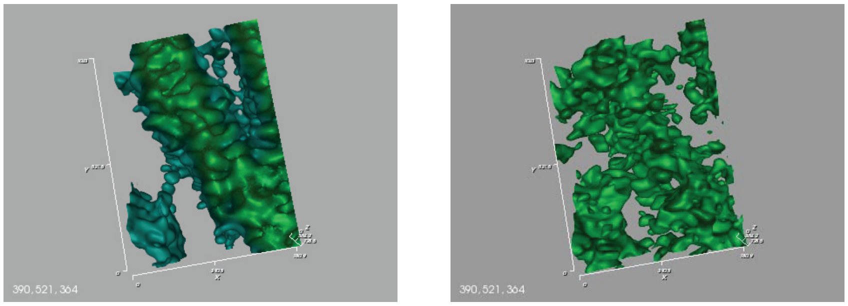
(a) Lambda reconstruction. (b) Low-pass FBP reconstruction.

FIG. 3. *The boundaries are better defined in the Lambda reconstruction when compared to the low-pass (*10 *nm-resolution) FBP reconstruction. The background noise is also suppressed. This makes the analysis of the IgG molecule easier.*



(a) Lambda reconstruction. (b) Low-pass FBP reconstruction.

FIG. 4. *The "V" shaped region containing the slit diaphragm is more clearly defined in the Lambda reconstruction than the low-pass (*10 *nm-resolution) FBP reconstruction.*

$\mathbb{R}^n$, we use the normalization

$$\mathcal{F}(f)(\boldsymbol{\xi}) = \widehat{f}(\boldsymbol{\xi}) := \int_{\boldsymbol{x}\in\mathbb{R}^n} e^{-i\boldsymbol{x}\cdot\boldsymbol{\xi}} f(\boldsymbol{x})\, d\boldsymbol{x}.$$

The two-dimensional Fourier transform on the plane $\boldsymbol{\omega}^\perp$ is defined in a similar way, and in the coordinates we chose for single axis tilt (see section 5), it is

$$\mathcal{F}_{\boldsymbol{\omega}^\perp}(g)(\boldsymbol{\eta},\theta) := \int_{(y_1,y_{\boldsymbol{\sigma}})\in\mathbb{R}^2} e^{-i(y_1,y_{\boldsymbol{\sigma}})\cdot(\eta_1,\eta_{\boldsymbol{\sigma}})} g(\boldsymbol{y},\theta)\, d\boldsymbol{y} \quad \text{for } \boldsymbol{\eta}\in\mathbb{R}^2.$$

Our next theorem characterizes the reconstruction operator as a convolution PDO with a symbol that is singular all along the ξ_1-axis. This has specific implications for reconstructions based on $\mathcal{L}$, as we explain in Theorem A.2 and Example A.5.

THEOREM A.1. *Let $\mathcal{P}^*_{\theta_{\text{cut}}}$ be defined by* (5.7)*, where the smooth function φ satisfies the assumptions given in* (5.6)*, $\mathcal{P}$ is defined by* (5.5)*, and $\mu \geq 0$. For $\boldsymbol{\xi} = (\xi_1,\xi_2,\xi_3) \in \mathbb{R}^3$, let $\boldsymbol{\xi}' = (\xi_2,\xi_3)$, and for $\boldsymbol{\xi}' \neq \mathbf{0}$, let $\arg(\boldsymbol{\xi}')$ be one of the* *angles in the plane from the ξ_2-axis to $\boldsymbol{\xi}'$.*[8] *Then, for $\mu \neq 0$ the operator $\mathcal{L}$ is defined for distributions of compact support. For $\mu = 0$, $\mathcal{L}$ is a continuous map from $\mathscr{H}^{\alpha+1}(\mathbb{R}^3)$ to $\mathscr{H}^{\alpha}(\mathbb{R}^3)$ for all $\alpha \in \mathbb{R}$. Moreover, in the coordinates defined above, $\mathcal{L}(f) = f * k$, and its symbol is the Fourier transform of k,*

$$\sigma(\boldsymbol{x}, \boldsymbol{\xi}) = \widehat{k}(\boldsymbol{\xi}) := \left(\frac{\varphi\big(\arg(\boldsymbol{\xi}') + \pi/2\big)}{(2\pi)^2 \|\boldsymbol{\xi}'\|} \right) \big(\mu + \|\boldsymbol{\xi}'\|^2\big). \tag{A.1}$$

Proof. To prove Theorem A.1, we need to show that

$$\mathcal{L}(f)(\boldsymbol{x}) = \frac{1}{(2\pi)^2} \int_{\boldsymbol{\xi} \in \mathbb{R}^3} e^{i\boldsymbol{x}\boldsymbol{\xi}}\, \widehat{k}(\boldsymbol{\xi}) \mathcal{F}(f)(\boldsymbol{\xi})\, d\boldsymbol{\xi}, \quad \text{where } \widehat{k} \text{ is given by (A.1).}$$

Initially, we assume f is a smooth function of compact support, but by continuity in distribution space, the end results will be true for distributions of compact support, as we will explain when needed. We use the convention that if $\boldsymbol{x} = (x_1, x_2, x_3) \in \mathbb{R}^3$, then $\boldsymbol{x}' = (x_2, x_3)$, and we begin the calculations in the plane $x_1 =$ constant. It is straightforward to show using polar coordinates in this plane that

$$\mathcal{P}^*_{\theta_{\text{cut}}} \mathcal{P}(f)(\boldsymbol{x}) = \int_{\boldsymbol{y}' \in \mathbb{R}^2} \frac{\varphi\big(\arg(\boldsymbol{y}')\big)}{\|\boldsymbol{y}'\|} f\big(\boldsymbol{x} + (0, \boldsymbol{y}')\big)\, dy'. \tag{A.2}$$

To write (A.2) as a PDO, we first fix x_1 and take the Fourier transform of (A.2) in $\boldsymbol{x}'$. Then, we use the fact about Fourier transforms of homogeneous functions [25, sect. 4, equation (7), p. 61] that the Fourier transform of $\varphi\big(\arg(\boldsymbol{y}')\big)/\|\boldsymbol{y}'\|$ is given by the first expression in parentheses in (A.1). To finish the proof, we take the inverse Fourier transform in x' and then the Fourier transform and inverse transform in x_1. This shows that

$$\mathcal{P}^*_{\theta_{\text{cut}}} \mathcal{P}(f)(\boldsymbol{x}) = \frac{1}{(2\pi)^2} \int_{\boldsymbol{\xi} \in \mathbb{R}^3} e^{i\boldsymbol{x}\boldsymbol{\xi}} \left(\frac{\varphi\big(\arg(\boldsymbol{\xi}') + \pi/2\big)}{\|\boldsymbol{\xi}'\|} \right) \mathcal{F}(f)(\boldsymbol{\xi})\, d\boldsymbol{\xi}. \tag{A.3}$$

Note that $\mathcal{P}^*_{\theta_{\text{cut}}} : \mathscr{E}'(Y) \to \mathscr{D}'(\mathbb{R}^3)$ is continuous, and a cutoff[9] applied to $\mathcal{P}$ is continuous from $\mathscr{E}'(\mathbb{R}^3)$ to $\mathscr{E}'(Y)$ by duality. These observations explain why $\mathcal{P}^*_{\theta_{\text{cut}}}\mathcal{P}$ and $\mathcal{L}$ are defined and continuous from $\mathscr{E}'(\mathbb{R}^3)$ to $\mathscr{D}'(\mathbb{R}^3)$.

To write $\mathcal{L}$ as a PDO, we first observe that, by an integration by parts, $D^2_\sigma \mathcal{P}(f) = \mathcal{P}\big(\Delta_{\boldsymbol{x}'} f\big)$, where $\Delta_{\boldsymbol{x}'} = \frac{\partial^2}{\partial x_2^2} + \frac{\partial^2}{\partial x_3^2}$. This is clearly true for functions and true on $\mathscr{E}'$ by continuity. Then, we note that

$$\mathcal{L}(f) = \mathcal{P}^*_{\theta_{\text{cut}}} \mathcal{P}\big((\mu - \Delta_{\boldsymbol{x}'}) f\big), \tag{A.4}$$

so using (A.3) on $(\mu - \Delta_{\boldsymbol{x}'}) f$ gives (A.1).

Finally, let $\mathcal{L}^0$ be defined as $\mathcal{L}$ with $\mu = 0$. The Sobolev continuity of $\mathcal{L}^0$ follows immediately from the calculation of its symbol above since the symbol of $\mathcal{L}^0$ is bounded above by $(1 + \|\xi\|^2)^{1/2}$ since $\|\xi'\| \leq \|\xi\|$ and $|\varphi|$ is bounded above by 1. This proves the Sobolev continuity of $\mathcal{L}^0$. Note that $\mathcal{L}$ is not defined on $\mathscr{H}^\alpha$ because of the singularity of $1/\|\boldsymbol{\xi}'\|$ at $\xi' = 0$. This concludes the proof of Theorem A.1. □

[8] Note that $\varphi\big(\arg(\boldsymbol{\xi}')\big)$ is well defined since φ is π-periodic.

[9] Let ψ be a smooth function that is one on $[-\theta_{\text{cut}}, \theta_{\text{cut}}]$ and supported in $(-\theta_{\max}, \theta_{\max})$; then $\psi\mathcal{P} : \mathscr{E}'(\mathbb{R}^3) \to \mathscr{E}'(Y)$ is continuous, and $\mathcal{P}^*_{\theta_{\text{cut}}} \psi \mathcal{P} = \mathcal{P}^*_{\theta_{\text{cut}}} \mathcal{P}$.

We describe what $\mathcal{L}$ does to wavefront sets in our next theorem and in Example A.5.

THEOREM A.2. *Let $\mathcal{L}$ be as in Theorem* A.1*, and f is a distribution of compact support in the unit disk D. Finally, define*

$$\mathcal{V} := \left\{ \left(\boldsymbol{x}, \boldsymbol{\xi dx}\right) \in T^*(\mathbb{R}^3) \setminus 0 \;\middle|\; \xi_2 \neq 0,\, |\xi_3/\xi_2| < \tan\theta_{\mathrm{cut}} \right\}, \tag{A.5}$$

$$\mathcal{A} := \left\{ (\boldsymbol{x}, \xi_1 \boldsymbol{dx}_1) \;\middle|\; x_1 \in [-1,1],\, \boldsymbol{x}' \in \mathbb{R}^2,\, \xi_1 \in \mathbb{R} \setminus 0 \right\}. \tag{A.6}$$

Then,

$$\mathrm{WF}^{\alpha}\big(\mathcal{L}(f)\big) \cap \mathcal{V} = \mathrm{WF}^{\alpha+1}(f) \cap \mathcal{V}, \tag{A.7}$$

$$\mathrm{WF}^{\alpha}\big(\mathcal{L}(f)\big) \subset \big(\mathrm{WF}^{\alpha+1}(f) \cap \mathrm{cl}(\mathcal{V})\big) \cup \mathcal{A}. \tag{A.8}$$

The set $\mathcal{V}$ in (A.5) is the set of "reliably visible" singularities. Equation (A.7) implies that singularities of f in those codirections are visible in the reconstruction $\mathcal{L}(f)$, and they are one order less smooth in Sobolev scale in the reconstruction than the corresponding singularities of f. Recall that visible covectors have to be conormal to lines in the data set by Theorem 6.3, and directions in $\mathcal{V}$ are all such covectors except for the "bad" cotangent directions, those in the $\pm\boldsymbol{dx}_1$ codirection.

Inclusion (A.8) and Example A.5 demonstrate that $\mathcal{L}$ can give additional singularities in the set $\mathcal{A}$ (in the $\pm\boldsymbol{dx}_1$ codirection). Therefore they do not affect singularities in the visible directions, namely those in $\mathcal{V}$. In Remark A.4, we prove that these added singularities are really a smearing of singularities of f in planes conormal the bad codirections, that is, planes $x_1 = a$.

Proof. In the proof of Theorem A.2 we will follow the conventions in [13, Chapter 8] and allow wavefront directions to be in $\mathbb{R}^n \setminus 0$ rather than in the cotangent space. Let us now give an outline of the proof. If $\mathcal{L}$ were a standard PDO, then the proof would follow from standard results. Our case is complicated by the fact that $\mathcal{L}$ is not a standard PDO since its symbol,

$$\sigma(\boldsymbol{x}, \boldsymbol{\xi}) = \left(\frac{\varphi\big(\arg(\boldsymbol{\xi}') + \pi/2\big)}{\|\boldsymbol{\xi}'\|} \right) \big(\mu + \|\boldsymbol{\xi}'\|^2\big),$$

does not satisfy the decay conditions on the derivatives in the ξ_1 direction. We introduce an operator $\mathcal{M}$ (A.10) that cuts off in the ξ_1 direction and show that $\mathcal{M}$ and $\mathcal{L}$ can be composed to become a standard PDO that detects singularities of f essentially in $\mathcal{V}$. Next, we show that $(1 - \mathcal{M})\mathcal{L}$ contributes to the wavefront set only near the ξ_1 direction. Finally, we put this together to show that the wavefront in directions in $\mathcal{V}$ are visible and that the only added directions are in $\mathcal{A}$. Theorem 8.2.9 and other results in [13, section 8.2] can be used to prove parts of this theorem without introducing the operator $\mathcal{M}$. We include that operator in order to provide an elementary proof of the other properties of $\mathcal{L}$. We begin with a useful lemma.

LEMMA A.3. *Let $f \in \mathscr{S}'(\mathbb{R}^n)$, and let $U \subset \mathbb{R}^n$ be a nonempty open cone containing the vector $\boldsymbol{\xi}_0$. Assume the Fourier transform $\mathcal{F}(f)$ is zero on U except for a compact set (which could be empty). Then, for all $\boldsymbol{x}_0 \in \mathbb{R}^n$, $(\boldsymbol{x}_0, \boldsymbol{\xi}_0) \notin \mathrm{WF}(f)$, where $\mathrm{WF}(f)$ denotes the $\mathscr{C}^\infty$ wavefront set of f.*

The proof follows from [13]. In particular, $\boldsymbol{\xi}_0$ is not in the limit cone at infinity of $\operatorname{supp} \mathcal{F}f$, and so, by [13, Lemma 8.1.7, p. 258], for any point $\boldsymbol{x}_0$, $(\boldsymbol{x}_0, \boldsymbol{\xi}_0) \notin \mathrm{WF}(f)$.

We now define the operator $\mathcal{M}$ such that $\mathcal{ML}$ is a standard PDO that detects most singularities in $\mathcal{V}$. Denote the set of second coordinates in $\mathcal{V}$ by

$$\mathcal{W} := \left\{ \boldsymbol{\xi} \in \mathbb{R}^3 \setminus 0 \;\middle|\; \xi_2 \neq 0,\, |\xi_3/\xi_2| < \tan\theta_{\mathrm{cut}} \right\}. \tag{A.9}$$

Let U be a small conic open neighborhood of $\pm\boldsymbol{e}_1$, and let U' be a conic open subset of U such that $\pm\boldsymbol{e}_1 \in U'$ and $\mathrm{cl}(U') \subset \bigl(U \cup \{0\}\bigr)$. Now let $m(\boldsymbol{\xi})$ be a function that is homogeneous of degree zero in $\mathbb{R}^3$, smooth away from the origin, zero in U', and equal to one off of U. Define

$$\mathcal{M}(f)(\boldsymbol{x}) = \mathcal{F}^{-1}\bigl(m(\cdot)\mathcal{F}(f)(\cdot)\bigr)(\boldsymbol{x}). \tag{A.10}$$

Then, $\mathcal{M}$ is a classical PDO of order zero in Sobolev scale.

It is a straightforward justification using Fourier transforms that one can compose $\mathcal{L}$ with $\mathcal{M}$ (or $(1-\mathcal{M})$) for distributions of compact support, and we will assume this. $\mathcal{ML}$ is a classical PDO because its symbol,

$$m(\boldsymbol{\xi})\left(\frac{\varphi\bigl(\arg(\boldsymbol{\xi}') + \pi/2\bigr)}{\|\boldsymbol{\xi}'\|}\right)\bigl(\mu + \|\boldsymbol{\xi}'\|^2\bigr),$$

is the sum of a term homogeneous of degree (-1) and one homogeneous of degree 1. Since the terms are smooth away from the origin ($m(\xi)$ cuts off the near the nonsmooth ξ_1 direction), $\mathcal{ML}$ is a classical PDO of order one. Since its symbol is elliptic on the open set $\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U')\bigr)$, $\mathcal{L}$ is elliptic on that set. Furthermore, by local Sobolev continuity, the $\mathscr{H}^{\alpha+1}$ wavefront of f in $\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U)\bigr)$ corresponds to the $\mathscr{H}^{\alpha}$ wavefront of $\mathcal{ML}(f)$ on that set,

$$\mathrm{WF}^{\alpha}\bigl(\mathcal{ML}(f)\bigr) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U)\bigr)\Bigr) = \mathrm{WF}^{\alpha+1}(f) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U)\bigr)\Bigr). \tag{A.11}$$

Because $\mathrm{supp}\bigl(1 - m(\boldsymbol{\xi})\bigr) \subset \mathrm{cl}(U)$, $\mathcal{F}\bigl((1-\mathcal{M})\mathcal{L}(f)\bigr)$ has support contained in $\mathrm{cl}(U)$. So, by Lemma A.3,

$$\mathrm{WF}\bigl((1-\mathcal{M})\mathcal{L}(f)\bigr) \subset \mathbb{R}^3 \times \mathrm{cl}(U). \tag{A.12}$$

In addition, since $\mathcal{L} = \mathcal{ML} + (1-\mathcal{M})\mathcal{L}$, the $\mathscr{H}^{\alpha+1}$ wavefront set of $\mathcal{L}(f)$ off of $\mathbb{R}^3 \times \mathrm{cl}(U)$ is the same as that of $\mathcal{ML}(f)$. Using (A.11), we see that

$$\mathrm{WF}^{\alpha}\bigl(\mathcal{L}(f)\bigr) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U)\bigr)\Bigr) = \mathrm{WF}^{\alpha+1}(f) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathcal{W} \setminus \mathrm{cl}(U)\bigr)\Bigr).$$

By making U arbitrarily close to $\boldsymbol{e}_1$, we establish (A.7).

To prove the containment (A.8), we fix U, U', and $\mathcal{M}$ as above. We will now prove

$$\mathrm{WF}^{\alpha}\bigl(\mathcal{ML}(f)\bigr) \subset \left(\mathrm{WF}^{\alpha+1}(f) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathrm{cl}(\mathcal{W}) \setminus \mathrm{cl}(U)\bigr)\Bigr)\right) \cup \bigl(\mathbb{R}^3 \times \mathrm{cl}(U)\bigr). \tag{A.13}$$

First, because the symbol of $\mathcal{ML}$ is supported on the closed set $\mathbb{R}^3 \times \bigl(\mathrm{cl}(\mathcal{W}) \setminus U'\bigr)$,

$$\mathrm{WF}^{\alpha}\bigl(\mathcal{ML}(f)\bigr) \subset \mathbb{R}^3 \times \bigl(\mathrm{cl}(\mathcal{W}) \setminus U'\bigr).$$

Because of (A.11), we need only consider $\boldsymbol{\xi} \in \mathrm{bd}(\mathcal{W}) \setminus \mathrm{cl}(U)$ and $\boldsymbol{x}_0 \in \mathbb{R}^3$ such that $(\boldsymbol{x}_0, \boldsymbol{\xi}) \notin \mathrm{WF}^{\alpha+1}(f)$. Since $\mathcal{ML}$ is a standard PDO of order one, $(\boldsymbol{x}_0, \boldsymbol{\xi}) \notin \mathrm{WF}^{\alpha}\bigl(\mathcal{ML}(f)\bigr)$. This shows (A.13).

Next, the wavefront set of a sum is contained in the union of the wavefront set of the terms. Combining this fact with (A.12) and (A.13) yields

$$\mathrm{WF}\bigl(\mathcal{L}(f)\bigr) \subset \left(\mathrm{WF}^{\alpha+1}(f) \cap \Bigl(\mathbb{R}^3 \times \bigl(\mathrm{cl}(\mathcal{W}) \setminus \mathrm{cl}(U)\bigr)\Bigr)\right) \cup \bigl(\mathbb{R}^3 \times \mathrm{cl}(U)\bigr).$$

The inclusion in (A.8) now follows when we let U shrink to $\pm\boldsymbol{e}_1$.

We claim that if f is supported in B, then $\operatorname{supp}\mathcal{L}(f) \subset [-1,1]\times\mathbb{R}^2$. This is true by a global version of the argument at the end of Remark A.4. This concludes the proof of Theorem A.2. $\square$

Remark A.4. *Note that if $f \in \mathscr{E}'(\mathbb{R}^3)$ is smooth in the $\pm\boldsymbol{dx}_1$ codirection at all points, then, for sufficiently small U, $(1-\mathcal{M})(f)$ is smooth, and so*

$$\mathcal{L}(f) = \mathcal{M}\mathcal{L}(f) + \mathcal{L}(1-\mathcal{M})(f)$$

has no wavefront in the $\pm\boldsymbol{d\xi}_1$ codirection. In other words, for this f there are no added singularities.

A local version of this statement is true: if $a \in \mathbb{R}$ and f is smooth in the $\pm\boldsymbol{dx}_1$ codirection at all points in the plane $x_1 = a$, i.e., $\big((a,\boldsymbol{x}');\pm\boldsymbol{dx}_1\big) \notin \mathrm{WF}(f)$ for all $\boldsymbol{x}' \in \mathbb{R}^2$), then $\mathcal{L}(f)$ is smooth in the $\pm\boldsymbol{dx}_1$ codirection above all points on the plane $x_1 = a$. To see this we observe that because supp f *is compact and wavefront sets are conical and closed, one can find a function $g \in \mathscr{C}_c^\infty(\mathbb{R})$ is not zero near $x_1 = a$ and a sufficiently small neighborhood U of $\boldsymbol{e}_1$ such that $g(x_1)(1-\mathcal{M})(f)$ is smooth, and so $g\mathcal{L}(f)$ is smooth in the $\pm\boldsymbol{dx}_1$ codirection at all points. Thus, $\mathcal{L}(f)$ is smooth in this direction at all points in the plane $x_1 = a$.*

That is, wavefront is not added if f is smooth in this codirection at all points on the plane $x_1 = a$. However, Example A.5 *demonstrates that wavefront can be spread in the plane $x_1 = a$ if f has wavefront in the $\pm\boldsymbol{dx}_1$ direction at points in this plane.*

We now introduce a new operator, $\mathcal{L}_\triangle$, which is related to an operator of Louis and Maaß for cone beam CT. Louis and Maaß adapted Lambda tomography to cone beam tomography in a very clever way [17] by taking a Laplacian in the detector plane before taking cone-beam backprojection. This adds extra singularities to the reconstruction as proven in general in [8] and for the cone beam transform in $\mathbb{R}^3$ in [7, 14]. The natural generalization of the Louis–Maaß operator to our setting is

$$\mathcal{L}_\triangle(f) := \mathcal{P}^*_{\theta_{\mathrm{cut}}}\big((\mu - \Delta_{\boldsymbol{\omega}^\perp})\mathcal{P}(f)\big), \tag{A.14}$$

where $\Delta_{\boldsymbol{\omega}^\perp}$ is the Laplacian operator in the detector plane and $\mu \geq 0$. In Example A.5 we will show that $\mathcal{L}_\triangle$ adds stronger singularities than $\mathcal{L}$.

Anastasio et al. [1], Katsevich [15], and Ye, Yu, and Wang [31] have developed refinements of Louis and Maaß's operator for cone beam CT. They decrease the added singularities by taking a derivative in only one direction rather than taking the Laplacian in the detector plane. This is analogous to our operator $\mathcal{L}$, in which the derivative is D_σ^2. Although these results are related, they do not apply to parallel beam data, as our methods do.

The arguments in our proof of Theorem A.1 can be used to show that $\mathcal{L}_\triangle$ is a PDO with a singular symbol

$$\left(\frac{\varphi(\arg(\boldsymbol{\xi}') + \pi/2)}{\|\boldsymbol{\xi}'\|}\right)\big(\mu + \|\boldsymbol{\xi}\|^2\big)$$

and (A.7) and (A.8) hold for $\mathcal{L}_\triangle$. For fixed $\boldsymbol{\xi}'$, the symbol of $\mathcal{L}_\triangle$ is of order 2 as $\boldsymbol{\xi}_1 \to \infty$, although it is of order 1 in other directions. The symbol of $\mathcal{L}$ is more mildly singular since, although it is not differentiable when $\boldsymbol{\xi}' = \boldsymbol{0}$ (on the ξ_1-axis), it is of order zero as $\boldsymbol{\xi}_1 \to \infty$ when $\boldsymbol{\xi}'$ is fixed.

Our next example justifies the addition of the set $\mathcal{A}$ in (A.8), a set on which wavefront can be added by $\mathcal{L}$ and $\mathcal{L}_\triangle$. The example also shows how $\mathcal{L}_\triangle$ adds stronger singularities than $\mathcal{L}$.

EXAMPLE A.5. *Let $\alpha \in \mathbb{R}$, and let $\epsilon > 0$ be arbitrary. We construct a function $f \in \mathscr{H}^{\alpha+1}(\mathbb{R}^3)$ supported in $S := [-1/2, 1/2]^3$ with the following properties:*

1. *$\mathcal{L}_\triangle(f) \notin \mathscr{H}^\alpha_{\mathrm{loc}}(\mathbb{R}^3)$, and $\mathcal{L}_\triangle(f)$ has $\mathscr{H}^\alpha$ wavefront set in the $\pm\boldsymbol{dx}_1$ direction even though f is in $\mathscr{H}^{\alpha+1}$ everywhere. This is true even for points outside* $\operatorname{supp} f$, *points at which f is smooth.*
2. *$\mathcal{L}(f)$ is in $\mathscr{H}^{\alpha+1}_{\mathrm{loc}}(\mathbb{R}^3)$ but has $\mathscr{H}^{\alpha+1+\epsilon}$ wavefront set in the $\pm\boldsymbol{dx}_1$ codirection outside of* $\operatorname{supp} f$. *Therefore, $\mathcal{L}$ also spreads singularities, but, for this case, the singularities are weaker. This weakening is suggested by the fact that $\mathcal{L}^0$, which is defined as $\mathcal{L}$ with $\mu = 0$, is continuous of order one in Sobolev scale.*

The actual construction of f goes as follows: Let $\epsilon' = \min\{\epsilon, 1/2\}$, and let $\phi_1 \in \mathscr{H}^{\alpha+1}(\mathbb{R})$ with $\operatorname{supp}\phi_1 = [-1/2, 1/2]$ *such that*

$$\mathrm{WF}^{\alpha+1+\epsilon'}(\phi_1) = \big\{(x_1, t\boldsymbol{dx}_1) \bigm| x_1 \in [-1/2, 1/2],\ t \neq 0\big\}. \tag{A.15}$$

Also, let ϕ_2 be a nonnegative smooth function in $\mathbb{R}^2$ with $\operatorname{supp}\phi_2 = [-1/2, 1/2]^2$.

For $x_1 \in \mathbb{R}$ and $\boldsymbol{x}' \in \mathbb{R}^2$ define $f(x_1, \boldsymbol{x}') = \phi_1(x_1)\phi_2(\boldsymbol{x}')$. For $g \in \mathscr{C}^\infty_c(\mathbb{R}^2)$ define

$$\mathcal{H}(g)(\boldsymbol{x}') := \int_{\boldsymbol{y}' \in \mathbb{R}^2} \frac{\varphi\big(\arg(\boldsymbol{y}')\big)}{\|\boldsymbol{y}'\|} g(\boldsymbol{x}' + \boldsymbol{y}')\, d\boldsymbol{y}'; \tag{A.16}$$

then $\mathcal{H}$ is really $\mathcal{P}^*_{\theta_{\mathrm{cut}}}\mathcal{P}$ restricted to a fixed plane (compare with (A.2)*). Since $\mathcal{H}$ is a classical PDO, $\mathcal{H}$ is continuous from domain $\mathscr{C}^\infty_c(S)$ to $\mathscr{C}^\infty(\mathbb{R}^2)$.*

It is straightforward to show that $\mathcal{L}_\triangle(f) = -\phi_1''\mathcal{H}(\phi_2) + \phi_1\mathcal{H}\big((\mu - \Delta_{\boldsymbol{x}'})\phi_2\big)$, where ϕ_1'' is the second derivative of ϕ_1. Since ϕ_1 is chosen to be in $\mathscr{H}^{\alpha+1}$ and not $\mathscr{H}^{\alpha+1+\epsilon'}$, the first term in the expression for $\mathcal{L}_\triangle(f)$ is not in $\mathscr{H}^\alpha_{\mathrm{loc}}$, although the other terms are. Thus, $\mathcal{L}_\triangle(f)$ is not in $\mathscr{H}^\alpha_{\mathrm{loc}}$. Because of (A.15),

$$\mathrm{WF}^\alpha\big(\mathcal{L}_\triangle(f)\big) = \big\{(x_1, \boldsymbol{x}', t\boldsymbol{dx}_1) \bigm| x_1 \in [-1/2, 1/2],\ \boldsymbol{x}' \in \operatorname{supp}\mathcal{H}(\phi_2),\ t \neq 0\big\}. \tag{A.17}$$

Furthermore, since φ_2 is nonnegative and not the zero function, $\mathcal{H}(\varphi_2)$ has unbounded support. Thus $\mathcal{L}_\triangle$ adds Sobolev wavefront both inside and outside $\operatorname{supp} f$ *even though $f \in \mathscr{H}^{\alpha+1}_c(\mathbb{R}^3)$.*

In a similar way, one shows that $\mathcal{L}(f) = \phi_1\mathcal{H}\big((\mu - \Delta_{\boldsymbol{x}'})\phi_2\big)$, and so $\mathcal{L}f$ is in $\mathscr{H}^{\alpha+1}_{\mathrm{loc}}$ (because ϕ_1 is in $\mathscr{H}^{\alpha+1}$ and the other term is smooth), but

$$\begin{aligned}&\mathrm{WF}^{\alpha+1+\epsilon'}\big(\mathcal{L}(f)\big)\\ &\qquad = \Big\{(x_1, \boldsymbol{x}', t\boldsymbol{dx}_1) \bigm| x_1 \in [-1/2, 1/2],\ \boldsymbol{x}' \in \operatorname{supp}\mathcal{H}\big((\mu - \Delta_{\boldsymbol{x}'})\phi_2\big),\ t \neq 0\Big\}.\end{aligned}$$

Note that $\operatorname{supp}\mathcal{H}\big((\mu - \Delta_{\boldsymbol{x}'})\phi_2\big)$ *must be unbounded,*[10] *so $\mathcal{L}$ spreads singularities of f, but they are weaker than those for $\mathcal{L}_\triangle(f)$.*

To state Theorem 6.3, we need a little more notation. Covectors in $T^*(Y)$ will be denoted by $\big((y_1, y_{\boldsymbol{\sigma}}, \theta); \nu_1\boldsymbol{dy}_1 + \nu_2\boldsymbol{dy}_{\boldsymbol{\sigma}} + \nu_3\boldsymbol{d\theta}\big)$, where $(\nu_1, \nu_{\boldsymbol{\sigma}}, \nu_\theta) \in \mathbb{R}^3$ and $\boldsymbol{dy}_1$ is the covector dual to the tangent vector $\partial/\partial y_1$, $\boldsymbol{dy}_{\boldsymbol{\sigma}}$ is dual to $\partial/\partial y_\sigma$, and $\boldsymbol{d\theta}$ is dual to $\partial/\partial\theta$. Using these conventions we can state the following theorem that gives the basic microlocal analysis of $\mathcal{P}$ with the limited data given in our ET problem.

THEOREM A.6. *Let f be a distribution of compact support on $\mathbb{R}^3$, $\theta_{\max} \in\,]0, \pi/2[$, and assume $\mathcal{P}(f)(\boldsymbol{y}, \theta)$ is given on an open set $U \subset Y$. Moreover, let $(y_1, y_{\boldsymbol{\sigma}}, \theta_0) \in U$,*

[10] The two-dimensional version of the proof of (A.3) shows that the two-dimensional Fourier transform $\mathcal{F}\mathcal{H}(\phi_2)$ is a product including $\varphi\big(\arg(\boldsymbol{\xi}') + \pi/2\big)$ and so is zero on an open set. If $\mathcal{H}(\phi_2)$ had compact support, then $\phi_2 = 0$ since $\mathcal{F}\mathcal{H}(\phi_2)$ would be real-analytic.

let $\boldsymbol{\xi}_0$ be a nonzero vector perpendicular to $\boldsymbol{\omega}(\theta_0)$ written as $\boldsymbol{\xi}_0 = \xi_1\boldsymbol{e}_1 + \xi_{\boldsymbol{\sigma}}\boldsymbol{\sigma}(\theta_0)$, and assume $\xi_{\boldsymbol{\sigma}} \neq 0$ (i.e., $\boldsymbol{\xi}_0$ is not parallel to $\boldsymbol{e}_1$). Finally, let $\boldsymbol{x}_0 \in \ell(y_1, y_{\boldsymbol{\sigma}}, \theta_0)$. Then, $(\boldsymbol{x}_0; \boldsymbol{\xi}_0\boldsymbol{dx}) \in \mathrm{WF}^{\alpha}(f)$ if and only if

$$\text{(A.18)} \qquad \Big((y_1, y_{\boldsymbol{\sigma}}, \theta_0); \xi_1\boldsymbol{dy}_1 + \xi_{\boldsymbol{\sigma}}\boldsymbol{dy}_a + \big(\xi_{\boldsymbol{\sigma}}\boldsymbol{x}\cdot\boldsymbol{\omega}(\theta_0)\big)\boldsymbol{d\theta}\Big) \in \mathrm{WF}^{\alpha+1/2}\big(\mathcal{P}(f)\big).$$

The proof follows from the fundamental results in [9] that show that Radon transforms are FIOs and also from the analysis of the general X-ray transform in [8] (see also [2]). The proof involves first calculating the canonical relation of $\mathcal{P}$, next noting that $\mathcal{P}$ is elliptic, and finally using the calculus of FIOs [12] to tell what $\mathcal{P}f$ does to the wavefront set. A proof of this result is given for more general curves of directions in S^2 given in [22].

Acknowledgments. The authors are indebted to Prof. Ulf Skoglund for invaluable help, support, and knowledge as well as for generous access to data sets. The authors thank Prof. Jan Boman of Stockholm University for extremely valuable comments that helped clarify the microlocal analysis in the article. We thank Dr. Hans Rullgård of Stockholm University for carefully reading the manuscript, and we thank the referees for their thorough reviews and helpful comments. The first author thanks Prof. Dr. Alfred Louis and Universität des Saarlandes and Prof. Dr. Andreas Rieder and Universität Karlsruhe for their hospitality while this article was being researched and written.

BOUNDARY CONDITIONS FOR THE MICROSCOPIC FENE MODELS*

CHUN LIU† AND HAILIANG LIU‡

Abstract. We consider the microscopic equation of finite extensible nonlinear elasticity (FENE) models for polymeric fluids under a steady flow field. It is shown that for the underlying Fokker–Planck type of equations, any preassigned distribution on the boundary will become redundant once the nondimensional number $Li := \frac{Hb}{k_B T} \geq 2$, where H is the elasticity constant, $\sqrt{b}$ is the maximum dumbbell extension, T is the temperature, and k_B is the usual Boltzmann constant. Moreover, if the probability density function is regular enough for its trace to be defined on the sphere $|m| = \sqrt{b}$, then the trace is necessarily zero when $Li > 2$. These results are consistent with our numerical simulations as well as some recent well-posedness results by preassuming a zero boundary distribution.

Key words. microscopic finite extensible nonlinear elasticity models, boundary condition, polymer fluids, Fokker–Planck equation, Fichera function

1. Introduction.

The two-scale macro-micro models have been proven successful in describing the dynamics of many polymeric fluids. The systems usually consist of a macroscopic momentum equation (the force balance equation) and a microscopic evolution of the probability distribution functions (PDFs) through Fokker–Planck equations [4, 5]. The coupling of the micro-macro interaction is through the transport of the PDF in the microscopic equations and the induced elastic stress in the macroscopic equations. It is through this interaction, the competition between the kinetic energy and the (multiscale) elastic energies, that all different hydrodynamical and rheological properties of these materials arise [5, 14]. Let y be the macroscopic Eulerian (observer's) coordinate and m the microscopic molecule configurational variable. The distinguished representation of the variables represents the nature of the scale separation of these models. Let $u = u(y,t)$ be the macroscopic velocity field of the flow and $y(X,t)$ be the induced flow map (trajectory) with macroscopic material coordinate X. $f = f(t,m,y)$, $(m,y) \in \mathbb{R}^{2d}$ is the PDF of the molecule separation. The dependence of the macroscopic coordinate of f is attributed to the macroscopic anisotropy of the materials. Moreover, the models assume that the microscopic deformation is the same as the macroscopic deformation through the macroscopic covariant (or anticovariant) deformation of m. In the case of $m = F\tilde{m}$, with $F = \frac{\partial y}{\partial X}$ the (macroscopic) deformation tensor induced by the flow map $y(X,t)$, and $\tilde{m}$ the undeformed configuration, we have the following microscopic evolution equation [17]:

$$\partial_t f + u \cdot \nabla_y f + \nabla_m \cdot (\kappa m f) = \frac{2}{\gamma}\left[(\nabla_m \cdot (\nabla_m U f) + k_B T \Delta_m f)\right], \tag{1.1}$$

where $\kappa = \nabla_y u$ is the strain rate tensor; U denotes the spring potential; γ is the friction coefficient; T is the absolute temperature; and k_B is the Boltzmann constant. Equation (1.1) models both the convection and stretching of the polymers by the macroscopic flow and the microscopic convection diffusion evolution. The latter mechanism can be interpreted with its corresponding SDE [11, 16]:

$$dm = \left(-\frac{2}{\gamma}\nabla_m U\right) dt + \sqrt{\frac{4k_BT}{\gamma}}dW_t,$$

where W_t is a standard Brownian motion, which in turn gives the Fokker–Planck dynamic to the PDF. Much of the material properties can be attributed to different microscopic energies. The simplest spring potential is given by the Hookean law $U(m) = H|m|^2/2$, where H is the elasticity constant. This potential has the distinguished feature that the system is closed under second moment closure, which yields the usual Oldroyd models [3, 5, 17]. A more commonly used model is with the following finite extensible nonlinear elasticity (FENE) potential:

$$U(m) = -\frac{Hb}{2}\log\left(1 - \frac{|m|^2}{b}\right),$$

which takes into account a finite-extensibility constraint by assigning infinite energy when the molecule length approaches $\sqrt{b}$, the maximum dumbbell extension [3]. In this case, the convective spring force becomes

$$\nabla_m U = \frac{Hm}{1 - |m|^2/b}, \tag{1.2}$$

which also becomes infinity on the boundary of $B_{\sqrt{b}}$. Intuitively, this should mean that the Fokker–Planck equation (1.1) is defined only on the open ball $\Omega = \{m \in \mathbb{R}^d : |m|^2 < b\}$, where $d = 2, 3$, disregarding the boundary condition preimposed on the solution of (1.1). On the other hand, the diffusion due to the thermofluctuation does have infinite propagation speed. Also, the Brownian motion is unbounded in the L^∞ norm. The main complexity with the FENE potential lies mainly with the singularity of the equation at the boundary. In this paper, we will discuss boundary conditions for the Fokker–Planck equation alone, with the fluid velocity being steady and homogeneous. The velocity gradient will be treated as a constant matrix. Observe that since (1.1) experiences singularity on the sphere $|m| = \sqrt{b}$, the data may not necessarily be well defined. The main issues of our interest in this work are the following:

- Are the boundary conditions necessary or redundant?
- If the PDF solution is regular enough to have a trace on the boundary, what is its trace, regardless of whether or not the data is preimposed?

These issues for the underlying FENE models are fundamental and attracted much attention in the study of the well-posedness in certain weighted Sobolev spaces (see, e.g., [15]) as well as in the two-dimensional SDE framework [13]. However, the whole issue remained open. Our key observation in this paper is that the answer to the above questions hinges on whether the nondimensional quantity

$$Li := \frac{Hb}{k_BT} \tag{1.3}$$

crosses a critical value 2. The main goals of this paper are to show two new results: (i) for the underlying Fokker–Planck equation (1.1), any boundary condition will become redundant once the nondimensional number $Li \geq 2$; (ii) if the PDF f is regular enough for its trace to be defined on the sphere $|m| = \sqrt{b}$, then the trace is necessarily zero when $Li > 2$. Physically speaking, no boundary condition is necessary for the case with the given spring at low temperature or the case at fixed temperature with the large product of H and b. To put our work in a proper perspective we recall that well-posedness of the coupled micro-macro system or Fokker–Planck equation alone has attracted much attention recently [2, 6, 7, 12]. In particular, the local existence results of [23] in the weighted Sobolev space will also force the zero boundary condition. Up to now, most works have been with prescribed boundary conditions. On the other hand, numerical simulations seemed to indicate that the solutions are not sensible to such boundary conditions. We also refer the reader to [15] for the study of large-time behavior of the coupled micro-macro system and a rigorous formulation of the no-flux boundary condition. We now proceed to identify the key quantity Li defined in (1.3) by making the following scaling:

$$(y, u, t, m, b) \to \left(\frac{y}{L_0}, \frac{u}{U_0}, \frac{t}{T_c}, \frac{m}{l}, \frac{b}{l^2} \right),$$

where $T_c := L_0/U_0$ is the macroscopic convective time scale and $l := \sqrt{\frac{k_B T}{H}}$ serves as the mesoscopic length scale of the spring. We further introduce the nondimensional parameter $De = \frac{T_r}{T_c}$, where $T_r = \frac{\gamma}{4H}$ characterizes the mesoscopic relaxation time scale of the spring, and De is often called the Deborah number, which is a unique parameter in non-Newtonian fluids. Putting all of the above together and still using (y, u, t, m, b) for the scaled quantities, (1.1) thus reduces to

$$\partial_t f(t, m) + \nabla_m \cdot (\kappa m f) = \frac{1}{2\,De}(\nabla_m \cdot (\nabla_m U f) + \Delta_m f), \tag{1.4}$$

where $\kappa = \nabla_y u$ is the steady homogeneous velocity gradient. $\mathrm{Tr}(\kappa) = \nabla_y \cdot u = 0$ for the incompressible flow. Note that the corresponding square of radius for the nondimensional configuration variable m is exactly the key parameter $Li = b/l^2 = \frac{Hb}{k_B T}$ as given in (1.3) (though still denoted by b in what follows). The potential in nondimensional form thus reads

$$\nabla_m U = \frac{m}{1 - |m|^2/b}. \tag{1.5}$$

In order to simplify the notation, we simply take $De = 1$ and obtain

$$\partial_t f(t, m) + \nabla_m \cdot (\kappa m f) = \frac{1}{2}(\nabla_m \cdot (\nabla_m U f) + \Delta_m f). \tag{1.6}$$

For (1.6) with scaled potential (1.5) our first result is that $b = 2$ is a critical extension parameter for deciding whether boundary conditions are necessary for a well-defined problem (in the sense that the well-posedness results are expected to be obtained in standard Sobolev spaces).

Theorem 1.1. *Consider* (1.6) *in* $\{m \mid |m| < \sqrt{b}\}$ *for* $t > 0$ *subject to certain initial data. The extension parameter* $b = 2$ *is a critical value in the sense that the Dirichlet boundary condition leads to a well-defined problem, provided that* (i) *when* $b < 2$*, the distribution* f *on boundary* $|m|^2 = b$ *must be imposed; and* (ii) *when* $b \geq 2$*, any preassigned distribution on boundary* $|m|^2 = b$ *will become redundant.*

It is known that the parameter range of physical interest is $b > 2$ [3]. Therefore, in this regime for b, the original problem can be formulated as follows: find a distribution function $f(t, m)$ such that (1.6) holds for $t > 0$ and

$$f(0, m) = f_0(m), \quad |m| < \sqrt{b}, \tag{1.7}$$

where $f_0 \geq 0$ is a given bounded measurable function.

Here we would like to make several remarks:

(1) The statement in this theorem is justified based on the use of Fichera's criterion [8], which is sketched in the appendix.

(2) The well-posedness for the case $b < 2$ with imposed distribution on $|m| = \sqrt{b}$ follows from Theorem 4.2 in the appendix, with an extra constraint on the nontrivial shear rate k. The proof of the well-posedness for the case $b \geq 2$ is more delicate. In this work the redundancy of boundary conditions is stated in the sense of trace for weak solutions. We note that boundary conditions can also be discussed in terms of trajectories of the stochastic process; see, e.g., Stroock and Varadhan [20]. The second order linear equations with nonnegative characteristic form attracted much interest in the 1960's and 1970's [18, 21]. The existence results are customarily in Sobolev spaces with certain disjointness assumptions on the relevant boundary parts with the irrelevant parts and the non(negative) characteristic parts. Regularity of solutions with continuity up to the boundary can be further discussed [18]. As for the FENE models considered in this paper, we will present a description of the existence of the full system (coupled with the flow field) in a separate paper.

(3) The corresponding analogue of this statement in the SDE framework is known [13], where for the two-dimensional case the authors show that if $b \geq 2$, then the trajectories of the stochastic process representing the evolution of the end-to-end vector does not touch the boundary of radius $\sqrt{b}$, which means the polymer does not reach its maximal extensibility. Our second result determines the trace of the PDF on the sphere $|m|^2 = b$.

THEOREM 1.2. *Consider the initial value problem* (1.6)–(1.7) *in* $|m| < \sqrt{b}$. *Let* $f_0(m)$ *be a bounded measurable function with* $\mathrm{supp}(f_0(m)) \subset \{m, |m| \leq \sqrt{b^*}, b^* < b\}$. *Then for* $b > 2$ *the solution* $f(t, m)$ *of* (1.6) *remains bounded and satisfies*

$$|f| \leq |f_0| \left(\frac{b - |m|^2}{b - b^*} \right)^{b/2 - \alpha} e^{Kt},$$

where α *and* K *satisfy*

$$0 < \alpha < \frac{b}{2} - 1, \quad K > K^* := \frac{\beta^2}{16b\alpha(b - 2 - 2\alpha)} - \rho(b - 2\alpha)$$

with $\beta = \rho(b - \alpha)r^2 + 2\alpha(d + b - 2 - 2\alpha)$ *and* $\rho = \sqrt{\mathrm{Tr}(\kappa^\top \kappa)}$.

In comparison we mention that the solution to the SDE associated with (1.6) is shown to exist and has trajectorial uniqueness if and only if $b \geq 2$ [12]. We also refer the reader to [2] for an existence result with prescribed zero boundary data. Our results also show that for $b \geq 2$ well-posedness requires no prescribed boundary value on $|m|^2 = b$, and for $b > 2$ the distribution function, if regular enough to have a trace, must have zero trace:

$$f(t, m)|_{|m| = \sqrt{b}} = 0. \tag{1.8}$$

In other words, one is not allowed to prescribe boundary data on the sphere $|m| = \sqrt{b}$ other than (unnecessary) $f = 0$ or a natural no-flux boundary condition. The difficulty of the problem lies in the singularity of the equation occurring at the boundary. The key to our approach is to rewrite the equation into a second order equation having standard nonnegative characteristic form, for which we apply the Fichera function criterion to check when boundary conditions are unnecessary [8, 18, 21]. We further investigate the trace of the PDF on the sphere $|m| = \sqrt{b}$ where no data is preimposed. Our approach is to convert the equation by a delicate transformation in such a way that the resulting equation supports a maximum principle. This paper is organized as follows: in section 2, we use the Fichera function criterion to prove Theorem 1.1. Section 3 is devoted to the trace analysis of the PDF on the sphere $|m| = \sqrt{b}$. The presentation is split into two parts, without and with homogeneous flow involved.

2. Critical parameter $b = 2$ and boundary conditions. In this section we shall show that $b = 2$ is a critical value in the sense that for $b < 2$ a boundary condition is necessary and when $b \geq 2$ the boundary distribution becomes redundant. Note that (1.6) has a singular lower order term on boundary $|m| = \sqrt{b}$; our approach is to first transform this equation into a second equation degenerating near the boundary. We then employ the method of the Fichera function [1, 8, 18, 21] to study the corresponding relevant boundary value points on the boundary [18], as sketched in the appendix. We now introduce the following transformation:

$$f(t, m) = g(t, m) \exp(-U(m)), \tag{2.1}$$

which gives

$$\partial_t g + \nabla_m \cdot (\kappa m g) - \nabla_m U \cdot (\kappa m g) = \frac{1}{2}[\Delta_m g - \nabla_m U \cdot \nabla_m g]. \tag{2.2}$$

The right-hand side of the equation becomes the dual form of the original Fokker–Planck equation [9, 19]. We note a different transformation in [6, 10, 22], $f(t, m) = g(t, m) \exp(-U(m)/2)$, which was used to remove the singularity at the boundary in the resulting equation. Applying further rescaling,

$$x = \sqrt{2}m, \quad r^2 = 2b, \quad v(t, x) = g(t, m), \tag{2.3}$$

we obtain

$$\partial_t v + \nabla_x \cdot (\kappa x v) + a(x) \cdot (\nabla_x v - \kappa x v) = \Delta_x v, \tag{2.4}$$

where

$$a(x) := \frac{bx}{r^2 - |x|^2}.$$

Note that $\nabla_x \cdot (\kappa x) = \mathrm{Tr}(\kappa) = 0$; the above equation reduces to

$$\partial_t v + (a(x) + \kappa x) \cdot \nabla_x v - a(x) \cdot \kappa x v = \Delta_x v. \tag{2.5}$$

Once v is determined, the PDF f can be recovered through

$$f(t, m) = v(t, \sqrt{2}m)(1 - |m|^2/b)^{b/2}. \tag{2.6}$$

Rewrite (2.5) as

$$L(v) = 0, \quad x \in \mathbb{R}^d, \tag{2.7}$$

where

$$
\begin{aligned}
L(v) := (r^2 - |x|^2)\Delta_x v - (r^2 - |x|^2)v_t \\
- (bx + (r^2 - |x|^2)\kappa x) \cdot \nabla_x v + bx^\top \kappa x v
\end{aligned}
$$

has a standard form:

$$L(v) :\equiv a^{kj}(\xi)D_{kj}v + b^k(\xi)D_k v + c(\xi)v = 0, \quad k, j = 0 \cdots d.$$

Here the repeated indices are summed from 1 to d, $\xi = (t, x)$:

$$a^{00} = 0, \quad b^0 = -(r^2 - |x|^2), \quad c(\xi) = bx^\top \kappa x$$

and

$$a^{kk}(\xi) = (r^2 - |x|^2), \quad b^k = -[bx_k + (r^2 - |x|^2)\kappa_{kj}x_j], \quad k = 1 \cdots d.$$

Note that the new equation is degenerate at boundary $|x| = r$. This second order equation has nonnegative characteristic form in domain $\Omega = \{(t, x),\, 0 < t < T^*,\, |x| < r\}$ for any $T^* > 0$, since

$$a^{kj}(\xi)y_k y_j \geq 0$$

for any real vector y and any point $\xi \in \Omega$. Hence there are no negative characteristic points on the boundary.

Next we check the sign of Fichera's function

$$\mathfrak{F} = (b^k - a^{kj}_{\xi_j})n_k$$

at points on $\partial\Omega$. At boundary $|x| = r$, $0 < t < T^*$, one has $n_0 = 0$, $n_k = -x_k/r$, $k = 1 \cdots d$; thus

$$
\begin{aligned}
\mathfrak{F}(t, x) &= \sum_{k=1}^{d} (b^k - a^{kk}_{x_k})n_k \\
&= \sum_{k=1}^{d} (-bx_k + 2x_k) \cdot (-x_k/r) \\
&= (b - 2)r.
\end{aligned}
$$

If $\mathfrak{F} \geq 0$, that is, $b \geq 2$, all boundary points are irrelevant and no boundary condition is needed. Otherwise, in the case $b < 2$, all boundary points are relevant and an appropriate boundary condition has to be imposed. We now examine the boundary $t = T^*$ and $|x| < r$, on which one has $n^0 = -1$, $n^k = 0$; thus

$$
\begin{aligned}
\mathfrak{F}(t, x) &= (b^k - a^{kj}_{\xi_j})n_k = b^0 n_0 \\
&= r^2 - |x|^2 > 0.
\end{aligned}
$$

No condition needs to be imposed at $t = T^*$ either. Similarly at $t = 0$, $|x| < r$, one obtains $\mathfrak{F}(t, x) = |x|^2 - r^2 < 0$; thereby a condition at $t = 0$, the initial condition, has to be imposed. This completes the proof of Theorem 1.1.

Remark. For the transformed equation $L[v] = 0$ with $\kappa = 0$, we have

$$\frac{1}{2}D_i b^i - \frac{1}{2}D_{ij}a^{ij} - c = d\left(1 - \frac{b}{2}\right) > 0$$

for $b < 2$. Hence the existence theorem (Theorem 4.2) in the appendix applies only to the case $b < 2$.

3. The trace of the distribution function on the sphere $|m| = \sqrt{b}$ for $b > 2$. We now restrict ourselves to the case of $b > 2$. The proof in the above section shows that the presence of the fluid velocity does not affect the relevancy of the boundary points with respect to the equation. In this section, we will show, if the solution exists and assumes a trace on the boundary, that the trace of the resulting PDF has to be zero.

3.1. No-flow case. We will start from the case $\kappa = 0$. Equation (2.4) becomes

$$\partial_t v + a(x) \cdot \nabla_x v = \Delta_x v, \quad a(x) := \frac{bx}{r^2 - |x|^2}, \tag{3.1}$$

with the initial condition

$$v(0, x) = v_0(x) = f_0\left(\frac{x}{\sqrt{2}}\right)\left(1 - \frac{|x|^2}{r^2}\right)^{-b/2}, \quad \operatorname{supp}(v_0) \subset [-r, r];$$

we are going to show that there exists an α satisfying $0 < \alpha < b/2$ and a $K > 0$ such that

$$|v(t, x)| \leq Me^{Kt}(r^2 - x^2)^{-\alpha} \quad \forall t > 0.$$

Combining with the original transformation (2.1) and (2.3), which yield

$$f(t, m) = v(t, x)(1 - |x|^2/r^2)^{b/2},$$

we arrive at

$$|f(t, m)| \leq C(r^2 - x^2)^{b/2-\alpha}e^{Kt}. \tag{3.2}$$

This leads to the zero trace for the PDF:

$$f(t, m)|_{|m|^2=b} = 0 \quad \forall t > 0.$$

The main difficulty of Theorem 1.2 lies in the singularity at the boundary. Equation (2.7) for v solves $L(v) = 0$ with

$$L(v) := (r^2 - |x|^2)\Delta_x v - bx \cdot \nabla_x v - (r^2 - |x|^2)\partial_t v.$$

We now introduce the transformation

$$v(t, x) := w(t, x)(r^2 - |x|^2)^{-\alpha}e^{Kt},$$

with α and K to be determined. A simple calculation gives

$$\begin{aligned}
\partial_t v &= (w_t + Kw)(r^2 - |x|^2)^{-\alpha}e^{Kt},\\
\nabla_x v &= [\nabla_x w(r^2 - |x|^2)^{-\alpha} + 2\alpha w x(r^2 - |x|^2)^{-\alpha-1}]e^{Kt},\\
\Delta_x v &= [\Delta_x w(r^2 - |x|^2)^{-\alpha} + 4\alpha x \cdot \nabla_x w(r^2 - |x|^2)^{-\alpha-1}\\
&\qquad + 4\alpha(\alpha + 1)w|x|^2(r^2 - |x|^2)^{-\alpha-2}]e^{Kt}\\
&\qquad + 2\alpha d w(r^2 - |x|^2)^{-(\alpha+1)}e^{Kt}.
\end{aligned}$$

Substitution of these terms into the equation $L(v) = 0$ multiplied by $(r^2-|x|^2)^{\alpha+1}e^{-Kt}$ gives

$$A(w) = 0,$$

where the operator $A(w)$ is defined as

$$\begin{aligned} A(w) := (r^2-|x|^2)^2\Delta_x w + (4\alpha-b)(r^2-|x|^2)x\cdot\nabla_x w \\ -(r^2-|x|^2)^2\partial_t w + c(x)w, \end{aligned}$$

in which the coefficient

$$c(x) = -K(r^2-|x|^2)^2 + 2\alpha[dr^2+(2\alpha+2-d-b)|x|^2].$$

In order to apply a maximum principle to $A(w)=0$, we need to choose α and K such that $c<0$ in $\Omega(T^*)$. Setting $|x|^2=\theta r^2$, we have

$$\begin{aligned} c &= -Kr^4(1-\theta)^2 + 2\alpha dr^2 + 2\alpha(2\alpha+2-d-b)\theta r^2 \\ &= -r^2\left\{Kr^2\theta^2 - 2((2\alpha+2-d-b)\alpha+Kr^2)\theta + Kr^2 - 2d\alpha\right\}. \end{aligned}$$

Thus as a function of θ, c achieves its maximum

$$c = K^{-1}\alpha\left\{2Kr^2(2\alpha+2-b) + \alpha(2\alpha+2-d-b)^2\right\}$$

at

$$\theta^* = 1 + \frac{\alpha}{Kr^2}(2-d-b+2\alpha).$$

The coefficient c can be made negative if its maximum value is negative, which is true provided that

$$\alpha < \frac{b}{2}-1$$

and

$$Kr^2 > \frac{\alpha(d+b-2-2\alpha)^2}{2(b-2-2\alpha)} > 0.$$

With these choices we apply the maximum principle [18] to the equation $A(w)=0$ and find that w achieves a positive maximum only at initial time, i.e., in the region $\{(0,x),\, |x|<r^2\}$. Therefore we have

$$0 \le w(t,x) \le \|w(0,\cdot)\|_{L^\infty}.$$

Note that

$$w_0(x) = v_0(x)(r^2-|x|^2)^\alpha = f_0(m)r^h(r^2-|x|^2)^{\alpha-b/2}.$$

Assume that $f_0(m)\neq 0$ for $|m|^2 \le b^* < b$. Then

$$\|w_0\|_\infty \le \|f_0\|_\infty r^b(r^2-2b^*)^{\alpha-b/2}.$$

Thus from

$$f(t,m) = v(t,x)(1-|x|^2/r^2)^{b/2} = w(t,x)r^{-b}(r^2-|x|^2)^{b/2-\alpha}e^{Kt},$$

it follows that

$$|f(t,m) \le \|f_0\|_\infty \le \left(\frac{r^2-|x|^2}{r^2-2b^*}\right)^{b/2-\alpha} e^{Kt}.$$

Replacing $r^2=2b$ and $|x|^2=2|m|^2$ we have obtained the desired estimate stated in Theorem 1.2. Therefore the trace of f on the sphere $|m|=\sqrt{b}$ must be null.

3.2. Coupled with flow $\kappa \neq 0$. We now show the null trace when flow is involved. In this case (2.7) has the form $L(v) = 0$ with

$$\begin{aligned} L(v) := {} & (r^2 - |x|^2)\Delta_x v - (bx + (r^2 - |x|^2)\kappa x) \cdot \nabla_x v \\ & - (r^2 - |x|^2)\partial_t v + (bx^\top \kappa x)v. \end{aligned}$$

We again apply the transformation

$$v(t, x) := w(t, x)(r^2 - |x|^2)^{-\alpha} e^{Kt},$$

with α and K to be determined. This transformation applied to $L(v)(r^2-|x|^2)^{\alpha+1}e^{-Kt}$ leads to the following equation:

$$B(w) = 0,$$

with the operator $B(w)$ being

$$\begin{aligned} B(w) = {} & (r^2 - |x|^2)^2\Delta_x w + (r^2 - |x|^2)[(4\alpha - b)x \\ & - (r^2 - |x|^2)\kappa x] \cdot \nabla_x w - (r^2 - |x|^2)^2\partial_t w + c(x)w, \end{aligned}$$

and the coefficient of the last term being

$$\begin{aligned} c(x) = {} & -K(r^2 - |x|^2)^2 + 2\alpha[dr^2 + (2\alpha + 2 - d - b)|x|^2] \\ & + (b - 2\alpha)x^\top \kappa x(r^2 - |x|^2). \end{aligned}$$

Using a similar argument as in the no-flow case, we proceed to determine α and K so that c stays negative in $\Omega(T)$. Let ρ be the largest eigenvalues of the deformation tensor

$$S = (\kappa + \kappa^\top)/2;$$

one has

$$x^\top \kappa x \leq \rho|x|^2.$$

We first choose α in such a way that $\alpha < b/2 - 1$, which implies $h - 2\alpha > 0$. Thus we obtain

$$\begin{aligned} c(x) \leq \bar{c} = {} & -K(r^2 - |x|^2)^2 + 2\alpha[dr^2 + (2\alpha + 2 - d - b)|x|^2] \\ & + \rho(b - 2\alpha)|x|^2(r^2 - |x|^2) \\ = {} & -[K + \rho(b - 2\alpha)]|x|^4 + [2Kr^2 + \rho(h - 2\alpha)r^2 \\ & + 2\alpha(2\alpha + 2 - d - b)]|x|^2 + 2\alpha dr^2 - Kr^4 \\ \leq {} & 2\alpha dr^2 - Kr^4 \\ & + \frac{[2Kr^2 + \rho(b - 2\alpha)r^2 + 2\alpha(2\alpha + 2 - d - b)]^2}{4[K + \rho(h - 2\alpha)]} \\ \leq {} & 2\alpha r^2(2\alpha + 2 - b) + \frac{\beta^2}{4[K + \rho(b - 2\alpha)]}, \end{aligned}$$

where

$$\beta := \rho(b - 2\alpha)r^2 - 2\alpha(2\alpha + 2 - d - b).$$

Therefore we can choose K such that

$$K > \frac{\beta^2}{8\alpha r^2(b-2-2\alpha)} - \rho(b-\alpha),$$

and the following is always true:

$$c(x) \le \bar{c} < 0, \quad |x| \le r^2.$$

We thus can apply the maximum principle [18] to the equation

$$B(w) = 0$$

and obtain that u achieves its positive maximum only at initial time, i.e., in the region $\{(0,x),\, |x| < r^2\}$. This will give the result that

$$0 \le w(t,x) \le \|w(0,\cdot)\|_{L^\infty}.$$

Converting back to f we prove the results stated in Theorem 1.2.

4. Appendix.

In this appendix, we recall some basic facts concerning the Fichera function which we used in section 2. Consider the second order equation

$$L[u] := a^{jk}D_{jk}u + b^i D_i u + cu = f \text{ in } \Omega$$

with the condition

$$a^{ij}(x)\xi_i\xi_j \ge 0$$

for any $\xi \in \mathbb{R}^d$ and $x \in \Omega$. This class of equations with noncharacteristic form includes equations of elliptic and parabolic types, first order equations, the equations of Brownian motion, and others. The first boundary value problem in its general form was set up by Fichera [8]. We assume that $a^{ij} \in C^2(\Omega)$, $b^i \in C^1(\Omega)$, and $c \in C^0(\Omega)$. Let n denote the unit outward normal vector to $\Gamma = \partial\Omega$ at $x \in \Gamma$. The Fichera function is defined as

$$\mathfrak{F} = (b^k - D_j a^{kj})n_k(x) : \Gamma \to \mathbb{R}.$$

Thus the boundary is classified into several parts based on the sign of Fichera function $\mathfrak{F}$:

$$\Gamma = \Gamma_e \cup \Gamma_h,$$

where $\Gamma_e := \{x \in \Gamma,\, a^{ij}n_in_j > 0\}$ is the noncharacteristic (positive characteristic) part, and $\Gamma_h := \{x \in \Gamma,\, a^{ij}n_in_j = 0\}$, in which there are two subsets (irrelevant and relevant parts):

$$\Gamma_+ = \{x,\, \mathfrak{F}(x) \ge 0\}, \quad \Gamma_- = \{x,\, \mathfrak{F}(x) < 0\}.$$

The classical theory of Fichera [8] says that the Dirichlet boundary condition leads to a well-posed problem: find a function u in $\Omega \cup \Gamma$ such that

$$L(u) = f \text{ in } \Omega, \quad u = g \text{ on } \Gamma_e \cup \Gamma_-. \tag{4.1}$$

In other words, no Dirichlet boundary data is necessarily imposed on Γ_-, where $\mathfrak{F} \ge 0$.

It was shown that the sign of the Fichera function at points on Γ_h does not change under smooth nondegenerate changes of independent variables in the equation. Consequently, we have the following theorem.

THEOREM 4.1 (see [18]). *The subsets $\Gamma_e, \Gamma_+, \Gamma_-$ of the boundary Γ, defined for the operator L, remain invariant under smooth nonsingular changes of independent variables in the equation.*

To define the weak solution for the underlying problem, we introduce an adjoint operator as

$$L^*[v] = -D_{ij}(a^{ij}v) - D_i(b^i v) + cv.$$

Then for $v \in C^2(\bar{\Omega})$ and $v = 0$ on $\Gamma_e \cup \Gamma_-$ the weak formulation of the equation becomes

$$\int_\Omega uL^*[v]dx = \int_\Omega vL[u]dx.$$

Weak solution in $L^2(\Omega)$. A bounded measurable function $u(x)$ will be called a weak solution of the above problem with $u \in \{L^2(\Omega),\, u = 0,\, x \in \Gamma_e \cup \Gamma_-\}$ if

$$\int_\Omega uL^*[v]dx = (f, v)$$

for all $v \in \{C^2(\bar{\Omega}),\, v = 0,\, x \in \Gamma_e \cup \Gamma_-\}$, where $(\cdot, \cdot)$ denotes the inner product in L^2. Weak solution in other spaces such as the L^p space or general Hilbert space can be defined; and solution smoothness can be further studied once existence of a weak solution is established. Existence results have been proven under various assumptions, e.g., the following theorem.

THEOREM 4.2. *Suppose the inequality*

$$\frac{1}{2}D_i b^i - \frac{1}{2}D_{ij}a^{ij} - c \geq c_0 > 0$$

is satisfied in $\bar{\Omega}$, and let $f \in L^2(\Omega)$. Then there exists a function $u \in L^2(\Omega)$ which is a weak solution of (4.1) *in the sense stated above.*

TRAVELING WAVES AND SHOCKS IN A VISCOELASTIC GENERALIZATION OF BURGERS' EQUATION*

VICTOR CAMACHO†, ROBERT D. GUY‡, AND JON JACOBSEN†

Abstract. We consider traveling wave phenomena for a viscoelastic generalization of Burgers' equation. For asymptotically constant velocity profiles we find three classes of solutions corresponding to smooth traveling waves, piecewise smooth waves, and piecewise constant (shock) solutions. Each solution type is possible for a given pair of asymptotic limits, and we characterize the dynamics in terms of the relaxation time and viscosity.

Key words. non-Newtonian fluids, fast-slow dynamics, vanishing viscosity solutions

1. Introduction.

Burgers' equation

$$u_t + uu_x = \epsilon u_{xx} \tag{1.1}$$

is perhaps the simplest model that couples the nonlinear convective behavior of fluids with the dissipative viscous behavior. Introduced by Burgers [5] as a model for turbulence, (1.1) and its inviscid counterpart,

$$u_t + uu_x = 0, \tag{1.2}$$

are essential for their role in modeling a wide array of physical systems such as traffic flow, shallow water waves, and gas dynamics [17, 18, 19, 23]. The equations also provide fundamental pedagogical examples for many important topics in nonlinear PDEs such as traveling waves, shock formation, similarity solutions, singular perturbation, and numerical methods for parabolic and hyperbolic equations (see, e.g., [9, 14, 20, 23]).

The parabolic equation (1.1) has the property that smooth initial data yield smooth solutions for all $t > 0$. In contrast, smooth initial data for the hyperbolic equation (1.2) can develop jump discontinuities in finite time (shock formation). One technique for studying shock wave solutions of (1.2) is to study smooth traveling wave solutions of (1.1) in the limit as $\epsilon \to 0$.

In this paper we consider how the addition of viscoelasticity affects traveling wave solutions of Burgers' equation. The equations we consider are

$$u_t + uu_x = \sigma_x, \tag{1.3}$$

$$\sigma_t + u\sigma_x - \sigma u_x = \alpha u_x - \beta\sigma. \tag{1.4}$$

The constitutive law (1.4) resembles a one-dimensional version of the upper convected Maxwell model [11]. The relaxation time is $\lambda = \beta^{-1}$, and $\alpha = \mu\lambda^{-1}$ could be interpreted as the elastic modulus of the material if there were no relaxation of stress ($\beta = 0$). In the other limit of instantaneous relaxation of stress ($\lambda \to 0$), (1.4) reduces to $\sigma = \mu u_x$, and the system (1.3)–(1.4) is equivalent to Burgers' equation (1.1) with fluid viscosity $\mu = \epsilon$.

The remainder of the paper is organized as follows. In section 2 we give a brief introduction to viscoelastic fluids and explain the reduction and constitutive law for our model. We show in section 3 that traveling wave solutions to (1.3)–(1.4) exist only when the viscosity (or elastic modulus) is above a certain threshold. As the viscosity approaches this threshold, singularities in the derivative appear, and numerical experiments suggest that shocks develop when the viscosity is below threshold. The system (1.3)–(1.4) is nonconservative, and therefore the classical theory for systems of conservation laws (cf. [9, 23]) cannot be used to analyze singular solutions. A generalized theory of weak solutions to nonconservative hyperbolic equations has been developed for such problems [2, 7, 8].

We take a different approach and analyze the shock solutions by introducing an additional viscosity to regularize the problem. Using singular perturbation theory, we show in section 4 that traveling waves exist for all parameters in the regularized problem, and the waves limit to shock solutions as the additional viscosity goes to zero. This method of *vanishing viscosity* is a well-known technique for analyzing weak solutions of nonconservative hyperbolic equations such as the Hamilton–Jacobi equations [9]. Finally, in section 5 we discuss the effect of different parameters on the solution structure, how the results depend on the choice of one-dimensional reduction, and a possible application of the results to numerical methods for viscoelastic flows.

2. Viscoelastic fluids. In this section we discuss how the constitutive law in (1.4) is related to a standard constitutive law for viscoelastic fluids. The discussion here is not meant to be extensive. For more comprehensive treatments of viscoelastic fluids, see [3, 4, 11, 12].

The incompressible Navier–Stokes equations are

$$\rho\left(\boldsymbol{u}_t + \boldsymbol{u}\cdot\nabla\boldsymbol{u}\right) = -\nabla p + \mu\Delta\boldsymbol{u}, \tag{2.1}$$

$$\nabla\cdot\boldsymbol{u} = 0. \tag{2.2}$$

The momentum equation (2.1) can be expressed as

$$\rho\left(\boldsymbol{u}_t + \boldsymbol{u}\cdot\nabla\boldsymbol{u}\right) = -\nabla p + \nabla\cdot\boldsymbol{\sigma}_{\mathbf{v}}, \tag{2.3}$$

where the (Newtonian) viscous stress $\boldsymbol{\sigma}_{\mathbf{v}}$ is defined by

$$\boldsymbol{\sigma}_{\mathbf{v}} = 2\mu\boldsymbol{D} = \mu\left(\nabla\boldsymbol{u} + \nabla\boldsymbol{u}^{\mathrm{T}}\right). \tag{2.4}$$

This Newtonian constitutive law means that the fluid stress is proportional to the deformation rate tensor. In contrast, the stress in viscoelastic fluids includes some time history of the deformation.

One of the simplest constitutive laws for viscoelastic materials is the Maxwell model. Consider a linear spring and dashpot in series, with spring constant k and damping coefficient μ. The stress, σ, in the element is

$$\lambda\dot{\sigma} + \sigma = \mu\dot{\epsilon}, \tag{2.5}$$

where ϵ is the strain in the element, and $\lambda = k/\mu$ is the relaxation time. The linear Maxwell model for a continuum is

$$\lambda \boldsymbol{\sigma}_t + \boldsymbol{\sigma} = 2\mu \boldsymbol{D}. \tag{2.6}$$

However, this is not a valid constitutive law because it is not frame invariant [11]. That is, the stress depends on the reference frame. Frame invariance is achieved by choosing an appropriate time derivative, akin to the material derivative for the velocity field. One frame invariant time derivative is the upper convected derivative, defined by

$$\overset{\triangledown}{\boldsymbol{S}} = \boldsymbol{S}_t + \boldsymbol{u} \cdot \nabla \boldsymbol{S} - \nabla \boldsymbol{u}\, \boldsymbol{S} - \boldsymbol{S}\, \nabla \boldsymbol{u}^{\mathrm{T}}. \tag{2.7}$$

Replacing the partial time derivative in (2.6) with the upper convected derivative gives the upper convected Maxwell (UCM) equation

$$\lambda \overset{\triangledown}{\boldsymbol{\sigma}} + \boldsymbol{\sigma} = 2\mu \boldsymbol{D}. \tag{2.8}$$

The ij component in (2.8) satisfies

$$\lambda \left(\frac{\partial \sigma_{ij}}{\partial t} + u_k \frac{\partial \sigma_{ij}}{\partial x_k} - \frac{\partial u_i}{\partial x_k} \sigma_{kj} - \sigma_{ik} \frac{\partial u_j}{\partial x_k} \right) + \sigma_{ij} = \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right), \tag{2.9}$$

where summation is over the repeated index k. Although there are many other frame invariant derivatives, in this paper we consider a one-dimensional reduction, in which case they yield identical reductions.

A one-dimensional version of the UCM equation is

$$\lambda \left(\sigma_t + u\sigma_x - \sigma u_x \right) + \sigma = \mu u_x. \tag{2.10}$$

However, there are other reasonable choices for a one-dimensional UCM equation. For example, the equation for σ_{11} when $\boldsymbol{u} = (u_1, 0, 0)$ is

$$\lambda \left(\sigma_t + u\sigma_x - 2\sigma u_x \right) + \sigma = 2\mu u_x, \tag{2.11}$$

where we have dropped the subscripts on the stress and velocity. The upper convected derivative must be used in (2.8) because this is the time derivative of a tensor in a moving continuum. In one dimension, the stress is a scalar, so it would also be reasonable to simply use the material derivative for the time derivative. In this case the constitutive law is

$$\lambda \left(\sigma_t + u\sigma_x \right) + \sigma = \mu u_x. \tag{2.12}$$

In this paper we analyze the first UCM equation (2.10). While all three models have similar results, (2.10) is more robust, in that all of the phenomena that occur in (2.11) and (2.12) also occur in (2.10). In section 5 we discuss how the results change if (2.11) or (2.12) is used instead.

Equation (2.10) is equivalent to (1.4). This is seen by dividing through by the relaxation time λ to get

$$\sigma_t + u\sigma_x - \sigma u_x = \alpha u_x - \beta\sigma, \tag{2.13}$$

where

$$\alpha = \mu\lambda^{-1}, \tag{2.14}$$

$$\beta = \lambda^{-1}. \tag{2.15}$$

The parameter α could be interpreted as the elastic modulus of the material if there were no relaxation of stress ($\beta = 0$). It is somewhat arbitrary whether the constitutive law is expressed in terms of the relaxation time (λ) and viscosity (μ) or elastic modulus (α) and decay rate (β). In this paper we primarily use the latter, but sometimes we express results using both sets of parameters for additional insight.

In section 4 we consider a modification to the Maxwell constitutive law (1.4). We include a second viscous term, one without memory, so that the system becomes

$$u_t + uu_x = \sigma_x + \epsilon u_{xx}, \tag{2.16}$$

$$\sigma_t + u\sigma_x - \sigma u_x = \alpha u_x - \beta\sigma. \tag{2.17}$$

The addition of the second viscous term can be considered as a one-dimensional version of the Oldroyd-B constitutive law [12].

We note that the one-dimensional constitutive law studied in this paper is not a *physical* reduction from the three-dimensional UCM. It is a reduction in the same sense that Burgers' equation is a reduction. One may wonder what, if any, physical significance there is to the problem that we analyze in this paper. Using high-resolution Godunov schemes for the advection terms in the Navier–Stokes equations requires solving Burgers' equation [1]. Analogously, systems of the form (2.10) and (2.11) arise in the application of wave propagation schemes to viscoelastic fluids [10, 22]. This was the original inspiration for this study but not the sole motivation. It is interesting to explore what happens to traveling waves in Burgers' equation (1.1) if the viscous term is replaced by a viscoelastic term, and the most natural starting point is the Maxwell model. Thus the one-dimensional constitutive laws considered were chosen to resemble the UCM equation.

3. Traveling waves.

To find traveling wave solutions to (1.3)–(1.4) we consider solutions of the form $u(x,t) = U(\xi)$ and $\sigma(x,t) = S(\xi)$, where $\xi = x - ct$ for some constant c. In traveling wave coordinates, the system is

$$-cU' + UU' = S', \tag{3.1}$$

$$-cS' + US' - SU' = \alpha U' - \beta S. \tag{3.2}$$

We consider traveling waves that correspond to heteroclinic connections between two equilibrium points with given velocity values at infinity. The equilibrium points of the system correspond to all states with $S = 0$, and thus we assume the following asymptotic boundary conditions:

$$U(-\infty) = u_\ell, \quad S(-\infty) = 0, \tag{3.3}$$

$$U(\infty) = u_r, \quad S(\infty) = 0. \tag{3.4}$$

In the next section we examine for which values of u_ℓ, u_r, α, and β do solutions of this problem exist.

3.1. Existence.

Integrating (3.1) gives the stress in terms of the velocity as

$$S = \frac{U^2}{2} - cU + A, \tag{3.5}$$

where A is the integration constant. Applying the boundary conditions, the wave speed and integration constant are

$$A = \frac{u_\ell u_r}{2}, \tag{3.6}$$

$$c = \frac{u_\ell + u_r}{2}. \tag{3.7}$$

Note that if a traveling wave exists, then it moves with the same speed as traveling waves in Burgers' equation (1.1) and shock waves in the inviscid Burgers equation (1.2).

We obtain the equation for the velocity profile, U, by using (3.1) and (3.5) to eliminate S and S' in (3.2) to get

$$U' = \frac{-\beta\big(U\,(U/2 - c) + A\big)}{U\,(U/2 - c) + c^2 - A - \alpha}. \tag{3.8}$$

Using (3.6) and (3.7), this simplifies to

$$U' = \frac{-\beta(U - u_\ell)(U - u_r)}{(U - u_\ell)(U - u_r) + 2\left(\left(\frac{u_\ell - u_r}{2}\right)^2 - \alpha\right)}. \tag{3.9}$$

From the dynamics of this equation we extract conditions for the existence of traveling waves. The two equilibrium points are clearly $U = u_\ell$ and $U = u_r$, and a traveling wave corresponds to a one-dimensional flow from one equilibrium point to the other. There are two cases to consider: $u_\ell > u_r$ and $u_\ell < u_r$.

First we suppose that $u_\ell > u_r$. For a traveling wave to exist, we need that $U' < 0$ for $U \in (u_r, u_\ell)$. The numerator of (3.9) is positive in this interval. The maximum value of $(U - u_\ell)(U - u_r)$ is 0, and so the denominator is always negative, provided $((u_\ell - u_r)/2)^2 - \alpha < 0$, in which case $U' < 0$ for $U \in (u_r, u_\ell)$.

Next, consider the case $u_\ell < u_r$. A traveling wave exists if $U' > 0$ for $U \in (u_\ell, u_r)$. As before, the numerator of (3.9) is positive for $U \in (u_\ell, u_r)$, and thus we examine the sign of the denominator. The minimum value of $(U - u_\ell)(U - u_r)$ is $-\left((u_\ell - u_r)/2\right)^2$, in which case it follows that $U' > 0$, provided $((u_\ell - u_r)/2)^2 - 2\alpha > 0$.

Combining these two cases, we have the following result: a traveling wave solution to (1.3)–(1.4) with boundary conditions (3.3)–(3.4) exists if and only if

$$u_\ell > u_r \quad \text{and} \quad \alpha > \left(\frac{u_\ell - u_r}{2}\right)^2 \tag{3.10}$$

or

$$u_\ell < u_r \quad \text{and} \quad 2\alpha < \left(\frac{u_\ell - u_r}{2}\right)^2. \tag{3.11}$$

Equivalently, no traveling wave solutions exist if

$$\frac{(u_\ell - u_r)^2}{8} \le \alpha \le \frac{(u_\ell - u_r)^2}{4}. \tag{3.12}$$

Using (2.14) to express this condition in terms of the relaxation time and viscosity, we see that no traveling wave solution exists if

$$\frac{(u_\ell - u_r)^2}{8} \le \frac{\mu}{\lambda} \le \frac{(u_\ell - u_r)^2}{4}. \tag{3.13}$$

In comparison, for the viscous Burgers equation (1.1), traveling waves with $u_\ell > u_r$ exist for any positive viscosity. By adding elasticity we see that, for a fixed relaxation time λ, there is now a minimal viscosity required for such waves to exist. In the following sections we explore what happens to these wave solutions when the viscosity is reduced beyond this minimal viscosity.

3.2. Wave profile. The shape of the wave is found by integrating (3.9). The solution is

$$\beta\,(\xi - \xi_0) = \frac{2\Big(\left(\frac{u_\ell - u_r}{2}\right)^2 - \alpha\Big)}{u_\ell - u_r} \log\left|\frac{U(\xi) - u_r}{U(\xi) - u_\ell}\right| - U(\xi). \tag{3.14}$$

When a traveling wave exists, the profile is defined implicitly by (3.14). However, when a traveling wave fails to exist, we can still plot the implicit solutions of (3.14). In Figure 3.1 we plot the curve defined by (3.14) for four different values of α, while keeping the other parameter values fixed at $u_\ell = 2$, $u_r = 0$, and $\beta = 1$. For these parameter values, a traveling wave exists when $\alpha > 1$. In Figure 3.1(a) the wave profile is shown for $\alpha = 1.2$. As α approaches 1, the wave profile approaches the piecewise linear function shown in Figure 3.1(b). As α is decreased further, the curve becomes multivalued and the asymptotic values are no longer satisfied. Figure 3.1(c) shows the solution for $\alpha = 0.9$. As α decreases even further, the solution of (3.14) returns to being single-valued but no longer yields a traveling wave solution with the given asymptotic limits. This transition occurs at $\alpha = \frac{1}{2}\left(\frac{u_\ell - u_r}{2}\right)^2$, which corresponds to when U' returns to being one-signed (now positive), corresponding to the lower limit of (3.13). Figure 3.1(d) shows the solution for $\alpha = 0.25$.

3.3. Numerical simulations. In this section we consider numerical simulations of the full PDE system (1.3)–(1.4). According to (3.10), when $u_\ell > u_r$ there is a minimal viscosity in order for traveling waves to exist. In numerical simulations of this case, these traveling wave solutions appear to be stable and travel with the speed $c = (u_\ell + u_r)/2$, as in (3.7). We found that for any initial data, as long as the asymptotic limits were maintained, the solution approached the traveling wave profile given by (3.14). On the other hand, according to (3.11), when $u_\ell < u_r$, traveling waves exist as long as the viscosity is below a certain threshold. In simulations of the PDE system for this case, these waves did not appear to be stable; rather the solutions always rarefy. Accordingly, from this point on we consider only the stable case of $u_\ell > u_r$.

We next consider what happens when the viscosity is below the minimal value, corresponding to the implicit plots shown in Figure 3.1(c)–(d). We solve the full system (1.3)–(1.4) numerically by splitting the update at each time step into three substeps. First we take a step including only the advection terms

$$u_t + uu_x = 0, \tag{3.15}$$

$$\sigma_t + u\sigma_x = 0 \tag{3.16}$$

and use an upwinding method. Next we take a step including the elastic terms

$$u_t = \sigma_x, \tag{3.17}$$

$$\sigma_t - \sigma u_x = \alpha u_x. \tag{3.18}$$

We linearize the σu_x term in each grid cell by treating this term as $\sigma_j^n u_x$ through the time step, where σ_j^n is the value of the stress at time step n at grid cell j. This

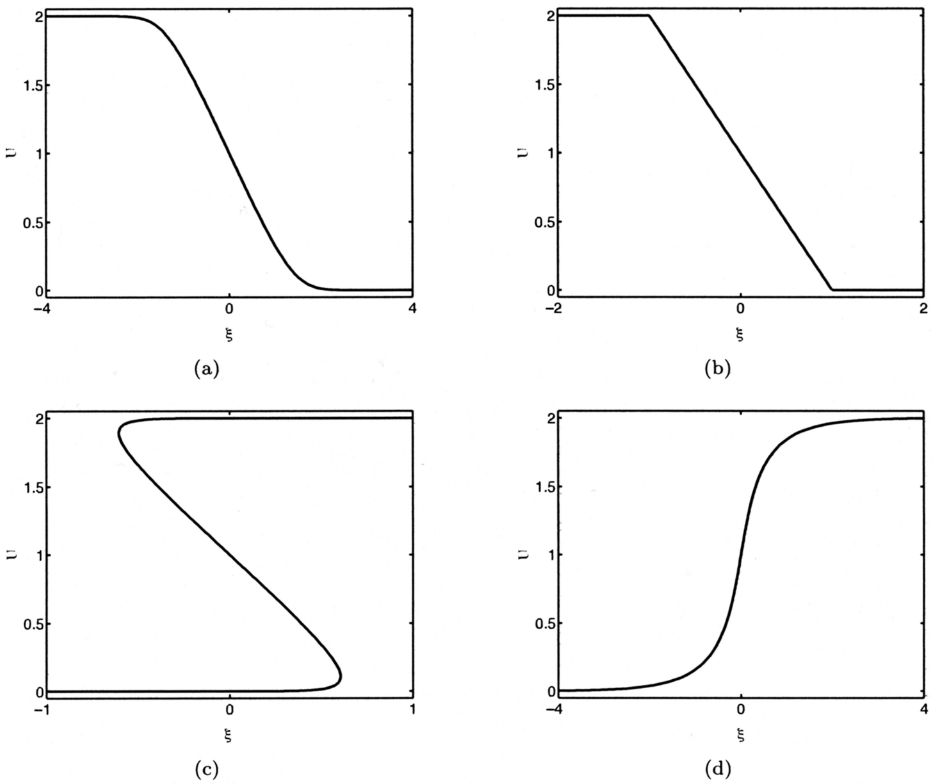

FIG. 3.1. *Plots of the solution curves to* (3.14)*. The parameters are* $u_\ell = 2$*,* $u_r = 0$*,* $\beta = 1$*. Four different values of* α *are plotted:* (a) $\alpha = 1.2$*,* (b) $\alpha = 1$*,* (c) $\alpha = 0.9$*,* (d) $\alpha = 0.25$*. For these values of* u_ℓ *and* u_r*, no wave exists for* $\alpha < 1$*.*

linearized system is a variable coefficient wave equation, which we update by a wave propagation method as described in [16]. Finally, we update the stress by taking a step of

$$\sigma_t = -\beta\sigma. \tag{3.19}$$

For the initial condition we set the velocity equal to the traveling wave profile corresponding to the viscous Burgers equation with a given viscosity and set the stress to zero.

As suggested by Figure 3.1(c)–(d), we find two distinct cases, corresponding to whether

$$\frac{1}{2}\left(\frac{u_\ell - u_r}{2}\right)^2 < \alpha < \left(\frac{u_\ell - u_r}{2}\right)^2 \tag{3.20}$$

or

$$0 < \alpha < \frac{1}{2}\left(\frac{u_\ell - u_r}{2}\right)^2. \tag{3.21}$$

In both cases we find that the solutions develop into traveling waves, now, however, with jump discontinuities in the wave profile. These numerical solutions propagate with the wave speed $c = (u_\ell + u_r)/2$, the same wave speed as smooth traveling wave solutions. When α satisfies (3.20) the profile is piecewise smooth, with two shocks, as indicated in Figure 3.2(a). We refer to this solution as the double-shock solution. As α ranges between the limiting values of (3.20) the height of each jump discontinuity ranges from 0 when $\alpha = \left(\frac{u_\ell - u_r}{2}\right)^2$ to 1 when $\alpha = \frac{1}{2}\left(\frac{u_\ell - u_r}{2}\right)^2$, which yields a piecewise constant solution. This piecewise constant solution persists when α satisfies (3.21), as indicated in Figure 3.2(b). This resembles a classic shock solution of the Riemann problem for the inviscid Burgers equation.

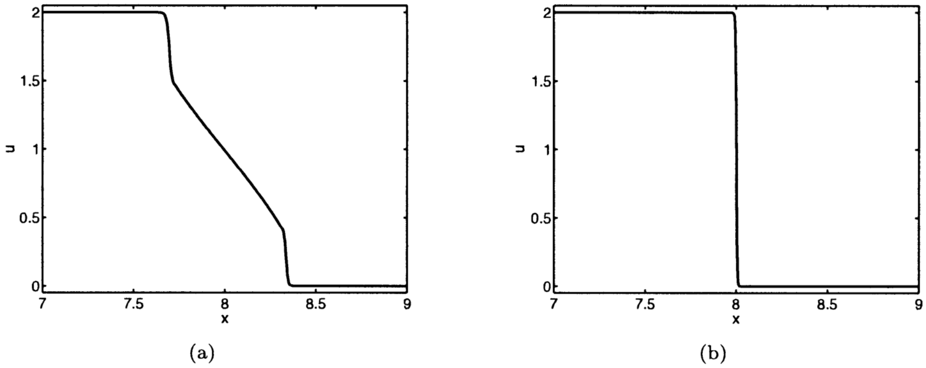

FIG. 3.2. *Plots of the wave profile found by solving* (1.3)–(1.4) *with smooth traveling wave initial data. The simulations were run until the profile stabilized. The smooth waves develop apparent jump discontinuities, whose type depends on whether α satisfies* (3.20) *or* (3.21)*, and travel with fixed speed. The parameter values are $u_\ell = 2, u_r = 0, \beta = 1$, and* (a) $\alpha = 0.8$*;* (b) $\alpha = 0.25$.

When solving equations with discontinuities care must be taken in order to capture the correct solution. These numerical solutions may not be the correct solutions, but they raise several questions that warrant further investigation. For example, as the PDE is not given by a system of conservation laws, what is the "correct" weak solution? In the case of the double-shock solution, what determines the shock height? What determines the shape of the solution between the two shocks? Why is it that we see a double-shock solution? In the next section we answer these questions by introducing a second viscous term to regularize the equations and analyzing the system in the limit of small viscosity.

4. Vanishing viscosity solution.

In this section we add a viscous regularization term on the velocity:

$$u_t + uu_x = \sigma_x + \epsilon u_{xx}, \tag{4.1}$$

$$\sigma_t + u\sigma_x - \sigma u_x = \alpha u_x - \beta\sigma \tag{4.2}$$

for $\epsilon > 0$. With the extra viscous term, this system can be viewed as a one-dimensional version of the Oldroyd-B constitutive law [12]. To study the double-shock and shock solutions of (1.3)–(1.4) we consider traveling wave solutions of this extended system in the limit $\epsilon \to 0$.

In traveling wave coordinates, the system becomes

$$-cU' + UU' = S' + \epsilon U'', \tag{4.3}$$

$$-cS' + US' - SU' = \alpha U' - \beta S. \tag{4.4}$$

Integrating (4.3), applying the asymptotic boundary conditions, and eliminating U' in (4.4) yields the system

$$\epsilon U' = \frac{1}{2}(U-u_\ell)(U-u_r) - S, \tag{4.5}$$

$$\epsilon(U-c)S' = (S+\alpha)\left(\frac{1}{2}(U-u_\ell)(U-u_r) - S\right) - \epsilon\beta S. \tag{4.6}$$

This system has precisely two equilibrium points: $(u_\ell, 0)$ and $(u_r, 0)$. A traveling wave solution of the PDE system (4.1)–(4.2) corresponds to a heteroclinic orbit connecting these two equilibrium points, as in Figure 4.1 (recall that we are assuming $u_\ell > u_r$).

Note that if a traveling wave of the original system (1.3)–(1.4) exists (i.e., when $\alpha > (u_\ell - u_r)^2/4$), then the wave corresponds to the trajectory in the phase plane defined by (3.5), or, equivalently,

$$S = \frac{1}{2}(U-u_\ell)(U-u_r). \tag{4.7}$$

This is the U-nullcline from (4.5) (for all ϵ).

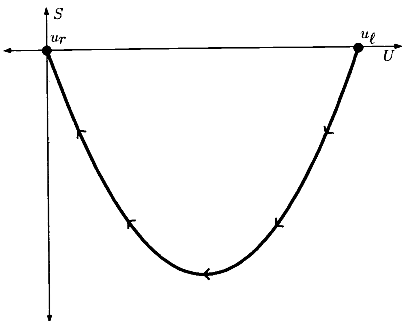

FIG. 4.1. *Heteroclinic orbit corresponding to traveling wave solution of system* (4.1)–(4.2).

The system (4.5)–(4.6) exhibits symmetric behavior about the line $U = c$, where $c = (u_\ell + u_r)/2$ is the wave speed for the inviscid case ($\epsilon = 0$). In particular, if $(\widehat{U}(\xi), \widehat{S}(\xi))$ solves (4.5)–(4.6) with $\widehat{U} > c$ for $\xi \in (-b, \xi_0)$ and $\widehat{U}(\xi_0) = c$, then $(U(\xi), S(\xi)) = (2c - \widehat{U}(-\xi + 2\xi_0), \widehat{S}(-\xi + 2\xi_0))$ solves (4.5)–(4.6) for $\xi \in (\xi_0, b + 2\xi_0)$, with $U < c$ and $U(\xi_0) = c$. This corresponds to the reflection of the trajectory through the line $U = c$.

The Jacobian of the system at the equilibrium point $(u_\ell, 0)$ is

$$J = J(u_\ell, 0) = \begin{bmatrix} \frac{d}{2\epsilon} & -\frac{1}{\epsilon} \\ \frac{\alpha}{\epsilon} & -\frac{2(\alpha+\beta\epsilon)}{\epsilon d} \end{bmatrix}, \tag{4.8}$$

where $d = u_\ell - u_r$. Since $\det(J) = -\frac{\beta}{\epsilon} < 0$, it follows that $(u_\ell, 0)$ is a saddle point for all $\epsilon > 0$. Thus the reflection through $U = c$ maps the unstable manifold of $(u_\ell, 0)$ to the stable manifold of $(u_r, 0)$. For this reason, to establish the existence of a heteroclinic orbit connecting the two, it suffices to establish that the unstable manifold of $(u_\ell, 0)$ crosses the line $U = c$.

The positive eigenvalue of $J(u_\ell, 0)$ is

$$\lambda_\ell = \frac{1}{4\epsilon d}\left(d^2 - 4(\alpha+\beta\epsilon) + \sqrt{(d^2 - 4(\alpha+\beta\epsilon))^2 + 16d^2\beta\epsilon}\right), \tag{4.9}$$

with an associated eigenvector

$$\boldsymbol{v}_\ell = \left[1, \frac{d^2+4\alpha+4\beta\epsilon-\sqrt{(d^2+4\alpha+4\beta\epsilon)^2-16\alpha d^2}}{4d}\right]. \tag{4.10}$$

The expansion of λ_ℓ for small ϵ is

$$\lambda_\ell = \frac{1}{4\epsilon d}\left((d^2-4\alpha)+|d^2-4\alpha|\right)+O(1). \tag{4.11}$$

Thus,

$$\alpha > \frac{d^2}{4} \quad \text{implies} \quad \lambda_\ell = O(1) \quad \text{as } \epsilon \to 0, \tag{4.12}$$

and

$$\alpha < \frac{d^2}{4} \quad \text{implies} \quad \lambda_\ell = \frac{1}{\epsilon}\left(\frac{d^2-4\alpha}{2d}\right)+O(1) \quad \text{as } \epsilon \to 0. \tag{4.13}$$

This transition occurs precisely at the critical α value in (3.10), which determines the existence of traveling waves of the original system ($\epsilon = 0$). Thus the onset of the solutions containing shocks corresponds to the introduction of a fast dynamic along the unstable manifold of $(u_\ell, 0)$ as $\epsilon \to 0$. Our motivation for introducing the viscous regularization was to understand the behavior of the wave solutions in the limit of $\epsilon \to 0$. Accordingly, we now focus on the case $0 < \alpha < d^2/4$, the range for which classical traveling waves of the original system ($\epsilon = 0$) fail to exist. There are two cases, depending on whether $0 < \alpha < d^2/8$ or $d^2/8 < \alpha < d^2/4$.

4.1. Case 1: $d^2/8 < \alpha < d^2/4$. The U-nullcline is the parabola given by (4.7). There are two distinct nullclines for S which correspond to the solutions of

$$(S+\alpha)\left(\frac{1}{2}(U-u_\ell)(U-u_r)-S\right)-\epsilon\beta S = 0. \tag{4.14}$$

To plot the S-nullclines, we arrange (4.14) to

$$(U-c)^2 = 2S+\frac{d^2}{4}+\frac{2\beta S}{\alpha+S}\epsilon. \tag{4.15}$$

When $\epsilon = 0$, the curve

$$(U-c)^2 = 2S+\frac{d^2}{4} \tag{4.16}$$

is identical to the U-nullcline given by (4.7).

One S-nullcline is located above (in the U-S plane) the horizontal line $S = -\alpha$ and the other below this line. For $-\alpha < S < 0$, the last term in (4.15), $2\beta S/(\alpha+S)$, is always negative. This decreases U^2, meaning that there is an S-nullcline just above the U-nullcline (just below for $S > 0$). As $\epsilon \to 0$, this S-nullcline converges to the U-nullcline.

On the second S-nullcline, $S < -\alpha$. In this region, the last term in (4.15) is always positive, and for S close to $-\alpha$ it dominates the linear term. The minimum value of S on the U-nullcline is $-d^2/8$. Since $\alpha > d^2/8$, this second S-nullcline is

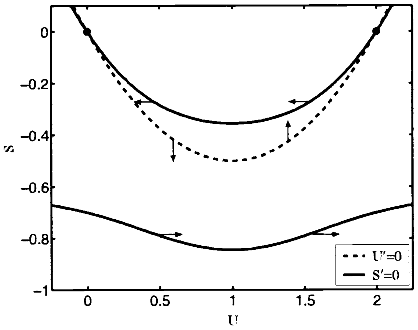

FIG. 4.2. *Typical nullclines for system* (4.5)–(4.6) *with* $d^2/8 < \alpha < d^2/4$. *Here the parameter values are* $u_\ell = 2$, $u_r = 0, \beta = 1, \alpha = 0.6, \epsilon = 0.1$.

below the U-nullcline and bounded away from it as $\epsilon \to 0$. A sample plot of all three nullclines is shown in Figure 4.2.

To find a traveling wave solution, we show that the unstable manifold of $(u_\ell, 0)$ flows to the line $U = c$. The eigenvector $\boldsymbol{v}_\ell$ from (4.10) is tangent to the unstable manifold at $(u_\ell, 0)$. Expanding this eigenvector for small ϵ yields

$$\boldsymbol{v}_\ell = \left[1, \frac{2\alpha}{d}\right] + \epsilon\left[0, \frac{-8\alpha\beta}{d(d^2 - 4\alpha)}\right] + O(\epsilon^2). \tag{4.17}$$

Thus, in the limit as $\epsilon \to 0$ the eigenpair $(\lambda_\ell, \boldsymbol{v}_\ell) \to (\infty, [1, 2\alpha/d])$. The slope of the U-nullcline at $(u_\ell, 0)$ is $d/2$ (independent of ϵ), and the slope of the S-nullcline at $(u_\ell, 0)$ is $d/2(1 + \beta\epsilon/\alpha)^{-1} = d/2(1 - \beta\epsilon/\alpha) + O(\epsilon^2)$. Thus, for $\epsilon < \alpha/\beta$, the unstable manifold enters the region above both the S- and U-nullclines whenever $\alpha < d^2/4$. Moreover, as $\epsilon \to 0$ the speed with which it enters the region approaches infinity.

The trajectories of the system (4.5)–(4.6) satisfy

$$\frac{dS}{dU} = \frac{(S + \alpha)F(U, S) - \epsilon\beta S}{(U - c)F(U, S)}, \tag{4.18}$$

where $F(U, S) = \frac{1}{2}(U - u_\ell)(U - u_r) - S$. Note that $F(U, S) = 0$ defines the U-nullcline and is the leading order approximation of the S-nullcline above it. The unstable manifold quickly flows away from these nullclines into the region where $F(U, S) = O(1)$. In this case, the curves defined by (4.18) are approximated by

$$\frac{dS}{dU} = \frac{(S + \alpha)}{(U - c)}. \tag{4.19}$$

The solutions of (4.19) are lines of the form $|S + \alpha| = A(U - c)$. The solution passing through the equilibrium $(u_\ell, 0)$ has slope $A = 2\alpha/d$, which is precisely the slope of the unstable manifold as $\epsilon \to 0$. Therefore the leading order approximation to the unstable manifold is

$$S = \frac{2\alpha}{d}(U - c) - \alpha, \tag{4.20}$$

which is a valid approximation as long as this trajectory remains away from the nullclines. The line (4.20) eventually intersects the S-nullcline. To leading order, this intersection occurs at

$$U^* = \frac{4\alpha}{d} + u_r, \tag{4.21}$$

$$S^* = \frac{2\alpha}{d^2}\left(4\alpha - d^2\right). \tag{4.22}$$

Since $\alpha > d^2/8$, it follows that $U^* > c$ at the point of intersection. Near the nullclines, the solution to the system (4.5)–(4.6) can be approximated by the quasi-steady solution

$$S = \frac{1}{2}(U - u_\ell)(U - u_r) + O(\epsilon). \tag{4.23}$$

This trajectory intersects the line $U = c$. Thus, by the symmetry of the system, this solution is part of a heteroclinic orbit connecting the points $(u_\ell, 0)$ and $(u_r, 0)$ and corresponds to a traveling wave solution of (4.1)–(4.2).

The above analysis explains the double-shock solution. When $\alpha < d^2/4$, the dynamics near the point $(u_\ell, 0)$ on the unstable manifold are very fast $(O\left(\epsilon^{-1}\right))$. Leaving the equilibrium point, the unstable manifold moves away from the nullclines, but eventually this trajectory approaches the nullclines near the point (U^*, S^*) away from the equilibrium point. This path in phase space (in the limit $\epsilon \to 0$) corresponds to the shock. Once near the nullclines, the solution flows along the nullclines to the line $U = c$. The flow between the point (U^*, S^*) and its reflected point $(2c - U^*, S^*)$ corresponds to the smooth portion of the double-shock solution between the two shocks. Figure 4.3(a) shows the path of the heteroclinic orbit in phase space corresponding to a double-shock solution. The path shown was generated by integrating (4.5)–(4.6) for $\epsilon = 10^{-3}$. The trajectory is very close to our asymptotic solution, which is not shown because it is indistinguishable from the numerical solution on this scale. In Figure 4.3(b) we show the wave profile for decreasing values of ϵ. The solutions were generated by integrating (4.5)–(4.6) for $U > c$ and using the symmetry condition for $U < c$. For finite ϵ the wave is smooth, but, as the figure indicates, the profile approaches the double-shock solution as $\epsilon \to 0$.

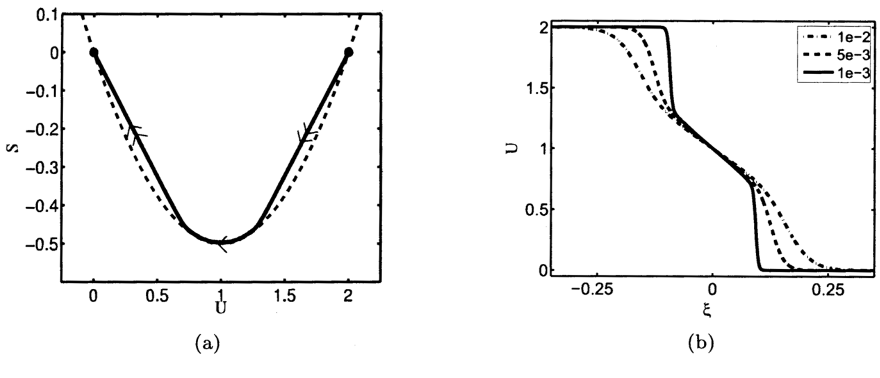

FIG. 4.3. (a) *Path of the heteroclinic orbit for the double-shock traveling wave. The double arrows indicate that the dynamics are much faster along these paths, which correspond to the shocks in the limit $\epsilon \to 0$. The trajectory shown is for $\epsilon = 10^{-3}$, generated by integrating* (4.5)–(4.6). *The solution is indistinguishable from the asymptotic solution on the scale shown.* (b) *For finite ϵ, the wave profile is smooth, but as $\epsilon \to 0$ the solution approaches the double-shock wave. The parameter values are $u_\ell = 2$, $u_r = 0, \beta = 1, \alpha = 0.65$.*

The height of each of the shocks in the double-shock solution is given by

$$[u] = u_\ell - U^* = \frac{d^2 - 4\alpha}{d}. \tag{4.24}$$

Below $\alpha = d^2/4$ smooth traveling waves no longer exist, and at this value of α the shock height is zero. As α decreases from this value, the height of the shocks increases. When $\alpha = d^2/8$, the height of each shock is $d/2$ so that the two shocks come together, and the double-shock solution as analyzed in this section no longer exists. What happens below this value of α is considered in the next section.

