PERFECTLY MATCHED LAYERS FOR HYPERBOLIC SYSTEMS: GENERAL FORMULATION, WELL-POSEDNESS, AND STABILITY*

DANIEL APPELÖ†, THOMAS HAGSTROM‡, AND GUNILLA KREISS†

Abstract. Since its introduction the perfectly matched layer (PML) has proven to be an accurate and robust method for domain truncation in computational electromagnetics. However, the mathematical analysis of PMLs has been limited to special cases. In particular, the basic question of whether or not a stable PML exists for arbitrary wave propagation problems remains unanswered. In this work we develop general tools for constructing PMLs for first order hyperbolic systems. We present a model with many parameters, which is applicable to all hyperbolic systems and which we prove is well-posed and perfectly matched. We also introduce an automatic method for analyzing the stability of the model and establishing energy inequalities. We illustrate our techniques with applications to Maxwell's equations, the linearized Euler equations, and arbitrary 2×2 systems in $(2 + 1)$ dimensions.

Key words. perfectly matched layers, stability

1. Introduction.

Many important wave propagation problems are posed on unbounded or large domains. Such problems must be solved on a truncated domain if numerical methods are to be used. There exist many techniques for truncating the original domain (see the review papers [15, 16, 23]), but one that has proved both efficient and accurate is the perfectly matched layer (PML) technique. The PML technique surrounds the domain where the solution is desired (the computational domain) by an artificial layer. The layer is constructed so that waves traveling across the interface between the layer and the computational domain are not reflected; that is, the layer is perfectly matched. Moreover, the layer is constructed so that, inside the layer, the solution decays exponentially in the direction normal to the interface. Hence, if the layer is sufficiently wide, the solution will be close to zero at the outer boundary, and therefore any stable boundary condition can be used there.

Besides the perfect matching and damping properties of the layer it is also desirable that the equations governing the PML be well-posed. This is especially important if a PML derived for a linear problem is to be applied to a nonlinear problem or a problem with variable coefficients. If the linearized problem is only weakly well-posed the corresponding nonlinear or variable coefficient problem can be ill-posed; see [20]. Well-posedness, by definition, allows the solution to grow exponentially in time, and therefore, for a PML to be practically useful, it must also be stable (in time). To

summarize, the key properties of a PML are perfect matching, well-posedness, and stability.

PMLs were originally introduced for Maxwell's equations by Bérenger [8]. Well-posedness and stability of the Bérenger PML has been the topic of numerous works. For example, Abarbanel and Gottlieb [2] showed that Bérenger's "split-field" PML was only weakly well-posed and that it supported linearly growing modes. Similar results were also obtained via Fourier and energy techniques by Bécache and Joly in [6]. The issue of weak well-posedness led to the development of various well-posed "physical" or "un-split" PMLs for Maxwell's equations; see [3, 13, 24]. These "un-split" PMLs were further improved by the inclusion of the so-called complex frequency shift (CFS), which has been used by Bécache, Petropoulos, and Gedney [7] to remove late-time linear growth.

For other applications such as the linearized Euler equations [18], the linearized shallow water equations [22], and anisotropic elasticity [10], there have been reports of exponentially growing solutions. In [1] Abarbanel, Gottlieb, and Hesthaven found that a stable PML could be derived for the linearized Euler equations by transforming the equations into a system whose dispersion relation resembled the dispersion relation of Maxwell's equations. The same transform was later used again to develop a stable PML for the linearized Euler equations [19, 11] and for the linearized shallow water equations [22].

Today there exist stable PML models for many important problems, but there are also problems, e.g., anisotropic elasticity and linearized Magneto Hydro Dynamics (MHD), for which stable PMLs have not yet been found. An open issue, then, is whether stable PMLs can be constructed in general. Also, stability and well-posedness for general hyperbolic systems has received less attention than particular cases. One exception is the paper [5] where Bécache, Fauqueux, and Joly give necessary conditions for stability of the split-field PML in terms of the geometrical properties of the dispersion relation. Also, in [4] we construct stable PMLs for arbitrary 2×2 symmetric hyperbolic systems in $(2 + 1)$ dimensions.

In this work we generalize the formulation of PML models for hyperbolic systems introduced in [17]. To make the model suitable for future applications, we introduce a very general formulation including many free parameters. One of these parameters adds a parabolic term in the tangential directions. By including this parameter, we can show that the equations of the PML are well-posed as long as the original hyperbolic system is well-posed. In addition, we give a proof that the layer is perfectly matched.

We also study the stability of our PML model. The question of stability is not trivial, and in general it has to be investigated separately for each new application. To simplify these investigations we introduce a technique, based on criteria for the number of zeros of a polynomial in a half-plane, that can be used to derive necessary and sufficient conditions for stability of any first order constant coefficient Cauchy problem. Moreover, if these conditions are fulfilled, there is also a local energy density that decays with time (see [14]). This energy density is automatically generated from the necessary and sufficient conditions. We use the technique to derive stability results for three interesting applications of our general model.

The rest of this paper will be organized as follows. In section 2 we present the general PML model for symmetric hyperbolic systems and show that it is perfectly matched and well-posed. In section 3 we introduce techniques from [14] used to determine the stability of a first order system with constant coefficients. If the system is stable, the technique will yield an energy with a local density that decays with time. In section 4 we analyze the stability of a PML model for Maxwell's equation in

two dimensions. The PML is constructed by using the general PML model described in section 2. We use the techniques from section 3 to establish the stability of the PML and list two associated energies. In section 5 we analyze a PML model for the linearized Euler equations and show that it is stable. In section 6 we consider the specialization of our general PML formulation to 2×2 symmetric hyperbolic systems in $(2+1)$ dimensions. In [4] we demonstrated how to choose the layer parameters as functions of the coefficient matrices. Here we prove that these choices will lead to a stable PML. In section 7 we conclude and discuss some possible extensions of the presented work.

2. A general PML. We consider the symmetric hyperbolic system in d dimensions:

$$\frac{\partial u}{\partial t} + A_x \frac{\partial u}{\partial x} + \sum_{l=1}^{d-1} A_{y_l} \frac{\partial u}{\partial y_l} + Cu = 0, \tag{1}$$

with initial data, u_0, supported in $-H < x < -h$, $h > 0$. Here $A_x = A_x^T$ and $A_{y_l} = A_{y_l}^T$. For simplicity we assume that A_x is invertible; if A_x is singular, we apply the PML only to the equations involving x derivatives.

Our construction of the layer equations matched to (1) follows the ideas suggested in [17]. It is based on a modification of the eigenvalues of the eigenvalue problem (equation (9) in the next section) obtained after Fourier and Laplace transformation of (1). Then one can consider a general transformation of the eigenvalues which is rationally dependent on the transform parameters, where the restriction to rationally dependent transformations leads to localizable layer equations. Considering a fairly general transformation, we are led to consider the following general PML model:

$$\frac{\partial u}{\partial t} + A_x \left((1+\sigma\eta)\frac{\partial u}{\partial x} + \sigma \left(\sum_{l=1}^{d-1} \xi_l \frac{\partial u}{\partial y_l} + \mu u \right) + \sum_j \phi_j \right) + \sum_{l=1}^{d-1} A_{y_l} \frac{\partial u}{\partial y_l} + Cu = 0, \tag{2}$$

$$\frac{\partial \phi_j}{\partial t} + \sigma\phi_j + \alpha_j \phi_j + \sum_{l=1}^{d-1} \beta_{jl} \frac{\partial \phi_j}{\partial y_l} - \sum_{l=1}^{d-1} \varepsilon_{jl} \frac{\partial^2 \phi_j}{\partial y_l^2} = \sigma \left(\gamma_j \frac{\partial u}{\partial x} + \sum_{l=1}^{d-1} \delta_{jl} \frac{\partial u}{\partial y_l} + \nu_j u \right). \tag{3}$$

Here all the additional parameters are real, and we also assume

$$1 + \sigma\eta > 0, \qquad \varepsilon_{jl} \geq 0. \tag{4}$$

To obtain spatial decay of waves propagating through the layer it is necessary that the real parts of the modified eigenvalues be bounded away from zero. As yet we have no general method for constructing stable layers, and it is conceivable that problems exist which require many more parameters than have been required in the examples treated so far. Thus we will analyze (2)–(3) in its full complexity when feasible. The effect of many of the parameters is not yet understood, but we know from the example in section 6 that acceptable parameter values depend on the matrices in system (1).

2.1. Perfect matching. To investigate the perfect matching of the layer we consider two problems. In the first, whose solution we denote u_1, (1) holds in $R^d \times R$, and in the second, whose solution is denoted u_2, we suppose that (1) holds in $x < 0$ and that (2) and (3) hold in $x > 0$. We also insist that u_2 be continuous. Our goal is to show that the restrictions of each solution to $x < 0$ are identical; that is, the layer is perfectly matched.

We begin by performing a Fourier–Laplace transformation in the tangential directions and in time. The duals of $y = [y_1, \ldots, y_{d-1}]$ are denoted by $k = [k_1, \ldots, k_{d-1}]$ and the dual of t by s. This leads to the problems

$$A_x \frac{\partial \hat{u}_1}{\partial x} + \left(sI + \sum_l ik_l A_{y_l} + C \right) \hat{u}_1 = \hat{u}_0, \quad x \in R, \tag{5}$$

and in the second case, for $x < 0$,

$$A_x \frac{\partial \hat{u}_2^L}{\partial x} + \left(sI + \sum_l ik_l A_{y_l} + C \right) \hat{u}_2^L = \hat{u}_0, \tag{6}$$

and for $x > 0$,

$$\begin{aligned} A_x &\left((1 + \sigma\eta) \frac{\partial \hat{u}_2^R}{\partial x} + \sigma \left(\sum_l ik_l \xi_l + \mu \right) \hat{u}_2^R + \sum_j \hat{\phi}_j \right) \\ &+ \left(sI + \sum_l ik_l A_{y_l} + C \right) \hat{u}_2^R = 0, \end{aligned} \tag{7}$$

$$\left(s + \sigma + \alpha_j + \sum_l ik_l \beta_{jl} + \sum_l \varepsilon_{jl} k_l^2 \right) \hat{\phi}_j = \sigma \left(\gamma_j \frac{\partial \hat{u}_2^R}{\partial x} + \left(\sum_l ik_l \delta_{jl} + \nu_j \right) \hat{u}_2^R \right). \tag{8}$$

The solution of (5) follows from the solution of the eigenvalue problem

$$\lambda A_x w + \left(sI + \sum_l ik_l A_{y_l} + C \right) w = 0. \tag{9}$$

We note that for $\Re s > |C|_2$ the eigenvalues, λ, cannot be purely imaginary. In particular if we normalize w to have length one, a straightforward computation yields

$$\Re\lambda = -\frac{\Re s + \Re w^* C w}{w^* A_x w}, \tag{10}$$

which implies

$$|\Re\lambda| > (\rho(A_x))^{-1} (\Re s - |C|_2). \tag{11}$$

Thus, taking $\Re s$ sufficiently large, we may assume that solutions of (9) fall into two sets labeled by the sign of the real parts of the eigenvalues:

$$\Re\lambda_1, \ldots, \Re\lambda_r < 0, \tag{12}$$

$$\Re\lambda_{r+1}, \ldots, \Re\lambda_n > 0. \tag{13}$$

Moreover, the matrix

$$M(s,k) = -A_x^{-1} \left(sI + \sum_l ik_l A_{y_l} + C \right), \tag{14}$$

can be block diagonalized:

$$QMQ^{-1} = \begin{pmatrix} S^- & 0 \\ 0 & S^+ \end{pmatrix}, \tag{15}$$

where the eigenvalues (12) are the eigenvalues of S^- and the eigenvalues (13) are the eigenvalues of S^+. Now the bounded solution of (5) is easy to write down as

$$\hat{u}_1 = Q^{-1} \begin{pmatrix} \int_{-\infty}^{x} e^{S^-(x-y)} f^-(y)dy \\ -\int_{x}^{\infty} e^{S^+(x-y)} f^+(y)dy \end{pmatrix}, \tag{16}$$

where

$$QA_x^{-1}\hat{u}_0 = \begin{pmatrix} f^- \\ f^+ \end{pmatrix}. \tag{17}$$

In particular the support properties of $\hat{u}_0$ and thus $f^{\pm}$ guarantee the existence of the integrals in (16). We note that at $x = 0$,

$$\hat{u}_1 = Q^{-1} \begin{pmatrix} \int_{-H}^{-h} e^{-S^- y} f^-(y)dy \\ 0 \end{pmatrix}. \tag{18}$$

We now compute $\hat{u}_2$ in each region. We first note that (8) can be solved directly:

$$\hat{\phi}_j = \frac{\sigma\left(\gamma_j \frac{\partial \hat{u}_2^R}{\partial x} + (\sum_l ik_l\delta_{jl} + \nu_j)\hat{u}_2^R\right)}{s + \sigma + \alpha_j + \sum_l ik_l\beta_{jl} + \sum_l \varepsilon_{jl}k_l^2}. \tag{19}$$

Now for $x > 0$ we transform the solution using the same transformation Q, which block diagonalizes the problem for $x < 0$. Setting $v = Q\hat{u}_2^R$, we find

$$v_x = \frac{1}{r(s,k) + \sigma p(s,k)} \begin{pmatrix} r(s,k)S^- - \sigma q(s,k)I & 0 \\ 0 & r(s,k)S^+ - \sigma q(s,k)I \end{pmatrix} v, \tag{20}$$

where the polynomials r, p, and q are defined up to a constant multiple by

$$\eta + \sum_j \frac{\gamma_j}{s + \sigma + \alpha_j + \sum_l ik_l\beta_{jl} + \sum_l \varepsilon_{jl}k_l^2} = \frac{p(s,k)}{r(s,k)}, \tag{21}$$

$$\sum_l ik_l\xi_l + \mu + \sum_j \frac{\sum_l ik_l\delta_{jl} + \nu_j}{s + \sigma + \alpha_j + \sum_l ik_l\beta_{jl} + \sum_l k_l^2\varepsilon_{jl}} = \frac{q(s,k)}{r(s,k)}. \tag{22}$$

We will argue that for $\Re s$ sufficiently large these blocks have eigenvalues with negative and positive real parts, respectively. In particular we note that

$$\lim_{|s|\to\infty} \frac{p}{r} = \eta, \qquad \lim_{|s|\to\infty} \frac{q}{r} = \sum_l ik_l\xi_l + \mu. \tag{23}$$

Thus for large s the eigenvalues are approximately

$$\frac{\lambda_j - \sigma(\sum_l ik_l\xi_l + \mu)}{1 + \sigma\eta}. \tag{24}$$

Now by (11) and (4) we conclude that the signs of their real parts are the same as the signs of $\Re\lambda_j$ if we choose $\Re s$ sufficiently large, which was what we wished to prove.

From this argument we conclude that the transform of the causal solution in $x > 0$ takes the form

$$\hat{u}_2^R = Q^{-1} \begin{pmatrix} e^{(r+\sigma p)^{-1}(rS^- - \sigma q I)x} v^- \\ 0 \end{pmatrix}. \tag{25}$$

We see that this can be "perfectly matched" to the restriction of $\hat{u}_1$ to $x < 0$ by setting

$$v^- = \int_{-H}^{-h} e^{-S^- y} f^-(y) dy. \tag{26}$$

Thus we have proven that u_1 and u_2 restricted to $x < 0$ are identical.

We note that we can interpret the layer as an (s, k)-dependent change of variables:

$$\hat{u}(x) \to e^{-a\tilde{x}} \hat{u}(\tilde{x}), \tag{27}$$

where

$$\tilde{x} = \frac{r}{r + \sigma p} x, \qquad a = \sigma \frac{q}{r}. \tag{28}$$

With this interpretation, the new layer can be viewed as a generalization of the Bérenger layer from the viewpoint of complex coordinate stretching, as introduced by Chew and Weedon [9].

2.2. Well-posedness of the layer equations. For the applications considered in this paper it will be sufficient to include only one set of auxiliary variables, leading to the PML model

$$\begin{aligned} &\frac{\partial u}{\partial t} + A_x \left((1 + \sigma\eta) \frac{\partial u}{\partial x} + \sigma \left(\sum \xi_l \frac{\partial u}{\partial y_l} + \mu u \right) + \phi \right) + \sum A_{y_l} \frac{\partial u}{\partial y_l} + Cu = 0, \\ &\frac{\partial \phi}{\partial t} + \sigma\phi + \alpha\phi + \sum \beta_l \frac{\partial \phi}{\partial y_l} - \sum \varepsilon_l \frac{\partial^2 \phi}{\partial y_l^2} = \sigma \left(\gamma \frac{\partial u}{\partial x} + \sum \delta_l \frac{\partial u}{\partial y_l} + \nu u \right). \end{aligned} \tag{29}$$

Even with just one set of auxiliary variables, there are many free parameters that must be chosen. Our experience is that the parameters $\mu, \xi, \beta_l, \delta_l, \gamma$ can be determined from the coefficients of the matrices A_x and A_y. The parameter η is introduced in the model to increase the damping of evanescent modes. The parameter α, which is usually referred to as the CFS, typically enhances stability properties at late time.

To our knowledge the parabolic terms $\varepsilon_l \phi_{y_l y_l}$ (hereafter called parabolic CFS) have not been included in PML models before. We have chosen to include them to guarantee the well-posedness of the model (29). To see this we freeze the coefficients and perform a Fourier transform in space (k_x is the dual of x). Excluding the zero order terms in the symbol of the equations (29), we obtain

$$P_1(ik) = - \begin{bmatrix} (ik_x(1 + \sigma\eta) + \sum ik_l \xi_l \sigma) A_x + \sum ik_l A_{y_l} & 0 \\ -(ik_x \sigma\gamma + \sum ik_l \delta_l \sigma) I & \sum \varepsilon_l k_l^2 I + \sum ik_l \beta_l I \end{bmatrix}. \tag{30}$$

Denote the upper diagonal block in P_1, (30), by P_{11}. By the hyperbolicity of the original problem, P_{11} is diagonalizable with imaginary eigenvalues.

Without the parabolic complex frequency shift the lower diagonal block also has purely imaginary eigenvalues, but the system may be only weakly hyperbolic. This is the case if, for some set of $k_1, \ldots, k_{d-1}$,

$$\sum_l i k_l \beta_l \tag{31}$$

coincides with one of P_1's eigenvalues while

$$k_x \sigma \gamma + \sum k_l \delta_l \sigma \neq 0. \tag{32}$$

Then it is not possible to diagonalize P_1, and the problem is not well-posed. Otherwise the system is strongly hyperbolic and thus well-posed.

If all $\varepsilon_l \neq 0$, the lower diagonal block always has eigenvalues that are distinct from the eigenvalues of P_{11}, as shown by the following argument. When at least one k_l is nonzero, the eigenvalue of the lower block has negative real part. For $k_1 = \cdots = k_{d-1} = 0$, P_{11} is nonsingular since A_x is nonsingular, while the lower diagonal block is zero. It follows that P_1 is always diagonalizable, and the system is well-posed. This proves the following claim.

LEMMA 1. *If $\varepsilon_l > 0$, $l = 1, \ldots, d-1$, and the original system* (1) *is well-posed, then the PML* (29) *is also well-posed.*

We conclude this section by noting that the PML for many problems is well-posed without the parabolic CFS. Additionally, if the parabolic CFS is used, ε_l should be chosen relative to the grid size such that it does not impose restrictions on the time-stepping.

3. Construction of energy estimates for constant coefficient Cauchy problems via annihilating polynomials. As we have seen in the previous section, the construction of a layer which is well-posed and perfectly matched is rather straightforward. However, it is not so straightforward to choose the free parameters η, ξ, μ, α_j, β_{jl}, δ_{jl}, ε_{jl}, and ν_j, for a given hyperbolic system, such that the solution does not grow with time. Related to this question is the stability of the constant coefficient Cauchy problem

$$\frac{\partial u(x,t)}{\partial t} = P\left(\frac{\partial}{\partial x}\right) u(x,t), \quad u(x,0) = u_0(x), \quad x \in \mathbf{R}^d, \quad 0 \geq t \geq T. \tag{33}$$

If we perform a Fourier transform in space, (33) reduces to a system of ordinary differential equations

$$\frac{\partial \hat{u}(k,t)}{\partial t} = P(ik)\hat{u}(k,t), \qquad k \in \mathbf{R}^s, \quad 0 \geq t \geq T, \tag{34}$$

$$\hat{u}(k,0) = \hat{u}_0(k). \tag{35}$$

We will distinguish between the following two types of stability.

DEFINITION 2 (stability). *We say that the Cauchy problem* (33) *is*

(i) strongly stable *if all solutions satisfy an estimate* $\|u(\cdot,t)\|_{L^2} \leq K\|u_0(\cdot)\|_{L^2}$*;*

(ii) weakly stable *if the solutions satisfy an estimate* $\|u(\cdot,t)\|_{L^2} \leq K(1+t)^p\|u_0(\cdot)\|_{H^s}$, *where* $s > 0$.

Note that if (33) is well-posed, we can replace H^s by L^2 in (ii). In the remainder of this paper we will drop the subscript of the L^2-norm, i.e., $\|\cdot\| \equiv \|\cdot\|_{L^2}$.

A necessary and sufficient condition for weak stability is that all eigenvalues λ_j of the symbol $P(ik)$ satisfy

$$\Re\{\lambda_j(P(ik))\} \leq 0. \tag{36}$$

Condition (36) can be checked by various methods that determine the number of zeros of polynomials in a half-plane. Below, we will first present a method that automatically generates a finite number of algebraic inequalities that can be used to check (36). Then we will show that if (36) holds, the method can also be used to construct a local energy density that decays with time.

We begin by recalling some definitions from matrix theory (see, e.g., [12]).

DEFINITION 3 (annihilating polynomial). *We say that a scalar polynomial $f(\lambda)$ is an* annihilating polynomial *of the square matrix A if*

$$f(A) = 0.$$

Two important annihilating polynomials are the characteristic polynomial and the minimal polynomial.

DEFINITION 4 (characteristic polynomial). *The scalar polynomial $f(\lambda)$ defined as*

$$f(\lambda) \equiv \det(\lambda I - A)$$

is called the characteristic polynomial of the matrix A.

DEFINITION 5 (minimal polynomial). *By $m_A(\lambda)$ we will denote the uniquely defined annihilating polynomial of lowest degree and with lead coefficient* 1. *The polynomial $m_A(\lambda)$ is called the* minimal polynomial *of A.*

Now, let $m_P(\lambda)$ be the minimal polynomial of the symbol $P(ik)$. Suppose its degree is n. To determine the number of roots with positive and negative real part of $m_P(\lambda) = 0$ for fixed k we can use the following lemma, which is a special case of Corollary (38,1b) in [21].

LEMMA 6. *Consider any polynomial $q(\lambda)$ of degree n. Let D be a real number, and define the polynomials Q_0 and Q_1 with real coefficients by*

$$q(iD) \equiv i^n \left[Q_0(D) + iQ_1(D)\right]. \tag{37}$$

Then there is a continued fraction

$$\frac{Q_1(D)}{Q_0(D)} = \cfrac{1}{c_1 D + d_1 - \cfrac{1}{c_2 D + d_2 - \cfrac{1}{c_3 D + d_3 - \cdots - \cfrac{1}{c_{n_r} D + d_{n_r}}}}}, \tag{38}$$

with $c_j \neq 0$ and $n_r \leq n$. The number of roots with positive (negative) real part equals the number of positive (negative) c_j. There are $n - n_r$ roots on the imaginary axis.

When we apply Lemma 6 to $m_p(\lambda)$, the number of nonzero coefficients c_j may depend on k. A change in sign corresponds to a root crossing the imaginary axis. We have the following corollary.

COROLLARY 7. *A necessary and sufficient condition for weak stability is that all c_j defined in* (38) *are negative, i.e.,*

$$c_j(k) < 0, \quad j = 1, 2, \ldots, n_r(k). \tag{39}$$

Remark. Strong stability follows if all eigenvalues (i.e., the roots of $m_P(\lambda) = 0$) have strictly negative real part for all k. However, in many cases there are certain k for which some roots have zero real part. If the corresponding eigenvectors span their respective invariant subspace, then the problem is still strongly stable. This condition must be checked in each case. We note that if (33) is well-posed, then, for sufficiently large $|k| \geq K$, $P(ik)$ can always be diagonalized. Thus, we need to check the eigenvectors only for roots that have zero real part at bounded $|k|$.

PROPOSITION 8. *Let $\hat{u}$ be the solution of the Fourier transformed system* (34). *Then any component $\hat{u}_i$ satisfies the equation*

$$g\left(\frac{\partial}{\partial t}\right)\hat{u}_i = 0,$$

where $g(\lambda)$ is any annihilating polynomial of the symbol $P(ik)$. In particular we have for the minimal polynomial of $P(ik)$

$$m_P\left(\frac{\partial}{\partial t}\right)\hat{u}_i(k,t) = 0. \tag{40}$$

Proof. By definition we have $g(P(ik)) = 0$. Multiplying by the solution vector from the right yields $g(P(ik))\hat{u} = 0$. By an easy induction argument we have, for any integer q, $(P(ik))^q\hat{u} = \frac{\partial^q \hat{u}}{\partial t^q}$. The proposition follows. ∎

By the following theorem we can construct decaying energies for the problem (33).

THEOREM 9. *Let $\hat{u}_i$ satisfy*

$$q\left(\frac{\partial}{\partial t}\right)\hat{u}_i = 0. \tag{41}$$

If (39) *holds for Q_0 and Q_1 defined as in Lemma* 6*, there exists an energy*

$$\mathcal{E}(t;k) \equiv \frac{1}{2}\sum_{j=1}^{n_r} |c_j||\hat{z}^{(j)}(k,t)|^2 \tag{42}$$

satisfying

$$\frac{\partial}{\partial t}\mathcal{E}(t;k) = -|\hat{z}^{(1)}(k,t)|^2. \tag{43}$$

The functions $\hat{z}^{(j)}$, $j = 1, \ldots, n$, are related to $\hat{u}_i(k,t)$ via the equations

$$\begin{aligned} &\prod_{j=1}^{n-n_r}\left(\frac{\partial}{\partial t} + ib_j(k)\right)\hat{u}_i(k,t) = -i\hat{z}^{(1)}(k,t), \qquad \Im b_j(k) = 0, \\ &\frac{\partial}{\partial t}\begin{bmatrix} |\,c_1|\hat{z}^{(1)} \\ \vdots \\ \vdots \\ |\,c_{n_r}|\hat{z}^{(n_r)} \end{bmatrix} = \begin{bmatrix} id_1 - 1 & -i & \cdots & 0 \\ -i & id_2 & \cdots & 0 \\ 0 & \vdots & \ddots & -i \\ 0 & \vdots & -i & id_{n_r} \end{bmatrix}\begin{bmatrix} \hat{z}^{(1)} \\ \vdots \\ \vdots \\ \hat{z}^{(n_r)} \end{bmatrix}. \end{aligned} \tag{44}$$

For the proof of Theorem 9 we refer to [14]. Note that system (44) can be used to eliminate all $\hat{z}^{(j)}$ so that the energy (42) is expressed in $\hat{u}_i$ alone.

3.1. Localization of $\mathcal{E}(t;k)$. Since the coefficients c_j are rational functions in k, localization can be accomplished by multiplication with a suitable polynomial in k. In particular let $\gamma(k)$ be a polynomial such that $\tilde{c}_j(k) = -\gamma(k)^2 c_j(k)$ is also a polynomial in k. Then, since by assumption $\tilde{c}_j(k) > 0$ for all k, it can be decomposed as

$$\tilde{c}_j(k) = \sum_l q_l^2(k), \tag{45}$$

where $q_l(k)$ are real polynomials in k. By multiplying (43) with $\gamma(k)^2$ we get

$$\begin{aligned} \frac{d}{dt}\frac{1}{2}\sum_{j=1}^{n_r} |\gamma(k)^2 c_j(k)|\,|\hat{z}^{(j)}(t,k)|^2 &= \frac{d}{dt}\frac{1}{2}\sum_{j=1}^{n_r}\sum_l \left|q_l(k)\,\hat{z}^{(j)}(t,k)\right|^2 \\ &= -\left|\gamma(k)\,\hat{z}^{(1)}(t,k)\right|^2. \end{aligned} \tag{46}$$

Integrating over k yields

$$\begin{aligned} &\frac{d}{dt}\frac{1}{2}\sum_{j=1}^{n_r}\sum_l \int_{\mathbb{R}^s} \left|q_l(k)\,\gamma(k)\,\hat{z}^{(j)}(t,k)\right|^2 dk \\ &\qquad = -\int_{\mathbb{R}^s} \left|\gamma(k)\,\hat{z}^{(1)}(t,k)\right|^2 dk, \end{aligned}$$

and by applying Parseval's formula $\int |\hat{f}(k)|^2 dk = \|f(x)\|^2$, we obtain the following result.

COROLLARY 10. *There exists a polynomial $\gamma(k)$ such that the inverse transform of* (46) *is*

$$\frac{d}{dt}E(t) = -\left\|\mathcal{F}^{-1}\left\{\gamma(k)\,\hat{z}^{(1)}(t,k)\right\}\right\|^2. \tag{47}$$

Here

$$E(t) = \frac{1}{2}\sum_{j=1}^{n}\sum_l \left\|\mathcal{F}^{-1}\left\{q_l(k)\,\hat{z}^{(j)}(t,k)\right\}\right\|^2 \tag{48}$$

contains only local quantities.

Note that Theorem 9 can be used with any annihilating polynomial of $P(ik)$. If the minimal polynomial is available, it is advantageous to use it since it has lower degree and thus will produce an energy with lower order derivatives. Its lower degree also simplifies the computation of the continued fraction.

4. PML for Maxwell's equations. The first problem we consider is the scaled TM_z problem in a lossless medium. Then Maxwell's equations can be written

$$\begin{gathered} \frac{\partial u}{\partial t} + A_x\frac{\partial u}{\partial x} + A_y\frac{\partial u}{\partial y} = 0, \\ A_x = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & -1 & 0 \end{bmatrix}, \quad A_y = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 0 \end{bmatrix}, \end{gathered}$$

where $u = [H_x, H_y, E_z]^T$. We consider a layer in the x direction. Here A_x is singular and there are only two modes that propagate in the x direction. Hence, we add auxiliary variables only to the x-propagating H_y and E_z fields. The layer we will consider is defined by the equations

$$\begin{aligned}
\frac{\partial H_x}{\partial t} + \frac{\partial E_z}{\partial y} &= 0,\\
\frac{\partial H_y}{\partial t} - (1+\eta\sigma)\frac{\partial E_z}{\partial x} &= \sigma\phi_2,\\
\frac{\partial E_z}{\partial t} - (1+\eta\sigma)\frac{\partial H_y}{\partial x} + \frac{\partial H_x}{\partial y} &= \sigma\phi_1,\\
\frac{\partial \phi_1}{\partial t} + \frac{\partial E_z}{\partial x} &= -(\sigma+\alpha)\phi_1 + \varepsilon\frac{\partial^2\phi_1}{\partial y^2},\\
\frac{\partial \phi_2}{\partial t} + \frac{\partial H_y}{\partial x} &= -(\sigma+\alpha)\phi_2 + \varepsilon\frac{\partial^2\phi_2}{\partial y^2}.
\end{aligned} \tag{49}$$

Here we have included the parameter η, which will improve the damping of evanescent modes. Note that if $\varepsilon = 0$, the above equations are only weakly hyperbolic and thus only weakly well-posed. To ensure strong well-posedness we take $\varepsilon > 0$.

4.1. Stability for constant σ. When σ is constant we can take the Fourier transform in x and y. For simplicity let $\eta = 0$. The symbol of (49) then becomes

$$P(ik) = -\begin{bmatrix} ik_xA_x + ik_yA_y & \sigma D \\ ik_xE & (\alpha+\sigma+\varepsilon k_y^2)I \end{bmatrix}, \tag{50}$$

where

$$D = \begin{bmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \end{bmatrix}^T, \qquad E = -\begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}.$$

The minimal polynomial of (50) coincides with the characteristic polynomial and can be written as a product of the two polynomials $m_P(\lambda) = m_1(\lambda)m_4(\lambda)$:

$$\begin{aligned}
m_1(\lambda) &= \lambda,\\
m_4(\lambda) &= \big(\lambda^4 + 2(\tau+\sigma)\lambda^3 + (k_x^2 + k_y^2 + (\tau+\sigma)^2)\lambda^2\\
&\quad + 2(\tau k_x^2 + (\tau+\sigma)k_y^2)\lambda + k_x^2\tau^2 + (\tau+\sigma)^2k_y^2\big),
\end{aligned}$$

where we have introduced $\tau = \alpha + \varepsilon k_y^2$.

To determine the sign of the eigenvalues we apply Lemma 6 to $m_4(\lambda)$. The coefficients in the continued fraction (38) are

$$c_1 = -\frac{1}{2(\tau+\sigma)}, \tag{51}$$

$$c_2 = -\frac{2(\tau+\sigma)^2}{(\tau+\sigma)^3 + \sigma k_x^2}, \tag{52}$$

$$c_3 = -\frac{\left((\tau+\sigma)^3 + \sigma k_x^2\right)^2}{2\sigma k_x^2\left((\tau+\sigma)(\tau^2+\sigma\tau+k_y^2) + \tau k_x^2\right)(\tau+\sigma)}, \tag{53}$$

$$c_4 = -\frac{2\sigma k_x^2\left((\tau+\sigma)(\tau^2+\tau\sigma+k_y^2) + \tau k_x^2\right)}{\left((\tau+\sigma)^2k_y^2 + k_x^2\tau^2\right)\left((\tau+\sigma)^3 + \sigma k_x^2\right)}, \tag{54}$$

$$d_1 = d_2 = d_3 = d_4 = 0. \tag{55}$$

Clearly all c_j are negative and defined except for the cases $k_x = k_y = 0$ and $k_x = 0, k_y \neq 0$. When $k_x = 0$ the minimal equation reduces to $\lambda(\lambda^2 + k_y^2)(\lambda + \sigma + \tau)^2 = 0$ with solutions $\lambda = 0, \pm ik_y, -(\sigma+\tau), -(\sigma+\tau)$. The eigenvalues with zero real part are distinct as long as $k_y \neq 0$. For the case $k_y = 0$ there could potentially be algebraic growth. However, it is easily checked that there are three independent eigenvectors when $k_x = k_y = 0$. Thus (49) is strongly stable when $\eta = 0$. When $\eta \neq 0$ the coefficients are somewhat more complicated, but strong stability follows similarly. This concludes the proof of the following lemma.

LEMMA 11. *For constant $\sigma > 0$, $\alpha > 0$, $\varepsilon > 0, \eta\sigma + 1 > 0$, the system (49) is strongly stable.*

4.2. Energy estimates. We now consider decaying energies of the system (49). We start by noticing that $m_4(P(ik))$ annihilates $\hat{E}_z$ and $\hat{\phi}_2$, while $m_P(\partial/\partial t)$ annihilates $\hat{H}_x$, $\hat{H}_y$, and $\hat{\phi}_1$. Thus we have that

$$m_4\left(\frac{\partial}{\partial t}\right)\hat{v} = 0 \quad \text{for} \quad \hat{v} = \hat{E}_z, \hat{\phi}_2, \frac{\partial \hat{H}_x}{\partial t}, \frac{\partial \hat{H}_y}{\partial t}, \frac{\partial \hat{\phi}_1}{\partial t}.$$

It follows from Theorem 9 and (51)–(55) that the energy

$$\mathcal{E}(t;k) \equiv \frac{1}{2}\sum_{j=1}^{4} |c_j||\hat{z}^{(j)}(k,t)|^2 \tag{56}$$

decays with time. To express (56) in $\hat{v}$ we use (44). This yields

$$\begin{aligned}
|z^{(1)}| &= |\hat{v}|, \qquad |z^{(2)}| = \left|\left(|c_1|\frac{\partial}{\partial t} + 1\right)\hat{v}\right|, \\
|z^{(3)}| &= \left|\left(|c_2|\frac{\partial}{\partial t}\left(|c_1|\frac{\partial}{\partial t} + 1\right) + 1\right)\hat{v}\right|, \\
|z^{(4)}| &= \left|\left(|c_3|\frac{\partial}{\partial t}\left(|c_2|\frac{\partial}{\partial t}\left(|c_1|\frac{\partial}{\partial t} + 1\right) + 1\right) + \left(|c_1|\frac{\partial}{\partial t} + 1\right)\right)\hat{v}\right|.
\end{aligned} \tag{57}$$

Since $\mathcal{E}$ is a function of c_3 and c_4, whose denominators vanish for certain k_x and k_y, it is not bounded. To formulate energies in physical space, we first remove the singularities of $\mathcal{E}$ by multiplying (56) by a suitable polynomial in k_x and k_y. Here we will consider two different polynomials, the first producing a semilocal energy and the second a fully local energy.

4.2.1. A semilocal energy. We would like the order of the spatial derivatives of v appearing in the energy in physical space to be as low as possible. At the same time, the energy must be bounded for all k_x and k_y so that we can use Parseval. The energy

$$\mathcal{E}_{SL}(t;k) = 2(\tau+\sigma)k_x^2\left((\tau+\sigma)^2k_y^2 + k_x^2\tau^2\right)\mathcal{E}(t;k) \tag{58}$$

satisfies these requirements. We can split $\mathcal{E}_{SL}$ into a local and a nonlocal part

$$\mathcal{E}_{SL}(t;k) = \mathcal{E}_L + \mathcal{E}_{NL}. \tag{59}$$

The local and nonlocal energies are

$$\mathcal{E}_L = k_x^2\left((\tau+\sigma)^2k_y^2 + k_x^2\tau^2\right)|\hat{v}|^2, \tag{60}$$

$$\mathcal{E}_{NL} = 2(\tau+\sigma)k_x^2\left((\tau+\sigma)^2k_y^2 + k_x^2\tau^2\right)\sum_{j=2}^{4}|c_j||\hat{z}^{(j)}(k,t)|^2. \tag{61}$$

Now by using Parseval we get

$$\frac{d}{dt}\left(E_L(t;v)+E_{NL}(t)\right) = -2(\sigma+\alpha)E_L(t;v) - 2\varepsilon E_L(t;\partial_y v), \tag{62}$$

where

$$\begin{aligned} E_L(t;v) = (\alpha+\sigma)^2\|\partial_x\partial_y v(\cdot,t)\|^2 + \alpha^2\|\partial_x^2 v(\cdot,t)\|^2 + 2\varepsilon(\alpha+\sigma)\|\partial_x\partial_y^2 v(\cdot,t)\|^2 \\ + \varepsilon^2\|\partial_x\partial_y^3 v(\cdot,t)\|^2 + 2\varepsilon\alpha\|\partial_x^2\partial_y v(\cdot,t)\|^2 + \varepsilon^2\|\partial_x^3\partial_y v(\cdot,t)\|^2. \end{aligned} \tag{63}$$

We do not state $E_{NL}(t)$ explicitly, since for our purpose it is sufficient to know that it is bounded and nonnegative. However, we note that $E_{NL}(t)$ is nonlocal in space.

We see that

$$E_L(t;v) \le E_L(0\,;v) + E_{NL}(0\,;v), \tag{64}$$

which proves the following claim.

LEMMA 12. *Let v be any of the fields*

$$E_z, \phi_2, \frac{\partial H_x}{\partial t}, \frac{\partial H_y}{\partial t}, \frac{\partial \phi_1}{\partial t}.$$

If $\sigma > 0$, $\alpha > 0$, $\varepsilon > 0$ and constant, then v satisfies the estimate

$$(\alpha+\sigma)^2\|\partial_x\partial_y v(\cdot,t)\|^2 + \alpha^2\|\partial_x^2 v(\cdot,t)\|^2 \le C = E_L(0\,;v) + E_{NL}(0\,;v). \tag{65}$$

4.2.2. A local energy. To obtain a fully local energy we need to clear the denominators of (56) and (57). Again, this is done by multiplying $\mathcal{E}$ by a suitable factor. For this case we define the fully local energy by

$$\begin{aligned} \mathcal{E}_{FL} \equiv\ & (\tau+\sigma)^2((\tau+\sigma)^3+\sigma k_x^2) \\ & \times \left((\tau+\sigma)^2 k_y^2 + k_x^2\tau^2\right) k_x^2 \left((\tau+\sigma)(\tau^2+\sigma\tau+k_y^2)+\tau k_x^2\right)\mathcal{E}. \end{aligned}$$

$\mathcal{E}_{FL}(t;k)$ can be split into

$$\mathcal{E}_{FL}(t;k) = \mathcal{E}^I + \mathcal{E}^{II} + \mathcal{E}^{III} + \mathcal{E}^{IV},$$

where

$$\begin{aligned} \mathcal{E}^I &= \frac{1}{2}(\tau+\sigma)((\tau+\sigma)^3+\sigma k_x^2)\left((\tau+\sigma)^2 k_y^2 + k_x^2\tau^2\right) \\ &\quad \times k_x^2\left((\tau+\sigma)(\tau^2+\sigma\tau+k_y^2)+\tau k_x^2\right)|\hat{v}|^2, \\ \mathcal{E}^{II} &= 2(\tau+\sigma)^2 k_x^2\left((\tau+\sigma)^2 k_y^2 + k_x^2\tau^2\right) \\ &\quad \times \left((\tau+\sigma)(\tau^2+\sigma\tau+k_y^2)+\tau k_x^2\right)\Big|\underbrace{(\frac{1}{2}\partial_t+\tau+\sigma)\hat{v}}_{\hat{\chi}_1}\Big|^2, \\ \mathcal{E}^{III} &= \frac{1}{2\sigma}(\tau+\sigma)((\tau+\sigma)^3+\sigma k_x^2)\left((\tau+\sigma)^2 k_y^2 + k_x^2\tau^2\right) \\ &\quad \times \Big|\underbrace{\left((\sigma+\tau)\partial_t^2 + 2(\sigma+\tau)^2\partial_t + (\tau+\sigma)^3+\sigma k_x^2\right)\hat{v}}_{\hat{\chi}_2}\Big|^2, \\ \mathcal{E}^{IV} &= \left|\left(((\tau+\sigma)^3+\sigma k_x^2)\partial_t\left(\frac{(\tau+\sigma)}{2\sigma}\partial_t^2 + \frac{(\tau+\sigma)^2}{\sigma}\partial_t + \frac{1}{2\sigma}\right)\right.\right. \\ &\quad \left.\left. + k_x^2((\tau+\sigma)(\tau^2+\sigma\tau+k_y^2)+\tau k_x^2)\left(\frac{1}{2}\partial_t+\sigma+\tau\right)\right)\hat{v}\right|^2. \end{aligned}$$

To localize the energies we need to write them in the form (45). This is a straightforward operation, but the resulting expressions become lengthy (they contain many combinations of higher derivatives) and are therefore presented in Appendix A.

Let E^n be the physical space version of the energy $\mathcal{E}^n$. Then we have that

$$\frac{d}{dt}\left(E^I(t) + E^{II}(t) + E^{III}(t) + E^{IV}(t)\right) = -E^I(t), \tag{66}$$

which means that

$$\left(E^I(t) + E^{II}(t) + E^{III}(t) + E^{IV}(t)\right) \leq \left(E^I(0) + E^{II}(0) + E^{III}(0) + E^{IV}(0)\right).$$

Thus E^I, E^{II}, E^{III}, and E^{IV} all remain bounded.

It may be possible to derive sharper results from this fully local energy by using the system (49). We note that the energy estimates obtained by Bécache, Petropoulos, and Gedney in [7] are stated in terms of the fields rather than the derivatives of the fields, so that strong stability is a straightforward consequence of the energy inequality. We emphasize that our results also imply strong stability, even though the energy is stated in terms of derivatives of the fields.

5. The linearized Euler equations. The next problem we consider is the Euler equations in two dimensions linearized around a subsonic skew flow

$$\frac{\partial u}{\partial t} + A_x \frac{\partial u}{\partial x} + A_y \frac{\partial u}{\partial y} = 0,$$

where

$$u = \begin{bmatrix} \rho \\ v_x \\ v_y \\ p \end{bmatrix}, \quad A_x = \begin{bmatrix} M_x & 1 & 0 & 0 \\ 0 & M_x & 0 & 1 \\ 0 & 0 & M_x & 0 \\ 0 & 1 & 0 & M_x \end{bmatrix}, \quad A_y = \begin{bmatrix} M_y & 0 & 1 & 0 \\ 0 & M_y & 0 & 0 \\ 0 & 0 & M_y & 1 \\ 0 & 0 & 1 & M_y \end{bmatrix}.$$

Here ρ is the density; v_x and v_y are the velocities in the x and y directions, respectively; p is the pressure; and M_x and M_y are the Mach numbers in the x and y directions. We have that $0 < M_x < 1, 0 < M_y < 1$ since the flow is assumed to be subsonic.

From [17] we conclude that a suitable layer in the x-direction should be of the form

$$\begin{aligned} &\frac{\partial u}{\partial t} + A_x\left(\frac{\partial u}{\partial x} + \mu\sigma u + \sigma\phi\right) + A_y \frac{\partial u}{\partial y} = 0, \\ &\frac{\partial \phi}{\partial t} + \frac{\partial u}{\partial x} + M_y \frac{\partial \phi}{\partial y} + (\sigma + \alpha)(\mu u + \phi) = 0. \end{aligned} \tag{67}$$

The symbol $P(ik)$ of (67) is

$$P(ik) = -\begin{bmatrix} (ik_x + \mu\sigma)A_x + ik_y A_y & \sigma A_x \\ ik_x I + (\sigma + \alpha)\mu I & (ik_y M_y + \sigma + \alpha)I \end{bmatrix}. \tag{68}$$

Note that here we do not need to include the parabolic CFS. To establish well-posedness, we simply freeze the coefficients and consider the principal part of $P(ik)$,

$$P_1(ik) = -\begin{bmatrix} ik_x A_x + ik_y A_y & 0 \\ ik_x I & ik_y M_y I \end{bmatrix}. \tag{69}$$

The eigenvalues of the upper diagonal block are easy to compute. They coincide with $ik_y M_y I$ only when $k_x = 0$. Thus P_1 is diagonalizable, and well-posedness follows.

5.1. Stability for constant σ. In [17] it was shown that the choice

$$\mu = \frac{M_x}{1 - M_x^2} \tag{70}$$

is necessary for the solution in a layer closely related to (67) to decay in space. Similar conclusions, from another point of view, were reached by Hu in [19]. The results for decay in space from [17] apply directly to (67). Here we will show that (70) is also necessary and sufficient for stability (in time) for (67).

First we show that (70) is sufficient. We note that the real part of the eigenvalues of $P(ik)$ (with μ given by (70)) coincides with the real part of the eigenvalues of the matrix $\tilde{P}(ik) \equiv P(ik) - ik_y M_y I$. Since $\tilde{P}(ik)$ has a sparser structure, it is easier to check that its eigenvalues have nonpositive real part.

The minimal polynomial of $\tilde{P}(ik)$ can be factored $m_{\tilde{P}}(\lambda) = m_1(\lambda)m_2(\lambda)$, where

$$m_1(\lambda) = \lambda^2 + \left(ik_x M_x + \frac{\sigma}{\zeta} + \alpha \right) \lambda + ik_x \alpha M_x \tag{71}$$

and

$$\begin{aligned} m_2(\lambda) =& \lambda^4 + 2\left(ik_x M_x + \frac{\sigma}{\zeta} + \alpha \right) \lambda^3 \\ &+ \left(4\alpha i k_x M_x + \zeta k_x^2 + k_y^2 + \frac{(\sigma+\alpha)^2 - M_x^2 \alpha^2}{\zeta} \right) \lambda^2 \\ &+ 2\left(ik_x \alpha M_x + \zeta \alpha k_x^2 + (\alpha + \sigma) k_y^2 \right) \lambda + \zeta \alpha^2 k_x^2 + (\alpha+\sigma)^2 k_y^2. \end{aligned} \tag{72}$$

Here we have introduced $\zeta = 1 - M_x^2$. The continued fraction coefficients for (71) are

$$c_1 = -\frac{\zeta}{2(\sigma + \alpha\zeta)}, \tag{73}$$

$$c_2 = -\frac{2(\sigma + \alpha\zeta)^3}{\alpha\sigma M_x^2 \zeta^2 k_x^2}. \tag{74}$$

For (72) the coefficients are

$$c_1 = -\frac{\zeta}{2(\sigma + \alpha\zeta)}, \tag{75}$$

$$c_2 = -\frac{2(\sigma + \alpha\zeta)^3}{c_{2a}}, \tag{76}$$

$$c_3 = -\frac{c_{2a}^3}{2\sigma\zeta(\sigma + \alpha\zeta)^4 c_{3a}}, \tag{77}$$

$$c_4 = -\frac{2(\alpha\zeta + \sigma)^4 c_{3a}^3 \sigma}{c_{2a}^4 (k_y^2 M_x^2 - \zeta k_x^2)^2 (\alpha^2 \zeta k_x^2 + (\alpha+\sigma)^2 k_y^2) c_{4a}}, \tag{78}$$

where c_{2a}, c_{3a}, c_{4a} are positive for all k_x and k_y and can be found in Appendix B. We see that all the coefficients are negative and defined for all k_x and k_y except the cases (a) $k_x = k_y = 0$, (b) $k_x = 0$, $k_y \neq 0$, and (c) $(1 - M_x^2)k_x^2 = M_x^2 k_y^2$. We will consider these cases separately.

First we consider the case (a), for which we easily can compute the eigenvalues of $\tilde{P}(k_x = 0, k_y = 0) = P(k_x = 0, k_y = 0)$. They are

$$0, \quad -\frac{\sigma}{1 - M_x} - \alpha, \quad -\frac{\sigma}{1 + M_x} - \alpha, \quad -\frac{\sigma}{1 - M_x^2} - \alpha.$$

The zero eigenvalue has multiplicity four, and there could potentially be algebraic growth. However, straightforward calculations show that there are also four independent eigenvectors, and this mode will be strongly stable.

For the case (b), the minimal polynomial of $\tilde{P}(ik)$ can be factored into

$$m_{\tilde{P}}(\lambda) = n_1(\lambda)n_2(\lambda)n_3(\lambda),$$
$$n_1(\lambda) = \lambda, \quad n_2(\lambda) = \lambda + \frac{\sigma + \alpha\zeta}{\zeta}, \quad n_3(\lambda) = m_2(\lambda; k_x = 0).$$

Directly, we see that the eigenvalues $\lambda = 0$ and $\lambda = -(\sigma/\zeta + \alpha)$, being solutions to $n_1(\lambda) = 0$ and $n_2(\lambda) = 0$, have nonpositive real parts. The double zero eigenvalue of $\tilde{P}(ik)$ corresponds to the double eigenvalue $\lambda = -ik_y M_y$ of $P(ik)$. Associated with $\lambda = -ik_y M_y$ there are two linearly independent eigenvectors, and thus stability will not be lost.

For $n_3(\lambda)$, we compute the coefficients in the continued fraction. They are

$$c_1 = -\frac{\zeta}{2(\sigma + \alpha\zeta)},$$
$$c_2 = -\frac{2(\sigma + \zeta\alpha)^2}{\sigma M_x^2 k_y^2 \zeta + (\sigma + \alpha(1 + M_x))(\sigma + \alpha(1 - M_x))(\sigma + \zeta\alpha)},$$
$$c_3 = -\frac{(\sigma M_x^2 k_y^2 \zeta + (\sigma + \alpha(1 + M_x))(\sigma + \alpha(1 - M_x))(\sigma + \zeta\alpha))^2}{2k_y^2 \zeta \sigma M_x^2 (\sigma + \alpha)(\sigma\alpha + \zeta(\alpha^2 + k_y^2))},$$
$$c_4 = -\frac{2\sigma M_x^2 (\sigma\alpha + \zeta(\alpha^2 + k_y^2))}{(\sigma + \alpha)(\sigma M_x^2 k_y^2 \zeta + (\sigma + \alpha(1 + M_x))(\sigma + \alpha(1 - M_x))(\sigma + \zeta\alpha))}.$$

Due to the assumptions $0 < M_x < 1$, $\zeta > 0$, $\sigma > 0$, and $\alpha > 0$ they are all negative.

Finally we consider case (c). For this case $m_{\tilde{P}}(\lambda)$ again factors into three polynomials

$$m_{\tilde{P}}(\lambda) = o_1(\lambda)o_2(\lambda)o_3(\lambda),$$
$$o_1(\lambda) = \lambda - ik_x \frac{\zeta}{M_x}, \quad o_2(\lambda) = m_1(\lambda),$$

$$o_3(\lambda) = \lambda^3 + \left(2\frac{\sigma + \zeta\alpha}{1 - M_x^2} + ik_x \frac{1 + M_x^2}{M_x}\right)\lambda^2 + \left(\frac{(\sigma + \alpha)^2 - \alpha^2 M_x^2}{\zeta} + ik_x \frac{2(\sigma + \alpha(1 + M_x^2))}{M_x}\right)\alpha + ik_x \frac{(\sigma + \alpha)^2 + \alpha^2 M_x^2}{M_x}.$$

The eigenvalue belonging to $o_1(\lambda)$ is distinct and does not affect strong stability, and the polynomial $o_2(\lambda) = m_1(\lambda)$ has already been checked. It only remains to check the coefficients of the continued fraction arising from $o_3(\lambda)$. They are

$$c_1 = -\frac{\zeta}{2(\sigma + \alpha\zeta)}, \tag{79}$$
$$c_2 = -\frac{2(\sigma + \alpha\zeta)^3}{c_{2a}}, \tag{80}$$
$$c_3 = -\frac{c_{2a}^3 M_x^2}{4(\sigma + \alpha\zeta)^4 k_x^2 \sigma \zeta^2 (\alpha^2 M_x^2 + (\sigma + \alpha)^2)} \times \frac{1}{\alpha M_x^2 (\alpha + \sigma)(\sigma + \alpha\zeta)^2 + \zeta^2 k_x^2 (\sigma + \alpha(1 + M_x^2))^2}, \tag{81}$$

where

$$c_{2a} = (\sigma + \alpha\zeta)^2((\sigma + \alpha)^2 - \alpha^2 M_x^2) + 2\sigma k_x^2 \zeta^2(\sigma + \alpha(1 + M_x^2)). \tag{82}$$

Clearly, (79)–(81) are negative and defined unless $k_x = k_y = 0$. However, that particular case has already been checked.

To see that (70) is a necessary condition we use the parameterization $k_y = \kappa$, $k_x = \gamma\kappa$ and compute the minimal polynomial of $\tilde{P}(\kappa, \gamma)$ with μ as a free parameter. Again the minimal polynomial can be factored into a quadratic and a quartic. If we compute the coefficients in the continued fraction for the quartic, we see that for κ large the sign of the coefficients c_3 and c_4 will be determined by the sign of the expression

$$\kappa^4(M_x^2 - \gamma^2 + \gamma^2 M_x^2)(M_x^2\mu^2\gamma^2 + 2\gamma^2\mu M_x + \gamma^2 - \mu^2\gamma^2 - \mu^2). \tag{83}$$

Since the expression $(M_x^2 - \gamma^2 + \gamma^2 M_x^2)$ will change sign when $\gamma^2 = M_x^2/(1 - M_x^2)$ we must choose μ such that the sign of the last expression in (83) changes simultaneously. Hence μ must satisfy

$$(M_x^4 - 1)\mu^2 + 2M_x^3\mu + M_x^2 = 0;$$

i.e., we must choose

$$\mu = -\frac{M_x}{1 + M_x^2} \quad \text{or} \quad \mu = \frac{M_x}{1 - M_x^2}.$$

The first choice will violate the conditions for c_2 when k_x is large and cannot be used, while the second choice, as we have seen above, yields a strongly stable PML.

We summarize the results in the following lemma.

LEMMA 13. *For constant $\sigma > 0$, $\alpha > 0$, and $0 < M_x < 1$, a necessary and sufficient condition for strong stability of the system* (67) *is that*

$$\mu = \frac{M_x}{1 - M_x^2}. \tag{84}$$

6. A stable PML for general 2×2 symmetric hyperbolic systems. Our final example is the symmetric hyperbolic system

$$\frac{\partial u}{\partial t} + \underbrace{\begin{bmatrix} a_{11} & a_{12} \\ a_{12} & a_{22} \end{bmatrix}}_{A} \frac{\partial u}{\partial x} + \underbrace{\begin{bmatrix} b_{11} & b_{12} \\ b_{12} & b_{22} \end{bmatrix}}_{B} \frac{\partial u}{\partial y} = 0. \tag{85}$$

Here A and B are real matrices, and we can choose $a_{12} = 0$ without loss of generality. Note that the convective wave equation

$$\left(\frac{\partial}{\partial t} + M\frac{\partial}{\partial x}\right)^2 u = C^2\nabla^2 u$$

is a special case of (85) if we choose

$$a_{11} = M + C, \quad a_{22} = M - C, \quad b_{12} = C, \quad a_{12} = b_{11} = b_{22} = 0.$$

Equation (85) also contains the anisotropic wave equation as a special case:

$$\frac{\partial^2 u}{\partial t^2} = \nabla \cdot (T\,\nabla u),$$
$$T = \begin{bmatrix} a & b \\ b & c \end{bmatrix}, \quad a > 0, \quad c > 0, \quad ac - b^2 > 0,$$

describing electromagnetic waves propagating in an anisotropic dielectric media. Here

$$a_{11} = -a_{22}, \quad a_{12} = 0, \quad b_{11} = -b_{22},$$
$$a_{11} = \sqrt{a}, \quad b_{11} = \frac{b}{\sqrt{a}}, \quad b_{12} = \sqrt{c - \frac{b^2}{a}}.$$

The direction in which the waves supported by the system (85) propagate depends on the coefficients of A and B. If A is nonsingular, there are three distinct cases:

(i) $a_{11}a_{22} < 0, b_{12} \neq 0$: coupled waves moving in opposite x-directions.
(ii) $a_{11}a_{22} > 0, b_{12} \neq 0$: coupled waves moving in the same x-direction.
(iii) $b_{12} = 0$, $a_{11}a_{22} \neq 0$: decoupled waves.

For the cases (ii) and (iii), there is no need to use a PML since waves can be damped without reflection by simply adding a damping term

$$\begin{bmatrix} \sigma_1(x) & 0 \\ 0 & \sigma_2(x) \end{bmatrix} u$$

to (85). The appropriate signs of σ_1 and σ_2 can be determined by the sign of a_{jj}; see also [4]. The case (i) is more interesting. In [4], the following PML model is suggested:

$$\begin{aligned} \frac{\partial u}{\partial t} + A\left(\frac{\partial u}{\partial x} + \sigma\mu u + \phi\right) + B\frac{\partial u}{\partial y} &= 0, \\ \frac{\partial \phi}{\partial t} + (\sigma+\alpha)\phi + \beta\frac{\partial \phi}{\partial y} &= \sigma\left(\gamma\frac{\partial u}{\partial x} + \mu(\sigma+\alpha)u + \delta\frac{\partial u}{\partial y}\right), \end{aligned} \tag{86}$$

where

$$\delta = \frac{b_{22} - b_{11}}{a_{11} - a_{22}}, \qquad \mu = -\frac{a_{11} + a_{22}}{2|a_{11}a_{22}|}, \tag{87}$$

$$\beta = -\frac{b_{11}a_{22} - b_{22}a_{11}}{a_{11} - a_{22}}, \qquad \gamma = -1, \quad \alpha \geq 0. \tag{88}$$

We note that this is a special case of the general layer studied above. With this choice of parameters we have the following claim.

LEMMA 14. *For $\sigma > 0$ and constant, $a_{11}a_{22} < 0$, and $\alpha \geq 0$, the system* (86) *is at least weakly stable.*

Proof. For simplicity we give the proof only for the case $\alpha = 0$. For the general choice of $\alpha \neq 0$ the coefficients are more complicated, but stability follows similarly. We consider three different cases, (a) $k_x \neq 0, k_y \neq 0$, (b) $k_x \neq 0, k_y = 0$, and (c) $k_x = k_y = 0$. First we consider the case (a) and compute the coefficients in the continued fraction, (38) in Lemma 6. They are

$$c_1 = \frac{2a_{22}a_{11}}{\sigma\left(a_{11} - a_{22}\right)^2},$$
$$c_2 = -\frac{2\sigma\left(a_{11} - a_{22}\right)^4}{c_{2a}},$$
$$\begin{aligned} c_{2a} = \sigma^2(a_{11} - a_{22})^4 + 4a_{11}^2a_{22}^2\left(k_x(a_{11} - a_{22}) + k_y(b_{11} - b_{22})\right)^2 \\ - 4a_{11}a_{22}b_{12}^2k_y^2(a_{11} + a_{22})^2\big), \end{aligned}$$

$$c_3 = \frac{1}{32}\frac{c_{2a}^3}{(a_{11}-a_{22})^2 c_{3a} a_{22}^2 a_{11}^2 b_{12}^2 k_y^2 \sigma},$$

$$c_{3a} = \sigma^2(a_{11}-a_{22})^4 c_{3b} + 4a_{22}a_{11}c_{3b}^2,$$

$$c_{3b} = -k_y^2 b_{12}^2 (a_{11}+a_{22})^2 + a_{22}a_{11}(k_y(b_{11}-b_{22}) + k_x(a_{11}-a_{22}))^2,$$

$$c_4 = -8\frac{c_{3a}^3 a_{22} a_{11}}{c_{4a}^4 \sigma c_{4b}^2},$$

where c_{4a} and c_{4b} can be found in Appendix C. The coefficients are negative except for the cases (b) and (c), but then the eigenvalues can be computed directly. For case (b) they are

$$0, \quad ika_{11}a_{22} - \frac{\sigma}{2}\left(1 - \frac{a_{11}}{a_{22}}\right), \quad ika_{11}a_{22} - \frac{\sigma}{2}\left(1 - \frac{a_{22}}{a_{11}}\right),$$

and for the case (c) they are

$$0, \quad -\frac{\sigma}{2}\left(1 - \frac{a_{11}}{a_{22}}\right), \quad -\frac{\sigma}{2}\left(1 - \frac{a_{22}}{a_{11}}\right).$$

Since $a_{11}a_{22} < 0$ they all have nonnegative real part, and the lemma is proved. ∎

As a final remark, in many cases the words "at least weakly" in Lemma 14 can be replaced by "strongly." However, to prove this we need to consider all cases when c_{4a} or c_{4b} vanish. Considering the complexity of the expressions c_{4a} and c_{4b}, we expect the necessary calculations to be quite tedious.

7. Summary. We have presented a very general PML model for first order hyperbolic systems. We believe that the generality should make the model suitable for many future applications. We have also proven that the equations in the layer are perfectly matched to the equations in the computational domain. For the model formulated with one set of auxiliary variables, we have also shown that the layer equations can always be made strongly well-posed.

The critical step in the construction of a PML is to choose the free parameters so that the solution in the layer is stable. To simplify the analysis of this step, we have presented a method with which the stability of the layer can be determined by checking a fixed number of algebraic inequalities, which in turn can be generated automatically. Additionally, if these inequalities hold, we showed that there is an energy density in Fourier space that decays with time. By simple algebraic manipulations and application of Parseval's relation, this energy density can be converted to a decaying energy in physical space. The energy contains only the solution and its spatial and temporal derivatives; i.e., the energy is local.

We have used the introduced techniques to show strong stability for a PML for Maxwell's equations and a PML for the linearized Euler equations. We also showed weak stability for a PML for a general 2×2 hyperbolic system in $(2+1)$ dimensions. For the PML for Maxwell's equations, we also derived a semilocal and a local energy. These energies guarantee the time-decay of higher order derivatives in space and time of the solution.

Unlike techniques that only involve checking the roots of the characteristic polynomial, our method is applicable to variable coefficient problems. This is important since in "real life" the damping parameter σ is not constant. The stability of the variable coefficient problem can be analyzed as a perturbation of the constant coefficient problem. If the constant coefficient problem is stable, our method generates an energy. Since the energy decays for constant σ we expect it to decay at least for slowly varying σ.

Appendix A. Space-time energies for Maxwell PML. The space-time energy version of $\mathcal{E}^{IV}$ is obtained by integration over all wavenumbers and application of Parseval. It is

$$\begin{aligned} E^{IV} = \Bigg\| \Bigg(& ((\alpha - \varepsilon\partial_y^2 + \sigma)^3 - \sigma\partial_x^2)\partial_t \left(\frac{1}{2\sigma}(\alpha - \varepsilon\partial_y^2 + \sigma)\partial_t^2 + \frac{1}{\sigma}(\alpha - \varepsilon\partial_y^2 + \sigma)^2\partial_t + \frac{1}{2\sigma} \right) \\ & - \partial_x^2 \left((\alpha - \varepsilon\partial_y^2 + \sigma)((\alpha - \varepsilon\partial_y^2)^2 + \sigma(\alpha - \varepsilon\partial_y^2) - \partial_y^2) + \alpha - \varepsilon\partial_y^2 k_x^2 \right) \\ & \times \left(\frac{1}{2}\partial_t + \sigma + \alpha - \varepsilon\partial_y^2 \right) v(\cdot, t) \Bigg) \Bigg\|^2 . \end{aligned}$$

For $\mathcal{E}^{III}$ we first rewrite

$$\begin{aligned} & \frac{1}{2\sigma}(\tau+\sigma)((\tau+\sigma)^3 + \sigma k_x^2)\left((\tau+\sigma)^2 k_y^2 + k_x^2\tau^2\right) \\ & \qquad = \frac{1}{2\sigma}(\tau+\sigma)^6 k_y^2 + \frac{1}{2\sigma}(\tau+\sigma)^4 k_x^2\tau^2 \\ & + \frac{\alpha+\sigma}{2}(\tau+\sigma)^2 k_x^2 k_y^2 + \frac{\alpha+\sigma}{2}\tau^2 k_x^4 + \frac{\varepsilon}{2}(\tau+\sigma)^2 k_x^2 k_y^4 + \frac{\varepsilon}{2}\tau^2 k_x^4 k_y^2. \end{aligned}$$

Integrating over k and applying Parseval to each term in $\mathcal{E}^{III}$, we get

$$\begin{aligned} E^{III} = & \frac{1}{2\sigma}\|(\alpha + \sigma - \varepsilon\partial_y^2)^3\partial_y \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2 \\ & + \frac{1}{2\sigma}\|(\alpha + \sigma - \varepsilon\partial_y^2)^2(\alpha - \varepsilon\partial_y^2)\partial_x \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2 \\ & + \frac{\sigma+\alpha}{2}\|(\alpha + \sigma - \varepsilon\partial_y^2)\partial_x\partial_y \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2 \\ & + \frac{\sigma+\alpha}{2}\|(\alpha - \varepsilon\partial_y^2)\partial_x^2 \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2 \\ & + \frac{\varepsilon}{2}\|(\alpha + \sigma - \varepsilon\partial_y^2)\partial_x\partial_y^2 \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2 \\ & + \frac{\varepsilon}{2}\|(\alpha - \varepsilon\partial_y^2)\partial_x^2\partial_y \mathcal{F}^{-1}\{\hat{\chi}_2\}\|^2, \end{aligned}$$

where

$$\mathcal{F}^{-1}\{\hat{\chi}_2\} = \left((\sigma + \alpha - \varepsilon\partial_y^2)\partial_t^2 + 2(\sigma + \alpha - \varepsilon\partial_y^2)^2\partial_t + (\sigma + \alpha - \varepsilon\partial_y^2)^3 + \sigma\partial_x^2\right) v(x,t).$$

In the same way we get for $\mathcal{E}^{II}$

$$\begin{aligned}
E^{II} = {} & 2\alpha\|(\alpha+\sigma-\varepsilon\partial_y^2)^3\partial_x\partial_y\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)^3\partial_x\partial_y^2\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2(\alpha+\sigma)\|(\alpha+\sigma-\varepsilon\partial_y^2)^2\partial_x\partial_y^2\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)^2\partial_x\partial_y^3\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\alpha\|(\alpha+\sigma-\varepsilon\partial_y^2)^2\partial_x^2\partial_y\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)^2\partial_x^2\partial_y^2\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\alpha\|(\alpha+\sigma-\varepsilon\partial_y^2)^2(\alpha-\varepsilon\partial_y^2)\partial_x^2\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)^2(\alpha-\varepsilon\partial_y^2)\partial_x^2\partial_y\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2(\alpha+\sigma)\|(\alpha+\sigma-\varepsilon\partial_y^2)(\alpha-\varepsilon\partial_y^2)\partial_x\partial_y\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)(\alpha-\varepsilon\partial_y^2)\partial_x^2\partial_y^2\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\alpha\|(\alpha+\sigma-\varepsilon\partial_y^2)(\alpha-\varepsilon\partial_y^2)\partial_x^3\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2 \\
& + 2\varepsilon\|(\alpha+\sigma-\varepsilon\partial_y^2)(\alpha-\varepsilon\partial_y^2)\partial_x^3\partial_y\mathcal{F}^{-1}\{\hat{\chi}_1\}\|^2,
\end{aligned}$$

where

$$\mathcal{F}^{-1}\{\hat{\chi}_1\} = \left(\frac{1}{2}\partial_t + \sigma + \alpha - \varepsilon\partial_y^2\right)v. \tag{89}$$

By similar operations, we can obtain an expression for E^I. However, since we have to split the factor in front of $|\hat{v}|^2$ in $\mathcal{E}^I$ into many terms, the expression for E^I becomes very lengthy and we have chosen not to include it here.

Appendix B.

$$\begin{aligned}
c_{2a} &= \sigma\zeta^2(\sigma+3M_x^2\alpha+\alpha)k_x^2 + M_x^2\sigma\zeta(\sigma+\zeta\alpha)k_y^2 \\
&\quad + (\sigma+\zeta\alpha)^2(\sigma+\alpha(1+M_x))(\sigma+\alpha(1-M_x)), \\
c_{3a} &= (c_{3b}+c_{3c}k_x^4+c_{3d}k_y^4+c_{3e}k_x^2k_y^2+c_{3f}k_x^2+c_{3g}k_y^2), \\
c_{3b} &= (-\zeta k_x^2+M_x^2k_y^2)^2(\sigma\alpha\zeta^3k_x^2+\sigma(\sigma+\alpha)\zeta^2k_y^2), \\
c_{3c} &= \alpha\zeta^3(5{M_x}^4\alpha^3+12\sigma{M_x}^2\alpha^2+10{M_x}^2\alpha^3+2\alpha\sigma^2{M_x}^2+5\alpha\sigma^2 \\
&\quad + 2\sigma^3+4\sigma\alpha^2+\alpha^3), \\

BIFURCATION ANALYSIS OF A MATHEMATICAL MODEL FOR MALARIA TRANSMISSION*

NAKUL CHITNIS†, J. M. CUSHING‡, AND J. M. HYMAN§

Abstract. We present an ordinary differential equation mathematical model for the spread of malaria in human and mosquito populations. Susceptible humans can be infected when they are bitten by an infectious mosquito. They then progress through the exposed, infectious, and recovered classes, before reentering the susceptible class. Susceptible mosquitoes can become infected when they bite infectious or recovered humans, and once infected they move through the exposed and infectious classes. Both species follow a logistic population model, with humans having immigration and disease-induced death. We define a reproductive number, R_0, for the number of secondary cases that one infected individual will cause through the duration of the infectious period. We find that the disease-free equilibrium is locally asymptotically stable when $R_0 < 1$ and unstable when $R_0 > 1$. We prove the existence of at least one endemic equilibrium point for all $R_0 > 1$. In the absence of disease-induced death, we prove that the transcritical bifurcation at $R_0 = 1$ is supercritical (forward). Numerical simulations show that for larger values of the disease-induced death rate, a subcritical (backward) bifurcation is possible at $R_0 = 1$.

1. Introduction.

Malaria is an infectious disease caused by the *Plasmodium* parasite and transmitted between humans through the bite of the female *Anopheles* mosquito. An estimated 40% of the world's population live in malaria endemic areas. The disease kills about 1 to 3 million people a year, 75% of whom are African children. The incidence of malaria has been growing recently due to increasing parasite drug-resistance and mosquito insecticide-resistance. Therefore, it is important to understand the important parameters in the transmission of the disease and develop effective solution strategies for its prevention and control.

Mathematical modeling of malaria began in 1911 with Ross's model [25], and major extensions are described in Macdonald's 1957 book [20]. The first models were two-dimensional with one variable representing humans and the other representing mosquitoes. An important addition to the malaria models was the inclusion of acquired immunity proposed by Dietz, Molineaux, and Thomas [11]. Further work on acquired immunity in malaria has been conducted by Aron [2] and Bailey [5]. Anderson and May [1], Aron and May [3], Koella [15] and Nedelman [21] have written some good reviews on the mathematical modeling of malaria. Some recent papers have also included environmental effects [19], [27], and [28]; the spread of resistance to drugs

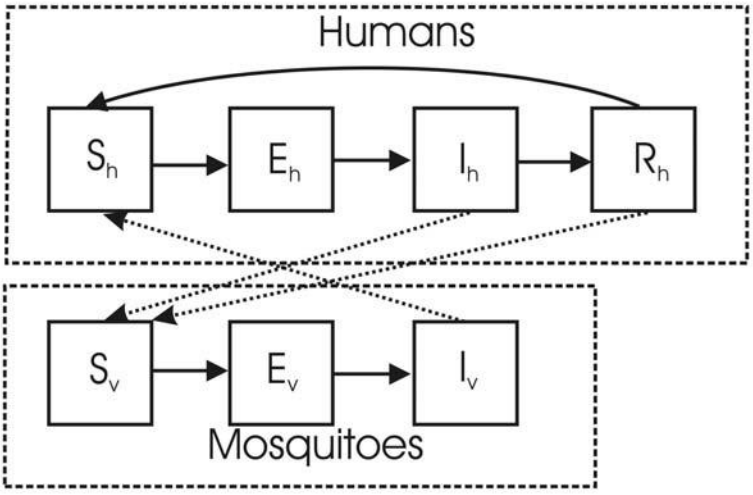

FIG. 1.1. *Susceptible humans, S_h, can be infected when they are bitten by infectious mosquitoes. They then progress through the exposed, E_h, infectious, I_h, and recovered, R_h, classes, before re-entering the susceptible class. Susceptible mosquitoes, S_v, can become infected when they bite infectious or recovered humans. The infected mosquitoes then move through the exposed, E_v, and infectious, I_v, classes. Both species follow a logistic population model, with humans having additional immigration and disease-induced death. Birth, death, and migration into and out of the population are not shown in the figure.*

[4] and [16]; and the evolution of immunity [17].

Recently, Ngwa and Shu [23] and Ngwa [22] proposed an ordinary differential equation (ODE) compartmental model for the spread of malaria with a susceptible-exposed-infectious-recovered-susceptible (SEIRS) pattern for humans and a susceptible-exposed-infectious (SEI) pattern for mosquitoes. In a Ph.D. dissertation, Chitnis [7] analyzed a similar model for malaria transmission. In this paper we extend the Chitnis model.

The new model (Figure 1.1) divides the human population into four classes: susceptible, S_h; exposed, E_h; infectious, I_h; and recovered (immune), R_h. People enter the susceptible class either through birth (at a constant per capita rate) or through immigration (at a constant rate). When an infectious mosquito bites a susceptible human, there is some finite probability that the parasite (in the form of sporozoites) will be passed on to the human and that the person will move to the exposed class. The parasite then travels to the liver where it develops into its next life stage. After a certain period of time, the parasite (in the form of merozoites) enters the blood stream, usually signaling the clinical onset of malaria. In our model, people from the exposed class enter the infectious class at a rate that is the reciprocal of the duration of the latent period. After some time, the infectious humans recover and move to the recovered class. The recovered humans have some immunity to the disease and do not get clinically ill, but they still harbor low levels of parasite in their blood streams and can pass the infection to mosquitoes. After some period of time, they lose their immunity and return to the susceptible class. Humans leave the population through a density-dependent per capita emigration and natural death rate, and through a per capita disease-induced death rate.

We divide the mosquito population into three classes: susceptible, S_v; exposed,

E_v; and infectious, I_v. Female mosquitoes (we do not include male mosquitoes in our model because only female mosquitoes bite animals for blood meals) enter the susceptible class through birth. The parasite (in the form of gametocytes) enters the mosquito with some probability when the mosquito bites an infectious human or a recovered human (the probability of transmission of infection from a recovered human is much lower than that from an infectious human), and the mosquito moves from the susceptible to the exposed class. After some period of time, dependent on the ambient temperature and humidity, the parasite develops into sporozoites and enters the mosquito's salivary glands, and the mosquito moves from the exposed class to the infectious class. The mosquito remains infectious for life. Mosquitoes leave the population through a per capita density-dependent natural death rate.

The extension of the Ngwa and Shu model [23] includes human immigration, excludes direct human recovery from the infectious to the susceptible class, and generalizes the mosquito biting rate so that it applies to wider ranges of populations. In [23], the total number of mosquito bites on humans depends only on the number of mosquitoes, while in our model, the total number of bites depends on both the human and mosquito population sizes. Human migration is present throughout the world and plays a large role in the epidemiology of diseases, including malaria. In many parts of the developing world, there is rapid urbanization as many people leave rural areas and migrate to cities in search of employment. We include this movement as a constant immigration rate into the susceptible class. We do not include immigration of infectious humans, as we assume that most people who are sick will not travel. We also exclude the movement of exposed humans because, given the short time of the exposed stage, the number of exposed people is small. We make the simplifying assumption that there is no immigration of recovered humans. We also exclude the direct infectious-to-susceptible recovery that the model of Ngwa and Shu [23] contains. This is a realistic simplifying assumption because most people show some period of immunity before becoming susceptible again. As our model includes an exponential distribution of movement from the recovered to the susceptible class, it will include the quick return to susceptibility of some individuals. The model in Chitnis [7] is the same as the model in this paper except for the mosquito biting rate, which is the same as in [23].

We first describe the mathematical model including the definition of a domain where the model is mathematically and epidemiologically well-posed. Next, we prove the existence and stability of a disease-free equilibrium point, define the reproductive number, and describe the existence and stability of the endemic equilibrium point(s).

2. Malaria model. The state variables (Table 2.1) and parameters (Table 2.2) for the malaria model (Figure 1.1) satisfy the equations in (2.1). All parameters

TABLE 2.1
The state variables for the malaria model (2.1).

S_h:	Number of susceptible humans
E_h:	Number of exposed humans
I_h:	Number of infectious humans
R_h:	Number of recovered (immune and asymptomatic, but slightly infectious) humans
S_v:	Number of susceptible mosquitoes
E_v:	Number of exposed mosquitoes
I_v:	Number of infectious mosquitoes
N_h:	Total human population
N_v:	Total mosquito population

TABLE 2.2
The parameters for the malaria model (2.1) *and their dimensions.*

Λ_h:	Immigration rate of humans. Humans $\times$ Time^{-1}.
ψ_h:	Per capita birth rate of humans. Time^{-1}.
ψ_v:	Per capita birth rate of mosquitoes. Time^{-1}.
σ_v:	Number of times one mosquito would want to bite humans per unit time, if humans were freely available. This is a function of the mosquito's gonotrophic cycle (the amount of time a mosquito requires to produce eggs) and its anthropophilic rate (its preference for human blood). Time^{-1}.
σ_h:	The maximum number of mosquito bites a human can have per unit time. This is a function of the human's exposed surface area. Time^{-1}.
β_{hv}:	Probability of transmission of infection from an infectious mosquito to a susceptible human, given that a contact between the two occurs. Dimensionless.
β_{vh}:	Probability of transmission of infection from an infectious human to a susceptible mosquito, given that a contact between the two occurs. Dimensionless.
$\tilde{\beta}_{vh}$:	Probability of transmission of infection from a recovered (asymptomatic carrier) human to a susceptible mosquito, given that a contact between the two occurs. Dimensionless.
ν_h:	Per capita rate of progression of humans from the exposed state to the infectious state. $1/\nu_h$ is the average duration of the latent period. Time^{-1}.
ν_v:	Per capita rate of progression of mosquitoes from the exposed state to the infectious state. $1/\nu_v$ is the average duration of the latent period. Time^{-1}.
γ_h:	Per capita recovery rate for humans from the infectious state to the recovered state. $1/\gamma_h$ is the average duration of the infectious period. Time^{-1}.
δ_h:	Per capita disease-induced death rate for humans. Time^{-1}.
ρ_h:	Per capita rate of loss of immunity for humans. $1/\rho_h$ is the average duration of the immune period. Time^{-1}.
μ_{1h}:	Density-independent part of the death (and emigration) rate for humans. Time^{-1}.
μ_{2h}:	Density-dependent part of the death (and emigration) rate for humans. Humans^{-1} $\times$ Time^{-1}.
μ_{1v}:	Density-independent part of the death rate for mosquitoes. Time^{-1}.
μ_{2v}:	Density-dependent part of the death rate for mosquitoes. Mosquitoes^{-1} $\times$ Time^{-1}.

are strictly positive with the exception of the disease-induced death rate, δ_h, which is nonnegative. The mosquito birth rate is greater than the density-independent mosquito death rate, $\psi_v > \mu_{1v}$, ensuring that we have a stable positive mosquito population.

$$\frac{dS_h}{dt} = \Lambda_h + \psi_h N_h + \rho_h R_h - \lambda_h(t) S_h - f_h(N_h) S_h, \tag{2.1a}$$

$$\frac{dE_h}{dt} = \lambda_h(t) S_h - \nu_h E_h - f_h(N_h) E_h, \tag{2.1b}$$

$$\frac{dI_h}{dt} = \nu_h E_h - \gamma_h I_h - f_h(N_h) I_h - \delta_h I_h, \tag{2.1c}$$

$$\frac{dR_h}{dt} = \gamma_h I_h - \rho_h R_h - f_h(N_h) R_h, \tag{2.1d}$$

$$\frac{dS_v}{dt} = \psi_v N_v - \lambda_v(t) S_v - f_v(N_v) S_v, \tag{2.1e}$$

$$\frac{dE_v}{dt} = \lambda_v(t) S_v - \nu_v E_v - f_v(N_v) E_v, \tag{2.1f}$$

$$\frac{dI_v}{dt} = \nu_v E_v - f_v(N_v) I_v, \tag{2.1g}$$

where $f_h(N_h) = \mu_{1h} + \mu_{2h} N_h$ is the per capita density-dependent death and emigration rate for humans and $f_v(N_v) = \mu_{1v} + \mu_{2v} N_v$ is the per capita density-dependent death rate for mosquitoes. The total population sizes are $N_h = S_h + E_h + I_h + R_h$ and

$N_v = S_v + E_v + I_v$, with

$$\frac{dN_h}{dt} = \Lambda_h + \psi_h N_h - f_h(N_h)N_h - \delta_h I_h, \tag{2.2a}$$

$$\frac{dN_v}{dt} = \psi_v N_v - f_v(N_v)N_v, \tag{2.2b}$$

and the infection rates are

$$\lambda_h = b_h(N_h, N_v) \cdot \beta_{hv} \cdot \frac{I_v}{N_v} \quad \text{and} \quad \lambda_v = b_v(N_h, N_v) \cdot \left(\beta_{vh} \cdot \frac{I_h}{N_h} + \tilde{\beta}_{vh} \cdot \frac{R_h}{N_h}\right). \tag{2.3}$$

We define the force of infection from mosquitoes to humans, λ_h, as the product of the number of mosquito bites that one human has per unit time, b_h, the probability of disease transmission from the mosquito to the human, β_{hv}, and the probability that the mosquito is infectious, I_v/N_v. We define the force of infection from humans to mosquitoes, λ_v, as the sum of the force of infection from infectious humans and from recovered humans. These are defined as the number of human bites one mosquito has per unit time, b_v; the probability of disease transmission from the human to the mosquito, β_{vh} and $\tilde{\beta}_{vh}$; and the probability that the human is infectious or recovered, I_h/N_h and R_h/N_h. Here, we model the total number of mosquito bites on humans as

$$b = b(N_h, N_v) = \frac{\sigma_v N_v \sigma_h N_h}{\sigma_v N_v + \sigma_h N_h} = \frac{\sigma_v \sigma_h}{\sigma_v (N_v/N_h) + \sigma_h} N_v, \tag{2.4}$$

so that the total number of mosquito-human contacts depends on the populations of both species. We define $b_h = b_h(N_h, N_v) = b(N_h, N_v)/N_h$ as the number of bites per human per unit time, and $b_v = b_v(N_h, N_v) = b(N_h, N_v)/N_v$ as the number of bites per mosquito per unit time. In the limit that the mosquito population goes to zero or the human population goes to infinity, the model reduces to that in Chitnis [7] and has the same mosquito-human interaction as in Ngwa and Shu [23] and the Ross–Macdonald model (as described by Anderson and May [1]), where the total number of bites is limited by the mosquito population. The number of bites per mosquito is then σ_v (denoted by σ_{vh} in [7]), and the number of bites per human is $\sigma_v N_v/N_h$. We show a summary of the model of mosquito-human interactions and its limits in Table 2.3.

TABLE 2.3
Number of mosquito bites on humans in the malaria transmission model (2.1) *and its limiting cases with population changes.*

	Number of bites per human, b_h	Number of bites per mosquito, b_v	Total number of bites, b
General model	$\frac{\sigma_v N_v \sigma_h}{\sigma_v N_v + \sigma_h N_h}$	$\frac{\sigma_v \sigma_h N_h}{\sigma_v N_v + \sigma_h N_h}$	$\frac{\sigma_v N_v \sigma_h N_h}{\sigma_v N_v + \sigma_h N_h}$
As $N_h \to \infty$ or $N_v \to 0$	$\frac{\sigma_v N_v}{N_h}$	σ_v	$\sigma_v N_v$
As $N_h \to 0$ or $N_v \to \infty$	σ_h	$\frac{\sigma_h N_h}{N_v}$	$\sigma_h N_h$

To simplify the analysis of the malaria model (2.1), we work with fractional quantities instead of actual populations by scaling the population of each class by the

total species population. We let

$$e_h = \frac{E_h}{N_h}, \quad i_h = \frac{I_h}{N_h}, \quad r_h = \frac{R_h}{N_h}, \quad e_v = \frac{E_v}{N_v}, \quad \text{and} \quad i_v = \frac{I_v}{N_v}, \tag{2.5}$$

with

$$S_h = s_h N_h = (1 - e_h - i_h - r_h)N_h \quad \text{and} \quad S_v = s_v N_v = (1 - e_v - i_v)N_v. \tag{2.6}$$

Differentiating the scaling equations (2.5) and solving for the derivatives of the scaled variables, we obtain

$$\frac{de_h}{dt} = \frac{1}{N_h}\left[\frac{dE_h}{dt} - e_h\frac{dN_h}{dt}\right] \quad \text{and} \quad \frac{de_v}{dt} = \frac{1}{N_v}\left[\frac{dE_v}{dt} - e_v\frac{dN_v}{dt}\right] \tag{2.7}$$

and so on for the other variables.

This creates a new seven-dimensional system of equations with two dimensions for the two total population variables, N_h and N_v, and five dimensions for the fractional population variables with disease, e_h, i_h, r_h, e_v, and i_v:

$$\frac{de_h}{dt} = \left(\frac{\sigma_v\sigma_h N_v\beta_{hv}i_v}{\sigma_v N_v + \sigma_h N_h}\right)(1 - e_h - i_h - r_h) - \left(\nu_h + \psi_h + \frac{\Lambda_h}{N_h}\right)e_h + \delta_h i_h e_h, \tag{2.8a}$$

$$\frac{di_h}{dt} = \nu_h e_h - \left(\gamma_h + \delta_h + \psi_h + \frac{\Lambda_h}{N_h}\right)i_h + \delta_h i_h^2, \tag{2.8b}$$

$$\frac{dr_h}{dt} = \gamma_h i_h - \left(\rho_h + \psi_h + \frac{\Lambda_h}{N_h}\right)r_h + \delta_h i_h r_h, \tag{2.8c}$$

$$\frac{dN_h}{dt} = \Lambda_h + \psi_h N_h - (\mu_{1h} + \mu_{2h}N_h)N_h - \delta_h i_h N_h, \tag{2.8d}$$

$$\frac{de_v}{dt} = \left(\frac{\sigma_v\sigma_h N_h}{\sigma_v N_v + \sigma_h N_h}\right)\left(\beta_{vh}i_h + \tilde{\beta}_{vh}r_h\right)(1 - e_v - i_v) - (\nu_v + \psi_v)e_v, \tag{2.8e}$$

$$\frac{di_v}{dt} = \nu_v e_v - \psi_v i_v, \tag{2.8f}$$

$$\frac{dN_v}{dt} = \psi_v N_v - (\mu_{1v} + \mu_{2v}N_v)N_v. \tag{2.8g}$$

The model (2.8) is epidemiologically and mathematically well-posed in the domain

$$\mathcal{D} = \left\{ \begin{pmatrix} e_h \\ i_h \\ r_h \\ N_h \\ e_v \\ i_v \\ N_v \end{pmatrix} \in \mathbb{R}^7 \;\middle|\; \begin{array}{c} e_h \geq 0, \\ i_h \geq 0, \\ r_h \geq 0, \\ e_h + i_h + r_h \leq 1, \\ N_h > 0, \\ e_v \geq 0, \\ i_v \geq 0, \\ e_v + i_v \leq 1, \\ N_v > 0 \end{array} \right\}. \tag{2.9}$$

This domain, $\mathcal{D}$, is valid epidemiologically as the fractional populations e_h, i_h, r_h, e_v, and i_v are all nonnegative and have sums over their species type that are less than or equal to 1. The human and mosquito populations, N_h and N_v, are positive. We use the notation f' to denote df/dt. We denote points in $\mathcal{D}$ by $x = (e_h, i_h, r_h, N_h, e_v, i_v, N_v)$.

THEOREM 2.1. *Assuming that the initial conditions lie in $\mathcal{D}$, the system of equations for the malaria model* (2.8) *has a unique solution that exists and remains in $\mathcal{D}$ for all time $t \geq 0$.*

Proof. The right-hand side of (2.8) is continuous with continuous partial derivatives in $\mathcal{D}$, so (2.8) has a unique solution. We now show that $\mathcal{D}$ is forward-invariant. We can see from (2.8) that if $e_h = 0$, then $e_h' \geq 0$; if $i_h = 0$, then $i_h' \geq 0$; if $r_h = 0$, then $r_h' \geq 0$; if $e_v = 0$, then $e_v' \geq 0$; and if $i_v = 0$, then $i_v' \geq 0$. It is also true that if $e_h + i_h + r_h = 1$, then $e_h' + i_h' + r_h' < 0$; and if $e_v + i_v = 1$, then $e_v' + i_v' < 0$. Finally, we note that if $N_h = 0$, then $N_h' > 0$ and if $N_v = 0$, then $N_v' = 0$. If $N_h > 0$ at time $t = 0$, then $N_h > 0$ for all $t > 0$. Similarly, if $N_v > 0$ at time $t = 0$, then $N_v > 0$ for all $t > 0$. Therefore, none of the orbits can leave $\mathcal{D}$, and a unique solution exists for all time. ∎

3. Disease-free equilibrium point and reproductive number.

3.1. Existence of the disease-free equilibrium point. Disease-free equilibrium points are steady-state solutions where there is no disease. We define the "*diseased*" classes as the human or mosquito populations that are either exposed, infectious, or recovered, that is, e_h, i_h, r_h, e_v, and i_v. We denote the positive orthant in $\mathbb{R}^7$ by $\mathbb{R}^7_+$, and the boundary of $\mathbb{R}^7_+$ by $\partial\mathbb{R}^7_+$. The positive equilibrium human and mosquito population values, in the absence of disease, for (2.8) are

$$N_h^* = \frac{(\psi_h - \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}}{2\mu_{2h}} \quad \text{and} \quad N_v^* = \frac{\psi_v - \mu_{1v}}{\mu_{2v}}. \tag{3.1}$$

THEOREM 3.1. *The malaria model* (2.8) *has exactly one equilibrium point, $x_{dfe} = (0, 0, 0, N_h^*, 0, 0, N_v^*)$, with no disease in the population (on $\mathcal{D} \cap \partial\mathbb{R}^7_+$).*

Proof. We need to show that x_{dfe} is an equilibrium point of (2.8) and that there are no other equilibrium points on $\mathcal{D} \cap \partial\mathbb{R}^7_+$. Substituting x_{dfe} into (2.8) shows all derivatives equal to zero, so x_{dfe} is an equilibrium point. We know from Lemma A.1 that on $\mathcal{D} \cap \partial\mathbb{R}^7_+$, $e_h = i_h = r_h = e_v = i_v = 0$. For $i_h = 0$, the only equilibrium point for N_h from (2.8d) is N_h^*, and the only equilibrium point for N_v in $\mathcal{D}$ from (2.8g) is N_v^*. Thus, the only equilibrium point on $\mathcal{D} \cap \partial\mathbb{R}^7_+$ is x_{dfe}. ∎

3.2. Reproductive number. We use the next generation operator approach as described by Diekmann, Heesterbeek, and Metz in [10] to define the reproductive number, R_0, as the number of secondary infections that one infectious individual would create over the duration of the infectious period, provided that everyone else is susceptible. We define the next generation operator, K, which provides the number of secondary infections in humans and mosquitoes caused by one generation of infectious humans and mosquitoes, as

$$K = \begin{pmatrix} 0 & K_{hv} \\ K_{vh} & 0 \end{pmatrix}, \tag{3.2}$$

where we use the following definitions:

K_{hv}: The number of humans that one mosquito infects through its infectious lifetime, assuming all humans are susceptible.

K_{vh}: The number of mosquitoes that one human infects through the duration of the infectious period, assuming all mosquitoes are susceptible.

Using the ideas of Hyman and Li [14], we define K_{hv} and K_{vh} as products of the probability of surviving till the infectious state, the number of contacts per unit

time, the probability of transmission per contact, and the duration of the infectious period:

$$K_{hv} = \left(\frac{\nu_v}{\nu_v + \mu_{1v} + \mu_{2v}N_v^*}\right) \cdot b_v^* \cdot \beta_{hv} \cdot \left(\frac{1}{\mu_{1v} + \mu_{2v}N_v^*}\right), \tag{3.3a}$$

$$\begin{aligned} K_{vh} = &\left(\frac{\nu_h}{\nu_h + \mu_{1h} + \mu_{2h}N_h^*}\right) \cdot b_h^* \cdot \beta_{vh} \cdot \left(\frac{1}{\gamma_h + \delta_h + \mu_{1h} + \mu_{2h}N_h^*}\right) \\ &+ \left(\frac{\nu_h}{\nu_h + \mu_{1h} + \mu_{2h}N_h^*} \cdot \frac{\gamma_h}{\gamma_h + \delta_h + \mu_{1h} + \mu_{2h}N_h^*}\right) \\ &\cdot b_h^* \cdot \tilde{\beta}_{vh} \cdot \left(\frac{1}{\rho_h + \mu_{1h} + \mu_{2h}N_h^*}\right). \end{aligned} \tag{3.3b}$$

In (3.3a), $\nu_v/(\nu_v + \mu_{1v} + \mu_{2v}N_v^*)$ is the probability that a mosquito will survive the exposed state to become infectious;[1] $b_v^* = b_v(N_h^*, N_v^*)$ is the number of contacts that one mosquito has with humans per unit time; and $1/(\mu_{1v} + \mu_{2v}N_v^*)$ is the average duration of the infectious lifetime of the mosquito. In (3.3b), the total number of mosquitoes infected by one human is the sum of the new infections from the infectious and from the recovered states of the human; $\nu_h/(\nu_h + \mu_{1h} + \mu_{2h}N_h^*)$ is the probability that a human will survive the exposed state to become infectious; $\gamma_h/(\gamma_h + \delta_h + \mu_{1h} + \mu_{2h}N_h^*)$ is the probability that the human will then survive the infectious state to move to the recovered state; $b_h^* = b_h(N_h^*, N_v^*)$ is the number of contacts that one human has with mosquitoes per unit time; $1/(\gamma_h + \delta_h + \mu_{1h} + \mu_{2h}N_h^*)$ is the average duration of the infectious period of a human; and $1/(\rho_h + \mu_{1h} + \mu_{2h}N_h^*)$ is the average duration of the recovered period of a human.

We define R_0 as the spectral radius of the next generation operator, K, i.e., $R_0^2 = K_{vh}K_{hv}$. Then, R_0^2 is the number of humans that one infectious human will infect, through a generation of infections in mosquitoes, assuming that previously all other humans and mosquitoes were susceptible.

DEFINITION 3.2. *We define the reproductive number, R_0, as*

$$R_0 = \sqrt{K_{vh}K_{hv}}, \tag{3.4}$$

where K_{vh} and K_{hv} are defined in (3.3).

The original definition of the reproductive number of the Ross–Macdonald model [1] and [3], and the Ngwa and Shu model [23], is equivalent to the square of this R_0. They ([1], [3], and [23]) use the traditional definition of the reproductive number, which approximates the number of secondary infections in humans caused by one infected human, while the R_0 in Definition 3.2 is consistent with the definition given by the next generation operator approach [10], which approximates the number of secondary infections due to one infected individual (be it human or mosquito). Our definition of R_0 includes the generation of infections in mosquitoes, so is the square root of the original definition. The threshold condition for both definitions is the same.

3.3. Stability of the disease-free equilibrium point.

THEOREM 3.3. *The disease-free equilibrium point, x_{dfe}, is locally asymptotically stable if $R_0 < 1$ and unstable if $R_0 > 1$.*

The proof of this theorem is in the appendix section A.1.

[1] In defining periods of time and probabilities for R_0, we use the original system of equations (2.1) and not the scaled equations (2.8). As the two models are equivalent, the reproductive number is the same with either definition: $\mu_{1h} + \mu_{2h}N_h^* = \psi_h + \Lambda_h/N_h^*$ and $\mu_{1v} + \mu_{2v}N_v^* = \psi_v$.

4. Endemic equilibrium points. Endemic equilibrium points are steady-state solutions where the disease persists in the population (all state variables are positive). We use general bifurcation theory to prove the existence of at least one endemic equilibrium point for all $R_0 > 1$. We prove that the transcritical bifurcation at $R_0 = 1$ is supercritical (forward) when $\delta_h = 0$ (there is no disease-induced death). However, numerical results show that the bifurcation can be subcritical (backward) for some positive values of δ_h, giving rise to endemic equilibria for $R_0 < 1$.

We first rewrite the equilibrium equations for $u = (e_h, e_v)$ in (2.8) as a nonlinear eigenvalue problem in a Banach space:

$$u = G(\zeta, u) = \zeta L u + h(\zeta, u), \tag{4.1}$$

where $u \in Y \subset \mathbb{R}^2$, with Euclidean norm $\|\cdot\|$; $\zeta \in Z \subset \mathbb{R}$ is the bifurcation parameter; L is a compact linear map on Y; and $h(\zeta, u)$ is $\mathcal{O}(\|u\|^2)$ uniformly on bounded ζ intervals. We require that both Y and Z be open and bounded sets, and that Y contain the point 0. We define Z as the open and bounded set $Z = \{\zeta \in \mathbb{R} | -M_Z < \zeta < M_Z\}$. This set is defined to include the characteristic values (reciprocals of eigenvalues) of L, so there is minimum value that M_Z can have, but M_Z may be arbitrarily large. We use

$$\zeta = \frac{\sigma_v \sigma_h}{\sigma_v N_v^* + \sigma_h N_h^*} \tag{4.2}$$

for the bifurcation parameter. We also define $\Omega = Z \times Y$ so that the pair $(\zeta, u) \in \Omega$. We denote the boundary of Ω by $\partial\Omega$.

A corollary by Rabinowitz [24, Corollary 1.12] states that if $\zeta_0 \in Z$ is a characteristic value of L of odd multiplicity, then there exists a continuum of nontrivial solution-pairs (ζ, u) of (4.1) that intersects the trivial solution (that is, $(\zeta, 0)$ for any ζ) at $(\zeta_0, 0)$ and either meets $\partial\Omega$ or meets $(\hat{\zeta}_0, 0)$, where $\hat{\zeta}_0$ is also a characteristic value of L of odd multiplicity. We use this corollary to show that there exists a continuum of solution-pairs $(\zeta, u) \in \Omega$ for the eigenvalue equation (4.1). To each of these solution-pairs there corresponds an equilibrium-pair (ζ, x^*). We define the equilibrium-pair, $(\zeta, x^*) \in Z \times \mathbb{R}^7$, as the collection of a parameter value, ζ, and the corresponding equilibrium point, x^*, for that parameter value, of the malaria model (2.8).

THEOREM 4.1. *The model* (2.8) *has a continuum of equilibrium-pairs,* $(\zeta, x^*) \in Z \times \mathbb{R}^7$*, that connects the point* (ξ_1, x_{dfe}) *to the hyperplane* $\zeta = M_Z$ *in* $\mathbb{R} \times \mathbb{R}^7$ *on the boundary of* $Z \times \mathbb{R}^7$ *for any* $M_Z > \xi_1$*, where* x^* *is in the positive orthant of* $\mathbb{R}^7$*. Here* $\xi_1 = 1/\sqrt{AB}$*, where* A *and* B *are defined in* (A.19).

We show the proof of this theorem and related lemmas in appendix section A.2.

THEOREM 4.2. *The transcritical bifurcation point at* $\zeta = \xi_1$ *corresponds to* $R_0 = 1$*. For the set of* ζ *for which there exists an equilibrium-pair* (ζ, x^*)*, the corresponding set of values for* R_0 *includes, but is not necessarily identical to, the interval* $1 < R_0 < \infty$*. Thus, there exists at least one endemic equilibrium point of the malaria model* (2.8) *for all* $R_0 > 1$*.*

Proof. Using the definition of ζ, (4.2), some algebraic manipulations of R_0 (see (3.4)) produce

$$R_0 = \zeta \sqrt{AB}. \tag{4.3}$$

Thus, R_0 is linearly related to ζ, and when $\zeta = \xi_1$, $R_0 = 1$. For any $R_0 > 1$, (4.3) defines a corresponding ζ. We pick an M_Z larger than this ζ. Then, Theorem 4.1

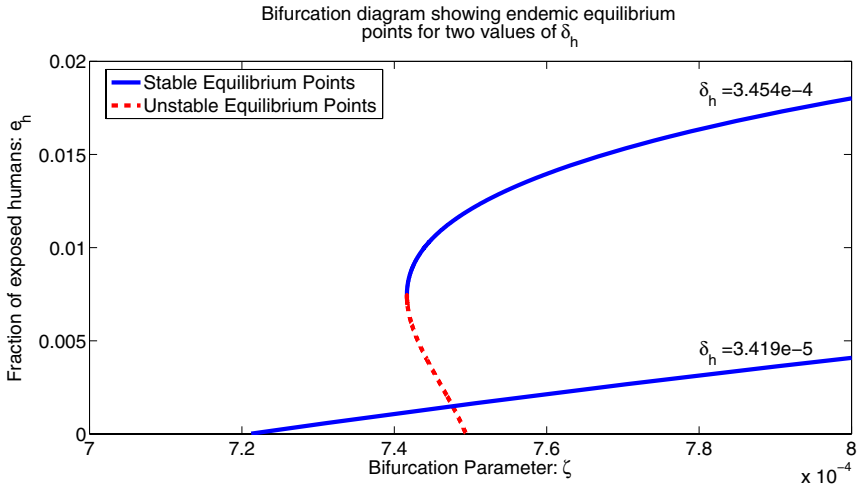

FIG. 4.1. *Bifurcation diagrams for* (2.8) *showing the endemic equilibrium values for the fraction of exposed humans,* e_h*, plotted for the parameters in Table* 4.1 *(except for* σ_v *and* σ_h*, which vary with* ζ*) and two values of the disease-induced death rate* ($\delta_h = 3.454 \times 10^{-4}$ *and* $\delta_h = 3.419 \times 10^{-5}$)*. For the parameter values in Table* 4.1*, there are three equilibrium points in* $\mathcal{D}$*: a locally asymptotically stable disease-free equilibrium point,* x_{dfe}*, on the boundary of the positive orthant of* $\mathbb{R}^7$*, and two endemic equilibrium points inside the positive orthant. Linear stability analysis shows that the "larger" endemic equilibrium point is locally asymptotically stable, while the "smaller" point is unstable. Further linear analysis with an increased value of* $\sigma_v = 0.7000$*,* $\sigma_h = 21.00$*, and all other parameters as in Table* 4.1 *(with* $R_0 = 1.155$*) shows that* x_{dfe} *is unstable, and there is one locally asymptotically stable endemic equilibrium point.*

guarantees the existence of an endemic equilibrium point for ζ, and thereby for the corresponding value of R_0. It is possible, though not necessary, for the continuum of equilibrium-pairs to include values of $\zeta < \xi_1$ ($R_0 < 1$). □

Typically in epidemiological models, bifurcations at $R_0 = 1$ tend to be supercritical (i.e., positive endemic equilibria exist for $R_0 > 1$ near the bifurcation point). In this model (2.8), in the absence of disease-induced death ($\delta_h = 0$), we prove, using the Lyapunov–Schmidt expansion as described by Cushing [9], that the bifurcation is supercritical (forward).

THEOREM 4.3. *In the absence of disease-induced death* ($\delta_h = 0$)*, the transcritical bifurcation at* $R_0 = 1$ *is supercritical (forward).*

Details of this proof are in appendix section A.2.

In the general case, a subcritical (backward) bifurcation can occur for some parameter values, where near the bifurcation point, positive endemic equilibria exist for $R_0 < 1$. Other examples of epidemiological models with subcritical bifurcations at $R_0 = 1$ include those described by Castillo-Chavez and Song [6], Gómez-Acevedo and Yi [13], and van den Driessche and Watmough [26]. The model of Ngwa and Shu [23] exhibits only a supercritical bifurcation at $R_0 = 1$. Although we cannot prove the existence of a subcritical bifurcation, we show through numerical examples that it is possible for some positive values of δ_h. This is important because it implies that there can be a stable endemic equilibrium even if $R_0 < 1$.

We use the bifurcation software program AUTO [12] to create two bifurcation diagrams around $R_0 = 1$ (Figure 4.1) with parameter values in Table 4.1, except for σ_h, σ_v, and δ_h. σ_h and σ_v change as ζ is varied, as shown in the figure; however, their ratio, $\theta = \sigma_h/\sigma_v = 30$, remains constant. One curve has δ_h as in Table 4.1,

TABLE 4.1

The parameter values for which there exist positive endemic equilibrium points when $R_0 < 1$: $R_0 = 0.9898$. The unit of time is days.

$\Lambda_h = 3.285 \times 10^{-2}$	
$\psi_h = 7.666 \times 10^{-5}$	$\psi_v = 0.4000$
$\beta_{vh} = 0.8333$	$\beta_{hv} = 2.000 \times 10^{-2}$
$\tilde{\beta}_{vh} = 8.333 \times 10^{-2}$	
$\sigma_v = 0.6000$	$\sigma_h = 18.00$
$\nu_h = 8.333 \times 10^{-2}$	$\nu_v = 0.1000$
$\gamma_h = 3.704 \times 10^{-3}$	
$\delta_h = 3.454 \times 10^{-4}$	
$\rho_h = 1.460 \times 10^{-2}$	
$\mu_{1h} = 4.212 \times 10^{-5}$	$\mu_{1v} = 0.1429$
$\mu_{2h} = 1.000 \times 10^{-7}$	$\mu_{2v} = 2.279 \times 10^{-4}$

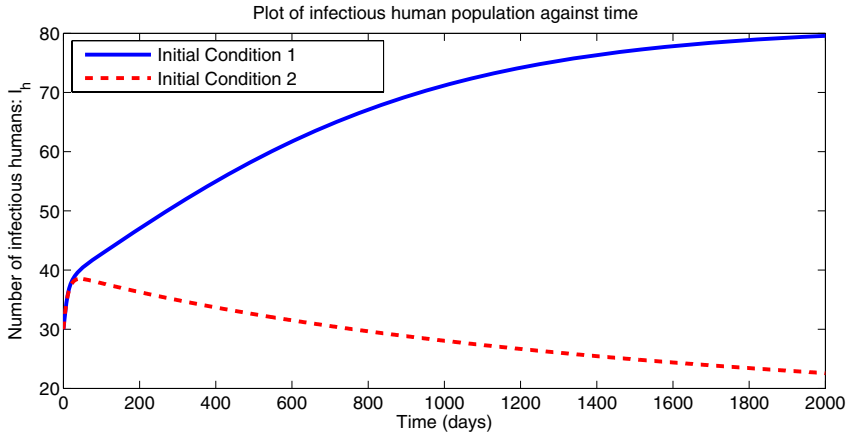

FIG. 4.2. *Solutions of the malaria model* (2.1) *with parameter values defined in Table* 4.1 *showing only the number of infectious humans, I_h, for two different initial conditions. The parameters correspond to $R_0 = 0.9898$. Initial condition* 1 *is $S_h = 400$, $E_h = 10$, $I_h = 30$, $R_h = 0$, $S_v = 1000$, $E_v = 100$, and $I_v = 50$. Initial condition* 2 *is $S_h = 700$, $E_h = 10$, $I_h = 30$, $R_h = 0$, $S_v = 1000$, $E_v = 100$, and $I_v = 50$. The solution for initial condition* 1 *approaches the locally asymptotically stable endemic equilibrium point, while the solution for initial condition* 2 *approaches the locally asymptotically stable disease-free equilibrium point.*

while the other has $\delta_h = 3.419 \times 10^{-5}$. The curve with $\delta_h = 3.454 \times 10^{-4}$ has both unstable and stable endemic equilibrium points. There is a subcritical bifurcation at $\zeta = 7.494 \times 10^{-4}$ ($R_0 = 1$), and a saddle-node bifurcation at $\zeta = 7.417 \times 10^{-4}$ ($R_0 = 0.9897$). Thus a locally asymptotically stable endemic equilibrium is possible for values of R_0 below 1. Further bifurcation analysis (not presented here) indicates that as ζ is increased to $\zeta = 50$ ($R_0 = 66719$), the size of the projection of the endemic equilibrium on the fractional infected groups increases monotonically, and the equilibrium point remains stable. For comparison we show the bifurcation diagram with $\delta_h = 3.419 \times 10^{-5}$. Here, we see only a stable branch of endemic equilibrium points. There is a supercritical bifurcation at $\zeta = 7.209 \times 10^{-4}$ ($R_0 = 1$). There are no endemic equilibrium points for R_0 less than 1. As ζ is increased to $\zeta = 50$ ($R_0 = 69358$), the size of the projection of the endemic equilibrium on the fractional infected groups increases monotonically, and the equilibrium point remains stable.

Figure 4.2 shows the infectious human population, for two different initial condi-

tions, of the solutions to the unscaled equations (2.1) for parameter values in Table 4.1 with $R_0 < 1$. One solution approaches the locally asymptotically stable endemic equilibrium point, while the other approaches the locally asymptotically stable disease-free equilibrium point.

The parameter values in Table 4.1 are within the bounds of a realistically feasible range, except for the mosquito birth and death rates, ψ_v and μ_{1v}, which have been increased to lower R_0 below 1. More realistic values are $\psi_v = 0.13$ and $\mu_{1v} = 0.033$, which result in (with all other parameters as in Table 4.1) $R_0 = 1.6$. More lists of realistic parameter values, and their references, can be found in [7] and [8]. $\delta_h = 3.454 \times 10^{-4}$ corresponds to a death rate of 12.62% of infectious humans per year.

5. Summary and conclusions. We analyzed an ordinary differential equation model for the transmission of malaria, with four variables for humans and three variables for mosquitoes. We showed that there exists a domain where the model is epidemiologically and mathematically well-posed. We proved the existence of an equilibrium point with no disease, x_{dfe}. We defined a reproductive number, R_0, that is epidemiologically accurate in that it provides the expected number of new infections (in mosquitoes or humans) from one infectious individual (human or mosquito) over the duration of the infectious period, given that all other members of the population are susceptible. We showed that if $R_0 < 1$, then the disease-free equilibrium point, x_{dfe}, is locally asymptotically stable, and if $R_0 > 1$, then x_{dfe} is unstable.

We also proved that an endemic equilibrium point exists for all $R_0 > 1$ with a transcritical bifurcation at $R_0 = 1$. The analysis and the numerical simulations showed that for $\delta_h = 0$ (no disease-induced death), and for some small positive values of δ_h, there is a supercritical transcritical bifurcation at $R_0 = 1$ with an exchange of stability between the disease-free equilibrium and the endemic equilibrium. For larger values of δ_h, there is a subcritical transcritical bifurcation at $R_0 = 1$, with an exchange of stability between the endemic equilibrium and the disease-free equilibrium; and there is a saddle-node bifurcation at $R_0 = R_0^*$ for some $R_0^* < 1$. Thus, for some values of $R_0 < 1$, there exist two endemic equilibrium points, the smaller of which is unstable, while the larger is locally asymptotically stable.

Although we cannot prove in general that the endemic equilibrium point is unique and stable for $R_0 > 1$, numerical results for particular parameter sets suggest that there is a unique stable endemic equilibrium point for $R_0 > 1$. Also, from Theorem 2.1 it follows that all orbits of the malaria model (2.8) are bounded. Thus, if there were no stable endemic equilibria in $\mathcal{D}$, then there would exist a nonequilibrium attractor (such as a limit cycle or strange attractor), though for this model we have no evidence for nonequilibrium attractors.

The possible existence of a subcritical bifurcation at $R_0 = 1$ and a saddle-node bifurcation at some $R_0^* < 1$ can have implications for public health, when the epidemiological parameters are close to those in Table 4.1. Simply reducing R_0 to a value below 1 is not always sufficient to eradicate the disease; it is now necessary to reduce R_0 to a value less than R_0^* to ensure that there are no endemic equilibria. The existence of a saddle-node bifurcation also implies that in some areas with endemic malaria, it may be possible to significantly reduce prevalence or eradicate the disease with small increases in control programs (a small reduction in R_0 so that it is less than R_0^*). In some areas where malaria has been eradicated it is possible for a slight disruption, like a change in environmental or control variables or an influx of infectious humans or mosquitoes, to cause the disease to reestablish itself in the population with a significant increase in disease prevalence (increasing R_0 above R_0^*

or moving the system into the basin of attraction of the stable endemic equilibrium).

As we have an explicit expression for R_0, we can analytically evaluate its sensitivity to the different parameter values. We can also numerically evaluate the sensitivity of the endemic equilibrium to the parameter values. This allows us to determine the relative importance of the parameters to disease transmission and prevalence. As each malaria intervention strategy affects different parameters to different degrees, we can thus compare different control strategies for efficiency and effectiveness in reducing malaria mortality and morbidity. This analysis, in the limiting case of the Chitnis model [7] shows that malaria transmission is most sensitive to the mosquito biting rate, and prevalence is most sensitive to the mosquito biting rate and the human recovery rate. The sensitivity analysis for the new model (2.8) is forthcoming [8].

We are extending the model to include the effects of the environment on the spread of malaria. Some parameters, such as the mosquito birth rate and the incubation period in mosquitoes, depend on seasonal environmental factors such as rainfall, temperature, and humidity. We can include these effects by modeling these parameters as periodic functions of time. We would like to explore this periodically forced model for features not seen in the autonomous model, including the modifications to the definition of the reproductive number and the endemic states. This would provide a more accurate picture of malaria transmission and prevalence than that obtained from models using parameter values that are averaged over the seasons. Other planned improvements to the model include the addition of age and spatial structure.

An ultimate goal is to validate this model by applying it to a particular malaria-endemic region of the world to compare the predicted endemic states with the prevalence data.

Appendix. Lemmas and proofs of theorems.

LEMMA A.1. *For all equilibrium points on* $\mathcal{D} \cap \partial\mathbb{R}^7_+$, $e_h = i_h = r_h = e_v = i_v = 0$.

Proof. We need to show that for an equilibrium point in $\mathcal{D}$, if any one of the diseased classes is zero, all the rest are also equal to zero. We show, by setting the right-hand side of (2.8) equal to 0, that if any one of e_h, i_h, r_h, e_v, or i_v is equal to 0, then $e_h = i_h = r_h = e_v = i_v = 0$. For $i'_h = 0$, $e_h = 0$ if and only if $i_h = 0$.[2] Similarly, for $r'_h = 0$, $i_h = 0$ if and only if $r_h = 0$. Thus, if $e_h = 0$, $i_h = 0$, or $r_h = 0$, then $e_h = i_h = r_h = 0$. From $e'_h = 0$, we see that if $e_h = i_h = r_h = 0$, then $i_v = 0$. Also, for $i'_v = 0$, $e_v = 0$ if and only if $i_v = 0$. Thus, if $e_v = 0$ or $i_v = 0$, then $e_v = i_v = 0$. Finally, for $e'_v = 0$, if $e_v = i_v = 0$, then $i_h = r_h = 0$. □

A.1. Proof of Theorem 3.3.

Proof. The Jacobian of the malaria model (2.8) evaluated at x_{dfe} is of the form

$$J = \begin{pmatrix} J_{11} & 0 & 0 & 0 & 0 & J_{16} & 0 \\ J_{21} & J_{22} & 0 & 0 & 0 & 0 & 0 \\ 0 & J_{32} & J_{33} & 0 & 0 & 0 & 0 \\ 0 & J_{42} & 0 & J_{44} & 0 & 0 & 0 \\ 0 & J_{52} & J_{53} & 0 & J_{55} & 0 & 0 \\ 0 & 0 & 0 & 0 & J_{65} & J_{66} & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & J_{77} \end{pmatrix}. \tag{A.1}$$

[2] As the right-hand side of (2.8b) is a quadratic function of i_h, there are two possible solutions of i_h when $i'_h = 0$ and $e_h = 0$. However, the nonzero solution of i_h is greater than 1 and is thus outside of $\mathcal{D}$.

As the fourth and seventh columns (corresponding to the total human and mosquito populations) contain only the diagonal terms, these diagonal terms form two eigenvalues of the Jacobian:

$$\eta_6 = \psi_h - \mu_{1h} - 2\mu_{2h}N_h^* = -\sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}, \tag{A.2a}$$

$$\eta_7 = \psi_v - \mu_{1v} - 2\mu_{2v}N_v^* = -(\psi_v - \mu_{1v}). \tag{A.2b}$$

As we have assumed that $\psi_v > \mu_{1v}$, both η_6 and η_7 are always negative. The other five eigenvalues are the roots of the characteristic equation of the matrix formed by excluding the fourth and seventh rows and columns of the Jacobian (A.1):

$$A_5\eta^5 + A_4\eta^4 + A_3\eta^3 + A_2\eta^2 + A_1\eta + A_0 = 0 \tag{A.3}$$

with

$$\begin{aligned}
A_5 &= 1,\\
A_4 &= B_1 + B_2 + B_3 + B_4 + B_5,\\
A_3 &= B_1B_2 + B_1B_3 + B_1B_4 + B_1B_5 + B_2B_3 + B_2B_4 + B_2B_5 + B_3B_4\\
&\quad + B_3B_5 + B_4B_5,\\
A_2 &= B_1B_2B_3 + B_1B_2B_4 + B_1B_2B_5 + B_1B_3B_4 + B_1B_3B_5 + B_1B_4B_5 + B_2B_3B_4\\
&\quad + B_2B_3B_5 + B_2B_4B_5 + B_3B_4B_5,\\
A_1 &= B_1B_2B_3B_4 + B_1B_2B_3B_5 + B_1B_2B_4B_5 + B_1B_3B_4B_5 + B_2B_3B_4B_5\\
&\quad - B_6B_7B_8B_9,\\
A_0 &= B_1B_2B_3B_4B_5 - (B_3B_6B_7B_8B_9 + B_6B_7B_9B_{10}B_{11}),
\end{aligned}$$

and $B_1 = \nu_h + \psi_h + \Lambda_h/N_h^*$, $B_2 = \gamma_h + \delta_h + \psi_h + \Lambda_h/N_h^*$, $B_3 = \rho_h + \psi_h + \Lambda_h/N_h^*$, $B_4 = \nu_v + \psi_v$, $B_5 = \psi_v$, $B_6 = b_h^*\beta_{hv}$, $B_7 = \nu_h$, $B_8 = b_v^*\beta_{vh}$, $B_9 = \nu_v$, $B_{10} = \gamma_h$, and $B_{11} = b_v^*\tilde{\beta}_{vh}$.

To evaluate the signs of the roots of (A.3), we first use the Routh–Hurwitz criterion to prove that when $R_0 < 1$, all roots of (A.3) have negative real part. Then, using Descartes's rule of sign, we prove that when $R_0 > 1$, there is one positive real root.

The Routh–Hurwitz criterion [18, section 1.6-6(b)] for a real algebraic equation

$$a_nx^n + a_{n-1}x^{n-1} + \cdots + a_1x + a_0 = 0 \tag{A.4}$$

states that, given $a_n > 0$, all roots have negative real part if and only if $T_0 = a_n$, $T_1 = a_{n-1}$,

$$T_2 = \begin{vmatrix} a_{n-1} & a_n \\ a_{n-3} & a_{n-2} \end{vmatrix}, T_3 = \begin{vmatrix} a_{n-1} & a_n & 0 \\ a_{n-3} & a_{n-2} & a_{n-1} \\ a_{n-5} & a_{n-4} & a_{n-3} \end{vmatrix}, \ldots, T_n = \begin{vmatrix} a_{n-1} & \cdots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \cdots & a_0 \end{vmatrix}$$

are all positive, with $a_i = 0$ for $i < 0$. This is true if and only if all a_i and either all even-numbered T_k or all odd-numbered T_k are positive (the Liénard–Chipart test). Korn and Korn [18] in section 1.6-6(c) state Descartes's rule of sign as the number of positive real roots of a real algebraic equation (A.4) is equal to the number, N_a, of sign changes in the sequence, $a_n, a_{n-1}, \ldots, a_0$, of coefficients, where the vanishing terms are disregarded, or it is less than N_a by a positive even integer.

We show that when $R_0 < 1$, all the coefficients, A_i, of the characteristic equation (A.3), and T_0, T_2, and T_4, are positive, so by the Routh–Hurwitz criterion, all the eigenvalues of the Jacobian (A.1) have negative real part. We then show that when $R_0 > 1$, there is one and only one sign change in the sequence $A_5, A_4, \ldots, A_0$, so by Descartes's rule of sign there is one eigenvalue with positive real part, and the disease-free equilibrium point is unstable.

The expression for R_0^2 in (3.4) can be written, in terms of B_i, as

$$R_0^2 = \frac{B_3B_6B_7B_8B_9 + B_6B_7B_9B_{10}B_{11}}{B_1B_2B_3B_4B_5}. \tag{A.5}$$

For $R_0 < 1$, by (A.5),

$$B_3B_6B_7B_8B_9 + B_6B_7B_9B_{10}B_{11} < B_1B_2B_3B_4B_5, \tag{A.6}$$

$$B_6B_7B_8B_9 < B_1B_2B_4B_5. \tag{A.7}$$

As all the B_i are positive, A_5, A_4, A_3, and A_2 are always positive. From (A.7) we see that $A_1 > 0$, and from (A.6) we see that $A_0 > 0$. Thus, for $R_0 < 1$, all A_i are positive. We now show that the even-numbered T_k are positive for $R_0 < 1$. For the fifth-degree polynomial (A.3), $T_0 = A_5$, which is always positive. $T_2 = A_3A_4 - A_2A_5$, which we can show to be a positive sum of products of B_i's, so $T_2 > 0$. Lastly,

$$T_4 = A_1[A_2A_3A_4 - (A_1A_4^2 + A_2^2A_5)] - A_0[A_3(A_3A_4 - A_2A_5) - (2A_1A_4A_5 - A_0A_5^2)].$$

For ease of notation, we introduce

$$C_1 = A_2A_3A_4 - (A_1A_4^2 + A_2^2A_5),$$
$$C_2 = A_3(A_3A_4 - A_2A_5) - (2A_1A_4A_5 - A_0A_5^2),$$

where we can show that $C_1 > 0$ and $C_2 > 0$, so that $T_4 = A_1C_1 - A_0C_2$. We define

$$C_2^{(1)} = C_2 + B_6B_7B_9B_{10}B_{11}.$$

As $C_2^{(1)} > C_2$ and $A_0 > 0$, for $T_4^{(1)} = A_1C_1 - A_0C_2^{(1)}$, $T_4 > T_4^{(1)}$. Similarly, we define

$$A_0^{(1)} = A_0 + (B_3B_6B_7B_8B_9 + B_6B_7B_9B_{10}B_{11}).$$

As $A_0^{(1)} > A_0$ and $C_2^{(1)} > 0$, for $T_4^{(2)} = A_1C_1 - A_0^{(1)}C_2^{(1)}$, $T_4^{(1)} > T_4^{(2)}$. Finally, we define

$$A_1^{(1)} = A_1 - (B_1B_2B_4B_5 - B_6B_7B_8B_9).$$

As $A_1^{(1)} < A_1$ (for $R_0 < 1$) and $C_1 > 0$, for $T_4^{(3)} = A_1^{(1)}C_1 - A_0^{(1)}C_2^{(1)}$, $T_4^{(2)} > T_4^{(3)}$. We can show that $T_4^{(3)}$ is a sum of positive terms, so $T_4^{(3)} > 0$. As $T_4 > T_4^{(1)} > T_4^{(2)} > T_4^{(3)}$, $T_4 > 0$. Thus, for $R_0 < 1$, all roots of (A.3) have negative real parts.

When $R_0 > 1$

$$B_3B_6B_7B_8B_9 + B_6B_7B_9B_{10}B_{11} > B_1B_2B_3B_4B_5,$$

and so $A_0 < 0$. As A_5, A_4, A_3, and A_2 are positive, the sequence, $A_5, A_4, A_3, A_2, A_1, A_0$ has exactly one sign change. Thus, by Descartes's rule of sign, (A.3) has one positive real root when $R_0 > 1$.

Thus, the disease-free equilibrium point, x_{dfe}, is locally asymptotically stable if $R_0 < 1$ and unstable if $R_0 > 1$. If $R_0 < 1$, on average each infected individual infects fewer than one other individual, and the disease dies out. If $R_0 > 1$, on average each infected individual, infects more than one other individual, so we would expect the disease to spread. The Jacobian of (2.8) at x_{dfe} has one eigenvalue equal to 0 at $R_0 = 1$. □

A.2. Proofs of theorems and lemmas for the existence of endemic equilibrium points. The equilibrium equations for (2.8) are shown below in (A.8). In this analysis, we use the terms e_h, i_h, r_h, N_h, e_v, i_v, and N_v to represent their respective equilibrium values and not their actual values at a given time, t.

$$\left(\frac{\sigma_v\sigma_h N_v\beta_{hv}i_v}{\sigma_v N_v+\sigma_h N_h}\right)(1-e_h-i_h-r_h)-(\nu_h+\psi_h+\Lambda_h/N_h)e_h+\delta_h i_h e_h=0, \tag{A.8a}$$

$$\nu_h e_h-(\gamma_h+\delta_h+\psi_h+\Lambda_h/N_h)i_h+\delta_h i_h^2=0, \tag{A.8b}$$

$$\gamma_h i_h-(\rho_h+\psi_h+\Lambda_h/N_h)r_h+\delta_h i_h r_h=0, \tag{A.8c}$$

$$\Lambda_h+\psi_h N_h-(\mu_{1h}+\mu_{2h}N_h)N_h-\delta_h i_h N_h=0, \tag{A.8d}$$

$$\left(\frac{\sigma_v\sigma_h N_h}{\sigma_v N_v+\sigma_h N_h}\right)\left(\beta_{vh}i_h+\tilde{\beta}_{vh}r_h\right)(1-e_v-i_v)-(\nu_v+\psi_v)e_v=0, \tag{A.8e}$$

$$\nu_v e_v-\psi_v i_v=0, \tag{A.8f}$$

$$\psi_v N_v-(\mu_{1v}+\mu_{2v}N_v)N_v=0. \tag{A.8g}$$

We rewrite (A.8a) and (A.8e) in terms of the bifurcation parameter, ζ (4.2), and a new parameter, $\theta=\sigma_h/\sigma_v$, to obtain

$$\zeta\left(\frac{N_v^*+\theta N_h^*}{N_v+\theta N_h}\right)N_v\beta_{hv}i_v(1-e_h-i_h-r_h)-(\nu_h+\psi_h+\Lambda_h/N_h-\delta_h i_h)e_h=0, \tag{A.9a}$$

$$\zeta\left(\frac{N_v^*+\theta N_h^*}{N_v+\theta N_h}\right)N_h\left(\beta_{vh}i_h+\tilde{\beta}_{vh}r_h\right)(1-e_v-i_v)-(\nu_v+\psi_v)e_v=0. \tag{A.9b}$$

We can vary the bifurcation parameter, ζ, while keeping all other parameters fixed. In terms of the original variables, this corresponds to changing σ_h and σ_v while keeping the ratio between them fixed. We can pick θ, the ratio between them, and sweep out the entire parameter space.

We reduce the equilibrium equations to a two-dimensional system for e_h and e_v by solving for the other variables, either explicitly as functions of the parameters, or in terms of e_h and e_v. We solve (A.8g) for N_v, explicitly expressing the positive equilibrium for the total mosquito population in terms of parameters (exactly as in the disease-free case (3.1)):

$$N_v=\frac{\psi_v-\mu_{1v}}{\mu_{2v}}. \tag{A.10}$$

Solving for i_v in (A.8f) in terms of e_v, we find

$$i_v=\frac{\nu_v}{\psi_v}e_v. \tag{A.11}$$

We write the positive equilibrium for N_h in terms of i_h from (A.8d) as

$$N_h=\frac{(\psi_h-\mu_{1h}-\delta_h i_h)+\sqrt{(\psi_h-\mu_{1h}-\delta_h i_h)^2+4\mu_{2h}\Lambda_h}}{2\mu_{2h}}. \tag{A.12}$$

Using (A.12) in (A.8c), we solve for r_h in terms of i_h:

$$r_h = \frac{2\gamma_h i_h}{2\rho_h + (\psi_h + \mu_{1h} - \delta_h i_h) + \sqrt{(\psi_h - \mu_{1h} - \delta_h i_h)^2 + 4\mu_{2h}\Lambda_h}}. \tag{A.13}$$

Given the nonlinear nature of (A.8b), it is not feasible (or useful) to solve for i_h in terms of e_h explicitly. We therefore use (A.12) to rewrite (A.8b), and define the function $e_h = g(i_h)$ as

$$g(i_h) = \frac{\gamma_h + \delta_h + \frac{1}{2}\left((\psi_h + \mu_{1h} - \delta_h i_h) + \sqrt{(\psi_h - \mu_{1h} - \delta_h i_h)^2 + 4\mu_{2h}\Lambda_h}\right)}{\nu_h} i_h.$$

We note that $g(0) = 0$, and label the positive constant $g(1) = e_h^{max}$. As $g(i_h)$ is a smooth function of i_h with $g'(i_h) > 0$ for $i_h \in [0,1]$ and $e_h \in [0, e_h^{max}]$, there exists a smooth function $i_h = y(e_h)$ with domain $[0, e_h^{max}]$ and range $[0,1]$. As $g'(0) > 0$, the smooth function $y(e_h)$ would extend to some small $e_h < 0$. Substituting $i_h = y(e_h)$ into (A.12) and (A.13), we can also express N_h and r_h as functions of e_h.

We now introduce the bounded open subset of $\mathbb{R}^2$,

$$Y = \left\{ \begin{pmatrix} e_h \\ e_v \end{pmatrix} \in \mathbb{R}^2 \;\middle|\; \begin{array}{l} -\epsilon_h < e_h < e_h^{max} \\ -\epsilon_v < e_v < 1 \end{array} \right\}, \tag{A.14}$$

for some $\epsilon_v > 0$ and some $\epsilon_h > 0$. By substituting (A.10), (A.11), (A.12), (A.13), and $i_h = y(e_h)$ into (A.8a) and (A.8e), we reformulate the seven equilibrium equations (A.8) equivalently as two equations for the components $(e_h, e_v) \in Y$. To place these two equations into the Rabinowitz form (4.1), we need to determine lower order terms. We rewrite (A.8b) as $f(e_h, i_h) = 0$, where $f(e_h, i_h) =$

$$\nu_h e_h - \left[\gamma_h + \delta_h + \frac{1}{2}\left((\psi_h + \mu_{1h} - \delta_h i_h) + \sqrt{(\psi_h - \mu_{1h} - \delta_h i_h)^2 + 4\mu_{2h}\Lambda_h}\right)\right] i_h,$$

and use implicit differentiation to write $i_h = y(e_h)$ as a Taylor polynomial of the form

$$i_h = y_1 e_h + \mathcal{O}(e_h^2), \tag{A.15}$$

where

$$y_1 = -\left.\frac{\frac{\partial f}{\partial e_h}}{\frac{\partial f}{\partial i_h}}\right|_{i_h = e_h = 0} = \frac{\nu_h}{\gamma_h + \delta_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)}.$$

Finally, we substitute the Taylor approximation for i_h (A.15) into r_h (A.13) and N_h (A.12), and then all three, along with i_v (A.11) and N_v (A.10) into the equilibrium equations for e_h (A.9a) and e_v (A.9b), to provide first order approximations to the equilibrium equations:

$$\begin{pmatrix} 0 \\ 0 \end{pmatrix} = \begin{pmatrix} f_{1\_10} & f_{1\_01} \\ f_{2\_10} & f_{2\_01} \end{pmatrix} \begin{pmatrix} e_h \\ e_v \end{pmatrix} + \mathcal{O}\left(\begin{pmatrix} e_h \\ e_v \end{pmatrix}^2\right), \tag{A.16}$$

where

$$f_{1\_10} = -\left[\nu_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)\right], \tag{A.17a}$$

$$f_{1\_01} = \zeta \cdot \frac{\nu_v \beta_{hv}(\psi_v - \mu_{1v})}{\psi_v \mu_{2v}}, \tag{A.17b}$$

$$f_{2\_10} = \zeta \cdot \frac{\nu_h\left((\psi_h - \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\Lambda_h\mu_{2h}}\right)}{2\mu_{2h}\left(\gamma_h + \delta_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)\right)} \times \left[\beta_{vh} + \frac{\gamma_h\tilde{\beta}_{vh}}{\rho_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)}\right], \tag{A.17c}$$

$$f_{2\_01} = -\left(\psi_v + \nu_v\right). \tag{A.17d}$$

To apply Corollary 1.12 of Rabinowitz [24], we algebraically manipulate (A.16) to produce

$$u = \zeta L u + h(\zeta, u), \tag{A.18}$$

where

$$u = \begin{pmatrix} e_h \\ e_v \end{pmatrix} \quad \text{and} \quad L = \begin{pmatrix} 0 & A \\ B & 0 \end{pmatrix} \quad \text{with}$$

$$A = \frac{\nu_v \beta_{hv}(\psi_v - \mu_{1v})}{\psi_v \mu_{2v}\left(\nu_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)\right)}, \tag{A.19a}$$

$$B = \left(\beta_{vh} + \frac{\gamma_h\tilde{\beta}_{vh}}{\rho_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)}\right) \times \frac{\nu_h\left((\psi_h - \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)}{2\mu_{2h}(\psi_v + \nu_v)\left(\gamma_h + \delta_h + \frac{1}{2}\left((\psi_h + \mu_{1h}) + \sqrt{(\psi_h - \mu_{1h})^2 + 4\mu_{2h}\Lambda_h}\right)\right)}, \tag{A.19b}$$

and $h(\zeta, u)$ is $\mathcal{O}(u^2)$. The matrix, L, has two distinct eigenvalues: $\pm\sqrt{AB}$. Characteristic values of a matrix are the reciprocals of its eigenvalues. We denote the two characteristic values of L by $\xi_1 = 1/\sqrt{AB}$ and $\xi_2 = -1/\sqrt{AB}$. As both A and B are always positive (because we have assumed that $\psi_v > \mu_{1v}$), ξ_1 is real and corresponds to the dominant eigenvalue of L. The right and left eigenvectors corresponding to ξ_1 are, respectively,

$$v = \begin{pmatrix} \sqrt{A} \\ \sqrt{B} \end{pmatrix} \quad \text{and} \quad w = \begin{pmatrix} \sqrt{B} & \sqrt{A} \end{pmatrix}. \tag{A.20}$$

For $M_Z > \xi_1$, as $0 \in Y$, $(\xi_1, 0) \in \Omega$. By Corollary 1.12 of Rabinowitz [24], we know that there is a continuum of solution-pairs $(\zeta, u) \in \Omega$, whose closure contains the point $(\xi_1, 0)$, that either meets the boundary of Ω, $\partial\Omega$, or the point $(\xi_2, 0)$. We

denote the continuum of solution-pairs emanating from $(\xi_1, 0)$ by $\mathscr{C}_1$, where $\mathscr{C}_1 \subset \Omega$, and from $(\xi_2, 0)$ by $\mathscr{C}_2$, where $\mathscr{C}_2 \subset \Omega$. We introduce the sets

$$Z_1 = \{\zeta \in Z |\ \exists u \text{ such that } (\zeta, u) \in \mathscr{C}_1\}, \tag{A.21a}$$

$$U_1 = \{u \in Y |\ \exists \zeta \text{ such that } (\zeta, u) \in \mathscr{C}_1\}, \tag{A.21b}$$

$$Z_2 = \{\zeta \in Z |\ \exists u \text{ such that } (\zeta, u) \in \mathscr{C}_2\}, \tag{A.21c}$$

$$U_2 = \{u \in Y |\ \exists \zeta \text{ such that } (\zeta, u) \in \mathscr{C}_2\}. \tag{A.21d}$$

We denote the part of Y in the positive quadrant of $\mathbb{R}^2$ by $Y^+ = \{(e_h, e_v) \in Y \,|\, e_h > 0 \text{ and } e_v > 0\}$, and the internal boundary of Y^+ by

$$\partial Y^+ = \left\{ \begin{pmatrix} e_h \\ e_v \end{pmatrix} \in Y \,\middle|\, \begin{pmatrix} e_h > 0 \\ \text{and} \\ e_v = 0 \end{pmatrix} \text{ or } \begin{pmatrix} e_h = 0 \\ \text{and} \\ e_v > 0 \end{pmatrix} \text{ or } \begin{pmatrix} e_h = 0 \\ \text{and} \\ e_v = 0 \end{pmatrix} \right\}.$$

We can determine the initial direction of the continua of solution-pairs, $\mathscr{C}_1$ and $\mathscr{C}_2$, using the Lyapunov–Schmidt expansion, as described by Cushing [9]. Although we show the proofs only for the expansion of $\mathscr{C}_1$ around the bifurcation point at $\zeta = \xi_1$ in Lemmas A.2 and A.3, the results for $\mathscr{C}_2$ around $\zeta = \xi_2$ are similar. We begin by expanding the terms of the nonlinear eigenvalue equation (A.18) about the bifurcation point, $(\xi_1, 0)$. The expanded variables are

$$u = 0 + \varepsilon u^{(1)} + \varepsilon^2 u^{(2)} + \cdots, \tag{A.22a}$$

$$\zeta = \xi_1 + \varepsilon\zeta_1 + \varepsilon^2\zeta_2 + \cdots, \tag{A.22b}$$

$$\begin{aligned} h(\zeta, u) &= h(\xi_1 + \varepsilon\zeta_1 + \varepsilon^2\zeta_2 + \cdots, \varepsilon u^{(1)} + \varepsilon^2 u^{(2)} + \cdots) \\ &= \varepsilon^2 h_2(\xi_1, u^{(1)}) + \cdots. \end{aligned} \tag{A.22c}$$

We substitute the expansions (A.22) into the eigenvalue equation (A.18) and evaluate at different orders of ε. Evaluating the substitution of the expansions (A.22) into the eigenvalue equation (A.18) at $\mathcal{O}(\varepsilon^0)$ produces $0 = 0$, which gives us no information.

LEMMA A.2. *The initial direction of the branch of equilibrium points, $u^{(1)}$, near the bifurcation point, $(\xi_1, 0)$, is equal to the right eigenvector of L corresponding to the characteristic value, ξ_1.*

Proof. Evaluating the substitution of the expansions (A.22) into the eigenvalue equation (A.18) at $\mathcal{O}(\varepsilon^1)$, we obtain $u^{(1)} = \xi_1 L u^{(1)}$. This implies that $u^{(1)}$ is the right eigenvector of L corresponding to the eigenvalue $1/\xi_1$, v (A.20). Thus, close to the bifurcation point, the equilibrium point can be approximated by $e_h = \varepsilon\sqrt{A}$ and $e_v = \varepsilon\sqrt{B}$. ∎

LEMMA A.3. *The bifurcation at $\zeta = \xi_1$ of the nonlinear eigenvalue equation* (A.18) *is supercritical if $\zeta_1 > 0$ and subcritical if $\zeta_1 < 0$, where*

$$\zeta_1 = -\frac{w \cdot h_2}{w \cdot Lv}, \tag{A.23}$$

where v and w are the right and left eigenvectors of L corresponding to the characteristic value ξ_1, respectively.

Proof. Evaluating the substitution of the expansions (A.22) into the eigenvalue equation (A.18) at $\mathcal{O}(\varepsilon^2)$, we obtain $u^{(2)} = \xi_1 L u^{(2)} + \zeta_1 L u^{(1)} + h_2$, which we can

rewrite as

$$(\mathbb{I} - \xi_1 L)u^{(2)} = \zeta_1 Lv + h_2, \tag{A.24}$$

where $\mathbb{I}$ is the 2×2 identity matrix. As ξ_1 is a characteristic value of L, $(\mathbb{I} - \xi_1 L)$ is a singular matrix. Thus, for (A.24) to have a solution, $\zeta_1 Lv + h_2$ must be in the range of $(\mathbb{I} - \xi_1 L)$; i.e., it must be orthogonal to the null space of the adjoint of $(\mathbb{I} - \xi_1 L)$. The null space of the adjoint of $(\mathbb{I} - \xi_1 L)$ is spanned by the left eigenvector of L (corresponding to the eigenvalue $1/\xi_1$), w (A.20). The Fredholm condition for the solvability of (A.24) is $w \cdot (\zeta_1 Lv + h_2) = 0$. Solving for ζ_1 provides (A.23). If ζ_1 is positive, then for small positive ε, $u > 0$ and $\zeta > \xi_1$, and the bifurcation is supercritical. Similarly, if ζ_1 is negative, then for small positive ε, $u > 0$ and $\zeta < \xi_1$, and the bifurcation is subcritical. □

LEMMA A.4. *For all $u \in U_1$, $e_h > 0$ and $e_v > 0$.*

Proof. By Lemma A.1, there are no equilibrium points on ∂Y^+ other than $e_h = e_v = 0$, so $U_1 \cap \partial Y^+ = 0$. We know from Lemma A.2 that close to the bifurcation point $(\xi_1, 0)$, the direction of U_1 is equal to v, the right eigenvector corresponding to the characteristic value, ξ_1. As v contains only positive terms, U_1 is entirely contained in Y^+. Thus, for all $u \in U_1$, $e_h > 0$ and $e_v > 0$. □

LEMMA A.5. *The point $u = 0 \in Y$ corresponds to $x_{dfe} \in \mathbb{R}^7$ (on the boundary of the positive orthant of $\mathbb{R}^7$). For every solution-pair $(\zeta, u) \in \mathscr{C}_1$, there corresponds one equilibrium-pair $(\zeta, x^*) \in Z \times \mathbb{R}^7$, where x^* is in the positive orthant of $\mathbb{R}^7$.*

Proof. We first show that $u = 0$ corresponds to x_{dfe}. As $e_h = e_v = 0$, by Theorem 3.1 we know that the only possible equilibrium point is x_{dfe}. We now show that for every $\zeta \in Z_1$ there exists an x^* in the positive orthant of $\mathbb{R}^7$ for the corresponding $u \in U_1$. By Lemma A.4, we know that $e_h > 0$ and $e_v > 0$. We now need to show that for every positive e_h and e_v there exist corresponding positive i_h, r_h, i_v, N_h, and N_v. By looking at the equilibrium equation for i_v (A.11), we see that for every positive e_v there exists a positive i_v. The equilibrium equation for N_v has a positive and bounded solution, depending only on parameter values (A.10). From $i_h = y(e_h)$, we see that for every positive e_h there exists a positive i_h. The equilibrium equations for r_h (A.13) and N_h (A.12) show that for every positive i_h there exists a positive r_h and N_h. □

LEMMA A.6. *The set U_1 does not meet the boundary of Y.*

Proof. As Lemma A.4 shows us that for all $u \in U_1$, $e_h > 0$ and $e_v > 0$, we need to show that $e_h < e_h^{max}$ and $e_v < 1$. By Lemma A.5, we know that all state variables are positive. Therefore, for (A.8e) to have a solution, $e_v + i_v < 1$ so $e_v < 1$. From the properties of $e_h = g(i_h)$, we know that as i_h increases, e_h increases monotonically, reaching e_h^{max} at $i_h = 1$. However, we have already shown that when $e_h + i_h + r_h = 1$, $e_h' + i_h' + r_h' < 0$, and thus there can be no equilibrium point at $e_h + i_h + r_h = 1$. Therefore, i_h is always less than 1, and e_h is always less than e_h^{max}. □

Proof of Theorem 4.1. As shown in Lemma A.4, $U_1 \cap \partial Y^+ = 0$ and U_1 is entirely contained in Y^+. We can similarly show that U_2 is entirely outside of Y^+ because the right eigenvector corresponding to ξ_2 is $\begin{pmatrix} -\sqrt{A} & \sqrt{B} \end{pmatrix}^{\mathrm{T}}$. Therefore, $\mathscr{C}_1$ and $\mathscr{C}_2$ do not intersect, and by Corollary 1.12 of Rabinowitz [24], $\mathscr{C}_1$ meets $\partial\Omega$. By Lemma A.6, the set U_1 does not meet the boundary of Y, so $\mathscr{C}_1$ meets $\partial\Omega$ only at $\zeta = M_Z$.

By Lemma A.5, for every $u \in U_1$, there corresponds an x^* in the positive orthant of $\mathbb{R}^7$, and $u = 0$ corresponds to x_{dfe} (on the boundary of the positive orthant of $\mathbb{R}^7$). Thus, there exists a continuum of equilibrium-pairs $(\zeta, x^*) \in Z \times \mathbb{R}^7$ that connects the point (ξ_1, x_{dfe}) to the hyperplane $\zeta = M_Z$ in $\mathbb{R} \times \mathbb{R}^7$. □

Proof of Theorem 4.3. When $\delta_h = 0$, we can explicitly evaluate $h(\zeta, u)$ in the nonlinear eigenvalue equation (A.18) from the equilibrium equations (A.8) as

$$h = \zeta \begin{pmatrix} C_{(\delta_h=0)} e_h e_v \\ D_{(\delta_h=0)} e_h e_v \end{pmatrix} \tag{A.25}$$

since the coefficients of all the other higher order terms are zero. Although we do not show the explicit representations for $C_{(\delta_h=0)}$ and $D_{(\delta_h=0)}$, they are both negative. From (A.25) and (A.22) we can evaluate the second order expansion

$$h_2 = \xi_1 \begin{pmatrix} C_{(\delta_h=0)} \sqrt{A}\sqrt{B} \\ D_{(\delta_h=0)} \sqrt{A}\sqrt{B} \end{pmatrix} = \begin{pmatrix} C_{(\delta_h=0)} \\ D_{(\delta_h=0)} \end{pmatrix}. \tag{A.26}$$

As h_2 contains only negative terms and w, v, and L contain only nonnegative terms, (A.23) implies that ζ_1 is positive. Thus, by Lemma A.3, with no disease-induced death, for any positive values of the other parameters there is a supercritical bifurcation at $R_0 = 1$. □

Acknowledgements. The authors thank Karl Hadeler for his discussions and ideas on improving the model, including the mosquitoes' human-biting rates; Alain Goriely, Joceline Lega, Jia Li, Seymour Parter, and Joel Miller for their careful reading of the manuscript and valuable comments; and two anonymous referees for many helpful suggestions.

DERIVATION OF NEW QUANTUM HYDRODYNAMIC EQUATIONS USING ENTROPY MINIMIZATION*

ANSGAR JÜNGEL†, DANIEL MATTHES†, AND JOSIPA PINA MILIŠIĆ†

Abstract. New quantum hydrodynamic equations are derived from a Wigner–Boltzmann model, using the quantum entropy minimization method recently developed by Degond and Ringhofer. The model consists of conservation equations for the carrier, momentum, and energy densities. The derivation is based on a careful expansion of the quantum Maxwellian in powers of the Planck constant. In contrast to the standard quantum hydrodynamic equations derived by Gardner, the new model includes vorticity terms and a dispersive term for the velocity. Numerical current-voltage characteristics of a one-dimensional resonant tunneling diode for both the new quantum hydrodynamic equations and Gardner's model are presented. The numerical results indicate that the dispersive velocity term regularizes the solution of the system.

Key words. quantum moment hydrodynamics, entropy minimization, quantum Maxwellian, moment method, finite-difference discretization, numerical simulations, resonant tunneling diode, current-voltage characteristics

1. Introduction.

Quantum phenomena in semiconductor devices are increasingly important, as the characteristic lengths of modern devices are of the order of only deca-nanometers. In fact, there are devices, like resonant tunneling diodes, whose behavior is essentially based on quantum effects. Since the numerical solution of the Schrödinger equation (or one of its approximations) or the Wigner equation is very time-consuming, fluid-type quantum models seem to provide a compromise between accurate and efficient numerical simulations. Moreover, quantum fluid models have several advantages. First, they are formulated in macroscopic quantities like the current density, which can be measured. Second, for the macroscopic quantum models, the same types of boundary conditions are commonly employed as for their classical counterparts.

A fluid dynamical formulation of the Schrödinger equation has been known since the early years of quantum mechanics [26]. A simple derivation uses WKB wave functions $\psi = \sqrt{n}\exp(iS/\varepsilon)$ for the electron density $n(x,t)$ and the phase $S(x,t)$, where ε is the scaled Planck constant. Separating the real and the imaginary parts of the single-state Schrödinger equation gives Euler-type equations for n and the "velocity" $u = \nabla S$, which are called the *quantum hydrodynamic* (*QHD*) *model*. These equations include the so-called Bohm potential $\Delta\sqrt{n}/\sqrt{n}$ as a quantum correction [17, 20]. In the semiclassical limit $\varepsilon \to 0$, the classical pressureless Euler equations are recovered.

In order to incorporate many-particle effects, we are aware of two approaches. The first approach starts from the mixed-state Schrödinger–Poisson system [17, 20]. Defining the particle and current densities as the superpositions of all single-state

densities, quantum equations for the macroscopic variables (particle density, current density, and energy density) are derived. The system of equations is closed by expressing the heat flux heuristically in terms of the macroscopic variables.

The second approach starts from the (collisional) Wigner equation in position-momentum space,

$$\partial_t f + p\cdot\nabla_x f + \theta[V]f = Q(f), \qquad (x,p)\in\mathbb{R}^{2d},\ t>0, \tag{1.1}$$

where (x,p) is the position-momentum variable, $t>0$ is the time, and $\theta[V]$ is a pseudodifferential operator defined by

$$(\theta[V]w)(x,p,t)$$
$$= \frac{i}{(2\pi)^{d/2}}\int_{\mathbb{R}^{2d}}\frac{1}{\varepsilon}\left[V\left(x+\frac{\varepsilon}{2}\eta,t\right)-V\left(x-\frac{\varepsilon}{2}\eta,t\right)\right]w(x,p',t)e^{i\eta\cdot(p-p')}d\eta dp'.$$

The electric potential $V=V(x,t)$ is self-consistently coupled to the Wigner function $f(x,p,t)$ via Poisson's equation

$$\lambda^2\Delta V = \int_{\mathbb{R}^d} f dp - C, \tag{1.2}$$

where λ is the scaled Debye length and $C=C(x)$ the doping concentration characterizing the semiconductor device. Notice that the collisionless Wigner equation is formally equivalent to the Heisenberg equation for the density matrix.

The above approach allows for an abstract formulation of the collision operator. In fact, we assume only that its kernel consists of the quantum thermal equilibrium distribution (defined in section 2) and that the operator preserves certain moments.

The macroscopic variables are defined as the moments of the Wigner function over momentum space; more precisely, we consider the particle density $n=\langle 1\rangle$, the fluid-dynamical momentum density $nu=\langle p\rangle$, and the energy density $e=\langle\frac{1}{2}|p|^2\rangle$, where we have used the notation $\langle g(p)\rangle=\int f(\cdot,p)g(p)dp$ for functions $g(p)$. In order to obtain macroscopic equations as well, a moment method is applied to (1.1): we multiply the equation by 1, p, and $\frac{1}{2}|p|^2$ and integrate over the momentum space. This yields evolution equations for n, nu, and e. However, the resulting system of moment equations needs to be closed.

As a closure condition, Gardner [12] employed a quantum-corrected thermal equilibrium distribution function in place of f in the derivation of the moment equations. The use of this closure can be—formally—justified by a hydrodynamic scaling and passage to the limit of vanishing scaling parameter. Gardner bases his choice of the quantum equilibrium distribution on a result by Wigner [31]. Arguing that the electric potential is close to $\log n$ near equilibrium, he replaces V by $\log n$, which is the origin of the Bohm potential.

Another approach, avoiding second derivatives of the potential, consists of deriving an approximate solution to the Bloch equation by an asymptotic expansion of the solution for "small" potentials. This leads to the so-called smooth QHD equations in which the potential V is replaced by a smoothed potential $S[V]$, where S is a pseudodifferential operator [14]. The drawback of this approach is that the numerical solution of the "smooth" QHD model is a nontrivial task. Moreover, there is an ambiguity in the interpretation of the temperature (see the remark in section 6 of [28]).

Our approach to defining a closure is based on Levermore's entropy minimization principle. This method was first employed in the context of classical gas dynamics [25]

and has been recently extended to quantum fluids by Degond and Ringhofer [9]. The idea is to define the equilibrium distribution as the minimizer M_f of the quantum entropy subject to the constraints of given moments. (Here, we adopt the mathematical sign convention of decreasing entropy.) The minimizer is called the *quantum Maxwellian* since there are some similarities to the classical Maxwellian of gas dynamics (see section 2). The quantum Maxwellian M_f, as the solution of a constrained minimization problem, depends on Lagrange multipliers which can be interpreted in the $O(\varepsilon^2)$ approximation as the logarithm of the particle density, the fluid velocity, and the temperature, respectively. Expanding M_f in powers of ε^2 and assuming as in [12] that spatial variations of the temperature $T = T(x,t)$ are of the order $O(\varepsilon^2)$, we derive the following QHD equations up to order $O(\varepsilon^4)$:

$$\partial_t n + \operatorname{div}(nu) = 0, \tag{1.3}$$

$$\partial_t(nu) + \operatorname{div}(nu\otimes u) + \operatorname{div} P - n\nabla V = 0, \tag{1.4}$$

$$\partial_t e + \operatorname{div}\big((P+eI)u\big) + \operatorname{div} S - nu\cdot\nabla V = 0, \tag{1.5}$$

where I is the unit matrix in $\mathbb{R}^d$; the energy density equals

$$e = \frac{d}{2}nT + \frac{1}{2}n|u|^2 - \frac{\varepsilon^2}{24}n\bigg(\Delta\log n - \frac{1}{T}\operatorname{tr}(R^\top R)\bigg),$$

with the trace "tr" of a matrix; the quantities P (stress tensor) and S are given by

$$\begin{aligned}
P &= nTI - \frac{\varepsilon^2}{12}n\bigg((\nabla\otimes\nabla)\log n - \frac{1}{T}R^\top R\bigg),\\
S &= -\frac{\varepsilon^2}{12}n\bigg(\bigg(\frac{d}{2}+1\bigg)R\nabla\log n + \bigg(\frac{d}{2}+2\bigg)\operatorname{div} R + \frac{3}{2}\Delta u\bigg)\\
&\quad + \frac{\varepsilon^2}{12}\bigg(\frac{d}{2}+1\bigg)n(R\nabla\log n + \operatorname{div} R);
\end{aligned}$$

and the vorticity matrix $R = (R_{ij})$ is the antisymmetric part of the velocity derivative,

$$R_{ij} = \partial_{x_j}u_i - \partial_{x_i}u_j. \tag{1.6}$$

A more general model, allowing arbitrarily large spatial deviations of the temperature, is derived in section 3. Employing a Caldeira–Leggett-type collision operator, relaxation-time terms can also be included (see section 3.1).

The quantum correction $(\varepsilon^2/12)n(\nabla\otimes\nabla)\log n$ to the stress tensor in the QHD equations was first stated in the semiconductor context by Ancona and Iafrate [1] and Ancona and Tiersten [2]. Since

$$\frac{\varepsilon^2}{12}\operatorname{div}(n(\nabla\otimes\nabla)\log n) = \frac{\varepsilon^2}{6}n\nabla\bigg(\frac{\Delta\sqrt{n}}{\sqrt{n}}\bigg),$$

the quantum correction can be interpreted as a force including the Bohm potential $\Delta\sqrt{n}/\sqrt{n}$ [11]. The hydrodynamic formulation of quantum mechanics has been employed in solid-state physics for many years; see, for instance, [18] and the references in the review [22].

For $\varepsilon = 0$ in (1.3)–(1.5), we recover the classical hydrodynamic equations. For $\varepsilon > 0$ and constant temperature, we obtain the same equations as derived in [21],

where also the quantum entropy minimization method has been used. Our model differs from Gardner's QHD equations (formulas (1)–(3) in [12]) by the vorticity term R and the dispersive velocity term in the energy equation (1.5),

$$\operatorname{div} q_S = \frac{\varepsilon^2}{8}\operatorname{div}(n\Delta u). \tag{1.7}$$

The origin of this difference lies in the different choices of the quantum Maxwellian. We refer to section 3.5 for a detailed discussion.

The term q_S—but not the vorticity R—also appears in other QHD derivations. It was derived in [13] from a mixed-state Wigner model and interpreted as a dispersive "heat flux" (see formula (36) in [13]). Moreover, it appears in the QHD equations of [16] involving a "smoothed" potential, derived from the Wigner–Boltzmann equation by a Chapman–Enskog expansion.

An interesting feature of the dispersive term (1.7) is that it stabilizes the QHD system numerically. This statement needs some explanation. It is known that the numerical approximation of Gardner's QHD model (see (6.5)–(6.7)) is quite delicate. The usual approach is to employ a hyperbolic solver, for instance an upwind method [12] or a shock-capturing discontinuous Galerkin method [6], originally devised for the classical hydrodynamic equations. It has been argued in [24] that a hyperbolic solver may be inadequate for the QHD equations since the *numerical viscosity* might destroy the dispersive quantum effects. Therefore, a central finite-difference scheme provides an alternative (but still simple) numerical approach. In fact, a central finite-difference approach for Gardner's QHD equations fails, and a stabilization in the form of numerical viscosity seems to be necessary. The dispersive term (1.7) allows us to solve the new QHD equations by using a *central* scheme, thus avoiding numerical viscosity.

Another QHD model with *physical viscosity* has been derived in [19] using a Fokker–Planck collision operator. This operator describes the interaction of the electrons with a heat bath modeling the phonons of the semiconductor lattice. In numerical simulations of a resonant tunneling diode, it turns out that the shape of the current-voltage characteristic is unphysical if the temperature is kept constant [24], and that the diffusion effects are too strong compared to the quantum dispersion [23].

In this paper we present the first numerical simulations of a QHD model involving the term (1.7). More precisely, a simple one-dimensional resonant tunneling diode is simulated. The current-voltage characteristics show multiple regions of negative differential resistance. The dispersive term (1.7) has the effect of "smoothing" the current-voltage curve; i.e., it decreases the peak-to-valley ratio, the quotient of the peak to the valley current.

We also examine the existence of conserved quantities of the new QHD equations. Clearly, the mass is conserved. We prove that also the energy $E = \int (e+\lambda^2|\nabla V|^2/2)dx$ is conserved. This provides gradient estimates for the particle density, velocity, and temperature, which is useful in the mathematical analysis of the equations.

We summarize the advantages of our approach:

- Starting from the Wigner–BGK (Bhatganar–Gross–Krook) equation, no ad hoc assumptions are needed in order to derive the QHD equations.
- An energy for the new model can be defined, leading to useful mathematical estimates.
- The dispersive velocity term seems to stabilize the (numerical) solution of the system.
- The new model provides current-voltage characteristics showing negative differential resistance effects.

The paper is organized as follows. In section 2 we specify our definition of the quantum Maxwellian, which is used as the closure in the moment method developed in section 3. Section 4 is devoted to simplified QHD models, and the system (1.3)–(1.5) is derived. In section 5 we prove that the energy of the system is conserved. Finally, in section 6, the new QHD model (1.3)–(1.5) is numerically discretized and solved in one space dimension, and simulations of a resonant tunneling diode are presented.

2. Definition of the quantum Maxwellian. In order to define the quantum Maxwellian, we first recall the Wigner transform. Let A_ρ be an operator on $L^2(\mathbb{R}^d)$ with integral kernel $\rho(x,x')$, i.e.,

$$(A_\rho\phi)(x) = \int_{R^d} \rho(x,x')\phi(x')dx' \quad \text{for all } \phi \in L^2(\mathbb{R}^d).$$

The Wigner transform of A_ρ is defined by

$$W(A_\rho)(x,p) = \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d} \rho\left(x+\frac{\varepsilon}{2}\eta, x-\frac{\varepsilon}{2}\eta\right)e^{i\eta\cdot p}d\eta.$$

Its inverse W^{-1}, also called Weyl quantization, is defined as an operator on $L^2(\mathbb{R}^d)$:

$$(W^{-1}(f)\phi)(x) = \int_{\mathbb{R}^{2d}} f\left(\frac{x+y}{2}\right)\phi(y)e^{ip\cdot(x-y)/\varepsilon}dpdy \quad \text{for all } \phi \in L^2(\mathbb{R}^d).$$

With these definitions we are able to introduce the *quantum exponential* and the *quantum logarithm* formally by

$$\exp f = W(\exp W^{-1}(f)), \qquad \operatorname{Log} f = W(\log W^{-1}(f)),$$

where exp and log are the operator exponential and logarithm, respectively. In [8] it was (formally) shown that the quantum exponential and quantum logarithm are equal to the usual exponential and logarithm, respectively, up to order $O(\varepsilon^2)$,

$$\exp f = \exp f + O(\varepsilon^2), \qquad \operatorname{Log} f = \log f + O(\varepsilon^2). \tag{2.1}$$

The essential ingredient in the definition of the quantum Maxwellian is the relative quantum entropy. Let a quantum mechanical state be described by the Wigner function f solving the Wigner equation (1.1). Then its *relative quantum* (*von Neumann*) *entropy* is given by [9]

$$H(f) = \int_{\mathbb{R}^{2d}} f(x,p)\left((\operatorname{Log} f)(x,p) - 1 + \frac{|p|^2}{2} - V(x)\right)dxdp.$$

Whereas the classical entropy is a function on the configuration space, the above quantum entropy is a real number, underlining the nonlocal nature of quantum mechanics.

We define the quantum thermal equilibrium or *quantum Maxwellian* M_f for some given function $f(x,p)$ as the solution of the constrained minimization problem

$$H(M_f) = \min\left\{H(\hat{f}) : \int_{\mathbb{R}^d} \hat{f}(x,p,t)\begin{pmatrix}1\\ p\\ |p|^2/2\end{pmatrix}dp = \begin{pmatrix}n(x,t)\\ nu(x,t)\\ e(x,t)\end{pmatrix},\ x\in\mathbb{R}^d,\ t>0\right\}, \tag{2.2}$$

where

$$n(x,t) = \langle 1\rangle(x,t) = \int_{\mathbb{R}^d} f(x,p,t)dp,$$
$$nu(x,t) = \langle p\rangle(x,t) = \int_{\mathbb{R}^d} f(x,p,t)pdp,$$
$$e(x,t) = \frac{1}{2}\langle |p|^2\rangle(x,t) = \frac{1}{2}\int_{\mathbb{R}^d} f(x,p,t)|p|^2dp.$$

In [9] it is shown that the solution f^* of the constrained minimization problem (if it exists) is given by

$$M_f(x,p,t) = \exp\left(A(x,t) - \frac{|p-w(x,t)|^2}{2T(x,t)}\right). \tag{2.3}$$

The Lagrange multipliers A, w, and T are uniquely determined by the moments of f. They correspond in the classical setting to the logarithm of the particle density, the velocity, and the temperature, respectively (see Lemma 3.4).

3. Derivation of the general QHD model. The derivation of the new QHD equations is done in several steps. First, we derive the moment equations. Then the quantum exponential is expanded in powers of ε^2 up to order $O(\varepsilon^4)$. The third step is to expand the moments accordingly. Finally, the expansions are substituted into the moment equations.

3.1. Moment equations. We consider the Wigner–Boltzmann equation (1.1) in the hydrodynamic scaling; i.e., we introduce the scaling

$$x' = \delta x, \quad t' = \delta t,$$

for some parameter $\delta > 0$, which is assumed to be small compared to 1. Then (1.1) becomes for $f = f_\delta$ (omitting the primes)

$$\partial_t f_\delta + p\cdot\nabla_x f_\delta + \theta[V]f_\delta = \delta^{-1}Q(f_\delta), \quad (x,p)\in\mathbb{R}^{2d},\ t>0, \tag{3.1}$$

with initial condition $f_\delta(x,p,0) = f_I(x,p)$. We assume that the collision operator has the following properties: its kernel consists exactly of (multiples of) M_f and

$$\int_{\mathbb{R}^d} Q(f)dp = 0, \quad \int_{\mathbb{R}^d} Q(f)pdp = 0, \quad \int_{\mathbb{R}^d} Q(f)\tfrac{1}{2}|p|^2dp = 0 \quad \text{for all } f(x,p). \tag{3.2}$$

An example satisfying these conditions is the relaxation-time or BGK operator $Q(f) = M_f - f$ (with scaled relaxation time $\tau = 1$) [4].

A more general collision operator, allowing for relaxation-time terms in the macroscopic equations, can be defined as follows. Assume that the collision operator can be written as $Q(f) = Q_0(f) + \delta Q_1(f)$, where the operator $Q_0(f)$ models elastic collisions and satisfies the conditions (3.2); $Q_1(f)$ is given by the Caldeira–Leggett operator [5]

$$Q_1(f) = \frac{1}{\tau_p}(\mathrm{div}_p(pf) + \Delta_p f),$$

modeling inelastic collisions; and τ_p is the momentum relaxation time. Then

$$\int_{\mathbb{R}^d} Q_1(f)dp = 0, \quad \int_{\mathbb{R}^d} Q_1(f)pdp = -\frac{nu}{\tau_p}, \quad \int_{\mathbb{R}^d} Q_1(f)\tfrac{1}{2}|p|^2dp = -\frac{2}{\tau_p}\left(e - \frac{d}{2}n\right), \tag{3.3}$$

which is (a special case of) the momentum and energy relaxation-time terms employed in [12].

The formal limit $\delta \to 0$ in (3.1) yields $Q(f) = 0$, where $f = \lim_{\delta\to 0} f_\delta$, which implies that the limit f is equal to M_f. The moment equations are obtained from (3.1) by multiplication with 1, p, and $\frac{1}{2}|p|^2$, respectively, and integration over the momentum space. Since

$$\int_{\mathbb{R}^d} \theta[V] f dp = 0, \quad \int_{\mathbb{R}^d} \theta[V] f p dp = -n\nabla V, \quad \int_{\mathbb{R}^d} \theta[V] f \tfrac{1}{2}|p|^2 dp = -nu\cdot\nabla V$$

(see, e.g., [8]), we obtain

$$\partial_t n + \operatorname{div}(nu) = 0, \tag{3.4}$$

$$\partial_t (nu) + \operatorname{div}\langle p\otimes p\rangle - n\nabla V = 0, \tag{3.5}$$

$$\partial_t e + \operatorname{div}\langle \tfrac{1}{2}|p|^2 p\rangle - nu\cdot\nabla V = 0, \tag{3.6}$$

where $(p\otimes p)_{ij} = p_i p_j$ for $i,j = 1,\ldots,d$. Recall that the brackets denote integration against the Wigner function $f = M_f$; i.e., in multi-index notation,

$$\langle p^\alpha\rangle(x,t) = \int_{\mathbb{R}^d} M_f(x,p,t) p^\alpha dp,$$

for multi-indices $\alpha \in \mathbb{N}^d$. When employing the Caldeira–Leggett operator defined above, the right-hand sides of (3.4)–(3.6) equal the right-hand sides of (3.3). To close the system (3.4)–(3.6), we need to express the integrals $\langle p\otimes p\rangle$ and $\langle \frac{1}{2}|p|^2 p\rangle$ in terms of the moments n, nu, and e. This constitutes the main step of the derivation.

The following computations are simplified by working with the new variable $s = T^{-1/2}(p-w)$, where w is the Lagrange multiplier introduced in (2.3). In terms of s, the quantum Maxwellian reads as

$$M_f(x,p(s)) = \exp\left(A(x) - \frac{1}{2}|s|^2\right) =: g(x,s).$$

From now on, we omit the dependence of the time t since it acts only as a parameter. The substitution $p \mapsto s$ yields

$$\langle s^\alpha\rangle(x) = T^{d/2}\int_{\mathbb{R}^d} g(x,s) s^\alpha ds.$$

In the following lemma we express the moments $\langle p^\alpha\rangle$ in terms of moments in s. This allows for a more canonical form of the QHD equations.

LEMMA 3.1. *The system* (3.4)–(3.6) *is equivalent to*

$$\partial_t n + \operatorname{div}(nu) = 0, \tag{3.7}$$

$$\partial_t (nu) + \operatorname{div}(nu\otimes u) + \operatorname{div} P - n\nabla V = 0, \tag{3.8}$$

$$\partial_t e + \operatorname{div}\big((P+eI)u\big) + \operatorname{div} S - nu\cdot\nabla V = 0, \tag{3.9}$$

where I is the identity matrix, $u = (nu)/n$, $P = \langle (p-u)\otimes(p-u)\rangle$ is the stress tensor, and $S = \langle \frac{1}{2}(p-u)|p-u|^2\rangle$ is the (quantum) heat flux. Moreover, the following expansions hold:

$$P = T\langle s\otimes s\rangle + O(\varepsilon^4), \quad S = \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle - \left(\frac{d}{2}+1\right)T^{3/2}\langle s\rangle + O(\varepsilon^4). \tag{3.10}$$

Proof. The formulation (3.7)–(3.9) follows immediately from (3.4)–(3.6) since

$$\langle p\otimes p\rangle = P + nu\otimes u \quad \text{and} \quad \left\langle \frac{1}{2}|p|^2 p\right\rangle = S + (P+eI)u.$$

Using the expansion (2.1), elementary integrations yield for $i,j=1,\dots,d$,

$$\langle 1\rangle = T^{d/2}e^A \int_{\mathbb{R}^d} e^{-|s|^2/2}ds + O(\varepsilon^2) = (2\pi T)^{d/2}e^A + O(\varepsilon^2), \tag{3.11}$$

$$\langle s_i\rangle = T^{d/2}e^A \int_{\mathbb{R}^d} e^{-|s|^2/2}s_i ds + O(\varepsilon^2) = O(\varepsilon^2), \tag{3.12}$$

$$\langle s_i s_j\rangle = T^{d/2}e^A \int_{\mathbb{R}^d} e^{-|s|^2/2}s_i s_j ds + O(\varepsilon^2) = n\delta_{ij} + O(\varepsilon^2). \tag{3.13}$$

The relations $n=\langle 1\rangle$, $\langle w\rangle = w\langle 1\rangle = nw$, and $nu = \langle p\rangle = \langle T^{1/2}s + w\rangle = T^{1/2}\langle s\rangle + nw$ give for the second moments

$$\begin{aligned}
\langle p\otimes p\rangle &= T\langle s\otimes s\rangle + \Big\langle (T^{1/2}s+w)\otimes(T^{1/2}s+w) - (T^{1/2}s)\otimes(T^{1/2}s)\Big\rangle \\
&= T\langle s\otimes s\rangle + T^{1/2}\langle s\rangle\otimes w + T^{1/2}w\otimes\langle s\rangle + w\otimes w\langle 1\rangle \\
&= T\langle s\otimes s\rangle + \frac{1}{n}\langle T^{1/2}s+w\rangle\otimes\langle T^{1/2}s+w\rangle - \frac{T}{n}\langle s\rangle\otimes\langle s\rangle \\
&= T\langle s\otimes s\rangle + nu\otimes u + O(\varepsilon^4),
\end{aligned}$$

where in the last equality we have employed (3.12). Therefore, $P = \langle p\otimes p\rangle - nu\otimes u = T\langle s\otimes s\rangle + O(\varepsilon^4)$. In a similar way, we compute the third moment:

$$\begin{aligned}
\frac{1}{2}\langle |p|^2 p\rangle &= \frac{1}{2}T^{1/2}\langle |T^{1/2}s+w|^2 s\rangle + \frac{1}{2}w\langle |p|^2\rangle \\
&= \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle + T\langle s\otimes s\rangle w + \frac{1}{2}T^{1/2}|w|^2\langle s\rangle + ew \\
&= \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle + (P+eI)w + \frac{1}{2}T^{1/2}|w|^2\langle s\rangle.
\end{aligned}$$

By (3.11) and (3.12), the energy density can be expanded as

$$e = \frac{1}{2}\langle |p|^2\rangle = \frac{T}{2}\langle |s|^2\rangle + T^{1/2}w\cdot\langle s\rangle + \frac{1}{2}|w|^2\langle 1\rangle = \frac{d}{2}nT + \frac{1}{2}n|w|^2 + O(\varepsilon^2).$$

Thus, since $w = u - T^{1/2}\langle s\rangle/n$ and $P = nTI + O(\varepsilon^2)$, we obtain

$$\begin{aligned}
\frac{1}{2}\langle |p|^2 p\rangle &= \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle + (P+eI)u - \frac{T^{1/2}}{n}\left(P + eI - \frac{1}{2}n|w|^2 I\right)\langle s\rangle \\
&= \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle + (P+eI)u - \frac{T^{3/2}}{n}\left(\left(\frac{d}{2}+1\right)nI + O(\varepsilon^2)\right)\langle s\rangle.
\end{aligned}$$

This shows that $S = \langle \frac{1}{2}|p|^2 p\rangle - (P+eI)u = \frac{1}{2}T^{3/2}\langle |s|^2 s\rangle - (d/2+1)T^{3/2}n\langle s\rangle + O(\varepsilon^4)$. ∎

3.2. Expansion of the quantum exponential. We wish to give asymptotic expansions of P, S, and U up to order $O(\varepsilon^4)$. For this, we first need to expand the quantum Maxwellian. This is done by means of the following lemma, which is adopted from [9].

LEMMA 3.2. *Let $f(x,p)$ be a smooth symbol. Then the quantum exponential* $\exp f$ *can be expanded as follows:*

$$\exp f = e^f - \frac{\varepsilon^2}{8} e^f \mathcal{Q} + O(\varepsilon^4),$$

where, using Einstein's summation convention,

$$\begin{aligned}\mathcal{Q} &= \partial^2_{x_ix_j} f\, \partial^2_{p_ip_j} f - \partial^2_{x_ip_j} f\, \partial^2_{p_ix_j} f + \frac{1}{3}\partial^2_{x_ix_j} f\, \partial_{p_i} f\, \partial_{p_j} f \\ &\quad - \frac{2}{3}\partial^2_{x_ip_j} f\, \partial_{p_i} f\, \partial_{x_j} f + \frac{1}{3}\partial^2_{p_ip_j} f\, \partial_{x_i} f\, \partial_{x_j} f. \end{aligned} \tag{3.14}$$

In the situation at hand, the symbol is $f(x,p) = A(x) - |p - w(x)|^2/2T(x)$. Then we obtain the following result.

LEMMA 3.3. *The quantum correction* (3.14) *can be written for $f(x,p) = A(x) - |p-w(x)|^2/2T(x)$ as follows:*

$$\begin{aligned}\mathcal{Q}(s) &= T^{-1}\big(X^0 + X^1_i s_i + X^2_{ij} s_i s_j + X^3_{ijk} s_i s_j s_k \\ &\quad + Y^0|s|^2 + Y^1_i |s|^2 s_i + Y^2_{ij}|s|^2 s_i s_j + Z^0|s|^4\big), \end{aligned} \tag{3.15}$$

where the coefficients X^i, Y^i, and Z are defined by

$$\begin{aligned} X^0 &= -\Delta A - \frac{1}{3}|\nabla A|^2 + \frac{1}{2T}\mathrm{tr}\,(\widetilde{R}^\top \widetilde{R}), \\ X^1_i &= \frac{2}{T^{1/2}}\partial_{x_m}\left(\frac{1}{3}A - \log T\right)\widetilde{R}_{mi} - \frac{1}{\sqrt{T}}\Delta w_i, \\ X^2_{ij} &= \frac{1}{3}\partial^2_{x_ix_j} A + \frac{2}{3}\partial_{x_i}(\log T)\partial_{x_j} A - \partial_{x_i}(\log T)\partial_{x_j}(\log T) - \frac{1}{3T}(\widetilde{R}^\top \widetilde{R})_{ij} \\ X^3_{ijk} &= \frac{1}{3T^{1/2}}\partial^2_{x_ix_j} w_k, \\ Y^0 &= \nabla\left(\frac{1}{2}\log T - \frac{1}{3}A\right)\cdot\nabla(\log T) - \frac{1}{2}\Delta(\log T), \\ Y^1_i &= \frac{1}{3T^{1/2}}\partial_{x_m}(\log T)\widetilde{R}_{mi}, \\ Y^2_{ij} &= \frac{1}{6}\left(\partial^2_{x_ix_j}(\log T) + \partial_{x_i}(\log T)\partial_{x_j}(\log T)\right), \\ Z^0 &= -\frac{1}{12}|\nabla(\log T)|^2, \end{aligned}$$

and $\widetilde{R}_{ij} = \partial_{x_j} w_i - \partial_{x_i} w_j$. The symbol "tr" denotes the trace of a matrix.

Proof. The proof consists of computing the relevant derivatives of f with respect to x_i and p_j, namely,

$$\begin{aligned}
\partial_{x_i} f &= \partial_{x_i} A + T^{-1}\partial_{x_i} w_k (p-w)_k + \frac{1}{2}T^{-2}\partial_{x_i} T|p-w|^2 \\
&= \partial_{x_i} A + T^{-1/2}\partial_{x_i} w_k s_k + \frac{1}{2}T^{-1}\partial_{x_i} T|s|^2, \\
\partial^2_{x_i x_j} f &= \partial^2_{x_i x_j} A - T^{-1}\partial_{x_i} w_k \partial_{x_j} w_k - T^{-2}\partial_{x_j} T\partial_{x_i} w_k (p-w)_k + T^{-1}\partial^2_{x_i x_j} w_k (p-w)_k \\
&\quad - T^{-2}\partial_{x_i} T\partial_{x_j} w_k (p-w)_k - T^{-3}\partial_{x_i} T\partial_{x_j} T|p-w|^2 + \frac{1}{2}T^{-2}\partial^2_{x_i x_j} T|p-w|^2 \\
&= \partial^2_{x_i x_j} A - T^{-1}\partial_{x_i} w_k \partial_{x_j} w_k - T^{-3/2}\partial_{x_j} T\partial_{x_i} w_k s_k + T^{-1/2}\partial^2_{x_i x_j} w_k s_k \\
&\quad - T^{-3/2}\partial_{x_i} T\partial_{x_j} w_k s_k - T^{-2}\partial_{x_i} T\partial_{x_j} T|s|^2 + \frac{1}{2}T^{-1}\partial^2_{x_i x_j} T|s|^2, \\
\partial_{p_i} f &= -T^{-1}(p-w)_i = -T^{-1/2}s_i, \\
\partial^2_{p_i x_j} f &= T^{-1}\partial_{x_j} w_i + T^{-2}\partial_{x_j} T(p-w)_i = T^{-1}\partial_{x_j} w_i + T^{-3/2}\partial_{x_j} T s_i, \\
\partial^2_{p_i p_j} f &= -T^{-1}\delta_{ij},
\end{aligned}$$

and the products appearing in the sum (3.14), which are

$$\begin{aligned}
\partial^2_{x_i x_j} f\, \partial^2_{p_i p_j} F &= \big(- T^{-1}\Delta A - T^{-3/2}\Delta w_k + T^{-2}\|\nabla w\|^2 + 2T^{-5/2}\nabla T\cdot\nabla w_k\big)s_k \\
&\quad + \left(\frac{1}{2}T^{-2}\Delta T - T^{-3}|\nabla T|^2\right)|s|^2, \\
\partial^2_{x_i p_j} f\, \partial^2_{p_i x_j} f &= T^{-2}\partial_{x_i} w_j \partial_{x_j} w_i + 2T^{-5/2}\partial_{x_j} T\partial_{x_i} w_j s_i + T^{-3}\partial_{x_i} T\partial_{x_j} T s_i s_j, \\
\partial^2_{x_i x_j} f\, \partial_{p_i} f\, \partial_{p_j} f &= \big(T^{-1}\partial^2_{x_i x_j} A - T^{-2}\partial_{x_i} w_\ell \partial_{x_j} w_\ell\big)s_i s_j \\
&\quad + \big(T^{-3/2}\partial^2_{x_i x_j} w_k - 2T^{-5/2}\partial_{x_i} T\partial_{x_j} w_k\big)s_i s_j s_k \\
&\quad + \left(\frac{1}{2}T^{-2}\partial^2_{x_i x_j} T - T^{-3}\partial_{x_i} T\partial_{x_j} T\right)|s|^2 s_i s_j, \\
\partial^2_{x_i p_j} f\, \partial_{p_i} f\, \partial_{x_j} f &= -T^{-3/2}\partial_{x_\ell} A\partial_{x_i} w_\ell s_i - T^{-2}\partial_{x_i} T\partial_{x_j} A s_i s_j - T^{-2}\partial_{x_i} w_j \partial_{x_j} w_k s_i s_k \\
&\quad - T^{-5/2}\partial_{x_i} T\partial_{x_j} w_k s_i s_j s_k - \frac{1}{2}T^{-5/2}\partial_{x_i} w_j \partial_{x_j} T|s|^2 s_i \\
&\quad - \frac{1}{2}T^{-3}\partial_{x_i} T\partial_{x_j} T|s|^2 s_i s_j, \\
\partial^2_{p_i p_j} f\, \partial_{x_i} f\, \partial_{x_j} f &= -T^{-1}|\nabla A|^2 - 2T^{-3/2}\nabla A\cdot\nabla w_k s_k - T^{-2}\nabla A\cdot\nabla T|s|^2 \\
&\quad - T^{-2}\nabla w_k\cdot\nabla w_\ell s_k s_\ell - T^{-5/2}\nabla T\cdot\nabla w_k|s|^2 s_k - \frac{1}{4}T^{-3}|\nabla T|^2|s|^4.
\end{aligned}$$

Inserting these expressions into (3.14) and simplifying, we arrive at (3.15). ∎

3.3. Expansion of the moments. The aim of this subsection is to specify the integrals $\langle s^\alpha\rangle$ in order to expand the moments n, nu, and e. By Lemma 3.2, we obtain

$$\begin{aligned}
\langle s^\alpha\rangle &= T^{d/2}\int_{\mathbb{R}^d} g(x,s)s^\alpha ds \\
&= T^{d/2}\int_{\mathbb{R}^d} e^{A-|s|^2/2}\left(1-\frac{\varepsilon^2}{8}\mathcal{Q}(s)\right)s^\alpha ds + O(\varepsilon^4) \\
&= (2\pi T)^{d/2}e^A\left([s^\alpha] - \frac{\varepsilon^2}{8}[\mathcal{Q}(s)s^\alpha]\right) + O(\varepsilon^4),
\end{aligned}$$

where $[g]$ denotes the integral of a function $g = g(s)$ against the classical Gaussian kernel,

$$[g] = (2\pi)^{-d/2} \int_{\mathbb{R}^d} e^{-|s|^2/2} g(s) ds.$$

Notice that from the expansion

$$n = \langle 1 \rangle = (2\pi T)^{d/2} e^A \left(1 - \frac{\varepsilon^2}{8} [\mathcal{Q}(s)] \right) + O(\varepsilon^4) \tag{3.16}$$

it follows that

$$\langle s^\alpha \rangle = n \left([s^\alpha] + \frac{\varepsilon^2}{8} \big([\mathcal{Q}(s)][s^\alpha] - [\mathcal{Q}(s) s^\alpha] \big) \right) + O(\varepsilon^4). \tag{3.17}$$

Thus it remains to calculate the integrals $[\mathcal{Q}(s) s^\alpha]$.

Integrals of type $[s^\alpha]$ can be computed explicitly. Using

$$\int_{\mathbb{R}} t^m e^{-t^2/2} dt = \sqrt{2\pi} \times \begin{cases} 0 & \text{if } m \text{ is odd,} \\ 1 & \text{if } m = 0 \text{ or } m = 2, \\ 3 & \text{if } m = 4, \\ 15 & \text{if } m = 6, \end{cases}$$

it becomes a matter of combinatorics to conclude for i, j, m, $n = 1, \ldots, d$,

$$\begin{aligned}
[s_i s_j] &= \delta_{ij}, \\
[|s|^2] &= d, \\
[s_i s_j s_m s_n] &= \delta_{ij}\delta_{mn} + \delta_{im}\delta_{jn} + \delta_{in}\delta_{jm}, \\
[s_i s_j |s|^2] &= (d+2)\delta_{ij}, \\
[|s|^4] &= d(d+2), \\
[s_i s_j s_m s_n |s|^2] &= (d+4)(\delta_{ij}\delta_{mn} + \delta_{im}\delta_{jn} + \delta_{in}\delta_{jm}), \\
[s_m s_n |s|^4] &= (d+2)(d+4)\delta_{mn}.
\end{aligned}$$

Then the expansion of $\mathcal{Q}(s)$, given in (3.15), yields the following formulas:

$$[\mathcal{Q}(s)] = X^0 + \sum_\ell X^2_{\ell\ell} + dY^0 + (d+2) \sum_\ell Y^2_{\ell\ell} + d(d+2) Z^0, \tag{3.18}$$

$$[\mathcal{Q}(s) s_m] = X^1_m + \sum_\ell \left(X^3_{m\ell\ell} + X^3_{\ell m\ell} + X^3_{\ell\ell m} \right) + (d+2) Y^1_m, \tag{3.19}$$

$$\begin{aligned}
[\mathcal{Q}(s) s_m^2] = [\mathcal{Q}(s)] &+ 2X^2_{mm} + 2Y^0 + 2\sum_\ell Y^2_{\ell\ell} + 2(d+4) Y^2_{mm} \\
&+ 4(d+2) Z^0,
\end{aligned} \tag{3.20}$$

$$[\mathcal{Q}(s) s_m s_n] = \left(X^2_{mn} + X^2_{nm} \right) + (d+4) \left(Y^2_{mn} + Y^2_{nm} \right), \tag{3.21}$$

$$\begin{aligned}
[\mathcal{Q}(s)|s|^2 s_m] = (d+2) X^1_m &+ (d+4) \sum_\ell \left(X^3_{m\ell\ell} + X^3_{\ell m\ell} + X^3_{\ell\ell m} \right) \\
&+ (d+2)(d+4) Y^1_m.
\end{aligned} \tag{3.22}$$

LEMMA 3.4. *The moments n, nu, and e can be expressed in terms of the Lagrange multipliers A, w, and T asymptotically as follows:*

$$n = (2\pi T)^{d/2}e^A - \frac{\varepsilon^2}{24T}(2\pi T)^{d/2}e^A\bigg\{ -2\Delta A - |\nabla A|^2 + (d-2)\nabla\log T\cdot\nabla A - (d-1)\Delta\log T - \bigg(\frac{d}{2}-1\bigg)\bigg(\frac{d}{2}-2\bigg) \times|\nabla\log T|^2 + \frac{1}{2T}\mathrm{tr}\,(\widetilde{R}^\top\widetilde{R})\bigg\} + O(\varepsilon^4), \tag{3.23}$$

$$nu = nw + T^{-1}U, \tag{3.24}$$

$$e = \frac{d}{2}nT + \frac{1}{2}n|u|^2 - \frac{\varepsilon^2}{24}n\bigg\{\Delta\log n - \frac{1}{T}\mathrm{tr}\,(\widetilde{R}^\top\widetilde{R}) + \frac{d}{2}|\nabla\log T|^2 - \Delta\log T - \nabla\log T\cdot\nabla\log n\bigg\} + O(\varepsilon^4). \tag{3.25}$$

Notice that (3.23) and (3.24) imply the inverse relations

$$A = \log n - \frac{d}{2}\log T - \frac{d}{2}\log(2\pi) + O(\varepsilon^2), \quad w = u + O(\varepsilon^2). \tag{3.26}$$

In particular, the vorticity matrices $\widetilde{R}$ and R, defined in (1.6), coincide up to order $O(\varepsilon^2)$ since $\widetilde{R}_{ij} = \partial_j u_i - \partial_i u_j + O(\varepsilon^2) = R_{ij} + O(\varepsilon^2)$.

Proof. The formula for the particle density (3.23) is obtained by first substituting the expressions for the coefficients X, Y, and Z into (3.18). This yields $[\mathcal{Q}(s)]$ in terms of A, w, and T. Inserting the result into (3.16) then gives (3.23).

In order to derive (3.24), we write, by the definition of U (see (3.10)),

$$nu = \langle T^{1/2}s + w\rangle = T^{1/2}\langle s\rangle + w\langle 1\rangle = T^{-1}U + nw.$$

Hence, $u - w = U/nT = O(\varepsilon^2)$. The above equations also show that $T^{1/2}w\cdot\langle s\rangle = nu\cdot w - n|w|^2$. Hence, using $\langle 1\rangle = n$,

$$\begin{aligned} e &= \frac{1}{2}\langle|T^{1/2}s + w|^2\rangle = \frac{T}{2}\langle|s|^2\rangle + T^{1/2}w\cdot\langle s\rangle + \frac{1}{2}|w|^2\langle 1\rangle \\ &= \frac{T}{2}\langle|s|^2\rangle + nu\cdot w - \frac{1}{2}n|w|^2 = \frac{T}{2}\langle|s|^2\rangle + \frac{1}{2}n|u|^2 - \frac{1}{2}n|u-w|^2. \end{aligned}$$

In view of (3.26), we have $|u-w|^2 = O(\varepsilon^4)$, from which we conclude

$$e = \frac{T}{2}\langle|s|^2\rangle + \frac{1}{2}n|u|^2 + O(\varepsilon^4).$$

The bracket $\langle|s|^2\rangle$ can be computed from (3.17), employing $[|s|^2] = d$,

$$\langle|s|^2\rangle = dn + \frac{\varepsilon^2}{8}n\sum_m\big([\mathcal{Q}(s)] - [\mathcal{Q}(s)s_m^2]\big) + O(\varepsilon^4).$$

Substitution of (3.18) and (3.20) into the above expression and elimination of A and w, using (3.26), gives $\langle|s|^2\rangle$ in terms of n, nu, and T. This finally leads to (3.25). ∎

3.4. Expansion of the terms P, S, and U. The QHD equations (3.7)–(3.9) are determined by the following expansion of the auxiliary terms P, S, and U, defined in (3.10), in terms of the macroscopic variables n, nu, and e.

LEMMA 3.5. *The following expansion holds:*

$$P = nTI + \frac{\varepsilon^2}{12}n\bigg\{\bigg(\frac{d}{2}+1\bigg)\nabla\log T\otimes\nabla\log T - \nabla\log T\otimes\nabla\log n$$

$$- \nabla\log n\otimes\nabla\log T - (\nabla\otimes\nabla)\log(nT^2) + \frac{R^\top R}{T}\bigg\} \tag{3.27}$$

$$+ \frac{\varepsilon^2}{12}T\mathrm{div}\bigg(n\frac{\nabla\log T}{T}\bigg)I + O(\varepsilon^4),$$

$$S = -\frac{\varepsilon^2}{12}n\bigg\{\bigg(\frac{d}{2}+1\bigg)R\nabla\log\bigg(\frac{n}{T}\bigg) + \bigg(\frac{d}{2}+2\bigg)\mathrm{div}\,R + \frac{3}{2}\Delta u\bigg\} \tag{3.28}$$

$$+ \frac{\varepsilon^2}{12}\bigg(\frac{d}{2}+1\bigg)n\bigg\{R\nabla\log\bigg(\frac{n}{T^2}\bigg) + \mathrm{div}\,R\bigg\} + O(\varepsilon^4). \tag{3.29}$$

Proof. We apply formula (3.17) to obtain for all m, $n = 1,\ldots,d$,

$$P_{mn} = nT\bigg(\delta_{mn} + \frac{\varepsilon^2}{8}(\delta_{mn}[\mathcal{Q}(s)] - [\mathcal{Q}(s)s_m s_n])\bigg),$$
$$S_m = -\frac{\varepsilon^2}{16}nT^{3/2}[\mathcal{Q}(s)|s|^2 s_m] + \frac{\varepsilon^2}{8}\bigg(\frac{d}{2}+1\bigg)nT^{3/2}[\mathcal{Q}(s)s_m].$$

Then the components of P are computed by employing (3.18) and (3.21), substituting the definitions of the coefficients X, Y, and Z, and replacing A and w by n and nu according to (3.26). In a similar way, S is evaluated using (3.19) and (3.22). ∎

3.5. Discussion of the QHD equations. The differences between our QHD equations and Gardner's model can be understood as follows. In both approaches, closure is obtained by assuming that the Wigner function f is in thermal equilibrium. However, the notion of "thermal equilibrium" is different.

In order to illustrate the differences, we recall the classical situation. For a system with the Hamiltonian $h(x,p) = |p|^2/2 + V(x)$, the unconstrained thermal equilibrium distribution is given by the Gibbs measure $f_G(x,p) = \exp(-h(x,p)/T_0)$, which minimizes the relative entropy $S = \int f(\log f - 1 - h/T_0)dp$. Here, T_0 denotes a temperature constant. If mass, momentum, and energy densities are given, the constrained thermal equilibrium is realized by a suitable rescaling and a momentum-shift of the Gibbs state,

$$\widetilde{f}_G(x,p) = n(x)\,\exp\bigg(-\frac{h(x,p-u(x))}{T(x)}\bigg). \tag{3.30}$$

The temperature $T(x)$, which is a Lagrange multiplier coming from the minimization procedure, is determined from the given energy density. The choice of $\widetilde{f}_G$ as a thermal equilibrium function has its physical justification in the fact that it is the unique minimizer of the relative entropy S with the prescribed moments.

Analogously, a quantum system, which is characterized by its energy operator $W^{-1}(h)$ (recall that W^{-1} is the Weyl quantization), attains its minimum of the relative (von Neumann) entropy in the mixed state with Wigner function $f_Q = \exp(-h/T_0)$.

This state represents the unconstrained quantum thermal equilibrium. The expansion of f_Q in terms of the scaled Planck constant ε^2 was first given in [31],

$$f_Q(x,p) = \exp\left(-\frac{h(x,p)}{T_0}\right)(1+\varepsilon^2 f_2(x,p)) + O(\varepsilon^4)$$

with an appropriate function f_2. As a definition of the quantum equilibrium with moment constraints, Gardner employed this expansion of f_Q and modified it as follows:

$$\widetilde{f}_Q(x,p) = n(x)\,\exp\left(-\frac{h(x,p-u(x))}{T(x)}\right)\big(1+\varepsilon^2 f_2(x,p-u(x))\big) + O(\varepsilon^4). \tag{3.31}$$

These modifications mimic the passage from the Gibbs state to (3.30) in the classical situation. The use of $\widetilde{f}_Q$ as an equilibrium function results in simple formulas for the moment equations. However, the Wigner function (3.31) is an ad hoc ansatz. Moreover, in contrast to the classical case, $\widetilde{f}_Q$ is *not* the constrained minimizer for the relative von Neumann entropy.

The equilibrium state M_f used here is a genuine minimizer of the relative quantum entropy with respect to the given moments. In the spirit of the classical situation, these equilibria seem to be more natural. The price we have to pay is the appearance of various additional terms in the expansion of M_f.

If the temperature is assumed to be constant and if only the particle density is prescribed, both approaches to defining a thermal equilibrium coincide. In order to see this, we write Gardner's momentum-shifted quantum equilibrium more explicitly than in (3.31):

$$\widetilde{f}_G(x,p,t) = e^{-V/T-|p|^2/2T}\left\{1+\frac{\varepsilon^2}{8T^2}\left(-\Delta V+\frac{1}{3T}|\nabla V|^2+\frac{1}{3T}p_ip_j\partial_{x_ix_j}V\right)\right\}+O(\varepsilon^4).$$

The equilibrium function obtained from the entropy minimization with given particle density equals (see [21, Remark 3.3])

$$\begin{aligned}\widetilde{f}(x,p,t) &= \exp\left(A(x,t)-\frac{|p|^2}{2T}\right)\\ &= e^{A-|p|^2/2T}\left\{1+\frac{\varepsilon^2}{8T}\left(\Delta A+\frac{1}{3}|\nabla A|^2-\frac{1}{3T}p_ip_j\partial_{x_ix_j}A\right)\right\}+O(\varepsilon^4).\end{aligned}$$

Both approximations are essentially derived in the same way. Using $n=\int \widetilde{f}_Q dp = (2\pi T)^{d/2}e^{-V/T}+O(\varepsilon^2)$ and assuming constant (or "slowly varying") temperature, Gardner has substituted $\nabla V = -T\nabla\log n + O(\varepsilon^2)$ into the formula for $\widetilde{f}_Q$ in order to avoid the second-order derivatives of the potential. This substitution in fact yields the approximation $\widetilde{f}$ since, by (3.26), $\nabla A = \nabla\log n + O(\varepsilon^2)$, and thus, both expansions $\widetilde{f}_Q$ and $\widetilde{f}$ coincide.

4. Simplified QHD models. The full QHD model is given by (3.7)–(3.9) with the constitutive relations (3.27)–(3.29). In this section we will discuss some simplified versions. We recall the QHD equations

$$\partial_t n + \operatorname{div}(nu) = 0, \tag{4.1}$$

$$\partial_t(nu) + \operatorname{div}(nu\otimes u) + \operatorname{div} P - n\nabla V = 0, \tag{4.2}$$

$$\partial_t e + \operatorname{div}\big((P+eI)u\big) + \operatorname{div} S - nu\cdot\nabla V = 0, \tag{4.3}$$

where e is the energy density given by (3.25), and P, S, and U are given by (3.27)–(3.29) (without the $O(\varepsilon^4)$ terms).

First, we shall assume that the temperature is slowly varying in the sense of $\nabla\log T = O(\varepsilon^2)$. Then the expressions $\varepsilon^2\nabla\log T$ in (3.27)–(3.29) are of order $O(\varepsilon^4)$ and can therefore be neglected in our approximation:

$$P = nTI - \frac{\varepsilon^2}{12}n\bigg((\nabla\otimes\nabla)\log n - \frac{R^\top R}{T}\bigg), \tag{4.4}$$

$$S = -\frac{\varepsilon^2}{12}n\bigg\{\bigg(\frac{d}{2}+1\bigg)R\nabla\log n + \bigg(\frac{d}{2}+2\bigg)\operatorname{div}R + \frac{3}{2}\Delta u\bigg\}$$

$$+ \frac{\varepsilon^2}{12}\bigg(\frac{d}{2}+1\bigg)n\bigg\{R\nabla\log n + \operatorname{div}R\bigg\}, \tag{4.5}$$

$$e = \frac{d}{2}nT + \frac{1}{2}n|u|^2 - \frac{\varepsilon^2}{24}n\bigg(\Delta\log n - \frac{1}{T}\operatorname{tr}(R^\top R)\bigg). \tag{4.6}$$

The stress tensor P consists of the classical pressure nT on the diagonal, the "quantum pressure" $(\varepsilon^2/12)n(\nabla\otimes\nabla)\log n$, and the vorticity correction $(\varepsilon^2/12)nR^\top R/T$. The term S provides additional quantum corrections not present in [12]. The energy density consists of the thermal energy, kinetic energy, and quantum energy. Again, due to the vorticity R, the energy takes a different form than the expressions in [12, 16].

Further simplifications can be obtained if the vorticity is "small," i.e., $R = O(\varepsilon^2)$. In one space dimension this term always vanishes. If $R = O(\varepsilon^2)$, then $\varepsilon^2 R$ is of order $O(\varepsilon^4)$ and can be neglected. We obtain the QHD equations

$$\partial_t n + \operatorname{div}(nu) = 0, \tag{4.7}$$

$$\partial_t(nu) + \operatorname{div}(nu\otimes u) + \nabla(nT) - \frac{\varepsilon^2}{12}\operatorname{div}\big(n(\nabla\otimes\nabla)\log n\big) - n\nabla V = 0, \tag{4.8}$$

$$\partial_t e + \operatorname{div}\big((P+eI)u\big) - \frac{\varepsilon^2}{8}\operatorname{div}(n\Delta u) - nu\cdot\nabla V = 0, \tag{4.9}$$

with the stress tensor and energy density, respectively,

$$P = nTI - \frac{\varepsilon^2}{12}n(\nabla\otimes\nabla)\log n, \qquad e = \frac{d}{2}nT + \frac{1}{2}n|u|^2 - \frac{\varepsilon^2}{24}n\Delta\log n.$$

This system of equations corresponds to Gardner's QHD model (without relaxation-time terms) except for the dispersive velocity term $(\varepsilon^2/8)\operatorname{div}(n\Delta u)$. We already mentioned in the introduction that this term has been derived also by Gardner and Ringhofer [16] by employing a Chapman–Enskog expansion of the Wigner–Boltzmann equation. They do not obtain vorticity terms, since they assume that the quantum equilibrium distribution is an even function of the momentum p. Roughly speaking, this gives (in our context) the quantum exponential $\exp(A - |p|^2/2T)$ instead of $\exp(A - |p-w|^2/2T)$. The Lagrange multiplier w, however, is responsible for the presence of the vorticity term R.

Interestingly, most quantum terms cancel out in the energy equation. In fact, by substituting the above expression for the energy density in (4.9), a computation yields

$$\partial_t(nT) + \operatorname{div}(nTu) + \frac{2}{d}nT\operatorname{div}u - \frac{\varepsilon^2}{6d}\operatorname{div}(n\Delta u) = 0.$$

5. Conserved quantities. In this subsection we show that the mass and energy are conserved for the system (3.7)–(3.9) and (1.2) with the relations (3.27)–(3.29), neglecting the $O(\varepsilon^4)$ terms. The momentum is not conserved due to the electric force given by $\int n\nabla V dx$.

LEMMA 5.1. *The mass $N(t) = \int n dx$ and the energy*

$$E(t) = \int_{\mathbb{R}^d} \left(e + \frac{\lambda^2}{2}|\nabla V|^2 \right) dx,$$

where e is defined in (3.25) (*without the $O(\varepsilon^4)$ term*), *are conserved; i.e., $dN/dt(t) = 0$ and $dE(t)/dt = 0$ for all $t > 0$. Furthermore, the energy can be written as*

$$E(t) = \int_{\mathbb{R}^d} \left(\frac{d}{2} nT + \frac{1}{2} n|u|^2 + \frac{\lambda^2}{2}|\nabla V|^2 + \frac{\varepsilon^2}{6}|\nabla\sqrt{n}|^2 + \frac{\varepsilon^2 d}{48} n|\nabla \log T|^2 + \frac{\varepsilon^2}{24T} n \operatorname{tr}(R^\top R) \right) dx \geq 0. \tag{5.1}$$

Proof. The conservation of N is clear. In order to prove that E is conserved, we differentiate E and employ (4.3) and (1.2),

$$\frac{dE}{dt} = \int_{\mathbb{R}^d} (\partial_t e + \lambda^2 \nabla V \cdot \nabla \partial_t V) dx = \int_{\mathbb{R}^d} (nu \cdot \nabla V - \lambda^2 V \partial_t \Delta V) dx$$
$$= \int_{\mathbb{R}^d} (-\operatorname{div}(nu) V - V \partial_t n) dx = 0,$$

taking into account (4.1). Next we prove formula (5.1). The integral of the energy density e can be written as

$$E = \int_{\mathbb{R}^d} \left(\frac{d}{2} nT + \frac{1}{2} n|u|^2 + \frac{\varepsilon^2 d}{48} n|\nabla \log T|^2 + \frac{\varepsilon^2}{24T} n \operatorname{tr}(R^\top R) \right) dx$$
$$+ \frac{\varepsilon^2}{24} \int_{\mathbb{R}^d} \big(- n\Delta \log n + n\Delta \log T + n \nabla \log T \cdot \nabla \log n \big) dx.$$

The last integral equals, after an integration by parts,

$$\frac{\varepsilon^2}{24} \int_{\mathbb{R}^d} \big(4|\nabla\sqrt{n}|^2 - \nabla n \cdot \nabla \log T + n \nabla \log T \cdot \nabla \log n \big) dx = \frac{\varepsilon^2}{6} \int_{\mathbb{R}^d} |\nabla\sqrt{n}|^2 dx,$$

which shows (5.1). ∎

The energy (5.1) consists of, in this order, the thermal energy, the kinetic energy, the electrostatic energy, and the energy of the Bohm potential. The remaining two terms represent additional field quantum energies associated with spatial variations of the temperature and the vorticity. These last two energy terms are new; i.e., they do not appear in the QHD equations of [12].

In the case of the QHD equations with slowly varying temperature, i.e., (4.1)–(4.3) and (1.2) with the definitions (4.4)–(4.5), the energy is given by (5.1) except the term involving $|\nabla \log T|^2$. If, additionally, the vorticity is "small," i.e., in the case of the model (4.7)–(4.9) and (1.2), which is used in the numerical simulations of section 6, the energy is equal to (5.1) except for the last two terms.

Unfortunately, we are not able to prove the conservation of the $O(\varepsilon^4)$ approximation of the quantum entropy and the positivity of the particle density (as for the model in [9]) since we obtain $O(\varepsilon^4)$ correction terms which do not vanish.

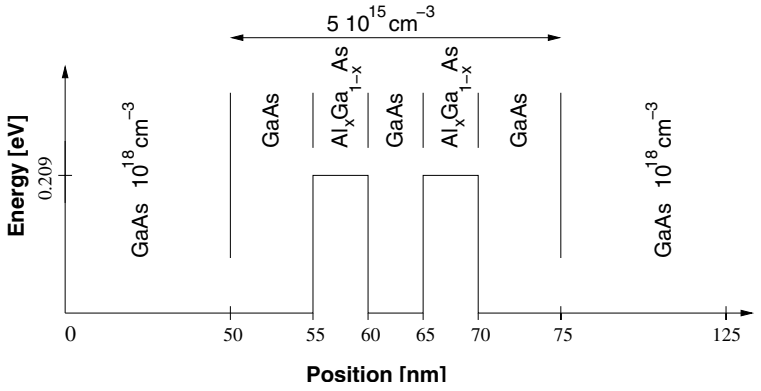

FIG. 6.1. *Geometry of the resonant tunneling diode and external potential modeling the double barriers. The Al mole fraction is* $x = 0.3$.

6. Numerical results. In this section we present the results from our numerical simulations of a simple one-dimensional Gallium arsenide (GaAs) resonant tunneling diode, using the new QHD system. The aim is also to compare the new equations with Gardner's QHD model; in particular, the influence of the dispersive velocity term will be explored.

The geometry of the tunneling diode is chosen essentially as in [12] (see Figure 6.1). The diode consists of highly doped 50 nm GaAs regions near the contacts and a lightly doped middle region (the channel) of 25 nm length. The channel contains a quantum well of 5 nm length, sandwiched between two 5 nm $Al_xGa_{1-x}As$ barriers with Al mole fraction $x = 0.3$. The double barrier heterostructure is placed between two 5 nm GaAs spacer layers. The total length of the device is thus 125 nm. The double barrier height is $B = 0.209\,\mathrm{eV}$. It is incorporated into the QHD equations by replacing V by $V + B$.

For our simulations, we use the one-dimensional stationary QHD equations for small temperature variations $\nabla \log T = O(\varepsilon^2)$ coupled to the Poisson equation for the electric potential. Including the physical parameters, these equations read as follows:

$$(nu)_x = 0, \tag{6.1}$$

$$m(nu^2)_x + k_B(nT)_x - \frac{\hbar^2}{12m}(n(\log n)_{xx})_x - qnV_x = 0, \tag{6.2}$$

$$\frac{5}{2}k_B(nTu)_x + \frac{1}{2}m(nu^3)_x - \frac{\hbar^2}{8m}(nu(\log n)_{xx} + nu_{xx})_x - qnuV_x = k_B\sigma(nT_x)_x, \tag{6.3}$$

$$\varepsilon_s V_{xx} = q(n - C). \tag{6.4}$$

The physical constants in the above equations are the effective mass m, the Boltzmann constant k_B, the reduced Planck constant $\hbar$, the elementary charge q, and the semiconductor permittivity ε_s. The values of these constants are given in Table 6.1. The parameter σ is defined by

$$\sigma = \kappa\tau_0\frac{k_BT_0}{m},$$

with the thermal conductivity κ, the relaxation time τ_0, and the lattice temperature T_0.

TABLE 6.1
Physical parameters for GaAs.

Parameter	Physical meaning	Value
q	Elementary charge	$1.602 \cdot 10^{-19}$ As
m	Eeffective electron mass	$0.067 \cdot m_0$ with $m_0 = 9.11 \cdot 10^{-31}$ kg
k_B	Boltzmann constant	$1.3807 \cdot 10^{-23}$ kg m^2/s^{2}K
$\hbar$	Reduced Planck constant	$1.0546 \cdot 10^{-34}$ kg m^2/s
ε_s	Semiconductor permittivity	$12.9 \cdot 8.8542 \cdot 10^{-12}$ A^{2}s^4/kg m^3
τ_0	Momentum relaxation time	$0.9 \cdot 10^{-12}$ s
T_0	Lattice temperature	77 K

We have allowed the heat flux $k_B\sigma(nT_x)_x$ since this term has also been used by Gardner [12] in his model, with which we wish to compare our numerical results. In fact, we need this term for numerical stability as it is needed in Gardner's QHD equations. We expect that the heat conductivity can be obtained by a Chapman–Enskog expansion of the Wigner–Boltzmann equation, but additional diffusion terms might appear.

Using a standard scaling (see, e.g., [19]), we derive the scaled QHD equations (1.2)–(1.5) of the introduction, where the nondimensional parameters are given by

$$\varepsilon^2 = \frac{\hbar^2}{mk_BT_0L^2}, \qquad \lambda^2 = \frac{\varepsilon_s k_B T_0}{q^2 C^* L^2}.$$

Here, L is the device length and C^* the maximal doping concentration. For the values we used in the numerical simulations below (see Table 6.1), we obtain $\varepsilon^2 \approx 0.011$, which justifies our expansion in ε^2.

We compare the numerical results with Gardner's QHD equations, which do not contain the dispersive expression (1.7) in the velocity but additional relaxation-time terms of Baccarani–Wordeman type [3]:

$$(nu)_x = 0, \tag{6.5}$$

$$m(nu^2)_x + k_B(nT)_x - \frac{\hbar^2}{12m}(n(\log n)_{xx})_x - qnV_x = -\frac{mnu}{\tau_p}, \tag{6.6}$$

$$\begin{aligned}\frac{5}{2}k_B(nTu)_x + \frac{1}{2}m(nu^3)_x - \frac{\hbar^2}{8m}(nu(\log n)_{xx})_x - qnuV_x \\ = k_B\sigma(nT_x)_x - \frac{1}{\tau_w}\left(e - \frac{3}{2}nT_0\right),\end{aligned} \tag{6.7}$$

together with the Poisson equation (6.4). Here, the momentum and energy relaxation times are given by, respectively,

$$\tau_p = \tau_0\frac{T_0}{T}, \qquad \tau_w = \frac{\tau_p}{2}\left(1 + \frac{3T}{mv_s^2}\right),$$

where τ_0 is given in Table 6.1 and $v_s = 2 \cdot 10^7$ cm/s is the saturation velocity. The inclusion of these terms (at least if $\tau_p = \tau_w/2$) can be justified by employing a Caldeira–Leggett scattering operator as exposed in section 3.1. We observed that the relaxation-time terms in Gardner's QHD model are necessary for numerical stability; on the other hand, they lead to severe numerical difficulties when included in the new QHD equations.

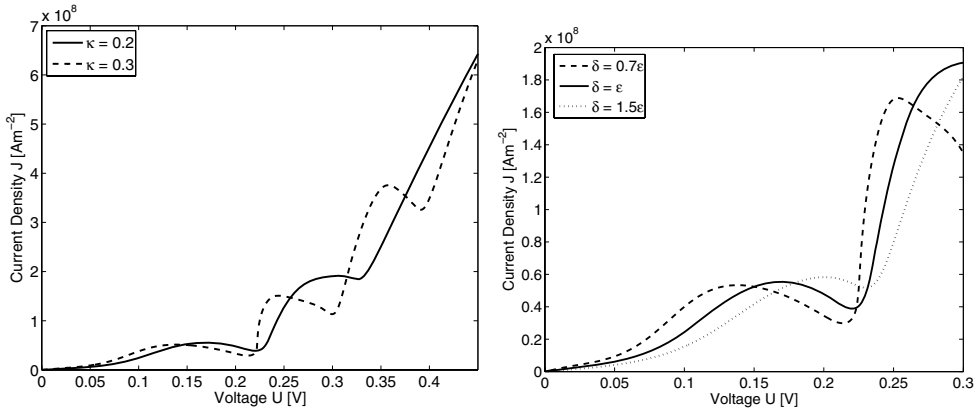

FIG. 6.2. *Left: Current-voltage characteristic for the new QHD system with thermal conductivities* $\kappa = 0.2$ (*solid line*) *and* $\kappa = 0.3$ (*dashed line*). *Right: Influence of the dispersive velocity term* $(\delta^2/8)(nu_{xx})_x$ *on the current-voltage curve for thermal conductivity* $\kappa = 0.2$.

The above QHD equations have to be solved in the interval $(0, 1)$ with the following boundary conditions taken from [12]:

$$n(0) = C(0), \quad n(1) = C(1), \quad n_x(0) = n_x(1) = 0,$$
$$u_x(0) = u_x(1) = 0, \quad T(0) = T(1) = T_0, \quad V(0) = 0, \quad V(1) = U_0,$$

where U_0 is the applied voltage.

First, we discretize the new QHD equations (6.1)–(6.4) using central finite differences on a uniform mesh with $N = 500$ points. This corresponds to a mesh size of $\triangle x = 1/500 = 0.002$. The resulting discrete nonlinear system is solved by a damped Newton method with damping parameter found by a line search method (see Algorithm A6.3.1 in [10]). We employ the following continuation method for the applied voltage: first the system of equations is solved for applied voltage $U_0 = 0\,\mathrm{V}$; then, given the solution corresponding to the voltage U_0, it is taken as an initial guess for the solution of the system with applied voltage $U_0 + \triangle U$. The voltage step is chosen as $\triangle U = 1\,\mathrm{mV}$.

The current-voltage characteristics using the thermal conductivities $\kappa = 0.2$ and $\kappa = 0.3$ are presented in Figure 6.2. There are apparently two regions of negative differential resistance (NDR) if $\kappa = 0.2$, and three NDR regions if $\kappa = 0.3$. It is well known for Gardner's QHD model that the behavior of the solutions is quite sensitive to changes of the value of the thermal conductivity. We observe a similar sensitive dependence: the peak-to-valley ratio, i.e., the ratio of local maximal to local minimal current density, is larger for larger thermal conductivities.

The electron density shows a charge enhancement in the quantum well, which is more pronounced for smaller κ (see Figure 6.3(left)). At the center of the right barrier, the electron density dramatically decreases. After the first valley in the current-voltage characteristics, the density develops a "wiggle." This phenomenon is not a numerical effect, since it has been observed in various numerical simulations [24, 27]. For larger values of the thermal conductivity, the minimum of the particle density increases, which stabilizes the numerical scheme.

Next, we study the influence of the dispersive velocity term $(\varepsilon^2/8)(nu_{xx})_x$. For this, we replace the factor $\varepsilon^2/8$ by $\delta^2/8$ and choose various values for δ. Clearly, only

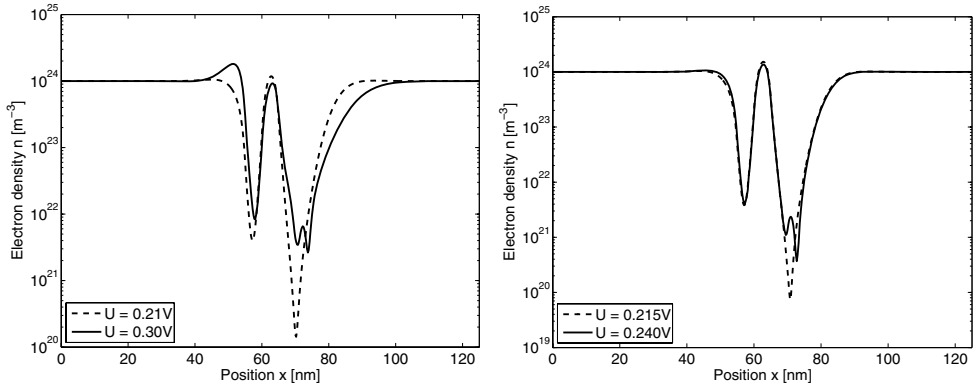

FIG. 6.3. *Electron density before* (*dashed line*) *and after* (*solid line*) *the first valley for thermal conductivities* $\kappa = 0.2$ (*left*) *and* $\kappa = 0.3$ (*right*).

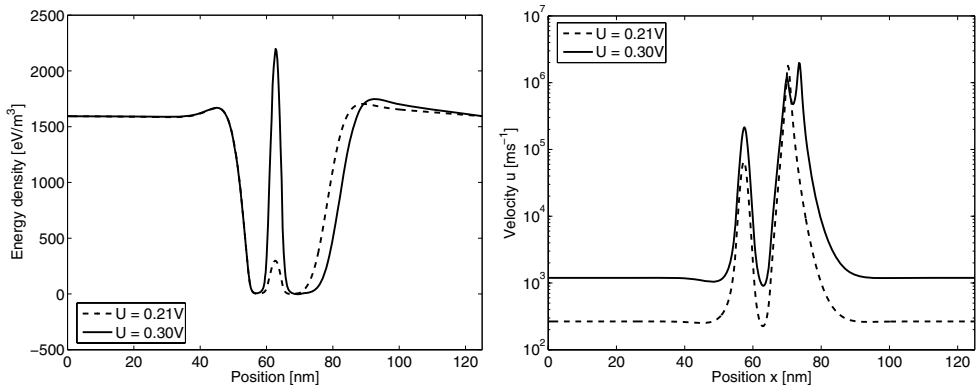

FIG. 6.4. *Thermal energy density* (*left*) *and velocity* (*right*) *before* (*dashed line*) *and after* (*solid line*) *the first valley computed from the new QHD model* (*thermal conductivity* $\kappa = 0.2$).

$\delta = \varepsilon$ corresponds to the physical situation. The dispersive velocity term indeed regularizes the equations in the sense that the current-voltage curves become "smoother" (see Figure 6.3(right)). A similar "smoothing" has been observed in [23, 24] for the viscous QHD equations, but there the smoothing originates from a diffusive and not from a dispersive term. For smaller values of δ, the peak-to-valley ratio of the first NDR region becomes larger. For $\delta = 0$, we arrive at Gardner's QHD equations without relaxation terms. We already mentioned that a central finite-difference discretization fails for this model; therefore, the limit $\delta \to 0$ cannot be done numerically.

In Figure 6.4 the thermal energy density $\frac{3}{2} n k_B T$ and the velocity $u = J/(qn)$ are reported. The velocity profile is very similar to that computed from Gardner's model (see Figure 6.5, $N = 500$). The velocity is high in the barriers and rather small in the well; i.e., the electrons spend more time in the quantum well than in the barriers. On the other hand, the temperature of the new QHD model differs from that obtained by Gardner's QHD model, particularly in the region between the barriers. The heating in the well in our model can probably be explained by the central scheme that we have used. Gardner's upwind scheme involves some numerical diffusion that seems to bring down the thermal energy in the quantum well. We notice that $\nabla \log T$ is *not*

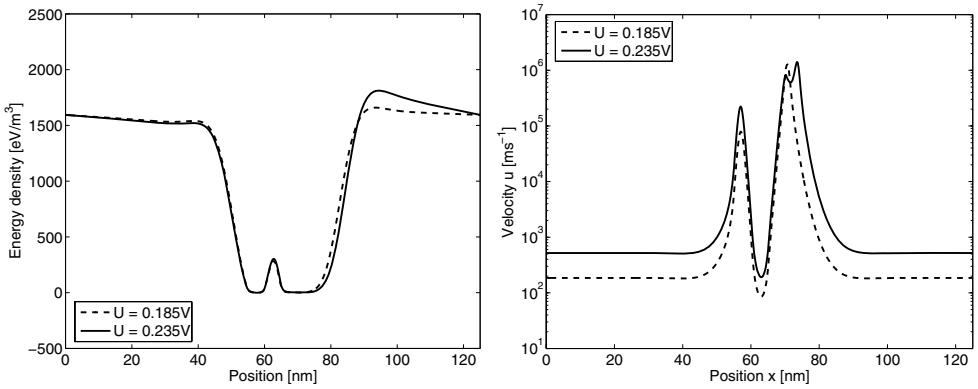

FIG. 6.5. *Thermal energy density (left) and velocity (right) before (dashed line) and after (solid line) the first valley computed from Gardner's QHD model (thermal conductivity $\kappa = 0.2$).*

of order $O(\varepsilon^2)$, as assumed in the derivation of the model, except in the high doped contact regions.

The influence of the effective mass on the current-voltage curves is shown in Figure 6.6(left). Corresponding to the effective masses $m = 0.067m_0$, $m = 0.092m_0$, $m = 0.126m_0$, the peak-to-valley ratios are 1.44, 1.79, 2.37, respectively. Here, m_0 denotes the electron mass at rest. Similarly to the quantum drift-diffusion model, the peak-to-valley ratio increases with the effective mass [22]. Strictly speaking, the effective mass is not constant in the whole device, but it is material-dependent. The use of a nonconstant effective mass would be more physical, but the modeling and the numerical approximation is—even in the much simpler quantum drift-diffusion model—a lot more involved [29, 30].

In Figure 6.6(right) the current-voltage curve for the barrier height $B = 0.3\,\mathrm{eV}$ is shown. As expected, the peak-to-valley ratio is larger if the barrier is higher (corresponding to a higher Al mole fraction); the values for the first NDR region are 1.44 for $B = 0.209\,\mathrm{eV}$ and 2.48 for $B = 0.3\,\mathrm{eV}$. The current densities are much smaller than in Figure 6.2, where the lower potential barrier $B = 0.209\,\mathrm{eV}$ has been used. Interestingly, there are at least three NDR regions, whereas there are only two regions

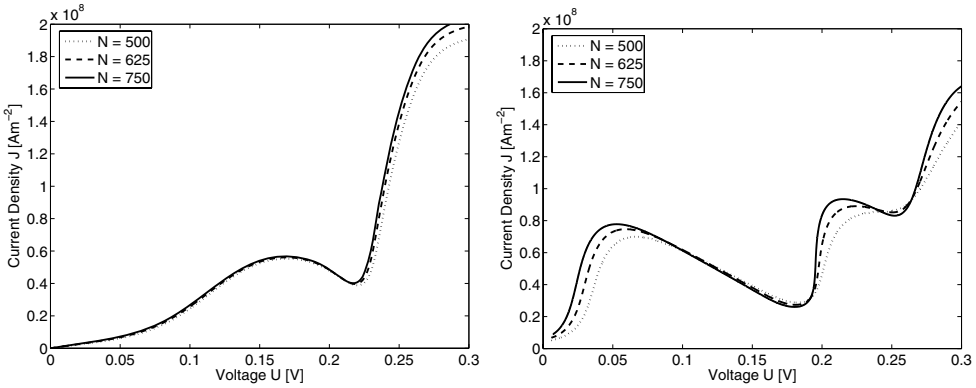

FIG. 6.7. *Influence of the number of discretization points on the current-voltage characteristics for the new QHD equations* (*left, using central finite differences*) *and for Gardner's QHD model* (*right, using an upwind scheme*). *In both pictures,* $\kappa = 0.2$.

for the barrier height $B = 0.209\,\mathrm{eV}$.

In Figure 6.7, the current-voltage curves for the new QHD equations and for Gardner's model are compared. Gardner's model is discretized using a second-order upwind method as in [12]. The right figure with $N = 500$ points corresponds to Figure 2 of the cited paper. Notice that close to thermal equilibrium there are well-known difficulties in computing the solution, which is not the case for our new model. Due to the numerical viscosity introduced by the upwind method, it is clear that the solution of Gardner's model depends on the mesh size. The solution to the new QHD equations is less mesh-dependent. In particular, the numerical results before the first valley are almost the same for $N \geq 500$ grid points. More importantly, the slope of the curve in Gardner's model becomes steeper in the region after the valley when the mesh size $\triangle x$ is decreased. On the other hand, the current-voltage curve of the new QHD model does not seem to develop such singular slopes. Moreover, it is possible to solve the discrete system for grid points $N > 750$ (not shown).

ELECTROSEISMIC PROSPECTING IN LAYERED MEDIA*

BENJAMIN S. WHITE† AND MINYAO ZHOU†

Abstract. Electroseismic (ES) prospecting is an experimental method that seeks to use the conversion of electromagnetic (EM) waves to seismic waves in the earth to explore for oil and gas. The wave conversion occurs through the phenomenon of electrokinetics, for which a complete set of partial differential equations was derived by S. Pride. In this paper, we show how Pride's equations in plane layered media can be written in a convenient mathematical form suggested by B. Ursin, who used this form to give a unified treatment of EM waves, acoustic waves, and the waves of isotropic elasticity in plane layered media. We use Ursin's formalism, which we develop and simplify for the case of a stack of homogeneous layers, to derive explicit formulas that can be made the basis of an efficient computer code. Numerical results are presented for spatially extended electrode sources that have been used in field tests of ES prospecting. More generally, the methods developed are applicable to any system that can be put into Ursin's form. In particular, the code that was written for ES can be modified to compute purely seismic waves, purely EM waves, or the waves of Biot theory, since all these phenomena are included in the equations of electrokinetics when parameters are specialized appropriately.

Key words. electrokinetics, layered media, seismic, electromagnetic, poroelastic

1. Introduction.

In prospecting for oil and gas, seismic methods are the main tool for imaging of the earth's subsurface [4] because of the high spatial resolution that is possible. However, skillful interpretation of the seismic images is necessary to distinguish hydrocarbon- from nonhydrocarbon-saturated rocks, because there are often only subtle differences in the rock properties (e.g., densities and compressibilities) that affect the seismic waves. In contrast, the electrical resistivity of hydrocarbon-saturated rocks is one to three orders of magnitude greater than that of the surrounding medium, making resistivity an excellent direct indicator of hydrocarbons. If the earth's electrical properties could be imaged with the same spatial resolution as is routine in seismic imaging, then many hydrocarbon reservoirs could be easily detected and delineated.

Electromagnetic (EM) exploration methods [14, 25] can be used to map the electrical properties of the subsurface. However, the earth is a conducting medium, so high-frequency EM waves are attenuated rapidly as they propagate in the earth. Thus EM surveys, except for shallow depths, typically rely on lower frequency/longer wavelength waves. Then the spatial resolution of the subsurface images are limited by the long wavelengths of the probes.

Electroseismic (ES) prospecting is an experimental method that seeks to use the conversion of EM waves to seismic waves in the earth to search for hydrocarbons. This wave conversion occurs through the phenomenon of electrokinetics [15], i.e., in a porous medium such as the earth, an EM wave will excite a seismic wave of the same frequency, and vice versa, through movement of ions in the pore fluids. Since EM waves have a much faster propagation speed than seismic, they have much

†ExxonMobil Corporate Strategic Research, Route 22 East, Annandale, NJ 08801 (benjamin.s.white@exxonmobil.com, minyaozhou@yahoo.com).

longer wavelengths than seismic waves of the same frequency. Thus using seismic frequencies some of the energy of a long wavelength EM wave probe will be converted by inhomogeneities in the earth to a shorter wavelength seismic wave, which might then be recorded at the earth's surface. The waves recorded will have information related to the earth's electrical properties, as is shown below.

In this paper we derive the mathematical basis for an efficient computer code for solving Pride's equations [15] of electrokinetics in plane layered media, i.e., earth models in which the material parameters are functions of the depth coordinate only. The resulting code has been implemented and, together with the three-dimensional asymptotic theory of [24], has been used for the planning and interpretation of field tests of ES prospecting. Although the tests are described elsewhere [21, 20, 18, 10, 9, 8], we will show here how the calculations were done for the type of experimental source/receiver configurations used in the field.

Our method is based on a formalism introduced by Ursin [23], who showed how Maxwell's equations for electromagnetism, the equations of acoustics, and the equations of isotropic elasticity all have a similar mathematical structure in layered media when each of these systems is written in an appropriate way. In this paper, we add the equations of electrokinetics to Ursin's list. We develop and simplify Ursin's formalism for the case of a stack of homogeneous layers, that is, when the material parameters are piecewise constant functions of depth. In this case many quantities can be computed with explicit algebraic formulas which can then be made the basis of a fast computer code.

Early field tests of electrokinetic phenomena in the earth were reported in the 1936 paper of Thompson [22]. More recent tests are reported in [19, 3, 12, 13, 5]. All these studies are more properly called "seismoelectric," i.e., seismic waves were used as a source and EM waves were recorded. The tests [21, 20, 18, 10, 9, 8] are "electroseismic," with EM sources and seismic geophones as receivers.

General properties of ES waves, e.g., source-receiver reciprocity, eigenvectors, and Green's functions in homogeneous media, were derived by Pride and Haartsen in [17]. These authors also wrote a computer code that computes electroseismics for point sources in layered media, using the "global matrix method," that is, inverting a large but banded matrix to solve simultaneously for all quantities in all layers [7]. In contrast, our method makes use of Ursin's mathematical structure to solve for reflection and/or transmission matrices at each layer boundary. Our method is closer to that adopted by Garambois and Dietrich [6], who also used reflection and transmission matrices, but in the form proposed by Kennett and Kerry [11]. We feel that although Ursin's formulation is less well known, using it one can make better use of the inherent mathematical structure of the wave problems, including, e.g., explicit formulas for the jumps across interfaces.

The asymptotic theory of [24] is applicable when seismic ray theory is, i.e., when the seismic wavelength is much smaller than any of the geometric scales in the earth model. With this theory, ES calculations can be done for media that are not plane-layered, but have nontrivial three-dimensional geometry. The asymptotic theory can then be used to compute the seismic waves that are converted from an EM wave incident on an interface, that is, a boundary between media whose material parameters differ. Numerical comparisons of that theory with the computer code described here are in [24].

The formulas of the asymptotic theory show that seismic signals are generated by an EM wave incident on an interface, and that a large discontinuity in the electric field is one of the factors that can cause large conversions of EM to seismic energy.

Now EM theory dictates that the normal electric field at an interface suffers a jump discontinuity in proportion to the ratio of electrical resistivities on each side of the interface (ignoring displacement currents, as is usual in EM prospecting [25]). Thus the asymptotic theory suggests that ES prospecting should illuminate the boundaries of hydrocarbon reservoirs—because the high contrast between the resistivity of hydrocarbons and that of the surrounding medium will produce a large discontinuity of the electric field there.

This paper is organized as follows: In section 2 we write Pride's equations in Ursin's form, complete with source terms and boundary conditions. In section 3 we give a self-contained derivation of Ursin's diagonalization method, in the form in which it is subsequently used. In section 4 we derive formulas for propagator matrices, jump matrices, and reflection and transmission matrices for any system that can be put in Ursin form, and in section 5 we couple the results of section 4 with general sources and boundary conditions, giving explicit formulas for Pride's equations. In sections 6 and 7 we look in some detail at seismic and EM sources, respectively, and in section 8 we show numerical results for the type of ES modeling used in our field tests. Conclusions are in section 9 and explicit formulas for eigenvalues and eigenvectors are in the appendices.

2. Pride's equations in layered media. Pride's equations for electrokinetics in a porous medium are [15], at each point $\mathbf{x} = (x_1, x_2, x_3)$ of space,

$$\begin{aligned}
\nabla \times \mathbf{E} &= i\omega\mu\mathbf{H}, \\
\nabla \times \mathbf{H} &= (\sigma - i\epsilon\omega)\mathbf{E} + L(-\nabla p + \omega^2\rho_f\mathbf{u} + \mathbf{f}) + \mathbf{j}, \\
-\omega^2(\rho\mathbf{u} + \rho_f\mathbf{w}) &= \nabla \cdot \tau + \mathbf{F}, \\
-i\omega\mathbf{w} &= L\mathbf{E} + (\kappa/\eta)(-\nabla p + \omega^2\rho_f\mathbf{u} + \mathbf{f}), \\
\tau &= (\lambda\nabla \cdot \mathbf{u} + C\nabla \cdot \mathbf{w})\mathbf{I} + G(\nabla\mathbf{u} + \nabla\mathbf{u}^{\mathbf{T}}), \\
-p &= C\nabla \cdot \mathbf{u} + M\nabla \cdot \mathbf{w}.
\end{aligned} \tag{2.1}$$

In (2.1) a time dependence of $\exp(-i\omega t)$, where ω is frequency, is assumed.

The sources in Pride's equations are the following: $\mathbf{F}$, the imposed force on the solid, $\mathbf{f}$, the imposed force on the pore fluid, and $\mathbf{j}$, the externally applied electrical current.

The following are the quantities to be calculated: $\mathbf{E}$, the electric field, $\mathbf{H}$, the magnetic field, $\mathbf{u}$, the solid displacement, $\mathbf{w}$, the relative fluid displacement, τ, the stress tensor, and p, the pressure in the pore fluid. $\mathbf{I}$ is the 3×3 identity matrix.

The material parameters in Pride's equations are as follows: μ, the magnetic permeability, ϵ, the dielectric constant, λ and G, the Lamé parameters, C and M, the Biot moduli, ρ, the bulk density, ρ_f, the density of the pore fluid, κ, the permeability, η, the pore fluid viscosity, and L, the electrokinetic mobility. It is $L \neq 0$ that couples the EM and mechanical systems. For $L = 0$ the equations reduce to uncoupled systems, with Maxwell's equations governing electromagnetism and Biot's equations governing fluid and solid motion in a porous medium [1, 2, 16].

We will write

$$\bar{\sigma} = \sigma - i\epsilon\omega. \tag{2.2}$$

It is customary in EM prospecting to make the quasi-static approximation [25] that $\sigma \gg \epsilon\omega$ in the subsurface $x_3 > 0$, so that $\bar{\sigma}$ can be replaced by σ there. This approximation is equivalent to ignoring displacement currents in the earth. In the

air, $x_3 < 0$, the conductivity is zero, and the dielectric constant is ϵ_0, so that we have $\bar{\sigma} = -i\epsilon_0\omega$ in the air.

We will also define

$$\begin{aligned} \beta_1 &= [C^2 - M(\lambda + 2G)]^{-1}, \\ \beta_2 &= \left[1 - \frac{\eta}{\kappa}\frac{L^2}{\bar{\sigma}}\right]^{-1}. \end{aligned} \tag{2.3}$$

For material parameters which depend only on the depth coordinate $x_3 = z$ we can take Fourier transforms in the two lateral coordinates x_1, x_2. Let $(k_1, k_2)^T$ be the horizontal wavenumber and let

$$k = \sqrt{k_1^2 + k_2^2}, \quad \gamma = k/\omega \tag{2.4}$$

be the magnitude of the horizontal wavenumber and the horizontal slowness, respectively. Define Fourier transforms

$$\hat{\mathbf{F}}(k_1, k_2, z) \equiv \mathcal{F}[\mathbf{F}] = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{-i(k_1x_1+k_2x_2)}\ \mathbf{F}(x_1, x_2, z)dx_1dx_2, \tag{2.5}$$

with similar expressions for $\hat{\mathbf{f}}, \hat{\mathbf{j}}, \hat{\mathbf{E}}, \hat{\mathbf{H}}, \hat{\mathbf{u}}, \hat{\mathbf{w}}, \hat{\tau}, \hat{p}$. The lateral Fourier transforms are inverted by the usual formulas, e.g.,

$$\mathbf{F}(x_1, x_2, z) \equiv \mathcal{F}^{-1}[\hat{\mathbf{F}}] = \frac{1}{4\pi^2}\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} e^{i(k_1x_1+k_2x_2)}\ \hat{\mathbf{F}}(k_1, k_2, z)dk_1dk_2, \tag{2.6}$$

with similar expressions for the other variables.

To write the equations in Fourier transform space, we first transform the sources to obtain $\hat{\mathbf{F}}, \hat{\mathbf{f}}, \hat{\mathbf{j}}$. Then for each $(k_1, k_2)^T$, plane wave sources of the form $e^{i(k_1x_1+k_2x_2)}\hat{\mathbf{F}}$, $e^{i(k_1x_1+k_2x_2)}\hat{\mathbf{f}}$, $e^{i(k_1x_1+k_2x_2)}\hat{\mathbf{j}}$ will produce plane wave responses with spatial dependence of the form $e^{i(k_1x_1+k_2x_2)}$. The equations are greatly simplified if we rotate to a coordinate system $(\tilde{x}_1, \tilde{x}_2, \tilde{x}_3)^T$ with the first coordinate oriented in the direction of the horizontal wavenumber $(k_1, k_2)^T$, so that all of these plane waves have a spatial dependence of the form $e^{ik\tilde{x}_1}$. Therefore, let

$$\Omega = \begin{bmatrix} \frac{k_1}{k} & \frac{k_2}{k} & 0 \\ -\frac{k_2}{k} & \frac{k_1}{k} & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{2.7}$$

and define

$$\begin{aligned} &\tilde{\mathbf{x}} = \Omega\mathbf{x}, \ \ \tilde{\mathbf{E}} = \Omega\hat{\mathbf{E}}, \ \ \tilde{\mathbf{H}} = \Omega\hat{\mathbf{H}}, \\ &\tilde{\mathbf{u}} = \Omega\hat{\mathbf{u}}, \ \ \tilde{\mathbf{w}} = \Omega\hat{\mathbf{w}}, \ \ \tilde{\tau} = \Omega\hat{\tau}\Omega^{\mathbf{T}}, \ \ \tilde{p} = \hat{p}, \\ &\tilde{\mathbf{F}} = \Omega\hat{\mathbf{F}}, \ \ \tilde{\mathbf{f}} = \Omega\hat{\mathbf{f}}, \ \ \tilde{\mathbf{j}} = \Omega\hat{\mathbf{j}}. \end{aligned} \tag{2.8}$$

A straightforward calculation yields the following form for the equations, since the governing equations (2.1) are invariant under rotations:

Let

$$\dot{\tilde{\mathbf{u}}} = -i\omega\tilde{\mathbf{u}}, \ \ \dot{\tilde{\mathbf{w}}} = -i\omega\tilde{\mathbf{w}} \tag{2.9}$$

be the solid and relative fluid velocities, and let

$$\Phi^{(1)} = \left[\dot{\tilde{u}}_3, \tilde{\tau}_{13}, -\dot{\tilde{w}}_3, \tilde{H}_2, \tilde{\tau}_{33}, \dot{\tilde{u}}_1, \tilde{p}, \tilde{E}_1\right]^{\mathbf{T}},$$
$$\Phi^{(2)} = \left[\dot{\tilde{u}}_2, \tilde{E}_2, \tilde{\tau}_{23}, -\tilde{H}_1\right]^{\mathbf{T}}. \tag{2.10}$$

Define $n_1 = 4$ and $n_2 = 2$. Then the $2n_m$-dimensional vectors $\Phi^{(m)}$, $m = 1, 2$, satisfy uncoupled systems of linear ordinary differential equations of the form suggested by Ursin [23],

$$\frac{d}{dz}\Phi^{(m)} = -i\omega\mathbf{M}^{(m)}\Phi^{(m)} + \mathbf{S}^{(m)}, \quad m = 1, 2, \tag{2.11}$$

where $\mathbf{S}^{(m)}$ are $2n_m$-dimensional source vectors and the $2n_m \times 2n_m$ matrices $\mathbf{M}^{(m)}$ are of the block form

$$\mathbf{M}^{(m)} = \begin{bmatrix} \mathbf{0} & \mathbf{M_1}^{(m)} \\ \mathbf{M_2}^{(m)} & \mathbf{0} \end{bmatrix} \tag{2.12}$$

with symmetric $n_m \times n_m$ submatrices

$$\mathbf{M_1}^{(m)} = \left(\mathbf{M_1}^{(m)}\right)^{\mathbf{T}}, \ \mathbf{M_2}^{(m)} = \left(\mathbf{M_2}^{(m)}\right)^{\mathbf{T}}. \tag{2.13}$$

The $(2n_1 = 8)$-dimensional System 1 is equivalent to what Haartsen and Pride [7] call the PSVTM system, since, as we will see, it contains compressional (P) waves, vertical shear (SV) waves, and transverse magnetic (TM) waves. For this system the submatrices are

(2.14)

$$\mathbf{M_1}^{(1)} = \begin{bmatrix} -\beta_1 M & \beta_1\gamma(C^2 - \lambda M) & -\beta_1 C & 0 \\ \beta_1\gamma(C^2 - \lambda M) & \rho + i\omega\rho_f^2\frac{\kappa}{\eta} - 4\beta_1\gamma^2 G[C^2 - M(\lambda + G)] & 2\beta_1\gamma GC - i\omega\rho_f\gamma\frac{\kappa}{\eta} & \rho_f L \\ -\beta_1 C & 2\beta_1\gamma GC - i\omega\rho_f\gamma\frac{\kappa}{\eta} & -\beta_1(\lambda + 2G) + i\omega\gamma^2\frac{\kappa}{\eta} & -\gamma L \\ 0 & \rho_f L & -\gamma L & \frac{\bar{\sigma}}{i\omega} \end{bmatrix},$$

$$\mathbf{M_2}^{(1)} = \begin{bmatrix} \rho & \gamma & -\rho_f & 0 \\ \gamma & \frac{1}{G} & 0 & 0 \\ -\rho_f & 0 & \frac{-\beta_2\eta}{i\omega\kappa} & \frac{-\beta_2\gamma L\eta}{\kappa\bar{\sigma}} \\ 0 & 0 & \frac{-\beta_2\gamma L\eta}{\kappa\bar{\sigma}} & -\mu - i\frac{\omega\beta_2\gamma^2}{\bar{\sigma}} \end{bmatrix}. \tag{2.15}$$

The corresponding source vector is

$$\mathbf{S}^{(1)} = \left[0, -\tilde{F}_1 - i\omega\rho_f\frac{\kappa}{\eta}\tilde{f}_1, ik\frac{\kappa}{\eta}\tilde{f}_1, -\tilde{j}_1 - L\tilde{f}_1, -\tilde{F}_3, 0, \tilde{f}_3 - \beta_2\frac{L\eta}{\kappa\bar{\sigma}}\tilde{j}_3, -ik\frac{\beta_2}{\bar{\sigma}}\tilde{j}_3\right]^{\mathbf{T}}. \tag{2.16}$$

Once $\Phi^{(1)}$ has been determined, we may also compute the following four variables, which are dependent on System 1 only:

$$\begin{aligned} \tilde{E}_3 &= \beta_2\left(\frac{ik}{\bar{\sigma}}\tilde{H}_2 - \frac{L\eta}{\kappa\bar{\sigma}}\dot{\tilde{w}}_3 - \frac{1}{\bar{\sigma}}\tilde{j}_3\right), \\ \dot{\tilde{w}}_1 &= L\tilde{E}_1 - ik\frac{\kappa}{\eta}\tilde{p} + i\omega\rho_f\frac{\kappa}{\eta}\dot{\tilde{u}}_1 + \frac{\kappa}{\eta}\tilde{f}_1, \\ \tilde{\tau}_{11} &= \beta_1\left(-4\gamma G(C^2 - M[\lambda + G])\dot{\tilde{u}}_1 + (C^2 - \lambda M)\tilde{\tau}_{33} + 2GC\tilde{p}\right), \\ \tilde{\tau}_{22} &= \beta_1\left(-2\gamma G[C^2 - \lambda M]\dot{\tilde{u}}_1 + [C^2 - \lambda M]\tilde{\tau}_{33} + 2GC\tilde{p}\right). \end{aligned} \tag{2.17}$$

The $(2n_2 = 4)$-dimensional System 2 is equivalent to what Haartsen and Pride [7] call the SHTE system, since, as we shall see, it contains shear horizontal (SH) waves and transverse electric (TE) waves. For this system we obtain

$$\mathbf{M_1}^{(2)} = \begin{bmatrix} \frac{1}{G} & 0 \\ 0 & -\mu \end{bmatrix}, \tag{2.18}$$

$$\mathbf{M_2}^{(2)} = \begin{bmatrix} \rho - G\gamma^2 + i\omega\rho_f^2 \frac{\kappa}{\eta} & \rho_f L \\ \rho_f L & \frac{\bar{\sigma}}{i\omega} + \frac{\gamma^2}{\mu} \end{bmatrix}, \tag{2.19}$$

and source vector

$$\mathbf{S}^{(2)} = \left[0, 0, -\tilde{F}_2 - i\omega\rho_f \frac{\kappa}{\eta}\tilde{f}_2, -\tilde{j}_2 - L\tilde{f}_2\right]^{\mathbf{T}}. \tag{2.20}$$

Once $\Phi^{(2)}$ has been determined, we may also compute the following three variables, which are dependent on System 2 only:

$$\begin{aligned} \tilde{H}_3 &= \frac{\gamma}{\mu}\tilde{E}_2, \\ \dot{\tilde{w}}_2 &= L\tilde{E}_2 + i\omega\frac{\kappa}{\eta}\rho_f\dot{\tilde{u}}_2 + \frac{\kappa}{\eta}\tilde{f}_2, \\ \tilde{\tau}_{12} &= -G\gamma\dot{\tilde{u}}_2. \end{aligned} \tag{2.21}$$

To construct an algorithm for a fast computer code, we will restrict the calculations to the case where the material parameters are piecewise constant. Thus it is assumed that the material properties are constant within each layer but change discontinuously as z is varied across a layer boundary which is a horizontal interface. Then (2.11) is satisfied within each layer, where $\mathbf{M}^{(m)}$ is constant. At layer boundaries we apply Pride's interface condition, that $\mathbf{u}, p$, the normal components of $\mathbf{w}$ and τ, and the tangential components of $\mathbf{E}$ and $\mathbf{H}$ are continuous. Then it is seen that the vectors $\Phi^{(m)}$ are continuous across layer boundaries.

It remains to give boundary conditions for Systems 1 and 2 at the earth/air interface at $z = 0$. Applying Pride's interface conditions, we get that the boundary conditions for System 1 are

$$\tilde{\tau}_{13} = \tilde{\tau}_{33} = 0, \quad \tilde{p} = 0, \quad \tilde{H}_2 = -\frac{\epsilon_0}{q_0}\tilde{E}_1 \quad \text{at } z = 0. \tag{2.22}$$

In (2.22) q_0 is the vertical slowness of an EM wave in the air, that is,

$$q_0 = \sqrt{\epsilon_0\mu_0 - \gamma^2}, \tag{2.23}$$

where μ_0 is the magnetic permeability of the air so that $\epsilon_0\mu_0$ is the reciprocal of the square of the speed of light. The last of equations (2.22) is derived from the fact that there are no downgoing waves in the air (all sources are in the subsurface), and this is the relationship for an upgoing EM wave.

The boundary conditions for System 2 are

$$\tilde{\tau}_{23} = 0, \;\; \tilde{H}_1 = \frac{q_0}{\mu_0}\tilde{E}_2 \quad \text{at } z = 0. \tag{2.24}$$

The second of these relationships is again derived as the condition that there are only upgoing EM waves in the air.

Note that (2.22) gives $n_1 = 4$ conditions for System 1, which has $2n_1 = 8$ variables. Similarly, (2.24) gives $n_2 = 2$ conditions for System 2, which has $2n_2 = 4$ variables. Consequently, for each system we will need an additional n_m conditions to completely specify the solution. These relations will come from the requirement that there are no upgoing waves from $z = \infty$. The decomposition into upgoing and downgoing waves in the subsurface will be accomplished in section 4.

3. Ursin diagonalization. For completeness we give a derivation of Ursin's diagonalization procedure [23] in the form that it will be used here. We consider matrices of the form (2.12), where for simplicity we drop the superscript $^{(m)}$.

Assume that $\mathbf{M_1M_2}$ has n distinct nonzero eigenvalues $q_1^2, q_2^2, \ldots, q_n^2$ with associated eigenvectors $\mathbf{a}_1, \mathbf{a_2}, \ldots, \mathbf{a}_n$, i.e.,

$$\mathbf{M_1M_2}\mathbf{a}_m = q_m^2\mathbf{a}_m, \tag{3.1}$$

normalized by the relation

$$\mathbf{a}_m^{\mathbf{T}}\mathbf{M_2}\mathbf{a}_m = q_m, \quad m = 1, \ldots, n. \tag{3.2}$$

Here $q_m = \sqrt{q_m^2}$ with the branch of the square root chosen so that $\mathrm{Im}(q_m) \geq 0$ and $q_m > 0$ if q_m is real. (With this choice, $e^{i\omega q_m z}$ represents a downgoing wave.) We adopt this branch of the square root throughout this paper.

Define

$$\mathbf{b}_m = \frac{1}{q_m}\mathbf{M_2}\mathbf{a}_m. \tag{3.3}$$

$\mathbf{b}_m$ is an eigenvector of $\mathbf{M_2M_1}$, with eigenvalue q_m^2, as can be seen by multiplying (3.3) by $\mathbf{M_2M_1}$ and using (3.1) and (3.3). From (2.13), $\mathbf{b}_m$ is a left eigenvector of $\mathbf{M_1M_2}$.

Now

$$q_m^2\mathbf{a}_j^{\mathbf{T}}\mathbf{b}_m = \mathbf{a}_j^{\mathbf{T}}\mathbf{M_2M_1}\mathbf{b}_m = \mathbf{b}_m^{\mathbf{T}}\mathbf{M_1M_2}\mathbf{a}_j = q_j^2\mathbf{a}_j^{\mathbf{T}}\mathbf{b}_m. \tag{3.4}$$

Therefore $\mathbf{a}_j^{\mathbf{T}}\mathbf{b}_m = 0$ for $j \neq m$. Coupling this with (3.2) and (3.3) we obtain

$$\mathbf{a}_j^{\mathbf{T}}\mathbf{b}_m = \delta_{j,m}. \tag{3.5}$$

Let $\mathbf{L_1}$ be the $n \times n$ matrix whose mth column is $\mathbf{a}_m$, and let $\mathbf{L_2}$ be the $n \times n$ matrix whose mth column is $\mathbf{b}_m$. Then (3.5) implies

$$\mathbf{L_1^{-1}} = \mathbf{L_2^T}, \ \ \mathbf{L_2^{-1}} = \mathbf{L_1^T}. \tag{3.6}$$

Let Λ be the $n \times n$ diagonal matrix with entries

$$\Lambda_{j,m} = q_j\delta_{j,m}. \tag{3.7}$$

Then (3.3) implies

$$\mathbf{L_2}\Lambda = \mathbf{M_2L_1}. \tag{3.8}$$

Multiplication of (3.3) by $\mathbf{M_1}$ and use of (3.1) implies

$$\mathbf{M_1 b}_m = q_m \mathbf{a}_m, \tag{3.9}$$

and so

$$\mathbf{M_1 L_2} = \mathbf{L_1}\Lambda. \tag{3.10}$$

Now (3.10), (3.8), and (3.6) yield

$$\mathbf{M_1} = \mathbf{L_1}\Lambda\mathbf{L_1^T}, \;\; \mathbf{M_2} = \mathbf{L_2}\Lambda\mathbf{L_2^T}. \tag{3.11}$$

Let $\mathbf{L}$ be the $2n \times 2n$ matrix defined in block form by

$$\mathbf{L} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{L_1} & \mathbf{L_1} \\ \mathbf{L_2} & -\mathbf{L_2} \end{bmatrix}, \tag{3.12}$$

and let $\tilde{\Lambda}$ be the diagonal matrix

$$\tilde{\Lambda} = \begin{bmatrix} \Lambda & \mathbf{0} \\ \mathbf{0} & -\Lambda \end{bmatrix}. \tag{3.13}$$

Then from (3.6) and (3.11) it is readily verified that

$$\mathbf{L}^{-1} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{L_2^T} & \mathbf{L_1^T} \\ \mathbf{L_2^T} & -\mathbf{L_1^T} \end{bmatrix} \tag{3.14}$$

and that

$$\mathbf{M} = \mathbf{L}\tilde{\Lambda}\mathbf{L}^{-1}. \tag{3.15}$$

In the appendices we give explicit algebraic formulas for $q_m, \mathbf{a}_m, \mathbf{b}_m$ for Systems 1 and 2 as described in section 2. From these formulas $\mathbf{L_1}, \mathbf{L_2}, \mathbf{L}, \mathbf{L}^{-1}, \Lambda$ can be calculated rapidly.

4. Upgoing and downgoing waves; reflection and transmission matrices. We first consider a homogeneous, source-free region of space. Then dropping the superscript $^{(m)}$ we have a $2n$-dimensional equation of the form (2.11), with (2.12) and (2.13), and with $\mathbf{M}$ constant and $\mathbf{S} = \mathbf{0}$. Let

$$\Phi = \mathbf{L}\Psi. \tag{4.1}$$

Insertion of (4.1) into (2.11) and use of (3.15) yields

$$\frac{d}{dz}\Psi = -i\omega\tilde{\Lambda}\Psi. \tag{4.2}$$

Let

$$\Psi = \begin{bmatrix} \mathbf{U} \\ \mathbf{D} \end{bmatrix}, \tag{4.3}$$

where $\mathbf{U}, \mathbf{D}$ are n-vectors. Then from (4.2), (4.3), and (3.13)

$$\Psi(z) = e^{-i\omega\tilde{\Lambda}(z-z_0)}\Psi(z_0) = \begin{bmatrix} e^{-i\omega\Lambda(z-z_0)} & \mathbf{U}(z_0) \\ e^{i\omega\Lambda(z-z_0)} & \mathbf{D}(z_0) \end{bmatrix}, \tag{4.4}$$

where z_0 is a fixed point in the same source-free region of space as z. Here $e^{\pm i\omega\Lambda(z-z_0)}$ are diagonal matrices with mth diagonal element equal to $e^{\pm i\omega q_m(z-z_0)}$. Therefore $\mathbf{U}$ are upgoing waves and $\mathbf{D}$ are downgoing waves.

Next consider an interface at $z=\bar{z}$, where the material parameters vary discontinuously across $\bar{z}$. We denote by superscript $^+$ quantities evaluated at $\bar{z}^+$, just below the interface, while superscript $^-$ denotes quantities evaluated at $\bar{z}^-$ just above the interface. Since Φ is continuous across $\bar{z}$, we obtain from (4.1) that $\mathbf{L}^+\Psi^+ = \mathbf{L}^-\Psi^-$ and so

$$\Psi^+ = \mathbf{J}\Psi^-, \quad \Psi^- = \mathbf{J}^{-1}\Psi^+, \tag{4.5}$$

where the jump matrix is

$$\mathbf{J} = \left(\mathbf{L}^+\right)^{-1}\mathbf{L}^- = \begin{bmatrix} \mathbf{J_A} & \mathbf{J_B} \\ \mathbf{J_B} & \mathbf{J_A} \end{bmatrix} \tag{4.6}$$

and, from (3.12) and (3.14), $\mathbf{J_A}, \mathbf{J_B}$ are the $n\times n$ matrices

$$\begin{aligned} \mathbf{J_A} &= \frac{1}{2}\Big[\left(\mathbf{L_2^+}\right)^{\mathbf{T}}\mathbf{L_1^-} + \left(\mathbf{L_1^+}\right)^{\mathbf{T}}\mathbf{L_2^-}\Big], \\ \mathbf{J_B} &= \frac{1}{2}\Big[\left(\mathbf{L_2^+}\right)^{\mathbf{T}}\mathbf{L_1^-} - \left(\mathbf{L_1^+}\right)^{\mathbf{T}}\mathbf{L_2^-}\Big]. \end{aligned} \tag{4.7}$$

$\mathbf{J}^{-1}$ can be computed by interchanging the roles of $\pm$. Using this fact in (4.6) and (4.7) yields

$$\mathbf{J}^{-1} = \begin{bmatrix} \mathbf{J_A^T} & -\mathbf{J_B^T} \\ -\mathbf{J_B^T} & \mathbf{J_A^T} \end{bmatrix}. \tag{4.8}$$

Now using that $\mathbf{J}\mathbf{J}^{-1} = \mathbf{J}^{-1}\mathbf{J} = \mathbf{I}$ yields four relations:

$$\mathbf{J_A}\mathbf{J_A^T} - \mathbf{J_B}\mathbf{J_B^T} = \mathbf{I}, \tag{4.9}$$

$$\mathbf{J_A^T}\mathbf{J_A} - \mathbf{J_B^T}\mathbf{J_B} = \mathbf{I}, \tag{4.10}$$

$$\mathbf{J_A}\mathbf{J_B^T} = \mathbf{J_B}\mathbf{J_A^T}, \tag{4.11}$$

$$\mathbf{J_A^T}\mathbf{J_B} = \mathbf{J_B^T}\mathbf{J_A}. \tag{4.12}$$

We next consider a stack of layers, with layer boundaries at the interfaces at depths $0 < z_1 < z_2 < \cdots < z_N < \infty$. Homogeneous, source-free regions are assumed in (z_m, z_{m+1}). We denote by subscript m a quantity at interface z_m, with superscripts $^\pm$ as before. From (4.3) and (4.5),

$$\begin{bmatrix} \mathbf{U}_N^- \\ \mathbf{D}_N^- \end{bmatrix} = \mathbf{J}_N^{-1}\begin{bmatrix} \mathbf{0} \\ \mathbf{D}_N^+ \end{bmatrix}, \tag{4.13}$$

where we have used that there is no upgoing wave below the last interface at $z=z_N$. From (4.8) and (4.13),

$$\begin{aligned} \mathbf{U}_N^- &= \Gamma_N\mathbf{D}_N^-, \\ \mathbf{D}_N^+ &= \mathbf{T}_N\mathbf{D}_N^-, \end{aligned} \tag{4.14}$$

where

$$\begin{aligned} \Gamma_N &= -\big(\mathbf{J}^{\mathbf{T}}_{\mathbf{B},N}\big)\big(\mathbf{J}^{\mathbf{T}}_{\mathbf{A},N}\big)^{-1}, \\ \mathbf{T}_N &= \big(\mathbf{J}^{\mathbf{T}}_{\mathbf{A},N}\big)^{-1}. \end{aligned} \tag{4.15}$$

Here Γ_N is the reflection matrix from a single interface at $z = z_N$ and can be used to compute the reflected wave, i.e., the upgoing wave from the top of the interface, when the incident wave, i.e., the downgoing wave on the top of the interface, is known. Similarly $\mathbf{T}_N$ is the single interface transmission coefficient and can be used to compute the transmitted wave, i.e., the downgoing wave beneath the interface, when the incident wave is known.

Let $j < N$ and define the layer thicknesses

$$\Delta z_m = z_{m+1} - z_m, \quad m = 1, 2, \ldots, N-1. \tag{4.16}$$

Then by jumping across the layer boundary using (4.5) and propagating through the layer using (4.4) we obtain

$$\begin{aligned} \mathbf{U}^-_m &= \mathbf{J}^{\mathbf{T}}_{\mathbf{A},m} e^{i\omega\Lambda_m \Delta z_m} \mathbf{U}^-_{m+1} - \mathbf{J}^{\mathbf{T}}_{\mathbf{B},m} e^{-i\omega\Lambda_m \Delta z_m} \mathbf{D}^-_{m+1}, \\ \mathbf{D}^-_m &= -\mathbf{J}^{\mathbf{T}}_{\mathbf{B},m} e^{i\omega\Lambda_m \Delta z_m} \mathbf{U}^-_{m+1} + \mathbf{J}^{\mathbf{T}}_{\mathbf{A},m} e^{-i\omega\Lambda_m \Delta z_m} \mathbf{D}^-_{m+1}. \end{aligned} \tag{4.17}$$

Define reflection and transmission matrices $\Gamma_m, \mathbf{T}_m$ by the relations that for any incident wave $\mathbf{D}^-_m$ at the top of the stack of layers underlying $z = z_m$

$$\begin{aligned} \mathbf{U}^-_m &= \Gamma_m \mathbf{D}^-_m, \\ \mathbf{D}^+_N &= \mathbf{T}_m \mathbf{D}^-_m. \end{aligned} \tag{4.18}$$

Therefore Γ_m computes the reflected wave from the stack and $\mathbf{T}_m$ computes the transmitted wave below the stack, when the incident wave is known. From (4.17) and (4.18) we obtain by induction

$$\Gamma_m = \big(\mathbf{J}^{\mathbf{T}}_{\mathbf{A},m} \tilde{\Gamma}_{m+1} - \mathbf{J}^{\mathbf{T}}_{\mathbf{B},m}\big)\big(-\mathbf{J}^{\mathbf{T}}_{\mathbf{B},m} \tilde{\Gamma}_{m+1} + \mathbf{J}^{\mathbf{T}}_{\mathbf{A},m}\big)^{-1}, \tag{4.19}$$

$$\mathbf{T}_m = \mathbf{T}_{m+1} e^{i\omega\Lambda_m \Delta z_m} \big(-\mathbf{J}^{\mathbf{T}}_{\mathbf{B},m} \tilde{\Gamma}_{m+1} + \mathbf{J}^{\mathbf{T}}_{\mathbf{A},m}\big)^{-1}, \tag{4.20}$$

where

$$\tilde{\Gamma}_{m+1} = e^{i\omega\Lambda_m \Delta z_m} \Gamma_{m+1} e^{i\omega\Lambda_m \Delta z_m}. \tag{4.21}$$

Now all the reflection and transmission matrices can be computed by recursion using (4.19) and (4.20), starting with (4.15).

Finally, it can be shown that Γ_m is symmetric:

$$\Gamma_m = \Gamma^{\mathbf{T}}_m. \tag{4.22}$$

To see this by induction, first note that Γ_N is symmetric by using (4.11) in (4.15) to obtain that Γ_N is equal to its transpose:

$$\Gamma_N = -\left(\mathbf{J}_{\mathbf{A},N}\right)^{-1}\left(\mathbf{J}_{\mathbf{B},N}\right). \tag{4.23}$$

Next, assume that Γ_{m+1} and therefore $\tilde{\Gamma}_{m+1}$ are symmetric. From (4.9) we obtain for any symmetric $\tilde{\Gamma}$

$$\tilde{\Gamma}\mathbf{J_B}\mathbf{J_B^T} + \mathbf{J_A}\mathbf{J_A^T}\tilde{\Gamma} = \tilde{\Gamma}\mathbf{J_A}\mathbf{J_A^T} + \mathbf{J_B}\mathbf{J_B^T}\tilde{\Gamma}. \tag{4.24}$$

From (4.11) we obtain

$$\tilde{\Gamma}\mathbf{J_B}\mathbf{J_A^T}\tilde{\Gamma} + \mathbf{J_A}\mathbf{J_B^T} = \tilde{\Gamma}\mathbf{J_A}\mathbf{J_B^T}\tilde{\Gamma} + \mathbf{J_B}\mathbf{J_A^T}. \tag{4.25}$$

Subtraction of (4.25) from (4.24) and factoring the result gives

$$\big(-\tilde{\Gamma}\mathbf{J_B} + \mathbf{J_A}\big)\big(\mathbf{J_A^T}\tilde{\Gamma} - \mathbf{J_B^T}\big) = \big(\tilde{\Gamma}\mathbf{J_A} - \mathbf{J_B}\big)\big(- \mathbf{J_B^T}\tilde{\Gamma} + \mathbf{J_A^T}\big). \tag{4.26}$$

Now use of (4.26) in (4.19) gives the alternative recursion formula

$$\Gamma_m = \big(-\tilde{\Gamma}_{m+1}\mathbf{J_{B},}_m + \mathbf{J_{A},}_m\big)^{-1}\big(\tilde{\Gamma}_{m+1}\mathbf{J_{A},}_m - \mathbf{J_{B},}_m\big). \tag{4.27}$$

Comparison of (4.27) with (4.19) gives (4.22).

5. Sources and boundary conditions. We consider a $2n$-dimensional system of type (2.11) with the superscript (m) omitted. Let the source, at a depth z_s, be of the form

$$\mathbf{S} = \mathbf{S_0}\delta(z - z_s) + \mathbf{S_1}\delta'(z - z_s) \tag{5.1}$$

with $\mathbf{S_0}, \mathbf{S_1}$ independent of z. More generally, sources distributed in the depth coordinate may be synthesized by superposition of sources of this type. Let

$$\Phi_\mathbf{0} = \Phi - \mathbf{S_1}\delta(z - z_s). \tag{5.2}$$

Then from (5.1), (5.2), and (2.11),

$$\frac{d}{dz}\Phi_\mathbf{0} = -i\omega\mathbf{M}\Phi_\mathbf{0} + [\mathbf{S_0} - i\omega\mathbf{M}\mathbf{S_1}]\,\delta(z - z_s). \tag{5.3}$$

Let $\mathbf{S_A}, \mathbf{S_B}$ be n-vectors defined so that

$$\begin{bmatrix}\mathbf{S_A}\\ \mathbf{S_B}\end{bmatrix} = i\omega\mathbf{M}\mathbf{S_1} - \mathbf{S_0}. \tag{5.4}$$

Then by integrating (5.3) from just above the source at z_s^- to just below the source at z_s^+, and using (5.2) and (5.4) we obtain the jump condition across the source:

$$\Phi(z_s^-) = \Phi(z_s^+) + \begin{bmatrix}\mathbf{S_A}\\ \mathbf{S_B}\end{bmatrix}. \tag{5.5}$$

We insert a fictitious layer boundary just below the source at $z = z_s^+$ and use the methods of section 4 to compute the reflection matrix $\Gamma_\mathbf{s} \equiv \Gamma(z_s^+)$ from the top of this layer. Note that at z_s^+, $\mathbf{J_A} = \mathbf{I}, \mathbf{J_B} = \mathbf{0}$, since the material properties do not change at z_s. Then the upgoing wave $\mathbf{U_s} \equiv \mathbf{U}(z_s^+)$ is related to the downgoing wave $\mathbf{D_s} \equiv \mathbf{D}(z_s^+)$ there by (4.18), and so

$$\Psi(z_s^+) = \begin{bmatrix}\Gamma_\mathbf{s}\mathbf{D_s}\\ \mathbf{D_s}\end{bmatrix}. \tag{5.6}$$

From (5.6), (5.5), (4.1), and (3.14) we obtain

$$\Psi(z_s^-) = \begin{bmatrix} \Gamma_{\mathbf{s}}\mathbf{D_s} \\ \mathbf{D_s} \end{bmatrix} + \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{L_2^T S_A} + \mathbf{L_1^T S_B} \\ \mathbf{L_2^T S_A} - \mathbf{L_1^T S_B} \end{bmatrix}. \tag{5.7}$$

The expression (5.7) may now be propagated upwards through layers, using (4.4) and jumped upwards across layer boundaries using (4.5) until we reach the earth/air interface at $z = 0+$. Then the n boundary conditions at $z = 0$ can be used to determine the n unknowns $\mathbf{D_s}$. We will write the formulas explicitly for when z_s is in the first subsurface layer, i.e., $0 < z_s < z_1$. In this case

$$\Psi(0^+) = \begin{bmatrix} e^{i\omega\Lambda z_s}\Gamma_{\mathbf{s}}\mathbf{D_s} \\ e^{-i\omega\Lambda z_s}\mathbf{D_s} \end{bmatrix} + \frac{1}{\sqrt{2}} \begin{bmatrix} e^{i\omega\Lambda z_s}\left(\mathbf{L_2^T S_A} + \mathbf{L_1^T S_B}\right) \\ e^{-i\omega\Lambda z_s}\left(\mathbf{L_2^T S_A} - \mathbf{L_1^T S_B}\right) \end{bmatrix}. \tag{5.8}$$

We next write

$$\Phi(0^+) = \begin{bmatrix} \mathbf{G_A}\Phi_{\mathbf{g}} \\ \mathbf{G_B}\Phi_{\mathbf{g}} \end{bmatrix}, \tag{5.9}$$

where $\Phi_{\mathbf{g}}$ is an n-vector of unknowns at $z = 0$ and $\mathbf{G_A}, \mathbf{G_B}$ are $n \times n$ matrices.

For System 1, let

$$\Phi_{\mathbf{g}}{}^{(1)} = \left[\dot{\tilde{u}}_3, -\dot{\tilde{w}}_3, \dot{\tilde{u}}_1, \tilde{E}_1\right]^{\mathbf{T}}_{z=0^+},$$

$$\mathbf{G_A}{}^{(1)} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & -\frac{\epsilon_0}{q_0} \end{bmatrix}, \tag{5.10}$$

$$\mathbf{G_B}{}^{(1)} = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

Then it may be checked that (5.9) holds for System 1 with the boundary conditions given by (2.22).

For System 2 let

$$\Phi_{\mathbf{g}}{}^{(2)} = \left[\dot{\tilde{u}}_2, \tilde{E}_2\right]^{\mathbf{T}}_{z=0^+},$$

$$\mathbf{G_A}{}^{(2)} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}, \tag{5.11}$$

$$\mathbf{G_B}{}^{(2)} = \begin{bmatrix} 0 & 0 \\ 0 & -\frac{q_0}{\mu_0} \end{bmatrix}.$$

Then it may be checked that (5.9) holds for System 2 with the boundary conditions given by (2.24).

Now using (4.1) we may combine equations (5.8) and (5.9) to get

$$\begin{aligned} \Phi_{\mathbf{g}} = &\left[e^{i\omega\Lambda z_s}\Gamma_{\mathbf{s}}e^{i\omega\Lambda z_s}\left(\mathbf{L_2^T G_A} - \mathbf{L_1^T G_B}\right) - \left(\mathbf{L_2^T G_A} + \mathbf{L_1^T G_B}\right)\right]^{-1} \\ &\times e^{i\omega\Lambda z_s}\left[\Gamma_{\mathbf{s}}\left(\mathbf{L_2^T S_A} - \mathbf{L_1^T S_B}\right) - \left(\mathbf{L_2^T S_A} + \mathbf{L_1^T S_B}\right)\right], \end{aligned} \tag{5.12}$$

$$\mathbf{D_s} = \frac{1}{\sqrt{2}} e^{i\omega\Lambda z_s} \left(\mathbf{L_2^T G_A} - \mathbf{L_1^T G_B}\right) \Phi_\mathbf{g} - \frac{1}{\sqrt{2}} \left(\mathbf{L_2^T S_A} - \mathbf{L_1^T S_B}\right). \tag{5.13}$$

In particular, when the source is just below the surface we get

$$\begin{aligned} \Phi_\mathbf{g} = &\left[(\Gamma_\mathbf{s} - \mathbf{I})\mathbf{L_2^T G_A} - (\Gamma_\mathbf{s} + \mathbf{I})\mathbf{L_1^T G_B}\right]^{-1} \\ &\times \left[(\Gamma_\mathbf{s} - \mathbf{I})\mathbf{L_2^T S_A} - (\Gamma_\mathbf{s} + \mathbf{I})\mathbf{L_1^T S_B}\right] \quad \text{as } z_s \downarrow 0. \end{aligned} \tag{5.14}$$

$\Phi_\mathbf{g}$ gives all of Φ at the surface $z = 0$, and $\mathbf{D_s}, \mathbf{U_s} = \Gamma_\mathbf{s}\mathbf{D_s}$ give all of Φ just below the source. Now Φ can theoretically be computed anywhere else in space by propagating through layers using (4.4) and jumping across the layer boundaries using (4.5). However, propagation of an upward-going wave in the downward direction is unstable numerically using (4.4), because the complex exponentials grow rather than decay with distance. So numerically, one must obtain $\mathbf{U}$ from $\mathbf{D}$ using Γ_m, or make use of the transmission matrices $\mathbf{T}_m$.

