencies admits a limit as* $\varepsilon \to 0$*:*

$$\mathbb{E}[T^\varepsilon_{jj}(\omega, L)\overline{T^\varepsilon_{ll}(\omega - \varepsilon^2 h, L)}] \stackrel{\varepsilon\to 0}{\longrightarrow} e^{Q_{jl}(\omega)L} \text{ if } j \neq l\,, \tag{6.3}$$

$$\mathbb{E}[T^\varepsilon_{jl}(\omega, L)\overline{T^\varepsilon_{jl}(\omega - \varepsilon^2 h, L)}] \stackrel{\varepsilon\to 0}{\longrightarrow} e^{-i\beta'_j(\omega)hL} \int \mathcal{W}^{(l)}_j(\omega, \tau, L)e^{ih\tau}d\tau\,, \tag{6.4}$$

$$\mathbb{E}[T^\varepsilon_{jm}(\omega, L)\overline{T^\varepsilon_{ln}(\omega - \varepsilon^2 h, L)}] \stackrel{\varepsilon\to 0}{\longrightarrow} 0 \text{ in the other cases,} \tag{6.5}$$

where $(\mathcal{W}^{(l)}_j(\omega, \tau, z))_{j=1,\ldots,N(\omega)}$ *is the solution of the system of transport equations*

$$\frac{\partial \mathcal{W}^{(l)}_j}{\partial z} + \beta'_j(\omega)\frac{\partial \mathcal{W}^{(l)}_j}{\partial \tau} = \sum_{n\neq j} \Gamma^{(c)}_{jn}(\omega)\left(\mathcal{W}^{(l)}_n - \mathcal{W}^{(l)}_j\right), \tag{6.6}$$

starting from $\mathcal{W}_j^{(l)}(\omega,\tau,z=0)=\delta(\tau)\delta_{jl}$. *The coefficients* $\Gamma_{jl}^{(c)}$ *are given by* (4.3). *The damping factors* Q_{jl} *are*

$$Q_{jl}(\omega)=\frac{\Gamma_{jj}^{(c)}(\omega)+\Gamma_{ll}^{(c)}(\omega)}{2}-\frac{\Gamma_{jj}^{(1)}(\omega)+\Gamma_{ll}^{(1)}(\omega)-2\Gamma_{jl}^{(1)}(\omega)}{2} +i\frac{\Gamma_{jj}^{(s)}(\omega)-\Gamma_{ll}^{(s)}(\omega)}{2}\,. \tag{6.7}$$

We note that the real parts of the damping factors Q_{jl} are negative and that the solutions of the transport equations are measures. If $j\neq l$, then $\mathcal{W}_j^{(l)}$ has a continuous density, but $\mathcal{W}_l^{(l)}$ has a Dirac mass at $\tau=\beta_l'(\omega)z$ with weight $\exp(\Gamma_{ll}^{(c)}z)$, where $\Gamma_{ll}^{(c)}$ is given by (4.3), and a continuous density denoted by $\mathcal{W}_{l,c}^{(l)}(\omega,\tau,z)$:

$$\mathcal{W}_l^{(l)}(\omega,\tau,z)d\tau=e^{\Gamma_{ll}^{(c)}(\omega)z}\delta(\tau-\beta_l'(\omega)z)d\tau+\mathcal{W}_{l,c}^{(l)}(\omega,\tau,z)d\tau\,.$$

Note also that by integrating the system of transport equations with respect to τ, we recover the result of Proposition 6.2.

The system of transport equations describes the coupling between the N right-going modes. It is the main theoretical result of this paper. It describes the evolution of the coupled powers of the modes in frequency and time, with transport velocities equal to the group velocities of the modes $1/\beta_j'(\omega)$. Therefore, the transport equations (6.6) could have been written as the natural space-time generalization of the coupled power equations (6.2). The mathematical content of Proposition 6.3 gives the precise connection between the quantities that satisfy this simple and intuitive space-time extension of (6.2) and the moments of the random transfer matrix. The two-frequency nature of the statistical quantities that satisfy the transport equations is clear in Proposition 6.3.

Proof. For fixed indices m and n we consider the product of two transfer matrices,

$$U_{jl}^{\varepsilon}(\omega,h,z)=T_{jm}^{\varepsilon}(\omega,z)\overline{T_{ln}^{\varepsilon}(\omega-\varepsilon^2h,z)}\,,$$

and note that it is the solution of

$$\frac{dU_{jl}^{\varepsilon}}{dz}=\sum_{j_1=1}^{N}\frac{1}{\varepsilon}H_{\omega,jj_1}^{(a)}\left(\frac{z}{\varepsilon^2}\right)U_{j_1l}^{\varepsilon}+\sum_{l_1=1}^{N}\frac{1}{\varepsilon}\overline{H_{\omega-\varepsilon^2h,ll_1}^{(a)}}\left(\frac{z}{\varepsilon^2}\right)U_{jl_1}^{\varepsilon}\,,$$

with the initial conditions $U_{jl}^{\varepsilon}(\omega,h,z=0)=\delta_{mj}\delta_{nl}$. We expand $\beta_\cdot(\omega-\varepsilon^2h)$ with respect to ε, and we introduce the Fourier transform

$$V_{jl}^{\varepsilon}(\omega,\tau,z)=\frac{1}{2\pi}\int e^{-ih(\tau-\beta_l'(\omega)z)}U_{jl}^{\varepsilon}(\omega,h,z)dh\,,$$

which is the solution of

$$\frac{\partial V_{jl}^{\varepsilon}}{\partial z}+\beta_l'(\omega)\frac{\partial V_{jl}^{\varepsilon}}{\partial\tau}=\sum_{j_1=1}^{N}\frac{1}{\varepsilon}H_{\omega,jj_1}^{(a)}\left(\frac{z}{\varepsilon^2}\right)V_{j_1l}^{\varepsilon}+\sum_{l_1=1}^{N}\frac{1}{\varepsilon}\overline{H_{\omega,ll_1}^{(a)}}\left(\frac{z}{\varepsilon^2}\right)V_{jl_1}^{\varepsilon}\,,$$

with the initial conditions $V_{jl}^{\varepsilon}(\omega,\tau,z=0)=\delta_{mj}\delta_{nl}\delta(\tau)$. We can now apply the diffusion approximation theorem [19] and get the result stated in the proposition. ∎

6.3. Probabilistic interpretation of the transport equations. The transport equations (6.6) have a probabilistic representation that can be used for Monte Carlo simulations as well as for getting a diffusion approximation result. It is primarily this diffusion approximation that we want to derive in this section. We will use it in the applications that follow. We introduce the jump Markov process J_z, whose state space is $\{1,\dots,N(\omega)\}$ and whose infinitesimal generator is

$$\mathcal{L}\phi(j) = \sum_{l\neq j} \Gamma^{(c)}_{jl}(\omega)\left(\phi(l)-\phi(j)\right) . \tag{6.8}$$

We also define the process $\mathcal{B}_z$ by

$$\mathcal{B}_z = \int_0^z \beta'_{J_s} ds\,, \quad z\geq 0\,, \tag{6.9}$$

which is well defined because J_z is piecewise constant. In a manner similar to that in [1], we get the probabilistic representation of the solutions to system (6.2) and the solutions to the transport equations (6.6) in terms of the jump Markov process J_z:

$$\mathcal{T}^{(n)}_j(\omega,L) = \mathbb{P}\left(J_L = j \mid J_0 = n\right) , \tag{6.10}$$

$$\int_{\tau_0}^{\tau_1} \mathcal{W}^{(n)}_j(\omega,\tau,L)d\tau = \mathbb{P}\left(J_L = j\ ,\ \mathcal{B}_L\in[\tau_0,\tau_1] \mid J_0 = n\right) . \tag{6.11}$$

The process J_z is an irreducible, reversible, and ergodic Markov process. Its distribution converges as $z\to\infty$ to the uniform distribution over $\{1,\dots,N\}$. The convergence is exponential with a rate that is equal to the second eigenvalue of the matrix $\Gamma^{(c)} = (\Gamma^{(c)}_{jl})_{j,l=1,\dots,N}$. The first eigenvalue of this matrix is zero and the associated eigenvector is the uniform distribution over $\{1,\dots,N\}$. The second eigenvalue can be written in the form $-1/L_{\text{equip}}$, which defines the equipartition distance L_{equip}.

We next determine the asymptotic distribution of the process $\mathcal{B}_z$. From the ergodic theorem we have that with probability one,

$$\frac{\mathcal{B}_z}{z} \overset{z\to\infty}{\longrightarrow} \overline{\beta'(\omega)}\,, \text{ where } \overline{\beta'(\omega)} = \frac{1}{N(\omega)}\sum_{j=1}^{N(\omega)} \beta'_j(\omega)\,. \tag{6.12}$$

We can interpret the z large limit to mean that z is considerably larger than L_{equip}.

For a planar waveguide we have that $\beta_j = \sqrt{\omega^2/c^2 - \pi^2 j^2/d^2}$ and $N(\omega) = [(\omega d)/(\pi\bar{c})]$. In the continuum limit $N(\omega)\gg 1$, we obtain the expression $\overline{\beta'(\omega)} = \pi/(2\bar{c})$, which is independent of ω. This ω independence property is likely to hold for a broad class of waveguides.

By applying a central limit theorem for functionals of ergodic Markov processes, we find that, in distribution,

$$\frac{\mathcal{B}_z - \overline{\beta'(\omega)}z}{\sqrt{z}} \overset{z\to\infty}{\longrightarrow} \mathcal{N}(0,\sigma^2_{\beta'(\omega)})\,. \tag{6.13}$$

Here $\mathcal{N}(0,\sigma^2_{\beta'(\omega)})$ is a zero-mean Gaussian random variable with variance

$$\sigma^2_{\beta'(\omega)} = 2\int_0^\infty \mathbb{E}_e\left[(\beta'_{J_0}(\omega)-\overline{\beta'(\omega)})(\beta'_{J_s}(\omega)-\overline{\beta'(\omega)})\right] ds\,, \tag{6.14}$$

where $\mathbb{E}_e$ stands for expectation with respect to the stationary process J_z. These limit theorems imply that when $L \gg L_{\rm equip}$, we have

$$\mathcal{T}_j^{(n)}(\omega, L) \overset{L\gg L_{\rm equip}}{\simeq} \frac{1}{N(\omega)}\,, \tag{6.15}$$

$$\mathcal{W}_j^{(n)}(\omega,\tau,L) \overset{L\gg L_{\rm equip}}{\simeq} \frac{1}{N(\omega)}\frac{1}{\sqrt{2\pi\sigma^2_{\beta'(\omega)}L}}\exp\left(-\frac{(\tau-\overline{\beta'(\omega)}L)^2}{2\sigma^2_{\beta'(\omega)}L}\right)\,. \tag{6.16}$$

The asymptotic result (6.15) shows that $\mathcal{T}_j^{(n)}$ becomes independent of n, the initial mode index, and uniform over $j \in \{1,\dots,N(\omega)\}$. This is the regime of energy equipartition among all propagating modes. The asymptotic result (6.16) is equivalent to the diffusion approximation for the system of transport equations (6.6).

7. Pulse propagation in random waveguides. We consider the transmitted field (5.2) obtained in the setup described in section 5, and we now address the case of a random waveguide. By Proposition 6.1, the mean transmitted field in the asymptotic $\varepsilon \to 0$ is given by

$$\mathbb{E}[p^\varepsilon_{tr}(t,\mathbf{x},L)] = \frac{1}{2}\sum_{j=1}^N \phi_j(\mathbf{x})\phi_j(\mathbf{x}_0)\bar{T}_j(\omega_0,L)e^{i\frac{\beta_j(\omega_0)L-\omega_0 t}{\varepsilon^2}} f\left(t-\beta_j'(\omega_0)L\right)\,.$$

As in the homogeneous case, the mean field is a superposition of modes in the random case, but the mean transmission coefficients are exponentially damped and vanish for L large, $L > L_{\rm equip}(\omega_0)$. Therefore, the mean field vanishes for large L. We now turn our attention to the mean intensity, which accounts for the conversion of the coherent field into incoherent wave fluctuations. We express the transmitted intensity as the expectation of a double integral

$$\begin{aligned}\mathbb{E}\left[\left|p^\varepsilon_{tr}(t,\mathbf{x},L)\right|^2\right] = \frac{1}{16\pi^2}\sum_{j,l=1}^N\sum_{m,n=1}^N \frac{\sqrt{\beta_l\beta_n}}{\sqrt{\beta_j\beta_m}}\phi_j(\mathbf{x})\phi_l(\mathbf{x}_0)\phi_m(\mathbf{x})\phi_n(\mathbf{x}_0)\\ \times e^{i\frac{[\beta_j(\omega_0)-\beta_m(\omega_0)]L}{\varepsilon^2}}\int\int \hat{f}\,(h)\,\overline{\hat{f}\,(h')}\mathbb{E}[T^\varepsilon_{jl}(\omega_0+\varepsilon^2 h)\overline{T^\varepsilon_{mn}(\omega_0+\varepsilon^2 h')}]\\ \times e^{i[\beta_j'(\omega_0)L-t]h-[\beta_m'(\omega_0)L-t]h'}dhdh'\,.\end{aligned}$$

Using Proposition 6.3 we see that there are two contributions to this integral:

$$\mathbb{E}\left[\left|p^\varepsilon_{tr}(t,\mathbf{x},L)\right|^2\right] = I_1^\varepsilon(t,\mathbf{x},L) + I_2^\varepsilon(t,\mathbf{x},L)\,. \tag{7.1}$$

The limit of the first contribution is

$$\begin{aligned}I_1^\varepsilon(t,\mathbf{x},L) \overset{\varepsilon\to 0}{\simeq} \frac{1}{4}\sum_{j\neq m=1}^N \phi_j(\mathbf{x})\phi_j(\mathbf{x}_0)\phi_m(\mathbf{x})\phi_m(\mathbf{x}_0)e^{i\frac{[\beta_j(\omega_0)-\beta_m(\omega_0)]L}{\varepsilon^2}}\\ \times e^{Q_{jm}(\omega_0)L}f(t-\beta_j'(\omega_0)L)f(t-\beta_m'(\omega_0)L)\,.\end{aligned} \tag{7.2}$$

We see that it decays exponentially with the propagation distance because of the damping factors $\exp(Q_{jm}(\omega_0)L)$. We can therefore neglect this contribution for $L \gg L_{\rm equip}(\omega_0)$. The limit of the second contribution is

$$I_2^\varepsilon(t,\mathbf{x},L) \overset{\varepsilon\to 0}{\simeq} \frac{1}{4}\sum_{j,l=1}^N \frac{\beta_l}{\beta_j}\phi_j^2(\mathbf{x})\phi_l^2(\mathbf{x}_0)\int \mathcal{W}_j^{(l)}(\omega_0,\tau,L)f(t-\tau)^2 d\tau\,. \tag{7.3}$$

In the asymptotic equipartition regime $L \gg L_{\rm equip}(\omega_0)$ we use the diffusion approximation (6.16). We conclude that

$$\lim_{\varepsilon\to 0} \mathbb{E}\left[\left|p^\varepsilon_{tr}\left(t,\mathbf{x},L\right)\right|^2\right] \overset{L\gg L_{\rm equip}}{\simeq} H_{\omega_0,\mathbf{x}_0}(\mathbf{x}) \times [K_{\omega_0,L} * (f^2)](t)\,, \tag{7.4}$$

where the spatial profile $H_{\omega_0,\mathbf{x}_0}$ and the time convolution kernel $K_{\omega_0,L}$ are given by

$$H_{\omega_0,\mathbf{x}_0}(\mathbf{x}) = \frac{1}{4N(\omega_0)} \sum_{j=1}^{N(\omega_0)} \frac{\phi_j^2(\mathbf{x})}{\beta_j(\omega_0)} \times \sum_{l=1}^{N(\omega_0)} \phi_l^2(\mathbf{x}_0)\beta_l(\omega_0)\,, \tag{7.5}$$

$$K_{\omega_0,L}(t) = \frac{1}{\sqrt{2\pi\sigma^2_{\beta'(\omega_0)}L}} \exp\left(-\frac{(t-\overline{\beta'(\omega_0)}L)^2}{2\sigma^2_{\beta'(\omega_0)}L}\right). \tag{7.6}$$

To sum up, the main results of this section are that

- the mean field decays exponentially with propagation distance,
- the mean transmitted intensity converges to the transverse spatial profile $H_{\omega_0,\mathbf{x}_0}$, and
- the mean transmitted intensity is concentrated around the time $\overline{\beta'(\omega_0)}L$ with a spread that is of the order of $\sigma_{\beta'(\omega_0)}\sqrt{L} \sim \sqrt{L L_{\rm equip}(\omega_0)}/\bar{c}$ for a pulse with carrier frequency ω_0.

Note that $\sigma_{\beta'(\omega_0)}\sqrt{L} \ll L/\bar{c}$, which means that pulse spreading increases as $\sqrt{L}$ in a random waveguide while it increases linearly in a homogeneous one. This is because the modes are strongly coupled together and propagate with the same "average" group velocity $1/\overline{\beta'(\omega_0)}$ in the random waveguide. The "average" group velocity is the harmonic average of the group velocities of the modes $1/\beta'_j(\omega_0)$. These results are intuitively clear, but they were not discussed in detail in the early literature [14, 5]. We note that in (7.4) it is the mean of the pulse intensity that has the asymptotic form that we have derived. The pulse intensity fluctuations can also be computed and are not small.

8. Time reversal in a waveguide.

8.1. Time reversal setup. We now consider time reversal in a waveguide. A point source located in the plane $z = 0$ at the lateral position $\mathbf{x}_0$ emits a pulse $f^\varepsilon(t)$ of the form (5.1). A time-reversal mirror is located in the plane $z = L/\varepsilon^2$ and occupies the subdomain $\mathcal{D}_M \subset \mathcal{D}$. The transmitted wave observed in the plane $z = L/\varepsilon^2$ at time t/ε^2 is (5.2). The time-reversal mirror records the field from time t_0/ε^2 up to time t_1/ε^2, time reverses it, and sends it back into the waveguide. The new source at the time-reversal mirror that generates the back propagating waves is

$$\begin{aligned}\mathbf{F}^\varepsilon_{\rm TR}(t,\mathbf{x},z) &= f^\varepsilon_{\rm TR}(t,\mathbf{x})\delta\left(z-\frac{L}{\varepsilon^2}\right)\mathbf{e}_z\,,\\ f^\varepsilon_{\rm TR}(t,\mathbf{x}) &= p^\varepsilon_{tr}\left(t_1-\varepsilon^2 t,\mathbf{x},L\right) G_1(t_1-\varepsilon^2 t) G_2(\mathbf{x})\,,\end{aligned} \tag{8.1}$$

where p^ε_{tr} is given by (5.2), G_1 is the time-window function of the form $G_1(t) = \mathbf{1}_{[t_0,t_1]}(t)$, and G_2 is the spatial-window function $G_2(\mathbf{x}) = \mathbf{1}_{\mathcal{D}_M}(\mathbf{x})$. We have seen that the power delay spread of the transmitted signal is not very long in the forward scattering approximation. This is because there is no backscattering to produce long codas (i.e., long incoherent wave fluctuations). Moreover, we focus our attention more on spatial effects in this paper, so it is reasonable to assume that we record the

field for all time at the time-reversal mirror. This means that we have $G_1(t) = 1$ and $\hat{G}_1(h) = 2\pi\delta(h)$. Therefore, the left-going propagating modes generated by this source have amplitudes

$$\hat{b}_m(\omega) = -\frac{\sqrt{\beta_m(\omega)}}{2}\int_{\mathcal{D}} \hat{f}^{\varepsilon}_{\rm TR}(\omega,\mathbf{x})\phi_m(\mathbf{x})d\mathbf{x}e^{i\beta_m(\omega)\frac{L}{\varepsilon^2}}$$

$$= \frac{1}{4\varepsilon^2}\sum_{j,l=1}^{N}\frac{\sqrt{\beta_l\beta_m}}{\sqrt{\beta_j}}M_{mj}\phi_l(\mathbf{x}_0)\overline{\hat{f}\left(\frac{\omega-\omega_0}{\varepsilon^2}\right)}\,\overline{T^{\varepsilon}_{jl}(\omega)}e^{i[\beta_m(\omega)-\beta_j(\omega)]\frac{L}{\varepsilon^2}+i\omega\frac{t_1}{\varepsilon^2}}\,, \tag{8.2}$$

where the coupling coefficients M_{jl} are given by

$$M_{jl} = \int_{\mathcal{D}} \phi_j(\mathbf{x})G_2(\mathbf{x})\phi_l(\mathbf{x})d\mathbf{x}\,. \tag{8.3}$$

We have explicit formulas for the coupling coefficients M_{jl} in two cases as follows:

- If the mirror spans the complete cross section $\mathcal{D}$ of the waveguide, then we have $G_2(\mathbf{x}) = 1$ and $M_{jl} = \delta_{jl}$.
- If the mirror is point-like at $\mathbf{x} = \mathbf{x}_1$, meaning $G_2(\mathbf{x}) = |\mathcal{D}|\delta(\mathbf{x}-\mathbf{x}_1)$, with the factor $|\mathcal{D}|$ added for dimensional consistency, then $M_{jl} = |\mathcal{D}|\phi_j(\mathbf{x}_1)\phi_l(\mathbf{x}_1)$.

The refocused field observed in the plane $z = 0$ in the Fourier domain is given by

$$\hat{p}_{\rm TR}(\omega,\mathbf{x},0) = \sum_{m,n=1}^{N}\frac{(\mathbf{T}^{\varepsilon})^T_{nm}(\omega)\hat{b}_m(\omega)}{\sqrt{\beta_n}}\phi_n(\mathbf{x})\,. \tag{8.4}$$

Here $(\mathbf{T}^{\varepsilon})^T(\omega)$ is the transfer matrix for the left-going modes propagating from L/ε^2 to 0, and it is the transpose of $\mathbf{T}^{\varepsilon}(\omega)$. This follows from the unitarity of the transfer matrix $\mathbf{T}^{\varepsilon}(\omega)$. In the time domain, the refocused field observed at time $t_{\rm obs}/\varepsilon^2$ is

$$p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x},0\right) = \frac{1}{4\pi}\sum_{j,l,m,n=1}^{N}\frac{\sqrt{\beta_l\beta_m}}{\sqrt{\beta_j\beta_n}}M_{mj}\phi_n(\mathbf{x})\phi_l(\mathbf{x}_0)e^{i[\beta_m-\beta_j](\omega_0)\frac{L}{\varepsilon^2}+i\omega_0\frac{t_1-t_{\rm obs}}{\varepsilon^2}}$$

$$\times\int\overline{\hat{f}\,(h)}\,\overline{T^{\varepsilon}_{jl}(\omega_0+\varepsilon^2 h)}T^{\varepsilon}_{mn}(\omega_0+\varepsilon^2 h)e^{i\{[\beta'_m-\beta'_j](\omega_0)L+(t_1-t_{\rm obs})\}h}dh\,. \tag{8.5}$$

8.2. Refocusing in a homogeneous waveguide. In this case, $T^{\varepsilon}_{jl} = \delta_{jl}$ and the refocused field is

$$p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x},0\right) = \frac{1}{2}e^{i\omega_0\frac{t_1-t_{\rm obs}}{\varepsilon^2}}\sum_{j,m=1}^{N}e^{i[\beta_m-\beta_j](\omega_0)\frac{L}{\varepsilon^2}}$$

$$\times M_{mj}\phi_m(\mathbf{x})\phi_j(\mathbf{x}_0)f\left([\beta'_m-\beta'_j](\omega_0)L+t_1-t_{\rm obs}\right)\,. \tag{8.6}$$

The refocused field is a weighted sum of modes, whose weights depend on the mirror through the coefficients M_{mj}. The oscillatory terms in (8.6) produce transverse sidelobes in the refocused field, as seen in Figure 8.1.

8.3. The mean refocused field in a random waveguide. In the analysis of time reversal considered up to now [3, 9, 2, 21], statistical stability is shown by a frequency decoherence argument. More precisely, it is shown that the refocused field is the superposition of many approximately uncorrelated frequency components, which ensures self-averaging in the time domain. This argument cannot be used in

the narrowband case (5.1) that we consider here. This is because the decoherence frequency, which is of order ε^2, is comparable to the bandwidth, which is also of order ε^2. In broadband cases with a bandwidth of order ε^p, $p \in [0,2)$, statistical stability can be obtained by the usual frequency decoherence argument [10].

First we compute the mean refocused field and then consider the statistical stability. By taking the expectation of (8.5), we find that the mean refocused field involves the second-order moments of the transfer matrix. From Proposition 6.3 we have the limit values of these second-order moments, so we can write

$$\mathbb{E}\left[p_{\mathrm{TR}}\left(\frac{t_{\mathrm{obs}}}{\varepsilon^2},\mathbf{x},0\right)\right] = p_1^\varepsilon + p_2^\varepsilon\,, \tag{8.7}$$

$$p_1^\varepsilon \overset{\varepsilon\to 0}{\simeq} \frac{1}{2}\sum_{j\neq m=1}^{N} M_{mj}\phi_m(\mathbf{x})\phi_j(\mathbf{x}_0)e^{i[\beta_m-\beta_j](\omega_0)\frac{L}{\varepsilon^2}+i\omega_0\frac{t_1-t_{\mathrm{obs}}}{\varepsilon^2}} \times e^{Q_{jm}(\omega_0)L} f\left([\beta'_m-\beta'_j](\omega_0)L+t_1-t_{\mathrm{obs}}\right)\,,$$

$$p_2^\varepsilon \overset{\varepsilon\to 0}{\simeq} \frac{1}{2}e^{i\omega_0\frac{t_1-t_{\mathrm{obs}}}{\varepsilon^2}} f\left(t_1-t_{\mathrm{obs}}\right)\sum_{j,l=1}^{N} M_{jj}\phi_l(\mathbf{x})\phi_l(\mathbf{x}_0)\mathcal{T}_j^{(l)}(\omega_0,L)\,.$$

The term p_1^ε decays exponentially with propagation distance because of the damping factors coming from Q_{jm}. We can therefore neglect this term in the asymptotic equipartition regime. The term p_2^ε does contribute and it refocuses around the time $t_{\mathrm{obs}} = t_1$ with the original pulse shape time reversed. The spatial focusing profile is a weighted sum of modes, with weights that depend on the time-reversal mirror through the coefficients M_{jl} and on the mean square transmission coefficients $\mathcal{T}_j^{(l)}$.

In the asymptotic equipartition regime $L \gg L_{\mathrm{equip}}$, the coefficients $\mathcal{T}_j^{(l)}(\omega_0,L)$ converge to $1/N$ for all j and l, which for the mean refocused field gives

$$\lim_{\varepsilon\to 0}\mathbb{E}\left[p_{\mathrm{TR}}\left(\frac{t_{\mathrm{obs}}}{\varepsilon^2},\mathbf{x},0\right)\right] \overset{L\gg L_{\mathrm{equip}}}{\simeq} e^{i\omega_0\frac{t_1-t_{\mathrm{obs}}}{\varepsilon^2}} f\left(t_1-t_{\mathrm{obs}}\right) \times\frac{1}{N(\omega_0)}\sum_{j}^{N(\omega_0)} M_{jj}\times\frac{1}{2}\sum_{l=1}^{N(\omega_0)}\phi_l(\mathbf{x})\phi_l(\mathbf{x}_0)\,. \tag{8.8}$$

We note the difference between this expression and (8.6) in a homogeneous waveguide. The oscillatory terms in (8.6) which generate the side-lobes are suppressed in (8.8). The analytical understanding of side-lobe suppression in time reversal in random waveguides is a new result in this paper.

The spatial refocusing profile can then be computed explicitly because it does not depend on the mirror shape or size. In the case of a planar waveguide, we have $\phi_j(x) = \sqrt{2/d}\sin(\pi jx/d)$, and in the continuum limit $N \gg 1$, we have

$$\frac{1}{2}\sum_{l=1}^{N}\phi_l(x)\phi_l(x_0) \overset{N\gg 1}{\simeq} \frac{1}{\lambda_0}\mathrm{sinc}\left(2\pi\frac{x-x_0}{\lambda_0}\right)\,.$$

The mean refocused field is therefore concentrated around the original source location x_0 with a resolution of half of a wavelength, which is the diffraction limit.

8.4. Statistical stability of the refocused field. As we noted already, we cannot claim that the refocused field is statistically stable by using the same argument

as in the broadband case, because here we have a narrowband pulse. However, we can achieve statistical stability through the summation over the modes. We will show this in the quasi-monochromatic case, where the pulse envelope $f(t) = 1$ and $\hat{f}(h) = 2\pi\delta(h)$. In this case, it is clear that statistical stability cannot arise from time averaging, and the refocused field is

$$p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x},0\right) = \frac{1}{2}\sum_{j,l,m,n=1}^{N}\frac{\sqrt{\beta_l\beta_m}}{\sqrt{\beta_j\beta_n}}M_{mj}\phi_n(\mathbf{x})\phi_l(\mathbf{x}_0) \times e^{i[\beta_m-\beta_j](\omega_0)\frac{L}{\varepsilon^2}+i\omega_0\frac{t_1-t_{\rm obs}}{\varepsilon^2}}\overline{T^\varepsilon_{jl}(\omega_0)}T^\varepsilon_{mn}(\omega_0)\,. \tag{8.9}$$

From (8.8), the mean refocused field at $\mathbf{x} = \mathbf{x}_0$ is in the asymptotic equipartition regime

$$\lim_{\varepsilon\to 0}\mathbb{E}\left[p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x}_0,0\right)\right] \overset{L\gg L_{\rm equip}}{\simeq} e^{i\omega_0\frac{t_1-t_{\rm obs}}{\varepsilon^2}}\frac{R_0^2}{2N}\sum_{j=1}^{N}M_{jj}\,, \tag{8.10}$$

where $R_0^2 = \sum_{l=1}^{N}\phi_l^2(\mathbf{x}_0)$. We now compute the second moment of the refocused field observed at $\mathbf{x} = \mathbf{x}_0$. By taking the expectation of the square of (8.9), we find that this moment involves fourth-order moments of the transfer matrix. From the results of section 4.3, we have

$$\lim_{\varepsilon\to 0}\mathbb{E}[\overline{T^\varepsilon_{jl}}T^\varepsilon_{mn}\overline{T^\varepsilon_{j'l'}}T^\varepsilon_{m'n'}] \overset{L\gg L_{\rm equip}}{\simeq} \begin{cases} \frac{2}{N(N+1)} & \text{if } (j,l)=(m,n)=(j',l')=(m',n')\,,\\ \frac{1}{N(N+1)} & \text{if } (j,l)=(m,n)\neq(j',l')=(m',n')\,,\\ \frac{1}{N(N+1)} & \text{if } (j,l)=(m',n')\neq(j',l')=(m,n)\,,\\ 0 & \text{otherwise}\,. \end{cases}$$

Using these fourth-order moment results in the expression for the second moment of the refocused field we see that, in the limit $\varepsilon \to 0$ and in the asymptotic equipartition regime $L \gg L_{\rm equip}$,

$$\lim_{\varepsilon\to 0}\mathbb{E}\left[\left|p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x}_0,0\right)\right|^2\right] \overset{L\gg L_{\rm equip}}{\simeq} \frac{R_0^4}{4N(N+1)}\left[\left(\sum_j M_{jj}\right)^2+\sum_{j,j'}M_{jj'}^2\right].$$

Let us introduce the relative standard deviation S of the refocused field amplitude,

$$S^2 := \lim_{\varepsilon\to 0}\frac{\mathbb{E}\left[\left|p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x}_0,0\right)\right|^2\right]-\left|\mathbb{E}\left[p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x}_0,0\right)\right]\right|^2}{\left|\mathbb{E}\left[p_{\rm TR}\left(\frac{t_{\rm obs}}{\varepsilon^2},\mathbf{x}_0,0\right)\right]\right|^2}\,. \tag{8.11}$$

We have statistical stability when S is small. In the asymptotic equipartition regime, S^2 is given by

$$S^2 \overset{L\gg L_{\rm equip}}{\simeq} -\frac{1}{N+1}+\frac{N}{N+1}\frac{1}{Q_{\rm mirror}}\,,\qquad Q_{\rm mirror} = \frac{\sum_{j,l=1}^{N}M_{jj}M_{ll}}{\sum_{j,l=1}^{N}M_{jl}^2}\,. \tag{8.12}$$

The quality factor $Q_{\rm mirror}$ depends only on the time-reversal mirror. We will have statistical stability when the number of modes N is large and when the quality factor $Q_{\rm mirror}$ is large. This analytical criterion for statistical stability in narrowband time reversal is a new result in this paper.

We can consider two extreme cases:

- If the time-reversal mirror spans the waveguide cross section, then $M_{jl} = \delta_{jl}$ and the quality factor is equal to N, which is optimal since the relative standard deviation is then zero for any N. This result is not surprising since the time-reversal mirror records the transmitted signal fully, in both time and space, which implies optimal refocusing.
- If the time-reversal mirror is point-like at $\mathbf{x}_1$, then $M_{jl} = \phi_j(\mathbf{x}_1)\phi_l(\mathbf{x}_1)$ and the quality factor is 1, which is bad, because the relative standard deviation S is asymptotically equal to $\sqrt{N-1}/\sqrt{N+1}$. The fluctuations of the refocused field are, therefore, of the same order as the mean field, which means that there is no statistical stability.

In the next section, we address a particular case which allows explicit calculations.

8.5. Numerical illustration. In this section we illustrate the time reversal results in the quasi-monochromatic case for a particular random waveguide. We consider a random planar waveguide with diameter d. The random process ν is stationary and mixing in the z-direction. Its autocorrelation function is

$$\mathbb{E}[\nu(x,z)\nu(x',z')] = \sigma^2 \exp\left(-\frac{|z-z'|}{l_c}\right) R(x,x')\,,$$

where the support of R is contained in $[0,d]^2$, σ is the standard deviation of the medium fluctuations, and l_c is the axial correlation length. This decomposition of the autocorrelation function makes it easy to compute the effective coefficients $\Gamma^{(c)}_{jl}$, $\Gamma^{(s)}_{jl}$, and $\Gamma^{(1)}_{jl}$. We obtain

$$\gamma^{(c)}_{jl} = \frac{2\sigma^2 l_c G_{l,j}}{1+(\beta_j-\beta_l)^2 l_c^2}\,, \qquad \gamma^{(s)}_{jl} = \frac{2\sigma^2(\beta_j-\beta_l) l_c^2 G_{l,j}}{1+(\beta_j-\beta_l)^2 l_c^2}\,, \qquad \gamma^{(1)}_{jl} = 2 l_c G_{l,j}\,,$$
$$G_{l,j} = S_{j-l,j-l} + S_{j+l,j+l} - S_{j-l,j+l} - S_{j+l,j-l}\,,$$

where

$$S_{j,l} = \frac{1}{d^2}\int_0^d \int_0^d \cos\left(\frac{j\pi x}{d}\right)\cos\left(\frac{l\pi x'}{d}\right) R(x,x')dxdx'\,.$$

For simplicity, we shall make two hypotheses. First, we introduce a band-limiting idealization; i.e., we assume that the support of S lies with a finite square so that $S(j,l) \neq 0$ only if $|j| \leq 1$ and $|l| \leq 1$. Second, we assume that l_c is smaller than $\beta_j - \beta_{j-1}$ for all j. The expressions of the effective coefficients can then be simplified. The matrix $\Gamma^{(s)}_{jl}$ is essentially zero, while the matrices $\Gamma^{(c)}_{jl}$ and $\Gamma^{(s)}_{jl}$ are tridiagonal,

$$\Gamma^{(c)}_{jl} \simeq \Gamma^{(1)}_{jl} \simeq \frac{\omega^4\sigma^2 l_c d S_{1,1}}{4\bar{c}^4\beta_j(\omega)\beta_l(\omega)} \text{ if } |j-l| = 1\,, \qquad \Gamma^{(1)}_{jj} \simeq \frac{\omega^4\sigma^2 l_c d S_{0,0}}{4\bar{c}^4\beta_j^2(\omega)}\,,$$

and $\Gamma^{(c)}_{jj}$ is chosen so that the lines of the matrix are zero.