4.2. Case 2: $0 < \alpha < d^2/8$. Much of the analysis from the previous section applies to this case. However, one exception is that the S-nullcline above the U-nullcline no longer converges to the U-nullcline as $\epsilon \to 0$. As before, one of the S-nullclines is located above the line $S = -\alpha$ and the other below. Recall that the U-nullcline is the parabola (4.7), and the minimum value of S on this nullcline is $-d^2/8$. When $\alpha < d^2/8$, the line $S = -\alpha$ intersects the U-nullcline, so that as $\epsilon \to 0$ the S-nullcline above the U-nullcline remains bounded away from the U-nullcline for a range of U values. This S-nullcline limits to

$$S = \begin{cases} \frac{1}{2}(U - u_\ell)(U - u_r) & (U - c)^2 > \frac{d^2 - 4\alpha}{8}, \\ -\alpha & (U - c)^2 \le \frac{d^2 - 4\alpha}{8}. \end{cases} \tag{4.25}$$

A sample plot of the nullclines is shown in Figure 4.4 for small ϵ.

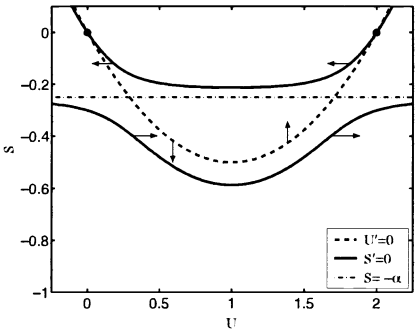

FIG. 4.4. *Typical nullclines for system* (4.5)–(4.6) *with* $0 < \alpha < d^2/8$. *Here the parameter values are* $u_\ell = 2$, $u_r = 0, \beta = 1, \alpha = 0.25, \epsilon = 0.05$.

As before, the unstable manifold of $(u_\ell, 0)$ flows into the region above the S-nullcline, and once the trajectory is $O(\epsilon)$ away from the equilibrium point the dynamics are fast $(O(\epsilon^{-1}))$. This unstable manifold is again approximated by the line (4.20). The unstable manifold eventually brings the flow back to the S-nullcline (4.25). These two curves intersect at the point $(U, S) = (c, -\alpha)$, and by symmetry the stable manifold of $(u_r, 0)$ also flows from this point. Thus the solution does not travel along the S-nullcline at all because the region of fast dynamics leaving $(u_\ell, 0)$ connects with the region of fast dynamics entering $(u_r, 0)$. Figure 4.5(a) shows the path of the heteroclinic orbit connecting $(u_\ell, 0)$ and $(u_r, 0)$ corresponding to the single-shock traveling wave. This solution was generated by integrating (4.5)–(4.6) for $\epsilon = 0.02$. The asymptotic solution is indistinguishable from the numerical solution on this scale. Figure 4.5(b) shows the wave profile for decreasing values of ϵ. For finite ϵ the wave profile is smooth, but it approaches a single shock as $\epsilon \to 0$.

The numerical simulations from section 3.3 suggested that for $\alpha < d^2/8$ the traveling wave solution was the shock solution from the inviscid Burgers equation. This analysis confirms this but provides more information on the structure of this shock for small viscosity. This shock is really a degenerate double-shock solution, in that the two shocks meet in the middle of the wave profile.

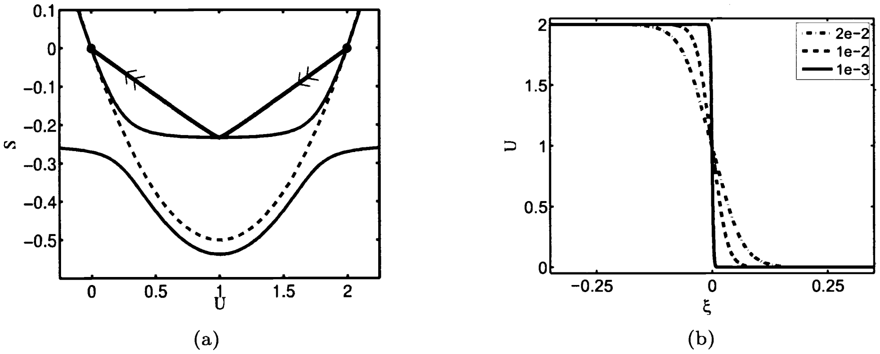

FIG. 4.5. (a) *Path of the heteroclinic orbit for the single-shock traveling wave that occurs when* $\alpha < d^2/8$. *The double arrows indicate the fast dynamics along these paths which correspond to the shocks in the limit* $\epsilon \to 0$. *This solution was generated by integrating* (4.5)–(4.6) *for* $\epsilon = 0.02$. *On this scale the asymptotic solution is indistinguishable from the numerical solution.* (b) *For finite* ϵ *the wave profile is smooth, but as* $\epsilon \to 0$ *the solution approaches the single-shock wave. The parameter values in both plots are* $u_\ell = 2$, $u_r = 0, \beta = 1, \alpha = 0.25$.

5. Discussion.

For given asymptotic values of the velocity, u_ℓ and u_r with $u_\ell > u_r$, the viscoelastic Burgers model (1.3)–(1.4) has three different types of traveling wave solutions, depending on the value of the elastic modulus α. For $\alpha > d^2/4$, smooth traveling waves exist, where $d = u_\ell - u_r$. When $d^2/8 < \alpha < d^2/4$, the profile of the traveling wave is piecewise smooth with two jump discontinuities, and when $\alpha < d^2/8$ the wave solution is a single shock. In all three cases the wave travels with unique speed $c = (u_\ell + u_r)/2$.

We address the physical significance of the threshold in the elastic modulus α for traveling waves to exist. For simplicity, consider the case in which $u_\ell = -u_r$, so that the speed of the traveling wave is 0. The condition $\alpha > d^2/4$ for a wave to exist reduces to $\alpha > u_\ell^2$, or $\sqrt{\alpha} > u_\ell$. The system linearized about $u = u_\ell$, $\sigma = 0$ is

$$u_t + u_\ell u_x = \sigma_x, \tag{5.1}$$

$$\sigma_t + u_\ell \sigma_x = \alpha u_x - \beta\sigma, \tag{5.2}$$

which can be written in the form

$$\boldsymbol{q}_t + A\boldsymbol{q}_x = B\boldsymbol{q}, \tag{5.3}$$

where $\boldsymbol{q} = (u, \sigma)^{\mathrm{T}}$. The wave speeds of this linearized system are $u_\ell \pm \sqrt{\alpha}$. The wave speeds are the sum of the advective speed u_ℓ and the elastic wave speeds $\pm\sqrt{\alpha}$. The advection terms tend to steepen the wave, which generates elastic forces that oppose this steepening. As long as the elastic wave speed is faster than the advective wave speed, smooth traveling waves exist. In the viscous Burgers equation ($\sigma = \epsilon u_x$), the viscous stresses propagate instantaneously, but in the viscoelastic model the elastic stresses propagate at a finite speed. Thus, the smooth traveling wave breaks down when the advective speed surpasses the elastic speed.

Recall that $\alpha = \mu/\lambda$, where μ and λ are the viscosity and relaxation time, respectively. For a fixed relaxation time, each of the three types of wave solutions is possible, depending on the size of the viscosity. For large enough viscosity, the smooth traveling wave results, and as the viscosity is decreased the solution transitions to the double-shock wave and then to the single-shock wave. Equivalently, for a fixed viscosity, the type of wave depends on the size of the relaxation time. The progression from the smooth wave to the double-shock wave to the single-shock wave occurs as the relaxation time increases. The regions of parameter space where the different wave solutions occur are illustrated in Figure 5.1.

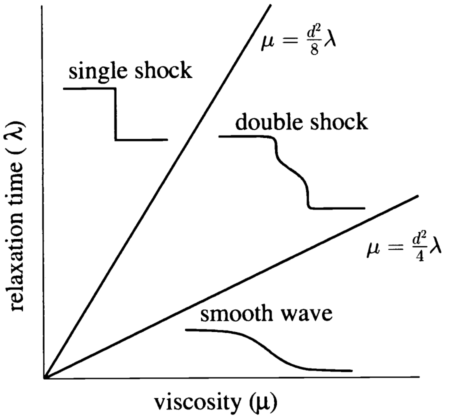

FIG. 5.1. *The values of the relaxation time λ and the viscosity μ determine the type of traveling wave solution. In parameter space the line $\mu = d^2\lambda/4$ is the boundary between smooth waves and double-shock solutions, and the line $\mu = d^2\lambda/8$ is the boundary between double shocks and single shocks.*

For $\lambda = 0$, only the smooth traveling wave is possible. In the limit that $\lambda \to 0$ for fixed μ, the constitutive law reduces $\sigma = \mu u_x$, and the model becomes Burgers' equation (1.1). This limit corresponds to the constitutive law for a viscous fluid. Taking the limit $\beta \to 0$ for a fixed value of α, the constitutive law limits to that of an elastic solid. The transitions between the different wave types are independent of the value of β. If we nondimensionalize the problem, the value of $\beta^{-1} = \lambda$ determines the time scale of the problem, which is related to the steepness of the wave profiles. As β gets smaller, the wave profiles steepen, meaning that as $\beta \to 0$ all wave solutions tend to shocks.

In section 2, we presented several different one-dimensional reductions of the UCM equation and in the remainder of the paper presented an analysis based on (2.10). However, the techniques employed apply to all three constitutive laws. Repeating the analysis for (2.11), we find that again there are smooth traveling waves for $\alpha > d^2/4$, but, for $\alpha < d^2/4$, only the single-shock solutions occur. For (2.12) there is a transition from a smooth traveling wave to a double-shock solution at $\alpha = c^2$, and the single-shock solution is approached as $\alpha \to 0$. Because (2.10) exhibits all three behaviors, we chose to present this case.

There are many different constitutive laws for viscoelastic fluids. In this paper we used the UCM model (Oldroyd-B when $\epsilon \neq 0$) because it is perhaps the simplest differential constitutive law and has been extensively studied in the past. Others have studied viscoelastic generalization of Burgers' equation [13, 21], and it would be interesting to explore how the behavior of the wave solutions analyzed in this paper is affected by different constitutive laws.

The problem in this paper is interesting in part because of its classical nature, but the analysis of one-dimensional waves in viscoelastic generalizations of Burgers' equations could also be used to develop numerical schemes for viscoelastic fluids. High-resolution finite volume methods have been used successfully in simulating high Reynolds number flows [1]. The algorithm for discretizing the convection terms in [1] is based on numerical methods for conservation laws [6]. These methods require solving one-dimensional Riemann problems, and it is not clear how to adapt this approach to nonconservative systems. Wave propagation algorithms [15] are more easily adapted to nonconservative problems, but these methods also require being able to solve one-dimensional Riemann problems. Recently finite volume methods for viscoelastic flows have been proposed [10, 22]. The techniques from this paper could be adapted to solve the Riemann problems that arise in these methods.

Acknowledgments. The authors would like to thank Andy Bernoff and Jim Keener for helpful discussions while writing this paper. We also thank the referees for their insightful comments.

THE CHAPMAN–JOUGUET CLOSURE FOR THE RIEMANN PROBLEM WITH VAPORIZATION*

VINCENT PERRIER[†]

Abstract. This work is devoted to the modeling of phase transition. The thermodynamic model for phase transition chosen is a model with two equations of state, each of them modeling one phase of a given fluid. The mixture equation of state is obtained by an entropy optimization criterion. Both equations of state are supposed to be convex, and a necessary condition is found to ensure the convexity of the mixture equation of state. Then we investigate the Riemann problem for the Euler system with these equations of state. More precisely, we propose to take into account metastable states, which may occur as noted in [J. R. Simões-Moreira and J. E. Shepherd, *J. Fluid Mech.*, 382 (1999), pp. 63–86]. We check whether the Chapman–Jouguet theory can be applied in our context, and that it is consistent with the entropy growth criterion. As the characteristic Lax criterion does not hold for this solution, an additional relation, the kinetic closure, is necessary. The common closure, i.e., the Chapman–Jouguet closure, is proved to be incorrect in general in that context.

Key words. fluid mechanics, phase transition, nonconvex equation of state, Riemann problem, Chapman–Jouguet theory

DOI. 10.1137/060650374

Introduction. We are interested in the study of some problems arising in the modeling of phase transition in compressible fluids. A widely used model for phase transition [2, 1, 14, 5] is the van der Waals model. Nevertheless, the very physical meaning of this model is questionable, because the resulting system of partial differential equations is not hyperbolic. Moreover, according to [16], the shock structure found in [14] does not seem to match with what experiments show. Another approach consists in modeling each phase by an equation of state, and in coupling them by optimizing the entropy [7, 9] to get a mixture equation of state. As explained in [12], the convexity of internal energy is necessary to ensure the local thermodynamic equilibrium. Whether the mixture equation of state is convex or not will be discussed in section 1.

We will then concentrate on the Euler system of partial differential equations, which models flow dynamics with neither viscosity nor thermal conduction. A fundamental step to approximate the solutions of the Euler system with a Godunov method is to solve the Riemann problem, i.e., the Cauchy problem where the initial condition is composed of two different constant states. If the solution of the Riemann problem for the Euler system is easy to solve for a convex equation of state, it becomes much harder when the equation of state suffers from loss of derivative and from local nonconvexity [19, 12, 20, 21, 16, 17, 18, 11], because the common entropy growth criterion fails to ensure the existence and uniqueness of the solution. Based on the experiments of [13], we propose to take into account out-of-thermodynamic-equilibrium states, or *metastable* states. The Chapman–Jouguet (CJ) theory will be used [4, 6], and the compatibility between the model of equation of state and this theory will be discussed.

Table 1
Thermodynamic notation.

T	temperature
τ	specific volume
ρ	density
s	specific entropy
μ	chemical potential
h	specific enthalpy

f	specific free energy
P	pressure
ε	specific internal energy
y	mass fraction
α	volume fraction

The entropy growth criterion will be shown to hold. Finally, we will show that the closure usually used to close the problem [10], i.e., the CJ closure, leads to a solution that does not in general continuously depend on its initial data, and this solution will therefore be rejected.

1. Thermodynamic preliminaries.

1.1. Thermodynamic with phase transition. We suppose that we have two phases of the same fluid. For the sake of simplicity, we will consider that one phase is liquid (subscript l) and the other one is the vapor (subscript v). For each phase, we will take the notation of Table 1. If we consider that we have a mixture of the two phases, then the total specific quantities are defined by

$$\tau_{tot} = y_l \tau_l + y_v \tau_v, \tag{1.1a}$$

$$\varepsilon_{tot} = y_l \varepsilon_l + y_v \varepsilon_v, \tag{1.1b}$$

$$s_{tot} = y_l s_l + y_v s_v. \tag{1.1c}$$

To find the thermodynamic equilibrium, the total entropy (1.1c) must be optimized. Of course, the optimization must be consistent with the following constraints:

$$\text{conservation of total energy} \qquad y_l \varepsilon_l + y_v \varepsilon_v = cste, \tag{1.2a}$$

$$\text{conservation of mass} \qquad y_l + y_v = 1. \tag{1.2b}$$

Moreover, we suppose that the two phases are locally nonmiscible, which means that

$$y_l \tau_l + y_v \tau_v = cste. \tag{1.2c}$$

We choose to optimize (1.1c) with the variables τ, ε, y for each phase. The first and second principles of thermodynamics impose that for each phase

$$\mathrm{d}s = \frac{\mathrm{d}\varepsilon}{T} + \frac{P}{T}\,\mathrm{d}\tau.$$

Then the differential of s_{tot} must belong to the set spanned by the gradients of the constraints; if we denote by $\lambda_1, \lambda_2, \lambda_3$ the Lagrange multipliers associated to the constraints (1.2a), (1.2b), (1.2c), we find (with the notation of Table 1)

$$s_l = \lambda_1 \varepsilon_l + \lambda_2 + \lambda_3 \tau_l, \tag{1.3a}$$

$$\frac{y_l}{T_l} = \lambda_1 y_l, \tag{1.3b}$$

$$\frac{y_l P_l}{T_l} = \lambda_3 y_l, \tag{1.3c}$$

$$s_v = \lambda_1 \varepsilon_v + \lambda_2 + \lambda_3 \tau_v, \tag{1.3d}$$

$$\frac{y_v}{T_v} = \lambda_1 y_v, \tag{1.3e}$$

$$\frac{y_v P_v}{T_v} = \lambda_3 y_v. \tag{1.3f}$$

If we suppose that both phases coexist, then (1.3b) and (1.3e) give

$$T_l = T_v =: T,$$

(1.3c) and (1.3f) give

$$P_l = P_v =: P,$$

and, finally, (1.3a) and (1.3d) lead to

$$\mu_l(P,T) = \mu_v(P,T). \tag{1.4}$$

It is well known that there exist a temperature T_c and a pressure P_c such that there is no longer any difference between the liquid and the gas phases above this temperature and pressure (the fluid is said to be *supercritical*). If we suppose that under these values we have

$$\tau_l(P,T) \neq \tau_v(P,T),$$

then we can apply the implicit function theorem to (1.4) to prove that P is locally a function of T:

$$P = P_{sat}(T).$$

The limit of thermodynamic stability of the mixture is given, in the (τ, P) plane, by the functions $\tau_v(P_{sat}(T),T)$ and $\tau_l(P_{sat}(T),T)$. The set of all the physical states lying between these curves is called the saturation dome. When there is no ambiguity, we will also denote by τ_v the function $T \mapsto \tau_v(P_{sat}(T),T)$ and by τ_l the function $T \mapsto \tau_l(P_{sat}(T),T)$. Thus, the thermodynamic plane can be divided into four parts (see Figure 1): two parts in which one of the two pure phases is stable, one part where a mixture of saturated liquid and vapor is stable and where the specific thermodynamic variables are defined as in (1.1), and one part with the supercritical fluid.

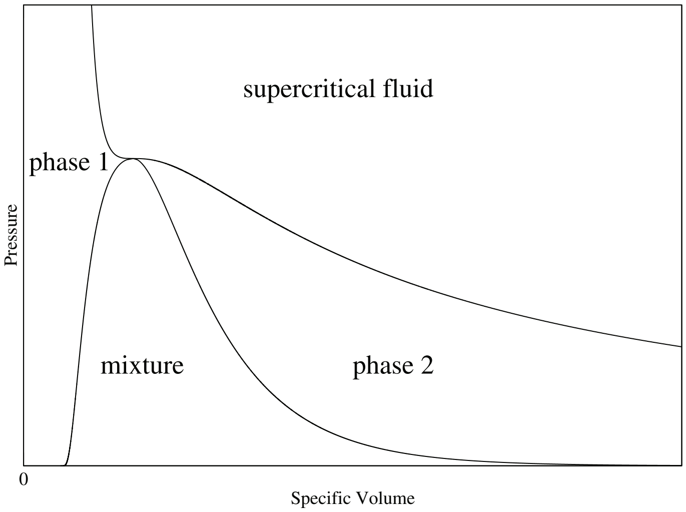

FIG. 1. *The thermodynamic plane (P, τ) is divided into four parts: two parts where the single phases are stable, one part where the mixture is stable, and one part where the fluid is supercritical.*

Moreover, if we differentiate the equality $\mu_v(P,T) = \mu_l(P,T)$ with respect to (P,T), we find the Clausius–Clapeyron relation

$$\frac{\mathrm{d}P_{sat}}{\mathrm{d}T}(T) = \frac{s_v(T) - s_l(T)}{\tau_v(T) - \tau_l(T)}. \tag{1.5}$$

For most of the solid-liquid phase transition (except for special cases such as bismuth or water) and for all of the liquid-gas phase transition, we have for all $T < T_c$

$$\tau_v(T) - \tau_l(T) > 0.$$

This means that in Figure 1, phase 1 is the liquid, and phase 2 is a gas.

For any phase transition, the entropy of the most compact constituent is lower than the entropy of the other constituent. Thus, in our case we have for all $T < T_c$

$$s_v(T) - s_l(T) > 0,$$

which induces $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0$.

1.2. Adimensioned thermodynamic coefficients. We adopted the notation of Table 1. As in [12], we define three adimensioned parameters as

$$\Gamma = -\frac{\tau}{T}\left(\frac{\partial T}{\partial \tau}\right)_s, \qquad \gamma = -\frac{\tau}{P}\left(\frac{\partial P}{\partial \tau}\right)_s, \qquad g = \frac{P\tau}{T^2}\left(\frac{\partial T}{\partial s}\right)_\tau. \tag{1.6}$$

γ is the adiabatic coefficient, and Γ is the Grüneisen coefficient. As in [12], we propose using these three thermodynamic coefficients to express all the thermodynamic quantities. One can then show that the following identities hold:

$$\mathrm{d}s = \frac{P\tau}{T^2}\,\frac{1}{g}\,\mathrm{d}T + \frac{P}{T}\,\frac{\Gamma}{g}\,\mathrm{d}\tau, \tag{1.7a}$$

$$\mathrm{d}s = -\frac{\tau}{T}\,\frac{\Gamma}{\gamma g - \Gamma^2}\,\mathrm{d}P + \frac{P\tau}{T^2}\,\frac{\gamma}{\gamma g - \Gamma^2}\,\mathrm{d}T, \tag{1.7b}$$

$$\mathrm{d}s = \frac{\tau}{T}\,\frac{1}{\Gamma}\,\mathrm{d}P + \frac{P}{T}\,\frac{\gamma}{\Gamma}\,\mathrm{d}\tau, \tag{1.7c}$$

$$\mathrm{d}\tau = -\frac{\tau}{P}\,\frac{g}{\gamma g - \Gamma^2}\,\mathrm{d}P + \frac{\tau}{T}\,\frac{\Gamma}{\gamma g - \Gamma^2}\,\mathrm{d}T, \tag{1.7d}$$

$$\mathrm{d}h = \tau\,\frac{\Gamma + 1}{\Gamma}\,\mathrm{d}P + P\,\frac{\gamma}{\Gamma}\mathrm{d}\tau, \tag{1.7e}$$

$$\mathrm{d}\varepsilon = \tau\,\frac{1}{\Gamma}\,\mathrm{d}P + P\,\frac{(\gamma - \Gamma)}{\Gamma}\,\mathrm{d}\tau. \tag{1.7f}$$

Thermodynamic stability requires that ε be convex as a function of τ and s, which leads to

$$g \geq 0, \qquad \gamma \geq 0, \qquad \gamma g - \Gamma^2 \geq 0. \tag{1.8}$$

1.3. The fundamental derivative. In [15], the fundamental derivative was defined as

$$\mathscr{G} = -\frac{\tau}{2}\,\frac{\left(\frac{\partial^3 \varepsilon}{\partial \tau^3}\right)_s}{\left(\frac{\partial^2 \varepsilon}{\partial \tau^2}\right)_s}.$$

The sign of $\mathscr{G}$ determines whether the Hugoniot curve and the isentropes are convex or not in the (τ, P) plane. We will suppose in the following that $\mathscr{G}$ is positive, so that no undercompressive discontinuity or expansion fans can exist (see [15, 20, 21]).

1.4. Mixture equation of state.

1.4.1. Parameterization of the mixture equation of state. In the following, we will denote with a subscript m all the variables relative to the mixture equation of state. The mixture equation of state is naturally parameterized by y, the mass fraction of the gas, and T, the temperature. Nevertheless, in the next sections, the parameters that will intervene are mostly τ and s. They are linked by the transformation

$$\Phi : \begin{pmatrix} y \\ T \end{pmatrix} \mapsto \begin{pmatrix} y\tau_v(T) + (1-y)\tau_l(T) \\ ys_v(T) + (1-y)s_l(T) \end{pmatrix} = \begin{pmatrix} \tau \\ s \end{pmatrix}. \tag{1.9}$$

Theorem 1. *For all points in the saturation dome, Φ is a local diffeomorphism provided that the equations of state of the liquid and of the gas are both convex.*

Proof. To show that Φ is a local diffeomorphism, it is sufficient to show that its Jacobian does not vanish. Differentiation of (1.9) and using the Clausius–Clapeyron relation lead to

$$\det(\mathrm{D}\Phi) = (\tau_v - \tau_l)\left(y\left(\frac{\mathrm{d}s_v}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_v}{\mathrm{d}T}\right) + (1-y)\left(\frac{\mathrm{d}s_l}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_l}{\mathrm{d}T}\right)\right). \tag{1.10}$$

We supposed that $\tau_v - \tau_l > 0$ (except at the critical point), so it remains to show that

$$y\left(\frac{\mathrm{d}s_v}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_v}{\mathrm{d}T}\right) + (1-y)\left(\frac{\mathrm{d}s_l}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_l}{\mathrm{d}T}\right) \tag{1.11}$$

never vanishes. The term (1.11) is a convex combination of

$$\frac{\mathrm{d}s_v}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_v}{\mathrm{d}T} \quad \text{and} \quad \frac{\mathrm{d}s_l}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_l}{\mathrm{d}T}. \tag{1.12}$$

Using (1.3a), (1.3b) for $P = P_{sat}(T)$ leads to

$$\frac{\mathrm{d}s_b}{\mathrm{d}T} - \frac{\mathrm{d}P_{sat}}{\mathrm{d}T}\frac{\mathrm{d}\tau_b}{\mathrm{d}T} = \frac{\gamma g - \Gamma^2}{g}\frac{P}{\tau}\left(\frac{\mathrm{d}\tau_b}{\mathrm{d}T}\right)^2 + \frac{P\tau}{T^2}\frac{1}{g} > 0 \tag{1.13}$$

for $b = g$ or l, which is positive provided that each pure phase equation of state is convex.

Therefore (1.11) is positive, because it is a convex combination of two terms as is (1.13). As a consequence, $\det(\mathrm{D}\Phi) > 0$. □

Thanks to the parameterization (1.9), we can calculate the adimensioned coefficients defined by (1.6), to show that the following theorem holds.

Theorem 2. *If both equations of state are convex, and if $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0$, then the mixture equation of state is convex, too; i.e., inequalities* (1.8) *hold.*

Proof. We denote by a subscript m the thermodynamic parameters relative to the mixture equation of state.

- *Calculation of* Γ_m. To calculate Γ_m, we first use the chain rule

$$\left(\frac{\partial\tau}{\partial T}\right)_s = \left(\frac{\partial y}{\partial T}\right)_s\left(\frac{\partial\tau}{\partial y}\right)_T + \left(\frac{\partial\tau}{\partial T}\right)_y.$$

Then the differentiation of the definition of mixture entropy shows that

$$\left(\frac{\partial y}{\partial T}\right)_s = \frac{y\frac{\mathrm{d}s_v}{\mathrm{d}T} + (1-y)\frac{\mathrm{d}s_l}{\mathrm{d}T}}{s_l - s_v},$$

which leads to

$$\left(\frac{\partial\tau}{\partial T}\right)_s = -\frac{y\frac{\mathrm{d}s_v}{\mathrm{d}T}+(1-y)\frac{\mathrm{d}s_l}{\mathrm{d}T}}{s_l-s_v}(\tau_l-\tau_v)+y\frac{\mathrm{d}\tau_v}{\mathrm{d}T}+(1-y)\frac{\mathrm{d}\tau_l}{\mathrm{d}T}.$$

Thanks to the Clausius–Clapeyron relation, we find

$$\left(\frac{\partial\tau}{\partial T}\right)_s = y\left(\frac{\mathrm{d}\tau_v}{\mathrm{d}T}-\frac{\mathrm{d}T}{\mathrm{d}P}\frac{\mathrm{d}s_v}{\mathrm{d}T}\right)+(1-y)\left(\frac{\mathrm{d}\tau_v}{\mathrm{d}T}-\frac{\mathrm{d}T}{\mathrm{d}P}\frac{\mathrm{d}s_l}{\mathrm{d}T}\right),$$

which is negative according to what we did for the Jacobian of Φ. Therefore

$$\Gamma_m = -\frac{T}{\tau}\left(\frac{\partial\tau}{\partial T}\right)_s \geq 0.$$

- *Calculation of* γ_m. As $P = P_{sat}(T)$ in the saturation area, we have

$$\left(\frac{\partial\tau}{\partial P}\right)_s = \frac{\mathrm{d}T_{sat}}{\mathrm{d}P}\left(\frac{\partial\tau}{\partial T}\right)_s.$$

Thus $\gamma_m = \Gamma_m\,\frac{T}{P}\,(\frac{\mathrm{d}P}{\mathrm{d}T})_{sat} \geq 0$.

- *Calculation of* g_m. By using the identity

$$\left(\frac{\partial T}{\partial s}\right)_\tau\left(\frac{\partial s}{\partial\tau}\right)_T\left(\frac{\partial\tau}{\partial T}\right)_s = -1,$$

we have

$$\left(\frac{\partial T}{\partial s}\right)_\tau = -\frac{1}{(\frac{\partial s}{\partial\tau})_T\,(\frac{\partial\tau}{\partial T})_s}.$$

Along an isotherm we have $\mathrm{d}s = (s_v - s_l)\mathrm{d}y$ and $\mathrm{d}\tau = (\tau_v - \tau_l)\mathrm{d}y$, so that

$$\left(\frac{\partial s}{\partial\tau}\right)_T = \left(\frac{\mathrm{d}P}{\mathrm{d}T}\right)_{sat}.$$

Therefore, we find

$$\left(\frac{\partial T}{\partial s}\right)_\tau = \left(\frac{\mathrm{d}T}{\mathrm{d}P}\right)_{sat}\frac{\Gamma_m T}{\tau},$$

which induces $\gamma_m g_m = \Gamma_m^2$. As $\gamma_m \geq 0$, this means that $g_m \geq 0$.
Therefore, we proved that $g_m \geq 0$, $\gamma \geq 0$, and that $\gamma_m g_m - \Gamma_m^2 = 0$, so that the convexity of energy is ensured. □

1.5. Adimensioned coefficients near a phase transition boundary. In this section, we continue denoting by the subscript m the thermodynamic coefficients of the mixture equation of state, while the coefficients with no subscript are of the pure phase.

In [12, p. 121], the following identity is proved:

$$\frac{\gamma-\gamma_m}{\gamma_m} = (\gamma g - \Gamma^2)\left(\frac{T}{\tau}\left(\frac{\mathrm{d}s_b}{\mathrm{d}P}\right)_{sat}\right)^2 > 0,$$

with $b = g$ or l. This identity proves that isentropes are stiffer in the pure phases than in the mixture. In the same manner it is proved that

$$\frac{\Gamma_m}{\Gamma} = \frac{\gamma_m - \xi}{\gamma - \xi}, \tag{1.14}$$

with $\xi = -\frac{\tau}{P}(\frac{\mathrm{d}P}{\mathrm{d}\tau})_{sat}$. As in [12], we suppose that the isentropes can be parameterized by τ, so that

$$\frac{\gamma_m - \xi}{\gamma - \xi} > 0, \tag{1.15}$$

and so that Γ is positive too, because $\Gamma_m > 0$.

1.6. Retrograde and regular behavior. In [16], the retrogradicity r was introduced to study the behavior of isentropes near a phase transition boundary

$$r = \left(\frac{\partial T}{\partial \tau}\right)_P \left(\frac{\mathrm{d}s_b}{\mathrm{d}P}\right).$$

Thanks to (1.7d) and as Γ is positive near a phase transition boundary, $(\frac{\partial T}{\partial \tau})_P$ is positive, so that the sign of r is the same as the sign of $\frac{\mathrm{d}s_b}{\mathrm{d}P}$.

We suppose now that a fluid undergoes a rarefaction isentrope: this is the only regular transformation that a fluid can undergo. In the (S, T) plane, this transformation is drawn as a vertical line. As the transformation is undercompressive, the temperature decreases (at least near the phase transition boundary, because $\Gamma > 0$ and $\Gamma_m > 0$). If $r > 0$, then the isentrope crosses the saturation curve from the pure phase to the mixture phase (as on both sides of the left-hand part of Figure 2 and the liquid side of the right-hand part of Figure 2). In this case, the fluid is said to be *regular*. If r is negative, then the isentrope crosses the saturation curve from the mixture to the pure phase, as on the gas side of the right-hand part of Figure 2.

In [12, p. 121], other expressions of r are given:

$$r = \frac{\Gamma_m}{\Gamma}\frac{\gamma g - \Gamma^2}{\gamma_m}\frac{\mathrm{d}s_b}{\mathrm{d}T} = \frac{\gamma - \gamma_m}{\gamma_m}\frac{\xi}{\xi - \gamma}.$$

Experiments show that the liquid saturation curve is always regular. The gas saturation curve can be either regular or retrograde.

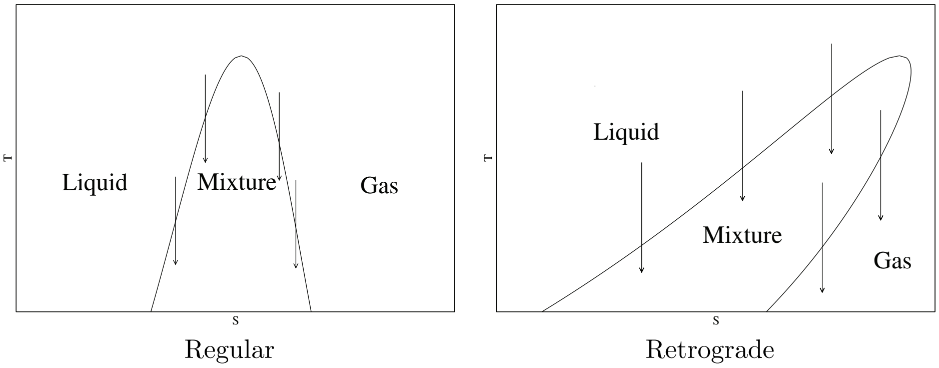

FIG. 2. *The saturation dome in the (S, T) plane. On the left, the fluid is regular: all the isentropes (drawn as arrows) cross the saturation dome from the pure phase to the mixture. On the right, the fluid is retrograde: the isentropes are crossing the liquid saturation curve from the pure phase to the mixture, whereas it is the contrary on the gas side.*

1.7. Validity domain of a model. To quickly compute a solution of the Riemann problem for fluid flows, simplified equations of state (perfect gas or stiffened gas, for example) are often preferred to tabulated ones. Nevertheless such equations of state often have only a narrow range of validity, outside of which they do not have a physical behavior (negative energy, nonconvexity).

If we want to use a simplified equation of state for both liquid and gas, we have to care not only about the physical behavior of the two equations of state but also about the mixture equation of state computed. If we look at the properties needed in section 1, we see that the property $\frac{\mathrm{d}P_{\mathrm{sat}}}{\mathrm{d}T} > 0$ is fundamental to ensuring the local convexity of energy. Nevertheless, it is not always true, as we show now with examples.

1.7.1. The two perfect gas model. This model was proposed by [8, 7]. The two phases are modeled with a perfect gas equation of state. To complete the equation of state, we suppose, moreover, that $C_v = 1$ for each fluid. We denote by $\overline{\Gamma}_i$ the Grüneisen coefficient of the phase i. Then we have

$$\varepsilon_i(P,\tau) = \frac{P\tau}{\overline{\Gamma}_i}, \tag{1.16a}$$

$$s_i(P,T) = \log\left(T\left(\frac{\overline{\Gamma}_i T}{P}\right)^{\overline{\Gamma}_i}\right), \tag{1.16b}$$

$$\mu_i(P,T) = (\overline{\Gamma}_i + 1)T - T\log\left(T\left(\frac{\overline{\Gamma}_i T}{P}\right)^{\overline{\Gamma}_i}\right). \tag{1.16c}$$

The equation $\mu_1(P,T) = \mu_2(P,T)$ can be explicitly solved to get $P = \beta T$, with $\beta = \exp(1)(\frac{\Gamma_2^{\Gamma_2}}{\Gamma_1^{\Gamma_1}})^{\frac{1}{\Gamma_1-\Gamma_2}}$. We see here that the condition $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0$ always holds. The limits of the saturation dome are given by the equations

$$T = \varepsilon = \frac{P_{sat}(T)\tau_i(T)}{\Gamma_i},$$

which gives $\tau_i(T) = \frac{\Gamma_i}{\beta}$. Thus, $T \mapsto \tau_i(T)$ is a constant function. In particular, the critical point does not exist. If we decide, for example, that $\Gamma_1 < \Gamma_2$, then we get the projections of the phase diagram in the (P,τ) plane and in the (S,T) plane that are drawn in Figure 3. The mixture equation of state can be explicitly calculated:

$$\begin{cases} P(\tau,\varepsilon) = \Gamma_2\dfrac{\varepsilon}{\tau} & \text{if} \quad \tau \leq \tau_2, \\ P(\tau,\varepsilon) = \Gamma_2\dfrac{\varepsilon}{\tau_2} = \Gamma_1\dfrac{\varepsilon}{\tau_1} & \text{if} \quad \tau_2 \leq \tau \leq \tau_1, \\ P(\tau,\varepsilon) = \Gamma_1\dfrac{\varepsilon}{\tau} & \text{if} \quad \tau_1 \leq \tau. \end{cases}$$

Nevertheless, we remark that the heaviest phase is described by the lowest adiabatic coefficient, which is in contradiction to what is described, for example, in [22, Chapter XI]. Thus, the two perfect gas model is a good mathematical model because the mixture equation of state can be explicitly calculated, but it cannot give a good account for the physical behavior.

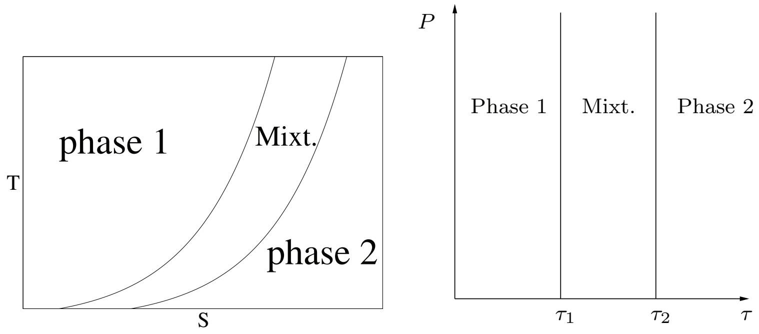

FIG. 3. *Shape of the saturation dome for the two perfect gas model. We note that the fluid is always retrograde.*

1.7.2. The two stiffened gas model. We model the two phases of a fluid with the stiffened gas equation of state, for which we have (see [9])

$$\varepsilon(P,\tau) = \frac{P+\overline{\gamma}P^{\infty}}{\overline{\gamma}-1}\tau + q, \tag{1.17a}$$

$$s(P,T) = C_v \log\left(\frac{T^{\overline{\gamma}}}{(P+P^{\infty})^{\overline{\gamma}-1}}\right) + q', \tag{1.17b}$$

$$G(P,T) = (\overline{\gamma}C_v - q')T - C_v T \log\left(\frac{T^{\overline{\gamma}}}{(P+P^{\infty})^{\overline{\gamma}-1}}\right) + q. \tag{1.17c}$$

For this equation of state, the adimensioned coefficients are given by

$$\gamma = \overline{\gamma}\left(1+\frac{P^{\infty}}{P}\right), \qquad \Gamma = \overline{\gamma}-1, \qquad g = \frac{(\overline{\gamma}-1)P}{P+P^{\infty}}.$$

The conditions $\gamma > 0$ and $g > 0$ are ensured if $\overline{\gamma} > 1$. In [9], the coefficients $q, q', C_v, \overline{\gamma}, P^{\infty}$ were calculated for the gaseous and liquid phases to fit with the saturation curves near $T = 298$K. These coefficients are given in Table 2. The resulting function $P_{\text{sat}}(T)$ was drawn in Figure 4. For the two stiffened gas model, we cannot be sure that the functions $T \mapsto s_v(T) - s_l(T)$ and $T \mapsto \tau_v(T) - \tau_l(T)$ simultaneously vanish. Therefore, the critical point does not really exist. As we saw in section 1.4, we need $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0$ to ensure the convexity of the mixture equation of state. Thus, the model is valid only when $\tau_v(T) - \tau_l(T)$ and $s_v(T) - s_l(T)$ are both positive. In our example, with the coefficients of Table 2, the function $T \mapsto P_{sat}(T)$ is drawn in Figure 4. We can see that the limit is near $T = 970\,\mathrm{K}$, for which $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T}$ vanishes.

1.8. Positivity of the fundamental derivative. In section 1.4, we found some criteria to ensure the convexity of the mixture equation of state. Nevertheless, we did not manage to find a simple criterion that can also ensure the positivity of the fundamental derivative of the mixture equation of state. Actually, as shown

TABLE 2
Thermodynamic coefficients for the liquid and gaseous phase of dodecane.

Phase	$\overline{\gamma}$	P^{∞}	C_v	q	q'
Gas	1.025	0	1956.45	-237547	-24485
Liquid	2.35	4.10^8 Pa	1077.7	-755269	0

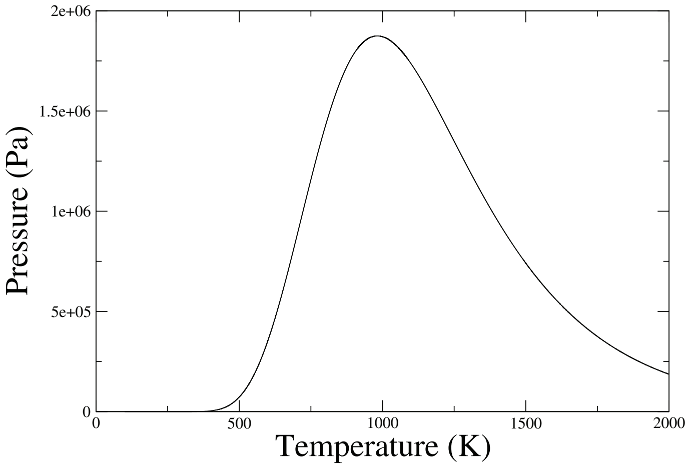

FIG. 4. *Numerical computation of the behavior of $P_{\text{sat}}(T)$ for two phases of the stiffened gas model with the coefficients of Table* 2. *For temperatures below* $970K$, $T \mapsto P_{\text{sat}}(T)$ *increases. For* $T \approx 970K$, *the function* $T \mapsto s_v(T) - s_l(T)$ *vanishes and its sign changes, whereas the function* $T \mapsto \tau_v(T) - \tau_l(T)$ *does not vanish. As a consequence,* $T \mapsto P_{\text{sat}}(T)$ *does not increase anymore, and the equation of state is no longer valid.*

numerically in Figure 5 for the thermodynamic coefficients of Table 2, the fundamental derivative of the mixture equation of state can be either positive or negative, even if both equations of state have a positive fundamental derivative. In that example, the equation of state can be considered as valid if $T \leq 715$K, where $\mathscr{G} > 0$.

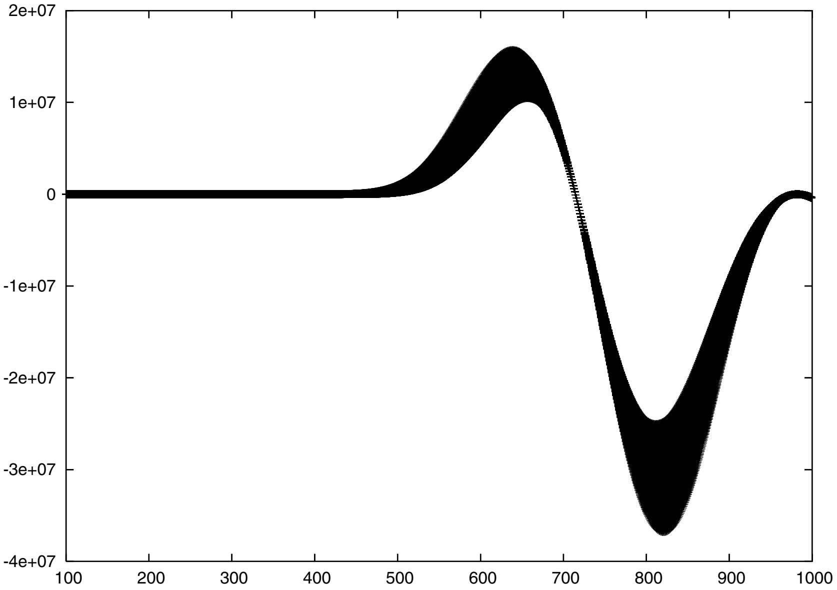

FIG. 5. *In this figure, we draw all the* $T \mapsto \mathscr{G}$ *for* $y \in [0;1]$. *The equation of state is the one of Table* 2. *For low temperatures* ($T \leq 715K$), *the fundamental derivative is positive, whereas for* $715 \leq T \leq 970K$ *the fundamental derivative is negative.*

2. Recollections of the Chapman–Jouguet theory (see [6, pp. 142–160]). Based on the experiments of [13, 16, 17], we propose to take into account out-of-thermodynamic-equilibrium states for solving the Riemann problem. By "out-of-equilibrium states" we mean *metastable states*, or *overheated* states, i.e., pure fluids that have a pressure P and a specific volume τ that lie in the saturation dome. Existence of such states is due to some phenomena such as capillarity, for example. In [13, 16, 17] it was observed that phase transition waves were self-similar waves, so that Rankine–Hugoniot relations hold across them: $\left[F(U) - \sigma U\right] = 0$, where σ is the velocity of the discontinuity. These relations can be put in the following form (see [6], for example):

$$\dot{M} = \frac{u_1 - u_0}{\tau_1 - \tau_0}, \tag{2.1a}$$

$$\dot{M}^2 = -\frac{P_1 - P_0}{\tau_1 - \tau_0}, \tag{2.1b}$$

$$\varepsilon_1 - \varepsilon_0 + \frac{1}{2}(P_1 + P_0)(\tau_1 - \tau_0) = 0, \tag{2.1c}$$

where $\dot{M}$ is the flow rate across the wave: $\dot{M} = \rho(u - \sigma)$. The interest of writing the Rankine–Hugoniot relations as in (2.1) is that the last two equations are purely thermodynamic. Equation (2.1b) describes the Rayleigh line in the (τ, P) plane. Equation (2.1c) describes the Crussard curve. The very difference with classical shock relations is that the set of the downstream states is not described with the same equation of state as that of the upstream one. For that sort of wave, we can use the CJ theory. Let us recall the main points of that theory (see [6] or [4] for the details and the proofs).

PROPERTY 1 (position of the initial state and the Crussard curve). *Suppose that the equation of state $(\tau, s) \mapsto P(\tau, s)$ has the properties*

$$\left(\frac{\partial P}{\partial \tau}\right)_s < 0 \qquad \textit{and} \qquad \left(\frac{\partial P}{\partial s}\right)_\tau > 0, \tag{2.2a}$$

and the reaction is exothermic:

$$\varepsilon_1(\tau_0, p_0) < \varepsilon_0(\tau_0, p_0). \tag{2.2b}$$

Then the point A_0 corresponding to the upstream state is under the Crussard curve.

In the first property, note that (2.2a) is always true provided that γ and Γ are both positive (thanks to (1.7c)). We will find in section 3.1 a condition to ensure the exothermic property (2.2b).

PROPERTY 2. *Suppose, moreover, that*

$$\left(\frac{\partial^2 P}{\partial \tau^2}\right)_s > 0;$$

then the Crussard curve is convex. Hence, the Rayleigh line (2.1b) *and the Crussard curve are crossing in zero or two points.*

Note that the Property 2 supposes that the pressure can be differentiated twice, which is not the case in our application, because of the local loss of derivative due to phase transition. Nevertheless, if Properties 1 and 2 hold for the equation of state

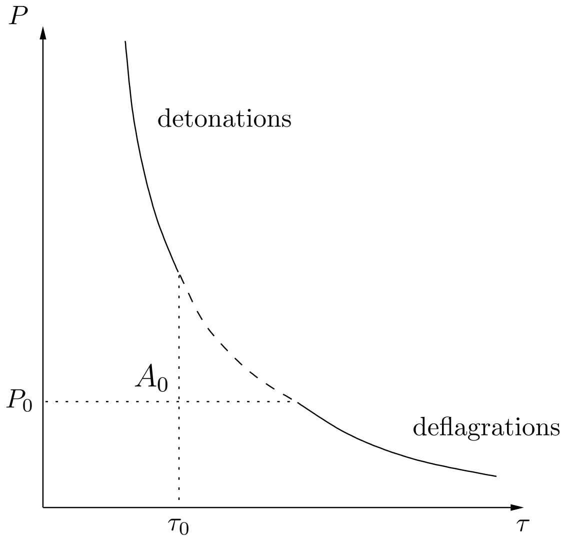

FIG. 6. *The Crussard curve related to an initial point* (τ_0, P_0). *The curve is cut into three parts: the upper one is the detonation branch, the lower one is the deflagration branch, and the middle part does not match the negative slope of the Rayleigh line.*

of the downstream states, then the Crussard curve can be schematically drawn as in Figure 6. The Crussard curve is cut into two parts: the upper part is called the detonation branch, and the lower one is the deflagration branch. In the middle part of the curve, $\frac{P_1-P_0}{\tau_1-\tau_0} > 0$. This does not match the negative slope of the Rayleigh line (2.1b).

Each part of the Crussard curve is itself cut into two parts, separated by the tangential point of the Rayleigh line with the Crussard curve (the existence of such a tangential point can be shown under some assumption on the asymptotic behavior of equation of state). Both branches are schematically drawn in Figure 7.

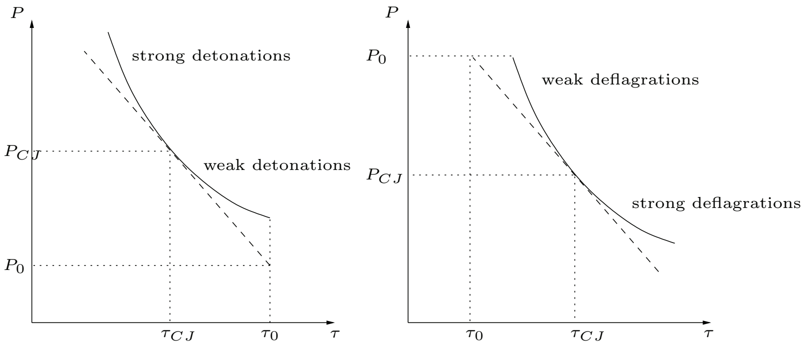

FIG. 7. *Zoom on the Crussard curve; on the left side, the detonation branch* $(P \geq P_0)$ *is cut into two parts by the CJ point. The upper part is the part of the strong detonations, and the lower part is called the part of the weak detonations. On the right side, the deflagration branch* $(P \leq P_0)$ *is cut into two parts by the CJ point. The upper part is the part of the weak deflagrations, and the lower part is called the part of the strong deflagrations.*

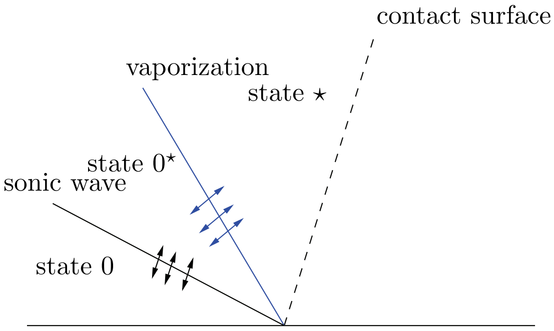

FIG. 8. *Structure of the half-Riemann problem: the state* 0 *is linked with the state* $0^\star$ *by a forerunner sonic wave (rarefaction wave or shock). Then the state* $0^\star$ *and the state* $\star$ *are linked with a deflagration wave. Eventually, there is a contact discontinuity.*

PROPERTY 3. *Along the Crussard curve, the velocity* $|v| = |u - \sigma|$ *has a local minimum on the CJ-detonation point and a local maximum on the CJ-deflagration point. More precisely, we have the following properties:*

$$\begin{array}{llll}
\textit{for a strong detonation} & : & |v_0| > c_0, & |v_1| < c_1, \\
\textit{for a weak detonation} & : & |v_0| > c_0, & |v_1| > c_1, \\
\textit{for a weak deflagration} & : & |v_0| < c_0, & |v_1| < c_1, \\
\textit{for a strong deflagration} & : & |v_0| < c_0, & |v_1| > c_1.
\end{array}$$

This last property is very important because it can allow us to know the structure of the half-Riemann problem with a combustion wave provided that we know which "family" the combustion wave belongs to. In our case, we are interested in waves which transform a heavy phase into a lighter one. Therefore, we expect that τ will increase, so that we will concentrate only on the deflagration branch of the Crussard curve.

Thanks to Property 3, we can give the structure of the Riemann problem in the case of strong and weak deflagrations. In both cases, from Property 2, the deflagration wave is always subsonic relative to the liquid; for example, if the liquid is on the left, we have $\dot{M} > 0$, and $u_0 - c_0 < \sigma < u_0$. For the position of the wave relative to the fields of 1, we have that

- if the wave is a strong deflagration, then $\sigma < u_1 - c_1$;
- if the wave is a weak deflagration, then $u_1 - c_1 < \sigma < u_1$.

In [4, p. 230], it is shown that under the assumption that a wave is a deflagration and that across that wave, the mass fraction of gas always increases, the reaction is a weak deflagration. We will suppose that we are always in that case in the following.

The structure of the Riemann problem with weak deflagrations is drawn in Figure 8. The problem for deflagrations is that the Lax characteristic criterion is not satisfied (see [6, p. 154]), and the Riemann problem cannot be solved with only the classical relations across the sonic wave and the Rankine–Hugoniot relations across the subsonic wave. There remains one indeterminate. The supplementary relation needed is often called "the kinetic closure."

3. Application to the solution of the Riemann problem with vaporization.

3.1. Useful verifications for the use of CJ theory.

In this section, we check whether the inequalities needed for applying the CJ theory hold.

THEOREM 3.

1. *If both equations of state are convex and if* $\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0$, *then inequalities* (2.2a) *hold.*
2. *If* (P, τ) *lie in the saturation dome and under the condition*

$$\frac{\gamma}{\Gamma} - \frac{T}{P}\frac{\mathrm{d}P_{sat}}{\mathrm{d}T} > 0, \tag{3.1}$$

then the inequality (2.2b) *holds.*

Proof. According to the identity (1.7c), it is sufficient to have γ and $\Gamma > 0$. This is supposed for pure fluids, and this is ensured for the mixture equation of state if $\frac{\mathrm{d}P_{\mathrm{sat}}}{\mathrm{d}T} > 0$, and thus (2.2a) holds.

Let us now check if the inequality (2.2b) is ensured. We suppose that (P, τ) lie in the saturation dome, so that the corresponding equilibrium downstream state is a mixture,

$$\varepsilon_1(\tau, P) = \varepsilon_m(\tau, P) = y_l\varepsilon_l(P, \tau_l(P)) + (1 - y_l)\varepsilon_v(P, \tau_v(P)),$$

and we want to know if $\varepsilon_1(P, \tau) - \varepsilon_0(P, \tau) < 0$, the state 0 being, of course, described by the liquid equation of state. For this, we denote

$$\delta\varepsilon(y_l) = y_l\varepsilon_l(P, \tau_l(P)) + (1 - y_l)\varepsilon_v(P, \tau_v(P)) - \varepsilon_l(P, y_l\tau_l(P) + (1 - y_l)\tau_v(P)),$$

and we immediately see that $\delta\varepsilon(1) = 0$. It remains to show that $\delta\varepsilon$ is an increasing function:

$$\begin{aligned}\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}y_l}(y_l) =& \varepsilon_l(P, \tau_l(P)) - \varepsilon_v(P, \tau_v(P))\\ &-(\tau_l(P) - \tau_v(P))\left(\frac{\partial\varepsilon_l}{\partial\tau}\right)_P(P, y_l\tau_l(P) + (1 - y_l)\tau_v(P)).\end{aligned}$$

Integration of the identity $\mathrm{d}\varepsilon + P\mathrm{d}\tau = T\mathrm{d}s$ across the saturation dome leads to

$$\varepsilon_l(P, \tau_l(P)) - \varepsilon_v(P, \tau_v(P)) + P(\tau_l(P) - \tau_v(P)) = T(s_l(P) - s_v(P)),$$

so that

$$\begin{aligned}\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}y_l}(y_l) =& -P(\tau_l(P) - \tau_v(P)) + T(s_l(P) - s_v(P))\\ &-(\tau_l(P) - \tau_v(P))\left(\frac{\partial\varepsilon_l}{\partial\tau}\right)_P(P, y_l\tau_l(P) + (1 - y_l)\tau_v(P)),\end{aligned}$$

which can be cast into the following form, thanks to (1.5) and (1.7f):

$$\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}y_l}(y_l) = P(\tau_v - \tau_l)\left(\frac{\gamma}{\Gamma} - \frac{T}{P}\frac{\mathrm{d}P_{\mathrm{sat}}}{\mathrm{d}T}\right).$$

As $P > 0$, $\tau_v - \tau_l > 0$, and as (3.1), $\delta\varepsilon$ increases, so that $\delta\varepsilon \leq \delta\varepsilon(1) = 0$. Thus, (2.2b) holds. ∎

Remark 1. Supposing that (τ, P) is always in the saturation dome is not a strong assumption. Indeed, as the upstream state is slightly compressible, its specific volume cannot increase a lot across a sonic wave, and it is likely that a metastable liquid with a specific volume equal to that of a gas at equilibrium cannot exist, except just near the critical point.

Remark 2. The condition (3.1) holds at least in the following two frameworks:

1. The terms $\frac{\gamma}{\Gamma}$ and $\frac{T}{P}\frac{\mathrm{d}P_{\mathrm{sat}}}{\mathrm{d}T}$ can easily be compared near the saturation curve. Indeed, if we use (1.7b) with saturated variables, we find

$$\frac{T^2(\gamma g-\Gamma^2)}{P\tau}\frac{\mathrm{d}s_l}{\mathrm{d}T}=\frac{\gamma}{\Gamma}-\frac{T}{P}\frac{\mathrm{d}P_{\mathrm{sat}}}{\mathrm{d}T}, \tag{3.2}$$

so that we have $\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}T}(1)=(\tau_v-\tau_l)\,\frac{T^2}{\tau}\,\frac{\gamma g-\Gamma^2}{\Gamma}\,\frac{\mathrm{d}s_l}{\mathrm{d}T}$.
Thus, if the liquid saturation curve is regular (which is always the case), then $\frac{\mathrm{d}s_l}{\mathrm{d}T}>0$, so that condition (3.1) is ensured.

2. For a simple model, such as perfect gas or stiffened gas, we have

$$\frac{\gamma}{\Gamma}=\frac{\bar\gamma\left(1+\frac{P^\infty}{P}\right)}{\bar\gamma-1},$$

so that $\frac{\gamma}{\Gamma}$ does not depend on the specific volume. Thus, equality (3.2) holds for any τ, so that condition (3.1) always holds.

Remark 3. The same calculations can be made for liquefaction. Then we find that, near the vapor saturation curve,

$$\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}T}(1)=(\tau_l-\tau_v)\,\frac{T^2}{\tau}\,\frac{\gamma g-\Gamma^2}{\Gamma}\,\frac{\mathrm{d}s_v}{\mathrm{d}T}.$$

Thus, if the fluid is regular, then $\frac{\mathrm{d}s_v}{\mathrm{d}T}<0$, and as $\tau_l-\tau_v<0$, then $\frac{\mathrm{d}\delta\varepsilon}{\mathrm{d}T}(1)>0$, so that locally we have $\varepsilon_m-\varepsilon_v<0$ and the CJ theory can be used. If the fluid is retrograde, then we find that locally $\varepsilon_m-\varepsilon_v>0$ and the CJ theory may be used, but by exchanging the upstream and the downstream states. Note that the Hugoniot curves can enter the saturation dome only in the retrograde case.

The CJ theory also relies heavily on the convexity properties of the Crussard curve (see Property 2 of section 2), which are ensured if the fundamental derivative $\mathscr{G}$ is positive. Nevertheless, even if we suppose that the liquid and the gas equations of state have a positive fundamental derivative, the mixture equation of state can have a negative fundamental derivative, as was shown numerically in section 1.8. This nonpositivity of the fundamental derivative can lead to a wrong behavior of the Crussard curve as shown in Figure 9: the CJ points do not exist anymore, and all the undercompressive downstream states are strong deflagrations. If the sign of the fundamental derivative changed many times along the Crussard curve, we could expect to observe several CJ points. From now, we suppose that $\mathscr{G}>0$.

3.2. Entropy growth criterion. As the particles are crossing the front from the liquid area to a mixture or pure phase area, we have to check whether the entropy growth criterion is ensured, i.e., if the entropy of the downstream state (gas or mixture) is greater than the entropy of the upstream state (liquid). We first prove the following theorem.

THEOREM 4. *Let $s=s_0$ be a liquid isentrope that crosses the liquid saturation curve. To any metastable point (τ_0,P_0) on that isentrope, we map the point (τ_P,P_0), point of constant pressure deflagration (see Figure* 10*). If we suppose that*

$$\forall(\tau_0,P_0)\qquad \gamma(\tau_0,P_0)>\gamma(\tau_P,P_0), \tag{3.3}$$

then $s(\tau_P,P_0)>s_0$.

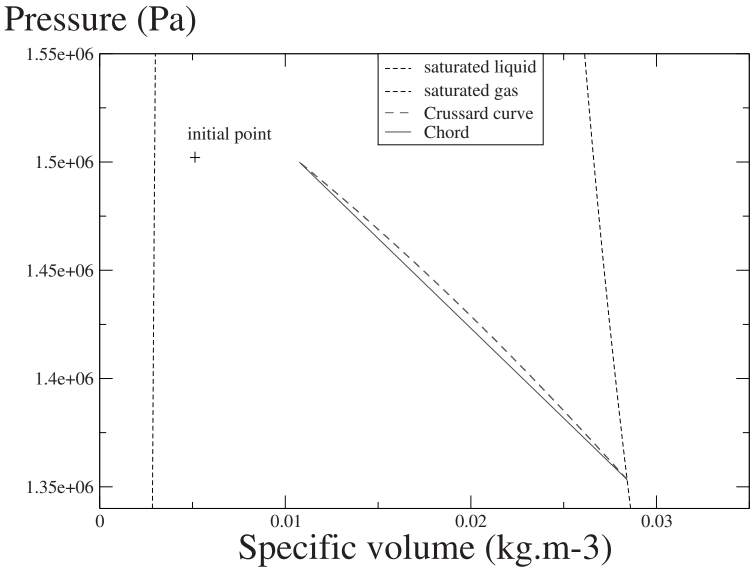

FIG. 9. *Wrong behavior of the mixture Crussard curve if the condition $\mathscr{G} > 0$ is violated. We notice that the Crussard curve is concave, which induces no existence of any CJ point. For a more complicated pair of equations of state, we could expect to observe two or three tangential points if the sign of $\mathscr{G}$ changed two or three times along the Crussard curve.*

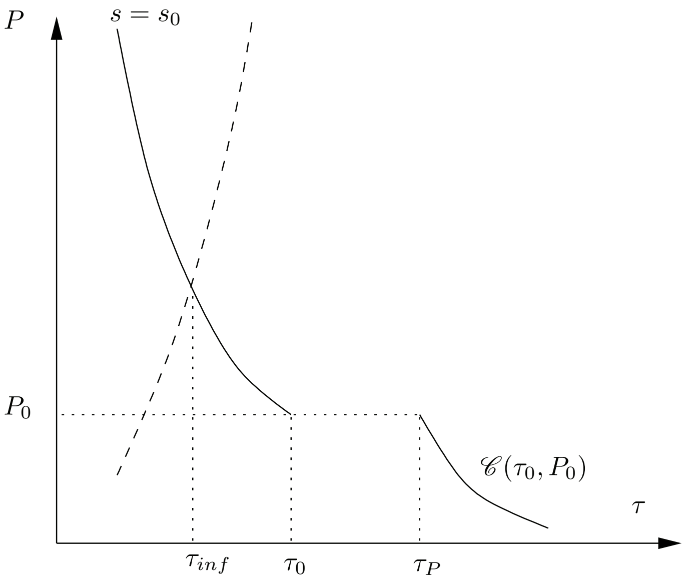

FIG. 10. *Entropy growth criterion. To any point (τ_0, P_0) on a given isentrope $s = s_0$, we associate the point on the Crussard curve (τ_P, P_0). The liquid saturation curve is drawn with dashed lines. When τ_0 is on the liquid saturation curve, we have $\tau_P = \tau_0$ so that $s_P = s_0$. Thus, to show that $s_P \geq s_0$, we only have to prove that entropy of the point P grows when τ_0 increases.*

Proof. To any point (τ_0, P_0) on this isentrope, we associate the point (τ_P, P_0), the point of constant pressure deflagration (see Figure 10). For greater convenience in notation, we suppose that (τ_P, P_0) is a mixture state (i.e., all the linked quantities have m). τ_P is defined by the implicit equation

$$\varepsilon_m(\tau_P, P_0) - \varepsilon_l(\tau_0, P_0) + P_0(\tau_P - \tau_0) = 0. \tag{3.4}$$

Differentiation of (3.4) with respect to τ_P is equal to $\frac{\gamma_m}{\Gamma_m}$, which never vanishes, so that according to the implicit function theorem, τ_P is a $\mathscr{C}^1$ function of τ_0 and P_0. Moreover, we can calculate its derivative with respect to τ_0 and P_0:

$$\begin{cases} \left(\dfrac{\partial \tau_P}{\partial \tau_0}\right)_{P_0} = \dfrac{\gamma_l}{\gamma_m}\dfrac{\Gamma_m}{\Gamma_l}, \\ \left(\dfrac{\partial \tau_P}{\partial P_0}\right)_{\tau_0} = \dfrac{\tau_0}{\gamma_m P_0}\left(\dfrac{\Gamma_m(\Gamma_l+1)}{\Gamma_l} - \dfrac{\tau_P}{\tau_0}(\Gamma_m+1)\right). \end{cases}$$

Besides, as we supposed that the points (P_0, τ_0) belong to the same isentrope, P_0 is actually a function of τ_0 with $\frac{\mathrm{d}P_0}{\mathrm{d}\tau_0} = -\frac{\gamma_l P_0}{\tau_0}$, so that τ_P is a function of the only variable τ_0 and

$$\begin{aligned} \frac{\mathrm{d}\tau_P}{\mathrm{d}\tau_0} &= \left(\frac{\partial \tau_P}{\partial \tau_0}\right)_{P_0} + \frac{\mathrm{d}P_0}{\mathrm{d}\tau_0}\left(\frac{\partial \tau_P}{\partial P_0}\right)_{\tau_0} \\ &= \frac{\gamma_l}{\gamma_m}\left(-\Gamma_m + \frac{\tau_P}{\tau_0}(\Gamma_m+1)\right). \end{aligned}$$

Now, we calculate the entropy variation of the point τ_P when the point (P_0, τ_0) follows the isentrope $s = s_0$:

$$\begin{aligned} \frac{\mathrm{d}s}{\mathrm{d}\tau_0} &= \frac{\mathrm{d}\tau_P}{\mathrm{d}\tau_0}\left(\frac{\partial s}{\partial \tau}\right)_P + \frac{\mathrm{d}P_0}{\mathrm{d}\tau_0}\left(\frac{\partial s}{\partial P}\right)_\tau \\ &= \frac{\gamma_m P_0}{T\Gamma_m}\left(\frac{\gamma_l \Gamma_m}{\gamma_m}\left(\frac{\tau_P}{\tau_0} - 1\right) + \frac{\tau_P}{\tau_0}\left(\frac{\gamma_l}{\gamma_m} - 1\right)\right). \end{aligned}$$

According to the hypothesis (3.3), $\gamma_l > \gamma_m$. Moreover, as we have $\tau_P - \tau_0 > 0$, s is an increasing function of τ_0. Furthermore, in the limit of no overheating, we have

$$\lim_{\tau_0 \to \tau_{\mathrm{inf}}} \tau_P(\tau_0, P_0) = \tau_{inf},$$

where τ_{inf} is the crossing point of the isentrope $s = s_0$ with the saturation curve. Thus $\lim\limits_{\tau_0 \to \tau_{\mathrm{inf}}} s(\tau_P, P_0) = s_0$. As a conclusion,

$$\forall \tau_0 \geq \tau_{inf} \qquad s(\tau_P, P_0) \geq s_0,$$

which ends the proof. □

Remark (about the hypothesis (3.3)*).*

1. We know that near the saturation curve, we have $\gamma_l > \gamma_m$. For actual data, we have $\gamma_l \gg \gamma_m$. Thus we can suppose that any γ is greater than any γ_m.
2. $\gamma_l > \gamma_v$ just means that the liquid phase is very much less compressible than the gas phase (see, e.g., [22, Chapter XI]).

Given an initial point, we know that the entropy grows from the constant pressure point to the CJ point, so that if the entropy growth criterion holds for the constant pressure deflagration point, it holds for all the downstream states between the constant pressure deflagration point and the CJ point; i.e., we have the following corollary.

Corollary 1. *Under the same hypothesis as in Theorem* 4*, the entropy growth criterion holds for all the weak deflagration points.*

3.3. Behavior of the Crussard curve near the gas saturation curve. In section 1.5, the behavior of the isentropes near the saturation curves was studied. The difference of the differential behavior of the pure phase and the mixture equation of state induced kinks in isentropes. Now we want to study the behavior of the Crussard curve when it crosses the vapor saturation curve. It is more difficult than the study of the isentrope, because the Crussard curve depends not only on the local variables, but also on the starting point (τ_0, P_0).

3.3.1. General study. We denote by C the point at which the Crussard curve crosses the saturation curve, and by

$$\zeta = -\frac{\tau}{P}\frac{\mathrm{d}P}{\mathrm{d}\tau}_{|\mathscr{C}}$$

the adimensioned slope of the Crussard curve.

The first thing we will prove for the behavior of the Crussard curve near the saturation curve is that it can be parameterized by τ under some conditions.

Theorem 5. *If all the equations of state are convex and if* $\Gamma > 0$*, then* $\zeta > 0$*. With the same hypothesis, the Crussard curve can be parameterized by* τ*, even near the saturation curve.*

Proof. As proved in [12, p. 101], we have

$$\zeta = \frac{\frac{\gamma}{\Gamma} - \frac{\Delta P}{2P}}{\frac{1}{\Gamma} + \frac{\Delta\tau}{2\tau}}. \tag{3.5}$$

Across a deflagration wave, we have $\Delta\tau > 0$ and $\Delta P < 0$. Moreover, we proved that $\Gamma_m > 0$, and we suppose that $\Gamma > 0$. The conditions $\gamma > 0$ and $\gamma_m > 0$ were already supposed to ensure the convexity of the specific energy. Then $\zeta > 0$. If we combine (3.5) with the identities near the saturation boundary of section 1.5, we get

$$\frac{\xi - \zeta}{\Gamma}\left(1 + \Gamma\frac{\Delta\tau}{2\tau}\right) = \frac{\xi - \zeta_m}{\Gamma_m}\left(1 + \Gamma_m\frac{\Delta\tau}{2\tau}\right). \tag{3.6}$$

Across a deflagration, we have $\Delta\tau > 0$. Then

$$\frac{\xi - \zeta}{\xi - \zeta_m} > 0,$$

which means that the Crussard curve, near a boundary, can be parameterized by τ. As $\zeta > 0$, the Crussard curve is a diffeomorphism of τ in each side of the saturation curve. As the Crussard curve can locally parameterize the Crussard curve near a boundary, we conclude that the Crussard curve is a homeomorphism of τ. □

Remark. As the Crussard curve is a decreasing homeomorphism in τ, the point of constant pressure deflagration is uniquely defined.

To be more precise on the relative behavior of the isentropes, the Crussard curve, and the saturation curve, we will prove that the following theorem holds.

Theorem 6. *The relative behavior of the isentropes and the Crussard curves, which gives the nature of the deflagration on each side of the saturation curve, follows the alternative*

- *if $\gamma > \xi$, then*
  - *either $\xi \geq \zeta$ (Case 1), and the deflagration is weak on both sides of the saturation curve,*
  - *or $\xi < \zeta$ (Case 2), and point C cannot be a weak deflagration simultaneously on both sides of the saturation curve;*
- *if $\gamma < \xi$, then*
  - *either $\xi \leq \zeta$ (Case 3), and the deflagration is strong on both of the sides of the saturation curve,*
  - *or $\xi > \zeta$ (Case 4), and the deflagration cannot be simultaneously strong on the mixture side and weak on the pure phase side.*

Proof. Equation (3.6) can be rewritten as

$$\frac{\xi - \zeta}{\xi - \zeta_m} = \frac{\frac{1}{\Gamma_m} + \frac{\Delta\tau}{2\tau}}{\frac{1}{\Gamma} + \frac{\Delta\tau}{2\tau}}$$

so that the discontinuity in the slope of the Crussard curve is directly linked with the sign of $\Gamma_m - \Gamma$ (we recall that $\Gamma_m > 0$ and that Γ has the same sign as Γ_m near the saturation curves). Equation (1.14) induces a separation into the following cases:

- $\gamma > \xi$.
  If $\gamma > \xi$ then we also have $\gamma_m > \xi$. As $\gamma_m < \gamma$, we have $\frac{\gamma_m - \xi}{\gamma - \xi} \leq 1$, so that $\Gamma_m \leq \Gamma$. Therefore

  $$\frac{\xi - \zeta}{\xi - \zeta_m} \geq 1.$$

  Suppose first that $\xi - \zeta \geq 0$ (Case 1). Then $\xi - \zeta \geq \xi - \zeta_m$ so that $\zeta \leq \zeta_m \leq \xi$. In that case, as shown in Figure 11, the relative behavior of the isentrope and the Crussard curve shows that on both sides of the saturation curve, the downstream state is a weak deflagration (see Figure 11). In that case, we have $\zeta \leq \zeta_m \leq \xi \leq \gamma_m \leq \gamma$.
  Suppose now that $\xi - \zeta \leq 0$ (Case 2). Then we have $\xi \leq \zeta_m \leq \zeta$. The nature of the deflagration is given by the relative position of the slope of the Crussard curve and the Rayleigh line, so that on the point saturation curve, there are three subcases (see Figure 12):
  - If the Rayleigh line has a lower slope than both of the slopes of the Crussard curve, then the two parts match with strong deflagrations. Thus, we have $\gamma_m \leq \zeta_m$ and $\gamma \leq \zeta$ (see Figure 12(a)).
  - If the slope of the Rayleigh line is between the slopes of the Crussard curve, then the mixture Crussard curve matches with strong deflagrations, whereas the pure phase Crussard curve matches with weak deflagrations. In that case, we have $\gamma_m \leq \zeta_m$ and $\gamma \geq \zeta$ (see Figure 12(b)). In that case we have $\xi \leq \zeta_m \leq \gamma_m \leq \gamma \leq \zeta$.
  - If the Rayleigh line has a greater slope than both of the slopes of the Crussard curve, then point C is a weak deflagration with respect to the pure and the mixture Crussard curves. Therefore, we have $\gamma_m \geq \zeta_m$ and $\gamma \geq \zeta$ (see Figure 12(c)).

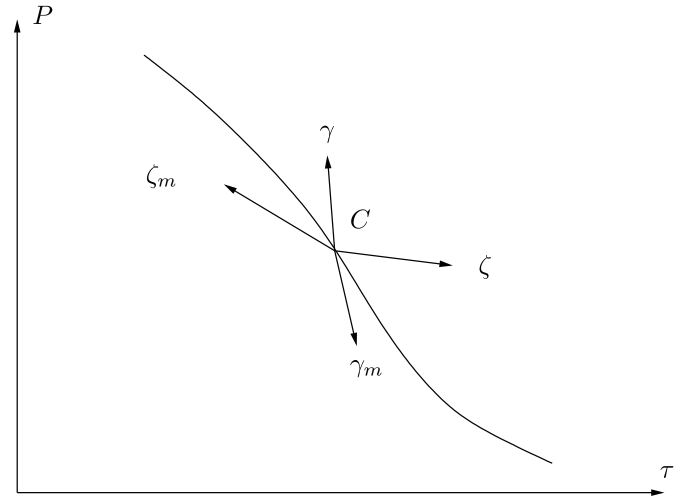

FIG. 11. *Qualitative relative behavior of the isentrope and of the Crussard curve when they cross the vapor saturation curve in the Case* 1. *Arrows represent the half-tangent of the Crussard curve (ζ) and of the isentrope (γ).*

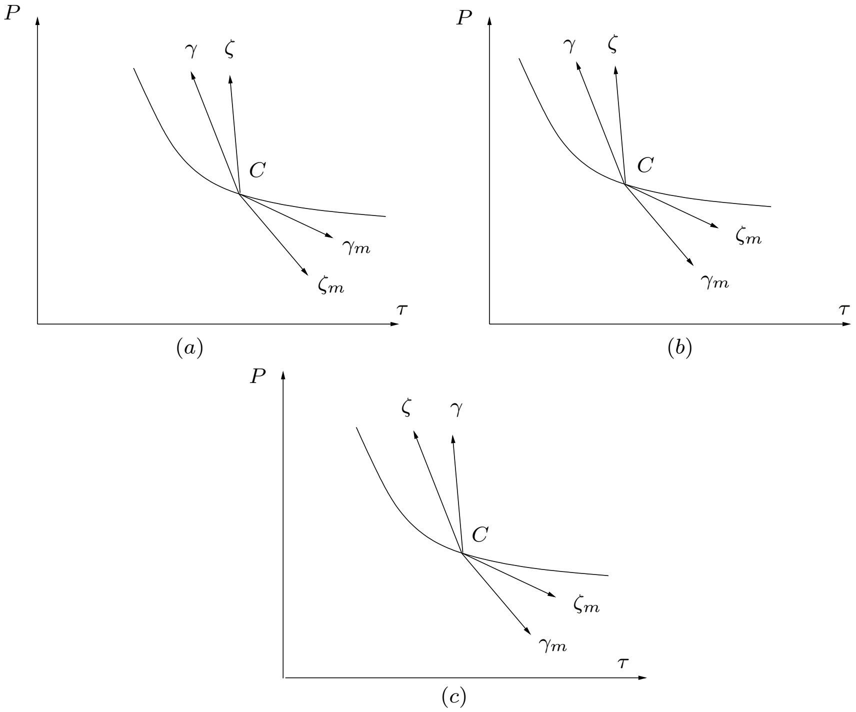

FIG. 12. *Qualitative relative behavior of the isentrope and of the Crussard curve when they cross the vapor saturation curve, Case* 2. *Arrows represent the half-tangent of the Crussard curve (ζ) and of the isentrope (γ).*

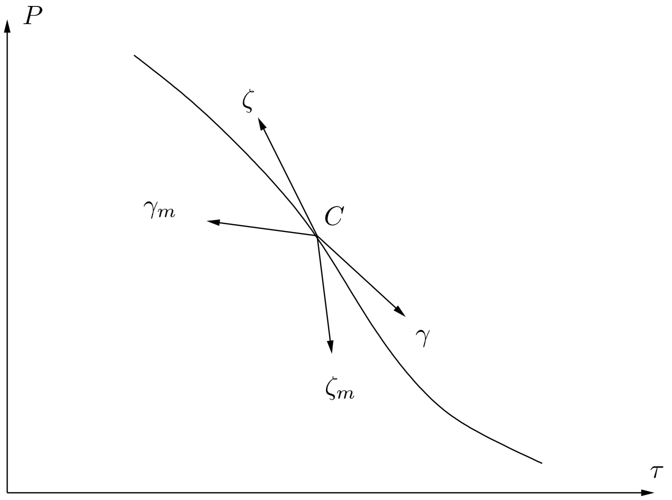

FIG. 13. *Qualitative relative behavior of the isentrope and of the Crussard curve when they cross the vapor saturation curve, Case* 3. *Arrows represent the half-tangent of the Crussard curve* (ζ) *and of the isentrope* (γ).

- $\gamma < \xi$.

  If $\gamma < \xi$, then we also have $\gamma_m < \xi$. As we know that $\gamma_m \leq \gamma$, we have $\frac{\gamma_m - \xi}{\gamma - \xi} \geq 1$, so that $\Gamma_m \geq \Gamma$ (thanks to (1.14)). Therefore

  $$\frac{\xi - \zeta}{\xi - \zeta_m} \leq 1.$$

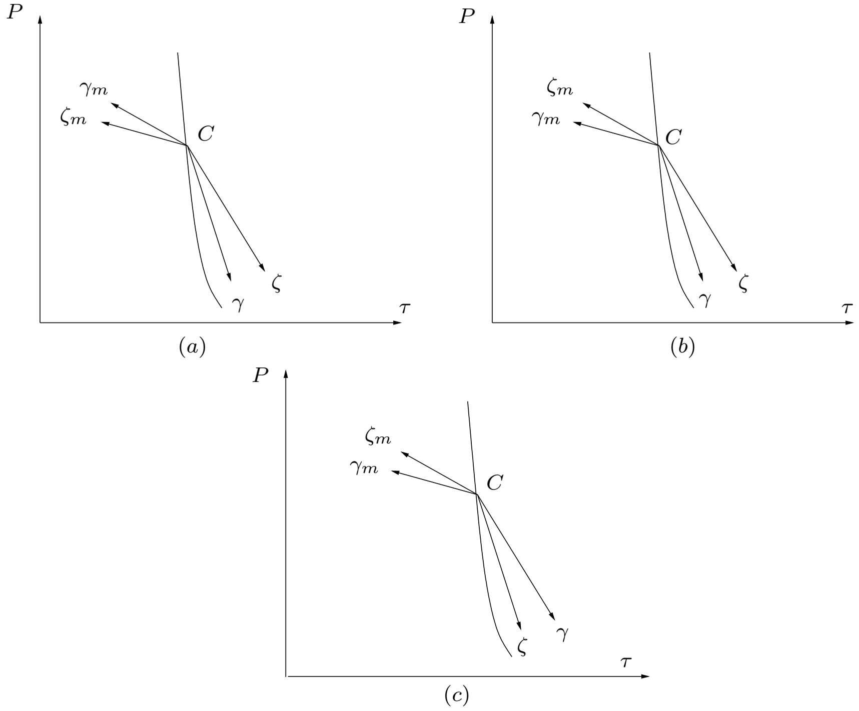
  We suppose first that $\xi - \zeta \leq 0$ (Case 3). Then we immediately have $\zeta \leq \zeta_m$. Thus, we have $\gamma_m \leq \zeta_m$ and $\gamma \leq \zeta$, so that point C matches on both sides of the Crussard curve with strong deflagrations (see Figure 13). In that case we have $\zeta_m \leq \zeta \leq \xi \leq \gamma \leq \gamma_m$.

  We suppose now that $\xi - \zeta \geq 0$ (Case 4). Then we have $\zeta_m \leq \zeta \leq \xi$. The nature of the deflagration is given by the relative position of the slope of the Crussard curve and the Rayleigh line, so that three subcases may happen (see Figure 14):

  - If the Rayleigh line has a lower slope than the slopes on both sides of the Crussard curve in C, then point C is a weak deflagration with respect to the mixture and the pure phase Crussard curve. We then have $\gamma \leq \zeta$ and $\gamma_m \leq \zeta_m$ (see Figure 14(a)).
  - If the slope of the Rayleigh line is between the slopes on each side of the Crussard curve, then point C is a strong deflagration for the mixture Crussard curve and a weak deflagration for the pure phase Crussard curve (see Figure 14(b)). In that case we have $\gamma_m \leq \zeta_m \leq \zeta \leq \gamma \leq \xi$.
  - If the Rayleigh line has a lower slope than both of the slopes of the Crussard curve, then point C is a strong deflagration with respect to the pure and the mixture Crussard curve. Therefore, we have $\gamma_m \geq \zeta_m$ and $\gamma \geq \zeta$ (see Figure 14(c)).

This ends the proof. □

3.3.2. Ill-posedness of the CJ closure. The following result comes immediately from Theorem 6.



(*a*) (*b*) (*c*)

FIG. 14. *Qualitative relative behavior of the isentrope and of the Crussard curve when they cross the vapor saturation curve, Case 4. Arrows represent the half-tangent of the Crussard curve (ζ) and of the isentrope (γ).*

COROLLARY 2. *Let (P_0, τ_0, u_0) be an initial state of liquid at thermodynamic equilibrium, such that the isentrope $\mathscr{C}_s$ coming from this point enters the saturation dome. If $(P_0^\star, \tau_0^\star)$ is a point in $\mathscr{C}_s$, we build $(P^\star, \tau^\star)$ in the following way:*

- *if $(P_0^\star, \tau_0^\star)$ is not in the saturation dome, then $P^\star = P_0^\star$ and $\tau^\star = \tau_0^\star$;*
- *if $(P_0^\star, \tau_0^\star)$ is in the saturation dome, then it is linked with $(P^\star, \tau^\star)$ with a CJ deflagration.*

If $(P^\star, \tau^\star)$ can reach the pure gas phase, then the curve $(P^\star, \tau^\star)$ is discontinuous.

Proof. We suppose that the set described is continuous. As $(P^\star, \tau^\star)$ can reach the saturation dome, it crosses the gas saturation curve at a point (P_c, τ_c). As it is a CJ point, we have $\gamma_m = \zeta_m$, so that we are in Case 4 in Figure 14. The third subcase of Case 4 is excluded because the Rayleigh line is tangential with the Crussard curve, so that the slope of the Rayleigh line is greater than the slope of the Crussard curve in the pure phase side. Thus, the point $\star$ matches with a weak deflagration with respect to the pure phase Crussard curve. As a consequence, the Crussard curve has another CJ point that lies in the pure phase area (see Figure 15), so that the curve $\mathscr{C}_{CJ}$ even has a branch in the pure gas area. $\square$

Eventually, we can state the following theorem.

THEOREM 7. *With the same hypothesis of Corollary 2, if we model the vaporization wave by a CJ deflagration, then the resulting solution of the Riemann problem is ill-posed in the L^1 sense: the solution does not depend continuously on the initial state.*

Proof. We fix a point for $x < 0$ in the liquid area for which the conditions of Corollary 2 hold, and we suppose that on the right, there is some gas. The Riemann

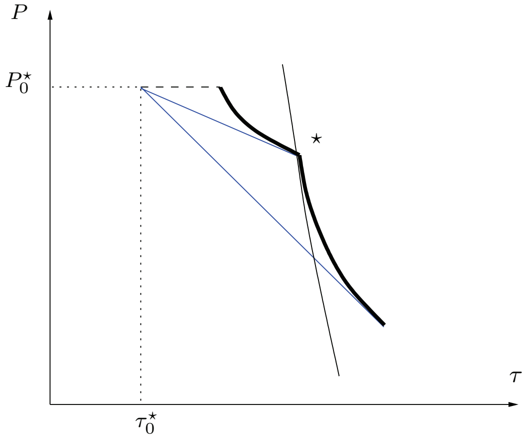


FIG. 15. *Qualitative behavior of the Rayleigh line and the Crussard curve when the Crussard curve crosses the saturation curve on a mixture CJ point. As $\zeta_m \le \zeta$, and as the Rayleigh line is tangential to the mixture Crussard curve, we are in the third subcase of Case* 4 *of the proof of Theorem* 6*. As a consequence, the pure phase side matches with a weak deflagration, too, so that there exists another CJ point.*

problem is composed (from left to right) of a sonic wave, a vaporization wave (if the intermediate state is metastable), a contact discontinuity (across which P and u are constant), and a sonic wave on the gas side. As is usually done [6], to solve the Riemann problem, we intersect the wave curve of the downstream state (sonic wave and maybe followed by a CJ vaporization) of the left side with the wave curve of the sonic wave of the right side, in the plane (P, u). Corollary 2 says that the wave curve of the left side is composed of (at least) two branches (see Figure 16). So that the gas wave curve intersects the liquid wave curve either in one mixture point (case (I)), or in two points (case (II)), or in one pure gas point (case (III)). Existence of case (I) and case (III) implies that we must jump from the mixture to the gas branch of the

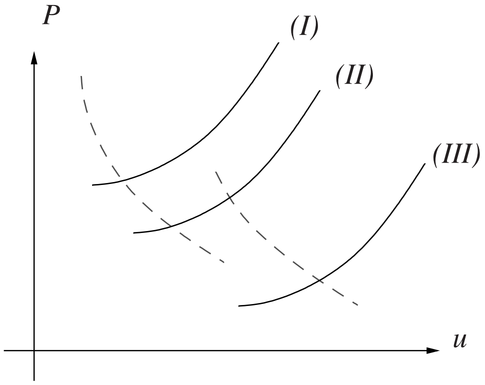

FIG. 16. *Dashed lines: the wave curve of the liquid side. Solid lines: different wave curves for the gas side, depending on the initial state. In case* (I)*, the gas wave curve intersects the liquid one in one mixture point. In case* (II)*, the gas wave curve intersects the liquid curve in the two branches: one mixture and one pure gas point. In case* (III)*, the gas wave curve intersects the liquid curve only on the pure phase branch.*

liquid wave curve. However, jumping from one branch to the other means that we significantly change the vaporized state (thus the L^1_{loc} norm, too) but hardly change the initial state. □

We finish this paper by drawing the curve $\mathscr{C}_{CJ}$ described in Corollary 2 for models we dealt with in section 1.

Example 1: The two perfect gas model.

As an example, we take the two perfect gas model. As we said before, this model enables us to make all the calculations, because the mixture equation of state is explicit.

- *Mixture CJ point.*
  In the case when the downstream state is a mixture, the equation of the Crussard curve is the following:

  $$\frac{P\tau_2}{\Gamma_2} - \frac{P_0\tau_0}{\Gamma_2} + \frac{1}{2}(P+P_0)(\tau-\tau_0) = 0,$$

  which gives an expression of τ as a function of P: $\tau = \tau_0 - \frac{2(P\tau_2 - P_0\tau_0)}{\Gamma_2(P+P_0)}$. The CJ point is such that $\frac{\mathrm{d}\tau}{\mathrm{d}P}(P_{CJ}) = \frac{\tau-\tau_0}{P-P_0}$, so that we find the following equation for P_{CJ}:

  $$\left(\frac{P}{P_0}\right)^2 - 2\frac{\tau}{\tau_0}\frac{P}{P_0} + 1 = 0,$$

  whose undercompressive solution is

  $$P_{CJ} = P_0\left(\frac{\tau_0}{\tau_2} - \sqrt{\left(\frac{\tau_0}{\tau_2}\right)^2 - 1}\right).$$

  τ_{CJ} is then given by

  $$\tau_{CJ} = \tau_2\left(\frac{\tau_0}{\tau_2} + \frac{2\sqrt{\frac{\tau_0}{\tau_2} - 1}}{\Gamma_2\left(\frac{\tau_0}{\tau_2} + 1 - \sqrt{\left(\frac{\tau_0}{\tau_2}\right)^2 - 1}\right)}\right).$$

  Of course, this point can be chosen only when the mixture is stable, that means, when $\tau_{CJ} \leq \tau_1$.
- *Vapor CJ point.*
  The equation of the Crussard curve is then

  $$\frac{\tau P}{\Gamma_1} - \frac{\tau_0 P_0}{\Gamma_2} + \frac{1}{2}(P+P_0)(\tau-\tau_0) = 0.$$

  As in [10], we first calculate the point of constant specific volume detonation, i.e., the downstream state such as $\tau = \tau_0$: $P_\tau = \frac{\Gamma_1}{\Gamma_2}P_0$. If we take the calculations of [10], we get

  $$P_{CJ} = \frac{\Gamma_1 P_0}{\Gamma_2}\left(1 - \sqrt{\left(1 - \frac{\Gamma_2}{\Gamma_1}\right)\left(1 + \frac{\Gamma_2}{\Gamma_1} + \frac{2\Gamma_2}{\Gamma_1(\gamma_1+1)}\right)}\right).$$

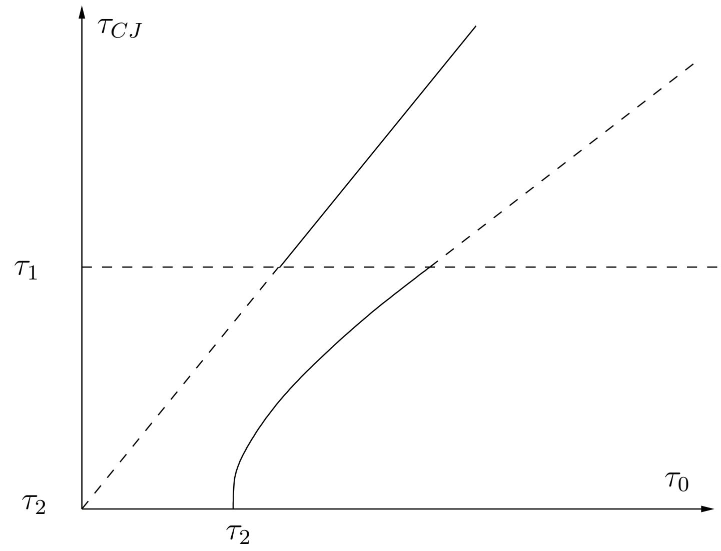

FIG. 17. *Qualitative behavior of the mixture and the vapor CJ points for the two perfect gas model. The horizontal dashed line represents the vapor saturation curve. The increasing line (dashed line, then solid line) is the set of the CJ points for the vapor equation of state. The other function (solid line, then dashed line) is the set of the mixture CJ points. The solid lines of the curves correspond to the part in which they match with the equation of state used.*

We remark that P_{CJ} is a linear function of P_0. If we use the equation of the Crussard curve, we get the following expression for τ_{CJ}:

$$\tau_{CJ} = \tau_0 \frac{\frac{\gamma_2+1}{\gamma_2-1} P_0 + P_{CJ}}{\frac{\gamma_1+1}{\gamma_1-1} P_{CJ} + P_0}.$$

As P_{CJ} is a linear function of P_0, we see that τ_{CJ} is a linear function of τ_0.

The CJ point of pure vapor can be chosen only when $\tau_{CJ} \geq \tau_1$.

The two functions τ_{CJ}, for the vapor and mixture equations of state, are drawn in Figure 17, highlighting the fact that they cannot be linked continuously.

Example 2: The two stiffened gas model.

As already mentioned, the mixture equation of state cannot be computed when we deal with the two stiffened gas model. Therefore we can show only a numerical computation as an illustration. We chose the model of dodecane for which coefficients lie in Table 2. We begin on the point $P_0 = 900000\,\text{Pa}$ with a specific volume of $\tau_0 = 0.0025\,\text{kg.m}^{-3}$. We compute all the states $0^\star$ that can be linked with that initial point via an isentrope. If the state $0^\star$ is overheated (i.e., lies in the saturation dome), then we compute the CJ point(s) corresponding to a mixture downstream state and/or to a pure vapor downstream state. Numerical results are in Figure 18.

4. Conclusion. In section 1 we studied the model with two convex equations of state. In particular, we gave a necessary and sufficient condition for the convexity of the mixture equation of state resulting from an entropy optimization:

$$\frac{\mathrm{d}P_{\text{sat}}}{\mathrm{d}T} > 0.$$

Then we proposed to take into account metastable states in the solution of the Riemann problem. For that, we used the CJ theory. We first proved that this theory

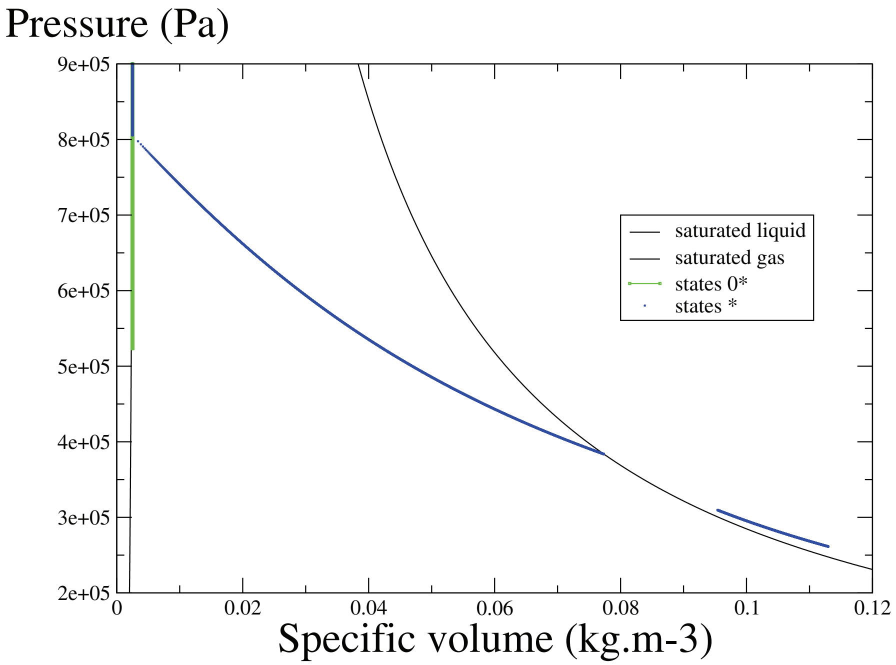

FIG. 18. *Set of all the CJ points that can be reached from a given point. The isentrope is drawn in green and is nearly vertical. In blue, the set of all the CJ points is drawn, showing a jump between the mixture CJ points and the pure vapor CJ point.*

can be applied. We emphasized the link between whether the metastable states are overheated or overcooled and the retrograde or regular behavior of the fluid. In one particular case, when γ/Γ does not depend on τ, the condition of regular behavior of the fluid is necessary and sufficient to ensure that the energy of a metastable liquid is lower than the energy of a mixture at thermodynamic equilibrium with the same pressure and specific volume.

For the entropy growth condition, we proved that it is ensured provided that $\gamma_l > \gamma_m$ and $\gamma_l > \gamma_v$.

The problem with the deflagration waves is that the Lax characteristic criterion is not ensured, so that the problem is underdeterminated. The only thing that we can state with no further hypothesis is that the set of all the downstream states lies in an area limited on the top by the set of all the constant pressure deflagrations, which is continuous, and limited below by the set of all the CJ points, which was proved to be discontinuous thanks to a detailed study of the behavior of the Crussard curve near the saturation curve. As the set of all the CJ points is discontinuous, the use of the CJ closure as in [10] for solving the Riemann problem leads to a solution that does not depend continuously on its initial data in general. A first step in finding a right kinetic closure would be, for example, to study traveling waves for a relaxation model as given in [3]. As we know that liquid-vapor phase transition is governed by a competition between relaxation phenomena and thermal conduction, it would be more relevant (but much harder) to study traveling waves with a relaxation model and thermal conductivity.

Acknowledgment. The author would like to thank Siegfried Müller from the Institut für Geometrie und Praktische Mathematik (Aachen, Germany) for profitable discussions on the Riemann problem with phase transition at thermodynamic equilibrium.

SELF-SIMILAR SOLUTIONS FOR THE TRIPLE POINT PARADOX IN GASDYNAMICS*

ALLEN M. TESDALL[†], RICHARD SANDERS[‡], AND BARBARA L. KEYFITZ[†]

Abstract. We present numerical solutions of a two-dimensional Riemann problem for the compressible Euler equations that describes the Mach reflection of weak shock waves. High resolution finite volume schemes are used to solve the equations formulated in self-similar variables. We use extreme local grid refinement to resolve the solution in the neighborhood of an apparent but mathematically inadmissible shock triple point. The solutions contain a complex structure: instead of three shocks meeting in a single standard triple point, there is a sequence of triple points and tiny supersonic patches behind the leading triple point, formed by the reflection of weak shocks and expansion waves between the sonic line and the Mach shock. An expansion fan originates at each triple point, resolving the von Neumann triple point paradox.

Key words. triple point paradox, von Neumann paradox, self-similar solutions

1. Introduction.

Consider a plane normal shock in an inviscid, compressible, perfect gas which hits a fixed wedge with half angle θ_w, as depicted in Figure 1. For a given upstream state with density $\rho = \rho_r$, velocity $\mathbf{u} = (u, v) = (0, 0)$, and pressure $p = p_r$, the fluid properties downstream of a *fast* (i.e., $u + c$) shock are given by

$$\frac{\rho_l}{\rho_r} = \frac{(\gamma+1)\,M^2}{2+(\gamma-1)\,M^2}, \qquad \frac{u_l}{c_r} = \frac{2}{\gamma+1}\left(M - \frac{1}{M}\right), \qquad \frac{p_l}{p_r} = \frac{2\gamma}{\gamma+1}M^2 - \frac{\gamma-1}{\gamma+1}, \tag{1.1}$$

where γ is the ratio of specific heats and $M > 1$ is the shock Mach number, defined as the shock speed given by the Rankine–Hugoniot relations divided by the upstream sound speed $c_r = \sqrt{\gamma p_r/\rho_r}$. Following interaction of the shock with the wedge wall, a number of self-similar reflection patterns are possible, depending on the values of M and θ_w. The simplest pattern is *regular reflection*, in which there is a single reflected shock, depicted in Figure 1(a). For small wedge angles or strong shocks, regular reflection is replaced by *Mach reflection.* The simplest type of Mach reflection is called single Mach reflection, in which the incident and reflected shocks move off the wedge and a single shock called the Mach stem extends down to the wall; see Figure 1(b). The point where the three shocks meet is called the triple point, and a contact discontinuity also originates there.

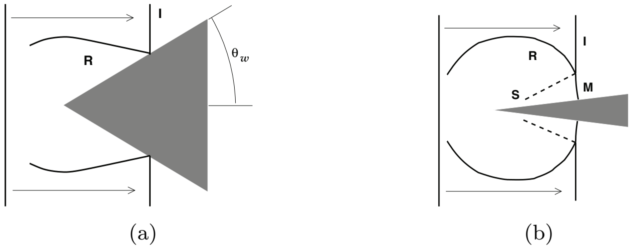

Fig. 1. *A planar shock moving from left to right impinges on a wedge. After contact, I indicates the incident shock and R indicates the reflected shock. Regular reflection is depicted in* (a) *and Mach reflection in* (b). *In* (b), *the dotted line S indicates a contact discontinuity and M is the Mach stem.*

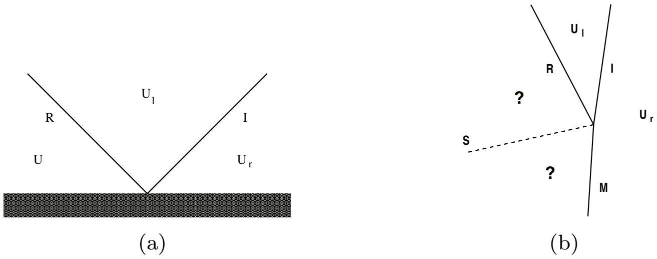

Fig. 2. *An enlargement of the incident and reflected shock intersections in Figure* 1. *Regular reflection is depicted in* (a) *and Mach reflection in* (b). *The constant states upstream and downstream of the incident shock are denoted by U_r and U_l. Whether or not constant states indicated by the question marks in* (b) *exist depends on the strength of I.*

The basic equations that describe regular and Mach reflection were formulated by von Neumann in 1943 [10] and are known as two-shock and three-shock theory, respectively. His analysis is based on the assumption that Mach reflection solutions can be locally approximated by constant states separated by plane discontinuities (this is also true, in a finite neighborhood, for flows that are supersonic at the reflection point; see Figure 2 for an illustration of this assumption). The oblique shock relations of gasdynamics connect the constant states. To explain transition between regular and Mach reflection, von Neumann suggested several criteria. For weak incident shocks he proposed that transition occurs at the detachment angle, which is a function of M. For a shock with a given M impinging on a wedge, when the wedge angle is larger than the detachment angle there are two regular reflection solutions, one with a strong reflected shock and one with a weak reflected shock (only the weak reflected shock solution is observed experimentally). At the detachment angle the two solutions coalesce, and for smaller wedge angles there is no regularly reflected solution. This is a possible condition for transition but has not been definitively established. Several criteria for transition can be obtained using von Neumann's approach; see Henderson [7] for a detailed discussion.

Good agreement between the von Neumann theory and experiment is obtained for regular and Mach reflection for a wide range of conditions. For sufficiently weak shocks, however, application of the three-shock theory indicates that triple point solutions such as those depicted in Figure 2(b) do not exist. Transition from regular to Mach reflection is impossible, and the theory is unable to predict what kind of reflection does occur for weak shocks reflecting off thin wedges. However, experiments in which a very weak shock reflects off a thin wedge appear to show a pattern of reflection containing three shocks meeting at a triple point. This discrepancy is referred to as the von Neumann, or triple point, paradox.

Over the years, a number of ways to resolve the paradox have been proposed. A singularity could occur in the solution behind the triple point [15] or in the reflected shock curvature at the triple point [14], so that a local approximation of the solution by plane waves separated by constant states is invalid; there could be an unobserved fourth shock at the triple point [6]; or the reflected shock could decay into a continuous wave before hitting the incident shock, so that there is no triple point [4]. In 1947 Guderley [5] proposed the existence of an expansion fan and a supersonic region behind the triple point in a steady weak shock Mach reflection (the same triple point paradox occurs in the case of steady flow as in unsteady reflection off a wedge). He demonstrated that one could construct local solutions consisting of three plane shocks, an expansion fan, and a contact discontinuity meeting at a point. However, despite intensive study, no evidence of an expansion fan or a supersonic patch was seen either in experiments (see, for example, [1, 11, 14]) or in numerical solutions (see [4, 2, 15]).