From the tilde variables, the lateral Fourier transforms, i.e., the hat variables, can be computed by inverting the rotation in (2.8) via the formulas

$$\begin{aligned} &\hat{\mathbf{E}} = \Omega^\mathbf{T}\tilde{\mathbf{E}}, \;\; \hat{\mathbf{H}} = \Omega^\mathbf{T}\tilde{\mathbf{H}}, \\ &\hat{\mathbf{u}} = \Omega^\mathbf{T}\tilde{\mathbf{u}}, \;\; \hat{\mathbf{w}} = \Omega^\mathbf{T}\tilde{\mathbf{w}}, \\ &\hat{\tau} = \Omega^\mathbf{T}\tilde{\tau}\Omega, \;\; \hat{p} = \tilde{p}. \end{aligned} \tag{5.15}$$

It remains to invert the lateral Fourier transforms via (2.6) to get the solution in real space. Note that the matrices for Systems 1 and 2 depend only on the magnitude, k (or equivalently the slowness γ), of the vector $(k_1, k_2)^T$ and not on its direction. However, factors of k_1 and k_2 are introduced by the transformation (5.15) and possibly by the directionality of the source. For any function $\hat{g}(k)$ let

$$\Theta_{m_1,m_2} \equiv \mathcal{F}^{-1}\left[k_1^{m_1} k_2^{m_2} \hat{g}(k)\right] = (-i)^{m_1+m_2} \left(\frac{\partial}{\partial x_1}\right)^{m_1} \left(\frac{\partial}{\partial x_2}\right)^{m_2} \mathcal{F}^{-1}\left[\hat{g}(k)\right]. \tag{5.16}$$

In cylindrical coordinates $x_1 = r\cos\theta, x_2 = r\sin\theta, x_3 = z$ these quantities may be computed as Hankel transforms. Let J_m be the Bessel functions, and for nonnegative integers m_1, m_2 let

$$\mathcal{B}_{m_1,m_2}[\hat{g}] = \frac{1}{2\pi} \int_0^\infty k^{m_1} J_{m_2}(kr)\hat{g}(k)dk. \tag{5.17}$$

Then, in particular,

$$\begin{aligned} &\Theta_{0,0} = \mathcal{B}_{1,0}, \;\; \Theta_{1,0} = i\cos\theta\mathcal{B}_{2,1}, \;\; \Theta_{0,1} = i\sin\theta\mathcal{B}_{2,1}, \\ &\Theta_{1,1} = \sin\theta\cos\theta\left[\mathcal{B}_{3,0} - \frac{2}{r}\mathcal{B}_{2,1}\right], \;\; \Theta_{2,0} = \cos^2\theta\mathcal{B}_{3,0} - \frac{\left(\cos^2\theta - \sin^2\theta\right)}{r}\mathcal{B}_{2,1}, \\ &\Theta_{0,2} = \sin^2\theta\mathcal{B}_{3,0} + \frac{\left(\cos^2\theta - \sin^2\theta\right)}{r}\mathcal{B}_{2,1}. \end{aligned} \tag{5.18}$$

6. Dynamite; hammer, weight drop, and vibroseis. For a dynamite source we take the imposed forces on the solid and the fluid to be

$$\mathbf{F}(\mathbf{x}) = \mathbf{f}(\mathbf{x}) = -\hat{h}(\omega)\nabla\delta(\mathbf{x} - \mathbf{x}_s), \tag{6.1}$$

where the position of the dynamite charge is $\mathbf{x}_s = (0, 0, z_s)^T$ and $\hat{h}(\omega)$ is the spectrum of the seismic moment $h(t)$. There are no externally applied electrical currents, so $\mathbf{j} = \mathbf{0}$. Lateral Fourier transform via (2.5) yields

$$\hat{\mathbf{F}}(k_1, k_2, z) = \hat{\mathbf{f}}(k_1, k_2, z) = -\hat{h}(\omega) \begin{bmatrix} ik_1\delta(z - z_s) \\ ik_2\delta(z - z_s) \\ \delta'(z - z_s) \end{bmatrix}, \tag{6.2}$$

and rotation by Ω via (2.8) yields

$$\tilde{\mathbf{F}}(k_1, k_2, z) = \tilde{\mathbf{f}}(k_1, k_2, z) = -\hat{h}(\omega) \begin{bmatrix} ik\delta(z - z_s) \\ 0 \\ \delta'(z - z_s) \end{bmatrix}. \tag{6.3}$$

Substitution of (6.3) into (2.16) yields the source for System 1, in the form (5.1), with

$$\begin{aligned} \mathbf{S_0}^{(1)} &= \hat{h}(\omega) \left[0, ik\left(1 + i\omega\rho_f \frac{\kappa}{\eta}\right), k^2 \frac{\kappa}{\eta}, ikL, 0, 0, 0, 0\right]^T, \\ \mathbf{S_1}^{(1)} &= \hat{h}(\omega) \left[0, 0, 0, 0, 1, 0, -1, 0\right]^T. \end{aligned} \tag{6.4}$$

Substitution of (6.3) into (2.20) shows that the source for System 2 is identically zero, and so all variables associated with System 2 are zero. This is to be expected because System 2 contains SH waves, which are not excited by dynamite.

Substitution of (6.4) into (5.4) gives

$$\begin{aligned} \mathbf{S_A}^{(1)} &= i\beta_1 \hat{h}(\omega) \left[\omega(C - M), 2kG(M - C), \omega(\lambda + 2G - C), 0\right]^T, \\ \mathbf{S_B}^{(1)} &= \mathbf{0}. \end{aligned} \tag{6.5}$$

Now (6.5) may be used in (5.12) and (5.13), or in (5.14) for a shallow source, to get all the tilde variables.

To invert the rotation Ω, using (5.15), note that from (2.10) and (2.21) and the vanishing of System 2, the following variables are identically zero: $\dot{\tilde{u}}_2, \tilde{E}_2, \tilde{\tau}_{23}, \tilde{H}_1, \tilde{H}_3$, $\dot{\tilde{w}}_2, \tilde{\tau}_{12}$. Furthermore, all the remaining tilde variables are functions of k alone, not k_1, k_2 individually. Therefore

$$\begin{aligned} \dot{\hat{u}}_1 &= \frac{k_1}{k} \dot{\tilde{u}}_1, \quad \hat{E}_1 = \frac{k_1}{k} \tilde{E}_1, \quad \hat{H}_1 = -\frac{k_2}{k} \tilde{H}_2, \\ \dot{\hat{u}}_2 &= \frac{k_2}{k} \dot{\tilde{u}}_1, \quad \hat{E}_2 = \frac{k_2}{k} \tilde{E}_1, \quad \hat{H}_2 = \frac{k_1}{k} \tilde{H}_2, \\ \dot{\hat{u}}_3 &= \dot{\tilde{u}}_3, \qquad \hat{E}_3 = \tilde{E}_3, \qquad \hat{H}_3 = 0, \end{aligned} \tag{6.6}$$

and so the transforms can be inverted in cylindrical coordinates (r, θ, z) using (5.16)–(5.18):

$$\begin{aligned} \dot{\mathbf{u}} &= \left(i\mathcal{B}_{1,1}\left[\dot{\tilde{u}}_1\right]\right) \mathbf{e_r} + \left(\mathcal{B}_{1,0}\left[\dot{\tilde{u}}_3\right]\right) \mathbf{e_z}, \\ \mathbf{E} &= \left(i\mathcal{B}_{1,1}\left[\tilde{E}_1\right]\right) \mathbf{e_r} + \left(\mathcal{B}_{1,0}\left[\tilde{E}_3\right]\right) \mathbf{e_z}, \\ \mathbf{H} &= \left(i\mathcal{B}_{1,1}\left[\tilde{H}_2\right]\right) \mathbf{e}_\theta. \end{aligned} \tag{6.7}$$

Here $\mathbf{e_r}, \mathbf{e}_\theta, \mathbf{e_z}$ are unit vectors in the r, θ, z coordinate directions, respectively.

The stress tensor may be inverted similarly. For the stresses, we get from (5.15)

$$
\begin{aligned}
&\hat{\tau}_{11} = \frac{1}{k^2}\left[k_1^2\tilde{\tau}_{11} + k_2^2\tilde{\tau}_{22}\right], \quad \hat{\tau}_{12} = \frac{k_1k_2}{k^2}\left[\tilde{\tau}_{11} - \tilde{\tau}_{22}\right], \\
&\hat{\tau}_{22} = \frac{1}{k^2}\left[k_2^2\tilde{\tau}_{11} + k_1^2\tilde{\tau}_{22}\right], \\
&\hat{\tau}_{13} = \frac{k_1\tilde{\tau}_{13}}{k}, \quad \hat{\tau}_{23} = \frac{k_2\tilde{\tau}_{13}}{k}, \quad \hat{\tau}_{33} = \tilde{\tau}_{33},
\end{aligned} \tag{6.8}
$$

and so the inverse Fourier transforms to real space are

$$
\begin{aligned}
&\tau_{11} = \Theta_{2,0}\left[\frac{1}{k^2}\tilde{\tau}_{11}\right] + \Theta_{0,2}\left[\frac{1}{k^2}\tilde{\tau}_{22}\right], \quad \tau_{12} = \Theta_{1,1}\left[\frac{1}{k^2}\left(\tilde{\tau}_{11} - \tilde{\tau}_{22}\right)\right], \\
&\tau_{22} = \Theta_{0,2}\left[\frac{1}{k^2}\tilde{\tau}_{11}\right] + \Theta_{2,0}\left[\frac{1}{k^2}\tilde{\tau}_{22}\right], \quad \tau_{13} = \Theta_{1,0}\left[\frac{\tilde{\tau}_{13}}{k}\right], \\
&\tau_{23} = \Theta_{0,1}\left[\frac{\tilde{\tau}_{13}}{k}\right], \quad \tau_{33} = \Theta_{0,0}\left[\tilde{\tau}_{33}\right].
\end{aligned} \tag{6.9}
$$

These stresses may now be computed in cylindrical coordinates from (5.18) using Hankel transforms of the appropriate tilde variables.

We next consider a source which is a vertical point force acting on the earth's surface. This models hammer, weight drop, and vibroseis (a shaking truck) sources [4]. Thus we take

$$
\mathbf{F} = \mathbf{f} = \left[0, 0, \hat{h}(\omega)\right]^T \delta(x_1)\delta(x_2)\delta(x_3 - z_s), \tag{6.10}
$$

where $\hat{h}(\omega)$ is the spectrum of the force and $z_s \downarrow 0$ puts the force on the earth's surface. By lateral Fourier transform and rotation by Ω we get

$$
\hat{\mathbf{F}} = \hat{\mathbf{f}} = \tilde{\mathbf{F}} = \tilde{\mathbf{f}} = \left[0, 0, \hat{h}(\omega)\right]^T \delta(z - z_s). \tag{6.11}
$$

From (2.16) we obtain

$$
\mathbf{S}^{(1)} = [0, 0, 0, 0, -1, 0, 1, 0]^T \hat{h}(\omega)\delta(z - z_s). \tag{6.12}
$$

From (2.20) we obtain

$$
\mathbf{S}^{(2)} = \mathbf{0}. \tag{6.13}
$$

Therefore all variables in System 2 are zero, as was the case for dynamite.

From (5.1), (6.12), and (5.4) we obtain

$$
{\mathbf{S}_\mathbf{A}}^{(1)} = \mathbf{0}, \quad {\mathbf{S}_\mathbf{B}}^{(1)} = [1, 0, -1, 0]^T \hat{h}(\omega). \tag{6.14}
$$

Now all the tilde variables at the earth's surface may be computed from equation (5.14) as $z_s \downarrow 0$ and propagated anywhere else in space. Note that ${\mathbf{S}_\mathbf{A}}^{(1)}, {\mathbf{S}_\mathbf{B}}^{(1)}$ are independent of k_1, k_2, so that the tilde variables depend only on k and not on wavenumber direction. Therefore, as for dynamite we can transform to the hat variables using (6.6) and (6.8) and transform back to real space using (6.7) and (6.9).

7. Source currents in a plane. We consider a distribution of horizontal source currents in the source plane $z = z_s$. Because of linearity and horizontal translation invariance, we need only consider a horizontal point dipole at $\mathbf{x} = (0, 0, z_s)^T$, with source current

$$\mathbf{j} = \mathbf{d}\ \delta(x_1)\delta(x_2)\delta(x_3 - z_s), \tag{7.1}$$

where

$$\mathbf{d} = (d_1, d_2, 0)^T. \tag{7.2}$$

Solutions for other horizontal sources in the plane $z = z_s$ can be synthesized by translation and superposition of sources of this type. Then by taking Fourier transforms and rotating via (2.5) and (2.8) we obtain

$$\tilde{\mathbf{j}} = \tilde{\mathbf{d}}\ \delta(z - z_s), \tag{7.3}$$

where

$$\begin{aligned} \tilde{d}_1 &= (k_1 d_1 + k_2 d_2)/k, \\ \tilde{d}_2 &= (-k_2 d_1 + k_1 d_2)/k, \\ \tilde{d}_3 &= 0. \end{aligned} \tag{7.4}$$

From (2.16) and (2.20) we obtain

$$\mathbf{S}^{(1)} = \tilde{d}_1 \bar{\mathbf{S}}^{(1)},\ \ \mathbf{S}^{(2)} = \tilde{d}_2 \bar{\mathbf{S}}^{(2)}, \tag{7.5}$$

where

$$\begin{aligned} \bar{\mathbf{S}}^{(1)} &= [0, 0, 0, -1, 0, 0, 0, 0]^T\ \ \delta(z - z_s), \\ \bar{\mathbf{S}}^{(2)} &= [0, 0, 0, -1]^T\ \ \delta(z - z_s). \end{aligned} \tag{7.6}$$

Let $\bar{\Phi}^{(1)}$ be the solution of System 1 with source $\bar{\mathbf{S}}^{(1)}$, i.e., with

$$\bar{\mathbf{S}}^{(1)}_{\mathbf{A}} = [0, 0, 0, 1]^T, \quad \bar{\mathbf{S}}^{(1)}_{\mathbf{B}} = \mathbf{0}, \tag{7.7}$$

and let $\bar{\Phi}^{(2)}$ be the solution of System 2 with source $\bar{\mathbf{S}}^{(2)}$, i.e., with

$$\bar{\mathbf{S}}^{(2)}_{\mathbf{A}} = \mathbf{0}, \quad \bar{\mathbf{S}}^{(2)}_{\mathbf{B}} = [0, 1]^T. \tag{7.8}$$

Then by linearity

$$\Phi^{(1)} = \tilde{d}_1 \bar{\Phi}^{(1)}, \quad \Phi^{(2)} = \tilde{d}_2 \bar{\Phi}^{(2)}. \tag{7.9}$$

Note that $\bar{\Phi}^{(1)}, \bar{\Phi}^{(2)}$ depend on k but not on k_1, k_2 individually. We denote the elements of these vectors, analogous to (2.10), as

$$\begin{aligned} \bar{\Phi}^{(1)} &= \left[\dot{\bar{u}}_3, \bar{\tau}_{13}, -\dot{\bar{w}}_3, \bar{H}_2, \bar{\tau}_{33}, \dot{\bar{u}}_1, \bar{p}, \bar{E}_1\right]^{\mathbf{T}}, \\ \Phi^{(2)} &= \left[\dot{\bar{u}}_2, \bar{E}_2, \bar{\tau}_{23}, -\bar{H}_1\right]^{\mathbf{T}} \end{aligned} \tag{7.10}$$

and define the corresponding auxiliary variables for System 1 with normalized sources analogously to equations (2.17), e.g.,

$$\bar{E}_3 = \beta_2 \left(\frac{ik}{\bar{\sigma}} \bar{H}_2 - \frac{L\eta}{\kappa\bar{\sigma}} \dot{\bar{w}}_3 \right), \tag{7.11}$$

and the auxiliary variables for the normalized System 2 analogously to equations (2.21), e.g.,

$$\bar{H}_3 = \frac{\gamma}{\mu}\bar{E}_2. \tag{7.12}$$

Since $\dot{\tilde{u}}_1, \dot{\tilde{u}}_3$ are in System 1, while $\dot{\tilde{u}}_2$ is in System 2,

$$\dot{\tilde{u}}_1 = \tilde{d}_1\dot{\bar{u}}_1, \quad \dot{\tilde{u}}_2 = \tilde{d}_2\dot{\bar{u}}_2, \quad \dot{\tilde{u}}_3 = \tilde{d}_1\dot{\bar{u}}_3. \tag{7.13}$$

Therefore, using (7.13), (7.4), and (5.15),

$$\begin{aligned}
\dot{\hat{u}}_1 &= (d_1k_1^2 + d_2k_1k_2)\frac{\dot{\bar{u}}_1(k,z)}{k^2} + (d_1k_2^2 - d_2k_1k_2)\frac{\dot{\bar{u}}_2(k,z)}{k^2},\\
\dot{\hat{u}}_2 &= (d_1k_1k_2 + d_2k_2^2)\frac{\dot{\bar{u}}_1(k,z)}{k^2} + (-d_1k_1k_2 + d_2k_1^2)\frac{\dot{\bar{u}}_2(k,z)}{k^2},\\
\dot{\hat{u}}_3 &= (d_1k_1 + d_2k_2)\frac{\dot{\bar{u}}_3(k,z)}{k}.
\end{aligned} \tag{7.14}$$

Inverting the Fourier transforms via (5.16) gives $\dot{\mathbf{u}}$ in real space:

$$\begin{aligned}
\dot{u}_1 &= d_1\Theta_{2,0}\left[\frac{\dot{\bar{u}}_1}{k^2}\right] + d_2\Theta_{1,1}\left[\frac{\dot{\bar{u}}_1}{k^2}\right] + d_1\Theta_{0,2}\left[\frac{\dot{\bar{u}}_2}{k^2}\right] - d_2\Theta_{1,1}\left[\frac{\dot{\bar{u}}_2}{k^2}\right],\\
\dot{u}_2 &= d_1\Theta_{1,1}\left[\frac{\dot{\bar{u}}_1}{k^2}\right] + d_2\Theta_{0,2}\left[\frac{\dot{\bar{u}}_1}{k^2}\right] - d_1\Theta_{1,1}\left[\frac{\dot{\bar{u}}_2}{k^2}\right] + d_2\Theta_{2,0}\left[\frac{\dot{\bar{u}}_2}{k^2}\right],\\
\dot{u}_3 &= d_1\Theta_{1,0}\left[\frac{\dot{\bar{u}}_3}{k}\right] + d_2\Theta_{0,1}\left[\frac{\dot{\bar{u}}_3}{k}\right].
\end{aligned} \tag{7.15}$$

Now $\dot{\mathbf{u}}$ can be written in cylindrical coordinates using the Hankel transform relations (5.18).

Next, note that $\tilde{E}_1$ is in System 1, $\tilde{E}_2$ is in System 2, and $\tilde{E}_3$ is an auxiliary variable in System 1. Therefore

$$\tilde{E}_1 = \tilde{d}_1\bar{E}_1, \quad \tilde{E}_2 = \tilde{d}_2\bar{E}_2, \quad \tilde{E}_3 = \tilde{d}_1\bar{E}_3. \tag{7.16}$$

Comparison of (7.16) with (7.13) shows that $\mathbf{E}$ may be obtained in real space with (7.15) by replacing $\dot{\mathbf{u}}$ with $\mathbf{E}$ and $\dot{\bar{\mathbf{u}}}$ with $\bar{\mathbf{E}}$.

For the magnetic field, note that $\tilde{H}_1, \tilde{H}_3$ are in System 2, while $\tilde{H}_2$ is in System 1. Therefore

$$\tilde{H}_1 = \tilde{d}_2\bar{H}_1, \quad \tilde{H}_2 = \tilde{d}_1\bar{H}_2, \quad \tilde{H}_3 = \tilde{d}_2\bar{H}_3. \tag{7.17}$$

Similar to the procedure for $\dot{\mathbf{u}}$, we first use (7.17) to write $\hat{\mathbf{H}}$ and then invert the Fourier transform using (5.16) to get $\mathbf{H}$ in real space:

$$\begin{aligned}
H_1 &= -d_1\Theta_{1,1}\left[\frac{\bar{H}_1}{k^2}\right] + d_2\Theta_{2,0}\left[\frac{\bar{H}_1}{k^2}\right] - d_1\Theta_{1,1}\left[\frac{\bar{H}_2}{k^2}\right] - d_2\Theta_{0,2}\left[\frac{\bar{H}_2}{k^2}\right],\\
H_2 &= -d_1\Theta_{0,2}\left[\frac{\bar{H}_1}{k^2}\right] + d_2\Theta_{1,1}\left[\frac{\bar{H}_1}{k^2}\right] + d_1\Theta_{2,0}\left[\frac{\bar{H}_2}{k^2}\right] + d_2\Theta_{1,1}\left[\frac{\bar{H}_2}{k^2}\right],\\
H_3 &= -d_1\Theta_{0,1}\left[\frac{\bar{H}_3}{k}\right] + d_2\Theta_{1,0}\left[\frac{\bar{H}_3}{k}\right].
\end{aligned} \tag{7.18}$$

Again $\mathbf{H}$ can be written in cylindrical coordinates using the Hankel transform relations (5.18).

A similar treatment can be given for the other variables. However, we will focus on $\dot{u}_3$, i.e., the vertical velocity of the ground, since at the surface $z = 0$ this is the response of a conventional geophone. So the behavior of $\dot{u}_3$ gives the seismic response in an ES land survey. From (7.15) and (5.18) the seismic response for a horizontal dipole is given in cylindrical coordinates by the order 1 Hankel transform

$$\dot{u}_3(r,\theta,z) = i(d_1\cos\theta + d_2\sin\theta)\mathcal{B}_{1,1}[\dot{u}_3(k,z)]. \tag{7.19}$$

Alternatively, from (7.15), (5.16), and (5.18),

$$\dot{u}_3(r,\theta,z) = -\mathbf{d}\cdot\nabla R(r,z), \tag{7.20}$$

where the response function R is the order 0 Hankel transform

$$R(r,z) = i\mathcal{B}_{0,0}[\dot{u}_3(k,z)]. \tag{7.21}$$

Note that for the vertical component of the geophone response, only $\dot{u}_3$ need be computed, so it is not necessary to solve System 2.

The preceding results are for a point dipole at $\mathbf{x} = (0,0,z_s)^T$. Now consider a source which is a current sheet in a horizontal plane, so that

$$\begin{aligned} \mathbf{j} &= \mathbf{C}(x_1,x_2)\,\delta(x_3 - z_s), \\ \mathbf{C} &= [C_1, C_2, 0]^T. \end{aligned} \tag{7.22}$$

The vertical velocity for this source may be computed by superposition,

(7.23)

$$\begin{aligned} \dot{u}_3(r,\theta,z) &= -\int_{-\infty}^{\infty}\int_{-\infty}^{\infty} \mathbf{C}(x_1',x_2')\cdot\nabla R\Big(\sqrt{(x_1-x_1')^2+(x_2-x_2')^2}, z\Big)\,dx_1'dx_2' \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} (-\nabla'\cdot\mathbf{C}(x_1',x_2'))\,R\Big(\sqrt{(x_1-x_1')^2+(x_2-x_2')^2}, z\Big)\,dx_1'dx_2', \end{aligned}$$

where the second expression comes from the divergence theorem, assuming that $\mathbf{C}$ is smooth and vanishes sufficiently rapidly at ∞. Therefore the geophone response is a superposition of cylindrically symmetric scalar response functions R weighted at each point by the current leakage $-\nabla\cdot\mathbf{C}$. In particular, only the leakage of current from the source plane contributes to the geophone response.

We may obtain a related result for the response to a leaky wire in the plane $z = z_s$, when the wire follows the path $(\bar{x}_1(\alpha), \bar{x}_2(\alpha), z_s)$, where α is arclength along the path and $0 \le \alpha \le l$. If $I(\alpha)$ is the current in the wire at position α, then the source current is

$$\mathbf{j} = \int_0^l I(\alpha) \begin{bmatrix} \frac{d\bar{x}_1}{d\alpha} \\ \frac{d\bar{x}_2}{d\alpha} \\ 0 \end{bmatrix} \delta\left(x_1 - \bar{x}_1(\alpha)\right)\ \ \delta\left(x_2 - \bar{x}_2(\alpha)\right)\delta\left(x_3 - z_s\right)d\alpha. \tag{7.24}$$

Let

$$\bar{r}(\alpha, x_1, x_2) = \sqrt{(x_1 - \bar{x}_1(\alpha))^2 + (x_2 - \bar{x}_2(\alpha))^2}. \tag{7.25}$$

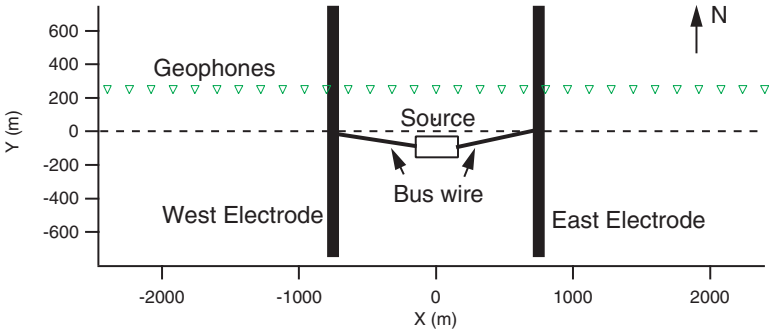

FIG. 1. *Configuration of electrodes and geophones.*

Then superposition of response functions gives the expression

(7.26)

$$\dot{u}_3 = -\int_0^l I(\alpha) \begin{bmatrix} \frac{d\bar{x}_1}{d\alpha} \\ \frac{d\bar{x}_2}{d\alpha} \\ 0 \end{bmatrix} \cdot \nabla R\left(\bar{r}(\alpha, x_1, x_2), z\right) d\alpha$$

$$= I(l)R(\bar{r}(l, x_1, x_2), z) - I(0)R(\bar{r}(0, x_1, x_2), z) + \int_0^l \left(-\frac{dI}{d\alpha}\right) R(\bar{r}(\alpha, x_1, x_2), z) d\alpha.$$

Again, only the leakage, both at the end points and along the length of the wire, contributes to the geophone response.

In particular, for an insulated wire I is constant. Then we have only the end-point contributions, and the path of the wire between its end points is immaterial. If the insulated wire is a closed loop, then the end points cancel and the geophone response vanishes. This fact was derived by Haartsen and Pride [7] for the special case of a circular current loop.

8. Electroseismic prospecting. A computer code based on the theory of this paper was written and used for planning and interpretation of several field tests [21, 20, 18, 10, 9, 8]. In these tests, an EM source was used, and geophones on the surface of the earth recorded the vertical velocity of the ground.

Figure 1 describes the "railroad track" electrode design used for these tests. The electrodes are two parallel transmission lines buried in the shallow subsurface. The length and separation of the electrodes are comparable to the desired depth of investigation, which for the deeper tests is on the order of a kilometer. A power source is located midway between the two tracks, and insulated bus wires feed current from the power source to the centers of the two electrodes.

From the center of the west electrode, current from the bus wire flows outward toward the electrode ends, leaking into the ground all along the electrode's length. Because of this leakage the current carried by the electrode decreases linearly from a maximum at the bus wire feed point to zero at each end. The current behavior in the east electrode is similar to that described for the west electrode, but with sign reversed.

A number of factors influenced this electrode design. Horizontal sources were chosen because they allow a large scale geometry that would be impractical with vertical structures. However, as shown in section 7, current leakage is essential for horizontal sources if we are to obtain a seismic response from a conventional geophone.

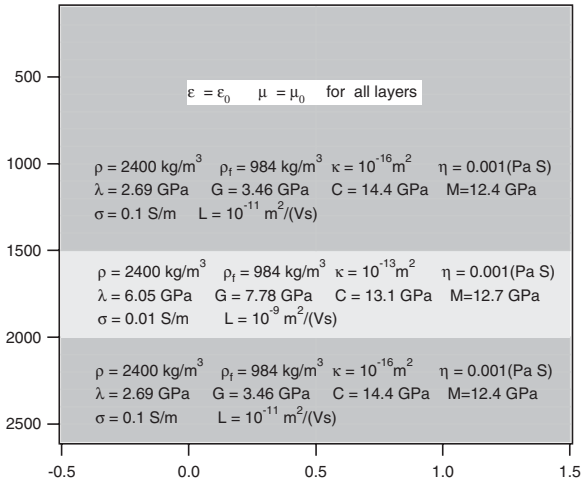

FIG. 2. *Three-layer model.*

For example, as shown in section 7, a source consisting of an insulated wire loop, as is common in EM prospecting [14, 25], would give no seismic response at all in a layered earth. Furthermore, maximizing the current leakage is essential for enhancing the magnitude of the seismic signal. Also, because Pride's equations are linear, the seismic response for any electrode configuration is directly proportional to the source current; so the greatest practically obtainable current level is desired in order to produce the greatest possible seismic response.

To model the ES response to these electrodes over a layered earth, we first obtain for the specified earth model the horizontal dipole response function $R(r, 0)$ on the surface of the earth $z = 0$ using (7.21). The electrodes and bus wires are described mathematically as segments of curves in the plane, carrying varying amounts of current at each point along the length. That is, I is constant in the bus wires, and $dI/d\alpha$ is constant along each half of each electrode. Then the second expression in (7.26) is used to calculate the geophone response. Note that in this calculation, the path of the bus wires is immaterial, because they are insulated.

In modeling the current in the electrodes as linearly decreasing from the bus wire feed to the end points, we have neglected phase changes in $I(\alpha)$ caused by the inductance of the earth. Calculation of the inductance is beyond the scope of the present paper.

Figure 2 shows a layered earth model with three layers, where the free space ϵ_0, μ_0 are assumed in all layers. Figure 3 shows a typical trace, as recorded at a geophone at coordinates $x = 1000\,\mathrm{m}$, $y = 250\,\mathrm{m}$. In transforming the computer calculations to the time domain, a 15 Hz Ricker wavelet pulse form was used. In the actual field tests pulses are not used; instead a periodic source function is generated and repeated many times, after which the received seismic signal is averaged over a period [8, 21, 20, 10, 9]. This methodology allows a great amount of EM energy to be put into the ground to enhance the received seismic response. The resulting data can then be Fourier transformed to the frequency domain and a pulse wavelet inserted before inverse transforming back to the time domain. In this way a trace of the type of Figure 3, analogous to the geophone responses used in conventional seismic interpretation, can be constructed.

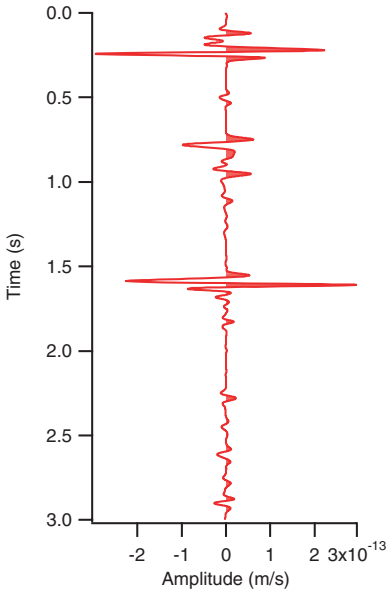

FIG. 3. *Trace at* $x = 1000$ m.

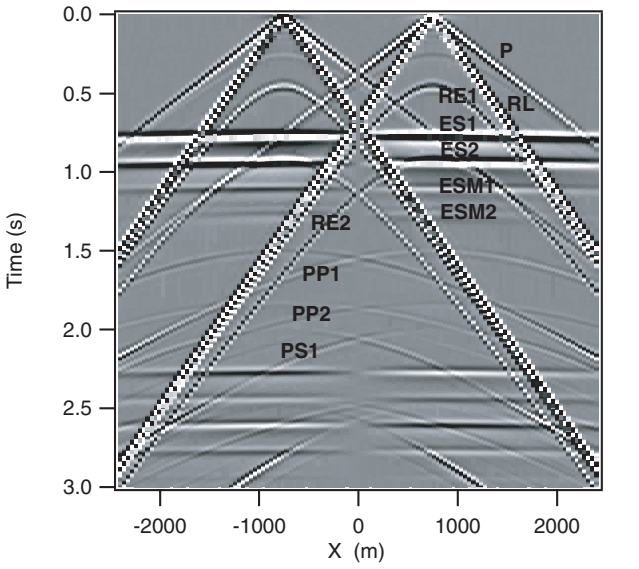
Note that the scale in Figure 3 predicts that very small signals will be received. These signals are within the sensitivity of a geophone, but smaller than many noise sources that can be identified in the field, so considerable signal averaging will be necessary for detection to be at all feasible. In the computation, we have assumed a current leakage of 1 amp/m of electrode length, for a total leakage of 1500 amps. All the results scale linearly with the current, so the small signals predicted can be enhanced by increasing the current.

Figure 4 shows the resulting electroseismogram, analogous to a conventional seismic gather, for a line of geophones orthogonal to the two electrodes and offset 250 m from the center. We have labeled a number of the events in Figure 4. Event ES1 results from energy that has been converted from EM to seismic at the first interface and has subsequently propagated upward to the surface. Note that this event is flat, that is, the arrival times are the same at all the receivers. This behavior is in contrast to that of a conventional seismic reflection, which has "moveout" caused by the geometry of the ray paths, i.e., a hyperbolic dependence of arrival time with offset of the receiver from the source. In contrast, the asymptotic theory of ES conversion [24] shows that the seismic rays resulting from an incident EM wave leave the interface normal to it. For a layered earth, this means that all the converted seismic rays travel vertically. Since the propagation of EM energy is virtually instantaneous on the seismic time scale, the converted seismic signals propagating vertically from each point on the interface arrive at the surface simultaneously. Another way to understand this phenomenon intuitively is to note that the EM wave speed is much greater than the seismic wave speed. Therefore Snell's law predicts that the converted seismic waves leave the interface in approximately the normal direction.

Note also that the amplitudes of event ES1 go to zero at a point midway between the electrodes, with a sign reversal as this midpoint is crossed. This is a result of symmetry of the problem. The asymptotic theory [24] shows that the P-wave con-



P : Direct arrival of P wave
RL : Rayleigh wave from east line electrode
RE1 : Rayleigh wave from north end of east electrode
RE2 : Rayleigh wave from south end of east electrode
ES1 : ES conversion at first interface
ES2 : ES conversion at second interface
ESM1 : Mutiple of ES conversion at first interface
ESM2 : Mutiple of ES conversion at second interface
PP1 : P wave reflection at first interface
PP2 : P wave reflection at second interface
PS1 : PS conversion or/and SP conversion at first interface

FIG. 4. *Electroseismogram* (*three-layer model*).

version is dependent on the electric field normal to the interface, which for a layered earth is in the vertical direction. From symmetries of the electrode, the vertical **E** field changes sign on a line midway between the electrodes, and so the ES conversion to P-waves changes sign there also.

Moreover, only the P-wave response of the energy converted at an interface contributes to the vertical velocity of the ground. This is because the converted S-waves, which likewise travel vertically, have a particle motion orthogonal to their direction of travel, i.e., they contribute a purely horizontal component to the solid velocity. Furthermore the Biot slow wave is undetectable at the surface. Although Biot slow waves are generated at the interfaces by the EM field, their rapid decay (typically on a scale of inches!) makes their amplitudes transcendentally small at the surface.

The amplitude of ES1 peaks at a position 160 m from each electrode, outside of the area bounded by the two electrodes. This is a general property of conversions from a single interface, and is used in planning the placement of the geophones. Typically geophones are placed to cover an area where significant signals are expected. The geophone line shown here is for illustrative purposes only.

Returning to Figure 4, other flat events, e.g., events ES2, ESM1, and ESM2, can be identified by comparing their times of arrival with the P-wave velocities in the

layers. Event ES2 results from the primary conversion to seismic propagating upward from the second interface. Events ESM1 and ESM2 are multiples: Event ESM1 is energy converted to seismic at the first interface, directed downward where it is reflected upward as seismic at the second interface and finally received at the geophones. Event ESM2 is energy converted at the second interface, with seismic reverberation between the first and second interfaces before being received at the surface. As is usual, amplitudes of the multiples are considerably less than those of the primaries.

Other events, which do not have simultaneous arrival times, result from conversion of EM to seismic energy directly where the electrode contacts the ground. This produces a small, order of L, seismic survey along with the ES survey. Of course the ES conversions at the interfaces, which are the signals we seek, are also of order L. So conversion at the electrodes cannot be ignored.

Event P is the direct arrival of the P-wave generated at the electrodes, traveling just below the surface. Events PP1 and PP2 are reflections of the P-wave generated at the electrodes from the first and second interfaces, respectively. Event PS1 is a combination of P to S and S to P conversions at the second interface.

Event RL is a Rayleigh wave, or "ground roll" traveling along the surface and generated at all points of the east electrode. It is identified by the Rayleigh wave speed and linear dependence of arrival time with distance from the source. In the layer code, the Rayleigh wave manifests itself as a pole in k space, and care must be taken in numerical integration of the Hankel transforms as the path of integration nears this pole. Since the pole is near the real axis, numerical stability is enhanced by giving the frequency a small positive imaginary part, that is, replacing $\omega \to \omega + i\delta$. The effects of complex frequency can then be removed in the time domain by multiplication by a factor of $e^{\delta t}$. Also, to enhance numerical stability, the wavenumber can be given a small negative imaginary part.

Event RL is approximately what would be obtained if the electrode were an infinite line source. However, because the actual electrode is of finite length, there are end-point contributions RE1 and RE2 from the north and south ends of the east electrode, and these manifest as separate events.

Many more events can be identified in Figure 4, and interpretation becomes increasingly complicated as the number of layers increases to model realistic exploration geometries.

The conductivity in layer 2 is representative of that of an oil reservoir. In Figure 5 we compare this model with that of a similar model where layer 2 conductivity is an order of magnitude higher, indicating that there is no oil. Shown is the amplitude versus offset for the ES conversion at the first interface. As expected, the presence of oil enhances the signal considerably. In contrast, changing the permeability by an order of magnitude has virtually no effect, as is shown in Figure 6. These results are qualitatively consistent with conclusions based on the asymptotic theory [24].

In Figure 7 we show that in some carefully chosen cases, the presence of very small layers can have a dramatic effect on the amplitudes of the received signals. We compare the model of Figure 2 with a similar model that has a 10 cm gas sand inserted just above the reservoir, i.e., between layers 1 and 2. The result is that the ES conversion is more than doubled.

This effect can be understood qualitatively as arising from the much greater compressibility of a gas compared to a liquid; the enhanced compressibility provided by even a small layer of gas allows for much more movement of the solid matrix. Mathematically, a small layer can have an effect only if the exponential matrices $e^{i\omega\Lambda_m\Delta z_m}$ that occur in (4.21) differ substantially from the identity matrix. Of course these

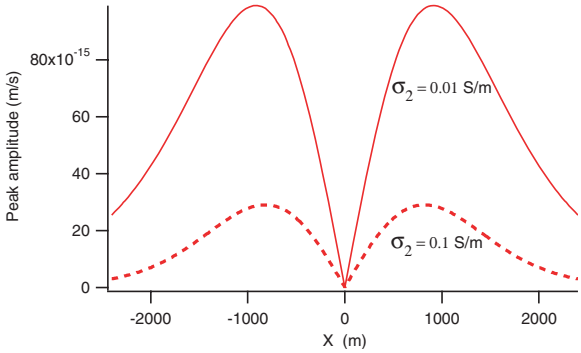


FIG. 5. *Conductivity dependence of ES conversion.*

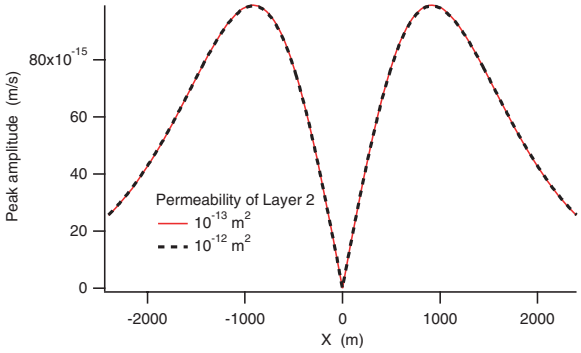

FIG. 6. *Permeability dependence of ES conversion.*

matrices must approach the identity as the layer thickness Δz_m becomes sufficiently small. However, the Biot slow wave has a very large slowness, as is discussed asymptotically in [24]. The complex Biot slow wave slowness is one of the eigenvalues of Λ_m, namely, q_2 in (A.1), and has been computed for the parameters of Figure 2 (and horizontal slowness $\gamma = 0$) as $q_2 = .348(1 + i)$. Therefore the matrices in question have a second diagonal element of $e^{3.28(-1+i)}$, which differs substantially from unity. In general it is the potentially large slowness of the Biot slow wave, i.e., its short wavelength, that allows the possibility that a small layer might have an order one effect.

A small layer can also have a large effect by substantially changing the local electric field, as is illustrated in Figure 8. For the base case in this figure, we consider the same model parameters as in Figure 2, except that the reservoir thickness is reduced to 10 m. The result of this model may be compared with case 1, in which we insert a thin, 2 cm, highly resistive layer just below the top of the reservoir, with a varying conductivity profile as shown in Figure 9. This continuously variable conductivity profile is simulated by discretizing it over 200 layers, each with a thickness of .1 mm. The result is a dramatic rise of the amplitude of the ES conversion by more than an order of magnitude, as compared with the base case. The much higher ES conversion may also be achieved with a constant resistivity layer at the top of the reservoir, as is illustrated in case 2. For this case, the highly resistive thin layer has a constant resistivity of $2500\,\Omega - m$ and a thickness of 5 cm.

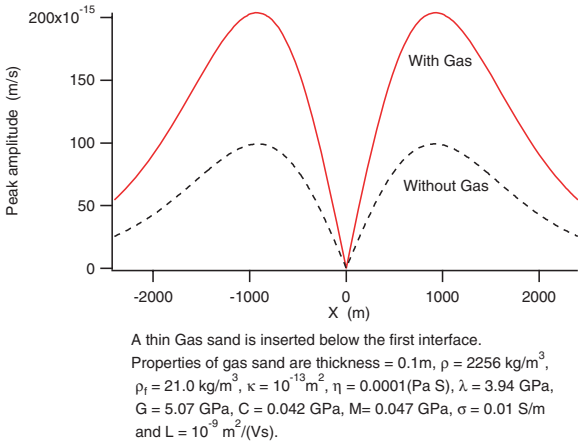

FIG. 7. *ES conversion enhancement due to gas presence.*

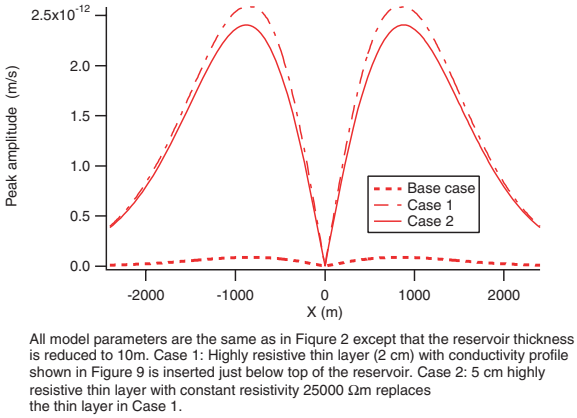

FIG. 8. *Effect of a high resistivity thin layer on ES conversion.*

The normal electric field for case 2 of Figure 8 is plotted in Figure 10. It is relatively constant over the thin resistive layer, with a discontinuity at the interface proportional to the ratio of resistivities, as is inherent in Maxwell's equations. In the asymptotic theory [24] the size of the discontinuity of the normal electric field is a major factor in the magnitude of the ES conversion at an interface. Although the layer in this example is too small for the strict validity of the asymptotic theory, the qualitative dependence of ES conversion on the normal electric field is seen to be similar here.

In Figure 11 we demonstrate how fine structure in a reservoir can also raise the amplitude of the ES conversion. In this figure, we consider a 20 m thick reservoir with a periodic structure of 67 gas-oil-shale layers, each of thickness 1 cm. The result is a substantial increase in converted wave amplitude, as compared with the case of a homogeneous reservoir.

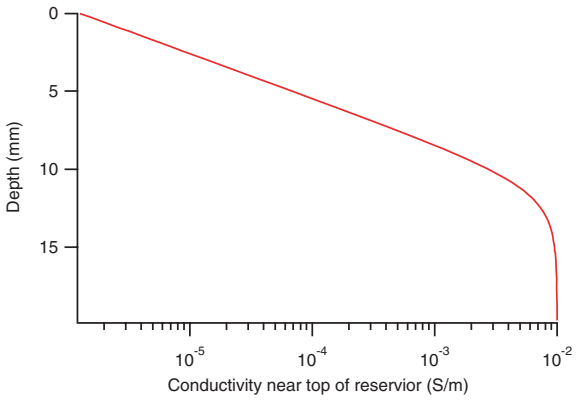

FIG. 9. *Profile of conductivity near top of reservoir.*

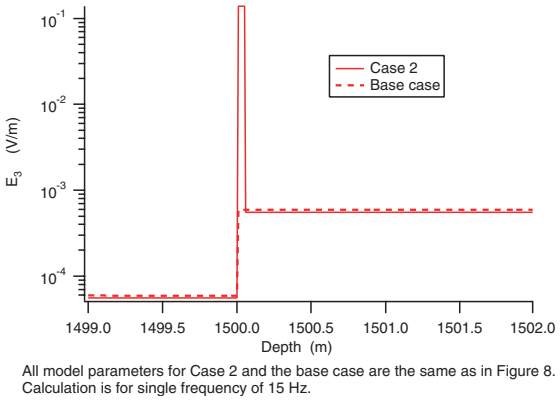

FIG. 10. *Local normal E field near a highly resistive thin layer.*

9. Conclusions. We have shown how the equations of electrokinetics can be put into Ursin's form in a plane-layered medium. Using this form we have derived explicit formulas that can be used as the basis of an efficient layer code, and have shown numerical results for spatially extended electrode sources that have been used in field tests.

More generally, the methods developed are applicable to any system that can be put into Ursin's form. In particular, the code that was written for ES waves can be modified to separately compute seismic waves, EM waves, or the waves of Biot theory, which are all included in Pride's equations: For seismic waves, isotropic elasticity is recovered from the third and fifth equations of (2.1) by simply taking $\rho_f = 0, C = 0$; then $\mathbf{E}, \mathbf{H}, \mathbf{w}, p$ vanish, so their components may be deleted to reduce the dimensionality of the systems. Similarly, in the limit $L \to 0$ we recover either Maxwell's equations or Biot's equations separately.

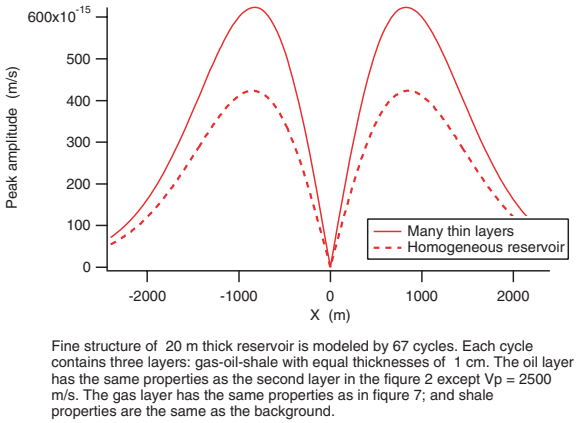

FIG. 11. *Effect of fine structure on ES conversion.*

As expected, the higher electrical resistivity of hydrocarbons does considerably enhance the ES waves converted at reservoir boundaries. For shallow reservoirs, ES signals should be detectable. However, our calculations show that there are significant technological challenges to make ES a reliable tool for detecting deep oil reservoirs because the received signals from depth are likely to be small unless a great amount of EM energy can be put into the ground. Effective signal processing techniques will be necessary to separate the signals from noise. Also, desired signals originating from deep interfaces may be obscured by conversions from shallow interfaces because the EM field is likely to be large at shallow depths where it has not attenuated much.

In comparison to purely EM prospecting, the EM waves used in ES can be of lower frequency to give the same wavelength of the returned (i.e., seismic) signal. Also, in ES prospecting the EM waves only go one way, i.e., down to the reservoir, as opposed to the round-trip taken by the EM waves in an EM survey. Since EM waves attenuate with propagation distance, and with shortened wavelength, these two effects favor ES. However, these effects are counterbalanced by the fact that in ES only a small fraction of the EM energy is converted to seismic at an interface, giving a corresponding reduction in the amplitude of the ES signal.

The ES conversions at interfaces are generally consistent with the asymptotic theory of [24], which gives three-dimensional effects not included in layered earth modeling. However, the layer code predicts a surprising result that is not computable with the asymptotic theory: the possibility that layers very much smaller than a seismic wavelength can have a large effect on the amplitude of the received ES signal. This was demonstrated by the model of a thin gas sand overlying an oil reservoir, by the model of a thin but highly resistive layer, and by a cyclical model of reservoir fine structure. The possibility of signal enhancement through this mechanism must be considered in analyzing the amplitudes of electroseismograms.

Another challenge is the interpretation of the many different types of events seen in electroseismograms. For example, we have shown that ES conversions where the electrode contacts the ground produce a multitude of signals; these signals are a sort of source-generated noise, which can obscure the returns from EM waves converted to seismic at reservoir boundaries. Modeling of the type we have shown here is essential for proper interpretation and classification of all these signals.

Appendix A. Eigenvectors for System 1. See also [17, 7]. The four modes for system 1 are

- $m = 1$: fast compressional wave (P-wave);
- $m = 2$: Biot slow wave;
- $m = 3$: vertical shear wave (SV-wave);
- $m = 4$: transverse magnetic wave (TM-wave).

$m = 1, 2$ are longitudinal waves. For these modes

(A.1)
$$q_m^2 = -\gamma^2 + \beta_1\Bigg(C\rho_f - \frac{1}{2}M\rho - \frac{i}{2}(\lambda+2G)\left(\frac{\eta}{\kappa\omega}\right)\beta_2 \pm\frac{1}{2}\sqrt{\left(i(\lambda+2G)\left(\frac{\eta}{\kappa\omega}\right)\beta_2 - M\rho\right)^2 - 4\left(M\rho_f - i\left(\frac{\eta}{\omega\kappa}\right)C\beta_2\right)\left(C\rho - (\lambda+2G)\rho_f\right)}\Bigg), \quad m = 1, 2.$$

In (A.1) the plus sign is for $m = 1$ (P-waves) and the minus sign is for $m = 2$ (Biot slow waves). Then for $m = 1, 2$

$$\text{(A.2)}\qquad \mathbf{a}_m = \bar{a}_m\begin{bmatrix} -1 \\ 2\gamma G \\ \xi_m \\ 0 \end{bmatrix}, \quad \mathbf{b}_m = \frac{\bar{a}_m}{q_m}\begin{bmatrix} 2\gamma^2 G - \rho - \rho_f\xi_m \\ \gamma \\ \rho_f + i\left(\frac{\eta}{\omega\kappa}\right)\beta_2\xi_m \\ -\gamma\left(\frac{\eta L}{\kappa\bar{\sigma}}\right)\beta_2\xi_m \end{bmatrix}, \quad m = 1, 2,$$

where

(A.3)
$$\xi_m = \frac{\left(C\rho_f - M\rho - \frac{\left(q_m^2+\gamma^2\right)}{\beta_1}\right)}{\left(M\rho_f - i\left(\frac{\eta}{\omega\kappa}\right)C\beta_2\right)} = \frac{(C\rho - (\lambda+2G)\rho_f)}{\left(\frac{\left(q_m^2+\gamma^2\right)}{\beta_1} - C\rho_f + i(\lambda+2G)\left(\frac{\eta}{\omega\kappa}\right)\beta_2\right)}, \quad m = 1, 2,$$

and

$$\text{(A.4)}\qquad \bar{a}_m = \sqrt{\frac{q_m}{\rho + 2\rho_f\xi_m + i\left(\frac{\eta}{\omega\kappa}\right)\beta_2\xi_m^2}}, \quad m = 1, 2.$$

$m = 3, 4$ are transverse waves. For these modes

$$\text{(A.5)}\qquad q_m^2 = -\gamma^2 + \frac{1}{2G}\left(\rho + i\rho_f^2\left(\frac{\omega\kappa}{\eta}\right) + i\frac{\bar{\sigma}\mu G}{\omega}\right) \mp \frac{1}{2G}\sqrt{\left(i\frac{\bar{\sigma}\mu G}{\omega} - \rho - i\rho_f^2\left(\frac{\omega\kappa}{\eta}\right)\right)^2 - 4L^2\rho_f^2\mu G}, \quad m = 3, 4.$$

In (A.5) the minus sign is for $m = 3$ (SV-waves) and the plus sign is for $m = 4$ (TM-waves). Then

$$\text{(A.6)}\qquad \mathbf{a}_m = -\frac{\bar{b}_m}{q_m}\begin{bmatrix} -\gamma \\ G(\gamma^2 - q^2) \\ i\gamma\rho_f\left(\frac{\omega\kappa}{\eta}\right) + \gamma L\xi_m \\ -L\rho_f + i\frac{\bar{\sigma}}{\omega}\xi_m \end{bmatrix}, \quad \mathbf{b}_m = \bar{b}_m\begin{bmatrix} 2\gamma G \\ 1 \\ 0 \\ \xi_m \end{bmatrix}, \quad m = 3, 4,$$

where

$$\xi_m = \frac{\rho_f L\mu}{\left(\frac{i\bar{\sigma}\mu}{\omega}\right) - q_m^2 - \gamma^2} = \frac{G}{\rho_f L}\left(q_m^2 + \gamma^2 - \frac{\rho}{G} - i\left(\frac{\rho_f^2}{G}\right)\left(\frac{\omega\kappa}{\eta}\right)\right), \quad m = 3, 4, \tag{A.7}$$

and

$$\bar{b}_m = \sqrt{\frac{q_m}{G\left(q_m^2 + \gamma^2\right) + \rho_f L\xi_m - i\left(\frac{\bar{\sigma}}{\omega}\right)\xi_m^2}}, \quad m = 3, 4. \tag{A.8}$$

Appendix B. Eigenvectors for System 2. See also [17, 7]. The two modes for system 1 are

- $m = 1$: horizontal shear wave (SH-wave);
- $m = 2$: transverse electric wave (TE-wave).

The eigenvalues are the same as for the transverse modes of System 1, i.e.,

$$\begin{aligned} q_m^2 = &-\gamma^2 + \frac{1}{2G}\left(\rho + i\rho_f^2\left(\frac{\omega\kappa}{\eta}\right) + i\frac{\bar{\sigma}\mu G}{\omega}\right) \\ &\mp \frac{1}{2G}\sqrt{\left(i\frac{\bar{\sigma}\mu G}{\omega} - \rho - i\rho_f^2\left(\frac{\omega\kappa}{\eta}\right)\right)^2 - 4L^2\rho_f^2\mu G}, \quad m = 1, 2. \end{aligned} \tag{B.1}$$

In (B.1) the minus sign is for $m = 1$ (SH-waves) and the plus sign is for $m = 2$ (TE-waves). The eigenvectors are of the form

$$\mathbf{a}_m = \bar{a}_m \begin{bmatrix} 1 \\ \xi_m \end{bmatrix}, \quad \mathbf{b}_m = \frac{\bar{a}_m}{q_m}\begin{bmatrix} Gq_m^2 \\ \rho_f L + \xi_m\left(\frac{\gamma^2}{\mu} - \frac{i\bar{\sigma}}{\omega}\right) \end{bmatrix}, \quad m = 1, 2, \tag{B.2}$$

where

$$\begin{aligned} \xi_m = &\frac{G}{2\rho_f L}\left[\left(\frac{i\bar{\sigma}\mu}{\omega}\right) - \left(\frac{\rho}{G} + i\omega\frac{\rho_f^2\kappa}{G\eta}\right)\right] \\ &\mp \frac{G}{2\rho_f L}\sqrt{\left[\left(\frac{i\bar{\sigma}\mu}{\omega}\right) - \left(\frac{\rho}{G} + i\omega\frac{\rho_f^2\kappa}{G\eta}\right)\right]^2 - 4\frac{\mu\rho_f^2 L^2}{G}}, \quad m = 1, 2, \end{aligned} \tag{B.3}$$

and

$$\bar{a}_m = \sqrt{\frac{q_m}{Gq_m^2 + \rho_f L\xi_m + \xi_m^2\left(\frac{\gamma^2}{\mu} - i\frac{\bar{\sigma}}{\omega}\right)}}. \tag{B.4}$$

Again, in (B.3) the minus sign is for $m = 1$ (SH-waves) and the plus sign is for $m = 2$ (TE-waves).

Acknowledgment. We thank Max Deffenbaugh for his tests of the computer code.

A QUEUE-LENGTH CUTOFF MODEL FOR A PREEMPTIVE TWO-PRIORITY $M/M/1$ SYSTEM*

QIANG GONG† AND RAJAN BATTA‡

Abstract. We consider a two-priority, preemptive, single-server queueing model. Each customer is classified into either a high-priority class or a low-priority class. The arrivals of the two-priority classes follow independent Poisson processes, and service time is assumed to be exponentially distributed. A queue-length cutoff method is considered. Under this discipline the server responds only to high-priority customers until the queue length of the other class exceeds a threshold L. After that the server switches to handle only the low-priority queue. Steady-state balance equations are established for this system. Then we introduce two-dimensional generating functions to obtain the average number of customers for each priority class. We then focus on the preemptive resume case while allowing for weights associated with both priority class queues. We develop methodologies to obtain the optimal cutoffs for the situation when the weights of both queues are constant (i.e., not a function of queue length) and the situation when the weights change linearly with the queue lengths. It is important to point out that our method does not lead to a closed-form exact solution, but rather to a numerical approximation, from which cutoff policies are analyzed.

Key words. priority queue, queue-length cutoff, generating function

1. Introduction and literature review. Our research is primarily motivated by a disaster-relief project which deals with how to rescue casualties after a disaster occurs. We consider a dynamic disaster environment (e.g., earthquake), in which thousands of casualties need to be treated. The casualties in such a disaster setting are usually placed into four levels (see the description of HAZUS, a GIS-enabled software used by the Federal Emergency Management Agency (FEMA) for the purpose of earthquake loss estimation, in the paper by Al-Momani and Harrald [1]):

1. Severity level 1: injuries will require medical attention, but hospitalization is not needed.
2. Severity level 2: injuries will require hospitalization but are not considered life threatening.
3. Severity level 3: injuries will require hospitalization and can become life threatening if not promptly treated.
4. Severity level 4: victims are killed by the earthquake.

In an earthquake disaster-relief setting (e.g., the one that occurred in Northridge, CA, in 1994) severity level 1 and 4 calls are initially not responded to. Thus the system operates as a two-priority queue, with severity level 3 being priority 1 and severity level 2 being priority 2. Since injuries can rapidly deteriorate when unattended, it is possible that severity level 2 injuries that are left unattended for a long period of time can become even more critical than a typical severity level 3 injury. Thus operating in

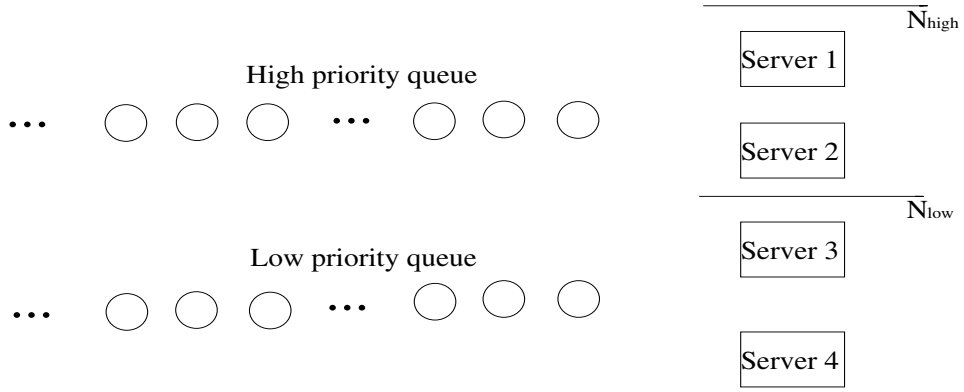

FIG. 1. *Server cutoff model.*

a strict priority queue model in a heavy-traffic situation would be detrimental. This provides the motivation to study a two-priority queueing system with a queue-length cutoff. This cutoff model is being implemented in the software for disaster relief being developed at the Center for Multisource Information Fusion at the University at Buffalo (SUNY). Details of its effectiveness via case studies developed for an earthquake scenario in Northridge, CA, will be presented in a later paper.

There are other applications of this queue-length cutoff model. For example, telecommunication in ATM (asynchronous transfer mode) networks also has this flavor. Voice data must flow through the network without noticeable distortion or delay. Losing a chunk of voice data isn't a problem, but a delay or receiving data out of order is. So voice is "delay sensitive, loss insensitive." On the contrary, computer data are "delay insensitive, loss sensitive," since individual chunks are not of much use until they are all received, but in many cases data delay in transmission is often acceptable. Based on the characteristics of both types of data, voice is classified as a high-priority class, computer data as a low-priority class. Again, computer data cannot be indefinitely delayed, so it makes sense to have a queue-length cutoff model in such a situation.

Previous research in the area of priority queueing models may be categorized as either server cutoff or queue-length cutoff. Figures 1 and 2 illustrate two straightforward examples for both types of models, respectively.

Depending upon the number of available servers, server cutoff discipline determines which classes of patients are qualified for service. The example shown in Figure 1 has two cutoffs, N_{high} and N_{low}. Obviously, N_{high} is equal to the total number of servers. Low-priority customers enter service only if fewer than $N_{low}(\leq N_{high})$ servers are busy. The purpose of this method is to reserve servers for high priorities. Taylor and Templeton [2] studied two variants of a simple two-priority server cutoff model: one assumes high-priority customers backlogged in the queue, while the other assumes they are lost if all servers are busy. Schaack and Larson [3] extended the two-priority case to the T-priority problem ($T \geq 3$). In a subsequent paper, Schaack and Larson [4] derived waiting time distribution of each class for an extension of this model, which assumes that customers require a random number of servers for service.

The queue-length cutoff priority queueing model can be regarded as the dual problem of the server cutoff model. Instead of considering the number of available servers, it manipulates the system based on the queue lengths. In the example shown

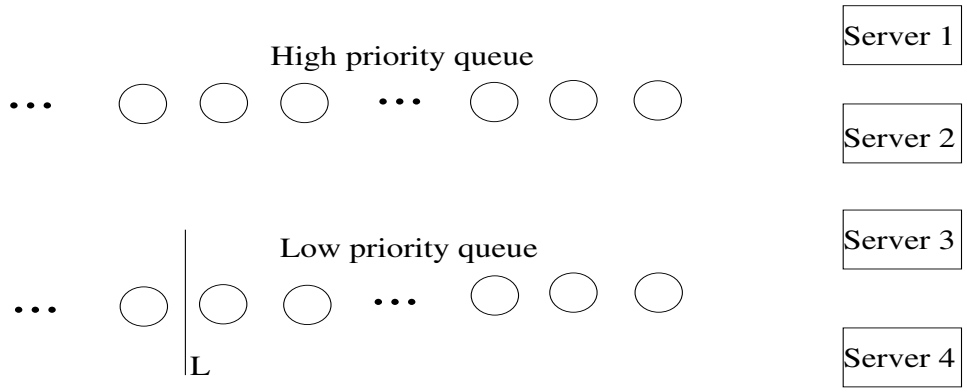

FIG. 2. *Queue-length cutoff model.*

in Figure 2, a cutoff number L is set on the low-priority queue. The servers process the high-priority queue only if the low-priority queue length is less than or equal to L. Once the threshold L is exceeded, part of or all of the servers go to serve the low-priority queue. Gross and Harris [5] published solutions of expected queue length and expected waiting time for a special two-priority model, which assumes the head-of-the-line discipline (i.e., $L = \infty$). Miller [6] obtained the steady-state probabilities by a matrix-geometric method for the same model. Recently, Knessl, Choi, and Tier [7] derived the joint queue-length distribution as an integral for their dynamic two-priority queue-length cutoff model. Our work builds upon their research by developing methodologies to obtain the desired queue-length cutoff L in the preemptive resume case for the situation when the weights associated with customers in both queues are constant and the situation when these weights change linearly with the queue lengths. In a disaster setting the weight signifies the importance associated with timely medical treatment of the patient.

2. Model formulation. Customers are designated one of two priority classes which are numbered as class-1 and class-2 so that the smaller the number, the higher the priority. The arrivals follow independent Poisson processes with rates λ_1 and λ_2, respectively. A single server processes both types of the customers with a mean rate μ. In order to make the system stable, we assume the stability condition as $\rho_1 + \rho_2 < 1$, where $\rho_1 = \frac{\lambda_1}{\mu}$ and $\rho_2 = \frac{\lambda_2}{\mu}$.

Let $X(t)$ and $Y(t)$ be the number of class-1 and class-2 customers in the system at time t, respectively. We consider the bivariate process $\{(X(t), Y(t)), t \geq 0\}$ with state space $S = \{(i, j) : i, j = 0, 1, 2, \dots\}$. The steady-state probabilities are defined as $p_{ij} = Pr\{\text{in steady-state } i \text{ class-1 customers and } j \text{ class-2 customers in the system}\}$.

The service discipline is controlled by the queue-length cutoff policy. A cutoff number L is set on the lower priority class. If the number of customers in the lower priority queue is less than or equal to L, only class-1 customers are served. Once the threshold L is exceeded, the server preempts the customer of class-1 currently in service. The server keeps serving class-2 customers until the queue length of class-2 is shortened to L. Then the server preempts the class-2 customer who is being processed and switches back to service class-1 customers. The sequence within each class is ordered on a first come, first served basis. When there is an empty queue, the server only processes the other queue regardless of the threshold L.

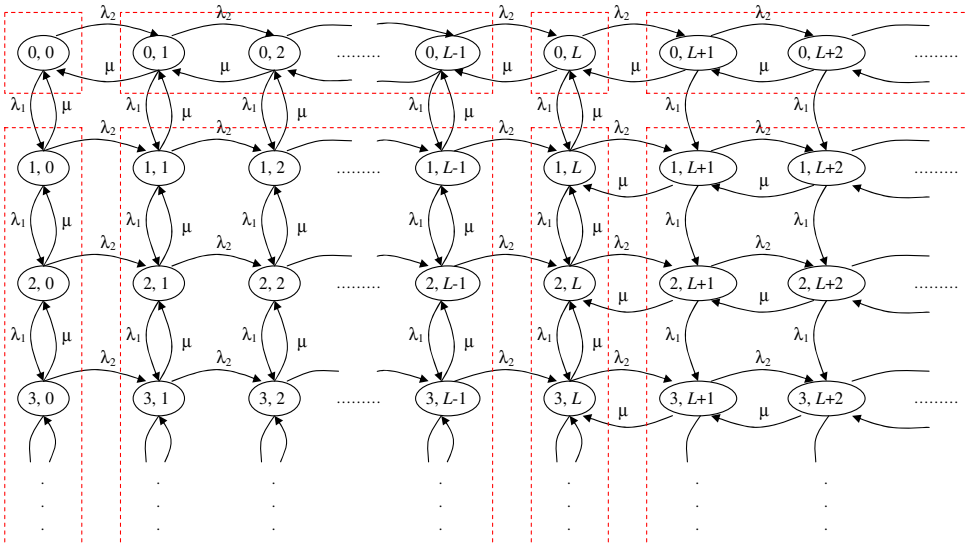

FIG. 3. *Rate transition diagram.*

This problem, in summary, is a Poisson-arrival, exponential-service, single-server, two-priority queue with the preemptive queue-length cutoff discipline.

3. Balance equations and generating functions. Our model is the same as that in [7]. The rate transition diagram is shown in Figure 3. The system is separated into two main parts by the threshold L. The first one gives class-1 customers higher priority, while class-2 customers receive higher priority in the second one.

Equating flow in to flow out, we get the balance equations for all sets of states in the dashed boxes in Figure 3 as follows:
$i = 0$ and $j = 0$:

$$(\lambda_1 + \lambda_2)p_0 = \mu p_{01} + \mu p_{10}. \tag{3.1}$$

$i = 0$ and $1 \le j \le L - 1$:

$$(\lambda_1 + \lambda_2 + \mu)p_{0j} = \lambda_2 p_{0,j-1} + \mu p_{0,j+1} + \mu p_{1j}. \tag{3.2}$$

$i = 0$ and $j = L$:

$$(\lambda_1 + \lambda_2 + \mu)p_{0L} = \lambda_2 p_{0,L-1} + \mu p_{0,L+1} + \mu p_{1L}. \tag{3.3}$$

$i = 0$ and $j \ge L + 1$:

$$(\lambda_1 + \lambda_2 + \mu)p_{0j} = \lambda_2 p_{0,j-1} + \mu p_{0,j+1}. \tag{3.4}$$

$i \ge 1$ and $j = 0$:

$$(\lambda_1 + \lambda_2 + \mu)p_{i0} = \mu p_{i+1,0} + \lambda_1 p_{i-1,0}. \tag{3.5}$$

$i \ge 1$ and $1 \le j \le L - 1$:

$$(\lambda_1 + \lambda_2 + \mu)p_{ij} = \lambda_1 p_{i-1,j} + \lambda_2 p_{i,j-1} + \mu p_{i+1,j}. \tag{3.6}$$

$i \geq 1$ and $j = L$:

$$(\lambda_1 + \lambda_2 + \mu)p_{iL} = \lambda_1 p_{i-1,L} + \lambda_2 p_{i,L-1} + \mu p_{i+1,L} + \mu p_{i,L+1}. \tag{3.7}$$

$i \geq 1$ and $j \geq L + 1$:

$$(\lambda_1 + \lambda_2 + \mu)p_{ij} = \lambda_1 p_{i-1,j} + \lambda_2 p_{i,j-1} + \mu p_{i,j+1}. \tag{3.8}$$

In view of the difficulty in obtaining the solutions from the recursive method, Knessl, Choi, and Tier [7] first derived the generating functions from the balance equations, then got the probabilities by inverting the generating function. Of interest in most applications are the measured system performances such as the expected number of class-1 customers N_1 and the expected number of class-2 customers N_2 in the system. However, their joint queue length is given by an integral which makes it difficult to calculate or even estimate N_1 and N_2.

We calculate N_1 and N_2 by computing the first moment of the generating function. To facilitate this we introduce the two-dimensional generating functions as follows:

$$H_j(w) = \sum_{i=0}^{\infty} p_{ij} w^i, \ 0 \leq j \leq L - 1, \tag{3.9}$$

$$H(w, z) = \sum_{i=0}^{\infty} \sum_{j=0}^{L-1} p_{ij} w^i z^j = \sum_{j=0}^{L-1} z^j H_j(w), \tag{3.10}$$

$$G(w, z) = \sum_{i=0}^{\infty} \sum_{j=L}^{\infty} p_{ij} w^i z^j, \tag{3.11}$$

$$F(w, z) = H(w, z) + G(w, z). \tag{3.12}$$

4. Expressions for generating functions. Since the threshold L divides the system into two parts, we need to calculate $H(w, z)$ and $L(w, z)$ separately to obtain the generating function $F(w, z)$ for the whole system.

We first consider $H(w, z)$. From (3.1), (3.2), (3.5), and (3.6), it is found that

$$H(w, z) = \frac{\left(\frac{\mu}{w} - \mu\right) p_0 + \lambda_2 z^L H_{L-1}(w) + \left(\frac{\mu}{w} - \frac{\mu}{z}\right) \sum_{j=1}^{L-1} p_{0j} z^j - \mu z^{L-1} p_{0L}}{\lambda_1 w + \lambda_2 z - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{w}}. \tag{4.1}$$

Details of this derivation are shown in Appendix A.

Similarly, (3.3), (3.4), (3.7), and (3.8) yield

$$\begin{aligned} &\left[\lambda_1 w + \lambda_2 z - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{z}\right] G(w, z) \\ &\quad = z^L \left[-\lambda_2 H_{L-1}(w) + \mu \left(\frac{1}{z} - \frac{1}{w}\right) H_L(w) + \frac{\mu}{w} p_{0L}\right]. \end{aligned} \tag{4.2}$$

Details of this derivation are shown in Appendix B. By the method presented by Knessl, Choi, and Tier [7], the left-hand side of (4.2) can be rewritten as

$$\frac{\lambda_2}{z} [(z - z_-(w))(z - z_+(w))] G(w, z), \tag{4.3}$$

where

$$z_-(w) = \frac{\mu + \lambda_1 + \lambda_2 - \lambda_1 w - \sqrt{(\mu + \lambda_1 + \lambda_2 - \lambda_1 w)^2 - 4\lambda_2 \mu}}{2\lambda_2}, \tag{4.4}$$

$$z_+(w) = \frac{\mu + \lambda_1 + \lambda_2 - \lambda_1 w + \sqrt{(\mu + \lambda_1 + \lambda_2 - \lambda_1 w)^2 - 4\lambda_2 \mu}}{2\lambda_2}. \tag{4.5}$$

By setting $z = z_-(w)$, we can get $H_L(w)$ in terms of $H_{L-1}(w)$ and p_{0L} as

$$H_L(w) = \frac{z_-(w)\left[\rho_2 w H_{L-1}(w) - p_{0L}\right]}{w - z_-(w)}. \tag{4.6}$$

Substituting (4.6) into (4.2) gives

$$G(w,z) = \left(\frac{p_{0L} - \rho_2 w H_{L-1}(w)}{\rho_2 (w - z_-(w))}\right)\left(\frac{z^L}{z - z_+(w)}\right). \tag{4.7}$$

It follows that

$$F(w,z) = \frac{\left(\frac{\mu}{w} - \mu\right) p_0 + \lambda_2 z^L H_{L-1}(w) + \left(\frac{\mu}{w} - \frac{\mu}{z}\right)\sum_{j=1}^{L-1} p_{0j} z^j - \mu z^{L-1} p_{0L}}{\lambda_1 w + \lambda_2 z - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{w}} + \left[\frac{p_{0L} - \rho_2 w H_{L-1}(w)}{\rho_2 (w - z_-(w))}\right]\left[\frac{z^L}{z - z_+(w)}\right]. \tag{4.8}$$

In order to evaluate the expression for $F(w,z)$ given in (4.8) p_0, p_{0j} $(j = 1, \ldots, L-1)$, $H_{L-1}(w)$, and p_{0L} have to be determined.

We first focus on finding the initial state probability p_0. Intuitively, for our problem p_0 is solely determined by μ, λ_1, and λ_2 and is not affected by the ordering of service. Thus, the probability of idleness should be the same as the one in the $M/M/1$ model with two input streams. We formally establish this result in Proposition 4.1.

PROPOSITION 4.1. *The idle probability is given by* $p_0 = 1 - \rho_1 - \rho_2$.

Proof. Setting $z = 1$ in (4.1) and (4.7), we have

$$H(w,1) = \frac{\lambda_2 H_{L-1}(w) + \mu\left(\frac{1}{w} - 1\right)\sum_{j=1}^{L-1} p_{0j} + \mu\left(\frac{1}{w} - 1\right) p_0 + \mu p_{0L}}{\lambda_1 w - (\lambda_1 + \mu) + \frac{\mu}{w}}$$

and

$$G(w,1) = \left(\frac{p_{0L} - \rho_2 w H_{L-1}(w)}{\rho_2 (w - z_-(w))}\right)\left(\frac{1}{1 - z_+(w)}\right).$$

Then we set $w = 1$ in the equations above and use l'Hôpital's rule to get

$$H(1,1) = \frac{\mu}{\lambda_2}\left(\sum_{j=1}^{L-1} p_{0j} + p_{0L}\right)$$

and

$$G(1,1) = -\frac{\mu}{\lambda_2}\left(\sum_{j=1}^{L-1} p_{0j} + p_{0L}\right) + \left(\frac{\mu}{\mu - \lambda_1 - \lambda_2}\right) p_0.$$

By employing the condition that $F(1,1) = 1$, we find that $p_0 = 1 - \rho_1 - \rho_2$. ∎

Now we are going to describe how to calculate p_{0j} $(j = 1, \ldots, L-1)$. Define p'_{ij} $(i, j = 1, 2, \ldots)$ to be the state probabilities in the head-of-the-line case. Miller [6] presented a series of recursive formulas for calculating p'_{ij}. Knessl, Choi, and Tier [7] explained that p_{ij} in our model are the same as the corresponding p'_{ij} for all i and $0 \le j \le L-1$. Therefore, Miller's method [6] can be directly used for our problem to obtain p_{0j} $(j = 1, \ldots, L-1)$.

Our next focus is on deriving the expression for $H_{L-1}(w)$. Equations (3.1) and (3.5) yield

$$\left[\lambda_1 w - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{w}\right] H_0(w) = -\mu p_{01} + \mu\left(\frac{1-w}{w}\right) p_0. \tag{4.9}$$

From (3.2) and (3.6), the relationship between $H_j(w)$ and $H_{j-1}(w)$ is found as

$$\begin{aligned}\left[\lambda_1 w - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{w}\right] H_j(w) + \lambda_2 H_{j-1}(w) \\ = -\mu p_{0,j+1} + \frac{\mu}{w} p_{0j},\ 1 \le j \le L-1.\end{aligned} \tag{4.10}$$

By setting $A(w) = \lambda_1 w - (\lambda_1 + \lambda_2 + \mu) + \frac{\mu}{w}$ and solving (4.9) and (4.10) recursively, we can establish the following result (presented without proof).

PROPOSITION 4.2. *The general form of* $H_j(w)$ $(1 \le j \le L-1)$ *is*

$$\begin{aligned}H_j(w) = \mu \Bigg[-\frac{1}{A(w)} p_{0,j+1} + \left(\frac{A(w) + w\lambda_2}{w\,(A(w))^{j+1}}\right) \left(\sum_{k=0}^{j-1} (A(w))^{j-k-1}\, p_{0,j-k} (-\lambda_2)^k\right) \\ + (-\lambda_2)^j \left(\frac{1-w}{w\,(A(w))^{j+1}}\right) p_0 \Bigg], \quad 1 \le j \le L-1.\end{aligned} \tag{4.11}$$

By setting $j = L-1$ and $w = 1$ in (4.11), we get p_{0L} as

$$p_{0L} = \rho_2 H_{L-1}(1). \tag{4.12}$$

Knessl, Choi, and Tier [7] presented an exact formula of $H_{L-1}(1)$ as an integral. However, as they noticed, for $L > 30$ the calculation becomes intractable. Thus we use an approximate method to calculate $H_{L-1}(1)$. From (3.9) we know that $H_{L-1}(1) = \sum_{i=0}^{\infty} p_{i,L-1}$. Thus $H_{L-1}(1)$ is approximated by $\sum_{i=0}^{M} p_{i,L-1}$, where M is a sufficiently large number—in particular, we will later see in section 7 that using $M = 5L$ works well in numerical tests.

5. Derivation of expected numbers in system. Armed with an expression of the generating function $F(w, z)$, we proceed to calculate L_1 and L_2. We take the partial derivatives of $F(w, z)$ in terms of both w and z and evaluate at (1,1) to get the results:

$$\begin{aligned}N_1 = {} & \frac{2\mu\lambda_1 \left(\sum_{j=1}^{L-1} p_{0j} + p_0\right) - 2\mu\lambda_2 H'_{L-1}(1) - \lambda_2(\mu - \lambda_1) H''_{L-1}(1)}{2(\mu - \lambda_1)^2} \\ & + \frac{2H'_{L-1}(1) + H''_{L-1}(1)}{2(z'_-(1) - 1)(1 - z_+(1))} - \frac{(H_{L-1}(1) + H'_{L-1}(1))(z''_-(1))}{2(1 - z'_-(1))^2 (1 - z_+(1))} \\ & - \frac{(H_{L-1}(1) + H'_{L-1}(1))(z'_+(1))}{(1 - z'_-(1))(1 - z_+(1))^2}\end{aligned} \tag{5.1}$$

and

$$N_2 = (L-1)H_{L-1}(1) + \frac{1}{\rho_2}\sum_{j=1}^{L-1}(j-1)p_{0j} + \left[\frac{H_{L-1}(1)+H'_{L-1}(1)}{z'_-(1)-1}\right]\left[\frac{L(1-z_+(1))-1}{(1-z_+(1))^2}\right]. \tag{5.2}$$

To evaluate N_1 and N_2, we observe that we further need to know the values of $z'_-(1)$, $z''_-(1)$, $z_+(1)$, $z'_+(1)$, $H'_{L-1}(1)$, and $H''_{L-1}(1)$. These are as follows:

$$z'_-(1) = \frac{\lambda_1}{\mu-\lambda_2}, \qquad z''_-(1) = \frac{2\mu\lambda_1^2}{(\mu-\lambda_2)^3},$$
$$z_+(1) = \frac{\mu}{\lambda_2}, \qquad z'_+(1) = -\frac{\mu\lambda_1}{(\mu-\lambda_2)\lambda_2},$$
$$H'_{L-1}(1) = \mu\left[\left(\frac{\lambda_1-\mu}{\lambda_2^2}\right)p_{0L} + \left(\frac{\lambda_1+\lambda_2-\mu}{\lambda_2^2}\right)\left(\sum_{j=1}^{L-1}p_{0j}\right) + \frac{p_0}{\lambda_2}\right],$$

and

$$H''_{L-1}(1) = \mu\left[\left(\frac{2\mu\lambda_2+2(\mu-\lambda_1)^2}{\lambda_2^3}\right)p_{0L} + \left(\frac{2\mu\lambda_2+2(\mu-\lambda_1-\lambda_2)(L\mu-L\lambda_1+\lambda_2)}{\lambda_2^3}\right)\left(\sum_{j=1}^{L-1}p_{0j}\right) + \left(\frac{2(\mu-\lambda_1-\lambda_2)(\lambda_1-\mu)}{\lambda_2^3}\right)\left(\sum_{j=2}^{L-1}(j-1)p_{0j}\right) - \left(\frac{2(L\mu-L\lambda_1+\lambda_2)}{\lambda_2^2}\right)p_0\right].$$

6. Properties. Having studied the generating functions and derived the formulas for N_1 and N_2, we are ready to discuss some important properties of this queueing system.

As mentioned previously in section 1, our queueing model is a generalization of the head-of-the-line model. The first two properties are straightforward to establish. The reader is referred to [8] for detailed proofs.

PROPERTY 6.1. *When $L = \infty$, the queue-length cutoff model is reduced to the head-of-the-line model.*

The next property has been discovered through intuitive observation. The point here is to investigate the mean number of customers (including both class-1 and class-2) in the system. If we consider the two classes as a whole, it is instructive to point out that changing the value of L only changes the order of the service and never changes the mean number of customers in the system. Clearly, the mean number of customers in our problem is the same as the one in the head-of-the-line model, or even the same as the one in the nonpriority $M/M/1$ model. It needs to be noted that the service rates of the two classes have been assumed to be equal and the classes have the same weight—hence the class-1 and class-2 jobs are indistinguishable.

PROPERTY 6.2. *Independent of the queue-length cutoff L, the mean number of customers $N_1 + N_2$ is a constant, which is given by*

$$N_1 + N_2 = \frac{\lambda_1+\lambda_2}{\mu-\lambda_1-\lambda_2}. \tag{6.1}$$

Although the mean total number of customers in the system is a constant, it is quite natural to see that N_1 and N_2 do change as L changes. Consider the example of increasing the value of L. It is intuitively clear that the server spends more time on the high-priority queue than before. Thus N_1 decreases as L increases. Conversely, N_2 is an increasing function in terms of L.

Basically, there are two different preemptive priority disciplines: preemptive resume and preemptive repeat. Preemptive resume allows preempted customers to continue their service where they left off when they reenter service, while preemptive repeat requires preemptive customers to pick up a new value of service time from the service-time distribution whenever they reenter service. The following property is presented and proved under the first case only, i.e., preemptive resume.

PROPERTY 6.3. *Under the preemptive resume priority discipline, suppose there are two queue-length cutoffs L and L', where $L < L'$. Then the following statements are true:*

$$N_1(L) \geq N_1(L') \tag{6.2}$$

and

$$N_2(L) \leq N_2(L'). \tag{6.3}$$

Proof. Since it is not even clear how $H_{L-1}(1)$ and $\sum_{j=1}^{L-1} p_{0j}$ behave as L changes, it seems impossible to prove this property directly by (5.1) and (5.2). The remarkable difficulty makes us resort to the following method.

We consider an arbitrary busy period. Obviously, when the priority discipline is preemptive resume, the total service time of a class-1 or class-2 customer is in no way affected by the number of times he/she is preempted. That is, changing the value of L only changes the order of service, while the duration of any busy period is always equivalent to the total service time of the customers in that period.

A typical example is shown in Figure 4, where the queue-length cutoff $L = 4$. It is instructive to see that N_1 and N_2 in a busy period can be calculated as

$$N_i = \frac{\text{Area}(N_i^L)}{D}, \quad i = 1, 2, \tag{6.4}$$

where

$$\begin{aligned} \text{Area}(N_i^L) &= \text{area covered by class-}i\text{ customers given that the queue-length} \\ &\qquad \text{cutoff is } L, \text{and} \\ D &= \text{duration of that busy period.} \end{aligned}$$

In this proof, we only focus on (6.2). The assertion of (6.3) can be derived in a similar manner. Suppose the current queue-length cutoff is L. If there is no preemption for class-1 customers in this period, it is easy to see that the number of preemptions for class-1 customers is still zero if L is increased to L'.

Consider now that there is at least one preemption for the high-priority queue. We pick up an arbitrary preemption to study. An example is shown in Figure 5. We can see that the preempted time point and the resume time point have been shifted from P^L and R^L to $P^{L'}$ and $R^{L'}$, respectively. Clearly, this shifting does not affect the area before time point P^L. Changes only occur after that time point. Since the interarrival time between two customers and the service time of a customer cannot

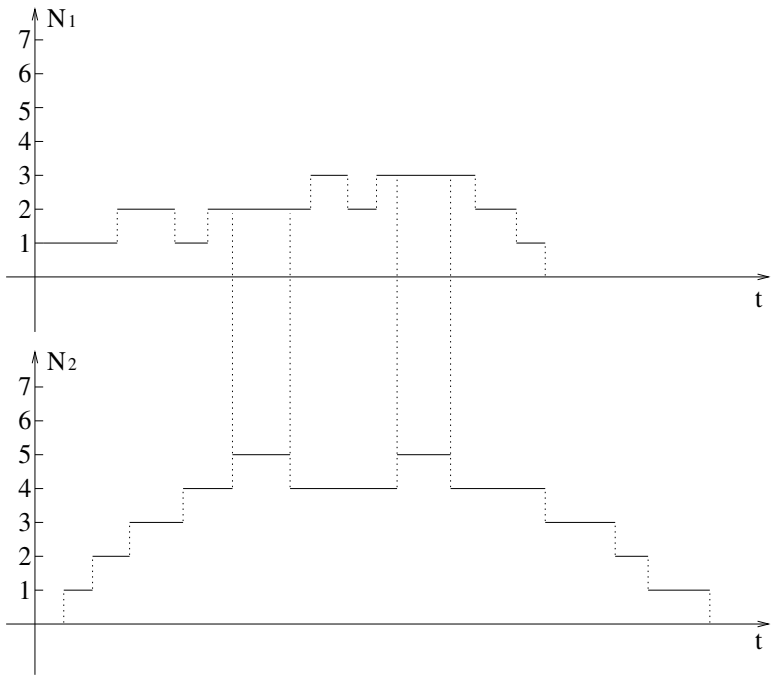

FIG. 4. *An example of a busy period.*

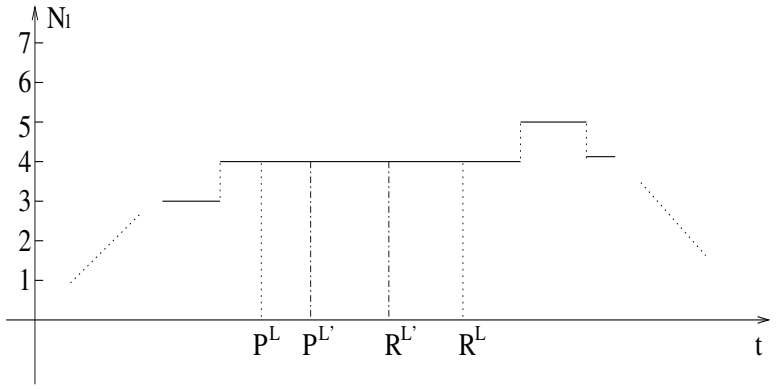

FIG. 5. *An example of a preemption.*

be zero, the preemption time $R^{L'} - P^{L'}$ is strictly less than the one $R^L - P^L$. This result leads to another conclusion: at any time t ($\geq P^L$), $X(t)$ in the second case is less than or equal to the corresponding quantity in the first case. Thus, when L is increased to L', the area after time point P^L is strictly decreased. Combining the two areas together, we can conclude that Area(N_1) is a decreasing function of L. This yields the final result that $N_1(L) \geq N_1(L')$ when $L < L'$. The property follows. □

Property 6.2 tells us that the total number of customers in the system is constant. However, let us consider an example. Suppose that there are 8 priority-1 customers and 2 priority-2 customers in case 1 and that there are 2 priority-1 customers and 8 priority-2 customers in case 2. Although the total number of customers is 10 for

both cases, it is obvious that case 1 is much worse than case 2. The reason is that we usually assign a higher weight, π_1, to priority-1 customers and a lower weight, π_2, to priority-2 customers. In consideration of the weighted number of customers in the system, Properties 6.2 and 6.3 lead us to the following result for minimizing the function $\pi_1 N_1 + \pi_2 N_2$ for certain choices of weights.

PROPERTY 6.4. *In the preemptive resume model, suppose that π_1 and π_2 are constant, where $\pi_1 > \pi_2 > 0$ and $\pi_1 + \pi_2 = 1$. The optimal queue-length cutoff is given by $L^* = \infty$.*

Proof. We consider two queue-length cutoffs L and L' with $L < L'$. Suppose that the average number of priority-1 customers is N_1 and that the average number of priority-2 customers is N_2 if the cutoff is L. Thus the weighted number of customers for this case is calculated as

$$\pi_1 N_1 + \pi_2 N_2. \tag{6.5}$$

When L is increased to L', Property 6.3 tells us that N_1 decreases. Suppose the number of priority-1 customers changes to $N_1 - \epsilon$, where $\epsilon > 0$. Then Property 6.2 shows that the number of priority-2 customers changes to $N_2 + \epsilon$. The weighted number of customers is given by

$$\pi_1 N_1 + \pi_2 N_2 + (\pi_2 - \pi_1)\epsilon. \tag{6.6}$$

It is easy to see that the value of (6.6) is smaller than the value of (6.5). Thus we conclude that the optimal cutoff is given by $L^* = \infty$. □

We now address the more interesting case—which is particularly relevant to the disaster-relief application—where the weight of a priority class may vary as the queue length changes. Generally speaking, the weight increases (decreases) as the queue length increases (decreases). Since π_1 and π_2 correlate each other ($\pi_1 = 1 - \pi_2$), we only need to specify one of them, e.g., π_2. We consider the case when the weight is a linear function of the queue length, i.e., the function can be expressed as $\pi_2 = KN_2 + C$. The function is shown in Figure 6, where $N_{2L_{min}}$ and $N_{2L_{max}}$ stand for the numbers of priority-2 customers under the minimal cutoff ($L = 3$) and the maximal cutoff ($L = \infty$) cases, respectively. The weights, $\pi_{2L_{min}}$ and $\pi_{2L_{max}}$, for these two extreme cases are assumed to be given. The parameters K and C are then determined uniquely by the two points $(N_{2L_{min}}, \pi_{2L_{min}})$ and $(N_{2L_{max}}, \pi_{2L_{max}})$ as follows:

$$K = \frac{\pi_{2L_{max}} - \pi_{2L_{min}}}{N_{2L_{max}} - N_{2L_{min}}} \tag{6.7}$$

and

$$C = \pi_{2L_{max}} - \frac{(\pi_{2L_{max}} - \pi_{2L_{min}})N_{2L_{max}}}{N_{2L_{max}} - N_{2L_{min}}}. \tag{6.8}$$

The weighted number of customers for the minimal cutoff case is given by

$$\pi_{1L_{min}} N_{1L_{min}} + \pi_{2L_{min}} N_{2L_{min}}. \tag{6.9}$$

Assume that L' is an arbitrary cutoff that is larger than L_{min}. Define δ and Δ to be the values increased from $\pi_{2L_{min}}$ to $\pi_{2L'}$ and from $N_{2L_{min}}$ to $N_{2L'}$, respectively. We can verify that $\delta = K\Delta$. Then the weighted number of customers for this case is calculated as

$$(\pi_{1L_{min}} - \delta)(N_{1L_{min}} - \Delta) + (\pi_{2L_{min}} + \delta)(N_{2L_{min}} + \Delta), \tag{6.10}$$

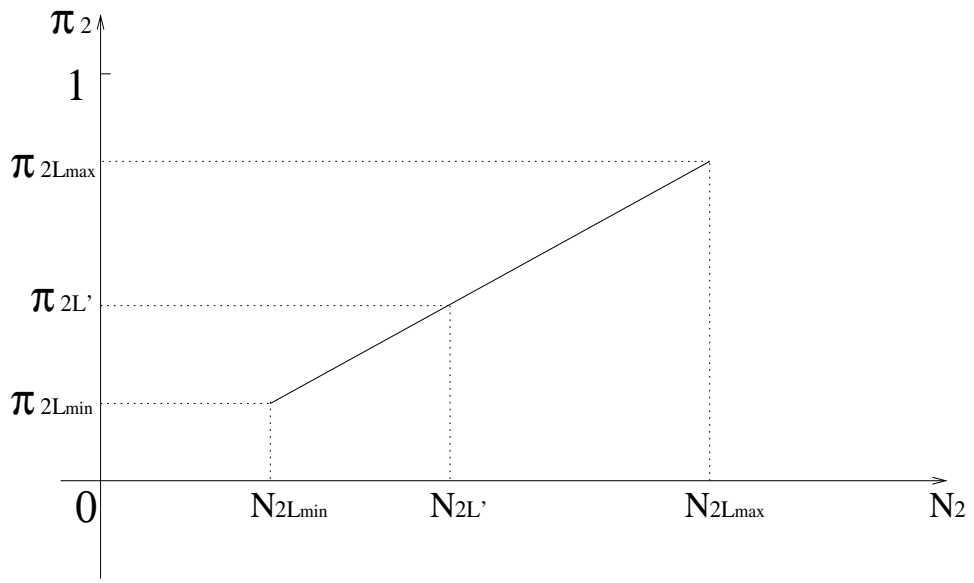

FIG. 6. *A linear weight function.*

which is equivalent to

$$(\pi_{1L_{min}} N_{1L_{min}} + \pi_{2L_{min}} N_{2L_{min}}) + \{2K\Delta^2 + [(\pi_{2L_{min}} - \pi_{1L_{min}}) + (N_{2L_{min}} - N_{1L_{min}})]\Delta\}. \tag{6.11}$$

Comparing (6.11) with (6.9), we see that the optimal cutoff is determined by the discrete function

$$f(\Delta) = 2K\Delta^2 + [(\pi_{2L_{min}} - \pi_{1L_{min}}) + (N_{2L_{min}} - N_{1L_{min}})]\Delta. \tag{6.12}$$

Since $K > 0$, the value Δ^*, which minimizes the *continuous* equation (6.12), is

(6.13)

$$\Delta^* = \frac{(1 - 2\pi_{2L_{min}})(N_{2L_{max}} - N_{2L_{min}}) + (\pi_{2L_{max}} - \pi_{2L_{min}})(N_{1L_{min}} - N_{2L_{min}})}{4(\pi_{2L_{max}} - \pi_{2L_{min}})}.$$

However, considering that $0 \le \Delta \le N_{2L_{max}} - N_{2L_{min}}$, we can identify the following three cases:

Case 1: $\Delta^* \le 0$. In this case, $L^* = L_{min}$.

Case 2: $\Delta^* \ge N_{2L_{max}} - N_{2L_{min}}$. In this case, $L^* = L_{max}$.

Case 3: $0 < \Delta^* < N_{2L_{max}} - N_{2L_{min}}$. The function $f(\Delta)$ in our research is discrete. Usually the optimal Δ^* does not correspond to points in this discrete set. In this case, we only need to identify two points as follows:

$$\Delta_1 = \min\{\Delta : f(\Delta) \le f(\Delta^*)\}$$

and

$$\Delta_2 = \min\{\Delta : f(\Delta) > f(\Delta^*)\}.$$

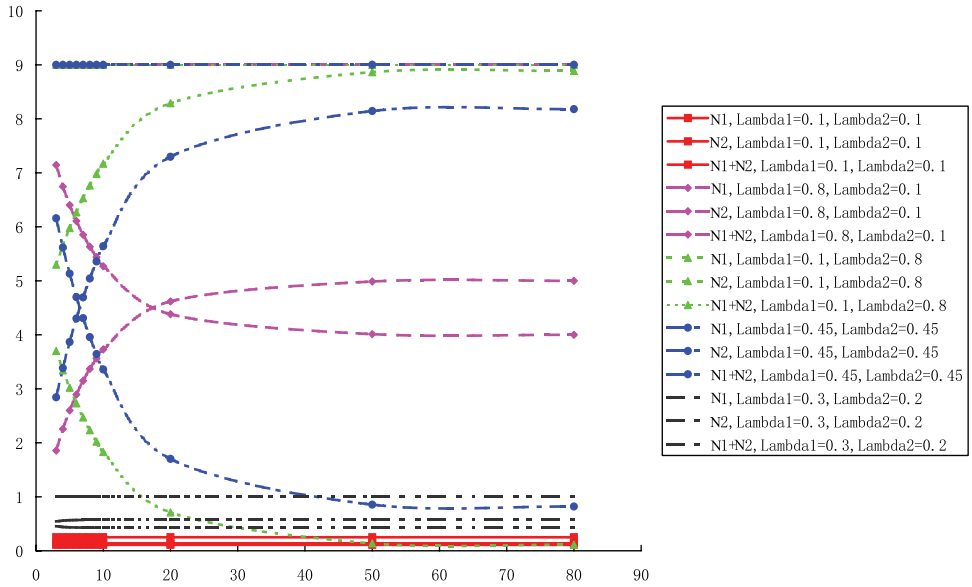

FIG. 7. *Computational results of* N_1, N_2, *and* $N_1 + N_2$.

The optimal value of Δ, denoted as Δ^{**}, is given by

$$\Delta^{**} = \text{argmin}\{f(\Delta_1), f(\Delta_2)\}.$$

The cutoff L^* which corresponds to Δ^{**} is the optimal solution.

7. Computational results. Before proceeding with the numerical results, we first investigate the approximate method of calculating $H_{L-1}(1)$. As discussed in section 4, for $L > 30$ an appropriate value of M needs to be used in order to make $\sum_{i=0}^{M} p_{i,L-1}$ as a good estimation of $H_{L-1}(1)$. We conduct a series of numerical experiments using various combinations of λ_1 and λ_2. We employ eight different values of L (from 3 to 10) in each experiment. The exact results calculated by the method in [7] are used as benchmarks. After some trial runs, we find that $\sum_{i=0}^{M} p_{i,L-1}$ can provide a good approximation of $H_{L-1}(1)$ if $M = 5L$. In most of the cases, the errors are within 0.1%. Table 1 shows a sample of results from these experiments.

Next we focus on calculating N_1 and N_2. The results are shown in Figure 7. We can see that for all cases our model approaches the head-of-the-line case as L increases. The total number of customers in the system is a constant, while N_1 and N_2 decrease and increase, respectively.

TABLE 2
Optimal cutoffs.

	L^*	Weighted no. of customers
$\lambda_1 = 0.1, \lambda_2 = 0.1$	3	0.118114
$\lambda_1 = 0.1, \lambda_2 = 0.8$	5	3.9845
$\lambda_1 = 0.45, \lambda_2 = 0.45$	9	4.39441
$\lambda_1 = 0.8, \lambda_2 = 0.1$	13	4.47104
$\lambda_1 = 0.1, \lambda_2 = 0.88$	37	24.0178
$\lambda_1 = 0.49, \lambda_2 = 0.49$	42	24.2835
$\lambda_1 = 0.88, \lambda_2 = 0.1$	46	24.4654

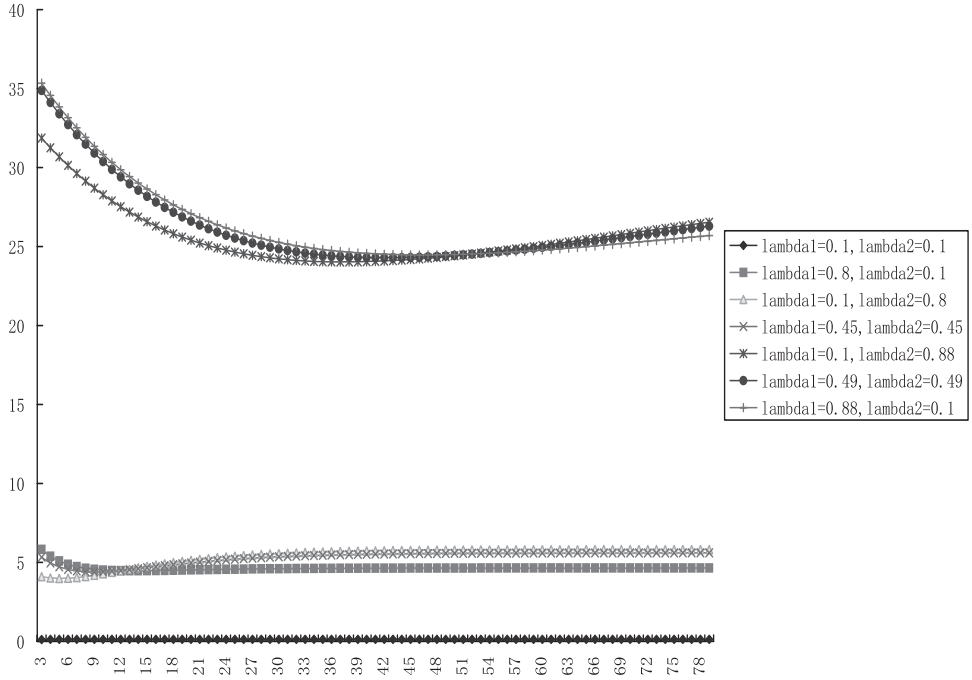

FIG. 8. *Computational results of weighted number of customers.*

We now present an example which calculates the weighted number of customers under the case of a linear weight function. We set $\pi_{2L_{min}} = 0.45$ and $\pi_{2L_{max}} = 0.65$. The results are shown in Table 2. We consider seven different combinations of λ_1 and λ_2. In the case of $\lambda_1 = \lambda_2 = 0.1$, since $\Delta^*(= -0.006849)$ is less than zero, we have $L^* = L_{min}$. The values of Δ^* in all the other cases satisfy the condition $0 < \Delta^* < N_{2L_{max}} - N_{2L_{min}}$, and thus different finite optimal cutoffs are obtained as shown in Table 2.

Figure 8 also illustrates the detailed results. When both λ_1 and λ_2 are small ($\lambda_1 = \lambda_2 = 0.1$), the change of the average weighted number of customers is negligible with a change in the value of L. This is because the system is in an *unsaturated* status, which leads to very little change of N_1 and N_2 values. When either λ_1 or λ_2 (or both) increases, the average number of customers becomes much larger than in the *unsaturated* case. We focus on the three cases ($\lambda_1 = 0.1, \lambda_2 = 0.8$; $\lambda_1 = 0.45, \lambda_2 = 0.45$; $\lambda_1 = 0.8, \lambda_2 = 0.1$) in which the total arrival rates are the same. We can see that the optimal cutoff increases as λ_1 increases. Given the condition that $\lambda_1 + \lambda_2$ is a constant, Property 6.2 shows that $N_1 + N_2$ is a constant no matter

what the specific values of λ_1 and λ_2 are. Thus the increase of λ_1 causes an increase in N_1 and a decrease in N_2. More priority-1 customers lead to an increase in the optimal cutoff value. As the system approaches the *saturated* status, both N_1 and N_2 increase dramatically. Consequently, the average number of customers also increases significantly. This causes a sharp increase in the optimal cutoff value.

8. Summary and future work. A two-priority, preemptive, single-server system with a queue-length cutoff queueing discipline has been studied in this paper. This is a generic problem for various applications such as disaster relief and telecommunication. Expressions for calculating the number of class-1 customers and the number of class-2 customers are developed based on a generating function approach. The method we present does not lead to a closed-form solution, but rather to an effective numerical approximation.

We have shown that our model reduces to the head-of-the-line model if $L = \infty$. The total number of customers in the system is shown to be constant with respect to L. Then we focus on the preemptive resume case, in which N_1 and N_2 are decreasing and increasing functions of L, respectively. The weighted average number of customers is first analyzed for the case where the weights for both queues are constant. We prove that the optimal policy is to set $L^* = \infty$. Then the case where the weights change linearly with the queue lengths is analyzed and a procedure is developed to find the optimal cutoff. Numerical results illustrate the properties and other results.

There are several possible directions for future work:

(1) In our model, the moment that the number of low-priority jobs hits threshold L, the server stops working on high-priority jobs entirely. An alternative threshold policy in which the server is shared when the threshold is reached should be studied.
(2) For analytical tractability we assumed that the service rate for the high- and low-priority jobs is the same. The more realistic case where the service rates are class dependent should be studied.
(3) Another direction of future work is to consider the use of an alternate solution method, namely, dimensionality reduction for Markov chains. The work of Osogami, Harchol-Balter, and Scheller-Wolf [9] serves as a useful starting point.
(4) A further opportunity is in analyzing the multiserver version of our model, which is closer to reality for a disaster-relief application.
(5) By applying the memoryless property of the exponential distribution it may be possible to establish Property 6.3 for the preemptive repeat case.

Appendix A. Derivation of (4.1). From (3.10), we get

$$\begin{aligned}&(\lambda_1+\lambda_2+\mu)H(w,z)\\ &\quad=(\lambda_1+\lambda_2+\mu)\left(p_0+\sum_{j=1}^{L-1}p_{0j}z^j+\sum_{i=1}^{\infty}p_{i0}w^i+\sum_{i=1}^{\infty}\sum_{j=1}^{L-1}p_{ij}w^iz^j\right).\end{aligned}\tag{A.1}$$

From (3.1), (3.2), (3.5), and (3.6), the right-hand side of (A.1) can be written as

$$\begin{aligned}&(\lambda_1+\lambda_2+\mu)p_0+\sum_{j=1}^{L-1}(\lambda_2p_{0,j-1}+\mu p_{0,j+1}+\mu p_{1j})z^j+\sum_{i=1}^{\infty}(\mu p_{i+1,0}+\lambda_1p_{i-1,0})w^i\\ &+\sum_{i=1}^{\infty}\sum_{j=1}^{L-1}(\lambda_1p_{i-1,j}+\lambda_2p_{i,j-1}+\mu p_{i+1,j})w^iz^j.\end{aligned}\tag{A.2}$$

Regrouping the terms in (A.2) according to λ_1, λ_2, and μ, we have

$$
\begin{aligned}
&(\lambda_1+\lambda_2+\mu)H(w,z)\\
&\quad=\lambda_1\left(p_0+\sum_{i=1}^{\infty}p_{i-1,0}w^i+\sum_{i=1}^{\infty}\sum_{j=1}^{L-1}p_{i-1,j}w^iz^j\right)\\
&\quad\quad+\lambda_2\left(p_0+\sum_{j=1}^{L-1}p_{0,j-1}z^j+\sum_{i=1}^{\infty}\sum_{j=1}^{L-1}p_{i,j-1}w^iz^j\right)\\
&\quad\quad+\mu\left[p_0+\sum_{j=1}^{L-1}(p_{0,j+1}+p_{1j})z^j+\sum_{i=1}^{\infty}p_{i+1,0}w^i+\sum_{i=1}^{\infty}\sum_{j=1}^{L-1}p_{i+1,j}w^iz^j\right].
\end{aligned}
\tag{A.3}
$$

Then we arrange the terms on the right-hand side in (A.3) and obtain

$$
\begin{aligned}
&(\lambda_1+\lambda_2+\mu)H(w,z)\\
&\quad=\lambda_1wH(w,z)+\lambda_2(zH(w,z)-z^LH_{L-1}(w))\\
&\quad\quad+\frac{\mu}{w}H(w,z)+\left(\frac{\mu}{z}-\frac{\mu}{w}\right)\sum_{j=1}^{L-1}p_{0j}z^j+\mu p_0-\frac{\mu}{w}p_0+\mu z^{L-1}p_{0L}.
\end{aligned}
\tag{A.4}
$$

Equation (A.4) immediately yields

$$
H(w,z)=\frac{\left(\frac{\mu}{w}-\mu\right)p_0+\lambda_2z^LH_{L-1}(w)+\left(\frac{\mu}{w}-\frac{\mu}{z}\right)\sum_{j=1}^{L-1}p_{0j}z^j-\mu z^{L-1}p_{0L}}{\lambda_1w+\lambda_2z-(\lambda_1+\lambda_2+\mu)+\frac{\mu}{w}}.
\tag{A.5}
$$

Appendix B. Derivation of (4.2). From (3.11), we get

$$
\begin{aligned}
&(\lambda_1+\lambda_2+\mu)G(w,z)\\
&\quad=(\lambda_1+\lambda_2+\mu)\left(p_{0L}z^L+\sum_{i=1}^{\infty}p_{iL}w^iz^L+\sum_{j=L+1}^{\infty}p_{0j}z^j+\sum_{i=1}^{\infty}\sum_{j=L+1}^{\infty}p_{ij}w^iz^j\right).
\end{aligned}
\tag{B.6}
$$

From (3.3), (3.4), (3.7), and (3.8), the right-hand side of (B.6) can be written as

$$
\begin{aligned}
&z^L(\lambda_2p_{0,L-1}+\mu p_{0,L+1}+\mu p_{1L})+z^Ls\sum_{i=1}^{\infty}(\lambda_1p_{i-1,L}+\lambda_2p_{i,L-1}+\mu p_{i+1,L}+\mu p_{i,L+1})w^i\\
&\quad+\sum_{j=L+1}^{\infty}(\lambda_2p_{0,j-1}+\mu p_{0,j+1})z^j+\sum_{i=1}^{\infty}\sum_{j=L+1}^{\infty}(\lambda_1p_{i-1,j}+\lambda_2p_{i,j-1}+\mu p_{i,j+1})w^iz^j.
\end{aligned}
\tag{B.7}
$$

Regrouping the terms in (B.7) according to λ_1, λ_2, and μ, we have

$$
\begin{aligned}
&(\lambda_1+\lambda_2+\mu)G(w,z)\\
&\quad=\lambda_1 w\left(z^L\sum_{i=1}^{\infty}p_{i-1,L}w^{i-1}+\sum_{i=1}^{\infty}\sum_{j=L+1}^{\infty}p_{i-1,j}w^{i-1}z^j\right)\\
&\qquad+\lambda_2 z\left(z^{L-1}p_{0,L-1}+\sum_{j=L+1}^{\infty}p_{0,j-1}z^{j-1}+z^{L-1}\sum_{i=1}^{\infty}p_{i,L-1}w^i\right.\\
&\qquad\left.+\sum_{i=1}^{\infty}\sum_{j=L+1}^{\infty}p_{i,j-1}w^iz^{j-1}\right)+\frac{\mu}{z}\left[z^{L+1}(p_{0,L+1}+p_{1L})+\sum_{j=L+1}^{\infty}p_{0,j+1}z^{j+1}\right.\\
&\qquad\left.+z^{L+1}\sum_{i=1}^{\infty}(p_{i+1,L}+p_{i,L+1})w^i+\sum_{i=1}^{\infty}\sum_{j=L+1}^{\infty}p_{i,j+1}w^iz^{j+1}\right].
\end{aligned}
\tag{B.8}
$$

Then we arrange the terms on the right-hand side in (B.8) and obtain

$$
\begin{aligned}
&(\lambda_1+\lambda_2+\mu)G(w,z)\\
&\quad=\lambda_1 wG(w,z)+\lambda_2 zG(w,z)+\lambda_2 z^LH_{L-1}(w)\\
&\qquad+\frac{\mu}{z}G(w,z)+z^L\left[\mu\left(-\frac{1}{z}H_L(w)+\frac{1}{w}H_L(w)\right)-\frac{\mu}{w}p_{0L}\right].
\end{aligned}
\tag{B.9}
$$

Equation (B.9) immediately yields

$$
\begin{aligned}
&\left[\lambda_1 w+\lambda_2 z-(\lambda_1+\lambda_2+\mu)+\frac{\mu}{z}\right]G(w,z)\\
&\quad=z^L\left[-\lambda_2H_{L-1}(w)+\mu\left(\frac{1}{z}-\frac{1}{w}\right)H_L(w)+\frac{\mu}{w}p_{0L}\right].
\end{aligned}
\tag{B.10}
$$

Acknowledgment. The authors are grateful for constructive comments from two anonymous referees that led to a much tighter presentation of the results.

FLAME BALLS FOR A FREE BOUNDARY COMBUSTION MODEL WITH RADIATIVE TRANSFER*

JAN BOUWE VAN DEN BERG†, VINCENT GUYONNE‡, AND JOSEPHUS HULSHOF†

Abstract. We study radial flame ball solutions of a three-dimensional free boundary problem (FBP), which models combustion of a gaseous mixture with dust in a microgravity environment. The model combines diffusion of mass and temperature with reaction at the flame front, the reaction rate being temperature dependent. The radiative flux due to the presence of dust enters the equation for the temperature in the form of a divergence term. This flux is modeled by Eddington's radiative transfer equation. The main parameters are the dimensionless opacity and the ratio of radiative and thermal fluxes. We prove existence of spherical flame ball solutions for the FBP. Bifurcation diagrams are obtained, exhibiting the multiplicity of solutions. Singular limit cases of the parameter values are also discussed.

1. Introduction.

Combustion processes in gaseous mixtures exhibit a variety of phenomena, such as propagating flame fronts, and, in zero- or microgravity situations, flame balls. The latter are perhaps harder to observe, but the advantage is that they are stationary. From a mathematical point of view they are easier to understand, namely as equilibria rather than traveling wave solutions of the mathematical models used to describe the combustion processes. From a physical point of view, because of the force and speed of the reaction, it is hard to do controlled experiments on flame fronts, whereas the combustion is much less violent in flame balls, which can be observed for prolonged periods of time at the cost of having to transfer the experiment to a microgravity environment. In any case, the high costs and experimental difficulties in combustion research highlight the need for a thorough understanding of the mathematical models.

Since the work of Zeldovich et al. [1], flame balls are known to exist for models of combustion with simple chemistry, such as a one step reaction in which a gaseous reactant is converted into a gaseous product. Figure 1 is a sketch of a flame ball in the nonradiative case. Note that, in this particular situation, the temperature θ_b in the burnt region is constant inside the ball. In this model, commonly referred to as the adiabatic case, flame balls are linearly unstable, in apparent agreement with the absence of experimentally observed flame balls. That was, until 1984, when Ronney discovered, by surprise, the existence during drop tower experiments of physical flame balls, later confirmed by experiments in the space shuttle [2, 3]. Since then, several effects have been taken into account in combustion models to explain stabilization of

flame balls, particularly (radiative) heat losses from the combustion products inside the flame ball. We refer to [3] and references therein; see also the SOFBALL (structure of flame balls at low lewis number) home page [4].

In fact, the radiative transfer of heat in combustion processes taking place in inert not fully transparent media (e.g., dust, porous media, ...) involves both emission and absorption of radiation and may significantly influence the flame temperature (see Figure 2), its propagation speed, and the flammability of the medium itself. This occurs, for instance, in forest fires and fires in confined spaces such as tunnels, and the importance of radiative transfer has been noted and stressed in [5, 6, 7]. In this paper, we concentrate on the effects of radiative transfer on flame balls.

There are two common formulations for modeling combustion processes: the reaction-diffusion and the free boundary formulation. Although both formulations are widely used in the combustion literature, the relation between the two approaches has so far largely been based on numerical simulation and heuristic arguments.

The basic thermo-diffusive model of combustion with simple chemistry is a reaction-diffusion system (RDS) that is written as

$$Y_t = \frac{1}{\mathrm{Le}}\Delta Y - YF(\theta), \tag{1a}$$

$$\theta_t = \Delta\theta + YF(\theta), \tag{1b}$$

where Y denotes the mass fraction of the reactant, θ the temperature, and Le the Lewis number (ratio between conductivity and diffusivity). The function F is an Arrhenius-type reaction rate involving a small parameter ε which is the inverse of the activation energy. The Arrhenius law is often modified by the choice of an ignition temperature, below which the reaction rate is taken to be zero. In this framework, (linearly) unstable flame balls are known to exist. For Lewis number close to unity,

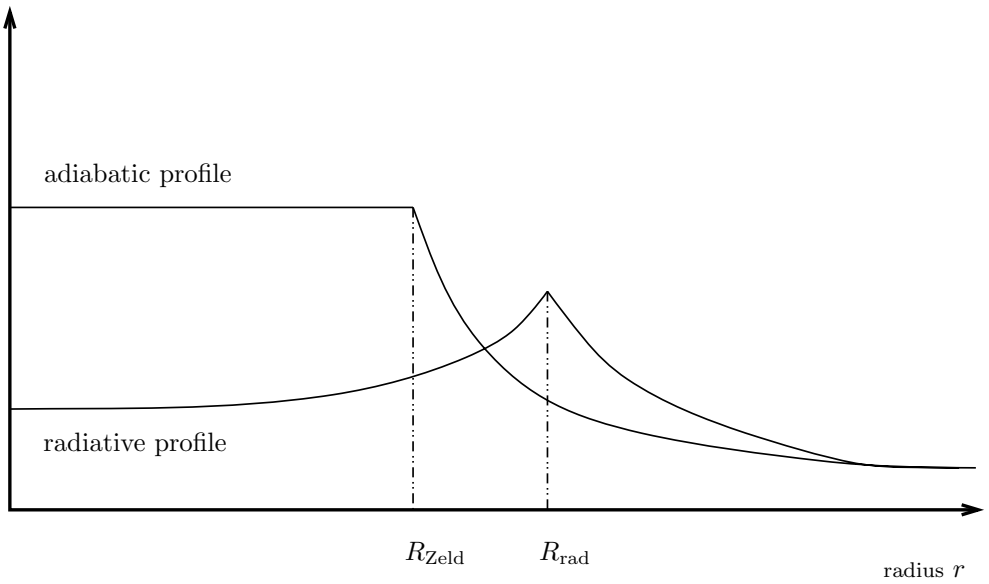

FIG. 2. *Difference of temperature profiles in the adiabatic and in the radiative case.*

the growth of the radius has been described using an integro-differential equation derived formally by Buckmaster, Joulin, and Ronney [8] and rigorously validated by Lederman, Roquejoffre, and Wolansky [9].

When one assumes that the flame occurs in a very thin region, it is quite natural to define a free boundary problem (FBP). Its derivation from the RDS formulation has been justified formally in [10] under the assumption of high activation energy. Its validity is also confirmed by numerical simulations on the RDS, and its great advantage is that several analytical aspects are simpler to treat. The FBP reads as follows:

$$Y_t = \frac{1}{\text{Le}}\Delta Y \qquad \text{for } x \notin R(t), \tag{2a}$$

$$\theta_t = \Delta\theta \qquad \text{for } x \notin R(t), \tag{2b}$$

with

$$[\theta] = Y = 0, \quad -[\theta_n] = \frac{1}{\text{Le}}[Y_n] = F(\theta), \qquad \text{for } x \in R(t), \tag{2c}$$

where $R(t)$ represents the location of the free boundary (the flame front) and brackets denote jumps across the free boundary (in the direction of the normal n). The mass flux into the flame is balanced by (reaction) heat flux coming out of the flame, with a (predominantly) temperature dependent reaction rate. Note that at the flame front we impose the condition that $Y = 0$. Usually, one imposes only that the jump $[Y] = 0$, silently assuming that $Y \equiv 0$ on the burnt side of the flame front. Without such an assumption, the FBP formulation with $[Y] = 0$ instead of $Y = 0$ is underdetermined. As an FBP this model should not be confused with the well-studied model for nearly equidiffusional flames (NEF), which was derived by Sivashinsky by means of an asymptotic analysis, in which he coupled the deviation of the Lewis number from unity to ε, the inverse of the activation energy (see [11, 12]), and derived what is now known as the Kuramoto–Sivashinsky equation.

The remaining step is to incorporate a model for the radiative effects. The first models developed by Buckmaster, Joulin, and Ronney [8, 13] and Shah, Thachter, and Dold [10], for example, are based on rather ad hoc heat loss assumptions (whereas in the present paper we will consider a more thorough radiative transfer model). We would like to recall at this point some results obtained in this context. In [8], heat losses are assumed to occur in the volume enclosed by the flame sheet only. In this framework two stationary solution branches exist, corresponding to small and large radius. Concerning the ensuing stability issues, the authors showed that, provided that the Lewis number is less than unity, all small flames are unstable to one-dimensional (radial) perturbations. Large flames are unstable to three-dimensional perturbations, but only if they have a radius greater than some critical value. Thus there is a band of large flames, lying between the quenching point and unstable flames, that are stable. In [13], the authors extend this result by including the effects of heat loss in the far field (unburned gas), and they conclude that far field losses do not qualitatively change the (stability) properties of the solutions. Finally, in [10], flame balls are studied in a porous medium that serves to exchange heat with the gas, and two heat loss models are considered. One of these treats the heat loss as being constant in the burnt region and linear in the unburned region. The other does not distinguish between burnt and unburnt gas and is based on a (nonlinear) Stefan's law. For both heat loss models, the authors find, again, two branches of solutions of small and large flame balls, respectively. For Lewis number greater than unity the solutions are unstable, while at Lewis number less than unity part of the branch of large flame balls becomes stable, solutions with the nonlinear radiative law being stable over a smaller range of parameters. The stable parameter region increases when the heat capacity of the porous medium is increased. It is clear from the considerations in [8, 10, 13] that the stability properties depend strongly on the Lewis number. More details and a comparison with our model can be found in section 4.

In this paper, we would like to go one step further in the description of the radiative effects and introduce a physically more realistic radiative transfer model. Let us start with a microscopic description of the radiative transfer, which is given by the equation

$$\partial_t I + \Omega \cdot \nabla I = \sigma(B(\nu, \theta) - I),$$

where $I = I(x, t, \Omega, \nu)$ is a total radiative intensity, x the position, t the time, Ω the direction of emission vector, ν the frequency, σ the opacity of the medium, and $B(\nu, \theta)$ the Planck distribution: $B(\nu, \theta) = \frac{2h\nu^3}{c^2}(\exp(\frac{h\nu}{k\theta}) - 1)^{-1}$. Since numerical simulations of this model are very cumbersome, radiation is most commonly described by simplified models, such as the (Milne–)Eddington diffusion equations, valid in the limit of isotropic radiation; the Rosseland model, valid for high opacity media; or the optically thin model, valid for nonabsorbent media [14, 15].

In this paper we adopt the Eddington diffusion model [14, 15, 16, 17, 18, 19], namely,

$$-\nabla(\nabla \cdot q) + 3\alpha^2 q = -\alpha \nabla \theta^4, \tag{3}$$

where q is the radiative flux. Thus, the radiative effects are a direct consequence of temperature variations. Following Joulin and Buckmaster and coworkers [5, 6, 7], these radiative effects couple back to the temperature equation, in which the divergence of the radiative flux appears with coupling constant β, the Boltzmann constant.

Thus β is a measure of the ratio between the radiative and the diffusive flux. For flame fronts, this extended model was proposed and studied in [5, 6, 7], and in [20, 21].

In this paper we study equilibria of the resulting FBP in the radially symmetric case, i.e., steady spherically symmetric flame balls. If we set $r = |x|$, we may thus write the Laplacian operator as $\Delta = \partial_{rr} + \frac{2}{r}\partial_r$, so that the problem can be viewed as a system of ordinary differential equations. Hence, throughout the paper all functions depend on the radial coordinate r only, and they all have zero derivative at $r = 0$. To make the mathematical analysis easier, we do not use the vector equation (3) but work with the scalar equation

$$-\Delta u + 3\alpha^2 u - \alpha\Delta\theta^4 = 0,$$

where $-u = \nabla \cdot q$, the divergence of the radiation flux as it appears in the modified temperature equation. This equation is nonlinear and therefore does not allow us to compute explicit solutions for the full problem defined below. On the other hand, if one considers θ instead of θ^4, i.e., the "linear" problem, one can write down explicitly the solution, and in section 4 we compare the solutions of the linear and nonlinear equations. The FBP reads

$$\frac{1}{\mathrm{Le}}\Delta Y = 0 \qquad \text{for } r \neq R, \tag{4a}$$

$$-\Delta\theta - \beta u = 0 \qquad \text{for } r \neq R, \tag{4b}$$

$$-\Delta u + 3\alpha^2 u - \alpha\Delta\theta^4 = 0. \tag{4c}$$

Equation (4c) is satisfied in the whole space in the sense of the distributions (and classically for $r \neq R$). The jump conditions at $r = R$ are

$$[\theta] = Y = 0, \qquad -[\theta_r] = \frac{1}{\mathrm{Le}}[Y_r] = F(\theta(R)), \tag{4d}$$

with u being continuous, while the size of the jump in u_r follows automatically from (4c) and (4d). The asymptotic boundary conditions are

$$Y \to Y_f, \quad \theta \to \theta_f, \quad u \to 0 \quad \text{as } r \to \infty. \tag{4e}$$

The parameters θ_f and Y_f denote the temperature and the mass fraction far away in the fresh region. We recall that R is the free boundary variable corresponding to the flame front, and that $F(\theta(R))$ is the reaction rate evaluated at $r = R$. Note that we will not specify the reaction rate and work only with general reaction rates F. The reason is that, to prove existence properties, we need to know only that F is a positive function of the temperature at the flame front. The main result of this paper is the following.

THEOREM 1 (existence). *Let $\alpha \geq 0$, $\beta \geq 0$, let F be continuous and positive, and let $\theta_f > 0$, $Y_f > 0$. Then there exists a radial solution $(\theta(r), Y(r), u(r), R)$ to (4). Moreover, for generic choices of the parameters the number of solutions is odd.*

Let us briefly outline the method of the proof. We first observe that the FBP formulation, with the Arrhenius law acting only on the flame front, allows us to decouple (4a) for Y from the two others, (4b) and (4c). The only bounded function Y which solves (4a) and satisfies $Y = 0$ at $r = R$ and $Y \to Y_f$ as $r \to \infty$ is given by

$$Y(r) = \begin{cases} 0 & \text{for } r \leq R, \\ Y_f\left(1 - \frac{R}{r}\right) & \text{for } r > R. \end{cases} \tag{5}$$

Here R is still unknown. We now drop one of the free boundary conditions, namely the last equality in (4d), and solve the problem with R as a parameter. In other words, we drop the reaction rate and fix R. The next theorem provides us with a unique solution of the resulting reduced problem, parameterized by the now prescribed flame ball radius R.

THEOREM 2 (uniqueness and existence for R fixed). *Fix $R > 0$ and let $\alpha \geq 0$, $\beta \geq 0$, $\theta_f > 0$, $Y_f > 0$. Then there exists a unique solution $(\theta_R(r), Y_R(r), u_R(r))$ to (4), with $\theta > 0$.*

To prove this theorem, we will first decompose the temperature as $\theta = \theta_h + w$, where θ_h is an adiabatic profile with an arbitrary fixed radius R. Because we seek radial solutions, we can explicitly compute θ_h, namely,

$$\theta_h = \theta_f + \frac{Y_f}{\mathrm{Le}} \min\left(1, \frac{R}{r}\right). \tag{6}$$

Then we show that w satisfies a nonlinear elliptic equation defined on all $\mathbb{R}$. Thus θ_h is the temperature component of the solution of the reduced problem with given R, in the case that $\beta = 0$. The subscript h stands for "homogeneous," because θ_h is the solution of the homogeneous part of (4b) which satisfies the jump condition. The other part w in the splitting will then be the solution of the full inhomogeneous equation (4b), which is smooth (i.e., $[w] = [w_r] = 0$) across $r = R$. Hence w satisfies the equation $-\Delta w = u$ globally, just as u solves (4c) globally, in the sense of the distributions. To solve this equation, we consider the problem on a bounded domain, more precisely on a ball $B_\rho = B(0, \rho) \subset \mathbb{R}^3$, with $\rho > R$ large. Using sub- and supersolution arguments, one obtains a solution on the bounded domain. Then we let $\rho \to \infty$, and, by a diagonal process, this leads to a solution on $\mathbb{R}^3$. Uniqueness is proved using classical arguments (see section 2 for details).

Remark 1. We consider only positive θ; the solution $\theta_R(r)$ depends continuously on R, and θ_R is bounded between θ_f and $\theta_f + \frac{Y_f}{\mathrm{Le}}$.

Going back to the proof of Theorem 1, we need to find a value of R for which $\theta_R(r)$ satisfies the final free boundary condition in (4d). As we know Y explicitly, we are left with one "algebraic" equation,

$$\frac{Y_f}{\mathrm{Le}} \frac{1}{R} = F(\theta_R(R)). \tag{7}$$

Thus the reaction rate F plays a role in the analysis only at this final stage. From Figure 3 we can easily see that (7) has at least one solution (see section 2 for more details). This ends the proof of Theorem 1.

Remark 2. When solving (7), one can easily see from Remark 1 and Figure 3 that the radiative radius R_{rad} is bounded between two values. If the reaction rate F is an increasing function of the temperature, as is usually the case, the lower bound on the flame radius is given by the adiabatic or Zeldovich radius $R_{\mathrm{Zeld}} = \frac{Y_f}{\mathrm{Le}} \frac{1}{F(\theta_f + Y_f/\mathrm{Le})}$ (i.e., the radius in the absence of radiative effects; see section 2 for more details), whereas the upper bound is $\frac{Y_f}{\mathrm{Le}} \frac{1}{F(\theta_f)}$.

In section 3 we examine limit cases of problem (4). The cases $\alpha \to \infty$ with β fixed, and $\alpha \to 0$ (or transparent limit) lead to the adiabatic case and are the easiest to justify. A more subtle analysis is needed to treat the cases $\beta \to \infty$ (large Boltzmann limit) and $\alpha \to 0$ supposing $\alpha\beta = \chi$ fixed (transparent limit combined with large Boltzmann numbers). In the large Boltzmann limit, we prove that the temperature profile converges to a constant profile, namely to the fresh temperature θ_f. On the

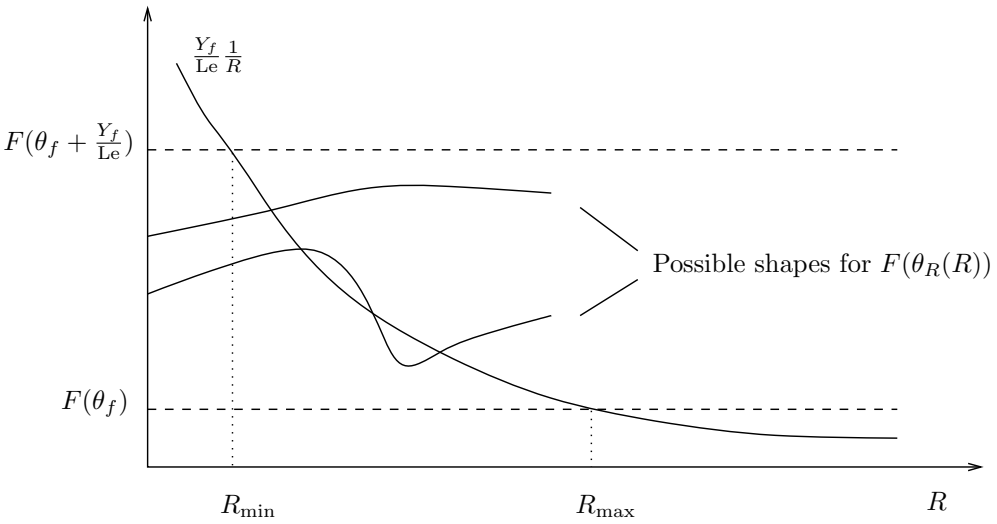

FIG. 3. *Sketch of the graphs occurring in* (7). *The dashed lines are the bounds on* $F(\theta_R(R))$*; they are depicted here for the case of increasing* F.

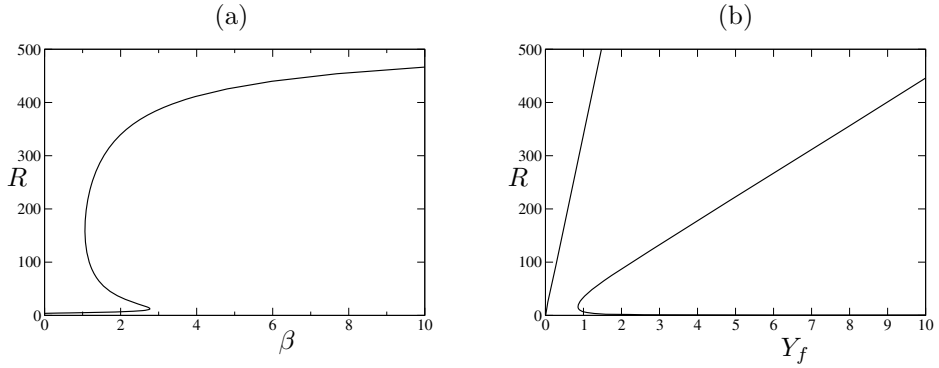

FIG. 4. *Bifurcation curves exhibiting turning points:* (a) *with* β *used as bifurcation parameter;* (b) *with* Y_f *as the parameter.*

other hand, in the transparent limit combined with large Boltzmann numbers, the temperature profile does not converge to a constant profile, but to a radiative one (cf. Figure 2).

Finally, in section 4 we compare the analytic expressions in the asymptotic limits to numerical computations for the full problem. We also make a comparison with analytic calculations for a "linearized" system; see section 4.1 for details. As an example, in Figure 4(a) we depict a typical bifurcation diagram, where β is used as the bifurcation parameter. For a range of parameter values there are three distinct flame ball solutions (for the adiabatic (nonradiative) problem there is always only one solution). Examining the corresponding solution profiles, the upper branch turns out to be physically irrelevant, since the temperature profile is almost identically equal to θ_f. In Figure 4(b) the fuel mass fraction Y_f in the fresh region is used as a bifurcation parameter. Again, multiple solutions are obtained, on two disconnected branches.

2. Existence of solutions. In this section we sketch the arguments that lead to Theorem 2 and subsequently to Theorem 1. All remaining details of the proofs are provided in the appendix. We recall that in order to fix R, we consider problem (4), and we drop the equation involving the reaction rate F in (4d). The expression for Y is of course given by (5). Theorem 1 follows immediately from Theorem 2 when we combine it with the fact that the algebraic equation (7) has a solution.

To begin with, we reduce (4b) and (4c) to one elliptic equation. To do this, we first need to introduce a splitting of the solution θ that we are looking for, writing

$$\theta = \theta_h^R + w. \tag{8}$$

Here θ_h^R is the solution of

$$-\Delta\theta_h^R = 0 \qquad \text{for } r \neq R, \tag{9a}$$

with jump conditions

$$[\theta_h^R] = 0, \quad -\left[\frac{\partial\theta_h^R}{\partial r}\right] = \frac{1}{\mathrm{Le}}\left[\frac{\partial Y}{\partial r}\right] \quad \text{at } r = R, \tag{9b}$$

and the asymptotic boundary condition

$$\theta_h^R \to \theta_f \quad \text{as } r \to \infty. \tag{9c}$$

We note that (9) can be solved explicitly, where θ_h^R is given by (6). The advantage of the splitting (8) is that w must have zero jumps,

$$[w] = [w_r] = 0,$$

and $w \to 0$ as $r \to \infty$. Hence it must be a solution of

$$-\Delta w = \beta u \tag{10}$$

on the *whole space* in the sense of the distributions.

Next we observe that (4c) implies that

$$u = \alpha(3\alpha^2 - \Delta)^{-1}\Delta\theta^4,$$

which expresses u in terms of θ^4 by means of the bounded operator

$$\alpha(3\alpha^2 - \Delta)^{-1}\Delta = \alpha\Delta(3\alpha^2 - \Delta)^{-1},$$

which operates from $L^\infty \to L^\infty$. Note that the Laplacian and its resolvent commute because $3\alpha^2 > 0$. Combining this with (10), it follows that

$$\Delta(w + \alpha\beta(3\alpha^2 - \Delta)^{-1}\theta^4) = 0,$$

whence, since both w and θ^4 are bounded, $w + \alpha\beta(3\alpha^2 - \Delta)^{-1}\theta^4$ must be a constant:

$$w + \alpha\beta(3\alpha^2 - \Delta)^{-1}\theta^4 = C.$$

Subtracting θ_f^4 from θ^4 only changes the constant. Moreover, $\theta^4 - \theta_f^4$ has zero limit at infinity ($r \to \infty$), a property which is preserved by the resolvent $(3\alpha^2 - \Delta)^{-1}$, and

also $w \to 0$ as $r \to \infty$. Thus $w + \alpha\beta(3\alpha^2 - \Delta)^{-1}(\theta^4 - \theta_f^4) = 0$. Applying $(3\alpha^2 - \Delta)^{-1}$ to both sides, we arrive at

$$(3\alpha^2 - \Delta)w + \alpha\beta\left((w + \theta_h^R)^4 - \theta_f^4\right) = 0, \tag{11a}$$

which again should hold globally, with asymptotic boundary condition

$$w \to 0 \quad \text{as } r \to \infty. \tag{11b}$$

We note that $w(r)$ is a solution of a second order ordinary differential equation (globally). Thus it has zero jumps $[w]$ and $[w_r]$ at $r = R$. We have split the problem for θ, which was inhomogeneous because of the jump in $r = R$ and the nonzero limit as $r \to \infty$, on the one hand, and the presence of βu in (4b), on the other, into two parts. The first part, θ_h^R, takes care of the jumps and limits, while the second, w, corresponds to the inhomogeneous term βu in (4b).

The crucial idea in the existence proof is the above reduction of the system of two equations (4b) and (4c) to one elliptic equation (11a). Therefore, existence of a solution pair (θ, u) for (4b) and (4c) is equivalent to the existence of a solution w for problem (11). In order to solve this problem, we first consider (11a) on a ball $B_\rho \subset \mathbb{R}^3$, with the boundary condition (11b) being replaced by $w = 0$ on ∂B_ρ. Then, using classical monotone iteration methods, we can prove existence on this finite domain. Finally, we take the limit $\rho \to \infty$ and arrive at the following result.

LEMMA 3. *For R fixed, there exists a unique solution w_R of problem* (11) *satisfying the bound*

$$-\frac{Y_f}{\mathrm{Le}} \min\left(1, \frac{R}{|x|}\right) \le w \le 0. \tag{12}$$

The solution w_R is $C^2(\mathbb{R})$, radially symmetric, monotonically increasing in $|x|$, and depends continuously on R.

Thus, this proves Theorem 2 and shows that, omitting the reaction rate from the problem formulation, there exists for every $R > 0$ a unique solution triple (θ, Y, u) with $\theta > 0$. It remains, in order to prove Theorem 1, to solve (7) with $\theta_R(R)$ given by Theorem 2. Lemma 3 shows that $\theta_R(R)$ depends continuously on R. Moreover, in view of estimate (12), $\theta_f \le \theta_R(R) \le \theta_f + \frac{Y_f}{\mathrm{Le}}$. Hence, Theorem 1 is an easy consequence of the intermediate value theorem applied to (7). All details of the proof, as well as additional estimates, can be found in the appendix.

3. Limit cases of the radiative parameters. In this section we examine some singular limit cases. We recall that we introduced the splitting $\theta = \theta_h^R + w$. Throughout this section, we consider a pair $(\theta_{\mathrm{par}}, R_{\mathrm{par}})$ depending on some parameters, and we seek a limit. Let us start by noting the following.

Remark 3. As R_{par} lies in a compact set (see Remark 9), one can extract a subsequence converging to a limit, called R. Along the subsequence, $\theta_h^{R_{\mathrm{par}}}$ converges to θ_h^R (uniformly).

3.1. The limit case $\alpha \to \infty$ with β fixed. The limit $\alpha \to \infty$, β fixed is usually called the optically thick limit for an opaque medium. In this limit the effect of the radiation is lost. Indeed, we have the following claim.

LEMMA 4. *The solution w of problem* (11) *converges to zero uniformly as $\alpha/\beta \to \infty$.*

As a consequence of this lemma, and in view of (19), the flame ball solution has a temperature profile that converges to the Zeldovich solution, and also the flame ball radius converges to the Zeldovich radius as $\alpha/\beta \to \infty$.

Proof. We simply modify the subsolution in the proof of Lemma 9 in such a way that it pushes the solution obtained in Lemma 3, and thereby w itself, to zero. A negative constant w is a subsolution, provided

$$3\alpha^2 w + \beta\alpha((\theta_h^R + w)^4 - \theta_f^4) \le 0.$$

This is certainly the case if

$$\left(\theta_f + \frac{Y_f}{\mathrm{Le}} + w\right)^4 - \theta_f^4 = -\frac{3\alpha}{\beta} w,$$

which has a unique solution $w \in (-\frac{Y_f}{\mathrm{Le}}, 0)$, which is easily seen to converge to zero as $\alpha/\beta \to \infty$. This completes the proof. ∎

Remark 4. Note that the limit is the same as the one for α fixed and $\beta \to 0$, i.e., radiative flux negligible with respect to convective flux.

3.2. The transparent limit $\alpha \to 0$ with β fixed. Surprisingly, as opposed to the traveling wave case (see [20]), this limit also reproduces the adiabatic (Zeldovich) flames. As in the previous section we have the next claim.

LEMMA 5. *The solution w of problem* (11) *converges to zero uniformly if $\alpha \to 0$ with β fixed.*

Proof. We have, in view of (12),

$$-\Delta w = -3\alpha^2 w - \alpha\beta\left((\theta_h^R + w)^4 - \theta_f^4\right) \to 0$$

uniformly, as $\alpha \to 0$ and $\alpha\beta \to 0$. Also, again because of (12), w is uniformly small for large r. By the maximum principle for the Laplacian, this implies that $w \to 0$ uniformly as $\alpha \to 0$ and $\alpha\beta \to 0$. ∎

3.3. Large Boltzmann numbers $\beta \to \infty$ with α fixed. With large Boltzmann numbers the solution loses its physical meaning because the temperature profile becomes flat. We have the following result.

LEMMA 6. *For α fixed and $\beta \to \infty$ the temperature profile θ converges to θ_f uniformly.*

Proof. Let us set $w_n = w_{\beta_n}$, with $\beta_n \to \infty$ as $n \to \infty$. We are looking for a limit of the problem

$$-\Delta w_n = -3\alpha^2 w_n - \alpha\beta((\theta_h^{R_n} + w_n)^4 - \theta_f^4), \tag{13}$$

with asymptotic boundary condition $w_n \to 0$ as $|x| \to \infty$.

Writing the weak formulation of (13) and dividing by β_n, we find that, for any test function $\varphi \in C_c^\infty([0,\infty))$, in view of (12),

$$\int \left((\theta_h^{R_n} + w_n)^4 - \theta_f^4\right)\varphi = -\frac{1}{\beta_n}\int 3\alpha^2 w_n\varphi + \frac{1}{\alpha\beta_n}\int w_n\Delta\varphi \to 0 \qquad \text{as} \quad n \to \infty.$$

By the bound (12), the functions

$$(\theta_h^{R_n} + w_n)^4 - \theta_f^4 \tag{14}$$

are nonnegative. Thus we may conclude that they converge to the zero function in L^1_{loc} strongly. Next, we rewrite (14) as

$$G(Z_{R_n} + w_n),$$

where $G(\xi) = (\theta_f + \xi)^4 - \theta_f^4$ and $Z_R(r) = \frac{Y_f}{\text{Le}} \min\left(1, \frac{R}{r}\right)$.

Again in view of (12), the variable $\xi = Z_R + w$ ranges between 0 and Z_R. In this range G' is positive and bounded away from zero and infinity. Consequently, the functions $Z_{R_n} + w_n$ also converge strongly to zero in L^1_{loc}. However, Z_{R_n} converges if we restrict to a further subsequence, along which R_n converges, not only in L^1_{loc} but also in L^∞.

We claim that for any sequence R_n bounded away from zero and infinity, and for any sequence $\beta_n \to \infty$, the corresponding solutions w_n of (11) have the property that $\theta_n = \theta_h^{R_n} + w_n \to \theta_f$ uniformly on $[0, \infty)$. To prove this, we apply the following simple lemma.

LEMMA 7. *Let f_n and g_n be functions on $\mathbb{R}_+$ such that*

- *$f_n + g_n \geq 0$,*
- *$f_n + g_n \to 0$ in $L^1(0, \rho)$ for all $\rho > 0$,*
- *$f_n' \geq -C$ in a weak sense,*
- *$g_n' \geq 0$;*

then $f_n + g_n \to 0$ in $L^\infty(0, \rho)$ for all $\rho > 0$.

Proof. The proof is immediate from the estimate

$$f_n(r) + g_n(r) \geq f_n(r_0) + g_n(r_0) - C(r - r_0)$$

if $r > r_0 > 0$. ∎

This lemma applies to $f_n = Z_{R_n}$ and $g_n = w_n$, which is monotone by Lemma 3. As before, we conclude that $\theta_n - \theta_f \to 0$ in $L^\infty(\mathbb{R})$. ∎

3.4. The transparent limit combined with large Boltzmann numbers: $\alpha \to 0$ with $\alpha\beta = \chi$ fixed. Finally, we consider the limit $\alpha \to 0$, $\alpha\beta = \chi > 0$ fixed, which was also treated in the traveling wave context; see [20, 21]. We show that in this limit solutions of the radiative transfer problem converge to solutions of a radiative heat loss problem, where θ solves

$$\Delta\theta - \chi(\theta^4 - \theta_f^4) = 0, \qquad r \neq R,$$

and R is the flame radius of the limit solution. This will follow along the same lines as in the previous sections from the following.

LEMMA 8. *In the limit $\alpha \to 0$ with $\alpha\beta = \chi > 0$ fixed, the solution w of (11) converges along subsequences to a solution of*

$$-\Delta w + \chi((\theta_h^R + w)^4 - \theta_f^4) = 0, \tag{15}$$

with $w \to 0$ as $r \to \infty$.

Proof. In view of the a priori bounds on w and on R, and in view of Remark 7, we know that w, w', and w'' are (uniformly) equicontinuous on bounded balls. This suffices again to conclude that, as $\alpha \to 0$, a subsequence converges in $C^2(\overline{B_\rho})$, for any $\rho > 0$, to a solution of (15). As before, a diagonal process finishes the proof. ∎

Remark 5. In this limit w remains nontrivial in the sense that it does not coincide with one of the bounds in (12). Thus, in the limit we will have a bifurcation diagram given by

$$\frac{Y_f}{\text{Le}R} = F\left(\theta_f + \frac{Y_f}{\text{Le}} + w(R)\right),$$

and the right-hand side truly depends on R.

4. Numerical calculations. In this section we examine the flame balls numerically. We will compare the outcome of the computations with analytic formulas for the "linearized" problem, which we present below.

4.1. Analytic solutions for the linear case. In this first part, we derive a bifurcation diagram equation for the linear case. Namely, we still consider problem (4), except that (4c) is replaced by the linear equation

$$-\Delta u + 3\alpha^2 u - \alpha\Delta\theta = 0. \tag{16}$$

We can compute explicit formulas for the temperature θ and the variable u. To simplify the notation we introduce

$$\mu = \mu_{\alpha\beta} = \sqrt{3\alpha^2 + \alpha\beta}.$$

Then

$$\theta(r) = \begin{cases} \dfrac{B_1}{r}\sinh(\mu r) + B_3 + \theta_f & \text{for } r \le R, \\ \dfrac{B_2}{r}\exp(-\mu r) + \dfrac{B_3 R}{r} + \theta_f & \text{for } r > R, \end{cases}$$

where the constants are given by

$$B_1 = \frac{\alpha\beta Y_f}{\mathrm{Le}\mu^3}\exp(-\mu R), \qquad B_2 = \frac{\alpha\beta Y_f}{\mathrm{Le}\mu^3}\sinh(\mu R), \qquad B_3 = \frac{3\alpha^2 Y_f}{\mathrm{Le}\mu^2}.$$

The expression for u is

$$u(r) = \begin{cases} -\dfrac{B_1\mu^2}{\beta r}\sinh(\mu r) & \text{for } r \le R, \\ -\dfrac{B_2\mu^2}{\beta r}\exp(-\mu r) & \text{for } r > R. \end{cases}$$

Finally, the equation that fixes the flame radius R, and that determines the bifurcation diagrams, reads

$$F\left(\frac{\alpha\beta Y_f}{2\mu^3 \mathrm{Le} R}\left[1 - 2\mu R - e^{-2\mu R}\right] + \frac{Y_f}{\mathrm{Le}} + \theta_f\right) = \frac{Y_f}{\mathrm{Le} R}. \tag{17}$$

4.2. Bifurcation diagrams. Let us turn to the numerical investigation of the problem. Since we know from Theorem 1 that a solution is uniquely determined by its flame radius R, we exhibit diagrams in which the flame ball is represented by R along the vertical axis, and the horizontal axis is reserved for a control parameter such as Y_f or one of the radiative parameters α or β.

We can do numerical simulations only on bounded domains, so we choose a large ball B_ρ on which we impose Dirichlet boundary conditions, as used in the existence proof. From the proof of Lemma 3 we know that the solution on the bounded ball B_ρ approaches the solution on $\mathbb{R}^3$ as $\rho \to \infty$, and in the numerical calculations we always make sure that $\rho \gg R$. Since the flame balls are radially symmetric, the problem is thus reduced to a boundary value problem for an ordinary differential equation, and we use the continuation software [22] to compute the bifurcation diagrams.

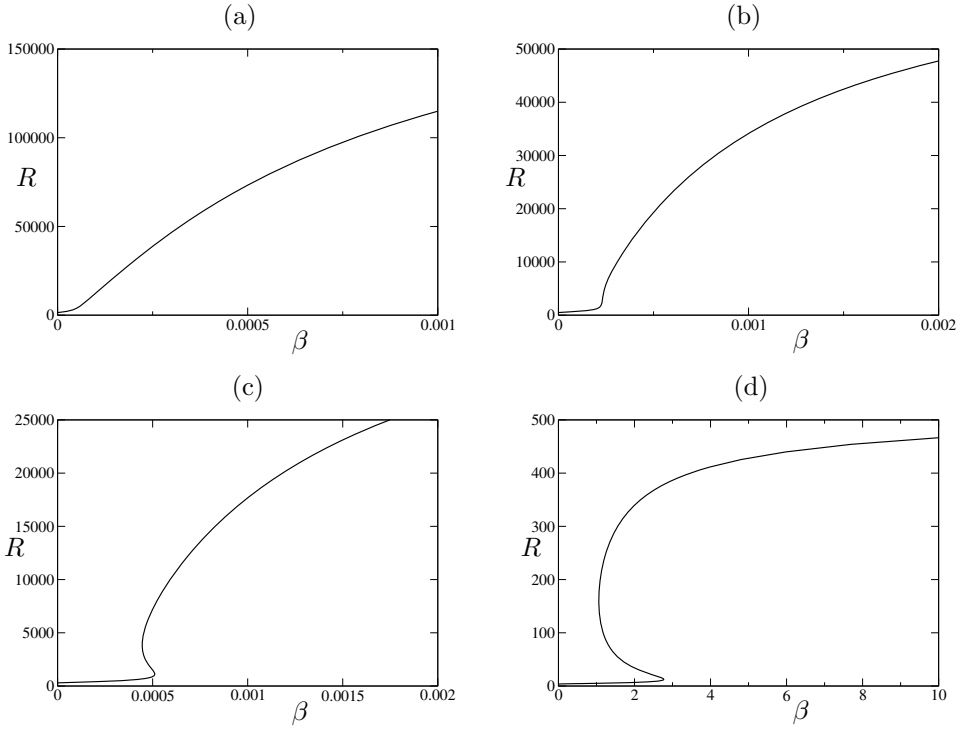

FIG. 5. *Bifurcation diagrams with β as the bifurcation parameter for* (a) $A = 0.1$, (b) $A = 0.3$, (c) $A = 0.5$, (d) $A = 40$.

We need an explicit expression for the reaction rate. Following the literature, e.g., [23, 24], we choose a simple Arrhenius law

$$F(\theta(R)) = A \exp\left(-\frac{1}{\varepsilon\theta(R)}\right), \tag{18}$$

where ε is a normalized inverse activation energy and $A > 0$ is the pre-exponential factor. Next we must choose values for the parameters. Unless mentioned otherwise, in all computations we take

$$\theta_f = 1, \quad Y_f = 1, \quad \mathrm{Le} = 1, \quad \varepsilon = 0.1, \quad A = 40, \quad \alpha = 10^{-4}, \quad \beta = 2.$$

In fact, the parameters Y_f and Le appear in the stationary problem only in the combination Y_f/Le, so we will use this ratio as a parameter in what follows.

In Figure 5 bifurcation diagrams are shown with β as the bifurcation parameter, for various values of the pre-exponential constant A. We see that a turning point appears in the bifurcation diagram as we increase A. Hence, for A sufficiently large there is a range of values of the Boltzmann number β for which there exist multiple stationary flame balls. Increasing A corresponds to making the function in the Arrhenius law (18) steeper. In the context of traveling wave solutions (moving flame fronts) it was already observed (and extensively analyzed) that a steeper Arrhenius law may lead to turning points in bifurcation diagrams; see [21]. We note that the presence of turning points is due to the radiative effects being incorporated in the model, since

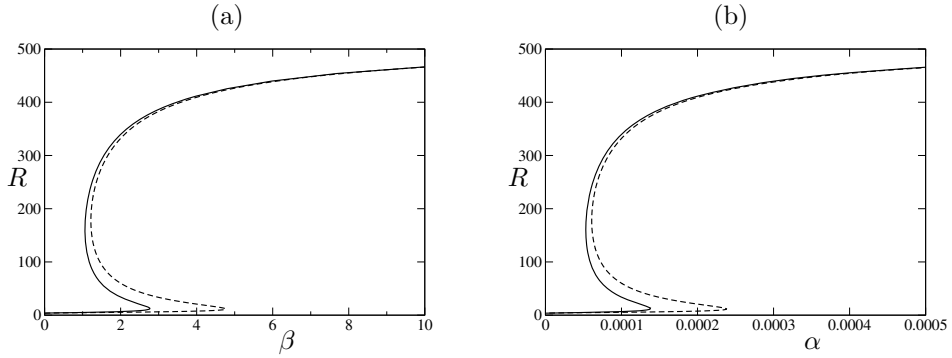

FIG. 6. *Comparison between the nonlinear problem (solid line) and the linearized one (dashed line) with* (a) β *and* (b) α *as the bifurcation parameter.*

uniqueness of the adiabatic flame ball implies the absence of turning points in the adiabatic problem.

Figure 5 also corroborates the study of the limit cases in section 3. In the limit $\beta \to 0$ the flame radius R converges to the Zeldovich radius (the minimal possible radius); see Remarks 2 and 4. On the other hand, as proved in Lemma 6, in the limit $\beta \to \infty$ the temperature profile converges to θ_f, which corresponds to the maximal radius (see again Remark 2).

To make a useful comparison between the full, nonlinear problem and the "linearized" equation (16) from section 4.1, we need to linearize the term θ^4 around some *characteristic temperature* θ_c: $\theta^4 \approx \theta_c^4 + 4\theta_c^3(\theta - \theta_c)$. Introducing the rescaled variable $\tilde{u} = \beta u$, we then arrive at the system

$$\begin{cases} \Delta\theta + \tilde{u} = 0, \\ \Delta\tilde{u} - 3\alpha^2\tilde{u} + 4\alpha\beta\theta_c^3\Delta\theta = 0. \end{cases}$$

Therefore, solutions of the full problem should be compared to solutions of the linearized problem for $\tilde{\beta} = 4\beta\theta_c^3$. Hence, in all figures, for the (dashed) curves representing the analytic expression (17) for the linearized problem, the scaling factor $4\theta_c^3$ is taken into account. As the characteristic temperature we simply adopt $\theta_c = \theta_f$ throughout.

In Figure 6 we compare the outcome of the numerical computations on the nonlinear problem with the analytic expression for the linearized one, using both α and β as bifurcation parameters. In Figure 6(a) we see that the nonlinear and linear problems are qualitatively very similar. In the limit $\beta \to \infty$ we know from Lemma 6 that $\theta \to \theta_f$ uniformly, so our choice of $\theta_c = \theta_f$ leads to quantitative agreement for large β. In the adiabatic limit, i.e., $\beta \to 0$, the solution becomes independent of the radiative effect, irrespective of the equations being linear or not.

Figure 6(b) is, up to a scaling in the horizontal direction, the same as Figure 6(a). The reason is that α is so small that α^2 is negligible compared to $\alpha\beta$, so that to good approximation the solution in this parameter regime depends only on the combination $\alpha\beta$.

From Lemma 4 we know that for large α the solution converges to the adiabatic one, and the radius decreases towards the Zeldovich radius. Indeed, when we continue the bifurcation curve of Figure 6(b) for larger values of α we obtain Figure 7, where we need three different scales to be able to see the full picture. In accordance with

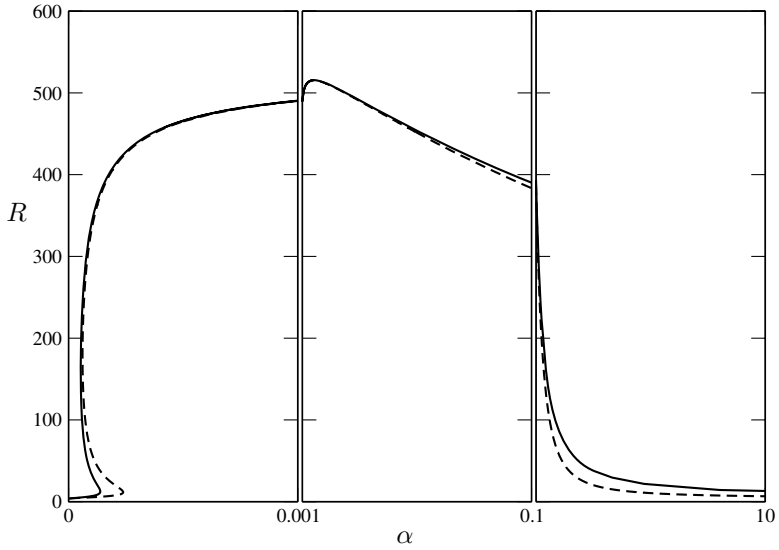

FIG. 7. *The complete* (α, R) *bifurcation diagram, on three different scales.*

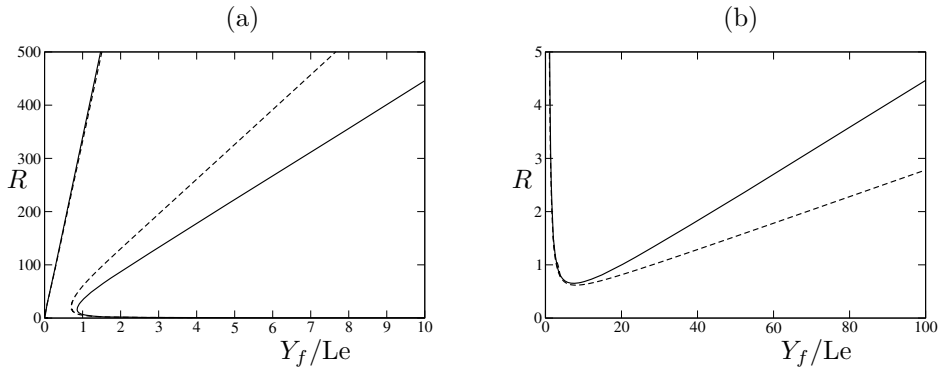

FIG. 8. *Comparison between the nonlinear problem* (*solid line*) *and the linearized one* (*dashed line*) *with* Y_f/Le *as bifurcation parameter, depicted at two different scales.*

Lemmas 4 and 5, the flame radius R tends to the $\frac{Y_f}{\mathrm{Le}} \frac{1}{F(\theta_f + Y_f/\mathrm{Le})}$ in both limits $\alpha \to 0$ and $\alpha \to \infty$, while it makes an excursion near $\frac{Y_f}{\mathrm{Le}} \frac{1}{F(\theta_f)}$ in between.

In Figure 8 we employ Y_f/Le as the bifurcation parameter. For Y_f/Le sufficiently large there are again three solutions, and we need to examine two different scales to see them. The linearized problem does not mimic the nonlinear one too closely, since for large values of Y_f/Le the temperature varies too much to be adequately represented by the characteristic temperature θ_c.

The linear behavior of the curves in Figure 8 can be understood from the fact that α is chosen very small. In this asymptotic regime it is not hard to calculate the slopes for the linearized problem. In fact $R \sim C_i \frac{Y_f}{\mathrm{Le}}$, where the two slopes $C_{1,2}$ in Figure 8(a)

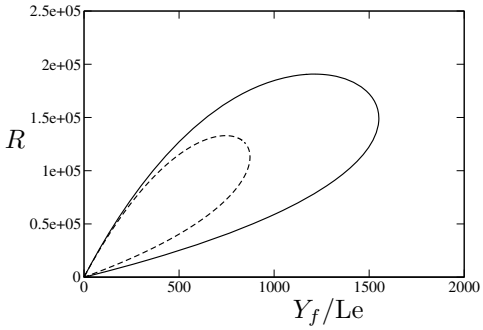

FIG. 9. *The global picture of the* $(Y_f/\mathrm{Le}, R)$ *bifurcation diagram. Note that there is a branch of solutions* (*almost*) *coinciding with the horizontal axis.*

are approximately given by the two largest solutions of $F(\frac{1}{2\sqrt{\alpha\beta}}C^{-1}+\theta_f) = C^{-1}$, while the slope C_3 in Figure 8(b) is approximately equal to A^{-1}. Of course, the reason we can determine these slopes is that we have the explicit expression (17) for the bifurcation curve in the linearized problem. For the nonlinear problem, determining the slopes is an exercise in asymptotic analysis that falls outside the scope of this paper. Note that near the origin the slope is given by $F(\theta_f)^{-1}$ for both the linearized and the nonlinear problem.

Finally, while Figure 8(a) suggests that there are two disconnected solution branches, the global bifurcation diagram depicted in Figure 9 shows that these branches are in fact connected to each other for large values of R and Y_f/Le.

The multiplicity of flame ball solutions, also found in heat loss models [8, 10, 13], leads to questions about stability, which we intend to study in future work. As in the heat loss case, it is in these stability issues that the Lewis number, which plays a somewhat subdued role in the analysis of the stationary problem, will be crucial.

Multiplicity of solutions and stability in the heat loss case are discussed in the introduction. At this point we would like to make some comparisons with our results using the Eddington equation for radiative transfer. One may notice that for some range of parameter values there are three branches of stationary solutions, compared to two in the heat loss models; see, for example, Figure 5. Here one needs to keep in mind that for large R (i.e., the extreme part of the upper branch) the temperature profile is almost flat and therefore does not correspond to a physical flame ball. On the other hand, near the turning point, there are truly three stationary flame balls, of which we expect the *middle* one (see also Figure 6) to be stable, at least in some range of the parameters. In the bifurcation diagram in Figure 8 we may also expect stability of the middle branch. Detailed analysis of stability is the subject of current research. Some preliminary *in*stability results have been obtained in [25].

5. Conclusion. Radiation can significantly influence combustion processes. In this paper we investigate a free boundary model for combustion in a gaseous mixture, where we couple the usual diffusion equations to the radiation field. The radiation itself is described by the Eddington equation, which models radiative transfer in a dusty medium under (near) isotropic conditions. This model thus incorporates both emission and absorption of radiation, in contrast to the usual simplified heat loss models; cf. [5, 10]. Mathematically, this leads to the addition of an elliptic equation

describing the radiation field, which is coupled to the (parabolic) diffusion equations.

In this context we prove the existence of radially symmetric stationary solutions, or *flame balls*, which are physically observed in microgravity environments [3]. We find that a solution exists for any combination of the parameters in the model. Since we consider a free boundary model, determining the radius of the flame is part of the problem. Our strategy is to split the analysis into two parts. First we fix the free boundary and solve an elliptic problem on a fixed domain. Subsequently, we solve the remaining algebraic equation to select the correct flame radius.

Having proved the existence of stationary flame balls, we then turn our attention to asymptotic regimes of the radiative parameters, namely the opacity α of the medium and the Boltzmann number β. In both the limits $\alpha \to 0$ and $\alpha \to \infty$ we recover the adiabatic (nonradiative or "Zeldovich") flames. The same limit is obtained in the limit $\beta \to 0$, whereas when $\beta \to \infty$ the temperature profile becomes flat. The limit $\alpha \to 0$, $\beta \to \infty$ with fixed $\alpha\beta$, leads to a nontrivial limit problem with a truly radiative asymptotic profile.

Finally, by using numerical computations and by examining analytically a "linearized" problem, we investigate the multiplicity of solutions (for fixed parameter values). We find large parameter regimes where multiple stationary flame balls exist. This of course raises interesting stability questions, which we plan to address in a forthcoming paper (extending the work of Buckmaster, Joulin, and Ronney [8] on the heat loss case). We expect the Lewis number Le, which is of minor importance for the stationary problem, to play a crucial role in the stability issues for radiative flame balls.

Appendix. Existence proof. In this appendix we collect the details of the proofs of the statements in section 2, particularly Lemma 3. We also provide additional uniform estimates on the function w.

A.1. Existence on a bounded domain. Let us consider (11) on a ball $B_\rho = B(0,\rho) \subset \mathbb{R}^3$, the boundary condition (11b) being replaced by $w = 0$ on ∂B_ρ. We assume $\rho > R$.

LEMMA 9. *For fixed $0 < R < \rho$, there is a unique solution w of* (11a) *with $\theta = \theta_h^R + w \geq 0$ on B_ρ and $w = 0$ on ∂B_ρ. The solution is radial, and as such it belongs to $C^2([0,\rho])$ as well as to $C^2(\overline{B_\rho})$. It satisfies the bounds*

$$-\frac{Y_f}{\mathrm{Le}} \min\left(1, \frac{R}{|x|}\right) \leq w \leq 0.$$

Remark 6. The estimate (12) is independent of the parameters α and β. It provides us with a uniform estimate on the decay rate of w towards zero as $r \to \infty$.

Proof. We first establish the existence of w. The function $\overline{w} \equiv 0$ is a supersolution of (11a) with zero Dirichlet boundary data, because substituting $w = \overline{w} \equiv 0$ into (11a), we end up with $\alpha\beta((\theta_h^R)^4 - \theta_f^4) > 0$. On the other hand, the function $\underline{w} = -\frac{Y_f}{\mathrm{Le}} \min(1, \frac{R}{r})$ is a subsolution: it is negative in $r = \rho$, and substituting $w = \underline{w}$, we obtain $3\alpha^2\underline{w} - \Delta\underline{w}$. The first term is negative, the latter too, but in the sense of the distributions. More precisely, $-\Delta\underline{w}$ is a negative "Dirac" measure supported on $r = R$. It is straightforward to mollify $\underline{w}$ into a family of smooth subsolutions $\underline{w}^\varepsilon$ with $\underline{w}^\varepsilon \to \underline{w}$ uniformly as $\varepsilon \to 0$, and $\underline{w}^\varepsilon \equiv \underline{w}$ outside the interval $(R-\varepsilon, R+\varepsilon)$. By standard arguments, e.g., [26], it follows that there is a solution of (11a) with $w = 0$ in $r = \rho$ which lies between $\underline{w}$ and $\overline{w}$. This solution is obtained using an iteration argument starting from either the sub- or the supersolution, both of which are radial.

As a consequence, the constructed solution is also radial. The regularity of w, i.e., $w \in C^2(B_\rho)$, follows directly from ODE arguments. In fact the bounded solutions w of (11a) with $w = 0$ on ∂B_ρ are in $C^2(\overline{B_\rho})$; see again [26].

If w_1 and w_2 are two such solutions, then we set

$$f(x, w) = \alpha\beta\left((w + \theta_h^R(x))^4 - \theta_f^4\right)$$

and

$$c(x) = \int_0^1 \frac{\partial f}{\partial w}(x, tw_1(x) + (1-t)w_2(x))dt.$$

The function $v = w_1 - w_2$ is a solution of

$$\begin{cases} -\Delta v + (3\alpha^2 + c(x))v = 0 & \text{in } B_\rho, \\ v = 0 & \text{on } \partial B_\rho, \end{cases}$$

where $c \in C(\overline{B}_\rho)$. By the maximum principle (see [26]), $v \equiv 0$ if c is nonnegative. Thus we have uniqueness in the class of functions w which satisfy $w(x) + \theta_h^R(x) \geq 0$, i.e., the functions w for which the corresponding temperature profile θ is positive, and it is natural to restrict to this class. This completes the proof. ∎

Remark 7. Writing (11a) as an ODE, i.e.,

$$w'' = -\frac{2}{r}w' + 3\alpha^2 w + \alpha\beta\big(\big(w + \theta_h^R(r)\big)^4 - \theta_f^4\big),$$

with initial conditions $w(0) = w_0$ and $w'(0) = 0$, this initial value problem is well-posed and behaves nicely in terms of continuous dependence on parameters. In particular, w, w', w'', and w''' are uniformly bounded on bounded intervals (for bounded ranges of α^2 and $\alpha\beta$). Alternatively, to examine regularity, one could proceed from the PDE (11a) directly using bootstrap arguments and Hölder estimates for elliptic equations; see, e.g., [26].

Remark 8. We emphasize that w is defined for $0 \leq r \leq \rho$ and that ρ as well as R are parameters with $0 < R < \rho$. Thus we write $w = w_\rho^R$.

A.2. Solutions on the whole space. In this section we take the limit $\rho \to \infty$ to prove existence of a solution w of problem (11).

LEMMA 10. *For R fixed, there exists a solution w of problem* (11) *which satisfies the bound* (12). *The solution belongs to $C^2(\mathbb{R})$ and is unique in the class of radial and nonradial functions.*

Proof. Take a sequence $\rho_n \to \infty$ as $n \to \infty$, and set $w_n = w_{\rho_n}^R$, so w_n is a solution of

$$\begin{cases} -\Delta w_n + 3\alpha^2 w_n = -\alpha\beta\big((w_n + \theta_h^R)^4 - \theta_f^4\big) & \text{in } B_{\rho_n}, \\ w_n = 0 & \text{on } \partial B_{\rho_n}, \end{cases}$$

as constructed in section A.1. We extend w_n to the whole of $\mathbb{R}^3$ by setting $w_n \equiv 0$ for $r \geq \rho_n$. Clearly estimate (12) continues to hold for w_n.

Now fix some $\rho = \bar{\rho}$ and consider the solutions w_n with $\rho_n > \bar{\rho}$, and in particular their restrictions to $B_{\bar{\rho}}$. It follows directly from Remark 7 that w_n and its first and second order derivatives are bounded and equicontinuous. Note that the nonlinear term in (11) is Lipschitz continuous if w is. Thus, we may extract a subsequence along which w_n converges in $C^2(\overline{B_{\bar{\rho}}})$. Choosing $\bar{\rho} = 1, 2, 3, \ldots$, a standard diagonal argument now produces a subsequence along which w_n converges in $C^2(\overline{B_{\bar{\rho}}})$ for every

$\bar{\rho} > 0$. It follows that the limit w exists on the whole space, and that it satisfies (11a) as well as the bound (12). Clearly w corresponds to a temperature profile $\theta = \theta_h^R + w > 0$ on $\mathbb{R}^3$.

Now suppose we have two such profiles. Reasoning as in the uniqueness proof in Lemma 9, we find that $v = w_1 - w_2$ is bounded and satisfies

$$-\Delta v + (3\alpha^2 + c(x))v = 0 \quad \text{in}\,\mathbb{R}^3.$$

When $v \to 0$ as $|x| \to \infty$ (uniformly) the maximum principle implies that $v \equiv 0$, provided that the coefficient $3\alpha^2 + c(x)$ of v is nonnegative. Thus we have uniqueness in the class of solutions w which have $w(x) \to 0$ as $|x| \to \infty$ uniformly. □

A.3. Proof of Theorem 1. In the previous section we proved Theorem 2 and showed that, omitting the reaction rate from the problem formulation, there exists for every $R > 0$ a unique solution triple (θ, Y, u) with $\theta > 0$. It remains to solve (7) with $\theta_R(R)$ given by Theorem 2.

Remark 9. In view of the estimate (12) the flame temperature $\theta(R)$ is bounded between θ_f and $\theta_f + \frac{Y_f}{\mathrm{Le}}$. As F is a continuous positive function, let us define the positive numbers

$$m = \min_{\theta \in [\theta_f,\, \theta_f + Y_f/\mathrm{Le}]} F(\theta) \quad \text{and} \quad M = \max_{\theta \in [\theta_f,\, \theta_f + Y_f/\mathrm{Le}]} F(\theta).$$

Then any solution of the full flame ball problem must satisfy

$$\frac{Y_f}{\mathrm{Le}}\,\frac{1}{M} \le R \le \frac{Y_f}{\mathrm{Le}}\,\frac{1}{m}. \tag{19}$$

Equation (7) has a left-hand side which goes from $+\infty$ to 0 as R goes from 0 to ∞. Its right-hand side is bounded between m and M. Thus the existence of the solution in Theorem 1 is immediate once we know that Remark 1 (about continuity of $\theta_R(R)$) is true. More precisely, we have the following claim.

LEMMA 11. *If $R_n \to R > 0$, then the corresponding functions θ_{R_n} converge uniformly to θ_R on $[0, \infty)$.*

Proof. Clearly this will follow from the same statement for w_R, where w_R is the solution of (11) obtained in Lemma 3. In view of the bound (12), uniform convergence on bounded subsets implies uniform convergence on $[0, \infty)$. By exactly the same arguments as in the proof of Lemma 3 in section A.2, it follows that along a subsequence of $n \to \infty$, w_{R_n} (as well as its first and second order derivatives) converges uniformly on any bounded interval to a solution of (11) satisfying (12). Since this solution is unique, it follows that $w_{R_n} \to w_R$ along this subsequence. In fact, every sequence of $n \to \infty$ has a subsequence for which this is the case. But then there cannot be a sequence of n for which $||w_{R_n} - w_R||_\infty$ is bounded away from zero. This completes the proof of Lemma 11 and thereby of Theorem 1. □

Remark 10. Instead of using this sequence argument, one could also invoke an implicit function argument to conclude that $R \to \theta_R(R)$ (or $R \to w_R(R)$) is smooth. Furthermore, assuming the derivatives of the left- and right-hand sides of (7) to be different at solutions, it follows immediately that the number of solutions is odd. This is the statement that in general situations the number of solutions is odd.

A.4. Uniform estimates. As we have seen, solutions of the flame ball problem are given by $\theta = \theta_h^R + w_R$, where R is such that (7) holds, and where w_R is a C^2-function (of course, θ_h^R is not). Moreover, w_R satisfies (11). In this section we show that w is monotone in r.

LEMMA 12. *The solution $w = w_R$ of (11) has $w' \geq 0$.*

Proof. w solves

$$-w'' - \frac{2}{r}w' = g(r,w) = -3\alpha^2 w - \alpha\beta\left((w + \theta_h^R(r))^4 - \theta_f^4\right), \tag{20}$$

where g satisfies

$$\frac{\partial g}{\partial w} < 0 \quad \text{and} \quad \frac{\partial g}{\partial r} \geq 0,$$

the latter being discontinuous in $r = R$, of course, but with limits existing from both sides. Moreover, $w'(0) = 0$ by symmetry.

If w' is negative somewhere, then there must be points r_1 and r_2 such that $w'(r_1) = w'(r_2) = 0$, while $w' < 0$ on (r_1, r_2). This follows from $w'(0) = 0$ and $0 > w(r) \to 0$ as $r \to \infty$.

Clearly then $g(r_1, w_1(r_1)) = -w''(r_1) \geq 0$ and $g(r_2, w_1(r_2)) = -w''(r_2) \leq 0$, contradicting

$$\frac{d}{dr}g(r,w(r)) = \frac{\partial g}{\partial r} + \frac{\partial g}{\partial w}\frac{\partial w}{\partial r} > 0 \quad \text{on } (r_1, r_2). \qquad \square$$

LEMMA 13. *There exists a constant C depending on α^2 and $\alpha\beta$ such that*

$$\int_0^\infty w'(r)^2 dr < C.$$

Proof. Multiplying (20) by w and integrating from r_1 to r_2 $(0 < r_1 < r_2 < \infty)$, we obtain

$$-\int_{r_1}^{r_2} w''w dr = \int_{r_1}^{r_2} \frac{2}{r}w'w dr + \int_{r_1}^{r_2} g(r,w)w dr,$$

so that

$$\int_{r_1}^{r_2} |w'|^2 dr + w'(r_1)w(r_1) = w'(r_2)w(r_2) + \int_{r_1}^{r_2} \frac{2}{r}w'w dr + \int_{r_1}^{r_2} g(r,w)\, w dr.$$

Letting $r_1 \to 0$ and using $w' \geq 0$, $w < 0$, it follows that, also using (12),

$$\int_0^{r_2} |w'|^2 dr \leq \int_0^{r_2} g(r, w(r))\, w(r) dr \leq C,$$

where C is a constant depending linearly on α^2 and $\alpha\beta$, but not on r_2. This proves the claim. $\square$

Going one step further, we get the following.

LEMMA 14. *w belongs to $H^2(0,\infty)$.*

Proof. Multiplying (20) by $-w''$ and integrating from r_1 to r_2, we find

$$\int_{r_1}^{r_2} |w''|^2 dr + \int_{r_1}^{r_2} \frac{2}{r}w'w'' dr + \int_{r_1}^{r_2} g(r,w)\, w'' dr = 0.$$

Hence, with, e.g., $r_1 = 2$,

$$\begin{aligned}\int_2^{r_2} |w''|^2 dr \leq &\left(\int_2^{r_2} |w'|^2 dr\right)^{\frac{1}{2}} \left(\int_2^{r_2} |w''|^2 dr\right)^{\frac{1}{2}} \\ &+ \left(\int_2^{r_2} |g(r,w(r))|^2 dr\right)^{\frac{1}{2}} \left(\int_2^{r_2} |w''|^2 dr\right)^{\frac{1}{2}}.\end{aligned}$$

In view of (12), (20), and Lemma 13, we conclude that

$$\int_2^\infty |w''|^2 dr \le C,$$

where C depends on α^2 and $\alpha\beta$. The fact that w is C^2 implies that also $\int_0^\infty |w''|^2$ is bounded. Lemma 13 and inequality (12) finish the proof. □

Remark 11. If we consider the problem in $\mathbb{R}^3$, one can easily check that w belongs to $W^{2,p}(\mathbb{R}^3)$ if $p > 3$.

SPATIAL SPREAD OF RABIES REVISITED: INFLUENCE OF AGE-DEPENDENT DIFFUSION ON NONLINEAR DYNAMICS*

CHUNHUA OU† AND JIANHONG WU‡

Abstract. We consider the spatio-temporal patterns of disease spread involving structured populations. We start with a general model framework in population biology and spatial ecology where the individual's spatial movement behaviors depend on its maturation status, and we show how delayed reaction diffusion equations with nonlocal interactions arise naturally. We then consider the impact of this delayed nonlocal interaction on the disease spread by revisiting the spatial spread of rabies in continental Europe during the period between 1945 and 1985. We show how the distinction of territorial patterns between juvenile and adult foxes, the main carriers of the rabies under consideration, yields a class of partial differential equations involving delayed and nonlocal terms that are implicitly defined by a hyperbolic-parabolic equation, and we show how incorporating this distinction into the model leads to a formula describing the relation of the minimal wave speed and the maturation time of foxes. We show how the homotopy argument developed by Chow, Lin, and Mallet-Paret can be applied to obtain the existence of a heteroclinic orbit between a disease-free equilibrium and an endemic state for the spatially averaged system of delay differential equations, and we illustrate how the technique developed by Faria, Huang, and Wu can be used to establish the existence of a family of traveling wavefronts in the neighborhood of the heteroclinic orbit for the corresponding spatial model.

1. Introduction.

Spatial movement and reaction time lag are certainly two intrinsic features in biological systems; their interaction seems to be one of the many factors for possible complicated spatio-temporal patterns in a single species population without an external time-dependent forcing term. Modeling this interaction is nevertheless a highly nontrivial task, and recent progress indicates diffusive (partial or lattice) systems with nonlocal and delayed reaction nonlinearities arise very naturally. Such systems were investigated in the earlier work of Yamada [34], Pozio [24, 25], Redlinger [26, 27], and the modeling and analysis effort in the ground-breaking work by Britton [3], Gourley and Britton [9], Smith and Thieme [28] marked the beginning of the systematic study of a new class of nonlinear dynamical systems directly motivated by consideration of biological realities [10, 11].

This new class of nonlinear dynamical systems can be derived from the classical structured population model involving maturation-dependent spatial diffusion rates and nonlinear birth and natural maturation processes. More specifically, if we use $u(t, x)$ to denote the total number of matured individuals in a single species population

and if we assume the maturation time is a fixed constant τ, then we have

$$\frac{\partial}{\partial t}u(t,x) = D\frac{\partial^2}{\partial x^2}u(t,x) - du(t,x) + j(t,\tau,x), \tag{1.1}$$

where D and d are the diffusion and death rates of the adult population (that are assumed to be age-independent), and $j(t,\tau,x)$ is the maturation rate that is given by the rate where an individual was born exactly time $t-\tau$ ago in all possible spatial locations but moved to the current position x upon maturation. This maturation rate is thus regulated by the birth process and the dynamics of the individual during the maturation phase. In the work of So, Wu, and Zou [29], this is derived from the structured population model

$$\Big(\frac{\partial}{\partial t} + \frac{\partial}{\partial a}\Big)j(t,a,x) = D_I\frac{\partial^2}{\partial x^2}j(t,a,x) - d_I j(t,a,x) \tag{1.2}$$

for the density $j(t,a,x)$ of the immature individual with $a \in (0,\tau]$ as the variable for age, subject to some (spatial) boundary conditions (if the space is bounded) and the following (age) boundary condition:

$$j(t,0,x) = b(u(t,x)), \tag{1.3}$$

where b is the birth rate function that is assumed to be dependent on the matured population, and D_I and d_I are the diffusion and death rates of the immature individual (these rates are allowed to depend on the age a in [29]). The maturation rate $j(t,\tau,x)$ can be obtained by solving the linear hyperbolic-parabolic equation (1.2) subject to the boundary condition (1.3). In the case of unbounded one-dimensional space, we have

$$j(t,\tau,x) = e^{-d_I\tau}\int_R b(u(t-\tau,y))f(x-y)dy. \tag{1.4}$$

In other words, the maturation rate at time t and spatial location x is the sum of the birth rate at time $t-\tau$ at the spatial location y, times the probability $f(x-y)$ of the individual moved from y to the current position x, and then times the survival rate $e^{-d_I\tau}$ during the entire maturation phase. Incorporating (1.4) into (1.1), we then obtain a closed system of reaction diffusion equations with nonlocal delayed nonlinearity as follows:

$$\frac{\partial}{\partial t}u(t,x) = D\frac{\partial^2}{\partial x^2}u(t,x) - du(t,x) + e^{-d_I\tau}\int_R b(u(t-\tau,y))f(x-y)dy, \tag{1.5}$$

where

$$f(x) = \frac{1}{\sqrt{4\pi D_I\tau}}e^{\frac{-x^2}{4D_I\tau}}.$$

For the existence of positive solutions to (1.5) with various initial and boundary conditions, we refer to [19, 33]. Recently, there has been some rapid development towards a qualitative theory for the asymptotic behaviors of solutions to the above equation with various types of assumptions on the birth functions. Notably, in comparison with the ordinary reaction diffusion analogue, we will have more prototypes than the so-called monostable and bistable cases. See [11].

The analytic form above for f was derived in [29]. It is possible to obtain such an analytic form here since the dynamical process during the maturation phase is governed by a linear hyperbolic-parabolic equation with time-independent constant

coefficients. Such a possibility disappears in an ecological system consisting of multiple species with age- or stage-dependent diffusion rates when these species interact during their maturation phases. This is also the case for the spread of a disease even if its main carrier involves only a single species, since the model describing the infection process must involve the transfers of individuals from one compartment to another, and some of these transfers such as the force of infection from the susceptible compartment to the infective compartment are nonlinear.

We will illustrate the above difficulty and usefulness of modeling the spread of diseases involving stage-dependent spatial diffusion by considering the spatial spread of rabies in continental Europe during the period 1945–1985. Our focus is on the front of the epizootic wave of rabies, starting on the edge of the German/Polish border and moved westward at an average speed of about 30–60 km a year. This traveling wavefront has been investigated quite successfully (see [15, 22]), where the minimal wave speed was calculated from basic epidemiological and ecological parameters, and compared well with field observation data. It was also noted that juvenile foxes leave their home territory in the autumn traveling distances that typically may be 10 times a territory size in search of a new territory. If a fox happened to have contracted rabies around the time of such long-distance movement, it could certainly increase the spreading of the disease into uninfected areas. This observation has not been considered in the existing models. It turns out that incorporating the differential spatial movement behaviors of adult and juvenile foxes into a deterministic model yields a much more complicated system of reaction diffusion equations with delayed nonlinear nonlocal interactions.

More precisely, the celebrated work [15, 22] used a system of a reaction diffusion equation for the infective, coupled with an ODE for the susceptible foxes—the main carrier of the disease—under the assumption that the infective compartment consists of both rabid foxes and those in the incubation stage, and that susceptible foxes are territorial and thus their spatial movement can be ignored. It was already pointed out, in both papers mentioned above and their later extensions and further detailed studies, that the spatial movement behaviors of susceptible juvenile foxes are different since they prefer to leave their home territories in search of new territories of their own. How to describe this stage-dependent diffusion pattern of susceptible foxes and how stage-dependent diffusion affects the spatial spread of rabies are the main focus of the current paper.

It turns out, as will be shown in section 2, that such a stage-dependent diffusion of susceptible foxes and the random movement of rabid foxes due to the loss of the sense of direction and territorial behaviors yield a coupled system of reaction diffusion equations with nonlocal delayed nonlinearity for the juvenile susceptible foxes $M(t,x)$ and total rabies foxes $J(t,x)$. Unlike system (1.5) for a single species population with simple dynamics during the maturation phase, the coupled system for (M,J) involves the density of the juvenile foxes $S(t,a,y)$ for all $y \in R$ and the maturation rate $S(t,\tau,x)$ (again, τ is assumed to be a constant maturation time of the foxes) and the force of infection that is proportional to the product of $J(t,x)\int_0^\tau S(t,a,x)da$. This density of the juvenile foxes cannot be solved explicitly in terms of $M(s,\cdot)$ with $s \le t$ although it is given implicitly by solving a hyperbolic-parabolic equation with a nonlinear term.

Some of the key issues related to the spatial spread can nevertheless be addressed, despite the aforementioned difficulty in obtaining an explicit analytic formula of $S(t,a,x)$ in terms of the historical values of M at all spatial locations. As shall be shown in section 3, the linear stability of two spatially homogeneous equilibria

can be fully investigated and the minimal wave speed can be calculated. One of the results we obtain from this calculation is that the minimal wave speed is a function of the average maturation time. More precisely, knowing the carrying capacities for the adult and juvenile foxes, the minimal wave speed is a decreasing function of the maturation period. This results coincide in principle with the speculation in [15, 22], and give a more precise qualitative description of the influence of maturation time on the propagation of the disease in space.

Establishing the existence of traveling waves turns out to be a very difficult task due to the loss of monotonicity of the nonlocal delayed nonlinearity. In section 4, we utilize a general result of Faria, Huang, and Wu [8] that claims the existence of traveling waves in the neighborhood of a heteroclinic orbit between the two equilibria of a corresponding ordinary delay differential system obtained from the delayed reaction diffusion system for (J, M) through a spatial average, and we obtain the existence of this heteroclinic orbit by an approach based on a combination of perturbation analysis [23], the Fredholm theory, and some fixed point theorems [5, 13]. This will be developed in detail in section 4, along with some numerical simulations to show how the maturation time affects the calculation of the minimal wave speed, and how the diffusion of the juvenile foxes impacts the amplitudes and frequencies of the oscillatory long tails of the traveling wavefronts.

2. Derivation of the model. Here we use a deterministic approach to describe the spatial spread of rabies. Following [15, 22], we divide the fox population into two groups: the infective and the susceptible. The former consists of both rabid foxes and those in the incubation stage. The basic facts and assumptions of our model are as follows:

(H1) The rabies virus is contained in the saliva of the rabid fox and is normally transmitted by bite. Therefore, contact between a rabid and a susceptible fox is necessary for the transmission of the disease.

(H2) Rabies is invariably fatal in foxes.

(H3) Adult susceptible foxes are territorial and seem to divide the countryside into nonoverlapping home ranges which are marked out by scent. They do occasionally travel considerable distances but always return to their home territory. However, for young susceptible juvenile foxes, their behaviors are different, because they prefer to leave their home territories in search of new territories of their own.

(H4) The rabies virus enters the central nervous system and induces behavioral changes of foxes. If the spinal cord is involved, it often takes the form of paralysis. However, if the virus enters the limbic system, the foxes become aggressive, lose their sense of direction and territorial behavior, and wander about in a more or less random way.

Modeling the distinction of diffusion patterns of young and adult susceptible foxes, already observed in [15, 22], is the main focus of this paper. Because of this distinction, we shall incorporate age structure into our model and consider the fox population with two age classes: the immature and the mature. Let $I(t, a, x)$ and $S(t, a, x)$ denote the population density at time t, age $a \geq 0$, and spatial location $x \in R = (-\infty, \infty)$ for the infective and the susceptible foxes, respectively, and let τ be the maturation time which is assumed to be a constant. Then the integral

$$J(t, x) = \int_0^\infty I(t, a, x)da \tag{2.1}$$

is the total population of the infective foxes and

$$M(t,x)=\int_{\tau}^{\infty} S(t,a,x)da \tag{2.2}$$

is the total population of the adult susceptible foxes. Using Fick's diffusive law and the mass active incidence, we have

$$\left(\frac{\partial}{\partial t}+\frac{\partial}{\partial a}\right) I(t,a,x)=D_I\frac{\partial^2}{\partial x^2}I(t,a,x)+\beta S(t,a,x)J(t,x)-d_I I(t,a,x), \tag{2.3}$$

where D_I is the diffusive coefficient, d_I is the death rate for the infective foxes, and β is the transmission rate. Using $I(t,\infty,x)=0$ and $I(t,0,x)=0$, we obtain from (2.1) and (2.3) that

$$\begin{aligned}\frac{\partial J(t,x)}{\partial t}&=\int_0^{\infty}\frac{\partial I(t,a,x)}{\partial t}da\\ &=D_I\frac{\partial^2 J(t,x)}{\partial x^2}+\beta M(t,x)J(t,x)-d_I J(t,x)\\ &\quad+\beta J(t,x)\int_0^{\tau} S(t,a,x)da.\end{aligned} \tag{2.4}$$

For $S(t,a,x)$ with $a\geq\tau$, we have the structured population model (see [20] or [32])

$$\left(\frac{\partial}{\partial t}+\frac{\partial}{\partial a}\right) S(t,a,x)=-\beta S(t,a,x)J-d_S S(t,a,x), \tag{2.5}$$

where the constant d_S is the death rate for the susceptible foxes. Using $S(t,\infty,x)=0$, we get from (2.2) and (2.5) that

$$\frac{\partial M(t,x)}{\partial t}=-\beta M(t,x)J(t,x)-d_S M(t,x)+S(t,\tau,x). \tag{2.6}$$

To obtain a closed system for (J,M), we need to formulate $S(t,a,x)$ with $0\leq a\leq\tau$ in terms of (J,M). This is achieved by using the following structured hyperbolic-parabolic equation with the initial condition given by the birth process:

$$\begin{cases}\left(\frac{\partial}{\partial t}+\frac{\partial}{\partial a}\right) S(t,a,x)=D_Y\frac{\partial^2}{\partial x^2}S(t,a,x)-\beta S(t,a,x)J(t,x)-d_Y S(t,a,x),\\ S(t,0,x)=b(M(t,x)),\end{cases} \tag{2.7}$$

where D_Y is the diffusive coefficient for the immature susceptible foxes and $b(\cdot)$ is the birth function of the susceptible foxes.

Combining (2.4) and (2.6) together gives

$$\begin{cases}\frac{\partial J(t,x)}{\partial t}=D_I\frac{\partial^2 J(t,x)}{\partial x^2}+\beta M(t,x)J(t,x)-d_I J(t,x)+\beta J(t,x)\int_0^{\tau}S(t,a,x)da,\\ \frac{\partial M(t,x)}{\partial t}=-\beta M(t,x)J(t,x)-d_S M(t,x)+S(t,\tau,x),\end{cases} \tag{2.8}$$

where $S(t,a,x)$, $0\leq a\leq\tau$, is determined by solving the hyperbolic-parabolic system (2.7).

REMARK 2.1. *$S(t,a,x)$ in (2.7) depends on t, a, $M(t,y)$, and $J(s,y)$ for all $0 \le s \le t$ and $y \in R$, but an explicit formula for $S(t,a,x)$ cannot be found. We shall write $F(t,a,x) = F(a,M,J)(t,a,x)$ to indicate this functional relation. It is easy to show that*

$$F(a,M,J_1)(t,a,x) \ge F(a,M,J_2)(t,a,x) \quad \text{if } 0 \le J_1(s,y) \le J_2(s,y) \tag{2.9}$$

for $0 \le s \le t$ and $y \in R$, and for $t \ge a$,

$$F(a,M,J_1)(t,a,x) = b(M(t-a,x))e^{-\int_{t-a}^{t}(d_Y+\beta J(u,x))du} \quad \text{when } D_Y = 0. \tag{2.10}$$

REMARK 2.2. *When $\tau = 0$, system (2.8) reduces to*

$$\begin{cases} \frac{\partial J(t,x)}{\partial t} = D_I \frac{\partial^2 J(t,x)}{\partial x^2} + \beta J(t,x)S(t,x) - d_I J(t,x), \\ \frac{\partial M(t,x)}{\partial t} = -\beta J(t,x)M(t,x) - d_S M(t,x) + b(M(t,x)). \end{cases} \tag{2.11}$$

This model was studied in [7] *and* [15] *by assuming that the birth function obeys the well-known logistic growth, that is, the (gross) birth function $b(M) := d_S M + b_0 M(1 - M/S_0)$, where S_0 is the carrying capacity of the susceptible fox population and b_0 is the net birth rate for the susceptible foxes when the population density is close to zero. After rescaling by*

$$u(t,x) = J(t,x)/S_0,\ v(t,x) = M(t,x)/S_0,\ x^* = (\beta S_0/D_I)^{1/2}x,\ t^* = \beta S_0 t,\ r = \frac{d_I}{\beta S_0}$$

and dropping the asterisk, we can transform (2.11) into

$$\begin{cases} \frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + u(v - r), \\ \frac{\partial v}{\partial t} = -uv + kv(1 - v), \end{cases} \tag{2.12}$$

where $k = b_0/\beta S_0$. In [7], *it was proved that if $r = \frac{d_I}{\beta S_0} < 1$, then the infective and the susceptible foxes coexist, and there exists a family of traveling wavefronts $(J = S_0 u(x+ct), M = S_0 v(x+ct))$ for (2.11) which connect $(0, S_0)$ to $(kS_0(1-r), S_0 r)$ with the wave speed c satisfying*

$$c \ge c_{\min} = 2\sqrt{\beta S_0 D_I}\sqrt{1 - \frac{d_I}{\beta S_0}} = 2\sqrt{D_I(\beta S_0 - d_I)}.$$

In addition, it was shown that there is a constant $k^* > 0$ so that (a) *if $k = b_0/\beta S_0 > k^*$, then the wavefront (u,v) approaches $(k(1-r)S_0, rS_0)$ monotonically;* (b) *if $k = b_0/\beta S_0 \le k^*$, then the wavefront (u,v) approaches $(k(1-r)S_0, rS_0)$ with oscillatory damping.*

In [14] *and* [15], *instead of the logistic growth, a static population of the susceptible is assumed in the sense that deaths are equally balanced by births. This yields the simple model*

$$\begin{cases} \frac{\partial J}{\partial t} = D_I \frac{\partial^2 J}{\partial x^2} + \beta JM - d_I J, \\ \frac{\partial M}{\partial t} = -\beta JM, \end{cases} \tag{2.13}$$

where M and J are the total numbers of susceptible and infective foxes, respectively. It was shown that with initial (maximum) susceptible population S_0, if $r = \frac{d_I}{\beta S_0} > 1$

(that is, the mortality rate of the infective foxes is greater than the rate of recruitment of new infective), the infection dies out quickly. If $r = \frac{d_I}{\beta S_0} < 1$*, there is a family of traveling wavefronts to the system* (2.13) *with the minimal speed*

$$c_{\min} = 2[D_I(\beta S_0 - d_I)]^{1/2}.$$

See [1, 6] for related work.

REMARK 2.3. *When* $D_Y = 0$*, system* (2.7)–(2.8) *reduces to the following model:*

$$\begin{cases} \frac{dJ}{dt} = D_I \frac{\partial^2 J}{\partial x^2} + \beta MJ - d_I J + \beta J \int_0^\tau b(M(t-a)) e^{\int_0^a -(d_Y + \beta J(t-s))ds} da, \\ \frac{dM}{dt} = -\beta MJ - d_S M + b(M(t-\tau)) e^{\int_{t-\tau}^t -(d_Y + \beta J(s))ds}. \end{cases} \tag{2.14}$$

This is a delayed reaction diffusion system with distributed delay but without spatial averaging. We will numerically compare the behavior of solutions to (2.14) *with that of* (2.7)–(2.8) *in section* 4.3.

In the remaining part of this paper, we consider the dynamics of (2.7)–(2.8) using the birth function

$$b(M) = b_0 M e^{-\bar{a}M},$$

where $\bar{a} > 0$ is a positive parameter, and $b_0 = b'(0)$ is the birth rate when the population size is small. This birth function exhibits the logistic growth nature of the fox population in the absence of the disease. Such a function has been used in the well-studied Nicholson blowfly model [12] and is common in models of fish. The specific form of such a function is not so important for the method developed below, though the specific form facilitates and simplifies our qualitative analysis since, as will be shown, constant equilibria can be explicitly described.

3. Structure of equilibria. In this section, we describe the structure of equilibria of biological interest. At an equilibrium, (J, M) takes on a constant value, namely,

$$J \equiv J_0, \quad M \equiv M_0,$$

for constants J_0 and M_0. Then from (2.7) we have

$$\begin{cases} (\frac{\partial}{\partial t} + \frac{\partial}{\partial a})S = D_Y \frac{\partial^2}{\partial x^2} S - d_Y S - \beta S J_0, \\ S(t, 0, x) = b(M_0). \end{cases} \tag{3.1}$$

To solve (3.1), we define $V^s(t, x) = S(t, t-s, x)$ and obtain, for $t \geq s$, that

$$\begin{aligned} \frac{\partial}{\partial t} V^s(t, x) &= \frac{\partial S}{\partial t}(t, a, x)|_{a=t-s} + \frac{\partial S(t, a, x)}{\partial a}|_{a=t-s} \\ &= D_Y \frac{\partial^2}{\partial x^2} V^s(t, x) - d_Y V^s(t, x) - \beta J_0 V^s(t, x). \end{aligned} \tag{3.2}$$

Note that (3.2) is a linear reaction diffusion equation with constant coefficients. The associated initial condition is

$$V^s(s, x) = b(M_0), \quad x \in R. \tag{3.3}$$

To ensure uniqueness of solutions, we also impose biologically realistic boundary conditions as follows:

$$|V^s(t,\pm\infty)| < \infty. \tag{3.4}$$

The solution of (3.2)–(3.4) is given by

$$V^s(t,x) = b(M_0)e^{-(d_Y+\beta J_0)(t-s)}. \tag{3.5}$$

That is,

$$S(t,t-s,x) = b(M_0)e^{-(d_Y+\beta J_0)(t-s)} \tag{3.6}$$

and

$$S(t,a,x) =: F(a,M_0,J_0) =: b(M_0)e^{-(d_Y+\beta J_0)a},\ 0 \le a \le \tau,$$

from which, with (2.8), it follows that equilibrium (M_0, J_0) is given by the following algebraic equations:

$$\begin{cases} \beta M_0 J_0 - d_I J_0 + \beta J_0 \frac{b(M_0)}{(d_Y+\beta J_0)}(1 - e^{-(d_Y+\beta J_0)\tau}) = 0, \\ -\beta M_0 J_0 - d_S M_0 + b(M_0)e^{-(d_Y+\beta J_0)\tau} = 0. \end{cases} \tag{3.7}$$

We now solve (3.7) for equilibria.

When $J_0 = 0$, the second equation in (3.7) gives

$$-d_S M_0 + b(M_0)e^{-d_Y\tau} = 0. \tag{3.8}$$

Thus M_0 can take on two different values: $M_0 = 0$ or $M_0 = M^\tau_{\max} = \frac{1}{\bar{a}}\ln(b_0/d_S e^{d_Y\tau}))$. Biological consideration requires that

$$\frac{b_0}{d_S e^{d_Y\tau}} > 1$$

or, equivalently,

$$\tau < \tau_{\max} = \frac{1}{d_Y}\ln\frac{b_0}{d_S}, \tag{3.9}$$

so that $M^\tau_{\max} > 0$.

When $J_0 \neq 0$, obviously from the second equation of (3.7) we can simplify the relation between J_0 and M_0 to yield

$$M_0 = \frac{1}{\bar{a}}\left(\ln\frac{b_0}{\beta J_0 + d_S} - (d_Y + \beta J_0)\tau\right).$$

Viewing M_0 as a function of J_0, that is, $M_0 = h_0(J_0)$ with h_0 being given by

$$h_0(J_0) = \frac{1}{\bar{a}}\left(\ln\frac{b_0}{\beta J_0 + d_S} - (d_Y + \beta J_0)\tau\right), \tag{3.10}$$

we find that $h_0(J_0)$ is decreasing for $J_0 \ge 0$ with

$$h_0(0) = M^\tau_{\max} > 0 \quad \text{and} \quad h_0(+\infty) < 0.$$

From the first equation of (3.7) we have

$$\frac{\beta b(M_0)}{d_I - \beta M_0} = \frac{d_Y + \beta J_0}{1 - e^{-(d_Y+\beta J_0)\tau}}. \tag{3.11}$$

The monotonic increasing property of the function on the right-hand side of (3.11) is obvious for $J_0 \in [0, \infty)$. We now check the monotonicity of the function on the left-hand side. Using the definition of $b(\cdot)$ and defining $f(x) := \beta b(x)/(d_I - \beta x)$, we have

$$\begin{aligned} f'(x) &= \beta \frac{b'(x)(d_I - \beta x) + \beta b(x)}{(d_I - \beta x)^2} \\ &= \beta \frac{b_0 e^{-\bar{a}x}(\bar{a}\beta x^2 - \bar{a} d_I x + d_I)}{(d_I - \beta x)^2}. \end{aligned}$$

It is easy to know that the function $f(x) = \beta b(x)/(d_I - \beta x)$ is increasing with respect to x provided that

$$\bar{a} d_I < 4\beta.$$

Therefore, under the above condition, a careful examination of the left-hand side of (3.11) shows that (3.11) gives a unique function $M_0 = h_1(J_0)$ ($M_0 < d_I/\beta$, $J_0 \geq 0$) which is increasing for $J_0 \in (0, \infty)$ and satisfies

$$h_1(\infty) = \frac{d_I}{\beta}.$$

It is easy to see that the intersection point of the two curves $M_0 = h_0(J_0)$ and $\mathrm{M}_0 = h_1(J_0)$ corresponds to the third equilibrium (J_*^τ, M_*^τ) of our system. As to the existence and positivity of this particular point, we have the following.

THEOREM 3.1. *Assume $\tau < \tau_{\max}$ and $ad_I < 4\beta$. Then system* (2.7)–(2.8) *has a unique positive equilibrium (J_*^τ, M_*^τ) if and only if*

$$C_0(\tau) := \frac{d_I}{\beta M_{\max}^\tau} - \frac{b(M_{\max}^\tau)(1 - e^{-d_Y\tau})}{M_{\max}^\tau d_Y} < 1, \tag{3.12}$$

where

$$M_{\max}^\tau = \frac{1}{\bar{a}} \ln \frac{b_0}{d_S e^{d_Y\tau}}.$$

Proof. The condition $\tau < \tau_{\max}$ implies that $M_{\max}^\tau$ is positive and the condition $ad_I < 4\beta$ guarantees that h_1 is increasing. Note that $h_0(0) = M_{\max}^\tau$. By the monotonicity properties of functions h_0 and h_1 and the fact that $h_0(\infty) < 0$ and $h_1(\infty) = \frac{\beta}{d_I} > 0$, it follows that the functions h_0 and h_1 have a positive intersection point if and only if $h_1(0) < h_0(0) = M_{\max}^\tau$. Now we show that $h_1(0) < h_0(0) = M_{\max}^\tau$ if and only if $C_0(\tau) < 1$. We consider two cases:

(i) $M_{\max}^\tau \geq \beta/d_I$;
(ii) $M_{\max}^\tau < \beta/d_I$.

In the first case, the proof is obvious and will be omitted here. For the second case, the inequality $C_0(\tau) < 1$ is actually equivalent to

$$\frac{d_I}{\beta M_{\max}^\tau} - \frac{b(M_{\max}^\tau)(1 - e^{-d_Y\tau})}{M_{\max}^\tau d_Y} < 1,$$

or to

$$\frac{d_Y}{(1-e^{-d_Y\tau})} < \frac{\beta b(M^\tau_{\max})}{d_I - \beta M^\tau_{\max}}. \tag{3.13}$$

From (3.11) we note that $h_1(0)$ $(< \frac{d_I}{\beta})$ is determined by

$$\frac{\beta b(h_1(0))}{d_I - \beta h_1(0)} = \frac{d_Y}{1-e^{-d_Y\tau}}. \tag{3.14}$$

This means by (3.13) that $C_0(\tau) < 1$ is equivalent to

$$\frac{\beta b(h_1(0))}{d_I - \beta h_1(0)} = \frac{d_Y}{1-e^{-d_Y\tau}} < \frac{\beta b(M^\tau_{\max})}{d_I - \beta M^\tau_{\max}}. \tag{3.15}$$

Since the function $f(y) = \beta b(y)/(d_I - \beta y)$ is strictly increasing for $y \in (-\infty, d_I/\beta)$, from (3.15) we have the desired result that $h_1(0) < M^\tau_{\max} \Longleftrightarrow C_0(\tau) < 1$, and the proof is complete.

REMARK 3.2. *Inequality* (3.12) *can be rewritten as*

$$\frac{d_I}{\beta} < M^\tau_{\max} + b(M^\tau_{\max})\frac{(1-e^{-d_Y\tau})}{d_Y}. \tag{3.16}$$

The right side of (3.16) *is the sum of the population of the mature and the immature foxes when they reach equilibria in the disease-free case. This sum is the carrying capacity of the environment. The left-hand side d_I/β is the critical minimum threshold fox density; see* [14]. *Theorem* 3.1 *means that when the carrying capacity of the environment is greater than the critical threshold-value d_I/β, the rabid foxes and the susceptible foxes can coexist and a positive equilibrium exists.*

4. Traveling wave solutions. In this section, we consider the behavior of solutions to system (2.7)–(2.8) in unbounded domain $(-\infty, \infty)$ under the conditions in Theorems 3.1. In section 4.1, we use the standard stability analysis to investigate possible patterns of traveling waves. An explicit formula for the minimal wave speed is given and this wave solution is confirmed by numerical simulations in section 4.3. In section 4.2, we prove that traveling wavefronts with large wave speeds indeed exist by using perturbation analysis developed in [8].

4.1. Local analysis of the traveling wavefronts. Standard stability analysis is employed here to discuss the existence of traveling wavefronts. As usual, we linearize the wave equation of (2.7)–(2.8) near their equilibria and find the associated eigenvalues and eigenvectors. Sketching this information in the system's phase plane yields a useful suggestion about a possible heteroclinic connection between these equilibria. We show the details as follows.

First of all, we linearize (2.7)–(2.8) around its equilibrium (J_0, M_0). Recall that when $J \equiv J_0$, $M \equiv M_0$, we have $S(t, t-s, x) = F(t-s, M_0, J_0)$. Assume that

$$J = J_0 + \Delta J, \quad M = M_0 + \Delta M, \quad S(t, t-s, x) = F(t-s, M_0, J_0) + \Delta S.$$

We first obtain the following linearized system for ΔS:

$$\begin{cases} \frac{\partial \Delta S}{\partial t} = D_Y \frac{\partial^2}{\partial x^2}\Delta S - d_Y \Delta S - \beta J_0 \Delta S - \beta F(t-s, M_0, J_0)\Delta J, \\ \Delta S|_{t=s} = b'(M_0)\Delta M. \end{cases} \tag{4.1}$$

We then use Fourier transforms to solve this equation. Let

$$\Delta\tilde{S} = \int_{-\infty}^{\infty} \Delta S\, e^{i\omega y} dy,$$

and let f be the Fourier transform of the term $-\beta F(t-s, M_0, J_0)\Delta J$, that is,

$$f = -\beta F(t-s, M_0, J_0) \int_{-\infty}^{\infty} \Delta J\, e^{i\omega y} dy.$$

Then, after taking Fourier transforms to both sides of (4.1), we arrive at a new linear equation for $\Delta\tilde{S}$ that can be solved easily to yield

$$\begin{aligned}
\Delta\tilde{S} &= e^{-(D_Y\omega^2+d_Y+\beta J_0)(t-s)} \int_{-\infty}^{\infty} b'(M_0)\Delta M(s,y)e^{i\omega y}dy \\
&\quad + \int_s^t f\, e^{-\int_{u-s}^{t-s}(D_Y\omega^2+d_Y+\beta J_0)dv} du \\
&= e^{-(D_Y\omega^2+d_Y+\beta J_0)(t-s)} \int_{-\infty}^{\infty} b'(M_0)\Delta M(s,y)e^{i\omega y}dy \\
&\quad - \beta \int_s^t F(u-s, M_0, J_0) \int_{-\infty}^{\infty} \Delta J(u,y)\, e^{i\omega y} dy\, e^{-(D_Y\omega^2+d_Y+\beta J_0)(t-u)} du.
\end{aligned}$$

We now take inverse Fourier transforms to obtain

$$\begin{aligned}
\Delta S(t,s,x) &= \frac{1}{2\pi} \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} b'(M_0)\Delta M(s,y)e^{i\omega y}dy\, e^{-(D_Y\omega^2+d_Y+\beta J_0)(t-s)} e^{-i\omega x} d\omega \\
&\quad - \frac{\beta}{2\pi} \int_{-\infty}^{\infty}\int_s^t F(u-s, M_0, J_0) \\
&\quad \times \int_{-\infty}^{\infty} \Delta J(u,y)\, e^{-(D_Y\omega^2+d_Y+\beta J_0)(t-u)+i\omega(y-x)} dy\, du d\omega \\
&= \frac{b'(M_0)}{\sqrt{4\pi D_Y(t-s)}} e^{-(d_Y+\beta J_0)(t-s)} \int_{-\infty}^{\infty} \Delta M(s,y) e^{-(x-y)^2/(4D_Y(t-s))} dy \\
&\quad - \frac{\beta}{2\pi} \int_{-\infty}^{\infty} dy \int_s^t F(u-s, M_0, J_0)\Delta J(u,y) e^{-(d_Y+\beta J_0)(t-u)} \\
&\quad \times \int_{-\infty}^{\infty} e^{-\omega^2 D_Y(t-u)+i\omega(y-x)} du d\omega \\
&= \frac{b'(M_0)}{\sqrt{4\pi D_Y(t-s)}} e^{-(d_Y+\beta J_0)(t-s)} \int_{-\infty}^{\infty} \Delta M(t-a,y) e^{-(x-y)^2/(4D_Y(t-s))} dy \\
&\quad - \beta \int_{-\infty}^{\infty} dy \int_0^{t-s} F(t-v-s, M_0, J_0)\Delta J(t-v,y) \\
&\quad \times e^{-(d_Y+\beta J_0)v} \frac{e^{-(x-y)^2/(4D_Y v)}}{\sqrt{4\pi D_Y v}} dv
\end{aligned}$$

and

$$\Delta S(t,a,x) = \frac{b'(M_0)}{\sqrt{4\pi D_Y a}} e^{-(d_Y+\beta J_0)a} \int_{-\infty}^{\infty} \Delta M(t-a,y) e^{-(x-y)^2/(4D_Y a)} dy$$
$$- \beta \int_{-\infty}^{\infty} dy \int_0^a F(a-v, M_0, J_0) \Delta J(t-v,y)$$
$$\times e^{-(d_Y+\beta J_0)v} \frac{e^{-(x-y)^2/(4D_Y v)}}{\sqrt{4\pi D_Y v}} dv.$$

Thus we obtain from (2.4) and (2.6) the following linearized system:

$$\text{(4.2)} \quad \begin{cases} \frac{\partial \Delta J}{\partial t} = D_I \frac{\partial^2 \Delta J}{\partial x^2} + \beta M_0 \Delta J + \beta J_0 \Delta M - d_I \Delta J + \beta \Delta J \int_0^\tau F(a, M_0, J_0) da \\ \qquad + \beta J_0 \int_0^\tau \Delta S(t,a,x) da, \\ \frac{\partial \Delta M}{\partial t} = -\beta M_0 \Delta J - \beta J_0 \Delta M - d_S \Delta M + \Delta S(t,\tau,x). \end{cases}$$

Near the equilibrium $(J,M) = (0, M^\tau_{\max})$, it gives

$$\text{(4.3)} \quad \begin{cases} \frac{\partial \Delta J}{\partial t} = D_I \frac{\partial^2 \Delta J}{\partial x^2} + \beta M^\tau_{\max} \Delta J - d_I \Delta J + \beta b(M^\tau_{\max}) \frac{1-e^{d_Y \tau}}{d_Y} \Delta J, \\ \frac{\partial \Delta M}{\partial t} = -\beta M^\tau_{\max} \Delta J - d_S \Delta M + \Delta S(t,\tau,x), \end{cases}$$

where

$$\Delta S(t,\tau,x) = \frac{b'(M^\tau_{\max})}{\sqrt{4\pi D_Y \tau}} e^{-d_Y \tau} \int_{-\infty}^{\infty} \Delta M(t-\tau,y) e^{-(x-y)^2/(4D_Y \tau)} dy$$
$$- \beta \int_{-\infty}^{\infty} dy \int_0^\tau F(\tau - v, M_0, J_0) \Delta J(t-v,y) e^{-d_Y v} \frac{e^{-(x-y)^2/(4D_Y v)}}{\sqrt{4\pi D_Y v}} dv.$$

Looking for a traveling wavefront $\Delta J = f_1(x+ct)$, $\Delta M = g(x+ct)$, we have from (4.3) that

$$\text{(4.4)} \quad \begin{cases} c f_1' = D_I f_1'' + f_1(\beta M^\tau_{\max} - d_I + \frac{\beta b(M^\tau_{\max})}{d_Y}(1 - e^{-d_Y \tau})), \\ c g' = -\beta M^\tau_{\max} f_1 - d_S g + \frac{b'(M^\tau_{\max})}{\sqrt{4\pi D_Y \tau}} e^{-d_Y \tau} \int_{-\infty}^{\infty} g(y - c\tau) e^{-(\xi - y)^2/(4D_Y \tau)} dy \\ \qquad - \beta \int_{-\infty}^{\infty} dy \int_0^\tau F(\tau - v, M_0, J_0) f_1(y - cv) e^{-d_Y v} \sqrt{\frac{1}{4\pi D_Y v}} e^{-(\xi - y)^2/(4D_Y v)} dv. \end{cases}$$

This is a linear system of functional differential equations with mixed arguments. The corresponding eigenvalues are determined by either

$$\text{(4.5)} \qquad \lambda^2 - \frac{c}{D_I}\lambda + \frac{k_1}{D_I} = 0$$

or

$$-d_S + e^{-d_Y \tau} b'(M^\tau_{\max}) e^{\alpha \lambda^2 - \lambda c \tau} = c\, \lambda,$$

where

$$k_1 = \beta M^\tau_{\max} - d_I + \frac{\beta b(M^\tau_{\max})}{d_Y}(1 - e^{-\tau d_Y}).$$

Solving (4.5) yields

$$\lambda_{1,2} = \frac{c \pm \sqrt{c^2 - 4k_1 D_I}}{2D_I}.$$

The corresponding eigenvectors to the following system, which is equivalent to (4.4) by letting $f_2 = f_1'$,

$$\begin{cases} f_1' = f_2, \\ D_I f_2' = cf_2 - f_1(\beta M^\tau_{\max} - d_I + \frac{\beta b(M^\tau_{\max})}{d_y}(1 - e^{-d_y\tau})), \\ cg' = -\beta M^\tau_{\max} f_1 - d_S g + \frac{b'(M^\tau_{\max})}{\sqrt{4\pi D_Y \tau}} e^{-d_Y\tau} \int_{-\infty}^{\infty} g(y - c\tau) e^{-(\xi-y)^2/(4D_Y\tau)} dy \\ \quad - \beta \int_{-\infty}^{\infty} dy \int_0^\tau S_0(\tau - v) f_1(y - cv) e^{-d_Y v} \sqrt{\frac{1}{4\pi D_Y v}} e^{-(\xi-y)^2/(4D_Y v)} dv \end{cases}$$

are

$$\vec{v}_1 = \begin{pmatrix} 1 \\ \lambda_1 \\ 0 \end{pmatrix}, \ \vec{v}_2 = \begin{pmatrix} 1 \\ \lambda_2 \\ 0 \end{pmatrix}.$$

When

$$0 < c < 2\sqrt{k_1 D_I},$$

the eigenvalues $\lambda_{1,2}$ are complex and the eigensolutions are oscillatory and can be negative. This is not biologically meaningful. Therefore, a natural condition for the existence of traveling wavefronts starting from $(0, M^\tau_{\max})$ is

$$\begin{aligned} c \geq c_{\min}(\tau) &:= 2\sqrt{\beta M^\tau_{\max} D_I} \sqrt{1 - \frac{d_I}{\beta M^\tau_{\max}} + \frac{b(M^\tau_{\max})}{M^\tau_{\max} d_Y}(1 - e^{-d_Y\tau})} \\ &= 2\sqrt{\beta M^\tau_{\max} D_I} \sqrt{1 - C_0(\tau)}. \end{aligned} \tag{4.6}$$

We should mention that the minimal speed can also be expressed as

$$c_{\min}(\tau) = 2\sqrt{\beta D_I} \sqrt{M^\tau_{\max} + b(M^\tau_{\max}) \frac{1 - e^{-d_Y\tau}}{d_Y} - \frac{d_I}{\beta}},$$

from which we find the speed $c_{\min}$ depends not only on the diffusive coefficient D_I and the transmission rate β, but also on the difference between the carrying capacity $M^\tau_{\max} + b(M^\tau_{\max}) \frac{1-e^{-d_Y\tau}}{d_Y}$ and the critical threshold value d_I/β.

We now argue that it is impossible for a positive trajectory to go from $(0, M^\tau_{\max})$ to $(0, 0)$. To see this, linearizing around $(0, 0)$, we obtain

$$\begin{cases} \frac{\partial \Delta J}{\partial t} = D_I \frac{\partial^2 \Delta J}{\partial x^2} - d_I \Delta J, \\ \frac{\partial \Delta M}{\partial t} = -d_S \Delta M + \frac{b'(0)}{\sqrt{4\pi D_Y \tau}} e^{-d_Y\tau} \int_{-\infty}^{\infty} \Delta M(t - \tau, y) e^{-(x-y)^2/(4D_Y\tau)} dy. \end{cases}$$

This gives, by substituting $\Delta J = f_1(x + ct)$, $\Delta M = g(x + ct)$, the following:

$$\begin{cases} cf_1' = D_I f_1'' - d_I f_1, \\ cg' = -d_S g + \frac{b'(0)}{\sqrt{4\pi D_Y \tau}} e^{-d_Y\tau} \int_{-\infty}^{\infty} g(y - c\tau) e^{-(\xi-y)^2/(4D_Y\tau)} dy. \end{cases} \tag{4.7}$$

Thus at $(0, 0)$, the eigenvalues satisfy

$$\left[\lambda\left(\lambda - \frac{c}{D_I}\right) - \frac{d_I}{D_I}\right]\left[\frac{1}{c}\left(-d_S + e^{-d_Y\tau} b'(0) e^{\alpha\lambda^2 - \lambda c\tau}\right) - \lambda\right] = 0. \tag{4.8}$$

The second factor corresponds to the second equation of (4.7) that is in fact decoupled from the first equation of (4.7).

By (3.9) it is easy to see that every eigenvalue to equation

$$\frac{1}{c}\left(-d_S + e^{-d_Y\tau}b'(0)e^{\alpha\lambda^2-\lambda c\tau}\right) - \lambda = 0$$

cannot be negative and real, and hence there is no positive solution g such that $\lim_{t\to\infty} g(t) = 0$. This means that there's no positive orbit of (2.7)–(2.8) starting from $(0, M^\tau_{\max})$ and approaching $(0,0)$.

So the solution starting from $(0, M^\tau_{\max})$ could arrive at (J^τ_*, M^τ_*) under the condition (4.6). The asymptotic behavior of traveling wavefronts approaching (J^τ_*, M^τ_*) depends on eigenvalues of system (4.2) near the equilibrium (J^τ_*, M^τ_*). If all the eigenvalues with negative real parts are complex, then the traveling wave will tend to (J^τ_*, M^τ_*) with oscillatory damping. Otherwise it will approach (J^τ_*, M^τ_*) monotonically. We will see numerical evidence for oscillatory damping of wave patterns in later sections.

4.2. A rigorous proof of traveling wavefronts with large wave speeds. In this section, the existence of traveling wavefronts is rigorously established for system (2.7)–(2.8). To present our result, we first show the existence of a heteroclinic connection for a nondiffusive delayed system and then show that this is perturbed to a traveling wavefront with large wave speed for (2.7)–(2.8).

4.2.1. Heteroclinic connection for a nondiffusion delay system. We now study the heteroclinic connection of the delayed system

$$\begin{cases} \frac{dJ}{dt} = \beta MJ - d_I J + \beta J\int_0^\tau b(M(t-a))e^{\int_0^a -(d_Y+\beta J(t-s))ds}da, \\ \frac{dM}{dt} = -\beta MJ - d_S M + b(M(t-\tau))e^{\int_{t-\tau}^t -(d_Y+\beta J(s))ds}, \end{cases} \tag{4.9}$$

which is a reduced version of (2.7)–(2.8) when $D_I = D_Y = 0$. It is easy to see that (4.9) has three equilibria: $E_1 := (0,0)$, $E_2 := (0, M^\tau_{\max})$, and $E_3 := (J^\tau_*, M^\tau_*)$.

For initial continuous data $(J, M) = (j_0(s), m_0(s)) \geq 0$ for $s \in [-\tau, 0]$ with $(j_0(0), m_0(0)) > 0$, we claim that

$$(J(t), M(t)) > 0$$

for all $t > 0$. Indeed, dividing the first equation in (4.9) by J and integrating it from 0 to t, we have

$$J(t) = J(0)\exp\left(\beta M - d_I + \beta\int_0^\tau b(M(t-a)e^{\int_0^a -(d_Y+\beta J(t-s))ds}\right) > 0.$$

We then use the variation-of-constants formula in consecutive interval $[0,\tau], [\tau, 2\tau], \ldots$ to obtain

$$M(t) > 0$$

for $t \geq 0$.

When $\tau = 0$, the above system reduces to the ODE system

$$\begin{cases} \frac{dJ}{dt} = \beta MJ - d_I J, \\ \frac{dM}{dt} = -\beta MJ - d_S M + b(M). \end{cases} \tag{4.10}$$

Obviously, the three equilibria reduces to $E_1 = (0,0)$, $E_2 = (0, M^0_{\max})$, and $E_3 = (J^0_*, M^0_*) = (\frac{1}{\beta}(-d_S + b_0 e^{-\bar{a}d_I/\beta}), \frac{d_I}{\beta})$, and we have $J^0_* > 0$ if and only if $C_0(0) = \frac{d_I}{\beta M^0_{\max}} < 1$.

THEOREM 4.1. *When $\tau = 0$ and $C_0(0) = \frac{d_I}{\beta M^0_{\max}} < 1$, system (4.9) has a heteroclinic orbit $(J_0(t), M_0(t))$ connecting E_2 and E_3.*

Proof. First, we prove that the third equilibrium E_3 is a global attractor in the sense that it attracts every positive solution of (4.9) when $\tau = 0$. To see this, define a Lyapunov function as

$$V = \left[M - M^0_* - M^0_* \log \frac{M}{M^0_*}\right] + \left[J - J^0_* - J^0_* \log \frac{J}{J^0_*}\right].$$

Differentiating the function V along the solution (4.10) yields

$$\frac{dV}{dt} = b_0(e^{-\bar{a}M} - e^{-\bar{a}d_I/\beta})\left(M - \frac{d_I}{\beta}\right) < 0$$

provided that $M \neq d_I/\beta$. This means that the equilibrium E_3 is a global attractor by LaSalle's well-known invariance principle. Linearizing (4.10) around E_2 gives

$$\begin{pmatrix} \beta M^0_{\max}(1 - C_0(0)) - \lambda & 0 \\ -\beta M^0_{\max} & -d_S + b'(M^0_{\max}) - \lambda \end{pmatrix}$$

and the following characteristic equation:

$$(\beta M^0_{\max} - d_I - \lambda)(-d_S + b'(M^0_{\max}) - \lambda) = 0. \tag{4.11}$$

For $\lambda_1 = \beta M^0_{\max}(1 - C_0(0)) > 0$, we find an eigenvector $\vec{v}_1$ which points into the first quadrant of the $J - M$ plane. Therefore, the solution starting from the local unstable manifold of E_2 along the $\vec{v}_1$ direction will permanently stay in the first quadrant and tends to $(J^0_*, M^0_*)^T$ as $t \to \infty$ due to the global attractivity of E_3. This completes the proof.

When $\tau \neq 0$, deriving the global stability of the equilibrium E_3 is nontrivial. Even for the local stability, providing an explicit criterion is not easy. To demonstrate this, we linearize (4.9) around E_3 to obtain

$$\begin{aligned} \frac{dJ}{dt} = &\left(\beta M^\tau_* - d_I + \beta b(M^\tau_*)\frac{1 - e^{-(d_Y + \beta J^\tau_*)\tau}}{(d_Y + \beta J^\tau_*)}\right) J \\ &- \beta^2 J^\tau_* b(M^\tau_*) \int_0^\tau e^{-(d_Y + \beta J^\tau_*)a} \int_0^a J(t-s)dsda + \beta J^\tau_* M \\ &+ \beta J^\tau_* b'(M^\tau_*) \int_0^\tau M(t-a) e^{-(d_Y + \beta J^\tau_*)a} da \end{aligned} \tag{4.12}$$

and

$$\begin{aligned} \frac{dM}{dt} = &-\beta M^\tau_* J - \beta b(M^\tau_*) e^{-(d_Y + \beta J^\tau_*)\tau} \int_0^\tau J(t-s)ds \\ &+ \beta J^\tau_* M - d_S M + b'(M^\tau_*) e^{-(d_Y + \beta J^\tau_*)\tau} M(t-\tau). \end{aligned} \tag{4.13}$$

In order to understand the linear system (4.12) and (4.13), we first consider the special case when $\tau = 0$. In this case the characteristic equation is given by

$$\lambda^2 + (\beta J^0_* + d_S - b'(M^0_*))\lambda + \beta^2 M^0_* J^0_* = 0.$$

Since (4.10) yields $\beta J_*^0 + d_S = b(M_*^0)/M_*^0$, the above equation becomes

$$\lambda^2 + \bar{a}b_0 e^{-\bar{a}M_*^0}\lambda + \beta^2 M_*^0 J_*^0 = 0.$$

Hence, the eigenvalues are given by

$$\lambda_{1,2} = \frac{-\bar{a}b_0 e^{-\bar{a}M_*^0} \pm \sqrt{(\bar{a}b_0)^2 e^{-2\bar{a}M_*^0} - 4\beta^2 M_*^0 J_*^0}}{2}, \tag{4.14}$$

the real parts of which are negative as long as $J_*^0 > 0$ (or, equivalently, $C_0(0) < 1$). Because λ depends continuously on the parameter τ, we conclude that there exists a number $\tau_1 > 0$ so that when $\tau < \tau_1$, all the eigenvalues of the linearization at E_3 have a negative real part.

At the equilibrium E_2 when $\tau \neq 0$, we have the following characteristic equation:

$$(1 - C_0(\tau) - \lambda)\,(-d_S + b'(M_{\max}^\tau)e^{-d_Y\tau}e^{-\lambda\tau} - \beta M_{\max}^\tau \lambda) = 0. \tag{4.15}$$

It can be shown easily that there exists a constant τ_2 so that equilibrium E_2 is hyperbolic for $C(\tau) < 1$ and $\tau \in [0, \tau_2)$, where τ_2 is the first positive number satisfying

$$|b'(M_{\max}^{\tau_2})e^{-dy\tau_2}| > |d_S|, \quad \text{and} \quad \tau_2 = \frac{\pi - \arccos\frac{d_s}{|b'(M_{\max}^{\tau_2})e^{-d_y\tau_2}|}}{\sqrt{(b'(M_{\max}^{\tau_2})e^{-d_y\tau_2})^2 - d_s^2}}. \tag{4.16}$$

We should mention that formula (4.16) can be obtained by the well-known Hopf bifurcation theory, and that if there is no τ_2 satisfying (4.16), then we assume that $\tau_2 = \infty$.

With the above preparation, we are now ready to prove a theorem concerning the heteroclinic connection for (4.9) when $\tau \neq 0$. To present our result, we first introduce some notation.

- For a vector $x \in R^2$, we denote $||x|| = ||x||_{R^2}$.
- Let $X(R, R^2)$ be the space of continuous and bounded functions from R to R^2 equipped with the standard norm $||\phi|| = \sup\{||\phi(t)||,\, t \in R\}$.
- Let $X^1 = X^1(R, R^2) = \{\phi \in X : \phi' \in X\}$.
- Let $X_0 = \{\phi \in X : \lim_{t\to\pm\infty}\phi = 0\}$ and $X_0^1 = \{\phi \in X_0 : \phi' \in X_0\}$.

Under the conditions in Theorem 3.1, we have the following result.

THEOREM 4.2. *Assume that $C_0(\tau) < 1$. Then there exists a positive constant δ so that for $0 \le \tau \le \delta$, equation (4.9) has a heteroclinic orbit $(J(t), M(t))$ which connects E_2 and E_3.*

Proof. We first introduce the transformation

$$U = \frac{J(t)}{J_*^\tau}, \quad V = \frac{M_{\max}^\tau - M}{M_{\max}^\tau - M_*^\tau}$$

to get rid of the τ-dependence of E_2 and E_3. Substituting this into (4.9), we have the following system for U and V:

$$\begin{cases} \frac{dU}{dt} = \beta(M_{\max}^\tau - V(M_{\max}^\tau - M_*^\tau))U - d_I U \\ \qquad + \beta U \int_0^\tau \bar{b}(V(t-a)e^{\int_0^a -(d_Y + \beta J_*^\tau U(t-s))ds}da, \\ \frac{dV}{dt} = \frac{\beta J_*^\tau (M_{\max}^\tau - V(M_{\max}^\tau - M_*^\tau))U}{M_{\max}^\tau - M_*^\tau} + \frac{d_S(M_{\max}^\tau - V(M_{\max}^\tau - M_*^\tau))}{M_{\max}^\tau - M_*^\tau} \\ \qquad - \frac{\bar{b}(V(t-\tau)}{M_{\max}^\tau - M_*^\tau} e^{\int_{t-\tau}^t -(d_Y + \beta J_*^\tau U(s))ds}, \end{cases} \tag{4.17}$$

where $\bar{b}(V(t-\tau)) = b(M^\tau_{\max} - V(M^\tau_{\max} - M^\tau_*))$. Equation (4.17) has two equilibria $E_2 := (0,0)$ and $E_3 := (1,1)$. In particular when $\tau = 0$, we know from Theorem 4.1 that there exists a heteroclinic solution $(U_0(t), V_0(t))$ that connects two points E_2 and E_3 and satisfies

(4.18)
$$\begin{cases} \frac{dU_0}{dt} = F_1(u,v)|_{u=U_0,v=V_0} = \beta(M^0_{\max} - V_0(M^0_{\max} - M^0_*))U_0 - d_I U_0, \\ \frac{dV_0}{dt} = F_2(u,v)|_{u=U_0,v=V_0} = \frac{\beta J^0_*(M^0_{\max} - V_0(M^0_{\max} - M^0_*))V_0}{M^0_{\max} - M^0_*} + \frac{d_S(M^0_{\max} - V(M^0_{\max} - M^0_*))}{M^0_{\max} - M^0_*} \\ \qquad\qquad - \frac{\bar{b}(V_0(t))}{M^0_{\max} - M^0_*}. \end{cases}$$

Note that the relation between $M^\tau_{\max}$ and $M^0_{\max}$, M^τ_* and M^0_*, and J^τ_* and J^0_* can be described as

$$M^\tau_{\max} = M^0_{\max} + O(\tau), \quad M^\tau_* = M^0_* + O(\tau), \quad J^\tau_* = J^0_* + O(\tau). \tag{4.19}$$

We now show that there exists a constant δ such that (4.17) has a heteroclinic orbit $(U(t), V(t))$ connecting two points E_2 and E_3 provided $\tau < \delta$.

First of all, we let $W_1 = U - U_0$ and $W_2 = V - V_0$ and obtain the following equation for the remainder (W_1, W_2):

$$\begin{cases} \frac{dW_1}{dt} = \frac{\partial F_1(U_0,V_0)}{\partial u} W_1 + \frac{\partial F_1(U_0,V_0)}{\partial v} W_2 + \Gamma_1(t,\tau,W_1,W_2), \\ \frac{dW_2}{dt} = \frac{\partial F_2(U_0,V_0)}{\partial u} W_1 + \frac{\partial F_2(U_0,V_0)}{\partial v} W_2 + \Gamma_2(t,\tau,W_1,W_2), \end{cases} \tag{4.20}$$

where

$$\begin{aligned} &\Gamma_1(t,\tau,W_1,W_2) \\ &= \beta(M_{\max} - (V_0+W_2)(M^\tau_{\max} - M^\tau_*))(U_0+W_1) - d_I(U_0+W_1) \\ &\quad + \beta(U_0+W_1)\int_0^\tau \bar{b}(V_0(t-a) + W_1(t-a)) e^{\int_0^a -(d_Y + \beta J^\tau_*(U_0(t-s)+W(t-s)))ds} da \\ &\quad - F_1(U_0,V_0) - \left(\frac{\partial F_1(U_0,V_0)}{\partial u} W_1 + \frac{\partial F_1(U_0,V_0)}{\partial v} W_2\right) \end{aligned} \tag{4.21}$$

and

$$\begin{aligned} \Gamma_2(t,\tau,W_1,W_2) &= \frac{\beta J^\tau_*(M^\tau_{\max} - (V_0+W_2)(M^\tau_{\max} - M^\tau_*))(U_0+W_1)}{M^\tau_{\max} - M^\tau_*} \\ &\quad + \frac{d_S(M^\tau_{\max} - (V_0+W_2)(M^\tau_{\max} - M^\tau_*))}{M^\tau_{\max} - M^\tau_*} \\ &\quad - \frac{\bar{b}(V_0(t-\tau) + W_2(t-\tau))}{M^\tau_{\max} - M^\tau_*} e^{\int_{t-\tau}^t -(d_Y + \beta J^\tau_*(U_0(s)+W_1(s)))ds} \\ &\quad - F_2(U_0,V_0) - \left(\frac{\partial F_2(U_0,V_0)}{\partial u} W_1 + \frac{\partial F_2(U_0,V_0)}{\partial v} W_2\right). \end{aligned} \tag{4.22}$$

Define an operator $T : \Psi \in X^1 \to X$ from the homogeneous part of (4.20) as follows:

$$T\Psi = \Psi' - A(t)\Psi, \ t \in R, \tag{4.23}$$

where

$$A(t) = \begin{pmatrix} \frac{\partial F_1(U_0(t),V_0(t))}{\partial u} & \frac{\partial F_1(U_0(t),V_0(t))}{\partial v} \\ \frac{\partial F_2(U_0(t),V_0(t))}{\partial u} & \frac{\partial F_2(U_0(t),V_0(t))}{\partial v} \end{pmatrix}.$$

We remark that $(U_0(t), V_0(t))$ tends, respectively, to E_2 and E_3 when $t \to -\infty$ and $t \to \infty$. This means that the linear operator T is asymptotically hyperbolic as $t \to \pm\infty$ in the sense that

$$\Psi' - A(-\infty)\Psi = 0 \quad \text{and} \quad \Psi' - A(\infty)\Psi = 0$$

are hyperbolic due to (4.11) and (4.14). Furthermore, we know that every eigenvalue for the linear equation $\Psi' - A(\infty)\Psi = 0$ has a negative real part. Define the formal adjoint equation of $T\Psi = \Psi' - A(t)\Psi = 0$ as

$$\Phi' + A^T(t)\Phi = 0, \quad t \in R. \tag{4.24}$$

We now divide our proof into five steps.

Step 1. We claim that if $\Phi \in X$ is a solution of (4.24) and Φ is C^1-smooth, then $\Phi = 0$. Moreover, we have $R(T) = X$, where $R(T)$ is the range of T.

Indeed, assuming to the contrary that Φ is not zero at some point t_0, then we can solve (4.24) to obtain

$$\Phi(t) = \Phi(t_0)e^{-\int_{t_0}^{t} A^T(t)dt}.$$

Since when $t \to \infty$, $A^T(t)$ tends to $A^T(\infty)$ whose eigenvalues are negative, we deduce that

$$\lim_{t\to\infty} \Phi(t) = \infty,$$

which contradicts the fact that Φ is bounded.

By the classical Fredholm theory, this claim means further that $R(T) = X$ in the sense that for any $\Theta \in X$, there exists $\Psi \in X^1$ so that

$$T\Psi = \Theta.$$

Step 2. Let $\Theta \in X_0$ be given. If Ψ is a bounded solution of $T\Psi = \Theta$, then $\Psi \in X_0^1$. In fact, we need to show only that

$$\lim_{t\to\pm\infty} \Psi(t) = 0.$$

Actually when $t \to \infty$, equation

$$\Psi' - A(t)\Psi = \Theta \tag{4.25}$$

asymptotically tends to

$$\Psi' - A(\infty)\Psi = 0. \tag{4.26}$$

Note that for (4.26), the ω-limit set of every bounded solution is just the critical point $\Psi = 0$. Using the result from [21] or [18], every bounded solution of (4.25) also satisfies

$$\lim_{t\to\infty} \Psi(t) = 0.$$

When inverting the time from $-t$ to t, we can similarly prove that

$$\lim_{t\to-\infty}\Psi(t)=0.$$

Step 3. We rewrite (4.20) as

$$W'(t)+W=W+A(t)W+\Gamma(t), \tag{4.27}$$

where

$$W=(W_1,W_2)^T,\ \ \Gamma(t)=(\Gamma_1(s,\tau,W_1,W_2),\Gamma_2(s,\tau,W_1,W_2))^T.$$

Changing (4.27) into an integral equation gives

$$W(t)=\int_{-\infty}^{t}e^{-(t-s)I}(W(s)+A(s)W(s)+\Gamma(s))ds, \tag{4.28}$$

where I is the 2×2 identity matrix and $W(t)=(W_1(t),W_2(t))^T$.

Define a linear operator $L: X_0\to X_0$ as follows:

$$L(W)(t)=W(t)-\int_{-\infty}^{t}e^{-(t-s)I}(W(s)+A(s)W(s))ds,\ W\in X_0.$$

Obviously $L(W)\in X_0$ if $W\in X_0$. Now we prove that $R(L)=X_0$, that is, for each $Z\in X_0$, we can have a $W\in X_0$ so that

$$W(t)-\int_{-\infty}^{t}e^{-(t-s)I}(W(s)+A(s)W(s))ds=Z(t).$$

To see this, assuming that $\xi=W-Z$, we obtain an equation for ξ as follows:

$$\xi(t)=\int_{-\infty}^{t}e^{-(t-s)I}(\xi(s)+A(s)\xi(s))ds+\int_{-\infty}^{t}e^{-(t-s)I}(Z(s)+A(s)Z(s))ds.$$

Differentiating both sides yields

$$T(\xi)(t)=\xi'(t)-A(t)\xi(t)=Z(t)+A(t)Z(t). \tag{4.29}$$

Using the results that $R(T)=X$ in Step 2, one can obtain that there exists a solution ξ for (4.29) and $\xi\in X_0^1$. Returning to the variable W, we have $W=\xi+Z\in X_0$.

Step 4. Let $N(L)$ be the null space of the operator L. Define $N^{\perp}(L)=X_0/N(L)$. It is clear that $N^{\perp}(L)$ is a Banach space. If we let $S=L|_{N^{\perp}(L)}$ be the restriction of L on $N^{\perp}(L)$, then $S: N^{\perp}(L)\to X_0$ is one-to-one and onto. By the well-known Banach inverse operator theorem, we have that $S^{-1}: X_0\to X_0/N(L)$ is a linear bound operator.

Step 5. When L is restricted on $N^{\perp}(L)$, equation (4.28) can be written as

$$S(W)(t)=\int_{-\infty}^{t}e^{-(t-s)I}\Gamma(s,W,\tau)ds$$

or

$$W(t)=S^{-1}\left(\int_{-\infty}^{t}e^{-(t-s)I}\Gamma(s,W,\tau)ds\right). \tag{4.30}$$

The term $\int_{-\infty}^{t} e^{-(t-s)I}\Gamma(s)ds$ on the right-hand side can be estimated. Actually when τ is small and $W \in X_0^1$, from (4.19), (4.21), and (4.22), we have the following estimations:

$$\left|\int_{-\infty}^{t} e^{-(t-s)}\Gamma_1(s)ds\right| = O(\tau) + O(\tau||W||_{X_0}) + O(||W||_{X_0}^2) \tag{4.31}$$

and

$$\left|\int_{-\infty}^{t} e^{-(t-s)}\Gamma_2(s)ds\right| = O(\tau) + O(\tau||W||_{X_0}) + O(||W||_{X_0}^2) \tag{4.32}$$

as $\tau \to 0$ and $||W|| \to 0$. To derive (4.31) and (4.32), we have made use of the following result:

$$\int_{-\infty}^{t} e^{-(t-s)}\left(W_i(s-\tau)) - W_i(s)\right) ds = O(\tau||W||), \quad i = 1, 2. \tag{4.33}$$

Actually, if $W \in X_0^1$, by exchanging the order integration and by integration by parts, we have

$$\begin{aligned}
&\left|\int_{-\infty}^{t} e^{-(t-s)}\big(W_i(s-\tau) - W_i(s)\big)ds\right| \\
&= \left|\tau\int_{-\infty}^{t} e^{-(t-s)}\int_0^1 W_i'(s-\tau u)duds\right| \\
&= \left|\tau\int_0^1\int_{-\infty}^{t} e^{-(t-s)}W_i'(s-\tau u)dsdu\right| \\
&= \left|\tau\int_0^1\left(W_i(t-\tau u) - \int_{-\infty}^{t} e^{-(t-s)}W_i(s-\tau u)ds\right)du\right| \\
&= O(\tau||W||),\ i = 1, 2,
\end{aligned}$$

leading to (4.33). Using the fact that X_0^1 is dense in X_0, we conclude that (4.31) and (4.32) hold for any $W \in X_0$.

Let $B(\sigma)$ denote the closed ball in X_0 with radius σ and center at the origin. Since the norm $||S^{-1}||$ is independent of τ, it follows from (4.31) and (4.32) that there exist $\sigma > 0$, $\delta > 0$, and $0 < \rho < 1$ such that for all $\tau \in (0, \delta]$ and $\varphi, \psi, W \in B(\sigma) \subset X_0$,

$$\left|\left|S^{-1}\left(\int_{-\infty}^{t} e^{-(t-s)I}\Gamma(s, W, \tau)ds\right)\right|\right| \le \frac{1}{3}\left(||W|| + \sigma\right)$$

and

$$\left|\left|S^{-1}\left(\int_{-\infty}^{t} e^{-(t-s)I}\Gamma(s, \varphi, \tau)ds\right) - S^{-1}\left(\int_{-\infty}^{t} e^{-(t-s)I}\Gamma(s, \psi, \tau)ds\right)\right|\right| \le \rho||\varphi - \psi||.$$

Hence, $S^{-1}\left(\int_{-\infty}^{t} e^{-(t-s)I}\Gamma(s, W, \tau)ds\right)$ is a uniform contractive mapping of $W \in X_0 \cap B(\sigma)$. By using the classical fixed point theorem, it follows that for $\tau \in [0, \delta]$, (4.30) has a unique solution $W \in X_0/N(L)$. Returning to the original variable, we get that $(W_1 + U_0,\ W_2 + V_0)$ is a heteroclinic connection between E_2 and E_3. This completes our proof.

REMARK 4.3. *When $\tau \geq \delta$, we can rescale the time variable $t \to t\tau$ to obtain*

$$\begin{cases} \frac{dJ}{dt} = \tau\beta MJ - \tau d_I J + \tau\beta J \int_0^1 b(M(t-a)e^{\int_0^a -(d_Y+\beta J(t-s))ds} da, \\ \frac{dM}{dt} = -\tau\beta MJ - \tau d_s M + \tau b(M(t-1))e^{\int_{t-1}^t -(d_Y+\beta J(s))ds}. \end{cases} \tag{4.34}$$

At $\tau = \delta$, by Theorem 4.2*, equation* (4.34) *has a heteroclinic connection. We can as well show that if $C_0(\tau) < 1$, there exists a constant δ_1, $\delta < \delta_1 < \min\{\tau_1, \tau_2\}$, such that if $\delta \leq \tau \leq \delta_1$, equation* (4.9) *has a heteroclinic orbit $(J(t), M(t))$ which connects E_2 and E_3. The proof is the same as that of Theorem* 4.2*. The method is referred as to a homotopy approach (see* [5]*); namely, we view τ as a varying parameter and start with* (4.34)*, and extend the result from δ to $\delta_1 \in (\delta, \min\{\tau_1, \tau_2\})$ by replacing the arguments in Step* 1 *to Step* 5 *by those of the parallel theory in linear delay differential equations. It would be interesting to see how far this homotopy argument can be applied to push the upper bound τ.*

4.2.2. Traveling wavefronts with large wave speeds. We now consider the reaction diffusion system (2.7)–(2.8) for which we will use Theorem 1.1 in [8] to give traveling wavefronts in the case when the wave speed c is large. The main idea of this result is simple: if the nondiffusive equation has a heteroclinic connection between E_2 and E_3, then the diffusive system has a family of traveling wavefronts from E_2 to E_3 with large wave speeds.

THEOREM 4.4. *Assume that $\tau \leq \delta$. Then there exists a $c^* > 0$ such that for any $c \geq c^*$, system* (2.7)–(2.8) *has a traveling wavefront $(J(t,x), W(t,x)) = (u(ct+x), v(ct+x))$ which connects E_2 and E_3.*

Proof. First we observe that if there is no diffusion, that is, if $D_I = 0$ and $D_Y = 0$, our equations (2.7)–(2.8) reduce to (4.9). When $\tau \leq \delta$, the equilibria E_2 and E_3 are hyperbolic, and, in particular, all the eigenvalues to E_3 have negative real parts. From Theorem 4.2, we know that when $\tau \leq \delta$, equation (4.9) has a heteroclinic connection. So conditions (H_1), (H_2), and (H_3) in [8, Theorem 1.1] are satisfied. Last, for our kernel function $f(x) = \frac{1}{\sqrt{4\pi}} \exp(-\frac{y^2}{4})$, it is easy to see that

$$\frac{1}{\sqrt{4\pi}} \int_{-\infty}^{\infty} \exp\left(-\frac{y^2}{4}\right) |y| dy < \infty.$$

So all conditions in [8, Theorem 1.1] are satisfied. Hence by [8, Theorem 1.1], we conclude that there exists a $c^* > 0$ so that for any $c > c^*$, system (2.7)–(2.8) has a traveling wavefront $(J(t,x), W(t,x)) = (u(ct+x),\ v(ct+x))$ which connects E_2 and E_3.

4.3. Numerical simulations. In this subsection, we will numerically study the traveling wavefronts of our model (2.7)–(2.8).

We first describe our numerical methods. We give initial data

$$J(s,x) = j_0(s,x),\ M(s,x) = m_0(s,x),\ -\tau \leq s \leq 0,\ x \in [-L, L],$$

and solve (2.7) and (2.8) to obtain $(J(t,x), M(t,x))$ in a sufficiently large interval $[-L, L]$ for $t \geq 0$ and some $L > 0$. As usual, in the process of finding numerical solutions, we take the homogeneous Neumann boundary conditions at the end points $x = \pm L$. Depending on other parameters in our model and the solution patterns, we may adjust the parameter L from 100 to 1000 so as to present a clear view of our graphs. We take a constant h satisfying

$$M_*^\tau < h < M_{\max}^\tau.$$

For any fixed t, we find the first position $x = z(t,h) > -L$ so that

$$M(t, z(t,h)) = h.$$

Choose a sequence $\{t_j\}_{j=1}^{\infty}$, and consider

$$(J(t_j, x + z(t_j,h)), M(t_j, x + z(t_j,h))). \tag{4.35}$$

If the numerical solutions $(J(t_j, x + z(t_j,h)),\ M(t_j, x + z(t_j,h)))$, $j = 1, 2, 3, \ldots$, converge uniformly to a nonconstant function $(J(\cdot), M(\cdot))$ which satisfies the boundary conditions

$$\lim_{\xi \to -\infty} (J(\xi), M(\xi)) = E_2 \ \text{ and } \lim_{\xi \to +\infty} (J(\xi), M(\xi)) = E_3,$$

then the limit $(J(\cdot), M(\cdot))$ is viewed as a traveling wavefront. Theoretically, this process has also been used to prove the existence of traveling wavefronts for certain monotone dynamics; see [4]. The limit

$$\lim_{j \to \infty} \frac{z(t_{j+1},h) - z(t_j,h)}{t_{j+1} - t_j} \tag{4.36}$$

is correspondingly thought of as the asymptotic wave speed of the traveling wavefront.

We now discuss the parameter values from relevant references [2, 15, 16]. First of all, we note that [16, p. 126] suggests 9 to 12 months for the maturation time, and we will therefore restrict our attention to the range of τ to $[0.5, 0.8]$ (year). The diffusion coefficient $D_I = 60$ km^2/year will be used, based on the value in [15].

For red foxes, the average per capita intrinsic death rate is 0.5 year^{-1} [2], so we take $d_S = 0.5$ year^{-1}. Since it is known that the death rate of juvenile foxes is greater than that of adult foxes, we take $d_Y = 0.8$ year^{-1} [16, p. 127].

An infective fox first goes through an incubation period that can vary from 12 to 110 days. A life expectancy of about 35 days gives d_I as approximately 10 year^{-1}. For the transmission coefficient, we derive $\beta = 10$ km^2/year by using formula (5) in [15]. The number of cubs in a litter ranges from 1 to 10, with a mean of 4.7 in Europe [2, 17, 16, 30, 31]. Sex ratios are in general close to unity at birth, and the pregnancy rate is in the region of 90% [17, 16], with a further 10% of vixens failing to produce offspring [2]. In view of this information, the average per capita birth rate b_0 is taken to be 1.9 year^{-1}.

We now calculate the minimal wave speed $c_{\min}$. The carrying capacity S_0 is assumed to be 2 foxes per km^2, as in Figure 4 of [2], and it is the sum of the population of the immature and the adult foxes when they reach the stable equilibria in the disease-free case, that is,

$$S_0 = M^{\tau}_{\max} + b(M^{\tau}_{\max}) \frac{1 - e^{-d_Y \tau}}{d_Y}.$$

We need further information in order to estimate the maturation time, which is related to the parameter $\bar{a}$ in the birth function. By Table 26 in [16], the number of adult foxes per km^2 varies from 0.5 to 1.8, and the number of litters found per km^2 varies from 0.16 to 0.6. Thus we take the mean value of the ratio of the adult foxes to the litter foxes as $1.15 : 0.38$. Using the facts $S_0 = M^{\tau}_{\max} + b(M^{\tau}_{\max}) \frac{1 - e^{-d_Y \tau}}{d_Y} = 2$ and

$$M^{\tau}_{\max} : b(M^{\tau}_{\max}) \frac{1 - e^{-d_Y \tau}}{d_Y} = 1.15 : 0.38,$$

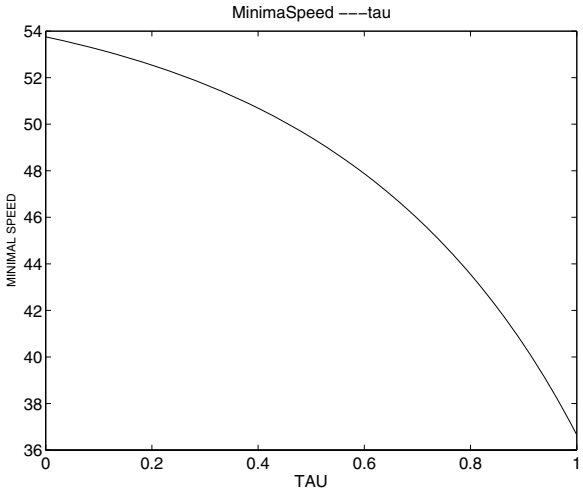

FIG. 1. *Graph of $c_{min}(\tau)$ as a decreasing function of τ.*

we calculate that the carrying capacity is 2 when the parameters $\tau = 0.5305$ and

$$\bar{a} = \frac{1}{S_0}\left(1 + \frac{d_S}{d_Y}(e^{d_Y\tau} - 1)\right)\ln\frac{b_0}{d_S e^{d_Y\tau}} = 0.6057.$$

The result calculated in [15] gives the minimal speed $c_{old} = 48.9898$ km/year. In our calculation, $c_{\min}$ is a decreasing function of τ, with $c_{\min} = 53.757$ km/year if $\tau = 0$; and

$$\begin{aligned} c_{\min} &= 2\sqrt{\beta M^\tau_{\max} D_I}\sqrt{1 - \frac{d_I}{\beta M^\tau_{\max}} + \frac{b(M^\tau_{\max})}{M^\tau_{\max} d_Y}(1 - e^{-d_Y\tau})} \\ &= 2\sqrt{\beta D_I}\sqrt{M^\tau_{\max} + b(M^\tau_{\max})\frac{(1 - e^{-d_Y\tau})}{d_Y} - \frac{d_I}{\beta}} \\ &= 43.549 \text{ km/year} \end{aligned}$$

if $\tau = 0.8$. The graph of $c_{\min}$ as a function of τ is given in Figure 1.

To describe numerically the solution patterns, we first scale the variable x by $\sqrt{D_I}x$ so that the diffusion rate for rabid foxes in our simulations becomes constant 1. The length L of the half interval is taken to be 300. We use the the Neumann boundary condition and the initial values

$$M(t,x) = \begin{cases} M^\tau_{\max}, & -300 \le x \le 150,\ \tau \le t \le 0, \\ 0.6, & 150 < x \le 300,\ \tau \le t \le 0, \end{cases}$$

and

$$J(t,x) = \begin{cases} 0, & -300 \le x \le 150,\ \tau \le t \le 0, \\ 0.05, & 150 < x \le 300,\ \tau \le t \le 0. \end{cases}$$

A finite difference method coupled with iterative techniques is used in our numerical approximation via the software MATLAB, and the numerical result when $D_Y = 0$

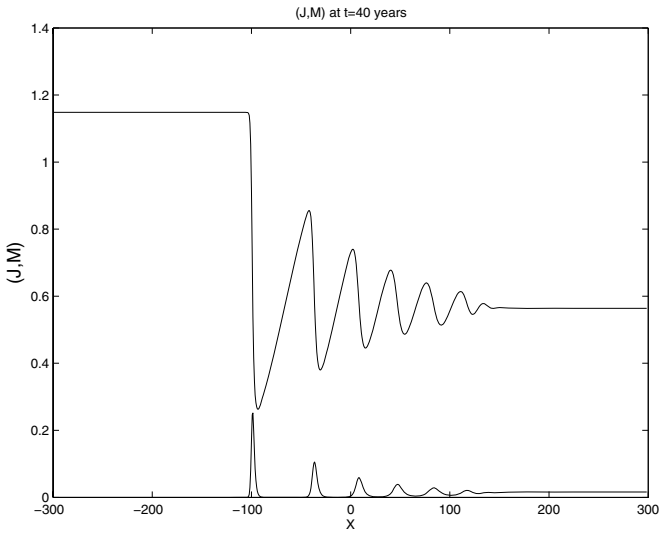

FIG. 2. *Graph of solutions M (upper) and J (lower) at $t = 40$ years, here $\tau = 0.8$, $d_I = 10$, $d_S = 0.5$, $d_Y = 0.8$, $S_0 = 2$, $b_0 = 2$, and $\beta = 10$. There exist long wave tails for both J and M.*

and $\tau = 0.8$ shows that the solution stabilizes to a traveling wavefront with minimal speed 43.549 km/year. The numerical result when $t = 40$ years is shown in Figure 2.

Fixing other parameters, we carry out simulations in the cases when $D_Y = 0.25D_I$ and $D_Y = D_I$. It is found that in both cases, the spreading speeds stabilize to the same minimal wave speed 43.549 km/year and the change of the diffusion rate D_Y has impact only on the amplitudes and frequencies of oscillation for the long tail in the traveling wave, and its impact on the shape of the solution is less apparent if we confine the value D_Y/D_I to the interval $[0, 1]$. This result is what we should expect because the maturation time τ is relatively small that the contribution of D_Y to the pattern of solutions is limited. See Figure 3 for the comparison of M up to $t = 40$ years between the case $D_Y/D_I = 0$ and the case $D_Y/D_I = 1$.

Our simulations agree with the theoretical analysis in the above sections that the minimal wave speed of rabies depends on the maturation time τ, while the amplitude and frequencies of oscillations of the long tail are influenced also by the diffusion rate of juvenile foxes.

We conclude with a remark about the limitation of this work. We assumed two age classes and homogeneity within each age class. Namely, many parameters in the model such as death and diffusion rates and force of infection are all assumed to be constants that depend on the age class but are independent of the precise age. This is certainly only an approximation to the biological reality, and parameter values should be thought of as some sort of averages during the whole juvenile or adult period. For example, newborn susceptible juveniles would not be moving at all and the search for new territories by juveniles must happen only during a particular phase of childhood. In [16], it was noted that breeding season varies from region to region but usually begins early in the year, then in the autumn following birth the pups of the litter will disperse to their own territories. Ideally, we should use age-dependent coefficients and parameters, and hence the model would become an age-structured reaction diffusion equation that cannot be reduced to a system of reaction diffusion equations with delayed nonlocal nonlinearities.

MODELING VISCOELASTIC BEHAVIOR OF ARTERIAL WALLS AND THEIR INTERACTION WITH PULSATILE BLOOD FLOW*

SUNČICA ČANIĆ†, JOSIP TAMBAČA‡, GIOVANNA GUIDOBONI†, ANDRO MIKELIĆ§, CRAIG J. HARTLEY¶, AND DOREEN ROSENSTRAUCH‖

Abstract. Fluid-structure interaction describing wave propagation in arteries driven by the pulsatile blood flow is a complex problem. Whenever possible, simplified models are called for. One-dimensional models are typically used in arterial sections that can be approximated by the cylindrical geometry allowing axially symmetric flows. Although a good first approximation to the underlying problem, the one-dimensional model suffers from several drawbacks: the model is not closed (an ad hoc velocity profile needs to be prescribed to obtain a closed system) and the model equations are quasi-linear hyperbolic (oversimplifying the viscous fluid dissipation), typically producing shock wave solutions not observed in healthy humans. In this manuscript we derived a simple, *closed* reduced model that accounts for the viscous fluid dissipation to the leading order. The resulting fluid-structure interaction system is of hyperbolic-parabolic type. Arterial walls were modeled by a novel, linearly *viscoelastic* cylindrical Koiter shell model and the flow of blood by the incompressible, viscous Navier–Stokes equations. Kelvin–Voigt-type viscoelasticity was used to capture the hysteresis behavior observed in the measurements of the arterial stress-strain response. Using the a priori estimates obtained from an energy inequality, together with the asymptotic analysis and ideas from homogenization theory for porous media flows, we derived an effective model which is an ϵ^2-approximation to the three-dimensional axially symmetric problem, where ϵ is the aspect ratio of the cylindrical arterial section. Our model shows two interesting features of the underlying problem: bending rigidity, often times neglected in the arterial wall models, plays a nonnegligible role in the ϵ^2-approximation of the original problem, and the viscous fluid dissipation imparts long-term viscoelastic memory effects on the motion of the arterial walls. This does not, to the leading order, influence the hysteresis behavior of arterial walls. The resulting model, although two-dimensional, is in the form that allows the use of one-dimensional finite element method techniques producing fast numerical solutions. We devised a version of the Douglas–Rachford time-splitting algorithm to solve the underlying hyperbolic-parabolic problem. The results of the numerical simulations were compared with the experimental flow measurements performed at the Texas Heart Institute, and with the data corresponding to the hysteresis of the human femoral artery and the canine abdominal aorta. Excellent agreement was observed.

1. Introduction. The study of flow of a viscous incompressible fluid through a compliant tube is of interest to many applications. A major application is blood flow through human arteries. Understanding wave propagation in arterial walls, local hemodynamics, and temporal wall shear stress gradient is important in understanding the mechanisms leading to various complications in the cardiovascular function. Many clinical treatments can be studied in detail only if a reliable model describing the response of arterial walls to the pulsatile blood flow is considered.

It has been well accepted that in medium-to-large arteries blood can be modeled as a viscous, incompressible Newtonian fluid. Although blood is a suspension of red blood cells, white blood cells, and platelets in plasma, its non-Newtonian nature due to the particular rheology is relevant in small arteries (arterioles) and capillaries where the diameter of the arteries becomes comparable to the size of the cells. In medium-to-large arteries, such as the coronary arteries (medium) and the abdominal aorta (large), the Navier–Stokes equations for an incompressible viscous fluid are considered to be a good model for blood flow.

Devising an accurate model for the mechanical behavior of arterial walls is more complicated. Arterial walls are anisotropic and heterogeneous, composed of layers with different biomechanical characteristics [21, 22, 29, 44]. A variety of different models has been suggested in the literature to model the mechanical behavior of arteries [1, 2, 3, 21, 22, 23, 29, 27, 33, 44, 51]. They range from the detailed description of each of the layers to the average description of the total mechanical response of the vessel wall assuming homogeneous, linearly elastic behavior.

To study the *coupling* between the motion of the vessel wall and pulsatile blood flow, a detailed description of the vessel wall biomechanical properties may lead to a mathematical and numerical problem whose complexity is beyond today's computational capabilities. The nonlinearity of the underlying fluid-structure interaction is so severe that even simplified description of the vessel wall mechanics assuming homogeneous, linearly elastic behavior leads to the complicated numerical algorithms with challenging stability and convergence properties. To devise a mathematical model that will lead to a problem which is amenable to numerical methods producing computational solutions in a reasonable time-frame, various simplifications need to be introduced. They can be based on the simplifying model *assumptions* capturing only the most important physics of the problem and/or on the simplifications utilizing *special problem features* such as, for example, special geometry, symmetry, and periodicity.

A common set of simplifying assumptions that captures only the most important physics in the description of the mechanical properties of arterial walls includes homogeneity of the material with "small" displacements and "small" deformation gradients leading to the hypothesis of linear elasticity. A common set of special problem features that leads to simplifying models includes "small" vessel wall thickness allowing a reduction from three-dimensional models to two-dimensional shell models, and cylindrical geometry of a section of an artery where no branching is present allowing the use of cylindrical shell models. Neglecting bending rigidity of arteries, studied in [18, 21], reduces the shell model to a membrane model. Further simplifications include axial symmetry of the loading exerted by the blood flow to the vessel walls in the approximately straight cylindrical sections, leading to axially symmetric models with a potential of further reduction to one-dimensional models. One-dimensional models, although a good first approximation to the underlying problem, suffer from several drawbacks: they are not closed (an ad hoc velocity profile needs to be prescribed to

obtain a closed system), and the model equations are quasi-linear hyperbolic, typically producing shock wave solutions, not observed in healthy humans [5]. In particular, the wall shear stress calculated using one-dimensional models is a consequence of the form of the prescribed velocity profile.

Two-dimensional and three-dimensional models of the fluid-structure interaction between the incompressible viscous fluid flow and the motion of a linearly elastic cylindrical membrane are rather complex. Often times additional ad hoc terms of viscoelastic nature are added to the vessel wall model to provide stability and convergence of the underlying numerical algorithm [40, 44], or to provide enough regularity in the proof of the existence of a solution [10, 16, 24, 49], thereby showing well-posedness of the underlying problem. To this day there is no analytical result proving well-posedness of the fluid-structure interaction problem without assuming that the structure model includes the higher-order derivative terms capturing some kind of viscoelastic behavior [10, 16, 24, 49], or with the terms describing bending (flexion) rigidity in elastic shells or plates [10, 15]. In fact, current literature on well-posedness of the fluid-structure interaction between a viscous incompressible Newtonian fluid and a viscoelastic structure includes many additional simplifying assumptions such as the smallness of the data [49], periodic boundary conditions [24, 49], or flow in a closed cavity [10, 15, 16], not appropriate for the blood-flow application. Thus, the well-posedness of the fluid-structure interaction problem describing blood flow in compliant (elastic or viscoelastic) arteries remains an open problem. However, even in those simplifying problems when the data is infinitesimally small the higher-order regularizing terms in the structure model play a crucial role in providing the stabilizing mechanism. Thus, ignoring the terms that account for bending rigidity of the vessel walls and/or viscous dissipation might mean oversimplifying the physics, giving rise to a problem which might not have a solution.

Keeping this in mind we turn to the theory of elastic/viscoelastic shells to model the mechanical properties of arterial walls. Thus, we will be assuming that the vessel walls are homogeneous, that the thickness of the wall is small in comparison to the vessel radius, and that the state of stress is approximately plane, allowing us to consider shell theory. See section 2. The equations of shell theory have been derived by many authors; see [19] and the references therein. Due to variations in approach and rigor the variety of equations occurring in the literature is overwhelming. Among all the equations of shell theory the Koiter shell equations appear to be the simplest consistent first approximation in the general theory of thin elastic shells [32, 31]. In addition, they have been mathematically justified using asymptotic methods to be consistent with three-dimensional elasticity [12, 13]. Ciarlet and Lods showed in [12] that the Koiter shell model has the same asymptotic behavior as the three-dimensional membrane model, the bending model, and the generalized membrane model in the respective regimes in which each of them holds. Motivated by these remarkable properties of the Koiter shell model, in this manuscript we derived the Koiter shell equations for the cylindrical geometry and extended the linearly elastic Koiter model to include the viscous effects observed in the measurements of the mechanical properties of vessel walls [1, 2, 3]. We utilized the Kelvin–Voigt viscoelastic model, which has been shown in [1, 2, 3] to approximate well the experimentally measured viscoelastic properties of the canine aorta and of the human femoral and carotid arteries. In [43] a version of the Kelvin–Voigt model was used to model the vessel walls as a linearly viscoelastic membrane. In the Kelvin–Voigt model the total stress is linearly proportional to the strain and the time-derivative of strain. More

precisely, for a three-dimensional isotropic and homogeneous body, the Kelvin–Voigt model relates the total stress tensor, whose components we denote by t_{kl}, to the infinitesimal strains e_{kl} and the time-derivative of the strains $\partial_t e_{kl}$ through the following relationship [20]:

$$t_{kl} = (\lambda_e + \lambda_v \partial_t) I_e \delta_{kl} + 2(\mu_e + \mu_v \partial_t) e_{kl}, \quad k, l = 1, 2, 3, \tag{1.1}$$

where λ_e and μ_e are the Lamé constants of elasticity, λ_v and μ_v are their corresponding viscoelastic counterparts, δ_{kl} is the Kronecker delta, and $I_e := \sum_{i=1}^{3} e_{ii}$. In section 8 we show that the fluid-structure interaction algorithm based on the viscoelastic Koiter shell equations coupled with the Navier–Stokes equations for a viscous incompressible fluid captures the experimentally measured viscoelastic properties of arterial walls in the human femoral artery and in the canine aorta. This is, in a nutshell, the main result of this manuscript; using the a priori estimates based on an energy inequality, coupled with the asymptotic analysis and homogenization theory, we derived an effective, closed fluid-structure interaction model and a fast numerical solver whose solutions capture the viscoelastic properties of major arteries. We show that our effective model approximates the original three-dimensional axially symmetric problem to the ϵ^2-accuracy, where ϵ is the aspect ratio of the cylindrical domain (vessel). Our reduced, effective model reveals several interesting features of the coupled fluid-structure interaction problem:

(1) Our model explicitly shows how the leading-order viscous fluid dissipation imparts long-term viscoelastic memory effects on the motion of the vessel wall. This is studied in section 5; see (5.11). We show that this does not influence, to the leading order, the viscoelastic hysteresis loop observed in the stress-strain (or the pressure-diameter) measurements of the arterial viscoelastic properties.

(2) Our model shows that bending rigidity of vessel walls plays a nonnegligible role in the asymptotic behavior of the underlying fluid-structure interaction problem. See the equation for p^0 in (4.17). We found that for the parameters describing blood flow through medium-to-large arteries the leading-order terms in the coupling of the stresses at the vessel wall include not only the membrane terms but also a correction accounting for the bending rigidity of the wall, often times neglected in the description of the mechanical properties of vessel walls.

We developed a fast numerical solver based on the one-dimensional finite element approach and compared the computational solution with the experimental measurements. First, the reduced *elastic* model was tested experimentally using a mock circulatory flow loop with latex tubing, assembled at the Research Laboratory at the Texas Heart Institute. Then the *viscoelastic* model was compared to the hysteresis measurements of the viscoelastic properties of the human femoral artery and the canine aorta. In both cases, excellent agreement between the experiment and the numerical solution was obtained.

2. The viscoelastic cylindrical Koiter shell model. In this section we focus on the derivation of the viscoelastic cylindrical Koiter shell model. We begin with the linearly elastic Koiter shell model as it was derived in [31, 32] and specialize it to the cylindrical shell geometry. Following standard texts in conventional plate and shell theories (see, for example, [20, 41, 45, 50, 52]), we then derive the stress-strain relationship for the Koiter shell model and extend it to include the Kelvin–Voigt viscoelasticity, which has been experimentally observed to approximate well the viscoelastic mechanical properties of arterial walls [1, 2, 3]. We summarize the main steps next.

2.1. The linearly elastic Koiter shell model. Consider a clamped cylindrical shell with the reference radius of the middle surface equal to $r = R$, with the shell thickness h and the cylinder length L, $z \in (0, L)$. The basic assumptions under which the Koiter shell model holds are [31, 32] that

- the shell is thin ($h/R \ll 1$);
- the strains are small everywhere, although large deflections are admitted, and the strain energy per unit volume of the undeformed body is represented by the quadratic function of the strain components for an isotropic solid (Hooke's law);
- the state of stress is approximately plane.