Homogeneous waveguide. In the homogeneous case the spatial profile of the refocused field is (8.6). Let us consider a time-reversal mirror of size a located in $x \in [d/2-a/2, d/2+a/2]$: $G_2(x) = \mathbf{1}_{[d/2-a/2,d/2+a/2]}(x)$. We then have

$$M_{jl} = \frac{a}{d}\left[\cos\left(\frac{(j-l)\pi}{2}\right)\operatorname{sinc}\left(\frac{(j-l)\pi a}{2d}\right) - \cos\left(\frac{(j+l)\pi}{2}\right)\operatorname{sinc}\left(\frac{(j+l)\pi a}{2d}\right)\right].$$

Using these formulas, we plot in Figure 8.1 the spatial profile of the refocused field for different sizes a of the time-reversal mirror. The peak at the original source location is there in all cases, but for small time-reversal mirrors, large side-lobes appear.

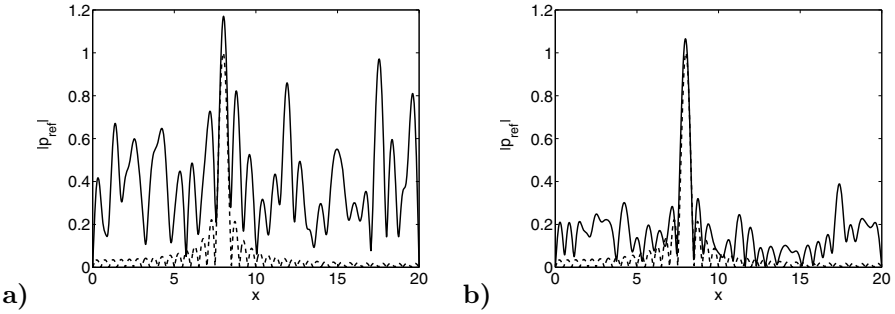

FIG. 8.1. *Transverse profile of the refocused field in a homogeneous waveguide with diameter d and length L. Here $d = 20$, $L = 200$, and $\lambda_0 = 1$, so there are 40 modes. The original source location is $x_0 = 8$. The dashed curve is the sinc profile, which is the focusing profile of a full-size time-reversal mirror. The solid curves are refocusing profiles for time-reversal mirrors of size $a = 2.5$* (a) *and $a = 10$* (b).

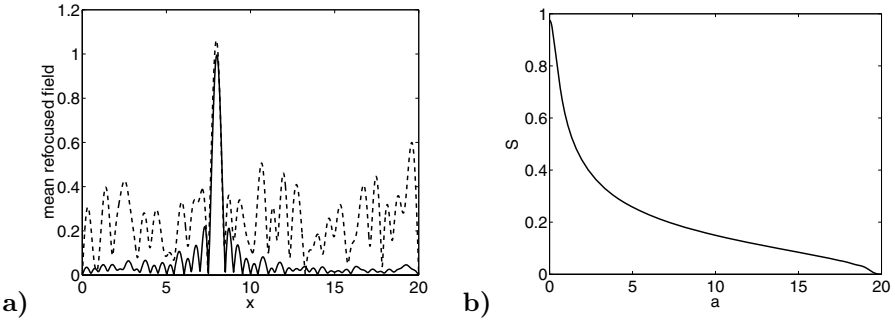

FIG. 8.2. (a) *Transverse profile of the mean refocused field in a random waveguide with diameter d and length L. Here $d = 20$, $L = 200$, $\lambda_0 = 1$, the time-reversal mirror has size $a = 5$, and the original source location is $x_0 = 8$. The axial correlation length of the random medium is $l_c = 0.25$ and the random fluctuations have standard deviation σ. The dashed curve is the spatial profile obtained in homogeneous medium $\sigma = 0$. The solid lines stand for the mean profiles obtained in random media $\sigma = 0.015$. The random case is very close to the equipartition regime, for which the focusing profile is a sinc.* (b) *The relative standard deviation S, from* (8.12)*, of the refocused field in the equipartition regime as a function of the mirror size a. Here $d = 20$ and $\lambda_0 = 1$.*

Random waveguide. The mean spatial profile of the refocused field is (8.7). In the absence of randomness, this formula reduces to (8.6). The mean spatial profile is plotted in Figure 8.2(a), which illustrates the transition from the poor spatial refocusing in a homogeneous medium to the diffraction-limited refocusing obtained in the equipartition regime. In the equipartition regime $L \gg L_{\rm equip}$, the mean spatial profile is given by (8.8) and becomes independent of the mirror size, up to an amplitude factor. However, the statistical stability of the refocused field depends on the size of the time-reversal mirror, as shown in Figure 8.2(b).

9. Summary and conclusions. The main result of this paper is the derivation from first principles of the system of transport equations (6.6) for the coupled mode powers, in the asymptotic limit of section 3. It is easy to write such equations by simply adding a time-dispersive term in (4.11). We identify here the field quantity that has the mean which satisfies this space-time transport equation.

We apply the transport equation (6.6) to pulse spreading in order to get (7.4),

which shows how randomness reduces time dispersion at the expense of introducing random fluctuations. We also apply it to time reversal in a random waveguide, in a narrowband regime, and show in (8.8) how side-lobes are suppressed in refocusing. We also show in (8.12) how statistical stability depends on the quality factor Q_{mirror}. This quality factor does not depend on the random medium in the energy equipartition regime, but it does depend on the size of the time-reversal mirror relative to the waveguide cross section.

THE DYNAMICS AND INTERACTION OF QUANTIZED VORTICES IN THE GINZBURG–LANDAU–SCHRÖDINGER EQUATION*

YANZHI ZHANG†, WEIZHU BAO‡, AND QIANG DU§

Abstract. The dynamic laws of quantized vortex interactions in the Ginzburg–Landau–Schrödinger equation (GLSE) are analytically and numerically studied. A review of the reduced dynamic laws governing the motion of vortex centers in the GLSE is provided. The reduced dynamic laws are solved analytically for some special initial data. By directly simulating the GLSE with an efficient and accurate numerical method proposed recently in [Y. Zhang, W. Bao, and Q. Du, *Numerical simulation of vortex dynamics in Ginzburg–Landau–Schrödinger equation*, European J. Appl. Math., to appear], we can qualitatively and quantitatively compare quantized vortex interaction patterns of the GLSE with those from the reduced dynamic laws. Some conclusive findings are obtained, and discussions on numerical and theoretical results are made to provide further understanding of vortex interactions in the GLSE. Finally, the vortex motion under an inhomogeneous potential in the GLSE is also studied.

1. Introduction.

One of the most well-studied equations in nonlinear science is the Ginzburg–Landau–Schrödinger equation (GLSE) of the form [36]

$$(\alpha - i\beta)\partial_t \psi(\mathbf{x}, t) = \nabla^2 \psi + \frac{1}{\varepsilon^2}\left(V(\mathbf{x}) - |\psi|^2\right)\psi, \qquad \mathbf{x} \in \mathbb{R}^2, \quad t > 0, \tag{1.1}$$

$$\psi(\mathbf{x}, 0) = \psi_0(\mathbf{x}), \qquad \mathbf{x} \in \mathbb{R}^2. \tag{1.2}$$

Here, t is time, $\mathbf{x} = (x, y)^T \in \mathbb{R}^2$ is the Cartesian coordinate vector, (r, θ) is the polar coordinate system, $\psi = \psi(\mathbf{x}, t)$ is a complex-valued wave function (or order parameter), $V(\mathbf{x})$ is a real-valued external potential satisfying $\lim_{|\mathbf{x}|\to\infty} V(\mathbf{x}) = 1$, $\varepsilon > 0$ is a constant, and α and β are two nonnegative constants satisfying $\alpha + \beta > 0$. A vortex-like solution satisfies a nonzero far-field condition as follows: For a given integer $m \in \mathbb{Z}$,

$$|\psi(\mathbf{x}, t)| \to 1 \text{ (e.g., } \psi \to e^{im\theta}), \quad t \geq 0, \quad \text{when } r = |\mathbf{x}| = \sqrt{x^2 + y^2} \to \infty. \tag{1.3}$$

The GLSE (1.1) describes a large variety of nonlinear phenomena, including nonlinear waves, phase transitions, superconductivity, superfluidity, liquid crystals, and

strings in the field theory. For example, when $\alpha = 1$ and $\beta = 0$, it collapses into the nonlinear heat equation (NLHE) or the Ginzburg–Landau equation (GLE) [27, 28]. The GLE with a complex order parameter is well known for modeling superconductivity [10, 11, 14, 12, 19], while that with a real order parameter corresponds to the Allen–Cahn equation in phase transition [13]. When $\alpha = 0$ and $\beta = 1$, the GLSE reduces to the nonlinear Schrödinger equation (NLSE) [27, 31, 22] for modeling, for example, superfluidity or Bose–Eistein condensation (BEC). While $\alpha > 0$ and $\beta > 0$, it is the complex Ginzburg–Landau equation (CGLE), or NLSE with a damping term [3], which also arises in the study of the hydrodynamic instability [1].

It is known that there are stationary *vortex solutions* with a single winding number or index $m \in \mathbb{Z}$ of the GLSE (1.1) with $\varepsilon = 1$ and $V(\mathbf{x}) \equiv 1$ [27, 14, 36], which take the form

$$\phi_m(\mathbf{x}) = f_m(r)\, e^{im\theta}, \qquad \mathbf{x} = (r\cos\theta, r\sin\theta)^T \in \mathbb{R}^2, \tag{1.4}$$

where the modulus $f_m(r)$ is a real-valued function satisfying

$$\frac{1}{r}\frac{d}{dr}\left(r\frac{df_m(r)}{dr}\right) - \frac{m^2}{r^2} f_m(r) + \left(1 - f_m^2(r)\right) f_m(r) = 0, \qquad 0 < r < \infty, \tag{1.5}$$

$$f_m(0) = 0, \qquad f_m(r) = 1 \quad \text{when} \quad r \to \infty. \tag{1.6}$$

The modulus as well as the core sizes of such vortex states have been calculated in the literature [27, 36] by numerically solving the boundary value problem (1.5)–(1.6). Numerical and analytical results suggest that the vortex states with winding number $m = \pm 1$ are dynamically stable, and, respectively, $|m| > 1$ dynamically unstable [27, 34, 25, 26, 22, 2, 36] (note that the stability and interaction laws of a quantized vortex in the Gross–Pitaevskii equation for BEC [3, 4, 5] may be very different from that studied here due to the different far-field boundary conditions).

In this paper, we study the GLSE (1.1) with initial conditions containing several, say N, vortices. A precise definition of vortex solutions can be found in [22, 19]. We are mainly concerned with the following initial condition:

$$\psi_0(\mathbf{x}) = \prod_{j=1}^{N} \phi_{m_j}\left(\mathbf{x} - \mathbf{x}_j^0\right) = \prod_{j=1}^{N} \phi_{m_j}\left(x - x_j^0,\, y - y_j^0\right), \qquad \mathbf{x} \in \mathbb{R}^2, \tag{1.7}$$

where N is the total number of vortices and ϕ_{m_j} is the vortex state as defined in (1.4) with winding number $m_j = \pm 1$ (see [36] for their numerical solutions). We may then consider the interaction of N vortices with their initial centers shifted from the origin $(0,0)$ to $\mathbf{x}_j^0 = \left(x_j^0, y_j^0\right)^T$ $(1 \le j \le N)$. Taking $m = \sum_{j=1}^{N} m_j$ in (1.3), we refer to vortices with the same winding numbers as *like vortices* and those with different winding numbers as *opposite vortices*.

When $\varepsilon = 1$ and $V(\mathbf{x}) \equiv 1$ in (1.1), it is known that for N well-separated vortices of winding numbers $m_j = \pm 1$ and locations $\mathbf{x}_j$ $(1 \le j \le N)$, the leading asymptotic expansion of the energy is

$$E \sim \sum_{j=1}^{N} E_j - \pi \sum_{j \ne l} m_j\, m_l \ln\left|\mathbf{x}_l - \mathbf{x}_j\right|, \tag{1.8}$$

where E_j is the self-energy of the vortex at $\mathbf{x}_j$, and the second term corresponds to the well-known Kirchoff–Onsager Hamiltonian. From (1.8), we can obtain the

vortex dynamic laws of the induced motion in the leading order, i.e., the adiabatic approximation [27]. For the GLE, i.e., $\alpha = 1$ and $\beta = 0$ in (1.1), the vortex dynamics satisfies [27, 14, 15, 19]

$$\kappa \mathbf{v}_j(t) := \kappa \frac{d\mathbf{x}_j(t)}{dt} = 2m_j \sum_{l=1,\, l\neq j}^{N} m_l \frac{\mathbf{x}_j(t) - \mathbf{x}_l(t)}{|\mathbf{x}_j(t) - \mathbf{x}_l(t)|^2}, \qquad t \geq 0, \tag{1.9}$$

$$\mathbf{x}_j(0) = \mathbf{x}_j^0, \qquad 1 \leq j \leq N, \tag{1.10}$$

where κ is a constant determined from the initial setup (1.7). On the other hand, for the NLSE, i.e., $\alpha = 0$ and $\beta = 1$ in (1.1), it satisfies [27, 14, 8, 19]

$$\mathbf{v}_j(t) := \frac{d\mathbf{x}_j(t)}{dt} = 2 \sum_{l=1,\, l\neq j}^{N} m_l \frac{\mathbf{J}\,(\mathbf{x}_j(t) - \mathbf{x}_l(t))}{|\mathbf{x}_j(t) - \mathbf{x}_l(t)|^2}, \qquad t \geq 0, \tag{1.11}$$

$$\mathbf{x}_j(0) = \mathbf{x}_j^0, \qquad 1 \leq j \leq N, \tag{1.12}$$

where $\mathbf{J}$ is a symplectic matrix defined as

$$\mathbf{J} = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{1.13}$$

For asymptotic study of the vortex motions in the GLE and the NLSE, we refer to [7, 8, 9, 6, 20, 18, 29, 31, 32, 33, 35] and references therein.

The aim of this paper is to provide a more detailed and accurate account of the vortex dynamics governed by the GLSE, in particular, to address some open questions concerning the range of validity of the reduced dynamic laws. Our approach is to first solve analytically the ordinary differential equations (ODEs) (1.9) and (1.11) for any N under a few types of initial data, and then compare these solutions with those from direct simulation results of the GLSE (1.1) by using the efficient and accurate numerical method proposed recently in [36]. The key features of the numerical method include (i) the application of a time-splitting technique for decoupling the nonlinearity in the GLSE; (ii) the adoption of polar coordinates to effectively match and resolve the nonzero far-field conditions (1.3) in phase space; and (iii) the utilization of Fourier pseudospectral discretization in the transverse direction and a second order (or fourth order) finite difference or (finite element) discretization in the radial direction [36].

There are naturally many interesting issues concerning the vortex dynamics in various limiting cases, such as the interaction of well-separated vortices with smaller and smaller vortex cores ($\varepsilon \to 0$), and when the distances between the vortices become comparable with the core sizes (initially, both ε and the distances are of $O(1)$). Our approach and numerical methods are applicable to both of these situations, but due to page limitation, our main focus here is on the latter and we leave the discussion on the former to future studies. The main findings in this paper provide justification of the asymptotic vortex dynamic laws in some situations while unveiling limitations in other cases; they also reveal interesting phenomena on the sound wave propagation and the radiation effect associated with the vortex interaction.

The results of the paper are organized as follows. In section 2, based on the nonlinear ODEs of the reduced dynamic laws, we prove the conservation of the mass center and signed mass center of the N vortex centers, respectively, and solve analytically the reduced dynamic laws with a few types of initial data. In section 3, the dynamics and interaction of quantized vortices in the GLE are directly simulated by

solving (1.1) and compared with those from the reduced dynamic laws. Similar results for the NLSE are reported in section 4. The vortex motions in the CGLE, and in the GLSE under an inhomogeneous external potential, are reported in section 5. Finally, some conclusions are drawn in section 6.

2. The reduced dynamic laws. In this section, we first prove the conservation of the mass center and signed mass center of the N vortex centers in the reduced dynamic laws (1.9) and (1.11) for the GLE and the NLSE, respectively. These conservation properties can be used to solve the dynamic laws in special cases and to compare with the direct numerical simulation results of the GLE and the NLSE. We then solve the nonlinear ODEs analytically for several special types of initial data; such analytical solutions can again be compared with the numerical solutions of the GLE and the NLSE.

2.1. Conservation laws. Define, respectively, the mass center $\overline{\mathbf{x}}$ and the signed mass center $\widetilde{\mathbf{x}}$ of the N vortices as

$$\overline{\mathbf{x}}(t) := \frac{1}{N}\sum_{j=1}^{N}\mathbf{x}_j(t) \quad \text{and} \quad \widetilde{\mathbf{x}}(t) := \frac{1}{N}\sum_{j=1}^{N} m_j\,\mathbf{x}_j(t). \tag{2.1}$$

Let

$$Z_j = \sum_{l=1,\, l\neq j}^{N} m_l \frac{\mathbf{x}_j(t)-\mathbf{x}_l(t)}{|\mathbf{x}_j(t)-\mathbf{x}_l(t)|^2}.$$

It is easy to see that

$$\sum_{j=1}^{N} m_j Z_j = \sum_{j=1}^{N-1}\sum_{j<1\le N}^{N} m_j\, m_l \left[\frac{\mathbf{x}_j(t)-\mathbf{x}_l(t)}{|\mathbf{x}_j(t)-\mathbf{x}_l(t)|^2} + \frac{\mathbf{x}_l(t)-\mathbf{x}_j(t)}{|\mathbf{x}_l(t)-\mathbf{x}_j(t)|^2}\right] = 0. \tag{2.2}$$

Then we have the following.

LEMMA 2.1. *The mass center of the N vortices in the reduced dynamic laws* (1.9) *for the GLE is conserved, i.e.,*

$$\overline{\mathbf{x}}(t) := \frac{1}{N}\sum_{j=1}^{N}\mathbf{x}_j(t) \equiv \overline{\mathbf{x}}(0) := \frac{1}{N}\sum_{j=1}^{N}\mathbf{x}_j(0) = \frac{1}{N}\sum_{j=1}^{N}\mathbf{x}_j^0, \qquad t \ge 0. \tag{2.3}$$

Proof. Summing (1.9) for $1 \le j \le N$ and noting (2.1) and (2.2), we get for $t \ge 0$,

$$\frac{d\overline{\mathbf{x}}(t)}{dt} = \frac{1}{N}\sum_{j=1}^{N}\frac{d\mathbf{x}_j(t)}{dt} = \frac{2}{\kappa N}\sum_{j=1}^{N} m_j Z_j = 0.$$

Thus the conservation law (2.3) is a combination of the above and (1.7). ∎

Similarly, we have the following.

LEMMA 2.2. *The signed mass center of the N vortices in the reduced dynamic laws* (1.11) *for the NLSE is conserved, i.e.,*

$$\widetilde{\mathbf{x}}(t) := \frac{1}{N}\sum_{j=1}^{N} m_j\,\mathbf{x}_j(t) \equiv \widetilde{\mathbf{x}}(0) := \frac{1}{N}\sum_{j=1}^{N} m_j\,\mathbf{x}_j(0) = \frac{1}{N}\sum_{j=1}^{N} m_j\,\mathbf{x}_j^0, \quad t \ge 0. \tag{2.4}$$

Proof. Multiplying (1.11) by $m_j N \mathbf{J}^{-1}$, summing (1.11) for $1 \le j \le N$, and noting (2.1) and (2.2), we have for $t \ge 0$,

$$N\mathbf{J}^{-1}\frac{d\widetilde{\mathbf{x}}(t)}{dt} = \sum_{j=1}^{N} m_j \mathbf{J}^{-1}\frac{d\mathbf{x}_j(t)}{dt} = 2\sum_{j=1}^{N} m_j Z_j = 0.$$

Thus the conservation law (2.4) is a combination of the above and (1.7). ∎

2.2. Initial conditions used for the study of vortex dynamics. Due to the special structures of the nonlinear ODEs (1.9) and (1.11), we can solve them analytically when the N vortices are initially located symmetrically on a circle or at its center. By the conservation of the mass center and signed mass center in (1.9) and (1.11), we assume without loss of generality that the circle is centered at the origin with radius $r_0 = a > 0$.

For simplicity, we denote θ_0 as a given constant, denote $m_0 = +1$ or -1, and consider the following five patterns for the initial conditions in (1.7).

Pattern I. N ($N \ge 2$) like vortices uniformly located on a circle, i.e.,

$$\mathbf{x}_j^0 = a\left(\cos\left(\frac{2j\pi}{N}+\theta_0\right), \sin\left(\frac{2j\pi}{N}+\theta_0\right)\right)^T, \quad \text{and } m_j = m_0 \quad \text{for } 1 \le j \le N. \tag{2.5}$$

Pattern II. N ($N \ge 3$) like vortices located on a circle and its center, i.e.,

$$\mathbf{x}_N^0 = (0,0)^T, \qquad m_{_N} = m_0, \tag{2.6}$$

and for $1 \le j \le N-1$,

$$\mathbf{x}_j^0 = a\left(\cos\left(\frac{2j\pi}{N-1}+\theta_0\right), \sin\left(\frac{2j\pi}{N-1}+\theta_0\right)\right)^T \quad \text{with} \quad m_j = m_0. \tag{2.7}$$

Pattern III. The same as Pattern II, except $m_{_N} = -m_0$ for the center vortex.

Pattern IV. Two opposite vortices, i.e., for $j = 1, 2$,

$$\mathbf{x}_j^0 = a\left(\cos\left(j\pi+\theta_0\right), \sin\left(j\pi+\theta_0\right)\right)^T \quad \text{with} \quad m_1 = -m_2 = m_0. \tag{2.8}$$

Pattern V. Three vortices ($N = 3$) with nonsymmetric initial setups.

Here we consider the following three different cases (with $m_1 = m_3 = +1$):

Case 1. $\mathbf{x}_1^0 = (-a, -b/2)^T$, $\mathbf{x}_2^0 = (0, b)^T$, $\mathbf{x}_3^0 = (a, -b/2)^T$, $m_2 = +1$.

Case 2. $\mathbf{x}_1^0 = (-\sqrt{3}a/2, -a/2)^T$, $\mathbf{x}_2^0 = (0, a)^T$, $\mathbf{x}_3^0 = (\sqrt{3}a/2, -a/2)^T$, $m_2 = -1$.

Case 3. $\mathbf{x}_1^0 = (-a, -b/2)^T$, $\mathbf{x}_2^0 = (0, b)^T$, $\mathbf{x}_3^0 = (a, -b/2)^T$, $m_2 = -1$.

Notice that for all five types of patterns, we have $\overline{\mathbf{x}}(t) = \overline{\mathbf{x}}(0) = (0,0)^T$ for $t \ge 0$. Moreover, for the first three patterns and the first case of Pattern V, we have $\widetilde{\mathbf{x}}(t) = \widetilde{\mathbf{x}}(0) = 0$.

2.3. Analytical solutions of the reduced dynamics for the GLE. Noting (2.3), we can solve the nonlinear ODEs (1.9) analytically when the initial conditions in (1.10) are given by Patterns I–IV.

LEMMA 2.3. *If the initial data in* (1.10) *satisfy* (2.5)*, i.e., Pattern* I*, then the solutions of* (1.9)–(1.10) *can be given, for* $1 \le j \le N$ *with* $N \ge 2$*, by*

$$\mathbf{x}_j(t) = \sqrt{a^2 + \frac{2\,(N-1)}{\kappa}\,t}\,\left(\cos\left(\frac{2j\pi}{N}+\theta_0\right), \sin\left(\frac{2j\pi}{N}+\theta_0\right)\right)^T, \quad t \ge 0. \tag{2.9}$$

Proof. For any $N \geq 2$, based on the structures of the ODEs (1.9) and the initial data (2.5), we take the ansatz for the solution as

$$\mathbf{x}_j(t) = c_{_N}(t)\mathbf{x}_j^0, \qquad t \geq 0, \quad 1 \leq j \leq N, \tag{2.10}$$

where $c_{_N}(t)$ is a function of time t and $c_{_N}(0) = 1$. Substituting (2.10) into (1.9), applying a dot-product on both sides by $\mathbf{x}_j^0$, and noting (2.5), we get

$$\begin{aligned} c_{_N}'(t) &= \frac{2}{\kappa a^2 c_{_N}(t)} \sum_{l=1,\, l\neq j}^{N} m_j m_l \frac{(\mathbf{x}_j^0 - \mathbf{x}_l^0)\cdot \mathbf{x}_j^0}{|\mathbf{x}_j^0 - \mathbf{x}_l^0|^2} \\ &= \frac{2}{\kappa a^2 c_{_N}(t)} \sum_{l=1,\, l\neq j}^{N} \frac{a^2 - \mathbf{x}_l^0 \cdot \mathbf{x}_j^0}{2a^2 - 2\mathbf{x}_l^0 \cdot \mathbf{x}_j^0} = \frac{N-1}{\kappa a^2 c_{_N}(t)}, \quad t \geq 0. \end{aligned}$$

Solving the above ODE and noting that $c_{_N}(0) = 1$, we obtain

$$c_{_N}(t) = \sqrt{1 + \frac{2(N-1)}{a^2\kappa}\, t}, \qquad t \geq 0. \tag{2.11}$$

Thus the solution (2.9) is a combination of (2.10), (2.11), and (2.5). ∎

From the results in Lemma 2.3 we can see that, when the N vortices are uniformly located on a circle initially, i.e., as in Pattern I, by the reduced dynamic law each vortex moves outside along the line passing through its initial location and the origin, and these N vortices are located on a circle at any time t with its radius increasing by time $c_{_N}(t)$ as in (2.11).

LEMMA 2.4. *If the initial data in* (1.10) *satisfy* (2.6)–(2.7)*, i.e., Pattern* II*, then the solutions of* (1.9)–(1.10) *are*

$$\mathbf{x}_N(t) \equiv (0,0)^T, \qquad t \geq 0, \tag{2.12}$$

and for $1 \leq j \leq N-1$ *with* $N \geq 3$*,*

$$\mathbf{x}_j(t) = \sqrt{a^2 + \frac{2N}{\kappa}\, t}\, \left(\cos\left(\frac{2j\pi}{N-1} + \theta_0\right), \sin\left(\frac{2j\pi}{N-1} + \theta_0\right)\right)^T, \quad t \geq 0. \tag{2.13}$$

Proof. Due to the symmetry of the ODEs (1.9), the initial data (2.5), and the conservation of mass center (2.3), we can immediately obtain the solution (2.12). As in the proof of Lemma 2.3, we assume

$$\mathbf{x}_j(t) = d_N(t)\mathbf{x}_j^0, \qquad t \geq 0, \quad 1 \leq j \leq N-1,$$

where $d_N(t)$ is a function of time t and $d_N(0) = 1$. Substituting the above into (1.9), applying a dot-product on both sides by $\mathbf{x}_j^0$, and noting (2.7) and (2.12), we get

$$\begin{aligned} d_N'(t) &= \frac{2}{\kappa a^2 d_N(t)} \left[m_j m_{_N} \frac{(\mathbf{x}_j^0 - \mathbf{x}_N^0)\cdot \mathbf{x}_j^0}{|\mathbf{x}_j^0 - \mathbf{x}_N^0|^2} + \sum_{l=1,\, l\neq j}^{N-1} m_j m_l \frac{(\mathbf{x}_j^0 - \mathbf{x}_l^0)\cdot \mathbf{x}_j^0}{|\mathbf{x}_j^0 - \mathbf{x}_l^0|^2} \right] \\ &= \frac{2}{\kappa a^2 d_N(t)} \left[m_0^2 + \sum_{l=1,\, l\neq j}^{N-1} m_0^2 \frac{a^2 - \mathbf{x}_l^0 \cdot \mathbf{x}_j^0}{2a^2 - 2\mathbf{x}_l^0 \cdot \mathbf{x}_j^0} \right] = \frac{N}{\kappa a^2 d_N(t)}, \quad t \geq 0. \end{aligned}$$

Solving the above ODE and noting that $d_N(0) = 1$, we obtain

$$d_N(t) = \sqrt{1 + \frac{2N}{a^2\kappa}\, t}, \qquad t \geq 0. \tag{2.14}$$

Thus the solution (2.13) is a combination of the above and (2.7). ∎

From the results in Lemma 2.4 we can see that, for the dynamics of (1.9)–(1.10) in Pattern II, by the reduced dynamic law the vortex initially at the center of the circle does not move for any time $t \geq 0$, each of the other $N-1$ vortices moves outside along the line passing through its initial location and the origin, and these $N-1$ vortices are located on a circle at any time t with its radius increasing by time $d_N(t)$ as in (2.14).

LEMMA 2.5. *If the initial data in* (1.10) *are as in Pattern* III*, then the solutions of* (1.9)–(1.10) *are*

$$\mathbf{x}_N(t) \equiv (0,0)^T, \qquad t \geq 0, \tag{2.15}$$

and for $1 \leq j \leq N-1$ *with* $N \geq 3$*,*

$$\mathbf{x}_j(t) = \sqrt{a^2 + \frac{2(N-4)}{\kappa}\, t}\, \left(\cos\left(\frac{2j\pi}{N-1} + \theta_0\right), \sin\left(\frac{2j\pi}{N-1} + \theta_0\right)\right)^T. \tag{2.16}$$

The proof follows from the analogous results in Lemma 2.4. From the results in Lemma 2.5 we can see that, for the dynamics of (1.9)–(1.10) in Pattern III, by the reduced dynamic law (i) the vortex initially at the origin does not move during the interaction, each of the other $N-1$ vortices moves along the line passing through its initial location and the origin, and these $N-1$ vortices are located on a circle at any time t; (ii) when $N = 3$, the two vortices with the same index move towards each other and collide with the vortex having the opposite index at the origin and at time $t = t_c = \kappa a^2/2$; (iii) when $N = 4$, all four vortices do not move but remain at their initial locations for any $t \geq 0$; and (iv) when $N \geq 5$, the $N-1$ vortices with the same index move outside and never collide with the vortex with the opposite index no matter how small the initial radius of the circle is.

LEMMA 2.6. *If the initial data in* (1.10) *satisfy* (2.8)*, i.e., Pattern* IV*, then the solutions of* (1.9)–(1.10) *can be given by*

$$\mathbf{x}_j(t) = \sqrt{a^2 - \frac{2}{\kappa}\, t}\, \left(\cos\left(j\pi + \theta_0\right), \sin\left(j\pi + \theta_0\right)\right)^T, \quad 0 \leq t \leq t_c, \quad j = 1, 2, \tag{2.17}$$

with $t_c = \kappa a^2/2$.

The proof is similar to that of Lemma 2.3. From the results in Lemma 2.6 we can see that, for the dynamics of (1.9)–(1.10) in Pattern IV, when $0 \leq t < t_c = a^2\kappa/2$ the two vortices move towards each other along a line passing through their initial locations and collide at the origin at time $t = t_c = O(a^2)$ according to the reduced dynamic law.

2.4. Analytical solutions of the reduced dynamics for the NLSE. Similarly, noting (2.4) we can also solve the nonlinear ODEs (1.11) analytically when the initial conditions in (1.12) are given by Patterns I–IV.

LEMMA 2.7. *If the initial data in* (1.12) *satisfy* (2.5)*, i.e., Pattern* I*, then the solutions of* (1.11)–(1.12) *can be given, for* $1 \leq j \leq N$ *with* $N \geq 2$*, by*

$$\mathbf{x}_j(t) = a\left(\cos\left(\frac{2j\pi}{N} + \theta_0 + \frac{m_0(N-1)}{a^2}\, t\right), \sin\left(\frac{2j\pi}{N} + \theta_0 + \frac{m_0(N-1)}{a^2}\, t\right)\right)^T. \tag{2.18}$$

Proof. For any $N \geq 2$, based on the structures of the ODEs (1.11) and the initial data (2.5), we take the ansatz for the solution with $1 \leq j \leq N$ as

$$\mathbf{x}_j(t) = a\left(\cos\left(\frac{2j\pi}{N} + \theta_0 + \alpha_N(t)\right), \sin\left(\frac{2j\pi}{N} + \theta_0 + \alpha_N(t)\right)\right)^T, \quad t \geq 0, \tag{2.19}$$

where $\alpha_N(t)$ is a function of time and $\alpha_N(0) = 0$.

Now, let $\mathbf{x}_j^{\perp}(t) = a\left(-\sin\left(\frac{2j\pi}{N} + \theta_0 + \alpha_N(t)\right), \cos\left(\frac{2j\pi}{N} + \theta_0 + \alpha_N(t)\right)\right)^T$. By (1.13), we have the elementary identity

$$\begin{aligned} &\sum_{l=1,\, l\neq j}^{N} m_0 \frac{\mathbf{x}_j^{\perp} \cdot (\mathbf{J}\mathbf{x}_j) - \mathbf{x}_j^{\perp} \cdot (\mathbf{J}\mathbf{x}_l)}{|\mathbf{x}_j|^2 + |\mathbf{x}_l|^2 - 2\mathbf{x}_j \cdot \mathbf{x}_l} \\ &= \sum_{l=1,\, l\neq j}^{N} m_0 \frac{1 - \cos\left(\frac{2(j-l)\pi}{N}\right)}{2 - 2\cos\left(\frac{2(j-l)\pi}{N}\right)} = \frac{m_0(N-1)}{2}. \end{aligned} \tag{2.20}$$

Inserting (2.19) into (1.11) and applying a dot-product on both sides with $\mathbf{x}_j^{\perp}(t)$, we get

$$\alpha_N'(t) = \frac{2}{a^2} \sum_{l=1,\, l\neq j}^{N} m_l \frac{\mathbf{x}_j^{\perp} \cdot [\mathbf{J}(\mathbf{x}_j - \mathbf{x}_l)]}{|\mathbf{x}_j - \mathbf{x}_l|^2} = \frac{m_0(N-1)}{a^2}, \qquad t \geq 0.$$

Solving the above ODE and noting that $\alpha_N(0) = 0$, we obtain $\alpha_N(t) = m_0(N-1)t/a^2$ for $t \geq 0$. Thus a combination of the above leads to the solution (2.18). ∎

From the results in Lemma 2.7 we can see that, when the N like vortices are uniformly located on a circle initially, i.e., for the dynamics of (1.11)–(1.12) in Pattern I, they rotate along the circle (counterclockwise if $m_0 = +1$ and clockwise if $m_0 = -1$) with angular frequency $\omega = (N-1)/a^2$ (cf. Figure 13(a),(d)).

LEMMA 2.8. *If the initial data in* (1.12) *satisfy* (2.6)–(2.7)*, i.e., Pattern* II*, then the solutions of* (1.11)–(1.12) *are*

$$\mathbf{x}_N(t) \equiv (0,0)^T, \qquad t \geq 0, \tag{2.21}$$

and for $1 \leq j \leq N-1$ *with* $N \geq 3$*,*

$$\mathbf{x}_j(t) = a\left(\cos\left(\frac{2j\pi}{N-1} + \theta_0 + \frac{m_0 N}{a^2}\, t\right), \sin\left(\frac{2j\pi}{N-1} + \theta_0 + \frac{m_0 N}{a^2}\, t\right)\right)^T. \tag{2.22}$$

Proof. Due to the symmetry of the ODEs (1.11), the initial data (2.6)–(2.7), and the conservation of signed mass center (2.4), we can immediately get the solution (2.21). As in the proof of Lemma 2.7, we assume for $1 \leq j \leq N-1$ that

$$\mathbf{x}_j(t) = a\left(\cos\left(\frac{2j\pi}{N-1} + \theta_0 + \beta_N(t)\right), \sin\left(\frac{2j\pi}{N-1} + \theta_0 + \beta_N(t)\right)\right)^T, \tag{2.23}$$

where $\beta_N(t)$ is a function of time and $\beta_N(0) = 0$. Inserting (2.23) into (1.11), applying a dot-product on both sides with

$$\mathbf{x}_j^{\perp}(t) = a\left(-\sin\left(\frac{2j\pi}{N-1} + \theta_0 + \beta_N(t)\right), \cos\left(\frac{2j\pi}{N-1} + \theta_0 + \beta_N(t)\right)\right)^T,$$

and noting (1.13), (2.21), and (2.20) (with N replaced by $N-1$), we get

$$\begin{aligned}\beta_N'(t) &= \frac{2}{a^2}\left[m_{_N}\frac{\mathbf{x}_j^{\perp}\cdot[\mathbf{J}(\mathbf{x}_j-\mathbf{x}_N)]}{|\mathbf{x}_j-\mathbf{x}_N|^2}+\sum_{l=1,\,l\neq j}^{N-1} m_l\frac{\mathbf{x}_j^{\perp}\cdot[\mathbf{J}(\mathbf{x}_j-\mathbf{x}_l)]}{|\mathbf{x}_j-\mathbf{x}_l|^2}\right]\\ &= \frac{2}{a^2}\left[m_0\frac{\mathbf{x}_j^{\perp}\cdot(\mathbf{J}\mathbf{x}_j)}{|\mathbf{x}_j|^2}+\sum_{l=1,\,l\neq j}^{N-1} m_0\frac{\mathbf{x}_j^{\perp}\cdot(\mathbf{J}\mathbf{x}_j)-\mathbf{x}_j^{\perp}\cdot(\mathbf{J}\mathbf{x}_l)}{|\mathbf{x}_j|^2+|\mathbf{x}_l|^2-2\mathbf{x}_j\cdot\mathbf{x}_l}\right]=\frac{m_0N}{a^2}\end{aligned}$$

for $t\geq 0$. Solving the above ODE and noting that $\beta_N(0)=0$, we obtain $\beta_N(t)=m_0Nt/a^2$ for $t\geq 0$. Thus a combination of the above leads to the solution (2.22). ∎

From the results in Lemma 2.8 we can see that, for the dynamics of (1.11)–(1.12) in Pattern II, the vortex initially at the center of the circle does not move for any time $t\geq 0$, and the other $N-1$ vortices rotate along the circle (counterclockwise if $m_0=+1$ and clockwise if $m_0=-1$) with angular frequency $\omega=N/a^2$ (cf. Figure 14(a),(d)).