The first indication that Guderley's proposed resolution might be essentially correct was contained in numerical solutions of shock reflection problems for the unsteady transonic small disturbance equations (UTSDE) in [8] and the compressible Euler equations in [18]. Solutions containing a supersonic patch embedded in the subsonic flow directly behind the triple point in a weak shock Mach reflection were presented there. Subsequently, Zakharian et al. [19] found a supersonic region in a numerical solution of the compressible Euler equations. The supersonic region in all of these solutions is extremely small, explaining why it had never been observed before, experimentally or numerically.

The supersonic patches obtained in the solutions in [8, 18, 19] appeared to confirm Guderley's four wave solution. The patch indicates that it is plausible for an expansion fan to be an unobserved part of the observed three-shock confluence, since the flow must be supersonic for an expansion wave to occur. However, these solutions are not sufficiently well resolved to show the structure of the flow inside the supersonic region. In [16] numerical solutions were obtained of a problem for the UTSDE that describes the reflection of weak shocks off thin wedges, with the equations formulated in special self-similar variables. The advantage of using self-similar coordinates is that the point of interest remains fixed on the computational grid, and a steady self-similar solution is obtained by letting a pseudotime $t \to \infty$. In a parameter range for which regular reflection is impossible, the solutions contain a remarkably complex structure: there is a sequence of triple points and tiny supersonic patches immediately behind the leading triple point, formed by the reflection of weak shocks and expansion fans between the sonic line and the Mach shock. A centered expansion fan originates at each triple point. It was shown that the triple points with expansion fans observed numerically are consistent with theory and resolve the paradox. The term *Guderley Mach reflection* was chosen in [9] to name this new reflection pattern.

Following the detection of Guderley Mach reflection in [16], a problem for the nonlinear wave system that is analogous to the reflection of weak shocks off thin wedges was studied numerically in [17]. The nonlinear wave system is a simple 3×3 hyperbolic system which resembles the Euler equations, but is not obtained from them via a limit, and which has no known physical relevance. It is obtained from the isentropic Euler equations by dropping the momentum transport terms from the momentum equations, and it has a characteristic structure similar to that of the compressible

Euler equations: nonlinear acoustic waves coupled (weakly) with linearly degenerate waves. In a parameter range where regular reflection is not possible, a numerical solution of this system formulated in self-similar variables was obtained which again contains a sequence of triple points in a tiny region behind the leading triple point, with a centered expansion fan originating at each triple point. This solution is very similar in pattern to those obtained for the UTSDE. The discovery of Guderley Mach reflection in a solution of this system leads one to expect that a sequence of supersonic patches and triple points is a generic feature of two-dimensional Riemann problems for some class of hyperbolic conservation laws. This class is possibly characterized by "acoustic waves," as defined in [3]. The compressible Euler system for gasdynamics is another member of this class, suggesting that weak shock solutions of the Euler equations—the subject of the present work—would contain Guderley Mach reflection solutions as well.

The numerical solutions in [8, 18, 19] were obtained by solving an initial value problem for the unsteady equations. The problem of inviscid shock reflection at a wedge is self-similar, and there are advantages to solving the problem in self-similar, rather than unsteady, variables. In the unsteady formulation local grid refinement near the triple point is difficult, because any waves which are present initially move through the numerical domain, requiring the refined region to move as well. Solutions of the self-similar equations are stationary, making local grid refinement easier to implement. Also, in self-similar variables a global grid continuation procedure can be used in which a partially converged solution on a coarse grid is interpolated onto a fine grid and then driven to convergence on the fine grid. Procedures for solving the UTSDE in self-similar variables were developed in [16] and extended to apply to the nonlinear wave system in [17]. The procedures used to solve the nonlinear wave system have been applied, with only slight modification, in the present work to obtain solutions of the full Euler system.

In this paper we present high resolution numerical solutions of the shock reflection problem for the full Euler equations computed in self-similar coordinates. Our most highly resolved solution shows that Guderley Mach reflection occurs at a set of parameter values where Mach reflection is impossible: there is a sequence of tiny supersonic patches and triple points behind the leading triple point in a weak shock Mach reflection. This numerical solution is remarkably similar to those obtained for the UTSDE in [16] and for the nonlinear wave system in [17].

Experimental confirmation of these results is challenging simply because the computed structure is so small and weak. Nevertheless, recent experimental evidence appears to confirm that Guderley Mach reflection occurs when a weak shock reflects off a thin wedge. Skews and Ashworth in [12] modified an existing shock tube in order to obtain Mach stem lengths more than an order of magnitude larger than those possible with conventional shock tubes. They present photographic images of shock reflection experiments that clearly show an expansion wave behind the triple point in a weak shock Mach reflection, a terminating shocklet, and evidence of a second terminating shocklet. The supersonic region is extremely small, as predicted by the computations in [16, 17] and the present work. Further experimental improvements and data acquisition are underway.

This paper is organized as follows. In section 2 we describe the shock reflection problem for the full Euler equations. In section 3 we discuss our approach to solving this problem numerically. The numerical results obtained are presented in section 4. In section 5 we discuss questions raised by our results. Finally, we summarize our findings in section 6.

2. The shock reflection problem for the Euler equations.

We consider a problem for the full Euler equations that describes the reflection of a shock wave off a wedge. The shock reflection problem consists of the compressible Euler equations,

$$\begin{aligned}\rho_t + (\rho u)_x + (\rho v)_y &= 0,\\ (\rho u)_t + (\rho u^2 + p)_x + (\rho uv)_y &= 0,\\ (\rho v)_t + (\rho uv)_x + (\rho v^2 + p)_y &= 0,\\ (\rho e)_t + ((\rho e + p)u)_x + ((\rho e + p)v)_y &= 0,\end{aligned} \tag{2.1}$$

with piecewise constant Riemann data consisting of two states separated by a discontinuity located at $x = 0$. Here, ρ is the density, u and v are the x and y components of velocity, respectively, p is the pressure, and e is the energy. We use an ideal gas equation of state,

$$p = (\gamma - 1)\rho\left(e - \frac{1}{2}(u^2 + v^2)\right),$$

where the ratio of specific heats γ is taken to be 1.4. The initial data correspond to a vertical plane shock hitting the corner of a wedge at $t = 0$. Letting $U(x, y, t) = (\rho, u, v, p)$,

$$U(x, y, 0) = \begin{cases} U_R \equiv (\rho_R, 0, 0, p_R) & \text{if } x > 0,\\ U_L \equiv (\rho_L, u_L, 0, p_L) & \text{if } x < 0,\end{cases} \tag{2.2}$$

where the left- and right-hand states are connected by the Rankine–Hugoniot jump conditions for a shock with Mach number M. The boundary condition on the wedge wall is

$$\mathbf{u} \cdot \mathbf{n} = 0, \tag{2.3}$$

where $\mathbf{u} = (u, v)$ and $\mathbf{n}$ is the unit normal vector at the wall. The shock propagates to the right into stationary gas with speed Mc, where c is the sound speed in the fluid ahead of the shock at state U_R. The location of the incident shock is given by

$$x = (Mc)t. \tag{2.4}$$

For a gas with a given equation of state, there are two parameters in the shock reflection problem: the wedge angle θ and the strength of the incident shock, which we parameterize by the shock Mach number M. For sufficiently small Mach numbers and small wedge angles, neither Mach reflection nor regular reflection solutions exist (see [7, 10]).

3. The numerical method.

The problem (2.1)–(2.3) is self-similar, so the solution depends only on the similarity variables

$$\xi = \frac{x}{t}, \qquad \eta = \frac{y}{t}.$$

We write (2.1) in the form

$$U_t + F_x + G_y = 0, \tag{3.1}$$

where

$$U = (\rho, \rho u, \rho v, \rho e), \quad F = (\rho u, \rho u^2 + p, \rho uv, \rho ue + up),$$
$$\text{and} \quad G = (\rho v, \rho uv, \rho v^2 + p, \rho ve + vp).$$

Writing (3.1) in terms of ξ, η, and a pseudotime variable $\tau = \log t$, we obtain

$$U_\tau - \xi U_\xi - \eta U_\eta + F_\xi + G_\eta = 0. \tag{3.2}$$

As $\tau \to +\infty$, solutions of (3.2) converge to a pseudosteady, self-similar solution that satisfies

$$-\xi U_\xi - \eta U_\eta + F_\xi + G_\eta = 0. \tag{3.3}$$

Equation (3.3) is hyperbolic when $c^2 < \bar{u}^2 + \bar{v}^2$, corresponding to supersonic flow in a self-similar coordinate frame, and of mixed type when $c^2 > \bar{u}^2 + \bar{v}^2$, corresponding to subsonic flow, where $\bar{u} = u - \xi, \bar{v} = v - \eta$. Here, $c = \sqrt{\gamma p/\rho}$ is the local sound speed. The sonic line is given by

$$\bar{u}^2 + \bar{v}^2 = c^2. \tag{3.4}$$

By abuse of notation, we have referred to the locus of transition points between $c^2 < \bar{u}^2 + \bar{v}^2$ and $c^2 > \bar{u}^2 + \bar{v}^2$ as the sonic line, whether the flow is continuous there or not. We define a local self-similar Mach number $\bar{M}^2 = \frac{\bar{u}^2+\bar{v}^2}{c^2}$. When $\bar{M} > 1$, the flow is supersonic, and when $\bar{M} < 1$, the flow is subsonic.

In order to solve (3.2) numerically, we write it in conservative form as

$$U_\tau + (F - \xi U)_\xi + (G - \eta U)_\eta + 2U = 0. \tag{3.5}$$

In these self-similar variables, the full Euler system has the form of the unsteady equations (3.1) with modified flux functions and a lower-order source term.

An essential feature of our numerical method is the use of local grid refinement in the area of the apparent triple point. We designed a sequence of successively refined, nonuniform, logically rectangular finite volume grids. See Figure 3 for a diagram of the computational domain. We use grid continuation, in which partially converged coarse grid solutions are interpolated onto more refined grids and converged on the refined grids. For each grid, inside a given box surrounding the triple point, uniform grid spacing is used. Outside of this box, the grid is exponentially stretched in both grid directions.

The basic finite volume scheme is quite standard. Each grid cell, Ω, is a quadrilateral, and using $\vec{\nu} = (\nu_\xi, \nu_\eta)$ to denote the normal vector to a typical side of Ω, numerical fluxes are designed to be consistent with

$$\widetilde{F}(U) = (F(U) - \xi U)\,\nu_\xi + (G(U) - \eta U)\,\nu_\eta = \begin{pmatrix} \nu_\xi \rho u + \nu_\eta \rho v - \bar{\xi}\,\rho \\ \nu_\xi(\rho u^2 + p) + \nu_\eta \rho u v - \bar{\xi}\,\rho u \\ \nu_\xi \rho u v + \nu_\eta(\rho v^2 + p) - \bar{\xi}\,\rho v \\ \nu_\xi(\rho u e + u p) + \nu_\eta(\rho v e + v p) - \bar{\xi}\,\rho e \end{pmatrix},$$

where $\bar{\xi} = (\vec{\xi} \cdot \vec{\nu})$ and $\vec{\xi} = (\xi, \eta)$. Since $\vec{\xi}$ varies, our numerical flux formulae evaluate $\vec{\xi}$ frozen at the midpoint of each cell side. We use essentially the same numerical scheme as in [17], a high-order scheme based on the Roe numerical flux. High-order accuracy is achieved by using piecewise quadratic reconstruction limited in characteristic variables, together with the Roe flux

$$H_{Roe} = \frac{1}{2}(\widetilde{F}(U_l) + \widetilde{F}(U_r) - R\Lambda L\,(U_r - U_l)),$$

where $\Lambda = \mathrm{diag}(|-\bar{\xi} - c|, |-\bar{\xi}|, |-\bar{\xi} + c|)$, and R and L are the matrices of right and left eigenvectors to the Jacobian of $\widetilde{F}$. As in [17], we simplify the Roe approach by

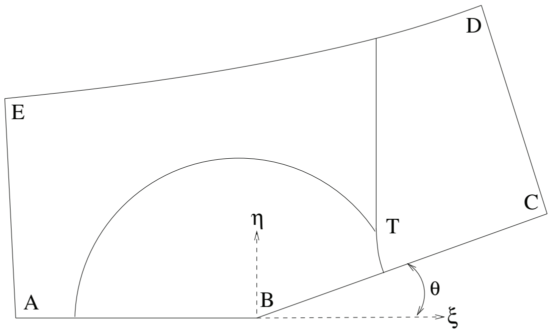

FIG. 3. *A schematic diagram of the computational domain. ABC is the wall; BC is the wedge, with angle θ. CDEA is the far field numerical boundary. The incident shock is perpendicular to AB. The incident (above T), reflected (left of T), and Mach (below T) shocks meet at the triple point T.*

evaluating R and L at the midpoint $U_{Roe} = \frac{1}{2}(U_l + U_r)$, which for the Euler equations is only an approximation to the Roe average. To avoid spurious expansion shocks, artificial dissipation on the order of $|U_r - U_l|$ is appended to the diagonal part of the Roe dissipation matrix in a field-by-field manner.

Time integration is accomplished using Heun's method, which can be written in two step predictor-corrector form (using overbars to denote predicted values) as

$$\begin{aligned}\frac{U^{\overline{n+1}} - U^n}{\Delta\tau} + \frac{1}{|\Omega|}\int_{\partial\Omega} H^n_{Roe}\, ds + 2U^n &= 0,\\ \frac{2U^{n+1} - U^{\overline{n+1}} - U^n}{\Delta\tau} + \frac{1}{|\Omega|}\int_{\partial\Omega} H^{\overline{n+1}}_{Roe}\, ds + 2U^{\overline{n+1}} &= 0.\end{aligned}$$

3.1. The grid and boundary conditions. We computed solutions of the problem (2.1)–(2.3) in the finite computational domain shown schematically in Figure 3. We use a nonuniform grid with a locally refined area of uniformly spaced grid very close to the triple point, as illustrated in Figure 4. The grid is defined by a conformal map of the form $z = w^\alpha$, so it is orthogonal with a singularity at the ramp apex $x = y = 0$. The refined uniform grid area is so small that it is obscured in the main plot shown in Figure 4. The inset plots show enlargements of the grid in the indicated rectangular regions, and the smaller inset plot contains a small superimposed box which delineates the refined uniform grid region. The grid is stretched exponentially from the edge of the uniform grid region to the outer numerical boundaries and the wall, with a stretching factor of 1%.

We use a sequence of such grids, with each grid corresponding to a level of grid refinement. The uniform grid region of each grid is refined by a factor of two in both x/t and y/t in relation to the uniform grid region of the previous grid. We obtain solutions on coarse grids, interpolate these onto more refined grids, and converge the solutions on the refined grids. We repeat this process until no further change is observed in the solution near the apparent triple point and *grid continue* to a steady state. This process is illustrated in Figure 5, which shows a coarse grid (dashed lines) overlaid with a refined grid (solid lines) in the uniform grid region of both grids. A solution is obtained on the coarse grid, and the computation on the coarse grid is stopped. This solution is interpolated onto the refined grid, and the computation

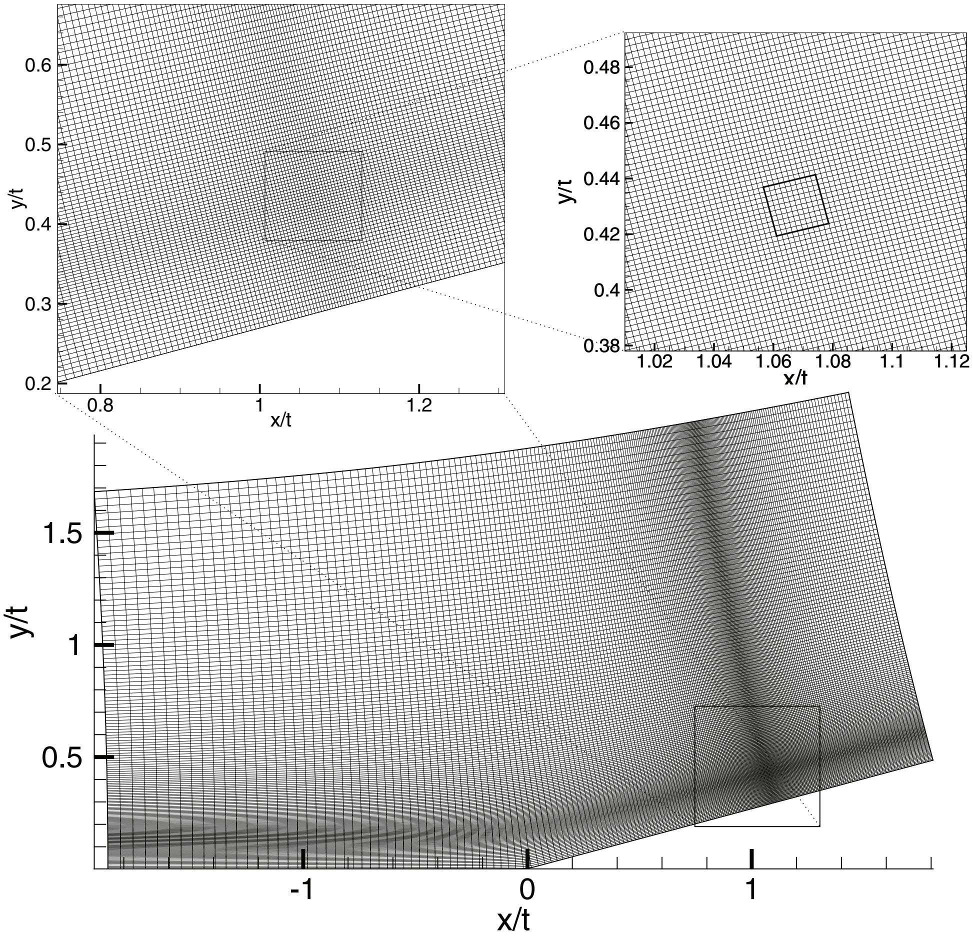

FIG. 4. *The grid structure, illustrating the region of uniform local refinement, which is outlined by the small box superimposed on the grid in the inset plot at the upper right. Outside of this small box, the grid is stretched. The main plot shows the entire grid. The locally refined region in this very coarse grid contains* 10×10 *grid cells, with* $\Delta\xi = \Delta\eta = 0.002$. *The locally refined region in our most refined grid is shown in Figure* 7(a).

is resumed on the refined grid. We found that bilinear interpolation gave the best results, while higher-order methods such as biquadratic interpolation resulted in large overshoots at the shocks.

Every grid in the sequence is designed so that the refined uniform grid region surrounds the apparent triple point as it appears in the currently available solution (the solution obtained with the previous grid). As the grids are refined and the shocks become better resolved, the triple point location can be determined more precisely, and the refined grid area can be repositioned and reduced in size. In fact, the refined uniform grid region depicted in the coarse grid shown in Figure 4 is more than 1000 times as large as the refined uniform grid region in our finest grid. The total number of grid cells in our finest grid is approximately six million, of which $300 \times 1000 = 3 \times 10^5$ ($\Delta\xi = \Delta\eta = 1 \times 10^{-6}$) are devoted to the local refinement.

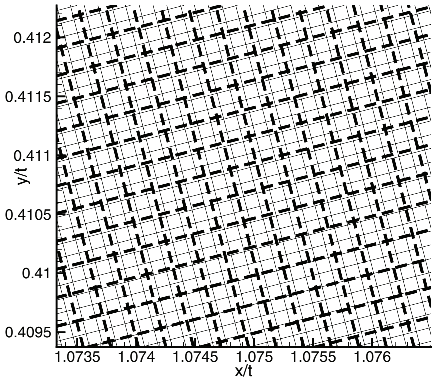

FIG. 5. *A solution on a coarse grid such as the one depicted in Figure* 4 *is interpolated onto a refined grid and converged on the refined grid. The locally refined region of the coarse grid (dashed lines) in this example has* $\Delta\xi = \Delta\eta = 0.00025$*, and the fine grid (solid lines) has* $\Delta\xi = \Delta\eta = 0.000125$*. The region shown in the plot is in the locally refined region of both grids.*

On the wall boundary ABC in Figure 3 we impose reflecting boundary conditions, equivalent to the physical no-flow condition (2.3). In addition, we require numerical boundary conditions on the outer computational boundaries, which we determine as follows.

The incident shock location (2.4) in self-similar variables is

$$\xi = Mc,$$

where c is the sound speed ahead of the shock. Boundary data on the left, right, and top are given to exactly agree with this shock, so that

$$U(\xi, \eta) = \begin{cases} U_R, & \xi > Mc, \\ U_L, & \xi < Mc, \end{cases} \tag{3.6}$$

where the fluid properties U_L behind the shock are obtained from the Rankine–Hugoniot conditions. We use (3.6) as a boundary condition for (3.5) on $CDEA$.

4. Numerical results. We computed numerical solutions of (2.1)–(2.3) for a shock Mach number M equal to 1.075 and a wedge angle θ equal to 15 degrees. These data correspond to parameter $a \approx 1/2$ in the UTSDE model used in [16]. This problem is well outside the range for which regular reflection can occur. However, Mach reflection is also not possible for shocks this weak, and so this example illustrates a classic triple point paradox. In our computations we used $\rho_R = 1.4$ and $p_R = 1$ in (2.2) and determined the values U_L behind the shock from the Rankine–Hugoniot conditions. Table 4.1 gives the initial values of the fluid variables. We give our finest grid results in the plots which follow. Figure 6(a)–(b) shows a numerical solution that gives an overall picture of the shock reflection. The plots in (a) and (b) show Mach number and pressure contours, respectively, as functions of $(x/t, y/t)$. Here, we refer to the local Mach number of the solution, not to the shock Mach number M. The numerical solution appears to show a simple Mach reflection, with three shocks meeting at a triple point. Ahead of the incident shock, the pressure is equal to 1 and

Table 4.1

Left and right states for an incident shock with Mach number $M = 1.075$ and $\gamma = 1.4$.

Fig. 6. *Contour plots over the full numerical domain, showing what appears to be a Mach reflection—three shocks and a contact discontinuity (visible as a jump in the Mach contours in* (a)*) meeting in a point. The Mach contour spacing in* (a) *and the pressure contour spacing in* (b) *are both* 0.002. *The full grid contains* 2250×2710 *finite volume cells.*

the Mach number is 0. As the shock moves it induces a flow in the fluid behind it and a corresponding increase in pressure. The reflected shock is much weaker than the incident shock and decreases in strength as it moves away from the apparent triple point. The Mach shock increases in strength as it moves away from the triple point, reaching a maximum at the wall where it becomes a normal shock. Here, the pressure and the induced flow velocity are largest. A very weak contact discontinuity can be seen in the Mach contours in Figure 6(a). This is not visible in the plot in (b) because pressure does not jump across a contact discontinuity.

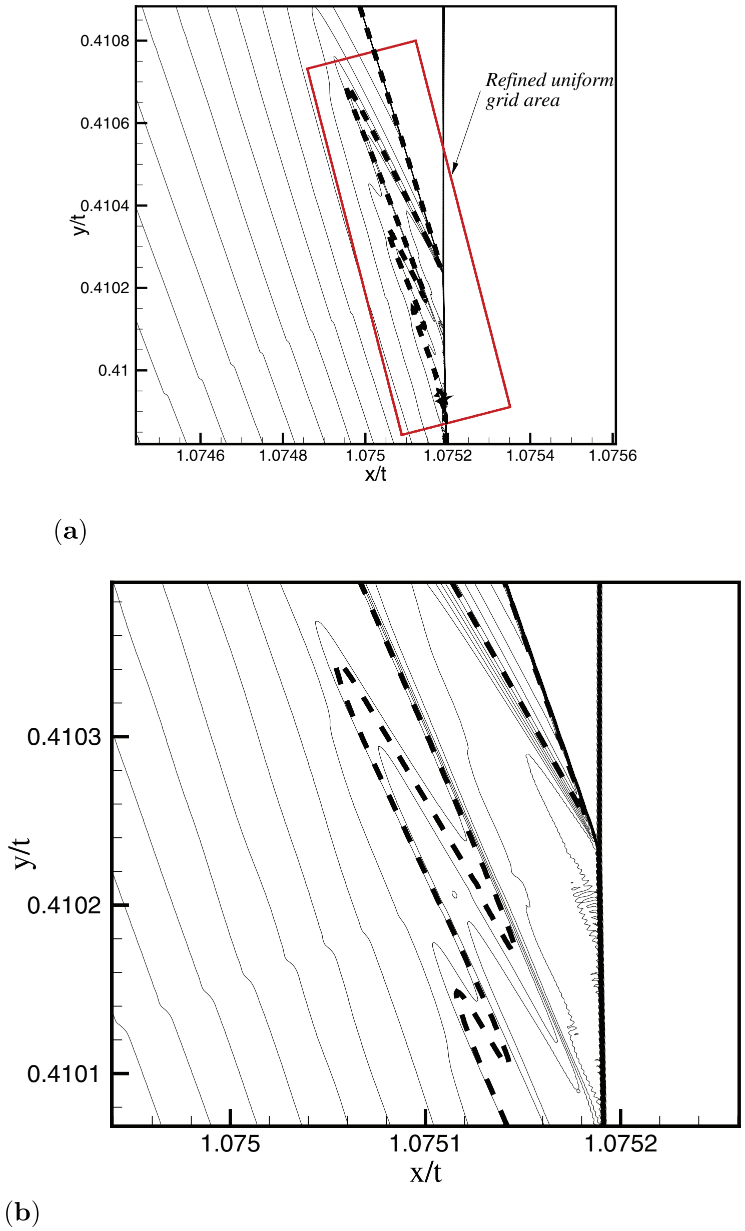

Fig. 7. *The solution near the triple point for* $M = 1.075$ *and* $\theta = 15$ *degrees. The Mach contour spacing is* 0.001 *in* (a) *and* 0.0005 *in* (b). *The dashed line in both plots is the sonic line. The refined uniform grid is contained within the box shown in* (a) *and has* 300×1000 *cells* ($\Delta\xi = \Delta\eta = 1 \times 10^{-6}$). *Two reflected shock/expansion wave pairs are clearly visible, with indications of a third. A contact discontinuity appears as a very weak jump in Mach number.*

In Figure 7(a), we show Mach number contours in the most refined region near the apparent triple point. The refined uniform grid, as indicated, is approximately aligned with the reflected shock. The dashed line in the figure is the numerically

Table 4.2

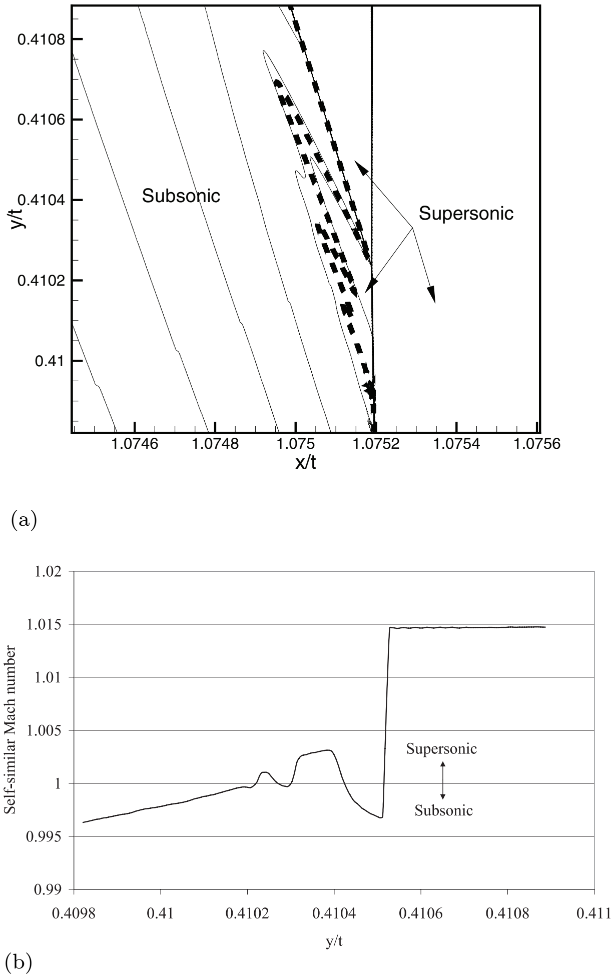
Approximate values of the reflected shock strengths for the three reflected shocks visible in Figure 7, beginning with the leading reflected shock, from the numerical data. For each shock, ρ_1 and ρ_0 denote the approximate values of ρ ahead of and behind the shock, respectively.

Shock	ρ_1	ρ_0	$[\rho]$
1	1.577	1.596	0.019
2	1.592	1.596	0.004
3	1.594	1.596	0.002

computed location of the sonic line, (3.4). (This sonic line is displayed more clearly in Figure 8(a).) Flow to the right of this line is supersonic, and the figure shows that the solution contains a small region of supersonic flow behind the triple point. There is an expansion fan centered at the leading triple point, but it cannot be seen clearly at this level of magnification. To show this expansion fan more clearly, in Figure 7(b) we show an enlargement of the solution, using more closely spaced contours, in a tiny region near the confluence of the incident, reflected, and Mach shocks. Behind the leading triple point, there is a sequence of very weak shocks that intersect the Mach shock, forming a sequence of triple points, with a very weak expansion fan centered at each triple point. Each shock-expansion wave pair in the sequence is smaller and weaker than the one preceding it. Three reflected shocks appear to be visible in the plots in Figure 7(a)–(b). Their approximate strengths, beginning with the leading reflected shock, are given in Table 4.2. The jump $[\rho]$ in ρ across a reflected shock is measured near the point where the flow behind the shock is sonic. This point is very close to the corresponding triple point on the Mach shock, as shown in Figure 7. In principle, a contact discontinuity originates at each triple point. However, the only contact discontinuity that is strong enough to be resolved numerically is the one at the leading triple point.

To depict the regions of supersonic and subsonic flow in a Guderley Mach reflection, we plot widely spaced Mach contours and the sonic line near the triple point in Figure 8(a). In the plot in (b), we give a cross section of Mach number $\bar{M}$ taken vertically through the region shown in the plot in (a), at a location slightly to the left of the Mach shock. The height $\Delta(y/t)$ of the supersonic region behind the triple point is approximately 0.00075, and the width $\Delta(x/t)$ is approximately 0.0001. Here, the height $\Delta(y/t)$ is a numerical estimate of the difference between the maximum value of y/t on the sonic line and the minimum value of y/t at the rear sonic point on the Mach shock. The width $\Delta(x/t)$ is an estimate of the width of the supersonic region at the value of y/t corresponding to the leading triple point. The height of the supersonic region is approximately 0.6% of the length of the Mach shock.

We found that a certain minimum grid resolution was necessary to resolve the supersonic region behind the triple point. As we refined the grid beyond this minimum resolution, a detailed flowfield structure became visible in the supersonic region. Figure 9 shows Mach number contours for a sequence of solutions computed on successively refined grids. In Figure 9(a)–(b), the sonic line appears fairly smooth. The supersonic patch appears to be shock-free. After two further grid refinements, each by a factor of two in both x/t and y/t (Figure 9(c)), a shock is visible behind the leading triple point. Our finest grid solution is shown in the plot in Figure 9(d). Two shocks are visible behind the leading triple point. Further refinement of the grid resulted in almost no observable change in the solution, as shown in the plot in Figure 10, an indication of grid convergence. At resolutions lower than the one shown in Figure 9(a), the supersonic region disappears entirely, and the sonic line runs down the inside of



(a)

Fig. 8. *The supersonic and subsonic regions near the triple point. The dashed line in* (a) *is the sonic line. It delineates the supersonic patch within the subsonic zone behind the triple point; the Mach contour spacing is* 0.0025. *In* (b) *a vertical cross section of $\bar{M}$ is taken at the location $x/t = 1.0751$, slightly to the left of the incident shock/Mach stem. The large jump is the leading reflected shock. Note the crossings at $\bar{M} = 1$, indicating jumps across weak reflected shocks or smooth transitions across the sonic line.*

the reflected shock, through the triple point, and down the Mach shock.

Figure 11 illustrates the size and location of the region where extreme local grid refinement is performed. The refined grid area is too small to be visible in the main plot shown in Figure 11. The inset figures show enlargements of the solution contained within the small rectangular box centered about the apparent triple point, as indicated. The solution shown in the smaller inset figure also contains a small box centered at the apparent triple point, indicating the approximate size and location of the region shown in Figures 7(a) and 8(a).

To further explore the wedge angle–shock strength parameter range in which the triple point paradox occurs, we also computed a solution of the shock reflection

monatomic gas ($\gamma = 1.4$ corresponds to a diatomic gas such as air). These data again correspond to parameter $a \approx 1/2$ in the UTSDE model used in [16]. Figure 12 shows Mach number contours and the sonic line in the neighborhood of the apparent triple point. Just as in our solution for $M = 1.075$, $\theta = 15$ degrees, and $\gamma = 1.4$, there is a sequence of triple points, reflected shocks, and expansion fans behind the leading triple point. Two reflected shock/expansion wave pairs are evident from the shape of the sonic line, with a slight indication of a third. At this lower shock strength, twice the grid refinement in both directions was required to obtain a solution comparable to that obtained for a $M = 1.075$ incident shock. The incident, reflected, and Mach shocks at the leading triple point are so weak that no contact discontinuity is visible.

5. Discussion.

These numerical results display a structure that is remarkably similar to the solutions of the shock reflection problem for the UTSDE model in [16] (compare Figures 7(a) and (b) with Figures 5 and 6 of [16], for example) and to its analogue for the nonlinear wave system in [17] (see Figure 6, p. 331). In all three cases, a weak shock reflection in a parameter range where regular reflection is impossible results in a sequence of triple points and supersonic patches in a tiny region behind the leading triple point, with an expansion fan originating at each triple point. The results presented here appear to confirm the validity of the UTSDE as a model for weak shock reflection. In addition, it now appears that this solution structure may occur generically in a class of conservation laws that includes the physically important Euler equations of gasdynamics.

An important feature of the numerical solution is the small size of the supersonic region. In our solution for a shock with $M = 1.075$ impinging on a 15 degree ramp, the height of the supersonic region is approximately 0.6% of the length of the Mach shock. This can be compared to the results in [16]. The UTSDE model used there depends on a single order-one transonic similarity parameter $a = \theta/\sqrt{2(M^2 - 1)}$. Solutions were obtained over a range of values of a, and the supersonic regions found in the solutions varied in height from approximately 0.05% to 3% of the length of the Mach shock, depending on the value of a. Our $M = 1.075/15°$ problem corresponds to $a = 0.5$, a value for which the height of the supersonic region in [16] was approximately 1.9% of the height of the Mach shock, somewhat larger than the region obtained in the present work. The UTSDE are an asymptotic reduction of the Euler equations in the limit of weak shocks and thin wedges (see [8]), and we do not expect exact agreement between solutions of the problem for the asymptotic equations and the problem for the Euler equations. For wedge angles closer to 0 and Mach numbers closer to 1, we would expect closer agreement with the solutions in [16]. The computation we performed with $M = 1.04$, $\theta = 11.5$ degrees displayed in Figure 12 serves as a check of this statement. The height of the supersonic region in our solution for this choice of parameters is approximately 1% of the length of the Mach shock, indeed closer to the figure of 1.9% obtained in [16].

The supersonic regions behind the triple point in our solutions for $M = 1.075$, $\theta = 15°$ and $M = 1.04$, $\theta = 11.5°$ are much larger in height than in width. Defining an aspect ratio $\Delta(y/t)/\Delta(x/t)$, these solutions have aspect ratios of approximately 8:1 and 9:1, respectively. This quantity agrees closely with the solutions in [16]. There, solutions obtained over a range of values of a contain supersonic regions with aspect ratios from approximately 2.75:1 to 8.5:1. The solution in [16] with $a = 1/2$ has an aspect ratio of 8:1, approximately the same as the solutions presented here, which correspond to this value of a. Although the supersonic regions obtained in the present work are smaller in size than the one obtained in [16] for $a = 1/2$, the shape of the regions obtained agrees quite closely.

Table 4.2 gives an indication of how the reflected shock strength decays in the sequence of shocks/expansions which comprise a Guderley Mach reflection. From the table, the strength of the first three reflected shocks is approximately in the ratio $9.5 : 2 : 1$. This is quite similar to the UTSDE result for $a = 1/2$ in [16]. There, four reflected shocks were visible in the solution; the strengths of the first three were in the approximate ratio $8 : 2 : 1$. For the nonlinear wave system solution in [17], the ratio was approximately $12 : 3 : 1$. We do not know precisely how the sequence of supersonic patches and shocks/expansions in Guderley Mach reflection decreases in size and strength, respectively, nor do we know if the sequence is finite or infinite.

The experimental results of Skews and Ashworth in [12] appear to confirm the existence of the Guderley Mach reflection structure reported here. The experiments were carried out on a 15° ramp with incident shock Mach numbers ranging from 1.05 to 1.1. The size of the expansion wave and terminating shocklet which were observed behind the leading triple point in experiments with measured Mach numbers of $M = 1.069$ and $M = 1.084$ was estimated to be less than 2% of the length of the Mach stem, a figure which, again, is somewhat larger than the wave structure observed numerically in the present work. The incident shock wave that is generated by the shock tube apparatus used in [12] is only approximately planar, however, and this may be one reason for the discrepancy. In addition, density gradients, which are visualized by the schlieren photo-optical technique used in [12], persist well beyond the supersonic patch into the subsonic region, making it difficult to estimate the extent of the supersonic patch from schlieren photographs. Nevertheless, the structure found in the experiments is very similar to the numerically computed Guderley Mach reflection solution. More recent experimental results [13] show more convincing evidence: the expansion fan and first terminating shocklet observed under conditions corresponding to $a \approx 1/2$ are more clearly visible, and the region appears to have an aspect ratio similar to the value of approximately 8:1 obtained in the solutions presented here.

Guderley's resolution was largely correct: a fourth wave, a centered expansion fan, originates at the triple point, although Guderley did not have any evidence that this is what actually occurs, nor did he suggest that there might be, in fact, a sequence of expansion fans and triple points. It is interesting, as noted in [12], that experimental observations of weak shock reflections off thin wedges show that not only does an apparent Mach reflection occur but that the slip line disappears or becomes ill defined. Figures 6(a) and 7(a) show that the slip line still exists in a weak shock reflection, but that it is extremely weak, making it difficult to observe experimentally.

6. Conclusion. We have presented numerical evidence of a sequence of triple points, each containing a centered expansion fan, in solutions of a shock reflection problem for the full Euler equations. This result is in agreement with previous numerical solutions of shock reflection problems for the UTSDE and the nonlinear wave system. The present work provides further evidence that the reflection pattern we call Guderley Mach reflection occurs when a weak shock reflects off a thin wedge.

AN ASYMPTOTIC FACTORIZATION METHOD FOR INVERSE ELECTROMAGNETIC SCATTERING IN LAYERED MEDIA*

ROLAND GRIESMAIER†

Abstract. We consider the inverse problem to reconstruct the number and the positions of a collection of finitely many small perfectly conducting scatterers buried within the lower halfspace of an unbounded two-layered background medium from near field measurements of time harmonic electromagnetic fields. For this purpose we first study the direct scattering problem and derive an asymptotic expansion of the scattered field, as the size of the scatterers tends to zero. Integral equation methods and a factorization of the corresponding near field measurement operator are applied to prove this expansion. In the second part of this work we use the asymptotic expansion to justify a noniterative reconstruction algorithm, which is a combination of factorization methods and MUSIC-type methods. We illustrate the feasibility of this method by a numerical example.

1. Introduction.

We consider a simple but fully three dimensional model for the electromagnetic exploration of perfectly conducting objects buried within the lower half-space of an unbounded two-layered background medium. In possible applications, such as, e.g., humanitarian demining or, more generally, the exploration of the ground's subsurface to detect and identify buried objects, the two layers would correspond to air and soil. Moving a set of electric devices parallel to the surface of ground to generate a time harmonic field, the induced field is measured within the same devices. The goal is to retrieve information about buried scatterers from these data.

This work originated in the project [23] on humanitarian demining. In the course of this project mathematical methods for analyzing data obtained from standard off-the-shelf metal detectors have been developed. The aim of the project has been to reduce the number of false alarms produced by such devices used for humanitarian demining.

In mathematical terms, we consider an inverse scattering problem for Maxwell's equations in a two-layered background medium. An iterative method for such a problem was recently proposed by Delbary et al. [17]. Among the so-called qualitative methods (see Cakoni and Colton [10]), the linear sampling method was studied by Gebauer et al. [20] and by Cakoni, Fares, and Haddar [11]. Moreover, the factorization method was applied by Kirsch [29] and by Gebauer, Hanke, and Schneider [21]. In numerical experiments these methods turned out to be quite sensitive to noise. This is of course due to the ill-posedness of the inverse problem.

In order to handle this ill-posedness it is generally advisable to incorporate all available a priori knowledge about the measurement device and the scatterers and

†Institut für Mathematik, Johannes Gutenberg-Universität, 55099 Mainz, Germany (griesmaier@math.uni-mainz.de).

to determine very specific features. Standard off-the-shelf metal detectors used for humanitarian demining work at relatively low frequencies around 20 kHz; cf., e.g., [22]. In vacuum this corresponds to wavelengths of approximately 15 km. Thus the typical size of the objects of interest, which is only a few centimeters, is very small with respect to the wavelength of the incident field. We use this a priori knowledge to justify a noniterative reconstruction method that determines only the number and the position of the unknown scatterers but is more robust against noise in the data.

This method is a generalization of a method which was originally developed for electrical impedance tomography by Brühl, Hanke, and Vogelius [8]. It is based on an asymptotic expansion of the scattered field on the measurement device as the size of the scatterers tends to zero. A similar reconstruction method was recently investigated by Ammari et al. [2] for homogeneous background media and by Iakovleva et al. [24] for two-layered background media. In contrast to the present investigation, these works study a discrete measurement array, which can be considered as a special case of the measurement device studied here. We expect that the theoretical results obtained for nondiscrete measurement devices can be applied to even more realistic models for the measurement process; cf., e.g., [17]. Moreover, the asymptotic expansions of the scattered field were obtained only formally in [2] and [24]. Here we give a rigorous justification of these formulas for two-layered background media. For bounded background domains related formulas were rigorously proven by Ammari et al. [6, 4, 5], and these results were extended to unbounded homogeneous media and plane wave incident fields by Ammari and Volkov [7]. But this analysis applies neither to layered media nor to near field measurements such as considered here.

Our proof of the asymptotic formula employs a factorization of the near field measurement operator that maps magnetic dipole distributions on the measurement device to the corresponding scattered field on the same device. We apply layer potential techniques to describe the three operators occurring in this factorization and expand them separately as the size of the scatterers tends to zero. Then these expansions are combined to calculate the leading order term in the asymptotic expansion of the scattered field. This generalizes the approach we used in [1] for a boundary value problem in electrostatics. By contrast, in [6, 4, 5, 7] variational methods were applied.

Then, we derive a characterization of the location of the scatterers in terms of the range of the leading order term of the asymptotic expansion of the near field measurement operator, similar to range criteria known from factorization methods, introduced first by Kirsch [28], and MUSIC-type methods, applied first to inverse scattering problems by Devaney [18]. We use a MUSIC-type strategy to implement this range criterion numerically; basically, MUltiple SIgnal Classification is a method of characterizing the range of finite rank operators on Hilbert spaces; see Cheney [12].

The article is organized as follows. After introducing some notation in the next section we describe our model and define the measurement operator in section 3. In section 4 we derive a factorization of this operator, and in section 5 we collect some facts concerning boundary integral operators arising in electromagnetic scattering theory for layered background media. Sections 6 and 7 are devoted to the asymptotic expansion of the measurement operator. Then, in section 9 we derive a characterization of the scatterers in terms of a range criterion, and in section 10 we comment on how to implement this criterion numerically. Finally, we present numerical results.

2. Preliminaries.

We introduce our notation and recall some facts concerning function spaces used in the context of Maxwell's equations. For further details we refer the reader to [9, 31, 32]. Suppose $D \subset \mathbb{R}^3$ is a bounded domain of class $C^{2,\alpha}$, $0 < \alpha < 1$. Denote by $(\boldsymbol{e}_1, \boldsymbol{e}_2, \boldsymbol{e}_3)$ the usual Cartesian basis of $\mathbb{R}^3$, by $\boldsymbol{x} = (x_1, x_2, x_3)^\top$ a generic point in $\mathbb{R}^3$, and by $\boldsymbol{\nu}$ the unit outward normal to ∂D. Throughout let $\boldsymbol{x} \cdot \boldsymbol{y}$ and $\boldsymbol{x} \times \boldsymbol{y}$ be the scalar product and the vector product of $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3$, respectively, and let $|\boldsymbol{x}|$ denote the Euclidean norm of $\boldsymbol{x}$. The standard complex valued Sobolev spaces $H^r(D)$, $H^r_{\mathrm{loc}}(\mathbb{R}^3 \setminus \overline{D})$ for any $r \in \mathbb{R}$ and $H^s(\partial D)$ for $s \in [-2, 2]$ are defined on D, $\mathbb{R}^3 \setminus \overline{D}$ and on the boundary ∂D, respectively; see [30]. Let $\gamma_0 : H^r(D) \to H^{r-1/2}(\partial D)$, $1/2 < r \leq 2$, be the standard trace operator. We also need the spaces $\boldsymbol{H}(\mathbf{curl}, D)$, $\boldsymbol{H}_{\mathrm{loc}}(\mathbf{curl}, \mathbb{R}^3 \setminus \overline{D})$, $\boldsymbol{H}(\mathrm{div}, D)$, and $\boldsymbol{H}_{\mathrm{loc}}(\mathrm{div}, \mathbb{R}^3 \setminus \overline{D})$ of (locally) square integrable vector fields with (locally) square integrable curl and divergence, respectively.

The surface gradient $\nabla_{\partial D}$ and the surface vector curl $\mathbf{curl}_{\partial D}$ are defined on ∂D in the usual way by a localization argument. The adjoint operators of $-\nabla_{\partial D}$ and $\mathbf{curl}_{\partial D}$ are the surface divergence $\mathrm{div}_{\partial D}$ and the surface scalar curl $\mathrm{curl}_{\partial D}$, respectively. We introduce the Hilbert space $\boldsymbol{H}_t^{-1/2}(\partial D)$ of tangential vector fields in $H^{-1/2}(\partial D)^3$ and the Hilbert spaces $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$ of vector fields in $\boldsymbol{H}_t^{-1/2}(\partial D)$ with surface divergence and surface scalar curl in $H^{-1/2}(\partial D)$, respectively. The space $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$ is naturally identified with the dual space of $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$. We denote the corresponding duality pairing by $\langle \boldsymbol{b}, \boldsymbol{a} \rangle_{\partial D} = \int_{\partial D} \boldsymbol{b} \cdot \boldsymbol{a} \, \mathrm{d}s$ for any $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{b} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$.

For any regular vector field $\boldsymbol{u}$ we define the normal trace $\gamma_n(\boldsymbol{u}) := \boldsymbol{u}|_{\partial D} \cdot \boldsymbol{\nu}$, the tangential trace $\gamma_t(\boldsymbol{u}) := \boldsymbol{\nu} \times \boldsymbol{u}|_{\partial D}$, and the projection on the tangent plane $\pi_t(\boldsymbol{u}) := (\boldsymbol{\nu} \times \boldsymbol{u}|_{\partial D}) \times \boldsymbol{\nu}$. Furthermore, let $r(\boldsymbol{a}) := \boldsymbol{\nu} \times \boldsymbol{a}$ for any regular vector field $\boldsymbol{a}$ on ∂D. Then γ_n, γ_t, π_t, and r can be extended to continuous linear, surjective operators

$$\gamma_n : \boldsymbol{H}(\mathrm{div}, D) \to H^{-1/2}(\partial D), \qquad \gamma_t : \boldsymbol{H}(\mathbf{curl}, D) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D),$$
$$\pi_t : \boldsymbol{H}(\mathbf{curl}, D) \to \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D), \qquad r : \boldsymbol{H}_t^{-1/2}(\partial D) \to \boldsymbol{H}_t^{-1/2}(\partial D).$$

The extension of r is an isomorphism with $r^{-1} = r^\top = -r$, which maps $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ to $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$ and vice versa. For $\boldsymbol{u} \in \boldsymbol{H}(\mathbf{curl}, D)$ we have $\gamma_t(\boldsymbol{u}) = r(\pi_t(\boldsymbol{u}))$ and $\pi_t(\boldsymbol{u}) = -r(\gamma_t(\boldsymbol{u}))$. We note that for $\boldsymbol{a} \in \boldsymbol{H}_t^{-1/2}(\partial D)$,

$$\mathrm{div}_{\partial D}\, \boldsymbol{a} = \mathrm{curl}_{\partial D}\, r(\boldsymbol{a}) \quad \text{and} \quad \mathrm{curl}_{\partial D}\, \boldsymbol{a} = -\,\mathrm{div}_{\partial D}\, r(\boldsymbol{a}). \tag{2.1}$$

Furthermore, for $f \in H^1(D)$,

$$\nabla_{\partial D} \gamma_0(f) = \pi_t(\nabla f) \quad \text{and} \quad \mathbf{curl}_{\partial D} \gamma_0(f) = -r(\nabla_{\partial D} \gamma_0(f)) = -\gamma_t(\nabla f). \tag{2.2}$$

Finally, for $\boldsymbol{u} \in \boldsymbol{H}(\mathbf{curl}, D)$, it holds that

$$-\,\mathrm{div}_{\partial D}\, \gamma_t(\boldsymbol{u}) = \mathrm{curl}_{\partial D}\, \pi_t(\boldsymbol{u}) = \gamma_n(\mathbf{curl}\boldsymbol{u}). \tag{2.3}$$

Throughout we let scalar operators operate on vectors componentwise and vector operators on matrices column by column. For Banach spaces X and Y we denote by $\mathcal{L}(X, Y)$ the set of all bounded linear operators on X to Y. We write $\mathcal{L}(X)$ for $\mathcal{L}(X, X)$. Moreover, in our estimates we shall use a generic constant C.

3. The mathematical setting.

We decompose the space $\mathbb{R}^3 = \mathbb{R}^3_+ \cup \Sigma_0 \cup \mathbb{R}^3_-$ in a hyperplane $\Sigma_0 := \{\boldsymbol{x} \in \mathbb{R}^3 \mid x_3 = 0\}$ corresponding to the surface of the ground, and the two halfspaces $\mathbb{R}^3_+ := \{\boldsymbol{x} \in \mathbb{R}^3 \mid x_3 > 0\}$ and $\mathbb{R}^3_- := \{\boldsymbol{x} \in \mathbb{R}^3 \mid x_3 < 0\}$

above and below Σ_0 representing air and ground, respectively. For convenience we set $\mathbb{R}^3_0 := \mathbb{R}^3 \setminus \Sigma_0$. We assume that both halfspaces are filled with homogeneous materials with dielectricity ε and permeability μ given by

$$\varepsilon(\boldsymbol{x}) := \begin{cases} \varepsilon_+, & \boldsymbol{x} \in \mathbb{R}^3_+, \\ \varepsilon_-, & \boldsymbol{x} \in \mathbb{R}^3_-, \end{cases} \qquad \mu(\boldsymbol{x}) := \begin{cases} \mu_+, & \boldsymbol{x} \in \mathbb{R}^3_+, \\ \mu_-, & \boldsymbol{x} \in \mathbb{R}^3_-, \end{cases}$$

and we require that ε_+ as well as $\mu_\pm$ are positive numbers, whereas ε_- may be complex with positive real and nonnegative imaginary parts to allow for soil materials that are conducting. The associated (discontinuous) wavenumber is $k := \omega\sqrt{\varepsilon\mu}$, where we assume $\omega > 0$. If $\varepsilon_- \notin \mathbb{R}$, then k is taken to have positive imaginary part. Throughout we investigate radiating solutions of the time harmonic Maxwell system

$$\mathbf{curl}\boldsymbol{H} + \mathrm{i}\,\omega\varepsilon\boldsymbol{E} = 0, \quad \mathbf{curl}\boldsymbol{E} - \mathrm{i}\,\omega\mu\boldsymbol{H} = 0 \tag{3.1}$$

in the exterior of some compact set $C \subset \mathbb{R}^3$. By this we understand, cf., e.g., [16, 31], solutions $\boldsymbol{E}, \boldsymbol{H} \in \boldsymbol{H}_{\mathrm{loc}}(\mathbf{curl}, \mathbb{R}^3 \setminus C)$ which obey the integral radiation condition

$$\int_{\partial B_R(0)} \left| \frac{\boldsymbol{x}}{R} \times \boldsymbol{H}(\boldsymbol{x}) + \Big(\frac{\varepsilon(\boldsymbol{x})}{\mu(\boldsymbol{x})}\Big)^{1/2} \boldsymbol{E}(\boldsymbol{x}) \right|^2 \mathrm{d}s(\boldsymbol{x}) = o(1) \qquad \text{as } R \to \infty, \tag{3.2}$$

where $B_R(0) := \{\boldsymbol{x} \in \mathbb{R}^3 \mid |\boldsymbol{x}| < R\}$ denotes the ball of radius $R > 0$ around the origin.

For layered medium we have to distinguish between the electric and the magnetic dyadic Green's functions. The electric dyadic Green's function $\mathbb{G}^e$ is the radiating (distributional) solution of

$$\mathbf{curl}_x \frac{1}{\mu(\boldsymbol{x})} \mathbf{curl}_x\, \mathbb{G}^e(\boldsymbol{x}, \boldsymbol{y}) - \omega^2 \varepsilon(\boldsymbol{x}) \mathbb{G}^e(\boldsymbol{x}, \boldsymbol{y}) = \frac{1}{\mu(\boldsymbol{x})} \delta(\boldsymbol{x} - \boldsymbol{y})\, \mathbb{I}_3, \qquad \boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3,$$

where $\mathbb{I}_3$ denotes the 3×3 identity matrix. Note that we are using $\boldsymbol{x}$ as an independent variable and $\boldsymbol{y}$ denotes the position of the source. The magnetic dyadic Green's function $\mathbb{G}^m$ fulfills the same equation, but ε and μ have to be swapped. From the derivation of these Green's tensors in [31, pp. 318–327] (cf. also [34, 17, 33]), we find that $\mathbb{G}^e$ and $\mathbb{G}^m$ can be written as

$$\mathbb{G}^{e/m}(\boldsymbol{x}, \boldsymbol{y}) = \Pi^{e/m}(\boldsymbol{x}, \boldsymbol{y}) + \frac{1}{k(\boldsymbol{x})^2} \nabla_x \operatorname{div}_x \Pi^{e/m}(\boldsymbol{x}, \boldsymbol{y})$$

for $\boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3_0$, $\boldsymbol{x} \neq \boldsymbol{y}$. Here the (matrix valued) functions Π^e and Π^m are given by

$$\Pi^{e/m}(\boldsymbol{x}, \boldsymbol{y}) := \Phi_{k(\boldsymbol{x})}(\boldsymbol{x} - \boldsymbol{y})\, \mathbb{I}_3 + F^{e/m}(\boldsymbol{x}, \boldsymbol{y}), \qquad \boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3_0,\ \boldsymbol{x} \neq \boldsymbol{y}, \tag{3.3}$$

where Φ_{k_+} and Φ_{k_-} denote the fundamental solution for the scalar Helmholtz equation in homogeneous medium with wavenumber k_+ and k_-, respectively; cf. [15, p. 16]. The functions Π^e and Π^m solve

$$(\Delta_x + k(\boldsymbol{x})^2) \Pi^{e/m}(\boldsymbol{x}, \boldsymbol{y}) = -\delta(\boldsymbol{x} - \boldsymbol{y})\, \mathbb{I}_3, \qquad \boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3_0,$$

and so F^e and F^m solve

$$(\Delta_x + k(\boldsymbol{x})^2) F^{e/m}(\boldsymbol{x}, \boldsymbol{y}) = 0, \qquad \boldsymbol{x}, \boldsymbol{y} \in \mathbb{R}^3_0.$$

Applying a regularity result due to Weber [35, Thm. 2.9], we find that $\mathbb{G}^{e/m}|_{\mathbb{R}^3_\pm}(\cdot,\boldsymbol{y}) \in C^\infty(\overline{\mathbb{R}^3_\pm} \setminus \{\boldsymbol{y}\})$ for $\boldsymbol{y} \in \mathbb{R}^3_0$. Thus, $F^e(\cdot,\boldsymbol{y})$ and $F^m(\cdot,\boldsymbol{y})$ are smooth functions in $\mathbb{R}^3_0$ for $\boldsymbol{y}$ in any compact subset of $\mathbb{R}^3_0$.

Using Maxwell's equations and integration by parts the following reciprocity relations can be proven; cf. also [16, 24, 13]:

$$\mu(\boldsymbol{y})\mathbb{G}^e(\boldsymbol{x},\boldsymbol{y}) = \mu(\boldsymbol{x})\mathbb{G}^{e^\top}(\boldsymbol{y},\boldsymbol{x}) \qquad \text{for } \boldsymbol{x},\boldsymbol{y} \in \mathbb{R}^3_0,\ \boldsymbol{x} \neq \boldsymbol{y}, \tag{3.4a}$$

$$\varepsilon(\boldsymbol{y})\mathbb{G}^m(\boldsymbol{x},\boldsymbol{y}) = \varepsilon(\boldsymbol{x})\mathbb{G}^{m^\top}(\boldsymbol{y},\boldsymbol{x}) \qquad \text{for } \boldsymbol{x},\boldsymbol{y} \in \mathbb{R}^3_0,\ \boldsymbol{x} \neq \boldsymbol{y}, \tag{3.4b}$$

$$k^2(\boldsymbol{y})\mathbf{curl}_x\mathbb{G}^e(\boldsymbol{x},\boldsymbol{y}) = k^2(\boldsymbol{x})(\mathbf{curl}_y\mathbb{G}^m)^\top(\boldsymbol{y},\boldsymbol{x}) \qquad \text{for } \boldsymbol{x},\boldsymbol{y} \in \mathbb{R}^3_0,\ \boldsymbol{x} \neq \boldsymbol{y}. \tag{3.4c}$$

We denote by $\Sigma_d := \{\boldsymbol{x} \in \mathbb{R}^3_+ \mid \boldsymbol{x}\cdot\boldsymbol{e}_3 = d\} \subset \mathbb{R}^3_+$ the hyperplane parallel to the surface of the ground at height $d > 0$ and assume that measurements and excitations are restricted to an open bounded sheet $\mathcal{M} \subset \Sigma_d$ supporting the device. A time harmonic excitation, given by a magnetic dipole density $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M}) := L^2(\mathcal{M})^3$ on $\mathcal{M}$, leads to a primary electromagnetic field $(\boldsymbol{E}^i, \boldsymbol{H}^i)$ satisfying (3.1) in $\mathbb{R}^3 \setminus \mathcal{M}$, where the magnetic field has the form

$$\boldsymbol{H}^i = k_+^2 \int_{\mathcal{M}} \mathbb{G}^m(\cdot,\boldsymbol{y})\boldsymbol{\varphi}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}); \tag{3.5}$$

cf., e.g., Sommerfeld [34].

We suppose that $\mathbb{R}^3_-$ contains a finite number of perfectly conducting scatterers, each of the form $D_{\delta,j} := \boldsymbol{z}_j + \delta B_j$, where B_j is a bounded domain of class $C^{2,\alpha}$, $0 < \alpha < 1$, containing the origin, such that all components of B_j are simply connected, and their boundaries are connected, $1 \le j \le m$. The points $\boldsymbol{z}_j \in \mathbb{R}^3_-$, $1 \le j \le m$, that determine the location of the scatterers are assumed to satisfy $|\boldsymbol{z}_j - \boldsymbol{z}_l| \ge c_0$ for $j \neq l$ and $\operatorname{dist}(\boldsymbol{z}_j, \Sigma_0) \ge c_0$ for some constant $c_0 > 0$, $1 \le j, l \le m$. The value of $0 < \delta \le 1$, the common order of magnitude of the diameters of the scatterers, is assumed to be small enough such that the scatterers are disjoint and compactly contained in $\mathbb{R}^3_-$. So the total collection of scatterers takes the form $D_\delta := \bigcup_{j=1}^m (\boldsymbol{z}_j + \delta B_j)$. The perfect conductor sitting in D_δ induces a secondary field $(\boldsymbol{E}^s, \boldsymbol{H}^s)$ which is a radiating solution of (3.1) in $\mathbb{R}^3 \setminus \overline{D_\delta}$ subject to the boundary condition

$$\boldsymbol{\nu} \times \boldsymbol{E}^s = -\boldsymbol{\nu} \times \boldsymbol{E}^i \qquad \text{on } \partial D_\delta. \tag{3.6}$$

For a mathematical treatment of this direct problem we refer the reader to [16, 31, 17]. We define the (measurement) operator G_δ, which maps given excitations $\boldsymbol{\varphi}$ onto the corresponding secondary magnetic field $\boldsymbol{H}^s|_{\mathcal{M}}$ on $\mathcal{M}$, i.e.,

$$G_\delta :\ \boldsymbol{L}^2(\mathcal{M}) \to \boldsymbol{L}^2(\mathcal{M}), \quad G_\delta\boldsymbol{\varphi} := \boldsymbol{H}^s|_{\mathcal{M}}. \tag{3.7}$$

As in [20, Thm. 2.1] it can be seen that G_δ is a compact operator.

4. The factorization of G_δ.

In this section we study a factorization of the measurement operator G_δ from (3.7) similar to the one developed in [20], but here we do not restrict ourselves to tangential excitations and measurements.

Suppose $\boldsymbol{\psi} \in \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)$ and denote by $(\boldsymbol{E}^\psi, \boldsymbol{H}^\psi)$ the associated radiating solution of the exterior Maxwell boundary value problem

$$\mathbf{curl}\boldsymbol{H}^\psi + \mathrm{i}\,\omega\varepsilon\boldsymbol{E}^\psi = 0, \quad \mathbf{curl}\boldsymbol{E}^\psi - \mathrm{i}\,\omega\mu\boldsymbol{H}^\psi = 0 \qquad \text{in } \mathbb{R}^3 \setminus \overline{D_\delta}, \tag{4.1a}$$

$$\boldsymbol{\nu} \times \boldsymbol{E}^\psi = \boldsymbol{\psi} \qquad \text{on } \partial D_\delta. \tag{4.1b}$$

Uniqueness of solutions follows for $\Im\varepsilon_- = 0$ from [16, Prop. 2.5]. For $\Im\varepsilon_- > 0$ this was proven in [17, Thm. 2.1]. Existence of solutions will be shown in the next sections by reducing the boundary value problem to an integral equation of the second kind and applying Riesz–Fredholm theory. We define

$$L_\delta : \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta) \to \boldsymbol{L}^2(\mathcal{M}), \quad L_\delta \boldsymbol{\psi} := \boldsymbol{H}^{\psi}|_{\mathcal{M}}. \tag{4.2}$$

Then L_δ is a bounded linear operator. In particular, if $\boldsymbol{E}^i$ and $\boldsymbol{H}^s$ are the primary electric and secondary magnetic fields introduced in section 3, respectively, then $\boldsymbol{\psi} := -\boldsymbol{\nu} \times \boldsymbol{E}^i|_{\partial D_\delta}$ yields $\boldsymbol{H}^{\psi} = \boldsymbol{H}^s$. This means that $L_\delta : -\boldsymbol{\nu} \times \boldsymbol{E}^i|_{\partial D_\delta} \mapsto \boldsymbol{H}^s|_{\mathcal{M}}$.

We denote the standard bilinear form on $\boldsymbol{L}^2(\mathcal{M})$ by $\langle \cdot, \cdot \rangle_{\mathcal{M}}$ and the corresponding transpose of L_δ by $L_\delta^\top : \boldsymbol{L}^2(\mathcal{M}) \to \boldsymbol{H}^{-1/2}_{\mathrm{curl}}(\partial D_\delta)$.

Proposition 4.1. *Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$. Denote by $\boldsymbol{H}^i$ and $\boldsymbol{H}^s$ the associated primary and secondary magnetic fields introduced in section* 3. *Then*

$$L_\delta^\top \boldsymbol{\varphi} = \frac{1}{\mathrm{i}\,\omega\mu_+}(\boldsymbol{\nu} \times \boldsymbol{H}|_{\partial D_\delta}) \times \boldsymbol{\nu} \qquad \text{on } \partial D_\delta, \tag{4.3}$$

where $\boldsymbol{H} = \boldsymbol{H}^i + \boldsymbol{H}^s$ is the total magnetic field.

Proof. Given $\boldsymbol{\psi} \in \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)$, let $(\boldsymbol{E}^{\boldsymbol{\psi}}, \boldsymbol{H}^{\boldsymbol{\psi}})$ be the radiating solution to (4.1). For any $\boldsymbol{y} \in \mathbb{R}^3 \setminus \overline{D_\delta}$ we have the representation formula

$$\boldsymbol{H}^{\boldsymbol{\psi}}(\boldsymbol{y}) = \int_{\partial D_\delta} \frac{\varepsilon(\boldsymbol{y})}{\varepsilon(\boldsymbol{x})}\Big(\mathbb{G}^{m\top}(\boldsymbol{x},\boldsymbol{y})(\boldsymbol{\nu} \times \mathbf{curl}\boldsymbol{H}^{\boldsymbol{\psi}})(\boldsymbol{x}) + (\mathbf{curl}_x\mathbb{G}^m)^\top(\boldsymbol{x},\boldsymbol{y})(\boldsymbol{\nu} \times \boldsymbol{H}^{\boldsymbol{\psi}})(\boldsymbol{x})\Big)\,\mathrm{d}s(\boldsymbol{x});$$

cf. [16, Prop. A.9]. Using this formula the proposition can be proven by applying (4.1), (3.5), (3.6), two times partial integration as in [31, Thm. 3.31], and (3.2). See also [20] for a corresponding result for tangential densities $\boldsymbol{\varphi}$ on $\mathcal{M}$. □

Finally, we consider the diffraction problem

$$\mathbf{curl}\boldsymbol{H}^d + \mathrm{i}\,\omega\varepsilon\boldsymbol{E}^d = 0, \quad \mathbf{curl}\boldsymbol{E}^d - \mathrm{i}\,\omega\mu\boldsymbol{H}^d = 0 \qquad \text{in } \mathbb{R}^3 \setminus \partial D_\delta, \tag{4.4a}$$

with the jump conditions

$$[(\boldsymbol{\nu} \times \boldsymbol{H}^d) \times \boldsymbol{\nu}]_{\partial D_\delta} = \boldsymbol{\chi}, \qquad [\boldsymbol{\nu} \times \boldsymbol{E}^d]_{\partial D_\delta} = 0 \qquad \text{on } \partial D_\delta. \tag{4.4b}$$

Here, $\boldsymbol{\chi} \in \boldsymbol{H}^{-1/2}_{\mathrm{curl}}(\partial D_\delta)$ is a given tangential field on ∂D_δ, and the square brackets denote the differences between the respective traces from outside and inside. We are looking for a radiating solution $(\boldsymbol{E}^d, \boldsymbol{H}^d)$ of this problem. Uniqueness of solutions has been stated in [29, Thm. 3.4] for $\Im\varepsilon_- = 0$. If $\Im\varepsilon_- > 0$ this can be shown by the same arguments as used in [33, pp. 61–63]. Existence of solutions will be shown later by writing them in terms of layer potentials. Given the solution, we define

$$F_\delta : \boldsymbol{H}^{-1/2}_{\mathrm{curl}}(\partial D_\delta) \to \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta), \quad F_\delta\boldsymbol{\chi} := \boldsymbol{\nu} \times \boldsymbol{E}^d|_{\partial D_\delta}. \tag{4.5}$$

Then F_δ is a bounded linear operator. For $\boldsymbol{\chi} = (\boldsymbol{\nu} \times \boldsymbol{H}|_{\partial D_\delta}) \times \boldsymbol{\nu}$, i.e., the tangential component of the total magnetic field corresponding to some excitation $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ as described in section 3, the solution of the diffraction problem (4.4) can be constructed from the corresponding primary and secondary fields, namely,

$$\boldsymbol{E}^d = \begin{cases} \boldsymbol{E}^s, & x \in \mathbb{R}^3 \setminus \overline{D_\delta}, \\ -\boldsymbol{E}^i, & x \in D_\delta, \end{cases} \qquad \boldsymbol{H}^d = \begin{cases} \boldsymbol{H}^s, & x \in \mathbb{R}^3 \setminus \overline{D_\delta}, \\ -\boldsymbol{H}^i, & x \in D_\delta. \end{cases}$$

Consequently, we have $F_\delta:\ (\boldsymbol{\nu}\times\boldsymbol{H}|_{\partial D_\delta})\times\boldsymbol{\nu}\mapsto\boldsymbol{\nu}\times\boldsymbol{E}^s|_{\partial D_\delta}=-\boldsymbol{\nu}\times\boldsymbol{E}^i|_{\partial D_\delta}$. Altogether, we obtain the mapping sequence

$$\boldsymbol{\varphi}\xmapsto{L_\delta^\top}\frac{1}{\mathrm{i}\,\omega\mu_+}(\boldsymbol{\nu}\times\boldsymbol{H}|_{\partial D_\delta})\times\boldsymbol{\nu}\xmapsto{F_\delta}-\frac{1}{\mathrm{i}\,\omega\mu_+}\boldsymbol{\nu}\times\boldsymbol{E}^i|_{\partial D_\delta}\xmapsto{L_\delta}\frac{1}{\mathrm{i}\,\omega\mu_+}\boldsymbol{H}^s|_{\mathcal{M}}.$$

This yields the following theorem; cf. [20] for a corresponding result in case of tangential densities $\boldsymbol{\varphi}$ on $\mathcal{M}$.

THEOREM 4.2. *Given L_δ from* (4.2) *and F_δ from* (4.5) *the measurement operator G_δ from* (3.7) *admits the factorization*

$$G_\delta=\mathrm{i}\,\omega\mu_+L_\delta F_\delta L_\delta^\top. \tag{4.6}$$

5. Surface potentials.

Here, we collect some results concerning boundary integral operators for electromagnetic scattering in two-layered media.

5.1. Surface potentials for homogeneous media.

First, we consider a homogeneous medium with wavenumber k_-. If $D\subset\mathbb{R}^3$ is a bounded domain of class $C^{2,\alpha}$, $0<\alpha<1$, the single layer potential with smooth density f is defined by

$$(\mathcal{S}_D^-f)(\boldsymbol{x}):=\int_{\partial D}\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})f(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}),\qquad \boldsymbol{x}\in\mathbb{R}^3\setminus\partial D.$$

Then $\mathcal{S}_D^-f$ and $\boldsymbol{\nu}\times\nabla\mathcal{S}_D^-f$ are continuous across ∂D; cf. [14, Thm. 2.12, Thm. 2.17]. It can be shown [30, Thm. 6.11] that the mapping $\mathcal{S}_D^-:H^{-1/2}(\partial D)\to H^1_{\mathrm{loc}}(\mathbb{R}^3)$ is bounded. The jump relations on ∂D remain valid for $f\in H^{-1/2}(\partial D)$, but they have to be interpreted in the sense of trace theorems.

Analogously, the vector potential with smooth tangential density $\boldsymbol{a}$ is given by

$$(\mathcal{A}_D^-\boldsymbol{a})(\boldsymbol{x}):=\int_{\partial D}\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}),\qquad \boldsymbol{x}\in\mathbb{R}^3\setminus\partial D.$$

Then $\mathcal{A}_D^-\boldsymbol{a}$, $\boldsymbol{\nu}\cdot\mathbf{curl}\mathcal{A}_D^-\boldsymbol{a}$, and $\boldsymbol{\nu}\times\mathbf{curl}\,\mathbf{curl}\mathcal{A}_D^-\boldsymbol{a}$ are continuous across ∂D; cf. [14, Thm. 2.24] and [15, Thm. 6.11]. The tangential components of $\boldsymbol{\nu}\times\mathbf{curl}\mathcal{A}_D^-\boldsymbol{a}$ are discontinuous across ∂D and satisfy the jump relation

$$\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}\mathcal{A}_D^-\boldsymbol{a}\big|_{\partial D}^{\pm}(\boldsymbol{x})=\int_{\partial D}\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}_x(\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y}))\,\mathrm{d}s(\boldsymbol{y})\pm\frac{1}{2}\boldsymbol{a}(\boldsymbol{x})$$

for $\boldsymbol{x}\in\partial D$. It can be shown [30, Thm. 6.11] that $\mathcal{A}_D^-:\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)\to\boldsymbol{H}_{\mathrm{loc}}(\mathbf{curl},\mathbb{R}^3)$ is bounded and that the jump relations on ∂D remain valid for $\boldsymbol{a}\in\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$. Furthermore, for smooth tangential densities $\boldsymbol{a}$ we define

$$\begin{aligned}(M_D^-\boldsymbol{a})(\boldsymbol{x})&:=\int_{\partial D}\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}_{\boldsymbol{x}}(\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y}))\,\mathrm{d}s(\boldsymbol{y}), &&\boldsymbol{x}\in\partial D,\\ (N_D^-\boldsymbol{a})(\boldsymbol{x})&:=\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}\,\mathbf{curl}\int_{\partial D}\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})\boldsymbol{\nu}(\boldsymbol{y})\times\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}), &&\boldsymbol{x}\in\partial D.\end{aligned}$$

Combining results from [30, 15] and [27], it can be seen that the operators $M_D^-:\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)\to\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $N_D^-:\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)\to\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ are continuous. Moreover, M_D^- is compact, and its transpose with respect to the bilinear form $\langle\cdot,\cdot\rangle_{\partial D}$ is given by $M_D^{-\top}=rM_D^-r$. The operator N_D^- is symmetric. We also need the following identity (see [15, p. 170]:

$$\operatorname{div}\mathcal{A}_D^-\boldsymbol{a}=\mathcal{S}_D^-\operatorname{div}_{\partial D}\boldsymbol{a},\qquad \boldsymbol{a}\in\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D). \tag{5.1}$$

5.2. The potential theoretic limit. For $k_- = 0$ the expression Φ_{k_-} reduces to the fundamental solution Φ_0 of Laplace's equation. Substituting Φ_{k_-} by Φ_0 in the definitions above, we obtain integral operators

$$\mathcal{S}_D^0 : H^{-1/2}(\partial D) \to H^1_{\mathrm{loc}}(\mathbb{R}^3), \qquad \mathcal{A}_D^0 : \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{loc}}(\mathbf{curl}, \mathbb{R}^3),$$
$$M_D^0 : \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D), \qquad N_D^0 : \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D).$$

The corresponding mapping properties and jump relations remain valid for $k = 0$. Suppose that all components of D are simply connected and the complement of D is connected. Then the operator $\frac{1}{2}I + M_D^0$ has trivial nullspace in $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ [14, Thm. 5.5]. Therefore, we can apply Fredholm's alternative and find that $\frac{1}{2}I + M_D^0$ and $\frac{1}{2}I + {M_D^0}^\top$ are invertible on $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$, respectively. From ${M_D^0}^\top = r M_D^0 r$ we observe that for any $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ it holds that

$$\left(\frac{1}{2}I \pm {M_D^0}^\top\right) r\boldsymbol{a} = r\left(\frac{1}{2}I \mp M_D^0\right)\boldsymbol{a}. \tag{5.2}$$

Thus, $-\frac{1}{2}I + M_D^0$ and $-\frac{1}{2}I + {M_D^0}^\top$ are invertible on $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$, respectively, too.

Furthermore, given a scalar smooth function f we define

$$(K_D^0 f)(\boldsymbol{x}) := \int_{\partial D} \frac{\partial \Phi_0(\boldsymbol{x}-\boldsymbol{y})}{\partial \boldsymbol{\nu}(\boldsymbol{y})} f(\boldsymbol{y}) \,\mathrm{d}s(\boldsymbol{y}), \qquad \boldsymbol{x} \in \partial D.$$

It can be shown [32, Thm. 4.4.1] that the mapping $K_D^0 : H^{1/2}(\partial D) \to H^{1/2}(\partial D)$ is compact. The operator $-\frac{1}{2}I + K_D^0$ has trivial nullspace in $H^{1/2}(\partial D)$ [3, Lem. 2.5]. Hence, by Fredholm's alternative $-\frac{1}{2}I + K_D^0$ and $-\frac{1}{2}I + {K_D^0}^\top$ are invertible on $H^{1/2}(\partial D)$ and $H^{-1/2}(\partial D)$, respectively.

Lemma 5.1. (a) *The operators* $\pm\frac{1}{2}I + M_D^0$ *are isomorphisms on*

$$\boldsymbol{H}_{\mathrm{div},0}^{-1/2}(\partial D) := \{\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \mid \mathrm{div}_{\partial D}\, \boldsymbol{a} = 0\}.$$

(b) *For any* $f \in H^{1/2}(\partial D)$,

$$\left(\pm\frac{1}{2}I + {M_D^0}^\top\right)^{-1} \nabla_{\partial D} f = -\nabla_{\partial D}\left(\mp\frac{1}{2}I + K_D^0\right)^{-1} f. \tag{5.3}$$

Proof. Part (a) follows at once from

$$\mathrm{div}_{\partial D}\, M_D^0 \boldsymbol{a} = -{K_D^0}^\top \mathrm{div}_{\partial D}\, \boldsymbol{a}, \qquad \boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D); \tag{5.4}$$

cf. [15, p. 169]. By duality, (5.4) yields ${M_D^0}^\top \nabla_{\partial D} f = -\nabla_{\partial D} K_D^0 f$ for $f \in H^{1/2}(\partial D)$. Thus, we find

$$\left(\pm\frac{1}{2}I + {M_D^0}^\top\right)\nabla_{\partial D} f = -\nabla_{\partial D}\left(\mp\frac{1}{2}I + K_D^0\right) f,$$

which gives (5.3). □

5.3. Surface potentials for layered media. Here, we consider again the two-layered medium introduced in section 3. Let $D \subset \mathbb{R}^3_-$ be a bounded domain of class $C^{2,\alpha}$, $0 < \alpha < 1$, such that $\operatorname{dist}(D, \Sigma_0) \geq c_0$ for some constant $c_0 > 0$. We define modified vector potentials with smooth tangential density $\boldsymbol{a}$ by

$$\begin{aligned}(\mathcal{A}_D^{e/m}\boldsymbol{a})(\boldsymbol{x}) :=& \int_{\partial D} \Pi^{e/m}(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y})\\ &=(\mathcal{A}_D^{-}\boldsymbol{a})(\boldsymbol{x}) + \int_{\partial D} F^{e/m}(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}), \qquad \boldsymbol{x} \in \mathbb{R}^3 \setminus \partial D,\end{aligned}$$

and boundary integrals

$$(R_D^{e/m}\boldsymbol{a})(\boldsymbol{x}) := \int_{\partial D} \boldsymbol{\nu}(\boldsymbol{x}) \times \mathbf{curl}_x(F^{e/m}(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y}))\,\mathrm{d}s(\boldsymbol{y}), \qquad \boldsymbol{x} \in \partial D, \tag{5.5}$$

$$\begin{aligned}(M_D^{e/m}\boldsymbol{a})(\boldsymbol{x}) :=& \int_{\partial D} \boldsymbol{\nu}(\boldsymbol{x}) \times \mathbf{curl}_x(\Pi^{e/m}(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y}))\,\mathrm{d}s(\boldsymbol{y})\\ &=(M_D^{-}\boldsymbol{a})(\boldsymbol{x}) + (R_D^{e/m}\boldsymbol{a})(\boldsymbol{x}), \qquad \boldsymbol{x} \in \partial D.\end{aligned} \tag{5.6}$$

Because $F^{e/m}(\cdot,\boldsymbol{y})$ is smooth in $\mathbb{R}^3_0$ for $\boldsymbol{y}$ in any compact subset of $\mathbb{R}^3_0$, we find that $\mathcal{A}_D^{e/m}\boldsymbol{a}$ and $\boldsymbol{\nu} \times \mathbf{curl}\,\mathbf{curl}\mathcal{A}_D^{e/m}\boldsymbol{a}$ are continuous across ∂D. Furthermore,

$$\boldsymbol{\nu} \times \mathbf{curl}\mathcal{A}_D^{e/m}\boldsymbol{a}\big|_{\partial D}^{\pm} = \Big(\pm\frac{1}{2}I + M_D^{e/m}\Big)\boldsymbol{a} \qquad \text{on } \partial D.$$

The mapping $\mathcal{A}_D^{e/m} : \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{loc}}(\mathbf{curl}, \mathbb{R}^3_0)$ is continuous, and the operators $R_D^{e/m} : \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $M_D^{e/m} : \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ are compact. Assume that the exterior of D is connected and that the wavenumber k_- is not an interior Maxwell eigenvalue for D. Then the operator $\frac{1}{2}I + M_D^m$ has trivial nullspace in $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$. This can be proven in essentially the same way as [14, Thm. 4.23] for homogeneous medium and continuous densities. So we can apply Fredholm's alternative to obtain that $\frac{1}{2}I + M_D^m$ and $\frac{1}{2}I + M_D^{m\top}$ are invertible on $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$, respectively.

6. First estimates. In the following two sections we consider the case of a single scatterer, i.e., $D_\delta = \boldsymbol{z} + \delta B$. Multiple scatterers will be studied in section 8.

We often have to deal with changes of coordinates; thus we introduce the following notation. Given $\boldsymbol{a} \in C(\partial D_\delta)^3$ and $\boldsymbol{b} \in C(\partial B)^3$ we define $\hat{\boldsymbol{a}}, (\boldsymbol{a})^\wedge \in C(\partial B)^3$ and $\check{\boldsymbol{b}}, (\boldsymbol{b})^\vee \in C(\partial D_\delta)^3$ by

$$(\boldsymbol{a})^\wedge(\boldsymbol{\xi}) := \hat{\boldsymbol{a}}(\boldsymbol{\xi}) := \boldsymbol{a}(\delta\boldsymbol{\xi} + \boldsymbol{z}) \quad \text{and} \quad (\boldsymbol{b})^\vee(\boldsymbol{x}) := \check{\boldsymbol{b}}(\boldsymbol{x}) := \boldsymbol{b}\Big(\frac{\boldsymbol{x}-\boldsymbol{z}}{\delta}\Big) \tag{6.1}$$

for $\boldsymbol{\xi} \in \partial B$ and $\boldsymbol{x} \in \partial D_\delta$, respectively. This notation is also applied to functions from Sobolev spaces.

For arbitrary bounded domains $D \subset \mathbb{R}^3$ of class $C^{2,\alpha}$, $0 < \alpha < 1$, we use the following norms on $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)$:

$$\|\boldsymbol{a}\|_{\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D)} := \inf_{\boldsymbol{u}\in\boldsymbol{H}(\mathbf{curl},D),\,\gamma_t(\boldsymbol{u})=\boldsymbol{a}} \|\boldsymbol{u}\|_{\boldsymbol{H}(\mathbf{curl},D)} \qquad \text{for } \boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D),$$

$$\|\boldsymbol{b}\|_{\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D)} := \inf_{\boldsymbol{u}\in\boldsymbol{H}(\mathbf{curl},D),\,\pi_t(\boldsymbol{u})=\boldsymbol{b}} \|\boldsymbol{u}\|_{\boldsymbol{H}(\mathbf{curl},D)} \qquad \text{for } \boldsymbol{b} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D).$$

A simple calculation (cf. [1, Lem. 4.1] for a similar result) yields the following scaling properties of these norms under changes of coordinates as in (6.1). Suppose $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$, $\boldsymbol{b} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta)$, and assume $0 < \delta \leq 1$. Then

$$\delta^{\frac{3}{2}} \|\hat{\boldsymbol{a}}\|_{\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)} \leq \|\boldsymbol{a}\|_{\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)} \leq \delta^{\frac{1}{2}} \|\hat{\boldsymbol{a}}\|_{\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)}, \tag{6.2a}$$

$$\delta^{\frac{3}{2}} \|\hat{\boldsymbol{b}}\|_{\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)} \leq \|\boldsymbol{b}\|_{\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta)} \leq \delta^{\frac{1}{2}} \|\hat{\boldsymbol{b}}\|_{\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)}. \tag{6.2b}$$

In order to derive the asymptotic expansion in section 7 we need to expand the fundamental solution $\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y}) = \Phi_{k_-}(\delta(\boldsymbol{\xi}-\boldsymbol{\eta}))$ for $\boldsymbol{x} = \delta\boldsymbol{\xi}+\boldsymbol{z} \neq \delta\boldsymbol{\eta}+\boldsymbol{z} = \boldsymbol{y} \in \partial D_\delta$, i.e., $\boldsymbol{\xi} \neq \boldsymbol{\eta} \in \partial B$, as $\delta \to 0$. Expanding $e^{\mathrm{i}\,k_-\delta|\boldsymbol{\xi}-\boldsymbol{\eta}|}$ in a power series we obtain the following formulas:

$$\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y}) = \frac{1}{\delta}\left(\Phi_0(\boldsymbol{\xi}-\boldsymbol{\eta}) + \frac{\mathrm{i}\,k_-\delta}{4\pi} + \mathcal{O}(\delta^2)\right) \qquad \text{as } \delta \to 0, \tag{6.3}$$

$$\nabla_x \Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y}) = \frac{1}{\delta^2}\left(\nabla_\xi \Phi_0(\boldsymbol{\xi}-\boldsymbol{\eta}) - \frac{k_-^2\delta^2}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|} + \mathcal{O}(\delta^3)\right) \qquad \text{as } \delta \to 0. \tag{6.4}$$

Remark 6.1 (eigenvalues). In section 5.3 we had to assume that the wavenumber k_- is not an interior Maxwell eigenvalue for the bounded domain D to obtain invertibility of the operators $\frac{1}{2}I + M_D^m$ and $\frac{1}{2}I + M_D^{m\top}$. Interior Maxwell eigenvalues for D are wavenumbers κ such that Maxwell's equations (3.1) in D with homogeneous boundary condition $\boldsymbol{\nu} \times \boldsymbol{E}|_{\partial D} = 0$ on ∂D have a nontrivial solution. If $\Im\kappa > 0$, it is well known that solutions to the interior Maxwell boundary value problem are unique (cf. [31, Thm. 4.17]), and thus κ is no eigenvalue. On the other hand, there is a discrete set of real eigenvalues $\kappa_j > 0$, $j \in \mathbb{N}$, for D accumulating only at infinity; cf. [31, Thm. 4.18].

Let $\{k_j\}_{j\in\mathbb{N}}$ be the set of interior Maxwell eigenvalues corresponding to the reference domain B. By a change of coordinates in the variational formulation of the eigenvalue problem (see [31, p. 96]), we find that $\{\delta^{-1}k_j\}_{j\in\mathbb{N}}$ is the set of eigenvalues corresponding to the domain $D_\delta = z + \delta B$, $0 < \delta \leq 1$. Therefore, we can assume henceforth in the derivation of the asymptotic expansion without loss of generality that δ is small enough so that $k_- \notin \{\delta^{-1}k_j\}_{j\in\mathbb{N}}$, i.e., that k_- is no interior Maxwell eigenvalue for the domains D_δ considered hereafter.

In the next lemma we investigate the scaling properties of the operator $M_{D_\delta}^m$.

LEMMA 6.2. *For $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$ we have*

$$M_{D_\delta}^m \boldsymbol{a} = (M_B^0 \hat{\boldsymbol{a}})^\vee + (E_M^m \hat{\boldsymbol{a}})^\vee.$$

Here E_M^m is a bounded linear operator, which is $\mathcal{O}(\delta^2)$ in $\mathcal{L}(\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B))$ as $\delta \to 0$, independent of $\boldsymbol{a}$.

Proof. Let $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$ and $\boldsymbol{a}_j$, $j \in \mathbb{N}$, be smooth tangential vector fields with smooth surface divergence on ∂D_δ so that $\boldsymbol{a}_j$ converges to $\boldsymbol{a}$ in $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$. For fixed $j \in \mathbb{N}$ and $\boldsymbol{x} \in D_\delta$ we observe by a change of variables $\boldsymbol{\xi} := \frac{\boldsymbol{x}-\boldsymbol{z}}{\delta}$ and $\boldsymbol{\eta} := \frac{\boldsymbol{y}-\boldsymbol{z}}{\delta}$ that

$$(M_{D_\delta}^0 \boldsymbol{a}_j)(\boldsymbol{x}) = \int_{\partial B} \boldsymbol{\nu}(\boldsymbol{\xi}) \times \frac{1}{\delta}\mathbf{curl}_\xi \left(\hat{\boldsymbol{a}}_j(\boldsymbol{\eta}) \frac{1}{4\pi\delta|\boldsymbol{\xi}-\boldsymbol{\eta}|}\right) \delta^2 \,\mathrm{d}s(\boldsymbol{\eta}) = (M_B^0 \hat{\boldsymbol{a}}_j)(\boldsymbol{\xi}),$$

i.e., $M_{D_\delta}^0 \boldsymbol{a}_j = (M_B^0 \hat{\boldsymbol{a}}_j)^\vee$. From (6.4) we find

$$\nabla_x(\Phi_{k_-} - \Phi_0)(\boldsymbol{x}-\boldsymbol{y}) = \frac{1}{\delta^2}\left(-\frac{k_-^2\delta^2}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|} + \mathcal{O}(\delta^3)\right)$$

for $\boldsymbol{x} \neq \boldsymbol{y}$ as $\delta \to 0$. So, again by a change of coordinates we obtain for $\boldsymbol{x} \in \partial D_\delta$

$$\begin{aligned}\big((M^-_{D_\delta} - M^0_{D_\delta})\boldsymbol{a}_j\big)(\boldsymbol{x}) &= \int_{\partial D_\delta} \boldsymbol{\nu}(\boldsymbol{x}) \times \big(\nabla_x(\Phi_{k_-} - \Phi_0)(\boldsymbol{x}-\boldsymbol{y}) \times \boldsymbol{a}_j(\boldsymbol{y})\big)\,\mathrm{d}s(\boldsymbol{y})\\ &= \delta^2 \int_{\partial B} \boldsymbol{\nu}(\boldsymbol{\xi}) \times \bigg(\Big(-\frac{k_-^2}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|} + \mathcal{O}(\delta)\Big) \times \hat{\boldsymbol{a}}_j(\boldsymbol{\eta})\bigg)\,\mathrm{d}s(\boldsymbol{\eta}) =: (E^-_M \hat{\boldsymbol{a}}_j)(\boldsymbol{\xi}).\end{aligned}$$

The kernel of E^-_M is pseudohomogeneous of class -2 (cf. [32, pp. 168–175]), and hence E^-_M is continuous from $H^{-1/2}(\partial B)^3$ into $H^{3/2}(\partial B)^3$; cf. [32, Thm. 4.3.2]. So E^-_M is also continuous from $\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)$ to $\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)$; in particular, it is $\mathcal{O}(\delta^2)$ in $\mathcal{L}(\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B))$ as $\delta \to 0$. Thus, recalling the continuity properties of the operators $M^-_{D_\delta}$, M^0_B, and E^-_M and letting $j \to \infty$, we obtain

$$M^-_{D_\delta}\boldsymbol{a} = (M^0_B \hat{\boldsymbol{a}})^\vee + (E^-_M \hat{\boldsymbol{a}})^\vee.$$

Recalling (5.6) it remains to estimate the norm of $R^m_{D_\delta}\boldsymbol{a}$. For this purpose, we denote by $\tilde{R}^m_{D_\delta}\boldsymbol{a}$ the extension of $R^m_{D_\delta}$ to $\boldsymbol{H}(\mathbf{curl}, D_\delta)$ (with respect to the trace operator γ_t), which is obtained canonically from (5.5) via

$$\tilde{R}^m_{D_\delta}\boldsymbol{a} := \int_{\partial D_\delta} \mathbf{curl}_x F^m(\cdot, \boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}) \qquad \text{in } D_\delta.$$

Then, because F^m is smooth near the center of the scatterer,

$$\begin{aligned}\|R^m_{D_\delta}\boldsymbol{a}\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)} &= \inf_{\boldsymbol{u}\in \boldsymbol{H}(\mathbf{curl},D_\delta),\, \gamma_t(\boldsymbol{u}) = R^m_{D_\delta}\boldsymbol{a}} \|\boldsymbol{u}\|^2_{\boldsymbol{H}(\mathbf{curl},D_\delta)} \leq \|\tilde{R}^m_{D_\delta}\boldsymbol{a}\|^2_{\boldsymbol{H}(\mathbf{curl},D_\delta)}\\ &= \int_{D_\delta}\Big|\int_{\partial D_\delta} \mathbf{curl}_x F^m(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y})\Big|^2\,\mathrm{d}\boldsymbol{x}\\ &\quad + \int_{D_\delta}\Big|\mathbf{curl}_x \int_{\partial D_\delta} \mathbf{curl}_x F^m(\boldsymbol{x},\boldsymbol{y})\boldsymbol{a}(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y})\Big|^2\,\mathrm{d}\boldsymbol{x}\\ &\leq \int_{D_\delta}\Big(\|\mathbf{curl}_x F^m(\boldsymbol{x},\cdot)\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{curl}}(\partial D_\delta)}\\ &\qquad\quad + \|\mathbf{curl}_x\,\mathbf{curl}_x F^m(\boldsymbol{x},\cdot)\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{curl}}(\partial D_\delta)}\Big)\|\boldsymbol{a}\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)}\,\mathrm{d}\boldsymbol{x}\\ &\leq C\delta^3\|\boldsymbol{a}\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)}\int_{D_\delta} 1\,\mathrm{d}\boldsymbol{x} \leq C\delta^6\|\boldsymbol{a}\|^2_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)}.\end{aligned}$$

Using (6.2) we find

$$\|(R^m_{D_\delta}\boldsymbol{a})^\wedge\|_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)} \leq \delta^{-\frac{3}{2}}\|R^m_{D_\delta}\boldsymbol{a}\|_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)} \leq C\delta^2\|\hat{\boldsymbol{a}}\|_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)}.$$

Thus, we define

$$E^m_M\boldsymbol{b} := E^-_M\boldsymbol{b} + (R^m_{D_\delta}\check{\boldsymbol{b}})^\wedge, \qquad \boldsymbol{b} \in \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B),$$

and obtain the desired result. ∎

For $\boldsymbol{a} \in \boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial D_\delta)$ Lemma 6.2 yields

$$\Big(\frac{1}{2}I + M^m_{D_\delta}\Big)\boldsymbol{a} = \Big(\Big(\frac{1}{2}I + M^0_B + E^m_M\Big)\hat{\boldsymbol{a}}\Big)^\vee.$$

Thus,

$$(6.5)\quad \Big(\frac{1}{2}I+M^m_{D_\delta}\Big)^{-1}\boldsymbol{a} = \Big(\Big(\frac{1}{2}I+M^0_B+E^m_M\Big)^{-1}\hat{\boldsymbol{a}}\Big)^\vee = \Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\hat{\boldsymbol{a}}\Big)^\vee+(\tilde{E}^m_M\hat{\boldsymbol{a}})^\vee,$$

where $\tilde{E}^m_M$ is a bounded linear operator, which is $\mathcal{O}(\delta^2)$ in $\mathcal{L}(\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B))$ as $\delta \to 0$, independent of $\boldsymbol{a}$.

7. Asymptotic expansion. In this section we expand the three operators L_δ, $L_\delta^\top$, and F_δ occurring in the factorization (4.6) of the measurement operator G_δ separately as the inhomogeneity size δ tends to zero. Then, we use these expansions to calculate the leading order term in the asymptotic expansion of G_δ.

First, we consider the exterior Maxwell boundary value problem (4.1) and study the asymptotic behavior of the operator L_δ from (4.2). A radiating solution of this problem is given by

$$\begin{aligned}
\boldsymbol{E}^\psi &:= \frac{\varepsilon_-}{\varepsilon}\mathbf{curl}\mathcal{A}^m_{D_\delta}\Big(\frac{1}{2}I+M^m_{D_\delta}\Big)^{-1}\boldsymbol{\psi} && \text{in } \mathbb{R}^3_0\setminus\overline{D_\delta},\\
\boldsymbol{H}^\psi &:= -\,\mathrm{i}\,\omega\varepsilon_-\int_{\partial D_\delta}\mathbb{G}^m(\cdot,\boldsymbol{y})\Big(\Big(\frac{1}{2}I+M^m_{D_\delta}\Big)^{-1}\boldsymbol{\psi}\Big)(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}) && \text{in } \mathbb{R}^3_0\setminus\overline{D_\delta}.
\end{aligned}$$

By Taylor expansion we obtain for $\boldsymbol{x}\in\mathcal{M}$, $\boldsymbol{z}\in\mathbb{R}^3_-$ with $\mathrm{dist}(\boldsymbol{z},\Sigma_0)\geq c_0$ for some constant $c_0>0$, and $\boldsymbol{\eta}\in\partial B$ as $\delta\to 0$ that

$$\mathbb{G}^m(\boldsymbol{x},\delta\boldsymbol{\eta}+\boldsymbol{z}) = \mathbb{G}^m(\boldsymbol{x},\boldsymbol{z})+\delta\sum_{l=1}^3\frac{\partial\mathbb{G}^m}{\partial y_l}(\boldsymbol{x},\boldsymbol{z})\eta_l+\mathcal{O}(\delta^2).$$

Thus, by a change of coordinates, applying (6.5) we have

$$\begin{aligned}
\boldsymbol{H}^\psi(\boldsymbol{x}) &= -\,\mathrm{i}\,\omega\varepsilon_-\delta^2\int_{\partial B}\mathbb{G}^m(\boldsymbol{x},\delta\boldsymbol{\eta}+\boldsymbol{z})\Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\hat{\boldsymbol{\psi}}\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})+\mathcal{O}(\delta^4)\\
&= -\,\mathrm{i}\,\omega\varepsilon_-\delta^2\mathbb{G}^m(\boldsymbol{x},\boldsymbol{z})\int_{\partial B}\Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\hat{\boldsymbol{\psi}}\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})\\
&\quad -\,\mathrm{i}\,\omega\varepsilon_-\delta^3\int_{\partial B}\sum_{l=1}^3\eta_l\frac{\partial\mathbb{G}^m}{\partial y_l}(\boldsymbol{x},\boldsymbol{z})\Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\hat{\boldsymbol{\psi}}\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})+\mathcal{O}(\delta^4)
\end{aligned}$$

for $\boldsymbol{x}\in\mathcal{M}$ as $\delta\to 0$. The last term on the right-hand side is bounded by $C\delta^4\|\hat{\boldsymbol{\psi}}\|_{\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)}$, where the constant C is independent of δ and $\boldsymbol{\psi}$, uniformly for $\boldsymbol{x}\in\mathcal{M}$. We define $L_0:\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)\to\boldsymbol{L}^2(\mathcal{M})$,

$$(7.1)\qquad L_0\boldsymbol{a} := -\,\mathrm{i}\,\omega\varepsilon_-\mathbb{G}^m(\cdot,\boldsymbol{z})\int_{\partial B}\Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\boldsymbol{a}\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}),$$

and $L_1:\boldsymbol{H}^{-1/2}_{\mathrm{div}}(\partial B)\to\boldsymbol{L}^2(\mathcal{M})$,

$$(7.2)\qquad L_1\boldsymbol{a} := -\,\mathrm{i}\,\omega\varepsilon_-\int_{\partial B}\sum_{l=1}^3\eta_l\frac{\partial\mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z})\Big(\Big(\frac{1}{2}I+M^0_B\Big)^{-1}\boldsymbol{a}\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}).$$

Then L_0 and L_1 are bounded linear operators, and we have the following asymptotic behavior.

Proposition 7.1. *For all $\boldsymbol{\psi} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$,*

$$L_\delta \boldsymbol{\psi} = \delta^2 L_0 \hat{\boldsymbol{\psi}} + \delta^3 L_1 \hat{\boldsymbol{\psi}} + E_L \hat{\boldsymbol{\psi}}, \tag{7.3}$$

where E_L is a bounded linear operator, which is $\mathcal{O}(\delta^4)$ in $\mathcal{L}(\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B), \boldsymbol{L}^2(\mathcal{M}))$ as $\delta \to 0$, independent of $\boldsymbol{\psi}$.

Next we consider the asymptotic behavior of the operator $L_\delta^\top$ from (4.3). Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ and $\boldsymbol{\psi} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$. For $X \in \{B, D_\delta\}$ we denote by $\langle \cdot, \cdot \rangle_{\partial X}$ the duality pairing between $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial X)$ and $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial X)$. Using (7.3) we obtain

$$\begin{aligned}\langle L_\delta^\top \boldsymbol{\varphi}, \boldsymbol{\psi} \rangle_{\partial D_\delta} &= \langle \boldsymbol{\varphi}, L_\delta \boldsymbol{\psi} \rangle_{\mathcal{M}} = \langle \delta^2 L_0^\top \boldsymbol{\varphi} + \delta^3 L_1^\top \boldsymbol{\varphi} + E_L^\top \boldsymbol{\varphi}, \hat{\boldsymbol{\psi}} \rangle_{\partial B} \\ &= \langle (L_0^\top \boldsymbol{\varphi})^\vee + \delta (L_1^\top \boldsymbol{\varphi})^\vee + \delta^{-2} (E_L^\top \boldsymbol{\varphi})^\vee, \boldsymbol{\psi} \rangle_{\partial D_\delta},\end{aligned}$$

where $L_0^\top, L_1^\top, E_L^\top : \boldsymbol{L}^2(\mathcal{M}) \to \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)$ are the dual operators of L_0, L_1, and E_L, respectively. Because by duality $E_L^\top$ is $\mathcal{O}(\delta^4)$ in $\mathcal{L}(\boldsymbol{L}^2(\mathcal{M}), \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B))$, we obtain the following asymptotic behavior.

Proposition 7.2. *For all $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$,*

$$L_\delta^\top \boldsymbol{\varphi} = (L_0^\top \boldsymbol{\varphi})^\vee + \delta (L_1^\top \boldsymbol{\varphi})^\vee + \delta^{-2} (E_L^\top \boldsymbol{\varphi})^\vee,$$

where $E_L^\top$ is a bounded linear operator, which is $\mathcal{O}(\delta^4)$ in $\mathcal{L}(\boldsymbol{L}^2(\mathcal{M}), \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B))$ as $\delta \to 0$, independent of $\boldsymbol{\varphi}$.

Now we calculate the operators $L_0^\top$ and $L_1^\top$ explicitly. Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ and $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$. Recalling the definition of the operator L_0 from (7.1) we find

$$\begin{aligned}\langle \boldsymbol{\varphi}, L_0 \boldsymbol{a} \rangle_{\mathcal{M}} &= \int_{\mathcal{M}} \Big(-\mathrm{i}\,\omega \varepsilon_- \mathbb{G}^m(\boldsymbol{x}, \boldsymbol{z}) \int_{\partial B} \Big(\Big(\frac{1}{2} I + M_B^0 \Big)^{-1} \boldsymbol{a} \Big)(\boldsymbol{\eta}) \,\mathrm{d}s(\boldsymbol{\eta}) \Big) \cdot \boldsymbol{\varphi}(\boldsymbol{x}) \,\mathrm{d}s(\boldsymbol{x}) \\ &= \Big(-\mathrm{i}\,\omega \varepsilon_- \int_{\mathcal{M}} \mathbb{G}^{m\top}(\boldsymbol{x}, \boldsymbol{z}) \boldsymbol{\varphi}(\boldsymbol{x}) \,\mathrm{d}s(\boldsymbol{x}) \Big) \cdot \int_{\partial B} \Big(\Big(\frac{1}{2} I + M_B^0 \Big)^{-1} \boldsymbol{a} \Big)(\boldsymbol{\eta}) \,\mathrm{d}s(\boldsymbol{\eta}).\end{aligned}$$

Recalling (3.4b) and (3.5), we obtain

$$\begin{aligned}\langle \boldsymbol{\varphi}, L_0 \boldsymbol{a} \rangle_{\mathcal{M}} &= \frac{1}{\mathrm{i}\,\omega \mu_+} \boldsymbol{H}^i(\boldsymbol{z}) \cdot \int_{\partial B} \Big(\Big(\frac{1}{2} I + M_B^0 \Big)^{-1} \boldsymbol{a} \Big)(\boldsymbol{\eta}) \,\mathrm{d}s(\boldsymbol{\eta}) \\ &= \int_{\partial B} \frac{1}{\mathrm{i}\,\omega \mu_+} \Big(\Big(\frac{1}{2} I + M_B^{0\top} \Big)^{-1} \pi_t \big(\boldsymbol{H}^i(\boldsymbol{z}) \big) \Big)(\boldsymbol{\xi}) \cdot \boldsymbol{a}(\boldsymbol{\xi}) \,\mathrm{d}s(\boldsymbol{\xi}),\end{aligned}$$

where π_t denotes the projection on the tangent plane to ∂B. Therefore, we have

$$L_0^\top \boldsymbol{\varphi} = \frac{1}{\mathrm{i}\,\omega \mu_+} \Big(\frac{1}{2} I + M_B^{0\top} \Big)^{-1} \pi_t (\boldsymbol{H}^i(\boldsymbol{z})). \tag{7.4}$$

In the same way we obtain from (7.2) that

$$\langle \boldsymbol{\varphi}, L_1 \boldsymbol{a} \rangle_{\mathcal{M}} = \int_{\partial B} \frac{1}{\mathrm{i}\,\omega \mu_+} \Big(\Big(\frac{1}{2} I + M_B^{0\top} \Big)^{-1} \pi_t \Big(\sum_{l=1}^{3} \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z}) \Big) \Big)(\boldsymbol{\xi}) \cdot \boldsymbol{a}(\boldsymbol{\xi}) \,\mathrm{d}s(\boldsymbol{\xi}).$$

Here, η_l denotes the lth component of the surface variable on ∂B. Thus we have

$$L_1^\top \boldsymbol{\varphi} = \frac{1}{\mathrm{i}\,\omega \mu_+} \Big(\frac{1}{2} I + M_B^{0\top} \Big)^{-1} \pi_t \Big(\sum_{l=1}^{3} \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z}) \Big). \tag{7.5}$$

We return to the diffraction problem (4.4) and the operator F_δ from (4.5). Given $\boldsymbol{\chi} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta)$, we define

$$\begin{aligned} \boldsymbol{E}^d &:= -\frac{1}{\mathrm{i}\,\omega\varepsilon}\mathbf{curl}\frac{\mu_-}{\mu}\mathbf{curl}\mathcal{A}^e_{D_\delta}(\boldsymbol{\nu}\times\boldsymbol{\chi}) && \text{in } \mathbb{R}^3_0 \setminus \partial D_\delta, \\ \boldsymbol{H}^d &:= \frac{\mu_-}{\mu}\mathbf{curl}\mathcal{A}^e_{D_\delta}(\boldsymbol{\nu}\times\boldsymbol{\chi}) && \text{in } \mathbb{R}^3_0 \setminus \partial D_\delta. \end{aligned}$$

Then $(\boldsymbol{E}^d, \boldsymbol{H}^d)$ is a radiating solution to (4.4), and recalling (3.3), (5.1), and (2.1) we find

$$\begin{aligned} \boldsymbol{\nu}\times\boldsymbol{E}^d\big|_{\partial D_\delta}(\boldsymbol{x}) &= -\frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}_x\,\mathbf{curl}_x\int_{\partial D_\delta}\Pi^e(\boldsymbol{x},\boldsymbol{y})(\boldsymbol{\nu}\times\boldsymbol{\chi})(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}) \\ &= \mathrm{i}\,\omega\mu_-\boldsymbol{\nu}(\boldsymbol{x})\times\int_{\partial D_\delta}\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})(\boldsymbol{\nu}\times\boldsymbol{\chi})(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}) \\ &\quad+\frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}(\boldsymbol{x})\times\int_{\partial D_\delta}\nabla_x\Phi_{k_-}(\boldsymbol{x}-\boldsymbol{y})(\mathrm{curl}_{\partial D_\delta}\boldsymbol{\chi})(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y}) \\ &\quad-\frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}(\boldsymbol{x})\times\mathbf{curl}_x\,\mathbf{curl}_x\int_{\partial D_\delta}F^e(\boldsymbol{x},\boldsymbol{y})(\boldsymbol{\nu}\times\boldsymbol{\chi})(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y})\,. \end{aligned}$$

Remark 7.3. The previous formula employs a slight abuse of notation, because pointwise evaluation is not defined for elements of $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$. However, we included the argument for better readability.