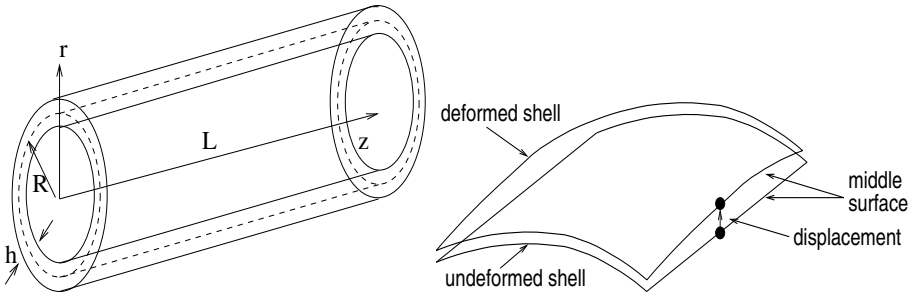

FIG. 2.1. *Left: Cylindrical shell (reference configuration) with middle surface radius R and shell thickness h. Right: Deformed shell.*

The weak formulation, describing the variation of the strain energy density function, depends on the change of metric and the change of curvature tensors of the surface. The change of metric tensor captures the stretching of the surface and the change of curvature tensor captures the bending effects. The weak formulation of the Koiter shell describes variation of the energy that is due to stretching and bending of the shell.

Denote by $\boldsymbol{\xi}(z) = (\xi_z(z), \xi_r(z))$ the displacement of the middle surface at z (see Figure 2.1), where $\xi_z(z)$ and $\xi_r(z)$ denote the longitudinal and the radial component of the displacement, respectively. Here the axial symmetry of the problem has already been taken into account assuming that the displacement in the θ-direction is zero, and that nothing in the problem depends on θ. The change of metric and the change of curvature tensors for a cylindrical shell are given, respectively, by [11]

$$\boldsymbol{\gamma}(\boldsymbol{\xi}) = \begin{bmatrix} \xi_z' & 0 \\ 0 & R\xi_r \end{bmatrix}, \quad \boldsymbol{\varrho}(\boldsymbol{\xi}) = \begin{bmatrix} -\xi_r'' & 0 \\ 0 & \xi_r \end{bmatrix}.$$

Here $'$ denotes the derivative with respect to the longitudinal variable z. Introduce the following function space:

$$\begin{aligned} V_c &= H_0^1(0,L) \times H_0^2(0,L) \\ &= \big\{(\xi_z, \xi_r) \in H^1(0,L) \times H^2(0,L) : \xi_z(0) = \xi_z(L) = \xi_r(0) = \xi_r(L) = 0, \\ &\qquad \xi_r'(0) = \xi_r'(L) = 0\big\}. \end{aligned}$$

Then the weak formulation of the linearly elastic cylindrical Koiter shell is given by the following: find $\boldsymbol{\eta} = (\eta_z, \eta_r) \in V_c$ such that

$$\frac{h}{2}\int_0^L \mathcal{A}\boldsymbol{\gamma}(\boldsymbol{\eta}) \cdot \boldsymbol{\gamma}(\boldsymbol{\xi}) R dz + \frac{h^3}{24}\int_0^L \mathcal{A}\boldsymbol{\varrho}(\boldsymbol{\eta}) \cdot \boldsymbol{\varrho}(\boldsymbol{\xi}) R dz = \int_0^L \boldsymbol{f} \cdot \boldsymbol{\xi} R dz, \quad \boldsymbol{\xi} \in V_c, \tag{2.1}$$

where $\cdot$ denotes the scalar product

$$A \cdot B := \mathrm{Tr}\left(AB^T\right), \quad A, B \in M_2(\mathbb{R}) \cong \mathbb{R}^4. \tag{2.2}$$

Here $\boldsymbol{f}$ is the surface density of the force applied to the shell, and $\mathcal{A}$ is the elasticity tensor given by [11]

$$\mathcal{A}\mathbf{E} = \frac{4\lambda\mu}{\lambda+2\mu}(\mathbf{A}^c \cdot \mathbf{E})\mathbf{A}^c + 4\mu\mathbf{A}^c\mathbf{E}\mathbf{A}^c, \quad \mathbf{E} \in \mathrm{Sym}\,(\mathbb{R}^2), \quad \text{with}$$
$$\mathbf{A}_c = \begin{bmatrix} 1 & 0 \\ 0 & R^2 \end{bmatrix}, \quad \mathbf{A}^c = \begin{bmatrix} 1 & 0 \\ 0 & \frac{1}{R^2} \end{bmatrix},$$

where λ and μ are the Lamé constants. Written in terms of the displacement, the weak formulation reads

$$\begin{aligned}
&\frac{h}{2}\int_0^L \left(\frac{4\mu\lambda}{\lambda+2\mu}\left(\eta_z' + \frac{1}{R}\eta_r\right)\cdot\left(\xi_z' + \frac{1}{R}\xi_r\right) + 4\mu\left(\eta_z'\xi_z' + \frac{1}{R^2}\eta_r\xi_r\right)\right)dz \\
&+ \frac{h^3}{24}\int_0^L \left(\frac{4\mu\lambda}{\lambda+2\mu}\left(-\eta_r'' + \frac{1}{R^2}\eta_r\right)\cdot\left(-\xi_r'' + \frac{1}{R^2}\xi_r\right) + 4\mu\left(\eta_r''\xi_r'' + \frac{1}{R^4}\eta_r\xi_r\right)\right)dz \\
&= \int_0^L (f_z\xi_z + f_r\xi_r)dz \quad \forall(\xi_z, \xi_r) \in V_c.
\end{aligned}$$

Using the following relationships between the Lamé constants and Young's modulus of elasticity E and the Poisson ratio σ

$$\frac{2\mu\lambda}{\lambda+2\mu} + 2\mu = 4\mu\frac{\lambda+\mu}{\lambda+2\mu} = \frac{E}{1-\sigma^2}, \quad \frac{2\mu\lambda}{\lambda+2\mu} = 4\mu\frac{\lambda+\mu}{\lambda+2\mu}\frac{1}{2}\frac{\lambda}{\lambda+\mu} = \frac{E}{1-\sigma^2}\sigma,$$

the elasticity tensor $\mathcal{A}$ reads

$$\mathcal{A}\mathbf{E} = \frac{2E\sigma}{1-\sigma^2}(\mathbf{A}^c \cdot \mathbf{E})\mathbf{A}^c + \frac{2E}{1+\sigma}\mathbf{A}^c\mathbf{E}\mathbf{A}^c, \quad \mathbf{E} \in \mathrm{Sym}\,(\mathbb{R}^2).$$

From here we get the weak formulation (2.1) as

$$\begin{aligned}
&h\int_0^L \left(\frac{E\sigma}{1-\sigma^2}\left(\eta_z' + \frac{1}{R}\eta_r\right)\left(\xi_z' + \frac{1}{R}\xi_r\right) + \frac{E}{1+\sigma}\left(\eta_z'\xi_z' + \frac{1}{R^2}\eta_r\xi_r\right)\right)dz \\
&+ \frac{h^3}{12}\int_0^L \left(\frac{E\sigma}{1-\sigma^2}\left(-\eta_r'' + \frac{1}{R^2}\eta_r\right)\left(-\xi_r'' + \frac{1}{R^2}\xi_r\right) + \frac{E}{1+\sigma}\left(\eta_r''\xi_r'' + \frac{1}{R^4}\eta_r\xi_r\right)\right)dz \\
&= \int_0^L (f_z\xi_z + f_r\xi_r)dz, \quad (\xi_z, \xi_r) \in V_c.
\end{aligned} \tag{2.3}$$

The terms multiplying $h/2$ account for the stored energy density due to stretching (membrane effects) and the terms multiplying $h^3/12$ account for the stored energy density due to bending (flexural shell effects). Integration by parts gives rise to the static equilibrium equations. Written in differential form they read

$$\boxed{\begin{aligned}
-\frac{hE}{1-\sigma^2}\left(\eta_z'' + \sigma\frac{1}{R}\eta_r'\right) &= f_z, \\
\frac{hE}{R(1-\sigma^2)}\left(\sigma\eta_z' + \frac{\eta_r}{R}\right) + \frac{h^3E}{12(1-\sigma^2)}\left(\eta_r'''' - 2\sigma\frac{1}{R^2}\eta_r'' + \frac{1}{R^4}\eta_r\right) &= f_r.
\end{aligned}} \tag{2.4}$$

The Linearly Elastic Cylindrical Koiter Shell Model

We employ these equations to study the response of arteries to pulsatile blood flow. For this purpose, we assume that the in vivo arteries are *prestretched* under internal pressure load, that the arterial walls are *longitudinally tethered*, and that the *longitudinal displacement is negligible* [38, 42].

The assumption that the longitudinal displacement is negligible has been justified in [38]. More precisely, in [38] we considered the equations of *three-dimensional* linear elasticity to model the vessel wall, coupled with the Navier–Stokes equations for a viscous, incompressible fluid to model the flow of blood in cylindrical geometry. In addition, we assumed that the "thickness" h of the structure (the radial dimension of the three-dimensional elastic body) is less than or comparable to the radius of the domain occupied by the fluid, i.e., $h/R \leq 1$ (this includes the scenario $h/R \ll 1$ considered in this manuscript). Starting from the assumption that both the radial and longitudinal displacement of the three-dimensional structure are nonzero, we showed that the effective model obtained by considering small aspect ratio $\epsilon = R/L$ embodies negligible longitudinal displacement of the structure.

Taking this into account we emply here the equations of a linearly elastic cylindrical Koiter shell model with negligible longitudinal displacement:

$$\boxed{\left(\frac{hE}{R(1-\sigma^2)} + p_{\text{ref}}\right)\frac{\eta_r}{R} + \frac{h^3E}{12(1-\sigma^2)}\left(\eta_r'''' - 2\sigma\frac{1}{R^2}\eta_r'' + \frac{1}{R^4}\eta_r\right) = f_r.} \tag{2.5}$$

This is obtained from the weak formulation (2.3), assuming $\eta_z = 0$, and the test space

$$V_c^0 := V_c \cap \{\xi_z = 0\}.$$

In order to include the fact that the reference configuration is prestressed at reference pressure p_{ref}, and that the arterial walls are viscoelastic, we study the stress-strain relationship corresponding to the Koiter shell model and modify it to include these two effects. This is presented next.

2.2. The linearly viscoelastic Koiter shell model. The stress-strain relationship is given by the "stress resultant," which relates the internal force with the change of metric tensor, and the "stress couples," which describe the bending moments in terms of the change of curvature tensor [20]. As noted by Koiter in his original paper [31], the stress resultant and the stress couples can be obtained from (2.1) as gradients of the stored energy function, given by the integrand on the left-hand side of (2.1), with respect to the middle surface strains and changes of curvature. Following this approach one obtains

- *stress resultant (or the internal force) for the elastic Koiter shell*

$$N := \frac{h}{2}\mathcal{A}\boldsymbol{\gamma}(\boldsymbol{\eta}) = \frac{h}{2}\begin{bmatrix} \frac{2E\sigma}{1-\sigma^2}\frac{\eta_r}{R} & 0 \\ 0 & \frac{2E}{1-\sigma^2}\frac{\eta_r}{R^3} \end{bmatrix}, \tag{2.6}$$

- *stress couples (bending moment) for the elastic Koiter shell*

$$M := \frac{h^3}{24}\mathcal{A}\boldsymbol{\varrho}(\boldsymbol{\eta}) = \frac{h^3}{24}\begin{bmatrix} -\frac{2E}{1-\sigma^2}\eta_r'' + \frac{2E\sigma}{1-\sigma^2}\frac{\eta_r}{R^2} & 0 \\ 0 & \frac{2E}{1-\sigma^2}\frac{u_r}{R^4} - \frac{2E\sigma}{1-\sigma^2}\frac{1}{R^2}\eta_r'' \end{bmatrix}. \tag{2.7}$$

At this point we also introduce the effects of prestress by defining the stress resultant N_{ref} that relates the reference pressure p_{ref} with the circumferential strain [17, 34, 35]

$$\frac{h}{2}N_{\text{ref}} = hR\mathbf{A}^c\begin{bmatrix} 0 & 0 \\ 0 & p_{ref}\frac{R}{h}\eta_r \end{bmatrix}\mathbf{A}^c \tag{2.8}$$

so that the total stress resultant, including the effects of prestress, reads

- *stress resultant for the prestressed elastic Koiter shell*

$$N = \frac{h}{2}\mathcal{A}\boldsymbol{\gamma}(\boldsymbol{\eta}) + \frac{h}{2}N_{\text{ref}}. \tag{2.9}$$

We focus now on introducing the viscous effects to the linearly elastic, prestressed cylindrical Koiter shell model. For this purpose assume that the displacement is not only a function of position z but also a function of time: $\boldsymbol{\eta} = \boldsymbol{\eta}(z,t)$ and that the velocity of the displacement is linearly proportional to the stress as described in (1.1). Employing the Kelvin–Voigt model (1.1) to describe this viscoelastic behavior one writes the constitutive relations in which the stress is linearly proportional to the strain plus the time-derivative of strain [20]. For the linearly viscoelastic Koiter shell model we define

- *stress resultant for the viscoelastic prestressed Koiter shell*

$$N := \frac{h}{2}\mathcal{A}\boldsymbol{\gamma}(\boldsymbol{\eta}) + \frac{h}{2}\mathcal{B}\boldsymbol{\gamma}(\dot{\boldsymbol{\eta}}) + \frac{h}{2}N_{\text{ref}}, \tag{2.10}$$

- *stress couples for the viscoelastic Koiter shell*

$$M := \frac{h^3}{24}\mathcal{A}\boldsymbol{\varrho}(\boldsymbol{\eta}) + \frac{h^3}{24}\mathcal{B}\boldsymbol{\varrho}(\dot{\boldsymbol{\eta}}), \tag{2.11}$$

where $\mathcal{B}$ is given by

$$\mathcal{B}\mathbf{E} = \frac{4\lambda_v\mu_v}{\lambda_v + 2\mu_v}(\mathbf{A}^c \cdot \mathbf{E})\mathbf{A}^c + 4\mu_v\mathbf{A}^c\mathbf{E}\mathbf{A}^c, \quad \mathbf{E} \in \text{Sym}\,(\mathbb{R}^2),$$

with μ_v and λ_v corresponding to the viscous counterpart of the Lamé constants μ and λ. With these constitutive relations we now define the weak formulation of the linearly viscoelastic prestressed Koiter shell model by the following: for each $t > 0$ find $\eta(t) \in V_c$ such that $\forall \boldsymbol{\xi}(t) \in V_c$

$$\begin{aligned}\frac{h}{2}\int_0^L (N_{\text{ref}} + \mathcal{A}\boldsymbol{\gamma}(\boldsymbol{\eta}) + \mathcal{B}\boldsymbol{\gamma}(\dot{\boldsymbol{\eta}})) \cdot \boldsymbol{\gamma}(\boldsymbol{\xi})Rdz + \frac{h^3}{24}\int_0^L (\mathcal{A}\boldsymbol{\varrho}(\boldsymbol{\eta}) + \mathcal{B}\boldsymbol{\varrho}(\dot{\boldsymbol{\eta}})) \cdot \boldsymbol{\varrho}(\boldsymbol{\xi})Rdz \\ + \rho_w h\int_0^L \frac{\partial^2\boldsymbol{\eta}}{\partial t^2} \cdot \boldsymbol{\xi} = \int_0^L \boldsymbol{f} \cdot \boldsymbol{\xi}Rdz,\end{aligned} \tag{2.12}$$

where $\dot{\boldsymbol{\eta}}$ denotes the time-derivative. Written in terms of the displacement, after employing the notation

$$C_v := \frac{2\lambda_v\mu_v}{\lambda_v + 2\mu_v} + 2\mu_v, \quad D_v := \frac{2\lambda_v\mu_v}{\lambda_v + 2\mu_v}, \tag{2.13}$$

the weak formulation of the linearly viscoelastic prestressed Koiter shell model reads

$$\begin{aligned}&\int_0^L f_r\xi_r dz = \rho_w h\int_0^L \frac{\partial^2\eta_r}{\partial t^2}\xi_r + h\int_0^L \left(\left(\frac{E}{1-\sigma^2} + p_{\text{ref}}\frac{R}{h}\right)\frac{1}{R}\eta_r + C_v\frac{1}{R}\frac{\partial\eta_r}{\partial t}\right)\frac{\xi_r}{R}dz \\ &+ \frac{h^3}{12}\int_0^L \left(\left(\frac{E\sigma}{1-\sigma^2}\left(-\frac{\partial^2\eta_r}{\partial z^2} + \frac{\eta_r}{R^2}\right) + D_v\left(-\frac{\partial^3\eta_r}{\partial t\partial z^2} + \frac{1}{R^2}\frac{\partial\eta_r}{\partial t}\right)\right)\left(-\frac{\partial^2\xi_r}{\partial z^2} + \frac{\xi_r}{R^2}\right)\right. \\ &\left. + \left(\frac{E}{1+\sigma}\frac{\partial^2\eta_r}{\partial z^2} + (C_v - D_v)\frac{\partial^3\eta_r}{\partial t\partial z^2}\right)\frac{\partial\xi_r}{\partial z^2} + \left(\frac{E}{1+\sigma}\frac{1}{R^2}\eta_r + (C_v - D_v)\frac{1}{R^2}\frac{\partial\eta_r}{\partial t}\right)\frac{\xi_r}{R^2}\right)dz\end{aligned}$$

$\forall \boldsymbol{\xi}(t) \in V_c^0$. Integration by parts gives rise to the equilibrium equation

(2.14)
$$\boxed{f_r = \rho_w h \frac{\partial^2 \eta_r}{\partial t^2} + C_0 \eta_r - C_1 \frac{\partial^2 \eta_r}{\partial z^2} + C_2 \frac{\partial^4 \eta_r}{\partial z^4} + D_0 \frac{\partial \eta_r}{\partial t} - D_1 \frac{\partial^3 \eta_r}{\partial t \partial z^2} + D_2 \frac{\partial^5 \eta_r}{\partial t \partial z^4}},$$

where ρ_w denotes the shell density (see Table 4.1) and

(2.15)
$$C_0 = \frac{h}{R^2} \frac{E}{1-\sigma^2} \left(1 + \frac{h^2}{12R^2}\right) + \frac{p_{\text{ref}}}{R}, \quad C_1 = 2\frac{h^3}{12R^2} \frac{E\sigma}{1-\sigma^2}, \quad C_2 = \frac{h^3}{12} \frac{E}{1-\sigma^2},$$
$$D_0 = \frac{h}{R^2} C_v \left(1 + \frac{h^2}{12R^2}\right), \qquad D_1 = 2\frac{h^3}{12R^2} D_v, \qquad D_2 = \frac{h^3}{12} C_v.$$

We use this equation to model the motion of compliant arterial walls interacting with the time-dependent fluid flow driven by the pulsatile inlet and outlet pressure data. To simplify notation, from this point on in this manuscript we will be using η to denote the radial displacement η_r.

3. Fluid-structure interaction: The three-dimensional model. In medium to large arteries blood can be modeled as an incompressible, Newtonian viscous fluid. We will be assuming that the viscosity of blood is constant, utilizing the data from biomedical literature (see, e.g., [21, 39, 44]), providing the viscosity coefficient $\mu_F = 3500$ kg/ms. The Navier–Stokes equations for a viscous, incompressible fluid have been well accepted as a model for blood flow in medium-to-large arteries. Assuming cylindrical geometry and axially symmetric flow, the fluid velocity $\boldsymbol{v}(r,z,t) = (v_r(r,z,t), v_z(r,z,t))$ and pressure $p(r,z,t)$ satisfy

$$\rho_F \left\{ \frac{\partial v_r}{\partial t} + v_r \frac{\partial v_r}{\partial r} + v_z \frac{\partial v_r}{\partial z} \right\} - \mu_F \left(\frac{\partial^2 v_r}{\partial r^2} + \frac{\partial^2 v_r}{\partial z^2} + \frac{1}{r}\frac{\partial v_r}{\partial r} - \frac{v_r}{r^2} \right) + \frac{\partial p}{\partial r} = 0, \tag{3.1}$$

$$\rho_F \left\{ \frac{\partial v_z}{\partial t} + v_r \frac{\partial v_z}{\partial r} + v_z \frac{\partial v_z}{\partial z} \right\} - \mu_F \left(\frac{\partial^2 v_z}{\partial r^2} + \frac{\partial^2 v_z}{\partial z^2} + \frac{1}{r}\frac{\partial v_z}{\partial r} \right) + \frac{\partial p}{\partial z} = 0, \tag{3.2}$$

$$\frac{\partial v_r}{\partial r} + \frac{\partial v_z}{\partial z} + \frac{v_r}{r} = 0. \tag{3.3}$$

Here ρ_F is the fluid density and μ_F is the fluid dynamic viscosity coefficient, where the subscript F stands for the fluid quantities. The Navier–Stokes equations hold in the cylindrical domain

$$\Omega(t) = \left\{ x \in \mathbb{R}^3; x = (r\cos\vartheta, r\sin\vartheta, z),\ r < R + \eta(z,t),\ 0 < z < L \right\} \tag{3.4}$$

bounded by the viscoelastic lateral boundary

$$\Sigma(t) = \left\{ ((R(z) + \eta(t,z))\cos\theta, (R(z) + \eta(t,z))\sin\theta, z) \in \mathbb{R}^3 : \theta \in (0, 2\pi), z \in (0, L) \right\}.$$

See Figure 3.1. The reference configuration corresponds to that of a straight cylinder with radius R and length L. (The same results can be obtained for a cylinder with a slowly varying radius $R(z)$ under the assumption that $R'(z) < \epsilon$ [47].) The following inlet ($z = 0$) and outlet ($z = L$) boundary data lead to a well-defined problem:

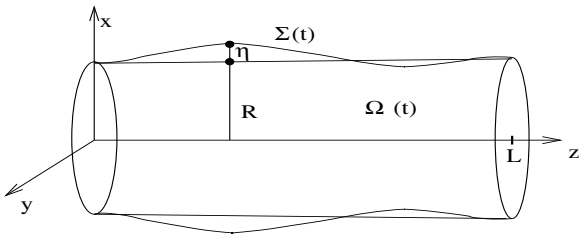

FIG. 3.1. *Deformed domain* $\Omega(t)$.

1. The dynamic pressure is prescribed at both ends:

$$p + \rho(v_z)^2/2 = P_{0,L}(t) + p_{\text{ref}} \text{ at } z = 0, L. \tag{3.5}$$

2. The fluid enters and leaves the tube parallel to the axis of symmetry, with zero displacement:

$$v_r = 0, \quad \eta = 0 \text{ at } z = 0, L. \tag{3.6}$$

3. The tube is clamped so that

$$\frac{\partial \eta}{\partial z} = 0 \text{ at } z = 0, L. \tag{3.7}$$

In the reduced model (see section 4), the zero displacement condition is relaxed. This is typical for reduced models where the boundary layer phenomena near the edges with high stress concentrations are lost [8].

Initially, the fluid and the wall are assumed to be at rest, with zero displacement from the reference configuration:

$$\boldsymbol{v} = 0, \quad \eta = 0, \quad \frac{\partial \eta}{\partial t} = 0. \tag{3.8}$$

These initial and boundary conditions describe well our experimental set up, described in section 7.

The coupling between the fluid flow and vessel wall dynamics is performed via the following kinematic and dynamic lateral boundary conditions [9]:

- The kinematic condition requiring continuity of velocity:

$$v_r(R + \eta(z,t), z, t) = \frac{\partial \eta(z,t)}{\partial t}, \quad v_z(R + \eta(z,t), z, t) = 0. \tag{3.9}$$

- The dynamic condition requiring balance of forces (the contact force of the fluid is counterbalanced by the contact force of the wall):

$$f_r = [(p - p_{\text{ref}})\mathbf{I} - 2\mu_F D(\boldsymbol{v})]\, \boldsymbol{n} \cdot \boldsymbol{e}_r \left(1 + \frac{\eta}{R}\right) \sqrt{1 + (\partial_z \eta)^2}, \tag{3.10}$$

  where f_r is given by the viscoelastic shell model (2.14). The right-hand side of (3.10) describes the contact force of the fluid, where $D(\boldsymbol{v})$ is the symmetrized gradient of velocity, defined in (3.12), $\boldsymbol{n}$ is the vector normal to the deformed boundary $\Sigma(t)$, and $\boldsymbol{e}_r$ is the radial unit vector.

See [9] for more details.

Thus, the complete fluid-structure interaction problem consists of solving the fluid equations (3.1)–(3.3) on the domain $\Omega(t)$ defined by (3.4) with a moving boundary $\Sigma(t)$, satisfying the initial and boundary data given by (3.5)–(3.10) where the contact force of the structure f_r is given by (2.14).

3.1. Weak formulation. To derive a weak formulation of the fluid-structure interaction problem we take the standard approach: multiply the fluid equations by a test function, integrate by parts, and take into account the initial and boundary conditions to obtain the integral form of the problem. For that purpose, introduce the following test spaces.

DEFINITION 3.1 (the test spaces). *Let*

(3.11)

$$V(\Omega(t)) = \{\varphi = \varphi_r \boldsymbol{e}_r + \varphi_z \boldsymbol{e}_z \in H^2(\Omega(t))^2 \mid \varphi_r(r,z) = \partial_z \varphi_r(r,z) = 0 \text{ at } z = 0, L,$$
$$\varphi_z(R + \gamma(z,t), z) = 0, \ \textit{and } \operatorname{div} \varphi = 0 \textit{ in } \Omega(t) \textit{ a.e.}\}.$$

For each $t \in [0,T]$, the test space is the space $H^1(0,T;V(\Omega(t)))$.

To specify the weak solution we introduce the spaces containing the candidates for the radial displacement and the velocity. They are deduced from the a priori solution estimates, presented in section 3.2.

DEFINITION 3.2 (the solution spaces).

- *The space Γ consists of all the functions*

$$\eta \in L^\infty(0,T;H^2(0,L)) \cap C^1([0,T];L^2(0,L)) \cap C([0,T];H^2(0,L))$$

such that $\eta(t,0) = \eta(t,L) = 0$, $\partial_z \eta(t,0) = \partial_z \eta(t,L) = 0$, and $\eta(0,z) = \partial_t \eta(0,z) = 0$.

- *The space V consists of all the functions*

$$v = (v_r, v_z) \in L^2(0,T;H^1(\Omega(t))^2) \cap C([0,T];L^2(\Omega(t))^2)$$

such that $\operatorname{div} \boldsymbol{v} = 0$ in $\Omega(t) \times \mathbb{R}_+$, $v_r = 0$ for $z = 0, L$, and $\boldsymbol{v} = 0$ at $t = 0$.

To define the weak form recall that the symmetrized gradient of velocity $D(\boldsymbol{\varphi})$, defined for an axially symmetric vector valued function $\boldsymbol{\varphi} = \varphi_r \boldsymbol{e}_r + \varphi_z \boldsymbol{e}_z$, is given by

$$D(\boldsymbol{\varphi}) = \begin{pmatrix} \dfrac{\partial \varphi_r}{\partial r} & 0 & \dfrac{1}{2}\Big(\dfrac{\partial \varphi_r}{\partial z} + \dfrac{\partial \varphi_z}{\partial r}\Big) \\ 0 & \dfrac{\varphi_r}{r} & 0 \\ \dfrac{1}{2}\Big(\dfrac{\partial \varphi_r}{\partial z} + \dfrac{\partial \varphi_z}{\partial r}\Big) & 0 & \dfrac{\partial \varphi_z}{\partial z} \end{pmatrix}. \tag{3.12}$$

Define the matrix norm $|\cdot|$ through the scalar product

$$A \cdot B := \operatorname{Tr}\left(AB^T\right), \quad A, B \in \mathbb{R}^9. \tag{3.13}$$

DEFINITION 3.3. *A* weak solution *of problem* (3.1)–(3.10) *is a function $(\eta, \boldsymbol{v}) \in \Gamma \times V$ such that $\forall \varphi \in H^1(0,T;V(\Omega(t)))$ the following integral equation holds:*

$$\begin{aligned} &2\mu_F \int_{\Omega(t)} D(v) \cdot D(\varphi)\ r dr dz + \rho \int_{\Omega(t)} \left\{ \frac{\partial v}{\partial t} + (v(t)\nabla)v \right\} \varphi\ r dr dz \\ &+ R \int_0^L \left\{ C_0 \eta\ \varphi_r|_{R+\eta} + C_1 \frac{\partial \eta}{\partial z}\ \frac{\partial \varphi_r}{\partial z}\bigg|_{R+\eta} + C_2 \frac{\partial^2 \eta}{\partial z^2}\ \frac{\partial^2 \varphi_r}{\partial z^2}\bigg|_{R+\eta} \right. \\ &\left. + D_0 \frac{\partial \eta}{\partial t}\ \varphi_r|_{R+\eta} + D_1 \frac{\partial^2 \eta}{\partial t \partial z}\ \frac{\partial \varphi_r}{\partial z}\bigg|_{R+\eta} + D_2 \frac{\partial^3 \eta}{\partial t \partial z^2}\ \frac{\partial^2 \varphi_r}{\partial z^2}\bigg|_{R+\eta} \right\} dz \\ &+ R\rho_w h \int_0^L \frac{\partial^2 \eta}{\partial t^2} \varphi_r(R + \eta(t,z), z, t)\ dz = -\int_0^R \left\{ P_2(t) - \frac{\rho}{2}(v_z^2)|_{z=L} \right\} \varphi_z|_{z=L} r dr \\ &+ \int_0^R \left\{ P_1(t) - \frac{\rho}{2}(v_z^2)|_{z=0} \right\} \varphi_z|_{z=0} r dr, \end{aligned} \tag{3.14}$$

where $\Omega(t)$ *is given by* (3.4) *and* η *and* v_r *are linked on* $\Sigma(t)$ *through* (3.9).

Notice that the domain as well as the solution and test spaces depend on time. To get a global weak formulation one can use the a priori solution estimates, presented below, and define a global weak solution via a fixed point mapping, defined on a fixed, "fictitious" domain. This approach is used in [9] to define a global weak solution for a related fluid-structure interaction problem using the linearly elastic membrane equations to model the vessel walls. We do not pursue this approach here but continue with the derivation of the energy and a priori estimates.

3.2. The energy and a priori estimates. By replacing the test function with the fluid velocity and using the kinematic lateral boundary condition (3.9) one obtains the following proposition.

PROPOSITION 3.4 (energy equality). *Solution* $(\eta, \boldsymbol{v})$ *of problem* (3.1)–(3.10) *satisfies the following energy equality:*

$$\begin{aligned}
&\frac{\rho}{2}\frac{d}{dt}\int_{\Omega(t)}|\boldsymbol{v}|^2\,dV+\frac{\pi R}{2}\frac{d}{dt}\int_0^L\left\{C_0|\eta|^2+C_1\left|\frac{\partial\eta}{\partial z}\right|^2+C_2\left|\frac{\partial^2\eta}{\partial z^2}\right|^2\right\}dz\\
&+\frac{\pi R}{2}\rho_w h\frac{d}{dt}\int_0^L\left|\frac{\partial\eta}{\partial t}\right|^2dz+\pi R\int_0^L\left\{D_0\left|\frac{\partial\eta}{\partial t}\right|^2+D_1\left|\frac{\partial^2\eta}{\partial t\partial z}\right|^2+D_2\left|\frac{\partial^3\eta}{\partial t\partial z^2}\right|^2\right\}dz\\
&+2\mu_F\|D(\boldsymbol{v})\|^2_{L^2(\Omega(t))}=-\int_0^R P_2(t)v_z(t,r,L)\;rdr+\int_0^R P_1(t)v_z(t,r,0)\;rdr,
\end{aligned}\tag{3.15}$$

with $v_r(t,R+\eta,z)=\frac{\partial\eta}{\partial t}(t,z)$ *and* $v_z(t,R+\eta,z)=0$ *on* $(0,L)\times(0,T)$.

To obtain the a priori estimates and the correct scales for the problem, we introduce the nondimensional time

$$\hat{t}:=\omega t.\tag{3.16}$$

The characteristic frequency ω will be specified later in (3.21). The choice of ω determines the time-scale for the natural oscillations of the structure in terms of the inlet and outlet pressure data. As it will be seen later, the quantity $L\omega$ corresponds to the "sound speed" of the natural oscillations of the structure, and the choice of ω given in (3.21) gives rise to the structure sound speed reported in Fung [21]. From now on we will be working with the nondimensional time $\hat{t}$ but will drop the "hat" notation for simplicity. Whenever physical time t is used, this will be explicitly specified.

Take the rescaled time into account and integrate the energy equality with respect to time to obtain

$$\begin{aligned}
&\frac{\rho\omega}{2}\int_{\Omega(t)}|\boldsymbol{v}|^2\,dV+\frac{\pi R\omega}{2}\int_0^L\left\{C_0|\eta|^2+C_1\left|\frac{\partial\eta}{\partial z}\right|^2+C_2\left|\frac{\partial^2\eta}{\partial z^2}\right|^2\right\}dz\\
&+\frac{\pi R\omega^3}{2}\rho_w h\int_0^L\left|\frac{\partial\eta}{\partial t}\right|^2dz+\pi R\omega^2\int_0^t\int_0^L\left\{D_0\left|\frac{\partial\eta}{\partial t}\right|^2+D_1\left|\frac{\partial^2\eta}{\partial t\partial z}\right|^2+D_2\left|\frac{\partial^3\eta}{\partial t\partial z^2}\right|^2\right\}dzd\tau\\
&+2\mu_F\int_0^t\|D(\boldsymbol{v})\|^2_{L^2(\Omega(\tau))}d\tau=-\int_0^t\int_0^R\left(P_2(\tau)v_z(\tau,r,L)-P_1(\tau)v_z(\tau,r,0)\right)rdr\tau.
\end{aligned}\tag{3.17}$$

By estimating the right-hand side in a manner similar to the estimates in [9] and [6]

one obtains

$$\frac{\rho\omega}{2}\|\boldsymbol{v}\|^2_{L^2(\Omega(t))} + \pi\omega^3\rho_w hR\,\|\partial_t\eta\|^2 + \frac{\pi\omega RC_0}{2}\|\eta\|^2 \leq \frac{16\pi LR\omega}{C_0}\left(\sup_{z,t}|\hat{p}|^2 + \left(\sup_z\int_0^t|\partial_t\hat{p}|d\tau\right)^2\right) + \frac{8T\pi R^2}{\rho\omega L}\int_0^t|A(\tau)|^2d\tau, \tag{3.18}$$

where

$$A(t) = P_L(t) - P_0(t), \quad \hat{p}(t) = \frac{A(t)}{L}z + P_0(t), \tag{3.19}$$

and $T > 0$ denote the physical time such that

$$T \leq \frac{1}{4}\frac{R\sqrt{\rho_w hC_0}}{\|p\|_\infty}. \tag{3.20}$$

For example, for $p_{\text{ref}} = 0$, this inequality reads $T \leq 1/[4(1-\sigma^2)]h\sqrt{E\rho_w}/\|p\|_\infty$.

This is the point were we define the frequency ω. Choose ω so that the contribution of all the terms involving the pressure data have the same weight. Namely, choose ω so that the time-scale of the captured oscillations is determined by the pressure drop $A(t)$, the inlet and outlet maximum pressure, and by the time-average of the steepness of the pressure front $\partial_t\hat{p}$ to obtain

$$\omega = \frac{1}{L}\sqrt{\frac{RC_0}{2\rho}}. \tag{3.21}$$

This choice of ω gives rise to the sound speed of the waves in the "structure" ωL which is exactly the sound speed reported by Fung in [21]. After taking this form of ω into account, and after dividing (3.18) by ω, we obtain the following energy inequality from which the a priori estimates will follow.

PROPOSITION 3.5. *Weak solution* $(\eta, \boldsymbol{v})$ *satisfies*

$$\frac{\rho}{2}\|\boldsymbol{v}\|^2_{L^2(\Omega(t))} + \pi\omega^2\rho_w hR\,\|\partial_t\eta\|^2 + \frac{\pi R}{2}C_0\|\eta\|^2 \leq \frac{16\pi LR}{C_0}\,\mathcal{P}^2, \text{ where}$$

$$\mathcal{P}^2 := \sup_{z,t}|\hat{p}|^2 + \left(\sup_z\int_0^t|\hat{p}_t|d\tau\right)^2 + T\int_0^t|A(\tau)|^2. \tag{3.22}$$

Using this result we obtain the a priori estimates for the L^2-norms of the fluid velocity, the displacement, and the time-derivative of the displacement.

LEMMA 3.6. *Weak solution* $(\eta, \boldsymbol{v})$ *satisfies the following a priori estimates:*

$$\frac{1}{L}\|\eta(t)\|^2_{L^2(0,L)} \leq \frac{32}{C_0^2}\mathcal{P}^2, \quad \frac{1}{L}\,\|\partial_t\eta(t)\|^2_{L^2(0,L)} \leq \frac{16}{\rho_W\omega^2 hC_0}\mathcal{P}^2,$$

$$\frac{1}{LR^2\pi}\|\boldsymbol{v}\|^2_{L^2(\Omega(t))} \leq \frac{32}{\rho_F RC_0}\mathcal{P}^2,$$

$$\int_0^t\left\{\|\partial_r v_r\|^2_{L^2(\Omega(\tau))} + \left\|\frac{v_r}{r}\right\|^2_{L^2(\Omega(\tau))} + \|\partial_z v_z\|^2_{L^2(\Omega(\tau))}\right\}d\tau \leq \frac{4\pi R^2}{\mu_F}\sqrt{\frac{2}{\rho_F RC_0}}\mathcal{P}^2,$$

$$\int_0^t\left\{\|\partial_r v_z\|^2_{L^2(\Omega(\tau))} + \|\partial_z v_r\|^2_{L^2(\Omega(\tau))}\right\}d\tau \leq \frac{4R^2}{\mu_F}\sqrt{\frac{2}{\rho RC_0}}\mathcal{P}^2.$$

Furthermore, we obtain the following estimates for the functions describing the viscoelastic behavior of the structure.

COROLLARY 3.7. *The following estimates hold for the viscoelastic thin shell model:*

$$\frac{\omega}{L}\int_0^t \left\|\frac{\partial\eta}{\partial t}\right\|_{L^2}^2 d\tau \le \frac{32}{C_0D_0}\mathcal{P}^2, \quad \frac{\omega}{L}\int_0^t \left\|\frac{\partial^2\eta}{\partial t\partial z}\right\|_{L^2}^2 d\tau \le \frac{32}{C_0D_1}\mathcal{P}^2,$$
$$\frac{\omega}{L}\int_0^t \left\|\frac{\partial^3\eta}{\partial t\partial^2 z}\right\|_{L^2}^2 d\tau \le \frac{32}{C_0D_0}\mathcal{P}^2,$$

where $\mathcal{P}$ is given by (3.22)*, and ω by* (3.21)*.*

The a priori estimates obtained in this section will be used to derive the reduced model presented below.

4. Fluid-structure interaction: A reduced model. We proceed by deriving a closed, effective, reduced model, approximating the full, original axially symmetric problem to the ϵ^2-accuracy.

We begin by considering (3.1)–(3.3) written in nondimensional form. The scalings for the dependent variables $\boldsymbol{v}$ and η are obtained from the a priori estimates presented in Lemma 3.6

$$\boldsymbol{v} = V\tilde{\boldsymbol{v}}, \text{ where } 2V = \frac{\mathcal{P}}{\sqrt{\rho_F}}\left(\frac{hE}{R(1-\sigma^2)} + p_{\text{ref}}\right)^{-\frac{1}{2}}, \tag{4.1}$$

$$\eta = \Xi\tilde{\eta}, \text{ where } 2\Xi = \mathcal{P}R\left(\frac{hE}{R(1-\sigma^2)} + p_{\text{ref}}\right)^{-1}. \tag{4.2}$$

Consider $p = C_p\tilde{p}$, where C_p will be determined later; see (4.11). The nondimensional independent variables $\tilde{r}$, $\tilde{z}$, and $\tilde{t}$ are introduced via

$$r = R\tilde{r}, \quad z = L\tilde{z}, \quad t = \frac{1}{\omega}\tilde{t}, \text{ where } \omega = \frac{1}{L}\sqrt{\frac{1}{\rho_F}\left(\frac{hE}{R(1-\sigma^2)} + p_{\text{ref}}\right)}. \tag{4.3}$$

At this point we could continue by performing singular perturbation analysis of the rescaled system (3.1)–(3.10), (2.14). As in [9], we would find a two-dimensional reduced free-boundary problem approximating the initial problem to the ϵ^2-accuracy. This problem involves a hydrostatic approximation of the pressure, and it is usually written as an analogue of the shallow water system. Elimination of the radial component of the velocity leads to a nonlocal degenerate term. The resulting equations are too complex to be used in the calculation of the solution, and simplifications involving an ad hoc axial velocity profile are typically considered in the literature. Typically considered v_z-profiles are in the form of a product of an unknown function of z and t and a generalized Poiseuille profile in r (see, e.g., [44]). The resulting variant of the shallow water equations is then closed, but the closure hypothesis could introduce an error of order 1.

In order to find a closure that results from the problem itself and gives rise to an ϵ^2-approximation of the full three-dimensional axially symmetric problem, we are going to use homogenization theory [4]. Homogenization theory is used to find effective equations for nonhomogeneous flows. For porous media problems homogenization theory can be applied when (a) the pore size (characteristic size of the fluid region free of another phase) is smaller than the characteristic length of the macroscopic

problem (here, vessel diameter) or (b) the pore includes a large number of molecules to be considered as continuum [28].

At a first glance using this approach in our setting is pointless. A simple averaging of the equations for the fluid phase over the cross-section of the vessel should provide a good approximation. Unfortunately, as remarked above, this approach leads to a problem that is not closed and might ultimately give rise to the errors of order 1. On the other hand, we know how to obtain closed models related to nonlinear filtration laws in rigid periodic porous media by homogenization [36, 37]. In rigid periodic porous media the expansions are of lower order of precision, but the resulting models are closed. It was shown in [36, 37] that in this case it is possible to link the homogenized equations with the nonlinear algebraic relations between the pressure gradient and the velocity (Forchheimer's filtration law), found in experiments. In a similar way, Robertson and Sequeira [46] obtained a closed model for blood flow in rigid wall tubes by replacing the averaged momentum equation with a variant of Forchheimer's law, and no closure assumption was needed to derive a closed system.

In our case we are concerned with viscoelastic walls. How do we link the flow of blood through viscoelastic arteries with the filtration through porous media? Due to the uniform bound on the maximal value of the radial displacement, obtained in section 3.2, our artery can be placed into a rectangle with the length of order 1 and of small width ϵ. By repeating periodically this geometry in the radial direction, we get a network of parallel, long, and narrow tubes, with no cross-flow from one horizontal tube to another. This is one of the simplest porous media which one can imagine. It is not a rigid but a *deformable* porous medium, just as are the domains in Biot's theories of deformable porous media. All results that are valid for deformable porous media are also valid in our situation. Motivated by the results from [36] and [37], where closed effective porous medium equations were obtained using homogenization techniques, we set up a problem that mimics a similar scenario.

Introduce $y = \frac{1}{\epsilon}\tilde{z}$ and assume periodicity in y of the domain and of the velocity and the pressure. Furthermore, recalling that we have a narrow long tube with $\tilde{r} = \frac{1}{R}r = \frac{1}{\epsilon}\frac{r}{L}$, assume periodicity in the radial direction thereby forming a network of a large number of strictly separated, parallel tubes. Follow the approach first presented in [9]. In [9] a closed, reduced model was derived in the case when the vessel walls were approximated by a linearly elastic membrane equations. In the present manuscript, the introduction of a linearly viscoelastic Koiter shell model introduces minor differences in the derivation of the reduced model. Thus, we present only the main steps in the derivation and omit the details which can be found in [9].

Following standard approach in homogenization theory [28, 4], we look for the unknown functions that explicitly depend on the "slow variables" r and $\tilde{z}$ as well as on the "fast variables" r/ϵ and $\tilde{z}/\epsilon =: y$. In our problem the slow and fast variables are related through $z = L\tilde{z} := L\epsilon y = Ry$, $r = R\tilde{r}$. Thus, we look for the functions

$$\tilde{\boldsymbol{v}} = \tilde{\boldsymbol{v}}(\tilde{t}, r, r/\epsilon, \tilde{z}, \tilde{z}/\epsilon), \quad \tilde{\eta} = \tilde{\eta}(\tilde{t}, r, r/\epsilon, \tilde{z}, \tilde{z}/\epsilon), \quad \text{and } \tilde{p} = \tilde{p}(\tilde{t}, r, r/\epsilon, \tilde{z}, \tilde{z}/\epsilon) \tag{4.4}$$

that are 1-periodic in $y = \tilde{z}/\epsilon$ and r/ϵ and satisfy the Navier–Stokes equations (3.1)–(3.3). Keeping both the fast and the slow variables in the derivation of the equations, namely keeping r, r/ϵ, $\tilde{z}$, and y in the problem, will help us determine the proper scaling for the pressure and lead us to a closed, reduced effective model.

Expand the functions in (4.4) in terms of the small parameter ϵ

$$\boldsymbol{v} = V\left\{\tilde{\boldsymbol{v}}^0 + \epsilon\tilde{\boldsymbol{v}}^1 + \cdots\right\}, \quad \eta = \Xi\left\{\tilde{\eta}^0 + \epsilon\tilde{\eta}^1 + \cdots\right\}, \quad p = C_p\left\{\tilde{p}^0 + \epsilon\tilde{p}^1 + \cdots\right\} \tag{4.5}$$

TABLE 4.1
Table with parameter values.

Parameters	Aorta/iliacs	Latex Tube
Char. radius R(m)	0.006-0.012 [44]	0.011
Char. length L(m)	0.065-0.2 [14]	0.34
Dyn. viscosity $\mu_F(\frac{\text{kg}}{\text{ms}})$	3.5×10^{-3} [44]	3.5×10^{-3}
Young's modulus E(Pa)	$10^5 - 10^6$ [44, 1, 3]	1.0587×10^6
Wall thickness h(m)	$1 - 2 \times 10^{-3}$ [44]	0.0009
Wall density $\rho_W(\text{kg/m}^3)$	1.1×10^3 [44]	1.1×10^3
Fluid density $\rho_F(\text{kg/m}^3)$	1050 [44]	1000
Wall viscosity coef. $hC_v/R(\text{Pa} \cdot \text{s})$	$10^3 - 8 \times 10^3$ [1, 2, 3]	0

and plug this into the Navier–Stokes equations (3.1)–(3.3). We look for a solution to the zeroth-order approximation of the problem plus its ϵ-correction. The zeroth-order approximation corresponds to the leading-order approximation of the flow in the limit in which the wavelength of the disturbance and the length scale of tube variation are large compared with the tube radius.

4.1. The zeroth-order approximation. The leading-order Navier–Stokes equations read

$$Sh_0 \frac{\partial \tilde{v}_z^0}{\partial \tilde{t}} + (\tilde{v}^0 \nabla_{\tilde{r},y}) \tilde{v}_z^0 + \frac{\partial \tilde{p}^0}{\partial \tilde{z}} + \frac{\partial \tilde{p}^1}{\partial y} - \frac{1}{Re_0} \left\{ \frac{1}{\tilde{r}} \frac{\partial}{\partial \tilde{r}} \left(\tilde{r} \frac{\partial \tilde{v}_z^0}{\partial \tilde{r}} \right) + \frac{\partial^2 \tilde{v}_z^0}{\partial y^2} \right\} = 0, \tag{4.6}$$

$$Sh_0 \frac{\partial \tilde{v}_r^0}{\partial \tilde{t}} + (\tilde{v}^0 \nabla_{\tilde{r},y}) \tilde{v}_r^0 + \frac{\partial \tilde{p}^0}{\partial r} + \frac{\partial \tilde{p}^1}{\partial \tilde{r}} - \frac{1}{Re_0} \left\{ \frac{1}{\tilde{r}} \frac{\partial}{\partial \tilde{r}} \left(\tilde{r} \frac{\partial \tilde{v}_r^0}{\partial \tilde{r}} \right) + \frac{\partial^2 \tilde{v}_r^0}{\partial y^2} \right\} = 0, \tag{4.7}$$

$$\nabla_{\tilde{r},y} \tilde{p}^0 = 0, \tag{4.8}$$

$$\frac{\partial}{\partial \tilde{r}} \left(\tilde{r} \tilde{v}_r^0 \right) + \frac{\partial}{\partial y} \left(\tilde{r} \tilde{v}_z^0 \right) = 0, \tag{4.9}$$

$$\text{with } \tilde{v}_r^0, \tilde{v}_z^0, \text{ and } \tilde{p}^1 \text{ 1-periodic in } y \text{ and } \tilde{v}_r^0 = \tilde{v}_z^0 = 0 \text{ at } \tilde{r} = 1 + \frac{\Xi}{R} \tilde{\eta}, \tag{4.10}$$

where $Sh_0 := \frac{\epsilon L \omega^\epsilon}{V}$ and $Re_0 := \frac{\rho_F R V}{\mu_F}$. Here the following scaling for the pressure is used:

$$p = \frac{\rho_F V^2}{\epsilon} \tilde{p}, \quad \text{thus} \quad C_p = \frac{\rho_F V^2}{\epsilon}. \tag{4.11}$$

Notice $Sh_0 = \epsilon Sh$ and $Re_0 = Re/\epsilon$. For the average values from Table 4.1 Sh_0 is of order 1 and Re_0 is around 1000. We remark that (4.8) corresponds to the ϵ^{-1}-term and the others to the ϵ^0-term.

The leading-order behavior for the boundary conditions evaluated at the lateral boundary $\tilde{r} = 1 + \frac{\Xi}{R} \tilde{\eta}^0$ is the following:

- The kinematic boundary condition:

$$\tilde{v}_r^1 = \frac{\partial \tilde{\eta}^0}{\partial \tilde{t}} + \mathcal{O}(\epsilon^2). \tag{4.12}$$

- The dynamic boundary condition:

$$\begin{aligned} \tilde{p}^0 - \tilde{p}_{\text{ref}} = {} & \frac{\epsilon}{\rho_F V^2} \frac{\Xi}{R} \frac{hE}{R(1-\sigma^2)} \left(1 + \frac{h^2}{12R^2} \right) \tilde{\eta}^0 + \tilde{p}_{\text{ref}} \frac{\Xi}{R} \tilde{\eta}^0 \\ & + \frac{\epsilon}{\rho_F V^2} \frac{\Xi}{R} \frac{hC_V \omega}{R} \left(1 + \frac{h^2}{12R^2} \right) \frac{\partial \tilde{\eta}^0}{\partial \tilde{t}} + \mathcal{O}(\epsilon^2). \end{aligned} \tag{4.13}$$

Notice that for the parameter values in Table 4.1, $\omega \approx 100$ and the values of the leading-order coefficients are both of order one: $\frac{\epsilon}{\rho_F V^2}\frac{\Xi}{R}\frac{hE}{R(1-\sigma^2)}(1+\frac{h^2}{12R^2}) = \mathcal{O}(1)$, $\frac{\epsilon}{\rho_F V^2}\frac{\Xi}{R}\frac{hC_V\omega}{R}(1+\frac{h^2}{12R^2}) = \mathcal{O}(1)$. This is the ϵ^2-approximation of the pressure-displacement relationship describing the linearly viscoelastic cylindrical Koiter shell model. The terms multiplying h^3 account for the bending rigidity of the Koiter shell. These terms are not present in the pressure-displacement relationship describing a viscoelastic membrane.

To obtain a closed system of reduced equations notice that system (4.6)–(4.10) admits a unique strong (nonstationary) unidirectional solution independent of y [48] for every given smooth pressure $\tilde{p}^0$:

$$\tilde{v}_r^0 = 0, \quad \tilde{v}_z^0 = \tilde{v}_z^0(\tilde{r}, \tilde{z}, \tilde{t}), \tag{4.14}$$

where $\tilde{v}_z^0$ satisfies

$$\begin{cases} Sh_0 \dfrac{\partial \tilde{v}_z^0}{\partial \tilde{t}} - \dfrac{1}{Re_0}\dfrac{1}{\tilde{r}}\dfrac{\partial}{\partial \tilde{r}}\left(\tilde{r}\dfrac{\partial \tilde{v}_z^0}{\partial \tilde{r}}\right) = -\dfrac{\partial \tilde{p}^0}{\partial \tilde{z}}(\tilde{z}, \tilde{t}), \\ \tilde{v}_z^0(0, \tilde{z}, \tilde{t}) \text{ bounded}, \quad \tilde{v}_z^0(1 + \Xi\tilde{\eta}^0(\tilde{z}, \tilde{t})/R, \tilde{z}, \tilde{t}) = 0, \quad \text{and } \tilde{v}_z^0(\tilde{r}, \tilde{z}, 0) = 0, \end{cases} \tag{4.15}$$

and $\tilde{p}^1$ is a linear function of y, independent of $\tilde{r}$. Since $\tilde{p}^1$ is 1-periodic $\tilde{p}^1$ cannot depend on y. Thus, the derivatives of $\tilde{p}^1$ with respect to $\tilde{r}$ and y are both zero.

To complement (4.15) in the calculation of $\tilde{v}_z^0$ and $\tilde{p}^0$ we use the conservation of mass equation (3.3) averaged with respect to the cross-section. The leading-order terms in (3.3) read

$$\frac{\partial}{\partial \tilde{r}}\left(\tilde{r}\tilde{v}_r^1\right) + \frac{\partial}{\partial \tilde{z}}\left(\tilde{r}\tilde{v}_z^0\right) = 0.$$

Integrated with respect to $\tilde{r}$ from 0 to $1 + \frac{\Xi}{R}\tilde{\eta}^0$ one obtains

$$\frac{\partial\left(1 + \frac{\Xi}{R}\tilde{\eta}^0\right)^2}{\partial \tilde{t}} + \frac{\Xi}{R}\frac{\partial}{\partial \tilde{z}}\int_0^{1+\frac{\Xi}{R}\tilde{\eta}^0} 2\tilde{v}_z^0\tilde{r}\,d\tilde{r} = 0, \tag{4.16}$$

where we have used the kinematic boundary condition (4.12) to couple the flow velocity and lateral boundary motion.

Equations (4.16), (4.15), and (4.13) give rise to a nonlinear free-boundary problem for the zeroth-order approximation of the flow. In dimensional variables, the nonlinear free-boundary problem for $(\boldsymbol{v}^0, \eta^0, p^0) = (v_z^0, 0, \eta^0, p^0)$ reads

$$\begin{aligned} &\frac{\partial (R+\eta^0)^2}{\partial t} + \frac{\partial}{\partial z}\int_0^{R+\eta^0} 2rv_z^0 dr = 0, \\ &\varrho_F \frac{\partial v_z^0}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^0}{\partial r}\right) = -\frac{\partial p^0}{\partial z}, \\ &p^0 - p_{\text{ref}} = \frac{hE}{R^2(1-\sigma^2)}\left(1 + \frac{h^2}{12R^2}\right)\eta^0 + p_{\text{ref}}\frac{\eta^0}{R} + \frac{hC_V}{R^2}\left(1 + \frac{h^2}{12R^2}\right)\frac{\partial \eta^0}{\partial t}, \\ &v_z^0|_{r=0} - \text{ bounded}, \quad v_z^0|_{r=R+\eta^0} = 0, \quad v_z^0|_{t=0} = 0, \\ &\eta^0|_{t=0} = 0, \quad p^0|_{z=0} = P_0, \quad p^0|_{z=L} = P_L. \end{aligned} \tag{4.17}$$

4.2. The first-order correction. The first-order correction to the solution defined by (4.17) is obtained by solving the equations that result from the coefficients at the ϵ^1-terms in the expanded Navier–Stokes equations (3.1)–(3.3)

(4.18)
$$Sh_0\frac{\partial\tilde{v}_z^1}{\partial\tilde{t}}+\tilde{v}_z^0\left\{\frac{\partial\tilde{v}_z^1}{\partial y}+\frac{\partial\tilde{v}_z^0}{\partial\tilde{z}}\right\}+\tilde{v}_r^1\frac{\partial\tilde{v}_z^0}{\partial\tilde{r}}+\frac{\partial\tilde{p}^1}{\partial\tilde{z}}+\frac{\partial\tilde{p}^2}{\partial y}=\frac{1}{Re_0}\left\{\frac{1}{\tilde{r}}\frac{\partial}{\partial\tilde{r}}\left(\tilde{r}\frac{\partial\tilde{v}_z^1}{\partial\tilde{r}}\right)+\frac{\partial^2\tilde{v}_z^1}{\partial y^2}\right\},$$

$$Sh_0\frac{\partial\tilde{v}_r^1}{\partial\tilde{t}}+\tilde{v}_z^0\frac{\partial\tilde{v}_r^1}{\partial y}+\frac{\partial\tilde{p}^2}{\partial\tilde{r}}=\frac{1}{Re_0}\left\{\frac{1}{\tilde{r}}\frac{\partial}{\partial\tilde{r}}\left(\tilde{r}\frac{\partial\tilde{v}_r^1}{\partial\tilde{r}}\right)+\frac{\partial^2\tilde{v}_r^1}{\partial y^2}\right\}, \tag{4.19}$$

$$\frac{\partial}{\partial\tilde{r}}\left(\tilde{r}\tilde{v}_r^1\right)+\frac{\partial}{\partial y}\left(\tilde{r}\tilde{v}_z^1\right)+\tilde{r}\frac{\partial\tilde{v}_z^0}{\partial\tilde{z}}=0, \tag{4.20}$$

$$\tilde{v}_r^1,\tilde{v}_z^1,\tilde{p}^2 \text{ 1-periodic in } y;\ \tilde{v}_r^1=\frac{\partial\tilde{\eta}^0}{\partial\tilde{t}},\quad \tilde{v}_z^0=0 \text{ at } \tilde{r}=1+\frac{\Xi}{R}\tilde{\eta}^0. \tag{4.21}$$

Using the same arguments as in [9] one can show that $\tilde{p}^1=\tilde{p}^2=0$ and we have a closed linear system, known as a nonstationary Oseen system, defined on a fixed domain $(0,L)\times(0,1+\Xi/R\eta^0)$.

To calculate the ϵ-correction to the velocity we look for a solution $\tilde{v}_z^1$ that is independent of the "artificial" fast variable y. In this case the conservation of mass equation (4.20) can be integrated with respect to $\tilde{r}$ to obtain an explicit formula for $\tilde{v}_r^1$ in terms of the already calculated $\tilde{v}_z^0$:

$$\tilde{r}\tilde{v}_r^1(\tilde{r},\tilde{z},\tilde{t})=\left(1+\frac{\Xi\tilde{\eta}^0}{R}\right)\frac{\partial\tilde{\eta}^0}{\partial\tilde{t}}+\int_{\tilde{r}}^{1+\Xi\tilde{\eta}^0/R}\frac{\partial\tilde{v}_z^0}{\partial\tilde{z}}(\xi,\tilde{z},\tilde{t})\ \xi\ d\xi. \tag{4.22}$$

The axial momentum equation (4.18) defines a linear problem for $\tilde{v}_z^1$:

$$Sh_0\frac{\partial\tilde{v}_z^1}{\partial\tilde{t}}-\frac{1}{Re_0}\frac{1}{\tilde{r}}\frac{\partial}{\partial\tilde{r}}\left(\tilde{r}\frac{\partial\tilde{v}_z^1}{\partial\tilde{r}}\right)=-\tilde{v}_r^1\frac{\partial\tilde{v}_z^0}{\partial\tilde{r}}-\frac{\partial}{\partial\tilde{z}}\left(\frac{(\tilde{v}_z^0)^2}{2}\right), \tag{4.23}$$

$$\tilde{v}_z^1(0,\tilde{z},\tilde{t}) \text{ bounded},\quad \tilde{v}_z^1(1+\Xi\tilde{\eta}^0(\tilde{z},\tilde{t})/R,\tilde{z},\tilde{t})=0, \tag{4.24}$$

$$\tilde{v}_z^1(\tilde{r},\tilde{z},0)=0,\quad \tilde{v}_z^1(\tilde{r},0,t)=\tilde{v}_z^1(\tilde{r},L,t)=0. \tag{4.25}$$

Notice that the quadratic transport terms appear in this higher-order approximationi. They are linearized around the zeroth-order approximation of the solution.

Equations (4.22)–(4.25) define the ϵ-correction of the solution. In dimensional form the system reads

$$\begin{aligned}
&v_r^1(r,z,t)=\frac{1}{r}\left(R\frac{\partial\eta^0}{\partial t}+\int_r^R\xi\frac{\partial v_z^0}{\partial z}(\xi,z,t)d\xi\right),\\
&\rho_F\frac{\partial v_z^1}{\partial t}-\mu_F\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^1}{\partial r}\right)=-\rho_F\left(v_r^1\frac{\partial v_z^0}{\partial r}+v_z^0\frac{\partial v_z^0}{\partial z}\right),\\
&v_z^1|_{\overline{r}=0}- \text{ bounded},\quad v_z^1|_{r=R}=0,\quad v_z^1|_{t=0}=0.
\end{aligned} \tag{4.26}$$

PROPOSITION 4.1. *The velocity field* $\boldsymbol{v}=(v_z^0+v_z^1,v_r^1)$*, the radial displacement* $\eta=\eta^0$*, and the pressure* $p=p^0$*, defined by* (4.17) *and* (4.26)*, satisfy the original problem* (3.1)–(3.10) *to* $\mathcal{O}(\epsilon^2)$.

The proof is the same as that of Proposition 7.1 in [9].

We end this section by summarizing the main assumptions under which the simplified, effective problem (4.17), (4.26) holds and the parameter values assumed.

Assumptions.

(1) The domain is cylindrical with small aspect ratio $\epsilon = R_{\max}/L$.
(2) The problem is axially symmetric.
(3) Longitudinal displacement is negligible.
(4) Radial displacement is not too large, i.e., $\delta := \Xi/R \leq \epsilon$.
(5) The reference tube radius varies slowly: $R'(z) < \epsilon$.
(6) The Reynolds number Re is small to medium (Re ≈ 1000).
(7) The z-derivatives of the nondimensional quantities are $O(1)$ (not too large).

5. Viscoelasticity of the fluid-structure interaction. We emphasize in this section that the viscoelastic behavior of the coupled fluid-structure interaction problem comes from two distinct effects. One is the viscoelasticity of the structure itself, and the other is the viscoelasticity due to the interaction between the structure (not necessarily viscoelastic) with a viscous fluid. To explicitly capture the leading-order effects that the viscous fluid imparts on the motion of the structure we proceed as follows. First, we simplify the free-boundary problem (4.17) by expanding the underlying problem (4.17), (4.26), with respect to the radial displacement. The free-boundary problem will be approximated by two fixed boundary problems of similar form. Each of the two fixed boundary problems consists of solving a system of two equations (see (5.1), (5.3)) that are of hyperbolic-parabolic type. In each of the two problems, we can "explicitly solve" the parabolic equation for the velocity, plug the velocity into the resulting equation for the structure, and obtain a single equation describing the motion of the structure. The resulting equation incorporates the viscous fluid effects in terms of a convolution integral. If we will assume, for the moment, that the structure is purely elastic, the resulting equation describes the dynamics of an elastic structure under a viscous fluid load; see (5.11). It corresponds to a model of a viscoelastic string with viscous long-term memory effects. Thus, the fluid viscosity influences the dynamics of an elastic structure through a long-term memory effect.

We begin by expanding the free-boundary problem (4.17) and the ϵ-correction (4.26) with respect to the radial displacement whose magnitude is measured, in nondimensional variables, by Ξ/R. Thus, assume that

$$\delta := \frac{\Xi}{R} \leq \epsilon$$

and introduce the following expansions with respect to δ:

$$\tilde{\eta}^0 = \tilde{\eta}^{0,0} + \delta\tilde{\eta}^{0,1} + \cdots, \quad \tilde{p}^0 = \tilde{p}^{0,0} + \delta\tilde{p}^{0,1} + \cdots,$$
$$v_z^0 = v_z^{0,0} + \delta v_z^{0,1} + \cdots, \quad \tilde{v}_z^1 = \tilde{v}_z^{1,0} + \cdots, \quad \tilde{v}_r^1 = \tilde{v}_r^{1,0} + \cdots.$$

The first superscript denotes the expansion with respect to ϵ and the second with respect to δ. Then using the same approach as in [9] one obtains a set of equations approximating the original problem to the ϵ^2-accuracy. The resulting problem, in dimensional variables, consists of finding the functions

$$v_z = v_z^{0,0} + v_z^{0,1} + v^{1,0} + \mathcal{O}(\epsilon^2),\ v_r = v_r^{1,0} + \mathcal{O}(\epsilon^2),\ \eta = \eta^{0,0} + \mathcal{O}(\epsilon^2)\, p = p^{0,0} + \mathcal{O}(\epsilon^2)$$

satisfying the following set of closed, well-defined problems.

The zeroth-order approximation. Find $(\eta^{0,0}, v_z^{0,0})$ such that

$$
\begin{aligned}
&\frac{\partial \eta^{0,0}}{\partial t} + \frac{1}{R}\frac{\partial}{\partial z}\int_0^R r v_z^{0,0} dr = 0,\\
&\varrho_F \frac{\partial v_z^{0,0}}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^{0,0}}{\partial r}\right) = -\frac{\partial p^{0,0}}{\partial z},\\
&v_z^{0,0}|_{r=0} - \text{ bounded}, \quad v_z^{0,0}|_{t=R} = 0, \quad v_z^{0,0}|_{t=0} = 0,\\
&\eta^{0,0}|_{t=0} = 0, \quad p^{0,0}|_{z=0} = P_0, \quad p^{0,0}|_{z=L} = P_L,
\end{aligned}
\tag{5.1}
$$

where

$$
p^{0,0} = \frac{Eh}{(1-\sigma^2)R}\left(1 + \frac{h^2}{12R^2}\right)\frac{\eta^{0,0}}{R} + p_{\text{ref}}\frac{\eta^{0,0}}{R} + \frac{hC_v}{R^2}\left(1 + \frac{h^2}{12R^2}\right)\frac{\partial \eta^{0,0}}{\partial t}. \tag{5.2}
$$

The δ correction. Find $(\eta^{0,1}, v_z^{0,1})$ such that

$$
\begin{aligned}
&\frac{\partial \eta^{0,1}}{\partial t} + \frac{1}{R}\frac{\partial}{\partial z}\int_0^R r v_z^{0,1} dr = -\frac{1}{2R}\frac{\partial}{\partial t}\left(\eta^{0,0}\right)^2,\\
&\varrho_F \frac{\partial v_z^{0,1}}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^{0,1}}{\partial r}\right) = -\frac{\partial p^{0,1}}{\partial z},\\
&v_z^{0,1}|_{r=0} - \text{ bounded}, \quad v_z^{0,1}|_{r=R} = -\eta^{0,0}\frac{\partial v_z^{0,0}}{\partial r}|_{r=R}, \quad v_z^{0,1}|_{t=0} = 0,\\
&\eta^{0,1}|_{t=0} = 0, \quad \eta^{0,1}|_{z=0} = 0, \quad \eta^{0,1}|_{z=L} = 0,
\end{aligned}
\tag{5.3}
$$

where

$$
\begin{aligned}
p^{0,1} = &\left(\frac{Eh}{(1-\sigma^2)R}\left(1 + \frac{h^2}{12R^2}\right) + p_{\text{ref}}\right)\left(\frac{\eta^{0,1}}{R} - \left(\frac{\eta^{0,0}}{R}\right)^2\right)\\
&+ \frac{hC_v}{R^2}\left(1 + \frac{h^2}{12R^2}\right)\left(\frac{\partial \eta^{0,1}}{\partial t} - \frac{\eta^{0,0}}{R}\frac{\partial \eta^{0,1}}{\partial t}\right).
\end{aligned}
\tag{5.4}
$$

The ϵ-correction. Find $(v_r^{1,0}, v_z^{1,0})$ such that

$$
v_r^{1,0}(r,z,t) = \frac{1}{r}\left(R\frac{\partial \eta^{0,0}}{\partial t} + \int_r^R \xi \frac{\partial v_z^{0,0}}{\partial z}(\xi,z,t)d\xi\right), \tag{5.5}
$$

$$
\begin{aligned}
&\rho_F \frac{\partial v_z^{1,0}}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^{1,0}}{\partial r}\right) = -\rho_F\left(v_r^{1,0}\frac{\partial v_z^{0,0}}{\partial r} + v_z^{0,0}\frac{\partial v_z^{0,0}}{\partial z}\right),\\
&v_z^{1,0}|_{\bar{r}=0} - \text{ bounded}, \quad v_z^{1,0}|_{r=R} = 0, \quad v_z^{1,0}|_{t=0} = 0.
\end{aligned}
\tag{5.6}
$$

Systems (5.1) and (5.3) can be solved by considering the auxiliary problem

$$
\begin{cases}
\dfrac{\partial \zeta}{\partial t} - \dfrac{1}{r}\dfrac{\partial}{\partial r}\left(r\dfrac{\partial \zeta}{\partial r}\right) = 0 \quad \text{in } (0,R)\times(0,\infty),\\
\zeta(0,t) \text{ is bounded}, \quad \zeta(R,t) = 0 \text{ and } \zeta(r,0) = 1.
\end{cases}
\tag{5.7}
$$

For example, the solution of the parabolic equation for the velocity $v_z^{0,0}$ can be written as the convolution

$$
v_z^{0,0} = -\frac{1}{\rho_F}\int_0^t \zeta\left(r, \frac{\mu_F(t-\tau)}{\rho_F}\right)\frac{\partial p^{0,0}}{\partial z}(z,\tau)d\tau.
$$

Plugging this expression for the velocity into the first equation one obtains

$$\frac{\partial \eta^{0,0}}{\partial t} - \frac{1}{\rho_F R}\frac{\partial}{\partial z}\int_0^R r \int_0^t \zeta\left(r, \frac{\mu_F(t-\tau)}{\rho_F}\right)\frac{\partial p^{0,0}}{\partial z}(z,\tau)d\tau dr = 0. \tag{5.8}$$

Denote the mean of ζ in the radial direction by

$$\mathcal{K}(t) = 2\int_0^R \zeta(r,t)\, r dr, \tag{5.9}$$

and assume, for the moment, that the Koiter shell is purely elastic so that

$$p^{0,0} = C_0\eta^{0,0}, \text{ where } C_0 = \frac{h}{R^2}\frac{E}{1-\sigma^2}\left(1+\frac{h^2}{12R^2}\right) + \frac{p_{\text{ref}}}{R}.$$

Then (5.8) becomes

$$\frac{\partial \eta^{0,0}}{\partial t} - \frac{C_0}{2\rho_F R}\int_0^t \mathcal{K}\left(\frac{\mu_F(t-\tau)}{\rho_F}\right)\frac{\partial^2 \eta^{0,0}}{\partial z^2}d\tau = 0. \tag{5.10}$$

Differentiate with respect to t to obtain

$$\frac{\partial^2 \eta^{0,0}}{\partial t^2} = \frac{C_0 R}{2\rho_F}\frac{\partial^2 \eta^{0,0}}{\partial z^2} + \mu_F\frac{C_0}{2\rho_F^2 R}\int_0^t \mathcal{K}'\left(\frac{\mu_F(t-\tau)}{\rho_F}\right)\frac{\partial^2 \eta^{0,0}}{\partial z^2}. \tag{5.11}$$

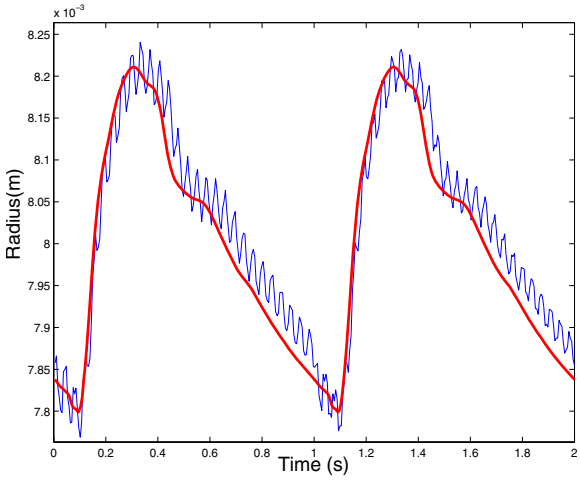

FIG. 5.1. *A comparison between the solutions of* (5.11) *with* $\mu_F = 0$ *(thin solid line) and* $\mu_F = 3.5 \times 10^{-3}$ *(thick solid line). The radius, shown in these graphs, is taken at the midpoint of the tube during two cardiac cycles.*

This is a model describing the motion of a linearly viscoelastic string with the viscous effects described by the convolution integral on the right-hand side of (5.11). The kernel in the convolution corresponds to the derivative of $\mathcal{K}$ which decays in time exponentially fast, with the decay rate equal to the first zero of the Bessel function J_0. This is the only term that incorporates the viscosity of the fluid μ_F. Thus, the fluid impacts the motion of the structure through this long-term memory effect. Numerical simulations presented in Figure 5.1 show the motion of the structure (displacement $\eta^{0,0}$) with $\mu_F = 0$ and with $\mu_F = 3.5 \times 10^{-3}$. The smoothing by the viscous fluid dissipation is obvious.

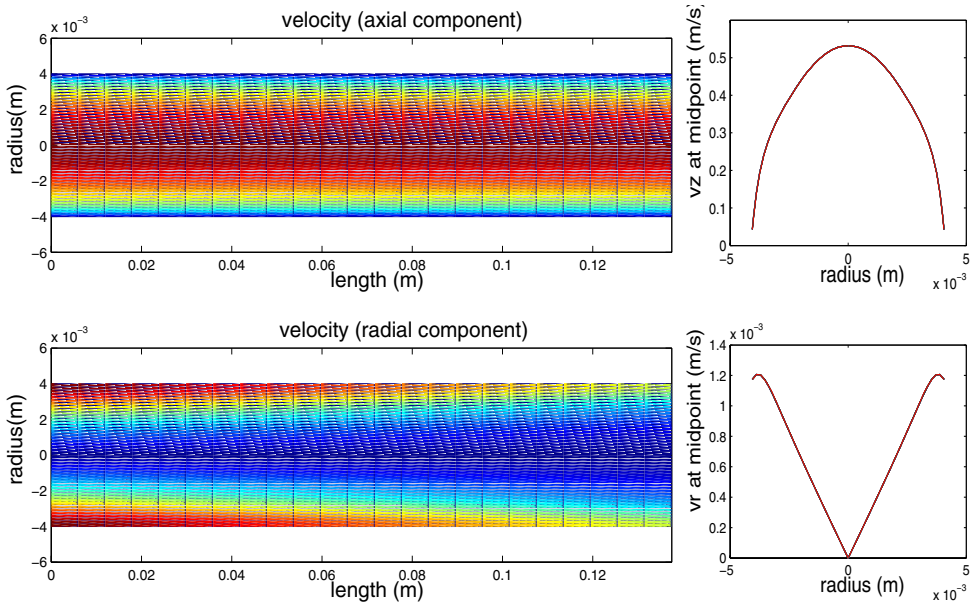

FIG. 6.1. *The axial (top) and radial (bottom) components of the velocity obtained at a first half of the systole (*1/6 *of the cardiac cycle). The magnitude of the axial component of the velocity is between* 0 *and* 0.52 m/s. *The magnitude of the radial component of the velocity is between* 0 *and* 0.0014 m/s. *The pictures on the right show the velocity profiles calculated at the midpoint of the tube.*

6. Numerical algorithm. To solve problems (5.1) and (5.3) numerically it is convenient to rewrite each of the systems of equations as a second-order hyperbolic-parabolic problem. Namely, after differentiating the first equation in (5.1) with respect to time, and plugging the second equation into the first, problem (5.1) can be rewritten as

$$\frac{\partial^2 \eta^{0,0}}{\partial t^2} - \frac{R}{2\rho_F}\frac{\partial^2 p^{0,0}}{\partial z^2} = -\frac{\mu_F}{\rho_F}\frac{\partial}{\partial z}\left(\frac{\partial v_z^{0,0}}{\partial r}\bigg|_{r=R}\right), \tag{6.1}$$

$$\rho_F \frac{\partial v_z^{0,0}}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^{0,0}}{\partial r}\right) = -\frac{\partial p^{0,0}}{\partial z}, \tag{6.2}$$

with the initial and boundary conditions specified in (5.1) and $p^{0,0}$ substituted by (5.2). Similarly, problem (5.3) can be written as

$$\frac{\partial^2 \eta^{0,1}}{\partial t^2} - \frac{R}{2\rho_F}\frac{\partial^2 p^{0,1}}{\partial z^2} = -\frac{\mu_F}{\rho_F}\frac{\partial}{\partial z}\left(\frac{\partial v_z^{0,0}}{\partial r}\bigg|_{r=R}\right) - \frac{1}{2R}\frac{\partial^2}{\partial t^2}\left(\eta^{0,0}\right)^2, \tag{6.3}$$

$$\rho_F \frac{\partial v_z^{0,1}}{\partial t} - \mu_F \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial v_z^{0,1}}{\partial r}\right) = -\frac{\partial p^{0,1}}{\partial z}, \tag{6.4}$$

with initial and boundary conditions given in (5.3) and $p^{0,1}$ substituted by (5.4). The first equation in both subproblems can be thought off as a one-dimensional wave equation in z and t, and the second as the one-dimensional heat equation in r and t. The systems for the $0,0$ and $0,1$ approximations have the same form. They are solved using a one-dimensional finite element method. Since the mass and stiffness matrices are the same for both problems, up to the boundary conditions, they are

generated only once. Both systems are solved simultaneously using a time-iteration procedure. First, the parabolic equation is solved for $v_z^{0,0}$ at the time step t_{i+1} by explicitly evaluating the right-hand side at the time-step t_i. Then the wave equation is solved for $\eta^{0,0}$ with the evaluation of the right-hand side at the time-step t_{i+1}. Using these results for $v_z^{0,0}$ and $\eta^{0,0}$, computed at t_{i+1}, a correction at t_{i+1} is calculated by repeating the process with the updated values of the right-hand sides. This method is a version of the Douglas–Rachford time-splitting algorithm which is known to be of first-order accuracy.

Calculating approximation $1,0$ is straightforward once the approximations $0,0$ and $0,1$ are obtained. In this algorithm a sequence of one-dimensional problems is solved, so the numerical complexity is that of one-dimensional solvers. However, leading-order two-dimensional effects are captured to the ϵ^2-accuracy. Figure 6.1 presents the axial and radial components of the velocity, showing two-dimensional effects that cannot be captured using one-dimensional models.

7. Experimental validation. A mock circulatory loop was used to validate our simplified, effective mathematical flow model (5.1)–(5.6). The circulatory loop was assembled at the Research Laboratory at the Texas Heart Institute. Figure 7.1 shows the experimental setup and a sketch of the main components of the mock circulatory loop. The main components of the flow loop include the left ventricular assist device (LVAD Heart Mate, Thoratex Corp., Woburn, MA), which is a pulsatile flow pump used in patients with failing hearts to aid the function of the left ventricle, the inlet and outlet LVAD valves, two compliance chambers (wash bottles; 250 ml in volume), a reservoir (Nalgene canister), and pressure transducers (TruEave, Edwards Lifesciences, Irvine, CA) placed at the inlet and outlet of the test segment. Latex tubing (Kent Elastomer Products Inc.) was used to simulate compliant vessels. See Figure 7.1. The straight latex tube segment was attached to the hard plastic connectors placed at the inlet and at the outlet of the segment, keeping the inlet and outlet displacement together with its derivative equal to zero, i.e., $\eta = \partial\eta/\partial z = 0$ at $z = 0, L$, as well as the inlet and outlet velocity approximately such that $v_r = 0$.

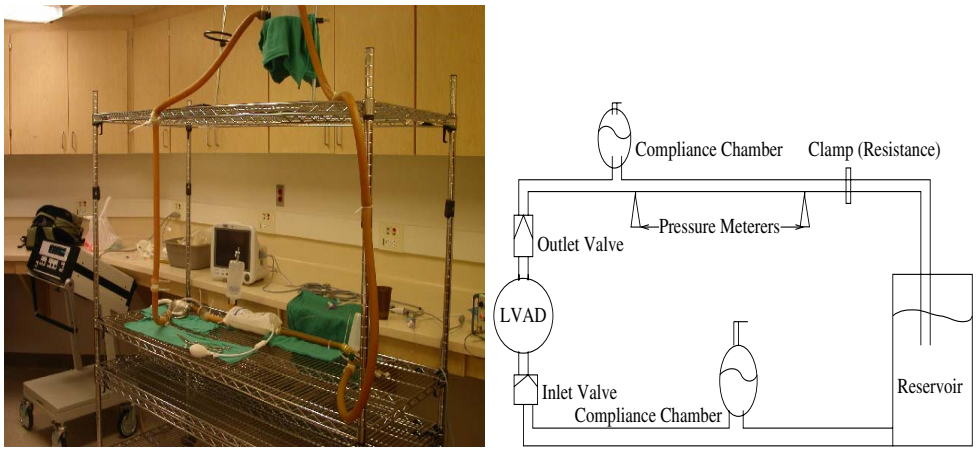

FIG. 7.1. *Flow loop at the Research Laboratory at the Texas Heart Institute (left), a sketch of the flow loop (right).*

One of the goals of this experiment was to recreate the pressure waves and fluid velocity at the middle section of the straight test segment similar to those typical

for the human abdominal aorta. To achieve this goal a clamp located downstream from the test segment was added to mimic downstream resistance by the capillary bed. Figure 7.2(left) shows the measured (filtered) pressure data at the inlet and at the outlet of the test segment. This compares well with the typical inlet and outlet pressure data of the human abdominal aorta, shown in Figure 7.2(right). Ultrasonic imaging and Doppler methods were used to measure the axial velocity of the flow. Nondairy coffee creamer was dispersed in water to enable reflection for ultrasound measurements. A high-frequency (20 MHz) single crystal probe was inserted through a catheter at several locations of the tube. This method has been validated in vivo by measuring the velocity and wall motion in mice to a precision of 0.1 um; see [25, 26].

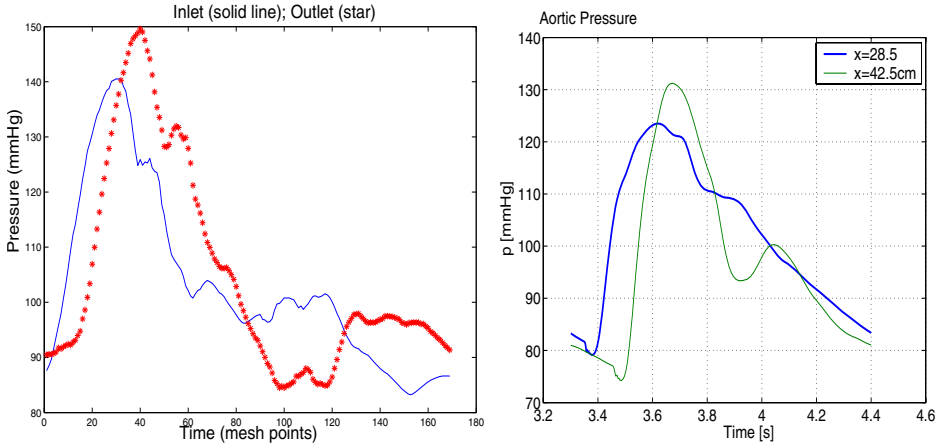

FIG. 7.2. *Inlet and outlet pressure data used in the numerical simulations. Left: Circulatory flow loop data (filtered). Right: aortic data* [14].

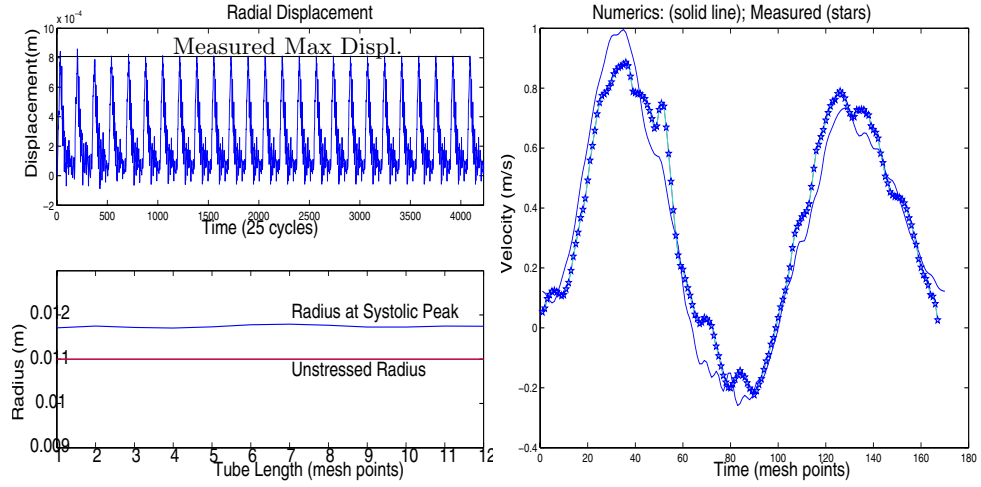

FIG. 7.3. *The figure shows a comparison between the numerical simulations and the experimental measurements. Left: Displacement. Right: axial component of the velocity, evaluated at the midpoint of the tube (midpoint with respect to the length and the diameter of the tube). The solid line corresponds to the numerically calculated solution; the line with asterisks corresponds to the experimentally collected data.*

To determine Young's modulus of the tube wall we measured the tube diameter d at the reference pressure of 84 mmHg ($d = 2.22$ cm) and at the maximal systolic pressure of 148 mmHg ($d = 2.38$ cm), utilizing the linear pressure-displacement relationship described by the equations of p^0 in (4.17) with $C_V = 0$ and the data for the tube wall thickness provided by the manufacturer of the latex tube, Kent Elastomer Products Inc. The value of $E = 1.0587 \times 10^6$ Pa was obtained. Using the numerical solver described in section 6 system of equations (5.1)–(5.6) was solved. The results were compared with the experimental measurements. At the top of Figure 7.3(left) is a comparison between the numerically calculated displacement and the experimentally measured maximal displacement of 0.0008 m. Figure 7.3(right) shows a comparison between the numerically calculated (solid line) and experimentally measured (asterisks) axial velocity. Excellent agreement was obtained indicating that this model captures well the fluid-structure interaction between a linearly elastic structure such as a latex tube, and the flow of a viscous incompressible fluid such as water, in the flow regime corresponding to the abdominal aorta.

8. Hysteresis behavior of viscoelastic arteries. In this section we compare the results of our viscoelastic model with the measurement of the viscoelastic properties of the human and canine arteries presented in [1, 2, 3]. In [1] Armentano et al. studied the viscoelastic aortic properties in dogs. In particular, they measured the magnitude of the viscous modulus corresponding to our coefficient hC_v/R. The values corresponding to dogs aortas, reported in [1], belong to the interval

$$\begin{aligned}\frac{hC_v}{R}|_{(\text{dog aorta})} &\in (3.8 \pm 1.3 \times 10^4, 7.8 \pm 1.1 \times 10^4)\ dyn \cdot \text{s/cm}^2 \\ &= (3.8 \pm 1.3 \times 10^3, 7.8 \pm 1.1 \times 10^3)\ \text{Pa} \cdot \text{s}.\end{aligned}$$

Taking into account the radius of the studied aortas (≈ 0.008 m) and the average wall thickness (≈ 0.0014 m), one obtains

$$C_v|_{(\text{dog aorta})} \in (2.17 \times 10^4, 4.45 \times 10^4)\ \text{Pa} \cdot \text{s}.$$

In [1] the measurements of the viscoelastic properties of the canine aorta were obtained, showing a hysteresis in the stress-strain diagram, where the stress (τ) and strain (e) were defined using

$$\tau = \frac{2p(r_e r_i)^2}{r_e^2 - r_i^2}\frac{1}{R^2}, \quad e = \frac{R+\eta}{R}. \tag{8.1}$$

Here r_e and r_i are the external and internal vessel radii calculated using $r_{e,i} = R \pm 0.5\ h$. The results of the measurements are shown in Figure 8.1(left). We used the data presented in [1] as a guide in the numerical simulation of the dynamics of the canine aorta utilizing the effective viscoelastic model (4.17), (4.26). Unfortunately, [1] does not include the pressure data at the inlet and outlet of the canine aorta. Thus, it was impossible to recreate the simulation that would correspond exactly to the scenario studied in [1]. However, using the data available to us, in particular the viscous modulus C_V, we were able to approximate the scenario studied in [1] and capture the main viscoelastic properties of the canine aorta. The results are shown in Figure 8.1. The top figures show the pressure and the scaled diameter in one cardiac cycle. Both waves exhibit the same morphology, but the diameter shows a time delay with respect to the pressure, which is due to the viscosity of the vessel wall. The

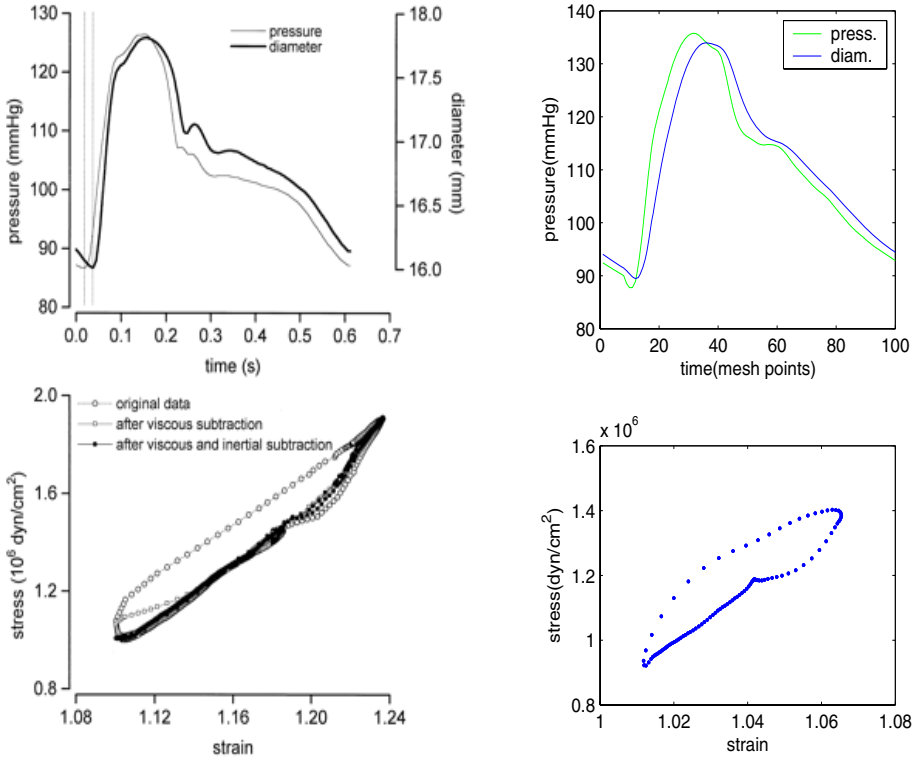

FIG. 8.1. *Left: Measured viscoelastic behavior of the canine aorta reported in* [1] *(top: aortic diameter and pressure wave forms, bottom: stress-strain relationship). Right: Numerical simulation of the reduced one-and-a-half-dimensional model showing viscoelastic behavior of vessel walls (top: aortic diameter and pressure wave forms, bottom: stress-strain relationship).*

bottom figures show the hysteresis behavior in the stress-strain relationship. The upper "half" of the hysteresis corresponds to the loading and the lower "half" to the unloading portion of the cardiac cycle. The hysteresis curves and the time-lag between the pressure and scaled diameter show similar qualitative behavior.

An even better approximation of the hysteresis behavior in the dynamics of major arteries was obtained for the data corresponding to a healthy human femoral artery. One reason for this is that the inlet and outlet pressure data that were used in all of our numerical simulations correspond to the human data. We compared our numerical simulations to the measurements data presented in [2]. In [2] Armentano et al. estimated the magnitude of the coefficient multiplying the term $\partial D/\partial t$, where D is the vessel diameter of a human femoral artery. The value of the coefficient was estimated to be $266 \times$ Pa $\cdot$ s/m. Using the values for the measured femoral artery diameter ($0.00625m$) and the wall thickness (0.001 m), one obtains

$$C_v|_{(\text{human femoral})} \approx 5.2 \times 10^3 \text{ Pa} \cdot \text{s}. \tag{8.2}$$

Thus, the corresponding viscous modulus hC_v/R is

$$\left.\frac{hC_v}{R}\right|_{(\text{human femoral})} \approx 1.6 \times 10^3 \text{ Pa} \cdot \text{s}, \tag{8.3}$$

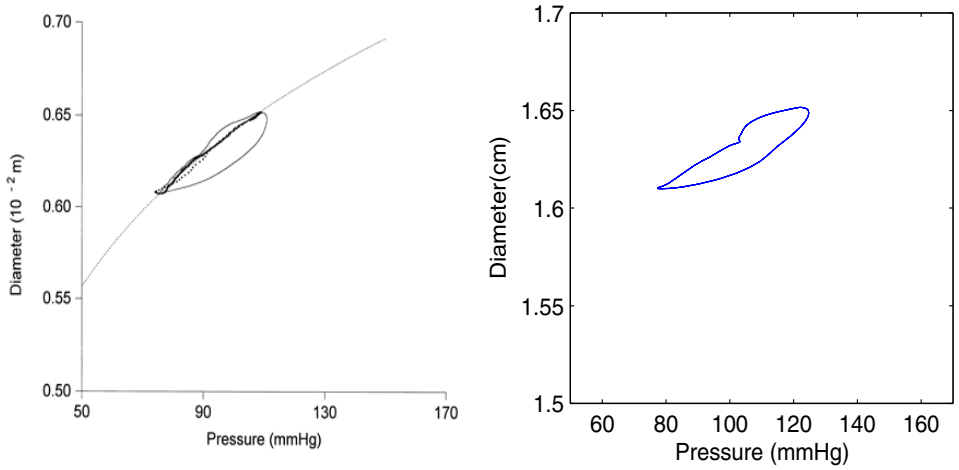

FIG. 8.2. *Left: Measurements of the diameter-pressure hysteresis loop in human femoral artery reported in* [2]. *Right: Numerical simulation of the diameter-pressure hysteresis loop with parameters from Table* 4.1 *($E = 1.3 \times 10^6$ Pa, $h = 0.001$ m, $R = 0.008$ m, $L = 0.13$ m, $hC_v/R = 10^3$ Pa · s).*

which is of the same order of magnitude as the viscous modulus corresponding to the dogs aortas. Figure 8.2 shows a comparison between our numerical simulations and measurements. There, a pressure-diameter relationship is plotted, showing hysteresis behavior. The graph in Figure 8.2(left) corresponds to the measurements of the human femoral artery reported in [2], and the graph in Figure 8.2(right) shows the pressure-diameter relationship in the simulations obtained using the reduced model (5.1), (5.6). Again, similar viscoelastic behavior is detected.

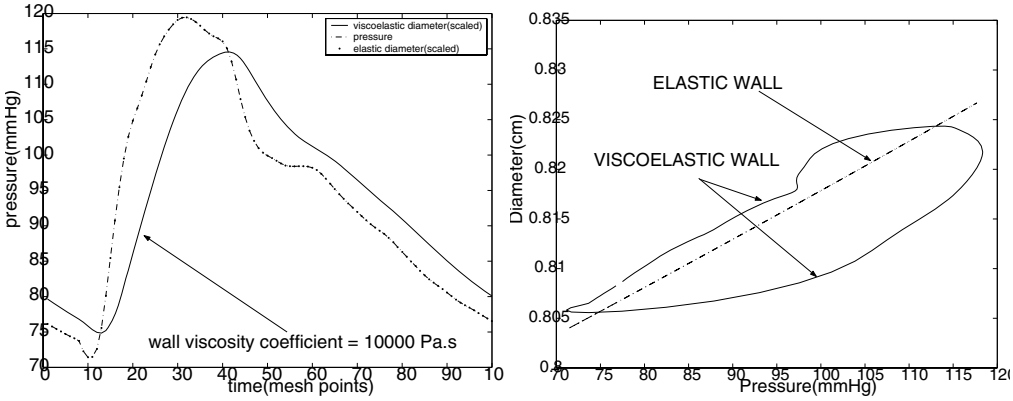

FIG. 9.1. *Elastic vs. viscoelastic wall model. The figure on the left shows the pressure and the scaled diameter (elastic and viscoelastic) over one cardiac cycle (the pressure wave and the elastic diameter coincide). The figure on the right shows the pressure-diameter plot for the viscoelastic model (hysteresis) and the elastic model (straight line).*

9. Elastic vs. viscoelastic model. We conclude this manuscript by presenting a comparison between the results of the fluid-structure interaction models assuming elastic vs. viscoelastic wall model with a relatively large viscoelastic constant $hC_v/R =$

10^4 Pa · s. Figure 9.1(left) shows the pressure and the scaled diameter values for the two models plotted over one cardiac cycle. One can easily detect the time-shift in the diameter of the viscoelastic model compared with the diameter of the elastic wall model which coincides (the scaled diameter) with the pressure wave. Figure 9.1(right) shows the pressure-diameter plot emphasizing the hysteresis in the viscoelastic model superimposed over the straight line pressure-diameter plot corresponding to the elastic model.

10. Conclusions. In this manuscript we derived a simple, effective closed model that describes blood flow through viscoelastic arteries in cylindrical geometry assuming axially symmetric flows. Using homogenization theory and asymptotic analysis, this fluid-structure interaction problem was reduced to a free-boundary problem of hyperbolic-parabolic type in two space dimensions. Although the model is two-dimensional, its simple form allows the use of one-dimensional solvers giving rise to a numerical algorithm of one-dimensional complexity. In contrast with the "classical" one-dimensional models where an ad hoc assumption on the axial velocity profile needs to be used to close the model, the system we obtained in this manuscript is closed, producing the axial as well as radial velocity as a solution of the problem. We showed that the reduced model approximates the original three-dimensional axially symmetric model to the ϵ^2-accuracy, where ϵ is the aspect ratio of the tube approximating straight arterial sections. The main novelty in this manuscript is the derivation of a viscoelastic cylindrical Koiter shell model to describe the behavior of arterial walls. Viscoelasticity of Kelvin–Voigt type was utilized to derive the model which appoximates well the hysteresis behavior observed in the vessel wall measurements. We showed that in this fluid-structure interaction model bending rigidity of arterial walls plays a nonnegligible role in the leading-order approximation of the problem. This effect, together with the viscosity of vessel walls, explicitly derived in this manuscript, provides the regularizing mechanisms for the stability of the solutions.

INVERSE BOUNDS AND BULK PROPERTIES OF COMPLEX-VALUED TWO-COMPONENT COMPOSITES*

CHRISTIAN ENGSTRÖM†

Abstract. The bulk properties of composites are known to depend strongly on the microstructure. This dependence can be quantified in terms of a representation introduced by D. Bergman, which factorizes the geometry dependence from the contrast. Based on this analytic representation of the effective permittivity, we present a general scheme to estimate the microstructural parameters such as the volume fraction and the anisotropy of two-component composites. The estimates are given as bounds, that is, the largest parameter region which is compatible with the available information. Thus, more information produces better estimates on the microstructural parameters. The method, which uses complex-valued measurements of bulk properties of the composite, is illustrated by numerical examples.

Key words. composite, inverse bounds, inverse homogenization, Stieltjes integral, Padé approximations

1. Introduction.

In many cases of interest when considering the interaction of electromagnetic waves with composites the wavelength is much longer than the characteristic length of the microstructure. The composite then reacts to the slowly varying field in much the same way as a homogeneous material, with some effective material parameters.

The determination of the effective properties of composite materials, with known periodic geometry or from simulations of random materials, constitutes a classical problem in physics. In the case of a two-component mixture, a representation formula that separate the dependence on the phases and the dependence on the microstructure was developed by Bergman [6] and Golden and Papanicolaou [22].

The structural information is associated with a spectral measure, and much effort has been focused on the reconstruction of this measure from a known geometry [24, 19, 29]. When the measure is calculated, a single integral gives the effective property for any value of the phases. One drawback is that a complete knowledge of the geometry rarely is available.

A direct approach to characterize the microstructure is in terms of an infinite set of correlation functions [4, 37]. Except for some special cases, the infinite set of correlation functions is not known, and hence an exact solution is not possible. Using images of cross sections, some correlation functions can be estimated. When the material is finely scaled, the computation of the volume fraction is a large computational problem, and calculations of higher-order correlation functions is in general very demanding.

Instead of using correlation functions, information from measurements of one effective property can be used to improve bounds on a related property. Prager [35] used measurements of the effective magnetic permeability to improve the bounds on

†Department of Electroscience, Lund Institute of Technology, P.O. Box 118, 221 00 Lund, Sweden (christian.engstrom@es.lth.se).

the thermal conductivity. These bounds are called cross-property bounds or coupled bounds. The pioneering work of Prager was followed by the papers of Bergman [5, 6] and Milton [33], among others. The problem of bounding the structural parameters that characterize the microstructure from known values of an effective property is by some authors called inverse homogenization, and the bounds are called inverse bounds.

Inverse bounds for the volume fraction were first derived in [31]. In recent years the representation formula introduced by Bergman [6] has been used to study the inverse problem. Explicit formulas for bounds on the volume fraction can in the case of measurements of lossy materials be found in [14]. If the measurements are on a real-valued effective property, the formulas for the volume fraction in [14] cannot be used. In the case of real-valued measurements the author in [21] provides a schedule to derive inverse bounds and give explicit formulas for bounds on the three lowest moments of the measure, where the first moment corresponds to the volume fraction.

Various inverse algorithms for recovering the structural parameters (the spectral measure) of composites from experimental data have been developed [15, 17, 13]. In [18] the algorithm developed in [17] was successfully used to recover the measure from 4000 reflectance data points.

The numerical algorithms are useful, but one disadvantage with this approach is that we lose the concept of bounds. If we have limited information from measurements (few or inaccurate measurements), the numerical methods cannot recover the measure. Using the numerical approximations of the measure can then result in bounds on an effective property that are not valid.

In this paper inverse bounds using information from measurements of lossy materials are derived. These bounds are used to derive cross-property bounds, which are exemplified by a frequency-dependent permittivity. We use and improve the geometry-independent bounds on the structural parameters that were derived in [21]. In other words, restrictions on the moments of the measure are derived.

The asymptotic behavior of the formulas in this paper is superior to the formulas in [21], but the formulas presented here cannot be used if the effective property is real-valued. The two papers complement each other, and the formulas in the two papers can be combined.

2. Bounds on the effective permittivity. Assume that inside the composite the electric field $\boldsymbol{E}$ and the electric flux density $\boldsymbol{D}$ satisfy the constitutive relation

$$\boldsymbol{D}(\boldsymbol{x}) = \boldsymbol{\epsilon}(\boldsymbol{x})\boldsymbol{E}(\boldsymbol{x}). \tag{2.1}$$

The permittivity matrix $\boldsymbol{\epsilon}$ is the description of the material on the fine scale, where $\boldsymbol{\epsilon}$ and thereby the fields oscillate rapidly. On a much larger scale the averaged fields have no oscillations on the length scale of the microstructure, since they are smoothed out, but they retain slow macroscopic variations.

We seek an effective permittivity matrix $\boldsymbol{\epsilon}^{\text{eff}}$ which relates the average of the electric displacement field $\langle \boldsymbol{D} \rangle$ to the average of the electric field $\langle \boldsymbol{E} \rangle$. The average is over a volume having large size compared with the microstructure.

In general the $\boldsymbol{D}$-field satisfies $\nabla \cdot \boldsymbol{D} = \rho$, where ρ is the charge density. Using for example a two-scale expansion [2, p. 138] of Maxwell's equations, we have $\nabla \times \boldsymbol{E} = 0$.

From the constitutive relation (2.1) it follows that, for a charge-free region, the $\boldsymbol{E}$-field satisfies

$$\nabla \times \boldsymbol{E} = 0, \quad \nabla \cdot (\boldsymbol{\epsilon}\boldsymbol{E}) = 0. \tag{2.2}$$

This system represents, besides dielectrics, several other physical phenomena such as electrical and thermal conductivity, magnetism, diffusion, and flow in porous media.

Let $\langle \boldsymbol{\Psi} \rangle$ denote the average of the vector field $\boldsymbol{\Psi}$ over the unit cell $\mathrm{U} = [0,1[^d$ in d dimensions. If the $\boldsymbol{E}$-field is Lebesgue integrable and the equations (2.2) are satisfied in a weak sense, the homogenization rule

$$\langle \boldsymbol{\epsilon} \boldsymbol{E} \rangle = \boldsymbol{\epsilon}^{\mathrm{eff}} \langle \boldsymbol{E} \rangle \tag{2.3}$$

can be proven [25, p. 15].

The materials in this paper are assumed to be d-dimensional and to consist of two homogeneous, isotropic phases. The two-component material is locally modelled by the scalar relative permittivity

$$\epsilon(\epsilon_1, \epsilon_2) = \epsilon_1 \chi_1(\boldsymbol{x}) + \epsilon_2 \chi_2(\boldsymbol{x}), \tag{2.4}$$

where the components are isotropic with constant permittivity ϵ_1 and ϵ_2. We use complex-valued permittivities and assume that the imaginary parts are greater than or equal to zero.

The volume fraction of phase χ_i is denoted f_i, and the characteristic function χ_i is defined as

$$\chi_i(\boldsymbol{x}) = \begin{cases} 1, & \boldsymbol{x} \text{ in phase } i, \\ 0 & \text{otherwise} \end{cases}$$

and $f_1 + f_2 = 1$. When the composite is periodic and the characteristic function χ_1 is known, we can calculate $\boldsymbol{\epsilon}^{\mathrm{eff}}$ from (2.2), (2.3) using a standard finite element program, but in many cases the geometry is unknown. Another drawback with this approach is that the problem (2.2), (2.3) depends not only on the microstructure but also on the contrast. If we change the contrast, all calculations need to be repeated.

2.1. Analytic representation of the effective matrix. Due to the homogeneity property $\epsilon^{\mathrm{eff}}(c\epsilon_1, c\epsilon_2) = c\epsilon^{\mathrm{eff}}(\epsilon_1, \epsilon_2)$, the effective permittivity depends on the ratio ϵ_1/ϵ_2. The main property of the solution to the problem in (2.2) and (2.3) is that the function

$$\frac{\boldsymbol{\epsilon}^{\mathrm{eff}}(\epsilon_1, \epsilon_2)}{\epsilon_2} = \boldsymbol{\epsilon}^{\mathrm{eff}} \left(\frac{\epsilon_1}{\epsilon_2}, 1 \right) \tag{2.5}$$

is analytic in $\epsilon_1/\epsilon_2 \in \mathbb{C} \backslash]-\infty, 0]$ and that it maps the upper half-plane to the upper half-plane; i.e., the function $\boldsymbol{\epsilon}^{\mathrm{eff}}/\epsilon_2$ is a Herglotz function [1]. The function $\boldsymbol{\epsilon}^{\mathrm{eff}}/\epsilon_2$ has the Stieltjes-integral representation

$$\boldsymbol{\epsilon}^{\mathrm{eff}}(\epsilon_1, \epsilon_2) = \epsilon_2 \mathbf{I} - \epsilon_2 \mathbf{G}(s), \tag{2.6}$$

where

$$\mathbf{G}(s) = \int_0^1 \frac{\mathrm{d}\mathbf{m}(y)}{s - y}, \quad s = \frac{\epsilon_2}{\epsilon_2 - \epsilon_1}. \tag{2.7}$$

The matrix-valued measure $\mathbf{m}$ on $[0,1]$ is derived from the spectral measure of the operator $\Gamma = P\chi_1$, where $P = \nabla(-\Delta)^{-1}(\nabla\cdot)$. The operator Γ is bounded $||\Gamma|| \leq 1$ and self-adjoint in $L^2(\mathrm{U})^d$ equipped with the scalar product $(\boldsymbol{\Psi}_1, \boldsymbol{\Psi}_2) = \langle \chi_1 \boldsymbol{\Psi}_1 \cdot \boldsymbol{\Psi}_2 \rangle$ [22].

The representation formula (2.6), valid for $s \notin [0,1]$, was derived for the periodic case in [6] and in the general case in [22].

The measure $\mathbf{m}$ is a purely geometric quantity. It depends on the microstructure but not on the value of the two phases. If the microstructure is the same, the single integral (2.7) gives the effective permittivity, independent of the value of the phases. This is particularly useful when the permittivity is frequency- or temperature-dependent.

2.2. Bounds on $\boldsymbol{\epsilon}^{\mathbf{eff}}$ using Padé approximations. If the microstructure is only partly known, we can get bounds on the effective permittivities. When the permittivities of the two materials, together with the volume fraction f_1, are known, the effective permittivity is bounded by the harmonic and arithmetic means. If more structural information is known, we get tighter bounds such as the Hashin–Shtrikman bounds and the Beran bounds.

We focus on the diagonal elements in the effective permittivity matrix and use the power series expansion

$$\boldsymbol{\epsilon}^{\mathrm{eff}} = \epsilon_2 \mathbf{F}(z), \quad \mathbf{F}(z) = \sum_{n=0}^{\infty} \mathbf{c}_n z^n, \tag{2.8}$$

where $z = -1/s = (\epsilon_1 - \epsilon_2)/\epsilon_2$ is the contrast. The series (2.8) is convergent in $|z| < 1$.

The integral (2.7) vanishes in the limit $s \to \infty$, implying $\mathbf{c}_0 = \mathbf{I}$. This is a consequence of (2.8), because $z = 0$ when $\epsilon_1 = \epsilon_2$, which means that we have only one material.

For $|s| > 1$ the function $(s-y)^{-1}$ has a power expansion in y/s. The integral $\mathbf{G}(s)$ then has the power expansion

$$\mathbf{G}(s) = \sum_{n=0}^{\infty} \frac{1}{s^{n+1}} \int_0^1 y^n \, \mathrm{d}\mathbf{m}(y). \tag{2.9}$$

The integral in this expression is, for $n = 0, 1, \ldots$, the (Hausdorff) moments of the measure $\mathbf{m}$. The coefficients $\mathbf{c}_n$ in the power series expansion (2.8) and the measure $\mathbf{m}$ are connected by the moments

$$\mathbf{c}_{n+1} = (-1)^n \int_0^1 y^n \, \mathrm{d}\mathbf{m}(y). \tag{2.10}$$

Since the measure $\mathbf{m}$ is defined on the compact set $[0,1]$ it follows that $\mathbf{m}$ is bounded and uniquely determined by the moments [1]. If all the moments are known, the effective matrix is obtained from the series (2.8). Thus, the local information about $\epsilon_1 = \epsilon_2$ gives the effective permittivity independent of the contrast.

The volume fraction f_1 is given by the total weight [6, 22]

$$\mathbf{c}_1 = \int_0^1 \mathrm{d}\mathbf{m}(y) = f_1 \mathbf{I}. \tag{2.11}$$

Higher-order moments depend on the geometrical structure. Bergman [6] derived the general constraint $\operatorname{Tr} \mathbf{c}_2 = -c_1(1-c_1)$ and that, in the case of a statistically isotropic composite, the second moment is

$$\mathbf{c}_2 = -\int_0^1 y \, \mathrm{d}\mathbf{m}(y) = -\frac{c_1(1-c_1)}{d}\mathbf{I}. \tag{2.12}$$

Higher-order moments can be calculated exactly in a few special cases; see, for instance, [16] or [19].

The power series (2.8) with coefficients given by the moments (2.10) defines a series of Stieltjes. Series of Stieltjes have known upper and lower bounds in the form of continued fractions or Padé approximations [1]. We use Padé approximations of the power series (2.8).

Let ϵ^{eff} be one of the diagonal elements in the matrix $\boldsymbol{\epsilon}^{\text{eff}} = \epsilon_2\mathbf{F}(z)$. The $\epsilon_{p,q}$ Padé approximant to ϵ^{eff} is defined by the equation

$$\epsilon^{\text{eff}}(z)Q(z) - P(z) = \mathcal{O}(z^{p+q+1}), \tag{2.13}$$

where P and Q are polynomials of degree at most p and q, respectively [1]. This equation gives us an approximation of the effective permittivity by the rational function

$$\epsilon_{p,q} = \frac{P(z)}{Q(z)} = \frac{a_0 + \cdots + a_p z^p}{1 + b_1 z + \cdots + b_q z^q}. \tag{2.14}$$

When $\epsilon_2 > \epsilon_1$ and $N \geq 1$, the N-point upper bounds $\boldsymbol{\epsilon}_N^{\text{U}}$ are obtained by forming the approximations

$$\boldsymbol{\epsilon}_{2M+1}^{\text{U}} = \epsilon_2\boldsymbol{\epsilon}_{M+1,M}(\mathbf{F}), \quad \boldsymbol{\epsilon}_{2M}^{\text{U}} = \epsilon_2\boldsymbol{\epsilon}_{M,M}(\mathbf{F}). \tag{2.15}$$

The inverse of the matrix $\boldsymbol{\epsilon}^{\text{eff}}(\epsilon_1/\epsilon_2, 1)$ is analytic in $\epsilon_1/\epsilon_2 \in \mathbb{C}\backslash]-\infty, 0]$. The analyticity implies that it has a power series expansion in z. Lower bounds on $\boldsymbol{\epsilon}^{\text{eff}}$ are given from Padé approximations of the series

$$\left(\frac{\boldsymbol{\epsilon}^{\text{eff}}}{\epsilon_1}\right)^{-1} = \tilde{\mathbf{F}}(z), \quad \text{where} \quad \tilde{\mathbf{F}}(z) = \sum_{n=0}^{\infty} \tilde{\mathbf{c}}_n z^n. \tag{2.16}$$

The coefficients $\mathbf{c}_n$ and $\tilde{\mathbf{c}}_n$ in the two series are related according to

$$\tilde{\mathbf{c}}_0 = \mathbf{I}, \quad \tilde{\mathbf{c}}_1 = (1 - c_1)\mathbf{I}, \quad \tilde{\mathbf{c}}_n = -\sum_{k=0}^{n-1} \tilde{\mathbf{c}}_k \mathbf{c}_{n-k}. \tag{2.17}$$

The coefficient c_1 is the volume fraction of phase one (2.11) and $\tilde{c}_1$ is the volume fraction of phase two. The N-point lower bounds $\boldsymbol{\epsilon}_N^{\text{L}}$, when $\epsilon_2 > \epsilon_1$ and $N \geq 1$, are obtained from

$$\boldsymbol{\epsilon}_{2M+1}^{\text{L}} = \epsilon_1[\boldsymbol{\epsilon}_{M+1,M}(\tilde{\mathbf{F}})]^{-1}, \quad \boldsymbol{\epsilon}_{2M}^{\text{L}} = \epsilon_1[\boldsymbol{\epsilon}_{M,M}(\tilde{\mathbf{F}})]^{-1}. \tag{2.18}$$

For example the $\boldsymbol{\epsilon}_{1,0}$ Padé approximant of the expansion (2.16) is the harmonic mean

$$\boldsymbol{\epsilon}_1^{\text{L}} = \frac{\epsilon_1}{1 + \tilde{c}_1 z}\mathbf{I} = \left(\frac{f_1}{\epsilon_1} + \frac{f_2}{\epsilon_2}\right)^{-1}\mathbf{I} \tag{2.19}$$

and the $\boldsymbol{\epsilon}_{1,0}$ Padé approximant of (2.8) gives the arithmetic mean

$$\boldsymbol{\epsilon}_1^{\text{U}} = (\epsilon_2 + c_1\epsilon_2 z)\mathbf{I} = (f_1\epsilon_1 + f_2\epsilon_2)\mathbf{I}. \tag{2.20}$$

Wiener [41] first derived these bounds on an effective material parameter. In the same way the $\boldsymbol{\epsilon}_{1,1}$ Padé approximant of the expansion (2.16) is the lower bound

$$\boldsymbol{\epsilon}_2^{\text{L}} = \epsilon_1[\tilde{c}_1\mathbf{I} - \tilde{\mathbf{c}}_2 z][\tilde{c}_1\mathbf{I} - \tilde{\mathbf{c}}_2 z + \tilde{c}_1^2 z\mathbf{I}]^{-1}, \tag{2.21}$$

where $\tilde{\mathbf{c}}_2 = -\mathbf{c}_2 - c_1\tilde{c}_1\mathbf{I}$. The $\boldsymbol{\epsilon}_{1,1}$ Padé approximant of (2.8) gives the upper bound

$$\boldsymbol{\epsilon}_2^{\mathrm{U}} = \epsilon_2[c_1\mathbf{I} - \mathbf{c}_2 z + c_1^2 z\mathbf{I}][c_1\mathbf{I} - \mathbf{c}_2 z]^{-1}. \tag{2.22}$$

These bounds were first derived in [33]; see also [28, 39].

In the isotropic case, $\mathbf{c}_2 = -(c_1\tilde{c}_1/d)\mathbf{I}$, the two-point bounds (2.21) and (2.22) are equivalent to the Hashin–Shtrikman bounds [23], and the bounds $\boldsymbol{\epsilon}_3^{\mathrm{L}}, \boldsymbol{\epsilon}_3^{\mathrm{U}}$ reduce to the Beran bounds [3, 38]. The Padé approximations give a hierarchy of bounds that become progressively narrower as more structural information is used [34, 1, 40, 11]. The bounds (2.21) and (2.22) are optimal, since they are attained for a variety of geometries [7, 32]. In general, the bounds on the effective permittivity (2.15) and (2.18) can be improved by incorporating phase exchange relations. Milton [32] first exploited the phase exchange equality in two dimensions [26] for derivation of bounds, and Bergman [9, 10] first used the phase exchange inequality in three dimensions [36] to improve bounds on the effective permittivity.

2.3. Complex bounds on the permittivity. Let c_n be one of the diagonal elements in $\mathbf{c}_n$. In the general case when the values of the phases are complex, the real segment $l = \{c_n;\, c_n^{\min} \le c_n \le c_n^{\max}\}$ is for fixed values on $c_1, c_2, \ldots, c_{n-1}$ mapped by $\epsilon_n^{\mathrm{L}}(c_n)$ and $\epsilon_n^{\mathrm{U}}(c_n)$ on a circle or a line segment.

The minimum $c_n^{\min}$ and the maximum $c_n^{\max}$ are functions of the lower-order parameters $c_1, c_2, \ldots, c_{n-1}$. The extreme values can be determined by varying the c_n parameter in the n-point bounds and using that the n-point bounds are forbidden to violate the $(n-1)$-point bounds. This procedure was used in [21].

For example, we get complex bounds from the lens-shaped region bounded by

$$\epsilon_2^{\mathrm{L}}(\tilde{c}_2; \epsilon_1, \epsilon_2, \tilde{c}_1), \quad \epsilon_2^{\mathrm{U}}(c_2; \epsilon_1, \epsilon_2, c_1) \tag{2.23}$$

with the structural parameter $\tilde{c}_2$ and c_2 varying between

$$c_2^{\min} = -c_1(1 - c_1), \quad c_2^{\max} = 0. \tag{2.24}$$

Alternatively, we can describe the bounds $\epsilon_n^{\mathrm{L}}(c_n)$ and $\epsilon_n^{\mathrm{U}}(c_n)$ in terms of the points through which the circle passes [8, 33]. Let $\mathrm{Arc}(z_0, z_1, z_2)$ denote the arc of a circle joining the points z_0 and z_1 that when extended passes through z_2. For example, the effective permittivity ϵ^{eff} is in the complex case bounded by the intersection of the circles

$$\mathrm{Arc}(\epsilon_1, \epsilon_1^{\mathrm{L}}, \epsilon_1^{\mathrm{U}}), \quad \mathrm{Arc}(\epsilon_2, \epsilon_1^{\mathrm{L}}, \epsilon_1^{\mathrm{U}}). \tag{2.25}$$

We have $\epsilon_2^{\mathrm{L}} \to \epsilon_1$ and $\epsilon_2^{\mathrm{U}} \to \epsilon_2$ when $c_2 \to -\infty$. It follows that in terms of the structural parameters c_2, the circles are described by

$$\mathrm{Arc}(\epsilon_2^{\mathrm{L}}(-\infty), \epsilon_2^{\mathrm{L}}(c_2^{\min}), \epsilon_2^{\mathrm{L}}(c_2^{\max})), \quad \mathrm{Arc}(\epsilon_2^{\mathrm{U}}(-\infty), \epsilon_2^{\mathrm{U}}(c_2^{\min}), \epsilon_2^{\mathrm{U}}(c_2^{\max})). \tag{2.26}$$

The arcs (2.25) or (2.26), defining the points through which the circles pass, provide a geometrical characterization of the bounds. The alternative representation of the arcs (2.23) gives, in terms of c_2, directly a parameterization of the lens-shaped boundary.

3. Inverse bounds and bulk properties. The task in inverse homogenization is to calculate the structural parameters $\mathbf{c}_n$, or equally, the measure $\mathbf{m}$, given information from experiments.

When only measured values of the effective permittivity are known, the moments cannot be determined. Given a finite number of measurements, there exist in general several geometries that give the same $\boldsymbol{\epsilon}^{\text{eff}}$. Moreover, any measurement contains noise, which limits the accuracy.

The measurements can be on one effective property of the material at different temperatures or in a range of frequencies. It is also possible to get information from measurements of several related parameters such as the permittivity, the permeability, and the thermal conductivity. The important thing is that the microstructure is the same.

Bounds on the volume fraction c_1, using information from measurements, were derived in [31, 14, 21]. In [14], the authors derived bounds on the volume fraction that are valid in the general anisotropic case and tighter bounds on the volume fraction when the material is statistically isotropic.

We focus on the diagonal elements in $\mathbf{c}_n$ and provide a method to derive bounds on any diagonal element c_n. Moreover, we give examples where c_1, c_2, and c_3 are bounded, using information from measurements. We assume that the measurements are on the effective permittivity ϵ^{eff} at different frequencies $\omega_0, \omega_1, \ldots, \omega_n$, although the measurements could very well pertain to several other physical parameters associated with the same microstructure [34].

The bounds on the structural parameters c_n give geometrical information about the composite, but in many cases the composite's effective bulk properties as a function of frequency or temperature is what is desired. The bounds on the structural parameters imply cross-property bounds on the effective properties, which gives bounds on the effective permittivity at all frequencies where the homogenization theory is valid.

3.1. Geometry-independent inverse bounds. The volume fraction $f_1 = c_1$ is bounded between zero and one. The higher-order parameters depend on the geometry, and bounds on c_n are not known a priori. In the general anisotropic case, the parameter c_2 is bounded by

$$-c_1\tilde{c}_1 \leq c_2 \leq 0, \tag{3.1}$$

where $\tilde{c}_1 = 1 - c_1$. This geometry-independent bound on c_2 was proven in [12]. The author uses properties of the scalar measure $m(y)$ to derive the moment constraint

$$0 \leq \int_0^1 y \, \mathrm{d}m(y) \leq f_1 f_2, \tag{3.2}$$

which is equivalent to (3.1); see also [6, 27, 37, 21].

In [21] the author provides a general scheme to derive bounds on the structural parameter c_n, using lower-order parameters; see section 2.3 for the connection to complex bounds. The bounds on the c_n-parameters depend on the lower-order parameters $c_1, \ldots, c_{n-1}$.

Here, we use that c_3 is bounded by $c_3^{\min} \leq c_3 \leq c_3^{\max}$ with [21]

$$c_3^{\min} = \frac{c_2^2}{c_1}, \quad c_3^{\max} = -c_2\left(1 + \frac{c_2}{\tilde{c}_1}\right) \tag{3.3}$$

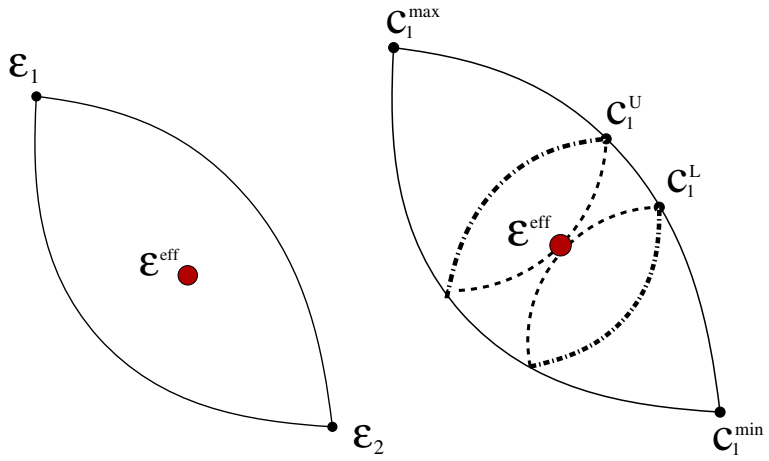

FIG. 1. *Left: The effective permittivity* ϵ^{eff} *is bounded by* $\epsilon_1^{\text{L}}(c_1)$ *and* $\epsilon_1^{\text{U}}(c_1)$. *Right: For some value* $c_1 = c_1^{\text{L}}$, *the effective permittivity* ϵ^{eff} *is on the boundary of* $\epsilon_2^{\text{L}}(c_2; c_1^{\text{L}}, \omega_0)$, $\epsilon_2^{\text{U}}(c_2; c_1^{\text{L}}, \omega_0)$ *and for some value* $c_1 = c_1^{\text{U}}$, *the effective permittivity is on the boundary of* $\epsilon_2^{\text{L}}(c_2; c_1^{\text{U}}, \omega_0)$, $\epsilon_2^{\text{U}}(c_2; c_1^{\text{U}}, \omega_0)$.

and that the structural parameter c_4 is bounded by $c_4^{\min} \leq c_4 \leq c_4^{\max}$, where [21]

$$c_4^{\min} = \frac{c_2^3 + \tilde{c}_1 c_2^2 + c_2 c_3(\tilde{c}_1 - c_1) + c_3(c_3 - c_1\tilde{c}_1)}{c_2 + c_1\tilde{c}_1}, \quad c_4^{\max} \leq \frac{c_3^2}{c_2}. \tag{3.4}$$

3.2. Bounds using one measurement. Assume that the complex value of one effective parameter $\epsilon^{\text{eff}}(\omega_0)$ is measured for some frequency ω_0. We derive bounds on c_1, together with bounds on the effective parameter $\epsilon^{\text{eff}}(\omega_1)$, when $\epsilon_1(\omega_0)$, $\epsilon_2(\omega_0)$, $\epsilon_1(\omega_1)$, and $\epsilon_2(\omega_1)$ are known constants. If the volume fraction c_1 is known, the parameter c_2 is bounded, and so on.

We assume that at least one of the phases has a positive imaginary part. That is, we assume that there are losses somewhere in the composite material. In the case of real values of both the phases, the method developed in [21] can be used to obtain bounds on c_1 and on ϵ^{eff}. In the lossless case, a direct calculation of the inverse of $\epsilon_1^{\text{L}}(c_1)$ and $\epsilon_1^{\text{U}}(c_1)$ is possible. When the measurements are complex-valued, a different approach is needed.

The measured value $\epsilon^{\text{eff}}(\omega_0)$ is inside the lens-shaped region bounded by

$$\epsilon_1^{\text{L}}(c_1; \omega_0) = \frac{1}{1 + \tilde{c}_1 z(\omega_0)}, \quad \epsilon_1^{\text{U}}(c_1; \omega_0) = \epsilon_1(\omega_0) + c_1 \epsilon_2(\omega_0) z(\omega_0), \tag{3.5}$$

with $z(\omega_0) = (\epsilon_1(\omega_0) - \epsilon_2(\omega_0))/\epsilon_2(\omega_0)$, $\tilde{c}_1 = 1 - c_1$, and $0 \leq \tilde{c}_1 \leq 1$. The boundary of the region is depicted in Figure 1.

For some values of c_1 and c_2, the effective parameter $\epsilon^{\text{eff}}(\omega_0)$ is on the curve $\epsilon_2^{\text{U}}(c_2, c_1; \omega_0)$; see Figure 1. The parameters c_1 and c_2 then solve the equation

$$\epsilon^{\text{eff}}(\omega_0) = \epsilon_2(\omega_0) \frac{c_1 - c_2 z(\omega_0) + c_1^2 z(\omega_0)}{c_1 - c_2 z(\omega_0)}, \tag{3.6}$$

with $0 \leq c_1 \leq 1$ and $-c_1\tilde{c}_1 \leq c_2 \leq 0$. We show below that (3.6) has one solution (c_1, c_2), except for trivial cases.

At the minimum volume fraction $c_1 = 0$ and at the maximum volume fraction $c_1 = 1$, the ϵ_2^{U}-bound reduces to

$$\epsilon_2^{\mathrm{U}}(0, c_2) = \epsilon_2^{\mathrm{U}}(0, 0) = \epsilon_1^{\mathrm{U}}(0) = \epsilon_2, \quad \epsilon_2^{\mathrm{U}}(1, c_2) = \epsilon_2^{\mathrm{U}}(1, 0) = \epsilon_1^{\mathrm{U}}(1) = \epsilon_1, \tag{3.7}$$

which implies that (3.6) has the solutions

$$\epsilon_2 = \epsilon_2^{\mathrm{U}}(0, 0) = \epsilon^{\mathrm{eff}}, \quad \epsilon_1 = \epsilon_2^{\mathrm{U}}(1, 0) = \epsilon^{\mathrm{eff}}. \tag{3.8}$$

By multiplying (3.6) with the denominator in ϵ_2^{U} we obtain

$$(c_1 - c_2 z)\epsilon^{\mathrm{eff}} = \epsilon_2(c_1 - c_2 z + c_1^2 z^2). \tag{3.9}$$

We assume that $\epsilon^{\mathrm{eff}} \neq \epsilon_1$ and look for solutions to (3.9) when $0 \leq c_1 \leq 1$ and $-c_1\tilde{c}_1 \leq c_2 \leq 0$. Taking the real and imaginary part of (3.9), which is quadratic in c_1 and linear in c_2, gives one solution (c_1, c_2), except for the trivial solution $(c_1, c_2) = (0, 0)$.

The calculated value on c_1 is a lower bound $c_1^{\mathrm{L}}(\omega_0)$ on the volume fraction c_1. Explicitly, the volume fraction is bounded from below by

$$c_1^{\mathrm{L}} = \Im(z)\frac{(\Im(\epsilon^{\mathrm{eff}}) - \Im(\epsilon_2))^2 + (\Re(\epsilon^{\mathrm{eff}}) - \Re(\epsilon_2))^2}{|z|^2(\Im(\epsilon^{\mathrm{eff}})\Re(\epsilon_2) - \Re(\epsilon^{\mathrm{eff}})\Im(\epsilon_2))}. \tag{3.10}$$

In the same way, for some values of $\tilde{c}_1$ and $\tilde{c}_2$, the effective parameter $\epsilon^{\mathrm{eff}}(\omega_0)$ is on the curve $\epsilon_2^{\mathrm{L}}(\tilde{c}_2, \tilde{c}_1; \omega_0)$. That is, we solve the equation

$$\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_1(\omega_0)\frac{\tilde{c}_1 - \tilde{c}_2 z(\omega_0)}{\tilde{c}_1 - \tilde{c}_2 z(\omega_0) + \tilde{c}_1^2 z(\omega_0)} \tag{3.11}$$

when $0 \leq \tilde{c}_1 \leq 1$ and $-\tilde{c}_1(1 - \tilde{c}_1) \leq \tilde{c}_2 \leq 0$. Equation (3.11) has one solution (c_1, c_2), except for the trivial cases below.

At the endpoints $(c_1, c_2) = (0, 0)$ and $(c_1, c_2) = (1, 0)$, (3.11) has the solutions

$$\epsilon_1 = \epsilon_2^{\mathrm{L}}(0, 0) = \epsilon^{\mathrm{eff}}, \quad \epsilon_2 = \epsilon_2^{\mathrm{L}}(1, 0) = \epsilon^{\mathrm{eff}}. \tag{3.12}$$

Assume that $\epsilon^{\mathrm{eff}} \neq \epsilon_2$, and multiply (3.11) with the denominator in ϵ_2^{L}. The resulting equation has one solution, except for the trivial solution $(\tilde{c}_1, \tilde{c}_2) = (0, 0)$.

The solution to the equation $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_2^{\mathrm{L}}(\tilde{c}_1, \tilde{c}_2)$ and the relation $c_1 = 1 - \tilde{c}_1$ give an upper bound $c_1^{\mathrm{U}}(\omega_0)$ on the volume fraction c_1. Explicitly, the volume fraction is bounded from above by

$$c_1^{\mathrm{U}} = 1 - \Im(z)\frac{(\Im(\epsilon^{\mathrm{eff}}) - \Im(\epsilon_1))^2 + (\Re(\epsilon^{\mathrm{eff}}) - \Re(\epsilon_1))^2}{|z|^2(\Re(\epsilon^{\mathrm{eff}})\Im(\epsilon_1) - \Im(\epsilon^{\mathrm{eff}})\Re(\epsilon_1))}. \tag{3.13}$$

The derived bounds (3.10) and (3.13) on the volume fraction are equivalent to the bounds in [14]. Here we use a different method, which seems to be easier to generalize.

If $c_1 = c_1^{\mathrm{L}}$, the measured value $\epsilon^{\mathrm{eff}}(\omega_0)$ is equal to ϵ_2^{U} for some value of c_2. If $c_1 = c_1^{\mathrm{U}}$, the effective permittivity $\epsilon^{\mathrm{eff}}(\omega_0)$ is equal to ϵ_2^{L} for some value on c_2. The effective permittivity is bounded by the one-point bounds $\epsilon_1^{\mathrm{L}}(c_1)$ and $\epsilon_1^{\mathrm{U}}(c_1)$. From the calculations above and Figure 1, it follows that the effective permittivity also is bounded by the two-point bounds

$$\epsilon_2^{\mathrm{L}}(c_2, c_1^{\mathrm{L}}), \quad \text{with} \quad -c_1^{\mathrm{L}}(1 - c_1^{\mathrm{L}}) \leq c_2 \leq 0 \tag{3.14}$$

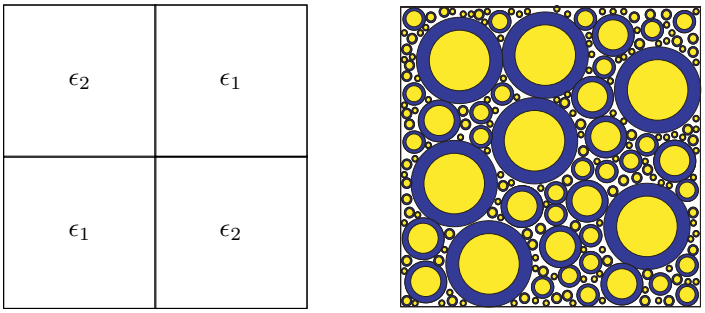

FIG. 2. *Left: The checkerboard structure, a two-dimensional and periodic problem. Right: The Hashin structure. Coated spheres that are composed of a spherical core of permittivity ϵ_2 are surrounded by a concentric shell of permittivity ϵ_1.*

and

$$\epsilon_2^{\mathrm{U}}(c_2, c_1^{\mathrm{U}}), \quad \text{with} \quad -c_1^{\mathrm{U}}(1 - c_1^{\mathrm{U}}) \leq c_2 \leq 0. \tag{3.15}$$

These bounds can, for example, be used to check the volume fraction in experiments when it is difficult to determine the volume fraction from direct measurements. If we measure the lossy permittivity for more than one frequency, the minimum of the calculated bounds on c_1 is the optimal.

3.2.1. Asymptotic behavior. Write c_2 on the form $c_2 = -\alpha c_1 \tilde{c}_1$, $0 \leq \alpha \leq 1$, and let $\epsilon_1 = 1$ and $\epsilon_2 = 1 + \delta w$, where w is a complex number with nonzero imaginary part and modulus one. Using the expansion (2.8), the asymptotic behavior when $\delta \to 0$ is

$$c_1^{\mathrm{U}} - c_1^{\mathrm{L}} = c_1 \hat{c}_1 \alpha (1 - \alpha) \delta^2 + \mathcal{O}(\delta^3). \tag{3.16}$$

For a fixed δ, the difference is small when the c_2 parameter is close to the endpoints (3.1) and when the volume fraction $c_1 = f_1$ is close to its endpoints.

In the case of real-valued phases, the parameter c_1 is bounded by [21]

$$c_1^{\mathrm{L}} = \frac{1/\epsilon^{\mathrm{eff}} - 1/\epsilon_2}{1/\epsilon_1 - 1/\epsilon_2}, \quad c_1^{\mathrm{U}} = \frac{\epsilon_2 - \epsilon^{\mathrm{eff}}}{\epsilon_2 - \epsilon_1}. \tag{3.17}$$

To proceed, let $\epsilon_1 = 1$ and $\epsilon_2 = 1 + \delta$. Using the expansion (2.8), the asymptotic behavior when $\delta \to 0$ is in the lossless case given by

$$c_1^{\mathrm{U}} - c_1^{\mathrm{L}} = c_1 \hat{c}_1 \delta + \mathcal{O}(\delta^2). \tag{3.18}$$

The convergence is faster in the complex-valued case, which in many cases of interest implies much tighter bounds on the volume fraction. One interpretation of the result is that a measurement of a complex value contains more information compared to a measurement of a real value.

3.2.2. Examples. As a first illustration of the theory presented above, assume that one of the phases is a frequency-independent material $\epsilon_1(\omega) = 3$ in the chosen range of frequencies. Moreover, phase two is lossy and measured at the frequencies ω_0, ω_1, and ω_2. We use the checkerboard structure and the Hashin structure; see Figure 2 to exemplify the method.

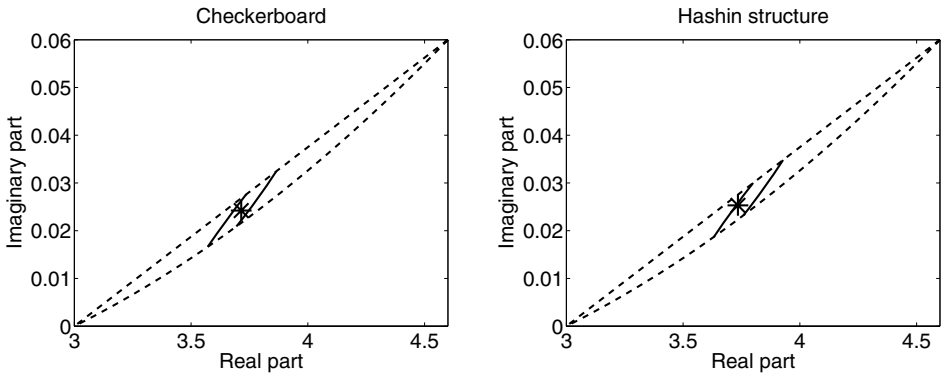

FIG. 3. *The star to the left is the effective permittivity in the checkerboard case and the star to the right corresponds to* ϵ^{eff} *for the Hashin structure. In both figures, the dashed lines* $\epsilon_1^{\text{L}}(c_1)$ *and* $\epsilon_1^{\text{U}}(c_1)$ *bound* $\epsilon^{\text{eff}}(\omega_1)$ *and the solid lines are the tighter bounds* $\epsilon_2^{\text{L}}(c_2; c_1^{\text{L}})$ *and* $\epsilon_2^{\text{U}}(c_2; c_1^{\text{U}})$.

Phase two has the value $\epsilon_2(\omega_0) = 4.1 + 4.5\text{i}$ at frequency ω_0. The checkerboard structure has the exact effective permittivity [34]

$$\epsilon_{\text{C}}^{\text{eff}}(\omega) = \sqrt{\epsilon_1(\omega)\epsilon_2(\omega)}. \tag{3.19}$$

It is interesting to notice that the checkerboard structure corresponds exactly to Bruggemans formula [34] at the percolation threshold $c_1 = 0.5$.

As described above, the solutions of the equations $\epsilon_{\text{C}}^{\text{eff}} = \epsilon_2^{\text{L}}$ and $\epsilon_{\text{C}}^{\text{eff}} = \epsilon_2^{\text{U}}$ bound the volume fraction c_1. Figure 3 shows the bounds on $\epsilon_{\text{C}}^{\text{eff}}(\omega_1)$ when $\epsilon_2(\omega_1) = 4.6{+}0.06\text{i}$ is known and the bounds on c_1 are calculated to $c_1^{\text{L}}(\omega_0) = 0.46$ and $c_1^{\text{U}}(\omega_0) = 0.54$. The exact value on the volume fraction is $c_1 = 0.5$.

The Hashin structure [34] (see Figure 2) in d dimensions has the effective permittivity

$$\epsilon_{\text{H}}^{\text{eff}}(\omega) = \epsilon_1(\omega)\frac{(d-1)c_1(\epsilon_1(\omega) - \epsilon_2(\omega)) + d\epsilon_2(\omega)}{d\epsilon_1(\omega) + c_1(\epsilon_2(\omega) - \epsilon_1(\omega))}. \tag{3.20}$$

We consider the three-dimensional case, $d = 3$, with the volume fraction $c_1 = 0.5$. Using the values of ϵ_1, ϵ_2, and $\epsilon_{\text{H}}^{\text{eff}}$ at $\omega = \omega_0$ the bounds on c_1 are calculated to $c_1^{\text{L}}(\omega_0) = 0.42$ and $c_1^{\text{U}}(\omega_0) = 0.50$. Figure 3 shows the bounds on $\epsilon_{\text{H}}^{\text{eff}}(\omega_1)$ when $\epsilon_2(\omega_1)$ is known.

3.2.3. Bounds when the volume fraction is known. If the volume fraction c_1 is known, we obtain in the same way bounds on c_2. The measured value $\epsilon^{\text{eff}}(\omega_0)$ is bounded by the lens-shaped region $\epsilon_2^{\text{L}}(c_2; \omega_0)$ and $\epsilon_2^{\text{U}}(c_2; \omega_0)$, with $-c_1\tilde{c}_1 \le c_2 \le 0$.

For some values of c_2 and c_3, the effective parameter $\epsilon^{\text{eff}}(\omega_0)$ is on the boundary of $\epsilon_3^{\text{U}}(c_2, c_3; \omega_0)$, which is given by the Padé approximation $\epsilon_{1,1}$ of the series (2.8). On the curve, the parameters c_2 and c_3 satisfy the equation

$$\epsilon^{\text{eff}}(\omega_0) = \epsilon_2\frac{c_2 + c_1c_2z + c_2^2z^2 - c_3z(1 + c_1z)}{c_2 - c_3z}, \tag{3.21}$$

with $-c_1\tilde{c}_1 \le c_2 \le 0$ and $c_2^2/c_1 \le c_3 \le -c_2(1 + c_2/\tilde{c}_1)$.

At the minimum, $c_2 = -c_1\tilde{c}_1$, (3.21) has the solution

$$\epsilon_1^{\text{L}}(c_1) = \epsilon_2^{\text{U}}(c_2^{\min}) = \epsilon_3^{\text{U}}(c_2^{\min}, c_3^{\min}(c_2^{\min})) = \epsilon^{\text{eff}}, \tag{3.22}$$

where $c_3^{\min}(c_2^{\min}) = c_1(1-c_1)^2$, and at the maximum $c_2 = 0$, the solution to the equation is

$$\epsilon_1^{\mathrm{U}}(c_1) = \epsilon_2^{\mathrm{U}}(c_2^{\max}) = \epsilon_3^{\mathrm{U}}(c_2^{\max}, c_3^{\max}(c_2^{\max})) = \epsilon^{\mathrm{eff}}, \tag{3.23}$$

where $c_3^{\max}(c_2^{\max}) = 0$. By multipling (3.21) with the denominator in ϵ_3^{U} an equation quadratic in c_2 and linear in c_3 is obtained. Assume that $\epsilon^{\mathrm{eff}} \neq \epsilon_1^{\mathrm{L}}(c_1)$. Taking the real and imaginary part gives one solution (c_2, c_3), except for the trivial solution when $(c_2, c_3) = (0, 0)$. The calculated value on c_2 is an upper bound $c_2^{\mathrm{U}}(\omega_0)$ on the structural parameter c_2.

Analogously, for some values of $\tilde{c}_2$ and $\tilde{c}_3$, the effective parameter $\epsilon^{\mathrm{eff}}(\omega_0)$ is located on the boundary of $\epsilon_3^{\mathrm{L}}(\tilde{c}_2, \tilde{c}_3; \omega_0)$, which is given by the Padé approximation $\epsilon_{1,1}$ of the series (2.16). That is, the equation

$$\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_1 \frac{\tilde{c}_2 - \tilde{c}_3 z}{\tilde{c}_2 + \tilde{c}_1\tilde{c}_2 z + \tilde{c}_2^2 z^2 - \tilde{c}_3 z(1 + \tilde{c}_1 z)} \tag{3.24}$$

is solved with respect to $\tilde{c}_2$ and $\tilde{c}_3$. Using that the coefficients c_n and $\tilde{c}_n$ are related by (2.17), and solving the equation $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_3^{\mathrm{L}}(c_2, c_3)$, gives a lower bound $c_2^{\mathrm{L}}(\omega_0)$ on the structural parameter c_2. As before, the equation has one solution, except for the cases when $\epsilon^{\mathrm{eff}} = \epsilon_1^{\mathrm{L}}(c_1)$ and when $\epsilon^{\mathrm{eff}} = \epsilon_1^{\mathrm{U}}(c_1)$.

It is possible to derive explicit formulas for c_2^{L} and c_2^{U}, but they contain many terms and will for this reason not be presented.

The effective permittivity is bounded by the two-point bounds $\epsilon_2^{\mathrm{L}}(c_2)$ and $\epsilon_1^{\mathrm{U}}(c_2)$. We have shown that the effective permittivity also is bounded by the three-point bounds

$$\epsilon_3^{\mathrm{L}}(c_3, c_2^{\mathrm{U}}), \quad \text{with} \quad \frac{c_2^{\mathrm{U}}}{c_1} \leq c_3 \leq -c_2^{\mathrm{U}}\left(1 + \frac{c_2^{\mathrm{U}}}{1-c_1}\right) \tag{3.25}$$

and

$$\epsilon_3^{\mathrm{U}}(c_3, c_2^{\mathrm{L}}), \quad \text{with} \quad \frac{c_2^{\mathrm{L}}}{c_1} \leq c_3 \leq -c_2^{\mathrm{L}}\left(1 + \frac{c_2^{\mathrm{L}}}{1-c_1}\right), \tag{3.26}$$

where c_2^{U} is calculated from (3.21) and c_2^{L} is the solution to (3.24). The bounds on c_3 are given by (3.3).

In many cases of interest, the composite is known to be isotropic, $c_2 = -c_1\hat{c}_1/d$. The bounds on c_2 can then be used to check experimental data. If the volume fraction c_1 is known and $-c_1\hat{c}_1/d$ does not belong to the interval $[c_2^{\mathrm{L}}, c_2^{\mathrm{U}}]$, the experimental value on ϵ^{eff} is inconsistent with the bounds.

3.2.4. Examples. The checkerboard structure and the Hashin structure, with the same values on the phases as before, are used to illustrate the method.

The checkerboard has volume fraction $c_1 = 0.5$, which is assumed to be known. Figure 4 shows bounds on $\epsilon^{\mathrm{eff}}(\omega_1)$ when the bounds on c_2 are calculated to $c_2^{\mathrm{L}}(\omega_0) = -0.135$ and $c_2^{\mathrm{U}}(\omega_0) = -0.115$. The checkerboard problem is two-dimensional and isotropic. The second moment, (2.12), with $c_1 = 0.5$ is then exactly $c_2 = -1/8 = -0.125$.

The Hashin structure is three-dimensional and isotropic. Using $c_1 = 0.5$, the second moment is $c_2 = -1/12 \approx -0.0833$. In this case the solution of the equations (3.21) and (3.24), when $c_1 = 0.5$ is known, determines c_2 numerically. The lower

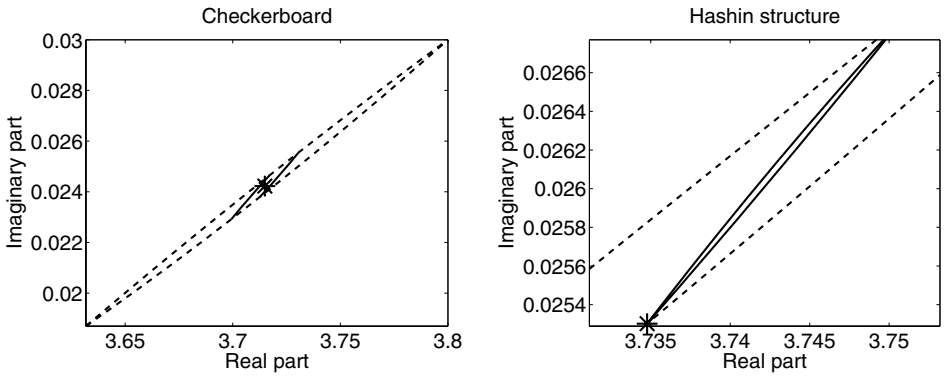

FIG. 4. *The star to the left is the effective permittivity in the checkerboard case and the star to the right corresponds to* ϵ^{eff} *for the Hashin structure. In both figures, the dashed lines* $\epsilon_2^{\text{L}}(c_2)$ *and* $\epsilon_2^{\text{U}}(c_2)$ *bound* $\epsilon^{\text{eff}}(\omega_1)$ *and the solid lines are the tighter bounds* $\epsilon_3^{\text{L}}(c_3; c_2^{\text{U}})$ *and* $\epsilon_2^{\text{U}}(c_3; c_2^{\text{L}})$.

bound and the upper bound on c_2 have 15 digits in common when the equations are solved with Mathematica (www.wolfram.com). In the following section, we use the approximative value $c_2 = c_2^{\text{U}}(\omega_0) = c_2^{\text{L}}(\omega_0) = -0.0833$. Figure 4 shows bounds on $\epsilon^{\text{eff}}(\omega_1)$ when $\epsilon_2(\omega_1) = 4.6 + 0.06\text{i}$ is known.

3.2.5. Bounds on isotropic materials. If the volume fraction c_1, together with the c_2 parameter, is known (for example, if the material is isotropic, $\mathbf{c}_2 = -(c_1\tilde{c}_1/d)\mathbf{I}$), the equations

$$\epsilon^{\text{eff}}(\omega_0) = \epsilon_4^{\text{U}}(c_3, c_4; \omega_0), \quad \epsilon^{\text{eff}}(\omega_0) = \epsilon_4^{\text{L}}(\tilde{c}_3, \tilde{c}_4; \omega_0) \tag{3.27}$$

give us bounds on c_3. In general, if the structural parameters $c_1, c_2, \ldots, c_n$ are known, we obtain bounds on c_{n+1} from the equations

$$\epsilon^{\text{eff}}(\omega_0) = \epsilon_{n+1}^{\text{U}}(c_{n+1}, c_{n+2}; \omega_0), \quad \epsilon^{\text{eff}}(\omega_0) = \epsilon_{n+1}^{\text{L}}(\tilde{c}_{n+1}, \tilde{c}_{n+2}; \omega_0). \tag{3.28}$$

We can also get bounds on one structural parameter c_n if $c_1, c_2, \ldots, c_{n-1}$ and c_{n+1} are known. For example, if the material is known to be isotropic, $c_2 = -c_1(1-c_1)/d$, the Hashin–Shtrikman bounds give us tighter bounds on the volume fraction than the solution to (3.6).

3.2.6. Examples. The bounds on $c_1(\omega_0)$ for the checkerboard structure above were calculated to $c_1^{\text{L}}(\omega_0) = 0.46$ and $c_1^{\text{U}}(\omega_0) = 0.54$. We now use that $c_2 = -0.125$ and solve $\epsilon^{\text{eff}}(\omega_0) = \epsilon_3^{\text{L}}$ and $\epsilon^{\text{eff}}(\omega_0) = \epsilon_3^{\text{U}}$ with respect to c_1 and c_3. Excluding trivial solutions, we get the bounds

$$c_1^{\text{L}}(\omega_0) = 0.492, \quad c_1^{\text{U}}(\omega_0) = 0.508. \tag{3.29}$$

When the composite is known to be isotropic and the volume fraction is known, the effective permittivity is bounded by the three-point bounds $\epsilon_3^{\text{L}}(c_3)$ and $\epsilon_3^{\text{U}}(c_3)$. The effective value is also bounded by the four-point bounds

$$\epsilon_4^{\text{L}}(c_4, c_3^{\text{L}}), \quad \text{with} \quad c_4^{\min}(c_3^{\text{L}}) \le c_4 \le c_4^{\max}(c_3^{\text{L}}) \tag{3.30}$$

and

$$\epsilon_4^{\text{U}}(c_4, c_3^{\text{U}}), \quad \text{with} \quad c_4^{\min}(c_3^{\text{U}}) \le c_4 \le c_4^{\max}(c_3^{\text{U}}), \tag{3.31}$$

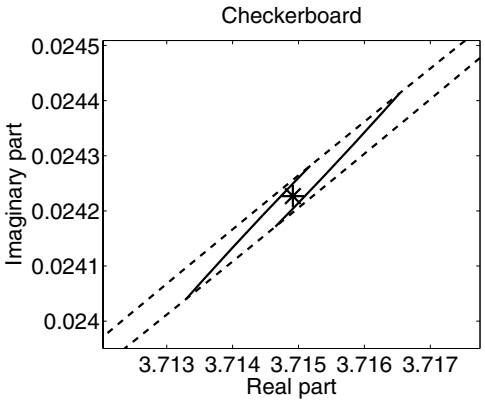

FIG. 5. *The star is the effective permittivity* $\epsilon^{\text{eff}}(\omega_1)$ *in the checkerboard case. The dashed lines* $\epsilon_3^{\text{L}}(c_3)$ *and* $\epsilon_3^{\text{U}}(c_3)$ *bound* $\epsilon^{\text{eff}}(\omega_1)$ *and the solid lines are the tighter bounds* $\epsilon_4^{\text{L}}(c_4; c_3^{\text{L}})$ *and* $\epsilon_4^{\text{U}}(c_4; c_3^{\text{U}})$.

where the bounds on c_4 are given by (3.4). We use that the checkerboard is isotropic and that the volume fraction is $c_1 = 0.5$. Using the same values on the phases as above, the bounds on c_3 are calculated to $c_3^{\text{L}}(\omega_0) = 0.0601$ and $c_3^{\text{U}}(\omega_0) = 0.0649$, respectively. The geometry-independent bounds (3.3) are in this case $c_3^{\min} = 0.0315$ and $c_3^{\max} = 0.09375$.

The exact value on c_3 can be identified from a Taylor expansion of $\epsilon^{\text{eff}} = \sqrt{\epsilon_1\epsilon_2}$ when $\epsilon_1 = 1$ and $\epsilon_2 = 1 + \eta$, $\eta < 1$. The effective permittivity ϵ^{eff} is then

$$\epsilon^{\text{eff}}(1, 1+\eta) = 1 + \frac{1}{2}\eta - \frac{1}{8}\eta^2 + \frac{1}{16}\eta^3 - \frac{5}{128}\eta^4 + \cdots . \tag{3.32}$$

The bounds on c_3 are tight, and the arithmetic mean $(c_3^{\text{L}}(\omega_0)+c_3^{\text{U}}(\omega_0))/2$ provides an accurate approximation of $c_3 = 1/16 = 0.0625$. Figure 5 shows the bounds on $\epsilon^{\text{eff}}(\omega_1)$ when the volume fraction is $c_1 = 0.5$ and the composite is known to be isotropic, $c_2 = -0.125$.

The Hashin structure is three-dimensional and isotropic. Using the same values as above, the solution of $\epsilon_4^{\text{U}} = \epsilon_{\text{H}}^{\text{L}}$ gives the lower bound $c_3^{\text{L}} = c_3^{\max}$. This solution determines c_3 numerically. The lower bound c_3^{L} and the maximum $c_3^{\max}$ have 16 digits in common when the equations are solved with Mathematica.

The properties $\epsilon_3^{\text{U}}(c_3^{\max}) = \epsilon_2^{\text{L}}(c_2, c_1)$ and $\epsilon_3^{\text{L}}(c_3^{\max}) = \epsilon_2^{\text{L}}(c_2, c_1)$ imply that $\epsilon^{\text{eff}} = \epsilon_2^{\text{L}}(c_2, c_1)$.

When the composite is isotropic, the lower bound ϵ_2^{L} is equivalent to the Maxwell–Garnett formula [30, 34]. This formula, commonly used by experimentalists, is a good approximation formula if c_3 is close to $c_3^{\max}$.

3.3. Bounds using two measurements. We cannot determine bounds on more than one structural parameter with information from one measurement. If we have two measurements, which give us different bounds on c_1, it is also possible to get bounds on c_2 without any assumptions on the microstructure. Geometrically, we fail to get bounds on c_2 from one measurement, because the effective permittivity is (by construction) on the boundary of the $\epsilon_2^{\text{L}}/\epsilon_2^{\text{U}}$-bounds, when $c_1 = c_1^{\text{L}}$ or $c_1 = c_1^{\text{U}}$.

Assume that the measurement of $\epsilon^{\text{eff}}(\omega_0)$ gives us tighter bounds $c_1^{\text{L}}(\omega_0) \le c_1 \le c_1^{\text{U}}(\omega_0)$ than the measurement of $\epsilon^{\text{eff}}(\omega_1)$. If we use the tighter bounds $c_1^{\text{L}}(\omega_0) \le c_1 \le c_1^{\text{U}}(\omega_0)$, together with the measurement $\epsilon^{\text{eff}}(\omega_1)$, we avoid the boundary and can

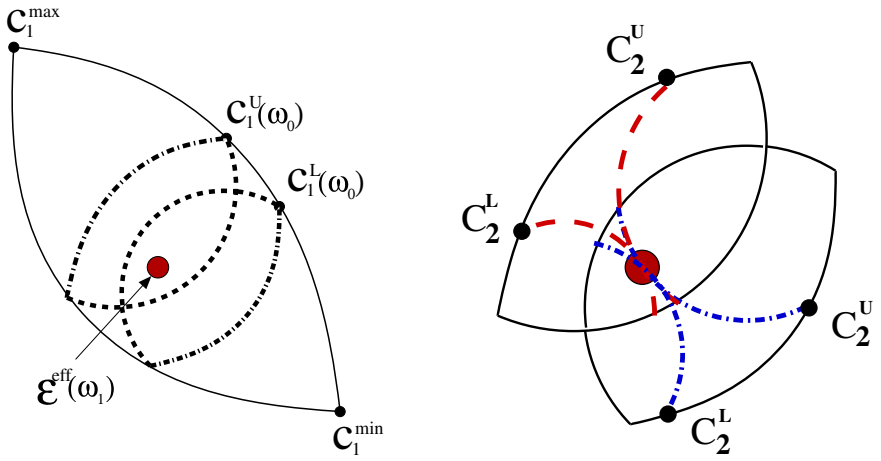

FIG. 6. *Left: The union of the regions* $\epsilon_2^{\mathrm{L}}(c_2;c_1^{\mathrm{L}})$, $\epsilon_2^{\mathrm{U}}(c_2;c_1^{\mathrm{L}})$ *and* $\epsilon_2^{\mathrm{L}}(c_2;c_1^{\mathrm{U}})$, $\epsilon_2^{\mathrm{U}}(c_2;c_1^{\mathrm{U}})$ *bound* $\epsilon^{\mathrm{eff}}(\omega_1)$. *Right: For some values on* $c_2 = c_2(c_1)$, *the effective permittivity* $\epsilon^{\mathrm{eff}}(\omega_1)$ *is on the boundary of* $\epsilon_3^{\mathrm{L}}(c_3;c_2(c_1),c_1,\omega_1)$, $\epsilon_2^{\mathrm{U}}(c_3;c_2(c_1),c_1,\omega_1)$. *The two lens-shaped regions correspond to two different values on the volume fraction* c_1.

continue to bound c_2. This simple observation is the key to the construction of the bounds on any structural parameter.

To bound the c_1-dependent parameter c_2 with a fixed value on c_1 the equations

$$\epsilon^{\mathrm{eff}}(\omega_1) = \epsilon_3^{\mathrm{U}}(c_3,c_2;c_1(\omega_0)), \quad \epsilon^{\mathrm{eff}}(\omega_1) = \epsilon_3^{\mathrm{L}}(c_3,c_2;c_1(\omega_0)) \tag{3.33}$$

are solved in the range $c_1^{\mathrm{L}}(\omega_0) \le c_1 \le c_1^{\mathrm{U}}(\omega_0)$. By construction, the two lens-shaped regions $\epsilon_2^{\mathrm{L}}(c_2;c_1^{\mathrm{L}},\omega_0)$, $\epsilon_2^{\mathrm{U}}(c_2;c_1^{\mathrm{L}},\omega_0)$ and $\epsilon_2^{\mathrm{L}}(c_2;c_1^{\mathrm{U}},\omega_0)$, $\epsilon_2^{\mathrm{U}}(c_2;c_1^{\mathrm{U}},\omega_0)$ intersect; see Figure 6. From the bound ϵ_3^{U}, we get an upper bound $c_2^{\mathrm{U}}(c_1)$ on c_2, and the lower bound ϵ_3^{L} provides a lower bound $c_2^{\mathrm{U}}(c_1)$ on c_2.

We can now construct three-point bounds on ϵ^{eff} by forming

$$\epsilon_3^{\mathrm{L}}(c_3,c_2^{\mathrm{U}}(c_1),c_1), \quad \epsilon_3^{\mathrm{U}}(c_3,c_2^{\mathrm{L}}(c_1),c_1), \tag{3.34}$$

with $c_1 \in [c_1^{\mathrm{L}}(\omega_0),c_1^{\mathrm{U}}(\omega_0)]$ and $c_3 \in [c_3^{\min},c_3^{\max}]$. The c_1-dependent maximum $c_3^{\max}$ and the minimum $c_3^{\max}$ are taken from the expression (3.3).

From the derivation of the maximum $c_3^{\max}$ and the minimum $c_3^{\min}$ in [21] we have the equalities $\epsilon_3^{\mathrm{L}} = \epsilon_2^{\mathrm{L}}$ when $c_3 = c_3^{\max}$ and $\epsilon_3^{\mathrm{L}} = \epsilon_2^{\mathrm{U}}$ when $c_3 = c_3^{\min}$. In the same way the upper bound ϵ_3^{U} can be used to limit the c_3-parameter. We obtain the equalities $\epsilon_3^{\mathrm{U}} = \epsilon_2^{\mathrm{L}}$ when $c_3 = c_3^{\max}$ and $\epsilon_3^{\mathrm{U}} = \epsilon_2^{\mathrm{U}}$ when $c_3 = c_3^{\min}$. Using these properties, the bounding region in (3.34) that depends on two variables c_1 and c_3 can be expressed as a set of bounds, depending on one single variable. The new bounds are

$$\epsilon_3^{\mathrm{U}}(c_3;c_2^{\mathrm{L}}(c_1^{\mathrm{U}}),c_1^{\mathrm{U}}), \quad \epsilon_3^{\mathrm{U}}(c_3;c_2^{\mathrm{L}}(c_1^{\mathrm{L}}),c_1^{\mathrm{L}}), \quad \epsilon_2^{\mathrm{U}}(c_1,c_2^{\mathrm{L}}(c_1)), \quad \epsilon_2^{\mathrm{L}}(c_1,c_2^{\mathrm{L}}(c_1)) \tag{3.35}$$

and

$$\epsilon_3^{\mathrm{L}}(c_3;c_2^{\mathrm{U}}(c_1^{\mathrm{U}}),c_1^{\mathrm{U}}), \quad \epsilon_3^{\mathrm{L}}(c_3;c_2^{\mathrm{U}}(c_1^{\mathrm{L}}),c_1^{\mathrm{L}}), \quad \epsilon_2^{\mathrm{U}}(c_1,c_2^{\mathrm{U}}(c_1)), \quad \epsilon_2^{\mathrm{L}}(c_1,c_2^{\mathrm{U}}(c_1)), \tag{3.36}$$

where the two-point bounds depend on $c_1 \in [c_1^{\mathrm{L}}(\omega_0),c_1^{\mathrm{U}}(\omega_0)]$ and the three-point bounds depend on $c_3 \in [c_3^{\min},c_3^{\max}]$. If some of the structural parameters are known,

for example, if the volume fraction is known and the material is isotropic, the two measurements give bounds on the higher-order moments c_3 and c_4.

The upper bound $c_2^{\mathrm{U}}(c_1)$ and the lower bound $c_2^{\mathrm{L}}(c_1)$ are both second-degree polynomials in c_1, which are easily maximized and minimized. Global, c_1-independent, bounds on c_2 are defined as

$$c_2^{\mathrm{L}}(\omega_1) = \min_{c_1 \in [c_1^{\mathrm{L}}, c_1^{\mathrm{U}}]} \{c_2^{\mathrm{L}}(c_1)\}, \quad c_2^{\mathrm{U}}(\omega_1) = \max_{c_1 \in [c_1^{\mathrm{L}}, c_1^{\mathrm{U}}]} \{c_2^{\mathrm{U}}(c_1)\}. \tag{3.37}$$

The global bounds on c_2 can be used to simplify the above formulas at the expense of less tight bounds.

3.4. The checkerboard. We give an example of the method when no structural information is known using the checkerboard structure. Assume, as before, that $\epsilon_2(\omega_0) = 4.1 + 4.5\mathrm{i}$ and $\epsilon_2(\omega_1) = 4.6 + 0.06\mathrm{i}$ are known and that $\epsilon_1 = 3$ independent of the frequency ω. Moreover, we assume that $\epsilon^{\mathrm{eff}}(\omega_0)$ and $\epsilon^{\mathrm{eff}}(\omega_1)$ are measured and seek bounds on $\epsilon^{\mathrm{eff}}(\omega_2)$ when $\epsilon_2(\omega_2) = 3.7 + 0.04\mathrm{i}$ is known.

The second measurement on frequency ω_1 gives the tightest bounds on $c_1 = 0.5$,

$$c_1^{\mathrm{L}}(\omega_1) = 0.494, \quad c_1^{\mathrm{U}}(\omega_1) = 0.506. \tag{3.38}$$

We use the measurement of the effective permittivity on the frequency ω_0 to bound c_2. The solutions to the equations $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_3^{\mathrm{L}}$ and $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_3^{\mathrm{U}}$ when $c_1 \in [c_1^{\mathrm{L}}(\omega_1), c_1^{\mathrm{U}}(\omega_1)]$ are

$$c_2^{\mathrm{L}}(c_1) = 1.09296 - 6.0343c_1 + 7.15922c_1^2 \tag{3.39}$$

and

$$c_2^{\mathrm{U}}(c_1) = -2.21787 + 7.28412c_1 - 6.15921c_1^2. \tag{3.40}$$

These functions have no stationary point when $c_1 \in [0.494, 0.506]$. The endpoints give the global bounds on $c_2 = -0.125$,

$$c_2^{\mathrm{L}}(\omega_0) = -0.141, \quad c_2^{\mathrm{U}}(\omega_0) = -0.108. \tag{3.41}$$

The bounds (3.35) and (3.36) that bound $\epsilon^{\mathrm{eff}}(\omega_1)$ are depicted in Figure 7.

3.5. An anisotropic example. Using the same material parameters as above, we also give an example in the anisotropic and periodic case; see Figure 8.

We use FEMLAB (www.comsol.com) to numerically calculate the solution to the local problem (2.2), (2.3). At the frequencies ω_0 and ω_1, the results are

$$\epsilon^{\mathrm{eff}}(\omega_0) = 3.9426 + 0.9852\mathrm{i}, \quad \epsilon^{\mathrm{eff}}(\omega_1) = 3.5147 + 0.01554\mathrm{i}. \tag{3.42}$$

The second measurement at the frequency ω_1 gives the tightest bounds on c_1,

$$c_1^{\mathrm{L}}(\omega_1) = 0.5941, \quad c_1^{\mathrm{U}}(\omega_1) = 0.6007. \tag{3.43}$$

We use the measurement of the effective permittivity on frequency ω_0 to bound c_2. The solutions to the equations $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_3^{\mathrm{L}}$ and $\epsilon^{\mathrm{eff}}(\omega_0) = \epsilon_3^{\mathrm{U}}$ when $c_1 \in [c_1^{\mathrm{L}}(\omega_1), c_1^{\mathrm{U}}(\omega_1)]$ are

$$c_2^{\mathrm{L}}(c_1) = 7.07395 - 26.20256c_1 + 23.50343c_1^2 \tag{3.44}$$

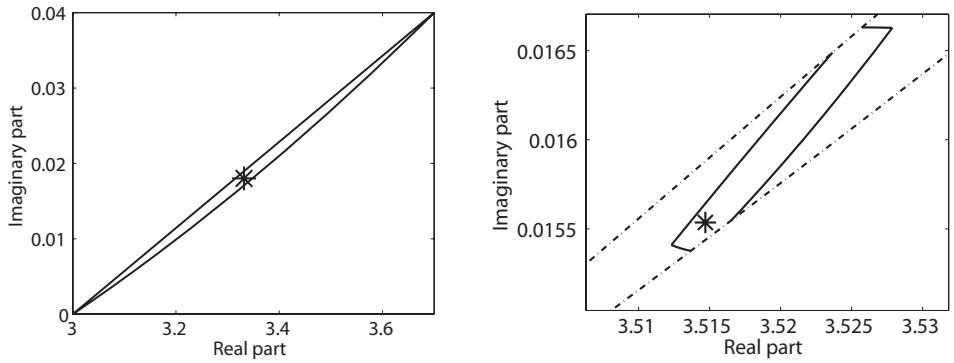

FIG. 7. *Left: The star is the location of the effective permittivity* $\epsilon^{\text{eff}}(\omega_1)$ *in the checkerboard case. The solid lines* (3.35) *and* (3.36) *bound* $\epsilon^{\text{eff}}(\omega_1)$. *Right: The star corresponds to* ϵ^{eff} *for the rods. and

$$c_2^{\text{U}}(c_1) = -2.46585 + 6.37039c_1 - 4.27488c_1^2. \tag{3.45}$$

These functions have no stationary point when $c_1 \in [0.5941, 0.6007]$. The endpoints give the global bounds

$$c_2^{\text{L}}(\omega_0) = -0.1974, \quad c_2^{\text{U}}(\omega_0) = -0.1817. \tag{3.46}$$

The bounds on $\epsilon^{\text{eff}}(\omega_2)$ when $\epsilon_2(\omega_2) = 3.7 + 0.04\text{i}$ are known are depicted in Figure 7. The effective permittivity is numerically calculated to $\epsilon^{\text{eff}}(\omega_2) = 3.253 + 0.01306\text{i}$.

In practice, the effective permittivity (3.42) is the result of measurements and cannot in general be given with this accuracy. A computer program that takes into account that measurements have errors has been written. If we assume that the error in the measurements of $\epsilon^{\text{eff}}(\omega)$ is 1%, the bounds on the volume fraction are numerically computed to

$$0.57 \leq c_1 \leq 0.62. \tag{3.47}$$

In a separate paper [20], the method derived here will be used to analyze data from real measurements.

3.5.1. Bounds when the volume fraction is known. Assume that we have one measurement at ω_0 and one measurement at ω_2 (that here is numerically calcu-

lated in FEMLAB). The effective permittivity at ω_2 is

$$\epsilon^{\text{eff}}(\omega_2) = 3.253 + 0.01306\text{i}. \tag{3.48}$$

The measurement at frequency ω_2 gives the tightest bounds on c_1,

$$c_1^{\text{L}}(\omega_2) = 0.5984, \quad c_1^{\text{U}}(\omega_2) = 0.6002. \tag{3.49}$$

The bounds on c_1 are in this case very tight. The arithmetic mean of $c_1^{\text{L}}(\omega_2)$ and $c_1^{\text{U}}(\omega_2)$ is then approximately $c_1^{\text{app}}(\omega_2) = 0.6$, which is the exact value on the volume fraction.

If $c_1 = 0.6$ is used, the same schedule as above can be used to bound the parameters c_2 and c_3. The solution to the equations $\epsilon^{\text{eff}}(\omega_2) = \epsilon_3^{\text{L}}$ and $\epsilon^{\text{eff}}(\omega_2) = \epsilon_3^{\text{U}}$, with $c_1 = 0.6$, gives the tightest bounds on c_2,

$$c_2^{\text{L}}(\omega_2) = -0.18413, \quad c_1^{\text{U}}(\omega_2) = -0.18403. \tag{3.50}$$

The solutions to the equations $\epsilon^{\text{eff}}(\omega_0) = \epsilon_4^{\text{L}}$ and $\epsilon^{\text{eff}}(\omega_0) = \epsilon_4^{\text{U}}$, with $c_2 \in [c_2^{\text{L}}(\omega_1), c_2^{\text{U}}(\omega_1)]$, are

$$c_3^{\text{L}}(c_2) = 1.37544 + 12.75996c_2 + 31.54795c_2^2 \tag{3.51}$$

and

$$c_3^{\text{U}}(c_2) = -7.60752 - 84.64558c_2 - 232.47525c_2^2. \tag{3.52}$$

These functions have no stationary point when $c_2 \in [c_2^{\text{L}}(\omega_1), c_2^{\text{U}}(\omega_1)]$. The endpoints give the global bounds

$$c_3^{\text{L}}(\omega_0) = 0.0955, \quad c_3^{\text{U}}(\omega_0) = 0.0966. \tag{3.53}$$

The bounds on $\epsilon^{\text{eff}}(\omega_2)$ were tight when the volume fraction was unknown, and they are now even tighter. We use a composite with larger contrast to illustrate the bounds. Assume that $\epsilon_1(\omega_3) = 3 + 0.1\text{i}$ and $\epsilon_2(\omega_3) = 2 + 20\text{i}$ are known. The bounds $\epsilon_4^{\text{L}}(c_4, c_3^{\text{L}}(c_2))$ and $\epsilon_4^{\text{U}}(c_4, c_3^{\text{L}}(c_2))$ on the effective permittivity $\epsilon^{\text{eff}}(\omega_3)$ are depicted in Figure 9. The effective permittivity is numerically calculated to $\epsilon^{\text{eff}}(\omega_3) = 5.409 + 1.038\text{i}$.

The geometry and the values on the phases were previously used in [21], where the value on the volume fraction c_1 and the anisotropy c_2 were assumed to be known. Here we obtain almost as tight bounds as in [21] by using the values of two measurements of a bulk property.

The bounds on c_2 from the measurement on ω_2 are close. If we use the arithmetic mean of $c_2^{\text{L}}(\omega_2)$ and $c_2^{\text{U}}(\omega_2)$ as an approximation, the same schedule can be used to bound the parameters c_3 and c_4.

4. Discussion and conclusions. We have developed a method to calculate inverse bounds on the structural parameters from measurements of lossy two-component composites. For example, measurements can be used to determine the frequency-dependent effective permittivity.

If no structural information is known, data from two measurements determine bounds on the volume fraction and on the isotropy parameter. The bounds on the structural parameters are used to bound the permittivity at some frequency of interest or a related effective property such as the electrical and thermal conductivity, magnetism, diffusion, and flow in porous media.

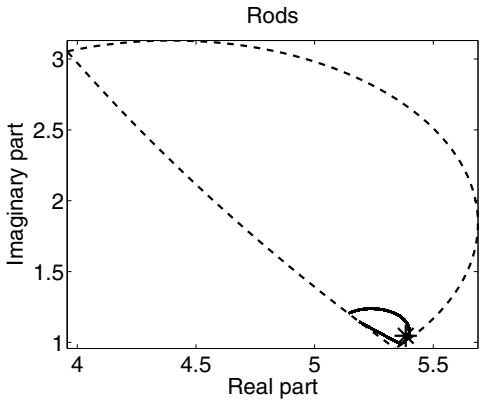

FIG. 9. *The star is the effective permittivity* $\epsilon^{\text{eff}}(\omega_3)$ *bounded by the dashed lines* $\epsilon_3^{\text{L}}(c_3; c_2^{\text{U}})$ *and* $\epsilon_3^{\text{U}}(c_3; c_2^{\text{L}})$. *The solid lines are the tighter bounds* $\epsilon_4^{\text{L}}(c_4, c_3^{\text{L}}(c_2))$ *and* $\epsilon_4^{\text{U}}(c_4, c_3^{\text{L}}(c_2))$.

In the case when some of the structural parameters are known, for example, if the composite is known to be isotropic and the volume fraction is known, the same schedule can be used to bound higher-order moments. The method can be extended to bound higher-order moments, provided that we have information from more measurements of the bulk parameters.

Numerical experiments, with reasonable values for the permittivity, were used to illustrate the method.

Acknowledgments. The author is grateful to Daniel Sjöberg and Gerhard Kristensson for many helpful discussions and comments on different parts of this paper.

COMPUTATIONAL MODELING OF TEXTURE FORMATION AND OPTICAL PERFORMANCE OF LIQUID CRYSTAL FILMS ON PATTERNED SURFACES*

DAE KUN HWANG† AND ALEJANDRO D. REY†

Abstract. An integrated microstructural-optical model based on the tensorial Landau–de Gennes liquid crystal theory, the Matrix–Berreman optical model, and the finite-difference time-domain (FDTD) optical method is used to investigate texture formation and polarized light propagation in thin nematic liquid crystal (NLC) films for various anchoring boundary conditions mimicking surface conditions of an existing liquid crystal (LC)-based biosensor device used to detect biological binding events. The integrated mathematical model of the optical device describes the signal generation process of the biosensor based on LC vision. The FDTD optical method predicts two important optical signatures of the transmitted polarized light: oscillations and nonsymmetric optical signals. However, the approximate Matrix–Berreman optical method cannot predict these important optical responses when strong lateral orientation gradients are present. The model predictions are found to be in good agreement with actual experimental results, and can be used to detect interfacial LC orientation due to bound biomolecules.

1. Introduction.

Liquid crystals (LCs) are anisotropic electroptical materials [1] widely used in displays, light valves, and more recently in biosensor applications [1, 2, 3, 4]. This paper presents a mathematical and computational study of uniaxial rod-like low-molar mass nematic liquid crystal (NLC) [5] films for biosensor applications [3, 4, 6, 7].

Liquid crystal films are soft materials where weak substrate forces can alter orientation states and generate topological defects [1, 2]. Furthermore, LC films are thermodynamically stable and possess long-range orientational order and optical anisotropy [5, 8]. Thus LC films exhibit unique optical textures when observed under cross-polars due to spatial heterogeneities of macroscopic orientation [5, 8]; in this paper, orientation refers to the average molecular orientation of the rod-like molecules composing the NLC phase, and it is described by the unit vector or director $\mathbf{n}$; the director $\mathbf{n}$ is the optic axis [5]. The unique combination of soft material, sensitivity to substrate chemistry and geometry, and optical anisotropy provides unique opportunities in the development of LC-based biosensors [3, 4, 6, 7].

Surface treatments that affect physicochemical surface conditions of substrates such as surface topology and chemical compositions lead to defect-free LC structures needed for display applications [9]. One popular method of substrate preparation for obtaining defect-free LC structures is mechanical rubbing of glass plate substrates in one direction to create a sinusoidal topology; the rubbing direction creates an

easy-axis $\mathbf{E}$ or preferred orientation [9], and the director $\mathbf{n}$ aligns along $\mathbf{E}$; strong anchoring denotes the state at the surface $\mathbf{n} = \mathbf{E}$. Since desirable LC structures on various substrates have been obtained using many different procedures and physiochemical surface treatments, LCs have been successfully used in display applications. In addition to display applications, Skaife and Abbott have demonstrated another successful application of LCs biosensors in order to detect biological binding events on nano-structured surfaces supporting LC films [3, 6]. The basis of the sensor is the presence of uniform orientation in the absence of biomolecular surface-covering. On the other hand, the presence of surface-bound proteins or viruses modifies the aligning properties of the surface, creating textures or spatial heterogeneities in the optic axis that are easily detectable and quantifiable using light transmission under cross-polars [3, 6]. Thus, surface-bound biomolecules can be detected and their surface density quantified through measurement of the optical output [3, 6]. Denoting by $\mathbf{k}$ the unit surface normal, substrates in contact with NLCs can induce homeotropic (or normal, $\mathbf{E} = \mathbf{k}$), oblique (or tilted, $0 < (\mathbf{E} \cdot \mathbf{k})^2 < 1$), degenerate planar (tangential, $(\mathbf{E} \cdot \mathbf{k}) = 0$), and uniform planar surface orientation ($\mathbf{E} \cdot \mathbf{k} = 0, \mathbf{E} = \mathbf{t}_o$, and $\mathbf{t}_o$ a tangential unit vector) [5, 9]. Recent work by Abbott and coworkers [4, 7], demonstrates that a uniform planar orientation of LCs can be obtained by a special protein deposition on functionalized nano-structured surfaces. The preferred tangential orientation of the surface director ($\mathbf{n} = \mathbf{t}_o$) was then determined by measuring the modulation of transmitted optical intensity upon rotating the LC films with respect to fixed cross-polars [7]. Sample rotation under fixed cross-polars provides a simple and useful way to detect specific planar orientations on protein-covered substrates. The optical principle operating here is based on the fact that maximum light transmittance through cross-polars in a NLC film is obtained when $\mathbf{n}$ is at 45° from the cross-polars. Hence, to find $\mathbf{t}_o$ in a substrate, the sample is rotated under fixed cross-polars until the maximum optical transmittance is found. This paper uses computational optical modeling to predict a uniform planar surface orientation on partially covered substrates, as observed in experiments [4, 7].

Despite the great advantages of the LC-based biosensors [3, 4, 6, 7] and their potential uses, the sensor functionalities and fundamental relationships between optical responses and complex surface-driven LC texture formation processes are not fully understood. The integration of surface-induced texture formation of LCs with its optical responses has not been fully explored. Optical computations of light propagation and texture formation modeling studies considering multiscale phenomena provide a better understanding of the LC-based biosensor functionalities and eventually may lead to simulation-based biosensor design and optimization.

In this paper we simulate texture formation in NLC films using the tensor Landau–de Gennes liquid crystal theory [5] and compute light transmittance through cross-polars using the Matrix–Berreman method and the FDTD method, as described below. The geometry and surface conditions replicate the experiments [4, 7]. We study texture formation of low-molar NLCs in a thin film between two patterned surfaces containing two distinct vertical regions: (i) a nonprinted protein region, with strong planar anchoring (i.e., $\mathbf{n} \cdot \mathbf{k} = \mathbf{0}$) on its lower surface and strong homeotropic anchoring (i.e., $\mathbf{n} \cdot \mathbf{k} = \mathbf{1}$) on its upper surface, and (ii) a printed protein region, with homeotropic anchoring on its upper surface (i.e., $\mathbf{n} \cdot \mathbf{k} = \mathbf{1}$) and one preferred tangential easy-axis (i.e., $\mathbf{n} = \mathbf{t_o}$) on its lower surface where printed protein is present.

Two popular computational optical methods for solving the Maxwell equations have been applied in order to describe light propagation through NLC films: (i) the

Berreman method [10, 11, 12, 13, 14, 15, 16] and (ii) the finite-difference time-domain (FDTD) method [17, 18, 19, 20]. The Berreman method is an approximate matrix-type method based on the stratified approach, and the FDTD method is a direct numerical simulation of the Maxwell equations. Despite the wide use of the Berreman method in computational optical studies for LC displays, this method has one major limitation due to the assumption that variation of the dielectric tensor occurs only in the direction of light propagation. Thus the Berreman method is best suited to one dimensional problems [10, 11, 12, 13, 14, 15, 16]. Thus, the Berreman method may not be appropriate for studying optical responses in the LC-based biosensor, where the dielectric tensor varies over small length scales in multiple directions.

Application of the FDTD method in LC films, especially for LC displays, is relatively recent compared with the Berreman method [17, 18, 19, 20, 21, 22]. In contrast to the Berreman method, detailed optical responses and important optical features of LC structures observed in advanced LC displays are successfully predicted by the FDTD method [19, 20, 21, 22]. However, the performance of the FDTD method in optical studies of textured NLCs with multiscale heterogeneities remains to be explored and quantified. Our previous studies [23, 24, 25] on computational optics on textured NLC films containing wedge, twist, and twist loop defects show that the FDTD method has excellent abilities to accurately compute light transmittance in heterogeneous films. In this paper we extend our previous work [23, 24, 25] and simulate the light transmittance of an NLC thin film with surface and bulk heterogeneities of relevance to biosensors.

The objectives of this paper are the following:

(a) to simulate transient texture formation in NLC thin films with a substrate containing a sequence of nonprinted-protein and printed-protein regions;
(b) to characterize the computational optical responses of the predicted orientation structures using the Berreman and FDTD methods;
(c) to evaluate the FDTD and Berreman methods;
(d) to determine the preferred alignment of NLCs on a printed-protein region in NLC films

The organization of this paper is as follows. Section 2 presents the Landau–de Gennes LC theory and governing equations for describing orientation structures in NLCs in thin films. Section 3 presents the main features of the Berreman and FDTD optical methods. Section 4 presents and discusses the predicted results. Section 5 presents the conclusions.

2. Theory and governing equations.

2.1. Description of orientation and alignment of NLCs. The multiscale description of the microstructure of NLCs is characterized by the second moment of the orientation distribution function, referred to as a second-order symmetric traceless tensor $\mathbf{Q}$ [5], defined as

$$\mathbf{Q} = \mathrm{S}\left(\mathbf{nn} - \frac{1}{3}\delta\right) + \frac{1}{3\mathrm{P}}(\mathbf{mm} - \mathbf{ll}), \tag{2.1}$$

with the following restrictions:

$$\mathbf{Q} = \mathbf{Q}^{\mathrm{T}}, \tag{2.2}$$

$$\mathrm{tr}(\mathbf{Q}) = 0, \tag{2.3}$$

$$-\frac{1}{2} \leq S \leq 1, \tag{2.4}$$

$$-\frac{3}{2} \leq P \leq \frac{3}{2}, \tag{2.5}$$

$$\mathbf{n} \cdot \mathbf{n} = \mathbf{m} \cdot \mathbf{m} = \mathbf{l} \cdot \mathbf{l} = 1, \tag{2.6}$$

$$\mathbf{nn} + \mathbf{mm} + \mathbf{ll} = \delta = \begin{Bmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{Bmatrix}, \tag{2.7}$$

where $\mathbf{n}$, $\mathbf{m}$, $\mathbf{l}$ are referred as the uniaxial director and the first and second biaxial directors forming the orthogonal director triad, which defines the macroscopic orientation of NLCs. The scalar order parameters S and P are measures of the molecular alignment; the magnitude of the uniaxial scalar order parameter S is a degree of the molecular alignment along the uniaxial director $\mathbf{n}$, and the magnitude of the biaxial scalar order parameter P is a degree of the molecular alignment along the first biaxial director. On the principal axis, the tensor order parameter $\mathbf{Q}$ is

$$\mathbf{Q} = \begin{pmatrix} -\frac{1}{3}(S-P) & 0 & 0 \\ 0 & -\frac{1}{3}(S+P) & 0 \\ 0 & 0 & \frac{2}{3}S \end{pmatrix}, \tag{2.8}$$

where $S = \frac{3}{2}(\mathbf{n} \cdot \mathbf{Q} \cdot \mathbf{n})$ and $P = \frac{3}{2}(\mathbf{m} \cdot \mathbf{Q} \cdot \mathbf{m} - \mathbf{l} \cdot \mathbf{Q} \cdot \mathbf{l})$. Depending on the values of the parameters S and P, the tensor $\mathbf{Q}$ is able to describe three states: isotropic ($S = 0, P = 0$), uniaxial ($S \neq 0, P = 0$), and biaxial ($S \neq 0, P \neq 0$).

2.2. Landau–de Gennes model for NLCs. According to the Landau–de Gennes model [2, 5, 26, 27], the total free energy density f of NLCs in the absence of external fields is expressed as the sum of three contributions, isotropic (f_i), homogeneous (f_h), and gradient (f_g) contributions:

$$f = f_i\,(T, P) + f_h\,(T, \mathbf{Q}) + f_g\,(T, \mathbf{Q}, \nabla\mathbf{Q})\,, \tag{2.9}$$

where f_i represents the free energy of the isotropic state and is a function of conventional thermodynamic parameters such as temperature and pressure while independent of $\mathbf{Q}$; $f_h\,(T, \mathbf{Q})$ is the homogeneous contribution and captures the isotropic↔ nematic phase transition, given by [2, 5, 26, 27]

$$f_s = \frac{1}{2}a(T - T^*)Q_{\alpha\beta}Q_{\beta\alpha} - \frac{1}{3}bQ_{\alpha\beta}Q_{\beta\gamma}Q_{\gamma\alpha} + \frac{1}{4}c(Q_{\alpha\beta}Q_{\beta\alpha})^2, \tag{2.10}$$

where $\{\alpha, \beta, \gamma, \delta\} = 1, 2, 3$ denote the components along the three orthogonal axes in a Cartesian coordinate system; a, b, and c are constants, and T^* is the isotropic↔ nematic transition temperature.

The gradient f_g term is due to long-range elastic effects and expressed in terms of the gradient of $\mathbf{Q}$ [2, 5, 26, 27]:

$$\begin{aligned} f_g =& \frac{1}{2}L_1\nabla_\alpha Q_{\beta\gamma}\nabla_\alpha Q_{\beta\gamma} + \frac{1}{2}L_2\nabla_\alpha Q_{\alpha\gamma}\nabla_\beta Q_{\beta\gamma} \\ &+ \frac{1}{2}L_3 Q_{\alpha\beta}\nabla_\alpha Q_{\gamma\delta}\nabla_\beta Q_{\gamma\delta}, \end{aligned} \tag{2.11}$$

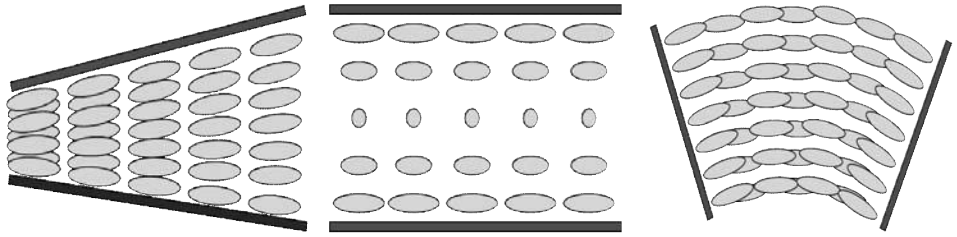

FIG. 2.1. *Schematics of the three elastic deformations of rod-like uniaxial nematics:* (a) *splay mode,* (b) *twist mode, and* (c) *bend mode, corresponding to elastic constants* K_{11}*,* K_{22}*, and* K_{33}*, respectively.*

where L_1, L_2, and L_3 are phenomenological parameters of LCs. To ensure stability, the Landau coefficients L_1, L_2, and L_3 are restricted (under uniaxiality) as follows [2, 5, 26, 27]:

$$2L_1 + L_2 - \frac{2}{3}SL_3 > 0, \quad 2L_1 - \frac{2}{3}SL_3 > 0, \quad 2L_1 + L_2 + \frac{4}{3}SL_3 > 0. \tag{2.12}$$

Under elastic isotropy (one constant approximation), $L_2 = L_3 = 0$; under the constant uniaxial scalar order parameter condition, (2.11) yields the Frank–Oseen gradient energy density [5, 8], based on the director model. The relation between the Landau elastic constants of the tensor model and the Frank elastic constants of the vector model is [28, 29]

$$L_1 = \frac{3K_{22} - K_{11} + K_{33}}{6S^2}, \quad L2 = \frac{K_{11} - K_{22}}{S^2}, \quad L3 = \frac{K_{33} - K_{11}}{2S^3}, \tag{2.13}$$

where K_{11}, K_{22}, K_{33} are the splay, twist, and bend elastic constants, respectively. These elastic modes are shown in Figure 2.1. Planar distortions contain no twist. Nonplanar distortions are trimodal.

Using the Doi model of LCs in conjunction with the Landau–de Gennes model, the dimensionless free energy density equations (2.10) and (2.11) are [26, 30]

$$\widetilde{f_h} = \frac{1}{2}\left(1 - \frac{U}{3}\right) Q_{\alpha\beta}Q_{\beta\alpha} - \frac{U}{3}Q_{\alpha\beta}Q_{\beta\gamma}Q_{\gamma\alpha} + \frac{U}{4}(Q_{\alpha\beta}Q_{\beta\alpha})^2, \tag{2.14}$$

$$\begin{aligned}\widetilde{f}_g = &\left(\frac{\xi}{X}\right)^2 \left(\frac{1}{2}\widetilde{\nabla}_\alpha Q_{\beta\gamma}\widetilde{\nabla}_\alpha Q_{\beta\gamma} + \frac{1}{2}\widetilde{L}_1\widetilde{\nabla}_\alpha Q_{\alpha\gamma}\widetilde{\nabla}_\beta Q_{\beta\gamma}\right.\\ &\left. + \frac{1}{2}\widetilde{L}_2 Q_{\alpha\beta}\widetilde{\nabla}_\alpha Q_{\gamma\delta}\widetilde{\nabla}_\beta Q_{\gamma\delta}\right)\end{aligned} \tag{2.15}$$

$$\widetilde{f} = \frac{f}{\varphi kT}, \quad U = 3\frac{T^*}{T}, \quad a = \varphi k, \quad b = c = \varphi kTU, \quad \xi = \sqrt{\frac{L_1}{\varphi kT}}, \tag{2.16}$$

$$\widetilde{L}_2 = \frac{L_2}{L_1}, \quad \widetilde{L}_3 = \frac{L_3}{L_1}, \quad \widetilde{\nabla} = X\nabla, \tag{2.17}$$

where φ and k are the concentration and Boltzman's constant, respectively. The nematic potential U controls the stability such that: $U < 8/3$ corresponds to the

isotropic phase, $8/3 \leq U \leq 3$ to the biphasic isotropic-nematic equilibrium, and $U > 3$ to the uniaxial nematic phase. The internal length scale ξ is the characteristic scale for changes in S and is of the order of a defect core [5]. X indicates the external length scale of the system, which in this paper is the half length of SPR region (see Figure 4.1).

The microstructure evolution, in the absence of flow, is given by a standard gradient flow dynamic equation [26, 30]:

$$-\gamma(\mathbf{Q})\frac{\partial \mathbf{Q}}{\partial t} == \left(\frac{\delta f}{\delta \mathbf{Q}}\right)^{[s]} = \left(\frac{\partial f}{\partial \mathbf{Q}} - \nabla \cdot \frac{\partial f}{\partial \nabla \mathbf{Q}}\right)^{[s]}, \tag{2.18}$$

where γ is the rotational viscosity and the superscript $[s]$ denotes a symmetric and traceless tensor. Substituting (2.14) and (2.15) into (2.18) yields the dynamical equation for $\mathbf{Q}$:

$$\begin{aligned} -\frac{\partial \mathrm{Q}_{ij}}{\partial \widetilde{t}} &= \left(1 - \frac{U}{3}\right) Q_{ij} - U\left(Q_{i\alpha}Q_{\alpha j} - \frac{1}{3Q_{\beta\alpha}Q_{\alpha\beta}\delta_{ij}}\right) + UQ_{\alpha\beta}Q_{\beta\alpha}Q_{ij} \\ &\quad - R\widetilde{\nabla}_k\widetilde{\nabla}_k Q_{ij} - R\tilde{L}_2\left(\frac{1}{2}(\widetilde{\nabla}_i\widetilde{\nabla}_\alpha Q_{\alpha j} + \widetilde{\nabla}_j\widetilde{\nabla}_\alpha Q_{\alpha i}) - \frac{1}{3}\widetilde{\nabla}_\beta\widetilde{\nabla}_\alpha Q_{\alpha\beta}\delta_{ij}\right) \\ &\quad - R\tilde{L}_3(\widetilde{\nabla}_k Q_{\alpha k}\widetilde{\nabla}_\alpha Q_{ij} + Q_{\alpha k}\widetilde{\nabla}_k\widetilde{\nabla}_\alpha Q_{ij}) \\ &\quad + R\tilde{L}_3\left(\widetilde{\nabla}_i Q_{\gamma\delta}\widetilde{\nabla}_j Q_{\gamma\delta} - \frac{1}{3\widetilde{\nabla}_\alpha Q_{\gamma\delta}\widetilde{\nabla}_\alpha Q_{\gamma\delta}\delta_{ij}}\right), \end{aligned} \tag{2.19}$$

where $\widetilde{t} = \varphi k T^* t/\gamma$ is the dimensionless time and

$$R = \left(\frac{\xi}{X}\right)^2 \tag{2.20}$$

is the square of the internal/external length scale ratio. The dimensionless numbers $\wp$ that control the dynamics of $\mathbf{Q}$ are

$$\wp : \left\{U, R, \tilde{L}_2, \tilde{L}_3\right\}. \tag{2.21}$$

As mentioned above, U controls the stability, and for a stable homogenous uniaxial nematic phase the relation between U and the equilibrium scalar order parameter S_{eq} is

$$S_{eq} = \frac{1}{4} + \frac{3}{4}\sqrt{1 - \frac{8}{3U}}. \tag{2.22}$$

For low molar mass NLCs, we estimate $\xi = 10$–20nm [5, 31], and for films in the micron range this gives $X/\xi \approx 100$. Hence using this model to simulate realistic materials and realistic geometries gives rise to a PDE system with a small parameter. This small parameter is responsible for the ability of the model to capture topological defects and changes in the scalar order parameter close to bounding surfaces [32, 33]. The $R = 0$ limit of tensor equation (2.20), with $S = S_{eq}$ and $P = 0$, yields the dynamic version of the Frank–Oseen director model [5]. Lastly, $\tilde{L}_2$ and $\tilde{L}_3$ denote elastic anisotropy in the system. For low molar mass nematics, such as 5CB (4-pentyl-4'-cyanobiphenly) the values for these dimensionless elastic constants are $\tilde{L}_2 = 0.85, \tilde{L}_3 = 0.87$ [34, 35]. In the material system under study here, elastic anisotropy is not a significant effect.

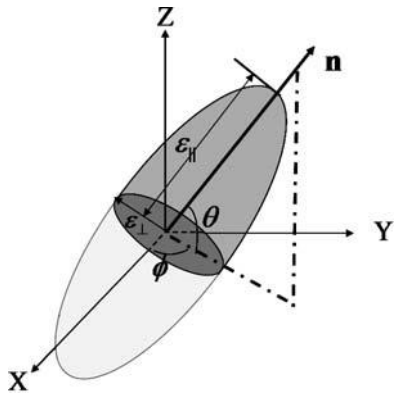

FIG. 3.1. *Schematic diagram of the optical component of the dielectric tensor ε, ordinary dielectric constant $\varepsilon_{\perp}$ and the extraordinary dielectric constant $\varepsilon_{\parallel}$, with respect to the optic axis $\mathbf{n}$ described by the two Euler angles, azimuthal ϕ and polar θ, for a uniaxial rod-like NLCs in a rectangular (x,y,z) coordinate system. The unit vector $\mathbf{n}$ also represents the local director.*

3. Optical modeling of LCs. NLCs are optically transparent and anisotropic materials. These properties provide unique and interesting optical features of light propagation through NLC films. The Matrix–Berreman and FDTD method have been successfully applied to describe classical defects observed in NLCs such as wedge, twist, and loop defects [23, 24, 25]. In this section, we discuss the main features of the two optical methods of direct relevance to the objectives of the paper; other details are found in various references and texts [10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 36].

The Maxwell curl equations and constitutive equations in the absence of current and for nonmagnetic materials are given by

$$\frac{\partial \mathbf{D}}{\partial t} = \nabla \times \mathbf{H}, \quad \frac{\partial \mathbf{B}}{\partial t} = \nabla \times \mathbf{E}, \quad \mathbf{D} = \varepsilon \mathbf{E}, \quad \mathbf{B} = \mu_o \mathbf{H}, \tag{3.1}$$

where $\mathbf{D}$ is the electric flux, $\mathbf{E}$ and $\mathbf{H}$ are the electric and magnetic fields, and μ_o is the magnetic permeability in a vacuum. Figure 3.1 shows the optic axis, two dielectric constants, and Euler angles of rod-like uniaxial NLCs. The optically anisotropic properties of NLCs are included in the dielectric tensor ε. The Euler azimuthal ϕ and polar angle θ describe the direction of the optic axis $\mathbf{n}$ for rod-like uniaxial NLCs in a rectangular coordinate system. The optic axis coincides with the local director $\mathbf{n}$ of uniaxial NLCs. The six components of the symmetric dielectric tensor ε for uniaxial NLCs in two dimensions are given by

$$\varepsilon(x,z) = \begin{pmatrix} \varepsilon_{\perp} + \Delta\varepsilon \cos^2\theta \cos^2\phi & \Delta\varepsilon \cos^2\theta \sin\phi \cos\phi & \Delta\varepsilon \sin\theta \cos\theta \cos\phi \\ \Delta\varepsilon \cos^2\theta \sin\phi \cos\phi & \varepsilon_{\perp} + \Delta\varepsilon \cos^2\theta \sin^2\phi & \Delta\varepsilon \sin\theta \cos\theta \sin\phi \\ \Delta\varepsilon \sin\theta \cos\theta \cos\phi & \Delta\varepsilon \sin\theta \cos\theta \sin\phi & \varepsilon_{\perp} + \Delta\varepsilon \sin^2\theta \end{pmatrix}, \tag{3.2}$$

where $\Delta\varepsilon = \varepsilon_{\perp} - \varepsilon_{\parallel}$, $\varepsilon_{\perp}$ is the ordinary and $\varepsilon_{\parallel}$ the extraordinary dielectric constant. The Maxwell equations (3.1) in two dimensions can be decoupled into two separated waves, ordinary (transverse magnetic) and extraordinary (transverse electric), known as TM and TE mode fields, under the condition that the dielectric tensor is dependent only on one of Euler angles. For example, LCs exhibit only planar structures, $\theta = 0$; otherwise, the decoupling of the Maxwell equations into TM and TE fields is not feasible [20].

3.1. Berreman method [10, 11, 12, 13, 14, 15]. Reformulation of the Maxwell equations (3.1) into four linear differential equations is possible under the assumption that variation of the dielectric tensor occurs only in the light propagation direction and is negligible in the transverse directions, where the Euler angles are only functions of z or the spatial gradient of the Euler angles with respect to x is moderate in a long range. The four linear differential equations are given by [10]

$$\frac{d\psi}{dz} = -i\frac{\omega}{c}\Delta(z)\psi, \qquad \psi = (E_x, H_y, E_y, -H_x)^T, \tag{3.3}$$

where c is the light propagation velocity in vacuum, ω is the angular frequency, and E_x, E_y, H_x, and H_y are electric and magnetic components. Optical properties of NLCs, polarizations due to local molecular orientation of NLCs, and multiple reflections due to the presence of different media are imposed in the 4×4 matrix $\Delta(z)$. Thus, the space-dependent $\Delta(z)$ are mainly functions of $\varepsilon(z)$.

The global computational domain of the NLC film including substrates is divided into local cubic lattices. Each local lattice is assumed to be a homogenous medium whose dielectric tensor is uniform ε_i; the subscript i indicates the local cubic lattice. Solution vectors for transmitted waves ψ_t and reflected waves ψ_r after the incident waves ψ_i travel through the global computational domain from z_0 to z_n are obtained by solving the linear equation (3.3). The solution vectors are obtained as follows:

$$\psi_{\mathbf{t}}(z_n) = \mathbf{F}(i,n)(\psi_{\mathbf{i}}(z_o) + \psi_{\mathbf{r}}(z_o)), \tag{3.4}$$

$$\mathbf{F}(i,n) = \mathbf{p}_{i+n}(\varepsilon_{i+n}(h))\mathbf{p}_{i+n-1}(\varepsilon_{i+n}(h))\dots\mathbf{p}_{i+1}(\varepsilon_{i+1}(h))\mathbf{p}_i(\varepsilon_i(h)), \tag{3.5}$$

$$\mathbf{p}_i(h) = \exp\left[-i\left(\frac{\omega}{c}\right)\Delta h\right], \tag{3.6}$$

where $\mathbf{F}$ is the global transfer matrix, $\mathbf{p}_i$ is the local transfer matrix for each local cubic lattice i, and h is the thickness of each local lattice. $\mathbf{F}$ is just the multiplication of each local transfer matrix $\mathbf{p}_i$. Thus, the main computational cost and challenge of the Berreman method is to obtain solutions of the local transfer matrices. The exponent matrix $\mathbf{p}_i$ can be expressed using a Taylor series as follows:

$$\begin{aligned}\mathbf{p}_i(h) &= \exp\left(-i\frac{\omega}{c}\mathbf{\Delta}h\right)\\ &= \mathbf{I} + \left(-i\frac{\omega h}{c}\mathbf{\Delta}\right) + \frac{1}{2!}\left(-i\frac{\omega h}{c}\right)^2\mathbf{\Delta}^2 + \frac{1}{3!}\left(-i\frac{\omega h}{c}\right)^3\mathbf{\Delta}^3 + \cdots,\end{aligned} \tag{3.7}$$

where $\mathbf{I}$ is the unit matrix. The higher term of (3.7) can be neglected in the case when the thickness h of each local lattice is sufficiently small and thus each lattice is a uniform medium with $\varepsilon_{i+n}(h)$. In addition, analytical expressions of the local matrix $\mathbf{p}_i$ can be obtained in case the optic axis has a planar structure where the dielectric tensor is dependent only on a single Euler angle. The detailed expression of analytical solutions of the local matrix $\mathbf{P}$ can be found in the literature [14, 15, 16]. In this study, the dielectric tensor is a function of both Euler angles, azimuthal ϕ and polar angle θ. The local transfer matrix is obtained using (3.7) with the assistance of the built-in function called "expm" in Matlab 7 [37].

In this paper we consider a monochromatic incident wave, and the solution vectors are obtained using (3.5) after considering transmission through ideal crossed polarizers.

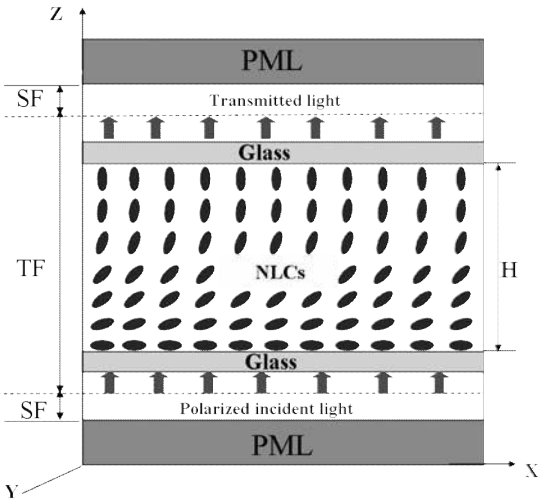

FIG. 3.2. *Schematic of the computational domain used in the FDTD method. H indicates the thickness of an NLC film, and the arrows indicate the normal propagation direction of polarized light. The polarizer and analyzer are placed along the x and y directions. PMLs are placed in the z direction, and periodic conditions are used in the x direction. Oval shapes indicate the average LC molecules' orientation, known as director* $\mathbf{n}$.

3.2. FDTD method [17, 18, 19, 20, 21, 22, 36]. The Maxwell equations (3.1), rewritten in a rescaled form using $\widetilde{\mathbf{D}} = \frac{1}{\sqrt{\varepsilon_o \mu_o}}\mathbf{D}$ and $\widetilde{\mathbf{E}} = \sqrt{\frac{\varepsilon_o}{\mu_o}}\mathbf{E}$, are given by [38]

$$\frac{\partial \widetilde{\mathbf{D}}}{\partial t} = \frac{1}{\sqrt{\varepsilon_o \mu_o}} \nabla \times \mathbf{H}, \quad \widetilde{\mathbf{D}} = \varepsilon^* \widetilde{\mathbf{E}}, \quad \frac{\partial \mathbf{H}}{\partial \mathbf{t}} = -\frac{\mathbf{1}}{\sqrt{\varepsilon_\mathbf{o} \mu_\mathbf{o}}} \nabla \times \widetilde{\mathbf{E}}. \tag{3.8}$$

One of the main challenges and important issues of the FDTD method in solving the Maxwell equations is to implement boundary layer conditions in order to truncate the computational space. Any artificial and nonphysical reflections of outgoing waves, which arise from truncation of the computational space, back into the domain of interest causes contamination of solutions. Thus, it is highly desirable to prevent outgoing waves leaving the domain of interest from reflecting back into the domain. Berenger [39] first introduced a perfectly matched layer (PML) as boundary layers in order to truncate the computational space and to absorb waves leaving the computational domain of interest and entering into the PML without any reflections. However, some difficulties arise in implementing the PML in the case of dielectric anisotropic media and high dimensions. Simpler and more effective formulations of material-independent PML have been developed and successfully implemented in LC application with high performance [38, 40, 41, 42]. Among the formulations, a simplified formulation of the PML called *unsplit PML* is used in this study [38]. One of the benefits of rescaling the Maxwell equations as shown in (3.8) is that it provides a simpler implementation of the unsplit PML method, regardless of level of the complexity in the optical properties of the medium [38]. Figure 3.2 shows a schematic of the computation domain and the three main components of the optical system: (1) the thin NLC film, (2) two supporting glass substrates, and (3) two PML layers used in the FDTD method. The PML layers are used in order to truncate the computational

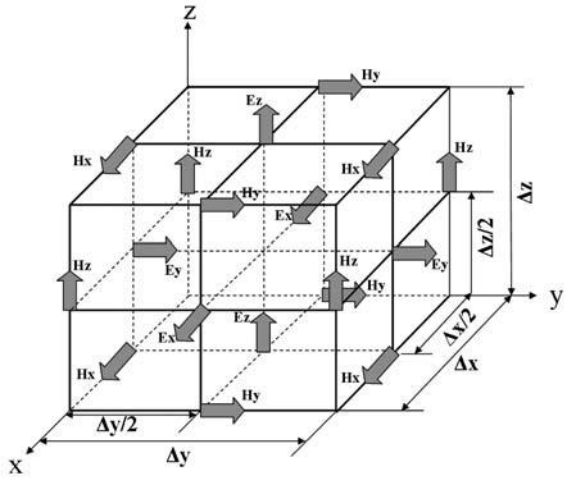

FIG. 3.3. *Schematic of a cubic unit lattice of the Yee cell.*

domain in the z direction. Lateral periodic boundary conditions are used in order to truncate the computational domain in the x direction. The periodic boundary conditions in the x direction are justified when assuming repetition of the system in the x direction. The entire computational domain is subdivided into staggered cubic lattices, and the lattices follow a Yee cell configuration [43]. The Yee cell shown in Figure 3.3 consists of electrical and magnetic components in a staggered lattice in which the electric and magnetic components are located by the half space, so that each **E** and **H** component is surrounded by the four circulating **H** and **E** components. A second-order central finite difference is used to discretize the normalized (3.8) in both space and time on the basis of the Yee algorithm and a fully explicit leap frog scheme, respectively [36]. One example of the finite-difference expression of Dy and Hy components in the rectangular (x, z) coordinate system is given by

$$Dy|_{x,z}^{n+1} = Dx|_{x,z}^{n} + \frac{\Delta t}{\sqrt{\varepsilon_o \mu_o}} \left(\frac{Hx|_{x,z+1/2}^{n+1/2} - Hx|_{x,z-1/2}^{n+1/2}}{\Delta z} - \frac{Hz|_{x+1/2,z}^{n+1/2} - Hz|_{x-1/2,z}^{n+1/2}}{\Delta x} \right), \tag{3.9}$$

$$\mathbf{E}|_{x,z}^{n+1} = \varepsilon^*(x,z)^{-1}\, \mathbf{D}|_{x,z}^{n+1}\,, \tag{3.10}$$

$$Hy|_{x+1/2,z+1/2}^{n+3/2} = Hy|_{x+1/2,z+1/2}^{n+1/2} + \frac{\Delta t}{\sqrt{\varepsilon_o \mu_o}} \left(\frac{Ez|_{x+1,z+1/2}^{n+1} - Ez|_{x,z+1/2}^{n+1}}{\Delta x} - \frac{Ex|_{x+1/2,z+1}^{n+1} - Ex|_{x+1/2,z}^{n+1}}{\Delta z} \right), \tag{3.11}$$

where Δx, Δz and Δt indicate space and time increments, respectively, and n indicates the time step. The **D** field is advanced in time by the half time increment based on the previous advanced **H** field according to (3.9). Then, the **E** field is obtained with the inverse of the dielectric tensor and the previously obtained **D** field. The updated **E** field is used to obtain a new **H** field according to (3.11). This procedure continues

until an initial transient period vanishes and the steady-solution vectors **E** and **H** are obtained, after considering transmission through the ideal crossed polarizers.

In the initial time step, a known monochromatic incident wave is introduced into the computation domain using the total field and scattered field (TF/SF) formulation at the lower interface between the TF/SF regions, as shown in Figure 3.2. The TF/SF formulation at the lower interface is expressed by [36]

$$\mathbf{E_{total}} = \mathbf{E_{inc}} + \mathbf{E_{scat}}, \quad \mathbf{H_{total}} = \mathbf{H_{inc}} + \mathbf{H_{scat}} \quad \text{for total field region,} \tag{3.12}$$

$$\mathbf{E_{scat}} = \mathbf{E_{total}} - \mathbf{E_{inc}}, \quad \mathbf{H_{scat}} = \mathbf{H_{total}} - \mathbf{H_{inc}} \quad \text{for scattered field region,} \tag{3.13}$$

where $\mathbf{E}_{inc}$ indicates the incident electric components and $\mathbf{E}_{scat}$ indicates the electric component due to reflection, scattering, and retardation of incident waves induced by the presence of different media and spatial variations in the NLC orientation. The electric and magnetic fields are advanced in time and space according to (3.9) and (3.11). Only scattered electric and magnetic components are allowed to leave from the total region and enter into the scattered region. Then the scattered waves enter into PML layers, which have fictitious exponential conductivities $\sigma(z)$. In the PML layers, all of the $\mathbf{E}_{scat}$ and $\mathbf{H}_{scat}$ are absorbed exponentially, regardless of any propagation directions of the entering scattered waves. Therefore, no reflections of the waves into the computational domain of interest occur.

4. Results and discussion. In this section, we present details of computational issues and numerical results of texture formation in a NLC thin film on a patterned surface based on the Landau–de Gennes theory and its optical responses using the FDTD and Berreman methods. The optical results are validated using the experimental data of [7].

4.1. Texture formation. In the present paper, we are interested in computing texture formation in a low-molar mass NLC film such as 5CB, used in biosensor applications [3, 4, 6, 7], where the elastic anisotropy effects on the director field conformation are moderate. Hence a one-elastic-constant approximation ($L_2 = L_3 = 0$) is used.

Figure 4.1 shows a schematic of the computational geometry of a thin NLC film used for computing texture formation. The two dimensional computational domain

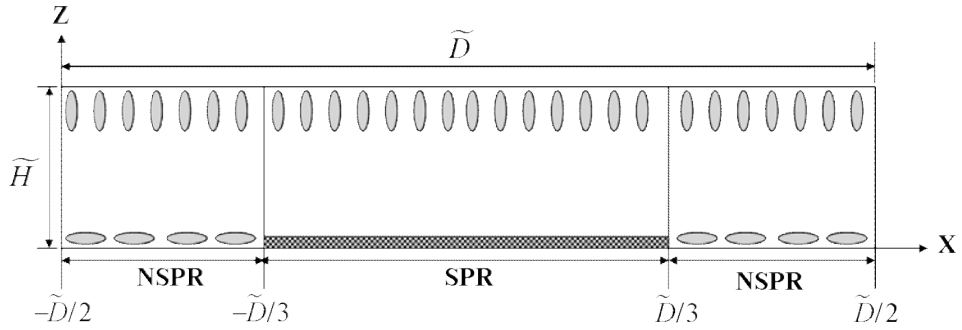

FIG. 4.1. *Schematic of the computational geometry of LC film.* $\widetilde{H}$ *and* $\widetilde{D}$ *indicate dimensionless thickness and length of the film, respectively. The NSPR includes the region* $-1.5 \le x \le -1$ *and* $1 \le x \le 1.5$ *for both* $z = -0.2$ *and* $z = 0.2$*, and the SPR covers* $-1 < x < 1$*,* $z = -0.2$*. Oval shapes on the surface represent fixed anchoring boundary conditions. The check-patterned box indicates stamped proteins where various boundary conditions are used.*

of the thin NLC film shown in Figure 4.1 consists of the area enclosed by the external boundaries, of dimensionless thickness $\widetilde{H} = 0.4$ and dimensionless length $\widetilde{D} = 3$. The computational domain also consists of three distinct regions: two nonstamped protein regions (NSPR) ($-\widetilde{D}/2 \le x \le -\widetilde{D}/3,\ \widetilde{D}/2 \le x \le \widetilde{D}/3$) and one stamped protein region (SPR) ($-\widetilde{D}/3 < x < \widetilde{D}/3$) in Figure 4.1. The two dimensional computational domain replicates the experimental geometry used in [4, 7], so as to keep the same thickness-to-length ratio, the same NSPR-to-SPR length ratio, and same boundary conditions as in the experiments of [4, 7].

Periodic boundary conditions are employed in the x direction, which are consistent with the lateral boundary conditions used for optical modeling. The tensor order parameter $\mathbf{Q}(x, z, t)$ on the boundary ($x = -\widetilde{D}/2, \widetilde{D}/2$) is given by

$$\begin{aligned} &\mathbf{Q}|_{x=-\widetilde{D}/2} = \mathbf{Q}|_{x=\widetilde{D}/2}, \qquad \left.\frac{\partial \mathbf{Q}}{\partial x}\right|_{x=-\widetilde{D}/2} = \left.\frac{\partial \mathbf{Q}}{\partial x}\right|_{x=\widetilde{D}/2}, \\ &\left.\frac{\partial \mathbf{Q}}{\partial y}\right|_{x=-\widetilde{D}/2} = \left.\frac{\partial \mathbf{Q}}{\partial y}\right|_{x=\widetilde{D}/2}. \end{aligned} \tag{4.1}$$

For the remaining boundaries in the z direction, the Dirichlet boundary conditions are implemented, as shown in Figure 4.1. The upper surface ($z = \widetilde{H}/2$) provides a strong homeotropic boundary condition in both SPR and NPR regions; the lower surface ($z = -\widetilde{H}/2$) in the NSPR region provides a strong planar boundary condition parallel to the x direction. Hence, the tensor order parameter $\mathbf{Q}$ on these boundaries is given by

$$\mathbf{Q}_b = S_{eq}\left(\mathbf{n}_b\mathbf{n}_b - \frac{1}{3}\delta\right), \tag{4.2}$$

$$\mathbf{n}_b = (0, 0, 1), \qquad z = \frac{\widetilde{H}}{2}, \quad -\frac{\widetilde{D}}{2} < x < \frac{\widetilde{D}}{2}, \tag{4.3}$$

$$\mathbf{n}_b = (1, 0, 0), \qquad z = -\frac{\widetilde{H}}{2}, \quad -\frac{\widetilde{D}}{2} \le x \le \frac{\widetilde{D}}{3}, \quad \frac{\widetilde{D}}{3} \le x \le \frac{\widetilde{D}}{2}, \tag{4.4}$$

where $\mathbf{n}_b$ is the prescribed uniaxial director or optic axis at $\tilde{z} = \pm\tilde{H}/2$. Since NLCs on the SPR lower surface exhibit a preferred orientation, which we are interested in capturing, we vary boundary conditions on the surface with a strong planar assumption as follows:

$$(1, 0, 0) \le \mathbf{n}_b \le (0, 1, 0), \qquad z = -\frac{\widetilde{H}}{2}, \quad -\frac{\widetilde{D}}{3} \le x \le -\frac{\widetilde{D}}{3}. \tag{4.5}$$

The surface director Euler angles are

$$\theta = 0, \quad 0 \le \phi \le \frac{\pi}{2}, \quad z = -\frac{\widetilde{H}}{2}, \quad -\frac{\widetilde{D}}{3} \le x \le -\frac{\widetilde{D}}{3}. \tag{4.6}$$

The system is initially quenched from isotropic state, and the initial conditions are

$$\begin{aligned} &\mathbf{Q}_{in}(x, z, \widetilde{t} = 0) = S_{in}\left(\mathbf{nn} - \frac{1}{3}\delta\right), \qquad S_{in} \approx 0, \\ &-\frac{\widetilde{H}}{2} < z < \frac{\widetilde{H}}{2}, \qquad -\frac{\widetilde{D}}{2} < x < \frac{\widetilde{D}}{2}. \end{aligned} \tag{4.7}$$

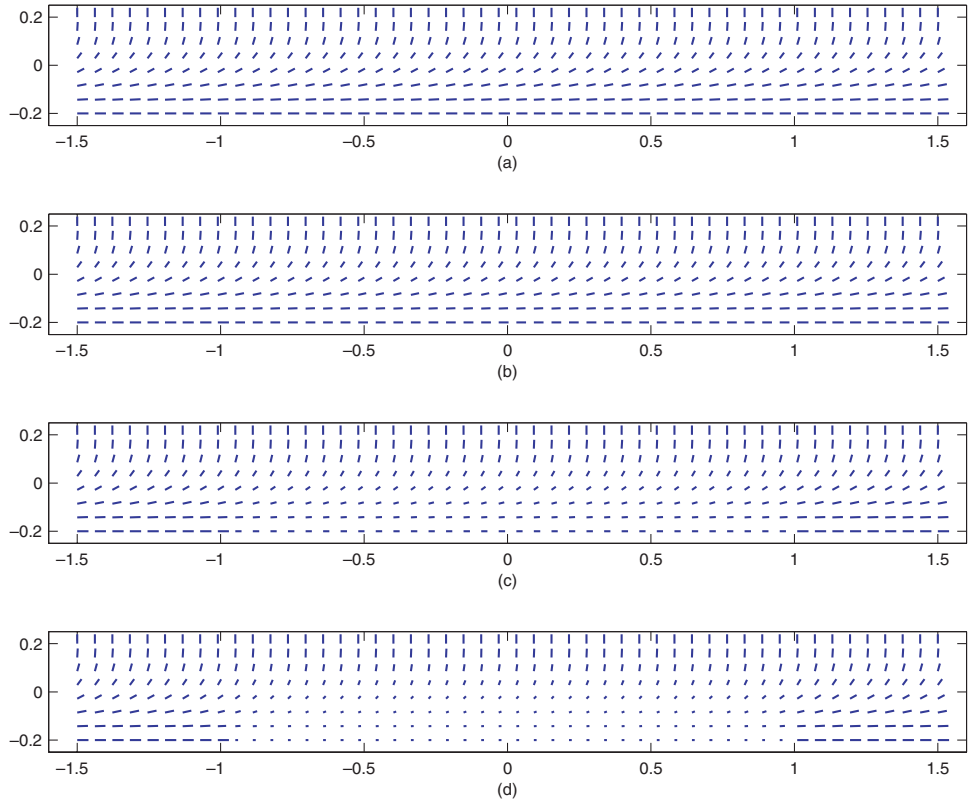

FIG. 4.2. *Computed director profiles of the liquid crystal films for the anchoring boundary conditions on the lower surface of the SPR:* (a) $\phi = 0$, (b) $\phi = \pi/12$, (c) $\phi = \pi/6$, *and* (d) $\phi = \pi/4$. *The values of the axes of the x-z plane are equal to the dimensionless length and thickness.*

The nematic potential $U = 3\frac{T^*}{T}$ is set to be 3.5, which corresponds to S_{eq}=0.615. The spatio-temporal behavior of $\mathbf{n}$ is predicted by solving (2.18), subject to (4.5)–(4.7) for various different anchoring conditions on the lower surface of the SPR, according to (4.5), (4.6).

Figure 4.2 shows computed visualizations of the steady-state director profiles corresponding to the following director boundary conditions on the SPR lower surface region: (a) $\phi = 0$, (b) $\phi = \pi/12$, (c) $\phi = \pi/6$, and (d) $\phi = \pi/4$, respectively, for $\frac{\xi}{H}$=0.01. The NLC structure in Figure 4.2(a) exhibits hybrid alignment and a planar director field with splay and bend distortions. Figures 4.2(b–d) show a nonplanar director field with splay-twist-bend modes. The twist mode occurs in a stripe around the center region ($x \approx 0$). The splay-bend-twist distortions are concentrated close to the interface between the adjacent NSPR and SPR regions.

Figure 4.3 shows computed director profiles corresponding to increasingly larger values of the anchoring boundary conditions: (a) $\phi = \pi/3$, (b) $\phi = \pi/2.57$, (c) $\phi = \pi/2.25$, and (d) $\phi = \pi/2$. As expected, in the vicinity of the interface between two adjacent NSPR and SPR regions, deformation of the NLCs increases with increases in the twist angle ϕ.

In partial summary, as the twist angle ϕ in the SPR increases, the steady-state texture evolves from a diffuse planar splay-bend mode to a sharp nonplanar splay-

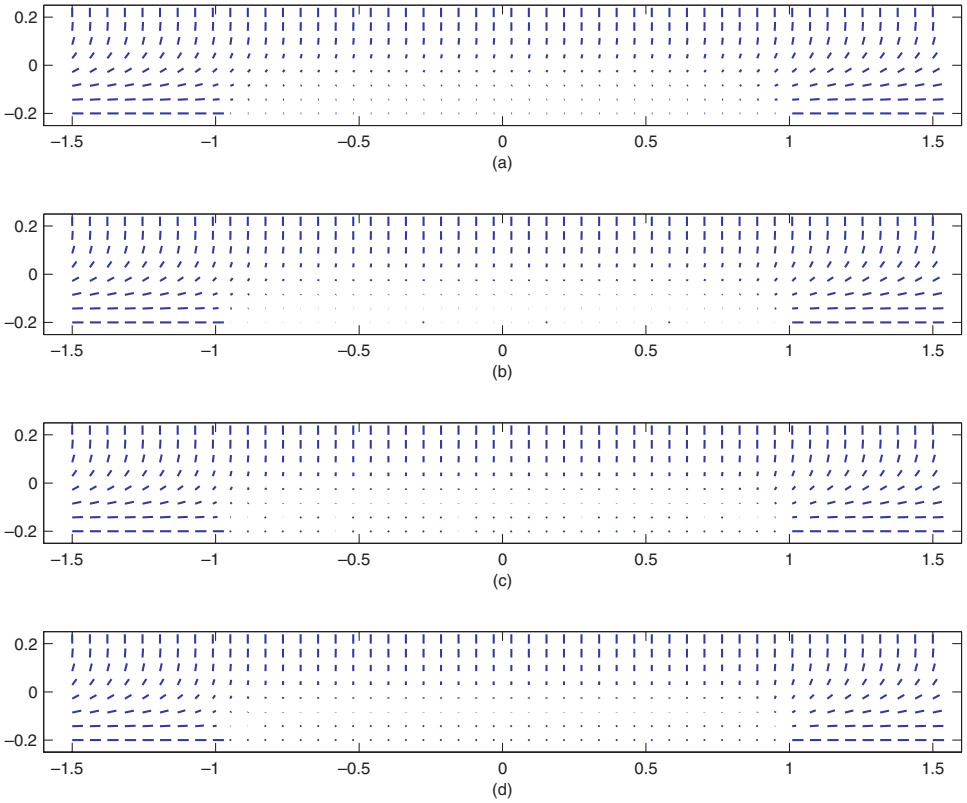

FIG. 4.3. *Computed director profiles of the LC films for the anchoring boundary conditions on the lower surface of the SPR:* (a) $\phi = \pi/3$, (b) $\phi = \pi/2.57$, (c) $\phi = \pi/2.25$, *and* (d) $\phi = \pi/2$. *The values of the axes of the x-z plane are equal to the dimensionless length and thickness.*

twist-bend mode, exhibiting a box-like region over the SPR with uniform escape into the third dimension ("y" axis). The NLC director profiles shown in Figures 4.2 and 4.3, as well as results from other anchoring conditions (not shown for brevity), are used for optical texture modeling, shown next.

4.2. Optical texture formation. The FDTD and Berreman methods for optical computation are applied to predict optical response of the obtained NLC textures. The computational domain for the NLC structure consists of 577×77 rectangular cubic lattices for the Berreman method, and rectangular Yee cells for the FDTD method. A grid size of each cell is set to $\lambda/30$, which is selected in order to prevent numerical dispersion for a mean refractive index close to 1.6. The selected grid size is $\Delta z = \Delta x = 20$nm, and the dimensionless time step is equal to $\Delta t = 3.3356 \times 10^{-17}$, which is selected for numerical stability. Extra cubic lattices for the supporting glass layers in the Berreman method and extra Yee cells are added for the glass layers and the PML layers in the FDTD along the light propagation direction. A linearly polarized monochromatic plane wave along the x direction with free wavelength $\lambda = 600$ is introduced into the computational domain. Only normal incidence is considered. The refractive indices of 5CB are equal to 1.71 for the extraordinary index, no, and 1.53 for the ordinary index, ne [44]. These values correspond to the selected wavelength $\lambda = 600$. The supporting refractive index is equal to 1.52.

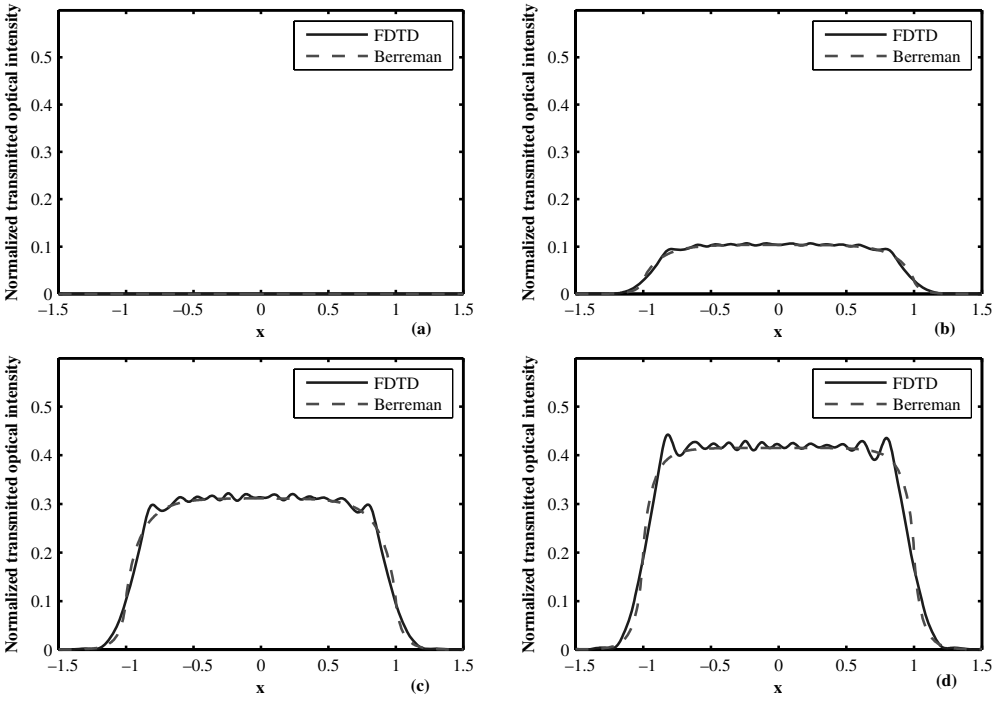

FIG. 4.4. *Normalized optical intensities of transmitted polarized light using the FDTD and Berreman method in the case of* (a) $\phi = 0$, (b) $\phi = \pi/12$, (c) $\phi = \pi/6$, *and* (d) $\phi = \pi/4$ *anchoring boundary conditions corresponding to NLS structures in the corresponding panels of Figure* 4.2. *The normalized intensities are a function of distance along the x direction.*

Figure 4.4 shows the normalized optical intensity of transmitted light through the NLC textures (see Figure 4.2 for the following anchoring conditions in the SPR: (a) $\phi = 0$, (b) $\phi = \pi/12$, (c) $\phi = \pi/6$, and (d) $\phi = \pi/4$, computed using the FDTD and Berreman methods). The optical intensities are plotted as a function of distance in the x direction after considering the presence of the ideal analyzer parallel to the y direction. For $\phi = \pi, 0$, as shown in Figure 4.4(a), the transmitted light from the NLC film is completely extinguished by the analyzer placed along the y direction, so that zero magnitude of the transmitted light is predicted in this case, and the NLC film appears completely dark. This is expected because there is no deviation of the azimuthal angle with respect to the polarizer placed parallel to x-axis; when the optic axis of NLCs uniformly aligns parallel or perpendicular to either polarizer or analyzer (here we consider cross-polars), the NLC film appears dark. Hence, as the surface azimuthal angle deviates from the polarizer in the SPR region (which means the deviation of NLC orientation with respect to the polarizer increases), the intensity of the transmitted light increases in the SPR, but in the NSPR region the intensity vanishes, as shown in Figure 4.2(b–c). Consequently, the maximum optical intensity is predicted by both optical methods when $\phi = \pi/4$ (Figure 4.4(d)).

In weakly heterogeneous textures, the FDTD and Berreman methods predict similar transmitted light intensity magnitudes under cross-polars. However, disagreement between the two methods for sharply textured LC films is significant, as shown in Figure 4.2. This disagreement originates from the optical intensity oscillations predicted by the FDTD method, due to scattering effects from lateral optic axis gradients

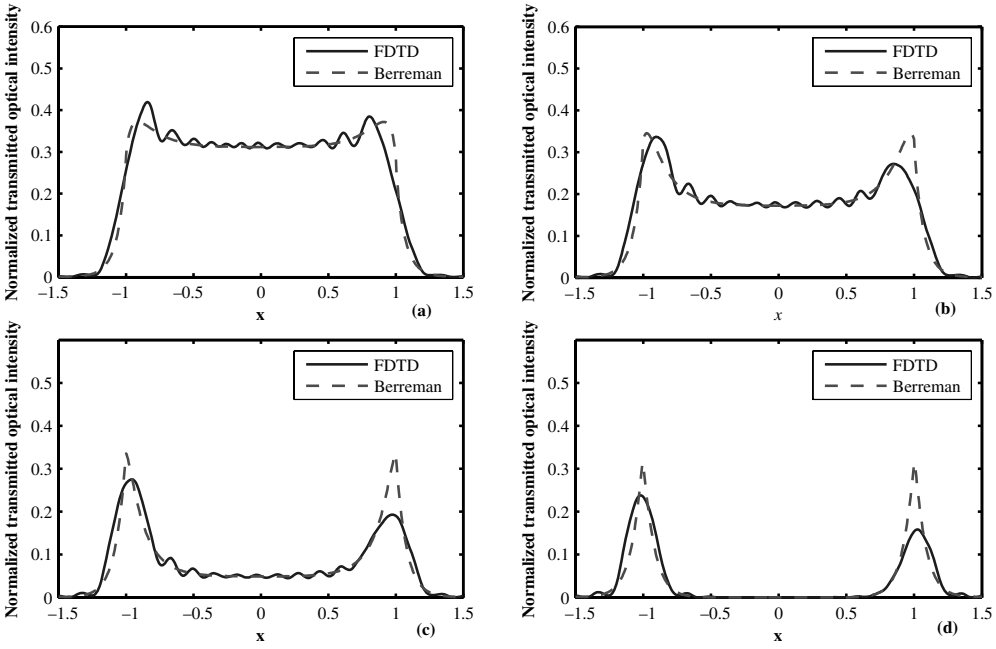

FIG. 4.5. *Normalized optical intensities of transmitted polarized light using the FDTD and Berreman method in the case of* (a) $\phi = \pi/3$, (b) $\phi = \pi/2.57$, (c) $\phi = \pi/2.25$, *and* (d) $\phi = \pi/2$ *anchoring boundary conditions corresponding to NLS structures in the corresponding panels of Figure* 4.3. *The normalized intensities are a function of distance along the x direction.*

$(\partial \mathbf{n}/\partial \mathrm{x})$ in the adjacent two interfaces regions between the NSPR and SPR. On the other hand, the Berreman method fails to capture this effect because lateral gradients in the optic axis are not taken into account [20, 21, 22, 23, 24, 25]. From this result, it is to be expected that the magnitude of deviation between the two optical methods will increase as lateral gradients $(\partial \mathbf{n}/\partial x)$ increase.

Figure 4.5 shows the normalized optical intensity of transmitted light through the NLC textures (see Figure 4.3), computed using the FDTD and Berreman methods, for the following anchoring conditions in the SPR; (a) $\phi = \pi/3$, (b) $\phi = \pi/2.57$, (c) $\phi = \pi/2.25$, and (d) $\phi = \pi/2$. Once again, the intensities of the transmitted light in the SPR region continually decay as the azimuthal angle increases above$\phi = \pi/4$, as shown in Figure 4.5. On the other hand, the degree of the disagreement in the optical intensities between both methods continually increases, due to an increase in the lateral gradient of the optic axis near the interface between the NSPR and SPR. The results show that the maximum level of the disagreement corresponds to $\phi = \pi/2$ (Figure 4.5(d)), where two surface defects are present on the two interfaces between the NSPR and SPR. An additional difference between the two predicted outputs is found by considering the symmetry properties of optical signals. FDTD always predicts asymmetric optical signals, while Berreman's method predicts a symmetric optical signal:

$$\begin{aligned} &\text{Berreman method:} \quad B(x) = B(-x), \\ &\text{FDTD method:} \quad F(x) \neq F(-x), \end{aligned}$$

where $B(x)$ is the Berreman optical signal and $F(x)$ is the FDTD signal, shown by Figures 4.5(a–d).

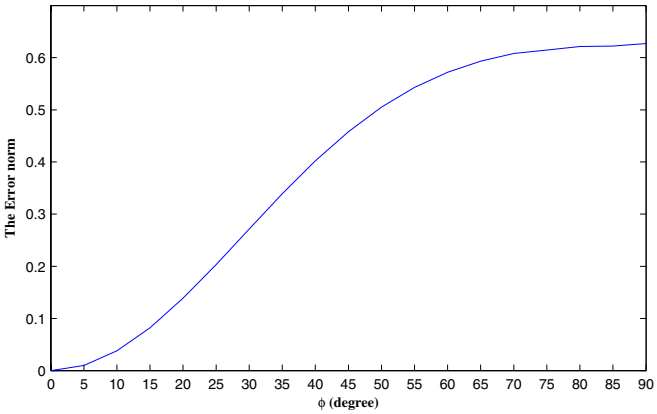

FIG. 4.6. *Error norm $\|E(\phi)\|$ based on the difference of the optical response between the two optical methods, FDTD and Berreman, as a function of ϕ azimuthal anchoring conditions.*

The norm of the asymmetry function $|F(x) - F(-x)|$ increases with increases in the lateral gradient orientation, and for $\phi = \pi/2$, when two surface defects are present, the two peaks of the optical signal differ by 0.1, as shown in Figure 4.5(d). This asymmetric optical feature is due to nonsymmetric orientation gradients along the x direction. The asymmetric optical feature due to nonsymmetric orientation gradients has been reported in the literature [20, 21, 22]. Next we assess the difference between optical signals predicted by the two methods as a function of the azimuthal angle ϕ on the lower surface containing the SPR, by introducing the error norm $\|E(\phi)\|$:

$$\|E(\phi)\| = \sqrt{\sum_{i=1}^{m} |\mathrm{F}(i) - \mathrm{B}(i)|^2}, \tag{4.8}$$

where **F** and **B** are the optical vector solutions of the FDTD and Berreman, respectively; i is the discretized location along the x dimension; and m is equal to 577.

Figure 4.6 shows the error norm $\|E(\phi)\|$ as a function of the azimuthal angle. The error norm $\|E(\phi)\|$ initially increases exponentially with ϕ and eventually reaches a maximum at $\phi = \pi/2$, where there is maximum in the lateral gradient $\left|\frac{\partial \mathbf{n}}{\partial x}\right|$. The major contribution of the deviations between the two optical methods arises from the interfaces between the NSPR and SPR, where strong variations of the lateral gradients are present. Next we consider the practical problem of how to use optical transmission to find surface orientation; this is an inverse problem that arises in the actual use of the LC biosensor. Modulation of transmitted optical intensity under fixed cross-polar upon gradual rotation of an NLC film is one of methods used to determine the degree of alignment and texture type in NLC films [45, 46]. In this work using the accurate FDTD method we have simulated the effect of sample rotation under fixed cross-polars on the optical output in order to determine the preferred orientation in the SPR region; the simulation results are validated with experiments [4, 7]. The simulation steps are as follows:

1. specify the anchoring condition on the SPR by selecting ϕ;
2. solve the texture equation and obtain the director field;
3. with fixed cross-polars, rotate the computational domain by a small angle ψ;

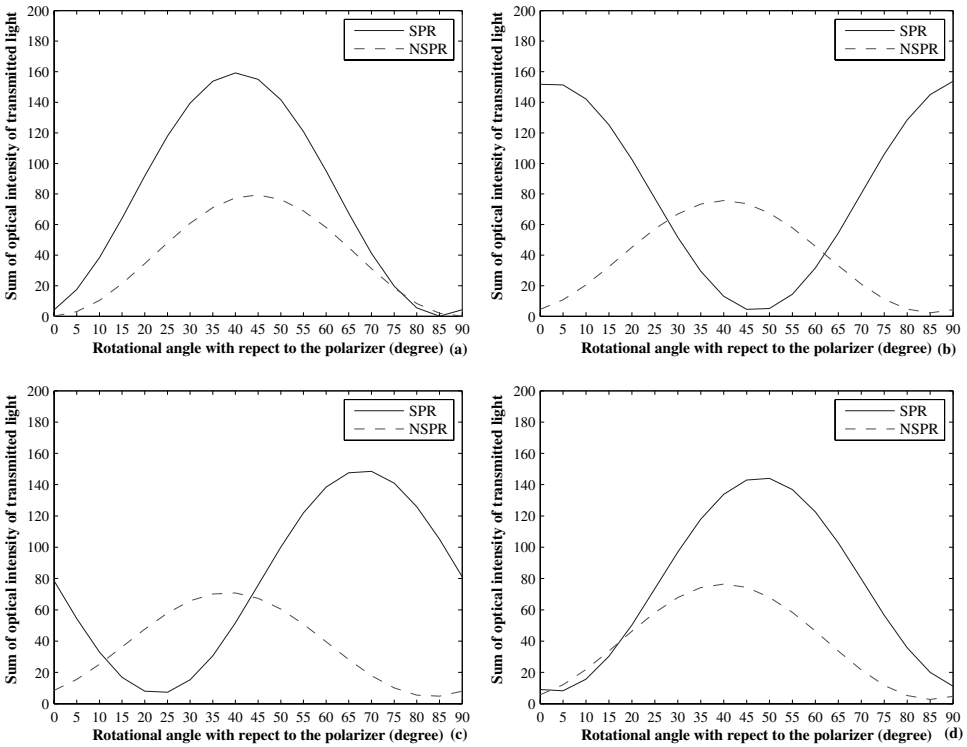

FIG. 4.7. *Modulation of the transmitted intensities of polarized light during rotation with respect to polarizer for the NSPR and SPR regions of the NLC structures corresponding to anchoring boundary conditions for the SPR:* (a) $\phi = \pi/36$, (b) $\phi = \pi/4$, (c) $\phi = \pi/2.57$, *and* (d) $\phi = \pi/2$. *Dashed lines indicate the sum of normalized intensities of transmitted light in the NSPR from* $-1.5 \le x \le -1$ *and* $1 \le x \le 1.5$ *at each rotation angle from* 0 *to* 90°. *Solid lines indicate the sum of normalized intensities of transmitted light in the SPR from* $-1 < x < 1$, *at each rotation angle from* 0 *to* 90°.

4. compute $\mathbf{F}(i), \mathbf{B}(i)$ and $\|E(\phi, \psi)\|$;
5. increase rotation angle and repeat step 4 until total rotation is $\pi/2$;
6. repeat steps 1–5 for $0 \le \phi \le \pi/2$.

The key point in this technique is that the cross-polars are fixed and the sample is rotated.

Figure 4.7 shows optical modulation of the NLS structures for (a) $\phi = \pi/36$, (b) $\phi = \pi/4$, (c) $\phi = \pi/2.57$, and (d) $\phi = \pi/2$ under sample rotation ($0 \le \psi \le \pi/2$) between fixed cross-polars using the FDTD. Comparing the dashed profiles in Figures 4.7(a–d), it is seen that the maximum optical intensity of polarized light appears near $\psi = \pi/4$ and that the profiles are nearly independent of ϕ. The magnitude of ϕ on the SPR region has no effect on $\mathbf{F}$ in the NSPR. Comparing the full-line profiles in Figures 4.7(a–d), it is seen that the extremum in optical intensity is a strong function of ϕ. The profiles shown in Figure 4.7, their specific features, and their response to changes in the azimuthal angle are in good agreement with experimental results [4, 7, 45, 46].

Figure 4.8 shows the extrema in the optical output in the SPR region in terms of ψ as a function of ϕ. Each dot is found from the maximum in optical transmission; for example, in Figure 4.7(a), the maximum corresponds to ψ =0.74, $\phi = 0$. The maximum optical intensities are predicted near $\psi = \pi/4$, for both $\phi = 0$ and $\phi = \pi/2$. Comparing the predicted results of the modulation pattern of the transmitted optical

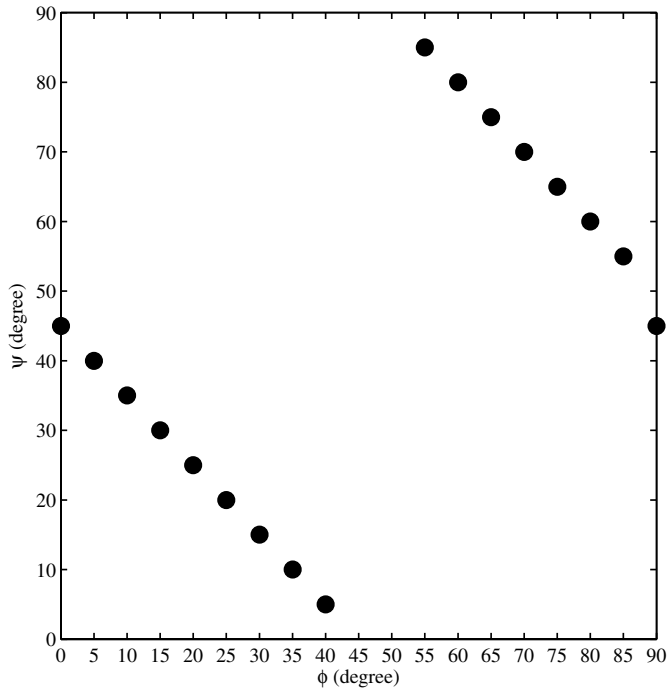

FIG. 4.8. *Extrema in the optical output in the SPR region in terms of ψ as a function of ϕ. ψ and ϕ represent the rotational angle (0 to 90°) and anchoring conditions, respectively, in the SPR region $-1 \leq x \leq 1$.*

intensity with the extrema shown in Figures 4.7 and 4.8 by the FDTD method with the experimental results [4, 7], a preferred orientation of NLCs on the SPR lower surface is confirmed to be near 50 to 55° with the respect to the polarizer.

5. Conclusions. A computational model based on the classical Landau–de Gennes tensor theory for LCs has been developed and implemented in order to describe orientation and surface defects in an NLC film exhibiting two distinct regions due to surface condition changes arising from protein deposition. Optical models using the FDTD and Berreman methods are evaluated in order to predict optical behavior of the heterogeneous films and to determine possible surface anchoring conditions.

Texture formation for complex surface conditions was predicted and characterized as a function of azimuthal anchoring conditions on a lower surface. These predicted textures were then used for optical modeling. Two significant optical features, oscillations and nonsymmetric optical signals, are predicted by the FDTD method but are absent in the Matrix–Berreman method due to its inability to capture effects arising from gradients of the optic axis in the lateral direction. The oscillation's amplitude and magnitude of the nonsymmetric optical response increase with increasing magnitude in the lateral orientation gradients. The optical simulations indicate that the magnitude of the lateral orientation gradient and its symmetry are important factors in the optical behavior of textured NLC films, and hence the FDTD method is more appropriate than the Berreman method for textured samples.

The optical responses of textured LC films in contact with partially covered substrates containing adsorbed proteins were simulated in order to determine the preferred orientation of the optic axis on the protein-covered section of the substrate. Prediction of modulation of transmitted polarized light under fixed cross-polars during sample rotation was used to define a possible preferred orientation on the lower surface where the printed proteins are present. The optical simulations were in good agreement with experimental results [4, 7], indicating that the preferred orientation of the optic axis on the protein patch is approximately 50 to 55° with the respect to the polarizer.

The integrated microstructure-optical simulation model based on the Landau–de Gennes-FDTD method provides for firm foundations on which to further develop biosensors based on LC vision.

ON BUDAEV AND BOGY'S APPROACH TO DIFFRACTION BY THE 2D TRACTION-FREE ELASTIC WEDGE*

V. V. KAMOTSKI†, L. JU. FRADKIN‡, B. A. SAMOKISH§, V. A. BOROVIKOV¶, AND V. M. BABICH‖

Abstract. Several semianalytical approaches are now available for describing diffraction of a plane wave by the 2D (two-dimensional) traction free isotropic elastic wedge. In this paper we follow Budaev and Bogy, who reformulated the original diffraction problem as a singular integral one. This comprises two algebraic and two singular integral equations. Each integral equation involves two unknowns, a function and a constant. We discuss the underlying integral operators and develop a new semianalytical scheme for solving the integral equations. We investigate the properties of the solution obtained and argue that it is the solution of the original diffraction problem. We describe a comprehensive code verification and validation program.

Key words. diffraction, elastic wedge, Sommerfeld transform, singular integral problem

1. Introduction.

Evaluation of the wave fields diffracted by an isotropic elastic wedge is a challenging problem. A review of various attempts to solve it over the past fifty years is given, e.g., in [5]. It appears that a purely analytical solution is impossible, and instead there have been two major semianalytical approaches developed so far. These are based on

1. a representation of the displacement in the form of a single layer potential—the superposition of the fields radiated by imaginary point sources situated on the faces of the wedge. Their Fourier transforms satisfy integral equations, which can be solved numerically (see, e.g., [12, 11, 10, 13, 14] and references therein), or
2. a representation of the elastodynamic potentials in the form of the Sommerfeld integral—the superposition of plane waves propagating in all (including complex) directions. The amplitudes of the plane waves belong to a certain class of analytical functions and satisfy a system of functional equations. Budaev [4] has reformulated this problem as a singular integral one, involving a

combination of algebraic and singular integral equations. Budaev and Bogy [5, 6, 9] have offered a numerical schedule for solving the problem, and for the incident Rayleigh wave they calculated the Rayleigh reflection and transmission coefficients. However, the schedule has never been given a transparent description.

In sections 2 and 3 we outline our own semianalytical recipe for solution of the singular integral problem, and in section 4 we verify and validate the resulting code. In Appendix A we describe the nomenclature, and in other appendices, we offer the necessary theoretical considerations, formulas, and numerical options.

2. Statement of the problem and the Sommerfeld amplitudes. Let us briefly present the full statement of the original diffraction problem. We seek the elastodynamic potentials $\psi_i = \psi_i(kr, \theta)$ that satisfy the Helmholtz equations in the two-dimensional (2D) wedge of angle 2α with traction-free faces; that is, we address the boundary value problem

$$\Delta\psi_0 + \gamma^2 k^2 \psi_0 = 0, \qquad \Delta\psi_1 + k^2\psi_1 = 0, \qquad |\theta| < \alpha, \tag{2.1}$$

$$\left[\frac{2}{r}\frac{\partial^2\psi_0}{\partial\theta\partial r} + \frac{1}{r^2}\frac{\partial^2\psi_1}{\partial\theta^2} - \frac{\partial^2\psi_1}{\partial r^2} + \frac{1}{r}\frac{\partial\psi_1}{\partial r} - \frac{2}{r^2}\frac{\partial\psi_0}{\partial\theta}\right] = 0, \qquad |\theta| = \alpha, \tag{2.2}$$

$$\frac{1}{\gamma^2}\left[\frac{1}{r^2}\frac{\partial^2\psi_0}{\partial\theta^2} + \frac{\partial^2\psi_0}{\partial r^2} + \frac{1}{r}\frac{\partial\psi_0}{\partial r}\right] - 2\left[\frac{\partial^2\psi_0}{\partial r^2} + \frac{1}{r}\frac{\partial^2\psi_1}{\partial\theta\partial r} - \frac{1}{r^2}\frac{\partial\psi_1}{\partial\theta}\right] = 0, \qquad |\theta| = \alpha. \tag{2.3}$$

Above and everywhere below, the parameter k is the shear wave number; $\gamma = c_S/c_P$ is the ratio of the shear and compressional speeds c_S and c_P, and the subscript i takes values 0 or 1. The geometry of the problem is shown in Figure 2.1. Given an incident wave, we seek the scattered potentials satisfying the radiation conditions at infinity (analogous to the ones in [17, Theorem 4.1]]; also see [15, Appendix C]) and bounded elastic energy condition at the wedge tip.

Note that the potentials are related to displacement $\mathbf{u} = \mathbf{u}(\mathbf{x})$ via $\mathbf{u} = \nabla\psi_0 + \nabla^\perp\psi_1$, where the nabla operators are $\nabla = (\partial_x, \partial_y)$, $\nabla^\perp = (\partial_y, -\partial_x)$. Note too that

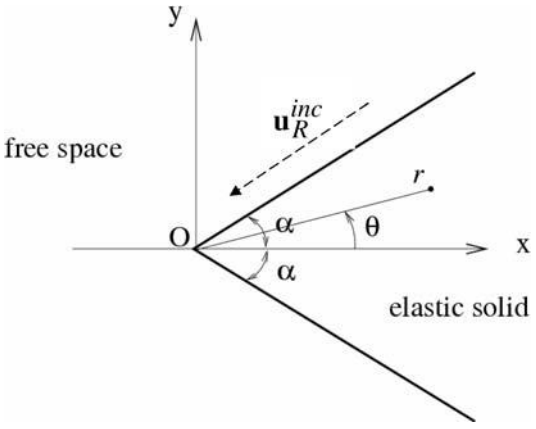

FIG. 2.1. *Geometry of the traction-free elastic wedge.*

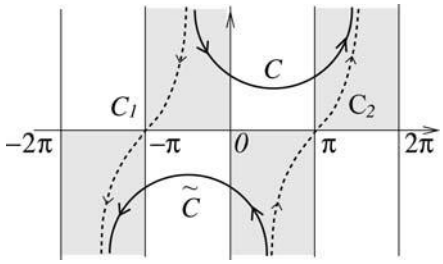

FIG. 2.2. *The Sommerfeld contours in the complex ω-plane.*

in view of this representation the Helmholtz equations imply

$$\psi_0(\mathbf{x}) = -(\gamma k)^{-2}\nabla\cdot\mathbf{u}(\mathbf{x}), \qquad \psi_1(\mathbf{x}) = -k^{-2}\nabla^{\perp}\cdot\mathbf{u}(\mathbf{x}). \tag{2.4}$$

It follows that $\psi_i(kr,\theta)$ are uniquely defined by $\mathbf{u}(\mathbf{x})$, and since for the corresponding Lamé problem in $\mathbf{u}(\mathbf{x})$ the existence and uniqueness results have been proven [16]. [17, Theorem 3.1], the above diffraction problem as formulated in terms of the potentials has a unique solution too. Moreover, due to (2.4) all the analytical properties of $\mathbf{u}(\mathbf{x})$ established in [17] imply the corresponding properties of $\psi_i(kr,\theta)$.

The solutions $\psi_i(kr,\theta)$ of the Helmholtz equations can be represented in the form of the Sommerfeld integrals

$$\psi_i(kr,\theta) = \int_{C\bigcup\widetilde{C}} \Psi_i(\omega+\theta)\mathrm{e}^{\mathrm{i}\gamma kr\cos\,\omega}\mathrm{d}\omega, \tag{2.5}$$

which can be rewritten as

$$\psi_i(kr,\theta) = \int_{C} \Big[\Psi_i(\omega+\theta) - \Psi_i(-\omega+\theta)\Big]\mathrm{e}^{\mathrm{i}\gamma kr\cos\,\omega}\mathrm{d}\omega. \tag{2.6}$$

Here the Π-shaped contour C runs from $-\pi/2+\mathrm{i}\infty$ to $3\pi/2+\mathrm{i}\infty$. The contour $\widetilde{C}$ is the reflection of C with respect to the origin, and the full integration contour $C\bigcup\widetilde{C}$ is shown in Figure 2.2. One can justify (2.6) by applying the Laplace transform in kr to $\psi_i(kr,\theta)$, changing the Laplace variable s to ω, such that $s=\mathrm{i}\cos\,\omega$, and exploiting the behavior of $\psi_i(kr,\theta)$ both in the vicinity of the wedge tip and at infinity (for details see [15, Appendix A]). It follows that the analytic functions $\Psi_i(\omega)$ possess a finite number of singularities in any vertical strip and are regular at the imaginary infinity. Moreover, in Appendix B we show that the tip behavior of $\psi_i(kr,\theta)$ determines the asymptotic expansion of $\Psi_i(\omega)$ at the imaginary infinity and provides us with an asymptotic estimate

$$\Psi_i(\omega) = O(\mathrm{e}^{-\mathrm{Re}\;p\;|\,\mathrm{Im}\;\omega|}), \quad \mathrm{Re}\;p>-1, \quad |\,\mathrm{Im}\;\omega|\to\infty, \tag{2.7}$$

which assures the convergence of integrals (2.6). Note that these integrals are invariant under the transformation $\Psi_i(\omega)\to\Psi_i(\omega)+\mathrm{const}$. In Appendix B we also show that as $\mathrm{Im}\;\omega\to\infty$, the asymptotic expansion of the preexponential factor in (2.6) contains a constant term. Below, we choose $\Psi_i(\omega)$, $i=0,1$ so that the constant terms in their asymptotic expansions valid as $\mathrm{Im}\;\omega\to\infty$ and $\mathrm{Im}\;\omega\to-\infty$ differ only by sign. We call those $\Psi_i(\omega)$ the Sommerfeld amplitudes.

Introducing the closed contour $C\bigcup(-\mathrm{C}_2)\bigcup\widetilde{C}\bigcup(-C_1)$, the Sommerfeld integrals (2.5) can be evaluated as the contributions of the poles and branch points inside that

contour plus the sum of integrals over the steepest descent contours C_1 and C_2. The former describe all bulk and surface waves arising in the problem, as well as the head waves, and the latter can be evaluated using the steepest descent method to provide a description of the tip diffracted body waves. It follows that all physically meaningful poles and branch points of $\Psi_i(\omega+\theta)$ must be located between the contours C_1 and C_2, and in this region the Sommerfeld amplitudes $\Psi_i(\omega)$ should contain no physically meaningless singularities. Since inside the wedge we have $|\theta| \le \alpha$, this means that all physically meaningful singularities—and only those—must lie at a finite distance from the horizontal axis between the contours C_1 and C_2 as shifted horizontally by $-\alpha$ and α, respectively; that is, within the Malyuzhinets region

$$\left\{\omega: \ -\frac{\pi}{2}-\alpha-2\tan^{-1}(\mathrm{e}^{-\operatorname{Im}\ \omega}) \le \operatorname{Re}\ \omega \le \frac{3\pi}{2}+\alpha-2\tan^{-1}(\mathrm{e}^{-\operatorname{Im}\ \omega})\right\}. \tag{2.8}$$

To summarize, the scattered field can be fully described once an efficient algorithm is produced for calculating the Sommerfeld amplitudes $\Psi_i(\omega)$ in the region (2.8). We proceed with this task.

3. Problem reformulation. In view of its symmetry with respect to the polar angle, the original problem naturally splits into "symmetric" and "antisymmetric," corresponding respectively to the symmetric and antisymmetric parts of the incident wave. These involve functions $\Psi_i^{\pm}(\omega)$ such that we have

$$\Psi_i^{\pm}(\omega) = \frac{1}{2}[\Psi_i(\omega) + (-1)^{i+1}\Psi_i(-\omega)]. \tag{3.1}$$

We follow the approach pioneered in elastodynamics by [4] and first substitute (2.6) into the boundary conditions (2.2) and (2.3) to obtain the system of functional equations. We then employ the singular integral transforms to reformulate the problem as a system of algebraic and singular integral equations.

3.1. Functional equations. Let us start with the symmetric problem. The boundary conditions (2.2) and (2.3) imply

$$\begin{aligned}&\int_C \gamma^2 a_1(\omega)\Big[\Psi_0^+(\omega+\theta)-\Psi_0^+(\omega-\theta)\Big]\mathrm{e}^{\mathrm{i}\gamma kr\ \cos\ \omega}\mathrm{d}\omega\\ &\qquad -\int_C a_2(\omega)\Big[\Psi_1^+(\omega+\theta)-\Psi_1^+(\omega-\theta)\Big]\mathrm{e}^{\mathrm{i}kr\cos\ \omega}\mathrm{d}\omega = 0,\end{aligned} \tag{3.2}$$

$$\begin{aligned}&\int_C \gamma^2\left[a_3(\omega)+\frac{1}{\gamma^2}\right]\Big[\Psi_0^+(\omega+\theta)+\Psi_0^+(\omega-\theta)\Big]\mathrm{e}^{\mathrm{i}\gamma kr\cos\ \omega}\mathrm{d}\omega\\ &\qquad -\int_C a_1(\omega)\Big[\Psi_1^+(\omega+\theta)+\Psi_1^+(\omega-\theta)\Big]\mathrm{e}^{\mathrm{i}kr\cos\ \omega}\mathrm{d}\omega = 0,\end{aligned} \tag{3.3}$$

where $a_1(\omega) = \sin 2\omega, a_2(\omega) = -\cos 2\omega$, and $a_3(\omega) = -2\cos^2\omega$. Introducing in the first terms of both (3.2) and (3.3) the new integration variable $\breve{\omega}$ such that $\cos\breve{\omega} = \gamma\cos\omega$, dropping the check, and transforming the contour of integration back to C, the equations acquire the form

$$\int_C f(\omega)\mathrm{e}^{\mathrm{i}kr\cos\ \omega}\mathrm{d}\omega = 0, \tag{3.4}$$

where, due to (2.7), as $|\operatorname{Im}\ \omega| \to \infty$, $f(\omega) = O(\exp(\operatorname{Im}\ \omega\ [2-\operatorname{Re}\ p]))$, with $\operatorname{Re}\ p > -1$. Using the Malyuzhinets theorem [20], f is an odd trigonometric polynomial of

the second order. It follows that the pair $\Psi_i^+(\omega)$ satisfies (3.2) and (3.3) if and only if it satisfies the functional equations

$$t_{11}\Big\{\Psi_0^+[g(\omega)+\alpha]+\Psi_0^+[g(\omega)-\alpha]\Big\}+t_{12}\Big\{\Psi_1^+(\omega+\alpha)+\Psi_1^+(\omega-\alpha)\Big\}=Q_1^+,$$

$$t_{21}\Big\{\Psi_0^+[g(\omega)+\alpha]-\Psi_0^+[g(\omega)-\alpha]\Big\}+t_{22}\Big\{\Psi_1^+(\omega+\alpha)-\Psi_1^+(\omega-\alpha)\Big\}=Q_2^+, \tag{3.5}$$

where $t_{11}=\cos 2\omega \sin\omega/\sqrt{\gamma^2-\cos^2\omega}$, $t_{12}=t_{21}=\sin 2\omega$, $t_{22}=-\cos 2\omega$, and we have

$$Q_j^+=c_{j1}^+\sin\omega+c_{j2}^+\sin 2\omega, \tag{3.6}$$

with c_{jk}^+, $j,k=1,2$, unknown constants. The function $g(\omega)=\cos^{-1}(\gamma^{-1}\cos\omega)$ relates the shear incidence angles to compressional reflection angles, and its branch cuts are chosen so that the deformed contour of integration $\breve{C}=\{\breve{\omega}=g(\omega):\omega\in C\}$ may be transformed back to C without touching them. They are the segments

$$[-\theta_h+\pi n,\theta_h+\pi n],\quad \theta_h=\cos^{-1}\gamma,\quad n\ -\ \text{integer}. \tag{3.7}$$

The branch of $g(\omega)$ is chosen so that it has the properties

$$\begin{aligned} &g\left(\frac{\pi}{2}\right)=\frac{\pi}{2},\\ &g(\omega+\pi n)=g(\omega)+\pi n,\\ &g(\omega)\simeq\omega-\mathrm{i}\ln\gamma+O\big(\mathrm{e}^{-2|\mathrm{Im}\omega|}\big)\ \text{ as } \mathrm{Im}\,\omega\to\infty. \end{aligned} \tag{3.8}$$

In order to investigate restrictions on c_{ij}^+ let us substitute expansions (B.7) of the Sommerfeld amplitudes into (3.5) and equate the coefficients of the leading asymptotic terms in the resulting equations. First, we note that in the symmetric case, (B.7) contains no constant terms, and therefore there are no $\exp(-2\mathrm{i}\omega)$ terms in the left-hand sides of these equations. This implies that $c_{12}^+=c_{22}^+=0$. Secondly, since the tip asymptotics of $\psi_i^+(kr,\theta)$ contain the terms with the exponent 1, these sides contain the $\exp(-\mathrm{i}\omega)$ terms. Equating the coefficients of the $\exp(-\mathrm{i}\omega)$ terms, we obtain

$$(\gamma\Psi_{0m}^+ +\mathrm{i}\Psi_{1m}^+)\cos\alpha=\frac{\mathrm{i}}{2}c_{11}^+,\qquad -(\gamma\Psi_{0m}^+ +\mathrm{i}\Psi_{1m}^+)\sin\alpha=\frac{\mathrm{i}}{2}c_{21}^+. \tag{3.9}$$

Hence we have

$$c_{21}^+=-c_{11}^+\tan\alpha. \tag{3.10}$$

Note that if $\gamma\Psi_{0m}^+ +\mathrm{i}\Psi_{1m}^+=0$, then $c_{21}^+=-c_{11}^+=0$.

It follows that the right-hand sides in (3.5) *might be*—and, as we show in sections 4 and 5, *are*—nonzero, so that we have

$$Q_1^+=c_1^+\sin\omega,\qquad Q_2^+=-c_1^+\tan\alpha\sin\omega, \tag{3.11}$$

where from now on, for simplicity, we use the notation $c_1^+=c_{11}^+$.

The antisymmetric problem can be treated similarly, with one minor modification: For all wedge angles α, expansion (B.7) might contain a nonzero constant term Ψ_{00}^-, and therefore the functional equations might contain a second order term. However, this term can be eliminated by subtracting Ψ_{00}^- from the Sommerfeld amplitude $\Psi_0^-(\omega)$, redefining it in the process. The corresponding functional equations are

$$t_{21}\Big\{\Psi_0^-[g(\omega)+\alpha]+\Psi_0^-[g(\omega)-\alpha]\Big\}+t_{22}\Big\{\Psi_1^-(\omega+\alpha)+\Psi_1^-(\omega-\alpha)\Big\}=Q_1^-,$$

$$t_{11}\Big\{\Psi_0^-[g(\omega)+\alpha]-\Psi_0^-[g(\omega)-\alpha]\Big\}+t_{12}\Big\{\Psi_1^-(\omega+\alpha)-\Psi_1^-(\omega-\alpha)\Big\}=Q_2^-, \tag{3.12}$$

with

$$Q_1^- = c_1^- \sin\omega, \qquad Q_1^- = c_1^- \tan\alpha \sin\omega. \tag{3.13}$$

We note that the above reasoning involves only the asymptotic terms with $p_m^- = 0$ or else with $p_m^\pm = 1$ and $N_m^\pm = 1$, and therefore applies to all wedge angles under consideration. We note too that Budaev and Bogy [5] have made several attempts to establish restrictions on the constants. They first used the arguments of the type outlined above in [7]. By excluding from consideration the terms with $p_m^\pm = 1$, it is easy to reach the erroneous conclusion that all constants $c_{jk}^\pm$ are zero. In the static problems, such exclusion is justified, because the terms describe body translations. By contrast, in the dynamic problems, their presence is indicative of nontrivial phenomena.

We proceed by discussing the singularities of the Sommerfeld amplitudes. First, we assume that the incident wave is plane or Rayleigh, so that it manifests itself in $\Psi_i^\pm(\omega)$ in the form of terms which contain simple poles $\theta_{i\ell}$ in the strip $|\operatorname{Re}\ \omega| \le \alpha$. The functional equations (3.5) and (3.12) can be recast as

$$\begin{pmatrix} \Psi_0^\pm(g(\omega)+\alpha) \\ \Psi_1^\pm(\omega+\alpha) \end{pmatrix} = \pm \begin{pmatrix} \mathrm{r}_{11}(\omega) & \mathrm{r}_{12}(\omega) \\ \mathrm{r}_{21}(\omega) & \mathrm{r}_{22}(\omega) \end{pmatrix} \begin{pmatrix} \Psi_0^\pm(g(\omega)-\alpha) \\ \Psi_1^\pm(\omega-\alpha) \end{pmatrix} + c_1^\pm \frac{\sqrt{\gamma^2 - \cos^2\omega}}{\Delta(\omega)} \begin{pmatrix} e_1^\pm(\omega) \\ e_2^\pm(\omega) \end{pmatrix}, \tag{3.14}$$

where the reflection coefficients for the traction-free elastic half space $\mathrm{r}_{jk}(\omega)$, $j,k = 1,2$, as well as the Rayleigh function $\Delta(\omega)$, and functions $e_j^\pm(\omega)$ are given in Appendix A. The system (3.14) can be used to effect the analytical continuation from the strip $|\operatorname{Re}\ \omega| \le \alpha$ and thus find all poles $\theta_{i\ell}$ of the Sommerfeld amplitudes, with their respective residues, which are located in the strip $\operatorname{Re}\ \omega \,\epsilon\, I = [\pi/2-\alpha,\ \pi/2+\alpha]$. The rationale behind the choice of the latter strip is clarified below. The poles are incidence and reflection angles of the respective incident, reflected, and multiply reflected waves, and their residues describe the amplitudes of these waves—see [5, (17) and (18)]. The first index in $\theta_{i\ell}$ refers to the mode of the wave, and the second to its place in a sequence of all incident and (multiply) reflected waves (see [15, Appendix D]).

Let us now again follow the above authors and introduce the decomposition

$$\Psi_i^\pm(\omega) = \widehat{\Psi}_i^\pm(\omega) + \widetilde{\Psi}_i^\pm(\omega), \tag{3.15}$$

where the unknown $\widetilde{\Psi}_i^\pm(\omega)$ is regular in the strip $\operatorname{Re}\ \omega \,\epsilon\, I$, and the known $\widehat{\Psi}_i^\pm$ is

$$\widehat{\Psi}_i^\pm(\omega) = \sum_\ell \operatorname{Res}\ (\Psi_i^\pm; \theta_{i\ell}) \sigma(\omega - \theta_{i\ell}), \quad \operatorname{Re}\ \theta_{i\ell} \,\epsilon\, I. \tag{3.16}$$

Above, an otherwise arbitrary function $\sigma(\omega)$ should be chosen to be analytic everywhere inside the strip $\operatorname{Re}\ \omega \,\epsilon\, I$, except for a simple pole at zero, where it has the residue 1. The weakest restriction we can impose on behavior of $\sigma(\omega)$ at the imaginary infinity is that it grows more slowly than $\exp(|\operatorname{Im}\ \omega|\pi/2\alpha)$. Instead, we impose a stronger restriction—that it behaves as the amplitudes in (2.7). If $\sigma(\omega)$ possesses singularities which lie outside the strip $\operatorname{Re}\ \omega \,\epsilon\, I$, the functions $\widehat{\Psi}_i^\pm(\omega)$ contain extra poles which describe waves that are outgoing at physical reflection angles but have nonphysical amplitudes. This causes no complication, since the corresponding singular terms in $\widehat{\Psi}_i^\pm(\omega)$ and $\widetilde{\Psi}_i^\pm(\omega)$ mutually cancel.