LEMMA 2.9. *If the initial data in* (1.12) *are as in Pattern* III*, then the solutions of* (1.11)–(1.12) *are*

$$\mathbf{x}_N(t)\equiv(0,0)^T,\qquad t\geq 0, \tag{2.24}$$

and for $1\leq j\leq N-1$ *with* $N\geq 3$*,*

$$\mathbf{x}_j(t)=a\left(\cos\left(\frac{2j\pi}{N-1}+\theta_0+m_0\omega_N t\right),\,\sin\left(\frac{2j\pi}{N-1}+\theta_0+m_0\omega_N t\right)\right)^T, \tag{2.25}$$

where $\omega_N=(N-4)/a^2$.

The proof is similar to that of Lemma 2.8. From the results in Lemma 2.9, we can see for the dynamics of (1.11)–(1.12) in Pattern III that (i) the vortex initially at the origin does not move during the interaction; (ii) when $N=3$, the two vortices initially located on a circle rotate along the same circle (clockwise if $m_0=+1$ and counterclockwise if $m_0=-1$) with frequency $\omega(a)=1/a^2$ (cf. Figure 15(a)); (iii) the case of $N=4$ is rather special, and the reduced dynamics implies that all four vortices do not move and stay at their initial locations for any $t\geq 0$ (cf. Figure 15(d)); and (iv) when $N\geq 5$, the $N-1$ vortices initially located on a circle rotate along the same circle (counterclockwise if $m_0=+1$ and clockwise if $m_0=-1$) with angular frequency $\omega_N=(N-4)/a^2$ (cf. Figure 15(g)).

LEMMA 2.10. *If the initial data in* (1.12) *satisfy* (2.8)*, i.e., Pattern* IV*, then the solutions of* (1.11)–(1.12) *can be given by*

$$\mathbf{x}_j(t)=\mathbf{x}_j^0+\frac{m_0}{a}\,t\,(-\sin\theta_0,\,\cos\theta_0)^T,\qquad t\geq 0,\quad j=1,2. \tag{2.26}$$

Proof. From the conservation of the signed mass center (2.4), we have

$$\widetilde{\mathbf{x}}(t)=\frac{\mathbf{x}_1(t)-\mathbf{x}_2(t)}{2}\equiv\frac{\mathbf{x}_1(0)-\mathbf{x}_2(0)}{2}=a\,(\cos\theta_0,\,\sin\theta_0)^T,\quad t\geq 0. \tag{2.27}$$

On the other hand, from the ODEs (1.11), we obtain

$$\frac{d\mathbf{x}_1(t)}{dt}=-2m_0\frac{\mathbf{J}\,(\mathbf{x}_1(t)-\mathbf{x}_2(t))}{|\mathbf{x}_1(t)-\mathbf{x}_2(t)|^2},\qquad \frac{d\mathbf{x}_2(t)}{dt}=2m_0\frac{\mathbf{J}\,(\mathbf{x}_2(t)-\mathbf{x}_1(t))}{|\mathbf{x}_2(t)-\mathbf{x}_1(t)|^2}.$$

Summing up the above equations and combining with (2.27), we get

$$\frac{d\mathbf{x}_1(t)}{dt} = -\frac{m_0}{a}\mathbf{J}\,(\cos\theta_0,\,\sin\theta_0)^T, \quad t \geq 0, \quad \text{with} \quad \mathbf{x}_1(0) = \mathbf{x}_1^0. \tag{2.28}$$

Solving (2.28) and noting (2.27), we obtain (2.26) immediately. □

From the results in Lemma 2.10 we can see that, for the dynamics of (1.11)–(1.12) in Pattern IV, the two opposite vortices move along two parallel lines which are perpendicular to the line passing through their initial locations with constant velocity (cf. Figures 16(b) and 20(a))

$$\mathbf{v}(t) = \frac{d\mathbf{x}_1(t)}{dt} = \frac{d\mathbf{x}_2(t)}{dt} \equiv \frac{m_0}{a}\,(-\sin\theta_0,\,\cos\theta_0)^T, \qquad t \geq 0. \tag{2.29}$$

3. Numerical results for vortex dynamics in the GLE. In this section, we report the numerical results of the vortex dynamics and interaction by directly simulating the GLE; i.e., we take $\alpha = 1$, $\beta = 0$, $\varepsilon = 1$, and $V(\mathbf{x}) \equiv 1$ in (1.1), with the efficient and accurate time-splitting method introduced in [36]. For the choice of mesh size and time step, as well as the size of the bounded computational domain, we refer to [36]. For comparison, we also exhibit the motion of the vortex centers solved from the reduced dynamics (1.9) in each case. In the figures, the symbols used include + (center of a vortex with index $m = +1$), − (center of a vortex with index $m = -1$), and o (collision position of two or more opposite vortices).

3.1. Interactions of N ($N \geq 2$) like vortices, Patterns I and II. Figure 1 displays the surface plots of $-|\psi|$ at different times when the initial data in (1.7) are chosen as (2.5) with $N = 2$, $m_0 = +1$, and $a = 2$, and Figure 2 shows the time evolution of the vortex centers for different number of vortices $N \geq 2$, i.e., Pattern I. In addition, Figure 3 shows the time evolution of the vortex centers when the initial data in (1.7) is chosen as (2.6)–(2.7) with $m_0 = +1$ and $a = 3$ for different number of vortices $N \geq 3$, i.e., Pattern II.

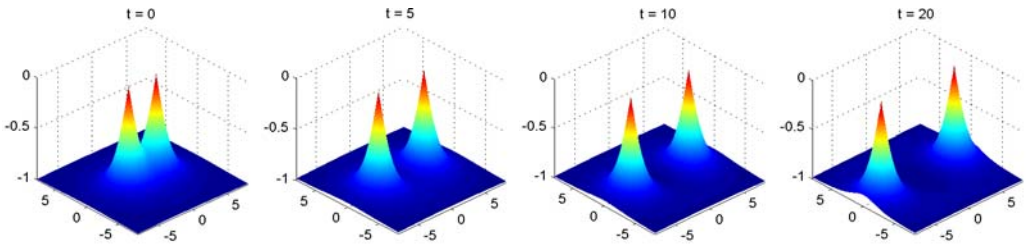

FIG. 1. *Surface plots of* $-|\psi|$ *at different times for the GLE when the initial condition is chosen as Pattern* I *with* $N = 2$, $m_0 = +1$, *and* $a = 2$ *in* (2.5).

From Figures 1–3, and additional numerical experiments not shown here, we can draw the following conclusions for the interaction of N like vortices in the GLE when the initial data are chosen as either Pattern I or II:

(i) The mass center of the vortex centers is conserved for any time $t \geq 0$ (cf. Figures 2 and 3), which confirms the conservation law in (2.3).

(ii) Vortices with the same index undergo a repulsive interaction and they never collide (cf. Figures 1, 2, and 3). Their speeds depend on their distances to the origin, i.e., the larger the distance, the slower the motion (cf. Figures 2 and 3). In addition,

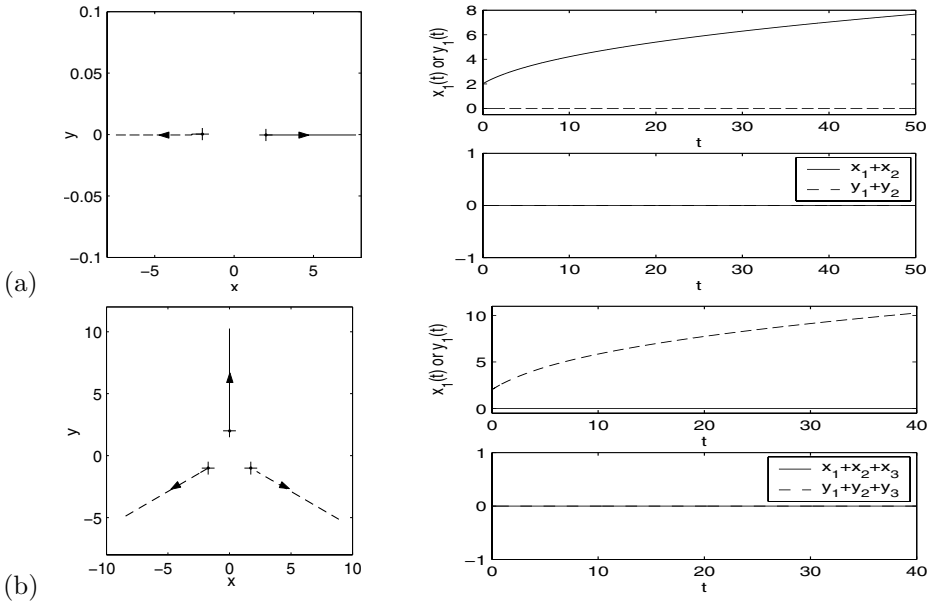

FIG. 2. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Pattern* I *with* $a = 2$ *and* $m_0 = +1$ *for different* N. (a) $N = 2$; (b) $N = 3$.

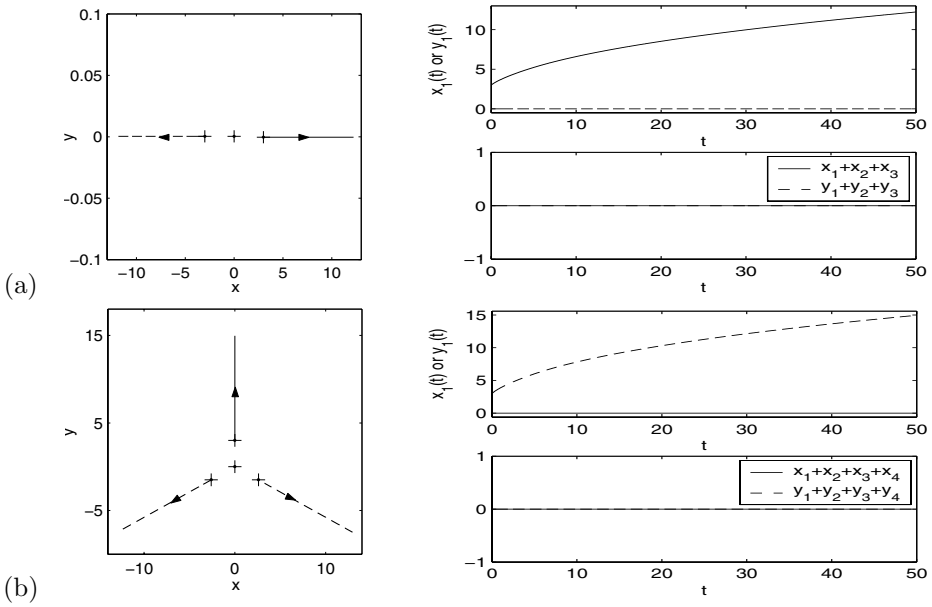

FIG. 3. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Pattern* II *with* $a = 3$ *and* $m_0 = +1$ *for different* N. (a) $N = 3$; (b) $N = 4$.

in Pattern II the vortex initially at the origin does not move during the dynamics (cf. Figure 3), which confirms the analytical solution (2.12).

(iii) Due to the symmetry of the initial data, the vortices of those initially located on a circle move along lines passing through their initial locations and the origin, and

at any time $t \geq 0$, these vortex centers are always on a circle (cf. Figures 2 and 3), which confirms the analytical solutions (2.9) and (2.13).

(iv) In Patterns I and II, the solutions of the reduced dynamic laws agree qualitatively with our numerical results of the GLE, and quantitatively if a proper κ in (1.9) is chosen, which depends on the initial setup in (1.7). For example, in Pattern I with $N = 2$, we numerically find that the two solutions are the same when we choose $\kappa \approx 2.1279$, 2.1690, 2.2589, and 2.3116 for $a = 4$, 5, 10, and 20, respectively, which suggests that $\frac{1}{\kappa} \approx 0.424 + \frac{0.1897}{a}$ when $a \geq 4$.

3.2. Interactions of N ($N \geq 3$) opposite vortices, Pattern III. Figure 4 shows time evolution of the vortex centers when the initial data in (1.7) are chosen as Pattern III with $m_0 = +1$ and $a = 3$ for different $N \geq 3$.

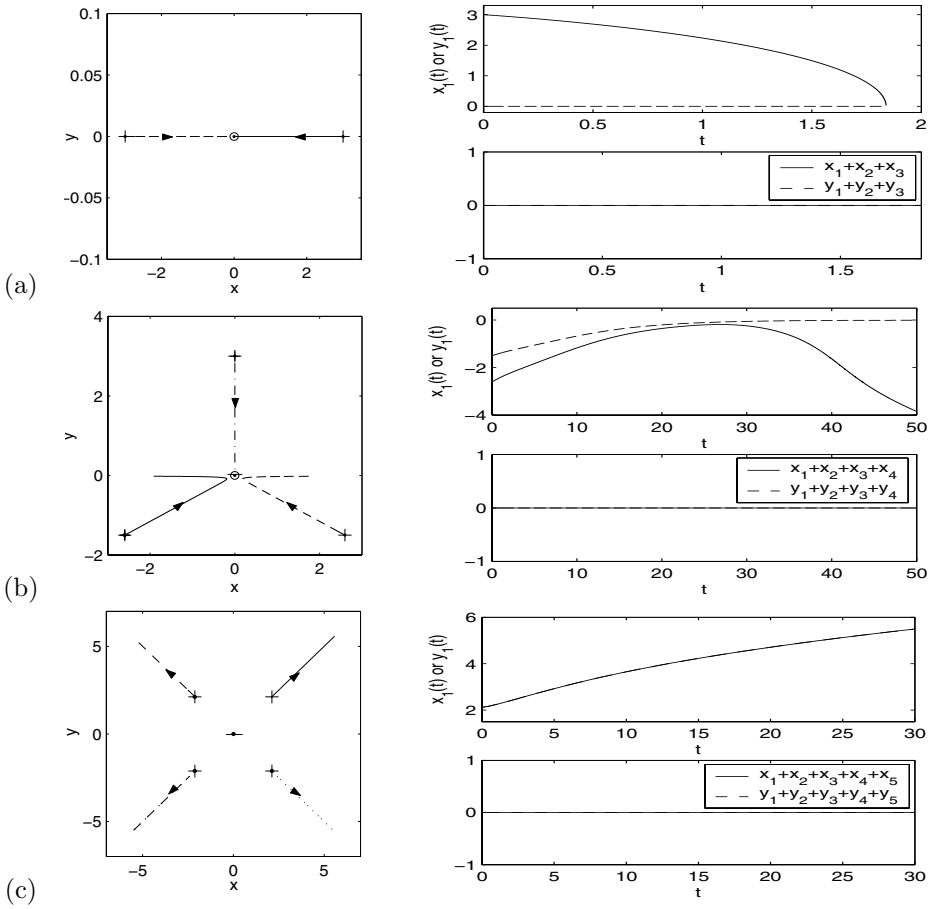

FIG. 4. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Pattern* III *with* $a = 3$ *and* $m_0 = +1$ *for different* N. (a) $N = 3$; (b) $N = 4$; (c) $N = 5$.

From Figure 4, and additional numerical experiments not shown here, we can draw the following conclusions for the interaction of N opposite vortices in the GLE when the initial data are chosen as Pattern III:

(i) The mass center of the vortex centers is conserved for any time $t \geq 0$ (cf. Figure 4), which confirms the conservation law in (2.3).

(ii) The vortex initially at the origin does not move for any time $t \geq 0$ (cf. Figure 4), which confirms the analytical solution (2.15). The vortices of those initially located on a circle move to the origin when $N = 3$ or 4 and, respectively, move away when $N \geq 5$, along lines passing through their initial location and the origin, and at any time $t \geq 0$, these vortex centers are always on a circle (cf. Figure 4), which confirms the analytical solutions (2.16). Their speeds depend on their distances to the origin, i.e., the larger the distance, the slower the motion.

(iii) When $N = 3$ or 4, collisions between the vortex centers are observed at a critical time t_c (cf. Figure 4(a),(b)). The collision time is quadratically proportional to the initial distance a. Before collision, the interaction is attractive. When $N = 3$, they collide at the origin, and after the collision, there is one vortex with index $m = m_0$ left, and it stays at the origin forever (cf. Figure 4(a)). On the other hand, when $N = 4$, one of the three vortices initially located on the circle collides with the one initially at the origin. After the collision, two like vortices remain and they undergo a repulsive interaction (cf. Figure 4(b)).

(iv) When $N \geq 5$, the vortices undergo repulsive interactions and never collide (cf. Figure 4(c)).

(v) In Pattern III, when $N = 3$ or $N \geq 5$, the solutions of the reduced dynamic laws qualitatively agree with our numerical results of the GLE. On the contrary, they are completely different for $N = 4$. One may argue that a possible cause is the fact that this case corresponds to a degenerate case of the reduced dynamics (1.9)–(1.10) for which the vortices remain stationary, and thus the next order effect becomes important in the underlying vortex motion of the original GLE. In fact, the collision time needed for $N = 4$ ($t_c \approx 28$; cf. Figure 4(b)) is much longer than that for $N = 3$ ($t_c \approx 1.8$; cf. Figure 4(a)) with the same initial radius of the circle at $a = 3$.

3.3. Interactions of two opposite vortices, Pattern IV. Figure 5 displays the surface plots of $-|\psi|$ at different times and Figure 6 shows time evolution of the vortex centers when the initial data in (1.7) are chosen as (2.8) with $m_0 = +1$ and $a = 1.5$, i.e., Pattern IV.

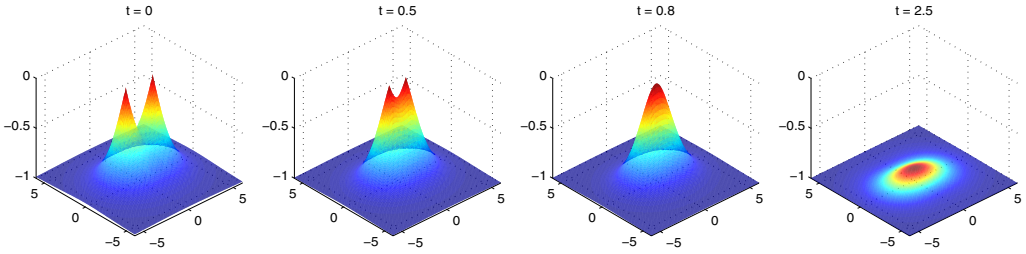

FIG. 5. *Surface plots of* $-|\psi|$ *at different times for the GLE when the initial condition is chosen as Pattern* IV (2.8) *with* $m_0 = +1$ *and* $a = 1.5$.

From Figures 5–6, we can draw the following conclusions for the interaction of two opposite vortices in the GLE when the initial condition is chosen as Pattern IV:

(i) The mass center of the two vortex centers is conserved for any time $t \geq 0$ (cf. Figure 6), which again confirms the conservation law in (2.3).

(ii) Two vortices with opposite winding numbers undergo an attractive interaction (cf. Figure 5), and their centers move along a straight line passing through their locations at $t = 0$ (cf. Figure 6). The speed of the motion for the two vortex

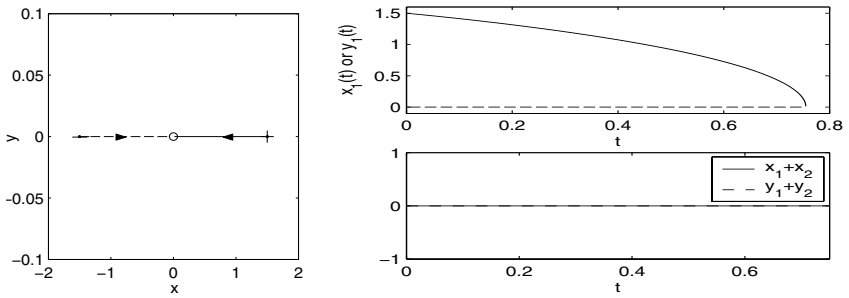

FIG. 6. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Pattern* IV *with* $a = 1.5$ *and* $m_0 = +1$.

centers depends on their distance. The smaller the distance, the faster the motion (cf. Figure 6).

(iii) There exists a critical time $t_c > 0$, and the two opposite vortices collide with each other at the origin (cf. Figure 5). From our numerical results, we find numerically that the collision time depends on the distance of the two vortex centers at $t = 0$ as

$$t_c \approx \frac{1}{14.8710}\, d_0^{2.0715} \quad \text{with} \quad d_0 = 2a, \qquad a > 0. \tag{3.1}$$

This immediately implies that $t_c = O\left(a^2\right)$, which confirms the analytical result of the collision time in Lemma 2.6.

(iv) Again, in Pattern IV the solutions of the reduced dynamic laws agree qualitatively with our numerical results of the GLE, and quantitatively if a proper κ in (1.9) is chosen, which depends on the initial distance between the two vortex centers.

3.4. Interactions of vortices with nonsymmetric setups. Figures 7–9 show the time evolution of the vortex centers when the initial data in (1.7) are chosen as the three cases in Pattern V, respectively.

Based on Figures 7–9 and our additional numerical experiments, we can draw the following conclusions for three vortices with nonsymmetric initial setups:

(i) When they have the same index, they never collide (cf. Figure 7). On the contrary, when they have opposite indices, they collide at a finite time (cf. Figures 8 and 9), and after collision, only one vortex is left.

(ii) The mass centers of the vortex centers are not conserved (cf. Figures 7–9) during the dynamics within the time frame we computed the solutions, which suggests that there is a considerable discrepancy between the reduced dynamics law (1.9)–(1.10) and the original dynamics in some regimes. One may argue that a possible cause is the fact that the reduced dynamic law is the adiabatic approximation in the leading order when the N vortices are well separated, and thus the next order effect becomes important in the underlying vortex motion of the original GLE when the N vortices are not well separated. In fact, in our numerical results, the larger the distance between the vortex centers, the better the conservation of the mass center (cf. Figures 7–9). This suggests that the reduced dynamics law (1.9)–(1.10) is still a reasonable approximation to the vortex motion of the original GLE in a nonsymmetric initial setup when the N vortices are well separated.

4. Numerical results for vortex dynamics in the NLSE. Similarly, in this section we report the numerical results of the vortex dynamics and interaction by

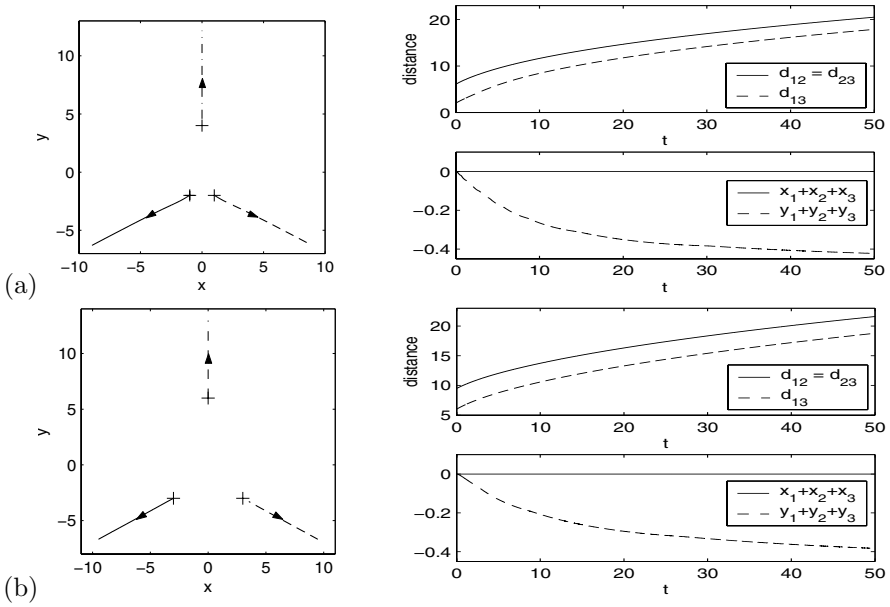

FIG. 7. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Case* 1 *in Pattern* V *with different* a *and* b. (a) $a = 1$, $b = 4$; (b) $a = 3$, $b = 6$.

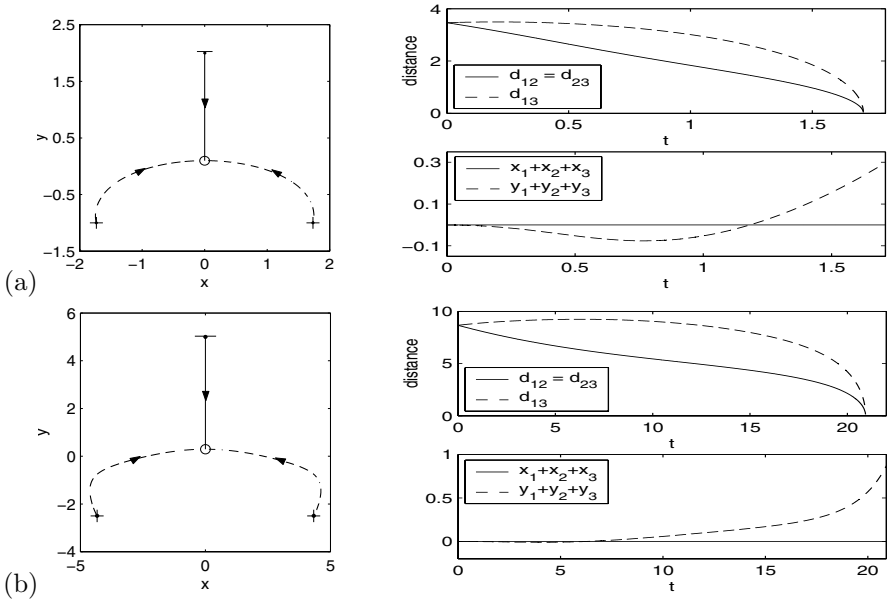

FIG. 8. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Case* 2 *in Pattern* V *with different* a. (a) $a = 2$; (b) $a = 5$.

directly simulating the nonlinear Schrödinger equation; i.e., we take $\alpha = 0$, $\beta = 1$, $\varepsilon = 1$, and $V(\mathbf{x}) \equiv 1$ in (1.1), with the numerical method introduced in [36]. All the computational setups are the same as in the previous section.

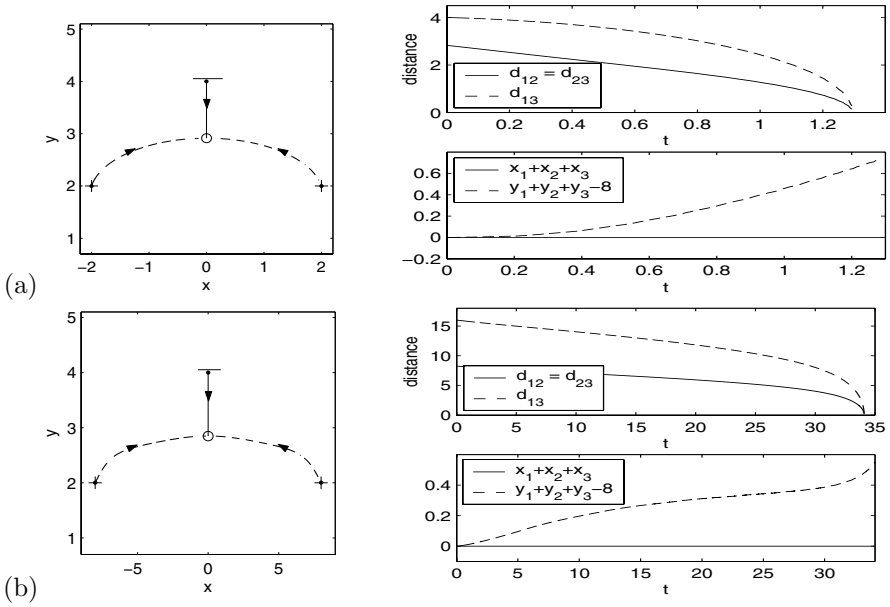

FIG. 9. *Time evolution of vortex centers by directly simulating the GLE when the initial data are chosen as Case* 3 *in Pattern* V *with different* a *and* b. (a) $a = 2$, $b = 4$; (b) $a = 8$, $b = 4$.

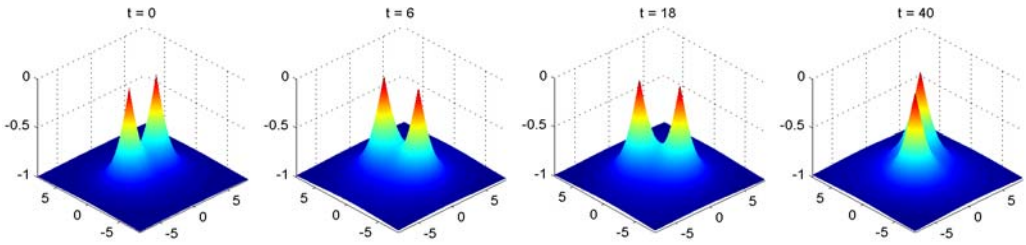

FIG. 10. *Surface plots of* $-|\psi|$ *at different times for the NLSE when the initial condition is chosen as Pattern* I (2.5) *with* $N = 2$, $m_0 = +1$, *and* $a = 2$.

4.1. Interactions of N ($N \geq 2$) like vortices, Patterns I and II. Figures 10–12 give the surface plots of $-|\psi|$ at different times, the slice plots of $|\psi(x, 0, t)|$ at different times, and some dynamical laws when the initial data in (1.7) are chosen as (2.5) with $N = 2$ and $m_0 = +1$, i.e., interaction of two like vortices. In addition, Figure 13 shows time evolution of the vortex centers when the initial condition is chosen as Pattern I (2.5) for different $N \geq 2$, and Figure 14 depicts similar results for Pattern II (2.6)–(2.7).

From Figures 10–14, and additional numerical experiments not shown here, we can draw the following conclusions for the interaction of N like vortices in the NLSE when the initial condition is chosen as either Pattern I or II:

(i) The signed mass center of the vortex centers is conserved for any time $t \geq 0$ (cf. Figures 13(b),(c),(e),(f); 14(b),(c),(e),(f)), which confirms the conservation law in (2.4).

(ii) Vortices with the same index behave like point vortices in an ideal fluid and never collide (cf. Figures 10, 13, and 14). In fact, there exists a critical time $t_0 > 0$,

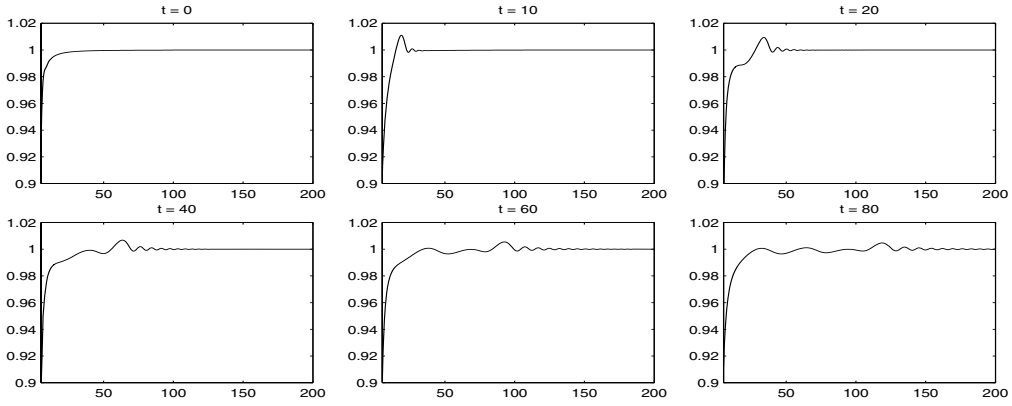

FIG. 11. *Plots of* $|\psi(x,0,t)|$ $(x \geq 4)$ *at different times for the NLSE when the initial condition is chosen as Pattern* I (2.5) *with* $N = 2$, $m_0 = +1$, *and* $a = 2$, *showing the sound wave propagation.*

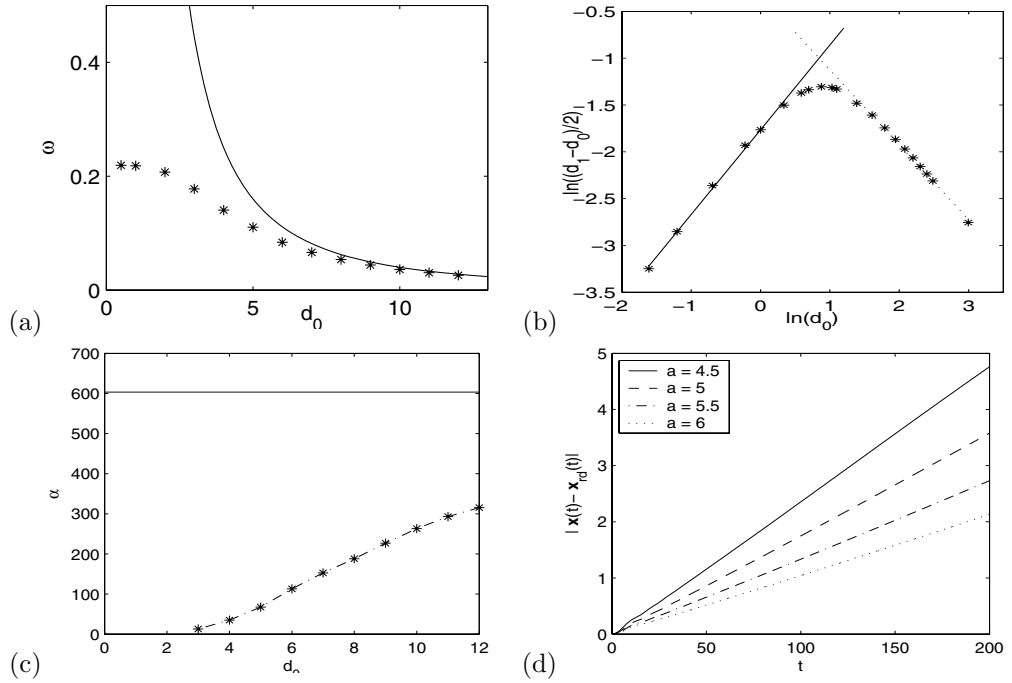

FIG. 12. *Dynamical laws of interaction between two like vortices, i.e., Pattern* I *with* $N = 2$, *in the NLSE.* (a) *Frequency* ω *of the rotation (solid line is from* (2.18) *and asterisks are our numerical results);* (b) *diameter* $d_1 = |\mathbf{x}_1(t_0) - \mathbf{x}_2(t_0)|$ *when the two vortices start to rotate on a circle;* (c) $\alpha(d_0)$ *in* (4.1) (*the asterisks are our numerical results and the solid line is from the theoretical predication* $\alpha = 2^6 \cdot 3\pi$ [30]); (d) *errors of the vortex centers between the solution* (2.18) *of the reduced dynamic laws* (*denoted* $\mathbf{x}_{\rm rd}(t)$) *and our directly simulating results of the NLSE* (*denoted* $\mathbf{x}(t)$) *for different initial distance* $d_0 = 2a$.

depending on the initial distance to the origin, i.e., a, such that before time t_0, i.e., when $0 \leq t \leq t_0$, the vortices initially located on a circle move from their initial locations to another circle, and the change in distance between each vortex to the origin is rapid (cf. Figures 13(b), 14(b)); after time t_0, i.e., for $t \geq t_0$, the vortices

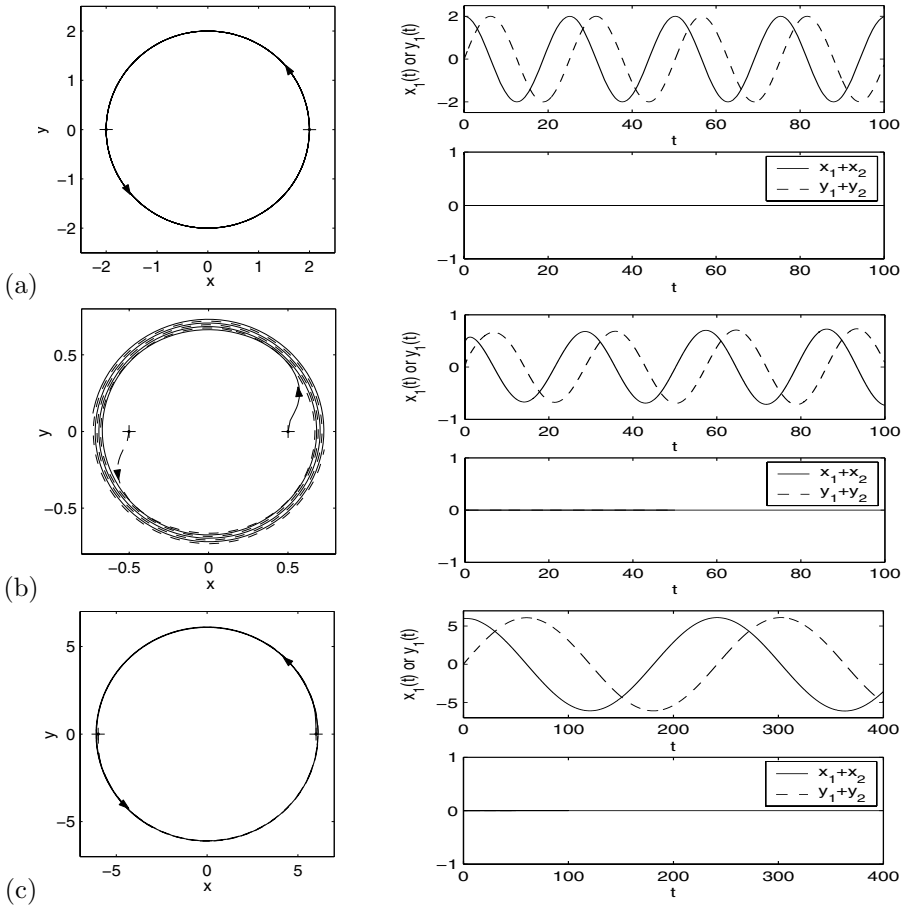

FIG. 13. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Pattern* I *with different* N. (a) *and* (d) *are from the reduced dynamic laws* (2.18)*;* (b) *and* (e) *and* (c) *and* (f) *show direct simulation results of the NLSE with* $a = O(r_1^0)$ *and* $a \gg r_1^0$*, respectively. Case* 1: $N = 2$ *with* (b) $a = 0.5$ *and* (c) $a = 6$.

rotate uniformly along a circle (counterclockwise when winding number $m_0 = +1$ and clockwise when $m_0 = -1$) with angular frequency ω depending on a and the radius of the circle increasing very slowly. The sound wave propagation is clearly observed during the interaction (cf. Figure 11). In addition, in Pattern II, the vortex initially at the origin does not move during the dynamics (cf. Figure 14(b),(c),(e),(f)), which confirms the analytical solution (2.21).