Define $P_{D_\delta} : \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial D_\delta)$ by

$$P_{D_\delta}\boldsymbol{a} := -\frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}\times\mathbf{curl}\,\mathbf{curl}\int_{\partial D_\delta}F^e(\cdot,\boldsymbol{y})(\boldsymbol{\nu}\times\boldsymbol{a})(\boldsymbol{y})\,\mathrm{d}s(\boldsymbol{y})$$

for $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta)$. Then we can see as in the proof of Lemma 6.2 that

$$\|(P_{D_\delta}\boldsymbol{a})^\wedge\|_{\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)} \le C\delta^2\|\hat{\boldsymbol{a}}\|_{\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)}.$$

Therefore, by change of coordinates, applying (6.3) and (6.4), we obtain

$$\begin{aligned} (\boldsymbol{\nu}\times\boldsymbol{E}^d\big|_{\partial D_\delta})^\wedge(\boldsymbol{\xi}) &= \delta^{-1}\frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}(\boldsymbol{\xi})\times\int_{\partial B}\nabla_{\boldsymbol{\xi}}\Phi_0(\boldsymbol{\xi}-\boldsymbol{\eta})(\mathrm{curl}_{\partial B}\,\hat{\boldsymbol{\chi}})(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}) \\ &\quad+\delta\,\mathrm{i}\,\omega\mu_-\boldsymbol{\nu}(\boldsymbol{\xi})\times\int_{\partial B}\Phi_0(\boldsymbol{\xi}-\boldsymbol{\eta})(\boldsymbol{\nu}\times\hat{\boldsymbol{\chi}})(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}) \\ &\quad+\delta\,\mathrm{i}\,\omega\mu_-\boldsymbol{\nu}(\boldsymbol{\xi})\times\int_{\partial B}\frac{1}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|}(\mathrm{curl}_{\partial B}\,\hat{\boldsymbol{\chi}})(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})+\mathcal{O}(\delta^2) \end{aligned}$$

as $\delta \to 0$. The $\mathcal{O}(\delta^2)$-term in (6.3) and the $\mathcal{O}(\delta^3)$-term in (6.4) define pseudohomogeneous kernels of class -3 (cf. [32, pp. 168–174]); i.e., the corresponding integral operators are continuous from $H^{-1/2}(\partial B)^3$ into $H^{5/2}(\partial B)^3$ (cf. [32, Thm. 4.4.1]). Thus, these operators are also continuous from $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)$ into $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$, and together with the (constant) $\mathcal{O}(\delta)$-term in (6.3) they lead to terms of order $\mathcal{O}(\delta^2)$ in $\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$ in the asymptotic expansion of $\boldsymbol{\nu}\times\boldsymbol{E}^d|_{\partial D_\delta}$ as $\delta \to 0$.

We define $F_0 : \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$,

$$(F_0\boldsymbol{a})(\boldsymbol{\xi}) := \frac{1}{\mathrm{i}\,\omega\varepsilon_-}\boldsymbol{\nu}(\boldsymbol{\xi})\times\int_{\partial B}\nabla_{\boldsymbol{\xi}}\Phi_0(\boldsymbol{\xi}-\boldsymbol{\eta})(\mathrm{curl}_{\partial B}\,\boldsymbol{a})(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}), \tag{7.6}$$

and $F_1 : \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B) \to \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$,

$$(7.7)\quad (F_1\boldsymbol{a})(\boldsymbol{\xi}) := \mathrm{i}\,\omega\mu_-\big(\boldsymbol{\nu}\times\mathcal{A}_B^0(\boldsymbol{\nu}\times\boldsymbol{a})\big|_{\partial B}\big)(\boldsymbol{\xi}) + \mathrm{i}\,\omega\mu_-\boldsymbol{\nu}(\boldsymbol{\xi})\times\int_{\partial B}\frac{1}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|}(\mathrm{curl}_{\partial B}\,\boldsymbol{a})(\boldsymbol{\eta})\;\mathrm{d}s(\boldsymbol{\eta}).$$

Note that $-\mathrm{i}\,\omega\varepsilon_- F_0 = N_B^0$. Thus, F_0 and the first part of F_1 are bounded. Because the kernel of the second part of F_1 is homogeneous of class -2 (cf. [32, sec. 4.3.2]), the second part of F_1 is continuous also. We obtain the following asymptotic behavior.

Proposition 7.4. *For all $\boldsymbol{\chi}\in\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial D_\delta)$,*

$$F_\delta\boldsymbol{\chi} = \delta^{-1}(F_0\hat{\boldsymbol{\chi}})^\vee + \delta(F_1\hat{\boldsymbol{\chi}})^\vee + (E_F\hat{\boldsymbol{\chi}})^\vee,$$

where E_F is a bounded linear operator, which is $\mathcal{O}(\delta^2)$ in $\mathcal{L}(\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B), \boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B))$ as $\delta\to 0$, independent of $\boldsymbol{\chi}$.

Next we consider the boundary value problem of finding $\boldsymbol{u}\in\boldsymbol{H}(\mathbf{curl}, B)$ such that

$$(7.8a)\qquad \mathbf{curl}\,\mathbf{curl}\boldsymbol{u} = 0 \qquad \text{in } B,$$

$$(7.8b)\qquad \operatorname{div}\boldsymbol{u} = 0 \qquad \text{in } B,$$

$$(7.8c)\qquad \boldsymbol{\nu}\times\boldsymbol{u} = \boldsymbol{c} \qquad \text{on } \partial B,$$

where $\boldsymbol{c}\in\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$ is a given tangential function. We show that (7.8) has at most one solution and use this fact to prove that $F_0L_0^\top = 0$ on $\boldsymbol{L}^2(\mathcal{M})$ and $L_0F_0 = 0$ on $\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)$.

Lemma 7.5. *Let $\boldsymbol{c}\in\boldsymbol{H}_{\mathrm{div}}^{-1/2}(\partial B)$. Then the boundary value problem* (7.8) *has at most one solution in $\boldsymbol{H}(\mathbf{curl}, B)$.*

Proof. Using integration by parts we find for any solution $\boldsymbol{u}\in\boldsymbol{H}(\mathbf{curl}, B)$ of (7.8) with homogeneous boundary condition $\boldsymbol{c} = 0$ that

$$\begin{aligned}0 &= \int_B \mathbf{curl}\,\mathbf{curl}\boldsymbol{u}(\boldsymbol{x})\cdot\overline{\boldsymbol{u}(\boldsymbol{x})}\;\mathrm{d}\boldsymbol{x}\\ &= \int_B |\mathbf{curl}\boldsymbol{u}(\boldsymbol{x})|^2\;\mathrm{d}\boldsymbol{x} + \big\langle\gamma_t(\mathbf{curl}\boldsymbol{u}), \overline{\pi_t(\boldsymbol{u})}\big\rangle_{\partial B} = \int_B |\mathbf{curl}\boldsymbol{u}(\boldsymbol{x})|^2\;\mathrm{d}\boldsymbol{x}.\end{aligned}$$

Hence, $\mathbf{curl}\boldsymbol{u} = 0$ in B, and because the boundaries of all components of B are assumed to be connected, we obtain from [31, Thms. 3.41 and 3.42] a scalar potential $p\in H^1(B)$ with $\gamma_0(p) = 0$ on ∂B such that $\boldsymbol{u} = \nabla p$. Finally, because $\Delta p = \operatorname{div}\boldsymbol{u} = 0$ in B by (7.8b), we have $p = 0$ in B. Hence, $\boldsymbol{u} = \nabla p = 0$ in B. □

Proposition 7.6. *Let $\boldsymbol{\varphi}\in\boldsymbol{L}^2(\mathcal{M})$ and $\boldsymbol{a}\in\boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)$. Then $F_0L_0^\top\boldsymbol{\varphi} = 0$ and $L_0F_0\boldsymbol{a} = 0$.*

Proof. Given $\boldsymbol{\varphi}\in\boldsymbol{L}^2(\mathcal{M})$, by (7.4) and (7.6) we find that on ∂B

$$F_0L_0^\top\boldsymbol{\varphi} = \frac{1}{\omega^2\varepsilon_-\mu_+}\boldsymbol{\nu}\times\mathbf{curl}\,\mathbf{curl}\mathcal{A}_B^0\Big(\boldsymbol{\nu}\times\Big(\frac{1}{2}I + {M_B^0}^\top\Big)^{-1}\pi_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big),$$

where $\boldsymbol{H}^i(\boldsymbol{z})$ is given by (3.5). An easy computation applying (5.2) shows that

$$(7.9)\qquad \pm\boldsymbol{\nu}\times\Big(\pm\frac{1}{2}I + {M_B^0}^\top\Big)^{-1}\pi_t(\cdot) = \mp\Big(\mp\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t(\cdot)\,.$$

Therefore,

$$F_0 L_0^\top \boldsymbol{\varphi} = -\frac{1}{\omega^2 \varepsilon_- \mu_+} \boldsymbol{\nu} \times \mathbf{curl}\,\mathbf{curl} \mathcal{A}_B^0 \Big(-\frac{1}{2} I + M_B^0\Big)^{-1} \gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big).$$

Now let

$$\boldsymbol{u} := \mathbf{curl} \mathcal{A}_B^0 \Big(-\frac{1}{2} I + M_B^0\Big)^{-1} \gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big) \qquad \text{in } B;$$

then $\boldsymbol{u}$ is a solution to (7.8) with $\boldsymbol{c} = \gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)$. From Lemma 7.5 we obtain that $\boldsymbol{u} = \boldsymbol{H}^i(\boldsymbol{z})$ is constant in B. Hence,

$$F_0 L_0^\top \boldsymbol{\varphi} = -\frac{1}{\omega^2 \varepsilon_- \mu_+} \gamma_t(\mathbf{curl} \boldsymbol{u}) = 0 \qquad \text{on } \partial B.$$

Because F_0 is symmetric, also $L_0 F_0 \boldsymbol{a} = 0$ for each $\boldsymbol{a} \in \boldsymbol{H}_{\mathrm{curl}}^{-1/2}(\partial B)$. □

Recalling Theorem 4.2, we can we put our results together and obtain the following asymptotic expansion of the measurement operator G_δ.

THEOREM 7.7. *Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$; then*

$$G_\delta \boldsymbol{\varphi} = \mathrm{i}\,\omega \mu_+ \delta^3 \left(L_0 F_1 L_0^\top \boldsymbol{\varphi} + L_1 F_0 L_1^\top \boldsymbol{\varphi}\right) + \mathcal{O}(\delta^4)$$

in $\boldsymbol{L}^2(\mathcal{M})$ as $\delta \to 0$. More precisely, the last term on the right-hand side is bounded by $C\delta^4 \|\boldsymbol{\varphi}\|_{\boldsymbol{L}^2(\mathcal{M})}$, where the constant C is independent of δ and $\boldsymbol{\varphi}$.

The proof of this theorem follows straightforwardly from the previous propositions and Theorem 4.2. We refer the reader to [1, Thm. 5.9] for a similar proof in the electrostatic case.

Finally, for $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$, we are going to calculate $L_0 F_1 L_0^\top \boldsymbol{\varphi}$ and $L_1 F_0 L_1^\top \boldsymbol{\varphi}$ explicitly.

LEMMA 7.8. *For each $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ we have*

$$F_0 L_1^\top \boldsymbol{\varphi} = -\frac{1}{\omega^2 \varepsilon_- \mu_+} \gamma_t\big(\mathbf{curl} \boldsymbol{H}^i(\boldsymbol{z})\big) \qquad \text{on } \partial B. \tag{7.10}$$

Proof. Given $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$, by (7.5) and (7.6), applying (7.9) we find

$$\begin{aligned} F_0 L_1^\top \boldsymbol{\varphi} &= \frac{1}{\omega^2 \varepsilon_- \mu_+} \boldsymbol{\nu} \times \mathbf{curl}\,\mathbf{curl} \mathcal{A}_B^0 \bigg(\boldsymbol{\nu} \times \Big(\frac{1}{2} I + M_B^{0\,\top}\Big)^{-1} \pi_t \Big(\sum_{l=1}^3 \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z})\Big)\bigg) \\ &= -\frac{1}{\omega^2 \varepsilon_- \mu_+} \boldsymbol{\nu} \times \mathbf{curl}\,\mathbf{curl} \mathcal{A}_B^0 \Big(-\frac{1}{2} I + M_B^0\Big)^{-1} \gamma_t \Big(\sum_{l=1}^3 \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z})\Big). \end{aligned}$$

Let

$$\boldsymbol{u} := \mathbf{curl} \mathcal{A}_B^0 \Big(-\frac{1}{2} I + M_B^0\Big)^{-1} \gamma_t \Big(\sum_{l=1}^3 \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z})\Big) \qquad \text{in } B;$$

then $\boldsymbol{u}$ is a solution to (7.8) with $\boldsymbol{c} = \gamma_t(\sum_{l=1}^3 \eta_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z}))$. From Lemma 7.5 we obtain $\boldsymbol{u}(\boldsymbol{\xi}) = \sum_{l=1}^3 \xi_l \frac{\partial \boldsymbol{H}^i}{\partial y_l}(\boldsymbol{z})$ for a.e. $\boldsymbol{\xi} \in B$. An easy calculation shows that therefore $\mathbf{curl} \boldsymbol{u} = \mathbf{curl} \boldsymbol{H}^i(\boldsymbol{z})$ in B, which ends the proof. □

Lemma 7.9. *For each $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ we have*

$$F_1 L_0^\top \boldsymbol{\varphi} = -\frac{\mu_-}{\mu_+}\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big) \qquad \text{on } \partial B. \tag{7.11}$$

Proof. Given $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$, by (7.4) and (7.7), applying (2.1) and (7.9) we find that on ∂B

$$\begin{aligned}(F_1 L_0^\top \boldsymbol{\varphi})(\boldsymbol{\xi}) =& -\frac{\mu_-}{\mu_+}\Big(\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\xi})\\ &+\frac{\mu_-}{\mu_+}\boldsymbol{\nu}(\boldsymbol{\xi}) \times \int_{\partial B}\frac{1}{8\pi}\frac{\boldsymbol{\xi}-\boldsymbol{\eta}}{|\boldsymbol{\xi}-\boldsymbol{\eta}|}\Big(\mathrm{div}_{\partial B}\Big(\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}).\end{aligned} \tag{7.12}$$

By Lemma 5.1(a), $-\frac{1}{2}I + M_B^0$ is an isomorphism on $\boldsymbol{H}^{-1/2}_{\mathrm{div},0}(\partial B)$. Therefore, because by (2.3) it holds that $\mathrm{div}_{\partial B}\,\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big) = -\gamma_n\big(\mathbf{curl}\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\big) = 0$, we find

$$\mathrm{div}_{\partial B}\Big(\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big) = 0.$$

Hence, the second term on the right-hand side of (7.12) vanishes, and we obtain the desired result. □

Definition 7.10. *For a bounded $C^{2,\alpha}$ domain $D \subset \mathbb{R}^3$ we define the magnetic polarizability tensor $\mathbb{M}_D^0 \in \mathbb{R}^{3\times 3}$ by $\mathbb{M}_D^0 := (m_{ij}^0)_{i,j=1}^3$ with*

$$m_{ij}^0 := -\int_{\partial D}\eta_j\Big(\Big(-\frac{1}{2}I + {K_D^0}^\top\Big)^{-1}\nu_i\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}), \qquad 1 \le i,j \le 3.$$

The electric polarizability tensor $\mathbb{M}_D^\infty \in \mathbb{R}^{3\times 3}$ corresponding to the domain D is given by $\mathbb{M}_D^\infty := (m_{ij}^\infty)_{i,j=1}^3$ with

$$m_{ij}^\infty := \int_{\partial D}\eta_j\Big(\Big(\frac{1}{2}I + {K_D^0}^\top\Big)^{-1}\nu_i\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta}), \qquad 1 \le i,j \le 3.$$

The magnetic and the electric polarizability tensor are symmetric and positive definite matrices; cf. [3, 19].

Proposition 7.11. *For each $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ we have*

$$L_1 F_0 L_1^\top \boldsymbol{\varphi} = \frac{1}{\mathrm{i}\,\omega\mu_+}\frac{\mu_-}{\mu_+}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z})\mathbb{M}_B^\infty\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}) \qquad \text{on } \mathcal{M}.$$

Proof. Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$. By (7.10) and (7.2),

$$L_1 F_0 L_1^\top \boldsymbol{\varphi} = -\frac{1}{\mathrm{i}\,\omega\mu_+}\int_{\partial B}\sum_{l=1}^3 \eta_l\frac{\partial\mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z})\Big(\Big(\frac{1}{2}I{+}M_B^0\Big)^{-1}\gamma_t\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})$$

on $\mathcal{M}$. Applying (7.9), we find

$$\begin{aligned}&-\int_{\partial B}\sum_{l=1}^3 \eta_l\frac{\partial\mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z})\Big(\Big(\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})\\ &\quad= \sum_{l=1}^3\frac{\partial\mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z})\int_{\partial B}\eta_l\,\mathbb{I}_3\Big(\boldsymbol{\nu}\times\Big(-\frac{1}{2}I + {M_B^0}^\top\Big)^{-1}\pi_t\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\eta})\,\mathrm{d}s(\boldsymbol{\eta})\end{aligned}$$

on $\mathcal{M}$. Because by (2.2)

$$\pi_t\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\big) = \pi_t\big(\nabla_\eta\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\cdot\boldsymbol{\eta}\big)\big) = \nabla_{\partial B}\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\cdot\boldsymbol{\eta}\big)$$

on ∂B, where $\boldsymbol{\eta}$ denotes the coordinate function in a neighborhood of ∂B, we can apply (5.3) and (2.2) to obtain for $1 \le l \le 3$ that

$$\begin{aligned}\int_{\partial B} \eta_l\, \mathbb{I}_3 \Big(\boldsymbol{\nu} \times \Big(-\frac{1}{2}I + M_B^{0\,\top}\Big)^{-1} \pi_t\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\eta})\ \mathrm{d}s(\boldsymbol{\eta})&\\ = \int_{\partial B} \pi_t(\eta_l\, \mathbb{I}_3)^\top \Big(\mathbf{curl}_{\partial B}\Big(\frac{1}{2}I + K_B^0\Big)^{-1}\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\cdot\boldsymbol{\eta}\big)\Big)(\boldsymbol{\eta})\ \mathrm{d}s(\boldsymbol{\eta}).&\end{aligned}$$

From the duality of $\mathbf{curl}_{\partial B}$ and $\mathrm{curl}_{\partial B}$, and from (2.3), we find

$$\begin{aligned}\int_{\partial B} \pi_t(\eta_l\, \mathbb{I}_3)^\top \Big(\mathbf{curl}_{\partial B}\Big(\frac{1}{2}I + K_B^0\Big)^{-1}\big(\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\cdot\boldsymbol{\eta}\big)\Big)(\boldsymbol{\eta})\ \mathrm{d}s(\boldsymbol{\eta})&\\ = \int_{\partial B} \big(\boldsymbol{\nu}\cdot\mathbf{curl}(\eta_l\, \mathbb{I}_3)\big)^\top(\boldsymbol{\xi}) \bigg(\Big(\Big(\frac{1}{2}I + K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\xi})\cdot\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\bigg)\ \mathrm{d}s(\boldsymbol{\xi}).&\end{aligned}$$

An easy calculation reveals

$$\sum_{l=1}^{3} \frac{\partial \mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z})\mathbf{curl}_\eta(\eta_l\, \mathbb{I}_3)^\top = \big(\mathbf{curl}_y \mathbb{G}^{m\top}\big)^\top(\cdot,\boldsymbol{z}).$$

Applying (3.4b) and (3.4c), we observe

$$\big(\mathbf{curl}_y \mathbb{G}^{m\top}\big)^\top(\cdot,\boldsymbol{z}) = \frac{\mu_-}{\mu_+}\mathbf{curl}_x \mathbb{G}^e(\cdot,\boldsymbol{z}).$$

So, we find

$$\begin{aligned}\sum_{l=1}^{3} \frac{\partial \mathbb{G}^m}{\partial y_l}(\cdot,\boldsymbol{z}) \int_{\partial B} \big(\boldsymbol{\nu}\cdot\mathbf{curl}(\eta_l\, \mathbb{I}_3)\big)^\top(\boldsymbol{\xi}) \bigg(\Big(\Big(\frac{1}{2}I + K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\xi})\cdot\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\bigg)\ \mathrm{d}s(\boldsymbol{\xi})&\\ = \frac{\mu_-}{\mu_+}\mathbf{curl}_x \mathbb{G}^e(\cdot,\boldsymbol{z}) \int_{\partial B} \boldsymbol{\nu}(\boldsymbol{\xi}) \bigg(\Big(\Big(\frac{1}{2}I + K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\xi})\cdot\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\bigg)\ \mathrm{d}s(\boldsymbol{\xi})&\\ = \frac{\mu_-}{\mu_+}\mathbf{curl}_x \mathbb{G}^e(\cdot,\boldsymbol{z})\mathbb{M}_B^\infty \mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}). \qquad \square&\end{aligned}$$

PROPOSITION 7.12. *For each $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ we have*

$$L_0 F_1 L_0^\top \boldsymbol{\varphi} = \mathrm{i}\,\omega\varepsilon_- \frac{\mu_-}{\mu_+}\mathbb{G}^m(\cdot,\boldsymbol{z})\mathbb{M}_B^0 \boldsymbol{H}^i(\boldsymbol{z}).$$

Proof. Let $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$ and set

$$\boldsymbol{u} := \mathbf{curl}\mathcal{A}_B^0\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(z)\big) \qquad \text{in } B.$$

As in the proof of Proposition 7.6 we find that $\boldsymbol{u} = \boldsymbol{H}^i(\boldsymbol{z})$ in B. So we obtain

$$\gamma_n\Big(\mathbf{curl}\mathcal{A}_B^0\Big(-\frac{1}{2}I + M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(z)\big)\Big) = \gamma_n\big(\boldsymbol{H}^i(\boldsymbol{z})\big) \qquad \text{on } \partial B. \tag{7.13}$$

By (7.11) and (7.1),

$$
\begin{aligned}
&L_0 F_1 L_0^\top \boldsymbol{\varphi}\\
&= \mathrm{i}\,\omega\varepsilon_- \frac{\mu_-}{\mu_+}\mathbb{G}^m(\cdot,\boldsymbol{z})\int_{\partial B}\Big(\Big(\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\eta})\;\mathrm{d}s(\boldsymbol{\eta})
\end{aligned}
$$

on $\mathcal{M}$. Observing that $\pi_t(\mathbb{I}_3) = \nabla_{\partial B}\boldsymbol{\eta}$ on ∂B, where $\boldsymbol{\eta}$ again denotes the surface variable on ∂B, and applying (2.2), we can calculate

$$
\begin{aligned}
&\int_{\partial B}\Big(\Big(\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\eta})\;\mathrm{d}s(\boldsymbol{\eta})\\
&\quad=\int_{\partial B}\Big(\Big(\frac{1}{2}I+{M_B^0}^\top\Big)^{-1}\nabla_{\partial B}\boldsymbol{\eta}\Big)^\top(\boldsymbol{\xi})\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\xi})\;\mathrm{d}s(\boldsymbol{\xi}).
\end{aligned}
$$

Applying (5.3), the duality of $-\nabla_{\partial B}$ and $\mathrm{div}_{\partial B}$, and (2.3), we have

$$
\begin{aligned}
&\int_{\partial B}\Big(\Big(\frac{1}{2}I+{M_B^0}^\top\Big)^{-1}\nabla_{\partial B}\boldsymbol{\eta}\Big)^\top(\boldsymbol{\xi})\gamma_t\Big(\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)(\boldsymbol{\xi})\;\mathrm{d}s(\boldsymbol{\xi})\\
&=\int_{\partial B}\Big(\Big(-\frac{1}{2}I+K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\eta})\Big(-\gamma_n\Big(\mathbf{curl}\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\eta})\;\mathrm{d}s(\boldsymbol{\eta}).
\end{aligned}
$$

Finally, recalling (7.13), we obtain

$$
\begin{aligned}
&\int_{\partial B}\Big(\Big(-\frac{1}{2}I+K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\eta})\Big(-\gamma_n\Big(\mathbf{curl}\mathcal{A}_B^0\Big(-\frac{1}{2}I+M_B^0\Big)^{-1}\gamma_t\big(\boldsymbol{H}^i(\boldsymbol{z})\big)\Big)\Big)(\boldsymbol{\eta})\;\mathrm{d}s(\boldsymbol{\eta})\\
&\quad=-\int_{\partial B}\Big(\Big(-\frac{1}{2}I+K_B^0\Big)^{-1}\boldsymbol{\eta}\Big)(\boldsymbol{\eta})\big(\boldsymbol{\nu}(\boldsymbol{\eta})\cdot\boldsymbol{H}^i(\boldsymbol{z})\big)\;\mathrm{d}s(\boldsymbol{\eta})=\mathbb{M}_B^0\boldsymbol{H}^i(\boldsymbol{z}). \qquad\square
\end{aligned}
$$

From Theorem 7.7 and Propositions 7.11 and 7.12 we obtain the following corollary.

Corollary 7.13. *Let $\boldsymbol{\varphi}\in\boldsymbol{L}^2(\mathcal{M})$, and let $\boldsymbol{H}^i$ be the corresponding incident field from* (3.5). *Then*

$$
G_\delta\boldsymbol{\varphi}=\delta^3\Big(-k_-^2\mathbb{G}^m(\cdot,\boldsymbol{z})\mathbb{M}_B^0\boldsymbol{H}^i(\boldsymbol{z})+\frac{\mu_-}{\mu_+}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z})\mathbb{M}_B^\infty\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z})\Big)+\mathcal{O}(\delta^4)
$$

in $\boldsymbol{L}^2(\mathcal{M})$, as $\delta\to 0$. More precisely, the last term on the right-hand side is bounded by $C\delta^4\|\boldsymbol{\varphi}\|_{\boldsymbol{L}^2(\mathcal{M})}$, where the constant C is independent of δ and $\boldsymbol{\varphi}$.

8. Multiple scatterers.

The results of the previous sections can be extended to the practically important case of finitely many well-separated small scatterers as introduced in section 3. This generalization works in the same way as we did in [1, section 6] for the electrostatic case. Because the calculations are rather technical and no new ideas are needed, we just mention the final result and leave the details to the reader.

Let $\mathbb{M}_{B_1}^0,\dots,\mathbb{M}_{B_m}^0$ and $\mathbb{M}_{B_1}^\infty,\dots,\mathbb{M}_{B_m}^\infty$ denote the magnetic and electric polarizability tensors corresponding to $B_1,\dots,B_m$, respectively. In case of multiple scatterers Corollary 7.13 reads as follows.

Corollary 8.1. *Let $\boldsymbol{\varphi}\in\boldsymbol{L}^2(\mathcal{M})$, and let $\boldsymbol{H}^i$ be the corresponding incident field from* (3.5). *Then*

(8.1)

$$
G_\delta\boldsymbol{\varphi}=\delta^3\sum_{l=1}^m\Big(-k_-^2\mathbb{G}^m(\cdot,\boldsymbol{z}_l)\mathbb{M}_{B_l}^0\boldsymbol{H}^i(\boldsymbol{z}_l)+\frac{\mu_-}{\mu_+}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z}_l)\mathbb{M}_{B_l}^\infty\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}_l)\Big)+\mathcal{O}(\delta^4)
$$

in $\boldsymbol{L}^2(\mathcal{M})$, as $\delta \to 0$. More precisely, the last term on the right-hand side is bounded by $C\delta^4\|\boldsymbol{\varphi}\|_{\boldsymbol{L}^2(\mathcal{M})}$, where the constant C is independent of δ and $\boldsymbol{\varphi}$.

9. A characterization of the scatterers.

Using the asymptotic formula (8.1) we can now derive a characterization of the centers of the scatterers $\boldsymbol{z}_1, \dots, \boldsymbol{z}_l$ using a range criterion. For this purpose we introduce the operator $T : \boldsymbol{L}^2(\mathcal{M}) \to \boldsymbol{L}^2(\mathcal{M})$ describing the leading order term in the asymptotic expansion (8.1), given by

$$T\boldsymbol{\varphi} := \sum_{l=1}^{m}\Big(-k_-^2\,\mathbb{G}^m(\cdot,\boldsymbol{z}_l)\mathbb{M}^0_{B_l}\boldsymbol{H}^i(\boldsymbol{z}_l) + \frac{\mu_-}{\mu_+}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z}_l)\mathbb{M}^\infty_{B_l}\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}_l)\Big). \tag{9.1}$$

Because (3.5) implies that $\boldsymbol{H}^i$ depends linearly on $\boldsymbol{\varphi}$, it follows that T is linear. From Corollary 8.1 we obtain

$$G_\delta = \delta^3 T + \mathcal{O}(\delta^4) \tag{9.2}$$

as $\delta \to 0$ in $\mathcal{L}(\boldsymbol{L}^2(\mathcal{M}))$. Next we define the operator $R : \mathbb{C}^{3\times 2m} \to \boldsymbol{L}^2(\mathcal{M})$:

$$R\boldsymbol{a} := k_-^2\sum_{l=1}^{m}\Big(\mathbb{G}^m(\cdot,\boldsymbol{z}_l)\boldsymbol{a}_l + \frac{\mu_-}{\mu_+}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z}_l)\boldsymbol{a}_{m+l}\Big) \tag{9.3}$$

for $\boldsymbol{a} = (\boldsymbol{a}_1, \dots, \boldsymbol{a}_{2m}) \in \mathbb{C}^{3\times 2m}$, $\boldsymbol{a}_l \in \mathbb{C}^3$. Endowing $\mathbb{C}^{3\times 2m}$ with the bilinear form $\langle \boldsymbol{a}, \boldsymbol{b}\rangle_{\mathbb{C}^{3\times 2m}} := \sum_{l=1}^{2m}\boldsymbol{a}_l\cdot\boldsymbol{b}_l$ for $\boldsymbol{a} = (\boldsymbol{a}_1, \dots, \boldsymbol{a}_{2m})$ $\boldsymbol{b} = (\boldsymbol{b}_1, \dots, \boldsymbol{b}_{2m}) \in \mathbb{C}^{3\times 2m}$ with $\boldsymbol{a}_l$, $\boldsymbol{b}_l \in \mathbb{C}^3$, using (3.5), (3.4b), and (3.4c), we obtain

$$\begin{aligned}\langle R\boldsymbol{a}, \boldsymbol{\varphi}\rangle_{\mathcal{M}} =& \sum_{l=1}^{m}\boldsymbol{a}_l\cdot k_-^2\int_{\mathcal{M}}\mathbb{G}^{m\top}(\boldsymbol{x},\boldsymbol{z}_l)\boldsymbol{\varphi}(\boldsymbol{x})\,\mathrm{d}s(\boldsymbol{x})\\ &+\sum_{l=1}^{m}\boldsymbol{a}_{l+m}\cdot k_-^2\frac{\mu_-}{\mu_+}\int_{\mathcal{M}}(\mathbf{curl}_x\mathbb{G}^e)^\top(\boldsymbol{x},\boldsymbol{z}_l)\boldsymbol{\varphi}(\boldsymbol{x})\,\mathrm{d}s(\boldsymbol{x})\\ =&\sum_{l=1}^{m}\Big(\boldsymbol{a}_l\cdot\frac{\mu_-}{\mu_+}\boldsymbol{H}^i(\boldsymbol{z}_l) + \boldsymbol{a}_{l+m}\cdot\frac{\mu_-}{\mu_+}\mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}_l)\Big)\end{aligned}$$

for any $\boldsymbol{a} \in \mathbb{C}^{3\times 2m}$ and $\boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M})$. So, $R^\top : \boldsymbol{L}^2(\mathcal{M}) \to \mathbb{C}^{3\times 2m}$ is given by

$$R^\top\boldsymbol{\varphi} = \frac{\mu_-}{\mu_+}\big(\boldsymbol{H}^i(\boldsymbol{z}_1), \dots, \boldsymbol{H}^i(\boldsymbol{z}_m), \mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}_1), \dots, \mathbf{curl}\boldsymbol{H}^i(\boldsymbol{z}_m)\big). \tag{9.4}$$

LEMMA 9.1. (a) *R is injective.* (b) *$R^\top$ is surjective.*

Proof. (a) Suppose $\boldsymbol{a} \in \mathbb{C}^{3\times 2m}$ such that $R\boldsymbol{a} = 0$. Then

$$\tilde{\boldsymbol{H}} := k_-^2\sum_{l=1}^{m}\Big(\mathbb{G}^m(\cdot,\boldsymbol{z}_l)\boldsymbol{a}_l + \frac{\mu_-}{\mu}\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z}_l)\boldsymbol{a}_{m+l}\Big)$$

together with the associated electric field $\tilde{\boldsymbol{E}} := -1/(\mathrm{i}\,\omega\varepsilon)\mathbf{curl}\tilde{\boldsymbol{H}}$ is a radiating solution of Maxwell's equations (3.1) in $\mathbb{R}^3 \setminus \bigcup_{l=1}^m\{\boldsymbol{z}_l\}$ that satisfies $\tilde{\boldsymbol{H}}|_{\mathcal{M}} = 0$. Now we can follow the proof of [20, Thm. 3.2] and obtain $\tilde{\boldsymbol{H}} = 0$ in $\mathbb{R}^3 \setminus \bigcup_{l=1}^m\{\boldsymbol{z}_l\}$.

Let $l \in \{1, \dots, m\}$; then of course $\lim_{t\to 0}\tilde{\boldsymbol{H}}(\boldsymbol{z}_l + t\boldsymbol{b}) = 0$ for any $\boldsymbol{b} \in \mathbb{R}^3$. A short calculation shows that the singularity of $\mathbb{G}^m(\cdot,\boldsymbol{z}_l)$ in $\boldsymbol{z}_l$ is of order 3, while the singularity of $\mathbf{curl}_x\mathbb{G}^e(\cdot,\boldsymbol{z}_l)$ in $\boldsymbol{z}_l$ is of order 2. So, from $\lim_{t\to 0}\mathbb{G}^m(\boldsymbol{z}_l + t\boldsymbol{e}_3,\boldsymbol{z}_l)\boldsymbol{a}_l = 0$ it follows that $\boldsymbol{a}_l = 0$. Indeed, otherwise the singularity of $\mathbb{G}^m(\cdot, \boldsymbol{z}_l)\boldsymbol{a}_l$ at $\boldsymbol{z}_l$ would imply that $\lim_{t\to 0} |\tilde{\boldsymbol{H}}(\boldsymbol{z}_l + t\boldsymbol{e}_3)| = \infty$. Accordingly, $\lim_{t\to 0} \mathbf{curl}_x \mathbb{G}^e(\boldsymbol{z}_l + t\boldsymbol{e}_1, \boldsymbol{z}_l)\boldsymbol{a}_{m+l} = 0$ and $\lim_{t\to 0} \mathbf{curl}_x \mathbb{G}^e(\boldsymbol{z}_l + t\boldsymbol{e}_2, \boldsymbol{z}_l)\boldsymbol{a}_{m+l} = 0$ yield $\boldsymbol{a}_{m+l} = 0$. Because $l \in \{1, \dots, m\}$ was arbitrary, we are done.

(b) This part of the proof follows from part (a) and the well-known relation $\mathcal{R}(R^\top) = \mathcal{N}(R)^a$ between ranges and null spaces of dual operators with finite rank. Here, $\mathcal{N}(R)^a$ denotes the annihilator of $\mathcal{N}(R)$ in $\mathbb{C}^{3\times 2m}$. □

Comparing the formulas (9.3) and (9.4) for R and $R^\top$ and the definition (9.1) of T, we find that these operators are related by $T = RMR^\top$, where the operator $M : \mathbb{C}^{3\times 2m} \to \mathbb{C}^{3\times 2m}$ is given by

$$M\boldsymbol{a} := \frac{\mu_+}{\mu_-}\left(-\mathbb{M}^0_{B_1}\boldsymbol{a}_1, \dots, -\mathbb{M}^0_{B_m}\boldsymbol{a}_m, \frac{1}{k_-^2}\mathbb{M}^\infty_{B_1}\boldsymbol{a}_{m+1}, \dots, \frac{1}{k_-^2}\mathbb{M}^\infty_{B_m}\boldsymbol{a}_{2m}\right).$$

From the positive definiteness of the magnetic and electric polarizability tensors $\mathbb{M}^0_{B_1}, \dots, \mathbb{M}^0_{B_m}$ and $\mathbb{M}^\infty_{B_1}, \dots, \mathbb{M}^\infty_{B_m}$ we conclude that M is invertible. Taking a closer look at the range of T, we first observe that $\mathcal{R}(T) \subset \mathcal{R}(R)$. We show that this inclusion is actually an equality.

PROPOSITION 9.2. *The range of T has dimension $6m$ and is given by*

$$\mathcal{R}(T) = \operatorname{span}_{\mathbb{C}}\left\{\mathbb{G}^m(\cdot, \boldsymbol{z}_l)\boldsymbol{e}_j\,,\, \mathbf{curl}_x\mathbb{G}^e(\cdot, \boldsymbol{z}_l)\boldsymbol{e}_j \;\middle|\; j = 1, 2, 3;\ l = 1, \dots, m\right\}.$$

Proof. The surjectivity of $R^\top$ and M implies $\mathcal{R}(T) = \mathcal{R}(RMR^\top) = \mathcal{R}(R)$. The proposition is then an immediate consequence of (9.3) and Lemma 9.1(a). □

Now we present the main tool for the identification of the positions $\boldsymbol{z}_l$: the characterization of the centers of the scatterers in terms of the range of the leading order term T of the asymptotic expansion of the measurement operator G_δ.

PROPOSITION 9.3. *Let $\boldsymbol{d} = (\boldsymbol{d}_1, \boldsymbol{d}_2) \in (\mathbb{C}^3 \times \mathbb{C}^3) \setminus \{(0,0)\}$, $\boldsymbol{z} \in \mathbb{R}^3_-$, and*

$$\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} := \big(\mathbb{G}^m(\cdot, \boldsymbol{z})\boldsymbol{d}_1 + \mathbf{curl}_x\mathbb{G}^e(\cdot, \boldsymbol{z})\boldsymbol{d}_2\big)|_{\mathcal{M}}.$$

Then, $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} \in \mathcal{R}(T)$ if and only if $\boldsymbol{z} \in \{\boldsymbol{z}_1, \dots, \boldsymbol{z}_m\}$.

Proof. Assume that $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} \in \mathcal{R}(T)$. As a consequence of Proposition 9.2, $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$ may be represented as

$$\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} = \sum_{l=1}^m \big(\mathbb{G}^m(\cdot, \boldsymbol{z}_l)\boldsymbol{a}_l + \mathbf{curl}_x\mathbb{G}^e(\cdot, \boldsymbol{z}_{l+m})\boldsymbol{a}_{l+m}\big) \qquad \text{on } \mathcal{M},$$

with $\boldsymbol{a}_1, \dots, \boldsymbol{a}_{2m} \in \mathbb{C}^3$. But then both

$$\boldsymbol{H}^a := \sum_{l=1}^m \Big(\mathbb{G}^m(\cdot, \boldsymbol{z}_l)\boldsymbol{a}_l + \frac{\mu_+}{\mu}\mathbf{curl}_x\mathbb{G}^e(\cdot, \boldsymbol{z}_{l+m})\boldsymbol{a}_{l+m}\Big)$$

and

$$\boldsymbol{H}^b := \mathbb{G}^m(\cdot, \boldsymbol{z})\boldsymbol{d}_1 + \frac{\mu_+}{\mu}\mathbf{curl}_x\mathbb{G}^e(\cdot, \boldsymbol{z})\boldsymbol{d}_2,$$

together with their associated electric fields, are radiating solutions of Maxwell's equations (3.1) in $\mathbb{R}^3 \setminus (\bigcup_{l=1}^m\{\boldsymbol{z}_l\} \cup \{\boldsymbol{z}\})$ that coincide on $\mathcal{M}$. So, $\tilde{\boldsymbol{H}} := \boldsymbol{H}^a - \boldsymbol{H}^b$ together with its electric field is a radiating solution of (3.1) in $\mathbb{R}^3 \setminus (\bigcup_{l=1}^m\{\boldsymbol{z}_l\} \cup \{\boldsymbol{z}\})$ that satisfies $\tilde{\boldsymbol{H}}|_{\mathcal{M}} = 0$. Following the proof of [20, Thm. 3.2] we conclude that $\tilde{\boldsymbol{H}} = 0$ everywhere in $\mathbb{R}^3 \setminus (\bigcup_{l=1}^m\{\boldsymbol{z}_l\} \cup \{\boldsymbol{z}\})$. Thus $\boldsymbol{H}^a = \boldsymbol{H}^b$ in $\mathbb{R}^3 \setminus (\bigcup_{l=1}^m\{\boldsymbol{z}_l\} \cup \{\boldsymbol{z}\})$. This is only possible if $\boldsymbol{z} \in \{\boldsymbol{z}_1, \dots, \boldsymbol{z}_m\}$, and we have established the necessity of this condition. The sufficiency follows from Proposition 9.2. □

10. Determining the position of the inhomogeneities. Let $(\cdot,\cdot)_{\boldsymbol{L}^2(\mathcal{M})}$ denote the (complex) scalar product on $\boldsymbol{L}^2(\mathcal{M})$. Because G_δ is a compact operator on $\boldsymbol{L}^2(\mathcal{M})$, it admits a singular value decomposition

$$G_\delta \boldsymbol{\varphi} = \sum_{j=1}^{\infty} \sigma_j^\delta (\boldsymbol{\varphi}, \boldsymbol{v}_j^\delta)_{\boldsymbol{L}^2(\mathcal{M})} \boldsymbol{u}_j^\delta, \qquad \boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M}),$$

where $((\sigma_j^\delta)^2)_{j\in\mathbb{N}}$ are the eigenvalues of $G_\delta^* G_\delta$, written in decreasing order with multiplicity, $\sigma_j^\delta \geq 0$. Similarly, the finite rank operator T can be decomposed as

$$T\boldsymbol{\varphi} = \sum_{l=1}^{6m} \sigma_l (\boldsymbol{\varphi}, \boldsymbol{v}_l)_{\boldsymbol{L}^2(\mathcal{M})} \boldsymbol{u}_l, \qquad \boldsymbol{\varphi} \in \boldsymbol{L}^2(\mathcal{M}),$$

with $s_1 \geq s_2 \geq \cdots \geq s_{6m} > 0$. From (9.2) we obtain

$$G_\delta^* G_\delta = \delta^6 T^* T + \mathcal{O}(\delta^7)$$

in $\mathcal{L}(\boldsymbol{L}^2(\mathcal{M}))$ as $\delta \to 0$. So, applying [26, Thm. V.4.10] we get the following aymptotic formula for the singular values as $\delta \to 0$:

$$(10.1) \qquad (\sigma_j^\delta)^2 = \delta^6 \sigma_j^2 + \mathcal{O}(\delta^7), \qquad j \in \mathbb{N},$$

where we have set $\sigma_l = 0$ for $l \geq 6m$. Next, for $j \in \mathbb{N}$ and $l = 1, \ldots, 6m$, let

$$P_j^\delta : \boldsymbol{L}^2(\mathcal{M}) \to \operatorname{span}_{\mathbb{C}}\{\boldsymbol{u}_1^\delta, \ldots, \boldsymbol{u}_j^\delta\} \qquad \text{and} \qquad P_l : \boldsymbol{L}^2(\mathcal{M}) \to \operatorname{span}_{\mathbb{C}}\{\boldsymbol{u}_1, \ldots, \boldsymbol{u}_l\}$$

denote the orthogonal projections onto these subspaces, respectively. We can write these projections as line integrals of the resolvent of $G_\delta G_\delta^*$ and $\delta^6 T T^*$, respectively; see [26, III-(6.19)]. Then, a short calculation shows that

$$(10.2) \qquad P_l^\delta = P_l + \mathcal{O}(\delta), \qquad l = 1, \ldots, 6m,$$

as $\delta \to 0$ in $\mathcal{L}(\boldsymbol{L}^2(\mathcal{M}))$, provided that we make appropriate choices of eigenvectors $\boldsymbol{u}_l^\delta$ and $\boldsymbol{u}_l$, $l = 1, \ldots, 6m$.

In Proposition 9.3 we have seen that a point $\boldsymbol{z} \in \mathbb{R}^3_-$ coincides with one of the positions $\boldsymbol{z}_l$, $l = 1, \ldots, m$, if and only if $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} \in \mathcal{R}(T)$ or, equivalently, $(I - P_{6m})\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} = 0$. If we decompose the test function orthogonally as $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} = P_{6m}\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} + (I - P_{6m})\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$ and define the angle $\beta(\boldsymbol{z}) \in [0, \pi/2]$ by

$$\cot \beta(\boldsymbol{z}) := \frac{\|P_{6m}\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}\|_{\boldsymbol{L}^2(\mathcal{M})}}{\|(I - P_{6m})\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}\|_{\boldsymbol{L}^2(\mathcal{M})}},$$

then we have

$$\boldsymbol{z} \in \{\boldsymbol{z}_l \mid l = 1, \ldots, m\} \Longleftrightarrow \beta(\boldsymbol{z}) = 0 \Longleftrightarrow \cot \beta(\boldsymbol{z}) = \infty.$$

Unfortunately, we cannot compute $\beta(\boldsymbol{z})$, because P_{6m} corresponds to the leading order term T of the asymptotic expansion (9.2), but what we measure is the full measurement operator G_δ. However, in view of (10.2), for small values of δ the projected test function $P_{6m}\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$ is well approximated by $P_{6m}^\delta \boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$, and the projectors

P_p^δ can be computed for each $p \in \mathbb{N}$ by means of the singular value expansion of the measurement operator G_δ. Hence, for $p \in \mathbb{N}$, we define the angle $\beta_p^\delta(\boldsymbol{z}) \in [0, \pi/2]$ by

$$\cot \beta_p^\delta(\boldsymbol{z}) := \frac{\|P_p^\delta \boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}\|_{\boldsymbol{L}^2(\mathcal{M})}}{\|(I - P_p^\delta)\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}\|_{\boldsymbol{L}^2(\mathcal{M})}} = \left(\frac{\sum_{j \le p} |(\boldsymbol{u}_j^\delta, \boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}})_{\boldsymbol{L}^2(\mathcal{M})}|^2}{\sum_{j > p} |(\boldsymbol{u}_j^\delta, \boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}})_{\boldsymbol{L}^2(\mathcal{M})}|^2} \right)^{1/2} .$$

If we plot $\cot \beta_{6m}^\delta(\boldsymbol{z})$, we expect to see large values for points $\boldsymbol{z}$ which are close to the positions $\boldsymbol{z}_l$, $l = 1, \ldots, m$.

Because the number m of unknown scatterers is usually not known a priori, it has to be estimated somehow. Two different strategies are available: On the one hand, recalling (10.1), m may be estimated by looking for a gap in the set of singular values σ_l^δ of G_δ. This works if δ is small enough and the noise level is not too high. Otherwise it may give misleading results. On the other hand, we can plot $\cot \beta_p^\delta(\boldsymbol{z})$ for increasing values of p, until the number of reconstructed scatterers does not increase any more. This is reasonable, because for any subspace $U \subset \mathcal{R}(T)$ Proposition 9.3 reduces to

$$\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}} \in U \quad \Longrightarrow \quad \boldsymbol{z} \in \{\boldsymbol{z}_1, \ldots, \boldsymbol{z}_m\}.$$

So, testing whether $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$ is contained in a subspace $U \subset \mathcal{R}(T)$, we can only expect to reconstruct a (possibly empty) subset of $\{\boldsymbol{z}_1, \ldots, \boldsymbol{z}_m\}$. The number of reconstructed scatterers is monotonically increasing as $\dim(U)$ increases until all m scatterers are reconstructed for $\dim(U) = 6m$. Because none of the singular vectors of G_δ corresponding to singular values σ_j^δ, $j > 6m$, is expected to be exactly of the form $\boldsymbol{g}^{\boldsymbol{z},\boldsymbol{d}}$, $\boldsymbol{z} \notin \{\boldsymbol{z}_1, \ldots, \boldsymbol{z}_m\}$, the number of reconstructed scatterers should be constant for moderately sized $j > 6m$. Both strategies have been successfully tested in [8].

Finally, we show numerical results to illustrate the feasibility of the reconstruction method. We consider a two-layered background medium; the upper layer is empty ($\varepsilon_+ = \varepsilon_0 = 8.85 \cdot 10^{-12}$ Fm^{-1}, $\mu_+ = \mu_0 = 1.25 \cdot 10^{-6}$ Hm^{-1}), while the lower halfspace is filled with soil ($\varepsilon_- = \varepsilon_0(\varepsilon_r + \mathrm{i}\,\frac{\sigma}{\omega\varepsilon_0}) = 8.67 \cdot 10^{-11} + \mathrm{i}\, 5.95 \cdot 10^{-9}$ Fm^{-1}, $\mu_- = (1 + \chi)\mu_0 = 1.25 \cdot 10^{-6}$ Hm^{-1}, i.e., $\sigma = 7.5 \cdot 10^{-4}$ Sm^{-1}, $\chi = 1.9 \cdot 10^{-5}$, and $\varepsilon_r = 9.8$). The parameters for the lower halfspace are measurement data taken by Igel and Preetz [25] in the course of the project [23].

The measurement device operates on a square of size 50×50 cm^2 parallel to the surface of ground centered at $(0, 0, 10)$ cm. We simulate the measurement operator G_δ as done in [20]. For this purpose we impose magnetic dipoles with three linearly independent polarizations and a frequency of 20 kHz on a 6×6 equidistant grid on the measurement device. Then we approximate the corresponding scattered fields on the same grid using a boundary element method. The scatterers are two ellipsoids with semiaxes $(0.1, 0.2, 0.3)$ cm and $(2, 3, 1)$ cm buried at position $(-15, 15, -10)$ cm and $(15, -15, -40)$ cm, respectively. The simulated forward data contain an estimated numerical error of 4%. Additionally, we perturb the simulated scattered field by a uniformly distributed relative error of 3%.

The values of $\cot \beta_{12}^\delta(\boldsymbol{z})$ for $\boldsymbol{z} \in [-25, 25]^2 \times [-50, 0]$ cm^3 are used to visualize the location of the scatterers. The numerical implementation is essentially the same that has been used in [20] for a linear sampling method. Concerning implementation details, we refer the reader to this work; see also [8]. Figure 10.1 shows the first 20 singular values of the measurement operator G_δ and horizontal cross sections of $\cot \beta_{12}^\delta(\boldsymbol{z})$ for $z_3 = -10$ cm and $z_3 = -40$ cm, respectively. There is no distinct gap after the first 12 singurar values. One reason for this is the (numerical) error

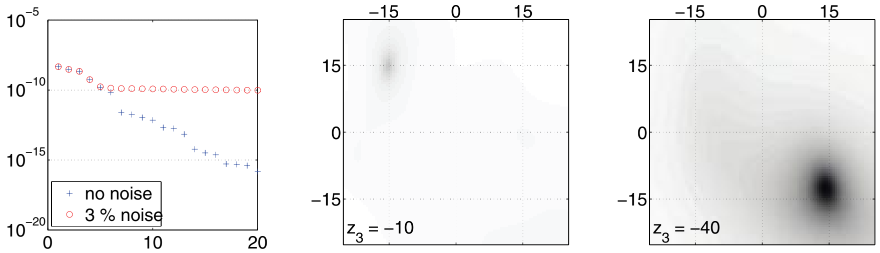

FIG. 10.1. *Singular values of G_δ and cross-sectional plots of* $\cot\beta_{12}^\delta(\boldsymbol{z})$ *for* $z_3 = -10$ *cm and* $z_3 = -40$ *cm with* 3% *noise.*

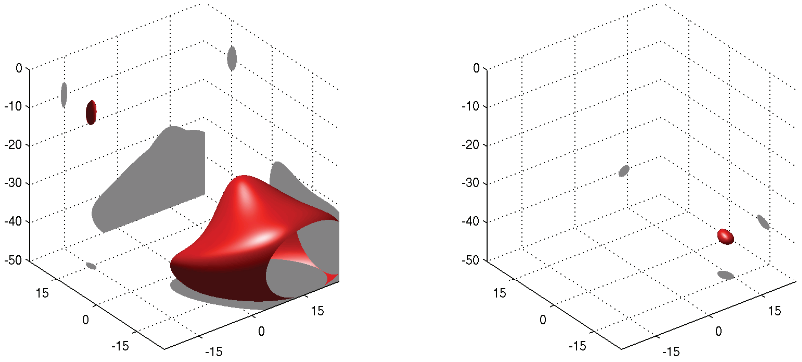

FIG. 10.2. *Isosurface plots* $\cot\beta_{12}^\delta(\boldsymbol{z}) = 25$ *and* $\cot\beta_{12}^\delta(\boldsymbol{z}) = 125$ *with* 3% *noise.*

in the forward data. Here the iterative procedure described above can be used to estimate the number of the scatterers. In the cross sectional plots the centers of the scatterers are clearly determined. Figure 10.2 shows isosurface plots $\cot\beta_{12}^\delta(\boldsymbol{z}) = 20$ and $\cot\beta_{12}^\delta(\boldsymbol{z}) = 200$. We emphasize that these visualizations should not be mistaken as reconstructions of the shape of the scatterers. These plots give just an idea of possible positions of buried scatterers; they can be expected to be inside the (red) surfaces. Our method does not allow a binary test for whether some point belongs to a scatterer or not. If we perturb the simulated forward data in this example with 5% equally distributed noise, the reconstructions of the positions of the scatterers get worse, but still two scatterers are reconstructed. For higher amounts of noise the method fails.

Note that this is only one particular numerical example that by no means covers all possible situations of interest. Comparing the method proposed here with the linear sampling method from [20], using (among others) the example above, we found that the linear sampling method is more sensitive to uncorrelated noise. Using the unperturbed simulated data, the position of the scatterers has been reconstructed by the linear sampling method. But with 3% noise in the data the linear sampling method failed. The MUSIC-type reconstruction method studied in [24] gives numerical results comparable to the results presented here, although we mention that much higher frequencies have been used in [24]. In their final implementation both methods are quite similar. Our analysis from sections 9 and 10 is meant to be an extension of [24] and a rigorous justification of both methods.

11. Conclusions. We have considered an inverse scattering problem for small scatterers in a two-layered background medium which originated in the project [23] on humanitarian demining. An asymptotic expansion of the near field measurement operator as the size of the scatterers tends to zero has been proven. We used the asymptotic formula to justify a noniterative reconstruction method that can be interpreted as an asymptotic version of a factorization method, or as a MUSIC-type method. First numerical results indicate that this method may be appropriate to detect small buried objects from sufficiently accurate measurements of the scattered field above the surface of ground. Although our results have been derived for an idealized setting, we expect that the asymptotic expansion as well as the reconstruction method can be applied to more realistic models for measurement devices used for humanitarian demining, including special coil geometries such as, e.g., the double D design considered in [17]. We intend to address this in the future.

Acknowledgments. We would like to thank Christoph Schneider for providing us with his code for the linear sampling method from [20], which we adapted to implement the reconstruction method presented here. The boundary element method we used for generating simulated measurement data for multiple scatterers is an extension of a boundary element code for single scatterers developed by Roland Potthast and his group at the University of Göttingen; see also [17]. Last but not least, the author thanks Habib Ammari, Bastian Gebauer, Martin Hanke, Andreas Kirsch, and Christoph Schneider for useful discussions and valuable hints.

ANALYTICAL AND NUMERICAL SOLUTIONS FOR TORSIONAL FLOW BETWEEN COAXIAL DISCS WITH HEAT TRANSFER*

DAVID O. OLAGUNJU[†], ANAND B. VYAS[†], AND SHANGYOU ZHANG[†]

Abstract. We consider nonisothermal torsional flow between two coaxial parallel plates with heat transfer at the upper rotating plate, constant temperature on the lower stationary plate, and no heat loss at the fluid-air interface. Viscous heating is modelled by a Nahme law with exponential dependence on temperature. Due to the highly nonlinear nature of the governing equations an exact solution is not feasible. Therefore we solve the problem using both numerical and perturbation methods. Specifically, analytical solutions are obtained using asymptotic expansions based on the aspect ratio and the Nahme–Griffith number, a measure of viscous heating, as perturbation parameters. The numerical solutions are obtained by a finite element method. Good agreement is found between the analytical and numerical solutions in the appropriate parameter range. In viscometric applications the torque exerted by the fluid on the lower plate is an important quantity. For isothermal flow the dimensionless torque can easily be calculated. In this paper we obtain an analytical formula that can be used to calculate nonisothermal correction to the torque.

Key words. parallel-plate flow, viscous heating, axisymmetric finite elements

1. Introduction.

The problem of viscous heating in viscometric flow of Newtonian and non-Newtonian liquids is of both theoretical and practical interest. An exact solution was obtained for flow of a Newtonian fluid between two infinite parallel plates by Nahme in 1940 [1]. The viscosity was modelled by an exponential function of temperature. A similar result was obtained by Kearsley [2] for the pressure gradient flow of a Newtonian fluid in a tube. Bird and Turian [3] analyzed the viscous heating problem for the flow of a Newtonian fluid between a cone and a plate. The equations for the temperature and velocity were uncoupled by assuming an isothermal velocity profile. The variational form for the temperature was then solved numerically. Isothermal boundary conditions were imposed at the physical boundaries and zero heat loss imposed at the air-liquid interface. Their analysis showed that viscous heating can lead to observable errors in the cone-and-plate viscometer. In a subsequent paper, Turian and Bird [4] extended the theoretical investigation to plane Couette flow of Newtonian fluids with temperature dependent viscosity and thermal conductivity. The thermal conductivity was assumed to be a linear function of temperature, while the viscosity was assumed to obey a Nahme law with exponential dependence on temperature. A regular perturbation solution in powers of the Brinkman number was obtained for the velocity and temperature. A perturbation solution in powers of the Brinkman number were later obtained for non-Newtonian liquids described by the power-law and Ellis models [5]. The boundary conditions were the same as those used in [4]. Exact analytical solutions have also been obtained by Martin [6] for flows between infinite concentric cylinders and infinite parallel plates for Newtonian and power-law fluids. Two types of boundary conditions were considered, one in which

[†]Department of Mathematical Sciences, University of Delaware, Newark, DE 19716 (olagunju@math.udel.edu, abvyas@math.udel.edu, szhang@udel.edu).

both surfaces were isothermal and the other in which one was isothermal and the other adiabatic. Closed-form solutions similar to those of Nahme and Kearsley were obtained for isothermal and adiabatic boundary conditions by Gavis and Laurence [7].

These early analytical studies were motivated by the need to quantify the deviation form isothermal flow in viscometers when viscous dissipation is significant and to provide simple formulas to correct for such deviations in quantities such as the torque on the stationary plate in parallel-plate flow. In recent years renewed interest in this matter has been spurred by experiments in elastic instabilities of viscoelastic fluids. It has been observed that viscous heating could lead to qualitatively and quantitatively significant deviation from isothermal theory in the stability property of a viscoelastic fluid. Experimental study of the stability of isothermal flow of viscoelastic torsional flow was first reported by Magda and Larson [8] and McKinley et al. [9]. Linear stability analysis was first carried out by Oztekin and Brown [10] for flow between parallel-plate flow in which the boundary condition at the fluid-air interface was neglected. Linear stability results for flow in a finite domain incorporating boundary conditions at the free surface have also been considered [11, 12, 13].

Experiments on the effect of viscous heating on the stability of torsional flow of viscoelastic fluids was first reported by Rothstein and McKinley [14]. The results were found to be remarkably different from those of isothermal flows. It was shown that viscous heating tended to stabilize the flow. A linear stability for the nonisothermal problem was later analyzed by Olagunju, Cook, and McKinley [15] which agrees qualitatively with their experimental results. In that paper isothermal boundary conditions on the plates were used, while those at the free surface were neglected. However, as noted by Arigo [16], it is practically impossible to control the temperature on the upper rotating cone (or plate in the case of the parallel-plate torsional viscometer). He also notes that the upper rotating cone (or plate) is cooled by convection of ambient air at 23–24 degrees Celsius. A more realistic set of boundary conditions is to treat the bottom plate as isothermal, the free surface as an insulated boundary, and the top plate as a thermal mass. The insulation boundary condition surface can be justified on the grounds that for a small gap thickness, the surface available for heat transfer to the ambience through the radial interface is practically negligible. It is hoped that this will give results that are in quantitative agreement with experiments. A heat transfer boundary condition was used for the viscoelastic Taylor–Couette problem by Al-Mubaiyedh, Suresh Kumar, and Khomani [17]. In their study, the heat transfer boundary condition was used to numerically simulate the experiments of Baumert and Muller [18, 19]. Another assumption that was made in [15] is that the parallel plates are infinite in extent. In order to obtain better agreement between theory and experiments we think that it is necessary to relax these assumptions. As a first step in this direction we study the effect of the finite geometry and the more realistic boundary conditions on the base flow. In [20], Olagunju showed that for torsional flow of a viscoelastic fluid the base flow is not always purely circumferential. He showed that viscous heating leads to secondary flows with recirculating roll cells in the base solution.

In this paper, we obtain perturbation and numerical solutions for the flow between two parallel plates of a Newtonian fluid with temperature dependent viscosity. Specifically we will assume an exponential dependence of Nahme type. As noted above this problem has been solved for flow between two infinite parallel plates [1, 4]. In this limit the problem reduces to two coupled ordinary differential equations for the temperature and azimuthal velocity. We propose solving the problem in a finite geometry with a fluid-air interface. In this case we obtain two coupled partial differential equations for the temperature and velocity. Bird and Turian (see [5]) have also analyzed the problem in a finite geometry between a cone and a plate. However, they assumed that the velocity profile was isothermal, thereby reducing the problem to a single partial differential equation for the temperature. In all previous work that we know the boundary conditions are either isothermal on both plates or isothermal on one plate and zero heat transfer on the other. We will adopt the more realistic boundary conditions described above, namely the isothermal condition on the stationary plate, heat transfer on the upper plate, and zero heat transfer at the fluid-air interface. To the best of our knowledge exact analytical solutions for this problem have not been previously reported. Having an analytical solution for this problem will enable one to estimate errors in the torque calculations due to heat transfer and edge effects if needed. This is important in viscometry. Analytical solutions can also be used to validate numerical calculations. For viscoelastic flows in which secondary flow in the base flow is weak or nonexistent the solution provided here provides an accurate approximation to the base flow needed in any linear stability analysis.

2. Governing equations.

We consider the flow of a fluid in the region between two coaxial parallel plates of radius a and separation h in which the top plate rotates at a constant angular speed ω and the bottom plate is stationary. Following Olagunju [21], the nondimensionalized equations governing the primary flow for the azimuthal velocity W and a scaled temperature Θ are given in cylindrical coordinates as

$$\frac{\partial^2 W}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 W}{\partial r^2} + \frac{1}{r}\frac{\partial W}{\partial r} - \frac{W}{r^2} \right) = \frac{\partial \Theta}{\partial z}\frac{\partial W}{\partial z} + \alpha^2 \frac{\partial \Theta}{\partial r}\left(\frac{\partial W}{\partial r} - \frac{W}{r} \right), \tag{1}$$

$$\frac{\partial^2 \Theta}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 \Theta}{\partial r^2} + \frac{1}{r}\frac{\partial \Theta}{\partial r} \right) = -\mathrm{Na}_0 \, e^{-\Theta} \left[\left(\frac{\partial W}{\partial z} \right)^2 + \alpha^2 \left(\frac{\partial W}{\partial r} - \frac{W}{r} \right)^2 \right] \tag{2}$$

with boundary conditions

$$\text{at } z = 0, \qquad W = 0, \qquad \Theta = \vartheta_w, \tag{3}$$

$$\text{at } z = 1, \qquad W = r, \qquad \frac{\partial \Theta}{\partial z} + B\,\Theta = B\vartheta_a, \tag{4}$$

$$\text{at } r = 0, \qquad W = 0, \qquad |\Theta| < \infty, \tag{5}$$

$$\text{at } r = 1, \qquad \frac{\partial W}{\partial r} - \frac{W}{r} = 0. \qquad \frac{\partial \Theta}{\partial r} = 0. \tag{6}$$

Here ϑ_w and ϑ_a are the scaled temperature at the stationary plate and the ambient. The aspect ratio $\alpha = h/a$ and the modified Biot number B are defined in section A.1 of the appendix. The Nahme–Griffith number Na_0, which is a measure of viscous heating in the fluid, is zero for isothermal flows. It is defined as $\mathrm{Na}_0 \equiv (\eta_0 \delta a^2 \omega^2)/(kT_0)$. The quantity η_0 is the isothermal viscosity, δ a thermal sensitivity parameter, k the thermal conductivity, and T_0 a reference temperature [14]. Since the equations are nonlinear finding an exact analytical solution valid for all parameter values is impractical. Therefore we will solve the equations numerically using a finite element method. We will also obtain analytical solutions using perturbation expansions in Nahme–Griffith number Na and aspect ratio α.

3. Analytical solutions.

3.1. An exact solution for $\alpha = 0$ and $B = 0$. An exact solution of equations (1)–(6) can be found for $\alpha = 0$, $B = 0$, and all values of Na_0. This corresponds to plane Couette flow with the upper plate insulated. This solution does not satisfy the boundary conditions at the fluid-air interface $r = 0$. However, we will show that it provides an excellent approximation to the solution for small α except very close to $r = 1$. In addition we will show that the torque exerted by the fluid on the lower plate is very well approximated by this exact solution when the aspect ratio α is small. An analytical formula is provided which can be used to calculate nonisothermal correction to the torque, as is often required in rheometry. To the best of our knowledge, this analytical representation for the torque has not been previously reported. Note that the exact solution obtained by Nahme [1] corresponds to $\alpha = 0$ and $B = \infty$.

Setting α and B to zero, (1)–(6) reduce to the following:

$$\frac{d^2W}{dz^2} = \frac{d\Theta}{dz}\frac{dW}{dz}, \tag{7}$$

$$\frac{d^2\Theta}{dz^2} = -\mathrm{Na}_0 e^{-\Theta}\left(\frac{dw}{dz}\right)^2. \tag{8}$$

The boundary conditions are

$$W = 0, \quad \Theta = \vartheta_w \quad \text{for} \quad z = 0 \tag{9}$$

and

$$W = r, \quad \frac{\partial\Theta}{\partial z} = 0 \quad \text{for} \quad z = 1. \tag{10}$$

It is straightforward to obtain the solution which is given by

$$W = \frac{r}{2} - \frac{1}{\mu\mathrm{Na}}\tanh[E(1-2z)], \tag{11}$$

$$\Theta = \vartheta_w + \ln\left[\left(1 + \frac{r^2\mathrm{Na}}{8}\right)\operatorname{sech}^2[E(1-2z)]\right], \tag{12}$$

where $\mathrm{Na} = \mathrm{Na}_0 e^{-\vartheta_w}$,

$$E = \tanh^{-1}(r\mu\mathrm{Na}/2),$$

and

$$\mu = \left[2\mathrm{Na}\left(1 + \frac{r^2}{8}\mathrm{Na}\right)\right]^{-\frac{1}{2}}.$$

The dimensionless torque on the lower plate is defined as

$$\mathcal{T} = \int_0^1\int_0^1\left(\frac{dW}{dz}\right)_{z=0} r^2 dr dz.$$

Using the solution obtained above, a series solution for $\mathcal{T}$ valid for $\mathrm{Na} < 2$ is given by

$$\mathcal{T} = \sum_{n=0}^{\infty}\sum_{k=0}^{\infty}(-1)^k\left(\frac{\mathrm{Na}}{2}\right)^{n+k}\frac{(n+k)!}{n!k!}\frac{1}{(2n+1)(2n+2k+4)}. \tag{13}$$

For other values of Na the integral can easily be computed numerically. These solutions will be compared to asymptotic and numerical solutions below.

3.2. Asymptotic solution for Na $\ll 1$: $\vartheta_w = \vartheta_a$. We seek a regular expansion in Nahme number for W and Θ as follows:

$$W = W_0 + \text{Na}\, W_1 + O(\text{Na}^2), \qquad \Theta = \Theta_0 + \text{Na}\, \Theta_1 + O(\text{Na}^2). \tag{14}$$

Here and in what follows $\text{Na} = \text{Na}_0 e^{-\vartheta_w}$. The governing equations for W_0 and Θ_0 are

$$\frac{\partial^2 W_0}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 W_0}{\partial r^2} + \frac{1}{r}\frac{\partial W_0}{\partial r} - \frac{W_0}{r^2} \right) = \frac{\partial \Theta_0}{\partial z}\frac{\partial W_0}{\partial z} + \alpha^2 \frac{\partial \Theta_0}{\partial r}\left(\frac{\partial W_0}{\partial r} - \frac{W_0}{r} \right), \tag{15}$$

$$\frac{\partial^2 \Theta_0}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 \Theta_0}{\partial r^2} + \frac{1}{r}\frac{\partial \Theta_0}{\partial r} \right) = 0 \tag{16}$$

with the boundary conditions

$$\text{at } z = 0, \quad W_0 = 0, \quad \Theta_0 = \vartheta_w, \tag{17}$$

$$\text{at } z = 1, \quad W_0 = r, \quad \frac{\partial \Theta_0}{\partial z} + B\, \Theta_0 = B\, \vartheta_w, \tag{18}$$

$$\text{at } r = 0, \quad W_0 = 0, \quad |\Theta_0| < \infty, \tag{19}$$

$$\text{at } r = 1, \quad \frac{\partial W_0}{\partial r} - \frac{W_0}{r} = 0, \quad \frac{\partial \Theta_0}{\partial r} = 0. \tag{20}$$

The leading order solution for $\text{Na} = 0$ gives the isothermal solution

$$W_0 = rz, \tag{21}$$

$$\Theta_0 = \vartheta_w. \tag{22}$$

Note that this solution is valid for all values of α.

The solution at order Na corresponding the first nonisothermal correction satisfies the following equations:

$$\frac{\partial^2 W_1}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 W_1}{\partial r^2} + \frac{1}{r}\frac{\partial W_1}{\partial r} - \frac{W_1}{r^2} \right) = r\frac{\partial \Theta_1}{\partial z}, \tag{23}$$

$$\frac{\partial^2 \Theta_1}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 \Theta_1}{\partial r^2} + \frac{1}{r}\frac{\partial \Theta_1}{\partial r} \right) = -r^2 \tag{24}$$

with boundary conditions

$$\text{at } z = 0, \quad W_1 = 0, \quad \Theta_1 = 0, \tag{25}$$

$$\text{at } z = 1, \quad W_1 = 0, \quad \frac{\partial \Theta_1}{\partial z} + B\Theta_1 = 0, \tag{26}$$

$$\text{at } r = 0, \quad W_1 = 0, \quad |\Theta_1| < \infty, \tag{27}$$

$$\text{at } r = 1, \quad \frac{\partial W_1}{\partial r} - \frac{W_1}{r} = 0, \quad \frac{\partial \Theta_1}{\partial r} = 0. \tag{28}$$

Note that (23)–(24) are now uncoupled. The equations can be solved exactly by separation of variables as follows:

$$\Theta_1 = -\sum_{n=1}^{\infty} \frac{\bar{\Gamma}_n}{\lambda_n^2} \left[\frac{2\alpha^3}{\lambda_n} \frac{I_0\left(\frac{\lambda_n r}{\alpha}\right)}{I_1\left(\frac{\lambda_n}{\alpha}\right)} - \frac{4\alpha^4}{\lambda_n^2} - \alpha^2 r^2 \right] \sin(\lambda_n z) \tag{29}$$

and

$$W_1 = \sum_{m=1}^{\infty} F_m(r) \sin(m\pi z), \tag{30}$$

where $\lambda_n, n = 1, 2, \dots,$ are positive solutions of the transcendental equation

$$\tan(\lambda_n) + \frac{\lambda_n}{B} = 0, \tag{31}$$

and $\Gamma_n = -\frac{1}{\alpha^2} \frac{4(1-\cos(\lambda_n))}{2\lambda_n - \sin(2\lambda_n)}$. This equation has infinitely many positive roots. Here I_n is the modified Bessel function of the first kind. This solution is also valid for all values of the aspect ratio α.

The expression for $F_m(r)$ involves complicated integrals of Bessel functions (see the appendix for details).

3.3. Asymptotic solution for Na $\ll$ 1 : $\boldsymbol{\vartheta_w \neq \vartheta_a}$. The governing equations for W_0 and Θ_0, W_1 and Θ_1 are the same as in the previous section.

At zeroth order in Na we have the isothermal solution

$$\Theta_0 = \chi z + \vartheta_w, \quad \text{where} \quad \chi \equiv \frac{B(\vartheta_a - \vartheta_w)}{1 + B}, \tag{32}$$

$$W_0 = \left(\frac{e^{\chi z} - 1}{e^{\chi} - 1} \right) r. \tag{33}$$

The equations at order Na are

$$\frac{\partial^2 W_1}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 W_1}{\partial r^2} + \frac{1}{r}\frac{\partial W_1}{\partial r} - \frac{W_1}{r^2} \right) = \frac{\chi \ r \ e^{\chi z}}{e^{\chi} - 1} \frac{\partial \Theta_1}{\partial z} + \chi \frac{\partial W_1}{\partial z}, \tag{34}$$

$$\frac{\partial^2 \Theta_1}{\partial z^2} + \alpha^2 \left(\frac{\partial^2 \Theta_1}{\partial r^2} + \frac{1}{r}\frac{\partial \Theta_1}{\partial r} \right) = -\frac{\chi^2 r^2 e^{\chi z}}{\left(e^{\chi} - 1\right)^2} \tag{35}$$

with boundary conditions

$$\text{on } z = 0, \qquad W_1 = 0, \qquad \Theta_1 = 0, \tag{36}$$

$$\text{on } z = 1, \qquad W_1 = 0, \qquad \frac{\partial \Theta_1}{\partial z} + B\Theta_1 = 0, \tag{37}$$

$$\text{on } r = 0, \qquad W_1 = 0, \qquad |\Theta_1| < \infty, \tag{38}$$

$$\text{on } r = 1, \qquad \frac{\partial W_1}{\partial r} - \frac{W_1}{r} = 0, \qquad \frac{\partial \Theta_1}{\partial r} = 0. \tag{39}$$

Although these equations can also be solved exactly the solutions are rather too complicated. Therefore we will obtain the solution as an expansion in α. This limit has applications in rheometric devices where α is typically less than 0.1. For the case $\alpha = O(1)$ the solution will be computed numerically. Because the limit $\alpha \to 0$ is singular we use the method of matched asymptotic expansion. Thus we seek an outer solution and an inner solution and then obtain a composite expansion for the solution by matching.

Outer solution. For the outer solution we expand as follows:

$$W_1 = W_{10}^o + \alpha W_{11}^o + O(\alpha^2), \qquad \Theta_1 = \Theta_{10}^o + \alpha \Theta_{11}^o + O(\alpha^2), \tag{40}$$

where the superscript (o) refers to the outer solution.

The governing equations at zeroth order in α are

$$\frac{\partial^2 W_{10}^o}{\partial z^2} = \frac{\chi\ r\ e^{\chi z}}{e^{\chi} - 1} \frac{\partial \Theta_{10}^o}{\partial z} + \chi \frac{\partial W_{10}^o}{\partial z}, \tag{41}$$

$$\frac{\partial^2 \Theta_{10}^o}{\partial z^2} = -\frac{\chi^2 r^2 e^{\chi z}}{(e^{\chi} - 1)^2} \tag{42}$$

with the corresponding boundary conditions

$$\text{at } z = 0, \quad W_{10}^o = 0, \quad \Theta_{10}^o = 0, \tag{43}$$

$$\text{at } z = 1, \quad W_{10}^o = 0, \quad \frac{\partial \Theta_{10}^o}{\partial z} + B\Theta_{10} = 0. \tag{44}$$

The solution satisfying the above governing equations and the boundary conditions are

$$\Theta_{10}^o = \frac{r^2}{(e^{\chi} - 1)^2} \left[1 - e^{\chi z} + z \frac{(\chi + B)e^{\chi} - B}{1 + B} \right], \tag{45}$$

$$\begin{aligned} W_{10}^o = {} & \frac{\chi r^3}{(e^{\chi} - 1)^3} \left[-\frac{e^{2\chi z}}{2\chi} + ((\chi + B)e^{\chi} - B) \frac{e^{\chi z}(\chi z - 1)}{(1 + B)\chi^2} \right] \\ & - \frac{\chi e^{\chi z} r^3}{(e^{\chi} - 1)^4} \left[\frac{1 - e^{2\chi}}{2\chi} + ((\chi + B)e^{\chi} - B) \frac{1 + (\chi - 1)e^{\chi}}{(1 + B)\chi^2} \right] \\ & - \frac{r^3}{(e^{\chi} - 1)^4} \left[\frac{e^{2\chi} - e^{\chi}}{2} - \frac{e^{\chi} \left((\chi + B)e^{\chi} - B \right)}{1 + B} \right]. \end{aligned} \tag{46}$$

Further, it is also determined that

$$W_{11}^o = 0, \qquad \Theta_{11}^o = 0. \tag{47}$$

Inner solution. For the inner expansion we introduce the stretched variable, $\xi \equiv \frac{1-r}{\alpha}$, and seek an expansion of the form

$$W_1^i = W_{10}^i + \alpha W_{11}^i + O(\alpha^2), \quad \Theta_1^i = \Theta_{10}^i + \alpha \Theta_{11}^i + O(\alpha^2). \tag{48}$$

The governing equations and the boundary conditions at zeroth order in α are

$$\frac{\partial^2 W_{10}^i}{\partial z^2} + \frac{\partial^2 W_{10}^i}{\partial \xi^2} - \chi \frac{\partial W_{10}^i}{\partial z} = \frac{\chi e^{\chi z}}{(e^\chi - 1)} \left(\frac{\partial \Theta_{10}^i}{\partial z} \right), \tag{49}$$

$$\frac{\partial^2 \Theta_{10}^i}{\partial z^2} + \frac{\partial^2 \Theta_{10}^i}{\partial \xi^2} = -\frac{\chi^2 e^{\chi z}}{(e^\chi - 1)^2}, \tag{50}$$

$$\text{at } z = 0, \qquad W_{10}^i = 0, \qquad \Theta_{10}^i = 0, \tag{51}$$

$$\text{at } z = 1, \qquad W_{10}^i = 0, \qquad \frac{\partial \Theta_{10}^i}{\partial z} + B\Theta_{10}^i = 0, \tag{52}$$

$$\text{at } \xi = 0, \qquad \frac{\partial W_{10}^i}{\partial \xi} = 0, \qquad \frac{\partial \Theta_{10}^i}{\partial \xi} = 0. \tag{53}$$

It is straightforward to obtain the following expressions:

$$\Theta_{10}^i = \frac{1}{(e^\chi - 1)^2} \left[1 - e^{\chi z} + z \frac{(\chi + B)e^\chi - B}{1 + B} \right], \tag{54}$$

$$\begin{aligned} W_{10}^i = {} & \frac{\chi}{(e^\chi - 1)^3} \left[-\frac{e^{2\chi z}}{2\chi} + ((\chi + B)e^\chi - B) \frac{e^{\chi z}(\chi z - 1)}{(1 + B)\chi^2} \right] \\ & - \frac{\chi e^{\chi z}}{(e^\chi - 1)^4} \left[\frac{1 - e^{2\chi}}{2\chi} + ((\chi + B)e^\chi - B) \frac{1 + (\chi - 1)e^\chi}{(1 + B)\chi^2} \right] \\ & - \frac{1}{(e^\chi - 1)^4} \left[\frac{e^{2\chi} - e^\chi}{2} - \frac{e^\chi \left((\chi + B)e^\chi - B \right)}{1 + B} \right]. \end{aligned} \tag{55}$$

The order α equations are

$$\frac{\partial^2 \Theta_{11}^i}{\partial z^2} + \frac{\partial^2 \Theta_{11}^i}{\partial \xi^2} = \frac{2\xi \chi^2 e^{\chi z}}{(e^\chi - 1)^2}, \tag{56}$$

$$\frac{\partial^2 W_{11}^i}{\partial z^2} + \frac{\partial^2 W_{11}^i}{\partial \xi^2} - \chi \frac{\partial W_{11}^i}{\partial z} = \frac{\partial W_{01}^i}{\partial z} \left(\frac{\partial \Theta_{10}^i}{\partial z} \right) + \frac{\partial W_{00}^i}{\partial z} \left(\frac{\partial \Theta_{11}^i}{\partial z} \right). \tag{57}$$

The boundary conditions are the same as above. The solution of the equations is

$$\Theta_{11}^i = -2\xi \Theta_{10}^i - 2 \sum_{n=1}^{\infty} \frac{\tilde{\Gamma}_n e^{-\frac{\lambda_n (1-r)}{\alpha}}}{\lambda_n^3} \sin(\lambda_n z), \tag{58}$$

$$\begin{aligned} W_{11}^i = {} & -3\xi W_{10}^i + \sum_{m=1}^{\infty} \frac{2\tilde{A}_m e^{-\Lambda_m \xi} e^{\frac{\chi z}{2}}}{\Lambda_m^2} \sin(m\pi z) \\ & + \sum_{m=1}^{\infty} \sum_{n=1}^{\infty} \frac{\tilde{\Gamma}_n \tilde{B}_{mn}}{\lambda_n^2 (\Lambda_m^2 - \lambda_n^2)} \left(e^{-\lambda_n \xi} - \frac{\lambda_n e^{-\Lambda_m \xi}}{\Lambda_m} \right) e^{\frac{\chi z}{2}} \sin(m\pi z), \end{aligned} \tag{59}$$

where

$$\tilde{\Gamma}_n = \frac{\chi^2 \int_0^1 e^{\chi z} \sin(\lambda_n z) \mathrm{d}z}{(e^{\chi} - 1)^2 \int_0^1 \sin^2(\lambda_n z) \mathrm{d}z} \tag{60}$$

and

$$\Lambda_m^2 = \frac{\chi^2}{4} + m^2\pi^2,$$

$$\tilde{A}_m = \frac{\chi}{(e^{\chi}-1)^3} \frac{\int_0^1 \left(-\chi e^{\chi z} + \frac{(\chi+B)e^{\chi}-B}{1+B}\right) e^{\frac{\chi z}{2}} \sin(m\pi z)\mathrm{d}z}{\int_0^1 \sin^2(m\pi z)\mathrm{d}z},$$

$$\tilde{B}_{mn} = \frac{2\chi}{e^{\chi}-1} \frac{\int_0^1 e^{\frac{\chi z}{2}} \cos(\lambda_n z) \sin(m\pi z)\mathrm{d}z}{\int_0^1 \sin^2(m\pi z)\mathrm{d}z}. \tag{61}$$

Composite solution. In order to use the Van Dyke matching principle, the outer solution for the velocity and the temperature distribution is expressed in terms of the inner variable including terms of the first order in α,

$$(\Theta^o)^i = \chi z + \vartheta_w + \mathrm{Na}(1 - 2\alpha\xi)\Theta_{10}^i + O(\mathrm{Na}^2), \tag{62}$$

$$(W^o)^i = \left(\frac{e^{\chi z}-1}{e^{\chi}-1}\right) r + \mathrm{Na}(1 - 3\alpha\xi)W_{10}^i + O(\mathrm{Na}^2). \tag{63}$$

The Van Dyke matching principle is expressed using the formulas

$$W^c = W^o + W^i - (W^o)^i, \qquad \Theta^c = \Theta^o + \Theta^i - (\Theta^o)^i. \tag{64}$$

The composite solution for temperature and velocity distribution is then given by

$$\begin{aligned}\Theta^c = \chi z + \vartheta_w + \mathrm{Na}\left(\frac{r^2}{(e^{\chi}-1)^2}\left[1 - e^{\chi z} + z\frac{(\chi+B)e^{\chi}-B}{1+B}\right]\right)\\ -2\mathrm{Na}\alpha \sum_{n=1}^{\infty} \frac{\tilde{\Gamma}_n e^{-\frac{\lambda_n(1-r)}{\alpha}}}{\lambda_n^3} \sin(\lambda_n z) + O(\mathrm{Na}^2),\end{aligned} \tag{65}$$

$$\begin{aligned}W^c = \left(\frac{e^{\chi z}-1}{e^{\chi}-1}\right) r + \mathrm{Na}W_1^o + \mathrm{Na}\alpha \sum_{m=1}^{\infty} \frac{2\tilde{A}_m e^{-\Lambda_m \frac{(1-r)}{\alpha}} e^{\frac{\chi z}{2}}}{\Lambda_m^2} \sin(m\pi z)\\ +\mathrm{Na}\alpha \sum_{m=1}^{\infty}\sum_{n=1}^{\infty} \frac{\tilde{\Gamma}_n \tilde{B}_{mn}}{\lambda_n^2(\Lambda_m^2 - \lambda_n^2)} \left(e^{-\lambda_n \frac{(1-r)}{\alpha}} - \frac{\lambda_n e^{-\Lambda_m \frac{(1-r)}{\alpha}}}{\Lambda_m}\right) e^{\frac{\chi z}{2}} \sin m\pi z.\end{aligned} \tag{66}$$

4. Numerical solution. The domain Ω for numerical computation is $0 < z < 1$ and $0 < r < 1$, shown in Figure 1. In order to apply the finite element method, we need to rewrite the two partial differential equations in variational forms. We multiply the continuity equation (1) by $rV(r,z)$ (cf. [22, 24, 25, 26]), the test function with boundary conditions specified in Figure 1. Then we apply the integration by parts to obtain

$$\begin{aligned}\int_{\Omega}\left(\frac{\partial W}{\partial z}\frac{\partial V}{\partial z} + \alpha^2\frac{\partial W}{\partial r}\frac{\partial V}{\partial r} + \alpha^2\frac{WV}{r^2}\right) r dr dz - \int_{r=1} \alpha^2 WV dz\\ = \int_{\Omega}\left(-\frac{\partial\Theta}{\partial z}\frac{\partial W}{\partial z} - \alpha^2\frac{\partial\Theta}{\partial r}\left(\frac{\partial W}{\partial r} - \frac{W}{r}\right)\right) V r dr dz.\end{aligned} \tag{67}$$

We do the same for (2), with a test function $rV(r,z)$, but having different boundary conditions shown in Figure 1:

$$\begin{aligned}\int_\Omega \left(\frac{\partial\Theta}{\partial z}\frac{\partial V}{\partial z} + \alpha^2 \frac{\partial\Theta}{\partial r}\frac{\partial V}{\partial r}\right) r dr dz - \int_{z=1} r(B\vartheta_a - B\Theta)V dr \\ = \mathrm{Na}\int_\Omega e^{-\Theta}\left(\left(\frac{\partial W}{\partial z}\right)^2 + \alpha^2\left(\frac{\partial W}{\partial r} - \frac{W}{r}\right)^2\right) V r dr dz.\end{aligned} \tag{68}$$

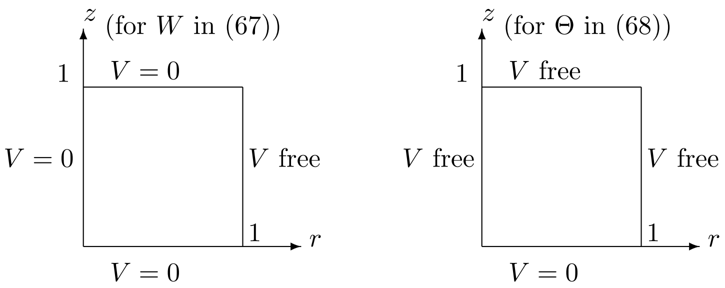

FIG. 1. *Boundary conditions for the test functions V (for W and Θ in* (67)–(68)*).*

To obtain homogeneous boundary conditions for the variational problems (67)–(68), we use the following decompositions:

$$W = W^b + W^0, \qquad W^b = rz, \tag{69}$$

$$\Theta = \Theta^b + \Theta^0, \qquad \Theta^b = \vartheta_w + z\frac{B}{1+B}(\vartheta_a - \vartheta_w). \tag{70}$$

We seek solutions W^0 and Θ^0 instead, which have homogeneous boundary conditions, also depicted in Figure 2:

$$W^0\big|_{r=0,z=0,z=1} = 0, \qquad \left.\frac{\partial W^0}{\partial r}\right|_{r=1} = \frac{W^0}{r},$$

$$\Theta^0\big|_{z=0} = 0, \qquad \left.\frac{\partial \Theta^0}{\partial r}\right|_{r=0,r=1} = 0, \qquad \left.\frac{\partial \Theta^0}{\partial z}\right|_{z=1} = -B\Theta^0.$$

That is, we will find finite element solutions W_h^0 and Θ_h^0, where h stands for the grid size.

To discretize (67) and (68), due to the special domain of the unit square, one may use spectral methods (cf. [22]) or tensor product methods (cf. [23]) to get a high order approximation. To handle the nonlinearity of the coupled system, and to handle possible irregular domains in future, we use Q^k finite elements, continuous and piecewise polynomials of separate degree k or less, on uniform grids $\mathcal{K}_h = \{K \mid K = [r_i - h, r_i] \times [z_j - h, z_j],\ i, j = 1, \ldots, 1/h\}$ of Ω:

$$\mathcal{Q}_h := \left\{ V \in C(\Omega) \mid V|_K = \sum_{0 \le i,j \le k} a_{ij} r^i z^j \ \forall K \in \mathcal{K}_h \right\} \subset H^1(\Omega).$$

We use the following notation for the discrete spaces with homogeneous boundary conditions:

$$\mathcal{Q}_{h,W} := \mathcal{Q}_h \cap \{V = V(r,z) \in C(\Omega) \mid V(0,z) = V(r,0) = V(r,1) = 0\}, \tag{71}$$

$$\mathcal{Q}_{h,\Theta} := \mathcal{Q}_h \cap \{V = V(r,z) \in C(\Omega) \mid V(r,0) = 0\}. \tag{72}$$

FIG. 2. *Boundary conditions for W^0 and Θ^0 in* (69)–(70).

The finite element discretizations of (67)–(68) read as follows: Find $(W_h^0, \Theta_h^0) \in \mathcal{Q}_{h,W} \times \mathcal{Q}_{h,\Theta}$ such that

$$A_W(W_h^0, V) = F_{W,\Theta}(V) - A_W(W^b, V) \qquad \forall V \in \mathcal{Q}_{h,W}, \tag{73}$$

$$A_\Theta(\Theta_h^0, V) = G_{W,\Theta}(V) - A_\Theta(\Theta^b, V) + Bc_z(\vartheta_a, V) \qquad \forall V \in \mathcal{Q}_{h,\Theta}, \tag{74}$$

where the bilinear forms and functionals are defined by

$$A_W(U, V) = a(U, V) + \alpha^2 \left(\frac{U}{r}, \frac{V}{r}\right)_r - \alpha^2 c_r(U, V), \tag{75}$$

$$A_\Theta(U, V) = a(U, V) + Bc_z(U, V), \tag{76}$$

$$F_{W,\Theta}(V) = \left(-\frac{\partial \Theta}{\partial z}\frac{\partial W}{\partial z} - \alpha^2 \frac{\partial \Theta}{\partial r}\left(\frac{\partial W}{\partial r} - \frac{W}{r}\right), V\right)_r, \tag{77}$$

$$G_{W,\Theta}(V) = \mathrm{Na}\left(e^{-\Theta}\left[\left(\frac{\partial W}{\partial z}\right)^2 + \alpha^2\left(\frac{\partial W}{\partial r} - \frac{W}{r}\right)^2\right], V\right)_r, \tag{78}$$

$$a(U, V) = \int_\Omega \left(\frac{\partial U}{\partial z}\frac{\partial V}{\partial z} + \alpha^2 \frac{\partial U}{\partial r}\frac{\partial V}{\partial r}\right) r dr dz, \tag{79}$$

$$(U, V)_r = \int_\Omega UV r dr dz, \tag{80}$$

$$c_r(U, V) = \int_{r=1, 0 \le z \le 1} UV dz, \tag{81}$$

$$c_z(U, V) = \int_{z=1, 0 \le r \le 1} rUV dz. \tag{82}$$

We solve the nonlinear system of equations (73)–(74) numerically by a straightforward Seidel iteration. That is, initially given some guesses (both zero in computation) of W_h^0 and Θ_h^0, we generate the right-hand side of (73) and use the conjugate gradient method to solve (73) to get a new W_h^0. Then the new W_h^0 and the old Θ_h^0 would be used to generate the right-hand side vector in (74). We solve (74) again by the conjugate gradient method to get a new Θ_h^0. The next lemma shows that the two linear systems at each step described above are uniquely solvable, because both the coefficient matrices are symmetric and positive definite.

LEMMA 4.1. *For any $V \in \mathcal{Q}_{h,\Theta} \cup \mathcal{Q}_{h,W}$ and $V \neq 0$,*

$$a(V,V) > 0. \tag{83}$$

For any $V \in \mathcal{Q}_{h,W}$ and $V \neq 0$,

$$A_W(V,V) > 0. \tag{84}$$

For any $V \in \mathcal{Q}_{h,\Theta}$, $V \neq 0$, and $B \geq 0$,

$$A_\Theta(V,V) > 0. \tag{85}$$

Proof. Equations (83) and (84) are shown in [27]. Equation (85) is a corollary of (83), noting the sign of B is positive. □

ALGORITHM 4.1. *The coupled nonlinear system* (73)–(74) *is solved by the Seidel iteration with the given initial guess $W_{h,0}^0 = 0$ and $W_{\Theta,0}^0 = 0$. For $j = 1, 2, \ldots,$*

$$W_{h,j}^0 = W_{h,j-1}^0 + e_W,$$

where e_W solves the equation

$$A_W(e_W, V) = F_{W_{j-1},\Theta_{j-1}}(V) - A_W(W^b, V) - A_W(W_{h,j-1}^0, V) \qquad \forall V \in \mathcal{Q}_{h,W} \tag{86}$$

and

$$\Theta_{h,j}^0 = \Theta_{h,j-1}^0 + e_\Theta,$$

where e_Θ solves the equation

(87)

$$A_\Theta(e_\Theta, V) = G_{W_j,\Theta_{j-1}}(V) - A_\Theta(\Theta^b, V) + Bc_z(\vartheta_a, V) - A_\Theta(\Theta_{h,j-1}^0, V) \qquad \forall V \in \mathcal{Q}_{h,\Theta}.$$

Here $W_j = W^b + W_{h,j}^0$ and $\Theta_j = \Theta^b + \Theta_{h,j}^0$ for $j = 0, 1, 2, \ldots.$

A typical pair of solutions (W_h, Θ_h) is shown in Figure 3.

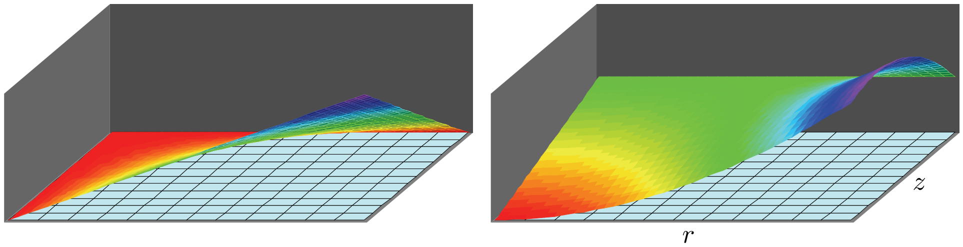

FIG. 3. *Solutions W and Θ for* (1) *and* (2) *when $\alpha = .01$, $Na = 1$, $\vartheta_w = 1.5$, $\vartheta_a = 1$, $B = 0.1$.*

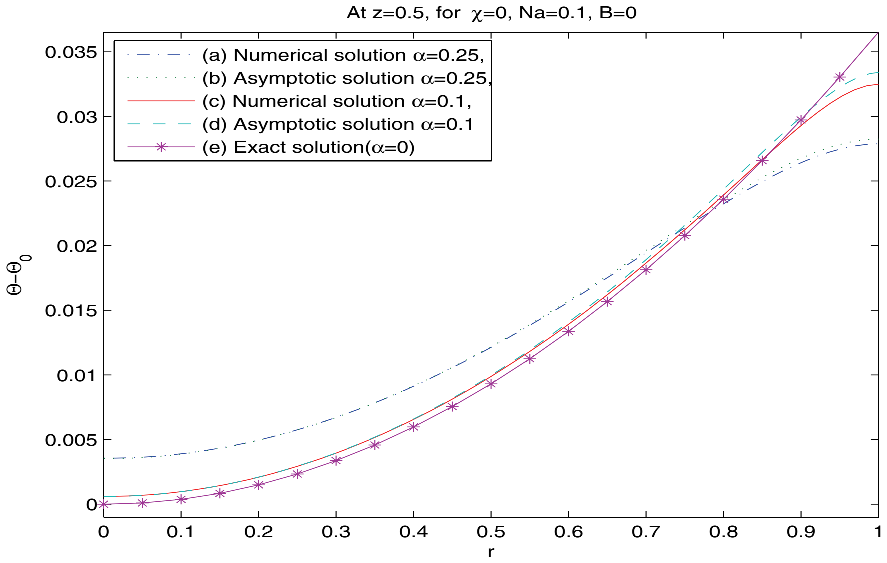

FIG. 4. *Solutions obtained by* (73)–(74), (29)–(30), *and* (11)–(12).

5. Discussion. In this section we compare the analytical solutions obtained in section 3 with the finite element solution obtained in section 4. The exact solution given in (11)–(12) is valid for $\alpha = 0$, $B = 0$, and all values of Na, the perturbation solution given in (29)–(30) is valid for all values of α and small Na, while the solution found in (65)–(66) is valid only for small α and Na. The numerical solution, on the other hand, is valid for all parameter values.

The plots in Figures 4–8 depict the deviation of the temperature and velocity from the isothermal solution. We plot $\Theta - \Theta_0$ and $W - W_0$, where Θ_0 and W_0 are the isothermal solutions. Figures 4 and 5 show the deviation of temperature at $z = 0.5$ and $r = 0.5$, respectively, for Na $= 0.1$, $B = 0$, and selected values of α. The case $B = 0$ corresponds to insulated boundary condition on the upper plate. For $\alpha = 0.1$ all three solutions agree very well except near the free surface $r = 1$. The error in the exact solution for $\alpha = 0$ arises because it does not satisfy the boundary condition at the free surface. The error between the numerical and asymptotic solutions is otherwise very small. Figure 6 shows the deviation of the velocity for the same values of the parameters. The agreement among all three solutions is again very good. In Figure 7, the deviation in temperature is shown for $\alpha = 0, 1$, $B = 1$, $\theta_w = 1.0$, $\theta_a = 1.5$ for two values of Na. While the agreement between numerical and asymptotic solutions is excellent for Na $= 0.1$, there is a small discrepancy for the case Na $= 1.0$. This is actually quite good since the perturbation expansion was truncated at order $O(\text{Na})$.

Figure 8 shows the deviation of the velocity for a large value of the Biot number B. In this limit the two plates are nearly isothermal, and we see a qualitative difference from the solution for $B = O(1)$. Specifically, the profile is symmetric about the midplane $z = 0$, whereas for smaller values of B the profile is asymmetric. Another qualitative difference is the location of the maximum temperature. On any fixed

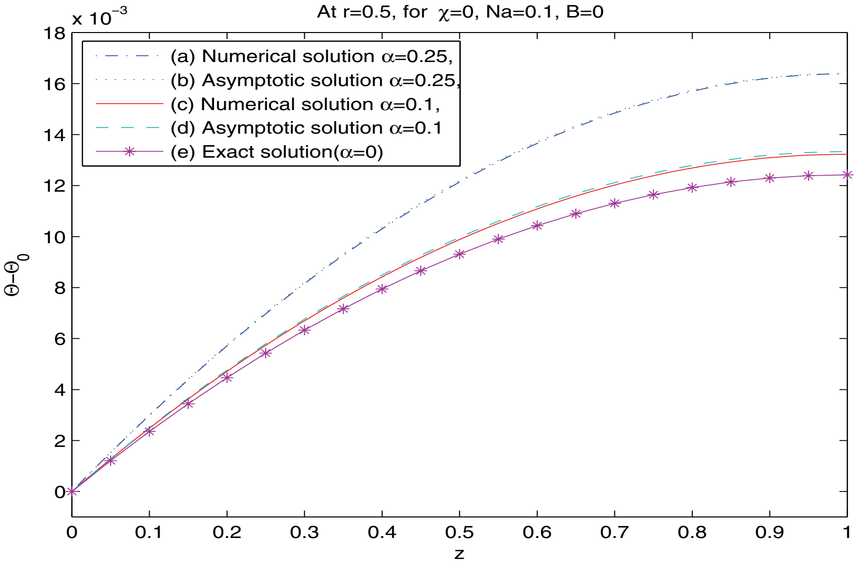

Fig. 5. *Solutions obtained by* (73)–(74), (29)–(30), *and* (11)–(12).

plane the maximum occurs at the free surface $r = 1$ when $B = 0$. As B increases the location of the maximum moves away from the free surface. From these figures we also see that the deviation in temperature and velocity from the isothermal solution is order $O(\mathrm{Na})$ when Na is small.

Finally, in Figure 9 we plot the torque on the lower stationary plate as a function of the Nahme number Na for selected values of α and B. Although the exact solution is valid only for $\alpha = 0$ and $B = 0$ the agreement with the numerical solution for $\alpha = 0.1$ and $B = 0.1$ is excellent. Thus, in applications in which the aspect ratio α is small the exact solution can be used to obtain very accurate corrections to the torque in viscometric applications. We also show the series representation for the torque equation (13), and the agreement is excellent for $\mathrm{Na} < 2$.

6. Summary. Nonisothermal torsional flow with the heat transfer boundary condition at the upper rotating plate, the isothermal boundary condition at the lower stationary plate, and the insulated boundary condition at the fluid/air interface has been analyzed. It is assumed that viscosity is an exponential function of temperature. We have obtained analytical solutions valid in the limit of small aspect ratio α and in the limit of small Nahme–Griffith number Na. The nonlinear coupled partial differential equations have also been solved numerically using the finite element method. Our results show that the asymptotic solutions agree very well with the numerical solution. For small vales of Na the deviation of temperature and velocity from the isothermal solution is small, approximately of order $O(\mathrm{Na})$. Furthermore, we show that for viscometric applications in which the aspect ratio α is typically less than 0.1, the exact solution obtained for $\alpha = 0$ and $B = 0$ gives very accurate results for the nonisothermal correction to the torque for small values of α and the Biot number B.