Next we substitute decomposition (3.15) into the functional equations (3.5) and then (3.12) to obtain the following inhomogeneous systems of equations for the regular components of the Sommerfeld amplitudes:

$$\Big\{\widetilde{\Psi}_0^+[g(\omega)+\alpha]+\widetilde{\Psi}_0^+[g(\omega)-\alpha]\Big\}+B\Big[\widetilde{\Psi}_1^+(\omega+\alpha)+\widetilde{\Psi}_1^+(\omega-\alpha)\Big]=R_1^+ +c_1^+S_1,$$

$$A\Big\{\widetilde{\Psi}_0^+[g(\omega)+\alpha]-\widetilde{\Psi}_0^+[g(\omega)-\alpha]\Big\}+\Big[\widetilde{\Psi}_1^+(\omega+\alpha)-\widetilde{\Psi}_1^+(\omega-\alpha)\Big]=R_2^+ +c_1^+\tan\alpha\, S_2,$$

(3.17)

and

$$A\Big\{\widetilde{\Psi}_0^-[g(\omega)+\alpha]+\widetilde{\Psi}_0^-[g(\omega)-\alpha]\Big\}+\Big[\widetilde{\Psi}_1^-(\omega+\alpha)+\widetilde{\Psi}_1^-(\omega-\alpha)\Big]=R_2^- +c_1^-S_2,$$

$$\Big\{\widetilde{\Psi}_0^-[g(\omega)+\alpha]-\widetilde{\Psi}_0^-[g(\omega)-\alpha]\Big\}+B\Big[\widetilde{\Psi}_1^-(\omega+\alpha)-\widetilde{\Psi}_1^-(\omega-\alpha)\Big]=R_1^- -c_1^-\tan\alpha\, S_1,$$

(3.18)

where we use the notation

$$A=\frac{t_{21}(\omega)}{t_{22}(\omega)}=-\tan 2\omega,\qquad B=\frac{t_{12}(\omega)}{t_{11}(\omega)}=\frac{2\cos\,\omega\sqrt{\gamma^2-\cos^2\omega}}{\cos\,2\omega},$$

$$R_1^\pm=-\Big\{\widehat{\Psi}_0^+[g(\omega)\pm\alpha]\pm\widehat{\Psi}_0^\pm[g(\omega)-\alpha]\Big\}-B\Big[\widehat{\Psi}_1^\pm(\omega+\alpha)\pm\widehat{\Psi}_1^\pm(\omega-\alpha)\Big],$$

$$R_2^\pm=-A\Big\{\widehat{\Psi}_0^\pm[g(\omega)+\alpha]\mp\widehat{\Psi}_0^\pm[g(\omega)-\alpha]\Big\}-\Big[\Psi_1^\pm(\omega+\alpha)\mp\widehat{\Psi}_1^\pm(\omega-\alpha)\Big],$$

$$S_1=\frac{\sqrt{\gamma^2-\cos^2\,\omega}}{\cos\,2\omega},\qquad S_2=\frac{\sin\,\omega}{\cos\,2\omega}. \tag{3.19}$$

To summarize, following Budaev and Bogy, the original problem can be reformulated as the following boundary value problem in the theory of analytic functions: Seek constants $c_1^\pm$ and functions $\widetilde{\Psi}_i^\pm(\omega)$ such that

1. $\widetilde{\Psi}_i^\pm(\omega)$ are analytic for Re $\omega\,\epsilon\, I$ and satisfy the asymptotic estimate (2.7);
2. the values that $\widetilde{\Psi}_i^\pm(\omega)$ take on the boundaries of the strip Re $\omega\,\epsilon\, I$ are linked by (3.17) and (3.18) (that is, we solve these equations for Re $\omega=\pi/2$).

The above considerations and the properties of the Sommerfeld transform, which are outlined in [15, Appendix A], show that such a pair exists if there exists a solution of the original problem. The uniqueness of $\Psi_i^\pm(\omega)$ is a more complicated issue, which we address in section 5.

3.2. Singular integral equations. Budaev [4] has suggested exploiting the fact that for all functions $F(\omega)$ satisfying the first of the above assumptions, the singular integral transform

$$(HF)(\omega)=\frac{1}{2\alpha\mathrm{i}}\mathrm{V.P.}\int_{\pi/2-\mathrm{i}\infty}^{\pi/2+\mathrm{i}\infty}\frac{F(\xi)\mathrm{d}\xi}{\sin\,[\frac{\pi}{2\alpha}(\xi-\omega)]},\quad \mathrm{Re}\ \omega=\frac{\pi}{2}, \tag{3.20}$$

has the property

$$H:\ F(\omega+\alpha)+F(\omega-\alpha)\to F(\omega+\alpha)-F(\omega-\alpha),\quad \mathrm{Re}\ \omega=\frac{\pi}{2}, \tag{3.21}$$

with V. P. standing for the Cauchy principal value. This means that on the vertical line Re $\omega=\pi/2$, the terms in the square brackets in (3.17) and (3.18) are related by

H. The terms in the curly brackets are linked by a similar explicit transform,

$$\overline{H}F(\omega) = \frac{1}{2\alpha \mathrm{i}}\, V.P. \int_{\pi/2-\mathrm{i}\infty}^{\pi/2+\mathrm{i}\infty} \frac{F(\xi)g'(\xi)\mathrm{d}\xi}{\sin\left\{\frac{\pi}{2\alpha}[g(\xi)-g(\omega)]\right\}}, \quad \mathrm{Re}\ \omega = \frac{\pi}{2}, \tag{3.22}$$

where $g'(\xi) = dg/d\xi$. This suggests introducing new unknown functions

$$X^{\pm}(\omega) = \widetilde{\Psi}_0^{\pm}[g(\omega)+\alpha] + \widetilde{\Psi}_0^{\pm}[g(\omega)-\alpha], \quad Y^{\pm}(\omega) = \widetilde{\Psi}_1^{\pm}(\omega+\alpha) + \widetilde{\Psi}_1^{\pm}(\omega-\alpha). \tag{3.23}$$

Note that the line Re $\omega = \pi/2$ is of special significance, because the function $g(\omega)$ maps it onto itself. We can now use (3.21) to transform (3.17) and (3.18) into the system comprising algebraic equations and singular integral equations which hold on the vertical line Re $\omega = \frac{\pi}{2}$. This is the crux of Budaev and Bogy's approach.

Changing to the new independent real variable η, such that $\omega = \pi/2 + \mathrm{i}\eta$, the symmetric problem becomes

$$x^+(\eta) + b(\eta)y^+(\eta) = r_1^+(\eta) - c_1^+ \frac{\sqrt{\gamma^2 + \sinh^2\eta}}{\cosh 2\eta}, \tag{3.24}$$

$$a(\eta)\overline{\mathcal{H}}x^+(\eta) + \mathcal{H}y^+(\eta) = r_2^+(\eta) - c_1^+ \tan\alpha \frac{\cosh\eta}{\cosh 2\eta}, \tag{3.25}$$

where we have

$$x^{\pm}(\eta) = X^{\pm}\left(\frac{\pi}{2} + \mathrm{i}\eta\right), \quad y^{\pm}(\eta) = Y^{\pm}\left(\frac{\pi}{2} + \mathrm{i}\eta\right). \tag{3.26}$$

Standardizing notations and substituting (3.24) into (3.25), the problem transforms to a final *singular integral equation* in two unknowns, a function $y^+(\eta)$ and a constant c_1^+,

$$M^+y^+(\eta) = q_0^+(\eta) + c_1^+ q_1^+(\eta), \quad \eta - \text{real}, \tag{3.27}$$

where $M^+ = \mathcal{H} - a\overline{\mathcal{H}}b$. Using the same approach, the antisymmetric problem transforms to

$$a(\eta)x^-(\eta) + y^-(\eta) = r_2^-(\eta) + c_1^- \frac{\cosh\eta}{\cosh 2\eta}, \tag{3.28}$$

$$M^-x^-(\eta) = q_0^-(\eta) + c_1^- q_1^-(\eta), \quad \eta - \text{real}, \tag{3.29}$$

where $M^- = \overline{\mathcal{H}} - b\mathcal{H}a$. The rest of the nomenclature can be found in Appendix A.

4. A new numerical schedule. Budaev and Bogy [5, 6, 9] have advanced various implementations of the numerical schedule for computing $\Psi_i^{\pm}(\omega)$, all of which involve the following three steps:

1. evaluating $y^+(\eta)$ and $x^-(\eta)$ on the line $\eta = 0$ (Re $\omega = \pi/2$) by solving the singular integral equations (3.27) and (3.29), and then evaluating $x^+(\eta)$ and $y^-(\eta)$ by solving the algebraic equations (3.24) and (3.28);
2. evaluating $\widetilde{\Psi}_i^{\pm}(\omega)$ in the strip Re $\omega\, \epsilon\, I$, using the convolution type transforms (4.13) and (4.14) below, with the kernels singular on the boundary of this strip;
3. continuing the computed Sommerfeld amplitudes $\Psi_i^{\pm}(\omega)$ analytically to the right of the strip Re $\omega\, \epsilon\, I$ by using the functional equations (3.14). Recasting these equations to effect the continuation to the left of Re $\omega\, \epsilon\, I$.

We have developed an alternative recipe for carrying out the first two steps.

4.1. Solving singular integral equations in two unknowns on the line $\eta = 0$ (Re $\omega = \pi/2$). Let us consider the symmetric case first. Operator M^+ is not analytically invertible, but [5] suggest that (3.27) can be rewritten as

$$(\mathcal{H}d + K)y^+(\eta) = q_0^+(\eta) + c_1^+ q_1^+(\eta), \tag{4.1}$$

where $\mathcal{H}$ is the singular operator introduced above, analytically invertible in the space of bounded functions; K is a regular operator; and $d(t)$ is an exponentially decreasing function. Importantly, $\mathcal{H}$ has the property

$$\int_{-\infty}^{\infty} \mathcal{H}f(\eta)d\eta = 0, \tag{4.2}$$

and therefore its range consists of all $L^2(\mathbb{R})$ functions, with the zero integral, where $L^2(\mathbb{R})$ is the space of all integrable functions of real variable. Budaev and Bogy [6] state that they regularize (4.1) by applying $\mathcal{H}^{-1}$ to both its sides. They carry out numerical evaluation of the resulting singular integral equation by using (4.2) as a constraint, and calculate c_1 and $y(\eta)$ both at once. By contrast, below we argue that the right-hand side of (4.1) belongs to the domain of $\mathcal{H}^{-1}$ for only one value of c_1, and we carry out the regularization by finding this value and thus arriving at a singular integral equation in one unknown, $y(\eta)$. At present, our schedule works only for $\alpha < \pi/2$.

We start by observing that (4.1) is solvable only if its right-hand side belongs to the range of $\mathcal{H}d + K$. We cannot describe this range explicitly. However, it is clear that $(-Ky^+ + q_0^+ + c_1^+ q_1^+)(\eta)$ should be in the range of $\mathcal{H}$. It follows that we must have

$$\int_{-\infty}^{\infty} \left[(Ky^+)(\eta) - q_0^+(\eta) - c_1^+ q_1^+(\eta)\right]\, d\eta = 0. \tag{4.3}$$

All our numerical experiments confirm that neither $q_0^+(\eta)$ nor $q_1^+(\eta)$ are in the range of $\mathcal{H}d + K$—by producing the nonzero "solution defects" λ_0^+ and λ_1^+ defined by (4.11) below. Therefore, (4.1) is solvable only if the right-hand side of (4.1) is in the range. This gives the following relationship between c_1^+ and $y^+(\eta)$:

$$c_1^+ = \int_{-\infty}^{\infty} \left[(Ky^+)(\eta) - q_0^+(\eta)\right]\, d\eta \left[\int_{-\infty}^{\infty} q_1^+(\eta)\, d\eta\right]^{-1}. \tag{4.4}$$

By substituting (4.4) into (4.1), c_1^+ is eliminated and we obtain

$$(\mathcal{H}d + P_{q_1^+}K)y^+(\eta) = P_{q_1^+}q_0^+, \tag{4.5}$$

where an unbounded projector

$$(P_{q_1^+}u)(\eta) = u(\eta) - q_1^+(\eta)\int_{-\infty}^{\infty} u(t)\, dt \left[\int_{-\infty}^{\infty} q_1^+(t)\, dt\right]^{-1} \tag{4.6}$$

maps any function in $L^2(\mathbb{R})$ with a finite integral into the range of $\mathcal{H}$ and has the property

$$P_q u(\eta) = \begin{cases} u(\eta) & \text{for all } u(\eta) \text{ such that } \int_{-\infty}^{\infty} u(t)\, dt = 0, \\ 0 & \text{for } u(\eta) = q(\eta). \end{cases} \tag{4.7}$$

We refer to the function $q(\eta)$ as the projector kernel.

Note that in (4.5), the integrals of both $P_{q_1^+}Ky^+(\eta)$ and $P_{q_1^+}q_0^+(\eta)$ are zero, and therefore the inverse operator $\mathcal{H}^{-1}$ can now be safely applied to both sides. Introducing on top of that a new unknown function $\widetilde{y}^+(\eta) = d^{1/2}(\eta)y^+(\eta)$, the final regularized integral equation is

$$\widetilde{y}^+(\eta) + \widetilde{L}^+\widetilde{y}^+(\eta) = \widetilde{q}^+(\eta), \tag{4.8}$$

where $\widetilde{L}^+ = d^{-1/2}\mathcal{H}^{-1}P_{q_1^+}Kd^{-1/2}$, an operator with a smooth kernel, and $\widetilde{q}^+(\eta) = d^{-1/2}(\eta)\mathcal{H}^{-1}P_{q_1^+}q_0^+(\eta)$. The equation involves one unknown, $\widetilde{y}^+(\eta)$, and can be solved using a standard quadrature method (see, e.g., [1]). Note that normalizing the original unknown by $d^{1/2}(\eta)$ rather than $d(\eta)$ leads to a new operator with a bounded kernel (cf. [5]). The normalization achieves symmetrization of the kernel, so that whether $\eta \to \infty$ or $t \to \infty$, it exhibits the same singular behavior.

Equations (4.4) and (4.5) imply (4.1). This means that the combination of c_1^+ and a solution of (4.5) gives us the solution of (4.1). However, in our code instead of solving (4.8), we implement a slightly different approach: Since $q_1^+(\eta)$ is rather complex, instead of $P_{q_1^+}$ we employ the projector P_{q_2}, with the kernel

$$q_2(\eta) = \frac{1}{2\alpha}\frac{1}{\cosh\frac{\pi}{2\alpha}\eta}. \tag{4.9}$$

Numerical experiments have shown that this kernel leads to a stable evaluation scheme. We then regularize and solve two equations

$$(\mathcal{H}d + P_{q_2}K)y_i^+(\eta) = P_{q_2}q_i^+(\eta), \quad i = 0, 1 \tag{4.10}$$

(see Appendix C). The "solution defects"

$$\lambda_i^+ = \int_{-\infty}^{\infty}\big[(Ky_i^+)(t) - q_i^+(t)\big]dt, \quad i = 0, 1, \tag{4.11}$$

turn out to be nonzero, indicating that neither $q_0^+(\eta)$ nor $q_1^+(\eta)$ is in the range of $\mathcal{H}d + K$. It follows that the solution $(y^+(\eta), c_1^+)$ of (3.27) can be obtained using

$$c_1^+ = -\frac{\lambda_0}{\lambda_1}, \qquad y^+(\eta) = y_0^+(\eta) + c_1^+y_1^+(\eta). \tag{4.12}$$

The antisymmetric problem can be treated in a similar manner (see Appendix C).

4.2. Evaluating $\widetilde{\Psi}_i^{\pm}(\omega)$ in the strip Re $\omega \in I$. As already mentioned above, according to [5], evaluation of $\widetilde{\Psi}_i^{\pm}(\omega)$ in the strip Re $\omega \in I$ can be carried out by using the singular convolution-type integrals,

$$\Psi_0^{\pm}(\omega) = \frac{1}{4\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f_0^{\pm}(\eta)}{\cos\frac{\pi}{2\alpha}(\frac{\pi}{2} - \omega + \mathrm{i}\chi(\eta))}d\eta, \tag{4.13}$$

with $f_0^+(\eta) = y^+(\eta)\tanh 2\eta - \mathrm{i}c_1^+\cosh\eta/\cosh 2\eta + \mathrm{i}r_1^+(\eta)\chi'(\eta)$, $f_0^-(\eta) = \mathrm{i}x^-(\eta)\chi'(\eta)$, $\chi'(\eta) = d\chi/d\eta$, and

$$\widetilde{\Psi}_1^{\pm}(\omega) = \pm\frac{1}{4\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f_1^{\pm}(\eta)\,d\eta}{\cos\frac{\pi}{2\alpha}(\frac{\pi}{2} - \omega + \mathrm{i}\eta)}, \tag{4.14}$$

with $f_1^+(\eta) = \mathrm{i}y^+(\eta)$ and $f_1^-(\eta) = x^-(\eta)\tanh 2\eta - \mathrm{i}c_1^-\cosh\eta/\cosh 2\eta - \mathrm{i}r_1^-(\eta)$.

If—as is the case for the Sommerfeld amplitudes of the solution of the original problem—as Im $\omega \to \pm\infty$, the leading terms in (B.7) are $O(\exp(\pm \mathrm{i} p\omega))$, with Re $p > 0$, then for $\alpha < \pi$, $-\operatorname{Re} p - \pi/2\alpha < 0$, and therefore the above integrals converge.

We start with the integral of the type (4.14). Its generic form is

$$\text{V.P.}\int_{-\infty}^{\infty} \frac{f(\eta)}{\cos\frac{\pi}{2\alpha}(\xi + \mathrm{i}\eta)} d\eta, \qquad |\operatorname{Re}\ \xi| \le \alpha, \tag{4.15}$$

where the new complex variable is $\xi = \pi/2 - \omega$. When $|\operatorname{Re}\ \xi| < \alpha$, the integral (4.15) can be approximated using the trapezoidal rule. The approximation error is of order $O\left[\exp\left(-2\pi\sigma/h\right)\right]$, with h—the distance between the nodes of a uniform mesh and $\sigma(\omega)$—the half width of the strip that is centered on the real line and inside which the integrand is regular. In our case, $\sigma \le \min\{\alpha - \operatorname{Re}\ \xi, \alpha + \operatorname{Re}\ \xi\}$, and as $\operatorname{Re}\xi \to \alpha$, the accuracy of the trapezoidal rule deteriorates. Therefore, a more robust quadrature formula is required, with accuracy depending on the function $f(\eta)$ and not on parameter ξ. One such formula may be obtained with a modified sinc function,

$$\omega_h(\eta) = \frac{h}{2\alpha} \frac{\sin\frac{\pi}{h}\eta}{\sinh\frac{\pi}{2\alpha}\eta}. \tag{4.16}$$

Note that we have

$$\omega_h(nh) = \begin{cases} 1, & n = 0, \\ 0, & n \ne 0, \end{cases} \tag{4.17}$$

and

$$f(\eta) \approx \sum_{n=-\infty}^{\infty} f(nh)\omega_h(\eta - nh), \tag{4.18}$$

where the sum on the right-hand side interpolates $f(\eta)$. Therefore, the integral (4.15) may be approximated by

$$\text{V.P.}\int_{-\infty}^{\infty} \frac{f(\eta)}{\cos\frac{\pi}{2\alpha}(\xi + \mathrm{i}\eta)} d\eta \approx \sum_{-\infty}^{\infty} \mathcal{A}_n(\xi) f(nh), \tag{4.19}$$

with the coefficients given by

$$\mathcal{A}_n(\xi) = \text{V.P.}\int_{-\infty}^{\infty} \frac{\omega_h(\eta - nh)}{\cos\frac{\pi}{2\alpha}(\xi + \mathrm{i}\eta)} d\eta. \tag{4.20}$$

These can be evaluated approximately by introducing new variables $\check{\eta} = \eta - nh$ and $\check{\xi} = \xi + \mathrm{i}nh$. Then (4.20) can be rewritten as

$$\begin{aligned} \mathcal{A}_n(\xi) &= \frac{h}{2\alpha}\text{V.P.}\int_{-\infty}^{\infty} \frac{\sin\frac{\pi}{h}\check{\eta}}{\sinh\frac{\pi}{2\alpha}\check{\eta}} \frac{d\check{\eta}}{\cos\frac{\pi}{2\alpha}(\check{\xi} + \mathrm{i}\check{\eta})} \\ &= \frac{h}{4\alpha\mathrm{i}}\text{V.P.}\int_{-\infty}^{\infty} \frac{\mathrm{e}^{\frac{\pi}{h}\check{\eta}\mathrm{i}}}{\sinh\frac{\pi}{2\alpha}\check{\eta}} \frac{d\check{\eta}}{\cos\frac{\pi}{2\alpha}(\check{\xi} + \mathrm{i}\check{\eta})} - \frac{h}{4\alpha\mathrm{i}}\text{V.P.}\int_{-\infty}^{\infty} \frac{\mathrm{e}^{-\frac{\pi}{h}\check{\eta}\mathrm{i}}}{\sinh\frac{\pi}{2\alpha}\check{\eta}} \frac{d\check{\eta}}{\cos\frac{\pi}{2\alpha}(\check{\xi} + \mathrm{i}\check{\eta})}. \end{aligned} \tag{4.21}$$

In the upper (lower) half plane, where we can utilize the Jordan lemma to evaluate the first (second) integral, each of the respective integrands possesses two sets of poles, zeros of $\sinh\pi\check{\eta}/2\alpha$, $\check{\eta} = \pm 2\alpha m\mathrm{i}$, $m = 0, 1, 2\ldots$, with the respective residues

$$\pm\frac{2\alpha}{\pi} \frac{\mathrm{e}^{-\frac{2\alpha\pi}{h}m}}{\cos\frac{\pi}{2\alpha}\check{\xi}}, \tag{4.22}$$

and zeros of $\cos\,(\pi(\check{\xi}+\mathrm{i}\check{\eta})/(2\alpha))$, $\check{\eta}=\mathrm{i}[\check{\xi}\pm\alpha(2m+1)]$, with the respective residues

$$\mp\frac{2\alpha}{\pi}\frac{\mathrm{e}^{\frac{\pi}{h}[\mp\check{\xi}-\alpha(2m+1)]}}{\cos\,\frac{\pi}{2\alpha}\check{\xi}}. \tag{4.23}$$

It is clear that a significant contribution to (4.21) is made only by the poles, $\check{\eta}=0$ and $\check{\eta}=\mathrm{i}[\check{\xi}\pm\alpha]$ (in the upper and lower half plane, respectively); other residues contain small exponential factors. Therefore, applying the Cauchy residue theorem and taking into account that the first pole lies on the contour of integration, we have

$$\frac{h}{4\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\pm\frac{\pi}{h}\check{\eta}\mathrm{i}}}{\sinh\,\frac{\pi}{2\alpha}\check{\eta}}\frac{d\check{\eta}}{\cos\,\frac{\pi}{2\alpha}(\check{\xi}+\mathrm{i}\check{\eta})}\approx\pm\frac{h}{\cos\,\frac{\pi}{2\alpha}\check{\xi}}\left(\frac{1}{2}-\mathrm{e}^{-\frac{\pi\alpha}{h}\mp\frac{\pi}{h}\check{\xi}}\right), \tag{4.24}$$

which—returning to the original variables ξ and η—gives us a new quadrature formula

$$\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f(\eta)}{\cos\,\frac{\pi}{2\alpha}(\xi+\mathrm{i}\eta)}d\eta\approx h\sum_{n=-\infty}^{\infty}\frac{1}{\cos\,\frac{\pi}{2\alpha}(\xi+\mathrm{i}nh)}\left[1-2(-1)^n\mathrm{e}^{-\frac{\pi}{h}\alpha}\cosh\frac{\pi}{h}\xi\right]f(nh),$$
$$|\,\mathrm{Re}\;\xi|<\alpha. \tag{4.25}$$

Let us now consider the integrals of the type (4.13). Their generic form is

$$\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f(\eta)}{\cos\,\frac{\pi}{2\alpha}[\xi+\mathrm{i}\chi(\eta)]}d\eta,\quad|\,\mathrm{Re}\;\xi|<\alpha, \tag{4.26}$$

where $\chi(\eta)$ is a smooth monotone function. We could change the integration variable η to $\chi(\eta)$, reduce (4.26) to the integral of type (4.15), and evaluate the result using a uniform mesh in χ. However, both integrals (4.15) and (4.26) involve the solution of (3.27), and therefore it is more reasonable to evaluate both integrals using the same mesh. Then following the same reasoning as above, (4.26) may be approximated by

$$\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f(\eta)}{\cos\,\frac{\pi}{2\alpha}[\xi+\mathrm{i}\chi(\eta)]}d\eta\approx\sum_{-\infty}^{\infty}\mathcal{B}_n(\xi)f(nh), \tag{4.27}$$

where the coefficients are given by

$$\mathcal{B}_n(\xi)=\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{\omega_h(\eta-nh)}{\cos\,\frac{\pi}{2\alpha}[\xi+\mathrm{i}\chi(\eta)]}d\eta, \tag{4.28}$$

and the main contributions to (4.28) are made by the zero $\check{\eta}=0\,(\eta=nh)$ of the hyperbolic sine in ω_h and the zero $\check{\eta}=\mathrm{i}a_\pm-nh\,(\eta=\mathrm{i}a_\pm)$ of the cosine-function, where $\xi+\mathrm{i}\chi(\mathrm{i}a_\pm)=\mp\alpha$. The latter equation implies that $\mathrm{i}\chi(\mathrm{i}a_\pm)=-\sin^{-1}(\gamma^{-1}\sin\,a_\pm)=\mp\alpha-\xi$, and therefore we have

$$a_\pm=\sin^{-1}\big[\gamma\,\sin\,(\xi\pm\alpha)\big], \tag{4.29}$$

with $\mathrm{Re}\;a_+>0$ and $\mathrm{Re}\;a_-<0$. Applying to (4.28) the Cauchy residue theorem and noting that the pole $\check{\eta}=0$ lies on the contour of integration, we obtain

$$\frac{h}{4\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{\mathrm{e}^{\pm\frac{\pi}{h}\check{\eta}\mathrm{i}}}{\sinh\,\frac{\pi}{2\alpha}\check{\eta}}\frac{d\check{\eta}}{\cos\,\frac{\pi}{2\alpha}[\xi+\mathrm{i}\chi(\check{\eta}+nh)]}$$
$$\approx h\left\{\pm\frac{1}{2\cos\,\frac{\pi}{2\alpha}[\xi+\mathrm{i}\chi(nh)]}\mp\frac{\mathrm{e}^{\mp\frac{\pi}{h}(a_\pm+\mathrm{i}nh)}}{\chi'(a_\pm)\sin\,\frac{\pi}{2\alpha}(a_\pm+\mathrm{i}nh)}\right\}, \tag{4.30}$$

where $\chi'(a_\pm) = \cos a_\pm / \sqrt{\gamma^2 - \sin^2 a_\pm}$. Returning to the original variable η, the resulting quadrature formula is

$$\text{V.P.}\int_{-\infty}^{\infty} \frac{f(\eta)}{\cos\,\frac{\pi}{2\alpha}[\xi + \mathrm{i}\chi(\eta)]}d\eta \approx h \sum_{n=-\infty}^{\infty} \left\{ \frac{1}{\cos\,\frac{\pi}{2\alpha}[\xi + \mathrm{i}\chi(nh)]} - (-1)^n \left[\frac{\mathrm{e}^{-\frac{\pi}{h}a_+}}{\chi'(a_+)\sin\,\frac{\pi}{2\alpha}(a_+ + inh)} + \frac{\mathrm{e}^{\frac{\pi}{h}a_-}}{\chi'(a_-)\sin\,\frac{\pi}{2\alpha}(a_- + inh)} \right] \right\} f(nh), \quad |\,\mathrm{Re}\;\xi| < \alpha. \tag{4.31}$$

The first terms on the right of both (4.25) and (4.31) effect the trapezoidal rule, and the second give a correction. When Re $\xi \le \alpha - 10^{-6}$, $\Psi_i^{\pm}(\omega)$ can be approximated as $[\Psi_i^{\pm}(\omega - 0.05) + \Psi_i^{\pm}(\omega + 0.05)]/2$.

5. Code testing. Using the above considerations, we have developed a new code for evaluating the Rayleigh reflection and transmission coefficients for elastic wedges (see Appendix E). The integral equations we solve have the form of the Fredholm equations of the second kind, but it can be shown that the operators involved are not Fredholm (cf. the statements in [5, p. 251]. We possess no analytical proof that these equations can be solved uniquely. Nevertheless, our code produces a solution, and below we describe verification tests that allow us to state with confidence that when transformed back to the physical space this solution satisfies the original diffraction problem. We also describe successful validation tests, comparing output of our code with published numerical and experimental data. Of course, the positive outcomes of these tests do not constitute a theoretical proof that the code is correct. Note that throughout this section we characterize materials by their Poisson ratios ν, where $\gamma = \sqrt{(1-2\nu)/[2(1-\nu)]}$.

5.1. Code verification. We have designed verification tests to establish that the computed functions $\Psi_i(\omega)$ are the solutions of the original physical problem; in particular, that they

(i) are bounded at imaginary infinity;
(ii) are analytic at the boundary of the strip Re $\omega \,\epsilon\, I$;
(iii) possess only physically meaningful singularities.

The property (i) is confirmed by direct examination of the computed functions $\widetilde{x}^-(\eta)$ and $\widetilde{y}^+(\eta)$ divided by $\exp(-|\eta|)$. At large $|\eta|$ the ratios appear to behave as $O(1)$. It follows that the amplitudes $\Psi_i(\omega)$ obtained by the analytical continuation must be bounded at the imaginary infinity, $\eta = \mathrm{Im}\;\omega \to \infty$.

Since the last step in the analytical continuation is carried out strip-by-strip, all 2α wide, there is no guarantee that any computed $\Psi_i(\omega)$ should be smooth at the boundaries of the initial strip Re $\omega \,\epsilon\, I$. However, examination of the numerical data used to plot Figures 5.1–5.3 confirm that our approximations *are* smooth. It follows that the property (ii) is satisfied. Interestingly, when attempting to solve an incorrect problem, with the constants $c_1^{\pm}$ put to zero, the computed $\Psi_i(\omega)$ themselves jump at the boundaries by about 10^{-2}.

Similarly to (ii), the property (iii) should be satisfied by the Sommerfeld amplitudes of the solutions of the original wedge diffraction problem, but it is not obvious that the computed solutions of the corresponding functional equations should satisfy it as well. Indeed, the way they are constructed assures that the computed amplitudes $\Psi_i(\omega)$ have physically meaningful poles, and since the functional equations that are used to effect the analytical continuation involve reflection coefficients $\mathrm{r}_{jk}(\omega)$, with

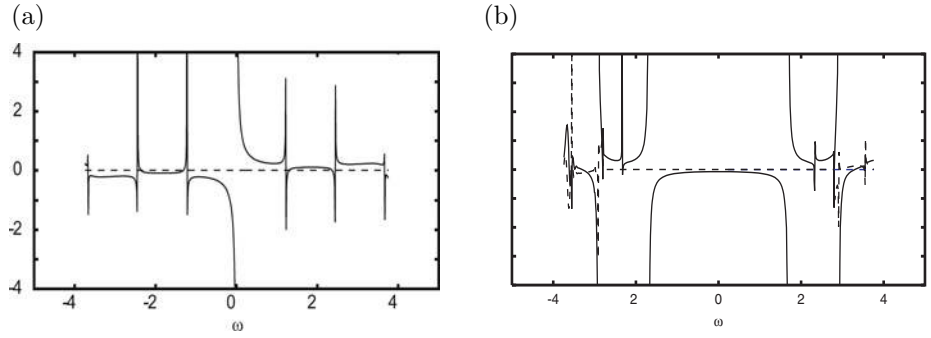

FIG. 5.1. *The computed Sommerfeld amplitudes:* (a) Re $\Psi_0(\omega)$—*dashed line and* Im $\Psi_0(\omega)$—*solid line,* (b) Re $\Psi_1(\omega)$—*dashed line and* Im $\Psi_1(\omega)$—*solid line. Wedge angle* $2\alpha = 70°$, $I = [0.96, 2.18]$, *Poisson's ratio* $\nu = 0.25$, *incident wave—compressional and* $\theta^{inc} = 0°$.

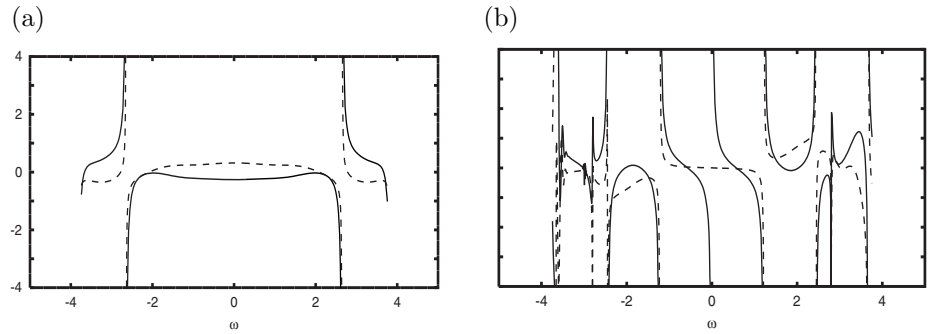

FIG. 5.2. *The computed Sommerfoeld amplitudes:* (a) Re $\Psi_0(\omega)$—*dashed line and* Im $\Psi_0(\omega)$—*solid line,* (b) Re $\Psi_1(\omega)$—*dashed line and* Im $\Psi_1(\omega)$—*solid line. Wedge angle* $2\alpha = 70°$, $I = [0.96, 2.18]$, *Poisson's ratio* $\nu = 0.25$, *incident wave—shear and* $\theta^{inc} = 0°$.

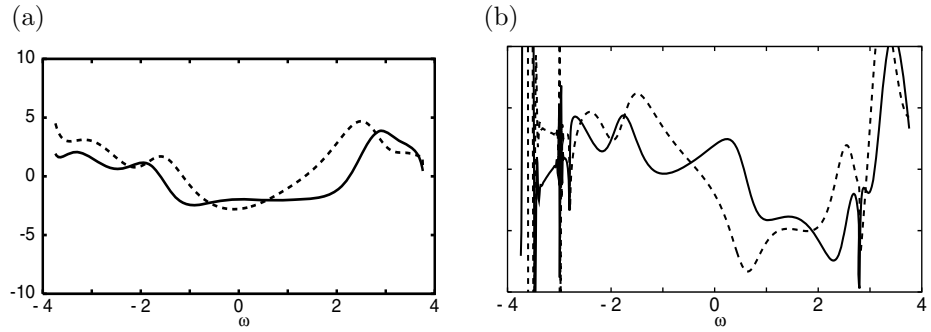

FIG. 5.3. *The computed Sommerfeld amplitudes:* (a) Re $\Psi_0(\omega)$—*dashed line and* Im $\Psi_0(\omega)$—*solid line,* (b) Re $\Psi_1(\omega)$—*dashed line and* Im $\Psi_1(\omega)$—*solid line. Wedge angle* $2\alpha = 70°$, $I = [0.96, 2.18]$, *Poisson's ratio* $\nu = 0.25$, *incident wave—Rayleigh and* Re $\theta^{inc} = -\alpha$.

the branch point at $\omega = \theta_h$ and poles at $\omega = \pm i\beta_R$ (see (3.14) and Appendix A), they possess physically meaningful branch points and Rayleigh poles too. However, by the same token, the analytical continuation scheme *might* endow these amplitudes with *extra, physically meaningless singularities.* Remarkably, when the incident wave is compressional or shear at $\omega = -\alpha \pm i\beta_R$ all our computed residues are of order

10^{-7}, i.e., are numerical zeros. Thus, the computed Sommerfeld amplitudes possess no Rayleigh poles corresponding to physically meaningless Rayleigh waves incoming from infinity. Furthermore, Figures 5.1–5.2, which respectively relate to a purely symmetric and purely asymmetric case, confirm that inside a neighborhood of zero which includes the strip Re $\omega \epsilon I$, the computed Sommerfeld amplitudes possess the symmetries described in (3.1); that is, $\Psi_0^+(\omega)$ and $\Psi_1^-(\omega)$ are odd, while $\Psi_1^+(\omega)$ and $\Psi_0^-(\omega)$ are even. (Outside this neighborhood, the symmetries are not apparent in Figures 5.1– 5.3 due to the accumulation of numerical errors.) As we show in Appendix D, such symmetries imply the absence of physically meaningless branch points.

The properties (i), (ii), and (iii) of the computed Sommerfeld amplitudes respectively imply that they possess all the properties expected of the Sommerfeld amplitudes of the solutions $\psi_i(kr, \theta)$ of the original diffraction problem, so that their corresponding Sommerfeld integrals satisfy (i) the Helmholtz equations and correct tip condition; (ii) zero stress boundary conditions; and (iii) radiation conditions (which exclude nonphysical Rayleigh or head waves incoming from infinity).

Figure 5.1 provides one more confirmation that the computed functions $\Psi_i(\omega)$ are the Sommerfeld amplitudes of solutions $\psi_i(kr, \theta)$ of the original wedge problem: It shows that for the symmetric compressional wave incidence, both $\Psi_i(\omega)$ are imaginary, and therefore the corresponding displacements are real. This is consistent with the physics of the problem, since unlike with the symmetric shear wave incidence, there is no total internal reflection, that is, no imaginary displacement component.

Finally, a numerical stability of the scheme is ascertained by the fact that different choices of adjustable function $\sigma(\omega)$ in (3.16) all give similar results (see Appendix F).

5.2. Code validation. Our first validation results are presented in Tables 5.1 and 5.2, where the approximate values of amplitudes and phases of reflection and transmission coefficients R^{ref} and R^{tran} as computed with our code are compared with numerical results of [11]. Each Fujii's column contains values corresponding to different choices of an adjustable parameter. The parameter allows one to evaluate singular integrals on the real axis by moving the poles away from the axis into the complex plane. This is equivalent to employing the radiation condition at infinity in the form of the limiting absorption principle. From the physical point of view, the singularities cannot be moved too far. However, when they are too close the evaluation algorithm becomes numerically unstable. The top rows in the tables are obtained with

the parameter values that correspond to a more physically meaningful situation, and the bottom ones, with the values that give better numerical stability. The tables demonstrate that for the larger wedge angles the agreement with our computations is quite good, but for the smaller ones our values lie outside Fujii's range. This is not surprising, because when the wedge angles are small there are many multiply reflected waves, and the residues of many resulting poles are large. For this reason, when the wedge angles are small, the present version of our code loses its numerical stability.

To continue, in Figure 5.4(a) and (b) we present our Rayleigh reflection and transmission coefficients as functions of the wedge angle, computed for $\nu = 0.234$. They fit Fujii's numerical and experimental data extremely well (see our Figure 5.5 or [11, Figure 7]. Note that on Fujii's plots the solid lines represent his numerical results, and discrete points, his experimental data.) Indeed, for the wedge angles between 45° and 150° we cannot put the results on the same graph—there is no visible difference. Note that the jumps in the phase of the reflection coefficient that take place at the wedge angles of about 45° and 145° are from 180° to −180° and −180° to 180°, respectively, and therefore no jumps in physical quantities take place. For the wedge angles between 150° and 180° the reflection coefficients are practically zero. This is understandable, because when the wedge angle is 180° there is no reflection. In this region, the phases of our reflection coefficients differ from Fujii's, but the limiting value of 90° agrees with the one obtained by [13]. It appears that in this region Fujii's scheme loses its stability.

The amplitude curves reported by Budaev and Bogy [8] are the same as ours (see their Figure 6 and our Figure 5.4(a)), but for the larger wedge angles, the phase of their reflection coefficient is somewhat different—see Figure 5.4(b). The discrepancy might not be crucial, because at these angles the amplitudes of the reflection coefficients are very small, but the problem is indicative of numerical instability. Note that the results on the wedge angles greater than 180° as presented by [6] are incorrect—see their errata [9]. Note too that even though Poisson's ratio used by Budaev and Bogy [8] is $\nu = 0.294$, the above comparison is valid: The coefficients should not be effected by a small difference in ν (see, e.g., Figure 5.6.)

We finish this section by comparing our computed Rayleigh reflection and transmission coefficients for the quarter space with Gautesen's [13]. On taking into account that Gautesen's coefficients are complex conjugates of ours and thus our phases must have the opposite sign, the agreement between the calculations is very good (see Figure 5.6).

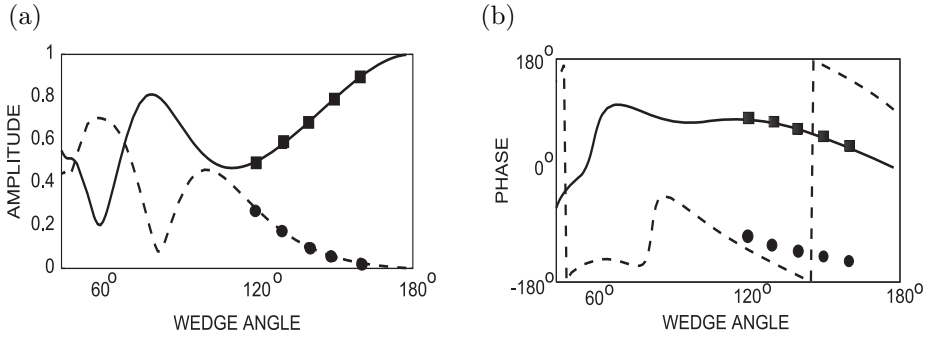

FIG. 5.4. *Rayleigh transmission coefficients (solid line) and reflection coefficients (dashed line) computed with our code versus the coefficients computed with Budaev and Bogy's code (squares and circles, respectively—see Budaev and Bogy* [8]*, Figure* 6*). Poisson's ratio* $\nu = 0.234$*, incident wave—Rayleigh and* Re $\theta^{inc} = -\alpha$.

Wedge angle* 90°*, incident wave—Rayleigh and* Re $\theta^{inc} = -\alpha$.

6. Conclusions. We have studied the properties of the underlying integral operators and developed a new numerical schedule for solving the singular integral problem that arises in Budaev and Bogy's approach to diffraction by 2D traction-free isotropic elastic wedges. We have also developed new quadrature formulas for evaluating the

singular convolution-type integrals that are utilized in this approach. Although the analytical justification of the method is not entirely rigorous, the code has undergone a series of stringent internal verification tests directed at establishing that it solves the original physical problem, as well as validation tests against numerical and experimental results reported by other authors. It appears to be successful when simulating diffraction by wedges of angles between 40° and 178° of plane incident waves, compressional or shear. When the incident wave is a Rayleigh, the lower limit of applicability goes up to 45°.

Appendix A. Nomenclature.

$$a(\eta) = -\mathrm{i}\tanh 2\eta,$$

$$b(\eta) = \frac{2\mathrm{i}\sinh\eta\sqrt{\gamma^2+\sinh^2\eta}}{\cosh 2\eta},$$

$$d(\eta) = 1 - \frac{\tanh^2 2\eta}{\chi'(\eta)},$$

$$e_1^+(\omega) = -\tan\alpha\sin\,2\omega + \cos\,2\omega,$$

$$e_1^-(\omega) = \tan\alpha\cos\,2\omega + \sin\,2\omega,$$

$$e_2^+(\omega) = \tan\alpha\cos\,2\omega\frac{\sin\,\omega}{\sqrt{\gamma^2-\cos^2\omega}} + \sin\,2\omega,$$

$$e_2^-(\omega) = \tan\alpha\sin\,2\omega - \cos\,2\omega\frac{\sin\,\omega}{\sqrt{\gamma^2-\cos^2\omega}},$$

$$g(\omega) = \cos^{-1}(\gamma^{-1}\cos\,\omega),$$

$$\mathcal{H}f(\eta) = \frac{1}{2\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f(t)\mathrm{d}t}{\sinh[\frac{\pi}{2\alpha}(t-\eta)]},$$

$$(\mathcal{H}^{-1}f)(\eta) = \frac{1}{2\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\coth\frac{\pi}{2\alpha}(t-\eta)f(t)\,dt,$$

$$\overline{\mathcal{H}}f(\eta) = \frac{1}{2\alpha\mathrm{i}}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{f(t)\chi'(t)\mathrm{d}t}{\sinh\frac{\pi}{2\alpha}[\chi(t)-\chi(\eta)]},$$

$$Kf(\eta) = \frac{1}{2\alpha\mathrm{i}}\int_{-\infty}^{\infty}\left\{\frac{\tanh^2 2t}{\chi'(t)\sinh\frac{\pi}{2\alpha}(t-\eta)} - \frac{\tanh 2t\tanh 2\eta}{\sinh\frac{\pi}{2\alpha}[\chi(t)-\chi(\eta)]}\right\}f(t)\,dt,$$

$$q_0^+(\eta) = r_2^+(\eta) - a(\eta)\overline{\mathcal{H}}r_1^+(\eta),$$

$$q_1^+(\eta) = -\tan\alpha\frac{\cosh\eta}{\cosh 2\eta} - \frac{\tanh 2\eta}{2\alpha}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{\gamma\cosh\tau d\tau}{(1+2\gamma^2\sinh^2\tau)\sinh\frac{\pi}{2\alpha}[\tau-\chi(\eta)]},$$

$$q_0^-(\eta) = r_1^-(\eta) - b(\eta)\mathcal{H}r_2^-(\eta),$$

$$q_1^-(\eta) = -\tan\alpha\frac{\cosh\eta}{\chi'(\eta)\cosh 2\eta} - \frac{\tanh 2\eta}{2\alpha\chi'(\eta)}\mathrm{V.P.}\int_{-\infty}^{\infty}\frac{\cosh\tau\,d\tau}{\cosh 2\tau\,\sinh\frac{\pi}{2\alpha}(\tau-\eta)},$$

$$\begin{aligned} r_1^\pm(\eta) = &-\left[\widehat{\Psi}_0^\pm\left(g\left(\frac{\pi}{2}+\mathrm{i}\eta\right)+\alpha\right) \pm \widehat{\Psi}_0^\pm\left(g\left(\frac{\pi}{2}+\mathrm{i}\eta\right)-\alpha\right)\right] \\ &- b(\eta)\left[\widehat{\Psi}_1^\pm\left(\frac{\pi}{2}+\alpha+\mathrm{i}\eta\right) \pm \widehat{\Psi}_1^\pm\left(\frac{\pi}{2}-\alpha+\mathrm{i}\eta\right)\right], \\ r_2^\pm(\eta) = &-a(\eta)\left[\widehat{\Psi}_0^\pm\left(g\left(\frac{\pi}{2}+\mathrm{i}\eta\right)+\alpha\right) \mp \widehat{\Psi}_0^\pm\left(g\left(\frac{\pi}{2}+\mathrm{i}\eta\right)-\alpha\right)\right] \\ &- \left[\widehat{\Psi}_1^\pm\left(\frac{\pi}{2}+\alpha+\mathrm{i}\eta\right) \mp \widehat{\Psi}_1^\pm\left(\frac{\pi}{2}-\alpha+\mathrm{i}\eta\right)\right], \end{aligned}$$

$$\mathrm{r}_{11}(\omega) = -\mathrm{r}_{22}(\omega) = \frac{2\sin\,2\omega\,\cos\,\omega\sqrt{\gamma^2-\cos^2\,\omega}-\cos^2\,2\omega}{\Delta(\omega)},$$
$$\mathrm{r}_{12}(\omega) = -\frac{4\cos\,2\omega\,\cos\,\omega\sqrt{\gamma^2-\cos^2\,\omega}}{\Delta(\omega)},$$
$$\mathrm{r}_{21}(\omega) = -\frac{2\sin\,2\omega\,\cos\,2\omega}{\Delta(\omega)},$$
$$\Delta(\omega) = \cos^2\,2\omega + 2\,\sin\,2\omega\,\cos\,\omega\sqrt{\gamma^2-\cos^2\,\omega},$$
$$\chi(\eta) = \sinh^{-1}(\gamma^{-1}\sinh(\eta)),$$
$$\chi'(\eta) = \frac{\cosh\eta}{\sqrt{\gamma^2+\sinh^2\eta}}.$$

Note that the Rayleigh function $\Delta(\omega)$ has the purely imaginary root $\mathrm{i}\beta_{\mathrm{R}}$, with $\beta_{\mathrm{R}} > 0$.

Appendix B. The tip asymptotics of the elastic potentials and asymptotics of the Sommerfeld amplitudes at infinity. The behavior of solutions of the elliptic problems in regions with piecewise smooth boundaries has been studied by many authors (see [21] and references therein). A rigorous theory has been developed after a breakthrough by Kondrat'ev [13], who constructed and justified the field asymptotics in the vicinity of conical and edge points. The theory implies that the solution of the underlying Lamé problem must have the asymptotic expansion

$$\mathbf{u}(kr,\theta) \sim \sum_{\ell,m=0}^{\infty} (kr)^{q_m+2\ell} \sum_{n=0}^{N_m-1} \mathbf{u}_{\ell,m,n}(\theta)\,(\ln kr)^n, \quad kr \to 0, \tag{B.1}$$

where for one m, $q_m = 0$ and $N_m = 1$ (otherwise, the tip conditions are violated); for any other m, Re $q_m > 0$ and q_m is a root of a transcendental equation, with a natural number N_m being its multiplicity.

The asymptotic expansions (B.1) can be differentiated and substituted into the boundary conditions. Therefore, using (2.4), similar expansions may be written for the elastodynamic potentials $\psi_i^{\pm}(kr,\theta)$ as

$$\psi_i^{\pm}(kr,\theta) \sim \sum_{\ell,m=0}^{\infty} (kr)^{p_m^{\pm}+2\ell} \sum_{n=0}^{N_m^{\pm}-1} \psi_{i,\ell,m,n}^{\pm}(\theta)(\ln kr)^n, \quad kr \to 0. \tag{B.2}$$

Let us arrange the sets of exponents $\{p_m^+,\ m = 0,1,\dots\}$ and $\{p_m^-,\ m = 0,1,\dots\}$, each in order of the increasing real part. Following [19], these sets may be described as follows: Each contains 1, while any other element is a root of the transcendental equation

$$(p^{\pm}+1)\,\sin\,2\alpha \pm \sin\,2\alpha(p^{\pm}+1) = 0 \tag{B.3}$$

and satisfies condition

$$\mathrm{Re}\ p^{\pm} > -1 \tag{B.4}$$

(otherwise, the tip conditions are violated). Note that if in (B.1) a $q_m \neq 0$, then in (B.2) the corresponding p_m^+ or p_m^- equals $q_m - 1$, but applying the nabla operator to the term with $q_m = 0$ and $\ell = 0$ always gives us zero—because the corresponding $N_m = 1$. Thus, for $q_m = 0$, only the next, r^2, term in (B.1) gives rise to a nonzero term

in (B.2). The corresponding $p_m^{\pm} = 1$. Note that while for any wedge angle there exists an m such that $p_m^- = 0$ is a solution of (B.3), in our range of wedge angles $2\alpha \in (0, \pi)$, all p_m^+ differ from zero. The full set of solutions of the transcendental equations (B.3) is described in [19]. The main facts can be summarized in plots representing roots of the transcendental equations as functions of the wedge angle 2α (see, e.g., [22]). The analysis of these plots shows that in our range of wedge angles, the tip conditions are assured for those nonnegative exponents with minimal real part that are either 1 or else are solutions of the corresponding transcendental equations, with real part less than or equal to 1. In other words, all leading exponents in (B.1), that is, the exponents with the minimal real part, lie in the strip

$$0 \le \operatorname{Re} p_0^{\pm} \le 1. \tag{B.5}$$

The root loci in [22] also show that at one wedge angle, $2\alpha_* \approx 0.8\pi$, we have a degeneracy: In the corresponding symmetric problem, the exponent with the minimal real part, $p_*^+ \approx 0.76$, is a multiple root of the corresponding transcendental equation (B.3). The corresponding multiplicity $N_*^+ = 2$. There are no multiple roots p_0^- which have the minimal real part and simultaneously satisfy (B.5). It follows that for α_*, the leading terms in (B.1) are

$$\psi_{i,0,1,1}^+ (kr)^{p_*^+} \ln kr = O\big((kr)^p\big), \quad 0 < p < p_*^+. \tag{B.6}$$

The behavior of potentials $\psi_i^{\pm}(kr, \theta)$ in the vicinity of the wedge tip dictates the asymptotic behavior of the Sommerfeld amplitudes $\Psi_i^{\pm}(\omega)$ at infinity: For example, it is easy to check that for any small $\varepsilon > 0$, as $\operatorname{Im}\ \omega \to \infty$, $\Psi_i^{\pm}(\omega)$ have expansions

$$\Psi_i^{\pm}(\omega) \sim \sum_{0 \le \operatorname{Re}\ p_m^{\pm} \le 1} \Psi_{im}^{\pm} \mathrm{e}^{\mathrm{i}p_m^{\pm}\omega} + O(\mathrm{e}^{\mathrm{i}(1+\varepsilon)\omega}), \qquad \alpha \ne \alpha_*,\ 0 < \alpha < \frac{\pi}{2},$$

$$\Psi_i^+(\omega) \sim \overline{\Psi}_{i*} \omega \mathrm{e}^{\mathrm{i}p_*^+\omega} + \Psi_{i*} \mathrm{e}^{\mathrm{i}p_*^+\omega} + \Psi_{i1} \mathrm{e}^{\mathrm{i}\omega} + O(\mathrm{e}^{\mathrm{i}(2+\varepsilon)\omega}), \qquad \alpha = \alpha_*. \tag{B.7}$$

Note that in the symmetric case, the expansions contain no constant terms (so that the leading exponents are 1 and possibly a solution of (B.3), with the real part in $(0, 1)$), but these may be present in the antisymmetric case (so that the leading exponents there are 0 and 1).

Appendix C. The integral equations for one unknown.

Symmetric problem. The two final regularized integral equations to solve are

$$\widetilde{y}_i^+(\eta) + \widetilde{L}^+ \widetilde{y}_i^+(\eta) = \widetilde{q}_i^+(\eta), \quad i = 0, 1, \tag{C.1}$$

where $\widetilde{L}^+$ is an operator with a smooth kernel

$$(\widetilde{L}^+ u)(\eta) = -\frac{1}{4\alpha^2} \int_{-\infty}^{\infty} \frac{l^+(\eta, t) \tanh 2t}{\sqrt{d(t)}\sqrt{d(\eta)} \cosh \frac{\pi}{2\alpha}\eta} u(t)\, dt, \tag{C.2}$$

with

$$l^+(\eta, t) = \mathrm{V.P.} \int_{-\infty}^{\infty} \frac{\cosh \frac{\pi}{2\alpha}\tau}{\sinh \frac{\pi}{2\alpha}(\tau - \eta)} \left\{ \frac{\tanh 2t}{\chi'(t) \sinh \frac{\pi}{2\alpha}(t - \tau)} - \frac{\tanh 2\tau}{\sinh \frac{\pi}{2\alpha}[\chi(t) - \chi(\tau)]} \right\} d\tau.$$

The respective right-hand sides of (C.1) are given by

$$\widetilde{q}_i^+(\eta) = \frac{1}{2\alpha \mathrm{i} \sqrt{d(\eta)} \cosh \frac{\pi}{2\alpha}\eta} \mathrm{V.P.} \int_{-\infty}^{\infty} \frac{\cosh \frac{\pi}{2\alpha}t}{\sinh \frac{\pi}{2\alpha}(t - \eta)} q_i^+(t)\, dt, \tag{C.3}$$

with $q_i^+(\eta)$ given in Appendix A. On solving (C.1), $y^+(\eta)$ is obtained using

$$y^+(\eta) = d^{-1/2}(\eta)[\widetilde{y_0^+}(\eta) + c_1^+ \widetilde{y_1^+}(\eta)], \tag{C.4}$$

where $c_1^+ = -\lambda_0^+/\lambda_1^+$ and we have

$$\lambda_i^+ = \int_{-\infty}^{\infty} \big[\widetilde{y_i^+}(t) d^{-1/2}(t)(B^+\mathbb{I})(t) - q_i^+(t)\big]\,dt, \quad , i = 0, 1,$$
$$(B^+\mathbb{I})(t) = \frac{\gamma^2 \tanh 2t}{2\alpha \mathrm{i}} \int_{-\infty}^{\infty} \frac{\sinh 2(\chi(t)+\tau)}{1 + 2\gamma^2 \sinh^2(\tau + \chi(t))} \cdot \frac{d\tau}{\sinh \frac{\pi}{2\alpha}\tau}.$$

Antisymmetric problem. Analogously to the symmetric case, the two final regularized integral equations to solve are

$$\widetilde{x_i^-}(\eta) + \widetilde{L}^- \widetilde{x_i^-}(\eta) = \widetilde{q_i^-}(\eta), \quad i = 0, 1, \tag{C.5}$$

where the integral operator is

$$(\widetilde{L}^- u)(\eta) = -\frac{1}{4\alpha^2} \int_{-\infty}^{\infty} \frac{l^-(\eta, t) \tanh 2t}{\sqrt{d(t)}\sqrt{d(\eta)} \cosh \frac{\pi}{2\alpha}\chi(\eta)} u(t)\,dt, \tag{C.6}$$

with

$$l^-(\eta, t) = -\mathrm{V.P.} \int_{-\infty}^{\infty} \frac{\cosh \frac{\pi}{2\alpha}\tau}{\sinh \frac{\pi}{2\alpha}[\chi(\eta) - \tau]} \left\{ \frac{\tanh 2t}{\sinh \frac{\pi}{2\alpha}(\chi(t) - \tau)} + \frac{\tanh 2\chi^{-1}(\tau)(\chi^{-1})'(\tau)}{\sinh \frac{\pi}{2\alpha}[\chi^{-1}(\tau) - t]} \right\} d\tau.$$

The respective right-hand sides of (C.5) are given by

$$\widetilde{q_i^-}(\eta) = \frac{1}{2\alpha \mathrm{i}\sqrt{d(\eta)} \cosh \frac{\pi}{2\alpha}\chi(\eta)} \mathrm{V.P.} \int_{-\infty}^{\infty} \frac{\cosh \frac{\pi}{2\alpha}t}{\sinh \frac{\pi}{2\alpha}[t - \chi(\eta)]} q_i^-(\chi^{-1}(t))\,dt, \tag{C.7}$$

with $q_i^-(\eta)$ given in Appendix A. As above, x^- is obtained on solving (C.5) using

$$x^-(\eta) = d^{-1/2}(\eta)[\widetilde{x_0^-}(\eta) + c_1^- \widetilde{x_1^-}(\eta)], \tag{C.8}$$

where $c_1^- = -\lambda_0^-/\lambda_1^-$ and we have

$$\lambda_i^- = \int_{-\infty}^{\infty} \big[\widetilde{x_i^-}(t) d^{-1/2}(t)(B^-\chi')(t) - q_i^-(t)\chi'(t)\big]\,dt, \quad i = 0, 1,$$
$$(B^-\chi')(t) = \frac{\tanh 2t}{2\alpha \mathrm{i}} \int_{-\infty}^{\infty} \frac{\tanh 2(t+\tau)\,d\tau}{\sinh \frac{\pi}{2\alpha}\tau}.$$

Appendix D. The branch points of $\Psi_i(\omega)$. Let us show that the Sommerfeld amplitudes $\Psi_i^+(\omega)$ that satisfy the functional equations (3.5) and conditions (3.1) can have only physically meaningful branch points. For simplicity of presentation, let us assume that $\theta_h < 2\alpha$ (in the opposite case, a slightly more involved argument still goes through.) Using the branch points of $g(\omega)$, the only branch points that $\Psi_1^+(\omega)$ can have inside (2.8) are $\pm(\pi + \alpha - \theta_h)$. The corresponding branch cuts run along the segments $[-\pi - \alpha - \theta_h,\ -\pi - \alpha + \theta_h]$ and $[\pi + \alpha - \theta_h,\ \pi + \alpha + \theta_h]$. Note that the branch points $\pm(\pi + \alpha + \theta_h)$ lie outside the physical region (2.8). The analogous branch points of $\Psi_0^+(\omega)$ can be only $\pm(\pi + \alpha \pm \mathrm{i}\cosh^{-1}(1/\theta_h))$, with the

cuts along the segments $[-\pi-\alpha+\mathrm{icosh}^{-1}(1/\theta_h),\ -\pi-\alpha-\mathrm{icosh}^{-1}(1/\theta_h)]$ and $[\pi+\alpha+\mathrm{icosh}^{-1}(1/\theta_h),\ \pi+\alpha-\mathrm{icosh}^{-1}(1/\theta_h)]$.

Indeed, all possible branch points of $g(\omega)$ are $\pi n\pm\theta_h$ (see (3.7)). In principle, applying (3.5), they could generate many branch points in $\Psi_1^+(\omega)$ which have no physical interpretation. Let us start by showing that $-\alpha+\theta_h$ is not a branch point: Let us use the fact that $\Psi_0^+(\omega)$ is odd to rewrite the functional equation (3.5) as

(D.1)
$$t_{11}(\omega+\alpha)\{\Psi_0^+[\alpha+g(\omega+\alpha)]-\Psi_0^+[\alpha-g(\omega+\alpha)]\}+t_{12}(\omega+\alpha)[\Psi_1^+(\omega+2\alpha)+\Psi_1^+(\omega)]=Q_1^+,$$

(D.2)
$$t_{21}(\omega+\alpha)\{\Psi_0^+[\alpha+g(\omega+\alpha)]+\Psi_1^+[\alpha-g(\omega+\alpha)]\}+t_{22}(\omega+\alpha)[\Psi_1^+(\omega+2\alpha)-\Psi_1^+(\omega)]=Q_1^+.$$

In the vicinity of θ_h, there exist the constants a_n such that we have

$$g(\omega+\alpha)=\sum_{n=0}^{\infty}a_n(\omega+\alpha-\theta_h)^{n+1/2}. \tag{D.3}$$

Since $\Psi_0^+[\alpha+g(\omega+\alpha)]-\Psi_0^+[\alpha-g(\omega+\alpha)]$ is odd in g, there also exist constants A_n such that this function has the expansion

$$\Psi_0^+[\alpha+g(\omega+\alpha)]-\Psi_0^+[\alpha-g(\omega+\alpha)]=\sum_{n=0}^{\infty}A_n(\omega+\alpha-\theta_h)^{n+1/2}. \tag{D.4}$$

On the other hand, there exist constants b_n such that we can write

$$t_{11}(\omega+\alpha)=\sum_{n=0}^{\infty}b_n(\omega+\alpha-\theta_h)^{n-1/2}. \tag{D.5}$$

Thus, the first term on the left-hand side of (D.1) contains no branch points. The coefficient t_{12} has no branch points either. It follows that there are no branch points in (D.1) at all.

Let us move on to (D.2). The function $\Psi_0^+[\alpha+g(\omega+\alpha)]+\Psi_0^+[\alpha-g(\omega+\alpha)]$ is an even function of g, and therefore there exist constants B_n such that we can write

$$\Psi_0^+[\alpha+g(\omega+\alpha)]+\Psi_0^+[\alpha-g(\omega+\alpha)]=\sum_{n=0}^{\infty}B_n(\omega+\alpha-\theta_h)^{n}. \tag{D.6}$$

Since the coefficients $t_{21}(\omega)$ and $t_{22}(\omega)$ have no branch points, there are no branch points in (D.2). It follows that the point $-\alpha+\theta_h$, which does not have any physical interpretation, is not a branch point of the function $\Psi_1^+(\omega)$. Similarly, it can be shown that the points $-\alpha-\theta_h$ and $\alpha\pm\theta_h$ are not branch points of $\Psi_1^+(\omega)$. Analogous considerations apply in the antisymmetric case.

We conclude that the branch points of the Sommerfeld amplitudes of the solution of the original problem that lie in the physical region (2.8), and therefore give rise to physical waves, lie outside the strip Re $\omega\,\epsilon\, I$. This means that they do not have to be taken into account in the functional equations for $\widetilde{\Psi}_i^{\pm}(\omega)$ or, by the same token, in the resulting singular integral problem. On the other hand, we have no theoretical proof that the $\Psi_i^{\pm}(\omega)$ that we eventually compute have only physical branch points in the physical region (2.8). We can confirm this fact only by carrying out numerical tests.

Appendix E. The Rayleigh reflection and transmission coefficients. When evaluating (2.5), a pole $\theta_{1\mathrm{R}}^{\mathrm{inc}} = \alpha - \mathrm{i}\beta_{\mathrm{R}}$ of $\Psi_1(\omega)$, with $\beta_{\mathrm{R}} > 0$, corresponds to a plane wave with the phase factor

$$\mathrm{e}^{\mathrm{i}kr\cos\,(\theta-\theta_{1\mathrm{R}}^{\mathrm{inc}})} = \mathrm{e}^{\mathrm{i}kr\cos\,(\theta-\alpha)\cosh\beta_{\mathrm{R}}}\mathrm{e}^{-kr\sin\,(\alpha-\theta)\sinh\beta_{\mathrm{R}}}, \tag{E.1}$$

so that its amplitude is exponentially small everywhere except for a small neighborhood of the wedge face $\theta = \alpha$. Thus, we describe a Rayleigh wave incident from infinity along the upper face $\theta = \alpha$ by two potentials

$$\psi_i^{\mathrm{inc}}(kr,\theta) = 4\pi\mathrm{i}\psi_{i0}\mathrm{e}^{\mathrm{i}\gamma kr\cos(\theta-\theta_{i\mathrm{R}}^{\mathrm{inc}})}, \tag{E.2}$$

where $\psi_{00} = 1$ and $\psi_{10} = -2\mathrm{i}\gamma_{\mathrm{R}}\sqrt{\gamma_{\mathrm{R}}^2-\gamma^2}/(2\gamma_{\mathrm{R}}^2-1)$; $\gamma_{\mathrm{R}} = c_{\mathrm{S}}/c_{\mathrm{R}}$ with c_{S} being the Rayleigh wave speed and $\theta_{0\mathrm{R}}^{\mathrm{inc}} = \alpha - g(\mathrm{i}\beta_{\mathrm{R}})$. The reflected wave propagates along the same wedge face as the incident but from the tip to infinity, and the transmitted propagates along the other face, again away from the tip. They are described respectively by

$$\begin{aligned}\psi_i^{\mathrm{ref}}(kr,\theta) &= 4\pi\mathrm{i}R^{\mathrm{ref}}\psi_{i0}\mathrm{e}^{-\mathrm{i}\gamma kr\cos(\theta-\theta_{i\mathrm{R}}^{\mathrm{sc}})},\\ \psi_i^{\mathrm{tran}}(kr,\theta) &= 4\pi\mathrm{i}R^{\mathrm{tran}}\psi_{i0}\mathrm{e}^{-\mathrm{i}\gamma kr\cos(\theta+\theta_{i\mathrm{R}}^{\mathrm{sc}})},\end{aligned} \tag{E.3}$$

with "scattering angles" $\theta_{i\mathrm{R}}^{\mathrm{sc}}$ being the complex conjugates of $\theta_{i\mathrm{R}}^{\mathrm{inc}}$, so that $\theta_{0\mathrm{R}}^{\mathrm{sc}} = \alpha + g(\mathrm{i}\beta_{\mathrm{R}})$ and $\theta_{1\mathrm{R}}^{\mathrm{sc}} = \alpha + \mathrm{i}\beta_{\mathrm{R}}$. Above, R^{ref} and R^{tran} are the Rayleigh reflection and transmission coefficients

$$R^{\mathrm{ref}} = \frac{1}{2}[R^{+\mathrm{ref}} + R^{-\mathrm{ref}}], \qquad R^{\mathrm{tran}} = \frac{1}{2}[R^{+\mathrm{ref}} - R^{-\mathrm{ref}}], \tag{E.4}$$

with the symmetric and antisymmetric parts given respectively by

$$R^{\pm\mathrm{ref}} = \mathrm{Res}[\Psi_0^{\pm};\, g(\omega_{\mathrm{R}}) + \alpha], \;\text{ with } \omega_{\mathrm{R}} = \pi + \mathrm{i}\beta_{\mathrm{R}}, \tag{E.5}$$

so that, using the additional angles $\theta_{0,\mathrm{R}} = -\alpha + g(\omega_{\mathrm{R}})$ and $\theta_{1,\mathrm{R}} = -\alpha + \omega_{\mathrm{R}}$, we have

$$R^{\pm\mathrm{ref}} = \pm\sum_{k=1}^{2}\mathrm{r}_{1k}(\omega_{\mathrm{R}})\Psi_{k-1}^{\pm}(\theta_{k-1,\mathrm{R}}) + c_1^{\pm}e_1^{\pm}(\omega_{\mathrm{R}})\frac{g'(\omega_{\mathrm{R}})\Delta(\omega_{\mathrm{R}})}{\Delta'(\omega_{\mathrm{R}})}\sqrt{\gamma^2-\cos^2\omega_{\mathrm{R}}}. \tag{E.6}$$

As before, the dash denotes the derivative with respect to the argument.

Appendix F. Adjustable functions and parameters in singular terms. As with any other numerical code, ours relies on a choice of certain options which effect a tradeoff between numerical accuracy and either running time or else numerical stability. Apart from the relevant grids, these options are the following

(i) *The adjustable function $\sigma(\omega)$ in* (3.15). In most cases, $\sigma(\omega)$ is chosen to be

$$\sigma(\omega) = \frac{\frac{\pi}{2\alpha}}{\sin\frac{\pi}{2\alpha}\omega} \tag{F.1}$$

(cf. [5, (15)]). The choice is convenient, because it simplifies the right-hand sides of our functional, and therefore integral, equations. Also, $\sigma(\omega)$ in (F.1) decays at infinity reasonably fast. However, for any wedge angle 2α, there

exists a critical incident angle θ_0^{inc} such that one of the poles of $\Psi_i^{\pm}(\omega)$ lies on the boundary of the strip Re $\omega \epsilon I$. For illustration purposes, let it be $\widehat{\Psi}_1^{\pm}(\omega)$, and let the pole be $\theta_0 = \pi/2 - \alpha$. Then the corresponding term Res $(\Psi_1^{\pm}; \theta_0)\sigma(\omega - \theta_0)$ has one more nonphysical pole, $\theta_0 + 2\alpha$. In situations like these, another choice of $\sigma(\omega)$ is called for, with poles further apart. We have tested

$$\sigma(\omega) = \frac{\beta}{\sin \beta\omega}, \tag{F.2}$$

with various values $\beta < \pi/(2\alpha)$. However, any $\sigma(\omega)$ different from (F.1) leads to more cumbersome right-hand sides of the integral equations and exhibits a slower decay. As a result, the function (F.2), while increasing the stability of the solution, increases the code run time roughly tenfold. For this reason, we abandon (F.1) only when θ^{inc} is near critical angle. In this region we use (F.2), with $\beta = \pi/(6\alpha)$.

(ii) *Number of poles.* When evaluating the poles of the Sommerfeld amplitudes we do not have to restrict ourselves to the strip Re $\omega \epsilon I$. The more poles that are utilized in evaluation, the wider the domain of analyticity of the corresponding unknowns $\widetilde{\Psi}_i(\omega)$, and therefore the higher the accuracy. On the other hand, some nonphysical poles possess residues with large amplitudes and cause numerical instability. In the present version of the code, when θ is away from the critical angle we take into account all poles in the strip Re $\omega \epsilon I$, and when θ is near the critical angle we take into account all poles in the wider strip Re $\omega \epsilon [\pi/2 - 2\alpha, \pi/2 + 2\alpha]$.

GLOBAL ANALYSIS OF NEW MALARIA INTRAHOST MODELS WITH A COMPETITIVE EXCLUSION PRINCIPLE*

ABDERRHAMAN IGGIDR†, JEAN-CLAUDE KAMGANG‡, GAUTHIER SALLET†, AND JEAN-JULES TEWA§

Abstract. In this paper we propose a malaria within-host model with k classes of age for the parasitized red blood cells and n strains for the parasite. We provide a global analysis for this model. A competitive exclusion principle holds. If $\mathcal{R}_0$, the basic reproduction number, satisfies $\mathcal{R}_0 \leq 1$, then the disease-free equilibrium is globally asymptotically stable. On the contrary if $\mathcal{R}_0 > 1$, then generically there is a unique endemic equilibrium which corresponds to the endemic stabilization of the most virulent parasite strain and to the extinction of all the other parasites strains. We prove that this equilibrium is globally asymptotically stable on the positive orthant if a mild sufficient condition is satisfied.

Key words. nonlinear dynamical systems, intrahost models, global stability, *Plasmodium falciparum*, competitive exclusion principle

DOI. 10.1137/050643271

1. Introduction.

In this paper we consider intrahost models for malaria. These models describe the interaction of a parasite, namely a protozoa *Plasmodium falciparum*, with its target cells, the red blood cells (RBC). During the past decade there has been considerable work on the mathematical modeling of *Plasmodium falciparum* infection [2, 14, 21, 22, 24, 23, 25, 28, 30, 52, 55, 56, 58, 64]. A review has been done by Molineaux and Dietz in [59].

We give a brief review of the features of malaria. Malaria in a human begins with an inoculum of *Plasmodium* parasites (sporozoites) from a female *Anopheles* mosquito. The sporozoites enter the liver within minutes. After a period of asexual reproduction in the liver the parasites (merozoites) are released in the bloodstream where the asexual erythrocyte cycle begins. The merozoites enter RBC, grow, and reproduce over a period of approximately 48 hours after which the erythrocyte ruptures releasing 8–32 "merozoites" daughter parasites that quickly invade a fresh erythrocyte to renew the cycle. This blood cycle can be repeated many times, in the course of which some of the merozoites instead develop in the sexual form of the parasites: gametocytes. Gametocytes are benign for the host and are waiting for the mosquitoes.

The first mathematical model of the erythrocyte cycle was proposed by Anderson, May, and Gupta [3]. This original model has been extended in different directions [2, 3, 21, 25, 28, 30, 64].

The original model [3] is given by the following system:

$$\begin{cases} \dot{x} = \Lambda - \mu_x x - \beta x\, m, \\ \dot{y} = \beta x\, m - \mu_y\, y, \\ \dot{m} = r\, \mu_y\, y - \mu_m\, m - \beta\, x\, m. \end{cases} \tag{1.1}$$

The state variables are denoted by x, y, and m. The variable x denotes the concentration of uninfected RBC, y the concentration of parasitized red blood cells (PRBC), and m the concentration of the free merozoites in the blood.

We briefly sketch the interpretation of the parameters. Parameters μ_x, μ_y, and μ_m are the death rates of the RBC, PRBC, and free merozoites, respectively. The parameter β is the contact rate between RBC and merozoites. Uninfected blood cells are recruited at a constant rate Λ from the bone marrow and have a natural life-expectancy of $\frac{1}{\mu_x}$ days. Death of a PRBC results in the release of an average number of r merozoites. Free merozoites die or successfully invade a RBC.

This system is isomorphic to numerous systems considered in the mathematical modeling of virus dynamics; see [60, 61, 62] and the references therein. Some authors ignore the loss term $-\beta\, x\, m$ that should appear in the m equation. Indeed without this loss term, merozoites can infect RBC without themselves being absorbed, and this allows one merozoite *to infect more than one RBC*.

The original and the derived malaria models were intended to explain observations, namely parasitaemia, i.e., the concentration y of PRBC and also the decrease of the healthy RBC leading to anaemia. An important characteristic of *Plasmodium falciparum*, the most virulent malaria parasite, is sequestration. At the halfway point of parasite development, the infected erythrocyte leaves the circulating peripheral blood and binds to the endothelium in the microvasculature of various organs where the cycle is completed. A measurement of *Plasmodium falciparum* parasitaemia taken from a blood smear therefore samples young parasites only. Physician treating malaria use the number of parasites in peripheral blood smears as a measure of infection, and this does not give the total parasite burden of the patient. In some respects this is a weak point of the model (1.1). Moreover antimalarial drugs are known to act preferentially on different stages of parasite development. These facts lead some authors to give a general approach to modeling the age structure of *Plasmodium* parasites [22, 23, 24, 57]. Their model is a linear catenary compartmental model. This model is based on a finite number of compartments, each representing a stage of development of the parasite inside the PRBC. The models describe only the dynamics of the morphological stage evolution of the parasites and make no allowance for the dynamics of the healthy RBC.

In this paper we propose a model which combines the advantages of the two approaches. We also consider this model with different strains for the parasites. To encompass the different models of the literature we allow, in this model, to ignore or not the loss term in the m equation. To begin we consider the model with one strain:

$$\left\{\begin{array}{l} \dot{x} = f(x) - \mu_x x - \beta x\, m, \\ \dot{y}_1 = \beta x\, m - \alpha_1\, y_1, \\ \dot{y}_2 = \gamma_1\, y_1 - \alpha_2\, y_2, \\ \cdots \\ \dot{y}_k = \gamma_{k-1}\, y_{k-1} - \alpha_k\, y_k, \\ \dot{m} = r\, \gamma_k\, y_k - \mu_m\, m - u\, \beta\, x\, m. \end{array}\right. \tag{1.2}$$

In this system $f(x) - \mu_x\, x$ is the density-dependent growth rate of RBC. The other parameters are positive. In the model of Gravenor et al. [21] $\alpha_i = \gamma_i + \mu_i$, and hence $\alpha_i > \gamma_i$. We do not need this requirement, which implies that our model is not necessarily a catenary compartmental model. In the literature the parameter u takes the values $u = 0$ when the loss of the merozoite when it enters a RBC is ignored or takes $u = 1$ when this loss is not ignored. In our analysis u is simply a nonnegative

parameter. Except for these generalizations this system has already been suggested by Gravenor and Lloyd [21] in their reply to the criticism of Saul [64]. We provide a global analysis of this system related to the basic reproduction ratio $\mathcal{R}_0$ of the considered model.

One problem is how to decide upon the number of parasite compartments in the model. A starting point can be the morphological appearance of the parasite. But if the objective is to reflect the distribution of cycle lengths, the number of compartment can be increased to obtain a gamma distribution. Finally the two approaches can be combined: some compartments are for morphological reasons and others are for behavioral reasons. Then this model can also be interpreted as the application of the method of stages (or the linear chain trick) to the life cycle of PRBC [3, 31, 47, 49, 48, 51]. In other words a chain of compartments is included to generate a distribution of lags. It is also possible to add a class y_{k+1} in order to allow for the production of gametocytes. Different numbers of stages, ranging from 5 to 48, are used in [20, 22, 23, 24].

It is well grounded that a *falciparum* infection consists of distinct parasite genotypes. The model of Anderson, May, and Gupta has been extended in this direction [25, 66]. With regard to such features we propose a model with k stages for the infected RBC, production of gametocytes, and n genotypes, in the population of parasites.

One of the important principles of theoretical ecology is the competitive exclusion principle which states that no two species can indefinitely occupy the same ecological niche [7, 8, 11, 17, 25, 39, 53, 54]. We provide a global analysis of this model and obtain a generic competitive exclusion result within one host individual. This confirms the simulation results obtained in [25]. We compute the basic reproduction ratio $\mathcal{R}_0$ of the model. For this model there is always a disease-free equilibrium (DFE). To put it more precisely this equilibrium corresponds to the extinction of all the parasites, including the free parasites and the intraerythrocyte parasites. We prove that if $\mathcal{R}_0 \leq 1$, then the DFE is globally asymptotically stable (GAS); in other words the parasites are cleared. If $\mathcal{R}_0 > 1$, then, generically, a unique endemic equilibrium exists corresponding to the extinction of all the strains of parasites but one. We prove that this equilibrium is GAS on the positive orthant under a mild condition. For example this condition is automatically satisfied when $u = 0$ and $f(x) = \Lambda - \mu_x\, x$. When $u \neq 0$ the criteria, obtained for deciding the winning strain, differs from other results in the literature. To each i-strain can be associated a basic reproduction number $\mathcal{R}_0^i$ and a threshold $\mathcal{T}_0^i$. It turns out, when $u \neq 0$, that this is precisely this threshold $\mathcal{T}_0^i$ which distinguishes the fate of the strain and not $\mathcal{R}_0^i$ at the difference of [7, 11].

The paper is organized as follows. In section 2 we introduce the model with k stages for the infected RBC and one parasite strain, with and without gametocyte production. We compute the basic reproduction number and provide a stability analysis.

In section 3 we consider the model of Anderson, May, and Gupta with n distinct genotypes and production of gametocytes. This model with a constant recruitment function for the erythrocytes, two strains, and one class of age has been proposed in [25]. We have studied this model in [1]. Here using the computation of section 2, we prove for the general n strain k class of age model that if $\mathcal{R}_0 \leq 1$, then the parasites are cleared and if $\mathcal{R}_0 > 1$, then generically the different genotypes cannot coexist. Namely a unique equilibrium exists, for which only one genotype is positive, and which is GAS on a dense subset of the nonnegative orthant. This result confirms the simulations given in [25].

Global results of stability for the DFE as well for the endemic equilibrium for epidemic models are not so common [26, 27, 33, 43, 65, 67, 68]. Global stability

results for the endemic equilibrium have often been obtained by using monotone system techniques [29, 36]. Usually the Poincaré–Bendixson property of monotone systems in dimension 3 is used [40, 41, 42, 43, 44, 45]. Our results generalize the results of [13].

2. Stability analysis of a one strain model with *k* stages. We consider a general class of systems. The haemopoiesis is a complex system. In the cited references the recruitment of RBC is given by $\Lambda - \mu_x\, x$. In this paper we will use a more general function $\varphi(x)$. In a more complex system the haemopoiesis could be an input coming from another system:

$$\left\{\begin{array}{l} \dot{x} = f(x) - \mu_x x - \beta x\, m = \varphi(x) - \beta\, x\, m, \\ \dot{y}_1 = \beta x\, m - \alpha_1\, y_1, \\ \dot{y}_2 = \gamma_1\, y_1 - \alpha_2\, y_2, \\ \dots \\ \dot{y}_k = \gamma_{k-1}\, y_{k-1} - \alpha_k\, y_k, \\ \dot{m} = r\, \gamma_k\, y_k - \mu_m\, m - u\, \beta\, x\, m. \end{array}\right. \tag{2.1}$$

We denote by y the column vector $(y_1, \dots, y_k)^T$. The parameter u is nonnegative. The reason for this parameter is to encompass some malaria models in which the term $-\beta\, x\, m$ can appear or not. In [2] Anderson has considered a system without the $-\beta\, x\, m$ in the $\dot{m}$ equation. In [60] all the basic models of virus dynamics are also without this term. One feature of *Plasmodium falciparum*, responsible for the deadly case of malaria, is that more than one parasite can invade RBC. In this case u is the mean number of parasites invading RBC and thus disappearing from the circulating blood.

Some authors [25, 56] have included in the model production of gametocytes. In the course of the production of merozoites from bursting erythrocytes, some invading merozoites develop into the sexual, nonreplicating transmission stages known as gametocytes. The gametocytes are benign and transmissible to mosquitoes. We can also, following these authors, include a production of gametocytes in our model. If we denote by y_{k+1} the "concentration of gametocytes," the model becomes

$$\left\{\begin{array}{l} \dot{x} = f(x) - \mu_x x - \beta x\, m = \varphi(x) - \beta\, x\, m, \\ \dot{y}_1 = \beta x\, m - \alpha_1\, y_1, \\ \dot{y}_2 = \gamma_1\, y_1 - \alpha_2\, y_2, \\ \dots \\ \dot{y}_k = \gamma_{k-1}\, y_{k-1} - \alpha_k\, y_k, \\ \dot{y}_{k+1} = \rho\, \gamma_k\, y_k - \alpha_{k+1}\, y_{k+1}, \\ \dot{m} = r\, \gamma_k\, y_k - \mu_m\, m - u\, \beta\, x\, m. \end{array}\right. \tag{2.2}$$

We start to analyze the system with minimal hypothesis on f but nevertheless plausible from the biological point of view. The function f gives the production of erythrocytes from the bone marrow. The function $\varphi(x) = f(x) - \mu_x x$ models the population dynamic of RBC in the absence of parasites. The RBC have a finite lifetime, and then μ_x represents the average per capita death rate of RBC. The function f models in some way homeostasis. In this paper we suppose that f depends only on x. It could be assumed that the recruitment function depends on x and the total population of erythrocytes $x + \sum_i y_i$. In this paper we will analyze the simplified case which is the model considered in all the referenced literature. The rationale behind this simplification is that in a malaria primo-infection typically y is in the order of 10^{-1}

to 10^{-4} of the concentration of healthy erythrocytes x. This can be confirmed from the data of malaria therapy. In the last century neurosyphilitic patients were given malaria therapy, which was routine care at that time. Some of them were infected with *Plasmodium falciparum*. Data were collected at the National Institutes of Health laboratories in Columbia, SC and Milledgeville, GA during the period 1940 to 1963 [12].

We assume that f is a $\mathcal{C}^1$. Since homeostasis is maintained we assume that the dynamic without parasites is asymptotically stable. In other words, for the system

$$\dot{x} = f(x) - \mu_x\, x = \varphi(x)$$

there exists a unique $x^* > 0$ such that

$$\varphi(x^*) = 0, \quad \text{and} \ \ \varphi(x) > 0 \quad \text{for} \ \ 0 \le x < x^*, \ \ \text{and} \ \ \varphi(x) < 0 \ \ \text{for} \ x > x^*. \tag{2.3}$$

2.1. Notation. We will rewrite systems (2.1) and (2.2) in a condensed simpler form.

Before we introduce some classical notation.

We identify vectors of $\mathbb{R}^n$ with $n \times 1$ column vectors. $\langle\, |\, \rangle$ denotes the euclidean inner product. $\|z\|_2^2 = \langle\, z \mid z\, \rangle$ is the usual euclidean norm.

The family $\{e_1, \ldots, e_n\}$ denotes the canonical basis of the vector space $\mathbb{R}^n$. For example $e_1 = (1, 0, \ldots, 0)^T$. We denote by e_ω the last vector of the canonical basis, $e_\omega = (0, \ldots, 0, 1)^T$.

If $z \in \mathbb{R}^n$, we denote by z_i the ith component of z. Equivalently $z_i = \langle\, z \mid e_i\, \rangle$.

For a matrix A we denote by $A(i, j)$ the entry at the row i, column j. For matrices A, B we write $A \le B$ if $A(i, j) \le B(i, j)$ for all i and j, $A < B$ if $A \le B$ and $A \ne B$, and $A \ll B$ if $A(i, j) < B(i, j)$ for all i and j.

A^T denotes the transpose of A. Then $\langle\, z_1 \mid z_2\, \rangle = z_1^T\, z_2$. The notation A^{-T} will denote the transpose of the inverse of A.

For this section we rewrite the systems (2.1) and (2.2) under a unique form:

$$\begin{cases} \dot{x} = \varphi(x) - \beta\, x\, \langle\, e_\omega \mid z\, \rangle, \\ \dot{z} = \beta\, x\, \langle\, e_\omega \mid z\, \rangle\, e_1 + A_0\, z - u\, \beta\, x\, \langle\, e_\omega \mid z\, \rangle\, e_\omega. \end{cases} \tag{2.4}$$

In the case of the system (2.1) we have for A_0

$$A_0 = \begin{bmatrix} -\alpha_1 & 0 & 0 & \cdots & 0 & 0 \\ \gamma_1 & -\alpha_2 & 0 & \cdots & 0 & 0 \\ 0 & \gamma_2 & -\alpha_3 & \cdots & 0 & 0 \\ \vdots & \ddots & \ddots & \ddots & \vdots & \vdots \\ 0 & \cdots & 0 & \gamma_{k-1} & -\alpha_k & 0 \\ 0 & \cdots & 0 & 0 & r\gamma_k & -\mu_m \end{bmatrix} \tag{2.5}$$

and an analogous formula for (2.2).

We define the matrix $A(x) = A_0 - \beta\, x\, e_\omega\, e_\omega^T$. This a Metzler stable matrix. (A Metzler matrix is a matrix with nonnegative off-diagonal entries [5, 32, 50].)

It is not difficult to check that the nonnegative orthant is positively invariant by (2.4) and that there exists a compact absorbing set K for this system. An absorbing set D is a neighborhood such that a trajectory of the system starting from any initial condition enters and remains in D for a sufficiently large time T.

2.2. Global stability results. We can now give the main result of this section.

THEOREM 2.1. *We consider the system* (2.4) *with the hypothesis* (2.3) *on* φ *satisfied. We define the basic reproduction ratio of the system* (2.1) *and* (2.2) *by*

$$\mathcal{R}_0 = \frac{r\beta x^*}{\mu_m + u\,\beta\,x^*}\,\frac{\gamma_1\cdots\gamma_k}{\alpha_1\cdots\alpha_k}. \tag{2.6}$$

1. *The system* (2.1) *is GAS on* $\mathbb{R}^{k+2}_+$ *(respectively,* (2.2) *on* $\mathbb{R}^{k+3}_+$*) at the DFE* $(x^*, 0, \ldots, 0)$ *if and only if* $\mathcal{R}_0 \le 1$.

2. *If* $\mathcal{R}_0 > 1$*, then the DFE is unstable and there exists a unique endemic equilibrium (EE) in the positive orthant,* $(\bar{x}, \bar{z}) \gg 0$*, given by*

$$\begin{cases} \bar{x} = \dfrac{\mu_m}{\beta\left[r\dfrac{\gamma_1\cdots\gamma_k}{\alpha_1\cdots\alpha_k} - u\right]}, \\ \bar{z} = \varphi(\bar{x})\,(-A_0)^{-1}\,(e_1 - u\,e_\omega). \end{cases} \tag{2.7}$$

Denoting $\alpha^* = -\max_{x\in[0,x^*]}(\varphi'(x))$*, if*

$$u\,\beta\,\varphi(\bar{x}) \le \alpha^*\,\mu_m, \tag{2.8}$$

then the EE is GAS on the nonnegative orthant, except for initial conditions on the x-axis.

Proof of Theorem 2.1. To begin we will consider the system (2.1) without gametocytes, i.e., the system (2.4) with A_0 as defined in (2.5). The stability analysis for (2.2) follows easily from the stability analysis of (2.1).

In a first step we will compute $\mathcal{R}_0 \le 1$. We use our preceding notation and define $A^* = A(x^*)$, i.e., the matrix computed at the equilibrium x^* of φ, which is a stable Metzler matrix. We will use, repeatedly in what follows, the property that if M is a stable Metzler matrix, then $-M^{-1} \ge 0$ [5]. The expression of $\mathcal{R}_0$ is obtained easily by using the next generation matrix of the system (2.1) [9, 15, 16]. We have for the basic reproduction number

$$\mathcal{R}_0 = \beta\,x^*\left\langle -(A^*)^{-1}\,e_1 \mid e_\omega \right\rangle.$$

If we remark that the matrix A^* is the matrix A_0 modified by a rank-one matrix, namely $A^* = A_0 - u\,\beta\,x^*\,e_\omega\,e_\omega^T$, we can use the Sherman–Morrison–Woodbury formula

$$-(A^*)^{-1} = -A_0^{-1} - \frac{u\,\beta\,x^*}{1 + u\,\beta\,x^*\,e_\omega^T\,(-A_0)^{-1}\,e_\omega}\,(-A_0)^{-1}\,e_\omega\,e_\omega^T\,(-A_0)^{-1}$$

or equivalently

$$-(A^*)^{-1} = -A_0^{-1} - \frac{u\,\beta\,x^*}{\mu_m + \beta\,x^*}\,e_\omega\,e_\omega^T\,(-A_0)^{-1}.$$

This shows that $-(A^*)^{-1}$ is obtained from $-A_0^{-1}$ by multiplying the last line of $-A_0^{-1}$ by $\frac{\mu_m}{\mu_m + u\,\beta\,x^*}$. Then we get

$$\mathcal{R}_0 = \beta\,x^*\,\frac{\mu_m}{\mu_m + u\,\beta\,x^*}\left\langle -(A_0)^{-1}\,e_1 \mid e_\omega \right\rangle,$$

and then in computing the last entry of the first column of A_0 we obtain (2.6).

We remark that $\mathcal{R}_0 > 1$ is equivalent to the following threshold condition:

(2.9)
$$\mathcal{T}_0 = \frac{\beta\, x^*}{\mu_m}\left[\mu_m \left\langle -(A_0)^{-1}\, e_1 \mid e_\omega \right\rangle - u\right] = \beta\, x^* \left\langle -(A_0)^{-1}\, (e_1 - u\, e_\omega) \mid e_\omega \right\rangle > 1.$$

We are now ready to analyze the stability of the DFE.

It is well known that if $\mathcal{R}_0 > 1$, then the DFE is unstable [15], which implies that the condition $\mathcal{R}_0 \leq 1$ is necessary for stability.

To prove the sufficiency, in a second step, we consider the following function defined on the nonnegative orthant:

$$V_{DFE}(z) = \beta\, x^* \langle\, e_\omega \mid (-A_0^{-1})z \,\rangle. \tag{2.10}$$

Its time derivative along the trajectories of system (2.4) is

$$\dot{V}_{DFE} = \beta\, x \langle\, e_\omega \mid z \,\rangle\, \beta\, x^* \langle\, e_\omega \mid (-A_0)^{-1}\, (e_1 - u\, e_\omega) \,\rangle - \beta\, x^* \langle\, e_\omega \mid z \,\rangle$$

or equivalently, using the expression of $\mathcal{T}_0$ given in (2.9),

$$\dot{V}_{DFE} = \beta \langle\, e_\omega \mid z \,\rangle\, (\mathcal{T}_0\, x - x^*)\,. \tag{2.11}$$

Now we take as a candidate Liapunov function, defined on the nonnegative orthant minus the hyperplane face $x = 0$,

$$V = (x - x^* \ln x) - x^*(1 - \ln x^*) + V_{DFE}(z).$$

This function is positive definite (relatively to the DFE) on $\mathbb{R}^{k+2}_{+,x>0} = \{(x, y, m) \in \mathbb{R}^{k+2}_{+} \;:\; x > 0\}$. Its time derivative is given by

$$\dot{V} = \frac{x - x^*}{x}\, \varphi(x) - (x - x^*)\, \beta \langle\, e_\omega \mid z \,\rangle + \beta \langle\, e_\omega \mid z \,\rangle\, (\mathcal{T}_0\, x - x^*)$$

or assuming $\mathcal{R}_0 \leq 1$

$$\dot{V} = \frac{x - x^*}{x}\, \varphi(x) + \beta\, x \langle\, e_\omega \mid z \,\rangle\, (\mathcal{T}_0 - 1) \;\leq\; 0.$$

By assumption (2.3) we have $(x - x^*)\varphi(x) \leq 0$ for all $x \geq 0$. Therefore $\dot{V} \leq 0$ for all $(x, z) \in \mathbb{R}^{k+2}_{+,x>0}$, which proves the stability of the DFE. Its attractivity follows from LaSalle's invariance principle [6, 37, 38], since the largest invariant set contained in $\{(x, z) \in \mathbb{R}^{k+2}_{+,x>0} \;:\; \dot{V} = 0\}$ is reduced to the DFE. On the other hand the vector field is strictly entrant on the face $x = 0$. Hence the whole orthant $\mathbb{R}^{k+2}_{+}$ belongs to the region of attraction of the DFE.

Now we assume that $\mathcal{R}_0 > 1$. The equilibria $(\bar{x}, \bar{z})$ of the system, different from the DFE, are determined by the relations

$$\bar{z} = \beta\, \bar{x} \langle\, \bar{z} \mid e_\omega \,\rangle\, (-A_0)^{-1}\, (e_1 - u\, e_\omega).$$

Replacing $\bar{z}$ in $\langle\, \bar{z} \mid e_\omega \,\rangle$ we obtain

$$\langle\, \bar{z} \mid e_\omega \,\rangle = \beta\, \bar{x} \langle\, \bar{z} \mid e_\omega \,\rangle \langle\, (-A_0)^{-1}\, (e_1 - u\, e_\omega) \mid e_\omega \,\rangle. \tag{2.12}$$

If $\langle\, \bar{z} \mid e_\omega \,\rangle = 0$, then $\varphi(\bar{x}) = 0$, we obtain $\bar{x} = x^*$, and hence $\bar{z} = 0$; i.e., the corresponding equilibrium is the DFE. In the other case, i.e., $\langle\, \bar{z} \mid e_\omega \,\rangle \neq 0$, the relation (2.12) gives

$$\beta\, \bar{x} \left\langle\, (-A_0)^{-1}\, (e_1 - u\, e_\omega) \mid e_\omega \,\right\rangle = 1. \tag{2.13}$$

Using $\langle\, (-A_0)^{-1}\, e_\omega \mid e_\omega \,\rangle = \frac{1}{\mu_m}$ we finally have

$$\bar{x} = \frac{\mu_m}{\beta\, \left[\mu_m \,\langle\, (-A_0)^{-1}\, e_1 \mid e_\omega \,\rangle - u\right]} = \frac{x^*}{\mathcal{T}_0}.$$

We deduce that if $\mathcal{R}_0 > 1$, then $0 < \bar{x} < x^*$, and hence $\varphi(\bar{x}) > 0$. Therefore

$$\bar{z} = \varphi(\bar{x})\ (-A_0)^{-1}\, (e_1 - u\, e_\omega).$$

The last component of $\bar{z}$, $\langle\, \bar{z} \mid e_\omega \,\rangle = \bar{m}$, is given by

$$\bar{m} = \frac{\varphi(\bar{x})}{\beta\, \bar{x}} > 0.$$

The k first components of $\bar{z}$ are given by the k first components of $\varphi(\bar{x})\ (-A_0)^{-1}\, e_1$. It is straightforward to check that the first column of $(-A_0)^{-1}$ namely $(-A_0)^{-1}\, e_1 \gg 0$, which proves that $\bar{z} \gg 0$. We have then proved that there is a unique EE in the positive orthant if and only if $\mathcal{R}_0 > 1$.

Finally we will prove a sufficient condition for the global asymptotic stability of the EE. To this end we define the following candidate Liapunov function on the positive orthant minus the face corresponding to $x = 0$:

$$V_{EE}(x, y, m) = a(x - \bar{x} \ln x) + \sum_{i=1}^{k} b_i\, (y_i - \bar{y}_i \ln y_i)\ + b_{k+1}\, (m - \bar{m}\ \ln m). \tag{2.14}$$

This function has a unique global minimum in $(\bar{x}, \bar{y}, \bar{m})$. We will choose the coefficients a, b_i, b_{k+1} such that in the computation of $\dot{V}$, the linear terms in y_i and m and the bilinear terms in $x\, m$ cancel. Let us show that it is possible with positive coefficients. To this end we rewrite the function V_{EE} using the notation $z = (y, m)^T$, $\ln z = (\ln z_1, \ln z_2, \ldots, \ln z_{k+1})^T$, and $b = (b_1, \ldots, b_k, b_{k+1})^T$:

$$V_{EE}(x, z) = a(x - \bar{x} \ln x) + \langle\, b \mid z - diag(\bar{z}) \ln z \,\rangle.$$

Consider the block matrix

$$M = \begin{bmatrix} -1 & (e_1 - u\, e_\omega)^T \\ \beta\, \bar{x}\, e_\omega & A_0^T \end{bmatrix}.$$

Using classical Schur complement techniques and the relation (2.13) on $\bar{x}$, we have

$$\begin{aligned} \det(M) &= \det(A_0)[-1 + \beta\, \bar{x} (e_1 - u\, e_\omega)^T\, (-A_0^{-T})\, e_\omega] \\ &= \det(A_0)[-1 + \beta\, \bar{x}\, \langle\, -A_0^{-1}\, (e_1 - u\, e_\omega) \mid e_\omega \,\rangle] = 0. \end{aligned}$$

Since the matrix M is obviously of codimension 1 (A_0 is nonsingular) the kernel of M is of dimension 1. Then there exists $a \in \mathbb{R}$ and $b \in \mathbb{R}^{k+1}$ such that

$$a = (e_1 - u\, e_\omega)^T\, b = \langle\, b \mid e_1 - u\, e_\omega \,\rangle \tag{2.15a}$$

and

$$b = a\,\beta\,\bar{x}\,(-A_0^{-T})\,e_\omega. \tag{2.15b}$$

Since the kernel is one dimensional, a can be chosen arbitrarily. Thanks to the structure of A_0, if $a > 0$, then $b \gg 0$.

The derivative of V along the trajectories of (2.4) is given by

$$\begin{aligned}\dot{V}_{EE} &= a\,\frac{x-\bar{x}}{x}\,\varphi(x) - a\,\beta x\,\langle\, e_\omega \mid z\,\rangle + a\,\beta\,\bar{x}\,\langle\, e_\omega \mid z\,\rangle + \beta\,x\,\langle\, e_\omega \mid z\,\rangle\,\langle\, b \mid e_1 - u\,e_\omega\,\rangle \\ &\quad + \langle\, b \mid A_0 z\,\rangle + \langle\, b \mid \operatorname{diag}(\bar{z})\operatorname{diag}(z)^{-1}\,\dot{z}\,\rangle \\ &= a\,\frac{x-\bar{x}}{x}\,\varphi(x) + \langle\, b \mid \operatorname{diag}(\bar{z})\operatorname{diag}(z)^{-1}\,\dot{z}\,\rangle \\ &\quad + a\,\beta\,\bar{x}\,\langle\, e_\omega \mid z\,\rangle + \langle\, b \mid A_0 z\,\rangle + \beta x\,\langle\, e_\omega \mid z\,\rangle\,\big(\langle\, b \mid e_1 - u\,e_\omega\,\rangle - a\big).\end{aligned}$$

Using the relation (2.15b) we see that

$$\langle\, b \mid A_0\,z\,\rangle = -a\,\beta\,\bar{x}\,\langle\,(A_0^{-T})\,e_\omega \mid A_0 z\,\rangle = -a\,\beta\,\bar{x}\,\langle\, e_\omega \mid z\,\rangle.$$

Therefore the linear terms in z cancel. The same is true for the bilinear terms thanks to the relation (2.15a). Finally we get

$$\dot{V}_{EE} = a\,\frac{x-\bar{x}}{x}\,\varphi(x) + \langle\, b \mid \operatorname{diag}(\bar{z})\operatorname{diag}(z)^{-1}\,\dot{z}\,\rangle.$$

We choose $b_{k+1} = 1 = \langle\, b \mid e_\omega\,\rangle = a\,\beta\,\bar{x}\,\langle\, -A^{-T}\,e_\omega \mid e_\omega\,\rangle = a\,\beta\,\bar{x}\frac{1}{\mu_m}$. In other words $a = \frac{\mu_m}{\beta\,\bar{x}}$. With the hypothesis $\mathcal{R}_0 > 1$ we have $a > 0$, and hence $b \gg 0$ as wanted. With this choice developing $\dot{V}$ gives

$$\begin{aligned}\dot{V}_{EE} &= a\,f(x) - a\mu_x\,x - af(x)\frac{\bar{x}}{x} + a\,\mu_x\,\bar{x} - b_1\,\beta\bar{y}_1\,\frac{xm}{y_1} - \sum_{i=2}^{k} b_i\gamma_{i-1}y_{i-1}\frac{\bar{y}_i}{y_i} \\ &\quad + \sum_{i=1}^{k} b_i\,\alpha_i\,\bar{y}_i - r\,\gamma_k\,y_k\,\frac{\bar{m}}{m} + u\,\beta\bar{m}x + \mu_m\bar{m}.\end{aligned}$$

We collect some useful relations between our coefficients at the EE. We have from the definitions of a and b, since $b_{k+1} = 1$,

$$\begin{cases} a + u = b_1, \\ b_1\,\alpha_1 = \gamma_1\,b_2, \\ b_2\,\alpha_2 = \gamma_2\,b_3, \\ \cdots \\ b_{k-1}\,\alpha_{k-1} = \gamma_{k-1}\,b_k, \\ b_k\,\alpha_k = r\,\gamma_k. \end{cases} \tag{2.16}$$

From these relations and the properties of the EE $\bar{z}$ we have

$$b_1\,\beta\,\bar{x}\,\bar{m} = b_i\,\alpha_i\,\bar{y}_i = b_i\,\gamma_{i-1}\,\bar{y}_{i-1} = r\,\gamma_k\,\bar{y}_k \tag{2.17}$$

and

$$a\alpha_1\bar{y}_1 = \mu_m\,\bar{m}. \tag{2.18}$$

Replacing, in the expression of $\dot{V}$, $a\mu_x\bar{x}$ by $a\,f(\bar{x}) - a\beta\bar{x}\bar{m} = af(\bar{x}) - a\alpha_1\,\bar{y}_1$ we obtain

$$\dot{V}_{EE} = kr\gamma_k\bar{y}_k + af(\bar{x}) + af(x) + (u\,\beta\bar{x}\bar{m} - a\mu_x\bar{x})\frac{x}{\bar{x}} - af(x)\frac{\bar{x}}{x} - b_1\,\beta\,\bar{x}\,\bar{m}\,\frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k} b_i\gamma_{i-1}\bar{y}_{i-1}\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - r\gamma_k\bar{y}_k\frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}.$$

Using again the relations between the coefficients we get

$$\dot{V}_{EE} = kr\gamma_k\bar{y}_k + af(\bar{x}) + af(x) + (r\gamma_k\bar{y}_k - af(\bar{x}))\frac{x}{\bar{x}} - af(x)\frac{\bar{x}}{x} - r\,\gamma_k\,y_k\,\frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k} r\gamma_k\bar{y}_k\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - r\gamma_k\bar{y}_k\frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}$$

and finally

$$\dot{V}_{EE} = a\left[f(x) + f(\bar{x}) - f(\bar{x})\frac{x}{\bar{x}} - f(x)\frac{\bar{x}}{x}\right] + r\,\gamma_k\,\bar{y}_k\left[k + \frac{x}{\bar{x}} - \frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k}\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - \frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}\right].$$

Now we will use the fact that there exists ξ in the open interval $\xi \in]x, \bar{x}[$ such that $f(x) = f(\bar{x}) + (x - \bar{x})\,f'(\xi)$. Replacing in the preceding expression gives

$$\dot{V}_{EE} = af(\bar{x})\left[2 - \frac{x}{\bar{x}} - \frac{\bar{x}}{x}\right] + a\,f'(\xi)\frac{(x-\bar{x})^2}{x} + r\,\gamma_k\,\bar{y}_k\left[k + \frac{x}{\bar{x}} - \frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k}\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - \frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}\right].$$

Using the relations (2.16)–(2.17) we have

$$af(\bar{x}) = (b_1 - u)f(\bar{x}) = b_1(\mu_x\bar{x} + \beta\bar{x}\bar{m}) - u\,f(\bar{x}) = b_1\,\mu_x\,\bar{x} + r\gamma_k\bar{y}_k - u\,f(\bar{x}).$$

Replacing in the preceding expression of $\dot{V}$ gives

$$\dot{V}_{EE} = (b_1\,\mu_x\,\bar{x} - u\,f(\bar{x}))\,\left[2 - \frac{x}{\bar{x}} - \frac{\bar{x}}{x}\right] + a\,f'(\xi)\frac{(x-\bar{x})^2}{x} + r\,\gamma_k\,\bar{y}_k\left[k + 2 - \frac{\bar{x}}{x} - \frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k}\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - \frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}\right].$$

This can also be written

$$\dot{V}_{EE} = \Phi(x, y, m) = -\left[b_1\,\mu_x\,\bar{x} - u\,f(\bar{x}) - a\,\bar{x}\,f'(\xi)\right]\frac{(x-\bar{x})^2}{x\bar{x}} + r\,\gamma_k\,\bar{y}_k\left[k + 2 - \frac{\bar{x}}{x} - \frac{x}{\bar{x}}\,\frac{m}{\bar{m}}\,\frac{\bar{y}_1}{y_1} - \sum_{i=2}^{k}\frac{y_{i-1}}{\bar{y}_{i-1}}\frac{\bar{y}_i}{y_i} - \frac{y_k}{\bar{y}_k}\frac{\bar{m}}{m}\right]. \tag{2.19}$$

The term between brackets in the last expression of $\dot{V}$ is nonpositive by the inequality between the arithmetical mean and the geometrical mean. Then a sufficient condition for $\dot{V} \leq 0$ is

$$b_1\,\mu_x\,\bar{x} - u\,f(\bar{x}) - a\,\bar{x}\,f'(\xi) \geq 0.$$

Moreover with this condition $\dot{V}$ is negative, except at the EE for the system (2.1). This proves the global asymptotic stability of the EE on the positive orthant for the system (2.1).

The vector field associated with the system is strictly entrant on the faces of the orthant, except the x-axis, where it is tangent. The basin of attraction of the EE is then the orthant, except the x-axis, which is the stable manifold of the DFE.

Using the function $\varphi(x) = f(x) - \mu_x\,x$ the preceding condition is equivalent to

$$u\,\varphi(\bar{x}) \leq -a\,\bar{x}\,\varphi'(\xi),$$

or equivalently, replacing a by its value $a = \frac{\mu_m}{\beta\,\bar{x}}$, the condition becomes

$$u\,\beta\,\varphi(\bar{x}) \leq -\mu_m\,\varphi'(\xi).$$

Setting $\alpha^* = -\max_{x\in[0,x^*]}\varphi'(x)$ a sufficient condition for global asymptotic stability of the EE is

$$\mathcal{R}_0 > 1 \quad \text{and} \quad u\,\beta\,\varphi(\bar{x}) \leq \mu_m\alpha^*.$$

We have proved the theorem for the system without gametocytes. We have seen that $\mathcal{R}_0$ does not depend on the production of gametocytes. If $\mathcal{R}_0 \leq 1$, it is easy, integrating the linear stable y_{k+1} equations of (2.2) from the solutions of (2.1), to see that the DFE is asymptotically stable and that all the trajectories converge to the equilibrium. The same argument is used when $\mathcal{R}_0 > 1$. This ends the proof of Theorem 2.1. □

Remark 1. If this model is a model for a within-host model of malaria, each coefficient α_i is made of the mortality of the i-class and the rate of transmission in the $i+1$-class: $\alpha_i = \mu_i + \gamma_i$. This implies that $\gamma_i \leq \alpha_i$. We do not need this assumption, and our conclusions are valid for our more general model. The only hypothesis is that the parameters of the system are positive.

Remark 2. In the proof of Theorem 2.1 the quantity

$$\beta\,x^*\left\langle -(A_0)^{-1}\,(e_1 - u\,e_\omega) \mid e_\omega \right\rangle,$$

which we have called $\mathcal{T}_0$ when $\mathcal{R}_0 > 1$, plays a prominent role. When $\mathcal{R}_0 \leq 1$ and $u \neq 0$ three cases occur: $0 < \mathcal{T}_0 \leq 1$ or $\mathcal{T}_0 < 0$ or $\mathcal{T}_0 = 0$.

In the two first cases we can define $\bar{x} = \frac{x^*}{\mathcal{T}_0}$, and we obtain an equilibrium $(\bar{x}, \bar{z})$ of the system which is not in the nonnegative orthant (either $\bar{x} < 0$ or $\bar{z} < 0$).

In the third case, the computations, done in the proof of Theorem 2.1, for the research of an equilibrium show that $\langle\, z \mid e_\omega \,\rangle = 0$, and hence $z = 0$, and finally the equilibrium is the DFE $(x^*, 0)$.

We introduce a definition of $\mathcal{T}_0$ that will simplify future computations. The case $\mathcal{T}_0 = 0$ is special, since $\mathcal{T}_0 = \frac{x^*}{\bar{x}}$ is no longer true. However this case can be thought, by convention and misuse of language, as $\bar{x} = +\infty$.

DEFINITION 2.2. *We define for the system* (2.1) *the threshold*

$$\mathcal{T}_0 = \frac{x^*}{\dfrac{\mu_m}{\beta\left[r\dfrac{\gamma_1\cdots\gamma_k}{\alpha_1\cdots\alpha_k} - u\right]}} = \beta\, x^* \left\langle -(A_0)^{-1}\,(e_1 - u\, e_\omega) \mid e_\omega \right\rangle. \tag{2.20}$$

When $\mathcal{T}_0 \neq 0$ *we have also* $\mathcal{T}_0 = \frac{x^*}{\bar{x}}$.

Remark 3. It should be pointed out that the kind of Liapunov function defined by (2.14) has a long history of application to Lotka–Volterra models [18, 19] and was originally discovered by Volterra himself, although he did not use the vocabulary and the theory of Liapunov functions. Since epidemic models are "Lotka–Volterra" like models, the pertinence of this function is not surprising. Similar Liapunov functions have been used in epidemiology [4, 34, 35, 46, 63], although with different parameters. We have already used this kind of function in a simplified version of this paper in [1].

2.3. Comparison with known results. Our stability result improves the one of De Leenheer and Smith [13] in two directions:

1. We introduce n stages for latent classes.
2. Our sufficient condition for the global asymptotic stability of the endemic equilibrium is weaker than the one provided in [13]; for instance the sufficient condition given in Theorem 2.1 is satisfied for malaria parameters given in [3], while the condition of [13] is not satisfied.

2.4. Application to the original AMG model [3]. The original Anderson–May–Guptka model is a three dimensional system (1.1) which has the same form as system (2.1) with $f(x) = \Lambda$. The sufficient condition (2.8) applied to the AMG model (1.1) can be written

$$\beta\Lambda \leq \frac{r}{r-1}\,\mu_x\,\mu_m. \tag{2.21}$$

For the system (1.1), it is possible to give a weaker sufficient stability condition.

PROPOSITION 2.3. *If* $\mathcal{R}_0 > 1$ *and* $\beta\Lambda \leq (\sqrt{r} + \sqrt{r-1})^2\,\mu_x\,\mu_m$, *then the EE is a GAS steady state for system* (1.1) *with respect to initial states not on the* x*-axis.*

Since in general the parameter r is larger than 2 (see, for instance, [28]), we have $(\sqrt{r} + \sqrt{r-1})^2 > \frac{r}{r-1}$.

Proof. Thanks to the computations done before, we have for system (1.1)

$$\dot{V}_{EE} = (r-1)\Lambda\left[2 - \frac{x}{\bar{x}} - \frac{\bar{x}}{x}\right] + r\,\mu_y\,\bar{y}\left[1 + \frac{x}{\bar{x}} - \frac{y}{\bar{y}}\frac{\bar{m}}{m} - \frac{x}{\bar{x}}\frac{m}{\bar{m}}\frac{\bar{y}}{y}\right].$$

Define $X = \frac{x}{\bar{x}}$ and $S = \frac{y}{\bar{y}}\frac{\bar{m}}{m}$. Then one can write

$$\begin{aligned}\dot{V}_{EE} &= -(r-1)\Lambda\tfrac{(X-1)^2}{X} + r\,\mu_y\,\bar{y}\left(1 + X - S - \tfrac{X}{S}\right)\\ &= -(r-1)\Lambda\tfrac{(X-1)^2}{X} + r\,\mu_y\,\bar{y}\;\Psi(X,S).\end{aligned}$$

We have $\Psi(X,S) \geq 0 \Leftrightarrow X \leq S \leq 1$ or $X \geq S \geq 1$. On the other hand $\Psi(X,S) \leq \Psi(X,\sqrt{X}) = (\sqrt{X}-1)^2$. Therefore

$$\begin{aligned}&\dot{V}_{EE} \leq (r-1)\Lambda(\sqrt{X}-1)^2\left(\tfrac{r\,\mu_y\,\bar{y}}{(r-1)\Lambda} - \left(1 + \tfrac{1}{\sqrt{X}}\right)^2\right),\\ &\dot{V}_{EE} \leq (r-1)\Lambda(\sqrt{X}-1)^2\left(\sqrt{\tfrac{r\,\mu_y\,\bar{y}}{(r-1)\Lambda}} + 1 + \tfrac{1}{\sqrt{X}}\right)\left(\sqrt{\tfrac{r\,\mu_y\,\bar{y}}{(r-1)\Lambda}} - 1 - \tfrac{1}{\sqrt{X}}\right).\end{aligned} \tag{2.22}$$

We have $\frac{\mu_y\,\bar{y}}{\Lambda} = \frac{\Lambda-\mu_x\bar{x}}{\Lambda} < 1$. Hence for $X \le X^* = \frac{x^*}{\bar{x}} = \frac{(r-1)\beta}{\mu_m}x^*$ we have the following: $\sqrt{\frac{r\,\mu_y\,\bar{y}}{(r-1)\Lambda}} - 1 - \frac{1}{\sqrt{X}} < \sqrt{\frac{r}{(r-1)}} - \frac{\sqrt{\mu_m}}{\sqrt{(r-1)\beta x^*}} - 1 \le 0$, since by assumption $\frac{\beta x^*}{\mu_m} = \frac{\beta\Lambda}{\mu_x\mu_m} \le (\sqrt{r}+\sqrt{r-1})^2$. Therefore, the derivative of V_{EE} along the trajectories of system (1.1) is negative definite on the set $\mathcal{D}_0 = \{(x,y,m) \in \mathbb{R}^3_+ \,:\, 0 < x \le x^*,\ y > 0,\ m > 0\}$. By continuity, there exists $\epsilon > 0$ such that $\dot{V}_{EE}$ is negative definite on the set $\mathcal{D}_\epsilon = \{(x,y,m) \in \mathbb{R}^3_+ \,:\, 0 < x < x^* + \epsilon,\ y > 0,\ m > 0\}$. The global asymptotic stability of the EE follows from the fact that $\mathcal{D}_\epsilon$ is an absorbing set for system (1.1). □

3. The general case: n strains with k classes of parasitized erythrocytes. We define the following system with k classes and n parasite strains:

$$
\left\{
\begin{array}{l}
\dot{x} = f(x) - \mu_x x - \; x \displaystyle\sum_{i=1}^{n} \beta_i\, m_i = \varphi(x) - \; x \sum_{i=1}^{n} \beta_i\; m_i \\
\text{and for } i = 1, \ldots, n, \\
\dot{y}_{1,i} = \beta_i x\, m_i - \alpha_{1i}\, y_{1,i}, \\
\dot{y}_{2,i} = \gamma_{1,i}\, y_{1,i} - \alpha_{2,i}\, y_{2,i}, \\
\cdots \\
\dot{y}_{k,i} = \gamma_{k-1,i}\, y_{k-1,i} - \alpha_{k,i}\, y_{k,i}, \\
\dot{g}_i = \delta_i\, y_{k,i} - \mu_{g_i}\, g_i, \\
\dot{m}_i = r_i\, \gamma_{k,i}\, y_{k,i} - \mu_{m_i}\, m_i - u\, \beta_i\, x\, m_i.
\end{array}
\right. \tag{3.1}
$$

As in preceding sections we rewrite the system as

$$
\left\{
\begin{array}{l}
\dot{x} = \varphi(x) - \; x \displaystyle\sum_{i=1}^{n} \beta_i \,\langle\, z_i \mid e_{i,\omega} \,\rangle \\
\text{and for } i = 1, \ldots, n, \\
\dot{z}_i = x\, \beta_i \,\langle\, z_i \mid e_{i,\omega} \,\rangle\, e_{i,1} + A_i\, z_i - u\, x\, \beta_i \,\langle\, z_i \mid e_{i,\omega} \,\rangle\, e_{i,\omega},
\end{array}
\right. \tag{3.2}
$$

where the matrix A_i is the analogous of the matrix A_0 defined in section 2.2, but corresponding to the genotype i, and the vectors $e_{i,1}$ and $e_{i,\omega}$ are defined accordingly. We drop the index 0 in A for readability.

THEOREM 3.1. *We consider the system* (3.1) *with the hypotheses* (2.3) *satisfied. We define the basic reproduction ratio* $\mathcal{R}_0$ *of the system* (3.1) *by*

$$\mathcal{R}_0^i = \frac{r_i \beta_i x^*}{\mu_{m_i} \; + u\, \beta_i\, x^*} \, \frac{\gamma_{1,i} \cdots \gamma_{k,i}}{\alpha_{1,i} \cdots \alpha_{k,i}}$$

and

$$\mathcal{R}_0 = \max_{i=1,\ldots,n} \mathcal{R}_0^i.$$

1. *The system* (3.1) *is GAS on* $\mathbb{R}_+$ *at the DFE* $(x^*, 0, \ldots, 0)$ *if and only if* $\mathcal{R}_0 \le 1$.

2. *If* $\mathcal{R}_0 > 1$, *then the DFE is unstable. If* $R_0^i > 1$, *there exists an EE in the nonnegative orthant corresponding to the genotype* i, *the value for the other indexes*

$j \neq i$ are $y_j = m_j = 0$, and

$$\text{(3.3)} \qquad \begin{cases} \bar{x}_i = \dfrac{\mu_{m_i}}{\beta_i \left[r_i \dfrac{\gamma_{1,i} \cdots \gamma_{k,i}}{\alpha_{1,i} \cdots \alpha_{k,i}} - u \right]}, \\ \bar{z}_i = \varphi(\bar{x}_i)\ (-A_i)^{-1} (e_{i,1} - u\, e_{i,\omega}), \\ \bar{g}_i = \dfrac{\delta_i}{\mu_{g_i}} \bar{z}_{i,k}, \end{cases}$$

where we denote by $\bar{z}_{i,k}$ the kth *component of $\bar{z}_i$.*

3. *We assume $\mathcal{R}_0 > 1$. We define $\mathcal{T}_0^i$ as in Definition* 2.2. *We assume that the generic conditions $\mathcal{T}_0^i \neq \mathcal{T}_0^j$ are satisfied for $i \neq j$. We suppose that the genotypes have been indexed such that*

$$\mathcal{T}_0^1 > \mathcal{T}_0^2 \geq \cdots \geq \mathcal{T}_0^n.$$

Then the EE corresponding to $\bar{x}_1$ is asymptotically stable and the EEs corresponding to $\bar{x}_j$ for $j \neq 1$ (for those which are in the nonnegative orthant) are unstable.

4. *We assume that the preceding hypothesis $\mathcal{T}_0^1 > \mathcal{T}_0^j$ is satisfied with $\mathcal{R}_0 > 1$. We denote it by $\alpha^* = -\max_{x \in [0, x^*]} (\varphi'(x))$. Then if*

$$u\, \beta_1\, \varphi(\bar{x}_1) \leq \mu_{m_1}\, \alpha^*,$$

the equilibrium $(\bar{x}_1, \bar{y}_1, \bar{m}_1, \bar{g}_1, 0, \ldots, 0)$ is GAS on the orthant minus the x-axis and the faces of the orthant defined by $y_1 = m_1 = g_1 = 0$. In other words the most virulent strain is the winner and the other strains go extinct.

Proof. As in Theorem 2.1 there exists a forward invariant compact absorbing set in the nonnegative orthant for the system (3.1), and hence all the forward trajectories are bounded. The variables g_i do not affect the dynamical evolution of the variables $x,\ y_{i,j},\ m_i$, and so we can consider the system without the production of gametocytes. We use the Liapunov function

$$V_{DFE}(z) = \sum_{i=1}^{n} V_{DFE}(z_i) = \sum_{i=1}^{n} \beta_i\, x^* \langle\, e_{i,\omega} \mid (-A_i^{-1}) z_i \,\rangle.$$

Using the system written as (3.2) and the computation (2.11) we easily obtain

$$\dot{V}_{DFE} = \sum_{i=1}^{n} \beta_i \langle\, e_{i,\omega} \mid z_i \,\rangle \left(\mathcal{T}_0^i\, x - x^* \right).$$

Now we define the Liapunov function on the nonnegative orthant minus the hyperplane face $x = 0$

$$V(x, z) = (x - x^*\, \ln x) - x^*(1 - \ln x^*) + \sum_{i=1}^{n} V_{DFE}(z_i)$$

which gives

$$\begin{aligned} \dot{V} &= \frac{x - x^*}{x}\, \varphi(x) + \sum_{i=1}^{n} x^* \beta_i \langle\, z_i \mid e_{i,\omega} \,\rangle - \sum_{i=1}^{n} x \beta_i \langle\, z_i \mid e_{i,\omega} \,\rangle \\ &\quad + \sum_{i=1}^{n} \beta_i \langle\, e_{i,\omega} \mid z_i \,\rangle \left(\mathcal{T}_0^i\, x - x^* \right) \\ &= \frac{x - x^*}{x}\, \varphi(x) + \sum_{i=1}^{n} \beta_i \langle\, e_{i,\omega} \mid z_i \,\rangle\, x \left(\mathcal{T}_0^i\ - 1 \right). \end{aligned}$$

Since $\mathcal{R}_0^i \leq 1$ for all index i, we have $\mathcal{T}_0^i \leq 1$, and hence $\dot{V} \leq 0$. The conclusion follows by Lasalle's invariance principle and consideration of the boundary of the positive orthant.

Now we assume $\mathcal{R}_0 > 1$. The instability of the DFE follows from the properties of $\mathcal{R}_0$ [15]. We assume that the genotypes are indexed such that their corresponding threshold are in decreasing order $\mathcal{T}_0^1 > \mathcal{T}_0^2 \geq \cdots \geq \mathcal{T}_0^n$.

We will define a Liapunov function on the nonnegative orthant minus the manifold defined by the equations $x = y_1 = m_1 = 0$. For this we need to recall the definition of the function $V_{EE}(x, y_1, m_1)$ defined in (2.14):

$$V_{EE}(x, y, m) = a(x - \bar{x} \ln x) + \sum_{i=1}^{k} b_{1,i} \left(y_{1,i} - \bar{y}_{1,i} \ln y_{1,i}\right) + b_{1,k+1} \left(m_1 - \bar{m}_1 \ln m_1\right).$$

The coefficients $(a, b_{1,i})$ are positive and defined from A_1 as in the proof of Theorem 2.1 from section 2.2. We also use the function V_{EE} defined in (2.10) to consider

$$V(x, z) = \mathcal{T}_0^1 V_{EE}(x, z_1) + a \sum_{i=2}^{n} V_{DFE}(z_i)$$

or equivalently

$$V(x, z) = \mathcal{T}_0^1 V_{EE}(x, z_1) + a \sum_{i=2}^{n} \beta_i x^* \langle e_{i,\omega} \mid (-A_i^{-1}) z_i \rangle.$$

Using the relation (2.19) and (2.11), we can compute the derivative of V along the trajectories of (3.2):

$$\dot{V} = \mathcal{T}_0^1 \Phi(x, z_1) + a \mathcal{T}_0^1 \sum_{i=2}^{n} \beta_i \bar{x}_1 \langle e_{i\omega} \mid z_i \rangle - a \mathcal{T}_0^1 \sum_{i=2}^{n} \beta_i x \langle e_{i\omega} \mid z_i \rangle + a \sum_{i=2}^{n} \beta_i \langle z_i \mid e_{i,\omega} \rangle \left(\mathcal{T}_0^i x - x^*\right).$$

Using $\mathcal{T}_0^1 \bar{x}_1 = x^*$ from the Definition 2.2 for the threshold we get

$$\dot{V} = \mathcal{T}_0^1 \Phi(x, z_1) + a \sum_{i=2}^{n} \beta_i \langle z_i \mid e_{i,\omega} \rangle x \left(\mathcal{T}_0^i - \mathcal{T}_0^1\right) \leq 0.$$

By Liapunov theorem this ends the proof for the stability. The global asymptotic stability is obtained by a straightforward use of LaSalle's invariance principle, which ends the proof of Theorem 3.1. □

Remark 4. In the nongeneric case it can be shown, with the help of the Liapunov functions used in the theorem, that there exists a continuum of stable EE. We omit the proof.

In the generic case, the dynamics of the system are completely determined. The nonnegative orthant is stratified in the union of stable manifolds corresponding to the different equilibria. Only the equilibrium corresponding to the winning strain has a basin of attraction with a nonempty interior.

Remark 5. We have proved that the most virulent strain, that is, the strain which maximizes its respective threshold $\mathcal{T}_0^i$, eliminates the other. We obtain the

same kind of result as in [7], where the authors consider a SIR model with n strains of parasite. They consider that infection by one parasite strain excludes superinfection by other strains (this is also our case) and induces permanent immunity against all strains in case of recovery. They also guarantee limited population by considering a recruitment depending on the density in a monotone decreasing way. They find that the strain which maximizes the basic reproduction ratio eliminates the others. In the case considered by the authors, actually, using our notation, $\mathcal{R}_0 = \frac{x^*}{\bar{x}}$. In fact in this model $\mathcal{T}_0$ and $\mathcal{R}_0$ coincide. This is also the case in our model when $u = 0$. Hence our result compares with the result of [7]. However in the case $u \neq 0$ this is $\mathcal{T}_0^i$, and not $\mathcal{R}_0^i$, which distinguishes the fate of the strain. Our result is then different from [7], where this role is devoted to $\mathcal{R}_0$. The same kind of remarks apply to [10] and [11].

Remark 6. In our model the chains are of equal length for each strain. If the chains are of unequal length, the proof is unchanged. We use equal length for notational convenience. A reason to have unequal length could be to model different behavior for two different strains of the parasite.

4. Conclusion. In this article we have given a parasitic within-host model and have provided a stability analysis of this model.

This model incorporates a number k of compartments for the parasitized target cells and considers n strains for the parasite. The rationale for including multicompartments can be multiple. One reason is to take into account biological reasons, e.g., consideration of morphological or age classes. The second is for behavioral modeling reasons, e.g., to model delays described by gamma distribution functions.

This model has been conceived from malaria infection, since it is well grounded that malaria is a multistrain infection. However other parasitic infections can be considered by this model.

We prove that if the basic reproduction number satisfies $\mathcal{R}_0 \leq 1$, then the DFE is GAS; i.e., the parasite is cleared from the host. Our stability result when $\mathcal{R}_0 > 1$ can be summarized as a competitive exclusion principle. To each i-strain we associate an individual threshold condition $\mathcal{T}_0^i$ as in Definition 2.2. If $\mathcal{R}_0 > 1$, if one strain has its individual threshold strictly larger than the thresholds of the other strains and if a mild sufficient condition is satisfied (for a constant recruitment, i.e., $f(x) = \Lambda$, this condition is simply $u\beta\Lambda \leq \frac{r}{r-u}\,\mu_x\mu_m$), then there exists a GAS equilibrium on the positive orthant. This equilibrium corresponds to the extinction of all strains, except the strain with the largest threshold. This winning strain maximizes the threshold and not its individual basic reproduction number, which is different from previous analogous results of the literature.

A SPHERICAL PARTICLE MOVING SLOWLY IN A FLUID WITH A RADIALLY VARYING VISCOSITY*

SHIMON HABER†

Abstract. The Stokesian flow field induced by a spherical particle that undergoes a slow rotational and translational motion in an unbounded quiescent fluid with radially varying viscosity is investigated. For a rotating particle, it is demonstrated that only the near viscosity field contributes effectively to the hydrodynamic torque exerted on the particle. A powerful screening effect exists in which the contribution of the distant viscosity field is weighted with the inverse of the distance from the particle to the fourth power. Two specific cases are investigated in which the viscosity field varies either exponentially or periodically. The latter is of particular interest, since it may serve to model the torque exerted on a particle rotating in a suspension. It is shown that a small test particle rotating in a suspension consisting of larger particles is almost unaffected by the large particles and mainly "senses" the fluid viscosity, whereas a large test particle "senses" the suspension viscosity. For a translating particle, a general expression is obtained for the induced velocity, pressure, and drag force exerted on the particle. An approximate result is obtained for the case in which the viscosity field varies slowly with the distance from the particle. An exact solution is obtained for a case in which the viscosity field varies algebraically with the distance from the particle center. An explicit numerical scheme is also suggested, which may assist in obtaining the drag force exerted on a particle translating in a flow field with an arbitrary radially varying viscosity distribution. Based on this numerical scheme and on the approximate solution obtained for a slowly varying viscosity, the drag force exerted on a particle translating inside a fluid with periodically varying viscosity is calculated. We hypothesize that such a periodic distribution can be viewed as a suspension under low Péclet number conditions. Based on this assumption, we obtain that if a test particle is much smaller than the suspended particles, the initial drag force exerted on the test particle is insensitive to the composition of the suspended particles or droplets, and senses the viscosity of only the continuous liquid, provided that the test particle is far from the suspended particles. However, up to first order in suspension concentration, the apparent viscosity of a dilute suspension is indifferent to whether the test particle is forced to move with a constant velocity or is subjected to a constant external force, provided that the test particle is arbitrarily located between the suspended particles.

Key words. Stokes flows, variable viscosity, particle translation, particle rotation, suspensions

1. Introduction.

The fluid-dynamical problem addressed in this paper is motivated by the search for insight into the transport of particles in suspensions or in fluids that may experience strong temperature gradients. Though the backbone of the paper consists of an analytical investigation of a flow model for a spherical particle motion in a fluid with variable viscosity, the introduction also provides a brief elucidation of the foregoing physical problems.

Suspension hydrodynamics was the focus of extensive past investigation. Past models attempted to explain such effects as hindered settling velocity of a suspension under gravity (e.g., Batchelor (1972)), increase in the suspension effective viscosity (e.g., the Einstein viscosity of dilute suspensions), and the effect of shear induced diffusion (e.g., Leighton and Acrivos (1987a,b) and Gadala-Maria and Acrivos (1980))

in which particles in a suspension cross streamlines, a phenomenon that a single freely suspended particle in shear flow does not experience (Happel and Brenner (1983)).

It is well accepted that the fundamental mechanism governing all of the foregoing results stems from multiparticle hydrodynamic interactions. However, an analytical solution of a multiparticle system is not tractable, and basically three important approaches were used to circumvent this difficulty. The first, numerical, approach termed Stokesian dynamics was applied by Brady (1988) and by others (e.g., Hassonjee, Ganatos, and Pfeffer (1988), Brenner et al. (1990), Hassonjee, Pfeffer, and Ganatos (1992), Chang and Powell (1993), Nott and Brady (1994)), in which many suspended particles were tracked simultaneously using either collocation or boundary integral methods.

A second approach was to apply simplified models for the complex microstructure of suspensions. For instance, the microscopic conformation of a suspension was viewed as a spatially periodic array. In essence, a unit cell approach was addressed that requires the hydrodynamic solution of a single particle in a bounded field. Yet another simplified approach was to solve the flow field generated by a generic two/three body subsystem. In many cases, the foregoing models were sufficiently simple to be handled analytically and to encapsulate the main effects stemming from hydrodynamic interactions between the particles. For example, Zuzovsky, Adler, and Brenner (1983) and Adler, Zuzovsky, and Brenner (1985) used a spatially periodic model to obtain the rheological properties of a suspension. Batchelor (1972) used two-body interactions to calculate the sedimentation velocity of a dilute suspension of rigid spherical particles under gravity; Batchelor and Green (1972b) used two-body interaction to calculate the rheology of a dilute suspension; Haber, Brenner, and Shapira (1990) used two-body interactions to derive the dispersion coefficient of a dilute suspension containing flexible dumbbells; and Wang, Mauri, and Acrivos (1998) utilized a three-body interaction to calculate the transverse shear induced gradient diffusion of dilute suspensions, etc.

A third phenomenological approach was used by Leighton and Acrivos (1987b), Philips et al. (1992), and others to explain shear induced migration. Thus, for instance, a self diffusion shear induced coefficient was defined that was based on scaling considerations and the available experimental data, circumventing the microscopic details of the problem and providing a direct macroscopic view. It proved quite successful for the case of a narrow gap Couette device (Acrivos, Mauri, and Fan (1993)).

The mathematical problem addressed in this paper deals with the flow field generated by a single particle rotating and translating in an unbounded single phase fluid with variable viscosity. We suggest that the solution of the foregoing problem may possibly be utilized to explore the mechanisms that govern the motion of a single test particle immersed in suspensions of various concentrations. Such an interpretation of the results stems from the observation that a suspension (or an emulsion) of particles (or droplets) is a two phase fluid with two different viscosities, which may be approximated by a single phase fluid with a *continuous* variable viscosity field. One can further assume that the suspension is at equilibrium where the concentration distribution ϕ_∞ satisfies the equation (e.g., Brenner (1979))

$$\nabla \cdot [De^{-E}\nabla(e^{E}\phi_\infty)] = 0. \tag{1a}$$

Here E is the energy potential function, and D stands for diffusion coefficient of the particles comprising the suspension. Henceforth, we assume that E is radially symmetric (i.e., the external force is centrally symmetric), and thereby the solution of (1a) yields a radially symmetric function ϕ_∞.

Introduction of a moving "test particle" into the suspension induces a velocity *disturbance* $\mathbf{v}'$, which in turn may cause a concentration *disturbance* ϕ' that destroys the assumed radial symmetry. A first order approximation for the differential equation governing this concentration disturbance is

$$\frac{\partial \phi'}{\partial t} + \mathbf{v}' \cdot \nabla \phi_\infty = \nabla \cdot [De^{-E} \nabla (e^E \phi')], \tag{1b}$$

where $\mathbf{v}'$ scales with the test particle velocity. Thus, the significance of the symmetry-destroying convective term vis-à-vis the restoring diffusion term is determined by the Péclet number based on the test particle velocity and diameter and the diffusion coefficient of the suspended particles. If this Péclet number is much smaller than unity, the diffusion mechanism will rapidly restore the concentration to its initial equilibrium concentration. Consequently, the initial equilibrium concentration distribution will practically prevail for all times. As shall be shown later, the small Péclet number assumption is not required for the case of a rotating sphere in a flow field with a radially symmetric viscosity (the convective term vanishes identically). For the case of a translating sphere, however, this assumption must be made so that local equilibrium is restored rapidly and the solution is meaningful for all times.

The paper is divided into the following main sections. In section 2 a simple closed analytical solution is obtained for the flow field induced by a sphere rotating in an unbounded fluid with radially varying viscosity. In section 3 the flow field generated by a sphere translating in an unbounded flow field is addressed.

In section 4 several examples are investigated exploiting the general expressions obtained in sections 2 and 3. For a rotating sphere, an exact solution is obtained for the case in which the viscosity field increases or decreases exponentially with the distance from the test particle. For a translating sphere, three cases are addressed. In case A, a weak radial variation of the viscosity field is assumed, and an approximate analytical solution is derived. In case B, the viscosity field increases or decreases algebraically with the distance from the test particle, and an exact solution is obtained. In case C, based on a semianalytical approach, an efficient numerical algorithm is suggested, by which the drag force can be obtained for general viscosity distributions.

In section 5 a solution is obtained for a test particle rotating and translating in a radially periodic viscosity field. The results are interpreted vis-à-vis particle motion in a homogeneous suspension. In section 6 a summary of the results is provided.

2. A sphere rotating in a field with radially varying viscosity.

2.1. Statement of problem. A spherical rigid particle of radius a rotates slowly with angular velocity ω inside an unbounded incompressible flow field with initial radially varying viscosity

$$\mu = \mu_0 \lambda(r), \tag{2}$$

where r is the radial distance measured from the center of the particle and μ_0 is a characteristic viscosity of the fluid. The Reynolds number based on a, ω, μ_0 and the fluid density is assumed to be smaller than unity, so that the quasi-steady creeping flow equations apply (Gurbebeck and Sprossig (1993)), namely,

$$\mu \nabla^2 \mathbf{v} + 2\nabla \mu \cdot \mathbf{S} = \nabla p, \qquad \nabla \cdot \mathbf{v} = 0, \tag{3a}$$

where $\mathbf{v}$ is the fluid velocity, p is the pressure, and $\mathbf{S}$ is the rate of strain dyadic,

$$\mathbf{S} = 0.5[\nabla \mathbf{v} + (\nabla \mathbf{v})^T]. \tag{3b}$$

The velocity field satisfies the no-slip condition over the sphere boundary, namely,

$$\mathbf{v} = \boldsymbol{\omega} \times \mathbf{r} \quad \text{at} \quad |\mathbf{r}| = a, \tag{4}$$

and decays to zero at infinity. Here, $\mathbf{r}$ is the radius vector measured from the sphere center.

If we assume that the viscosity depends on the volumetric concentration $\mu = \mu(\phi)$, the viscosity field at equilibrium, $\mu_\infty \equiv \mu(\phi_\infty) \equiv \mu_0 \lambda(r)$, is also radially symmetric. However, introduction of the test sphere may introduce a viscosity *disturbance* μ' that undergoes convection and diffusion and is governed by the following first order approximation of the convection-diffusion differential equation:

$$\frac{\partial \mu'}{\partial t} + \mathbf{v} \cdot \nabla \mu_\infty = \left[\frac{d\mu}{d\phi}\right]_{\phi_\infty} \nabla \cdot \left[De^{-E} \nabla \left(e^E \left[\frac{d\phi}{d\mu}\right]_{\phi_\infty} \mu' \right) \right] \tag{5a}$$

juxtaposed with the initial condition at $t = 0$,

$$\mu' = 0. \tag{5b}$$

2.2. Method of solution. Generally, the velocity, pressure, and viscosity fields are time-dependent, and (3) to (5) must be solved simultaneously. Equation (5) is nonlinear and couples the velocity and viscosity fields. However, it will be shown that the solution for the viscosity is time-independent, and the initial viscosity field remains unchanged for all times. In such a case, the problem is linear, and the differential equation (3) and boundary condition (4) imply that the velocity and pressure fields must linearly depend upon $\boldsymbol{\omega}$. Thus, their general form in Cartesian tensor notation is

$$v_i = V_{ij}\omega_j, \qquad p = \mu_0 P_j \omega_j + p_\infty, \tag{6}$$

where V_{ij} and P_j are the velocity second rank tensor and the pressure vector, respectively. Substituting (6) into (3), (4) and using (2) yields

$$\lambda \frac{\partial^2 V_{ij}}{\partial x_l \partial x_l} + \frac{\partial \lambda}{\partial x_l}\left(\frac{\partial V_{ij}}{\partial x_l} + \frac{\partial V_{lj}}{\partial x_i}\right) = \frac{\partial P_j}{\partial x_i}, \quad \frac{\partial V_{ij}}{\partial x_i} = 0, \tag{7}$$

$$V_{ij} = \varepsilon_{ijk} x_k \quad \text{at} \quad |\mathbf{r}| = a, \tag{8}$$

where V_{ij} vanishes at infinity and ε_{ijk} is the third rank permutation pseudotensor.

It is clear from (7) and (8) that V_{ij} and P_j must be pseudotensors that depend only on the permutation tensor ε_{ijk}, the particle radius a, the radius vector x_i, and its magnitude r. The latter is due to the isotropy of the sphere and the radial symmetry of the viscosity field. Equations (7) and (8) also prove that neither V_{ij} nor P_j depends on the angular velocity $\boldsymbol{\omega}$.

In this case, the velocity tensor must possess the tensorial form,

$$V_{ij} = \varepsilon_{ijk} x_k f(r), \tag{9a}$$

and the pressure vector field P_i must vanish (the only possible pseudovector that combines ε_{ijk} and x_j is $\varepsilon_{ijk} x_j x_k$, which is zero identically):

$$P_i = 0. \tag{9b}$$

Here, $f(r)$ is a scalar function of r (and a) to be determined.

Introducing the flow field $\mathbf{v}$ (see (9a)) into (5) yields that the second term in the LHS of (5) vanishes identically, and consequently the viscosity disturbance vanishes identically. Thus, our basic assumption is validated, and the viscosity field remains unaltered during particle rotation.

Substituting (9) into (7) yields an ordinary differential equation for f,

$$\lambda\left(\frac{d^2f}{dr^2}+\frac{4}{r}\frac{df}{dr}\right)+\frac{d\lambda}{dr}\frac{df}{dr}=0. \tag{10}$$

From (8) and the condition at infinity we obtain that

$$f(a)=1 \quad \text{and} \quad f(\infty)=0. \tag{11}$$

The general solution of (10) subjected to boundary conditions (11) is

$$f(r)=\frac{\int_r^\infty \frac{dr}{\lambda(r)r^4}}{\int_a^\infty \frac{dr}{\lambda(r)r^4}}. \tag{12}$$

Obviously, for (12) to represent a valid solution, (9a) requires that the rf product vanish at infinity. Consequently, a formal solution exists even if the viscosity λ vanishes at infinity (approaches asymptotically to zero no faster than $1/r^3$). Clearly, this remarkable result is quite hypothetical, since in this case the Reynolds number at infinity would grow without bound, and the creeping flow equations are no longer valid.

If λ is fixed, the well-known creeping flow solution for a rotating sphere in a field with uniform viscosity is recovered. Equation (12) also manifests that the sphere "senses" the viscosity field near the sphere boundary, whereas the far field contribution is insignificant due to the r^4 factor in the integrand denominator.

If a suspension of small particles can be perceived as a single phase fluid with variable viscosity (say, λ is infinite inside the particles and uniform inside the suspending fluid), then (12) offers an approximate solution for a rotating sphere in a suspension. It clearly manifests the "screening" effect of the adjacent particles and that the contribution of particles far from the rotating sphere is negligible. A more detailed analysis of this example will be provided in section 5.

2.3. The torque exerted on the particle. The torque about the sphere center that the fluid exerts on a rotating particle is

$$(T_o)_i=\varepsilon_{ijk}\int_S x_j\sigma_{kl}n_l dS, \tag{13}$$

where "O" denotes the sphere center, n_l is the unit vector normal to the sphere boundary S, and σ_{kl} stands for the symmetric hydrodynamic stress,

$$\sigma_{kl}=\mu_0\omega_m\left[-P_m\delta_{kl}+\lambda\left(\frac{\partial V_{km}}{\partial x_l}+\frac{\partial V_{lm}}{\partial x_k}\right)\right], \tag{14}$$

where δ_{kl} is the second rank idem-tensor. Substitution of (9) and (12) into (14) and (13) and utilization of the tensorial identities

$$\int_S x_ix_jdS=\frac{4\pi a^4}{3}\delta_{ij}, \quad \int_S x_ix_jx_kx_ldS=\frac{4\pi a^6}{15}(\delta_{ij}\delta_{kl}+\delta_{ik}\delta_{lj}+\delta_{il}\delta_{kj}) \tag{15}$$

yields the following simple formula:

$$(T_o)_i = -8\pi\mu_0 a^3 \omega_i C_T, \tag{16}$$

where the dimensionless correction factor C_T is

$$C_T = \frac{1}{3}\left(a^3 \int_a^\infty \frac{dr}{\lambda(r) r^4}\right)^{-1}. \tag{17}$$

Thus, as expected, the torque is colinear with ω and resists the rotation of the particle. For a fluid with uniform viscosity, the correction factor $C_T = 1$, and the well-known Kirchoff law for a slowly rotating sphere is recovered. Equation (17) also manifests that the torque is significantly affected by the viscosity field close to the rotating sphere and that the effect of the far-field viscosity is normally negligible.

It is also convenient to view $\mu_0 C_T$ as the mean viscosity of the flow field affecting a rotating sphere. One would expect a result that is related to a weighted mean of the viscosity reciprocal. (E.g., the mean viscosity $\bar{\mu}$ of two phase fluids with viscosities μ_A and μ_B and respective volumetric concentrations ϕ_A and ϕ_B is commonly calculated by the formula $(\bar{\mu})^{-1} = \phi_A(\mu_A)^{-1} + \phi_B(\mu_B)^{-1}$.) However, the "screening-factor" of r^4 in (17) is not obvious.

3. A sphere translating in a field with radially varying viscosity (for $P_e \ll 1$).

3.1. Statement of problem. A sphere of radius a translates slowly with velocity $\mathbf{U}$ inside an unbounded incompressible flow field $\mathbf{v}$ that possesses an initial radially varying viscosity $\mu = \mu_0\lambda(r)$. The Reynolds number based on a, U, μ_0, and the fluid density is assumed to be smaller than unity, so that the quasi-steady creeping flow equations (3) can be applied. The velocity field satisfies the no-slip condition over the sphere boundary, namely,

$$\mathbf{v} = \mathbf{U} \quad \text{at} \quad |\mathbf{r}| = a, \tag{18}$$

and decays to zero at infinity.

3.2. Method of solution. The general quasi-steady solution for the velocity and pressure fields strongly depends on the time-dependent viscosity field. As time evolves, the radially symmetric structure of the viscosity field is no longer preserved. Since (5) is nonlinear and couples the velocity and viscosity fields, a general *analytic* time-dependent solution is probably hopeless. Notwithstanding, as we have shown in the introduction, if the Péclet number $P_e = Ua/D$ is much smaller than unity, the second convection term in (5) can be neglected, and the system rapidly regains its initial equilibrium radial distribution. Henceforth, we shall limit our discussion to Péclet numbers much smaller than unity, so that the initial radial viscosity distribution $\mu_\infty(r)$ remains practically unaltered.

Boundary condition (18) implies that the velocity and pressure fields must linearly depend upon $\mathbf{U}$. Thus, the general form of the velocity and pressure field (in Cartesian tensor notation) is

$$v_i = V_{ij}U_j, \qquad p = \frac{\mu_0 P_j U_j}{a} + p_\infty, \tag{19}$$

where V_{ij} and P_j are the dimensionless velocity second rank tensor and the pressure vector, respectively. It is convenient to scale distances with a and define the

dimensionless Cartesian coordinates

$$y_i = \frac{x_i}{a}, \qquad y = \frac{r}{a} = \frac{(x_i x_i)^{1/2}}{a}. \tag{20}$$

Substituting (19) and (20) into (3) and using (2) yields the differential equations

$$\lambda \frac{\partial^2 V_{ij}}{\partial y_l \partial y_l} + \frac{\partial \lambda}{\partial y_l}\left(\frac{\partial V_{ij}}{\partial y_l} + \frac{\partial V_{lj}}{\partial y_i}\right) = \frac{\partial P_j}{\partial y_i}, \qquad \frac{\partial V_{ij}}{\partial y_i} = 0, \tag{21a}$$

which are subjected to the boundary conditions

$$V_{ij} = \delta_{ij} \quad \text{at} \quad |\mathbf{y}| = 1, \tag{21b}$$

and the condition that V_{ij}, P_j vanish at infinity.

From (21), V_{ij} and P_j must be tensors that depend only upon the second rank tensor δ_{ij} and the dimensionless radius vector y. The latter is due to the isotropy of the sphere and the radial symmetry of the viscosity field. Equations (21a, b) also prove that neither V_{ij} nor P_j depends on the particle velocity U.

Consequently, the velocity and pressure tensors must possess the tensorial form

$$V_{ij} = y_i y_j g(y) + \delta_{ij} h(y), \qquad P_j = y_j q(y), \tag{22}$$

where $g(y)$, $h(y)$, and $q(y)$ are scalar functions of y to be determined.

Substitution of (22) into (21) yields three coupled ordinary differential equations for g, h, and q,

$$-q + \lambda\left(2g + \frac{2h_y}{y} + h_{yy}\right) + \lambda_y(yg + h_y) = 0, \tag{23a}$$

$$-\frac{q_y}{y} + \lambda\left(\frac{6g_y}{y} + g_{yy}\right) + \lambda_y\left(\frac{3g}{y} + 2g_y + \frac{h_y}{y^2}\right) = 0, \tag{23b}$$

$$4yg + y^2 g_y + h_y = 0, \tag{23c}$$

and boundary conditions

$$\begin{aligned} &g(1) = 0, && h(1) = 1, \\ &\left[y^2 g\right]_{y\to\infty} \to 0, && [h]_{y\to\infty} \to 0, \quad [yq]_{y\to\infty} \to 0, \end{aligned} \tag{24}$$

where the subscript y denotes differentiation with respect to y.

Elimination of h and q from (23) yields a third order equation in g:

$$g_{yyy} + \left(\frac{11}{y} + 2\frac{\lambda_y}{\lambda}\right) g_{yy} + \left(\frac{24}{y^2} + \frac{14}{y}\frac{\lambda_y}{\lambda} + \frac{\lambda_{yy}}{\lambda}\right) g_y + \left(\frac{12}{y^2}\frac{\lambda_y}{\lambda} + \frac{3}{y}\frac{\lambda_{yy}}{\lambda}\right) g = 0. \tag{25}$$

We define a new independent variable z,

$$z = \ln(y), \tag{26}$$

to transform (25) into

$$g_{zzz} + \left(8 + 2\frac{\lambda_z}{\lambda}\right) g_{zz} + \left(15 + 11\frac{\lambda_z}{\lambda} + \frac{\lambda_{zz}}{\lambda}\right) g_z + \left(9\frac{\lambda_z}{\lambda} + 3\frac{\lambda_{zz}}{\lambda}\right) g = 0, \tag{27}$$

where the subscript z denotes differentiation with respect to z.

A remarkable, exact first integral of (27) exists (notice that (36) can serve as a simple clue to its existence):

$$g_{zz} + \left(5 + \frac{\lambda_z}{\lambda}\right) g_z + 3\frac{\lambda_z}{\lambda} g = C_D \frac{e^{-3z}}{\lambda}, \tag{28}$$

where C_D is a yet undetermined constant of integration, subsequently shown to relate closely to the drag force exerted on the translating particle. Utilizing a new dependent variable G,

$$G(z) = e^{3z} g(z), \tag{29}$$

equation (28) is transformed into a simplified second order differential equation:

$$G_{zz} - \left(1 - \frac{\lambda_z}{\lambda}\right) G_z - 6G = \frac{C_D}{\lambda}. \tag{30}$$

Notice that the original Stokes equation and (30) possess only first order derivatives of the viscosity field. Hence, a second order derivative appearing in (27) is redundant and is not truly required.

The differential equation (23c) in terms of G is

$$h_z = -e^{-z}(G + G_z). \tag{31}$$

Upon substitution of (26) and (29) into (24), the transformed boundary conditions are

$$\begin{aligned} &G(z=0) = 0, \qquad h(z=0) = 1, \\ &[e^{-z}G]_{z\to\infty} \to 0, \quad [h]_{z\to\infty} \to 0 \quad [e^z q]_{z\to\infty} \to 0. \end{aligned} \tag{32}$$

Thus, a workable solution scheme is as follows: A general solution of (30) for G is obtained first; subsequently, (31) is solved for h so that boundary conditions (32) can be applied; a solution for q is then easily obtained upon direct substitution of the solutions for G and h into (23a).

3.3. The general expression for the drag force exerted on a translating particle. The drag force that the fluid exerts on a translating particle can be obtained from either of the following integrals:

$$F_i = \int_{S_B} \sigma_{il} n_l dS = \int_{S_\infty} \sigma_{il} n_l dS, \tag{33}$$

where S_B stands for the sphere boundary and S_∞ denotes any surface enclosing the particle. The second equality in (33) can easily be proven using the divergence theorem and applying the momentum equation $\partial\sigma_{il}/\partial x_i = 0$. Here, σ_{il} stands for the hydrodynamic stress:

$$\sigma_{il} = \mu_0 U_m \left[-P_m \delta_{il} + \lambda\left(\frac{\partial V_{im}}{\partial x_l} + \frac{\partial V_{lm}}{\partial x_i}\right)\right]. \tag{34}$$

Substitution of (22) into (33) and (34) and utilizing identities (15) yields

$$F_i = -\frac{4\pi}{3}\mu_0 a U_i [y^3 q(y) + 10y^3\lambda(y)g(y) + 2y^4\lambda(y)g_y(y)], \tag{35}$$

where $y > 1$ is an arbitrary radius of a sphere that encompasses the particle and whose center coincides with that of the particle. Substitution of (23a) and (26) into (35) yields

$$\begin{aligned} F_i &= \frac{4\pi}{3}\mu_0 a U_i[\lambda(g_{zz}+5g_z)+\lambda_z(g_z+3g)]e^{3z} \\ &= \frac{4\pi}{3}\mu_0 a U_i C_D. \end{aligned} \tag{36}$$

The last equality stems from (28). Thus, as expected, the drag force exerted on the particle is independent of y (or z) and depends solely upon the single yet undetermined constant of integration C_D.

4. Particular cases for various viscosity distributions. In the following section we focus on several particular cases exploiting the general formulas derived in sections 2 and 3 for the torque and drag force exerted on a rotating or translating sphere in an unbounded flow field with variable viscosity.

4.1. A rotating particle in an exponentially varying viscosity. Assume that λ varies exponentially from $1-\alpha$, near the rotating sphere, to 1 as r approaches infinity; namely,

$$\lambda = 1 - \alpha e^{-\beta(r-a)/a}. \tag{37}$$

Here β is a positive known parameter, and $\alpha < 1$ could be either a positive or a negative parameter. The correction factor C_T is calculated numerically for various values of α and β and is illustrated in Figure 1. For α and β values smaller than unity, (17) can be analytically evaluated, and the following result is obtained:

$$\begin{aligned} C_T^{-1} &= 1 + 3\sum_{n=1}^{\infty}(\alpha e^{\beta})^n E_4(n\beta) \\ &= \frac{1}{1-\alpha} - \frac{\beta\alpha e^{\beta}}{2}\sum_{n=1}^{\infty} n(\alpha e^{\beta})^{n-1}\left[e^{-n\beta}(1-n\beta) - n^2\beta^2 Ei(-n\beta)\right], \end{aligned} \tag{38}$$

where E_i and E_4 are the exponential integral functions,

$$Ei(-x) = -\int_1^{\infty}\frac{e^{-xt}}{t}dt, \qquad E_4(x) = \int_1^{\infty}\frac{e^{-xt}}{t^4}dt. \tag{39}$$

The RHS of (38) proves that, to leading order in α and β, the rotating sphere senses the viscosity field close to it. This is also verified by numerically calculating C_T (depicted in Figure 1).

4.2. A translating particle. Three different cases are addressed. In case A, a multiple-scale approximate solution of (30) is described for flow fields with weakly varying viscosity fields. In case B, an exact solution of (30) is obtained for flow fields with a rapidly varying viscosity field; namely, the viscosity field grows or decays exponentially in z-space (or algebraically in r-space). In case C we outline an analytical/numerical method for viscosity fields that increase asymptotically at a smaller than exponential rate in z-space.

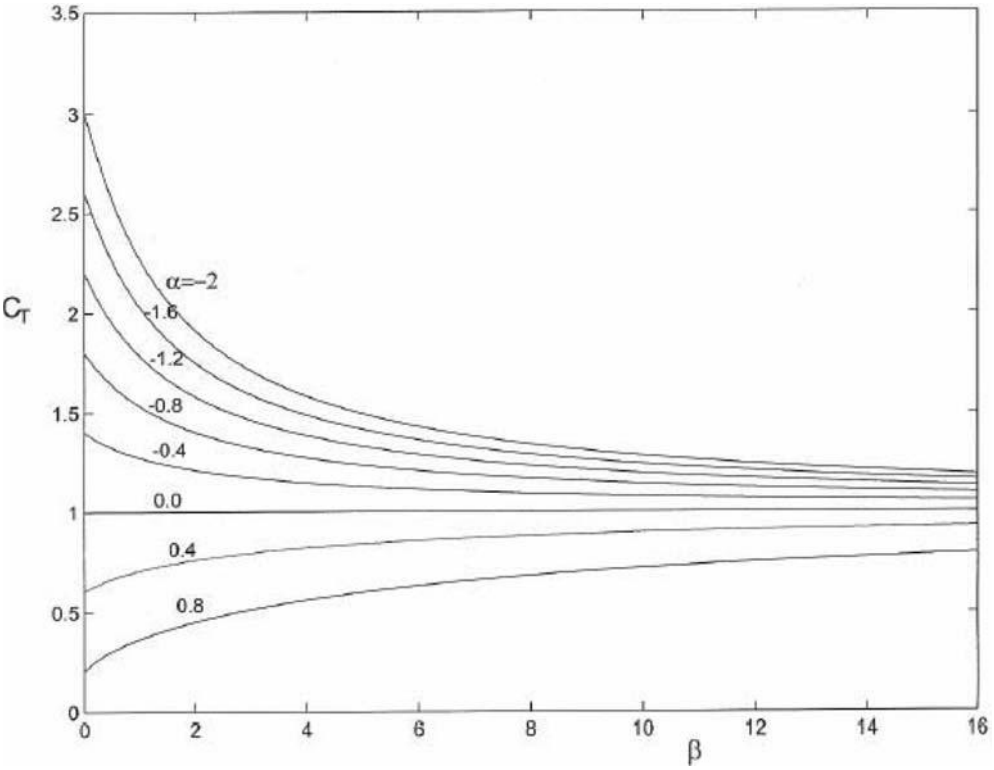

FIG. 1. *The dimensionless torque* $C_T = T_o/(-8\pi\mu_0 a^3\omega)$ *exerted on a spherical particle immersed in an unbounded quiescent fluid with an exponentially varying viscosity* $\mu_\infty = \mu_0[1 - \alpha e^{-\beta(r-a)/a}](\alpha < 1)$.

Case A: A translating particle in a weakly varying viscosity field. In case the viscosity field varies slowly with position, the viscosity field depends upon the "slow" variable:

$$\zeta = \varepsilon z, \tag{40}$$

where $\varepsilon < 1$ is a smallness parameter. Thus,

$$\lambda = \lambda(\zeta), \qquad \lambda_z = \varepsilon\lambda_\zeta. \tag{41}$$

The multiple-scale approximate method (Bender and Orszag (1999)) is applied to solve (30). Substitution of (40) and (41) into (30) and (31) and treating z and ζ as independent variables yields the following partial differential equations for G and h:

$$G_{zz} - G_z - 6G + \varepsilon[2G_{z\zeta} - G_\zeta + (\lambda_\zeta/\lambda)G_z] + \varepsilon^2[G_{\zeta\zeta} + (\lambda_\zeta/\lambda)G_\zeta] = C_D/\lambda, \tag{42a}$$

$$h_z + e^{-z}(G + G_z) + \varepsilon[h_\zeta + e^{-z}G_\zeta] = 0. \tag{42b}$$

The solutions for G, h, and the constant C_D can be approximately represented by a power series in ε:

$$G = G^{(0)} + \varepsilon G^{(1)} + \varepsilon^2 G^{(2)} + \cdots, \tag{43a}$$

$$h = h^{(0)} + \varepsilon h^{(1)} + \varepsilon^2 h^{(2)} + \cdots, \tag{43b}$$

$$C_D = C_D^{(0)} + \varepsilon C_D^{(1)} + \varepsilon^2 C_D^{(2)} + \cdots. \tag{43c}$$

Substituting (43) into (42) and collecting terms of zero, first, and second order in ε yields the following differential equations and boundary conditions for $G^{(i)}$ and $h^{(i)}$ $(i = 0, 1, 2)$:

For the zeroth order:

$$G^{(0)}_{zz} - G^{(0)}_{z} - 6G^{(0)} = C^{(0)}_D/\lambda(\zeta), \tag{44a}$$

$$h^{(0)}_z = -e^{-z}(G^{(0)} + G^{(0)}_z), \tag{44b}$$

$$[G^{(0)}]_{z=0} = 0, \quad [h^{(0)}]_{z=0} = 1, \quad [e^{-z}G^{(0)}]_{z\to\infty} \to 0, \quad [h^{(0)}]_{z\to\infty} \to 0. \tag{44c}$$

For the first order:

$$G^{(1)}_{zz} - G^{(1)}_{z} - 6G^{(1)} = -2G^{(0)}_{z\zeta} + G^{(0)}_{\zeta} - (\lambda_\zeta/\lambda)G^{(0)}_z + C^{(1)}_D/\lambda(\zeta), \tag{45a}$$

$$h^{(1)}_z = -e^{-z}(G^{(1)} + G^{(1)}_z) - h^{(0)}_\zeta - e^{-z}G^{(0)}_\zeta, \tag{45b}$$

$$[G^{(1)}]_{z=0} = 0, \quad [h^{(1)}]_{z=0} = 0, \quad [e^{-z}G^{(1)}]_{z\to\infty} \to 0, \quad [h^{(1)}]_{z\to\infty} \to 0. \tag{45c}$$

For the second order:

$$\begin{aligned} G^{(2)}_{zz} - G^{(2)}_{z} - 6G^{(2)} = {} & -2G^{(1)}_{z\zeta} + G^{(1)}_{\zeta} - (\lambda_\zeta/\lambda)G^{(1)}_z \\ & - G^{(0)}_{\zeta\zeta} - (\lambda_\zeta/\lambda)G^{(0)}_\zeta + C^{(2)}_D/\lambda(\zeta), \end{aligned} \tag{46a}$$

$$h^{(2)}_z = -e^{-z}(G^{(2)} + G^{(2)}_z) - h^{(1)}_\zeta - e^{-z}G^{(1)}_\zeta, \tag{46b}$$

$$[G^{(2)}]_{z=0} = 0, \quad [h^{(2)}]_{z=0} = 0, \quad [e^{-z}G^{(2)}]_{z\to\infty} \to 0, \quad [h^{(2)}]_{z\to\infty} \to 0. \tag{46c}$$

Further, drag force exerted on the particle is given by

$$\mathbf{F} = \frac{4}{3}\pi\mu_0 a\mathbf{U}(C^{(0)}_D + \varepsilon C^{(1)}_D + \varepsilon^2 C^{(2)}_D + \cdots). \tag{47}$$

The zeroth order solution. The general solution of (44a) is

$$G^{(0)}(z,\zeta) = A^{(0)}(\zeta)e^{3z} + B^{(0)}(\zeta)e^{-2z} - \frac{C^{(0)}_D}{6\lambda(\zeta)}, \tag{48}$$

where $A^{(0)}(\zeta)$ and $B^{(0)}(\zeta)$ are yet undetermined functions of ζ. Application of boundary conditions (44c) results in

$$\begin{aligned} & A^{(0)}(\zeta) = 0, \\ & B^{(0)}(\zeta = 0) - \frac{C^{(0)}_D}{6\lambda_S} = 0, \end{aligned} \tag{49}$$

where we define

$$\lambda_S = \lambda(\zeta = 0) = \lambda(r = a). \tag{50}$$

From (44b), (48), and (50), the solution for $h^{(0)}$ is

$$h^{(0)} = -\frac{1}{3}B^{(0)}(\zeta)e^{-3z} - \frac{C_D^{(0)}}{6\lambda(\zeta)}e^{-z}, \tag{51}$$

where from (44c),

$$-\frac{1}{3}B^{(0)}(\zeta=0) - \frac{C_D^{(0)}}{6\lambda_S} = 1. \tag{52}$$

Thus, from (50) and (52),

$$\begin{aligned} C_D^{(0)} &= -\frac{9}{2}\lambda_S, \\ B^{(0)}(\zeta=0) &= -\frac{3}{4}. \end{aligned} \tag{53a, b}$$

Consequently, from (47b) and (53a), the zeroth order approximation for the drag force exerted on a spherical particle translating in a quiescent fluid with a weakly radially varying viscosity is

$$\mathbf{F}^{(0)} = \frac{4}{3}\pi\mu_0 a\mathbf{U}C_D^{(0)} = -6\pi a\mathbf{U}\mu(r=a). \tag{54}$$

Equation (54) is the well-known Stokes law; only here, to a leading order, the particle senses the viscosity field near its surface.

It should be noted that an explicit expression for the function $B^{(0)}(\zeta)$ is not required to determine the zeroth order expression for the drag force. It must, however, be solved to obtain higher order corrections. Common to multiscale analyses, $B^{(0)}(\zeta)$ can be determined by demanding that secular terms in higher order approximations vanish. Upon substitution of (48) and (50) into (45a), the following differential equation for $G^{(1)}$ is obtained:

$$G_{zz}^{(1)} - G_z^{(1)} - 6G^{(1)} = \left(5B_\zeta^{(0)} + 2\frac{\lambda_\zeta}{\lambda}B^{(0)}\right)e^{-2z} + C_D^{(0)}\frac{\lambda_\zeta}{6\lambda^2} + \frac{C_D^{(1)}}{\lambda}. \tag{55}$$

To eliminate secular terms from the solution of $G^{(1)}$ we need that

$$5B_\zeta^{(0)} + 2\frac{\lambda_\zeta}{\lambda}B^{(0)} = 0. \tag{56}$$

A solution of (56) satisfying boundary condition (53b) is

$$B^{(0)} = -\frac{3}{4}\left(\frac{\lambda_S}{\lambda(\zeta)}\right)^{2/5}. \tag{57}$$

Consequently, the zeroth order solutions for $G^{(0)}$ and $h^{(0)}$ are

$$G^{(0)} = -\frac{3}{4}\left(\frac{\lambda_S}{\lambda(\zeta)}\right)^{2/5}e^{-2z} + \frac{3}{4}\frac{\lambda_S}{\lambda(\zeta)}, \tag{58a}$$

$$h^{(0)} = \frac{1}{4}\left(\frac{\lambda_S}{\lambda(\zeta)}\right)^{2/5}e^{-3z} + \frac{3}{4}\frac{\lambda_S}{\lambda(\zeta)}e^{-z}. \tag{58b}$$

The first order correction. A general solution of (55) subjected to (56) is

$$G^{(1)} = A^{(1)}(\zeta)e^{3z} + B^{(1)}(\zeta)e^{-2z} - \frac{C_D^{(0)}}{36}\frac{\lambda_\zeta}{\lambda^2} - \frac{C_D^{(1)}}{6\lambda}, \tag{59}$$

where $A^{(1)}$ and $B^{(1)}$ are yet undetermined functions of ζ. Application of boundary conditions (45c) results in

$$\begin{aligned} &A^{(1)}(\zeta) = 0, \\ &B^{(1)}(\zeta = 0) - \frac{C_D^{(1)}}{6\lambda_S} = -\frac{(\lambda_\zeta)_S}{8\lambda_S}, \end{aligned} \tag{60a, b}$$

where

$$(\lambda_\zeta)_S = \left[\frac{\partial\lambda}{\partial\zeta}\right]_{\zeta=0} = \frac{a}{\varepsilon}\left[\frac{\partial\lambda}{\partial r}\right]_{r=a}. \tag{61}$$

From (45b), (58), and (59), the solution for $h^{(1)}$ is

$$h^{(1)} = \frac{1}{15}\frac{\lambda_\zeta}{\lambda}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}e^{-3z} - \left(\frac{C_D^{(1)}}{6\lambda} + \frac{11}{8}\frac{\lambda_\zeta\lambda_S}{\lambda^2}\right)e^{-z} - \frac{B^{(1)}(\zeta)}{3}e^{-3z}. \tag{62}$$

Hence, from (45c),

$$\frac{B^{(1)}(\zeta = 0)}{3} + \frac{C_D^{(1)}}{6\lambda_S} = -\frac{157}{120}\frac{(\lambda_\zeta)_S}{\lambda_S}. \tag{63}$$

Thus, from (60b) and (63),

$$C_D^{(1)} = -\frac{57}{10}(\lambda_\zeta)_S, \qquad B^{(1)}(\zeta = 0) = -\frac{43}{40}\frac{(\lambda_\zeta)_S}{\lambda_S}. \tag{64a, b}$$

Consequently, from (47b) and (53a), an approximate expression for the drag force exerted on a spherical particle is

$$\begin{aligned} \mathbf{F} &= \frac{4}{3}\pi\mu_0 a\mathbf{U}(C_D^{(0)} + \varepsilon C_D^{(1)}) = -6\pi a\mathbf{U}\mu(r = a)\left\{1 + \varepsilon\frac{19}{15}\frac{(\lambda_\zeta)_S}{\lambda_S} + O(\varepsilon^2)\right\} \\ &= -6\pi a\mathbf{U}\mu(r = a)\left\{1 + \frac{19}{15}a\left[\frac{1}{\mu}\frac{\partial\mu}{\partial r}\right]_{r=a} + O(\varepsilon^2)\right\}. \end{aligned} \tag{65}$$

To obtain higher order corrections a solution for $B^{(1)}(\zeta)$ must be provided. The differential equation governing $B^{(1)}(\zeta)$ is obtained by demanding that secular terms in the differential equation for $B^{(2)}(\zeta)$ vanish.

The latter is derived upon substitution of (59) and (60a) into (46a):

$$\begin{aligned} G_{zz}^{(2)} - G_z^{(2)} - 6G^{(2)} = e^{-2z}&\left(5B_\zeta^{(1)} + 2\frac{\lambda_\zeta}{\lambda}B^{(1)} - B_{\zeta\zeta}^{(0)} - \frac{\lambda_\zeta}{\lambda}B_\zeta^{(0)}\right) \\ &+ C_D^{(0)}\left(\frac{5}{18}\frac{\lambda_\zeta^2}{\lambda^3} - \frac{7}{36}\frac{\lambda_{\zeta\zeta}}{\lambda^2}\right) + C_D^{(1)}\frac{\lambda_\zeta}{6\lambda^2} + C_D^{(2)}\frac{1}{\lambda}. \end{aligned} \tag{66}$$

Thus, the governing differential equation for $B^{(1)}(\zeta)$ is

$$5B^{(1)}_{\zeta}+2\frac{\lambda_\zeta}{\lambda}B^{(1)}=B^{(0)}_{\zeta\zeta}+\frac{\lambda_\zeta}{\lambda}B^{(0)}_{\zeta}. \tag{67}$$

Subjected to boundary conditions (60b) and (46c), the solutions for $B^{(1)}$ and $h^{(1)}$ are easily obtained:

$$B^{(1)}=\frac{3}{50}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\int_0^\zeta \lambda^{-3/5}\frac{d(\lambda^{-2/5}\lambda_\zeta)}{d\zeta}d\zeta-\frac{43}{40}\frac{(\lambda_\zeta)_S}{\lambda_S^{3/5}\lambda^{2/5}}, \tag{68}$$

$$\begin{aligned} h^{(1)}=&\left(\frac{57}{60}\frac{(\lambda_\zeta)_S}{\lambda}-\frac{11}{8}\frac{\lambda_\zeta\lambda_S}{\lambda^2}\right)e^{-z}\\ &-\left[\frac{1}{50}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\int_0^\zeta \lambda^{-3/5}\frac{d(\lambda^{-2/5}\lambda_\zeta)}{d\zeta}d\zeta\right.\\ &\left.-\frac{43}{120}\frac{(\lambda_\zeta)_S}{\lambda_S^{3/5}\lambda^{2/5}}-\frac{1}{15}\frac{\lambda_\zeta}{\lambda}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\right]e^{-3z}. \end{aligned} \tag{69}$$

From (66) and (67), the general solutions for $G^{(2)}$, $h^{(2)}$ that satisfy the boundary conditions at an infinite distance from the sphere are

$$G^{(2)}=B^{(2)}(\zeta)e^{-2z}+\frac{5}{24}\frac{\lambda_S\lambda_\zeta^2}{\lambda^3}-\frac{7}{48}\frac{\lambda_S\lambda_{\zeta\zeta}}{\lambda^2}+\frac{19}{120}\frac{(\lambda_\zeta)_S\lambda_\zeta}{\lambda^2}-C_D^{(2)}\frac{1}{6\lambda}, \tag{70}$$

$$\begin{aligned} h^{(2)}=&e^{-3z}\left\{-\frac{43}{900}\left(\frac{\lambda}{\lambda_S}\right)^{3/5}\frac{(\lambda_\zeta)_S\lambda_\zeta}{\lambda^2}-\frac{7}{225}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\frac{\lambda_\zeta^2}{\lambda^2}\right.\\ &+\frac{1}{45}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\frac{\lambda_{\zeta\zeta}}{\lambda}+\frac{1}{375}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\frac{\lambda_\zeta}{\lambda}\int_0^\zeta\lambda^{-3/5}\frac{d}{d\zeta}(\lambda^{-2/5}\lambda_\zeta)d\zeta\\ &\left.-\frac{1}{150}\left(\frac{\lambda_S}{\lambda}\right)^{2/5}\lambda^{-3/5}\frac{d}{d\zeta}(\lambda^{-2/5}\lambda_\zeta)+\frac{1}{3}\frac{\partial B^{(1)}}{\partial\zeta}-3B^{(2)}\right\}\\ &-e^{-z}\left\{\frac{67}{24}\frac{\lambda_S\lambda_\zeta^2}{\lambda^3}+\frac{67}{48}\frac{\lambda_S\lambda_{\zeta\zeta}}{\lambda^2}+\frac{627}{360}\frac{(\lambda_\zeta)_S\lambda_\zeta}{\lambda^2}\right\}. \end{aligned} \tag{71}$$

Application of boundary conditions (46c) yields

$$C_D^{(2)}=-\frac{49703}{2000}\frac{(\lambda_\zeta^2)_S}{\lambda_S}-\frac{2011}{400}(\lambda_{\zeta\zeta})_S. \tag{72}$$

Hence, from (47b), a second order correction for the drag force exerted on a spherical

particle translating in a fluid with radially symmetric viscosity is

(73)
$$\begin{aligned}\mathbf{F} &= \frac{4}{3}\pi\mu_0 a\mathbf{U}(C_D^{(0)} + \varepsilon C_D^{(1)} + \varepsilon^2 C_D^{(2)}) \\ &= -6\pi a\mathbf{U}\mu(r=a)\left\{1 + \varepsilon\frac{19}{15}\frac{(\lambda_\zeta)_S}{\lambda_S} + \varepsilon^2\left(\frac{49703}{9000}\frac{(\lambda_\zeta^2)_S}{\lambda_S^2} + \frac{2011}{1800}\frac{(\lambda_{\zeta\zeta})_S}{\lambda_S}\right) + O(\varepsilon^3)\right\} \\ &= -6\pi a\mathbf{U}\mu(r=a)\left\{1 + \frac{19}{15}a\left[\frac{1}{\mu}\frac{\partial\mu}{\partial r}\right]_{r=a} + \frac{49703}{9000}a^2\left(\left[\frac{1}{\mu}\frac{\partial\mu}{\partial r}\right]_{r=a}\right)^2\right. \\ &\qquad \left. + \frac{2011}{1800}a^2\left[\frac{1}{\mu}\frac{\partial^2\mu}{\partial r^2}\right]_{r=a} + O(\varepsilon^3)\right\}.\end{aligned}$$

Case B: A particle translating in an algebraically varying viscosity fields in r-space. An analytic solution can easily be obtained in case the viscosity field varies algebraically in r-space (equivalently, varies exponentially in z-space), namely,

$$\lambda(z) = \exp(\alpha z) \equiv y^\alpha, \tag{74}$$

where α is an arbitrary constant. Notice that for α positive, the viscosity field increases without bound at infinity or becomes rigid far from the spherical particle. For α negative, the viscosity field vanishes at infinity, or the fluid becomes ideal far from the particle.

Introduction of (74) into (30) yields a simple linear nonhomogeneous second order equation with constant coefficients,

$$G_{zz} - (1-\alpha)G_z - 6G = C_D\exp(-\alpha z). \tag{75}$$

The general solution of (75) that satisfies boundary conditions (30c, d, e) at $z \to \infty$ is

$$G = \frac{C_D}{\alpha - 6}\exp(-\alpha z) + C_1'\exp(-sz) \quad \text{for } \alpha \neq 6 \quad \text{and} \quad \alpha > -1 \tag{76a}$$

and

$$G = (C_1'' - zC_D/7)\exp(-6z) \quad \text{for } \alpha = 6, \tag{76b}$$

where C_D, C_1', and C_1'' are constants of integration and

$$s = 0.5[\alpha - 1 + \sqrt{(\alpha-1)^2 + 24}] \tag{77}$$

is positive for any value of α.

Notice that the condition $\alpha > -1$ stems from (30e), i.e., that the viscosity field must decay to zero no faster than $1/r$ to obtain a velocity and pressure fields that vanish at an infinite distance from the particle.

Substituting (76) into (31) and integrating yields the respective expressions for h,

$$h = C_D\frac{1-\alpha}{(1+\alpha)(\alpha-6)}\exp[-(1+\alpha)z] + C_1'\frac{1-s}{1+s}\exp[-(s+1)z] \quad \text{for } \alpha \neq 6 \tag{78a}$$

and

$$h = \left[-\frac{5C_1''}{7} + C_D\left(\frac{5z}{49} - \frac{2}{343}\right)\right]\exp(-7z) \quad \text{for } \alpha = 6. \tag{78b}$$

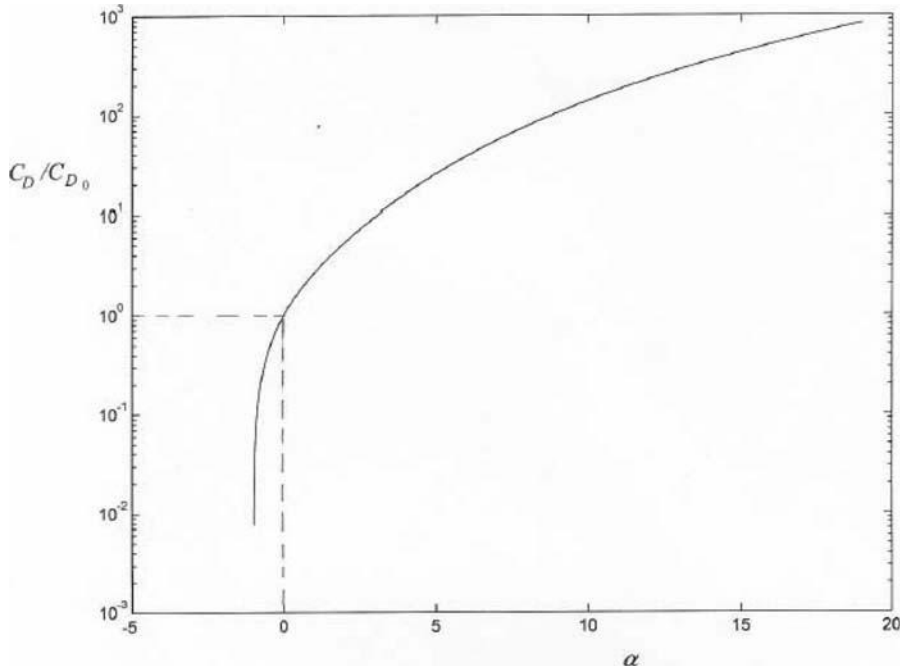

FIG. 2. *The dimensionless drag force* $C_D = F/(4\pi\mu_0 Ua/3)$ *exerted on a spherical particle immersed in an unbounded quiescent fluid with an algebraically varying viscosity* $\mu_\infty = \mu_0(r/a)^\alpha$ $(\alpha > -1)$ *and normalized with* $C_{D0} = -9/2$*, the corresponding dimensionless drag force exerted on a particle immersed in a fluid with uniform viscosity* $(\alpha = 0)$.

Utilizing boundary conditions (32a, b) makes it possible to determine the unknown coefficients C_1' and C_1'' and the drag coefficient C_D,

$$C_1' = -\frac{C_D}{(\alpha - 6)}, \qquad C_1'' = 0,$$
$$C_D = -\frac{(6-\alpha)(1+\alpha)(1+s)}{2(s-\alpha)} \quad \text{for } \alpha \neq 6 \text{ and } \alpha > -1 \tag{79a}$$

and

$$C_D = -\frac{343}{2} \quad \text{for } \alpha = 6. \tag{79b}$$

It is easy to show that C_D is negative for all values of $\alpha > -1$, and for $\alpha = 0$ (a uniform viscosity field) $C_D = C_{D0} = -9/2$ and Stokes law is recovered. Figure 2 illustrates the ratio between the drag coefficients for any viscosity parameter α and that of $\alpha = 0$. For α approaching -1 the drag coefficient decreases to zero. Obviously, for a very small fluid viscosity, the creeping flow approximation is no longer valid. Notwithstanding, the limit seems to approach the result of zero drag known from potential flow theory of ideal fluids.

Case C: A numerical algorithm. Equations (30), (31) and boundary conditions (32) constitute a boundary value problem where conditions must be satisfied simultaneously at $z = 0$ and at infinity. A numerical shooting scheme may encounter great difficulties despite the fact that the governing equations (30), (31) are linear. When

the asymptotic behavior of λ satisfies the relation $O(1) \leq \lambda \ll e^z$ as $z \to \infty$, the homogeneous part of (30) possesses a decaying (desired) and fast-growing (undesired) mode (see the appendix). Consequently, assuming the known values of G and h at $z = 0$ (see (32b, d)), an arbitrary value for the derivative of G at $z = 0$ is most likely to yield an exponentially divergent result, due to the overwhelming contribution of the undesired mode.

Nevertheless, a divergent solution (which may be obtained numerically from an arbitrary set of initial conditions for G and its derivative) can be utilized to construct convergent homogeneous and particular solutions of (30). Let us assume that $G_{H1}(z)$ is a *positive-definite* divergent solution of the homogeneous part of (30). Utilizing the method of variation of parameters, it is easy to show that a second independent homogeneous solution is given by

$$G_{H2}(z) = G_{H1}(z) \int_z^\infty \frac{e^x}{\lambda G_{H1}^2} dx \tag{80}$$

and that the particular solution of (30) with $C_D = 1$ is given by

$$G_P(z) = -G_{H1}(z) \int_z^\infty \frac{e^x}{\lambda G_{H1}^2} \left(\int_0^x G_{H1}(y) e^{-y} dy \right) dx. \tag{81}$$

By a simple application of l'Hopital's rule and accounting for the asymptotic behavior of G_{H1} at infinity (see the appendix), it is easy to show that G_{H2} vanishes at infinity and G_P approaches $-1/(6\lambda)$.

A general solution that satisfies (30) is given by

$$G = AG_{H1} + BG_{H2} + C_D G_P, \tag{82}$$

where A, B, and C_D are yet undetermined constants. However, A must vanish to satisfy the vanishing boundary condition at infinity. Thus, substituting (81) into (31) and integrating yields the general form of h,

(83)

$$\begin{aligned} h(z) = &\int_{w=z}^\infty (G_{H1} + G'_{H1}) e^{-w} \left[B \int_w^\infty \frac{e^x dx}{\lambda G_{H1}^2} - C_D \int_w^\infty \frac{e^x}{\lambda G_{H1}^2} \left(\int_0^x G_{H1} e^{-y} dy \right) dx \right] dw \\ &- \int_{x=z}^\infty \frac{1}{\lambda G_{H1}} \left[B - C_D \int_0^x G_{H1} e^{-y} dy \right] dx. \end{aligned}$$

Substituting boundary conditions (32b, d) into (82) and (83) yields two linear equations for the two unknowns B and C_D, which can readily be solved:

$$B \int_0^\infty \frac{e^x dx}{\lambda G_{H1}^2} - C_D \int_0^\infty \frac{e^x}{\lambda G_{H1}^2} \left(\int_0^x G_{H1} e^{-y} dy \right) dx = 0, \tag{84a}$$

$$\begin{aligned} &B \left\{ \int_0^\infty (G_{H1} + G'_{H1}) e^{-z} \left(\int_z^\infty \frac{e^x dx}{\lambda G_{H1}^2} \right) dz - \int_0^\infty \frac{dz}{\lambda G_{H1}} \right\} \\ &- C_D \left\{ \int_0^\infty (G_{H1} + G'_{H1}) e^{-z} \left[\int_z^\infty \frac{e^x}{\lambda G_{H1}^2} \left(\int_0^x G_{H1} e^{-y} dy \right) dx \right] dz \right. \\ &\left. - \int_0^\infty \frac{1}{\lambda G_{H1}} \left(\int_0^z G_{H1} e^{-y} dy \right) dz \right\} = 1. \end{aligned} \tag{84b}$$

Notice that we assume that both G_{H1} and its derivative G'_{H1} are known. Normally, this would *not* require a cumbersome numerical differentiation of G_{H1}. Indeed, the second order equation (30) would normally be replaced by a system of two first order equations for G_{H1} and G'_{H1}, so that a numerical solution for these functions would be obtained simultaneously.

Several terms in (84) include integration over an infinite domain, an operation that seems to pose some difficulty. However, due to the exponential behavior of G_{H1}, integration can be carried out over a finite domain without a significant loss of accuracy. A difficult case that involves a periodically varying viscosity is attempted in the next chapter.

5. Homogeneous suspensions. An intriguing example is the case in which the spherical particle rotates and translates in a spatially periodic viscosity, namely,

$$\lambda(r) = 1 - \alpha \cos\left[\frac{\beta(r-a)}{a}\right], \tag{85}$$

where α and β are known dimensionless parameters and a is the radius of the "test" particle that moves in the field.

Equation (85) can be loosely interpreted as the local viscosity of a homogeneous suspension. Frequently, a suspension is perceived as a single phase fluid with a homogeneous uniform effective viscosity that depends upon the viscosities of the constituent fluids and their volumetric fraction. For instance, the effective viscosity of a dilute suspension of droplets is $\mu_0 = \mu\big[1 + \big(\frac{1+2.5\mu_i/\mu}{1+\mu_i/\mu}\big)\phi\big]$, where μ and μ_i are the continuous fluid and droplet viscosities, respectively, and ϕ is the volumetric concentration of the droplets (Taylor (1932)). It is, however, plausible to view a suspension as a nonhomogeneous single phase fluid that possesses periodical fluctuations in the viscosity field. In this case, (85) represents a truncated Fourier series of the nonuniform viscosity field. If the effective mean viscosity of the suspension is employed as the characteristic viscosity μ_0, (e.g., $\mu_0 = \mu(1+2.5\phi)$ for a dilute suspension of rigid particles), then the parameter α stands for the amplitude of the first harmonic in a Fourier series expansion of the fluctuating viscosity field. We suggest that α is proportional to the viscosity difference $(\mu_0 - \mu)/\mu_0$. Thus, for a dilute suspension of rigid spheres, α is proportional to

$$\alpha \propto \frac{2.5\phi}{(1+2.5\phi)}. \tag{86}$$

Notice that, according to (85), the viscosity field near the rotating sphere is equal to the viscosity of the suspending fluid.

It is also plausible to assume that the length-scale of viscosity variations is determined by the distance between particles constituting the suspension. Thus, the parameter β is proportional to the reciprocal of the mean distance between particles,

$$\beta \propto \frac{a}{b\phi^{-1/3}}, \tag{87}$$

where b is the mean radius of a particle in the suspension. A positive α value pertains to a dense suspension of rigid particles, while a negative value pertains to a highly dense emulsion consisting of droplets (or bubbles) with viscosity lower than that of the surrounding continuous fluid. A large β value pertains to a large test particle $(a/b \gg 1)$ moving inside a dense suspension of smaller particles.

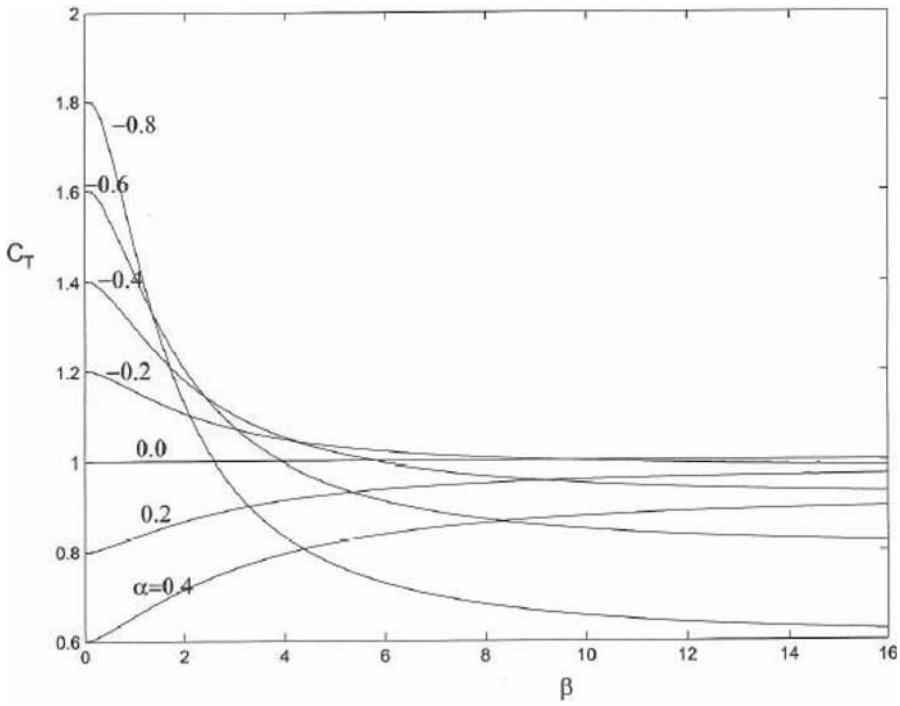

FIG. 3. *The dimensionless torque* $C_T = T_o/(-8\pi\mu_0 a^3\omega)$ *exerted on a spherical particle immersed in an unbounded quiescent fluid with a periodically varying viscosity* $\mu_\infty = \mu_0\{1-\alpha\cos[\beta(r-a)/a]\}$ $(|\alpha| < 1)$.

5.1. A particle rotating inside a suspension. Substitution of (85) into (17) yields the correction factor C_T depicted in Figure 3. For very small β's, the particles constituting the suspension are far from the rotating particle and have almost no effect on the moment exerted on the particle. Thus, the effective viscosity that the rotating particle senses is that of the fluid ($C_T \sim 1-\alpha$). However, for large β's (the mean distance between the suspended particles is smaller than the radius of the rotating test particle) the effective viscosity asymptotically approaches the value of the effective viscosity μ_0, irrespective of the sign of α. The latter fact coincides with known data. (See, for instance, Almog and Brenner (1998) for a rotating test particle in a dilute suspension.) In addition, it demonstrates that the results are insensitive to the exact location of the particle relative to the particles comprising the suspension (say, you replace the cosine with a sine function in (85)). For dilute suspensions or emulsions where $|\alpha| < 0.2$ and $\beta > 16$, the effective viscosity is higher than 0.98 μ_0. However, for high α values the solutions do not seem to reach the asymptotic value of μ_0. This is possibly due to the fact that the Fourier series (85) that contains only a first harmonic term is an insufficient representation of such strongly fluctuating viscosity fields.

5.2. A particle translating inside a dilute suspension. When α and β in (85) are small (which pertains to the case in which a small particle is embedded in a dilute suspension consisting of large particles), substitution of (85) into (73) yields

$$\mathbf{F} = -6\pi a\mathbf{U}\mu_0\left(1-\alpha+\frac{2011}{1800}\alpha\beta^2+O(\beta^3)\right). \tag{88a}$$

Thus, in such a case, a particle senses mainly the *fluid* viscosity with a second order correction in β. Notice, however, that if a *sine* distribution had been assumed in (85), the drag force would have been different,

$$\mathbf{F} = -6\pi a \mathbf{U}\mu_0 \left(1 - \frac{19}{15}\alpha\beta + \frac{49703}{9000}\alpha^2\beta^2 + O(\beta^3)\right), \tag{88b}$$

and the particle senses the *suspension* viscosity to a leading order in β. A possible explanation is that in the latter case the location of the small test particle is implicitly closer to the large particles comprising the suspension, increasing the drag force. This conclusion has also been noted by Almog and Brenner (1997), who showed in their two-sphere model that a small test particle would be strongly affected by a suspended particle adjacent to it, and as a result would spend a longer time traveling close to it.

We have shown in the Introduction that when a small particle moves inside a suspension its effect on the suspension configuration is negligible, provided that the Péclet number is smaller than unity. For a homogeneous suspension we hypothesize that the viscosity field retains its centrally symmetric configuration for all times, with the test particle always keeping its central position. Thus, if one desires to obtain the mean velocity of the test particle under a fixed external force, say gravity, or the mean force exerted on the test sphere, given that it moves with a fixed velocity, we suggest the following method: Instead of following the particle as it moves in the suspension, one may average over all realizations of the particle position with respect to the suspended particles. The viscosity field is centrally symmetric and is comprised of both sine and cosine radial distributions, accounting for a general location of the test particle with respect to the suspended particles, namely,

$$\frac{\mu}{\mu_0} = \lambda(r) = 1 - \alpha\cos\left[\frac{\beta(r-a)}{a} + \delta\right], \tag{89}$$

where $0 < \delta < 2\pi$ is an arbitrary phase angle with probability density $p(\delta)$. Implicitly, $\delta = 0$ pertains to the case in which the test particle is far from the suspended particles, while $\delta = \pi$ relates to a test particle placed near the suspended particles. Substituting (89) into (73) yields

$$\mathbf{F} = -6\pi a \mathbf{U}\mu_0 \Bigg(1 - \alpha\cos\delta + \frac{19}{15}\alpha\beta\sin\delta + \frac{2011}{1800}\alpha\beta^2\cos\delta + \frac{49703}{9000}\alpha^2\beta^2\frac{\sin^2\delta}{1-\cos\delta} + O(\beta^3)\Bigg).$$

Consequently, a small test particle of density ρ_p would move with a *mean* velocity

$$\bar{\mathbf{U}} = \int_0^{2\pi} \mathbf{U}p(\delta)d\delta = \frac{2(\rho_p - \rho)\mathbf{g}}{9\mu_0\sqrt{1-\alpha^2}}\left[1 - \frac{55373}{18000}\frac{\alpha^2\beta^2}{1-\alpha^2} + O(\beta^3)\right] \tag{90}$$

under gravity g in a suspension of density ρ, assuming that all realizations with respect to δ are equally probable (i.e., $p(\delta) = 1/2\pi$). Thus, the apparent viscosity is

$$\mu_{app.}(\text{constant force}) = \frac{\mu_0\sqrt{1-\alpha^2}}{\left[1 - \frac{55373}{18000}\frac{\alpha^2\beta^2}{1-\alpha^2} + O(\beta^3)\right]}. \tag{91}$$

The result (91) demonstrates that the sedimentation velocity of the test particle under gravity is practically determined by the suspension viscosity μ_0, and that *first*

order corrections in α and β vanish identically. Obviously, this result is based on the assumption that all realizations with respect to δ are equally probable. How good is that assumption? One may write the Fokker–Planck convection-diffusion equation for p, an approach used previously by Batchelor (1972) and others for a dilute suspension. However, if the Péclet number based on the diameter of the test particle is smaller than unity, the diffusion part of the Fokker–Planck equation dominates the probability density distribution, and the assumption that $p(\delta)$ is uniformly distributed is plausible. Surprisingly, Miliken et al. (1989), who performed experiments with large falling spheres of different diameters under gravity in a suspension comprised of neutrally buoyant spheres, obtained results that concur with our conclusions despite the fact that in those experiments the Péclet number was not small. They observed that only for dense concentrations ($\phi = 0.5, 0.55$) is there a noticeable effect of the ratio between test and suspension sphere diameters.

In the case when U is forced to be constant, one could calculate the mean force exerted on the particle to obtain the apparent viscosity. Assuming as before that all realizations with respect to δ are equally probable, we obtain

$$\bar{\mathbf{F}} = -6\pi a \mathbf{U} \mu_0 \left(1 + \frac{49703}{4500}\pi\alpha^2\beta^2 + O(\beta^3)\right), \tag{92}$$

and the apparent viscosity is given by

$$\mu_{app.}(\text{constant velocity}) = \mu_0 \left(1 + \frac{49703}{4500}\pi\alpha^2\beta^2 + O(\beta^3)\right). \tag{93}$$

Notice that the apparent viscosities in the foregoing two different cases (91) and (93) are identical up to first order terms in α and β. Moreover, these leading terms are independent of the ratio between the radii of suspension particles and test particles (as long as β is much smaller than unity). Thus, the apparent viscosities up to order ϕ are identical, a very gratifying result that implies that the viscosity μ_0 can be viewed as an intrinsic property of the suspension. Only second order terms in (91) and (93) appear to be different. However, these terms, which are of order $\alpha^2 \sim \phi^2$ for a dilute suspension, might be of limited value, since the expression for the viscosity field was assumed to retain only first order terms of the Fourier expansion.

Mondy, Graham, and Jensen (1986), who measured the velocity of a test sphere falling under gravity in a suspension of spherical rigid particles, also reached a similar conclusion. They used velocity measurements to calculate the apparent viscosity of the suspension (and wall effects induced by the suspension container). They concluded that in the absence of wall effects, and for a wide range of test sphere diameters larger than the suspended spheres, the apparent viscosity of a suspension is practically independent of the ratio of the diameters of the test sphere and the suspended spheres. In addition, for dilute suspensions, this apparent viscosity is essentially identical to the shear viscosity obtained by Couette or parallel-plates rheometers (see Figure 6 in Mondy, Graham, and Jensen (1986)).

A deviation of order ϕ in the apparent viscosities for constant velocity and constant force cases was obtained by Almog and Brenner (1997) for a very dilute suspension. The difference in our results is likely to stem from the different configurations assumed for the suspension. In our case the suspension is essentially perceived as a fixed three-dimensional lattice arranged around the test particle, and its position within the lattice is equally probable, while Almog and Brenner (1997) assumed that only a single particle in the suspension affects the test particle at any instant, and that

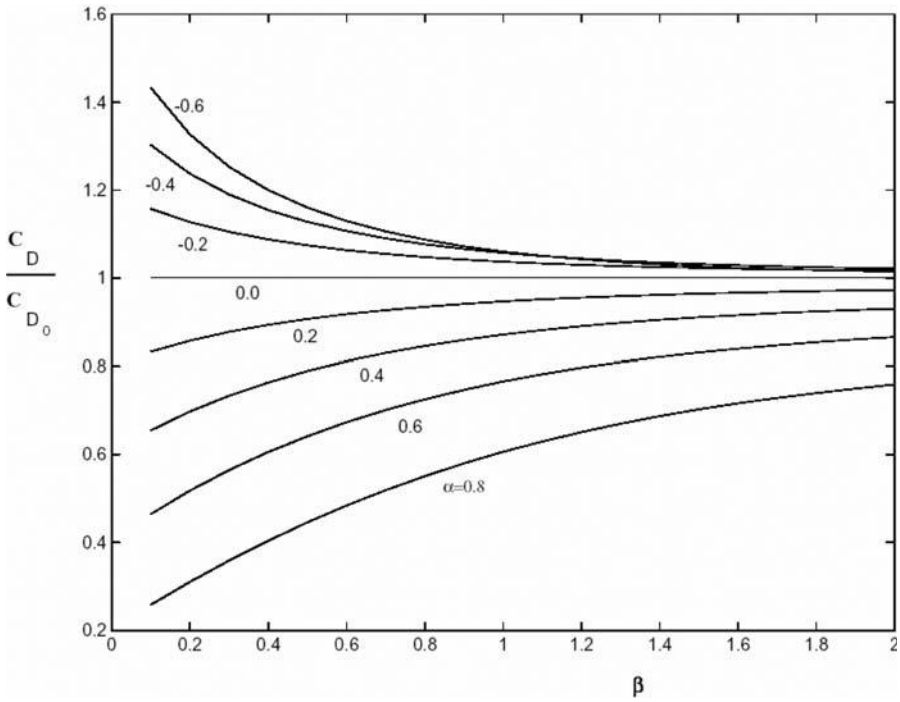

FIG. 4. *The dimensionless drag force* $C_D = F/(4\pi\mu_0 Ua/3)$ *exerted on a spherical particle immersed in an unbounded quiescent fluid with a periodically varying viscosity* $\mu_\infty = \mu_0\{1-\alpha\cos[\beta(r-a)/a]\}$ $(|\alpha| < 1)$ *and normalized with* $C_{D0} = -9/2$*, the corresponding dimensionless drag force exerted on a particle immersed in a fluid with uniform viscosity* $(\alpha = 0)$.

the probability density depends on the distance between the test and the suspended particles.

5.3. Computation of the drag force exerted on a particle translating inside a suspension. In this section we employ the numerical scheme suggested in section 4.2, case C, to obtain the drag force exerted on a rigid sphere translating in a flow field with periodically varying viscosity (89), for α and β not necessarily small and $\delta = 0$. Thus, only the drag force exerted on a particle positioned as far as possible from the suspended particles is considered.

Figure 4 depicts the numerical values obtained for the drag coefficient for a variety of α and β values. Evidently, in the case $\alpha = 0$ the viscosity field is uniform and the drag coefficient should be $C_D = C_{D0} = -4.5$, regardless of the value of β. Indeed, this known theoretical result was utilized to measure the accuracy of our numerical scheme. We observed that, replacing $z = \infty$ with $z = 8$ in (84), the error in C_{D0} was about 0.1%. For very small β's, the particles making up the suspension are far from the translating particle and have almost no effect on the force exerted on the particle. Thus, the effective viscosity that the translating particle senses is that of the fluid, and $C_D/C_{D0} \sim 1 - \alpha$. However, for larger β's (when the mean distance between the suspended particles is smaller than the radius of the translating test particle) the effective viscosity reaches asymptotically the value of the effective viscosity μ_0, irrespective of the sign of α. Comparison with known data can be done only qualitatively, since only one realization of the viscosity distribution according

to (89) was addressed. Miliken et al. (1989) examined experimentally the effect of falling test sphere diameter on the apparent viscosity of a dense suspension composed of spherical rigid particles. They observed (Figure 5 in their article) that for dense suspensions $\phi = (0.5, 0.55)$ the apparent viscosity deviates from its macroscopic average viscosity for test particles smaller than the suspended particles, while for larger test particles the apparent viscosity is practically independent of the ratio between the test and suspended particle radii. The value of β for $a/b = 1$ and $\phi = 0.5$ is 1.26. For this value of β, Figure 4 demonstrates that for $\alpha = 0.2$ the value of apparent viscosity deviates from the suspension viscosity by about 5%. For higher α values this deviation increases, possibly because the Fourier expansion of the viscosity field was limited to the first cosine term only. Nonetheless, for all α values the apparent viscosity asymptotically reaches the suspension viscosity for increasing values of β, a trend that was also observed by Miliken et al. (1989).

6. Summary. General solutions for the velocity and pressure fields were obtained for a rotating (section 2) and translating (section 3) spherical particle moving in an unbounded quiescent field with radially varying viscosity. An explicit formula, (17) was obtained for the torque exerted on a rotating particle. It manifests that only the near viscosity field affects the torque, whereas the far field is strongly screened. General analytical expressions (22) were obtained for the velocity and pressure fields, and a simplified expression (36) was obtained for the drag force exerted on a particle translating in an unbounded quiescent fluid. Three particular cases were addressed: In case A, weak radial variation of the viscosity field was assumed, and a second order approximate analytical solution (73) was derived for the drag force. In case B, the viscosity field increased or decreased algebraically, and an exact solution was obtained. It manifests that for a vanishing viscosity at infinity the drag force vanishes, a known result for the drag force exerted on a translating particle in ideal fluids. The latter result is quite surprising, in light of the fact that the Stokes equation for creeping flows is no longer a valid governing equation of the flow field. In case C, an effective numerical algorithm was suggested, by which the drag force can also be obtained for viscosity distributions that vary at a smaller than algebraic rate. In section 5 we addressed the difficult problem of a particle moving in a field with periodically varying viscosity. We hypothesized that such a viscosity field can be viewed as a continuous manifestation of a bimodal viscosity field of a suspension. For a rotating particle a screening effect of the near viscosity field was observed, a well-known fact for a particle rotating in a suspension. For a translating particle, the results demonstrate again that for large β's (i.e., the mean distance between the suspended particles is smaller than the radius of the rotating test particle) the effective viscosity asymptotically reaches the value of the shear suspension viscosity μ_0. For small values of β, namely when the test particle is much smaller than the suspended particles, the initial drag force exerted on the test particle is insensitive to the composition of the particles or droplets and "senses" the viscosity of the continuous liquid only, provided that it is positioned far from the suspended particles. However, if the particle is positioned with equal probability at an arbitrary distance from the suspended particles, the apparent viscosities of a dilute suspension, in case a constant external force is exerted on the test particle or in case it is forced to move with a constant velocity, are both equal to the shear viscosity up to first order in particle concentration.

Appendix. The asymptotic behavior of G at infinity under the asymptotic condition that $\lambda_z/\lambda \ll 1$ as $z \to \infty$ follows the general methods presented by Bender and Orszag (1999). We shall first investigate the asymptotic behavior of the homo-

geneous solution of (30). To this end, it is convenient to apply the transformation $w = 1/z$, rewrite (30) in terms of w, and investigate the asymptotic behavior of (30) near $w \to 0$.

Thus, (30) possesses the following form:

$$G_{ww} + \left(\frac{1}{w^2} + \frac{2}{w} + \frac{\lambda_w}{\lambda}\right) G_w - \frac{6G}{w^4} = 0. \tag{A1}$$

Since $w = 0$ is an irregular singular point, the controlling factor of G as $w \to 0$ is of the form of an exponential,

$$G \sim e^{S(w)}. \tag{A2}$$

Substitution of (A2) into the homogeneous part (A1) yields

$$S'' + S'^2 = -\left(\frac{1}{w^2} + \frac{2}{w} + \frac{\lambda_w}{\lambda}\right) S' + \frac{6}{w^4}. \tag{A3}$$

However, since $\lambda_w/\lambda \ll 1/w^2$ and $S'' \ll S'^2$ as $w \to 0$, the asymptotic differential equation that determines the controlling factor is

$$S'^2 \sim -\frac{S'}{w^2} + \frac{6}{w^4}.$$

Thus, $S'_{1,2} = 2/w^2, -3/w^2$ or $S_1 = -2/w$ and $S_2 = 3/w$. Thus, the homogeneous equation possesses convergent and divergent controlling factors near $z \to \infty$,

$$G \sim e^{3z} \quad \text{and} \quad G \sim e^{-2z}. \tag{A4}$$

A better leading behavior can be obtained by assuming that

$$S_1 = -\frac{2}{w} + C(w), \tag{A5}$$

given that $C \ll -2/w$ as $w \to 0$. Substituting (A5) into (A3) and collecting leading order terms yields

$$C' \sim -\frac{2}{5}\frac{\lambda_w}{\lambda} \quad \text{or} \quad C \sim \ln\lambda^{-2/5}. \tag{A6}$$

Hence

$$G_1 \sim \lambda^{-2/5} e^{-2z} \quad \text{as } z \to \infty, \tag{A7}$$

and similarly,

$$G_2 \sim \lambda^{-3/5} e^{3z} \quad \text{as } z \to \infty. \tag{A8}$$

Not surprisingly, this local behavior was also revealed in case A, which addressed the global behavior of G for all values of z.

The general homogeneous solution is given by

$$G_H = C_1 G_1 + C_2 G_2,$$

where C_1 and C_2 are arbitrary constants. Obviously, unless C_2 is identically zero, the homogeneous solution diverges for large values of z.

The asymptotic local behavior of the particular solution at $z \to \infty$ is easily derived by the method of dominant balance. The dominant term that balances the forcing term in (30) is the last term on the LHS of the equation. Thus,

$$G \sim -\frac{C_D}{6\lambda} \tag{A9}$$

and $G' \ll C_D/\lambda$ and $G'' \ll C_D/\lambda$, since $\lambda_z/\lambda \ll 1$ as $z \to \infty$. Equation (A9) is also the leading term in (62) of case A.

RESCUE OF THE QUASI-STEADY-STATE APPROXIMATION IN A MODEL FOR OSCILLATIONS IN AN ENZYMATIC CASCADE*

THOMAS ERNEUX† AND ALBERT GOLDBETER‡

We wish to dedicate this paper to the memory of L. A. Segel who contributed to many aspects of mathematical biology and for whom the quasi-steady-state hypothesis was a favorite topic of research

Abstract. A three-variable model describing the oscillatory activity of a cascade of enzyme reactions is analyzed. A quasi-steady-state approximation reduces the three equations to a system of two equations which admits only a stable steady state. This apparent failure of the quasi-steady-state approximation to describe the limit-cycle oscillations observed in the full, three-variable system is analyzed in detail. We first show that the oscillations occur in the full system provided the Michaelis constants are sufficiently small. We then develop a method for determining the correct limit for application of the quasi-steady-state approximation. The leading problem consists of two equations for a conservative oscillator, and a higher order analysis is required in order to determine the amplitude of the limit-cycle oscillations. Finally, we observe a good agreement when comparing exact numerical and approximate bifurcation diagrams.

Key words. enzyme reactions, limit-cycle oscillations, quasi-steady-state approximation, singular perturbation

1. Introduction.

The quasi-steady-state approximation (QSSA) of chemical kinetics is a mathematical way of simplifying the differential equations describing some chemical kinetic systems. This approximation is a powerful tool for analyzing the dynamics of enzymatic reactions [1, 2, 3] exhibiting a wide range of time scales. The QSSA often yields revealing analytic formulas, and it frequently circumvents problems of stiffness in the numerical integration of systems of differential equations. Originally devised by biochemists on the basis that enzymes as catalysts act with small concentrations compared to the concentrations of their substrates, the QSSA is now recognized as belonging to singular perturbation theory. Ideally, this theory provides a method for the correct use of the QSSA, but it is too complicated for general use. Various investigations of special cases, such as the Michaelis–Menten reaction [4, 5, 6], give some indications of the applicability of the QSSA. But further clarification is called for, especially since the QSSA is virtually unavoidable in introductory texts on chemical or biochemical kinetics [1, 2, 3, 7, 8]. Biological oscillations often exhibit different time or amplitude scales, and the QSSA is widely used to analyze excitability and limit-cycle oscillations in the phase plane (see [9, 10, 11] for biochemical examples). In this paper, we concentrate on a three-variable model for the oscillations in

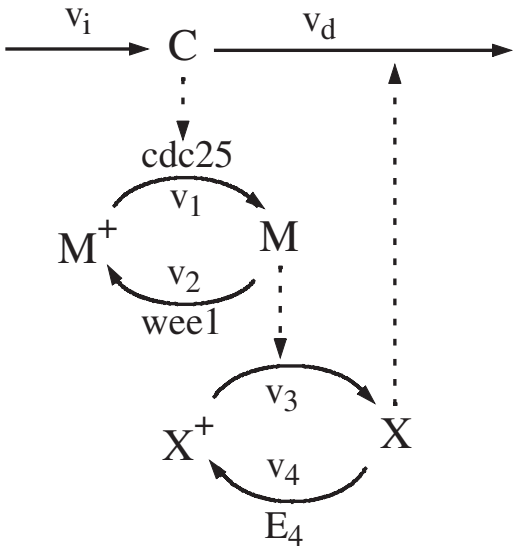

FIG. 1. *Bicyclic cascade model for the mitotic oscillator underlying the early cell cycle in amphibian embryos* [16, 17]. *Cyclin (C) is synthesized at a constant rate (v_i) and activates cdc*25 *phosphatase. The activated cdc*25 *phosphatase in turn activates cdc*2 *kinase (M) by dephosphorylating the inactive form (M^+). The activated cdc*2 *kinase is inactivated by the kinase wee*1. *In addition, a cyclin protease X is activated by cdc*2 *kinase and inactivated by an additional phosphatase (E_4). V_j ($j = 1 - 4$) denotes the effective maximum rate of each of the four converter enzymes; v_d denotes the maximum rate of cyclin degradation by protease X.*

the embryonic cell cycle and discover that the immediate application of the QSSA fails to describe these oscillations. Our main objective is to determine why the QSSA failed and how we may correctly use it in our problem.

Models for biochemical oscillations often contain one or more sigmoidal functions. Combined with positive and/or negative feedback loops, these functions allow the emergence of simple or complex oscillatory behavior. The sigmoidal dependence originates at the molecular level either from cooperative interactions in allosteric enzymes or from the phenomenon of zero-order ultrasensitivity in which two enzymes catalyzing opposite covalent modification reactions (e.g., phosphorylation-dephosphorylation) are saturated by their protein substrate [12]. While allosteric enzymes are abundant in metabolic regulation, covalent modification also plays an important role in biological signaling and cell regulation. Models for the oscillatory activity of allosteric enzymes have been studied analytically by taking advantage of the relatively large values of the allosteric constants [13, 14, 15]. However, the case of several enzymes working in a covalent modification cascade and exhibiting oscillatory activities has never been examined from an analytical point of view. In this paper, we consider a minimal model for biochemical oscillations underlying the embryonic cell cycle [16, 17]. See Figure 1. This model pertains to the situation encountered in early amphibian embryos, where the accumulation of cyclin suffices to trigger the onset of mitosis. In yeast and somatic cells, the mechanism involves additional checkpoints; see [2, 3, 18] and references therein. But what remains common to the various types of cell cycle mechanisms is the fact that they rely on the periodic activation of kinase cdc2 (also known as the cyclin-dependent kinase 1, cdk1). Cyclin activates the kinase cdc2, which promotes the degradation of cyclin. To produce oscillations, however,

activation and degradation cannot occur simultaneously and the negative feedback loop must be coupled to thresholds and time delays, which are naturally associated with phosphorylation-dephosphorylation cascades [16, 17].

The model is formulated in terms of the following three ordinary differential equations for the cyclin concentration C, the fraction of active cdc2 kinase M, and the fraction of active cyclin protease X [16, 17]:

$$\frac{dC}{dt} = v_i - v_d X \frac{C}{K_d + C} - k_d C, \tag{1}$$

$$\frac{dM}{dt} = V_{M1} \frac{C}{K_c + C} \frac{1 - M}{K_1 + 1 - M} - V_2 \frac{M}{K_2 + M}, \tag{2}$$

$$\frac{dX}{dt} = V_{M3} M \frac{1 - X}{K_3 + 1 - X} - V_4 \frac{X}{K_4 + X}. \tag{3}$$

In these equations, $1-M$ and $1-X$ represent the fractions of inactive cdc2 kinase and cyclin protease, respectively. v_i and v_d are the constant rate of cyclin synthesis and the maximum rate of cyclin degradation by protease X ($X = 1$), respectively. K_d and K_c denote the Michaelis constants for cyclin degradation and for cyclin activation of the cdc25 phosphatase acting on the phosphorylated form of the cdc2 kinase, respectively. k_d represents an apparent first-order rate constant related to nonspecific degradation of cyclin. The remaining parameters V_i and K_i ($i = 1$ to 4) denote the effective maximum rates and the Michaelis constants, respectively, for each of the enzymes E_i involved in the two cycles of phosphorylation-dephosphorylation. Moreover, the effective maximum rates $V_1(C)$ and $V_3(M)$ are given by $V_1 = V_{M1}C/(K_c + C)$ and $V_3 = V_{M3}M$.

The parameter K_d has been introduced to avoid the possibility that C becomes negative [16, 17]. For all our numerical solutions, however, we used $K_d = 0$ and found that C is always positive. Equation (1) with $K_d = 0$ is linear, and the nonlinearities necessary for the limit-cycle oscillations are given by the right-hand sides of (2) and (3). At steady state, the functions $M = M(C)$ and $X = X(M)$ obtained by setting the right-hand sides of (2) and (3) equal to zero are sigmoidal functions of M and X. The role of these functions for the oscillations is discussed in [16, 17]. Examples of limit-cycle oscillations for moderate and high values of V_{M1} and V_2 ($V_2/V_{M1} = 1/2$ fixed) are shown in Figure 2. They have been obtained by numerically solving (1)–(3). In Figure 2, top, the maximum rates V_{M1} and V_2 are moderate. The kinase M is activated as soon as C reaches a value close to 0.5. In Figure 2, bottom, the maximum rates V_{M1} and V_2 are large. In contrast to Figure 2, top, C remains close to 0.5. Time t, concentration C, and all parameters except the Michaelis constants have units as in [16, 17], where simulations are compared to experiments. We keep these equations in this form because they appear in all previous studies [16, 17, 30, 31].

We wish to describe the limit-cycle oscillations by using phase plane techniques. To this end, we propose to eliminate either M or X by using a QSSA. But, as we shall demonstrate, the reduced two-variable equations do no more than exhibit limit-cycle oscillations. By using a singular perturbation method, we then determine the correct two-variable limit that allows us to recover sustained oscillatory behavior. This analysis involves two steps. We first show that the leading approximation of the limit-cycle solution satisfies a two-variable conservative system of equations such as the Lotka–Volterra equations of chemical kinetics [1]. This system gives the correct relation

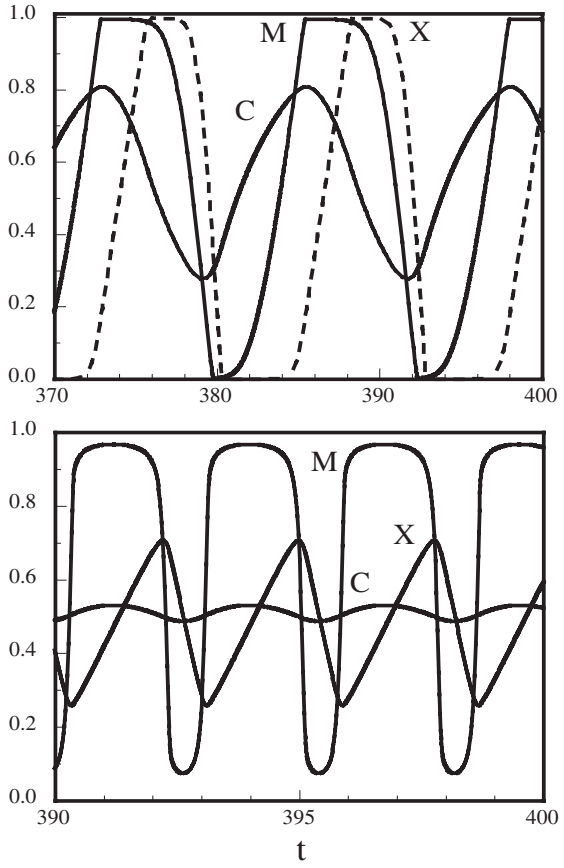

FIG. 2. *Limit-cycle oscillations in the enzymatic cascade model. M is dimensionless, C is measured in μM, and time t is measured in minutes. The values of the parameters are $K_j = K = 10^{-3}$ $(j = 1 - 4)$ and (in min^{-1}), $V_{M3} = 1$, $V_4 = 0.7$, $k_d = 0.25$; (in μM min^{-1}), $v_i = v_d = 0.25$; (in μM), $K_c = 0.5$, $K_d = 0$. Top: $V_{M1} = 3$ min^{-1} and $V_2 = 1.5$ min^{-1}; bottom: $V_{M1} = 3000$ min^{-1} and $V_2 = 1500$ min^{-1}.*

between the period and the amplitude of the oscillations. But in order to find how the amplitude changes with a given control parameter, a higher order analysis leading to a condition for bounded periodic solutions is needed. Similar singular perturbation techniques for particular Hopf bifurcation problems have been studied for chemical and biochemical relaxation oscillations [20], pulsating solidification fronts [21], and pulsating laser oscillations [24, 25].

The plan of the paper is as follows. In section 2, we show the failure of the standard QSSA and identify the source of the problem. Section 3 summarizes the results of our analysis, leading to the correct limit. The bifurcation diagram of the reduced two-variable equations is compared to the bifurcation diagram of the original three-variable equations. The main results are summarized in section 4. Mathematical details are given in appendices.

2. Failure of the QSSA. Equations (1)–(3) are too complicated for phase space analysis. A popular technique for simplifying the problem is to apply a QSSA for one of the dependent variables. This approximation (also called a pseudo-steady-state

hypothesis [26], steady-state assumption [27], or adiabatic elimination [28, 29]) is based on the assumption that the enzyme reacts so fast with the substrate that it can be taken as being in equilibrium, that is to say, $dM/dt \approx 0$ or $dX/dt \approx 0$. This approximation has been highly documented for the Michaelis–Menten reaction [1, 2, 3, 4, 5, 6] but has been used successfully for more complex systems exhibiting several enzymatic intermediates [2, 11]. The approximation is justified mathematically if a small parameter multiplies the time derivative of one of the dependent variables. This occurs in our problem if we consider the case of large values of both V_{M1} and V_2 (or, similarly, if we consider large values of V_{M3} and V_4). The proper way to apply the QSSA is to introduce the large parameter V defined as

$$V \equiv V_{M1} \tag{4}$$

and scale V_2 as

$$V_2 = V v_2, \tag{5}$$

where the coefficient v_2 is assumed to be an order one quantity. We may then factorize V in the right-hand side of (2) and rewrite this equation as

$$V^{-1}\frac{dM}{dt} = \frac{C}{K_c + C}\frac{1 - M}{K_1 + 1 - M} - v_2\frac{M}{K_2 + M}. \tag{6}$$

The coefficient of dM/dt is small because V is large. Thus, unless dM/dt is large, we may neglect this term and formulate the following algebraic equation for M and C:

$$\frac{C}{K_c + C}\frac{1 - M}{K_1 + 1 - M} - v_2\frac{M}{K_2 + M} = 0. \tag{7}$$

The QSSA is the assumption $V^{-1}dM/dt = 0$. Solving (7) for M and introducing $M = M(C)$ into (1) and (3) leads to two equations for only C and X. The two-variable problem represents a major simplification of our original three-variable equations, and we wonder if this reduced problem still admits limit-cycle oscillations. To this end, we examine the linear stability of the unique steady state $(C, X) = (C_s, X_s)$. We find that the coefficients of the characteristic equation for the growth rate σ are always positive. This means that $\mathrm{Re}(\sigma)$ is negative, implying stability of the steady state. A similar conclusion is obtained if we consider the case when V_{M3} and V_4 are large and eliminate the variable X.

We have thus found that a naive QSSA which allowed us to eliminate either M or X fails to describe the limit-cycle oscillations. But this approximation is nothing else than the leading term of an asymptotic solution and, like any asymptotic solution, it may admit different limits depending on the values of the other parameters in the problem. Returning to the original three-variable equations (1)–(3), we numerically investigate the behavior of the limit-cycle oscillations for progressively larger values of $V = V_{M1}$ and V_2 ($v_2 = V_2/V_{M1}$ fixed). We find that these oscillations persist only if we decrease the Michaelis constants K_j. The importance of these constants can be substantiated analytically by analyzing the Hopf bifurcation conditions in the double limits $V \to \infty$ and $K_j = K \to 0$ ($j = 1, 4$). The detailed analysis is given in Appendix A, where we show that the Hopf bifurcation point $K = K_H(V)$ scales like

$$K_H \sim V^{-1/2} \tag{8}$$

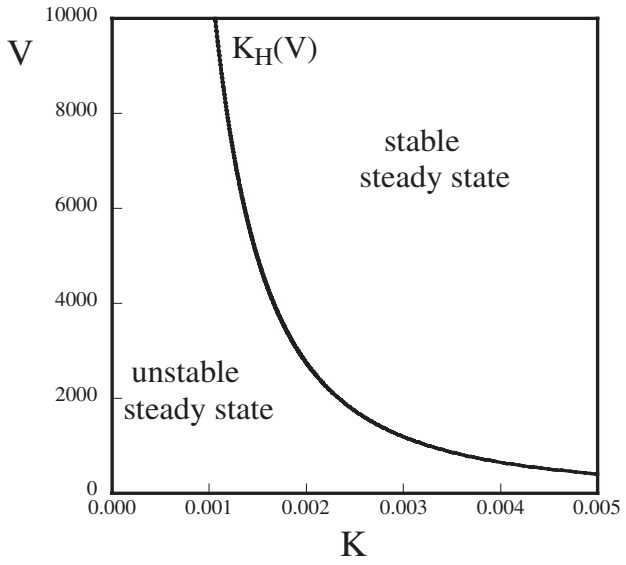

FIG. 3. *Hopf bifurcation line in the (K, V) parameter space. $V \equiv V_{M1}$ and $V_2 = V_{M1}/2$. The values of the other parameters are the same as in Figure 2. For progressively larger values of the maximum rate V, it is necessary to decrease the Michaelis constants (all equal to K) in order to keep the limit-cycle oscillations.*

as $V \to \infty$. Figure 3 shows the exact numerical Hopf bifurcation line for large values of V. It is in very good agreement with the approximation (47) derived in Appendix A. At a fixed value of V, the unique steady state undergoes a Hopf bifurcation at $K = K_H$, and the steady-state solution is unstable if $K < K_H$. From the Hopf conditions, we also learn that the frequency ω_H of the oscillations at the Hopf bifurcation point scales like

$$\omega_H \sim V^{1/4} \tag{9}$$

as $V \to \infty$, suggesting a short period oscillation for V large. We conclude that the QSSA based on the sole limit $V \to \infty$ cannot describe the oscillations unless we scale K as a $V^{-1/2}$ quantity and introduce a new time proportional to $V^{1/4}t$. In [16, 17], the value of V was much lower, allowing a larger K, for the observation of sustained oscillations.

3. Rescue of the QSSA. Phosphorylation-dephosphorylation cascades were already analyzed in the limit of small values of the Michaelis constants [19]. The difficulty here is that we need to scale both the maximum velocities and the Michaelis constants in order to describe the oscillations. Using the definitions (4) and (5), and motivated by the scaling laws (8) and (9), we introduce a small parameter ε, defined by

$$\varepsilon \equiv V^{-1/4}, \tag{10}$$

and scale the parameters V_2 and K_j $(j = 1 - 4)$ with respect to ε as

$$V_2 = \varepsilon^{-4} v_2 \text{ and } K_j = \varepsilon^2 k_j \ (j = 1 - 4). \tag{11}$$

In (11), v_2 and k_j are assumed to be order one coefficients. We also take into account (9) by introducing a new basic time T defined by

$$T \equiv \varepsilon^{-1} t. \tag{12}$$

Inserting (10)–(12) into (1)–(3) gives

$$\varepsilon^{-1} \frac{dC}{dT} = v_i - v_d X \frac{C}{K_d + C} - k_d C, \tag{13}$$

$$\frac{dM}{dT} = \varepsilon^{-3} \left[\frac{C}{K_c + C} \frac{1 - M}{\varepsilon^2 k_1 + 1 - M} - v_2 \frac{M}{\varepsilon^2 k_2 + M} \right], \tag{14}$$

$$\varepsilon^{-1} \frac{dX}{dT} = V_{M3} M \frac{1 - X}{\varepsilon^2 k_3 + 1 - X} - V_4 \frac{X}{\varepsilon^2 k_4 + X}. \tag{15}$$

Our QSSA now means the solution of these equations in the limit ε small. The analysis is long and tedious and is relegated to Appendix B. The results of our analysis are, however, simple and are summarized as follows for the case $K_d = 0$.

The leading approximation of the solution of (13)–(15) is described in terms of the variables M, U, and W, where U and W are defined as the deviations of C and X from their steady-state values

$$U \equiv \varepsilon^{-2}(C - C_0) \text{ and } W \equiv \varepsilon^{-1}(X - X_0). \tag{16}$$

In (16), C_0 and X_0 represent the steady-state values of C and X evaluated at $K_j = 0$ $(j = 1 - 4)$. They are defined as

$$C_0 \equiv \frac{K_c v_2}{1 - v_2} \text{ and } X_0 \equiv \frac{(v_i - k_d C_0)}{v_d}. \tag{17}$$

The leading order equations for M and W are then given by

$$F'(M) \frac{dM}{dT} = -v_d W, \tag{18}$$

$$\frac{dW}{dT} = V_{M3} M - V_4, \tag{19}$$

where

$$F(M) \equiv \frac{K_c v_2}{(1 - v_2)^2} \left[\frac{k_1}{1 - M} - \frac{k_2}{M} \right] \tag{20}$$

and

$$U = F(M). \tag{21}$$

Equations (18) and (19) form a conservative system of equations which admits a one-parameter family of periodic solutions. See Figure 4. For each point in the phase plane (W, M), there exists a closed orbit surrounding the center located at $(W, M) = (0, V_4/V_{M3})$. As the amplitude of the orbit increases, the period increases. The orbit becomes more and more rectangular and spends most of its time near $M = 1$ and $M = 0$.

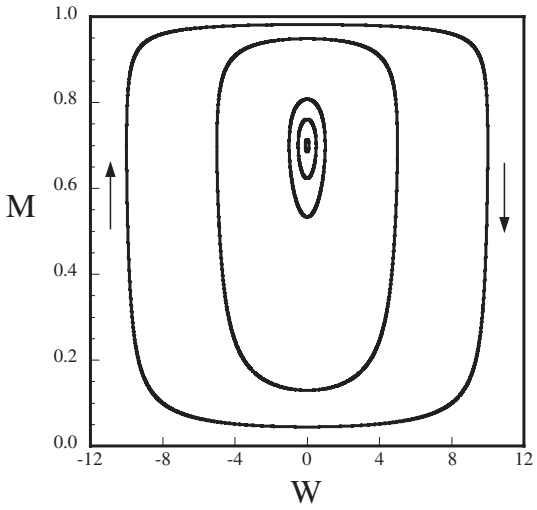

FIG. 4. *Orbits in the phase plane* (W, M) *obtained numerically from* (18)–(20). *The values of the parameters are* $v_2 = 0.5$, $V_{M3} = 1$, $V_{M4} = 0.7$, $v_d = 0.25$, $k_1 = k_2 = 1$, $K_c = 0.5$. *Each orbit corresponds to a periodic solution starting from a different initial point.* $M(0) = V_4/V_{M3} = 0.7$ *and* $W(0) = -0.1, -1, -5, -10$ *from the smallest to the largest orbit. The arrows indicate the direction of the time evolution.*

We now select the orbit of period P in the family of periodic solutions of (18) and (19). It is denoted by $U = U_P(T)$, $W = W_P(T)$, and $M = M_P(T)$. In order to determine how the period P (or equivalently, $U_P(T)$, $W_P(T)$, or $M_P(T)$) changes as we change a parameter, a higher order analysis is needed. This analysis is detailed in Appendix B. It leads to a solvability condition for bounded periodic solutions given by

$$v_d V_{M3} \frac{K_c}{(1-v_2)^2} \int_0^P \left(\frac{dM_P}{dT}\right)^2 dT - k_d \int_0^P \left(\frac{dU_P}{dT}\right)^2 dT = 0. \tag{22}$$

The two integrals must be computed numerically. This condition is the bifurcation equation since it relates the period of the oscillations and the physical parameters. In the limit of small amplitude solutions, $dU/dT = F'(M_0)dM/dT$, where $M_0 = V_4/V_{M3}$, and with $k_1 = k_2 = k$, (22) reduces to

$$\left[v_d V_{M3} \frac{K_c}{(1-v_2)^2} - k_d F'^2(M_0)\right] \int_0^P \left(\frac{dM_P}{dT}\right)^2 dT = 0 \tag{23}$$

which implies, using (20), that

$$k = k_H \equiv \sqrt{\frac{v_d V_{M3}}{k_d K_c}} \frac{(1-v_2)}{v_2} \left[\frac{1}{(1-M_0)^2} + \frac{1}{M_0^2}\right]^{-1}. \tag{24}$$

Using now $K = V_{M1}^{-1/2} k$ and $v_2 = V_2/V_{M1}$, expression (24) exactly matches the expression of the Hopf bifurcation point (47) obtained from the linearized theory in Appendix A. The expression (47) also is in excellent agreement with the exact numerical Hopf bifurcation line shown in Figure 3. We have thus verified that the bifurcation equation (22) correctly leads to the Hopf bifurcation point in the limit of small amplitude periodic solutions.

We next wish to find from (18)–(22) how the amplitude of the oscillations changes as we change the deviation $k - k_H$. To this end, we introduce

$$W = \sqrt{k}w \text{ and } T = \sqrt{k}s \tag{25}$$

into (18), (19) and obtain two equations for M and w that do not depend on k. They are of the form

$$f'(M)\frac{dM}{ds} = -v_d w, \tag{26}$$

$$\frac{dw}{ds} = V_{M3}M - V_4, \tag{27}$$

where

$$f(M) \equiv \frac{K_c v_2}{(1-v_2)^2}\left[\frac{1}{(1-M)} - \frac{1}{M}\right]. \tag{28}$$

Furthermore, substituting (25) into the bifurcation equation (22) leads to an expression for k^2 given by

$$k^2 = \frac{v_d V_{M3} K_c}{k_d(1-v_2)^2} \frac{\int_0^P \left(\frac{dM_P}{ds}\right)^2 ds}{\int_0^P f'^2(M)\left(\frac{dM_P}{ds}\right)^2 ds}. \tag{29}$$

The bifurcation equation (29) is now ready to be solved numerically: k appears only in the left-hand side, and the right-hand side is a function of the amplitude of the solution. Practically, we determine a P-periodic solution of (26) and (27) using the initial conditions

$$M(0) = V_4/V_{3M} \text{ and } w(0) = E, \tag{30}$$

where E is the parameter (in Figure 4, the orbits of different solutions are shown for $E = -0.1$, -1, -5, and -10). We then compute the two integrals in (29) and evaluate k^2. From an analysis of (26) and (27) in the phase plane, we note that $w = \pm E$ are the two extrema of $w(s)$. By gradually changing E from zero, we determine the function $E = E(k^2)$. Knowing E, we determine the extrema of W and X using first (25) and then (16). The bifurcation diagram of the extrema of X is shown in Figure 5 by the solid lines. As the amplitude of the periodic solutions increases, the Hopf bifurcation branch is first subcritical ($K > K_H$) and then folds back.

4. Discussion. The QSSA is widely used in the study of oscillations in biological and physical systems as a means to analyze limit-cycle behavior in the phase plane. Focusing on a biochemical model for limit-cycle oscillations in the embryonic cell cycle, we showed that a routine application of the QSSA leads to a two-variable system of equations that does not exhibit sustained oscillations. This apparent failure of the QSSA is, however, not a limitation of the method. We need to remember that the QSSA originates from an asymptotic method that considers a specific limit of a parameter (here the limit $V_{M1} = V$ large assuming V_2/V_{1M} fixed). From the Hopf bifurcation conditions, we showed that periodic solutions can be found only in the full system if we consider small values of the Michaelis constants. The correct scaling between these parameters and the other parameters in the model is provided by a careful analysis of the Hopf bifurcation conditions. A nonlinear analysis motivated by

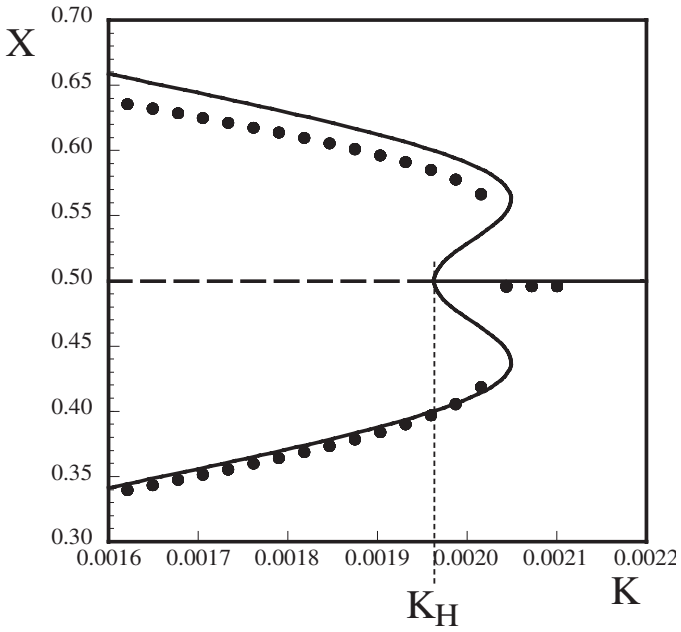

FIG. 5. *Maximum and minimum of the oscillations in X as a function of K. The approximation of the bifurcation diagram (solid lines) is compared to the bifurcation diagram of the original evolution equations* (1)–(3) *(dots). Parameter values are the same as in Figure* 4. *We represent the extrema of X as a function of K. The horizontal line is the steady state $X = 0.5$ which is unstable if $K < K_H \simeq 1.963 \times 10^{-3}$. The value of $\varepsilon = 0.135$. The agreement becomes better if we consider smaller values of ε (i.e., higher values of V_{M1} and V_2).*

these scalings then leads to a two-variable problem as the leading approximation. This problem admits conservative oscillations and therefore does not provide the bifurcation diagram of the amplitude of limit-cycle oscillations as a function of the control parameter. A higher order analysis was necessary in order to derive the bifurcation diagram. In other words, the limit-cycle solution is captured by a two-variable problem as one particular orbit in a family of periodic solutions, but the relation of this orbit to a specific value of the control parameter requires an extra solvability condition. In the strict spirit of the QSSA, the technique, even corrected by taking into account the scaling between parameters, is unable to provide a two-variable system exhibiting limit-cycle oscillations. However, it is not a limitation of the singular perturbation method, which tell us how to rescue the QSSA by supplementing it with a solvability condition.

Our results came from investigating two orders of a perturbation analysis after scaling parameters and variables with respect to a small parameter ε. It is not a local analysis near a Hopf bifurcation point because M is arbitrary even if C and X are assumed close to their steady-state values. This is why we obtained the global bifurcation diagram in Figure 5. An alternative to the perturbation theory is possible if we directly introduce the new variables T, U, and W into the original equations (1)–(3). Inserting (16) into (13)–(15) and simplying, we obtain the following equations for U, M, and W:

$$\frac{dU}{dT} = -v_d W - \varepsilon k_d U, \tag{31}$$

$$\frac{dM}{dT} = \varepsilon^{-1}\left[\begin{array}{c}\frac{U(1-v_2)^2(1-M)-v_2\left(K_c+\varepsilon^2U(1-v_2)\right)k_1}{(K_c+\varepsilon^2U(1-v_2))(1-M+\varepsilon^2k_1)}\\ +\ \frac{v_2k_2}{M+\varepsilon^2k_2}\end{array}\right], \tag{32}$$

$$\frac{dW}{dT} = V_{M3}\frac{M(1-X_0-\varepsilon W)}{1-X_0-\varepsilon W+\varepsilon^2k_3} - V_4\frac{X_0+\varepsilon W}{X_0+\varepsilon W+\varepsilon^2k_4}, \tag{33}$$

where X_0 is defined as in (17). The ε^{-1} term multiplying the right-hand side of (32) suggests that M will quickly approach a two-dimensional slow manifold. In this paper, we concentrated on the limit-cycle solution and did not investigate the evolution towards this slow manifold.

The standard QSSA failed in our three-variable model because the small parameter that motivated the elimination of one of the dependent variables also controlled the time scale of the remaining variables. This problem is known for two-variable models exhibiting relaxation oscillations [20] and for the standard laser rate equations [22]. A change of variables allows us to eliminate the singular perturbation difficulty. For three-variable systems, the problem has been analyzed for laser dynamical systems [23, 24, 25].

Appendix A. Linear theory. The Hopf bifurcation boundaries were investigated only numerically [30, 31]. In this appendix, we determine analytically the steady-state solution of (1)–(3) and its Hopf bifurcation point for the particular case when

$$K_d = 0 \text{ and } K_j = K \ (j = 1-4). \tag{34}$$

The steady-state solution $(C, M, X) = (C_s, M_s, X_s)$ satisfies the following three conditions:

$$v_i - v_dX - k_dC = 0, \tag{35}$$

$$\frac{V_{M1}C}{K_c+C}\frac{1-M}{K+1-M} - \frac{V_2M}{K+M} = 0, \tag{36}$$

$$V_{M3}M\frac{1-X}{K+1-X} - V_4\frac{X}{K+X} = 0. \tag{37}$$

If $K \to 0$, the steady state (C_s, M_s, X_s) approaches the limit (C_0, M_0, X_0). From (35)–(36) with $K = 0$, we find

$$C_0 = \frac{K_cV_2}{V_{M1}-V_2} > 0,\ M_0 = \frac{V_4}{V_{M3}},\ \text{and}\ X_0 = \frac{v_i-k_dC_0}{\nu_d} > 0. \tag{38}$$

Introducing the deviations $u = C - C_s$, $v = M - M_s$, and $w = X - X_s$, the linearized problem is given by

$$\left(\begin{array}{c}u'\\v'\\w'\end{array}\right) = \left(\begin{array}{ccc}-k_d & 0 & -v_d\\ \frac{V_{M1}K_c}{(K_c+C)^2}\frac{1-M}{K+1-M} & -F_1 & 0\\ 0 & V_{M3}\frac{1-X}{K+1-X} & -F_2\end{array}\right)\left(\begin{array}{c}u\\v\\w\end{array}\right), \tag{39}$$

where we have omitted the subscript s for the steady state. F_1 and F_2 are positive coefficients defined by

$$\begin{aligned}F_1 &\equiv K\left[\frac{C}{K_c+C}\frac{V_{M1}}{(K+1-M)^2} + \frac{V_2}{(K+M)^2}\right],\\ F_2 &\equiv K\left[\frac{V_{M3}M}{(K+1-X)^2} + \frac{V_4}{(K+X)^2}\right].\end{aligned} \tag{40}$$

From (39), we formulate the characteristic equation for the growth rate σ as

$$\sigma^3 - T_1\sigma^2 + T_2\sigma - T_3 = 0, \tag{41}$$

where

$$\begin{aligned} T_1 &= -k_d - F_1 - F_2, \\ T_2 &= k_d(F_1 + F_2) + F_1F_2, \\ T_3 &= -k_dF_1F_2 - V_{M3}V_{M1}v_d\frac{1-X}{K+1-X}\frac{K_c}{(K_c+C)^2}\frac{1-M}{K+1-M}. \end{aligned} \tag{42}$$

The conditions for a Hopf bifurcation are obtained by substituting $\sigma = i\omega$ into (41) and by separating the real and imaginary parts. We find

$$T_1T_2 - T_3 = 0 \text{ and } \sigma^2 = T_2 > 0. \tag{43}$$

The second condition is always verified. In order to satisfy the first condition, we determine $T_1T_2 - T_3$ and obtain

$$\begin{aligned} T_1T_2 - T_3 = &-k_d^2(F_1+F_2) - k_d(F_1+F_2)^2 - (F_1+F_2)F_1F_2 \\ &+ V_{M3}V_{M1}v_dK_c\frac{1-X}{K+1-X}\frac{1}{(K_c+C)^2}\frac{1-M}{K+1-M}. \end{aligned} \tag{44}$$

We wish to determine an approximation of (44) in the double limit K small and V large (V_{M1}/V_2 fixed). To this end, we need the leading expressions of F_1 and F_2 for K small. From (40) and using (38), we obtain

$$F_1 \simeq V_2K\left(\frac{1}{(1-M_0)^2} + \frac{1}{M_0^2}\right) \text{ and } F_2 \simeq V_4K\left(\frac{1}{(1-X_0)^2} + \frac{V_4}{X_0^2}\right). \tag{45}$$

We next consider the limit V_2 large (V_{M1}/V_2 fixed). In this limit, $F_1 \gg F_2$ and (44) simplifies as

$$\begin{aligned} T_1T_2 - T_3 &\simeq -k_dF_1^2 + V_{M3}V_{M1}v_d\frac{K_c}{(K_c+C_0)^2} \\ &= \left[\begin{array}{c} -k_dV_2^2K^2\left(\frac{1}{(1-M_0)^2} + \frac{1}{M_0^2}\right)^2 \\ + V_{M3}v_d\frac{(V_{M1}-V_2)^2}{K_cV_{M1}} \end{array}\right], \end{aligned} \tag{46}$$

where we eliminate C_0 using (38). The Hopf bifurcation point satisfies the condition $T_1T_2 - T_3 = 0$. Using (46) we find an expression of the Hopf bifurcation point $K = K_H$ given by

$$K_H = \frac{(V_{M1}-V_2)}{V_2\sqrt{V_{M1}}}\sqrt{\frac{V_{M3}v_d}{k_dK_c}}\left[\frac{1}{(1-M_0)^2} + \frac{1}{M_0^2}\right]^{-1}. \tag{47}$$

We have verified that this approximation compares well with the exact numerical solution shown in Figure 3. From (47), K_H scales like $V^{-1/2}$ as $V \to \infty$ ($V \equiv V_{M1}$, V_2/V_{M1} fixed). We also note from (43) that the frequency of the oscillations scales like

$$\omega = \sqrt{T_2} \simeq \sqrt{k_dF_1} = O(\sqrt{V_2K}) = O(V^{1/4}). \tag{48}$$

We conclude that a Hopf bifurcation is possible in the quasi-steady-state limit $V = V_{M1} \to \infty$ (V_2/V_{M1} fixed) provided that K is sufficiently small. The steady-state solution is unstable if $T_1T_2 - T_3 < 0$, which implies the inequality $K < K_H$.

Appendix B. Nonlinear bifurcation theory. Our starting point is (13)–(15), which we rewrite as

$$\frac{dC}{dT} = \varepsilon \left[v_i - v_d X \frac{C}{K_d + C} - k_d C \right], \tag{49}$$

$$\varepsilon^3 \frac{dM}{dT} = \frac{C}{K_c + C} \frac{1 - M}{\varepsilon^2 k_1 + 1 - M} - v_2 \frac{M}{\varepsilon^2 k_2 + M}, \tag{50}$$

$$\frac{dX}{dT} = \varepsilon \left[V_{M3} M \frac{1 - X}{\varepsilon^2 k_3 + 1 - X} - V_4 \frac{X}{\varepsilon^2 k_4 + X} \right] \tag{51}$$

so that all powers of ε are positive. We next seek a periodic solution of the form

$$\begin{gathered} C = C_0 + \varepsilon C_1 + \varepsilon^2 C_2 + \cdots,\ M = M_0 + \varepsilon M_1 + \varepsilon^2 M_2 + \cdots, \\ \text{and } X = X_0 + \varepsilon X_1 + \varepsilon^2 X_2 + \cdots . \end{gathered} \tag{52}$$

After introducing (52) into (49)–(51), we equate to zero the coefficients of each power of ε. This leads to a sequence of problems for the coefficients in (52). The leading order equations are

$$\frac{dC_0}{dT} = 0,\ \frac{C_0}{K_c + C_0} - v_2 = 0,\ \frac{dX_0}{dT} = 0. \tag{53}$$

Equation (53) admits the solution

$$C_0 = \frac{K_c v_2}{1 - v_2} \text{ and } X_0 = cst, \tag{54}$$

where X_0 is an unknown constant. The fact that X_0 and M_0 are unknown motivates the higher order analysis. The next problem is $O(\varepsilon)$ and is given by the following three equations:

$$\frac{dC_1}{dT} = v_i - v_d X_0 \frac{C_0}{K_d + C_0} - k_d C_0, \tag{55}$$

$$\frac{K_c C_1}{(K_c + C_0)^2} = 0, \tag{56}$$

$$\frac{dX_1}{dT} = V_{M3} M_0 - V_4. \tag{57}$$

From (56) and then from (55), we find C_1 and X_0 as

$$C_1 = 0 \text{ and } X_0 = \frac{(v_i - k_d C_0)(K_d + C_0)}{v_d C_0}. \tag{58}$$

We have determined X_0 but M_0 is still unknown. Thus, we consider the next problem, which is $O(\varepsilon^2)$:

$$\frac{dC_2}{dT} = -v_d \frac{C_0}{K_d + C_0} X_1, \tag{59}$$

$$\frac{K_c C_2}{(K_c + C_0)^2} - \frac{C_0}{K_c + C_0} \frac{k_1}{1 - M_0} + v_2 \frac{k_2}{M_0} = 0, \tag{60}$$

$$\frac{dX_2}{dT} - V_{M3} M_1 = 0. \tag{61}$$

From (60), we may determine M_0 as a function of C_2. Specifically, we define $M_0 = G(C_2)$ as the implicit solution of

$$C_2 = F(M_0) = \frac{K_c v_2}{(1-v_2)^2}\left[\frac{k_1}{1-M_0} - \frac{k_2}{M_0}\right]. \tag{62}$$

From (57) and (59), we eliminate X_1 and formulate a second-order differential equation for C_2:

$$\frac{d^2C_2}{dT^2} + \frac{v_d C_0}{K_d + C_0}\left[V_{M3}G(C_2) - V_4\right] = 0. \tag{63}$$

This equation is conservative and admits a one-parameter family of periodic solutions. This can be demonstrated in the phase plane by determining a first integral. The conservative nature of the oscillations means that the amplitude is arbitrary, and we still need to examine the higher order problem.

An equation for X_2 is already given by (61). From the $O(\varepsilon^3)$ equations, we obtain equations for C_3 and M_1 given by

$$\frac{dC_3}{dT} = -v_d X_2 \frac{C_0}{K_d + C_0} - v_d X_0 \frac{K_d}{(K_d + C_0)^2} C_2 - k_d C_2 \tag{64}$$

and

$$\frac{dM_0}{dT} = \frac{K_c C_3}{(K_c + C_0)^2} - \frac{C_0}{K_c + C_0}\frac{k_1 M_1}{(1-M_0)^2} - v_2 \frac{k_2 M_1}{M_0^2}. \tag{65}$$

Using (65), we determine M_1 as

$$M_1 = G'(C_2)C_3 - \frac{K_c}{(1-v_2)^2} G'(C_2)^2 \frac{dC_2}{dT}. \tag{66}$$

Then, using (61), (64), and (66), we obtain

$$\begin{aligned}\frac{d^2C_3}{dT^2} + v_d \frac{C_0}{K_d + C_0} V_{M3} G'(C_2) C_3 = v_d \frac{C_0}{K_d + C_0} V_{M3} \frac{K_c}{(1-v_2)^2} G'(C_2)^2 \frac{dC_2}{dT} \\ - \left[v_d X_0 \frac{K_d}{(K_d + C_0)^2} + k_d\right] \frac{dC_2}{dT}.\end{aligned} \tag{67}$$

By differentiating (63) with respect to T, we note that the homogeneous linear problem for C_3 admits the solution $C_{3H} = dC_2/dT$. The condition for a bounded periodic solution then implies that the right-hand side of (67) satisfies a solvability condition (Fredholm alternative [32]). Because the homogeneous problem is self-adjoint, this condition requires that the right-hand side is orthogonal to C_{3H}. This leads to the integral

$$\int_0^P \left[\begin{array}{c} v_d \frac{C_0}{K_d + C_0} V_{M3} \frac{K_c}{(1-v_2)^2} G'(C_2)^2 \\ - \left(v_d X_0 \frac{K_d}{(K_d + C_0)^2} + k_d\right) \end{array}\right] \left(\frac{dC_2}{dT}\right)^2 dT = 0 \tag{68}$$

and is the bifurcation equation. This equation can be further simplified, noting that

$$G'(C_2)^2 \left(\frac{dC_2}{dT}\right)^2 = \left(\frac{dM_0}{dT}\right)^2. \tag{69}$$

Equation (68) is then reformulated as

$$\int_0^P \left[\begin{array}{c} v_d \frac{C_0}{K_d+C_0} V_{M3} \frac{K_c}{(1-v_2)^2} \left(\frac{dM_0}{dT}\right)^2 \\ - \left(v_d X_0 \frac{K_d}{(K_d+C_0)^2} + k_d \right) \left(\frac{dC_2}{dT}\right)^2 \end{array} \right] dT = 0. \tag{70}$$

This condition determines the amplitude of the oscillations as a function of the physical parameters. If $K_d = 0$, it reduces to condition (22), which is analytically and numerically investigated.

THE TRIPLE POINT PARADOX FOR THE NONLINEAR WAVE SYSTEM*

ALLEN M. TESDALL†, RICHARD SANDERS‡, AND BARBARA L. KEYFITZ†

Abstract. We present numerical solutions of a two-dimensional Riemann problem for the *nonlinear wave system* which is used to describe the Mach reflection of weak shock waves. Robust low order as well as high resolution finite volume schemes are employed to solve this equation formulated in self-similar variables. These, together with extreme local grid refinement, are used to resolve the solution in the neighborhood of an apparent but mathematically inadmissible shock triple point. Rather than observing three shocks meeting in a single standard triple point, we are able to detect a primary triple point containing an additional wave, a centered expansion fan, together with a sequence of secondary triple points and tiny supersonic patches embedded within the subsonic region directly behind the Mach stem. An expansion fan originates at each triple point. It is our opinion that the structure observed here resolves the von Neumann triple point paradox for the nonlinear wave system. These solutions closely resemble the solutions obtained in [A. M. Tesdall and J. K. Hunter, *SIAM J. Appl. Math.*, 63 (2002), pp. 42–61] for the unsteady transonic small disturbance equation.

Key words. weak shock reflection, self-similar solutions, nonlinear wave system, two-dimensional Riemann problems, von Neumann paradox

1. Introduction.

Experiments in which a weak shock wave reflects off a thin wedge appear to show a pattern of reflection in which three shocks meet at a triple point. However, the von Neumann theory of shock reflection [11] shows that Mach reflection, in which three shocks and a contact discontinuity meet at a triple point, is impossible for weak shocks. This apparent disagreement between theory and experiment was pointed out by von Neumann in 1943 and is referred to as the von Neumann, or triple point, paradox [8, 13].

In [13] numerical solutions were obtained of a problem for the unsteady transonic small disturbance equations that describes the reflection of weak shocks off thin wedges. The solutions were obtained in a parameter range where regular reflection is impossible, and contain a sequence of triple points in a tiny region behind the leading triple point, with a centered expansion fan originating at each triple point. It was shown that the triple points with expansion fans observed numerically are in fact consistent with theory, and that the presence of the expansion fans at the triple points resolves the paradox. A solution containing a supersonic patch and an expansion fan was first proposed by Guderley [5, 6]. Although Guderley did not offer evidence that

this is what really occurs nor suggest that there is actually a sequence of expansion fans and triple points to resolve the triple point paradox, the term *Guderley Mach reflection* was chosen in [14] to name this new reflection pattern.

The nonlinear wave system is a simplification of the isentropic Euler equations obtained by dropping the momentum transport terms from the momentum equations [4]. Compared to the unsteady transonic small disturbance equations, the nonlinear wave system is closer in structure to the Euler equations: it is linearly well-posed in space and time, it has a characteristic structure similar to the Euler equations, and change of type takes the equations from a hyperbolic to a mixed-type system. These features make the nonlinear wave system a useful prototype for studying two-dimensional Riemann problems for the full Euler equations.

A problem for the nonlinear wave system that is the analogue of the reflection of weak shocks off thin wedges was studied in [3]. In a parameter range where regular reflection is not possible, the authors showed existence of the subsonic solution behind the Mach shock and reflected wave by solving a free boundary problem for the Mach shock. They did not find the actual reflected shock, but instead based their solution on modeling it as a continuous function with a singularity in the derivative at the sonic boundary. They showed that the composite solution they obtained is not a weak solution near the sonic line. The actual solution, therefore, is different from the construction they present, and they suggest two alternatives. Since triple point solutions do not exist for the nonlinear wave system, one possibility is that the reflected shock is a weak shock that has zero strength at the reflection point. Another possibility is Guderley Mach reflection, as obtained in [13].

Several numerical solutions of the weak shock reflection problem for the nonlinear wave system have been computed. In separate work, R. Sanders, A. Kurganov, and M. Lukacova-Medvidova (all unpublished; see [9]) computed numerical solutions of the problem studied in [3] over a wide range of parameter space where regular reflection is impossible. None of these solutions, however, are sufficiently well resolved to determine the nature of the solution near the apparent triple point. For example, it cannot be determined from any of these solutions whether the reflected shock has zero strength at the triple point, or if some other reflection pattern, such as Guderley Mach reflection, occurs. In fact, in the best resolved of these solutions, three shocks do appear to meet at a triple point—the triple point paradox.

In this paper we present high resolution numerical solutions of the shock reflection problem for the nonlinear wave system. Our most highly resolved solution shows that Guderley Mach reflection occurs at a set of parameter values where regular reflection is impossible: there is a sequence of supersonic patches behind the leading triple point, formed by a sequence of expansion fans and shocks that reflect between the sonic line and the Mach shock. This numerical solution is remarkably similar to those obtained for the unsteady transonic small disturbance equations in [13], and as in [13] the numerical results suggest that the sequence of triple points in an inviscid weak shock Mach reflection may be infinite.

Recent experimental evidence appears to confirm that the resolution of the triple point paradox obtained in [13] and again in the present paper is correct. Skews and Ashworth in [12] obtained schlieren photographs of shock reflection experiments which show a sequence of shocks and expansion waves behind the triple point in a weak shock Mach reflection. The supersonic region is extremely small, as discussed in [13], which is why it had never been observed before. Skews and Ashworth overcame this difficulty by using a specially designed shock tube and flow visualization enhancement techniques.

The numerical solutions of Sanders, Kurganov, and Lukacova-Medvidova were obtained by solving an initial-value problem for the unsteady nonlinear wave system. The problem of inviscid shock reflection off a wedge is self-similar, and there are advantages to solving the problem in self-similar, rather than unsteady, variables. In the unsteady formulation any waves which are present initially move through the numerical domain, making local grid refinement strategies difficult. By contrast, a solution of the self-similar equations is stationary, and local grid refinement near the triple point is much easier to implement. Moreover, in self-similar variables a global grid continuation procedure can be used in which a partially converged solution on a coarse grid is interpolated onto a fine grid, and then driven to convergence on the fine grid. In this paper we present numerical solutions of the shock reflection problem for the nonlinear wave system computed in self-similar coordinates. Procedures for solving the unsteady transonic small disturbance equations in self-similar variables were developed in [13], and are extended here to apply to the nonlinear wave system.

This paper is organized as follows. In section 2 we describe the shock reflection problem for the nonlinear wave system. In section 3 we discuss our approach to solving this problem numerically. The numerical results obtained are presented in section 4. In section 5 we discuss questions raised by our results. Finally, we summarize our findings in section 6.

2. The shock reflection problem for the nonlinear wave system. We consider a problem for the nonlinear wave system that is analogous to the reflection of weak shocks off thin wedges [3]. The shock reflection problem consists of the nonlinear wave system

$$\begin{aligned} &\rho_t + (\rho u)_x + (\rho v)_y = 0, \\ &(\rho u)_t + p(\rho)_x = 0, \\ &(\rho v)_t + p(\rho)_y = 0 \end{aligned} \tag{2.1}$$

in the half space $x > 0$ with piecewise constant Riemann data consisting of two states separated by a discontinuity located at $x = \kappa y$. Here, $\rho(x, y, t)$ is the density, $u(x, y, t)$ and $v(x, y, t)$ are the x and y components of velocity, respectively, and $p(\rho)$ is the pressure. For convenience, we assume a polytropic gas law

$$p(\rho) = C\rho^\gamma,$$

where C is a constant and γ is the ratio of specific heats. Letting $U = (\rho, m, n)$ denote the vector of conserved variables, where $m = \rho u$ and $n = \rho v$, the Riemann data are

$$U(x, y, 0) = \begin{cases} U_1 \equiv (\rho_1, 0, 0) & \text{if } x < \kappa y, \\ U_0 \equiv (\rho_0, 0, n_0) & \text{if } x > \kappa y. \end{cases} \tag{2.2}$$

We choose $\rho_0 > \rho_1$ to obtain an upward moving shock in the far field, and determine n_0 so that the one-dimensional wave between U_0 and U_1 at angle κ consists of a shock and a contact discontinuity with a constant middle state between them. The following expression for n_0 was obtained in [3]:

$$n_0 = \frac{1}{\kappa}\sqrt{(1 + \kappa^2)(p(\rho_0) - p(\rho_1))(\rho_0 - \rho_1)}. \tag{2.3}$$

Strictly speaking, data for reflection from a wedge of angle θ radians would explicitly include the wedge as a discontinuous change of slope, of angle θ, in the boundary

at the point $(0,0)$. In replacing a domain that imitates the physics by a half-plane $(x > 0)$, we are assuming that the reflection pattern near the apparent triple point is a local phenomenon. The physical wedge angle θ in this model is related to κ in (2.2), (2.3) by

$$\theta = \tan^{-1}(1/\kappa). \tag{2.4}$$

This problem depends on two parameters: the inverse slope κ of the incident shock, and the incident shock strength ρ_0/ρ_1 (see Appendix A). For values of κ greater than a critical value κ_R which depends on ρ_0 and ρ_1, a regularly reflected solution of (2.1)–(2.3) is impossible. In addition, triple point solutions of (2.1), in which three plane shocks separated by constant states meet at a point, do not exist (see Appendix B for a proof of this). We note that a self-similar solution in which three shocks and a linear wave meet at a point can be constructed. However, this is not consistent with the initial data, since (2.1) implies $(m_y - n_x)_t = 0$, even for weak solutions, and slip lines are characterized by nonzero values of $m_y - n_x$. Therefore, Mach reflection cannot occur when regular reflection becomes impossible, and the shock reflection problem for the nonlinear wave system embodies the triple point paradox in an essential form.

The problem (2.1)–(2.3) is self-similar, so the solution depends only on the similarity variables

$$\xi = \frac{x}{t}, \qquad \eta = \frac{y}{t}.$$

We write (2.1) in the form

$$U_t + F_x + G_y = 0, \tag{2.5}$$

where

$$U = (\rho, m, n), \qquad F = (m, p, 0), \quad \text{and} \quad G = (n, 0, p).$$

Writing (2.5) in terms of ξ, η, and a pseudo-time variable $\tau = \log t$, we obtain

$$U_\tau - \xi U_\xi - \eta U_\eta + F_\xi + G_\eta = 0. \tag{2.6}$$

As $\tau \to +\infty$, solutions of (2.6) converge to a pseudosteady, self-similar solution that satisfies

$$-\xi U_\xi - \eta U_\eta + F_\xi + G_\eta = 0. \tag{2.7}$$

Equation (2.7) is hyperbolic when $c^2(\rho) < \xi^2 + \eta^2$, corresponding to supersonic flow in a self-similar coordinate frame, and of mixed type when $c^2(\rho) > \xi^2 + \eta^2$, corresponding to subsonic flow. Here, $c(\rho) = \sqrt{p_\rho}$ denotes the local sound speed. The equation changes type across the sonic line given by

$$\xi^2 + \eta^2 = c^2(\rho). \tag{2.8}$$

3. The numerical method. In order to solve (2.6) numerically, we write it in conservative form as

$$U_\tau + (F - \xi U)_\xi + (G - \eta U)_\eta + 2U = 0. \tag{3.1}$$

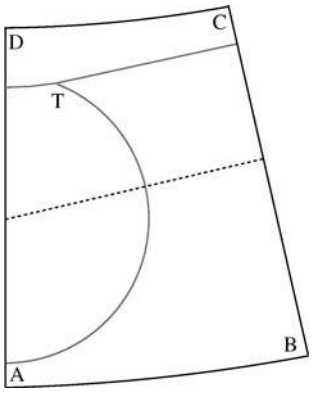

FIG. 1. *A schematic diagram of the computational domain. AD is the wall and ABCD is the far field numerical boundary. The incident shock enters the computational domain normal to BC. The incident (right of T), reflected (below T), and Mach (left of T) shocks meet at the triple point T.*

In self-similar variables, the nonlinear wave system has the form of the unsteady equations (2.5) with modified flux functions and a lower-order source term.

The essential feature of the numerical method is the capability to locally refine the grid in the area of the apparent triple point. We designed several nonuniform, logically rectangular, finite volume grids so that a given incident shock is aligned with the grid in the far field; see Figure 1. Specifically, each problem with a given incident shock angle has an associated fitted finite volume C-grid. Grid continuation is employed whereby partially converged numerical solutions are quadratically interpolated onto a refined grid. Inside a given box surrounding the triple point, uniform grid spacing is used. Outside of this box, the grid is exponentially stretched in both grid directions.

The basic finite volume scheme is quite standard. Each grid cell, Ω, is a quadrilateral, and using $\vec{\nu} = (\nu_\xi, \nu_\eta)$ to denote the normal vector to a typical side of Ω, numerical fluxes are designed to be consistent with

$$\widetilde{F}(U) = (F(U) - \xi U)\,\nu_\xi + (G(U) - \eta U)\,\nu_\eta = \begin{pmatrix} \nu_\xi m + \nu_\eta n - \bar{\xi}\,\rho \\ \nu_\xi p - \bar{\xi}\,m \\ \nu_\eta p - \bar{\xi}\,n \end{pmatrix},$$

where $\bar{\xi} = (\vec{\xi} \cdot \vec{\nu})$ and $\vec{\xi} = (\xi, \eta)$. Since $\vec{\xi}$ varies, our numerical flux formulae evaluate $\vec{\xi}$ frozen at the midpoint of each cell side. We use two distinctly different numerical fluxes in our results presented below: a first-order Lax–Friedrichs numerical flux and a high-order variant of the Roe numerical flux. The Lax–Friedrichs flux is

$$H_{LF} = \frac{1}{2}\left(\widetilde{F}(U_l) + \widetilde{F}(U_r) - \Lambda\,(U_r - U_l)\right),$$

where $\Lambda > 0$ is a scalar constant chosen to be larger than the fastest wave speed found on the computational domain. While the Lax–Friedrichs method yields only first-order accurate approximations, we regard it to be extremely robust. Our high-order Roe scheme is obtained from piecewise linear reconstruction with characteristic variable limiting, together with the Roe flux

$$H_{Roe} = \frac{1}{2}\left(\widetilde{F}(U_l) + \widetilde{F}(U_r) - R\Lambda L\,(U_r - U_l)\right),$$

where $\Lambda = \mathrm{diag}(|-\bar{\xi}-c|, |-\bar{\xi}|, |-\bar{\xi}+c|)$, and R and L are the matrices of right and left eigenvectors to the Jacobian of $\widetilde{F}$ evaluated at the midpoint $U_{Roe} = \frac{1}{2}(U_l + U_r)$. Below, we use the equation of state $p = 1/2\rho^2$. Therefore, using the midpoint for evaluation yields an exact Roe average since in this case $\widetilde{F}$ is quadratic.

Time integration is accomplished by the forward Euler method for the Lax–Friedrichs scheme:

$$\frac{U^{n+1} - U^n}{\Delta\tau} + \frac{1}{|\Omega|}\int_{\partial\Omega} H^n_{LF}\, ds + 2U^n = 0.$$

For reasons of linear stability, we use the explicit trapezoidal rule to integrate the high-order Roe scheme, as follows:

$$\frac{U^{n+1/2} - U^n}{\Delta\tau} + \frac{1}{|\Omega|}\int_{\partial\Omega} H^n_{Roe}\, ds + 2U^n = 0,$$
$$\frac{2U^{n+1} - U^{n+1/2} - U^n}{\Delta\tau} + \frac{1}{|\Omega|}\int_{\partial\Omega} H^{n+1/2}_{Roe}\, ds + 2U^{n+1/2} = 0.$$

3.1. The grid, initialization, and boundary conditions. We computed solutions of the half-space problem (2.1)–(2.3) in the finite computational domain shown schematically in Figure 1. We use a nonuniform grid that has a locally refined area of uniform grid very close to the triple point, and is stretched exponentially away from the triple point toward the outer numerical boundaries and the wall. (Exponential stretching of 1% means $\Delta x_{i+1} = 1.01\,\Delta x_i$.) In the solutions shown below, the nonuniform grids are stretched by amounts between 0.5% and 1%. The total number of grid points in our largest grid is approximately 11×10^6, of which approximately 2.5×10^6 cover a very small region surrounding the triple point. (See Figure 3(c) below where this small region is depicted.)

We impose reflecting boundary conditions, equivalent to the physical no-flow condition, on the wall AD. A standard first-order ghost cell implementation, with fictitious cells located to the left of the boundary AD, is given by

$$\begin{aligned} \rho_{-1} &= \rho_0, \\ m_{-1} &= -m_0, \\ n_{-1} &= n_0, \end{aligned} \tag{3.2}$$

where the subscripts -1 and 0 indicate values at ghost cells and at the first real cell adjacent to the boundary, respectively. In our higher-order computations we used a second-order formulation of this boundary condition. In addition, we require numerical boundary conditions on the outer computational boundaries.

In [3] expressions were given for the one-dimensional wave between U_0 and U_1 in the far field. The constant middle state $U_m = (\rho_0, m_m, n_m)$ between the contact discontinuity (the dotted line in Figure 1), located at $\xi = \kappa\eta$, and the incident shock, located at $\xi = \kappa\eta + \chi$, is given by

$$\begin{aligned} m_m &= -\sqrt{\frac{(p(\rho_0) - p(\rho_1))(\rho_0 - \rho_1)}{1+\kappa^2}}, \\ n_m &= -\kappa m_m, \\ \text{with} \quad \chi &= -\sqrt{1+\kappa^2}\sqrt{\frac{p(\rho_0) - p(\rho_1)}{\rho_0 - \rho_1}}. \end{aligned} \tag{3.3}$$

On the outer numerical boundary $ABCD$, we impose Dirichlet data corresponding to the incident shock/contact discontinuity solution in (2.2), (2.3), (3.3). We find that

$$U(\xi,\eta) = \begin{cases} U_1, & \xi < \kappa\eta + \chi, \\ U_m, & \kappa\eta + \chi < \xi < \kappa\eta, \\ U_0, & \xi > \kappa\eta. \end{cases} \tag{3.4}$$

We impose (3.4) as a boundary condition for (3.1) on $ABCD$.

4. Numerical results. We computed numerical solutions of (2.1)–(2.3) for κ equal to 1, 2, 4, and 8. In our computations we used ρ_0/ρ_1 equal to 64, 8, and 2. In the following figures we present solutions with $\rho_1 = 1$ and ρ_0/ρ_1 equal to 64. The solutions for other values of ρ_0/ρ_1 are similar to the ones presented here. For all computations, the polytropic gas law $p = \frac{1}{2}\rho^2$ was used. Figure 2 shows ρ-contour plots of the global solutions as a function of $(x/t, y/t)$. From (2.4), increasing κ corresponds to decreasing the wedge angle that is modeled by our problem. Hence, the sequence of plots in Figure 2(a)–(d) is a numerical representation of a series of shock reflection experiments in which the wedge angle is decreased, while holding the shock strength ρ_0/ρ_1 constant.

The numerical solutions appear to show a simple Mach reflection, with three shocks meeting at a triple point. The Mach shock becomes longer and weaker as κ increases, and the strength of the reflected shock also decreases when κ increases. For a fixed value of κ, the strength of the Mach shock increases as it moves away from the triple point, reaching a maximum at the wall $x = 0$.

For the value $\kappa = 1$, we used local grid refinement to obtain a highly resolved solution in the neighborhood of the triple point. In Figure 3(a)–(c), we show ρ-, m-, and n-contours and the numerically computed location of the sonic line, equation (2.8), near the triple point for $\kappa = 1$. The solution contains a small region of supersonic flow behind the triple point. The width $\Delta(x/t)$ of the patch is approximately 0.03, and the height $\Delta(y/t)$ is approximately 0.01. Here, the width $\Delta(x/t)$ is a numerical estimate of the difference between the maximum value of x/t on the sonic line and the minimum value of x/t at the rear sonic point on the Mach shock. The height $\Delta(y/t)$ is an estimate of the difference between the value of y/t at the triple point and the minimum value of y/t at the rear sonic point on the Mach shock. The width of the supersonic region is approximately 5% of the length of the Mach shock. The expansion fan centered at the leading triple point can be clearly seen. Behind the leading triple point, there is a sequence of shocks and expansion fans. The thickening of the incident shock as it moves away from the triple point in Figure 3(a)–(c) is caused by the use of a stretched grid.