(iii) For Pattern I with $N = 2$, we also present the comparison quantitatively (cf. Figure 12). In this case, denote $d_0 = |\mathbf{x}_1^0 - \mathbf{x}_2^0| = 2a$ and $d_1 = |\mathbf{x}_1(t_0) - \mathbf{x}_2(t_0)|$ for the initial distance and the diameter of the circle at time $t = t_0$ of the two vortices, respectively. The angular frequency predicted by the reduced dynamics is confirmed by our numerical simulations (cf. Figure 12(a)) when $d_0 = 2a$ is large, and it is invalid when d_0 is small; i.e., the reduced dynamics is invalid when the vortex pair initially has overlapping support. Furthermore, even when the two vortices are well separated, the reduced dynamics fails to take into account the effect of the excessive energy and the radiation, which play important roles in the NLSE vortex dynamics. For example,

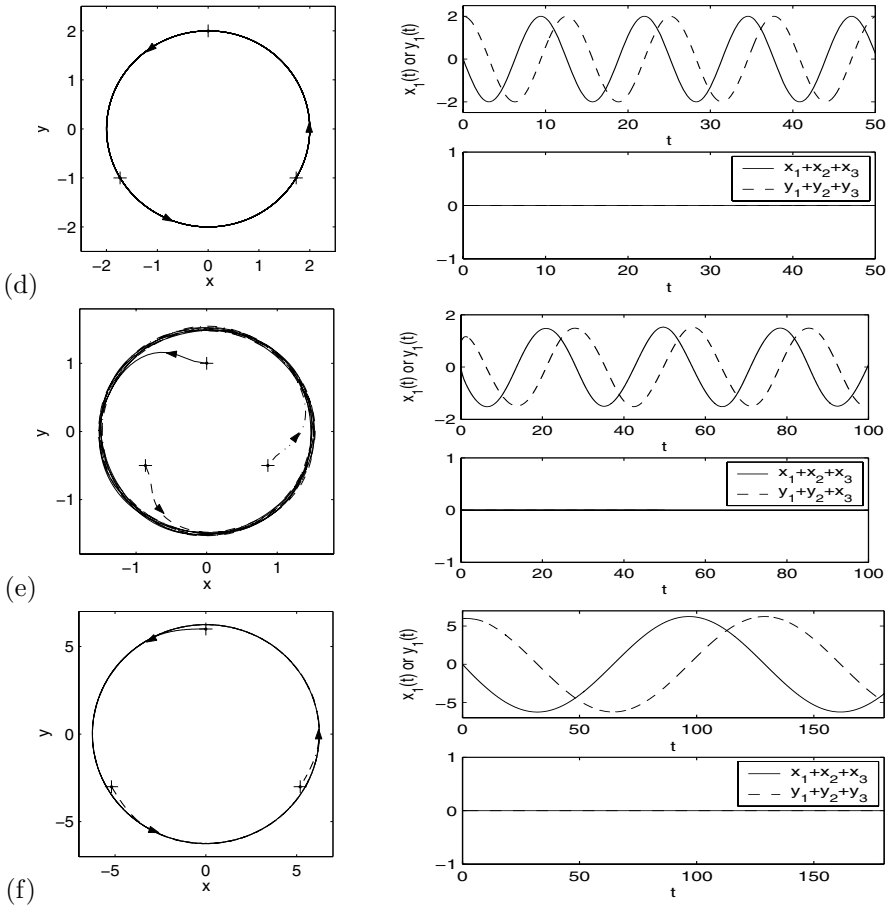

FIG. 13 (*cont.*). *Case* 2: $N = 3$ *with* (e) $a = 1$ *and* (f) $a = 6$.

by analyzing the next-order approximation for the interaction of two well-separated vortices in the NLSE, it was derived in [30] that the diameter of the circle increases on the order of $O(t^{1/6})$, i.e., asymptotically,

$$d(t) = |\mathbf{x}_1(t) - \mathbf{x}_2(t)| = \left(|\mathbf{x}_1^0 - \mathbf{x}_2^0|^6 + 2^6 \cdot 3\pi t\right)^{1/6} = \left(d_0^6 + 2^6 \cdot 3\pi t\right)^{1/6}. \tag{4.1}$$

This departs from the constant distance prediction made from the reduced dynamic laws (1.11). Numerically, we fit the distance between the two vortex centers $d(t) = |\mathbf{x}_1(t) - \mathbf{x}_2(t)|$ for $t \geq t_0$ by

$$d(t) = |\mathbf{x}_1(t) - \mathbf{x}_2(t)| = \left(d(t_0)^6 + \alpha(d_0)(t - t_0)\right)^{1/6}, \qquad t \geq t_0, \tag{4.2}$$

with $\alpha(d_0)$ being a constant depending on d_0. The results show that (4.1) is a very good prediction (cf. Figure 12(c)). Of course, much more detailed information on the vortex dynamics in the NLSE can be found through our numerical simulations. For example, our simulations suggest that when the initial distance between the two vortex centers increases, the time t_0 increases, the diameter $d_1 = d(t_0)$ of the circle at $t = t_0$ increases (cf. Figure 12(b)), and $\alpha(d_0)$ in (4.2) increases (cf. Figure 12(c)). From Fig-

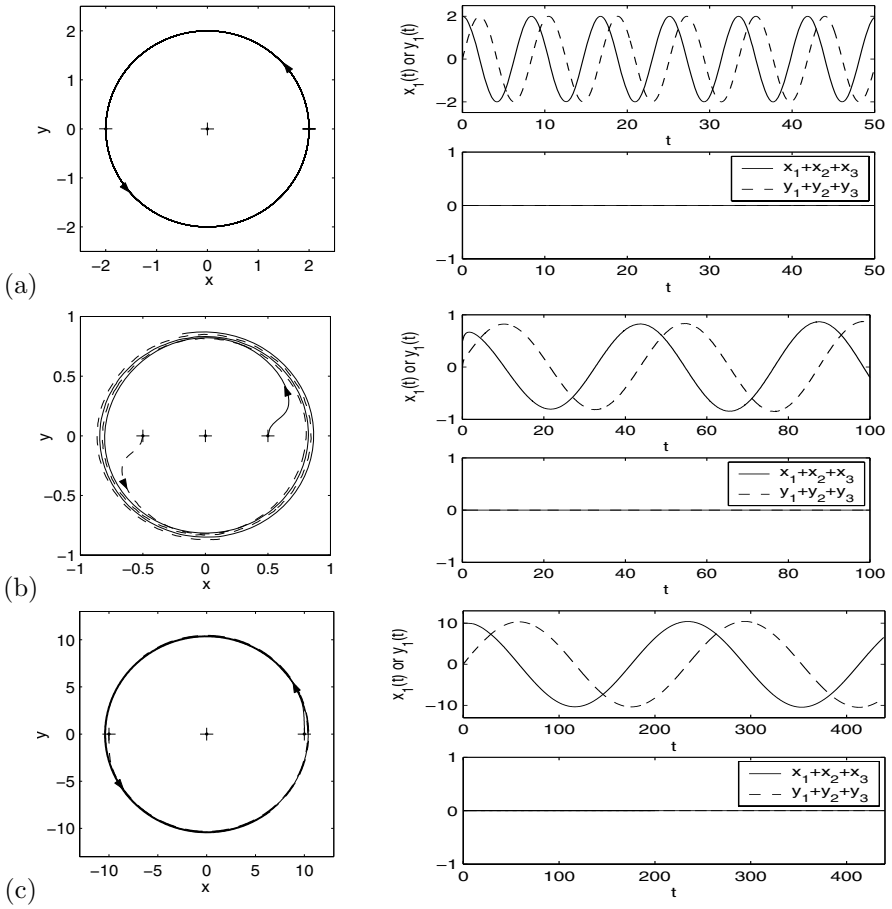

FIG. 14. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Pattern* II *with different* N. (a) *and* (d) *are from the reduced dynamic laws* (2.21)–(2.22)*;* (b) *and* (e) *and* (c) *and* (f) *show direct simulation results of the NLSE with* $a = O(r_1^0)$ *and* $a \gg r_1^0$*, respectively. Case* 1: $N = 3$ *with* (b) $a = 0.5$ *and* (c) $a = 10$.

ure 12(b), we have the numerical dynamical laws for the diameter d_1 for different d_0:

$$d_1 := d(t_0) \approx \begin{cases} d_0 + d_0^{0.9053}/2.9189, & d_0 < r_1^0, \\ d_0 + 1.4453/d_0^{0.7996}, & d_0 > 2r_1^0, \end{cases}$$

where $r_1^0 \approx 1.75$ [36] is the core size for the vortex state ϕ_m in (1.4) of the GLSE with winding number $m = \pm 1$.

(iv) In Patterns I and II, the solutions of the reduced dynamic laws agree qualitatively with our numerical results of the NLSE, and quantitatively when time t is small and they are well separated, i.e., $a \gg r_1^0 = 1.75$ [36]. In general, for a fixed initial distance, i.e., a, the error increases when time increases; for a given time, the error decreases when the initial distance increases (cf. Figure 12(d)). This again suggests that the reduced dynamics for governing time evolution of the vortex centers in the NLSE is valid only when time t is small and the initial distance is very large. Corrections must be added, e.g., such as (4.1), when either the time t is large or the initial distance is not very large.

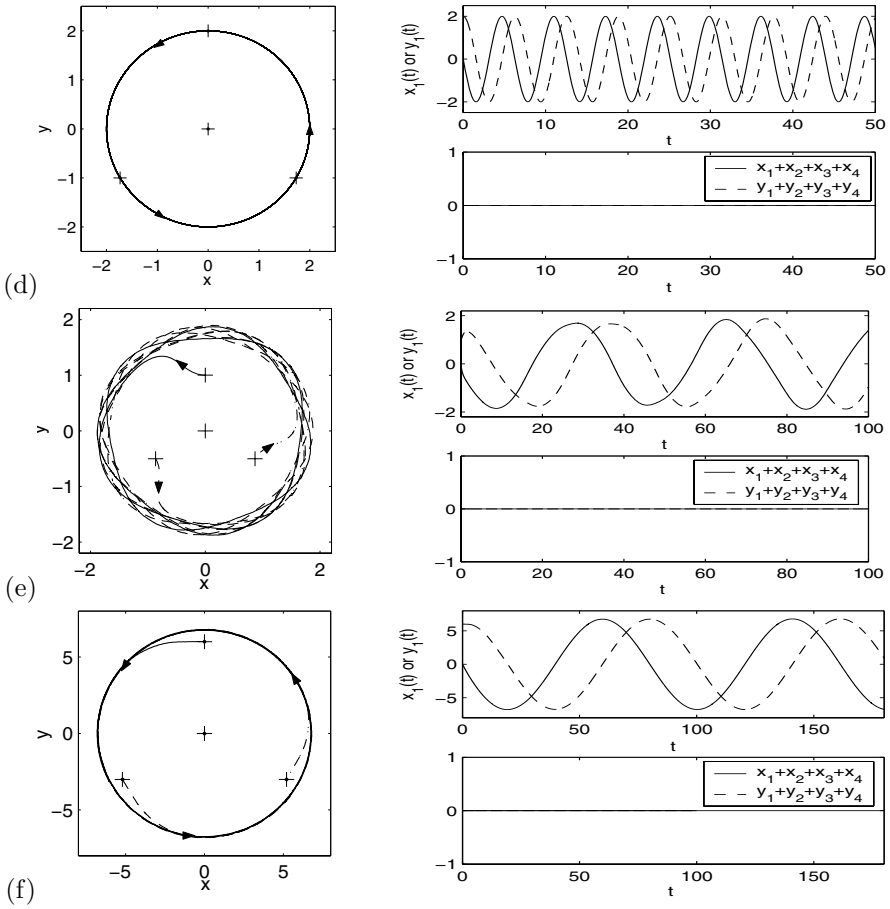

FIG. 14 (*cont.*). *Case* 2: $N = 4$ *with* (e) $a = 1$ *and* (f) $a = 6$.

(v) The results in Figure 12, as well as in Figure 21, also confirm Kirchoff's laws rigorously derived in [23, 24] for the interaction of two vortices in the NLSE, i.e., $\alpha = 0$, $\beta = 1$, $V(\mathbf{x}) \equiv 1$ in (1.1), when $\varepsilon \to 0$ with the initial distance between the two vortex centers fixed. In fact, the vortex interactions of (1.1) with $V(\mathbf{x}) \equiv 1$, $\varepsilon = 1$, and increased initial distances between the vortex centers are equivalent to those of (1.1) with $V(\mathbf{x}) \equiv 1$, $\varepsilon \to 0$, and fixed initial distances between the vortex centers by applying a rescaling.

4.2. Interactions of N ($N \geq 3$) opposite vortices, Pattern III. Figure 15 shows the time evolution of the vortex centers for different $N \geq 3$ when the initial data in (1.7) are chosen as in Pattern III with $m_0 = +1$ for different N and a.

From Figure 15, and additional numerical experiments not shown here, we can draw the following conclusions for the interaction of N opposite vortices in the NLSE when the initial data are chosen as Pattern III:

(i) The signed mass center of the vortex centers is conserved for any time $t \geq 0$ (cf. Figure 15(b),(c),(e),(f),(h),(i)), which confirms the conservation law in (2.4).

(ii) The vortex initially at the origin does not move for any time $t \geq 0$ (cf. Figure 15(b),(c),(e),(f),(h),(i)), which confirms the analytical solution (2.24). After a critical

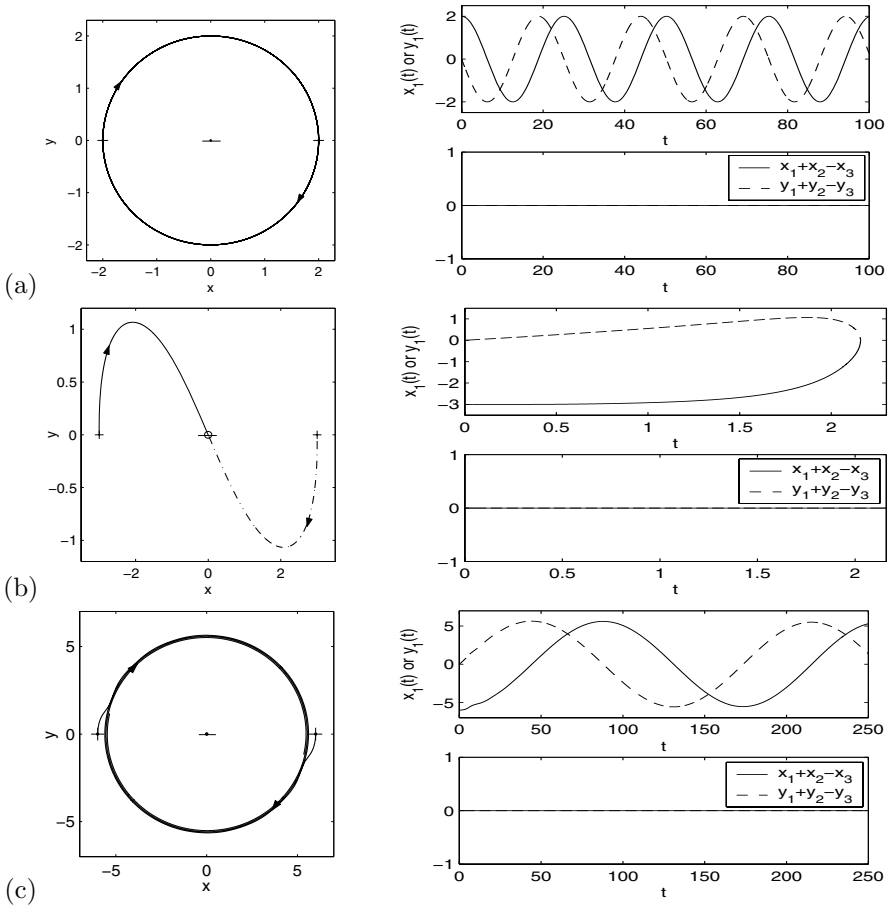

FIG. 15. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Pattern* III *with different* N *and* a. (a), (d), *and* (g) *are from the reduced dynamic laws* (2.25); (b), (e), *and* (h) *and* (c), (f), *and* (i) *show direct simulation results of the NLSE with* $a = O(r_1^0)$ *and* $a \gg r_1^0$, *respectively. Case* 1: $N = 3$ *with* (b) $a = 3$ *and* (c) $a = 6$.

time t_c depending on the initial radius a, the vortices initially located on a circle rotate clockwise when $N = 3$ and $a > a_{\rm cr} \approx 2r_1^0$ or $N = 4$, and, respectively, counterclockwise when $N \geq 5$, along a circle, and at any time $t \geq 0$, these vortex centers are always on a circle (cf. Figure 15(b),(c),(e),(f),(h),(i)), which confirms the analytical solutions (2.25). Their angular frequencies depend on their distances to the origin, i.e., the larger the distance, the slower the motion.

(iii) For the case of $N = 3$, when the initial radius $a < 2r_1^0$, the three vortices undergo attractive interactions, and the two vortices initially on a circle move symmetrically towards the center before a critical time t_c. When $t = t_c$, they collide at the origin (cf. Figure 15(b)), and after it, only one vortex with a winding number m_0 is left and stays at the point $(0, 0)$ for any time $t > t_c$. On the other hand, when $a > 2r_1^0$, the two vortices rotate (clockwise for $m_0 = +1$, and, respectively, counterclockwise for $m_0 = -1$) on a circle whose radius increases very slowly with time t (cf. Figure 15(c)).

(iv) When $N = 4$, the three vortices initially on a circle move to another circle

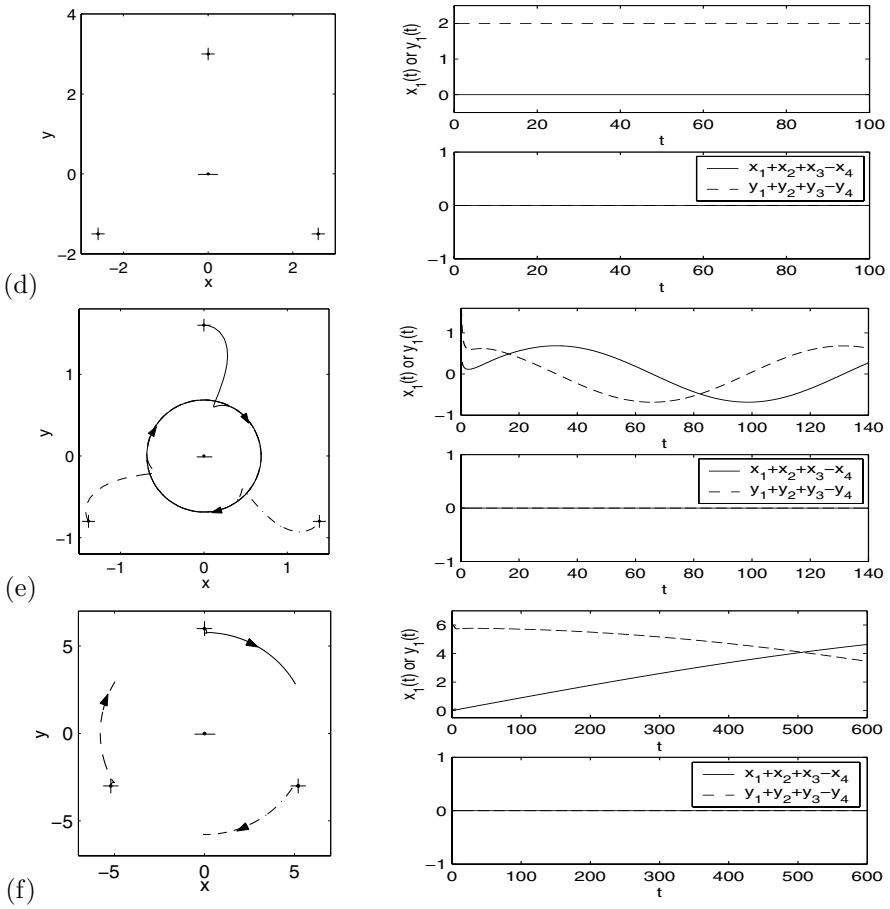

FIG. 15 (*cont.*). *Case* 2: $N = 4$ *with* (e) $a = 1.6$ *and* (f) $a = 6$.

with radius $a_1 < a$; then they rotate (clockwise for $m_0 = +1$, and, respectively, counterclockwise for $m_0 = -1$) on a circle whose radius increases very slowly with time t (cf. Figure 15(e),(f)). The four vortices never collide no matter how small a is.

(v) When $N \geq 5$, the $N-1$ vortices initially on a circle move to another circle with radius $a_1 > 0$; then they rotate (counterclockwise for $m_0 = +1$, and, respectively, clockwise for $m_0 = -1$) on a circle whose radius increases very slowly with time t (cf. Figure 15(h),(i)).

(vi) In Pattern III, when $N = 3$ and $a > 2r_1^0$ or $N \geq 5$, the solutions of the reduced dynamic laws agree qualitatively with our numerical results of the NLSE. On the contrary, when $N = 4$ or $N = 3$ with $a < 2r_1^0$, they are completely different! This may be attributed to the lack of well separation between the vortex cores and/or the next-order effect in the underlying vortex motion of the original NLSE. In fact, the angular frequency for $N = 4$ is much larger than that for $N = 3$ with the same initial radius of the circle (cf. Figure 15(c),(f)).

4.3. Interactions of two opposite vortices, Pattern IV. Figure 16 displays the surface plots of $-|\psi|$ at different times when the initial data in (1.7) are chosen as (2.8), i.e., Pattern IV, with $m_0 = +1$ and $a = 1.5$ or $a = 5$. Figures 17 and 18–19 plot $|\psi(x, y(t), t)|$ and $|\psi(0, y, t)|$, respectively, to show the sound wave propagation

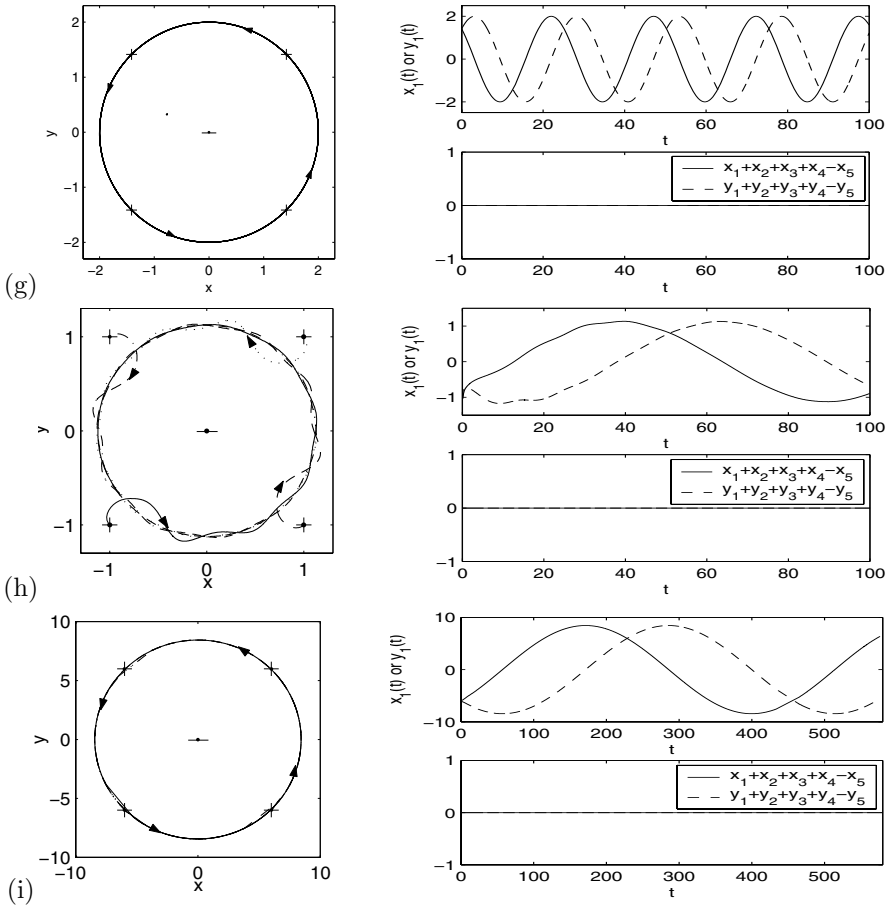

FIG. 15 (*cont.*). *Case* 3: $N = 5$ *with* (h) $a = 1$ *and* (i) $a = 6$.

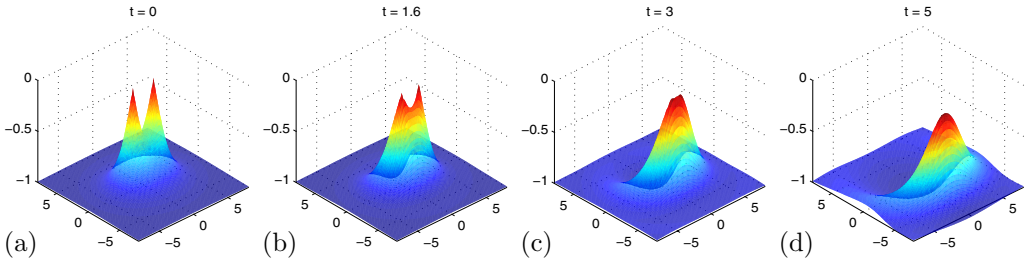

FIG. 16. *Surface plots of* $-|\psi|$ *at different times for the NLSE when the initial condition is chosen as Pattern* IV (2.8) *with* $m_0 = +1$. I. $a = 1.5 = O(r_1^0)$.

during the dynamics. Figure 20 shows the time evolution of the two vortex centers with different $d_0 = 2a$. In addition, Figure 21 shows some dynamical laws for the interaction.

From Figures 16–21, we can draw the following conclusions for the interaction of two opposite vortices in the NLSE when the initial condition is chosen as Pattern IV:

(i) The signed mass center of the two vortex centers is not conserved, at least when either the initial distance between the two vortices is not large or time t is small

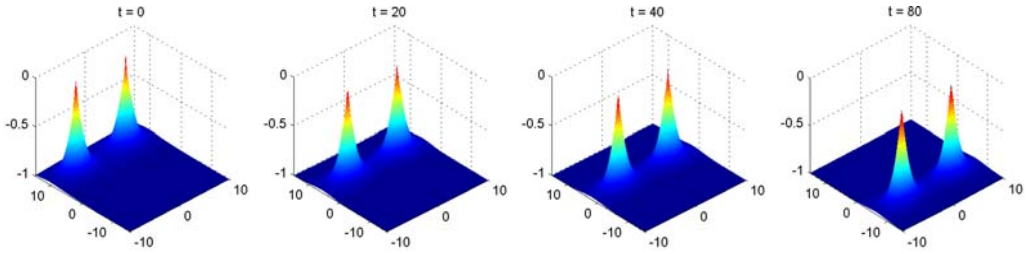

FIG. 16 (*cont.*). II. $a = 5 \gg r_1^0$.

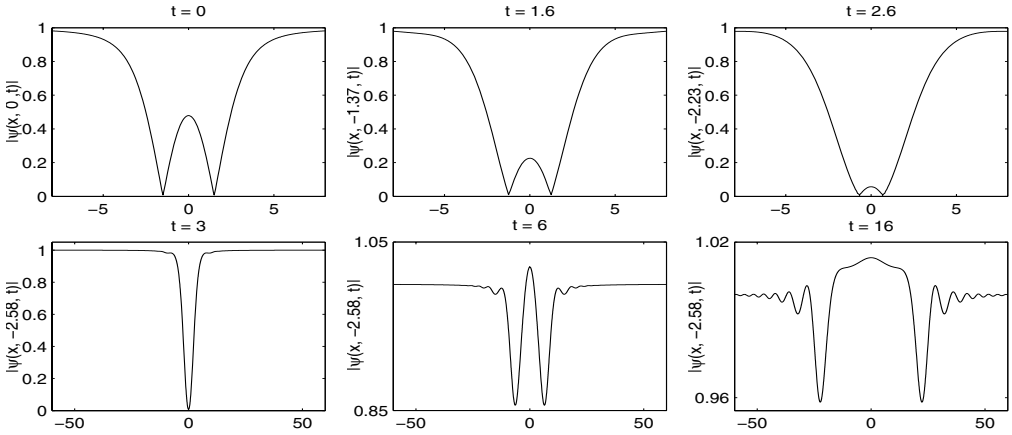

FIG. 17. *Plots of* $|\psi(x, y(t), t)|$ *at different times for the NLSE when the initial condition is chosen as Pattern* IV (2.8) *with* $m_0 = +1$ *and* $a = 1.5$*, showing sound wave propagation and radiation with the values of* $y(t)$ *given in the labels. Here* $y = y(t)$ *is the line passing through the two vortex centers at time* t *before they merge with each other around* $t_c \approx 3.0$.

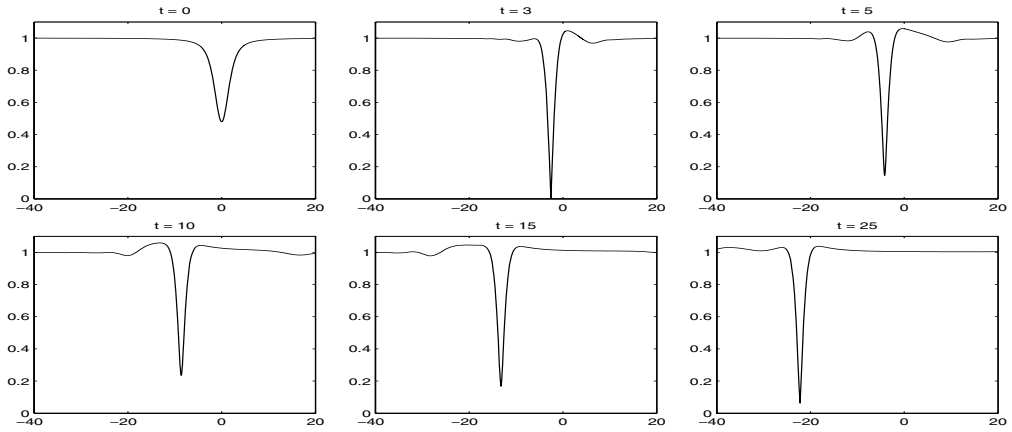

FIG. 18. *Plots of* $|\psi(0, y, t)|$ *at different times for the NLSE when the initial condition is chosen as Pattern* IV (2.8) *with* $m_0 = +1$ *and* $a = 1.5$*, showing solitary-like wave propagation.*

(cf. Figure 20(b),(c),(d)), which suggests that the conservation law in (2.4) is invalid when the initial distance between the two vortex centers at time $t = 0$ is not large.

(ii) There is a critical distance $d_{\rm cr}$ satisfying that, for $d_0 = |\mathbf{x}_1^0 - \mathbf{x}_2^0| < d_{\rm cr}$, the

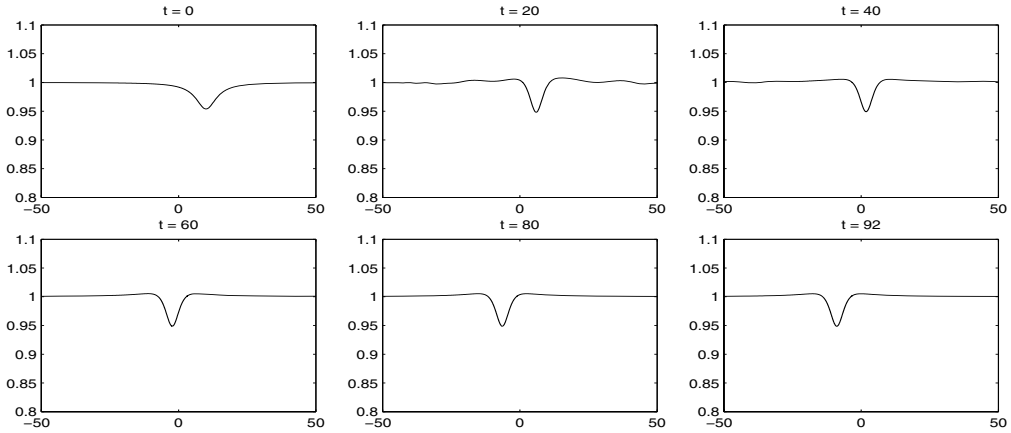

FIG. 19. *Plots of* $|\psi(0, y, t)|$ *at different times for the NLSE when the initial condition is chosen as Pattern* IV (2.8) *with* $m_0 = +1$ *and* $a = 5 \gg r_1^0$ *for solitary wave propagation.*

two vortices approach each other while drifting sideways and then collide and are annihilated at time $t = t_c$ (cf. Figures 16, 20(b)), and for $d_0 = |\mathbf{x}_1^0 - \mathbf{x}_2^0| > d_{cr}$, they move almost in a parallel course, perpendicular to the line joining them (cf. Figures 19, 20(c),(d)). Our numerical simulations suggest that $d_{\rm cr} \approx 2r_1^0 = 2 \times 1.75 = 3.5$, i.e., double the size of the core size r_1^0, which is almost triple the size of the theoretical prediction $d_{\rm cr} \approx \sqrt{2}$ derived in [30].