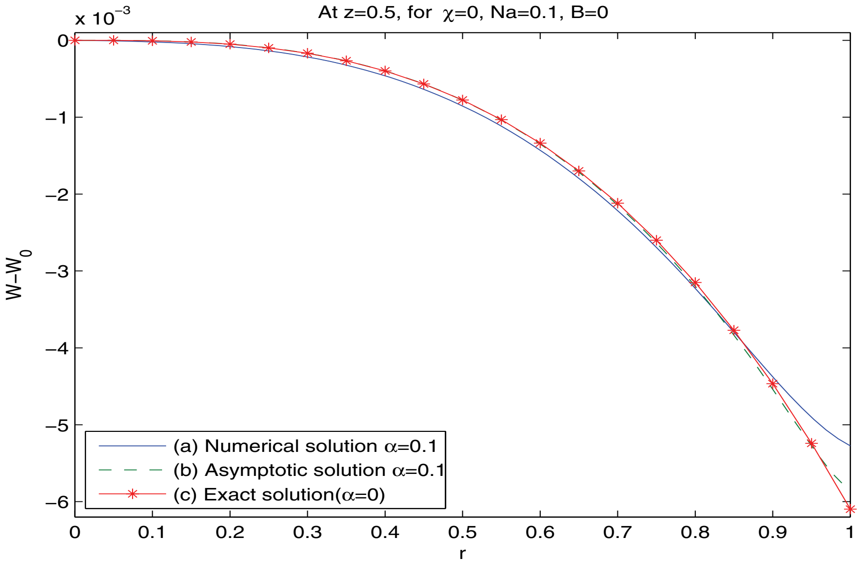

FIG. 6. *Solutions obtained by* (73)–(74), (29)–(30), *and* (11)–(12).

Appendix.

A.1. Heat transfer boundary condition. In this section, the derivation of the heat transfer boundary condition at the upper rotating plate is detailed. Following the convention adopted in Ozisik [29],

$$-k\frac{\partial \tilde{T}}{\partial \tilde{z}} = \hbar\left(\tilde{T} - \tilde{T}_a\right) \qquad \text{at the surface S,} \tag{88}$$

where $\hbar$ is the heat transfer coefficient and k is the thermal conductivity of the rotating plate. The surface S corresponds to the surface of the upper rotating plate at $z = 1$. After normalization of variables and introducing the thickness of the plate H, to procure a meaningful parameter, the Biot number $Bi = \frac{\hbar H}{k}$:

$$\frac{\partial T}{\partial z} = \frac{Bih}{H}\left(-T + T_a\right), \tag{89}$$

where h is the thickness of the gap between the two plates [28, 29]. In dimensionless form this becomes

$$\frac{\partial \Theta}{\partial z} + B\Theta = B\vartheta_a, \tag{90}$$

where $B \equiv \frac{Bi\ h}{H}$.

A.2. The function $F_m(r)$. The function $F_m(r)$ appearing in (30) satisfies the following ordinary differential equation:

$$r^2 F_m'' + rF_m' - \left(1 + \frac{m^2\pi^2 r^2}{\alpha^2}\right)F_m = \varphi(r),$$

$$\varphi = 2r^3 \sum_{n=1}^{\infty}\left[\frac{m\pi\bar{\Gamma}_n\left(1 - \cos(m\pi)\cos(\lambda_n)\right)}{m^2\pi^2 - \lambda_n^2}\right]\left[\frac{2\alpha}{\lambda_n^2}\frac{I_0(\frac{\lambda_n r}{\alpha})}{I_1(\frac{\lambda_n}{\alpha})} - \frac{r^2}{\lambda_n^2} - \frac{4\alpha^2}{\lambda_n^4}\right]. \tag{91}$$

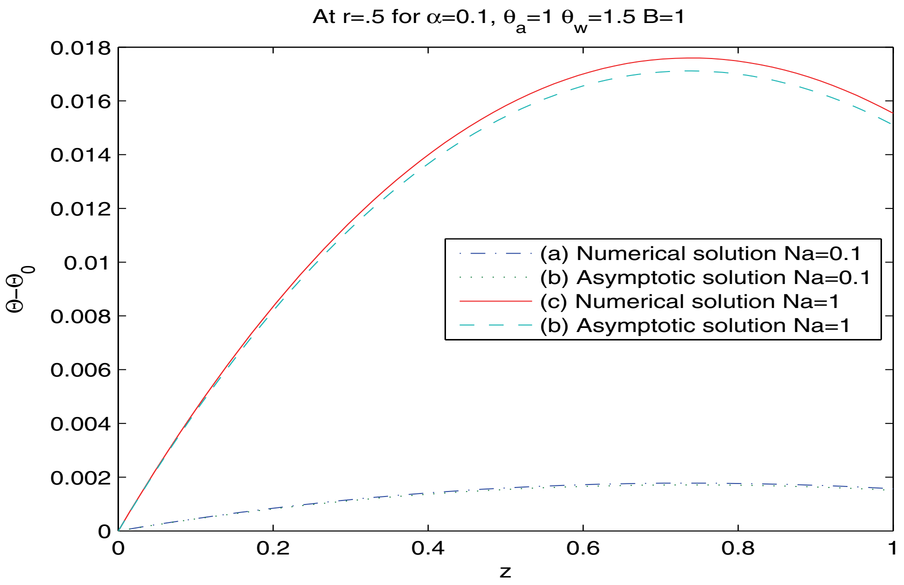

FIG. 7. *Solutions obtained by* (73)–(74), (29)–(30), *and* (11)–(12).

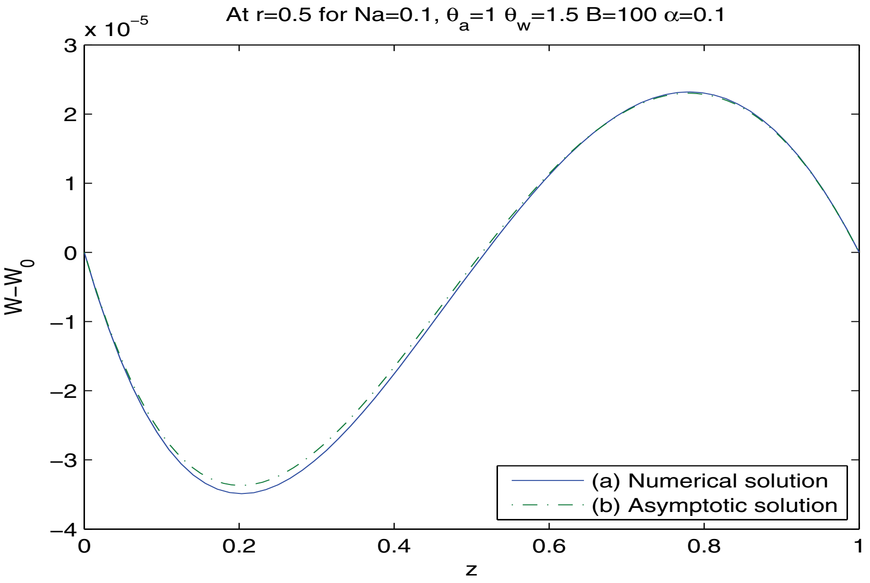

FIG. 8. *Solutions obtained by* (73)–(74), (29)–(30), *and* (11)–(12).

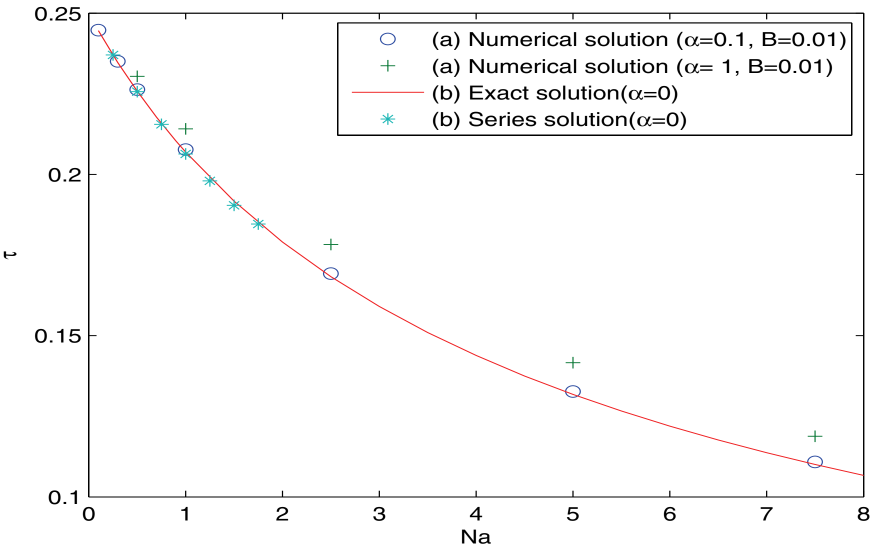

FIG. 9. *Plot of the torque $\mathcal{T}$ versus* Na.

The general solution to the above ordinary differential equation is

$$\begin{aligned} F_m(r) = {} & C_1 I_1\left(\frac{m\pi r}{\alpha}\right) + C_2 K_1\left(\frac{m\pi r}{\alpha}\right) + I_1\left(\frac{m\pi r}{\alpha}\right)\left[\int \frac{\varphi(r)K_1(\frac{m\pi r}{\alpha})}{r}\mathrm{d}r\right] \\ & - K_1\left(\frac{m\pi r}{\alpha}\right)\left[\int \frac{\varphi(r)I_1(\frac{m\pi r}{\alpha})}{r}\mathrm{d}r\right], \end{aligned} \tag{92}$$

where K_0 and K_1 are modified Bessel functions of the second kind.

The evaluation of the integrals is shown next:

$$\begin{aligned} \int \frac{\varphi(r)K_1(\frac{m\pi r}{\alpha})}{r}\mathrm{d}r = {} & 2\sum_{n=1}^{\infty} \frac{m\pi\bar{\Gamma}_n\,(1-\cos(m\pi)\cos(\lambda_n))}{\lambda_n(m^2\pi^2-\lambda_n^2)}\left[\frac{-4m\pi r\alpha^3}{\lambda_n(m^2\pi^2-\lambda_n^2)^2}\right. \\ & \times\frac{\lambda_n I_1(\frac{\lambda_n r}{\alpha})K_0(\frac{m\pi r}{\alpha}) + m\pi I_0(\frac{\lambda_n r}{\alpha})K_1(\frac{m\pi r}{\alpha})}{I_1(\frac{\lambda_n}{\alpha})} - \frac{2r^2\alpha^2}{\lambda_n(m^2\pi^2-\lambda_n^2)} \\ & \times\frac{\lambda_n I_1(\frac{\lambda_n r}{\alpha})K_1(\frac{m\pi r}{\alpha}) + m\pi I_0(\frac{\lambda_n r}{\alpha})K_0(\frac{m\pi r}{\alpha})}{I_1(\frac{\lambda_n}{\alpha})} + \frac{\alpha r^4}{m\pi}K_2\left(\frac{m\pi r}{\alpha}\right) \\ & \left. + \frac{2\alpha^2 r^3}{m^2\pi^2}K_3\left(\frac{m\pi r}{\alpha}\right) + \frac{4\alpha^3 r^2}{m\pi\lambda_n^2}K_2\left(\frac{m\pi r}{\alpha}\right)\right], \end{aligned} \tag{93}$$

$$\begin{aligned} \int \frac{\varphi(r)I_1(\frac{m\pi r}{\alpha})}{r}\mathrm{d}r = {} & 2\sum_{n=1}^{\infty} \frac{m\pi\bar{\Gamma}_n(1-\cos(m\pi)\cos(\lambda_n))}{\lambda_n(m^2\pi^2-\lambda_n^2)}\left[\frac{4m\pi r\alpha^3}{\lambda_n(m^2\pi^2-\lambda_n^2)^2}\right. \\ & \times\frac{\lambda_n I_0(\frac{m\pi r}{\alpha})I_1(\frac{\lambda_n r}{\alpha}) - m\pi I_0(\frac{\lambda_n r}{\alpha})I_1(\frac{m\pi r}{\alpha})}{I_1(\frac{\lambda_n}{\alpha})} - \frac{2r^2\alpha^2}{\lambda_n(m^2\pi^2-\lambda_n^2)} \end{aligned} \tag{94}$$

$$\times\frac{\lambda_n I_1(\frac{m\pi r}{\alpha} I_1(\frac{\lambda_n r}{\alpha}) - m\pi I_0(\frac{\lambda_n r}{\alpha}) I_0)\frac{m\pi r}{\alpha})}{I_1(\frac{\lambda_n}{\alpha})} - \frac{\alpha r^4}{m\pi} I_2\left(\frac{m\pi r}{\alpha}\right)$$
$$+ \frac{2\alpha^2 r^3}{m^2\pi^2} I_3\left(\frac{m\pi r}{\alpha}\right) - \frac{4\alpha^3 r^2}{m\pi\lambda_n^2} I_2\left(\frac{m\pi r}{\alpha}\right)\Bigg].$$

The boundary conditions $F_m = 0$ at $r = 0$ and $F_m' - \frac{F_m}{r} = 0$ at $r = 1$ are used to determine the constants in the above equation. The boundary condition on the axis causes the constant of integration C_2 to be zero. The other boundary condition is used to determine the constant of integration C_1. However, because of the complexity of the nature of the solution as judged from the above equations, the constant C_1 is shown to be determined in principle. However, the actual formulation is employed to generate plots via CAS (computer algebra system):

$$\begin{aligned} C_1 = &- \left[\int \frac{\varphi(r) K_1(\frac{m\pi r}{\alpha})}{r} \mathrm{d}r\right]_{r=1} \\ &- \frac{K_0(\frac{m\pi}{\alpha}) + K_2(\frac{m\pi}{\alpha}) - \frac{2\alpha}{m\pi} K_1(\frac{m\pi}{\alpha})}{I_0(\frac{m\pi}{\alpha}) + I_2(\frac{m\pi}{\alpha}) - \frac{2\alpha}{m\pi} I_1(\frac{m\pi}{\alpha})} \left[\int \frac{\varphi(r) I_1(\frac{m\pi r}{\alpha})}{r} \mathrm{d}r\right]_{r=1}. \end{aligned} \tag{95}$$

STABILITY OF SOLITARY WAVES IN A SEMICONDUCTOR DRIFT-DIFFUSION MODEL*

C. M. CUESTA† AND C. SCHMEISER‡

Abstract. We consider a macroscopic (drift-diffusion) model describing a simple microwave generator, consisting of a special type of semiconductor material that, when biased above a certain threshold voltage, generates charge waves. These waves correspond to travelling wave solutions of the model equation which, however, turn out to be unstable in a standard formulation of the travelling wave problem. Here a different formulation of this problem is considered, where an external voltage condition is applied in the form of an integral constraint. Global existence of this novel Cauchy problem is proven and the results of numerical experiments are presented, which suggest the stability of solitary waves. In addition, a small amplitude limit is considered, for which linearized orbital stability of solitary waves can be proven.

Key words. Gunn effect, drift-diffusion equation, solitary waves, global constraint

1. Introduction.

In this paper we consider the nondimensionalized one-dimensional semiconductor drift-diffusion model

$$\partial_t n = \partial_x(\partial_x n - v(E)\, n)\,, \tag{1.1}$$

$$\partial_x E = n - 1 \tag{1.2}$$

for $(x,t) \in \mathbb{R} \times (0,\infty)$, where $n(x,t)$ denotes the electron density and $E(x,t)$ the (negative) electric field. In the drift-diffusion equation (1.1), $v(E)$ is the field dependent drift velocity, and in the Poisson equation (1.2), the constant 1 represents the scaled constant doping concentration. The special feature of the model is the nonmonotonicity of $v(E)$, made precise below.

The system will be considered subject to the initial condition

$$n(0,x) = n_I(x) \quad \text{for all } x \in \mathbb{R}\,, \tag{1.3}$$

where initially and, thus, for all times, we assume global charge neutrality:

$$\int_{\mathbb{R}} (n_I - 1)dx = 0\,.$$

This has the consequence that the field takes the same value

$$E_\infty(t) := \lim_{|x|\to\infty} E(t,x)$$

at $x = \pm\infty$. Instead of prescribing $E_\infty(t)$, we leave it as an unknown and pose the integral constraint

$$\int_{\mathbb{R}} (E(t,x) - E_\infty(t))\, dx = U(t)\,, \tag{1.4}$$

where the function $U(t)$ is given for $t \geq 0$.

This problem arises from a one-dimensional model of a simple microwave generator. When biased above a certain voltage threshold, the generator produces current oscillations based on dipole charge waves travelling through the semiconductor material. This is known as the Gunn effect; see [4] and [5].

The system (1.1), (1.2) subject to (1.3), (1.4) will be motivated below by scaling arguments. We start with the unscaled equations describing the flow of electrons in a piece of homogeneous n-type semiconductor material of length L (cf. [9]),

$$\partial_t n = \partial_x (D\partial_x n - v(E)\, n)\,, \quad \text{with } t > 0,\ x \in (-L, L)\,, \tag{1.5}$$

$$\varepsilon_s \partial_x E = q(n - C), \quad \text{with } x \in (-L, L)\,. \tag{1.6}$$

This is the standard unipolar drift-diffusion model where the transport of holes is neglected. The constant parameters are the diffusivity D, the permittivity ε_s of the semiconductor material, the elementary charge q, and the donor concentration $C > 0$. Since this fixed background charge density is positive, the negatively charged electrons will dominate among the mobile charges, satisfying the omission of the positively charged holes from the model. The function v stands for the drift velocity of electrons and depends on the field, thus leading to a nonlinear coupling of the system, which is supplemented by an initial condition $n(0,x) = n_I(x)$ and by Dirichlet boundary conditions for the electron concentration:

$$n(t,-L) = n(t,L) = C \quad \text{for } t > 0\,. \tag{1.7}$$

In addition, the application of an exterior (given) voltage $\bar{U}$ is described by the integral condition

$$\int_{-L}^{L} E(t,x)\, dx = \bar{U}(t)\,. \tag{1.8}$$

For standard semiconductor materials such as silicon, measurements of the drift velocity $v(E)$ yield an odd nonlinear increasing function of the field E, almost linear for small fields, and bounded from above by a velocity saturation value v_{sat}. However, there are semiconductor materials such as *gallium arsenide* (GaAs), for which the velocity v reaches a maximum at a certain threshold value of the field E_T (cf. [13]), with the profile of v decreasing for $E > E_T$ to v_{sat}; see Figure 1. This nonmonotonicity of the velocity is responsible for the existence of pulse like solutions, namely solitary (travelling) waves, which are necessary for the Gunn effect. We are interested in studying the stability of these waves.

Using L as characteristic length, L/v_{sat} as characteristic time, v_{sat} as characteristic velocity, C as characteristic electron density, and E_T as characteristic field strength, one obtains the dimensionless equations

$$\partial_t n = \partial_x (\nu \partial_x n - n v(E))\,, \tag{1.9}$$

$$\lambda^2 \partial_x E = n - 1\,, \tag{1.10}$$

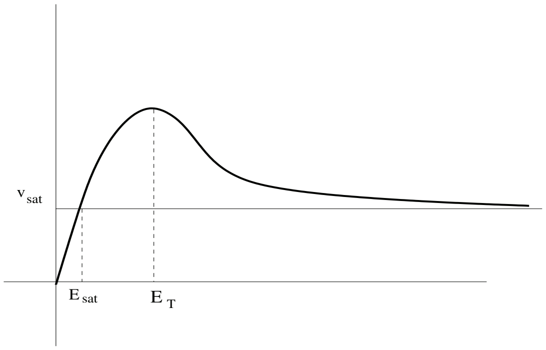

FIG. 1. *Electron drift velocity.*

subject to the conditions

$$n(t,-1) = n(t,1) = 1\,, \tag{1.11}$$

$$\int_{-1}^{1} E(t,x)\,dx = \bar{U}(t)\,, \tag{1.12}$$

where the drift velocity v is now normalized in the sense that it takes its maximum at $E = 1$ and satisfies $\lim_{E\to\infty} v(E) = 1$. The dimensionless parameters

$$\lambda^2 = \frac{\varepsilon_s E_T}{L^2 qC}\,, \quad \nu = \frac{D}{Lv_{sat}}$$

are, respectively, the square of the scaled Debye length and the relative strength of diffusive and convective terms. We are interested in the case of a high doping concentration and a long device; therefore the parameters λ^2 and ν are both small. We shall make the scaling assumption that they are of the same order of magnitude and, for simplicity, actually set $\nu = \lambda^2$.

We recall that for a given constant voltage, the homogeneous steady state solution

$$n \equiv 1, \quad E \equiv \frac{1}{2}\bar{U}$$

of (1.9), (1.10) is stable if $\bar{U} \leq 2$ ($E \leq 1$) and unstable if $\bar{U} > 2$ ($E > 1$); cf. [14], [1]. Stable solitary waves are expected to arise in the latter case. The appropriate space-time scaling for these waves is achieved by $(t,x) \to (t/\lambda^2, x/\lambda^2)$, which expands both the temporal and the spatial domains. It leads to (1.1)–(1.2), and the integral condition (1.12) becomes

$$\lambda^2 \int_{-\frac{1}{\lambda^2}}^{\frac{1}{\lambda^2}} E(t,x)\,dx = \bar{U}(t)\,. \tag{1.13}$$

In the "Gunn operation mode" we expect waves travelling through the device, whose typical length is of order one in terms of the new x-variable. Away from the wave, i.e., in most of the device, we expect an almost constant electric field, and we denote an approximation by $E_{1/\lambda^2}(t)$. The condition (1.13) can then be rewritten as

$$\lambda^2 \int_{-\frac{1}{\lambda^2}}^{\frac{1}{\lambda^2}} (E(t,x) - E_{1/\lambda^2}(t))\,dx = \bar{U}(t) - 2E_{1/\lambda^2}(t)\,. \tag{1.14}$$

Passing to the limit $\lambda^2 \to 0$ formally gives $E_\infty(t) = \bar{U}(t)/2$ with $E(t,x) \to E_\infty(t)$ as $|x| \to \infty$. In [15] Szmolyan considered the problem (1.1), (1.2) subject to this boundary condition and an initial condition for n. It is striking that, with standard linearization techniques, he proved that solitary waves are unstable in this case.

These results are rather unexpected if compared with the experimental evidence on Gunn diodes. The aim of this work is to study a reformulation of the problem, which seems to stabilize the solitary waves. Formally, the reformulation can be derived by introducing

$$U(t) := \lim_{\lambda \to 0} \frac{1}{\lambda^2} \left(\bar{U}(t) - 2E_{1/\lambda^2}(t) \right)$$

and passing to the limit in (1.14) after dividing by λ^2. Obviously, this leads to the integral condition (1.4).

In the language of asymptotic analysis, the assumption that the small parameters ν and λ^2 are of the same order of magnitude leads to a significant limit, since the small parameters can then be eliminated from the differential equations by the above rescaling. However, since the ratio λ^2/ν depends on both the device length and the doping concentration, situations where this ratio is either very small or very large can also be physically relevant. An asymptotic analysis of travelling waves in the former case can be found in [9]. It turns out that in this case all travelling wave solutions have a far-field value of the electric field close to E_{sat} (see Figure 1). This result can be seen as a (not very strong) physical justification of prescribing $U(t)$, since this is then close to prescribing the contact voltage $\bar{U}(t)$.

For convenience we introduce the unknown

$$e(t,x) := E(t,x) - E_\infty(t) = \int_{-\infty}^{x} (n(t,y) - 1)\, dy \quad \text{with } t > 0,\ x \in \mathbb{R}\,.$$

Substituting $n = \partial_x e + 1$ into (1.1) and integrating with respect to x gives the equation

$$\partial_t e = \partial_x^2 e - v(e + E_\infty)\, \partial_x e + v(E_\infty) - v(e + E_\infty)\,, \tag{1.15}$$

subject to the initial condition

$$e(0,x) = e_I(x) = \int_{-\infty}^{x} (n_I(y) - 1)\, dy\,, \tag{1.16}$$

with n_I as in (1.3), and to the integral constraint (1.4), which now simply reads

$$\int_{\mathbb{R}} e(t,x)\, dx = U(t)\,. \tag{1.17}$$

Differentiation with respect to time gives

$$U'(t) = \int_{\mathbb{R}} (v(E_\infty(t)) - v(E_\infty(t) + e(t,x)))dx\,. \tag{1.18}$$

We shall solve (1.15) subject to (1.18) instead of (1.17). This will be favorable since (1.18) can be seen as an equation for E_∞ for given $U'(t)$ and e.

The formulation of the problem will be completed by specifying the precise assumptions on the drift velocity.

Assumption 1. We assume $v \in C_B^3([0,\infty))$, $v(0) = 0$, $\operatorname{sign} v'(E) = \operatorname{sign}(1 - E)$, $\lim_{E\to\infty} v(E) = 1$, $\exists\, E_i > 1$ such that $\operatorname{sign} v''(E) = \operatorname{sign}(E - E_i)$. Finally, $v''' \geq 0$ on $(1, E_i)$.

The equation $v(E_{sat}) = 1$ uniquely defines $E_{sat} < 1$. We also introduce $\sigma_i = \sup_{E>0} |d^i v/dE^i(E)|$, $i = 1, 2, 3$.

The paper is organized as follows. In section 2 we review the existence of solitary waves but incorporate the condition (1.4) into the problem. It turns out that for all $U > 0$ there exists a unique (up to translation) solitary wave having $E_\infty < 1$. In section 3 we prove existence of solutions of (1.15)–(1.18) for positive $U(t)$. Actually there is also a restriction on the values of $U'(t)$, which is required to be in the range of the right-hand side of (1.18). The existence proof uses a fixed point argument involving the operator defined by solving the condition (1.18) (for given e). This operator is only locally Lipschitz in $L_x^1(\mathbb{R})$. This difficulty does not ensue in bounded domains; see [8]. There is still no general result on the stability of solitary waves. In section 4, however, we provide strong numerical evidence that we succeeded in stabilizing the travelling waves by the new formulation. Moreover, in section 5 we consider a *small* wave limit by imposing a small external voltage. We prove linear asymptotic stability of the limiting solitary waves. It turns out that the limit equation is the so-called conserved Fisher equation with a constant competition rate, a model of population dynamics with global regulation [11]. In particular, our proof shows linearized asymptotic stability of its stationary solutions.

2. Solitary waves. In this section we prove existence of solitary waves subject to the constraint (1.4). Let $\xi =: x - ct$ be the travelling wave variable, where $c > 0$ is the wave speed. Then a solitary wave solution $(E(\xi), n(\xi))$ of (1.1)–(1.2) is a solution of

$$\begin{aligned} n' &= n(v(E) - c) - v(E_\infty) + c\,, \\ E' &= n - 1 \end{aligned}$$

that satisfies

$$n \to 1 \quad \text{and} \quad E \to E_\infty \qquad \text{as } |\xi| \to \infty\,. \tag{2.1}$$

A straightforward computation using both differential equations leads to

$$\frac{n-1}{n} n' - (v(E) - v(E_\infty))E' = \frac{(n-1)^2}{n}(v(E_\infty) - c)\,.$$

Since the right-hand side does not change sign, integration with respect to ξ and the far-field conditions imply that a solution exists only if $c = v(E_\infty)$ holds, which we assume in the following:

$$n' = n(v(E) - v(E_\infty)), \tag{2.2}$$

$$E' = n - 1. \tag{2.3}$$

We incorporate the condition (1.4), which in the travelling wave variable reads

$$\int_{\mathbb{R}} (E(\xi) - E_\infty)\, d\xi = U, \tag{2.4}$$

where U is a given constant, and E_∞ will be determined as part of the solution of (2.1)–(2.4). The main result of this section is the following theorem.

THEOREM 2.1. *For each $U > 0$ there exists a solution (n, E, E_∞) of* (2.1)–(2.4) *which is unique up to translation in ξ and satisfies $E_{sat} < E_\infty < 1$. The far-field value E_∞ of the field is a strictly decreasing function of U, satisfying*

$$\lim_{U\to 0} E_\infty(U) = 1 \quad \textit{and} \quad \lim_{U\to\infty} E_\infty(U) = E_{sat}\,. \tag{2.5}$$

Before we prove the theorem we recall the existence result of (2.1)–(2.3) for a given value of E_∞.

LEMMA 2.2. *For every $E_\infty \in (E_{sat}, 1)$, there exists a unique (up to translation in ξ) solution (n, E) of* (2.1)–(2.3) *that satisfies $E > E_\infty$. The total charge density $n - 1$ has one simple zero, to the left of which it is positive (and negative to the right).*

This lemma is just a reformulation of the existence result that appears in [15]. The proof uses the fact that (2.2), (2.3) is a conservative system and uses the first integral relation

$$n - \log n - 1 = \int_{E_\infty}^{E} (v(y) - v(E_\infty))\, dy\,. \tag{2.6}$$

Proof of Theorem 2.1. By Lemma 2.2 it is sufficient to prove that the relation between E_∞ and U is one-to-one. With the solution (n, E) of (2.1)–(2.3) for given $E_\infty \in (E_{sat}, 1)$, we define

$$\mathcal{U}(E_\infty) := \int_{\mathbb{R}} (E(\xi) - E_\infty) d\xi\,.$$

The derivative can be written as $\mathcal{U}' := \int_{\mathbb{R}}(\hat{E}(\xi) - 1)d\xi$, where we define $\hat{E} = dE/dE_\infty$ and $\hat{n} = dn/dE_\infty$. The latter satisfy the equations

$$\hat{E}' = \hat{n}\,, \qquad \frac{n-1}{n}\hat{n} = (v(E) - v(E_\infty))\hat{E} - v'(E_\infty)(E - E_\infty)\,,$$

by differentiating (2.3) and (2.6) with respect to E_∞. Let us, without loss of generality, fix the point where $n - 1$ changes sign at $\xi = 0$, i.e., $n(0) = 1$. The second equation above implies that

$$\hat{E}(0) = v'(E_\infty)\frac{E(0) - E_\infty}{v(E(0)) - v(E_\infty)}\,.$$

The properties of v, $E_\infty < 1$, and $E > E_\infty$ imply that $\hat{E}(0) < 1$. Away from $\xi = 0$, $\hat{E}$ solves

$$\begin{aligned}\hat{E}' = {} & \frac{n}{n-1}[v(E) - v(E_\infty)](\hat{E} - 1) \\ & + \frac{n}{n-1}[v(E) - v(E_\infty) - v'(E_\infty)(E - E_\infty)]\,.\end{aligned}$$

The term in the second line is negative for large negative ξ and positive for large positive ξ. This implies $\hat{E} < 1$ for large $|\xi|$. Extrema of $\hat{E}$ away from $\xi = 0$ satisfy $\hat{E} = v'(E_\infty)\frac{E-E_\infty}{v(E)-v(E_\infty)} < 1$ analogously to the above. This shows that $\hat{E}(\xi) < 1$ for all ξ and, thus, $\mathcal{U}'(E_\infty) < 0$.

The assertion (2.5) then also follows since the amplitude of the wave tends to zero for $E_\infty \to 1$ and to infinity for $E_\infty \to E_{sat}$. ▯

3. Existence. In this section existence of solutions of (1.15), (1.16), (1.18) will be proven for given bounded $U(t) \in C_B^1(\mathbb{R}_+)$ and for initial data e_I satisfying

$$e_I \in L_x^1(\mathbb{R}) \cap L_x^\infty(\mathbb{R}), \quad e_I(x) > 0 \text{ a.e. in } x\,. \tag{3.1}$$

Clearly $U(t)$ is fixed by $U(0) = \int_{\mathbb{R}} e_I(x)\,dx > 0$ and by $U'(t)$ appearing in (1.18).

Assumption 2. There are positive constants δ and K, such that

$$0 < \delta \le U(t) \le K \quad \text{and} \quad \|e_I\|_\infty \le K\,,$$

where $\|\cdot\|_p$ denotes the norm in $L_x^p(\mathbb{R})$.

The derivative $U'(t)$ will have to be small enough as specified below. We start by the derivation of an a priori estimate.

PROPOSITION 3.1. *For solutions of* (1.15), (1.16), (1.18), $\|e(t,\cdot)\|_\infty \le C(\sigma_1)K$ *with* $C(\sigma_1) = \sqrt{2}\,\max\{2, c\sqrt{\sigma_1}\}$ *holds for all* $t \ge 0$.

Proof. The proof follows the idea of a similar result in [7]. Multiplying (1.15) by e^{p-1} for $p \ge 2$ and integration gives the estimate

$$\frac{d}{dt}\int_{\mathbb{R}} e^p\,dx \le -4\frac{(p-1)}{p}\int_{\mathbb{R}}(\partial_x e^{p/2})^2\,dx + p\sigma_1\int_{\mathbb{R}} e^p\,dx\,. \tag{3.2}$$

We observe that, by interpolation,

$$\|e_I\|_p \le \|e_I\|_\infty^{(p-1)/p}\,\|e_I\|_1^{1/p} \le K\,.$$

Our aim is to derive a uniform-in-p and uniform-in-time estimate on $\|e(t,\cdot)\|_p$ for a sequence of p such that $p \to \infty$. We use the Nash inequality [10]

$$\|u\|_2^3 \le c\|u\|_1^2\|\partial_x u\|_2$$

in one space dimension with $u = e^{p/2}$; thus, with the notation $z_p(t) = \|e(t,\cdot)\|_p^p$,

$$\frac{dz_p}{dt} \le p\sigma_1 z_p\left(1 - \frac{\tilde{c}(p-1)}{p^2}\frac{z_p^2}{z_{p/2}^4}\right)\,, \tag{3.3}$$

where $\tilde{c} = 4/(c^2\sigma_1)$. Starting with $z_1(t) = U(t) \le K$, the above inequality can be used recursively for obtaining bounds M_k for $z_{2^k}(t)$. Suppose $z_{2^{k-1}}(t) \le M_{k-1}$; then

$$z_{2^k}(t) \le M_k = \max\left\{K^{2^k}, \frac{2^k}{\sqrt{\tilde{c}(2^k-1)}}M_{k-1}^2\right\}\,.$$

Let us now examine the sequence M_k, defined by the recursion and by $M_0 = K$. Since, obviously, $M_{k-1} \ge K^{2^{k-1}}$ and $2^k/\sqrt{2^k-1} \ge 1$,

$$K^{2^k} \le \frac{2^k}{\sqrt{2^k-1}}M_{k-1}^2$$

holds. Thus, we make the upper bound M_k larger by the new definition

$$M_k = B2^{(k+1)/2}M_{k-1}^2\,, \quad M_0 = K\,, \quad B := \max\{1, \tilde{c}^{-1/2}\}\,,$$

where we have used $2^k/\sqrt{2^k-1} \le 2^{(k+1)/2}$. This recursion can be solved explicitly:

$$M_k = (\sqrt{2}\,B)^{a_k}2^{b_k/2}K^{2^k}\,,$$

where $a_k = \sum_{n=0}^{k-1} 2^n = 2^k - 1 < 2^k$ and $b_k = \sum_{n=0}^{k-1}(k-n)2^n = 2^{k+1} - 2 - k < 2^{k+1}$. Thus, since $B \geq 1$,

$$M_k \leq (2\sqrt{2}\, BK)^{2^k} \,,$$

and hence

$$\|e(t,\cdot)\|_{2^k} \leq \sqrt{2}\, K \, \max\{2, c\sqrt{\sigma_1}\} \quad \text{for all } k\,.$$

The proof is completed by passing to the limit $k \to \infty$. $\square$

Now we prepare a decoupled solution approach and examine (1.18) as an equation for $E_\infty(t)$.

Proposition 3.2. *Let the function $e \in L_x^1(\mathbb{R}) \cap L_x^\infty(\mathbb{R})$ satisfy $\|e\|_1 \geq \gamma > 0$ and $\|e\|_\infty \leq M$. Then the function $F(E;e) := \int_{\mathbb{R}}(v(E) - v(E+e(x)))dx$ is strictly increasing on $(0,\bar{E})$ with*

$$\bar{E}(\gamma, M) = 1 - \frac{v'(1+M)\gamma}{2M^2\sigma_3} > 1\,.$$

Furthermore,

$$F(0;e) \leq -v(M)\frac{\gamma}{M}\,, \quad F(\bar{E};e) \geq \frac{3v'(1+M)^2\gamma^2}{8M^3\sigma_3}\,,$$
$$F'(E;e) \geq -\frac{v'(1+M)\gamma}{2M} \quad \text{for } 0 \leq E \leq \bar{E}\,.$$

Proof. By the convexity of v' on $(0,E_i)$ and by the fact that v' is increasing and negative on (E_i,∞), the secant between E and $E+M$ lies above the graph of v' for $E \leq 1$. Therefore

$$F'(E) \geq \int_{\mathbb{R}} \left(v'(E) - v'(E)\left(1 - \frac{e}{M}\right) - v'(E+M)\frac{e}{M}\right)dx$$
$$= \int_{\mathbb{R}} (v'(E) - v'(E+M))\frac{e}{M}dx \geq (v'(E) - v'(E+M))\frac{\gamma}{M}$$

for $0 \leq E \leq 1$. Again by the same properties of v', the right-hand side takes its minimum value for $E = 1$, so $F'(E) \geq -v'(1+M)\gamma/M$ for $0 \leq E \leq 1$.

Since

$$|F''(E)| \leq \int_{\mathbb{R}} |v''(E) - v''(E+e)|dx \leq \sigma_3 M\,,$$

the derivative of F for $E > 1$ can be estimated by

$$F'(E) \geq -v'(1+M)\frac{\gamma}{M} - (E-1)\sigma_3 M\,,$$

proving that F is increasing on $(0,\bar{E})$ and the lower bound on F' in the statement of the proposition. The lower bound for $F(\bar{E})$ is obtained by integrating the above inequality from $E = 1$ to $E = \bar{E}$ and using that $F(1) > 0$, which holds, obviously, since v has its maximum at $E = 1$.

For estimating $F(0) = -\int_{\mathbb{R}} v(e)dx$, we use the L^∞-bound on e and the fact that secants between the origin and other points on the graph of v lie below the graph by the properties of v:

$$F(0) \leq -\int_{\mathbb{R}} v(M)\frac{e}{M}dx \leq -v(M)\frac{\gamma}{M}\,,$$

where the second inequality is due to the lower bound on the L^1-norm of e. $\square$

On the other hand, we consider the problem for e with given E_∞. In this case, the integral of e will not necessarily be equal to $U(t)$, which was the basis of the proof of Proposition 3.1. As a consequence, the estimates below are not uniform in time.

PROPOSITION 3.3. *Let $E_\infty(t)$ be given. Then the problem* (1.15), (1.16) *for e has a unique positive solution satisfying*

$$\int_{\mathbb{R}} e(t,x)dx \geq U(0)e^{-t\sigma_1} \quad \text{and} \quad e(t,x) \leq K e^{t\sigma_1}\,, \quad x \in \mathbb{R},\ t > 0\,.$$

Proof. Existence and uniqueness are standard results for semilinear parabolic equations. Positivity is a consequence of the maximum principle. The first estimate follows easily from integration of (1.15). The upper bound in the second estimate is a supersolution. □

We are now ready to formulate the main existence result.

THEOREM 3.4. *Let $M = C(\sigma_1)K$ denote the bound from Proposition* 3.1 *and let*

$$-v(M)\frac{\delta}{M} < U'(t) < \frac{3v'(1+M)^2\delta^2}{8M^3\sigma_3}\,, \quad t \geq 0\,.$$

Then the problem (1.15)–(1.18) *has a unique global solution satisfying $0 < E_\infty(t) < \bar{E}(\delta, M)$ and $0 < e(t,x) \leq M$.*

Remark 3.5. It seems unsatisfactory that the bounds on $U(t)$ (in Assumption 2) and on its derivative (in the formulation of the theorem) are required. However, examples of nonexistence of a solution for data violating such bounds are easily constructed. The range of the function $F(E_\infty, e(t,\cdot))$ (the right-hand side of (1.18)) as a function of E_∞ is a subset of $(-\sigma_1 U(t), \sigma_1 U(t))$. Therefore it is a necessary condition for the existence of a solution that $U'(t)$ lies in this interval for all t. The more restrictive bounds of the theorem guarantee stable (unique) solvability. For an example of nonexistence see the following section.

Proof. The first step is the construction of a local solution by a fixed point iteration on E_∞ acting on the set $\mathcal{E} := \{E(t) \in L_t^\infty((0,T)) :\ 0 \leq E(t) \leq \bar{E}\}$ with $T > 0$. For a given $E \in \mathcal{E}$, we first solve the problem (1.15), (1.16) with E_∞ replaced by E. By Proposition 3.3, this problem has a unique solution $e[E]$ satisfying

$$Ke^{t\sigma_1} \geq \int_{\mathbb{R}} e[E](t,x)dx \geq U(0)e^{-t\sigma_1} \geq \delta e^{-T\sigma_1} =: \gamma_T$$

and

$$e[E](t,x) \leq Ke^{t\sigma_1} \leq Me^{T\sigma_1} =: M_T$$

for $0 \leq t \leq T$. With Proposition 3.2, the range of $F(\cdot\,; e[E])$ includes the interval $(-v(M_T)\frac{\gamma_T}{M_T}, \frac{3v'(1+M_T)^2\gamma_T^2}{8M_T^3\sigma_3})$. For T small enough, this in turn includes the range of $U'(t)$ as given in the formulation of the theorem. Therefore the equation $F(\hat{E}; e[E]) = U'$ has a unique solution $\hat{E} = \mathcal{F}(E) \in [0, \bar{E}]$ which completes the definition of the fixed point operator $\mathcal{F} :\ \mathcal{E} \to \mathcal{E}$.

We shall prove that, for T small enough, $\mathcal{F}$ is a contraction and start with the mild formulation of (1.15), (1.16):

$$\begin{aligned} e(t,\cdot) = G(t,\cdot) * e_I &+ \int_0^t \partial_x G(t-s,\cdot) * [V(E(s)+e(s,\cdot)) - V(E(s))]ds \\ &+ \int_0^t G(t-s,\cdot) * [v(E(s)) - v(E(s)+e(s,\cdot))]ds\,, \end{aligned}$$

where $G(t,x) = (4\pi t)^{-1/2}e^{-x^2/(4t)}$ is the fundamental solution of the one-dimensional heat equation, $*$ denotes convolution with respect to x, and V is a primitive of v. For estimating the difference between $e_1 = e[E_1]$ and $e_2 = e[E_2]$, we start with

$$\begin{aligned}
&|v(E_1) - v(E_1+e_1) - v(E_2) + v(E_2+e_2)| \\
&\le \left|\int_{E_2}^{E_1} (v'(E) - v'(E+e_1))dE\right| + |v(E_2+e_2) - v(E_2+e_1)| \\
&\le e_1\,\sigma_2|E_1 - E_2| + \sigma_1|e_1 - e_2|\,,
\end{aligned}$$

and, analogously,

$$\begin{aligned}
&|V(E_1) - V(E_1+e_1) - V(E_2) - V(E_2+e_2)| \\
&\le e_1\sigma_1|E_1 - E_2| + \sigma_0|e_1 - e_2|\,.
\end{aligned}$$

We shall also use the properties

$$\int_{\mathbb{R}} G(t,x)\,dx = 1\,, \qquad \int |\partial_x G(t,x)|\,dx = \frac{1}{\sqrt{t\pi}} \quad \text{for all } t > 0$$

of the fundamental solution as well as the convolution inequality $\|f*g\|_1 \le \|f\|_1\|g\|_1$. A combination of these ingredients leads to an estimate of the form

$$\begin{aligned}
&\sup_{0<t<T} \|e_1(t,\cdot) - e_2(t,\cdot)\|_1 \\
&\le c\sqrt{T}\left(\sup_{0<t<T} \|e_1(t,\cdot) - e_2(t,\cdot)\|_1 + \sup_{0<t<T} |E_1(t) - E_2(t)|\right)
\end{aligned}$$

for $T \le 1$. It is an obvious consequence that the map $E \mapsto e[E]$ from $\mathcal{E}$ to $L_t^\infty((0,T), L_x^1(\mathbb{R}))$ is Lipschitz continuous with an arbitrarily small Lipschitz constant for small enough T.

Denoting $\hat{E}_1 = \mathcal{F}(E_1)$ and $\hat{E}_2 = \mathcal{F}(E_2)$, then $F(\hat{E}_i; e_i) = U'(t)$ holds for $i = 1, 2$. The difference of the two equations can be written as

$$F'(\tilde{E}; e_1)(\hat{E}_1 - \hat{E}_2) + \int_{\mathbb{R}} [v(\hat{E}_2 + e_2) - v(\hat{E}_2 + e_1)]dx = 0\,,$$

with $\tilde{E}$ between $\hat{E}_1$ and $\hat{E}_2$. This implies the estimate

$$\sup_{0<t<T} |\hat{E}_1(t) - \hat{E}_2(t)| \le -\frac{2M\sigma_1}{v'(1+M)\gamma} \sup_{0<t<T} \|e_1(t,\cdot) - e_2(t,\cdot)\|_1\,,$$

proving Lipschitz continuity also for the second step of the fixed point map. This concludes the proof of existence and uniqueness of a local solution.

Since solutions satisfy the uniform-in-time bounds $0 < e \le M$ and $\int_{\mathbb{R}} e\,dx \ge \delta$ and the above construction of local solutions works for initial conditions satisfying these bounds, the solution actually exists for all times, concluding the proof. □

4. Numerical results. In this section we present numerical experiments approximating (1.1)–(1.4) by solving the initial value problem for (1.15) subject to (1.18). In the time iteration we solve alternatively (1.18) and (1.15); for a given bounded positive initial condition e_I with finite mass we find the corresponding initial value of E_∞

by solving (1.18), this value is then used in (1.15) to get e in the next time step, and so on.

We discretize the equations on a domain $(0, L)$ and impose Neumann boundary conditions for (1.15). The scheme treats the second order term implicitly (backward Euler) and the first order term explicitly (forward Euler) in time. Also, the first order term is discretized in space by first order upwinding. For a given $U'(t)$ we approximate the integral (1.18) in the interval $[0, L]$ as a Riemann integral by using the trapezoidal rule. At each time step k a unique solution of the discretized equation

$$\int_0^L \{v(E_\infty^{k+1}) - v(E_\infty^{k+1} + e^k)\}dx - U'(t_k) = 0$$

is achieved by using the MATLAB implemented routine fzero, where the starting guess is E_∞^k.

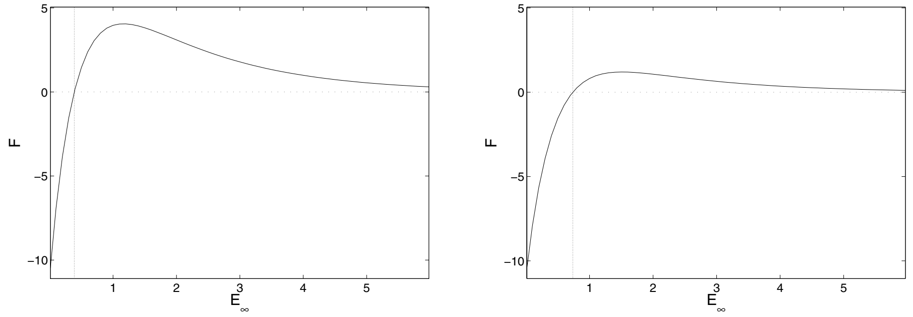
In all examples below we have taken $L = 200$, the spatial step $h = 0.1$, and the time step $\tau = 0.01$. As electron velocity function we use

$$v(E) = c\,e^{-a\,E} - d\,e^{-b\,E} + 1\,, \tag{4.1}$$

with

$$a = \ln(6)/3\,,\ b = 4\ln(6)/3\,,\ c = 2,\ \text{and } d = 3.$$

This v is normalized according to Assumption 1.



(a) $F(E_\infty, e_I)$ for e_I as in (4.2) with $l = 5$. (b) $F(E_\infty, e_I)$ for e_I as in (4.2) with $l = 1$.

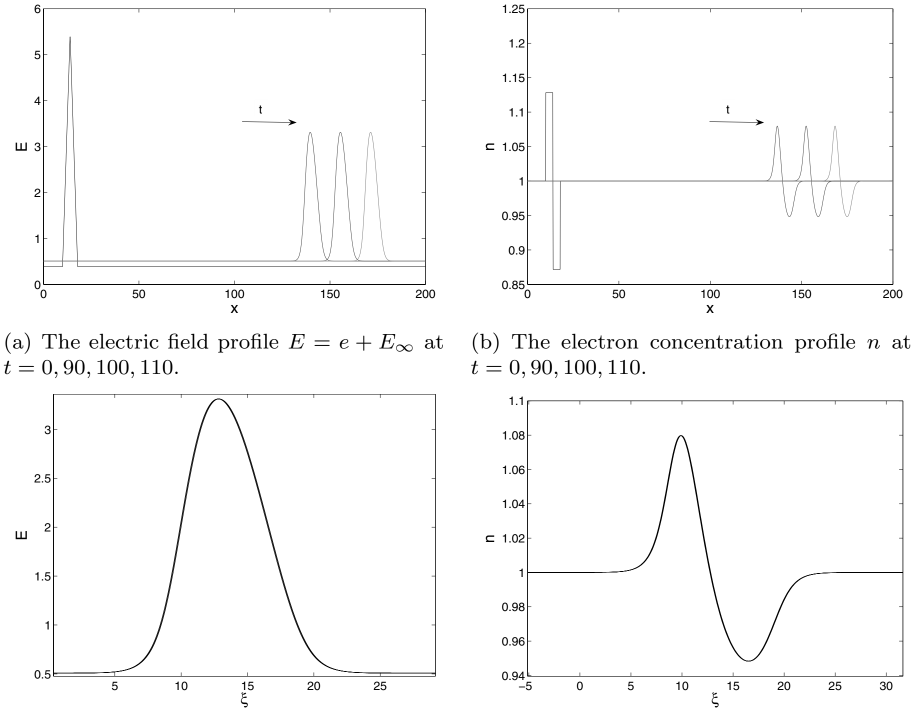
FIG. 2. *The function F computed for the initial data* (4.2).

As initial condition we take the piecewise linear function

$$e_I(x) = \begin{cases} 0 & \text{if } 0 \le x \le 10 \text{ or } x > 18, \\ \frac{l}{4}x - \frac{5}{2}l & \text{if } 10 < x \le 14, \\ -\frac{l}{4}x + \frac{9}{2}l & \text{if } 14 < x \le 18; \end{cases} \tag{4.2}$$

here l is the maximum of e_I giving the initial voltage $U(0) = 4l$. The function $E_\infty \to F(E, e_I)$ for e_I with $l = 1$ and $l = 5$, respectively, is plotted in Figure 2(a). Observe that the values at which F vanishes are, respectively, $E_\infty(0) \approx 0.77$ and $E_\infty(0) \approx 0.37$; i.e., the smaller the integral of e, the closer is E_∞ to 1, as expected for solitary waves (see Theorem 2.1). Since the speed of the solitary waves is given by $c = v(E_\infty)$, we expect the profiles to move to the right faster for smaller values of l. From now on we take $l = 5$ in (4.2); in this case $U(0) = 20$.

We start with examples for constant U. Figures 3(a) and 3(b) show, respectively, electric field and electron concentration profiles at $t = 0$ and $t = 90, 100, 110$. Figures 3(c) and 3(d) show the same solutions against the moving variable $\xi = x - ct$, where the speed $c = v(E_\infty(t))$ is evaluated at $t = 110$. The profiles at times $t = 90, 100, 110$ overlap in this frame, suggesting the stability of solitary waves.



(a) The electric field profile $E = e + E_\infty$ at $t = 0, 90, 100, 110$.

(b) The electron concentration profile n at $t = 0, 90, 100, 110$.

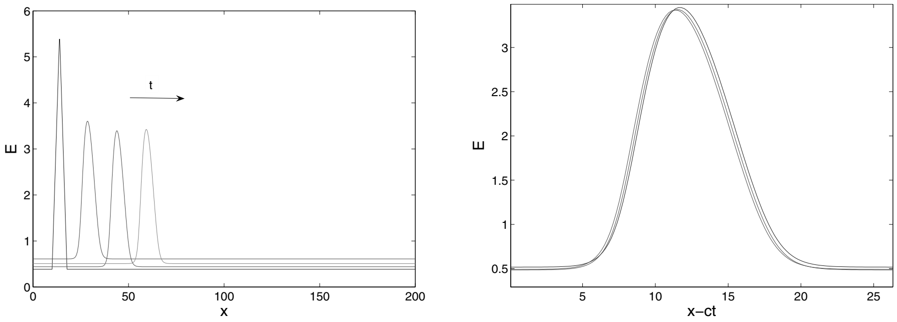
(c) The electric field profile $E = e + E_\infty$ at $t = 90, 100, 110$ against the travelling wave coordinate ξ.

(d) The electron concentration profile n at $t = 90, 100, 110$ against ξ.

FIG. 3. *Numerical solutions for constant U. Figures* 3(a) *and* 3(c) *show electric field values, and for completeness those corresponding to the electron concentration are shown to the right in Figures* 3(b) *and* 3(d)*. The wave speed used above has been computed by using the value of E_∞ at $t = 110$; here $E_\infty(110) \approx 0.5$ and $c \sim v(E_\infty) \approx 1.58$.*

For nonconstant U we first choose $U'(t) = 4\sin(4t)/(1 + t/10)$. Thus initially $U'(0) = 0$, and $U'(t)$ oscillates about this value, while the amplitude of the oscillations decays to 0 as $t \to \infty$. Figure 4(a) shows electric field profiles initially and at times $t = 10, 20, 30$. In Figure 4(b) electric field profiles are shown at times $t = 90, 80, 110$ against the variable $x - ct$. Since $U(t) \to const.$ as $t \to \infty$, we have taken $c = v(E_\infty(t))$ for $t = 110$, as before. The profiles now do not overlap precisely, but are fairly close to each other, again suggesting convergence to a solitary wave as $t \to \infty$ with wave speed $c = \lim_{t\to\infty} v(E_\infty(t))$.

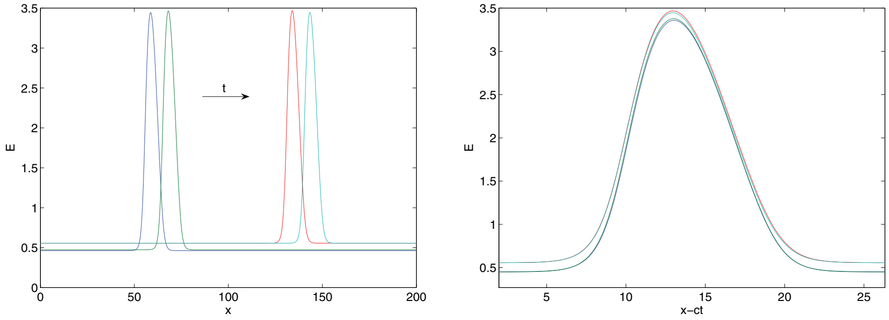
We now consider a t-periodic U, simply choosing $U'(t) = \sin(t)$. Although U does not approach a constant value as $t \to \infty$ and convergence to solitary waves is not expected, the solution profiles move to the right with an apparently constant speed. Figure 5(a) shows the solution profiles at $t = 31, 37$ (left) and at $t = 79, 85$ (right), i.e., profiles at, roughly, the beginning and the end of two time periods. The two



(a) Electric field profile at $t = 0, 10, 20, 30$.

(b) Electric field profile at $t = 90, 100, 110$ against $x - ct$ with $c = v(E_\infty(110)) \approx 1.55$.

FIG. 4. *Numerical solutions with* $U'(t) = 4\sin(4t)/(1 + t/10)$. *Only electric field profiles are shown. Figure* 4(a) *shows profiles at early time steps, where the amplitude of the oscillations of* $U'(t)$ *is appreciated. In Figure* 4(b) *late time steps are shown in the moving frame* ξ.



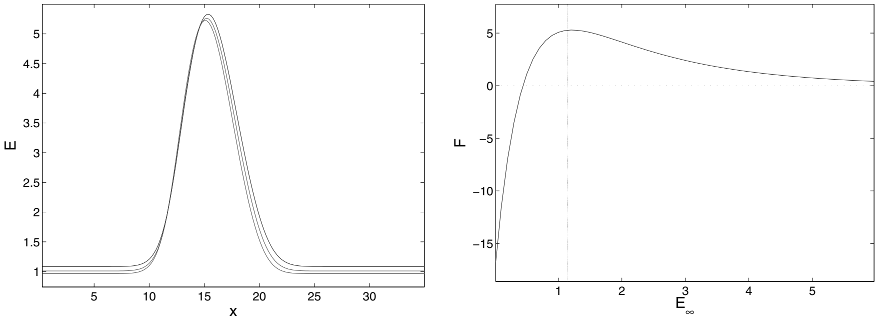
(a) Electric field profile at $t = 31, 37$ (left) and at $t = 79, 85$ (right).

(b) Electric field profile at against $x - ct$ with average speed $c \approx 1.57$.

FIG. 5. *Numerical solutions with* $U'(t) = \sin(t)$. *Only electric field profiles are shown. Figure* 5(a) *shows profiles at times* $t = 31, 37$ *(left) and at* $t = 79, 85$ *(right). Figure* 5(b) *shows the same profiles as Figure* 5(a) *against the coordinate* $x - ct$ *with the average speed* $c = \sum_{t_k=50}^{100} v(E_\infty(t_k))/5000 \approx 1.57$.

profiles to the left are almost a translation of each other, so are the two profiles on the right. This indicates that, as $t \to \infty$, a t-periodic "translating speed" is reached, presumably given by $c = v(E_\infty(t))$. To support this idea, we have computed the "averaged" speed of the solution at late time steps, including at least one period, namely $c = \sum_{t_k=50}^{100} v(E_\infty(t_k))/5000 \approx 1.57$. Figure 5(b) shows well-centered profiles against the moving coordinate with the average speed; these are at times $t = 51, 57$ and at $t = 79, 85$ (on top).

Finally, as an illustration of nonexistence we take $U'(t) = t^2 + 3.8$, so that initially U' is close to the maximum of F; see Figure 2(b). In this case the (numerical) solution ceases to exist at $t = 1.23$; i.e., $U'(1.22)$ exceeds the maximum of F. Electric field profiles for $t < 1.23$ are shown in Figure 6(a). The function F for e at $t = 1.2$ is shown in Figure 6(b). Observe that the maximum of F is approximately attained at $E_\infty = 1.1$ and that the solution (e, E_∞) has $E_\infty(1.2) \approx 1.084$.



(a) Electric field profile at $t = 1, 1.1, 1.2$.

(b) The function F for e at $t = 1.2$.

FIG. 6. *Numerical solutions for $U'(t) = t^2 + 3.8$ and the function F for e evaluated at $e(1.2, x)$. In this case the numerical solution ceases to exist at $t = 1.23$ when the value of $U'(t)$ exceeds the maximum of F.*

5. Small wave limit: Linearized stability. In this section we prove linearized stability of *small* solitary waves. We consider a small given constant voltage:

$$U = \varepsilon \ll 1\,.$$

We derive the limit $\varepsilon \to 0$ formally. From Theorem 2.1, solitary waves have $E_\infty \sim 1$ as $\varepsilon \to 0$, hence also $c \sim v(1)$ as $\varepsilon \to 0$. The amplitude of the waves is also small by (2.6). With this in mind we introduce the moving coordinate $\xi = x - v(1)t$ and the scaling

$$e = \varepsilon^2 e_1\,,\ E_\infty = 1 - \varepsilon^2 E_1\,,\ \tau = \varepsilon^2 t\,,\ \eta = \varepsilon\xi\,.$$

Then, in (1.15), after dividing by ε^4 and formally passing to the limit $\varepsilon \to 0$, we obtain

$$\partial_\tau e_1 = \partial_\eta^2 e_1 + \frac{v''(1)}{2}(2E_1 e_1 - e_1^2) \tag{5.1}$$

and, from (1.17) and (1.18),

$$\int_{\mathbb{R}} e_1\, d\eta = 1\,, \quad 2E_1 = \int_{\mathbb{R}} e_1^2\, d\eta\,. \tag{5.2}$$

As mentioned in the introduction, problem (5.1)–(5.2) is the conserved Fisher equation; see [11]. We now look at stability of stationary solutions to (5.1), since these are the limiting profiles of solitary waves as $\varepsilon \to 0$.

With the abbreviation

$$\kappa := -v''(1) > 0\,,$$

the family of stationary solutions is given explicitly by

$$\bar{e}(\eta) = \frac{\kappa}{48}\,\mathrm{sech}^2\left(\frac{\kappa}{24}(\eta + C)\right)\,, \quad \bar{E} = \frac{\kappa}{144}\,, \tag{5.3}$$

with the shift $C \in \mathbb{R}$.

We observe that rescaling with

$$\eta \to \kappa^{-1}\eta\,,\ e_1 \to \kappa e_1\,,\ E_1 \to \kappa E_1\,,\ \tau \to \kappa^{-2}\tau\,,$$

we can set $\kappa = 1$ in (5.1), with no changes in (5.2).

Denoting perturbations of e_1 and E_1 by u and A, respectively, the linearized problem (with $\kappa = 1$) reads

$$\partial_\tau u = \partial_\eta^2 u + (\bar{e} - \bar{E})u - \bar{e}A[u]\,, \tag{5.4}$$

$$\int_{\mathbb{R}} u\,d\eta = 0\,, \qquad A[u] = \int_{\mathbb{R}} \bar{e}\,u\,d\eta\,, \tag{5.5}$$

with

$$\bar{e}(\eta) = \frac{1}{48}\operatorname{sech}^2\left(\frac{\eta}{24}\right)\,, \quad \bar{E} = \frac{1}{144}\,, \tag{5.6}$$

where, without loss of generality, the shift has been set to zero. Note that there is a one-dimensional family of stationary solutions spanned by $u = \bar{e}'$, $A = 0$. This fact corresponds to the translation invariance of the nonlinear problem.

THEOREM 5.1. *The family of stationary solutions of* (5.4), (5.5) *is asymptotically stable: for an initial condition u_0 satisfying*

$$\int_{\mathbb{R}} u_0\,\bar{e}'\,d\eta = 0\,,$$

the solution of (5.4), (5.5) *subject to $u(\tau = 0) = u_0$ satisfies*

$$\|u(\tau,\cdot)\|_2 \le e^{\mu\tau}\|u_0\|_2 \quad \textit{with} \quad \mu \le -\frac{1}{192} < 0\,.$$

Proof. The linearized operator can be written as the sum of two self-adjoint operators on the space $L_0^2(\mathbb{R}) = \{u \in L^2(\mathbb{R}) :\ \int_{\mathbb{R}} u\,d\eta = 0\}$ equipped with the L^2-inner product $\langle\cdot,\cdot\rangle$:

$$\mathcal{L}u = \mathcal{L}_1 u + \mathcal{L}_2 u\,, \qquad \mathcal{L}_1 u = \partial_\eta^2 u + (\bar{e} - \bar{E})u\,,\ \mathcal{L}_2 u = -\bar{e}A[u]\,.$$

Obviously, $\mathcal{L}_2$ is nonpositive: $\langle \mathcal{L}_2 u, u\rangle = -A[u]^2 \le 0$.

The spectrum of $\mathcal{L}_1$ considered on all of $L^2(\mathbb{R})$ can be computed explicitly; see [6]: we obtain the essential spectrum $(-\infty, -\bar{E}]$ and the isolated eigenvalues

$$\lambda_1 = -\frac{3}{4}\bar{E} = -\frac{1}{192}\,, \quad \lambda_2 = 0\,, \quad \lambda_3 = \frac{5}{4}\bar{E}\,.$$

This can be obtained by using (5.6) and transforming the linear eigenvalue problem for $\mathcal{L}_1$ into a hypergeometric equation; see [3] for details. In the computation of λ_1 we also used (5.6).

The eigenfunction corresponding to λ_3 has $\int_{\mathbb{R}} u\,d\eta \ne 0$, since, according to the Sturm–Liouville theory (see, e.g., [2]), the eigenfunction corresponding to the largest eigenvalue does not change sign. This implies that in the restricted space $L_0^2(\mathbb{R})$ we actually have $\langle \mathcal{L}_1 u, u\rangle \le 0$.

Finally, $\bar{e}'$ is the eigenfunction corresponding to λ_2 and $\ker(\mathcal{L}_1) = \operatorname{span}\{\bar{e}'\}$. If P is the spectral projection onto $\ker(\mathcal{L}_1)$ then for $u \in L^2(\mathbb{R})$ satisfying (5.5), we have

$$\langle \mathcal{L}_1(I-P)u, (I-P)u\rangle \le \lambda_1 \|(I-P)u\|_2^2\,. \tag{5.7}$$

Since $\mathcal{L}_1$ is self-adjoint, P can be expressed as $Pu = \langle u, \bar{e}'\rangle\,\bar{e}'$.

By choosing the initial condition u_0 of (5.4), (5.5) such that $Pu_0 = 0$, it is easily checked that also $Pu = 0$ for all $t > 0$, which finishes the proof. □

ASYMMETRIC CHANNEL DIVIDER IN STOKES FLOW*

I. DAVID ABRAHAMS†, ANTHONY M. J. DAVIS‡, and
STEFAN G. LLEWELLYN SMITH‡

Abstract. This article examines the classic problem of Stokes flow into a divided channel with, in contrast to previous literature, the divider barrier asymmetrically placed with respect to the moving, parallel channel walls. The boundary value problem is reduced to a Wiener–Hopf equation that is of matrix form and of a class for which no exact solution is known. An explicit approximate solution, in general accurate to any specified degree, is obtained by a recent method which employs Padé approximants. Numerical results exhibit the flows due to moving walls or various combinations of downstream pressure gradients.

Key words. Stokes flow, channel flow, Wiener–Hopf technique, matrix Wiener–Hopf equations, Padé approximants

1. Introduction.

A classic problem in two-dimensional creeping flow, having an analogy in plane elastostatics, is the disturbance created by the presence of a semi-infinite barrier in a channel flow (see Figure 1.1) driven by a pressure gradient and or shearing. The "parallel lines" geometry suggests the use of the Wiener–Hopf technique; however, the advantage of the constricting walls in creating unidirectional flows both upstream and downstream is offset by the appearance, in general, of a matrix Wiener–Hopf system. The exception is the case of symmetric geometry which yields Wiener–Hopf equations of standard (scalar) type [1], since then the flow components that are even and odd with respect to the centerline can be considered separately. Despite this simplification, the even problem (no flow across the line of the barrier), which is the case of greater interest, requires an intricate factorization constructed and used by Buchwald and Doran [2] and Foote and Buchwald [3]. An erroneous attempt was presented earlier by Graebel [4] with the aim of achieving better accuracy than the approximate, yet still complicated, solutions given by Koiter [5]. Richardson [6] neglected an important feature of the factorization in [2]. Jensen and Halpern [7] verified the calculations of Buchwald and coworkers in using their solution to examine the role of the stress singularity at the edge of surfactant between thin fluid layers. Without a general procedure for solving matrix Wiener–Hopf problems (see further discussion on this point is section 3.1), an alternative strategy for the biharmonic equation is to employ complex variable techniques, facilitated by the removal of one wall (that is, the receding of one channel wall to infinity). Approximations are still required using this approach, as presented by Moore, Buchwald, and Brewster [8] for a Stokesian entry problem, in which the remaining wall translates, and by Kim, Choi, and Jeong [9] for a model of the half-pitot tube, in which a shear flow is prevented from generating any flux into the channel. The following study is both an application

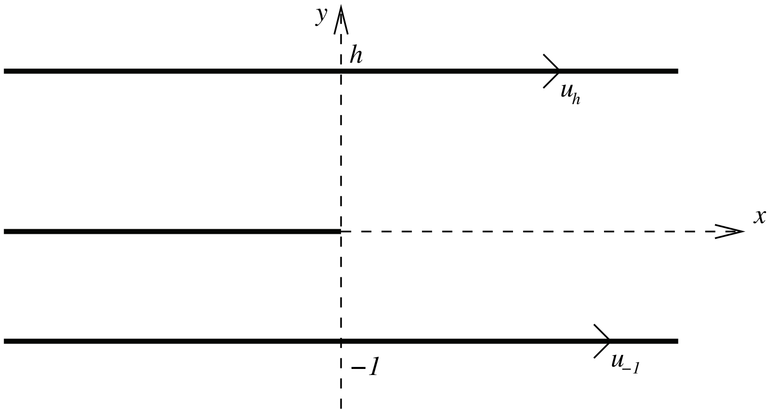

FIG. 1.1. *Geometry of problem.*

of a new Padé approximant procedure [10] and the first solution of this classic problem by the Wiener–Hopf technique.

Consider the unidirectional flow between rigid walls at $y = -1$, h, where (x, y) are Cartesian coordinates, at which the velocity u has the prescribed values u_{-1}, u_h, respectively (see Figure 1.1). The flow $u^\infty(y)\hat{\mathbf{x}}$, where $\hat{\mathbf{x}}$ is the unit vector in the x direction, is given by

$$u^\infty(y) = u_h\left(\frac{y+1}{h+1}\right) + u_{-1}\left(\frac{h-y}{h+1}\right) - \frac{G}{2\mu}(h-y)(y+1). \tag{1.1}$$

Here the first two terms of the velocity profiles may be identified as a shear flow with different wall speeds and the last term with a flow driven by a pressure gradient G that accounts for the prescribed flux being different from the flux generated by the shear flow. It is readily observed from (1.1) that only the weighted average of the wall velocities has a role in the study of the disturbance flow generated by the introduction of a fixed plate at $y = 0, x < 0$. With $u_h + u_{-1}h = -U(h+1)$, this occurs when the flow speed at $y = 0$, namely

$$u^\infty(0) = \frac{u_h + u_{-1}h}{h+1} - \frac{Gh}{2\mu} = -\left(U + \frac{Gh}{2\mu}\right), \tag{1.2}$$

is nonzero, or when there is a flux “mismatch” in $(-1, 0)$ between the upstream flow and that in the downstream channel.

In terms of pressure gradients G_-, G_+ at infinity (as shown in Figure 1.1), the downstream $(x \to -\infty)$ unidirectional velocity profiles are given by

$$u_-^\infty(y) = -u_{-1}y + \frac{G_-}{2\mu}y(y+1), \qquad -1 < y < 0, \tag{1.3}$$

$$u_+^\infty(y) = u_h\frac{y}{h} - \frac{G_+}{2\mu}y(h-y), \qquad 0 < y < h, \tag{1.4}$$

whose total flux must equal that in the upstream $(x \to \infty)$ unidirectional velocity profile (1.1). Thus

$$\frac{(G_+ - G)h^3 + (G_- - G)}{6\mu} = (h+1)\left(U + \frac{Gh}{2\mu}\right), \tag{1.5}$$

which is to be viewed as determining the upstream pressure gradient G in terms of G_+, G_-, U. The flux "mismatch," ΔQ, is now given by

$$\Delta Q = \int_{-1}^{0} \left[u^\infty(y) - u_-^\infty(y)\right] dy = -\frac{1}{2}\left(U + \frac{Gh}{2\mu}\right) + \frac{(G_- - G)}{12\mu}. \tag{1.6}$$

Evidently the sets of values of the wall velocities and pressure gradients in (1.1), (1.3) for which the presence of the semi-infinite barrier creates a disturbance flow form a two-parameter family described by nonzero values of the vector $[u^\infty(0), \Delta Q]$, with only its direction being significant. Thus any two flows of type (1.1), (1.3) that yield parallel values of this vector, determined by (1.2), (1.6), may be regarded as equivalent because their suitably weighted difference must be a unidirectional flow with zero velocity at $y = 0$.

For example, the two flows determined by $G_- = 0 = G$ and either $u_{-1} = 0, u_h = V^*$ or $u_{-1} = -V, u_h = 0$ both yield values of $[u^\infty(0), \Delta Q]$ that are parallel to $(2, 1)$ because, if $V^* = -Vh$, they differ by the shear flow $u = Vy$. The former is the finite version of the two-dimensional model of a half-pitot tube studied by Kim, Choi, and Jeong [9], whose motivation was the experimental work reported by Stanton, Marshall, and Bryant [11] and Taylor [12]. The latter is the finite version of a Stokesian entry problem, with no pressure gradient far down the semi-infinite channel, studied by Moore, Buchwald, and Brewster [8]. The condition of no pressure gradient upstream ensures, for any u_h, that their flow is recovered in the limit $h \to \infty$.

In the case of symmetric geometry, $h = 1$ and evidently (1.2)–(1.6) show that flows with $u_{-1} = -U = u_h$, $G_+ = G_-$ are equivalent to the even case:

$$\Delta Q = 0, \quad u_-^\infty(-y) = u_+^\infty(y), \quad 0 < y < 1, \tag{1.7}$$

which consists downstream of a shear and pressure-driven flow combination, while flows with $u_{-1} = 0 = u_h$, $G_+ = -G_-$ are equivalent to the odd case:

$$G = 0, \quad u^\infty(0) = 0, \quad \Delta Q = \frac{G_-}{12\mu}, \quad u_-^\infty(-y) = -u_+^\infty(y), \quad 0 < y < 1, \tag{1.8}$$

which is a pressure-driven flow out of one channel into the other.

In view of the above discussion, a generic study which covers *all possible* flow cases in fact need only consider forcing due solely to the moving walls and various combinations of downstream pressure gradients. The two cases are therefore the following:

1. $U \neq 0$ and $G_+ = 0 = G_-$. Therefore, $[u^\infty(0), \Delta Q]$ is parallel to $[2(h^2 - h + 1), h(h-1)]$, so its direction depends on h only.
2. $U = 0$ and various flux ratios. Hence

$$\frac{\Delta Q}{u^\infty(0)} = \frac{3h + 1 - G_-/G}{6h}, \tag{1.9}$$

which displays a two-parameter dependence.

As an illustration of the use of MATLAB, a computational solution of this channel flow, using approximate boundary conditions, was given by Fehribach and Davis [13].

2. The Wiener–Hopf problem.

The equations of steady creeping flow, the Stokes equations [14], are

$$\nabla p = \mu \nabla^2 \mathbf{v}, \qquad \nabla \cdot \mathbf{v} = 0, \tag{2.1}$$

where $\mathbf{v}$ is the velocity, p the dynamic pressure, and μ the viscosity. For two-dimensional flow referred to Cartesian coordinates (x, y), equations (2.1) allow a stream function $\psi(x, y)$ to be introduced such that

$$\mathbf{v} = \frac{\partial \psi}{\partial y}\hat{\mathbf{x}} - \frac{\partial \psi}{\partial x}\hat{\mathbf{y}}, \qquad \nabla^4 \psi = 0. \tag{2.2}$$

Consider the flow between rigid walls at $y = -1$, h and a semi-infinite fixed barrier at $y = 0$, $x < 0$ at which the stream function has distinct constant values and its y-derivative has the prescribed values $u_{-1} = -U$, $u_h = -U$, 0, respectively (see Figure 1.1). Then $\mathbf{v} \sim u^{\infty}(y)\hat{\mathbf{x}}$ as $x \to \infty$ and $\mathbf{v} \sim u^{\infty}_{\pm}(y)\hat{\mathbf{x}}$ as $x \to -\infty$, where $u^{\infty}(y)$ and $u^{\infty}_{\pm}(y)$ are given by (1.1) and (1.3), (1.4), with the upper "plus" (lower "minus") sign referring to the upper (lower) duct region. It is advantageous to choose for the disturbance field not $\mathbf{v} - u^{\infty}(y)\hat{\mathbf{x}}$ but rather $\mathbf{v} - u^{\infty}_{\pm}(y)\hat{\mathbf{x}}$. Thus, on setting, as in (2.2),

$$\mathbf{v} - u^{\infty}_{\pm}(y)\hat{\mathbf{x}} = \frac{\partial \bar{\psi}}{\partial y}\hat{\mathbf{x}} - \frac{\partial \bar{\psi}}{\partial x}\hat{\mathbf{y}}, \qquad \begin{cases} 0 < y < h, \\ -1 < y < 0, \end{cases} \tag{2.3}$$

the disturbance stream function $\bar{\psi}(x, y)$ is biharmonic, satisfies the homogeneous conditions

$$\bar{\psi} = 0 = \frac{\partial \bar{\psi}}{\partial y} \text{ at } y = -1, h, \quad -\infty < x < \infty, \quad \text{ and } y = 0, \quad x < 0, \tag{2.4}$$

is continuous along with its y-derivative on $y = 0$, $x > 0$, and, according to (1.3), (1.4), and (2.3), is generated by the discontinuities

$$\left[\frac{\partial^2 \bar{\psi}}{\partial y^2}\right]_{0-}^{0+} = U\frac{h+1}{h} + \frac{G_+ h + G_-}{2\mu}, \qquad \left[\frac{\partial^3 \bar{\psi}}{\partial y^3}\right]_{0-}^{0+} = -\frac{G_+ - G_-}{\mu} \tag{2.5}$$

on $y = 0, x > 0$. If, for convenience, these discontinuities tend to zero as $x \to \infty$, i.e., (2.5) is modified to

$$\left[\frac{\partial^2 \bar{\psi}}{\partial y^2}\right]_{0-}^{0+} = \left[U\frac{h+1}{h} + \frac{G_+ h + G_-}{2\mu}\right] e^{-\epsilon x}, \qquad \left[\frac{\partial^3 \bar{\psi}}{\partial y^3}\right]_{0-}^{0+} = -\frac{G_+ - G_-}{\mu} e^{-\epsilon x} \tag{2.6}$$

on $y = 0, x > 0$, where ϵ is a small positive real constant, then the disturbance stream function $\bar{\psi}$ and its derivatives tend to zero as $x \to \pm\infty$ as a consequence of the choice (2.3), which further implies that the unknown functions $s(x)$, $t(x)$, defined by

$$\left[\frac{\partial^2 \bar{\psi}}{\partial y^2}\right]_{0-}^{0+} = s(x), \quad \left[\frac{\partial^3 \bar{\psi}}{\partial y^3}\right]_{0-}^{0+} = t(x), \quad y = 0, \quad x < 0, \tag{2.7}$$

also decay to zero as $x \to -\infty$. On completion of the solution procedure ϵ will be set to zero.

In terms of the Fourier transform

$$\Psi(k, y) = \int_{-\infty}^{\infty} \bar{\psi}(x, y) e^{ikx} dx, \tag{2.8}$$

the boundary conditions (2.4), (2.6), (2.7) yield

$$\Psi(k, -1) = 0 = \Psi_y(k, -1), \qquad \Psi(k, h) = 0 = \Psi_y(k, h), \tag{2.9}$$

$$\Psi(k,0)=\int_0^\infty \bar\psi(x,0)e^{ikx}dx=\Psi^+(k,0), \qquad \Psi_y(k,0)=\Psi_y^+(k,0), \tag{2.10}$$

$$\begin{aligned}[\Psi_{yy}(k,y)]_{0-}^{0+}&=\int_{-\infty}^0 s(x)e^{ikx}dx+\left[U\frac{h+1}{h}+\frac{G_+h+G_-}{2\mu}\right]\int_0^\infty e^{ix(k+i\epsilon)}dx\\&=S^-(k)+\left[U\frac{h+1}{h}+\frac{G_+h+G_-}{2\mu}\right]\frac{i}{k+i\epsilon},\end{aligned} \tag{2.11}$$

$$\begin{aligned}[\Psi_{yyy}(k,y)]_{0-}^{0+}&=\int_{-\infty}^0 t(x)e^{ikx}dx-\frac{G_+-G_-}{\mu}\int_0^\infty e^{ix(k+i\epsilon)}dx\\&=T^-(k)-\frac{G_+-G_-}{\mu}\frac{i}{k+i\epsilon}.\end{aligned} \tag{2.12}$$

Convergence of the above Fourier full- and half-range transforms is ensured if k lies in an infinite strip containing the real line, here and henceforth referred to as $\mathcal{D}$, with its width limited from below by the singularity at $k=-i\epsilon$. Evidently (see [1]) the unknown pairs of (half-range transform) functions $\Psi^+(k,0)$, $\Psi_y^+(k,0)$ and $S^-(k)$, $T^-(k)$ are regular in the region above and including $\mathcal{D}$, denoted $\mathcal{D}^+$, and the region below and including $\mathcal{D}$, denoted $\mathcal{D}^-$, respectively. Thus, $\mathcal{D}^+\cap\mathcal{D}^-\equiv\mathcal{D}$.

In view of the behavior of $\bar\psi$ at $x=\pm\infty$, the Fourier transform (2.8) can be applied to the biharmonic equation, whence

$$\left(\frac{d^2}{dy^2}-k^2\right)^2\Psi=0 \tag{2.13}$$

and hence a general solution which satisfies (2.9) is

$$\begin{aligned}\Psi(k,y)&=A(k)k(1+y)\sinh[k(1+y)]\\&\quad+B(k)\{k(1+y)\cosh[k(1+y)]-\sinh[k(1+y)]\}, \qquad -1<y<0,\end{aligned} \tag{2.14}$$

$$\begin{aligned}\Psi(k,y)&=C(k)k(h-y)\sinh[k(h-y)]\\&\quad+D(k)\{k(h-y)\cosh[k(h-y)]-\sinh[k(h-y)]\}, \qquad 0<y<h.\end{aligned} \tag{2.15}$$

Application of the conditions (2.10) now yields

$$\begin{aligned}\begin{pmatrix}A(k)\\B(k)\end{pmatrix}&=\frac{1}{\sinh^2k-k^2}\\&\times\begin{pmatrix}k\sinh k & -(k\cosh k-\sinh k)\\ -(k\cosh k+\sinh k) & k\sinh k\end{pmatrix}\begin{pmatrix}\Psi^+(k,0)\\k^{-1}\Psi_y^+(k,0)\end{pmatrix},\end{aligned} \tag{2.16}$$

$$\begin{aligned}\begin{pmatrix}C(k)\\D(k)\end{pmatrix}&=\frac{1}{\sinh^2kh-k^2h^2}\\&\times\begin{pmatrix}kh\sinh kh & kh\cosh kh-\sinh kh\\ -(kh\cosh kh+\sinh kh) & -kh\sinh kh\end{pmatrix}\begin{pmatrix}\Psi^+(k,0)\\k^{-1}\Psi_y^+(k,0)\end{pmatrix}.\end{aligned} \tag{2.17}$$

As $\Psi^+(k,y)$ and $\Psi_y^+(k,y)$ are continuous across the line $y=0$, the discontinuities (2.11), (2.12) may be regarded as conditions on $\Psi_{yy}-k^2\Psi$ and its derivative, which facilitates the deduction of the following *matrix* Wiener–Hopf equation:

$$\begin{pmatrix}T^-(k)\\-S^-(k)\end{pmatrix}-\frac{i}{k+i\epsilon}\left(U\frac{h+1}{h}\begin{bmatrix}0\\1\end{bmatrix}+\frac{1}{2\mu}\begin{bmatrix}2G_+-2G_-\\G_+h+G_-\end{bmatrix}\right)=\mathbf{K}(k)\begin{pmatrix}\Psi^+(k,0)\\\Psi_y^+(k,0)\end{pmatrix}, \tag{2.18}$$

where

$$\mathbf{K}(k) = \begin{pmatrix} k^2[f(k)+g(k)] & -ke(k) \\ -ke(k) & g(k)-f(k) \end{pmatrix}, \tag{2.19}$$

$$e(k) = 2k\left(\frac{k^2}{\sinh^2 k - k^2} - \frac{k^2h^2}{\sinh^2 kh - k^2h^2}\right), \tag{2.20}$$

$$f(k) = 2k\left(\frac{k}{\sinh^2 k - k^2} + \frac{kh}{\sinh^2 kh - k^2h^2}\right), \tag{2.21}$$

$$g(k) = k\left[\frac{\sinh 2k}{\sinh^2 k - k^2} + \frac{\sinh 2kh}{\sinh^2 kh - k^2h^2}\right]. \tag{2.22}$$

It can easily be seen that $\mathbf{K}(k)$ possesses the properties

$$\mathbf{K}(k) = \mathbf{K}(-k) = [\mathbf{K}(k)]^T, \tag{2.23}$$

where T denotes the transpose, a fact that is exploited subsequently. The determinant of the kernel is

$$|\mathbf{K}(k)| = \frac{4k^4[\sinh^2 k(h+1) - k^2(h+1)^2]}{(\sinh^2 kh - k^2h^2)(\sinh^2 k - k^2)}. \tag{2.24}$$

The forcing term in (2.18) displays the two independent flows identified above. In the case of symmetric geometry, $h = 1$ implies that $e(k)$ is identically zero, and hence the Wiener–Hopf equation (2.18) separates into disjoint scalar equations of standard type. Then, in the even case, $G_+ \equiv G_-$ implies that T^- and Ψ^+ vanish, while, in the odd case, $U \equiv 0 \equiv G_+ + G_-$ implies that S^- and Ψ_y^+ vanish, as expected.

It remains to consider the pressure singularity at the barrier edge. In the neighborhood of $r = 0$, using the obvious polar coordinate representation,

$$\bar{\psi} \sim 2^{1/2} r^{3/2} \cos\frac{1}{2}\theta[\Lambda_1 \sin\theta + \Lambda_2(1+\cos\theta)] \tag{2.25}$$

$$= \Lambda_1(r+x)^{1/2}y + \Lambda_2(r+x)^{3/2}, \tag{2.26}$$

after rejecting the more singular terms of order $r^{1/2}$. Thus

$$\bar{\psi}(x,0) \sim \Lambda_2(2x)^{3/2}, \qquad \frac{\partial\bar{\psi}}{\partial y}(x,0) \sim \Lambda_1(2x)^{1/2} \text{ as } x \to 0+, \tag{2.27}$$

and by writing, for $x < 0$,

$$\bar{\psi} \sim \frac{\Lambda_1 y|y|}{(r-x)^{1/2}} + \frac{\Lambda_2|y|^3}{(r-x)^{3/2}}; \tag{2.28}$$

it follows that

$$\frac{\partial^2\bar{\psi}}{\partial y^2}(x,0) \sim \pm\Lambda_1\left(\frac{2}{-x}\right)^{1/2}, \qquad \frac{\partial^3\bar{\psi}}{\partial y^3}(x,0) \sim \pm\Lambda_2\frac{6}{(-2x)^{3/2}} \tag{2.29}$$

as $x \to 0-$ on the upper/lower side of the barrier. The latter result indicates that the pressure jump across the barrier behaves as $6\mu\Lambda_2(2/(-x))^{1/2}$ as the edge is approached. This agrees with the asymptotic form

$$\mu^{-1}\bar{p} \sim 2^{1/2} r^{-1/2} \left(-\Lambda_1 \cos \frac{1}{2}\theta + 3\Lambda_2 \sin \frac{1}{2}\theta \right), \tag{2.30}$$

obtained from (2.25) by noting that (2.1) and (2.2) ensure that $\bar{p}$ and $\mu\nabla^2\bar{\psi}$ are conjugate functions. The rejection of order $r^{1/2}$ terms in (2.25) thus minimizes the *order* of this edge singularity in the pressure, as, for example, in the calculations for the spherical cap [15] and the hollow sphere with caps removed [16]. A bounded pressure jump occurs if $\Lambda_2 = 0$, which may be achieved by a suitable choice of the direction of the forcing vector in (2.18). Such a procedure is unnecessary for the geometrically symmetric even case since then Λ_2 must be zero for $\bar{\psi}$ to be an odd function of θ in (2.25). The Wiener–Hopf calculation [2, 3, 5] generates an entire function that is identically zero, from which it is deduced that $\Lambda_1 = 2/\sqrt{\pi}$.

3. Factorization of the duct kernel.

3.1. Introduction and overview of the factorization procedure. In the previous section the matrix Wiener–Hopf equation was derived, in which the kernel, $\mathbf{K}(k)$, is written in (2.19). The aim of this section is to factorize $\mathbf{K}(k)$ into a product of two matrices

$$\mathbf{K}(k) = \mathbf{K}^{-}(k)\mathbf{K}^{+}(k), \tag{3.1}$$

one containing those singularities of $\mathbf{K}(k)$ lying in the lower half-plane, referred to as $\mathbf{K}^{+}(k)$, and $\mathbf{K}^{-}(k)$, which is analytic in the lower half-plane $\mathcal{D}^{-}$ and hence contains the singularities of $\mathbf{K}(k)$ lying above the strip $\mathcal{D}$. Note that $[\mathbf{K}^{+}(k)]^{-1}$ and $[\mathbf{K}^{-}(k)]^{-1}$ are also analytic in the regions $\mathcal{D}^{+}$ and $\mathcal{D}^{-}$, respectively. Further, it is necessary for successful completion of the Wiener–Hopf procedure that $\mathbf{K}^{\pm}(k)$ are at worst of algebraic growth (see Noble [1]). Unfortunately, although matrix kernel factorization with the requisite growth behavior has been proven to be possible for a wide class of kernels (Gohberg and Krein [17]), to which the kernel (2.19) belongs, no constructive method has been found to complete this in general. There are classes of matrices for which product factorization can be achieved explicitly, the most important of which are those amenable to Hurd's method [18] and Khrapkov–Daniele commutative matrices [19, 20]. Details of these, and an extensive bibliography on matrix kernel factorization, can be found in [21, 10, 22]. The present problem yields a kernel which, to the authors' knowledge, falls outside of the classes permitting an exact factorization, and so an approximate decomposition will be performed here. The approach follows that developed recently by one of the authors and has been successfully applied to problems in elasticity [21, 22] and acoustics [10]. Essentially, the procedure is to rearrange the kernel into an appropriate form, namely, to resemble a Khrapkov (commutative) matrix, and then to replace a scalar component of it by a function which approximates it accurately in the strip of analyticity $\mathcal{D}$. The new approximate kernel is able to be factorized exactly (into an explicit noncommutative decomposition), and, in the previous cases cited above, strong numerical evidence was offered for convergence of the resulting approximate factors to the exact ones as the scalar approximator is increased in accuracy. Further, the convergence to the solution has been validated for one particular matrix kernel [23], where an *exact* noncommutative factorization can be derived by an alternative procedure.

The kernel in (2.19) appears, on face value, significantly simpler to factorize than those in the previously mentioned articles [21, 10], because it contains only simple pole singularities rather than branch cuts. Therefore, it could perhaps be considered as more appropriately factorized by pole removal methods, such as those suggested by Idemen [24], Noble [1], Rawlins [25], Abrahams [26], and Abrahams and Wickham [27], reducing the problem down to an infinite algebraic system of equations which needs to be solved numerically. However, there are three reasons why this approach is not useful here. The first is a technical point; it can be shown that the procedure for removing singularities from the kernel, and thereby obtaining the kernel factors $\mathbf{K}^{\pm}(k)$, is not nearly as straightforward as for those kernels considered by the aforementioned authors. Second, the pole locations are complex and are found from the zeros of the determinant of the kernel $\mathbf{K}(k)$ in (2.24), i.e., the roots of the transcendental Papkovich–Fadle dispersion relation. This creates further complications in the factorization scheme. The third, and most compelling, reason for avoiding this approach is that we would like a final solution which will offer *uniformly* accurate results for all values of upper duct height h, from $h = 1$ to $h = \infty$, a range that does not imply any loss of generality. Clearly, as $h \to \infty$, more and more of the Papkovich–Fadle poles need to be included to maintain constant accuracy (more and more move down close to the strip $\mathcal{D}$), and so the corresponding algebraic system to solve has to be truncated after a greater and greater number of terms. Thus, we cannot expect to recover the $h \to \infty$ case, that is, when the upper duct top wall is removed, so we could not employ such a factorization in a solution which we would hope to compare with other results for this particular flow domain (Moore, Buchwald, and Brewster [8], Kim, Choi, and Jeong [9], etc.)

In view of the above arguments we aim to employ the Wiener–Hopf approximant matrix (WHAM) method [10] discussed previously and to do this in such a way that maintains the requisite accuracy over all values of $h \geq 1$. As mentioned in the introduction, when $h = 1$, then the kernel should reduce to two scalar functions, reflecting the symmetric and antisymmetric motions clearly evident to exist from the symmetry in duct geometry. When $h = \infty$, the upper duct wall is removed, and although others have tackled this by alternative approximate/numerical means, it can, in fact, be shown that the kernel actually reduces to a commutative (Khrapkov) form [23]. Therefore, an exact factorization is again achievable. Hence, if the approximate factorization, to be achieved here by the WHAM method, is organized so that in both limits, $h \to 1$ and $h \to \infty$, it reduces to the exact kernel decomposition, then very good accuracy can be expected for all intermediate h values. This is what will be done below. However, as a complication to this factorization, we must take account of two unfortunate features of the kernel. The first is the fact that the elements of $\mathbf{K}(k)$, and in particular $e(k)$, $f(k)$ shown in (2.20)–(2.22), differ by a factor of k near the origin. This is identical to that found for the kernel in [21] and can be handled by a suitable rearrangement of terms. The second is due to the fact that $\mathbf{K}(k)$ must be written as a product of three matrices such that the inner matrix $\mathbf{L}(k)$ (see (3.6) below) has a determinant with behavior proportional to k^{-2} as $k \to 0$. This is a removable singularity because it is pre- and postmultiplied by matrices which each have determinant k. Unfortunately, the inner matrix is the one we initially factorize, and so additional arrangement is necessary to take this small-k behavior into account. With these points of explanation in mind, the factorization procedure is now elucidated.

3.2. Conditioning of the matrix kernel.

3.2.1. Behavior for large $|k|$. The matrix $\mathbf{K}(k)$ is characterized by its elements $e(k)$, $f(k)$, $g(k)$, given in (2.20)–(2.22), and in particular by their behavior for large and small k. For large k it is easily deduced that

$$e(k) \sim 8k^3(e^{-2|k|} - h^2 e^{-2|k|h}), \quad |k| \to \infty, \quad k \in \mathcal{D}, \tag{3.2}$$

$$f(k) \sim 8k^2(e^{-2|k|} + h e^{-2|k|h}), \quad |k| \to \infty, \quad k \in \mathcal{D}, \tag{3.3}$$

$$g(k) \sim 4|k|, \quad |k| \to \infty, \quad k \in \mathcal{D}. \tag{3.4}$$

It is appropriate to arrange the kernel to be diagonally dominant as $k \to \infty$ in $\mathcal{D}$, and so simple algebra gives

$$\mathbf{K}(k) = \frac{1}{2}\begin{pmatrix} 0 & -k \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & -1 \\ i & i \end{pmatrix}\mathbf{L}(k)\begin{pmatrix} i & 1 \\ i & -1 \end{pmatrix}\begin{pmatrix} k & 0 \\ 0 & 1 \end{pmatrix}, \tag{3.5}$$

where $\mathbf{L}(k)$ may be written in the form

$$\mathbf{L}(k) = g(k)\mathbf{I} + \begin{pmatrix} 0 & f(k) + ie(k) \\ f(k) - ie(k) & 0 \end{pmatrix}, \tag{3.6}$$

with $\mathbf{I}$ the identity.

3.2.2. Behavior of the kernel near the origin. Near the origin the scalar functions $e(k)$, $f(k)$, $g(k)$ take the form

$$e(k) \sim 6\left(\frac{h^2-1}{h^2}\right)\frac{1}{k}, \tag{3.7}$$

$$f(k) \sim 6\left(\frac{h^3+1}{h^3}\right)\frac{1}{k^2}, \tag{3.8}$$

$$g(k) \sim 6\left(\frac{h^3+1}{h^3}\right)\frac{1}{k^2}, \tag{3.9}$$

to leading order, and it is easy to show that at the next order

$$g(k) - f(k) \sim 4\left(\frac{h+1}{h}\right), \tag{3.10}$$

so that we may write

$$g(k) - f(k) \sim \beta^2 k^2 f(k), \tag{3.11}$$

in which

$$\beta^2 = \frac{2}{3}\frac{h^2}{h^2-h+1}. \tag{3.12}$$

Note that β^2 tends to its minimum value $2/3$ as $h \to 1$ or $h \to \infty$ and takes the maximum value $8/9$. This small variation in value over all h is important to ensure an eventually uniform factorization accuracy. We may also express $e(k)$ in terms of $f(k)$ near the origin:

$$e(k) \sim \delta k f(k), \tag{3.13}$$

where the parameter δ takes the value

$$\delta = \frac{h(h-1)}{h^2-h+1} \tag{3.14}$$

and is monotonic in h going from $\delta = 0$ at $h = 1$ to $\delta = 1$ at $h = \infty$. Again, this small variation will prove helpful to the factorization.

We now arrange $\mathbf{L}(k)$ to appear in Khrapkov form, namely, that the square of the second matrix term should be a scalar polynomial in k times the identity. We can do this by removing the factor $\sqrt{f^2(k) + e^2(k)}$ from this matrix in (3.6). However, as

$$f(k) \pm ie(k) \sim f(k)(1 \pm i\delta k), \qquad k \to 0, \tag{3.15}$$

it is more effective [21] to write $\mathbf{L}(k)$ as

$$\mathbf{L}(k) = g(k)\mathbf{I} + \sqrt{\frac{f^2(k) + e^2(k)}{1 + \delta^2 k^2}}\mathbf{J}(k), \tag{3.16}$$

$$\mathbf{J}(k) = \begin{pmatrix} 0 & d(k)(1 + i\delta k) \\ d^{-1}(k)(1 - i\delta k) & 0 \end{pmatrix}, \tag{3.17}$$

in which

$$d(k) = \sqrt{\left(\frac{f(k) + ie(k)}{f(k) - ie(k)}\right)\left(\frac{1 - i\delta k}{1 + i\delta k}\right)}. \tag{3.18}$$

It is a simple matter to show that we can choose a branch of $d(k)$ which is regular in $\mathcal{D}$, takes the value unity at $k = 0$, and, in view of the relative magnitudes of $e(k)$, $f(k)$ as $|k| \to \infty$ in $\mathcal{D}$, (3.2), (3.3), also tends to unity at infinity in the strip. If we had omitted the factor $(1 - i\delta k)/(1 + i\delta k)$ in $d(k)$, then $\arg(d(k))$ would not have tended to zero as $k \to \pm\infty$.

The matrix $\mathbf{L}(k)$ now appears to be in Khrapkov form, in view of the property

$$\mathbf{J}^2(k) = \Delta^2(k)\mathbf{I}, \tag{3.19}$$

where $\Delta^2(k)$ is the polynomial

$$\Delta^2(k) = 1 + \delta^2 k^2. \tag{3.20}$$

However, $\mathbf{J}(k)$ is not entire, as required for a Khrapkov factorization, but contains $d(k)$, which has infinite sequences of finite branch cuts at rotationally symmetric locations in the upper and lower half-planes. These will have to be considered once the partial Khrapkov decomposition is complete but, for the present, will be ignored.

3.3. Partial decomposition of $\mathbf{K}(k)$.

3.3.1. Limiting values of $\mathbf{L}(k)$. The first point to remark here is that (3.19) is arranged in appropriate form for the limiting values of h. As $h \to 1$, expression (2.20) reveals immediately that $e(k) = 0$ and similarly, from (3.14), $\delta = 0$. Hence $\mathbf{L}(k)$ reduces to

$$\mathbf{L}(k) = g(k)\mathbf{I} + f(k)\begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad h = 1. \tag{3.21}$$

By adding and subtracting rows this can be trivially reduced to two scalar decomposition problems, but this will also be decomposed *exactly* in the following Khrapkov factorization as $d(k) \equiv 1$. Similarly, as $h \to \infty$, $\delta \to 1$ and

$$e(k) = kf(k) = \frac{2k^3}{\sinh^2 k - k^2}, \qquad h \to \infty. \tag{3.22}$$

Hence in this limit $d(k) = 1$ also and

$$\mathbf{L}(k) = g(k)\mathbf{I} + f(k)\begin{pmatrix} 0 & 1+ik \\ 1-ik & 0 \end{pmatrix}, \qquad h = \infty, \tag{3.23}$$

which also permits an exact factorization [23] and justifies the particular form of $d(k)$ chosen in (3.18).

3.3.2. Introduction of resolvent matrix. Before performing the Khrapkov factorization on $\mathbf{L}(k)$, there is a problem, alluded to above, which must be resolved first. Note that as $k \to 0$, from (3.6), (3.11), and (3.13),

$$\mathbf{L}(k) \sim f(k)\begin{pmatrix} 1+\beta^2k^2 & 1+i\delta k \\ 1-i\delta k & 1+\beta^2k^2 \end{pmatrix} \tag{3.24}$$

so that

$$|\mathbf{L}(k)| \sim \left[6\frac{h^3+1}{h^3k^2}\right]^2 (2\beta^2-\delta^2)k^2 \sim \frac{12(h+1)^4}{h^4k^2} + \mathcal{O}(1). \tag{3.25}$$

This is clearly singular at the origin and therefore violates the original assumption of regularity in $\mathcal{D}$. Of course, this is because we are working with $\mathbf{L}(k)$ and not the original kernel $\mathbf{K}(k)$. To overcome this "removable singularity" in the determinant it is convenient to introduce the new matrix, $\mathbf{R}(k)$, called the resolvent, where

$$\mathbf{R}^{-1}(k) = (1+\beta^2k^2)\mathbf{I} - \mathbf{J}(k), \tag{3.26}$$

with $\mathbf{J}(k)$ as in (3.17), which commutes with $\mathbf{L}(k)$. The combined matrix

$$\mathbf{T}(k) = \mathbf{R}^{-1}(k)\mathbf{L}(k) \tag{3.27}$$

has determinant value

$$\left[\frac{2(h+1)^3}{h(h^2-h+1)}\right]^2 \tag{3.28}$$

at $k = 0$, and so $\mathbf{T}(k)$ may now be factorized instead of $\mathbf{L}(k)$. We will later have to deal with factorizing $\mathbf{R}(k)$, but this will not prove to be a problem.

3.3.3. Partial decomposition of matrix $\mathbf{T}(\boldsymbol{k})$. We have seen above that $\mathbf{R}^{-1}(k)$ and $\mathbf{L}(k)$ commute, and indeed any matrices of the form $\alpha\mathbf{I} + \beta\mathbf{J}(k)$ will commute with any other. Therefore, we may pose (see [19]) the product factors of $\mathbf{T}(k)$ in the form

$$\mathbf{T}^{\pm}(k) = r^{\pm}(k)\left(\cosh[\Delta(k)\theta^{\pm}(k)]\mathbf{I} + \frac{1}{\Delta(k)}\sinh[\Delta(k)\theta^{\pm}(k)]\mathbf{J}(k)\right), \tag{3.29}$$

where $r^{\pm}(k)$, $\theta^{\pm}(k)$ are scalar functions of k with the analyticity property indicated by their superscript. The function $\Delta(k)$, given by (3.20), generates no branch cuts because (3.29) contains only even powers of $\Delta(k)$. The scalar factors $r^{\pm}(k)$, $\theta^{\pm}(k)$ are deduced by equating

$$\mathbf{T}(k) = \mathbf{T}^{+}(k)\mathbf{T}^{-}(k), \tag{3.30}$$

which yields

$$r^+(k)r^-(k)\cosh[\Delta(k)(\theta^+(k)+\theta^-(k))] = g(1+\beta^2k^2) - \Delta\sqrt{f^2+e^2}, \tag{3.31}$$

$$r^+(k)r^-(k)\sinh[\Delta(k)(\theta^+(k)+\theta^-(k))] = \sqrt{f^2+e^2}(1+\beta^2k^2) - \Delta g. \tag{3.32}$$

These may be separated to give

$$[r^+(k)r^-(k)]^2 = (g^2-f^2-e^2)\left[(2\beta^2-\delta^2)+\beta^4k^2\right]k^2, \tag{3.33}$$

$$\tanh[\Delta(k)(\theta^+(k)+\theta^-(k))] = \frac{\sqrt{f^2+e^2}(1+\beta^2k^2)-\Delta g}{g(1+\beta^2k^2)-\Delta\sqrt{f^2+e^2}}, \tag{3.34}$$

and by the usual sum-split formula (e.g., equation (1.17) of Noble [1])

$$\begin{aligned}\theta^+(k) &= \frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{1}{\Delta(\zeta)}\tanh^{-1}\left\{\frac{\sqrt{f^2(\zeta)+e^2(\zeta)}(1+\beta^2\zeta^2)-\Delta(\zeta)g(\zeta)}{g(\zeta)(1+\beta^2\zeta^2)-\Delta(\zeta)\sqrt{f^2(\zeta)+e^2(\zeta)}}\right\}\frac{d\zeta}{\zeta-k}\\ &= \frac{k}{\pi i}\int_0^{\infty}\frac{1}{\Delta(\zeta)}\tanh^{-1}\left\{\frac{\sqrt{f^2(\zeta)+e^2(\zeta)}(1+\beta^2\zeta^2)-\Delta(\zeta)g(\zeta)}{g(\zeta)(1+\beta^2\zeta^2)-\Delta(\zeta)\sqrt{f^2(\zeta)+e^2(\zeta)}}\right\}\frac{d\zeta}{\zeta^2-k^2},\end{aligned} \tag{3.35}$$

valid for $\Im(k) > 0$. Note that the last result is true because the integrand is even in ζ, and this further implies that

$$\theta^-(k) = \theta^+(-k), \qquad k \in \mathcal{D}^-. \tag{3.36}$$

Actually, the full range integral could be taken along any path in $\mathcal{D}$ parallel to the real axis, and so if $\theta^+(k)$ is required for real k, then the first integral would be indented below (above for $\theta^-(k)$) this point. We can confirm that the integral representations in (3.35) exist by examining the integrand as $\zeta \to 0$ and $\zeta \to \infty$ (it is finite valued at all other points in $\mathcal{D}$). From (3.7)–(3.9) a little algebra reveals that the right-hand side of (3.34) is $\mathcal{O}(k^2)$, $k \to 0$, and similarly (3.2)–(3.4) suggests that (3.34) is $\mathcal{O}(k^{-1})$, $k \to \infty$. Hence, the first integrand in (3.35) is bounded in $\mathcal{D}$ and decays proportionally to $\mathcal{O}(\zeta^{-3})$ as $|\zeta| \to \infty$ in the strip. Therefore, this representation is ideal for computing $\theta^\pm(k)$ and can be directly coded for numerical evaluation.