The area covered by the most refined uniform grid is indicated by the box contained in Figure 3(c), and the figure caption gives the number of grid points in the most refined area of the grid. The box appears to be skewed because of the use of a C-grid. To illustrate the size and location of the refined uniform grid, in Figure 3(d) we plot ρ-contour lines over the entire numerical domain, for $\kappa = 1$. The refined grid area is too small to be visible in the main plot shown in Figure 3(d). The inset figure shows an enlargement of the solution contained within the small rectangular box centered about the reflection point, as indicated. The solution shown in the inset figure also contains a small box centered at the reflection point, indicating the approximate size and location of the region shown in Figure 3(a)–(c).

We found that, as in [13], a certain minimum grid resolution was required to resolve the supersonic region behind the triple point. As we refined the grid beyond

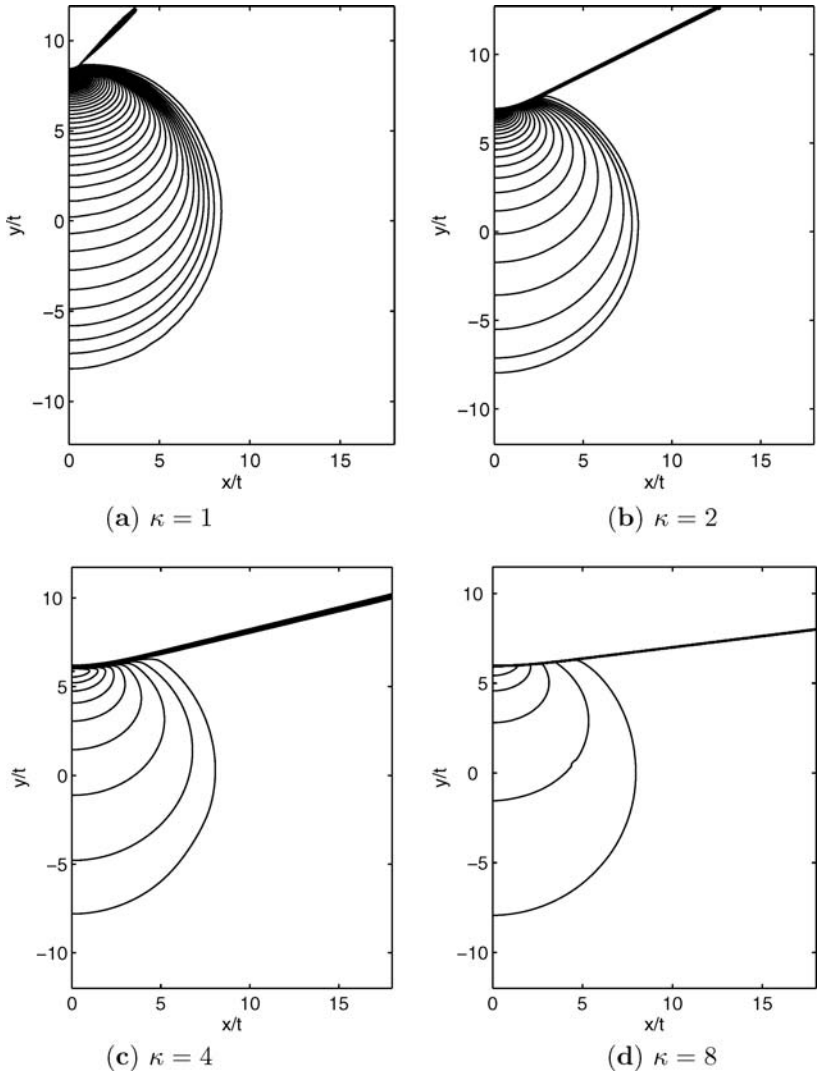

FIG. 2. *Contour plots of ρ for increasing values of κ. The ρ-contour spacing is* 1.0. *The shock strength $\rho_0/\rho_1 = 64$; $\rho_1 = 1$.*

this minimum level, details of the flow field near the triple point became clearer. Figure 4 shows ρ-contours and the sonic line near the triple point for a sequence of solutions for $\kappa = 1$, using a Lax–Friedrichs numerical flux. The sequence was computed using successively refined grids, with each grid refined by a factor of two in x/t and y/t in relation to the previous grid. The resolution of the locally refined areas is indicated on the plots. In Figure 4(a)–(b), the sonic line appears smooth. At the next level of refinement, shown in Figure 4(c), there is a steepening of the contours at the rear of the patch, and an indication of a shock forming there. Further shocks appear in our highest resolution solution in Figure 3. At resolutions lower than shown in the figure, the supersonic region disappears entirely.

There is a small discrepancy between the location of the triple point in these figures and the theoretical location of the incident shock, given in (3.3). The reason for

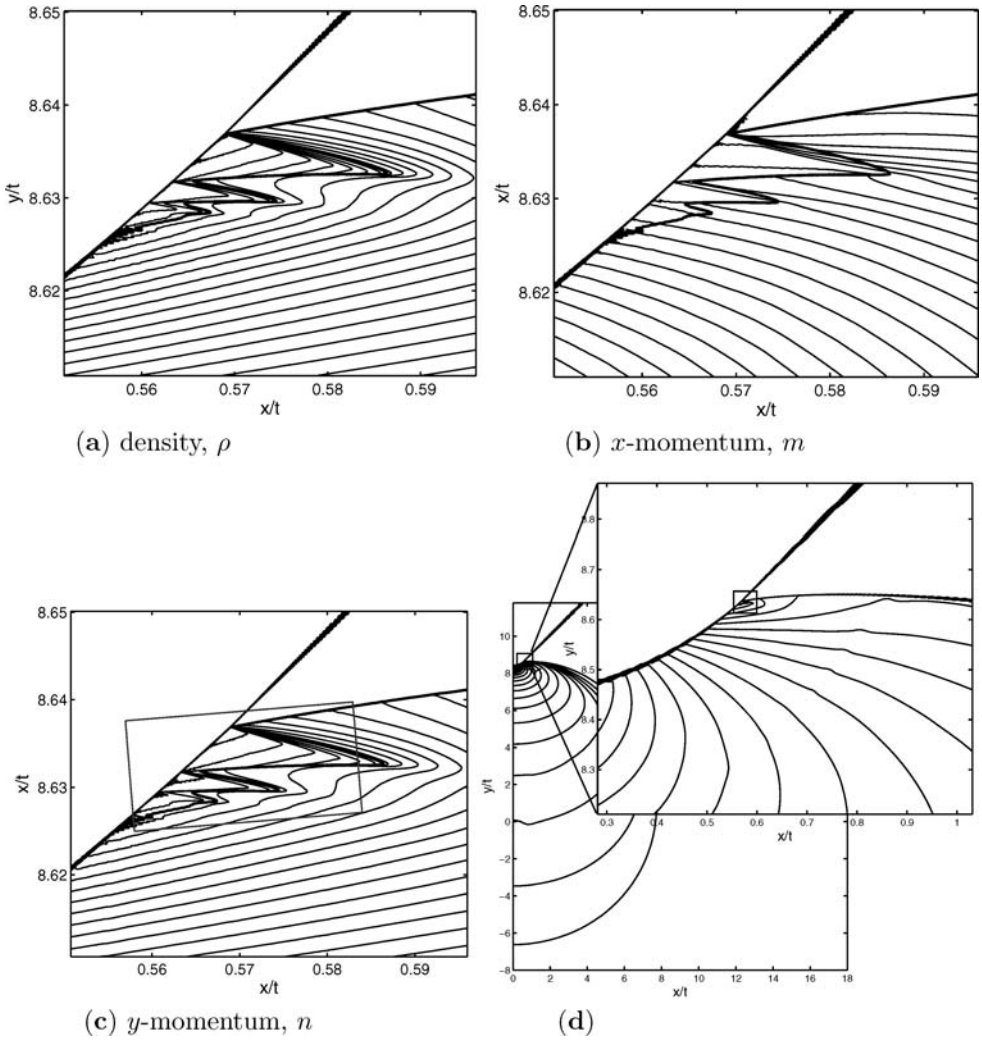

FIG. 3. *The contour plots in* (a)–(c) *show the true nature of the solution near the triple point for* $\kappa = 1$. *The* ρ*-contour spacing is* 0.5 *in* (a), *the* m*-contour spacing is* 1.5 *in* (b), *and the* n*-contour spacing is* 5.25 *in* (c). *The heavy line is the sonic line. The box in* (c) *indicates the area of the refined uniform grid, which has* 2048×1320 *grid points. A second-order Roe numerical flux was used. The plot in* (d) *is an illustration of the approximate size and location of the region shown in the plots in* (a)–(c), *which is contained in the small rectangular box shown in the inset figure; the plot shows contour lines of* ρ.

the discrepancy is that the numerical boundary conditions did not give an incident shock that was of exactly constant strength and exactly straight in the $(x/t, y/t)$ coordinates. However, the deviation of the numerical solution for the incident shock from the exact uniform solution was small. For example, in our numerical solution shown in Figure 3, the numerically computed value of the y/t coordinate of the triple point differs by 0.1% from the theoretical value obtained from (3.3) using the numerically computed value of x/t, and the nonuniformity in ρ in the state behind the incident shock near the triple point is about 0.6%. We tried a number of different implementations of the numerical boundary conditions and computational mesh, but none of

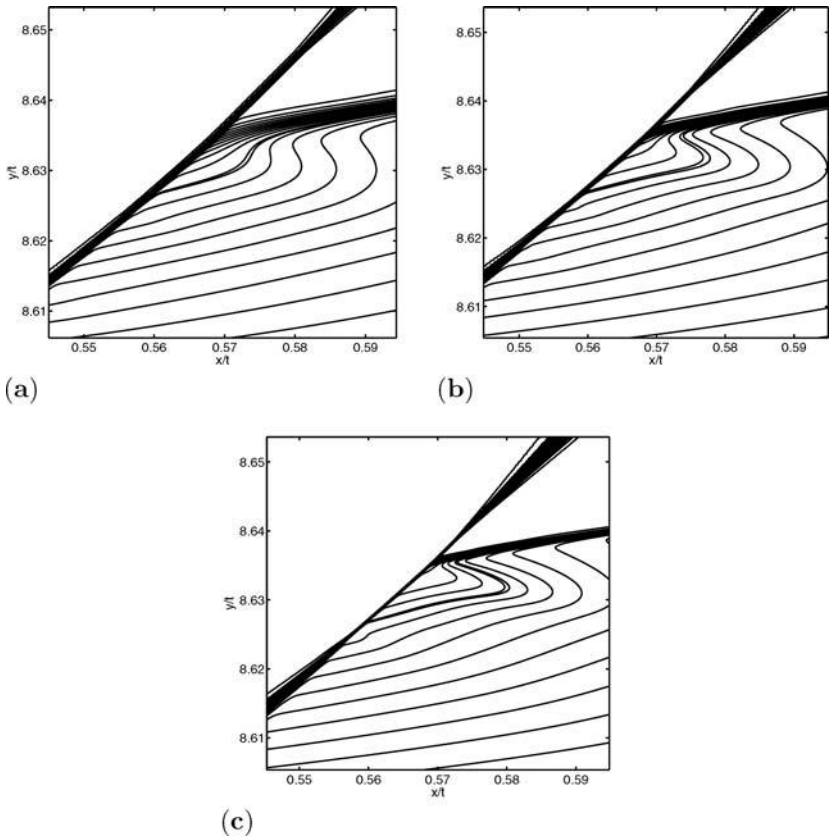

FIG. 4. *A sequence of contour plots illustrating the effect of increasing grid resolution on the numerical solution. The solutions plotted here are for* $\kappa = 1$. *The figures show* ρ*-contours in the refined grid area near the triple point, with a* ρ*-contour spacing of* 1.0. *Each grid is refined by a factor of two in relation to the previous grid. The region shown includes the refined uniform grid area. The heavy line is the sonic line. In* (a)*, the refined uniform grid contains* 760×760 *grid points. A supersonic region is visible as a bump in the sonic line, but it is poorly resolved. In* (b)*, the refined uniform grid area contains* 1280×1024 *grid points. them gave an incident shock that was of exactly constant strength. Nevertheless, the presence of a supersonic patch did not depend on the particular implementation.

In the computation for $\kappa = 1$, we partially converged a solution on a coarse grid, resampled the data onto a refined grid, and repeated the process until the necessary resolution was obtained. Three consecutive intermediate solutions in this computation are shown in Figure 4. Computations on less refined grids were made using a Lax–Friedrichs numerical flux, and after partial convergence on the most refined grid we switched to the more expensive Roe method. Figure 5 shows ρ-contours for a solution made using a first-order Roe scheme. Further computation using a second-order Roe scheme yielded the final solution shown in Figure 3. The solution on the final grid was evolved until no further change was observed in the details of the solution near the triple point. The solutions shown in Figures 4(c), 5, and 3 were obtained on the same grid using different methods. All three of the solutions contain a small supersonic region behind the triple point. The solutions shown in Figures 5 and 3,

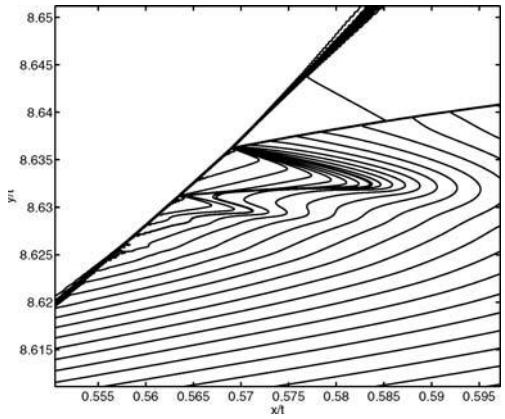

FIG. 5. *A contour plot of ρ near the triple point computed using a first-order Roe method. The number of points in the refined uniform grid is the same as in Figure* 4, *which shows a Lax–Friedrichs solution, and in Figure* 3(a)–(c), *which shows a second-order Roe method solution. The ρ-contours are plotted at the same levels of ρ as in Figure* 3(a).

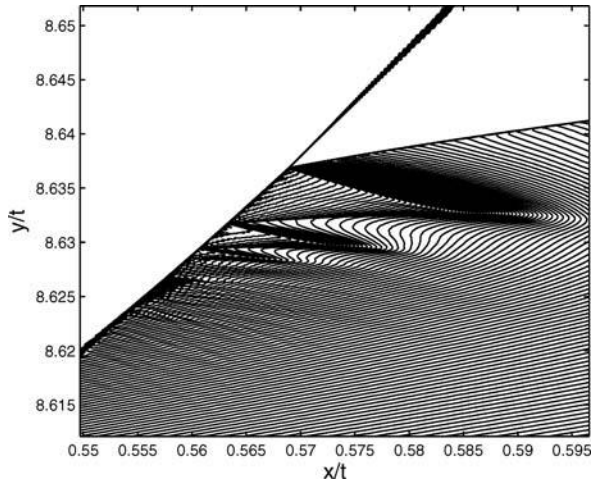

FIG. 6. *A detailed plot of contour lines for ρ illustrating Guderley Mach reflection. The ρ-contour spacing is* 0.1. *Three reflected shock/expansion wave pairs are clearly visible, with indications of a fourth. The region shown contains the refined uniform grid, which has* 2048×1320 *grid points.*

which are more highly resolved, contain a sequence of supersonic patches and triple points, which is better defined in Figure 3.

In Figure 6 we plot closely spaced ρ-contours to give a detailed picture of the sequence of shocks and expansion waves in a Guderley Mach reflection for $\kappa = 1$. Each shock-expansion pair in the sequence is smaller and weaker than the one preceding it. Three reflected shocks appear to be visible in the plot. From the numerical data, their approximate strengths, beginning with the leading reflected shock, are given in Table 1. The jump $[\rho]$ in ρ across a reflected shock is measured near the point where the flow behind the shock is sonic. This point is very close to the corresponding triple point on the Mach shock, as shown in Figure 3.

TABLE 1

Approximate values of the reflected shock strengths for the three reflected shocks visible in Figure 6, beginning with the leading reflected shock, from the numerical data. For each shock, ρ_1 and ρ_0 denote the approximate values of ρ ahead of and behind the shock, respectively.

Shock	ρ_1	ρ_0	$[\rho]$
1	64	76	12
2	72	75	3
3	74	75	1

5. Discussion. These numerical results are remarkably similar to the computed solutions of the shock reflection problem for the unsteady transonic small disturbance equations in [13]. In both cases, a weak shock reflection in a parameter range where regular reflection is impossible results in a sequence, possibly infinite, of triple points and supersonic patches embedded in the subsonic flow behind the Mach and reflected shocks. The unsteady transonic small disturbance equations can be derived from the full Euler equations by a systematic asymptotic expansion, and are considered to give an adequate description of the physical flow near the shock interaction point for weak shocks and small wedge angles. The nonlinear wave system, however, is not a systematic reduction of the Euler equations, and it does not appear to have any immediate physical relevance. It is therefore noteworthy that the shock reflection problem for the nonlinear wave system has a solution that resembles the solutions in [13], and is consistent with the experimental results in [12].

The nonlinear wave system has a characteristic structure similar to the two-dimensional Euler equations: nonlinear acoustic waves coupled (weakly) with linearly degenerate waves. The nonlinear wave system also respects the spatial (Euclidean) symmetries of gas dynamics, but not the space-time (Galilean) symmetry. In fact (see [10]), they are essentially the simplest system one can construct with these symmetries. The existence of a Guderley Mach reflection solution for a system that is only loosely related to gas dynamics suggests that the behavior may be typical of equations with this characteristic structure, and is not restricted to equations that describe gas dynamic phenomena. We conjecture that a sequence of supersonic patches and triple points is a generic feature of two-dimensional Riemann problems for some class of hyperbolic systems of conservation laws. Possibly this class is characterized by "acoustic waves," as defined in [2]. It is possible that numerical solutions of the weak shock reflection problem for the full Euler equations will contain a sequence of supersonic patches as well.

An important feature of the numerical solution is the small size of the supersonic region. In our solution for $\kappa = 1$, the width of the supersonic patch is approximately 5% of the length of the Mach shock. This is somewhat larger than the supersonic regions in the solutions in [13], which were obtained over a range of parameter values and varied in height from approximately 0.05% to 3% of the length of the Mach shock. Based on the dependence of patch size on wedge angle observed in [13], we expect solutions for larger values of κ to contain even larger supersonic regions. However, the strength of the reflected shock near the triple point decreases as κ increases, making it very difficult to resolve numerically the details of the solution near the triple point. We have displayed a solution with $\kappa = 1$ because it offers a good compromise between the size of the supersonic region and the strength of the sequence of reflected shocks and expansions.

One of the scenarios proposed in [3] for resolving the triple point paradox in the nonlinear wave system is that the reflected shock have zero strength at the shock

interaction point. In that case, there would be no triple point, and presumably no supersonic patch. We have obtained solutions, using different numerical schemes, which contain a supersonic region behind the triple point in a weak shock reflection. In these solutions, the reflected shocks have finite strength at the point where they collide with the Mach shock. Although we have not obtained numerical evidence of the zero strength reflected shock solution, we note that in the problem studied in [3], it is assumed that κ is large enough that the incident shock intersects the sonic circle, equation (2.8), corresponding to the state U_0 behind the shock. For shock reflection data with $\kappa = 1$, the incident shock does not intersect the sonic circle, so the partial solution presented in [3] is not available here. We also note, however, that in [13], several solutions were obtained in a parameter range for which the incident shock does intersect the sonic line for the state behind the incident shock. All of these solutions contained a reflected shock of nonzero strength at the triple point, and a supersonic region. For the nonlinear wave system, since we have obtained a solution containing a supersonic region at only one set of parameter values, we do not know if Guderley Mach reflection occurs over the entire set of parameter values for which regular reflection is impossible, or if solutions at large enough values of κ contain a reflected shock with zero strength at the triple point.

6. Conclusion. We have presented numerical evidence of a structure of reflected shocks and expansion waves, and a sequence of triple points and supersonic patches, in a small region behind the leading triple point in a shock reflection problem for the nonlinear wave system. This result is consistent with previous numerical solutions of a shock reflection problem for the unsteady transonic small disturbance equations, and with recent experimental results for weak shocks reflecting off thin wedges.

Appendix A. Symmetry. Equation (2.1) admits the usual Euclidean symmetries of gas dynamics (translation invariance and equivariance under rotation and reflection in the plane), but not the Galilean symmetry. For a polytropic gas law $p(\rho) = C\rho^\gamma$, where γ is the ratio of specific heats and C is a constant, it is also invariant under the scaling

$$(x, y) \mapsto \rho_1^{\frac{\gamma-1}{2}}(x, y), \qquad \rho \mapsto \rho_1\rho, \qquad (m, n) \mapsto \rho_1^{\frac{\gamma+1}{2}}(m, n).$$

Based on this, we see that solutions of the nonlinear wave system depend on the density only through a characteristic density ratio ρ_0/ρ_1, or equivalently, through the velocity ratio or the Mach number $M = c(\rho_0)/c(\rho_1) = (\rho_0/\rho_1)^{(\gamma-1)/2}$.

Appendix B. Nonexistence of triple points. To examine triple points in the nonlinear wave system we note, first, that this system does not have the Galilean invariance of the gas dynamics equations, so we cannot assume that the flow is stationary at a triple point. However, because of rotational symmetry we can assume that one of the shocks is horizontal, and we do so to simplify the calculation. We can also choose one set of momentum components to be zero.

We label the horizontal shock S_a, and proceeding counterclockwise, the other two are S_b and S_c (Figure 7). The state between S_a and S_b is $U_1 = (\rho_1, 0, 0)$; the other two states, also proceeding counterclockwise, are U_2 and $U_0 = (\rho_0, 0, n_0)$. The value of ρ_0 can be any number greater than ρ_1. Note that the component $m_0 = 0$ because S_a is horizontal. The equation of S_a is $\{\eta = \omega_a\}$, where $\omega_a = \sqrt{(p_0 - p_1)/(\rho_0 - \rho_1)}$, and $n_0 = \omega_a[\rho] = \sqrt{(p_0 - p_1)(\rho_0 - \rho_1)}$, using (2.3). (Note that $\kappa_a = \infty$ here and that U_0 corresponds to U_m in (3.3).)

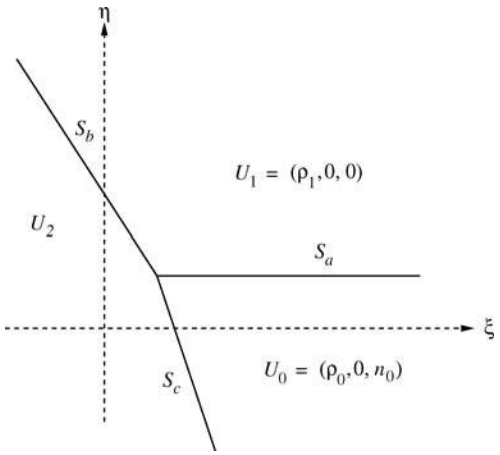

FIG. 7. *Triple point configuration.*

We introduce the notation $P_{ab} = \sqrt{(p_a - p_b)(\rho_a - \rho_b)}$. We have the following proposition.

PROPOSITION B.1. *For any convex equation of state $p(\rho)$, there is no nontrivial set of solutions to the Rankine–Hugoniot equations for constant states $\{U_0, U_1, U_2\}$ separated by shocks S_a, S_b, S_c, irrespective of whether the three shocks intersect in a point or not.*

Proof. The Rankine–Hugoniot equations at S_b and S_c imply (see [4, Appendix A])

$$m_2 - m_1 = \frac{P_{21}}{\sqrt{1+\kappa_b^2}}, \qquad m_2 - m_0 = \frac{P_{20}}{\sqrt{1+\kappa_c^2}},$$
$$n_2 - n_1 = -\frac{P_{21}}{\sqrt{1+\kappa_b^2}}\kappa_b, \quad n_2 - n_0 = -\frac{P_{20}}{\sqrt{1+\kappa_c^2}}\kappa_c.$$

Using the values $m_1 = m_0 = n_1 = 0, n_0 = P_{01}$, we get two equations:

$$m_2 = \frac{P_{21}}{\sqrt{1+\kappa_b^2}} = \frac{P_{20}}{\sqrt{1+\kappa_c^2}}, \quad n_2 = -\frac{P_{21}}{\sqrt{1+\kappa_b^2}}\kappa_b = P_{01} - \frac{P_{20}}{\sqrt{1+\kappa_c^2}}\kappa_c. \tag{B.1}$$

In principle, we can solve this pair of equations to obtain κ_b and κ_c as functions of the data ρ_0 and ρ_1. We get a 1-parameter family of solutions parameterized by ρ_2. However, the solutions obtained are not real numbers. For, if we substitute the first equation in (B.1) into the second, we get

$$-\kappa_b \frac{P_{20}}{\sqrt{1+\kappa_c^2}} = P_{01} - \kappa_c \frac{P_{20}}{\sqrt{1+\kappa_c^2}},$$

or

$$\kappa_b = \kappa_c - \sqrt{1+\kappa_c^2}\frac{P_{01}}{P_{20}}. \tag{B.2}$$

Now square the first relation in (B.1), write it as

$$1 + \kappa_b^2 = (1+\kappa_c^2)\frac{P_{21}^2}{P_{20}^2},$$

and substitute (B.2), to obtain

$$1+\left(\kappa_c-\sqrt{1+\kappa_c^2}\frac{P_{01}}{P_{20}}\right)^2=(1+\kappa_c^2)\frac{P_{21}^2}{P_{20}^2},$$

or

$$(P_{20}^2+P_{01}^2-P_{21}^2)\sqrt{1+\kappa_c^2}=2\kappa_c P_{01}P_{20}.$$

Square this and solve for κ_c^2:

$$\kappa_c^2=\frac{(P_{20}^2+P_{01}^2-P_{21}^2)^2}{4P_{01}^2P_{20}^2-(P_{20}^2+P_{01}^2-P_{21}^2)^2}.$$

Now, after a calculation,

$$P_{20}^2+P_{01}^2-P_{21}^2=(\rho_2-\rho_0)(p_1-p_0)+(\rho_1-\rho_0)(p_2-p_0).$$

So

$$4P_{01}^2P_{20}^2-(P_{20}^2+P_{01}^2-P_{21}^2)^2=-[(\rho_2-\rho_0)(p_1-p_0)-(\rho_1-\rho_0)(p_2-p_0)]^2\le 0.$$

In fact, this quantity is less than zero unless

$$\frac{p_2-p_0}{\rho_2-\rho_0}=\frac{p_1-p_0}{\rho_1-\rho_0}.$$

For a convex function p, this implies $\rho_2=\rho_1$, a degenerate case with only two distinct states.

Thus, no solutions exist. Note that the proof did not require the three shocks to intersect in a point, and that therefore this is a somewhat stronger result than simply the nonexistence of triple points. □

In a similar manner it is possible to show that, as in gas dynamics, a self-similar solution consisting of three shocks and a linear wave meeting at a point can be constructed. However, as mentioned in section 2, because of the invariance in time of the quantity (m_y-n_x), the linear characteristic coordinate, a linear wave cannot be present in the solution unless it is present in the data. For the data given in (2.2), therefore, solutions containing a triple point with a linear wave cannot exist. The same triple point paradox occurs in gas dynamics, of course, where solutions containing a triple point with a contact discontinuity cannot occur for sufficiently weak shocks (see [7] for a discussion of this).

GLOBAL STABILITY FOR A VIRUS DYNAMICS MODEL WITH NONLINEAR INCIDENCE OF INFECTION AND REMOVAL*

PAUL GEORGESCU† AND YING-HEN HSIEH‡

Abstract. Global dynamics of a compartmental model which describes virus propagation in vivo is studied using the direct Lyapunov method, where the incidence rate of the infection and the removal rate of the virus are assumed to be nonlinear. In the case where the functional quotient between the force of infection and the removal rate of the virus is a nonincreasing function of the virus concentration, the existence of a threshold parameter, i.e., the basic reproduction number or basic reproductive ratio, is established and the global stability of the equilibria is discussed. Moreover, in the absence of the above-mentioned monotonicity property, estimations for the sizes of the domains of attraction are given. Biological significance of the results and possible extensions of the model are also discussed.

Key words. virus propagation, compartmental model, global stability, Lyapunov functional, endemic equilibrium, basic reproduction number

1. Introduction.

We consider a compartmental model for the propagation of a virus in vivo, in the form

$$\text{(S)} \qquad \begin{cases} S' = n(S) - c(S)f(V), \\ E' = c(S)f(V) - c_1 i(E), \\ I' = c_2 i(E) - c_3 p(I), \\ V' = c_4 p(I) - r(V). \end{cases}$$

Here, S denotes the concentration of the cells in the susceptible (i.e., uninfected) class, E denotes the concentration of cells in the exposed (i.e., latent) class, I denotes the concentration of cells in the infected class, and V denotes the concentration of the virus itself.

The intrinsic growth rate of the susceptible class, which includes both production of new cells and natural mortality of cells, is given by $n(S)$ with all the newly produced cells assumed to be susceptible. The movement of cells from the exposed class into the infected class and the production of free virus from infected cells are given by $c_2 i(E)$ and $c_4 p(I)$, respectively. By $c_1 i(E)$ and $c_3 p(I)$, we denote the removal of the exposed and infected classes, respectively, which include the mortality of cells in the above-mentioned classes.

It is assumed that the infection process is characterized by the incidence rate $c(S)f(V)$, where $c(S)$ denotes the contact function at concentration S and $f(V)$ denotes the force of infection by virus at concentration V. We note that our incidence

rate is sufficiently general to encompass many forms of commonly used incidence rate, including simple mass action. The removal rate of the virus is denoted by $r(V)$. All functions c, f, i, p, r, n are allowed to be nonlinear and all constants c_1, c_2, c_3, c_4 are assumed to be positive.

We thereby assume that the major infection pathway is virus-to-cell, since the cell-to-cell pathway is sometimes less documented and therefore less considered, particularly in diseases such as AIDS (see Perelson and Nelson [18]).

While this model has been studied in Bonhoeffer et al. [1], Korobeinikov [7], Nowak and May [14], and Perelson and Nelson [18], among others, for linear c, f, i, p, r, n, it is perhaps important to account for a number of nonlinear features of the biological phenomena which are involved, especially for the nonlinearity of the incidence rate, which is influenced by the availability of susceptible cells and by the force of infection of viral cells. As the concentration of viral cells becomes higher, the simple mass action law βSV may not necessarily suffice. Moreover, the rate at which an infected cell or virus will die as a function of their concentrations is generally not known, and hence we make a further generalization by assuming that the removal rate is also nonlinear. For a detailed discussion on the virus dynamics of HIV, readers are referred to Perelson and Nelson [18].

We note that in (S), for $i(x) = x$ and $p(x) = x$, the constant $1/c_1$ represents the average time spent by a cell in the latent state, while $1/c_3$ represents the average lifetime of an infected cell. Also, $c_1 \geq c_2$ and $c_1 - c_2$ represents the mortality rate of the exposed cells, while c_4 relates to the production of virus from infected cells.

As noted by Korobeinikov in [7], if there is no exposed class E and consequently $c(S)f(V)$ represents the movement of cells from the susceptible class directly into the infected class, the (reduced three-dimensional) system (S) is equivalent to a SEIR model with a constant population assumption. It is therefore expected that the dynamics of our model will share some features with the dynamics of a SEIR model. Some perspectives and results from the global stability theory for SEIR models would also be relevant for our discussion. See Korobeinikov and Maini [8], Li et al. [11], Li and Muldowney [12], and Li, Muldowney, and van den Driessche [13] for global stability results for SEIR models. However, in [11, 12, 13] the approach is essentially geometrical, using a stability criteria which extends the Poincaré–Bendixson theorem and ruling out periodic orbits, rather than constructing a Lyapunov functional.

A related investigation pertaining to the dynamics of infectious disease models which incorporated nonlinear incidence rates of a very general form has recently been performed by Korobeinikov and Maini in [9] by using the Lyapunov method. In [9], the local stability of the equilibria for SIRS and SEIRS models has been considered assuming that the incidence rate is given by an arbitrary function $f(S, I, N)$, while the global stability of the equilibria for SIR and SEIR models has been considered assuming that the incidence rate is of the form $f(I)g(S)$. However, apart from the incidence rate, the other functions which appear in the models considered in [9] are linear and a constant population assumption is used, while for our model full nonlinearity is assured and a constant population assumption would not be an option. Moreover, the analysis performed in [9] is done in a somewhat different manner, with a focus on the role of the concavity of the nonlinear incidence rate in the existence and stability of the endemic equilibrium.

Substantial results regarding the global dynamics of a three-dimensional HIV model have been obtained by De Leenheer and Smith [3] using a different approach; their result distinguishes whether or not the term $-kVT$, which models the loss of a free virus particle once it enters the target cell, can be absorbed into the general loss

term $-\gamma V$. In [3], V is the concentration of free virus particles in the blood and T is the concentration of T cells. De Leenheer and Smith start with general assumptions on the function f which models T cell dynamics in a healthy individual and then specialize their results for two particular functions: $f_1(T) = \delta - \alpha T + pT(1 - T/T_{max})$ as used by Perelson and Nelson in [18] and $f_2(T) = \delta - \alpha T$ as used by Nowak and May in [14]. Certain linearity assumptions on some other functions appearing in the model are also made.

In the particular case in which the term $-kVT$ is absorbed into the general loss term (as done in [18] and [14])) and $f = f_2$, the model used in [3] can be thought of as a reduced version of our model, with no exposed class and extra linearity assumptions. However, the proof of our global stability result uses in an unavoidable manner the monotonicity assumption on n, which corresponds to f in [3], and therefore it can accommodate the case $f = f_2$ only and not the case $f = f_1$. In particular, our model does not admit orbitally asymptotically stable periodic solutions, which are obtained in [3] for $f = f_1$; see [3, Theorem 1] for details.

The paper is organized in the following manner. We propose the model to be studied in section 2 and discuss its well-posedness. In section 3 we give results on the stability of the disease-free equilibrium and persistence of the system, while sections 4 and 5 contain discussions on the existence, uniqueness, and global stability of the endemic equilibrium. Finally, in section 6, we give some remarks on the biological interpretation of our results, as well as some further extensions of the model one can make.

2. The model and its well-posedness. We assume that c, f, i, p, r are real locally Lipschitz functions defined at least on $[0, \infty)$ which satisfy

$$\begin{aligned} c(0) = f(0) = i(0) = p(0) = r(0) = 0, \\ c(t), f(t), i(t), p(t), r(t) > 0 \quad \text{for } t > 0 \end{aligned}$$

and that n is a real locally Lipschitz function defined at least on $[0, \infty)$ with $n(0) > 0$ such that the equation $n(S) = 0$ has a single solution S_0. We also assume that

$$\begin{aligned} (n(S) - n(S_0))(S - S_0) < 0 \quad \text{for } S \neq S_0, \\ (c(S) - c(S_0))(S - S_0) > 0 \quad \text{for } S \neq S_0 \end{aligned} \tag{2.1}$$

together with

$$\int_{0+}^{1} \frac{1}{\varphi(\tau)} d\tau = +\infty \quad \text{for all } \varphi \in \{c, f, i, p\}. \tag{D}$$

Note that (2.1) is satisfied if, for instance, n is strictly decreasing and c is strictly increasing. We also suppose that there are k_n, k_i, k_p, k_v, $\tilde{k}_n > 0$ such that

$$\begin{aligned} &n(S) \leq \tilde{k}_n - k_n S \text{ for } S \geq 0, \quad i(E) \geq k_i E \text{ for } E \geq 0, \quad p(I) \geq k_p I \text{ for } I \geq 0, \\ &r(V) \geq k_r V \text{ for } V \geq 0. \end{aligned} \tag{G}$$

The set of growth conditions (G) will be used to establish, in our general setting, the global existence of the solution for the Cauchy problem associated with the system (S). We note that these conditions may be dropped if the global existence property is known or the a priori boundedness of the solutions may be established by other methods. We shall indicate in section 6 how to remove conditions (G) at the expense

of other conditions on the behavior of c, f, i, p near $+\infty$ if f/r is nonincreasing on $(0, \infty)$.

First, it can be easily shown that a solution of the system (S) which starts in $[0, \infty)^4$ remains there on its whole interval of existence. To this purpose, we note that the vector (R_1, R_2, R_3, R_4) points inside $Q = [0, \infty)^4$ at all points of ∂Q, where R_1, R_2, R_3, and R_4 are the right-hand sides appearing in (S), and hence Nagumo's tangency conditions are satisfied. See [15] for details.

From our assumptions, it is clear that the system (S) has a unique saturated (i.e., nonextendable) solution for any initial data $(S(0), E(0), I(0), V(0))$. Using (G), it is possible to prove that all saturated solutions are global. To this aim, note that

$$\left(S + E + \frac{c_1}{2c_2} I + \frac{c_1 c_3}{4c_2 c_4} V\right)' \leq \tilde{k}_n - k_n S - \frac{c_1 k_i}{2} E - \frac{c_1 c_3}{4c_2} k_p I - \frac{c_1 c_3}{4c_2 c_4} k_r V,$$

it follows that there is $\delta = \delta(k_n, k_i, k_p, k_r, c_1, c_2, c_3, c_4) > 0$ small enough such that

$$\left(S + E + \frac{c_1}{2c_2} I + \frac{c_1 c_3}{4c_2 c_4} V\right)' + \delta \left(S + E + \frac{c_1}{2c_2} I + \frac{c_1 c_3}{4c_2 c_4} V\right) \leq \tilde{k}_n,$$

which implies that

$$\begin{aligned} &S + E + \frac{c_1}{2c_2} I + \frac{c_1 c_3}{4c_2 c_4} V - \frac{\tilde{k}_n}{\delta} \\ &\quad \leq \left(S(0) + E(0) + \frac{c_1}{2c_2} I(0) + \frac{c_1 c_3}{4c_2 c_4} V(0) - \frac{\tilde{k}_n}{\delta}\right) e^{-\delta t} \quad \text{for } t \geq 0, \end{aligned}$$

and therefore S, E, I, V are bounded on their maximal interval of existence. It follows that the functions $S(t)$, $E(t)$, $I(t)$, $V(t)$ are defined on $[0, \infty)$, and so the Cauchy problem with nonnegative initial data is well-posed for the system (S). Moreover, if we denote

$$F = \left\{(S, E, I, V) \in [0, \infty)^4; S + E + \frac{c_1}{2c_2} I + \frac{c_1 c_3}{4c_2 c_4} V \leq \frac{\tilde{k}_n}{\delta}\right\},$$

it follows that F is a feasible region for the system (S). Of course, the feasible region determined above is neither minimal nor unique, and the parameter δ above is obviously not uniquely determined. We shall simply choose

$$\delta = \min\left(k_n, \frac{c_1}{2} k_i, \frac{c_3}{2} k_p, k_r\right). \tag{2.2}$$

If S is small, then $S' = n(S) - c(S)F(V) > 0$ if V stays in a bounded set, since $n(0) > 0$ and $\lim_{S \to 0} c(S) = 0$, and we may infer that for any $S(0) > 0$ there is $\varepsilon_{S(0)} > 0$ such that $S(t) \geq \varepsilon_{S(0)}$ for all $t > 0$. This means that all solutions which start with positive $S(0)$ do not reach any point with $S = 0$ in future time. If $S(0) = 0$, then $S' > 0$ in a vicinity of 0 and, again, $S(t)$ raises over a certain minimum value (of course, the case in which $S(0) = 0$ does not make much biological sense). Also, it can be seen that the only w-limit point of (S) on the boundary of F is the disease-free equilibrium $(S_0, 0, 0, 0)$ and the only points on the boundary of $[0, \infty)^4$ which can be attained in finite time are situated on $[OS$, the positive S-semiaxis containing the origin.

3. Stability of disease-free equilibrium. Since the equation $n(S) = 0$ has a single solution S_0 and $f(0) = i(0) = p(0) = r(0) = 0$, it is easy to see that the system (S) admits a unique disease-free equilibrium $(S_0, 0, 0, 0)$. We now turn our attention to the study of its stability.

Consider the Lyapunov functional

$$U_1(S, E, I, V) = \int_{S_0}^{S} \frac{c(\tau) - c(S_0)}{c(\tau)} d\tau + E + \frac{c_1}{c_2} I + \frac{c_1 c_3}{c_2 c_4} V.$$

Since $(c(S) - c(S_0))(S - S_0) > 0$ for $S \neq S_0$, it is seen that U_1 increases whenever any of $|S - S_0|$, E, I, V increases and $U_1(S, E, I, V) \geq 0$ for all $S, E, I, V \geq 0$, while $U_1(S, E, I, V) = 0$ if and only if $(S, E, I, V) = (S_0, 0, 0, 0)$.

We now compute the time derivative of U_1 along the solutions of (S). It is seen that

$$\begin{aligned} \dot{U_1} = \left(1 - \frac{c(S_0)}{c(S)}\right)(n(S) - c(S)f(V)) + (c(S)f(V) - c_1 i(E)) \\ + \frac{c_1}{c_2}(c_2 i(E) - c_3 p(I)) + \frac{c_1 c_3}{c_2 c_4}(c_4 p(I) - r(V)), \end{aligned}$$

and since $n(S_0) = 0$, we can deduce that

$$\dot{U_1}(S, E, I, V) = \left(1 - \frac{c(S_0)}{c(S)}\right)(n(S) - n(S_0)) + \left[c(S_0)f(V) - \frac{c_1 c_3}{c_2 c_4} r(V)\right]. \tag{3.1}$$

Due to (2.1), it is easily seen that

$$\left(1 - \frac{c(S_0)}{c(S)}\right)(n(S) - n(S_0)) < 0 \quad \text{for } S \neq S_0, \tag{3.2}$$

and the first term in the right-hand side of (3.1) is negative. It is then seen that the stability of the disease-free equilibrium is related to the sign of the remaining term in the right-hand side of (3.1).

THEOREM 3.1. *Suppose that there is a number $V_R > 0$ such that*

$$c(S_0)\frac{f(V)}{r(V)}\frac{c_2 c_4}{c_1 c_3} \leq 1 \quad \textit{for } V \in (0, V_R), \tag{3.3}$$

and let $m = U_1(S_0, 0, 0, V_R)$. Then the disease-free equilibrium $(S_0, 0, 0, 0)$ is locally asymptotically stable and its domain of attraction includes the set

$$M_m = \left\{(S, E, I, V) \in (0, \infty) \times [0, \infty)^3; U_1(S, E, I, V) < m\right\}.$$

Proof. From (3.1), (3.2), and (3.3), it is seen that $\dot{U_1}(S, E, I, V) \leq 0$ for $0 \leq V < V_R$, with equality if and only if $S = S_0$ and either $V = 0$ or the equality in (3.3) holds.

Let us denote $\tilde{M} = \left\{(S, E, I, V) \in (0, \infty) \times [0, \infty)^3, 0 \leq V < V_R\right\}$ and take $k < m$ arbitrary. Since for all $V \geq V_R$ one has $U_1(S, E, I, V) \geq U_1(S_0, 0, 0, V_R)$, it is seen that $M_k \subset \tilde{M}$. Consequently, $U_1(S, E, I, V) \leq 0$ on M_k, with equality if and only if $S = S_0$ and the equality in (3.3) holds.

We now find the invariant subsets $\tilde{P}$ within the set

$$P = \left\{(S, E, I, V) \in M_k; \dot{U_1}(S, E, I, V) = 0\right\}.$$

Since $S = S_0$ on $\tilde{P}$ and consequently $S' = -c(S_0)f(V)$, it is seen that $V = 0$ and one similarly deduces that $E = I = 0$; that is, the only invariant subset of P is the singleton $\tilde{P} = \{(S_0, 0, 0, 0)\}$. From LaSalle's invariance principle (see LaSalle [10]) and the fact that $k < m$ was arbitrary, the conclusion follows. □

To complement Theorem 3.1, we further consider the case in which the disease-free equilibrium is unstable and give some remarks related to the persistence of the system. The system (S) is said to be *uniformly persistent* on F if there is a constant $\varepsilon_0 > 0$ such that any solution of (S) which starts in $(S(0), E(0), I(0), E(0)) \in \overset{\circ}{F}$ satisfies

$$\liminf_{t\to\infty} S(t) \geq \varepsilon_0, \quad \liminf_{t\to\infty} E(t) \geq \varepsilon_0, \quad \liminf_{t\to\infty} I(t) \geq \varepsilon_0, \quad \liminf_{t\to\infty} V(t) \geq \varepsilon_0.$$

See also Butler, Freedman, and Waltman [2] or Hofbauer and So [6].

Consider the Lyapunov function

$$U_2(S, E, I, V) = E + \frac{c_1}{c_2} I + \frac{c_1 c_3}{c_2 c_4} V.$$

Similar to the derivation of (3.1), the time derivative of U_2 along the solutions of (S) is given by

$$\dot{U}_2(S, E, I, V) = c(S)f(V) - \frac{c_1 c_3}{c_2 c_4} r(V). \tag{3.4}$$

Obviously, if (S) is uniformly persistent, then the disease remains endemic and stability for the disease-free equilibrium is excluded. In this regard, we have already observed that if (3.3) is satisfied on some interval $(0, V_R)$, then the disease-free equilibrium is locally asymptotically stable. If, on the other hand, the opposite of (3.3) is satisfied on some interval $(0, V_R)$, then the system (S) is uniformly persistent in the sense mentioned above.

THEOREM 3.2. *Assume that there is a number $V_R > 0$ such that*

$$c(S^0)\frac{f(V)}{r(V)}\frac{c_2 c_4}{c_1 c_3} > 1 \quad \text{for } V \in (0, V_R). \tag{3.5}$$

Then (S) *is uniformly persistent and the disease-free equilibrium* $(S_0, 0, 0, 0)$ *is unstable, with the positive semiaxis* $[OS$ *as its stable variety.*

Proof. From (3.4), (3.5), and the continuity of the function c at S_0, it follows that $\dot{U}_2 > 0$ on a small vicinity of $(S_0, 0, 0, 0)$, except for the points with $V = 0$. It then follows that any solution which starts in that vicinity remains away from $(S_0, 0, 0, 0)$, except for those starting on the positive semiaxis $[OS$, which tend to $(S_0, 0, 0, 0)$ while remaining on $[OS$. It may now be obtained, as in Proposition 3.3 in Li et al. [11], that the system (S) is uniformly persistent. This amounts to observing that $(S_0, 0, 0, 0)$ is the unique compact invariant set on the boundary of our feasible domain (so it is isolated) and its stable variety is the positive semiaxis $[OS$, which is contained in the boundary of the feasible domain. Then the use of Theorem 4.1 in Hofbauer and So [6], together with the remark that a flow and its time one map have the same maximal compact invariant set and the same stable set in a region, concludes the proof. □

It now remains to indicate some situations in which (3.3) or (3.5) are satisfied. Suppose for the moment that f/r is nonincreasing on $(0, \infty)$ and define a basic reproduction number R_0 of the system (S) by

$$R_0 = c(S_0)\frac{c_2 c_4}{c_1 c_3}\lim_{V\to 0}\frac{f(V)}{r(V)} \tag{3.6}$$

(note that the limit $\lim_{V\to 0}\frac{f(V)}{r(V)}$ does indeed exist, since f/r is monotone on $(0, \infty)$).

If $R_0 \leq 1$, then (3.3) is satisfied on $[0,\infty)$, while if $R_0 > 1$, then (3.5) is satisfied for V in a vicinity of 0. Also, it may be seen that $\lim_{V_R\to\infty} U_1(S_0,0,0,V_R) = +\infty$. One then obtains the following result, which establishes that R_0 is the threshold parameter for the stability of the disease-free equilibrium.

THEOREM 3.3. *Suppose that f/r is nonincreasing on $(0,\infty)$.*

1. *If $R_0 \leq 1$, then the disease-free equilibrium $(S_0,0,0,0)$ is globally asymptotically stable.*
2. *If $R_0 > 1$, then* (S) *is uniformly persistent and the disease-free equilibrium $(S_0,0,0,0)$ is unstable, with the positive semiaxis $[OS$ as its stable variety.*

In fact, if f/r is nonincreasing on $(0,\infty)$, more can be said for the case $R_0 > 1$, and it will be shown in sections 4 and 5 that, in this situation, the system (S) admits a positive endemic equilibrium, which is globally asymptotically stable.

We also note that if the functions f and r are of class C^1 and the limit $\lim_{V\to 0} \frac{f'(V)}{r'(V)}$ exists, then by the L'Hôpital theorem

$$R_0 = c(S_0)\frac{c_2c_4}{c_1c_3}\lim_{V\to 0}\frac{f'(V)}{r'(V)},$$

which is in agreement with the definition of the basic reproduction number given by van den Driessche and Watmough in [19] for a large class of compartmental models, including the present model. We do not need, however, to assume C^1 regularity for the functional coefficients throughout our proofs. We also note that, since no C^1 regularity is assumed, local stability analysis based on Jacobian matrices would fail.

4. Existence of endemic equilibrium. We now try to establish some sufficient conditions for the existence of the endemic equilibrium (S^*,E^*,I^*,V^*). Since it would be somehow unrealistic to attempt to solve the system (EQ) in its greatest generality, we impose some additional conditions on our functional coefficients. Let us suppose the following:

(4.1)
f/r is nonincreasing on $(0,\infty)$,

(4.2)
c, f, i, p are strictly increasing on $[0,\infty)$ and n is strictly decreasing on $[0,\infty)$,

(4.3)
$$\lim_{x\to\infty} i(x) = \lim_{x\to\infty} p(x) = +\infty.$$

Necessarily, $S^*,E^*,I^*,V^* > 0$, and the following equilibrium relations are satisfied:

$$\text{(EQ)}\qquad \begin{aligned} &n(S^*) = c(S^*)f(V^*), \quad c(S^*)f(V^*) = c_1 i(E^*), \quad c_2 i(E^*) = c_3 p(I^*),\\ &c_4 p(I^*) = r(V^*). \end{aligned}$$

To solve the equilibrium system (EQ), note first that from the last three equalities in (EQ) one obtains

$$c(S^*)f(V^*) = \frac{c_1c_3}{c_2c_4}r(V^*).$$

Let us define

$$F_1(S,V) = n(S) - c(S)f(V), \quad F_2(S,V) = c(S)f(V) - \frac{c_1c_3}{c_2c_4}r(V).$$

Since $S \mapsto F_1(S,V)$ is strictly decreasing and $F_1(0,V) \cdot F_1(S_0,V) < 0$ for all V, the equation $F_1(S,V) = 0$ can be uniquely solved with respect to S as a function of V for all V. That is, there is a function $S = \psi_1(V)$ which satisfies

$$\frac{n(\psi_1(V))}{c(\psi_1(V))} = f(V). \tag{4.4}$$

Since n/c is strictly decreasing and f is strictly increasing, it follows that ψ_1 is strictly decreasing. Note also that due to (4.4), $\lim_{V\to\infty} \psi_1(V) = 0$.

Similarly, $S \mapsto F_2(S,V)$ is strictly increasing and $F_2(0,V) < 0$ for all V. However, in this instance it is not necessarily true that $F_2(S_0,V) > 0$, and hence the same approach we used to solve the equation $F_2(S,V) = 0$ would not work. However, for our purpose we do not actually need the global solvability of the equation $F_2(S,V) = 0$, since we are searching for a unique endemic equilibrium and consequently for a single V^*. In some situations, local solvability may suffice.

To gain insight, suppose for the moment that the equation $F_2(S,V) = 0$ may also be uniquely solved with respect to S as a function of V (locally for V). That is, there is a function $S = \psi_2(V)$ which satisfies

$$c(\psi_2(V)) = \frac{c_1c_3}{c_2c_4}\frac{r(V)}{f(V)}.$$

Since c is strictly increasing, it follows that ψ_2 is strictly increasing.

Since ψ_1 is strictly decreasing, ψ_2 is strictly increasing and $\lim_{V\to\infty} \psi_1(V) = 0$, the curves defined by $S = \psi_1(V)$ and $S = \psi_2(V)$ have a common point (S^*, V^*) with $S^* > 0$ and $V^* > 0$ if and only if $\psi_1(0) > \psi_2(0)$, or equivalently, $c(\psi_1(0)) > c(\psi_2(0))$. Since $\psi_1(0) = S_0$ and $c(\psi_2(0)) = \frac{c_1c_3}{c_2c_4} \lim_{V\to 0} \frac{r(V)}{f(V)}$, the existence condition is $c(S_0) > \frac{c_1c_3}{c_2c_4} \lim_{V\to 0} \frac{r(V)}{f(V)}$. Using the basic reproduction number of the system (S) as defined in (3.6) (note again that f/r is monotone), this condition may be rewritten as $R_0 > 1$.

Up to now, we have shown that if the equation $F_2(S,V) = 0$ is solvable with respect to S as a function of V, then the necessary and sufficient condition for the existence of positive (S^*, V^*) is that $R_0 > 1$. In this case, we have

$$F_2(S,V) = \frac{c_1c_3}{c_2c_4} r(V) \left[c(S) \frac{c_2c_4}{c_1c_3} \frac{f(V)}{r(V)} - 1 \right];$$

and $F_2(S_0,V)$ is positive for V in a vicinity of 0. Since we have already noted that $F_2(0,V) < 0$ for all V, it follows that the equation $F_2(S,V) = 0$ is solvable with respect to S as a function of V (locally for V) if $R_0 > 1$, which is precisely what we needed. That is, we have shown that the existence of positive (S^*, V^*) is equivalent to the validity of condition $R_0 > 1$.

Also, if i, p are strictly increasing on $[0,\infty)$ and $\lim_{x\to\infty} i(x) = \lim_{x\to\infty} p(x) = +\infty$, then the equations $i(E) = \frac{1}{c_1} n(S^*)$ and $p(I) = \frac{c_2}{c_3c_1} n(S^*)$ will have unique positive solutions E^*, I^*, respectively. In view of the above, we can summarize our discussion with the following result.

THEOREM 4.1. *Assume that conditions* (4.1), (4.2), *and* (4.3) *are satisfied. Then there is a unique positive endemic equilibrium* (S^*, E^*, I^*, V^*) *of* (S) *if and only if* $R_0 > 1$, *where* R_0 *is the basic reproduction number for the system* (S), *as defined in* (3.6).

We note that conditions (4.1), (4.2), and (4.3) (combined with $R_0 > 1$) are sufficient for the existence of the endemic equilibrium but not necessary. Actually, if

one assumes that the removal rate $r(V)$ of the virus is influenced by treatment which is administered if an increase of the virus load over a certain value is observed, while the force of infection $f(V)$ is not, it is easy to think of a function f/r which is not monotone, for instance. In this situation, the disease-free equilibrium may coexist with multiple positive endemic equilibria. It is perhaps also worth noting that the stability of the equilibria depends essentially on the behavior of the function f/r and depends on the contact function c only through the basic reproduction number R_0.

5. Stability of endemic equilibrium. In this section we assume that the system (S) admits a positive endemic equilibrium (S^*, E^*, I^*, V^*) and study its stability. However, we do not assume that (4.1), (4.2), and (4.3) are satisfied and establish our results under somewhat weaker hypotheses. This is consistent with the remark that conditions (4.1), (4.2), and (4.3) are sufficient for the existence of the endemic equilibrium but not necessary. For our purpose, apart from the existence of the endemic equilibrium, we assume that

$$\text{(P)}\qquad \begin{aligned} (c(S)-c(S^*))\,(S-S^*) &> 0 \quad \text{for } S\neq S^*, S\geq 0,\\ (f(V)-f(V^*))\,(V-V^*) &> 0 \quad \text{for } V\neq V^*, V\geq 0,\\ (i(E)-i(E^*))\,(E-E^*) &> 0 \quad \text{for } E\neq E^*, E\geq 0,\\ (p(I)-p(I^*))\,(I-I^*) &> 0 \quad \text{for } I\neq I^*, I\geq 0 \end{aligned}$$

and

$$\text{(N)}\qquad (n(S)-n(S^*))\,(S-S^*)\leq 0 \quad \text{for all } S\geq 0.$$

Note that conditions (P) and (N) are satisfied if (4.2) holds. However, nonmonotone functions c, f, i, p, n can also satisfy (P) and (N).

We consider the Lyapunov function

$$\begin{aligned} U_3(S,E,I,V) = &\int_{S^*}^{S}\frac{c(\tau)-c(S^*)}{c(\tau)}d\tau + \int_{E^*}^{E}\frac{i(\tau)-i(E^*)}{i(\tau)}d\tau\\ &+\frac{c_1}{c_2}\int_{I^*}^{I}\frac{p(\tau)-p(I^*)}{p(\tau)}d\tau + \frac{c_1c_3}{c_2c_4}\int_{V^*}^{V}\frac{f(\tau)-f(V^*)}{f(\tau)}d\tau. \end{aligned}$$

Due to the sign conditions (P), it is seen that U_3 increases whenever any of $|S-S^*|$, $|E-E^*|$, $|I-I^*|$, $|V-V^*|$ increases and $U_3(S,E,I,V)\geq 0$ for all $S,E,I,V\geq 0$, while $U_3(S,E,I,V)=0$ if and only if $(S,E,I,V)=(S^*,E^*,I^*,V^*)$. We note that if any of S,E,I,V tends to 0, then $U_3(S,E,I,V)$ tends to ∞ due to the divergence condition (D). It then follows that all level sets of U_3 have no limit points on the boundary of $(0,\infty)^4$.

We now compute the time derivative of U_3 along the solutions of (S).

LEMMA 5.1. *The time derivative of U_3 with respect to the solutions of* (S) *is*

$$\begin{aligned} \dot{U_3}&(S,E,I,V)\\ &= (n(S)-n(S^*))\left(1-\frac{c(S^*)}{c(S)}\right) + c(S^*)r(V)\left(\frac{f(V^*)}{f(V)}-1\right)\left(\frac{f(V^*)}{r(V^*)}-\frac{f(V)}{r(V)}\right)\\ &\quad - c_1 i(E^*)\left[\frac{c(S^*)}{c(S)}+\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}-4\right]. \end{aligned}$$

If the inequality

$$c(S^*)r(V)\left(\frac{f(V^*)}{f(V)}-1\right)\left(\frac{f(V^*)}{r(V^*)}-\frac{f(V)}{r(V)}\right)\leq 0 \tag{5.1}$$

holds true for V in some given interval (V_L,V_R), then $\dot{U}_3(S,E,I,V)\leq 0$ for $V\in(V_L,V_R)$, with equality if and only if

$$S=S^* \quad \textit{and} \quad \frac{i(E)}{i(E^*)}=\frac{f(V)}{f(V^*)}=\frac{p(I)}{p(I^*)}.$$

Proof. It is seen that

$$\begin{aligned}
\dot{U}_3 &= \left(1-\frac{c(S^*)}{c(S)}\right)(n(S)-c(S)f(V))+\left(1-\frac{i(E^*)}{i(E)}\right)(c(S)f(V)-c_1i(E))\\
&\quad+\frac{c_1}{c_2}\left(1-\frac{p(I^*)}{p(I)}\right)(c_2i(E)-c_3p(I))+\frac{c_1c_3}{c_2c_4}\left(1-\frac{f(V^*)}{f(V)}\right)(c_4p(I)-r(V))\\
&= n(S)\left(1-\frac{c(S^*)}{c(S)}\right)+c(S^*)f(V)-\frac{i(E^*)}{i(E)}c(S)f(V)+c_1i(E^*)-c_1\frac{p(I^*)}{p(I)}i(E)\\
&\quad+\frac{c_1c_3}{c_2}p(I^*)-\frac{c_1c_3}{c_2c_4}r(V)-\frac{c_1c_3}{c_2}\frac{f(V^*)}{f(V)}p(I)+\frac{c_1c_3}{c_2c_4}\frac{f(V^*)}{f(V)}r(V).
\end{aligned}$$

Using the equilibrium relations (EQ), it follows that

$$\begin{aligned}
\dot{U}_3 &= n(S)\left(1-\frac{c(S^*)}{c(S)}\right)+c(S^*)f(V)-c_1i(E^*)\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+c_1i(E^*)\\
&\quad-c_1i(E^*)\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+c_1i(E^*)-c_1i(E^*)\frac{r(V)}{r(V^*)}-c_1i(E^*)\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}\\
&\quad+c_1i(E^*)\frac{f(V^*)}{f(V)}\frac{r(V)}{r(V^*)}\\
&= n(S)\left(1-\frac{c(S^*)}{c(S)}\right)+c(S^*)f(V)+c_1i(E^*)\left(\frac{f(V^*)}{f(V)}\frac{r(V)}{r(V^*)}-\frac{r(V^*)}{r(V)}\right)\\
&\quad-c_1i(E^*)\left[\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}-2\right]\\
&= n(S)\left(1-\frac{c(S^*)}{c(S)}\right)+c_1i(E^*)\frac{f(V)}{f(V^*)}+c_1i(E^*)\left(\frac{f(V^*)}{f(V)}\frac{r(V)}{r(V^*)}-\frac{r(V)}{r(V^*)}\right)\\
&\quad-c_1i(E^*)\left[\frac{c(S^*)}{c(S)}+\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}-4\right]\\
&\quad+c_1i(E^*)\frac{c(S^*)}{c(S)}-2c_1i(E^*).
\end{aligned}$$

This implies that

$$\begin{aligned}
\dot{U}_3 &= (n(S)-c_1i(E^*))\left(1-\frac{c(S^*)}{c(S)}\right)\\
&\quad+c_1i(E^*)\left(\frac{f(V^*)}{f(V)}\frac{r(V)}{r(V^*)}-\frac{r(V)}{r(V^*)}+\frac{f(V)}{f(V^*)}-1\right)\\
&\quad-c_1i(E^*)\left[\frac{c(S^*)}{c(S)}+\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}-4\right],
\end{aligned}$$

and since $c_1 i(E^*) = n(S^*)$, it follows that

$$\begin{aligned}\dot{U_3}&(S,E,I,V)\\ &= (n(S)-n(S^*))\left(1-\frac{c(S^*)}{c(S)}\right)+c_1 i(E^*)\left(\frac{f(V^*)}{f(V)}-1\right)\left(\frac{r(V)}{r(V^*)}-\frac{f(V)}{f(V^*)}\right)\\ &\quad - c_1 i(E^*)\left[\frac{c(S^*)}{c(S)}+\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}-4\right].\end{aligned}$$

Using the relation $c_1 i(E^*) = c(S^*)f(V^*)$, one gets the required conclusion. Now, from the sign condition (N) it is seen that

$$(n(S)-n(S^*))\left(1-\frac{c(S^*)}{c(S)}\right)\le 0 \quad \text{for } S\ge 0,$$

with equality if and only if $S = S^*$, and from the *AM-GM* inequality (which says that the algebraic mean is not smaller than the geometric mean) it is seen that

$$\frac{c(S^*)}{c(S)}+\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}+\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}+\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}\ge 4,$$

with equality if and only if

$$\frac{c(S^*)}{c(S)}=\frac{i(E^*)}{i(E)}\frac{c(S)}{c(S^*)}\frac{f(V)}{f(V^*)}=\frac{i(E)}{i(E^*)}\frac{p(I^*)}{p(I)}=\frac{f(V^*)}{f(V)}\frac{p(I)}{p(I^*)}=1. \tag{5.2}$$

It then follows that if the inequality

$$c(S^*)r(V)\left(\frac{f(V^*)}{f(V)}-1\right)\left(\frac{f(V^*)}{r(V^*)}-\frac{f(V)}{r(V)}\right)\le 0$$

holds true for $v\in(V_L,V_R)$, then $\dot{U_3}(S,E,I,V)\le 0$. For the equality case, we note that $c(S^*) = c(S)$ if and only if $S = S^*$, and substituting this into (5.2) one obtains that

$$\frac{i(E)}{i(E^*)}=\frac{f(V)}{f(V^*)}=\frac{p(I)}{p(I^*)}. \qquad \square$$

It is now obvious that the stability of the endemic equilibrium (S^*,E^*,I^*,V^*) is related to the validity of the inequality (5.1). Subsequently, we estimate the size of the domain of attraction associated with (S^*,E^*,I^*,V^*).

THEOREM 5.2. *Assume that the sign conditions* (P) *and* (N) *are satisfied and there are V_L and V_R such that*

$$\begin{aligned}&\frac{f(V)}{r(V)}\le\frac{f(V^*)}{r(V^*)} \quad \textit{for } V^*\le V<V_R,\\ &\frac{f(V)}{r(V)}\ge\frac{f(V^*)}{r(V^*)} \quad \textit{for } V_L<V\le V^*.\end{aligned} \tag{5.3}$$

Define $m = \min\left(U_3(S^*,E^*,I^*,V_L), U_3(S^*,E^*,I^*,V_R)\right)$. Then (S^*,E^*,I^*,V^*) is locally asymptotically stable and its domain of attraction includes the set

$$M_m=\left\{(S,E,I,V)\in(0,\infty)^4; U_3(S,E,I,V)<m\right\}.$$

Proof. Denote

$$\tilde{M} = \left\{(S, E, I, V) \in (0, \infty)^4; V_L < V < V_R\right\}.$$

From (5.3) it follows that (5.1) is satisfied for $V \in (V_L, V_R)$, and using Lemma 5.1 one may infer that $\dot{U}_3(S, E, I, V) \leq 0$ on $\tilde{M}$, with equality if and only if

$$S = S^* \quad \text{and} \quad \frac{i(E)}{i(E^*)} = \frac{f(V)}{f(V^*)} = \frac{p(I)}{p(I^*)}.$$

Take an arbitrary $k < m$. Since U_3 increases whenever any of $|S - S^*|$, $|E - E^*|$, $|I - I^*|$, $|V - V^*|$ increases, it follows easily that, for all V outside (V_L, V_R), one has $U_3(S, E, I, V) \geq m$ for all $S, E, I > 0$. Consequently $M_k \subset \tilde{M}$. Moreover, as noted previously, M_k is a bounded set which has no limit points on the boundary of $\tilde{M}$.

We now find the invariant subsets $\tilde{N}$ within the set

$$N = \left\{(S, E, I, V) \in M_k; \dot{U}_3(S, E, I, V) \leq 0\right\}.$$

Since $S = S^*$ on $\tilde{N}$ and consequently $S' = n(S^*) - c(S^*)f(V)$, it follows that $S' = c(S^*)(f(V^*) - f(V))$, and so $S' = 0$ if and only if $V = V^*$. From $\frac{i(E)}{i(E^*)} = \frac{p(I)}{p(I^*)} = 1$ we then deduce that $E = E^*$ and $I = I^*$ by using the sign condition (P).

Therefore, using LaSalle's invariance principle (see LaSalle [10]) one obtains that any trajectory which starts in M_k tends to (S^*, E^*, I^*, V^*) as $t \to \infty$. Then the endemic equilibrium (S^*, E^*, I^*, V^*) is locally asymptotically stable and the set M_k belongs to its domain of attraction. Since k was arbitrary and less than m, one obtains the required conclusion. □

We now continue with a few considerations on the inequalities (5.3). Since

$$\lim_{V_L \to 0} U_3(S^*, E^*, I^*, V_L) = \lim_{V_R \to \infty} U_3(S^*, E^*, I^*, V_R) = +\infty,$$

one obtains that if the following inequalities are satisfied,

$$\begin{aligned} &\frac{f(V)}{r(V)} \leq \frac{f(V^*)}{r(V^*)} \quad \text{for } V^* \leq V, \\ &\frac{f(V)}{r(V)} \geq \frac{f(V^*)}{r(V^*)} \quad \text{for } 0 < V \leq V^*, \end{aligned} \tag{5.4}$$

then (S^*, E^*, I^*, V^*) is globally asymptotically stable in $(0, \infty)^4$.

Regarding the inequalities (5.4) (or (5.3)), it is easy to see that they are verified if the function f/r is nonincreasing on $(0, \infty)$ (or on (V_L, V_R)); however, this monotonicity property is only sufficient and not necessary. If $r(V) = kV$, for some k, then the above monotonicity property is satisfied for three common incidence rates, namely $c_1(S)f_1(V) = \beta_1 SV$, $c_2(S)f_2(V) = \beta_2 S^p V^q$, where $0 < q \leq 1$, and $c_3(S)f_3(V) = \beta_3 SV/(1 + a_1 V)$.

We also remark that the inequalities (5.4) alone imply the uniqueness of the endemic equilibrium (S^*, E^*, I^*, V^*). To show this, suppose that there is another endemic equilibrium $(S_1^*, E_1^*, I_1^*, V_1^*)$. Apart from (EQ), one then has

$$\begin{aligned} (\text{EQ}') \qquad & n(S_1^*) = c(S_1^*)f(V_1^*), \quad c(S_1^*)f(V_1^*) = c_1 i(E_1^*), \quad c_2 i(E_1^*) = c_3 p(I_1^*), \\ & c_4 p(I_1^*) = r(V_1^*). \end{aligned}$$

It follows that

$$c(S^*) - c(S_1^*) = \frac{c_1 c_3}{c_2 c_4}\left(\frac{r(V^*)}{f(V^*)} - \frac{r(V_1^*)}{f(V_1^*)}\right), \tag{5.5}$$

$$n(S^*) - n(S_1^*) = \frac{c_1 c_3}{c_2 c_4}\left(r(V^*) - r(V_1^*)\right) \tag{5.6}$$

and therefore

$$\left(c(S^*) - c(S_1^*)\right)\left(V^* - V_1^*\right) \geq 0.$$

If $V^* > V_1^*$, then, from (5.5), $c(S^*) \geq c(S_1^*)$, $S^* \geq S_1^*$, which implies $n(S^*) \leq n(S_1^*)$ and consequently from (5.6), $r(V^*) \leq r(V_1^*)$, which is a contradiction. The case $V^* < V_1^*$ is dismissed in a similar manner, subsequently $V^* = V_1^*$ and from (5.5), $S = S_1^*$. Substituting these equalities into (EQ) and (EQ′) we obtain that $i(E^*) = i(E_1^*)$ and $p(I^*) = p(I_1^*)$, and hence $E^* = E_1^*$ and $I^* = I_1^*$; that is, the endemic equilibrium is uniquely determined. However, we should point out that inequalities (5.4) ensure the uniqueness of the endemic equilibrium only and not necessarily its existence.

6. Discussions and concluding remarks. The earlier analysis clearly indicates the importance of the quantity

$$c(S_0)\frac{f(V)}{r(V)}\frac{c_2 c_4}{c_1 c_3}$$

in the discussion on local stability of the disease-free equilibrium and persistence for the system. Moreover, under the monotonicity condition on $f(V)/r(V)$, we obtain the basic reproduction number

$$R_0 = c(S_0)\frac{c_2 c_4}{c_1 c_3}\lim_{V\to 0}\frac{f(V)}{r(V)}. \tag{6.1}$$

We will now give a biological interpretation of this result. From (S), it is obvious that the terms in the numerator denote the growth in the concentrations of the infected cells, E and I, and of the virus V. The terms in the denominator, on the other hand, denote the removal (or decrease in concentration) of these three same classes. Therefore, the ratio of the two can be considered as a measurement of the combined "productivity," perhaps more aptly, the *basic reproductive ratio* of the infected classes in the system. The fact that the stability of the disease-free equilibrium and the persistence of the system depend on whether this quantity is less than one or not (Theorems 3.1 and 3.2) further confirms our assertion.

The quantity $f(V)/r(V)$ is also important for our results. It can be interpreted as the efficiency of the virus, that is, the ratio of its infectivity to its removal, as a function of the virus concentration. Theorems 3.3, 4.1, and 5.2 require $f(V)/r(V)$ to be a nonincreasing function of V. Some recent studies (see, e.g., [16, 17]) let $f(V) = r(V) = V$, an assumption which is supported by some clinical data. We note that in this case $f(V)/r(V) = 1$, and hence our condition of nonincreasing ratio $f(V)/r(V)$, which generalizes to the models with nonlinear $f(V)$ and $r(V)$, is satisfied. For HIV, it has been observed that the productivity of the virus, $f(V)$, increases as the virus concentration increases. Our analysis is valid if the increase in removal of the virus $r(V)$ as virus concentration increases is at least to the same level as the increase in $f(V)$. Further studies are needed to verify whether our assertion holds.

On the other hand, if the function f/r is indeed increasing on $(0,\infty)$, then U_1 and U_3 are not necessarily global Lyapunov functionals and therefore do not create their own boundedness structure for the solutions of (S). For the global existence of the solutions, growth conditions (G) (see section 2) need to be imposed. If f/r is nonincreasing on $(0,\infty)$, however, the boundedness structures created by the level sets of U_1 and U_3 render the growth conditions unnecessary.

Suppose that f/r is nonincreasing on $(0,\infty)$ and $R_0 > 1$. Assume that the following conditions are satisfied:

$$\text{(B)} \qquad \lim_{y\to\infty}\left(y-\varphi(x)\int_x^y \frac{1}{\varphi(\tau)}d\tau\right)=+\infty \quad \text{for all } x>0 \text{ and } \varphi\in\{c,f,i,p\}\,.$$

Note that (B) is satisfied for a function φ such that $\lim_{y\to\infty}\varphi(y)=+\infty$, since in this situation

$$\lim_{y\to\infty}\frac{\int_x^y \frac{1}{\varphi(\tau)}d\tau}{y}=\lim_{y\to\infty}\frac{1}{\varphi(y)}=0 \quad \text{for } \varphi\in\{c,f,i,p\}\,.$$

However, condition (B) is also satisfied for $\varphi(x)=x^p/(1+ax^p), 0<p\le 1$ (this is, for instance, the case when $\varphi(V)=f(V)=V^p/(1+aV^p)$ is a nonlinear force of infection with saturation), which does not tend to $+\infty$ as $x\to+\infty$.

Regarding conditions (D), since the only points on the boundary of $[0,\infty)^4$ which can be reached in finite time are situated on $[OS$ and the only w-limit point of (S) on the boundary of $[0,\infty)^4$ is the disease-free equilibrium $(S_0,0,0,0)$, a less restrictive condition than (D) would suffice to avoid these situations, namely

$$\text{(D}')\qquad \int_{0+}^1 \frac{1}{\varphi(\tau)}d\tau=+\infty \quad \text{for some } \varphi\in\{f,i,p\}\,.$$

Then, by the results in the previous section, there is a unique positive endemic equilibrium which verifies relations (EQ). Take $(S(0),E(0),I(0),V(0))\in(0,\infty)^4$. Then $U_3\le 0$ for all t, and it follows that $(S(t),E(t),I(t),V(t))$ stays in a level set of U_3 on its whole interval of existence. Since the level sets of U_3 are bounded due to (B), it follows that the saturated solution which starts in $(S(0),E(0),I(0),V(0))$ exists on $[0,\infty)$. The growth conditions (G), which were used to obtain global existence, therefore become unnecessary and the proof proceeds in the same manner. Then, as in section 3, all solutions which start in $[0,\infty)^4$ tend to (S^*,E^*,I^*,V^*), except for those which start on $[OS$ and tend to $(S_0,0,0,0)$ as $t\to\infty$. The growth conditions become unnecessary for the proof of the uniform persistence result as well, since the system (S) admits an endemic equilibrium and it is obviously uniformly persistent.

If $R_0\le 1$, the reasoning is quite similar, with U_1 in place of U_3, and it is obtained again that all the saturated solutions are global and the stability result remains valid. We then summarize our discussion in the following result.

THEOREM 6.1. *Suppose that f/r is nonincreasing on $(0,\infty)$ and conditions* (4.2), (4.3), (B), *and* (D′) *are satisfied.*

1. *If $R_0\le 1$, then the disease-free equilibrium $(S_0,0,0,0)$ is globally asymptotically stable.*
2. *If $R_0>1$, then the system* (S) *admits a unique positive endemic equilibrium which is globally asymptotically stable. The disease-free equilibrium $(S_0,0,0,0)$ is unstable, with the positive semiaxis $[OS$ as its stable variety.*

Obviously, in statement 2 the stable variety of the endemic equilibrium actually excludes $[OS$.

As an example to illustrate the usefulness of our results, it is easy to see that a system which fits into our framework is

$$\text{(RS)} \qquad \begin{cases} S' = b - mS - \beta S \dfrac{V^p}{1 + aV^p}, \\ E' = \beta S \dfrac{V^p}{1 + a_1 V^p} - c_1 E, \\ I' = c_2 E - c_3 I, \\ V' = c_4 I - kV^\gamma \end{cases}$$

for $b, m, \beta, k > 0$, $a \geq 0$, and $0 < p \leq \gamma \leq 1$. In this situation, $c(S) = \beta S$, $f(V) = V^p/(1 + aV^p)$, $i(E) = E$, $p(I) = I$, $r(V) = V^\gamma$, $n(S) = b - mS$.

It follows that $f/r = 1/((1 + a_1 V^p)V^{\gamma - p})$ is nonincreasing on $(0, \infty)$,

$$\lim_{E \to \infty} E = \lim_{I \to \infty} I = \lim_{V \to \infty} kV^\gamma = +\infty,$$

and $\lim_{V \to \infty} V^p/(1 + aV^p) = +\infty$ if $a = 0$, while if $a > 0$, then

$$\lim_{V \to \infty} \left(V - \frac{x^p}{1 + ax^p} \int_x^V \frac{1 + a\tau^p}{\tau^p} d\tau \right) = +\infty \quad \text{for all } x > 0.$$

Also, $\int_{0+}^1 \frac{1}{E} dE = +\infty$. Note that if $a = 0$ and $p \in (0, 1)$, then $f(V) = V^p$ is not Lipschitzian on $[0, \infty)$ due to its behavior near 0. However, our solutions which start with $V > 0$ do not reach points for which $V = 0$ in finite time. Hence the uniqueness property is not impaired. The same remark applies to the function r. We can therefore apply the results in the previous sections and obtain the following result.

THEOREM 6.2.

1. *If $p < \gamma$, the basic reproduction number R_0 of the system* (RS) *is $+\infty$. The system* (RS) *admits a positive endemic equilibrium which is globally asymptotically stable. The disease-free equilibrium $(S_0, 0, 0, 0)$ is unstable, with the positive semiaxis $[OS$ as its stable variety.*
2. *If $p = \gamma$, the basic reproduction number R_0 of the system* (RS) *is*

$$R_0 = \frac{\beta b}{m} \frac{c_2 c_4}{c_1 c_3} \frac{1}{k}.$$

In this case, if $R_0 \leq 1$, then the disease-free equilibrium $(S_0, 0, 0, 0)$ is globally asymptotically stable, while if $R_0 > 1$, the system (RS) *admits a positive endemic equilibrium which is globally asymptotically stable. The disease-free equilibrium $(S_0, 0, 0, 0)$ is unstable, with the positive semiaxis $[OS$ as its stable variety.*

Again, the "global" stable variety of the endemic equilibrium is understood to exclude $[OS$. Note that for $p = \gamma = 1$ and $a = 0$ we obtain the results given in Korobeinikov [7].

As a final remark, we note that similar analysis can be extended to a system of the form

$$\text{(SE)}\qquad \begin{cases} S' = n(S) - c(S)f(V), \\ E' = c(S)f(V) - c_1 i(E), \\ I_1' = c_2 i(E) - k_1 p_1(I_1), \\ I_j' = \tilde{k}_{j-1} p_{j-1}(I_{j-1}) - k_j p_j(I_j), \quad 2 \le j \le n, \\ V' = \tilde{k}_n p_n(I_n) - r(V). \end{cases}$$

The associated Lyapunov functionals are in this case

$$U_1(S, E, I_1, \dots, I_n) = \int_{S_0}^{S} \frac{c(\tau) - c(S_0)}{c(\tau)} d\tau + E + \frac{c_1}{c_2} \sum_{i=1}^{n} \left(\prod_{j=1}^{i-1} \frac{k_j}{\tilde{k}_j} \right) I_i + \frac{c_1}{c_2} \prod_{j=1}^{n} \frac{k_j}{\tilde{k}_j} V,$$

$$U_2(S, E, I_1, \dots, I_n) = E + \frac{c_1}{c_2} \sum_{i=1}^{n} \left(\prod_{j=1}^{i-1} \frac{k_j}{\tilde{k}_j} \right) I_i + \frac{c_1}{c_2} \prod_{j=1}^{n} \frac{k_j}{\tilde{k}_j} V,$$

and

$$\begin{aligned} U_3(S, E, I_1, \dots, I_n) = {} & \int_{S^*}^{S} \frac{c(\tau) - c(S^*)}{c(\tau)} d\tau + \int_{E^*}^{E} \frac{i(\tau) - i(E^*)}{i(\tau)} d\tau \\ & + \frac{c_1}{c_2} \sum_{i=1}^{n} \left(\prod_{j=1}^{i-1} \frac{k_j}{\tilde{k}_j} \right) \int_{I_i^*}^{I_i} \frac{p_i(\tau) - p_i(I_i^*)}{p_i(\tau)} d\tau \\ & + \frac{c_1}{c_2} \left(\prod_{j=1}^{n} \frac{k_j}{\tilde{k}_j} \right) \int_{V^*}^{V} \frac{c(\tau) - c(V^*)}{c(\tau)} d\tau, \end{aligned}$$

with the convention $\prod_{j=1}^{0} \frac{k_j}{\tilde{k}_j} = 1$.

Again, related asymptotic stability can be obtained as in previous sections, and the size of the domain of attraction depends essentially on the behavior of the function f/r. If the function f/r is nonincreasing on $(0, \infty)$, the threshold parameter R_0 is given by

$$R_0 = c(S_0) \frac{c_2}{c_1} \left(\prod_{j=1}^{n} \frac{\tilde{k}_j}{k_j} \right) \lim_{V \to 0} \frac{f(V)}{r(V)}.$$

The first Lyapunov functional of type $\sum_{i=1}^{n} d_i \big(x_i - x_i^* - x_i^* \ln \frac{x_i}{x_i^*} \big)$, to which our functional U_3 reduces when c, f, i, p are linear functions, has been used by Volterra in [20] to treat a two-dimensional predator-prey model which describes the interaction between sharks and predated fish in the Mediterranean Sea. (See also Goh [4].) In [5], Harrison constructed a Lyapunov functional of this type for a two-dimensional predator-prey model which accounted for very general numerical and functional responses of the predator. The computation of the derivatives is straightforward and hence omitted for brevity.

Acknowledgment. The authors would like to thank the referees for their constructive comments.

SUFFICIENT CONDITIONS FOR MONOTONE LINEAR STABILITY OF STEADY AND OSCILLATORY HAGEN–POISEUILLE FLOW*

VÍT PRŮŠA†

Abstract. Sufficient conditions for the monotone decay of disturbances to oscillatory and steady Hagen–Poiseuille flow are rigorously derived within the framework of linear stability theory. The conditions hold both for axisymmetric and nonaxisymmetric disturbances, whereas the result for nonaxisymmetric disturbances to the oscillatory flow is of particular importance because in this case even numerical results are not available in the literature. Furthermore, the conditions provide explicit bounds on the range of parameters that must be examined in any prospective search for instability by numerical means. The derivation of the sufficient conditions on monotone decay is based on a detailed analysis of the spectrum of the Stokes operator.

Key words. linear stability, nonaxisymmetric disturbances, Hagen–Poiseuille flow, oscillatory Hagen–Poiseuille flow

1. Introduction.

Hagen–Poiseuille flow is a flow of incompressible Newtonian fluid in a pipe of infinite length that is driven by pressure gradient in the direction of the pipe's axis. For steady flow the gradient is given by the formula

$$\frac{\partial p}{\partial z} = -\Delta_s,$$

where Δ_s is constant. In the oscillatory case the pressure gradient is a harmonic function of time

$$\frac{\partial p}{\partial z} = -\Delta_p e^{i\omega t}, \tag{1.1}$$

where Δ_p denotes the amplitude of the pressure gradient and ω denotes the frequency of oscillations. The flow generated by the pressure gradient (1.1) can serve as a simple model for the oscillating component of the blood flow in arteries (see McDonald [6] and Womersley [14] for details), and therefore a detailed examination of properties of the flow is important from a mathematical point of view as well as from a physiological point of view.

Governing equations for the flows are the well-known Navier–Stokes equations, and for both oscillatory and steady flow it is possible to find an analytical formula for the base flow. Having analytical formulas for the base flows, the question of stability of the base flows naturally arises. The present work is focused on the rigorous derivation of an explicit sufficient condition for monotone linear stability of the oscillatory flow, whereas special attention is given to stability of nonaxisymmetric disturbances. The reason for the focus on nonaxisymmetric disturbances is that stability characteristics of the oscillatory flow are—especially from the analytical point of view—mainly

unknown (see the discussion below). Nevertheless, the method presented here can also be used in the steady case, and its outcomes can be compared to previously achieved results.

Concerning stability of the steady flow, the pioneering works are that of Salwen and Grosch [9] and Salwen, Grosch, and Cotton [10], where the linear stability of the base flow was examined by numerical methods, and it was found that the steady Hagen–Poiseuille flow is stable for a wide range of parameters. The results of Salwen and Grosch [9] and Salwen, Grosch, and Cotton [10] were reproduced many times,[1] and now it is commonly accepted that the steady Hagen–Poiseuille flow is stable to all possible disturbances (as far as the disturbances can be described by the linear stability theory).

Important results in the analytical approach to the stability of the steady flow are the works of Herron [4], who proved that the base flow is linearly stable to axisymmetric disturbances,[2] and Joseph and Carmi [5], who proved (by semianalytical methods) that the base flow is monotonically stable to all possible disturbances if the Reynolds number is less than 81.49.

In the oscillatory case the situation is more complicated because the numerical calculations in the framework of the linear stability theory were—from the earliest one, that of Yang and Yih [15], to the most recent one by Blennerhassett and Bassom [2]—focused only on axisymmetric disturbances, and behavior of nonaxisymmetric disturbances remains unknown. Furthermore it seems that the oscillatory flow is in contrast to the steady flow linearly unstable for high Reynolds numbers.[3] The inadequacy of restriction of calculations only to axisymmetric disturbances is evident and was commented on by von Kerczek and Tozzi [12], but even in this work nonaxisymmetric disturbances to the oscillatory flow were not considered.

Analytical results comparable to Herron [4] and Joseph and Carmi [5] are not available for the oscillatory flow; therefore, a need to establish some analytical results is obvious. Furthermore, the lack of numerical results for nonaxisymmetric disturbances opens a possibility to extend analytical results to the area that was not yet examined by numerical means. In this work it is shown that it is indeed possible to establish a sufficient condition for monotone linear stability of the oscillatory flow and that this condition holds for both axisymmetric and nonaxisymmetric disturbances.

2. Problem formulation.

2.1. Governing equations for disturbances. In the framework of the linear stability theory (see, for example, Schmidt and Henningson [11]), the nondimensional governing equations for the disturbance $\vec{v}$ to the base flow $\vec{V}$ are

$$\frac{\partial \vec{v}}{\partial t} + [\nabla \vec{V}]\vec{v} + [\nabla \vec{v}]\vec{V} = -\nabla p + \frac{1}{\mathcal{R}}\Delta \vec{v}, \tag{2.1}$$

$$\operatorname{div} \vec{v} = 0, \tag{2.2}$$

together with the no-slip boundary condition on the pipe's wall and the periodic boundary condition on the ends of the pipe. The monotone stability is defined in the standard manner.

[1] See, for example, Meseguer and Trefethen [7] for a precise numerical calculation for high Reynolds numbers.

[2] Thus disturbances with $n = 0$; see (2.4) below.

[3] See Blennerhassett and Bassom [2] for details. Yang and Yih [15], however, claim that the flow is linearly stable, but they did not examine extreme parameter values as did Blennerhassett and Bassom [2].

DEFINITION 2.1 (monotone stability). *The flow is monotonically stable if for all disturbances* $\vec{v}$

$$\frac{1}{2}\frac{d}{dt}\|\vec{v}\|^2 < 0, \tag{2.3}$$

where $\|\vec{v}\|^2 = \int_\Omega \vec{v} \bullet \vec{v} dx$ *is kinetic energy of the disturbance in the volume* Ω.

The solution to the disturbance equations is sought in the form of waves

$$\vec{v}(r, \varphi, z, t) = \tilde{\vec{v}}(r, t) e^{i\alpha z + in\varphi}, \tag{2.4}$$

where $(\alpha, n) \in \mathbb{R} \times \mathbb{Z}$ is the wave vector of the disturbance and r, φ, and z are the cylindrical coordinates. In the pipe flow case, the scalar product is defined (see Salwen and Grosch [9] for a discussion) as integration over a section of the pipe that is bounded by two planes perpendicular to the pipe's axis and one wavelength apart[4]:

$$\langle \vec{v}, \vec{u} \rangle = \int_{r=0}^{1} \int_{\varphi=0}^{2\pi} \int_{z=0}^{\frac{2\pi}{\alpha}} \tilde{\vec{v}} \bullet \tilde{\vec{u}}^\star r dr d\varphi dz = \frac{4\pi^2}{\alpha} \int_{r=0}^{1} \tilde{\vec{v}} \bullet \tilde{\vec{u}}^\star r dr. \tag{2.5}$$

The norm in (2.3) is naturally the norm induced by the scalar product (2.5).

2.2. Base flow velocity. The base flow velocity has in both the oscillatory and steady cases a nonzero component only in the direction of the pipe's axis. For the steady flow the nondimensional base flow velocity is given by the well-known formula

$$V^{\hat{z}}(r) = (1 - r^2), \tag{2.6}$$

and the Reynolds number is defined in the standard manner—the characteristic length is equal to the pipe's radius R and the characteristic velocity U is equal to the centerline velocity $U = \frac{\Delta_s R^2}{4\rho\nu}$, where ρ is the density and ν is the kinematic viscosity.

In the oscillatory case there are several possibilities for introducing dimensionless variables. The approach of Womersley [14] is followed in this work. The Reynolds number is thus defined in the standard manner as $\mathcal{R} = \frac{RU}{\nu}$, where the characteristic velocity U is equal to $U = \frac{\Delta_p R^2}{4\rho\nu}$. The characteristic length is again the pipe's radius R. The second dimensionless parameter that is necessary in the oscillatory case is the Womersley number $\mathcal{W}$ defined by the formula $\mathcal{W} = \sqrt{\frac{\omega}{\nu}} R$.

Expressions for the base flow velocity and other characteristics of the oscillatory base flow were derived in Womersley [14] and McDonald [6]. Using the scaling introduced above, the dimensionless base flow is given by the formula

$$V^{\hat{z}}(r, t) = -i\frac{4}{\mathcal{W}^2}\left(1 - \frac{\mathrm{J}_0(i^{\frac{3}{2}}\mathcal{W}r)}{\mathrm{J}_0(i^{\frac{3}{2}}\mathcal{W})}\right) e^{i\omega t}, \tag{2.7}$$

where $\mathrm{J}_k(x)$ denotes the Bessel function of the first kind and of order k. Application of basic identities for the Bessel functions then immediately gives the following formula for the base flow velocity derivative:

$$\frac{\partial V^{\hat{z}}}{\partial r}(r, t) = -i^{\frac{5}{2}}\frac{4}{\mathcal{W}}\frac{\mathrm{J}_1(i^{\frac{3}{2}}\mathcal{W}r)}{\mathrm{J}_0(i^{\frac{3}{2}}\mathcal{W})} e^{i\omega t}. \tag{2.8}$$

[4] In the singular case $\alpha = 0$ the integration is only with respect to the r and φ variables.

3. Analytical results. The governing equation for the disturbance energy can be easily obtained by multiplying the governing equation for disturbances (2.1) by the disturbance itself and using the scalar product (2.5) to give

$$\left\langle \frac{\partial \tilde{\vec{v}}}{\partial t}, \tilde{\vec{v}} \right\rangle + \left\langle [\nabla \vec{V}]\tilde{\vec{v}} + [\nabla \tilde{\vec{v}}]\vec{V}, \tilde{\vec{v}} \right\rangle = \left\langle -\nabla \tilde{p} + \frac{1}{\mathcal{R}} \Delta \tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle.$$

From the above equation it then follows that

$$\frac{1}{2}\frac{d}{dt}\|\tilde{\vec{v}}\|^2 = \Re\left(\left\langle -\nabla \tilde{p} + \frac{1}{\mathcal{R}} \Delta \tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle - \left\langle [\nabla \vec{V}]\tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle - \left\langle [\nabla \tilde{\vec{v}}]\vec{V}, \tilde{\vec{v}} \right\rangle \right), \tag{3.1}$$

where $\Re$ denotes real part.

The equation (3.1) is the governing equation for the disturbance energy measured in the norm induced by the scalar product. To prove monotone stability (monotone decay of disturbance energy) it is necessary to prove that the right-hand side of (3.1) is negative. The first term in the bracket is real and has a negative sign and it is even possible to estimate its magnitude—this can be done using eigenvalues of the Stokes operator (see section 3.1 for the properties of the Stokes operator). The last two terms in the bracket are complex and its real part has no definite sign. The real part must therefore be estimated by the absolute value. The steps described above are formally summarized in the following lemma.

LEMMA 3.1 (estimate of disturbance energy derivative). *Let $\alpha \in \mathbb{R}$, $n \in \mathbb{Z}$. Then the time derivative of kinetic energy of the disturbance with a wave vector (α, n) can be estimated as*

$$\frac{1}{2}\frac{d}{dt}\|\tilde{\vec{v}}\|^2 \leq \left(-\lambda_1 + |\alpha| \sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|V^{\hat{z}}\right| + \sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|\frac{\partial V^{\hat{z}}}{\partial r}\right| \right) \|\tilde{\vec{v}}\|^2, \tag{3.2}$$

where λ_1 is the lowest eigenvalue of the Stokes problem (3.6)–(3.7)*, and $V^{\hat{z}}$ is the component of the base flow velocity in the direction of the z-axis.*

Proof. Let us consider terms on the right-hand side of (3.1). For the first term it can be shown that (see section 3.1 for the properties of the Stokes operator)

$$\Re\left(\left\langle -\nabla \tilde{p} + \frac{1}{\mathcal{R}} \Delta \tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle \right) = \left\langle -\nabla \tilde{p} + \frac{1}{\mathcal{R}} \Delta \tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle \leq -\lambda_1 \left\langle \vec{v}, \vec{v} \right\rangle = -\lambda_1 \|\vec{v}\|^2, \tag{3.3}$$

where λ_1 is the lowest positive eigenvalue of the Stokes problem.

The last two terms on the right-hand side of (3.1) can be estimated by absolute value. The estimate for the first term is

$$\left| \left\langle [\nabla \vec{V}]\tilde{\vec{v}}, \tilde{\vec{v}} \right\rangle \right| = \left| \int_{r=0}^{1} \frac{\partial V^{\hat{z}}}{\partial r} \tilde{v}^{\hat{r}} \left(\tilde{v}^{\hat{z}}\right)^* r dr \right| \leq \sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|\frac{\partial V^{\hat{z}}}{\partial r}\right| \|\tilde{\vec{v}}\|^2, \tag{3.4}$$

and for the second term we find that

$$\left| \left\langle [\nabla \tilde{\vec{v}}]\vec{V}, \tilde{\vec{v}} \right\rangle \right| = \left| \int_{r=0}^{1} i\alpha V^{\hat{z}} \begin{bmatrix} \tilde{v}^{\hat{r}} \\ \tilde{v}^{\hat{\varphi}} \\ \tilde{v}^{\hat{z}} \end{bmatrix} \bullet \begin{bmatrix} \tilde{v}^{\hat{r}} \\ \tilde{v}^{\hat{\varphi}} \\ \tilde{v}^{\hat{z}} \end{bmatrix}^{\star} r dr \right| \leq |\alpha| \sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|V^{\hat{z}}\right| \|\tilde{\vec{v}}\|^2. \tag{3.5}$$

Substituting estimates (3.3)–(3.5) into the equation for the disturbance energy (3.1) yields the inequality in the lemma. □

To determine a sufficient condition for monotone stability it is necessary to investigate the dependence of the terms in the inequality (3.2) on the free parameters of the problem—namely on the Reynolds number $\mathcal{R}$, the Womersley number $\mathcal{W}$ (for the oscillatory case only), and the wave vector (α, n) of the disturbance.

The required estimates on the base flow velocity and the base flow velocity derivative in terms of free parameters are given in section 3.2, and the estimate of the lowest eigenvalue λ_1 of the Stokes problem is derived in section 3.1. In these paragraphs various inequalities and identities for the Bessel functions are used. The identities can be found in Abramowitz and Stegun [1] or—including proofs—in Watson [13].

3.1. Stokes problem. The eigenvalue problem for the Stokes operator in a circular pipe is given by

$$-\frac{1}{\mathcal{R}}\Delta\vec{v} + \nabla p = \lambda\vec{v}, \tag{3.6}$$

$$\operatorname{div}\vec{v} = 0, \tag{3.7}$$

together with the no-slip boundary condition on the pipe's wall and the periodic boundary condition on the ends of the pipe.

It can be proved (see, for example, Constantin and Foias [3]) that the spectrum of the Stokes operator consists only of a point spectrum and that the eigenvalues of the Stokes operator are all positive. Furthermore, the eigenvectors form a complete orthogonal basis in an appropriate function space.

The Fourier transformed version[5] of the eigenvalue problem for the Stokes operator is considered in Salwen and Grosch [9] and Rummler [8]. In can be shown that the Fourier transformed eigenvalue problem has the same properties as the eigenvalue problem in real space (the eigenvalues are real, positive, and simple and the eigenfunctions form a complete orthogonal basis in an appropriate function space), and furthermore the eigenfunctions and the eigenvalues of the Fourier transformed problem can be explicitly calculated for all wave vectors (α, n).

The eigenvalues of the Fourier transformed problem are given by a complicated implicit equation and can be found by numerical means. However the aim of this work is to obtain an explicit condition for stability, and the mere fact that it is possible to calculate the eigenvalues by numerical solution of the implicit equation is clearly not sufficient for this purpose. To obtain wanted explicit conditions it is therefore necessary to find some explicit estimate of the lowest eigenvalue of the Stokes operator—this is done in the following lemma.

LEMMA 3.2 (estimate of the lowest eigenvalue of the Stokes operator). *Let λ_1 be the lowest positive eigenvalue of the Fourier transformed Stokes operator and let $\mathrm{j}_{k,l}$ denote the lth positive root of the Bessel function $\mathrm{J}_k(x)$.*

If $\alpha = 0$ and $n = 0$ then

$$\lambda_1 = \frac{1}{\mathcal{R}}\mathrm{j}_{0,1}^2. \tag{3.8}$$

If $\alpha = 0$ and $n \neq 0$ then

$$\lambda_1 = \frac{1}{\mathcal{R}}\mathrm{j}_{n,1}^2. \tag{3.9}$$

[5]The solution is sought in the wavy form (2.4).

If $\alpha \neq 0$ *and* $n = 0$ *then*

$$\lambda_1 = \frac{1}{\mathcal{R}} \left(\alpha^2 + \mathrm{j}_{1,1}^2 \right). \tag{3.10}$$

If $\alpha \neq 0$ *and* $n \neq 0$ *then*

$$\lambda_1 \geq \frac{1}{\mathcal{R}} \left(\alpha^2 + \mathrm{j}_{n-1,1}^2 \right). \tag{3.11}$$

Proof. In Rummler [8] it is shown that the eigenvalues of the Fourier transformed Stokes operator are equal to $\lambda_k = \frac{1}{\mathcal{R}} \left(\alpha^2 + \beta_k^2 \right)$, where the parameters β_k are roots of certain characteristic equations according to the value of the wavevector (α, n).

For $\alpha = 0$ and $n = 0$ parameters β_k are positive roots[6] of equations $\mathrm{J}_1(\beta_k) = 0$ and $\mathrm{J}_0(\beta_k) = 0$. For the Bessel functions it is known that for $m, l \in \mathbb{N}$, $m < l$ there is $\mathrm{j}_{m,1} < \mathrm{j}_{l,1}$. It is therefore obvious that the lowest eigenvalue is in this case given by (3.8).

For $\alpha = 0$ and $n \neq 0$ parameters β_k are positive roots of equations $\mathrm{J}_n(\beta_k) = 0$ and $\mathrm{J}_{|n|+1}(\beta_k) = 0$. The result (3.9) is then obtained by the same argument as in the previous case.

For $\alpha \neq 0$ and $n = 0$ parameters β_k are positive roots of equations

$$\mathrm{J}_1(\beta_k) = 0 \tag{3.12}$$

and

$$|\alpha| \mathrm{I}_0(|\alpha|) \mathrm{J}_1(\beta_k) - \beta \mathrm{I}_1(|\alpha|) \mathrm{J}_0(\beta_k) = 0, \tag{3.13}$$

where $\mathrm{I}_k(x)$ denotes the modified Bessel function of the first kind and of order k.

Dividing (3.13) by $|\alpha| \mathrm{I}_0(|\alpha|)$ and taking the limit $|\alpha| \to +\infty$ or $|\alpha| \to 0+$ yield asymptotic equations $\mathrm{J}_1(\beta_k) = 0$ and $-\frac{\beta_k}{2} \mathrm{J}_2(\beta_k) = 0$ respectively. It is obvious that roots of these asymptotic equations cannot be roots of the original (3.13). From the asymptotic equations, continuity of the left-hand side of (3.13), and the fact that the eigenvalues of the Stokes problem must be simple for all α and n, it follows that the first positive root of (3.13) must be for all $|\alpha|$ localized in the interval $(\mathrm{j}_{1,1}, \mathrm{j}_{2,1})$. The first positive β_k is therefore the first positive solution to (3.12), and equality (3.10) indeed holds.

For $\alpha \neq 0$ and $n \neq 0$ parameters β_k are roots of the following equation:

$$\begin{aligned} -2|\alpha| \mathrm{I}_n(|\alpha|) \mathrm{J}_{n-1}(\beta_k) \mathrm{J}_{n+1}(\beta_k) + \beta_k \mathrm{I}_{n+1}(|\alpha|) \mathrm{J}_{n-1}(\beta_k) \mathrm{J}_n(\beta_k) \\ - \beta_k \mathrm{I}_{n-1}(|\alpha|) \mathrm{J}_n(\beta_k) \mathrm{J}_{n+1}(\beta_k) = 0. \end{aligned} \tag{3.14}$$

In this case it is possible to apply the same approach as above. Dividing the equation by $|\alpha| \mathrm{I}_n(|\alpha|)$ and taking the limit $|\alpha| \to +\infty$ yield

$$-2 \mathrm{J}_{n-1}(\beta_k) \mathrm{J}_{n+1}(\beta_k) = 0, \tag{3.15}$$

and dividing (3.14) by $\mathrm{I}_{n-1}(|\alpha|)$ and taking the limit $|\alpha| \to 0+$ lead to the asymptotic equation

$$-\beta_k \mathrm{J}_n(\beta_k) \mathrm{J}_{n+1}(\beta_k) = 0. \tag{3.16}$$

[6] Trivial root $\beta = 0$ would lead to the trivial solution of the eigenvalue problem for the Stokes operator.

The first positive root of (3.15) is $\mathrm{j}_{n-1,1}$ and the first positive root of (3.16) is $\mathrm{j}_{n,1}$. Again it is obvious that neither $\mathrm{j}_{n-1,1}$ nor $\mathrm{j}_{n,1}$ are roots of the original (3.14) and—as in the previous case—it follows that the first positive root of the original equation is localized in the interval $(\mathrm{j}_{n-1,1}, \mathrm{j}_{n,1})$, and therefore the inequality (3.11) indeed holds. ∎

3.2. Estimates on the base flow. The last step necessary to rewrite the right-hand side of the inequality (3.2) as an explicit function of $\mathcal{R}$, $\mathcal{W}$, α, and n is to find some estimates of the expressions appearing in the inequalities (3.5) and (3.4). The appropriate estimates are given below.

LEMMA 3.3 (estimate of base flow velocity). *Let $V^{\hat{z}}$ be the base flow velocity given by the formula* (2.7)*. Then*

$$\sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|V^{\hat{z}}(r,t)\right| \le \frac{8}{\mathcal{W}^2}. \tag{3.17}$$

Proof. The proof of the lemma is straightforward:

$$\left|V^{\hat{z}}(r,t)\right| \le \frac{4}{\mathcal{W}^2}\left(1+\left|\frac{\mathrm{J}_0(i^{\frac{3}{2}}\mathcal{W}r)}{\mathrm{J}_0(i^{\frac{3}{2}}\mathcal{W})}\right|\right) \le \frac{8}{\mathcal{W}^2}.$$

The last estimate in the inequality is obvious from the identity

$$\begin{aligned}\left|\mathrm{J}_\nu(i^{\frac{3}{2}}x)\right|^2 &= \left|\mathrm{ber}_\nu(x)+i\,\mathrm{bei}_\nu(x)\right|^2 \\ &= \left(\frac{x}{2}\right)^{2\nu}\sum_{k=0}^{+\infty}\frac{1}{\Gamma(\nu+k+1)\Gamma(\nu+2k+1)}\frac{\left(\frac{x^2}{4}\right)^{2k}}{k!}.\end{aligned} \tag{3.18}$$

∎

LEMMA 3.4 (estimate of base flow velocity derivative). *Let $V^{\hat{z}}$ be the base flow velocity given by the formula* (2.7)*. Then*

$$\sup_{r\in[0,1],\ t\in[0,\frac{2\pi}{\omega}]} \left|\frac{\partial V^{\hat{z}}}{\partial r}(r,t)\right| \le \frac{4}{\mathcal{W}}. \tag{3.19}$$

Proof. The estimate easily follows from the above-mentioned identity (3.18) and basic inequality $|\mathrm{J}_0(i^{\frac{3}{2}}x)| > |\mathrm{J}_1(i^{\frac{3}{2}}x)|$. ∎

3.3. Sufficient condition for monotone linear stability. Combining estimates from sections 3.1 and 3.2 leads to the sufficient condition for monotone linear stability of the oscillatory and the steady Hagen–Poiseuille flow.

THEOREM 3.5 (sufficient condition for monotone linear stability). *Let $\tilde{\vec{v}}$ be a disturbance to the oscillatory Hagen–Poiseuille flow determined by the Reynolds number $\mathcal{R}$ and the Womersley number $\mathcal{W}$, and let (α, n) be the wave vector of the disturbance. If $\alpha = 0$, $n = 0$, and*

$$-\frac{1}{\mathcal{R}}\mathrm{j}_{0,1}^2 + |\alpha|\frac{8}{\mathcal{W}^2} + \frac{4}{\mathcal{W}} < 0, \tag{3.20}$$

or if $\alpha = 0$, $n \neq 0$, and

$$-\frac{1}{\mathcal{R}}\mathrm{j}_{n,1}^2 + \frac{4}{\mathcal{W}} < 0, \tag{3.21}$$

or if $\alpha \neq 0$, $n = 0$, *and*

$$-\frac{1}{\mathcal{R}}\left(\alpha^2 + \mathrm{j}_{1,1}^2\right) + |\alpha|\frac{8}{\mathcal{W}^2} + \frac{4}{\mathcal{W}} < 0, \tag{3.22}$$

or if $\alpha \neq 0$, $n \neq 0$,

$$-\frac{1}{\mathcal{R}}\left(\alpha^2 + \mathrm{j}_{n-1,1}^2\right) + |\alpha|\frac{8}{\mathcal{W}^2} + \frac{4}{\mathcal{W}} < 0, \tag{3.23}$$

then the disturbance energy monotonically decays in time.

Proof. The proposition is a immediate consequence of the energy estimate (Lemma 3.1), the estimate of the lowest eigenvalue of the Stokes operator (Lemma 3.2), and estimates of base flow velocity and base flow velocity derivative (Lemmas 3.3 and 3.4). ∎

The first condition in the theorem is in fact exceedingly strict. It can be proved that the disturbance with $(\alpha, n) = (0, 0)$ monotonically decays in time for all values of the Reynolds number $\mathcal{R}$ and the Womersley number $\mathcal{W}$. Indeed, in this case—due to a special form of the eigenfunctions of the Stokes operator[7]—the second and third terms on the right-hand side of (3.2) are equal to zero, and therefore there is no need to balance positive and negative terms using the estimates (3.5) and (3.4).

A theorem similar to Theorem 3.5 can be also derived in the steady case. Estimates on the base flow velocity analogous to the estimates (3.17) and (3.19) are in this case trivial. For example, in the most general case $\alpha \neq 0$ and $n \neq 0$, the condition for monotone decay of disturbances to the steady Hagen–Poiseuille flow reads

$$-\frac{1}{\mathcal{R}}\left(\alpha^2 + \mathrm{j}_{n-1,1}^2\right) + |\alpha| + 2 < 0. \tag{3.24}$$

Using Theorem 3.5 it is easy to derive the following condition for monotone decay of all possible disturbances.

Corollary 3.6 (explicit bound on Reynolds number). *If the Reynolds number* $\mathcal{R}$ *for the oscillatory Hagen–Poiseuille flow satisfies the inequality* $\mathcal{R} < \mathcal{R}_{\mathrm{crit}}$, *where*

$$\mathcal{R}_{\mathrm{crit}} = \frac{\mathcal{W}^2}{8}\left(2\sqrt{\left(\frac{\mathcal{W}}{2}\right)^2 + \mathrm{j}_{0,1}^2} - \mathcal{W}\right), \tag{3.25}$$

then the flow is monotonically linearly stable to all possible disturbances.

If the Reynolds number $\mathcal{R}$ *for the steady Hagen–Poiseuille satisfies the inequality* $\mathcal{R} < \mathcal{R}_{\mathrm{crit}}$, *where*

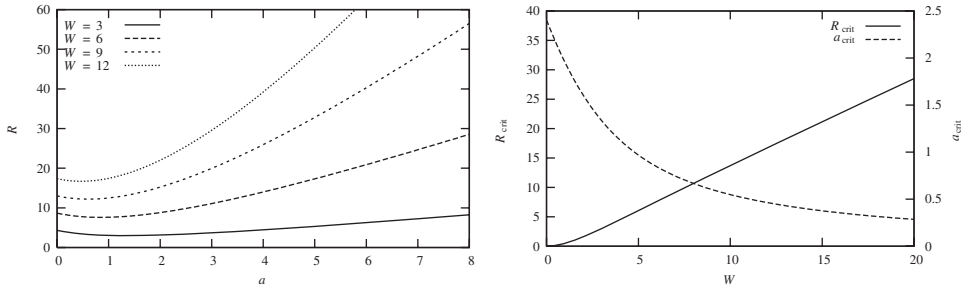
$$\mathcal{R}_{\mathrm{crit}} = 2\left(\sqrt{4 + \mathrm{j}_{0,1}^2} - 2\right), \tag{3.26}$$

then the flow is monotonically linearly stable to all possible disturbances.

Proof. The inequality $\mathrm{j}_{n,1} < \mathrm{j}_{n+1,1}$ that holds for all $n \in \mathbb{N}$, together with the estimates from Theorem 3.5, leads to the following general sufficient condition that ensures monotone decay for all n:

$$-\frac{1}{\mathcal{R}}\left(\alpha^2 + \mathrm{j}_{0,1}^2\right) + |\alpha|\frac{8}{\mathcal{W}^2} + \frac{4}{\mathcal{W}} < 0. \tag{3.27}$$

[7] See Rummler [8] for explicit formulas for the eigenfunctions in this special case.



(a) stable regions according to (3.23)

(b) critical values according to (3.25) and (3.29)

FIG. 3.1. *Sufficient condition for monotone stability of oscillatory Hagen–Poiseuille flow.*

The condition can be rewritten as

$$\mathcal{R} < \frac{\alpha^2 + \mathrm{j}_{0,1}^2}{\alpha\frac{8}{\mathcal{W}^2} + \frac{4}{\mathcal{W}}}, \tag{3.28}$$

and the corollary is then a straightforward consequence of minimization of the right-hand side with respect to α. The critical value of α where the function on the right-hand side attains its minimum is equal to

$$\alpha_{\mathrm{crit}} = \sqrt{\left(\frac{\mathcal{W}}{2}\right)^2 + \mathrm{j}_{0,1}^2} - \frac{\mathcal{W}}{2}, \tag{3.29}$$

and substitution of this value back into (3.28) gives the proposition.

In the steady case the proposition is proved by the same arguments; the key inequality analogous to (3.28) is in this case $\mathcal{R} < \frac{\alpha^2+\mathrm{j}_{0,1}^2}{\alpha+2}$. □

A plot of parameter regions which satisfy condition (3.23) for $n = 1$ (and thus also the general condition (3.23) that is uniform with respect to n) is shown in Figure 3.1(a). All pairs $(\alpha, \mathcal{R})$ that for a given Womersley number $\mathcal{W}$ lie below the corresponding curve in Figure 3.1(a) lead to monotonically decaying disturbances. The dependence of the critical Reynolds number $\mathcal{R}_{\mathrm{crit}}$ and the critical wavelength α_{crit} on the Womersley number $\mathcal{W}$ is shown in Figure 3.1(b).

4. Conclusion. Explicit sufficient conditions for monotone linear stability of the oscillatory and steady Hagen–Poiseuille flow were found by purely analytical means.

In the case of the steady Hagen–Poiseuille flow a numerical evaluation of the sufficient condition (3.26) leads to the conclusion that if the Reynolds number is less than approximately 2.26, then the flow is monotonically stable to all possible disturbances. This bound on monotone stability is low compared to the bound given by Joseph and Carmi [5], but the value of the present result is that it was achieved by purely analytical means. Herron [4] proved stability (but not monotone stability) for axisymmetric disturbances, and his result holds without any further conditions on the magnitude of the Reynolds number. In light of this result, the present sufficient condition (3.26) is clearly exceedingly restrictive for axisymmetric disturbances; however, the condition (3.26) becomes important if it is necessary to describe behavior of nonaxisymmetric disturbances that are beyond the scope of the Herron result.

Considering the oscillatory Hagen–Poiseuille flow, the condition (3.25) is more valuable because of the lack of analytical and numerical results particularly for nonaxisymmetric disturbances. Especially for nonaxisymmetric disturbances, where even numerical results are not available, the condition provides an important description of stability properties of the flow. However, the bound on the Reynolds number given in the condition (3.25) is very strict, and the condition is difficult—but not impossible—to meet in a practically important situation. For example, if the first harmonic component of oscillatory flow in the femoral artery of a dog (see Womersley [14]) is considered, then $\mathcal{W} = 3.3$ and $\mathcal{R} = 648$, while the condition (3.25) ensures stability for the Reynolds number less than 1.7. Nevertheless, for the sixth harmonic (sine) component, there are $\mathcal{W} = 8.2$ and $\mathcal{R} = 12.3$, while the Reynolds number sufficient for monotone stability is equal to 4.7.

Sufficient conditions set in Theorem 3.5 are important not only from the analytical point of view, but also from the numerical point of view, because they for a given Reynolds number and Womersley number provide rigorous bounds on the range of wavevectors (α, n) that must be examined in any future search for instability by numerical means. Furthermore, the critical wavelength α_{crit} provides a clue to the question of which wavelength α could be expected to be the least stable or even unstable.

AN ASYMPTOTIC FRAMEWORK FOR FINITE HYDRAULIC FRACTURES INCLUDING LEAK-OFF*

S. L. MITCHELL†, R. KUSKE†, AND A. P. PEIRCE†

Abstract. The dynamics of hydraulic fracture, described by a system of nonlinear integro-differential equations, is studied through the development and application of a multiparameter singular perturbation analysis. We present a new single expansion framework which describes the interaction between several physical processes, namely viscosity, toughness, and leak-off. The problem has nonlocal and nonlinear effects which give a complex solution structure involving transitions on small scales near the tip of the fracture. Detailed solutions obtained in the crack tip region vary with the dominant physical processes. The parameters quantifying these processes can be identified from critical scaling relationships, which are then used to construct a smooth solution for the fracture depending on all three processes. Our work focuses on plane strain hydraulic fractures on long time scales, and this methodology shows promise for related models with additional time scales, fluid lag, or different geometries, such as radial (penny-shaped) fractures and the classical Perkins–Kern–Nordgren (PKN) model.

Key words. asymptotic solutions, crack tip, critical scales, hydraulic fractures, integral-differential equations, leak-off

1. Introduction.

Hydraulic fractures are propagated in an elastic material due to the pressure exerted by a viscous fluid on the fracture. These fractures occur naturally in volcanic dikes where magma causes fracture propagation below the surface of the earth [37, 38, 55]. In the oil and gas industry hydraulic fractures are deliberately propagated in reservoirs to increase production. Hydraulic fracture models need to account for the primary physical mechanisms involved: deformation of the rock, fracturing of the rock, flow of viscous fluid within the fracture, and leak-off of the fracturing fluid into the permeable rock. The parameters that characterize these processes are, respectively, Young's modulus E and Poisson's ratio ν, the rock toughness K_{Ic}, the fluid viscosity μ, and the leak-off coefficient C_l.

The challenges for analysis of these models originate from the nonlinearity of the equation describing the flow of fluid in the fracture, the nonlocal character of the elastic response of the fracture, and the history-dependence of the equation governing the exchange of fluid between the fracture and the rock. The singular tip behavior, which can be difficult to resolve numerically, dominates these solutions and is highly dependent on the relative importance of the contributing physical processes. Therefore, the objectives of analytic treatment of these models are as follows: to characterize the structure of the near-tip solution that can be embedded in numerical algorithms, to provide benchmark solutions to test numerical codes, and to determine the parameter values and length scales that characterize the transitions between distinct combinations of physical processes. In this paper we use a novel asymptotic framework that enables us to characterize the different propagation regimes and provide asymptotic solutions when more than two physical processes are competing simultaneously. This

is distinct from previous analytic work on such models, which have been restricted to considering at most two competing physical processes [6, 23, 24, 26].

There has been a significant amount of work in the last half century involving the mathematical modeling of hydraulic fractures [1, 8, 14, 28, 30, 31, 32, 33, 45, 48, 55]. As discussed in [21] and the references therein, the aim of these models is to calculate the fluid pressure, opening, and size of the fracture given the properties of the rock, the injection rate, and the fluid characteristics. More recent work has been concerned with developing numerical algorithms to simulate three-dimensional propagation of hydraulic fractures in layered strata [5, 7, 12, 46, 47, 53]; this is in contrast to earlier work where approximate solutions were found for simple fracture geometries [1, 8, 28, 33, 45, 48, 55]. A substantial difference between hydraulic fracturing and other studies of fracture (see [22, 49, 52]) is the coupling with the equations for the fluid and fracture geometry. Most models in hydraulic fracturing only consider planar fractures rather than kinked or curved cracks [13, 41, 42].

The relevant fracture geometry that we consider in this paper, known as the KGD (plane strain) model, was developed independently by Khristianovic and Zheltov [33] and Geertsma and de Klerk [28]. The fracture is assumed to be an infinite vertical strip so that horizontal cross-sections are in a state of plane strain. This model is applicable to large aspect ratio rectangular planar fractures and was extended in [54] to include toughness. A major contribution to this mathematical modeling was made by Spence and Sharp [54], who initiated the work on self-similar solutions and scaling for a KGD crack propagating in an elastic, impermeable medium with finite toughness. This approach has been continued through asymptotic analyses of near-tip processes, yielding the results from [15] for zero toughness in an impermeable rock, and from [36] for zero toughness when leak-off is dominant. Several papers [16, 19, 27] have extended this analysis to include toughness and fluid lag, where regions devoid of fluid develop close to the crack tip, along with transitional regions. In this paper we assume that fluid lag is negligible and so these effects can be ignored.

Certain phases of hydraulic fracture propagation are characterized within a dimensionless parametric space [21, 20], with boundaries controlled by the dominant processes, namely, viscosity, toughness, or leak-off. This framework has been the basis for semianalytical solutions for simple geometries (KGD and penny-shaped) and benchmarks for numerical simulators. These include the following asymptotic regimes: impermeable with zero toughness [2, 10, 50], small toughness [24], finite toughness [3, 54], and large toughness [26, 50]; and permeable with zero toughness [4].

Since much of our analysis is closely related and complementary to these most recent studies, we outline the context here, with further discussion given in section 1.1 in terms of the specific model. Previous analyses [2, 9, 10, 24, 25, 26, 27] have been limited to parameter regimes where one or two physical processes dominate the dynamics, with the remainder of the related nondimensional quantities set to unity. In each case there is a different set of scaling parameters defined, depending on the dominant process(es), corresponding to the edges and corners of the parameter space [6, 21]. These methods lead to asymptotic expansions for the tip behavior, where the terms in the expansion involve powers of the distance from the tip. In the case of vanishing leak-off, this method has also been used to describe the transition in behavior between different power law expansions [2]. Recent preliminary studies [23, 34, 35] have also used combinations of power law expansions in the context of a semi-infinite approximation for the fracture, combined with numerical methods to understand transitions between different scaling regimes.

In this paper we present a unifying scaling framework based on singular perturbation techniques which analyzes how the physical processes, namely, viscosity, toughness, and leak-off, all influence the KGD crack behavior. Avoiding semi-infinite approximations, it involves the simultaneous scaling of all three processes relative to the distance from the fracture tip: this means that the approach is applicable for different combinations of the dominant physical processes. It has been used in [44] for the impermeable case in which only the processes of viscous dissipation and energy release compete. Thus it provides a construction of the solution in the crucial tip region, identifying the parameter combinations which quantify spatial transitions in the behavior of the fracture. The scaling exponents of the physical processes are determined as part of the method, so that it can be applied to construct approximate solutions in intermediate parameter regimes where several processes are in balance. The resulting asymptotic approximation provides verification of the conditions under which self-similar solutions are appropriate, and indicates regimes in which a more complicated time-dependence is involved, as discussed in section 4. We also briefly outline how the technique can be generalized to regimes where there is more than one transition in the behavior near the tip.

The fracture propagation is formulated as a system of coupled integrodifferential equations, and our method proves to be very beneficial in understanding the nonlocal and local effects that arise. It can be applied to different geometries, such as the classical Perkins–Kern–Nordgren (PKN) model [43], and we expect that it can be extended to model other effects such as stress jumps and fluid lag.

1.1. Problem formulation and dimensional results. The solution of the KGD hydraulic fracture problem (shown in Figure 1.1) consists of determining the fracture opening w and the net pressure p (the difference between the fluid pressure p_f and the far-field stress σ_o) as functions of space and time, as well as the fracture half-length, $l(t)$. These functions depend on the volumetric fluid injection rate Q_0, assumed constant in this paper, and on the four material parameters E', μ', K', and

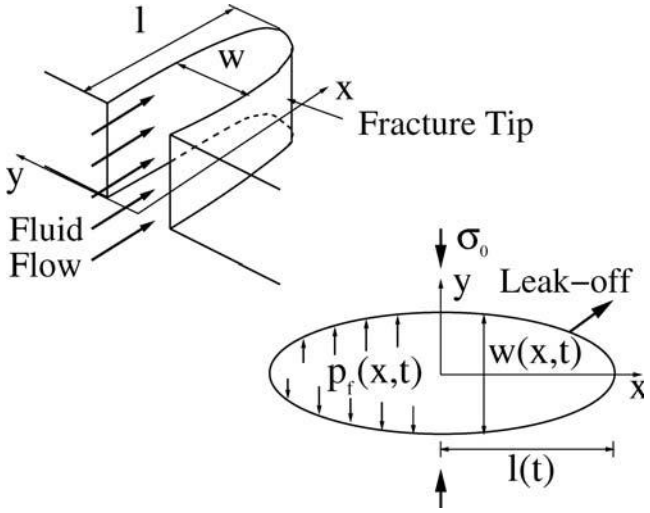

FIG. 1.1. *Diagrams showing the KGD crack and its cross-section.*

C', respectively, defined as

$$E' = \frac{E}{1-\nu^2}, \qquad \mu' = 12\mu, \qquad K' = 4\left(\frac{2}{\pi}\right)^{1/2} K_{Ic}, \qquad C' = 2C_l, \tag{1.1}$$

which are combinations of the parameters quantifying the primary physical mechanisms described at the beginning of this section. The rock toughness K_{Ic} is assumed to be equal to the stress intensity factor K_I which, for this geometry, can be expressed as an integral of the pressure

$$K_{Ic} = K_I = 2\sqrt{\frac{l}{\pi}} \int_0^l \frac{p}{\sqrt{l^2 - x^2}}\, \mathrm{d}x. \tag{1.2}$$

The equations for the KGD fracture are as follows:

$$\text{Reynolds' (lubrication) equation:} \quad \frac{\partial w}{\partial t} + g = \frac{1}{\mu'} \frac{\partial}{\partial x}\left[w^3 \frac{\partial p}{\partial x}\right] + Q_0 \delta(x), \tag{1.3}$$

which describes the conservation of fluid mass for an incompressible fluid. Note that g is the leak-off term which describes the fluid infiltration into the surrounding rock.

$$\text{Elasticity equation:} \qquad p(x,t) = -\frac{E'}{4\pi} \int_{-l}^{l} \frac{\partial w}{\partial s} \frac{\mathrm{d}s}{s-x}, \tag{1.4}$$

which describes the balance of forces and is a nonlocal equation relating the fracture opening w and net pressure p for a state of plane strain.

$$\text{Propagation condition:} \quad w = \frac{K'}{E'}\sqrt{l-x} + O\big[(l-x)^{3/2}\big], \qquad x \longrightarrow \pm l, \tag{1.5}$$

which accounts for the energy required to break the rock and is the condition that the fracture is in mobile equilibrium.

$$\text{Boundary conditions:} \qquad w = 0, \qquad w^3 \frac{\partial p}{\partial x} = 0, \qquad \text{at } x = \pm l. \tag{1.6}$$

$$\text{Global volume balance condition:} \quad Q_0 t = \int_{-l}^{l} w(s,t)\, \mathrm{d}s + \int_0^t \int_{-l}^{l} g(s,\tau)\, \mathrm{d}s\, \mathrm{d}\tau, \tag{1.7}$$

which equates the crack volume to the volume of injected fluid and amount lost to the surrounding rock mass, obtained by integrating (1.3) and applying (1.6). If $t_0(x)$ is the time at which the crack tip arrived at the point x, and t is the current time, then the leak-off function g is defined as

$$\text{Carter's leak-off model:} \qquad g(x,t) = \frac{C' H(t - t_0)}{\sqrt{t - t_0(x)}}. \tag{1.8}$$

The memory term $t_0(x)$ implies that the leak-off function $g(x,t)$ depends on the entire history of the fracture front locations, which significantly complicates the analysis.

Since its introduction in 1957, Carter's leak-off model [11] has been widely accepted and successfully used in the oil and gas industry to design hydraulic fracturing

treatments and has been referred to as "the standard model of fracturing fluid loss" (see [36]). We briefly summarize the steps involved in the derivation of the model and discuss its applicability for high confinement geological situations, which are becoming more important as deeper reserves are being exploited.

The first assumption made in the derivation of Carter's leak-off model is that the hydraulic load $\Delta p = p_f - p_0$ driving the leak-off process is approximately constant, where p_0 is the reservoir pore pressure. This assumption can be justified in high confinement reservoirs where $p_f \approx \sigma_0 \gg p_0$. In this case the hydraulic load is much larger than the net pressure $p = p_f - \sigma_0$ and is approximately constant, i.e., $\Delta p \approx \sigma_0 - p_0$. The second assumption made in the derivation of (1.8) is in approximating the leak-off process by a one-dimensional flow perpendicular to the crack propagation axis that does not account for any lateral interaction. Modeling this gradient-driven flow involves incorporating the growth of an impermeable *filter cake* layer via the deposition of polymer molecules by the leaking fluid, the growth of an *invaded zone* of fluid that penetrates the filter cake, and a pressure diffusion zone within the reservoir. Combining these three physical processes in series yields (1.8), in which the lumped coefficient C' is known as the *Carter leak-off coefficient* (see [6, 11, 39, 51] and the references therein).

Assuming that $l(t) = at^{1/2}$, Gordeyev and Entov [29] derived a similarity solution to the two-dimensional pressure diffusion equation, which yields a leak-off velocity of the same form as (1.8). In this case the fracture is growing sufficiently rapidly for the leak-off process to be one-dimensional, a situation that is likely to persist for power laws in which the fracture evolves more rapidly: $l(t) = at^{\lambda}$, where $\lambda \geq \frac{1}{2}$. Carter's model (1.8), which is based on the pressure diffusion equation, ignores feedback coupling between the reservoir pressure field and the elastic strain in the rock. This pure diffusion approximation can be justified using poroelasticity theory [17, 18] in which the elastic strain feedback due to the hydraulic load Δp is shown to vanish identically. Moreover, for high confinement reservoirs the mechanical load effect (due to the net pressure p which forces the crack to open) on the reservoir pressure is insignificant compared to that of the hydraulic load, since $\Delta p \gg p$.

There may be a question as to the validity of Carter's model right at the crack tip. However, the analysis presented in this paper is based on the fact that the dominant physical process governing the behavior of the fracture at the tip, which we refer to as the *near-tip region*, is the energy released in the breaking of the rock as characterized by the fracture toughness. Since the leak-off process is subdominant to this and only manifests itself a distance away from the tip in the *intermediate-tip region*, we make use of the model only in a region where it is still valid. We could include other higher order effects to model the leak-off more carefully in the near-tip region, but this is neglected in our analysis since it is not the dominant process.

The method presented in this paper involves an iterative construction of the asymptotic solution: the lubrication and elasticity equations (1.3)–(1.4) alternatively give the form of the solution. The volume balance equation (1.7) is applied to complete the solution: it verifies the balance of physical processes, determines unknown constants, and provides a consistency check on the temporal behavior of the solution. The propagation condition (1.5) manifests itself in the asymptotic behavior of the tip when the influence of the toughness is dominant; this depends on the relative scalings of the parameters and the distance from the tip.

We give the main results for w in terms of the dimensional variables; the expansions for p can then be determined from (1.4). For $\mathcal{P}_{ckm} \gg (\ll) (1-\xi)^{1/2}$, respectively,

we find that

$$w \sim \frac{K'}{E'} l^{1/2} \left\{ \left(1 - \frac{x}{l}\right)^{1/2} + \left[\frac{8\pi}{3}\gamma^{3/2}\mathcal{P}_{km}^{-1} + 4\sqrt{2}\pi\gamma\mathcal{P}_{ckm}^{-1}\right]\left(1 - \frac{x}{l}\right)\right\}, \tag{1.9}$$

$$w \sim \left(\frac{C'\mu'}{E'}\right)^{1/4} \frac{l^{3/4}}{t^{1/8}}\gamma^{-3/4}\left\{\tilde{C}_{01}\left(1 - \frac{x}{l}\right)^{5/8} + \mathcal{B}_1\left(1 - \frac{x}{l}\right)^{1/8} + \mathcal{B}_2\mathcal{P}_{cm}^{-1/4}\left(1 - \frac{x}{l}\right)^{3/4} + \mathcal{B}_3\left(1 - \frac{x}{l}\right)^{r}\right\}, \tag{1.10}$$

where $\tilde{C}_{01}$, $\mathcal{B}_1$, $\mathcal{B}_2$, $\mathcal{B}_3$, and r are constants determined in the solution process, and γ is an $O(1)$ quantity introduced in the rescaling below. The three key parameter combinations

$$\mathcal{P}_{km} := \frac{K'^3}{\mu' E'^2}\frac{\gamma^{3/2}t}{l^{3/2}}, \qquad \mathcal{P}_{cm} := \frac{C'^3 E'}{\mu'}\frac{\gamma^3 t^{5/2}}{l^3}, \qquad \mathcal{P}_{ckm} := \frac{K'^4}{C'\mu' E'^3}\frac{\gamma t^{1/2}}{l} \tag{1.11}$$

characterize the different behavior regimes, as shown in the analysis. The leading order term in (1.10) was established by [36] for the stationary solution and then confirmed in [6] for zero toughness. In a preliminary study [9], which considers the infinite limit of a nondimensional parameter for the volume of injected fluid (2.2), the first and last terms in both (1.9) and (1.10) are also determined. However, the other terms are not found there, since certain parameter combinations are fixed (see section 3.2 for further discussion.) These additional terms allow us to analytically construct a uniform solution near the tip, instead of numerically as in [24] for zero leak-off. Near and far-field solutions for semi-infinite approximations of the fracture [23, 35, 34] also use expansions in powers of $(1-\xi)$, which include some of the powers from (1.9)–(1.10) in addition to other terms related to the semi-infinite limit. Power law expansions similar to (1.9)–(1.10) for the zero leak-off case are derived in [44]. Some of these terms are also determined in [6, 24], but the additional terms found in [44] allow the uniform tip behavior to be constructed analytically.

The asymptotic expansions (1.9)–(1.10) explicitly identify the critical parameter combinations (1.11) that dictate transitions between (1.9) and (1.10) in the tip vicinity. These quantities are combinations of the dimensionless parameters that arise in the rescaling below, which quantify the physical processes viscosity, toughness, and leak-off. From the construction of expansions (1.9)–(1.10) we can understand the changes in tip behavior as we scale the quantities (1.11) with a parameter related to the distance from the tip $\xi = 1$. Our method does not use a semi-infinite approximation, and therefore can be extended to study additional time dependencies, transients, and other types of hydraulic fractures, such as finger-like geometries, known as the PKN fracture [45, 48].

In section 2 we describe the new approach and in section 3 obtain expansions when all three processes play a role, in the case that leak-off dictates the leading order behavior. The construction leads to the identification of the parameter combinations (1.11) which are necessary for describing the transition between the near- and intermediate-tip solutions (1.9)–(1.10). Section 4 summarizes our results and briefly outlines extensions of our methodology to situations where time-dependence must be scaled explicitly, or cases where there is more than one transition in the dominant shape of the fracture.

2. Approach of the new method. We introduce the nondimensional quantities, following [6, 26, 24] and others:

$$\xi = x/l, \qquad l = L\gamma, \qquad w = \epsilon L\Omega, \qquad p = \epsilon E'\Pi. \tag{2.1}$$

It is convenient to work with the dimensionless quantities Ω (the opening), Π (the net pressure), and γ (a fracture length), which are all $O(1)$. The parameter ϵ is used in [6, 26, 24] to relate w/l to p/E', so for comparison purposes we include it in our analysis; however, it plays no role here and so could be set to unity. Also, L denotes a length scale and is of the same order as the fracture length l.

We also define four nondimensional quantities,

$$\mathcal{G}_v = \frac{Q_0 t}{\epsilon L^2}, \qquad \mathcal{G}_m = \frac{\mu'}{\epsilon^3 E' t}, \qquad \mathcal{G}_k = \frac{K'}{\epsilon E' L^{1/2}}, \qquad \mathcal{G}_c = \frac{C' t^{1/2}}{\epsilon L}, \tag{2.2}$$

and determine different solutions depending on the size of combinations of these parameters (1.11) without setting any to unity. The governing equations (1.3)–(1.7) are now

$$\frac{t(\epsilon L)_t}{\epsilon L}\Omega + \dot{\Omega} t - \xi \frac{t(L\gamma)_t}{L\gamma}\frac{\partial \Omega}{\partial \xi} + \mathcal{G}_c \Gamma_l = \frac{1}{\mathcal{G}_m}\frac{1}{\gamma^2}\frac{\partial}{\partial \xi}\left[\Omega^3 \frac{\partial \Pi}{\partial \xi}\right], \tag{2.3}$$

$$\Pi = -\frac{1}{4\pi\gamma}\int_{-1}^{1} \frac{\partial \Omega}{\partial \chi}\frac{\mathrm{d}\chi}{\chi - \xi}, \tag{2.4}$$

$$\Omega = \mathcal{G}_k \gamma^{1/2}(1 \mp \xi)^{1/2}, \quad \xi \longrightarrow \pm 1; \qquad \Omega = 0, \quad \Omega^3 \frac{\partial \Pi}{\partial \xi} = 0, \quad \text{at } \xi = 1^{\pm}, \tag{2.5}$$

$$\mathcal{G}_v = \gamma \int_{-1}^{1} \Omega \, \mathrm{d}\chi + \mathcal{G}_c \frac{1}{L}\int_0^1 l(\theta t)\theta^{-1/2} \int_{-1}^{1} \Gamma_l \, \mathrm{d}\chi \, \mathrm{d}\theta, \tag{2.6}$$

where Γ_l is the dimensionless leak-off function discussed below.

The new approach relies on two main ingredients: (i) a scaling parameter $\delta \ll 1$ that relates distance from the tip to the key dimensionless quantities in (2.2), and (ii) a flexible asymptotic expansion which can handle behavior dominated by different physical quantities. Thus we define

$$1 - \delta z = \xi, \tag{2.7}$$

$$\mathcal{G}_v = \delta^{\beta_v}\hat{\mathcal{G}}_v, \quad \mathcal{G}_k = \delta^{\beta_k}\hat{\mathcal{G}}_k, \quad \mathcal{G}_m = \delta^{\beta_m}\hat{\mathcal{G}}_m, \quad \mathcal{G}_c = \delta^{\beta_c}\hat{\mathcal{G}}_c, \tag{2.8}$$

where the $\hat{\mathcal{G}}_{()}$'s are $O(1)$ quantities. The different regimes are then characterized by inequalities between the values of the exponents β_v, β_k, β_m, β_c. Here δ is introduced as a bookkeeping parameter that disappears from the expansion in the end. We assume that z is $O(1)$ and so $\delta \ll 1$ essentially describes the distance from the tip $\xi = 1$. Through this scaling we can explore the dominant behavior of the propagating fracture in a very general way: we have not yet specified the distance from the tip and we do not make a semi-infinite approximation, as used in previous studies such as [6, 26, 24], amongst others.

Because of the symmetry of the solution about $\xi = 0$ (see Figure 1.1), we can restrict our attention to the interval $0 < \xi < 1$ and write the equations in terms of z. The integral in (2.4) is then written as

$$\Pi = -\frac{1}{4\pi\gamma}\int_{-1}^{1} \frac{\mathrm{d}\Omega}{\mathrm{d}\chi}\frac{\mathrm{d}\chi}{\chi - \xi} = -\frac{1}{2\pi\gamma}\int_0^1 \frac{\mathrm{d}\Omega}{\mathrm{d}\chi}\frac{\chi \, \mathrm{d}\chi}{\chi^2 - \xi^2}, \tag{2.9}$$

and similarly for the integrals in (2.6).

Then applying (2.7) and (2.8) in the governing equations (2.3)–(2.6) yields

$$\frac{t(\epsilon L)_t}{\epsilon L}\Omega + (1-\delta z)\frac{t(L\gamma)_t}{L\gamma}\delta^{-1}\frac{\mathrm{d}\Omega}{\mathrm{d}z} + \hat{\mathcal{G}}_c\delta^{\beta_c}\Gamma_l = \frac{1}{\hat{\mathcal{G}}_m\gamma^2}\delta^{-\beta_m-2}\frac{\mathrm{d}}{\mathrm{d}z}\left[\Omega^3\frac{\mathrm{d}\Pi}{\mathrm{d}z}\right], \tag{2.10}$$

$$\Pi = -\frac{1}{2\pi\gamma}\delta^{-1}\int_0^{1/\delta}\frac{\mathrm{d}\Omega}{\mathrm{d}r}\frac{(1-\delta r)}{r(2-\delta r)-z(2-\delta z)}\,\mathrm{d}r, \tag{2.11}$$

$$\Omega = \hat{\mathcal{G}}_k\gamma^{1/2}\delta^{\beta_k+1/2}z^{1/2}, \quad z\longrightarrow 0; \qquad \Omega = 0, \ \ \Omega^3\frac{\mathrm{d}\Pi}{\mathrm{d}z} = 0, \quad \text{at } z=0, \tag{2.12}$$

$$\delta^{\beta_v}\hat{\mathcal{G}}_v = 2\gamma\delta\int_0^{1/\delta}\Omega\,\mathrm{d}r + 2\frac{\hat{\mathcal{G}}_c}{L}\delta^{\beta_c+1}\int_0^1 l(\theta t)\theta^{-1/2}\int_0^{1/\delta}\Gamma_l\,\mathrm{d}r\,\mathrm{d}\theta. \tag{2.13}$$

Here we look for self-similar solutions $\Omega = \Omega(z)$ and $\Pi = \Pi(z)$. We justify the use of these types of solutions in section 3.3. In (2.10)–(2.13) the powers of δ appear explicitly, and they play a central role in understanding the spatial behavior of the solution relative to the key dimensionless quantities.

For $\delta \ll 1$, we expand the solution Ω and Π as follows:

$$\Omega = \delta^{\beta_k+1/2}\big(\Omega_{00} + \delta^{\alpha_1}\Omega_{01} + \delta^{\alpha_2}\Omega_2 + \cdots\big), \tag{2.14}$$

$$\Pi = \delta^{\beta_k}\Pi_{00} + \delta^{\sigma_1}\Pi_{01} + \delta^{\sigma_2}\Pi_2 + \cdots, \tag{2.15}$$

where the exponents α_i and σ_i are determined in terms of the exponents $\beta_{()}$ in (2.8) as part of the method. The prefactor δ^{β_k} corresponds to the dimensionless parameter $\mathcal{G}_k$, and its inclusion in the leading terms is discussed below.

We substitute Ω and Π into the lubrication and elasticity equations (2.10) and (2.11), so that they become, respectively,

$$\begin{aligned}
&\frac{t(\epsilon L)_t}{\epsilon L}\delta^{\beta_k+1/2}\big(\Omega_{00}+\delta^{\alpha_1}\Omega_{01}+\cdots\big)\\
&\quad + (1-\delta z)\frac{t(L\gamma)_t}{L\gamma}\delta^{\beta_k-1/2}\left(\frac{\mathrm{d}\Omega_{00}}{\mathrm{d}z}+\delta^{\alpha_1}\frac{\mathrm{d}\Omega_{01}}{\mathrm{d}z}+\cdots\right) + \hat{\mathcal{G}}_c\delta^{\beta_c}\Gamma_l\\
&\quad = \frac{1}{\hat{\mathcal{G}}_m\gamma^2}\delta^{-\beta_m-1/2+3\beta_k}\frac{\mathrm{d}}{\mathrm{d}z}\left[\big(\Omega_{00}+\delta^{\alpha_1}\Omega_{01}+\big)^3\left(\delta^{\beta_k}\frac{\mathrm{d}\Pi_{00}}{\mathrm{d}z}+\delta^{\sigma_1}\frac{\mathrm{d}\Pi_{01}}{\mathrm{d}z}+\cdots\right)\right],
\end{aligned} \tag{2.16}$$

$$\begin{aligned}
&\delta^{\beta_k}\Pi_{00}+\delta^{\sigma_1}\Pi_{01}+\cdots\\
&\quad = -\frac{1}{2\pi\gamma}\delta^{\beta_k-1/2}\int_0^{1/\delta}\left(\frac{\mathrm{d}\Omega_{00}}{\mathrm{d}r}+\delta^{\alpha_1}\frac{\mathrm{d}\Omega_{01}}{\mathrm{d}r}+\cdots\right)\frac{(1-\delta r)}{r(2-\delta r)-z(2-\delta z)}\,\mathrm{d}r.
\end{aligned} \tag{2.17}$$

The nondimensionalized leak-off function Γ_l is defined as

$$\Gamma_l = \frac{1}{\sqrt{1-t_0(\xi l)/t}} = \frac{1}{\sqrt{1-\xi^{1/\lambda}}} = \frac{1}{\sqrt{1-(1-\delta z)^{1/\lambda}}}, \tag{2.18}$$

where $t_0(\cdot)$ is defined following (1.8), and we have written it in the rescaled coordinates (2.7). This follows from the definition of $t_0(x)$, the time lapsed between the current time t and the time at which the crack tip arrived at the point x, so that $x(t_0(x)) = l(t_0)$. Using $l = \gamma L$, $L = C_L t^\lambda$, and $\xi = x/l$, we find

$$l(t_0) = C_L\gamma\left(\frac{t_0}{t}\right)^\lambda t^\lambda \qquad \text{and} \qquad \frac{t_0}{t} = \xi^{1/\lambda}. \tag{2.19}$$

To motivate the equations which are solved below to leading order in the different regions, we briefly consider the lubrication equation in the form of (2.10). The leading order terms for $\delta \ll 1$ satisfy

$$\lambda\delta^{-1}\frac{\mathrm{d}\Omega}{\mathrm{d}z} + \frac{\hat{\mathcal{G}}_c\delta^{\beta_c-1/2}}{\sqrt{1-(1-\delta z)^{1/\lambda}}} = \frac{1}{\hat{\mathcal{G}}_m\gamma^2}\delta^{-\beta_m-2}\frac{\mathrm{d}}{\mathrm{d}z}\left[\Omega^3\frac{\mathrm{d}\Pi}{\mathrm{d}z}\right]. \tag{2.20}$$

The form of the expansions (2.14) and (2.15) distinguish where toughness dominates, with the sign of α_1 playing a significant role. We consider three cases:

(i) The right-hand side of (2.20) is dominant and set equal to zero. This gives $\Pi = \text{constant}$ to leading order (see Appendix A.1). Then Ω is found using the propagation condition (2.12), giving the leading order square root behavior for Ω_{00} and $\Pi_{00} = \text{constant}$. This case is described by $\alpha_1 > 0$, where toughness dominates the leading order behavior, and thus justifies the use of the prefactor δ^{β_k} in expansions (2.14) and (2.15). The details of this *near-tip* case are given in section 3.1 below.

(ii) The first term on the left-hand side balances with the right-hand side, thus neglecting the term with coefficient $\mathcal{G}_c$ to leading order. This case is described by $\alpha_1 < 0$, where viscosity, not leak-off, dictates the leading order behavior of $z^{2/3}$ [6, 15, 24]. When $\alpha_1 < 0$, the ordering of the terms in (2.14) and (2.15) changes; then Ω_{01} and Π_{01} become leading order and so Ω_{00} and Π_{00} are zero in regions where the toughness is not dominant.

(iii) The second term on the left-hand side matches the right-hand side. We obtain the solution $z^{5/8}$ to leading order, as in [6, 36]. This situation also holds for $\alpha_1 < 0$, with both leak-off and viscosity dictating the leading order behavior. Again, Ω_{00} and Π_{00} are zero, and Ω_{01} and Π_{01} are the leading order terms. The details of this *intermediate-tip* case are given in section 3.1 below. In section 3.3 we show that $\lambda = 1/2$ for sufficiently large time, as in [6], and so we use $\Gamma_l = 1/\sqrt{\delta z(2-\delta z)}$ in (2.18) for this case.

3. The expansion including toughness, leak-off, and viscosity. We consider the case with nonzero leak-off $\mathcal{G}_c \neq 0$ in addition to nonzero toughness and viscosity ($\mathcal{G}_k \neq 0$ and $\mathcal{G}_m \neq 0$.) The expansions (2.14) and (2.15) are used to determine exponents by balancing terms, leading to important combinations of the parameters in (1.11) which characterize the different cases. We focus on scenarios with significant leak-off, leading to the study of transitions between regimes where toughness and leak-off dominate the behavior, namely, cases (i) and (iii). The analysis identifies a critical scaling involving all three processes and gives a parametric characterization for significant leak-off as $\mathcal{G}_c^3/\mathcal{G}_m = O(1)$ or larger. In contrast, case (ii) occurs in regimes where leak-off plays a secondary role, $\mathcal{G}_c^3/\mathcal{G}_m \ll 1$ and $\mathcal{G}_c < \mathcal{G}_k$, and corresponds to the purely viscosity-dominated case with $z^{2/3}$ power law to leading order away from the tip. A straightforward extension of the analysis in [44] of the impermeable case can be used to include higher order corrections involving leak-off in this parameter region, so we do not consider it here. The intermediate case where $\mathcal{G}_c^3/\mathcal{G}_m \ll 1$ and $\mathcal{G}_c < \mathcal{G}_k$ has two transition regions, from the $z^{1/2}$ to $z^{5/8}$ to $z^{2/3}$ behavior. The analyses presented below and in [44] can be extended easily to treat these two transitions, and we outline this situation in section 4.

3.1. Local expansions. *Near-tip behavior* ($\alpha_1 > 0$): The leading order terms in (2.16) and (2.17) for $\delta \ll 1$ satisfy

$$0 = \delta^{-\beta_m - 1/2 + 4\beta_k} \frac{\mathrm{d}}{\mathrm{d}z}\left[\Omega_{00}^3 \frac{\mathrm{d}\Pi_{00}}{\mathrm{d}z}\right], \tag{3.1}$$

$$\delta^{\beta_k}\Pi_{00} = -\frac{1}{2\pi\gamma}\delta^{\beta_k - 1/2}\int_0^{1/\delta} \frac{\mathrm{d}\Omega_{00}}{\mathrm{d}r}\frac{(1-\delta r)}{r(2-\delta r) - z(2-\delta z)}\,\mathrm{d}r. \tag{3.2}$$

From these two equations we deduce that the solution of Ω_{00} is

$$\Omega_{00}(z) = C_{00}\sqrt{z(2-\delta z)}, \tag{3.3}$$

where $C_{00} = 4\pi\Pi_{00}$, and $\Pi_{00} =$ constant, as discussed in Appendix A.1. The expression (3.3) is the eigenfunction solution which, when substituted into (3.2), gives $\Pi_{00} =$ constant exactly; its leading order behavior matches the tip condition (2.12) and it is symmetric about $\xi = 0$. We use the tip condition (2.12) to find $C_{00} = \hat{\mathcal{G}}_k\sqrt{\gamma/2}$. Note that for $\alpha_1 > 0$, the leading order term in the expansion for Ω involves the rescaled toughness parameter $\mathcal{G}_k$.

The next order terms for $\delta \ll 1$ in (2.16) and (2.17) satisfy

$$\lambda\delta^{\beta_k - 1/2}\frac{\mathrm{d}\Omega_{00}}{\mathrm{d}z} + \hat{\mathcal{G}}_c\sqrt{\lambda}\delta^{\beta_c - 1/2}z^{-1/2} = \frac{1}{\hat{\mathcal{G}}_m\gamma^2}\delta^{-\beta_m + 3\beta_k - 1/2 + \sigma_1}\frac{\mathrm{d}}{\mathrm{d}z}\left[\Omega_{00}^3\frac{\mathrm{d}\Pi_{01}}{\mathrm{d}z}\right], \tag{3.4}$$

$$\delta^{\sigma_1}\Pi_{01} = -\frac{1}{2\pi\gamma}\delta^{\beta_k - 1/2 + \alpha_1}\int_0^{1/\delta}\frac{\mathrm{d}\Omega_{01}}{\mathrm{d}r}\frac{(1-\delta r)}{r(2-\delta r) - z(2-\delta z)}\,\mathrm{d}r. \tag{3.5}$$

For the moment we do not balance exponents of δ, but leave them in the expression. Solving (3.4) and (3.5) gives Ω_{01} and Π_{01}: we find $\Omega_{01}(z) = C_{01}z$ and Π_{01} satisfies

$$\Pi_{01} = -\frac{C_{01}}{4\pi\gamma}\ln\left(1 - \frac{1}{2-\delta z}\right) - \frac{C_{01}}{4\pi\gamma}\left[\ln(1-\delta z) - \ln(\delta z)\right] \tag{3.6}$$

for $z = O(1)$. The constant of integration in (3.4) is zero; otherwise the solution for Π_{01} yields an infinite stress intensity factor, as shown in Appendix A.2. The details of the calculation of Π_{01} are similar to the analysis in Appendix B. We now determine C_{01} by substituting Π_{01} into (3.4), and considering the leading order terms only. Hence

$$\delta^{\sigma_1}C_{01} = \hat{\mathcal{G}}_m\gamma^2\left[\delta^{\beta_m - 2\beta_k}\lambda\frac{2\pi\gamma}{C_{00}^2} + \delta^{\beta_c + \beta_m - 3\beta_k}\frac{4\pi\gamma\sqrt{\lambda}\hat{\mathcal{G}}_c}{\sqrt{2}C_{00}^3}\right]. \tag{3.7}$$

Notice that the terms on the right-hand side of (3.7) change order depending on the relative magnitude of $\mathcal{G}_k$ and $\mathcal{G}_c$ (i.e., δ^{β_k} and δ^{β_c}.) If $\mathcal{G}_c \ll \mathcal{G}_k$, then the first term on the right-hand side is dominant and we obtain

$$\alpha_1 = 1/2 + \beta_m - 3\beta_k, \qquad \sigma_1 = \beta_m - 2\beta_k, \qquad C_{01} = 2\pi\lambda\frac{\hat{\mathcal{G}}_m\gamma^3}{C_{00}^2}. \tag{3.8}$$

However, if $\mathcal{G}_c \gg \mathcal{G}_k$, then the second term on the right-hand side of (3.7) is dominant. The exponents α_1 and σ_1 and coefficient C_{01} are now

$$\alpha_1 = 1/2 + \beta_c + \beta_m - 4\beta_k, \qquad \sigma_1 = \beta_c + \beta_m - 3\beta_k, \qquad C_{01} = \frac{4\pi\sqrt{\lambda}\hat{\mathcal{G}}_c\hat{\mathcal{G}}_m\gamma^3}{\sqrt{2}C_{00}^3}. \tag{3.9}$$

Since both of these cases represent particular solutions to the linear equations (3.4)–(3.5), we can treat them simultaneously. Thus if $\alpha_1 > 0$, the first three terms in the expansion (2.14) for Ω are

$$\Omega \sim \delta^{\beta_k+1/2}\left[C_{00}\sqrt{z(2-\delta z)} + \delta^{1/2+\beta_m-3\beta_k}C_{01}z + \delta^{1/2+\beta_c+\beta_m-4\beta_k}C_{02}z\right], \tag{3.10}$$

where C_{02} is the redefined C_{01} coefficient from (3.9). Then the second term dominates over the third term when $\mathcal{G}_c \ll \mathcal{G}_k$, and vice versa when $\mathcal{G}_c \gg \mathcal{G}_k$.

Intermediate-tip behavior ($\alpha_1 < 0$): The leading order terms in (2.16) are

$$\lambda\delta^{\beta_k-1/2+\alpha_1}\frac{\mathrm{d}\Omega_{01}}{\mathrm{d}z} + \frac{\hat{\mathcal{G}}_c\delta^{\beta_c-1/2}}{\sqrt{z(2-\delta z)}} = \frac{\delta^{-\beta_m+3\beta_k-1/2+3\alpha_1+\sigma_1}}{\hat{\mathcal{G}}_m\gamma^2}\frac{\mathrm{d}}{\mathrm{d}z}\left[\Omega_{01}^3\frac{\mathrm{d}\Pi_{01}}{\mathrm{d}z}\right], \tag{3.11}$$

coupled with the elasticity equation (3.5). Note that we now use the form of Γ_l with $\lambda = 1/2$, as mentioned in case (iii) above, since we are in the leak-off–dominated regime. In the case that $\mathcal{G}_c^3/\mathcal{G}_m \gg (1-\xi)^{1/2}$, the second term on the left-hand side of (3.11) is dominant over the term with $\Omega_{01}'(z)$. Then balancing powers of δ in (3.11) and the elasticity equation (3.5) gives

$$\alpha_1 = 1/8 + (\beta_c+\beta_m)/4 - \beta_k, \qquad \sigma_1 = -3/8 + (\beta_c+\beta_m)/4. \tag{3.12}$$

Note that if the first term in (3.11) is dominant, then the leading order terms for Ω_{01} are the same as in the case of zero leak-off studied in [6, 15, 24, 44]. This corresponds to the case $\delta^{1/8+(\beta_m+\beta_c)/4} > \delta^{\beta_c}$ or, equivalently, $\mathcal{G}_c^3/\mathcal{G}_m \ll (1-\xi)^{1/2}$. Ignoring this term to leading order is consistent with the fact that leak-off is dominant, i.e., $\mathcal{G}_c^3/\mathcal{G}_m = O(1)$ or larger, as discussed in section 3.

The form of Ω_{01} is written as a combination of powers in z, namely,

$$\Omega_{01} = \tilde{C}_{01}z^q + \hat{\mathcal{B}}_1 z^g + \hat{\mathcal{B}}_2 z^p + \hat{\mathcal{B}}_3 z^r. \tag{3.13}$$

This is equivalent to a perturbation expansion for the solution of (3.11) when $\hat{\mathcal{B}}_i \ll 1$, which we verify below. The elasticity equation (3.5) is then solved to give

$$\begin{aligned}\Pi_{01} = {} & \cot\pi q\frac{\tilde{C}_{01}q}{4\gamma}z^{q-1} + \cot\pi g\frac{\hat{\mathcal{B}}_1 g}{4\gamma}z^{g-1} + \cot\pi p\frac{\hat{\mathcal{B}}_2 p}{4\gamma}z^{p-1} + \cot\pi r\frac{\hat{\mathcal{B}}_3 r}{4\gamma}z^{r-1} \\ & + \frac{\tilde{C}_{01}q\delta^{1-q}(2-\delta z)^{-1}}{4\pi\gamma} + \frac{\hat{\mathcal{B}}_1 g\delta^{1-g}(2-\delta z)^{-1}}{4\pi\gamma} + \frac{\hat{\mathcal{B}}_2 p\delta^{1-p}(2-\delta z)^{-1}}{4\pi\gamma} \\ & + \frac{\hat{\mathcal{B}}_3 r\delta^{1-r}(2-\delta z)^{-1}}{4\pi\gamma} + O(\delta^{1-q},\delta^{1-g},\delta^{1-p},\delta^{1-r}).\end{aligned} \tag{3.14}$$

By using the definitions of α_1 and σ_1 from (3.12) we integrate (3.11) to obtain

$$\lambda\delta^{1/8+\beta_m/4-3\beta_c/4}\Omega_{01} + \hat{\mathcal{G}}_c\sqrt{2}\left(z^{1/2} + \frac{1}{12}\delta z^{3/2}\right) + k = \frac{1}{\hat{\mathcal{G}}_m\gamma^2}\Omega_{01}^3\frac{\mathrm{d}\Pi_{01}}{\mathrm{d}z}, \tag{3.15}$$

where k is an arbitrary constant. We then have four expressions enabling us to determine q, g, p, and r. The leading order terms are

$$\sqrt{2}\hat{\mathcal{G}}_c z^{1/2} = \cot\pi q\frac{\tilde{C}_{01}^4 q(q-1)}{4\hat{\mathcal{G}}_m\gamma^3}z^{4q-2}, \tag{3.16}$$

which yields $q = 5/8$ and gives the coefficient $\tilde{C}_{01}$,

$$\tilde{C}_{01} = \left\{ \frac{4\sqrt{2}\hat{\mathcal{G}}_c\hat{\mathcal{G}}_m\gamma^3}{q(q-1)\cot\pi q} \right\}^{1/4}. \tag{3.17}$$

Then the next order terms satisfy

$$k = \frac{\tilde{C}_{01}^3\hat{\mathcal{B}}_1}{4\hat{\mathcal{G}}_m\gamma^3}\big[g(g-1)\cot\pi g + 3q(q-1)\cot\pi q\big] z^{3q+g-2}, \tag{3.18}$$

$$\lambda\delta^{1/8+(\beta_m-3\beta_c)/4}\tilde{C}_{01}z^q = \frac{\tilde{C}_{01}^3\hat{\mathcal{B}}_2}{4\hat{\mathcal{G}}_m\gamma^3}\big[p(p-1)\cot\pi p + 3q(q-1)\cot\pi q\big] z^{3q+p-2}, \tag{3.19}$$

$$\lambda\delta^{1/8+(\beta_m-3\beta_c)/4}\hat{\mathcal{B}}_1z^g = \frac{\tilde{C}_{01}^3\hat{\mathcal{B}}_3}{4\hat{\mathcal{G}}_m\gamma^3}\big[r(r-1)\cot\pi r + 3q(q-1)\cot\pi q\big] z^{3q+r-2}. \tag{3.20}$$

For simplicity of presentation we assume $\delta^{1/8+(\beta_m-3\beta_c)/4} > \delta$, which means we can neglect the $z^{3/2}$ term in (3.15). This corresponds to the case $\mathcal{G}_c^3/\mathcal{G}_m \ll (1-\xi)^{-7/2}$. Including this term results in an additional contribution to Ω_{01} in (3.13) with power law $z^{13/8}$. This term can be shown to be higher order in the matching below and could be included in a straightforward manner if $\mathcal{G}_c^3/\mathcal{G}_m = O((1-\xi)^{-7/2})$ or larger.

Matching exponents of z in (3.18)–(3.19) gives $g = 1/8$ and $p = 3/4$, respectively. Since $\hat{\mathcal{B}}_1$ is assumed small, the left-hand side of (3.20) is of higher order; r must be approximated by solving the following nonlinear algebraic equation corresponding to the right-hand side of (3.20) vanishing:

$$r(r-1)\cot\pi r + 3q(q-1)\cot\pi q = 0, \tag{3.21}$$

and we find that $r \approx 0.0699928$. Then

$$\hat{\mathcal{B}}_2 = \delta^{1/8+(\beta_m-3\beta_c)/4}\mathcal{B}_2, \qquad \mathcal{B}_2 = \lambda\frac{4\hat{\mathcal{G}}_m\gamma^3}{\tilde{C}_{01}^2\big[p(p-1)cot\pi p + 3q(q-1)cot\pi q\big]}, \tag{3.22}$$

and the coefficients $\hat{\mathcal{B}}_1$ and $\hat{\mathcal{B}}_3$ are determined by matching with the near-tip expansion (3.10) in the next section. Since $q,\ g,\ p,\ r \neq 1/2$, the solution (3.13) cannot satisfy the $\sqrt{z}$ behavior from the propagation condition (2.12) for $\hat{\mathcal{G}}_k > 0$. Observe that for $\alpha_1 < 0$, toughness does not dominate the leading order behavior in this regime and the terms $\Omega_{00} = \Pi_{00} = 0$. Then the first term in the expansion (2.14) for Ω is

$$\Omega \sim \delta^{(\beta_c+\beta_m)/4}\left[\tilde{C}_{01}(\delta z)^{5/8} + \mathcal{B}_1(\delta z)^{1/8} + \mathcal{B}_2\delta^{(\beta_m-3\beta_c)/4}\frac{\hat{\mathcal{G}}_m^{1/4}}{\hat{\mathcal{G}}_c^{3/4}}(\delta z)^{3/4} + \mathcal{B}_3(\delta z)^r\right] \tag{3.23}$$

for $\alpha_1 < 0$. Note that we have redefined $\tilde{C}_{01}$ and $\mathcal{B}_2$ without the $\hat{\mathcal{G}}_()$ terms, which allows us to highlight explicitly the dependence of Ω on the key dimensionless quantities $\mathcal{G}_()$ in (2.2). The coefficients $\hat{\mathcal{B}}_1$ and $\hat{\mathcal{B}}_3$ are redefined as $\mathcal{B}_1$ and $\mathcal{B}_3$ and they are found in the following section.

3.2. Transition in spatial behavior and matching. Now we compare the two local expansions, (3.10) and (3.23), in terms of the parameter combinations

$$\mathcal{P}_{km} = \frac{\mathcal{G}_k^3}{\mathcal{G}_m}, \qquad \mathcal{P}_{cm} = \frac{\mathcal{G}_c^3}{\mathcal{G}_m}, \qquad \mathcal{P}_{ckm} = \frac{\mathcal{G}_k^4}{\mathcal{G}_c\mathcal{G}_m}, \tag{3.24}$$

which appear explicitly in both expansions and were introduced in (1.11). We consider the range of parameters for which either $\mathcal{P}_{cm} \gg (1-\xi)^{1/2}$ or $\mathcal{P}_{km} \gg (1-\xi)^{1/2}$, i.e., parameter values away from the viscosity-dominated regime. For $\mathcal{G}_c = O(1)$ this corresponds to $\mathcal{G}_m \ll 1$ or $\beta_m > 1$. Other situations are discussed in the next section.

Then the expansions for Ω in terms of $\mathcal{P}_{km}$, $\mathcal{P}_{cm}$, and $\mathcal{P}_{ckm}$ are

$$\Omega \sim \mathcal{G}_k \left[C_{00}\sqrt{1-\xi^2} + C_{01}\mathcal{P}_{km}^{-1}(1-\xi) + C_{02}\mathcal{P}_{ckm}^{-1}(1-\xi) \right] \quad \text{for } \alpha_1 > 0, \tag{3.25}$$

$$\Omega \sim (\mathcal{G}_c\mathcal{G}_m)^{1/4} \left[\tilde{C}_{01}(1-\xi)^{5/8} + \mathcal{B}_1(\mathcal{P}_{ckm})(1-\xi)^{1/8} + \mathcal{P}_{cm}^{-1/4}\mathcal{B}_2(1-\xi)^{3/4} + \mathcal{B}_3(\mathcal{P}_{ckm})(1-\xi)^{r} \right] \quad \text{for } \alpha_1 < 0. \tag{3.26}$$

We have redefined C_{00}, C_{01}, and C_{02} in (3.25) without the $\hat{\mathcal{G}}_{()}$ terms which are incorporated into the dimensionless $\mathcal{G}_{()}$ terms. Also, observe that the δ's have disappeared from the expressions. The expansions (3.25)–(3.26) give a transition in behavior of Ω for $1-\xi = O(\mathcal{P}_{ckm}^2)$: the unknown coefficients $\mathcal{B}_1(\mathcal{P}_{ckm})$ and $\mathcal{B}_3(\mathcal{P}_{ckm})$ are determined by matching the expansions in this transition region. The leading order term in (3.26) was given in [36] and later in [6] for vanishing toughness. In a preliminary study [9] some of the terms in (3.26) are obtained. There, both the global balance and lubrication equations are scaled by ${\mathcal{G}_v}^{-1}$, and they consider the limit of small toughness, with $\mathcal{G}_v \to \infty$, for fixed nondimensional parameters $\mathcal{G}_c/\mathcal{G}_v = \mathcal{G}_m\mathcal{G}_v = 1$. Then some of the terms in (3.26) are excluded for large $\mathcal{G}_v$.

The motivation for defining the parameter $\mathcal{P}_{ckm}$ follows directly from the expression for α_1 in both cases, i.e., (3.9) and (3.12). Since the $\hat{\mathcal{G}}_{()}$ quantities are $O(1)$, the condition $\alpha_1 > (<)\, 0$ can be rewritten as $\mathcal{P}_{ckm} \gg (\ll)\,(1-\xi)^{1/2}$. The solution for $\alpha_1 > 0$ is physically significant in the toughness dominated regime ($\mathcal{G}_k \gg \mathcal{G}_c$), which is close to the tip and corresponds to $\mathcal{P}_{ckm} \gg (1-\xi)^{1/2}$. As $(1-\xi)^{7/2}$ approaches $\mathcal{P}_{ckm}$, the first and third terms in (3.25) and the first term in (3.26) are the same order of magnitude. A transition occurs in the region $(1-\xi) = O(\mathcal{P}_{ckm}^{1/2})$ and the solution in the intermediate-tip region is found by considering $\alpha_1 < 0$ in (3.26). This corresponds to the leak-off dominated regime, which is away from the tip for $\mathcal{P}_{ckm} \ll (1-\xi)^{1/2}$. Hence the expansion in (3.25) holds for $1-\xi < \mathcal{P}_{ckm}^2$ and the expansion in (3.26) holds for $1-\xi = O(\mathcal{P}_{ckm}^s)$ (see Figure 3.1), with $0 < s < 2$, and $\mathcal{P}_{ckm} \ll 1$.

To construct a uniform asymptotic approximation by matching (3.25) and (3.26), we note that they are obtained by solving (2.20) in different asymptotic limits. The matching is therefore straightforward in the transition region where $\mathcal{G}_k^4/(\mathcal{G}_c\mathcal{G}_m) = O((1-\xi)^{1/2})$; to leading order the solution satisfies (2.20) together with the propagation condition (2.12). While there is no closed form solution in this region, it can be constructed numerically where $1-\xi = O(\mathcal{P}_{ckm}^2)$ for $0 < \mathcal{P}_{ckm} \ll 1$.

Alternatively, one can give an analytical expression for the matching of (3.25) and (3.26), obtained from solving for the remaining unknown coefficients $\mathcal{B}_1(\mathcal{P}_{ckm})$ and $\mathcal{B}_3(\mathcal{P}_{ckm})$. Writing these expressions in terms of the critical scaling $1-\xi = \mathcal{P}_{ckm}^2\zeta$ for $\zeta = 0(1)$, (3.25) and (3.26) are, respectively,

$$\Omega \sim \mathcal{G}_k \left[C_{00}\mathcal{P}_{ckm}\zeta^{1/2}\sqrt{2-\mathcal{P}_{ckm}^2\zeta} + \left(C_{01}\mathcal{P}_{km}^{-1} + C_{02}\mathcal{P}_{ckm}^{-1}\right)\mathcal{P}_{ckm}^2\zeta \right], \tag{3.27}$$

$$\Omega \sim (\mathcal{G}_c\mathcal{G}_m)^{1/4} \left[\tilde{C}_{01}\mathcal{P}_{ckm}^{5/4}\zeta^{5/8} + \mathcal{B}_1(\mathcal{P}_{ckm})\mathcal{P}_{ckm}^{1/4}\zeta^{1/8} + \mathcal{P}_{cm}^{-1/4}\mathcal{B}_2\mathcal{P}_{ckm}^{3/2}\zeta^{3/4} + \mathcal{B}_3(\mathcal{P}_{ckm})\mathcal{P}_{ckm}^{2r}\zeta^{r} \right]. \tag{3.28}$$

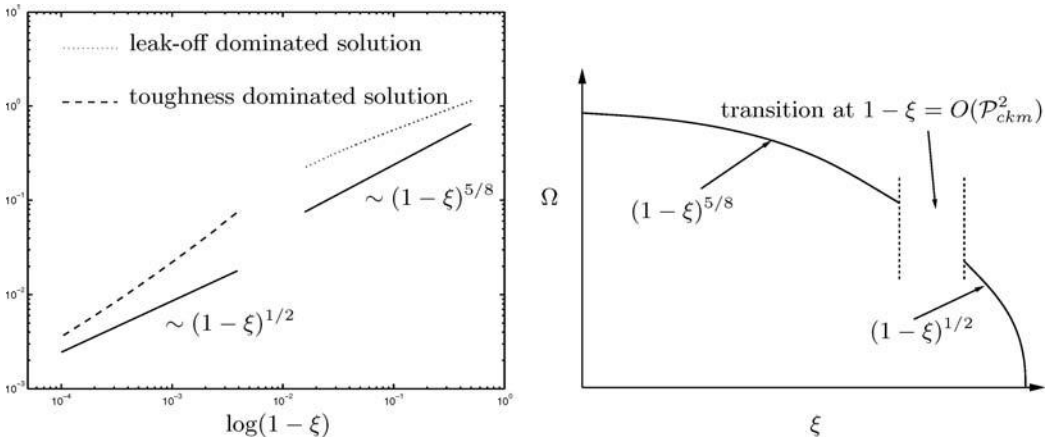

FIG. 3.1. *The left plot shows* $\log\Omega$ *vs.* $\log(1-\xi)$ *with* $\mathcal{G}_c = 1$, $\mathcal{G}_m = 0.2$, *and* $\mathcal{G}_k = 0.35$ *(and so* $\mathcal{P}_{ckm} = 0.075$*.) The solid lines denote the leading order power law solutions, as indicated above. The right plot shows a diagram of the solution* Ω *vs.* ξ *near the fracture tip for the leak-off–dominated regime. The transition region is* $1-\xi = O(\mathcal{P}_{ckm}^2)$.

Equating (3.27) and (3.28) and their first derivatives yields $\mathcal{B}_1(\mathcal{P}_{ckm})$ and $\mathcal{B}_3(\mathcal{P}_{ckm})$, which is equivalent to matching the first two terms in a Taylor series expansion about $1-\xi = O(\mathcal{P}_{ckm}^2)$ where Ω is regular. Figure 3.2 shows solution profiles of Ω, matched at $1-\xi = \mathcal{P}_{ckm}^2$. In these parameter regimes all three processes contribute to the transition between the near- and intermediate-tip behavior, described by (3.25) and (3.26). There the coefficients $\mathcal{B}_1(\mathcal{P}_{ckm})$ and $\mathcal{B}_3(\mathcal{P}_{ckm})$ are

$$\mathcal{B}_1(\mathcal{P}_{ckm}) = \frac{\mathcal{P}_{ckm}}{8r-1}\Big[(8r-4)\sqrt{2}C_{00} + (8r-8)\big(C_{01}\mathcal{P}_{km}^{-1}\mathcal{P}_{ckm} + C_{02}\big) - (8r-5)\tilde{C}_{01} - (8r-6)\mathcal{B}_2\mathcal{P}_{cm}^{-1/4}\mathcal{P}_{ckm}^{1/4}\Big], \tag{3.29}$$

$$\mathcal{B}_3(\mathcal{P}_{ckm}) = \frac{\mathcal{P}_{ckm}^{-2r+5/4}}{8r-1}\Big[3\sqrt{2}C_{00} + 7C_{01}\mathcal{P}_{km}^{-1}\mathcal{P}_{ckm} + 7C_{02} - 4\tilde{C}_{01} - 5\mathcal{B}_2\mathcal{P}_{cm}^{-1/4}\mathcal{P}_{ckm}^{1/4}\Big], \tag{3.30}$$

which are small since $\mathcal{P}_{ckm} \ll 1$. As $\mathcal{P}_{ckm}$ increases we observe that the transition region moves away from the tip. Figure 3.2 also shows two solution profiles when (3.25) holds to leading order for both near- and intermediate-tip behavior for $\mathcal{P}_{ckm} < \mathcal{P}_{km}$ and $\mathcal{P}_{ckm} > \mathcal{P}_{km}$. The shape of Ω depends on whether the second or third term in (3.25) plays a larger role in the correction to the leading order behavior. Also, Figure 3.1 shows a log-log plot of Ω for both the leak-off and toughness-dominated regimes. In the near- and intermediate-tip regions we obtain the asymptotic 1/2 and 5/8 power law solutions, respectively, but in the transition region the correction terms are important, so that the behavior cannot be described by a purely power law solution, also observed in [6, 24] for zero leak-off.

For completeness we write down the near- and intermediate-tip expansions for Π, which are determined using the elasticity equation (2.11). Hence we obtain, for

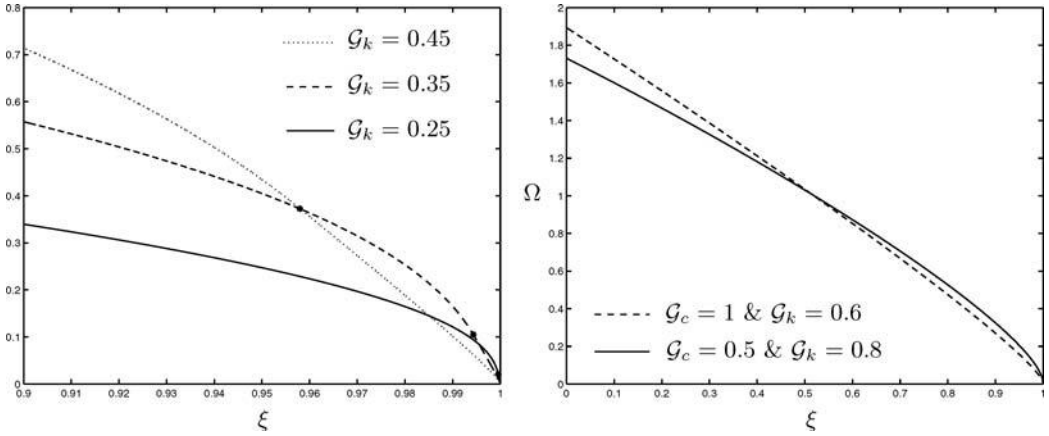

FIG. 3.2. *Solution profiles of* Ω *vs.* ξ. *On the left,* $\mathcal{G}_c = 1$, $\mathcal{G}_m = 0.2$, *and* $\mathcal{G}_k = 0.45, 0.35, 0.25$ *(and* $\mathcal{P}_{ckm} = 0.205, 0.075, 0.020$, *respectively). The transition region is* $1 - \xi = O(\mathcal{P}_{ckm}^2)$, *indicated by* $*$*'s at* $\xi = 1 - \mathcal{P}_{ckm}^2$ *on the graphs. On the right,* $\mathcal{G}_m = 0.1$; *then, for the toughness dominated regime (solid line),* $\mathcal{P}_{ckm} = 8.192$ *and* $\mathcal{P}_{km} = 5.12$, *and for the leak-off dominated regime (dashed line),* $\mathcal{P}_{ckm} = 1.296$ *and* $\mathcal{P}_{km} = 2.16$.

$\mathcal{P}_{ckm} \gg (\ll) (1-\xi)^{1/2}$, respectively,

$$\Pi \sim \mathcal{G}_k \left[\Pi_{00} - \frac{1}{4\pi\gamma} \left(C_{01} \mathcal{P}_{km}^{-1} + C_{02} \mathcal{P}_{ckm}^{-1} \right) \left\{ \ln \left| 1 - \frac{1}{1+\xi} \right| + \ln \left| \frac{1}{1-\xi} \right| + \ln \xi \right\} \right], \tag{3.31}$$

$$\Pi \sim (\mathcal{G}_c \mathcal{G}_m)^{1/4} \left[q \cot \pi q \frac{\tilde{C}_{01}}{4\gamma} (1-\xi)^{-3/8} + g \cot \pi g \frac{\mathcal{B}_1(\mathcal{P}_{ckm})}{4\gamma} (1-\xi)^{-7/8} \right.$$

$$\left. + p \cot \pi p \frac{\mathcal{P}_{cm}^{-1/4} \mathcal{B}_2}{4\gamma} (1-\xi)^{-1/4} + r \cot \pi r \frac{\mathcal{B}_3(\mathcal{P}_{ckm})}{4\gamma} (1-\xi)^{r-1} \right]. \tag{3.32}$$

The details of this calculation are given in Appendix B. In Figure 3.3 we graph Π for different values of $\mathcal{G}_k \ll 1$ with $\mathcal{G}_m = 0.2$ and $\mathcal{G}_c = 1$. We observe that as $\mathcal{P}_{ckm}$ increases, which in this case corresponds to increasing the toughness parameter $\mathcal{G}_k$ since $\mathcal{G}_m$ and $\mathcal{G}_c$ are fixed, the transition point between the two regimes moves away from the tip and Π drops off at a faster rate. This is due to the power law behavior in (3.32) being matched with the near-tip behavior in (3.31), which becomes more dominant through the logarithmic correction for increasing $\mathcal{G}_k$.

3.3. The global volume balance condition. The constants (i.e., the coefficients C_{00}, C_{01}, C_{02}, $\tilde{C}_{01}$, and γ) are determined by applying the global volume balance condition (2.13) and balancing terms according to the size of the parameters. This condition also checks the consistency of the expansion and shows when we need to consider additional time-dependencies which we discuss below.

The global volume balance equation in terms of the ξ scaling is given by (2.6). Since $l = \gamma L$ and $L = C_L t^{\lambda}$, where C_L is an undetermined constant, we use Γ_l defined in (2.18) to simplify the double integral. Hence (2.6) reduces to

$$\mathcal{G}_v = 2\gamma \int_0^1 \Omega \, \mathrm{d}\chi + \frac{2\lambda\sqrt{\pi}\gamma\Gamma(\lambda)\mathcal{G}_c}{(\lambda + 1/2)\Gamma(\lambda + 1/2)}, \tag{3.33}$$

where $\Gamma(\cdot)$ represents the Gamma function. We must analyze the different situations that arise for $\mathcal{P}_{ckm} \gg 1$ and $\mathcal{P}_{ckm} \ll 1$. The former case corresponds to toughness

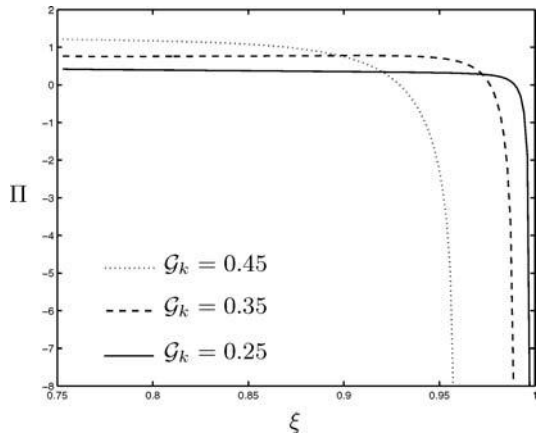

FIG. 3.3. *Solution profiles of* Π *against* ξ *with fixed* $\mathcal{G}_c = 1$, $\mathcal{G}_m = 0.2$, *and* $\mathcal{G}_k = 0.45, 0.35, 0.25$ *(and* $\mathcal{P}_{ckm} = 0.205, 0.075, 0.020$, *respectively).*

dominating the behavior over the whole fracture, with $\alpha_1 > 0$, and is discussed in detail in [44]. Then the left-hand side balances with the integral on the right-hand side to leading order; it follows that $\lambda = 2/3$, that is, $L = C_L t^{2/3}$. Substitution of (3.25) then leads to an expression for γ in terms of $\mathcal{G}_v$ and $\mathcal{G}_k$. The integral is evaluated using the asymptotic expansion near the tip and using numerical evaluation away from the tip where the behavior is regular [6, 24].

In contrast, for the case of $\mathcal{P}_{ckm} \ll 1$, the expansion (3.26) with $\alpha_1 < 0$ must be used for $\mathcal{G}_k^4/(\mathcal{G}_c\mathcal{G}_m) < (1-\xi)^{1/2}$. For this range of ξ the leading order terms in the lubrication equation are those with coefficients $\mathcal{G}_c$ and $\mathcal{G}_m^{-1}$. Together with the elasticity equation, these terms indicate that Ω and Π must scale with $(\mathcal{G}_c\mathcal{G}_m)^{1/4}$, as in (3.26). Then the global balance condition has the form

$$\mathcal{G}_v/\mathcal{G}_c = \text{const} \cdot \mathcal{P}_{cm}^{-1/4} + \text{const}. \tag{3.34}$$

As discussed in section 3.1 following (3.11), $\mathcal{P}_{cm} \gg 1$ in this case, and so the leading order terms are the first and third, and the contribution from the integral is higher order. Then we equate the leading order terms to obtain γ analytically. The global balance equation verifies that the self-similar solution is appropriate for sufficiently large $\mathcal{P}_{cm}$. Writing the t dependence explicitly in (3.34) and using the definitions in (2.2) with $L = C_L t^\lambda$ gives

$$\frac{Q_0}{\epsilon C_L^2} t^{1-2\lambda} = \text{const} \cdot \left(\frac{C'\mu'}{\epsilon^4 C_L E'}\right)^{1/4} t^{-(2\lambda+1)/8} + \text{const} \cdot \frac{C'}{\epsilon C_L} t^{1/2-\lambda}. \tag{3.35}$$

Comparing exponents and balancing the first and third terms gives $\lambda = 1/2$ and the expression for γ simplifies to $\gamma = \mathcal{G}_v/\pi\mathcal{G}_c$. Balancing the first and second terms leads to a contradiction unless $t < 1$. The second term in (3.35) can be neglected for $t^{-1/4} \ll 1$, corresponding to $\mathcal{P}_{cm}^{-1/4} \ll 1$ as in (3.34). This verifies that it is appropriate to use $\lambda = 1/2$ for the leak-off–dominated intermediate-tip behavior in section 3.1 for sufficiently large t. If this condition is violated, for example, for short times, we can no longer conclude that γ is constant, and additional time-dependence must be included in the expansion.

4. Discussion and future work. In conclusion, we have introduced a new approach for studying the system of integrodifferential equations that are found in hydraulic fracturing problems. Our method enables us to simultaneously consider the three primary physical mechanisms, namely, viscosity, toughness, and leak-off, and we have obtained a continuous solution for the fracture opening w when one or more of these processes are in balance. The technique determines critical relationships between the nondimensional distance from the tip $1-\xi$ and the key nondimensional quantities $\mathcal{G}_k$, $\mathcal{G}_c$, $\mathcal{G}_m$, and $\mathcal{G}_v$, representing toughness, leak-off, viscosity, and injected fluid volume, respectively.

For small toughness and $O(1)$ leak-off, the behavior of Ω follows from combining (3.25) for values of ξ in the near-tip region, and (3.26) for ξ in the intermediate-tip region. The critical parameter combination in this case is $\mathcal{P}_{ckm} = \mathcal{G}_k^4/\mathcal{G}_c\mathcal{G}_m$, with the transition layer occurring for values of $\mathcal{P}_{ckm} = O((1-\xi)^{1/2})$. Additional higher order corrections depend on the relative magnitude of extra parameter combinations, $\mathcal{P}_{km}$ and $\mathcal{G}_c^3/\mathcal{G}_m = \mathcal{P}_{cm}$. These results are obtained by simultaneously solving the elasticity and lubrication equations (2.10)–(2.11). The physical process of leak-off has often been ignored in previous studies, and the new terms in expansions (3.25) and (3.26) allow us to match expansions in different regions analytically, in contrast to previous work [24] for zero leak-off. This analysis is new and the flexibility is invaluable in extending the technique to other fracture geometries, namely, the PKN fracture [43], and adding different effects, such as stress-jumps and fluid lag. It is important to determine analytic solutions such as those derived in this paper, which can be used to test the validity of the model against more complete numerical models as well as data from laboratory and field experiments.

The application of the global volume balance equation is used to determine the remaining constants in the solution, and it also provides valuable information related to time dependence. In the regimes considered in this paper, we find that it provides a consistency check for the use of a self-similar solution (2.14)–(2.15) with the coefficient γ constant to leading order. We also determine the time-dependence of L, which gives the power law scaling in time of the length of the fracture.

The global volume balance equation can also be used to determine regimes where additional time-dependence must be included in the solution. For example, using this equation, for finite leak-off we can deduce that for large but finite time the coefficient γ varies on a slow time scale, $T = \mathcal{P}_{cm}^{-1/4}t$ for $\mathcal{P}_{cm} \gg 1$. For small time this analysis is not sufficient: then a multiple-scale analysis of the resulting equations is necessary to describe additional time dependence and transient behavior.

As noted in section 1.1 of the introduction, the results presented here rely on the use of Carter's leak-off model (1.8). However, our framework does not depend on a specific form for the leak-off term, so its implementation is not restricted to the use of (1.8). These results are valid for the balance of physical processes corresponding to $O(1)$ (or smaller) leak-off, which is typical of many fracturing treatments due to the cake-building properties of the fracturing fluid [51]. Specifically, we require that the combined parameter $\mathcal{P}_{cm} := \mathcal{G}_c^3/\mathcal{G}_m \gg 1$. In situations where $\mathcal{G}_c \gg 1$, such as in waterflood fractures, the leak-off term is not a higher order correction at the tip, and therefore it would require a different modeling approach in that region.

Typical values of Carter's leak-off coefficient C' range from 4–64×10^{-5} m/s$^{-1/2}$, as discussed in [6] and the references therein. Suppose we consider the case $\mathcal{P}_{ckm} \ll 1$ and set $\mathcal{G}_v = \mathcal{G}_c = 1$. Then the expression for γ, as found in section 3.3, is simply $\gamma = 1/\pi$. Typical values of the other parameters are found in [6, 19, 27]: $Q_0 = 4$–40×10^{-4} m^2/s, $E = 10000$–25000 MPa, $\nu = 0.15$, $\mu = 1 \times 10^{-7}$ MPa$\cdot$s, and

$K_{Ic} = 1$ MPa $\cdot$ m$^{1/2}$. For example, using $Q_0 = 4 \times 10^{-4}$ m^2/s, $C' = 16 \times 10^{-5}$, and $E = 10000$ MPa, the combined parameters can be shown to satisfy $\mathcal{P}_{cm} \approx 0.0022t$, $\mathcal{P}_{ckm} \approx 0.20$, and $\mathcal{P}_{km} \approx 0.066t^{1/4}$. Then the transition region is at $\xi = O(1-\mathcal{P}_{ckm}^2) \approx 0.96$, which supports the values used in the figures in section 3. This also shows that our analysis is applicable for large time, since we require $\mathcal{P}_{cm} \gg 1$. If we increase E and Q_0, say to 14000 MPa and 7×10^{-4} m^2/s, respectively, then $\mathcal{P}_{cm} \approx 0.00058t$, $\mathcal{P}_{ckm} \approx 0.042$, $\mathcal{P}_{km} \approx 0.014t^{1/4}$, and the transition region is at $\xi \approx 0.998$, which is now much closer to the tip.

For the situation when the rock is impermeable, that is, for zero leak-off with $\mathcal{G}_c = 0$, we have used the same procedure to obtain an analytically matched asymptotic solution in the tip region [44]. The expansions for Ω in terms of the key parameter $\mathcal{P}_{km} := \mathcal{G}_k^3/\mathcal{G}_m$ are, for $\mathcal{P}_{km} \gg (\ll) (1-\xi)^{1/2}$, respectively,

$$\Omega \sim \mathcal{G}_k \left[C_{00}\sqrt{1-\xi^2} + C_{01}\mathcal{P}_{km}^{-1}(1-\xi) \right], \tag{4.1}$$

$$\Omega \sim \mathcal{G}_m^{1/3} \left[\bar{C}_{01}(1-\xi)^{2/3} + \mathcal{A}_1(\mathcal{P}_{km})(1-\xi)^h + \mathcal{A}_2(\mathcal{P}_{km}) \right]. \tag{4.2}$$

Hence the expansion (4.1) holds for values of ξ in the near-tip region, the expansion (4.2) holds for ξ in the intermediate-tip region, and the analysis yields

$$C_{00} = \hat{\mathcal{G}}_k \sqrt{\frac{\gamma}{2}}, \qquad C_{01} = 2\pi\lambda \frac{\hat{\mathcal{G}}_m \gamma^3}{C_{00}^2}, \qquad \bar{C}_{01} = \left\{ \frac{4\hat{\mathcal{G}}_m \lambda \gamma^3}{m(m-1)\cot \pi m} \right\}^{1/3}, \tag{4.3}$$

where $m = 2/3$. The motivation for defining the parameter $\mathcal{P}_{km}$ again follows directly from the dominant behavior expressed by balancing the exponents of δ, which becomes $\mathcal{P}_{km} \gg (\ll) (1-\xi)^{1/2}$. The expansion (4.1) is physically significant in the toughness dominated regime or valid close to the tip when $\mathcal{G}_k^3/\mathcal{G}_m \gg (1-\xi)^{1/2}$, and the expansion (4.2) corresponds to the viscosity dominated regime in which $\mathcal{G}_k^3/\mathcal{G}_m \ll (1-\xi)^{1/2}$. Previous work [24] give some of the terms in (4.1)–(4.2), but the matching is done numerically. The additional terms allow us to give an analytical expression for the matching of (4.1) and (4.2), obtained by solving for the remaining unknown coefficients $\mathcal{A}_1(\mathcal{P}_{km})$ and $\mathcal{A}_2(\mathcal{P}_{km})$, as shown in [44].

In other asymptotic limits, for example, for $\mathcal{P}_{cm} \ll (1-\xi)^{1/2}$ and $\mathcal{G}_c > \mathcal{G}_k$, one can obtain solutions which involve more than one transition region, as discussed at the start of section 3. In particular, for sufficiently large leak-off and viscosity, the solution for Ω consists of a leading order behavior with power law $(1-\xi)^{1/2}$ for ξ in the near-tip region, $(1-\xi)^{5/8}$ for an intermediate-tip region, and $(1-\xi)^{2/3}$ for values of ξ farther from the tip. In the case $\mathcal{G}_c > \mathcal{G}_k$, a transition must occur at $1-\xi = O(\mathcal{P}_{ckm}^2)$ between the near-tip square root behavior and the $(1-\xi)^{5/8}$ behavior. If, in addition, $\mathcal{P}_{cm}$ is such that $\mathcal{P}_{cm} \ll (1-\xi)^{1/2}$, then there is another transition farther from the tip at $1-\xi = O(\mathcal{P}_{cm}^2)$ between the $(1-\xi)^{5/8}$ and $(1-\xi)^{2/3}$ behavior. The construction of the nondimensionalized width Ω proceeds as in the previous sections by identifying the appropriate balance of $(1-\xi)$ with combinations of the parameters $\mathcal{G}_c$, $\mathcal{G}_k$, and $\mathcal{G}_m$. Finally, in the same way as the analysis described here in section 3.2 and in [44], we can match across the two regions to determine the unknown coefficients which are now in terms of both $\mathcal{P}_{cm}$ and $\mathcal{P}_{ckm}$.

Appendix A. Results on Π in the toughness-dominated regime.

A.1. Π_{00} is constant. Consider (3.1). We integrate to obtain

$$\Omega_{00}^3 \frac{\mathrm{d}\Pi_{00}}{\mathrm{d}z} = k_1 \tag{A.1}$$

for some constant $k_1 \neq 0$. Using the propagation condition (2.12) for Ω_{00} in (A.1) and integrating with respect to z yields

$$\Pi_{00} = -\frac{2k_1}{\hat{\mathcal{G}}_k^3 \gamma^{3/2}} z^{-1/2} + \text{ const} \tag{A.2}$$

for $z \ll 1$. Now we compare this with the result from the elasticity equation (3.2), again using the propagation condition (2.12) for Ω_{00}, to get

$$\delta^{\beta_k}\Pi_{00} = \text{const} * \int_0^{1/\delta} \frac{\mathrm{d}\Omega_{00}}{\mathrm{d}r} \frac{(1-\delta r)}{r(2-\delta r) - z(2-\delta z)}\,\mathrm{d}r = \text{ const}$$

to leading order. This contradicts (A.2) so that $k_1 = 0$. Thus, from (A.1) it follows that Π_{00} is constant.

A.2. Integration constant from the lubrication equation is zero. Integrating (3.4) with respect to z, using the leading order behavior $(2z)^{-1/2}$ for the leak-off term, gives

$$\lambda\delta^{\beta_k - 1/2}\Omega_{00} + \hat{\mathcal{G}}_c \delta^{\beta_c - 1/2}\sqrt{2} z^{1/2} + k_2 = \frac{1}{\hat{\mathcal{G}}_m \gamma^2}\Omega_{00}^3 \frac{\mathrm{d}\Pi_{01}}{\mathrm{d}z} \tag{A.3}$$

for some constant $k_2 \neq 0$. Using the propagation condition (2.12) for Ω_{00} in (A.3) and integrating with respect to z yields

$$\delta^{\sigma_1}\Pi_{01} = \frac{\hat{\mathcal{G}}_m}{\hat{\mathcal{G}}_k^3}\delta^{\beta_m - 3\beta_k}\left[\lambda\gamma\hat{\mathcal{G}}_k\delta^{\beta_k}\ln z + \sqrt{2\gamma}\hat{\mathcal{G}}_c\delta^{\beta_c}\ln z - 2\sqrt{\gamma}k_2\delta^{1/2}z^{-1/2}\right] + k_3. \tag{A.4}$$

Without loss of generality, we set the integrating constant $k_3 = 0$, as it can be incorporated into Π_{00}. We now consider the stress intensity factor K_I given in (1.2). This can be rewritten in the ξ scaling as

$$\mathcal{G}_k = \frac{8\sqrt{2}}{\pi}\gamma^{1/2}\int_0^1 \frac{\Pi}{\sqrt{1-\xi^2}}\,\mathrm{d}\xi. \tag{A.5}$$

For $\xi = 1 - \delta z$, we consider the contribution to (A.5) obtained from the term in (A.4) with coefficient k_2, namely,

$$\text{const} * \frac{8\sqrt{2}}{\pi}\gamma^{1/2}\delta^{1/2}\int_0^{1/\delta} \frac{k_2}{z\sqrt{2-\delta z}}\,\mathrm{d}z. \tag{A.6}$$

For $k_2 \neq 0$, this term is infinite at $z = 0$. So $k_2 = 0$ to maintain a finite energy.

Appendix B. Calculation of the expression for Π. We summarize the calculation of the asymptotic behavior of Π from (2.9) to find the leading order behavior. We introduce a parameter ξ^* which is in the transition region $1 - \xi = O(\mathcal{P}_{ckm}^2)$. Then the expansion (3.25) holds near the tip and (3.26) holds away from the tip, i.e.,

$$\Omega \sim \mathcal{G}_k\left[C_{00}\sqrt{1-\xi^2} + C_{01}\mathcal{P}_{km}^{-1}(1-\xi) + C_{02}\mathcal{P}_{ckm}^{-1}(1-\xi)\right] \tag{B.1}$$

for $\xi^* < \xi < 1$, and

$$\begin{aligned}\Omega \sim (\mathcal{G}_c\mathcal{G}_m)^{1/4}\Big[&\tilde{C}_{01}(1-\xi)^{5/8} + \mathcal{B}_1(\mathcal{P}_{ckm})(1-\xi)^{1/8} \\ &+ \mathcal{P}_{cm}^{-1/4}\mathcal{B}_2(1-\xi)^{3/4} + \mathcal{B}_3(\mathcal{P}_{ckm})(1-\xi)^r\Big]\end{aligned} \tag{B.2}$$

for $\xi < \xi^*$, and (2.9) becomes

(B.3)

$$\begin{aligned}\Pi =& -\frac{\mathcal{G}_k C_{00}}{4\pi\gamma}\int_{\xi^*}^1 \frac{\left[\sqrt{1-\chi^2}\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2} - \frac{\mathcal{G}_k\left[C_{01}\mathcal{P}_{km}^{-1}+C_{02}\mathcal{P}_{ckm}^{-1}\right]}{4\pi\gamma}\int_{\xi^*}^1 \frac{\left[(1-\chi)\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2}\\ &-(\mathcal{G}_c\mathcal{G}_m)^{1/4}\left\{\frac{\tilde{C}_{01}}{4\pi\gamma}\int_0^{\xi^*}\frac{\left[(1-\chi)^{5/8}\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2} + \frac{\mathcal{B}_1(\mathcal{P}_{ckm})}{4\pi\gamma}\int_0^{\xi^*}\frac{\left[(1-\chi)^{1/8}\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2}\right\}\\ &-(\mathcal{G}_c\mathcal{G}_m)^{1/4}\left\{\frac{\mathcal{P}_{cm}^{-1/4}\mathcal{B}_2}{4\pi\gamma}\int_0^{\xi^*}\frac{\left[(1-\chi)^{3/4}\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2} + \frac{\mathcal{B}_3(\mathcal{P}_{ckm})}{4\pi\gamma}\int_0^{\xi^*}\frac{\left[(1-\chi)^{r}\right]' 2\chi \mathrm{d}\chi}{\chi^2-\xi^2}\right\}\\ =:& \ I_1+I_2+I_3+I_4+I_5+I_6.\end{aligned}$$

In the intermediate region $1-\xi = O(\mathcal{P}_{ckm}^s)$ for $0 < s < 2$, the integrals I_1 and I_2 can be evaluated to give

$$\begin{aligned}I_1 =& \frac{\mathcal{G}_k C_{00}}{4\pi\gamma}(1+\xi)^{-1}\sqrt{2}(1-\xi^*)^{1/2}\left\{\left(1+O\big(1-\xi^*\big)\right)+O\left(\frac{1-\xi^*}{1+\xi}\right)\right\}\\ &+\frac{\mathcal{G}_k C_{00}}{4\pi\gamma}(1-\xi)^{-1}\sqrt{2}(1-\xi^*)^{1/2}\left\{\left(1+O\big(1-\xi^*\big)\right)+O\left(\frac{1-\xi^*}{1-\xi}\right)\right\},\\ I_2 =& -\frac{\mathcal{G}_k\left[C_{01}\mathcal{P}_{km}^{-1}+C_{02}\mathcal{P}_{ckm}^{-1}\right]}{4\pi\gamma}\left\{\ln\left|1-\frac{1-\xi^*}{1+\xi}\right|+\ln\left|1-\frac{1-\xi^*}{1-\xi}\right|\right\},\end{aligned} \tag{B.4}$$

while in the near-tip region $1-\xi = O(\mathcal{P}_{ckm}^s)$ for $s > 2$ the integrals are of the form

(B.5)

$$\begin{aligned}I_1 =& \frac{\mathcal{G}_k C_{00}}{4\pi\gamma}(1+\xi)^{-1}\sqrt{2}(1-\xi^*)^{1/2}\left\{\left(1+O\big(1-\xi^*\big)\right)+O\left(\frac{1-\xi^*}{1+\xi}\right)\right\}\\ &+\frac{\mathcal{G}_k C_{00}}{4\pi\gamma}\left\{\pi-\arctan\left(\frac{\xi^*}{\sqrt{1-\xi^{*2}}}\right)+\frac{\xi}{\sqrt{1-\xi^2}}\ln\left|\frac{1-\xi^*\xi+\sqrt{1-\xi^2}\sqrt{1-\xi^{*2}}}{\xi-\xi^*}\right|\right\},\\ I_2 =& -\frac{\mathcal{G}_k\left[C_{01}\mathcal{P}_{km}^{-1}+C_{02}\mathcal{P}_{ckm}^{-1}\right]}{4\pi\gamma}\left\{\ln\left|1-\frac{1-\xi^*}{1+\xi}\right|+\ln\left|\frac{1-\xi^*}{1-\xi}\right|+\ln\left|1-\frac{1-\xi}{1-\xi^*}\right|\right\}.\end{aligned}$$

We briefly outline the calculation of I_3, I_4, I_5, and I_6 for a general integral of that form with parameter $0 < a < 1$: then the results follow from setting $a = 5/8$, $1/8$, $3/4$, r, respectively. Thus the integral is

$$J_3 = \int_0^{\xi^*}(1-\chi)^{a-1}\frac{2\chi \mathrm{d}\chi}{\chi^2-\xi^2}, \tag{B.6}$$

which is now split as

$$J_3 = \int_0^{\xi^*}\frac{(1-\chi)^{a-1}}{\chi-\xi}\,\mathrm{d}\chi - \int_{-\xi^*}^0\frac{(1+\chi')^{a-1}}{\chi'-\xi}\,\mathrm{d}\chi' =: J_3^A + J_3^B. \tag{B.7}$$

Note that ξ can vary over the whole interval, i.e., $-1 < \xi < 1$. Then asymptotic expansions for the integrals are used, depending on whether ξ is inside or outside the interval of integration. It is convenient to use a change of variables which captures the asymptotic behavior of Π near the tip. It is also convenient to use different variables on different intervals, such as $\delta Z = 1-\xi$, $\delta R = 1-\chi$ in J_3^A and, $\delta Z = 1+\xi$,

$\delta R = 1 + \chi$ in J_3^B. We describe the procedure for the integral J_3^A (then J_3^B follows from an analogous calculation). This is split into three parts as

$$J_3^A = -\delta^{a-1}\left(\int_0^\infty - \int_{1/\delta}^\infty - \int_0^{(1-\xi^*)/\delta}\right)\frac{R^{a-1}}{R-Z}\,\mathrm{d}R. \tag{B.8}$$

In the intermediate region $1-\xi = O(\mathcal{P}_{ckm}^s)$ for $0 < s < 2$, the leading order behavior is determined by the first integral for $\delta = \mathcal{P}_{ckm}^2 \ll 1$ (as given in [40]), and so

$$J_3^A = (\delta Z)^{a-1}\pi\cot\pi a + O(1).$$

Then, for intermediate values of $\xi < \xi^*$, the integrals I_1, I_2, and J_3^B all give $O(1)$ contributions, which are lower order compared to the leading order term in J_3^A. The integral for J_4 is calculated in the same way. Hence the expression for Π in (B.3) is

$$\begin{aligned}\Pi = (\mathcal{G}_c\mathcal{G}_m)^{1/4}&\left\{\frac{q\tilde{C}_{01}}{4\pi\gamma}(1-\xi)^{q-1}\pi\cot\pi q + \frac{g\mathcal{B}_1(\mathcal{P}_{ckm})}{4\pi\gamma}(1-\xi)^{g-1}\pi\cot\pi g\right\}\\ &+(\mathcal{G}_c\mathcal{G}_m)^{1/4}\left\{\frac{p\mathcal{P}_{cm}^{-1/4}\mathcal{B}_2}{4\pi\gamma}(1-\xi)^{p-1}\pi\cot\pi p\right.\\ &\left.+\frac{r\mathcal{B}_3(\mathcal{P}_{ckm})}{4\pi\gamma}(1-\xi)^{r-1}\pi\cot\pi r\right\} + O(1),\end{aligned}$$

where $q = 5/8$, $g = 1/8$, $p = 3/4$ and the $O(1)$ terms are higher order with respect to $1-\xi \ll 1$.

Similarly, for values of ξ in the near-tip region $1-\xi = O(\mathcal{P}_{ckm}^s)$ for $s > 2$, the integral I_3 gives $O(1)$ contributions, and the leading order term is the singularity in I_2 defined in (B.5). Hence the expression for Π is now

$$\begin{aligned}\Pi = \mathcal{G}_k&\left[\frac{C_{00}}{4\gamma} - \frac{C_{01}\mathcal{P}_{km}^{-1} + C_{02}\mathcal{P}_{ckm}^{-1}}{4\pi\gamma}\left\{\ln\left|1-\frac{1-\xi^*}{1+\xi}\right| + \ln\left|\frac{1-\xi^*}{1-\xi}\right| + \ln\left|1-\frac{1-\xi}{1-\xi^*}\right|\right\}\right]\\ &+O(1).\end{aligned}$$

Here we have explicitly included the leading order term from I_1 for comparison with (3.31). Additional error terms not shown here also result from the fact that higher order derivatives for $\Omega(\xi)$ are not matched in the transition region: these can be shown to be higher order for $\mathcal{P}_{ckm} \ll 1$.

Acknowledgments. We would like to thank Emmanuel Detournay, José Adachi, and Dmitry Garagash for their very helpful comments and for sharing a number of preprints with us.

STOCHASTIC DIFFERENTIAL DELAY EQUATION, MOMENT STABILITY, AND APPLICATION TO HEMATOPOIETIC STEM CELL REGULATION SYSTEM*

JINZHI LEI† AND MICHAEL C. MACKEY‡

Abstract. We study the moment stability of the trivial solution of a linear differential delay equation in the presence of additive and multiplicative white noise. The results established here are applied to examining the local stability of the hematopoietic stem cell (HSC) regulation system in the presence of noise. The stability of the first moment for the solutions of a linear differential delay equation under stochastic perturbation is identical to that of the unperturbed system. However, the stability of the second moment is altered by the perturbation. We obtain, using Laplace transform techniques, necessary and sufficient conditions for the second moment to be bounded. In applying the results to the HSC system, we find that the system stability is sensitive to perturbations in the stem cell differentiation and death rates, but insensitive to perturbations in the proliferation rate.

Key words. stochastic differential delay equation, moment stability, hematopoietic disease

1. Introduction.

Delays in feedback regulation are ubiquitous in biological control systems, where the retardation usually originates from maturing processes or finite signaling velocities [4, 15, 16, 17, 21, 30, 34, 36, 37, 39, 45, 46]. Differential delay equation model systems with retarded arguments have been extensively developed in the past several decades (see [3, 10, 11, 18, 19, 20] and the references therein). However, in applied areas, deterministic systems fail to capture the essence of the fluctuations in the real situation, and one must instead consider models with stochastic processes that take into account the perturbations present in the real world. In situations where delays are important, models with stochastic perturbations are framed by stochastic differential delay equations.

The current study is motivated by an investigation of the stability of the hematopoietic regulatory system and its connection with several hematological diseases [5, 7, 8, 9, 21, 30, 39]. All blood cells originate from the hematopoietic stem cells (HSC) in the bone marrow. These stem cells differentiate and proliferate, giving rise to the three major cell lines: the leukocytes (white blood cells), the platelets, and the erythrocytes (red blood cells). The three peripheral regulatory loops are all of a negative feedback nature, and are mediated by a variety of cytokines including erythropoietin (EPO), thrombopoietin (TPO), and granulocyte colony-stimulating factor (G-CSF) [1, 50, 53, 55, 58]. These cytokines are synthesized and released by cells of the hematopoietic system. They control the hematopoietic system by regulating the growth, differentiation, and survival of cells.

A mathematical model of the hematopoietic regulation system that combines the delay for cell maturation and negative feedback of the differentiated cells has been studied in [7, 8]. The numbers of circulating cells in a healthy person usually fluctuate with small amplitude around their normal levels. However, there are several hematological diseases that display a highly dynamic nature characterized by statistically significant oscillations in one or more of the circulating progeny of the HSC [21]. These diseases include, but are not limited to, cyclical neutropenia [8, 21, 22, 23], periodic chronic myelogenous leukemia [7, 12, 52], cyclical thrombocytopenia [49, 54, 59], and periodic hemolytic anemia [33, 45]. For example, cyclical neutropenia is a rare genetic blood disease in which the patient's neutrophil level drops to an extremely low level for six to eight days every three weeks. Neutrophils are a type of white blood cell important in the defense of the body against infection. Since stem cell oscillations are thought to drive oscillations in several periodic hematological diseases [21], understanding the HSC dynamics is important.

The differential delay equations that model the HSC dynamics have been developed for a G_0 cell cycle model in [13, 31, 32, 33, 39, 51]. The delays in these models reflect the nonzero time that it takes the cells to complete the proliferative phase of the cell cycle. For example, the HSC takes about 2.8 days to complete one cell cycle. Previous studies suggested that the HSC population becomes unstable and develops oscillations when the steady state corresponding to the healthy state is destabilized, for example by increasing the apoptosis (death) rate or the differentiation rate in the stem cells. However, in these studies, the stochastic perturbations that occur in the real world, and which might lead to instability and oscillation, were not taken into account. In this paper, we will investigate the effects of random perturbation and answer the following two questions:

1. If the steady state of the system without noise is unstable, is it possible to stabilize the steady state by noise perturbation?

2. If the steady state of the system without noise is stable, is it possible to destabilize the steady state by noise perturbation? If the answer is "YES," such perturbation usually originates from the perturbation in the system parameters. Therefore, there are thresholds for each of the parameters such that the steady state is stable when the perturbation is smaller than this threshold and unstable otherwise. The quantitative estimation of these thresholds will also be considered in this paper.

The answers to these two questions offer insight into the stability of the hematopoietic system in the face of stochastic perturbations.

The HSC dynamics with stochastic perturbation is modeled by a nonlinear stochastic differential delay equation. To answer the questions posed above, we linearize the equation around the steady state and study the stability of the resulting equation.

Consider the process described by the differential delay equation

$$\frac{dz}{dt} = f(z, z_\tau), \tag{1.1}$$

where $z_\tau = z(t-\tau)$. It may be the case that the function $f(z, z_\tau)$ is subject to some random effect (noise), so that we have

$$\frac{dz}{dt} = f(z, z_\tau) + \sigma(t, z, z_\tau) \cdot \xi_t(\omega), \tag{1.2}$$

where $\xi_t(\omega)$ is a stochastic process that represents the noise term. In our study of the hematopoietic system, this noise is internal to the system because of random

fluctuations in the system parameters, e.g., fluctuations in the differentiation rate, death rate, or proliferation rate of stem cells. However, the precise properties of the noise are not known. To gain insight into the effect of noise on the system, we assume the noise to be Gaussian distributed white noise with zero mean and a delta function autocorrelation $\langle \xi_t \xi_s \rangle = \delta(t-s)$. We assume further that the function σ does not depend on t explicitly. Using the definition of Gaussian white noise ξ_t as the derivative of the Wiener process $W(t)$, equation (1.2) can be written as

$$dz = f(z, z_\tau)dt + \sigma(z, z_\tau)dW(t). \tag{1.3}$$

From a formal point of view, we can solve (1.3) and write the stochastic process $z(t) = z(t;\omega)$ as

$$z(t) = z(0) + \int_0^t f(z(s), z_\tau(s))ds + \text{“}\int_0^t \sigma(z(s), z_\tau(s))dW(s).\text{”} \tag{1.4}$$

There are two interpretations for the stochastic integral

$$\text{“}\int_0^t \sigma(z(s), z_\tau(s))dW(s),\text{”}$$

the Itô interpretation and the Stratonovich interpretation. The Itô interpretation is usually used when the noise is white, but when the noise is colored (i.e., does not have a delta function autocorrelation), the Stratonovich interpretation is preferable. This issue has been discussed by many people (see, for example, [26, pp. 232–237], [28, pp. 346–351], [29, pp. 152–155], and [48, pp. 35–37]), and it is safe to say that the debate over the issue is far from settled. In this study we adopt the Itô interpretation for two reasons. First, the Itô approach is mathematically preferable [29], and second it is relatively straightforward to pass from results obtained using the Itô interpretation to one appropriate for the Stratonovich interpretation.

Indeed, assuming that the stochastic integral is to be interpreted as an Itô integral, (1.4) can be written as

$$z(t) = z(0) + \int_0^t f(z(s), z_\tau(s))ds + \int_0^t \sigma(z(s), z_\tau(s))dW(s). \tag{1.5}$$

There is a simple relation between the Itô interpretation and the Stratonovich interpretation [14, 48, 57]. Thus, the solution of (1.3) using the Stratonovich interpretation of the stochastic integral

$$z(t) = z(0) + \int_0^t f(z(s), z_\tau(s))ds + \int_0^t \sigma(z(s), z_\tau(s)) \circ dW(s)$$

is equivalent to the solution of the modified Itô equation

$$\begin{aligned} z(t) = z(0) &+ \int_0^t f(z(s), z_\tau(s))ds + \frac{1}{2}\int_0^t \sigma'_z(z(s), z_\tau(s))\sigma(z(s), z_\tau(s))ds \\ &+ \int_0^t \sigma(z(s), z_\tau(s))dW(s). \end{aligned}$$

Thus, the results in this paper obtained from the Itô approach are also applicable to a Stratonovich interpretation after replacing $f(z, z_\tau)$ in (1.3) by

$$f(z, z_\tau) + \frac{1}{2}\sigma'_z(z, z_\tau)\sigma(z, z_\tau). \tag{1.6}$$

We will see below that these two different interpretations can lead to significant changes in the predicted stability of the system.

Assume that $z = z_*$ is a steady state of (1.1); i.e., $f(z_*, z_*) = 0$. What we are interested to know is the effect of the noise perturbation on the steady state. In general, we do not have $\sigma(z_*, z_*) = 0$. Hence, $z(t) \equiv z_*$ is not a solution of the perturbed equation (1.3). We will address the question of under what condition the stochastic process $z(t)$ satisfying the perturbed equation (1.3) remains close to the steady state $z = z_*$, i.e., when the solution $z = z_*$ is "stable" under stochastic perturbation.

Linearizing (1.3) around the steady state yields the linear stochastic differential delay equation

$$dx = (ax + bx_\tau)dt + (\sigma_0 x + \sigma_1 x_\tau + \sigma_2)dW(t), \tag{1.7}$$

where $x(t) = z(t) - z_*$ and a, b, σ_i are constants given by

$$a = f'_z(z_*, z_*), \quad b = f'_{z_\tau}(z_*, z_*),$$

$$\sigma_0 = \sigma'_z(z_*, z_*), \quad \sigma_0 = \sigma'_{z_\tau}(z_*, z_*), \quad \sigma_2 = \sigma(z_*, z_*).$$

At this point, we will study the moment stability of (1.7) to answer the following questions:

1. Under what conditions does the ensemble mean of the solutions of (1.7) approach 0 when $t \to \infty$?

2. Under what condition is the variance of the solutions bounded (or unbounded) for all $t > 0$?

3. When the variance is bounded, then the upper limit of the variance, when $t \to \infty$, provides the estimation of its upper bound when t is large. Therefore, the estimation of the variance when $t \to \infty$ is interesting and will be studied in this paper.

Despite the apparently simple form of (1.7), the stability problem is not trivial, because of the combination of delay and stochastic terms.

Stochastic differential delay equations were introduced by Itô and Nisio in the 1960s [24]. Those authors also discussed the existence and uniqueness of the solution. However, progress in this area has been slow, and most of the results including stochastic stability, numerical approximation, etc., have been developed in the last decade [2, 27, 40, 41, 42, 43, 44, 47]; see [25] for a recent survey of these results. Despite the efforts of many researchers, this field is still in its infancy. For example, conditions for the stability of (1.7), a linear stochastic differential delay equation with constant coefficients, are not known. In the case of a stochastic ordinary differential equation ($b = \sigma_1 = 0$) and a delay differential equation ($\sigma_i = 0$), the stability conditions of the equation have been well established [20, 41]. However, when trying to extend these results to stochastic differential delay equations, one encounters serious difficulties because of the combination of delay and stochastic processes, and the explicit solution of (1.7) is not known.

The Lyapunov function method is useful for studying the stability of differential equations and has been developed for both differential delay equations and stochastic differential equations. In the 1990s, Mao extended this method to stochastic functional differential equations [41, Chapter 5]. Because of the results of Mao, we have some results for the stability of stochastic differential delay equations (see [41, section 5.6] for details). However, when applying these results to (1.7), we find that they are applicable only when $a < 0$. In our study of the hematopoietic system, the case $a > 0$

is the most interesting, and we therefore need to develop new results for the moment stability of (1.7).

In this paper, we will first develop the mathematical theory for the moment stability of the linear stochastic differential delay equation (1.7), and then apply the result to studying the stability of the hematopoietic system under stochastic perturbation. The paper is organized as follows. In section 2 we briefly present the mathematical preliminaries for linear differential delay equations needed for the rest of the paper. Section 3 examines the effect of stochastic perturbation on the behavior of the first and second moments of (1.7). This section contains the main mathematical results for the moment stability. The first moment is discussed in section 3.1. Section 3.2 considers the second moment and is divided into two parts according to the type of stochastic perturbation, namely, additive white noise and general cases. Section 4 studies the stability of the hematopoietic regulation system under stochastic perturbations. The paper concludes with a brief discussion in section 5.

In what follows, we will take $\tau = 1$ by normalizing the time through

$$(x, t, a, b, \sigma_i, \tau) \to (x, t/\tau, a/\tau, b/\tau, \sigma_i/\tau, 1).$$

Thus, we will study the equation

$$dx = (ax + bx_1)dt + (\sigma_0 x + \sigma_1 x_1 + \sigma_2)dW(t). \tag{1.8}$$

2. Mathematical preliminaries: The system without noise. When the σ_i in (1.8) are zero, we have the linear differential delay equation

$$\frac{dx}{dt} = ax + bx_1. \tag{2.1}$$

The differential delay equation (2.1) has been studied extensively, and [20] can be consulted for a detailed exposition.

The characteristic function of (2.1) is

$$h(\lambda) = \lambda - a - be^{-\lambda}. \tag{2.2}$$

The fundamental solution of (2.1), denoted by $X(t)$, has a Laplace transform given by $h^{-1}(\lambda)$ [20, Chapter 1]. This fundamental solution of (2.1) will be essential in following study.

Let $C([-1, 0], \mathbb{R})$ be the family of continuous functions ϕ from $[-1, 0]$ to $\mathbb{R}$ with the norm $\|\phi\| = \sup_{-1\le\theta\le 0} |\phi(\theta)|$. Using the fundamental solution, the solution of (2.1) with initial condition $x(\theta) = \phi(\theta) \in C([-1, 0], \mathbb{R})$ is given by

$$x_\phi(t) = X(t)\phi(0) + \int_{-1}^{0} X(t - 1 - s)\phi(s)ds. \tag{2.3}$$

From (2.3), the asymptotic behavior of $x_\phi(t)$ is determined by the fundamental solution $X(t)$. We have following result.

THEOREM 2.1 (see [20, Chapter 1, Theorem 5.2]). *If $\alpha_0 = \max\{\Re(\lambda) : h(\lambda) = 0\}$, then, for any $\alpha > \alpha_0$, there is a constant $K = K(\alpha)$ such that the fundamental solution X satisfies the inequality*

$$|X(t)| \le Ke^{\alpha t} \qquad (t \ge 0). \tag{2.4}$$

From Theorem 2.1, the solutions (2.3) with any $\phi(\theta) \in C([-1,0],\mathbb{R})$ approach 0 as $t \to \infty$ if and only if $\alpha_0 < 0$. The region in the (a,b)-plane such that $\alpha_0 < 0$ is given by [20]

$$S = \{(a,b) \in \mathbb{R}^2 \mid -a\sec\xi < b < a, \text{ where } \xi = a\tan\xi,\ a < 1,\ \xi \in (0,\pi)\}. \tag{2.5}$$

Here, the values of α_0 and $K(\alpha)$ are significant for understanding the stability of the system. The estimation of α_0 and $K(\alpha)$ are given below.

The number α_0 is given by the maximum real solution of the equation

$$(\alpha_0 - a)^2 - b^2 e^{-2\alpha_0} + \left[\arccos\frac{\alpha_0 - a}{be^{-\alpha_0}}\right]^2 = 0. \tag{2.6}$$

When $b \neq 0$, for any $\alpha > \alpha_0$ define

$$K(\alpha) = 1 + \xi(\alpha) + \frac{(|a-\alpha_0|e^{\alpha} + |b|)\log 2}{|b|\pi}, \tag{2.7}$$

where

$$\xi(\alpha) = \frac{1}{2\pi}\left|\int_{-2|b|e^{-\alpha}}^{2|b|e^{-\alpha}} \frac{a + be^{-(\alpha+iz)} - \alpha_0}{(\alpha - \alpha_0 + iz)h(\alpha+iz)}dz\right|.$$

Then (2.4) is satisfied. When $b = 0$, it is obvious that (2.4) holds with $K(\alpha) = 1$ whenever $\alpha \geq a$.

When $|b| < -a$, it is not difficult to prove that

$$|X(t)| \leq e^{(a+\mu)t} \quad (\forall t > 0), \tag{2.8}$$

where $|b| < \mu < -a$ is such that $\mu e^{a+\mu} - |b| = 0$. Thus, we can specify $K(\alpha) = 1$ with $\alpha = a + \mu$ when $|b| < -a$.

These considerations provide a framework for computing α_0 and $K(\alpha)$ with $\alpha > \alpha_0$ that satisfies (2.4).

3. Moment stability: The system with noise perturbation. We now turn to a study of the system with noise; i.e., the parameters σ_i in (1.8) are not all zero.

From the fundamental solution $X(t)$ in the previous section, the solution of (1.8) with the initial function $x(\theta) = \phi(\theta) \in C([-1,0],\mathbb{R})$ is a stochastic process given by

$$x(t;\phi) = x_\phi(t) + \int_0^t X(t-s)(\sigma_0 x(s;\phi) + \sigma_1 x_1(s;\phi) + \sigma_2)dW(s), \tag{3.1}$$

where $x_1(s;\phi) = x(s-1;\phi)$ and $x_\phi(t)$, the solution of the deterministic equation (2.1), is defined by (2.3). The existence and uniqueness theorem for the stochastic differential delay equation has been established in [24] (see also [41, Chapter 5]). The solution $x(t;\phi)$ is a stochastic process with distribution at any time t determined by the initial function $\phi(\theta)$. From the Chebyshev inequality, the possible range of x at time t is "almost" determined by its mean and variance at time t. Thus, the first and second moments of the solution are important for investigating the solution behavior and will be studied in this section. We first define pth moment exponential stability and pth moment boundedness.

DEFINITION 3.1. *The solution of* (1.8) *is said to be first moment exponentially stable if there is a pair of positive constants* λ *and* C *such that*

$$|Ex(t;\phi)| \le C\|\phi\|e^{-\lambda t} \quad (\forall t > 0)$$

for all $\phi \in C([-1,0],\mathbb{R})$. *When* $p \ge 2$, *the solution of* (1.8) *is said to be pth moment exponentially stable if there is a pair of positive constants* λ *and* C *such that*

$$E\left(|x(t;\phi) - E(x(t;\phi))|^p\right) \le C\|\phi\|^p e^{-\lambda t} \quad (\forall t \ge 0)$$

for all $\phi \in C([-1,0],\mathbb{R})$.

DEFINITION 3.2. *For* $p \ge 2$, *the solution of* (1.8) *is said to be pth moment bounded if there is a constant* A *such that*

$$E\left(|x(t;\phi) - E(x(t;\phi))|^p\right) \le A \quad (\forall t \ge 0)$$

for all $\phi \in C([-1,0],\mathbb{R})$. *Otherwise, the pth moment is said to be unbounded.*

We have used E to denote the mathematical expectation. In this paper, we will study the exponential stability of the first moment and the boundedness of the second moment. Hereinafter, we denote $x(t;\phi)$ simply by $x(t)$.

3.1. The first moment. Taking the mathematical expectation of both sides of (1.8), we have, with the Itô interpretation,

$$\frac{dEx(t)}{dt} = aEx(t) + bEx(t-1). \tag{3.2}$$

Thus, we obtain a differential delay equation for the first moment $Ex(t)$. From the discussion in the previous section, the first moment $Ex(t)$ approaches 0 as $t \to \infty$ if and only if the parameter α_0 defined in Theorem 2.1 is less than 0. In fact, by (3.1) and the properties of Itô integral, we have

$$Ex(t) = X(t)\phi(0) + \int_{-1}^{0} X(t-1-s)\phi(s)ds. \tag{3.3}$$

THEOREM 3.3. *If* $\alpha_0 = \max\{\Re(\lambda) : h(\lambda) = 0\}$, *then for any* $\alpha > \alpha_0$ *there is a constant* $K_1 = K_1(\alpha)$ *such that*

$$|Ex(t)| \le K_1\|\phi\|e^{\alpha t} \qquad (t \ge 0). \tag{3.4}$$

Therefore, if $\alpha_0 < 0$, *then* (1.8) *is first moment exponentially stable.*

3.2. The second moment. We now turn to the behavior of the second moment of the solution $x(t)$. From Theorem 3.3, the stability condition of the first moment is identical to that of the unperturbed system and is determined exclusively by a and b. Thus the stability of the first moment is independent of the parameters σ_i. However, the situation of second moment is more complicated and depends on σ_i. When $\sigma_2 \ne 0$, we cannot expect the second moment to be exponentially stable. Let $M(t)$ be the second moment of the solution at a time t. Then the Chebyshev inequality yields

$$P\left[|x(t) - Ex(t)| \ge k\sqrt{M(t)}\right] \le \frac{1}{k^2} \tag{3.5}$$

for any $k > 0$. Thus, when the second moment is bounded, the solutions of (1.8) are also bounded in some sense. We will answer in this section when the second moment is bounded for all $t > 0$.

The following notation will be used. Let $x(t)$ be a solution of (1.8), and define

$$\tilde{x}(t) = x(t) - Ex(t), \tag{3.6}$$

$$M(t) = E(\tilde{x}(t)^2), \quad M_1(t) = M(t-1), \quad N(t) = E(\tilde{x}(t)\tilde{x}(t-1)), \tag{3.7}$$

$$F(t) = \int_0^t X^2(t-s)(\sigma_0 Ex(s) + \sigma_1 Ex_1(s) + \sigma_2)^2 ds. \tag{3.8}$$

$M(t)$ is the second moment studied below. Applying the Itô isometry to $M(t)$, a simple computation yields that

$$M(t) = F(t) + \int_0^t X^2(t-s)(\sigma_0^2 M(s) + \sigma_1^2 M_1(s) + 2\sigma_0\sigma_1 N(s))ds. \tag{3.9}$$

3.2.1. Additive noise. When $\sigma_0 = \sigma_1 = 0$, we have the additive noise case, and the second moment is given explicitly by

$$M(t) = \sigma_2^2 \int_0^t X^2(t-s)ds. \tag{3.10}$$

By Theorem 2.1, we have the following result in the case of additive noise.

THEOREM 3.4. *Let* $\alpha_0 = \{\Re(\lambda) : h(\lambda) = 0\}$. *If* $\sigma_0 = \sigma_1 = 0$, *the second moment of* (1.8) *is bounded if and only if* $\alpha_0 < 0$. *Furthermore, for any* $\alpha_0 < \alpha < 0$, *there exists* $K = K(\alpha)$ *such that*

$$\left| M(t) - \sigma_2^2 \int_0^\infty X^2(s)ds \right| \le -\frac{\sigma_2^2 K^2}{2\alpha} e^{2\alpha t}. \tag{3.11}$$

From Theorem 3.4, the boundedness of the second moment is characterized by α_0, which is in turn determined by a and b of the unperturbed equation. This result was presented in [38], but the proof in [38] is in error. We reprove this result here and the estimation of the second moment $M(t)$ when $t \to \infty$ is given by

$$\lim_{t\to\infty} M(t) = \sigma_2^2 \int_0^\infty X^2(s)ds \le -\frac{\sigma_2^2 K^2}{2\alpha}. \tag{3.12}$$

3.2.2. General cases ($\sigma_0 \neq 0$ or $\sigma_1 \neq 0$). When $\sigma_0 \neq 0$ or $\sigma_1 \neq 0$, the noise at time t depends on x at time t or time $(t-1)$. In this general case, there is no simple form for the second moment. First, we have by (3.9) that

$$M(t) \ge F(t).$$

When $\alpha_0 \ge 0$, we have $X(t) = O(e^{\alpha_0 t})$ as $t \to \infty$. Thus, we can always take an initial function $\phi(\theta)$ such that $F(t)$ tends to infinity when $t \to \infty$, for example, the initial functions $\phi(\theta)$ such that

$$Ex(t) = \sum_i c_i e^{\lambda_i t},$$

where $h(\lambda_i) = 0$ and c_i are nonzero constants.

Therefore, we have the following necessary condition for the boundedness of the second moment.

LEMMA 3.5. *If the second moment of* (1.8) *is bounded, then* $\alpha_0 < 0$*; i.e., the unperturbed equation is exponentially stable.*

From now on, we will always assume that $\alpha_0 < 0$. In this situation, we have

$$\lim_{t\to\infty} F(t) = \sigma_2^2 \int_0^\infty X^2(s)ds. \tag{3.13}$$

We next study the second moment using the Laplace transform. We denote by $\mathcal{L}(p)(s)$ the Laplace transform of $p(t)$ when

$$p(t) < Pe^{at} \quad (t > 0)$$

for constants P and a.

Let $X_1(t) = X(t-1)$. It is easy to check that the functions $X^2(t)$, $X(t)X_1(t)$, $M(t)$, and $N(t)$ have Laplace transforms.

The following theorem establishes the condition for the second moment of the solution of (1.8) to be bounded.

THEOREM 3.6. *Let*

$$f(s) = \frac{\mathcal{L}(XX_1)(s)}{\mathcal{L}(X^2)(s)}, \qquad g(s) = \frac{\mathcal{L}(N)(s)}{\mathcal{L}(M)(s)}, \tag{3.14}$$

and

$$H(s) = s - (2a + \sigma_0^2) - (2bf(s) + 2\sigma_0\sigma_1 g(s)) - \sigma_1^2 e^{-s}. \tag{3.15}$$

The second moment of the solution of (1.8) *is bounded if and only if all solutions of the characteristic equation* $H(s) = 0$ *have negative real part. Furthermore, when the second moment is bounded, it approaches a constant exponentially when* $t \to \infty$.

Proof. We will divide the proof into several steps.

(1) By (3.9), we have

$$M(t) = F(t) + X^2 * (\sigma_0^2 M + \sigma_1^2 M_1 + 2\sigma_0\sigma_1 N),$$

where $*$ denotes convolution. Taking the Laplace transform of both sides and solving the resulting equation for $\mathcal{L}(M)(s)$, we have

$$\mathcal{L}(M)(s) = \frac{\mathcal{L}(F)(s)}{1 - \mathcal{L}(X^2)(s)(\sigma_0^2 + \sigma_1^2 e^{-s} + 2\sigma_0\sigma_1 g(s))}, \tag{3.16}$$

where $\mathcal{L}(X^2)(s)$ is given by

$$\mathcal{L}(X^2)(s) = \frac{1}{s - 2a - 2bf(s)}.$$

Thus, by (3.16), we have

$$\mathcal{L}(M)(s) = \frac{\mathcal{L}(F)(s)}{\mathcal{L}(X^2)(s)} H^{-1}(s).$$

Let

$$G(t) = \mathcal{L}^{-1}\left[\frac{\mathcal{L}(F)}{\mathcal{L}(X^2)}\right](t) = (\sigma_0 Ex(t) + \sigma_1 Ex_1(t) + \sigma_2)^2$$

and $Y(t) = \mathcal{L}^{-1}(H^{-1})(t)$. Then we have

$$M(t) = G * Y = \int_0^t G(t-s)Y(s)ds. \tag{3.17}$$

(2) Let $\beta_0 = \max\{\Re(s) : H(s) = 0\}$. We will prove that for any $\beta > \beta_0$ there is a constant $K_2 = K_2(\beta)$ such that

$$|Y(t)| \le K_2 e^{\beta t}. \tag{3.18}$$

To start, we will show that $\beta_0 < \infty$ is well defined. To do this, noting that there exist A_1 and A_2 such that if $\Re(s)$ is large enough,

$$|f(s)| \le A_1 e^{-\Re(s)/2} \quad \text{and} \quad |g(s)| \le A_2 e^{-\Re(s)/2}. \tag{3.19}$$

We omit the proof of (3.19) due to space constraints. Thus, when $\Re(s)$ is large enough, $H(s) > 0$, and therefore the value $\beta_0 < \infty$ is well defined.

Now, (3.18) follows from the inverse Laplace transform

$$Y(t) = \lim_{T\to\infty} \frac{1}{2\pi} \int_{\beta-iT}^{\beta+iT} H^{-1}(s)e^{st}ds \le K_2 e^{\beta t}$$

for any $\beta \ge \beta_0$ and a constant $K_2 = K_2(\beta)$. The details of the proof are exactly the same as for the proof given in [20, pp. 20–21], and we omit the details here.

(3) Now we have

$$M(t) = \int_0^t G(t-s)Y(s)ds,$$

with $|Y(t)| \le K_2 e^{\beta t}$ for any $\beta > \beta_0$. Furthermore, for any $\alpha_0 < \alpha < 0$ there exists $K_3 = K_3(\alpha, \phi)$ such that

$$|G(t)| \le \sigma_2^2 + K_3 e^{\alpha t}.$$

If $\beta_0 < 0$, we choose $\beta_0 < \beta < 0$ and K_2 as above. Then

$$|M(t)| \le \int_0^t (\sigma_2^2 + K_3 e^{\alpha(t-s)})K_2 e^{\beta s}ds,$$

and thus the second moment $M(t)$ is bounded for any initial function $\phi(\theta)$. In this situation, let

$$M_\infty = \sigma_2^2 \int_0^\infty Y(s)ds,$$

so that

$$|M(t) - M_\infty| \le K_2\sigma_2^2 e^{\beta t} + \frac{K_2K_3}{\beta - \alpha}(e^{\beta t} - e^{\alpha t}).$$

Thus, there exists a positive constant $K_4 = K_4(\alpha, \beta, \phi)$ such that

$$|M(t) - M_\infty| \le K_4 e^{t\max\{\alpha,\beta\}};$$

i.e., $M(t)$ approaches to M_∞ exponentially when $t \to \infty$.

If $\beta_0 \geq 0$, by the inverse Laplace transform, we have $Y(t) = O(e^{\beta_0 t})$ when t is large enough. We can choose an initial function $\phi(\theta)$ such that

$$Ex(t) = \sum_i c_i e^{\lambda_i t},$$

where $h(\lambda_i) = 0$ and c_i are nonzero constants. For this particular initial function, we have either $G(t) = O(1)$ as $t \to \infty$ when $\sigma_2 \neq 0$, or $G(t) = O(e^{2\alpha t})$ as $t \to \infty$ for some $\alpha \leq \alpha_0 < 0$ when $\sigma_2 = 0$. In either case,

$$M(t) = \int_0^t G(t-s)Y(s)ds = O(e^{\beta_0 t})$$

when $t \to \infty$, and hence the second moment is unbounded. ∎

Theorem 3.6 establishes a criterion for the second moment of the linear stochastic delay differential equation to be bounded. However, this criterion is not particularly useful. The function $g(s)$ in (3.15) involves the Laplace transforms of $M(t)$ and $N(t)$ that are unknown. In many applications, perturbations for system parameters affect only the right-hand side of the equation that involves either the current state or the retarded state, and thus either $\sigma_1 = 0$ or $\sigma_0 = 0$. In this situation, the function $H(s)$ reads

$$H(s) = s - (2a + \sigma_0^2) - 2bf(s) - \sigma_1^2 e^{-s}$$

and is determined by the system coefficients and by $f(s)$, which depends on the Laplace transforms of $X^2(t)$ and $X(t)X_1(t)$. Nevertheless, it is not trivial to obtain the explicit form of $f(s)$ for a given system. In the rest of this section, we will develop some estimates for $f(s)$ and $g(s)$ and present direct criteria for the second moment stability.

THEOREM 3.7. *If $b < 0$, $\sigma_0\sigma_1 \leq 0$, and either*

$$(\sigma_0 + \sigma_1)^2 \geq -2(a+b) \tag{3.20}$$

or

$$u = \begin{cases} \dfrac{-(b+\sigma_0\sigma_1) - \sqrt{(b+\sigma_0\sigma_1)^2 - 4\sigma_1^2}}{2\sigma_1^2}, & \sigma_1 \neq 0, \\ -\dfrac{1}{b}, & \sigma_1 = 0, \end{cases}$$

such that $0 < u < 1$ and

$$-2\log u - (2a + \sigma_0^2) - (2b + 2\sigma_0\sigma_1)u - \sigma_1^2 u^2 \leq 0, \tag{3.21}$$

then the second moment is unbounded.

Proof. Let

$$H_0(s) = s - (2a + \sigma_0^2) - (2b + 2\sigma_0\sigma_1)e^{-s/2} - \sigma_1^2 e^{-s}.$$

Then when $b < 0$ and $\sigma_0\sigma_1 \leq 0$, we have $H(s) \leq H_0(s)$ for all $s \in \mathbb{R}$. Therefore, either (3.20) or (3.21) implies that there exists $s_* > 0$ such that $H(s) \leq H_0(s_*) \leq 0$. However, $H(s) > 0$ when s is large enough. Therefore the equation $H(s) = 0$ has a nonnegative solution. Thus, the theorem follows from Theorem 3.6. ∎

Theorem 3.7 tells us when the second moment is unbounded. The following result will tell us when the second moment is bounded.

THEOREM 3.8. *If there exists* $\alpha < 0$ *and* $K = K(\alpha) > 0$ *such that*

$$|X(t)| \le Ke^{\alpha t} \quad (t \ge 0) \tag{3.22}$$

and

$$(|\sigma_0| + |\sigma_1|)^2 < -\frac{2\alpha}{K^2}, \tag{3.23}$$

then the second moment $M(t)$ *is bounded when* $t > 0$.

Theorem 3.8 will be proved using the following delay-type Gronwall inequality, the proof of which (which we omit) is similar to that of the Gronwall inequality.

LEMMA 3.9. *If* $y(t)$ *is a nonnegative continuous function on* $[-1, \infty)$ *and there are positive constants* p *and* q *such that*

$$y(t) \le p\int_0^t y(s)ds + q\int_0^t y(s-1)ds + r(t), \tag{3.24}$$

then for any $\beta > 0$ *such that*

$$\beta - p - qe^{-\beta} > 0$$

and

$$\sup_{t\ge 0} |r(t)e^{-\beta t}| < \infty$$

there exists $A = A(\beta)$ *such that*

$$y(t) \le Ae^{\beta t} \quad (t \ge 0). \tag{3.25}$$

We can now turn to the proof of Theorem 3.8.

Proof of Theorem 3.8. Note that

$$M(t) \le (|\sigma_0| + |\sigma_1|)\int_0^t X^2(t-s)(|\sigma_0|M(s) + |\sigma_1|M_1(s))ds + F(t). \tag{3.26}$$

For α such that (3.22) is satisfied, we have $K_5 = K_5(\alpha, \phi)$ such that

$$0 \le F(t) \le K_5(1 - e^{2\alpha t}).$$

Thus from (3.26) it follows that

$$M(t) \le K^2\,(|\sigma_0| + |\sigma_1|)e^{2\alpha t}\int_0^t (|\sigma_0|e^{-2\alpha s}M(s) + |\sigma_1|e^{-2\alpha s}M_1(s))ds + K_5(1 - e^{2\alpha t}).$$

Let

$$y(t) = e^{-2\alpha t}M(t), \qquad r(t) = K_5(e^{-2\alpha t} - 1),$$

and

$$p = K^2|\sigma_0|(|\sigma_0| + |\sigma_1|), \qquad q = K^2|\sigma_1|(|\sigma_0| + |\sigma_1|)e^{-2\alpha}.$$

Then

$$y(t) \le p\int_0^t y(s)ds + q\int_0^t y_1(s)ds + r(t).$$

The inequality (3.23) implies

$$-2\alpha - p - qe^{2\alpha} > 0.$$

Thus, by Lemma 3.9 there is a constant A such that

$$M(t)e^{-2\alpha t} = y(t) \le Ae^{-2\alpha t},$$

i.e., $M(t) \le A$ for all $t > 0$. □

From Theorem 3.6, if the second moment $M(t)$ is bounded, it exponentially approaches a constant M_∞. Let $t \to \infty$ in (3.26) and apply (3.13) so that we have

$$M_\infty \le \frac{\sigma_2^2 \int_0^\infty X^2(s)ds}{1 - (|\sigma_0| + |\sigma_1|)^2 \int_0^\infty X^2(s)ds} \le -\frac{\sigma_2^2 K^2(\alpha)}{2\alpha + (|\sigma_0| + |\sigma_1|)^2 K^2(\alpha)} \tag{3.27}$$

for any α and $K(\alpha)$ given in Theorem 3.8. It follows from (3.27) that when $\sigma_2 = 0$, boundedness of the second moment implies exponential stability.

From Theorems 3.3 and 3.8, for any parameter pair (a, b) in the region S defined in (2.5), the first moment of the solution of the stochastic differential delay equation (1.8) approaches 0 as $t \to \infty$. Furthermore, there exists $P(a, b) > 0$ such that if

$$(|\sigma_0| + |\sigma_1|)^2 < P(a, b), \tag{3.28}$$

the second moment of the solution is bounded with an upper bound, as $t \to \infty$, given by (3.27).

From the estimates of α_0 and $K(\alpha)$ given in section 2, the function $P(a, b)$ can be computed, and its graph is shown in Figure 3.1.

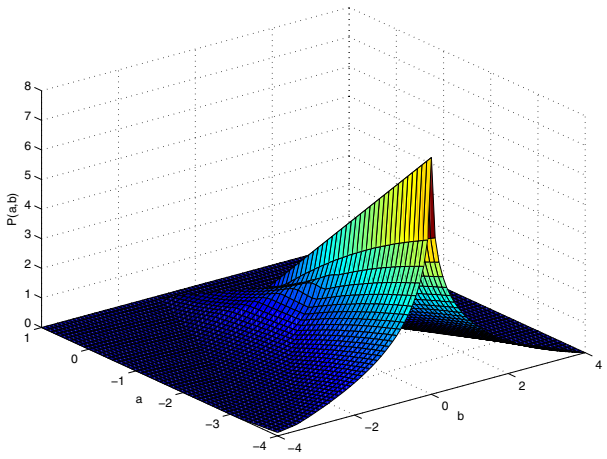

FIG. 3.1. *The function* $P(a, b)$.

4. Stability of the hematopoietic regulation system under stochastic perturbation. In this section, we will study the stability of the HSC in the face of stochastic perturbation, using the results of the previous sections. The HSC regulation system is modeled by a classical G_0 model [6, 35, 56]. Blood cells differentiate from HSC in the resting (G_0) phase. The HSC has high self-renewal capacity with the re-entry rate dependent on the number of HSC through a negative feedback loop. The proliferating phase cells include those cells in S phase (DNA synthesis), M phase (mitosis), and two segments known as the G_1 and G_2 phases (the G stands for "gap"). In addition, there is a loss of proliferating phase cells due to apoptosis (see Figure 4.1).

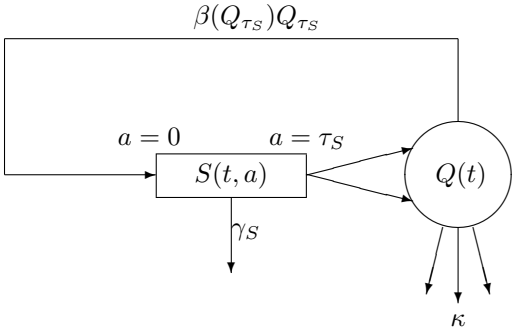

FIG. 4.1. *A cartoon representation of the HSC model.*

The HSC dynamics is modeled by a differential delay equation [7, 8, 9, 13, 51]

$$\frac{dQ}{dt} = -\beta(Q)Q - \kappa(N,R,P)Q + 2e^{-\gamma_S\tau_S}\beta(Q_{\tau_S})Q_{\tau_S}, \tag{4.1}$$

where Q, N, R, P are the quiescent stem cells, leukocytes, erythrocytes, and platelets, respectively, and $Q_{\tau_S} = Q(t-\tau_S)$. The model parameters are the apoptosis (death) rate γ_S, the maturation delay τ_S, the HSC self-renewal (proliferation) rate β, and the differentiation rate κ at which the HSC forms the three peripheral cell lines. The proliferation rate β and differentiation rate κ involve negative feedback loops that take the form of a Hill function [5, 7, 8],

$$\beta(Q) = k_0\frac{\theta_2^s}{\theta_2^s + Q^s},$$

$$\kappa(N,P,R) = f_0\frac{\theta_1^n}{\theta_1^n + N^n} + \frac{\bar{\kappa}_p}{1+K_pP^p} + \frac{\bar{\kappa}_r}{1+K_rR^r}.$$

Note that the rate κ depends on the state of three cell lines (leukocytes, erythrocytes, platelets), and thus (4.1) does not constitute a closed system. In this study, since we are interested only in the situation close to the steady state, we take the total differentiation out of the stem cell compartment to be a single constant. This decouples the model for the stem cell compartment from the full system.

Let us introduce nondimensional variables as follows:

$$q = \frac{Q}{\theta_2}, \quad \hat{t} = \frac{t}{\tau_S},$$

$$b_1 = \tau_S k_0, \quad \mu_1 = 2e^{-\gamma_S\tau_S}, \quad \delta = \tau_S\kappa.$$

We have the nondimensional form of (4.1) (see [9]),

$$\frac{dq}{dt} = -\frac{b_1}{1+q^s}q + \mu_1 \frac{b_1}{1+q_1^s}q_1 - \delta q, \tag{4.2}$$

where $q_1 = q(t-1)$ and $\hat{t}$ has been simply replaced by t. Typical values of the dimensionless parameters are $b_1 = 22.4$ and $\mu_1 = 1.64$. The parameter s, which denotes the number of cytokine molecules needed to trigger HSC proliferation in vitro, is chosen as $s = 4$ (see [9]).

When $\delta < b_1(\mu_1 - 1)$, equation (4.2) has a unique positive steady state

$$q^* = \left(\frac{b_1(\mu_1 - 1)}{\delta} - 1\right)^{1/4},$$

corresponding to the normal level of the stem cells. Linearizing (4.2) around this steady state, we obtain the variational equation

$$\frac{dx}{dt} = ax + bx_1,$$

where $x = q - q^*$,

$$a = -\frac{\delta}{b_1(\mu_1 - 1)^2}(-3b_1(\mu_1 - 1) + b_1(\mu_1 - 1)^2 + 4\delta),$$

and

$$b = \frac{\delta\mu_1}{b_1(\mu_1 - 1)^2}(-3b_1(\mu_1 - 1) + 4\delta).$$

From the discussion in section 2, there exists a critical value δ_c (≈ 0.16) such that the steady state is stable when $0 < \delta < \delta_c$.

We will now study the stability of the steady state when there are stochastic perturbations in the system parameters δ, b_1, or μ_1. We have the following equations for the perturbed system:

1. perturbation in δ:

$$dq = \left[-\frac{b_1 q}{1+q^4} - \delta q + \frac{b_1\mu_1 q_1}{1+q_1^4}\right]dt - \sigma q dW(t), \tag{4.3}$$

2. perturbation in b_1:

$$dq = \left[-\frac{b_1 q}{1+q^4} - \delta q + \frac{b_1\mu_1 q_1}{1+q_1^4}\right]dt + \sigma\left[-\frac{q}{1+q^4} + \frac{\mu_1 q_1}{1+q_1^4}\right]dW(t), \tag{4.4}$$

3. and perturbation in μ_1:

$$dq = \left[-\frac{b_1 q}{1+q^4} - \delta q + \frac{b_1\mu_1 q_1}{1+q_1^4}\right]dt + \sigma\frac{b_1 q_1}{1+q_1^4}dW(t), \tag{4.5}$$

where $W(t)$ is the standard Wiener process and σ is the noise amplitude. The linearized versions of (4.3)–(4.5) around the steady state $q = q^*$ are

$$dx = (ax + bx_1)dt - \sigma(x + q^*)dW(t), \tag{4.6}$$

$$dx = (ax + bx_1)dt + \left(\frac{\sigma}{b_1}\right)((a+\delta)x + bx_1 + \delta q^*)dW(t), \tag{4.7}$$

and

$$dx = (ax + bx_1)dt + \left(\frac{\sigma}{\mu_1}\right)\left(bx_1 + \delta q^* + \frac{b_1 q^*}{1 + q^{*4}}\right) dW(t), \tag{4.8}$$

respectively.

Applying the results from the previous section, when $0 < \delta < \delta_c$, the first moment of solutions of the perturbed system is locally stable. Furthermore, from Theorem 3.8, for any $0 < \delta < \delta_c$ (and b_1, μ_1 held at their typical values), there exists $\sigma_b(\delta)$ such that when $\sigma < \sigma_b(\delta)$ the second moment is bounded. Further, from Theorem 3.7, for any $0 < \delta < \delta_c$, there exists $\sigma_u(\delta)$ such that when $\sigma > \sigma_u(\delta)$ the second moment is unbounded. When $\sigma_b < \sigma < \sigma_u$, however, the previous results fail to delineate the stability of the second moment. A more accurate estimation for the characteristic function $H(s)$ in Theorem 3.6 is required to fill this gap. Graphs of the curves $\sigma = \sigma_b(\delta)$ and $\sigma = \sigma_u(\delta)$ are given in Figure 4.2.

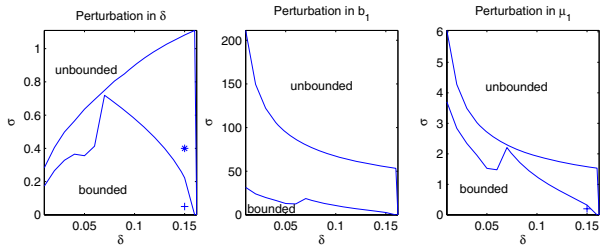

FIG. 4.2. *Parameter dependence for the second moment of the solution of the stochastic HSC system to be bounded.*

In Figure 4.2, the thresholds of the three parameter perturbations to ensure the stability of a steady state under noise perturbation are sorted from low to high as the threshold for δ, for μ_1, and for b_1. Thus, the HSC system is more easily destabilized by noise in the differentiation rate (δ) than in the death rate (μ_1), and least likely to be destabilized by perturbations in the proliferation rate (b_1).

Note that the solutions of (4.3)–(4.5) are always bounded because of the negative feedback. Thus, destabilization of the steady state may lead to fluctuating solutions characteristic of dynamic hematological disease (see Figure 4.3(b)). When the second moment is bounded, the range of the solution at time t can be estimated by the Chebyshev inequality (3.5). However, this cannot exclude the possibility of obtaining an oscillating solution (see Figure 4.3(c),(d)). In this situation, the amplitude of the oscillating solution is determined by the second moment, which is estimated by (3.27) when t is large. The graphs of M_∞ as a function of δ and σ are shown in Figure 4.4 for each of the cases. From Figure 4.4, for given values of b_1, μ_1, δ, and the perturbation amplitude σ, the second moment of the solutions of the HSC model with random perturbation in δ is larger than when there are perturbations in μ_1 and in b_1. Thus, small fluctuations in δ are able to produce large amplitude fluctuations in HSC numbers. Larger perturbations in μ_1 are required to produce a fluctuating HSC solution with the same amplitude (Figure 4.3(c),(d)). The second moment of solutions of the HSC system with perturbations in b_1 is small and not likely to produce a large amplitude fluctuation in HSC numbers.

These numerical results suggest that the dynamic hematological diseases [16] characterized by oscillations in blood cell numbers could originate from the stochastic

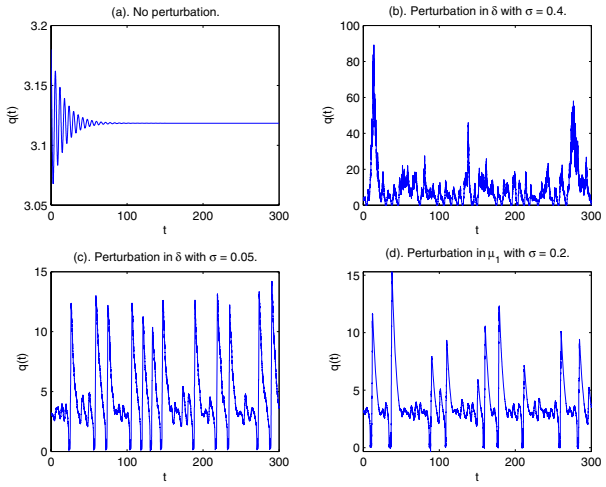

FIG. 4.3. *Sample solutions of the HSC system. In all these solutions, we choose* $b_1 = 22.4$, $\mu_1 = 1.64$, $\delta = 0.15$. *The perturbation is added to* δ *with* $\sigma = 0.4$ *and* $\sigma = 0.05$ *(cf. Figure* 4.2, *left-hand panel, marked by the "*" and "+," respectively), and to* μ_1 *with* $\sigma = 0.2$ *(cf. Figure* 4.2, *middle panel, marked with a "+"). The solution of the system without perturbation is also shown.*

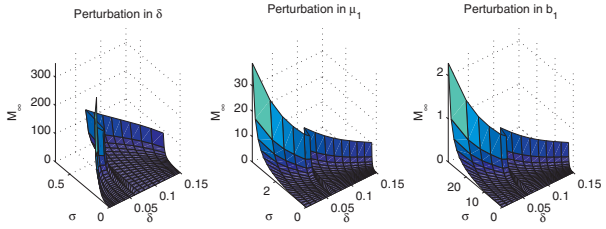

FIG. 4.4. *The function* M_∞ *as a function of* δ *and* σ.

perturbation of the differentiation rate and/or the death rate of HSCs. On the other hand, the system is relatively insensitive to perturbations in the proliferation rate.

5. Discussion. We have investigated the effects of white noise on the stability of the trivial solution of a linear differential delay equation by deriving the solutions for the first and second order moments and examining the exponential estimation by the Laplace transform method.

We have shown that the stability domain of the first moment is identical to that of the unperturbed system (Theorem 3.3). This result is also true for the second moment when the perturbation is simple additive noise (Theorem 3.4). However, when there is multiplicative white noise, there are no simple results on the stability (bounded nature) of the second moment. From our study, when the trivial solution of the unperturbed equation is unstable, the second moment of solutions of the perturbed equation is unbounded. The condition for the second moment to be bounded has been shown to be related to the solutions of a characteristic equation given in Theorem 3.6. Nevertheless, the explicit expression of the characteristic equation is not available in terms of the system parameters. We have presented several direct criteria for the second moment to be bounded (Theorems 3.7 and 3.8).

Significant oscillations in one or more of the circulating progeny of the HSC

are often characteristic of dynamic hematological diseases like cyclical neutropenia, cyclical thrombocytopenia, and periodic chronic myelogenous leukemia. The steady state of the HSC system can be destabilized by increasing the differentiation rate, and this has been implicated in the genesis of the hematological disorder cyclical neutropenia [21].

We have applied these results to examining the stability of HSC dynamics in the presence of stochastic perturbation. Our results indicate that stochastic perturbation cannot stabilize a large amplitude oscillation solution. When random perturbations are introduced in parameters characterizing the HSCs when the steady state is locally stable, we found that as the amplitude of the noise perturbation is increased, the system can be destabilized in the sense that the second moment becomes unbounded. In this situation, the system can display a large amplitude fluctuating solution.

When the second moment is large and bounded, however, we cannot exclude the possibility of an oscillatory solution, since the HSC system may have a large amplitude oscillatory solution in this circumstance.

We have obtained estimates of the second moment for three different types of perturbation (see Figure 4.4). These results suggest that small perturbations in the HSC differentiation or apoptosis (death) rate are able to generate large amplitude fluctuations in HSC numbers, but a much larger perturbation of the proliferation rate is needed to generate comparable fluctuations in HSC numbers. These results suggest that the HSC model system is more sensitive to random perturbations in the differentiation or death rate than in the proliferation rate.

The results in this paper were obtained under the Itô interpretation of stochastic integrals. Analogous results can be obtained for the Stratonovich interpretation. When Stratonovich interpretation is used, the solution of (1.8) can be expressed as

$$x(t) = x(0) + \int_0^t (\tilde{a}x(s) + \tilde{b}x_1(s) + \tilde{c})ds + \int_0^t (\sigma_0 x(s) + \sigma_1 x_1(s) + \sigma_2)dW(s), \tag{5.1}$$

in terms of the Itô integral, where

$$\tilde{a} = a + \frac{1}{2}\sigma_0^2, \quad \tilde{b} = b + \frac{1}{2}\sigma_0\sigma_1, \quad \tilde{c} = \frac{1}{2}\sigma_0\sigma_2. \tag{5.2}$$

Unlike the situation when the Itô interpretation is used, namely that the first moment stability is determined merely by the unperturbed system, the first moment stability is changed when we use a Stratonovich interpretation. Let

$$\tilde{h}(\lambda) = \lambda - \tilde{a} - \tilde{b}e^{-\lambda}, \qquad x_* = -\frac{\tilde{c}}{\tilde{a} + \tilde{b}},$$

so that we have the following theorem.

THEOREM 5.1. *If $\tilde{\alpha}_0 = \max\{\Re(\lambda) : \tilde{h}(\lambda) = 0\}$, then, for any $\alpha > \alpha_0$, there is a constant $\tilde{K} = \tilde{K}(\alpha)$ such that*

$$|Ex(t;\phi) - x_*| \le \tilde{K}\|\phi\|e^{\alpha t} \tag{5.3}$$

for any $\phi \in C([-1, 0], \mathbb{R})$.

When $\tilde{\alpha}_0 < 0$, Theorem 5.1 implies that $Ex(t;\phi)$ approaches x_* exponentially when $t \to +\infty$. Thus, the expectation of the solutions drifts from zero to x_* due to the stochastic perturbation. Note that $\tilde{a} \ge a$; it is easy to show that the stochastic perturbation is able to destabilize the first moment of (1.8). On the other hand, the

first moment cannot be stabilized by stochastic perturbation when the zero solution of the system without noise is unstable.

To study the second moment, let $y = x - x_*$, so that $y(t)$ satisfies

$$y(t) = y(0) + \int_0^t (\tilde{a}y(s) + \tilde{b}y_1(s))ds + \int_0^t (\sigma_0 y(s) + \sigma_1 y_1(s) + \tilde{\sigma}_2)dW(s), \tag{5.4}$$

where

$$\tilde{\sigma}_2 = \sigma_2 + (\sigma_0 + \sigma_1)x_*.$$

Applying the results in section 3 to the Itô equation (5.4), we can obtain the corresponding results for second moment stability of (1.8) in terms of the Stratonovich interpretation. The statement of these results is straightforward by replacing a, b, and σ_2 with $\tilde{a}$, $\tilde{b}$, and $\tilde{\sigma}_2$, respectively, and we omit them here.

SOME VECTOR BORNE DISEASES WITH STRUCTURED HOST POPULATIONS: EXTINCTION AND SPATIAL SPREAD*

STEPHEN A. GOURLEY†, RONGSONG LIU‡, AND JIANHONG WU§

Abstract. We derive from a structured population model a system of delay differential equations describing the interaction of five subpopulations, namely susceptible and infected adult and juvenile reservoirs and infected adult vectors, for a vector borne disease with particular reference to West Nile virus, and we also incorporate spatial movements by considering the analogue reaction-diffusion systems with nonlocal delayed terms. Specific conditions for the disease eradication and sharp conditions for the local stability of the disease-free equilibrium are obtained using comparison techniques coupled with the spectral theory of monotone linear semiflows. A formal calculation of the minimal wave speed for the traveling waves is given and compared with field observation data.

Key words. stage-structure, epidemic, delay, traveling front, vector borne disease

1. Introduction.

Vector borne diseases are infectious diseases that are carried by insects from one host to another. Examples include malaria, West Nile virus, yellow fever, dengue fever, lyme disease, and plague. In many of these diseases it is the mosquito that carries the virus, but ticks and fleas can also be responsible. The diseases can be spread to humans, birds, and other animals.

Much has been done in terms of modeling and analysis of the transmission dynamics and spatial spread of vector borne diseases; see Anderson and May [1], Murray [20], Brauer and Castillo-Chavez [4], Edelstein-Keshet [6], Hethcote [10], Kot [13], Jones and Sleeman [12], Wonham and coworkers [26, 27], etc. However, one important biological aspect of the hosts—the stage structure—seems to have received little attention, although structured population models have been intensively studied (see Diekmann and Heesterbeek [5]) in the context of population dynamics and spatial ecology, and the interaction of stage-structure with spatial dispersal has been receiving considerable attention in association with the theoretical development of the so-called reaction-diffusion equations with nonlocal delayed feedback (see the papers by Gourley, So, and Wu [7] and Gourley and Wu [8] and the references therein).

The developmental stages of hosts have a profound impact on the transmission dynamics of vector borne diseases. In the case of West Nile virus the transmission cycle involves both mosquitoes and birds, the crow species being particularly important. *Nestling* crows are crows that have hatched but are helpless and stay in the nest, receiving more-or-less continuous care from the mother for up to two weeks and less

continuous care thereafter. *Fledgling* crows are old enough to have left the nest (they leave it after about five weeks), but they cannot fly very well. After three or four months these fledglings will be old enough to obtain all of their food by themselves. As these facts demonstrate, the maturation stages of adult birds, fledglings, and nestlings are all very different from a biological and an epidemiological perspective, and a realistic model needs to take these different stages into account. For example, in comparison with grown birds, the nestlings and fledglings have much higher disease-induced death rate, much poorer ability to avoid being bitten by mosquitoes, and much less spatial mobility [18, 2, 22]. In this paper we shall, in fact, assume that there is only one preadult stage for the host population, which in the West Nile virus context could be thought of as the fledgling stage of crows.

The aim of this paper is to formulate a model for the evolution of some vector borne diseases whose transmission dynamics and patterns are similar to those of West Nile virus. Other recent mathematical models for this disease include the works of Bowman et al. [3], Lewis, Renclawowicz, and van den Driessche [16], and Wonham et al. [26, 27], some of which use a different incidence function normalized by bird density. We start with the classical McKendrick von-Foerster equations for an age-structured reservoir population divided into two epidemiological compartments of susceptible and infected (and infectious), coupled with a scalar delay differential equation for the adult vector population under the assumption that the total vector population is maintained at a constant level. We then use the standard technique of integration along characteristics to reduce the model to a system of five coupled delay differential equations for the susceptible and infected juvenile and adult reservoir populations and the adult infected vector. If spatial diffusion is allowed, a similar derivation leads to a reaction-diffusion system with nonlocal and highly nonlinear delayed interactions. The model derivation is carried out in detail in sections 2 (for ODE models) and 3 (for PDE models), together with some detailed biological and epidemiological explanations of all terms involved.

We consider the qualitative behaviors of the reduced ordinary delay differential system in subsections 2.1–2.4. We establish the positiveness and boundedness of the reduced system, and we emphasize the need to restrict the initial data to the subset which is biologically and epidemiologically realistic. We then establish a concrete criterion, expressed in terms of the model parameters, for disease eradication. This is achieved using some comparison techniques and differential inequalities. We also obtain a necessary and sufficient condition for the disease-free equilibrium to be locally asymptotically stable—this is done using an application of the spectral properties of a linear delay differential system due to Smith [23]. The sharpness of the disease eradication condition is then tested using the available data and parameters for West Nile virus, and our simulations show that sustained oscillation can occur, should this disease eradication condition be violated.

In section 3, consider the issue of spatial spread of the disease in a one-dimensional setting. We provide a detailed formal calculation of the so-called minimal wave speed that is expected to coincide with the propagation speed of the disease, and we compare the predicted wave speed with data in the literature relating to the observed speed of spread of West Nile virus across North America. Finally, in section 4, we discuss our findings together with some of the corresponding results for a modified model with a different incidence function.

2. Model derivation. We shall think of the disease as mosquito borne, since mosquitoes are responsible for transmitting many of the vector borne diseases that

currently constitute significant public health issues in various parts of the world.

We will also refer to the reservoir as the host, and assume that the host population is age-structured. We start with a simple division of the host population into susceptible hosts $s(t,a)$ and infected hosts $i(t,a)$ at time t and age a. These host populations are assumed to evolve according to the McKendrick von-Foerster equations for an age-structured population:

$$\frac{\partial s}{\partial t} + \frac{\partial s}{\partial a} = -d_s(a)s(t,a) - \beta(a)s(t,a)m_i(t) \tag{2.1}$$

and

$$\frac{\partial i}{\partial t} + \frac{\partial i}{\partial a} = -d_i(a)i(t,a) + \beta(a)s(t,a)m_i(t), \tag{2.2}$$

where $m_i(t)$ is the number of infected adult mosquitoes satisfying another equation below, and $\beta(a)$ is the age-dependent transmission coefficient, and it is assumed that conversion of hosts from susceptible to infected occurs through interaction of susceptible hosts with infected mosquitoes, and at this stage we assume that the rate of conversion is given by mass action. We shall discuss the limitations of the model involving mass action and shall indicate how our work can be extended to include a more standard incidence term that includes dividing by the density of the host population. The functions $d_s(a)$ and $d_i(a)$ are the age-dependent death rates of susceptible and infected hosts.

We shall further split the host population into juveniles and adults, defined respectively as those of age less than some number τ and those of age greater than τ. We will work with the following choices for the death rates and the transmission coefficient $\beta(a)$:

$$d_s(a) = \begin{cases} d_{sj}, & a < \tau, \\ d_{sa}, & a > \tau, \end{cases} \qquad d_i(a) = \begin{cases} d_{ij}, & a < \tau, \\ d_{ia}, & a > \tau, \end{cases} \tag{2.3}$$

and

$$\beta(a) = \begin{cases} \beta_j, & a < \tau, \\ \beta_a, & a > \tau. \end{cases} \tag{2.4}$$

The subscripts in these quantities refer to disease and juvenile/adult status; thus, for example, the per capita death rates for susceptible juveniles and infected adults would be d_{sj} and d_{ia}, respectively. The above choices enable us to formulate a closed system of delay differential equations involving only the total numbers of hosts classified as adult susceptibles, adult infected, juvenile susceptibles, and juvenile infected. These total numbers are given respectively, using self-explanatory notations, by

$$\begin{aligned} A_s(t) &= \int_\tau^\infty s(t,a)\,da, \qquad A_i(t) = \int_\tau^\infty i(t,a)\,da, \qquad J_s(t) = \int_0^\tau s(t,a)\,da, \\ &\qquad\qquad J_i(t) = \int_0^\tau i(t,a)\,da. \end{aligned} \tag{2.5}$$

We assume no vertical transmission in the system (both from host and vector). On the further assumption that the birth rate is a function of the total number of susceptible adult hosts, we have the following expressions for the birth rates $s(t,0)$ and $i(t,0)$:

$$s(t,0) = b(A_s(t)), \qquad i(t,0) = 0, \tag{2.6}$$

where $b(\cdot)$ is the birth rate function for hosts (we shall later introduce $B(\cdot)$ as the birth rate function for mosquitoes). Equations (2.1) and (2.2) are solved subject to (2.6).

Let us now find a differential equation for $A_s(t)$. Differentiating the expression for $A_s(t)$ in (2.5), making use of (2.1), (2.3), and (2.4), and assuming (reasonably) that $s(t,\infty)=0$, we quickly find that

$$\frac{dA_s}{dt} = s(t,\tau) - d_{sa}A_s(t) - \beta_a m_i(t)A_s(t). \tag{2.7}$$

Next we need to find $s(t,\tau)$. This will be achieved by solving (2.1) for $0<a<\tau$. Set

$$s_\xi(a) = s(\xi+a,a).$$

Then

$$\begin{aligned}\frac{ds_\xi}{da} &= \left[\frac{\partial s}{\partial t} + \frac{\partial s}{\partial a}\right]_{t=\xi+a}\\ &= -s_\xi(a)[d_s(a) + \beta(a)m_i(\xi+a)],\end{aligned}$$

so that

$$\begin{aligned}s(\xi+a,a) = s_\xi(a) &= s_\xi(0)\exp\left(-\int_0^a (d_s(\eta)+\beta(\eta)m_i(\xi+\eta))\,d\eta\right)\\ &= b(A_s(\xi))\exp\left(-\int_0^a (d_s(\eta)+\beta(\eta)m_i(\xi+\eta))\,d\eta\right).\end{aligned} \tag{2.8}$$

Setting $a=\tau$ and $\xi = t-\tau$ and using (2.3), (2.4) gives

$$s(t,\tau) = b(A_s(t-\tau))\exp\left(-\int_0^\tau (d_{sj}+\beta_j m_i(t-\tau+\eta))\,d\eta\right).$$

Substituting this into (2.7) gives, after a change of variables in the integral,

$$\frac{dA_s}{dt} = b(A_s(t-\tau))\exp\left(-\int_{t-\tau}^t (d_{sj}+\beta_j m_i(u))\,du\right) - d_{sa}A_s(t) - \beta_a m_i(t)A_s(t). \tag{2.9}$$

In much the same way, we obtain the following equation for $J_s(t)$:

$$\begin{aligned}\frac{dJ_s}{dt} &= b(A_s(t)) - b(A_s(t-\tau))\exp\left(-\int_{t-\tau}^t (d_{sj}+\beta_j m_i(u))\,du\right)\\ &\quad - d_{sj}J_s(t) - \beta_j m_i(t)J_s(t).\end{aligned} \tag{2.10}$$

The differential equation for $A_i(t)$ turns out to be more complicated. Differentiating the expression for $A_i(t)$ in (2.5), assuming $i(t,\infty)=0$, and using (2.3) and (2.4) gives

$$\frac{dA_i(t)}{dt} = i(t,\tau) - d_{ia}A_i(t) + \beta_a m_i(t)A_s(t), \tag{2.11}$$

and we need to find $i(t,\tau)$, by solving (2.2) for $0<a<\tau$. Setting $i_\xi(a) = i(\xi+a,a)$ and differentiating with respect to a, we find from (2.2) that

$$\frac{di_\xi(a)}{da} + d_{ij}i_\xi(a) = \beta_j m_i(\xi+a)s(\xi+a,a).$$

Integrating this from 0 to a and recalling that $i_\xi(0) = i(\xi, 0) = 0$ by (2.6), we find that

$$i(\xi + a, a) = i_\xi(a) = \beta_j \int_0^a e^{-d_{ij}(a-\eta)} m_i(\xi + \eta) s(\xi + \eta, \eta)\, d\eta.$$

Therefore,

$$\begin{aligned} i(t, \tau) &= \beta_j \int_0^\tau e^{-d_{ij}(\tau-\eta)} m_i(t - \tau + \eta) s(t - \tau + \eta, \eta)\, d\eta \\ &= \beta_j \int_{t-\tau}^t e^{-d_{ij}(t-\xi)} m_i(\xi) s(\xi, \xi + \tau - t)\, d\xi. \end{aligned} \tag{2.12}$$

In this integral the second argument of $s(\xi, \xi + \tau - t)$ goes from 0 to τ, and therefore an expression for $s(\xi, \xi + \tau - t)$ can be obtained from the earlier analysis. From (2.8),

$$s(\xi, \xi + \tau - t) = b(A_s(t - \tau)) \exp\left(- \int_{t-\tau}^\xi [d_{sj} + \beta_j m_i(v)]\, dv \right).$$

Insertion of this expression into (2.12) yields an expression for $i(t, \tau)$ that involves only the state variables in (2.5) and $m_i(t)$, and insertion of this expression for $i(t, \tau)$ into (2.11) finally gives the differential equation for $A_i(t)$ to be

$$\begin{aligned} \frac{dA_i(t)}{dt} &= -d_{ia} A_i(t) + \beta_a m_i(t) A_s(t) \\ &\quad + \beta_j b(A_s(t - \tau)) \int_{t-\tau}^t m_i(\xi) e^{-d_{ij}(t-\xi)} \exp\left(- \int_{t-\tau}^\xi (d_{sj} + \beta_j m_i(v))\, dv \right) d\xi. \end{aligned} \tag{2.13}$$

Similarly, the differential equation for $J_i(t)$ can be shown to be

$$\begin{aligned} \frac{dJ_i(t)}{dt} &= -d_{ij} J_i(t) + \beta_j m_i(t) J_s(t) \\ &\quad - \beta_j b(A_s(t - \tau)) \int_{t-\tau}^t m_i(\xi) e^{-d_{ij}(t-\xi)} \exp\left(- \int_{t-\tau}^\xi (d_{sj} + \beta_j m_i(v))\, dv \right) d\xi. \end{aligned} \tag{2.14}$$

To close the system we still need a differential equation for the variable $m_i(t)$, but first we would like to discuss the ecological interpretation of the complicated integral term appearing in (2.13) and (2.14). The first two terms in the right-hand side of (2.13) are easy to interpret. They are, respectively, the death rate of infected adults and conversion of susceptible adults to infected adults via contact with infected mosquitoes. The last term in (2.13) tells us the rate at which infected immatures become infected adults having contracted the disease in childhood. This term is the rate at which infected individuals pass through age τ. Now, an individual that is of age τ at time t will have been born at time $t - \tau$. Recall, however, that all individuals are born as susceptibles. This is why the birth rate $b(A_s(t-\tau))$ is involved. The individuals we are presently discussing have each acquired the infection at some stage during childhood, so assume that a particular individual acquires it at a time $\xi \in (t - \tau, t)$. This particular individual remained susceptible from its birth at time $t - \tau$ until time ξ, and the probability of this happening is

$$\exp\left(- \int_{t-\tau}^\xi (d_{sj} + \beta_j m_i(v))\, dv \right).$$

The probability that the individual will survive from becoming infected at time ξ until becoming an adult at time t is

$$e^{-d_{ij}(t-\xi)}.$$

These two exponentials both feature in the last term in (2.13). The product $\beta_j m_i(\xi)$ is the per capita conversion rate of susceptible juveniles to infected juveniles at time ξ, and ξ running from $t-\tau$ to t totals up the contributions from all possible times at which infected individuals passing into adulthood might have acquired the infection.