(iii) When $d_0 < d_{\rm cr} = 2r_1^0$, before collision, our numerical simulation reveals that two sound waves moving towards each other are generated along the line joining the centers of the two vortices (cf. Figure 17), which cause the collision, while no radiation is observed; after the collision, some outgoing radiation is observed along with a solitary-like sound wave also being observed in the y-axis (cf. Figure 18). In addition, a discontinuity or shock wave in the hydrodynamic velocity is observed just after the collision. Furthermore, for the initial setup in Pattern IV, the two vortices collide at the point $(0, -d_2)$ with $d_2 > 0$ when $t = t_c$. When the initial distance d_0 increases, both t_c and d_2 increase, and our numerical results suggest the following relation between them:

$$t_c \approx \frac{1}{7.0790}\, d_0^{2.0954}, \qquad d_1 \approx \frac{1}{1.9300}\, d_0^{1.0365}, \quad \text{with} \quad d_1 = \sqrt{d_0^2 + d_2^2}.$$

(iv) When $d_0 \gg d_{\rm cr} = 2r_1^0$, the two vortices drift almost on two parallel lines, perpendicular to the line joining them with a constant speed. Our numerical results confirm the speed (2.29) when $d_0 = 2a$ is large (cf. Figure 21(a)). In addition, a solitary wave is observed during the dynamics (cf. Figure 19).

(v) Again, in Pattern IV the solutions of the reduced dynamic laws agree qualitatively with our numerical results of the NLSE when $a \gg r_1^0$ and they are completely invalid when a is small (cf. Figure 20). When $a > r_1^0$, in general, for a fixed initial distance, the error increases when time increases; for a given time, the error decreases when the initial distance increases (cf. Figure 21(b)).

4.4. Interactions of vortices with nonsymmetric setups. Figures 22–24 show time evolution of the vortex centers when the initial data in (1.7) are chosen as the three cases in Pattern V, respectively.

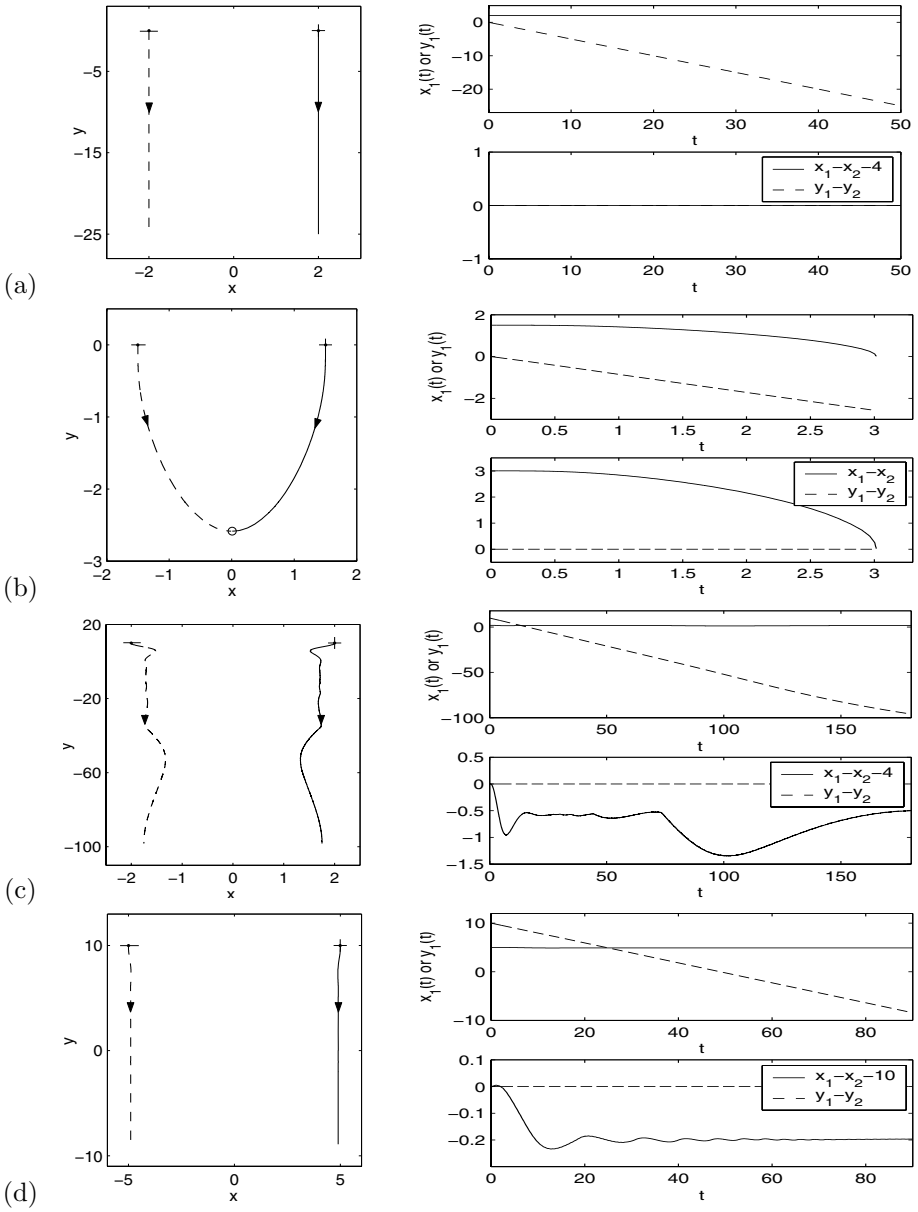

FIG. 20. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Pattern* IV. (a) *is from the reduced dynamic laws* (2.26)*, and* (b), (c)*, and* (d) *show direct simulation results of the NLSE with* $m_0 = +1$ *and* $a = 1.5 < r_1^0$*,* $a = 2 > r_1^0$*, and* $a = 5 \gg r_1^0$*, respectively.*

Based on Figures 22–24 and our additional numerical experiments, we can draw the following conclusions for three vortices with nonsymmetric initial setups:

(i) When they have the same index, they rotate and never collide (cf. Figure 22). On the contrary, when they have opposite indices, there exists a critical distance $d_{\rm cr}$, when their initial distances are less than $d_{\rm cr}$, they collide at finite time (cf. Figures 23(a), 24(a)), and after collision, only one vortex is left; on the other hand, when their

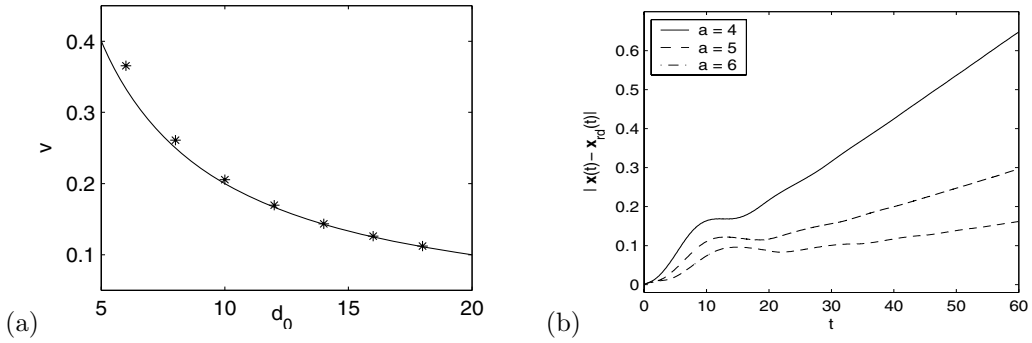

FIG. 21. *Dynamic laws for two opposite vortices, i.e., Pattern* IV *with* $N = 2$*, in the NLSE.* (a) *Speed* v *of the parallel motion.* (b) *Errors of the vortex centers between the solution* (2.26) *of the reduced dynamic laws* (*denoted as* $\mathbf{x}_{\rm rd}(t)$) *and our directly simulating results of the NLSE* (*denoted as* $\mathbf{x}(t)$) *for different initial distance* $d_0 = 2a$.

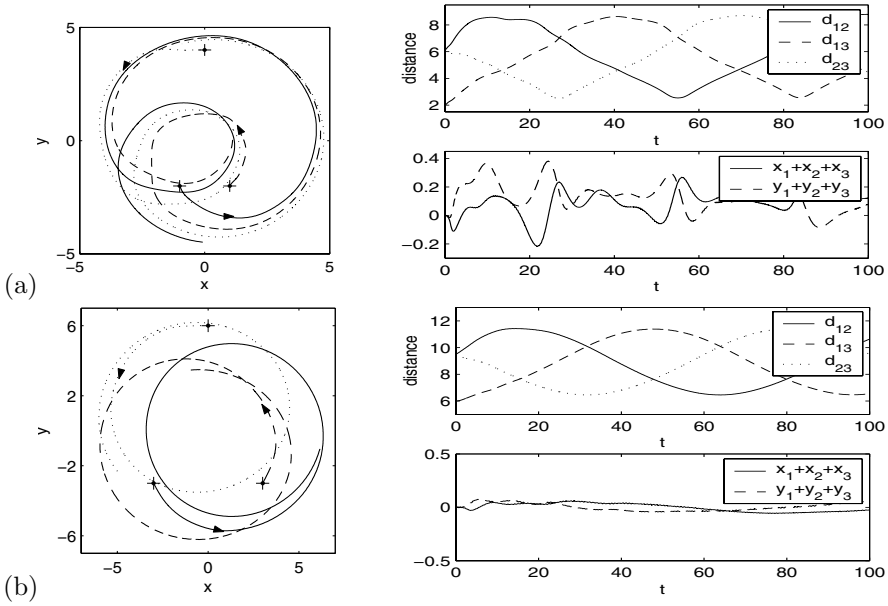

FIG. 22. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Case* 1 *in Pattern* V *with different* a *and* b. (a) $a = 1$, $b = 4$. (b) $a = 3$, $b = 6$.

initial distances are larger than $d_{\rm cr}$, two of them move in a parallel course and never collide (cf. Figures 23(b), 24(b)).

(ii) The signed mass centers of the vortex centers are not conserved (cf. Figures 22–24) during the dynamics, and these suggest that the reduced dynamics law (1.11)–(1.12) has considerable discrepancy in some regimes. Again, one may argue that a possible cause is the fact that the reduced dynamic law is the adiabatic approximation in the leading order when the N vortices are well separated, and thus the next-order effect becomes important in the underlying vortex motion of the original NLSE when the N vortices are not well separated. Also in our numerical results, the larger the distance between the vortex centers, the better the conservation of the signed mass center (cf. Figures 22–24). This again suggests that the reduced dynam-

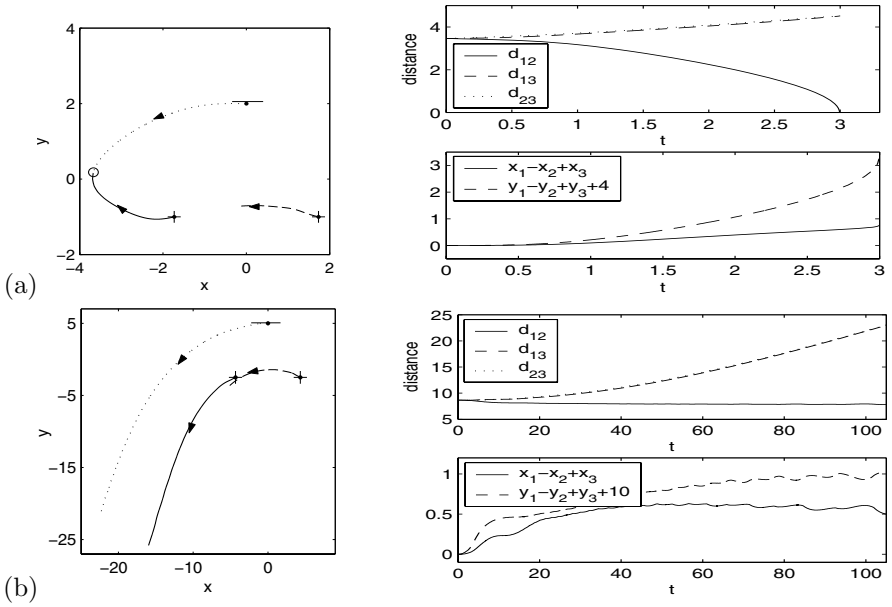

FIG. 23. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Case* 2 *in Pattern* V *with different* a. (a) $a = 2$. (b) $a = 5$.

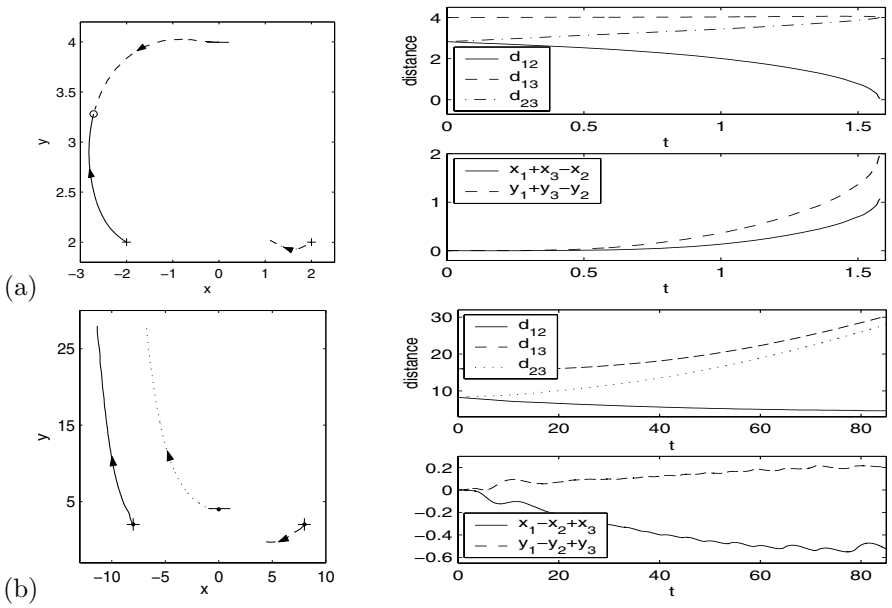

FIG. 24. *Time evolution of vortex centers for the NLSE when the initial condition is chosen as Case* 3 *in Pattern* V *with different* a *and* b. (a) $a = 2$, $b = 4$. (b) $a = 8$, $b = 4$.

ics law (1.11)–(1.12) is still a reasonable approximation to the vortex motion of the original NLSE in a nonsymmetric initial setup when the N vortices are well separated.

5. Vortex dynamics in the CGLE or in the GLSE with an external potential. In many applications of the GLSE, the physical situation is often more

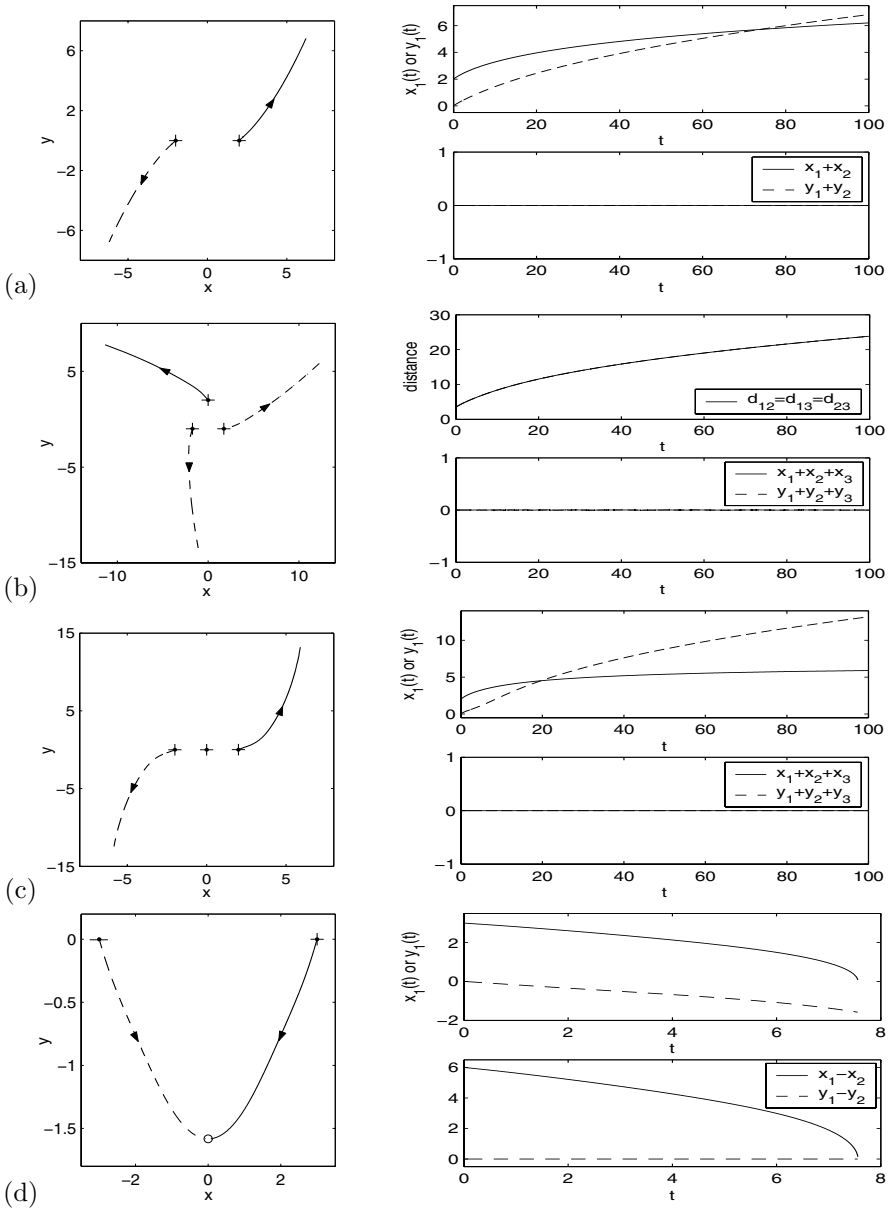

FIG. 25. *Time evolution of vortex centers for the CGLE when the initial condition is chosen as Patterns* I–IV *with different a.* (a) *Pattern* I *with* $N = 2$ *and* $a = 2$. (b) *Pattern* I *with* $N = 3$ *and* $a = 1.5$. (c) *Pattern* II *with* $N = 3$ *and* $a = 2$. (d) *Pattern* IV *with* $a = 3$.

complicated than the GLE and NLSE cases considered in the earlier sections. As an illustration, in this section we report numerical results of vortex interaction in the CGLE and vortex motion in the GLSE with an inhomogeneous external potential.

5.1. Numerical results for vortex dynamics in the CGLE. We take $\alpha = \beta = 1$, $\varepsilon = 1$, and $V(\mathbf{x}) \equiv 1$ in (1.1). Figure 25 shows the various time evolutions of the vortex centers when the initial data in (1.7) are chosen as Patterns I, II, and IV.

Based on Figure 25 and our additional numerical experiments, we can draw the following conclusions for vortex dynamics in the CGLE:

(i) Vortices with the same index undergo repulsive interactions and never collide. The trajectories are combinations of those from the GLE and the NLSE (cf. Figure 25(a), (b), and (c)).

(ii) Two vortices with opposite indices collide after some time t_c (cf. Figure 25(d)) and the collision position is $(0, -d_2)$. The collision time and position depend on the initial distance between the two vortices $d_0 = 2a$. Our numerical results suggest the following relation between them:

$$t_c \approx \frac{1}{8.9837}\, d_0^{2.0655}, \qquad d_1 \approx \frac{1}{4.7781}\, d_0^{1.0184}, \quad \text{with} \quad d_1 = \sqrt{d_0^2 + d_2^2}.$$

In addition, based on the numerical results in Figure 25 it is reasonable to make the following conjecture about the reduced dynamic laws for the interaction of N well-separated vortices with winding number $m_j = +1$ or -1:

$$\mathbf{v}_j(t) := \frac{d\mathbf{x}_j(t)}{dt} = 2 \sum_{l=1,\, l\neq j}^{N} m_l \frac{\mathbf{Q}_j\,(\mathbf{x}_j(t) - \mathbf{x}_l(t))}{|\mathbf{x}_j(t) - \mathbf{x}_l(t)|^2}, \qquad t \geq 0, \tag{5.1}$$

$$\mathbf{x}_j(0) = \mathbf{x}_j^0, \qquad 1 \leq j \leq N, \tag{5.2}$$

where $\mathbf{Q}_j$ is given as

$$\mathbf{Q}_j = \begin{pmatrix} m_j\,\kappa_1 & -\kappa_2 \\ \kappa_2 & m_j\,\kappa_1 \end{pmatrix} = m_j \kappa_1\, I + \kappa_2\, J, \qquad j = 1, 2, \ldots, N,$$

with κ_1 and κ_2 being constants determined from α, β in (1.1) and the initial setup (1.7). Formal derivation of the above reduced dynamics laws (5.1) for the CGLE can be followed from those in [27] for the GLE and NLSE. Again, the nonlinear ODEs (5.1) can be solved analytically as those in section 2.3 for the GLE and section 2.4 for the NLSE when the initial conditions in (5.2) are given by Patterns I–IV in section 2.2. The details are omitted here. For comparison, Figure 26 shows numerical solutions of (5.1) for different initial setups. This figure clearly confirms our conjecture (5.1) about the reduced dynamic laws of the CGLE for the interaction of N well-separated vortices with winding number $m_j = +1$ or -1.

5.2. Vortex motion under an inhomogeneous external potential. The particular external potential we take is of the form

$$V(\mathbf{x}) = \frac{\frac{1}{2} + \gamma_x x^2 + \gamma_y y^2}{1 + \gamma_x x^2 + \gamma_y y^2} = 1 - \frac{1}{2\,(1 + \gamma_x x^2 + \gamma_y y^2)}, \qquad \mathbf{x} \in \mathbb{R}^2, \tag{5.3}$$

where γ_x and γ_y are two positive constants. It is easy to see that $V(\mathbf{x})$ attains its minimum value $1/2$ at the origin $(0, 0)$. Here we study numerically the dynamics of a vortex in the following two cases:

Case I. Isotropic external potential, e.g., $\gamma_x = \gamma_y = 1$ in (5.3).

Case II. Anisotropic external potential, e.g., $\gamma_x = 1$ and $\gamma_y = 5$ in (5.3).

For the GLE, i.e., $\alpha = 1$ and $\beta = 0$ in (1.1), the velocity of the induced motion due to the inhomogeneous impurities was obtained in [17]:

$$\mathbf{v}(t) := \frac{d\mathbf{x}(t)}{dt} = -\nabla \ln V(\mathbf{x}(t)), \quad t \geq 0, \qquad \text{with} \quad \mathbf{x}(0) = \mathbf{x}^0. \tag{5.4}$$

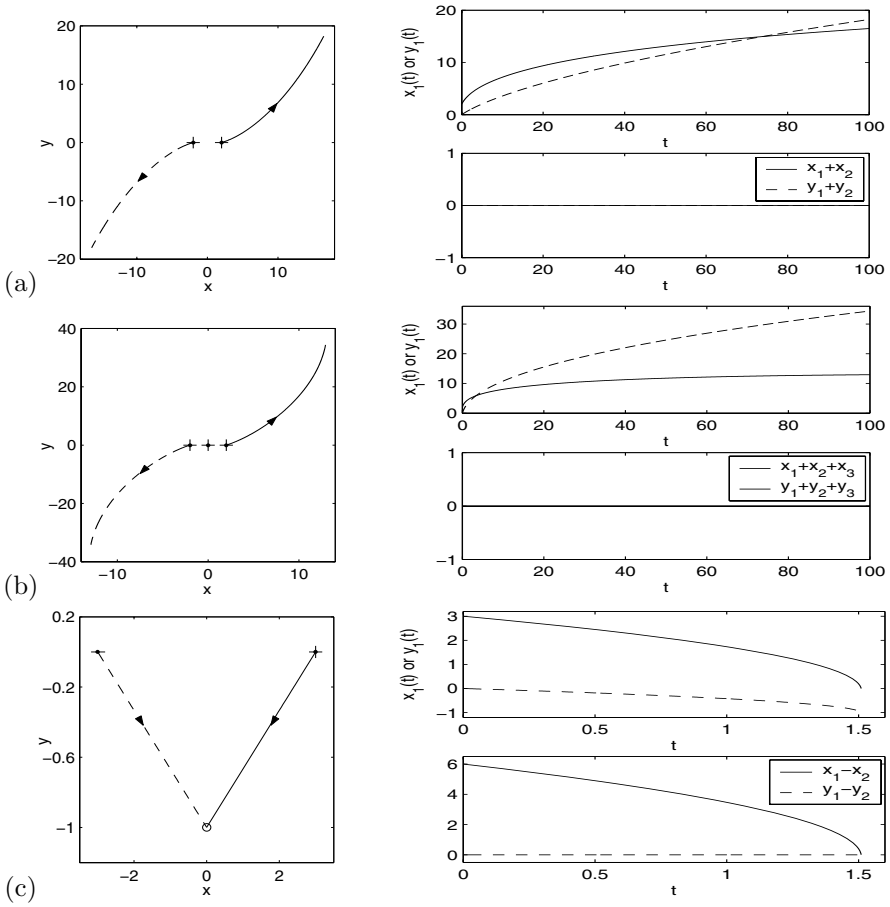

FIG. 26. *Numerical solutions of the reduced dynamical laws* (5.1) *for the CGLE with* $\kappa_1 = 3$ *and* $\kappa_2 = 1$ *for different initial setups.* (a) *Pattern* I *with* $N = 2$ *and* $a = 2$. (b) *Pattern* II *with* $N = 3$ *and* $a = 2$. (c) *Pattern* IV *with* $a = 3$.

This implies that here, the vortex would move to the minimizer of the external potential $V(\mathbf{x})$. Furthermore, if the external potential is isotropic, the trajectory is a segment connecting $\mathbf{x}^0$ and the minimization point of $V(\mathbf{x})$, while for the NLSE and CGLE, the dynamic laws with impurities remain to be established.

The initial condition in (1.2) is chosen as $\psi(\mathbf{x}, 0) = \phi_1\left(\mathbf{x} - \mathbf{x}^0\right)$ for $\mathbf{x} \in \mathbb{R}^2$, where $\phi_1 = \phi_1(\mathbf{x})$ is the vortex state solution (1.4) with winding number $m = +1$ and $\mathbf{x}^0$ is a given point. Figure 27 displays the time evolution of the vortex center in the GLE with $\mathbf{x}^0 = (1, 2)^T$ for different ε, and Figures 28 and 29 show similar results for the CGLE and NLSE, respectively.

From Figures 27–29, we can draw the following conclusions. First, for the GLE and CGLE, the vortex center moves monotonically to the position where the external potential $V(\mathbf{x})$ attains its minimum value (cf. Figures 27 and 28). The speed of the motion depends on the values of the parameter ε. The trajectory of the vortex center depends on the external potential $V(\mathbf{x})$, which agrees with the analytical results for the GLE in [16, 17, 21]. After the vortex reaches the minimum point of the external potential, it always stays at that point, which illustrates the pinning effect. Second,

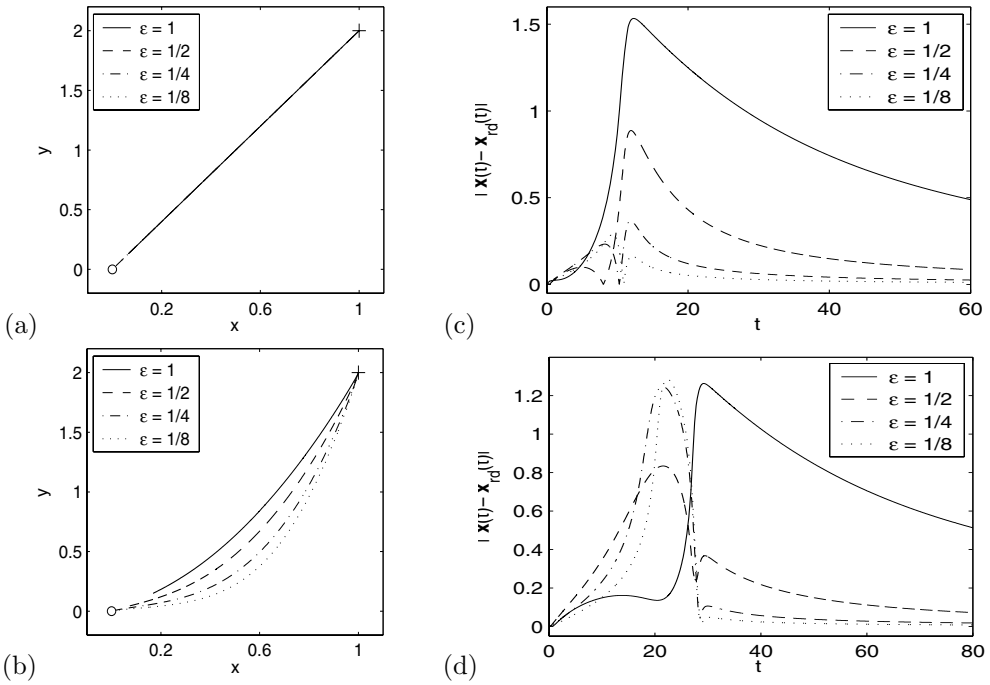

FIG. 27. *Time evolution of the vortex center under an inhomogeneous external driving potential in the GLE.* (a), (b): *Case* I *and* II, *respectively. Trajectory for different* ε. (c), (d): *Errors between the numerical results of the GLE* (*denoted as* $\mathbf{x}(t)$) *and the solution of the reduced dynamic laws* (5.4) (*denoted as* $\mathbf{x}_{\rm rd}(t)$).

for the NLSE, the vortex center moves rotationally clockwise when $m = +1$ and counterclockwise when $m = -1$, to the minimum position of the external potential (cf. Figure 29). The smaller ε, the longer the vortex center stays on a circle. Additional experiments were carried out for Case II. Similar motion patterns were observed, so the results are omitted here.

Based on the numerical results in Figures 28–29, it is reasonable to make the following conjectures about the vortex motion in the NLSE and CGLE: For the NLSE under an inhomogeneous potential, the velocity of the induced motion satisfies (cf. the right-hand side of Figure 29)

$$\mathbf{v}(t) := \frac{d\mathbf{x}(t)}{dt} = -m\kappa\,\mathbf{J}\nabla \ln V(\mathbf{x}(t)), \quad t \geq 0, \qquad \text{with} \quad \mathbf{x}(0) = \mathbf{x}^0, \tag{5.5}$$

where m is the winding number of the vortex, κ is a constant, and $\mathbf{J}$ is the symplectic matrix given in (1.13), while for the CGLE, it can be given by (cf. Figure 28(c),(d))

$$\mathbf{v}(t) := \frac{d\mathbf{x}(t)}{dt} = -\mathbf{Q}\nabla \ln V(\mathbf{x}(t)), \quad t \geq 0, \qquad \text{with} \quad \mathbf{x}(0) = \mathbf{x}^0, \tag{5.6}$$

where the matrix $\mathbf{Q} = m\,\kappa\mathbf{J} + \mathbf{I}$ with κ a constant, and $\mathbf{J}$ and $\mathbf{I}$ are the symplectic matrix in (1.13) and identity matrix, respectively. Their rigorous mathematical justification is not yet available.

6. Conclusion. We have studied the dynamics and interaction of quantized vortices in the Ginzburg–Landau–Schrödinger equation (GLSE) for modeling superconductivity and superfluidity both analytically and numerically. Along the analytical

front, we proved the conservation of the mass center and the signed mass center of N vortex centers governed by the reduced dynamic laws for the Ginzburg–Landau equation (GLE) and nonlinear Schrödinger equation (NLSE), respectively. We also solved analytically the nonlinear ordinary differential equations (ODEs) governing the reduced dynamic laws of the GLE and NLSE for some initial data with symmetrically placed vortices. On the numerical side, by applying an efficient, accurate, and unconditionally stable numerical method for the GLSE with nonzero far-field conditions in two dimensions, we numerically examined issues such as the interaction of vortices and the motion of a vortex under an inhomogeneous external potential in the GLSE. Comparisons between the solutions of the reduced dynamic laws and direct simulation results of the GLSE were provided. Some conclusive findings were obtained, and discussions on numerical and theoretical results were provided for further understanding of vortex interactions in the GLSE. In addition, the vortex motion under an inhomogeneous external potential in the GLSE was investigated numerically for the first time and some conjectures for the motion were made based on our computational findings. In the future, we will extend our efficient and accurate numerical method to the study of the dynamics and the interaction of vortex line states in three dimensions and in bounded domains for the GLSE.

SMALL- AND WAITING-TIME BEHAVIOR OF THE THIN-FILM EQUATION*

JAMES F. BLOWEY†, JOHN R. KING‡, AND STEPHEN LANGDON§

Abstract. We consider the small-time behavior of interfaces of zero contact angle solutions to the thin-film equation. For a certain class of initial data, through asymptotic analyses, we deduce a wide variety of behavior for the free boundary point. These are supported by extensive numerical simulations.

Key words. thin-film, waiting-time, interface, nonlinear degenerate parabolic

1. Introduction.

This paper is concerned with the small-time behavior of interfaces of zero contact angle solutions to the "thin-film" equation

$$\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x}\left(h^n \frac{\partial^3 h}{\partial x^3}\right), \tag{1.1a}$$

$$\text{with} \quad h = h_0(x) \quad \text{at } t = 0 \quad \text{and} \tag{1.1b}$$

$$h = \frac{\partial h}{\partial x} = h^n \frac{\partial^3 h}{\partial x^3} = 0 \quad \text{at } x = s(t), \tag{1.1c}$$

where $h \geq 0$ represents the thickness of a fluid film and $x = s(t)$ denotes the right-hand interface (with $h \equiv 0$ for $x > s(t)$); since we are concerned with the local behavior at such an interface we need not specify conditions at any left-hand moving boundary. The first boundary condition of (1.1c) defines the moving boundary (as the point at which the film thickness reaches zero), the second ensures a zero contact angle, and the third represents conservation of mass.

In the last few years the range $0 < n \leq 3$ has been considered in the literature from a modeling point of view. With $n = 3$, (1.1a–c) models the lubrication approximation of a surface tension-driven thin viscous film spreading on a solid horizontal surface, with a no-slip condition at the solid/liquid/air interface [5, 6, 10, 11, 12, 14, 34]. However, the no-slip condition implies an infinite force at the interface [19, 27]. To avoid this, more realistic models allowing slip have been proposed (see, e.g., [4, 22, 26]) for which it has been shown that the qualitative behavior of solutions in the vicinity of the interface corresponds to that of the solution of (1.1a–c) with $n \in (0, 3)$; this applies to questions of spreading or nonspreading as well as to questions of locally preserved positivity and local film rupture [17]. We also note that an application of

(1.1a) with $2 < n < 3$ to power-law shear-thickening fluids is derived in [30]. With $n \in (0, 3)$ it is also well known (see, e.g., [7, 8]) that (1.1a–c) admits solutions with a finite speed of propagation property; i.e., $s(t)$ represents a moving boundary, which moves at finite speed.

In this paper we thus consider only values of n in the moving front regime $0 < n < 3$, and we assume further that the film is thick enough that Van der Waals forces play no part. When considering solutions to (1.1a–c), the primary physical question is often to do with the movement of the free boundary. Where $h = 0$ there is no diffusion in (1.1a), and this can lead to waiting-time behavior, where the interface remains stationary for a period before moving; alternatively the interface may either advance or retreat immediately. A determination of the regimes in which such behavior can occur has considerable implications regarding the possibility of film rupture in the presence of a very thin prewetting layer; see, e.g., [31].

There has been much recent effort in the literature to answer outstanding questions about the initial movement of the interface. Theoretical results in [4, 5] have shown that the interface cannot retreat if $n \geq 3/2$, but that film rupture may occur for $n < 1/2$ (see also [13, 14]). Moreover, numerical evidence [4, 10, 12] suggests that for small values of n solutions which are initially strictly positive may vanish at some point x_0 after a finite time t_0, with the solution becoming zero on a set of positive measure shortly after the finite time singularity, a phenomenon called "dead core" in other fields. The existence of a *critical exponent* (a value of $n_* > 0$ for which solutions stay positive for $n > n_*$ and where finite-time singularities are possible for $n \leq n_*$) has been conjectured in [11], where it is remarked that numerical simulations suggest $1 < n_* < 3.5$. Our results below support and clarify these conjectures; in particular, here we provide the first concrete solutions to (1.1a–c) displaying retreat.