This procedure has to be modified for $[r^+(k)r^-(k)]^2$ in (3.33) whose right-hand side tends to $[2(h+1)^3/h(h^2-h+1)]^2$ as $k \to 0$ and $\sim 16\beta^4k^6$ as $|k| \to \infty, k \in \mathcal{D}$. The latter behavior is not suitable for direct application of the product decomposition formula (Noble [1, equation (1.20)]), which requires a function that tends to the value unity at infinity. This is simply circumvented by applying a suitable divisor to (3.33), employing the standard factorization formula, and then decomposing the divisor into upper- and lower-half functions by inspection. This yields

$$\begin{aligned}r^+(k) = &\left[3^{1/2}\left(\frac{h+1}{h}\right)-2ik\right]^{1/2}\left[3^{1/4}\left(\frac{h+1}{h}\right)(1+i)-2ik\right]^{1/2}\\ &\times\left[3^{1/4}\left(\frac{h+1}{h}\right)(1-i)-2ik\right]^{1/2}\frac{h}{[3(h^2-h+1)]^{1/2}}\\ &\times\exp\left\{\frac{1}{4\pi i}\int_{-\infty}^{\infty}\log\left[\frac{[g^2(\zeta)-f^2(\zeta)-e^2(\zeta)]\zeta^2}{12\left(\frac{h+1}{h}\right)^4+16\zeta^4}\right]\frac{d\zeta}{\zeta-k}\right\}\end{aligned} \tag{3.37}$$

for $\Im(k) > 0$, and indentation of the contour below k is taken if k is real. Note that the exponential function in this expression may be reexpressed as

$$\exp\left\{\frac{k}{2\pi i}\int_0^\infty \log\left[\frac{[g^2(\zeta)-f^2(\zeta)-e^2(\zeta)]\zeta^2}{12\left(\frac{h+1}{h}\right)^4+16\zeta^4)}\right]\frac{d\zeta}{\zeta^2-k^2}\right\}, \tag{3.38}$$

where convergence of this and the above integral are now ensured. The function $r^-(k)$, analytic in the lower half-plane, is again, due to the symmetry, simply obtained from

$$r^-(-k) = r^+(k), \qquad k \in \mathcal{D}^+. \tag{3.39}$$

Hence $\mathbf{T}^\pm(k)$ have been determined (see (3.29), (3.35), (3.37)) in a form which can be evaluated directly, and these are analytic in their indicated half-planes, $\mathcal{D}^\pm$, except for the singularities occurring in $\mathbf{K}(k)$ (due to $d(k)$) which have yet to be resolved.

3.3.4. Partial decomposition of the resolvent matrix. Having introduced the inverse of $\mathbf{R}(k)$ above in order to improve the convergence of $\mathbf{L}(k)$, we now need to factorize it directly. The form of $\mathbf{R}(k)$ has been chosen to enable us to do this easily. First, $\mathbf{R}^{-1}(k)$ may, by inspection, be written in the form

$$\frac{1}{2}[(1+ik\sqrt{2\beta^2-\delta^2})\mathbf{I}-\mathbf{J}(k)][(1-ik\sqrt{2\beta^2-\delta^2})\mathbf{I}-\mathbf{J}(k)], \tag{3.40}$$

where both matrices are entire save for the finite cuts in the scalar function $d(k)$ contained within $\mathbf{J}(k)$. The first matrix has determinant

$$-2\beta^2 k(k-i\gamma), \tag{3.41}$$

where

$$\gamma = \frac{\sqrt{2\beta^2-\delta^2}}{\beta^2} = \frac{\sqrt{3}}{2}\left(\frac{h+1}{h}\right), \tag{3.42}$$

and the second has determinant

$$-2\beta^2 k(k+i\gamma). \tag{3.43}$$

Hence we may write

$$\mathbf{R}(k) = 2\mathbf{R}^+(k)\mathbf{R}^-(k), \tag{3.44}$$

where

$$\mathbf{R}^\pm(k) = \frac{1}{2\beta^2 k(k\pm i\gamma)}\left[(1\mp ik\beta^2\gamma)\mathbf{I}+\mathbf{J}(k)\right] \tag{3.45}$$

are the partial decomposition matrices; i.e., they are analytic in their indicated half-planes except for poles at $k=0$ and the finite branch cuts in $d(k)$. Note that $\mathbf{R}^\pm(k)$ commute with each other and with $\mathbf{T}^\pm(k)$, while the pole at $k=i\gamma$ lies in the upper half-plane. Hence, this completes the partial product factorization of $\mathbf{K}(k)$, and from (3.5), (3.27), (3.30), (3.44), we obtain

$$\mathbf{K}(k) = \mathbf{Q}^-(k)\mathbf{Q}^+(k), \tag{3.46}$$

where

$$\mathbf{Q}^-(k) = \begin{pmatrix} -ik & -ik \\ 1 & -1 \end{pmatrix} \mathbf{R}^-(k)\mathbf{T}^-(k), \tag{3.47}$$

$$\mathbf{Q}^+(k) = \mathbf{T}^+(k)\mathbf{R}^+(k) \begin{pmatrix} ik & 1 \\ ik & -1 \end{pmatrix}. \tag{3.48}$$

Note that $\mathbf{Q}^{\pm}(k)$ are free of a pole singularity at $k = 0$ even though $\mathbf{R}^{\pm}(k)$ contain this singularity (verified in section 3.4.3). All that remains is to remove (approximately) the residual singularities appearing in $\mathbf{J}(k)$.

3.4. Approximate factorization.

3.4.1. Padé approximation and partial decomposition of approximate kernel. There is no exact procedure known for eliminating the finite branch cuts in $d(k)$ from the upper (lower) half-planes of the matrix factor $\mathbf{Q}^+(k)$ ($\mathbf{Q}^-(k)$). To obtain an approximate factorization we replace the original matrix $\mathbf{K}(k)$ by a new one, $\mathbf{K}_N(k)$, where

$$\mathbf{K}_N(k) = \frac{1}{2}\begin{pmatrix} 0 & -k \\ 1 & 0 \end{pmatrix}\begin{pmatrix} 1 & -1 \\ i & i \end{pmatrix}\mathbf{L}_N(k)\begin{pmatrix} i & 1 \\ i & -1 \end{pmatrix}\begin{pmatrix} k & 0 \\ 0 & 1 \end{pmatrix}, \tag{3.49}$$

$$\mathbf{L}_N(k) = g(k)\mathbf{I} + \sqrt{\frac{f^2(k) + e^2(k)}{1 + \delta^2 k^2}}\mathbf{J}_N(k), \tag{3.50}$$

and $\mathbf{J}_N(k)$ is as given in (3.17) but with a modified scalar $d(k) \to d_N(k)$, i.e.,

$$\mathbf{J}_N(k) = \begin{pmatrix} 0 & d_N(k)(1 + i\delta k) \\ d_N^{-1}(k)(1 - i\delta k) & 0 \end{pmatrix}. \tag{3.51}$$

We follow the procedure outlined in articles [21, 10, 23, 22] closely and so do not give the arguments here, contained in those papers, for the convergence of approximate factors to the exact ones. It will suffice to later verify the results obtained herein by numerical experiment. The scalar $d_N(k)$ is any function which approximates $d(k)$ accurately in the strip $\mathcal{D}$, and for efficacy of the following method it is most convenient to use a rational function approximation

$$d_N(k) = \frac{P_N(k)}{Q_N(k)}, \tag{3.52}$$

where $P_N(k)$, $Q_N(k)$ are polynomial functions of order N. Note that the order of each polynomial is the same, as we require that $d_N(k) \to 1$ as $|k| \to \infty$. There is a variety of ways of generating the coefficients of these polynomials, and the simplest and perhaps most justifiable (in terms of its analyticity properties) is to use Padé approximants [28]. As a note of caution, we must check that $d_N(k)$ does not introduce spurious singularities into the strip of analyticity $\mathcal{D}$; otherwise we will produce an inaccurate factorization. One-point Padé approximants, if they exist, are determined uniquely from the Taylor series expansion of the original function at any point of regularity. If we work with the origin, then the (one-point) Padé approximant of $d(k)$ is found by solving

$$\sum_{i=0}^{\infty} e_i k^i - \frac{P_N(k)}{Q_N(k)} = \mathcal{O}(k^{2N+1}), \tag{3.53}$$

where $\sum_{i=0}^{\infty} e_i k^i$ is the Maclaurin expansion of $d(k)$. This provides ample accuracy for our purposes (see section 5), due to the rapid decay at large real k that is otherwise present in the Fourier transform inversion formulas (4.7) and (4.8).

Note that the approximation of just $d(k)$ ensures that the scalar Khrapkov factors (3.35), (3.37) remain the same, etc., and so a partial decomposition of $\mathbf{K}_N(k)$ is simply

$$\mathbf{K}_N(k) = \mathbf{Q}_N^-(k)\mathbf{Q}_N^+(k), \tag{3.54}$$

in which $\mathbf{Q}_N^{\pm}(k)$ are given by (3.47), (3.48), with $\mathbf{R}^{\pm}(k)$ replaced by $\mathbf{R}_N^{\pm}(k)$ and $\mathbf{T}^{\pm}(k)$ replaced by $\mathbf{T}_N^{\pm}(k)$, for which the subscript N denotes that $\mathbf{J}_N(k)$, given by (3.51), replaces $\mathbf{J}(k)$ everywhere. Thus, the factorization of $\mathbf{K}_N(k)$ has been accomplished apart from sequences of poles, arising from the zeros and poles of $d_N(k)$ occurring in both half-planes exterior to $\mathcal{D}$. If we can remove these singularities, then an explicit exact factorization of $\mathbf{K}_N(k)$ will have been achieved, which approximates the actual factors $\mathbf{K}^{\pm}(k)$ in their regions of analyticity.

3.4.2. Removal of pole singularities. The exact factorization of $\mathbf{K}_N(k)$, given by (3.49), may be written as

$$\mathbf{K}_N(k) = \mathbf{K}_N^-(k)\mathbf{K}_N^+(k), \tag{3.55}$$

$$\mathbf{K}_N^-(k) = \mathbf{Q}_N^-(k)\mathbf{M}(k), \qquad \mathbf{K}_N^+(k) = \mathbf{M}^{-1}(k)\mathbf{Q}_N^+(k), \tag{3.56}$$

in which $\mathbf{M}(k)$ must be a meromorphic matrix which has to be chosen to eliminate the poles of $\mathbf{Q}_N^-(k)$ in the lower half-plane and the poles of $\mathbf{Q}_N^+(k)$ in $\mathcal{D}^+$. We can pose a (nonunique) ansatz for $\mathbf{M}(k)$ after noting certain symmetry properties of $\mathbf{Q}_N^{\pm}(k)$. First, from (3.18),

$$d(-k) = 1/d(k), \tag{3.57}$$

which must be reflected in the similar approximant behavior:

$$d_N(-k) = 1/d_N(k). \tag{3.58}$$

Thus,

$$\mathbf{J}_N(-k) = [\mathbf{J}_N(k)]^T, \tag{3.59}$$

where the superscript denotes the transpose, and so by inspection of (3.45),

$$\mathbf{R}_N^+(-k) = [\mathbf{R}_N^-(k)]^T. \tag{3.60}$$

Similarly, from (3.36), (3.39) and the obvious evenness of $\Delta(k)$ in (3.20), changing k to $-k$ in (3.29) reveals

$$\mathbf{T}_N^+(-k) = [\mathbf{T}_N^-(k)]^T. \tag{3.61}$$

Hence we find (see (3.48)) that

$$\mathbf{Q}_N^+(-k) = [\mathbf{T}_N^-(k)]^T[\mathbf{R}_N^-(k)]^T \begin{pmatrix} -ik & -ik \\ 1 & -1 \end{pmatrix}^T = [\mathbf{Q}_N^-(k)]^T \tag{3.62}$$

and deduce that the second equation in (3.56) gives

$$\mathbf{K}_N^+(-k) = \mathbf{M}^{-1}(-k)[\mathbf{Q}_N^-(k)]^T. \tag{3.63}$$

Symmetry properties dictate, by comparison with the first equation of (3.56), that we can construct a suitably scaled $\mathbf{M}(k)$ so that

$$\mathbf{M}^{-1}(-k) = [\mathbf{M}(k)]^T. \tag{3.64}$$

After this is achieved, it suffices to eliminate poles of $\mathbf{K}_N^-(k)$ in the lower half-plane.

Now suppose that $d_N(k)$ has N_p poles in the upper half-plane at $k = ip_n$, $n = 1, 2, \ldots, N_p$ ($ip_n \notin \mathcal{D}^-$), and N_q poles in the region below the strip at $k = -iq_n$, $n = 1, 2, \ldots, N_q$. That is, $Q_N(k)$ in (3.52) has zeros at $k = ip_n, -iq_n$. As has already been stated, there are, in total,

$$N_p + N_q = N \tag{3.65}$$

simple poles in the complex plane, and, due to the symmetry (3.58), there are N simple zeros of $P_N(k)$ at

$$k = -ip_n, \qquad n = 1, 2 \ldots, N_p; \qquad k = iq_n, \qquad n = 1, 2 \ldots, N_q, \tag{3.66}$$

in the lower and upper regions, respectively. Thus, $d_N(k)$ and its inverse may be expressed as Mittag–Leffler expansions:

$$d_N(k) = 1 + \sum_{n=1}^{N_p} \frac{\alpha_n}{p_n + ik} + \sum_{n=1}^{N_q} \frac{\beta_n}{q_n - ik}, \tag{3.67}$$

$$\frac{1}{d_N(k)} = 1 + \sum_{n=1}^{N_p} \frac{\alpha_n}{p_n - ik} + \sum_{n=1}^{N_q} \frac{\beta_n}{q_n + ik}, \tag{3.68}$$

where both tend to unity at infinity by virtue of $d_N(k)$ being a one-point Padé approximant of $d(k)$ in (3.18). The coefficients α_n, β_n are easily determined from the coefficients of the polynomials $P_N(k)$, $Q_N(k)$, the numerator and denominator, respectively, of $d_N(k)$. By inspection of the location of $d_N(k)$ in $\mathbf{Q}_N^-(k)$, the ansatz for $\mathbf{M}(k)$ is now posed (cf. those offered in [10, 23]) as

$$\begin{aligned} &\mathbf{M}(k) \\ &= \begin{pmatrix} \frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{A_n}{p_n+ik} + \sum_{n=1}^{N_q} \frac{B_n}{q_n-ik} & -\left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{C_n}{p_n+ik} + \sum_{n=1}^{N_q} \frac{D_n}{q_n-ik}\right) \\ \left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{C_n}{p_n-ik} + \sum_{n=1}^{N_q} \frac{D_n}{q_n+ik}\right) & \frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{A_n}{p_n-ik} + \sum_{n=1}^{N_q} \frac{B_n}{q_n+ik} \end{pmatrix}, \end{aligned} \tag{3.69}$$

where A_n, B_n, C_n, D_n are as yet undetermined constants. This form encapsulates the zeros and singularities of $d_N(k)$ and is chosen to satisfy the symmetry relation (3.64). However, the latter holds only if $|\mathbf{M}(k)| \equiv 1$, whereas (3.69) gives

$$\begin{aligned} |\mathbf{M}(k)| = {} & \left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{A_n}{p_n + ik} + \sum_{n=1}^{N_q} \frac{\bar{B}_n}{q_n - ik}\right) \left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{A_n}{p_n - ik} + \sum_{n=1}^{N_q} \frac{B_n}{q_n + ik}\right) \\ & + \left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{C_n}{p_n - ik} + \sum_{n=1}^{N_q} \frac{D_n}{q_n + ik}\right) \left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p} \frac{C_n}{p_n + ik} + \sum_{n=1}^{N_q} \frac{D_n}{q_n - ik}\right). \end{aligned} \tag{3.70}$$

The four sets of poles can be eliminated by setting the coefficients to satisfy the two systems of equations

$$\begin{aligned} &A_m\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{A_n}{p_n+p_m}+\sum_{n=1}^{N_q}\frac{B_n}{q_n-p_m}\right)\\ &+C_m\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{C_n}{p_n+p_m}+\sum_{n=1}^{N_q}\frac{D_n}{q_n-p_m}\right)=0 \quad (1\le m\le N_p), \end{aligned}\tag{3.71}$$

$$\begin{aligned} &B_m\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{A_n}{p_n-q_m}+\sum_{n=1}^{N_q}\frac{B_n}{q_n+q_m}\right)\\ &+D_m\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{C_n}{p_n-q_m}+\sum_{n=1}^{N_q}\frac{D_n}{q_n+q_m}\right)=0 \quad (1\le m\le N_q). \end{aligned}\tag{3.72}$$

Then $|\mathbf{M}(k)|$ is entire and takes the value unity at infinity. Hence Liouville's theorem implies that the determinant is indeed $|\mathbf{M}(k)|=1$ everywhere, as required.

By premultiplying $\mathbf{M}(k)$ by $\mathbf{R}^-(k)\mathbf{T}^-(k)$ and eliminating poles in the lower half-plane, conditions relating these coefficients can be found. From (3.29) and (3.45) we know that

$$\begin{aligned} &\left[(1+ik\beta^2\gamma)\mathbf{I}+\mathbf{J}_N(k)\right]\\ &\times\left[\cosh[\Delta(k)\theta^-(k)]\mathbf{I}+\frac{1}{\Delta(k)}\sinh[\Delta(k)\theta^-(k)]\mathbf{J}_N(k)\right]\mathbf{M}(k) \end{aligned}\tag{3.73}$$

must be analytic in $\mathcal{D}^-$, and so from (3.51) we wish to remove poles in the lower half-plane from

$$\begin{pmatrix} a^-(k) & b^-(k)(1+i\delta k)d_N(k)\\ b^-(k)(1-i\delta k)/d_N(k) & a^-(k)\end{pmatrix}\mathbf{M}(k),\tag{3.74}$$

where

$$a^\pm(k)=(1\mp ik\beta^2\gamma)\cosh[\Delta(k)\theta^\pm(k)]+\Delta(k)\sinh[\Delta(k)\theta^\pm(k)],\tag{3.75}$$

$$b^\pm(k)=\cosh[\Delta(k)\theta^\pm(k)]+\frac{(1\mp ik\beta^2\gamma)}{\Delta(k)}\sinh[\Delta(k)\theta^\pm(k)]\tag{3.76}$$

are scalar functions analytic in the indicated regions. Note that

$$a^-(k)=a^+(-k),\qquad b^-(k)=b^+(-k).\tag{3.77}$$

The top-left element of the matrix in (3.74) is, by employing (3.67),

$$\begin{aligned} &a^-(k)\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{A_n}{p_n+ik}+\sum_{n=1}^{N_q}\frac{B_n}{q_n-ik}\right)+b^-(k)(1+i\delta k)\\ &\times\left(1+\sum_{n=1}^{N_p}\frac{\alpha_n}{p_n+ik}+\sum_{n=1}^{N_q}\frac{\beta_n}{q_n-ik}\right)\left(\frac{1}{\sqrt{2}}+\sum_{n=1}^{N_p}\frac{C_n}{p_n-ik}+\sum_{n=1}^{N_q}\frac{D_n}{q_n+ik}\right), \end{aligned}\tag{3.78}$$

which appears to contain simple poles at $k=-ip_n$, $n=1,\dots,N_p$, $k=-iq_n$, $n=1,\dots,N_q$, in the lower half-plane unless they are suppressed. However, there are in fact no poles at $k = -ip_n$ because the sum of these terms multiplies $d_N(k)$, which we know is zero at these points. Thus, setting the expression in (3.78) to remain finite at the remaining singularity locations $k = -iq_n$ gives the relation, after use of (3.77),

(3.79)

$$a^+(iq_m)B_m + b^+(iq_m)\beta_m(1+\delta q_m)\left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p}\frac{C_n}{p_n - q_m} + \sum_{n=1}^{N_q}\frac{D_n}{q_n + q_m}\right) = 0, \qquad 1 \le m \le N_q.$$

Similarly the bottom-left element of (3.74) contains no poles in the lower half-plane if and only if

(3.80)

$$a^+(ip_m)C_m + b^+(ip_m)\alpha_m(1-\delta p_m)\left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p}\frac{A_n}{p_n + p_m} + \sum_{n=1}^{N_q}\frac{B_n}{q_n - p_m}\right) = 0, \qquad 1 \le m \le N_p.$$

Likewise, suppression of the lower half-plane poles in the second column of (3.74) yields

(3.81)

$$a^+(iq_m)D_m - b^+(iq_m)\beta_m(1+\delta q_m)\left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p}\frac{A_n}{p_n - q_m} + \sum_{n=1}^{N_q}\frac{B_n}{q_n + q_m}\right) = 0, \qquad 1 \le m \le N_q,$$

(3.82)

$$a^+(ip_m)A_m - b^+(ip_m)\alpha_m(1-\delta p_m)\left(\frac{1}{\sqrt{2}} + \sum_{n=1}^{N_p}\frac{C_n}{p_n + p_m} + \sum_{n=1}^{N_q}\frac{D_n}{q_n - p_m}\right) = 0, \qquad 1 \le m \le N_p.$$

By inspection, (3.79), (3.81) imply (3.72) and similarly (3.80), (3.82) imply (3.71). Therefore, not only do (3.79)–(3.82) enforce $\mathbf{K}_N^-(k)$ to be analytic in $\mathcal{D}^-$ as required, but relations (3.56), (3.62)–(3.64) reveal that they are also sufficient to ensure that $\mathbf{K}_N^+(k)$ is free of singularities in the half-plane $\mathcal{D}^+$, as are the inverses $[\mathbf{K}_N^{\pm}(k)]^{-1}$ in their indicated half-planes $\mathcal{D}^{\pm}$.

Thus (3.79)–(3.82) constitute a linear system of $2N$ equations for the $2N$ unknowns A_m, B_m, C_n, D_n and are easily solved to determine their values. Note that it may transpire that $1+\delta q_m$ or $1-\delta p_m$ is zero for particular choices of m, h, N, etc., in which case (B_m, D_m) or (A_m, C_m) would vanish. However, this does not present any difficulty (cf. equation (80) in [10]), and no cases have been encountered in which the system for A_m–D_m is singular.

3.4.3. Approximate noncommutative factorization. The explicit approximate factorization of $\mathbf{K}(k)$ is complete, having obtained an exact noncommutative matrix product decomposition of $\mathbf{K}_N(k)$. The factors $\mathbf{K}_N^{\pm}(k)$ are constructed from

(3.56), with $\mathbf{Q}_N^{\pm}(k)$ given from (3.51), (3.47), (3.48), (3.45), and (3.29). The meromorphic matrix $\mathbf{M}(k)$ takes the explicit form (3.69), in which the coefficients satisfy algebraic equations (3.79)–(3.82). As N increases it is expected that $\mathbf{K}_N^{\pm}(k)$ will converge rapidly to the exact factors $\mathbf{K}^{\pm}(k)$, and this will be borne out by numerical results given in section 5. All that remains here is to verify that the apparent pole at $k = 0$ in $\mathbf{R}^{\pm}(k)$ is removed and to give the behavior of $\mathbf{K}_N^{\pm}(k)$ for large $|k|$ in $\mathcal{D}^{\pm}$.

As $k \to 0$, we know that $d_N(k) \to 1$ by virtue of the function $d(k)$ in (3.18), and hence $\mathbf{R}_N^{\pm}(k)$ behaves as, from (3.45), (3.51),

$$\mathbf{R}_N^{\pm}(k) = \frac{\mp i}{2\beta^2 k\gamma}\begin{pmatrix} 1 & 1 \\ 1 & 1 \end{pmatrix} + \mathcal{O}(1). \tag{3.83}$$

Therefore,

$$\begin{pmatrix} -ik & -ik \\ 1 & -1 \end{pmatrix}\mathbf{R}_N^{-}(k) \sim \frac{1}{\beta^2\gamma}\begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix} + \mathcal{O}(1), \qquad k \to 0. \tag{3.84}$$

Now, $\mathbf{T}_N^{\pm}(k)$, from their definitions, are bounded at the origin, and, by inspection, so is $\mathbf{M}(k)$ in (3.69). Hence, from (3.56) and (3.84) we can deduce that

$$\mathbf{K}_N^{-}(k) = \mathcal{O}(1), \qquad k \to 0. \tag{3.85}$$

Similarly, from above,

$$\mathbf{R}_N^{+}(k)\begin{pmatrix} ik & 1 \\ ik & -1 \end{pmatrix} = \mathcal{O}(1), \qquad k \to 0, \tag{3.86}$$

and so $\mathbf{K}_N^{+}(0)$ is bounded too.

As $|k|$ tends to infinity it is a straightforward matter to deduce the asymptotic behavior of the product factors. First, by inspection of (3.45),

$$\mathbf{R}_N^{\pm}(k) \sim \frac{i}{2\beta^2 k}\begin{pmatrix} \mp\beta^2\gamma & +\delta \\ -\delta & \mp\beta^2\gamma \end{pmatrix}, \tag{3.87}$$

in view of the fact that we *defined* $d_N(k)$ in $\mathbf{J}_N(k)$ to behave as

$$d_N(k) \to 1, \qquad |k| \to \infty. \tag{3.88}$$

Second, the asymptotic form of the Krapkhov decomposition elements $r^{\pm}(k)$, $\theta^{\pm}(k)$ can be deduced from their integral definitions written in (3.37), (3.39), and (3.35), (3.36), respectively. The latter identities are easily shown to give

$$\theta^{\pm}(k) = \pm\epsilon/k + \mathcal{O}(k^{-2}), \qquad |k| \to \infty, k \in \mathcal{D}^{\pm}, \tag{3.89}$$

where

$$\epsilon = \frac{i}{\pi}\int_0^{\infty} \frac{1}{\Delta(\zeta)} \tanh^{-1}\left\{\frac{\sqrt{f^2(\zeta) + e^2(\zeta)}(1 + \beta^2\zeta^2) - \Delta(\zeta)g(\zeta)}{g(\zeta)(1 + \beta^2\zeta^2) - \Delta(\zeta)\sqrt{f^2(\zeta) + e^2(\zeta)}}\right\} d\zeta, \tag{3.90}$$

and for $r^{\pm}(k)$ the integral in the exponent of (3.37) is also $\mathcal{O}(k^{-1})$ for large $|k|$. Hence by inspection we find that

$$r^{\pm}(k) = 2\beta(\mp ik)^{3/2} + \mathcal{O}(k^{1/2}), \qquad |k| \to \infty, k \in \mathcal{D}^{\pm}, \tag{3.91}$$

and so the asymptotic form of $\mathbf{T}_N^{\pm}(k)$, (3.29), is

$$\mathbf{T}_N^{\pm}(k) \sim 2\beta(\mp ik)^{3/2} \begin{pmatrix} \cosh(\epsilon\delta) & \pm i\sinh(\epsilon\delta) \\ \mp i\sinh(\epsilon\delta) & \cosh(\epsilon\delta) \end{pmatrix}. \tag{3.92}$$

Therefore, $\mathbf{Q}_N^{\pm}(k)$ in (3.47), (3.48) can be estimated. Finally, the meromorphic matrix (3.69) has the large $|k|$ form

$$\mathbf{M}(k) = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}. \tag{3.93}$$

Thus the asymptotic growth of $\mathbf{K}_N^{\pm}(k)$ in (3.56) is found to be

$$\begin{aligned} \mathbf{K}_N^{-}(k) \sim -\frac{(ik)^{1/2}}{\sqrt{2}\beta} & \begin{pmatrix} -ik & -ik \\ 1 & -1 \end{pmatrix} \begin{pmatrix} \beta^2\gamma & \delta \\ -\delta & \beta^2\gamma \end{pmatrix} \\ & \times \begin{pmatrix} \cosh(\epsilon\delta) & -i\sinh(\epsilon\delta) \\ +i\sinh(\epsilon\delta) & \cosh(\epsilon\delta) \end{pmatrix} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}, \end{aligned} \tag{3.94}$$

$$\begin{aligned} \mathbf{K}_N^{+}(k) \sim -\frac{(-ik)^{1/2}}{\sqrt{2}\beta} & \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix} \begin{pmatrix} \cosh(\epsilon\delta) & i\sinh(\epsilon\delta) \\ -i\sinh(\epsilon\delta) & \cosh(\epsilon\delta) \end{pmatrix} \\ & \times \begin{pmatrix} \beta^2\gamma & -\delta \\ \delta & \beta^2\gamma \end{pmatrix} \begin{pmatrix} ik & 1 \\ ik & -1 \end{pmatrix}. \end{aligned} \tag{3.95}$$

The kernel decomposition is now complete.

4. Solution of the Wiener–Hopf equation.

Having obtained an approximate factorization of $\mathbf{K}(k)$, it is now a straightforward matter to complete the solution of the Wiener–Hopf equation (2.18). Dropping the subscript N in the factorization (3.55) for brevity, the Wiener–Hopf equation can be recast into the form

$$\begin{aligned} & [\mathbf{K}^-(k)]^{-1} \begin{pmatrix} T^-(k) \\ -S^-(k) \end{pmatrix} - \frac{i}{k+i\epsilon} \left\{ [\mathbf{K}^-(k)]^{-1} - [\mathbf{K}^-(-i\epsilon)]^{-1} \right\} \\ & \times \left(U\frac{h+1}{h} \begin{bmatrix} 0 \\ 1 \end{bmatrix} + \frac{1}{2\mu} \begin{bmatrix} 2G_+ - 2G_- \\ G_+h + G_- \end{bmatrix} \right) = \mathbf{E}(k) = \mathbf{K}^+(k) \begin{pmatrix} \Psi^+(k,0) \\ \Psi_y^+(k,0) \end{pmatrix} \\ & + \frac{i}{k+i\epsilon} [\mathbf{K}^-(-i\epsilon)]^{-1} \left(U\frac{h+1}{h} \begin{bmatrix} 0 \\ 1 \end{bmatrix} + \frac{1}{2\mu} \begin{bmatrix} 2G_+ - 2G_- \\ G_+h + G_- \end{bmatrix} \right), \end{aligned} \tag{4.1}$$

where $k \in \mathcal{D}$. The left-hand side is analytic in $\mathcal{D}^-$, whereas the right-hand side is regular in $\mathcal{D}^+$. Thus the equation has been arranged so that the two sides offer analytic continuation into the whole complex k-plane which must therefore be equal to an entire function, denoted $\mathbf{E}(k)$, say. To determine $\mathbf{E}(k)$ we must examine the growth at infinity of both sides of (4.1) in their respective half-planes of analyticity. To do this we require the large k behavior of $T^-(k)$, $S^-(k)$, $\Psi^+(k)$, $\Psi_y^+(k)$, which relate directly to the values of the untransformed physical variables near the tip of the splitter plate. For example, a function which behaves like x^n, $x \to 0+$, has a half-range (0 to ∞) Fourier transform which decays like $\mathcal{O}(k^{-n-1})$, $k \to \infty$, in the upper half-plane (see equation (1.74) of [1]). Hence from (2.27) and (2.29) we deduce, respectively, that

$$\Psi^{+}(k,0)=\mathcal{O}(k^{-5/2}),\qquad \Psi_y^{+}(k,0)=\mathcal{O}(k^{-3/2}) \tag{4.2}$$

as $|k|\to\infty$, $k\in\mathcal{D}^{+}$ and hence

$$\left(\begin{array}{c} T^{-}(k)\\ -S^{-}(k)\end{array}\right)-\frac{i}{k}\left(U\frac{h+1}{h}\left[\begin{array}{c}0\\1\end{array}\right]+\frac{1}{2\mu}\left[\begin{array}{c}2G_{+}-2G_{-}\\ G_{+}h+G_{-}\end{array}\right]\right)=\left(\begin{array}{c}\mathcal{O}(k^{1/2})\\ \mathcal{O}(k^{-1/2})\end{array}\right) \tag{4.3}$$

as $|k|\to\infty, k\in\mathcal{D}^{-}$. These are used, together with the asymptotic forms (3.94), (3.95), to reveal that both elements of the left-hand side of (4.1) decay as $\mathcal{O}(k^{-1})$ in the lower half-plane, and similarly the right-hand side has the form $\mathcal{O}(k^{-1})$ as $|k|\to\infty$ in the upper half-plane. Hence, $\mathbf{E}(k)$ is an entire function which decays to zero at infinity and so, by Liouville's theorem, is identically zero. Thus, the solution of the Wiener–Hopf equation is

$$\begin{aligned}\left(\begin{array}{c}\Psi^{+}(k,0)\\ \Psi_y^{+}(k,0)\end{array}\right)&=-\frac{i}{k+i\epsilon}[\mathbf{K}^{+}(k)]^{-1}[\mathbf{K}^{-}(-i\epsilon)]^{-1}\\ &\quad\times\left(U\frac{h+1}{h}\left[\begin{array}{c}0\\1\end{array}\right]+\frac{1}{2\mu}\left[\begin{array}{c}2G_{+}-2G_{-}\\ \\ G_{+}h+G_{-}\end{array}\right]\right)\end{aligned} \tag{4.4}$$

or, equivalently,

$$\begin{aligned}\left(\begin{array}{c}T^{-}(k)\\ -S^{-}(k)\end{array}\right)&=\frac{i}{k+i\epsilon}\left\{\mathbf{I}-\mathbf{K}^{-}(k)[\mathbf{K}^{-}(-i\epsilon)]^{-1}\right\}\\ &\quad\times\left(U\frac{h+1}{h}\left[\begin{array}{c}0\\1\end{array}\right]+\frac{1}{2\mu}\left[\begin{array}{c}2G_{+}-2G_{-}\\ G_{+}h+G_{-}\end{array}\right]\right).\end{aligned} \tag{4.5}$$

From this we can directly deduce the coefficients $A(k)$–$D(k)$, via (2.16), (2.17), and hence establish $\Psi(k,y)$ in $-1<y<h$, from (2.14), (2.15). Finally, on setting the convergence factor ϵ to zero in (4.4), the disturbance stream function is

$$\bar{\psi}=\frac{1}{2\pi}\int_{-\infty}^{\infty}\Psi(k,y)e^{-ikx}dk, \tag{4.6}$$

where the integral path runs along the real line indented above the origin, and

$$\begin{aligned}\Psi(k,y)&=\frac{-i}{\sinh^2 k-k^2}\left(\begin{array}{c}(1+y)\sinh[k(1+y)]\\ (1+y)\cosh[k(1+y)]-k^{-1}\sinh[k(1+y)]\end{array}\right)^{T}\\ &\quad\times\left(\begin{array}{cc}k\sinh k & -(\cosh k-k^{-1}\sinh k)\\ -(k\cosh k+\sinh k) & \sinh k\end{array}\right)[\mathbf{K}^{+}(k)]^{-1}[\mathbf{K}^{-}(0)]^{-1}\\ &\quad\times\left(U\frac{h+1}{h}\left[\begin{array}{c}0\\1\end{array}\right]+\frac{1}{2\mu}\left[\begin{array}{c}2G_{+}-2G_{-}\\ G_{+}h+G_{-}\end{array}\right]\right)\end{aligned} \tag{4.7}$$

in $-1<y<0$, whereas in $0<y<h$

$$\begin{aligned}\Psi(k,y)&=\frac{-i}{\sinh^2 kh-k^2h^2}\left(\begin{array}{c}(h-y)\sinh[k(h-y)]\\ (h-y)\cosh[k(h-y)]-k^{-1}\sinh[k(h-y)]\end{array}\right)^{T}\\ &\quad\times\left(\begin{array}{cc}kh\sinh kh & h\cosh kh-k^{-1}\sinh kh\\ -(kh\cosh kh+\sinh kh) & -h\sinh kh\end{array}\right)[\mathbf{K}^{+}(k)]^{-1}[\mathbf{K}^{-}(0)]^{-1}\\ &\quad\times\left(U\frac{h+1}{h}\left[\begin{array}{c}0\\1\end{array}\right]+\frac{1}{2\mu}\left[\begin{array}{c}2G_{+}-2G_{-}\\ G_{+}h+G_{-}\end{array}\right]\right).\end{aligned} \tag{4.8}$$

It is a straightforward matter to verify that this solution satisfies the biharmonic equation and the boundary and jump conditions (2.4), (2.5), (2.7). From this the downstream velocity field is determined from (2.3).

Formulas (4.7), (4.8) are suitable for evaluating $\bar{\psi}$, given by (4.6), in the $x < 0$ channels by completing the contour in the upper half-plane. Consistent with (2.3), there is no contribution from the pole at $k = 0$ to (4.6), which consists of Papkovich–Fadle strip eigenfunctions, generated by residues at the zeros of $\sinh^2 k - k^2$ or $\sinh^2 kh - k^2h^2$. These infinite sums describe how, in each channel, the flow differs from its far downstream profile $u^{\infty}_{\mp}$.

However, the evaluation of $\bar{\psi}$ in the upstream ($x > 0$) channel is achieved by completing the contour in the lower half-plane. When $[\mathbf{K}^{+}(k)]^{-1}$ is replaced, according to (3.1), by $\operatorname{adj}\mathbf{K}(k)\mathbf{K}^{-}(k)/|\mathbf{K}(k)|$, the substitution of (2.19), (2.24) into (4.7) yields

$$\begin{aligned}(4.9)\qquad &\Psi(k,y)\\ &= \frac{i}{k^2[\sinh^2 k(h+1) - k^2(h+1)^2]}\begin{pmatrix} (1+y)\sinh[k(1+y)] \\ (1+y)\cosh[k(1+y)] - k^{-1}\sinh[k(1+y)] \end{pmatrix}^{T}\\ &\times \mathbf{V}(k)\begin{pmatrix} 1 & 0 \\ 0 & -k \end{pmatrix}\mathbf{K}^{-}(k)[\mathbf{K}^{-}(0)]^{-1}\left(U\frac{h+1}{h}\begin{bmatrix} 0 \\ 1 \end{bmatrix} + \frac{1}{2\mu}\begin{bmatrix} 2G_{+} - 2G_{-} \\ G_{+}h + G_{-} \end{bmatrix}\right),\end{aligned}$$

in which the elements of $\mathbf{V}(k)$ are concisely defined by

$$V_{11} + V_{22} = kh(h+1)\sinh k, \qquad V_{11} - V_{22} = -\sinh kh \sinh k(h+1),$$

$$V_{21} + V_{12} = k^{-1}\sinh kh \sinh k(h+1) - kh(h+1)\cosh k,$$

$$V_{21} - V_{12} = \sinh kh \cosh k(h+1) - h\sinh k.$$

The residue at the pole $k = 0$ yields the upstream behavior ($x \to \infty$)

$$\begin{aligned}(4.10)\qquad \bar{\psi} \sim h&\begin{pmatrix} \left(\frac{1+y}{h+1}\right)^2 & \left(\frac{1+y}{h+1}\right)^3 \end{pmatrix}\begin{pmatrix} -\frac{h}{2} & 1-\frac{h}{2} \\ \frac{h}{6}(h+3) & -1 \end{pmatrix}\\ &\times\left(U\frac{h+1}{h}\begin{bmatrix} 0 \\ 1 \end{bmatrix} + \frac{1}{2\mu}\begin{bmatrix} 2G_{+} - 2G_{-} \\ G_{+}h + G_{-} \end{bmatrix}\right)\end{aligned}$$

in $-1 < y < 0$, which, when substituted into (2.3), gives the net upstream flow form. That is, the y-derivative of (4.10) is verified, with use of (1.5), to equal $u^{\infty}(y) - u^{\infty}_{-}(y)$, given by (1.1), (1.3). A similar calculation, based on (4.8), verifies that $u^{\infty}(y) - u^{\infty}_{+}(y)$ is obtained in $(0, h)$. Identical series of Papkovich–Fadle eigenfunctions arise in (4.6) from residues associated with the zeros of $[\sinh^2 k(h+1) - k^2(h+1)^2]$. This infinite sum describes how the flow differs from its far upstream profile u^{∞} in $-1 < y < h$.

5. Numerical computation. The calculations are performed with MATLAB, except for the evaluation of the Padé approximants d_{2m} by means of Maple. The resulting fractions are then converted to floating points (16 digit accuracy) and returned to MATLAB. Accuracy is low unless $N = 2M$ with M even to take account of symmetries about both axes. Maximum accuracy occurs at about $N = 2$, $M = 16$ and could be increased by means of variable precision arithmetic. The poles $ip_m, -iq_m$

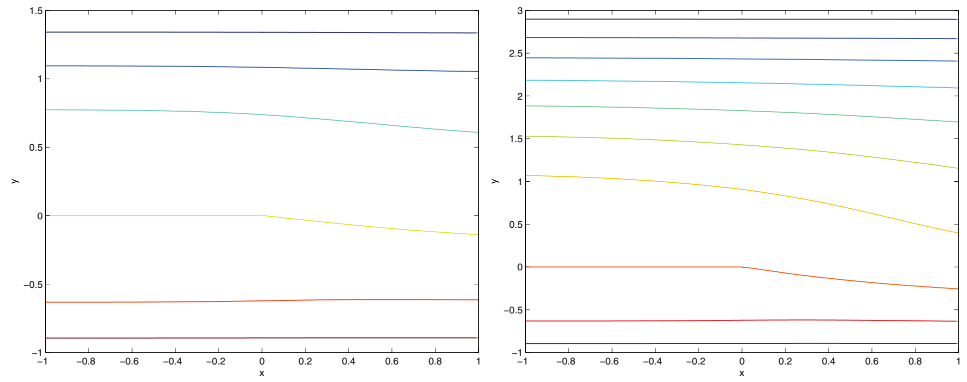

FIG. 5.1. *Stream function plots for the downstream shear case with $U = 1$ for (left) $h = 1.5$ and (right) $h = 3$ (note the different y-scale). The difference in stream function values (volume flux) between contours is* 0.2.

and coefficients α_m, β_m in (3.67) are then readily determined, followed by $\mathbf{J}_N(k)$ and $\mathbf{R}_N^+(k)$. Evaluation of $r_N^+(k), \theta_N^+(k)$ yields $\mathbf{T}_N^+(k)$ and hence $\mathbf{Q}_N^+(k)$, given by (3.48). The scalar Wiener–Hopf decomposition of r and θ is achieved by using standard MATLAB numerical integration. The default relative accuracy of 10^{-6} easily suffices because higher accuracy is actually obtained, as in many contour integrals of analytic functions. Finally, $\mathbf{K}_N^+(k)$ is constructed. The stream function, $\psi(x, y)$, is evaluated in either of the $x < 0$ channels as a sum of the residues of (4.7) or (4.8) at the respective first 50 poles in the upper half-plane. Note that knowledge of the two sets of residues allows the inverse Fourier transform (4.6) to be computed for any $x(< 0)$ at essentially zero marginal cost. The companion matrix function $\mathbf{K}_N^-(k)$, needed in (4.9) for $x > 0$, is constructed similarly.

The numerical evaluation of the approximation $[\mathbf{K}_N^+(k)]^{-1}$ to $[\mathbf{K}^+(k)]^{-1}$ in (4.7), (4.8) depends on the accurate determination of the coefficients $a^+(ip_m), \ldots$ in (3.79)–(3.82). These are given by (3.75), (3.76), in which $\Delta(k)$ appears analytically, but branch cuts may arise from the presence $\theta^\pm(k)$ in the sinh functions. By factoring $\Delta(\zeta)$ from the numerator of the fraction in (3.35), it is evident that the branch cuts created by the approximate factorization arise solely from the square root in the definition (3.16) of $\mathbf{L}(k)$.

Very high accuracy would require variable precision arithmetic and a large number of terms in the residue sum, especially when computing the stream function values near the entrance to the downstream channels.

Figure 5.1 displays streamlines for $h = 1.5$ and $h = 3$ in the downstream shear case ($G_+ = 0 = G_-$). For the same values of h, Figure 5.2 shows streamlines when the walls are stationary ($U = 0$) with respective flux ratios $\Lambda = 1, -0.5, -2$, which typify the physically distinct ranges, $\Lambda > 0$, $-1 < \Lambda < 0$, $\Lambda < -1$. The curves have an imperceptible defect at $x = 0$; the values of $\psi(0, y)$ computed using (4.7) and (4.9) are not exactly the same in the Padé approximant technique but would be identical for the exact matrix $\mathbf{K}$. This discrepancy provides an estimate of the error, which is found to decrease with N until at least $N = 12$, which is the value used in the figures. While the qualitative behavior in the pressure-driven case depends only on Λ, plots require a normalization of G_- and G_+: for convenience, $G_- = 12\mu$ was taken.

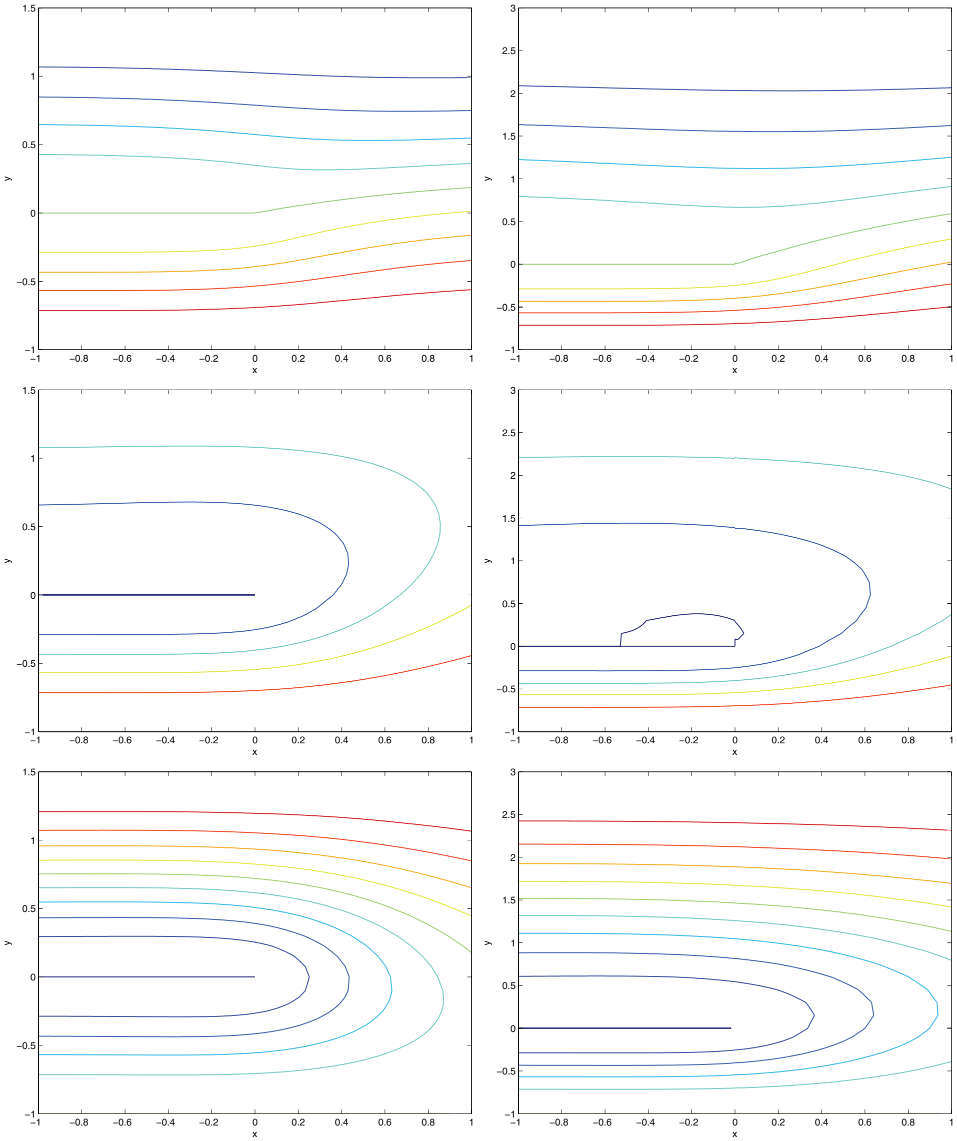

FIG. 5.2. *Stream function plots for the pressure-driven case. Left-hand panels:* $h = 1.5$*; right-hand panels:* $h = 3$*. Top row:* $\Lambda = 1$*, middle row:* $\Lambda = -0.5$*, bottom row:* $\Lambda = -2$*. The difference in stream function values (volume flux) between contours is* 0.2*. The jagged contour for* $h = 3$*,* $\Lambda = -0.5$ *is a contouring artifact.*

6. Conclusion. The Padé approximant technique for matrix Wiener–Hopf equations yields accurate numerical results for a classic Stokes flow problem for all channel width ratios. The theory is complicated by the need for successive modifications $\mathbf{L}$, $\mathbf{T}$ of the kernel and $\mathbf{M}$, $\mathbf{M}^{-1}$ of the matrix factors $\mathbf{Q}^{-}$, $\mathbf{Q}^{+}$ in order to establish the required analyticity of $\mathbf{K}^{-}$ and $\mathbf{K}^{+}$. The numerical implementation is not difficult conceptually but demands the usual careful attention to the analyticity properties of the functions involved. The technique provides a constructive scheme to obtain the physical solution without the major difficulties encountered in matching the three sets of biorthogonal Papkovich–Fadle eigenfunctions.

GLOBAL ASYMPTOTIC STABILITY FOR A CLASS OF NONLINEAR CHEMICAL EQUATIONS[*]

DAVID F. ANDERSON[†]

Abstract. We consider a class of nonlinear differential equations that arises in the study of chemical reaction systems known to be locally asymptotically stable and prove that they are in fact globally asymptotically stable. More specifically, we will consider chemical reaction systems that are weakly reversible, have a deficiency of zero, and are equipped with mass action kinetics. We show that if for each $c \in \mathbb{R}^m_{>0}$ the intersection of the stoichiometric compatibility class $c + S$ with the subsets on the boundary that could potentially contain equilibria, L_W, are at most discrete, then global asymptotic stability follows. Previous global stability results for the systems considered in this paper required $(c + S) \cap L_W = \emptyset$ for each $c \in \mathbb{R}^m_{>0}$.

Key words. chemical systems, deficiency, global stability, persistence, Petri nets

1. Introduction.

This paper is motivated by the consideration of a class of nonlinear systems that arises in the study of chemistry and biochemistry. Suppose there are m chemical species, $\{X_1, \dots, X_m\}$, undergoing a series of chemical reactions. For a given reaction, denote by $y, y' \in \mathbb{Z}^m_{\geq 0}$ the vectors representing the number of molecules of each species consumed and created in one instance of that reaction, respectively. Using a slight abuse of notation, we associate each such y (and y') with a linear combination of the species in which the coefficient of X_i is y_i. For example, if $y = [1, 2, 3]^T$ for a system consisting of three species, we associate with y the linear combination $X_1 + 2X_2 + 3X_3$. Under this association, each y (and y') is termed a *complex* of the system. We may now denote any reaction by the notation $y \to y'$, where y is the source, or reactant, complex and y' is the product complex. We note that each complex may appear as both a source complex and a product complex in the system. Let $\mathcal{S} = \{X_i\}$, $\mathcal{C} = \{y\}$, and $\mathcal{R} = \{y \to y'\}$ denote the sets of species, complexes, and reactions, respectively. Denote the concentration vector of the species as $x \in \mathbb{R}^m$. In order to know how the state of the system is changing, we need to know the rate at which each reaction is taking place. Therefore, for each reaction $y \to y'$, there is a C^1 function $R_{y\to y'}(\cdot)$ satisfying the following:

1. $R_{y\to y'}(\cdot)$ is a function of the concentrations of those species contained in the source complex, y.
2. $R_{y\to y'}(\cdot)$ is monotone increasing in each of its inputs, and $R_{y\to y'}(x) = 0$ if *any* of its inputs are zero.

The dynamics of the system are then given by the coupled set of ordinary differential equations

$$\dot{x}(t) = \sum_{y\to y'\in\mathcal{R}} R_{y\to y'}(x(t))(y' - y) \doteq f(x(t)), \tag{1}$$

where the last equality is a definition. The functions $R_{y\to y'}$ are typically referred to as the *kinetics* of the system. This notation closely matches that of Feinberg, Horn, and Jackson, and it is their work that the main results in this paper extend [12, 7, 9, 10, 8].

Integrating (1) gives

$$x(t) = x(0) + \sum_{y\to y'\in\mathcal{R}} \left(\int_0^t R_{y\to y'}(x(s))ds \right) (y' - y).$$

Therefore, $x(t) - x(0)$ remains in the linear space $S = \text{Span}\{y' - y\}_{y\to y'\in\mathcal{R}}$ for all time. We shall refer to the space S as the stoichiometric subspace of the system and refer to the sets $c + S$, for $c \in \mathbb{R}^m$, as stoichiometric compatibility classes, or just compatibility classes. Later we will demonstrate that trajectories with positive initial conditions remain in $\mathbb{R}^m_{>0}$ for all time. The sets $(c+S)\cap\mathbb{R}^m_{>0}$ will therefore be referred to as the *positive stoichiometric compatibility classes.* Given that trajectories remain in their positive stoichiometric compatibility classes for all time, we see that the types of questions that one should ask about these systems differ from the questions one normally asks about nonlinear systems. For example, instead of asking whether there is a unique equilibrium value to the system (1) and then asking about its stability properties, it is clearly more appropriate to ask whether there is a unique equilibrium *within each positive stoichiometric compatibility class* and, if so, what are its stability properties *relative to its compatibility class.*

The most common kinetics chosen is that of *mass action kinetics.* A chemical reaction system is said to have mass action kinetics if

$$R_{y\to y'}(x) = k_{y\to y'} x_1^{y_1} x_2^{y_2} \cdots x_m^{y_m} \tag{2}$$

for some constant $k_{y\to y'}$. It has been shown that, for many systems of the form (1) with mass action kinetics, there is within each stoichiometric compatibility class precisely one equilibrium with strictly positive components, and that equilibrium is locally asymptotically stable relative to its class [12, 9, 8]. In order to show that the equilibrium values are locally stable, the following Lyapunov function is used (one for each compatibility class):

$$V(x,\bar{x}) = V(x) = \sum_{i=1}^m \left[x_i(\ln(x_i) - \ln(\bar{x}_i) - 1) + \bar{x}_i \right], \tag{3}$$

where $\bar{x}$ is the unique equilibrium of a given positive stoichiometric compatibility class. It turns out that the function V "almost" acts as a global Lyapunov function. That is, V is nonnegative for $x \in (\bar{x}+S)\cap\mathbb{R}^m_{>0}$, zero only at $\bar{x}$, and strictly decreasing along trajectories. However, V does not tend to infinity as trajectories near the boundary of $(\bar{x}+S)\cap\mathbb{R}^m_{>0}$, and without such unboundedness one cannot, in general, conclude global stability. It has been shown in numerous papers, however, that global stability of $\bar{x}$ does hold if there are no equilibria on the boundary of $(\bar{x}+S)\cap\mathbb{R}^m_{>0}$ [15, 2, 13, 14]. Therefore, work has been done giving sufficient conditions for the nonexistence of boundary equilibria in order to conclude that the equilibrium value within each compatibility class is globally stable relative to its class [2, 13, 14].

To each subset W of the set of species, the set of points L_W is defined to be

$$L_W = \{x \in \mathbb{R}^m : x_i = 0 \Leftrightarrow X_i \in W\}. \tag{4}$$

We will show that there are no boundary equilibria if and only if

$$[(c+S)\cap\mathbb{R}^m_{\geq 0}] \cap L_W = \emptyset \tag{5}$$

for all $c \in \mathbb{R}^m_{>0}$ and for certain subsets of the species, W. We will then prove that global stability holds if the intersection given in (5) is either empty or discrete for each $c \in \mathbb{R}^m_{>0}$ and those same subsets, W. This will imply that global stability holds even if there are boundary equilibria, so long as the boundary equilibria are extreme points of the positive stoichiometric compatibility classes. To the best of our knowledge there is only one other result concerning the global stability of mass action systems with boundary equilibria, and this is contained within the Ph.D. thesis of Chavez [6]. In order to guarantee global stability even if there exist boundary equilibria, Chavez requires that each boundary equilibrium be hyperbolic with respect to its stoichiometric compatibility class, and she requires another (more technical) condition on the stable subspaces of each boundary equilibrium (see [6, pg. 106] for details). As our results are applicable to systems with boundary equilibria that are nonhyperbolic, our results can be viewed as an extension of those in [6].

The layout of the paper is as follows. In section 2 we will introduce the systems we consider in this paper: weakly reversible, deficiency zero systems with mass action kinetics. We will then present some preliminary results and conclude with a proof that global stability follows if there are no equilibria on the boundary of the positive stoichiometric compatibility classes. No originality is claimed for this result as it is known. Also in section 2 we demonstrate how the "no boundary equilibria" assumption is equivalent to (5) holding for all $c \in \mathbb{R}^m_{>0}$ and certain subsets of the species, W. In section 3 we extend the previous theorems to prove that global stability still holds if the intersection given in (5) is always either empty *or* discrete for those same subsets, W. We also show in section 3 how the hypothesis that the intersection in (5) is always empty or discrete is equivalent to a condition on the extreme points of the nonnegative stoichiometric compatibility classes. In section 4, we demonstrate our results on a number of examples. Finally, in section 5 we sketch how to extend our results to systems with non-mass action kinetics.

2. Preliminary results.

We start with definitions taken from [12, 8, 9].

DEFINITION 2.1. *A chemical reaction network, $\{\mathcal{S}, \mathcal{C}, \mathcal{R}\}$, is called* weakly reversible *if for any reaction $y \to y'$, there is a sequence of directed reactions beginning with y' and ending with y. That is, there exist complexes $y_1, \dots, y_k$ such that the following reactions are in $\mathcal{R}$: $y' \to y_1$, $y_1 \to y_2, \dots, y_k \to y$.*

To each reaction network, $\{\mathcal{S}, \mathcal{C}, \mathcal{R}\}$, there is a unique, directed graph constructed in the following manner. The nodes of the graph are the complexes, $\mathcal{C}$. A directed edge is then placed from complex y to complex y' if and only if $y \to y' \in \mathcal{R}$. Each connected component of the resulting graph is termed a *linkage class* of the graph. We denote the number of linkage classes by l.

As shown in the introduction, each trajectory remains in its stoichiometric compatibility class for all time. There is another restriction on the trajectories of solutions to (1) that is given in the following lemma. The proof can be found in both [15] and [1].

LEMMA 2.2. *Let $x(t)$ be a solution to* (1) *with initial condition $x(0) \in \mathbb{R}^m_{>0}$. Then, $x(t) \in \mathbb{R}^m_{>0}$ for all $t > 0$.*

2.1. Persistence and ω-limit points.

By Lemma 2.2, each trajectory must remain within $\mathbb{R}^m_{>0}$ if its initial condition is in $\mathbb{R}^m_{>0}$; therefore the linear subsets of interest are the intersections of the stoichiometric compatibility classes and $\mathbb{R}^m_{>0}$. Recall that in the introduction these sets were termed the positive stoichiometric compatibility classes. This paper will mainly be concerned with showing that trajectories to systems given by (1) remain away from the boundaries of the positive stoichiometric compatibility classes. That is, we will show that the systems are *persistent.* To be precise, let $\phi(t,\xi)$ be the solution to (1) with initial condition $\xi \in \mathbb{R}^m_{>0}$. The set of ω-limit points of the trajectory is

$$\omega(\xi) \doteq \{x \in \mathbb{R}^m_{\geq 0} : \phi(t_n,\xi) \to x, \text{ for some } t_n \to \infty\}. \tag{6}$$

Definition 2.3. *A system is* persistent *if* $\omega(\xi) \cap \partial\mathbb{R}^m_{>0} = \emptyset$ *for each* $\xi \in \mathbb{R}^m_{>0}$.

We refer the reader to [4, 3, 5, 16] for some of the history and usage of the notion of persistence in the study of dynamical systems. In order to show that a chemical system is persistent, it is critical to understand which points on the boundary are capable of being ω-limit points. With that in mind, we introduce the following definition.

Definition 2.4. *A nonempty subset W of the set of species is called a* semilocking set *if for each reaction in which there is an element of W in the product complex, there is an element of W in the reactant complex. W is called a* locking set *if every reactant complex contains an element of W.*

Locking and semilocking sets are easily understood. First suppose that $W \subset \{X_1,\dots,X_m\}$ is a locking set. Then, because every reactant complex contains an element of W, if the concentration of each element of W is zero, each kinetic function, $R_{y\to y'}$, must equal zero. Therefore, all of the fluxes are zero, and $\dot{x}(t) = 0$. We therefore see that the system is "locked" in place. Now suppose W is a semilocking set. If the concentration of each element of W is zero, then any flux which affects the species of W is turned off, and the elements of W are "locked" at zero. Semilocking sets have another, important, interpretation in terms of the linkage classes and weak reversibility. If the concentrations of the elements of a semilocking set are equal to zero and the system is weakly reversible, then all of the fluxes of any linkage class with a complex containing an element of W are equal to zero (and so these linkage classes are "locked"), while the fluxes of the other linkage classes are not necessarily equal to zero. Therefore, the concept of a semilocking set and a locking set are equivalent for systems that are weakly reversible and have only one linkage class. We note that our notion of a semilocking set is analogous to the concept of a *siphon* in the theory of Petri nets. See [2] for a full discussion, including historical references, of the role of Petri nets in the study of chemical reaction networks.

The following theorem now characterizes the boundary points that have the capability of being ω-limit points of the system. This result was first proved in [2]; however, the proof given here is completely different and straightforward.

Theorem 2.5. *Let W be a nonempty subset of the species. If there exists a $\xi \in \mathbb{R}^m_{>0}$ such that $\omega(\xi) \cap L_W \neq \emptyset$, then W is a semilocking set.*

Proof. Suppose, in order to find a contradiction, that there is a $\xi \in \mathbb{R}^m_{>0}$ and a subset of the species, W, such that $\omega(\xi) \cap L_W \neq \emptyset$ and W is not a semilocking set. Let $y \in \omega(\xi) \cap L_W$. We note that there exists a species X_j, with $X_j \in W$, such that at least one input to X_j (term in f_j of (1) with a positive coefficient) is nonzero if the concentrations are given by y, for otherwise W would be a semilocking set. Therefore, because all outputs from species X_j (terms in f_j with a negative coefficient) are zero at y, there exist $\epsilon > 0$ and $k > 0$ such that if $x(t) \in \mathbb{R}^m_{>0} \cap B_\epsilon(y)$, then

$$f_j(x(t)) = x_j'(t) > k, \tag{7}$$

where $B_\epsilon(y) = \{x : |x-y| < \epsilon\}$.

Because $f(\cdot)$ is C^1, we have $\|f\|_{\infty,loc} < M$ for some $M > 0$, and this bound is valid in $\mathbb{R}^m_{>0} \cap B_\epsilon(y)$. Therefore, for any $0 < a < b$, if $x(t) \in \mathbb{R}^m_{>0} \cap B_\epsilon(y)$ for $t \in (a,b)$, we have that

$$|x(b) - x(a)| = \left| \int_a^b f(x(s))ds \right| \leq (b-a)M. \tag{8}$$

Now consider a partial trajectory starting on the boundary of $\mathbb{R}^m_{>0} \cap B_\epsilon(y)$ at time t_ϵ, ending on the boundary of $\mathbb{R}^m_{>0} \cap B_{\epsilon/2}(y)$ at time $t_{\epsilon/2}$, and remaining within that annulus for all time in $(t_\epsilon, t_{\epsilon/2})$. Note that one such partial trajectory must exist every time we enter $\mathbb{R}^m_{>0} \cap B_{\epsilon/2}(y)$, and this happens at least once by our assumption that $y \in \omega(\xi) \cap L_W$. By (8), $t_{\epsilon/2} - t_\epsilon \geq \epsilon/(2M)$. On the other hand, by (7), $x_j'(t) > k$ for $t \in (t_\epsilon, t_{\epsilon/2})$. Therefore,

$$\begin{aligned} x_j(t_{\epsilon/2}) &= x_j(t_\epsilon) + \int_{t_\epsilon}^{t_{\epsilon/2}} x_j'(s)ds \\ &\geq x_j(t_\epsilon) + \epsilon k/(2M) \\ &\geq \epsilon k/(2M). \end{aligned}$$

Combining the above with the fact that we still have $x_j'(t) > k$ on $\mathbb{R}^m_{>0} \cap B_{\epsilon/2}(y)$, we see that there cannot exist times t_n such that $x(t_n) \to y$, as $n \to \infty$. This is a contradiction and completes the proof. □

Remark. Theorem 2.5 is a powerful tool for understanding the dynamics of chemical reaction systems. We see that in order to prove that a chemical system is persistent, it is sufficient to show that $[(c+S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W = \emptyset$ for all $c \in \mathbb{R}^m_{>0}$ and all semilocking sets W. We will show in Lemma 2.8 that for many reaction systems such a condition is equivalent to having no equilibria on the boundaries of the positive stoichiometric compatibility classes.

2.2. Deficiency and the deficiency zero theorem. We require one more definition before we can state precisely the types of systems we consider in this paper.

Definition 2.6. *The* deficiency, *δ, of a reaction network $\{\mathcal{S}, \mathcal{C}, \mathcal{R}\}$ is given by $\delta = n - l - s$, where n is the number of complexes of the system, l is the number of linkage classes, and $s = dim S$, the dimension of the stoichiometric subspace.*

Remark. It has been shown that the deficiency of a reaction network is a nonnegative number. In fact, the deficiency is the dimension of a certain subspace associated with the system. See [9, 10, 8] for details.

The main types of systems considered in this paper are those with mass action kinetics that are weakly reversible and have a deficiency of zero. The following theorem by Feinberg [8, 10] is the catalyst for studying such systems. The proof can be found in [8] or [10].

Theorem 2.7 (the deficiency zero theorem). *Consider a system of the form* (1) *with mass action kinetics that is weakly reversible and has a deficiency of zero. Then, within each positive stoichiometric compatibility class there is precisely one equilibrium value, and it is locally asymptotically stable relative to its compatibility class.*

In order to prove that the systems considered in the deficiency zero theorem have equilibria that are locally asymptotically stable relative to their compatibility classes, the Lyapunov function (3) is used. It is shown that for $x \in (\bar{x} + S) \cap \mathbb{R}^m_{>0}$ (where $\bar{x}$ is the equilibrium guaranteed to exist by Theorem 2.7), $V(x) \geq 0$ with equality if and only if $x = \bar{x}$, and that $dV(x(t))/dt < 0$ for all trajectories with initial condition in $(\bar{x}+S) \cap \mathbb{R}^m_{>0}$. We will make use of these facts throughout the paper without reference; however, we point the interested reader to the original works [8, 10] for details.

2.3. Boundary equilibria. The following lemma shows that for weakly reversible, mass action systems with a deficiency of zero, having no equilibria on the boundaries of the positive stoichiometric compatibility classes is equivalent to $[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W=\emptyset$ for all $c\in\mathbb{R}^m_{>0}$ and semilocking sets W. Following Lemma 2.8 we present a theorem pertaining to any system equipped with a globally defined Lyapunov function that does not necessarily go to infinity as x goes to the boundary of the domain. We then use these results in combination with Theorem 2.5 to conclude that for weakly reversible, deficiency zero systems with mass action kinetics, having no equilibria on the boundaries of the positive stoichiometric compatibility classes implies global stability of the equilibrium values given by Theorem 2.7. We again note that it is already known that global asymptotic stability follows from a lack of boundary equilibria. For example, in [15] Sontag showed that all trajectories must converge to the set of equilibria, and so a lack of boundary equilibria implies convergence to the unique equilibrium in the interior of the positive stoichiometric compatibility class. We rederive this result here because our methods put it in a larger context in which global stability is understood through the intersections given in (5) and because it makes clear how our results in section 3 are truly a generalization of this fact.

LEMMA 2.8. *For any chemical reaction system, the set of equilibria on the boundaries of the positive stoichiometric compatibility classes is contained in* $\bigcup_c\bigcup_W[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W$, *where the first union is over* $c\in\mathbb{R}^m_{>0}$ *and the second union is over the semilocking sets. Further, if there are no equilibria on the boundaries of the positive stoichiometric compatibility classes for a weakly reversible, deficiency zero system with mass action kinetics, then* $[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W=\emptyset$ *for all* $c\in\mathbb{R}^m_{>0}$ *and semilocking sets* W.

Proof. Let y be an equilibrium on the boundary of a positive stoichiometric compatibility class. Let W be the set of species with a concentration of zero at y. Because each complex that contains an element of W is providing zero flux, in order for y to be an equilibrium value each reaction in which there is an element of W in the product complex must have an element of W in the reactant complex. Thus, W is a semilocking set and $y\in[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W$ for some $c\in\mathbb{R}^m_{>0}$.

In order to prove the second part of the lemma, we suppose W is a semilocking set for the system and suppose $y\in[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W$ for some $c\in\mathbb{R}^m_{>0}$. We will now produce an equilibrium value on the boundary of $(c+S)\cap\mathbb{R}^m_{>0}$. If $W=\mathcal{S}$, $y=\vec{0}$, and, because W is a semilocking set, y is an equilibrium. Otherwise, consider the system consisting only of those species not in the semilocking set W. By the arguments in [10], the linkage classes not "locked" by W form their own weakly reversible, deficiency zero system. Therefore, there is an equilibrium value with strictly positive components for that reduced system, $\bar{z}$. Let $\bar{y}=(\bar{z},\vec{0})$ (where we have potentially rearranged the ordering of the species so that those not in the semilocking set came first). $\bar{y}$ is a boundary equilibrium value to our original system. Therefore, the result is shown. □

THEOREM 2.9. *Let* $x(t)=x(t,x(0))$ *be the solution to* $\dot{x}=g(x)$ *with initial condition* $x(0)$, *where* g *is* C^1 *and the domain of definition of the system is the open set* $C\subset\mathbb{R}^m$. *Let* $\bar{x}\in C$ *be the unique equilibrium value to the system. Finally, suppose that there is a globally defined Lyapunov function* V *that satisfies the following:*

1. $V(x)\geq 0$ *with equality if and only if* $x=\bar{x}$.
2. $dV(x(t))/dt\leq 0$ *with equality if and only if* $x(t)=\bar{x}$.
3. $V(x)\to\infty$, *as* $|x|\to\infty$.

Then either $x(t)\to\bar{x}$ *or* $x(t)\to\partial C$.

Proof. Suppose that $x(t) \nrightarrow \bar{x}$. Because $V(\cdot)$ decreases along trajectories, the value $V(x(t))$ is bounded above by $V(x(0))$ for all $t > 0$. Therefore, because $V(x) \to \infty$ as $|x| \to \infty$, $x(t)$ remains bounded for all $t > 0$. Also, the local asymptotic stability of $\bar{x}$ combined with the fact that $x(t) \nrightarrow \bar{x}$ implies there is a $\rho > 0$ such that $|x(t) - \bar{x}| > \rho$ for all $t > 0$.

Let $\epsilon > 0$ and for $x \in C$ let $d(x, \partial C)$ represent the distance from x to the boundary of C. Let $C_\epsilon = \{x \in C \mid d(x, \partial C) \geq \epsilon \text{ and } |x - \bar{x}| \geq \rho\}$. Using that trajectories remain bounded for all time, we may use the continuity of the functions ∇V and g to conclude that there is a positive number $\eta = \eta(\epsilon)$ such that $\nabla V(x) \cdot g(x) < -\eta$ for all $x \in C_\epsilon$. Therefore, the amount of time that any trajectory spends in the set C_ϵ is bounded above by $V(x(0))/\eta$ (for, otherwise, $x(t) \to \bar{x}$). Because $\epsilon > 0$ was arbitrary we see that $x(t) \to \partial C$. □

COROLLARY 2.10. *If there are no equilibria on the boundaries of the positive stoichiometric compatibility classes for a weakly reversible deficiency zero system with mass action kinetics, then the unique positive equilibrium value within each positive stoichiometric compatibility class is globally asymptotically stable relative to its compatibility class.*

Proof. Trajectories are bounded because of the existence of the Lyapunov function (3). Combining this fact with Theorems 2.5 and 2.9 and Lemma 2.8 completes the proof. □

3. Main results. By Lemma 2.8, we see that the no boundary equilibria assumption for weakly reversible deficiency zero systems with mass action kinetics is equivalent to the assumption that $[(c + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W = \emptyset$ for all $c \in \mathbb{R}^m_{>0}$ and all semilocking sets W. This then implies global stability by Corollary 2.10. We will extend these results by proving that global stability holds if $[(c + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$ is empty *or* discrete for each $c \in \mathbb{R}^m_{>0}$ and each semilocking set W. The following definition is necessary.

DEFINITION 3.1. *For a vector $x \in \mathbb{R}^m$, the* support *of x, denoted* $\text{supp}(x)$*, is the subset of the species such that $X_i \in \text{supp}(x)$ if and only if $x_i \neq 0$.*

PROPOSITION 3.2. *Let $\{\mathcal{S}, \mathcal{C}, \mathcal{R}\}$ be a weakly reversible, deficiency zero, mass action chemical reaction system with dynamics given by* (1). *Suppose that $y \in \omega(x(0))$ for some $x(0) \in \mathbb{R}^m_{>0}$. Then there must exist a nonzero $z_0 \in S$ with* $\text{supp}(z_0) \subset \text{supp}(y)$.

Proof. If $y \in \mathbb{R}^m_{>0}$, there is nothing to show. Therefore, assume that y is on the boundary of the positive stoichiometric compatibility class. By Theorem 2.5, there is a semilocking set W such that $y \in [(x(0) + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$.

Let $V(x) : \mathbb{R}^m_{>0} \to \mathbb{R}$ be given by (3), and let

$$V_i(x_i) = x_i(\ln(x_i) - \ln(\bar{x}_i) - 1) + \bar{x}_i,$$

so that $V(x) = \sum_{i=1}^m V_i(x_i)$. Reordering the species if necessary, we suppose $W = \{X_1, \dots, X_d\}$. Choose $\rho > 0$ so small that for each $i \leq d$, $x_i < \rho \Longrightarrow \ln(x_i) - \ln(\bar{x}_i) < 0$. Let $\epsilon > 0$ satisfy $\epsilon < \rho$. Let t_ϵ be a time such that $x_i(t_\epsilon) \leq \epsilon$ for all $i \leq d$ and $|x_j(t_\epsilon) - y_j| < \epsilon$ for all $j \geq d + 1$. Let $T_\epsilon = \min\{t > t_\epsilon : |x_i(t) - y_i| \leq x_i(t_\epsilon)/2 \text{ for all } i \leq m\}$. We know such t_ϵ and T_ϵ exist because y is an ω-limit point of the system. Note that $T_\epsilon > t_\epsilon$ and that for each $i \leq d$, $x_i(T_\epsilon) < x_i(t_\epsilon)$. We consider how $V(x(t))$ changes from time t_ϵ to time T_ϵ. Applying the mean value theorem to each $V_i(\cdot)$ term gives

$$V(x(T_\epsilon)) - V(x(t_\epsilon)) = \sum_{i=1}^{m} V_i(x_i(T_\epsilon)) - V_i(x_i(t_\epsilon)) \tag{9}$$

$$\begin{aligned} &= \sum_{i=1}^{d} (\ln(\tilde{x}_i) - \ln(\bar{x}_i))(x_i(T_\epsilon) - x_i(t_\epsilon)) \\ &\quad + \sum_{i=d+1}^{m} (\ln(\tilde{x}_i) - \ln(\bar{x}_i))(x_i(T_\epsilon) - x_i(t_\epsilon)) \end{aligned} \tag{10}$$

for some $\tilde{x}_i \in [x_i(T_\epsilon), x_i(t_\epsilon)]$. Recalling that V decreases along trajectories of $x(t)$ by Theorem 2.7, we have $V(x(T_\epsilon)) - V(x(t_\epsilon)) < 0$. Note that because for $j \geq d+1$ we have $|\tilde{x}_j - y_j| < \epsilon$, there are positive constants c_j such that $c_j > |\ln(\tilde{x}_j) - \ln \bar{x}_j|$, and that bound is valid *for any* $\epsilon < \rho$. Let $C = \sum_{j=d+1}^{m} c_j$.

By our choices above, we know that for each $i \in \{1, \ldots, d\}$ the following inequalities hold:

1. $\ln(\tilde{x}_i) - \ln(\bar{x}_i) < 0$.
2. $x_i(T_\epsilon) - x_i(t_\epsilon) < 0$.

Therefore, each piece of the first sum in (10) is strictly positive. Thus, to ensure that V is decreasing along this trajectory, the second sum in (10) must be negative and, letting $\Delta x_i = x_i(T_\epsilon) - x_i(t_\epsilon)$ for each i, we have

$$\begin{aligned} \sum_{i=1}^{d} (\ln(\tilde{x}_i) - \ln(\bar{x}_i))\, \Delta x_i &< \left| \sum_{j=d+1}^{m} (\ln(\tilde{x}_j) - \ln(\bar{x}_j))\, \Delta x_j \right| \\ &\leq \sum_{j=d+1}^{m} c_j |\Delta x_j|. \end{aligned} \tag{11}$$

In fact, because each term on the left-hand side of (11) is positive, a similar inequality must hold for each $i = 1, \ldots, d$. That is, for $i \leq d$

$$(\ln(\tilde{x}_i) - \ln(\bar{x}_i))\Delta x_i \leq \sum_{j=d+1}^{m} c_j |\Delta x_j|.$$

For each $i \leq d$, $\tilde{x}_i \in [x_i(T_\epsilon), x_i(t_\epsilon)]$ and $x_i(T_\epsilon), x_i(t_\epsilon) < \epsilon$. Hence, letting $|\ln \bar{x}_i| = k_i$, we have that for each $i \leq d$

$$|\ln(\tilde{x}_i) - \ln(\bar{x}_i)| \geq |\ln \epsilon| - k_i.$$

Thus, for each $i = 1, \ldots, d$,

$$|\Delta x_i| \leq \frac{1}{|\ln \epsilon| - k_i} \sum_{j=d+1}^{m} c_j |\Delta x_j|.$$

Let $\Delta_{max} = \sup_{j \in \{d+1,\ldots,m\}} \{|\Delta x_j|\}$ and $\delta(\epsilon) = \sup_{i \in \{1,\ldots,d\}} (|\ln \epsilon| - k_i)^{-1}$. We know $\Delta_{max} \neq 0$ because if it were equal to zero, then the right-hand side of (11) would be zero, which it cannot be as it is strictly larger than the left-hand side. Combining the above shows that for each $i = 1, \ldots, d$,

$$|\Delta x_i| \leq \delta(\epsilon) C \Delta_{max}.$$

Now we consider the vector $\Delta x = x(T_\epsilon) - x(t_\epsilon) \in S$. Normalizing the vector Δx by dividing each entry by Δ_{max} then produces a vector $v(\epsilon) \doteq \frac{1}{\Delta_{max}} \Delta x$ with the following properties:

1. $v(\epsilon) \in S$.
2. For $i = 1, \dots, d$, $|v_i(\epsilon)| \leq \delta(\epsilon)C$.
3. There is at least one entry in $v(\epsilon)$ with norm 1 (the one for which the maximum in the definition of Δ_{max} was achieved), and none has a higher norm.
4. $1 \leq |v(\epsilon)| \leq m$.

Property 4 follows from property 3. $\epsilon > 0$ was arbitrary, so we may consider a sequence $\{\epsilon_n\}$ such that $\epsilon_n > \epsilon_{n+1}$ and $\epsilon_n \to 0$. For each ϵ_n we may redo the work above. This leads to a sequence of vectors $\{v(\epsilon_n)\}$ and a sequence of numbers $\{\delta(\epsilon_n)\}$ such that $\delta(\epsilon_n) \to 0$ and for each n all four properties above hold. Because each vector from the sequence $\{v(\epsilon_n)\}$ is contained in the compact space $\{v : 1 \leq |v| \leq m\} \cap S$, there is a convergent subsequence $\{v(\epsilon_{n_k})\}$ and a vector z_0 such that $v(\epsilon_{n_k}) \to z_0 \in \{v : 1 \leq |v| \leq m\} \cap S \subset S$, as $k \to \infty$. Note that z_0 cannot be the zero vector because $|z_0| > 1$. However, $\delta(\epsilon_{n_k}) \to 0$, and so the first d components of z_0 are equal to zero. Hence, $\text{supp}(z_0) \subset \text{supp}(y)$. □

We now present our main result.

Theorem 3.3. *Let $\{\mathcal{S}, \mathcal{C}, \mathcal{R}\}$ be a weakly reversible, deficiency zero, mass action chemical reaction system with dynamics given by* (1). *Suppose that for each $c \in \mathbb{R}^m_{>0}$ and each semilocking set W, the set $[(c+S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$ is either empty or discrete. Then the unique positive equilibrium of each stoichiometric compatibility class guaranteed to exist by the deficiency zero theorem is globally asymptotically stable relative to its compatibility class.*

Proof. We suppose, in order to find a contradiction, that there is a positive equilibrium, $\bar{x}$, that is not globally asymptotically stable relative to its compatibility class. By Theorems 2.5, 2.7, and 2.9, there is a semilocking set W, a $\xi \in \mathbb{R}^m_{>0}$, and a vector y such that $y \in [(\bar{x} + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$ and $y \in \omega(\xi)$. By Proposition 3.2, there exists a nonzero $z_0 \in S$ such that $\text{supp}(z_0) \subset \text{supp}(y)$. Because $y \in \bar{x} + S$ and $z_0 \in S$, for any $\eta > 0$ we have $y + \eta z_0 \in \bar{x} + S$. Further, because $\text{supp}(z_0) \subset \text{supp}(y)$, if η is small enough, we have that $y + \eta z_0 \in \mathbb{R}^m_{\geq 0} \cap L_W$. But this is valid for all η small enough, and so $[(\bar{x} + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$ is not discrete. This is a contradiction, and so the result is shown. □

Remark. In the chemistry literature there is a notion of an equilibrium value being *complex balanced*. Briefly, an equilibrium value is complex balanced if, at equilibrium, the total flux out of any complex is equal to the total flux into that complex. The conclusion of the deficiency zero theorem, including the existence of the Lyapunov function (3), holds so long as there is at least one equilibrium in the positive orthant that is complex balanced [8, 11]. The deficiency zero theorem gives a simple and checkable condition ($\delta = 0$) on the network structure alone that guarantees that a system has a complex balanced equilibrium for any choice of rate constants. We therefore note that the conclusion of Theorem 3.3 holds for any mass action system that has a complex balanced equilibrium in the positive orthant and for which $[(c + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$ is either empty or discrete for each $c \in \mathbb{R}^m_{>0}$ and semilocking set W.

Corollary 3.4. *Suppose that for a weakly reversible, deficiency zero, chemical reaction system with mass action kinetics, each semilocking set is a locking set. Suppose further that within each stoichiometric compatibility class, the set of equilibria on the boundary is discrete. Then the unique positive equilibrium of each stoichiometric compatibility class guaranteed to exist by the deficiency zero theorem is globally asymptotically stable relative to its compatibility class.*

Proof. Because each semilocking set is a locking set, the set of boundary equilibria for a given compatibility class is precisely given by $\bigcup_W [(c + S) \cap \mathbb{R}^m_{\geq 0}] \cap L_W$, where the union is over the set of semilocking sets. Therefore, each $[(c+S)\cap\mathbb{R}^m_{\geq 0}]\cap L_W$ is discrete, and invoking Theorem 3.3 completes the proof. □

Corollary 3.5. *Suppose that a weakly reversible, deficiency zero, chemical reaction system with mass action kinetics has only one linkage class. Suppose further that within each stoichiometric compatibility class, the set of equilibria on the boundary is discrete. Then the unique positive equilibrium of each stoichiometric compatibility class guaranteed to exist by the deficiency zero theorem is globally asymptotically stable relative to its compatibility class.*

Proof. For single linkage class systems that are weakly reversible, each semilocking set is a locking set. Using Corollary 3.4 completes the proof. □

3.1. Connection with extreme points.

We connect our results to a condition on the extreme points of the positive stoichiometric compatibility classes.

Proposition 3.6. *For $y\in\mathbb{R}^m_{\geq 0}$, let $W=\{X_i : y_i=0\}=\operatorname{supp}(y)^C$. Then the following are equivalent:*

(i) *y is an extreme point of $(y+S)\cap\mathbb{R}^m_{\geq 0}$.*

(ii) *$\left[(y+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W=\{y\}$.*

Proof. (i) $\Longrightarrow$ (ii). Suppose that (i) is true, but (ii) is not. Then, because $\left[(y+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W$ is not discrete, there exists a $v\in S\bigcap L_W$ such that for sufficiently small ϵ, $y\pm\epsilon v\in\left[(y+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W$. Noting that $y=(1/2)(y+\epsilon v)+(1/2)(y-\epsilon v)$ then shows that y is not an extreme point of $(y+S)\cap\mathbb{R}^m_{\geq 0}$, which is a contradiction.

(ii) $\Longrightarrow$ (i). Suppose that (ii) is true, but (i) is not. Because y is not an extreme point of $(y+S)\cap\mathbb{R}^m_{\geq 0}$, there exist nonzero vectors $v_1\neq y$, $v_2\neq y$ in $(y+S)\bigcap\mathbb{R}^m_{\geq 0}$ and $0<\lambda<1$ such that

$$y=\lambda v_1+(1-\lambda)v_2. \tag{12}$$

Because $v_1,v_2\in(y+S)\bigcap\mathbb{R}^m_{\geq 0}$, there exist $u,w\in S$ such that $v_1=y+u$ and $v_2=y+w$, and $u_i,w_i\geq 0$ if $X_i\in W$. However, because $\lambda, 1-\lambda>0$, we see by (12) that $u_i,w_i=0$ for all $X_i\in W$. Therefore, $v_1,v_2\in\left[(y+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W$, contradicting (ii). □

Theorem 3.3 can now be reformulated in the following way.

Theorem 3.7. *Let $\{\mathcal{S},\mathcal{C},\mathcal{R}\}$ be a weakly reversible, deficiency zero, mass action chemical reaction system with dynamics given by* (1). *For any boundary point $y\in[(c+S)\cap\mathbb{R}^m_{\geq 0}]$ of a positive stoichiometric compatibility class, let $W_y=\{X_i : y_i=0\}=\operatorname{supp}(y)^C$. Finally, suppose that W_y is a semilocking set only if y is an extreme point. Then the unique positive equilibrium of each stoichiometric compatibility class guaranteed to exist by the deficiency zero theorem is globally asymptotically stable relative to its compatibility class.*

Proof. Suppose W is a semilocking set. Let $y\in L_W$ be such that there exists a $c\in\mathbb{R}^m_{>0}$ with $y\in c+S$. If no such y and c exist, then $[(c+S)\bigcap\mathbb{R}^m_{\geq 0}]\bigcap L_W=\emptyset$ for all $c\in\mathbb{R}^m_{>0}$. If such a y and c do exist, then $W=W_y$ and, by assumption, y is an extreme point. Thus, by Proposition 3.6, $\left[(y+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W=\left[(c+S)\bigcap\mathbb{R}^m_{\geq 0}\right]\bigcap L_W$ is discrete. Invoking Theorem 3.3 completes the proof. □

4. Examples.

We begin with an example found in [6] for a receptor-ligand model. See [6] for full details.

Example 4.1. Consider the following system, which we assume has mass action kinetics:

$$\begin{tikzcd} 2A+C \arrow[r, shift left] \arrow[d, shift left] & A+D \arrow[l, shift left] \arrow[d, shift left] \\ B+C \arrow[u, shift left] \arrow[r, shift right] & E \arrow[l, shift right] \arrow[u, shift left] \end{tikzcd} . \tag{13}$$

For this example there are four complexes and one linkage class, and the dimension of the stoichiometric compatibility class is easily verified to be three. Therefore, the system has a deficiency of zero, and our results apply. The minimal semilocking sets (that is, those that must be contained in all others) are given by $W_1 = \{A, B, E\}$, $W_2 = \{A, C, E\}$, and $W_3 = \{C, D, E\}$. Therefore, showing that the set $\bigcup_{i=1}^{3} [(c + S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_i}$ is discrete for any $c \in \mathbb{R}^5_{>0}$ would also show that the sum over all semilocking sets is discrete. For this example, it is easily verified that

$$S = \text{Span}\left\{ \begin{bmatrix} 1 \\ 0 \\ 0 \\ 1 \\ -1 \end{bmatrix}, \begin{bmatrix} 0 \\ 1 \\ 0 \\ 2 \\ -2 \end{bmatrix}, \begin{bmatrix} 0 \\ 0 \\ 1 \\ -2 \\ 1 \end{bmatrix} \right\}. \tag{14}$$

One method to show that for a given i the set $[(c+S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_i}$ is at most discrete is to demonstrate that there are no nonzero vectors contained in S with support given by W_i^C. This method bypasses the need to check whether the intersection $[(c + S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_i}$ is nonempty. It is easily verified that there are no nonzero vectors contained in S with support given by W_1^C or W_2^C. In [6] it is shown that for each $c \in \mathbb{R}^5_{>0}$, $(c + S) \cap \mathbb{R}^5_{\geq 0}$ does intersect one of L_{W_1} or L_{W_2}. Therefore, there are always equilibria on the boundary; however, by our results or those found in [6], they will not affect the global stability of the interior equilibria.

Let $U_3 = \{x \in \mathbb{R}^5 \mid \text{supp}(x) \in W_3^C\}$. It is easy to show that $U_3 \bigcap S = \text{span}\{[2, -1, 0, 0, 0]^T\}$. Thus, the method used in the previous paragraph does not work. Therefore, for our results to apply, we need to verify that $[(c+S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_3} = \emptyset$ for any $c \in \mathbb{R}^5_{>0}$. Because L_{W_3} is characterized by having the last three entries equal to zero, in order to prove that $[(c+S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_3} = \emptyset$ for any $c \in \mathbb{R}^5_{>0}$, it is sufficient to show that the space spanned by the last three components of the vectors in (14) does not contain a vector with strictly negative components. We have

$$\text{Span}\left\{ \begin{bmatrix} 0 \\ 1 \\ -1 \end{bmatrix}, \begin{bmatrix} 0 \\ 2 \\ -2 \end{bmatrix}, \begin{bmatrix} 1 \\ -2 \\ 1 \end{bmatrix} \right\} = \text{Span}\left\{ \begin{bmatrix} 0 \\ -1 \\ 1 \end{bmatrix}, \begin{bmatrix} 1 \\ -1 \\ 0 \end{bmatrix} \right\}, \tag{15}$$

which does not include a strictly negative vector. Thus, $[(c+S) \cap \mathbb{R}^5_{\geq 0}] \cap L_{W_3} = \emptyset$ for any $c \in \mathbb{R}^5_{>0}$. Combining all of the above with Theorem 3.3 shows that for any choice of rate constants and initial condition, the system (13) has a globally asymptotically stable equilibrium value.

Example 4.2. Consider the system

$$2A \quad \rightleftarrows \quad A + B \quad \rightleftarrows \quad B + C. \tag{16}$$

There are three complexes and one linkage class, and the dimension of the stoichiometric compatibility class is two. Therefore, the system (16) has a deficiency of zero. The minimal semilocking sets are $W_1 = \{A, B\}$ and $W_2 = \{A, C\}$. The stoichiometric subspace is of dimension two and the quantity $A+B+C$ is conserved. Thus, each stoichiometric compatibility class is a plane that intersects each of $L_{W_1} = \{v : v_1 = v_2 = 0, v_3 \neq 0\}$ and $L_{W_2} = \{v : v_1 = v_3 = 0, v_2 \neq 0\}$ in precisely one point. See Figure 4.1. Therefore, by Theorem 3.3, for any choice of rate constants and initial condition, the system (16) has a globally asymptotically stable equilibrium value. We note that it is easily verified that the eigenvalues of the linearized problem around the equilibria

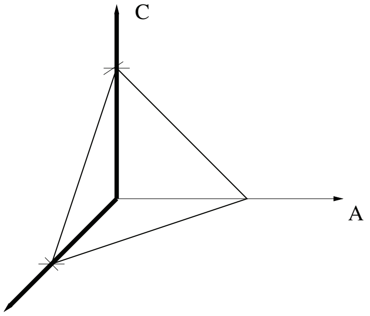

FIG. 4.1. *The stoichiometric compatibility class for the system* (16) *is a plane defined by the conservation law* $A+B+C=M$ *for some* $M>0$. *This plane intersects the sets* L_{W_1} *and* L_{W_2} *(bolded axes) each in precisely one point.*

associated with the semilocking set W_1 are all zero, and so the results of [6] do not apply here.

Example 4.3. Consider the system

$$2A \rightleftarrows A+B \qquad 2B \rightleftarrows A+C. \tag{17}$$

There are four complexes and two linkage classes, and the dimension of the stoichiometric compatibility class is two. Therefore, the system (17) has a deficiency of zero. The only minimal semilocking set is $W=\{A,B\}$, and this is also a locking set. The stoichiometric subspace is of dimension two, and the quantity $A+B+C$ is conserved. Thus, each stoichiometric compatibility class is a plane that intersects $L_W=\{v : v_1=v_2=0,\, v_3\neq 0\}$ in precisely one point. Therefore by Theorem 3.3 or Corollary 3.4, for any choice of rate constants and initial condition, the system (17) has a globally asymptotically stable equilibrium value. It is easily verified that the boundary equilibria are not hyperbolic with respect to their compatibility classes, and so the results of [6] do not apply in this case.

5. Non-mass action kinetics. In [15], Sontag extended the deficiency zero theorem to systems with non-mass action kinetics. He considered weakly reversible, deficiency zero system whose kinetic functions are given by

$$R_{y\to y'}(x)=k_{y\to y'}\theta(x_1)^{y_1}\cdots\theta(x_m)^{y_m}, \tag{18}$$

where the functions $\theta_i:\mathbb{R}\to[0,\infty)$ satisfy the following:

1. Each θ_i is locally Lipschitz.
2. $\theta_i(0)=0$.
3. $\int_0^1|\ln(\theta_i(y))|dy<\infty$.
4. The restriction of θ_i to $\mathbb{R}_{\geq 0}$ is strictly increasing and onto $\mathbb{R}_{\geq 0}$.

To prove the local asymptotic stability of the unique equilibrium within each stoichiometric compatibility class, the following Lyapunov function was used:

$$V(x)=\sum_{i=1}^{m}\int_{\bar{x}_i}^{x_i}\left(\rho_i(s)-\rho_i(\bar{x}_i)\right)ds, \tag{19}$$

where $\rho_i(s)=\ln\theta_i(s)$ and $\bar{x}$ is the unique equilibrium within the positive stoichiometric compatibility class. Note that $\theta(x)=|x|$ gives mass action kinetics, in which case the Lyapunov function given in (19) is the same as that in (3). The only dynamical property of the deficiency zero theorem used in this paper is that $\nabla V(x) \to -\infty$ as $x_i \to 0$. We note that for the Lyapunov function (19), we still have that property because

$$\nabla V(x) = \sum_{i=1}^{m} \rho_i(x_i) - \rho_i(\bar{x}_i),$$

and $\rho_i(x_i) = \ln \theta_i(x_i) \to -\infty$ as $x_i \to 0$ by the properties of $\theta_i(\cdot)$ given above. Therefore, our results in this paper, and in particular Theorem 3.3, Corollary 3.4, Corollary 3.5, and Theorem 3.7, are valid in the setting (18).

Acknowledgments. I would like to thank Gheorghe Craciun for several illuminating conversations pertaining to chemical reaction systems. I would also like to thank Martin Feinberg for pointing out the connection with extreme points.

VOLTAGE AND CURRENT EXCITATION FOR TIME-HARMONIC EDDY-CURRENT PROBLEMS[*]

ANA ALONSO RODRÍGUEZ[†] and ALBERTO VALLI[†]

Abstract. We give a systematic presentation of voltage or current intensity excitation for time-harmonic eddy-current problems. The key point of our approach resides in a suitable power law that permits us to understand the role of voltage excitation. We also shed light on the influence of the boundary conditions on the proposed formulations.

Key words. eddy-current problems, voltage excitation, current excitation, variational formulation, finite elements

1. Introduction and basic results.

In many electromagnetic phenomena it is useful to couple formulations in terms of electrical circuits with more general formulations based on Maxwell equations (or else on some reduced model like the eddy-current system).

This coupling is often performed by transforming some data like voltage or current intensity into suitable boundary conditions for the electromagnetic fields. In particular, it is interesting to devise efficient formulations of the eddy-current problem when the only excitation present is either an assigned voltage (typically, at contacts) or a given current intensity in the eddy-current region.

On the other hand, it is well known that the topological properties of the conductor and the type of boundary conditions imposed on the boundary of the computational domain have a strong influence on the general setting of the problem and on the structure of the solution.

Several possible approaches have been proposed in recent years, especially by engineers interested in practical computations. Let us mention only the contributions in [13], [22], [20], [21], [28], [29], [26], [19], [12], [23], [10], [8], and the references therein, though this list is far from complete.

In this paper we propose a systematic approach to eddy-current problems driven by voltage or current intensity. Our aim is to give a general mathematical formulation for these problems and to analyze their well-posedness. These theoretical results are then the basis for devising stable and convergent finite element approximation schemes.

A typical difficulty is that, in many situations, eddy-current problems are well-posed *even if* no additional condition like voltage or current intensity is imposed. As a consequence, to overcome this apparent contradiction it is necessary to focus on the modeling of the problem so that it becomes possible to impose the voltage or current intensity equation, but without giving up Maxwell equations (a flaw that was present in previous papers on this subject).

[†]Dipartimento di Matematica, Università di Trento, via Sommarive 14, I-38050 Povo (Trento), Italy (alonso@science.unitn.it, valli@science.unitn.it).

In the rest of this section we introduce notation and describe the problems we shall consider, and we present two basic results concerning well-posedness. In section 2 we discuss modeling, basing our argument on a global power law that relates voltage to current intensity. In the third section our proposal for treating voltage and current excitation problems is described. In section 4 we systematically present the variational formulations of these problems. Finally, the last section is devoted to giving a short description of some numerical approximation schemes based on finite elements.

In the following, for the sake of simplicity we assume that the domain $\Omega \subset \mathbb{R}^3$ is a simply connected bounded open set, with a connected boundary $\partial\Omega$. It is composed of two parts, a conductor Ω_C and an insulator Ω_I. The interface between Ω_C and Ω_I will be denoted by Γ. The unit outward normal vector on $\partial\Omega$ will be indicated by $\mathbf{n}$, while the unit normal vector on Γ, directed toward Ω_I, will be denoted by $\mathbf{n}_C = -\mathbf{n}_I$.

It is well known that (see, e.g., [15]) the time-harmonic eddy-current problem is given by Ampère and Faraday equations

$$\begin{aligned} \operatorname{curl} \mathbf{H} - \boldsymbol{\sigma}\mathbf{E} &= \mathbf{J}_e \quad \text{in } \Omega, \\ \operatorname{curl} \mathbf{E} + i\omega\boldsymbol{\mu}\mathbf{H} &= \mathbf{0} \quad \text{in } \Omega, \end{aligned}$$

where $\mathbf{H}$ and $\mathbf{E}$ are the magnetic and electric fields, respectively, $\mathbf{J}_e$ is the given electric current density, $\boldsymbol{\sigma}$ is the electric conductivity, $\boldsymbol{\mu}$ is the magnetic permeability, and $\omega \neq 0$ is a given angular frequency. Moreover, suitable boundary conditions have to be added (and also some conditions for the unique determination of the electric field in Ω_I). For a mathematical justification of the complete eddy-current model we refer the reader to [7] (see also [1], [18]).

Let us also note that the magnetic permeability $\boldsymbol{\mu}$ is assumed to be a symmetric tensor, uniformly positive definite in Ω, with entries in $L^\infty(\Omega)$. The same assumption holds for the dielectric coefficient $\boldsymbol{\epsilon}$ in Ω_I (this coefficient will come into play when imposing uniqueness conditions for $\mathbf{E}_I$), and for the electric conductivity $\boldsymbol{\sigma}$ in Ω_C; on the other hand, $\boldsymbol{\sigma}$ vanishes outside Ω_C.

We will distinguish between two different geometric situations and three different types of boundary conditions.

First geometric case: Electric ports. The conductor Ω_C is not strictly contained in Ω, namely, $\partial\Omega_C \cap \partial\Omega \neq \emptyset$. More precisely, for the sake of simplicity we assume that Ω_C is a simply connected domain with $\partial\Omega_C \cap \partial\Omega = \Gamma_E \cup \Gamma_J$, where Γ_E and Γ_J are connected and disjoint surfaces on $\partial\Omega$ ("electric ports"). Therefore, we have $\partial\Omega_C = \Gamma_E \cup \Gamma_J \cup \Gamma$. The boundary of the insulator Ω_I, which is connected, is given by $\partial\Omega_I = \Gamma_D \cup \Gamma$, where $\Gamma_D \subset \partial\Omega$. As a consequence, we have $\partial\Gamma = \partial\Gamma_D = \partial\Gamma_E \cup \partial\Gamma_J$ (see Figure 1, left).

Second geometric case: Internal conductor. The conductor Ω_C is strictly contained in Ω, namely, $\partial\Omega_C \cap \partial\Omega = \emptyset$. Moreover, for the sake of simplicity we assume that Ω_C is a torus-like domain. In this case, we simply have $\partial\Omega_C = \Gamma$ and $\partial\Omega_I = \partial\Omega \cup \Gamma$ (see Figure 1, right).

First set of boundary conditions. These are given by $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\partial\Omega$ for both the geometric cases.

Second set of boundary conditions. These are given by $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\Gamma_E \cup \Gamma_J$ and $\mathbf{H} \times \mathbf{n} = \mathbf{0}$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on Γ_D for the electric port case, and by $\mathbf{H} \times \mathbf{n} = \mathbf{0}$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on $\partial\Omega$ for the internal conductor case.

Third set of boundary conditions. These are given by $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\Gamma_E \cup \Gamma_J$, $\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on Γ_D for the electric port case, and by $\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on $\partial\Omega$ for the internal conductor case.

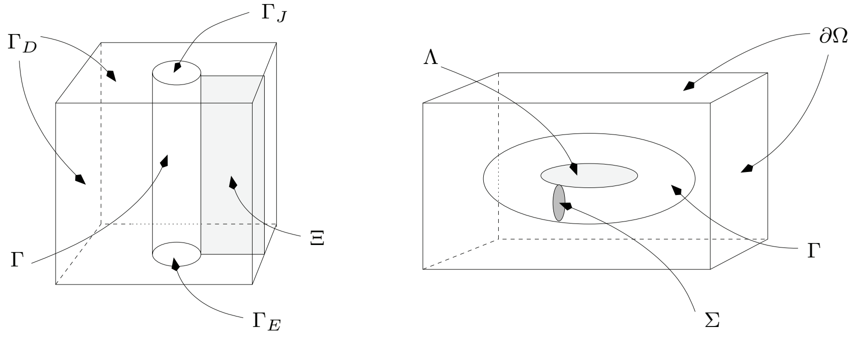

FIG. 1. *The geometry of the domain for the electric port case (left) and for the internal conductor case (right).*

Summing up, we are going to consider six different problems:

Case A. Electric ports, $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\partial\Omega$.

Case B. Electric ports, $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\Gamma_E \cup \Gamma_J$, $\mathbf{H} \times \mathbf{n} = \mathbf{0}$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on Γ_D.

Case C. Electric ports, $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\Gamma_E \cup \Gamma_J$, $\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on Γ_D.

Case D. Internal conductor, $\mathbf{E} \times \mathbf{n} = \mathbf{0}$ on $\partial\Omega$.

Case E. Internal conductor, $\mathbf{H} \times \mathbf{n} = \mathbf{0}$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on $\partial\Omega$.

Case F. Internal conductor, $\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$ and $\boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0$ on $\partial\Omega$.

Among the six boundary value problems described here above, Case C has some specific features. In fact, it is the only one for which the solution of the eddy-current problem is not unique.

Let us start by proving this result.

THEOREM 1.1. *Let us consider the solutions* $\mathbf{H}$ *and* $\mathbf{E}$ *of the eddy-current problem*

$$\begin{aligned} \operatorname{curl} \mathbf{H} - \boldsymbol{\sigma}\mathbf{E} &= \mathbf{J}_e \quad && \text{in } \Omega, \\ \operatorname{curl} \mathbf{E} + i\omega\boldsymbol{\mu}\mathbf{H} &= \mathbf{0} && \text{in } \Omega. \end{aligned}$$

The magnetic field $\mathbf{H}$ *in* Ω *and the electric field* $\mathbf{E}_C$ *in* Ω_C *are uniquely determined for each one of the set of boundary conditions described in Cases* A, B, D, E, *and* F.