Finally, we need differential equations for the mosquitoes. Let $m_T(t)$ be the total number of (adult) mosquitoes, divided into infected mosquitoes $m_i(t)$ and susceptible mosquitoes $m_T(t) - m_i(t)$. Death and reproductive activity for mosquitoes are assumed not to depend on whether they are carrying the disease or not, and so the total number of adult mosquitoes is assumed to obey

$$\frac{dm_T(t)}{dt} = e^{-d_l\sigma}B(m_T(t-\sigma)) - d_m m_T(t), \tag{2.15}$$

where d_l and d_m denote the death rates of larval and adult mosquitoes, respectively, and σ is the length of the larval phase from egg to adult. The function $B(\cdot)$ is the birth rate function for mosquitoes. It is possible but unnecessary to write down a differential equation for larval mosquitoes. Infected adult mosquitoes $m_i(t)$ are assumed to obey

$$\frac{dm_i(t)}{dt} = -d_m m_i(t) + \beta_m(m_T(t) - m_i(t))(J_i(t) + \alpha A_i(t)). \tag{2.16}$$

Thus, the rate at which mosquitoes become infected is given by mass action as the product of susceptible mosquitoes $m_T(t) - m_i(t)$ and infected birds which may be either juvenile or adult. The presence of the factor α is to account for the possibility that juvenile and adult birds might not be equally vulnerable to being bitten. Again, we defer the discussion of a more standard incidence term to the final section.

Certain assumptions will be made concerning the birth function $B(\cdot)$ for the mosquitoes. These assumptions, which are ecologically reasonable, are geared towards ensuring that the total number $m_T(t)$ of mosquitoes stabilizes and does not tend to zero (otherwise the disease is automatically eradicated and the model is not interesting). These assumptions are

$$\left.\begin{array}{l} B(0) = 0,\ B(\cdot) \text{ is strictly monotonically increasing, there exists } m_T^* > 0 \\ \text{such that } e^{-d_l\sigma}B(m) > d_m m \text{ when } m < m_T^* \text{ and } e^{-d_l\sigma}B(m) < d_m m \text{ when} \\ m > m_T^*. \end{array}\right\} \tag{2.17}$$

The quantity $m_T^* > 0$ in (2.17) is an equilibrium of (2.15), and $m_T(t) \to m_T^*$ as $t \to \infty$, provided $m_T(\theta) \geq 0$ and $m_T(\theta) \not\equiv 0$ on $\theta \in [-\sigma, 0]$ (see Kuang [14]). Accordingly, (2.16) is asymptotically autonomous, and we may replace $m_T(t)$ by m_T^* in (2.16), thereby lowering the order of the system to be studied, which we now note consists of (2.9), (2.10), (2.13), and (2.14) together with

$$\frac{dm_i(t)}{dt} = -d_m m_i(t) + \beta_m(m_T^* - m_i(t))(J_i(t) + \alpha A_i(t)), \tag{2.18}$$

which is the asymptotically autonomous limiting form of (2.16). Note that this system does not explicitly involve the delay σ, but this delay is still involved via the quantity m_T^*.

2.1. Positivity of solutions. We will prove that the system consisting of (2.9), (2.10), (2.13), (2.14), and (2.18) has a positivity preserving property. It is easy to appreciate that this system cannot have a positivity preserving property for completely arbitrary nonnegative initial data (a glance at the terms in the right-hand side of (2.14) makes this clear). However, positivity preservation does hold when some components of the initial data satisfy certain relations. These relations are easily seen to be the only ones that make sense ecologically and therefore are easily admitted. We therefore now append to the above-mentioned system the following initial data:

$$
\begin{aligned}
&A_s(\theta) = A_s^0(\theta) \geq 0, \qquad \theta \in [-\tau, 0],\\
&m_i(\theta) = m_i^0(\theta) \in [0, m_T^*], \qquad \theta \in [-\tau, 0],\\
&A_i(0) = A_i^0(0) \geq 0,\\
&J_s(0) = \int_{-\tau}^{0} b(A_s^0(\xi)) \exp\left(- \int_{\xi}^{0} [d_{sj} + \beta_j m_i^0(u)]\, du \right) d\xi,\\
&J_i(0) = \int_{-\tau}^{0} b(A_s^0(\xi)) \left\{ \int_{\xi}^{0} \beta_j m_i^0(\eta) e^{d_{ij}\eta} e^{-\int_{\xi}^{\eta} [d_{sj} + \beta_j m_i^0(v)]\, dv} d\eta \right\} d\xi,
\end{aligned}
\tag{2.19}
$$

where $A_s^0(\theta)$ and $m_i^0(\theta)$ are prescribed continuous functions of the variable $\theta \in [-\tau, 0]$, and $A_i^0(0)$ is also a given value. Note that $J_s(0)$ and $J_i(0)$ have to be calculated from the initial data for A_s and m_i. This is ecologically reasonable; after all, $J_s(0)$ is the number of juvenile susceptibles at time $t = 0$. The integral on the right in the expression for $J_s(0)$ is simply accounting for all these juvenile susceptibles at $t = 0$. Each one was born at some time $\xi \in [-\tau, 0]$—hence the presence of the birth rate $b(A_s^0(\xi))$—and each has to have survived and remained susceptible until time 0, hence the exponential term which represents the probability of this actually happening. The interpretation of the expression for $J_i(0)$ is similar but more complicated. Of the infected juveniles $J_i(0)$ at time 0, each one was born at some time $\xi \in [-\tau, 0]$ as a susceptible, and each of these newborns at time ξ then became infected at some subsequent time $\eta \in [\xi, 0]$.

We will now prove the following positivity preservation result.

PROPOSITION 2.1. *Let* (2.17) *hold. Then each component of the solution of the system consisting of* (2.9), (2.10), (2.13), (2.14), *and* (2.18) *for* $t > 0$, *subject to the initial conditions* (2.19), *remains nonnegative for all* $t > 0$. *Also,* $m_i(t) \leq m_T^*$ *for all* $t > 0$. *If, furthermore, the function* b *is bounded, then each component of the above solution is also bounded for all* $t > 0$.

Proof. First we will show that $m_i(t) \leq m_T^*$ for all $t > 0$. Suppose the contrary; then there must exist a time t_1 such that $m_i(t_1) = m_T^*$ and $dm_i(t_1)/dt \geq 0$. Evaluating (2.18) at time t_1 immediately gives a contradiction.

Next we prove nonnegativity of $A_s(t)$, for $t \in (0, \tau]$ in the first instance. On this interval,

$$
\frac{dA_s(t)}{dt} \geq -d_{sa} A_s(t) - \beta_a m_i(t) A_s(t).
$$

By comparison, $A_s(t)$ is bounded below by the solution of the corresponding differential equation obtained by replacing $\geq$ by $=$, and this differential equation contains a factor of $A_s(t)$ in its right-hand side. Since $A_s(0) \geq 0$, it follows that $A_s(t) \geq 0$ for all $t \in (0, \tau]$. This argument can be continued using the method of steps, and we conclude that $A_s(t) \geq 0$ for all $t > 0$.

Nonnegativity of $J_s(t)$ will be shown next. This can be seen by noting that the solution of (2.10), subject to the initial value for $J_s(0)$ given in (2.19), is

$$J_s(t) = \int_{t-\tau}^{t} b(A_s(\xi)) \exp\left(-\int_{\xi}^{t} [d_{sj} + \beta_j m_i(u)]\, du\right) d\xi, \tag{2.20}$$

which is nonnegative because A_s is nonnegative.

We still have to prove the nonnegativity of $A_i(t)$, $J_i(t)$, and $m_i(t)$. It will be helpful to note that the solution of (2.14), subject to the initial value for $J_i(0)$ given in (2.19), is

$$J_i(t) = \int_{t-\tau}^{t} b(A_s(\xi)) \left\{ \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-\int_{\xi}^{\eta} [d_{sj} + \beta_j m_i(v)]\, dv} d\eta \right\} d\xi, \tag{2.21}$$

which is nonnegative if $m_i(t)$ is nonnegative. Therefore, it suffices to prove nonnegativity of $A_i(t)$ and $m_i(t)$. These two functions can be viewed as the solution $(A_i(t), m_i(t))$ of the system of differential equations consisting of (2.13) and

$$\begin{aligned} \frac{dm_i(t)}{dt} &= -d_m m_i(t) + \beta_m (m_T^* - m_i(t)) \\ &\times \left(\int_{t-\tau}^{t} b(A_s(\xi)) \left\{ \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-\int_{\xi}^{\eta} [d_{sj} + \beta_j m_i(v)]\, dv} d\eta \right\} d\xi + \alpha A_i(t) \right) \end{aligned} \tag{2.22}$$

for $t > 0$, with initial data taken from (2.19), but with $A_s(t)$ thought of simply as some prescribed nonnegative function. Recalling that $m_i(t) \le m_T^*$, we now note that, even though this system does not satisfy a quasi monotonicity condition, Theorem 2.1 of Smith [23, p. 81] is applicable and gives us the nonnegativity of $A_i(t)$ and $m_i(t)$ immediately. The proof of the nonnegativity of each component of the solution is then complete.

The boundedness of $A_s(t)$ is simple since, by (2.9),

$$\frac{d}{dt} A_s(t) \le b_{\sup} - d_{sa} A_s(t) - \beta_a m_i(t) A_s(t),$$

where $b_{\sup} = \sup_{A \ge 0} b(A) < \infty$. The boundedness of $A_i(t)$ follows from (2.13) and the boundedness of $m_i(t)$. The boundedness of $J_s(t)$ and $J_i(t)$ follows from (2.20) and (2.21) directly. This completes the proof.

2.2. Global convergence to disease-free state. In this section we shall prove a theorem giving sufficient conditions for the system to evolve to the disease-free state (i.e., conditions that ensure A_i, J_i, and m_i go to zero as $t \to \infty$). Since the differential equations (2.10) and (2.14) can be solved to give (2.20) and (2.21), respectively, it is sufficient to study the system consisting of (2.9), (2.13), and (2.22), with initial data taken from (2.19). These equations form a closed system for $A_s(t)$, $A_i(t)$, and $m_i(t)$. Our aim will be to establish, using these three equations, a differential inequality for the variable $m_i(t)$ only, and to use this to find conditions which ensure that $m_i(t) \to 0$ as $t \to \infty$. Note that if $m_i(t) \to 0$, then from (2.21) it follows immediately that $J_i(t) \to 0$ and, furthermore, (2.13) then becomes an asymptotically autonomous ODE, from which it is easily seen that $A_i(t)$ tends to zero.

We will make certain assumptions concerning the birth rate function $b(\cdot)$ for hosts. These assumptions are

$$\left.\begin{array}{l} b(0)=0,\ b(A)>0 \text{ when } A>0,\ b_{\sup}:=\sup_{A\geq 0} b(A)<\infty, \text{ there exists} \\ A_s^*>0 \text{ such that } e^{-d_{sj}\tau}b(A)>d_{sa}A \text{ when } A<A_s^* \text{ and } e^{-d_{sj}\tau}b(A)< \\ d_{sa}A \text{ when } A>A_s^*. \end{array}\right\} \tag{2.23}$$

These assumptions are not the same as those for the birth rate function $B(\cdot)$ for mosquitoes (assumptions (2.17)); note in particular that we do not require $b(\cdot)$ to be monotone.

The reader will realize that the quantity A_s^* in (2.23) is, in fact, a nonzero equilibrium value for $A_s(t)$ in the case when the disease is absent. Assumptions (2.23) are geared towards ensuring that the population $A_s(t)$ of adult susceptible hosts does not go to zero even without the disease; otherwise the model is not interesting. This is important because if $e^{-d_{sj}\tau}b(A)<d_{sa}A$ for all $A>0$ (which means that, in the absence of the disease, adult recruitment of susceptible hosts is insufficient to offset natural death of adult susceptible hosts), then it is natural to expect that $A_s(t)\to 0$ even without the disease, and this can be mathematically shown to be the case, using (2.9).

We will prove the following theorem. Assumption (2.17) is needed to ensure the existence of m_T^*. We shall need the functions a_1 and a_0 defined by

$$\begin{aligned} a_1(\epsilon) &= d_m d_{ia}+d_m d_{ij}+d_{ia}d_{ij} \\ &\quad -\frac{\beta_m m_T^* b_{\sup}\beta_j}{d_{sj}}-\beta_m m_T^*\alpha\beta_a\left(\frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}}+\epsilon\right) \\ &\quad -e^{-d_{sj}\tau}\left(\frac{1-e^{-\tau(d_{ij}-d_m-d_{sj})}}{d_{ij}-d_m-d_{sj}}\right)\beta_m m_T^*\alpha\beta_j b_{\sup} \end{aligned} \tag{2.24}$$

and

$$\begin{aligned} a_0(\epsilon) &= d_m d_{ia}d_{ij}-\frac{d_{ia}\beta_m m_T^* b_{\sup}\beta_j}{d_{sj}}-d_{ij}\beta_m m_T^*\alpha\beta_a\left(\frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}}+\epsilon\right) \\ &\quad -d_{ij}e^{-d_{sj}\tau}\left(\frac{1-e^{-\tau(d_{ij}-d_m-d_{sj})}}{d_{ij}-d_m-d_{sj}}\right)\beta_m m_T^*\alpha\beta_j b_{\sup}. \end{aligned} \tag{2.25}$$

THEOREM 2.2. *Let* (2.17) *and* (2.23) *hold, and let* $A_s(t)$, $A_i(t)$, *and* $m_i(t)$ *satisfy* (2.9), (2.13), *and* (2.22), *with initial data taken from* (2.19). *Assume further that*

$$a_1(0)>0, \quad a_0(0)>0, \quad \textit{and} \quad (d_m+d_{ia}+d_{ij})a_1(0)>a_0(0), \tag{2.26}$$

where the functions a_1, a_0 *are defined by* (2.24) *and* (2.25). *Then* $(A_i(t),m_i(t))\to(0,0)$ *as* $t\to\infty$.

Remark. It is not hard to check that (2.26) can be satisfied for some parameter values. It is satisfied, for example, when the contact rates β_a, β_j, and β_m are sufficiently small, or when the mosquito capacity m_T^* is sufficiently small. These are situations in which we intuitively expect the theorem to hold. As such, an obvious control measure for achieving disease eradication is to reduce the mosquito capacity. Reducing β_m is an alternative approach.

Proof of Theorem 2.2. For the reasons explained above, we may concentrate on showing that $m_i(t)\to 0$ as $t\to\infty$. From positivity of solutions, we find from (2.9)

that

$$\begin{aligned}\frac{dA_s}{dt} &\le b(A_s(t-\tau))e^{-d_{sj}\tau} - d_{sa}A_s(t)\\ &\le b_{\sup}e^{-d_{sj}\tau} - d_{sa}A_s(t).\end{aligned}$$

Hence

$$\limsup_{t\to\infty} A_s(t) \le \frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}}.$$

By hypothesis (2.26) and by a continuity argument we may choose $\epsilon > 0$ sufficiently small that

$$a_1(\epsilon) > 0, \quad a_0(\epsilon) > 0, \quad \text{and} \quad (d_m + d_{ia} + d_{ij})a_1(\epsilon) > a_0(\epsilon). \tag{2.27}$$

There exists $T_1 > 0$ such that, for $t \ge T_1$,

$$A_s(t) \le \frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}} + \epsilon.$$

Using this estimate in (2.13), we find that, for $t \ge T_1$,

$$\begin{aligned}\frac{dA_i(t)}{dt} &\le -d_{ia}A_i(t) + \beta_a m_i(t)\left(\frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}} + \epsilon\right)\\ &+ \beta_j b_{\sup}\int_{t-\tau}^{t} m_i(\xi)e^{-d_{ij}(t-\xi)}\exp\left(-\int_{t-\tau}^{\xi}(d_{sj} + \beta_j m_i(v))\,dv\right)d\xi.\end{aligned} \tag{2.28}$$

Solving this differential inequality and ignoring a transient term involving $A_i(0)$, we find that

$$\begin{aligned}A_i(t) &\le \beta_a\left(\frac{b_{\sup}e^{-d_{sj}\tau}}{d_{sa}} + \epsilon\right)\int_0^t e^{-d_{ia}(t-\psi)}m_i(\psi)\,d\psi\\ &+ \beta_j b_{\sup}\int_0^t e^{-d_{ia}(t-\psi)}\int_{\psi-\tau}^{\psi} m_i(\xi)e^{-d_{ij}(\psi-\xi)}\exp\left(-\int_{\psi-\tau}^{\xi}(d_{sj} + \beta_j m_i(v))\,dv\right)d\xi\,d\psi.\end{aligned} \tag{2.29}$$

We shall use this estimate for $A_i(t)$ to obtain a differential inequality for $m_i(t)$ as follows. From (2.22), and using positivity of $m_i(t)$ and the bound on $b(\cdot)$,

$$\begin{aligned}\frac{dm_i(t)}{dt} &\le -d_m m_i(t) + \beta_m m_T^*\\ &\times\left(b_{\sup}\int_{t-\tau}^{t}\int_{\xi}^{t}\beta_j m_i(\eta)e^{-d_{ij}(t-\eta)}e^{-\int_{\xi}^{\eta}[d_{sj}+\beta_j m_i(v)]\,dv}d\eta\,d\xi + \alpha A_i(t)\right),\end{aligned}$$

so that, from (2.29),

$$\begin{aligned}
\frac{dm_i(t)}{dt} &\le -d_m m_i(t) \\
&+ \beta_m m_T^* b_{\sup} \int_{t-\tau}^{t} \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-\int_{\xi}^{\eta} [d_{sj}+\beta_j m_i(v)]\, dv} d\eta\, d\xi \\
&+ \beta_m m_T^* \alpha \beta_a \left(\frac{b_{\sup} e^{-d_{sj}\tau}}{d_{sa}} + \epsilon \right) \int_0^t e^{-d_{ia}(t-\psi)} m_i(\psi)\, d\psi \\
&+ \beta_m m_T^* \alpha \beta_j b_{\sup} \int_0^t e^{-d_{ia}(t-\psi)} \int_{\psi-\tau}^{\psi} m_i(\xi) e^{-d_{ij}(\psi-\xi)} \\
&\qquad \times \exp\left(- \int_{\psi-\tau}^{\xi} (d_{sj} + \beta_j m_i(v))\, dv \right) d\xi\, d\psi.
\end{aligned}$$

From this it is easy to see, using the positivity of $m_i(t)$, that $m_i(t)$ also obeys the following simpler linear differential inequality:

$$\begin{aligned}
\frac{dm_i(t)}{dt} &\le -d_m m_i(t) \\
&+ \beta_m m_T^* b_{\sup} \int_{t-\tau}^{t} \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-d_{sj}(\eta-\xi)} d\eta\, d\xi \\
&+ \beta_m m_T^* \alpha \beta_a \left(\frac{b_{\sup} e^{-d_{sj}\tau}}{d_{sa}} + \epsilon \right) \int_0^t e^{-d_{ia}(t-\psi)} m_i(\psi)\, d\psi \\
&+ \beta_m m_T^* \alpha \beta_j b_{\sup} \int_0^t e^{-d_{ia}(t-\psi)} \int_{\psi-\tau}^{\psi} m_i(\xi) e^{-d_{ij}(\psi-\xi)} e^{-d_{sj}(\xi-\psi+\tau)} d\xi\, d\psi.
\end{aligned} \tag{2.30}$$

To make progress we need to estimate some of these integrals. If we change the order of integration in the first double integral of (2.30), we reach the following estimate:

$$\begin{aligned}
&\int_{t-\tau}^{t} \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-d_{sj}(\eta-\xi)} d\eta\, d\xi \\
&= \int_{t-\tau}^{t} \int_{t-\tau}^{\eta} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-d_{sj}(\eta-\xi)} d\xi\, d\eta \\
&\le \frac{\beta_j}{d_{sj}} \int_{t-\tau}^{t} m_i(\eta) e^{-d_{ij}(t-\eta)} d\eta \\
&\le \frac{\beta_j}{d_{sj}} \int_{0}^{t} m_i(\eta) e^{-d_{ij}(t-\eta)} d\eta,
\end{aligned} \tag{2.31}$$

assuming $t > \tau$.

From (2.18) and Proposition 2.1 we have

$$\frac{dm_i(t)}{dt} \ge -d_m m_i(t).$$

Integrating from ξ to ψ gives

$$m_i(\xi) \le m_i(\psi) e^{d_m(\psi-\xi)}, \qquad \xi \le \psi.$$

Using this and (2.31), we obtain

$$\begin{aligned}\frac{dm_i(t)}{dt} &\le -d_m m_i(t) + \frac{\beta_m m_T^* b_{\sup}\beta_j}{d_{sj}} \int_0^t m_i(\eta) e^{-d_{ij}(t-\eta)}\, d\eta \\ &+ \beta_m m_T^* \alpha\beta_a \left(\frac{b_{\sup} e^{-d_{sj}\tau}}{d_{sa}} + \epsilon\right) \int_0^t e^{-d_{ia}(t-\psi)} m_i(\psi)\, d\psi \\ &+ \beta_m m_T^* \alpha\beta_j b_{\sup} e^{-d_{sj}\tau} \left(\frac{1 - e^{-\tau(d_{ij}-d_m-d_{sj})}}{d_{ij}-d_m-d_{sj}}\right) \int_0^t e^{-d_{ia}(t-\psi)} m_i(\psi)\, d\psi.\end{aligned} \tag{2.32}$$

By the theory of monotone systems [23], $m_i(t) \le M_i(t)$, where $M_i(t)$ is the solution of the differential equation obtained from (2.32) by replacing $\le$ by $=$, subject to the same initial data as that for m_i. Applying to this differential equation the Laplace transform, letting p be the transform variable and $\bar{M}_i(p)$ denote the Laplace transform of $M_i(t)$, we find after some algebra that

$$\bar{M}_i(p)\,\Lambda(p) = m_i(0)(p + d_{ia})(p + d_{ij}), \tag{2.33}$$

where

$$\Lambda(p) = p^3 + (d_m + d_{ia} + d_{ij})p^2 + a_1(\epsilon)p + a_0(\epsilon) \tag{2.34}$$

with $a_1(\epsilon)$ and $a_0(\epsilon)$ given by (2.24) and (2.25). Recall that the small number $\epsilon > 0$ has been chosen such that (2.27) holds. This fact, together with the Routh Hurwitz criteria, implies that all the roots of the cubic equation $\Lambda(p) = 0$ satisfy $\operatorname{Re} p < 0$, and so the same is true of all singularities of $\bar{M}_i(p)$. By the inversion formula for Laplace transforms, $M_i(t) \to 0$ as $t \to \infty$. Since $0 \le m_i(t) \le M_i(t)$, $m_i(t) \to 0$ as $t \to \infty$. By (2.13), $A_i(t) \to 0$ as $t \to \infty$. The proof of Theorem 2.2 is complete.

2.3. Local stability of disease-free equilibrium. If (2.23) holds, then the model (2.9), (2.10), (2.13), (2.14), and (2.18) has a disease-free equilibrium (DFE), obtained by substituting $J_i = 0$, $A_i = 0$, and $m_i = 0$ into the right-hand sides of those equations and setting them to zero, given by

$$E_0 = (A_s^*, J_s^*, 0, 0, 0), \tag{2.35}$$

where $A_s^* > 0$ and $J_s^* > 0$ are given by

$$\begin{cases} b(A_s^*)e^{-d_{sj}\tau} - d_{sa}A_s^* = 0, \\ J_s^* = \dfrac{b(A_s^*)}{d_{sj}}(1 - e^{-d_{sj}\tau}). \end{cases} \tag{2.36}$$

The previous section of this paper presented sufficient conditions for disease eradication (Theorem 2.2). In this section we investigate the linear stability of the DFE E_0 to gain further insight, and we shall present a condition (namely, condition (2.38) below) which is both necessary and sufficient for E_0 to be linearly stable. Though we do not establish disease eradication *globally* under this particular condition, it is clearly the weakest possible condition for disease eradication.

We first require the following simple preliminary result, which provides a condition for the linear stability of the DFE E_0 to perturbations in which the disease remains absent.

LEMMA 2.3. *Let* (2.23) *hold. Then* (A_s^*, J_s^*)*, given by* (2.36)*, is a locally asymptotically stable equilibrium of the subsystem*

$$\begin{cases} \dfrac{d\bar{J}_s(t)}{dt} = b(\bar{A}_s(t)) - b(\bar{A}_s(t-\tau))e^{-d_{sj}\tau} - d_{sj}\bar{J}_s(t), \\ \dfrac{d\bar{A}_s(t)}{dt} = b(\bar{A}_s(t-\tau))e^{-d_{sj}\tau} - d_{sa}\bar{A}_s(t) \end{cases} \tag{2.37}$$

if $d_{sa} > |b'(A_s^*)|e^{-d_{sj}\tau}$.

Proof. Obviously, (A_s^*, J_s^*) is an equilibrium of system (2.37). The linearization of (2.37) at this equilibrium has solutions of the form $\exp(\lambda t)$ whenever λ satisfies

$$\begin{vmatrix} -\lambda - d_{sj} & b'(A_s^*)(1 - e^{-(\lambda+d_{sj})\tau}) \\ 0 & -\lambda - d_{sa} + b'(A_s^*)e^{-(\lambda+d_{sj})\tau} \end{vmatrix} = 0.$$

Therefore, (A_s^*, J_s^*) is a locally stable solution of (2.37) if and only if all the roots λ of $-\lambda - d_{sa} + b'(A_s^*)e^{-(\lambda+d_{sj})\tau} = 0$ have negative real part. It is straightforward to show that this is the case if $d_{sa} > |b'(A_s^*)|e^{-d_{sj}\tau}$. The proof is complete.

Our main result of this section is the following theorem, which gives a necessary and sufficient condition for the linear stability of the disease-free state.

THEOREM 2.4. *Let* (2.17) *and the hypotheses of Lemma* 2.3 *hold, and assume additionally that*

$$\begin{aligned} d_m > \beta_m m_T^* \Bigg\{ & \frac{b(A_s^*)\beta_j}{d_{ij} - d_{sj}} \left[\frac{1 - e^{-d_{sj}\tau}}{d_{sj}} - \frac{(1 - e^{-d_{ij}\tau})}{d_{ij}} \right] \\ & + \frac{\alpha}{d_{ia}} \left[\beta_a A_s^* + \beta_j b(A_s^*) e^{-d_{sj}\tau} \frac{(1 - e^{-(d_{ij}-d_{sj})\tau})}{d_{ij} - d_{sj}} \right] \Bigg\}. \end{aligned} \tag{2.38}$$

Then the disease-free equilibrium E_0 *given by* (2.35) *is linearly asymptotically stable as a solution of the full model* (2.9), (2.10), (2.13), (2.14), (2.18).

Remark. The hypotheses of Theorem 2.4 are the weakest possible hypotheses that can guarantee the stated result. Recall from earlier remarks that if (2.17) or (2.23) is violated, then the mosquito or host population is doomed, irrespective of the disease. If the two sides of (2.38) are equal, then zero is an eigenvalue of the characteristic equation of the linearization about E_0 ((2.40) below), signaling the bifurcation of an endemic equilibrium. As will be shown numerically at the end of this section, a Hopf bifurcation of periodic solutions may further bifurcate from this endemic equilibrium. It remains a challenging problem to determine whether the hypotheses of Theorem 2.4 are sufficient to guarantee the global stability of E_0.

Proof. We aim for a linear equation in m_i only. Making use of the expression (2.21) for $J_i(t)$, solving for $A_i(t)$ the differential equation (2.13) on the interval $(-\infty, t)$, and then linearizing about $m_i = 0$, we obtain

$$\begin{aligned} \frac{dm_i(t)}{dt} &= -d_m m_i(t) \\ &+ \beta_m m_T^* b(A_s^*) \int_{t-\tau}^{t} \int_{\xi}^{t} \beta_j m_i(\eta) e^{-d_{ij}(t-\eta)} e^{-d_{sj}(\eta-\xi)} d\eta \, d\xi \\ &+ \beta_m m_T^* \alpha \beta_a A_s^* \int_{-\infty}^{t} e^{-d_{ia}(t-\psi)} m_i(\psi) \, d\psi \\ &+ \beta_m m_T^* \alpha \beta_j b(A_s^*) \int_{-\infty}^{t} e^{-d_{ia}(t-\psi)} \int_{\psi-\tau}^{\psi} m_i(\xi) e^{-d_{ij}(\psi-\xi)} e^{-d_{sj}(\xi-\psi+\tau)} d\xi \, d\psi. \end{aligned} \tag{2.39}$$

Solutions of the form $m_i(t) = e^{\lambda t}$ exist whenever λ satisfies

$$\lambda + d_m = \beta_m m_T^* \left\{ \frac{b(A_s^*)\beta_j}{\lambda + d_{ij} - d_{sj}} \left[\frac{1 - e^{-d_{sj}\tau}}{d_{sj}} - \frac{(1 - e^{-(\lambda + d_{ij})\tau})}{\lambda + d_{ij}} \right] + \frac{\alpha}{\lambda + d_{ia}} \left[\beta_a A_s^* + \beta_j b(A_s^*) e^{-d_{sj}\tau} \frac{(1 - e^{-(\lambda + d_{ij} - d_{sj})\tau})}{\lambda + d_{ij} - d_{sj}} \right] \right\}. \tag{2.40}$$

The structure of the linear equation (2.39) is such that the linear stability of its zero solution can be determined by considering only the real roots of the characteristic equation (2.40). This follows from Theorem 5.1 of Smith [23, p. 92] and Theorem 3.2 of Wu [28]. Our aim is therefore to show that, under condition (2.38), equation (2.40) does not have any nonnegative real roots. From simple graphical arguments, we see that it is sufficient to show that the right-hand side of (2.40) is monotonically decreasing as a function of $\lambda \in \mathbf{R}$ for $\lambda \geq 0$.

Let $F(\lambda)$ denote the right-hand side of (2.40), excluding the $\beta_m m_T^*$ factor. It is sufficient to show that $F'(\lambda) < 0$ for all $\lambda \geq 0$. Now

$$\begin{aligned} F(\lambda) &= \frac{\tau b(A_s^*)\beta_j}{\lambda + d_{ij} - d_{sj}} \left[f(d_{sj}\tau) - f((\lambda + d_{ij})\tau) \right] \\ &\quad + \frac{\alpha}{\lambda + d_{ia}} \left[\beta_a A_s^* + \tau \beta_j b(A_s^*) e^{-d_{sj}\tau} f((\lambda + d_{ij} - d_{sj})\tau) \right] \\ &=: F_1(\lambda) + \alpha F_2(\lambda), \end{aligned} \tag{2.41}$$

in which the function f is defined by

$$f(x) = \frac{1 - e^{-x}}{x}.$$

It is reasonably straightforward to see that f satisfies

$$f(x) > 0, \qquad f'(x) < 0, \qquad f''(x) > 0 \qquad \text{for all } x \in \mathbf{R}. \tag{2.42}$$

Indeed, (2.42) follows from the following inequalities:

$$(x + 1)e^{-x} \leq 1, \qquad x \in \mathbf{R},$$

and

$$\begin{aligned} e^{-x}(x^2 + 2x + 2) &< 2, \qquad x > 0, \\ e^{-x}(x^2 + 2x + 2) &> 2, \qquad x < 0. \end{aligned}$$

It is sufficient to show that $F_1'(\lambda) < 0$ and $F_2'(\lambda) < 0$ for all $\lambda \geq 0$, with the $F_i(\lambda)$ defined by (2.41). It is very easily seen, using (2.42), that $F_2'(\lambda) < 0$ for all $\lambda \geq 0$ (in fact for all $\lambda > -d_{ia}$). To show that $F_1'(\lambda) < 0$, introduce $\xi = \lambda + d_{ij} - d_{sj}$ and the function $g(\xi)$ defined by

$$g(\xi) = \frac{1}{\xi}(f(d_{sj}\tau) - f((\xi + d_{sj})\tau));$$

then it is more than sufficient to show that $g'(\xi) < 0$ for all $\xi \in \mathbf{R}$. However,

$$\begin{aligned} g'(\xi) &= \frac{1}{\xi^2}[f((\xi + d_{sj})\tau) - f(d_{sj}\tau)] - \frac{\tau}{\xi} f'((\xi + d_{sj})\tau) \\ &= \frac{\tau}{\xi} \left[f'((\theta\xi + d_{sj})\tau) - f'((\xi + d_{sj})\tau) \right] \\ &= (\theta - 1)\tau^2 f''(c) \end{aligned}$$

for some numbers $\theta \in (0,1)$ and $c \in \mathbf{R}$ which arise from applications of the mean value theorem. Since $f''(c) > 0$ by (2.42) it follows that $g'(\xi) < 0$, as desired. Thus, (2.40) does not have any nonnegative real roots.

With $m_i(t) \to 0$ it follows from (2.21) and (2.13) that $J_i(t) \to 0$ and $A_i(t) \to 0$. Then the hypotheses of Lemma 2.3, which are embodied within those of Theorem 2.4, imply that $A_s(t) \to A_s^*$ and $J_s(t) \to J_s^*$ in the linearized equations. The proof of Theorem 2.4 is complete.

2.4. Numerical simulations. Let us introduce the new variable W_1 defined by

$$W_1(t) = \int_{t-\tau}^{t} m_i(\xi) e^{-d_{ij}(t-\xi)} \exp\left(- \int_{t-\tau}^{\xi} (d_{sj} + \beta_j m_i(v))\, dv \right) d\xi,$$

so that we can rewrite the model (2.9), (2.10), (2.13), (2.14), and (2.18) in the form

(2.43)

$$\begin{aligned}
\frac{dJ_s(t)}{dt} &= b(A_s(t)) - b(A_s(t-\tau)) e^{-d_{sj}\tau} e^{-\int_{t-\tau}^{t} \beta_j m_i(v) dv} - d_{sj} J_s(t) - \beta_j m_i(t) J_s(t), \\
\frac{dA_s(t)}{dt} &= b(A_s(t-\tau)) e^{-d_{sj}\tau} e^{-\int_{t-\tau}^{t} \beta_j m_i(v) dv} - d_{sa} A_s(t) - \beta_a m_i(t) A_s(t), \\
\frac{dJ_i(t)}{dt} &= -d_{ij} J_i(t) + \beta_j m_i(t) J_s(t) - \beta_j b(A_s(t-\tau)) W_1(t), \\
\frac{dA_i(t)}{dt} &= -d_{ia} A_i(t) + \beta_a m_i(t) A_s(t) + \beta_j b(A_s(t-\tau)) W_1(t), \\
\frac{dm_i(t)}{dt} &= -d_m m_i(t) + (m_T(t) - m_i(t)) \beta_m (J_i(t) + \alpha A_i(t)), \\
\frac{dW_1(t)}{dt} &= W_1(t)(d_{sj} - d_{ij} + \beta_j m_i(t-\tau)) + m_i(t) e^{-d_{sj}\tau} e^{-\int_{t-\tau}^{t} \beta_j m_i(v) dv} \\
&\qquad - e^{-d_{ij}\tau} m_i(t-\tau).
\end{aligned}$$

The DFE of model (2.43) is the equilibrium in which

$$(J_s, A_s, J_i, A_i, m_i, W_1) \equiv (J_s^*, A_s^*, 0, 0, 0, 0).$$

In the simulations reported below, we take the birth function of mosquitoes and that of birds as

$$B(m_T) = b_m m_T e^{-a_m m_T}, \qquad b(A_s) = b_b A_s e^{-a_b A_s}, \tag{2.44}$$

respectively. These forms for the birth function have been used, for example, in the well-studied Nicholson blowflies equation [9].

Various parameter values are given in Table 1, taken from [18, 19, 3, 26] with reference to West Nile virus. We took the initial conditions to be

$$A_s(t) = 500, \qquad M_I(t) = 0$$

for $t \in [-\tau, 0]$ and $A_i(0) = 2$. This, together with the matching condition (2.19), gives $J_s(0) = 16700$ and $J_i(0) = 0$.

In Figure 1 the condition (2.38) is satisfied, and the infected populations go to zero. However, as we increase the contact rates, the condition (2.38) fails, and the disease sustains in the bird and mosquito population, as shown in Figure 2. If we continue to increase the contact rates, we eventually find oscillatory behaviors, as shown in Figure 3, suggesting the possibility of a Hopf bifurcation to periodic solutions.

TABLE 1
Meaning of parameters.

Parameter	Meaning of the parameter	Value
b_b	Maximum per capita daily bird production rate	0.5
$1/a_b$	Size of bird population at which the number of newborn birds is maximized	1000
b_m	Maximum per capita daily mosquito egg production rate	5
$1/a_m$	Size of mosquito population at which egg laying is maximized	10000
d_{sj}	Mortality rate of uninfected juveniles (per day)	0.005
d_{ij}	Mortality rate of infected juveniles (per day)	0.05
d_{sa}	Mortality rate of uninfected adults (per day)	0.0025
d_{ia}	Mortality rate of infected adults (per day)	0.015
d_m	Mortality rate of mosquito (per day)	0.05
β_j	Contact rate between uninfected juvenile and infected mosquito	Variable
β_a	Contact rate between uninfected adult and infected mosquito	Variable
β_m	Contact rate between uninfected mosquito and infected juvenile	Variable
$\alpha\beta_m$	Contact rate between uninfected mosquito and infected juvenile	Variable
τ	Duration of more vulnerable period of bird (day)	160
σ	Maturation time of mosquito (day)	10
d_l	Mortality rate of larva mosquito (per day)	0.1

3. Spatial speed of spread. In this section we will derive a reaction-diffusion analogue of the system we have studied thus far, and we will use this system to formally estimate the speed at which the disease epidemic would spread through space. For simplicity, diffusion will be modeled using Fick's law. Equations (2.1) and (2.2) become

$$\frac{\partial s}{\partial t} + \frac{\partial s}{\partial a} = D_s(a)\frac{\partial^2 s}{\partial x^2} - d_s(a)s(t,a,x) - \beta(a)s(t,a,x)m_i(t,x) \tag{3.1}$$

and

$$\frac{\partial i}{\partial t} + \frac{\partial i}{\partial a} = D_i(a)\frac{\partial^2 i}{\partial x^2} - d_i(a)i(t,a,x) + \beta(a)s(t,a,x)m_i(t,x) \tag{3.2}$$

on a one-dimensional spatial domain $x \in (-\infty, \infty)$, where $m_i(t,x)$ is the number of infected adult mosquitoes at (t,x) satisfying a reaction-diffusion equation mentioned later. We shall assume that the age-dependent diffusivities $D_s(a)$, $D_i(a)$ have the special form

$$D_s(a) = \begin{cases} D_{sj}, & a < \tau, \\ D_{sa}, & a > \tau, \end{cases} \qquad D_i(a) = \begin{cases} D_{ij}, & a < \tau, \\ D_{ia}, & a > \tau. \end{cases} \tag{3.3}$$

With this choice for the diffusivities, our concern for the moment is with deriving a system of four reaction-diffusion equations for the quantities

$$\begin{aligned} A_s(t,x) &= \int_\tau^\infty s(t,a,x)\,da, \qquad A_i(t,x) = \int_\tau^\infty i(t,a,x)\,da, \\ J_s(t,x) &= \int_0^\tau s(t,a,x)\,da, \qquad J_i(t,x) = \int_0^\tau i(t,a,x)\,da, \end{aligned} \tag{3.4}$$

which are analogous to the total numbers in (2.5). Differentiating the expression for $A_s(t,x)$ and using (3.1) and (3.3) gives

$$\frac{\partial A_s}{\partial t} = s(t,\tau,x) + D_{sa}\frac{\partial^2 A_s}{\partial x^2} - d_{sa}A_s - \beta_a m_i(t,x)A_s,$$

and we need to find $s(t, \tau, x)$. Set

$$s_\xi(a, x) = s(\xi + a, a, x).$$

Differentiating with respect to a and using (3.1) gives

$$\frac{\partial s_\xi}{\partial a} = D_s(a)\frac{\partial^2 s_\xi}{\partial x^2} - d_s(a)s_\xi(a, x) - \beta(a)s_\xi(a, x)m_i(\xi + a, x). \tag{3.5}$$

We would like to solve (3.5) exactly for $s_\xi(a, x)$, but this is impossible because the equation is nonautonomous. (The variable m_i satisfies a separate nonlinear partial differential equation, which appears below.) Our aim, however, will be to study the spatial spread of the disease by looking for traveling wave solutions which move leftwards through the spatial domain $x \in (-\infty, \infty)$, and which constitute a connection between the disease-free state and an endemic state. The PDEs we derive for the

variables (3.4), and for $m_i(t,x)$, will be studied only in the region far ahead of the advancing epidemic, i.e., as $x \to -\infty$, because we shall be assuming that the linearized equations in this region determine the speed of the epidemic wave. In the disease-free region $x \approx -\infty$, the variables $A_i(t,x)$, $J_i(t,x)$, and $m_i(t,x)$ are all close to zero. Thus, we solve (3.5) in the case when m_i is zero to find that in this case the solution subject to the first condition appearing below,

$$s(t,0,x) = b(A_s(t,x)), \qquad i(t,0,x) = 0 \tag{3.6}$$

(the analogue of (2.6)) is, for $a \le \tau$ and $\xi \ge 0$,

$$s_\xi(a,x) = s(\xi + a, a, x) = \int_{-\infty}^{\infty} \Gamma(D_{sj}a, x-y) b(A_s(\xi,y)) e^{-d_{sj}\tau}\, dy, \tag{3.7}$$

where

$$\Gamma(t,x) = \frac{1}{\sqrt{4\pi t}} e^{-x^2/4t}. \tag{3.8}$$

From (3.7) we find an expression for $s(t,\tau,x)$, and we deduce that for $t \geq \tau$ the PDE for $A_s(t,x)$ is

$$\begin{aligned} \frac{\partial A_s}{\partial t} &= \int_{-\infty}^{\infty} \Gamma(D_{sj}\tau, x-y) b(A_s(t-\tau,y)) e^{-d_{sj}\tau}\, dy \\ &\quad + D_{sa}\frac{\partial^2 A_s}{\partial x^2} - d_{sa}A_s(t,x) - \beta_a m_i(t,x) A_s(t,x), \end{aligned} \tag{3.9}$$

valid in the far left of the spatial domain $x \in (-\infty, \infty)$. Similarly, we obtain the following approximate equation for $J_s(t,x)$, also valid only in the far field $x \to -\infty$:

$$\begin{aligned}\frac{\partial J_s}{\partial t} &= b(A_s(t,x)) - \int_{-\infty}^{\infty} \Gamma(D_{sj}\tau, x-y) b(A_s(t-\tau,y)) e^{-d_{sj}\tau}\, dy \\ &\quad + D_{sj}\frac{\partial^2 J_s}{\partial x^2} - d_{sj} J_s(t,x) - \beta_j m_i(t,x) J_s(t,x).\end{aligned} \tag{3.10}$$

Next we shall derive the PDE for $A_i(t,x)$. Differentiating the expression for A_i in (3.4) and using (3.2) and (3.3) gives

$$\frac{\partial A_i}{\partial t} = i(t,\tau,x) + D_{ia}\frac{\partial^2 A_i}{\partial x^2} - d_{ia}A_i + \beta_a m_i(t,x) A_s,$$

and we need to find $i(t,\tau,x)$. Set

$$i_\xi(a,x) = i(\xi + a, a, x).$$

Since the calculation of $i(t,\tau,x)$ involves immature ages $a \in [0,\tau]$ only, from (3.2) we obtain

$$\frac{\partial i_\xi}{\partial a} = D_{ij}\frac{\partial^2 i_\xi}{\partial x^2} - d_{ij} i_\xi(a,x) + \beta_j m_i(\xi + a, x) s(\xi + a, a, x).$$

The solution of this equation satisfying the second condition in (3.6) is

$$i_\xi(a,x) = \beta_j \int_0^a e^{-d_{ij}(a-\zeta)} \int_{-\infty}^{\infty} \Gamma(D_{ij}(a-\zeta), x-y) m_i(\xi+\zeta, y) s(\xi+\zeta, \zeta, y)\, dy\, d\zeta,$$

where Γ is again given by (3.8). For $s(\xi+\zeta,\zeta,y)$ we use expression (3.7). Then, setting $a = \tau$ and $\xi = t - \tau$ in the above expression gives us $i(t,\tau,x)$, and thus we conclude that the evolution PDE for the variable $A_i(t,x)$ representing the number of adult infected hosts is, for $t \geq \tau$,

$$\begin{aligned}\frac{\partial A_i}{\partial t} &= D_{ia}\frac{\partial^2 A_i}{\partial x^2} - d_{ia}A_i(t,x) + \beta_a m_i(t,x) A_s(t,x) \\ &\quad + \beta_j \int_0^\tau e^{-d_{ij}(\tau-\zeta)} \int_{-\infty}^{\infty} \Gamma(D_{ij}(\tau-\zeta), x-y) m_i(t-\tau+\zeta, y) \\ &\quad \times \int_{-\infty}^{\infty} \Gamma(D_{sj}\zeta, y-\eta) b(A_s(t-\tau,\eta)) e^{-d_{sj}\zeta}\, d\eta\, dy\, d\zeta.\end{aligned} \tag{3.11}$$

This is again valid only in the far field $x \to -\infty$, since we have used expression (3.7). The last term in the right-hand side of (3.11) is the rate at which infected immatures become infected adults and has a similar interpretation to a term in the right-hand side of (2.13). This time the term involves additional integrals because of diffusion, but the reader may notice that in certain other respects the term in (3.11) is a little simpler than we might expect based on comparison with (2.13); this is due to the approximations we have made to derive (3.11) because of the restriction to the $x \approx -\infty$ zone. The interpretation of the term we are discussing is as follows. Each individual that reaches adulthood at point x at time t as an infected individual was born as a susceptible at time $t - \tau$ at some other point η. For an amount of time ζ that individual drifted around as a susceptible individual with diffusivity D_{sj} until

reaching a point y, where it became infected at time $t-\tau+\zeta$. For an amount of time $\tau-\zeta$, constituting the remainder of its childhood, it drifted around as an infected individual with diffusivity D_{ij} to reach point x at time t, where it becomes an adult. The two exponential factors represent the probability of surviving the susceptible and infected portions of childhood.

The PDE for $J_i(t,x)$ is derived similarly and turns out to be

$$\begin{aligned}\frac{\partial J_i}{\partial t} &= D_{ij}\frac{\partial^2 J_i}{\partial x^2} - d_{ij}J_i(t,x) + \beta_j m_i(t,x)J_s(t,x)\\ &\quad - \beta_j \int_0^\tau e^{-d_{ij}(\tau-\zeta)} \int_{-\infty}^{\infty} \Gamma(D_{ij}(\tau-\zeta), x-y) m_i(t-\tau+\zeta, y)\\ &\quad \times \int_{-\infty}^{\infty} \Gamma(D_{sj}\zeta, y-\eta) b(A_s(t-\tau,\eta)) e^{-d_{sj}\zeta}\, d\eta\, dy\, d\zeta.\end{aligned} \tag{3.12}$$

Finally we need a reaction-diffusion equation for the infected adult mosquitoes $m_i(t,x)$. We shall take

$$\frac{\partial m_i}{\partial t} = D_m\frac{\partial^2 m_i}{\partial x^2} - d_m m_i(t,x) + \beta_m(m_T^* - m_i(t,x))(J_i(t,x)+\alpha A_i(t,x)). \tag{3.13}$$

The system of PDEs to be solved thus consists of (3.9), (3.10), (3.11), (3.12), and (3.13). As explained previously, we shall look for solutions which constitute a leftward moving traveling wave-front and which invade what was formerly a disease-free zone; in other words, as $x \to -\infty$ we shall assume that the variables tend to the disease-free values in which A_i, J_i, and m_i are zero while $A_s^* > 0$ and $J_s^* > 0$ are given by (2.36), assuming that (2.23) holds. (If (2.23) does not hold, then the host population is eradicated even in the absence of the disease.)

We shall, in fact, look for a wave-front that constitutes a transition from the disease-free state to an endemic steady state, and so we need to be assured of the existence of an endemic state. The endemic state cannot be found explicitly, but fortunately we know the condition for its existence. This condition is the opposite of (2.38). Therefore, we assume in this section that

$$\begin{aligned}d_m < \beta_m m_T^* \Bigg\{ &\frac{b(A_s^*)\beta_j}{d_{ij}-d_{sj}}\left[\frac{1-e^{-d_{sj}\tau}}{d_{sj}} - \frac{(1-e^{-d_{ij}\tau})}{d_{ij}}\right]\\ &+ \frac{\alpha}{d_{ia}}\left[\beta_a A_s^* + \beta_j b(A_s^*)e^{-d_{sj}\tau}\frac{(1-e^{-(d_{ij}-d_{sj})\tau})}{d_{ij}-d_{sj}}\right]\Bigg\}.\end{aligned} \tag{3.14}$$

We linearize the equations for A_i, J_i, and m_i ((3.11), (3.12), and (3.13)) in the region $x \to -\infty$, where $A_s \to A_s^*$, $J_s \to J_s^*$, and the other variables approach zero. The linearized equations are then converted to traveling wave form by looking for solutions that are functions only of the variable $z = x + ct$ with $c \geq 0$. Then we look for nontrivial solutions of the linearized traveling wave equations of the form $(A_i, J_i, m_i) = (q_1, q_2, q_3)\exp(\lambda z)$. After a fair amount of algebra we find that the characteristic equation determining λ is

$$G_1(\lambda; c) = G_2(\lambda; c)G_3(\lambda; c), \tag{3.15}$$

where

$$\begin{aligned}G_1(\lambda;c) &= (D_{ia}\lambda^2 - d_{ia} - c\lambda)(D_{ij}\lambda^2 - d_{ij} - c\lambda)(D_m\lambda^2 - d_m - c\lambda)\\ &\quad - \beta_m m_T^*[\beta_j J_s^*(D_{ia}\lambda^2 - d_{ia} - c\lambda) + \alpha\beta_a A_s^*(D_{ij}\lambda^2 - d_{ij} - c\lambda)],\end{aligned} \tag{3.16}$$

$$G_2(\lambda;c) = \alpha(D_{ij}\lambda^2 - d_{ij} - c\lambda) - (D_{ia}\lambda^2 - d_{ia} - c\lambda), \tag{3.17}$$

and

$$G_3(\lambda;c) = \beta_m m_T^* \left(\frac{\beta_j b(A_s^*)(e^{-d_{sj}\tau} - e^{-d_{ij}\tau - \lambda c\tau + \lambda^2 D_{ij}\tau})}{d_{ij} - d_{sj} + \lambda c - \lambda^2 D_{ij}} \right). \tag{3.18}$$

Recall that A_s^* and J_s^* are given by (2.36) and that m_T^* is given by (2.17).

An epidemiologically feasible wave-front is one in which all the variables remain nonnegative as $x \to -\infty$ (as $z \to -\infty$ in the traveling wave variable formulation). The decay of A_i, J_i, and m_i to zero as $z \to -\infty$ must not be oscillatory. It is therefore necessary that there should exist at least one strictly positive real root λ of the characteristic equation (3.15) with the property that the corresponding eigenvector (q_1, q_2, q_3) points into the positive octant in $\mathbf{R}^3$. This actually happens only for c above some minimum value $c_{\min} > 0$. Define

$$c_{\min} = \inf\{c : \quad \exists \lambda \in (0, \tfrac{1}{2D_{ia}}(c + \sqrt{c^2 + 4d_{ia}D_{ia}})] \text{ satisfying (3.15)}\}. \tag{3.19}$$

The reason why the search for positive real roots λ of (3.15) is confined to the finite interval in (3.19) is that the eigenvector (q_1, q_2, q_3) corresponding to an eigenvalue λ exceeding $\frac{1}{2D_{ia}}(c + \sqrt{c^2 + 4d_{ia}D_{ia}})$ has q_1 and q_3 of opposite sign (implying that one of A_i or m_i is negative) so that such an eigenvalue corresponds to an infeasible solution. Note that the interval of λ in (3.19) is c dependent.

A calculation shows that, because of (3.14),

$$G_1(0;c) - G_2(0;c)G_3(0;c) > 0.$$

If for a fixed c one plots the graph of $G_1(\lambda;c) - G_2(\lambda;c)G_3(\lambda;c)$ against λ on the feasible domain $\lambda \in [0, \frac{1}{2D_{ia}}(c + \sqrt{c^2 + 4d_{ia}D_{ia}})]$, one finds that for a very small value of c the graph is always above the horizontal axis. The effect of increasing c is that a minimum begins to form within the feasible domain, and this minimum moves down and touches the horizontal axis at a critical c, the value $c_{\min}$ defined in (3.19) above. Figure 4 shows the critical situation for a particular set of parameter values shown in the caption, and for the two birth functions $b(\cdot)$ and $B(\cdot)$ chosen as in section 2.4. The value $c_{\min}$ can be found by numerically solving the simultaneous equations

$$G_1(\lambda;c) - G_2(\lambda;c)G_3(\lambda;c) = 0,$$
$$\frac{d}{d\lambda}[G_1(\lambda;c) - G_2(\lambda;c)G_3(\lambda;c)] = 0,$$

for c and λ with $c > 0$ and $\lambda \in (0, \frac{1}{2D_{ia}}(c + \sqrt{c^2 + 4d_{ia}D_{ia}})]$.

4. Discussion. The minimum speed of spread computed in the previous section according to the predictions of the linearized analysis was about 2.62 km/day, i.e., about 956 km/year. This is certainly roughly consistent with the speed at which West Nile virus has spread across the USA. The disease first emerged in New York in 1999 and had reached the West coast five years later. We should point out, however, that there is some uncertainty regarding the choice of parameter values, especially the diffusivities. We have availed ourselves of what data there is concerning the diffusivity of adult crows, but our choice of a value for the fledgling crows, which do not fly so well and may well spend some time on the ground (where they are, of course, vulnerable to predators such as cats) is purely our estimate. While the speed of spread does show a dependence on the diffusivities, we noted a lack of sensitivity to the values of

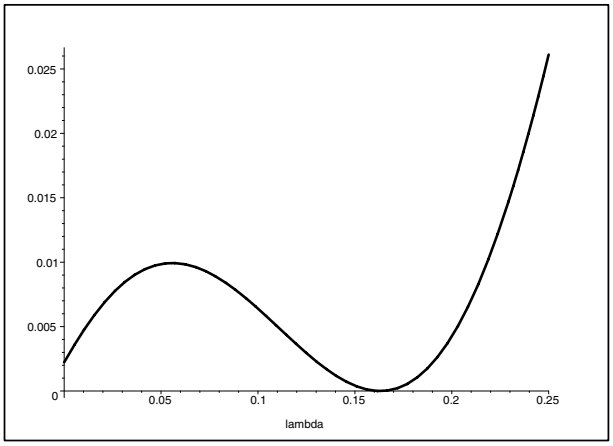

FIG. 4. *Parameter values are* $\beta_j = 3.15 \times 10^{-5}$, $\beta_a = 1.5 \times 10^{-5}$, $\beta_m = 2.925 \times 10^{-5}$, $\alpha\beta_m = 0.75 \times 10^{-5}$, $D_{ia} = 13$ km^2/day [16, 21] *(the diffusion rate of infected adult),* $D_{ij} = 6$ km^2/day *(the diffusion rate of infected juvenile),* $D_m = 0.1$ km^2/day *(the diffusion rate of mosquito), and other parameters have the values shown in Table* 1. *For these values, the minimum speed* $c_{\min}$*, computed as described in the text, equals* 2.623164094 *km/day.*

some of them (e.g., the diffusivity of mosquitoes) and a sensitivity to the values of other parameters, particularly the contact rates.

Ideally it would be desirable to have some information on whether the minimum speed $c_{\min}$ computed as described in section 3 is really the speed that solutions would evolve to, from ecologically realistic initial data such as a localized introduction of infectives. One must remember that in deriving the reaction-diffusion model, we were restricted to the vicinity of the DFE because the model derivation requires an explicit solution to a certain linear parabolic PDE that is nonautonomous except near that equilibrium. The inability to formulate a model that is valid everywhere in the spatial domain has made it impossible to numerically simulate the spatially extended model (such a simulation might have confirmed that the spread rate is indeed the minimal wave speed $c_{\min}$). The mathematical theory of the speed of spread in reaction-diffusion equations with functional terms is still far from complete, especially for coupled systems such as those in this paper. Relating the spread rate of the disease to the traveling wave with the minimal wave speed relies on the so-called linear conjecture (see [25, 15]). The fact that the minimal speed coincides with the spread rate has been theoretically verified only for dynamical systems enjoying certain order-preserving properties (see the two recent articles [24, 17]), and counterexamples when these properties do not hold have been reported [11]. Establishing this fact for our system (3.9)–(3.13) is even more difficult due to the interaction of time delay and spatial diffusion, in addition to the nonlocality of the nonlinear terms. Therefore, it has to be emphasized that our calculation of $c_{\min}$ is nothing more than a formal calculation of the minimum ecologically feasible speed according to the linearized equations ahead of the front.

Throughout this paper simple mass action terms have been used. In some virus infections, possibly including mosquito borne disease, one might argue for the inclusion of a term which represents the fact that a female mosquito takes a fixed number of blood meals per unit time (Anderson and May [1]). Such a modification involves dividing by bird density and has recently been utilized by Lewis, Renclawowicz, and

van den Driessche [16] and by Bowman et al. [3] in some simpler models for West Nile virus. In the present paper such a modification can be implemented only in the model without diffusion, which we have studied in section 2, and unfortunately not for the reaction-diffusion model of section 3, which becomes intractable. The type of modification we are discussing involves replacing (2.1) by

$$\frac{\partial s}{\partial t} + \frac{\partial s}{\partial a} = -d_s(a)s(t,a) - \frac{\beta(a)s(t,a)m_i(t)}{N(t)}, \tag{4.1}$$

with another similar modification to (2.2). The variable $N(t)$ stands for the total bird population,

$$N(t) = A_s(t) + A_i(t) + J_s(t) + J_i(t),$$

in which the variables are defined by (2.5). Equation (2.18) would be replaced by

$$\frac{dm_i(t)}{dt} = -d_m m_i(t) + \frac{\beta_m(m_T^* - m_i(t))}{N(t)}(J_i(t) + \alpha A_i(t)). \tag{4.2}$$

For this modified model it is possible to develop a parallel theory including equations for the total number variables analogous to (2.9), (2.10), (2.13), (2.14) and to prove theorems concerning positivity, boundedness, and global convergence. We shall confine ourselves in this paragraph only to a discussion of the linear stability of the DFE in the modified model involving division by bird density. The DFE itself is still given precisely by (2.35). Lemma 2.3, which concerns stability to perturbations in which the disease remains absent, still holds. For the modified model a necessary and sufficient condition for the DFE to be linearly asymptotically stable to arbitrary small perturbations is

$$\begin{aligned} d_m > \frac{\beta_m m_T^*}{N^*}\Bigg\{ & \frac{b(A_s^*)\beta_j}{N^*(d_{ij}-d_{sj})}\left[\frac{1-e^{-d_{sj}\tau}}{d_{sj}} - \frac{(1-e^{-d_{ij}\tau})}{d_{ij}}\right] \\ & + \frac{\alpha}{d_{ia}N^*}\left[\beta_a A_s^* + \beta_j b(A_s^*)e^{-d_{sj}\tau}\frac{(1-e^{-(d_{ij}-d_{sj})\tau})}{d_{ij}-d_{sj}}\right]\Bigg\}, \end{aligned} \tag{4.3}$$

which is similar to condition (2.38). Here, $N^* = A_s^* + J_s^*$, where A_s^* and J_s^* are given by (2.36).

There are a number of ways in which one could interpret conditions (2.38) and (4.3) for the simple mass action model and the modified model, respectively. First let us note that as far as the stability of the DFE is concerned the two models are similar: to get from one to the other we simply divide the contact rates by the total bird population at the equilibrium. Not surprisingly, in reality in the control of West Nile virus a great deal of emphasis goes into mosquito control. This may mean larval control, i.e., reducing the number of places mosquito larvae may inhabit such as old tires, blocked gutters, bird baths, flower pots, swimming pool covers, etc. Adult mosquito control using adulticides, which are sprayed into the air from a sprayer truck as very tiny droplets, is also practiced, especially when larval control measures are clearly inadequate or disease is imminent. The per capita mortality rate for adult mosquitoes manifests itself in our model as the parameter d_m. The per capita mortality rate for mosquito larvae is d_l, which does not feature directly in (2.38) or (4.3) but features indirectly through the quantity m_T^*. (In fact, m_T^* depends on both d_l and d_m.) If the birth function $B(\cdot)$ for mosquitoes is chosen as

in (2.44), then $m_T^* = \frac{1}{a_m}\ln(b_m/d_m) - d_l\sigma/a_m$, and so the right-hand side of (2.38) or (4.3) decreases linearly with d_l so that sufficiently effective larval control eradicates the disease. On the other hand, as d_m increases, the left-hand side increases linearly while the right-hand side decreases, suggesting that in percentage terms an increase in d_m might be more effective than an increase in larval mortality d_l. However, adult mosquito control is more expensive and more difficult to organize.

There are a number of other factors we have not considered in this paper at all. It seems that in reality seasonal effects probably play an important role and should be modeled. It is really only in the breeding season that crows, once paired, seek to establish individual territories to raise their broods. In the nonbreeding season crow activities tend to be centered around large communal roosts to which they return in the evenings after searching for food during the day (some roost locations may have been gathering points for crows for many decades). Crows also have a strong flocking instinct, something which Fickian diffusion does not model at all. Northern birds tend to fly south during the winter. All these considerations indicate possible areas for further investigation.

Acknowledgment. We are grateful to the referees for their valuable comments and suggestions which have led to an improved paper.

ANALYSIS OF THE DYNAMICS AND TOUCHDOWN IN A MODEL OF ELECTROSTATIC MEMS*

G. FLORES†, G. MERCADO‡, J. A. PELESKO§, AND N. SMYTH¶

Abstract. We study a reaction-diffusion equation in a bounded domain in the plane, which is a mathematical model of an idealized electrostatically actuated microelectromechanical system (MEMS). A relevant feature in these systems is the "pull-in" or "jump-to contact" instability, which arises when applied voltages are increased beyond a critical value. In this situation, there is no longer a steady state configuration of the device where mechanical members of the device remain separate. It may present a limitation on the stable operation regime, as with a micropump, or it may be used to create contact, as with a microvalve. The applied voltage appears in the equation as a parameter. We prove that this parameter controls the dynamics in the sense that before a critical value the solution evolves to a steady state configuration, while for larger values of the parameter, the "pull-in" instability or "touchdown" appears. We estimate the touchdown time. In one dimension, we prove that the touchdown is self-similar and determine the asymptotic rate of touchdown. The same type of results are obtained in a disk. We also present numerical simulations in some two-dimensional domains which allow an estimate of the critical voltage and of the touchdown time. This information is relevant in the design of the devices.

Key words. microelectromechanical system, touchdown, quenching

1. Introduction.

Lots of micro- and nanoelectromechanical systems rely upon electrostatic forces to make things move. Devices such as micropumps, microswitches, etc., can be modeled as electrostatically deflected elastic membranes.

Typically, the device consists of an elastic membrane suspended above a rigid ground plate, placed in series with a fixed voltage source and a fixed capacitor. In the limit of small aspect ratio, that is, small gap size relative to device length, the model can be reduced to a single scalar equation for the deflection of the membrane. Denoting this deflection by u, we have, in dimensionless variables,

$$\epsilon^2 u_{tt} + u_t - \triangle u = -\frac{\lambda f(x,y,t)}{(1+u)^2(1+\chi\int_\Omega \frac{1}{1+u})^2}$$

in Ω, with $u = 0$ on $\partial\Omega$. Here

$$\epsilon^2 = \frac{\rho E}{\nu^2} = \frac{\text{inertial terms}}{\text{damping terms}} \quad \text{and} \quad \lambda = \frac{V^2 L^2 \epsilon_0}{2Tl^2}.$$

For a derivation of the equation see [15].

The parameter V is the applied voltage, T the tension in the membrane, L a characteristic length of the domain, l a characteristic width of the gap between the membrane and the fixed electrode, and ϵ_0 the permittivity of free space. It is useful to think of λ as a control parameter proportional to the applied voltage. The function $f(x, y, t)$ may model varying dielectric properties of the membrane and an applied alternating current. Physically f is constrained to be positive. The integral in the equation arises when the device is placed in a circuit with a capacitor of fixed capacitance. The parameter χ is the ratio of this fixed capacitance to a reference capacitance of the device. The limit where $\chi = 0$ corresponds to removing the fixed capacitor from the circuit.

We shall study the viscosity dominated limit of the model above, that is, the limit where $\epsilon \to 0$. Further, we can remove the nonlocal integral term by introducing a new parameter and establishing a mapping between solutions to the nonlocal and a local problem. See [15] for details. The local problem corresponds to setting $\chi = 0$. For simplicity, we take $f \equiv 1$. The case of devices with dielectric properties which vary in space is treated in [9]. We also assume that the device starts from rest. So, we shall study

$$u_t - \triangle u = -\frac{\lambda}{(1+u)^2} \quad \text{in } \Omega, \quad \text{with } u = 0 \text{ on } \partial\Omega, \quad u(x, y, 0) = 0. \tag{1}$$

Electrostatically deflected elastic systems exhibit an instability known as "pull-in." For moderate voltages, the system is in a stable operation regime: the membrane approaches a steady state configuration and remains separate from the ground plate. When applied voltages are increased beyond a critical value, there is no longer a steady state configuration of the device, causing the membrane to collapse onto the ground plate. This phenomenon is what we call "touchdown."

The "pull-in" instability was observed in 1967 by Nathanson and coworkers in their investigation of electrostatic actuation as a method for designing a resonant gate transistor [12]. At around the same time, this instability was also observed by Taylor in his work on the coalescence of liquid drops held at different electric potentials [16].

Mathematically, the "pull-in" instability corresponds to $u = -1$ being achieved in Ω in finite time, which creates a singularity in (1).

What we call "touchdown" is also known as "pinching" or "quenching" in the mathematical literature, where it appears in the equation for the motion of a surface with a normal velocity proportional to its mean curvature. See [2], [8]. The analysis of parabolic equations with negative power nonlinearities began with the work of Kawarada in 1975 [10]. Quenching has been studied for semilinear and quasi-linear equations; see [4] and [11].

Our formulation, based on the fact that gravity acts downwards, leads to (1). For this reason, our solution takes negative values. To relate this to the study of quenching for positive solutions, it is enough to substitute u by $-u$ to obtain the parabolic equation in the standard form as it appears, for instance, in [11].

In this work, we describe the behavior of solutions in terms of the parameter λ: There exists a critical value λ^* such that solutions converge to a steady state for $\lambda \leq \lambda^*$, while for $\lambda > \lambda^*$ touchdown occurs.

We also characterize the asymptotic self-similar nature of touchdown by analyzing the one-dimensional equation in self-similar variables. We find a continuum of steady states, which correspond to self-similar solutions. We show that the nonconstant

steady states grow at infinity like e^{y^2}, thereby obtaining the constant solution as the only possible limiting configuration, as well as the asymptotic rate of touchdown. This asymptotic rate was also obtained by Guo, Pan, and Ward, using different techniques. See [9].

Finally, we present some numerical results for two-dimensional domains: ellipses and annular regions. We obtain bounds for the critical value of λ as well as for the touchdown time. One interesting feature of annular regions is that the touchdown set is a circle. Also, a thin annulus sustains a very large stable operation regime.

Some of the results presented here were either announced or proved in [6]. For the sake of completeness, we include some of the proofs from our previous work.

2. Steady state solutions. Let Ω be a convex, bounded domain in the plane with smooth boundary. We first prove the existence of stationary solutions for small values of λ.

LEMMA 2.1. *There exists $\lambda_0 > 0$ such that the Dirichlet problem for*

$$\Delta u = \frac{\lambda}{(1+u)^2} \tag{2}$$

has a solution for $\lambda \leq \lambda_0$.

Proof. Since $u \equiv 0$ is an upper solution, it is enough to construct nonpositive lower solutions. To this end, let u^* be the solution of $\Delta u^* = 1$ in Ω, $u = 0$ on $\partial\Omega$. By the maximum principle, $u^* < 0$ in Ω.

Let $m^* := \inf\{u^*(x) \,|x \in \Omega\}$ and $\alpha := \frac{-1}{2m^*}$. Now choose $\lambda \leq \alpha/4$; then

$$\Delta(\alpha u^*) - \frac{\lambda}{(1+\alpha u^*)^2} \geq \alpha - 4\lambda \geq 0. \tag{3}$$

Hence, u^* is a nonpositive lower solution for $\lambda \leq \alpha/4$. A standard monotone iteration scheme yields the existence of a stable stationary solution for $\lambda \leq \lambda_0$. This finishes the proof. □

In the case of a disk we get explicit bounds for λ_0.

COROLLARY 2.1. *If Ω is a disk of radius R, there exist stationary solutions for $\lambda \leq R^{-2}$.*

Proof. It follows from the fact that $u^*(x) = \frac{1}{4}(\sum_{i=1}^{2} x_i^2 - R^2)$ and that we can choose $\alpha = R^{-2}$.

Our next result gives a description of the structure of stationary solutions in terms of the parameter λ. □

THEOREM 2.1. *There exists $\lambda_* > 0$ such that there is at least one stationary solution for $\lambda < \lambda_*$ and none for $\lambda > \lambda_*$.*

Proof. This is a consequence of the fact that if u_1 is a stationary solution for $\lambda = \lambda_1$, then, for $\lambda < \lambda_1$,

$$\Delta u_1 = \frac{\lambda_1}{(1+u_1)^2} > \frac{\lambda}{(1+u_1)^2} \tag{4}$$

so that u_1 is a lower solution for all $\lambda < \lambda_1$.

Now let $E = \{\lambda > 0$ for which there is a stationary solution$\}$. By the paragraph above, E is a nonempty interval. Let $\lambda_* := \sup E$.

Our next task is to prove that λ_* is finite.

To this end, let μ_0 be the first eigenvalue of the Dirichlet Laplacian. We claim that for $\lambda > -\frac{4}{27}\mu_0$, the steady state problem has no solution.

This result is slightly more precise than Theorem 4.4 of [15]. The proof is similar: let u_0 be a positive eigenfunction corresponding to μ_0; then

$$\int_\Omega u_0 \left[\Delta u - \frac{\lambda}{(1+u)^2}\right] dx = \mu_0 \int_\Omega \frac{u_0}{(1+u)^2} \left[u(1+u)^2 - \frac{\lambda}{\mu_0}\right] dx. \tag{5}$$

If $\lambda > -\frac{4}{27}\mu_0$, then the right-hand side in the equation above is negative. This shows that there are no stationary solutions for such values of λ. The theorem is proved. □

In the one-dimensional case, with $\Omega = (-1/2, 1/2)$, we give a complete description of the structure of solutions of

$$u_{xx} = \frac{\lambda}{(1+u)^2} \quad \text{in} \quad \Omega \tag{6}$$

with $u(\pm 1/2) = 0$. Indeed, with the scaling $\xi = \sqrt{\lambda}x$, the previous equation becomes

$$u'' = \frac{1}{(1+u)^2} \quad \text{in} \quad (-\sqrt{\lambda}/2, \sqrt{\lambda}/2) \tag{7}$$

and $u(\pm\sqrt{\lambda}/2) = 0$.

The following result is a special case of Theorem 2.1 in [11]. However, our method of proof allows the explicit determination of the critical value of the parameter λ.

THEOREM 2.2. *There exists a constant C^* such that the previous equation has zero, one, or two solutions according as $\sqrt{\lambda}/2 > C^*$, $\sqrt{\lambda}/2 = C^*$, or $\sqrt{\lambda}/2 < C^*$. Moreover, the exact value is $C^* = .591611$, and this determines the critical value $\lambda^* = 1.400016469$.*

Proof. In the phase plane of u, $v = u'$, the integral curves satisfy

$$\frac{v^2}{2} + \frac{1}{1+u} = E_0,$$

where E_0 is the initial energy.

An integral curve starting at $(\overline{u}, 0)$ with $-1 < \overline{u} < 0$ reaches the v axis in finite time at $(0, \overline{v})$. It follows that

$$E_0 = \frac{\overline{v}^2}{2} + 1.$$

The equations for the integral curves take the form

$$v = \pm\sqrt{\overline{v}^2 + \frac{2u}{1+u}}, \tag{8}$$

which is defined for $u \geq -\frac{\overline{v}^2}{2+\overline{v}^2} = \overline{u}$. The travel time from $(\overline{u}, 0)$ to $(0, \overline{v})$ is given by the map T defined by

$$T(\overline{v}^2) = \int_{\overline{u}}^{0} \frac{du}{\sqrt{\overline{v}^2 + \frac{2u}{1+u}}}. \tag{9}$$

Note that $T \to 0$ as $\overline{v} \to 0$ and $+\infty$. We shall show that T has a unique maximum, from which the structure of stationary solutions is obtained.

To analyze the travel time map we let $\alpha = \overline{v}^2$ and $\beta = \frac{\alpha}{2+\alpha}$; then

$$T(\alpha) = \frac{1}{\sqrt{2+\alpha}} \int_{-\beta}^{0} \frac{\sqrt{1+u}}{\sqrt{u+\beta}}\, du = \frac{\sqrt{\alpha}}{2+\alpha} \int_{-\pi/2}^{0} \sqrt{1+\beta\sin(\theta)}\sqrt{1-\sin(\theta)}\, d\theta$$
$$= \int_{-\pi/2}^{0} F(\alpha,\theta) d\theta.$$

The critical value C^* is the maximum value of the travel time. The point where the maximum is achieved is computed explicitly and used in the integral representation of the travel time to determine C^*. This critical value is used to determine the critical parameter λ^*.

One can prove that the function $T(\alpha)$ has a unique maximum, as its second derivative is negative at critical points.

The proof is finished. □

The shape of the stationary solutions can be obtained from the trajectories in the phase plane. For instance, for small λ, there is one solution of small amplitude and a second solution with a peak at the center which gets close to -1. Both are even functions.

For a disk shaped domain we also have a complete picture of solutions. Details appear in [14]. Note that by Gidas, Ni, and Nirenberg, all stationary solutions are radially symmetric.

3. Dynamics: The stable operation and touchdown regimes. In this section we characterize the stable operation and touchdown regimes in terms of the parameter λ. We begin by establishing some general properties of solutions of the evolution equation (1).

THEOREM 3.1. *Assume that $u(x,y,t;\lambda) > -1$ for $\lambda > 0$, and for all $(x,y) \in \Omega$ and $t \in [0,T]$. Then we have the following:*

(i) *$u(x,y,t;\lambda)$ is decreasing in t at each $(x,y) \in \Omega$.*

(ii) *$u(x,y,t;\lambda)$ is a decreasing function of λ.*

(iii) *When $\Omega = (-1/2, 1/2)$, $u(x,t;\lambda)$ is an even function of x, it achieves its minimum at $x = 0$, and it is increasing for $x \in [0, 1/2]$.*

Proof.

(i) u_t is a solution of a linear parabolic equation with zero boundary values and initial value equal to $-\lambda$. By the maximum principle, $u_t \leq 0$, and the strict inequality holds in the interior of the domain.

(ii) It is an easy consequence of the maximum principle.

(iii) The symmetry of the solution is a consequence of the symmetry of the domain, of the initial, condition, and of the heat operator. It follows that $u_x(x,t)$ is an odd function of x; therefore $u_x(0,t) = 0$. Moreover, u_x is a solution of a parabolic equation for $x \in [0,1/2]$, and $t \in [0,T]$, with $u_x(0,t) = 0$ and, by the maximum principle, $u_x(1/2,t) > 0$. It follows that u_x cannot achieve a negative minimum, and hence $u_x \geq 0$. By the strong maximum principle, u_x cannot achieve its minimum in the region $x \in (0,1/2)$, and $t \in (0,T]$. Therefore, $u_x(x,t) > 0$ for $x \in (0,1/2)$, and $t \in (0,T]$. It follows that for a fixed $t \in (0,T]$, $u(x,t)$ achieves its minimum at $x = 0$ only.

The proof of the theorem is finished. □

Amplification. The plots of the profile u as a function of x suggest that it is a convex function. We have not been able to prove this, yet there is some sort of convexity in the approximations: if we solve (1) by iterations, starting with $u_0 \equiv 0$,

then the next approximation u_1 is a solution of the corresponding linear heat equation with forcing term $\equiv -\lambda$, and hence

$$u_1(x,t) = -\lambda \int_0^t \int_{-1/2}^{1/2} K(x,y,\tau)dy\,d\tau,$$

where $K(x,y,t)$ is the Dirichlet Green's function. It follows that

$$\frac{\partial^2 u_1}{\partial x^2} = \frac{\partial u_1}{\partial t} + \lambda = \lambda \left[1 - \int_{-1/2}^{1/2} K(x,y,\tau)\right] dy$$

and the last expression is positive by the maximum principle.

3.1. The stable operation regime. For $\lambda < \lambda_*$, the solution stabilizes to a steady state.

THEOREM 3.2. *For $\lambda < \lambda_*$, the solution $u(x,y,t;\lambda)$ converges to a stationary solution as $t \to \infty$.*

Proof. The solution $u(x,y,t;\lambda)$ is bounded below by any stationary solution. Hence, $u(x,y,t;\lambda)$ is defined for all $t > 0$ and, by the previous theorem, is decreasing in t at each $(x,y) \in \Omega$. Therefore, $u(x,y,t;\lambda)$ converges as $t \to \infty$.

The energy

$$\int_\Omega \left[\frac{1}{2}|\nabla u|^2 - \frac{\lambda}{1+u}\right] dx\,dy \tag{10}$$

decreases and is bounded below along such solutions. Therefore, the only points in the ω-limit set of such trajectories are steady states. The proof is finished. ∎

3.2. The touchdown regime. Our first result is an estimate on the values of λ for which touchdown occurs.

THEOREM 3.3. *For $\lambda > -\frac{4}{27}\mu_0$, $u(x,y,t;\lambda) = -1$ in finite time.*

Proof. Let μ_0 be the smallest eigenvalue of the Dirichlet Laplace operator on Ω and let u_0 be the corresponding eigenfunction. We note that u_0 may be chosen strictly positive in Ω and normalized so that

$$\int_\Omega u_0 = 1. \tag{11}$$

Now we derive an energy for our system. Multiply (1) by u_0 and integrate over the domain Ω. This yields

$$\frac{d}{dt}\int_\Omega u u_0 - \mu_0 \int_\Omega u u_0 = -\lambda \int_\Omega \frac{u_0}{(1+u)^2}, \tag{12}$$

where we have used Green's theorem to integrate by parts. We define

$$E(t) = \int_\Omega u u_0 \tag{13}$$

and rewrite as

$$\frac{dE}{dt} - \mu_0 E = -\lambda \int_\Omega \frac{u_0}{(1+u)^2}. \tag{14}$$

Then, applying Jensen's inequality and the initial condition on our problem, we arrive at

$$\frac{dE}{dt} - \mu_0 E \leq \frac{-\lambda}{(1+E)^2}, \tag{15}$$

$$E(0) = 0. \tag{16}$$

Now notice

$$E(t) = \int_\Omega u u_0 \geq \inf u \int_\Omega u_0 = \inf u. \tag{17}$$

Next, define ϕ to be the solution of

$$\frac{d\phi}{dt} = \mu_0 \phi - \frac{\lambda}{(1+\phi)^2}, \tag{18}$$

$$\phi(0) = 0. \tag{19}$$

By standard comparison principles we have

$$E(t) \leq \phi(t) \tag{20}$$

for all time. Hence

$$\inf u \leq \phi(t) \tag{21}$$

and the "worst" behavior of u is captured by $\phi(t)$. In the ODE for ϕ we can separate variables and integrate to time T:

$$T = -\int_0^{\phi(T)} \frac{d\phi}{-\mu_0 \phi + \frac{\lambda}{(1+\phi)^2}}. \tag{22}$$

If the integral

$$\int_{-1}^{0} \frac{d\phi}{-\mu_0 \phi + \frac{\lambda}{(1+\phi)^2}} \tag{23}$$

is finite, we have existence for ϕ only for a finite interval and touchdown must occur in finite time. The integral remains finite if the denominator is never zero. But, we can guarantee that the integral remains finite if $\lambda > -\frac{4}{27}\mu_0$. The proof is finished. □

As in the case of stationary solutions, the set of parameter values for which touchdown occurs is an interval.

THEOREM 3.4. *There exists $\lambda^* > 0$ such that touchdown occurs if $\lambda > \lambda^*$. Moreover, touchdown does not occur for $\lambda < \lambda^*$.*

Proof. It is a consequence of the maximum principle: solutions of the parabolic equation (1) are strictly decreasing functions of λ in Ω. Therefore $B := \{\lambda | \text{touchdown occurs}\}$ is an interval, it is nonempty by the previous theorem, and $\lambda^* := \text{infimum}\, B$ has the required property. The proof is finished. □

Note that $\lambda_* \le \lambda^*$. Fila and Kawohl have proved in [5] that quenching in infinite time is not possible for convex domains in the plane. It follows that there is no gap for the type of domains we are considering, that is, $\lambda_* = \lambda^*$. Another consequence of the above mentioned result is the fact that $u(x, y, t, \lambda^*)$ is uniformly bounded away from -1. The argument in the proof of Theorem 3.2 guarantees that $u(x, y, t, \lambda^*)$ converges to a stationary solution as $t \to \infty$. Thus, we have proved the following.

THEOREM 3.5. *There exists a critical value λ^* such that the solution $u(x, y, t, \lambda)$ of the parabolic equation* (1) *converges as $t \to \infty$ to a stationary solution if $\lambda \le \lambda^*$. For $\lambda > \lambda^*$, touchdown in finite time occurs.*

If we define T^* as the touchdown time, we can bound T^* from above. Assume λ is such that touchdown occurs; then

$$T^* \le \int_{-1}^{0} \frac{ds}{-\mu_0 s + \frac{\lambda}{(1+s)^2}}. \tag{24}$$

We can also bound T^* from below. Suppose $v(t)$ solves

$$v_t = -\frac{\lambda}{(1+v)^2} \tag{25}$$

with

$$v(0) = 0; \tag{26}$$

then v is a lower solution for our problem. But, v touches down at time $t = \frac{1}{3\lambda}$, and hence

$$\frac{1}{3\lambda} \le T^* \le \int_{-1}^{0} \frac{ds}{-\mu_0 s + \frac{\lambda}{(1+s)^2}}. \tag{27}$$

3.3. Self-similarity and asymptotics of touchdown. For convenience, we restrict ourselves to a one-dimensional domain and consider the new dependent variable $w = 1 + u$, which is a solution of

$$w_t = w_{xx} - \frac{\lambda}{w^2}. \tag{28}$$

Following Giga and Kohn [7], we analyze the structure of solutions near touchdown by means of self-similar variables $y = \frac{x}{\sqrt{T-t}}$, $\tau = \ln\left(\frac{1}{T-t}\right)$, and

$$v(y, \tau) = (T-t)^{-1/3} w(x, t) = e^{\tau/3} w(e^{-\tau/2} y; T - e^{-\tau}); \tag{29}$$

then $v(y, \tau)$ is a solution of

$$v_\tau = v_{yy} - \frac{y}{2} v_y + \frac{1}{3} v - \frac{\lambda}{v^2} \tag{30}$$

in the region $|y| \le \frac{1}{2} e^{\tau/2}, \tau \ge \tau_0 := \ln\left(\frac{1}{T}\right)$, with boundary conditions $v\left(\pm\frac{1}{2} e^{\tau/2}, \tau\right) = e^{\tau/3}$. The initial condition for v is $v(y, \tau_0) = T^{-1/3}$.

It follows that $v(y, \tau)$ is an even function of y for each $\tau \ge \tau_0$.

Generically, $v(y, \tau)$ will converge to a stationary solution. However, there is a continuum of steady states.

The behavior as $y \to \infty$ of stationary solutions as well as the self-similar nature of touchdown for (28) has been described by Fila and Hulshof [3], under the assumption of the existence of nonconstant global solutions. We prove the existence of a continuum of even stationary global solutions.

We study the problem of existence of even stationary solutions, as our solution of (30) is an even function of y.

Thus, we consider solutions of

$$v'' - \frac{y}{2}v' + \frac{1}{3}v - \frac{\lambda}{v^2} = 0 \tag{31}$$

in $y \geq 0$ with $v(0) = \alpha > 0, v'(0) = 0$.

THEOREM 3.6. *For each $\alpha > 0$, the solution of the initial value problem above is defined for all $y \in [0, \infty)$.*

Proof. Assume that $v(y)$ is a solution defined for $y \in [0, y_0]$ and satisfying $v(y) > 0$ in that interval.

Consider the energy

$$E(y) := \frac{v'^2(y)}{2} + \frac{v^2(y)}{6} + \frac{\lambda}{v(y)}; \tag{32}$$

then $\frac{dE}{dy} = \frac{y}{2}v'^2(y) \leq yE(y)$. Therefore $E(y) \leq E(0)e^{y^2/2}$ with $E(0) = \frac{\alpha^2}{6} + \frac{\lambda}{\alpha}$. It follows that for $y \in [0, y_0]$,

$$\frac{\lambda}{E(0)}e^{-y^2/2} \leq v(y) \leq \sqrt{6E(0)}e^{y^2/4}. \tag{33}$$

This estimate proves the theorem. □

The next step is to get bounds on our solution $v(y, \tau)$.

LEMMA 3.1. *There exist positive constants c_j, for $j = 1, 2, 3$, such that*

$$c_3 \leq v(y, \tau) \leq c_1 + c_2|y| \tag{34}$$

for all y and τ in the domain of (30).

Proof. Choose $c_3 < T^{-1/3}$; then c_3 is a lower solution for the parabolic initial-boundary problem defined by (30) and our solution.

The upper bound for v is obtained as follows: choose c_1 in such a way that $c_1^3 < 3\lambda$; then

$$f(y) := \frac{c_2}{6}y - \frac{c_1}{3} + \frac{\lambda}{(c_1 + c_2 y)^2}$$

satisfies $f(0) > 0$, $f'(0) < 0$, it is convex, and it achieves a positive minimum, provided $c_2 > 4\lambda$. Now it is easy to verify that $c_1 + c_2 y$ satisfies the appropriate differential inequality for (30) in the part of the domain corresponding to $y > 0$. The inequality for the boundary values is achieved as long as $c_1 > 0$ and $c_2 > e^{-\tau_0/6}$. For the initial values it is enough to require that $c_1 \geq T^{-1/3}$, which is consistent with the estimate (27). It now follows that the upper bound holds in the part of the domain corresponding to $y > 0$. The upper bound in the entire domain is obtained from the symmetry of the functions involved in the comparison.

The results of Fila and Hulshof guarantee that stationary solutions are increasing and convex for $\alpha < (3\lambda)^{1/3}$. If the inequality is reversed, stationary solutions have

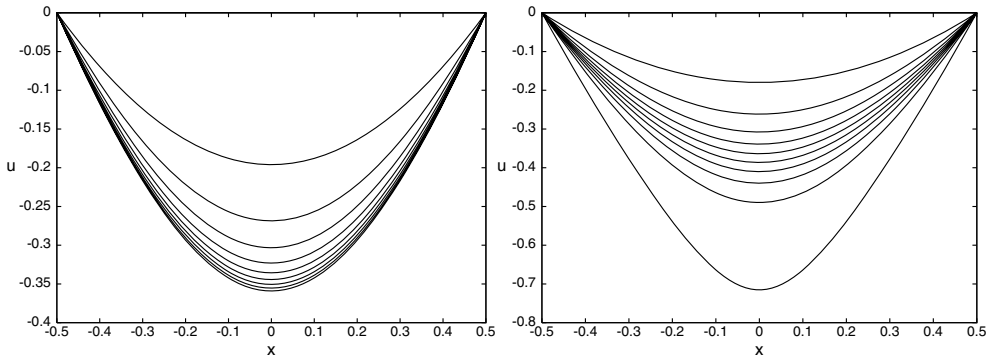

FIG. 1. *One dimension,* $\lambda = 1.4$*,* $t = 2$*, and* $\lambda = 1.45$*,* $t = 1.6$*.*

a single positive minimum in $(0, \infty)$. After that positive minimum, the solutions are increasing and convex.

By using variations of constants in (31), it is easy to see that a nonconstant stationary solution has a derivative that grows like $e^{y^2/4}$ as $y \to \infty$. This shows that our solution $v(y, \tau)$ converges to the constant stationary solution $(3\lambda)^{1/3}$, the convergence being uniform in bounded intervals of y. □

In summary, we have the following.

THEOREM 3.7. *Let* $u(x, t)$ *be the solution of* (5), (6), *and* (7)*; then*

$$u(x,t) = -1 + [3\lambda(T-t)]^{1/3}(1 + o(1)) \quad \text{as } t \to T. \tag{35}$$

The asymptotics is valid in the parabolic regions defined by $|y| \le C$*.*

Amplification. The asymptotic rate of touchdown obtained in Theorem 3.7 is valid if Ω is the unit disk. The same method of proof works since the only difference with respect to (31) is the extra term coming from the radial Laplacian. Thus, Theorem 3.6, Lemma 3.1, and Theorem 3.7 remain valid in a disk.

4. Numerics. We extensively use computing simulations to numerically solve (1) in the following domains: a strip shaped domain, an ellipse, and annular domains. In the one-dimensional case, we also show the validity of our analytical results by comparing numerical and analytical results in several regimes for the value of the parameter λ. The numerical simulation for the solutions of the initial boundary value problem is obtained by means of the Crank–Nicolson scheme, which is implicit and second order in space and time.

To present our numerical results in an accessible manner, we fixed the values of the parameters $\gamma = 1$, $q = 2$ and $\nu = 0.01$ and $\rho = 10$. Then we analyzed different regimes governed by the relative size of the dimensionless parameters λ. In particular we studied the regimes determined by $\lambda < \lambda^*$ and $\lambda > \lambda^*$, where the value of $\lambda^* = 1.400016469$ was obtained for a strip shaped domain in section 2.

4.1. One dimension, $\lambda < \lambda^*$ regime. Our numerical simulations confirm what our analytical results have shown above. As a solution of (1), we observe the generation of a smooth function on time and space with positive concavity which approximates the steady state solution as time goes to infinity. This is illustrated in Figure 1, where the zero initial condition evolves in the way just described. The value of λ for this particular example is 1.4. Note that we are very close to the critical value. The calculation ran up to time $T = 2$.

4.2. One dimension, $\lambda > \lambda^*$ regime. Here we used $\lambda = 1.45$, and the simulation went up to time $T = 1.6$. In Figure 1 we see clearly that at this time the solution is approaching the value -1 at $x = 0$. The solution $u(x,t)$ decreases in time up to what we have called touchdown time T_* when the solution ceases to be smooth. Due to the positive concavity of u, the local minimum also occurs at $x = 0$ where $\inf(u)$ is found. When the function reaches the value of -1 first at $x = 0$ the solution ceases to be continuously smooth and becomes a continuous function with a peak developed at this point. This occurs at a finite time that we called the "the touchdown time T_*." For $t \geq T_*$ we observe a smooth spatial profile, suggesting the existence of a weak solution after touchdown. See Figure 2, where the solution is plotted at time $t = 1.611$.

4.3. Two-dimensional geometries. We have also performed numerical calculation of the solutions for annular regions and ellipses. In the case of an ellipse, the solutions touch down at the center of the ellipse. In this case, the ellipse was transformed into a circle; then the most basic scheme for the heat equation was used, with first-order forward differences for the time derivative and second-order, centered differences for the space derivatives.

The graphs in Figure 3 correspond to the slice $y = 0$ and show the behavior of solutions for the ellipse with $a = 1$, $b = 1/2$. The values of λ are 1.3 and 1.8.

In the case of an annular region with outer radius 1, the solutions touch down at

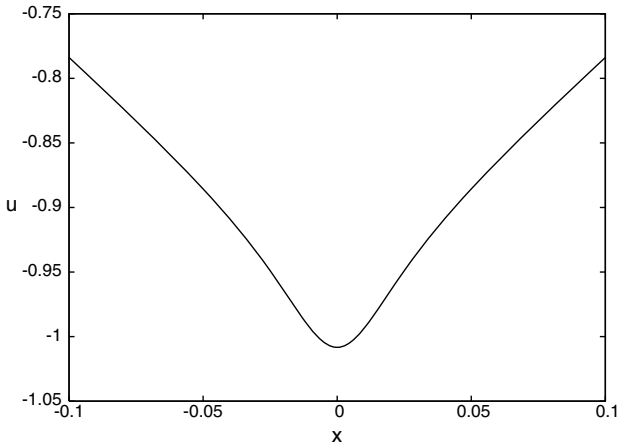

FIG. 2. *One dimension,* $\lambda = 1.45$, $t = 1.611$.

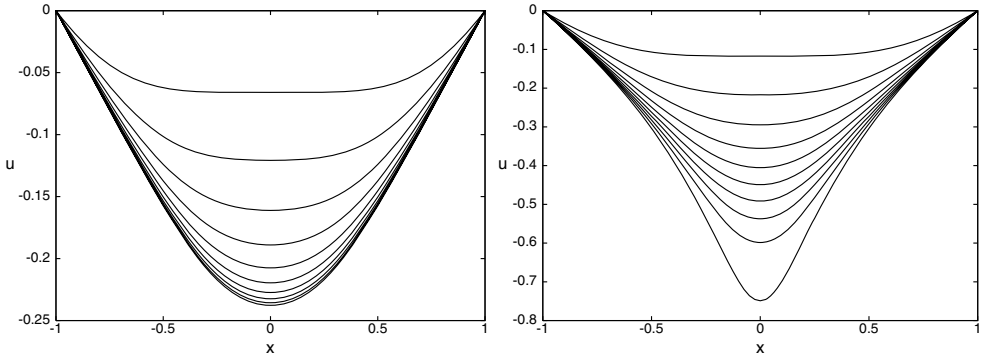

FIG. 3. *Ellipse,* $a = 1$, $b = .5$, $\lambda = 1.3$, $t = .5$, *and* $\lambda = 1.8$, $t = .63$.

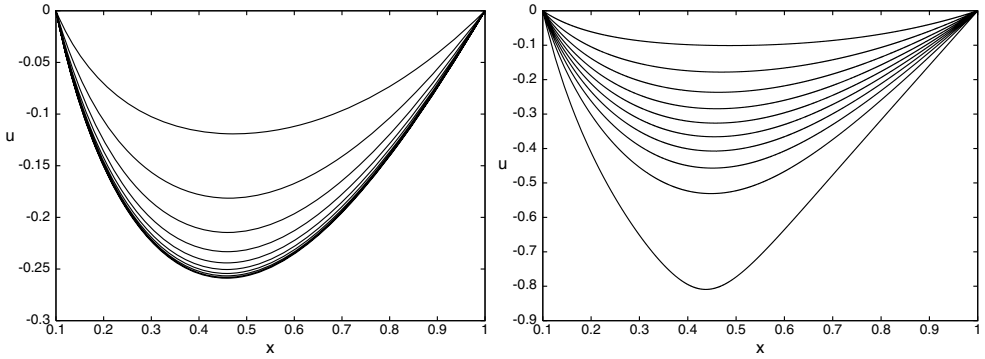

FIG. 4. *Annulus,* $r = .1$*,* $R = 1$*,* $\lambda = 1.4$*,* $t = 1$*, and* $\lambda = 1.8$*,* $t = .57$*.*

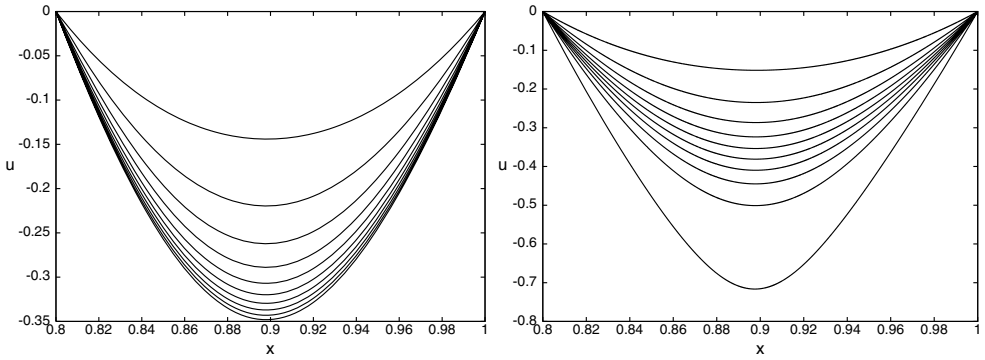

FIG. 5. *Annulus,* $r = .8$*,* $R = 1$*,* $\lambda = 35$*,* $t = .05$*, and* $\lambda = 37$*,* $t = .048$*.*

a circle, whose radius is an increasing function of the inner radius. In this case, we use the Crank-Nicolson method, as the problem is really one-dimensional.

It is interesting to observe the variation of the critical value λ^*: if the inner radius is .1, then $1.4 < \lambda^* < 1.8$. This is illustrated in Figure 4.

If the inner radius is .8, then $35 < \lambda^* < 37$, which resembles Corollary 2.1: thin annular regions have a very large critical value. See Figure 5.

Acknowledgments. We are grateful to A. Minzoni for pointing out the asymptotic behavior of stationary self-similar solutions and to A. Olvera for the numerical verification of this fact. We are also grateful to an anonymous referee for several helpful comments.

BOUNDARY-ROUGHNESS EFFECTS IN NEMATIC LIQUID CRYSTALS*

PAOLO BISCARI† AND STEFANO TURZI†

Abstract. We study the equilibrium configuration of a nematic liquid crystal bounded by a rough surface. The wrinkling of the surface induces a partial melting in the degree of orientation. This softened region penetrates the bulk up to a length scale which turns out to coincide with the characteristic wavelength of the corrugation. Within the boundary layer where the nematic degree of orientation decreases, the tilt angle steepens and gives rise to a nontrivial structure, which may be interpreted in terms of an effective weak anchoring potential. We determine how the effective surface extrapolation length is related to the microscopic anchoring parameters. We also analyze the crucial role played by the boundary conditions assumed on the degree of orientation. Quite different features emerge depending on whether they are Neumann- or Dirichlet-like. These features may be useful to ascertain experimentally how the degree of orientation interacts with an external boundary.

Key words. nematic liquid crystals, surface roughness, surface melting, weak anchoring

DOI. 10.1137/060656711

Introduction. Nematic liquid crystals are fluid aggregates of elongated molecules. When the nematic rods interact with an external surface, the elastic strain energy induces them to align parallel to the unit normal, even if the surface is not perfectly flat [1]. Recent experimental observations confirm that the surface alignment of the nematic director is completely determined by the roughness-induced surface anisotropy [2]. Further analytical calculations, performed within the classical Frank model with unequal elastic constants, have detected the bulk effects induced by a periodically molded external boundary [3, 4].

A crucial effect, still related to surface roughness, escapes the framework of Frank theory, where the only order parameter is the director. Indeed, it is physically intuitive that nematic molecules will disorder if we force them to follow a rapidly varying boundary condition. This *surface melting* was first experimentally detected in [5, 6]. Recent experimental observations have also measured a boundary-layer structure in the degree of orientation [7]. The surface melting has been confirmed by approximated analytical solutions [8], numerical calculations [9, 10], and molecular Monte Carlo simulations [11].

The combined effect of a rapidly varying director anchoring and surface melting gives rise to an effective weak-anchoring effect that was first observed in [12]. The problem of relating the effective anchoring extrapolation length to the microscopic roughness parameters has been studied in several theoretical papers, all framed within the Frank theory [13, 14, 15, 16]. This observation is of basic significance, since weak anchoring potentials have proven to influence deeply all nematic phenomena, beginning with Freedericksz transitions [17, 18, 19]. Indeed, several theoretical studies have already determined the influence on anchoring energies of the presence of permanent surface dipoles [20] or diluted surface potentials [21, 22].

In this paper we analyze in analytical detail the boundary-layer structure induced by a rough surface which bounds a nematic liquid crystal. We frame within the Landau–de Gennes order-tensor theory, to be able to detect the effects on both the director and the degree of orientation. Our results confirm the surface melting already obtained in [8] but allow us to detect new phenomena. First, the nematic director steepens close to the boundary, so giving rise to an effective weak anchoring potential, which turns out to be deeply related to the surface-melting effect, and thus can be correctly handled only within the order-tensor theory. Furthermore, the boundary layers display a strong dependence on the type of boundary conditions imposed on the degree of orientation. Indeed, the orders of magnitude of all the expected effects depend on whether the boundary conditions are Neumann- or Dirichlet-like. We discuss how these effects may help in ascertaining in experiments how the mesoscopic parameter, which measures the degree of order, interacts with an external surface.

The paper is organized as follows. In section 1 we present the model, we set the geometry of a roughly bounded sample, and derive the Euler–Lagrange partial differential equations that determine the equilibrium configurations. In section 2 we perform the perturbative two-scale analysis that provides all the analytical details of the boundary-layer structure. In section 3 we solve an effective problem, in which the rough surface is replaced by a weak-anchoring potential. As a result, we show that a weak-anchoring potential may be given a microscopic interpretation, and we relate the surface extrapolation length to the microscopic roughness parameters. In section 4 we draw our conclusions and discuss the validity of our geometric approximations. Two appendices collect the technical details of some lengthy calculations.

1. Equilibrium configurations. The degree of order decrease has been recognized by many authors as a crucial effect of surface roughness [8, 10]. We thus describe nematic configurations in the framework of the Landau–de Gennes $\mathbf{Q}$-tensor theory [23]. The order tensor is defined as the trace-free part of the second moment of the probability distribution of molecular orientations:

$$\mathbf{Q}(\mathbf{r}) := \int_{\mathbb{S}^2} (\mathbf{m} \otimes \mathbf{m})\, f_r(\mathbf{m})\, da - \frac{1}{3}\,\mathbf{I}\,, \tag{1.1}$$

where $\mathbf{I}$ denotes the identity tensor. $\mathbf{Q}$ is a second-order traceless symmetric tensor, with $\operatorname{sp}\mathbf{Q} \subset \left[-\frac{1}{3}, \frac{2}{3}\right]$ [18].

In order to keep computations simple, we adopt the one-constant approximation for the elastic part of the free-energy functional

$$f_{\mathrm{el}}[\mathbf{Q}] = \frac{1}{2}\, K\, |\nabla \mathbf{Q}|^2\,, \tag{1.2}$$

where K is an average elastic constant. We stress, however, that it is straightforward to generalize all what follows to take into account unequal material elastic constants.

The free-energy functional includes the Landau–de Gennes thermodynamic potential as well:

$$f_{\mathrm{LdG}}(\mathbf{Q}) = A \operatorname{tr}\mathbf{Q}^2 - B \operatorname{tr}\mathbf{Q}^3 + C \operatorname{tr}\mathbf{Q}^4\,. \tag{1.3}$$

The material parameter A depends on the temperature, and in particular it becomes negative deep in the nematic phase. By contrast, B, C can be assumed to be positive and temperature-independent. The potential (1.3) strongly favors uniaxial phases, in which at least two of the three eigenvalues of $\mathbf{Q}$ coincide. In fact, $\mathbf{Q}$ is expected

to abandon uniaxiality mainly close to director singularities [24, 25, 26]. We will not deal with any defect structure. Thus, though the uniaxiality constraint is not essential for our purposes, we follow the attitude of avoiding unnecessary complications and restrict our attention to uniaxial states

$$\mathbf{Q}(\mathbf{r}) = s(\mathbf{r}) \left(\mathbf{n}(\mathbf{r}) \otimes \mathbf{n}(\mathbf{r}) - \frac{1}{3}\mathbf{I} \right) . \tag{1.4}$$

We stress that we are not claiming that biaxiality effects are absent close to an external surface, since indeed the converse holds [27, 28, 29]. However, our results show that, even in the absence of biaxiality, a surface melting exists and an effective weak anchoring arises. A detailed treatment of the complete order-tensor theory would yield more precise quantitative estimates of the effects we will determine anyhow.

The scalar $s \in \left[-\frac{1}{2}, 1\right]$ and the unit vector $\mathbf{n}$ in (1.4) are, respectively, the *degree of orientation* and the *director*. With the aid of (1.4), the potentials (1.2), (1.3) can be written as

$$f_{\rm el}[s,\mathbf{n}] = K\left(s^2|\nabla\mathbf{n}|^2 + \tfrac{1}{3}|\nabla s|^2\right) \quad \text{and} \quad f_{\rm LdG}(s) = \tfrac{2}{3}A\,s^2 - \tfrac{2}{9}B\,s^3 + \tfrac{2}{9}C\,s^4 . \tag{1.5}$$

When $A \le B^2/(12C)$, the absolute minimum of the function $f_{\rm LdG}(s)$ occurs at the *preferred degree of orientation*

$$s_{\rm pr} := \frac{3B + \sqrt{9B^2 - 96AC}}{8C} > 0 . \tag{1.6}$$

In order to gain physical interpretation of the results, we also introduce the *nematic coherence length* ξ and the dimensionless (positive) parameter ω, defined as

$$\xi^2 := \frac{9K}{C} \qquad \text{and} \qquad \omega^2 := \frac{6}{C}\left(s_{\rm pr}B - 4A\right) . \tag{1.7}$$

The nematic coherence length compares the strength of the elastic and thermodynamic contributions to the free-energy functional. It characterizes the size of the domains where the degree of orientation may abandon its preferred value $s_{\rm pr}$. The number ω depends on the depth of the potential well associated with $s_{\rm pr}$. Indeed, it is defined in such a way that $f''_{\rm LdG}(s_{\rm pr}) = K\omega^2/\xi^2$.

By using (1.6), (1.7) we write the bulk free-energy density $f_{\rm b} := f_{\rm el} + f_{\rm LdG}$ as

$$\frac{f_{\rm b}[s,\mathbf{n}]}{K} = s^2|\nabla\mathbf{n}|^2 + \frac{1}{3}|\nabla s|^2 + \frac{1}{\xi^2}\left(s^4 - \frac{4}{3}s^3\left(2s_{\rm pr} - \frac{\omega^2}{s_{\rm pr}}\right) + 2s^2(s_{\rm pr}^2 - \omega^2)\right) . \tag{1.8}$$

1.1. Modeling a rough surface. We aim at analyzing the effects that a rough boundary induces in a nematic liquid crystal. Once again, we try to keep our analysis as simple as possible, while still catching the essential features. We thus follow, e.g., [13] in modeling roughness by imposing a sinusoidally perturbed homeotropic anchoring condition on a flat surface (see Figure 1.1). The amplitude and the wavelength characterizing the perturbation will be the crucial parameters in our results.

There are two nontrivial simplifications in our geometric setting. First, we are assuming that the boundary is perfectly sinusoidal, while a physical surface will clearly exhibit a whole roughness spectrum. Second, we are replacing an undulating boundary by an undulating boundary condition on a flat surface. We postpone until the final section a more detailed discussion on the validity of these simplifying assumptions. We anticipate, however, that none of them introduces qualitative errors. More precisely,

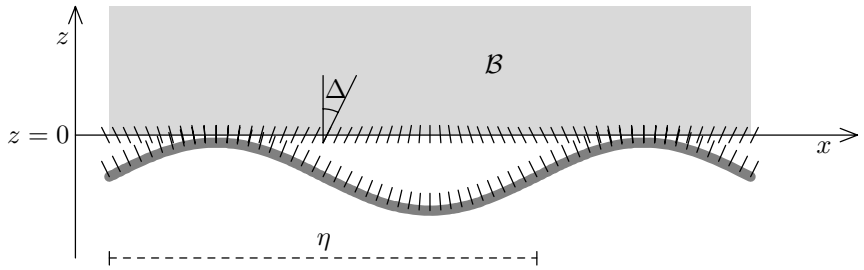

FIG. 1.1. *Geometric modeling of a rough surface. The physical surface oscillates with a characteristic wavelength η. The homeotropic anchoring at the oscillating boundary induces an oscillation of amplitude Δ in the boundary director. The bulk volume $\mathcal{B}$ is the grey region. Besides the microscopic roughness wavelength η, the two-scale analysis performed below is governed as well by the microscopic nematic coherence length ξ, introduced in* (1.7).

the latter amounts to performing an expansion in the roughness amplitude and keeping the leading order in the expansion. As for the treatment of the whole roughness spectrum, it turns out that at the same order of approximation one is allowed to treat a single wavelength at a time and eventually add up all the contributions.

We focus attention on a thin boundary layer, attached to the external surface. Consequently, we disregard the detailed structure of the bulk equilibrium configuration, which will enter our results only as asymptotic *outer* solution for the surface boundary layer. We introduce a Cartesian frame of reference $\{\mathbf{e}_x, \mathbf{e}_y, \mathbf{e}_z\}$ and assume that the nematic spreads in the whole half-space $\mathcal{B} = \{z \geq 0\}$. We further simplify the geometry by assuming that $\mathbf{n}(\mathbf{r}) = \sin\theta(\mathbf{r})\,\mathbf{e}_x + \cos\theta(\mathbf{r})\,\mathbf{e}_z$ and that the asymptotic bulk configuration depends only on z:

$$\theta(\mathbf{r}) \approx \theta_{\mathrm{b}}(z) \qquad \text{as} \quad z \to +\infty\,. \tag{1.9}$$

A crucial role in the developments below is played by $\mathrm{m} := \theta_{\mathrm{b}}'(0)$, the derivative of the asymptotic solution at $z = 0$, which has the physical dimensions of an inverse length. It represents the effect of any tilted bulk field that competes with the surface anchoring and may well be an electric or magnetic coherence length. Throughout our calculations we will assume that m^{-1} is much greater than both the nematic coherence length and the roughness wavelength. In the presence of an external field so strong that m^{-1} becomes of the order of, or even smaller than, the microscopic lengths above, the following asymptotic expansions fail. In particular, in this extreme regime the surface roughness effects may invade the whole bulk and cannot be replaced by an effective weak-anchoring potential.

In the presence of strong homeotropic anchoring on a flat surface, the boundary condition to be imposed on the director would be $\theta^{(\mathrm{flat})}(x, y, 0) = 0$. On the contrary, we will require

$$\theta(x, y, 0) = \Delta \cos\frac{x}{\eta}\,. \tag{1.10}$$

The boundary condition (1.10) mimics the rugosity of the external surface by introducing two new parameters: the (dimensionless) roughness amplitude Δ and the roughness wavelength η (see Figure 1.1). We remark that the oscillation rate increases as $\eta \to 0^+$, while all roughness effects are expected to vanish in the limit $\Delta \to 0^+$. The requirements (1.9), (1.10) imply that the free-energy minimizer will not exhibit

any dependence on the transverse y-coordinate, so that we will henceforth restrict our attention to the dependence on the coordinates (x, z).

It is more complex to ascertain the correct type of boundary conditions which are to be imposed on the degree of orientation s. From the mathematical point of view, it would be natural to imitate the (Dirichlet) strong anchoring imposed on the director and thus set $s(x, y, 0)$ to be equal to some fixed boundary value $\tilde{s}$. Nevertheless, while it is well established that we can induce an easy axis for the director on an external boundary, it is questionable whether we may fix the value of a mesoscopic parameter, which measures the degree of order in a distribution. From the physical point of view, stress-free (Neumann) boundary conditions on the degree of orientation deserve attention as well. In this latter case, we simply leave to the thermodynamic potential (1.3) the assignment of inducing the preferred value $s_{\rm pr}$ in the bulk ($z \to \infty$), while we perform no boundary action on the degree of orientation. To be safe, both possibilities (Dirichlet and Neumann) will be analyzed in section 2.

1.2. Euler–Lagrange equations. Once we consider that $|\nabla \mathbf{n}|^2 = |\nabla \theta|^2$, it is easy to derive the Euler–Lagrange partial differential equations associated with the functional (1.8). They read

$$s^2 \Delta\theta + 2\, s\, \nabla s \cdot \nabla\theta = 0 \qquad \text{and} \qquad \Delta s - 3\, s\, |\nabla\theta|^2 - 3\, \frac{\sigma(s)}{\xi^2} = 0\,, \tag{1.11}$$

where

$$\sigma(s) := s(s - s_{\rm pr}) \left(s - s_{\rm pr} + \frac{\omega^2}{s_{\rm pr}} \right) . \tag{1.12}$$

Since the boundary conditions (1.10) are x-periodic, with a period of $2\pi\eta$, we look for solutions of (1.11) in $C^2_{2\pi\eta}$ (the space of C^2-functions, $2\pi\eta$-periodic in the x-direction). To complete the differential system (1.10), in section 2.1 we will require

$$\begin{cases} \theta(x,0) = \Delta \cos \dfrac{x}{\eta} \\ \dfrac{\partial s}{\partial z}(x,0) = 0 \end{cases} \qquad \text{and} \qquad \begin{cases} \theta(x,z) \approx \theta_{\rm b}(z) \\ s(x,z) \approx s_{\rm pr} \end{cases} \qquad \text{as } z \to \infty\,, \tag{1.13}$$

while in section 2.2 we will choose

$$\begin{cases} \theta(x,0) = \Delta \cos \dfrac{x}{\eta} \\ s(x,0) = \tilde{s} \end{cases} \qquad \text{and} \qquad \begin{cases} \theta(x,z) \approx \theta_{\rm b}(z) \\ s(x,z) \approx s_{\rm pr} \end{cases} \qquad \text{as } z \to \infty\,. \tag{1.14}$$

2. Two-scale analysis. Before proceeding with the perturbation analysis of the differential equations, we state them in dimensionless form. It will turn out that the correct scaling is obtained by measuring lengths in η-units, so that we introduce the new dimensionless coordinates $\bar{x} = x/\eta$, $\bar{z} = z/\eta$ and define the dimensionless parameter $\varepsilon = \xi/\eta$. Equations (1.11) thus become

$$s^2 \Delta\theta + 2s\, \nabla s \cdot \nabla\theta = 0 \qquad \text{and} \qquad \varepsilon^2 \Delta s - 3\varepsilon^2 s\, |\nabla\theta|^2 - 3\sigma(s) = 0\,, \tag{2.1}$$

where both the gradient and the Laplacian are now to be intended with respect to the scaled variables. The nematic coherence length is usually much smaller than all other characteristic lengths. Consequently, we will look for uniformly asymptotic

solutions to (2.1), by treating ε as a small parameter. In this limit, $(2.1)_2$ is singular, so that a regular asymptotic expansion would not provide a uniform approximation of the solution. Indeed, the small parameter ε multiplies the highest derivative, so that we may expect the solution to have a steep behavior in a layer of thickness δ (to be determined), close to the boundary $z = 0$. We refer the reader to the books [30, 31, 32, 33] for the details of the singular perturbation theory we will apply henceforth and, in particular, for the technique of the two-scale method which directly yields a uniform approximation of the solution.

A standard dominant balance argument (that requires us to introduce a stretched variable $Z = \bar{z}/\delta$) allows us to recognize that the boundary layer thickness is $\delta = \varepsilon$. We then introduce the *fast* variable $Z = \bar{z}/\varepsilon$. The two-scale chain rule requires us to replace $\partial_{\bar{z}}$ by $\left(\partial_{\bar{z}} + \varepsilon^{-1}\partial_Z\right)$, and equations (2.1) take the form (when $s \neq 0$)

$$s\left(\varepsilon^2\theta_{,\bar{x}\bar{x}} + \varepsilon^2\theta_{,\bar{z}\bar{z}} + 2\varepsilon\theta_{,\bar{z}Z} + \theta_{,ZZ}\right) + 2\varepsilon^2 s_{,\bar{x}}\theta_{,\bar{x}} + 2(\varepsilon s_{,\bar{z}} + s_{,Z})(\varepsilon\theta_{,\bar{z}} + \theta_{,Z}) = 0\,, \tag{2.2}$$

$$\varepsilon^2 s_{,\bar{x}\bar{x}} + \varepsilon^2 s_{,\bar{z}\bar{z}} + 2\varepsilon s_{,\bar{z}Z} + s_{,ZZ} - 3s\left[\varepsilon^2(\theta_{,\bar{x}})^2 + (\varepsilon\theta_{,\bar{z}} + \theta_{,Z})^2\right] - 3\sigma(s) = 0\,, \tag{2.3}$$

where a comma denotes differentiation with respect to the indicated variable. In agreement with the two-scale method, θ and s are now to be intended as $\theta(\bar{x}, \bar{z}, Z)$ and $s(\bar{x}, \bar{z}, Z)$. In other words, θ and s are functions of $\bar{x}$, $\bar{z}$, and Z, which are to be regarded as *independent* variables. It will be only at the very end of our calculations that we will recast the connection between $\bar{z}$ and Z: $Z = \bar{z}/\varepsilon$. We seek solutions which may be given the formal expansions

$$\theta(\bar{x}, \bar{z}, Z) = \theta_0(\bar{x}, \bar{z}, Z) + \varepsilon\theta_1(\bar{x}, \bar{z}, Z) + \varepsilon^2\theta_2(\bar{x}, \bar{z}, Z) + O(\varepsilon^3)\,, \tag{2.4}$$

$$s(\bar{x}, \bar{z}, Z) = s_0(\bar{x}, \bar{z}, Z) + \varepsilon s_1(\bar{x}, \bar{z}, Z) + \varepsilon^2 s_2(\bar{x}, \bar{z}, Z) + O(\varepsilon^3)\,. \tag{2.5}$$

If we insert (2.4)–(2.5) into (2.2)–(2.3), we obtain the following differential equations to $\mathcal{O}(1)$, $\mathcal{O}(\varepsilon)$, and $\mathcal{O}\left(\varepsilon^2\right)$:

$$\begin{cases} \frac{1}{s_0}\left(s_0^2\theta_{0,Z}\right)_{,Z} = 0\,, \\ s_{0,ZZ} - 3s_0(\theta_{0,Z})^2 - 3\sigma(s_0) = 0\,, \end{cases} \tag{2.6}$$

$$\begin{cases} \frac{1}{s_0}\left(s_0^2\theta_{1,Z}\right)_{,Z} + \frac{1}{s_1}\left(s_1^2\theta_{0,Z}\right)_{,Z} = -2\left(s_0\theta_{0,Z}\right)_{,\bar{z}} - 2s_{0,Z}\theta_{0,\bar{z}}\,, \\ s_{1,ZZ} - 6s_0\theta_{0,Z}\theta_{1,Z} - 3s_1\left(\sigma'(s_0) + (\theta_{0,Z})^2\right) = 6s_0\theta_{0,Z}\theta_{0,\bar{z}} - 2s_{0,\bar{z}Z}\,, \end{cases} \tag{2.7}$$

$$\begin{cases} \frac{1}{s_0}(s_0^2\theta_{2,Z})_{,Z} + \frac{1}{s_2}(s_2^2\theta_{0,Z})_{,Z} = -\frac{1}{s_1}(s_1^2\theta_{1,Z})_{,Z} - \frac{1}{s_0}(s_0^2\theta_{0,\bar{z}})_{,\bar{z}} - \frac{1}{s_0}(s_0^2\theta_{0,\bar{x}})_{,\bar{x}} \\ \qquad\qquad - 2\left(s_0\theta_{1,Z}\right)_{,\bar{z}} - 2\left(s_1\theta_{0,Z}\right)_{,\bar{z}} - 2s_{1,Z}\theta_{0,\bar{z}} - 2s_{0,Z}\theta_{1,\bar{z}}\,, \\ s_{2,ZZ} - 3s_2\left[\sigma'(s_0) + (\theta_{0,Z})^2\right] - 6s_0\theta_{0,Z}\theta_{2,Z} = \frac{3}{2}s_1^2\sigma''(s_0) \\ \qquad + 3s_0\left[(\theta_{0,\bar{z}} + \theta_{1,Z})^2 + (\theta_{0,x})^2\right] \\ \qquad + 6\theta_{0,Z}\left(s_1\theta_{1,Z} + s_1\theta_{0,\bar{z}} + s_0\theta_{1,\bar{z}}\right) - 2s_{1,\bar{z}Z} - s_{0,\bar{z}\bar{z}} - s_{0,xx}\,. \end{cases} \tag{2.8}$$

Analogous equations can be easily derived at any desired order. For any $n \geq 1$, the differential system obtained at $\mathcal{O}(\varepsilon^n)$ is linear in the unknowns θ_n, s_n and may be solved analytically. By virtue of the multiscale method, we find the correct dependence on $\bar{z}, Z$ by requiring that all s_n, θ_n are uniformly bounded as $\varepsilon \to 0^+$ for expanding intervals of the type $0 \leq Z \leq Z^*/\varepsilon$, for a suitable positive constant Z^*. In most practical cases this requirement is equivalent to asking for the removal of secular terms (i.e., terms that diverge as $Z \to +\infty$).

2.1. Free surface degree of orientation. In terms of the scaled variables, the boundary conditions (1.13) require

$$\begin{cases} \theta(\bar{x},0) = \Delta\cos\bar{x} \\ s_{,\bar{z}}(x,0) = 0 \end{cases} \qquad \text{and} \qquad \begin{cases} \theta(\bar{x},\bar{z}) \approx \theta_{\mathrm{b}}(\eta\bar{z}) \\ s(\bar{x},\bar{z}) \approx s_{\mathrm{pr}} \end{cases} \qquad \text{when } \bar{z} \gg \eta\,. \tag{2.9}$$

The leading solutions in expansions (2.4), (2.5) are

$$s_0(x,z) = s_{\mathrm{pr}} \qquad \text{and} \qquad \theta_0(x,z) = \mathrm{m}\,z + \Delta \mathrm{e}^{-z/\eta}\cos\frac{x}{\eta}\,, \tag{2.10}$$

where $\mathrm{m} := \theta_{\mathrm{b}}'(0)$. Higher-order asymptotic solutions are gathered by means of laborious but straightforward calculations. After recasting the solutions in terms of the dimensional variables $x = \eta\,\bar{x}$ and $z = \eta\,\bar{z}$, we find

$$\begin{aligned} s(x,z) = s_{\mathrm{pr}} &- \frac{s_{\mathrm{pr}}\xi^2}{\omega^2}\left(\mathrm{m}^2 - \frac{2\,\mathrm{m}\,\Delta}{\eta}\,\mathrm{e}^{-z/\eta}\,\cos\frac{x}{\eta} + \frac{\Delta^2}{\eta^2}\,\mathrm{e}^{-2z/\eta}\right) \\ &+ \frac{2s_{\mathrm{pr}}\,\xi^3}{\sqrt{3}\,\omega^3}\,\mathrm{e}^{-\sqrt{3}\omega z/\xi}\left(\frac{\Delta^2}{\eta^3} - \frac{\mathrm{m}\,\Delta}{\eta^2}\cos\frac{x}{\eta}\right) + \mathcal{O}\left(\varepsilon^4\right) \end{aligned} \tag{2.11}$$

and

$$\begin{aligned} \theta(x,z) = \mathrm{m}\,z &+ \Delta\,\mathrm{e}^{-z/\eta}\,\cos\frac{x}{\eta} + \frac{\xi^2}{\omega^2}\left(\frac{2\,\mathrm{m}\,\Delta^2}{\eta}\left(1 - \mathrm{e}^{-2z/\eta}\right)\right. \\ &\left. - \frac{\Delta^3}{2\,\eta^2}\left(\mathrm{e}^{-z/\eta} - \mathrm{e}^{-3z/\eta}\right)\cos\frac{x}{\eta} - \frac{2\,\mathrm{m}^2\,\Delta}{\eta}\,z\,\mathrm{e}^{-z/\eta}\,\cos\frac{x}{\eta}\right) + \mathcal{O}\left(\varepsilon^4\right)\,. \end{aligned} \tag{2.12}$$

The above expansions have been carried out up to the first nontrivial correction of the 0th-order approximation. Indeed, all calculations must be pushed to $\mathcal{O}\left(\varepsilon^3\right)$, since an internal ξ-layer is necessary to satisfy the boundary condition (1.13) in $z = 0$. This layer is of $\mathcal{O}\left(\varepsilon^3\right)$ because in the Neumann case the boundary condition (1.13) concerns the first derivative of s, instead of the degree of orientation itself. We remark that the solutions (2.11)–(2.12) are coherently ordered for every fixed value of $\eta \neq 0$. However, they are not uniformly ordered when $\eta \in (0,\bar{\eta}]$; namely, we do not have a uniform solution if η is allowed to become of order ξ or, still worse, tend to zero. In other words, the above solutions remain valid as $\eta \to 0^+$ if and only if $\xi = o\,(\eta)$. The main properties of the equilibrium configurations in the mathematically appealing but physically uncommon case in which η is of the order of, or even smaller than, ξ will be presented elsewhere [34].

2.1.1. Surface melting. We can highlight three different contributions in the degree of orientation (2.11). First, we notice a uniform decrease in the degree of order, equal to $-s_{\mathrm{pr}}\mathrm{m}^2\xi^2/\omega^2$. This disordering effect is triggered by the θ-derivative m and was certainly to be expected. In fact, a glance to the free-energy functional (1.8) suffices to show that a reduction in s decreases the free energy whenever the gradient of the director is not null. We then find two boundary layers. The former, of thickness η and $\mathcal{O}\left(\varepsilon^2\right)$, is a further reduction of the degree of orientation due to the boundary roughness, which induces a director variation in the x-direction. An internal boundary layer, of thickness ξ and order $\mathcal{O}\left(\varepsilon^3\right)$, is finally needed in order to cancel the normal derivative of s at the external surface. If we take into account all

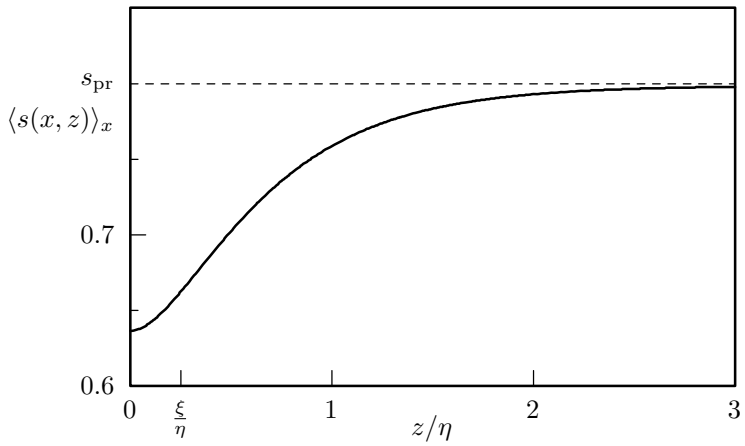

FIG. 2.1. *Boundary layers in the mean degree of orientation* $\langle s(x,z)\rangle_x$ *when* $\xi = 0.25\eta$, $s_{\rm pr} = 0.8$, $\omega = 0.6$, $\mathrm{m} = 0.1/\eta$, *and* $\Delta = 1.5$. *The plot exhibits the presence of* two *boundary layers, the internal one being required by the free boundary condition applied on* s.

the contributions, the mean surface degree of orientation, defined as the x-average of $s(x,0)$, turns out to be

$$\langle s(x,0)\rangle_x = s_{\rm pr}\left[1 - \frac{\mathrm{m}^2\xi^2}{\omega^2} - \frac{\Delta^2\xi^2}{\omega^2\eta^2} + \frac{2\Delta^2\xi^3}{\sqrt{3}\,\omega^3\eta^3}\right] + \mathcal{O}\left(\varepsilon^4\right) \ . \tag{2.13}$$

Figure 2.1 evidences the reported behavior of the mean degree of orientation as a function of the distance from the surface.

2.1.2. Effective surface angle. The tilt angle θ exhibits a boundary-layer structure as well. Equation (2.12) shows that such a layer is of $\mathcal{O}\left(\varepsilon^2\right)$ and thickness η. It gives rise to an interesting effective misalignment of the surface director. Indeed, if we allow $z \gg \eta$ in (2.12) we find that

$$\theta(x,z) \approx \theta_{\rm b}(z) = \frac{2\,\mathrm{m}\,\xi^2\Delta^2}{\eta\omega^2} + \mathrm{m}\,z \qquad \text{as} \quad z \gg \eta \ . \tag{2.14}$$

The asymptotic approximation (2.14) shows that an experimental observation, performed sufficiently far from the external plate (with respect to the microscopic scale η), would detect an *effective* tilt angle $\theta_{\rm b}$, whose value at the plate is different from zero, since

$$\theta_{\rm b}(0) = \frac{2\,\mathrm{m}\,\xi^2\Delta^2}{\eta\omega^2} \ . \tag{2.15}$$

Thus, a coarse observation of the nematic configuration measures a surface tilt angle slightly different from the homeotropic prescription $\theta_{\rm surf} = 0$. Figure 2.2 evidences this effect. In the next section we will analyze in more detail the result (2.15). Then we will show how it matches the predictions of an effective weak-anchoring potential. We remark that the tilt angle does not exhibit any further boundary layer at the smaller scale ξ.

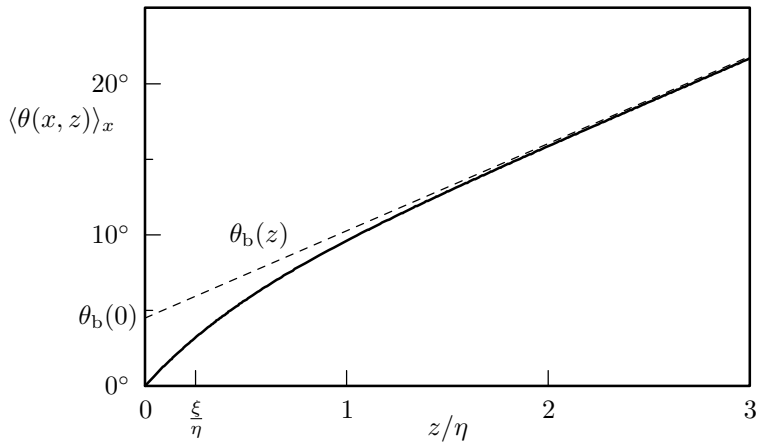

FIG. 2.2. *Boundary layer in the mean tilt angle* $\langle\theta(x,z)\rangle_x$ *when* $\xi = 0.25\eta$, $s_{\rm pr} = 0.8$, $\omega = 0.6$, $\mathrm{m} = 0.1/\eta$, *and* $\Delta = 1.5$. *The dashed line corresponds to the asymptotic, linear approximation* $\theta_{\rm b}(z)$.

2.2. Fixed surface degree of orientation. The perturbative analysis of the differential equations (1.11), with the Dirichlet boundary conditions (1.14), would be unnecessarily entangled because of the nonlinearity of the thermodynamic potential (1.12). In fact, in this case only implicit solutions for $s_0(x,z,Z)$ can be gathered. In order to pursue our analysis, and still catch the essential features of the solutions, we replace the function σ in (1.11) by its linear approximation $\sigma_1(s) = \omega^2(s - s_{\rm pr})$. This is tantamount to replacing the Landau–de Gennes potential in (1.5) by a tangent quadratic well, still centered in $s_{\rm pr}$. Such an approximation is certainly well justified deep in the nematic phase, when the isotropic state $s = 0$ becomes unstable, and the second well of the Landau–de Gennes potential can be neglected.

The asymptotic properties of the solutions in this case depend critically on the value $\tilde{s}$ forced on the surface. If $\tilde{s} \neq s_{\rm pr}$, the boundary layer induced by the Dirichlet condition dominates over the roughness effect. Indeed, the leading asymptotic solutions are given by

$$\begin{aligned} s(x,z) = {} & s_{\rm pr} - (s_{\rm pr} - \tilde{s})\, \mathrm{e}^{-\sqrt{3}\,\omega z/\xi} \\ & - \sqrt{3}\, (s_{\rm pr} - \tilde{s})\, \frac{\xi}{\omega}\, \mathrm{e}^{-\sqrt{3}\,\omega z/\xi} \left[\frac{\Delta^2}{4\eta} \left(1 - \mathrm{e}^{-2z/\eta}\right) + \frac{3}{2}\, \mathrm{m}^2\, z \right. \\ & \left. - 3\mathrm{m}\Delta \left(1 - \mathrm{e}^{-z/\eta}\right) \cos\frac{x}{\eta} + \frac{\Delta^2}{2\eta} \left(1 - \mathrm{e}^{-2z/\eta}\right) \cos\frac{2x}{\eta} \right] + \mathcal{O}\left(\varepsilon^2\right), \end{aligned} \tag{2.16}$$

$$\begin{aligned} \theta(x,z) = {} & \mathrm{m}\, z + \Delta \mathrm{e}^{-z/\eta} \cos\frac{x}{\eta} \\ & + \frac{\xi}{\sqrt{3}\,\omega} \left[h\left(\frac{z}{\xi}\right) - h(0) \right] \left(\mathrm{m} - \frac{\Delta}{\eta} \mathrm{e}^{-z/\eta} \cos\frac{x}{\eta} \right) + \mathcal{O}\left(\varepsilon^2\right), \end{aligned} \tag{2.17}$$

where

$$h(\zeta) = \log\left[s_{\rm pr} - (s_{\rm pr} - \tilde{s})\, \mathrm{e}^{-\sqrt{3}\,\omega\,\zeta} \right] - \frac{(s_{\rm pr} - \tilde{s})\, \mathrm{e}^{-\sqrt{3}\,\omega\,\zeta}}{s_{\rm pr} - (s_{\rm pr} - \tilde{s})\, \mathrm{e}^{-\sqrt{3}\,\omega\,\zeta}} \tag{2.18}$$

determines the tilt angle variation within the boundary layer. The bulk-asymptotic tilt angle is then given by

$$\theta(x,z) \approx \theta_{\mathrm{b}}(z) = \frac{\mathrm{m}\,\xi}{\sqrt{3}\,\omega}\left(\log\frac{s_{\mathrm{pr}}}{\tilde{s}} + \frac{s_{\mathrm{pr}}-\tilde{s}}{\tilde{s}}\right) + \mathrm{m}\,z \qquad \text{as} \quad z \gg \eta\,. \tag{2.19}$$

We remark that, when $\tilde{s} \neq s_{\mathrm{pr}}$, the leading contribution to $\theta_{\mathrm{b}}(0)$ is independent of Δ and thus does not depend on the surface roughness. Furthermore, the effective surface tilt angle depends linearly on ξ, which makes it significantly larger than the prediction (2.15), derived with Neumann-like boundary conditions on s, which possesses an extra ξ/η (small) factor. Finally, we remark the fact that $\theta_{\mathrm{b}}(0)$ shares the sign of m if and only if $\tilde{s} < s_{\mathrm{pr}}$. We will return below to the physical origin and implications of this result.

When the induced degree of orientation $\tilde{s}$ does exactly coincide with s_{pr}, all calculations simplify, since $h(\zeta) \equiv \log s_{\mathrm{pr}}$, and all first-order correction in (2.17) vanish. We therefore push our perturbation analysis and obtain

$$\begin{aligned} s(x,z) = s_{\mathrm{pr}} - \frac{s_{\mathrm{pr}}\xi^2}{\omega^2}\Bigg[\mathrm{m}^2 + \frac{\Delta^2}{\eta^2}\mathrm{e}^{-2z/\eta} - \frac{2\mathrm{m}\,\Delta}{\eta}\mathrm{e}^{-z/\eta}\cos\frac{x}{\eta} \\ - \mathrm{e}^{-\sqrt{3}\,\omega z/\xi}\left(\mathrm{m}^2 + \frac{\Delta^2}{\eta^2} - \frac{2\mathrm{m}\,\Delta}{\eta}\cos\frac{x}{\eta}\right)\Bigg] + \mathcal{O}\left(\varepsilon^3\right) \end{aligned} \tag{2.20}$$

$$\begin{aligned} \theta(x,z) = \mathrm{m}\,z + \Delta\,\mathrm{e}^{-z/\eta}\,\cos\frac{x}{\eta} + \frac{\xi^2}{\omega^2}\left(\frac{2\,\mathrm{m}\,\Delta^2}{\eta}\left(1-\mathrm{e}^{-2z/\eta}\right)\right. \\ \left. -\frac{\Delta^3}{2\,\eta^2}\left(\mathrm{e}^{-z/\eta}-\mathrm{e}^{-3z/\eta}\right)\cos\frac{x}{\eta} - \frac{2\,\mathrm{m}^2\,\Delta}{\eta}\,z\,\mathrm{e}^{-z/\eta}\,\cos\frac{x}{\eta}\right) + \mathcal{O}\left(\varepsilon^3\right)\,. \end{aligned} \tag{2.21}$$

Equation (2.21) allows us to compute the asymptotic tilt angle θ_{b} when $\tilde{s} = s_{\mathrm{pr}}$. In fact, once we drop all exponentially decaying terms in (2.21), we arrive at the interesting result that $\theta_{\mathrm{b}}(z)$ does exactly coincide with (2.14), that is, with the expression we derived with a Neumann-like boundary condition on the degree of orientation. In fact, the complete expression (2.21) for the tilt angle $\theta(x,z)$ coincides with (2.12) up to $\mathcal{O}\left(\varepsilon^3\right)$. Thus, any observation on the tilt angle is not able to distinguish among a free and a fixed boundary condition on the degree of orientation, as long as the imposed value $\tilde{s}$ coincides with the preferred value s_{pr}. This similarity between the Neumann and Dirichlet cases can be pursued further. Indeed, we can determine the $\mathcal{O}\left(\varepsilon^2\right)$-contributions in (2.16)–(2.17) also when $\tilde{s} \neq s_{\mathrm{pr}}$. If we then use them to compute the $\mathcal{O}\left(\varepsilon^2\right)$-correction to the asymptotic tilt angle (2.19), we arrive at the following expression, valid at $\mathcal{O}\left(\varepsilon^2\right)$ for any value of $\tilde{s}$:

$$\theta(x,z) \approx \theta_{\mathrm{b}}(z) = \left[\frac{\mathrm{m}\,\xi}{\sqrt{3}\,\omega}\left(\log\frac{s_{\mathrm{pr}}}{\tilde{s}} + \frac{s_{\mathrm{pr}}-\tilde{s}}{\tilde{s}}\right) + \frac{2\,\mathrm{m}\,\xi^2\Delta^2}{\eta\omega^2}\right] + \mathrm{m}\,z \quad \text{as } z \gg \eta, \tag{2.22}$$

which yields

$$\theta_{\mathrm{b}}(0) = \frac{\mathrm{m}\,\xi}{\sqrt{3}\,\omega}\left(\log\frac{s_{\mathrm{pr}}}{\tilde{s}} + \frac{s_{\mathrm{pr}}-\tilde{s}}{\tilde{s}}\right) + \frac{2\,\mathrm{m}\,\xi^2\Delta^2}{\eta\omega^2}\,. \tag{2.23}$$

The $\mathcal{O}\left(\varepsilon^2\right)$-contribution to the effective surface angle $\theta_{\mathrm{b}}(0)$ is thus fully a roughness effect and does not depend at all on the type of boundary conditions imposed on s.

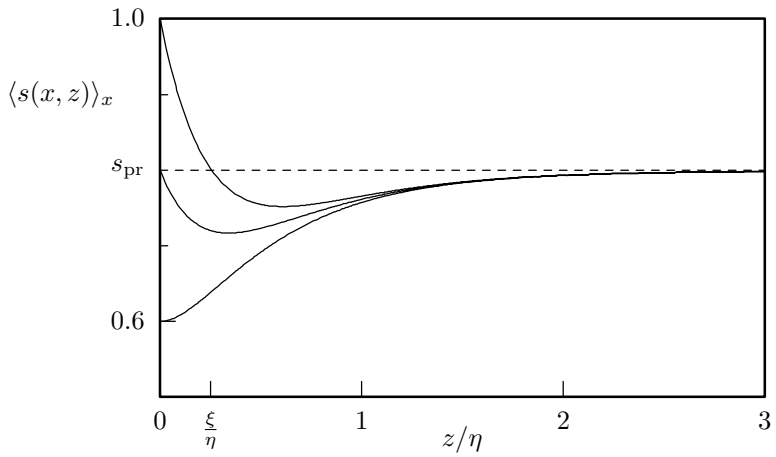

FIG. 2.3. *Boundary layers in the mean degree of orientation* $\langle s(x,z)\rangle_x$*, when* $\xi = 0.25\eta$*,* $s_{\rm pr} = 0.8$*,* $\omega = 0.6$*,* $\mathrm{m} = 0.1\eta$*, and* $\Delta = 1.5$*, when Dirichlet-like boundary conditions are applied on the degree of orientation. The boundary degree of orientation* $\tilde{s}$ *is, respectively, equal to* 1 *(top),* $s_{\rm pr}$ *(middle), and* 0.6 *(bottom).*

On the other hand, (2.23) confirms that the effective surface angle possesses also an $\mathcal{O}(\varepsilon)$-term when Dirichlet conditions are imposed on the degree of orientation, and $\tilde{s} \neq s_{\rm pr}$.

Figure 2.3 shows how the degree of orientation varies within the boundary layer as $\tilde{s}$ is fixed above, equal to, or below $s_{\rm pr}$. A double boundary-layer structure emerges. All plots exhibit a decrease of s in a region of characteristic size η: this effect comes from the $\mathcal{O}(\varepsilon^2)$-contribution. A similar surface melting was already presented and discussed in Figure 2.1. Close to the boundary, the $\mathcal{O}(1)$-term proportional to $(\tilde{s} - s_{\rm pr})\,\mathrm{e}^{-\sqrt{3}\,\omega z/\xi}$ settles the desired boundary value of s in a thin boundary layer of characteristic size ξ.

3. Effective weak anchoring. Once the boundary layer effects fade away, the main macroscopic effect of a rough surface on the director orientation is to allow for an effective surface tilt angle $\theta_{\rm b}(0)$, which apparently violates the homeotropic prescription $\theta(0) = 0$ (see (2.15) and (2.23)). It appears then natural to check whether the same macroscopic effect may be modeled through a weak anchoring potential, acting on a smooth surface. In this section we pursue this similarity, and we derive a relation connecting the microscopic roughness parameters with a macroscopic anchoring strength.

To solve the weak-anchoring problem, we consider a nematic liquid crystal which still spreads in the half-space $\mathcal{B} = \{z \geq 0\}$. To better compare our results with classical weak-anchoring models, we settle within Frank's director theory and thus look for the equilibrium distribution that minimizes the free-energy functional

$$\mathcal{F}[\mathbf{n}] := K \int_{\mathcal{B}} \left|\nabla \mathbf{n}\right|^2 dv + W \int_{\partial\mathcal{B}} f_{\rm w}[\mathbf{n}]\, da\,. \tag{3.1}$$

The bulk free-energy density in the functional (3.1) can be derived from its order-tensor theory counterpart by setting $s \equiv 1$ in (1.8). The anchoring potential $f_{\rm w}$ is required to attain its minimum at the homeotropic anchoring $\mathbf{n}\big|_{\partial\mathcal{B}} = \mathbf{e}_z$, while W is the *anchoring strength*.

We look again for equilibrium distributions of the type $\mathbf{n}(z) = \sin\theta(z)\,\mathbf{e}_x + \cos\theta(z)\,\mathbf{e}_z$. Thus, the free-energy functional (3.1) per unit transverse area can be written as

$$f[\theta] := K\int \theta'^2(z)\,dz + W\,f_{\mathrm{w}}\big(\theta(0)\big)\,, \tag{3.2}$$

where we assume $f'_{\mathrm{w}}(0) = 0$ and $f''_{\mathrm{w}}(0) > 0$, in order to guarantee the homeotropic preference. The minimizers of (3.2) satisfy the trivial Euler–Lagrange equation $\theta'' = 0$ and the boundary condition

$$K\theta'(0) - W f'_{\mathrm{w}}\big(\theta(0)\big) = 0\,. \tag{3.3}$$

When the anchoring strength W is large enough, the boundary condition (3.3) requires $\theta(0)$ to be small. When this is the case, a Taylor expansion in (3.3) supplies

$$\theta(0) \approx \frac{K\,\mathrm{m}}{W f''_{\mathrm{w}}(0)} = \zeta\,\mathrm{m}\,. \tag{3.4}$$

In (3.4) we have restored the notation $\mathrm{m} = \theta'(0)$, to better compare this estimate with our preceding results, and introduced the *surface extrapolation length*

$$\zeta := \frac{K}{W f''_{\mathrm{w}}(0)}\,, \tag{3.5}$$

a quantity that compares the relative strengths of the elastic and anchoring potentials.

The comparison between (3.4) and our results (2.15)–(2.23) relates the surface extrapolation length to the microscopic roughness parameters and/or the surface value of the degree of orientation. To further pursue this similarity we need to consider separately the different anchorings that may be applied to the degree of orientation.

- When s is free to choose its boundary value, (2.15) shows that the surface extrapolation length is given by

$$\frac{\zeta}{\xi} = \frac{2\Delta^2}{\omega^2}\,\frac{\xi}{\eta} + \mathcal{O}\left(\frac{\xi^2}{\eta^2}\right)\,. \tag{3.6}$$

  Thus, the anchoring strength increases when either the roughness amplitude Δ decreases (towards a smooth surface) or the roughness wavelength increases. An estimate of the order of magnitude of the effective roughness wavelength can be obtained by assuming typical values for the quantities involved in (3.6). Indeed, if we assume $\zeta \approx \xi$, $\Delta \approx 1$, and $\omega \approx \frac{1}{2}$, we arrive at $\eta \approx 10\xi$, which models a roughness wavelength in the hundredths of molecular lengths.
- When the boundary conditions fix the value of the degree of orientation at the surface, (2.23) yields

$$\frac{\zeta}{\xi} = \frac{1}{\sqrt{3}\,\omega}\left(\log\frac{s_{\mathrm{pr}}}{\tilde{s}} + \frac{s_{\mathrm{pr}} - \tilde{s}}{\tilde{s}}\right) + \frac{2\Delta^2}{\omega^2}\,\frac{\xi}{\eta} + \mathcal{O}\left(\frac{\xi^2}{\eta^2}\right)\,. \tag{3.7}$$

  Equation (3.7) shows that the surface extrapolation length includes two quite different contributions. The former depends on the difference between the boundary and the preferred values of the degree of orientation ($\tilde{s}$ and s_{pr}, respectively), while the latter depends on the surface roughness and indeed

coincides with (3.6). However, (3.7) may lose sense when $\tilde{s} > s_{\rm pr}$. Indeed, in this case ζ may become negative, so providing an *inverse* weak-anchoring effect. The physical origin of this odd result may be easily understood if we again resort to the $s^2|\nabla\theta|^2$-term in the free-energy density. By virtue of that term, the tilt angle prefers to limit its spatial variations in regions of higher s. If we force in the surface a higher degree of orientation than the bulk value, the tilt angle will flatten close to the surface, thus exhibiting the opposite behavior with respect to that shown in Figure 2.2. Equation (3.7) shows that this inverse effect may occur whenever

$$\frac{\tilde{s} - s_{\rm pr}}{s_{\rm pr}} \gtrsim \frac{\sqrt{3}\Delta^2}{\omega}\,\frac{\xi}{\eta} + \mathcal{O}\left(\frac{\xi^2}{\eta^2}\right)\,. \tag{3.8}$$

If we again replace the estimates above for Δ, ω, η, we arrive at the result that a fixed degree of orientation is able to completely hide the roughness-induced effective weak anchoring whenever $\tilde{s}$ exceeds $s_{\rm pr}$ by the 10% of the preferred value $s_{\rm pr}$ itself.

4. Discussion. We have examined both the boundary layer structure and the bulk effects of a rough surface bounding a nematic liquid crystal. Our main results may be summarized as follows.

- The roughness of the surface has been modeled by an oscillating anchoring condition, characterized by an oscillation amplitude Δ and a wavelength η. Figures 2.1 and 2.3 show that the rough boundary induces a partial melting in a neighborhood (of size η) of the external boundary. When Neumann-like boundary conditions are imposed on the degree of orientation, (2.13) quantifies the mean degree of order at the boundary. By contrast, were s to be forced to a prescribed value $\tilde{s}$ on the surface, (2.16) and (2.20) show that the boundary condition induces a thin boundary layer, determined by the nematic coherence length ξ.
- Once the degree of orientation decreases, the spatial variations of the tilt angle become cheaper, and thus θ is keen to steepen close to the external boundary. Figure 2.2 illustrates this effect. As a consequence, the effective boundary tilt angle $\theta_{\rm b}(0)$, extrapolated from the asymptotic outer solution $\theta_{\rm b}(z)$, becomes different from the null homeotropic prescription (see (2.15) and (2.23)). In section 3 we have shown that a similar effective anchoring breaking takes place when a weak-anchoring potential is assumed on a smooth surface (see (3.5) for the characteristic surface extrapolation length). The comparison between (3.4) and (2.15)–(2.23) allows one to relate the surface extrapolation length to the microscopic roughness parameters and/or the surface value of the degree of orientation (see (3.7) and (3.8)).

To conclude, we want to discuss the validity of two nontrivial simplifications we have introduced in our geometric setting. First, we have assumed that the boundary is perfectly sinusoidal, while a physical surface will exhibit a whole roughness spectrum. Second, we have replaced an undulating boundary by an undulating boundary condition on a flat surface. We collect in the appendices below the technical details of the calculations that may help in relaxing the above assumptions. Here we discuss the outcomes of such calculations.

As a first step towards dealing with a real, randomly wrinkled surface we have considered the case in which the boundary undulation may be described as a superposition of two sinusoidal undulations. We have thus solved the same equilibrium

problem by replacing the boundary condition (1.10) with the more general (A.1). Our main result, summarized in (A.2)–(A.3), is that the quantities that refer to the bulk *outer* solution simply add independently the contributions from each oscillation, without any interference effect. This result allows us to infer that, in the presence of a whole spectrum of independent roughness wavelengths, the global surface melting and the effective weak anchoring may be computed by simply adding each independent contribution in a Fourier integral.

We have then analyzed in detail how a homeotropic anchoring imposed on an undulating surface relaxes when entering the bulk. We have expanded the equilibrium configuration in power series of the dimensionless parameter δ, which represents the ratio between the height of the sinusoidal undulations and the roughness wavelength. A crucial result in the expansion is that the $O(\delta^n)$ contribution to the tilt angle possesses at most n nonzero Fourier components. Thus, taking into account only the first Fourier component when we evaluate the solution at a constant height (see (1.10)) amounts to neglecting $O(\delta^2)$ terms within the thin boundary layer. Equation (B.4) further supports our approximation. Indeed, it shows that the kth Fourier component induced by the undulating boundary decays in the bulk with a characteristic penetration length η/k. Thus, higher harmonics are penalized both by a higher-order δ^n coefficient and by a shorter penetration depth.

Appendix A. Roughness spectrum. Throughout the paper we have studied the bulk effects induced by the presence of a perfectly sinusoidal boundary. In real physical systems, however, the boundary roughness is mostly random, and a whole spectrum of roughness wavelengths is to be expected. In order to estimate whether the effects we have determined may be enforced or hidden by the interference between different wavelengths we briefly report here the results that may be obtained by replacing the boundary condition (1.10) by the more general

$$\theta(x,y,0) = \Delta_1 \cos\frac{x}{\eta_1} + \Delta_2 \cos\left(\frac{x}{\eta_2} + \phi_2\right) , \tag{A.1}$$

with $\eta_1/\eta_2 \notin \{\frac{1}{2}, 1, 2\}$, in order to avoid resonance effects.

We refer the reader to [34] for a complete overview and analysis of the results that follow. We here simply report how the main results are to be modified when stress-free (Neumann) boundary conditions are applied on the degree of orientation.

The first effect we have studied is the surface melting induced by the boundary roughness. Once we average along the x-direction and compute the solutions at the effective boundary $z = 0$, (2.13) is to be replaced by

$$\langle s(x,0)\rangle_x^{(2)} = s_{\mathrm{pr}}\left[1 - \frac{\mathrm{m}^2\xi^2}{\omega^2} - \frac{\xi^2}{\omega^2}\left(\frac{\Delta_1^2}{\eta_1^2} + \frac{\Delta_2^2}{\eta_2^2}\right) + \frac{2\xi^3}{\sqrt{3}\,\omega^3}\left(\frac{\Delta_1^2}{\eta_1^3} + \frac{\Delta_2^2}{\eta_2^3}\right)\right] + \mathcal{O}\left(\varepsilon^4\right) . \tag{A.2}$$

Expression (2.15) for the effective surface angle becomes

$$\theta_{\mathrm{b}}^{(2)}(0) = \frac{2\,\mathrm{m}\,\xi^2}{\omega^2}\left(\frac{\Delta_1^2}{\eta_1} + \frac{\Delta_2^2}{\eta_2}\right) . \tag{A.3}$$

Equations (A.2)–(A.3) show that the presence of more than one characteristic wavelength does not yield any dramatic result in the averaged quantities that interact with the bulk. In fact, they simply add their contributions, weighted by the roughness amplitudes. The situation is clearly more complex if we aim at computing the exact

solutions within the boundary layers [34]. In particular, the x-periodicity is lost as soon as the roughness wavelengths are not commensurable.

Appendix B. Modeling an undulating boundary. In section 1.1 we have modeled a homeotropic boundary condition imposed on an undulating surface through an oscillating boundary condition imposed on a flat surface. In this appendix we analyze the validity of such an approximation. In order to avoid unnecessarily lengthy calculations, we perform the present check within the Frank approximation, that is, by assuming that the nematic coherence length ξ is much smaller than all other lengths involved in the problem. When this is the case, the degree of orientation is constrained to the value $s_{\rm pr}$ that minimizes the Landau–de Gennes potential, the Euler–Lagrange equation $(1.11)_1$ becomes Laplace's equation, and thus the tilt angle θ is harmonic.

We consider the region $\mathcal{A} = \{(x,z) : z \geq \delta\eta \sin x\}$ and look for a x-periodic harmonic function $\theta : \mathcal{A} \to \mathbb{R}$ (with x-period η) that satisfies the boundary conditions

$$\theta(x, \delta\eta \sin \tfrac{x}{\eta}) = \arctan\bigl(\delta \cos \tfrac{x}{\eta}\bigr)\,, \qquad \theta(x,z) \approx \tilde{\theta}(z) \quad \text{as } z \to +\infty \tag{B.1}$$

for all values of x. The boundary condition $(B.1)_1$ guarantees that the unit vector $\mathbf{n} = \sin\theta\,\mathbf{e}_x + \cos\theta\,\mathbf{e}_z$ is homeotropically anchored to the physical boundary, while $(B.1)_2$ guarantees that the bulk configuration depends only on the z-coordinate. Let us expand the tilt angle in power series of the amplitude coefficient δ:

$$\theta(x,z) = \sum_{n=0}^{\infty} \theta_n(x,z)\,\delta^n\,. \tag{B.2}$$

We next Fourier-expand all functions θ_n along the periodic direction

$$\theta_n(x,z) = \sum_{k=0}^{\infty} a_{n,k}(z)\,\cos\frac{kx}{\eta} + \sum_{k=1}^{\infty} b_{n,k}(z)\,\sin\frac{kx}{\eta}\,. \tag{B.3}$$

The Laplace equation implies then

$$\theta_n(x,z) = \sum_{k=0}^{\infty} \alpha_{n,k}\,\mathrm{e}^{-kz/\eta}\cos\frac{kx}{\eta} + \sum_{k=1}^{\infty} \beta_{n,k}\mathrm{e}^{-kz/\eta}\,\sin\frac{kx}{\eta}\,, \tag{B.4}$$

where the coefficients $\{\alpha_{n,k}, \beta_{n,k}\}$ can be determined by requiring $(B.1)_1$ to hold.

Let us now compute the value the tilt angle attains at the (horizontal) height $z = \delta\eta$, which we aim to consider as effective flat boundary (see Figure 1.1). We obtain

$$\theta(x, \delta\eta) = \bigl(\delta - \delta^2\bigr)\cos\frac{x}{\eta} + \frac{\delta^2}{2}\sin\frac{2x}{\eta} + O(\delta^3)\,. \tag{B.5}$$

In general, it can be shown that the nth coefficient θ_n in expansion (B.2) contains only Fourier components up to $k \leq n$. Thus, the boundary condition (1.10) used in the text is exact up to $O(\delta^2)$. Furthermore, the roughness amplitude Δ simply coincides with δ, the (dimensionless) ratio between the height of the sinusoidal undulations and the roughness wavelength.

HIGH LEWIS NUMBER COMBUSTION WAVEFRONTS: A PERTURBATIVE MELNIKOV ANALYSIS*

SANJEEVA BALASURIYA†, GEORG GOTTWALD‡, JOHN HORNIBROOK‡, AND STÉPHANE LAFORTUNE§

Abstract. The wavefronts associated with a one-dimensional combustion model with Arrhenius kinetics and no heat loss are analyzed within the high Lewis number perturbative limit. This situation, in which fuel diffusivity is small in comparison to that of heat, is appropriate for highly dense fluids. A formula for the wavespeed is established by a nonstandard application of Melnikov's method and slow manifold theory from dynamical systems, and compared to numerical results. A simple characterization of the wavespeed correction is obtained: it is proportional to the ratio between the exothermicity parameter and the Lewis number. The perturbation method developed herein is also applicable to more general coupled reaction-diffusion equations with strongly differing diffusivities. The stability of the wavefronts is also tested using a numerical Evans function method.

1. Introduction.

In this article, we study the wavespeed of a combustion wavefront along a one-dimensional medium. This is a fundamental idealized problem towards understanding how flame fronts propagate and therefore has received a considerable amount of attention. There are several (nondimensional) parameters of importance: the Lewis number Le, the exothermicity parameter β, and the heat loss parameter ℓ. The first of these, the Lewis number, measures the relative importance of fuel diffusivity in comparison to that of heat. The exothermicity β is the ratio of the activation energy to the heat of reaction. The structure of the governing equations is such that an infinite Lewis number is considerably easier to deal with than allowing for fuel diffusivity. Many studies of this "solid" regime appear in the literature [5, 7, 28, 36, 37], and also the "gaseous" regime Le ≈ 1 has been frequently studied because of a symmetry in the equations [7, 20, 24, 37, 39]. Usually, the heat loss is neglected in these "adiabatic" studies. In several of these articles [28, 36, 37] the condition $\beta \gg 1$ is essential to the wavespeed and stability analysis. The case $\beta \ll 1$ has also been studied [8], in which a perturbative method is used to model the temperature. The bifurcation structure with respect to the heat loss parameter ℓ is addressed in [34], which obtains a stability diagram with respect to ℓ and the wavespeed.

We note that the limit of small fuel diffusivity (large, but not infinite, Lewis number) has not received much attention, perhaps because of the singularity of this limit in the governing equations. Yet this limit may be argued to be particularly appropriate for very high density fluids burning at high temperatures, such as would occur, for example, in the burning of toxic wastes at supercritical temperatures [25]. Even for solids, some mass diffusivity is to be expected at very high temperatures, particularly in the reaction zone in which liquification may occur. In [27], the mass diffusivity is modeled by an Arrhenius temperature dependence, which would result in a large effective Lewis number in certain situations (such as when the (scaled) adiabatic flame temperature is small in comparison to the activation energy for mass diffusion). It is this very large Lewis number limit which we study in this article, without restricting β. We do a detailed analysis of the wavespeed of combustion waves which can be supported. We also verify the linear stability of such wavefronts using an Evans function technique.

The model we use is for a premixed fuel in one dimension, with no heat loss and with an Arrhenius law for the reaction rate. These combustion dynamics can be represented in nondimensional form by [5, 8, 20, 24, 28, 34, 36, 37, 39]

$$\begin{cases} \dfrac{\partial u}{\partial t} = \dfrac{\partial^2 u}{\partial x^2} + y\, e^{-1/u}, \\ \dfrac{\partial y}{\partial t} = \dfrac{1}{\mathrm{Le}}\dfrac{\partial^2 y}{\partial x^2} - \beta\, y\, e^{-1/u}. \end{cases} \tag{1.1}$$

Here, $u(x,t)$ is the temperature, and $y(x,t)$ the fuel concentration, at a point x at time t. The parameters β and Le are as described earlier. We are neglecting heat loss (had we included it, an additional term $-\ell\,(u-u_a)$ for some ambient temperature u_a would be necessary on the right-hand side of the u equation in (1.1)). This one-dimensional model is also applicable to combustion in cylinders [30], with u and y being cross-sectionally averaged quantities in this case. See also [6, 7, 19, 26] for closely related governing equations. The nondimensionalization leading to (1.1) ensures that the cold boundary problem is circumvented (see [36] for a discussion). Since the Lewis number will be assumed large, set $\epsilon = 1/\mathrm{Le}$ with $0 \le \epsilon \ll 1$. This small ϵ limit clearly constitutes a singular perturbation in (1.1).

This article analyzes (1.1) as follows. In section 2, we determine the wavespeed as a function of β and ϵ. We initially consider the situation where $\mathrm{Le} = \infty$ (section 2.1), since this wavespeed is relevant to our subsequent perturbative analysis for $1 \ll \mathrm{Le} < \infty$ (sections 2.2, 2.3, and 2.4). While the infinite Lewis number situation is well studied, we are able to empirically determine a simple exponential formula for the wavespeed as a function of β. The case $1 \ll \mathrm{Le} < \infty$ is initially examined numerically in section 2.2, in which we obtain a method for computing the wavespeed. In the subsequent sections, we establish a theoretical estimate for the wavespeed with the help of two suitably modified tools from dynamical systems theory: a slow manifold reduction and Melnikov's method. In section 2.3, we reduce the dimensionality of the problem using a slow manifold reduction argument. This enables us in section 2.4 to utilize a nonstandard adaptation of Melnikov's method to find a theoretical estimate for the wavespeed. (This new technique is adaptable to other situations in which the wavespeed correction due to the presence of a small parameter is needed.) Our asymptotics enable the determination of a remarkably simple formula for the wavespeed, which is accurate for *all* β values (and not restricted to the "usual" large β limit). Essentially, we find that the relative wavespeed correction in going from an

infinite to a large Lewis number is proportional to (β/Le).

A brief stability analysis of the wavefronts is given in section 3. Having described the Evans function approach to stability in section 3, we compute the Evans function for high Lewis number combustion wavefronts using an exterior algebra [2, 16, 23, 40]. We note that in [20], an exterior algebra method has been successfully used to numerically investigate stability of wavefronts in combustion systems. A detailed stability analysis in the β-Le^{-1} plane is given therein for the system (1.1). As with infinite Lewis number fronts (see [5, 14, 28, 37]), [20] shows that stability occurs for small β but that, as β is increased, a Hopf bifurcation leads to an oscillatory instability. The β and Le values we test give results consistent with the stability boundary determined in [20]. Thus, stability properties remain essentially unaltered despite the singularity in the limit $\mathrm{Le} \to \infty$.

2. Wavespeed analysis. We seek wavefronts which travel in time, and hence set $u(x,t) = u(\xi)$ and $y(x,t) = y(\xi)$, where $\xi = x - c\,t$ and c is the traveling wave speed. Under this ansatz, (1.1) reduces to

$$\begin{cases} u'' + c\,u' + y\,e^{-1/u} = 0, \\ \epsilon\,y'' + c\,y' - \beta\,y\,e^{-1/u} = 0. \end{cases} \tag{2.1}$$

2.1. Wavefront for $\mathrm{Le} = \infty$. Set $\epsilon = 0$ in (2.1). Upon defining the new variable $v = u'$, the dynamics can be represented by a three-dimensional first-order system

$$\begin{cases} u' = v, \\ v' = -c\,v - y\,e^{-1/u}, \\ y' = \dfrac{\beta}{c}\,y\,e^{-1/u}. \end{cases} \tag{2.2}$$

The system (2.2) possesses a conserved quantity

$$H_c(u,v,y) = \beta\,v + \beta\,c\,u + c\,y, \tag{2.3}$$

since it is verifiable that $dH_c/d\xi = 0$ along trajectories of (2.2). Thus, motion is confined to planes defined by $H_c(u,v,y) = \text{constant}$. Now, for a wavefront, we require that $(u,v,y) \to (0,0,1)$ as $\xi \to \infty$; this corresponds to the region in which fuel is not yet burnt (and remains at its maximum nondimensional concentration of one) and the temperature (and its variation) is still zero. This point lies on $H_c(u,v,y) = c$, giving a well-known conservation relation [37]. At the other limit $\xi \to -\infty$, the fuel is completely burnt, and has reached a steady temperature, and so $(u,v,y) \to (u_B,0,0)$, where the temperature u_B is to be determined. Utilizing $H_c(u_B,0,0) = c$, we find that $u_B = 1/\beta$ is necessary; see also [8, 20, 37] for alternative ways to obtain this value.

Thus, we seek a heteroclinic solution of (2.2), which progresses between the fixed points $(1/\beta,0,0)$ and $(0,0,1)$, and is confined to the plane $\beta\,v + \beta\,c\,u + c\,y = c$; i.e., the fuel concentration obeys

$$y = 1 - \beta\,u - \frac{\beta}{c}\,v \tag{2.4}$$

at all values of ξ. Considering (2.2) under this restriction, we obtain

$$\begin{cases} u' = v, \\ v' = -\,c\,v - \left(1 - \beta\,u - \dfrac{\beta}{c}\,v\right)\,e^{-1/u}. \end{cases} \tag{2.5}$$

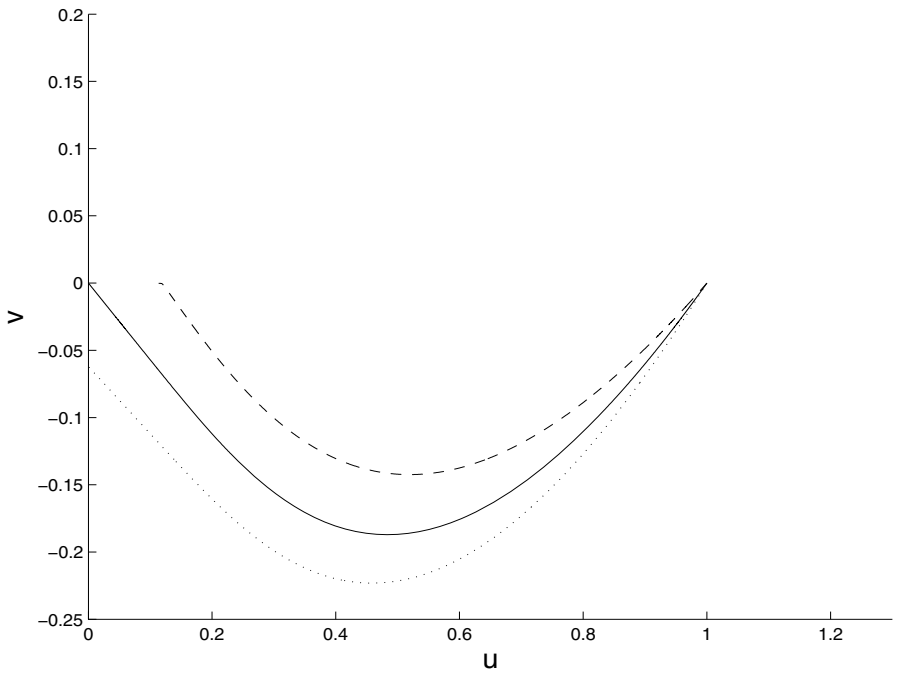

FIG. 2.1. *Projection onto the* (u, v)*-plane of trajectories of* (2.2) *lying on different planes* $H_c = c$*. Here,* $\beta = 1$*, and the three curves correspond to* $c = 0.5$ (*dotted*)*,* 0.5707 (*solid*)*, and* 0.7 (*dashed*)*.*

This is effectively a projection of the flow onto the particular invariant plane $H_c(u, v, y) = c$ onto the (u, v)-plane. Any value of c for which a heteroclinic connection exists between $(1/\beta, 0)$ and $(0, 0)$ is a permitted speed for the wavefront.

The unstable eigendirection of the point $(1/\beta, 0)$ is $(-c, -\beta e^{-\beta})$, and we determine c numerically by shooting along this direction and attempting to match up with a trajectory approaching the origin. In Figure 2.1 we show several numerically computed trajectories of this form, for different values of c, where we have chosen $\beta = 1$. Note that this is not a standard (u, v)-phase space for (2.5), since each curve corresponds to a different value of the parameter c. Rather, it is a projection onto the (u, v)-plane of specialized trajectories from the invariant planes $H_c(u, v, y) = c$ of the three-dimensional system (2.2). The one trajectory which makes the required connection lies in the invariant plane corresponding to $c = 0.5707$. The determination of this c value was obtained by making incremental adjustments of c until an appropriate connection is obtained.

We use this technique to numerically compute the wavespeeds for various values of the fuel parameter β, and we illustrate this dependence in Figure 2.2. The wavespeed decays with β. For fuels with larger β (poor fuels), the energy resulting from the reaction is insufficient to quickly activate combustion in nearby material, and combustion fronts propagate slowly. The data fits the exponential curve

$$c(\beta) = 0.927\, e^{-0.486\beta} \tag{2.6}$$

with correlation $\rho > 0.9999$. Equation (2.6) therefore provides an empirically determined formula of excellent accuracy for the speed of a wavefront in perfectly solid

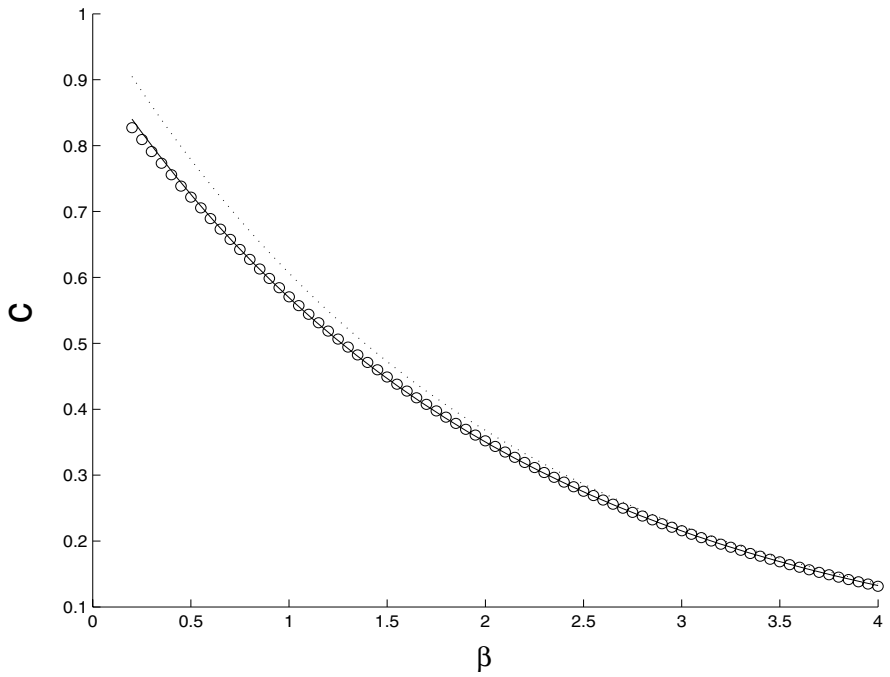

FIG. 2.2. *Variation of the wavespeed c with β: open circles (numerical results); unbroken curve (empirical curve (2.6)); dotted curve* $(\exp(-0.5\beta)$*, as obtained in* [7, 28, 36]).

adiabatic one-dimensional media. This result is close (and consistent with) a variety of sources: $\exp(-0.5\beta)$ is quoted in [36] for the small β limit; this same value is given as an upper bound in [7] and is also implied in eq. (10) in [28] using a large β limit within a discontinuous front approximation. See Figure 2.2 for a comparison with our results.

The structure of the temperature front is illustrated in Figure 2.3 for $\beta = 1$ (solid curve, left scale) and $\beta = 3$ (dashed curve, right scale), demonstrating that larger β fronts have a broader preheat layer preceding the front. Note that the preheat zone differs from the reaction zone [24]. The latter shrinks with increasing β [13]. Specifically, the reaction zone *as a fraction of the preheat zone* is $\mathcal{O}(1/\beta)$ [24, 28]. The reaction zone is well localized near the region of greatest temperature change [24] and is not immediately identifiable in temperature profiles as in Figure 2.3. Indeed, the increase in size of the preheat layer with β supports the $\mathcal{O}(1/\beta)$ expectation for the ratio between the reaction and the preheat zones.

2.2. Wavespeed for $1 \ll \mathbf{Le} < \infty$. When the Lewis number is not infinite, but large, ϵ is small, and weak fuel diffusion needs to be permitted. This is a *singular* limit in (1.1) and (2.1), and as a consequence has been hardly examined in the literature. By defining $v = u'$ as before, but now also $z = y'$, the governing equations (2.1) can be represented as a four-dimensional system

$$\begin{cases} u' = v, \\ v' = -c\,v - y\,e^{-1/u}, \\ y' = z, \\ z' = \dfrac{1}{\epsilon}\left(-c\,z + \beta\,y\,e^{-1/u}\right). \end{cases} \tag{2.7}$$

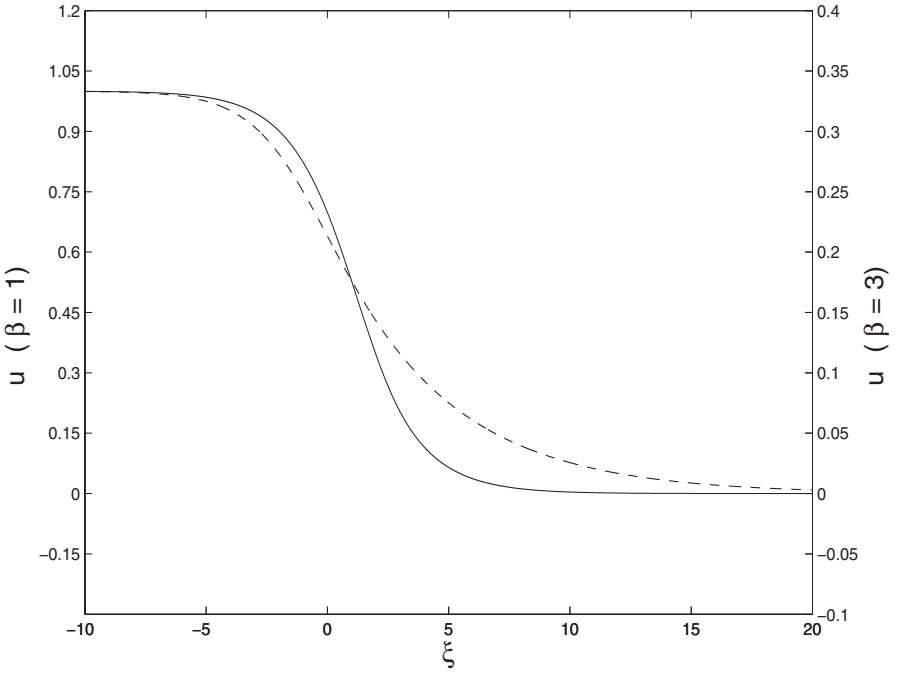

FIG. 2.3. *Temperature front at* $\beta = 1$ (*solid, left scale*) *and* $\beta = 3$ (*dashed, right scale*).

This is reducible to three dimensions: the quantity

$$G_c^\epsilon(u, v, y, z) = \beta\, v + \beta\, c\, u + c\, y + \epsilon\, z$$

can be verified to be a conserved quantity of (2.7). Hence, flow is confined to the invariant three-dimensional surfaces $G_c^\epsilon =$ constant. Now, we seek a wavefront solution which goes from $(u, v, y, z) = (u_B, 0, 0, 0)$ to a value $(0, 0, 1, 0)$, and we find that $G_c^\epsilon(u, v, y, z) = c$, and $u_B = 1/\beta$ as before. The three-dimensional invariant surface on which both points lie is

$$z = \frac{1}{\epsilon}\left(c - \beta\, v - \beta\, c\, u - c\, y\right) .$$

The dynamics of (2.7) on this surface can be projected onto the three variables (u, v, y), such that

$$\begin{cases} u' = v, \\ v' = -c\, v - y\, e^{-1/u}, \\ y' = \dfrac{1}{\epsilon}\left(c - \beta\, v - \beta\, c\, u - c\, y\right). \end{cases} \tag{2.8}$$

We seek the value of c which permits a heteroclinic connection from $(u, v, y) = (1/\beta, 0, 0)$ to $(0, 0, 1)$. The former point (corresponding to $\xi = -\infty$) has only one positive eigenvalue, given by $(-c + \sqrt{c^2 + 4\epsilon\beta e^{-\beta}})/(2\epsilon)$. For small ϵ, we "shoot" in the eigendirection corresponding to this, with an initial guess of the wavespeed given by (2.6). Thereafter, as in the previous section, we adjust c until we obtain a solution

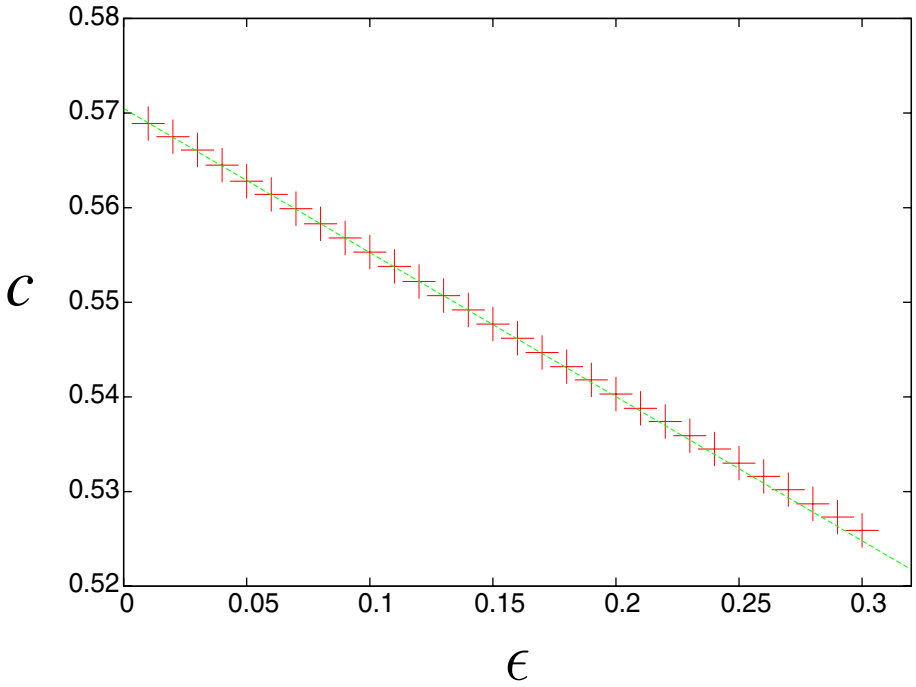

FIG. 2.4. *Numerically computed wavespeed variation with ϵ for $\beta = 1$ (the crosses). The dashed line is the theoretical approximation for $\beta = 1$ obtained from the methods of section* 2.4.

which approaches the point $(0, 0, 1)$ as $\xi \to \infty$. We do this numerically by considering the conditions $c\,y + \epsilon z = c$ and $v + c\,u = 0$, which the front must obey at $\xi = +\infty$, and using a root-finding algorithm to adjust c. For a fixed value $\beta = 1$, we illustrate how the wavespeed c varies with ϵ in Figure 2.4, with the crosses. The dashed curve in Figure 2.4 is a analytical/numerical approximation we obtain for the wavespeed in terms of an explicit formula (2.17). The next two sections describe how we obtain this formula.

We notice that c decreases as we increase ϵ, that is, when we *decrease* the Lewis number. Now, in dimensional form $\mathrm{Le} = \kappa/(\rho\, c_p\, D)$, where ρ, κ, c_p, and D are, respectively, the density, thermal conductivity, specific heat capacity, and molecular diffusivity of the fuel [6, 8, 30, 34, 37]. Increasing ϵ is equivalent to increasing the relative importance of D, ρ, and c_p in relation to κ. Reducing κ obviously decreases the ability of heat to move and hence the combustion speed. Higher densities result in increased fuel mass in each location, which means more heat is needed in a given area to ignite all of the fuel before the wave moves on. Fuels with increased c_p require more heat to increase the temperature by a specified amount. Finally, increasing D increases the transport of burnt fuel into the unburnt region and vice versa, interfering with front propagation.

We computed the changes to the wavefront profile (akin to Figure 2.3) when ϵ is changed (not shown). We verified the obvious physical conclusion that the fuel concentration front becomes less steep when ϵ is increased from zero.

2.3. Slow manifold reduction. We now show that in the limit of small ϵ, it is possible to further reduce the system (2.8) to a *two*-dimensional flow on a *slow*

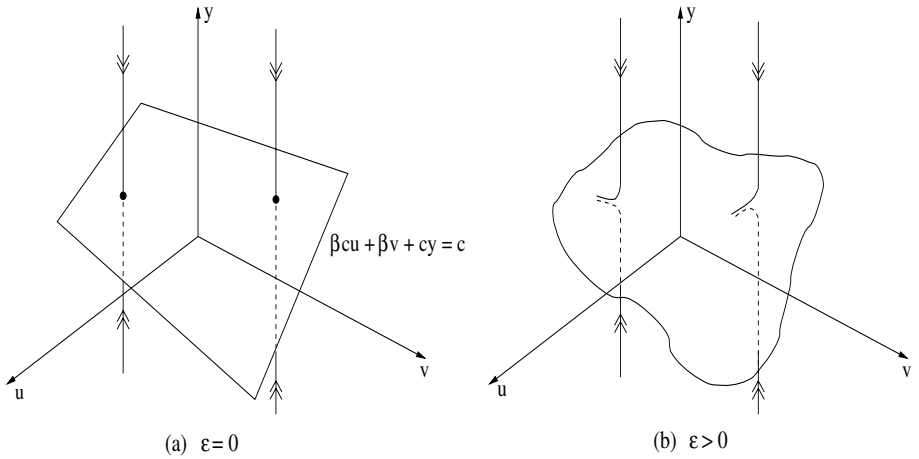

FIG. 2.5. *The hyperbolic invariant manifold* (a) $\mathcal{S}_0$ *for* (2.10) *and* (b) $\mathcal{S}_\epsilon$ *for* (2.9).

manifold. We begin with (2.8) and note that there are two "time"-scales in this singularly perturbed system, where we use "time" loosely to mean the independent variable ξ. We therefore adopt the standard dynamical systems trick of defining a new independent variable $\eta = \xi/\epsilon$ to elucidate motion in the fast "time" η. With a dot denoting the rate of change with respect to η, (2.8) becomes

$$\begin{cases} \dot{u} = \epsilon\, v, \\ \dot{v} = \epsilon \left(-c\, v - y\, e^{-1/u}\right), \\ \dot{y} = c - \beta\, v - \beta\, c\, u - c\, y. \end{cases} \tag{2.9}$$

In the $\epsilon = 0$ limit, the system collapses to

$$\begin{cases} \dot{u} = 0, \\ \dot{v} = 0, \\ \dot{y} = c - \beta\, v - \beta\, c\, u - c\, y, \end{cases} \tag{2.10}$$

in which it is clear that the plane $\mathcal{S}_0$ defined by $c - \beta\, v - \beta\, c\, u - c\, y = 0$ consists entirely of fixed points. This is the same plane as defined through $H_c(u, v, y) = c$ for (2.2), on which the interesting behavior occurred for perfectly solid fuels. Each fixed point has a one-dimensional stable manifold (in the y-direction), and a two-dimensional center manifold, which is $\mathcal{S}_0$. Thus the plane $\mathcal{S}_0$ is invariant and normally hyperbolic with respect to (2.10); there is exponential contraction towards it as illustrated in Figure 2.5(a).

Upon switching on ϵ and considering the dynamics (2.9), $\mathcal{S}_0$ perturbs to an invariant curved entity $\mathcal{S}_\epsilon$, which is order ϵ away from $\mathcal{S}_0$. This is because of the structural stability of normally hyperbolic sets [18], which also implies that normal hyperbolicity is preserved for small ϵ. Therefore, there is exponential decay of trajectories towards $\mathcal{S}_\epsilon$ on time-scales of order η, as shown in Figure 2.5(b). Motion on $\mathcal{S}_\epsilon$ occurs at a slower rate (on time-scales of order ξ), and hence it is termed a "slow manifold." The heteroclinic connection we seek lies on $\mathcal{S}_\epsilon$, from $(u, v, y) = (1/\beta, 0, 0)$ to $(0, 0, 1)$. Since $\mathcal{S}_\epsilon$ is invariant, two-dimensional, and not parallel to the y-axis, it therefore makes sense to project the motion onto the (u, v)-plane in order to describe behavior. To elucidate this motion, we need to once again return to the original time-scale ξ—the slow time associated with motion on the slow manifold.

We return to the relationship $G_c^\epsilon\,(u(\xi), v(\xi), y(\xi), z(\xi)) = c$, which upon differentiation yields

$$\beta\, v' + \beta\, c\, u' + c\, y' + \epsilon\, z' = 0\,,$$

and since $u' = v$ and $y' = z$,

$$z = -\frac{\beta}{c}\, v' - \beta\, v - \frac{\epsilon}{c} z'\,.$$

Substituting back into $G_c^\epsilon(u, v, y, z) = c$, we obtain

$$\beta\, v + \beta\, c\, u + c\, y + \epsilon \left(-\frac{\beta}{c}\, v' - \beta\, v + \mathcal{O}(\epsilon) \right) = c\,,$$

and thus

$$y = 1 - \frac{\beta}{c}\, v - \beta\, u + \epsilon\, \frac{\beta}{c^2}\, v' + \epsilon\, \frac{\beta}{c}\, v + \mathcal{O}(\epsilon^2)\,.$$

Substitution into the v' equation in (2.7) or (2.8) gives

$$v' \left(1 + \epsilon\, \frac{\beta}{c^2} e^{-1/u} \right) = -c\, v - \left(1 - \frac{\beta}{c}\, v - \beta\, u + \epsilon\, \frac{\beta}{c}\, v + \mathcal{O}(\epsilon^2) \right) e^{-1/u}\,.$$

Therefore

$$\begin{aligned} v' &= \left(1 - \epsilon\, \frac{\beta}{c^2} e^{-1/u} \right) \left[-c\, v - \left(1 - \frac{\beta}{c}\, v - \beta\, u + \epsilon\, \frac{\beta}{c}\, v \right) e^{-1/u} \right] + \mathcal{O}(\epsilon^2) \\ &= -c\, v - \left(1 - \frac{\beta}{c}\, v - \beta\, u \right) e^{-1/u} + \epsilon\, \frac{\beta}{c^2} \left(1 - \frac{\beta}{c}\, v - \beta\, u \right) e^{-2/u} + \mathcal{O}(\epsilon^2)\,. \end{aligned}$$

Retaining only $\mathcal{O}(\epsilon)$ terms, we obtain the (u, v)-projected approximate equations on the slow manifold

$$\text{(2.11)} \qquad \begin{cases} u' = v, \\ v' = -c\, v - \left(1 - \dfrac{\beta}{c} v - \beta\, u \right) e^{-1/u} + \epsilon\, \dfrac{\beta}{c^2} \left(1 - \dfrac{\beta}{c}\, v - \beta\, u \right) e^{-2/u}. \end{cases}$$

We will now show how to use these approximate dynamics to predict the correction to the wavespeed resulting from the inclusion of the finiteness of the Lewis number.

2.4. Perturbative formula for wavespeed. Here, we derive and numerically study a formula for the wavespeed correction in going from $\mathrm{Le} = \infty$ to finite Lewis number. Let

$$\text{(2.12)} \qquad c\,(\beta, \epsilon) = c_0\,(\beta) + \epsilon\, c_1\,(\beta) + \mathcal{O}\left(\epsilon^2\right),$$

where c_0 is the wavespeed associated with the infinite Lewis number ($\epsilon = 0$) combustion wavefront. In the spirit of perturbation analysis, we obtain a formula for the correction $c_1(\beta)$ purely in terms of the unperturbed ($\epsilon = 0$) wave, using a nontraditional application of "Melnikov's method" [29] from dynamical systems theory.

Melnikov's method is applied most commonly to area-preserving two-dimensional systems under time-periodic perturbations [4, 21, 38]. (Here, once again, ξ represents

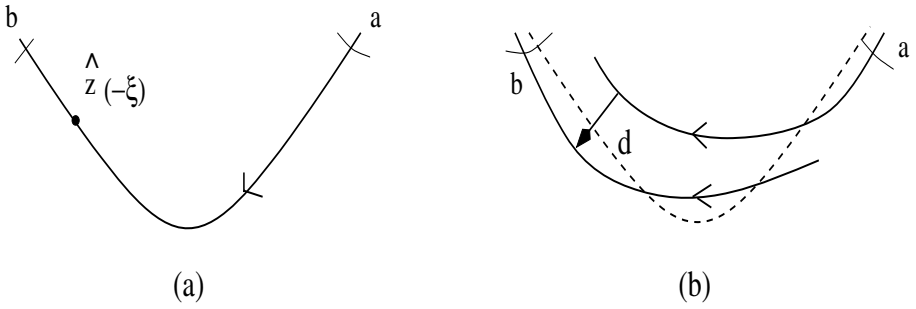

FIG. 2.6. *Manifold structure for the Melnikov approach:* (a) $\epsilon = 0$, (b) $\epsilon \neq 0$.

"time.") Our system (2.11) is not area-preserving and has a perturbation which is independent of the temporal variable. Under these conditions, we describe the method applied to the system

$$\mathbf{z}' = \mathbf{f}(\mathbf{z}) + \epsilon\, \mathbf{g}(\mathbf{z})\,. \tag{2.13}$$

When $\epsilon = 0$, suppose this system possesses a heteroclinic connection between the two saddle fixed points **a** and **b** as shown in Figure 2.6(a). A heteroclinic connection of this sort occurs when a branch of the one-dimensional unstable manifold of **a** coincides with a branch of the stable manifold of **b**. This heteroclinic trajectory can be represented as a solution $\mathbf{z} = \hat{\mathbf{z}}(\xi)$ to (2.13) with $\epsilon = 0$.

Now, for small $\epsilon > 0$ in (2.13), the fixed points **a** and **b** perturb by $\mathcal{O}(\epsilon)$ and retain their stable and unstable manifolds [18]. However, these need no longer coincide. Figure 2.6(b) shows how they can split apart, with the dashed curve showing the original manifold. Let $d(\xi, \epsilon)$ be a distance measure between these manifolds, measured along a perpendicular to the unperturbed heteroclinic drawn at $\hat{\mathbf{z}}(-\xi)$. The variable ξ can thus be used to identify the position along the heteroclinic curve (cf. "heteroclinic coordinates" of Section 4.5 in [38]). Since $d(\xi, 0) = 0$ for all ξ, this distance is Taylor expandable in ϵ in the form

$$d(\xi, \epsilon) = \epsilon\, \frac{M(\xi)}{|\mathbf{f}\,(\hat{\mathbf{z}}(-\xi))|} + \mathcal{O}(\epsilon^2)\,,$$

where the scaling factor $|f\,(\hat{\mathbf{z}}(-\xi))|$ in the denominator represents the unperturbed trajectory's speed at the location ξ. The quantity $M(\xi)$ is the "Melnikov function," for which an expression is

$$M(\xi) = \int_{-\infty}^{\infty} \exp\left[-\int_{-\xi}^{\mu} \nabla \cdot \mathbf{f}(\hat{\mathbf{z}}(s))\, ds\right] \mathbf{f}(\hat{\mathbf{z}}(\mu)) \wedge \mathbf{g}(\hat{\mathbf{z}}(\mu))\, d\mu\,, \tag{2.14}$$

where the wedge product between two vectors is defined by $(a_1, a_2)^T \wedge (b_1, b_2)^T = a_1 b_2 - a_2 b_1$. Obtaining the version (2.14) requires two adjustments to the standard Melnikov approaches [4, 21, 38]: incorporating the nonarea-preserving nature of the unperturbed flow of (2.13), and representing the distance in terms of heteroclinic coordinates. Details are provided in Appendix A. We need to ensure the persistence of a heteroclinic trajectory in (2.11) for $\epsilon > 0$ and thus require $d(\xi, \epsilon) = 0$ for all ξ. For this to happen for all small ϵ, we therefore need to set $M(\xi) \equiv 0$.

To apply this technique to our system, we begin by writing (2.11) in the form (2.13). Using the expansion (2.12), and utilizing binomial expansions for $1/(c_0+\epsilon c_1)$, we get

$$\begin{cases} u' = v, \\ v' = -c_0\, v - e^{-1/u}\Upsilon_{uv} + \epsilon\left(-c_1 v - \dfrac{\beta c_1 e^{-1/u}}{c_0^2} v + \dfrac{\beta e^{-2/u}}{c_0^2}\Upsilon_{uv}\right), \end{cases} \tag{2.15}$$

where higher-order terms in ϵ have been discarded, and

$$\Upsilon_{uv} = 1 - \beta\, u - \frac{\beta}{c_0}\, v\,.$$

By appropriately identifying $\mathbf{f}$ and $\mathbf{g}$ from (2.15) through comparison with (2.13), we see that

$$(\mathbf{f}\wedge\mathbf{g})\,(u,v) = v\left(-c_1 v - \frac{\beta c_1 e^{-1/u} v}{c_0^2} + \frac{\beta e^{-2/u}}{c_0^2}\Upsilon_{uv}\right)$$

and $\nabla\cdot\mathbf{f} = -c_0 + \beta e^{-1/u}/c_0$. Substituting into the Melnikov formula (2.14), and setting it equal to zero, we obtain

$$\int_{-\infty}^{\infty} \exp\left[\int_{-\xi}^{\mu}\left(c_0 - \frac{\beta}{c_0}e^{-1/u(s)}\right) ds\right] v\left(-c_1 v - \frac{\beta v c_1 e^{-1/u}}{c_0^2} + \frac{\beta e^{-2/u}}{c_0^2}\Upsilon_{uv}\right) d\mu = 0\,,$$

where each of $u(\mu)$ and $v(\mu)$ is evaluated along the $\epsilon = 0$ combustion wave. Notice, however, that for this infinite Lewis number combustion wave, (2.4) tells us that the fuel concentration $y(\mu) = \Upsilon_{uv}(\mu)$ for all μ. Therefore

$$c_1(\beta) = \beta\, \frac{\displaystyle\int_{-\infty}^{\infty} \exp\left[\int_{-\xi}^{\mu}\left(c_0 - \frac{\beta}{c_0}e^{-1/u(s)}\right) ds\right] v\, y\, e^{-2/u}\, d\mu}{\displaystyle\int_{-\infty}^{\infty} \exp\left[\int_{-\xi}^{\mu}\left(c_0 - \frac{\beta}{c_0}e^{-1/u(s)}\right) ds\right] v^2(c_0^2 + \beta\, e^{-1/u})\, d\mu}, \tag{2.16}$$

where $u(\mu)$, $v(\mu)$, and $y(\mu)$ in the integrands are obtained from the $\epsilon = 0$ combustion wave discussed in section 2.1. The apparent dependence of c_1 on the wave coordinate ξ is spurious: if I is an antiderivative of the inner integrals in (2.16), a multiplicative term $\exp[-I(-\xi)]$ emerges in both the numerator and denominator, which therefore cancels. Hence, any convenient value for ξ can be chosen in (2.16), for example, 0.

Equation (2.16) is a powerful expression in which the wavespeed correction is expressed purely in terms of the (unperturbed) infinite Lewis number wavefront and system parameters. This correction was obtained through an application of the slow manifold and Melnikov's method (suitably modified). While developed within the current specific context, we note that this technique can in fact be used in a variety of instances which are modeled through coupled reaction-diffusion equations in which the diffusivities are very different.

We note that $v < 0$ for the infinite Lewis number wavefront, as is clear from the phase portrait, Figure 2.1. Alternatively, u is smaller at the front of the wave, where fuel is yet to be burnt, and is therefore a decreasing function of μ, leading to $v = u' < 0$. Based on this, (2.16) immediately displays that $c_1 < 0$, proving the property that the wavespeed decreases when fuel diffusivity is included. This is in agreement with the numerical observations in section 2.2.

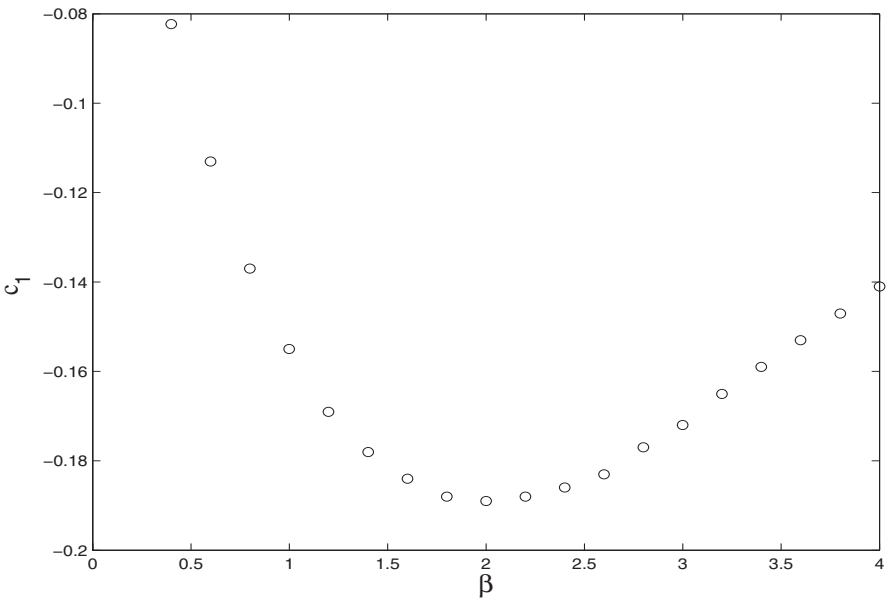

FIG. 2.7. *The perturbing wavespeed as a function of* β.

Equation (2.16) provides an explicit perturbative formula on how the wavespeed varies through the inclusion of the finiteness of the Lewis number, expressed entirely in terms of the infinite Lewis number combustion wave. This result is used to compute the solid line in Figure 2.4, which is the theoretical wavespeed $0.5707 - 0.1552\epsilon$ obtained by using (2.16) and (2.12) when $\beta = 1$. When ϵ is small, it forms an excellent approximation to the numerically obtained wavespeed, as described in section 2.2. Indeed, Figure 2.4 show that the theoretical line is tangential to the curve formed by the closed circles.

The perturbation wavespeed c_1 as a function of β appears in Figure 2.7. There is a value of β (around 2) at which the absolute influence of the finiteness of the Lewis number is greatest. Nevertheless, since c_0 is itself a function of β, it makes sense to investigate the *relative* influence c_1/c_0 of the perturbative term. This is presented in the numerically computed figure, Figure 2.8. The graph is virtually linear and has zero intercept. In other words, the complicated quotient in (2.16) is in fact proportional to the unperturbed wavespeed $c_0(\beta)$, with the proportionality factor *independent of* β. We therefore arrive at the approximation

$$c(\beta, \epsilon) = c_0(\beta)\,[1 - 0.267\,\epsilon\,\beta] = c_0(\beta)\left[1 - 0.267\,\frac{\beta}{\mathrm{Le}}\right], \tag{2.17}$$

for large Lewis numbers, with excellent validity across all β, and with $c_0(\beta)$ also known through (2.6).

Equation (2.17) shows that the wavespeed, as a fraction of the infinite Lewis number wavespeed, acquires a correction linear in the ratio β/Le. We are not aware of any such result being previously reported in the literature of combustion waves. Moreover, the simplicity of this expression is remarkable. For the specific instance $\beta = 1$, we apply this formula in order to arrive at the dashed line in Figure 2.4. Our perturbative theory has clearly given us a very accurate and simple approximation,

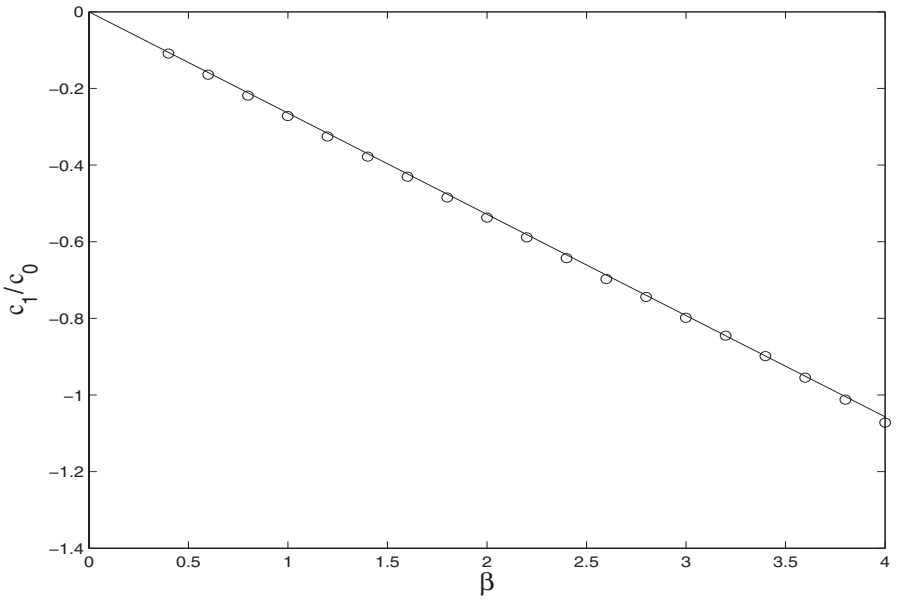

FIG. 2.8. *Relative size of perturbative wavespeed as a function of* β.

and elucidates the straightforward dependence of the wavespeed on the parameters β and Le.

3. Stability analysis. In this section, we test the stability of the combustion wavefront $(u, y) = (u_0(\xi), y_0(\xi))$ we have found as a solution to (1.1) at large Lewis numbers. Consider a perturbation of the form

$$u = u_0(\xi) + U(\xi)\, e^{\lambda t}, \qquad y = y_0(\xi) + Y(\xi)\, e^{\lambda t}. \tag{3.1}$$

At first order, U and Y satisfy an eigenvalue problem

$$\begin{pmatrix} U \\ V \\ Y \\ Z \end{pmatrix}' = \begin{pmatrix} 0 & 1 & 0 & 0 \\ \lambda - \frac{y_0}{u_0^2}\, e^{-1/u_0} & -c & -e^{-1/u_0} & 0 \\ 0 & 0 & 0 & 1 \\ \frac{\beta\, y_0}{\epsilon\, u_0^2}\, e^{-1/u_0} & 0 & \frac{\lambda}{\epsilon} + \frac{\beta}{\epsilon}\, e^{-1/u_0} & -\frac{c}{\epsilon} \end{pmatrix} \begin{pmatrix} U \\ V \\ Y \\ Z \end{pmatrix}. \tag{3.2}$$

Linear instability occurs if there are values of λ in the right half plane for which (3.2) possesses a solution uniformly bounded for all ξ. It turns out that such values of λ can be investigated by analyzing the Evans function [17], which is a complex analytic function $E(\lambda)$ whose zeros correspond to exactly these λ values. If, for example, it can be shown that $E(\lambda)$ has no zeros in the right half plane, the indications from the point spectrum of (3.2) is that the wavefront is stable. If there exist zeros of $E(\lambda)$ in the right half plane, the wavefront is unstable. A description of the Evans function as used in our study is given in Appendix B. This was proposed in [2, 16, 23, 40] and has been used by [20] for a detailed numerical analysis of (1.1). (It must also be mentioned that in the linear stability analysis, it is necessary to consider the essential spectrum associated with (3.2); it turns out that this has no intersection with the right half plane and therefore need not worry us further.)

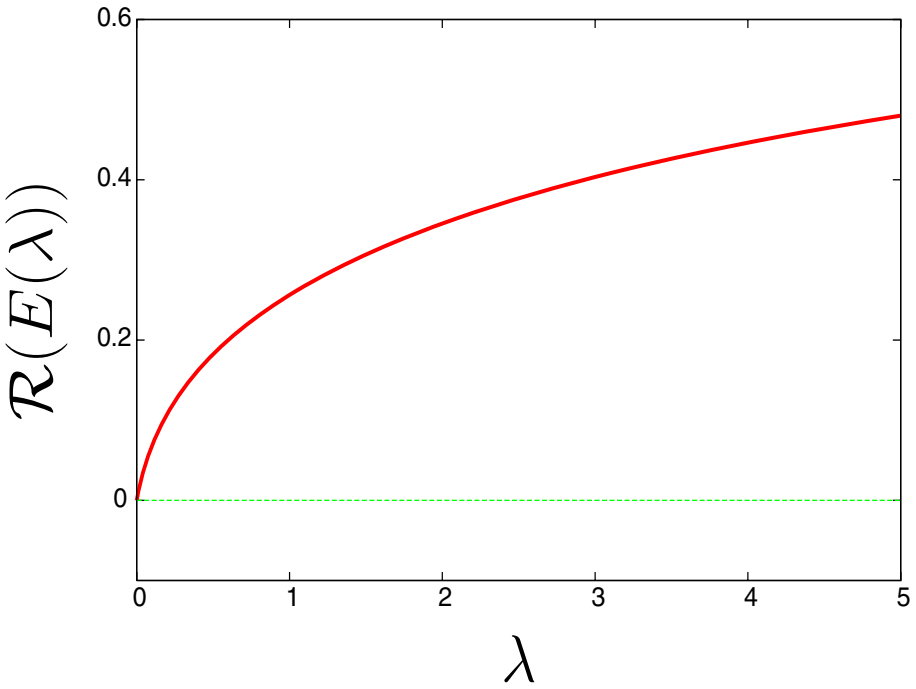

FIG. 3.1. *The real part of the Evans function* $E(\lambda)$ *for* Le=17 *and* $\beta = 1$ *as a function of* λ.

We begin with a traveling wave solution $u_0(\xi)$ and $y_0(\xi)$, obtained using standard shooting methods in section 2, and then compute the Evans function using the procedure outlined in Appendix B. We note that the system is very sensitive due to its stiffness. We found a solution to be accurate enough if we obtain $E(\lambda = 0) \sim \mathcal{O}(10^{-12})$. We are guided in our calculations by the detailed stability analysis of Gubernov et al. [20]. They show, for example, the lack of any eigenvalues of positive real part for small β but show that, for β large enough, two eigenvalues pop into the right half plane exhibiting a Hopf bifurcation. Physically, this corresponds to a pulsating instability in the wavefront, a well-known phenomenon also occurring for $\mathrm{Le} = \infty$ even in slightly different models [5, 14, 28, 37]. Gubernov et al. extend these infinite Lewis number analyses by producing in Figure 5 in [20] the stability boundary in β-ϵ space (their τ is our ϵ). We verify here that our numerically computed wavefronts display the characteristics outlined by them.

In Figure 3.1 we show the Evans function $E(\lambda)$ as it varies with increasing $\lambda \in \mathbb{R}$ for $\mathrm{Le} = 17$ and $\beta = 1$ (this corresponds to a stable regime in Figure 5 of [20]). We find that Evans function does not have any positive real roots. To test for complex roots we vary $\lambda \in i\mathbb{R}$; using Cauchy's theorem we can calculate the winding number to detect possible oscillatory instabilities. In the left panel of Figure 3.2 we show the complex Evans function. Since the system (1.1) is translationally invariant, the Evans function has at least a simple zero at $\lambda = 0$. We checked with a little off-set of the order $\mathcal{O}(10^{-5})$ whether the (real) value of the Evans function at $\lambda = 0$ is shifting towards larger values or smaller values. The off-set allows us to integrate parallel to the imaginary axis of λ and therefore excluding the zero of the Evans function stemming from the root at $\lambda = 0$. This enables us to attribute roots of the Evans function to either the translational mode or to a real instability. For the case depicted

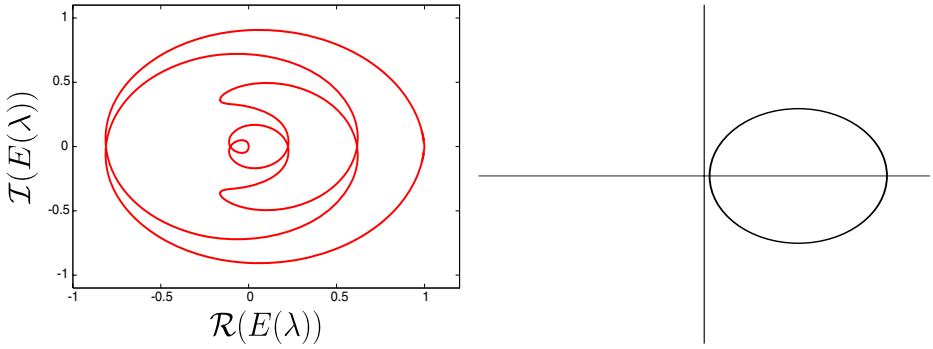

FIG. 3.2. *Left: The real versus the imaginary part of the Evans function* $E(\lambda)$ *for* Le=17 *and* $\beta = 1$. *The spectral parameter* λ *varies along the imaginary axis. Right: A sketch of a topologically equivalent Evans function. The winding number is clearly zero, indicating stability.*

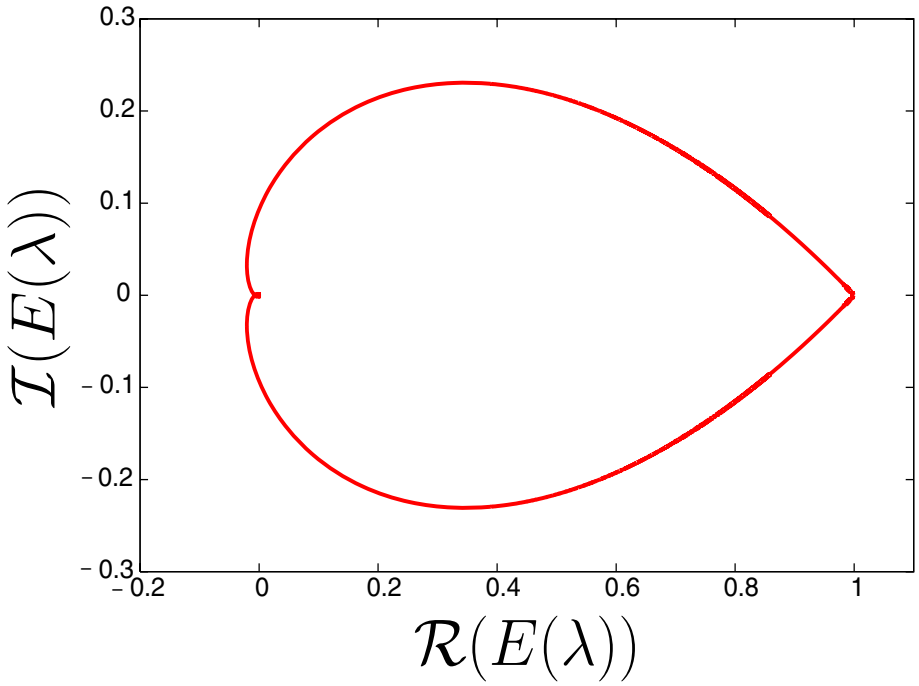

FIG. 3.3. *The real versus the imaginary part of the Evans function* $E(\lambda)$ *for* Le=100 *and* $\beta = 9$. *The spectral parameter* λ *varies along the imaginary axis.*

in Figure 3.2 we find that the Evans function moves to the right. This means that the Evans function can be cast in the topologically equivalent form depicted in the right panel of Figure 3.2 and it clearly has a winding number zero. We therefore find that at these parameter values there are no unstable eigenvalues. (Note that for this argument to work we need our definition of the Evans function to be analytic, which excludes standard methods such as Gram–Schmidt orthogonalizations.)

We next choose Le = 100 and $\beta = 9$, parameters at which (according to Figure 5 in [20]) an oscillatory instability is to be expected. In Figure 3.3 we show the Evans

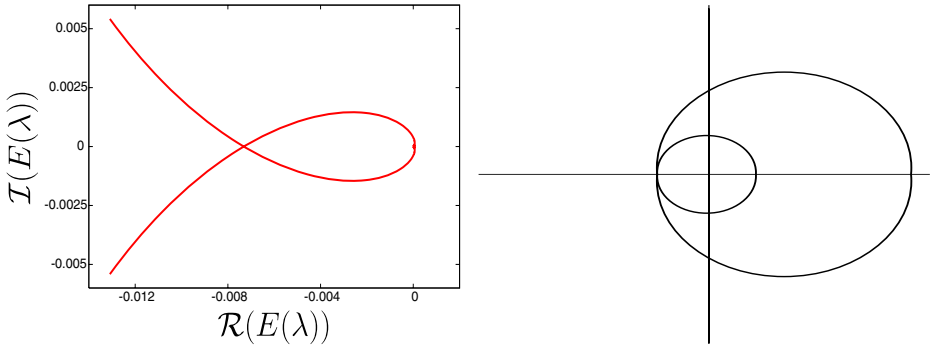

FIG. 3.4. *Left: Closeup of the Evans function depicted in Figure* 3.3 *into the region* $E(\lambda) = 0$. *Right: A sketch of a topologically equivalent Evans function. The winding number is clearly two, indicating an oscillatory instability.*

function in this situation, with a zoom in displayed in Figure 3.4. To determine the winding number we need to check whether or not the small circle of the Evans function in Figure 3.4 includes the zero. We can do so by allowing again for a small off-set of λ. We find that the circle includes zero. Unfolding the behavior of the Evans function then allows us to sketch a topologically equivalent Evans function as in the right panel of Figure 3.4. We verified that the instability is indeed oscillatory by examining the Evans function for $\lambda \in \mathbb{R}^+$, which reveals no zeros. Hence our wavefront displays the predicted characteristics of [20]. Stability properties are not affected unduly by the finiteness of the Lewis number, despite the singularity of this limit.

4. Concluding remarks. In this article, we have studied combustion wavefront in a one-dimensional medium. Our concentration was on very high Lewis numbers relevant to high-density supercritical combustion. We determine the wavespeed as a function of the exothermicity parameter β and the Lewis number Le, by seeking the wavespeed value which establishes a connection between the fixed points corresponding to the fully burnt and the unburnt states. The infinite Lewis number instance reveals an exponential dependence of the wavespeed on β, for which we determine an empirical formula. We then use several suitably modified dynamical systems techniques (slow manifold reduction and Melnikov's method) to compute an explicit formula (2.16) for the correction to the wavespeed when including the effect of a large, but not infinite, Lewis number. We hence obtain a simple formula (2.17) which shows that the relative change in the wavespeed is proportional to β/Le for large Lewis numbers. Our theory is shown to have excellent consistency with the numerically computed wavespeed for large Le, as we show in Figure 2.4.

The stability of the high Lewis number wavefronts is then tested numerically based on the Evans function technique. Our results are in agreement with the stability boundaries presented by Gubernov et al. in Figure 5 in [20].

We remark that the modified Melnikov's method that we have used can in fact be used in more general situations which are described by two coupled reaction-diffusion equations with strongly differing diffusivities. Based on a known wavefront or wave-pulse solution for when the smaller of the diffusivities is zero, our technique can in some instances be used to determine the wavespeed correction resulting from the inclusion of the (previously neglected) diffusivity. Alternatively, it can be adapted to situations in which the wavespeed changes due to some other small parameter. Our analysis of

high Lewis number wavefronts therefore provides a new perturbative methodology for analyzing certain classes of reaction-diffusion equations, pattern formation problems, and combustion waves.

Appendix A. Melnikov function derivation. We briefly outline the modifications needed to the standard Melnikov approaches [4, 21, 38] relevant to section 2.4. Our system is $\dot{\mathbf{z}} = f(\mathbf{z}) + \epsilon\, g(\mathbf{z})$, as given in (2.13). Consider a particular parametrization of the heteroclinic $\hat{\mathbf{z}}(\xi)$. Imagine the perturbed system as embedded in three-dimensional $(\mathbf{z}, s)$ space. In a "time"-slice $s = s_0$, let $\mathcal{T}$ be the normal vector to the heteroclinic drawn at the point $\hat{\mathbf{z}}(0) = \mathbf{z}_0$. The usual approach is to compute the distance between the perturbed manifolds measured along $\mathcal{T}$, and this is expandable as

$$d(s_0, \epsilon) = \epsilon\, \frac{M(s_0)}{|\mathbf{f}(\mathbf{z}_0)|} + \mathcal{O}(\epsilon^2)\,. \tag{A.1}$$

Let $\mathbf{z}^u(s)$ be the trajectory of the perturbed flow which intersects $\mathcal{T}$ and which backwards asymptotes to the perturbed fixed point $\mathbf{a}(\epsilon)$. In other words, $\mathbf{z}^u(s)$ is a trajectory lying on $\mathbf{a}(\epsilon)$'s unstable manifold. The standard approach [4, 21] is to represent

$$\mathbf{z}^\sigma(s) = \hat{\mathbf{z}}(s - s_0) + \epsilon\, \mathbf{z}_1^\sigma(s) + \mathcal{O}(\epsilon^2),$$

where $\sigma = u$ (for "unstable"), valid for $-\infty < s \leq s_0$. A similar expansion on $s_0 \leq s < \infty$ with $\sigma = s$ (for "stable") works for the trajectory $\mathbf{z}^s(s)$, which intersects $\mathcal{T}$ on the time-slice s_0 and which lies on the stable manifold of the perturbed fixed point $\mathbf{b}(\epsilon)$. Then, the standard Melnikov development (see [4, 21]) allows the representation

$$d(s_0, \epsilon) = \epsilon\, \frac{\Delta^u(s_0) - \Delta^s(s_0)}{|\mathbf{f}(\mathbf{z}_0)|} + \mathcal{O}(\epsilon^2)\,, \tag{A.2}$$

where

$$\Delta^\sigma(s) = \mathbf{f}(\hat{\mathbf{z}}(s - s_0)) \wedge \mathbf{z}_1^\sigma(s)$$

for $\sigma = u$ and $\sigma = s$. Now, [4, 21] derive that

$$\dot{\Delta}^\sigma = \nabla \cdot \mathbf{f}(\hat{\mathbf{z}}(s - s_0))\ \Delta^\sigma + \mathbf{f}(\hat{\mathbf{z}}(s - s_0)) \wedge \mathbf{g}(\hat{\mathbf{z}}(s - s_0), s) + \mathcal{O}(\epsilon) \tag{A.3}$$

but, since the unperturbed dynamical system is volume-preserving, have the luxury of ignoring the first term on the right-hand side. We cannot do so here, but we can neglect the second argument in $\mathbf{g}$, since our case is autonomous. To deal with the first term, we multiply (A.3) by the integrating factor

$$\mu(s) = \exp\left[-\int_0^s \nabla \cdot \mathbf{f}(\hat{\mathbf{z}}(r - s_0))\ dr\right]$$

before proceeding. Having done so, we integrate from $-\infty$ to s_0 by choosing $\sigma = u$, then integrate from s_0 to ∞ by choosing $\sigma = s$, and then add the two equations to get

$$\Delta^u(s_0) - \Delta^s(s_0) = \int_{-\infty}^{\infty} \frac{\mu(s)}{\mu(s_0)} \mathbf{f} \wedge \mathbf{g}(\hat{\mathbf{z}}(s - s_0))\ ds\,.$$

(This is an adaptation of the standard process [4, 21].) In conjunction with (A.1) and (A.2), and also employing the shift $s - s_0 \to s$ in the integrand, we obtain the Melnikov function

$$M(s_0) = \int_{-\infty}^{\infty} \exp\left[-\int_0^s \nabla \cdot \mathbf{f}\left(\hat{\mathbf{z}}(r)\right)\, dr\right] \mathbf{f} \wedge \mathbf{g}\left(\hat{\mathbf{z}}(s)\right) ds,$$

which no longer depends on s_0. Having dealt with the nonvolume-preserving instance, the next step is to change our attitude: rather than measuring the distance in a time-slice s but at a *specific* point $\mathbf{z}_0$, we ignore time-slices (since our perturbed system is itself autonomous) and allow the point to vary along the heteroclinic. To do so, choose a *different* parametrization $\hat{\mathbf{w}}(s) = \hat{\mathbf{z}}(s-\xi)$ of the heteroclinic. Thus, the point $\mathbf{w}_0 = \hat{\mathbf{w}}(0) = \hat{\mathbf{z}}(-\xi)$ can be varied along the heteroclinic by choosing different values of ξ. Therefore, ξ will represent different points along the heteroclinic at which the distance measurement is to be made (cf. "heteroclinic coordinates" of [38]). Using the $\mathbf{w}$ trajectory, our earlier results can be expressed as

$$d(s_0, \xi) = \epsilon \frac{M(s_0, \xi)}{|\mathbf{f}\left(\mathbf{w}_0\right)|} + \mathcal{O}(\epsilon^2) = \epsilon \frac{M(\xi)}{|\mathbf{f}\left(\mathbf{z}(-\xi)\right)|} + \mathcal{O}(\epsilon^2), \tag{A.4}$$

where

$$\begin{aligned} M(\xi) &= \int_{-\infty}^{\infty} \exp\left[-\int_0^s \nabla \cdot \mathbf{f}\left(\hat{\mathbf{w}}(r)\right) dr\right] \mathbf{f} \wedge \mathbf{g}\left(\hat{\mathbf{w}}(s)\right) ds \\ &= \int_{-\infty}^{\infty} \exp\left[-\int_0^s \nabla \cdot \mathbf{f}\left(\hat{\mathbf{z}}(r-\xi)\right) dr\right] \mathbf{f} \wedge \mathbf{g}\left(\hat{\mathbf{z}}(s-\xi)\right) ds \\ &= \int_{-\infty}^{\infty} \exp\left[-\int_0^{s+\xi} \nabla \cdot \mathbf{f}\left(\hat{\mathbf{z}}(r-\xi)\right) dr\right] \mathbf{f} \wedge \mathbf{g}\left(\hat{\mathbf{z}}(s)\right) ds \\ &= \int_{-\infty}^{\infty} \exp\left[-\int_{-\xi}^{s} \nabla \cdot \mathbf{f}\left(\hat{\mathbf{z}}(r)\right) dr\right] \mathbf{f} \wedge \mathbf{g}\left(\hat{\mathbf{z}}(s)\right) ds\,. \end{aligned}$$

This, in conjunction with (A.4), is the expression used in section 2.4.

Appendix B. Evans function definition. Here, we describe the Evans function approach for analyzing linear stability. In general, the linear stability of a localized traveling wave solution to a system of PDEs is obtained by studying the eigenvalue problem

$$\mathcal{L}\, w = \lambda\, w, \tag{B.1}$$

where the matrix differential operator $\mathcal{L}$ arises from the linearization of the PDEs. The traveling solution is said to be linearly stable if the spectrum of $\mathcal{L}$ lies in the closed left half plane.

The system (B.1) can be turned into a linear dynamical system of the form

$$U_\xi = \mathbf{A}(\xi, \lambda)\, U, \tag{B.2}$$

where $\mathbf{A}(\xi, \lambda)$ is an $n \times n$ square matrix depending on $\xi = x - c\,t$ and the spectral parameter λ (in our case, $n = 4$). It can be shown that the asymptotic behavior of the solutions to (B.2) is determined by the matrices

$$\mathbf{A}_{\pm\infty}(\lambda) = \lim_{\xi \to \pm\infty} \mathbf{A}(\xi, \lambda)$$

in the following sense (see [11] for details). If μ^+ (resp., μ^-) is an eigenvalue of $\mathbf{A}_{+\infty}$ (resp., $\mathbf{A}_{-\infty}$) with eigenvector v^+ (resp., v^-), then there exists a solution w^+ (resp., w^-) to (B.2) with the property that

$$\lim_{\xi\to\infty} w^+ e^{-\mu^+\xi} = v^+ \quad \left(\text{resp.}, \lim_{\xi\to-\infty} w^- e^{-\mu^-\xi} = v^-\right). \tag{B.3}$$

Note that the superscript "+" refers to exponentially decaying behavior at $\xi = +\infty$, while "−" refers to $\xi = -\infty$.

To study the linear stability, one should consider both the essential and point spectrum of $\mathcal{L}$. The essential spectrum of $\mathcal{L}$ consists of the values of λ for which $\mathbf{A}_\infty$ or $\mathbf{A}_{-\infty}$ has purely imaginary eigenvalues [22]. The point spectrum can be studied by means of the Evans function, first introduced by Evans [16] and later generalized [2]. Roughly speaking, the zeros of this complex-valued function are arranged to coincide with the point spectrum of $\mathcal{L}$.

Let Ω denote a domain of the complex λ plane with no intersection with the essential spectrum and let n_s and n_u denote, respectively, the number of eigenvalues of $\mathbf{A}_\infty$ with negative real part and the number of eigenvalues of $\mathbf{A}_{-\infty}$ with positive real part in Ω. We assume that $n_s + n_u = n$. Let $w_i^+(\lambda,\xi)$, $i = 1, 2, \ldots, n_s$ (resp., $w_i^-(\lambda,\xi)$, $i = 1, 2, \ldots, n_u$), be linearly independent solutions to (B.2) converging to zero as $\xi \to \infty$ (resp., $\xi \to -\infty$) which are analytic of λ in Ω. Clearly, a particular value of λ belongs to the point spectrum of $\mathcal{L}$ if (B.2) admits a solution that is converging to zero for both $\xi \to \pm\infty$, that is, if the space of solutions generated by the w_i^+ intersects with the one generated by the w_i^-. To detect such values of λ in Ω, one can use the definition of the Evans function given in [33],

$$E(\lambda) = \det\left(w_1^+, w_2^+, \ldots, w_{n_s}^+, w_1^-, w_2^-, \ldots, w_{n_u}^-\right),$$

in which the $w_i^\pm$ are evaluated at $\xi = 0$. This function is analytic in Ω and is real for real values of λ, and the locations of the zeros of $E(\lambda)$ correspond to eigenvalues of $\mathcal{L}$.

The first *numerical* computation of the Evans function was by Evans himself in [17] and followed by [32, 35]. However, in all three papers $n_s = 1$, in which case a standard shooting argument can be used. In standard shooting algorithms one follows the stable and/or unstable manifolds at $\xi = \pm\infty$. The Evans function is then given as the intersection of these manifolds. As shown in section 3, our system has $n = 4$ and $n_s = n_u = 2$. This causes the following practical problem: although the n_s (or n_u, respectively) eigenvectors are linear independent solutions of the eigenvalue problem (B.2) at $\xi = \pm\infty$, the numerical integration scheme will lead to an inevitable alignment with the eigendirection corresponding to the largest eigenvalue. This collapse of the eigendirections is usually overcome by using Gram–Schmidt orthogonalization. However, this is not desirable for calculating the Evans function, as it is a nonanalytic procedure which then subsequently prohibits the use of Cauchy's theorem (argument principle) to locate complex zeros of the Evans function. The Evans function is therefore best calculated using exterior algebra [1, 3, 9, 11, 12, 15, 31, 34].

We briefly review the method here, with specific regard to the situation in which $n = 4$ and $n_s = n_u = 2$. For more details the reader is referred to [1, 3, 11, 15] and to the numerical computation in [20]. The main idea behind exterior algebra methods (or compound matrices methods) is that the linear system (B.2) induces a dynamical system on the wedge-space $\bigwedge^2(\mathbb{C}^4)$ for $n_s = n_u = 2$. The wedge-space $\bigwedge^2(\mathbb{C}^4)$ is the

space of all two forms on $\mathbb{C}^n$. This is a space of dimension $\binom{4}{2} = 6$. The induced dynamics on the wedge-space $\bigwedge^2(\mathbb{C}^4)$ can be written as

$$\mathbf{U}_\xi = \mathbf{A}^{(2)}(\xi)\mathbf{U}, \quad \mathbf{U} \in \bigwedge^2(\mathbb{C}^4). \tag{B.4}$$

Here the linear operator (matrix) $\mathbf{A}^{(2)}$ is the restriction of $\mathbf{A}(\xi,\lambda) = \{a_{ij}\}$ to the wedge-space $\bigwedge^2(\mathbb{C}^4)$. Using the standard basis of $\bigwedge^2(\mathbb{C}^4)$

$$\begin{aligned} &\omega_1 = \mathbf{e}_1 \wedge \mathbf{e}_2, \quad \omega_2 = \mathbf{e}_1 \wedge \mathbf{e}_3, \quad \omega_3 = \mathbf{e}_1 \wedge \mathbf{e}_4, \\ &\omega_4 = \mathbf{e}_2 \wedge \mathbf{e}_3, \quad \omega_5 = \mathbf{e}_2 \wedge \mathbf{e}_4, \quad \omega_6 = \mathbf{e}_3 \wedge \mathbf{e}_4, \end{aligned} \tag{B.5}$$

where $\mathbf{e}_{1,2,3,4}$ is the standard basis of $\mathbb{C}^n$, we can find the matrix $\mathbf{A}^{(2)} : \bigwedge^2(\mathbb{C}^4) \to \bigwedge^2(\mathbb{C}^4)$ as a complex 6×6 matrix. With respect to the basis (B.5), $\mathbf{A}^{(2)}$ takes the explicit form

$$\mathbf{A}^{(2)} = \begin{bmatrix} a_{11}+a_{22} & a_{23} & a_{24} & -a_{13} & -a_{14} & 0 \\ a_{32} & a_{11}+a_{33} & a_{34} & a_{12} & 0 & -a_{14} \\ a_{42} & a_{43} & a_{11}+a_{44} & 0 & a_{12} & a_{13} \\ -a_{31} & a_{21} & 0 & a_{22}+a_{33} & a_{34} & -a_{24} \\ -a_{41} & 0 & a_{21} & a_{43} & a_{22}+a_{44} & a_{23} \\ 0 & -a_{41} & a_{31} & -a_{42} & a_{32} & a_{33}+a_{44} \end{bmatrix}.$$

General aspects of the numerical implementation of this theory and details for these constructions in more general systems can be found in [3, 11].

Linearity assures that the induced matrix $\mathbf{A}^{(2)}(\xi,\lambda)$ is also differentiable and analytic. Hence, the limiting matrices,

$$\mathbf{A}^{(2)}_{\pm\infty}(\lambda) = \lim_{\xi\to\pm\infty} \mathbf{A}^{(2)}(\xi,\lambda)\,,$$

will exist. It can readily be shown that the eigenvalues of the matrix $\mathbf{A}^{(2)}_{\pm\infty}(\lambda)$ consist of all possible sums of two eigenvalues of $\mathbf{A}_{\pm\infty}(\lambda)$. Therefore, for $\Re(\lambda) > 0$, the eigenvalue of $\mathbf{A}^{(2)}_{+\infty}(\lambda)$ with the most negative real part is given by $\sigma_+(\lambda) = \mu_1^+ + \mu_2^+$. The eigenvalue $\sigma_+(\lambda)$ has real part strictly less than any other eigenvalue of $\mathbf{A}^{(2)}_{+\infty}(\lambda)$. Analogously, the eigenvalue of $\mathbf{A}^{(2)}_{-\infty}(\lambda)$ with the largest nonnegative real part is given by $\sigma_-(\lambda) = \mu_1^- + \mu_2^-$. The eigenvalue $\sigma_-(\lambda)$ has real part strictly greater than any other eigenvalue of $\mathbf{A}^{(2)}_{-\infty}(\lambda)$. Note that the eigenvalues $\sigma_\pm$ are simple and are analytic functions of λ.

Let $\zeta^\pm(\lambda)$ be the eigenvectors associated with $\sigma_\pm(\lambda)$, defined by

$$\mathbf{A}^{(2)}_{+\infty}(\lambda)\zeta^+(\lambda) = \sigma_+(\lambda)\zeta^+(\lambda) \quad \text{and} \quad \mathbf{A}^{(2)}_{-\infty}(\lambda)\zeta^-(\lambda) = \sigma_-(\lambda)\zeta^-(\lambda)\,. \tag{B.6}$$

These vectors can always be constructed in an analytic way (see [11]) and are readily found to be $\zeta^\pm(\lambda) = v_1^\pm \wedge v_2^\pm$.

Let $\mathbf{U}^\pm(\xi,\lambda) \in \bigwedge^2(\mathbb{C}^4)$ be the solution of the linear system (B.4) which satisfies $\lim_{\xi\to\pm\infty} e^{-\sigma_\pm(\lambda)\xi}\mathbf{U}^\pm(\xi,\lambda) = \zeta^\pm(\lambda)$. This allows us to define the Evans function as

$$E(\lambda) = \mathcal{N}\,\mathbf{U}^-(\xi,\lambda) \wedge \mathbf{U}^+(\xi,\lambda)\,, \quad \lambda \in \Lambda, \tag{B.7}$$

where

$$\mathcal{N} = \mathrm{e}^{-\int_0^\xi \tau(s,\lambda)ds} \quad \text{and} \quad \tau(\xi,\lambda) = \mathrm{Tr}(\mathbf{A}(\xi,\lambda)). \tag{B.8}$$

Expressing $\mathbf{U}^{\pm}(\xi,\lambda)$ as a linear combination with respect to the basis (B.5),

$$\mathbf{U}^{\pm}(\xi,\lambda)=\sum_{j}^{6}U_j^{\pm}\omega_j,$$

the expression for the Evans function (B.8) can be simplified to

$$E(\lambda)=\mathcal{N}\left[\!\left[\mathbf{U}^{-}(\xi,\lambda),\mathbf{\Sigma}\mathbf{U}^{+}(\xi,\lambda)\right]\!\right]_6, \tag{B.9}$$

where $[\![\cdot,\cdot]\!]_6$ is the complex inner product in $\mathbb{C}^4$, and the representation of the Hodge-star operator $\mathbf{\Sigma}$ in the basis (B.5) is

$$\mathbf{\Sigma}=\begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 1\\ 0 & 0 & 0 & 0 & -1 & 0\\ 0 & 0 & 0 & 1 & 0 & 0\\ 0 & 0 & 1 & 0 & 0 & 0\\ 0 & -1 & 0 & 0 & 0 & 0\\ 1 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

Using the Hodge-star operator, we can relate the most unstable solution $\mathbf{U}^{-}$ of the linearized system at $\xi=-\infty$ with the most unstable solution of the adjoint system of (B.4) at $\xi=-\infty$. Details can be found in [3, 10, 11]. This suggests a normalization of the asymptotic eigenvectors according to

$$[\![\zeta^{-},\mathbf{\Sigma}\zeta^{+}]\!]_6=1, \tag{B.10}$$

which assures that $E(\lambda)\to 1$ for $|\lambda|\to\infty$.

Note that the translational invariance of (1.1) guarantees that the Evans function can be evaluated at any (fixed) spatial location $\xi^{\star}$. However, to avoid unwanted growing of the solutions $\mathbf{U}^{\pm}$ we will consider the scaled solutions

$$\widetilde{\mathbf{U}}^{\pm}(\xi,\lambda)=e^{-\sigma_{\pm}(\lambda)\xi}\mathbf{U}^{\pm}(\xi,\lambda). \tag{B.11}$$

The scaling (B.11) ensures that $\widetilde{\mathbf{U}}^{+}(\xi,\lambda)\big|_{\xi=\xi^{\star}}$ is bounded. The corresponding equation on $\bigwedge^2(\mathbb{C}^4)$,

$$\frac{d}{d\xi}\widetilde{\mathbf{U}}^{\pm}=[\mathbf{A}^{(2)}(\xi,\lambda)-\sigma_{\pm}(\lambda)\mathbf{I}]\widetilde{\mathbf{U}}^{\pm}\,,\quad \widetilde{\mathbf{U}}^{\pm}(\xi,\lambda)\big|_{\xi=L_{\pm\infty}}=\zeta^{\pm}(\lambda)\,, \tag{B.12}$$

is integrated from $\xi=L_{\pm\infty}$ to $\xi=\xi^{\star}$ (where $\xi^{\star}$ is arbitrary but fixed).

The system (B.12) can be integrated using the second-order implicit midpoint method. For a system in the form $\mathbf{U}_{\xi}=\mathbf{B}(\xi,\lambda)\mathbf{U}$, each step of the implicit midpoint rule takes the form

$$\mathbf{U}^{n+1}=[\mathbf{I}-\tfrac{1}{2}\Delta x\mathbf{B}_{n+1/2}]^{-1}[\mathbf{I}+\tfrac{1}{2}\Delta x\mathbf{B}_{n+1/2}]\,\mathbf{U}^{n}, \tag{B.13}$$

where $\mathbf{B}_{n+1/2}=\mathbf{B}(x_{n+1/2},\lambda)$.

Appendix C. The authors wish to thank Harvinder Sidhu, Konstantina Trivisa, Marshall Slemrod, and Joceline Lega for discussions and pointers. Detailed comments and suggestions from two anonymous referees, whose efforts revealed a substantial error in a previous version of this manuscript, are also gratefully acknowledged.

ON THE WAVE STRUCTURE OF TWO-PHASE FLOW MODELS*

STEINAR EVJE† AND TORE FLÅTTEN‡

Abstract. We explore the relationship between two common two-phase flow models, usually denoted as the *two-fluid* and *drift-flux* models. They differ in their mathematical description of momentum transfer between the phases. In this paper we provide a framework in which these two model formulations are unified. The drift-flux model employs a mixture momentum equation and treats interphasic momentum exchange indirectly through the *slip relation*, which gives the relative velocity between the phases as a function of the flow parameters. This closure law is in general highly complex, which makes it difficult to analyze the model algebraically. To facilitate the analysis, we express the quasi-linear formulation of the drift-flux model as a function of three parameters: the derivatives of the slip with respect to the vector of unknown variables. The wave structure of this model is investigated using a perturbation technique. Then we rewrite the drift-flux model with a general slip relation such that it is expressed in terms of the canonical two-fluid form. That is, we replace the mixture momentum equation and the slip relation with equivalent evolution equations for the momentums of each phase. We obtain a mathematically equivalent formulation in terms of a two-fluid model and by this bridge some of the gap between the drift-flux model and the two-fluid model. Finally, the effect of the various exchange terms on the wave structure of the two-fluid model is investigated.

Key words. hyperbolic system of conservation laws, two phase flow, drift-flux model, two-fluid model, perturbation method, eigenvalues, interface friction

1. Introduction.

In general, multiphase flows exhibit a complex dynamical behavior, where depending on the physical parameters several different *flow regimes* may occur. Flow regimes are commonly divided into *separated* (stratified, annular) and *mixed* (bubbly, dispersed) flows.

There exists no simple model formulation able to describe all these phenomena adequately. Rather, a variety of different models have been suggested with different applications in mind; see, for instance, [6, 8, 23, 24].

A classical way to obtain tractable models is to average in space. Of such models, two particular strategies have attracted considerable interest in the petroleum industry: the *two-fluid* [4, 20] and *drift-flux* [22] models. These models, described in sections 2 and 3, are the focus of the current paper.

The models contain a significant amount of additional closure laws. These closure relations typically depend on the flow structure and represent the main difficulty in the model formulation.

As noted by Bouré [9], the effect of closure relations may be viewed on two different levels:

1. Their *physical magnitude* affects the predicted values of the flow parameters.

*Received by the editors June 13, 2005; accepted for publication (in revised form) October 4, 2006; published electronically February 9, 2007. This work was supported by the Research Council of Norway through the BeMatA program.

2. Their *mathematical form* affects the propagation properties of the flow model. That is, differential closure terms affect the velocities and composition of the predicted waves, whereas nondifferential terms do not.

The drift-flux model and its closure relations are commonly formulated to model *mixed* flow regimes. Depending on the closure relations, the two-fluid model has more general validity. In its most basic form, it is nevertheless best suited for a description of *separated* flows. These different domains of applicability manifest themselves through the different wave structures of the common formulation of the two models.

The purpose of this paper is twofold.

(I) Primary aim. To demonstrate how *nondifferential* closure relations for the drift-flux model may be transformed into corresponding *differential* relations in the two-fluid framework. By this transformation, we obtain a two-fluid model whose underlying mathematical structure is identical to the original drift-flux model. Hence it becomes possible to alternate between the two formulations within a unified framework.

(II) Secondary aim. To demonstrate how the wave structure of the drift-flux model may be investigated by a perturbation technique, first applied to two-phase flows by Toumi and coworkers [27, 28], who considered the two-fluid model.

The paper is organized as follows: In sections 2 and 3 we describe the two-fluid and drift-flux models in question. Section 4 is dedicated to the secondary aim of the paper; here we investigate the wave structure of the drift-flux model.

In section 5 we confront the primary aim of our paper, writing the drift-flux model in the framework of a two-fluid model. A main result is equation (118), the explicit form of the interface friction that makes the two-fluid model mathematically equivalent to a general drift-flux model.

Armed with a thorough understanding of the mathematical structure of both models, we demonstrate in section 6 how the wave velocities of the two-fluid model gradually change by addition of the different terms of (118). This illustrates the *physical effects* of the different closure terms on the wave phenomena inherent in the models.

2. Two-fluid model. To be consistent with the dynamical behavior of the flow physics, the two-phase models we consider must describe the following wave phenomena:

- *Sonic waves*, conveying rapid variations in the pressure and the associated velocity fields. They are a consequence of the compressibility of the flow.
- *Material waves*, conveying large scale variations in the volumetric phase fractions and mixture density. They are responsible for the dynamics corresponding to mass transport.
- *Entropy waves*, representing thermodynamic properties transported along the flow.

As noted, for instance, by [9, 27], the entropy waves are uncoupled from the remaining wave structure. Phasic entropies are simply advected with the fluid velocities.

Hence the structure of the sonic and material waves may be studied with no loss of generality by considering only *isentropic* flow models. Such models are based on the physical principle of conservation of the mass and momentum variables, neglecting dynamic energy transfers.

Supplemented by proper closure relations, the models hence consist of mass and momentum balance equations, expressed in the form of *partial differential* equations.

2.1. Model formulation. For a gas (g) and a liquid (ℓ) phase, the isentropic two-fluid model may be written as follows:

- Conservation of mass

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}\right)+\frac{\partial}{\partial x}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}\right)=0, \tag{1}$$

$$\frac{\partial}{\partial t}\left(\rho_{\ell}\alpha_{\ell}\right)+\frac{\partial}{\partial x}\left(\rho_{\ell}\alpha_{\ell}v_{\ell}\right)=0, \tag{2}$$

- Momentum balances

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}\right)+\frac{\partial}{\partial x}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}^{2}\right)+\frac{\partial}{\partial x}\left(\alpha_{\mathrm{g}}p_{\mathrm{g}}\right)-p^{\mathrm{i}}\frac{\partial}{\partial x}\left(\alpha_{\mathrm{g}}\right)=Q_{\mathrm{g}}+M_{\mathrm{g}}^{\mathrm{i}}, \tag{3}$$

$$\frac{\partial}{\partial t}\left(\rho_{\ell}\alpha_{\ell}v_{\ell}\right)+\frac{\partial}{\partial x}\left(\rho_{\ell}\alpha_{\ell}v_{\ell}^{2}\right)+\frac{\partial}{\partial x}\left(\alpha_{\ell}p_{\ell}\right)-p^{\mathrm{i}}\frac{\partial}{\partial x}\left(\alpha_{\ell}\right)=Q_{\ell}+M_{\ell}^{\mathrm{i}}. \tag{4}$$

Here α_k is the volume fraction of phase k with

$$\alpha_{\mathrm{g}}+\alpha_{\ell}=1, \tag{5}$$

where ρ_k, p_k, and v_k denote the density, pressure, and fluid velocity of phase k, respectively, and p^{i} is the pressure at the gas-liquid interface. M_k^{i} represents interphasic momentum exchange terms with $M_{\mathrm{g}}^{\mathrm{i}}+M_{\ell}^{\mathrm{i}}=0$. Momentum sources acting on each phase separately, such as wall friction or gravitational forces, are represented by the terms Q_k.

2.2. Closure relations. The closure relations needed to complete the model may be divided into three groups.

2.2.1. Thermodynamic submodels. For each phase k, the thermodynamic *state relation*

$$p_k=p(\rho_k,S_k) \tag{6}$$

must be specified. Here S_k is the entropy of phase k. Furthermore, the interface pressure p^{i} must be expressed as a function of the phasic pressures:

$$p^{\mathrm{i}}=p^{\mathrm{i}}(p_{\mathrm{g}},p_{\ell}). \tag{7}$$

When the flows are separated due to gravitational forces, the relationships between the pressures p^{i}, p_{g}, and p_{ℓ} are commonly chosen to model the effects of *hydrostatics*. In this case, the two-fluid model is able to describe travelling surface waves on the gas-liquid interface; see, for instance, [2].

2.2.2. Phase-specific source terms. The main momentum sources acting on each phase separately are the following:

- *Gravity.*
  The effect of gravitational acceleration is expressed by

$$Q_k=-\rho_k\alpha_k g\sin\theta, \tag{8}$$

  where θ is the angle of the flow direction with respect to the horizontal.

- *Wall friction.*
  For separated flows, the wall friction for each phase is commonly expressed in terms of *friction factors* as follows:

$$Q_k = -f_k \frac{\rho_k \left| v_k \right| v_k}{2}. \tag{9}$$

  The Blasius equation is commonly used for calculating f_k; see, for instance, [1, 25]. According to [7], most *mixed* flow regimes may be modeled to acceptable accuracy by using friction factors corresponding to one-phase liquid flow ($f_{\mathrm{g}} = 0$).

2.2.3. Interphasic momentum exchange terms. The interactions between the phases are highly complex and different in character for each flow regime. Hence these terms are notoriously difficult to derive from theoretical considerations. Nor are they easily determined from experimental data, as their effects are only indirectly visible. We here briefly describe two of the most common approaches for modeling the interphasic momentum exchange, applied to separated and mixed flows, respectively.

- *Stratified flows.*
  For stratified flows it is common [1, 25] to express the interphasic momentum exchange in nondifferential form, as a function of a *friction factor* f_{i}:

$$M_\ell^{\mathrm{i}} = -M_{\mathrm{g}}^{\mathrm{i}} = f_{\mathrm{i}} \frac{\rho_{\mathrm{g}} \left| v_{\mathrm{g}} - v_\ell \right| (v_{\mathrm{g}} - v_\ell)}{2}. \tag{10}$$

  Andritsos and Hanratty [1] noted that waves existing on the gas-liquid interface have a significant effect on the magnitude of f_{i}. They suggested that for sufficiently small gas flow rates $\alpha_{\mathrm{g}} v_{\mathrm{g}} < U_{\mathrm{crit}}$, such that no waves are generated at the interface,

$$f_{\mathrm{i}} \approx f_{\mathrm{g}}. \tag{11}$$

  For $\alpha_{\mathrm{g}} v_{\mathrm{g}} > U_{\mathrm{crit}}$ they developed a correlation where $f_{\mathrm{i}}/f_{\mathrm{g}}$ increases linearly with $\alpha_{\mathrm{g}} v_{\mathrm{g}}$.
- *Bubbly flows.* For a two-phase mixture of gas dispersed within the liquid, the momentum transfer induced by a gas bubble *accelerating* with respect to the surrounding fluid must be taken into account. This effect, denoted as the *virtual mass force*, has been analyzed by Drew, Cheng, and Lahey [10]. By imposing the condition that this interface friction is invariant under a change of reference frame, they derived the expression

$$\begin{aligned} M_{\mathrm{g}}^{\mathrm{i}} = \alpha_{\mathrm{g}} \rho_\ell C_{\mathrm{vm}} \Big(& \partial_t \left(v_{\mathrm{g}} - v_\ell \right) + v_{\mathrm{g}} \partial_x \left(v_{\mathrm{g}} - v_\ell \right) \\ & + \left(v_{\mathrm{g}} - v_\ell \right) \left((\lambda - 2) \partial_x v_{\mathrm{g}} + (1 - \lambda) \partial_x v_\ell \right) \Big), \end{aligned} \tag{12}$$

  where λ and C_{vm} (the coefficient of virtual mass) are volume fraction dependent parameters. The value of C_{vm} is expected to be $1/2$ for noninteracting spheres and smaller for bubbles of other shapes.
  The wave structure of the two-fluid model with virtual mass force included has been analyzed in [18, 19, 28]. In particular, Lahey [19] discusses similarities between such a two-fluid model and the drift-flux model.

2.3. Canonical formulation. The multitude of possible closure relations gives rise to a large class of slightly different models, all falling under the heading of *two-fluid models*. In the following, we will find it useful to base our analyses on some common formulation of these models. By neglecting the phasic pressure difference ($p = p_{\mathrm{g}} = p_\ell$) and writing

$$\tau_{\mathrm{i}} = \left(p - p^{\mathrm{i}}\right) \frac{\partial \alpha_{\mathrm{g}}}{\partial x} - M^{\mathrm{i}}_{\mathrm{g}} = -\left(p - p^{\mathrm{i}}\right) \frac{\partial \alpha_\ell}{\partial x} + M^{\mathrm{i}}_\ell, \tag{13}$$

we arrive at the following *canonical* two-fluid model:

- Conservation of mass

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}} \alpha_{\mathrm{g}}\right) + \frac{\partial}{\partial x}\left(\rho_{\mathrm{g}} \alpha_{\mathrm{g}} v_{\mathrm{g}}\right) = 0, \tag{14}$$

$$\frac{\partial}{\partial t}\left(\rho_\ell \alpha_\ell\right) + \frac{\partial}{\partial x}\left(\rho_\ell \alpha_\ell v_\ell\right) = 0, \tag{15}$$

- Momentum balances

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}} \alpha_{\mathrm{g}} v_{\mathrm{g}}\right) + \frac{\partial}{\partial x}\left(\rho_{\mathrm{g}} \alpha_{\mathrm{g}} v_{\mathrm{g}}^2\right) + \alpha_{\mathrm{g}} \frac{\partial}{\partial x}\left(p\right) + \tau_{\mathrm{i}} = Q_{\mathrm{g}}, \tag{16}$$

$$\frac{\partial}{\partial t}\left(\rho_\ell \alpha_\ell v_\ell\right) + \frac{\partial}{\partial x}\left(\rho_\ell \alpha_\ell v_\ell^2\right) + \alpha_\ell \frac{\partial}{\partial x}\left(p\right) - \tau_{\mathrm{i}} = Q_\ell, \tag{17}$$

where the interfacial momentum exchange term τ_{i} may or may not contain differential operators.

3. Drift-flux model. A strategy to avoid the modeling difficulties associated with the momentum exchange terms, as mentioned in the previous section, is to reformulate the model such that these terms no longer directly appear. This is precisely the idea of the *drift-flux* formulation of two-phase flow. By making the simplifying assumption

$$p = p_{\mathrm{g}} = p_\ell, \tag{18}$$

and adding the two momentum equations (3) and (4), we obtain the conservation equation for the *mixture* momentum:

$$\frac{\partial}{\partial t}(\rho_{\mathrm{g}} \alpha_{\mathrm{g}} v_{\mathrm{g}} + \rho_\ell \alpha_\ell v_\ell) + \frac{\partial}{\partial x}\left(\rho_{\mathrm{g}} \alpha_{\mathrm{g}} v_{\mathrm{g}}^2 + \rho_\ell \alpha_\ell v_\ell^2 + p\right) = Q_{\mathrm{g}} + Q_\ell. \tag{19}$$

Note that (18) is consistent with the assumption of a *mixed* flow regime, which is the situation for which the drift-flux model is commonly applied.

The phasic momentums must satisfy a *slip relation* in the functional form

$$v_{\mathrm{g}} - v_\ell = \Phi(p, \alpha_{\mathrm{g}}, v_{\mathrm{g}}). \tag{20}$$

Hence the two momentum *evolution equations* (16)–(17) of the two-fluid model are replaced by one evolution equation (19) and one *functional relation* (20). Bouré [9] discusses *generalized* drift-flux models where Φ may also contain differential operators.

3.1. Model formulation. In summary, using the nomenclature

$$m_{\mathrm{g}} = \rho_{\mathrm{g}}\alpha_{\mathrm{g}}, \tag{21}$$

$$m_{\ell} = \rho_{\ell}\alpha_{\ell}, \tag{22}$$

$$I_{\mathrm{g}} = m_{\mathrm{g}}v_{\mathrm{g}}, \tag{23}$$

$$I_{\ell} = m_{\ell}v_{\ell}, \tag{24}$$

$$I = I_{\mathrm{g}} + I_{\ell}, \tag{25}$$

$$Q = Q_{\mathrm{g}} + Q_{\ell}, \tag{26}$$

we may express the drift-flux model as

$$\frac{\partial m_{\mathrm{g}}}{\partial t} + \frac{\partial I_{\mathrm{g}}}{\partial x} = 0, \tag{27}$$

$$\frac{\partial m_{\ell}}{\partial t} + \frac{\partial I_{\ell}}{\partial x} = 0, \tag{28}$$

$$\frac{\partial I}{\partial t} + \frac{\partial}{\partial x}\left(I_{\mathrm{g}}v_{\mathrm{g}} + I_{\ell}v_{\ell} + p\right) = Q, \tag{29}$$

supplemented with the following functional relations:

- *Thermodynamics:* $p = p(\rho_{\mathrm{g}}) = p(\rho_{\ell})$.
- *Slip relation:* $v_{\mathrm{g}} - v_{\ell} = \Phi(m_{\mathrm{g}}, m_{\ell}, v_{\mathrm{g}})$.

3.2. Quasi-linear formulation. The model (27)–(29) may be written in the following *quasi-linear form*:

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A}(\mathbf{U})\frac{\partial \mathbf{U}}{\partial x} = \mathbf{Q}(\mathbf{U}), \tag{30}$$

where

$$\mathbf{U} = \begin{bmatrix} m_{\mathrm{g}} \\ m_{\ell} \\ I \end{bmatrix} \tag{31}$$

and

$$\mathbf{Q}(\mathbf{U}) = \begin{bmatrix} 0 \\ 0 \\ Q \end{bmatrix}. \tag{32}$$

In the following, we will derive an expression for the Jacobi matrix $\mathbf{A}$. Towards this aim, we will follow the common practice of thermodynamics and take

$$\left(\frac{\partial X}{\partial Y}\right)_{a,b} \tag{33}$$

to mean the partial derivative of X with respect to Y under the assumption of constant a and b.

3.2.1. Some definitions. We now define the following basic abbreviations:

$$\mu_{\mathrm{g}} = \left(\frac{\partial \Phi}{\partial m_{\mathrm{g}}}\right)_{m_\ell, v_{\mathrm{g}}}, \tag{34}$$

$$\mu_\ell = \left(\frac{\partial \Phi}{\partial m_\ell}\right)_{m_{\mathrm{g}}, v_{\mathrm{g}}}, \tag{35}$$

$$\mu_{\mathrm{v}} = \left(\frac{\partial \Phi}{\partial v_{\mathrm{g}}}\right)_{m_{\mathrm{g}}, m_\ell}, \tag{36}$$

$$\zeta = \left(\frac{\partial v_\ell}{\partial v_{\mathrm{g}}}\right)_{m_{\mathrm{g}}, m_\ell}. \tag{37}$$

We further define the *pseudomass* $\hat{\rho}$:

$$\hat{\rho} = m_{\mathrm{g}} + \zeta m_\ell. \tag{38}$$

Remark 1. We observe that by writing (20) as

$$d\Phi = dv_{\mathrm{g}} - dv_\ell, \tag{39}$$

we obtain from (36) and (37) the basic relation

$$\mu_{\mathrm{v}} = 1 - \zeta. \tag{40}$$

We may now derive the following useful differentials.

Differential 1 (gas velocity). *We may expand* dI *as*

$$dI = m_{\mathrm{g}}\, dv_{\mathrm{g}} + v_{\mathrm{g}}\, dm_{\mathrm{g}} + v_\ell\, dm_\ell + m_\ell\, dv_\ell. \tag{41}$$

Using (39) *and*

$$d\Phi = \mu_{\mathrm{g}}\, dm_{\mathrm{g}} + \mu_\ell\, dm_\ell + \mu_{\mathrm{v}}\, dv_{\mathrm{g}}, \tag{42}$$

we obtain

$$dv_{\mathrm{g}} = \frac{1}{\hat{\rho}} \left(dI + (m_\ell \mu_{\mathrm{g}} - v_{\mathrm{g}})\ dm_{\mathrm{g}} + (m_\ell \mu_\ell - v_\ell)\ dm_\ell\right). \tag{43}$$

Differential 2 (gas momentum). *Using*

$$dI_{\mathrm{g}} = m_{\mathrm{g}}\, dv_{\mathrm{g}} + v_{\mathrm{g}}\, dm_{\mathrm{g}}, \tag{44}$$

we obtain from (43)

$$dI_{\mathrm{g}} = \frac{1}{\hat{\rho}} \left(m_{\mathrm{g}}\, dI + (m_{\mathrm{g}} m_\ell \mu_{\mathrm{g}} + \zeta m_\ell v_{\mathrm{g}})\ dm_{\mathrm{g}} + (m_{\mathrm{g}} m_\ell \mu_\ell - m_{\mathrm{g}} v_\ell)\ dm_\ell\right). \tag{45}$$

Differential 3 (liquid momentum). *Using*

$$dI = dI_{\mathrm{g}} + dI_\ell, \tag{46}$$

we obtain from (45)

$$dI_\ell = \frac{1}{\hat{\rho}} \left(\zeta m_\ell\, dI - (m_{\mathrm{g}} m_\ell \mu_{\mathrm{g}} + \zeta m_\ell v_{\mathrm{g}})\ dm_{\mathrm{g}} - (m_{\mathrm{g}} m_\ell \mu_\ell - m_{\mathrm{g}} v_\ell)\ dm_\ell\right). \tag{47}$$

DIFFERENTIAL 4 (pressure). *Writing* $\alpha_{\rm g} + \alpha_\ell = 1$ *as*

$$\frac{m_{\rm g}}{\rho_{\rm g}(p)} + \frac{m_\ell}{\rho_\ell(p)} = 1, \tag{48}$$

we obtain by differentiation

$$dp = \kappa\left(\rho_\ell\, dm_{\rm g} + \rho_{\rm g}\, dm_\ell\right), \tag{49}$$

where

$$\kappa = \frac{1}{(\partial\rho_{\rm g}/\partial p)\,\rho_\ell\alpha_{\rm g} + (\partial\rho_\ell/\partial p)\,\rho_{\rm g}\alpha_\ell}. \tag{50}$$

DIFFERENTIAL 5 (gas momentum convection). *We have*

$$d\left(I_{\rm g}v_{\rm g}\right) = I_{\rm g}\, dv_{\rm g} + v_{\rm g}\, dI_{\rm g}. \tag{51}$$

Hence from (43) *and* (45) *we obtain*

$$\begin{aligned} d\left(I_{\rm g}v_{\rm g}\right) = \frac{1}{\hat\rho}\Big(&2m_{\rm g}v_{\rm g}\, dI + \left(2m_{\rm g}m_\ell v_{\rm g}\mu_{\rm g} + (\zeta m_\ell - m_{\rm g})v_{\rm g}^2\right)\, dm_{\rm g} \\ &+ (2m_{\rm g}m_\ell v_{\rm g}\mu_\ell - 2m_{\rm g}v_{\rm g}v_\ell)\, dm_\ell\Big). \end{aligned} \tag{52}$$

DIFFERENTIAL 6 (liquid momentum convection). *We have*

$$dv_\ell = dv_{\rm g} - d\Phi = \zeta\, dv_{\rm g} - \mu_{\rm g}\, dm_{\rm g} - \mu_\ell\, dm_\ell. \tag{53}$$

From (43) *we obtain*

$$dv_\ell = \frac{1}{\hat\rho}\left(\zeta\, dI - (m_{\rm g}\mu_{\rm g} + \zeta v_{\rm g})\, dm_{\rm g} - (m_{\rm g}\mu_\ell + \zeta v_\ell)\, dm_\ell\right). \tag{54}$$

Hence from

$$d\left(I_\ell v_\ell\right) = I_\ell\, dv_\ell + v_\ell\, dI_\ell \tag{55}$$

we obtain

$$\begin{aligned} d\left(I_\ell v_\ell\right) = \frac{1}{\hat\rho}\Big(&2\zeta m_\ell v_\ell\, dI - (2m_{\rm g}m_\ell v_\ell\mu_{\rm g} + 2\zeta m_\ell v_{\rm g}v_\ell)\, dm_{\rm g} \\ &- \left(2m_{\rm g}m_\ell v_\ell\mu_\ell + (\zeta m_\ell - m_{\rm g})v_\ell^2\right)\, dm_\ell\Big). \end{aligned} \tag{56}$$

3.2.2. The Jacobi matrix. With the aid of these differentials we can more or less directly write down the Jacobi matrix

$$\mathbf{A}(\mathbf{U}) = \frac{1}{\hat\rho}\begin{bmatrix} m_{\rm g}m_\ell\mu_{\rm g} + \zeta m_\ell v_{\rm g} & m_{\rm g}m_\ell\mu_\ell - m_{\rm g}v_\ell & m_{\rm g} \\ -(m_{\rm g}m_\ell\mu_{\rm g} + \zeta m_\ell v_{\rm g}) & m_{\rm g}v_\ell - m_{\rm g}m_\ell\mu_\ell & \zeta m_\ell \\ A_{31} & A_{32} & 2(m_{\rm g}v_{\rm g} + \zeta m_\ell v_\ell) \end{bmatrix}, \tag{57}$$

where

$$A_{31} = \kappa\hat\rho\rho_\ell + 2m_{\rm g}m_\ell\mu_{\rm g}(v_{\rm g} - v_\ell) + (\zeta m_\ell - m_{\rm g})v_{\rm g}^2 - 2\zeta m_\ell v_{\rm g}v_\ell \tag{58}$$

and

$$A_{32} = \kappa\hat\rho\rho_{\rm g} + 2m_{\rm g}m_\ell\mu_\ell(v_{\rm g} - v_\ell) - (\zeta m_\ell - m_{\rm g})v_\ell^2 - 2m_{\rm g}v_{\rm g}v_\ell. \tag{59}$$

4. Wave structure analysis. As is well known from the theory of hyperbolic conservation laws, the velocities of the inherent wave phenomena of the system (30) are given by the eigenvalues of $\mathbf{A}$.

These eigenvalues satisfy the characteristic equation

$$\begin{aligned}(\lambda - v_{\mathrm{g}})(\lambda - v_\ell)(\hat{\rho}\lambda - m_{\mathrm{g}} v_{\mathrm{g}} - \zeta m_\ell v_\ell) + m_{\mathrm{g}} m_\ell \left(\mu_\ell (\lambda - v_{\mathrm{g}})^2 - \mu_{\mathrm{g}} (\lambda - v_\ell)^2\right) \\ + \kappa \rho_{\mathrm{g}} \rho_\ell \left(\alpha_{\mathrm{g}} \alpha_\ell (\rho_{\mathrm{g}} \mu_{\mathrm{g}} - \rho_\ell \mu_\ell) - \alpha_{\mathrm{g}} (\lambda - v_\ell) - \zeta \alpha_\ell (\lambda - v_{\mathrm{g}})\right) = 0.\end{aligned} \tag{60}$$

Remark 2 (eigenvectors). The eigenvector equation for $\mathbf{A}$ is

$$\mathbf{A}\omega = \lambda\omega. \tag{61}$$

From (57) we obtain

$$\omega = \begin{bmatrix} m_{\mathrm{g}} \left(m_\ell \mu_\ell + (\lambda - v_\ell)\right) \\ \zeta m_\ell (\lambda - v_{\mathrm{g}}) - m_{\mathrm{g}} m_\ell \mu_{\mathrm{g}} \\ \lambda \left(\hat{\rho}\lambda - m_{\mathrm{g}} m_\ell (\mu_{\mathrm{g}} - \mu_\ell) - m_{\mathrm{g}} v_\ell - \zeta m_\ell v_{\mathrm{g}}\right) \end{bmatrix}. \tag{62}$$

The eigenvalue equation (60), being a third-order polynomial, can in principle be solved exactly to yield algebraic expressions for the eigenvalues λ. However, as tools for understanding the wave structure of the drift-flux model, these exact solutions are of limited value due to their high degree of complexity. In practice, one would often prefer making some simplifying assumptions and study the resulting *approximate* eigenvalues.

4.1. The Zuber–Findlay relation. A very important special case is the Zuber–Findlay slip relation [30], which can be written in the following simple analytical form:

$$v_{\mathrm{g}} = K \left(\alpha_{\mathrm{g}} v_{\mathrm{g}} + \alpha_\ell v_\ell\right) + S \tag{63}$$

or equivalently

$$\Phi = \frac{(K-1)v_{\mathrm{g}} + S}{K\alpha_\ell}. \tag{64}$$

This expression was derived from continuity considerations by Zuber and Findlay [30], where two different effects are taken into account:

1. The effect of nonuniform velocity and concentration profiles. The *shape factor* K is defined as

$$K = \frac{\langle (\alpha_{\mathrm{g}} v_{\mathrm{g}} + \alpha_\ell v_\ell)\alpha_{\mathrm{g}} \rangle}{\langle \alpha_{\mathrm{g}} v_{\mathrm{g}} + \alpha_\ell v_\ell \rangle \langle \alpha_{\mathrm{g}} \rangle}, \tag{65}$$

   where

$$\langle \cdot \rangle = \frac{1}{A} \int_A (\cdot)(x, y, z) dA. \tag{66}$$

   Here A is the cross-sectional area in the (y, z)-plane.
2. The effect of local relative velocity. The *drift velocity* S is defined as the terminal velocity of a single gas bubble rising through the liquid.

The Zuber–Findlay relation (63) has been experimentally established for a broad range of parameters for both bubbly and slug flows [3, 15].

This particular drift-flux model has been extensively studied by Théron [26] and Benzoni-Gavage [5]. By making some simplifying assumptions (most notably constant K and S as well as an incompressible liquid phase) they obtained the eigenvalues

- *sonic waves*

$$\lambda_{\mathrm{s}} = v_\ell \pm \sqrt{\frac{p}{\rho_\ell \alpha_{\mathrm{g}} \left(1 - K\alpha_{\mathrm{g}}\right)}}, \tag{67}$$

- *material wave*

$$\lambda_{\mathrm{m}} = v_{\mathrm{g}}. \tag{68}$$

Benzoni-Gavage [5] demonstrated that the sonic characteristic fields are genuinely nonlinear, whereas the material field is linearly degenerate. Provided the liquid phase is incompressible, Gavrilyuk and Fabre [16] have demonstrated that under a suitable variable transformation, the drift-flux model with slip relation (63) is mathematically similar to the Euler equations of gas dynamics.

In the following sections, we demonstrate how the drift-flux model may be analyzed more generally using a perturbation technique suggested by Toumi and coworkers [27, 28, 29]. In particular, we allow the liquid to be compressible and recover the above results of [26, 5] as the low-order limit in the perturbation parameter.

4.2. A simplifying assumption. In the following, we will assume that the slip relation can be expressed in the Zuber–Findlay form (63). Here we allow the parameters K and S to be expressed as general functions:

$$K = K(p, v_{\mathrm{g}}), \tag{69}$$

$$S = S(p, v_{\mathrm{g}}). \tag{70}$$

Equivalently, this can be expressed as a differential equation:

$$\alpha_\ell \left(\frac{\partial \Phi}{\partial \alpha_\ell}\right)_p + \Phi = 0. \tag{71}$$

From (34), (35), and (48) we may derive the following identity:

$$\left(\frac{\partial \Phi}{\partial \alpha_\ell}\right)_p \equiv \rho_\ell \mu_\ell - \rho_{\mathrm{g}} \mu_{\mathrm{g}}. \tag{72}$$

Hence from (71) we obtain

$$\mu_\ell = \frac{\rho_{\mathrm{g}}}{\rho_\ell}\mu_{\mathrm{g}} + \frac{v_\ell - v_{\mathrm{g}}}{m_\ell} \tag{73}$$

and the eigenvalue equation (60) simplifies to

$$\begin{aligned}(\lambda - v_{\mathrm{g}})(\lambda - v_\ell)(\hat{\rho}\lambda - m_{\mathrm{g}} v_{\mathrm{g}} - \zeta m_\ell v_\ell) + m_{\mathrm{g}} m_\ell \left(\mu_\ell (\lambda - v_{\mathrm{g}})^2 - \mu_{\mathrm{g}} (\lambda - v_\ell)^2\right) \\ - \kappa \rho_{\mathrm{g}} \rho_\ell \left(\alpha_{\mathrm{g}} + \zeta \alpha_\ell\right)(\lambda - v_{\mathrm{g}}) = 0.\end{aligned} \tag{74}$$

4.3. Dimensionless formulation. By making the substitution

$$\lambda = v_{\mathrm{g}} + a\sigma \tag{75}$$

we will achieve some simplification, where a now plays the role of the unknown. We may now write (74) as

$$\begin{aligned} &a\sigma(v_{\mathrm{g}} - v_\ell + a\sigma)\left(\hat{\rho}a\sigma + \zeta m_\ell(v_{\mathrm{g}} - v_\ell)\right) + m_{\mathrm{g}}m_\ell\left(\mu_\ell a^2\sigma^2 - \mu_{\mathrm{g}}(v_{\mathrm{g}} - v_\ell + a\sigma)^2\right) \\ &- \kappa\rho_{\mathrm{g}}\rho_\ell\left(\alpha_{\mathrm{g}} + \zeta\alpha_\ell\right)a\sigma = 0. \end{aligned} \tag{76}$$

Now defining σ as

$$\sigma^2 = \kappa\hat{\rho}\left(\alpha_{\mathrm{g}} + \zeta\alpha_\ell\right) \tag{77}$$

and introducing the *dimensionless* variables

$$\varepsilon = \frac{v_{\mathrm{g}} - v_\ell}{\sigma}, \tag{78}$$

$$z = \frac{m_{\mathrm{g}}\alpha_\ell}{\sigma}\mu_{\mathrm{g}}, \tag{79}$$

$$\psi = \frac{\rho_{\mathrm{g}}}{\hat{\rho}}, \tag{80}$$

$$\varphi = \frac{\rho_\ell}{\hat{\rho}}, \tag{81}$$

the eigenvalue equation (76) may correspondingly be written in dimensionless form

$$a(\varepsilon + a)(a + \zeta\alpha_\ell\varphi\varepsilon) + z\psi a^2 - z\varphi(\varepsilon + a)^2 - \alpha_{\mathrm{g}}\psi\varepsilon a^2 - \varphi\psi a = 0. \tag{82}$$

Now introducing the *pseudoliquid fraction*

$$\hat{\alpha} = \zeta\alpha_\ell \tag{83}$$

and noting that

$$\alpha_{\mathrm{g}}\psi + \zeta\alpha_\ell\varphi = 1, \tag{84}$$

the eigenvalue equation (82) simplifies to

$$a^3 + \left(2\hat{\alpha}\varphi\varepsilon - z(\varphi - \psi)\right)a^2 + \varphi\left(\hat{\alpha}\varepsilon^2 - 2z\varepsilon - \psi\right)a - z\varphi\varepsilon^2 = 0. \tag{85}$$

4.4. A power series approximation. We may now write a as a power series expansion

$$a = \sum_{i=0}^{\infty}\beta_i\chi^i \tag{86}$$

for some perturbation parameter χ. Now several choices for χ are available through (78)–(81), depending on the values of the physical variables. In the following, we will use as our starting point the *incompressible* limit and obtain eigenvalues accurate to the lowest orders of compressibility.