As explained in [31], subsequent to any waiting time the local behavior of solutions to (1.1a–c) takes the form

$$h \sim \left(\frac{n^3 \dot{s}}{3(3-n)(2n-3)} (s-x)^3 \right)^{\frac{1}{n}} \quad \text{as } x \to s^- \quad \text{for } \frac{3}{2} < n < 3, \tag{1.2}$$

$$h \sim \left(\frac{3}{4} \dot{s} (s-x)^3 \ln \left[\frac{1}{(s-x)} \right] \right)^{\frac{2}{3}} \quad \text{as } x \to s^- \quad \text{for } n = \frac{3}{2}, \tag{1.3}$$

$$h \sim B(t)(s-x)^2 \quad \text{as } x \to s^- \quad \text{for } n < \frac{3}{2}. \tag{1.4}$$

With $0 < n < 3$, in (1.2) we require that $\dot{s} > 0$, whereas in (1.4) the interface velocity $\dot{s}$ may take either sign, with $B(t)$ determined as part of the solution. One of the key motivations for the current analysis is to provide criteria under which $\dot{s} < 0$ holds for sufficiently small time; since $\dot{s} > 0$ typically holds for large times, for example for the Cauchy problem with initial data of finite mass, a large-time analysis provides no insight into such matters.

For definiteness, we shall consider the case

$$h_0(x) \sim A_0(x_0 - x)^\alpha + C_0(x_0 - x)^\beta \quad \text{as } x \to x_0^-, \tag{1.5}$$

where A_0, α, and β are positive constants with $\beta > \alpha$; C_0 is a constant; and $x_0 = s(0)$.

Extensive studies of the small-time behavior have already been done for the corresponding second-order problem, the porous-medium equation:

$$\frac{\partial h}{\partial t} = \frac{\partial}{\partial x} \left(h^n \frac{\partial h}{\partial x} \right) \tag{1.6}$$

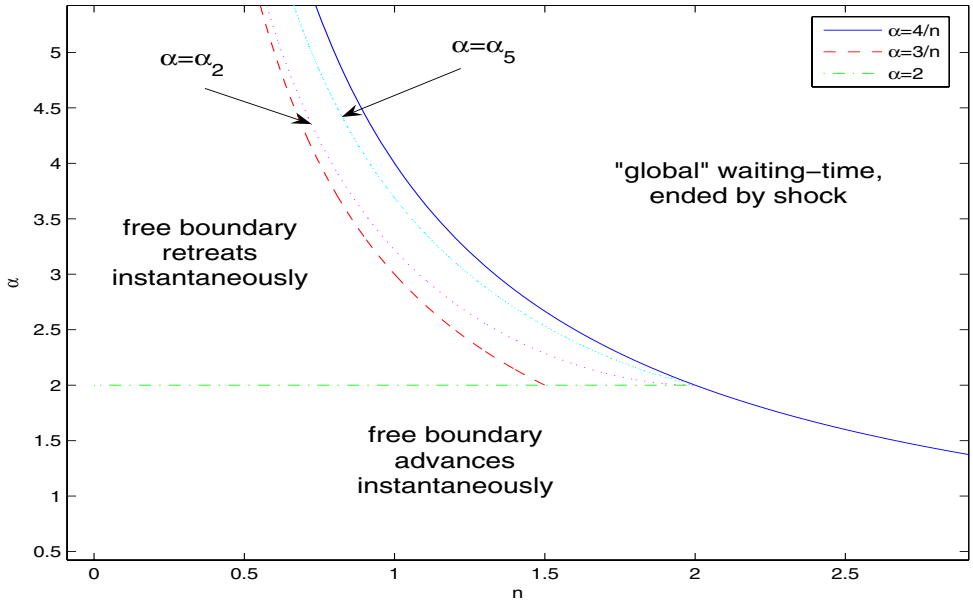

FIG. 1.1. *A summary of the possible small-time behaviors with respect to n and α. By "shock" we mean that a steep front suddenly overruns the interface. In the region* $\max(2, 3/n) < \alpha < 4/n$ *a diverse range of waiting-time scenarios are seen: specifically (see sections* 4.4.1 *and* 4.6.1*) the interface waits, but the local profile changes instantaneously from that of the initial data and can exhibit monotonic (if* $\alpha_5 < \alpha < 4/n$*) or oscillatory (if* $\alpha_2 < \alpha < \alpha_5$*) decay to the local solution, or limit-cycle behavior (if* $\max(2, 3/n) < \alpha < \alpha_2$*).*

with $n > 0$. We present our results in this context. The variety of possible small-time behaviors for (1.1a–c) is summarized in Figure 1.1, and can be characterized as follows:

(i) For α greater than some critical value, the interface "waits" for some finite time t_w, whereby

$$s(t) = x_0 \quad \text{for } 0 \le t \le t_w,$$

after which time it moves. (See also [18, 21, 23] for rigorous studies of such waiting-time phenomena for (1.1a).) For $\alpha = 4/n$ an upper bound on t_w can be deduced from the local behavior of the solution (cf. [33] for the corresponding case (1.6)); more generally, information about t_w can be obtained from the full (global) solution (cf. [32] for (1.6)).

(ii) For α below the critical value, the interface will move at once, with (in view of (1.2)–(1.3))

$$s(t) > x_0 \quad \text{for } t > 0$$

for $3/2 \le n < 3$ (cf. [25] for (1.6)). For $n < 3/2$, however, $\dot{s} < 0$ is also possible, so a further classification is required according to whether $\dot{s} > 0$ or $\dot{s} < 0$ for small $t > 0$. This does not arise in the corresponding analysis of (1.6), since $\dot{s} \ge 0$ necessarily holds.

In addition, the higher order of (1.1a) leads, as we shall see, to a much more diverse range of waiting-time scenarios than that which occurs for (1.6), as shown in Figure 1.1.

The definitions of α_2 and α_5 are rather complicated; for details we refer to section 4.4.1, section 4.6.1, and Appendix A.

In seeking a physical explanation for these results, we remark that larger n implies weaker slip, and large α a shallow initial "contact angle." Broadly speaking, the larger the value of n/α, the stronger is the tendency of solutions to stay positive. The current phenomena are associated with perfectly wetting (zero-contact-angle) boundary conditions and should not be confused with those associated with finite static contact angles. In the latter (i.e., partially wetting) case, for viscous fluids with an initial condition characterized by a contact angle sufficiently greater (respectively, less) than equilibrium, the droplet tends to spread (contract) with no waiting. For intermediate contact angles, waiting-time behavior associated with contact-angle hysteresis can occur. Although such behavior has some similarities with that described below (in particular, retreating contact lines are associated with initial data that are "smaller" than advancing ones), there are also important differences, notably that waiting-time behavior is in general associated with the "smallest" initial data.

We are not aware of any experimental evidence to support our conjectures, but in light of our results such experiments might be timely. For a discussion of the physical length scales pertinent to the slip-dominated ($n = 2$) model, see, for example, [20], and also references therein regarding such strong slip conditions. (We note that this paper also includes an additional term, not present in the thin-film equation, that is relevant for slip lengths even longer than those for which (1.1a–c) applies with $n = 2$.) Instead, we support our asymptotic conjectures with numerical results. Without loss of generality we assume that $s(0) > 0$ and, for numerical purposes, we first approximate (1.1a–c) by replacing (1.1c) by

$$\frac{\partial h}{\partial x} = h^n \frac{\partial^3 h}{\partial x^3} = 0 \quad \text{for } x = 0, l, \tag{1.7c}$$

where $l \gg s(0)$, and restrict (1.1a) to hold on $(0, l)$. Existence of solution concepts for (1.1a,b), (1.7c) may be found in [5, 9, 14] and the references cited therein.

As described in [2], we discretize (1.1a,b), (1.7c) using finite elements in space and finite differences in time, using uniform spatial and temporal discretization parameters δx and δt, respectively; see section 2 for details. We expect that this method will be able to compute the zero contact angle solution for the following reasons:

1. In [5], the existence of solutions to (1.1a,b), (1.7c) is proved for $0 < n < 3$, where $h(\cdot, t)$ may be $C^1([0, l])$ for almost every $t > 0$ (the zero contact angle solution), or alternatively $h(\cdot, t)$ may have nonexpansive support.
2. In [2] it was proved that the numerical solution converges, as $\delta x, \delta t \to 0$, to a weak solution of (1.1a,b), (1.7c) (in the sense of [5, 9, 14]). The only remaining question is whether this is the zero contact angle solution or a solution with nonexpansive support.
3. In a sequence of experiments, taking $\delta t = O(\delta x^{\frac{1}{2}})$, the numerical method computes a solution with nonexpansive support.
4. In a sequence of experiments, taking $\delta t = O(\delta x^2)$, the numerical method can compute solutions where $|\dot{s}(0)| = \infty$ (zero contact angle solutions).
5. In [2] a self-similar source type solution was successfully computed with $\delta t = O(\delta x^2)$. Moreover, taking a nonsmooth stationary solution as initial data, i.e., $h_0(x) = \alpha \max\{\gamma^2 - x^2, 0\}$ and $0 < \gamma < l$, the numerical method computed a smooth solution for $0 < n < 3$, and it was concluded that $h(x, t) \equiv h_0(x)$ for $n > 3$.

Hence in our experiments, in order to be sure that we are approximating the zero contact angle solution we always choose $\delta t = O(\delta x^2)$. We report that the numerical solution always appears to be smooth.

An outline of the paper is as follows. We begin in section 2 by describing our numerical scheme in more detail. We then proceed in sections 3 and 4 with a formal asymptotic analysis, supported by numerical experiments, for the two cases $\alpha \geq 4/n$ and $\alpha < 4/n$, respectively. Videos demonstrating more graphically how some of the numerical solutions of these sections evolve over time can be found online at http://www.personal.rdg.ac.uk/∼sms03sl/4thorder/4thorder.html. Finally, in section 5 we present some conclusions.

2. Numerical approximation. Following the approach of [2], and as described in section 1, we restrict (1.1a) to a finite space interval $(0, l)$, introduce a potential w, and rewrite it as the system of equations

$$\frac{\partial h}{\partial t} = \frac{\partial}{\partial x}\left(h^n \frac{\partial w}{\partial x}\right) \quad \text{in } (0,l)\times(0,T), \tag{2.1a}$$

$$-\frac{\partial^2 h}{\partial x^2} = w \quad \text{in } (0,l)\times(0,T). \tag{2.1b}$$

A nonnegativity constraint is imposed on (2.1b) via a variational inequality in the weak form, and then we discretize (2.1a,b) using the finite element method. Now, given positive integers N and M, denote by $\delta t := T/M$ and $\delta x := l/N$ the temporal and spatial discretization parameters, $t_k := k\delta t$, $k = 1, \ldots, M$, and $x_j = j\delta x$, $j = 0, \ldots, N$; then the discretization may be written in the following way.

For $k = 1, \ldots, M$ and $j = 1, \ldots, N-1$ find $\{H_j^{k+1}, W_j^{k+1}\}$ such that

$$\frac{H_j^{k+1} - H_j^k}{\delta t} + \frac{1}{\delta x^2}\left[\int_{x_{j-1}}^{x_j} \left(\frac{(x - x_{j-1})}{\delta x} H_j^k + \frac{(x_j - x)}{\delta x} H_{j-1}^k\right)^n \mathrm{d}x\right]\left(\frac{W_j^{k+1} - W_{j-1}^{k+1}}{\delta x}\right)$$

$$+ \frac{1}{\delta x^2}\left[\int_{x_j}^{x_{j+1}} \left(\frac{(x - x_j)}{\delta x} H_{j+1}^k + \frac{(x_{j+1} - x)}{\delta x} H_j^k\right)^n \mathrm{d}x\right]\left(\frac{W_j^{k+1} - W_{j+1}^{k+1}}{\delta x}\right) = 0, \tag{2.2a}$$

$$\left[\frac{-H_{j+1}^{k+1} + 2H_j^{k+1} - H_{j-1}^{k+1}}{\delta x^2} - W_j^{k+1}\right] H_j^{k+1} = 0, \tag{2.2b}$$

$$\frac{-H_{j+1}^{k+1} + 2H_j^{k+1} - H_{j-1}^{k+1}}{\delta x^2} - W_j^{k+1} \geq 0, \tag{2.2c}$$

$$H_j^{k+1} \geq 0, \tag{2.2d}$$

where $H_j^k \approx h(x_j, t_k)$, $W_j^k \approx w(x_j, t_k)$, $H_j^0 = h_0(x_j)$; similar equations/inequalities appropriate for boundary data (1.7c) hold for $j = 0, N$ when $k = 1, \ldots, M$. This nonlinear system is solved using a Gauss–Seidel algorithm in multigrid mode; for details we refer to [3]. We found this approach to have several advantages over some other algorithms previously proposed in the literature, such as the Uzawa-type algorithm [2, (3.7a–c)], [24]. Specifically, we find the following:

1. If $H_{j-1}^k = H_j^k = H_{j+1}^k = 0$, then it follows from (2.2a) that $H_j^{k+1} = H_j^k = 0$, so that the free boundary advances at most one mesh point from time level k

to time level $k+1$. The advantage of using the nonsymmetric Gauss–Seidel smoother is that this constraint is easier to impose on the numerical method than with a symmetric smoother.

2. Working within a multigrid framework significantly increases the rate of convergence. This allows us to reduce the tolerance for the stopping criterion of the iterative scheme (the maximum absolute difference in successive iterates is smaller than tol) to $tol = 10^{-12}$, as compared with $tol = 10^{-8}$ in [2], and therefore to solve the nonlinear system more accurately, thereby helping to avoid spurious behavior.
3. Nonnegativity of the computed numerical solution is guaranteed, and so defining the position x_c^k of the numerical free boundary at time t_k to be

$$x_c^k := \{x_j > 0 : H_m^k \le \epsilon \text{ for all } m \ge j,\ H_{j-1}^k > \epsilon\},$$

we take $\epsilon = 0$, which tracks the free boundary more accurately than with $\epsilon > 0$; this compares with $\epsilon = 10^{-6}$ in [2]. We remark that because the numerical free boundary is defined on a discrete set of points, its movement appears to "stutter" in the figures below. Although the interface always advances or retreats with a stepping motion, oscillations are seen only in certain cases. Moreover, it is sometimes the case that the oscillations in H_j^k begin and grow before the contact line moves; hence they do not appear to be caused by this "stuttering."

In the numerical experiments of sections 3 and 4 we solve (1.1a,b), (1.7c) with $l = 1$ and

$$h_0(x) = 5 \max\left\{\left(\tfrac{9}{16} - x^2\right)^{\alpha}, 0\right\}; \tag{2.3}$$

the key properties are that the maximum value of h_0 is $O(1)$ and the thin film is symmetrically distributed about 0 with $x_0 = 3/4$. These experiments were performed for a sequence of space steps δx, where $\delta t = C_{\alpha,n}\delta x^2$ and convergence of (2.2a)–(2.2d) to a weak solution of (1.1a,b), (1.7c), (2.3) was assured (see [2]). For reasons of space we refer to [15] for further figures and numerical results, including results from many more experiments with values of n and α closer to the edges of the parameter regimes.

3. Formal asymptotic analysis and numerical results for $\alpha \ge 4/n$. For $\alpha \ge 4/n$, the formal asymptotic analysis of this section suggests that we might expect waiting-time behavior. In particular, for $\alpha > 4/n$ (section 3.1) we anticipate "global" waiting-time behavior, by which we mean that the asymptotic expansion tells us to expect a waiting time but gives no clue as to the local behavior; in this case the interface starts to move due to shock formation, with the gradient becoming unbounded near the free boundary. For $\alpha = 4/n$ (section 3.2) this global breakdown can occur for the full range $0 < n < 3$, but for $2 < n < 3$ "local" waiting-time behavior is also possible; by this we mean that the dominant term in the asymptotic expansion switches at the end of the waiting time.

3.1. $\alpha > 4/n$: Global waiting-time behavior. Provided that $h_0(x)$ is analytic away from the interfaces, then the small-time expansion

$$h \sim h_0 - \frac{\mathrm{d}}{\mathrm{d}x}\left(h_0^3 \frac{\mathrm{d}^3 h_0}{\mathrm{d}x^3}\right) t \quad \text{as } t \to 0^+ \tag{3.1}$$

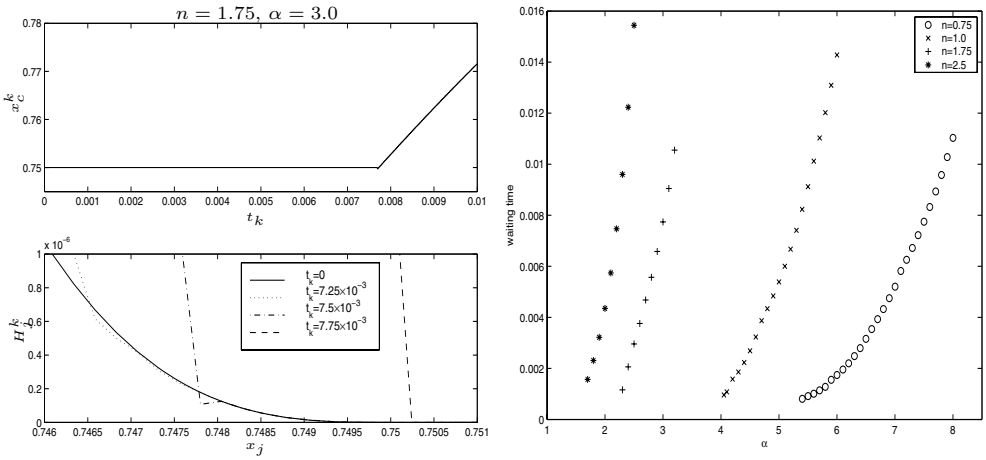

FIG. 3.1. *Waiting-time behavior, various* n, α.

holds, at least away from the interface. From (1.5) we have

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(h_0^n \frac{\mathrm{d}^3 h_0}{\mathrm{d}x^3}\right) \sim \alpha(\alpha-1)(\alpha-2)((n+1)\alpha-3)A_0^{n+1}(x_0-x)^{(n+1)\alpha-4} + \left(n\alpha(\alpha-1)(\alpha-2)+\beta(\beta-1)(\beta-2)\right)(n\alpha+\beta-3)A_0^n C_0 (x_0-x)^{n\alpha+\beta-4} \quad \text{as } x \to x_0^-; \tag{3.2}$$

for $\alpha > 4/n$ we have $(n+1)\alpha - 4 > \alpha$, and we may expect the local behavior

$$h \sim A_0(x_0-x)^\alpha \quad \text{as } x \to x_0^- \tag{3.3}$$

to hold up to some finite time $t = t_w > 0$, implying a waiting-time scenario in which the local behavior at the interface does not change for some nonzero waiting time.

To test this conjecture, we ran numerical experiments for a large range of n and $\alpha > 4/n$, considering in particular $n = 0.75$, 1.0, 1.75, and 2.5, so as to cover all of the different regimes important in the case $\alpha < 4/n$ (see section 4).

In the upper left panel of Figure 3.1 we plot x_c^k against t_k for $n = 1.75$ and $\alpha = 3.0 > 4/n = 2.29$. The numerical free boundary remains stationary for a period before advancing. We also plot profiles of H_j^k in the vicinity of the interface at times just before and just after x_c^k begins to move (lower left panel). Shock-type behavior at the end of the waiting time can be observed (cf. [32] for the second-order case).

Similar waiting-time behavior, with shock type behavior at the end of the waiting time, was observed for all n, α combinations tested in this range. Approximate waiting times are plotted against α in the right half of Figure 3.1, for $n = 0.75, 1.0, 1.75, 2.5$ and for various $\alpha > 4/n$. For fixed n, the waiting time increases as α increases.

3.2. $\alpha = 4/n$: Local waiting-time behavior for $2 < n < 3$. In the critical case, the leading term in (1.5) suggests the separable local behavior

$$h \sim \Lambda(t)(x_0-x)^{4/n} \quad \text{as } x \to x_0^-, \tag{3.4}$$

with (1.1a–c) implying

$$\dot{\Lambda} = -\tfrac{4}{n}\left(\tfrac{4}{n}-1\right)\left(\tfrac{4}{n}-2\right)\left(\tfrac{4}{n}+1\right)\Lambda^{n+1}.$$

Hence if $n \neq 2$ (recalling that we consider in this paper only $0 < n < 3$), then

$$\Lambda = A_0 \left(1 + \frac{8(4-n)(2-n)(n+4)A_0^n t}{n^3}\right)^{-\frac{1}{n}}. \tag{3.5}$$

This local solution also represents waiting-time behavior; (3.5) blows up in finite time if $2 < n < 3$, so the waiting time t_w then satisfies

$$t_w \leq t_c \equiv \frac{n^3}{8(4-n)(n-2)(n+4)A_0^n};$$

$\Lambda(t)$ decreases with time for $0 < n < 2$, but we nevertheless expect (3.4) to remain valid only up to some finite t_w, after which the front begins to move due to shock, as described in section 3.1. Thus for $2 < n < 3$ local waiting-time behavior ($t_w = t_c$) is possible, analogous to that for the porous-medium equation [33], while global breakdown ($t_w < t_c$ for $2 < n < 3$) can occur for the full range $0 < n < 3$ (cf. [32]).

4. Formal asymptotic analysis and numerical results for $\alpha < 4/n$. We begin in section 4.1 by deriving some local similarity solutions. Based on these and the local behavior indicated in (1.2)–(1.4), we conjecture in sections 4.2–4.6 some parameter regimes for the small-time behavior when $\alpha < 4/n$, in which case (3.3) fails for any $t > 0$. This does not mean that for $\alpha < 4/n$ there is no waiting-time behavior; on the contrary, unlike for the corresponding second-order problem (1.6), a diverse range of waiting-time scenarios can occur in this case. In addition to these waiting-time scenarios, the front may also advance or retreat instantaneously. Many of our conjectures are supported by extensive numerical verifications, detailed below; we leave open their rigorous confirmation.

4.1. Local similarity solutions. In view of (1.5), a natural conjecture for the small-time behavior for $\alpha < 4/n$ (balancing the terms in the expansion so that they are of the same size) is the self-similar form

$$h \sim t^{\frac{\alpha}{4-n\alpha}} f\left((x-x_0)/t^{\frac{1}{4-n\alpha}}\right), \quad s(t) \sim x_0 + \eta_0 t^{\frac{1}{4-n\alpha}}, \tag{4.1}$$

where with $\eta := (x-x_0)/t^{1/(4-n\alpha)}$, $f(\eta)$ satisfies the boundary-value problem

$$\frac{1}{4-n\alpha}\left(\alpha f - \eta \frac{\mathrm{d}f}{\mathrm{d}\eta}\right) = -\frac{\mathrm{d}}{\mathrm{d}\eta}\left(f^n \frac{\mathrm{d}^3 f}{\mathrm{d}\eta^3}\right), \tag{4.2}$$

$$\text{(4.3a) as } \eta \to -\infty,\ f \sim A_0(-\eta)^\alpha - \alpha(\alpha-1)(\alpha-2)((n+1)\alpha-3)A_0^{n+1}(-\eta)^{(n+1)\alpha-4},$$

$$\text{at } \eta = \eta_0, \quad f = \frac{\mathrm{d}f}{\mathrm{d}\eta} = f^n \frac{\mathrm{d}^3 f}{\mathrm{d}\eta^3} = 0. \tag{4.3b}$$

Here $s(t)$ is the position of the interface at time t, and η_0 is a free constant determined by the boundary-value problem.

The behavior as $\eta \to -\infty$ in (4.3a) thereby matches via (3.1) with the leading terms in (1.5) and (3.2). The constant A_0 can be removed via the change of variables

$$f = A_0^{\frac{4}{4-n\alpha}} \hat{f}, \quad \eta = A_0^{\frac{n}{4-n\alpha}} \hat{\eta},$$

suggesting in particular the delicacy of the limit $\alpha \to (4/n)^-$, and the transformation

$$f = |\eta|^{\frac{4}{n}} g(\xi), \quad \xi = \ln|\eta|$$

enables (4.2) to be reduced to a fourth-order autonomous problem. Nevertheless, the complexities of the resulting four-dimensional phase space mean that a global analysis of (4.2) (akin to that in [33] for the second-order problem) is not practicable here. Instead we base our conjectures in large part on a number of closed-form solutions to (4.2), which we now note. We assume (4.2)–(4.3a,b) to have a unique nonnegative solution.

(I) Separable solution

$$f(\eta) = \left(\frac{n^3}{8(4-n)(2-n)(n+4)} (-\eta)^4 \right)^{\frac{1}{n}} \tag{4.4}$$

is an explicit solution to (4.2) for $0 < n < 2$, providing a possible local behavior as $\eta \to 0^-$ for solutions with $\eta_0 = 0$; the circumstances under which (4.4) may be applicable are clarified in Appendix A.

(II) Steady-state solution

$$f(\eta) = A_0(-\eta)^2, \quad \eta_0 = 0, \tag{4.5}$$

gives the solution to (4.2)–(4.3a,b) when $\alpha = 2$.

(III) Traveling wave solution

$$f(\eta) = A_0(\eta_0 - \eta)^{\frac{3}{n}}, \quad \eta_0 = \frac{3(3-n)(2n-3)A_0^n}{n^3}, \tag{4.6}$$

is the solution to (4.2)–(4.3a,b) when $\alpha = 3/n$, $n \neq 3/2$; here $\eta_0 > 0$ if $3/2 < n < 3$, and $\eta_0 < 0$ if $0 < n < 3/2$.

To complete our catalogue of pertinent closed-form solutions we note that for $n = 1$ the polynomial solution (cf. [28])

$$\begin{aligned} h &= \frac{A_0^3}{4(1+30C_0^2t/A_0)C_0^2} \left((1 + C_0(x_0 - x)/A_0)^2 - (1 + 30C_0^2t/A_0)^{\frac{2}{5}} \right)^2, \\ s &= x_0 - A_0 \left((1 + 30C_0^2t/A_0)^{\frac{1}{5}} - 1 \right) / C_0, \end{aligned} \tag{4.7}$$

corresponds to

$$h_0 = A_0(x_0 - x)^2 + C_0(x_0 - x)^3 + C_0^2(x_0 - x)^4/(4A_0), \tag{4.8}$$

so that $\alpha = 2$, $\beta = 3$ in (1.5); hence s initially decreases if $C_0 > 0$ but increases if $C_0 < 0$, with

$$s(t) \sim x_0 - 15C_0t \quad \text{as } t \to 0^+, \tag{4.9}$$

this dependence on the sign of C_0 being perhaps counter intuitive, which is far from unusual in such high-order diffusion problems.

4.2. Small-time behavior for $2 < n < 3$. In this regime, the solution (4.4) is not available to describe the local behavior of $f(\eta)$ at the interface; (4.6) has the expected local behavior (1.2), while (4.5) corresponds to $\alpha > 4/n$ and therefore lies in the waiting-time regime discussed in section 3.1. We thus anticipate that for any $\alpha < 4/n$ the support of h expands immediately according to (4.1) with $\eta_0 > 0$ and, in (4.2)–(4.3a,b),

$$f(\eta) \sim \left(\frac{n^3\eta_0}{3(3-n)(2n-3)(4-n\alpha)} (\eta_0 - \eta)^3 \right)^{\frac{1}{n}} \quad \text{as } \eta \to \eta_0^-, \tag{4.10}$$

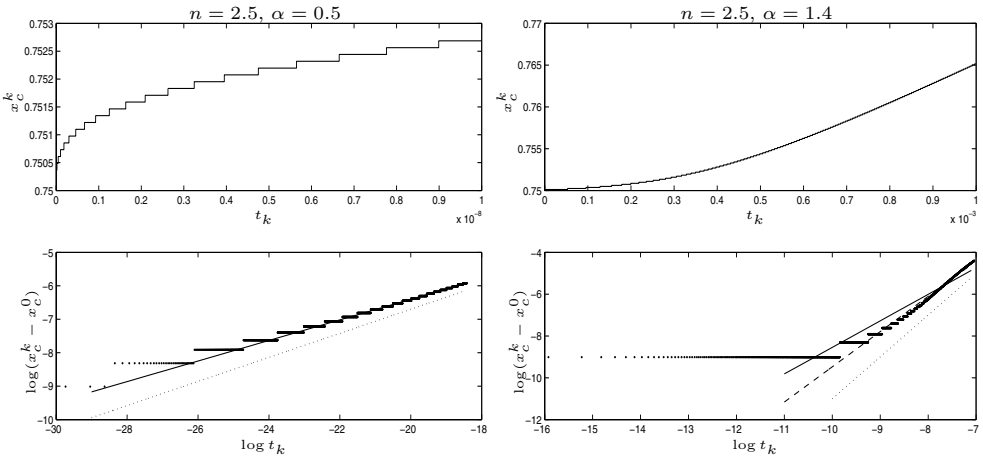

FIG. 4.1. *Numerical results for* $n = 2.5$, $\alpha = 0.5$, $T = 10^{-8}$ *(left), and for* $n = 2.5$, $\alpha = 1.4$, $T = 10^{-3}$ *(right). In the top panels the advancing free boundary is shown. In the bottom panels* $\log t_k$ *is plotted against* $\log(x_c^k - x_c^0)$ *as a discrete set of points, with the solid line following from a least squares fitting, the straight dotted line from asymptotic theory, and the dashed line in the lower right section from a least squares fitting with the early data removed.*

which follows from (1.2). The interface advances with unbounded initial velocity for $\alpha < 3/n$, with finite positive initial velocity if $\alpha = 3/n$ (with $f(\eta)$ given by (4.6)), and with velocity tending to zero as $t \to 0^+$ for $\alpha > 3/n$. The behavior in this regime is very much analogous to that exhibited by the porous-medium equation (cf. [25]).

To test this conjecture we ran numerical experiments for $n = 2.5$, for which $3/n = 1.2$ and $4/n = 1.6$, and for $\alpha \in [0.5, 1.5]$. Our results support the conjecture. In each case x_c^k advances, with the speed of the advance decreasing as α increases from 0.5 to 1.5. We plot x_c^k against t_k for $n = 2.5$ and for $\alpha = 0.5 < 3/n$ and $\alpha = 1.4 > 3/n$ in the upper half of Figure 4.1. Note the different time scales on the two plots.

In the lower half of Figure 4.1 we test the hypothesis that for small times

$$x_c^k = x_c^0 + At_k^\gamma, \tag{4.11}$$

for some constants $A > 0$ and γ, by plotting $\log(x_c^k - x_c^0)$ against $\log t_k$ (as a discrete set of points—these appear to "stutter" since the numerical free boundary advances by one discrete mesh point at a time). If the hypothesis is correct, we expect a straight line with slope γ. To estimate the value of γ we take a least squares fit. For presentational purposes we plot the best fitting least squares line as a solid line, and for comparison we also plot a dotted line with slope $(4 - n\alpha)^{-1}$, the expected value of γ (recall (4.1)).

For $\alpha = 0.5$ the log-log plot is fairly straight, and the estimated value of $\gamma = 0.31$ is close to the expected value of 0.36. For $\alpha = 1.4$ the best fitting least squares line gives an estimate of $\gamma = 1.27$, which is not close to the expected value of 2.00 and is a poor fit to the data. In this case the immediate yet slow advance of the free boundary means that, for t_k small, x_c^k overestimates the exact position of the free boundary. This is demonstrated by the fact that the lowest horizontal line of dots on the log-log plot, corresponding to the first step in the advance of x_c^k, matches very poorly with the rest of the data. In the lower right plot of Figure 4.1 we thus also show as a dashed line the best fitting least squares approximation to the data with the first step

TABLE 4.1
Estimated and expected values of γ for $n = 2.5$, various α.

α	0.5	0.6	0.7	0.8	0.9	1.0	1.1	1.2	1.3	1.4	1.5
$\frac{1}{4-n\alpha}$	0.36	0.40	0.44	0.50	0.57	0.67	0.80	1.00	1.33	2.00	4.00
γ	0.31	0.35	0.39	0.46	0.53	0.61	0.76	0.91	1.12	1.69	3.43

in the advance of x_c^k excluded (equivalently, taking $t_k \gtrapprox 5 \times 10^{-5}$ rather than $t_k > 0$ on the log-log plot). This dashed line, with a slope of 1.69, matches the slope of the data and the expected value of γ much more closely than our original estimate.

The expected and estimated values of γ for each value of α tested are shown in Table 4.1. For $\alpha \leq 1.3$ we estimate γ using all of the data, but for $\alpha = 1.4$ and $\alpha = 1.5$ we exclude the first step in the advance of x_c^k, as discussed above. The numerical results give a value of γ slightly lower than the expected value, but the difference is small, and the trend of γ increasing with α is clear. Our estimate for γ is more accurate for values of α away from the edges of the parameter regime.

4.3. Small-time behavior for $n = 2$. The behavior for $\alpha < 2$ is as described in section 4.2. However, for $\alpha = 2$ the solution (4.1) is not applicable and, partly because $\alpha = 2$ will also play an important role in what follows, additional comments regarding the resulting waiting-time scenario are instructive. The small-time solution (4.5) suggests that there is initially no change in local behavior, while (3.2) becomes

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(h_0^n \frac{\mathrm{d}^3 h_0}{\mathrm{d}x^3}\right) \sim (\beta+1)\beta(\beta-1)(\beta-2)A_0^2 C_0 (x_0-x)^\beta t; \tag{4.12}$$

both suggest seeking a local solution of the form

$$h \sim A_0(x_0-x)^2 + H(x,t) \quad \text{as } x \to x_0^-; \tag{4.13}$$

we note that H need not be positive on $x < x_0$ because it represents a correction term to the (quadratic) leading order behavior. Linearizing in H yields

$$\frac{\partial H}{\partial t} = -A_0^2 \frac{\partial}{\partial x}\left((x_0-x)^4 \frac{\partial^3 H}{\partial x^3}\right),$$

and so, given (1.5) in which $\beta > 2$ is required, the correction term takes the separable form

$$H = C_0(x_0-x)^\beta \exp\left(-(\beta+1)\beta(\beta-1)(\beta-2)A_0^2 t\right),$$

consistent with (3.1), (4.12). The perturbation to the quadratic term thus decays exponentially, and we expect (4.13) to persist up to some finite waiting time, after which the interface will start to move due to shock formation (as in other global waiting-time cases described here; see [32] for the second-order analogue).

4.4. Small-time behavior for $3/2 < n < 2$. In this case (4.6) again has the expected interface behavior (1.2), while (4.5) is nongeneric in the sense that it is smoother than (1.2) at the interface; the solution of (4.2)–(4.3a,b) for $\alpha = 2$ is therefore an exceptional connection in phase space and can be expected to play a role in separating distinct regimes, as we now suggest. The other noteworthy change to occur as n drops below two is that the local behavior (4.4) can come into play.

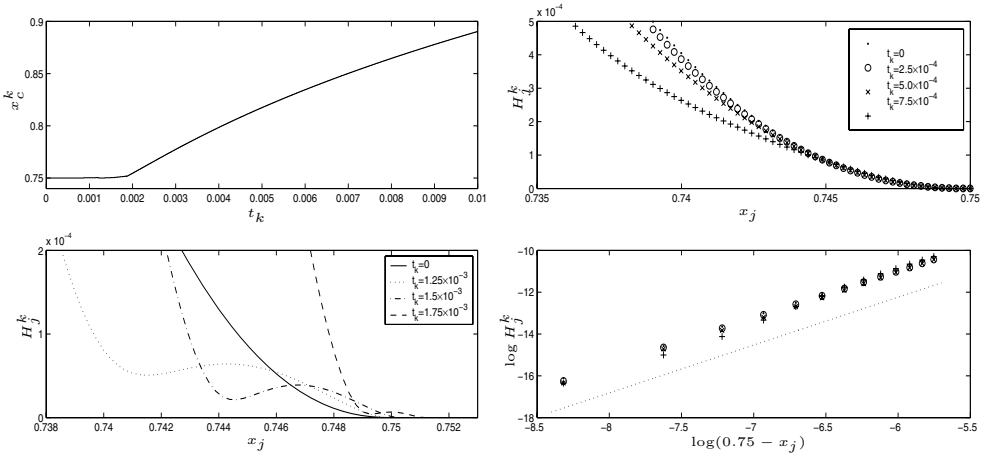

FIG. 4.2. *Numerical results for $n = 1.75$, $\alpha = 2.24$: waiting-time behavior (upper left plot); profiles of H_j^k near the interface while the free boundary is stationary (upper right plot), and as the free boundary advances (lower left plot); $\log H_j^k$ against $\log(0.75 - x_j)$ in the vicinity of the free boundary, with a dotted line from asymptotic theory (lower right plot—same legend as upper right).*

4.4.1. $2 < \alpha < 4/n$. The solution to (4.2)–(4.3a,b) has the local behavior which decays as $(-\eta)^{4/n}$ as $\eta \to 0^-$ and exhibits a finite waiting time; for $\alpha_2 < \alpha < 4/n$, where α_i, $i = 1, 2, 5$ are defined in Appendix A, $f(\eta)$ has local behavior (4.4), so the solution decreases such that

$$h \sim \left(\frac{n^3 (x_0 - x)^4}{8(4-n)(2-n)(n+4)t} \right)^{1/n} \quad \text{as } x \to x_0^-,\ 0 < t < t_w, \tag{4.14}$$

for the duration of the period of waiting. Moreover, for $\alpha_5 < \alpha < 4/n$ we expect nonoscillatory decay, whereas for $\alpha_2 < \alpha < \alpha_5$ we expect damped oscillations to occur. See Appendix A for details. For $2 < \alpha < \alpha_2$ the behavior is slightly more subtle, with a limit cycle (see (A.5) of Appendix A) arising in the local description for $0 < t < t_w$; the limiting behavior as $\alpha \to 2$ is addressed in Appendix B, providing additional support for conjectures about the (rather subtle) asymptotic behavior.