Proof. Assume that $\mathbf{J}_e = \mathbf{0}$ in Ω. Multiply the Faraday equation by $\overline{\mathbf{H}}$ (the complex conjugate of $\mathbf{H}$) and integrate in Ω. Integration by parts gives

$$0 = \int_\Omega \operatorname{curl} \mathbf{E} \cdot \overline{\mathbf{H}} + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} = \int_\Omega \mathbf{E} \cdot \operatorname{curl} \overline{\mathbf{H}} + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} + \int_{\partial\Omega} \mathbf{n} \times \mathbf{E} \cdot \overline{\mathbf{H}}.$$

Replacing $\mathbf{E}_C$ by $\boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C$, and recalling that $\operatorname{curl} \mathbf{H}_I = \mathbf{0}$ in Ω_I, we have

$$0 = \int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} + \int_{\partial\Omega} \mathbf{n} \times \mathbf{E} \cdot \overline{\mathbf{H}}.$$

Thus the uniqueness result follows at once if we prove that the boundary integral vanishes.

This is clearly the case if we are considering Cases A, B, D, and E. For Case F, we have $\operatorname{div}_\tau(\mathbf{E} \times \mathbf{n}) = \operatorname{curl} \mathbf{E} \cdot \mathbf{n} = -i\omega\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$ on $\partial\Omega$; hence there exists a scalar function W such that $\mathbf{E} \times \mathbf{n} = \operatorname{grad} W \times \mathbf{n}$ on $\partial\Omega$. Therefore,

$$\begin{aligned} \textstyle\int_{\partial\Omega} \mathbf{n} \times \mathbf{E} \cdot \overline{\mathbf{H}} &= \textstyle\int_{\partial\Omega} \overline{\mathbf{H}} \times \mathbf{n} \cdot \operatorname{grad} W = -\int_{\partial\Omega} \operatorname{div}_\tau(\overline{\mathbf{H}} \times \mathbf{n})\, W \\ &= \textstyle -\int_{\partial\Omega} \operatorname{curl} \overline{\mathbf{H}} \cdot \mathbf{n}\, W = 0 \end{aligned}$$

as $\operatorname{curl} \mathbf{H}_I = \mathbf{0}$ in Ω_I. □

Remark 1.2. It is worthwhile to note that, for Case C, assuming $\mathbf{J}_e = \mathbf{0}$, one has

$$\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + \int_{\Omega} i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} = W_{|\Gamma_J} \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n}.$$

In fact, we know that on the ports Γ_E and Γ_J we still have $\operatorname{div}_\tau(\mathbf{E} \times \mathbf{n}) = 0$, and also on Γ_D we have $\operatorname{div}_\tau(\mathbf{E} \times \mathbf{n}) = \operatorname{curl} \mathbf{E} \cdot \mathbf{n} = -i\omega\boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0$; thus we conclude that $\operatorname{div}_\tau(\mathbf{E} \times \mathbf{n}) = 0$ on $\partial\Omega$. Therefore, as before, we can write $\mathbf{E} \times \mathbf{n} = \operatorname{grad} W \times \mathbf{n}$ on $\partial\Omega$, and we see that W is constant on Γ_E and on Γ_J, say, $W = 0$ on Γ_E and $W = W_J$ on Γ_J. Thus

$$\int_{\partial\Omega} \mathbf{n} \times \mathbf{E} \cdot \overline{\mathbf{H}} = -\int_{\partial\Omega} \operatorname{curl} \overline{\mathbf{H}} \cdot \mathbf{n}\, W = -W_J \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n},$$

as $\operatorname{curl} \mathbf{H}_I \cdot \mathbf{n} = 0$ on Γ_D and $W = 0$ on Γ_E.

In particular, we see that there is still a free degree of freedom: it can be either the constant value of W on Γ_J (the voltage between the two ports of Ω_C) or the value $\int_{\Gamma_J} \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}$ (the current intensity in Ω_C). Therefore, in the present case uniqueness requires that one of these conditions also be imposed.

Case C has been proposed in [16] as a valid approximation of a realistic electric port problem. Thus it is a useful starting point for developing our considerations.

In [6] (see also [10]) the following has been proved.

THEOREM 1.3. *For each $\mathbf{J}_e \in (L^2(\Omega))^3$, there exists a unique solution $\mathbf{H}$ and $\mathbf{E}$ of the eddy-current problem (Case* C*)*

$$(1)\qquad \begin{array}{ll} \operatorname{curl} \mathbf{H} - \boldsymbol{\sigma}\mathbf{E} = \mathbf{J}_e & \text{in } \Omega, \\ \operatorname{curl} \mathbf{E} + i\omega\boldsymbol{\mu}\mathbf{H} = \mathbf{0} & \text{in } \Omega, \\ \operatorname{div}(\boldsymbol{\epsilon}_I \mathbf{E}_I) = 0 & \text{in } \Omega_I, \\ \mathbf{E} \times \mathbf{n} = \mathbf{0} & \text{on } \Gamma_E \cup \Gamma_J, \\ \boldsymbol{\epsilon}\mathbf{E} \cdot \mathbf{n} = 0 & \text{on } \Gamma_D, \\ \boldsymbol{\mu}\mathbf{H} \cdot \mathbf{n} = 0 & \text{on } \Gamma_D, \end{array}$$

with one of the following additional conditions:

$$(2)\qquad \textit{either}\quad W_J = V \quad \textit{or} \quad \int_{\Gamma_J} \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n} = I,$$

where the voltage V and the current intensity I are given complex numbers, and W_J denotes the constant value on Γ_J of the function W such that $\mathbf{E} \times \mathbf{n} = \operatorname{grad} W \times \mathbf{n}$ on $\partial\Omega$, having set $W = 0$ on Γ_E.

In [10] and [6] the convergence of a finite element approximation scheme is also proved (in the former the considered unknowns are $\mathbf{H}_C$ and a scalar magnetic potential; in the latter they are the same magnetic potential and $\mathbf{E}_C$).

Other finite element schemes can be found in [26] and [12], where the problem is described through the so-called **T**-Φ formulation, namely, in terms of a current vector potential and a scalar magnetic potential.

2. The power law. In [23], a paper that has deeply inspired our work, Hiptmair and Sterz propose using a suitable power law to relate the voltage and the current intensity. They define

$$(3)\qquad \widehat{P} := \int_{\Omega_C} \boldsymbol{\sigma}\mathbf{E}_C \cdot \overline{\mathbf{E}}_C + i\omega \int_{\Omega} \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}}$$

and assume that, for the problem at hand, the power law $\widehat{P} = V\,\overline{I}$ holds.

In this paper we propose to modify the definition of the power in the following way:

$$P := \int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu} \mathbf{H} \cdot \overline{\mathbf{H}}. \tag{4}$$

Since $\operatorname{curl} \mathbf{H} = \boldsymbol{\sigma}\mathbf{E} + \mathbf{J}_e$, when $\mathbf{J}_{e,C} = \mathbf{0}$ the two definitions are clearly the same: but we will see in the following that the presence of the current density has important consequences. In particular, the relation among power, voltage, and current intensity takes a more general form.

First we note that, when $\mathbf{J}_{e,C} \neq \mathbf{0}$ and $\sigma^{-1}\mathbf{J}_{e,C}$ is a gradient of a suitable scalar function, the solution of the eddy-current problem can take the form $\mathbf{H} = \mathbf{0}$ and $\mathbf{E}_C = -\sigma^{-1}\mathbf{J}_{e,C} \neq \mathbf{0}$; therefore, in that case one has $I = 0$ and $\widehat{P} \neq 0$, and the power law $\widehat{P} = V\,\overline{I}$ does not hold.

To motivate in a more precise way our definition of the power in (4), let us look at this example in further detail. Consider the eddy-current problem (1) (Case C) with a given assigned voltage V and with $\mathbf{J}_{e,I} = \mathbf{0}$, $\mathbf{J}_{e,C} = -V\boldsymbol{\sigma} \operatorname{grad} \phi_C$, where ϕ_C is the unique solution to

$$\begin{cases} \operatorname{div}(\boldsymbol{\sigma} \operatorname{grad} \phi_C) = 0 & \text{in } \Omega_C, \\ \phi_C = 1 & \text{on } \Gamma_J, \\ \phi_C = 0 & \text{on } \Gamma_E, \\ \boldsymbol{\sigma} \operatorname{grad} \phi_C \cdot \mathbf{n} = 0 & \text{on } \Gamma. \end{cases} \tag{5}$$

It is easily seen that the solution is given by $\mathbf{E} = V \operatorname{grad} \phi$ and $\mathbf{H} = \mathbf{0}$, where ϕ is equal to ϕ_C in Ω_C and to ϕ_I in Ω_I, ϕ_I being the unique solution to

$$\begin{cases} \operatorname{div}(\boldsymbol{\epsilon}_I \operatorname{grad} \phi_I) = 0 & \text{in } \Omega_I, \\ \phi_I = \phi_C & \text{on } \Gamma, \\ \boldsymbol{\epsilon}_I \operatorname{grad} \phi_I \cdot \mathbf{n} = 0 & \text{on } \Gamma_D. \end{cases} \tag{6}$$

Therefore, as we noted before, the current intensity I is equal to 0 and $\widehat{P} \neq 0 = V\,\overline{I}$; moreover, this example is also giving us some other useful information. In fact, for each complex number $q \in \mathbb{C}$, take now $\mathbf{J}_{e,C} = q\boldsymbol{\sigma} \operatorname{grad} \phi_C$, $\mathbf{J}_{e,I} = \mathbf{0}$. Computing the power P for the corresponding solution we find, by proceeding as in Theorem 1.1 and Remark 1.2,

$$\begin{aligned} P &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} \\ &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \mathbf{J}_{e,C} \cdot \operatorname{curl} \overline{\mathbf{H}}_C + V \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n} \\ &= q \textstyle\int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + V \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n}. \end{aligned}$$

On the other hand,

$$\begin{aligned} &\textstyle\int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C \\ &\qquad = -\textstyle\int_{\Omega_C} \phi_C \operatorname{div} \operatorname{curl} \overline{\mathbf{H}}_C + \int_{\Gamma_E \cup \Gamma_J \cup \Gamma} \phi_C \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n}_C \\ &\qquad = \textstyle\int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n}. \end{aligned} \tag{7}$$

as $\phi_C = 0$ on Γ_E, $\phi_C = 1$ on Γ_J, and $\operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}_C = \operatorname{curl} \mathbf{H}_I \cdot \mathbf{n}_C = 0$ on Γ.

In conclusion, P is still proportional to $\overline{I}$, as

$$P = (q + V) \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n} = (q + V)\,\overline{I};$$

moreover, this is telling us that, when considering Case C, assigning a voltage V is in some sense equivalent to imposing a current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$ in Ω_C.

More precisely, the solution $(\widetilde{\mathbf{H}}, \widetilde{\mathbf{E}})$ with voltage V and $\mathbf{J}_{e,C} = \mathbf{0}$ and the solution $(\widehat{\mathbf{H}}, \widehat{\mathbf{E}})$ with voltage 0 and $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$ satisfy $\widetilde{\mathbf{H}} = \widehat{\mathbf{H}}$; in fact, the difference $(\widetilde{\mathbf{H}} - \widehat{\mathbf{H}}, \widetilde{\mathbf{E}} - \widehat{\mathbf{E}})$ is a solution of the problem with voltage V and $\mathbf{J}_{e,C} = -V\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$. Therefore, as we have seen above, $\widetilde{\mathbf{E}} - \widehat{\mathbf{E}} = V\,\mathrm{grad}\,\phi$ and $\widetilde{\mathbf{H}} - \widehat{\mathbf{H}} = \mathbf{0}$.

This will lead us to propose a suitable formulation for the eddy-current problem with one of the boundary conditions described in Cases A, B, D, E, and F and, moreover, subjected to a given voltage or current intensity excitation; the key point will be that these excitations, unlike Case C, have to be interpreted as a particular applied current density.

Remark 2.1. Proceeding as in the proof of Theorem 1.1, when $\mathbf{J}_e \neq \mathbf{0}$, we have

$$\begin{aligned} P &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C \cdot \mathrm{curl}\,\overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} \\ &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1}\mathbf{J}_{e,C} \cdot \mathrm{curl}\,\overline{\mathbf{H}}_C - \int_{\Omega_I} \overline{\mathbf{J}}_{e,I} \cdot \mathbf{E}_I + \int_{\partial\Omega} \mathbf{E} \times \mathbf{n} \cdot \overline{\mathbf{H}}. \end{aligned}$$

The term $\int_{\partial\Omega} \mathbf{E} \times \mathbf{n} \cdot \overline{\mathbf{H}}$ is vanishing for Cases A, B, D, and E. Instead, for Case F we have $\int_{\partial\Omega} \mathbf{E} \times \mathbf{n} \cdot \overline{\mathbf{H}} = \int_{\partial\Omega} \overline{\mathbf{J}}_{e,I} \cdot \mathbf{n}\, W$, where W is the scalar function such that $\mathrm{grad}\, W \times \mathbf{n} = \mathbf{E} \times \mathbf{n}$ on $\partial\Omega$. Finally, for Case C we have (see Remark 1.2)

$$\int_{\partial\Omega} \mathbf{E} \times \mathbf{n} \cdot \overline{\mathbf{H}} = \int_{\Gamma_D} \overline{\mathbf{J}}_{e,I} \cdot \mathbf{n}\, W + W_J \int_{\Gamma_J} \mathrm{curl}\,\overline{\mathbf{H}}_C \cdot \mathbf{n},$$

where W_J is a constant and $W_{|\Gamma_J} = W_J$, $W_{|\Gamma_E} = 0$.

When $\mathbf{J}_{e,I} = \mathbf{0}$ and $\mathbf{J}_{e,C} = q\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$, we have seen that for Case C the power law holds in the generalized form $P = (q + V)\,\overline{I}$. This is showing us that we have to consider two voltages, say, an "electric" voltage V (the value $V = W_{|\Gamma_J} - W_{|\Gamma_E}$) and a "source" voltage q, associated to the current density $q\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$. Their sum $q + V$ is the total voltage.

When considering the other cases A, B, D, E, and F, only the "source" voltage has meaning.

3. Voltage and current excitation. Since the eddy-current problem has a unique solution for each of the sets of boundary conditions described in Cases A, B, D, E, and F (see Theorem 1.1), it is not possible to impose an additional condition, say, voltage or current intensity, if we do not relax some of the other equations.

Before starting, let us mention the formulations proposed in some preceding papers. In [23], where the voltage/current excitation problem has been considered in the most systematic way, it was proposed to slightly modify the formulation for Case A, requiring $\mathbf{E} \times \mathbf{n} = \mathrm{grad}\,\varphi \times \mathbf{n}$ on $\partial\Omega$, where $\varphi \in H^{1/2}(\partial\Omega)$, $\varphi = V$ on Γ_J, $\varphi = 0$ on Γ_E (and, therefore, $\varphi \neq \mathrm{const}$ in a transition region $\Theta \subset \Gamma_D$). In other words, $\mathbf{E} \times \mathbf{n} \neq \mathbf{0}$ in Θ. This formulation, which is proved to be well-posed, depends, however, on the choice of the region Θ and of the function φ in Θ. An alternative approach, also proposed in [23], valid for all the cases considered here and for which $\Theta = \emptyset$, ends up with the violation of the Faraday law on a specific surface (either the surface that "cuts" the basic nonbounding cycle in Ω_I, or else any surface crossing the interface Γ).

In [20] and [28] the internal conductor case is considered, having assigned a given voltage V. Also in this case the Faraday law is violated on the cutting surface Λ. Instead, the approach proposed in [21] gives a solution that does not satisfy the Faraday law across the interface Γ.

In [10] a formulation for the electric port case with assigned current intensity is given, leading to the solution also obtained in [6] for Case C; however, for Case A it can be checked that the Faraday law is violated on the cutting surface Ξ (instead, the violation of the Faraday law across the interface Γ occurs in [8], where the internal conductor case is considered).

Finally, in [26] and [12] the finite element approximation of Case C is considered for an assigned voltage, by means of a formulation based on a current vector potential and a magnetic scalar potential.

Let us come now to our point of view: clearly, on one side we do not want to give up Maxwell equations, namely, Faraday and Ampère equations; on the other side, we would like to formulate a problem for which only the physical quantities and the physical domains Ω_C and Ω_I play a role (and not artificial regions like, e.g., the transition zone Θ introduced in [23]).

The main point is to recall what we have proved for Case C, where a voltage V was "equivalent" (at least, for the determination of $\mathbf{H}$ and in the power law) to the current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$ in Ω_C. Note that the function $\mathrm{grad}\,\phi_C$ is the basis function of the space of harmonic fields

$$\begin{aligned}\widehat{\mathcal{H}}(\Omega_C) \ := \{\widehat{\boldsymbol{\eta}} \in (L^2(\Omega_C))^3 \mid \mathrm{curl}\,\widehat{\boldsymbol{\eta}} = \mathbf{0}, \mathrm{div}(\boldsymbol{\sigma}\widehat{\boldsymbol{\eta}}) = 0,\\ \boldsymbol{\sigma}\widehat{\boldsymbol{\eta}}\cdot\mathbf{n} = 0 \text{ on } \Gamma, \widehat{\boldsymbol{\eta}}\times\mathbf{n} = \mathbf{0} \text{ on } \Gamma_E\cup\Gamma_J\},\end{aligned}$$

normalized with the condition

$$\int_{\widehat{\gamma}} \widehat{\boldsymbol{\eta}}\cdot d\boldsymbol{\tau} = 1,$$

where $\widehat{\gamma}$ is a path joining Γ_E to Γ_J. Thus, for the internal conductor case we are led to introduce the space of harmonic fields

$$\mathcal{H}(\Omega_C) := \{\boldsymbol{\eta} \in (L^2(\Omega_C))^3 \mid \mathrm{curl}\,\boldsymbol{\eta} = \mathbf{0}, \mathrm{div}(\boldsymbol{\sigma}\boldsymbol{\eta}) = 0, \boldsymbol{\sigma}\boldsymbol{\eta}\cdot\mathbf{n} = 0 \text{ on } \Gamma\},$$

defining as $\boldsymbol{\rho}_C$ its basis function normalized with the condition

$$\int_{\gamma} \boldsymbol{\rho}_C\cdot d\boldsymbol{\tau} = 1,$$

where the (closed) cycle γ is internal to Ω_C (and we have freely chosen an orientation of γ).

The voltage or current excitation problem is therefore formulated as follows.

Voltage rule. *When the voltage V is imposed, modify Ohm's law in Ω_C by adding to the current density $\boldsymbol{\sigma}\mathbf{E}_C$ the "applied" current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\mathbf{Q}_C$, where $\mathbf{Q}_C = \mathrm{grad}\,\phi_C$ for the electric port case, and $\mathbf{Q}_C = \boldsymbol{\rho}_C$ for the internal conductor case. Thus the Ampère law reads*

$$\mathrm{curl}\,\mathbf{H}_C - \boldsymbol{\sigma}\mathbf{E}_C = V\boldsymbol{\sigma}\mathbf{Q}_C.$$

In the former case, we intend that the voltage passes from 0 on Γ_E to V on Γ_J; in the latter case, the voltage passes from 0 to V along the basic cycle γ.

Current intensity rule. *When the current intensity I is imposed, modify Ohm's law in Ω_C by adding to the current density $\boldsymbol{\sigma}\mathbf{E}_C$ the "applied" current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\mathbf{Q}_C$, where $\mathbf{Q}_C$ is as in the "voltage rule" and V has to be determined. Thus the Ampère law reads*

$$\mathrm{curl}\,\mathbf{H}_C - \boldsymbol{\sigma}\mathbf{E}_C - V\boldsymbol{\sigma}\mathbf{Q}_C = 0.$$

Then determine the field quantities and the voltage V such that the additional constraint

$$\int_S \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n} = I$$

is also satisfied, where $S = \Gamma_J$ for the electric port case, and $S = \Sigma$, a section of Ω_C, for the internal conductor case. In the former case, the unit vector $\mathbf{n}$ is the outward normal on Γ_J; in the latter case, the unit vector $\mathbf{n}$ on Σ is oriented the same as the basic cycle γ.

Let us show that, when adopting these two rules, we are respecting the power law. Assume that we have $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\mathbf{Q}_C$ and $\mathbf{J}_{e,I} = \mathbf{0}$. Then, by proceeding as in Theorem 1.1, and taking into account the boundary conditions of Cases A, B, D, E, and F, we have that

$$\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} = \int_{\Omega_C} \boldsymbol{\sigma}^{-1}\mathbf{J}_{e,C} \cdot \operatorname{curl} \overline{\mathbf{H}}_C,$$

and hence

$$P = \int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} = V \int_{\Omega_C} \mathbf{Q}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C.$$

On the other hand, from (7) we have

$$\int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C = \int_{\Gamma_J} \operatorname{curl} \overline{\mathbf{H}}_C \cdot \mathbf{n} = \overline{I};$$

thus if $\mathbf{Q}_C = \operatorname{grad} \phi_C$, we conclude with

$$\begin{aligned} P &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} \\ &= V \textstyle\int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C = V\,\overline{I}, \end{aligned}$$

the power law for the electric port case.

The internal conductor case needs some additional information in order to express the current intensity in a suitable way. Let us denote by Σ a section of Ω_C, namely, a surface in Ω_C cutting the basic nonbounding cycle γ. We know that the basis function $\boldsymbol{\rho}_C$ is the $L^2(\Omega_C)$-extension of the gradient of a suitable scalar function q, defined in $\Omega_C \setminus \Sigma$ and having a jump equal to 1 across Σ. Hence,

$$\begin{aligned} \textstyle\int_{\Omega_C} \operatorname{curl} \mathbf{H}_C \cdot \boldsymbol{\rho}_C &= \textstyle\int_{\Omega_C \setminus \Sigma} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{grad} q \\ &= -\textstyle\int_{\Omega_C \setminus \Sigma} q \operatorname{div} \operatorname{curl} \mathbf{H}_C + \int_\Gamma q \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}_C \\ &\qquad + \textstyle\int_\Sigma \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n} \\ &= \textstyle\int_\Sigma \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}, \end{aligned} \tag{8}$$

as $\operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}_C = \operatorname{curl} \mathbf{H}_I \cdot \mathbf{n}_C = 0$ on Γ and the jump of q on Σ is equal to 1. Hence we end up with

$$\begin{aligned} P &= \textstyle\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C + i\omega \int_\Omega \boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{H}} \\ &= V \textstyle\int_{\Omega_C} \boldsymbol{\rho}_C \cdot \operatorname{curl} \overline{\mathbf{H}}_C = V\,\overline{I}, \end{aligned}$$

the power law for the internal conductor case.

Remark 3.1. As is clear from our procedure, in the electric port case we could obtain a suitable formulation (namely, satisfying the power law) for any current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\,\mathrm{grad}\,\Phi_C$ such that $\Phi_C = 1$ on Γ_J and $\Phi_C = 0$ on Γ_E. Hence, how is the choice of ϕ_C introduced in (5) motivated?

In this respect, it should be noted that, from the Ampère equation $\mathrm{curl}\,\mathbf{H}_C = \boldsymbol{\sigma}\mathbf{E}_C + \mathbf{J}_{e,C}$, the electric field satisfies the (physically consistent) conditions $\mathrm{div}(\boldsymbol{\sigma}\mathbf{E}_C) = 0$ in Ω_C and $\boldsymbol{\sigma}\mathbf{E}_C \cdot \mathbf{n} = 0$ on Γ only if $\mathrm{div}\,\mathbf{J}_{e,C} = 0$ in Ω_C and $\mathbf{J}_{e,C} \cdot \mathbf{n} = 0$ on Γ, and therefore, only if $\Phi_C = \phi_C$, the solution to (5).

The same remark applies for the internal conductor case: in that situation, the integral

$$\int_{\Omega_C} \mathbf{u}_C \cdot \mathrm{curl}\,\overline{\mathbf{H}}_C$$

has the same value for any vector field $\mathbf{u}_C$ such that $\mathrm{curl}\,\mathbf{u}_C = \mathbf{0}$ and $\int_\gamma \mathbf{u}_C \cdot d\boldsymbol{\tau} = 1$. But if we also require that $\mathrm{div}(\boldsymbol{\sigma}\mathbf{u}_C) = 0$ in Ω_C and $\boldsymbol{\sigma}\mathbf{u}_C \cdot \mathbf{n} = 0$ on Γ, then we conclude $\mathbf{u}_C = \boldsymbol{\rho}_C$.

4. Variational formulations. We can consider **H**-based formulations, or **E**-based formulations. In our opinion, the simplest approach is in terms of **H**. We will focus first on the electric port case; however, we do not present here Case C, which, for a "hybrid" formulation which is related to the **H**-formulation, has been studied in [6]. Then we will consider the internal conductor case, whose formulation is quite similar, focusing in particular on Case F.

Electric ports: Voltage excitation, ***H****-formulation.* For Case A, the problem is as follows: for each given $V \in \mathbb{C}$ find the unique solution $\mathbf{H} \in X$ to

$$\int_{\Omega_C} \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{w}} = V \int_{\Omega_C} \mathrm{grad}\,\phi_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C \tag{9}$$

for each $\mathbf{w} \in X$, where

$$X := \{\mathbf{w} \in H(\mathrm{curl};\Omega) \mid \mathrm{curl}\,\mathbf{w}_I = \mathbf{0} \text{ in } \Omega_I\}.$$

Then set $\mathbf{E}_C := \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C - V\,\mathrm{grad}\,\phi_C$ in Ω_C, and in Ω_I define $\mathbf{E}_I$ to be the solution to

$$\begin{cases} \mathrm{curl}\,\mathbf{E}_I = -i\omega\boldsymbol{\mu}_I\mathbf{H}_I & \text{in } \Omega_I, \\ \mathrm{div}(\boldsymbol{\epsilon}_I\mathbf{E}_I) = 0 & \text{in } \Omega_I, \\ \mathbf{E}_I \times \mathbf{n}_I = -\mathbf{E}_C \times \mathbf{n}_C & \text{on } \Gamma, \\ \mathbf{E}_I \times \mathbf{n} = \mathbf{0} & \text{on } \Gamma_D. \end{cases} \tag{10}$$

Let us remark that the voltage excitation problem for Case B is trivial: in fact, from (7) and the Stokes theorem we have

$$\int_{\Omega_C} \mathrm{grad}\,\phi_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C = \int_{\Gamma_J} \mathrm{curl}\,\overline{\mathbf{w}}_C \cdot \mathbf{n} = \int_{\partial\Gamma_J} \overline{\mathbf{w}} \cdot d\boldsymbol{\tau} = 0,$$

as $\mathbf{w} \times \mathbf{n} = \mathbf{0}$ on Γ_D. Therefore, for any $V \in \mathbb{C}$ we find $\mathbf{H} = \mathbf{0}$; hence, we can assume that $V = 0$ and set $\mathbf{E} = \mathbf{0}$.

The well-posedness of problem (9) comes from the coerciveness in X of the sesquilinear form $\int_{\Omega_C} \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{w}}$.

Instead, a delicate point here is the unique solvability of problem (10). In fact, as is well known, boundary-value problems for the curl-div system in general need some compatibility conditions to be satisfied in order to ensure the existence of a solution and need suitable additional conditions to be imposed to guarantee its uniqueness; some of these conditions are related to the nontrivial topology of Ω_I.

More precisely, first one has to verify the conditions $\operatorname{div}(\boldsymbol{\mu}_I \mathbf{H}_I) = 0$ in Ω_I, $\operatorname{div}_\tau(\mathbf{E}_C \times \mathbf{n}_C) = i\omega \boldsymbol{\mu}_I \mathbf{H}_I \cdot \mathbf{n}_I$ on Γ, and $\boldsymbol{\mu}_I \mathbf{H}_I \cdot \mathbf{n}_I = 0$ on Γ_D.

It is possible to check that these conditions are satisfied by means of a suitable choice of test functions in (9) (for a similar procedure, see, for instance, [3]). In fact, the first follows from (9) taking as test function $\mathbf{w} = \operatorname{grad}\psi$, ψ a smooth function with a compact support in Ω (and in this way one also obtains $\boldsymbol{\mu}_C \mathbf{H}_C \cdot \mathbf{n}_C + \boldsymbol{\mu}_I \mathbf{H}_I \cdot \mathbf{n}_I = 0$ on Γ, as, indeed, $\operatorname{div}(\boldsymbol{\mu}\mathbf{H}) = 0$ in Ω). The second comes from the Faraday equation in Ω_C, which is obtained by integration by parts, and the relation $\operatorname{div}_\tau(\mathbf{E}_C \times \mathbf{n}_C) = \operatorname{curl}\mathbf{E}_C \cdot \mathbf{n}_C$. The last is obtained by taking as test function $\mathbf{w} = \operatorname{grad}\psi$, with $\psi \in H^1(\Omega)$.

Then one has to consider some spaces of harmonic fields. Concerning uniqueness, it is clear that we are interested in requiring that the solution $\mathbf{E}_I$ is orthogonal (with weight $\boldsymbol{\epsilon}_I$) to the space

$$\begin{aligned} \mathcal{H}_A^{\mathrm{un}}(\Omega_I) \ &:= \{\widehat{\boldsymbol{\eta}} \in (L^2(\Omega_I))^3 \mid \operatorname{curl}\widehat{\boldsymbol{\eta}} = \mathbf{0}, \operatorname{div}(\boldsymbol{\epsilon}_I \widehat{\boldsymbol{\eta}}) = 0, \\ &\qquad\qquad\qquad\qquad\qquad\qquad \widehat{\boldsymbol{\eta}} \times \mathbf{n} = \mathbf{0} \text{ on } \Gamma_D \cup \Gamma\}. \end{aligned}$$

However, this space is trivial (namely, it contains only $\widehat{\boldsymbol{\eta}} = \mathbf{0}$). In fact, cutting Ω_I with a surface Ξ transversal to Γ_D and Γ, an element $\widehat{\boldsymbol{\eta}}$ of $\mathcal{H}_A^{\mathrm{un}}(\Omega_I)$ in the set $\Omega_I \setminus \Xi$ is the gradient of a function p having a constant jump through Ξ. But, due to the fact that $\operatorname{grad} p \times \mathbf{n} = \mathbf{0}$ on $\Gamma_D \cup \Gamma$, a connected surface, p is constant on $\Gamma_D \cup \Gamma$, and therefore its jump through Ξ is equal to 0. Thus $\widehat{\boldsymbol{\eta}}$ is the gradient of a harmonic function p with constant boundary value: hence p is constant in Ω_I and $\widehat{\boldsymbol{\eta}} = \mathbf{0}$ in Ω_I.

Existence is instead associated to the space

$$\begin{aligned} \mathcal{H}_A^{\mathrm{ex}}(\Omega_I) \ &:= \{\widehat{\boldsymbol{\eta}} \in (L^2(\Omega_I))^3 \mid \operatorname{curl}\widehat{\boldsymbol{\eta}} = \mathbf{0}, \operatorname{div}\widehat{\boldsymbol{\eta}} = 0, \\ &\qquad\qquad\qquad\qquad\qquad\qquad \widehat{\boldsymbol{\eta}} \cdot \mathbf{n} = 0 \text{ on } \Gamma_D \cup \Gamma\}, \end{aligned}$$

which, proceeding as before, is easily shown to be one-dimensional; let us denote by $\widehat{\boldsymbol{\rho}}_I$ its basis vector. For the solvability of problem (10) one has to satisfy the compatibility condition

$$\int_{\Omega_I} i\omega \boldsymbol{\mu}_I \mathbf{H}_I \cdot \widehat{\boldsymbol{\rho}}_I + \int_\Gamma \mathbf{E}_C \times \mathbf{n}_C \cdot \widehat{\boldsymbol{\rho}}_I = 0, \tag{11}$$

which comes from $(10)_1$ and $(10)_3$ by integration by parts. This relation indeed follows from (9) by choosing the test function $\mathbf{w}_I = \widehat{\boldsymbol{\rho}}_I$ and $\mathbf{w}_C = \widehat{\boldsymbol{\rho}}^*$, where $\widehat{\boldsymbol{\rho}}^* \in H(\mathrm{curl}; \Omega_C)$ satisfies $\widehat{\boldsymbol{\rho}}^* \times \mathbf{n}_I = \widehat{\boldsymbol{\rho}}_I \times \mathbf{n}_I$ on Γ, integrating by parts and using the Faraday equation in Ω_C.

In conclusion, (10) is uniquely solvable. It is important to remark that this is not the case if one defines, as in [23], where the same formulation (9) has been proposed, the electric field $\mathbf{E}_C = \boldsymbol{\sigma}^{-1} \operatorname{curl}\mathbf{H}_C$ in Ω_C: in that case, in fact, (11) is not satisfied, and therefore it is not possible to determine $\mathbf{E}_I$.

It is worthwhile to note that (11) is indeed equivalent to the Faraday equation on the surface Ξ that cuts the basic nonbounding cycle in Ω_I. Hence, setting $\mathbf{E}_C = \boldsymbol{\sigma}^{-1} \operatorname{curl}\mathbf{H}_C$ leads to the violation of the Faraday equation on that surface.

Electric ports: Current intensity excitation, **H***-formulation.* Let us start noting that this problem does not have a meaning for Case B. In fact, one has

$$I = \int_{\Gamma_J} \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n} = \int_{\partial\Gamma_J} \mathbf{H} \cdot d\boldsymbol{\tau} = 0,$$

as $\mathbf{H} \times \mathbf{n} = \mathbf{0}$ on Γ_D.

Therefore, we consider only Case A. The problem can be expressed in this way: for each given $I \in \mathbb{C}$ find the unique solution $(\mathbf{H}, V) \in X \times \mathbb{C}$ to

$$(12) \qquad \begin{cases} \int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{w}}_C & + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{w}} \\ & - V \int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \overline{\mathbf{w}}_C = 0, \\ \int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \mathbf{H}_C = I & \end{cases}$$

for each $\mathbf{w} \in X$, where X is as in (9). Then $\mathbf{E}_C$ and $\mathbf{E}_I$ are determined in the same way as before. Let us also recall that, from (7), we have

$$\int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \mathbf{H}_C = \int_{\Gamma_J} \operatorname{curl} \mathbf{H}_C \cdot \mathbf{n}.$$

The well-posedness of problem (12) comes from the theory of saddle-point problems. In fact, the sesquilinear form $\int_{\Omega_C} \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C \cdot \operatorname{curl} \overline{\mathbf{w}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{w}}$ is coercive in X; moreover, since the unknown $V \in \mathbb{C}$ is a number, to show that the inf-sup condition is satisfied it is enough to find $\mathbf{w}^* \in X$ such that

$$\left| \int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \mathbf{w}^*_C \right| > 0.$$

This can be done by taking the solution $\mathbf{w}^*_C$ to

$$\begin{cases} \operatorname{curl} \mathbf{w}^*_C = \boldsymbol{\sigma} \operatorname{grad} \phi_C & \text{in } \Omega_C, \\ \operatorname{div} \mathbf{w}^*_C = 0 & \text{in } \Omega_C, \\ \mathbf{w}^*_C \cdot \mathbf{n} = 0 & \text{on } \Gamma_E \cup \Gamma_J \cup \Gamma \end{cases}$$

and the solution $\mathbf{w}^*_I$ to

$$\begin{cases} \operatorname{curl} \mathbf{w}^*_I = \mathbf{0} & \text{in } \Omega_I, \\ \operatorname{div} \mathbf{w}^*_I = 0 & \text{in } \Omega_I, \\ \mathbf{w}^*_I \times \mathbf{n}_I = -\mathbf{w}^*_C \times \mathbf{n}_C & \text{on } \Gamma, \\ \mathbf{w}^*_I \cdot \mathbf{n} = 0 & \text{on } \Gamma_D. \end{cases}$$

Formulation (12) has been proposed also in [10] (for both Cases A and C). However, there $\mathbf{E}_C = \boldsymbol{\sigma}^{-1} \operatorname{curl} \mathbf{H}_C$, thus violating, for Case A, the Faraday equation on the surface Ξ.

Electric ports: Voltage excitation, **E***-formulation.* Having clarified that voltage excitation is equivalent to a source $V\boldsymbol{\sigma} \operatorname{grad} \phi_C$, the electric field formulation for Case A is easily devised: for each given $V \in \mathbb{C}$ find $\mathbf{E} \in Y$ such that

$$(13) \qquad \int_\Omega \boldsymbol{\mu}^{-1} \operatorname{curl} \mathbf{E} \cdot \operatorname{curl} \overline{\mathbf{z}} + \int_{\Omega_C} i\omega\boldsymbol{\sigma}\mathbf{E}_C \cdot \overline{\mathbf{z}}_C = -i\omega V \int_{\Omega_C} \boldsymbol{\sigma} \operatorname{grad} \phi_C \cdot \overline{\mathbf{z}}_C$$

for each $\mathbf{z} \in Y$, where

$$Y := \{\mathbf{z} \in H(\operatorname{curl}; \Omega) \mid \operatorname{div}(\boldsymbol{\epsilon}_I \mathbf{z}_I) = 0 \text{ in } \Omega_I, \mathbf{z} \times \mathbf{n} = \mathbf{0} \text{ on } \partial\Omega\}.$$

The existence of a solution $\mathbf{E}$ to problem (13) follows at once from what was already proved for the $\mathbf{H}$-formulation. Uniqueness is straightforward.

The magnetic field $\mathbf{H}$ is then determined in Ω as $\mathbf{H} = -\frac{1}{i\omega}\boldsymbol{\mu}^{-1}\operatorname{curl}\mathbf{E}$.

A formulation similar to (13) (but based on the source term $V\boldsymbol{\sigma}\operatorname{grad}\Phi_C$, the function Φ_C having been defined in Remark 3.1) has been presented in [23]. However, there the electric field is not the solution to (13), but it is corrected, only in Ω_C, by adding $V\operatorname{grad}\Phi_C$. Since a curl-free vector field in Ω_I that has tangential component on Γ equal to $V\operatorname{grad}\Phi_C \times \mathbf{n}$ does not exist (again, this is related to the solvability of problem (10)), this leads to the violation of the continuity of the tangential component of $\mathbf{E}$ through the interface Γ and thus to the violation of the Faraday law.

Electric ports: Current intensity excitation, $\mathbf{E}$*-formulation.* Since $\operatorname{curl}\mathbf{H}_C = \boldsymbol{\sigma}\mathbf{E}_C + V\boldsymbol{\sigma}\operatorname{grad}\phi_C$, the variational formulation (for the sole Case A) now reads as follows: for each given $I \in \mathbb{C}$, find $(\mathbf{E}, V) \in Y \times \mathbb{C}$ such that

$$(14)\qquad \begin{cases} \int_\Omega \boldsymbol{\mu}^{-1}\operatorname{curl}\mathbf{E}\cdot\operatorname{curl}\overline{\mathbf{z}} + \int_{\Omega_C} i\omega\boldsymbol{\sigma}\mathbf{E}_C\cdot\overline{\mathbf{z}}_C \\ \qquad\qquad + i\omega V\int_{\Omega_C}\boldsymbol{\sigma}\operatorname{grad}\phi_C\cdot\overline{\mathbf{z}}_C = 0, \\ \int_{\Omega_C}\operatorname{grad}\phi_C\cdot\boldsymbol{\sigma}\mathbf{E}_C + V\int_{\Omega_C}\boldsymbol{\sigma}\operatorname{grad}\phi_C\cdot\operatorname{grad}\phi_C = I \end{cases}$$

for each $\mathbf{z} \in Y$.

As before, existence of a solution is ensured by the correspondent result for the magnetic field $\mathbf{H}$. Instead, uniqueness is a more delicate point. In fact, multiplying $(14)_2$ by $i\omega\overline{U}$, where $U \in \mathbb{C}$, we find

$$\begin{aligned} &\int_\Omega \boldsymbol{\mu}^{-1}\operatorname{curl}\mathbf{E}\cdot\operatorname{curl}\overline{\mathbf{z}} \\ &\qquad + i\omega\int_{\Omega_C}\boldsymbol{\sigma}(\mathbf{E}_C + V\operatorname{grad}\phi_C)\cdot(\overline{\mathbf{z}}_C + \overline{U}\operatorname{grad}\phi_C) = i\omega I\,\overline{U}. \end{aligned}$$

Thus, putting $I = 0$ and choosing $\mathbf{z} = \mathbf{E}$ and $U = V$, we obtain $\operatorname{curl}\mathbf{E} = \mathbf{0}$ in Ω and $\mathbf{E}_C + V\operatorname{grad}\phi_C = \mathbf{0}$ in Ω_C. Since Ω is simply connected, we also have $\mathbf{E} = \operatorname{grad}\psi$ in Ω, and the boundary condition $\mathbf{E}\times\mathbf{n} = \mathbf{0}$ on $\partial\Omega$ gives $\psi = \text{const}$ on $\partial\Omega$. Therefore, integrating $\mathbf{E}_C$ on the path $\widehat{\gamma}$ joining Γ_E to Γ_J, we find

$$\begin{aligned} 0 &= \int_{\widehat{\gamma}}\operatorname{grad}\psi_C\cdot d\boldsymbol{\tau} = \int_{\widehat{\gamma}}\mathbf{E}_C\cdot d\boldsymbol{\tau}, \\ &= -\int_{\widehat{\gamma}} V\operatorname{grad}\phi_C\cdot d\boldsymbol{\tau} = -V. \end{aligned}$$

Thus $V = 0$, and consequently $\mathbf{E} = \mathbf{0}$.

Also in this case, the magnetic field $\mathbf{H}$ is obtained in Ω by setting

$$\mathbf{H} = -\frac{1}{i\omega}\boldsymbol{\mu}^{-1}\operatorname{curl}\mathbf{E}.$$

Again, a formulation like (14) (but based on the source term $V\boldsymbol{\sigma}\operatorname{grad}\Phi_C$) has been proposed in [23]. The remark at the end of the preceding subsection still applies.

Internal conductor: Voltage excitation, $\mathbf{H}$*-formulation.* We have already made explicit the "voltage rule": applying a voltage is equivalent to considering a current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\boldsymbol{\rho}_C$. Then, for the $\mathbf{H}$-based formulation, Cases D and E can be studied as in [3]. Let us focus on Case F.

The problem reads as follows: for each given $V \in \mathbb{C}$ find the unique solution $\mathbf{H} \in X$ to

$$(15)\qquad \int_{\Omega_C}\boldsymbol{\sigma}^{-1}\operatorname{curl}\mathbf{H}_C\cdot\operatorname{curl}\overline{\mathbf{w}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H}\cdot\overline{\mathbf{w}} = V\int_{\Omega_C}\boldsymbol{\rho}_C\cdot\operatorname{curl}\overline{\mathbf{w}}_C$$

for each $\mathbf{w} \in X$, where

$$X := \{\mathbf{w} \in H(\mathrm{curl};\Omega) \,|\, \mathrm{curl}\,\mathbf{w}_I = \mathbf{0} \text{ in } \Omega_I\}.$$

Then set $\mathbf{E}_C := \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C - V\boldsymbol{\rho}_C$ in Ω_C, and in Ω_I define $\mathbf{E}_I$ to be the solution to

$$(16) \qquad \begin{cases} \mathrm{curl}\,\mathbf{E}_I = -i\omega\boldsymbol{\mu}_I\mathbf{H}_I & \text{in } \Omega_I, \\ \mathrm{div}(\boldsymbol{\epsilon}_I\mathbf{E}_I) = 0 & \text{in } \Omega_I, \\ \mathbf{E}_I \times \mathbf{n}_I = -\mathbf{E}_C \times \mathbf{n}_C & \text{on } \Gamma, \\ \boldsymbol{\epsilon}_I\mathbf{E}_I \cdot \mathbf{n} = 0 & \text{on } \partial\Omega. \end{cases}$$

Again, the main problem here is the solvability of (16). For the internal conductor, this has been already done in [3], to which we refer the reader.

Let us also recall that the same variational formulation (15) has been proposed in [20], [28], and [23]. However, there $\mathbf{E}_C := \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C$, leading to the violation of the Faraday equation on the surface Λ cutting the basic nonbounding cycle of Ω_I.

Internal conductor: Current intensity excitation, **H***-formulation.* Let us start focusing on Case F. Recalling (8), the problem is as follows: for each given $I \in \mathbb{C}$ find the unique solution $(\mathbf{H}, V) \in X \times \mathbb{C}$ to

$$(17) \qquad \begin{cases} \int_{\Omega_C} \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C + \int_\Omega i\omega\boldsymbol{\mu}\mathbf{H} \cdot \overline{\mathbf{w}} \\ \qquad\qquad - V\int_{\Omega_C} \boldsymbol{\rho}_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C = 0, \\ \int_{\Omega_C} \boldsymbol{\rho}_C \cdot \mathrm{curl}\,\mathbf{H}_C = I \end{cases}$$

for each $\mathbf{w} \in X$, where X is as in (15); then set $\mathbf{E}_C := \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C - V\boldsymbol{\rho}_C$ in Ω_C and determine $\mathbf{E}_I$ as in (16).

The well-posedness of problem (17) comes from the theory of saddle-point problems. Taking into account what we have already presented for the electric port case, it is enough to find $\mathbf{w}^* \in X$ such that

$$\left| \int_{\Omega_C} \boldsymbol{\rho}_C \cdot \mathrm{curl}\,\mathbf{w}_C^* \right| > 0.$$

This can be done by taking the solution $\mathbf{w}_C^*$ to

$$\begin{cases} \mathrm{curl}\,\mathbf{w}_C^* = \boldsymbol{\sigma}\boldsymbol{\rho}_C & \text{in } \Omega_C, \\ \mathrm{div}\,\mathbf{w}_C^* = 0 & \text{in } \Omega_C, \\ \mathbf{w}_C^* \times \mathbf{n}_C = c_0\boldsymbol{\rho}_I \times \mathbf{n}_C & \text{on } \Gamma \end{cases}$$

and the solution $\mathbf{w}_I^*$ to

$$\begin{cases} \mathrm{curl}\,\mathbf{w}_I^* = \mathbf{0} & \text{in } \Omega_I, \\ \mathrm{div}\,\mathbf{w}_I^* = 0 & \text{in } \Omega_I, \\ \mathbf{w}_I^* \times \mathbf{n}_I = c_0\boldsymbol{\rho}_I \times \mathbf{n}_I & \text{on } \Gamma, \\ \mathbf{w}_I^* \times \mathbf{n} = \mathbf{0} & \text{on } \partial\Omega, \\ \int_{\partial\Omega} \mathbf{w}_I^* \cdot \mathbf{n} = 0, \end{cases}$$

where $c_0 = \int_{\Omega_C} \boldsymbol{\sigma}\boldsymbol{\rho}_C \cdot \boldsymbol{\rho}_C$. Here $\boldsymbol{\rho}_I$ is the basis function of the space

$$\mathcal{H}(\Omega_I) := \{\boldsymbol{\eta} \in (L^2(\Omega_I))^3 \,|\, \mathrm{curl}\,\boldsymbol{\eta} = \mathbf{0}, \mathrm{div}\,\boldsymbol{\eta} = 0, \boldsymbol{\eta} \cdot \mathbf{n} = 0 \text{ on } \partial\Omega \cup \Gamma\},$$

normalized by $\int_{\widetilde{\gamma}} \boldsymbol{\rho}_I \cdot d\boldsymbol{\tau} = 1$, where $\widetilde{\gamma}$ is the basic nonbounding cycle entering the "handle" of Ω_C, and oriented consistently with the nonbounding cycle γ which runs in Ω_C (namely, each one is oriented counterclockwise with respect to the other). Note that the existence of the solution $\mathbf{w}_C^*$ is a consequence of the relation $\int_\Gamma (\boldsymbol{\rho}_C \times \mathbf{n}_C) \cdot \boldsymbol{\rho}_I = 1$.

To complete the presentation, let us note that, if interested in considering Case D, one has to substitute in (16) the boundary condition $\boldsymbol{\epsilon}_I \mathbf{E}_I \cdot \mathbf{n} = 0$ on $\partial\Omega$ with $\mathbf{E}_I \times \mathbf{n} = \mathbf{0}$ on $\partial\Omega$ and add the condition $\int_{\partial\Omega} \boldsymbol{\epsilon}_I \mathbf{E}_I \cdot \mathbf{n} = 0$.

Instead, concerning Case E, one has to use in (17) the space

$$X := \{\mathbf{w} \in H(\mathrm{curl};\Omega) \,|\, \mathrm{curl}\, \mathbf{w}_I = \mathbf{0} \text{ in } \Omega_I, \mathbf{w}_I \times \mathbf{n} = \mathbf{0} \text{ on } \partial\Omega\}.$$

Internal conductor: Voltage excitation, **E**-*formulation.* We are not going to give details for this case. In fact, the "voltage rule" is telling us that we have only to consider a current density $\mathbf{J}_{e,C} = V\boldsymbol{\sigma}\boldsymbol{\rho}_C$; hence this formulation is easily devised (for instance, for Cases D and E one can follow what was done in [5]). Moreover, the case in which excitation is due to the current intensity can also illustrate the functional framework to be used for the voltage excitation case (in this respect, see the first equation in (18)).

Internal conductor: Current intensity excitation, **E**-*formulation.* The "current intensity rule" says that the given current intensity I is generating not only the electric field but also a current density $V\boldsymbol{\sigma}\boldsymbol{\rho}_C$. Moreover, we have $\mathrm{curl}\, \mathbf{H}_C = \boldsymbol{\sigma}\mathbf{E}_C + V\boldsymbol{\sigma}\boldsymbol{\rho}_C$. Then, the problem is as follows: for each given $I \in \mathbb{C}$ find $(\mathbf{E}, V) \in Y \times \mathbb{C}$ such that

$$(18)\qquad \begin{cases} \int_\Omega \boldsymbol{\mu}^{-1} \mathrm{curl}\, \mathbf{E} \cdot \mathrm{curl}\, \overline{\mathbf{z}} + \int_{\Omega_C} i\omega\boldsymbol{\sigma}\mathbf{E}_C \cdot \overline{\mathbf{z}}_C \\ \qquad\qquad\qquad + i\omega V \int_{\Omega_C} \boldsymbol{\sigma}\boldsymbol{\rho}_C \cdot \overline{\mathbf{z}}_C = 0, \\ \int_{\Omega_C} \boldsymbol{\rho}_C \cdot \boldsymbol{\sigma}\mathbf{E}_C + V \int_{\Omega_C} \boldsymbol{\sigma}\boldsymbol{\rho}_C \cdot \boldsymbol{\rho}_C = I \end{cases}$$

for each $\mathbf{z} \in Y$, where

$$Y := \begin{cases} \{\mathbf{z} \in H(\mathrm{curl};\Omega) \,|\, \mathrm{div}(\boldsymbol{\epsilon}_I \mathbf{z}_I) = 0 \text{ in } \Omega_I, \\ \qquad \mathbf{z} \times \mathbf{n} = \mathbf{0} \text{ on } \partial\Omega, \int_{\partial\Omega} \boldsymbol{\epsilon}_I \mathbf{E}_I \cdot \mathbf{n} = 0\} & \text{for Case D,} \\ \{\mathbf{z} \in H(\mathrm{curl};\Omega) \,|\, \mathrm{div}(\boldsymbol{\epsilon}_I \mathbf{z}_I) = 0 \text{ in } \Omega_I, \\ \qquad \boldsymbol{\epsilon}_I \mathbf{z}_I \cdot \mathbf{n} = 0 \text{ on } \partial\Omega\} & \text{for Case E,} \\ \{\mathbf{z} \in H(\mathrm{curl};\Omega) \,|\, \mathrm{div}(\boldsymbol{\epsilon}_I \mathbf{z}_I) = 0 \text{ in } \Omega_I, \\ \qquad \boldsymbol{\epsilon}_I \mathbf{z}_I \cdot \mathbf{n} = 0 \text{ on } \partial\Omega, \mathrm{div}_\tau(\mathbf{z} \times \mathbf{n}) = \mathbf{0} \text{ on } \partial\Omega\} & \text{for Case F.} \end{cases}$$

As before, existence is a consequence of what was already proved for the **H**-formulation. Concerning uniqueness, by proceeding as in the electric port case we find $\mathrm{curl}\, \mathbf{E} = \mathbf{0}$ in Ω and $\mathbf{E}_C = -V\boldsymbol{\rho}_C$ in Ω_C. Since Ω is simply connected, we also have $\mathbf{E} = \mathrm{grad}\, \psi$ in Ω. Therefore, integrating $\mathbf{E}_C$ on the cycle γ, we find

$$\begin{aligned} 0 &= \int_\gamma \mathrm{grad}\, \psi_C \cdot d\boldsymbol{\tau} = \int_\gamma \mathbf{E}_C \cdot d\boldsymbol{\tau} \\ &= -\int_\gamma V\boldsymbol{\rho}_C \cdot d\boldsymbol{\tau} = -V. \end{aligned}$$

Thus $V = 0$, and consequently $\mathbf{E} = \mathbf{0}$.

Having solved (18), the magnetic field in Ω is as usual defined as

$$\mathbf{H} = -\frac{1}{i\omega}\boldsymbol{\mu}^{-1} \mathrm{curl}\, \mathbf{E}.$$

A similar formulation has been proposed in [23], [8] (in the former paper, by replacing the source $V\boldsymbol{\rho}_C$ by $V \,\mathrm{grad}\, \widetilde{\Phi}_C$, $\widetilde{\Phi}_C$ being a function jumping by 1 through a section Σ of Ω_C). However, in these papers the electric field is not the solution $\mathbf{E}_C$ to $(18)_1$ but is corrected in Ω_C by adding the source term. In this way the Faraday law is no longer verified across the interface Γ.

The same remark applies for the voltage excitation problem of the preceding subsection and the formulations proposed in [21], [23].

5. Numerical approximation. The variational formulations presented in the preceding section can be used as a starting point for devising finite element methods for approximating the solution.

In fact, the voltage excitation problem reduces to a standard problem with a given current density ($V\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_C$ or else $V\boldsymbol{\sigma}\boldsymbol{\rho}_C$); therefore, any method used for eddy-current problems can be applied. Without any attempt at being complete, let us mention only those proposed in [17], [9], [2], [4] for the $\mathbf{H}$-formulation and in [27], [11], [24], [25], [5] for the $\mathbf{E}$-formulation (or for the related magnetic vector potential formulation).

It is worthwhile to note that, when considering the $\mathbf{H}$-formulation, it is not necessary to construct the functions $\mathrm{grad}\,\phi_C$ or $\boldsymbol{\rho}_C$. In fact, to give an example for the electric port case, one can proceed in this way: consider a fixed (and coarse) mesh in Ω_C, and let $\mathcal{I}_*^C$ be the finite element interpolant taking value 0 everywhere, except on Γ_J, where it has value 1. Then define ϕ_* to be the solution to

$$\begin{cases} \mathrm{div}(\boldsymbol{\sigma}\,\mathrm{grad}\,\phi_*) = -\,\mathrm{div}(\boldsymbol{\sigma}\,\mathrm{grad}\,\mathcal{I}_*^C) & \text{in } \Omega_C, \\ \phi_* = 0 & \text{on } \Gamma_E \cup \Gamma_J, \\ \boldsymbol{\sigma}\,\mathrm{grad}\,\phi_* \cdot \mathbf{n} = -\boldsymbol{\sigma}\,\mathrm{grad}\,\mathcal{I}_*^C \cdot \mathbf{n} & \text{on } \Gamma. \end{cases}$$

Thus $\phi_C = \mathcal{I}_*^C + \phi_*$ in Ω_C, and

$$\begin{aligned} \textstyle\int_{\Omega_C} \mathrm{grad}\,\phi_C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C &= \textstyle\int_{\Omega_C} (\mathrm{grad}\,\mathcal{I}_*^C + \mathrm{grad}\,\phi_*) \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C, \\ &= \textstyle\int_{\Omega_C} \mathrm{grad}\,\mathcal{I}_*^C \cdot \mathrm{curl}\,\overline{\mathbf{w}}_C, \end{aligned}$$

as $\mathrm{div}\,\mathrm{curl}\,\overline{\mathbf{w}}_C = 0$, $\phi_* = 0$ on $\Gamma_E \cup \Gamma_J$, and $\mathrm{curl}\,\overline{\mathbf{w}}_C \cdot \mathbf{n} = 0$ on Γ.

Therefore, we have verified that in the $\mathbf{H}$-based variational formulations one can substitute ϕ_C by the easily computable $\mathcal{I}_*^C$, and the solution $\mathbf{H}$ remains the same. Clearly, the need to compute ϕ_C (namely, ϕ_*) comes into play again if one wants to recover $\mathbf{E}_C$, which is given by

$$\mathbf{E}_C = \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C - V\,\mathrm{grad}\,\phi_C = \boldsymbol{\sigma}^{-1}\,\mathrm{curl}\,\mathbf{H}_C - V\,\mathrm{grad}\,\mathcal{I}_*^C - V\,\mathrm{grad}\,\phi_*.$$

If the current intensity is given, the constraint $\int_{\Omega_C} \mathbf{Q}_C \cdot \mathrm{curl}\,\mathbf{H}_C = I$ has to be added (here $\mathbf{Q}_C = \mathrm{grad}\,\phi_C$ or else $\mathbf{Q}_C = \boldsymbol{\rho}_C$). In the $\mathbf{H}$-formulation, the voltage V plays the role of a Lagrange multiplier associated to this constraint, and the global problem is a saddle-point problem. For any type of conforming finite element discretization using edge elements in Ω_C, the presence of this Lagrange multiplier requires that an inf-sup condition like

$$\left| \int_{\Omega_C} \mathbf{Q}_C \cdot \mathrm{curl}\,\mathbf{w}_{C,h}^* \right| \geq \beta ||\mathbf{w}_h^*||_X$$

is satisfied for a constant $\beta > 0$, independent of h, and a suitable discrete vector function $\mathbf{w}_h^*$.

This can be done as follows (for instance, let us focus on the electric port case): expressing $\operatorname{grad} \phi_C$ in terms of $\operatorname{grad} \mathcal{I}^C_*$, as done before, we have by integration by parts and the Stokes theorem

$$\begin{aligned} \int_{\Omega_C} \operatorname{grad} \phi_C \cdot \operatorname{curl} \mathbf{w}^*_{C,h} &= \int_{\Omega_C} \operatorname{grad} \mathcal{I}^C_* \cdot \operatorname{curl} \mathbf{w}^*_{C,h} = \int_{\Gamma_J} \operatorname{curl} \mathbf{w}^*_{C,h} \cdot \mathbf{n} \\ &= \int_{\partial\Gamma_J} \mathbf{w}^*_{C,h} \cdot d\boldsymbol{\tau} = \int_{\partial\Gamma_J} \mathbf{w}^*_{I,h} \cdot d\boldsymbol{\tau}. \end{aligned}$$

Let us consider a fixed (and coarse) mesh in Ω, and let $\mathcal{I}^I_*$ be the finite element interpolant taking value 0 everywhere in Ω_I, except on the cutting surface Ξ, transversal to Γ_D and Γ, where it has a double value, 0 on one side and 1 on the other side (following the orientation of $\partial\Gamma_J$, that is, counterclockwise with respect to $\mathbf{n}$ on Γ_J). From now on we consider triangulations that are all obtained as a refinement of the basic coarse mesh in such a way that a discrete function on the coarse mesh is also a discrete function on all the other meshes. Then choose as $\mathbf{w}^*_{I,h}$ the $(L^2(\Omega_I))^3$-extension of $\operatorname{grad} \mathcal{I}^I_*$, computed in $\Omega_I \setminus \Xi$; note that $\operatorname{grad} \mathcal{I}^I_* \times \mathbf{n}$ is defined in a unique way on Ξ, as the jump of $\mathcal{I}^I_*$ on Ξ is equal to 1. Finally, take as $\mathbf{w}^*_{C,h}$ the edge element interpolant, on the coarse mesh in Ω_C, of the value $\mathbf{w}^*_{I,h} \times \mathbf{n}_I$ on Γ. It is easily checked that with this choice $\int_{\partial\Gamma_J} \mathbf{w}^*_{I,h} \cdot d\boldsymbol{\tau} = 1$ and that the norm $||\mathbf{w}^*_h||_X$ does not depend on h, and therefore the inf-sup condition is satisfied.

Coming to the **E**-formulation, when the current intensity is assigned it takes a nonstandard form: in fact, in (14) and (18) it is questionable if the sesquilinear forms on the left-hand sides are coercive, and, on the other hand, the current intensity condition is not a pure constraint, so that these problems are not saddle-point problems. In this paper we have proved existence and uniqueness of the solution for the infinite dimensional case, but a complete analysis of a finite element approximation method could be a more delicate point. However, this approach was used in [8] for an axisymmetric problem, with good numerical performances.

Remark 5.1. When the current intensity is assigned, it is possible to devise an alternative formulation in terms of a magnetic vector potential and an electric scalar potential, with the Coulomb gauge. Namely, one looks for $\mathbf{A}$ and v_C such that

$$\boldsymbol{\mu}\mathbf{H} = \operatorname{curl} \mathbf{A} \quad \text{in } \Omega, \quad \mathbf{E}_C = -i\omega \mathbf{A}_C - \operatorname{grad} v_C \quad \text{in } \Omega_C,$$

with $\operatorname{div} \mathbf{A} = 0$ in Ω and $\mathbf{A} \cdot \mathbf{n} = 0$ on $\partial\Omega$.

Writing (14) and (18) in terms of these unknowns, and inserting the gauging term as a penalization, as is usually done with this approach, one ends up with a sesquilinear form that can be proved to be coercive (for similar computations, see [14], where the analysis of the $\mathbf{A} - v_C$ method is presented when the excitation is due to a given current density $\mathbf{J}_e$).

Acknowledgments. It is a pleasure to thank Oszkár Bíró and Rafael Vázquez Hernández for some useful conversations about the subject of this paper.

GLOBAL STABILITY OF VIRUS SPREADING IN COMPLEX HETEROGENEOUS NETWORKS*

LIN WANG† AND GUAN-ZHONG DAI‡

Abstract. Various networks are possessed of an obvious heterogeneity in the connectivity properties, and it is of practical significance to study epidemic spreading in networks of this kind. Pastor-Satorras and Vespignani established the dynamical mean-field reaction rate equations for the spreading of infections in complex heterogeneous networks based on the well-known SIS model, and figured out an epidemic threshold λ_c such that if λ (effective spreading rate) is above λ_c, the infection spreads and becomes endemic. The significance of this result is far-reaching; however, the authors have not found a strict mathematical proof of their conclusion in the literature. In this paper, we approach this problem by proving that if λ is above λ_c, the infection spreads and approaches the unique positive stationary point of the reaction rate equations as long as there exist infected nodes in the network initially; i.e., the virus infection process is globally stable.

Key words. heterogeneity, spreading of infections, SIS, stability

1. Introduction.

In recent years, complex networks have been widely researched, with research mainly focused on network topology, network evolutionary models, network dynamics, and empirical studies on real networks; see, e.g., [1, 2, 3]. Various networks are complex heterogeneous networks, where there is an obvious heterogeneity in the connectivity properties of network nodes. The node degree distribution of these networks is found, through empirical studies, to follow power law, which implies an unexpected statistical abundance of vertices, so-called hubs, with very large degrees. Examples of such networks include the Internet [4], Reply Networks on Bulletin Board System [5], the network of airline connections [6], and the web of sexual contacts [7], just to list a few which are relevant to epidemic spreading. Thus, it is of practical significance to study epidemic spreading on complex heterogeneous networks.

The extreme heterogeneity of real networks relevant to epidemic spreading implies that traditional epidemiological models such as the SI model, SIS model, and SIR model need scrutiny in the framework of complex heterogeneous networks, and it has been discovered that in heterogeneous networks, these models behave much differently from those in homogeneous ones [8, 6, 9, 10, 11]. The work done by Pastor-Satorras and Vespignani is the famous representative research in this area, and they present a detailed analytical and numerical study on the SIS model in the framework of complex networks [10, 11].

In the SIS model, each node exists in only two discrete states, "healthy" or "infected." At each time step, the susceptible (healthy) node is infected with rate $\nu \times k'$ if it is connected to k' infected nodes. At the same time, infected nodes are cured and become again susceptible with rate δ. We define an effective spreading rate $\lambda = \nu/\delta$.

Without loss of generality, we can set $\delta = 1$. Since there exists a large difference in the degree values of nodes in complex networks, and since nodes with different degree values also have different probabilities of being connected to infected nodes, it is therefore very inaccurate to describe a virus infection process in complex networks with only one unifying dynamical reaction rate equation as in traditional epidemiological models. Pastor-Satorras and Vespignani established the following dynamical mean-field reaction rate equation based on the SIS model [10, 11]:

$$\frac{d\rho_k(t)}{dt} = -\rho_k(t) + \lambda k[1-\rho_k(t)]\Theta(t), \qquad k = 1, 2, \ldots, n, \qquad \lambda > 0, \tag{1.1}$$

where $\rho_k(t)$ denotes the relative density of infected nodes with given degree k, $k = 1, 2, \ldots, n$, n denotes the maximum degree values of all nodes, $P(i) \geq 0$ denotes the density of nodes with given degree i, $\Theta(t) = \langle k\rangle^{-1}\sum_{i=1}^{n} iP(i)\rho_i(t)$, and $\langle k\rangle$ denotes the mean of degree values; i.e., $\langle k\rangle = \sum_{i=1}^{n} iP(i)$. For convenience, we call (1.1) the Satorras–Vespignani (SV) rate equation.

The stationary point of the SV rate equation satisfies the following algebraic equation:

$$-\rho_k + \lambda k\left(1-\rho_k\right)\langle k\rangle^{-1}\sum_{i=1}^{n} iP(i)\rho_i = 0, \qquad \rho_k \geq 0. \tag{1.2}$$

Pastor-Satorra and Vespignani noticed the fact that if and only if $\lambda > \lambda_c = \langle k\rangle / \langle k^2\rangle$, the SV rate equation allows a positive stationary point, and in this case, there exists only one positive stationary point, where $\langle k^2\rangle = \sum_{k=1}^{n} k^2 P(k)$ denotes the second order moment of the node degree distribution. By virtue of this fact, Pastor-Satorras and Vespignani inferred that if $\lambda > \lambda_c$, the infection spreads and becomes endemic; i.e., the SV equation is globally stable. However, so far as the authors know, no current literature presents a theoretical proof of this conclusion.

In this paper, we give a detailed analytical solution to this problem. We prove that if $\lambda > \lambda_c$ and there exist infected nodes initially, i.e., $\sum_{i=1}^{n} iP(i)\rho_i(0) > 0$, the relative density of infected nodes with given connectivity k will approach the unique stationary point of the SV rate equation, i.e., $\lim_{t\to\infty}\rho_k(t) = \rho_k$.

2. Global stability of epidemic spreading. Before stating and proving the main theorem of this paper, we first prove the following lemma.

LEMMA 1. *Suppose that the initial relative infected densities* $0 \leq \rho_k(0) \leq 1$ *satisfy* $\sum_{i=1}^{n} iP(i)\rho_i(0) > 0$*; then as* $t > 0$*, the solution* $\rho_k(t)$ *of* (1.1) *satisfies* $0 < \Theta(t) < 1$, $0 < \rho_k(t) < 1$.

Proof. By (1.1), $\Theta(t)$ satisfies the following equation:

$$\frac{d\Theta(t)}{dt} = -\Theta(t) + \lambda\langle k\rangle^{-1}\sum_{k=1}^{n} k^2 P(k)[1-\rho_k(t)]\Theta(t). \tag{2.1}$$

Since $\Theta(0) = \langle k\rangle^{-1}\sum_{i=1}^{n} iP(i)\rho_i(0) > 0$, by virtue of the Picard–Lindelöf theorem on existence and uniqueness of solutions of differential equations, we know that $\Theta(t) \neq 0$ for any $t > 0$; therefore, as $t > 0$, $\Theta(t) > 0$.

Equation (1.1) can be rewritten as

$$\frac{d\rho_k(t)}{dt} = -\left[1 + \lambda k\Theta(t)\right]\rho_k(t) + \lambda k\Theta(t). \tag{2.2}$$

Since $\Theta(t) > 0$, we have

$$\frac{d\rho_k(t)}{dt} + [1 + \lambda k \Theta(t)]\, \rho_k(t) > 0. \tag{2.3}$$

Multiplying the above inequality by $\exp[t + \lambda k \int_0^t \Theta(s) ds]$ and integrating from 0 to t, we get

$$\rho_k(t) > \rho_k(0) \exp\left[-t - \lambda k \int_0^t \Theta(s) ds\right] \geq 0, \tag{2.4}$$

where $t > 0$.

On the other hand, it can be verified that the function $1 - \rho_k(t)$ satisfies the equation

$$\frac{d\,[1 - \rho_k(t)]}{dt} = -\,[1 + \lambda k \Theta(t)]\,[1 - \rho_k(t)] + 1. \tag{2.5}$$

Similarly to the above proof, we have $1 - \rho_k(t) > 0$. Thus, as $t > 0$, it follows that $0 < \rho_k(t) < 1$. □

The above lemma signifies that if there are infected nodes in the network initially, no matter how many and how distributed, then at any time after the infection process starts, there will appear infected nodes with any given degree.

Now, we prove the main theorem of this paper.

THEOREM 1. *Suppose that the initial relative infected densities* $0 \leq \rho_k(0) \leq 1$ *satisfy* $\sum_{i=1}^n iP(i)\rho_i(0) > 0$ *and that* $\lambda > \langle k \rangle \big/ \langle k^2 \rangle$*; then* $\rho_k(t)$*, the solution of the SV rate equation, satisfies* $\lim_{t\to\infty} \rho_k(t) = \rho_k$*, where* $\rho_1, \rho_2, \ldots, \rho_n$ *are the unique nonzero stationary points of the SV rate equation.*

Proof. In order to prove this theorem, we first prove that the limit $\lim_{t\to\infty} \rho_k(t)$ exists. For this purpose, we have to prove that

$$\liminf_{t\to+\infty} \rho_k(t) = \limsup_{t\to+\infty} \rho_k(t).$$

Letting $u_k^{(1)} = 1$, define the sequence

$$u_k^{(m+1)} = \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m)}}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m)}}, \qquad 1 \leq k \leq n, \qquad m = 1, 2, \ldots. \tag{2.6}$$

According to Lemma 1, for $1 \leq k \leq n$, $\limsup_{t\to+\infty} \rho_k(t) \leq 1 = u_k^{(1)}$. Applying Proposition 2 in the appendix repeatedly, we obtain

$$\limsup_{t\to+\infty} \rho_k(t) \leq u_k^{(m)}, \qquad 1 \leq k \leq n, \qquad m = 1, 2, \ldots. \tag{2.7}$$

Consider the convergence of the sequence defined by (2.6). By (2.6), for all k, $u_k^{(2)} \leq 1 = u_k^{(1)}$. If, for all k, $u_k^{(m+1)} \leq u_k^{(m)}$, it follows from (2.6) that

$$\begin{aligned} \forall k,\ u_k^{(m+2)} &= \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m+1)}}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m+1)}} \\ &\leq \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m)}}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) u_i^{(m)}} = u_k^{(m+1)}. \end{aligned} \tag{2.8}$$

By induction, we know that for each k, the sequence $u_k^{(m)}$ is decreasing, so its limit exists and is denoted by $u_k = \lim_{m\to\infty} u_k^{(m)}$. Leting $m \to \infty$ on both sides of (2.6)–(2.7), we deduce that $u_k = \lim_{m\to\infty} u_k^{(m)}$ satisfies the following relations:

$$\begin{aligned} &-u_k + \lambda k\,(1-u_k)\,\langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)u_i = 0, \\ &\limsup_{t\to+\infty} \rho_k(t) \le u_k, \qquad 1 \le k \le n. \end{aligned} \tag{2.9}$$

On the other hand, we consider the function

$$f(x) = \langle k\rangle^{-1} \sum_{k=1}^{n} \frac{\lambda k^2 P(k)x}{1+\lambda kx} - x. \tag{2.10}$$

By simple calculations, we obtain

$$\begin{aligned} f(0) &= 0, \\ f'(0) &= \langle k\rangle^{-1} \sum_{k=1}^{n} \lambda k^2 P(k) - 1 \\ &= \lambda \langle k\rangle^{-1} \left\langle k^2\right\rangle - 1 > 0. \end{aligned} \tag{2.11}$$

By the definition of derivatives, if $x > 0$ is sufficiently small, then $f(x) > f(0) = 0$.

According to Proposition 1 in the appendix and (2.11), we can take $l_k^{(1)}$ such that

$$\forall k,\ 0 < l_k^{(1)} < \liminf_{t\to\infty} \rho_k(t), \qquad f\left(\langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(1)}\right) > 0. \tag{2.12}$$

We define the following sequence:

$$l_k^{(m+1)} = \frac{\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(m)}}{1+\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(m)}}, \qquad 1 \le k \le n, \qquad m = 1, 2, \ldots. \tag{2.13}$$

By (2.12) and applying Proposition 2 in the appendix repeatedly, we have

$$\liminf_{t\to+\infty} \rho_k(t) \ge l_k^{(m)}, \qquad 1 \le k \le n, \qquad m = 1, 2, \ldots. \tag{2.14}$$

Now consider the convergence of the sequence defined by (2.13). First, according to (2.10), (2.12), and (2.13), we have

$$\langle k\rangle^{-1} \sum_{k=1}^{n} kP(k)l_i^{(2)} > \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(1)}. \tag{2.15}$$

By (2.13) and (2.15), we obtain

$$\begin{aligned} \forall k,\ l_k^{(3)} &= \frac{\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(2)}}{1+\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(2)}} \\ &> \frac{\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(1)}}{1+\lambda k \langle k\rangle^{-1} \sum_{i=1}^{n} iP(i)l_i^{(1)}} = l_k^{(2)}. \end{aligned} \tag{2.16}$$

If for all k, $l_k^{(m+1)} > l_k^{(m)}$, it follows from (2.13) that

$$\begin{aligned}\forall k,\ l_k^{(m+2)} &= \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) l_i^{(m+1)}}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) l_i^{(m+1)}} \\ &> \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) l_i^{(m)}}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^n iP(i) l_i^{(m)}} = l_k^{(m+1)}. \qquad (2.17)\end{aligned}$$

Thus, by induction, we know that, for each k, the sequence $l_k^{(m)}$, $m \geq 2$, is increasing, so its limit exists and is denoted by $l_k = \lim_{m\to\infty} l_k^{(m)}$. Letting $m \to \infty$ on both sides of (2.13)–(2.14), we deduce that the limit $l_k = \lim_{m\to\infty} l_k^{(m)}$ satisfies the following relations:

$$\begin{aligned} &-l_k + \lambda k (1 - l_k) \langle k \rangle^{-1} \sum_{i=1}^n iP(i) l_i = 0, \\ &l_k \leq \liminf_{t\to+\infty} \rho_k(t), \qquad 1 \leq k \leq n. \qquad (2.18)\end{aligned}$$

By (2.9) and (2.18), both $u_k = \lim_{m\to\infty} u_k^{(m)}$ and $l_k = \lim_{m\to\infty} l_k^{(m)}$ are positive stationary points of the SV rate equation; thus by the uniqueness of the positive stationary point of the SV rate equation, we have that $u_k = l_k = \rho_k$ and

$$\rho_k \leq \liminf_{t\to+\infty} \rho_k(t) \leq \limsup_{t\to+\infty} \rho_k(t) \leq \rho_k, \qquad 1 \leq k \leq n. \qquad (2.19)$$

That is, $\lim_{t\to\infty} \rho_k(t) = \rho_k$, and Theorem 1 is proved. □

Theorem 1 indicates that if $\lambda > \langle k \rangle / \langle k^2 \rangle$ and there exist infected nodes (no matter how few) in the network initially, then after a duration of transitions between healthy nodes and infected nodes, the infection process becomes stable and the relative density $\rho_k(t)$ of infected nodes with given degree k approaches the unique positive stationary point of the SV rate equation.

3. Conclusions. In this paper, we present a strict proof of global stability of dynamical mean-field reaction rate equations for the spreading of infections in complex heterogeneous networks based on the well-known SIS model established by Pastor-Satorras and Vespignani. According to our theorem, if the virus spread speed is above the threshold ($\langle k \rangle / \langle k^2 \rangle$), then as long as there exist infected nodes in the system, infections will spread, and the eventual proportion of infected nodes with given degree is independent of the initial number of infected nodes; i.e., the infection process is globally stable.

Appendix. Proof of two propositions. In the appendix, we will prove some properties about the solution and stationary point of the SV rate equation:

$$\frac{d\rho_k(t)}{dt} = -\rho_k(t) + \lambda k[1 - \rho_k(t)]\Theta(t), \qquad k = 1, 2, \ldots, n, \qquad \lambda > 0, \qquad (A.1)$$

where $\Theta(t) = \langle k \rangle^{-1} \sum_{i=1}^n iP(i)\rho_i(t)$.

PROPOSITION 1. *Suppose that the initial relative infected densities* $0 \leq \rho_k(0) \leq 1$ *satisfy* $\sum_{i=1}^n iP(i)\rho_i(0) > 0$ *and that* $\lambda > \langle k \rangle / \langle k^2 \rangle$*; then the solution* $\rho_k(t)$ *of* (A.1) *satisfies* $\inf_{t\geq 0} \Theta(t) > 0$*; for any* $\tau > 0$*,* $\inf_{t\geq\tau} \rho_k(t) > 0$.

Proof. According to Lemma 1, as $t \geq 0$, $\Theta(t) > 0$. By (2.1), we have

$$\frac{\frac{d\Theta(t)}{dt}}{\Theta(t)} = \left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda \langle k \rangle^{-1} \sum_{k=1}^{n} k^2 P(k) \rho_k(t). \tag{A.2}$$

It follows easily that

$$\frac{\frac{d\Theta(t)}{dt}}{\Theta(t)} \geq \left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda n \Theta(t). \tag{A.3}$$

We will prove that there exists $\bar{t} > 0$ such that as $t \geq \bar{t}$,

$$\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda n \Theta(t) < \frac{\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2}. \tag{A.4}$$

First notice that there exists $\bar{t} > 0$ such that as $t = \bar{t}$, (A.9) holds. Otherwise, for all $t > 0$, the following holds:

$$\begin{aligned} \frac{\frac{d\Theta(t)}{dt}}{\Theta(t)} &\geq \left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda n \Theta(t) \\ &\geq \frac{\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2}. \end{aligned} \tag{A.5}$$

By integrating on both sides of (A.5), we have, for all $t > 0$,

$$\Theta(t) \geq \Theta(0) \exp\left[\frac{t\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2}\right] \to \infty,$$

which contradicts $\Theta(t) < 1$. So, there exists $\bar{t} > 0$, such that as $t = \bar{t}$, (A.4) holds. Now, we further prove that as $t \geq \bar{t}$, (A.4) holds. If this were not true, there would exist $t_1 > \bar{t}$ such that

$$t_1 = \inf\left\{ t > \tau \,\middle|\, \left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda n \Theta(t) \geq \frac{\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2} \right\}. \tag{A.6}$$

Thus, as $0 < t < t_1$, (A.4) holds, while as $t = t_1$,

$$\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right) - \lambda n \Theta(t) = \frac{\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2}. \tag{A.7}$$

By (A.3), we have

$$\left.\frac{d\Theta(t)}{dt}\right|_{t=t_1} \geq \Theta(t_1) \frac{\left(\lambda \frac{\langle k^2 \rangle}{\langle k \rangle} - 1\right)}{2} > 0. \tag{A.8}$$

By the definition of derivatives, as t approaches t_1 from the left of t_1, $\Theta(t) < \Theta(t_1)$, so

$$\begin{aligned}\left(\lambda\frac{\langle k^2\rangle}{\langle k\rangle}-1\right)-\lambda n\Theta(t) &> \left(\lambda\frac{\langle k^2\rangle}{\langle k\rangle}-1\right)-\lambda n\Theta(t_1)\\ &= \frac{\left(\lambda\frac{\langle k^2\rangle}{\langle k\rangle}-1\right)}{2}, \qquad \text{(A.9)}\end{aligned}$$

which contradicts the definition of t_1, so, as $t \geq \bar{t}$, (A.4) holds. That is, as $t \geq \bar{t}$, the following holds:

$$\Theta(t) > \frac{1}{2\lambda n}\left(\lambda\frac{\langle k^2\rangle}{\langle k\rangle}-1\right). \qquad \text{(A.10)}$$

By virtue of Lemma 1 and continuity of $\Theta(t)$, we have

$$\inf_{t\geq 0}\Theta(t) = \min\left[\inf_{0\leq t\leq \bar{t}}\Theta(t), \inf_{t>\bar{t}}\Theta(t)\right] > 0. \qquad \text{(A.11)}$$

We prove the second conclusion next. Letting $\sigma = \inf_{t\geq 0}\Theta(t)$, by (A.1), as $t > 0$, the following holds:

$$\begin{aligned}\frac{d\rho_k(t)}{dt} &= -\left(1+\lambda k\Theta(t)\right)\rho_k(t)+\lambda k\Theta(t)\\ &\geq -\left(1+\lambda k\right)\rho_k(t)+\lambda k\sigma. \qquad \text{(A.12)}\end{aligned}$$

Multiplying both sides of the above inequality by $\exp\left[\left(1+\lambda k\right)t\right]$ and taking integration, we have

$$\begin{aligned}\rho_k(t) \geq\ & \exp\left[-\left(1+\lambda k\right)t\right]\rho_k(0)\\ &+\frac{\lambda k\sigma}{1+\lambda k}\left(1-\exp\left[-\left(1+\lambda k\right)t\right]\right), \qquad \text{(A.13)}\end{aligned}$$

from which we know that, for any $\tau > 0$, $\inf_{t\geq\tau}\rho_k(t) > 0$. □

The main theorem of this paper is proved by virtue of the following proposition.

PROPOSITION 2. *Suppose the solution* $\rho_k(t)$ *of* (A1) *satisfies* $\limsup_{t\to+\infty}\rho_k(t) \leq u_k$ *and* $\liminf_{t\to+\infty}\rho_k(t) \geq l_k$*, where* $u_k \geq 0$*,* $l_k \geq 0$*; then*

$$\begin{aligned}\limsup_{t\to+\infty}\rho_k(t) &\leq \frac{\frac{\lambda k}{\langle k\rangle}\sum_{i=1}^{n} iP(i)u_i}{1+\frac{\lambda k}{\langle k\rangle}\sum_{i=1}^{n} iP(i)u_i},\\ \liminf_{t\to+\infty}\rho_k(t) &\geq \frac{\frac{\lambda k}{\langle k\rangle}\sum_{i=1}^{n} iP(i)l_i}{1+\frac{\lambda k}{\langle k\rangle}\sum_{i=1}^{n} iP(i)l_i}. \qquad \text{(A.14)}\end{aligned}$$

Proof. Since $\limsup_{t\to+\infty}\rho_k(t) \leq u_k$, for all $\varepsilon > 0$, there exists $\tau > 0$ such that as $t \geq \tau$, $\rho_k(t) \leq u_k+\varepsilon$. According to Lemma 1, we have $1-\rho_k(t) > 0$, so, by (A.1), we know that, as $t \geq \tau$, the following holds:

$$\frac{d\rho_k(t)}{dt} \leq -\rho_k(t)+\lambda k[1-\rho_k(t)]\langle k\rangle^{-1}\sum_{i=1}^{n} iP(i)(u_i+\varepsilon). \qquad \text{(A.15)}$$

It follows easily that

$$\begin{aligned}\frac{d\rho_k(t)}{dt} \leq & -\left[1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)\right] \rho_k(t) \\ & + \lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon).\end{aligned} \tag{A.16}$$

It follows from (A.16) that

$$\begin{aligned}\rho_k(t) \leq & \frac{\rho_k(\tau)}{\exp\left\{\left(1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)\right)(t - \tau)\right\}} \\ & + \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)}.\end{aligned} \tag{A.17}$$

Taking the limit as $t \to +\infty$, we obtain

$$\limsup_{t \to +\infty} \rho_k(t) \leq \frac{\lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)}{1 + \lambda k \langle k \rangle^{-1} \sum_{i=1}^{n} iP(i)(u_i + \varepsilon)}. \tag{A.18}$$

Letting $\varepsilon \to +\infty$, we obtain the first inequality in (A.14). The second inequality in (A.14) can be proved similarly. □

ELECTRIC DISCHARGE SINTERING: A MATHEMATICAL MODEL[*]

G. A. KRIEGSMANN[†]

Abstract. In this paper we mathematically model the densification of metallic powders and the sintering of ceramic powders by electric discharge. The ordinary and partial differential equations governing these processes are the same with the exception of the effective electrical conductivity. This function is a monotonically decreasing (increasing) function of temperature for the metallic (ceramic) powders. We employ asymptotic methods to approximate the solution to these equations in the limit as $\epsilon \to 0$, where ϵ is the ratio of the discharge to diffusion time scales. We find on the shortest time scale that the temperature, voltage, and density satisfy a system of nonlinear, coupled ordinary equations. We solve these and find the relationship between the temperature and density, as functions of the input energy. The results on the short or discharge time scale do not take into account diffusion and heat loss into the surrounding medium. These occur on a much longer time scale, which we identify and exploit to deduce a new approximation. On this time scale the capacitor has no more energy to deposit into the powder. The temperature relaxes to that of its surroundings and the density increases to its final value. Our results show the functional relationship between the final density and the initial energy stored in the capacitor, as well as the initial density of the powder.

1. Introduction.

Over the last several years researchers have used electric discharges to sinter ceramic materials and to compact metal powders [1, 2, 3]. The experimental configurations have cylindrical dies, which contain a powdered material. The green powders are compacted with punches which also act as electrodes through which a short, powerful current pulse is passed. The source of the current is a capacitor bank that is charged to a few hundred volts and in some applications to metal powders, 20 kilovolts [2]. In all cases the dies are surrounded by a thermally insulating layer such as alumina, Al_2O_3. The short current pulse passing through the powder rapidly heats it to a temperature at which the ceramic powder sinters or the metallic powders meld together. A schematic of the experimental set-up is shown in Figure 1.

In this paper we introduce a mathematical model to describe this sintering or densification process. Specifically, our model takes the form of a heat equation, a Laplace equation describing the electric potential, and an evolution equation describing the densification of the powder. All of these equations are coupled and nonlinear. In addition, there is a differential equation relating the change in the capacitor voltage across the punches to the current flowing through them. Implicit in this mathematical description is the assumption that the powdered material can be treated as a continuum.

Our mathematical model is very similar to the one developed and analyzed to describe temperature surges in thermistors [4]. There are two obvious differences; the first is the addition of the evolution equation for the density, and the second, the

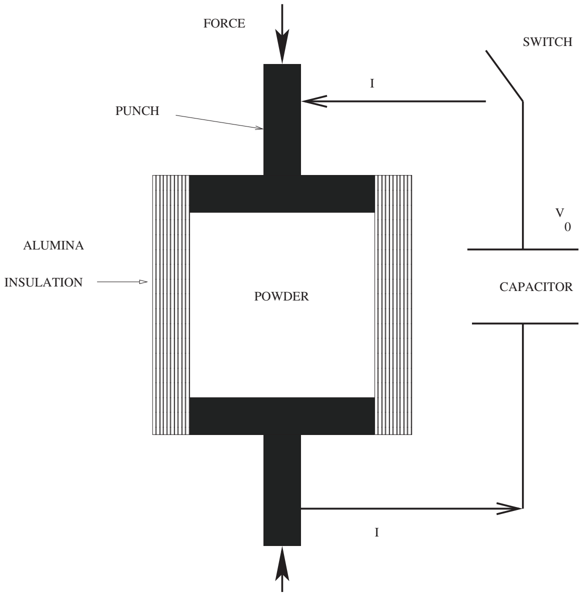

Fig. 1. *Schematic of experimental set-up.*

equation for the capacitor voltage. In reference [4] the external circuit was a battery and resistor in series with the thermistor. More subtle and important differences are the time scales. These produce different physical balances and hence different physics. For example, the time scale describing the source in our heat equation is commensurate with the capacitive discharge time scale; both are very small compared with the diffusion time scale along the axis of the experimental device. In the thermistor model the source and diffusion time scales are of the same order; the result is a nonlinear, nonlocal heat equation.

Denoting the ratio of the source to diffusion time scales by ϵ, we perform an asymptotic analysis of the solutions to our equations as $\epsilon \to 0$. Assuming that the sintering dynamics occur on the same time scale as the source, our analysis shows that the temperature, voltage, and density satisfy a system of three nonlinear ordinary differential equations to leading order. These are analyzed, and the qualitative features of the solutions are described. In particular, the capacitor voltage decays to zero, the density reaches a maximum, and the temperature achieves a maximum, too; all depend in a critical fashion on the initial energy stored in the capacitor. These results are valid only on the source time scale which we call the heating regime. On the much longer convective time scale, the thermal energy decays as the sample loses heat to the surrounding medium through the metallic punches. In this span of time the temperature of the sample decays to that of the surrounding environment. On this time scale, diffusion plays a minor role, yielding an $O(\epsilon^2)$ spatial variation along the axis of the experimental device.

If the sintering or the densification dynamics occur on the convective time scale, the results are more complicated. In the heating regime, the voltage again decays to zero, the density remains at its initial value, and the temperature achieves a maximum. This maximum depends upon the initial density and the initial energy stored in the capacitor. These results again are valid only in the heating regime. On the convective time scale the density increases to its final value, and the temperature decays to that of the surrounding medium. The final density depends critically upon its initial value and the energy stored in the capacitor. Our results explicitly show this dependence.

We close this introduction by giving a brief outline of the paper. Section 2 contains the mathematical formulation of our model. In section 3 a careful dimensional analysis is given identifying the relevant time scales for our problem. Section 4 contains our asymptotic analyses in both the heating and convective regimes. Here the time scale associated with the sintering dynamics is taken to be commensurate with the source time scale. In section 5 we present our analysis for the slow densification case. Here the sintering time scale is commensurate with the convective time scale. Finally, section 6 contains our conclusions.

2. Problem formulation. In Figure 1 we show a schematic of an electrodischarge consolidation experiment. The powder specimen to be densified is contained in an electrically nonconducting cylinder, of radius R_0 and height L, surrounded by a layer of alumina. Two punches compress the powder through an external force F. The punches also serve as electrodes connected to a capacitor charged to an initial voltage V_0 which can be on the order of a few hundred to several thousand volts. When the switch is closed the capacitor discharges and creates a current, I, which flows through the powder specimen. This rapidly heats the powder and causes it to sinter into a dense material.

We model the compacted powder as a continuum with a temperature T, defined inside the cylindrical region $0 < Z < L$, $0 < R < R_0$, satisfying

$$\frac{\partial}{\partial t}[\rho C_p T] = \nabla \cdot (K \nabla T) + \sigma(T)|\nabla \Phi|^2, \tag{1a}$$

where ρ is an averaged density, C_p the thermal capacity, K the thermal conductivity, and σ the electrical conductivity of the powder, which all can depend upon the temperature and the external force F, with the exception of C_p. In this equation Φ is the electric potential, caused by the discharging capacitor, which satisfies in the same region

$$\nabla \cdot (\sigma \nabla \Phi) = 0. \tag{1b}$$

Denoting the voltage across the capacitor as $V(t)$ and the current flowing from it as $I(t)$, we have from Kirchoff's current law

$$C\frac{dV}{dt} = -I, \tag{1c}$$

where C is the capacitance.

We shall now determine a relationship between the current, the temperature, and the potential. First, we recall that the current density is defined by $\mathbf{J} = \sigma \nabla \Phi$, where $\nabla \Phi$ is the electric field. Next, we assume that the R component of this current density vanishes at $R = R_0$, that is, $\sigma \frac{\partial \Phi}{\partial R} = 0$ there. This assumes no current flows out of the powder into the insulation. Next, we integrate (1b) over the cylindrical domain $Z_0 < Z < Z_1$, $0 < R < R_0$, where Z_0 and Z_1 are arbitrary, apply the divergence theorem, and use $\Phi_R = 0$ at $R = R_0$ to obtain

$$\iint_{Z=Z_1} \sigma \frac{\partial \Phi}{\partial Z}\, dX\, dY = \iint_{Z=Z_0} \sigma \frac{\partial \Phi}{\partial Z}\, dX\, dY.$$

This shows that the integral of $\sigma\Phi_Z$, the Z component of the current density, is independent of Z and hence a constant. This constant is the current in (1c) and is defined by

$$I = \iint_\Omega \sigma \frac{\partial \Phi}{\partial Z}\, dX\, dY, \tag{1d}$$

where Ω is an arbitrary circular cross-section of the powder sample.

Finally, to close these equations we must model the evolution of the powder density as it sinters. We assume the phenomenological equation

$$\frac{\partial \rho}{\partial t} = G(T)[\rho_1 - \rho] \tag{1e}$$

qualitatively describes this evolution [5], where the reaction rate G depends upon temperature and ρ_1 is the bulk density for a single species powder, or an average bulk density of a multispecies powder.

The boundary conditions we apply are

$$\frac{\partial T}{\partial R} = 0, \qquad \frac{\partial \Phi}{\partial R} = 0, \quad R = R_0, \quad 0 < Z < L, \tag{2a}$$

where the first assumes a perfect thermal insulation and the second is a restatement that no current flows radially out of the sample,

$$\Phi(X,Y,0,t) = 0, \quad \Phi(X,Y,L,t) = V(t), \tag{2b}$$

which relates the potential to the capacitor voltage, and

$$K\frac{\partial T}{\partial Z} - h(T - T_A) = 0, \quad Z = 0, \qquad K\frac{\partial T}{\partial Z} + h(T - T_A) = 0, \quad Z = L, \qquad 0 < R < R_0. \tag{2c}$$

Here, we thermally model the punches by a linear Newton law of cooling where T_A is the ambient temperature of the surrounding air and h is the effective heat transfer coefficient. This boundary condition removes the need to study heat diffusion in the punch and ultimately heat convection from the punch into the surrounding medium. It is valid when the mass of the punch is small and its thermal conductivity is large. Such are the cases in [1, 2, 3].

Finally, the initial conditions required are

$$T = T_A, \quad 0 < R < R_0, \quad 0 < Z < L, \quad V(0) = V_0, \quad \rho(0) = \rho_0(F), \tag{2d}$$

where V_0 is the initial voltage of the charged capacitor and $\rho_0(F)$ is the initial density of the powder which depends upon the forces on the punches.

3. Nondimensional analysis.

We begin this section by introducing the dimensionless dependent and independent variables

$$u = \frac{T}{T_A} - 1, \quad \phi = \frac{\Phi}{V_0}, \quad v = \frac{V}{V_0}, \quad i = \frac{I}{\sigma_A V_0 L}, \quad w = \frac{\rho}{\rho_1} \tag{3a}$$

and

$$\tau = \frac{t}{\theta_S}, \quad \mathbf{x} = \frac{\mathbf{X}}{L}, \quad r = \frac{R}{L}, \tag{3b}$$

respectively. Here and henceforth, the subscript A denotes that a function is evaluated at the ambient temperature, and $\theta_S = \frac{C_p \rho_1 T_A L^2}{\sigma_A V_0^2}$ is the time scale associated with the capacitive source. We also define the dimensionless functions

$$k(u) = \frac{K(T)}{K_A}, \quad f(u) = \frac{\sigma(T)}{\sigma_A}, \quad g(u) = \frac{G(T)}{G_A}. \tag{3c}$$

Introducing (3a)–(3c) into (1a)–(1e) and combining (1c) and (1d), we find that our dimensionless equations are

$$\frac{\partial[wu]}{\partial\tau} = \epsilon\nabla\cdot(k\nabla u) + f(u)|\nabla\phi|^2, \quad 0 < z < 1, \quad 0 < r < r_0 = \frac{R_0}{L}, \quad \tau > 0, \tag{4a}$$

$$\nabla\cdot(f\nabla\phi) = 0, \quad 0 < z < 1, \quad 0 < r < r_0, \quad \tau > 0, \tag{4b}$$

$$\frac{dv}{d\tau} = -\lambda \iint_{r<r_0} f(u)\frac{\partial\phi}{\partial z}\,dx\,dy, \tag{4c}$$

$$\frac{\partial w}{\partial\tau} = \gamma g(u)(1-w). \tag{4d}$$

Here we have defined three new parameters, each a ratio of time scales. The first is $\lambda = \theta_S/\theta_C$, where $\theta_C = C/\sigma_A L$ is the capacitive time scale. The second is $\gamma = \theta_S G_A$. We assume here that both these parameters are order one quantities. On the other hand, the third parameter $\epsilon = \theta_S/\theta_Z << 1$, where $\theta_Z = \rho_0 C_p/K_A L^2$ is the diffusive time scale in the Z direction. That is, we are assuming that heat diffuses much more slowly than the source time scale. The corresponding boundary conditions become

$$\frac{\partial u}{\partial r} = 0, \qquad \frac{\partial\phi}{\partial r} = 0, \quad r = r_0, \quad 0 < z < 1, \tag{5a}$$

$$\phi(x,y,0,\tau) = 0, \qquad \phi(x,y,1,\tau) = v(t), \quad 0 < r < r_0, \tag{5b}$$

$$k(u)\frac{\partial u}{\partial z} - Bu = 0, \quad z = 0, \qquad k(u)\frac{\partial u}{\partial z} + Bu = 0, \quad z = 1. \tag{5c}$$

In (5c) the Biot number is defined by $B = \theta_Z/\theta_{con}$, where $\theta_{con} = \rho_1 C_p L/h$ is the convective time scale at which the sample cools. The Biot number is also a small parameter for $L \sim$ several centimeters. We relate it to ϵ by $B = \beta\epsilon$, where $\beta = (\theta_Z/\theta_{con})(\theta_Z/\theta_S) = O(1)$. Finally, the dimensionless initial conditions are

$$u = 0, \quad 0 < r < r_0, \quad 0 < z < 1, \qquad v(0) = 1, \qquad w(0) = \frac{\rho_0(F)}{\rho_1}. \tag{5d}$$

Equations (4)–(5) constitute our dimensionless initial boundary value problem.

4. Analysis. This section contains two parts. In the first we analyze the evolution of u, v, and w on a time scale where $\tau = O(1)$. In this time frame diffusion and convective heat losses play a minor role as the powder sample rapidly heats. We shall provide a leading order asymptotic analysis of our problem. This result becomes nonuniform for large τ when diffusion and convection become important. The analysis on a much larger time scale is the subject of the second part of this section.

4.1. The heating regime.

We begin our analysis with the observation that the boundary data and initial conditions are all independent of r and the angle θ. Thus, we shall seek a solution of (4)–(5) that depends only upon z and τ. Accordingly, (4a)–(4c) become

$$\frac{\partial[uw]}{\partial\tau} = \epsilon\frac{\partial}{\partial z}\left(k\frac{\partial u}{\partial z}\right) + f(u)\left|\frac{\partial\phi}{\partial z}\right|^2, \quad 0 < z < 1, \quad \tau > 0, \tag{6a}$$

$$\frac{\partial}{\partial z}\left(f(u)\frac{\partial\phi}{\partial z}\right) = 0, \quad 0 < z < 1, \quad \tau > 0, \tag{6b}$$

$$\frac{dv}{d\tau} = -\Lambda f(u)\frac{\partial\phi}{\partial z}, \tag{6c}$$

where $\Lambda = \pi r_0^2\lambda$. Equation (4d) remains the same as do the boundary and initial equations, except now (5c) is replaced by

$$k(u)\frac{\partial u}{\partial z} - \beta\epsilon u = 0, \quad z = 0, \qquad k(u)\frac{\partial u}{\partial z} + \beta\epsilon u = 0, \quad z = 1. \tag{6d}$$

We now exploit the smallness of the parameter ϵ and seek an asymptotic solution of the form

$$u \sim u_0 + \epsilon u_1 + \epsilon^2 u_2 + \cdots \tag{7a}$$

$$\phi{\sim}\phi_0 + \epsilon\phi_1 + \epsilon^2\phi_2 + \cdots \tag{7b}$$

$$v \sim v_0 + \epsilon v_1 + \epsilon^2 v_2 + \cdots \tag{7c}$$

$$w \sim w_0 + \epsilon w_1 + \epsilon^2 w_2 + \cdots . \tag{7d}$$

Inserting these expansions into our equations, boundary, and initial conditions, we find to leading order that u_0, v_0, ϕ_0, and w_0 satisfy

$$\frac{\partial[u_0w_0]}{\partial\tau} = f(u_0)\left|\frac{\partial\phi_0}{\partial z}\right|^2, \quad \frac{\partial u_0}{\partial z} = 0,\ z = 0, 1, \quad u_0(z,0) = 0, \tag{8a}$$

$$\frac{\partial}{\partial z}\left(f(u_0)\frac{\partial\phi_0}{\partial z}\right) = 0, \quad \phi_0(0,\tau) = 0, \quad \phi(1,\tau) = v(\tau), \quad \tau > 0, \tag{8b}$$

$$\frac{dv_0}{d\tau} = -\Lambda f(u_0)\frac{\partial\phi_0}{\partial z}, \quad v_0(0) = 1, \tag{8c}$$

$$\frac{\partial w_0}{\partial\tau} = \gamma g(u_0)(1 - w_0), \quad w_0(0) = \frac{\rho_0(F)}{\rho_1}. \tag{8d}$$

We now integrate (8b) twice and employ the boundary conditions at $z = 0$ and $z = 1$ to find

$$\phi_0 = v_0(\tau)\,\frac{Q(z)}{Q(1)}, \quad Q(z) = \int_0^z \frac{1}{f(u_0)}\,dz'.$$

Now from this result we observe that $\frac{\partial\phi_0}{\partial z} = v_0/f(u_0)Q(1)$, which is independent of z. Thus, the right-hand side of (8a) is independent of z, too, and this implies that u_0 and w_0 are functions of τ alone. This observation yields

$$\phi_0 = z\,v_0(\tau), \tag{9}$$

and upon inserting this result into (8a), (8c), and (8d) we arrive at the third order system of ordinary differential equations

$$\text{(10a)} \qquad \frac{d[u_0 w_0]}{d\tau} = f(u_0)v_0^2, \quad u_0(0) = 0,$$

$$\text{(10b)} \qquad \frac{dv_0}{d\tau} = -\Lambda f(u_0)v_0, \quad v_0(0) = 1,$$

$$\text{(10c)} \qquad \frac{dw_0}{d\tau} = \gamma g(u_0)[1 - w_0], \quad w_0(0) = \frac{\rho_0(F)}{\rho_1}.$$

We next divide (10a) by (10b), integrate this result, and use the initial conditions to obtain the first integral

$$\text{(11)} \qquad v_0^2 = 1 - 2\Lambda u_0 w_0.$$

Combining this with (10a), differentiating the left-hand side, and using (10c) to eliminate the derivative of w_0, we find

$$\text{(12)} \qquad \frac{du_0}{d\tau} = \frac{1}{w_0}\{(1 - 2\Lambda u_0 w_0)f(u_0) - \gamma u_0 g(u_0)(1 - w_0)\}, \quad w_0(0) = \frac{\rho_0(F)}{\rho_1},$$

and this combined with (10c) yields a second order system, which describes the leading order heating process.

We begin by noting that $f(u)$ is a positive function; it may increase or decrease with u depending upon the powdered material. If we assume for the moment that $g(u)$ is also a positive function, then a simple phase plane analysis of our system reveals that u_0 and w_0 both evolve from their initial conditions $(0, \rho_0/\rho_1)$ to their steady state values (u_0^*, w_0^*), where $u_0^* = 1/2\Lambda$ and $w_0^* = 1$, as $\tau \to \infty$. Coupling this information with (10b) it is easy to deduce that v_0 decreases monotonically from its initial value of 1 to its steady state $v_0^* = 0$ as $\tau \to \infty$. It is interesting to note that the final state is independent of the dimensionless electrical conductivity $f(u)$ and the dimensionless reaction rate $g(u)$. These functions will of course affect the rate at which u_0, w_0, and v_0 approach their steady state values.

A more physically realistic assumption about the function $g(u)$ is to require it to vanish for $u < u_T$ and increase monotonically and smoothly for $u > u_T$. Here u_T denotes a dimensionless threshold temperature. This characterization is equivalent to assuming that no sintering or densification occurs below this temperature. For simplicity and concreteness of presentation we take

$$g(u) = \begin{cases} 0, & 0 \le u < u_T, \\ \tanh^2(\nu(u - u_T)), & u_T \ge u, \end{cases}$$

where ν controls how rapidly g switches. For this choice of g, or any other smooth switching function, there will be two cases to consider: low power, where $\frac{1}{2\Lambda} < u_T$, and high power, where $\frac{1}{2\Lambda} > u_T$.