Towards this aim, we observe that σ given by (77) will have a magnitude in the order of the phasic sound velocities (which tend to infinity in the incompressible limit). Hence, for subsonic flows, we expect

$$\varepsilon \ll 1. \tag{87}$$

Consequently we write

$$a = \sum_{i=0}^{\infty} \beta_i \varepsilon^i \tag{88}$$

and obtain the coefficients β_i by repeatedly solving (85) to the corresponding order in ε.

4.4.1. Material wave. From (85) we obtain

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \\ \vdots \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ -z/\psi \\ 2z^2/\psi^2 \\ \vdots \end{bmatrix}, \tag{89}$$

which translates into the eigenvalue

$$\lambda^{\mathrm{m}} = v_{\mathrm{g}} - \frac{\alpha_{\mathrm{g}}\alpha_\ell}{\alpha_{\mathrm{g}} + \zeta\alpha_\ell}\mu_{\mathrm{g}}\frac{(v_{\mathrm{g}} - v_\ell)^2}{\kappa} + \mathcal{O}(\varepsilon^3) \tag{90}$$

by the relations of section 4.3.

4.4.2. Sonic waves. We will find it convenient to introduce the shorthand

$$w = \sqrt{z^2(\psi - \varphi)^2 + 4\varphi\psi}. \tag{91}$$

From (85) we obtain

- *downstream pressure wave*

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} \left((\varphi - \psi)z + w\right)/2 \\ 2\varphi\left(z - \hat{\alpha}\beta_0\right)/w \\ \beta_1\left(4\varphi\psi(1 - \hat{\alpha}\varphi) - z^2(\varphi^2 - \psi^2) - 2\varphi w z\right)/(2\beta_0 w^2) \\ \vdots \end{bmatrix}, \tag{92}$$

- *upstream pressure wave* (obtained from (85))

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} \left((\varphi - \psi)z - w\right)/2 \\ -2\varphi\left(z - \hat{\alpha}\beta_0\right)/w \\ \beta_1\left(4\varphi\psi(1 - \hat{\alpha}\varphi) - z^2(\varphi^2 - \psi^2) + 2\varphi w z\right)/(2\beta_0 w^2) \\ \vdots \end{bmatrix}. \tag{93}$$

Now by writing the sonic eigenvalues in the form

$$\lambda^{\mathrm{p}} = \bar{v}^{\mathrm{p}} \pm c, \tag{94}$$

the coefficients (92)–(93) yield after some manipulation

$$\bar{v}^{\mathrm{p}} = \frac{m_{\mathrm{g}}v_{\mathrm{g}} + \zeta m_\ell v_\ell}{m_{\mathrm{g}} + \zeta m_\ell} + m_{\mathrm{g}}\alpha_\ell\mu_{\mathrm{g}}\frac{\rho_\ell - \rho_{\mathrm{g}}}{2\hat{\rho}} + \frac{\alpha_{\mathrm{g}}\alpha_\ell}{\alpha_{\mathrm{g}} + \zeta\alpha_\ell}\mu_{\mathrm{g}}\frac{(v_{\mathrm{g}} - v_\ell)^2}{2\kappa} + \mathcal{O}(\varepsilon^3), \tag{95}$$

as well as the sonic velocity c:

$$c = \frac{1}{2}w\sigma + \frac{z\varphi}{w}\left(2 - \hat{\alpha}(\varphi - \psi)\right)(v_{\mathrm{g}} - v_\ell) + \mathcal{O}(\varepsilon^2). \tag{96}$$

Remark 3. Given that

$$\operatorname{trace}(\mathbf{A}) = \sum_i \lambda_i, \tag{97}$$

the following *exact* relation between $\bar{v}^{\mathrm{p}}$ and λ^{m} is satisfied:

$$2\bar{v}^{\mathrm{p}} + \lambda^{\mathrm{m}} = \frac{1}{\hat{\rho}}\left(m_{\mathrm{g}} m_\ell \mu_{\mathrm{g}}\left(1 - \frac{\rho_{\mathrm{g}}}{\rho_\ell}\right)\right) + v_{\mathrm{g}} + 2\frac{m_{\mathrm{g}} v_{\mathrm{g}} + \zeta m_\ell v_\ell}{\hat{\rho}}. \tag{98}$$

Remark 4. Although these eigenvalue expressions have been obtained under the assumption (71), similar techniques may be applied to solve (60) for other slip relations not satisfying (71). However, some knowledge of the relationship between the parameters μ_{g}, μ_ℓ, and μ_{v} will be useful for simplifying the calculations and determining a good choice of perturbation parameter.

4.5. Zuber–Findlay revisited. We now revisit the special case of the Zuber–Findlay slip relation (63)

$$v_{\mathrm{g}} = K(\alpha_{\mathrm{g}} v_{\mathrm{g}} + \alpha_\ell v_\ell) + S, \tag{99}$$

but we now consider K and S to be *constants*, which depend on the flow regime. This further simplification of (71) is often used for practical calculations [11, 15, 30].

4.5.1. Slip derivatives. By differentiation, we obtain the following explicit expressions for the slip parameters (34)–(37):

$$\mu_{\mathrm{v}} = \frac{K-1}{K\alpha_\ell}, \tag{100}$$

$$\mu_{\mathrm{g}} = (v_{\mathrm{g}} - v_\ell)\kappa\frac{\partial \rho_\ell}{\partial p}, \tag{101}$$

$$\mu_\ell = -(v_{\mathrm{g}} - v_\ell)\kappa\frac{\alpha_{\mathrm{g}}}{\alpha_\ell}\frac{\partial \rho_{\mathrm{g}}}{\partial p}, \tag{102}$$

and

$$\zeta = \frac{1 - K\alpha_{\mathrm{g}}}{K\alpha_\ell}. \tag{103}$$

Asymptotic expressions for the eigenvalues could now be obtained by substituting (100)–(103) into the previously calculated expressions (90) and (95)–(96). Equivalently, we may also substitute (100)–(103) into (76) and repeat the power series analysis. This will greatly simplify the calculations, a point that will be demonstrated in the following.

4.5.2. Eigenvalue equation. From (101) we note that z, as defined by (79), may be written as

$$z = \eta\varepsilon, \tag{104}$$

where

$$\eta = m_{\mathrm{g}}\alpha_\ell\kappa\frac{\partial \rho_\ell}{\partial p}. \tag{105}$$

Substituting in (85) we obtain the eigenvalue equation

$$a^3 + \varepsilon\left(2\hat{\alpha}\varphi - \eta(\varphi - \psi)\right)a^2 + \varphi\left(\hat{\alpha}\varepsilon^2 - 2\eta\varepsilon^2 - \psi\right)a - \eta\varphi\varepsilon^3 = 0. \tag{106}$$

4.5.3. Material wave. Solving (106) to powers of ε yields the following coefficients:

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \beta_3 \\ \beta_4 \\ \beta_5 \\ \vdots \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ -\eta/\psi \\ 0 \\ \eta(2\eta - \hat{\alpha})/\psi^2 \\ \vdots \end{bmatrix}. \tag{107}$$

Hence

$$\lambda_{\mathrm{m}} = v_{\mathrm{g}} - K\alpha_{\mathrm{g}}\alpha_\ell \frac{\partial \rho_\ell}{\partial p}(v_{\mathrm{g}} - v_\ell)^3 + \mathcal{O}(\varepsilon^5). \tag{108}$$

Changes in the material composition are consequently propagated by the velocity of the gas bubbles, plus small correction terms representing volumetric changes due to compression. Note that $\lambda_{\mathrm{m}} = v_{\mathrm{g}}$ becomes an *exact* eigenvalue for $\eta = 0$, the limit of incompressible liquid [16].

4.5.4. Sonic waves. For the sonic waves, we obtain the following coefficients:

- *Downstream pressure wave*

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} \sqrt{\varphi\psi} \\ \eta(\phi - \psi)/2 - \hat{\alpha}\varphi \\ \left(2\varphi(4\eta + 2\hat{\alpha}\eta\psi - \eta^2\psi - 4\hat{\alpha}) + (2\hat{\alpha} - \eta)^2\varphi^2 + \eta^2\psi^2\right)/(8\sqrt{\varphi\psi}) \\ \vdots \end{bmatrix}, \tag{109}$$

- *Upstream pressure wave*

$$\begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \\ \vdots \end{bmatrix} = \begin{bmatrix} -\sqrt{\varphi\psi} \\ \eta(\phi - \psi)/2 - \hat{\alpha}\varphi \\ -\left(2\varphi(4\eta + 2\hat{\alpha}\eta\psi - \eta^2\psi - 4\hat{\alpha}) + (2\hat{\alpha} - \eta)^2\varphi^2 + \eta^2\psi^2\right)/(8\sqrt{\varphi\psi}) \\ \vdots \end{bmatrix}. \tag{110}$$

Hence

$$\bar{v}^{\mathrm{p}} = \frac{m_{\mathrm{g}}v_{\mathrm{g}} + \zeta m_\ell v_\ell}{m_{\mathrm{g}} + \zeta m_\ell} + m_{\mathrm{g}}\alpha_\ell\kappa\frac{\partial \rho_\ell}{\partial p}(v_{\mathrm{g}} - v_\ell)\frac{\rho_\ell - \rho_{\mathrm{g}}}{2\hat{\rho}} + \mathcal{O}(\varepsilon^3), \tag{111}$$

and the sound velocity c may be written as

$$c = \sqrt{\frac{\kappa\rho_{\mathrm{g}}\rho_\ell}{K\alpha_{\mathrm{g}}(\rho_{\mathrm{g}} - \rho_\ell) + \rho_\ell}} + \mathcal{O}(\varepsilon)^2. \tag{112}$$

Remark 5. Note that $\rho_{\mathrm{g}} \ll \rho_\ell$ implies $c \ll \sigma$, and the requirement $\varepsilon \ll 1$ (87) has a significantly broader range of validity than the assumption of subsonic slip, $|v_{\mathrm{g}} - v_\ell| \ll c$.

Remark 6. The sonic eigenvalues may be written as

$$\lambda_{\mathrm{s}} = v_\ell \pm \sqrt{\frac{(\partial p/\partial \rho_{\mathrm{g}})\rho_{\mathrm{g}}}{(1 - K\alpha_{\mathrm{g}})\rho_\ell\alpha_{\mathrm{g}}}} + \mathcal{O}(\eta) + \mathcal{O}(\psi) + \mathcal{O}(\varepsilon^2), \tag{113}$$

which reduces to the result (67) when $p(\rho_{\mathrm{g}})$ satisfies the ideal gas law.

5. Two-fluid formulation. In this section, we perform the transformation required to write the *general* drift-flux model of section 3.1 in *canonical two-fluid form* as described in section 2.3. In other words, we replace the conservation equation (19), together with the slip relation (20), with equivalent evolution equations for the momentums of each phase.

5.1. Momentum evolution equations. We first derive an explicit gas momentum evolution equation for the general drift-flux model with slip relation (20). Our starting point is the previously derived differential (45), which becomes

$$\frac{\partial I_{\mathrm{g}}}{\partial t} = \frac{1}{\hat{\rho}} \left(m_{\mathrm{g}} \frac{\partial I}{\partial t} + (m_{\mathrm{g}} m_\ell \mu_{\mathrm{g}} + \zeta m_\ell v_{\mathrm{g}}) \frac{\partial m_{\mathrm{g}}}{\partial t} + (m_{\mathrm{g}} m_\ell \mu_\ell - m_{\mathrm{g}} v_\ell) \frac{\partial m_\ell}{\partial t} \right), \tag{114}$$

when written as a partial derivative with respect to t.

By using the conservation equations (27)–(29), we obtain the gas momentum evolution equation, written in terms of spatial derivatives

$$\begin{aligned} &\frac{\partial I_{\mathrm{g}}}{\partial t} + \frac{m_{\mathrm{g}}}{\hat{\rho}} \frac{\partial}{\partial x} (I_{\mathrm{g}} v_{\mathrm{g}} + I_\ell v_\ell + p) + \frac{\zeta m_\ell}{\hat{\rho}} v_{\mathrm{g}} \frac{\partial I_{\mathrm{g}}}{\partial x} \\ &- \frac{m_{\mathrm{g}}}{\hat{\rho}} v_\ell \frac{\partial I_\ell}{\partial x} + \frac{m_{\mathrm{g}} m_\ell}{\hat{\rho}} \left(\mu_{\mathrm{g}} \frac{\partial I_{\mathrm{g}}}{\partial x} + \mu_\ell \frac{\partial I_\ell}{\partial x} \right) = \frac{m_{\mathrm{g}}}{\hat{\rho}} Q. \end{aligned} \tag{115}$$

Further manipulation of derivatives yields

$$\begin{aligned} &\frac{\partial I_{\mathrm{g}}}{\partial t} + \frac{\partial}{\partial x} (I_{\mathrm{g}} v_{\mathrm{g}}) + \frac{m_{\mathrm{g}}}{\hat{\rho}} \frac{\partial p}{\partial x} \\ &+ \frac{m_{\mathrm{g}} m_\ell}{\hat{\rho}} \left(v_\ell \frac{\partial v_\ell}{\partial x} - \zeta v_{\mathrm{g}} \frac{\partial v_{\mathrm{g}}}{\partial x} + \mu_{\mathrm{g}} \frac{\partial I_{\mathrm{g}}}{\partial x} + \mu_\ell \frac{\partial I_\ell}{\partial x} \right) = \frac{m_{\mathrm{g}}}{\hat{\rho}} Q. \end{aligned} \tag{116}$$

5.1.1. Canonical form. Writing (116) under the canonical two-fluid form of section 2.3,

$$\frac{\partial I_{\mathrm{g}}}{\partial t} + \frac{\partial}{\partial x} (I_{\mathrm{g}} v_{\mathrm{g}}) + \alpha_{\mathrm{g}} \frac{\partial p}{\partial x} + \tau_{\mathrm{i}} = Q_{\mathrm{g}}, \tag{117}$$

where $Q = Q_{\mathrm{g}} + Q_\ell$, we find that the interface friction τ_{i} is given by

$$\begin{aligned} \tau_{\mathrm{i}} = {} & \alpha_{\mathrm{g}} \alpha_\ell \frac{\rho_{\mathrm{g}} - \zeta \rho_\ell}{\hat{\rho}} \frac{\partial p}{\partial x} + \frac{\zeta m_\ell}{\hat{\rho}} Q_{\mathrm{g}} - \frac{m_{\mathrm{g}}}{\hat{\rho}} Q_\ell \\ &+ \frac{m_{\mathrm{g}} m_\ell}{\hat{\rho}} \left(v_\ell \frac{\partial v_\ell}{\partial x} - \zeta v_{\mathrm{g}} \frac{\partial v_{\mathrm{g}}}{\partial x} + \mu_{\mathrm{g}} \frac{\partial I_{\mathrm{g}}}{\partial x} + \mu_\ell \frac{\partial I_\ell}{\partial x} \right). \end{aligned} \tag{118}$$

5.1.2. Liquid momentum evolution. By inserting (118) into the canonical liquid momentum equation (17), we obtain

$$\begin{aligned} &\frac{\partial I_\ell}{\partial t} + \frac{\partial}{\partial x} (I_\ell v_\ell) + \frac{\zeta m_\ell}{\hat{\rho}} \frac{\partial p}{\partial x} \\ &- \frac{m_{\mathrm{g}} m_\ell}{\hat{\rho}} \left(v_\ell \frac{\partial v_\ell}{\partial x} - \zeta v_{\mathrm{g}} \frac{\partial v_{\mathrm{g}}}{\partial x} + \mu_{\mathrm{g}} \frac{\partial I_{\mathrm{g}}}{\partial x} + \mu_\ell \frac{\partial I_\ell}{\partial x} \right) = \frac{\zeta m_\ell}{\hat{\rho}} Q. \end{aligned} \tag{119}$$

5.2. Quasi-linear formulation. We may now express this rewritten drift-flux model in quasi-linear form:

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A}\frac{\partial \mathbf{U}}{\partial x} = \mathbf{Q}, \tag{120}$$

similar to section 3.2. However, the matrix $\mathbf{A}$ is now 4×4 and $\mathbf{U}$ is given by

$$\mathbf{U} = \begin{bmatrix} \rho_{\mathrm{g}}\alpha_{\mathrm{g}} \\ \rho_{\ell}\alpha_{\ell} \\ \rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}} \\ \rho_{\ell}\alpha_{\ell}v_{\ell} \end{bmatrix}, \tag{121}$$

whereas the vector of sources is

$$\mathbf{Q} = \frac{1}{\hat{\rho}} \begin{bmatrix} 0 \\ 0 \\ m_{\mathrm{g}}Q \\ \zeta m_{\ell}Q \end{bmatrix}. \tag{122}$$

We now split (118) into four parts:

$$\tau_{\mathrm{i}} = \tau_p + \tau_v + \tau_{\alpha} + \tau_Q, \tag{123}$$

where

$$\tau_p = \alpha_{\mathrm{g}}\alpha_{\ell}\frac{\rho_{\mathrm{g}} - \zeta\rho_{\ell}}{\hat{\rho}}\frac{\partial p}{\partial x}, \tag{124}$$

$$\tau_v = \frac{m_{\mathrm{g}}m_{\ell}}{\hat{\rho}}\left(v_{\ell}\frac{\partial v_{\ell}}{\partial x} - \zeta v_{\mathrm{g}}\frac{\partial v_{\mathrm{g}}}{\partial x}\right), \tag{125}$$

$$\tau_{\alpha} = \frac{m_{\mathrm{g}}m_{\ell}}{\hat{\rho}}\left(\mu_{\mathrm{g}}\frac{\partial I_{\mathrm{g}}}{\partial x} + \mu_{\ell}\frac{\partial I_{\ell}}{\partial x}\right), \tag{126}$$

and

$$\tau_Q = \frac{\zeta m_{\ell}}{\hat{\rho}}Q_{\mathrm{g}} - \frac{m_{\mathrm{g}}}{\hat{\rho}}Q_{\ell}. \tag{127}$$

This defines a natural decomposition of the Jacobi matrix as follows:

$$\mathbf{A}(\mathbf{U}) = \mathbf{A}_0 + \mathbf{A}_p + \mathbf{A}_v + \mathbf{A}_{\alpha}, \tag{128}$$

i.e., one additional contribution for each differential term of the interface friction.

5.2.1. $\mathbf{A_0}$. The Jacobi matrix for the canonical two-fluid model with $\tau_{\mathrm{i}} = 0$ is [12]

$$\mathbf{A}_0 = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ \kappa\rho_{\ell}\alpha_{\mathrm{g}} - v_{\mathrm{g}}^2 & \kappa\rho_{\mathrm{g}}\alpha_{\mathrm{g}} & 2v_{\mathrm{g}} & 0 \\ \kappa\rho_{\ell}\alpha_{\ell} & \kappa\rho_{\mathrm{g}}\alpha_{\ell} - v_{\ell}^2 & 0 & 2v_{\ell} \end{bmatrix}. \tag{129}$$

5.2.2. $\mathbf{A}_{\boldsymbol{p}}$. From (49) we obtain

$$\mathbf{A}_p(\mathbf{U}) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \kappa\rho_\ell\alpha_{\mathrm{g}}\alpha_\ell\frac{\rho_{\mathrm{g}}-\zeta\rho_\ell}{\hat{\rho}} & \kappa\rho_{\mathrm{g}}\alpha_{\mathrm{g}}\alpha_\ell\frac{\rho_{\mathrm{g}}-\zeta\rho_\ell}{\hat{\rho}} & 0 & 0 \\ -\kappa\rho_\ell\alpha_{\mathrm{g}}\alpha_\ell\frac{\rho_{\mathrm{g}}-\zeta\rho_\ell}{\hat{\rho}} & -\kappa\rho_\ell\alpha_{\mathrm{g}}\alpha_\ell\frac{\rho_{\mathrm{g}}-\zeta\rho_\ell}{\hat{\rho}} & 0 & 0 \end{bmatrix}. \tag{130}$$

5.2.3. $\mathbf{A}_{\boldsymbol{v}}$. From

$$dv_{\mathrm{g}} = \frac{1}{m_{\mathrm{g}}}\,dI_{\mathrm{g}} - \frac{v_{\mathrm{g}}}{m_{\mathrm{g}}}\,dm_{\mathrm{g}} \tag{131}$$

and

$$dv_\ell = \frac{1}{m_\ell}\,dI_\ell - \frac{v_\ell}{m_\ell}\,dm_\ell \tag{132}$$

we obtain

$$\mathbf{A}_v(\mathbf{U}) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ \frac{\zeta m_\ell}{\hat{\rho}}v_{\mathrm{g}}^2 & -\frac{m_{\mathrm{g}}}{\hat{\rho}}v_\ell^2 & -\frac{\zeta m_\ell}{\hat{\rho}}v_{\mathrm{g}} & \frac{m_{\mathrm{g}}}{\hat{\rho}}v_\ell \\ -\frac{\zeta m_\ell}{\hat{\rho}}v_{\mathrm{g}}^2 & \frac{m_{\mathrm{g}}}{\hat{\rho}}v_\ell^2 & \frac{\zeta m_\ell}{\hat{\rho}}v_{\mathrm{g}} & -\frac{m_{\mathrm{g}}}{\hat{\rho}}v_\ell \end{bmatrix}. \tag{133}$$

5.2.4. $\mathbf{A}_{\boldsymbol{\alpha}}$. We directly obtain

$$\mathbf{A}_\alpha(\mathbf{U}) = \begin{bmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_{\mathrm{g}} & \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_\ell \\ 0 & 0 & -\frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_{\mathrm{g}} & -\frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_\ell \end{bmatrix}. \tag{134}$$

5.2.5. End result. Adding all contributions we obtain from (128)

(135)

$$\mathbf{A}(\mathbf{U}) = \begin{bmatrix} 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \\ \frac{m_{\mathrm{g}}}{\hat{\rho}}\left(\kappa\rho_\ell - v_{\mathrm{g}}^2\right) & \frac{m_{\mathrm{g}}}{\hat{\rho}}\left(\kappa\rho_{\mathrm{g}} - v_\ell^2\right) & \left(2-\frac{\zeta m_\ell}{\hat{\rho}}\right)v_{\mathrm{g}} + \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_{\mathrm{g}} & \frac{m_{\mathrm{g}}}{\hat{\rho}}v_\ell + \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_\ell \\ \frac{\zeta m_\ell}{\hat{\rho}}\left(\kappa\rho_\ell - v_{\mathrm{g}}^2\right) & \frac{\zeta m_\ell}{\hat{\rho}}\left(\kappa\rho_{\mathrm{g}} - v_\ell^2\right) & \frac{\zeta m_\ell}{\hat{\rho}}v_{\mathrm{g}} - \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_{\mathrm{g}} & \left(2-\frac{m_{\mathrm{g}}}{\hat{\rho}}\right)v_\ell - \frac{m_{\mathrm{g}}m_\ell}{\hat{\rho}}\mu_\ell \end{bmatrix}.$$

5.2.6. Eigenvalues. The eigenvalues of the matrix $\mathbf{A}$ are the roots of the polynomial equation

$$\begin{aligned} &\lambda\Big[(\lambda - v_{\mathrm{g}})(\lambda - v_\ell)(\hat{\rho}\lambda - m_{\mathrm{g}}v_{\mathrm{g}} - \zeta m_\ell v_\ell) \\ &\quad + m_{\mathrm{g}}m_\ell\left(\mu_\ell(\lambda - v_{\mathrm{g}})^2 - \mu_{\mathrm{g}}(\lambda - v_\ell)^2\right) \\ &\quad + \kappa\rho_{\mathrm{g}}\rho_\ell\left(\alpha_{\mathrm{g}}\alpha_\ell(\rho_{\mathrm{g}}\mu_{\mathrm{g}} - \rho_\ell\mu_\ell) - \alpha_{\mathrm{g}}(\lambda - v_\ell) - \zeta\alpha_\ell(\lambda - v_{\mathrm{g}})\right)\Big] = 0. \end{aligned} \tag{136}$$

By direct comparison with (60), we see that this may be written as

$$\lambda P(\lambda) = 0, \tag{137}$$

where $P(\lambda)$ is the eigenvalue polynomial for the original drift-flux model.

Remark 7. We have written the drift-flux model as a quasi-linear system of four equations by deriving two momentum equations which replace the mixed momentum equation and the slip law. As a consequence, the characteristic speeds of this system are given by (137) showing that a new characteristic speed $\lambda = 0$, representing the slip relation, has been added to the characteristic speeds already given by the drift-flux model.

This situation is similar to what is observed for a much simpler problem. Consider the scalar equation

$$u_t + f(u)_x = k'(x)g(u), \tag{138}$$

where k, f, and g are given functions. A common approach for deriving numerical schemes for the model (138) is to first write the model as a quasi-linear system of two equations, by adding the trivial equation $k_t = 0$, which gives

$$U_t + A(U)U_x = 0, \qquad U = \begin{pmatrix} u \\ k \end{pmatrix}, \qquad A(U) = \begin{pmatrix} f'(u) & -g(u) \\ 0 & 0 \end{pmatrix}. \tag{139}$$

The characteristic speeds of this system are given by $\lambda_1 = f'(u)$ and $\lambda_2 = 0$. If $f'(u) = 0$ for some u, then the eigenvalues coincide, and we have so-called resonance; see, for instance, [17] and the references therein for more on this. Note that this phenomenon might well also occur for our system (120)–(126), since one of the solutions of $P(\lambda) = 0$ corresponding to the slow material wave (see below for more details) can be zero. This happens when $v_{\mathrm{g}} = v_\ell = 0$.

It is interesting to note that the form (139) often is used as the starting point for designing numerical schemes for solving (138). In a similar manner we could imagine to use the above two-fluid form (120)–(126) as a starting point for developing a numerical scheme for the drift-flux model, e.g., by using the numerical schemes more recently proposed in [13, 14] for the two-fluid model.

6. Interface friction and wave velocities. In this section, we investigate how the wave structure of the two-fluid model gradually changes as it is transformed into a drift-flux model by addition of the various terms of (123). Our starting point is the *canonical model* with $\tau_i = 0$:

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}\right) + \frac{\partial}{\partial x}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}\right) = 0, \tag{140}$$

$$\frac{\partial}{\partial t}\left(\rho_\ell\alpha_\ell\right) + \frac{\partial}{\partial x}\left(\rho_\ell\alpha_\ell v_\ell\right) = 0, \tag{141}$$

$$\frac{\partial}{\partial t}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}\right) + \frac{\partial}{\partial x}\left(\rho_{\mathrm{g}}\alpha_{\mathrm{g}}v_{\mathrm{g}}^2\right) + \alpha_{\mathrm{g}}\frac{\partial}{\partial x}\left(p\right) = Q_{\mathrm{g}}, \tag{142}$$

$$\frac{\partial}{\partial t}\left(\rho_\ell\alpha_\ell v_\ell\right) + \frac{\partial}{\partial x}\left(\rho_\ell\alpha_\ell v_\ell^2\right) + \alpha_\ell\frac{\partial}{\partial x}\left(p\right) = Q_\ell. \tag{143}$$

6.1. Wave structure of the canonical model. For different choices of τ_i, Toumi and coworkers [27, 28, 29] investigated the wave structure of the model with a perturbation technique. For $\tau_i = 0$, the wave velocities are precisely the eigenvalues of the matrix $\mathbf{A}_0$ given by (129). Now defining

$$\varepsilon = \frac{v_{\mathrm{g}} - v_\ell}{\hat{c}}, \tag{144}$$

where $\hat{c}$ is a *mixture* sonic velocity given by

$$\hat{c} = \sqrt{\frac{\rho_\ell \alpha_{\mathrm{g}} + \rho_{\mathrm{g}} \alpha_\ell}{(\partial \rho_{\mathrm{g}}/\partial p)\rho_\ell \alpha_{\mathrm{g}} + (\partial \rho_\ell/\partial p)\rho_{\mathrm{g}} \alpha_\ell}} = \sqrt{(\rho_\ell \alpha_{\mathrm{g}} + \rho_{\mathrm{g}} \alpha_\ell)\kappa}, \tag{145}$$

approximate eigenvalues for (140)–(143) were presented by Evje and Flåtten [12] as described below.

6.1.1. Material waves. Writing

$$\lambda_{\mathrm{m}} = \bar{v}^{\mathrm{v}} \pm \gamma, \tag{146}$$

we obtain

$$\bar{v}^{\mathrm{v}} = \frac{\rho_{\mathrm{g}} \alpha_\ell v_{\mathrm{g}} + \rho_\ell \alpha_{\mathrm{g}} v_\ell}{\rho_{\mathrm{g}} \alpha_\ell + \rho_\ell \alpha_{\mathrm{g}}} + \mathcal{O}(\varepsilon^3) \tag{147}$$

and

$$\gamma = i \frac{\sqrt{\rho_{\mathrm{g}} \rho_\ell \alpha_{\mathrm{g}} \alpha_\ell}(v_{\mathrm{g}} - v_\ell)}{\rho_{\mathrm{g}} \alpha_\ell + \rho_\ell \alpha_{\mathrm{g}}} + \mathcal{O}(\varepsilon^3). \tag{148}$$

Remark 8. Note that unless $v_{\mathrm{g}} = v_\ell$, γ is imaginary and the canonical two-fluid model with $\tau_i = 0$ loses hyperbolicity. Hence the inclusion of a differential interface friction τ_i is essential for obtaining a well-behaved mathematical solution.

Remark 9. Note that if $\rho_{\mathrm{g}} \ll \rho_\ell$, $\bar{v}^{\mathrm{v}} \approx v_\ell$ and the material waves travel with the velocity of the liquid phase. This is quite the opposite of the drift-flux model, where the velocity of the material wave corresponds to the gas velocity v_{g} (section 4.4).

6.1.2. Sonic waves. Writing

$$\lambda_{\mathrm{s}} = \bar{v}^{\mathrm{p}} \pm c, \tag{149}$$

we obtain

$$\bar{v}^{\mathrm{p}} = \frac{\rho_{\mathrm{g}} \alpha_\ell v_\ell + \rho_\ell \alpha_{\mathrm{g}} v_{\mathrm{g}}}{\rho_{\mathrm{g}} \alpha_\ell + \rho_\ell \alpha_{\mathrm{g}}} + \mathcal{O}(\varepsilon^3) \tag{150}$$

and

$$c = \hat{c}\left(1 + \mathcal{O}(\varepsilon^2)\right). \tag{151}$$

Remark 10. If $\rho_{\mathrm{g}} \ll \rho_\ell$, $\bar{v}^{\mathrm{p}} \approx v_{\mathrm{g}}$ and the part of the sonic wave that is transported along the flow travels with the velocity of the gas phase. Again this contrasts the drift-flux model, where the corresponding result of section 4.4 yields $\bar{v}^{\mathrm{p}} \approx v_\ell$.

6.2. Numerical investigations. In the framework of the canonical two-fluid model, the eigenvalues of the previous section correspond to $\tau_i = 0$, whereas the eigenvalues of section 4.4 correspond to the interface friction (123),

$$\tau_{\mathrm{i}} = \tau_p + \tau_v + \tau_\alpha + \tau_Q, \tag{152}$$

which was derived in section 5.1.1. We now study the relation between the interface friction and the wave velocities more closely, by looking at a specific example. More precisely, we consider a two-phase flow satisfying the Zuber–Findlay slip relation (63) with phasic properties roughly representing an air-water mixture.

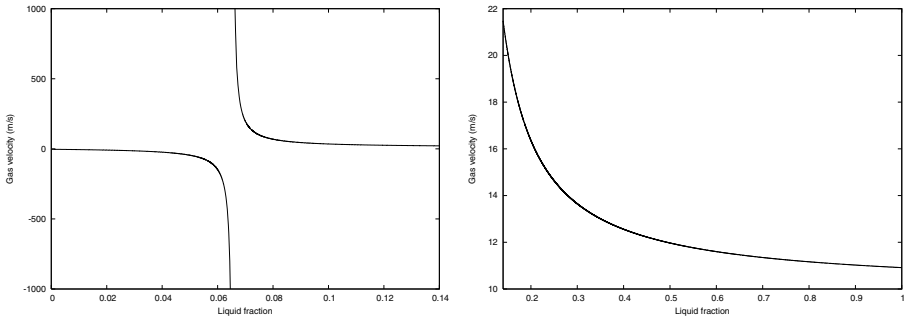

FIG. 1. *The Zuber–Findlay gas velocity as a function of liquid fraction. Left: Near singularity. Right: Physical region.*

6.2.1. Model parameters. In the following, we assume that the phasic velocities are related by the Zuber–Findlay slip relation

$$v_{\mathrm{g}} = K\left(\alpha_{\mathrm{g}} v_{\mathrm{g}} + \alpha_\ell v_\ell\right) + S, \tag{153}$$

where we choose

$$K = 1.07 \tag{154}$$

and

$$S = 0.216 \text{ m/s}. \tag{155}$$

Furthermore, we assume the flow conditions

$$v_\ell = 10 \text{ m/s}, \tag{156}$$

$$\rho_{\mathrm{g}} = 1.0 \text{ kg/m}^3, \tag{157}$$

$$\rho_\ell = 1000 \text{ kg/m}^3, \tag{158}$$

$$\partial p/\partial \rho_{\mathrm{g}} = 10^5 \text{ m}^2/\text{s}^2, \tag{159}$$

$$\partial p/\partial \rho_\ell = 10^6 \text{ m}^2/\text{s}^2. \tag{160}$$

6.2.2. Gas velocity. By inspecting the slip expression (153) we find there is a singularity corresponding to

$$\hat{\alpha} = \zeta \alpha_\ell = \frac{1 - K\alpha_{\mathrm{g}}}{K} = 0, \tag{161}$$

which with our choice of parameters occurs at

$$\alpha_\ell^{\mathrm{crit}} \approx 0.0654. \tag{162}$$

The gas velocity v_{g} changes sign from $-\infty$ to $+\infty$ across the singularity, as shown in Figure 1. However, $\alpha_\ell < \alpha_\ell^{\mathrm{crit}}$ implies large gas bubbles corresponding more or less to the *annular* flow regime, where the drift-flux model is not applicable [16]. Hence we discard the corresponding results as unphysical and base our further investigations on the assumption $\alpha_\ell > \alpha_\ell^{\mathrm{crit}}$.

6.2.3. Wave velocities. We now investigate the effect of the different terms of

$$\tau_{\mathrm{i}} = \tau_p + \tau_v + \tau_\alpha + \tau_Q \tag{163}$$

on the wave velocities of the canonical two-fluid model. Note that τ_Q, as given by (124), is purely nondifferential, and hence has no effect on the wave structure of the model. In the following plots we use the labels

- *two-fluid:* $\tau_i = 0$,
- *drift-flux:* $\tau_i = \tau_p + \tau_v + \tau_\alpha$

to denote the special choices of interface friction yielding the basic two-fluid and drift-flux wave structures, respectively, as described in sections 4 and 6.1.

Remark 11. Note that with our choice of slip relation (153), the expression (126) may by use of (101) and (102) be rewritten as

$$\tau_\alpha = (v_{\mathrm{g}} - v_\ell)\frac{m_{\mathrm{g}} m_\ell}{\hat{\rho}\alpha_\ell}\frac{\partial \alpha_\ell}{\partial t}. \tag{164}$$

In the following, wave velocities corresponding to different choices of τ_i (163) are calculated as the eigenvalues of the corresponding matrix $\mathbf{A}(\mathbf{U})$ as described in section 5.2. A numerical algorithm was used to calculate the eigenvalues, sorted in ascending order by their real parts as

$$\mathrm{Re}(\lambda_1) < \mathrm{Re}(\lambda_2) < \mathrm{Re}(\lambda_3) < \mathrm{Re}(\lambda_4). \tag{165}$$

Here λ_1 and λ_4 are sonic waves, whereas λ_2 and λ_3 represent slow waves.

6.2.4. Slip wave. As noted in Remark 7, the slip relation manifests itself as a stationary wave for the *drift-flux* interface friction ($\tau_i = \tau_p + \tau_v + \tau_\alpha$). Hence one of the two material waves described in section 6.1.1, corresponding to $\tau_i = 0$, will gradually transform into this stationary "slip wave" as the terms (124)–(126) are added to the interface friction.

The effect of this is illustrated in Figure 2, where $|\lambda_2|$ is plotted as a function of liquid fraction. Already for $\tau_i = \tau_p + \tau_v$, we obtain λ_2=0, which is left unchanged by the addition of τ_α. Note that $\tau_\alpha = 0$ corresponds to a special case of the drift-flux model, where the slip relation satisfies $\mu_{\mathrm{g}} = \mu_\ell = 0$. Hence the "drift-flux" character of the system ($\lambda_2 \equiv 0$) is fully manifest in the τ_p and τ_v components of the interface friction.

6.2.5. Material wave. As seen by the analyses of section 4.5 and 6.1, one material wave is gradually transformed from (146) ($\lambda_{\mathrm{m}} \approx v_\ell$) into (108) ($\lambda_{\mathrm{m}} \approx v_{\mathrm{g}}$).

This is illustrated in Figure 3, where $\mathrm{Re}(\lambda_3)$ is plotted as a function of liquid fraction. Note that without the inclusion of τ_α, the wave velocity is constant. This demonstrates the fact that $\tau_\alpha = 0$ implies that the slip is independent of volume fraction.

6.2.6. Sound velocity. Following sections 4.4.2 and 6.1.2, we write the sonic waves as a combination of two components as follows:

$$\lambda_{\mathrm{s}} = \bar{v}^{\mathrm{p}} \pm c, \tag{166}$$

where $\bar{v}^{\mathrm{p}}$ represents the part of the sonic wave that is transported with the flow, whereas c is the sonic velocity with respect to $\bar{v}^{\mathrm{p}}$. Hence we get

$$c = \frac{\lambda_4 - \lambda_1}{2} \tag{167}$$

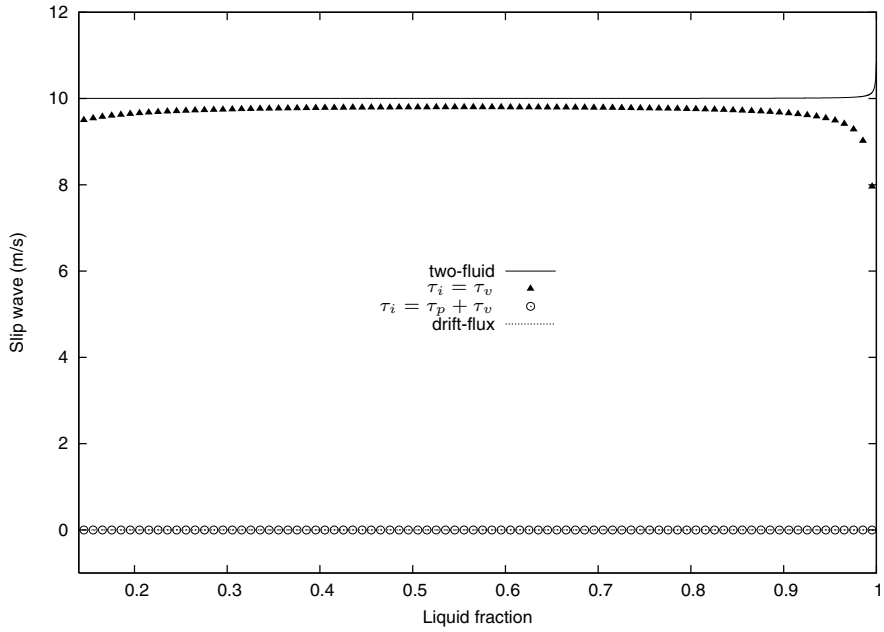

FIG. 2. *Slip wave velocity as a function of liquid fraction.*

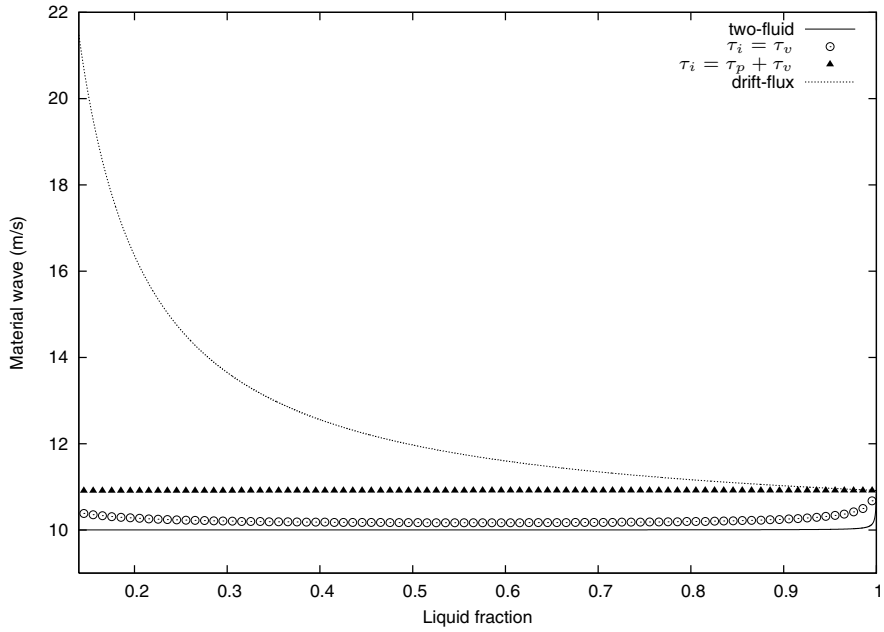

FIG. 3. *Material wave velocity as a function of liquid fraction.*

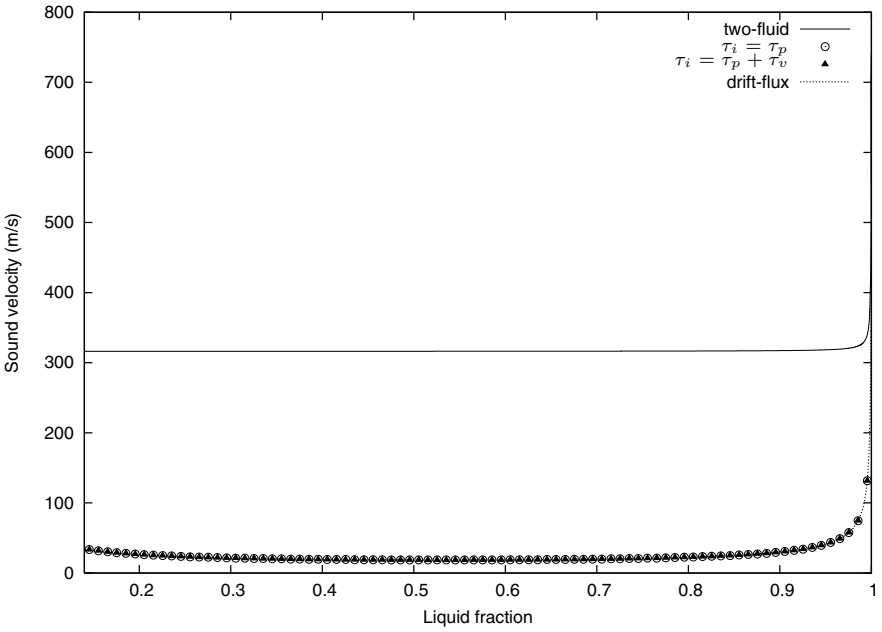

FIG. 4. *Mixture sound velocity as a function of liquid fraction.*

and

$$\bar{v}^{\mathrm{p}} = \frac{\lambda_1 + \lambda_4}{2}. \tag{168}$$

In Figure 4, the sound velocity c is plotted as a function of liquid fraction. We observe that c is transformed from the two-fluid sound velocity (145) into the drift-flux sound velocity (112) by the action of τ_p alone; the terms τ_v and τ_α have no additional effect.

Remark 12. This plot illustrates the fact that whereas for the two-fluid model

$$c_{\mathrm{tf}} \approx c_{\mathrm{g}}, \tag{169}$$

the drift-flux sonic velocity satisfies

$$c_{\mathrm{df}} \ll \min(c_{\mathrm{g}}, c_\ell). \tag{170}$$

A similar parabolic-like shape for $c_{\mathrm{mix}}(\alpha_\ell)$ was also derived by Nguyen, Winther, and Greiner [21] by considering the interface as an elastic wall. They also pointed out that this shape is consistent with experimental data for *mixed* flows.

6.2.7. Sonic transport velocity. The sonic transport velocity $\bar{v}^{\mathrm{p}}$ is plotted in Figure 5. We get more or less the inverse of Figure 3; now $\bar{v}^{\mathrm{p}} \approx v_{\mathrm{g}}$ (two-fluid model) is transformed into $\bar{v}^{\mathrm{p}} \approx v_\ell$ (drift-flux model) by the action of the interface friction (118).

7. Summary. A quasi-linear form of the *drift-flux* two-phase flow model has been derived. The wave structure of this model has been investigated by a perturbation technique, extending previous results of Théron [26] and Benzoni-Gavage [5].

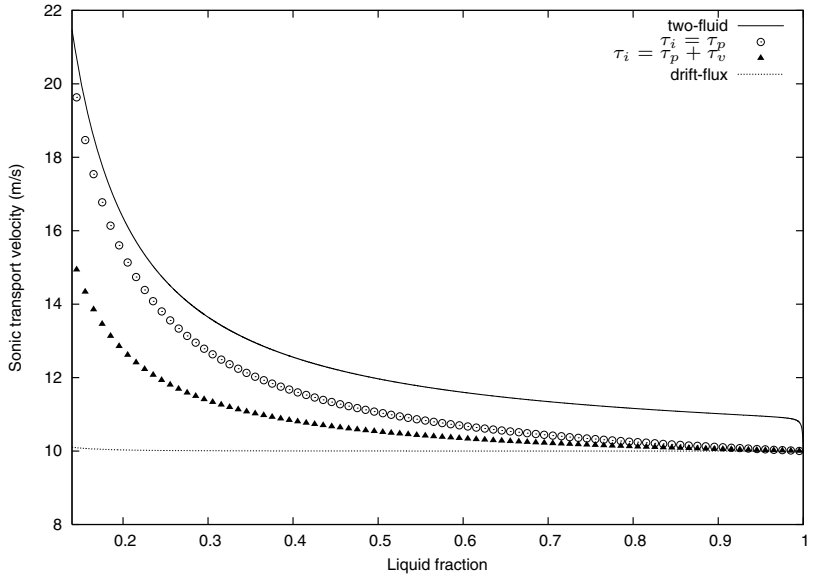

FIG. 5. *Sonic transport velocity* $\bar{v}^{\mathrm{p}}$ *as a function of liquid fraction.*

The drift-flux model has further been rewritten within the framework of a more general *two-fluid* model, by derivation of the proper form of the interface friction τ_i. Here the slip relation is represented as a stationary wave.

The interface friction τ_i may be split into four parts

$$\tau_i = \tau_p + \tau_v + \tau_\alpha + \tau_Q, \tag{171}$$

where the following hold:

- The terms τ_p and τ_v make up the *drift-flux* nature of the system (stationary slip wave).
- The term τ_p is almost exclusively associated with the mixture sound velocity c.
- The term τ_α is associated with the slow waves, imposing a dependency of volume fraction on the material wave.

The drift-flux and two-fluid formulations are often considered to be different modeling strategies with different domains of applicability. The unification presented in this paper may facilitate the implementation of both models within a single computer code. Furthermore, the link presented between the *observable* slip velocity and the underlying interface friction may serve as an aid for developing better physical models for two-phase flows.

Acknowledgments. We thank the editor and reviewers for their comments, which helped us improve the first version of this paper.

PATTERN FORMATION IN AN ARRAY OF OSCILLATORS WITH ELECTRICAL AND CHEMICAL COUPLING*

FATMA GUREL KAZANCI† AND BARD ERMENTROUT†‡

Abstract. Weak coupling theory is applied to a model for firing waves in the procerebral lobe of the slug. Inhibitory synapses and electrical synapses have different synchronizing properties. We show that, in concert, these two types of coupling can cause a bifurcation to a patterned state from synchrony which ultimately develops into traveling waves. Normal forms for the bifurcation are computed, and the results are compared to numerical simulations of the phase models.

Key words. electrical coupling, inhibition, oscillations, waves, synchrony

DOI. 10.1137/060661041

1. Introduction. Networks of coupled neural oscillators exhibit a variety of activity patterns according to the properties of the coupling. There is clear experimental evidence for the existence of electrical and chemical synapses in neocortical inhibitory networks [11]. The effect of each type of coupling in isolation is well studied [4, 17, 19]. Depending on the nature of the neural oscillation, inhibition can be either synchronizing or desynchronizing [19, 12]. Electrical coupling between oscillators is established via gap junctions. In numerous computational and theoretical studies, it has been shown that electrical coupling can promote either synchrony or antisynchrony [18, 1, 4, 3], depending on the shape of the action potential and the nature of the oscillator. Recently, the combined effects of these couplings have been an area of theoretical interest [16, 13, 2, 17]. In these papers, both the inhibition and the gap junctions encouraged synchronization. Coupling is between pairs of oscillators or in all-to-all coupled networks.

In a recent paper [6], Ermentrout et al. explored a biophysical model for the olfactory lobe of the garden slug. Under resting conditions the slug lobe produces slow periodic traveling waves of electrical activity. The oscillations are generated by a class of inhibitory bursting neurons, which are coupled via gap junctions and chemical inhibitory synapses. Experimentally, the wave of activity is biased to move in one direction because of an intrinsic gradient in the frequency of the bursting cells. In the above paper, the authors developed and simulated a biophysical model for the waves with both inhibition and gap junctions. They found that even in the absence of a gradient in frequency, it was possible to generate waves in an otherwise homogeneous network. With large enough gap junction coupling (or small enough inhibition), the network synchronized. However, with weak electrical coupling the network becomes desynchronized, breaking into clusters of cells with different phase-lags. At intermediate coupling strengths, the network produces waves.

Our broad goal in this paper is to explore what happens in spatially distributed

networks when one form of coupling (here, gap junctions) encourages synchrony but the other form of coupling (chemical inhibition) encourages (at least pairwise) anti-phase (half cycle apart) locking. More specifically, we suppose that the synchronous coupling is local and the desynchronizing coupling is long range. Since electrical junctions require that membranes of the cells be in direct contact, we expect that gap junction coupling is spatially localized. In contrast, chemical inhibition might be expected to have longer range. In the slug brain model, the inhibition is global, in that each cell inhibited all the other cells in the network, while the gap junctions were only between nearest neighbors. We show below that inhibition is desynchronizing for the slug model and that gap junctions synchronize, so the slug model serves as an example of a spatially distributed network in which the two types of coupling work in opposition. Ermentrout and Kopell [10] explored the effects of one or two long range desynchronizing interactions between cells that were coupled with local synchronizing interactions. Various types of waves were found via direct analytic calculations which were possible due to the simple form of the coupling.

In this paper, we explore the bifurcation to patterns in a general network of oscillators in which there is long range desynchronizing coupling and short range synchronizing coupling. The strength of the former coupling is a parameter which when increased causes the synchronous state to lose stability. We determine the critical values for this parameter via linear stability analysis, and the direction of the bifurcation via a normal form calculation. To make the analysis possible and to avoid the confound of boundary effects, we forgo the linear chain and work on a circular domain. Numerical results of the chain produce similar behavior, but the analysis is considerably more difficult. The normal form calculation is made somewhat more difficult by the presence of a zero eigenvalue arising from translation invariance. Our method is to first reduce the biophysical model to a chain of phase-coupled oscillators on which we can apply the general theory. Thus, in the first section, after introducing the biophysical model, we compute the interaction functions under the assumption of weak coupling. We show that for this model, gap junctions are synchronizing, while chemical inhibition is desynchronizing. Next, we analyze the bifurcation of patterned states from synchrony in a continuum chain of phase-oscillators. We find a novel phase-locked state which is patterned but not a traveling wave. We numerically illustrate the transition to traveling waves as predicted in the reduced system and provide conditions for the stability of the traveling wave.

2. The model and reduction. Ermentrout et al. introduced a biophysical model for a network of bursting and nonbursting cells in the procerebral lobe of Limax [6]. The bursting cells oscillate at about 1 Hz and are responsible for the electrical wave observed in the lobe. The nonbursting cells fire only in the presence of extrinsic stimuli. Thus, since we are interested only in the genesis of the wave, we focus on the bursting cells. Each cell is an intrinsic oscillator, and, in the model, two types of synapses couple the oscillating neurons: chemical inhibition and electrical or gap junctions. The membrane potential for each bursting cell obeys the following equations:

$$C\frac{dV}{dt} = -I_L - I_K - I_{Ca} - I_{gap} - I_{syn},$$

where each term is a current due respectively to the leak, the potassium channels, the calcium channels, the gap junction coupling, and the synaptic inhibition. We used the parameters given in Appendix B. The gap junction coupling is over nearest neighbors

and depends on the voltage difference between the pre- and postsynaptic cells:

$$I_{gap} = g_{gap}(V_{post} - V_{pre}).$$

Here, "post" refers to the cell receiving the connection from the "pre" cell. The inhibition, I_{syn}, is global—every cell inhibits every other cell. Each synaptic interaction adds a current of the form

$$I_{syn} = g_{syn} s_{pre}(V_{post} - E_{syn}),$$

where $E_{syn} = -78$ mV, and the synaptic conductance obeys an equation of the form

$$\frac{ds_{pre}}{dt} = \frac{0.1}{(1 + \exp(-(V_{pre} + 45)/5))} - \frac{s_{pre}}{100}.$$

Networks of coupled oscillators are generally difficult to analyze. However, the method of averaging has proven to be very useful for studying synchronization between oscillators [17]. That is, if we assume that the conductances g_{gap}, g_{syn} are sufficiently small, it is possible to reduce a network of coupled oscillators to a system of phase models where each oscillator is represented by its scalar phase and interactions are through the differences in the phases [21, 15, 9]. Let V_i be the membrane potential of the ith cell and s_i be the synaptic component of the ith cell. If

$$-I_{syn,i} = -g_{syn} \sum_j w_{ij} s_j (V_i - E_{syn})$$

is the synaptic current into the ith cell and w_{ij} is the weight of the connection between cell i and j, which is taken to be $1/N$, where N is the number of oscillators, then with the weak coupling assumption, the phase interactions will take the form

$$-\bar{I}_{syn,i} = g_{syn} \sum_j w_{ij} H_{syn}(\theta_j - \theta_i), \tag{2.1}$$

where

$$H_{syn}(\phi) = \frac{1}{T} \int_0^T V^*(t) s(t + \phi)(E_{syn} - V(t))\, dt.$$

$V^*(t)$ is the voltage component for the T-periodic solution to the adjoint equation for the stable limit cycle. $V(t)$, $s(t)$ are the voltage and synaptic components, respectively. For the gap junction coupling, we find

$$-\bar{I}_{gap,i} = g_{gap} \sum_j z_{ij} H_{gap}(\theta_j - \theta_i), \tag{2.2}$$

where

$$H_{gap}(\phi) = \frac{1}{T} \int_0^T V^*(t)(V(t + \phi) - V(t))\, dt.$$

The weights, z_{ij}, satisfy $z_{ij} = f(|i - j|)$, where f is a decreasing function in its argument. The phase of each oscillator, θ_i, obeys the reduced dynamics

$$\theta_i' = 1 - \bar{I}_{syn,i} - \bar{I}_{gap,i},$$

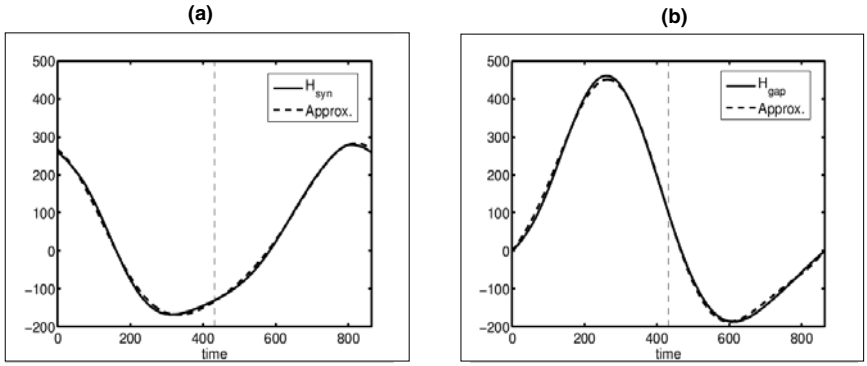

FIG. 2.1. *Coupling functions are computed using XPPAUT. Approximations are estimated from the Fourier expansion.* (a) *shows* H_{syn} *and its approximation, and* (b) *shows* H_{gap} *and its approximation. The functions are plotted over a period of the oscillations, and the dashed line marks the half period.*

where the two currents are given by (2.1) and (2.2). The phase of each oscillator maps directly onto the potential (or other variable) of each bursting cell once the zero phase is chosen. A standard choice of zero phase is the peak of the membrane potential.

Figure 2.1 shows both H_{syn} and H_{gap} for the Limax model evaluated numerically using XPPAUT [5], along with their approximations using the 0, 1, 2 order terms of the Fourier expansion. The Fourier approximations of these functions are used in bifurcation calculations in section 3, the stability arguments in section 4, and the numerical simulations of the phase model in section 5. Their values are given in Appendix B. Note that $H_{syn}(0) \neq 0$, $H_{gap} = 0$, $H'_{syn}(0) < 0$, and $H'_{gap}(0) > 0$.

To interpret the meaning of these inequalities, consider a pair of identical cells:

$$\theta'_1 = 1 + g_{syn}H_{syn}(\theta_2 - \theta_1) + g_{gap}H_{gap}(\theta_2 - \theta_1),$$
$$\theta'_2 = 1 + g_{syn}H_{syn}(\theta_1 - \theta_2) + g_{gap}H_{gap}(\theta_1 - \theta_2).$$

Let $\phi = \theta_2 - \theta_1$. Then

$$\phi' = g_{syn}[H_{syn}(-\phi) - H_{syn}(\phi)] + g_{gap}[H_{gap}(-\phi) - H_{gap}(\phi)] \equiv F(\phi).$$

Clearly, $F(0) = 0$, so synchrony, $\theta_2 = \theta_1$, is a solution. Synchrony is stable if $F'(0) < 0$ or

$$g_{syn}H'_{syn}(0) + g_{gap}H'_{gap}(0) > 0.$$

Since the conductances, g_{syn}, g_{gap} are nonnegative and $H'_{syn}(0) < 0$, $H'_{gap}(0) > 0$, synchrony is stable if the gap junctions dominate. Since $F(\phi)$ is an odd T-periodic function, $F(T/2) = 0$. This *antiphase* solution will be stable for the coupled pair if $F'(T/2) < 0$ or, equivalently,

$$g_{syn}H'_{syn}(T/2) + g_{gap}H'_{gap}(T/2) > 0.$$

As seen in Figure 2.1 by the dashed vertical lines at $T/2$, antiphase is stable for synaptic and unstable for gap junction coupling. In the models considered by Lewis and Rinzel, both synaptic and electrical coupling encourage stable synchrony [16]. Thus, the interaction of networks will lead to synchronous behavior. In contrast, for

the intrinsic dynamics in the Limax model, electrical coupling encourages synchrony, but synaptic inhibition opposes it. Our goal in the rest of this paper is to explore the consequences of these differences in a one-dimensional spatially organized array of N oscillators.

2.1. The spatial equations. We introduce a discrete model where we have all-to-all synaptic coupling and local gap junction coupling. The equations can be written down as

(2.3)
$$\frac{d\theta_j}{dt} = \omega + \frac{g_{syn}}{N}\sum_{k=1}^{N} H_{syn}(\theta_k - \theta_j) + g_{gap}\sum_{l=-m}^{m} J_l H_{gap}(\theta_{j+l} - \theta_j), \quad j = 1, \ldots, N,$$

where θ_j represents the phase of oscillator j, ω is the intrinsic frequency for all the oscillators, g_{syn} is the synaptic coupling strength, g_{gap} is the strength of electrical coupling, and H_{syn}, H_{gap} are the functions describing synaptic and gap junction coupling, respectively. We note that the key point in the weak coupling assumption is that the effects of different types of coupling are linear and additive. Thus, only the ratio of g_{syn} and g_{gap} in the phase model matter. The oscillators are arranged in a ring to avoid boundary effects. W.l.o.g., we assume that the ring has length 2π. The factor $\frac{1}{N}$ in front of the synaptic coupling contribution guarantees that the model also works when we allow $N \to \infty$. The weights J_l are taken to be nonnegative, and we assume that $J_{-l} = J_l$. m represents the scope of gap junction coupling. We also note that $m \ll N$, since we assume that gap junction coupling is local. Henceforth, we assume that the period of the oscillators (and thus of the coupling functions) is 2π. The function H_{syn} favors the antiphase state for pairwise interactions so that π is a stable fixed point for a pair of oscillators coupled with only synaptic coupling. The function H_{gap} favors the in-phase state for pairwise interactions so that 0 is a stable fixed point for a pair of oscillators coupled with only gap junction coupling. This is equivalent to saying the following:

A1. $H'_{syn}(0) < 0$.
A2. $H'_{gap}(0) > 0$.

For simplicity, we also need the following:

A3. $H_{syn}(0) = 0$.
A4. $H_{gap}(0) = 0$.

Note that A4 holds automatically for gap junctions, since a cell cannot be coupled to itself via gap junctions. If $H_{syn}(0) = \kappa \neq 0$, then let $\theta_j = \hat{\theta}_j + (\omega + g_{syn}\kappa)t$. We write

$$\frac{d\hat{\theta}_j}{dt} = \frac{g_{syn}}{N}\sum_{k=1}^{N} \hat{H}_{syn}(\hat{\theta}_k - \hat{\theta}_j) + g_{gap}\sum_{l=-m}^{m} J_l H_{gap}(\hat{\theta}_{j+l} - \hat{\theta}_j), \quad j = 1, \ldots, N,$$

where $\hat{H}_{syn}(\phi) = H_{syn}(\phi) - \kappa$. We can see that $\hat{H}_{syn}(0) = 0$, so w.l.o.g., we assume $H_{syn}(0) = 0$.

We also make a normalization assumption on J_l by taking the following:

A5*. $\sum_{l=-m}^{m} J_l = 1$.

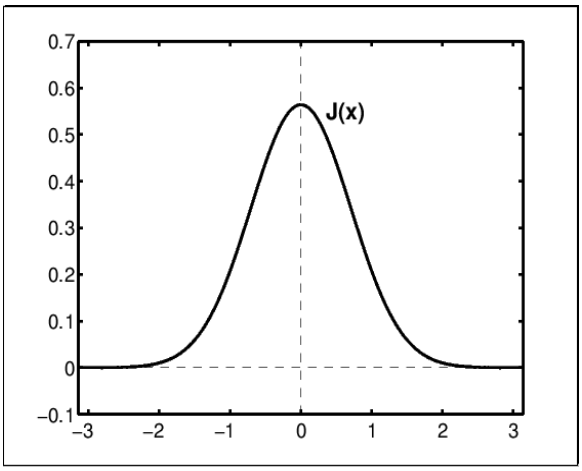

FIG. 2.2. *A plot of $J(x)$ where the sum was taken over $n = -2, -1, 0, 1, 2$.*

For the purposes of calculations, it is much easier to work with the continuum analogue of (2.3), so our analysis will be on a continuum version of the network. Hence, from now on, we study this model

$$\begin{aligned}\frac{\partial\theta}{\partial t} &= \omega + \frac{g_{syn}}{2\pi}\int_0^{2\pi} H_{syn}(\theta(y)-\theta(x))\,dy \\ &\quad + g_{gap}\int_0^{2\pi} J(x-y)\,H_{gap}(\theta(y)-\theta(x))\,dy,\end{aligned} \tag{2.4}$$

where analogous assumptions are made as for the discrete model. We remark that the continuum model can be derived from the discrete model in the limit as $N \to \infty$ with a suitable normalization assumption on the function J_ℓ. One difference is that the discrete model, θ_j, was a function of time and the discrete index j, whereas it is now a function of time and space. We assume that $J(x)$ is a nonnegative, symmetric kernel around 0 and that the normalization condition is

A5. $\int_0^{2\pi} J(y)\,dy = 1$.

In our numerical simulations, we assumed $J(x) = \sum_{n=-\infty}^{\infty} \exp(-(x+2\pi n)^2)/\sqrt{\pi}$. (See Figure 2.2.)

3. Linear stability analysis for synchronous solution. We want to study the spatial interactions between synchronizing and antisynchronizing influences. We start with the synchronous state and study its stability. The synchronous state is where all of the oscillators have the same phase. Note that if we assume heterogeneity in the intrinsic frequencies, synchrony is not a solution to the system. If we have homogeneity, $\theta(x,t) = \Omega t$ is a solution to (2.4), where $\Omega = \omega + g_{syn}H_{syn}(0)$ represents the frequency of the network. To determine the stability of synchrony, we let $\theta(x,t) = \Omega t + \psi(x,t)$ and write

$$\begin{aligned}\frac{\partial\psi}{\partial t} &= \frac{g_{syn}}{2\pi}\int_0^{2\pi} H'_{syn}(0)\,[\psi(y)-\psi(x)]\,dy \\ &\quad + g_{gap}\int_0^{2\pi} J(x-y)\,H'_{gap}(0)\,[\psi(y)-\psi(x)]\,dy + O\left(|\psi|^2\right).\end{aligned} \tag{3.1}$$

If we keep only the linear terms above, we can see that $\psi(x,t) = e^{inx}\ e^{\lambda_n t}$ solves (3.1) with the appropriate choice of λ_n. Let $I_n = \int_0^{2\pi} J(s)\ e^{-ins}\ ds$, and substitute $\psi(x,t)$ into (3.1) to get

$$\lambda_n = -g_{syn}\ H'_{syn}(0) + g_{gap}\ H'_{gap}(0)\ [I_n - 1] \tag{3.2}$$

for $n \neq 0$. For $n = 0$, $\lambda_0 = 0$. We choose $J(x)$ so that we have $I_1 \geq 1$ and $I_1 > I_2 > \cdots > I_n > I_{n+1} > \cdots$. This means that the first Fourier mode dominates. The Gaussian kernel shown in Figure 2.2 satisfies this criterion, as does, for example, the periodic version of an exponential kernel, $\exp(-|x|)$. With this assumption, it is easy to see that the first eigenvalue to cross over to positive values would be λ_1. We call $n = 1$ the most unstable node. To find the critical value of g_{syn}, we solve for $\lambda_1 = 0$, which gives us

$$g^*_{syn} = \frac{g_{gap}\ H'_{gap}(0)\ [I_1 - 1]}{H'_{syn}(0)}. \tag{3.3}$$

Here * is used to denote the value of g_{syn} at the bifurcation point. To study the stability of the bifurcating solutions we need to find the normal form for the bifurcation. We prove the following theorem.

THEOREM 3.1. *The system* (2.4) *with the assumptions* A1–A5 *has a pitchfork bifurcation at* g^*_{syn}*, and the corresponding normal form is*

$$0 = \zeta z^2 \bar{z} + \eta z.$$

The coefficients ζ *and* η *are*

$$\begin{aligned} \zeta &= 12B_{1,3} - 3B_{2,3} - 9B_{0,3} + 2C\ B_{0,2} - 2CB_{2,2}, \\ \eta &= -g_2\alpha_1, \end{aligned}$$

where

$$B_{n,j} = \int_0^{2\pi} A_j(y')\ e^{iny'}\ dy',$$

$$A_j(x) = \frac{g^*_{syn}}{2\pi}\ \alpha_j + g_{gap}\ \beta_j\ J(x),$$

$$C = \frac{2B_{1,2} - B_{2,2} - B_{0,2}}{B_{2,1} - B_{0,1}},$$

with $\alpha_j = \frac{H^j_{syn}(0)}{j!}$ *and* $\beta_j = \frac{H^j_{gap}(0)}{j!}$ *for* $j = 1, 2, \ldots$. *Here* $f^j(x_0)$ *represents the* i*th derivative at* x_0 *for* $f = H_{syn}, H_{gap}$.

Proof. We use a perturbation expansion for the solution ψ and g_{syn} as

$$\theta(x,t) = \Omega(\epsilon)\ t + \hat{\psi}(x,\epsilon), \tag{3.4}$$

where

$$\Omega(\epsilon) = \epsilon\ \Omega_1 + \epsilon^2\ \Omega_2 + \epsilon^3\ \Omega_3 + \cdots,$$

$$\hat{\psi}(x,\epsilon) = \epsilon\ \psi_1(x) + \epsilon^2\ \psi_2(x) + \epsilon^3\ \psi_3(x) + \cdots,$$

and

$$g_{syn} = g^*_{syn} + \epsilon\ g_1 + \epsilon^2\ g_2.$$

We define a linear operator $\mathcal{L}$ as follows:

$$\begin{aligned}
\mathcal{L}\psi &= \frac{g^*_{syn}}{2\pi}\int_0^{2\pi} H'_{syn}(0)[\hat{\psi}(y,\epsilon) - \hat{\psi}(x,\epsilon)]dy \\
&\quad + g_{gap}\int_0^{2\pi} J(x-y)H'_{gap}(0)[\hat{\psi}(y,\epsilon) - \hat{\psi}(x,\epsilon)]dy \\
&= \frac{g^*_{syn}}{2\pi}\int_0^{2\pi} H'_{syn}(0)[\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]dy' \\
&\quad + g_{gap}\int_0^{2\pi} J(y')H'_{gap}(0)[\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]dy' \qquad (3.5)
\end{aligned}$$

with the substitution $y' = x - y$. Note that $e^{\pm ix}$, $\mathbf{1}$ are in the null space of $\mathcal{L}$ and that $\mathcal{L}$ is self-adjoint. (Here, we use $\mathbf{1}$ to denote the constant function which is 1 for all x.) We need to find the Taylor expansions of H_{syn} and H_{gap} around 0 for the full system

$$\begin{aligned}
H_{syn}(x) &= H_{syn}(0) + H'_{syn}(0)\ x + \frac{H''_{syn}(0)}{2}\ x^2 + \frac{H'''_{syn}(0)}{6}\ x^3 + \cdots \\
&= \alpha_1\ x + \alpha_2\ x^2 + \alpha_3\ x^3 + \cdots, \\
H_{gap}(x) &= H_{gap}(0) + H'_{gap}(0)\ x + \frac{H''_{gap}(0)}{2}\ x^2 + \frac{H'''_{gap}(0)}{6}\ x^3 + \cdots \\
&= \beta_1\ x + \beta_2\ x^2 + \beta_3\ x^3 + \cdots.
\end{aligned}$$

Substituting θ in the form given in (3.4) into (2.4),

$$\begin{aligned}
\Omega(\epsilon) &= \frac{(g^*_{syn} + \epsilon g_1 + \epsilon^2 g_2)}{2\pi}\int_0^{2\pi} \alpha_1\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]\ dy' \\
&\quad + \frac{(g^*_{syn} + \epsilon g_1 + \epsilon^2 g_2)}{2\pi}\int_0^{2\pi} \alpha_2\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^2\ dy' \\
&\quad + \frac{(g^*_{syn} + \epsilon g_1 + \epsilon^2 g_2)}{2\pi}\int_0^{2\pi} \alpha_3\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^3\ dy' \\
&\quad + g_{gap}\int_0^{2\pi} J(y')\ \beta_1\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]\ dy' \\
&\quad + g_{gap}\int_0^{2\pi} J(y')\ \beta_2\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^2\ dy' \\
&\quad + g_{gap}\int_0^{2\pi} J(y')\ \beta_3\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^3\ dy' + O\left(|\hat{\psi}|^4\right). \qquad (3.6)
\end{aligned}$$

Let $A_j(x) = \frac{g^*_{syn}}{2\pi}\ \alpha_j + g_{gap}\ \beta_j J(x)$ for $j = 1, 2, 3$ and $Q(x) = \int_0^{2\pi}[\alpha_1(\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)) + \alpha_2(\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon))^2 + \alpha_3(\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon))^3]\ dy'$, which lets us to

rewrite (3.6) as

$$\begin{aligned}\Omega(\epsilon) = &\int_0^{2\pi} A_1(y')\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]\ dy' \\ &+ \int_0^{2\pi} A_2(y')\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^2\ dy' \\ &+ \int_0^{2\pi} A_3(y')\ [\hat{\psi}(x-y',\epsilon) - \hat{\psi}(x,\epsilon)]^3\ dy' \\ &+ \epsilon\ \frac{g_1}{2\pi}\ Q(x) + \epsilon^2\ \frac{g_2}{2\pi}\ Q(x) + O\left(|\hat{\psi}|^4\right). \end{aligned} \tag{3.7}$$

We match the coefficients of powers of ϵ terms from both sides of (3.7). This allows us to compute the coefficients for the normal form. The rest of the calculations are given in the appendix. The normal form for the bifurcation is

$$0 = \zeta z^2 \bar{z} + \eta z,$$

where $\zeta = 12B_{1,3} - 3B_{2,3} - 9B_{0,3} + 2CB_{0,2} - 2CB_{2,2} - 2CB_{2,2}$ and $\eta = -g_2\alpha_1$. Note that η is positive since $\alpha_1 < 0$ from our assumptions. Thus, depending on the sign of ζ, we can determine the stability of the new solutions. □

In our case, we compute $\zeta = -210.09$ and $\eta = 105g_2$, which tells us that we have a supercritical pitchfork bifurcation. The new solution bifurcating from synchrony is stable.

4. Existence and stability of the traveling wave. Next, we look at the existence and stability of the traveling wave, $\theta(x,t) = \Omega t + x$. Substituting θ back into (2.4) gives us

$$\Omega = \omega + \frac{g_{syn}}{2\pi}\int_0^{2\pi} H_{syn}(y)dy + g_{gap}\int_0^{2\pi} J(y)H_{gap}(y)dy. \tag{4.1}$$

W.l.o.g., we can assume that the average of $H_{syn}(y)$ is zero and so let $I = \int_0^{2\pi} J(y)H_{gap}(y)dy$; (4.1) reduces to $\Omega = \omega + g_{gap}I$. (The value of the frequency is irrelevant to the stability calculation since the right-hand sides always involve terms of the form $\theta(x,t) - \theta(y,t)$ so that adding Ct to θ, where C is any constant, has no effect.) We prove the following theorem about the stability of the traveling wave.

THEOREM 4.1. *The traveling wave solution, $\theta(x,t) = \Omega t + x$, is a stable solution to* (2.4) *if we have*

$$\begin{aligned} Re(\lambda_n) = &-\frac{1}{2}g_{syn}nb_n + 2\pi g_{gap}\sum_{m=-\infty}^{-n-1}\frac{m}{4}[(c_m f_{n+m} - d_m e_{n+m}) - (c_m f_m - d_m e_m)] \\ &- 2\pi g_{gap}\sum_{m=-n}^{-1}\frac{m}{4}[(c_m f_{n+m} + d_m e_{n+m}) + (c_m f_m - d_m e_m)] \\ &- 2\pi g_{gap}\sum_{m=1}^{\infty}\frac{m}{4}[(c_m f_{n+m} - d_m e_{n+m}) - (c_m f_m - d_m e_m)] \\ &\leq 0 \end{aligned}$$

for $n > 0$, where

$$H_{syn}(y) = \sum_{n=0}^{\infty} a_n \cos ny + b_n \sin ny,$$

$$H_{gap}(y) = \sum_{n=0}^{\infty} c_n \cos ny + d_n \sin ny,$$

$$J(y) = \sum_{n=0}^{\infty} e_n \cos ny + f_n \sin ny.$$

Proof. Letting $\theta(x,t) = \Omega t + x + \psi(x,t)$, we write

$$\begin{aligned} \frac{\partial \psi}{\partial t} = \frac{g_{syn}}{2\pi} &\int_0^{2\pi} H'_{syn}(y)\ [\psi(x+y) - \psi(x)]\ dy \\ &+ g_{gap} \int_0^{2\pi} J(-y)\ H'_{gap}(y)\ [\psi(x+y) - \psi(x)]\ dy + O\left(|\psi|^2\right). \end{aligned} \tag{4.2}$$

$\psi(x,t) = e^{inx} e^{\lambda_n t}$ solves (4.2) up to linear order. We solve for λ_n to get

$$\lambda_n = \frac{g_{syn}}{2\pi} \int_0^{2\pi} H'_{syn}(y)[e^{iny} - 1]dy + g_{gap} \int_0^{2\pi} J(-y)\ H'_{gap}(y)[e^{iny} - 1]dy. \tag{4.3}$$

We look at the real part of λ_n, for H_{syn}, H_{gap}, and J real-valued,

$$Re(\lambda_n) = \frac{g_{syn}}{2\pi} \int_0^{2\pi} H'_{syn}(y)[\cos ny - 1]dy + g_{gap} \int_0^{2\pi} J(-y)\ H'_{gap}(y)[\cos ny - 1]dy.$$

When $n = 0$, $Re(\lambda_0) = 0$, which corresponds to translation invariance. We need $Re(\lambda_n) \leq 0$ for $n \neq 0$. Also, we want to make our analysis as general as possible. For this reason we use the complex Fourier series expansion for H_{syn}, H_{gap}, and J. Let $J(y) = \sum_{k=-\infty}^{\infty} \alpha_k e^{iky}$, $H_{syn}(y) = \sum_{l=-\infty}^{\infty} \beta_l e^{ily}$, $H_{gap}(y) = \sum_{m=-\infty}^{\infty} \gamma_m e^{imy}$, where $\alpha_{-k} = \alpha_k$, $\beta_{-l} = \beta_l$, and $\gamma_{-m} = \gamma_m$. Substituting these into (4.3) gives

$$\lambda_n = -ig_{syn} n \beta_{-n} + 2\pi i g_{gap} \sum_{m=-\infty}^{\infty} [m\gamma_m(\alpha_{-(n+m)} - \alpha_{-m})].$$

If we look at the real part of λ_n, we see that

$$\begin{aligned} Re(\lambda_n) = &-\frac{1}{2} g_{syn} n b_n + 2\pi g_{gap} \sum_{m=-\infty}^{-n-1} \frac{m}{4}[(c_m f_{n+m} - d_m e_{n+m}) - (c_m f_m - d_m e_m)] \\ &- 2\pi g_{gap} \sum_{m=-n}^{-1} \frac{m}{4}[(c_m f_{n+m} + d_m e_{n+m}) + (c_m f_m - d_m e_m)] \\ &- 2\pi g_{gap} \sum_{m=1}^{\infty} \frac{m}{4}[(c_m f_{n+m} - d_m e_{n+m}) - (c_m f_m - d_m e_m)], \end{aligned}$$

where H_{syn}, H_{gap}, and J are given with the Fourier expansion with coefficients $a_0 = 2\beta_0$, $c_0 = 2\gamma_0$, $e_0 = 2\alpha_0$, $a_n = \beta_n + \beta_{-n}$, $b_n = i(\beta_n - \beta_{-n})$, $c_n = \gamma_n + \gamma_{-n}$, $d_n = i(\gamma_n - \gamma_{-n})$, $e_n = \alpha_n + \alpha_{-n}$, and $e_n = i(\alpha_n - \alpha_{-n})$. ∎

In our case, the traveling wave is always stable. Substituting our parameters into the eigenvalue equation, we see that $Re(\lambda_n) \leq -50g_{syn} - 824.27g_{gap} \leq 0$ for all positive values of g_{syn} and g_{gap}.

We close this section with some comments on the existence and stability of traveling waves in the discrete system for local gap junction coupling. Consider a discrete ring,

$$\frac{d\theta_j}{dt} = \omega + \sum_{i=-m}^{m} a_i H(\theta_{j+m} - \theta_j),$$

where $m \ll N$ and N is the number of oscillators. The coupling constants a_i are nonnegative. Suppose that H is 2π-periodic and that $H'(x) > 0$ for $-r < x < r$ and $r > 0$. Then, it follows from [7] that the synchronous state is asymptotically stable. Now, consider a traveling wave:

$$\theta_j = \Omega t + 2\pi j/N.$$

This satisfies the discrete model if and only if

$$\Omega = \omega + \sum_{i=-m}^{m} a_i H(2\pi i/N).$$

If m/N is sufficiently small, then

$$H'(\pm 2\pi m/M) > 0$$

since $H'(x)$ is positive in some neighborhood of 0. Thus, again from [7], the traveling wave is asymptotically stable. Figure 2.1(b) shows that $H'_{gap}(x) > 0$ over more than half the cycle surrounding the origin. Thus, we can pick m as large as $N/4$ and still be assured that the traveling wave is stable. This shows that there is bistability between traveling waves and synchrony in the discrete model with small enough synaptic coupling.

5. Numerical results. In this section we (i) show that the bifurcation theory developed for the continuum model appears to hold for the discrete model by numerically simulating the latter, (ii) numerically extend the local bifurcation analysis to get the full picture for the discrete phase-model, (iii) numerically simulate the conductance-based model and show patterns similar to those found via our analysis, and (iv) compute the bifurcation diagram for a line of 20 oscillators which are *not* connected in a ring.

Figure 5.1 depicts the steady-state relative phases for a ring of 20 phase-oscillators using the interaction functions shown in Figure 2.1. The strength of the gap junction coupling is fixed at .01, and g_{syn} is varied along the vertical axis. Simulations are done by starting the relative phases close to synchrony and then letting them evolve until a steady state is reached. Figure 5.1(a) shows this steady state (color-coded) for each value of g_{syn} examined. (We remark that in the phase model, the absolute value of the coupling parameters is irrelevant, and only their ratio matters.) Figure 5.1(b) shows vertical cross sections from part (a) to more clearly illustrate different types of solutions observed for various $\rho \equiv g_{syn}/g_{gap}$ values. For example, when $\rho = 0.3$, there is no difference in phases of the oscillators, indicating that the system is synchronized. In contrast, between $\rho \approx 0.35$ and $\rho \approx 0.87$, the solution is the

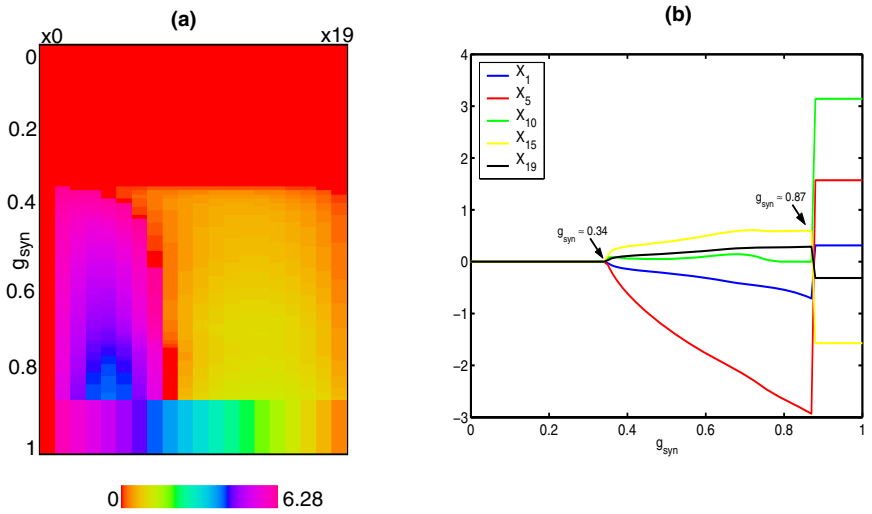

FIG. 5.1. *Transition from synchrony to intermediate state and then to traveling wave.* (a) *illustrates an array plot of the relative phases of the oscillators as* $\rho \equiv g_{syn}/g_{gap}$ *is increased;* (b) *shows the phases of some oscillators as* ρ *is increased.*

patterned state which bifurcates from the synchronous state as described in section 3. As ρ increases beyond 0.87, the patterned state (which qualitatively resembles a cosine wave) disappears and leaves a traveling wave as the only solution. The traveling wave is, in fact, stable for all ρ shown in the diagram, so that for $\rho < 0.87$ there is bistability. The loss of stability of the synchronous state occurs at $\rho \approx 0.35$, which is very close to the value of 0.3476 predicted in section 2.

To give the reader some intuition for the patterns, we depict the spatio-temporal patterns in terms of their absolute phase in Figure 5.2. As we increase the relative coupling strength, we see the transition from synchrony to a stable patterned state (compare 5.2(a) and (b)). This is the state which arises via the pitchfork bifurcation calculated in section 2. As we further increase g_{syn}, the patterned state disappears and produces traveling waves; the transition from the patterned state to the waves is shown in Figure 5.2(c). Finally, for larger g_{syn}, only the traveling wave remains.

The analytic calculations along with the numerical calculations of the phase reduced model show that as the inhibition increases, the synchronous state loses stability to a patterned state in which the relative phases are close to a cosine wave. Further increases in the inhibition result in a deepening of this pattern, followed by a transition to a traveling wave. In Figure 5.3, we show the result of a simulation of the biophysical model as the synaptic inhibition increases. To match the theory, we have made the connections periodic, so that the last cell is coupled to the first. Figure 5.3(a) shows a clear phase pattern in which the oscillators at the end lag the ones in the middle. This corresponds to the patterned state shown in Figures 5.2(b) and 5.1(a), when $\rho \approx 0.4$. For a larger amount of inhibition, the behavior becomes quite complicated and, after a long transient, begins a transition to traveling waves, as shown in Figure 5.3(b). Thus, the phase model provides a very good description of the full biophysical model and has the advantage of being simple enough to analyze.

We conclude this section with some comments on the simplification to a ring of oscillators instead of a line as in the original model. The main reason for assuming a

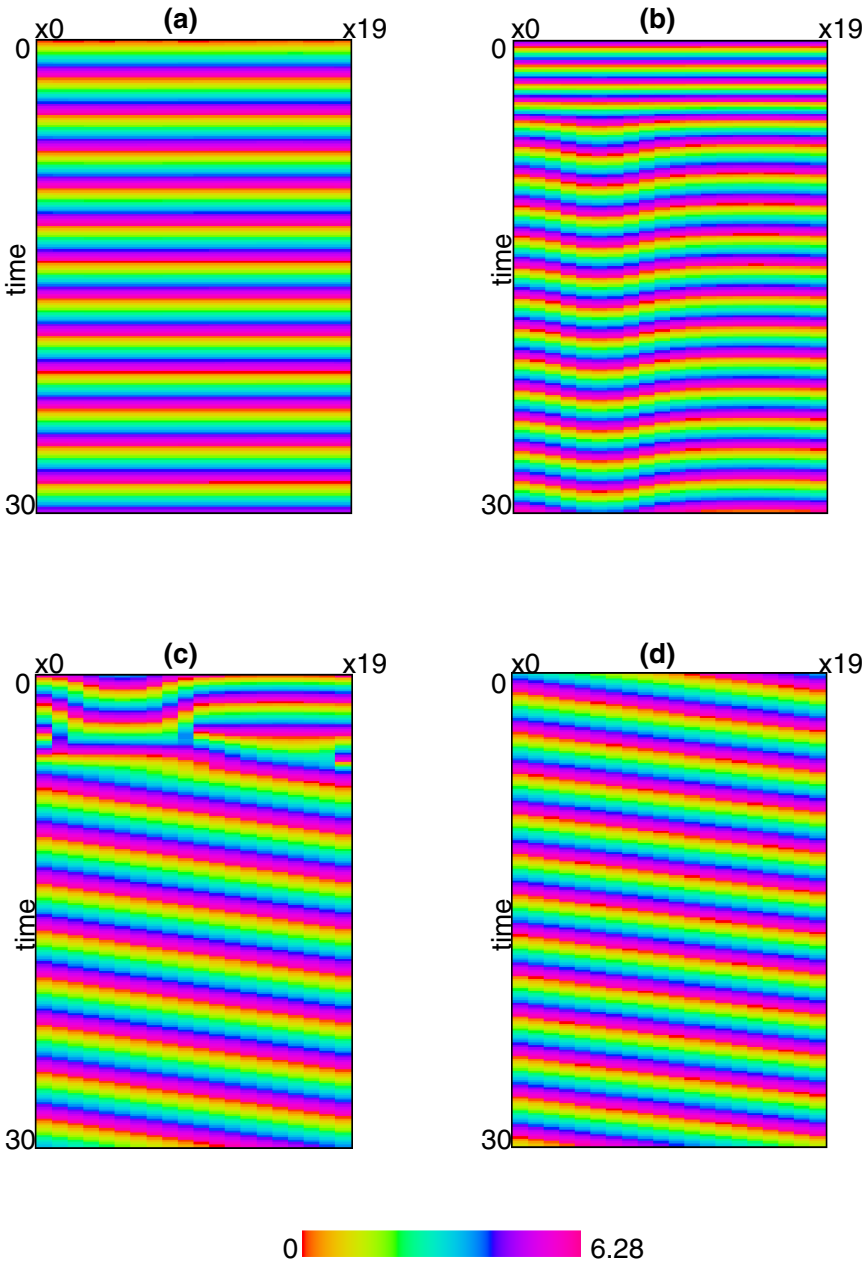

FIG. 5.2. *Evolution of the solution to the discrete phase model is shown as we change* g_{syn} *while* g_{gap} *is kept at the value* 0.03. (a) *shows synchronous solution when* $g_{syn} = 0.01$, (b) *shows the intermediate state when* $g_{syn} = 0.02$, (c) *shows the transition to the traveling wave solution when* $g_{syn} = 0.03$, *and* (d) *shows the traveling wave solution when* $g_{syn} = 0.04$.

ring is that the analytic calculations are then possible. If, instead of a ring, we consider a line of oscillators and choose the coupling functions so that the synchronous state exists, we can explore the stability and bifurcations as the antisynchronous (synaptic inhibition) coupling increases. Rather than attempt these calculations analytically, we instead display numerical simulations for the phase model with all-to-all synaptic

coupling and nearest neighbor gap junction coupling.

Figure 5.4 shows the behavior for a line of 20 oscillators. By considering a linear array, the symmetry in the ring model was broken, and we are able to use the AUTO bifurcation package [5]. We depict two pitchfork bifurcations. The first emerges as a stable supercritical bifurcation. The pattern is like a half of a cosine wave, as opposed to the full cycle seen in a ring. The ring of oscillators can be imagined as a pair of lines joined symmetrically through the midline. Thus, we expect that the first bifurcation would be "half" of that seen in the ring (see curve 1 in Figure 5.4(b)). As g_{syn} increases, this branch seems to approach a solution which looks like a traveling

wave (Figure 5.4(b) curves 2 and 3). There is no true traveling wave in the line due to the boundary conditions; however, the solutions in the figure look like traveling waves. A second branch bifurcates supercritically but it inherits the instability of the synchronous branch, so that it is unstable. The shape of this solution is shown by curve 4 in Figure 5.4(b). As these solutions were unstable, they were not continued beyond $g_{syn} = 0.5$. Thus, while the details are somewhat different, the ultimate result is the same for both a ring and a linear array: as g_{syn} increases, synchrony loses stability, and for large enough g_{syn} there is a traveling wave. The traveling wave exists for all values of g_{syn} in the ring model but not for the linear array.

6. Discussion. In this paper, we have shown that the combination of long range inhibitory synaptic coupling with local gap junction coupling was sufficient to induce a destabilization of the synchronous state. A new state which is not a traveling wave but rather a spatially organized phase shift stably appears and is lost as the amount of long range inhibitory coupling increases. Numerical solutions indicate that the only remaining attracting state is a traveling wave. Our mathematical results concern a network on a ring; the original motivation for this problem is the slug olfactory lobe, which is actually a line of oscillators. However, it is known from our earlier work [14] that boundary effects are enough to induce patterns of phases that depend very strongly on the choices of boundary conditions at the edges. To avoid this difficulty, we have considered periodic boundary conditions which eliminate questions about the behavior at the edges. In spite of this simplifying assumption, we see that the linear array and the ring behave similarly, at least when the inhibition is sufficiently large compared to electrical coupling.

A number of studies have investigated interactions between electrical coupling and synaptic coupling between neural oscillators. This problem is important since inhibitory interneurons in the mammalian neocortex appear to be coupled with both types of interactions. These networks may act as the "pacemakers" for 40 Hz oscillations observed in the cortex during various cognitive tasks [20]. Most theoretical explorations involve either pairs of cells or globally coupled networks. In most instances, both the synaptic and the electrical coupling encourage synchrony, so that there is not a chance for pattern formation. However, [4] has shown that gap junctions can either stabilize or destabilize synchrony, depending on the shape of the action potential, while [17] has shown that the intrinsic currents also affect whether or not electrical coupling is synchronizing. Combining coupling that destabilizes with coupling that stabilizes synchrony can be expected to produce other patterns of activity besides waves. Such patterns may play some role in cortical processing of information and may confer certain computational advantages [8].

Appendix A. To calculate the normal form for the bifurcation, we match the "ϵ" terms from (3.6):

$$\Omega_1 = \int_0^{2\pi} A_1(y')\ [\psi_1(x-y') - \psi_1(x)]\ dy' \equiv \mathcal{L}\ \psi_1.$$

We integrate both sides of the equation with respect to x to get $\Omega_1 = 0$. If we solve $\mathcal{L}\psi_1 = 0$, we get that $\psi_1(x) = ze^{ix} + \bar{z}e^{-ix}$ w.l.o.g. Next, we look at ϵ^2 terms:

$$\Omega_2 = \mathcal{L}\ \psi_2 + \int_0^{2\pi} A_2(y')\ [\psi_1(x-y') - \psi_1(x)]^2\ dy' + \frac{g_1\alpha_1}{2\pi} \int_0^{2\pi} [\psi_1(x-y') - \psi_1(x)]\ dy'. \tag{A.1}$$

Substituting ψ_1 into (A.1) and integrating with respect to x,

$$\int_0^{2\pi} \Omega_2 \, dx = 8\pi \; z \; \bar{z} \; [B_0(A_2) - B_1(A_2)],$$
$$\Omega_2 = 4z \; \bar{z} \; [B_0(A_2) - B_1(A_2)],$$

where $B_n(A_j) = \int_0^{2\pi} A_j(y') \; e^{\pm iny'} \; dy'$, $j = 1, 2, 3$. Now, we multiply (A.1) by e^{-ix},

$$0 = -2\pi \; g_1 \; \alpha_1 \; z,$$

which implies $g_1 = 0$. So, we can write $g_{syn} = g^*_{syn} + \epsilon^2 g_2$, and we solve for ψ_2:

$$0 = \mathcal{L} \; \psi_2 + (z^2 e^{2ix} + \bar{z}^2 e^{-2ix}) \; [B_2(A_2) + B_0(A_2) - 2B_1(A_2)]. \tag{A.2}$$

We now propose that $\psi_2 = C \; z^2 e^{2ix} + \bar{C} \; \bar{z}^2 e^{-2ix}$ and substitute back into (A.1) to get

$$0 = [B_2(A_1) - B_0(A_1)] \; (C \; z^2 e^{2ix} + \bar{C} \; \bar{z}^2 e^{-2ix})$$
$$+ [B(A_2) + B_0(A_2) - 2B_1(A_2)] \; (z^2 e^{2ix} + \bar{z}^2 e^{-2ix}).$$

Looking at the coefficients of the z^2 term gives

$$C = \frac{2B_1(A_2) - B_2(A_2) - B_0(A_2)}{B_2(A_1) - B_0(A_1)}. \tag{A.3}$$

We have to make sure here that the denominator is nonzero. This is easy to see, since $B_2(A_1) - B_0(A_1) = 0$ would imply that $g^*_{syn} = \frac{g_S \beta_1 (I_2 - 1)}{\alpha_2}$, which is not true since $g^*_{syn} = \frac{g_{gap} \beta_1 (I_1 - 1)}{\alpha_2}$ and $I_1 > I_2$.

Next, we look at ϵ^3 terms:

$$\Omega_3 = \mathcal{L} \; \psi_3 + \int_0^{2\pi} A_3(y') \; [\psi_1(x - y') - \psi_1(x)]^3 \; dy'$$
$$+ 2 \int_0^{2\pi} A_2(y') \; [\psi_1(x - y')\psi_2(x - y') + \psi_1(x)\psi_2(x)] \; dy'$$
$$- 2 \int_0^{2\pi} A_2(y') \; [\psi_1(x - y')\psi_2(x) + \psi_1(x)\psi_2(x - y')] \; dy'$$
$$+ \frac{g_2 \alpha_1}{2\pi} \int_0^{2\pi} [\psi_1(x - y') - \psi_1(x)] \; dy'. \tag{A.4}$$

Let us look at the terms in (A.4) closely:

$$[\psi_1(x - y') - \psi_1(x)]^3 = [z e^{ix} e^{-iy'} + \bar{z} e^{-ix} e^{iy'} - z e^{ix} - \bar{z} e^{-ix}]^3$$
$$= z^3 e^{3ix} e^{-3iy'} + 3z^2 \bar{z} e^{ix} e^{-iy'} + 3z \bar{z}^2 e^{-ix} e^{iy'} + \bar{z}^3 e^{-3ix} e^{3iy'}$$
$$- 3z^3 e^{3ix} e^{-2iy'} - 3z^2 \bar{z} e^{ix} e^{-2iy'} - 6z^2 \bar{z} e^{ix}$$
$$- 6z \bar{z}^2 e^{-ix} - 3z \bar{z}^2 e^{-ix} e^{2iy'} - 3\bar{z}^3 e^{-3ix} e^{2iy'}$$
$$+ 3z^3 e^{3ix} e^{iy'} + 3z^2 \bar{z} e^{ix} e^{iy'} + 6z^2 \bar{z} e^{ix} e^{-iy'}$$
$$+ 6z \bar{z}^2 e^{-ix} e^{iy'} + 3z \bar{z}^2 e^{-ix} e^{-iy'} + 3\bar{z}^3 e^{-3ix} e^{iy'}$$
$$- z^3 e^{3ix} - 3z^2 \bar{z} e^{ix} - 3z \bar{z}^2 e^{-ix} - \bar{z}^3 e^{-3ix}.$$

Let $T = [\psi_1(x-y')\psi_2(x-y') + \psi_1(x)\psi_2(x) - \psi_1(x-y')\psi_2(x) - \psi_1(x)\psi_2(x-y')]$; then

$$\begin{aligned}
T &= (ze^{ix}e^{-iy'} + \bar{z}e^{-ix}e^{iy'})(Cz^2e^{2ix}e^{-2iy'} + \bar{C}\bar{z}^2e^{-2ix}e^{2iy'}) \\
&\quad + (ze^{ix} + \bar{z}e^{-ix})(Cz^2e^{2ix} + \bar{C}\bar{z}^2e^{-2ix}) \\
&\quad - (ze^{ix}e^{-iy'} + \bar{z}e^{-ix}e^{iy'})(Cz^2e^{2ix} + \bar{C}\bar{z}^2e^{-2ix}) \\
&\quad - (ze^{ix} + \bar{z}e^{-ix})(Cz^2e^{2ix}e^{-2iy'} + \bar{C}\bar{z}^2e^{-2ix}e^{2iy'}) \\
&= Cz^3e^{3ix}e^{-3iy'} + \bar{C}z\bar{z}^2e^{-ix}e^{iy'} + Cz^2\bar{z}e^{ix}e^{-iy'} \\
&\quad + \bar{C}\bar{z}^3e^{-3ix}e^{3iy'} + Cz^3e^{3ix} + \bar{C}z\bar{z}^2e^{-ix} \\
&\quad + Cz^2\bar{z}e^{ix} + \bar{C}\bar{z}^3e^{-3ix} - Cz^3e^{3ix}e^{-iy'} - \bar{C}z\bar{z}^2e^{-ix}e^{-iy'} \\
&\quad - Cz^2\bar{z}e^{ix}e^{iy'} - \bar{C}\bar{z}^3e^{-3ix}e^{iy'} \\
&\quad - Cz^3e^{3ix}e^{-2iy'} - \bar{C}z\bar{z}^2e^{-ix}e^{2iy'} \\
&\quad - Cz^2\bar{z}e^{ix}e^{-2iy'} - \bar{C}\bar{z}^3e^{-3ix}e^{2iy'}.
\end{aligned}$$

Substituting ψ_1 and ψ_2 into (A.4) and using the expansions for $[\psi_1(x-y')-\psi_1(x)]^3$ and T, we then integrate with respect to x to get $\Omega_3 = 0$. Next, multiply both sides by e^{-ix} and integrate with respect to x to get

$$\begin{aligned}
0 &= z^2\bar{z}\int_0^{2\pi} A_3(y')\ [9e^{-iy'} + 3e^{iy'} - 3e^{-2iy'} - 9]\ dy' \\
&\quad + 2C\ z^2\bar{z}\int_0^{2\pi} A_2(y')\ [e^{-iy'} - e^{iy'} - e^{-2iy'} + 1]\ dy' - g_2\alpha_1 z.
\end{aligned}$$

We can simplify this as follows:

$$0 = z^2\ \bar{z}[12B_1(A_3) - 3B_2(A_3) - 9B_0(A_3) + 2C\ B_0(A_2) - 2CB_2(A_2)] - g_2\alpha_1 z.$$

By letting $\zeta = 12B_1(A_3) - 3B_2(A_3) - 9B_0(A_3) + 2C\ B_0(A_2) - 2CB_2(A_2)$ and $\eta = -g_2\alpha_1$, we have the normal form at the bifurcation point as

$$0 = \zeta z^2\bar{z} + \eta z.$$

Appendix B. We use the biophysical model given in [6]. Each uncoupled bursting cell in the Limax model has the form

$$\begin{aligned}
C\frac{dV}{dt} &= -I_L - I_K - I_{Ca} \\
&= -g_L(V - E_L) - g_K n^4(V - E_K) - g_{Ca}m^2h(V - E_{Ca}),
\end{aligned}$$

where n, h obey the equations

$$\begin{aligned}
\frac{dn}{dt} &= .075[a_n(V)(1-n) - b_n(V)n], \\
\frac{dh}{dt} &= \frac{1.125(h_\infty(V) - h)}{\tau_h(V)},
\end{aligned}$$

with

$$\begin{aligned}
a_n(V) &= .032(-48 - V)/(\exp(-(48+V)/5) - 1), \\
b_n(V) &= .5\exp(-(43+V)/40), \\
h_\infty(V) &= 1/(1 + \exp((V+86)/4)), \\
\tau_h(V) &= \begin{cases} \text{if } (V < (-80)), \text{then } (\exp((V+470)/66.6)), \\ \text{else } (28 + \exp((V+25)/-10.5)). \end{cases}
\end{aligned}$$

The activation gate for the T-type calcium current has the form

$$m(V) = 1/(1 + \exp(-(V + 60))).$$

The parameters are $C = 2.66$, $g_K = 5$, $g_L = 0.024$, $g_{Ca} = 2$, $E_K = -90$, $E_{Ca} = 140$, $E_L = -82$, and $E_{syn} = -78$. Using this model, we compute the approximations of the coupling functions as follows:

$$H_{syn}(x) = 35 + 200\cos(x) + 32\cos(2x) - 95\sin(x) - 5\sin(2x),$$

$$H_{gap}(x) = 87 - 50\cos(x) - 37\cos(2x) + 295\sin(x) - 65\sin(2x).$$

THE EFFECT OF NOISE ON β-CELL BURST PERIOD*

MORTEN GRAM PEDERSEN† AND MADS PETER SØRENSEN†

Abstract. Bursting electrical behavior is commonly observed in a variety of nerve and endocrine cells, including that in electrically coupled β-cells located in intact pancreatic islets. However, individual β-cells usually display either spiking or very fast bursting behavior, and the difference between isolated and coupled cells has been suggested to be due to stochastic fluctuations of the plasma membrane ion channels, which are supposed to have a stronger effect on single cells than on cells situated in clusters (the channel sharing hypothesis). This effect of noise has previously been studied using numerical simulations. We show here how the application of two recent methods allows an analytic treatment of the stochastic effects on the location of the saddle-node and homoclinic bifurcations, which determine the burst period. Thus, the stochastic system can be analyzed similarly to the deterministic system, but with a quantitative description of the effect of noise. This approach supports previous investigations of the channel sharing hypothesis.

1. Introduction.

The pancreatic β-cells are crucial for maintaining blood sugar levels in a narrow range. When subjected to glucose the β-cells produce and secrete insulin, and the amount of secreted insulin correlates with intracellular calcium levels [10].

In situ the β-cells are electrically coupled in the islets of Langerhans, where they show bursting electrical activity with burst periods of tens of seconds. Bursting consists of the membrane potential alternating between a silent hyperpolarized phase and an active phase of spiking rising from a depolarized plateau. During the active phase, calcium enters the cells, raises the intracellular Ca^{2+} concentration, and triggers insulin secretion. The plateau fraction, i.e., the ratio of the active phase duration to the burst period, is decisive for intracellular Ca^{2+} concentrations and for the amount of secreted insulin [2].

However, early recordings of single isolated pancreatic β-cells showed that the membrane potential exhibits noisy spiking activity [19], and although it was later found that only approximately one third of isolated cells spike, while half of the single cells are fast bursters with burst period less than 5 seconds [11], there is a fundamental difference in the behavior of single and electrically coupled cells. Importantly, this difference is reflected in intracellular calcium levels [24].

It was suggested early that stochastic fluctuations of ion channels in the plasma membrane were responsible for disrupting the bursting behavior and transforming the isolated cells to spikers, but that the effective sharing of the channels by electrically coupled cells averages the noise and lets the bursting phenomena appear [3]. This was analyzed by Chay and Kang [4] and Sherman, Rinzel, and Keizer [21] using mathematical modeling. The burst period and plateau fraction in the deterministic version

of the Sherman–Rinzel–Keizer model was later analyzed by bifurcation analysis and Melnikov's method [16].

De Vries and Sherman [6] studied the electrical behavior of coupled pancreatic β-cells with focus on the *beneficial* influence of noise. It had previously been shown that weak coupling between identical spiking cells can induce bursting [20], and it is now known that heterogeneous but spiking cells start to burst when coupled with physiologically realistic coupling strengths [7]. The main result presented in [6] is that noise dramatically increases the interval of coupling strengths for which bursting is seen for identical cells, and this observation was supported by analyzing a bifurcation diagram. It was later shown that the beneficial influence is more likely through heterogeneity masquerading as noise, and that the explanation of the enhancement of emergent bursting must be modified accordingly [14].

The investigations of the effect of noise on β-cells have so far been done partly by numerically solving the stochastic differential equations (SDEs) describing the system and partly by analyzing *deterministic* bifurcation diagrams [1, 4, 6, 14, 21]. The transition from the SDEs to the bifurcation analysis was rather weakly motivated from a theoretical point of view.

We look for a more natural deterministic description of the stochastic system, with the aim of characterizing how noise shortens or interrupts bursting. This is based on the ideas from Pernarowski, Miura, and Kevorkian [16] using a stochastic version of a polynomial minimal model [15].

For the transition from the silent to the active phase, we consider the distribution of the solution over time; i.e., we follow the probability that the system is in a certain area of state space over time. The time evolution of the distribution is described by the Fokker–Planck equation (FPE), which is a partial differential equation. Since bifurcation analysis is better performed on a system of ordinary differential equations (ODEs), and the FPE is computationally expensive to solve, we assume that the distribution solving the FPE, and hence describing the system, is Gaussian at any point in time. Doing this, we obtain a set of ODEs describing how the distribution evolves in time. This approach is based on work on models of noisy spiking neurons [18, 22], and the ODEs describe the evolution of the mean and lower order moments of the assumed Gaussian distribution. A similar approach [12, 13] assumed a Gaussian-like distribution around the deterministic solution, and was used to describe a neural burster [13]. For the transition out of the active phase we use a stochastic Melnikov method [9], thus allowing us to use the ideas from [16] in a stochastic setting.

We find that noise makes both the active and the silent phases terminate earlier than for the deterministic model, but that it has a stronger effect on the exit from the active phase than from the silent phase. Thus, we explain why simulations show that noise shortens both phases and consequently the burst period, in this way transforming normal bursters into fast bursters. This supports the idea that stochastic fluctuations in membrane ion channels can disrupt normal bursting and that channel sharing can restore it [3, 4, 21].

2. The β-cell model with noise. Pernarowski [15] introduced a minimal, deterministic, polynomial model capable of modeling both the spiking and the bursting phenomena seen in β-cells. The fact that the involved functions are polynomials will be of importance when describing the moments of the distribution [22]. The model is

$$\frac{du}{dt} = f(u) - w - z, \tag{2.1a}$$

$$\frac{d\,w}{dt} = g(u) - w + \sigma\Gamma_t, \tag{2.1b}$$

$$\frac{d\,z}{dt} = \epsilon(h(u) - z), \tag{2.1c}$$

where we have added the white noise term Γ_t to include noise, the strength of which is given by σ. f and g are third order polynomials, while h is a first order polynomial. u mimics the membrane potential of the cell, while w is a fast gating variable. We assume that the ion-channel controlled by w is fluctuating stochastically, and hence we add the noise term to this equation. z is, on the other hand, a slow gating variable due to the small number ϵ. Thus, we have a fast subsystem (u, w) responsible for the spikes during an active phase of bursting, and a slow z controlling the transition between the silent and active phases.

Following [15], we differentiate (2.1a) with respect to t and then transform system (2.1) to

$$\frac{d^2u}{dt^2} + F(u)\frac{d\,u}{dt} + G(u) + z = -\epsilon(h(u) - z) - \sigma\Gamma_t, \tag{2.2a}$$

$$\frac{d\,z}{dt} = \epsilon(h(u) - z), \tag{2.2b}$$

or, equivalently,

$$\frac{d\,u}{dt} = y, \tag{2.3a}$$

$$\frac{d\,y}{dt} = -F(u)y - G(u) - z - \epsilon(h(u) - z) - \sigma\Gamma_t, \tag{2.3b}$$

$$\frac{d\,z}{dt} = \epsilon(h(u) - z), \tag{2.3c}$$

where

$$F(u) = a\big((u - \hat{u})^2 - \eta^2\big), \tag{2.4}$$

$$G(u) = u^3 - 3(u + 1), \tag{2.5}$$

$$h(u) = \beta(u - u_\beta). \tag{2.6}$$

With appropriate parameters, the system shows a bursting pattern, but increasing the strength of the noise shortens the bursts; see Figure 1, left panels.

This simulation as well as all other simulations and bifurcation diagrams were done using XPPAUT [8]. The stochastic equations were solved by the backward Euler method with time step $dt = 0.005$. For each time step XPPAUT draws a random number from an appropriately scaled normal distribution to simulate the Wiener process. Control simulations showed that the use of smaller time steps did not change the results.

The deterministic system ($\sigma = 0$) can be analyzed from a bifurcation diagram of the fast subsystem with z as the bifurcation parameter [15, 17]. This is done by setting $\epsilon = 0$. The fixed points of the fast system fall on the Z-shaped curve $z = -G(u)$; see Figure 2. The fast system is stable for low z values, but upon increasing z, this stability is lost in a Hopf-bifurcation (HB in Figure 2). The fixed points on the middle branch of the Z-shaped curve are saddle-points, while they are stable on the lower branch. The middle branch meets the upper and lower branch in saddle-node bifurcations (SN in Figure 2). The Hopf-bifurcation gives rise to stable periodic solutions around the

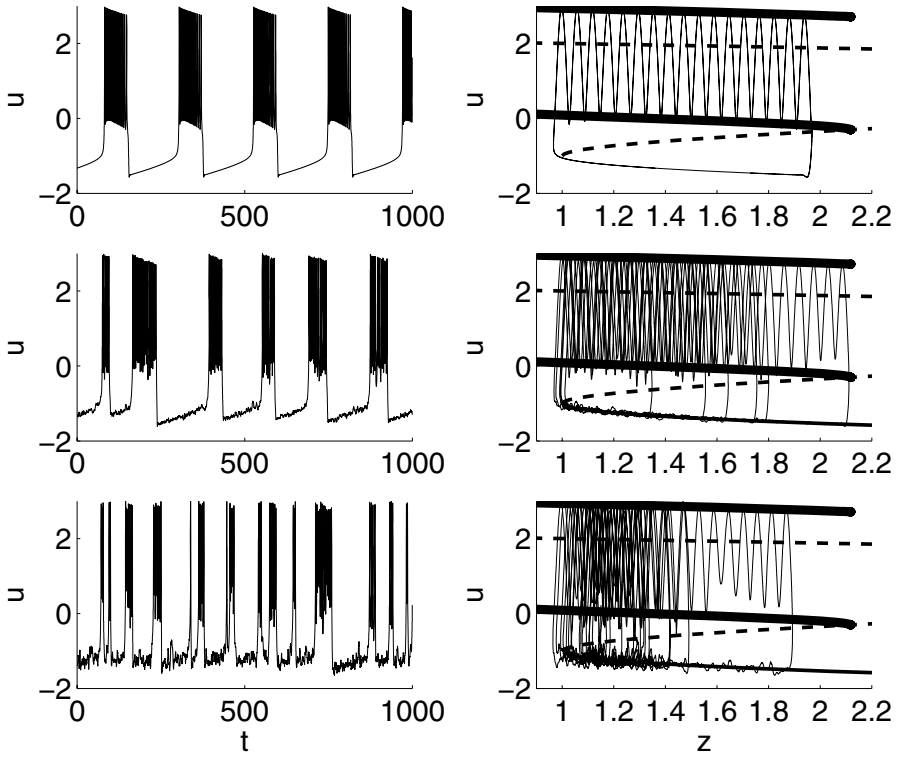

FIG. 1. *Numerical simulations of bursting with different noise strengths. The left panels show time series of the membrane potential u, while the right panels show the corresponding projection on the z-u plane and the deterministic bifurcation diagram from Figure* 2. *The upper panels show the deterministic case* $\sigma = 0$, *in the center panels* $\sigma = 0.1$, *and in the lower panels* $\sigma = 0.3$. *Other parameters are, here and throughout the manuscript,* $a = 0.25$, $\hat{u} = 1.6$, $\beta = 4$, $u_\beta = -0.954$, $\epsilon = 0.0025$, *and* $\eta = 0.7$.

unstable fixed points on the upper branch, but these periodic solutions disappear in a homoclinic bifurcation (HC in Figure 2) for sufficiently large z. The mechanism underlying bursting is based on the bistability between the stable fixed points on the lower branch and the stable periodic solutions for a range of z-values. When we reintroduce the slow variation of z for $0 < \epsilon \ll 1$, we can explain bursting. When the solution of the system is near the lower branch, trajectories move slowly to the left since u is low, and thus $\frac{dz}{dt} < 0$ here. This continues until the stable branch disappears in the left saddle-node bifurcation. The solution now leaves the lower branch (silent phase) and goes to the stable periodic solutions (active phase), where u is high and $\frac{dz}{dt} > 0$. Hence, the trajectory now moves to the right until it meets the homoclinic bifurcation and the stable periodic solutions disappear. The solution then leaves the active phase and settles on the lower branch, and the scenario is repeated.

This explanation gives a hint of how noise shortens the bursts. The random perturbations to the system can make trajectories leave the silent as well as the active phase prematurely when the system is randomly kicked across the corresponding thresholds. When the noise intensity increases, this will happen more often since the stochastic fluctuations are larger. In Figure 1 (right panels), we see that in general the noisy system leaves the active phase prematurely, while the early exit from the silent phase is less pronounced. We now aim at understanding this observation better.

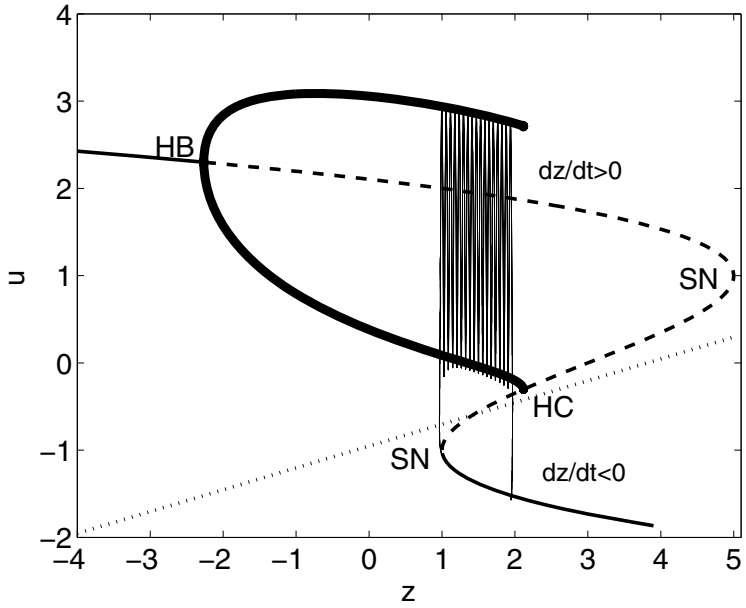

FIG. 2. *Bifurcation diagram of the fast subsystem with z as the bifurcation parameter. Thin solid curves indicate stable fixed points, thin broken curves correspond to unstable fixed points, and the thick solid curve shows the extrema of periodic solutions. The dotted curve shows the z-nullcline, $\frac{dz}{dt} = 0$. A simulation of the deterministic system is projected onto the z-u plane for comparison. See the text for more details.*

3. Location of the left saddle-node bifurcation. The exit from the silent phase happens near the left saddle-node bifurcation; see Figure 2. We expect that for increasing noise, the bifurcation will effectively happen for larger z-values, since the noise will tend to push the system across the threshold and into the active phase prematurely.

To analyze this, we look at the distribution of the system under all possible realizations of the noise. Since the fluctuations of u and y are rather small during the silent phase, we expect that for fixed z ($\epsilon = 0$) the distribution of (u, y) will be approximately Gaussian. This allows us to use the so-called G-method [22], which is a development of the method from [18].

The idea is that a Gaussian distribution is described completely by its mean and covariance matrix. Hence we follow, for fixed z, the means $\bar{u} = \langle u \rangle$ and $\bar{y} = \langle y \rangle$, the variances $S_u = Var(u)$, and $S_v = Var(y)$, and the covariance $C = Cov(u, y)$.

Following [22], we average (2.3a), (2.3b), and the time derivative of the (co)variances $(u - \bar{u})^2$, $(y - \bar{y})^2$, and $(u - \bar{u})(y - \bar{y})$ using Itô's formula and the fact that the odd moments vanish for a Gaussian distribution. To illustrate the procedure, we derive the equation for C in greater detail, as follows:

$$\begin{aligned}
\frac{dC}{dt} &= \frac{d}{dt}\Big\langle (u-\bar{u})(y-\bar{y})\Big\rangle = \Big\langle \frac{d}{dt}[(u-\bar{u})(y-\bar{y})]\Big\rangle \\
&= \Big\langle (u-\bar{u})\frac{d\,(y-\bar{y})}{dt}\Big\rangle + \Big\langle (y-\bar{y})\frac{d\,(u-\bar{u})}{dt}\Big\rangle \\
&= \Big\langle (u-\bar{u})(-F(u)y - G(u) - z - \sigma\Gamma_t)\Big\rangle + \Big\langle (y-\bar{y})^2\Big\rangle \\
&= -\Big\langle (u-\bar{u})F(u)y\Big\rangle - \Big\langle (u-\bar{u})G(u)\Big\rangle + S_y.
\end{aligned} \tag{3.1}$$

The first term is found from the Taylor polynomial of F around $\bar{u}$,

$$\begin{aligned}
&\Big\langle (u-\bar{u})F(u)y \Big\rangle \\
&= \left\langle (u-\bar{u})\big((y-\bar{y})+\bar{y}\big)\left(F(\bar{u})+F'(\bar{u})(u-\bar{u})+\frac{1}{2}F''(\bar{u})(u-\bar{u})^2\right)\right\rangle \\
&= F(\bar{u})C + F'(\bar{u})\bar{y}S_u + a\Big\langle (u-\bar{u})^3(y-\bar{y})\Big\rangle,
\end{aligned} \tag{3.2}$$

where we have again used that the odd moments vanish. Finally, the last term of (3.2) is equal to $3aS_uC$ by the Gaussian joint variable theorem. The second term of (3.1) is treated similarly.

In summary, we obtain the equations

$$\frac{d\,\bar{u}}{dt} = \bar{y}, \tag{3.3a}$$

$$\frac{d\,\bar{y}}{dt} = -F(\bar{u})\bar{y} - G(\bar{u}) - z - \big(F''(\bar{u})\bar{y} + G''(\bar{u})\big)\frac{S_u}{2} - F'(\bar{u})C, \tag{3.3b}$$

$$\frac{d\,S_u}{dt} = 2\ C, \tag{3.3c}$$

$$\frac{d\,S_y}{dt} = 2\ \big[-F(\bar{u})S_y - \big(F'(\bar{u})\bar{y} + G'(\bar{u})\big)\,C\,\big] + \sigma^2 - 6aS_u^2, \tag{3.3d}$$

$$\frac{d\,C}{dt} = S_y - \big(F'(\bar{u})\bar{y} + G'(\bar{u})\big)S_u - F(\bar{u})C - 3aS_uC. \tag{3.3e}$$

These are exact equations for the means and (co)variances due to F and G being polynomials [22]. Since the system (3.3) is deterministic, we can perform bifurcation analysis on these equations using z as the bifurcation parameter. Starting from the silent phase $\bar{u} \approx -1$, $\bar{y} = S_u = S_y = C = 0$, we find a branch of stable fixed points similar to the lower branch of Figure 2 (not shown). This branch ends in a saddle-node bifurcation, as for the deterministic case. However, the rest of the bifurcation structure breaks down, and the system (3.3) has, e.g., fixed points with negative S_y values, which are of course impossible solutions, since S_y is a variance. We believe that this breakdown is because the assumption of a Gaussian distribution holds only in the silent phase, and hence the system (2.3) is no longer described by system (3.3) after leaving the lower branch. Nevertheless, the saddle-node where the silent phase branch of (3.3) ends can be followed in a two-parameter bifurcation diagram with σ as the other bifurcation parameter; see Figure 3. For increasing noise intensity σ the saddle-node moves to the right, indicating that the noisy system leaves the silent phase earlier for greater noise strength. This corresponds well to direct simulations of the z-value for which the noisy system (2.3) leaves the silent phase (Figure 3).

4. Location of the homoclinic bifurcation. To follow the exit from the active phase for different noise intensities, we apply a stochastic Melnikov method. The deterministic Melnikov technique was first applied to β-cell models by Pernarowski, Miura, and Kevorkian [16] and for the model we use here in [15].

The Melnikov function is used to determine the distance between the stable and unstable manifolds of a saddle-point for systems, which are small perturbations of a Hamiltonian system with a homoclinic saddle-point. In the deterministic case of the β-cell model, the active phase ends in a homoclinic bifurcation, which happens exactly when the stable and unstable manifolds of the saddle-point coincide, i.e., when the Melnikov function is zero.

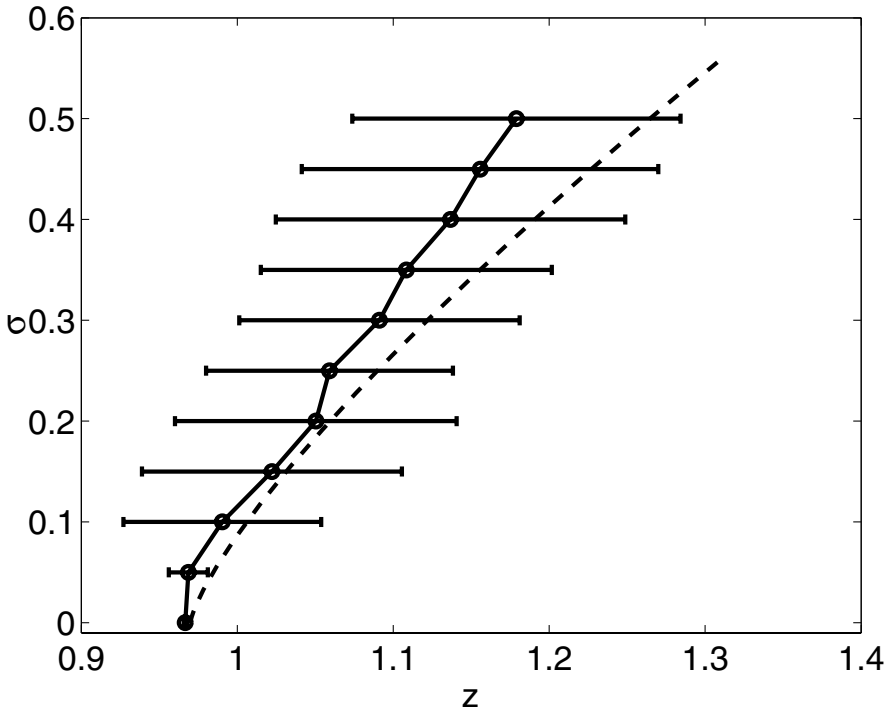

FIG. 3. *Two-parameter bifurcation diagram showing the location of the saddle-node bifurcation where the silent phase branch for system* (3.3) *ends (broken curve). This bifurcation corresponds to the left saddle-node bifurcation in Figure* 2. *Direct simulations of the noisy system* (2.2) *show that the prediction from* (3.3) *is faithful, since the z-values for which the system* (2.2) *leaves the silent phase (measured as u passing through the Poincaré section* $u = -0.55$ *from below) agree well. The bars are mean values of* $z \pm$ *one standard deviation for a simulation until* $t = 10000$. *We have shifted the broken curve* 0.03 *to the left, since the deterministic version overestimates the z-value by this amount.*

We write (2.3) with $\epsilon = 0$ as

$$\frac{d\,u}{dt} = y, \tag{4.1}$$

$$\frac{d\,y}{dt} = -G(u) - z \; + \; [-F(u)y - \sigma\Gamma_t], \tag{4.2}$$

from which it is seen that the term in the square brackets is a perturbation of the Hamiltonian system $\frac{d^2u}{dt^2} + G(u) + z = 0$, which has a saddle-point $(a_s(z), 0)$ with a homoclinic orbit (u_s, y_s) [5, 15]. The Hamiltonian is $H(p,u) = \frac{1}{2}p^2 + V(u; a_s(z))$ with potential

$$V(u, a_s) = \frac{1}{4}(u - a_s)^2[u^2 + 2a_s u + 3a_s^3 - 6]. \tag{4.3}$$

The homoclinic orbit can then be written as

$$(u_s, y_s) = (u_s, \pm\sqrt{-2V(u_s, a_s(z))}\;). \tag{4.4}$$

For the deterministic case, $\sigma = 0$, the square bracket in (4.2) reduces to $-F(u)y$. Pernarowski [15] showed that this term is indeed small for all z values between the

left saddle-node bifurcation and the homoclinic bifurcation, and Melnikov's method is therefore applicable. The Melnikov function is in the deterministic case [5, 15]

$$M_{det} = -a\left[e_2(a_s(z))(\hat{u}^2 - \eta^2) + e_1(a_s(z))\hat{u} + e_0(a_s(z))\right], \tag{4.5}$$

where

$$e_0(a_s) = -\frac{12}{5}\sqrt{3}(a_s^4 - 2a_s^2 - 4)\sqrt{1 - a_s^2} + 6\sqrt{2}a_s(a_s^2 - 3)\Delta(a_s), \tag{4.6}$$

$$e_1(a_s) = 6\sqrt{3}a_s(3 - a_s^2)\sqrt{1 - a_s^2} + 3\sqrt{2}(a_s^2 - 3)(a_s^2 + 1)\Delta(a_s), \tag{4.7}$$

$$e_2(a_s) = 4\sqrt{3}\sqrt{1 - a_s^2} + 2\sqrt{2}a_s(a_s^2 - 3)\Delta(a_s), \tag{4.8}$$

$$\Delta(a_s) = \cos^{-1}(2a_s/\sqrt{6 - 2a_s^2}). \tag{4.9}$$

We have changed the sign of M_{det} compared to [15] such that $M_{det} < 0$ when the stable manifold is outside the unstable manifold of the saddle-point [23]. In this case the fast subsystem has a limit cycle for a given fixed z; see Figure 2. When $M_{det} = 0$ the unstable and stable manifolds coincide and form a homoclinic orbit. This happens at the z-value when the homoclinic bifurcation occurs and the active phase terminates.

The Melnikov function is related to the phase space flux, which is a measure of the transport across the pseudoseparatix approximating the separatix of the Hamiltonian system [23]. For the β-cell model, we are interested in the transport from the inside to the outside of the pseudoseparatix, since this will terminate the active phase. The flux is given by the area of the *turnstile lobe* [23], and to first order it is found as

$$\phi_{det} \approx \int_{t_1}^{t_2} M_{det}^{+} dt = (t_2 - t_1)M_{det}^{+}, \tag{4.10}$$

since M_{det} does not depend on t. Here and in the following, $M^+ = \max\{0, M\}$ is the positive part of M, and t_1 and t_2 are the time points that define the lobe. Note that as long as $M_{det} < 0$, i.e., the unstable manifold lies inside the stable manifold, $\phi_{det} = 0$, indicating that there is no transport (flux) from inside to outside the separatix; i.e., the system is trapped. For the β-cell model the trajectories will follow the limit cycle characterizing the active phase.

Another related variable is the average phase space flux. To first order it is approximated by the flux factor given by [9]:

$$\Phi_{det} = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} M_{det}^{+} dt = M_{det}^{+}. \tag{4.11}$$

We now move to the stochastic case with $1 \gg \sigma > 0$ in (4.2). Frey and Simiu [9] approximated the noise process by a harmonic sum with random parameters, so-called Shinozuka noise. Since each realization of the noise—each path—is a harmonic sum, they argued that Melnikov theory can be applied to such scenarios as the one treated here when σ is sufficiently small, even for perturbations containing white noise processes as in (4.2). We note that the deterministic term $-F(u)y$ in the square bracket in (4.2) is still small for all values of z between the left saddle-node bifurcation and the homoclinic bifurcation (not shown) as for the deterministic case.

This approach uses, instead of the deterministic Melnikov function, a stochastic Melnikov process [9], which is given by

$$M_{stoch}(t) = M_{det} + \sigma\Xi_t, \tag{4.12}$$

where Ξ_t is a stochastic process with Gaussian distribution in the case of white noise perturbations Γ_t, which is the case considered here for the β-cell model. Ξ_t has mean zero and variance

$$\sigma_\Xi^2 = \int_0^\infty |H(k)|^2 dk, \tag{4.13}$$

where $H(k) = \int_{\mathbb{R}} h(t)e^{-ikt}dt$ is the Fourier transform of $h(t) = y_s(-t)$. For the Hamiltonian system (4.2), y_s is odd, and hence also h and H are odd. By Parseval's equation and (4.4) we then get

$$\begin{aligned}\sigma_\Xi^2 = \frac{1}{2}\int_{\mathbb{R}} |H(k)|^2 dk &= \frac{1}{2}\, 2\pi \int_{\mathbb{R}} |h(t)|^2 dt \\ &= 2\pi \int_0^\infty |y_s(t)|^2 dt = 2\pi \int_{a_s}^{b_s} \sqrt{-2V(u, a_s(z))}du,\end{aligned} \tag{4.14}$$

where $b_s = -a_s + \sqrt{6 - 2a_s^2}$ is the largest zero of V, corresponding to the point $(b_s, 0)$ on the separatix (u_s, y_s) furthest from the saddle-point [5]. Using standard tables, we get the following expression from (4.3):

$$\sigma_\Xi^2 = \sqrt{2}\pi \left(2\sqrt{6 - 6a_s^2} + a_s(a_s^2 - 3) \left(\pi - 2\sin^{-1} \frac{2a_s}{\sqrt{6 - 2a_s^2}} \right) \right). \tag{4.15}$$

The saddle-point $a_s = a_s(z)$ can be determined analytically. Thus, we have a complete description of the Melnikov process (4.12).

The unstable and stable manifolds of the saddle-point intersect when $M_{stoch}(t_0)$ changes sign and becomes positive, and then the system can escape from the inside of the pseudoseparatix. Hence, it is reasonable to assume that the probability of terminating the active phase at t_0 is proportional to the probability $Pr(M_{stoch}(t_0) > 0)$.

Having characterized the Melnikov process M_{stoch}, we now take a closer look at $Pr(M_{stoch}(t_0) > 0)$. We define $X = \frac{M_{stoch}(t_0) - M_{det}}{\sigma\sigma_\Xi}$, so that the probability of ending the active phase at t_0 is proportional to $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi})$ due to the above assumption. Note that $X \sim N(0, 1)$ is a standard Gaussian variable.

It seems plausible that we need at least a certain probability $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi}) = \alpha$ in order to effectively end the active phase during a spike period, and there seems to be no a priori reason why this probability should depend on σ. Note that for increasing σ and $M_{det} < 0$, the probability $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi})$ increases (for fixed z, and hence M_{det} and σ_Ξ), such that there is a higher probability of ending the active phase prematurely for higher noise strengths, as expected (see Figure 1). In the deterministic limit $\sigma \to 0$, this probability is either 0 (for $M_{det} < 0$) or 1 (for $M_{det} > 0$) in accordance with the above observations for the deterministic scenario.

Continuing this idea, we look for the z value for which the active phase terminates. This is a stochastic event, but on average we expect it to be closely related to the probability discussed above. Since the relation $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi}) = \alpha$ determines a fixed $\frac{-M_{det}}{\sigma\sigma_\Xi} = \mu$, we get that for larger σ a larger value of $-M_{det}/\sigma_\Xi$ will be needed for the system to effectively leave the active phase. $-M_{det}/\sigma_\Xi$ is a decreasing function of z (Figure 4), so solving $-M_{det}/\sigma_\Xi = \sigma\mu$ yields a lower z when σ is large than for small σ. This corresponds to the fact that the escape from the active phase will happen earlier for higher noise intensities.

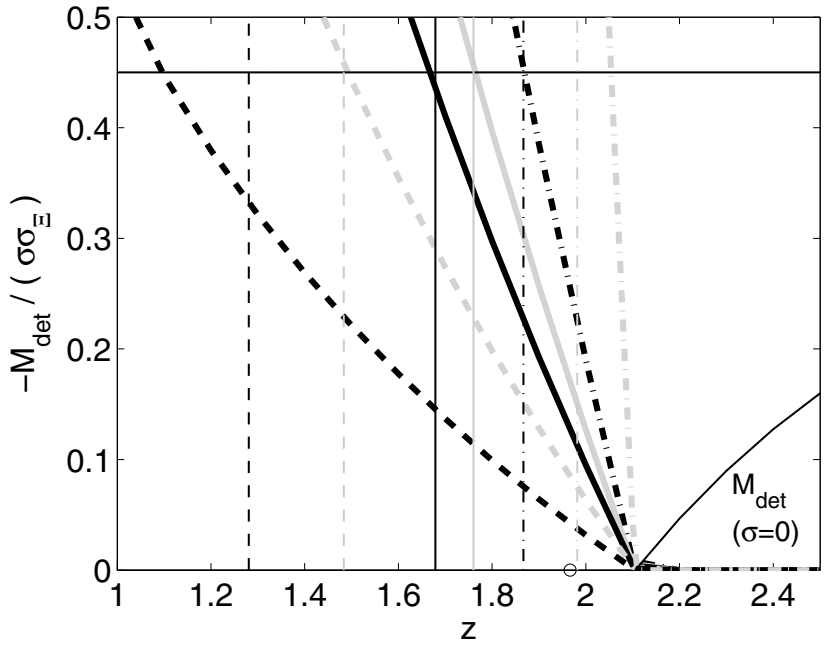

FIG. 4. *Stochastic escape from the active phase is explained by the condition* $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi}) \approx 0.32$ *for* $X \sim N(0,1)$. *This corresponds to* $\frac{-M_{det}}{\sigma\sigma_\Xi} \approx 0.45$ *(horizontal black line). The decreasing curves are* $\frac{-M_{det}}{\sigma\sigma_\Xi}$ *calculated for different z-values using* (4.5) *and* (4.15) *for different values of* σ*:* 0.3 *(dashed black curve),* 0.15 *(dashed grey curve),* 0.1 *(solid black curve),* 0.075 *(solid grey curve),* 0.05 *(dash-dotted black curve),* 0.01 *(dash-dotted grey curve). Each of the thin vertical lines indicates for a value of* σ *(same* σ *values and corresponding line types and colors as above) the mean value of a series of z values for which the system left the active phase, defined as passing from above to below* $u = -0.8$*, in a simulation of system* (2.3) *until* $t = 40000$. *For comparison, the full increasing curve is the deterministic* M_{det}. *Note that* M_{det} *does not pass through zero at the z value (*$\circ$*) for which the deterministic system leaves the active phase. This mismatch between the homoclinic bifurcation and the simulated escape from the active phase is also seen in Figures* 1 *and* 2.

These considerations are supported by numerical simulations, which also confirm that the end of the active phase on average happens for a fixed value of $\frac{-M_{det}}{\sigma\sigma_\Xi}$, which is found empirically to be ≈ 0.45 (Figure 4), corresponding to $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi}) \approx Pr(X > 0.45) \approx 0.32$. However, for very low or high σ this is not true. For high σ, the reason is that the system enters the active phase at $z > 1$, e.g., $z \approx 1.1$ for $\sigma = 0.3$ (Figure 3). Hence, there is a lower limit on the z value for which the escape can occur, and thus, the average value will be higher than predicted by the considerations above. For low σ we are near the case where $M_{det} = 0$, and hence the considerations above might break down in this deterministic limit, especially considering the probability considerations. For example, the period of the limit cycle in the fast subsystem, corresponding to the spike period of the full system, increases when z approaches the value where the homoclinic bifurcation occurs. This implies that even if the probability $Pr(M_{stoch}(t_0) > 0) = Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi})$ is smaller at each time point t_0, the probability of leaving the active phase during a spike, $\int_0^T Pr(M_{stoch}(t_0) > 0)dt_0 = T \cdot Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi})$, can still be large. Thus, the larger spike period compensates for

the lower instantaneous probability, such that the active phase terminates earlier than predicted from $Pr(M_{stoch}(t_0) > 0)$ alone. Moreover, the Melnikov approach predicts a value of z, for which the system leaves the active phase, that is too large even for the deterministic case. This imprecision could be more important for low noise strengths.

The instantaneous flux

$$\phi_{stoch} \approx M^+_{stoch} = (M_{det} + \sigma\Xi_t)^+ \tag{4.16}$$

is at every time t a truncated normal distribution. It has mean equal to the (nonrandom) flux factor Φ_{stoch} given by [9]

$$\Phi_{stoch} = M_{det} + \sigma\sigma_\Xi f(-M_{det}/(\sigma\sigma_\Xi)) - M_{det}F(-M_{det}/(\sigma\sigma_\Xi)), \tag{4.17}$$

where $f = \frac{1}{\sqrt{2\pi}}e^{-z^2/2}$ is the standard Gaussian density and $F(z) = \int_\infty^z f(x)dx$ is the corresponding distribution function. We remark that $\Phi_{stoch} \to M^+_{det} = \Phi_{det}$ for $\sigma \to 0$.

However, it is the flux during a finite interval that is relevant for the transition out of the active phase. This finite time flux varies randomly, and hence the mean flux Φ_{stoch} needs to be held against the variance of ϕ_{stoch} in order to determine when the system escapes from the active phase, in the same spirit as for M_{stoch} above. The variance of ϕ_{stoch} is given by

$$\begin{aligned} Var\left(\phi_{stoch}\right) = (\sigma\sigma_\Xi)^2 \Bigg[& \left(1 + \left(\frac{M_{det}}{\sigma\sigma_\Xi}\right)^2\right)\left(1 - F\left(-\frac{M_{det}}{\sigma\sigma_\Xi}\right)\right) + \frac{M_{det}}{\sigma\sigma_\Xi} f\left(-\frac{M_{det}}{\sigma\sigma_\Xi}\right) \\ & - \left(f\left(-\frac{M_{det}}{\sigma\sigma_\Xi}\right) + \frac{M_{det}}{\sigma\sigma_\Xi}\left(1 - F\left(-\frac{M_{det}}{\sigma\sigma_\Xi}\right)\right)\right)^2 \Bigg], \end{aligned} \tag{4.18}$$

and it is readily seen that $Var(\phi_{stoch}) \to 0$ for $\sigma \to 0$.

From simulations, it again appears that the end of the active phase happens for a roughly constant value of $\Phi_{stoch}/\sqrt{Var(\phi_{stoch})} \approx 0.182$ (Figure 5). Thus, as seen above for the Melnikov process, the related approach using phase space flux predicts that the exit from the active phase occurs for a fixed value of the standardized variable $\frac{\phi_{stoch} - \Phi_{stoch}}{\sqrt{Var(\phi_{stoch})}}$.

5. Discussion. We have shown that the escape from the silent as well as from the active phase of the noisy β-cell model can be studied analytically. For the silent phase we used a collective coordinate approach by assuming a Gaussian distribution and the G-method [18, 22]. We could then follow the saddle-node bifurcation at which the silent phase terminates as the noise strength σ varies (Figure 3). For the active phase we used a stochastic Melnikov approach [9], which is new in the context of noisy bursting. We gave an explanation of why a fixed value of $\frac{-M_{det}}{\sigma\sigma_\Xi}$ would predict the z value, for which the system would leave the active phase for different values of σ. The value of $Pr(X > \frac{-M_{det}}{\sigma\sigma_\Xi}) \approx 0.32$ is not obvious, and it should be interesting to see whether it holds for other stochastic systems that are nearly Hamiltonian.

Noise has a bigger influence on the exit from the active phase than on the escape from the silent phase. However, the plateau fraction is roughly unchanged, since a faster escape from the active phase corresponds to the system entering the silent phase later, and vice versa. This is in agreement with the fact that although

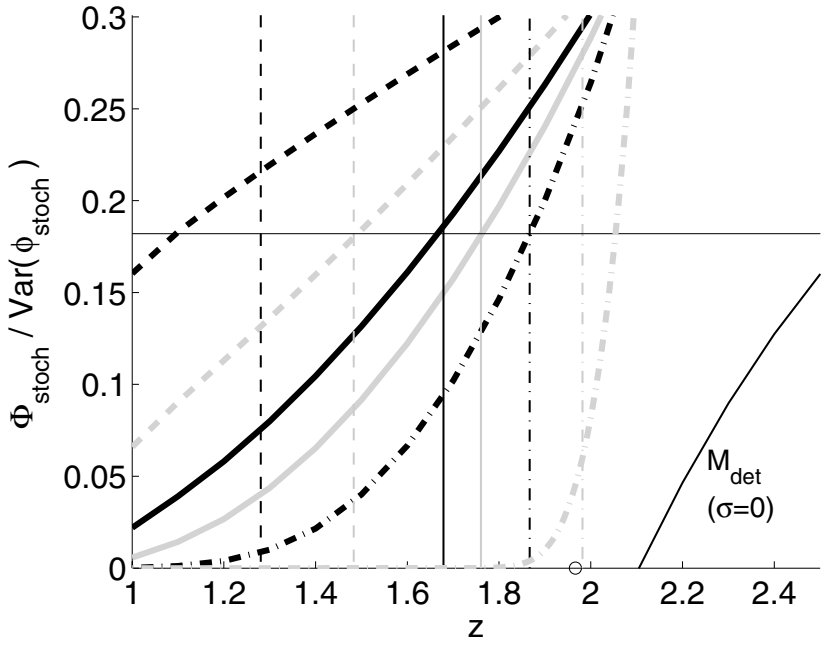

FIG. 5. *Stochastic escape from the active phase is explained by* $\Phi_{stoch}/Var(\phi_{stoch}) \approx 0.182$ *(horizontal black line). The thick curves show* $\Phi_{stoch}/Var(\phi_{stoch})$*, with the same legends and range of* σ *values as in Figure* 4*. They were calculated from* (4.15)*,* (4.17)*, and* (4.18)*. single cells have shorter burst periods, the plateau fraction is similar to that of intact islets [11].

We remark that the treatment of the stochastic Melnikov method in [9] was proved rigorously only for the case of uniformly bounded noise, since the paths are then uniformly bounded and current Melnikov theory is applicable. For unbounded processes such as white noise, the results were found and argued to be valid by limit arguments. Biologically, paths are bounded. For example, if w in (2.1) is a gating variable, we have $0 \leq w \leq 1$, which implies that the noise in (2.1) must be bounded. The white noise process was chosen here for mathematical convenience, but in the analysis of biologically more realistic stochastic models the Melnikov approach should be even more reliable.

Assuming that single cells and small clusters of β-cells have shorter burst periods due to noise, the channel sharing hypothesis can explain why. As seen in both simulations as well as the treatment presented here, the stronger the noise intensity, the lower the burst period. If we assume that the cells are coupled with infinite coupling strength (the supercell hypothesis) [4, 21], then in larger groups of cells, the noisy channels will be shared among several cells, and the individual cell would feel smaller fluctuations than if it were isolated, leading to longer burst periods. Extending the methods presented here to groups of coupled cells with finite coupling strength would be interesting in an attempt to gain deeper insight into previously published results [1, 6, 14].

AN OPTIMIZATION APPROACH TO MODELING SEA ICE DYNAMICS. PART 1: LAGRANGIAN FRAMEWORK*

HELGA S. HUNTLEY†, ESTEBAN G. TABAK‡, AND EDWARD H. SUH‡

Abstract. A new model for the dynamics of sea ice is proposed. The pressure field, instead of being derived from a local rheology as in most existing models, is computed from a global optimization problem. Here the pressure is seen as emerging not from an equation of state but as a Lagrange multiplier that enforces the ice's resistance to compression while allowing divergence. The resulting variational problem is solved by minimizing the pressure globally throughout the domain, constrained by the equations of momentum and mass conservation, as well as the limits on ice concentration (which has to stay between 0 and 1). This formulation has an attractive mathematical elegance while being physically motivated. Moreover, it leads to an analytic formulation that is also easily implemented in a numerical code, which exhibits marked stability and is suited to capturing discontinuities. In order to test the theory, the equations for a one-dimensional model are cast in terms of Lagrangian mass coordinates. The solution to the minimization problem is compared to an exact analytic solution derived using jump conditions in a simple test case. Another case is examined, which is somewhat more complicated but still allows our physical intuition to verify the qualitative results of the model. Good agreement is found. A final validation is performed by a comparison with a particle-based model, which tracks individual ice floes and their inelastic interaction in a one-dimensional domain.

Key words. ice dynamics, rheology, Lagrangian fluid dynamics

1. Introduction.

Unlike the dynamics of the ocean waters, sea ice dynamics is relatively little understood. Part of the problem is that ice is a somewhat peculiar substance; it is neither hard as steel, nor elastic like rubber, nor completely fluid like a liquid. Colliding ice floes do not behave like the familiar billiard balls with perfectly round shapes and elastic collisions. An additional challenge for the modeler interested in the large scales of the whole Arctic, or at least an entire strait, is the limit of resolution. It is impossible to follow individual ice floes. Instead the behavior of a field of floes on the order of several square kilometers must be summarized by tracking an average velocity (mass-weighted), a thickness distribution, and the concentration of ice in the grid box. On this scale, one can no longer rely on first physical principles for the solid bodies making up the ice. So what are the laws of physics describing the motion of a half empty box of solid substance that strongly resists compression up to its breaking point but is easily pulled apart due to a multitude of fractures?

Scientists over the years have suggested various analogies, two of which have shown enough promise to have stood the test of time: ice as a fluid, and ice as a granular material. Most models today following the first of these approaches in some way relate back to the sea ice rheology proposed by Hibler in [3], based on the postulate

that ice behaves like a nonlinear viscous-plastic compressible fluid. Improvements have been made on the original model, including an extension with an elastic component to the constitutive law, but the essential character has been maintained (cf., for example, [5]). Parts of the "state-of-the-art" formulation of the rheology are based on the observations that ice resists compression up to a breaking point (plastic); the viscous character is added to avoid multivalued functions, while the elastic terms are mostly introduced for greater numerical stability. While the numerical results are generally good, to some extent this is due to parameter tuning to available (though often scarce) data.

Models based on a cavitating fluid rheology also fall into this first category. They do not naturally incorporate shear strength (although this has been partially addressed), but are computationally somewhat simpler and less expensive, making use of an iterative correction scheme. These models also have had some success in reproducing realistic ice transport (cf., for example, [2]).

In the second category, a granular rheology has been developed by Tremblay and Mysak [11], as well as others (e.g., the CRREL[1] uses a high-resolution granular sea ice model, based on [4]). These are better equipped to handle such tasks as tracking leads in an ice field, although a much higher resolution is required for such problems.

Model intercomparison studies have found that the choice of rheology has a significant impact on the model output; see, e.g., [6] and [1]. A somewhat more comprehensive study, SIMIP, the Sea Ice Model Intercomparison Project, was carried out in the late 1990s. It compared viscous-plastic, cavitating fluid, compressible Newtonian fluid, and free-drift with velocity corrections rheologies. Overall, it was found that the viscous-plastic rheology produced the best results, while the free-drift simulation showed large errors in ice drift, thicknesses, and export through the Fram Strait, the compressible Newtonian model yielded excessive ice thickness build-up in the central Arctic, and the cavitating fluid rheology resulted in errors in ice drift and the thickness pattern. However, in some respects none of the models gave entirely satisfactory results. Thus, for example, in an analysis of the summer sea ice extent anomalies, none of the model results lies consistently within the error band of the observations (from satellite data). The same is true for anomalies of annual mean ice thickness in the Beaufort Sea (where the observational data was collected with upward looking sonars). These results were reported in [7]. The present work on a new approach to treating the internal stress term for sea ice dynamics was motivated in part by the realization that existing models not only disagree significantly with each other but also have remaining difficulties reproducing some observed phenomena, such as the formation of ice arches in the Canadian Arctic Archipelago.

We have chosen to follow the first approach, an analogy to fluids, but are employing a novel global formulation of the rheology as the solution to an optimization problem. We attempt to build a theoretical framework, with supporting numerical experiments, to reproduce and explain the relevant observations of sea ice dynamics. We start with the analogy that ice behaves like a fluid with some special properties. In particular, sea ice exhibits semi-incompressibility: It allows divergence without much resistance, due to the many cracks and leads within the ice pack, but strongly resists convergence at high concentration. The goal is to find an expression for the pressure enforcing this semi-incompressibility, which is mathematically elegant and computationally efficient, allowing for clean analytic solutions in simple cases and numerical simulations of more complicated ones. Reliance on parameterization is to

[1]Cold Regions Research and Engineering Laboratory of the US Army Corps of Engineers.

be minimized. To this end, we start with the fluid equations and investigate how they need to be modified to retain validity in the context of sea ice. The central hypothesis is that the pressure acting within the ice field is the minimum necessary to prevent the unrealistic situation of multiple floes occupying the same space. In other words, the pressure term enforces the condition that the area fraction covered by ice (the concentration) may not exceed 1. Our formulation permits the calculation of the pressure using linear programming, benefiting from existing schemes, without tuning to observations.

The goal of the work reported in this article is to demonstrate the feasibility of having the pressure solve a variational problem. To this end, we concentrate on the simplest possible scenario, one of unforced one-dimensional flows, with uniform ice thickness and infinite yield pressure, so that no crushing occurs. A companion paper (Part 2) discusses the effects of ice yielding. Current work, which will be reported in later publications, involves extending the flow to two horizontal dimensions and allowing for nontrivial ice thickness distributions. A more detailed discussion of many of the results in this paper can be found in [9]. Here we will consider a simplified Lagrangian system, which allows both analytic solutions to basic test cases and a straightforward numerical implementation to be tested against a particle-based model resolving individual ice floes. As will be shown, the minimal pressure hypothesis leads to very encouraging results in the studied test cases, justifying further investigation of this particular rheology.

2. Coarse grained ice dynamics as fluid dynamics. We shall use the following variables:

$$\begin{aligned} c &= \text{concentration of ice (fraction of sea surface area covered by ice)},\\ h &= \text{average thickness of the ice},\\ \mathbf{u} &= (u,v) = \text{horizontal velocities},\\ S &= \text{sources} - \text{sinks of ice (melting and freezing, precipitation)},\\ F^x, F^y &= \text{sum of zonal, meridional forces}\\ &\qquad \text{(Coriolis, wind, currents, sea surface tilt, pressure)}. \end{aligned}$$

Note that in the following we are taking the density of ice ρ, which is nearly constant, to be identically 1. This convention simplifies the notation and has no influence on the qualitative results we are interested in. Equivalently, one can describe this as absorbing the density into the thickness parameter, so that h is measured in $\mathrm{kg/m^2}$.

Most of today's sea ice dynamics models employ a thickness distribution function to allow for ice of various thicknesses in any one grid cell (cf. [10]). For the simple model we are building here to verify the minimal pressure hypothesis, we will not include this level of complexity at this time. Similarly, we are not concerned with tracking a velocity distribution within a grid cell, but assume the velocities u and v to be mass-averaged velocities for the entire box.

In Eulerian coordinates, the mass conservation and momentum conservation equations can be written as

$$(ch)_t + \nabla\cdot(ch\mathbf{u}) = S, \tag{1}$$

$$(chu)_t + \nabla\cdot(chu\mathbf{u}) = F^x, \tag{2}$$

$$(chv)_t + \nabla\cdot(chv\mathbf{u}) = F^y, \tag{3}$$

where the product ch (really $ch\rho$) plays the role of a density in analogy with the conventional fluid equations.

What differentiates the case of ice from standard fluids is that, in addition to these two conservation laws, we also have the constraint that c can vary (unlike the density of incompressible fluids) but may not exceed 1, which is enforced by a pressure force. In this paper, we want to investigate the nature of this pressure force and a new way to calculate it. To isolate this issue, we will consider the one-dimensional case without sources or sinks ($S = 0$). By defining $F = F^x/(ch)$, subtracting u times (1) from (2), and dividing by ch, the system reduces to

$$(ch)_t + (chu)_x = 0, \tag{4}$$

$$u_t + u\,u_x = F. \tag{5}$$

Notice that, even if F were given (which it is not, since the pressure is one of the variables to be determined), this system has only two equations but three unknowns. Mass conservation alone does not provide for a way to evolve the fractional area c and the mean thickness h separately. Extra physical assumptions are necessary to complete the system's description. In the absence of crushing (or sources or sinks), a natural assumption is that the thickness h is advected with ice floes:

$$h_t + u\,h_x = 0. \tag{6}$$

In words, when a pack of floes is pulled apart, the floes do not become thinner: It is the space between them that increases, thus reducing the fractional area coverage c. (The assumption of advection of h is relaxed in Part 2 of this work.)

3. The Lagrangian formulation. To gain further insight into this system and to make analytic solutions easier to obtain, we introduce the Lagrangian mass coordinates[2]

$$\begin{cases} \xi = \int_0^x ch\,d\hat{x}, \\ \tau = t. \end{cases} \tag{7}$$

The resulting Lagrangian equations in these coordinates for one-dimensional ice motion without sources or sinks are

$$\left(\frac{1}{ch}\right)_\tau = u_\xi, \tag{8}$$

$$u_\tau = F. \tag{9}$$

(See the appendix for the derivation.)

Introducing the variable $k \equiv \frac{1}{ch} - 1$ yields

$$k_\tau = u_\xi, \tag{10}$$

$$u_\tau = F. \tag{11}$$

While these equations have a beguilingly simple form, we have now lost sight of the crucial variable c, which we have to constrain. We would like to translate this

[2]Lagrangian mass coordinates are often used in astronomical papers, as well as in studies of hydrodynamics; cf., for just one example, [12].

constraint into a constraint on k. In the case where $h \equiv 1$, this is easily done: The constraint $c \leq 1$ now becomes $k \geq 0$. An extension to varying h is straightforward (the constraint becomes $k \geq \frac{1-h}{h}$), but it obscures the pressure effect. Thus, for easier visualization, we shall focus on the particular case of constant ice thickness $h \equiv 1$. (Variations in ice thickness are reintroduced in Part 2.) Note that, in addition to excluding melting and freezing processes as well as precipitation, fixing h also eliminates crushing from the problem. While a realistic and versatile ice model will ultimately require us to bring these components back, the nature of the pressure force and its role in ice dynamics can more easily be investigated in isolation. For this purpose we make one more simplification and isolate the pressure term by setting all other forces equal to zero.

What form this pressure term should take is not immediately obvious. Various suggestions have been made over the years, which fall into two main categories. On the one hand, there are the viscous-plastic or viscous-plastic-elastic models, which all hark back to the original formulation in terms of the stress/strain yield curve in [3]. On the other hand are the cavitating fluid models, which calculate the pressure in a series of correction steps (cf. [2]). While these are backed up by more or less realistic model outputs, they are dependent on empirical parameter tuning and exhibit some numerical shortcomings in the first case and follow an iterative relaxation scheme in the latter. The goal of our approach is to minimize the reliance on empirical parameter tuning and iterative schemes to the extent possible. Our physical intuition tells us that the pressure does not act unless it is necessary to prevent ice concentration from exceeding 1, i.e., to prevent two ice floes from occupying the same space. In other words, while c is far from 1, the pressure force $F = 0$, and the flow follows $u_\tau = 0$. Each parcel's velocity does not change with time. By adding a pressure to the system, we would like to deviate as little as possible from this route while satisfying the constraint. This suggests a mathematical formulation as a constrained optimization problem, where the pressure is defined as a Lagrange multiplier.

We do not expect the pressure force to push the ice apart, as any elastic rheology would. Rather, it builds up as the ice converges, solely to prevent multiple floes from occupying the same space. The goal then is to find a pressure that allows us to minimize the change in u over time. Lagrange multipliers were invented for just such constrained optimization problems. Here we have two constraints acting on u, the equation for the evolution of k and the lower limit on k. Since k is defined at each point ξ, this in fact amounts to infinitely many constraints, one for each $k(\xi)$.

A note on notation: In the following (except for section 9), we will be discussing only the Lagrangian formulation of the problem. Thus, we will simplify our notation by replacing the Greek letters for the independent variables by their Roman cousins again, i.e., by writing the Lagrangian mass coordinate ξ as x and the Lagrangian time coordinate τ as t.

4. Pressure as a Lagrange multiplier. The problem is at each time t to

(12)	minimize	$\|u_t\|$,
(13)	given	$k_t = u_x$,
(14)	subject to the constraint	$k \geq 0$.

Discretizing this system in time, using an implicit scheme, we can reformulate the

problem for each n as follows:

$$\text{minimize} \qquad \|u^{n+1} - u^n\|, \tag{15}$$

$$\text{given} \qquad k^{n+1} = k^n + \Delta t\, u_x^{n+1} \quad \forall\, n \geq 0, \tag{16}$$

$$\text{subject to the constraint} \qquad k^n \geq 0 \quad \forall\, n \geq 0. \tag{17}$$

To simplify the notation, let $\tilde{u} = u^{n+1}$, $u = u^n$, and $k = k^n$. Choosing to define the norm used on u_t as the 2-norm, our task is then to

$$\text{minimize} \quad \int (\tilde{u} - u)^2\, dx, \tag{18}$$

$$\text{subject to} \quad k + \Delta t\, \tilde{u}_x \geq 0. \tag{19}$$

The corresponding variational principle states that there exist Lagrange multipliers $\lambda(x) \leq 0$ such that

$$\delta \int \left\{ (\tilde{u} - u)^2 + \lambda(x)(k + \Delta t\, \tilde{u}_x) \right\} dx = 0, \tag{20}$$

from which it follows (as shown in the appendix) that

$$2\,(\tilde{u} - u) = \Delta t\, \lambda_x \quad \Longrightarrow \quad \frac{\tilde{u} - u}{\Delta t} = \frac{1}{2}\lambda_x.$$

The equivalent continuous statement is

$$u_t = \frac{1}{2}\,\lambda_x. \tag{21}$$

We will adopt the convention of writing the pressure as $p = -\lambda/2$. Our final system for the Lagrangian formulation of one-dimensional sea ice dynamics with constant thickness and without external forces is thus

$$k_t = u_x, \tag{22}$$

$$u_t = -p_x, \tag{23}$$

$$k \geq 0, \tag{24}$$

$$p \geq 0. \tag{25}$$

5. The conundrum is unresolved: Introducing the concept of minimal pressure. We have just derived a form for the pressure term as the x-derivative of a Lagrange multiplier. While this gives us the nice result that the pressure looks very much like the pressure for incompressible fluids, we still have little information about what the pressure actually is.

If we were able to resolve single floes, a constitutive law for frozen water would provide us with a way to calculate the pressure within each ice floe (provided that we know the external forces, including the pressure applied by other ice floes). Since we do not have resolution at this scale, however, we have to find a different method.

The pressure, constructed as a Lagrange multiplier, serves the purpose of enforcing the restriction that ice concentration cannot exceed 1 (or, equivalently, k cannot dip below 0). As long as k is far from 0, one would consequently expect p to equal 0. On the other hand, when k reaches 0, p needs to take on values to prevent it from decreasing further. (Note that this means that always one of k and p is zero.) There

is no reason, however, why it should push the ice apart, i.e., why the arising pressure should exceed the minimum necessary to satisfy the constraint. It is then a reasonable suggestion that the pressure should be calculated as the minimum necessary to enforce the constraint.

One should note at this point that in the more complex cases where h is allowed to vary, and in particular where crushing of the ice is permitted, this p needs to be limited by a maximal p. This is standard in other ice models (for two different formulations, see [3] and [8]). This extension for the minimization formulation for the pressure as we propose here will be discussed in Part 2.

Beyond the heuristic argument presented above, the formulation for the pressure as minimal suggested here is also mathematically appealing based on optimization theory. The first observation above (that $\mathbf{k} \cdot \mathbf{p} = 0$, where $\mathbf{k}$ and $\mathbf{p}$ denote the vectors of the respective discretized quantities) is nothing but the complementary slackness requirement of the Karush–Kuhn–Tucker conditions for constrained optimization problems.[3] Note also that because of (23), minimizing $\|u_t\|_2$ is equivalent to minimizing $\|p_x\|_2$. Since $p \geq 0$ and $p = 0$ whenever $k > 0$, minimizing $\|p_x\|_2$ is in turn equivalent to minimizing $\|p\|_2$ or $\|p\|_1$, as will be shown below in section 7. It is thus natural to choose a formulation that aids in the calculations, and we will use the 1-norm of p to take advantage of available robust linear optimization techniques.

6. An analytic solution to a well understood problem using jump conditions. To build a better understanding of the form that the pressure takes, let us start by considering a problem whose solution we know from physical considerations. We take the half-infinite (one-dimensional) domain $x \leq 0$, with a wall at $x = 0$. Ice is initially distributed according to the given function $k(0, x) = k_o(x)$ and moves according to $u(0, x) = u_o(x)$. We will assume that initially there are no patches of consolidated ice; i.e., $k_o(x) \neq 0 \ \forall x$. If we assume that pressure arises inside the ice only when necessary, it follows that $p(0, x) = 0 \ \forall x$.

If anywhere in the domain $u_x < 0$, then the ice will accumulate somewhere until $k = 0$ (or, equivalently, $c = 1$). The wall at $x = 0$ requires that $u(t, 0) = 0 \ \forall t$. Thus, a positive initial velocity anywhere will ensure ice accumulation.

The first problem we will consider has the first ice build-up occurring at the wall. (This can, for example, be achieved by setting $u_o(x) \equiv u_o = \text{constant} > 0$.) At the edge of the consolidated ice, a discontinuity in both concentration and velocity arises. We denote the location of this shock, marking the interface between the region with $k = 0$ ($c = 1$) and that with $k > 0$ ($c < 1$), by $x = x_c$ and the time when this shock first forms by $t = t_c$; i.e.,

$$t_c = \min \{t : k(t, x) = 0 \text{ for some } x < 0\}, \tag{26}$$

$$x_c(t) = \min \{\tilde{x} : k(t, x) = 0 \ \forall x \geq \tilde{x}\}. \tag{27}$$

For $t < t_c$, $p(t, x) = 0 \ \forall x$. The equations we solve for this portion are the very

[3] Physically, pressure is generally defined only up to a constant, since only its gradient enters into the dynamics. Similarly, here it is easy to see that adding an arbitrary (positive) constant to a p which solves the system (22)–(25) yields another solution. Strictly speaking, the KKT conditions do not necessitate $p \geq 0$ and $\mathbf{k} \cdot \mathbf{p} = 0$; they do provide for the *existence* of a p satisfying these conditions and solving the system (22)–(25). Hence we will choose the arbitrary constant such that they hold and $\min p = 0$.

simple set

$$k_t = u_x, \tag{28}$$

$$u_t = 0, \tag{29}$$

whose solution is

$$k(t,x) = k_o(x) + tu_{ox}(x), \tag{30}$$

$$u(t,x) = u_o(x), \tag{31}$$

$$p(t,x) = 0. \tag{32}$$

Assuming no consolidation except at the wall, this solution holds on $\{(t,x) : t < t_c \text{ or } x < x_c\}$. Once a region of consolidated ice starts to form along the wall, we know that for $x > x_c$,

$$k(t,x) = 0, \tag{33}$$

$$u(t,x) = 0. \tag{34}$$

Thus, for $t > t_c$ and $x > x_c$,

$$u = 0 \implies u_t = 0 \implies p_x = 0 \implies p(t,x) = p(t). \tag{35}$$

In other words, p is constant throughout the region of consolidation at a given point in time.

The only unknowns are p and x_c. While the solutions to the left and to the right of x_c are smooth, there is a discontinuity, both in k and in u, at x_c itself. Using the corresponding jump conditions, we can calculate p and x_c.

Equations (22) and (23), respectively, imply that

$$[\![k]\!]\dot{x_c} = -[\![u]\!], \tag{36}$$

$$[\![u]\!]\dot{x_c} = [\![p]\!], \tag{37}$$

where $[\![\cdot]\!]$ denotes the jump across the shock and $\dot{x_c}$ is the shock speed. It follows from (36) that

$$\dot{x_c} = -\frac{[\![u]\!]}{[\![k]\!]} = -\frac{u_o(x_c)}{k_o(x_c) + tu_{ox}(x_c)}. \tag{38}$$

Together with the initial condition provided by evaluating (27) at t_c, this completely determines x_c. Combining (36) and (37), we find

$$[\![p]\!] = -\frac{[\![u]\!]^2}{[\![k]\!]} \implies p(t,x) = \frac{[u_o(x_c)]^2}{k_o(x_c) + tu_{ox}(x_c)} \qquad \text{for } x > x_c. \tag{39}$$

One should note that this procedure of analyzing jump conditions to determine the pressure can easily be extended to examples with the consolidated ice not against a wall or with multiple consolidated regions. However, such an approach quickly becomes unmanageable, as the number of coupled nonlinear equations increases with the number of consolidated regions (two for each discontinuity, i.e., four for any region not against a wall). Besides, the locations of the interfaces between consolidated and nonconsolidated areas would need to be tracked, a laborious enterprise. Instead we want to use the minimal pressure hypothesis, which simplifies the calculations by making them global and, in the language of numerical conservation laws, is *capturing* rather than *tracking* the boundaries of the consolidated regions.

7. Pressure minimization and norm comparison. The toy problem we consider for a first validation of the minimal pressure hypothesis follows the example described in the previous section: Ice is moving towards a coast, where it consolidates and pressure builds up. We discretize (22) and (23) using a staggered grid and a backward Euler scheme as follows:

$$k_j^{n+1} = k_j^n + \frac{\Delta t}{\Delta x}\left(u_{j+\frac{1}{2}}^{n+1} - u_{j-\frac{1}{2}}^{n+1}\right), \tag{40}$$

$$u_{j+\frac{1}{2}}^{n+1} = u_{j+\frac{1}{2}}^{n} - \frac{\Delta t}{\Delta x}\left(p_{j+1}^{n+1} - p_j^{n+1}\right). \tag{41}$$

The constraints are

$$k_j^{n+1} \geq 0 \quad \forall\, j, n, \tag{42}$$

$$p_j^{n+1} \geq 0 \quad \forall\, j, n. \tag{43}$$

Note that it is necessary to use an implicit scheme for the evolution equation of k, in order to be able to satisfy the constraint. As p does not have an evolution equation, it is immaterial whether we use an explicit scheme or an implicit scheme for the u-equation. We have chosen to write it implicitly for consistency.

We place the wall at $j = 5$. As boundary conditions, we take that $p_{-1}^{n+1} = p_0^{n+1} = 0$ (until the shock reaches this boundary) and $p_5^{n+1} = p_4^{n+1}\ \forall\, n$. As initial conditions, we assume that the shock is located at $j = 2.75$. To the left of the shock, $p = 0$, $k = 1/2$, and $u = 1$. To the right of the shock, $k = 0$ and $u = 0$. Δt is set to 0.5, and Δx is set to 1. (This allows us to capture the shock, which travels with speed 2. Of course, this resolution is very coarse. However, it serves to illustrate the point in this toy example.)

After the first time step,

$$u_{j+\frac{1}{2}}^{1} = \begin{cases} 1 - \frac{1}{2}\left(p_{j+1}^{n+1} - p_j^{n+1}\right) & \text{if } j < 3, \\ -\frac{1}{2}\left(p_{j+1}^{n+1} - p_j^{n+1}\right) & \text{if } j \geq 3. \end{cases} \tag{44}$$

So the constraints (42) take the following form:

$$k_0^1 = \frac{1}{2} - \frac{1}{4}[p_1^1 - 2p_0^1 + p_{-1}^1] \geq 0, \tag{45}$$

$$k_1^1 = \frac{1}{2} - \frac{1}{4}[p_2^1 - 2p_1^1 + p_0^1] \geq 0, \tag{46}$$

$$k_2^1 = \frac{1}{2} - \frac{1}{4}[p_3^1 - 2p_2^1 + p_1^1] \geq 0, \tag{47}$$

$$k_3^1 = 0 - \frac{1}{2} - \frac{1}{4}[p_4^1 - 2p_3^1 + p_2^1] \geq 0, \tag{48}$$

$$k_4^1 = -\frac{1}{4}[p_5^1 - 2p_4^1 + p_3^1] \geq 0. \tag{49}$$

Now we have a system of five inequalities constraining p_1, p_2, p_3, and p_4. (Recall that $p_{-1} = p_0 = 0$ and $p_5 = p_4$.) Minimizing the 2-norm of p_x while satisfying these

constraints gives for $T = \Delta t$ that

$$\begin{aligned} p_0^1 &= 0, & k_0^1 &= \frac{1}{2}, & u_{.5}^1 &= 1, \\ p_1^1 &= 0, & k_1^1 &= \frac{1}{2}, & u_{1.5}^1 &= 1, \\ p_2^1 &= 0, & k_2^1 &= 0, & u_{2.5}^1 &= 0, \\ p_3^1 &= 2, & k_3^1 &= 0, & u_{3.5}^1 &= 0, \\ p_4^1 &= 2, & k_4^1 &= 0, & u_{4.5}^1 &= 0. \end{aligned}$$

From the jump conditions (cf. (39)) it follows that to the right of the shock

$$p = 2. \tag{50}$$

The shock speed can be calculated from (36) or (37) to be

$$\dot{x_c} = -2. \tag{51}$$

Thus the solution obtained by minimizing $\|p_x\|_2$ is exactly what the analytic solution predicts: After time $\Delta t = 0.5$, the shock traveled one step to the left, with u and k retaining the same values on either side of the shock, while $p = 2$ to the right of the shock. Similarly satisfying results were obtained for longer runs and for different initial conditions. In cases where the discretization does not allow for capturing the location of the shock exactly, a certain amount of numerical smoothing around the shock occurs, with p, k, and u taking on intermediate values.

The three norms we want to compare are

1. the 2-norm of p_x, i.e., $\sum (p_i - p_{i-1})^2$,
2. the 2-norm of p, i.e., $\sum p_i^2$,
3. the 1-norm of p, i.e., $\sum |p_i|$.

There are, of course, many other possible norms. These are some of the most natural choices and can be optimized with existing tools.

Solving the same problem above, but minimizing the 1- or 2-norm of p, gives exactly the same answer. This suggests that the norm chosen (at least from among these three) does not impact the result. In fact, this can be shown as follows.

First, consider $\|p_x\|_2$, with the additional condition that $\min p = 0$ (see footnote 3). Recall that the KKT conditions then require $p = 0$ when $k > 0$. Minimizing one of the norms of p itself also calls for p to be 0 whenever possible, in particular whenever $k > 0$.

Within regions of consolidated ice, where $k = 0$, we know that $k_t \geq 0$, and hence, by (22), $u_x \geq 0$.

(i) If $u_x > 0$, then $k_t > 0$ and $p_x = 0$ is a solution. (Physically, this is the situation where the consolidated ice is being pulled apart without the pressure acting.)

(ii) If $u_x = 0$, then $u_{xt} \geq 0 \Longrightarrow p_{xx} \leq 0$ (by (23)).

The values of p at the endpoints of the consolidated region are determined by the jump conditions, which have to be satisfied because of the constraining equations. Minimizing $\|p\|$, either as a 2-norm or as a 1-norm, with $p_{xx} \leq 0$ requires p to be linear within the consolidated region. The same is true for $\|p_x\|_2$. (Note, however, that minimizing the 1-norm of p_x leads to nonunique solutions, where the one found using the other norms is but one possibility.)

Thus, for any of the three norms:

(i) $p = 0$ outside consolidated regions.

(ii) p at the boundaries of consolidated regions is prescribed by the jump conditions imposed by the constraining equations.

(iii) p is linear within consolidated regions.

It follows that the solutions are exactly the same.

As mentioned before, we have decided for our numerical work to rely on the 1-norm of p in order to facilitate the numerical optimization.

8. The numerical model and another test case. Our one-dimensional Lagrangian ice dynamics model for ice with uniform and constant thickness and without forcing is based on the discretization (40)–(43). For the optimization step, we use either Matlab's built-in function `linprog` or a self-coded simplex method.

The problem described above (ice flowing towards a wall) can be successfully modeled this way (also with much better resolution and different initial conditions). We have also modeled, as another example, the case of a periodic domain, with initially uniformly distributed ice. The initial velocity function is sinusoidal with average velocity 0. Again, our physical intuition tells us what the solution should be: We expect the ice to consolidate in the middle of the domain. This is indeed what happens; see Figure 1. Given the initial conditions, we can also analytically calculate the first consolidation time, which in this case is $1/4\pi \approx 0.0796$. Again, the numerical results agree, predicting the first time for $c = 1$ to lie in the interval $[0.07875, 0.08]$ when a temporal step size of 0.00125 was chosen. The comparison of norms was again carried out in this model, which confirmed the previous conclusion that they yield the same answer, whereby minimizing the 1-norm of p is calculationally the least expensive. Various other initial conditions for u, including nonsymmetric cases, were studied, with the numerical results agreeing with the analytic solution (as far as this was easily obtained) and/or physical intuition.

9. Another validation: Comparison with a particle-based method. Further evidence in favor of the minimal pressure hypothesis comes from a comparison with a particle-based model. Here the one-dimensional sea ice motion is simulated as the interaction of individual "particles" (i.e., floes). Each of these is traced through space and time. Collisions are required to be mass- and momentum-conserving and inelastic (again following the observation that the pressure arising from collisions and consolidation does not lead to divergence). This is a rather costly method of modeling sea ice dynamics. However, for the purposes of validation, it is useful. After making the appropriate transformations from the respective coordinate system of each model to Eulerian coordinates, the concentration distributions resulting from the particle-based model and the continuum model with the minimal pressure hypothesis were compared, exhibiting remarkable agreement.

For the comparison, all external forces as well as crushing were again ignored. The initial concentration was taken to be constant c_o throughout the (periodic) domain. This is implemented in the collision model by an even spacing of identical particles. The number of particles corresponds to the resolution; the initial concentration determines the width of each particle. Later, the concentration is calculated at a particle point as the average area coverage between neighboring particles, i.e., at the point k

$$c(k) = \frac{2w}{x(k+1) - x(k-1)}, \tag{52}$$

where w is the width of a parcel, $c(k)$ is the concentration, and $x(k)$ is the location of the kth parcel. The velocities are tracked for each particle. They remain constant

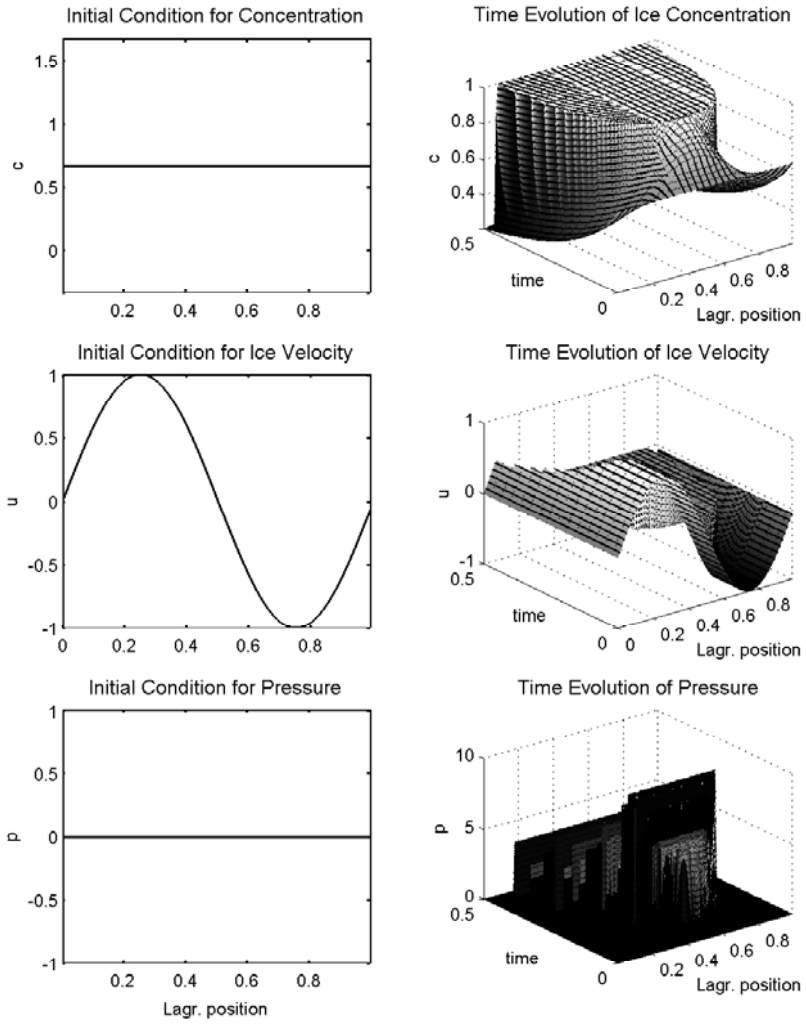

FIG. 1. *The numerical results for ice consolidating in the center of the domain. Initial conditions are given in the plots on the left. The evolution is exhibited in the plots on the right. Note that the x-coordinate here is the Lagrangian position.*

unless a collision occurs, in which case momentum conservation dictates the new velocity of the consolidated region: For particles j_1 through j_2 involved in the collision, each will have new velocity

$$u_{new} = \frac{\sum_{i=j_1}^{j_2} m_i\, u_i}{\sum_{i=j_1}^{j_2} m_i}, \tag{53}$$

where u_i denotes the velocity of the ith particle and m_i its mass. Here, as in the continuum model, constant thickness is assumed. Hence the concentration $c(i)$ is proportional to the mass m_i and can be substituted for it in the formula (53).

The initial velocity for both model runs was taken to be sinusoidal again, given

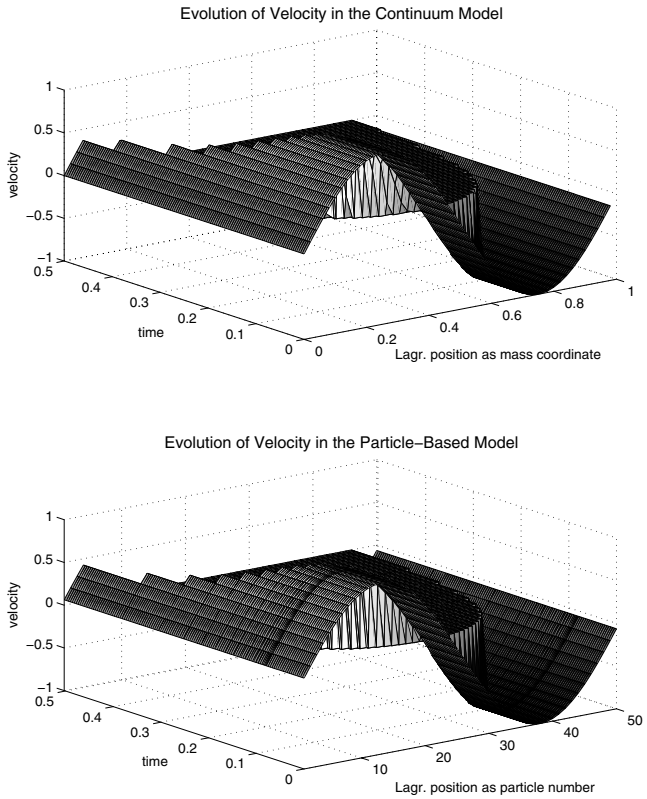

FIG. 2. *The velocity evolutions derived by the continuum model using the minimal pressure hypothesis (top frame) and the particle-based model (bottom frame). Note that the x-coordinates here are the Lagrangian x-coordinates of each model.*

in Eulerian coordinates as $u_i^E(x) = \sin(2\pi c_o x)$. (Note that this is equivalent to the case presented in the previous section. In the Lagrangian mass coordinates used there, the same velocity is written as $u_i^L(\xi) = \sin(2\,\pi\,\xi)$, where we are reverting to the Greek notation for clarification.) Two comparisons were carried out, one of the resulting velocity fields, the other of the resulting concentration fields. The Lagrangian coordinates of the continuum model with the minimal pressure hypothesis can be converted to Eulerian coordinates by numerically integrating the velocity u in time; the Eulerian positions of the particles in the collision model are recorded at each step.

Figure 2 shows the evolution of the velocities from the two models over 125 time steps. They are clearly very similar. A more detailed comparison is given in Figure 3. Here the Lagrangian coordinates are converted to Eulerian ones, and two different times are chosen. Note that in both plots, the velocities agree almost exactly. The one point of the particle model overshooting the continuum model (both in the positive and negative directions) in each plot is simply not resolved by the continuum model.

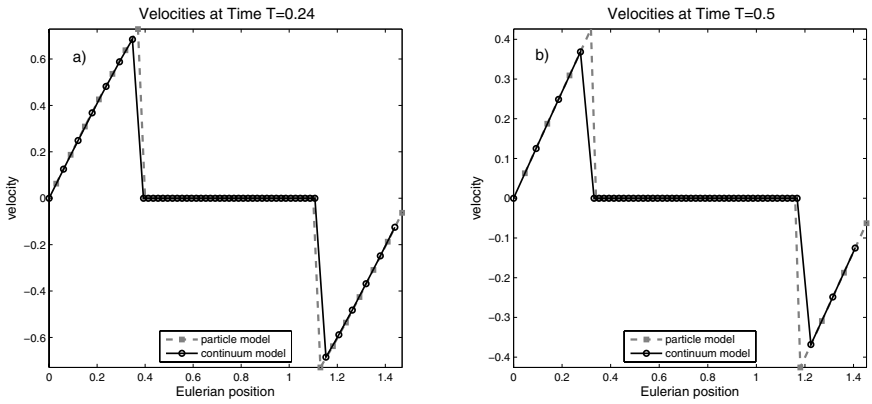

FIG. 3. *The velocities derived with the continuum (solid line, circles) and the particle (dashed line, squares) models are compared at* (a) *an intermediate time and* (b) *the end of the run. The x-coordinates here are Eulerian x-coordinates.*

Figure 4 shows the evolution of the concentrations from the two models over the 125 time steps. Again, a close similarity is apparent. To compare the concentration fields more exactly, we have chosen two points in time, one at the first collision (marked in the continuum model as the first time with nonzero pressure), the other at the end of the run. The results are shown in Figure 5. Up to the first collision, the concentration fields are identical between the two models. Recall that this time can be found analytically to be $\frac{1}{4\pi} \approx 0.0796$. With the resolution used here ($\Delta t = 0.004$, $\Delta\xi = 0.02$), the continuum model places it in the interval $[0.076, 0.080]$, while the particle model predicts that the first collision will occur at time 0.0796. In other words, both models are in good agreement with the exact value. At time $T = 0.5$, small differences in the concentration fields are discernible. However, once again much of this difference can be ascribed to the fact that the two models do not resolve the same points.

One can conclude then that the model suggested here, using a minimization technique to calculate internal pressure, which is used in turn to update the velocity field, produces results entirely consistent with the physical description of sea ice motion as the interaction of ice floes through inelastic collisions.

10. Conclusions. We propose here a new closure for the equations of motion for sea ice modeled as a fluid. In addition to the momentum and the mass conservation equations, an expression for the internal forcing due to pressure has to be found. Based on the observation that collisions of ice floes at natural speeds tend to be inelastic, it was hypothesized that the internal pressure should stay at the minimum required to enforce a concentration of at most 1. This formulation is also consistent with treating the pressure as a Lagrange multiplier in the optimization problem minimizing the deviation from the unforced path under the constraints of the mass conservation equation and the limits on the concentration ($0 \leq c \leq 1$).

To investigate the validity of this closure, a one-dimensional Lagrangian model was set up. Two classes of test cases were studied, ice moving towards a wall with initially constant velocity and ice moving in a periodic domain with initially sinusoidal velocity. Thickness was held constant for easier identification of the effects of the minimal pressure hypothesis, an assumption that will be relaxed in Part 2. For the

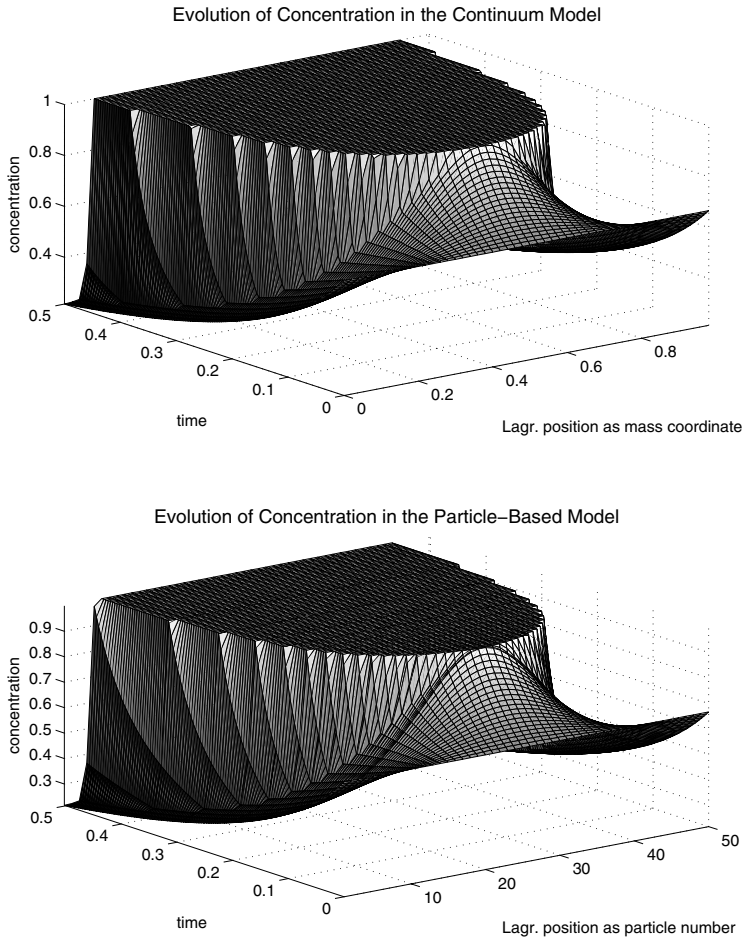

FIG. 4. *The concentration evolutions derived by the continuum model using the minimal pressure hypothesis (top frame) and the particle-based model (bottom frame). Note that the x-coordinates here are the Lagrangian x-coordinates of each model.*

first case, an exact analytic solution was derived—which was reproduced to high accuracy by the model (except for smoothing of the shock when the resolution was too coarse). The second case produced results consistent with physical intuition. A further validation was given by comparison with a particle-resolving model using inelastic collisions. Within the limits of their respective resolutions, the output of these two models was in exact agreement.

It is thus possible to conclude that the minimal pressure hypothesis leads to correct solutions, at least in the cases studied here. This is promising, because the work presented here forms the basis for more complex versions of the dynamics model using the minimal pressure hypothesis. The next step—a translation to Eulerian coordinates, allowing variable ice thickness, and implementing a finite ice strength—is presented in Part 2. Clearly, further study is required to determine the usefulness of this approach in large-scale simulations. Thus, for modeling real situations, an

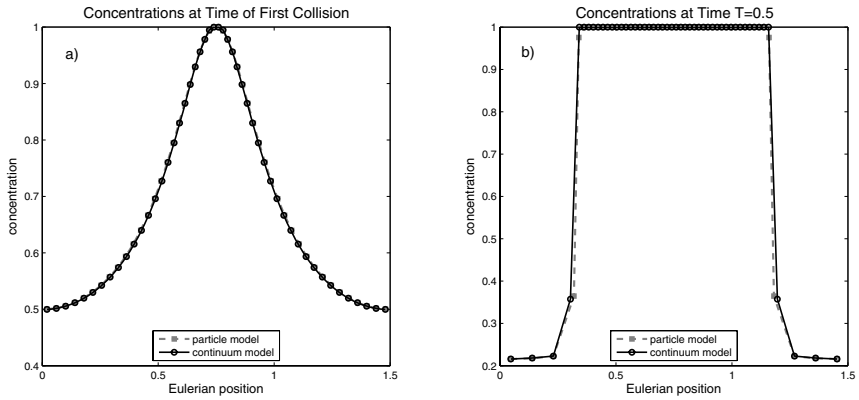

FIG. 5. *The concentrations derived with the continuum (solid line, circles) and the particle (dashed line, squares) models are compared at* (a) *the time of first collision and* (b) *the end of the run. The x-coordinates here are Eulerian x-coordinates.*

extension to two dimensions is necessary. Restoring the other forcing terms will be a minor task. The good agreement of the model results so far with analytic and particle-resolving model solutions justifies such further investigations, currently underway.

Appendix. Derivations.

A.1. Lagrangian equations. Recall that (7) defined the Lagrangian coordinates as

$$\begin{cases} \xi = \int_0^x ch\, d\hat{x}, \\ \tau = t. \end{cases}$$

The partial derivatives relating them to the Eulerian coordinates (t, x) are as follows:

$$\frac{\partial \xi}{\partial x} = ch, \tag{54}$$

$$\frac{\partial \xi}{\partial t} = -chu, \tag{55}$$

$$\frac{\partial \tau}{\partial x} = 0, \tag{56}$$

$$\frac{\partial \tau}{\partial t} = 1, \tag{57}$$

where (4) was used for the partial derivative $\partial\xi/\partial t$. Similarly,

$$\frac{\partial x}{\partial \xi} = \frac{1}{ch}, \tag{58}$$

$$\frac{\partial x}{\partial \tau} = u, \tag{59}$$

$$\frac{\partial t}{\partial \xi} = 0, \tag{60}$$

$$\frac{\partial t}{\partial \tau} = 1, \tag{61}$$

Now consider $u = u(t(\tau,\xi), x(\tau,\xi))$:

$$\begin{aligned}\frac{\partial u}{\partial \tau} &= u_t t_\tau + u_x x_\tau \\ &= u_t + u_x u \\ &= F \qquad\qquad \text{from (5).}\end{aligned}$$

This is (9).

Following the same pattern, we find

$$\begin{aligned}\frac{\partial u}{\partial \xi} &= u_t t_\xi + u_x x_\xi \\ &= \frac{u_x}{ch} \\ &= -\frac{1}{(ch)^2}\left[-(ch)u_x\right] \\ &= -\frac{1}{(ch)^2}\left[(ch)_t + (ch)_x u\right] \qquad \text{from (4)} \\ &= -\frac{1}{(ch)^2}\left[(ch)_t t_\tau + (ch)_x x_\tau\right] \\ &= \left(\frac{1}{ch}\right)_\tau .\end{aligned}$$

This yields (8).

A.2. Solution to the variational problem. The variational problem posed in section 4 is

$$\delta \int \left\{(\tilde{u}-u)^2 + \lambda(x)(k + \Delta t\, \tilde{u}_x)\right\}\, dx = 0.$$

Equivalently,

$$\begin{aligned}\forall\, f \in C_o^\infty, \quad 0 &= \left.\frac{d}{d\epsilon}\right|_{\epsilon=0} \int \left[(\tilde{u}+\epsilon f - u)^2 + \lambda\left(k + \Delta t\, \frac{\partial}{\partial x}(\tilde{u}+\epsilon f)\right)\right]\, dx \\ &= \int \left[2\tilde{u}f - 2uf + \Delta t\, \lambda f_x\right]\, dx \\ &= \int f\left[2\left(\tilde{u}-u\right) - \Delta t\, \lambda_x\right]\, dx,\end{aligned}$$

which implies that

$$2\left(\tilde{u}-u\right) = \Delta t\, \lambda_x.$$

Acknowledgments. We would like to thank David Holland for many fruitful conversations on the subject of sea ice dynamics, and Oliver Bühler for stimulating suggestions. We are also grateful to the anonymous reviewer for the valuable comments.

AN OPTIMIZATION APPROACH TO MODELING SEA ICE DYNAMICS, PART 2: FINITE ICE STRENGTH EFFECTS*

HELGA S. HUNTLEY† AND ESTEBAN G. TABAK‡

Abstract. The effects of a finite ice strength on a new model for sea ice dynamics, deriving the internal pressure field from a global optimization problem, rather than a local rheology, are examined. Building on the promising results from the one-dimensional Lagrangian model described previously, here we add one of the key properties of sea ice. In order to investigate the behavior of the model under ice yielding, the equations are cast in an Eulerian framework, now allowing for variable thickness. The model is first tested under conditions of infinite ice strength, to ensure that the numerics behave as desired. A finite ice strength is incorporated into the model as a second optimization step, minimizing the change in ice thickness necessary to satisfy the upper bound on the pressure, whereby ice strength is taken to be a linear function of thickness, following typical parameterizations in the literature. The theory is implemented numerically, and several test cases are discussed, which show good agreement with physically based expectations.

1. Introduction. Much progress has been made in the field of sea ice dynamics modeling over the last half a century, as models have evolved from using free drift to incorporating complex rheologies, derived from various physical considerations. Nonetheless, some salient features of the polar ice covers (as, for example, sea ice arches in the straits of the Canadian Arctic Archipelago) are still not being reproduced satisfactorily. With the ultimate goal of remedying this shortfall, we are developing a novel method for modeling the dynamics.

In Part 1 of this study [6], we introduced a new way to calculate the internal stress arising in converging sea ice; here we discuss how a finite ice strength can be incorporated into the model. The theory was developed in a Lagrangian frame of reference. This simplified the equations to a degree that it was possible to verify the numerical model results by comparing them to an analytic solution to a well-understood toy problem. Beginning with the analogy that coarse grained sea ice can be described as a semi-incompressible fluid (i.e., a fluid that is always allowed to diverge, but can converge only if the ice strength is insufficient to stop the motion), it was argued that the problem of finding the internal stress can be phrased as an optimization problem, where the pressure plays the role of a Lagrange multiplier.

In order to be able to carry out a relatively straightforward qualitative analysis of the results, we make (in both Parts 1 and 2) several simplifications to the full ice dynamics problem. Thus, thermodynamic effects are ignored. We also do not incorporate a thickness distribution. Thorndike et al. [11] and subsequent studies argued

well for the importance of and provided a method for tracking such a distribution. It is particularly relevant for thermodynamics, as the freezing and melting properties of thin ice and thick ice differ significantly. However, since ice strength is also a function of ice thickness, resolving subgridscale variations is desirable even in a purely dynamic model. Realizing the resulting limitations, we ignore these effects. Similarly, we do not employ a velocity distribution, but consider all velocities mass-averaged over a grid cell. As the work reported here is intended as a feasibility study, we also set all external forces equal to 0. (They are easily added back into the dynamics, as will be described below, but complicate the analysis of the results.) Finally, we restrict ourselves to one dimension, where only isotropic stress exists. How to handle shear stresses will be addressed in subsequent work. The assumption from Part 1 that is dropped here is that of constant ice thickness throughout the domain, in order to allow crushing of the ice.

The appealing simplicity of the equations derived in the Lagrangian framework in Part 1 resulted in part from the assumption of a constant ice thickness. Permitting the thideness to vary over the domain and especially for individual floes (or their grid-averaged equivalent) due to yielding negates the advantages of the formulation we used previously. Thus, following a quick review of the Lagrangian model in section 2, we will here return to an Eulerian point of view. The new theory is presented, and the corresponding numerical model, with variable ice thickness but still infinite ice strength, is compared to the Lagrangian one of Part 1 in sections 3 and 4. In section 5, then, ice strength is limited, and ice is allowed to yield. For the parameterization of ice strength, we rely on suggestions from the literature. (Note that, as we are not carrying out quantitative studies or direct checks against data, the *form* of the parameterization is more important than the exact empirical—or tuned—values used.) It turns out that employing the limiting ice strength as a truncation value for the internal pressure directly leads to undesirable effects. Hence, we instead reformulate the problem in terms of a double optimization, where the ice strength becomes a new constraint on the pressure. Some numerical results are discussed in section 6, and conclusions presented in section 7. The appendix provides some of the mathematical details of the model derivation; for greater detail on some of the other results, the reader is referred to [10].

2. Lagrangian dynamics. We will use the same notation as in Part 1 [6]. In particular, the variables are defined as follows:

c = concentration of ice (fraction of sea surface area covered by ice),
h = thickness of the ice, averaged over a grid box,
u = horizontal velocity,
F = sum of all forces under consideration,
p = internal stress.

Recall that we are not modeling any thermodynamic effects, so that all sources and sinks of ice (melting, freezing, and precipitation) are set to 0. Similarly, no forces other than the internal stress are considered in this paper, so that F denotes the force due to the internal stress. The density of ice, which is nearly constant, is taken to be identically 1. Alternatively, one can consider it as absorbed in h, which then represents the product of ice thickness and density or, in effect, an areal density. The authors find it most useful, however, to continue thinking of h as thickness.

The Eulerian spatial coordinate will be denoted by x, while the Lagrangian mass coordinate is given by

$$\xi = \int_0^x ch\, d\hat{x}. \tag{1}$$

For the Lagrangian formulation, we also define the new variable

$$k = \frac{1}{ch} - 1,$$

which simplifies the form of the governing equations.

The mass and momentum conservation equations in one dimension are given, in Eulerian coordinates, by

$$(ch)_t + (chu)_x = 0, \tag{2}$$

$$(chu)_t + (chu^2)_x = F. \tag{3}$$

We will return to these in the next section.

Translating the system into the Lagrangian coordinate defined above in (1) and substituting the new variable k yields

$$k_t = u_\xi, \tag{4}$$

$$u_t = \tilde{F}, \tag{5}$$

where $\tilde{F} = F/(ch)$ is still unknown.

We argued in Part 1 [6] (where ice strength was taken to be infinite) that the internal stress arises solely due to the semi-incompressibility of the ice. It serves the purpose of preventing further convergence when $c = 1$, or, in other words, of enforcing the constraint that $c \leq 1$, equivalently that $k \geq 0$ (for h constant and taken to be 1). Consequently, it was suggested that the problem of finding F amounts to a constrained optimization problem, which can be solved using Lagrange multipliers. The pressure arose naturally as such a multiplier. It was shown that for the case without ice yielding, minimizing $\|p\|$ is equivalent to minimizing $\|p_\xi\|$. So the system was ultimately phrased as follows:

$$\text{minimize } \|p\|, \tag{6}$$

$$\text{subject to the constraints } k_t = u_\xi, \tag{7}$$

$$u_t = -p_\xi, \tag{8}$$

$$k \geq 0, \tag{9}$$

$$p \geq 0. \tag{10}$$

As the numerical model arising from this theory behaved well under the verification tests (comparison to an analytic solution, comparison with a particle-resolving model, and qualitative assessment of other model runs), we concluded that this approach to sea ice dynamics is promising.

The analysis carried out in Part 1 [6], however, relied on the unrealistic assumptions of constant ice thickness and infinite ice strength. This paper is intended to carry the model one step further by eliminating those simplifications.

3. Translation to Eulerian coordinates. Allowing variable ice thickness in the Lagrangian model outlined in the previous section leads to some difficulties. For one, the constraint on k becomes the rather cumbersome $k \geq \frac{1-h}{h}$, versus the simple $k \geq 0$. In fact, this constraint is not even well defined if we let $h = 0$. Of course, in this case, c is also somewhat arbitrarily defined, but it is preferable to work with a variable that is not occasionally constrained to be greater than or equal to infinity. It should also be noted that the Lagrangian mass coordinate distorts the resolution in favor of thick ice. In the discretized optimization, then, minimizing the pressure in thicker parts weighs heavier than doing so for thinner parts, which distorts the pressure field as well. These observations argue strongly for proceeding in Eulerian coordinates. In addition, it is unclear whether the mass coordinates can be extended into a second dimension while retaining any of the desired simplifications. Thus, we return to Eulerian coordinates for studying the effects of a finite ice strength.

Translating the system (6)–(10) into Eulerian coordinates results in

$$\text{minimize } \|p\|, \tag{11}$$

$$\text{subject to the constraints } (ch)_t + (chu)_x = 0, \tag{12}$$

$$(chu)_t + (chu^2)_x = -p_x, \tag{13}$$

$$0 \leq c \leq 1, \tag{14}$$

$$0 \leq p. \tag{15}$$

As a side note, if one had decided not to ignore external forces, these could easily be added to the left-hand side of (13). Everything that follows could be carried out as described here (except, of course, that a discretization would have to be found for the additional terms).

The reader will notice that even once p is determined by the optimization, there are but two equations for the three unknowns c, h, and u. Let us continue to assume infinite ice strength for now, before adding this additional complexity in the next section. In this case, since ice does not crush, it is reasonable to take ice thickness to be conserved following ice floes, or, in other words, h to be advected:

$$h_t + u\,h_x = 0. \tag{16}$$

Using the mass conservation equation (12), we can rewrite this as

$$c_t + (cu)_x = 0. \tag{17}$$

This equation is then added as an additional constraint to the optimization problem (11)–(15).

For the numerical implementation, we chose to rewrite the momentum conservation equation as a velocity evolution equation:

$$u_t + \left(\frac{u^2}{2}\right)_x = -\frac{p_x}{ch}. \tag{18}$$

Retaining momentum (chu) as a fundamental variable to be updated each time step is attractive, since it can then be exactly conserved. However, a preliminary numerical implementation following this approach proved to be far more prone to numerical instabilities than one updating velocity explicitly. (It may be worth mentioning that velocity is updated directly in many of today's ice dynamics models; see, e.g., [4] and [5].)

Note that this derivation is valid only if $c \neq 0$. However, wherever $c = 0$, the velocity is intrinsically not well defined as a physical quantity. Defining the ratio on the right-hand side of (18) to be 0 in this case and evolving u accordingly provides for a solution for u to fill in the gaps. This particular choice has the advantage that regions without ice do not have to be treated separately in the numerical implementation. At first glance, one might expect that defining the ratio on the right-hand side to be 0 when $c = 0$ might lead to strange discontinuities in the forcing, since $\lim_{c\to 0} 1/c = \infty$. Yet there is no inconsistency, since the pressure is also zero whenever c is far from 1. The situation with $h = 0$ can be handled similarly. In this case, both u and c are arbitrary, so that c can be taken far from 1.

While advancing momentum as a fundamental variable leads to undesirable effects, we do retain mass (ch) as a fundamental variable, so that it can be conserved exactly. Thickness h never appears explicitly in the equations. It is tracked as a derived variable.

A staggered grid is used, defining u at half steps from c, ch, and p. This follows the setup for the Lagrangian model. Unlike in that case, however, it is here unfortunately not possible to avoid all need for interpolation of any variables. The placement of the variables was chosen to allow for a semi-implicit discretization for (17) (necessary to be able to satisfy the constraint on c) and to keep mass and concentration in the same locations for deriving thickness.

The discretizations of (17), (12), and (13) take the form

$$c_{j+\frac{1}{2}}^{n+1} = c_{j+\frac{1}{2}}^{n} - \frac{\Delta t}{\Delta x}\left(c_{j+1}^{n}\, u_{j+1}^{n+1} - c_{j}^{n}\, u_{j}^{n+1}\right), \tag{19}$$

$$(ch)_{j+\frac{1}{2}}^{n+1} = (ch)_{j+\frac{1}{2}}^{n} - \frac{\Delta t}{\Delta x}\left((ch)_{j+1}^{n}\, u_{j+1}^{n+1} - (ch)_{j}^{n}\, u_{j}^{n+1}\right), \tag{20}$$

$$u_{j}^{n+1} = u_{j}^{n} - \frac{1}{2}\frac{\Delta t}{\Delta x}\left[\left(u_{j+\frac{1}{2}}^{n}\right)^2 - \left(u_{j-\frac{1}{2}}^{n}\right)^2\right] - \frac{\Delta t}{\Delta x}\frac{1}{(ch)_{j}^{n}}\left[p_{j+\frac{1}{2}}^{n+1} - p_{j-\frac{1}{2}}^{n+1}\right]. \tag{21}$$

Observe that (20) serves only to update the variable (ch); it does, in fact, not represent an additional constraint in the optimization. Thus, the linear constraint for the minimization of $\|p\| = \sum p_i$ is given by (19), where (21) is used to substitute for u^{n+1}. The optimization provides updated values of p and c, which are then used to find updated values of u and subsequently of (ch). The variables are interpolated where necessary by a Godunov-type scheme. (See the appendix for more details.) The results presented here were obtained from an implementation on Matlab, using the built-in "`linprog`" function for the minimization, which uses a linear interior point solver. (Alternatively, a simplex method can be prescribed. The resulting differences in the output are negligible.) Also, periodic boundary conditions were imposed.

4. Results in Eulerian coordinates without yielding. A series of tests was carried out on this model to check its behavior under various initial conditions. Here we will present only two of the results. First, we will compare the behavior of this Eulerian model to that of the Lagrangian one from Part 1 [6]. The equations and hence the numerics are more complicated here, requiring the choice of an interpolation scheme in addition to a discretization. Moreover, it can be shown that, with the choices made here, in general,

$$\sum_j (ch)_j^{n+1} u_j^{n+1} - \sum_j (ch)_j^n u_j^n \neq 0.$$

In other words, momentum is not exactly conserved. It is, thus, desirable to check that the deviations are acceptably small.

For the comparison, we initialize both models with a sinusoidal initial velocity, constant ice thickness ($h_o = 1$), and uniform ice concentration. Since spatial and temporal resolutions are fixed throughout the runs but space is measured in different coordinates, it is not possible to retain equivalent spatial step sizes in the two models. In particular, the specifications are as follows:

$$\begin{aligned} c_o &= 0.5, & k_o &= 1, \\ u_o &= \sin(2\pi x), & u_o &= \sin(4\pi\xi), \\ \Delta x &= 0.0125, & \Delta\xi &= 0.0125, \\ \frac{\Delta t}{\Delta x} &= 0.1, & \frac{\Delta t}{\Delta\xi} &= 0.1. \end{aligned}$$

(Recall that k was defined as $k = (1 - ch)/ch$ and $\xi = \int_0^x ch\, d\tilde{x}$.)

For the plots, we have chosen four times:

$t = 0.0175$ fairly early on, after 15 time steps,

$t = 0.0500$ shortly before consolidation begins, after 41 time steps,

$t = 0.0900$ shortly after consolidation begins, after 73 time steps,

$t = 0.1500$ about 2/3 through this run, after 121 time steps.

At each of these times, we have converted the Lagrangian spatial coordinate to the Eulerian one for a direct comparison. Figures 1 and 2 display the concentrations and velocities from the two models corresponding to these times. Figure 3 shows the momenta.

The two models show good agreement in both concentration and velocity; the lines coincide almost exactly. The differences are mostly due to resolution, as different points are resolved in each model. The same is true for the momentum plots. Here the Eulerian model produces somewhat greater values for both the positive and the negative velocities near the consolidated region, which may be related to the interpolation. (The momentum is the product of two quantities that are tracked in different spatial locations. Thus, even for the Lagrangian results, interpolation is necessary to calculate it.) Recall that the Lagrangian model was designed to conserve momentum exactly. The discretization chosen for the Eulerian model, on the other hand, does not do the same. (Of course, in the limit as the resolution becomes finer, this error vanishes.) The fact that the momentum profiles from the Eulerian model agree so well is evidence that momentum is close to being conserved here as well. Further support comes from the fact that the constant velocity at which the consolidated ice travels is 0 (up to four decimal places), just as predicted by the theory based on momentum conservation. (This velocity test, by the way, holds up in other examples as well, although the accuracy degrades somewhat to only 10^{-2} when the average velocity is not 0. Some of this loss in accuracy can be ascribed to numerical diffusion.)

Before the ice begins to consolidate, the numerical solutions can also be compared to exact analytic solutions. Both the Lagrangian and the Eulerian model produce very good approximations (not shown). For the latter, the type of interpolation chosen can make a noticeable difference. (Again, see the appendix for a description of the scheme we use.) The first accumulation time (when c first reaches 1 and p becomes nonzero) is theoretically predicted in this example to be $1/4\pi \approx 0.079577$. The model here predicts it to be in the interval $[0.07875, 0.08000]$; i.e., it captures it very well.

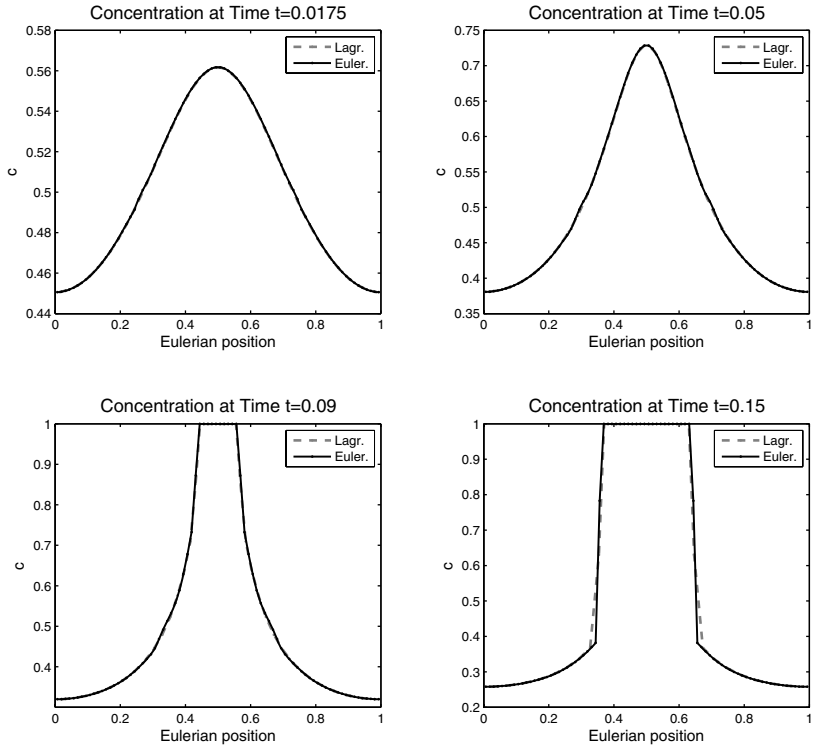

FIG. 1. *Comparing ice concentrations at various times from the Lagrangian and the Eulerian models. The Eulerian output is interpolated with a solid black line, the Lagrangian with a dashed grey line.*

To test how the model handles variable thickness (which, after all, was the primary purpose for it), we ran an example with a parabolic initial thickness distribution, while using again the sinusoidal initial velocity and uniform initial concentration. Figure 4 beautifully exhibits the behavior. As the ice is pushed together in the center of the domain, the thickness profile steepens. Once concentration reaches 1, h no longer changes. This agrees well with expectations from physical intuition.

5. Incorporating finite ice strength. Now that we have a model allowing for variable ice thickness, we can introduce the process of ice yielding.[1] It is well known that sea ice has a finite strength, which depends on ice thickness. It may also depend on other properties, such as the age of the ice or the salinity of the water from which it was formed. These variables are not being tracked in this model. The literature, moreover, seems to agree generally that thickness is the most important factor.

[1] We will use the terms "yielding," "crushing," and "ridging" interchangeably, although the actual processes of crushing and ridging may be quite different. Ridging typically occurs when ice floes slide under each other, while crushing implies that the ice actually breaks. The net result of both processes is thicker ice, as a consequence of yielding. It is generally accepted that resistance to crushing is significantly higher than that to ridging. Hence, most of the yielding accounted for here will technically be ridging rather than crushing.

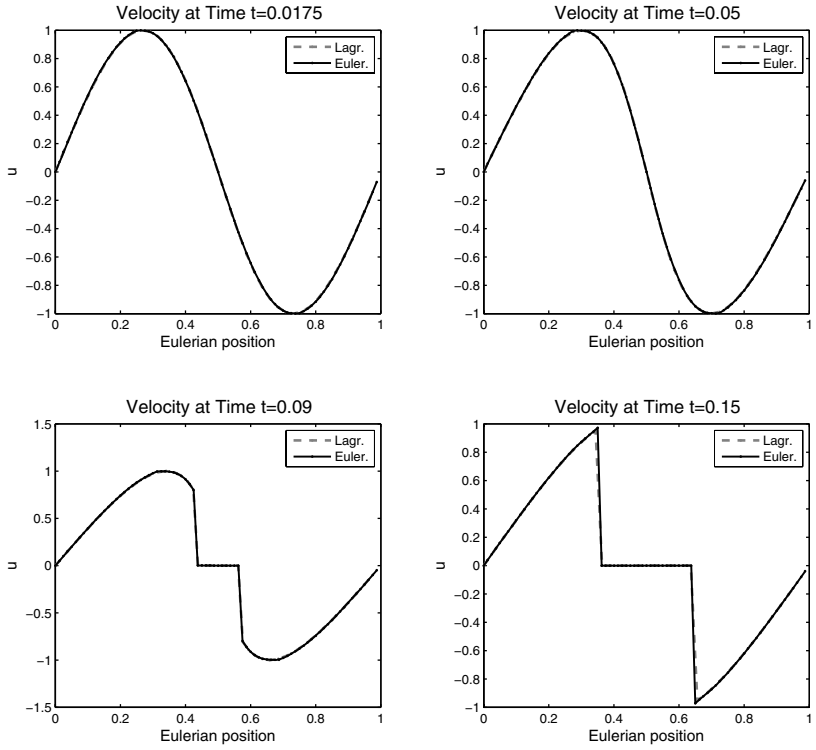

FIG. 2. *Comparing ice velocities at various times from the Lagrangian and the Eulerian models. The Eulerian output is interpolated with a solid black line, the Lagrangian with a dashed grey line.*

Ice dynamics models currently in use do not typically include dependence on anything but ice thickness and concentration.

The importance of a failure criterion for sea ice dynamics has been recognized at least since the mid-1970s (see [1]). It has been incorporated into plastic (e.g., [8]), viscous-plastic (e.g., [4]), elastic-plastic (e.g., [2] and [9]) and elastic-viscous-plastic (e.g., [5]) rheologies, but it has also appeared in other descriptions of the constituency law for ice, such as the cavitating fluid (e.g., [3]) and granular flow (e.g., [12]) rheologies.

The literature offers essentially two types of ice strength parameterizations. On the one hand is a formulation relating ice strength P^* to the potential energy change associated with the changes in ice thickness. This was first suggested by [9], was adopted by [11], and has been used ever since in connection with the thickness distribution theory pioneered by the latter.

For simpler models, using a two-category thickness distribution, distinguishing within a grid box only between ice and open water (the type employed here), ice strength has uniformly been taken as a function of ice thickness and concentration, although the functional dependence is not always the same. The other factors that may influence ice strength (such as age) are generally not taken into account.

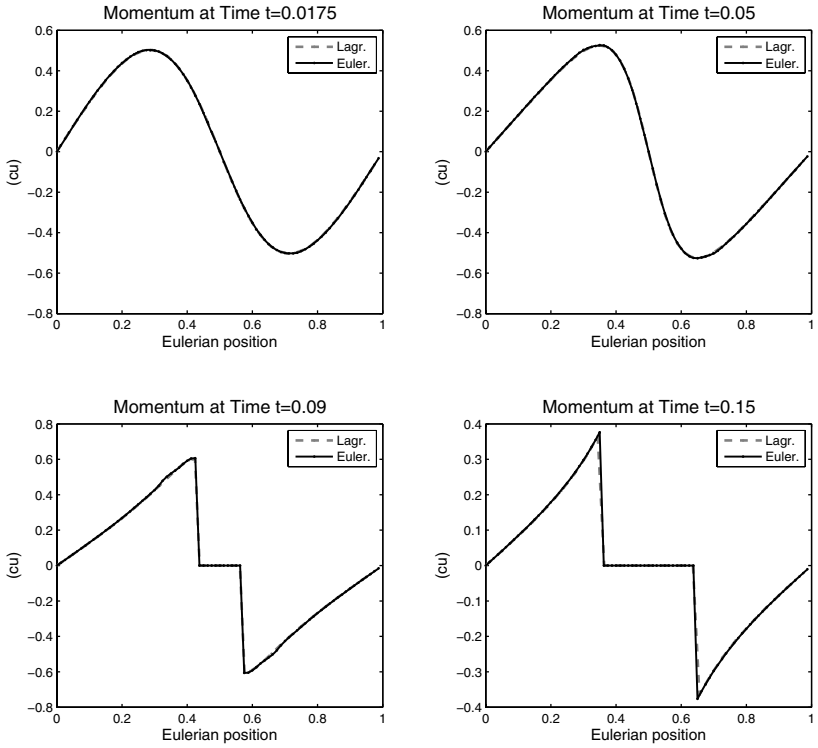

FIG. 3. *Comparing ice momenta at various times from the Lagrangian and the Eulerian models. The Eulerian output is interpolated with a solid black line, the Lagrangian with a dashed grey line.*

Most models follow the formulation presented by [4]:

$$P^* = P_o c h e^{-b(1-c)}, \tag{22}$$

where P^* is the ice strength expressed as a maximal pressure and P_o and b are empirical parameters.[2] This parameterization exhibits several of the desired properties. The thicker the ice, the stronger it is. The greater the concentration, the greater is the total strength. However, it is also apparent that even if c is relatively far from 1 (say 0.6 or so), the ice strength is still significant.

Overland and Pease [8] suggest an alternative. Instead of a linear dependence on h, a quadratic law is hypothesized, which leads to a better approximation in their study of observed ridging:

$$P^* = P_o \rho c h^2 e^{-b(1-c)}. \tag{23}$$

The only other difference is that they include a dependence on ice density, which is typically (as in this work) taken to be a constant and can hence be absorbed into P_o. The functional form (22) has proven to be the more popular of these two.

[2]Hibler's notation in the 1979 paper [4] is actually $P = P^* h \exp[-C(1-A)]$. The formulation here reflects the definition of the variables we are using throughout. Note also that Hibler's h is an *effective* ice thickness, i.e., more akin to ch in our notation.

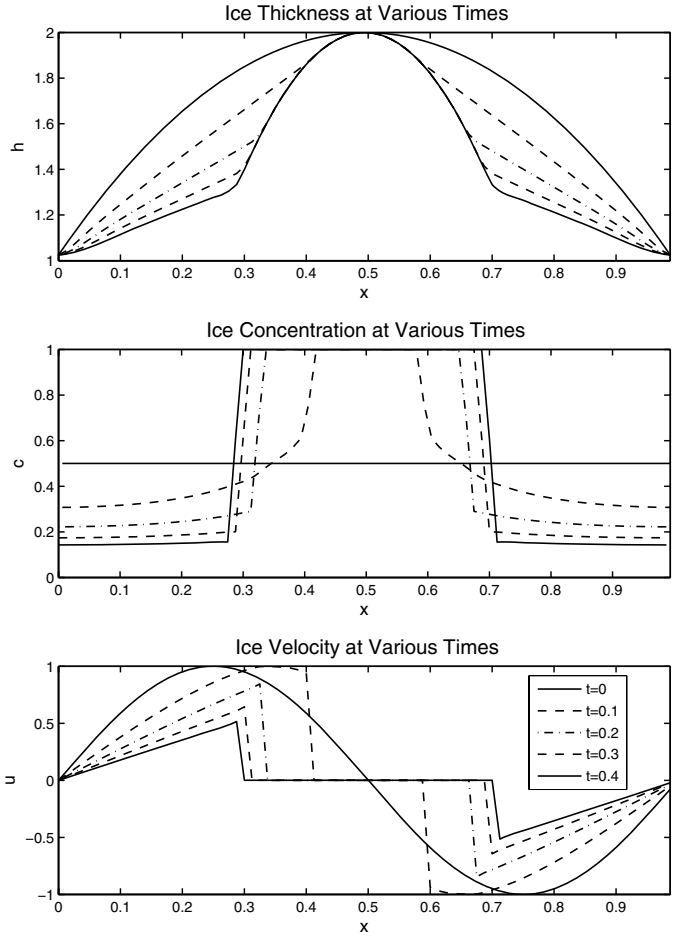

FIG. 4. *The Eulerian model was run with spatial step size set to* 0.0125 *and temporal step size set to* 0.00125. *Initial conditions were* $c_o = 0.5$, $h_o = -4x^2 + 4x + 1$, *and* $u_o = \sin(2\pi x)$. *The evolution of* h, c, *and* u *is illustrated in parallel with snapshots from five different times.*

For our purposes, either description would work; we have chosen a linear dependence of ice strength on ice thickness, mirroring (22). However, we do not include the dependence on ice concentration. One of the underlying assumptions of our model is that $p = 0$ whenever $c \neq 1$. Hence ice strength is irrelevant (or could be taken to be 0: the ice does not resist convergence) in this situation. Setting $c = 1$ in (22), the parameterization becomes simply

$$P^* = P_o h. \tag{24}$$

Flato and Hibler found empirical values for P_o (and the b appearing in the exponential term of (22)) in their 1992 paper [3]. We are not, at present, concerned with

producing *quantitatively* correct results and will hence adjust P_o to assist in investigating the effect of a limiting pressure value, rather than using their recommendation or an otherwise physically justified value.

Initially, the limiting ice strength was treated as a truncation value for the pressure. p was calculated as before as the solution to the constrained minimization problem (11) with constraints (13)–(15) and (17). Then it was truncated by P^*. The resulting values for p were used to calculate the updated values for u and (ch) using (14) and (12). Equation (17) no longer holds where ice begins to yield. Thus, it is valid only in regions without crushing. However, since ice only yields where it is consolidated, we know that everywhere else $c = 1$.

This procedure is not advisable. Since the limiting values of p depend on h, the truncated p can have undesirable shapes. In particular, a convex thickness can lead to a convex pressure, which causes the ice to diverge artificially. The error in this procedure lies in the assumption that ice yielding in one area of a consolidated region does not change the pressure anywhere else. This, however, is not necessarily true.

The algorithm we would like to suggest here hence rephrases the optimization problem, instead of attempting to correct the pressure profile after the minimization. The finite ice strength is, in fact, an additional constraint for the optimization. On the other hand, we lose the constraint (17), since we can no longer assume advection of thickness. This poses problems, since we need to be able to say something about the advanced c, in order to constrain it to stay between 0 and 1.

Observe that as long as the ice is not allowed to yield, $\frac{Dh}{Dt} = h_t + u\,h_x = 0$; ice thickness does not change following particles. When ice does buckle, it does so only to the degree necessary to satisfy the upper bound on the internal pressure. One can argue that h will change as little as possible—suggesting a second constrained optimization.

The new procedure then is as follows:

(1) Minimize the changes in ice thickness globally:

$$\text{find} \quad \min \left\| \frac{Dh}{Dt} \right\|, \tag{25}$$

$$\text{given the constraints} \quad (ch)_t + (chu)_x = 0, \tag{26}$$

$$(chu)_t + (chu^2)_x = -p_x, \tag{27}$$

$$\frac{Dh}{Dt} \geq 0, \tag{28}$$

$$0 \leq c \leq 1, \tag{29}$$

$$0 \leq p \leq P^*. \tag{30}$$

The first inequality constraint (28) arises because crushing can only increase ice thickness. Equation (26) again is used to advance (ch) rather than as a true constraint on the problem. The norm for (25) is chosen to be the 1-norm, primarily for numerical considerations: This choice keeps the problem linear.

This minimization will give values for c and p, which determine u and h, at the new time level that minimize $\left\| \frac{Dh}{Dt} \right\|$. However, the answer is typically not unique. The only unique quantity is the $\min \left\| \frac{Dh}{Dt} \right\|$.

(2) The first step provides the closure for h, so that it is now possible to proceed

with the pressure minimization:

$$\text{find} \quad \min \|p\|, \tag{31}$$

$$\text{given the constraints} \quad (ch)_t + (chu)_x = 0, \tag{32}$$

$$(chu)_t + (chu^2)_x = -p_x, \tag{33}$$

$$\left\| \frac{Dh}{Dt} \right\| = \text{value found in step (1)}, \tag{34}$$

$$\frac{Dh}{Dt} \geq 0, \tag{35}$$

$$0 \leq c \leq 1, \tag{36}$$

$$0 \leq p \leq P^*. \tag{37}$$

Note that the first inequality (35) needs to be retained in addition to the last equality constraint (34), since it is a pointwise, rather than an integral, statement.

This minimization must have a solution for c and p, from which u and h are derived, satisfying all the constraints, since one was found in the first step.

In the case where no ice yielding occurs, this two-step algorithm simplifies to the procedure outlined in section 3 above, as desired: The minimum of $\|Dh/Dt\|$ is zero. Since Dh/Dt is constrained to be nonnegative pointwise, this implies that, in fact, $Dh/Dt = 0$ everywhere. This is the constraint used in section 3.

The numerical implementation follows the pattern above, for the model without ice yielding. The same grid and discretizations are used. Recall that the variable h is not directly updated at each time step. The objective function for the first minimization is hence rewritten in terms of (ch) and c. It follows from mass conservation (see (26)) that

$$c\left[h_t + uh_x\right] = -h\left[c_t + (cu)_x\right]. \tag{38}$$

Since $c \geq 0$ and $h \geq 0$, the inequality constraint $\frac{Dh}{Dt} \geq 0$ is equivalent to $c_t + (cu)_x \leq 0$. Also, ice only crushes where $c = 1$. In other words, if $c \neq 1$, then $\frac{Dh}{Dt} = 0$. Hence minimizing $\left\| \frac{Dh}{Dt} \right\|$ is equivalent to minimizing $\left\| c\frac{Dh}{Dt} \right\|$ or $\left\| -\frac{(ch)}{c}[c_t + (cu)_x] \right\|$.

6. Results with ice yielding. To illustrate the effects of finite ice strength, we present here the model results from two different problems. First, we look at a somewhat degenerate example, where the initial ice thickness is taken to be constant. (Of course, here it does not remain constant, since P_o is chosen so that the ice does yield.) The initial concentration is also set constant at 0.5, while the velocity is initialized with a sine-curve.

Figure 5 shows the evolution of h, c, and u during the run up to time $t = 0.2$. As expected, the ice begins to consolidate in the center of the domain. Shortly after the concentration reaches 1, the pressure begins to exceed the ice strength, and the ice begins to ridge. Initially, this happens right at $x = 0.5$. Later, the ice yields at the edges of the consolidated region, where it is still thinner (not having ridged there yet), leading to a profile with multiple peaks. This can be seen in Figure 6, which shows several snapshots of the ice thickness from this run.

The attentive reader may have noticed a slight inconsistency in Figure 6: At some times (e.g., $t = 0.08750$ or $t = 0.10500$) the ice thickness actually decreases below its initial value of $h = 1$. This should not happen. On the other hand, these deviations

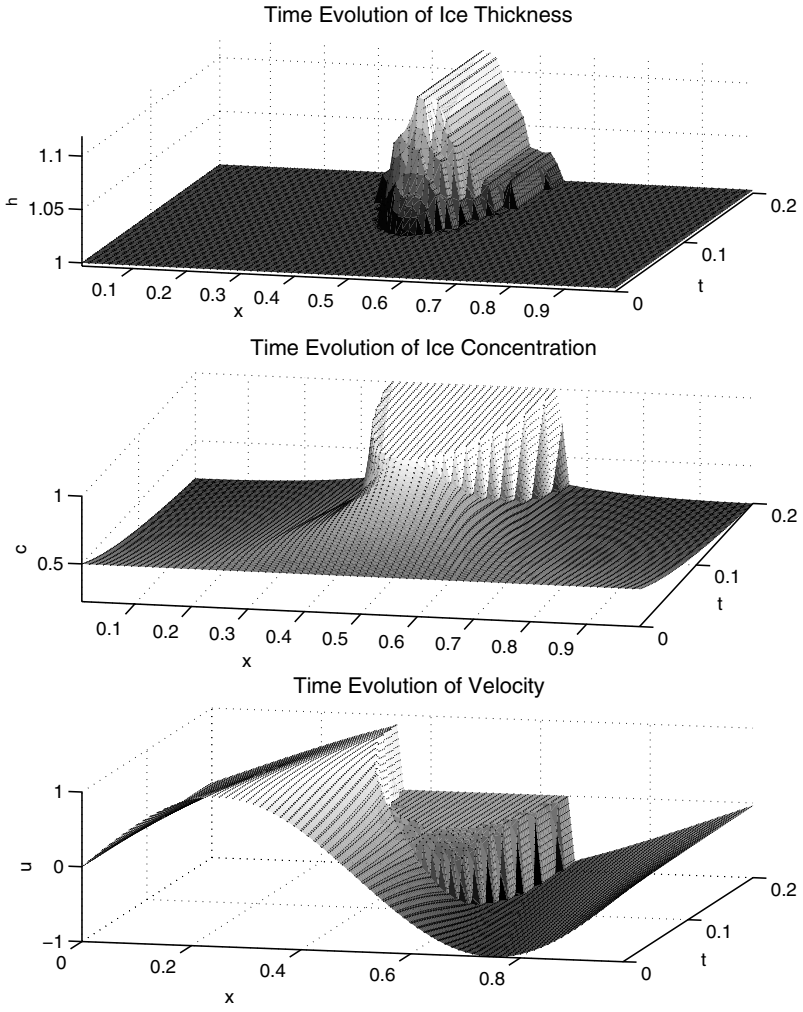

FIG. 5. *The model allowing for crushing was run with spatial step size set to* 0.0125 *and temporal step size set to* 0.00125. *Initial conditions were* $c_o = 0.5$, $h_o = 1$, *and* $u_o = \sin(2\pi x)$. P_o *was set to* 2. *The evolution of* h, c, *and* u *is shown up to time* $t = 0.2$.

are on a small scale, i.e., never greater than about 0.003. Moreover, recall that h is a derived quantity. The locations of the too-small values for h are invariably at the very edge of the consolidated domain, so that it stands to reason that the errors are due to a not quite precise enough capturing of the discontinuity in c. Indeed a higher spatial resolution does improve the situation. Thus, a halving of Δx leads to a reduction of the dips in h below 1 by a whole order of magnitude.

As a second example, we will examine a case where the ice thickness is not uniform, so that it is easier to predict where the ice should yield first. The initial conditions for this run are $c_o = 0.5$, $h_o = \cos(2\pi x) + 1.1$, and $u_o = \sin(2\pi x) + 1.5$. As expected,

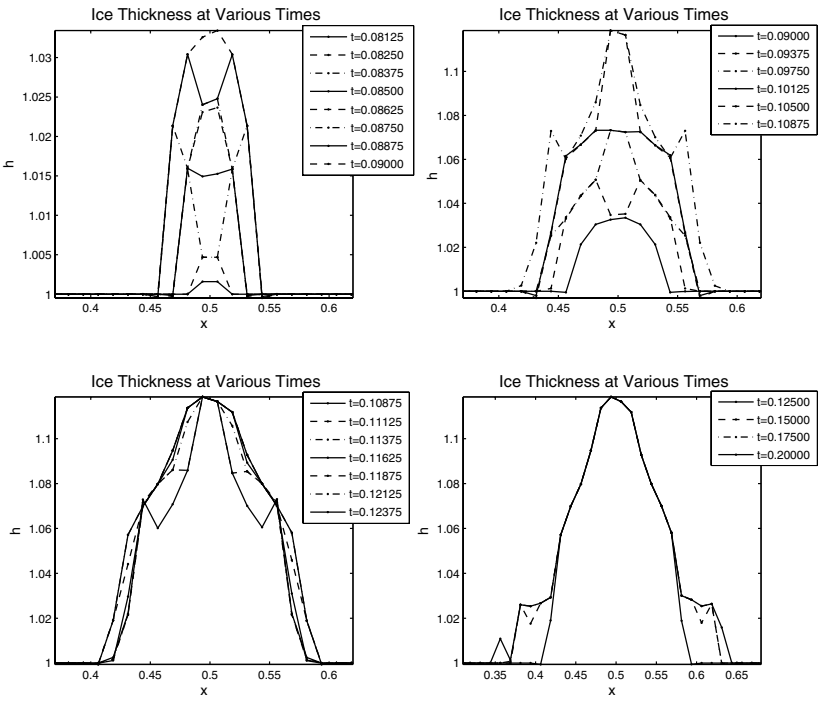

FIG. 6. *Snapshots from the thickness evolution of the run from Figure* 5. *The ice yields initially at the center of the domain, but later at other points within the consolidated region, leading temporarily to profiles with multiple peaks.*

the ice yields first where it is thinnest within the consolidated region. Figures 7 and 8 show the evolution of thickness, concentration, and velocity for this particular experiment. Note that the second figure is translated to the left, so that the center of the plot is at $x = 1$ rather than at $x = 0.5$. (Recall that periodic boundary conditions are being used.)

For a more detailed look, Figure 9 shows h, c, and u in one frame at two distinct times. In the plot on the left, for time $t = 0.2$, one can clearly see that the ice has begun to ridge in the consolidated region. It is also apparent that the velocity for this area is no longer constant; the yielding implies further convergence of the ice despite c equaling 1. In the plot on the right, for time $t = 0.4$, the ice is no longer yielding, and the consolidated ice travels at a uniform velocity of approximately 1.48 (close to the expected 1.5). By this time, the thickness profile within the region of $c = 1$ is again a more or less smooth valley; the thinner parts from the earlier picture have ridged as well.

7. Conclusions. We are investigating the feasibility of a novel formulation of the sea ice dynamics. In Part 1 [6], the method for calculating the internal pressure term as the solution to an optimization problem was derived, and results of a Lagrangian model with infinite ice strength were discussed. In this part, we set out to show how a finite ice strength can be handled by a model of this type. The implementation turns out to be easier in an Eulerian framework. Thus, we translated the formulation,

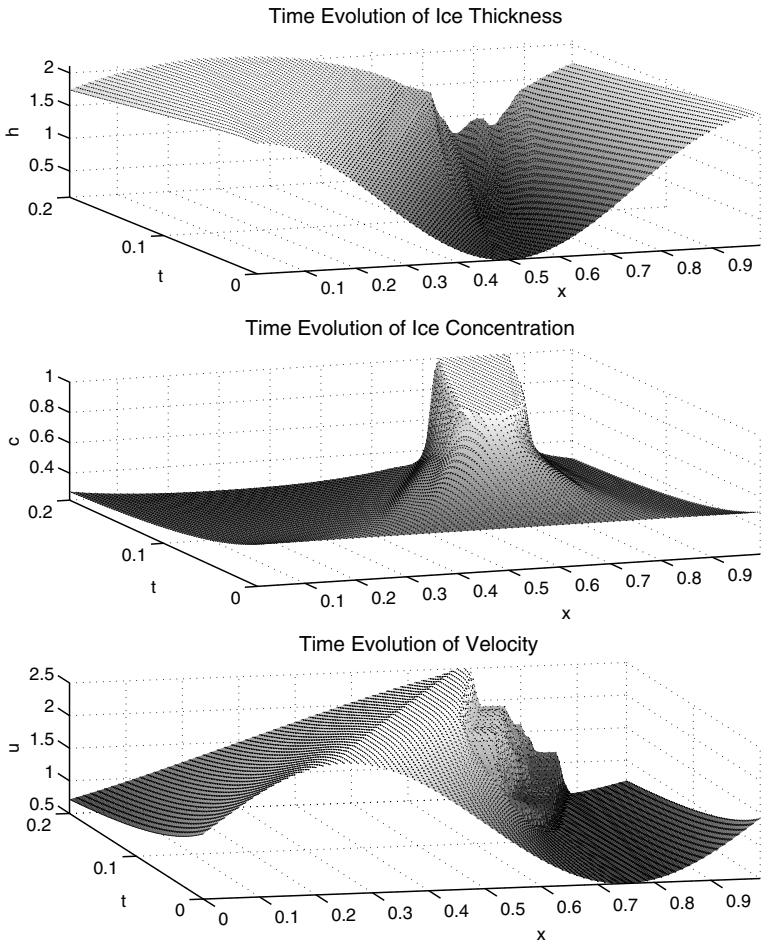

FIG. 7. *The model allowing for crushing was run with spatial step size set to* 0.0125 *and temporal step size set to* 0.00125. *Initial conditions were* $c_o = 0.5$, $h_o = \cos(2\pi x) + 1.1$, *and* $u_o = \sin(2\pi x) + 1.5$. P_o *was set to* 1. *The evolution up to time* $t = 0.2$ *is shown. The ice begins to yield at the weakest point.*

allowing now for a variable ice thickness, although initially still working with an infinite ice strength. This new model was compared to the Lagrangian one, to ensure that the choices made for the numerics, such as which variables to update explicitly at each time step and how to discretize the equations, did not lead to unreasonable results. In particular, we wanted to make sure that momentum, while not exactly conserved by the discretized equations, does not vary significantly over the course of a run. The Eulerian model output was also tested against an exact solution before consolidation, with very good agreement.

To incorporate a finite ice strength, we chose to adopt a parameterization of the ice strength as a multiple of the ice thickness, based on parameterizations common in the ice dynamics literature. Limiting the pressure the ice can withstand then requires

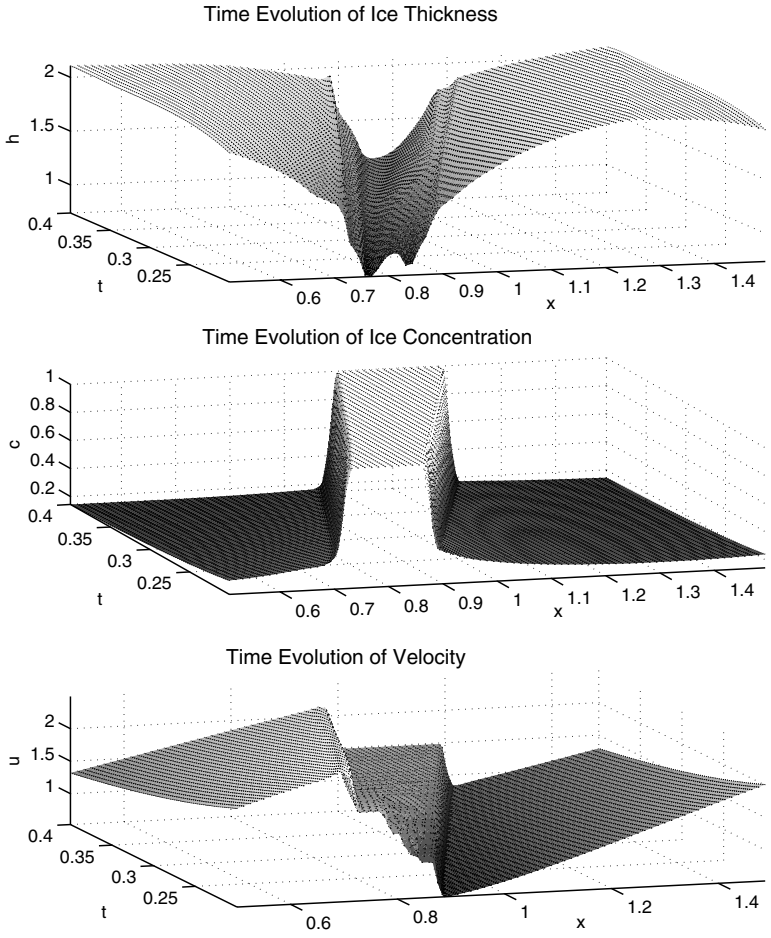

FIG. 8. *The continuation of the plot in Figure 7; here the evolution from time $t = 0.2$ until $t = 0.4$ is shown. Thinner ice yields first, leading to a smooth convex profile for h within the consolidated region at the end of the run.*

a second optimization problem, which determines how much the ice has to yield in order to satisfy this new constraint. While the solution to this minimization tends not to be unique, the minimum found is; this minimum then becomes an additional constraint on the second optimization, minimizing the pressure.

Two example runs were shown from this model, one beginning with a constant ice thickness, the second beginning with a varied one. In both cases, the behavior of the numerical results was qualitatively correct. Ice yields in the consolidated regions, whereby thinner ice tends to yield before thicker ice. Some convergence of the ice occurs during the ridging, but when the ice is thick enough to withstand the pressure exerted by the surrounding ice, all convergence is stopped—as desired.

It can be concluded, thus, that this procedure for determining internal stress for

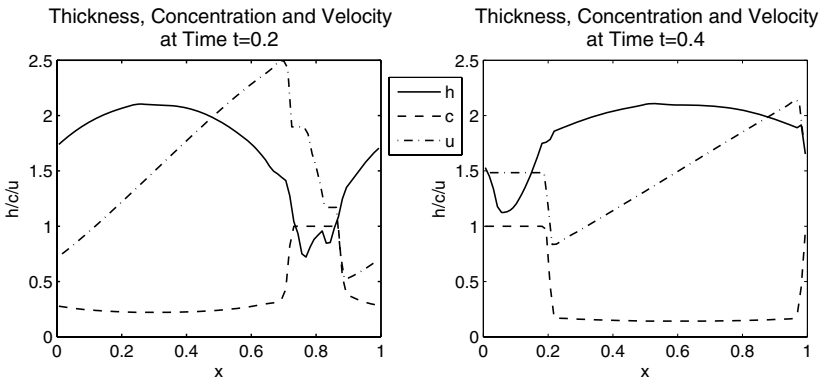

FIG. 9. *Detail for the second experiment, as in Figures* 7 *and* 8. *The left panel shows thickness (solid line), concentration (dashed line), and velocity (dot-dashed line) at time* $t = 0.2$. *The right panel shows the same measures at time* $t = 0.4$.

sea ice is indeed able to handle finite ice strength. Further work on a two-dimensional implementation is underway, where the new challenge of shear stresses and a limited shear strength arises. The findings presented here indicate that the method being investigated produces realistic results in one-dimensional cases, which is prerequisite to creating a working two-dimensional model.

Appendix. Interpolation scheme. As mentioned above, unlike the Lagrangian model, the Eulerian one requires that the variables be interpolated. They are defined on a staggered grid, but for the flux-form of the discretized equations we need to know their values at points in between. The strategy adopted here is a Godunov-type upwinding. See [7] for an extensive discussion of Godunov schemes.

For the concentration c and mass (ch), the upwinding works as follows: u is defined at the interfaces to which each of these is to be interpolated. The sign of the velocity determines the side from which the values are taken. In our implementation, we also perform a linear extrapolation. Thus, since c is defined at half steps of the grid,

$$c_j = \begin{cases} \frac{3}{2}c_{j-\frac{1}{2}} - \frac{1}{2}c_{j-\frac{3}{2}} & \text{if } u_j \geq 0, \\ \frac{3}{2}c_{j+\frac{1}{2}} - \frac{1}{2}c_{j+\frac{3}{2}} & \text{if } u_j < 0. \end{cases} \tag{39}$$

This method generally produces a better estimate of the value at the interface than a constant approximation (i.e., letting c_j equal either $c_{j-\frac{1}{2}}$ or $c_{j+\frac{1}{2}}$). However, one needs to include a safeguard not to overshoot the desired values. Thus, the extrapolations are capped by the minimum and the maximum of the adjoining points. If, for example, the extrapolation predicts a value for c_j larger than $\max\{c_{j-\frac{1}{2}}, c_{j+\frac{1}{2}}\}$, then it is reset to the maximum (similarly for the minimum). The variable (ch) is interpolated according to the same rules.

To find the value of $u_{j+\frac{1}{2}}$ is a somewhat more complex problem. One wants to solve the local Riemann problem for the system of equations

$$c_t + (ch)_x = 0, \tag{40}$$

$$(ch)_t + (chu)_x = 0, \tag{41}$$

$$(chu)_t + (chu^2)_x = -p_x. \tag{42}$$

(We assume no crushing here in between two time steps.) It turns out, however,

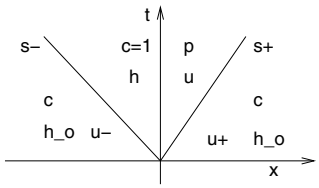

FIG. 10. *The two-shock setup with* $c^- = c^+$ *and* $h^- = h^+ = h_o$.

that this system of equations has only one set of characteristics and only one Riemann invariant. This is insufficient in general. In the case of divergence or contact discontinuities, there is no convergence, and hence we can assume that $p = 0$ is a solution. This observation allows us to simplify the momentum equation (42), using mass conservation (41), to Burgers' equation

$$u_t + \left(\frac{u^2}{2}\right)_x = 0. \tag{43}$$

Classical theory provides a solution to the local Riemann problem here. Thus, if we denote by u^- and u^+ the extrapolated values to the left and to the right, respectively, of the interface, then

$$u_{j+\frac{1}{2}} = \begin{cases} u^- & \text{if } u^+ \geq u^- \geq 0, \\ u^+ & \text{if } u^- \leq u^+ \leq 0, \\ 0 & \text{if } u^- < 0 < u^+. \end{cases} \tag{44}$$

The case of convergence and shocks is a little trickier. In fact, it can be shown that now p cannot be 0. Physical considerations suggest that when ice converges, not one but two discontinuities in the velocity form, one on each side of the newly consolidated ice. The general case for a nonstaggered grid, where concentration, thickness, and velocity all differ from one side of the interface to the other, requires an additional assumption, such as pressure minimization or thickness advection. (See [10] for a detailed discussion of this case.) Luckily, on the staggered grid we have chosen, this is not necessary. The two-shock setup of the local Riemann problem is illustrated in Figure 10. Ice thickness and concentration on each side of the interface (or the shocks, once these develop) are denoted by h_o and c, respectively. The velocities to the left and to the right (the extrapolated values) are denoted by u^- and u^+, as before. In between the shocks, the ice is consolidated; hence $c = 1$, the thickness is h, pressure p, and velocity u.

In the following derivation, we will assume that $0 < c < 1$; the other cases will be treated separately below.[3] For each shock, there are three jump conditions derived from (40)–(42):

$$s = \frac{[\![cu]\!]}{[\![c]\!]} = \frac{[\![chu]\!]}{[\![ch]\!]} = \frac{[\![chu^2 + p]\!]}{[\![chu]\!]}, \tag{45}$$

where s is the shock speed. Using s^- for the shock speed on the left and s^+ for that

[3]This restriction is desirable to ensure that the denominators in the jump conditions are nonzero.

on the right, these six equations become

$$s^- = \frac{cu^- - u}{c-1}, \tag{46}$$

$$\frac{cu^- - u}{c-1} = \frac{ch_o u^- - hu}{ch_o - h}, \tag{47}$$

$$\frac{ch_o u^- - hu}{ch_o - h} = \frac{ch_o (u^-)^2 - hu^2 - p}{ch_o u^- - hu}, \tag{48}$$

$$s^+ = \frac{cu^+ - u}{c-1}, \tag{49}$$

$$\frac{cu^+ - u}{c-1} = \frac{ch_o u^+ - hu}{ch_o - h}, \tag{50}$$

$$\frac{ch_o u^+ - hu}{ch_o - h} = \frac{ch_o (u^+)^2 - hu^2 - p}{ch_o u^+ - hu}. \tag{51}$$

Having six equations to constrain five unknowns (s^-, s^+, u, p, and h) opens the possibility for inconsistency. However, as we will see below, (47) and (50) are, in fact, redundant.

Solving (48) and (51) for p yields

$$p = \frac{ch_o h(u^- - u)^2}{h - ch_o} \tag{52}$$

and

$$p = \frac{ch_o h(u^+ - u)^2}{h - ch_o}. \tag{53}$$

By assumption, $c \neq 0$. One can also assume that $h \neq 0$ and $h_o \neq 0$, since this would mean that there is no ice near this interface and u becomes arbitrarily defined. Hence,

$$(u^- - u)^2 = (u^+ - u)^2. \tag{54}$$

Also, $u^- > u^+$ in the convergence case considered here, so that

$$u^- - u = u - u^+. \tag{55}$$

It follows that

$$u = \frac{u^- + u^+}{2}. \tag{56}$$

Note that one may have predicted this result, namely that the ice masses, once consolidated, move at the average velocity (since ice thickness and concentration are equal on each side).

Using (47), one can solve for h—which, as one might expect, turns out to be equal to h_o. (Since a finite ice strength does not enter this picture, there should not be any yielding or change in thickness.) Equation (50) yields the same answer (showing that one of them is unnecessary).

Substituting expression (56) for u into (46) and (49), we can solve for the two shock speeds:

$$s^- = \frac{u^+ + u^-(1-2c)}{2(1-c)}, \quad s^+ = \frac{u^- + u^+(1-2c)}{2(1-c)}. \tag{57}$$

In order for the picture in Figure 10 to be accurate, we also need that $s^- < s^+$. This is true.

Proof. Since we are only concerned with convergence, $u^- > u^+$. From (56), it can be concluded that $u^- > u > u^+$. Also $0 < c < 1$. It follows that

$$cu^- > cu, \qquad cu > cu^+, \tag{58}$$

$$u - cu^- < u - cu, \qquad u - cu < u - cu^+, \tag{59}$$

$$\frac{u - cu^-}{1 - c} < u, \qquad u < \frac{u - cu^+}{1 - c}, \tag{60}$$

$$s^- < u, \qquad u < s^+, \tag{61}$$

where (46) and (49) were used for the last step. ∎

The interpolation scheme resulting from this analysis is the following:

$$u_{j+\frac{1}{2}} = \begin{cases} u^- & \text{if } u^- \geq u^+, 0 < s^- < s^+, \\ u^+ & \text{if } u^- \geq u^+, s^- < s^+ < 0, \\ u = \frac{u^- + u^+}{2} & \text{if } u^- \geq u^+, s^- \leq 0 \leq s^+. \end{cases} \tag{62}$$

(We have chosen to group the cases $s^- = 0$ and $s^+ = 0$ into the last category, while they could as well fit into the two previous scenarios, respectively.)

Finally, we will say a word about the cases $c = 0$ and $c = 1$. If $c = 0$, there is no ice near the interface, and the velocity of the nonexisting ice is arbitrary. For consistency and smoothness, we will continue to use the same interpolation scheme as above (even though the derivation does not necessarily hold, starting with the observation that the concentration needs to be 1 between the shocks).

If $c = 1$, the ice is consolidated around the interface in question, which means that it should all be traveling at the same speed (in the absence of crushing). In other words, $u^- = u^+$. If this is not the case, due to numerical error, we set

$$u_{j+\frac{1}{2}} = \frac{u^- + u^+}{2}. \tag{63}$$

This completes the description of the interpolation scheme.

Acknowledgment. We would like to thank David Holland for his comments on this work.

A FAST AND ACCURATE MOMENT METHOD FOR THE FOKKER–PLANCK EQUATION AND APPLICATIONS TO ELECTRON RADIOTHERAPY*

MARTIN FRANK†, HARTMUT HENSEL‡, AND AXEL KLAR‡

Abstract. This paper represents a first step toward a moment method for dose calculations in radiotherapy. Starting from a deterministic transport model for electron radiation and its Fokker–Planck approximation, a new macroscopic model is presented. We investigate several ways to simplify the deterministic model having two goals in mind, lower computation times on the one hand and high accuracy and model inherent incorporation of tissue inhomogeneities on the other hand. While being fast, the second property is lost in the often used pencil-beam models. We discuss the properties of well-known macroscopic models and design a new model, which combines their advantages. Several test cases, including the irradiation of a water phantom, are presented.

Key words. radiotherapy, moment method, minimum entropy

1. Introduction.

Treatment with high energy ionizing radiation is one of the main methods in modern cancer therapy that is in clinical use. Since the early days of radiation treatment, high energy photons have been the most important type of radiation. Other types of radiation include high energy electrons and heavy charged particles like protons and ions. The latter type of radiation is of growing importance but has not reached the widespread use of photons and electrons, yet.

Before the treatment of the patient can be started, the expected dose distribution, i.e., the distribution of absorbed radiative energy in the patient, has to be calculated. During the past decades two main approaches to dose calculation were executed. The most accurate way to calculate the dose is given by Monte Carlo simulations [2]. Based on the well-known interactions of radiation in human tissue, a rigorous model of the energy distribution in the patient's body can be developed. Monte Carlo models allow for an exact computation of the dose distribution. Due to their high computational costs they have not found their way to everyday clinical use yet.

An alternative way to determine the dose was developed during the last 25 years. The so-called pencil-beam models [1] offer a reliable and fast alternative for most types of radiation treatment. These models are based on the Fermi–Eyges theory of radiative transfer [32, 14]. Despite their success in most clinical problems, they fail in complicated settings like air cavities or other inhomogeneities. This failure is caused by the underlying Fermi–Eyges theory because this approximation allows only for cross sections that vary spatially in the one-dimensional direction of the central axis of the beam. This assumption leads to a depth-dependence of the physical parameters

that is in general not observed in reality. Therefore pencil-beam models can account only for layered heterogeneities, and their effect on the dose has to be approximated by a rescaling of the kernels [18].

A third way to dose calculation has not attracted much attention in the medical physics community. This access is based on deterministic transport equations of radiative transfer. Similar to Monte Carlo simulations a rigorous model of the physical interactions in human tissue is modeled that can in principle be solved exactly. Recent studies for pure electron radiation can be found in [5, 7, 24, 22]. Electron and combined photon and electron radiation were studied in [36, 37] in the context of inverse therapy planning. The focus in these studies was more on rigorous analytical investigations with emphasis on mathematical aspects rather than a physically based modeling of the radiation-tissue interactions. A discrete transport model was proposed in [35, 19, 27, 20]. A consistent model of combined photon and electron radiation was developed [17] that includes the most important physical interactions. It allows for the computation of dose distributions for any geometric setting and is not restricted to layered inhomogeneities as the pencil-beam models are. Similar to Monte Carlo models, all interactions are modeled in detail which requires long computation times that are far beyond those needed for a clinical use.

This paper represents a first step toward simplified models for electron beam calculations in radiotherapy. In electron transport, small angle scattering with small energy loss, thus forward-peaked scattering kernels, is important. In transport calculations, these are either treated separately (e.g., $\delta - N$ method [34]) or the Boltzmann–Fokker–Planck equation can be used [31, 9]. In the latter approach, the scattering kernels are split into forward-peaked or more isotropic kernels, representing soft or hard collisions, respectively. Applying the Fokker–Planck asymptotic to the forward-peaked kernels, the (numerical) singularities are removed. In this work, we restrict ourselves to the Fokker–Plank approximation of the deterministic model although it does not contain all the physics necessary for realistic dose calculation. The reason for this is that the models we present here have all been successfully applied to radiative transfer with rather isotropic scattering, but it turns out that several of these models have problems in the Fokker–Planck limit of strong forward-peaked scattering. Here, we therefore modify the models to account for this difficulty alone. In future work, we will apply these new models to the combined Boltzmann–Fokker–Planck equation.

We investigate several ways to simplify the deterministic Fokker–Planck model having two goals in mind: On one hand the computation times should be lowered by several magnitudes. Our aim is a solver that can compute a typical dose distribution within minutes so that the model gets attractive for clinical use. On the other hand the errors in the dose distribution following the model simplifications should be very small. Especially the model inherent incorporation of tissue inhomogeneities must not be lost during the approximation steps. After all simplifications the model should still be able to fully reflect the heterogeneity of the human body, and the dose distribution should differ within only a few percent from more accurate benchmark simulations.

The rest of this paper is organized as follows. In section 2, we give an overview of the Boltzmann-type model, which was developed in [17] and serves as the starting point of our investigations. We also review the Fokker–Planck and Boltzmann–Fokker–Planck approximations. Well-known macroscopic approximations in the case of the Boltzmann equation are applied to the Fokker–Planck equation in section 3. Advantages and drawbacks of the macroscopic models are discussed in section 4. This discussion leads us to the proposal of a new model which unites some of the

best properties of the known models. We present numerical comparisons between several models in section 5 and include a realistic dose calculation using the full physical model from [17]. We conclude with a discussion of the results and present open problems for future work in section 6.

2. A deterministic model for dose calculation. A ray of high energy electrons that interacts with human tissue is subject to elastic scattering processes (Mott scattering) and inelastic ones (Møller scattering). Møller scattering is the electron-electron scattering process. It increases the number of free electrons when sufficient energy is transferred to the secondary electrons. It is this latter process that leads to energy deposition in the tissue, i.e., to the absorbed dose.

To formulate a transport equation for electrons we study their fluence in phase space. Let $\psi(r,\varepsilon,\Omega)\cos\Theta dA d\Omega d\epsilon_e dt$ be the number of electrons that move in time dt through area dA into the element of solid angle $d\Omega$ around Ω with an energy in the interval $(\epsilon_e, \epsilon_e + d\epsilon_e)$. The angle between direction Ω and the outer normal of dA is denoted by Θ. The direction is denoted by

$$\begin{aligned}\Omega = (\mu,\eta,\xi)^T &= (\mu, \sqrt{1-\mu^2}\cos\varphi, \sqrt{1-\mu^2}\sin\varphi)^T \\ &= (\cos\vartheta, \sin\vartheta\cos\varphi, \sin\vartheta\sin\varphi)^T,\end{aligned} \tag{2.1}$$

with φ and ϑ being the azimuth and polar angle in a cartesian coordinate system, respectively. The kinetic energy ϵ_e of the electrons is the relativistic kinetic energy.

2.1. Boltzmann transport equation. The transport equation formulated in [17] for the electrons is

$$\begin{aligned}\Omega\cdot\nabla\psi(r,\varepsilon,\Omega) = {}& \rho_e(r)\int_\varepsilon^\infty\int_{\mathcal{S}^2_{1/4}} \tilde\sigma_M(\epsilon_e',\epsilon_e,\Omega'\cdot\Omega)\psi(r,\varepsilon,\Omega')d\Omega_e' d\epsilon_e' \\ &+ \rho_e(r)\int_\varepsilon^\infty\int_{\mathcal{S}^2_{2/4}} \tilde\sigma_{M,\delta}(\epsilon_e',\epsilon_e,\Omega'\cdot\Omega)\psi(r,\varepsilon,\Omega')d\Omega_e' d\epsilon_e' \\ &+ \rho_c(r)\int_{\mathcal{S}^2}\sigma_{\mathrm{Mott}}(r,\epsilon_e,\Omega'\cdot\Omega)\psi(r,\varepsilon,\Omega')d\Omega_e' \\ &- \rho_e(r)\sigma_{M,\mathrm{tot}}(\epsilon_e)\psi(r,\varepsilon,\Omega) \\ &- \rho_c(r)\sigma_{\mathrm{Mott,tot}}(r,\epsilon_e)\psi(r,\varepsilon,\Omega),\end{aligned}$$

with $\tilde\sigma_M$ being the differential scattering cross section for Møller scattering of primary electrons; $\tilde\sigma_{M,\delta}$ being the differential Møller cross section for secondary electrons and σ_{Mott} being the differential cross section for Mott scattering; σ_M^{tot} and $\sigma_{\mathrm{Mott}}^{\mathrm{tot}}$ are the total cross sections for Møller and Mott scattering, respectively; and ρ_e and ρ_c are the densities of tissue electrons and tissue atomic cores, respectively. Explicit formulas for the cross sections can be found in Appendix A, see also [17]. In contrast to the model in [17] we set the lower energy bound of the transport equation to zero. The energy integration is performed over (ε,∞) since the electrons lose energy in every scattering event. Also, we consider only electron radiation. (2.2) could also be used to model electrons, which are generated by the interactions of photons with matter, as in [17]. In this case we would have an additional source term on the right-hand side for the generated electrons.

Due to kinematical reasons of the scattering processes, the range of solid angles in Møller (electron-electron) scattering is restricted. The electron, which has the

higher energy after the collision, is called the primary electron; the other electron is the secondary. Here, an incoming electron with energy ε' hits an electron at rest. After the collision, the angle between the directions of the electrons is at most $\pi/2$. Electrons are indistinguishable. For an angle in $[0, \pi/4]$, the electron with energy ε is the primary electron; for an angle in $[\pi/4, \pi/2]$, it is the secondary electron. Therefore we write the Møller term in the Boltzmann equation as

$$\int_{\mathcal{S}^2_{1/4}} f(\varphi,\vartheta)d\Omega := \int_0^{2\pi}\int_0^{\pi/4} f(\varphi,\vartheta)\sin\vartheta d\vartheta d\varphi \quad \text{and}$$
$$\int_{\mathcal{S}^2_{2/4}} f(\varphi,\vartheta)d\Omega := \int_0^{2\pi}\int_{\pi/4}^{\pi/2} f(\varphi,\vartheta)\sin\vartheta d\vartheta d\varphi,$$

where the axes of reference are given by Ω in the scattering integrals in (2.2).

Besides the transport equation one needs an equation for the absorbed dose. It was derived in [17] as an asymptotic limit of a model with a finite lower energy bound $\epsilon_{\mathrm{s}} > 0$. The formula is exact if one chooses the lower energy limit $\epsilon_{\mathrm{s}} = 0$, as we do here.

$$D(r) = \frac{T}{\rho(r)}\int_0^\infty S_{\mathrm{M}}(r,\epsilon'_{\mathrm{e}})\psi^{(0)}(r,\epsilon'_{\mathrm{e}})d\epsilon'_{\mathrm{e}},$$

with

$$\psi^{(0)}(r,\epsilon_{\mathrm{e}}) := \int_{S^2}\psi(r,\epsilon_{\mathrm{e}},\Omega')d\Omega', \tag{2.2}$$

T being the duration of the irradiation of the patient, and ρ being the mass density of the irradiated tissue. If all quantities are calculated in System Internationale (SI) units, (2.1) leads to SI units J/kg or Gray (Gy) for the dose.

S_{M} is the stopping power related to the Møller cross section. It is defined as

$$S_{\mathrm{M}}(r,\epsilon_{\mathrm{e}}) = \rho_{\mathrm{e}}(r)\int_{\epsilon_{\mathrm{B}}}^{(\epsilon_{\mathrm{e}}-\epsilon_{\mathrm{B}})/2}\epsilon'_{\mathrm{e}}\sigma_{\mathrm{M}}(\epsilon_{\mathrm{e}},\epsilon'_{\mathrm{e}})d\epsilon'_{\mathrm{e}}.$$

ϵ_{B} is the binding energy of electrons in tissue atoms or molecules, cf. [17] for details.

The above Boltzmann-type transport equation can be approximated by a Boltzmann–Fokker–Planck equation taking into account the fact that the great majority of the electron collisions are soft collisions. These collisions can be approximated by a Fokker–Planck-type term, see the next section. However, some electrons will also experience hard collisions with large changes in direction and energy losses which have to be described by Boltzmann integral terms. For reasons given above, we will consider only the Fokker–Planck part. Approximate methods for the full Boltzmann–Fokker–Planck equation will be considered in a forthcoming paper.

2.2. Fokker–Planck approximation. Electron transport in tissue has very distinctive properties. The soft collision differential scattering cross sections have a pronounced maximum for small scattering angles and small energy loss. This allows for a simplification of the scattering terms in the Boltzmann equation. The Fokker–Planck equation is the result of an asymptotic analysis for both small energy loss and small deflections. It has been rigorously derived in [30] and has been applied to the

above Boltzmann model in [17]. The Fokker–Planck equation is

$$\Omega\cdot\nabla\psi(r,\varepsilon,\Omega)=(T_{\mathrm{M}}(r,\varepsilon)+T_{\mathrm{Mott}}(r,\varepsilon))\Delta_\Omega\psi(r,\varepsilon,\Omega)+\partial_\varepsilon(S_{\mathrm{M}}(r,\varepsilon)\psi(r,\varepsilon,\Omega)), \tag{2.3}$$

with

$$T_{\mathrm{M}}(r,\varepsilon)=\pi\rho_{\mathrm{e}}(r)\int_{\varepsilon_{\mathrm{B}}}^{(\varepsilon-\varepsilon_{\mathrm{B}})/2}\int_{-1}^{1}(1-\mu)\tilde{\sigma}_{\mathrm{M}}(\varepsilon,\varepsilon',\mu)d\mu d\varepsilon', \tag{2.4}$$

$$T_{\mathrm{Mott}}(r,\varepsilon)=\pi\rho_{\mathrm{e}}(r)\int_{-1}^{1}(1-\mu)\sigma_{\mathrm{Mott}}(\varepsilon,\mu)d\mu, \tag{2.5}$$

and the Laplacian on the unit sphere

$$\Delta_\Omega=\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial}{\partial\varphi}. \tag{2.6}$$

In the following, we will interpret the energy variable ε as time. We assign boundary values to the Fokker–Planck equation (2.3) and will consider the following initial boundary value problem. We have the spatial domain $r\in\mathcal{Z}$ with boundary $\partial\mathcal{Z}$ and outward normal n, energy $\varepsilon\in[0,\infty)$, direction $\Omega\in\mathcal{S}^2$. We prescribe the ingoing radiation at the spatial boundary,

$$\psi(r,\varepsilon,\Omega)=\psi_b(r,\varepsilon,\Omega)\quad\text{for}\quad r\in\partial\mathcal{Z},n\cdot\Omega<0. \tag{2.7}$$

For the energy, we prescribe the "initial value"

$$\psi(r,\infty,\Omega)=0. \tag{2.8}$$

In the numerical simulations, we use a large cutoff energy.

2.3. Fermi–Eyges theory. To derive the Fermi–Eyges approximation, which is the basis of many schemes used in practice, several additional simplifying assumptions have to be made. As incident radiation, a monoenergetic pencil beam is assumed. We consider an infinite plate $(x,y,z)\in(0,1)\times\mathbb{R}^2$ and prescribe [7]

$$\psi(0,y,z,\varepsilon,\Omega)=\delta(y)\delta(z)\delta(\varepsilon-\varepsilon_0)\frac{\delta(1-\mu)}{2\pi}\quad\text{for}\quad 0<\mu<1, \tag{2.9}$$

$$\psi(1,y,z,\varepsilon,\Omega)=0\quad\text{for}\quad -1<\mu<0. \tag{2.10}$$

Energy transfer and change in direction are treated separately. First, if we neglect angular deflections, we obtain the straight ahead approximation,

$$\Omega\cdot\nabla\psi(r,\varepsilon,\Omega)=\frac{\partial}{\partial\varepsilon}(S_{\mathrm{M}}(r,\varepsilon)\psi(r,\varepsilon,\Omega)). \tag{2.11}$$

The method of characteristics for conservation laws relates energy and penetration depth by the initial value problem

$$\frac{d\varepsilon(x)}{dx}=-S_{\mathrm{M}}(x,\varepsilon(x)),\quad\varepsilon(0)=\varepsilon_0. \tag{2.12}$$

This means that we obtain the energy of the monoenergetic beam as a function of penetration depth. We have assumed that S_{M} depends only on the depth x.

On the other hand, we neglect energy loss and assume small angle scattering. The direction Ω is approximated by

$$\Omega = (\mu, \eta, \xi) \approx (1, \eta, \xi). \tag{2.13}$$

The Fokker–Planck equation becomes the Fermi equation

$$\begin{aligned} &\frac{\partial}{\partial x}\psi(r,\varepsilon,\eta,\xi) + \eta\frac{\partial}{\partial y}\psi(r,\varepsilon,\eta,\xi) + \xi\frac{\partial}{\partial z}\psi(r,\varepsilon,\eta,\xi) \\ &\qquad = \frac{T_{\mathrm{M}}(r,\varepsilon) + T_{\mathrm{Mott}}(r,\varepsilon)}{2}\Delta_{\eta,\xi}\psi(r,\varepsilon,\eta,\xi), \end{aligned} \tag{2.14}$$

where [5]

$$\Delta_{\eta,\xi} = \frac{\partial^2}{\partial\eta^2} + \frac{\partial^2}{\partial\xi^2} = \frac{1}{\mu}\frac{\partial}{\partial\mu}\left(\frac{1-\mu^2}{\mu}\frac{\partial}{\partial\mu}\right) + \frac{1}{1-\mu^2}\frac{\partial^2}{\partial\varphi^2}. \tag{2.15}$$

The Fermi equation permits only directions $\mu > 0$. An asymptotic derivation is given in [6].

The starting point of Fermi–Eyges theory is to combine the Fermi equation and the straight ahead approximation, i.e., $\varepsilon = \varepsilon(r)$ in (2.14). The Fermi equation is defined for $\eta^2 + \xi^2 < 1$. By artificially extending the range of η and ξ to the real line (ψ small for η, ξ large), Fermi ([32], pp. 265–268) was able to give an explicit solution for the pencil-beam problem for constant coefficients. Eyges [14] generalized this solution to space-dependent coefficients. Using the straight ahead approximation, it is thus possible to incorporate energy dependence.

In cylindrical coordinates, $r = (x, y, z) = (x, \rho\cos\phi, \rho\sin\phi)$, the Fermi equation reads

$$\frac{\partial}{\partial x}\psi(x,\rho,\eta) = -\eta\frac{\partial}{\partial\rho}\psi(x,\rho,\eta) + \frac{T_{\mathrm{M}}(x,\varepsilon(x)) + T_{\mathrm{Mott}}(x,\varepsilon(x))}{2}\frac{\partial^2}{\partial\eta^2}\psi(x,\rho,\eta). \tag{2.16}$$

Note that, due to symmetries in the pencil-beam problem, the solution depends neither on φ nor on ξ. Therefore pencil-beam models can account only for layered heterogeneities. Moreover, we assumed that the scattering coefficients T_{M} and T_{Mott} depend only on the penetration depth, i.e., the medium is layered. The explicit solution due to Eyges is

$$\psi_{FE}(x,\rho,\eta) = \frac{1}{2\pi\sqrt{A_0A_2(x) - A_1^2(x)}}\exp\left(-\frac{A_2(x)\eta^2 - 2A_1(x)\eta\rho + A_0\rho^2}{4A_0(A_0A_2(x) - A_1^2(x))}\right), \tag{2.17}$$

where

$$A_k(x) = \int_0^x (x-y)^k\frac{T_{\mathrm{M}}(y,\varepsilon(y)) + T_{\mathrm{Mott}}(y,\varepsilon(y))}{2}dy. \tag{2.18}$$

The so-called pencil-beam models based on the Fermi–Eyges theory offer a reliable and fast alternative for most types of radiation treatment as mentioned in the introduction. However, they fail in complicated settings, because the Fermi–Eyges approximation allows only for cross sections that vary spatially in the one-dimensional direction of the axis of the beam, i.e., for layered heterogeneities. Its generalization to nonlayered media is not obvious. Many heuristics have been introduced to that end [1]. Here, the basic Fermi–Eyges solution will serve as a comparison to the macroscopic methods.

3. Macroscopic models. In this section, we give an overview over several well-known macroscopic models as applied to the Fokker–Planck equation. For the sake of simplicity, we restrict ourselves to one space dimension. The ideas however are general and have been applied to two or three space dimensions.