We present numerical results for $n = 1.75$ (giving $3/n = 1.7143$, $\alpha_2(n) = 2.0768$, $\alpha_5(n) = 2.2$, $4/n = 2.2857$), and for $\alpha = 2.24$, 2.10 and 2.04, thus covering each of the three parameter regimes described above. In the upper left plots of Figures 4.2, 4.3, and 4.4, we plot x_c^k against t_k for $n = 1.75$ and $\alpha = 2.24$, 2.10, and 2.04, respectively. In each case x_c^k remains stationary for a period before advancing, with the length of the waiting period appearing to decrease as α decreases. We also plot in each figure profiles of H_j^k near the interface at various times while the free boundary is stationary (upper right plot) and just as the free boundary is beginning to advance (lower left plot). In each case as $x \to x_0^-$ the profile of H_j^k appears to remain unchanged for a short waiting period. In the lower right plot of each figure we plot $\log H_j^k$ against $\log(0.75 - x_j)$ in the vicinity of the free boundary at the same times and using the same legend as in the upper right plot of each figure, plotting also a dotted line with slope $4/n$ for comparison.

For $\alpha = 2.24$ (Figure 4.2) the (nearly) straight lines with slopes 2.26 for $t_k = 2.5 \times 10^{-4}$ and 2.29 for $t_k = 5.0 \times 10^{-4}$ (estimated as before) compare well with the value of $4/n = 2.29$ proposed in the conjecture. For $t_k = 7.5 \times 10^{-4}$ the log-log plot

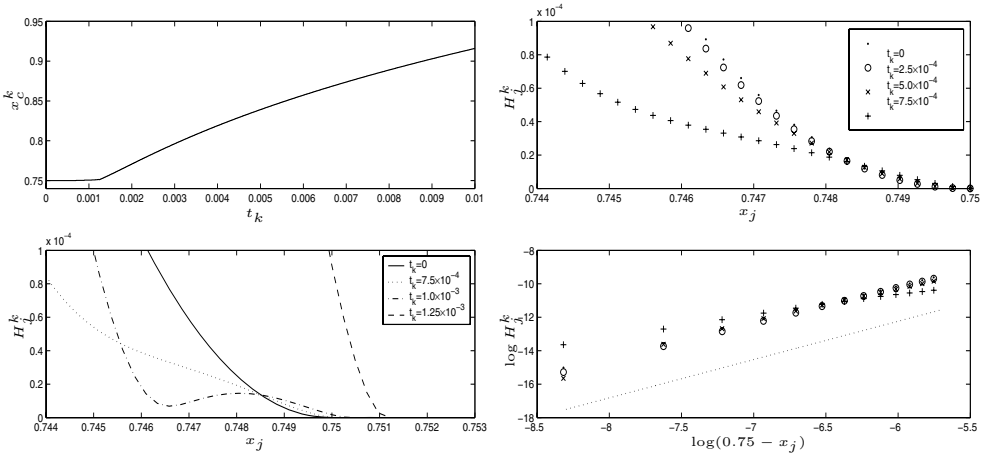

FIG. 4.3. *Numerical results for $n = 1.75$, $\alpha = 2.10$: waiting-time behavior (upper left plot); profiles of H_j^k near the interface while the free boundary is stationary (upper right plot), and as the free boundary advances (lower left plot); $\log H_j^k$ against $\log(0.75 - x_j)$ in the vicinity of the free boundary, with a dotted line from asymptotic theory (lower right plot—same legend as upper right).*

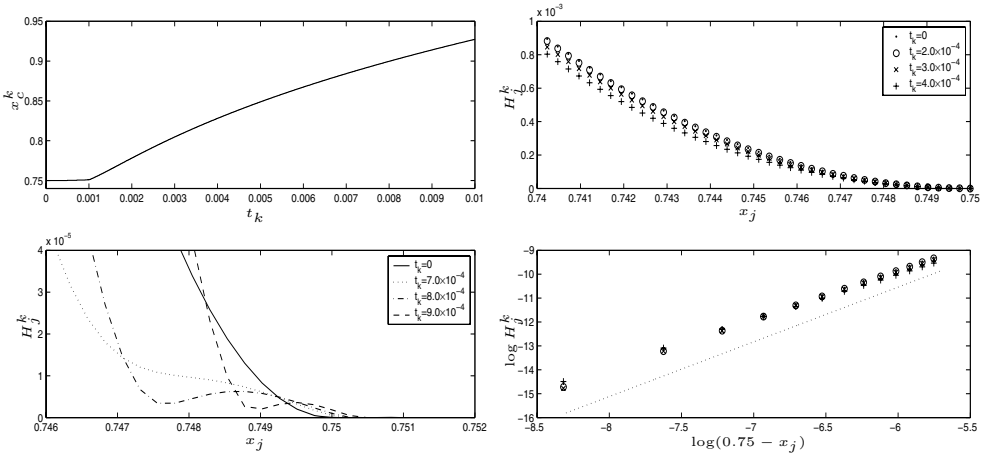

FIG. 4.4. *Numerical results for $n = 1.75$, $\alpha = 2.04$: waiting-time behavior (upper left plot); profiles of H_j^k near the interface while the free boundary is stationary (upper right plot), and as the free boundary advances (lower left plot); $\log H_j^k$ against $\log(0.75 - x_j)$ in the vicinity of the free boundary, with a dotted line from asymptotic theory (lower right plot—same legend as upper right).*

is no longer straight, and the best fitting least squares line has a slope of 2.47; by this time the profile of H_j^k has begun to change.

For $\alpha = 2.10$ (Figure 4.3), the (nearly) straight lines have slopes 2.17 for $t_k = 2.5 \times 10^{-4}$ and 2.18 for $t_k = 5.0 \times 10^{-4}$. These values are slightly lower than for $\alpha = 2.24$, but still compare fairly well with the value of $4/n = 2.29$ proposed in the conjecture. For $t_k = 7.5 \times 10^{-4}$ again the log-log plot is no longer straight, and the best fitting least squares line has a slope of 1.27; by this time the profile of H_j^k has again begun to change.

For $\alpha = 2.04$ (Figure 4.4) each log-log plot is again (nearly) a straight line;

however, the slopes of 2.09 for $t_k = 2.0 \times 10^{-4}$ and 2.08 for $t_k = 3.0 \times 10^{-4}$ are somewhat smaller than the value of $4/n = 2.29$. As t_k increases from zero, the slope of the log-log plot increases from 2.04 up to a maximum of 2.09 before decreasing. For $t_k = 4.0 \times 10^{-4}$ the line has a slope of 1.91; by this time the profile of H_j^k has begun to change noticeably.

4.4.2. $\alpha = 2$. This is the most delicate case, with the small-time behavior depending on the correction term in (1.5), with $\beta > 2$. In (3.2) we have

$$\frac{\mathrm{d}}{\mathrm{d}x}\left(h_0^n \frac{\mathrm{d}^3 h_0}{\mathrm{d}x^3}\right) \sim \beta(\beta-1)(\beta-2)(2n+\beta-3)A_0^n C_0 (x_0-x)^{2n+\beta-4}, \tag{4.15}$$

and (4.13) yields

$$\frac{\partial H}{\partial t} = -A_0^n \frac{\partial}{\partial x}\left((x_0-x)^{2n}\frac{\partial^3 H}{\partial x^3}\right), \tag{4.16}$$

implying, in view of (4.15), the small-time behavior

$$H = A_0^{\frac{n\beta}{4-2n}} C_0 t^{\frac{\beta}{4-2n}} \Phi(\xi), \qquad \xi = (x-x_0)/\left(A_0^{\frac{n}{4-2n}} t^{\frac{1}{4-2n}}\right),$$

being a similarity reduction of (4.16) in which $\Phi(\xi; n, \beta)$ is required to satisfy the matching conditions

$$\text{as } \xi \to -\infty, \quad \Phi \sim (-\xi)^\beta - \beta(\beta-1)(\beta-2)(2n+\beta-3)(-\xi)^{2n+\beta-4},$$
$$\text{at } \xi = 0^-, \quad \Phi = (-\xi)^{2n}\frac{\mathrm{d}^3\Phi}{\mathrm{d}\xi^3} = 0,$$

from which it follows that

$$\Phi \sim \kappa(\beta, n)(-\xi) \quad \text{as } \xi \to 0^- \tag{4.17}$$

for some constant κ (which could in principle take either sign, reliable intuition about the signs of such quantities being hard to come by in high-order diffusion problems). In fact, for $\beta = 1 + 2(2-n)N$ for integer N (such that $\beta > 2$), $\Phi(\xi)$ takes the form

$$\Phi = (-\xi)\sum_{m=0}^{N} a_m (-\xi)^{2(2-n)m}$$

with $a_N = 1$ and where a_0 alternates in sign with increasing N. More significantly, for $\beta = 2(1 + (2-n)N)$, we have

$$\Phi = (-\xi)^2 \sum_{m=0}^{N} a_m (-\xi)^{2(2-n)m},$$

so that

$$\kappa(2(1+(2-n)N), n) = 0 \tag{4.18}$$

gives explicitly the values of β,

$$\beta_N = 2(1+(2-n)N), \quad N = 1, 2, 3, \ldots, \tag{4.19}$$

at which κ changes sign. Thus κ changes sign infinitely often as $\beta \to \infty$.

In view of (4.13) and (4.17) there is a further, narrower, inner region with

$$x = x_0 + t^{\frac{\beta-1}{4-2n}}\zeta, \quad h \sim t^{\frac{\beta-1}{2-n}}\Psi(\zeta), \tag{4.20}$$

the dominant balance as $t \to 0^+$ being given by

$$\frac{\mathrm{d}}{\mathrm{d}\zeta}\left(\Psi^n \frac{\mathrm{d}^3\Psi}{\mathrm{d}\zeta^3}\right) = 0,$$

implying

$$\frac{\mathrm{d}^3\Psi}{\mathrm{d}\zeta^3} = 0. \tag{4.21}$$

For $C_0\kappa > 0$ we thus have instantaneous advance of the interface (with velocity zero at $t = 0^+$) with

$$\Psi = A_0(\zeta_0 - \zeta)^2, \quad \zeta_0 = A_0^{\frac{n(\beta+1)-4}{4-2n}} C_0\kappa, \quad s \sim x_0 + \zeta_0 t^{\frac{\beta-1}{4-2n}}, \tag{4.22}$$

in order to match with (4.17). A yet narrower inner region, with

$$\zeta = \zeta_0 + O(t^{(\beta-2)/(2n-3)}),$$

is then present near the interface, with scalings

$$x = s(t) + t^{\frac{\beta-5+2n}{2(2-n)(2n-3)}} z, \quad h \sim t^{\frac{\beta-5+2n}{(2-n)(2n-3)}}\phi(z), \tag{4.23}$$

whereby, matching with (4.22),

$$\frac{\beta-1}{4-2n}\zeta_0 = \phi^{n-1}\frac{\mathrm{d}^3\phi}{\mathrm{d}z^3}, \tag{4.24a}$$

$$\text{as } z \to -\infty, \quad \phi \sim A_0(-z)^2, \tag{4.24b}$$

$$\text{at } z = 0^-, \quad \phi = \frac{\mathrm{d}\phi}{\mathrm{d}z} = 0. \tag{4.24c}$$

This completes the description of the case $C_0\kappa > 0$.

The problem (4.24a–c) has no solution for $\zeta_0 < 0$, corresponding to the fact that interfaces cannot recede when $n \geq 3/2$; a different scenario is therefore needed when $C_0\kappa < 0$ in which $\zeta = \zeta_0$ in (4.22) no longer coincides with the interface; in other words, a quantity $\sigma(t)$, with

$$\sigma \sim x_0 + \zeta_0 t^{\frac{\beta-1}{4-2n}} \quad \text{as } t \to 0^+, \tag{4.25}$$

replaces $s(t)$ in (4.23) (with $s(t) = x_0$ now holding for $t \leq t_w$), and (4.24a–c) becomes

$$\frac{\beta-1}{4-2n}\zeta_0(\phi - \phi_\infty) = \phi^n\frac{\mathrm{d}^3\phi}{\mathrm{d}z^3}, \tag{4.26a}$$

$$\text{as } z \to -\infty, \quad \phi \sim A_0(-z)^2, \tag{4.26b}$$

$$\text{as } z \to \infty, \quad \phi \sim \phi_\infty, \tag{4.26c}$$

a boundary condition count indicating that, since $\zeta_0 < 0$, (4.26a–c) suffices to determine $\phi(z)$, up to translates in z, and ϕ_∞. The scaling properties of (4.26a–c) imply

that ϕ and ϕ_∞ are proportional to $(\zeta_0^2/A_0^3)^{1/(2n-3)}$, with z scaling as $(|\zeta_0|/A_0^n)^{1/(2n-3)}$. In $\sigma < x < x_0$, whereby

$$x_0 - x = O\left(t^{\frac{\beta-1}{4-2n}}\right), \quad h = O\left(t^{\frac{\beta-5+2n}{(2-n)(2n-3)}}\right),$$

we have to leading order that $\partial h/\partial t = 0$ with, in view of (4.25)–(4.26a–c), the matching condition

$$h \sim ((x_0 - x)/|\zeta_0|)^{\widehat{\alpha}(\beta)} \quad \text{on } t = \sigma^{-1}(x),$$

where

$$\widehat{\alpha}(\beta) := \frac{2(\beta - 5 + 2n)}{(\beta - 1)(2n - 3)},$$

implying that

$$h \sim ((x_0 - x)/|\zeta_0|)^{\widehat{\alpha}(\beta)} \quad \text{for } \sigma < x < x_0. \tag{4.27}$$

The exponent $\widehat{\alpha}(\beta)$ in (4.27) is monotonic increasing in β (given that $\beta > 2$) and satisfies

$$\widehat{\alpha}(2) = 2, \quad \widehat{\alpha}\left(1 + \frac{2n}{3}\right) = \frac{4}{n}, \quad \widehat{\alpha}(\infty) = \frac{2}{2n-3}.$$

It follows for $\beta > 1 + 2n/3$ that $\widehat{\alpha}$ lies in the regime of section 3.1, so that (4.27) describes the behavior near the interface up to the waiting time; for $2 < \beta < 1 + 2n/3$, however, $\widehat{\alpha}$ lies in the regime of section 4.4.1, so that (4.27) in turn breaks down sufficiently close to the interface and (4.14) is attained locally via a small-time similarity solution of the form (4.1)–(4.3a,b), with α replaced by $\widehat{\alpha}$. Such behavior represents a novel waiting-time phenomenon for degenerate parabolic equations (there being no corresponding scenario for the porous-medium equation), but there are similarities with, for example, Hele–Shaw flows with suction, whereby the free surface profile can instantly change to a new configuration (cf. (4.27)), which then persists (see [29]).

Analysis of cases with $\kappa = 0$ requires specification of an additional term in the local (1.5), and remarkably fine structure arises in consequence. Thus (cf. (4.18)) for

$$h_0(x) \sim A_0(x_0 - x)^2 + C_0(x_0 - x)^{2(1+(2-n)N)} + D_0(x_0 - x)^\gamma, \tag{4.28}$$

where $\gamma > 2(1 + (2 - n)N)$, we expect for each N a sequence of critical values of γ which represent further refined dividing lines between solutions that expand at once and those that wait; for those borderline values of γ, a further term in the expansion of (4.28) must be incorporated and so on. The first set of these dividing lines can be identified concisely via the one-degree-of-freedom (i.e., overspecified) family of local solutions (obtained by constructing an algebraic expansion for h about the leading-order term in (4.29))

$$h \sim a(t)(x_0 - x)^2 - \frac{\dot{a}(t)}{12(2-n)(5-2n)(3-n)a^n(t)}(x_0 - x)^{6-2n} + O((x_0 - x)^{10-4n}), \tag{4.29}$$

corresponding to (4.28) with $N = 1$ and

$$a(0) = A_0, \qquad \dot{a}(0) = -12(2-n)(5-2n)(3-n)A_0^n C_0,$$

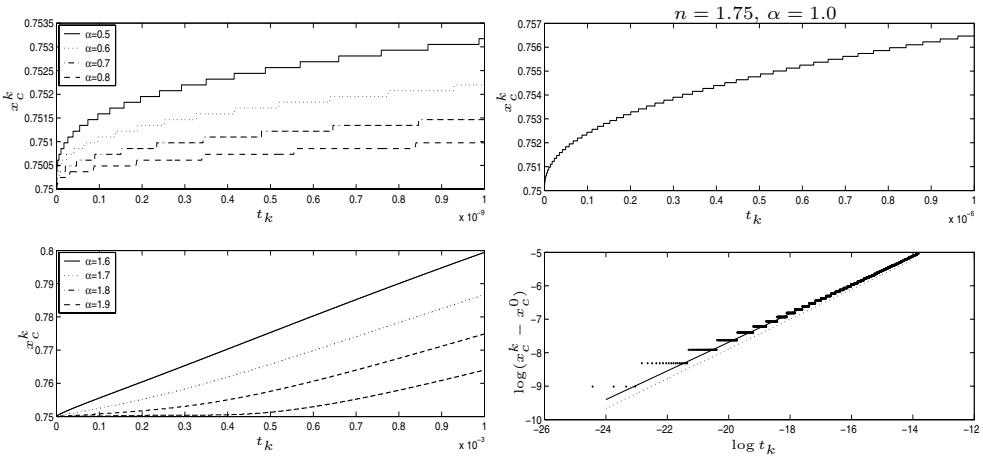

FIG. 4.5. *Numerical results for* $n = 1.75$, $\alpha < 2$. *On the left we show the numerical free boundary advancing for* $\alpha = 0.5, 0.6, 0.7, 0.8$, $T = 10^{-9}$ *(upper left plot) and for* $\alpha = 1.6, 1.7, 1.8, 1.9$, $T = 10^{-3}$ *(lower left plot); on the right we present results for* $\alpha = 1.0$, $T = 10^{-6}$, *with the numerical free boundary plotted against time in the upper right plot, and with* $\log t_k$ *plotted against* $\log(x_c^k - x_c^0)$ *as a discrete set of points in the lower right plot, with the solid line following from a least squares fitting and the straight dotted line from asymptotic theory.*

and identifying the first critical value of γ for $N = 1$ to be $7 - 4n$; higher values of N correspond to $\dot{a}(0) = 0$ in this local expansion. Because it is overspecified, the local expansion of (4.29) pertains only when the local form of the initial data is consistent with the powers of $x_0 - x$ therein and, as already implied, it represents a borderline between solutions of the form (1.2) and (4.14).

4.4.3. $\alpha < 2$. Here the interface advances immediately, with $f(\eta)$ having local behavior (4.10) and with unbounded initial velocity for $\alpha < 3/n$, finite for $\alpha = 3/n$, and tending to zero for $3/n < \alpha < 2$. The last of these ranges disappears as n drops below $3/2$, providing one indication of the need to address this regime separately.

To test this we ran numerical experiments for $n = 1.75$ (giving $3/n = 1.7143$, $4/n = 2.2857$), with $\alpha \in [0.5, 1.9]$. Our results again support the conjecture. In each case x_c^k advances, with the speed of the advance decreasing as α increases. This is shown in Figure 4.5, in which x_c^k is plotted against t_k for $n = 1.75$ with $\alpha = 0.5$, 0.6, 0.7, and 0.8 (upper left plot) and $\alpha = 1.6$, 1.7, 1.8, and 1.9 (lower left plot). Note the different time scales on the two axes.

In the upper right plot of Figure 4.5 we show the numerical free boundary advancing for $n = 1.75$ and $\alpha = 1.0 < 3/n$. As before, we test the hypothesis (4.11) by plotting $\log t_k$ against $\log(x_c^k - x_c^0)$ (in the lower right plot), and we estimate $\gamma = 0.43$. For comparative purposes we plot a dotted line with slope $(4 - n\alpha)^{-1} = 0.44$ on the same graph. The expected and estimated values of γ are shown in Table 4.2. For $\alpha = 1.9$ we exclude the first step in the advance of x_c^k, as discussed in section 4.2. The estimates for γ are very close to the expected values, with this being especially true for values of α away from the edges of the parameter regime.

4.5. Small-time behavior for $n = 3/2$. For $\alpha < 2$, the support of h expands immediately with unbounded velocity; in view of (1.3), the local behavior of $f(\eta)$ then

TABLE 4.2
Estimated and expected values of γ for various α, $n = 1.75$.

α	0.5	0.7	0.9	1.1	1.3	1.5	1.7	1.9
$(4-n\alpha)^{-1}$	0.32	0.36	0.41	0.48	0.58	0.73	0.98	1.48
γ	0.30	0.34	0.40	0.47	0.58	0.73	0.98	1.53

takes the form

$$f(\eta) \sim \left(\frac{3\eta_0}{2(8-3\alpha)}(\eta_0-\eta)^3 \ln\left(\frac{1}{(\eta_0-\eta)}\right)\right)^{\frac{2}{3}} \quad \text{as } \eta \to \eta_0^-.$$

For $2 < \alpha < 8/3$ the behavior is again as described in section 4.4.1. The case $\alpha = 2$ is particularly delicate, with the initial exponents $\alpha = 2$ and $\alpha = 3/n$ coinciding for $n = 3/2$. Much of the analysis in section 4.4.2 nevertheless still pertains—in particular (4.17)–(4.19) hold—so that $\beta_N = 2 + N$, as does (4.20)–(4.22). However, the scalings (4.23) are evidently inapplicable for $n = 3/2$, and the appropriate scalings are instead (for $C_0\kappa > 0$)

$$h = (s-x)^2\Phi(\xi,t), \quad \xi = t^{\beta-2}\ln(1/(s-x)), \quad s \sim x_0 + \zeta_0 t^{\beta-1}, \tag{4.30}$$

so that the spatial scaling is exponentially small in t, which yield as the dominant balance

$$(\beta-1)\zeta_0 = 2\Phi_0^{1/2}\frac{\mathrm{d}\Phi_0}{\mathrm{d}\xi},$$

and hence

$$\Phi_0 = \left(A_0^{3/2} + \frac{3}{4}(\beta-1)\zeta_0\xi\right)^{2/3}, \tag{4.31}$$

where we have matched with (4.22). For $C_0\kappa > 0$, this has the required local behavior (1.3) and completes the small-time analysis. For $C_0\kappa < 0$, we again introduce

$$\sigma \sim x_0 + \zeta_0 t^{\beta-1},$$

which specifies the interior layer location, and replace the scalings in (4.30) by

$$h = (\sigma - x)^2\Phi(\xi,t), \quad \xi = t^{\beta-2}\ln(1/(\sigma-x)),$$

to recover (4.31) with ζ_0 (given by (4.22)) negative. Hence ϕ_0 becomes zero at $\xi = \xi_c$, where

$$\xi_c = \frac{4A_0^{3/2}}{3(\beta-1)|\zeta_0|}.$$

There is now a further asymptotic region in which

$$x = \sigma(t) + \rho(t)\mathrm{e}^{-\xi_c/t^{\beta-2}}z, \quad h \sim |\dot\sigma|^{2/3}\rho^2\mathrm{e}^{2\xi_c/t^{\beta-2}}\phi, \tag{4.32}$$

where the scaling on h is chosen to obtain the appropriate leading order balance, namely (cf. (4.26a–c))

$$-(\phi-\phi_\infty) = \phi^{3/2}\frac{\mathrm{d}^3\phi}{\mathrm{d}z^3},$$

$$\text{as } z \to -\infty, \quad \phi \sim \left(\frac{3}{4}(-z)^3\ln(-z)\right)^{2/3},$$

$$\text{as } z \to \infty, \quad \phi \sim \phi_\infty,$$

where ϕ_∞ is again to be determined as part of the solution and we have matched with (4.31). The preexponential factor $\rho(t)$ is expected to be algebraic in t; its calculation would require correction terms in the various expansions to be evaluated and we shall not pursue such matters further. Applying arguments similar to those in section 4.4.2, we obtain from (4.32) that

$$\ln h \sim -2\xi_c|\zeta_0|^{\frac{\beta-2}{\beta-1}}/(x_0-x)^{\frac{\beta-2}{\beta-1}} \quad \text{for } \sigma < x < x_0, \tag{4.33}$$

so the height of the film left behind by the retreating interior layer at $x = \sigma$ is exponentially small (and thus in particular implies waiting-time behavior at $x = x_0$). This reflects the status of $n = 3/2$ as a critical case; as we shall shortly see, for $n < 3/2$ the interface $x = s$ itself retreats in the corresponding regime (in other words, the film thickness left behind $x = \sigma$ drops from being algebraically small for $3/2 < n < 2$, as in (4.27), through exponentially small for $n = 3/2$ (see (4.33)) to zero for $n < 3/2$).

4.6. Small-time behavior for $n < 3/2$. We have already alluded to the qualitatively new feature, implicit in the local behavior (1.4), which can occur in this regime, namely that the interface can retreat. Such behavior is most simply demonstrated by the case $\alpha = 3/n$ in which the small-time similarity solution is given by (4.6), with the interface retreating at a finite rate; in this regime (4.6) is nongeneric, being smoother than the expected local behavior (1.4). For $\alpha > 3/n$, we anticipate waiting-time behavior, as in section 4.4.1; see also Appendix A. (In addition, an analysis similar to that of Appendix B can be performed in the limit $\alpha \to (3/n)^+$.) The result for $\alpha = 3/n$ and $\alpha = 2$ suggests that for $\alpha < 2$ the interface expands at an unbounded rate, with

$$f(\eta) \sim \beta(\eta_0 - \eta)^2 \quad \text{as } \eta \to \eta_0^- \tag{4.34}$$

for some constant η_0, while for $2 < \alpha < 3/n$ contraction occurs at an unbounded rate, with $\eta_0 < 0$ in (4.34). The critical case $\alpha = 2$ is again of particular interest, in particular since waiting-time behavior can in principle occur in this case also (but only for extremely special initial data; cf. (4.29)). The analysis for $\alpha = 2$ is more straightforward than that above, since (4.22)–(4.24a–c) now apply right up to the interface for $C_0\kappa < 0$ (retreat) as well as for $C_0\kappa > 0$ (advance). Such behavior can be illustrated by the explicit solution (4.7)–(4.9) for $n = 1$, wherein $\beta = 3$ and $\kappa = -15$.

For $\alpha = 2$ we have that

$$s(t) \sim x_0 + \zeta_0 t^{\frac{\beta-1}{4-2n}} \quad \text{as } t \to 0^+,$$

which exhibits the same interface time-dependence as (4.1) with $\alpha = (4(\beta-2)+2n)/((\beta-1)n)$; since $\beta > 2$, it follows that this α lies in the range $2 < \alpha < 4/n$, and it implies that the same $s(t)$ can result from quite different initial data (in this case for $2 < \alpha < 3/n$, for which the interface retreats). This reflects the high order of (1.1a), whereby the local behavior at the interface contains a further degree of freedom in addition to $s(t)$ and contrasts with the situation for the second-order case (1.6) (cf. [1]).

4.6.1. $3/n < \alpha < 4/n$. In this regime we anticipate waiting-time behavior, as described in section 4.4.1. For $\alpha_5 < \alpha < 4/n$ we expect monotonic decay onto the $4/n$ solution, for $\alpha_2 < \alpha < \alpha_5$ we expect oscillatory decay, and for $3/n < \alpha < \alpha_2$ we expect a limit cycle to arise in the local description for $0 < t < t_w$ (see (A.5)).

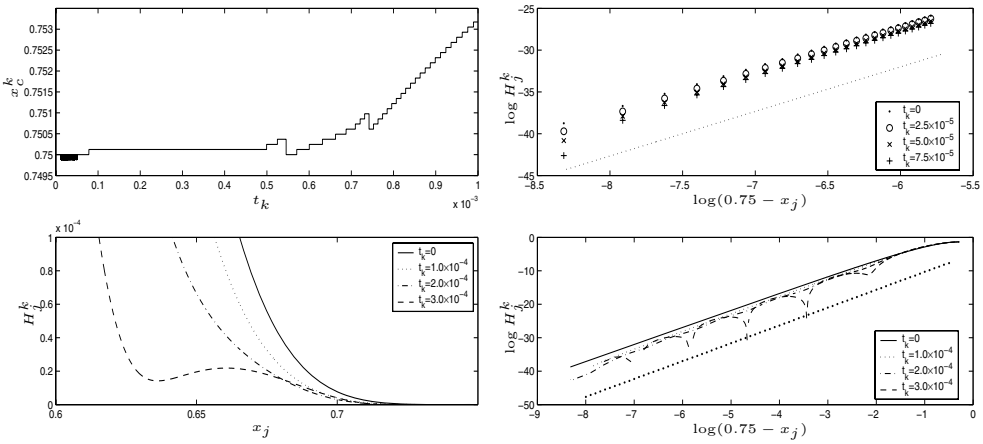

FIG. 4.6. *Numerical results for* $n = 0.75$, $\alpha = 5.1$: *waiting-time behavior (upper left plot)*; *profile of* H_j^k *near the interface at various times (lower left plot)*; $\log H_j^k$ *against* $\log(x_c^k - x_j)$ *in the vicinity of the free boundary (upper right plot), and over the whole range* $x_j \in [0, x_c^k)$ *(lower right plot), with a dotted line of gradient* $4/n$ *(from asymptotic theory) in each case.*

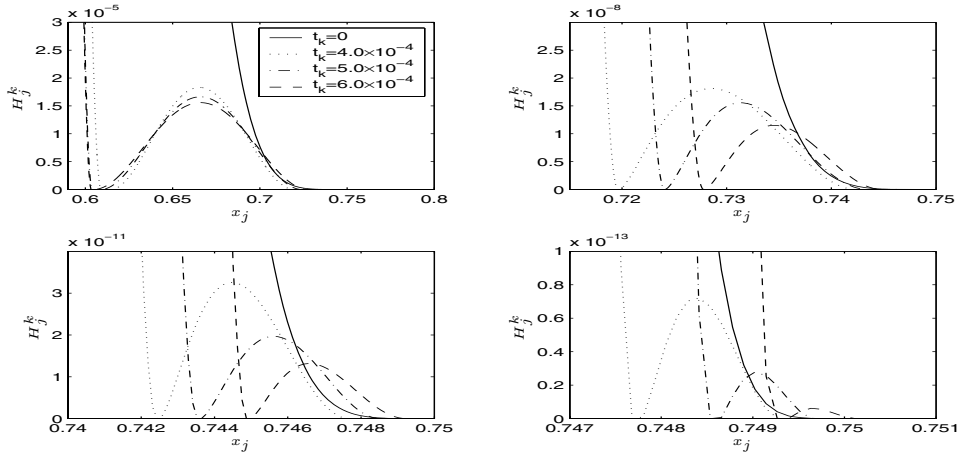

FIG. 4.7. *Numerical results for* $n = 0.75$, $\alpha = 5.1$; *profile of* H_j^k *near the interface at various times (same legend for each plot).*

By monotonic decay we mean decay like $\eta^{-\gamma}$, where γ is real, and by oscillatory decay we mean that the solution decays like $\eta^{-\gamma - \mathrm{i}\mu}$, where γ, μ are real. We present numerical results below for $n = 0.75$ (giving $3/n = 4$, $\alpha_2(n) = 4.2061$, $\alpha_5(n) = 4.9$, $4/n = 5.3333$), with $\alpha = 5.1$ (Figures 4.6 and 4.7), $\alpha = 4.5$ (Figures 4.8 and 4.9) and $\alpha = 4.1$ (Figures 4.10 and 4.11), thus covering each of the three parameter regimes described above (see also Appendix A). We also present results for $n = 1.0$ (for which $\alpha_2(n) = 3.2195$) with $\alpha = 3.1$ (Figures 4.12 and 4.13), with this second example in the range $3/n < \alpha < \alpha_2$ reflecting the extremely delicate nature of the results in this regime.

In the upper left plots of Figures 4.6, 4.8, 4.10, and 4.12 we plot x_c^k against t_k for each example. In Figures 4.6 and 4.8, x_c^k remains stationary for a period before

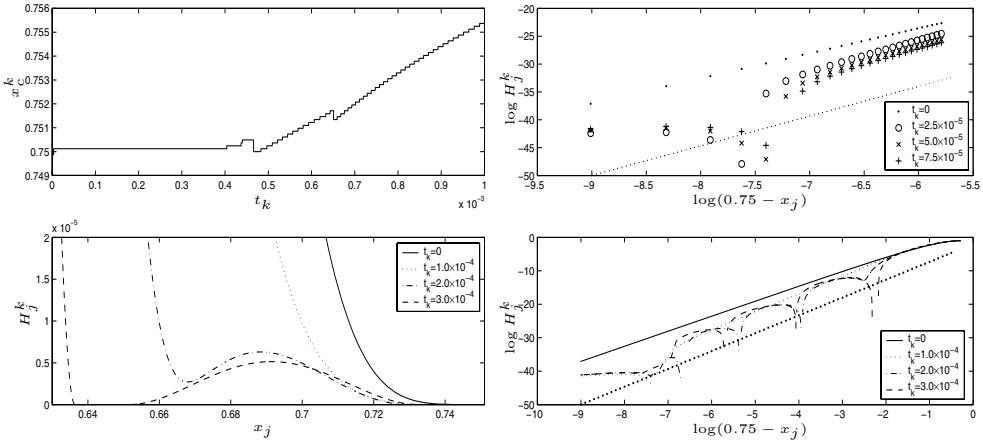

FIG. 4.8. *Numerical results for* $n = 0.75$, $\alpha = 4.5$: *waiting-time behavior (upper left plot)*; *profile of* H_j^k *near the interface at various times (lower left plot)*; $\log H_j^k$ *against* $\log(x_c^k - x_j)$ *in the vicinity of the free boundary (upper right plot), and over the whole range* $x_j \in [0, x_c^k)$ *(lower right plot), with a dotted line of gradient* $4/n$ *(from asymptotic theory) in each case.*

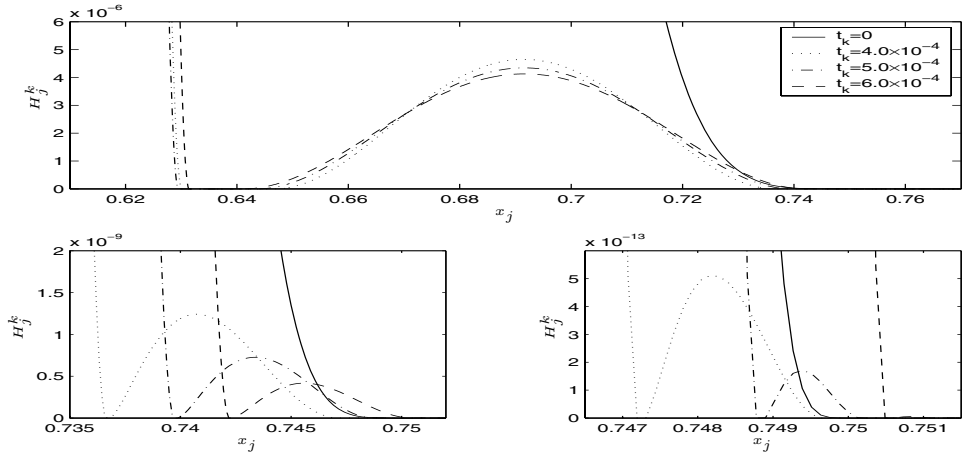

FIG. 4.9. *Numerical results for* $n = 0.75$, $\alpha = 4.5$; *profile of* H_j^k *near the interface at various times (same legend for each plot).*

advancing, with a shorter waiting period in Figure 4.8. In Figures 4.10 and 4.12, x_c^k appears to immediately retreat, wait, and then advance. However, this retreat is over a very short distance, and over a longer time scale the boundary appears to wait; note the different scales on the two plots in the upper left corner of Figure 4.12.