3.1. Spherical harmonics. The spherical harmonics approach was developed first for radiative transfer [21, 13]. With high orders of the expansion, it has been proposed for use in photon transport medical physics problems, see, e.g., [4]. The idea of the spherical harmonics approach is to express the angular dependence of the distribution function in terms of a truncated Fourier series,

$$\psi_{SH}(r,\varepsilon,\mu) = \sum_{l=0}^{N} \psi^{(l)}(r,\varepsilon)\frac{2l+1}{2}P_l(\mu), \tag{3.1}$$

where P_l are the Legendre polynomials. This means that we assume $\psi^{(l)} = 0$ for $l > N$. The Legendre polynomials form an orthogonal basis of the space of polynomials with respect to the standard scalar product on $[-1,1]$. The Fourier coefficients are the moments

$$\psi^{(l)}(r,\varepsilon) = \int_{-1}^{1} \psi(r,\mu,\varepsilon)P_l(\mu)d\mu. \tag{3.2}$$

We test the Fokker–Planck equation with P_l, integrate with respect to μ over $[-1,1]$, and use a recursion relation to obtain the P_N equations

$$\begin{aligned} -S_{\mathrm{M}}\partial_\varepsilon\psi^{(l)} + \partial_x\left(\frac{l+1}{2l+1}\psi^{(l+1)} + \frac{l}{2l+1}\psi^{(l-1)}\right) \\ = -\frac{T_{\mathrm{M}}+T_{\mathrm{Mott}}}{2}l(l+1)\psi^{(l)} + (\partial_\varepsilon S_{\mathrm{M}})\psi^{(l)} \end{aligned} \tag{3.3}$$

for $l = 0,\dots,N$. The P_3 equations, which we will use later, read

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(0)} + \partial_x\psi^{(1)} = (\partial_\varepsilon S_{\mathrm{M}})\psi^{(0)}, \tag{3.4}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(1)} + \partial_x\left(\frac{1}{3}\psi^{(0)} + \frac{2}{3}\psi^{(2)}\right) = -(T_{\mathrm{M}}+T_{\mathrm{Mott}})\psi^{(1)} + (\partial_\varepsilon S_{\mathrm{M}})\psi^{(1)}, \tag{3.5}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(2)} + \partial_x\left(\frac{2}{5}\psi^{(1)} + \frac{3}{5}\psi^{(3)}\right) = -(T_{\mathrm{M}}+T_{\mathrm{Mott}})\psi^{(2)} + (\partial_\varepsilon S_{\mathrm{M}})\psi^{(2)}, \tag{3.6}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(3)} + \partial_x\frac{3}{7}\psi^{(2)} = -(T_{\mathrm{M}}+T_{\mathrm{Mott}})\psi^{(3)} + (\partial_\varepsilon S_{\mathrm{M}})\psi^{(3)}. \tag{3.7}$$

3.2. Diffusion and Fermi age. The diffusion approximation can be derived in several ways. One way is to start from the first spherical harmonics moment equation,

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(0)} + \partial_x\psi^{(1)} = (\partial_\varepsilon S_{\mathrm{M}})\psi^{(0)}, \tag{3.8}$$

and to approximate the second equation by Fick's law,

$$\partial_x\frac{1}{3}\psi^{(0)} = -(T_{\mathrm{M}}+T_{\mathrm{Mott}})\psi^{(1)}. \tag{3.9}$$

This gives

$$-\partial_\varepsilon(S_{\mathrm{M}}(\varepsilon)\psi^{(0)}) = \frac{1}{3(T_{\mathrm{M}}+T_{\mathrm{Mott}})}\partial_x^2\psi^{(0)}. \tag{3.10}$$

Alternatively, the diffusion equation can be derived by scaling arguments. One may start with the Fokker–Planck equation (2.3). Using the diffusion scaling (spatial scale of order $1/\delta$) combined with a rescaling of the term $\partial_\varepsilon(S_{\mathrm{M}}(r,\varepsilon))$ of order δ^2, one obtains with the classical arguments, see, e.g., [25], the above diffusion equation. However, the relevant physical parameters, see the last section, do not coincide with such a scaling; i.e., we are not in the range of validity of the diffusion equation. See also the numerical results in the last section. In Fermi age theory, the name under which the diffusion approximation is known in nuclear; we introduce the slowing down density $\tilde{\psi} = S_{\mathrm{M}}\psi^{(0)}$. Furthermore, we introduce the age τ by

$$\frac{d\tau}{d\varepsilon} = -\frac{1}{3(T_{\mathrm{M}} + T_{\mathrm{Mott}})}\frac{1}{S_{\mathrm{M}}}. \tag{3.11}$$

Note that the age has dimension length squared. Its square root is a characteristic length called the fast diffusion length. The diffusion equation attains the simple form

$$\frac{\partial}{\partial\tau}\tilde{\psi} = \Delta\tilde{\psi}. \tag{3.12}$$

3.3. Minimum entropy. The approximations based on the expansion of the distribution function into a polynomial suffer from several drawbacks [11]. Most importantly, the distribution function can become negative, and thus the moments computed from the distribution can become unphysical. One way to overcome this problem is to use an entropy minimization principle to obtain the constitutive equation to close the moment equations. This principle has become the main concept of rational extended thermodynamics [29].

The minimum entropy $M1$ model [11, 3] for electrons [8] can be derived in the following way. We start with the first two equations of the spherical harmonics method above:

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(0)} + \partial_x\psi^{(1)} = (\partial_\varepsilon S_{\mathrm{M}})\psi^{(0)}, \tag{3.13}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(1)} + \partial_x\left(\frac{1}{3}\psi^{(0)} + \frac{2}{3}\psi^{(2)}\right) = -(T_{\mathrm{M}} + T_{\mathrm{Mott}})\psi^{(1)} + (\partial_\varepsilon S_{\mathrm{M}})\psi^{(1)}. \tag{3.14}$$

This system is underdetermined: two equations for three unknowns. To close the system we determine a distribution function ψ_{ME} that minimizes the entropy of the electrons,

$$H_R^*(\psi) = -\int_{-1}^{1}\psi\log\psi d\mu, \tag{3.15}$$

under the constraint that it reproduces the lower order moments,

$$\int_{-1}^{1}\psi_{ME}d\mu = \psi^{(0)} \quad \text{and} \quad \int_{-1}^{1}\mu\psi_{ME}d\mu = \psi^{(1)}. \tag{3.16}$$

The entropy minimizer can be written as [8]

$$\psi_{ME}(\mu) = \alpha e^{\beta\mu}. \tag{3.17}$$

This is a Maxwell–Boltzmann-type distribution, and α, β are Lagrange multipliers enforcing the constraints.

When dealing with nonlinear closure functions, it is always crucial to ask which moments can be realized by the concrete distribution. In this case, we have as a necessary condition that

$$\psi^{(0)} = \int_{-1}^{1} \psi_{ME} d\mu \geq 0 \quad \text{and} \quad |\psi^{(1)}| = |\int_{-1}^{1} \mu \psi_{ME} d\mu| \leq \psi^{(0)}. \tag{3.18}$$

This is also sufficient; i.e., for each pair of moments $(\psi^{(0)}, \psi^{(1)})$ that satisfies (3.18) one can find Lagrange multipliers α and β such that the moments are realized by the distribution function ψ_{ME}.

It is not possible to express the highest moment $\psi^{(2)}$ explicitly in terms of $\psi^{(0)}$ and $\psi^{(1)}$, but we can write for the flux function

$$\frac{1}{3}\psi^{(0)} + \frac{2}{3}\psi^{(2)} = \chi\left(\frac{\psi^{(1)}}{\psi^{(0)}}\right)\psi^{(0)}. \tag{3.19}$$

The Eddington factor χ is defined for $|\psi^{(1)}/\psi^{(0)}| \leq 1$ and can be computed numerically [8] from the set of equations

$$\frac{\psi^{(1)}}{\psi^{(0)}} = \beta \coth \beta - 1, \tag{3.20}$$

$$\chi\left(\frac{\psi^{(1)}}{\psi^{(0)}}\right) = \frac{\psi^{(2)}}{\psi^{(0)}} = \beta^2 + 2 - 4\beta \coth \beta, \tag{3.21}$$

where β is the Lagrange multiplier. However, also the models based on the minimum entropy closure yield unphysical solutions in certain situations, see, e.g., the numerical results.

3.4. Half-moment approximation. A model which has been successfully applied to anisotropic radiative transfer, removing some drawbacks of the minimum entropy model in the last section, is the half-moment approximation [33, 38]. A typical drawback of the minimum entropy solution is displayed in the simulations in Figure 5.1. The idea is to average not over all directions but over certain subsets, e.g., particles moving left or right. In one dimension, this means to integrate over $[-1, 0]$ and $[0, 1]$. We denote the half-moments by

$$\psi_+^{(l)}(r, \varepsilon) = \int_0^1 \psi(r, \varepsilon, \mu) P_l(\mu) d\mu \quad \text{and} \quad \psi_-^{(l)}(r, \varepsilon) = \int_{-1}^0 \psi(r, \varepsilon, \mu) P_l(\mu) d\mu. \tag{3.22}$$

Applying this approach to the Fokker–Planck equation we obtain

$$-S_{\mathrm{M}} \partial_\varepsilon \psi_+^{(0)} + \partial_x \psi_+^{(1)} = \frac{T_{\mathrm{M}} + T_{\mathrm{Mott}}}{2} \int_0^1 \partial_\mu (1 - \mu^2) \partial_\mu \psi d\mu + (\partial_\varepsilon S) \psi_+^{(0)}. \tag{3.23}$$

If we use integration by parts, the integral on the right-hand side becomes

$$\int_0^1 \partial_\mu (1 - \mu^2) \partial_\mu \psi d\mu = -\partial_\mu \psi(0). \tag{3.24}$$

We note that, in contrast to the spherical harmonics approach, on the right-hand side a microscopic term, i.e., the distribution itself instead of its moments, appears. In

a similar way, we can derive equations for higher moments, as well as the negative half-space:

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_+^{(0)} + \partial_x\psi_+^{(1)} = -\frac{T_{\mathrm{M}}+T_{\mathrm{Mott}}}{2}\partial_\mu\psi(0) + (\partial_\varepsilon S_{\mathrm{M}})\psi_+^{(0)}, \tag{3.25}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_+^{(1)} + \partial_x\left(\psi_+^{(2)} + \frac{1}{3}\psi_+^{(0)}\right) = \frac{T_{\mathrm{M}}+T_{\mathrm{Mott}}}{2}(\psi(0) - 2\psi_+^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_+^{(1)}, \tag{3.26}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_-^{(0)} + \partial_x\psi_-^{(1)} = \frac{T_{\mathrm{M}}+T_{\mathrm{Mott}}}{2}\partial_\mu\psi(0) + (\partial_\varepsilon S_{\mathrm{M}})\psi_-^{(0)}, \tag{3.27}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_-^{(1)} + \partial_x\left(\psi_-^{(2)} + \frac{1}{3}\psi_+^{(0)}\right) = \frac{T_{\mathrm{M}}+T_{\mathrm{Mott}}}{2}(-\psi(0) - 2\psi_-^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_-^{(1)}. \tag{3.28}$$

In principle, we can model the boundary terms with the underlying distribution, which is used to model the higher order moments. Again, we can choose either a polynomial or minimum entropy closure.

For the half-moment P_1 closure, sometimes also called the double P_1 closure, we take

$$\psi_{HP1}(\mu) = \begin{cases} \alpha_- + \beta_-\mu & \text{for} \quad \mu \in [-1,0], \\ \alpha_+ + \beta_+\mu & \text{for} \quad \mu \in [0,1]. \end{cases} \tag{3.29}$$

If we model the microscopic terms using this function by defining $\psi(0)$ and $\partial_\mu\psi(0)$ as the limit from the right and left, respective of the positive or negative half-space, we obtain the closed half-moment P_1 system:

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_+^{(0)} + \partial_x\psi_+^{(1)} = 3(T_{\mathrm{M}}+T_{\mathrm{Mott}})(\psi_+^{(0)} - 2\psi_+^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_+^{(0)}, \tag{3.30}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_+^{(1)} + \partial_x\left(\chi_+\left(\frac{\psi_+^{(1)}}{\psi_+^{(0)}}\right)\psi^{(0)}\right) = 2(T_{\mathrm{M}}+T_{\mathrm{Mott}})(\psi_+^{(0)} - 2\psi_+^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_+^{(1)}, \tag{3.31}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_-^{(0)} + \partial_x\psi_-^{(1)} = 3(T_{\mathrm{M}}+T_{\mathrm{Mott}})(\psi_-^{(0)} + 2\psi_-^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_-^{(0)}, \tag{3.32}$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_-^{(1)} + \partial_x\left(\chi_-\left(\frac{\psi_-^{(1)}}{\psi_-^{(0)}}\right)\psi^{(0)}\right) = 2(T_{\mathrm{M}}+T_{\mathrm{Mott}})(\psi_-^{(0)} + 2\psi_-^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_-^{(1)}. \tag{3.33}$$

The half-Eddington factors for the P_1 closure are

$$\chi_\pm\left(\frac{\psi_\pm^{(1)}}{\psi_\pm^{(0)}}\right) = -\frac{1}{6} \pm \frac{\psi_\pm^{(1)}}{\psi_\pm^{(0)}}. \tag{3.34}$$

The half-moment minimum entropy closure is

$$\psi_{HME}(\mu) = \begin{cases} \alpha_- e^{\beta_-\mu} & \text{for} \quad \mu \in [-1,0], \\ \alpha_+ e^{+\beta_+\mu} & \text{for} \quad \mu \in [0,1]. \end{cases} \tag{3.35}$$

All physically reasonable half-moments can be realized; i.e., for $\psi_+^{(0)} \geq 0$ and $0 \leq \psi_+^{(1)} \leq \psi_+^{(0)}$ there exist Lagrange multipliers α_+ and β_+ such that the moments are realized by ψ_{HME} (respectively for "$-$"). The half-Eddington factors and the additional terms must be computed numerically. They can be obtained from the

system

$$\frac{\psi_+^{(1)}}{\psi^{(0)}} = \frac{\beta_+\beta_- e^{\beta_+} - \beta_-(e^{\beta_+}-1)}{\beta_+\beta_-(e^{\beta_+}-1) + \beta_+^2(1-e^{-\beta_-})}, \tag{3.36}$$

$$\frac{\psi_-^{(1)}}{\psi^{(0)}} = \frac{\beta_+\beta_- e^{-\beta_-} - \beta_+(1-e^{-\beta_-})}{\beta_-^2(e^{\beta_+}-1) + \beta_+\beta_-(1-e^{-\beta_-})}, \tag{3.37}$$

$$\chi_+\left(\frac{\psi_+^{(1)}}{\psi_+^{(0)}}\right) = \frac{\beta_- e^{\beta_+}}{\beta_-(e^{\beta_+}-1) + \beta_+(1-e^{-\beta_-})} - \frac{2}{\beta_+}\frac{\psi_+^{(1)}}{\psi^{(0)}}, \tag{3.38}$$

$$\chi_-\left(\frac{\psi_-^{(1)}}{\psi_+^{(0)}}\right) = \frac{-\beta_+ e^{-\beta_-}}{\beta_+(e^{\beta_+}-1) + \beta_-(1-e^{-\beta_-})} - \frac{2}{\beta_-}\frac{\psi_-^{(1)}}{\psi^{(0)}}, \tag{3.39}$$

in which the Lagrange multipliers $\beta_\pm$ have to be eliminated.

The underlying distribution function for the minimum entropy half-moment model is never negative in contrast to the linear half-moment model. For many situations, e.g., in the case of Boltzmann-type transport equations, the nonlinear half-moment closure has, similar to the nonlinear full moment closure, many advantages compared to the linear closure. However, in the present setting the major problems, as, e.g., the appearance of terms in the balance equations, which depend on the distribution function and not only on the first moments, are present for both closures. This will be explained below in more detail. Thus we do not get into the details of the nonlinear numerical closure here.

4. A new approximation extending the method of moments. In this section we discuss the drawbacks of the above models and suggest a new moment model adapted to the original Fokker–Planck equations. The behavior of the spherical harmonics method, the diffusion approximation, and the minimum entropy method have been studied extensively. The half-moment method is not as well known as the other approximations. All methods have their individual advantages and drawbacks. We will sketch some of them.

The diffusion approximation leads to a scalar parabolic PDE, which makes it very fast and simple to solve. The three other methods give systems of hyperbolic equations, whose numerical analysis is more difficult. The key drawback of the diffusion approximation is its diffusivity, i.e., it smears out the solution. Furthermore, information is propagated infinitely fast, in contrast to the finite speed of propagation in hyperbolic equations and in reality.

The main disadvantage of the spherical harmonics approach is that it allows for negative particle distributions and has fixed characteristic speeds. The minimum entropy approximation, on the other hand, always has a positive distribution and adapts to the speed of propagation. However, it allows for discontinuous solutions [8, 12]. The individual drawbacks can be demonstrated in one example, the two beam case shown in Figure 5.1. The details of the test case are described in section 5.

The half-moment model was designed to remove the drawbacks of minimum entropy and spherical harmonics. This approach was successful in the case of radiative transfer [33]. The half-moment minimum entropy model guarantees positivity, adapts its speed of propagation, and eliminates the possibility of unphysical discontinuities. The half-moment P_N model is also an improvement over the P_N model but lacks the correct speed of propagation and does not guarantee positivity.

In the present case, the numerical results show that the half-moment model (both with polynomial and minimum entropy closure) fails dramatically. One hint at this

failure is the appearance of the terms $\partial_\mu \psi(0)$ in the derivation, which are depending on the distribution function and not directly on the moments of this function. A second indication that the half-moment model above is not a good approximation to the Fokker–Planck equation is that the "+" and "−" equations decouple. Thus the model cannot be a consistent discretization of the Fokker–Planck equation. The mathematical reason for the failure is that integration by parts is not allowed if the integrand is discontinuous. While full moment models (as opposed to half-moment models) and the diffusion approximation are invariant under the Fokker–Planck limit,

$$\sigma_{\text{tot}} \to \infty, \quad \frac{\sigma^{(1)} = \int_{-1}^{1} \mu\sigma(\mu)d\mu}{\sigma_{\text{tot}}} \to 1 \quad \text{with} \quad \sigma_{\text{tot}}\left(1 - \frac{\sigma^{(1)}}{\sigma_{\text{tot}}}\right) \text{ fixed}, \tag{4.1}$$

the half-moment models diverge in this limit. The reason for this divergence will be investigated in more detail in future work.

Driven by the success of the half-moment approach for radiative transfer, we seek to modify the approach in such a way that it is suitable for the Fokker–Planck equation. We want to use half-moments where possible but avoid ambiguous microscopic terms. We observe that the lowest order ansatz which satisfies these criteria is to test with P_0 and integrate over $[-1, 1]$ and then to test with P_1 and integrate over $[-1, 0]$ and $[0, 1]$ separately. We get

$$-S_{\text{M}}\partial_\varepsilon \psi^{(0)} + \partial_x(\psi_+^{(1)} + \psi_-^{(1)}) = (\partial_\varepsilon S_{\text{M}})\psi^{(0)}, \tag{4.2}$$

$$-S_{\text{M}}\partial_\varepsilon \psi_+^{(1)} + \partial_x\left(-\frac{1}{6}\psi_+^{(0)} + \psi_+^{(1)}\right) = \frac{T_{\text{M}} + T_{\text{Mott}}}{2}(\psi(0) - 2\psi_+^{(1)}) + (\partial_\varepsilon S_{\text{M}})\psi_+^{(1)}, \tag{4.3}$$

$$-S_{\text{M}}\partial_\varepsilon \psi_-^{(1)} + \partial_x\left(-\frac{1}{6}\psi_-^{(0)} - \psi_-^{(1)}\right) = \frac{T_{\text{M}} + T_{\text{Mott}}}{2}(-\psi(0) - 2\psi_-^{(1)}) + (\partial_\varepsilon S_{\text{M}})\psi_-^{(1)}. \tag{4.4}$$

If we close this system with an underlying distribution that is continuous, then the integration by parts which was performed to obtain the last two equations is justified. Furthermore, the microscopic term in the last two equations is unambiguously defined.

To close the model, we choose a modified minimum entropy (MME) closure function which is a mixture between half moment and full moment closure:

$$\psi_{MME} = \begin{cases} \alpha e^{\beta_+ \mu}, & \mu \in [0, 1], \\ \alpha e^{\beta_- \mu}, & \mu \in [-1, 0]. \end{cases} \tag{4.5}$$

Here, one could also consider a linear closure, but this has the drawback that it allows for negative energies and does not adapt to the correct speed of propagation similar to the radiative transfer case.

Whereas in the above minimum entropy closure functions all physically relevant moments could be attained, moment realizability is an issue here. Obviously,

$$\psi^{(0)} \geq 0, \quad 0 \leq \psi_+^{(1)} \leq \psi^{(0)}, \quad \text{and} \quad -\psi^{(0)} \leq \psi_-^{(1)} \leq 0 \tag{4.6}$$

are necessary conditions for the invertibility. Furthermore, we observe that

$$\begin{aligned} \psi_+^{(1)} - \psi_-^{(1)} &= \int_0^1 \mu e^{\beta_+ \mu} d\mu - \int_{-1}^0 \mu e^{\beta_- \mu} d\mu = \int_0^1 \mu e^{\beta_+ \mu} d\mu - \int_1^0 \mu e^{-\beta_- \mu} d\mu \\ &= \int_0^1 \mu(e^{\beta_+ \mu} + e^{-\beta_- \mu}) d\mu \leq \int_0^1 \mu(e^{\beta_+ \mu} + e^{-\beta_- \mu}) d\mu = \psi^{(0)}. \end{aligned} \tag{4.7}$$

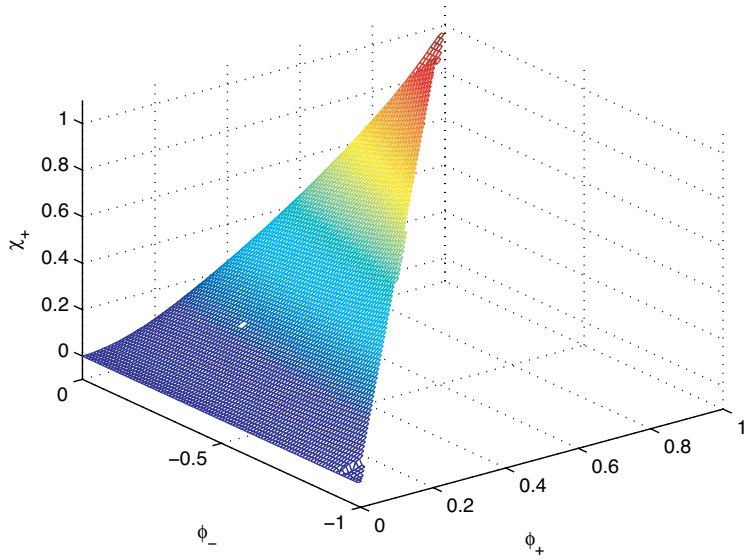

FIG. 4.1. *Minimum entropy Eddington factor* χ_+ *as a function of* $\phi_+ = \psi_+^{(1)}/\psi^{(0)}$ *and* $\phi_- = \psi_-^{(1)}/\psi^{(0)}$.

The numerical inversion of the system shows that conditions (4.6) and (4.7) are sufficient for realizability. This means that not all choices of the moments $(\psi^{(0)}, \psi_+^{(1)}, \psi_-^{(1)})$ in (4.6) are allowed here. In the test cases presented below, for realizable initial values, the moments always remained realizable during the evolution. A proof of this fact is crucial in the proof of the well-posedness of the system.

Again, the system cannot be closed analytically, but it can be written in the form

$$-S_{\mathrm{M}}\partial_\varepsilon\psi^{(0)} + \partial_x(\psi_+^{(1)} + \psi_-^{(1)}) = (\partial_\varepsilon S_{\mathrm{M}})\psi^{(0)},$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_+^{(1)} + \partial_x\left(\chi_+\left(\frac{\psi_+^{(1)}}{\psi^{(0)}}, \frac{\psi_-^{(1)}}{\psi^{(0)}}\right)\psi^{(0)}\right)$$

$$= \frac{T_{\mathrm{M}} + T_{\mathrm{Mott}}}{2}(2\psi^{(0)} - 5\psi_+^{(1)} + 3\psi_-^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_+^{(1)},$$

$$-S_{\mathrm{M}}\partial_\varepsilon\psi_-^{(1)} + \partial_x\left(\chi_-\left(\frac{\psi_-^{(1)}}{\psi^{(0)}}, \frac{\psi_+^{(1)}}{\psi^{(0)}}\right)\psi^{(0)}\right)$$

$$= \frac{T_{\mathrm{M}} + T_{\mathrm{Mott}}}{2}(-2\psi^{(0)} + 3\psi_+^{(1)} - 5\psi_-^{(1)}) + (\partial_\varepsilon S_{\mathrm{M}})\psi_-^{(1)}.$$

The Eddington factors satisfy the symmetry relation $\chi_+(\phi, \psi) = \chi_-(-\psi, -\phi)$. Figure 4.1 shows χ_+.

5. Numerical results. In this section we consider several test problems in slab geometry. We have a domain between two infinite parallel plates. Thus the problem becomes one-dimensional in space. We will compare the Fokker–Planck solution with diffusion, spherical harmonics P_3, minimum entropy, half-moment P_1, and our new model, which we will refer to as MME.

The numerical results for Fokker–Planck and diffusion have been obtained with standard finite differences. The hyperbolic models were solved with kinetic schemes. For more details on the numerical methods see [15].

In the one-dimensional setting, the Fermi–Eyges solution becomes particularly simple. First we can average over the directions parallel to the surfaces of the plate (perpendicular to the direction of propagation). Second, if we average over the angular variable, we obtain for the pencil-beam problem

$$\psi^{(0)}(x,\varepsilon;\varepsilon_0) = \delta(\varepsilon - \varepsilon(x;\varepsilon_0)). \tag{5.1}$$

For an arbitrary energy distribution ψ_b at the left boundary, the solution can be obtained by convolution:

$$\psi^{(0)}(x,\varepsilon) = \int_0^\infty \int_{-1}^1 \delta(\varepsilon - \varepsilon(x,\varepsilon'))\psi_b(0,\varepsilon',\mu)d\mu d\varepsilon'. \tag{5.2}$$

Our first (artificial) test case is the two-beam test case mentioned above. We ignore the complicated physics of the electron-tissue interaction and use the values $S_{\mathrm{M}} = 1$, $T_{\mathrm{M}} + T_{\mathrm{Mott}} = 0.01$. The spatial domain is $x \in [0,9]$; the cutoff energy (maximum energy) is 19.6. At the left side and at the right side of the domain, we consider forward-peaked incoming beams, represented by

$$\psi_b(x=0,\varepsilon,\mu) = \psi_0 e^{-(\varepsilon-\bar{\varepsilon})^2} e^{-100(1-\mu)^2}, \tag{5.3}$$

$$\psi_b(x=9,\varepsilon,\mu) = \psi_0 e^{-(\varepsilon-\bar{\varepsilon})^2} e^{-100(1+\mu)^2}, \tag{5.4}$$

with $\psi_0 = 10^5$. The models behave qualitatively similar if we take the values of water for S_{M} and $T_{\mathrm{M}} + T_{\mathrm{Mott}}$. With the values chosen above, however, their properties can be visualized in a single figure. The lowest order moment $\psi^{(0)}$ which can be seen as a measure for the total number of electrons, computed by the different models at $\varepsilon = 0.6\bar{\varepsilon}$, is shown in Figure 5.1.

The drawbacks of the classical macroscopic model are clearly visible. The diffusion approximation is smeared out, the spherical harmonics solution oscillates into the negative, and minimum entropy produces an unphysical shock. The half-moment model oscillates strongly, independently from the choice of the closure. The new MME model is a good approximation to the Fokker–Planck solution.

In our second example, we test our model in a real physical application. We consider a water phantom (an infinite plate filled with water) with depth 9 cm. The effective atomic number is $Z = 7.51$; the density of electrons is $\rho_{\mathrm{e}} = 3340 \cdot 10^{20}$ cm^3, $\rho_{\mathrm{c}} = \rho_{\mathrm{e}}/Z$, $\rho = 1g/\mathrm{cm}^3$ (parameters taken from [17]). The phantom is irradiated from one side by a beam

$$\psi_b(x=0,\varepsilon,\mu) = \psi_0 e^{-1(\varepsilon-\bar{\varepsilon})^2} e^{-10(1-\mu)^2} \tag{5.5}$$

with mean energy $\bar{\varepsilon} = 10$ MeV and amplitude $\psi_0 = 10^5$ MeV^{-1}s^{-1}. We compare the MME, diffusion, and Fermi–Eyges approximations with the Fokker–Planck solution. Snapshots of the energy spectrum of the beam for several depths are shown in Figure 5.2. As above, the diffusion approximation strongly smears out and loses the beam structure. The Fermi–Eyges approximation, on the other hand, retains the same shape as the incoming radiation. The energy spectrum is just gradually shifted

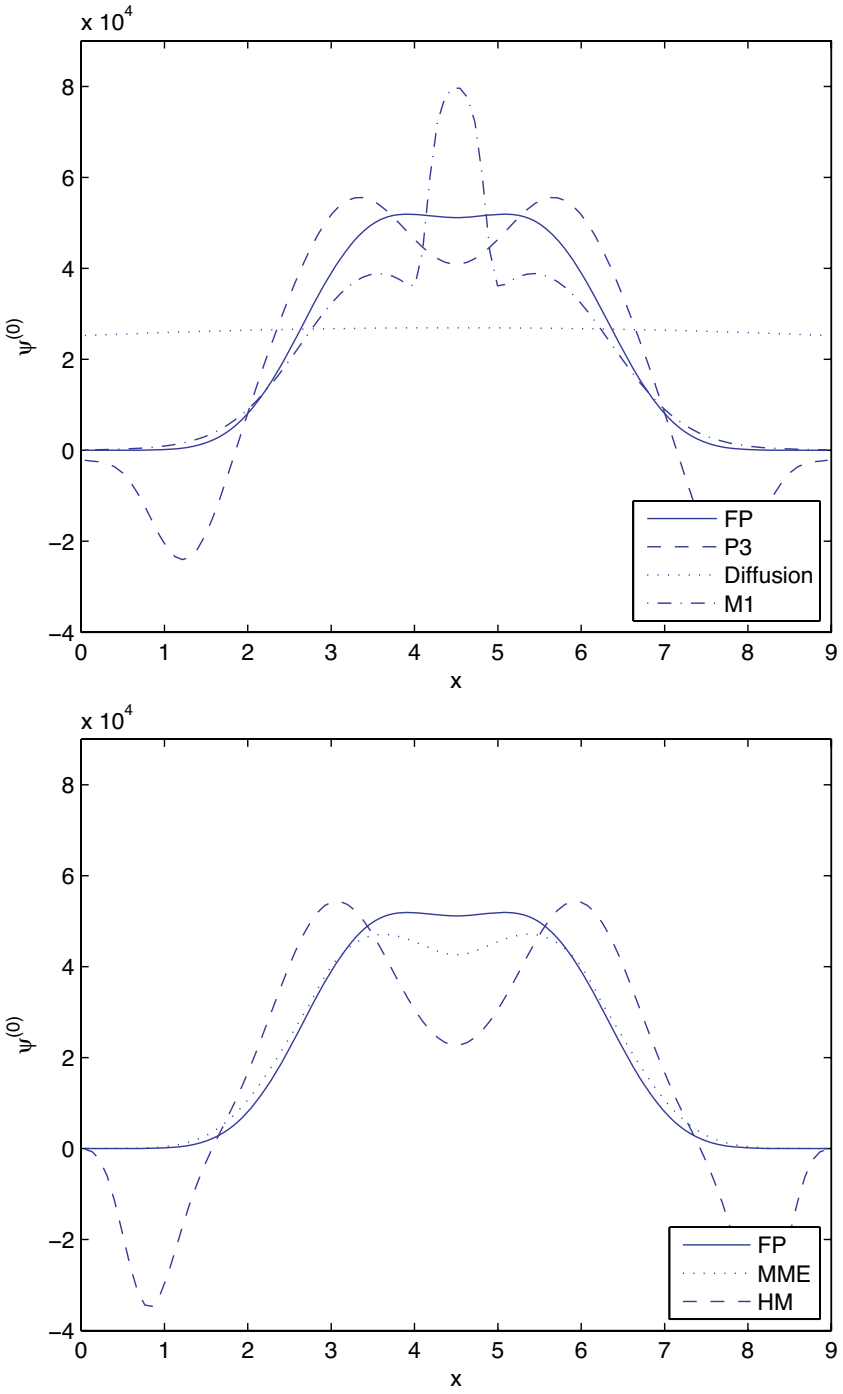

FIG. 5.1. *Distribution $\psi^{(0)}$ at $\varepsilon = 0.6\bar{\varepsilon}$ in two beam test case. Comparison between Fokker–Planck (FP), spherical harmonics P_3 (P3), diffusion, and minimum entropy M_1 (M1) solution (top). Comparison between Fokker–Planck (FP), MME, and half-moment (HM) solution (bottom).*

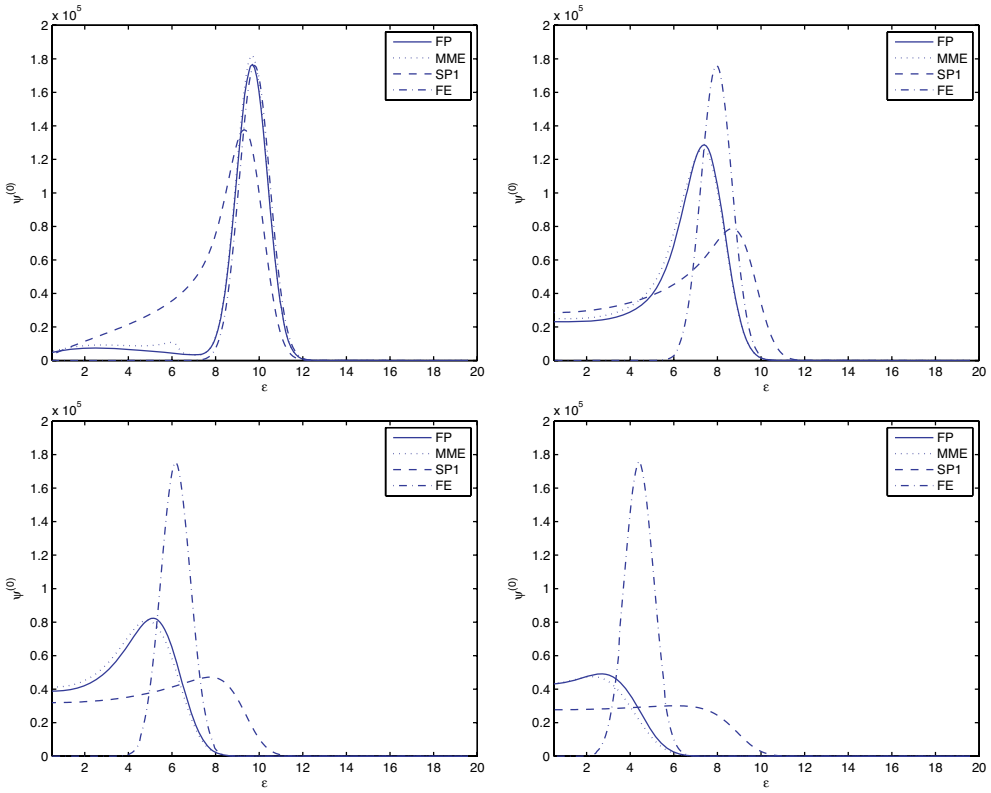

FIG. 5.2. *Snapshots of the energy spectrum. Distribution* $\psi^{(0)}$ *as a function of energy for different depths,* $x = 0.01$ *cm (top left),* $x = 1$ *cm (top right),* $x = 2$ *cm (bottom left), and* $x = 3$ *cm (bottom right). Comparison between Fokker–Planck solution (FP), MME, diffusion (SP*1*), and Fermi–Eyges (FE).*

according to the stopping power. The true behavior of the Fokker–Planck solution is inbetween the two extremes. The behavior is well matched by the MME approximation. The unmodified minimum entropy and the spherical harmonics solution (both not shown) give results similar to the MME model in the present case. The half-moment model oscillates strongly into negative energies.

For this test case, we also calculated the dose, using (2.1). The result is shown in Figure 5.3. As can be expected from the results above, the MME model is a good approximation to the dose computed using the Fokker–Planck solution. The diffusion is smeared out. The difference that can be seen, however, is less dramatic than for $\psi^{(0)}$. The Fermi–Eyges approximation is too simple to capture the absorption in the medium.

Finally, we should comment on the computation times the different models used. For the macroscopic models, the effort roughly scales with the number of equations: 1 for diffusion, 2 for minimum entropy, 3 for MME, 4 for spherical harmonics, and roughly 100 for Fokker–Planck, depending on the angular discretization. We did not optimize the convolution integrals in the Fermi–Eyges approximation, but it is expected that this method is faster than the diffusion approximation.

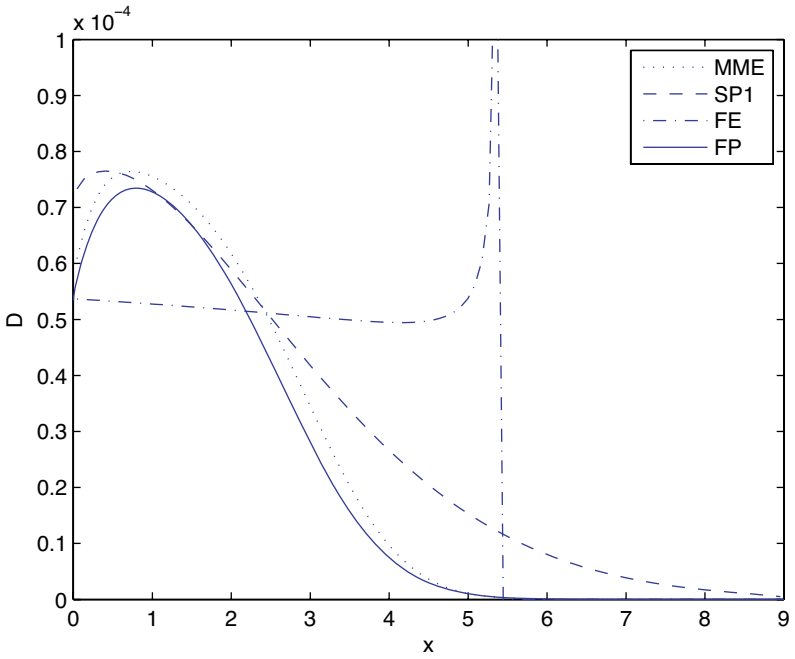

FIG. 5.3. *Dose deposited in tissue, computed with Fokker–Planck (FP), MME, diffusion (SP*1*), and Fermi–Eyges (FE).*

6. Conclusions. We derived and investigated a MME model as a computationally inexpensive but accurate model for dose calculation in electron radiotherapy. This model was derived from the Fokker–Planck equation and makes no assumption on the structure of the medium. In contrast to pencil-beam models, the treatment of inhomogeneities is model-inherent. Furthermore, we have demonstrated that the model preserves the positivity of the number of electrons and the shape of the energy spectrum better than several well-known macroscopic methods. We believe that the model is a first step toward a method which can compete with the techniques that are currently in clinical use.

Up to now numerical results have been obtained only in one dimension. The extension to two and three dimensions has been done with very good results in the case of radiative transfer, see, e.g., [15], using quarter space moments or other partial moment models. An extension of these methods to the present case is currently under investigation.

As mentioned in the beginning, the Fokker–Planck model lacks parts of the necessary physics for the description of electron radiotherapy. Some electrons will also experience hard collisions which have to be described by Boltzmann integral terms. Thus, the development of approximate methods for the original Boltzmann equation with forward-peaked scattering is a subject which has to be investigated as well.

Several open questions for further studies remain:

- The analytical properties of the new model, especially mathematical well-posedness, will be studied. We expect to obtain similar results as for the standard half-moment model [33, 16].

- The passage from the Boltzmann transport equation to the Fokker–Planck equation in the context of moment models should be studied in more detail. The half-moment model apparently breaks down in this limit. The exact reason for this breakdown is certainly an interesting subject of further study.
- The model will be generalized to two and three space dimensions. Results in the case of the radiative transfer equation [15] indicate that the advantage over diffusion and spherical harmonics methods becomes even more apparent.
- Moment models for the full Boltzmann equation will be developed and compared to the present approach.
- The model contains an accurate model of the microscopic interactions. In two and three dimensions, it should be validated using well-established codes for electron radiotherapy, experiments, and benchmark results.

Appendix A. Explicit formulas for the cross sections. This appendix lists all scattering cross sections that are used in the Boltzmann model. All cross sections are calculated for the laboratory system where the scattering centers are at rest before scattering. Except for elastic Mott scattering, all differential scattering cross sections are differential in energy and in solid angle. They can be decomposed into a product of a cross section, which is only differential in solid angle or energy, and a Dirac delta function, which guarantees energy and momentum conservation during the scattering event. The Mott cross section is only differential in solid angle. Total cross sections are calculated by integrating the double differential cross sections with respect to energy and solid angle. Because of the delta functions one integration is always trivial.

For all differential cross sections the following conventions are used: quantities with a prime belong to incoming particles, quantities without a prime to outgoing particles in a scattering event. The order of appearence in all differential cross sections is energy of incoming (ε'), energy of outgoing (ε), direction of incoming (Ω'), and direction of outgoing particles (Ω). To simplify notation and to keep the standard notation used in literature we use $\Omega' \cdot \Omega = \cos\vartheta \equiv \mu$, ϑ being the scattering angle in the laboratory system. Additionally we keep $\sin\vartheta$ and $\tan\vartheta$ in formulas to maintain a handy notation. The relationship to $\cos\vartheta$ is evident. Furthermore it should be kept in mind that $\epsilon_{\mathrm{B}} = \epsilon_{\mathrm{B}}(r)$ which is not explicitly written to keep notation short. In all formulas the classical electron radius $r_{\mathrm{e}} = 2.8179 \cdot 10^{-15}\,\mathrm{m}$ appears.

A.1. Differential cross section for Compton scattering of photons [10].

$$\tilde{\sigma}_{\mathrm{C},\gamma}(\epsilon'_\gamma, \epsilon_\gamma, \Omega'_\gamma \cdot \Omega_\gamma) = \sigma_{\mathrm{C},\gamma}(\epsilon'_\gamma, \Omega'_\gamma \cdot \Omega_\gamma)\delta_{\mathrm{C},\gamma}(\epsilon'_\gamma, \epsilon_\gamma)$$

with

$$\sigma_{\mathrm{C},\gamma}(\epsilon'_\gamma, \Omega'_\gamma \cdot \Omega_\gamma) = \frac{r_{\mathrm{e}}^2}{2}\left[\frac{1}{1+\epsilon'_\gamma(1-\cos\vartheta_\gamma)}\right]^2\left[1+\cos^2\vartheta_\gamma + \frac{\epsilon'^2_\gamma(1-\cos\vartheta_\gamma)^2}{1+\epsilon'_\gamma(1-\cos\vartheta_\gamma)}\right]$$

$$\delta_{\mathrm{C},\gamma}(\epsilon'_\gamma, \epsilon_\gamma) := \delta_\gamma\left(\epsilon_\gamma - \frac{\epsilon'_\gamma}{1+\epsilon'_\gamma(1-\cos\vartheta_\gamma)}g\right).$$

A.2. Total cross section for Compton scattering of photons [10].

$$\sigma^{\mathrm{tot}}_{\mathrm{C},\gamma}(\epsilon_\gamma) = 2\pi r_{\mathrm{e}}^2\left[\frac{1+\epsilon_\gamma}{\epsilon_\gamma^2}\left(\frac{2(1+\epsilon_\gamma)}{1+2\epsilon_\gamma} - \frac{1}{\epsilon_\gamma}\ln(1+2\epsilon_\gamma)\right) + \frac{1}{2\epsilon_\gamma}\ln(1+2\epsilon_\gamma) - \frac{1+3\epsilon_\gamma}{(1+2\epsilon_\gamma)^2}\right].$$

A.3. Differential cross section for Compton scattering of electrons [10].

$$\tilde{\sigma}_{\mathrm{C,e}}(\epsilon'_\gamma, \epsilon_\mathrm{e}, \Omega'_\gamma \cdot \Omega_\mathrm{e}) = \sigma_{\mathrm{C,e}}(\epsilon'_\gamma, \Omega'_\gamma \cdot \Omega_\mathrm{e})\delta_{\mathrm{C,e}}(\epsilon'_\gamma, \epsilon_\mathrm{e})$$

with

$$\begin{aligned}\sigma_{\mathrm{C,e}}(\epsilon'_\gamma, \Omega'_\gamma \cdot \Omega_\mathrm{e}) &= \frac{4r_\mathrm{e}^2(1+\epsilon'_\gamma)^2}{\cos^3\vartheta_\mathrm{e}} \frac{1}{(a(\epsilon'_\gamma, \vartheta_\mathrm{e}) + 2\epsilon'_\gamma)^2} \\ &\quad \times \left[1 - \frac{2}{a(\epsilon'_\gamma, \vartheta_\mathrm{e})} + \frac{2}{a^2(\epsilon'_\gamma, \vartheta_\mathrm{e})} + \frac{2\epsilon_\gamma^2}{a(\epsilon'_\gamma \vartheta_\mathrm{e})(a(\epsilon'_\gamma, \vartheta_\mathrm{e}) + 2\epsilon'_\gamma)}\right] \\ \delta_{\mathrm{C,e}}(\epsilon'_\gamma, \epsilon_\mathrm{e}) &:= \delta_\gamma\left(\epsilon_\mathrm{e} - \frac{2{\epsilon'_\gamma}^2}{2\epsilon'_\gamma + a(\epsilon'_\gamma, \vartheta_\mathrm{e})} g\right),\end{aligned}$$

where

$$a(\epsilon'_\gamma, \vartheta_\mathrm{e}) := (1+\epsilon'_\gamma)^2 \tan^2\vartheta_\mathrm{e} + 1.$$

A.4. Differential cross section for Møller scattering of primary electrons, i.e., $\epsilon_\mathrm{e} > (\epsilon'_\mathrm{e} - \epsilon_\mathrm{B})/2$ [23].

$$\tilde{\sigma}_\mathrm{M}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e}, \Omega'_\mathrm{e} \cdot \Omega_\mathrm{e}) = \sigma_\mathrm{M}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e})\delta_M(\mu_\mathrm{e}, \mu_p)\frac{1}{2\pi}, \quad \mu_\mathrm{e} = \Omega'_\mathrm{e} \cdot \Omega_\mathrm{e}$$

with

$$\begin{aligned}\sigma_\mathrm{M}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e}) &= \frac{2\pi r_\mathrm{e}^2(\epsilon'_\mathrm{e}+1)^2}{\epsilon'_\mathrm{e}(\epsilon'_\mathrm{e}+2)}\left[\frac{1}{\epsilon_\mathrm{e}^2} + \frac{1}{(\epsilon'_\mathrm{e}-\epsilon_\mathrm{e})^2} + \frac{1}{(\epsilon'_\mathrm{e}+1)^2} - \frac{2\epsilon'_\mathrm{e}+1}{(\epsilon'_\mathrm{e}+1)^2\epsilon_\mathrm{e}(\epsilon'_\mathrm{e}-\epsilon_\mathrm{e})}\right] \\ \delta_M(\mu_\mathrm{e}, \mu_p) &= \delta\left(\mu_\mathrm{e} - \sqrt{\frac{\epsilon_\mathrm{e}}{\epsilon'_\mathrm{e}}\frac{\epsilon'_\mathrm{e}+2}{\epsilon_\mathrm{e}+2}}\right), \quad \epsilon_\mathrm{e} > \frac{(\epsilon'_\mathrm{e} - \epsilon_\mathrm{B})}{2}.\end{aligned}$$

A.5. Differential cross section for Møller scattering of secondary electrons, i.e., $\epsilon_\mathrm{e} < (\epsilon'_\mathrm{e} - \epsilon_\mathrm{B})/2$ [23].

$$\tilde{\sigma}_{\mathrm{M},\delta}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e}, \Omega'_\mathrm{e} \cdot \Omega_\mathrm{e}) = \sigma_\mathrm{M}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e})\delta_{\mathrm{M},\delta}(\mu_\mathrm{e}, \mu_\delta)\frac{1}{2\pi}, \quad \mu_\mathrm{e} = \Omega'_\mathrm{e} \cdot \Omega_\mathrm{e}$$

with

$$\begin{aligned}\sigma_\mathrm{M}(\epsilon'_\mathrm{e}, \epsilon_\mathrm{e}) &= \frac{2\pi r_\mathrm{e}^2(\epsilon'_\mathrm{e}+1)^2}{\epsilon'_\mathrm{e}(\epsilon'_\mathrm{e}+2)}\left[\frac{1}{\epsilon_\mathrm{e}^2} + \frac{1}{(\epsilon'_\mathrm{e}-\epsilon_\mathrm{e})^2} + \frac{1}{(\epsilon'_\mathrm{e}+1)^2} - \frac{2\epsilon'_\mathrm{e}+1}{(\epsilon'_\mathrm{e}+1)^2\epsilon_\mathrm{e}(\epsilon'_\mathrm{e}-\epsilon_\mathrm{e})}\right] \\ \delta_{\mathrm{M},\delta}(\mu_\mathrm{e}, \mu_\delta) &= \delta\left(\mu_\mathrm{e} - \sqrt{\frac{\epsilon_\mathrm{e}}{\epsilon'_\mathrm{e}}\frac{\epsilon'_\mathrm{e}+2}{\epsilon_\mathrm{e}+2}}\right), \quad \epsilon_\mathrm{e} < \frac{(\epsilon'_\mathrm{e} - \epsilon_\mathrm{B})}{2}.\end{aligned}$$

A.6. Total cross section for Møller scattering of electrons [23].

$$\sigma_\mathrm{M}^\mathrm{tot}(\epsilon_\mathrm{e}) = \int_{\epsilon_\mathrm{B}}^{(\epsilon_\mathrm{e}-\epsilon_\mathrm{B})/2} \sigma_\mathrm{M}(\epsilon_\mathrm{e}, \epsilon'_\mathrm{e}) d\epsilon'_\mathrm{e}.$$

The lower limit of integration is due to the fact that the primary electron can be scattered only if at least the binding energy ϵ_B is transferred to the secondary electron

(of a tissue molecule). Besides the evident motivation of this choice based on our model, this is a standard way to avoid singularities in calculating total cross sections (see, e.g., [39]). The upper limit of integration is due to the fact that the primary electron has larger energy than the secondary electron and that the binding energy ϵ_{B} was introduced into the scattering processes (usually the upper limit is $\epsilon'_{\mathrm{e}}/2$). One gets

$$\sigma_{\mathrm{M}}^{\mathrm{tot}}(\epsilon_{\mathrm{e}}) = \frac{2\pi r_{\mathrm{e}}^2(\epsilon_{\mathrm{e}}+1)^2}{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)} \times \left\{ \frac{1}{\epsilon_{\mathrm{B}}} - \frac{3}{\epsilon_{\mathrm{e}}-\epsilon_{\mathrm{B}}} + \frac{2}{\epsilon_{\mathrm{e}}+\epsilon_{\mathrm{B}}} + \frac{\epsilon_{\mathrm{e}}-3\epsilon_{\mathrm{B}}}{2(\epsilon_{\mathrm{e}}+1)^2} + \frac{2\epsilon_{\mathrm{e}}+1}{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+1)} g\left[\ln\frac{\epsilon_{\mathrm{e}}+\epsilon_{\mathrm{B}}}{\epsilon_{\mathrm{e}}-\epsilon_{\mathrm{B}}} - \ln\frac{\epsilon_{\mathrm{e}}-\epsilon_{\mathrm{B}}}{\epsilon_{\mathrm{B}}} g \right] \right\}.$$

A.7. Differential cross section for Mott scattering of electrons [28, 26]. $\alpha \approx 1/137$ is the fine structure constant, and Z is the atomic number of the irradiated medium. Z depends on r to account for heterogeneous media.

$$\begin{aligned}\sigma_{\mathrm{Mott}}(r,\epsilon_{\mathrm{e}},\Omega'_{\mathrm{e}}\cdot\Omega_{\mathrm{e}}) &= \frac{Z^2(r) r_{\mathrm{e}}^2 (mc^2)^2}{4p^2c^2\beta^2 \sin^4\frac{\vartheta_{\mathrm{e}}}{2}} \left[1 - \beta^2 \sin^2\frac{\vartheta_{\mathrm{e}}}{2} + Z\pi\alpha\beta \sin\frac{\vartheta_{\mathrm{e}}}{2}\left(1-\sin\frac{\vartheta_{\mathrm{e}}}{2}\right)\right] \\ &\approx \frac{Z^2(r) r_{\mathrm{e}}^2 (mc^2)^2}{4p^2c^2\beta^2 \sin^4\frac{\vartheta_{\mathrm{e}}}{2}} \left[1 - \beta^2 \sin^2\frac{\vartheta_{\mathrm{e}}}{2}\right],\end{aligned}$$

with $\beta^2 = \frac{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)}{(\epsilon_{\mathrm{e}}+1)^2}$. The last approximation is justified, because in the energy range studied here and for typical low-Z media like water only small errors are made.

To avoid the singularity at $\vartheta_{\mathrm{e}} = 0$ a screening parameter η can be introduced [40] that models the screening effect of the electrons of the atomic shell:

$$\sigma_{\mathrm{Mott}}(r,\epsilon_{\mathrm{e}},\Omega'_{\mathrm{e}}\cdot\Omega_{\mathrm{e}}) = \frac{Z^2(r) r_{\mathrm{e}}^2 (1+\epsilon_{\mathrm{e}})^2}{4[\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)]^2(1+2\eta(r,\epsilon_{\mathrm{e}})-\cos\vartheta_{\mathrm{e}})^2} \left[1 - \frac{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)}{(1+\epsilon_{\mathrm{e}})^2} \sin^2\frac{\vartheta_{\mathrm{e}}}{2}\right]$$

with

$$\eta(r,\epsilon_{\mathrm{e}}) = \frac{\pi^2\alpha^2 Z^{\frac{2}{3}}(r)}{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)}.$$

A.8. Total cross section for Mott scattering of electrons.

$$\sigma_{\mathrm{Mott}}^{\mathrm{tot}}(r,\epsilon_{\mathrm{e}}) = \frac{\pi(Z(r)r_{\mathrm{e}})^2}{\epsilon_{\mathrm{e}}(\epsilon_{\mathrm{e}}+2)} \times \left[\frac{(\epsilon_{\mathrm{e}}+1)^2}{(\pi\alpha)^2 Z^{2/3}(r)(1+\eta(r,\epsilon_{\mathrm{e}}))} + \frac{1}{1+\eta(r,\epsilon_{\mathrm{e}})} + \ln\eta(r,\epsilon_{\mathrm{e}}) - \ln(1+\eta(r,\epsilon_{\mathrm{e}}))\right]$$

NONLINEAR ANALYSIS IN THE AW–RASCLE ANTICIPATION MODEL OF TRAFFIC FLOW*

ZHONG-HUI OU†, SHI-QIANG DAI†, PENG ZHANG†, AND LI-YUN DONG†

Abstract. In this paper, the Aw–Rascle anticipation (ARA) model is discussed from the perspective of the capability to reproduce nonlinear traffic flow behaviors observed in real traffic. For this purpose, a nonlinear traffic flow stability criterion is derived by using a wavefront expansion technique. The result of the nonlinear stability analysis can be used not only to judge the stability evolution of an initial traffic state but also to determine the pressure term in the ARA model. The KdV equation is derived from the ARA model added by the viscous term with the use of the reduction perturbation method. The soliton solution can be analytically obtained from the perturbed KdV equation only near the neutral stability line. Weighted essentially nonoscillatory schemes are employed to simulate the KdV soliton. The numerical results confirm the analytical KdV soliton solution.

1. Introduction.

A macroscopic model of vehicular traffic started with the first-order fluid approximation of traffic flow dynamics proposed by Lighthill, Whitham [1], and Richards [2] independently, i.e., the Lighthill–Whitham–Richards (LWR) model [3], which assumes the conservation of the number of vehicles and the equilibrium relation between flow and density. However, besides the continuity equation, one needs an extra dynamic velocity equation in order to describe the emergent traffic jams and stop-and-go traffic. This kind of two-equation model includes the Payne–Whitham (PW) model [4, 5, 1], the Kühne model [6, 7], the Kerner–Konhäuser (KK) model [8, 9], the Lee–Lee–Kim (LLK) model [10, 11], the gas-kinetic-based (GKT) model [12, 13, 14, 15], etc. But Daganzo pointed out that one characteristic velocity greater than the macroscopic fluid velocity in the two-equation models would lead to nonphysical effects [16]. Aw and Rascle replaced the space derivative of the "pressure" with a convective derivative in PW-type models to resolve the theoretical inconsistencies and then constructed the Aw–Rascle anticipation (ARA) model [17, 18, 19]. They discussed the solution to the Riemann problem and the admissibility of the elementary waves by the hyperbolic conservation laws in detail. Moreover, the ARA model is the typical form of the anisotropic traffic flow model, which can be reduced to other models from different viewpoints [20, 21].

A traffic flow model usually needs stability analysis and numerical simulation in the stable and unstable density regions in order to investigate the evolution of a traffic initial state [8, 12, 22, 20, 23, 24, 25, 26]. Since in the linear stability analysis higher-order terms are neglected, we propose a nonlinear stability analysis by utilizing

a wavefront expansion technique under large traffic disturbances. Moreover, some typical nonlinear waves such as the KdV soliton, triangular shock, and kink have been found through investigating the car-following models with the reduction perturbation method [27, 28, 29], but only Kurtze and Hong [30] and Berg and Woods [31] did similar work in the continuum model. The reduction perturbation method is more difficult to conduct in the continuum model than in the car-following model because the former has a much more complicated form than the latter. Therefore it is valuable for the anisotropic ARA model to make the nonlinear stability and wave analysis in traffic flow.

This paper is arranged as follows. We take the nonlinear stability analysis on the ARA model, and one stability criterion is used to determine the pressure term in section 2. The KdV equation is derived from the ARA model with the viscous term in section 3. Weighted essentially nonoscillatory schemes (WENO) schemes are used to simulate the KdV soliton in section 4. Concluding remarks are presented in section 5.

2. Nonlinear stability analysis. The ARA model is

$$\partial_t \rho + \partial_x(\rho v) = 0, \tag{1}$$

$$\partial_t(v + p(\rho)) + v\partial_x(v + p(\rho)) = \tau^{-1}(V(\rho) - v), \tag{2}$$

where $\rho(x,t)$ is the density at point x and time t, $v(x,t)$ is the velocity, τ is the relaxation time, $V(\rho)$ is the equilibrium function, $p(\rho) = \rho^\gamma$ is the pressure (the anticipation factor is more accurate), and γ is a positive constant which needs to be determined later [17]. The ARA model under conservative form is

$$\partial_t Y + \partial_x(f(Y)) = g(Y), \tag{3}$$

where the conservative vectors $Y = (\rho, y) = (\rho, \rho(v+p(\rho)))$, $f(Y) = (\rho v, \rho v(v+p(\rho)))$, and $g(Y) = \big(0, \tau^{-1}\rho(V(\rho) - v)\big)$.

The eigenvalues of (1) and (2) are

$$\lambda_1 = v - \rho p^{'}(\rho) \le \lambda_2 = v. \tag{4}$$

Formula (4) shows that all the waves propagate at a speed at most equal to the velocity v of the corresponding state. Daganzo has pointed out that continuum models (especially the hydrodynamic models) with one characteristic speed greater than the macroscopic fluid velocity encounter difficulties showing nonphysical effects in certain situations [16]. But the ARA model avoids these difficulties.

When the traffic jam happens, the density of the traffic jam is much higher than that of the neighboring section, so most traffic jams belong to large disturbances. When the disturbance is fairly large, the linearization method may produce incorrect results because of neglecting higher-order terms as pointed out by Whitham [1], which is the primary cause we propose a nonlinear stability analysis for traffic flow [1, 22, 23, 24]. If a disturbance starts at position x_0 in the homogeneous state of traffic flow, the wavefront is the propagation curve of the disturbance along the homogeneous traffic flow [1, 22, 23, 24]. The magnitude of the initial disturbance will not increase during its propagation if the traffic system is stable in propagation; otherwise, a disturbed density or velocity wave may increase in magnitude as it propagates upstream and ultimately form a shock wave or traffic jam on the highway. If the form of the initial density disturbance is given, the initial velocity disturbance can be determined by the equilibrium function. Furthermore, the profiles of density and velocity disturbances

are symmetrical to some degree along the x-axis in the simulation with the continuum model (e.g., monotone increase vs. monotone decrease, concavity vs. convexity, etc.) [8, 9, 15], which is still considered valid in the ARA model, and this fact will also be demonstrated by the following numerical simulation of the KdV soliton. Therefore, when we merely demand some mathematical assumptions for the density, they are automatically needed for the velocity, and most results are presented for either the density or the velocity. Assume that a disturbance initiates from the equilibrium state (ρ_0, v_0), the solutions of (1) and (2), in the homogeneous traffic flow. If the mth derivatives of ρ around the wavefront WF are the first ones to be discontinuous, the expanded Taylor series from ρ_0 starts with the term in the mth power of a small parameter, which is equally assumed for v_0. Without losing generality, we might as well assume that the first derivative of the density around the wavefront WF is discontinuous.

It is convenient to expand the solution of the system around the wavefront WF in powers of

$$\xi = x - X(t), \tag{5}$$

where $X(t)$ is the location of the wavefront WF at time t. Since the wavefront is the boundary of the disturbance in the homogeneous state, the characteristic method is still feasible in the near neighborhood of the wavefront WF. Therefore the wavefront has the characteristic velocity $v_{c1,2}$ in the equilibrium states, i.e.,

$$\dot{X}(t) = v_{c1,2}(\rho_0, v_0) = v_0 - \lambda_{1,2}. \tag{6}$$

Using (5), we can expand the flow variables ρ, v, their partial derivatives, $V(\rho)$ and $p_\rho(\rho)$, etc., in the power series of ξ as

$$\rho(x,t) = \rho_0 + \xi\rho_1(t) + \frac{1}{2}\xi^2\rho_2(t) + \cdots, \tag{7}$$

$$v(x,t) = v_0 + \xi v_1(t) + \frac{1}{2}\xi^2 v_2(t) + \cdots, \tag{8}$$

where

$$\rho_i(t) = \frac{\partial^i \rho}{\partial x^i}\bigg|_{(X(t)^-,t)}, \quad v_i(t) = \frac{\partial^i v}{\partial x^i}\bigg|_{(X(t)^-,t)}, \quad i = 1, 2, 3, \ldots,$$

$$\rho_t = -\dot{X}(t)\rho_1(t) + \xi\dot{\rho}_1(t) + \xi\left[-\dot{X}(t)\right]\rho_2(t) + \frac{1}{2}\xi^2\dot{\rho}_2(t) + \cdots, \tag{9}$$

$$\rho_x = \rho_1(t) + \xi\rho_2(t) + \frac{1}{2}\xi^2\rho_3(t) + \cdots, \tag{10}$$

$$v_t = -\dot{X}(t)v_1(t) + \xi\dot{v}_1(t) + \xi\left[-\dot{X}(t)\right]v_2(t) + \frac{1}{2}\xi^2\dot{v}_2(t) + \cdots, \tag{11}$$

$$v_x = v_1(t) + \xi v_2(t) + \frac{1}{2}\xi^2 v_3(t) + \cdots. \tag{12}$$

$$V(\rho) = V^0 + \xi V^0_\rho \rho_1(t) + \cdots, \tag{13}$$

where

$$V^0 = V(\rho_0) \quad \text{and} \quad V^0_\rho = \frac{\partial V}{\partial \rho}\bigg|_{(\rho_0, v_0)}.$$

$$p_\rho(\rho) = p^0_\rho + \xi p^0_{\rho\rho}\rho_1(t) + \cdots. \tag{14}$$

Substituting (7)–(14) into (1) and (2), for the coefficients of the first two terms ξ^0 and ξ^1, we obtain

$$u_0\rho_1 + \rho_0 v_1 = 0, \tag{15}$$

$$\dot{\rho}_1 + 2\rho_1 v_1 + u_0\rho_2 + \rho_0 v_2 = 0, \tag{16}$$

$$v_1 + p^0_\rho \rho_1 = 0, \tag{17}$$

$$u_0 v_2 + u_0 p^0_\rho \rho_2 + \dot{v}_1 + v_1^2 + p^0_\rho \dot{\rho}_1 + u_0 p^0_{\rho\rho} {\rho_1}^2 + v_1 p^0_\rho \rho_1 + \tau^{-1}\left(v_1 - V^0_\rho \rho_1\right) = 0, \tag{18}$$

where $u_0 = \lambda_{1,2}$.

Substituting (15) into (17) yields

$$u_0 - \rho_0 p^0_\rho = 0, \tag{19}$$

which shows that the coefficients of terms ρ_2 and v_2 are linearly dependent and can be eliminated from (16) and (18). Inserting $\rho_1 = -\rho_0 v_1/u_0$ obtained from (15) into (16) and (18) leads to the Bernoulli equation

$$\dot{v}_1 + \alpha v_1 + \beta v_1^2 = 0, \tag{20}$$

where

$$\alpha = \tau^{-1}\left(1 + \frac{V^0_\rho}{p^0_\rho}\right) \quad \text{and} \quad \beta = 2 + \frac{\rho_0 p^0_{\rho\rho}}{p^0_\rho} = \gamma + 1.$$

$\beta > 0$, if $p(\rho) = \rho^\gamma, \gamma > 0$.

If $\alpha = 0$, the solution of (20) is

$$v_1(t) = \frac{v_1(0)}{\beta v_1(0) t + 1}, \tag{21}$$

whose monotonicity is determined by

$$v_1'(t) = -\frac{\beta v_1^2(0)}{\left(\beta v_1(0) t + 1\right)^2}. \tag{22}$$

This situation is depicted in Figure 1.

If $\alpha \neq 0$, (20) has two constant solutions,

$$v_1^1(t) \equiv 0 \quad \text{and} \quad v_1^1(t) \equiv -\frac{\alpha}{\beta}, \tag{23}$$

and a general solution,

$$v_1(t) = \frac{\alpha}{\beta}\frac{e^{-\alpha t}}{\left[1 + \frac{\alpha}{\beta v_1(0)}\right] - e^{-\alpha t}}, \tag{24}$$

whose monotonicity is determined by

$$v_1'(t) = -\frac{\alpha^2}{\beta}\frac{\left[1 + \frac{\alpha}{\beta v_1(0)}\right] e^{-\alpha t}}{\left\{\left[1 + \frac{\alpha}{\beta v_1(0)}\right] - e^{-\alpha t}\right\}^2}. \tag{25}$$

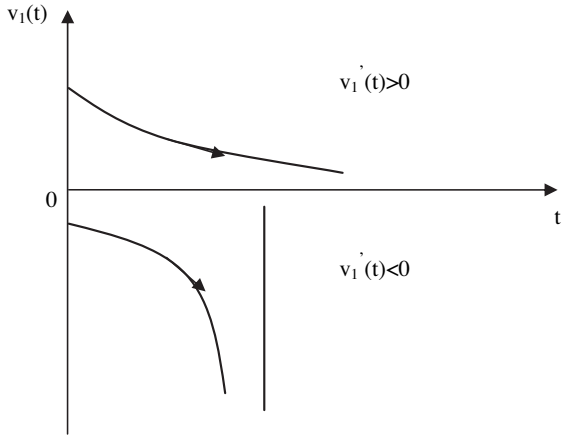

FIG. 1. $\alpha = 0$, $\beta > 0$. $v_1(t)$ *is the partial derivative of velocity.*

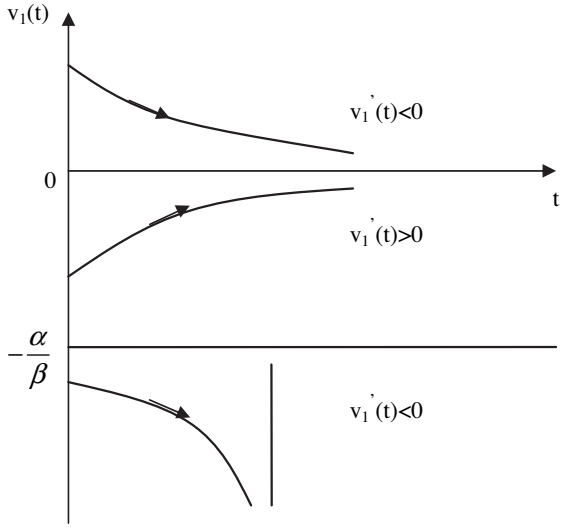

FIG. 2. $\alpha > 0$, $\beta > 0$.

This situation is depicted in Figures 2 and 3. Therefore we can judge the trend of $v_1(t)$ in the light of the parameter α and the initial equilibrium state according to Table 1. Without loss of generality, if the density disturbance is upward, the velocity perturbation is downward, i.e., $v_1(0) < 0$. If $v_1(0) \in [-\alpha/\beta, 0]$, $\alpha > 0$, i.e.,

$$V_\rho > -p_\rho. \tag{26}$$

The system is stable for traffic flow disturbances; otherwise, the system is unstable under $v_1(0) < 0$ and $\alpha < 0$, which is identical to the linear stability criterion. The linear stability result is usually only one condition obtained from the nonlinear analysis [22, 23]. Furthermore, the nonlinear stability results predict the ultimate trend of the slope of disturbance around the wavefront WF, i.e., converging to zero or diverging to negative infinity, which cannot be obtained from the linear stability analysis.

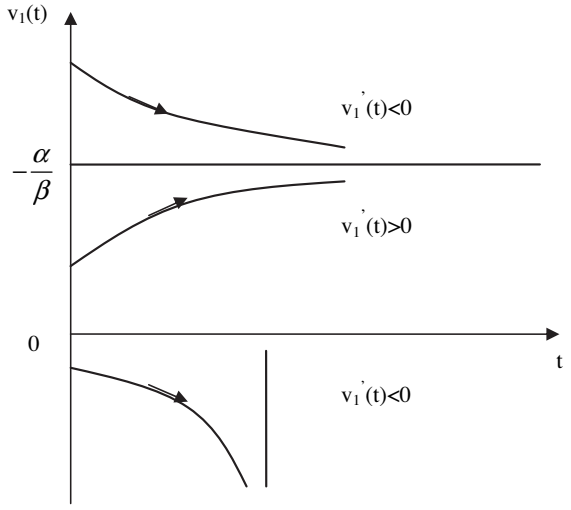

FIG. 3. $\alpha < 0$, $\beta > 0$.

TABLE 1
Stability conditions of (20).

α	Stable region	Unstable region
$\alpha > 0$	$v_1(0) \in (-\frac{\alpha}{\beta}, +\infty), v_1(t) \to 0$	$v_1(0) \in (-\infty, -\frac{\alpha}{\beta}), v_1(t) \to -\infty$
$\alpha = 0$	$v_1(0) \in (0, +\infty), v_1(t) \to 0$	$v_1(0) \in (-\infty, 0), v_1(t) \to -\infty$
$\alpha < 0$	$v_1(0) \in [0, +\infty), v_1(t) \to -\frac{\alpha}{\beta}$	$v_1(0) \in (-\infty, 0), v_1(t) \to -\infty$

Hydrodynamic models with equilibrium functions have been used to obtain reliable results which can reflect the real traffic [8, 9, 12, 15]. Although the ARA model doesn't belong to the hydrodynamic model, they are both higher-order continuum models, and we substitute the abstract form in the ARA model with the equilibrium functions given in previous hydrodynamic models, which are related to the time-independent and homogeneous traffic flow and are fitted by empirical data [4, 5, 8]. Some equilibrium functions established recently actually approach each other in the fundamental diagram [23, 24], and we choose a representative one, i.e., the KK equilibrium function first used in the KK model [8, 9], to displace the abstract form in the ARA model:

$$V(\rho) = V_f \left[\left(1 + \exp\left\{ \frac{\frac{\rho}{\rho_j} - 0.25}{0.06} \right\} \right)^{-1} - 3.72 \times 10^{-6} \right], \tag{27}$$

where V_f is the free flow velocity and ρ_j is the jam density. The KK equilibrium function is a monotonously decreasing function with respect to ρ, reaches the minimum 0 at the jam density, and possesses a turning point which is necessary for the derivation of the modified KdV equation [28, 29]. Moreover, stability criteria dependent on the equilibrium function need to contain the unstable condition because the traffic flow is unstable in one density or velocity subinterval.

The stability distribution of continuum traffic flow models along the whole density range abides by the following rule: stable at low density $\longrightarrow$ metastable $\longrightarrow$ unstable at medium density $\longrightarrow$ metastable $\longrightarrow$ stable at higher density, and in general the

dimensionless unstable density region is about $(0.15, 0.4)$ [8, 9, 23, 24]. According to this rule, we can determine the range of the pressure parameter by (26) with the KK equilibrium function:

$$p(\rho) = \rho^\gamma, \quad 0.1 < \gamma < 1.2. \tag{28}$$

Up to now, the propagation stability for (1) and (2) can thus be analyzed in terms of the initial condition $v_1(0)$ and the parameter α, and the pressure term has been determined by the stability criterion and the KK equilibrium function. We have programmed the completed ARA model with WENO schemes and succeeded in simulating the cluster and KdV soliton (the latter will be described in detail in section 4), which shows that the ARA model possesses the same numerical-simulation capability as other continuum models and the method of determining the pressure term is reasonable.

3. KdV equation. In order to obtain the unique weak solution of the nonlinear hyperbolic equation according to the weak solution theory and smoothing numerical solution, the continuum models always contain viscous terms, e.g., the KK model and the LLK model [8, 9, 10, 11]. Therefore it is necessary especially for the derivation of the KdV equation that the right-hand side of (2) be added by a higher-order viscous term, e.g., $\mu\partial_x^2 v$, $\mu > 0$, for a stable solution [9, 15, 30, 31]. We decompose the traffic flow into a linear combination of Fourier modes, each of which grows or decays with its own growth rate [30]. Thus we write

$$\rho(x,t) = \rho_0 + \sum_k \hat{\rho}_k \exp(ikx + \sigma_k t), \tag{29}$$

$$v(x,t) = v_0 + \sum_k \hat{v}_k \exp(ikx + \sigma_k t). \tag{30}$$

Substitute (29) and (30) into (1) and (2) with the viscous term, and linearize in $\hat{\rho}_k$ and $\hat{v}_k$. We find that each linear growth rate σ_k must satisfy the quadratic equation

$$0 = (ikv_0 + \sigma_k)^2 + \left(\frac{\mu}{\rho_0}k^2 - i\gamma{\rho_0}^\gamma k + \tau^{-1}\right)(ikv_0 + \sigma_k) + i\tau^{-1}V'\rho_0 k. \tag{31}$$

Both roots of (31) have negative real parts provided

$$V_\rho^0 + \gamma\rho_0^{\gamma-1} > 0, \tag{32}$$

while otherwise one root has a positive real part. (32) is an equivalent form of (26). (29)–(32) are the products of one kind of linear stability method, and the traffic flow is stable against all infinitesimal disturbances if they satisfy the linear stability condition (32). The neutral stability condition is

$$\eta \equiv V_\rho + \gamma\rho^{\gamma-1}|_{\rho=\rho_0} = 0. \tag{33}$$

The nonlinear stability analysis in section 2 is to take Taylor series expansions at the location of the wavefront, retain the constant and the first-order terms, obtain an ordinary differential equation, and finally determine the stability conditions by the convergence of solutions. However, the linear stability analysis in this section is to take Fourier series expansions with respect to the density and the velocity, linearize in the small density and velocity disturbances, obtain a quadratic equation of the growth rate

of Fourier modes, and ultimately determine the stability conditions only by judging the sign of the real parts of roots of the quadratic equation. The linear stability analysis cannot accurately distinguish each stability condition or present the stability evolution like Table 1. Moreover, there is another easier method to judge the stability according to the wave propagation rule: a higher-order partial differential equation with respect to small disturbances of the density and velocity can be obtained after the linearization of (1) and (2), the propagation speeds in the highest-order derivatives always determine the fastest and slowest signals, and the kinematic wave speed must intervene between the speeds of the fastest and slowest signals [1]. This is the so-called subcharacteristic condition, which is exactly another linear stability criterion [32]. Compared with the subcharacteristic conditions, the linear stability analysis listed in (29)–(33) also has its own advantage, i.e., some further results about the frequency and amplitude of the complex function can be worked out as follows [30].

Expanding (31) with ik near the neutral stability point yields

$$\sigma_k = -c(\rho_0)ik + \tau {\rho_0}^2 V_\rho^0 \eta k^2 + \mu\tau V_\rho^0 ik^3 - \mu\tau^2 V_\rho^0 \left(2\rho_0 V_\rho^0 + \gamma {\rho_0}^\gamma\right) k^4 + O(k^5), \tag{34}$$

where $c(\rho_0) = v_0 + \rho_0 V_\rho^0$ is the wave velocity, i.e., (6). Suppose the density of traffic flow near the neutral stability point is slightly perturbed. We quantify this supposition by writing

$$\eta = V'(\rho_0 + \delta\rho) + p'(\rho_0 + \delta\rho) = (V_{\rho\rho}^0 + p_{\rho\rho}^0)\delta\rho \equiv \theta\xi^2. \tag{35}$$

We consider the slowly varying behavior at long wavelengths near the neutral stability line. We wish to extract slow scales for space variable x and time variable t. The real part of (34) is $\tau {\rho_0}^2 V_\rho^0 \eta k^2$ and $-\mu\tau^2 V_\rho^0 \left(2\rho_0 V_\rho^0 + \gamma {\rho_0}^\gamma\right) k^4$. In order to balance the two terms, k scales as $k \propto \xi$, which leads to the scaling relation $x \propto \xi^{-1}$. The imaginary part of (34) is $-c(\rho_0)ik$ and $\mu\tau V_\rho^0 ik^3$. Since $-c(\rho_0)ik$ can be eliminated by a reference frame moving with the velocity $c(\rho_0)$, t scales as $t \propto \xi^{-3}$. Therefore we define the slow variables X and T [30, 27, 28, 29]:

$$X = \xi(x - ct) \qquad \text{and} \qquad T = \xi^3 t. \tag{36}$$

Finally we expect that an amplitude equation would balance the linear growth term of order $\xi^4 A$ with a stabilizing nonlinear term of order A^3; thus, we expect that the disturbance saturates at a size of order ξ^2. We implement the scalings by writing

$$\rho(x,t) = \rho_0 + \xi^2 \hat{\rho}(X,T), \tag{37}$$

$$v(x,t) = v_0 + \xi^2 \hat{v}(X,T). \tag{38}$$

Expanding each term in (1) and (2) added by $\mu\partial_x^2 v$ to the fifth order of ξ leads to the following nonlinear partial differential equations:

$$\xi^3 \left(-c\frac{\partial\hat{\rho}}{\partial X} + \rho_0\frac{\partial\hat{v}}{\partial X} + v_0\frac{\partial\hat{\rho}}{\partial X}\right) + \xi^5 \left(\frac{\partial\hat{\rho}}{\partial T} + \hat{\rho}\frac{\partial\hat{v}}{\partial X} + \hat{v}\frac{\partial\hat{\rho}}{\partial X}\right) = 0, \tag{39}$$

$$\begin{aligned}
&\xi^2\left(\rho_0\hat{v} - \rho_0 V_\rho^0\hat{\rho}\right) + \xi^3\left(-c\tau\rho_0\frac{\partial\hat{v}}{\partial X} + V\tau\rho_0\frac{\partial\hat{v}}{\partial X} - c\tau\gamma{\rho_0}^\gamma\frac{\partial\hat{\rho}}{\partial X} + V\tau\gamma{\rho_0}^\gamma\frac{\partial\hat{\rho}}{\partial X}\right)\\
&+\xi^4\left(\hat{\rho}\hat{v} - V_\rho^0\hat{\rho}^2 - \frac{1}{2}\rho_0 V_{\rho\rho}^0\hat{\rho}^2 - \mu\tau\frac{\partial^2\hat{v}}{\partial X^2}\right) + \xi^5\left(\tau\rho_0\frac{\partial\hat{v}}{\partial T} + \tau\gamma{\rho_0}^\gamma\frac{\partial\hat{\rho}}{\partial X} + \tau\rho_0\hat{v}\frac{\partial\hat{v}}{\partial X}\right.\\
&\left.-\tau c\hat{\rho}\frac{\partial\hat{v}}{\partial X} + \tau V^0\hat{\rho}\frac{\partial\hat{v}}{\partial X} + \tau\gamma{\rho_0}^\gamma\hat{v}\frac{\partial\hat{\rho}}{\partial X} - c\tau\gamma^2{\rho_0}^{\gamma-1}\hat{\rho}\frac{\partial\hat{\rho}}{\partial X} + V^0\tau\gamma^2{\rho_0}^{\gamma-1}\hat{\rho}\frac{\partial\hat{\rho}}{\partial X}\right) = 0.
\end{aligned} \tag{40}$$

The third-order term of ξ can be rewritten as

(41)
$$\xi^3\left(-c\tau\rho_0\frac{\partial\hat{v}}{\partial X}+V\tau\rho_0\frac{\partial\hat{v}}{\partial X}-c\tau\gamma{\rho_0}^{\gamma}\frac{\partial\hat{\rho}}{\partial X}+V\tau\gamma{\rho_0}^{\gamma}\frac{\partial\hat{\rho}}{\partial X}\right)=-\xi^5\left(\theta\tau V_\rho^0\rho_0^2\frac{\partial\hat{\rho}}{\partial X}\right).$$

From the second-order term of ξ, we obtain

$$\hat{v}=V_\rho^0\hat{\rho}+O(\xi^2). \tag{42}$$

From the fourth-order and fifth-order terms of ξ, we obtain

$$\begin{aligned}\hat{q}\equiv\hat{\rho}\hat{v}=&\left(V_\rho^0+\frac{1}{2}\rho_0V_{\rho\rho}^0\right)\hat{\rho}^2+\mu\tau\frac{\partial^2\hat{v}}{\partial X^2}+\xi\tau\rho_0\left\{\tau\mu{V_\rho^0}^2\frac{\partial^3\hat{\rho}}{\partial X^3}+\left(\theta V_\rho^0\rho_0-\gamma{\rho_0}^{\gamma-1}\right)\frac{\partial\hat{\rho}}{\partial X}\right.\\&\left.+\left[2{V_\rho^0}^2+\rho_0V_\rho^0V_{\rho\rho}^0+(\gamma-\gamma^2)V_\rho^0{\rho_0}^{\gamma-1}\right]\hat{\rho}\frac{\partial\hat{\rho}}{\partial X}\right\}.\end{aligned} \tag{43}$$

Substituting (43) into the fifth-order term of ξ in (39) leads to the KdV equation with the perturbed term:

$$\begin{aligned}&\frac{\partial\hat{\rho}}{\partial T}+\left(2V_\rho^0+\rho_0V_{\rho\rho}^0\right)\hat{\rho}\frac{\partial\hat{\rho}}{\partial X}+\tau\mu V_\rho^0\frac{\partial^3\hat{\rho}}{\partial X^3}=-\xi\tau\rho_0\frac{\partial^2}{\partial X^2}\left\{\tau\mu{V_\rho^0}^2\frac{\partial^2\hat{\rho}}{\partial X^2}\right.\\&\left.+\left(\theta V_\rho^0\rho_0-\gamma{\rho_0}^{\gamma-1}\right)\hat{\rho}+\frac{1}{2}\left[2{V_\rho^0}^2+\rho_0V_\rho^0V_{\rho\rho}^0+(\gamma-\gamma^2)V_\rho^0{\rho_0}^{\gamma-1}\right]\hat{\rho}^2\right\}.\end{aligned} \tag{44}$$

In order to derive the regularized equation, we make the following transformations:

$$\hat{\rho}=\frac{-h}{2V_\rho^0+\rho_0V_{\rho\rho}^0}\hat{\rho}',\quad X=-\sqrt{\frac{-\tau\mu V_\rho^0}{h}}X',\quad\text{and}\quad T=\sqrt{\frac{-\tau\mu V_\rho^0}{h^3}}T', \tag{45}$$

where h is a constant. With the use of (45), one obtains the regularized equation:

$$\frac{\partial\hat{\rho}'}{\partial T'}+\hat{\rho}'\frac{\partial\hat{\rho}'}{\partial X'}+\frac{\partial^3\hat{\rho}'}{\partial X'^3}=-\xi A_1\frac{\partial^2}{\partial X'^2}\left[A_2\frac{\partial^2\hat{\rho}'}{\partial X'^2}+A_3\hat{\rho}'+A_4\hat{\rho}'^2\right], \tag{46}$$

where A_1, A_2, A_3, and A_4 are constant coefficients. If one ignores the $O(\varepsilon)$ terms in (46), it is just the KdV equation with a soliton solution as the desired solution:

$$\hat{\rho}'(X',T')=A\,\mathrm{sech}^2\left[\sqrt{\frac{A}{12}}\left(X'-\frac{A}{3}T'\right)\right]. \tag{47}$$

Amplitude A of soliton solutions of the KdV equation is a free parameter. The disturbance term $O(\xi)$ of the perturbed KdV equation (46) selects a unique member of the continuous family of KdV solitons.

Next, assuming that $\hat{\rho}'(X',T')=\hat{\rho}_0'(X',T')+\xi\hat{\rho}_1'(X',T')$, we take into account the $O(\xi)$ correction. In order to determine the selected value of A for the soliton solution (47), it is necessary to satisfy the solvability condition:

$$(\hat{\rho}_0',M[\hat{\rho}_0'])\equiv\int_{-\infty}^{\infty}\hat{\rho}_0'M[\hat{\rho}_0']dX'=0, \tag{48}$$

where $M[\hat{\rho}_0']$ is the $O(\xi)$ term of (46).

By performing the integration in the solvability condition (48), one obtains the selected value

$$A = -\frac{7\theta\rho_0\left(2V_\rho^0 + \rho_0 V_{\rho\rho}^0\right)}{4h(1-\gamma)V_\rho^0}. \tag{49}$$

Rewriting each variable to the original one leads to the soliton solution of the density:

$$\rho = \rho_0 + \frac{7\eta\rho_0}{4(1-\gamma)V_\rho^0}\operatorname{sech}^2\left\{\sqrt{\frac{7\eta\rho_0\left(2V_\rho^0+\rho_0V_{\rho\rho}^0\right)}{48\tau\mu(1-\gamma){V_\rho^0}^2}}\left[x - ct + \frac{7\eta\rho_0\left(2V_\rho^0+\rho_0V_{\rho\rho}^0\right)}{12(1-\gamma)V_\rho^0}t\right]\right\}. \tag{50}$$

4. Numerical schemes. In this section, we will use the KdV soliton simulation to examine the analytical solution (50) and also to demonstrate that the ARA model can be used to reproduce the nonlinear traffic behaviors in real traffic. Because the solitary wave is a constant-shape traveling wave solution, we use WENO schemes to conduct numerical simulation. WENO schemes are high-order accurate finite difference schemes designed for the problems with piecewise smooth solutions containing discontinuities for hyperbolic conservation laws. The key idea lies at the approximation level, where a nonlinear adaptive procedure is used to automatically choose the locally smoothest stencil, hence avoiding crossing discontinuities in the interpolation procedure as much as possible. WENO schemes have been quite successful in applications, especially for problems containing both shocks and complicated smooth solution structures [33, 34, 35]. Because (3) with the viscous term is in the hyperbolic conservative form, λ_1 admits either shock waves or rarefactions, and $v_1(t)$ in (21) may be divergent, WENO schemes fit for the simulation of a unique smooth solution of nonlinear hyperbolic equations. Therefore, WENO schemes developed in [33, 34, 35] will be used in the following.

Let $\hat{f}$ be the numerical flux function corresponding to the flux f of (3) with the viscous term. Then, a standard conservative scheme of (3) with the viscous term reads as follows:

$$\frac{dY_i}{dt} + \frac{1}{\triangle x}(\hat{f}_{i+1/2} - \hat{f}_{i-1/2}) = g(Y_i). \tag{51}$$

In the following, the numerical flux $\hat{f}_{i+1/2}$ is reconstructed by the WENO method through the Lax–Friedrichs flux splitting. The third-order accurate WENO finite difference scheme applies the cell point values $\{Y_j\}_{j=i-1}^{i+1}$ to reconstruct $Y_{i+1/2}^-$, which is the cell boundary value of $x_{i+1/2}$ on the left-hand side. With $\{Y_j\}_{j=i}^{i+2}$, $Y_{i+1/2}^+$ is similarly constructed and is the cell boundary value of $x_{i+1/2}$ on the right-hand side. Thus, we use the Lax–Friedrichs numerical flux as follow:

$$\hat{f}_{i+1/2} = \frac{1}{2}\left[f\left(Y_{i+1/2}^-\right) + f\left(Y_{i+1/2}^+\right) - \alpha\left(Y_{i+1/2}^+ - Y_{i+1/2}^-\right)\right]. \tag{52}$$

(51) and (52) constitute a complete semidiscretized scheme. We apply the third-order accurate TVD Runge–Kutta time discretization, for which the semidiscrete scheme (51) is written as the ODEs: $Y_t = L(Y)$.

The equilibrium function in (1) and (2) with the viscous term is displaced by (27), and the dimensionless unstable region of the traffic system (3) with the viscous term, $(0.105, 0.414)$, can be obtained from (26) or (32). We design a density disturbance in

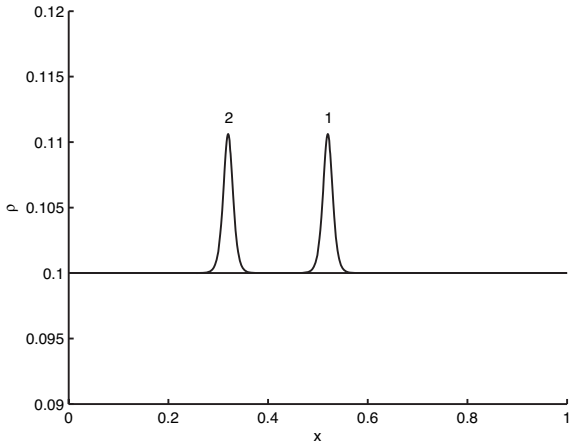

FIG. 4. *The analytical solution with* $\mu = 0.05$, (50).

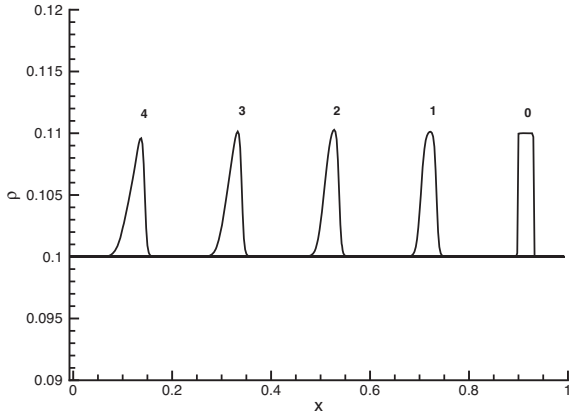

FIG. 5. *The numerical density solution in* 0, $0\triangle t$; 1, $3000\triangle t$; 2, $6000\triangle t$; 3, $9000\triangle t$; *and* 4, $12000\triangle t$.

the steady state as an initial condition:

$$\rho(x,0) = \begin{cases} \rho_0 + \hat{\rho} & x_0 - l \le x \le x_0 + l, \\ \rho_0 & \text{otherwise}, \end{cases} \tag{53}$$

where $\hat{\rho}$ is a small perturbation. The initial velocity is given by (27). The basic parameters are the pressure parameter $\gamma = 0.8$, the free velocity $v_f = 30$ m/s, the road length $L = 15000$ m, the relaxation time $\tau = 12$ s, the space interval $\triangle x = 37.5$ m, the perturbed radius $l = 0.03L$, and the dimensionless viscous coefficient $\mu = 0.05$ (see [10, 11]). The time interval $\triangle t$ must be less than 0.084 s for the numerical convergence, and we choose $\triangle t = 0.042$ s [11].

We have indeed obtained the numerical and analytical solutions of the KdV soliton near the neutral stability line as shown in Figures 4–6. In Figure 5, curve-1 is still affected by the initial condition (53) in $3000\triangle t$, and curve-2 in $6000\triangle t$ and curve-3 in $9000\triangle t$ are basically consistent with the analytic results in Figure 4. The amplitude, wave propagation velocity, and the basic shape of the numerical results are close to

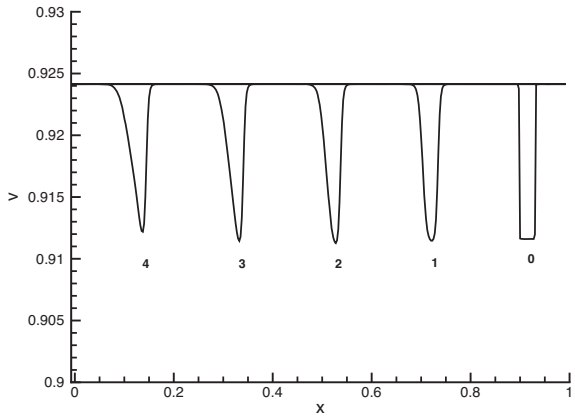

FIG. 6. *The numerical velocity solution in* 0, $0\triangle t$; 1, $3000\triangle t$; 2, $6000\triangle t$; 3, $9000\triangle t$; *and* 4, $12000\triangle t$.

those of the analytical solution, but the former are smoother than the latter, which may be caused by the numerical viscosity or the omission of the terms of the sixth and higher orders in the asymptotic expansion. Therefore the reduction perturbation method is superior to the semianalytical explanation in [31]. However, curve-4 in $12000\triangle t$ in Figure 5 shows that the dissipation term may decrease the amplitude, broaden the distribution, and contribute to an asymmetric effect. The propagation situation of the velocity is shown in Figure 6: the perturbed velocity profile is nearly symmetric to the perturbed density profile along the x-axis except the amplitude, which has examined our viewpoints in section 2. The consistency between the analytical and numerical results demonstrates that the reduction perturbation method in the continuum model originated by Kurtze and Hong [30] and further developed in this paper can really give the reasonable KdV soliton solution for traffic flow.

5. Summary. Considering that the previous two-equation models mimicked the gas dynamics equations with an unrealistic dependence on the acceleration with respect to the space derivative of the traffic pressure and consequently led to nonphysical effects, Aw and Rascle proposed the ARA model by replacing the space derivative with a convective derivative and rigidly discussed the solution to the Riemann problem and the admissibility of the elementary waves by the hyperbolic conservation laws. In this paper, we have discussed the application of the ARA model to investigating the traffic flow by the nonlinear stability and wave analyses. We have taken the nonlinear stability analysis on the ARA model through the wavefront expansion method. In comparison with the linear stability analysis, the nonlinear stability analysis additionally gives the analytical solution of the slope of the wavefront, and then the evolution of disturbances with time can be illuminated by stability parameters and initial conditions. We used the stability results to determine the anticipation factor. We obtained the KdV equation and analytical soliton solution from the "viscous" ARA model near the neutral stability line by extracting slow scales for space and time variables with the reduction perturbation method. The derivation of the KdV equation in the viscous continuum ARA model is similar to that in the car-following models but is more difficult because the continuum model has two equations. We applied WENO schemes to simulating the KdV soliton, and the simulation result is consistent with the analytical solution of the soliton density wave.

Acknowledgment. The authors are deeply appreciative to the referees for the insight represented in their constructive comments and suggestions.

AN EXACT EQUATION FOR THE FREE SURFACE OF A FLUID IN A POROUS MEDIUM*

WILLIAM ARTILES† AND ROBERTO A. KRAENKEL†

Abstract. We study the problem of the evolution of the free surface of a fluid in a saturated porous medium, bounded from below by a flat impermeable bottom, and described by the Laplace equation with moving-boundary conditions. By making use of a convenient conformal transformation, we show that the solution to this problem is equivalent to the solution of the Laplace equation on a fixed domain, with new variable coefficients, the boundary conditions. We use a kernel of the Laplace equation which allows us to write the Dirichlet-to-Neumann operator, and in this way we are able to find an *exact* differential-integral equation for the evolution of the free surface in one space dimension. Although not amenable to direct analytical solutions, this equation turns out to allow an easy numerical implementation. We give an explicit illustrative case at the end of the article.

Key words. free surface evolution, flow in porous media, mathematical modeling, conformal transformation, Dirichlet-to-Neumann, groundwater flow

1. Introduction.

In this work we shall address a conceptually simple, yet until now not fully solved, question: given a fluid totally contained in a homogeneous, saturated, porous medium, bounded from below by a flat impermeable bottom and with a free deformable surface above, write down the evolution equation for the free surface in the case where the fluid can be considered two-dimensional and unbounded in the horizontal direction.

This is a classical problem. It is mathematically expressed by the Laplace equation in two dimensions, with boundary conditions on an unknown, time-dependent, boundary. As will be clear from the equations in the next section, its solution corresponds to the determination of a Dirichlet-to-Neumann operator. The usual way to tackle it is by a perturbative approach. Small parameters are introduced, measuring the relative amplitude of the motion and the longness of the perturbation:

$$\alpha = \frac{a}{h_0}, \qquad \beta = \left(\frac{h_0}{\lambda}\right)^2, \tag{1.1}$$

where a is the amplitude of the surface displacement, h_0 is the unperturbed depth, and λ is the typical wavelength of the perturbation. When $\beta \ll 1$ we have the *Dupuit approximation*, corresponding to the physical assumption of hydrostatic motion. Its use, together with the Darcy law, leads through an asymptotic expansion to the Boussinesq equation for the total thickness of the fluid [1], which in convenient nondimensional variables (see below) reads simply

$$h_t = (h_x h)_x. \tag{1.2}$$

Equation (1.2) has been widely studied, not only in the context of porous media dynamics, but in such areas as high temperature gas dynamics [2] or convective instabilities [3]. Although not an integrable equation, its long-time behavior is known, being dominated by the self-similar solution, for localized initial data [4]. These self-similar solutions exhibit shocks, that is, propagating regions where the first derivative is singular. One speaks of diffusive waves to characterize these solutions.

Extensions of the Boussinesq equation have been proposed, in the same perturbation theoretic spirit, by several authors, encompassing higher order expansions in the longness parameter [5, 6, 7] together with a small α [8]. Still other works introduce a new perturbative parameter, the steepness $\alpha\sqrt{\beta}$ [9]. For localized initial conditions, the above-mentioned shocks become smoothed out, and we have propagating fronts.

A great analogy exists between the present problem and the determination of the evolution of a free surface of an inviscid fluid, the water-wave problem with the same two-dimensional geometry. Again, one studies the two-dimensional Laplace equation with a free boundary, but with different boundary conditions, and the determination of the evolution of the free surface is again equivalent to the determination of a Dirichlet-to-Neumann operator. Perturbative expansions have been widely used, dating back to the nineteenth century [10]. The same parameters α and β as above come into play. Assuming $\alpha \ll 1$ and $\beta \ll 1$ with $\mathcal{O}(\alpha) \approx \mathcal{O}(\beta)$ results in the asymptotic theory named *long waves in shallow water* and described by the Boussinesq system of equations, or the Benney–Luke equations [11], or the Korteweg–de Vries equation (for waves in a given direction) and its asymptotic equivalents, like the Kaup–Boussinesq [12] or the Benjamin–Bona–Mahoney–Peregrine equations [13, 14]. Alternatively, one can also directly expand the Dirichlet-to-Neumann operator in a Fourier series (due to a result on the analyticity of the Dirichlet-to-Neumann operator given in [15]), leading to numerically efficient integration schemes [16, 17]. So-called fully dispersive waves, where no assumption on β is made, have been obtained by making use of properties of harmonic functions, which is natural in the context of the two-dimensional Laplace equation, in [18]. Extensions to waves over variable topography have been obtained in [19] by using results on an analytical representation of the Dirichlet-to-Neumann operator given in [20]. All these results explore the smallness of one or two parameters in order to obtain an approximate expression for evolution of the free surface. On a different path, an important nonperturbative result was obtained in [21], where an exact integral-differential equation for the evolution of the free surface was obtained after the introduction of convenient conformal mappings. This equation was numerically studied by an FFT pseudospectral method in [22].

In the present work we will present an exact integral-differential equation for the evolution of a free surface in a porous medium which is analogous to the results obtained in [21, 22] for the water-wave problem, although we will follow some different steps from these papers. We will take advantage of a conformal map, mapping the region filled with fluid to a straight strip, thus transforming the free surface problem to a fixed domain problem for the Laplace equation, but with transformed boundary conditions, which, however, will be explicitly solvable. Although not promptly amenable to analytical calculations, the equation will lend itself to the implementation of an efficient numerical method.

The study of free surface dynamics in a porous medium finds its main applications in the investigations of groundwater oscillations in unconfined aquifers in coastal regions. In such regions, the fluctuations of the sea surface, in the form of either surface waves or tidal oscillations, induce watertable oscillations. These oscillations, in turn, affect the environmental dynamics in the region. Many works have addressed this

question [5, 6, 7, 8, 9, 23] on the theoretical side, providing equations to be used in larger integrated models for coastal environments. In particular, we should mention the effect caused by the periodic, tidal-induced, variation of the sea level, which is to induce a watertable over height with respect to the mean sea level. Our numerical calculations at the end of this article will illustrate this point.

2. Governing equations. The formulation of the problem is standard and can be found in textbooks [1, 24]. We place ourselves in a two-dimensional plane geometry. Let us call y the vertical axis, defined by gravity's direction, and x the perpendicular, horizontal, direction. Consider a fluid filling a porous medium, lying over a flat impermeable bottom, up to a total height limited by a free surface given by a curve described by $y = h(x)$. The relevant dynamical variable is the piezometric head $\Phi(x, y, t)$, defined as

$$\Phi = \frac{P}{\gamma} + y,$$

where P is the pressure and $\gamma = \rho g$ the specific weight. We assume Darcy's law; that is, we suppose that the seepage velocity is proportional to the gradient of the piezometric head, i.e,

$$\mathbf{u} = -K\nabla\phi,$$

where K is the permeability of the medium. Darcy's law is valid for the situation we have in mind, which is the flow of water percolating in rocks and soils. Theoretically it can be obtained from Stokes flow together with asymptotic expansions in a parameter measuring the ratio of microscopic (pores) length scales to macroscopic ones. Non-Darcian effects would typically arise if the flow in pores became turbulent (e.g., in high-rate gas wells).

Supposing the validity of Darcy's law and taking the flow as incompressible, we come to our dynamical equation

$$\Phi_{xx} + \Phi_{yy} = 0, \qquad 0 < y < h(x,t), \tag{2.1}$$

with the boundary conditions at the free surface given by

$$\Phi = h - h_0 \qquad \text{at} \quad y = h(x,t), \tag{2.2}$$

$$h_t - \frac{K}{n_e}\Phi_x h_x + \frac{K}{n_e}\Phi_y = 0 \quad \text{at} \quad y = h(x,t), \tag{2.3}$$

where n_e is the effective porosity and the displacement surface $h - h_0$ is an integrable function. At the bottom, we have a Neumann condition:

$$\Phi_y = 0, \qquad y = 0. \tag{2.4}$$

The problem is posed with an initial condition for the free surface, $h(x, 0) = \varphi(x)$. The reader will appreciate here that the above equations are directly connected to the Dirichlet-to-Neumann operator. In rescaled variables, (2.3) says that the time-derivative of $h(x, t)$ is proportional to the normal derivative of $\Phi(x, y, t)$ at the surface $y = h(x, t)$. We have thus the Laplace equation with a Dirichlet condition at the free boundary, (2.2) (in terms of the unknown function $h(x, t)$), and we have to find the normal derivative of the solution at this boundary (again in terms of $h(x, t)$) to insert

it into (2.4), implying an evolution equation for the free surface, $h(x,t)$. Therefore, the solution to our problem goes through a Dirichlet-to-Neumann operator. We will, however, avoid explicitly introducing it here, for the sake of simplicity and as we would not really gain much in doing so. Let us also point out here that the main difference between the equations governing the classical water-wave problem and those that govern the porous medium problem under consideration can be seen in (2.2), which in the last case is much simpler than in the former case, where it involves time-derivatives and nonlinear terms.

Our strategy to broach the problem will be the following: (i) first introduce nondimensional variables; (ii) next, define a conformal transformation from the strip $\Re \times (0, h(x))$ to $\Re \times (0, \mu)$, where μ is a constant to be defined below; (iii) this transformation eliminates the free-boundary problem, replacing it by a Laplace equation with new boundary conditions, involving the Jacobian of the transformation; (iv) we then solve the Laplace equation, with mixed Neumann-Dirichlet conditions, in terms of the unknown function describing the free surface, resulting in an equation for this surface, in conformal coordinates; (v) once this equation is obtained, we will develop an asymptotic analysis in a parameter measuring the longness of the wave with respect to the depth and obtain classical results on the problem; (iv) we close the paper with some numerical results on the full equations for the free surface.

3. Nondimensional equations and conformal transformation. We first write (2.1)–(2.4) in a nondimensional form. To do so, we introduce the following nondimensional variables:

$$x = \lambda\, x', \qquad y = \lambda\, y', \qquad h = h_0 h'(x', t'),$$
$$\Phi = h_0 \Phi', \qquad t = \frac{n_e}{K}\frac{\lambda^2}{h_0} t',$$

where λ is the typical wavelength of the free-surface perturbation and h_0 is the undisturbed depth of the fluid. In these new variables, we come to the following system of equations:

$$\Delta\Phi = 0, \qquad 0 < y < \mu h(x,t), \tag{3.1}$$
$$\Phi = h - 1, \qquad y = \mu h(x,t), \tag{3.2}$$
$$0 = h_t - \Phi_x h_x + \frac{1}{\mu}\Phi_y, \qquad y = \mu h(x,t), \tag{3.3}$$
$$\Phi_y = 0, \qquad y = 0, \tag{3.4}$$

where all primes have been omitted for notational convenience. A dimensionless parameter appears in these equations, $\mu = h_0/\lambda$. This would be the usual perturbative parameter for long-wave asymptotics (Dupuit approximation), where $\mu \ll 1$, meaning that the wavelength is much larger than the depth. We will not make this approximation from the beginning. Instead, we will obtain an exact equation for the free surface and only then take $\mu \ll 1$ in order to rederive previously known equations.

Further, we should note that we used a nondimensional variable so as to preserve the Laplacian, a fact of which we will make good use in what follows.

The crucial step in our procedure is the introduction of a conformal mapping. Consider a strip in the w-plane, $w = \xi + i\zeta$, given by $\Re \times [0, \mu]$. A mapping of this strip to the undulated strip in the z-plane, $z = x + iy$, given by $\Re \times [0, \mu h(x(\xi, \mu), t)]$,

is defined as a harmonic function, given as the solution of the Dirichlet problem

$$y_{\xi\xi} + y_{\zeta\zeta} = 0, \qquad 0 < y < \mu h(x(\xi,\mu),t), \tag{3.5}$$

$$y(\xi,\mu) = \mu h(x(\xi,\mu),t), \tag{3.6}$$

$$y(\xi,0) = 0 \tag{3.7}$$

if we suppose that we know the function $x(\xi,\mu)$ in the time t.

Time t plays the role of a parameter in these equations: for each t we have different functions $x(\xi,\zeta)$ and $y(\xi,\zeta)$. Equations (3.5)–(3.7) can be solved explicitly. Indeed, the solution is given by the imaginary part of

$$z(w) = \frac{1}{2}\int_{-\infty}^{\infty} \tanh\left[\frac{\pi}{2\mu}(w-\xi')\right] h(x(\xi',\mu),t)d\xi'. \tag{3.8}$$

Equation (3.5) is verified trivially, as well as (3.7). To show that (3.6) is also satisfied, we first obtain explicitly the imaginary part of (3.8). This is easily done with the help of the trigonometric identity

$$\tanh\left[\frac{\pi}{2\mu}(w-\xi')\right] \frac{\sinh[\frac{\pi}{\mu}(\xi-\xi')] + i\sin[\frac{\pi}{\mu}\zeta]}{\cosh[\frac{\pi}{\mu}(\xi-\xi')] + \cos[\frac{\pi}{\mu}\zeta]}, \tag{3.9}$$

which implies that

$$y(w) = \frac{1}{2}\int_{\Re} \frac{\sin[\frac{\pi}{\mu}\zeta]\, h(\xi',t)}{\cosh[\frac{\pi}{\mu}(\xi-\xi')] + \cos[\frac{\pi}{\mu}\zeta]} d\xi'. \tag{3.10}$$

We now use the fact that the convolution between two functions is equal to the inverse Fourier transform of the product of their Fourier transform, $\mathcal{F}^{-1}[\mathcal{F}(f)\star\mathcal{F}(g)] = f\star g$, and obtain that, after some algebra,

$$\begin{aligned} y(w) &= \mu\int_{\Re} \frac{\sinh[2\pi k\zeta]}{\sinh[2\pi k\mu]}\mathcal{F}[h]e^{2\pi i\kappa\xi}d\kappa \\ &= \mu\int_{\Re} \frac{\sinh[2\pi k\zeta]}{\sinh[2\pi k\mu]}\mathcal{F}[h-1]e^{2\pi i\kappa\xi}d\kappa + \zeta. \end{aligned} \tag{3.11}$$

Evaluated at $\zeta = \mu$, (3.11) gives (3.6) immediately. Therefore, we now have transformed our physical space, moving-boundary, domain to a fixed one through a time-dependent conformal mapping which is explicitly given by either (3.10) or (3.11).

4. Transformed equations and their solution: Free-surface evolution. Although the conformal transformation introduced in the last section leaves the Laplacian in (3.1) invariant, this is not so for the boundary conditions. In the new coordinates (ξ,ζ) the system given by (3.1)–(3.4) takes, nevertheless, a simple and convenient form. If we use that, at the upper surface, $y = \mu h(x(\xi,\mu),t)$, $\partial_\zeta = x_\xi(\partial_y - \mu h_x\partial_x)$, which follows from the Cauchy–Riemann conditions, $x_\xi = y_\zeta$ and $x_\zeta = -y_\xi$ and (3.6), we come to the transformed equations

$$\Delta\Phi = 0, \qquad 0 < \zeta < \mu, \tag{4.1}$$

$$\Phi = h - 1, \qquad \zeta = \mu, \tag{4.2}$$

$$0 = h_t + \frac{\Phi_\zeta}{\mu x_\xi}, \qquad \zeta = \mu, \tag{4.3}$$

$$\Phi_\zeta = 0, \qquad \zeta = 0. \tag{4.4}$$

This is now a system of equations defined on a fixed domain, with a coordinate-dependent coefficient in (4.3). The system of equations formed by (4.1), (4.2), (4.4) may now be seen as a Laplace equation to be solved with a Neumann condition at $\zeta = 0$ and a Dirichlet condition at $\zeta = \mu$, where $h - 1$ is the prescribed boundary value of $\Phi(\xi, \zeta)$. A solution to this problem reads

$$\Phi(\xi, \zeta, t) = \int_{-\infty}^{\infty} \mathcal{F}[\Phi(\xi, \mu, t)] \frac{\cosh[2\pi\kappa\zeta]}{\cosh[2\pi\kappa\mu]} \, e^{2\pi i\kappa\xi} d\kappa, \tag{4.5}$$

where $\mathcal{F}[\Phi](\kappa, \mu, t)$ is the Fourier transform of the piezometric head Φ at the surface $\zeta = \mu$, given in terms of $h - 1$.

Equation (4.5) solves (4.1), (4.2), (4.4). We may use it to obtain a relation between Φ_ζ and Φ at the surface (having thus implicitly constructed a Dirichlet-to-Neumann operator):

$$\Phi_\zeta(\xi, \mu, t) = \int_{-\infty}^{\infty} 2\pi\kappa \tanh[2\pi\kappa\mu] \mathcal{F}[\Phi] \, e^{2\pi i\kappa\xi} d\kappa \tag{4.6}$$

$$= \int_{-\infty}^{\infty} -i \tanh[2\pi\kappa\mu] \mathcal{F}[\Phi_\xi] \, e^{2\pi i\kappa\xi} d\kappa \equiv \mathbf{T}\partial_\xi[\Phi], \tag{4.7}$$

where $\mathbf{T}[-]$ is an integral operator defined by the above equation. It will be quite useful in the numerical calculations. For the moment, it is introduced for notational convenience. Inserting the above equation into (4.3) gives

$$h_t + \frac{1}{\mu x_\xi} \mathbf{T}\partial_x[h] = 0, \tag{4.8}$$

where use was made of the fact that $h_\xi = \Phi_\xi$ at $\zeta = \mu$. Equation (4.8) gives the time evolution of the free surface in the conformal coordinates (ξ, ζ). We should, however, note that x_ξ, which can be derived from (3.8), depends also on $h(x, t)$, making (4.8) nonlinear.

We can see the system formed by (3.8) and (4.8) as determining the time evolution of the free surface exactly. Let us, however, write it in a more compact form. If we note that the real part of (3.8) may be expressed as

$$\begin{aligned} x(\xi, \zeta) &= -i\mu \int_{-\infty}^{\infty} \frac{\cosh[2\pi\kappa\zeta]}{\sinh[2\pi\kappa\mu]} \mathcal{F}[h] e^{2\pi i\kappa\xi} d\kappa \\ &= -i\mu \int_{-\infty}^{\infty} \frac{\cosh[2\pi\kappa\zeta]}{\sinh[2\pi\kappa\mu]} \mathcal{F}[h - 1] e^{2\pi i\kappa\xi} d\kappa + \xi, \end{aligned} \tag{4.9}$$

where we again used (3.9) and the properties of the Fourier transform of the convolution of two functions, we can obtain x_ξ in the limit $\zeta \to \mu$:

$$x_\xi = \mu \int_{-\infty}^{\infty} 2\pi\kappa \coth[2\pi\kappa\mu] \, \mathcal{F}[h] e^{2\pi i\kappa\xi} d\kappa \tag{4.10}$$

or

$$x_\xi = -\mu \mathbf{T}^{-1} \partial_\xi[h]. \tag{4.11}$$

The evolution equation for the free surface is thus given in the conformal coordinates by

$$h_t = \frac{1}{\mu^2} \frac{\mathbf{T}\partial_\xi[h]}{\mathbf{T}^{-1}\partial_\xi[h]} = 0. \tag{4.12}$$

The above equation displays the time evolution of the free surface elegantly, although one could object that it could be difficult to use it in actual analytical calculations. We will, therefore, go further and show two distinct developments originating from (4.12): asymptotics and numerics.

5. Long-wave asymptotics. The theory of long-wave perturbation for a fluid in a porous medium is a classical subject, which has been extensively studied in many different aspects. Here we will systematically rederive this approximation from the exact equation (4.12), or equivalently, from (4.8), (4.11). It corresponds to the limit $\mu \ll 1$.

To proceed, we note first the identities

$$\mathbf{T}\partial_\xi[h] = \int_{-\infty}^{\infty} 2\pi\kappa \tanh[2\pi\kappa\mu]\mathcal{F}[h]\, e^{2\pi i\kappa\xi} d\kappa = -\tan(\mu\partial_\xi)\partial_\xi[h], \tag{5.1}$$

$$\mathbf{T}^{-1}\partial_\xi[h] = -\int_{-\infty}^{\infty} 2\pi\kappa \coth[2\pi\kappa\mu]\, \mathcal{F}[h] e^{2\pi i\kappa\xi} d\kappa = -\cot(\mu\partial_\xi)\partial_\xi[h], \tag{5.2}$$

where the tan and cot are defined by their series. Equations (4.8), (4.11) become respectively

$$\mu h_t x_\xi - \tan(\mu\partial_\xi)\partial_\xi[h] = 0, \tag{5.3}$$

$$x_\xi = \mu \cot(\mu\partial_\xi)\partial_\xi[h]. \tag{5.4}$$

Introduce now expansions up to order μ^2 of both equations. This implies

$$0 = h_t x_\xi - h_{\xi\xi} - \frac{\mu^2}{3} h_{\xi\xi\xi\xi} + \cdots, \tag{5.5}$$

$$x_\xi = h - \frac{\mu^2}{3} h_{\xi\xi} + \cdots. \tag{5.6}$$

The derivatives h_ξ may be rewritten iteratively as terms of h_x in an asymptotic sense:

$$h_\xi = h_x x_\xi = h_x h - \frac{\mu^2}{3} h_x h_{\xi\xi} + O(\mu^4), \tag{5.7}$$

and then

$$h_{\xi\xi} = (h_x h)_\xi - \frac{\mu^2}{3}(h_x h_{\xi\xi})_\xi + O(\mu^4) \tag{5.8}$$

$$= (h_x h)_x x_\xi - \frac{\mu^2}{3}(h_x h_{\xi\xi})_x x_\xi + O(\mu^4), \tag{5.9}$$

$$h_{\xi\xi\xi\xi} = (h_{\xi\xi\xi})_x x_\xi + O(\mu^2), \tag{5.10}$$

from which we obtain, by substituting into (5.5), the following:

$$\begin{aligned} h_t &= (h_x h)_x - \frac{\mu^2}{3}(h_x h_{\xi\xi})_x + \frac{\mu^2}{3}(h_{\xi\xi\xi})_x + \cdots \\ &= (h_x h)_x + \frac{\mu^2}{3}[-h_x h_{\xi\xi} + h_{\xi\xi x} x_\xi]_x + \cdots \\ &= (h_x h)_x + \frac{\mu^2}{3}[-2h_x h_{\xi\xi} + h_x h_{\xi\xi} + h_{\xi\xi x} h]_x + \cdots \end{aligned}$$

$$= (h_x h)_x + \frac{\mu^2}{3}[-2h_x h_{\xi\xi} + (h_{\xi\xi} h)_x]_x + \cdots$$
$$= (h_x h)_x + \frac{\mu^2}{3}[-2h_x (h_x h)_x h + ((h_x h)_x h^2)_x]_x + \cdots$$
$$= (h_x h)_x + \frac{\mu^2}{3}[-2h_x h (h_x h)_x + (h_{xx} h^3)_x + (h_x^2 h^2)_x]_x + \cdots .$$

Thus, to order μ^2, we have the equation

$$h_t = (h_x h)_x + \frac{\mu^2}{3}[h_{xx} h^3]_{xx} + \cdots , \tag{5.11}$$

which had been derived in [7]. It is quite evident that we could consistently continue the expansion to any desired order. Also, one notes that the approximation of small amplitude fluctuations was not made, but could consistently be introduced, as long as we previously state the order relations between μ^2 and the order of magnitude of the amplitude fluctuations. A further point here is to again mention the analogous problem for water waves. Equation (5.11) shows us that the problem at hand is, phenomenologically speaking, intrinsically diffusive. The first term in (5.11) represents a nonlinear diffusion, as if the diffusion coefficient were proportional to h, and the next terms are higher order and nonlinear diffusion ones. Water waves offer a comparison if one exchanges diffusion for dispersion.

6. The linear problem. In the last section we saw that it is possible to obtain a perturbative expansion in the wavelength parameter μ, giving rise to a nonlinear partial differential equation, even in the lowest order. In this section we will explore another possibility, which is to leave μ free, and obtain a new expansion based on the smallness of the amplitude of the surface elevation. The corresponding lowest order equation is a linear partial integro-differential equation, whose solution we will also present.

Let us go back to (4.12), and let us write $h = 1 + \eta$, where η is the displacement of the free surface from its undisturbed position. In the case where $\eta \ll 1$, as a first approximation we can obtain a differential equation for η by noting that

$$\begin{aligned} \eta_t &= -\frac{1}{\mu}\frac{\mathbf{T}[\eta_\xi]}{1 - \mu\mathbf{T}^{-1}[\eta_\xi]} \\ &= -\frac{1}{\mu}\mathbf{T}[\eta_\xi] - \mathbf{T}[\eta_\xi]\mathbf{T}^{-1}[\eta_\xi] + \cdots , \end{aligned} \tag{6.1}$$

and thus that the lowest order linear equation reads

$$\eta_t = -\frac{1}{\mu}\mathbf{T}[\eta_\xi]. \tag{6.2}$$

In order to give the solution of (6.2) in a compact way, define the dispersion relation as

$$w_k = \frac{2\pi k}{\mu}\tanh[2\pi k\mu], \tag{6.3}$$

and the function $G(\xi, t)$ as the inverse Fourier transform of $e^{-w_k t}$,

$$G(\xi, t) = \int_{\Re} e^{-w_k t}\, e^{2\pi i k\xi} dk, \tag{6.4}$$

where G satisfies $\lim_{t\to 0} G(\xi, t) = \delta(\xi)$.

This allows us to write the solution of (6.2), for $\xi \in \Re$, as

$$\begin{aligned} \eta(\xi,t) &= \int_{\Re} e^{-w_k t}\mathcal{F}[\varphi]\, e^{2\pi i k\xi} dk \\ &= \int_{\Re} G_t(\xi-\xi')\varphi(\xi')\, d\xi', \end{aligned} \tag{6.5}$$

where $\mathcal{F}[\varphi]$ is the Fourier transform of the initial free surface position $\eta(\xi,0)=\varphi(\xi)$. In the case $\mu \to 0$ then $w_k = (2\pi k)^2$, $G_t(\xi)$ is the Gaussian exponential, and the solution for η is

$$\eta(\xi,t) = \frac{1}{2\sqrt{\pi t}} \int_{\Re} e^{-\frac{(\xi-\xi')^2}{4t}} \varphi(\xi')\, d\xi', \tag{6.6}$$

a well-known formula for the small amplitude long-wave approximation. From the last two sections, it is clear that (4.8) may be used as starting point for other perturbative expansions involving relations between two perturbative parameters. As an example, one can substitute $h = 1+\eta$ into (5.11), write $\eta = \epsilon\overline{\eta}$ with $\epsilon \ll 1$, and have a two-parameter asymptotic expansion.

7. Numerics. In this section we will briefly describe a pseudospectral numerical method used to integrate (4.12) and display an example calculation for the classical problem of the tide-induced over-height in unconfined aquifers.

A very important point is that we were able to reduce the dynamics of a bi-dimensional boundary problem with a free surface to a one-dimensional problem given by a differential-integral equation in an exact way. Although (4.12) is somewhat odd for analytical calculations, it is quite convenient for numerical implementation. We do not need tools like, for instance, boundary integral methods involving singular operators. The Fourier-like transforms that appear in the integral operators are by no means a problem, as they can be easily managed by FFTs, resulting in a method with spectral accuracy. Let us now give a definite example of implementation of the method. We shall solve (4.12) with a periodic boundary condition $h(0,t) = 1 + \alpha\sin(wt)$ at $x=0$. This simulates the effect of ocean tides in contact with groundwater in a coastal aquifer, through an idealized vertical beach. We take $h_x(L,t)=0$ when $L \gg h_0$. This last condition allows us to make a periodic extension to the interval $2L$ by introducing an adjunct forced boundary condition as

$$h(0,t) = 1+\alpha\sin(wt) \quad \text{and} \quad h(2L,t) = 1+\alpha\sin(wt)$$

and, consequently, allowing the use of Fourier transform methods. In this model the parameter α gives a measure of the nonlinearity of the problem. As initial condition we take $h(x,0)=1$.

At each time step, the periodic functions (x, x_ξ, h) are expanded as discrete Fourier series in ξ using the FFT, and the T-transform is computed in Fourier space. For example, $\mathbf{T}[h_\xi]$ of a function can be found via FFT after multiplying the Fourier coefficients of h by $2\pi\kappa\tanh[2\pi\kappa\mu]$, as it follows from (4.7). In a similar way we may compute $\mathbf{T}^{-1}[h_\xi]$. After evaluating nonlinear terms in physical space, we advance the solution of (4.12) in time with a 4th order Runge–Kutta method.

We have worked with 516, 512, or 1024 spatial points. The spatial step size is chosen in a range between 0.01 and 0.1. Usually we work with the time step $\Delta t = 0.01$. We do not need a high-pass filter.

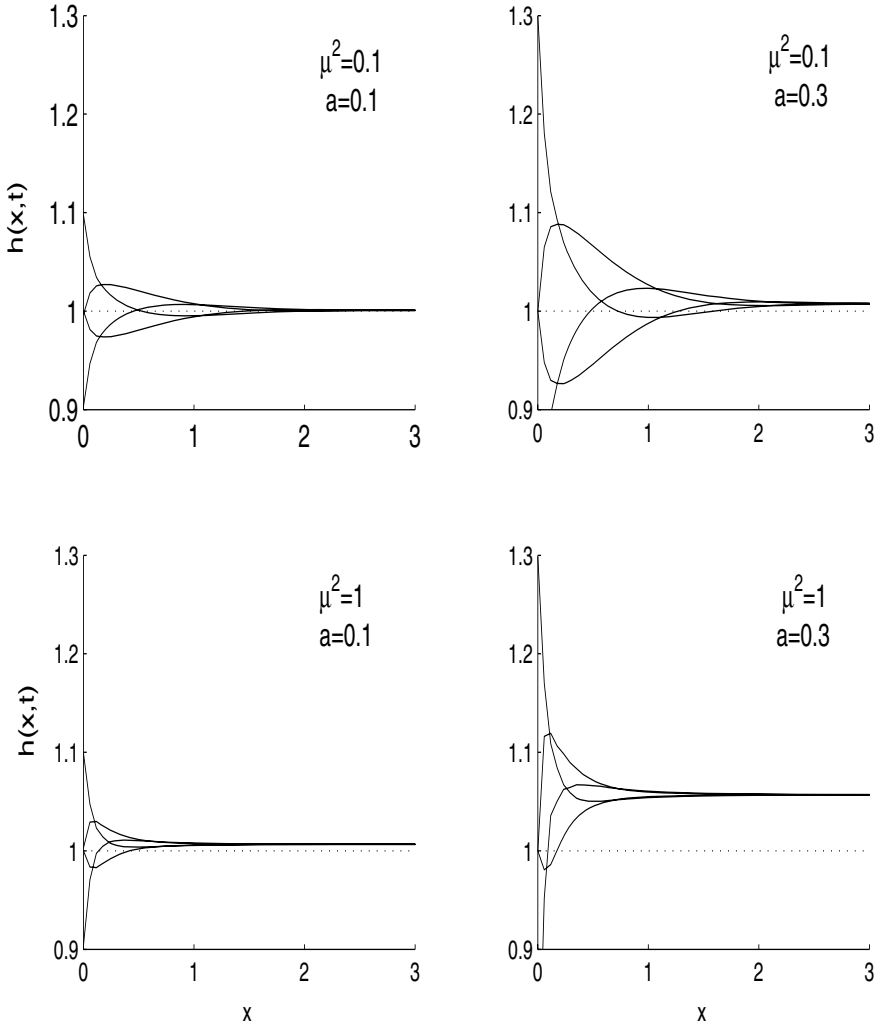

FIG. 7.1. *Different profiles for the free surface when* $t \to \infty$ *and phase* $wt = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$.

In Figure 7.1 we plot the surface profile for distinct values of α and μ. The figure presents the numerical solution for a combination of two values of α and three values of μ when $t \to \infty$, and for four values the phase $wt = 0, \frac{\pi}{2}, \pi, \frac{3\pi}{2}$.

We see the free surface displacement decaying with the distance from the boundary $x = 0$, while oscillating in both space and time. The decay rate is of the same order of magnitude of the parameter μ, and the free surface elevation for large x is of the order of α.

8. Conclusions. We have introduced a new differential-integral equation exactly describing the evolution of a free surface of a fluid totally immersed in a saturated porous medium and bounded from below by an impermeable bottom. Our equation, (4.12), is a porous-media analogue of the exact equation found for water waves in [21] and numerically studied in [22]. We have also shown that the asymptotic long-wave

expansion for this equations leads to known equations [7, 8]. The numerical implementation of (4.12) is easy, and we have provided a simple example.

The method that we have used is based on properties of harmonic functions and makes full use of a conformal transformation. Generalization to the case of an uneven bottom may follow quite easily and will be the object of future work. This should allow implementing calculations for more realistic cases of interaction of aquifers and tides through sloping beaches. A less evident generalization would be the extension of the results of this work for three-dimensional problems.

ON THE FORMATION OF GLASS MICROELECTRODES*

HUAXIONG HUANG†, JONATHAN J. WYLIE‡, ROBERT M. MIURA§, AND PETER D. HOWELL¶

Abstract. Glass microelectrodes are used widely in experimental studies of the electrophysiology of biological cells and their membranes. However, the pulling of these electrodes remains an art, based on trial and error. Following Huang et al. [*SIAM J. Appl. Math.*, 63 (2003), pp. 1499–1519], we derive a one-dimensional model for the stretching of a hollow glass tube that is being radiatively heated. Our framework allows us to consider two commonly used puller designs, that is, horizontal (constant force) and vertical (variable force) pullers. We derive explicit solutions and use these solutions to identify the principal factors that control the final shape of the microelectrodes. The design implications for pullers also are discussed.

Key words. free-boundary problem, glass microelectrode, heat transfer, incompressible fluids, long-wave approximation, partial differential equations, temperature-dependent viscosity

1. Introduction.

Glass microelectrodes have played an essential role in cell electrophysiology for decades and will continue to be an important tool in the future. These micropipettes are used to measure membrane potentials and inject electric current and dyes into cells. This is done by inserting the electrode tips through cellular membranes or by "patching" the electrode tip to the membrane. The data collected by these techniques provide crucial information about the electrical properties of the membrane, e.g., the voltage-gated and receptor-gated ion channels, under various conditions, including during drug applications. Laboratories generally produce these microelectrodes on a daily basis using commercially available glass tubes and mechanical microelectrode pullers. For more descriptions of the medical applications of these electrodes, we refer interested readers to [16, 15], and references therein.

Electrode pullers vary in design, but all have the same basic features. They start with a uniform glass tube and heat a small section using a radiative heating element. As the glass is heated, a pulling force is applied along the axis of the tube. When the glass temperature becomes sufficiently high, its viscosity decreases dramatically, and the glass tube stretches rapidly. The tube then becomes extremely thin, ultimately breaks, and each half of the tube can be used as an electrode. Pullers are designed to

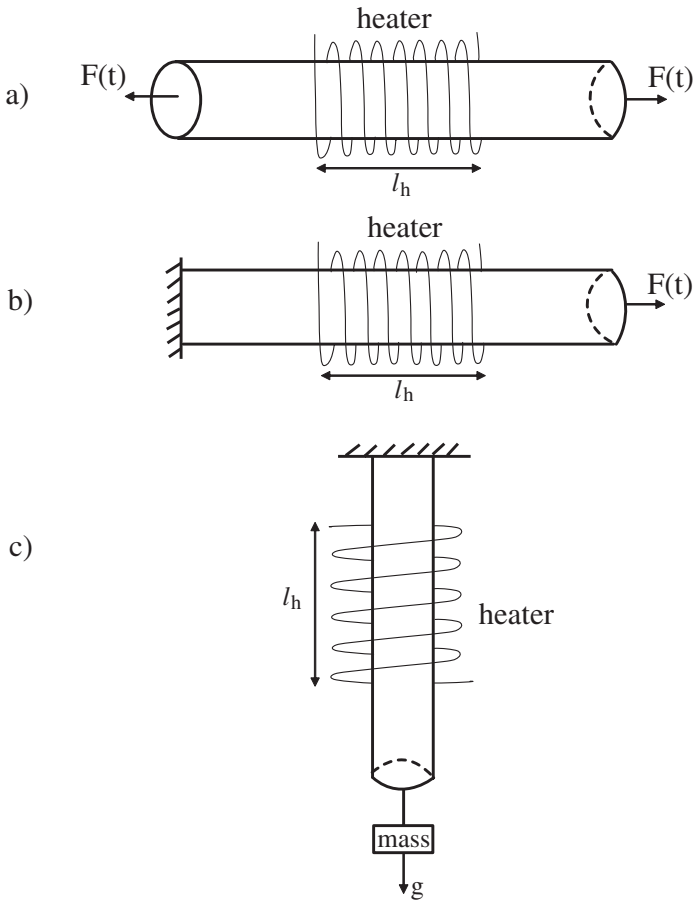

FIG. 1.1. *Three possible pullers.* (a) *Horizontal puller with free-moving ends and equal forces.* (b) *Horizontal puller with one fixed end and a single force.* (c) *Vertical puller with mass under gravity.*

achieve this result in different ways. For example, the pulling force may be achieved using electromagnets or by simply attaching a weight to one end of the tube. Electrodes may be formed in a single pull, or the glass can be stretched, allowed to cool, and subjected to a second pull that then breaks the tube. Designs for three possible pullers are shown in Figure 1.1.

Glass microelectrodes can be characterized by four experimentally relevant parameters. These are the tip length, tip diameter, electrode resistance, and electrode capacitance. Tip length is significant because it determines the physical strength of the electrode and the ease with which it can penetrate tissue and cells. A short steeply tapered tip is robust but does not penetrate tissue easily. The converse is true of long gently tapered tips. The tip shape also affects its electrical resistance and capacitance. More information on the relevance of the tip shape to physical parameters can be found in [8] and [18].

During the actual manufacturing process, the exact relationship between the variables (heater geometry, rate of pulling the glass tube, length of first pull (for a patch electrode), rate of the second pull, etc.) and electrode properties is usually determined empirically by trial and error. Although some work has been done towards

understanding how the final electrode shape is influenced by the heater geometry and width [8], in general the process is not well determined. In a previous paper [12], we developed a basic mathematical model for the formation process of these glass microelectrodes and, through computer simulations, showed that the model was capable of predicting, relatively closely, the breakup process observed in the laboratory.

The results in [12] illustrate several features that are fundamental in understanding the pulling process. First, the glass tube initially stretches very little due to the large value of the viscosity at room temperature. As the portion of the tube that is being heated by the heating element increases in temperature, the viscosity of the glass tube decreases dramatically, and the extension and breakup of the glass tube occur very rapidly. During this time, the temperature of the glass tube locally remains approximately constant; i.e., the effects of thermal diffusion and radiation are negligible.

In this paper, we derive a simplified model that captures the principal physics underlying the electrode formation. Using a dimensional analysis argument, we show that the conductive heat transfer is small compared to the radiative and convective heat transfer, and therefore conduction can be neglected in the temperature equation. We develop a general method to solve the model equations and, in some special cases, compute explicit solutions to the time-dependent equations. We carefully investigate the effects of the parameters on the final shape of the microelectrodes. Our results are relevant to existing pullers and have important implications for the future design of devices to fabricate microelectrodes.

There are certain similarities between the pulling of the glass microelectrodes and the drawing of optical and polymer fibers, which have been studied extensively in the literature [3, 4, 5, 6, 7]. For example, the governing equations for the extension of the tube or fiber can be obtained by taking the long-wave limit of the Navier–Stokes equation for incompressible fluids. However, most of the fiber drawing literature focuses on the steady state solution and its stability (drawing resonance) under isothermal conditions; cf. [6, 7, 3] and references therein. Nonisothermal cases also have been considered [11, 10, 9], but the focus is on the effect of the temperature variation on the drawing resonance. On the other hand, in the case of making glass microelectrodes, the problem is inherently transient. Another distinctive feature in the electrode pulling case is that the puller normally imposes a constant or variable force, instead of a fixed drawing speed.

Finally, the pulling of microelectrodes also has similar characteristics to extensional flow and break-off of viscous drops, which has been studied extensively; cf. [19] and references therein. However, these studies generally assume that the viscosity of the fluid remains constant, whereas in electrode production temperature-induced viscosity variations are critical.

The rest of the paper is organized as follows. In section 2, we state the basic assumptions and give the model equations. Details of the control-volume approach used in this derivation are similar to those used in [12] and [6] and therefore will be omitted. However, some issues, which have not previously been considered, such as the effects of surface tension on the inner and outer radii during stretching, will be carefully addressed on the basis of dimensional analysis. A general methodology for solving the model equations based on the method of characteristics is given.

In section 3, we obtain analytical solutions for a horizontal puller with fixed pulling force and uniform heating. For more general cases, approximate solutions are obtained using a simple numerical method. The role of parameter values is thoroughly investigated, and a particularly appealing and simple approximate theory is developed

to predict the radius of the tip at breaking. The consequences for puller design and other applications are discussed in section 4.

2. Model for glass microelectrode formation. The basic equations used in this paper to describe the stretching of the glass tube are similar to those derived in [12] for heated tubes and in [6] for isothermal tubes. In this section, we address the assumptions made in [12] and show that the flow equations reduce to those given in [12] when surface tension is negligible and can be further simplified using dimensional analysis. We also will show that the simplified model leads to a Lagrangian formulation, which can be used to compute the solution much more efficiently than the method used in [12].

2.1. Model formulation. We let ρ be the density of the glass and assume that variations in the density with temperature are negligible. We assume the tube is axisymmetric with length ℓ and inner and outer radii r and R, respectively. In the one-dimensional approximation, the velocity of the glass along the axis of the tube, which we denote by u, is independent of the radial position. When the pressure inside and outside the tube are equal, the momentum, mass, and energy conservation laws lead to the following equations:

$$\rho(R^2-r^2)\left(\frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}-g\right)=\frac{\partial}{\partial x}\left(3\mu(R^2-r^2)\frac{\partial u}{\partial x}+\gamma(R+r)\right), \tag{2.1}$$

$$\frac{\partial R^2}{\partial t}+u\frac{\partial R^2}{\partial x}+R^2\frac{\partial u}{\partial x}=-\frac{\gamma Rr}{\mu(R-r)}, \tag{2.2}$$

$$\frac{\partial r^2}{\partial t}+u\frac{\partial r^2}{\partial x}+r^2\frac{\partial u}{\partial x}=-\frac{\gamma Rr}{\mu(R-r)}, \tag{2.3}$$

$$\rho c_p\left(\frac{\partial \theta}{\partial t}+u\frac{\partial \theta}{\partial x}\right)=E_R, \tag{2.4}$$

where g is the gravitational constant, γ is the surface tension coefficient, t is the time, x is the coordinate measured along the axis of the cylinder, μ is the viscosity of the glass, θ is the temperature, c_p and k are the specific heat and thermal conductivity of the glass, respectively, and E_R represents the transport of thermal energy to the glass tube by radiation. This thermal radiation term is given by

$$\begin{aligned}E_R=2k_B\sqrt{\frac{\pi}{s(1-\beta^2)}}\Bigg[&E_h\frac{\varepsilon_h\alpha}{1-(1-\alpha)(1-\varepsilon_h)}\left(\theta_h^4-\theta^4\right)\\&+E_b\frac{\varepsilon_b\alpha}{1-(1-\alpha)(1-\varepsilon_b)}\left(\theta_b^4-\theta^4\right)\Bigg],\end{aligned} \tag{2.5}$$

where $s=\pi(R^2-r^2)$ is the cross-sectional area, $\beta=r/R$ is the ratio of the radii, k_B is the Boltzmann constant, α is the absorptivity of the glass to radiative thermal energy, ε_h and ε_b are the emissivities of the heater and background, respectively, and $\theta_h(x,t)$ and $\theta_b(x,t)$ are the temperatures of the heater and the background, respectively. The quantities E_h and E_b are geometric factors between the heater and the glass tube and between the background and the glass tube, respectively. These geometric factors can be derived by integrating over the surface of the heater (and surrounding body) visible to the element of the glass tube. The details can be found in [12]. The heating is usually applied to a highly localized region of the tube of length $\ell_h \gg R_0$.

These equations are valid if the glass tube is long and thin with a small radius to length aspect ratio, as shown in Table 2.1. In addition, they also require that

the viscosity variation in the radial direction be small compared to that in the axial direction, which is justified since the viscosity is temperature-dependent and the radial variation of temperature is small, compared to that in the axial direction, as shown in Appendix A. The derivation of (2.1)–(2.3) can be found in [6].

The above equations are subject to the following initial and boundary conditions. Initially, we assume that the glass tube has a uniform temperature θ_0, length ℓ_0, and inner and outer radii r_0 and R_0. The tube is being pulled at one end with force $F(t)$, i.e.,

$$3\mu\pi(R^2 - r^2)\frac{\partial u}{\partial x} + \gamma\pi(R + r) = F(t) \tag{2.6}$$

at $x = \ell(t)$, which is a moving boundary with speed

$$\frac{d\ell}{dt} = v, \tag{2.7}$$

where $v = u(\ell, t)$ is the velocity of the glass at $x = \ell$. For symmetric pulling, we apply the condition of symmetry at $x = 0$. For asymmetric pulling with a fixed end, we simply have

$$u = 0 \tag{2.8}$$

at $x = 0$.

For pulling of glass electrodes, we also apply a terminal condition. If the pulling process is successful, the glass tube breaks in the location where the stress exceeds the "breaking stress." The breaking stress is a material-dependent parameter that also depends on the temperature. For example, for the glass used in this study, the breaking stress, $\mathcal{S}_b$, is given by the empirical formula [17]

$$\mathcal{S}_b = \frac{B}{\sqrt{\theta}}, \tag{2.9}$$

where B is an empirically determined constant.[1] The glass tube breaks when the stress in the tube is greater than $\mathcal{S}_b$. We note that this empirical law indicates that it becomes easier to break this type of glass as the temperature increases.

The difference between horizontal and vertical pullers appears only in the boundary conditions. For vertical pullers, one end of the tube is attached to a fixed location while a weight is attached to the other end. In this case, as the tube stretches, the

[1]The concept of breaking stress used in this paper is the same as the strength of glass, explored by Coenen [1]. From observations of the processes in a glass melt during the formation of cavities and of new surfaces, the formula

$$\sigma \approx 27 \times 10^6 \sqrt{\gamma^3/\theta}$$

was given in [17, p. 272]. Here σ is the applied stress (in N/m^2), γ is the surface tension coefficient (in N/m), and θ is the temperature measured in K. The weakening of the glass melt strength is partially caused by the decrease of elastic modulus when the temperature increases. The dominant factor, however, is due to the surface damage that occurs upon heating, which leads to spontaneous fracture. This mechanism is different from the pinch-off of viscous jets, where surface tension is the dominant factor and normally the inner radius collapses. On the other hand, the functional glass microelectrodes produced by the pullers have open annuli at the tips formed by breaking.

By neglecting the temperature-dependence of the surface tension coefficient [17] and using $\gamma = 0.33$ N/m for a soda-lime glass melt at 800° C, we arrive at (2.9), with B given in Table 2.1.

weight accelerates, and so the force experienced by the end of the tube is decreased. We denote the weight by F_0, gravity by g, the distance along the tube from the fixed end by x, and the location of the end attached to the weight by $x = \ell(t)$. We obtain an expression for the force applied to the free end of the tube, $F(t)$, given by

$$F(t) = F_0 - \frac{F_0}{g}\frac{\mathrm{d}^2\ell}{\mathrm{d}t^2}. \tag{2.10}$$

For horizontal pullers, the situation is simpler, and the force applied to the ends of the tube is simply $F(t)$, a specified function of time.

Equations (2.2) and (2.3) can be combined to give an equation for the cross-sectional area, s, which is essentially the equation of mass conservation,

$$\frac{\partial s}{\partial t} + u\frac{\partial s}{\partial x} + s\frac{\partial u}{\partial x} = 0. \tag{2.11}$$

The equations (2.2) and (2.3) also imply that the ratio of the radii, $\beta = r/R$, satisfies

$$\frac{\partial \beta}{\partial t} + u\frac{\partial \beta}{\partial x} = -\frac{\gamma(1+\beta)}{2\mu R}. \tag{2.12}$$

In the rest of the paper, we will use (2.11) and (2.12) instead of (2.2) and (2.3).

In a certain range of glass temperatures, the viscosity varies rapidly, and this plays a fundamental role in controlling the dynamics. Empirical data for soda-lime [2] shows that for temperatures below 900 K, which generally will be the case for electrode formation, the viscosity has an exponential dependence on temperature given by

$$\mu(\theta) = \mu_0 \exp\left[-\frac{(\theta - \theta_0)}{\theta_a}\right], \tag{2.13}$$

where μ_0 is the viscosity at the ambient temperature, θ_0, and θ_a is the "activation temperature change" required to change the viscosity by a factor of e^{-1}.

The parameters for the glass tube and heater are given in Tables 2.1 and 2.2, respectively. The other parameter that is relevant to the puller is the maximum length that the glass can be extended. This is generally constrained by the physical size of the device. If the device does not allow the tube to be extended sufficiently, then the tube may not break, and so no electrode will be formed. In later sections, we will carefully examine how the required amount of extension is related to the other parameters.

In the following sections, we will consider the most complicated case of the vertical puller, where the force on the glass tube is due to a weight that is accelerating under the influence of gravity. The other cases of specified time-dependent forces are simpler, and we will explain how to treat these cases in section 2.5.

2.2. Dimensional analysis. For the vertical puller, we nondimensionalize the variables using the following scales:

$$u = \frac{\ell_0 F_0}{3\mu_0 s_0} u', \quad s = s_0 s', \quad x = \ell_0 x', \quad t = \frac{3\mu_0 s_0}{F_0} t', \quad F = F_0 F',$$
$$R = R_0 R', \quad \ell = \ell_0 \ell', \quad \theta = \theta_0 + \theta_a \theta', \quad \text{and} \quad \mu(\theta) = \mu_0 \mu'(\theta'), \tag{2.14}$$

where the dimensionless variables are labeled with primes. Here ℓ_0, s_0, R_0, and r_0 are the initial length, cross-sectional area, and the outer and inner radii of the glass tube. Note that we have used

$$u_0 = \frac{\ell_0 F_0}{3\mu_0 s_0}$$

as the velocity scale, by balancing the pulling weight F_0 with the viscous force in the glass tube using the elongation viscosity. After substitution and dropping primes, the momentum equation (2.1), mass conservation equation (2.11), equation for the radii ratio (2.12), and heat equation (2.4) become

$$Re\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} - \frac{1}{F_r}\right) = \frac{1}{s}\frac{\partial}{\partial x}\left(\mu s \frac{\partial u}{\partial x} + \lambda R(1+\beta)\right), \tag{2.15}$$

$$\frac{\partial s}{\partial t} + u\frac{\partial s}{\partial x} + s\frac{\partial u}{\partial x} = 0, \tag{2.16}$$

$$\frac{\partial \beta}{\partial t} + u\frac{\partial \beta}{\partial x} = -\frac{3}{2}(1-\beta_0^2)\lambda\frac{(1+\beta)}{\mu R}, \tag{2.17}$$

$$\theta_t + u\theta_x = \mathcal{H}\frac{H(x,\theta)}{s^{1/2}}\sqrt{\frac{1-\beta_0^2}{1-\beta^2}}. \tag{2.18}$$

(The derivation of (2.18) is given in Appendix A.) The dimensionless boundary conditions for the vertical puller are

$$u = 0 \ \text{ at } \ x = 0 \tag{2.19}$$

and

$$\mu s\frac{\partial u}{\partial x} + \lambda R(1+\beta) = 1 - F_r\frac{d^2\ell}{dt^2}, \qquad u = \frac{d\ell}{dt} \ \text{ at } \ x = \ell. \tag{2.20}$$

The initial conditions are

$$u = 0, \quad s = 1, \quad \theta = 0, \quad \ell = 1 \ \text{ at } \ t = 0. \tag{2.21}$$

The terminal condition is the nondimensional breaking criterion

$$\max_{0\le x\le \ell}\left\{\mu s\frac{\partial u}{\partial x} + \lambda R(1+\beta) - \frac{C_b s}{\sqrt{\theta + \frac{\theta_0}{\theta_a}}}\right\} = 0, \tag{2.22}$$

where

$$C_b = \frac{Bs_0}{F_0\sqrt{\theta_a}}.$$

The dimensionless parameters

$$Re = \frac{\rho F_0 \ell_0^2}{9\mu_0^2 s_0}, \quad F_r = \frac{u_0^2}{g\ell_0}, \quad \lambda = \frac{\pi\gamma R_0}{F_0}$$

are the ratio of inertia to viscous forces, the inertia to the gravity forces, and surface tension forces to the external pulling force, respectively. $\beta_0 = r_0/R_0$ is the initial value of β,

$$\mathcal{H} = \frac{6\mu_0\sqrt{s_0}k_B\epsilon_h\alpha\theta_h^4\sqrt{\pi}}{\rho c_p\theta_a F_0\sqrt{(1-\beta_0^2)}[1-(1-\alpha)(1-\epsilon_h)]}$$

is the dimensionless heater strength, and

(2.23)
$$H(x,\theta) = E_h(x)\left(1-\left(\frac{\theta_0+\theta\theta_a}{\theta_h}\right)^4\right) + \frac{\epsilon_b[1-(1-\alpha)(1-\epsilon_h)]E_b(x)(\theta_b^4-(\theta_0+\theta_a\theta)^4)}{\epsilon_h[1-(1-\alpha)(1-\epsilon_b)]\theta_h^4}$$

is the dimensionless radiation distribution. In the case when heater temperature is much higher than that of the glass and the background, then $H(x,\theta)$ can be approximated by a given function of x. The dimensionless heater strength, $\mathcal{H}$, can be thought of as the heat absorbed by a thread being pulled with constant force F_0 as it passes through the heater, divided by the heat required to significantly change the viscosity. Small values of $\mathcal{H}$ imply that the viscosity remains almost constant, and so the solution will be similar to the isothermal case. Large values of $\mathcal{H}$ imply that significant viscosity gradients will occur in the thread. The dimensionless radiation distribution is the normalized radiative heat flux.

We now can further simplify the governing equations based on the parameter estimates at two of the most relevant stages: the beginning of the pulling and when the glass tube breaks. Initially, the tube is cold and the viscosity is large, whereas near breaking, the tube will have absorbed a significant amount of heat, and the viscosity can be reduced by several orders of magnitude. As a consequence, dimensionless variables describing the flow can vary dramatically. Therefore, we need to consider the relative sizes of inertia, gravity, surface tension, and viscous and pulling forces at both stages.

Using the typical parameters in Tables 2.1 and 2.2, we see that dimensionless parameters

$$\lambda \approx 4\times 10^{-4}, \quad Re \approx 1.6\times 10^{-10}, \quad \text{and} \quad Re/F_r \approx 10^{-3}$$

are small, and therefore initially surface tension and inertial and gravitational forces can be ignored. Typically, $\mathcal{H} = O(200)$; therefore initially the heating of the tube dominates the advective term, and the tube temperature increases with very little motion. However, when the tube is heated, the viscosity decreases dramatically, the tube stretches quickly, and the tube diameter decreases rapidly. These large changes mean that the above dimensionless parameters may not adequately characterize the sizes of

the surface tension, inertial and gravitational forces when the tube is close to breaking. We therefore must also compare the inertial, surface tension, and gravitational forces with the size of the imposed force near breaking.

Assuming that the stress in the tube can be approximated by the pulling force divided by the cross-sectional area, the dimensionless breaking criterion for the vertical puller is given by

$$\frac{1}{s}\left(1 - F_r \frac{d^2\ell}{dt^2}\right) = \frac{C_b}{\sqrt{\theta + \frac{\theta_0}{\theta_a}}}. \tag{2.24}$$

We first must obtain order of magnitude estimates for the diameter at which the tube breaks, the highest temperature that the tube reaches, and the viscosity of the tube near breaking. The tube starts to stretch significantly when the advection and radiative heating terms are of the same order of magnitude. This means that the viscosity must drop by a factor of order $\mathcal{H} = 200$. Hence, the viscosity near breaking μ_b will be of order $1/200$, and the dimensionless temperature must rise by approximately 6 (which corresponds to a dimensional temperature change of approximately 300 K). Knowing the temperature, θ, and using the breaking stress formula (2.24), we can obtain an order of magnitude estimate for the dimensionless cross-sectional area at which breaking occurs, s_b, yielding $s_b = 10^{-2}$ (which corresponds to a dimensional cross-sectional area of order 10^{-4} cm^2).

We are now in a position to estimate the dimensionless ratios near the breaking time. Using (2.15) and (2.20), we see that the characteristic sizes of the surface tension and inertial and gravitational terms compared to the imposed force are given by

$$s_b^{1/2}\lambda = O(10^{-5}), \quad \frac{1}{\mu_b^2 s_b} Re = O(10^{-3}), \quad \text{and} \quad s_b \frac{Re}{F_r} = O(10^{-5}),$$

respectively. Therefore, we can conclude that surface tension, inertia, and gravity can be neglected during the entire pulling process. The acceleration term, $F_r\ d^2\ell/dt^2$, is negligible initially because it is $O(10^{-7})$, but near the breaking time, this term may be O(1), and so we must retain this term. Similarly, the ratio of the initial stress to the breaking stress, C_b, is $O(10^2)$, indicating that the tube is initially far from breaking, but eventually the tube will become sufficiently thin that the stress will approach the breaking stress.

We note that the above discussion considers only the case of successful pulling of microelectrodes; i.e., the breaking criterion is met during the extension of the glass tube. In practice, this is not always the case, and it is possible that the glass continues to extend without breaking. When this occurs, the glass may become very heavily extended, and the acceleration term $F_r\ d^2\ell/dt^2$ may approach unity. In this case, the inertia, surface tension, and the gravity may become important. Even though this is an interesting problem, it is not really relevant to successful production of glass microelectrodes and will not be pursued in this paper.

2.3. Eulerian formulation. If the surface tension terms are neglected in (2.17), we immediately see that β is conserved following material elements. We will make the natural assumption that the initial radii, r_0 and R_0, of the tube are uniform, and therefore, β will be a constant throughout the pulling process.

As a result of neglecting inertia, surface tension, and gravity, (2.15) becomes

$$(\mu(\theta) s u_x)_x = 0. \tag{2.25}$$

Since β is constant, the heat equation (2.18) reduces to

$$\theta_t + u\theta_x = \mathcal{H}\frac{H(x,\theta)}{s^{1/2}}. \tag{2.26}$$

Equations (2.25) and (2.26), combined with the mass equation

$$s_t + us_x + su_x = 0, \tag{2.27}$$

form a closed system. The glass tube does not break as long as the inequality

$$\frac{1}{s}\left(1 - F_r\frac{d^2\ell}{dt^2}\right) < \frac{C_b}{\sqrt{\theta + \frac{\theta_0}{\theta_a}}} \tag{2.28}$$

is valid for all x. If this criterion is violated, then the tube will break and the stretching process is terminated.

For vertical pullers, a mass is attached to one end of the glass tube. Thus, the pulling force $F(t)$ is determined by Newton's second law, in nondimensional form as

$$F(t) = 1 - F_r\frac{d^2\ell}{dt^2}. \tag{2.29}$$

The boundary condition is

$$\mu(\theta)su_x|_{x=\ell} = F(t). \tag{2.30}$$

For horizontal pullers, the pulling force $F(t)$ is externally prescribed. For a constant force puller, this is equivalent to setting $F_r = 0$ in (2.29).

The momentum equation (2.25) can be integrated as

$$\mu(\theta)su_x = 1 - F_r\frac{\mathrm{d}^2\ell}{\mathrm{d}t^2}. \tag{2.31}$$

Dividing this equation by $s\mu(\theta)$ and integrating from $x = 0$ to ℓ gives an expression for the velocity of the free end, denoted by v,

$$v(t) = u(\ell,t) = \frac{d\ell}{dt} = \left(1 - F_r\frac{\mathrm{d}v}{\mathrm{d}t}\right)\int_0^\ell \frac{\mathrm{d}\eta}{s(\eta,t)\mu(\theta(\eta,t))}. \tag{2.32}$$

This can be rewritten as a differential equation for v,

$$F_r\frac{\mathrm{d}v}{\mathrm{d}t} = 1 - v\left(\int_0^\ell \frac{\mathrm{d}\eta}{s(\eta,t)\mu(\theta(\eta,t))}\right)^{-1}. \tag{2.33}$$

Using (2.31) and (2.33), the mass equation (2.27) can be reduced to

$$s_t + us_x = -\frac{v}{\mu}\left(\int_0^\ell \frac{\mathrm{d}\eta}{s(\eta,t)\mu(\theta(\eta,t))}\right)^{-1}. \tag{2.34}$$

Finally, the temperature equation is unchanged as

$$\theta_t + u\theta_x = \mathcal{H}\frac{H(x,\theta)}{s^{1/2}}. \tag{2.35}$$

Equations (2.33)–(2.35) can be solved subject to the initial conditions

$$s = 1,\ \theta = 0,\ \ell = 1,\ u = 0,\ v = 0 \quad \text{at} \quad t = 0. \tag{2.36}$$

2.4. Lagrangian formulation. As shown in [20, 13, 19], the system of equations becomes significantly simpler if expressed in Lagrangian coordinates (ξ, τ). The relationship between the Lagrangian and Eulerian coordinates is given by $x = X(\xi, \tau)$ and $t = \tau$, and

$$x_\tau = \frac{\partial X(\xi, \tau)}{\partial \tau} = u. \tag{2.37}$$

When there is no ambiguity, we will use x as both Eulerian coordinate and the Lagrangian variable X, which is the spatial coordinate of a material point which was at the location $x = \xi$ at the initial time $\tau = 0$.

For a function $f(x, t)$ defined using Eulerian coordinates, its Lagrangian derivatives are

$$f_\tau = f_t + f_x x_\tau = f_t + u f_x, \qquad f_\xi = f_x x_\xi. \tag{2.38}$$

It follows immediately that

$$u_x = \frac{u_\xi}{x_\xi} = \frac{x_{\tau\xi}}{x_\xi}. \tag{2.39}$$

Using (2.38) and (2.39), the conservation-of-mass equation (2.16) can be rewritten as

$$s_\tau + s\frac{x_{\tau\xi}}{x_\xi} = 0 \rightarrow (s x_\xi)_\tau = 0.$$

Integrating and applying the initial conditions, $s(\xi, 0) = 1$ and $x(\xi, 0) = \xi$, gives

$$x_\xi = \frac{1}{s}. \tag{2.40}$$

Writing $\mu(\theta) = e^{-\theta}$ and using Lagrangian coordinates, (2.33)–(2.35) become

$$F_r\, v_\tau(\tau) = 1 - v(\tau)\left(\int_0^1 s(\eta, \tau)^{-2} e^{\theta(\eta,\tau)} \mathrm{d}\eta\right)^{-1}, \tag{2.41}$$

$$s_\tau(\xi, \tau) = -v(\tau) e^{\theta(\xi,\tau)}\left(\int_0^1 s(\eta, \tau)^{-2} e^{\theta(\eta,\tau)} \mathrm{d}\eta\right)^{-1}, \tag{2.42}$$

and

$$\theta_\tau(\xi, \tau) = \mathcal{H}\frac{H(x(\xi, \tau), \theta(\xi, \tau))}{s(\xi, \tau)^{1/2}}. \tag{2.43}$$

2.5. Horizontal puller with a specified time-dependent force. For the horizontal puller, we need specify only the time-dependent force, $F(t)$, applied to the ends of the tube. We use the same nondimensionalizations specified in (2.14), except that now F_0 would be the maximal value of $F(t)$ over the entire time period of application.

The dimensionless (2.22) then is replaced by the simpler expression

$$\frac{F(t)}{s} = \frac{C_b}{\sqrt{\theta + \frac{\theta_0}{\theta_a}}},$$

where on the left-hand side $F(t)$ is a dimensionless specified function of time. We note that for a horizontal puller with a constant force, the dimensionless force is given by $F(t) = 1$.

In the constant force case, setting $F_r = 0$ in (2.41) leads to an equation for the velocity at the free end, which is given by the algebraic equation

$$v(t) = \int_0^\ell \frac{\mathrm{d}\eta}{s(\eta, t)\mu(\theta(\eta, t))}. \tag{2.44}$$

In Lagrangian coordinates with $\mu(\theta) = e^{-\theta}$, the velocity at the free end is given by

$$v(\tau) = \int_0^1 s(\eta, \tau)^{-2} e^{\theta(\eta,\tau)} \mathrm{d}\eta. \tag{2.45}$$

Then (2.42) and (2.43) reduce to

$$s_\tau = -\frac{1}{\mu(\theta)} = -e^\theta \tag{2.46}$$

and

$$\theta_\tau = \frac{\mathcal{H}}{\sqrt{s}} H(x(\xi, \tau), \theta). \tag{2.47}$$

2.6. Numerical method. For a general heating profile or for time-dependent pulling forces, no explicit solutions can be obtained, and we must resort to numerical methods. For an arbitrary heating profile, $H(x, \theta)$, the equations (2.41)–(2.43) can be used as the basis for a simple numerical method. The Lagrangian description of the system allows us to implement a very simple numerical method that completely avoids the problem of numerical diffusion, which arises in finite difference methods.

In order to solve this problem, we discretize the domain in both ξ and τ. At any given time τ, we use the trapezoidal rule to compute the integral $\int_0^1 s^{-2} e^\theta \mathrm{d}\xi$. Having done this, we then integrate the system of equations given in (2.41)–(2.43) using an ODE solver, e.g., a simple Euler method. Since the heater profile is given in Eulerian coordinates, we need to know the location of the material point, which can be computed using a numerical quadrature of (2.40). We note that this method can cope easily with generalized heating profiles, asymmetrical pulling, variable pulling forces, and the inclusion of heat exchange terms, θ_a^4/θ_h^4.

3. Results. In this section, we consider a number of possible configurations for the puller and heating profiles. We begin with a symmetric puller with a heater that supplies spatially constant heating. In this case, we can derive an analytical solution of the equations, and this allows us to understand many of the important features leading to the shape formation of the electrode. We then go on to consider a symmetric puller with nonuniform heating, an asymmetric puller with nonuniform heating, and finally a vertical puller.

3.1. Symmetrical pulling with constant force and constant heating. In this section, we consider the case when the pulling force is a constant, that is, a horizontal puller. We assume that the pulling and heating are symmetric about $x = 0$, and so the velocity at $x = 0$ is zero by symmetry. Therefore, the point that is initially at the centerline, $\xi = 0$, will always correspond to the point $x = 0$. Since there is no direct coupling between the breaking criterion and the shape evolution, we

will derive the solution by initially computing the shape profile and then determining the time at which the breaking criterion is first satisfied.

In order to obtain an explicit solution, we make a physically relevant assumption about the heater profile that provides a number of important insights into the problem. We will assume that the tube is initially located in the region $-1/2 \le x \le 1/2$ and that the heater is localized to the region $-\ell_h/2 \le x \le \ell_h/2$, where $0 < \ell_h < 1$ is the length of the heater. We also assume that the geometric factor, $E_h(x)$, is a constant in the heater region and zero outside of the heater region. This is appropriate if the radius of the heater element is not much larger than the outer radius of the tube. Since the glass achieves a peak temperature that typically is significantly less than the heater temperature, we will neglect the terms that are $O(\theta_a^4/\theta_h^4)$. Hence, we approximate the heating in the heater region by a constant. After the tube absorbs a significant amount of heat, it is stretched rapidly before it breaks, and so there is very little time for cooling to occur outside of the heater region. This means that we can safely neglect the cooling terms.

Therefore, the heater profile is assumed to be piecewise constant, that is,

$$H(x) = \begin{cases} 1 & 0 \le x \le \ell_h/2, \\ 0 & x > \ell_h/2. \end{cases} \tag{3.1}$$

We now discuss the solution of (2.40), (2.46), and (2.47) when $H(x)$ is given by (3.1). For any time τ, there are three parts of the solution that need to be considered separately.

Region (i). We first consider material points that are initially in the heater region and remain in the heater region at time τ. We define $\tau_h(\xi)$ to be the solution of $x(\xi, \tau_h(\xi)) = \ell_h/2$, which represents the time that a material element that starts at $x = \xi$ exits the heater region (see Figure 3.1). When $\tau < \tau_h(\xi)$, the material element

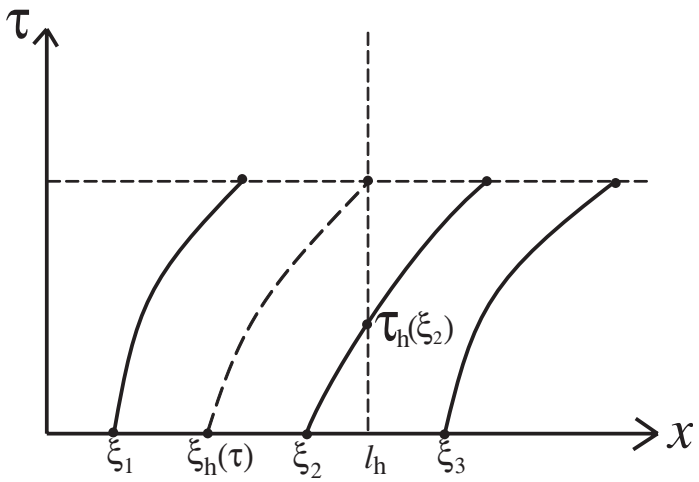

FIG. 3.1. *Symmetrical pulling with constant force and constant heating. Lagrangian trajectories.*

is subject to constant heating; thus, we need to solve the following equations:

$$s_\tau = -e^\theta, \quad \theta_\tau = \frac{\mathcal{H}}{\sqrt{s}}, \quad \text{and} \quad s x_\xi = 1, \tag{3.2}$$

subject to $s = 1$, $\theta = 0$, and $x = \xi$ at $\tau = 0$.

From (3.2), we obtain

$$\frac{\partial s}{\partial \theta} = -\frac{\sqrt{s} e^\theta}{\mathcal{H}}. \tag{3.3}$$

Integrating and applying the initial conditions yields

$$\sqrt{s} = \frac{1 + 2\mathcal{H} - e^\theta}{2\mathcal{H}}. \tag{3.4}$$

Substituting (3.4) into (3.2), we obtain

$$s_\tau = 2\mathcal{H}\sqrt{s} - (1 + 2\mathcal{H}) \quad \text{and} \quad \theta_\tau = \frac{2\mathcal{H}^2}{2\mathcal{H} + 1 - e^\theta}. \tag{3.5}$$

These two equations can be integrated again, and after applying the boundary conditions, we obtain

$$(2\mathcal{H} + 1)\theta - e^\theta + 1 = 2\mathcal{H}^2 \tau, \tag{3.6}$$

$$\sqrt{s} - 1 + \frac{2\mathcal{H} + 1}{2\mathcal{H}} \ln\left(2\mathcal{H} + 1 - 2\mathcal{H}\sqrt{s}\right) = \mathcal{H}\tau. \tag{3.7}$$

These equations can be solved explicitly in terms of the Lambert-W function that satisfies $W(x)e^{W(x)} = x$ to give

$$\theta = \frac{2\mathcal{H}^2\tau - 1}{2\mathcal{H} + 1} - W\left(-\frac{\exp\left(\frac{2\mathcal{H}^2\tau - 1}{2\mathcal{H}+1}\right)}{2\mathcal{H} + 1}\right) \tag{3.8}$$

and

$$s = \left(\frac{2\mathcal{H} + 1}{2\mathcal{H}}\right)^2 \left[1 + W\left(-\frac{\exp\left(\frac{2\mathcal{H}^2\tau - 1}{2\mathcal{H}+1}\right)}{2\mathcal{H} + 1}\right)\right]^2. \tag{3.9}$$

The Lambert function is defined only for values $x \geq -e^{-1}$. At the point $x = -e^{-1}$, its value is $W = -1$, and its gradient becomes singular. If the glass tube is allowed to extend, this singularity occurs at the finite time

$$\tau_{pinch} = \frac{(2\mathcal{H} + 1)\ln(2\mathcal{H} + 1) - 2\mathcal{H}}{2\mathcal{H}^2} \tag{3.10}$$

and corresponds to a pinch-off. However, in the case of pulling electrodes, pinch-off does not happen for the following reason. Note that at pinch-off, the cross-sectional area tends to zero, while the extension tends to infinity. In Figure 3.2, we plot the time at which pinch-off occurs as a function of the heating rate $\mathcal{H}$. We see that increasing the heating rate $\mathcal{H}$ causes the viscosity to decrease, and so the tube pinches off more quickly. In fact, this pinch-off will never occur because the stress in the tube will tend

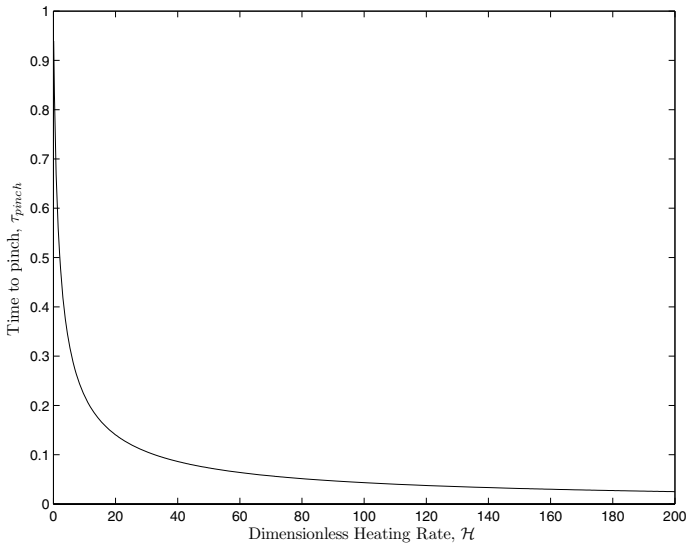

FIG. 3.2. *Dimensionless time to pinch-off as a function of the dimensionless heating rate.*

to infinity, hence exceeding the breaking stress. This means that the tube will always break before a pinch-off can occur. The time for pinch-off represents an upper bound on the duration of the pull. We will return with a more detailed discussion on the breaking of the glass tube after presenting the solutions for regions (ii) and (iii).

We note that in Lagrangian coordinates, the cross-sectional area, s, and the temperature, θ, are functions of τ only. Therefore, at time τ, we can use (3.2) to find the location of a material element that started at $x = \xi$ to obtain

$$x(\xi, \tau) = \int_0^{\xi} \frac{1}{s(\tau)} d\eta = \frac{\xi}{s(\tau)}. \tag{3.11}$$

Hence, a material element that started at $x = \xi$ will exit the heater region at a time $\tau_h(\xi)$, which can be found by solving

$$s(\tau_h(\xi)) = \frac{2\xi}{\ell_h}. \tag{3.12}$$

Substituting the above equation into (3.7), we find that

$$\tau_h(\xi) = \frac{1}{\mathcal{H}} \left[\sqrt{\frac{2\xi}{\ell_h}} - 1 + \frac{1 + 2\mathcal{H}}{2\mathcal{H}} \ln \left(2\mathcal{H} + 1 - 2\mathcal{H} \sqrt{\frac{2\xi}{\ell_h}} \right) \right]. \tag{3.13}$$

Note that points that were initially arbitrarily close to the center will exit the heater region when the time is sufficiently close to the pinching time.

In order to obtain the solution in the next region, we need the temperature of the material element that exits the tube at $\tau = \tau_h(\xi)$. This can be obtained by solving (3.4) and (3.12) to yield

$$\theta(\tau_h(\xi)) = \ln \left(2\mathcal{H} + 1 - 2\mathcal{H} \sqrt{\frac{2\xi}{\ell_h}} \right). \tag{3.14}$$

Region (ii). We now consider material points that are initially inside the heater region but exit the heater region before time τ. In other words, this region contains particles ξ for which $\tau_h(\xi) < \tau$. In this case, we can obtain the solution in a way similar to that used for region (i). Over the time interval $(0, \tau_h(\xi)]$, the solution for these particles is as given in region (i), while for the time interval $(\tau_h(\xi), \tau)$, the solution can be obtained as follows. Since the heating rate is zero, the temperature remains constant at $\theta(\tau_h(\xi))$. Therefore, the equations reduce to

$$s_\tau = -e^{\theta(\tau_h(\xi))} \quad \text{and} \quad s x_\xi = 1, \tag{3.15}$$

subject to $s = 2\xi/\ell_h$ and $x = \ell_h/2$ at $\tau = \tau_h(\xi)$. These can be solved easily to obtain

$$\theta(\xi, \tau) = \ln\left(2\mathcal{H} + 1 - 2\mathcal{H}\sqrt{\frac{2\xi}{\ell_h}}\right), \tag{3.16}$$

$$s(\xi, \tau) = \frac{2\xi}{\ell_h} - \left(2\mathcal{H} + 1 - 2\mathcal{H}\sqrt{\frac{2\xi}{\ell_h}}\right)(\tau - \tau_h(\xi)), \tag{3.17}$$

where $\tau_h(\xi)$ is given in (3.13). At time τ, we can find the location of a material element that started at $x = \xi$ using

$$x(\xi, \tau) = \frac{\ell_h}{2} + \int_{\xi_h(\tau)}^{\xi} \frac{1}{s(\eta, \tau)} d\eta, \tag{3.18}$$

where s is given in (3.17) and $\xi_h(\tau)$ is the original location of the material point that exits the heater at time τ. An explicit expression for $\xi_h(\tau)$ can be obtained by solving (3.13) to yield

$$\xi_h(\tau) = \frac{\ell_h}{2}\left(\frac{2\mathcal{H}+1}{2\mathcal{H}}\right)^2 \left(1 + W\left[-\frac{\exp\left(\frac{2\mathcal{H}^2\tau - 1}{2\mathcal{H}+1}\right)}{2\mathcal{H}+1}\right]\right)^2. \tag{3.19}$$

Region (iii). We finally consider material points that are initially outside the heater region, that is, $\ell_h/2 < \xi \le 1/2$. These points are never exposed to the heater; therefore, the temperature remains at zero. Thus, the equation for the cross-sectional area (2.42) becomes $s_\tau = -1$, which can be integrated once to yield

$$s = 1 - \tau.$$

Finally, (2.40) can be integrated to yield

$$x(\xi, \tau) = x\left(\frac{\ell_h}{2}, \tau\right) + \frac{\xi - \ell_h/2}{1 - \tau}.$$

Breaking criterion. In order to successfully make a microelectrode, the glass tube must break before the end of the tube reaches the maximum travel distance, ℓ_{max}. We begin by computing the time at which breaking occurs, τ_b. We use the solution obtained above along with the breaking criterion

$$\frac{1}{s_b}\sqrt{\theta_b + \frac{\theta_0}{\theta_a}} = C_b.$$

In the symmetric pulling case, the minimum cross-sectional area and maximum temperature occur at all the material points that have not yet exited the heater region at τ_b (region (i)). Thus, in principle, the tube can break at any of these material points. Since this region has uniform radii and the length of the region is small and of the same length as the heater, the ambiguity has little effect on the final tip radius of the electrode. For simplicity, we assume that the breaking will occur at $x = 0$, even though our model predicts that the glass tube can break anywhere in the heater region since the stress is the same. This is due to the fact that we have assumed that the heater strength is the same and the tube has uniform initial radii. In practice, of course, the middle of the heater is most likely to be the hottest; therefore, the glass will probably break in the middle. Using the solution obtained earlier, (3.4), the cross-sectional area at which breaking occurs, s_b, can be found by solving

$$\left[C_b^2 s_b^2 - \frac{\theta_0}{\theta_a}\right] = \ln\left[2\mathcal{H}(1-\sqrt{s_b})+1\right]. \tag{3.20}$$

If the tube is preheated such that $\theta_0 \gg \theta_a$, then this equation can be solved explicitly. Otherwise, it must be solved numerically, and this does not pose any serious challenges.

Having obtained s_b, we can compute the electrode profile at breaking. We first compute the time at which the tube breaks, τ_b,

$$\tau_b = \frac{1}{\mathcal{H}}\left[\sqrt{s_b} - 1 + \frac{2\mathcal{H}+1}{2\mathcal{H}}\ln\left(2\mathcal{H}+1-2\mathcal{H}\sqrt{s_b}\right)\right]. \tag{3.21}$$

Given τ_b, the initial location of the material element that is exiting the heater as the breaking occurs, $\xi_h(\tau_b)$, is obtained from (3.19). At breaking, the cross-sectional area profiles in the three different regions can be obtained using the formulas given earlier.

(i) In the heater region, $0 < \xi \le \xi_h(\tau_b)$, the cross-sectional area is independent of location and is given by $s = s_b$.

(ii) For points that were initially in the heater region but exited before breaking, $\xi_h(\tau_b) < \xi \le \ell_h/2$, the solution is given parametrically by

$$s(\xi,\tau_b) = \frac{2\xi}{\ell_h} - \left(2\mathcal{H}+1-2\mathcal{H}\sqrt{\frac{2\xi}{\ell_h}}\right)\left[\tau_b - \tau_h(\xi)\right], \tag{3.22}$$

$$x(\xi,\tau_b) = \frac{\ell_h}{2} + \int_{\xi_h(\tau_b)}^{\xi} \frac{1}{s(\eta,\tau_b)}d\eta, \tag{3.23}$$

where $\tau_h(\xi)$ is given in (3.13) and $\xi_h(\tau_b)$ is given in (3.19).

(iii) For material elements that were initially outside the heater region, $\ell_h/2 < \xi \le 1/2$, the cross-sectional area is also independent of location and is given by

$$s(\xi,\tau_b) = 1 - \tau_b.$$

The total extension of the glass tube is given by

$$x(1/2,\tau_b) = x\left(\frac{\ell_h}{2},\tau_b\right) + \frac{1-\ell_h}{2(1-\tau_b)}.$$

With the analytical expressions for the solution, we are in a position to discuss how to control the final electrode shape. First, we must ensure that the apparatus is long enough to allow sufficient extension so that breaking can occur, that is, $\ell_{max} > x(1, \tau_b)$. If breaking occurs, then each resulting electrode is composed of three parts: a region of length $\ell_h/2$ near the tip of the electrode with constant cross-sectional area s_b, a region from $x(\ell_h/2, \tau_b)$ to the end of the electrode with constant cross-sectional area $1 - \tau_b$, and a region of width $x(\ell_h/2, \tau_b) - \ell_h/2$ that connects these two regions. All of these quantities can be easily computed, and this allows one to determine puller settings to control the shape of the resulting tip.

In the following figures, we consider a heater with dimensionless length, $l_h = 0.5$, with a constant heating rate. In Figures 3.3 and 3.4, we plot the outer radius of the glass tube and the temperature as functions of the distance along the axis at various times before breaking and at the time of breaking. Initially, the glass is cool and the viscosity is relatively high, and so the glass tube deforms very little. However, after some time, the glass in the heater region becomes heated, and therefore the viscosity in this region drops. The dots in the figure show the evolution of material points that initially were spaced uniformly along the tube. From this, it is clear that the vast majority of the deformation occurs to material elements that initially were in the heater region.

We also see that as the breaking point is approached, the stretching occurs very quickly. This can be seen even more clearly in Figure 3.5, where we plot the minimum radius, which in this case occurs at the centerline, as a function of time. For the majority of the time, the material thins slowly, but once stretching begins, it occurs extremely rapidly. If we had ignored the breaking criteria, a pinching event would have occurred when the radius became zero. From this, it is clear that the breaking time can be well approximated by the time at which pinching occurs.

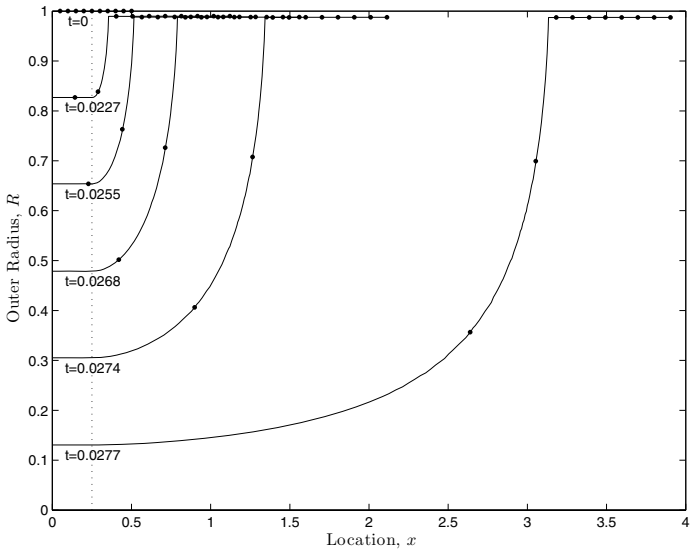

FIG. 3.3. *Outer radius of the glass tube as a function of position. The heater is located between* $x = 0$ *and* $x = 0.25$ *as indicated by the dotted line. The dots in this and subsequent figures show the evolution of material points that initially were spaced uniformly along the tube.*

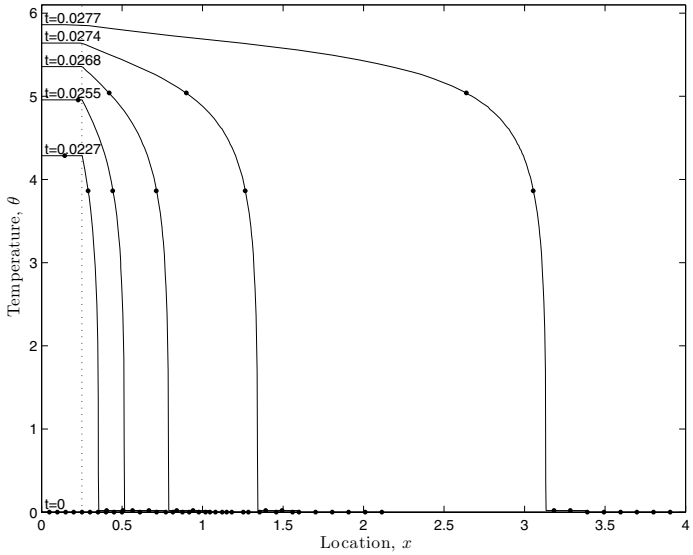

FIG. 3.4. *Temperature of the glass tube as a function of position. The heater is located between* $x = 0$ *and* $x = 0.25$ *as indicated by the dotted line.*

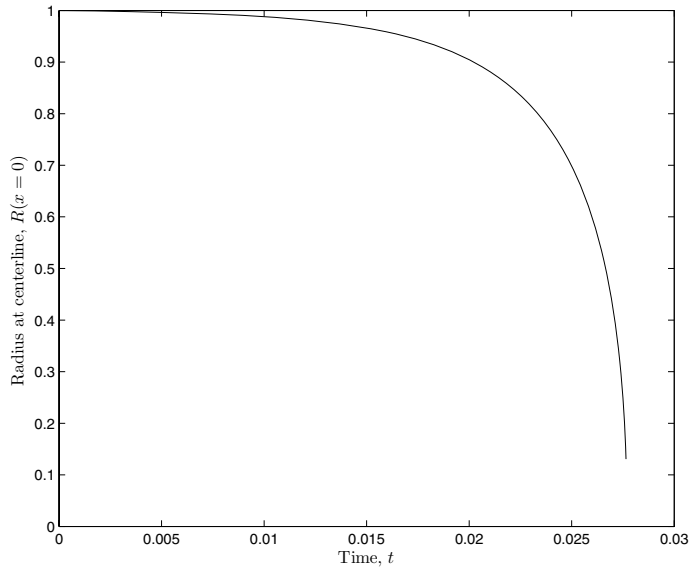

FIG. 3.5. *Minimum radius of the glass tube at the origin as a function of time.*

In Figure 3.6, we plot the dimensionless stress in the glass tube and the dimensionless breaking stress at the centerline as a function of time. As the glass tube thins, the stress increases dramatically, but breaking also is aided by heating, which acts to decrease the breaking stress. Nevertheless, during the time near breaking, the dynamics is dominated by increases in the stress.

3.2. Approximation of tip cross-sectional area. A distinct feature of the glass electrode formation process is the existence of two different regimes if the heating rate $\mathcal{H}$ is large. At early times, the glass is heated, but the viscosity is sufficiently large

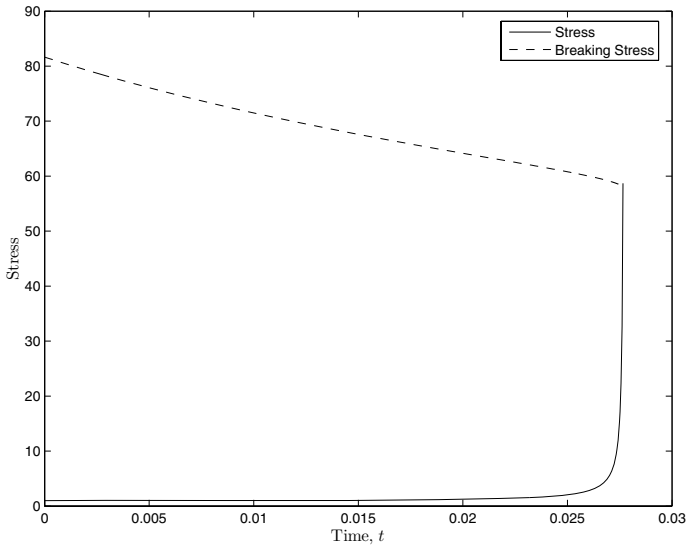

FIG. 3.6. *Dimensionless stress in the glass tube and the dimensionless breaking stress at the centerline as functions of time.*

that little stretching occurs. When the glass has absorbed sufficient thermal energy, the viscosity drops dramatically, and the glass stretches rapidly before breaking. This is largely due to two facts: the relatively large heater strength $\mathcal{H}$ and the exponential dependence of the viscosity on temperature. In the following, we will explain briefly how to use a local asymptotic analysis to obtain approximate solutions for these two regimes.

We start by examining (3.7) for the cross-sectional area s. For a more general case with nonuniform heater strength, we could apply the same local analysis to the set of governing equation (3.2). For simplicity, we will discuss only the case of constant heater strength. When $\mathcal{H} \gg 1$, we can distinguish two cases, i.e., $s \approx 1$ and $s \ll 1$.

3.2.1. Case 1: $s \approx 1$. When $s \approx 1$, or more precisely, $\sqrt{s} = 1 - o(\mathcal{H}^{-1})$, the first two terms in (3.7) essentially cancel, and the remaining two terms are in balance

$$\ln[1 + 2\mathcal{H}(1 - \sqrt{s})] = \mathcal{H}\tau,$$

which yields

$$s \approx 1 - \frac{e^{\mathcal{H}\tau} - 1}{\mathcal{H}}. \tag{3.24}$$

This approximation is valid from $\mathcal{H}\tau = 0$ up to $\mathcal{H}\tau = O(\ln 2\mathcal{H})$. Using (3.6), we find that during this regime the temperature rises from zero to $\theta \approx \ln(2\mathcal{H})$.

3.2.2. Case 2: $s \ll 1$. Near breaking, the glass tube has stretched significantly at the center and the cross-sectional area s tends to zero. Use of (3.7) yields the following approximation:

$$\sqrt{s} - 1 + \ln(1 + 2\mathcal{H}) + \ln\left(1 - \frac{2\mathcal{H}\sqrt{s}}{1 + 2\mathcal{H}}\right) = \mathcal{H}\tau.$$

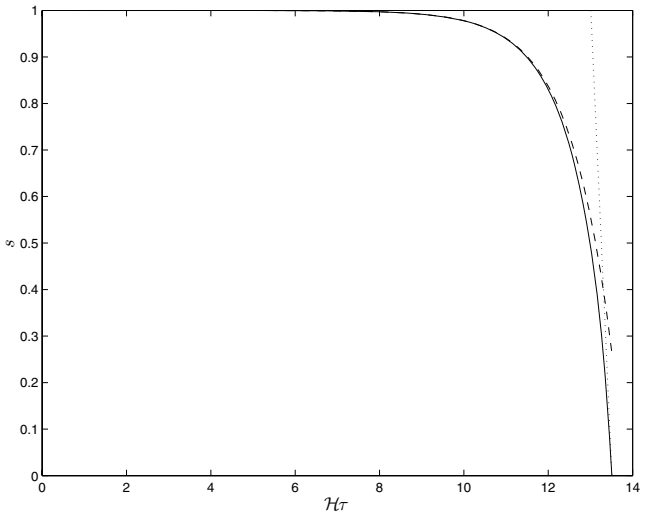

FIG. 3.7. *The cross-sectional area s is plotted as a function of the scaled time $\mathcal{H}\tau$ for a large value of $\mathcal{H} = 10^6$. The solid curve represents the exact solution, while the dashed curve represents the local asymptotic solution for $1 - s \ll 1$,* (3.24)*, and the dotted curve represents the local asymptotic solution for $s \ll 1$,* (3.25)*. The thread heats up with little thinning for a period of time $\tau = O(\mathcal{H}^{-1} \ln(2\mathcal{H}))$ and then thins over a period of time $\tau = O(\mathcal{H}^{-1})$.*

Expanding the logarithmic function in $\sqrt{s}$ yields

$$s \approx 2\ln(1 + 2\mathcal{H}) - 2(\mathcal{H}\tau + 1). \tag{3.25}$$

If the tube were not to break, it would pinch off at time

$$\tau = \frac{\ln(1 + 2\mathcal{H}) - 1}{\mathcal{H}}.$$

Hence, rapid stretching occurs within a relatively short period of time of $O(\mathcal{H}^{-1})$. This is much shorter than the initial phase, which lasted for a time on the order of $O(\mathcal{H}^{-1} \ln(2\mathcal{H}))$. Based on the approximate pinching time, temperature at pinch-off can be approximated by $\theta \approx \ln(2\mathcal{H} + 1)$. Thus the temperature variation during rapid stretching is much smaller than the $\ln(2\mathcal{H})$ variation that occurred in the initial phase.

In Figure 3.7, we have plotted the approximate solutions (3.24) and (3.25) and the exact solution (3.7). The local asymptotic solutions approximate the exact solution well in each regime.

3.2.3. Cross-sectional area at breaking. We now can find approximations that allow us to easily control the shape of the tip. The minimum area of the electrode, s_b, will be significantly smaller than the initial area of the tube; therefore, the breaking time occurs quite close to the pinch-off time. As discussed earlier, at the pinching time, the temperature is given by $\theta \approx \ln(2\mathcal{H} + 1)$. This temperature is also a good approximation for the temperature near the breaking time, because in the time between breaking and pinch-off the change in temperature is small. Hence, the breaking criterion is well approximated by

$$s_b \approx \frac{\sqrt{\ln(2\mathcal{H} + 1) + \theta_0/\theta_a}}{C_b}.$$

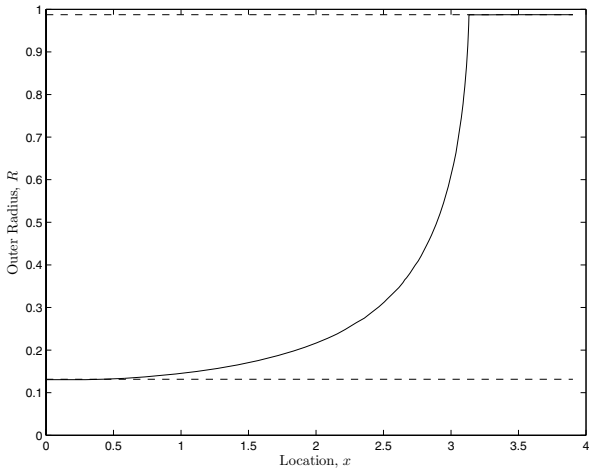

FIG. 3.8. *Microelectrode shape at the breaking time. Also included are the approximations for the tip width and the width of the glass tube far from the tip.*

Also, the area far from the tip, $1 - \tau_b$, can be approximated by $1 - \tau_{pinch}$ as the difference is $O(\mathcal{H}^{-1})$.

In Figure 3.8, we plot the final shape of the electrode along with the approximations to the tip width and the width far from the tip. They can be seen to be in excellent agreement, and this is the case over a wide range of parameters, especially for the tip width. We also have computed the difference between the two solutions, which is less than 2%.

3.3. Symmetric pulling with constant force and nonuniform heating. In this case, we also consider a tube that is initially located in the region $-1/2 \le x \le 1/2$ and a puller that is the same as in the above section except that the heating is spatially nonuniform. Rather than use a constant heating profile, we use the profile

$$H(x) = \exp(-4\pi x^2/l_h^2).$$

This has the property that the maximum heater intensity and the integrated heat intensity, $\int H(x)\mathrm{d}x$, are the same as for the piecewise constant heating used in the previous section.

In Figure 3.9, a numerical solution of the final shape of the electrode at the breaking time (solid line) is plotted along with the approximate theory for the tip radius and the radius far from the tip (horizontal dotted lines). In Figures 3.10 and 3.11, we plot the evolution of the outer radius and temperature. We see that the evolution of the glass tube profile is somewhat similar to that for the constant heating case. Of particular interest is the fact that the approximate theory for the uniform heating case still gives an extremely accurate approximation to the final tip radius. This can be understood by again dividing the dynamics into two stages: the first stage in which the glass heats up with little deformation and the second stage in which significant deformation takes place. We consider material elements near the location of the maximum in the heater intensity. In the first stage these points heat up with very little motion of the glass tube. Thus, the temperatures in the uniform and nonuniform calculations are almost identical. Then, since there is very little heating in the second stage, the breaking criteria will be achieved at approximately

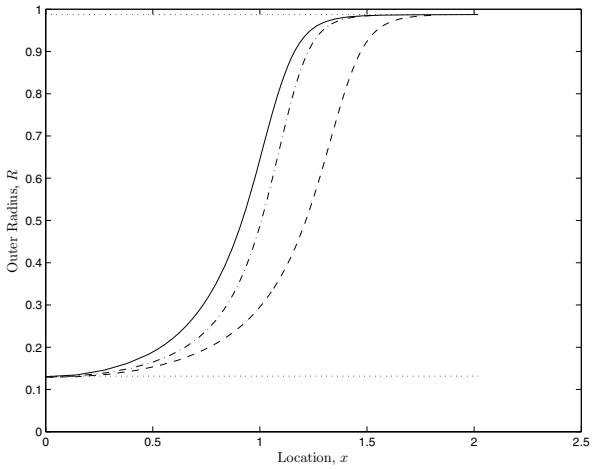

FIG. 3.9. *Final shapes at the breaking times of the microelectrodes for nonuniform heating. Profiles are given for the symmetrical pulling case (solid curve) and for the asymmetrical pulling case (dash-dot curve for the microelectrode formed from the part of the glass tube that remains attached to the fixed wall, dashed curve for the microelectrode formed by the part of the tube which is being pulled). Also, the tip radius and the radius far from the tip (horizontal dotted lines) are given by the approximate theory.*

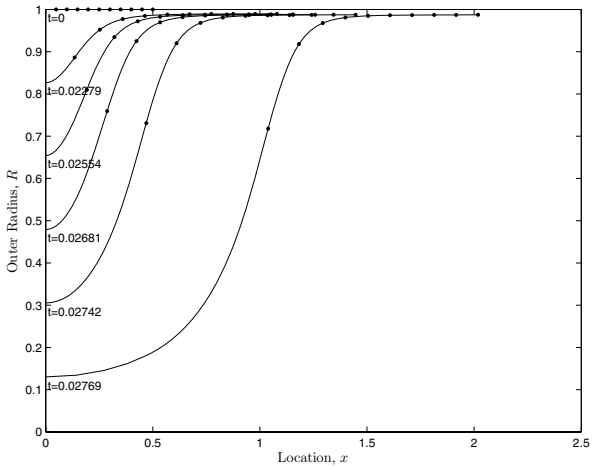

FIG. 3.10. *Outer radius of a glass tube during the evolution of the microelectrode formation under symmetric pulling with a constant force and nonuniform heating.*

the same radius in both the uniform and nonuniform cases. The only significant difference between the uniform and nonuniform cases is that uniform heating means that a larger section of the glass will be heated enough that it will significantly deform. Hence, the total extension of the glass tube before breaking is significantly longer.

3.4. Asymmetric pulling with constant force and nonuniform heating. We now consider the case of a tube that is initially located in the region $0 \leq x \leq 1$, is fixed at one end ($x = 0$), and is pulled at the other end with constant force. The tube

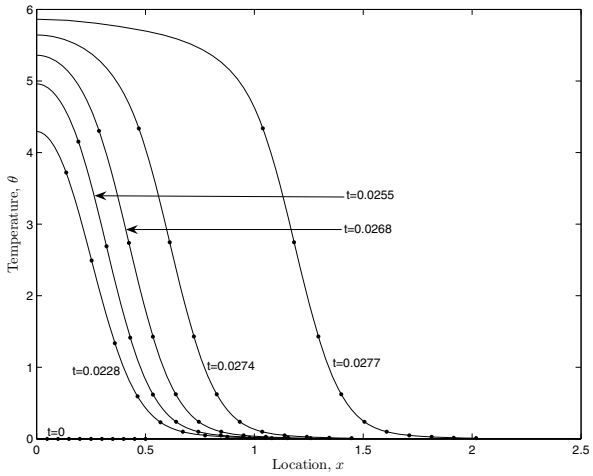

FIG. 3.11. *Temperature of a glass tube during the evolution of the microelectrode formation under symmetric pulling with a constant force and nonuniform heating.*

is heated in the same way as in the previous section, but with the maximum intensity centered on the midpoint of the tube,

$$H(x) = \exp\left(-\frac{4\pi(x-1/2)^2}{l_h^2}\right).$$

In Figure 3.9, we plotted the final shape of the electrodes at the breaking time. The dash-dot curve represents microelectrode shape of the section of the tube that remains attached to the fixed wall (reversed in x for comparison purposes), and the dashed curve represents the shape of the section to which the force was being applied. The horizontal dotted lines represent the approximate theory for the tip radius and radius far from the tip. In Figures 3.12 and 3.13, we plot the evolution of the outer radius and temperature. Again, the approximate theory gives an excellent approximation for the breaking tip radius, as explained in the above section. The difference between the electrode shapes to the left and right of the breaking point can be explained by the small differences that occur during the second stage of the evolution. Both microelectrode tips in the asymmetrical pulling case extend further than the tip for the symmetric case because the hottest part of the tube moves relative to the heater maximum. Therefore, more of the glass tube near the breaking point is significantly heated and can stretch more easily.

We note that, for spatially uniform heating, an analytical solution may be obtained using a procedure similar to that used in section 3.1. There are a number of cases to be considered, and the solutions become slightly complicated. Therefore, we present the results in Appendix B.

3.5. Variable pulling force. We now consider the case of a variable pulling force. We take a tube that is initially located in the region $0 \le x \le 1$, is fixed at one end ($x = 0$), and whose other end is attached to a mass that falls under gravity. In this case, the situation is slightly more complicated. For the vertical puller, the dimensionless stress is given by $s^{-1}(1 - F_r\ \mathrm{d}^2\ell/\mathrm{d}t^2)$. If one ignores breaking, it is easy to show that this solution will never pinch off and that $\ell \to t^2/(2F_r)$ as $t \to \infty$. This corresponds to the weight simply falling due to gravity, and the glass thread exerts a

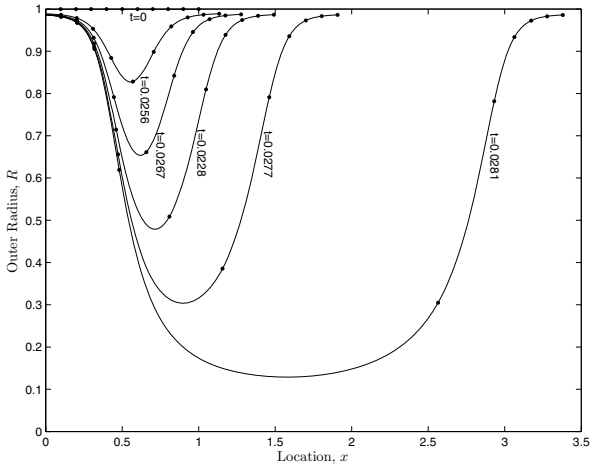

FIG. 3.12. *Outer radius of a glass tube during the evolution of the microelectrode formation under asymmetric pulling with a constant force and nonuniform heating.*

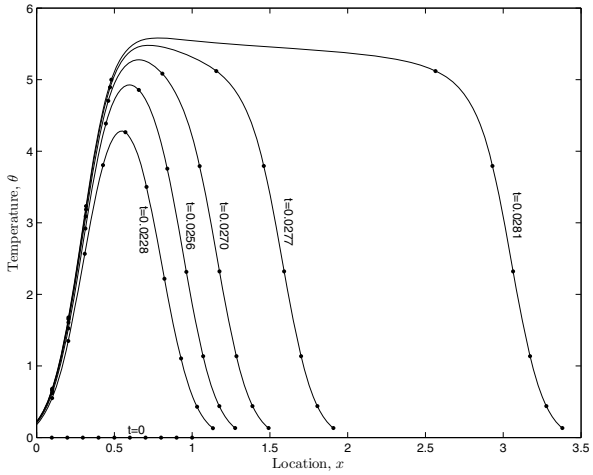

FIG. 3.13. *Temperature of a glass tube during the evolution of the microelectrode formation under asymmetric pulling with a constant force and nonuniform heating.*

negligible force on the weight. It is instructive to consider the case with no heating, i.e., the glass tube has a spatially uniform radius. In this case, it is easy to show that the stress is given by $\mathrm{d}\ln(\ell)/\mathrm{d}t$. Therefore, in the limit when $t \to \infty$, the stress tends to $2/t$, which is a decreasing function of time.

At early times, the behavior is similar to the constant force cases. This is because the initial viscosity is high and so the deformation, and hence the acceleration of the weight, are negligible. However, when the material becomes hot, it deforms rapidly. Thus, the stress increases due to thinning in the tube thickness. Therefore, the acceleration terms reduce the effective force experienced by the glass. Even though the glass is thinning, the overall stress decreases, because the force experienced by the glass is reduced by the acceleration of the weight in the same way as in the isothermal case. Therefore, we expect that the stress will attain a maximum value at finite time.

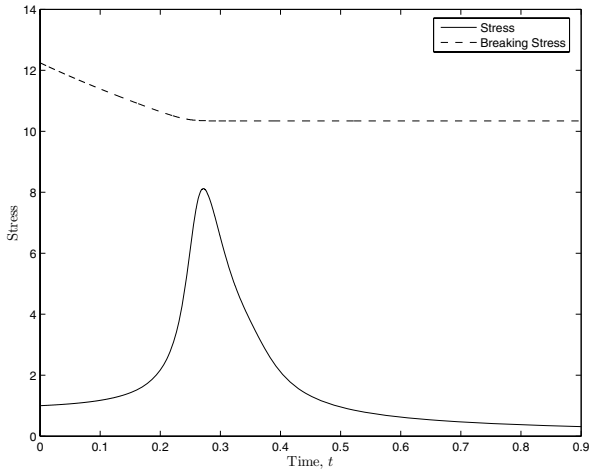

FIG. 3.14. *Dimensionless stress and dimensionless breaking stress in the glass tube closest to the location of breaking as a function of time. No breaking case.*

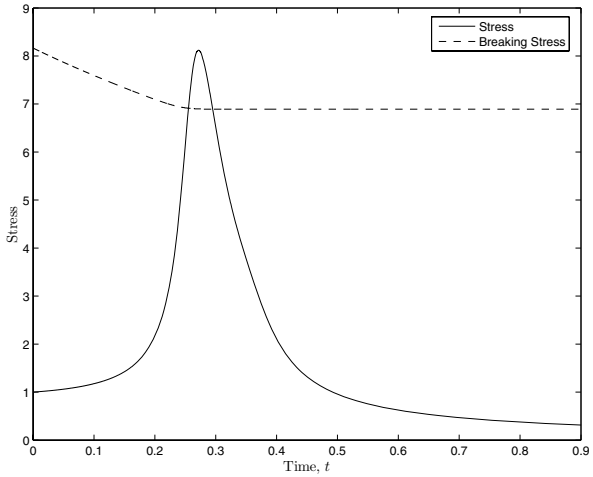

FIG. 3.15. *Dimensionless stress and dimensionless breaking stress in the glass tube closest to the location of breaking as a function of time. The tube breaks when the two curves first intersect.*

In Figures 3.14 and 3.15, we plot the dimensionless stress and the dimensionless breaking stress at the location that is closest to breaking as a function of time. For large values of $\mathcal{H}$ and C_b, as in Figure 3.14, the maximum stress is always less than the breaking stress. However, for smaller values of $\mathcal{H}$ and C_b, as in Figure 3.15, the stress may reach the breaking stress. This explains why vertical pullers typically require two pulls to break the glass tube. The first pull decreases the radius, which means that the new values of $\mathcal{H}$ and C_b for the second pull will be reduced. This implies that breaking will be more easily achieved in the second pull.

We caution that in the case when breaking does not occur, the tube becomes very thin, and inertia will ultimately become important, as shown by Stokes and Tuck [19]. Nevertheless, the inclusion of glass inertia will further reduce the viscous stress which makes it even more difficult to reach the breaking criterion. Therefore, the general

conclusion reached based on the simplified model remains useful. As we noted earlier, in this paper we focus only on successful pullings of microelectrodes, and the free-fall case will not be pursued here.

4. Discussion. We now discuss the effects of the parameters and puller designs on the shape of the final electrode. In order to do this, we will focus on the analytical solutions and results from the numerical method discussed in the previous section.

4.1. Shape control. There are two parameters that are relatively easy to vary continuously in an experimental context. These are the dimensional force, F_0, and the dimensional temperature of the heater, θ_h. In practice, one can use a graph of τ_{pinch} against $\mathcal{H}$ to choose the appropriate value of the heater strength $\mathcal{H}$ to achieve the required maximum area, $1 - \tau_{pinch}$. One then can choose C_b to give the required minimum area, s_b. Once the desired values of C_b and $\mathcal{H}$ are known, one simply chooses the dimensional force, F_0, to achieve the C_b value and then chooses θ_h to obtain the $\mathcal{H}$ value. This means that the appropriate operating conditions can be well approximated by simply using the universal graph of τ_{pinch} against $\mathcal{H}$.

While it is relatively easy to set the values of applied force and heater temperature, we also need to make sure that the glass breaks while the extension of the tube is within the physical length of the puller. This can be achieved by choosing the correct heater length, after the tip radius and other parameter values are determined. In Figure 4.1, we show how we can control the final tip radius by varying the applied force. We vary the applied force and use values of the other parameters from Tables 2.1 and 2.2. The simulation results (circles) and the approximate theory (solid line) show excellent agreement over many orders of magnitude in the applied force. By reducing the applied force, effectively, we can reduce the stress in the tube, and this allows the tube to reach a smaller radius before exceeding the breaking stress.

4.2. Sensitivity analysis. In order to determine the relative robustness of the symmetric and asymmetric methods, we performed a sensitivity analysis of the final shape with respect to changes in the parameters $\mathcal{H}$ and C_b. We found that the

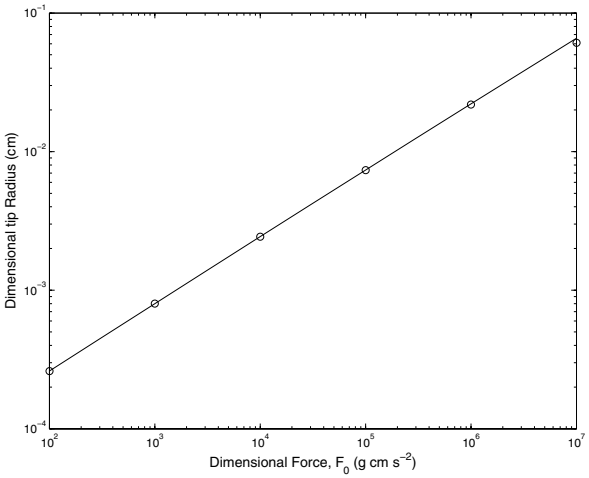

FIG. 4.1. *Dimensional tip radius as a function of the applied force.*

sensitivities are almost identical over a wide range of parameter values; therefore neither parameter has a significant advantage with regard to robustness. The symmetric puller has the advantage in that it can create two identical electrodes in a single pull. However, the asymmetric puller may be cheaper to build and easier to operate since it requires only a force be exerted at one end.

The sensitivity of vertical pullers to changes in parameters can be quite strong. This is particularly true if the glass breaks while the extension of the tube occurs near the maximum stress level. Then small increases in $\mathcal{H}$ or C_b might prevent the stress from reaching the breaking value, and no electrode would be formed. Even if this does not occur, the sensitivity of the variable force method is still substantially larger than for the constant force methods. The fact that a double pull is required also means that the procedure is much more difficult to implement and therefore less robust.

4.3. Concluding remarks. In this paper, we have simplified a model proposed in an earlier study (Huang et al., [10]) for glass microelectrode formation. Using a dimensional analysis argument, we have shown that the conductive heat transfer is small compared to the radiative and convective transfer and therefore can be neglected in the temperature equation. We have developed a Lagrangian-based method to solve the model equations and compute explicit solutions to the time-dependent equations for some simple cases. By investigating the effects of the parameters on the final shape of the microelectrodes, we have shown that vertical pullers are much less robust than horizontal pullers.

By considering the simplified models, we have been able to understand a number of important features of the resulting electrode. First, for typical parameter values, the surface tension is much smaller than the applied force, and we have shown that the ratio of the inner to outer radius will remain constant. Therefore, if a specified ratio is required in the final electrode, the only way to achieve this is to start with a tube that has that required ratio. Second, the length of the electrode tip is of the same order of magnitude as the length of the heater. This means that the tip length can be controlled by controlling the portion of the glass that is heated significantly. Third, using our approximate theory, we have shown that an excellent approximation to the tip width can be obtained from a very simple formula. This gives an extremely practical and straightforward method of determining the parameter values required to achieve a given tip radius.

In some cases, controlling the tip radius may not be sufficient, and the user may wish to control the entire tip profile. This can be achieved either by using a spatially dependent heater profile or by allowing a time-dependent pulling force. By choosing different heater profiles or pulling forces, one can produce a tip shape close to a desirable one. Since our method is simple, robust, and extremely efficient to implement numerically, it can be used to estimate the tip profile when the heating profile and/or pulling force are given. By using standard optimization techniques on this function, we then can achieve an approximation to the required profile.

Finally, the analysis and solution methodology presented in this paper are not restricted to glass microelectrode formation and may have a number of important applications in other glass formation processes. For example, the pulling of optical fibers uses a similar setup, even though the objective for optical fiber pulling is rather different. Instead of seeking the conditions to break the glass tube under stretching, a good optical fiber pulling device must ensure that the glass stretches without being broken. However, our model and numerical method can be readily applied to fiber pulling, with minor adjustments on the handling of boundary conditions.

Appendix A. Derivation of the temperature equation (2.18). In the long-wavelength limit of small radius to length aspect ratio, axial conduction can be neglected, and the heat equation is given by

$$\theta_t + u\theta_x = \frac{k}{\rho c_p}\frac{1}{y}\frac{\partial}{\partial y}\left(y\frac{\partial\theta}{\partial y}\right), \tag{A.1}$$

where y is the axisymmetric radial position and c_p and k are the specific heat capacity and the thermal conductivity of the fluid, respectively. The radiative boundary condition is given by

$$k\left.\frac{\partial\theta}{\partial y}\right|_{y=r} = 0, \tag{A.2}$$

$$-k\left.\frac{\partial\theta}{\partial y}\right|_{y=R} = \frac{k_B E_h \varepsilon_h \alpha\left(\theta_h^4 - \theta^4\right)}{1-(1-\alpha)(1-\varepsilon_h)} + \frac{k_B E_b \varepsilon_b \alpha\left(\theta_b^4 - \theta^4\right)}{1-(1-\alpha)(1-\varepsilon_b)}, \tag{A.3}$$

where k_B is the Boltzmann constant, α is the absorptivity, and θ_h is the heater temperature. We have assumed that the axial conduction is negligible and that the radiation heat exchange occurs only on the outer surface of the glass tube, as in [9].

We now nondimensionalize the heat equation (A.1) and the boundary condition (A.3) by using the scalings

$$u = u_0 u',\ \ s = s_0 s',\ \ y = R_0 y',\ \ x = \ell_0 x',\ \ t = \ell_0 u_0^{-1} t',\ \ \theta = \theta_0 + \theta_a \theta',\ \ u_0 = \frac{\ell_0 F_0}{3\mu_0 s_0}.$$

Dropping the primes, the heat equation becomes

$$Pe\left(\frac{\partial\theta}{\partial t} + u\frac{\partial\theta}{\partial x}\right) = \frac{1}{y}\frac{\partial}{\partial y}\left(y\frac{\partial\theta}{\partial y}\right), \tag{A.4}$$

where

$$Pe = \frac{\rho c_p u_0 R_0^2}{\ell_0 k} = 4.2\times 10^{-3} \tag{A.5}$$

is the transverse Peclet number, which represents the ratio of heat advected along the thread to heat conducted across the thread. The radiative boundary condition becomes

$$\left.\frac{\partial\theta}{\partial y}\right|_{y=\frac{r}{R_0}} = 0, \qquad \left.\frac{\partial\theta}{\partial y}\right|_{y=\frac{R}{R_0}} = BiH(x,\theta), \tag{A.6}$$

where

$$Bi = \frac{\alpha k_b \theta_h^4 R_0 \epsilon_h}{k\theta_a[1-(1-\alpha)(1-\epsilon_h)]} = 3.5\times 10^{-1} \tag{A.7}$$

is the Biot number. The dimensionless function

$$H(x,\theta) = E_h(x)\left(1-\left(\frac{\theta_0+\theta\theta_a}{\theta_h}\right)^4\right) + \frac{\epsilon_b[1-(1-\alpha)(1-\epsilon_h)]E_b(x)(\theta_b^4-(\theta_0+\theta_a\theta)^4)}{\epsilon_h[1-(1-\alpha)(1-\epsilon_b)]\theta_h^4}$$

represents the magnitude of the net heat flux that is absorbed when the temperature is θ. We now assume that both Bi and Pe are small, and from (2.2) we note that

$$\mathcal{H} \equiv \frac{2Bi}{(1-\beta_0^2)Pe}. \tag{A.8}$$

We assume that the temperature has an asymptotic expansion of the form

$$\theta = \Theta_0 + Bi\Theta_1 + \cdots; \tag{A.9}$$

then substituting this into (A.4) and (A.6) and collecting the terms to zeroth and first order in Bi yields

$$\frac{1}{y}\frac{\partial}{\partial y}\left(y\frac{\partial \Theta_0}{\partial y}\right) = 0 \quad \text{with} \quad \left.\frac{\partial \Theta_0}{\partial y}\right|_{y=\frac{r}{R_0}} = 0, \quad \left.\frac{\partial \Theta_0}{\partial y}\right|_{y=\frac{R}{R_0}} = 0 \tag{A.10}$$

and

$$\frac{1}{y}\frac{\partial}{\partial y}\left(y\frac{\partial \Theta_1}{\partial y}\right) = \frac{2}{(1-\beta_0^2)\mathcal{H}}\left(\frac{\partial \Theta_0}{\partial t} + u\frac{\partial \Theta_0}{\partial x}\right) \tag{A.11}$$

with

$$\left.\frac{\partial \Theta_1}{\partial y}\right|_{y=r} = 0, \quad \left.\frac{\partial \Theta_1}{\partial y}\right|_{y=R} = H\left(x, \Theta_0\right). \tag{A.12}$$

Equation (A.10) implies that at leading order Θ_0 is independent of y. Therefore, using (A.11)–(A.12), we see that Θ_0 satisfies

$$\frac{\partial \Theta_0}{\partial t} + u\frac{\partial \Theta_0}{\partial x} = \frac{\mathcal{H}H\left(x, \Theta_0\right)}{\sqrt{s}}\sqrt{\frac{1-\beta_0^2}{1-\beta^2}}, \tag{A.13}$$

where $\beta = r/R$. For notational brevity, we use θ to denote the leading order term, Θ_0, and obtain the equation in the final form as (2.18).

At the leading order, the viscosity is independent of the radial coordinate because the viscosity is a function of the temperature.

Appendix B. Exact solution for asymmetrical pulling. In this appendix, we obtain the exact solutions for the microelectrode shape and the temperature distribution for a glass tube undergoing asymmetrical pulling with uniform heating from a finite length heater. The initial velocity at each point in the glass tube is zero, and the other initial and boundary conditions are

$$\theta(\xi,0) = 0,\ s(\xi,0) = 1,\ x(\xi,0) = \xi,\ \theta(0,\tau) = 0,\ s(0,\tau) = 1,\ x(0,\tau) = 0. \tag{B.1}$$

The heater is located between $\xi = \ell_1$ and $\xi = \ell_2$. Let τ_b be the breaking time and τ_* be the time when the material point $\xi = \ell_1$ has passed location ℓ_2.

We need to consider two different cases: $\tau_b \le \tau_*$ and $\tau_b > \tau_*$.

B.1. Case 1: $\tau_b \le \tau_*$. Let $\xi_1(\tau_b)$ and $\xi_2(\tau_b)$ be the initial locations of the material points that are at ℓ_1 and ℓ_2 at τ_b. We have $\xi_1(\tau_b) < \ell_1 < \xi_2(\tau_b) < \ell_2$. Thus, there exist five regions: (1) $0 \le \xi \le \xi_1(\tau_b)$, (2) $\xi_1(\tau_b) \le \xi \le \ell_1$, (3) $\ell_1 \le \xi \le \xi_2(\tau_b)$, (4) $\xi_2(\tau_b) \le \xi \le \ell_2$, and (5) $\ell_2 \le \xi \le 1$.

B.1.1. $0 \le \xi \le \xi_1(\tau_b)$. In this region, for $0 < \tau < \tau_b$, we have

$$\theta_\tau = 0, \quad s_\tau = -e^\theta, \quad s x_\xi = 1,$$

which, combined with (B.1), gives

$$\theta_1 = 0, \quad s_1 = 1 - \tau, \quad x_1 = \frac{\xi}{1-\tau}.$$

Thus, at τ_b, the solution is

$$\theta_1 = 0, \quad s_1 = 1 - \tau_b, \quad x_1 = \frac{\xi}{1-\tau_b}, \tag{B.2}$$

from which we obtain $\xi_1(\tau_b) = (1-\tau_b)\ell_1$.

B.1.2. $\xi_1(\tau_b) \le \xi \le \ell_1$. (I). $0 \le \tau \le \tau_1(\xi)$, where $\tau_1(\xi)$ is the time when the material point that is initially at ξ crosses the point ℓ_1. The solution is

$$\theta_2^- = 0, \quad s_2^- = 1 - \tau, \quad x_2^- = \frac{\xi - \xi_1(\tau_b)}{1-\tau} + x_1(\xi_1(\tau_b), \tau) = \frac{\xi}{1-\tau},$$

from which we obtain

$$\ell_1 = \frac{\xi}{1 - \tau_1(\xi)}$$

or

$$\tau_1(\xi) = 1 - \frac{\xi}{\ell_1}.$$

(II). $\tau_1(\xi) \le \tau \le \tau_b$. In this region, we have

$$\theta_\tau = \frac{\mathcal{H}}{\sqrt{s}}, \quad s_\tau = -e^\theta, \quad s x_\xi = 1,$$

from which we obtain

$$\begin{aligned}
&\frac{2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1}{2\mathcal{H}} \ln\left[1 + 2\mathcal{H}\left(\sqrt{1-\tau_1(\xi)} - \sqrt{s_2^+}\right)\right] \\
&\quad = \sqrt{1-\tau_1(\xi)} - \sqrt{s_2^+} + \mathcal{H}[\tau - \tau_1(\xi)], \\
&\quad \left(2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1\right)\theta_2^+ + 1 - e^{\theta_2^+} = 2\mathcal{H}^2[\tau - \tau_1(\xi)], \\
&x_2^+ = \ell_1 + \int_{\xi_1(\tau)}^{\xi} \frac{1}{s_2^+(\tau_1(\eta))} d\eta.
\end{aligned}$$

Therefore,

$$\begin{aligned}
&\frac{2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1}{2\mathcal{H}} \ln\left[1 + 2\mathcal{H}\left(\sqrt{1-\tau_1(\xi)} - \sqrt{s_2^+}\right)\right] \\
&\quad = \sqrt{1-\tau_1(\xi)} - \sqrt{s_2^+} + \mathcal{H}[\tau_b - \tau_1(\xi)], \qquad \text{(B.3)} \\
&\quad \left(2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1\right)\theta_2^+ + 1 - e^{\theta_2^+} = 2\mathcal{H}^2[\tau_b - \tau_1(\xi)], \qquad \text{(B.4)} \\
&x_2^+ = \ell_1 + \int_{\xi_1(\tau_b)}^{\xi} \frac{1}{s_2^+(\tau_1(\eta))} d\eta. \qquad \text{(B.5)}
\end{aligned}$$

B.1.3. $\ell_1 \le \xi \le \xi_2(\tau_b)$. For $0 \le \tau \le \tau_b$, we have

$$\theta_\tau = \frac{\mathcal{H}}{\sqrt{s}}, \quad s_\tau = -e^\theta, \quad s x_\xi = 1,$$

from which we have

$$\begin{aligned}
&\sqrt{s_3} - 1 + \frac{2\mathcal{H}+1}{2\mathcal{H}} \ln\left(1 + 2\mathcal{H} - 2\mathcal{H}\sqrt{s_3}\right) = \mathcal{H}\tau,\\
&(2\mathcal{H}+1)\,\theta_3 + 1 - e^{\theta_3} = 2\mathcal{H}^2\tau,\\
&x_3 = \frac{\xi - \ell_1}{s_3(\tau)} + x_2^+(\ell_1, \tau).
\end{aligned}$$

At τ_b, we have

$$\sqrt{s_3} - 1 + \frac{2\mathcal{H}+1}{2\mathcal{H}} \ln\left(1 + 2\mathcal{H} - 2\mathcal{H}\sqrt{s_3}\right) = \mathcal{H}\tau_b, \tag{B.6}$$

$$(2\mathcal{H}+1)\,\theta_3 + 1 - e^{\theta_3} = 2\mathcal{H}^2\tau_b, \tag{B.7}$$

$$x_3 = \frac{\xi - \ell_1}{s_3(\tau_b)} + x_2^+(\ell_1, \tau_b). \tag{B.8}$$

From the above equation, we determine $\xi_2(\tau_b)$ to be

$$\xi_2(\tau_b) = \ell_1 + [\ell_2 - x_2^+(\ell_1, \tau_b)] s_3(\tau_b). \tag{B.9}$$

B.1.4. $\xi_2(\tau_b) \le \xi \le \ell_2$. (I). $0 \le \tau \le \tau_2(\xi)$, where $\tau_2(\xi)$ is the time at which the material point ξ crosses the point ℓ_2. In this case, we have

$$\theta_\tau = \frac{\mathcal{H}}{\sqrt{s}}, \quad s_\tau = -e^\theta, \quad s x_\xi = 1,$$

from which we have

$$\begin{aligned}
&\sqrt{s_4^-} - 1 + \frac{2\mathcal{H}+1}{2\mathcal{H}} \ln\left(1 + 2\mathcal{H} - 2\mathcal{H}\sqrt{s_4^-}\right) = \mathcal{H}\tau,\\
&(2\mathcal{H}+1)\,\theta_4^- + 1 - e^{\theta_4^-} = 2\mathcal{H}^2\tau,\\
&x_4^- = \frac{\xi - \xi_2(\tau_b)}{s_4^-(\tau)} + x_3(\xi_2(\tau_b), \tau).
\end{aligned}$$

From the last equation, we obtain

$$\ell_2 == \frac{\xi - \xi_2(\tau_b)}{s_4^-(\tau_2(\xi))} + x_3(\xi_2(\tau_b), \tau_2(\xi)). \tag{B.10}$$

From this equation, we can find the value of $\tau_2(\xi)$.

(II). $\tau_2(\xi) \le \tau \le \tau_b$. In this case,

$$\theta_\tau = 0, \quad s_\tau = -e^\theta, \quad s x_\xi = 1,$$

from which we have

$$\begin{aligned}
&\theta_4^+(\xi, \tau) = \theta_4^+(\tau_2(\xi)) = \theta_4^-(\tau_2(\xi)),\\
&s_4^+(\xi, \tau) = \tau_2(\xi) - \tau + s_4^+(\tau_2(\xi)) = \tau_2(\xi) - \tau + s_4^-(\tau_2(\xi)),\\
&x_4^+(\xi, \tau) = \ell_2 + \int_{\xi_2(\tau)}^{\xi} \frac{1}{s_4^+(\eta, \tau)} d\eta.
\end{aligned}$$

At τ_b, we have

$$\theta_4^+(\xi,\tau_b)=\theta_4^+(\tau_2(\xi))=\theta_4^-(\tau_2(\xi)), \tag{B.11}$$

$$s_4^+(\xi,\tau_b)=\tau_2(\xi)-\tau_b+s_4^+(\tau_2(\xi))=\tau_2(\xi)-\tau_b+s_4^-(\tau_2(\xi)), \tag{B.12}$$

$$x_4^+(\xi,\tau_b)=\ell_2+\int_{\xi_2(\tau_b)}^{\xi}\frac{1}{s_4^+(\eta,\tau_b)}d\eta. \tag{B.13}$$

B.1.5. $\ell_2 \le \xi \le 1$. In this region,

$$\theta_\tau=0,\quad s_\tau=-e^\theta,\quad sx_\xi=1$$

is valid for $0\le\tau\le\tau_b$, from which we have

$$\theta_5=0,\quad s_5=1-\tau,\quad x_5=\frac{\xi-\ell_2}{1-\tau}+x_4^+(\ell_2,\tau).$$

At τ_b, we have

$$\theta_5=0,\quad s_5=1-\tau_b,\quad x_5=\frac{\xi-\ell_2}{1-\tau_b}+x_4^+(\ell_2,\tau_b). \tag{B.14}$$

B.2. Case 2: $\tau_b > \tau_*$. In this case, there are also five regions: (1) $0\le\xi\le\xi_1(\tau_b)$, (2) $\xi_1(\tau_b)\le\xi\le\xi_2(\tau_b)$, (3) $\xi_2(\tau_b)\le\xi\le\ell_1$, (4) $\ell_1\le\xi\le\ell_2$, and (5) $\ell_2\le\xi\le1$.

B.2.1. $0\le\xi\le\xi_1(\tau_b)$. In this region, for $0<\tau<\tau_b$, the solution is the same as that in Case 1,

$$\theta_1=0,\quad s_1=1-\tau,\quad x_1=\frac{\xi}{1-\tau},$$

and at τ_b the solution is

$$\theta_1=0,\quad s_1=1-\tau_b,\quad x_1=\frac{\xi}{1-\tau_b}, \tag{B.15}$$

from which we obtain $\xi_1(\tau_b)=(1-\tau_b)\ell_1$.

B.2.2. $\xi_1(\tau_b)\le\xi\le\xi_2(\tau_b)$. (I). When $0\le\tau\le\tau_1(\xi)$, the solution is

$$\theta_2^-=0,\quad s_2^-=1-\tau,\quad x_2^-=\frac{\xi-\xi_1(\tau_b)}{1-\tau}+x_1(\xi_1(\tau_b),\tau)=\frac{\xi}{1-\tau},$$

from which we obtain

$$\ell_1=\frac{\xi}{1-\tau_1(\xi)}$$

or

$$\tau_1(\xi)=1-\frac{\xi}{\ell_1}.$$

(II). When $\tau_1(\xi)\le\tau\le\tau_b$ in this region, we have

$$\theta_\tau=\frac{\mathcal{H}}{\sqrt{s}},\quad s_\tau=-e^\theta,\quad sx_\xi=1,$$

from which we obtain

$$\frac{2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1}{2\mathcal{H}}\ln\left[1+2\mathcal{H}\left(\sqrt{1-\tau_1(\xi)}-\sqrt{s_2^+}\right)\right]$$
$$=\sqrt{1-\tau_1(\xi)}-\sqrt{s_2^+}+\mathcal{H}[\tau-\tau_1(\xi)],$$

$$\left(2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1\right)\theta_2^+ +1-e^{\theta_2^+}=2\mathcal{H}^2[\tau-\tau_1(\xi)],$$

$$x_2^+=\ell_1+\int_{\xi_1(\tau)}^{\xi}\frac{1}{s_2^+(\tau_1(\eta))}d\eta.$$

Therefore,

$$\frac{2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1}{2\mathcal{H}}\ln\left[1+2\mathcal{H}\left(\sqrt{1-\tau_1(\xi)}-\sqrt{s_2^+}\right)\right]$$
$$=\sqrt{1-\tau_1(\xi)}-\sqrt{s_2^+}+\mathcal{H}[\tau_b-\tau_1(\xi)], \tag{B.16}$$

$$\left(2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1\right)\theta_2^+ +1-e^{\theta_2^+}=2\mathcal{H}^2[\tau_b-\tau_1(\xi)], \tag{B.17}$$

$$x_2^+=\ell_1+\int_{\xi_1(\tau_b)}^{\xi}\frac{1}{s_2^+(\tau_1(\eta))}d\eta. \tag{B.18}$$

The value of $\xi_2(\tau_b)$ can be obtained from the following equation:

$$\ell_2=\ell_1+\int_{\xi_1(\tau_b)}^{\xi_2(\tau_b)}\frac{1}{s_2^+(\tau_1(\eta))}d\eta. \tag{B.19}$$

This is a nonlinear equation for $\xi_2(\tau_b)$, which can be obtained using an iterative method, after replacing the integral by a numerical quadrature.

B.2.3. $\boldsymbol{\xi_2(\tau_b)\le\xi\le\ell_1}$. (I). When $0\le\tau\le\tau_1(\xi)$, the solution is

$$\theta_3^-=0,\quad s_3^-=1-\tau,\quad x_3^-=\frac{\xi}{1-\tau}.$$

(II). When $\tau_1(\xi)\le\tau\le\tau_b$ in this region, we have

$$\theta_\tau=\frac{\mathcal{H}}{\sqrt{s}},\quad s_\tau=-e^\theta,\quad sx_\xi=1,$$

from which we obtain

$$\frac{2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1}{2\mathcal{H}}\ln\left[1+2\mathcal{H}\left(\sqrt{1-\tau_1(\xi)}-\sqrt{s_3^*}\right)\right]$$
$$=\sqrt{1-\tau_1(\xi)}-\sqrt{s_3^*}+\mathcal{H}[\tau-\tau_1(\xi)], \tag{B.20}$$

$$\left(2\mathcal{H}\sqrt{1-\tau_1(\xi)}+1\right)\theta_3^* +1-e^{\theta_3^*}=2\mathcal{H}^2[\tau-\tau_1(\xi)], \tag{B.21}$$

$$x_3^*=x_2^+(\xi_2(\tau_b),\tau)+\int_{\xi_2(\tau_b)}^{\xi}\frac{1}{s_3^*(\eta,\tau)}d\eta. \tag{B.22}$$

(III). When $\tau_* \le \tau \le \tau_b$ in this region, the solution is

$$\theta_3^+(\xi,\tau) = \theta_3^+(\xi,\tau_2(\xi)) = \theta_3^*(\xi,\tau_2(\xi)),$$
$$s_3^+(\xi,\tau) = s_3^+(\xi,\tau_2(\xi)) + \tau_2(\xi) - \tau = s_3^*(\xi,\tau_2(\xi)) + \tau_2(\xi) - \tau,$$
$$x_3^+(\xi,\tau) = \ell_2 + \int_{\xi_2(\tau)}^{\xi} \frac{1}{s_3^+(\eta,\tau)} d\eta,$$

where $\theta_3^*(\xi,\tau_2(\xi))$ and $s_3^*(\xi,\tau_2(\xi))$ are from (B.21) and (B.20), with τ replaced by $\tau_2(\xi)$, and $\tau_2(\xi)$ is obtained by applying (B.22) at ℓ_2:

$$\ell_2 = \ell_1 + \int_{\xi_1(\tau)}^{\xi} \frac{1}{s_3^*(\eta,\tau_2(\xi))} d\eta. \tag{B.23}$$

This is a nonlinear equation for $\tau_2(\xi)$, which can be solved using an iterative method.

At τ_b, we have

$$\theta_3^+(\xi,\tau_b) = \theta_3^+(\xi,\tau_2(\xi)) = \theta_2^*(\xi,\tau_2(\xi)), \tag{B.24}$$
$$s_3^+(\xi,\tau_b) = s_3^+(\xi,\tau_2(\xi)) + \tau_2(\xi) - \tau_b = s_2^*(\xi,\tau_2(\xi)) + \tau_2(\xi) - \tau_b, \tag{B.25}$$
$$x_3^+(\xi,\tau_b) = \ell_2 + \int_{\xi_2(\tau_b)}^{\xi} \frac{1}{s_3^+(\eta,\tau_b)} d\eta. \tag{B.26}$$

B.2.4. $\boldsymbol{\ell_1 \le \xi \le \ell_2}$. (I). When $0 \le \tau \le \tau_2'(\xi)$ in this region, we have

$$\sqrt{s_4^-} - 1 + \frac{2\mathcal{H}+1}{2\mathcal{H}} \ln\left(1 + 2\mathcal{H} - 2\mathcal{H}\sqrt{s_4^-}\right) = \mathcal{H}\tau,$$
$$(2\mathcal{H}+1)\,\theta_4^- + 1 - e^{\theta_4^-} = 2\mathcal{H}^2\tau,$$
$$x_4^- = \frac{\xi - \ell_1}{s_4^-(\tau)} + x_3^*(\ell_1,\tau).$$

From the last equation, we obtain

$$\ell_2 = \frac{\xi - \ell_1}{s_4^-(\tau_2'(\xi))} + x_3^*(\ell_1,\tau_2'(\xi)). \tag{B.27}$$

From this equation, we can find the value of $\tau_2'(\xi)$, which is the time that the material point which was initially at ξ crosses ℓ_2. Note that τ_2' is different from τ_2 in region (3) since the solutions in the two regions are different.

(II). When $\tau_2'(\xi) \le \tau \le \tau_*$ in this region, we have

$$\theta_4^*(\xi,\tau) = \theta_4^*(\tau_2'(\xi)) = \theta_4^-(\tau_2'(\xi)),$$
$$s_4^*(\xi,\tau) = \tau_2'(\xi) - \tau + s_4^*(\tau_2'(\xi)) = \tau_2'(\xi) - \tau + s_4^-(\tau_2'(\xi)),$$
$$x_4^*(\xi,\tau) = \ell_2 + \int_{\xi_2(\tau)}^{\xi} \frac{1}{s_4^*(\eta,\tau)} d\eta.$$

(III). When $\tau_* \le \tau \le \tau_b$ in this region we have

$$\theta_4^+(\xi,\tau) = \theta_4^+(\tau_2'(\xi),\tau_*),$$
$$s_4^+(\xi,\tau) = \tau_* - \tau + s_4^*(\tau_2'(\xi)),$$
$$x_4^+(\xi,\tau) = x_3^+(\ell_1,\tau) + \int_{\ell_1}^{\xi} \frac{1}{s_4^+(\eta,\tau)} d\eta.$$

At τ_b, we have

$$\theta_4^+(\xi,\tau_b) = \theta_4^+(\tau_2'(\xi),\tau_*), \tag{B.28}$$

$$s_4^+(\xi,\tau_b) = \tau_* - \tau_b + s_4^*(\tau_2'(\xi)), \tag{B.29}$$

$$x_4^+(\xi,\tau_b) = x_3^+(\ell_1,\tau_b) + \int_{\ell_1}^{\xi} \frac{1}{s_4^+(\eta,\tau_b)}\,d\eta. \tag{B.30}$$

B.2.5. $\ell_2 \le \xi \le 1$. In this region we have

$$\theta_5 = 0, \quad s_5 = 1-\tau, \quad x_5 = \frac{\xi-\ell_2}{1-\tau} + x_4^*(\ell_2,\tau)$$

for $0 \le \tau \le \tau_*$ and

$$\theta_5 = 0, \quad s_5 = 1-\tau, \quad x_5 = \frac{\xi-\ell_2}{1-\tau} + x_4^+(\ell_2,\tau)$$

for $\tau_* \le \tau \le \tau_b$.

At τ_b, we have

$$\theta_5 = 0, \quad s_5 = 1-\tau_b, \quad x_5 = \frac{\xi-\ell_2}{1-\tau_b} + x_4^+(\ell_2,\tau_b). \tag{B.31}$$

Acknowledgments. We wish to thank Drs. Demetrius Papageorgiou, Michael Siegel, Yuan-Nan Young, and Wendy Zhang for useful discussions at the Focused Research Group (FRG), in Banff. Also, we thank the Banff International Research Station (BIRS) for funding the FRG, and the staff at BIRS for their wonderful efforts to make the FRG such a productive event. Finally we wish to express our gratitude to the anonymous referees who helped us to improve the paper by providing constructive comments and suggestions.

PASSIVITY OF MAGNETOSTRICTIVE MATERIALS*

SINA VALADKHAN†, KIRSTEN MORRIS‡, AND AMIR KHAJEPOUR†

Abstract. Magnetostrictive materials display large force and displacement in response to an applied field, as well as short response time. However, their nonlinear and hysteretic behavior has hindered their use. We prove, using the physics of the material, that these materials are passive. The corresponding energy storage function is shown to be the Helmholtz energy. This result is independent of the model used. The effect of varying load is included. Passivity is important because it can be used to obtain control systems that maintain stability despite uncertainties and disturbances. The minima of the storage function are also obtained. The storage function is written explicitly in the case of a common model for these materials, the Preisach model.

Key words. passivity, smart materials, Preisach model, magnetostrictive materials, stability

1. Introduction.

There has been a growing demand by industry in recent years for micropositioning devices. Micropositioning actuators are now frequently seen in scanning microscopes, chip manufacturing machines, biological cell micromanipulation and optical fiber alignment devices. Currently, many of these micropositioning tasks are done with piezoceramic actuators. Piezoceramic actuators exhibit almost linear behavior and have a reasonably fast response time.

Still, there is a demand for actuators with a larger stroke and faster response time. For this reason, the possibility of using other active materials for actuation is being examined. Terfenol-D, an alloy of iron, terbium, and dysprosium, has many advantages. Terfenol-D is a magnetostrictive material. Compared to other active materials, it has very large force and displacement with a short response time that makes it an attractive choice for actuation.

The use of magnetostrictive materials has been hindered by the fact that their response is highly nonlinear and hysteretic. Because of this nonlinearity, Terfenol-D actuators are difficult to control. In many micropositioning tasks, submicron accuracy is required. To achieve the required performance, actuators need to be used in a closed-loop feedback system. The controller in the feedback system must be able to stabilize the system under all conditions.

Dependence of the hysteresis on many physical conditions together with the nonlinear nature of the system make it difficult to establish stability for the closed loop. External physical conditions such as mechanical loading and temperature affect the behavior of magnetostrictive materials. Stability and performance of the control system must be maintained despite these system uncertainties and also despite disturbances. One of the most useful methods for showing stability of nonlinear systems is *passivity*. There are many passive physical systems [1]. Passive systems are important because the stability of closed-loop passive systems can be easily established. For

many nonlinear systems, this approach is the only way to show stability. Passivity has been used to obtain closed-loop stability for nonlinear systems in over 300 papers published in the last 10 years.

The Preisach model [2] is among the oldest models for magnetic materials. This model has been successfully applied to many hysteretic systems [3, 4]. In [5], the Preisach model is used with a set of ordinary differential equations to develop a rate-dependent hysteresis model. Open-loop stability and other properties of the model are discussed. These results are used to develop a model inverse-based controller for a magnetostrictive actuator [6].

In [7], an energy-based version of the Preisach model is introduced. Unlike the classical Preisach model, this model is based on a physical model for the material. In [3], it is shown that the Preisach operator is passive if the system output is the time-derivative of the output. The associated storage function is also computed. The result is applied to the control of a shape memory alloy actuator. In [8], this approach is extended to position control. The passivity results [3] are used in [9] to establish asymptotic stability of closed-loop systems containing hysteresis.

In the next section we give a brief review of standard material on passivity. It is subsequently shown, using physics, that magnetostrictive materials are passive. The storage function is identified to be the Helmholtz energy. No assumption on the model is used. The effects of varying load are included. The Preisach model is then introduced and the energy storage function is written explicitly using this model. The system equilibrium points are identified and discussed.

2. Passivity. In this section, passivity is defined in a dynamical systems framework. This framework will be used later for magnetostrictive materials. Consider a system with input $u \in U$, output $y \in U$, and state $x \in X$. The following is a standard definition for dynamical systems [1].

DEFINITION 1. *A dynamical system is defined through input, output and state spaces U and X, a readout operator r, and a state transition operator ϕ. The readout operator is a map from $U \times X$ to U. The state transition operator is a map from $\mathbb{R}^2 \times X \times U$ to X. The state transition operator must have the following properties for all $x_0 \in X$, t_0, t_1, $t_2 \in \mathbb{R}$, u, u_1, $u_2 \in U$:*

Consistency: $\phi(t_0, t_0, x_0, u) = x_0$.

Determinism: $\phi(t_1, t_0, x_0, u_1) = \phi(t_1, t_0, x_0, u_2)$ *for all* $t_1 \geq t_0$ *when* $u_1(t) = u_2(t)$ *for all* $t_0 \leq t \leq t_1$.

Semigroup: $\phi(t_2, t_0, x_0, u) = \phi(t_2, t_1, \phi(t_1, t_0, x_0, u), u)$ *when* $t_0 \leq t_1 \leq t_2$.

Stationarity: $\phi(t_1 + T, t_0 + T, x_0, u_T) = \phi(t_1, t_0, x_0, u)$ *for all* $t_1 \geq t_0$, $T \in \mathbb{R}$ *when* $u_T(t) = u(t + T)$ *for all* $t \in \mathbb{R}$.

DEFINITION 2 (see [1]). *Consider a dynamical system with state variables x, an input u, and output y. If there is a real-valued function $S(x)$ satisfying the following relation for any $t_i \leq t_f$ and if $S(x)$ is bounded from below, the dynamical system is called passive:*

$$S(x(t_i)) + \int_{t_i}^{t_f} \langle u, y \rangle \, dt \geq S(x(t_f)). \tag{1}$$

In this definition, $\langle ., . \rangle$ is the inner product on U. The variables u and y are vectors of the same dimension, so that $\langle u, y \rangle$ is defined. The scalar function $S(x)$ is called the storage function. Passive systems are frequently seen in engineering. The storage function is often the energy.

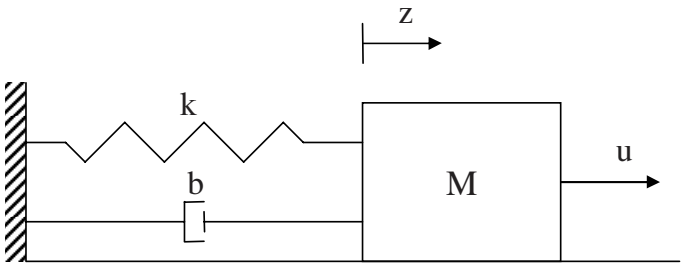

FIG. 1. *A spring-mass-dashpot system.*

Example. Consider a spring-mass-dashpot system (Figure 1). The following equation describes this system:

$$M\frac{d^2z}{dt^2} + b\frac{dz}{dt} + kz = u, \tag{2}$$

where u is the external force applied. The velocity of the mass $\dot{z}$ is considered to be the system output: $y = \dot{z}$. The state variables are z and $\dot{z}$. If both sides of (2) are multiplied by $\dot{z}$ and integrated from t_i to t_f, it becomes

$$\frac{M}{2}\left(\dot{z}^2(t_f) - \dot{z}^2(t_i)\right) + \int_{t_i}^{t_f} b\dot{z}^2 dt + \frac{k}{2}\left(z^2(t_f) - z^2(t_i)\right) = \int_{t_i}^{t_f} \langle u, y\rangle \, dt. \tag{3}$$

In this example, total energy is

$$E(z, \dot{z}) = \frac{1}{2}kz^2 + \frac{1}{2}M\dot{z}^2. \tag{4}$$

Using this definition, (3) can be rewritten as

$$E(z(t_i), \dot{z}(t_i)) + \int_{t_i}^{t_f} \langle u, y\rangle \, dt \geq E(z(t_f), \dot{z}(t_f)). \tag{5}$$

The storage function $E(z, \dot{z})$ is always nonnegative and, hence, bounded from below. As a result, this system is passive. When $u = 0$, the system goes to a state which minimizes E. The energy E is minimized when $z = 0$, $\dot{z} = 0$. This is the global system equilibrium point.

When the force applied to the system includes a constant force, such as gravity, its effect can be included in the system storage function. If the force applied to the mass is $F_{const} + u$, the following storage function is minimized at the equilibrium point:

$$\bar{E} = E - F_{const}z. \tag{6}$$

In this case, the equilibrium point is $z = \frac{F_{const}}{k}$, $\dot{z} = 0$.

Define the operator $\|.\|$ to be the Euclidean norm; that is, for any vector v, $\|v\|^2 = \langle v, v\rangle$. The following definitions are used to establish stability for the system [10, 11].

DEFINITION 3. *The set L_2 is the set of functions $x : \mathbb{R} \to \mathbb{R}^n$ for which the following expression is bounded:*

$$\int_0^\infty \|x(t)\|^2 \, dt < \infty. \tag{7}$$

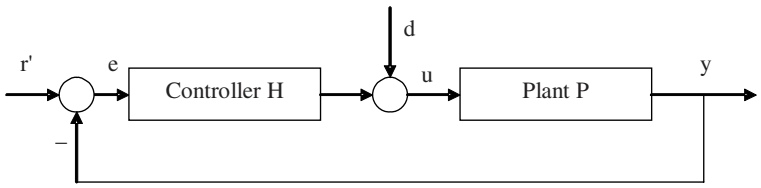

FIG. 2. *The standard feedback configuration.*

DEFINITION 4. *The set L_{2e} is the set of functions $x : \mathbb{R} \to \mathbb{R}^n$ for which the following expression is bounded for all $T \in \mathbb{R}$:*

$$\int_0^T \|x(t)\|^2 \, dt < \infty. \tag{8}$$

DEFINITION 5. *A mapping $R : L_{2e} \to L_{2e}$ is said to be L_2-stable if $x \in L_2$ implies that $Rx \in L_2$.*

Suppose that a given system P is passive. Consider the general feedback control configuration shown in Figure 2. If the controller H satisfies certain conditions, the following result can be used to show the stability of the controlled system.

THEOREM 6 (see [11, Theorem 10, p. 182]). *Consider the feedback system shown in Figure 2, where H and P map U to U. The set U is a subset of L_{2e}. Assume that for any r' and d in L_2 there are solutions e and u in L_{2e} and there are constants α_1, α_2, α_3, β_1, β_2, and β_3 such that for every real T and $x \in L_{2e}$ the following conditions hold:*

$$\begin{aligned} &\text{I} \quad \sqrt{\int_0^T \|Hx\|^2 \, dt} \le \alpha_1 \sqrt{\int_0^T \|x\|^2 \, dt} + \beta_1, \\ &\text{II} \quad \int_0^T \langle x, Hx \rangle \, dt \ge \alpha_2 \int_0^T \|x\|^2 \, dt + \beta_2, \\ &\text{III} \quad \int_0^T \langle Px, x \rangle \, dt \ge \alpha_3 \int_0^T \|Px\|^2 \, dt + \beta_3. \end{aligned} \tag{9}$$

If $\alpha_2 + \alpha_3 > 0$, then r', $d \in L_2$ implies that e, u, He, $y \in L_2$.

A passive system satisfies the third condition with $\alpha_3 = 0$ and $\beta_3 = \inf S(x) - S(x(0))$. The second and third conditions are similar to requiring that plant and controller be passive, but slightly stronger since $\alpha_2 + \alpha_3$ has to be strictly positive. The last line of the theorem states that the closed loop is L_2-stable.

This theorem can be used to establish stability for a large class of nonlinear systems. For many systems this theorem is the only way to establish stability. The passivity results which will be shown later can be used with this theorem to show stability for the magnetostrictive system.

3. Passivity for magnetostrictive materials. Since magnetostrictive materials dissipate energy, we expect them to be passive with some energy function as the storage function. In this section, the physical parameters of magnetostrictive materials are introduced. Three different energy functions for magnetostrictive materials and their suitability as a storage function are discussed. Finally, a proof of passivity is given.

Magnetostrictive materials react to a magnetic field. Suppose that a magnetostrictive sample is excited in a magnetic field produced by a coil. If there is an electrical

current in the coil, a nonzero magnetic field H is seen around the coil. Magnetic field H is a vector field, and it depends on the electrical current and the geometry. Magnetic field H acts on the magnetostrictive sample, and it is usually considered to be the input for the hysteretic system. As a result of this magnetic field, a magnetization M is seen in the material. The magnetization M is also a vector field, and it is considered to be the response or output of the hysteretic system. The relation between H and M depends on the material.

The magnetization M is not the only parameter affected by an external magnetic field H. The mechanical variables are also affected. For a material where the magnetic and mechanical responses are decoupled, the stress σ is usually considered to be the input for the mechanical part, and the strain ε, the response. For magnetostrictive materials, a magnetic field affects both magnetization and strain, and similarly for the stress. For magnetostrictive materials, generalized force and displacement are defined as follows:

$$F = \begin{pmatrix} \mu_0 H \\ \sigma \end{pmatrix}, \tag{10}$$

$$X = \begin{pmatrix} M \\ \varepsilon \end{pmatrix}. \tag{11}$$

Generalized force F is the system input and time-derivative of generalized displacement $\dot{X}$, the output. The constant μ_0 is a physical constant to ensure that $\mu_0 \langle H, M \rangle$ has the unit of energy per unit volume.

Various energy functions can be associated with magnetostrictive materials. Here these energy functions are introduced and their suitability as a storage function is discussed.

3.1. The internal energy. The internal energy U is the total potential energy stored in the material. The first law of thermodynamics holds for this energy function:

$$\frac{dU}{dt} = \frac{dQ}{dt} + \frac{dW}{dt}, \tag{12}$$

where $\frac{dQ}{dt}$ is the rate of thermal energy supplied to the material and $\frac{dW}{dt}$ is the rate of magnetic/mechanical work done on the system. The inequality of Clausius [12, p. 205] states that for any process $\frac{dS}{dt} \geq \frac{1}{T}\frac{dQ}{dt}$, where T is the temperature and S is the entropy. Using this inequality, the first law can be written as

$$\frac{dU}{dt} \leq T\frac{dS}{dt} + \frac{dW}{dt}. \tag{13}$$

A relation similar to the passivity inequality can be obtained by integrating both sides of (13) from t_i to t_f:

$$U_i + \int_{t_i}^{t_f} \left(T\frac{dS}{dt} + \frac{dW}{dt} \right) dt \geq U_f. \tag{14}$$

It is seen that thermal terms should appear in the system input/output; i.e., u should be $\begin{pmatrix} \mu_0 H \\ \sigma \\ T \end{pmatrix}$ and y should be $\begin{pmatrix} \dot{M} \\ \dot{\varepsilon} \\ \dot{S} \end{pmatrix}$. Since the energy stored in the material is limited, the amount of energy which can be pulled out of the material is also limited. This means that the energy function U has a lower bound. As a result, the internal energy U can be used as a storage function.

Thermal variables are usually difficult to work with, and for magnetostrictive materials they are difficult to measure. Extra thermal input and output are disadvantages to using internal energy as a storage function. For this reason, the internal energy is not chosen as the storage function.

3.2. The Gibbs energy. The following relation defines the Gibbs energy:

$$G = U - TS - \langle F, X \rangle . \tag{15}$$

Using the relation $\frac{dW}{dt} = \left\langle F, \frac{dX}{dt} \right\rangle$ and (10), (11) and (13), we obtain

$$\frac{dG}{dt} \leq -S\frac{dT}{dt} - \mu_0 \left\langle M, \frac{dH}{dt} \right\rangle - \varepsilon \frac{d\sigma}{dt}. \tag{16}$$

The Gibbs energy is a function of H. This means that H has to be included in the system states. This is awkward for several reasons. First, in this application H is an input. Second, consider a situation in which $\varepsilon = 0$ and H has a large value. The Gibbs energy can be made arbitrarily small by increasing H. This means that the Gibbs energy does not have a lower bound, and hence it is not a suitable storage function.

3.3. The Helmholtz energy. The Helmholtz free energy ψ is defined as

$$\psi = U - TS, \tag{17}$$

where T and S are the temperature and total entropy, respectively, of the system. Using the inequality of Clausius, the first law of thermodynamics can be written as

$$\frac{d\psi}{dt} \leq -S\frac{dT}{dt} + \frac{dW}{dt}. \tag{18}$$

Under constant temperature, this equation simplifies to

$$\frac{d\psi}{dt} \leq \frac{dW}{dt}. \tag{19}$$

This relation states that the work provided is more than the rate at which Helmholtz free energy is increased. It can be said that part of the work energy provided is absorbed by the system and added to the stored energy, while the rest is wasted in energy dissipation. It seems that the Helmholtz free energy is the energy actually stored in the system. In this respect, the Helmholtz energy is comparable to the energy storage function E in the mechanical example. Since the energy E is the storage function for the mechanical example, this comparison suggests the Helmholtz energy as the storage function. In the next subsection, a detailed proof of passivity, with the Helmholtz free energy as the storage function, is given.

3.4. Proof of passivity. It is assumed that, during any process discussed here, no phase transition occurs; for example, the material is not melting. This guarantees the existence of partial derivatives. All of the processes are under constant air pressure. Work done by the air pressure is neglected. For simplicity, from now on, it is also assumed that the thermal connection between the material and the surrounding environment is so good that the temperature of the material is always close to the room temperature T_0 and constant.

In a magnetic material, the ratio between the dipole magnetic energy and the energy of thermal fluctuations plays an important role. If the dipole magnetic energy

is small compared to thermal fluctuations, the material is called *paramagnetic*. In this case, the dipoles are mostly affected by thermal fluctuations and the external magnetic field H. Dipole-dipole interaction is weak. Because of thermal fluctuations, paramagnetic materials are memoryless and have no hysteresis. On the other hand, if the dipole magnetic energy is large compared to thermal fluctuations, the material is called *ferromagnetic*. Dipoles in a ferromagnetic sample retain their state, and the material has memory. These materials are hysteretic. Because of strong dipole-dipole interactions in ferromagnetic materials, the models available for these materials are complex and difficult to use. The energy of thermal fluctuations depends linearly on temperature. For this reason if a ferromagnetic material is heated, in a certain temperature it becomes paramagnetic. This transition temperature is called the Curie temperature T_c. Curie temperature is fairly high for most of the ferromagnetic materials. For iron $T_c = 1043\text{K}$.

When a ferromagnetic material is heated beyond T_c, it becomes paramagnetic, and during this heating process, the entropy of the materials is increased. In the following lemmas, this fact is used together with entropy relations for a paramagnetic material to show an upper bound for the entropy in a ferromagnetic material. The first lemma is used to show that the Helmholtz free energy has a lower bound.

LEMMA 7. *For a paramagnetic material at a constant temperature, the entropy S has an upper bound.*

Proof. The strength of a magnetic dipole is denoted by a constant positive half-integer J. This constant depends on the material under discussion. The following equations define entropy for a single dipole in a paramagnetic sample [13, pp. 213, 215, and 259]:

$$\begin{aligned} \beta &= \frac{1}{kT}, \\ \eta &= c\beta \left\| H \right\|, \\ Z &= \frac{\sinh\left[(J+\frac{1}{2})\eta\right]}{\sinh\left[\frac{1}{2}\eta\right]}, \\ S &= k\left(\ln Z - \beta \frac{\partial \ln Z}{\partial \beta}\right), \end{aligned} \tag{20}$$

where c is a positive constant and k is the Boltzmann constant $k = 1.38e-23\frac{\text{J}}{\text{K}}$.

In a paramagnetic sample with N dipoles, total magnetic entropy is simply N times the entropy of a single dipole. Total magnetic entropy is maximized when $H = 0$. (See the appendix.) This result is consistent with physics since in the presence of an external magnetic field, dipoles become oriented and the overall system disorder is reduced. Thus,

$$S_{\max} = S_{H=0} = kN \ln(2J+1). \tag{21}$$

Thus, at a constant temperature, the magnetic portion of entropy has an upper bound, $S_{\max}$.

The nonmagnetic portion of the entropy is a function of temperature and external load. At any temperature, this entropy is maximized for the highest possible (tensile) external load. This means that at any temperature, the nonmagnetic portion of the entropy has an upper bound. Thus at any temperature, the total entropy has an upper bound. □

The paramagnetic state is usually obtained at a high temperature. In order to have an upper bound for entropy in normal working conditions of the material, the lemma above should be extended to ferromagnetic materials.

LEMMA 8. *For any magnetic material at a constant temperature, the entropy S has an upper bound.*

Proof. Lemma 7 states that the entropy has an upper bound for the paramagnetic state. Here we are interested in the ferromagnetic state.

To obtain a relation for entropy in the ferromagnetic state, consider a process in which the ferromagnetic material is heated from an arbitrary initial state to a state in which the material is paramagnetic. The entropy and temperature for the initial state are S_i and T_i, respectively. For the paramagnetic state, the entropy and temperature are S_p and T_p, respectively. From Lemma 7, it is known that S_p has an upper bound.

The entropy is a function of the system states [12, p. 217]. The difference between any two arbitrary states is only a function of the states. This difference is independent of the process which connects the two states. This fact holds for the process mentioned above. The difference $S_p - S_i$ does not depend on the process as long as the initial and final conditions remain the same. For simplicity, consider a process in which the temperature is increased monotonically.

Since the temperature is always increasing during this process, there should be a nonnegative heat flow to the material during the process:

$$\frac{dQ}{dt} \geq 0. \tag{22}$$

The inequality of Clausius states that for any process $\frac{dS}{dt} \geq \frac{1}{T}\frac{dQ}{dt}$. As a result, in this process $\frac{dS}{dt} \geq 0$ or $S_p - S_i \geq 0$. Since S_p has an upper bound, S_i is bounded from above. This concludes the proof. ∎

The following is an immediate result of the lemma above.

THEOREM 9. *For a constant temperature, the Helmholtz free energy $\psi = U - TS$ is bounded from below.*

Proof. Lemma 8 states that the entropy has an upper bound. This means that $-TS$ has a lower bound. The internal energy U has a lower bound. This results in ψ being bounded from below. ∎

THEOREM 10. *The following passivity condition is satisfied when the storage function is the Helmholtz free energy ψ:*

$$\psi_i + \int_{t_i}^{t_f} \left\langle F, \frac{dX}{dt} \right\rangle dt \geq \psi_f. \tag{23}$$

Here, subscripts i and f denote initial and final conditions, respectively; F and X are the generalized force applied to the system and the generalized system output, respectively, as defined in (10) *and* (11)*; and σ and ε are stress and strain, respectively.*

Proof. If the temperature is constant, (18) can be written as

$$\frac{d\psi}{dt} \leq \frac{dW}{dt}, \tag{24}$$

where $\frac{dW}{dt} = \left\langle F, \frac{dX}{dt} \right\rangle$ is the rate of magnetic/mechanical work done on the system.

If both sides are integrated from t_i to t_f, we obtain

$$\psi_f - \psi_i \leq \int_{t_i}^{t_f} \left\langle F, \frac{dX}{dt} \right\rangle dt \tag{25}$$

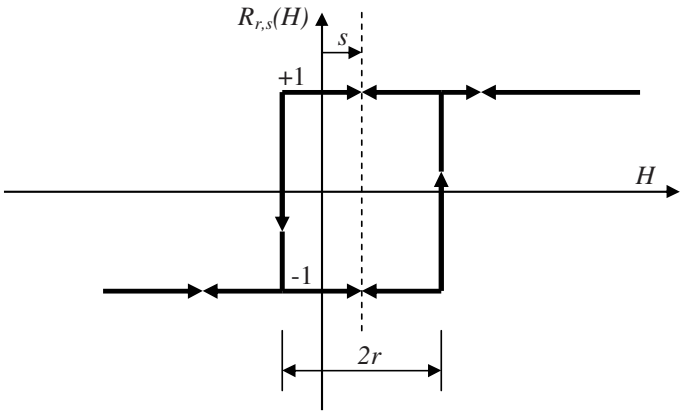

FIG. 3. *The Preisach relay.*

or

$$\psi_i + \int_{t_i}^{t_f} \left\langle F, \frac{dX}{dt} \right\rangle dt \geq \psi_f. \tag{26}$$

Theorem 9 shows that the Helmholtz free energy is bounded from below, which means that it is a valid storage function. This concludes the proof. □

The proof above shows the passivity of a magnetostrictive system with a three-dimensional magnetic field and a one-dimensional stress-strain. In this proof, no model for the magnetostrictive material is assumed. Passivity is shown with fundamental laws of physics only. In fact, the theorem above can be applied to any model for magnetostrictive materials.

4. The Preisach model. The Preisach model [2] is a very common model in the smart materials literature; for examples, see [3, 4, 14, 15]. In [15], it is used to model magnetostrictive materials. It has been shown that this model can represent magnetostrictive materials accurately [16]. This model is briefly explained here; for a detailed description, see [2]. In this model, a one-dimensional magnetic field is assumed, which results in the magnetic field H and magnetization M being scalars. It is assumed that the output is the weighted sum of the output of a continuum of hysteresis relays. The output of each relay can be either $+1$ or -1, determined by the previous relay value and the input, magnetic field H. In Figure 3 a typical hysteresis relay is shown.

The model output is

$$M(t) = \int_0^\infty \int_{-\infty}^\infty R_{r,s}[H(\cdot)](t)\mu(r,s)dsdr. \tag{27}$$

Here, $R_{r,s}$ is the output of the relay defined by r and s, and $\mu(r,s)$ is a weight function determined by experimental data.

Consider a two-dimensional coordinate system with variables r and s as shown in Figure 4. Each point r, s in this coordinate system is in a one-to-one relation with a Preisach relay $R_{r,s}$ and its corresponding weight $\mu(r,s)$. The plane defined by variables r and s is called the Preisach plane. Because the system input is limited, the relays with a large r or s do not change and cannot contribute to a change in the

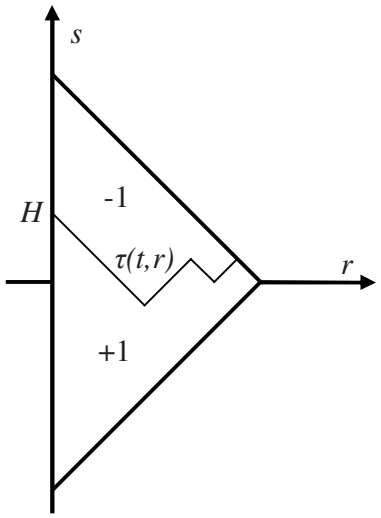

FIG. 4. *A typical Preisach plane boundary.*

model output. For simplicity, it is assumed that the weight function $\mu(r,s)$ is zero for these relays. In Figure 4, these relays are outside of the bold triangle. Since the output is not affected by these relays, they are not considered.

If, in the Preisach plane, the relays equal to -1 are separated with a line from the relays at $+1$, a boundary $s = \tau(t,r)$ will be produced, as shown in Figure 4. This boundary is important since if $\tau(t,r)$ is available, the output of all relays are known. Thus, knowledge of $\tau(t,r)$ and the input $H(t)$ determines future values of $\tau(t,r)$ and hence $M(t)$. In other words, $\tau(t,r)$ contains the *memory* of the system. The Preisach model is a dynamical system with $\tau(t,r)$ as the state [17]. The model output can be rewritten in terms of the boundary:

$$M(t) = 2\int_0^\infty \int_{-\infty}^{\tau(t,r)} \mu(r,s)dsdr - \int_0^\infty \int_{-\infty}^{\infty} \mu(r,s)dsdr. \tag{28}$$

Note that the Preisach boundary $\tau(t,r)$ and the vertical axis $r = 0$ in Figure 4 intersect at the current input value; that is,

$$\tau(t,0) = H. \tag{29}$$

4.1. Energy-based Preisach model. In this model, a physical model for magnetostrictive materials is used to develop a special type of Preisach model that is based on energy considerations [7, 16]. Here, the material is assumed to be composed of a large number of weakly interacting dipoles. The Helmholtz free energy for a single dipole can be modeled by three parabolas [7], [15, p. 188] (Figure 5):

$$\psi(M,\varepsilon) = \frac{1}{2}Y\varepsilon^2 - Y\gamma\varepsilon M^2 + \begin{cases} \frac{\mu_0\eta'}{2}(M+M_R)^2, & M \le -M_I, \\ \frac{\mu_0\eta'}{2}(M-M_R)^2, & M \ge M_I, \\ \frac{\mu_0\eta'}{2}(M_R-M_I)(M_R-\frac{M^2}{M_I}), & |M| < M_I, \end{cases} \tag{30}$$

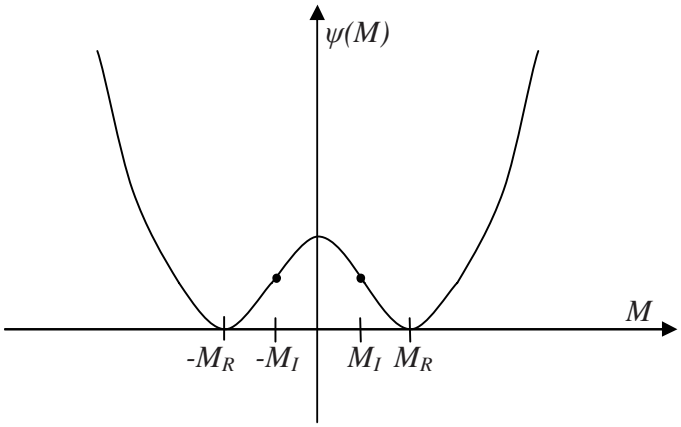

FIG. 5. *The Helmholtz free energy.*

where the variable M is the magnetization for the dipole, the parameter η' is a constant, γ is the magnetomechanical coupling constant, and Y is Young's modulus. The parameter M_R is the remanence magnetization. In the absence of strain ε, $\pm M_R$ are the minima of ψ. The parameter M_R is assumed to be the same for all dipoles. The parameter M_I is the inflection point where the second derivative of ψ changes sign. Unlike M_R, because of the nonhomogeneities and imperfections in the material, M_I is different for each dipole. For a valid Helmholtz free energy $M_R > M_I$. This ensures that the Helmholtz free energy has two distinct minima, as shown in Figure 5.

Define H_0 to be the local magnetic field at a dipole. Because of the imperfections and nonhomogeneities in the material, the local magnetic field H_0 might not be equal to the external magnetic field H. It is assumed that the difference $s = H - H_0$ is constant over time for each dipole.

The parameters s and M_I describe each dipole. Define

$$r = \eta'(M_R - M_I) + \frac{2}{\mu_0} Y\gamma\varepsilon M_I. \tag{31}$$

It will be shown later that it is easier to use r as defined in (31) to describe each dipole instead of M_I. This definition of r is consistent with r for a Preisach relay, as shown in Figure 3.

For a dipole, the Gibbs energy is

$$G_{r,s}(H_0, M_{r,s}, \sigma, \varepsilon) = \psi_{r,s}(M_{r,s}, \varepsilon) - \mu_0 H_0 M_{r,s} - \sigma\varepsilon, \tag{32}$$

as shown in Figure 6.

Consider a single dipole in a process in which the temperature, magnetic field H, and stress are constant. In this case, (16) simplifies to

$$\frac{dG_{r,s}}{dt} \leq 0. \tag{33}$$

This relation states that during this process, G has to either stay constant or decrease. At a stable equilibrium point, the Gibbs energy is minimized [15, pp. 65 and 184]. In this case, the derivative of Gibbs energy has to be zero with respect to

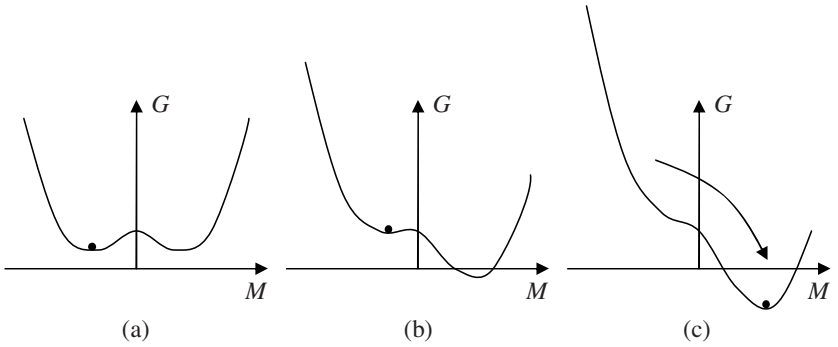

FIG. 6. (a) *Gibbs energy when* $H_0 = 0$, (b) *Gibbs energy for a positive* H_0, (c) *if* H_0 *is further increased, at some point, only one minimum exists.*

unconstrained variables:

$$\left(\frac{\partial G_{r,s}(H_0, M_{r,s}, \sigma, \varepsilon)}{\partial M_{r,s}}\right)_{T,H_0,\sigma,\varepsilon} = 0, \tag{34}$$

$$\left(\frac{\partial G_{r,s}(H_0, M_{r,s}, \sigma, \varepsilon)}{\partial \varepsilon}\right)_{T,H_0,\sigma,M_{r,s}} = 0. \tag{35}$$

By combining (32) and (34), the following relation is obtained:

$$\mu_0 H_0 = \left(\frac{\partial \psi}{\partial M_{r,s}}\right)_{T,\varepsilon}. \tag{36}$$

In a magnetic system with many dipoles, the dipole dynamics are very fast. If the magnetic field is not very rapidly changing, the magnetic field appears to be almost constant for each dipole over the time constant of the dipole. The magnetization for a dipole is a minimum of the Gibbs energy.

By combining (30), (32), and (36), the equilibrium magnetization for a dipole is obtained:

$$M^*_{r,s} = \frac{H - s + R_{r,s}\eta' M_R}{\eta' - \frac{2Y\gamma\varepsilon}{\mu_0}}. \tag{37}$$

If the dipole is in the left minimum in Figure 6(a), $R_{r,s} = -1$, and if the dipole is in the right minimum, $R_{r,s} = +1$.

As seen in Figure 6, if $H_0 = 0$, two minima exist. For a small positive H_0 as shown in Figure 6(b), still two minima exist, but if H_0 is further increased, at some point, one disappears, as shown in Figure 6(c). At this time, dipole magnetization moves to the new minimum. This transition is shown with an arrow in Figure 6(c).

Using (31), it can be shown that if $H \geq s + r$, the $R = -1$ minimum does not exist. Similarly, for $H \leq s - r$, the $R = +1$ minimum vanishes. For $s - r < H < s + r$, two minimums exist, which means that both $R = -1$ and $R = +1$ are possible. It is seen that for the Preisach relay introduced in Figure 3, the output -1 is nonexistent if $H \geq s + r$, and $+1$ vanishes if $H \leq s - r$. For the values between $s - r$ and $s + r$, both outputs are possible. This similarity between the dipole and a Preisach relay shows that the definition of r and s are consistent with r and s of a Preisach relay.

For a large magnetic field, the dipole magnetization is the right minimum. At this minimum, the Gibbs energy is

$$G_{r,s} = \frac{1}{2}Y\varepsilon^2 + \frac{\mu_0}{2}\eta M_R^2 - \frac{\mu_0(H - s + \eta M_R)^2}{2(\eta - \frac{2Y\gamma\varepsilon}{\mu_0})} - \sigma\varepsilon. \tag{38}$$

It is seen that, if $\varepsilon = 0$, the Gibbs energy can be made arbitrarily small by increasing H. This means that the Gibbs energy is unbounded from below.

Assuming a distribution $\mu(r, s)$ for the dipoles, the overall magnetization can be obtained:

$$M_{Tot} = C \int_0^\infty \int_{-\infty}^\infty M_{r,s}^* \mu(r, s) ds dr. \tag{39}$$

Define $\mathcal{I}_n$ to be

$$\mathcal{I}_n = \int_0^\infty \int_{-\infty}^\infty s^n \mu(r, s) ds dr, \tag{40}$$

where $n = 0, 1$, or 2. Using (37), M_{Tot} can be written as follows:

$$M_{Tot} = \frac{C}{\eta' - \frac{2Y\gamma\varepsilon}{\mu_0}} \left[\mathcal{I}_0(H - M_R\eta') - \mathcal{I}_1 + 2M_R\eta' \int_0^\infty \int_{-\infty}^{\tau(t,r)} \mu(r, s) ds dr \right], \tag{41}$$

where C is a constant and $\tau(t, r)$ is the Preisach boundary for the relay configuration $R_{r,s}$. The experimental data can be used to find the optimum weight function $\mu(r, s)$. A few common choices for $\mu(r, s)$ can be found in [16, 18].

Unlike the Preisach model, magnetization in this model depends on ε. In this model, σ and H are the inputs. The Preisach plane boundary $\tau(t, r)$ and strain ε are the system states. The outputs are ε and M. The magnetization is determined by (41). Combining (30), (32), and (35), we obtain

$$\varepsilon = \frac{\sigma}{Y} + \gamma M^2, \tag{42}$$

which determines strain ε.

4.2. Helmholtz free energy using the Preisach model. In this section, the total Helmholtz free energy for a magnetostrictive material is calculated using the physical Preisach model. Since this function is the system storage function, it is written as a function of system states $\tau(t, r)$ and ε.

As stated before, the local magnetic field H_0 might not be equal to the external magnetic field H. This difference between H and H_0 should have some effect on the energy functions. For example, consider a dipole with a negative s when the dipole magnetization is increased by dM and the external magnetic field H is constant: Work done by the external magnetic source is HdM, and work done on the dipole is $H_0 dM = HdM - sdM$. It is seen that the work done on the dipole is more that the work done by the external magnetic field. This extra work is not done by the external field. The imperfections and nonhomogeneities which are the source of the difference between H and H_0 should have done this work on the dipole. As a result, they need to be considered when the overall system Helmholtz free energy is computed.