In the lower left corner of Figures 4.6, 4.8, 4.10, and 4.12 we show profiles of H_j^k in the vicinity of the free boundary at various times before the free boundary has begun to advance. In each case the value of H_j^k drops faster further behind the free boundary, leading to the formation of humps near the boundary. In order to demonstrate the existence of more than one such hump, we show profiles of H_j^k on smaller and smaller scales nearer and nearer to the free boundary in Figures 4.7, 4.9, 4.11, and 4.13. Note the different scales on the horizontal and vertical axes of each

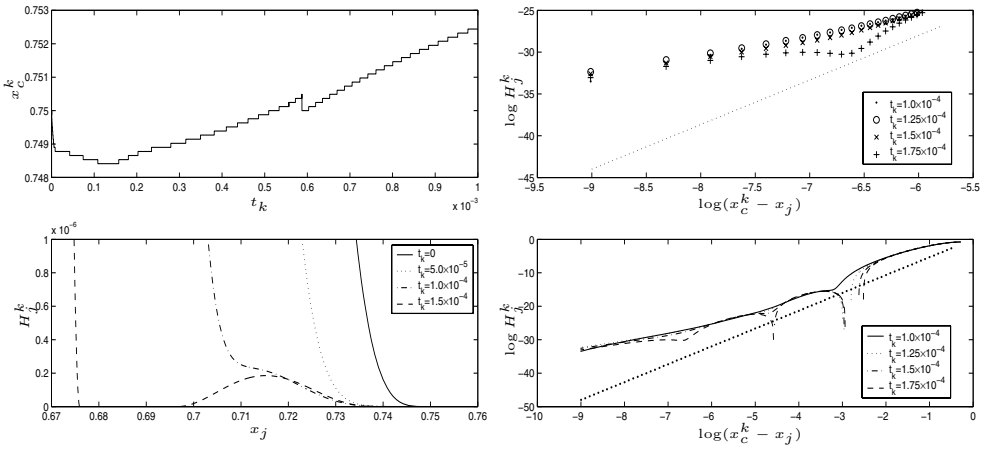

FIG. 4.10. *Numerical results for* $n = 0.75$, $\alpha = 4.1$: *motion of the numerical free boundary (upper left plot); profile of* H_j^k *near the interface at various times (lower left plot);* $\log H_j^k$ *against* $\log(x_c^k - x_j)$ *in the vicinity of the free boundary (upper right plot), and over the whole range* $x_j \in [0, x_c^k)$ *(lower right plot), with a dotted line of gradient* $4/n$ *(from asymptotic theory) in each case.*

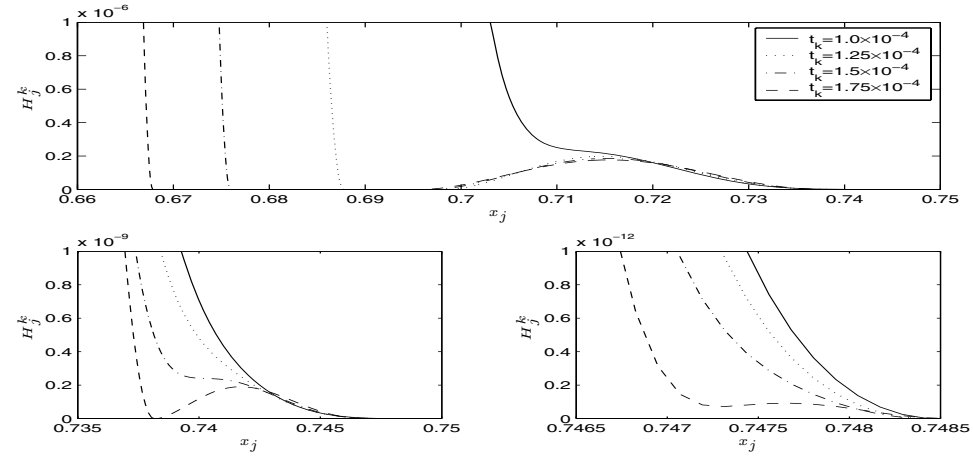

FIG. 4.11. *Numerical results for* $n = 0.75$, $\alpha = 4.1$; *profile of* H_j^k *near the interface at various times (same legend for each plot).*

plot in Figures 4.7, 4.9, 4.11, and 4.13. Due to the limitations of the numerical method and the scale of the plots it is possible that some of these results may be spurious, but the repetition of the evidence found on the larger scales does provide a degree of support for the conjectures.

The issue of whether these types of profiles lead to film break up (i.e., satellite droplets separated by dead cores in which h is identically zero) is an interesting one warranting further study. In the current context we note first that there remain open questions regarding the range of n for which such rupture can occur, which it would not be appropriate to explore here; second that the small-time similarity solutions cannot exhibit such break up (each satellite drop must conserve mass, which is inconsistent with their self-similar form); and finally, for $n < 1/2$ they could contain touch down

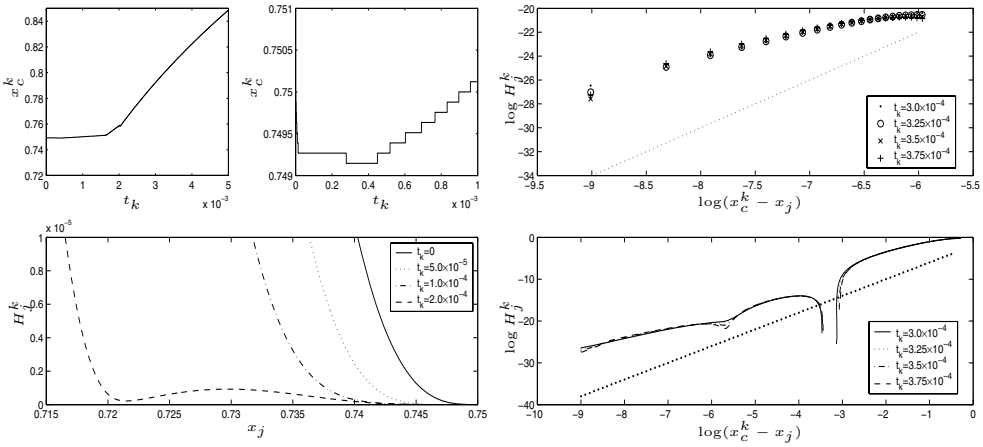

FIG. 4.12. *Numerical results for $n = 1.0$, $\alpha = 3.1$: motion of the numerical free boundary (upper left plots: note the different scales on each figure); profile of H_j^k near the interface at various times (lower left plot); $\log H_j^k$ against $\log(x_c^k - x_j)$ in the vicinity of the free boundary (upper right plot), and over the whole range $x_j \in [0, x_c^k)$ (lower right plot), with a dotted line of gradient $4/n$ (from asymptotic theory) in each case.*

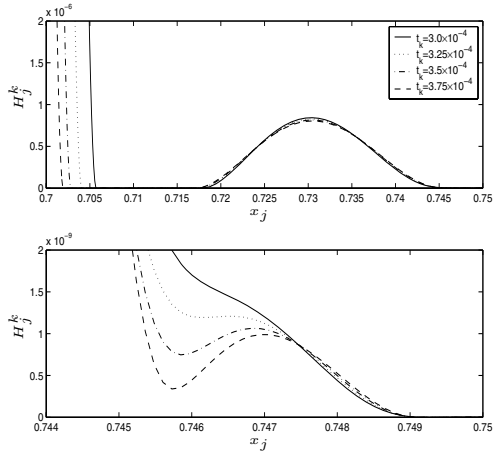

FIG. 4.13. *Numerical results for $n = 1.0$, $\alpha = 3.1$; profile of H_j^k near the interface at various times (same legend for each plot).*

points (at which $h = 0$), as analyzed in [31].

In the upper right corner of Figures 4.6, 4.8, 4.10 and 4.12 we plot $\log H_j^k$ against $\log(x_c^k - x_j)$ in the vicinity of the free boundary at various times before the free boundary has begun to advance. For comparison we also plot a dotted line with slope $4/n$ in each figure. In Figure 4.6, the best fitting least squares line for $t_k = 0$ has a slope of 5.10, rising to 5.26 for $t_k = 2.5 \times 10^{-5}$ and 5.45 for $t_k = 5.0 \times 10^{-5}$. For $t_k = 7.5 \times 10^{-5}$ the log-log plot is no longer very straight. We remark that in this case, with $n = 0.75$ and $\alpha = 5.1$, H_j^k is very close to zero quite far behind the free boundary, hence the numerical results are extremely delicate. In Figure 4.8, the log-log plot is not straight immediately in the vicinity of the free boundary for any $t_k > 0$, although

it is fairly straight further away from the free boundary. In Figures 4.10 and 4.12, the log-log plots are not very straight, and the best fitting least squares lines have slopes significantly lower than $4/n$.

In the lower right corners of Figures 4.6, 4.8, 4.10 and 4.12 we plot $\log H_j^k$ against $\log(x_c^k - x_j)$ over the whole range $x_j \in [0, x_c^k)$ at various times before the free boundary has begun to advance, plotting again a dotted line with slope $4/n$ for comparison. In Figure 4.6, as t_k increases, the log-log plot becomes less and less straight, and for $t_k = 3.0 \times 10^{-3}$ the periodic behavior of the solution near the interface can clearly be seen. The log-log plots for $t_k = 4.0 \times 10^{-3}$ and $t_k = 5.0 \times 10^{-3}$ are very similar to that for $t_k = 3.0 \times 10^{-3}$ but are not shown here. In Figure 4.8, the formation of humps further and further from the free boundary becomes apparent. For $t_k = 1.0 \times 10^{-4}$, the slope of the log-log plot away from the free boundary is close to $4/n$. For each of Figures 4.10 and 4.12, as t_k increases, the formation of extra humps in the vicinity of the free boundary becomes apparent.

4.6.2. $2 < \alpha < 3/n$. To test the conjecture that the free boundary retreats instantaneously with unbounded velocity, we ran experiments with $n = 1.0$ and $\alpha \in [2.1, 2.9]$. We plot x_c^k against t_k in the left panel of Figure 4.14 for $\alpha = 2.2$, 2.4, 2.6, and 2.8. The results support the conjecture. In each case the free boundary retreats, waits, and then advances, although the subsequent advance can only be seen in the figure for $\alpha = 2.2$. The initial velocity of x_c^k appears to decrease as α increases, although as α increases, the length of the period for which the free boundary retreats also increases, so that the maximum distance retreated occurs for $\alpha = 2.9$.

As before we test the hypothesis $x_c^k = x_c^0 - At_k^\gamma$ for some constants $A > 0$ and γ by plotting $\log(x_c^0 - x_c^k)$ against $\log t_k$. Again, if the hypothesis is correct, we expect a straight line with slope γ, and to estimate γ we take a least squares fit over the range for which the log-log plot is approximately straight. In the right half of Figure 4.14 we plot x_c^k against t_k (upper section) and this log-log plot (lower section) for $n = 1.0$ and $\alpha = 2.5$. The log-log plot is approximately straight, and the best fitting least

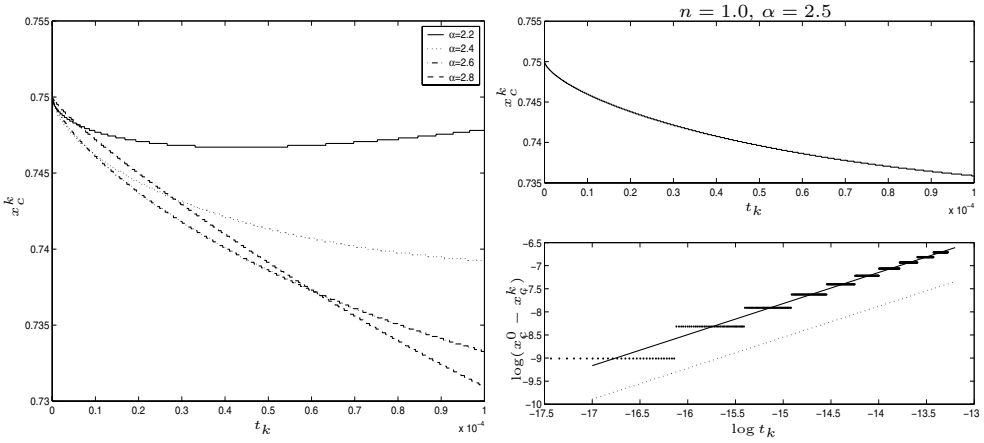

FIG. 4.14. *Numerical results for $n = 1.0$, $2 < \alpha < 3/n$. In the left panel we plot the retreating free boundary for various α. In the right panels we show results for $n = 1.0$, $\alpha = 0.5$: in the upper right section we show the retreating free boundary; in the lower right section we plot $\log t_k$ against $\log(x_c^0 - x_c^k)$ as a discrete set of points, with the solid line following from a least squares fitting and the straight dotted line from asymptotic theory.*

TABLE 4.3
Estimated and expected values of γ for $n = 1.0$, various α.

α	2.1	2.2	2.3	2.4	2.5	2.6	2.7	2.8	2.9
$(4-n\alpha)^{-1}$	0.53	0.56	0.59	0.63	0.67	0.71	0.77	0.83	0.91
γ	0.44	0.53	0.58	0.63	0.67	0.72	0.77	0.81	0.85

squares line is plotted as a solid line on the same figure. For comparison we also plot a dotted line with slope $(4-n\alpha)^{-1} = 0.67$. The estimated value of $\gamma = 0.67$ matches this exactly to two decimal places. The expected and estimated values of γ for each value of α tested are shown in Table 4.3. The trend of γ increasing with α is clear, and away from the edges of the parameter regime the estimated value of γ is very close to the expected value.

4.6.3. $\alpha < 2$. To test the conjecture that the free boundary advances instantaneously, with an unbounded velocity, we ran experiments with $n = 1.0$ and $\alpha \in [0.5, 1.9]$. We plot x_c^k against t_k for $\alpha = 0.6$, 0.7, 0.8, and 0.9 (upper left plot), and for $\alpha = 1.5$, 1.6, 1.7, and 1.8 (lower left plot) in Figure 4.15. Note the different time scales on the two plots. The results support the conjecture, and the initial velocity of x_c^k decreases as α increases.

We again test the hypothesis (4.11), plotting x_c^k against t_k (upper right section of Figure 4.15) and $\log(x_c^k - x_c^0)$ against $\log t_k$ (lower right section of Figure 4.15) for $n = 1.0$ and $\alpha = 1.2$. The log-log plot is approximately straight, and the best fitting least squares line, plotted as a solid line on the same figure, has a slope of 0.34. For comparison we also plot a dotted line with slope $(4-n\alpha)^{-1} = 0.36$ on the same figure. The expected and estimated values of γ are shown in Table 4.4. The trend of γ increasing with α is clear, and for values of α away from the borderline value $\alpha = 2$ the estimated value of γ is very close to the expected value.

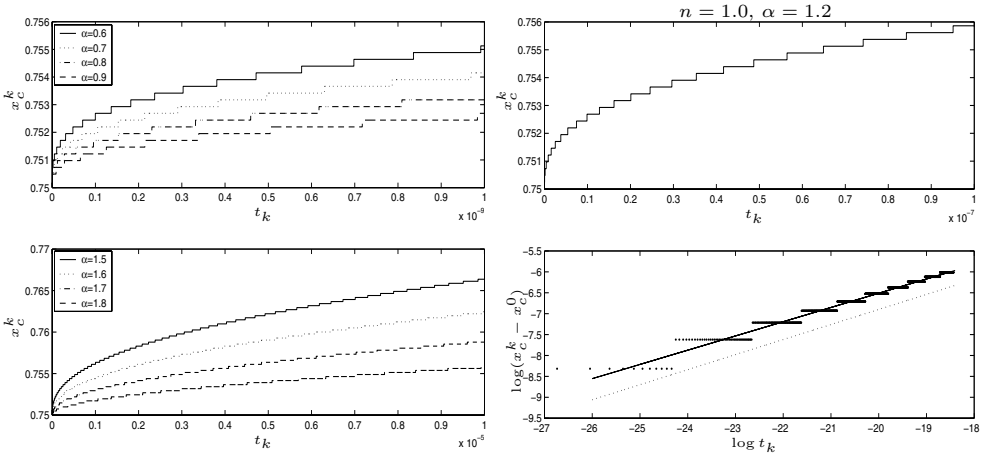

FIG. 4.15. $n = 1.0$, $\alpha < 2$. *In the left half of the figure we plot the advancing free boundary for various α (note the different time scales on the two plots). In the right half of the figure we show results for $n = 1.0$, $\alpha = 1.2$: in the upper right section we show the advancing free boundary; in the lower right section we plot $\log t_k$ against $\log(x_c^k - x_c^0)$ as a discrete set of points, with the solid line following from a least squares fitting and the straight dotted line from asymptotic theory.*

TABLE 4.4
Estimated and expected values of γ for $n = 1.0$, various $\alpha < 2$.

α	0.5	0.7	0.9	1.1	1.3	1.5	1.7	1.9
$(4 - n\alpha)^{-1}$	0.29	0.30	0.32	0.34	0.37	0.40	0.43	0.48
γ	0.28	0.29	0.31	0.33	0.36	0.40	0.43	0.53

5. Conclusions. As we have seen, the thin-film equation (1.1a) exhibits a much broader range of small-time phenomena than its second-order analogue, (1.6). Thus, while the behavior of the former with $2 < n < 3$ corresponds very closely to that of the latter with any $n > 0$, for $n < 2$ equation (1.1a) exhibits a range of α in which the interface waits but the local profile changes instantaneously from that of the initial data (this combination does not occur for (1.6)) and can exhibit monotonic or oscillatory decay to the local solution (4.14) or limit-cycle behavior of the form (A.5). Moreover, for $n < 3/2$ fronts can either advance or retreat, and our small-time classification gives rather precise criteria on the initial data in this regard. The very delicate interlacing of initial profiles leading to immediate expansion or to a finite waiting time, as outlined in section 4.4.2, for example, also deserves highlighting.

In Table 5.1 we demonstrate how these results apply to the cases $n = 1$ (which describes thin films in a Hele–Shaw cell [16] and the strong-slip limit of the Greenspan [22] slip regularization) and $n = 2$ (which corresponds to the strong-slip limit of the usual (Navier) slip-regularization; see [26], for example). See also [34] for further relevant background. It is noteworthy that the case $n = 2$ is a critical one in a number of respects (some of which are implicit in Figure 1.1).

The high-order problem (1.1) is a demanding one from the numerical point of view; this wealth of distinct behaviors occurring over short length and time scales necessitates particularly refined, careful, and detailed computational studies if the relevant phenomena are to be captured adequately, and we have sought to implement the required program of extensive numerical investigations. Taking into account the delicacy of some of the asymptotic results and the limitations of the numerical scheme, numerical results are shown only for those parameter regimes wide enough that suitable "intermediate" values of n and α can be used.

A number of generalizations immediately suggest themselves. In higher dimensions, the small-time behavior of an initially smooth interface will be locally one-dimensional, so most of the conclusions carry over. For $n \geq 3$, the smoothest solutions have fixed interfaces, and here waiting-time phenomena relate (for $3 \leq n < 4$) to a delay in the contact angle becoming finite; we shall not elaborate on such matters

TABLE 5.1
Small- and waiting-time behavior for $n = 1$ and $n = 2$.

n	Range of α	Behavior
1	$4/n = 4 < \alpha$	Global waiting-time, ended by shock.
	$\alpha_5 \approx 3.7 < \alpha < 4$	Interface waits but local profile changes instantaneously from that of initial data and can exhibit monotonic decay to local solution.
	$\alpha_2 \approx 3.2 < \alpha < 3.7$	As above, but with oscillatory decay.
	$3/n = 3 < \alpha < 3.2$	As above, but with limit cycle behavior.
	$2 < \alpha < 3$	Interface retreats instantaneously.
	$\alpha > 2$	Interface advances instantaneously.
2	$4/n = 2 \leq \alpha$	Global waiting time, ended by shock.
	$\alpha < 2$	Free boundary advances instantaneously.

here, noting only that the approaches we have described above apply equally well in such contexts. As a final instance, we note that for $n < 3$ a finite contact angle condition can be imposed in place of the second of (1.1c) and a similar investigation performed; again, we shall not report the results of such a study here.

Appendix A. Applicability of the local solution (4.4). In this appendix we use boundary condition counting arguments to assess the applicability of (4.4) as a local solution to (4.2) for $0 < n < 2$. Writing

$$f \sim \left(\frac{n^3}{8(4-n)(2-n)(n+4)} (-\eta)^4 \right)^{\frac{1}{n}} + F \tag{A.1}$$

and linearizing yields

$$\frac{1}{4-n\alpha}(\alpha F - \eta F_\eta) = -\frac{n^3}{8(4-n)(2-n)(n+4)} \frac{\mathrm{d}}{\mathrm{d}\eta} \left(\eta^4 \frac{\mathrm{d}^3 F}{\mathrm{d}\eta^3} \right) - \frac{n}{n+4} \frac{\mathrm{d}}{\mathrm{d}\eta} (\eta F),$$

with solutions

$$F = K(-\eta)^p, \tag{A.2}$$

where the possible p are the roots of the quartic

$$\frac{n^3 p(p-1)(p-2)(p+1)}{8(4-n)(2-n)(n+4)} + \frac{n(p+1)}{n+4} + \frac{\alpha - p}{4-n\alpha} = 0. \tag{A.3}$$

The expansion of (A.1) with F given by (A.2) is self-consistent if $\mathrm{Re}(p) > 4/n$, so the relations between α and n such that two roots of (A.3) have $\mathrm{Re}(p) = 4/n$ are crucial; these relations can be shown to be

$$\alpha_1(n) = \frac{\alpha_{-b} + \alpha_\Delta}{\alpha_d}, \qquad \alpha_2(n) = \frac{\alpha_{-b} - \alpha_\Delta}{\alpha_d},$$

where

$$\begin{aligned} \alpha_d &= 2\left(n^2 - n - 8\right)\left(7\,n^3 - 84\,n^2 + 400\,n - 640\right) n, \\ \alpha_{-b} &= 47n^5 - 674n^4 + 3384n^3 - 3520n^2 - 17408n + 36864, \\ \alpha_\Delta &= (n+4)(2-n)(8-n)\sqrt{9216 - 5632n + 896n^2 + 112n^3 - 31n^4}, \end{aligned}$$

so that

$$\alpha_1 \sim 2 + \frac{11}{10}(2-n) + O((2-n)^2) \text{ as } n \to 2^-, \quad \alpha_1 \sim \frac{3}{n} + \frac{5}{24} + O(n) \text{ as } n \to 0^+,$$
$$\alpha_2 \sim 2 + \frac{31}{22}(2-n)^2 + O((2-n)^3) \text{ as } n \to 2^-, \quad \alpha_2 \sim \frac{21}{5n} - \frac{1}{120} + O(n) \text{ as } n \to 0^+.$$

It is also instructive to note the curves in (α, n) space on which roots of (A.3) become complex, namely the repeated roots case in which (A.3) and

$$\frac{\mathrm{d}}{\mathrm{d}p}\left[\frac{n^3 p(p-1)(p-2)(p+1)}{8(4-n)(2-n)(n+4)} + \frac{n(p+1)}{n+4} + \frac{\alpha - p}{4-n\alpha} \right] = 0 \tag{A.4}$$

are satisfied simultaneously. These curves are shown in Figure A.1.

We define $\alpha_5 = \alpha_5(n)$ to be the repeated root case ($\mathrm{v_b}$) shown in Figure A.1. The various curves in (α, n) space relevant to our discussion are all shown in Figure A.2.

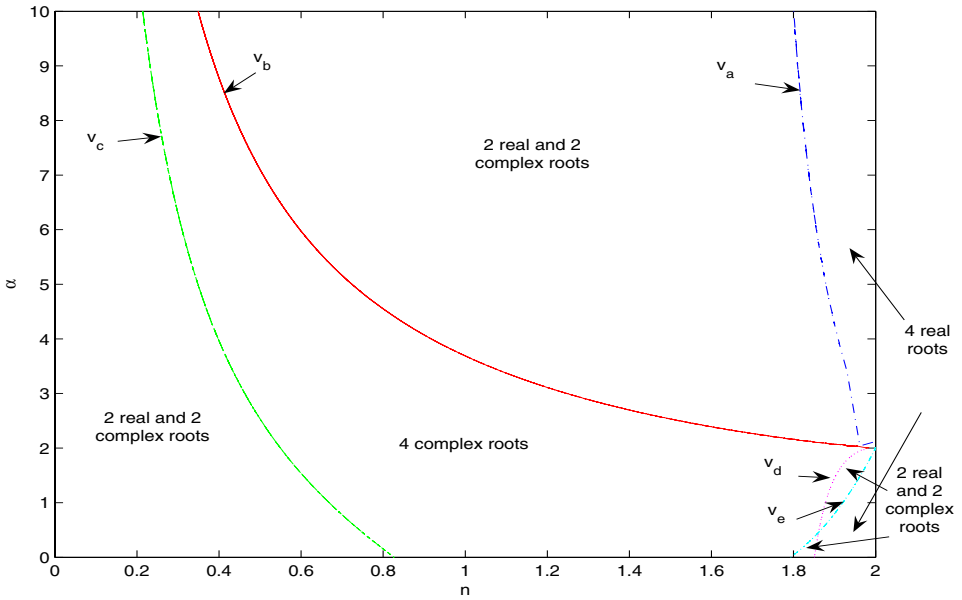

FIG. A.1. *The solutions to* (A.3) *and* (A.4). *To the right of* (v_a) *and of the rightmost of* (v_d) *and* (v_e) *there are four real roots: between* (v_a) *and* (v_b), *between* (v_d) *and* (v_e), *and to the left of* (v_c) *there are two real and two complex roots; between* (v_c), (v_b), *and the leftmost of* (v_d) *and* (v_e) *there are four complex roots.*

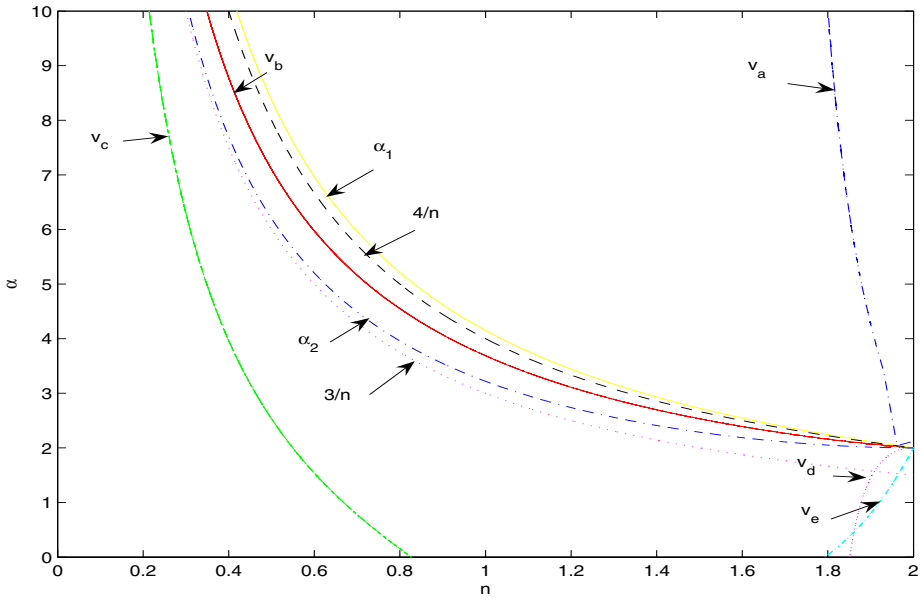

FIG. A.2. (α, n) *space, showing* $\alpha = \alpha_1$, $\alpha = 4/n$, $\alpha = \alpha_2$, $\alpha = 3/n$, *and the solutions to* (A.3) *and* (A.4). *Three of the roots become unbounded as* $\alpha = 4/n$ *is approached, with the fourth having* $p \sim 4/n$. *Above* $\alpha = \alpha_1$ *and below* $\alpha = \alpha_2$, *none of the roots have* $\mathrm{Re}(p) > 4/n$; *between* $\alpha = \alpha_2$ *and* (v_b), *two of the four complex roots have* $\mathrm{Re}(p) > 4/n$ *and the other two* $\mathrm{Re}(p) < 4/n$; *between* (v_b) *and* $\alpha = 4/n$ *both real roots satisfy* $p > 4/n$ *and both complex ones* $\mathrm{Re}(p) < 4/n$; *between* $\alpha = 4/n$ *and* $\alpha = \alpha_1$ *the real roots have* $p < 4/n$ *and the complex ones* $\mathrm{Re}(p) > 4/n$.

In $\alpha_2 < \alpha < \frac{4}{n}$, two roots of (A.3) have $\mathrm{Re}(p) > \frac{4}{n}$, and the local expansion (A.1) is correctly specified (the two degrees of freedom being the K's in (A.2) corresponding to those two roots). As α drops below α_2 we anticipate that a Hopf bifurcation occurs in (4.2)–(4.3a,b) with the local behavior as $\eta \to 0^-$ taking for $\alpha > \max(2, 3/n)$ the limit-cycle form

$$f \sim (-\eta)^{\frac{4}{n}} \Omega(-\ln(-\eta)), \tag{A.5}$$

where $\Omega(\xi)$ is periodic of period P, say, in ξ. Since on $\alpha = \alpha_2$

$$\mathrm{Im}(p) = \pm \frac{1}{\sqrt{2}n} \sqrt{96 - 24n - n^2 - \sqrt{9216 - 5632n + 896n^2 + 112n^3 - 31n^4}},$$

we anticipate that

$$P \sim \frac{2\sqrt{2}\pi n}{\sqrt{96 - 24n - n^2 - \sqrt{9216 - 5632n + 896n^2 + 112n^3 - 31n^4}}} \quad \text{as } \alpha \to \alpha_2^-.$$

Note that P will depend on α and n but, in view of the scaling properties of (4.2)–(4.3a,b), not on A_0. For $\alpha_5 < \alpha < \frac{4}{n}$, the decay to (4.4) is nonoscillatory, while for $\alpha_2 < \alpha < \alpha_5$ damped oscillations occur.

Appendix B. $3/2 < n < 2$, $\alpha \to 2$. We are concerned here with the behavior of (4.2)–(4.3a,b) for α close to two. Writing $\alpha = 2 + \epsilon$, $0 < |\epsilon| \ll 1$, we have for $\eta = O(1)$ that

$$f \sim A_0(-\eta)^2 + \epsilon f_1(\eta) \tag{B.1}$$

with

$$\frac{1}{2(2-n)} \left(2f_1 - \eta \frac{\mathrm{d}f_1}{\mathrm{d}\eta} + A_0(-\eta)^2 \right) = -A_0^n \frac{\mathrm{d}}{\mathrm{d}\eta} \left((-\eta)^{2n} \frac{\mathrm{d}^3 f_1}{\mathrm{d}\eta^3} \right), \tag{B.2a}$$

$$\text{as } \eta \to -\infty, \quad f_1 \sim A_0(-\eta)^2 \ln(-\eta) - 2(2n-1)A_0^{n+1}(-\eta)^{2(n-1)}, \tag{B.2b}$$

$$\text{as } \eta \to 0^-, \quad f_1 = (-\eta)^{2n} \frac{\mathrm{d}^3 f_1}{\mathrm{d}\eta^3} = 0. \tag{B.2c}$$

It follows from (B.2a–c) that

$$f_1 \sim -\mu(n) A_0^{\frac{4-n}{2(2-n)}} (-\eta) \quad \text{as } \eta \to 0^+; \tag{B.3}$$

we believe the constant μ, which is determined as part of the solution to (B.2a–c), to be positive; the dependence on A_0 in (B.3) follows from rescaling f_1 by $A_0^{2/(2-n)}$ and η by $A_0^{n/(2(2-n))}$ in (B.2a–c).

The expansion (B.1) breaks down for small η with inner scalings $\eta = |\epsilon|\xi$, $f = |\epsilon|^2 g(\xi)$, and $\frac{\mathrm{d}}{\mathrm{d}\xi}(g_0^n \frac{\mathrm{d}^3 g_0}{\mathrm{d}\xi^3}) = 0$. For $\epsilon < 0$ we thus have

$$g_0 = A_0(\xi_0 - \xi)^2, \quad \xi_0 = \frac{1}{2}\mu A_0^{\frac{n}{2(2-n)}}, \tag{B.4}$$

with $\eta_0 \sim |\epsilon|\xi_0$ and with inner-inner scalings $\eta = \eta_0 + |\epsilon|^{1/(2n-3)}\zeta$, $f = |\epsilon|^{2/(2n-3)} h(\zeta)$,

whereby

$$\frac{1}{2(2-n)}\xi_0 = h_0^{n-1}\frac{\mathrm{d}^3 h_0}{\mathrm{d}\zeta^3},$$
$$\text{as } \zeta \to -\infty, \quad h_0 \sim A_0(-\zeta)^2,$$
$$\text{as } \zeta \to 0^-, \quad h_0 \sim \left(\frac{n^3\xi_0}{6(3-n)(2n-3)(2-n)}(-\zeta)^3\right)^{\frac{1}{n}},$$

producing the desired local behavior (1.2). However, for $\epsilon > 0$ the expression (B.4) is replaced by

$$g_0 = A_0(-\xi_0 - \xi)^2, \quad \xi_0 = \frac{1}{2}\mu A_0^{\frac{n}{2(2-n)}}, \tag{B.5}$$

and (recalling that the interface cannot contract for $n > 3/2$) the inner-inner scalings read $\xi = -\xi_c(\epsilon) + \epsilon^{2(2-n)/(2n-3)}\zeta$, $g = \epsilon^{4(2-n)/(2n-3)}h(\zeta)$, where $\xi_c(0) = \xi_0$ and

$$-\frac{1}{2(2-n)}\xi_0(h_0 - H_\infty) = h_0^n\frac{\mathrm{d}^3 h_0}{\mathrm{d}\zeta^3}, \tag{B.6a}$$
$$\text{as } \zeta \to -\infty, \quad h_0 \sim A_0(-\zeta)^2, \tag{B.6b}$$
$$\text{as } \zeta \to \infty, \quad h_0 \to H_\infty, \tag{B.6c}$$

which determines both h_0 (up to translations in ζ) and H_∞, the decay of h_0 to H_∞ being nonoscillatory. In $-\xi_0 < \xi < 0$ we then have

$$h \sim H_\infty\frac{(-\xi)^2}{\xi_0^2}, \tag{B.7}$$

the left-hand side of (4.2) dominating. The scaling properties of (B.6a–c) show that h_0 and H_∞ scale with $A_0^{2/(2-n)}$ and ζ with $A_0^{n/(2(2-n))}$, so we may rewrite (B.7) as

$$h \sim \nu(n)A_0(-\xi)^2. \tag{B.8}$$

Now setting

$$f = \nu^{\frac{2}{2-n}}\epsilon^{\frac{8}{2n-3}}\widehat{f}, \qquad \eta = \nu^{\frac{n}{2(2-n)}}\epsilon^{\frac{2n}{2n-3}}\widehat{\eta}, \tag{B.9}$$

we have that

$$\widehat{f} \sim A_0(-\widehat{\eta})^2 + \epsilon f_1(\widehat{\eta}),$$

where f_1 satisfies (B.2a–c) with η replaced by $\widehat{\eta}$, implying that the above structure repeats itself on a sequence of finer and finer scales, consistent with the limit cycle behavior referred to in Appendix A. Thus if we denote the variables in the mth member of the sequence by $f^{(m)}$, $\eta^{(m)}$ with $f^{(0)} = f$ and $\eta^{(0)} = \eta$, we have from (B.9) that

$$f^{(m)} \sim \nu^{\frac{2}{2-n}}\epsilon^{\frac{8}{2n-3}}f^{(m-1)}, \qquad \eta^{(m)} \sim \nu^{\frac{n}{2(2-n)}}\epsilon^{\frac{2n}{2n-3}}\eta^{(m-1)},$$

implying that

$$f^{(m)}(\eta) \sim \nu^{\frac{2m}{2-n}}\epsilon^{\frac{8m}{2n-3}}f\left(\frac{\eta}{\nu^{\frac{mn}{2(2-n)}}\epsilon^{\frac{2mn}{2n-3}}}\right),$$

where leading-order expressions for f on the right-hand side are given through a single cycle of the oscillation by (B.1), (B.5), (B.6a–c), (B.8). This is consistent with (A.5) with

$$P \sim \frac{2n}{2n-3} \ln\left(\frac{1}{\epsilon}\right) - \frac{n}{2(2-n)} \ln \nu$$

being large; note that the region described by (B.6a–c) is particularly significant because it leads to the $(-\eta)^{4/n}$-type decay in (A.5), despite the solution behaving quadratically in other regions.