We begin by considering the high power case. Figure 2a shows two trajectories for different values of $w_0(0) = \rho_0/\rho_1$. Both trajectories remain horizontal, where w_0 is essentially fixed at its initial value, until they cross the threshold u_T, where w_0 increases with u_0. This continues until the right-hand side of (12) changes sign and u_0 decreases with increasing w_0. The functions u_0 and w_0 then approach the steady state

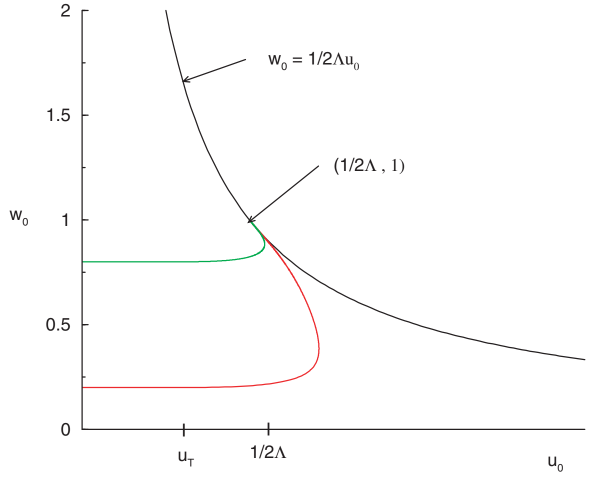

FIG. 2a. *Phase plane: High power.*

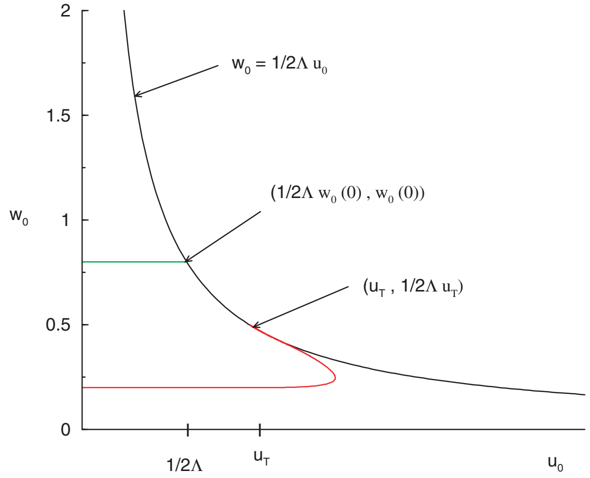

FIG. 2b. *Phase plane: Low power.*

values, $u_0^* = 1/2\Lambda$ and $w_0^* = 1$, respectively. The function v_0 converges to $v_0^* = 0$, as can be deduced from (11).

We next consider the case of low power, where the dynamics are more interesting. Figure 2b also shows two trajectories for different values of $w_0(0)$. For the larger initial condition the trajectory never crosses the threshold temperature u_T, remains horizontal, and approaches the hyperbola $w_0 = 1/2\Lambda u_0$ as $\tau \to \infty$. There $w_0^* = w_0(0)$ and $u_0^* = 1/2\Lambda w_0(0)$. The trajectory for the lower initial condition remains horizontal until it crosses u_T, where w_0 increases with u_0. This continues until the right-hand side of (12) changes sign and u_0 decreases with increasing w_0. The trajectory approaches its steady state on the hyperbola where $u_0^* = u_T$ and $w_0^* = 1/2\Lambda\, u_T$. Again, we deduce from (11) that $v_0^* = 0$.

In closing this subsection we express the final state of the system in terms of its dimensional quantities. We first consider the high power case $1/2\Lambda > u_T$ or, in dimensional terms,

$$\frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S} > T_T - T_A.$$

Here, T_T is the threshold temperature, V_S is the volume of the sample, and $\frac{1}{2}CV_0^2$ is the total energy initially stored in the capacitor. The steady state values of the density and temperature for this case are

$$\rho^* = \rho_1 w_0^* = \rho_1 \tag{13a}$$

and

$$T^* = T_A(1 + u_0^*) = T_A + \frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S}, \tag{13b}$$

respectively. The result (13a) is intuitively obvious, but (13b) is not. It states that the increase in the system's temperature above its ambient value depends very little upon the physical properties of the powder sample. In fact, it depends only upon the volume of the sample, the final density ρ_1, and the total energy initially stored in the capacitor.

In dimensional terms, the low power case occurs when

$$\frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S} < T_T - T_A.$$

If the initial density ρ_0 is sufficiently large, then, according to Figure 2b, the density remains constant and the temperature increases to $\frac{1}{2\Lambda w_0(0)}$. In terms of dimensional quantities, the steady state density and temperature are

$$\rho^* = \rho_1 w_0(0) = \rho_0 \tag{13c}$$

and

$$T^* = T_A + \frac{1}{2}\frac{CV_0^2}{\rho_0 C_p V_S}, \tag{13d}$$

respectively. The only difference between this final temperature and the one given for higher power (13b) is the presence of ρ_0 in the denominator. Finally, if the initial density is low enough, then the system evolves along the lower trajectory shown in Figure 2b. The steady state density and temperature are now given by

$$\rho^* = \rho_1 \frac{1}{2\Lambda u_T} = \frac{\rho_1}{2}\left\{\frac{CV_0^2}{\rho_1 C_P V_S}\right\}\frac{1}{T_T - T_A} \tag{13e}$$

and

$$T^* = T_A(1 + u_T) = T_T, \tag{13f}$$

respectively, where it must be recalled that the low power constraint implies $\rho^* < \rho_1$.

4.2. The cooling period. The analysis in the preceding section was concerned with times on the order of θ_S, the source time scale. Convective heat losses, modeled by Newton's law of cooling, are unimportant here. However, they do become important on a much longer time period where the powder sample cools back to the ambient temperature, T_A. We can analyze this behavior by introducing the long time scale $\bar{t} = \epsilon^2\tau$. In dimensional terms, this $\bar{t} = t/\beta\theta_{con}$; that is, we are now considering the temperature evolution on the convective time scale. Inserting this change of variable into (6a) gives

$$\epsilon\frac{\partial}{\partial\bar{t}}(uw) = \frac{\partial}{\partial z}\left(k\frac{\partial u}{\partial z}\right) + \frac{1}{\epsilon}S(z,\bar{t}), \quad 0 < z < 1, \quad \bar{t} > 0, \tag{14a}$$

where the source S is defined by $S = f(u)|\frac{\partial\phi}{\partial z}|^2$. The source term can be simplified by integrating (6b) twice and using the boundary conditions (5b) to obtain $\phi = v(\tau)Q(z)/Q(1)$, where now $Q(z) = \int_0^z \frac{1}{f(u)}\,dz'$. Differentiating this result with respect to z and replacing τ by $\bar{t}/\epsilon^2$, we find that the source term becomes

$$S(z,\bar{t}) = \frac{v^2(\bar{t}/\epsilon^2)}{f(u)Q^2(1)}. \tag{14b}$$

Now, on the cooling time scale $\bar{t} = O(1)$, which implies that the argument of v in (14b) is very large; alternatively, $\tau >> 1$. But for large values of τ we have shown that $v \sim v_0 \to 0$ exponentially. Thus, the S/ϵ is negligible and (14a) becomes a homogeneous diffusion equation on this time scale. Also, by inserting $\tau = \bar{t}/\epsilon^2$ into (14) and letting $\epsilon \to 0$ we obtain $\gamma g(u)\{1 - w\} = 0$. This is satisfied in both the high and low power cases. In the former, $w \sim w_0^* = 1$. In the latter, $u \sim u_0^* \leq u_T$ so that $g = 0$.

Taking the facts that $S = 0$ and $w = w_0^*$ into consideration, we find that u satisfies

$$\epsilon w_0^*\frac{\partial}{\partial\bar{t}}(u) = \frac{\partial}{\partial z}\left(k\frac{\partial u}{\partial z}\right), \quad 0 < z < 1, \quad \bar{t} > 0. \tag{15a}$$

In addition to this equation u must still satisfy the boundary conditions (6c) at $z = 0$ and $z = 1$. Finally, an initial condition must be prescribed to close the initial boundary value problem for u. Intuitively, this is given by the large τ value of u_0, namely,

$$u|_{\bar{t}=0} = u_0^*. \tag{15b}$$

We note here that the arguments of this paragraph can be put on more formal grounds by asymptotically matching the long time behavior of the solution on the heating time scale with the short time behavior of the solution on the cooling time scale.

We now proceed to find the behavior of $u(z,\bar{t})$ as $\epsilon \to 0$. As usual, we take

$$u \sim U_0(z,\bar{t}) + \epsilon U_1(z,\bar{t}) + \epsilon^2 U_2(z,\bar{t}) + \cdots$$

and insert this expression into (15) and (6c). Equating to zero the coefficients of the powers of ϵ yields a sequence of initial boundary value problems. The leading order problem is

$$\frac{\partial}{\partial z}\left(k\frac{\partial U_0}{\partial z}\right) = 0, \quad 0 < z < 1, \quad k\frac{\partial U_0}{\partial z} = 0, \quad z = 0,1, \quad U_0(z,0) = u_0^*. \tag{16}$$

Integrating this equation once and applying the boundary conditions, we find that $U_0(z,\bar{t}) = U_0(\bar{t})$, a function of $\bar{t}$ alone.

The first order correction U_1 satisfies

$$\frac{\partial}{\partial z}\left(k\frac{\partial U_1}{\partial z}\right) = w_0^*\frac{dU_0}{d\bar{t}}, \quad 0 < z < 1, \quad U_1(z,0) = 0, \tag{17a}$$

and the inhomogeneous boundary conditions

$$k\frac{\partial U_1}{\partial z} = \beta U_0, \quad z = 0, \qquad k\frac{\partial U_1}{\partial z} = -\beta U_0, \quad z = 1. \tag{17b}$$

Integrating the equation in (17a) between $z = 0$ and $z = 1$ and applying the boundary conditions in (17b), we find that U_0 satisfies the ordinary differential equation $\frac{dU_0}{d\bar{t}} = -2\frac{\beta}{w_0^*}U_0$. The solution of this equation satisfying the initial condition in (16) is

$$U_0 = u_0^* e^{-2\frac{\beta}{w_0^*}\bar{t}}. \tag{18}$$

The result given in (18) is the leading order approximation to u on the cooling time scale. For the high power case the result in terms of dimensional quantities becomes

$$T \sim T_A + \frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S}e^{-2t/\theta_{con}}, \tag{19a}$$

which explicitly shows that the temperature decays back to its ambient value on the cooling time scale θ_{con}. This scale depends upon the punches' ability to lose heat to their surroundings. For the low power, high initial density case we have

$$T \sim T_A + \frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S}e^{-2\frac{\rho_1}{\rho_0}t/\theta_{con}}, \tag{19b}$$

and for the low power, low initial density case,

$$T \sim T_A + \frac{1}{2}\frac{CV_0^2}{\rho_1 C_p V_S}e^{-2\frac{\rho^*}{\rho_0}t/\theta_{con}}. \tag{19c}$$

In (19c) the final density ρ^* is given in (13e). It is interesting to note that the low power cases decay more quickly to the ambient temperature than the high power scenario.

5. Slow sintering. Up until now, we have taken the dimensionless parameter γ, appearing in (4d), as an $O(1)$ quantity. That is, we have assumed that sintering occurs on the source time scale, τ. In this section we investigate the case where this process occurs on the much longer cooling time scale, $\bar{t}$. This assumption implies that $\gamma = \gamma_0\epsilon^2$, where γ_0 is now an order one quantity.

The heating regime analysis proceeds as before, the only difference being that (10c) is replaced by

$$\frac{dw_0}{d\tau} = 0, \qquad w_0(0) = \frac{\rho_0(F)}{\rho_1}, \tag{20}$$

from which it follows that $w_0 = \frac{\rho_0(F)}{\rho_1}$; that is, the density remains a constant on the source time scale. Equations (11) and (12) still remain the same. However,

$u_0 \to u_0^* = \frac{1}{2\Lambda w_0}$ as $\tau \to \infty$. Thus, the final temperature in the heating regime depends upon w_0. In terms of dimensional quantities, (13b) is now replaced by

$$T^* = T_A(1 + u_0^*) = T_A + \frac{1}{2}\frac{CV_0^2}{\rho_0(F)C_p V_S}. \tag{21}$$

Since $\rho_1/\rho_0 > 1$, the final temperature is higher in this case, although increasing the external force F on the punches diminishes the difference. Finally, we observe that v_0 still satisfies (11) and hence approaches zero as $\tau \to \infty$.

The cooling period analysis again proceeds as before. Equation (15) is now replaced by

$$\epsilon\frac{\partial(u\,w)}{\partial\bar{t}} = \frac{\partial}{\partial z}\left(k\frac{\partial}{\partial z}u\right), \quad u|_{\bar{t}=0} = \frac{1}{2\Lambda w_0}, \tag{22a}$$

and equation (4d) by

$$\frac{dw}{d\bar{t}} = \gamma_0 g(u)(1-w), \quad w|_{\bar{t}=0} = w_0 = \frac{\rho_0(F)}{\rho_1}, \tag{22b}$$

where we have replaced γ by $\gamma_0\epsilon^2$ and changed the time variable to $\bar{t}$. The temperature u still satisfies the boundary conditions contained in (6c).

We now expand both u and w in the asymptotic series $u \sim U_0 + \epsilon U_1 + \dots$ and $w \sim W_0 + \epsilon W_1 + \dots$, respectively, and perform the same analysis as in section 4.2. We find to leading order that U_0 and W_0 satisfy the ordinary differential equations and initial conditions

$$\frac{d}{d\bar{t}}W_0 = \gamma_0 g(U_0)\,(1 - W_0), \quad W_0(0) = \frac{\rho_0(F)}{\rho_1}, \tag{23a}$$

$$\frac{d}{d\bar{t}}U_0 = -\frac{1}{W_0}\{2\beta U_0 + \gamma U_0 g(U_0)(1 - W_0)\}, \quad U_0(0) = \frac{1}{2\Lambda W_0(0)}. \tag{23b}$$

Equation (23a) is the same as (10c), and (23b) is similar to (12). The difference in the latter is the new initial condition and the change in its right-hand side.

We again have the high and low power cases to consider, $\frac{1}{2\Lambda} \geq u_T$ and $\frac{1}{2\Lambda} \leq u_T$, respectively. The phase plane with typical trajectories is shown in Figure 3a for the former case. These trajectories begin on the hyperbola $W = 1/2\Lambda U$ and flow to the left with U_0 decreasing and W_0 increasing. When this curve crosses $U_0 = u_T$, it becomes horizontal, W_0 remains constant, and U_0 approaches zero. The final state is then $U_0^* = 0$ and $W_0^* = \psi(W_0(0))$, where ψ denotes the function mapping the initial data to its final state. This function is shown in Figure 3b for different values of Λ. Since $1/\Lambda$ is proportional to the power initially stored in the capacitor, i.e., CV_0^2, our results show that higher power levels produce higher densification.

The trajectories for the low power case are shown in Figure 4a, each again beginning on the hyperbola. If the initial density is large enough, the trajectory remains horizontal, U_0 monotonically decreases, and $W_0 = \rho_0/\rho_1$. If the initial density is sufficiently low, then W_0 initially increases and U_0 decreases until the threshold $U_0 = u_T$ is crossed. After this time W_0 remains fixed and U_0 approaches zero as $\bar{t} \to \infty$.

The final density W_0^* for the lower power case is also a function of the initial density $W_0(0)$, i.e., $W_0^* = \psi(W_0(0))$. This function is shown in Figure 4b for several values of Λ. Again, higher power levels for a given initial density produce more densification. However, for densities sufficiently large, the temperature is lower than the threshold and no sintering occurs. This is born out in the linear behavior of ψ as a function of ρ_0/ρ_1.

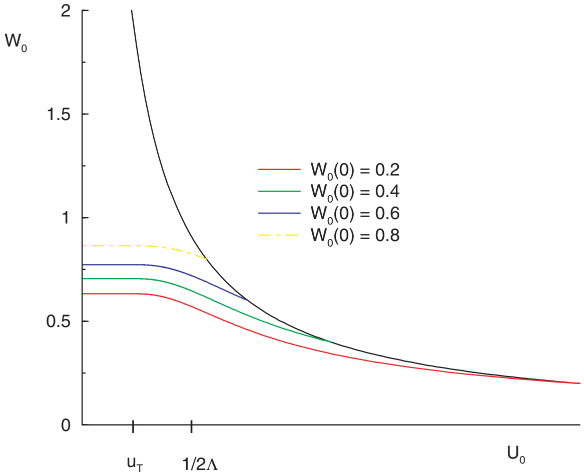

FIG. 3a. *Phase plane: High power.*

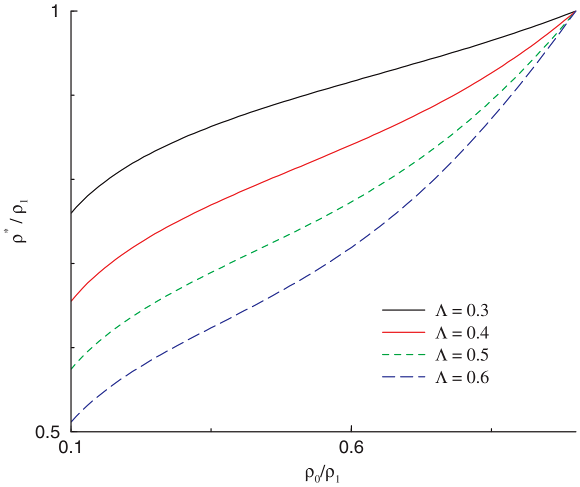

FIG. 3b. *Final density: High power.*

6. Conclusion. We have developed a model to describe a class of experiments that use an electric discharge to sinter or compact ceramic and metallic powders, respectively. Our mathematical description begins with the heat equation, Laplace's equation, and an evolution equation describing the densification of the powder. All these equations are coupled and nonlinear and have appended to them the appropriate initial and boundary conditions.

We have performed an asymptotic analysis to approximate the solutions of these equations. The appropriate small parameter is the ratio of the source to diffusion time scales. Our analysis shows that the leading order temperature, voltage across the sample, and relative density satisfy a third order system of nonlinear, ordinary differential equations. These are analyzed for a particular densification rate which possesses a temperature threshold, below which sintering or densification does not

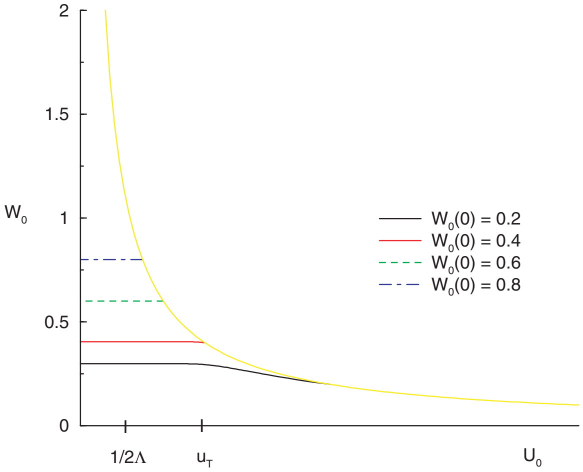

Fig. 4a. *Phase plane: Low power.*

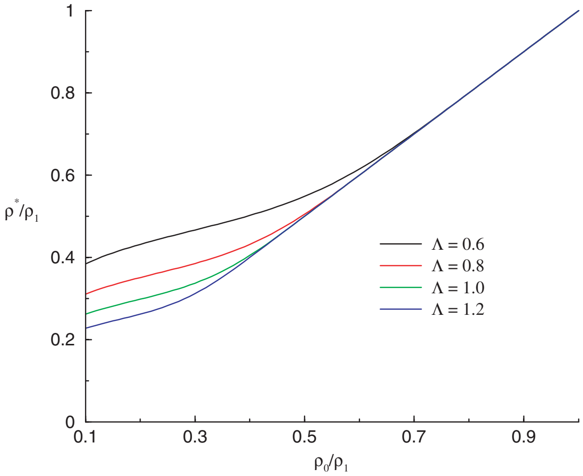

Fig. 4b. *Final density: Low power.*

occur. In particular, we have identified a critical power below which no densification occurs. We have presented a physical interpretation of our results.

The results described above are valid only on the source time scale where diffusion and heat loss to the surrounding environment are unimportant. We have identified a much longer convective time scale on which the heated powder sample loses energy through the punches to the surrounding medium. We have analyzed our equations on this time scale and found that the temperature decays back to its ambient value. The rate depends upon the energy initially stored in the capacitor as does the final density.

All of the preceding results are based on the assumption that the time scale associated with the densification rate is commensurate with the source time scale. We have also modified our analysis to take into account a much slower densification process that occurs on the convective time scale. During the initial heating of the powder, the temperature evolves to a steady state that depends upon the initial density and the energy stored in the capacitor. The density remains at its initial value. Then on the long convective time scale the temperature decays back to its ambient value and the density increases to its final value. This value depends upon the initial density and the energy stored in the capacitor.

We note that our model assumes that the die, which holds the powder sample, is perfectly insulated. If this restriction is removed, then ultimately heat will escape through the cylindrical sides. If the time scale associated with this process is commensurate with the other convective time scales, then a refined theory can be derived. Finally, we observe that heat conduction in the punches will become important when the experimental apparatus becomes larger and the punches more massive. Indeed, if the punches are massive enough, the temperature in them is T_A, the ambient value, and (6c) is replaced by $u = 0$ at $z = 0$ and $z = 1$. This and (6a) strongly suggest that boundary layers occur at the ends of the sample, and through them heat is transferred into the punches. This and the incorporation of more complicated die structures are topics of ongoing research.

NUMERICAL TESTS OF A PHASE FIELD MODEL WITH SECOND ORDER ACCURACY[*]

GUNDUZ CAGINALP[†], XINFU CHEN[†], and CHRISTOF ECK[‡]

Abstract. Numerical computations are performed for a recently derived phase field model for the interface between two phases. The rigorous results indicate that solutions to this new phase field model should converge more rapidly than traditional ones to solutions of the corresponding sharp interface (free boundary) formulation for sufficiently small values of the approximation parameter ε representing the thickness of the interfacial region. In particular, the distance between the sharp interface of the limiting model and the zero level set of the phase function in the phase field model is of order ε^2 rather than ε. Numerical computations within a three-dimensional spherically symmetric setting compare the computed solutions of this new model with the known exact solutions for the limiting free boundary problem and confirm the second order accuracy predictions of the theory for sufficiently small ε. The sets of parameters include those of succinonitrile used in dendritic experiments.

Key words. phase field model, matched asymptotic expansion, second order accuracy

1. Introduction.

Phase field models are now established as one of the most popular approaches for the computation of various types of dynamical phase transition models and problems with moving interfaces [4, 12, 13, 19, 20, 21, 22, 23, 35].

From the perspective of numerical simulation, these models can be interpreted as approximations of free boundary problems by problems without explicit interface conditions. This simplifies the numerical implementation of the model and, in particular, renders possible the application of standard software packages for partial differential equations (PDEs) to free boundary problems without implementing special front tracking and difficult treatment of topological change techniques. The required resolution for the diffuse interface that arises in the phase field models can be achieved by adaptive mesh refinement, a feature that is typically available in modern software packages.

Although the phase field (diffuse interface) approach can be used within a number of physical applications, many of the key ideas can be understood in terms of the two-phase problem with surface tension and kinetic undercooling. Starting with the free boundary approach for this physical problem, we consider a material in a spatial region $\Omega \subset \mathbb{R}^n$ $(n \geqslant 1)$ that can be in either of two phases (e.g., liquid or solid) separated by an interface, $\Gamma(t)$. Hence the mathematical problem consists of determining both the temperature $T(x,t)$ and the interface $\Gamma(t)$ from the system, in its full dimensional form,

$$
(1.1) \qquad \begin{cases} (\rho\, c\, T)_t = \operatorname{div}(K\, \nabla T) & \text{in} \quad \Omega \backslash \Gamma(t), \\ \rho\, \ell\, v_n = [\![K \nabla T \cdot \mathbf{n}]\!]_+^- & \text{on} \quad \Gamma(t), \\ T = T_E - \frac{\sigma}{[s]_{\mathrm{E}}} \left\{ \kappa + \alpha\, v_n \right\} & \text{on} \quad \Gamma(t), \end{cases}
$$

with ℓ and c as the latent heat and heat capacity per unit mass, K the diffusivity, ρ the density, T_E the equilibrium freezing temperature, $[s]_{\mathrm{E}}$ (energy/(volume $\cdot$ degree)) the entropy difference per volume, σ (energy/area) the surface tension, and α the strength of kinetic undercooling. The unit normal, sum of principal curvatures, and velocity of the interface are given by $\mathbf{n}$, κ, and v_n, while $[\![\cdots]\!]_-^+$ denotes the difference in the limits from the two sides of the interface.

The history of this problem dates back to 1831 when Lamé and Clapeyron [25] studied the freezing of the ground using (1.1) with $T = T_E$ replacing the third equation in (1.1). Reformulated in 1889, it became known as the classical Stefan problem [34]. It has the appealing mathematical feature that the temperature, $T(x,t)$, determines the phase at each point (x,t). By definition, $T(x,t) > T_E$ implies that the material is liquid at that point (or, more generally, in the phase with the higher internal energy), while $T(x,t) < T_E$ means that it is solid, and $T(x,t) = T_E$ defines the interface $\Gamma(t)$. Thus, the condition that $T(x,t) = T_E$ at the interface appears to be mathematically convenient. Nevertheless, the mathematical study of classical solutions to the Stefan model posed difficult challenges. Modern analysis (e.g., [26, 31]) converts (1.1) (with $\sigma = 0$) to the single equation $[e(u)]_t = D\Delta u$, where u is a scaled temperature, $e(u)$ is proportional to internal energy, and $D = K/(\rho c)$ is the heat diffusion coefficient. Since phase is assumed to be determined by temperature, one can write $e(u) = u + H(u)$ with H the Heaviside function.

Materials science research (e.g., [17]) in subsequent decades (after Lamé and Clapeyron [25]) showed that the interface temperature need not be at the equilibrium melting temperature, T_E, so that the material can be liquid well below the melting temperature, for example. In terms of mathematical modeling, there is a profound difference between the classical Stefan model ($T = T_E$ on $\Gamma(t)$) and the modern set of equations (1.1), since the temperature in the latter model can no longer retain its dual role of determining both the temperature and the phase. This means that using (1.1) directly necessitates tracking the interface in time, which is difficult but mathematically possible; see [15] for the well-posedness of the problem. Even if this is done, however, equations (1.1) are valid only so long as the interface does not self-intersect.

An alternative approach, known as the phase field or diffuse interface model, is to formulate the problem in terms of two variables, temperature and phase field (see [10] for more discussion). The mathematical problem is then to solve the following parabolic system for $(T_\varepsilon, \phi_\varepsilon)$ in its full dimensional form:

$$
(1.2) \qquad \begin{cases} (\alpha_\varepsilon\, \phi_\varepsilon)_t = \Delta \phi_\varepsilon - \varepsilon^{-2} W'(\phi_\varepsilon) + \varepsilon^{-1} [s]_E \sigma^{-1} G'(\phi_\varepsilon) [T_\varepsilon - T_E] \;, \\ (\rho c T_\varepsilon + \frac{1}{2} \rho \ell \phi_\varepsilon)_t = \operatorname{div}(K \nabla T_\varepsilon), \end{cases}
$$

where the unknowns $T_\varepsilon(x,t)$ and $\phi_\varepsilon(x,t)$ are, respectively, the temperature and the phase indicator ($\phi_\varepsilon = 1$ for liquid and -1 for solid) and ε is a small positive parameter representing the thickness of the interfacial region. Here W is a potential with double well of equal depth at ± 1 and G is a function relating microscopically how energy is relayed in the thin interfacial region. As discussed in full in [10], in order for the phase field model to approximate accurately the free boundary model (1.1), it is better to require G and α_ε to satisfy certain compatibility conditions; in particular, the following choice is sufficient:

$$W(s) = \frac{1}{2}(1-s^2)^2, \quad G(s) = s - \frac{1}{3}s^3, \quad \alpha_\varepsilon = \alpha + \frac{5}{12}\frac{\varepsilon\rho\ell[s]_{\mathrm{E}}}{(K\sigma)}. \tag{1.3}$$

The interface in this formulation is now defined as the level set

$$\Gamma_\varepsilon(t) := \{x \in \Omega(t) \mid \phi_\varepsilon(x,t) = 0\}\,; \tag{1.4}$$

thus there is no need to track it explicitly, and the practical problem is simply the computation of a smooth system of parabolic differential equations. A number of works (e.g., Caginalp and Chen [8, 9] and Soner [33]) have proved that solutions of the phase field equations converge to those of the corresponding free boundary problems as $\varepsilon \to 0$. The parameter ε represents the thickness of the interfacial region, whose true value is on an atomic scale. Computing with this true physical value would make many realistic computations unfeasible. However, it has been shown that the value of ε can be used essentially as a free parameter that can be increased by orders of magnitude without significantly altering the behavior of the interface [12]. Although the phase field approach provides a methodology for understanding the physical interface problems directly and has been used to derive the sharp interface models, one can also view it as a computational approach designed to approximate the limiting sharp interface (free boundary) problem. This is the perspective we adopt in this paper.

The use of phase field computations in realistic physical situations has led to a growing interest in developing and testing different phase field equations that better approximate the limiting free boundary problem. Let $\Gamma(t)$ and $\Gamma_\varepsilon(t)$ denote the interface of the free boundary problem (1.1) and the zero level set of the phase function $\phi_\varepsilon(x,t)$ of the phase field model (1.2), respectively. We are interested in approximating the free boundary problem with the phase field model by the following criteria: there exist positive constants C and ε_0 such that

$$\text{distance } (\Gamma(t), \Gamma_\varepsilon(t)) \le C\varepsilon^k \qquad \forall\, \varepsilon \in (0, \varepsilon_0]. \tag{1.5}$$

Established theoretical results (e.g., [8, 9]) and computations (e.g., [13, 19]) indicate that these estimates are valid for $k = 1$. Recently, in [10] we derived a phase field model that ensures a second order accuracy (namely, $k = 2$ in the bound above) for the approximation of the free boundary. Unlike the automatic [29] second order approximation of motion by mean curvature by the Allen–Cahn equation [2], the second order accuracy here is obtained by special choices of G and α_ε. In particular, by utilizing the choice (1.3), all first order terms automatically cancel out, thus leading to a second order model. Here the coefficient $\frac{5}{12}$ for the first order correction of α_ε is calculated from the special choices of W and G. The derivation and proof use a method that differs from the standard technique of matched asymptotic expansions [1, 6, 9, 11, 16]. In our recent work, the inner expansion is computed with respect to the interface $\Gamma(t)$ of the limit interface and not with respect to the level set $\Gamma_\varepsilon(t)$ of the phase field as in more traditional approaches. A key advantage of this new technique is that it permits tracking of the position of the perturbed interface by a distance function h_ε to the limit interface; see section 2.

There have been other studies attempting to derive phase field models that converge more rapidly to their sharp interface limits by an alternative procedure of finding conditions that eliminate undesired terms of first order, as done, e.g., in [3]. It is not always obvious, however, which terms should be cancelled in order to obtain robust approximation properties that are an improvement over the original models.

The rigorous theory does not establish the constant C in the estimates (1.5) or the value of the upper bound ε_0 for which the bounds are valid. Consequently, we perform numerical computations on this recently derived phase field equation to determine whether the second order accuracy described by these bounds is valid for typical parameter ranges and computational constraints. In particular, one of the tests utilizes the physical measurables for succinonitrile that is used in many of the dendritic experiments [18, 24].

2. The phase field model.

In this section, we state the phase field model (1.2) introduced in [10] in a form that is convenient for computation.

2.1. Nondimensionalization.

Using the fully physical dimensional form of equations has its advantage and convenience for practical considerations. Mathematically, however, it is awkward and numerically complicated in realizing the stiffness of the problem. From the viewpoint of scaling invariance, it is desirable to make a change of variables to transfer the fully dimensional version of the free boundary problem (1.1) and the phase field model (1.2) into their nondimensional counterparts.

To convert (1.1), introduce L, the diameter of the sample, and use the standard transformation

$$u := \frac{T - T_E}{\ell/c}, \qquad D := \frac{K}{\rho c}, \qquad d_0 := \frac{\sigma\ c}{[s]_E\ \ell}, \quad a := \alpha D,$$
$$d := \frac{d_0}{L}, \qquad \frac{x}{L} =: \tilde{x} \longrightarrow x, \qquad \frac{D}{L^2} t =: \tilde{t} \longrightarrow t.$$

The free boundary problem (1.1) then has the following dimensionless form:

$$\begin{cases} u_t^{\pm} = \Delta u^{\pm} & \text{in } \ \Omega^{\pm}(t), \\ u^{\pm} = -d\,(\kappa + a\mathrm{v}) & \text{on } \ \Gamma(t), \\ \mathrm{v} = [\![\nabla u \cdot \mathbf{n}]\!]_{+}^{-} & \text{on } \ \Gamma(t), \end{cases} \tag{2.1}$$

where $\Omega^+(t) \cup \Omega^-(t) \cup \Gamma(t) = \Omega$, $\mathbf{n}$ is the unit vector normal to $\Gamma(t)$ pointing toward $\Omega^+(t)$, κ is the sum of the principal curvatures of $\Gamma(t)$ (positive for convex solid), and v is the normal velocity of $\Gamma(t)$ (positive for solidification).

Note that the size of the sample (i.e., Ω) in the new, $\bar{x}$, units is 1 in (2.1). There are only two physical dimensionless parameters: a and d.

1. The constant a represents the strength of kinetic undercooling; it is a measurable *dimensionless material constant.*
2. While d_0 is a *material constant* that relates the surface tension or size of the nucleation radius, the dimensionless constant

$$d := \frac{d_0}{L}$$

depends on the particular experiment. For example, for a typical $d_0 = 10^{-7}$ cm, if the "sample size" or "macroscopic resolution size" is $L = 10^{-3}$ cm, then $d = 10^{-4}$.

Although d is small and the difference between the Gibbs–Thomson condition $u = -d\,(\kappa + a\mathrm{v})$ and the Stefan condition $u = 0$ on the free boundary may appear insignificant, the respective interface motion is known to be significantly different for the two conditions [28, 30].

3. We use a unit for time that matches the units of space. For example, if $D = 10^{-3}$ cm^2/s and $L = 10^{-3}$ cm, then $t = 1000$ represents a physical $L^2t/D = 1$ second. In other words, $t = 1$ represents one millisecond.
4. Here $u = 1$ represents the temperature that a liquid at melting temperature attains after absorbing an amount of energy equal to the latent heat. For water, $u = 1$ represents $T = 80°$ C $= 353$ Kelvin. In this problem there is another parameter, u_∞, the dimensionless temperature at the far field, that plays a role. When u_∞ is small, quite often it is convenient to use $u/|u_\infty|$ as the dimensionless temperature. For succinonitrile, $\ell/c = 23.13$ Kelvin, so $T_\infty = T_E - 0.2313$ Kelvin is equivalent to $u_\infty = -0.01$.

In addition to the dimensionless quantities above, it is useful to scale the extra parameter, ε, representing the thickness of interfacial region (5–100 atomic distances). Introducing dimensionless constants

$$\bar{\epsilon} := \frac{\varepsilon}{d_0}, \qquad \epsilon := \frac{\varepsilon}{L} = \frac{\varepsilon}{d_0}\,\frac{d_0}{L} = \bar{\epsilon}\, d,$$

the phase field model (1.2) has the following dimensionless form:

$$\text{(2.2)} \qquad \begin{cases} u_t + \frac{1}{2}\phi_t \;=\; \Delta u, \\ (a + \frac{5}{12}\,\bar{\epsilon})\phi_t \;=\; \Delta\phi + \epsilon^{-2}(2\phi + \bar{\epsilon}u)(1-\phi^2). \end{cases}$$

The stiffness of the phase field model comes from the largeness of the quantity ϵ^{-2} on the right-hand side of the second equation. Here the important correction term $\frac{5}{12}\bar{\epsilon}$ is an addition to the traditional phase field model. It eliminates the first order terms in the asymptotic expansion. As mentioned in the introduction, the applicability of the phase field model in numerical computations is due to the fact that one does not need to use the actual (atomic) size of ϵ. One can use ϵ that is much larger—though still small—without altering the solution significantly [12, 13].

2.2. Initial data. To obtain second order approximation, the initial value to the phase field system (2.2) has to be second order consistent with the free boundary problem (2.1). This leads to the following choice of initial data for (2.2) (see [10] for details):

$$\text{(2.3)} \quad \begin{cases} \phi(\cdot,0) \;= \tanh\frac{h}{\epsilon}, \\ u(\cdot,0) \;= \dfrac{u_0^+}{1+e^{-2h/\epsilon}} + \dfrac{u_0^-}{1+e^{2h/\epsilon}} + \dfrac{\epsilon}{2}\nabla h\cdot\nabla(u_0^+ - u_0^-)\displaystyle\int_{-\infty}^{h/\epsilon} z\, d\tanh z. \end{cases}$$

Here $h = h(x)$ is the signed distance from x to the initial interface $\Gamma(0)$, and $u_0^\pm = u_0^\pm(x)$ are smooth extensions of the initial temperature for the free boundary problem.

3. Analytic feature of the numerical example. The main purpose of this paper is to check numerically the validity of the assertion that the new phase field model (2.2) approximates the free boundary model (2.1) with second order accuracy, using physical parameters in one case. In particular, the computations can address the issue of the constants C and ε_0 in (1.5), thereby determining whether there is a computational advantage to the new phase field model in practical circumstances. The test example in our earlier paper [10] is one dimensional, so the curvature effect is not present. We would like to find a test case that has the following features:

1. Explicit solutions for the free boundary problem are available.
2. There are curvature effects.
3. There are kinetic undercooling effects.
4. The ratio between the curvature effect and kinetic undercooling effect can be adjusted.

There is an example in a three dimensional radially symmetric situation that models the solidification (growing) process of a solid ball in undercooled liquid [32]. The solution has the properties that (i) the free boundary is located at $|x| = R(t) = 2\gamma\sqrt{t}$, and (ii) the temperature is a combination of three self-similar solutions to the heat equation $u_t = \Delta u$:

$$u(x,t) = u_0 := 1,$$

$$u(x,t) = u_1(|x|,t), \qquad u_1(r,t) := \frac{\operatorname{erf}(r/\sqrt{4t})}{r}, \qquad \operatorname{erf}(z) := \frac{2}{\sqrt{\pi}}\int_0^z e^{-y^2}\,dy,$$

$$u(x,t) = u_2\Big(\frac{|x|}{\sqrt{4t}}\Big), \qquad u_2(z) := \int_z^\infty \frac{e^{-y^2}}{y^2}dy.$$

The following calculations verify that for each $\gamma > 0$, there is exactly one such solution to (2.1).

1. When the free boundary is given by $|x| = R(t) := 2\gamma\sqrt{t}$, one has

$$\kappa = \frac{2}{R(t)}, \qquad \mathrm{v} = \frac{dR(t)}{dt} = \frac{\gamma}{\sqrt{t}} = \frac{2\gamma^2}{R(t)}, \qquad \frac{a\mathrm{v}}{\kappa} = a\gamma^2.$$

The Gibbs–Thomson condition requires the temperature at the free boundary to be

$$u\Big|_{\Gamma(t)} = -d(\kappa + a\mathrm{v}) = -\frac{A}{R(t)}, \qquad A := 2d(1 + a\gamma^2).$$

2. In the ball $\{x \mid |x| < R(t)\}$, the material is in the solid phase. The only self-similar solution to the heat equation $u_t = \Delta u$ with boundary value $u(x,t) = -A/r$ at $r = |x| = R(t)$ and vanishing derivative at $r = 0$ is given by

$$u^-(x,t) = -\frac{Au_1(|x|,t)}{\operatorname{erf}(\gamma)}. \tag{3.1}$$

3. Outside the ball $\{x \mid |x| \le R(t)\}$, the material is in the liquid phase. There is a family, with parameter B, of solutions having boundary value $u(x,t) = -A/r$ at $r = |x| = R(t)$:

$$u^+(x,t) = -\frac{Au_1(|x|,t)}{\operatorname{erf}(\gamma)} + B\Big(u_2(\gamma) - u_2(|x|/\sqrt{4t})\Big). \tag{3.2}$$

The solution we need corresponds to that satisfying $\mathrm{v} = [\![u_r]\!]_+^-$. Thus, we have

$$\frac{2\gamma^2}{R(t)} = \frac{Bu_2'(\gamma)}{\sqrt{4t}}, \quad \text{i.e.,} \quad B = \frac{2\gamma}{u_2'(\gamma)} = -2\gamma^3 e^{\gamma^2}.$$

In conclusion, for each $\gamma > 0$ we have a solution to (2.1), given by

$$\text{(3.3)} \qquad \begin{cases} \Gamma(t) &= \{x \mid |x| = R(t) := 2\gamma\sqrt{t}\}, \\ u(x,t) &= -\dfrac{2d\,(1+a\gamma^2)\,\mathrm{erf}(|x|/\sqrt{4t})}{\mathrm{erf}(\gamma)\ |x|} - \displaystyle\int_\gamma^{\max\{\gamma,|x|/\sqrt{4t}\}} \frac{2\gamma^3 e^{\gamma^2-y^2}}{y^2}dy. \end{cases}$$

For such a solution, the ratio of the strength of the kinetic undercooling to the strength of the surface tension is $a\mathrm{v}/\kappa = a\gamma^2$. Also, there is an important physical quantity,

$$u_\infty := u|_{|x|=\infty} = -2\gamma^3 \int_\gamma^\infty \frac{e^{\gamma^2-y^2}}{y^2}dy.$$

Given $u_\infty < 0$, one can show that there is a unique positive γ that satisfies the above relation. Thus, the measure of the degree of undercooling u_∞ is equivalent to the measure of γ.

4. Numerical simulation. For a solution (3.3) of the free boundary problem (2.1), we solve numerically the corresponding radially symmetric solution to the phase field model (2.2) in the unit ball:

$$\Omega := \{x \in \mathbb{R}^3 \mid |x| < 1\}.$$

The system (2.2) is first discretized with respect to time by a second order scheme. Fix a time mesh size $\delta t > 0$. For every integer $k \geqslant 0$, denote by $(u_k(\cdot), \phi_k(\cdot))$ the approximation of the solution $(u(\cdot, k\delta t), \phi(\cdot, k\delta t))$ at time $t = k\delta t$. The semi-discretization in time has the form

$$\begin{aligned} \frac{u_{k+1}-u_k}{\delta t} + \frac{\phi_{k+1}-\phi_k}{2\,\delta t} &= \Delta\frac{u_{k+1}+u_k}{2}, \\ \epsilon^2 a_\epsilon \frac{\phi_{k+1}-\phi_k}{\delta t} - \epsilon^2\Delta\frac{\phi_{k+1}+\phi_k}{2} &= -W'(\phi_k) - \tfrac{1}{2}W''(\phi_k)[\phi_{k+1}-\phi_k] \\ &\quad + \frac{\bar\epsilon\,(u_k+u_{k+1})}{2}\Big\{G'(\phi_k) + \tfrac{1}{2}G''(\phi_k)[\phi_{k+1}-\phi_k]\Big\}, \end{aligned}$$

where

$$\bar\epsilon := \frac{\varepsilon}{d_0}, \quad \epsilon := \frac{\varepsilon}{L}, \quad a_\epsilon := a + \frac{5}{12}\,\bar\epsilon, \quad W(s) = \frac{1}{2}(1-s^2)^2, \quad G(s) = s - \frac{1}{3}s^3.$$

In the radial ($r = |x|$) coordinates, the Laplacian Δ is further discretized by linear finite elements on a uniform mesh of size $\delta r = 1/n$, where n is the total number of spatial mesh points. This scheme leads to a nonlinear system for each time step.

The boundary condition for temperature of the phase field model is taken as the known exact solution to the free boundary problem, whereas the boundary value for ϕ is taken as $\phi|_{|x|=1} = 1$. The solution is calculated for a time interval $[t_0, t_1]$ according to the timing of the solution (3.3) of the free boundary problem. Here $t_0 > 0$ is the initial time, and the terminal time t_1 satisfies $2\gamma\sqrt{t_1} < 1$. The initial condition (at time $t = t_0$) is taken as (2.3), where $h = h(x) = |x| - R(t_0)$, and u_0^- and u_0^+ are as in (3.1) and (3.2).

In what follows, Model 1 refers to the original phase field model where the correction term $\frac{5}{12}\,\bar\epsilon$ in the kinetic coefficient, a_ϵ, is not present; i.e., $a_\epsilon = a$. Model 2 is that with the correction added: $a_\epsilon = a + \frac{5}{12}\,\bar\epsilon$.

Remark. (1) In our actual implementation, the quantity $\frac{\bar{\epsilon}\,(u_k+u_{k+1})}{2}$ on the right-hand side of the second equation is replaced by $\bar{\epsilon}u_k$. The advantage of such a change is that the nonlinear system for (ϕ_{k+1}, u_{k+1}) is decoupled into two linear systems, one for ϕ_{k+1} and the other for u_{k+1}. Though theoretically the resulting discretization becomes first order in δt, the discretization is still stable, and in the special case when $\bar{\epsilon}$ is small, this change from $\frac{\bar{\epsilon}\,(u_k+u_{k+1})}{2}$ to $\bar{\epsilon}u_k$ can be regarded as second order.

(2) The initial condition (2.3) is derived only from model 2; namely, it may not apply to Model 1, where $a_\epsilon = a$. Thus, in numerical implementation for Model 1, the last term in (2.3) is not added in the initial value for u. This is a routine practice in traditional numerical simulations for the phase field models. Indeed, starting from any crude initial data, the phase field dynamics automatically produces a needed fine profile after a small initiation time.

Computation 1. We begin by testing the accuracy of the numerical scheme. That is, for fixed ϵ we find the rate of convergence of the numerical scheme with respect to the spatial mesh size $\delta r = 1/n$ and the time mesh size δt. This helps us to determine how fine a mesh is needed in order to compare the difference between the exact solution to (2.1) and the exact solution to (2.2).

As an illustration, we take the following values of the dimensionless quantities:

$$a = 20, \qquad d := \frac{d_0}{L} = 0.001, \quad \bar{\epsilon} = \frac{\varepsilon}{d_0} = 5, \qquad \epsilon = \frac{\varepsilon}{L} = 0.005, \qquad u_\infty = -0.0046\ .$$

The corresponding value of γ and the ratio of kinetic undercooling to curvature effect are, respectively,

$$\gamma = \frac{1}{20}, \qquad \frac{a\mathrm{v}}{\kappa} = a\gamma^2 = \frac{1}{20}.$$

We calculate the solution from time $t_0 = 1.0$ with initial radius of solid $R(t_0) = 0.1$ to time $t_1 = 9.0$ with final radius $R(t_1) = 0.3$. The numerical result is summarized in Table 1. For easy reference, errors to the exact solution of the phase field model (PFM) and differences to the solution of the free boundary problem (FBP) are calculated in their relative sizes. In calculating the relative error of the numerical scheme here, the exact solution is postulated to be the numerical solution with the finest mesh.

With this assumption we examine the previous level of refinement, namely $n = 3200$, $\delta t = 2.5 \times 10^{-5}$, and observe that the errors relative to the PFM are much smaller than those relative to the FBP. This indicates that the mesh refinement is more than adequate to test how accurately each of the two (phase field) models approximates the FBP. In particular (for $n = 3200$, $\delta t = 2.5 \times 10^{-5}$) the relative error of computation for Model 1 is 10^{-5}, while the difference between the computed and the exact values of the free boundary is 40 times larger at 4×10^{-4}. For Model 2 there is a factor of 17. Examining the prior two levels of refinement ($n = 1600$ and $n = 800$) for Model 1, we see that the relative error (computation compared with the PFM) diminishes from 2×10^{-4} ($n = 800$) to 4.7×10^{-5} ($n = 1600$) to 10^{-5} ($n = 3200$), i.e., factors of about 4, while the relative difference between computation and the FBP varies only from 2.2×10^{-4} ($n = 800$) to 3.7×10^{-4} ($n = 1600$) to 4.0×10^{-4} ($n = 3200$). Hence, the difference between the computed Model 1 and exact FBP stabilizes near 4.0×10^{-4}. The situation is similar for Model 2; i.e., the numerical error in computing the PFM is negligible compared to the difference between the Model (either 1 or 2) and the exact FBP. Note also that halving the time step has a very small effect on these errors.

Table 1

Computation 1. *The rate of convergence of the numerical scheme, shown in relative error to the partial differential equation (rel. error to PFM). Spatial and time mesh sizes are $\delta r = 1/n$ and δt. Also shown is the relative difference with respect to the solution to the free boundary problem (rel. diff. to FBP). Here $\epsilon = 0.005$.*

Thus the computations summarized in Table 1 provide a guide to the error in the numerical computations of the PDEs in terms of the mesh sizes for n and δt. With these numerical errors under control, we can pursue our central goal of distinguishing the differences between the models and the free boundary problems. In what follows we will vary ϵ and examine the behavior of these differences as a function of ϵ. In particular we would like to determine if the difference between Model 2 and the free boundary problem is indeed proportional to ϵ^2, particularly when we use material parameters that are drawn from experiments of dendrites (see Computation 4 below).

In the following examples, the numerical effects are controlled so that the difference shown can be regarded as that between the solutions to the phase field model (2.2) and to the free boundary model (2.1).

Computation 2. Using a sufficiently fine mesh that eliminates significant numerical error (as discussed above), we perform a set of calculations with the material parameters above. These computations involve a spectrum of values of ϵ, as shown in Table 2, and will be compared with the hypothesized relation

$$\left|1 - \frac{R_\epsilon}{R}\right| \sim C\epsilon^2 \tag{4.1}$$

that has been proved [10] using Model 2 for sufficiently small ϵ. In this first set of computations we explore the large ϵ part of this spectrum. For each model we compute $\log|1 - R_\epsilon/R|$ and plot it against $\log\epsilon$, so that a slope of 2 indicates agreement with (4.1), while a slope of 1 suggests an $O(\epsilon)$ error that is the expected result for Model 1. The results for Model 2 are

$$\log|1 - R_\epsilon/R| = 0.554 + 1.8556\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	0.554	0.112
Log(ϵ)	1.8556	0.054

with R-Sq = 99.7% and the F-value for the analysis of variance at 1181. The R-Sq value obtained is a statistical measure (not to be confused with the position R that we have above) that indicates that essentially all of the variation in the data points is explained by the linear model above. The F-value is a measure of the squares of differences between the linear model and the mean relative to the linear model and the data points. For four, five or six data points the F-value needed for 95% statistical confidence is 12, 10, and 9, respectively. A complete discussion of these measures can be found in a basic statistical text such as [27]. The coefficient of $\log(\epsilon)$ is $0.8556/0.054 = 15.84$ or almost 16 standard deviations away from the coefficient value of 1. This yields a p-value that is essentially zero; i.e., there is essentially zero probability that the slope differs from 1 due to randomness. In other words, the null hypothesis that the relative difference between Model 2 and the free boundary problem corresponds to an exponent of 1 must be rejected overwhelmingly (16 standard deviations). The values for Model 2 are plotted using the large dots.

A similar analysis for Model 1 (plotted with small dots) shows that the relative error displays a less regular pattern, yielding a coefficient of 0.832 (i.e., slightly less than a linear relationship), but with a p-value of only 0.154 and an F-value of only 3.61:

$$\log|1 - R_\epsilon/R| = -1.5276 + 0.832\log(\epsilon).$$

In practical terms, there is a significant improvement from Model 1 to Model 2 that is evident particularly for smaller values of ϵ. For the smallest value tested in these computations, namely, $\epsilon = 0.0025$, one has a ratio of $240/44 = 5.4545$ in the relative differences (between the two models) to the exact free boundary problem. The consistency of the results for Model 2 and the coefficient computed above suggest that the difference between the models grows as ϵ is made smaller.

Computation 3. We solve numerically the phase field model (2.2) with the following parameter values:

$$a = 20, \qquad d := \frac{d_0}{L} = 0.001, \qquad u_\infty = -0.011, \qquad \gamma = 0.08, \qquad \frac{a\mathrm{v}}{\kappa} = a\gamma^2 = 12.8\%.$$

The parameter ϵ is taken in the following range:

$$\epsilon = \frac{\varepsilon}{L} \in [0.0025, 0.04], \qquad \bar{\epsilon} = \frac{\varepsilon}{d_0} \in [2.5, 40].$$

The time window is $[0.390625, 3.515625]$ during which the interface moves from $R(t_0) = 0.1$ to $R(t_1) = 0.3$. The numerical results are reported in Table 3 and Figure 1(b).

TABLE 3
For Computation 3.

ϵ	Model 1		Model 2	
	$R_\epsilon(t_1)$	$\lvert 1 - R_\epsilon/R\rvert$	$R_\epsilon(t_1)$	$\lvert 1 - R_\epsilon/R\rvert$
0.0400	0.30169	5.6 e-3	0.29743	8.6 e-3
0.0200	0.30173	5.8 e-3	0.29941	2.0 e-3
0.0100	0.30105	3.5 e-3	0.29985	4.9 e-4
0.0050	0.30057	1.9 e-3	0.29996	1.3 e-4
0.0025	0.30030	9.9 e-4	0.29999	3.1 e-5
0	0.30000	0	0.30000	0

Performing a least squares analysis as in the previous example for Model 2, we have the result

$$\log|1 - R_\epsilon/R| = 0.741 + 2.01753\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	0.74126	0.03563
Log(ϵ)	2.01753	0.07058

with R-Sq = 100% and an F-value of 13402. Hence, for these parameters there is overwhelming evidence confirming the hypothetical exponent of 2. The coefficient calculated above differs from 1 by 1.0175/0.07058 = 14.42 standard deviations.

By comparison the data for Model 1 leads to the result

$$\log|1 - R_\epsilon/R| = -1.21 + 0.661\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	-1.21	0.2306
Log(ϵ)	0.661	0.1128

so that the relative difference between Model 1 and the exact free boundary solution behaves as $\epsilon^{0.661}$. A similar regression without the largest value of ϵ leads to $\epsilon^{0.85}$ power behavior.

Thus, one can conclude from this range of computations that Model 2 is within $O(\varepsilon^2)$, while Model 1 is even slightly worse than $O(\varepsilon)$ in these computations. Note that theorems establishing that Model 1 is $O(\varepsilon)$ are also of the form "there exists $\varepsilon_0 > 0$ such that for $\varepsilon < \varepsilon_0$ one has ...." Hence, the data in this range of parameters shows a significant practical improvement by using Model 2 in place of Model 1 that is analogous to the rigorous result.

Computation 4. Finally we provide an example using material data from succinonitrile. We take

$$D = 1.134 \times 10^{-3}\text{cm}^2/\text{s}, \qquad d_0 = 2.821 \times 10^{-7}\text{cm}, \qquad \frac{\ell}{c} = 23.13 \text{ Kelvin}, \qquad \alpha = 10^4\text{s}/\text{cm}^2.$$

Here D, d_0, and ℓ/c are from [24]. Note that there are no direct measurements on α and we choose α as in [4].

We focus on the part of the sample of size $L = 10^{-4}$ cm with undercooling $T_E - T_\infty = 0.2521$ Kelvin in a solidification process during which the solid ball grows from radius $R_0 = 10^{-5}$ cm to $R_1 = 4 \times 10^{-5}$ cm.

These dimensional numbers translate to the following dimensionless quantities:

$$a = \alpha D = 11.34, \qquad d := \frac{d_0}{L} = 0.002821, \qquad u_\infty = -\frac{0.2521}{23.13} = -0.0109,$$

$$\gamma = 0.079, \qquad \frac{a\text{v}}{\kappa} = a\gamma^2 = 7.2\%, \qquad t_0 = \left(\frac{R_0}{2\gamma L}\right)^2 = 0.40, \qquad t_1 = \left(\frac{R_1}{2\gamma L}\right)^2 = 6.40.$$

The amount of real time for such a solidification process takes $\frac{(t_1 - t_0)L^2}{D} = 5.2 \times 10^{-5}$ seconds.

To treat such a scenario within the capacity of computer power, we take ε in the range 10^{-5} cm to 2×10^{-7} cm. As we said earlier, the true size of ε is much smaller, but the interfacial motion is not very sensitive to the size of ε provided it is not very large. In dimensionless quantities, this translates to

$$\epsilon = \frac{\varepsilon}{L} \in [0.002,\ 0.1], \qquad \bar{\epsilon} = \frac{\varepsilon}{d_0} \in [1,\ 35], \qquad \bar{\epsilon}\,|u_\infty| \in [0.01,\ 0.35].$$

In Table 4 we list the relative differences between the solution of the phase field model and that of the free boundary problem, with ε given in cm.

Table 4

For Computation 4, the relative difference between solutions of the free boundary model and solutions of the phase field models 1 and 2.

ε	Model 1		Model 2	
	Position	$\vert 1 - R_\epsilon/R\vert$	Position	$\vert 1 - R_\epsilon/R\vert$
(cm)	(cm)		(cm)	
1 e-5	3.8435 e-5	3.9 e-2	3.8122 e-5	4.7 e-2
5 e-6	3.9723 e-5	6.9 e-3	3.9577 e-5	1.1 e-2
2 e-6	3.9993 e-5	1.8 e-4	3.9935 e-5	1.6 e-3
1 e-6	4.0013 e-5	3.3 e-4	3.9984 e-5	4.1 e-4
5 e-7	4.0011 e-5	2.7 e-4	3.9996 e-5	1.0 e-4
2 e-7	4.0005 e-5	1.3 e-4	3.9999 e-5	1.9 e-5
0	4.0000 e-5	0	4.0000 e-5	0

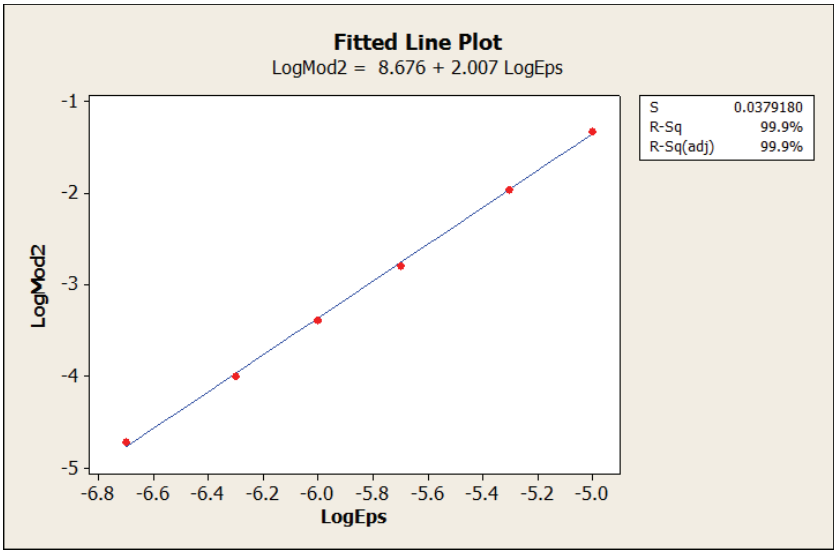

Fig. 2. *Computation 4, Model 2.*

Using the above procedure on Model 2, we obtain from the least squares analysis the result

$$\log|1 - R_\epsilon/R| = 8.6759 + 2.007\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	8.6759	0.1575
$\mathrm{Log}(\epsilon)$	2.007	0.02687

Hence, the exponent 2.007 differs from 1 by $1.007/0.02687 = 37.48$ standard deviations, establishing overwhelming evidence that the relative difference between Model 2 and the exact free boundary solution is better than linear in terms of ϵ. One also has that R-Sq $= 99.9\%$ and $F = 5580$ in the analysis of variance. As shown in Figure 2 the data points are indistinguishable from the straight line with slope 2.007. For this key set of physical parameters, the standard error of 0.02687 shows that the exponent is 2.007 ± 0.02687 so that the computational results are in agreement with the theoretical exponent of 2 in (4.1).

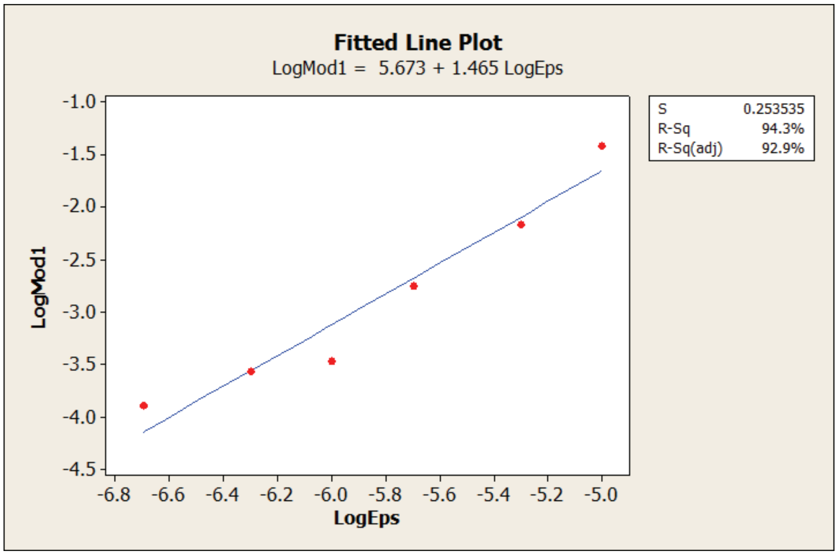

FIG. 3. *Computation 4, Model 1.*

The same analysis for Model 1 leads to the linear regression

$$\log|1 - R_\epsilon/R| = 5.673 + 1.465\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	5.673	1.053
Log(ϵ)	1.465	0.1796

The exponent of 1.47 ± 0.18 appears to be better than the theoretical expectation of 1. Note that the standard error of 0.18 is much larger than the corresponding 0.026 for Model 2 computed above. In Figure 3 one can observe that the slope appears to diminish for smaller ϵ. In particular, for the four smallest values of ϵ, one has the result

$$\log|1 - R_\epsilon/R| = 3.08 + 1.05\log(\epsilon)$$

Predictor	Coef	Std Error of Coef
Constant	3.08	1.793
Log(ϵ)	1.05	0.2899

Examining the practical differences between the exact solution and those rendered by Models 1 and 2 for the smallest ϵ in Table 4, one observes that the ratio of the error in Model 1 to the error in Model 2 is given by

$$\frac{1.3 \times 10^{-4}}{1.9 \times 10^{-5}} = 6.8421$$

so that a factor of almost seven is attained using Model 1. Note also that the improvement accuracy due to refining ε from 5×10^{-7} to 2×10^{-7} is $2.7/1.3 = 2.08$ for Model 1 but $10^{-4}/(1.9 \times 10^{-5}) = 5.2632$ for Model 2. Thus, one would expect that a calculation with $\varepsilon = 0.8 \times 10^{-7}$ would lead to a factor of

$$6.8421 \times \frac{5.2632}{2.08} = 17.313.$$

In other words, our analysis shows that for computing capacity that is capable of resolving the phase field model with $\varepsilon = 0.8 \times 10^{-7}$ the error (in approximating the free boundary) in Model 2 would be only $(17.313)^{-1} = 0.05776$, or less than 6% of the error of Model 1. Similarly, for $\varepsilon = 0.32 \times 10^{-7}$ the corresponding ratio would be

$$6.8421 \times \left(\frac{5.2632}{2.08}\right)^2 = 43.809,$$

leading to about 2% of the error.

The rigorous proof of second order convergence [10] is valid for $\varepsilon < \varepsilon_0$ for some positive ε_0. In any proof of this type one has no assurance that the ε_0 will be large enough to be of any practical significance. In the computations discussed above, particularly the last one in which we utilized material parameters of experiments, it is evident that one obtains this second order convergence using values of ε that are feasible with current computing capacity. Furthermore, there is the issue of the constant in (4.1). Although the constant in (4.1) is larger for Model 2 than for the corresponding expression for Model 1, the factor of ε^2 is small enough to render a much more accurate interface location (relative to the free boundary problem) as discussed above.

Hence, for computations using ε that is about half of the value we have used, one may conclude that our new phase field model (i.e., Model 2) can reduce the error in approximating a free boundary by a factor of 50.

5. Conclusion. We have presented numerical results for a classical phase field model and a new phase field model, demonstrating their asymptotic agreement with a free boundary (sharp interface) model using the Gibbs–Thomson condition and dynamical undercooling at the liquid-solid interface. For both phase field models, the interface, defined as the zero level set of the phase function, is compared with the free boundary of the sharp interface model which is the asymptotic limit of the phase field models. The results confirm the theoretical prediction that the distance between interface and free boundary is of order ε for the classical phase field model and of order ε^2 for the new model. Indeed, these asymptotic behaviors are seen more clearly in the new model than in the classical model. A well-behaved second order accuracy asymptotic behavior of the new model starts from a small ε which is much larger than that of the classical model, which is first order. While the classical model shows considerable deviations from its first order asymptotic behavior of approximating the free boundary model for ε that is not very small, the new model already demonstrates its second order approximation behavior. When ε is small, the new model always leads to a substantially better approximation than the classical one.

The theoretical assertion that the new phase field model is a second order accurate approximation of the free boundary model is derived in [10] from formal expansions in which $1/d := L/d_0$ is regarded as an order one constant and solutions are expanded in $\epsilon := \varepsilon/L$ power series. Here we omit the details of the formal asymptotic expansions and their rigorous verifications; we refer interested readers to the original formal expansions of Caginalp [5, 7] and rigorous verifications of Caginalp and Chen [9]. In reality it is true that $\epsilon = \varepsilon/L$ is smaller than $d = d_0/L$, but in numerical simulations such as those demonstrated in this paper, ε is taken as large as d_0; i.e., d is as small as ϵ.

In such a scenario, one can indeed assume that $\bar{\epsilon} := \varepsilon/d_0 = \epsilon/d$ is a fixed positive constant, expand the solution in ϵ or d power series, and demonstrate the following:

1. The leading (zeroth) order expansions of both the new and the classical phase

field models correspond to solutions of the classical Stefan problem, e.g., the solution (3.3) with $d = 0$.

2. The first order expansion of the solution of the new phase field model corresponds to a solution of the free boundary problem (2.1), e.g., the solution (3.3) with $0 < d \ll 1$.
3. The zero level set Γ_ϵ of the phase indicator function ϕ of the new phase field model is $O(\epsilon) = O(\bar{\epsilon}d)$ distance away from the free boundary of the classical Stefan model and is $O(\epsilon^2) = O(\bar{\epsilon}^2 d^2)$ distance away from that of the free boundary problem (2.1) (assuming that both free boundary problems admit smooth solutions).
4. On the other hand, the zero level set of the phase function of the classical phase field model is $O(\epsilon) = O(\bar{\epsilon}d)$ distance away from the free boundaries of both the Stefan problem and (2.1).

For the numerics of our current paper, which involve the mathematical limit of ε approaching zero, the computations are very close to the exact solutions even if ε/d_0 is not small. When $\bar{\epsilon} := \varepsilon/d_0$ is large in numerical simulation, the addition of $5\bar{\epsilon}/12$ to the kinetic undercooling coefficient from a to $a_\epsilon = a + 5\bar{\epsilon}/12$ can become significant.

To use the new phase field model (2.2) to approximate (2.1), one needs a resolution of order $o(d)$ at the interface. Since theoretical predication and numerical validation of this paper indicate that the error of this approximation at interface is $O(\epsilon^2)$, what we need is $\epsilon^2 = \bar{\epsilon}^2 d^2 = o(d)$, that is,

$$0 < \varepsilon \ll \sqrt{Ld_0}.$$

For example, in a dendritic growth experiment [22] with $d_0 = 8 \times 10^{-7}$ cm and $L = 0.8$ cm, the above criterion means that in numerical simulations using the new phase field model (2.2) to capture the Gibbs–Thomson condition, the parameter ε used should be smaller than $\sqrt{Ld_0} = 8 \times 10^{-4}$ cm, i.e., $\epsilon = \varepsilon/L < 0.001$. This amounts to thousands of grid points in each space dimension and millions of time steps for simulations of real experiments. Hence for values such as $\epsilon = 0.001$, yielding $\bar{\epsilon} = \varepsilon/d_0 = 1000$, there is a huge computational advantage in using the new phase field model with $a_\epsilon = a + 5\bar{\epsilon}/12$ replacing a of the traditional phase field model.

TIME REVERSAL FOCUSING OF THE INITIAL STATE FOR KIRCHHOFF PLATE*

KIM DANG PHUNG† AND XU ZHANG‡

Abstract. Consider a Kirchhoff plate $\partial_t^2 u + \Delta^2 u - \partial_t^2 \Delta u = 0$ in $\Omega \times (0,T)$, with boundary data $u = \Delta u = 0$ on $\partial\Omega \times (0,T)$ and unknown initial data $u(\cdot,0) = u_0$ and $\partial_t u(\cdot,0) = u_1$ in Ω. We study an inverse problem of determining (u_0,u_1) from an interior observation $u|_{\omega\times(0,T)}$. Here Ω is a bounded domain, ω a nonempty open subset of Ω, and $T > 0$ a suitable time duration. By means of an iterative time reversal technique, we derive an asymptotic formula of reconstructing (u_0,u_1) approximately with a logarithmical convergence rate for smooth initial data. The convergence becomes uniform and exponential when (Ω,ω,T) satisfies the geometric control condition introduced by Bardos, Lebeau, and Rauch.

Key words. Kirchhoff plate, inverse problem, quantitative unique continuation, observability estimate, time reversal technique

1. Introduction and main results.

Let $\Omega \subset \mathbb{R}^d$ ($d \in \mathbb{N}$) be a bounded open set with sufficiently smooth boundary $\partial\Omega$, ω a nonempty open subset of Ω, $T > 0$ a suitable time duration, and $\beta \in (0,1)$ any fixed parameter. Let $\mathcal{M} = \left(\alpha^{ij}\right)_{1\le i,j\le d} \in C^\infty\left(\overline{\Omega};\mathbb{R}^{d\times d}\right)$ be a symmetric and uniformly positive definite matrix (hence $(\beta^{ij})_{1\le i,j\le d} = \mathcal{M}^{1/2}$ is well defined). Denote by $1_{|\omega}$ the characteristic function of ω in Ω. Let $Q = \Omega \times (0,T)$ and $\Sigma = \partial\Omega \times (0,T)$. Throughout this paper, we shall use $C = C(\Omega,\omega,T,d,\beta,\mathcal{M})$ to denote a generic positive constant, which may change from line to line.

Denote by $\Delta = \sum_{i,j=1}^d \partial_{x_i}(\alpha^{ij}\partial_{x_j})$ the "Laplacian" associated to the matrix $\mathcal{M}$. We consider the following Kirchhoff plate equation in an inhomogeneous media:

$$\begin{cases} \partial_t^2 u + \Delta^2 u - \partial_t^2 \Delta u = 0 & \text{in } \Omega \times \mathbb{R}, \\ u = \Delta u = 0 & \text{on } \partial\Omega \times \mathbb{R}, \\ u(\cdot,0) = u_0, \quad \partial_t u(\cdot,0) = u_1 & \text{in } \Omega. \end{cases} \tag{1.1}$$

Let

$$\mathcal{H} \overset{\triangle}{=} \left\{ z \in H^3(\Omega) \;\middle|\; z = \Delta z = 0 \text{ on } \partial\Omega \right\} \times \left(H^2(\Omega) \cap H_0^1(\Omega) \right).$$

Clearly, $\mathcal{H}$ is a Hilbert space with the norm

$$||(u_0,u_1)||_{\mathcal{H}} \overset{\triangle}{=} \|(\nabla\Delta u_0, u_1, \Delta u_1)\|_{(L^2(\Omega))^d \times H_0^1(\Omega) \times L^2(\Omega)} .$$

Here and henceforth, $\nabla = (\sum_{j=1}^{d}\beta^{1j}\partial_{x_j}, \ldots, \sum_{j=1}^{d}\beta^{dj}\partial_{x_j})$. It is easy to rewrite (1.1) as an abstract Cauchy problem in $\mathcal{H}$, with an unbounded operator $\mathcal{A} : D(\mathcal{A}) \subset \mathcal{H} \to \mathcal{H}$ as the generator of the underlying C_0-group. Hence, for any initial data $(u_0, u_1) \in \mathcal{H}$, system (1.1) is well-posed in $\mathcal{H}$. From the standard operator semigroup theory, $D(\mathcal{A}^k)$ ($k \in \mathbb{N}$) are themselves Hilbert spaces with the graph norms.

For any $z \in C(\mathbb{R}; \mathcal{H})$, we denote by $E(z, t)$ the functional

$$E(z,t) \overset{\triangle}{=} \frac{1}{2}\int_{\Omega}\left[|\nabla\Delta z(x,t)|^2 + |\nabla\partial_t z(x,t)|^2 + |\Delta\partial_t z(x,t)|^2\right] dx. \tag{1.2}$$

It is clear that $\mathcal{H}$ is the *finite energy space* of system (1.1), and its energy $E(\cdot, t)$ is conservative in the sense that for any u solution of (1.1) and all $t \in \mathbb{R}$,

$$E(u,t) = \frac{1}{2}||(u_0, u_1)||^2_{\mathcal{H}}. \tag{1.3}$$

The main purpose of this paper is to investigate the state-observation problem for system (1.1), which is formulated as follows: To determine the initial data (u_0, u_1) of a solution u of (1.1) from the single interior measurement $u|_{\omega\times(0,T)}$. It is well known that the state-observation problem is closely related to the inverse source problem, i.e., to determine the source term which causes the evolution process from the boundary and/or interior measurement. Inverse source problems of PDEs have been the object of numerous studies in recent years. Extensive related references can be found, say, in [18, 24, 25, 26] for the hyperbolic equations, in [22] for the Euler–Bernoulli plate equation, and in other works cited therein. Most of the references on inverse source problems cited above are addressed to global uniqueness and stability; here we give a constructive strategy to recover the initial data from a partial measurement of the solution. Our strategy for identification of source is inspired by the time reversal method and may be more practical than the formal tools of control theory (e.g., [23]). By means of an iterative time reversal technique, we further establish an asymptotic formula to reconstruct the desired initial state (u_0, u_1) of (1.1) by superposing different solutions of some Kirchhoff plates depending only on the measurement $u|_{\omega\times(0,T)}$.

More precisely, the knowledge of u on $\omega \times (0, T)$ allows us to consider a sequence of solutions $\{v^{(j)}\}_{j\geq 0}$ given as follows. First, let $U^{(-1)} = \frac{1}{2}u$ in $\omega \times (0, T)$. Next, define $v^{(j)} = v^{(j)}(x, t)$ ($j = 0, 1, 2, \ldots$) inductively to be the solution of the following system:

$$\begin{cases} \partial_t^2 v^{(j)} + \Delta^2 v^{(j)} - \partial_t^2\Delta v^{(j)} + \partial_t\Delta v^{(j)} \cdot 1_{|\omega} = -2\partial_t\Delta U^{(j-1)}(\cdot, T-t)\cdot 1_{|\omega} & \text{in } Q, \\ v^{(j)} = \Delta v^{(j)} = 0 & \text{on } \Sigma, \\ v^{(j)}(\cdot,0) = \partial_t v^{(j)}(\cdot,0) = 0 & \text{in } \Omega, \end{cases} \tag{1.4}$$

where $U^{(j)} = U^{(j)}(x, t)$ is given by

$$U^{(j)}(x,t) = \begin{cases} v^{(0)}(x,t) - u(x,T-t), & j = 0, \\ v^{(j)}(x,t) - U^{(j-1)}(x,T-t), & j > 0, \end{cases} \quad \text{for } (x,t) \in \omega \times (0,T). \tag{1.5}$$

Note that the values of functions $U^{(j)}$ are defined only in $\omega \times (0, T)$. Nevertheless, by system (1.4), it suffices to determine the values of $v^{(j)}$ in the whole domain Q

from $\partial_t \Delta U^{(j-1)}\big|_{\omega\times(0,T)}$. It is easy to see that the functions $v^{(j)}$ depend only on $\partial_t\Delta u$ restricted to $\omega\times(0,T)$.

We say that (Ω,ω,T_0) satisfies the classical geometric control condition (GCC), introduced in [2, 3], if $\partial\Omega$ is C^∞ with no contact of infinite order with its tangent, and any generalized bicharacteristic ray $(x(\rho),t(\rho))$ of $\partial_t^2-\Delta$ starting at $\rho=0$ with $t(0)=0$ meets $\omega\times(0,T_0)$ (see also [4] for an improvement on the regularity of $\partial\Omega$ and of $\mathcal{M}$). Notice that GCC can be rephrased by a geodesic condition (see [17]).

The main results of this paper are stated as follows.

Theorem 1.1. *Under GCC, for any $T\geq T_0$ there exists a constant $\sigma>0$ such that for any initial data $(u_0,u_1)\in\mathcal{H}$ and any $N>0$, it holds that*

$$\left\|\left(\sum_{k=0}^{N} v^{(2k)}(\cdot,T)-u_0,\ \sum_{k=0}^{N}\partial_t v^{(2k)}(\cdot,T)+u_1\right)\right\|_{\mathcal{H}} \leq Ce^{-\sigma N}\left\|(u_0,u_1)\right\|_{\mathcal{H}}. \tag{1.6}$$

Theorem 1.2. *Suppose*

$$J_3 \overset{\triangle}{=} \sup_{j>0}\left\|\left(\sum_{k=0}^{j} v^{(2k)}(\cdot,T),\ \sum_{k=0}^{j}\partial_t v^{(2k)}(\cdot,T)\right)\right\|_{D(\mathcal{A}^3)} < +\infty$$

and that Ω is connected. Then, for any nonempty open subset ω of Ω and any $\beta\in(0,1)$, there exists a time $T>0$ such that for any initial data $(u_0,u_1)\in D(\mathcal{A}^3)$ and any $N>0$, it holds that

$$\left\|\left(\sum_{k=0}^{N} v^{(2k)}(\cdot,T)-u_0,\ \sum_{k=0}^{N}\partial_t v^{(2k)}(\cdot,T)+u_1\right)\right\|_{\mathcal{H}} \leq \frac{C}{\ln^\beta(1+N)}[J_3+\|(u_0,u_1)\|_{D(\mathcal{A}^3)}]. \tag{1.7}$$

The above results say that $(\sum_{k=0}^N v^{(2k)}(\cdot,T),\ -\sum_{k=0}^N \partial_t v^{(2k)}(\cdot,T))$ can be employed to serve as an asymptotic formula to recover the initial state (u_0,u_1) of system (1.1). The key point to do this is the time reversibility of Kirchhoff plate. Fink (see [6, 7]) experimented with the time reversal mirror and succeeded in generating many applications (e.g., in biomedical engineering and telecommunication). Next, many mathematicians were also interested in this phenomenon (e.g., [1, 8, 19]). Thanks to the refocusing properties of the time-reversed waves, the time reversal technique has been successfully used to solve inverse problems for acoustic waves or electromagnetic waves (see, e.g., [5, 12]). Nevertheless, the main novelty in Theorems 1.1 and 1.2 is, respectively, the explicit exponential and logarithmical convergence rates for $(\sum_{k=0}^N v^{(2k)}(\cdot,T),\ -\sum_{k=0}^N \partial_t v^{(2k)}(\cdot,T))$ to approximate (u_0,u_1) in the strong topology of $\mathcal{H}$. Note also that Theorem 1.2 is for the case without GCC on (Ω,ω,T), for which one can usually expect a much weaker result than the case with GCC (we refer the reader to [14, 20] for a different yet related topic for the hyperbolic equations).

Technically, the proofs of Theorems 1.1 and 1.2 are reduced to suitable observability estimates for system (1.1). Under GCC, the desired observability estimate follows from the known result in [2, 3] for the wave equation. For the treatment in the case without GCC, by the Fourier–Bros–Iagolnitzer transformation given in [14], the obtaining of the desired observability estimate for the evolution system (1.1) depends on some quantitative unique continuation property for a fourth order elliptic-like equation with multiple characteristics (see (3.1)), which, in turn, will be established by means of global Carleman estimate. Although global Carleman estimates are well understood for many PDEs with single characteristics or without characteristics, it seems that there is no reference for the multiple-characteristic PDEs. The crucial point for the possibility of applying the Carleman estimate to the above-mentioned multiple-characteristic equation is that this equation can be rewritten equivalently as two coupled elliptic equations of second order, and that, based on a useful pointwise estimate for second order differential operators with symmetric coefficients (without any sign condition), we are successful in using Carleman estimates with a common weight function for these equations.

To end this section, we remark that, if the first equation in (1.4) is replaced by

$$\partial_t^2 v^{(j)} + \Delta^2 v^{(j)} - \partial_t^2 \Delta v^{(j)} - (-\Delta)^{-1}\big(\partial_t v^{(j)} \cdot 1_{|\omega}\big) = 2(-\Delta)^{-1}\big(\partial_t U^{(j-1)}(\cdot, T-t)\cdot 1_{|\omega}\big),$$

while (u_0, u_1) is assumed only to belong to $D(\mathcal{A})$, then, based on inequality (5.7) in Theorem 5.2, the estimate (1.7) in Theorem 1.2 becomes

$$\left\| \left(\sum_{k=0}^{N} v^{(2k)}(\cdot, T) - u_0,\ \sum_{k=0}^{N} \partial_t v^{(2k)}(\cdot, T) + u_1 \right) \right\|_{\mathcal{H}} \le \frac{C}{\ln^{\beta}(1+N)} [J_1 + \|(u_0, u_1)\|_{D(\mathcal{A})}].$$

The rest of this paper is organized as follows. In section 2, we derive the desired pointwise estimate for second order differential operators with symmetric coefficients. Section 3 shows an interpolation inequality for the fourth order elliptic-like equation with multiple characteristics mentioned above. Section 4 is devoted to a quantitative unique continuation property for system (1.1). In section 5, we establish two observability estimates for solutions of (1.1). The proofs of Theorems 1.1 and 1.2 are given in section 6.

2. Pointwise estimate for second order differential operators with symmetric coefficients.

In this section, we will establish a pointwise estimate for second order differential operators with symmetric coefficients (without any sign condition), which will play a key role in what follows.

Let $m \in \mathbb{N}$. For simplicity, for a function u, we will use the notation $u_i = \frac{\partial u}{\partial x_i}$, where x_i is the ith coordinate of a generic point $(x_1, \dots, x_m)$ in $\mathbb{R}^m$.

For any

$$a^{ij} = a^{ji} \in C^1(\mathbb{R}^m), \qquad i, j = 1, 2, \dots, m, \tag{2.1}$$

we recall the following known identity (see [10, Theorem 4.1], and also [9, Theorem 1.1] for a variant version).

Lemma 2.1. *Assume $u, \ell, \Psi \in C^2(\mathbb{R}^m)$. Let $\theta = e^{\ell}$ and $v = \theta u$. Then*

$$\begin{aligned} \theta^2 \left| \sum_{i,j=1}^{m} (a^{ij} u_i)_j \right|^2 &+ 2\sum_{j=1}^{m} \Bigg\{ 2 \sum_{i,i',j'=1}^{m} a^{ij} a^{i'j'} \ell_{i'} v_i v_{j'} - \sum_{i,i',j'=1}^{m} a^{ij} a^{i'j'} \ell_i v_{i'} v_{j'} \\ &+ \Psi \sum_{i=1}^{m} a^{ij} v_i v - \sum_{i=1}^{m} a^{ij} \left[(A+\Psi)\ell_i + \frac{\Psi_i}{2} \right] v^2 \Bigg\}_j \\ = 2 \sum_{i,j=1}^{m} c^{ij} v_i v_j + B v^2 &+ \left| \sum_{i,j=1}^{m} (a^{ij} v_i)_j - A v \right|^2 + 4 \left| \sum_{i,j=1}^{m} a^{ij} \ell_i v_j \right|^2, \end{aligned} \tag{2.2}$$

where

$$\left\{\begin{aligned} &A \stackrel{\triangle}{=} -\sum_{i,j=1}^m \Big(a^{ij}\ell_i\ell_j - a^{ij}_j\ell_i - a^{ij}\ell_{ij}\Big) - \Psi,\\ &B \stackrel{\triangle}{=} 2\left\{A\Psi - \sum_{i,j=1}^m \big[(A+\Psi)a^{ij}\ell_i\big]_j\right\} + \Psi^2 - \sum_{i,j=1}^m \big(a^{ij}\Psi_j\big)_i,\\ &c^{ij} \stackrel{\triangle}{=} \sum_{i',j'=1}^m \Big[2a^{ij'}(a^{i'j}\ell_{i'})_{j'} - (a^{ij}a^{i'j'}\ell_{i'})_{j'}\Big] + \Psi a^{ij}. \end{aligned}\right. \tag{2.3}$$

In what follows, for any function $\psi \in C^4(\mathbb{R}^m)$, and any (large) parameters $\varsigma > 1$ and $\kappa > 1$, we choose the function ℓ in Lemma 2.1 as follows:

$$\ell = \varsigma\varphi, \qquad \varphi = e^{\kappa\psi}. \tag{2.4}$$

It is easy to check that

$$\ell_i = \varsigma\kappa\varphi\psi_i, \qquad \ell_{ij} = \varsigma\kappa^2\varphi\psi_i\psi_j + \varsigma\kappa\varphi\psi_{ij}, \qquad i,j = 1,2,\dots,m. \tag{2.5}$$

For $n \in \mathbb{N}$, we denote by $O(\kappa^n)$ a function of order κ^n for large κ (which is independent of ς); by $O_\kappa(\varsigma^n)$ a function of order ς^n for fixed κ and for large ς. The desired pointwise estimate for the operator "$\sum_{i,j=1}^m \frac{\partial}{\partial_{x_j}}\big(a^{ij}\frac{\partial}{\partial_{x_i}}\big)$" is stated as follows.

THEOREM 2.2. *Assume* (2.1) *holds, and* $u \in C^2(\mathbb{R}^m)$. *Let*

$$\theta = e^\ell, \quad v = \theta u, \quad \Psi = 2\sum_{i,j=1}^m a^{ij}\ell_{ij}. \tag{2.6}$$

Then

$$\begin{aligned} &\theta^2\left|\sum_{i,j=1}^m (a^{ij}u_i)_j\right|^2 + 2\sum_{i,j=1}^m \Bigg\{\sum_{i',j'=1}^m \Big[2a^{ij}a^{i'j'}\ell_{i'}v_iv_{j'} - a^{ij}a^{i'j'}\ell_iv_{i'}v_{j'}\Big]\\ &\qquad + \Psi a^{ij}v_iv - a^{ij}\left[(A+\Psi)\ell_i + \frac{\Psi_i}{2}\right]v^2\Bigg\}_j\\ &\geq 2\sum_{i,j=1}^m c^{ij}v_iv_j + Bv^2, \end{aligned} \tag{2.7}$$

where A, B, *and* c^{ij} *are given in* (2.3). *Moreover, for* ς *and* κ *large enough, the following estimates hold uniformly in any bounded set of* $\mathbb{R}^m$:

(2.8)

$$\begin{aligned} \sum_{i,j=1}^m c^{ij}v_iv_j \geq \varsigma\kappa\varphi\Bigg\{&\kappa\left(\sum_{i,j=1}^m a^{ij}\psi_i\psi_j\right)\left(\sum_{i,j=1}^m a^{ij}v_iv_j\right) + \sum_{i,j,i',j'=1}^m \Big[2a^{ij'}a^{i'j}\psi_{i'j'}\\ &+ a^{ij}a^{i'j'}\psi_{i'j'} + 2a^{ij'}a^{i'j}_{j'}\psi_{i'} - (a^{ij}a^{i'j'})_{j'}\psi_{i'}\Big]v_iv_j\Bigg\}, \end{aligned}$$

$$B = 2\varsigma^3\kappa^4\varphi^3\left(\sum_{i,j=1}^m a^{ij}\psi_i\psi_j\right)^2 + \varsigma^3\varphi^3O(\kappa^3) + O_\kappa(\varsigma^2).$$

Proof. Clearly, (2.7) is a direct consequence of Lemma 2.1. Recalling (2.3) for c^{ij}, and noting (2.6) and (2.5), we have

$$\begin{aligned}
&\sum_{i,j=1}^{m} c^{ij} v_i v_j \\
&= \sum_{i,j,i',j'=1}^{m} \Big[2a^{ij'}a^{i'j}\ell_{i'j'} + a^{ij}a^{i'j'}\ell_{i'j'} + 2a^{ij'}a^{i'j}_{j'}\ell_{i'} - (a^{ij}a^{i'j'})_{j'}\ell_{i'}\Big] v_i v_j \\
&= 2\varsigma\kappa^2\varphi\left(\sum_{i,j=1}^{m} a^{ij}\psi_i v_j\right)^2 + \varsigma\kappa^2\varphi\left(\sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j\right)\left(\sum_{i,j=1}^{m} a^{ij} v_i v_j\right) \\
&\quad + \varsigma\kappa\varphi \sum_{i,j,i',j'=1}^{m} \Big[2a^{ij'}a^{i'j}\psi_{i'j'} + a^{ij}a^{i'j'}\psi_{i'j'} + 2a^{ij'}a^{i'j}_{j'}\psi_{i'} - (a^{ij}a^{i'j'})_{j'}\psi_{i'}\Big] v_i v_j \\
&\geq \varsigma\kappa^2\varphi\left(\sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j\right)\left(\sum_{i,j=1}^{m} a^{ij} v_i v_j\right) \\
&\quad + \varsigma\kappa\varphi \sum_{i,j,i',j'=1}^{m} \Big[2a^{ij'}a^{i'j}\psi_{i'j'} + a^{ij}a^{i'j'}\psi_{i'j'} + 2a^{ij'}a^{i'j}_{j'}\psi_{i'} - (a^{ij}a^{i'j'})_{j'}\psi_{i'}\Big] v_i v_j,
\end{aligned}$$

which gives the first inequality in (2.8).

On the other hand, by (2.5), recalling the definitions of Ψ and A, we see that

$$\Psi = 2\varsigma\kappa^2\varphi \sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j + \varsigma\varphi O(\kappa), \qquad A = -\varsigma^2\kappa^2\varphi^2 \sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j + O_\kappa(\varsigma).$$

Hence, from the definition of B, we have

$$\begin{aligned}
B \;&= 2\Bigg\{ -2\varsigma^3\kappa^4\varphi^3\left(\sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j\right)^2 + \varsigma^3\varphi^3 O(\kappa^3) + O_\kappa(\varsigma^2) \\
&\qquad + \varsigma\kappa \sum_{i,j=1}^{m}\left[\left(\varsigma^2\kappa^2\varphi^3 \sum_{i',j'=1}^{m} a^{i'j'}\psi_{i'}\psi_{j'} + O_\kappa(\varsigma)\right) a^{ij}\psi_i\right]_j \Bigg\} + O_\kappa(\varsigma^2) \\
&= 2\Bigg\{ -2\varsigma^3\kappa^4\varphi^3\left(\sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j\right)^2 + \varsigma^3\varphi^3 O(\kappa^3) + O_\kappa(\varsigma^2) \\
&\qquad + \varsigma\kappa \sum_{i,j=1}^{m}\left(3\varsigma^2\kappa^3\varphi^3 \sum_{i',j'=1}^{m} a^{i'j'}\psi_{i'}\psi_{j'} + \varsigma^2\varphi^3 O(\kappa^2) + O_\kappa(\varsigma)\right) a^{ij}\psi_i\psi_j \Bigg\} \\
&= 2\varsigma^3\kappa^4\varphi^3\left(\sum_{i,j=1}^{m} a^{ij}\psi_i\psi_j\right)^2 + \varsigma^3\varphi^3 O(\kappa^3) + O_\kappa(\varsigma^2),
\end{aligned}$$

which yields the second inequality in (2.8). □

3. Interpolation inequality for a fourth order elliptic-like equation with multiple characteristics.

As a crucial preliminary, we derive in this section the following a priori estimate for a fourth order elliptic-like equation with multiple characteristics.

THEOREM 3.1. *Suppose that Ω is connected. Then, for any nonempty open subset ω of Ω, there exists a constant $C_0 = C_0(\Omega, \omega, d, \mathcal{M}) > 0$ such that for any $w = w(x,s) \in H^2(\Omega \times (-2,2))$ and $f = f(x,s) \in L^2(\Omega \times (-2,2))$ with*

$$\begin{cases} -\partial_s^2 w + \Delta^2 w + \partial_s^2 \Delta w = f & \text{in } \Omega \times (-2,2)\,, \\ w = \Delta w = 0 & \text{on } \partial\Omega \times (-2,2) \end{cases} \tag{3.1}$$

we have

$$\begin{aligned} \int_{-1}^{1}\int_{\Omega} |\Delta w|^2 \, dxds \le \; & C_0 e^{C_0/\varepsilon} \left[\int_{-2}^{2}\int_{\omega} \left(|w|^2 + |\Delta w|^2 \right) dxds + \int_{-2}^{2}\int_{\Omega} |f|^2 \, dxds \right] \\ & + e^{-2/\varepsilon} \int_{-2}^{2}\int_{\Omega} \left(|\Delta w|^2 + |\partial_s \Delta w|^2 \right) dxds \qquad \forall\, \varepsilon > 0. \end{aligned} \tag{3.2}$$

Notice that this interpolation estimate (3.2) or Hölder dependence continuous inequality has already appeared in [13] for second order elliptic operators in the framework of null controllability for the heat equation.

Before proving Theorem 3.1, we remark that inequality (3.2) is a kind of quantitative unique continuation of (3.1) in the following sense: If $w \in H^2(\Omega \times (-2,2))$ solves (3.1) with $f = 0$ in $\Omega \times (-2,2)$, and $w = 0$ in $\omega \times (-2,2)$, then, by Theorem 3.1, $w = 0$ in $\Omega \times (-1,1)$. On the other hand, it is easy to verify that any solution w to (3.1) with $f = 0$ in $\Omega \times (-2,2)$ is of the form

$$w(x,s) = \sum_{k=1}^{\infty} \left(a_k e^{s\sqrt{1+\lambda_k - \frac{1}{1+\lambda_k}}} + b_k e^{-s\sqrt{1+\lambda_k - \frac{1}{1+\lambda_k}}} \right) \varphi_k(x), \qquad a_k,\, b_k \in \mathbb{C},$$

where $\{\lambda_k\}_{k\ge 1}$ are the eigenvalues of $-\Delta$ with homogeneous Dirichlet boundary condition and $\{\varphi_k\}_{k=1}^{\infty}$ the corresponding eigenvectors (constituting an orthonormal basis of $L^2(\Omega)$). Therefore, $w(\cdot, s)$ is analytic with respect to s, which, in turn, implies $w = 0$ in $\Omega \times (-2,2)$.

Note also that (3.1) is not elliptic in the classical sense. Indeed, the symbol of its principal operator reads $\xi^4 + \xi^2\eta^2$, which vanishes for $\xi = 0$ and any $\eta \in \mathbb{R}$. As mentioned in the introduction, we use global Carleman estimates to establish (3.2). To do this, a key observation is the possibility of decomposing the operator $-\partial_s^2 + \Delta^2 + \partial_s^2\Delta$ as follows:

$$-\partial_s^2 + \Delta^2 + \partial_s^2\Delta = (\partial_s^2 + \Delta)(-I + \Delta) + \Delta, \tag{3.3}$$

where I is the identity. Consequently, in order to derive the desired inequality (3.2), it is natural to proceed in cascade by applying the global Carleman estimates to the second order elliptic operators $\partial_s^2 + \Delta$ and Δ. Thanks to Theorem 2.2, this is possible because only the symmetry of the matrix $(a^{ij})_{1\le i,j\le m}$ is required. Therefore, Theorem 2.2 applies to both the operators $\partial_s^2 + \Delta$ and Δ. We remark that, due to the necessity of using same weight function for these two different elliptic operators of second order, there seems no existing Carleman estimate in the literature for our purpose.

Proof of Theorem 3.1. The proof is divided into four steps.

Step 1. *Choice of the weight function.* In order to apply Theorem 2.2 in cascade to the operators $\partial_s^2 + \Delta$ and Δ, it is important to choose a common weight function $\theta = \theta(x, s)$ for these two different operators.

It is well known that (see [11] or [21], for example) there is a function $\widehat{\psi} \in C^4\left(\overline{\Omega}\right)$ such that $\widehat{\psi} > 0$ in Ω, $\widehat{\psi} = 0$ on $\partial\Omega$, and

$$0 < \sum_{i=1}^{d} \left|\partial_{x_i}\widehat{\psi}(x)\right|^2 \le C\left|\nabla\widehat{\psi}(x)\right|^2 \qquad \forall\, x \in \overline{\Omega\setminus\omega_0} \tag{3.4}$$

where $\omega_0 \subset \omega$ is an arbitrary fixed nonempty open subset of Ω such that $\overline{\omega_0} \subset \omega$. Therefore,

$$h \overset{\triangle}{=} \frac{1}{||\widehat{\psi}\,||_{L^\infty(\Omega)}} \min_{x\in\overline{\Omega\setminus\omega_0}} |\nabla\widehat{\psi}(x)| > 0. \tag{3.5}$$

Let us introduce

$$b = \sqrt{1 + \frac{1}{\kappa}\ln\left(2 + e^\kappa\right)}, \qquad b_0 = \sqrt{b^2 - \frac{1}{\kappa}\ln\left(\frac{1+e^\kappa}{e^\kappa}\right)}, \tag{3.6}$$

where $\kappa > \ln 2$ is the parameter that appeared in Theorem 2.2 and is chosen large enough. It is easy to see that

$$1 < b_0 < b \le 2.$$

Further, we choose

$$\psi(x, s) = \frac{\widehat{\psi}(x)}{||\widehat{\psi}\,||_{L^\infty(\Omega)}} + b^2 - s^2. \tag{3.7}$$

By (2.4) and (2.6), this gives the function $\varphi\left(x, s\right) = e^{\kappa\psi(x,s)}$ and the desired weight function $\theta\left(x, s\right) = e^{\varsigma e^{\kappa\psi(x,s)}}$ (recall Theorem 2.2 for the parameter ς). It is easy to check that

$$\begin{cases} \varphi\left(\cdot, s\right) \ge 2 + e^\kappa & \text{for any } s \text{ satisfying } |s| \le 1, \\ \varphi\left(\cdot, s\right) \le 1 + e^\kappa & \text{for any } s \text{ satisfying } b_0 \le |s| \le b. \end{cases} \tag{3.8}$$

Step 2. *Reduction of* (3.1) *to a cascade system.* Let

$$z = -w + \Delta w. \tag{3.9}$$

Then, in view of (3.3), system (3.1) can be written equivalently as the following elliptic system of second order in cascade:

$$\begin{cases} \Delta w = z + w & \text{in } \Omega\times\left(-2, 2\right), \\ \partial_s^2 z + \Delta z = f - z - w & \text{in } \Omega\times\left(-2, 2\right), \\ w = z = 0 & \text{on } \partial\Omega\times\left(-2, 2\right). \end{cases} \tag{3.10}$$

Note, however, that there is no (homogeneous) boundary condition for w (and hence z) at $s = \pm 2$. Now, we introduce a cut-off function $\phi = \phi(s) \in C_0^\infty(-b, b) \subset C_0^\infty(\mathbb{R})$ such that

$$\begin{cases} 0 \le \phi(s) \le 1, & |s| < b, \\ \phi(s) \equiv 1, & |s| \le b_0. \end{cases} \tag{3.11}$$

Let

$$\tilde{w} = \phi w, \qquad \tilde{z} = \phi z. \tag{3.12}$$

Then, noticing that ϕ does not depend on x, it follows by (3.10) that

$$\begin{cases} \Delta \tilde{w} = \tilde{z} + \tilde{w} & \text{in } \Omega \times (-2, 2), \\ \partial_s^2 \tilde{z} + \Delta \tilde{z} = \phi f + 2\partial_s \phi \partial_s z + z \partial_s^2 \phi - \tilde{z} - \tilde{w} & \text{in } \Omega \times (-2, 2), \\ \tilde{w} = \tilde{z} = 0 & \text{on } \partial\Omega \times (-2, 2), \\ \operatorname{supp} \tilde{w}(x, \cdot) \bigcup \operatorname{supp} \tilde{z}(x, \cdot) \subset (-b, b), & x \in \Omega. \end{cases} \tag{3.13}$$

Step 3. *Carleman estimates.* First, we apply Theorem 2.2 with $m = d + 1$, $x_{d+1} = s$, $(a^{ij})_{1 \le i,j \le d+1} = \left(\begin{smallmatrix} \mathcal{M} & 0 \\ 0 & 0 \end{smallmatrix}\right)$, u replaced by $\tilde{w}$, and the weight function θ given above. In this case, by the definition of c^{ij} in (2.3), it is easy to check that

$$c^{ij} = 0 \qquad \text{whenever one of } i \text{ and } j \text{ is equal to } d + 1. \tag{3.14}$$

Moreover, by (2.8), recalling (3.7) for the definition of ψ and (3.5) for the positive constant h, we conclude that there is a constant $\kappa_0 > 1$ such that for any $\kappa \ge \kappa_0$, one can find a constant $\varsigma_0 > 1$ so that for any $\varsigma \ge \varsigma_0$, the following estimates hold uniformly for $(x, s) \in \overline{\Omega \setminus \omega_0} \times [-b, b]$:

$$\begin{aligned} &\sum_{i,j=1}^{d} c^{ij} v_i v_j \ge \varsigma\varphi \Big\{ \kappa^2 |\nabla\psi|^2 + O(\kappa) \Big\} |\nabla v|^2 \ge \frac{h^2}{2} \varsigma \kappa^2 \varphi |\nabla v|^2, \\ &B = 2\varsigma^3 \kappa^4 \varphi^3 |\nabla\psi|^4 + \varsigma^3 \varphi^3 O(\kappa^3) + O_\kappa(\varsigma^2) \ge h^4 \varsigma^3 \kappa^4 \varphi^3, \end{aligned} \tag{3.15}$$

where $v = \theta\tilde{w}$. Now, integrating inequality (2.7) (with u replaced by $\tilde{w}$) of Theorem 2.2 in $\Omega \times (-b, b)$, recalling that ϕ vanishes near $s = \pm b$, $\widehat{\psi} = 0$ on $\partial\Omega$, and $v = 0$ on $\partial\Omega \times (-b, b)$, noting (3.15) and the first equation in (3.13), one arrives at

$$\begin{aligned} &\frac{1}{C} \left\{ \varsigma\kappa^2 \int_{-b}^{b} \int_\Omega \varphi |\nabla v|^2 dx ds + \varsigma^3 \kappa^4 \int_{-b}^{b} \int_\Omega \varphi^3 |v|^2 dx ds \right\} \\ &\le \int_{-b}^{b} \int_\Omega \theta^2 \left| \tilde{z} + \tilde{w} \right|^2 dx ds + \frac{\varsigma\kappa}{||\widehat{\psi}||_{L^\infty(\Omega)}} \int_{-b}^{b} \int_{\partial\Omega} \varphi \frac{\partial \widehat{\psi}}{\partial \nu} \left| \frac{\partial v}{\partial \nu_{\mathcal{M}}} \right|^2 d(\partial\Omega) ds \\ &\quad + C \left\{ \varsigma\kappa^2 \int_{-b}^{b} \int_{\omega_0} \theta^2 \varphi |\nabla \tilde{w}|^2 dx ds + \varsigma^3 \kappa^4 \int_{-b}^{b} \int_{\omega_0} \theta^2 \varphi^3 |\tilde{w}|^2 dx ds \right\}, \end{aligned} \tag{3.16}$$

where $\frac{\partial \widehat{\psi}}{\partial \nu} = \sum_{i=1}^{d} \widehat{\psi}_i \nu^i$, $\frac{\partial v}{\partial \nu_{\mathcal{M}}} = \sum_{i,j=1}^{d} \alpha^{ij} v_i \nu^j$, and $\nu = \left(\nu^1, \ldots, \nu^d\right) = \nu(x)$ is the unit outward normal vector of Ω at $x \in \partial\Omega$. For the boundary term in (3.16), we have used that

$$\sum_{i,j=1}^{d+1}\left\{\sum_{i',j'=1}^{d+1}\left[2a^{ij}a^{i'j'}\ell_{i'}v_iv_{j'}-a^{ij}a^{i'j'}\ell_iv_{i'}v_{j'}\right]\right\}\nu^j$$

$$=\frac{\varsigma\kappa\varphi}{||\widehat{\psi}\,||_{L^\infty(\Omega)}}\left(\sum_{i=1}^{d}\widehat{\psi}_i\nu^i\right)\left|\sum_{i,j=1}^{d}a^{ij}v_i\nu^j\right|^2=\frac{\varsigma\kappa\varphi}{||\widehat{\psi}\,||_{L^\infty(\Omega)}}\frac{\partial\widehat{\psi}}{\partial\nu}\left|\frac{\partial v}{\partial\nu_{\mathcal{M}}}\right|^2,$$

which follows from the fact that on $\partial\Omega\times(-b,b)$, we have for $j=1,\dots,d$,

$$v_j=\left(\sum_{i=1}^{d}v_i\nu^i\right)\nu^j,\, \ell_j=\varsigma\kappa\varphi\psi_j=\frac{\varsigma\kappa\varphi}{||\widehat{\psi}\,||_{L^\infty(\Omega)}}\widehat{\psi}_j=\frac{\varsigma\kappa\varphi}{||\widehat{\psi}\,||_{L^\infty(\Omega)}}\left(\sum_{i=1}^{d}\widehat{\psi}_i\nu^i\right)\nu^j,$$

and $\nu^{d+1}=0$.

Choose a cut-off function $g\in C_0^\infty(\omega)$ with $g\equiv1$ in ω_0 and $0\le g\le1$ in ω. Multiplying the first equation in (3.13) by $g\theta^2\varphi\tilde{w}$ and integrating it in $\Omega\times(-b,b)$, using integration by parts, one obtains

$$\int_{-b}^{b}\int_{\omega_0}\theta^2\varphi|\nabla\tilde{w}|^2dxds\le C\left[\varsigma\kappa^2\int_{-b}^{b}\int_{\omega}\theta^2\varphi^2|\tilde{w}|^2dxds+\int_{-b}^{b}\int_{\omega}\theta^2|\tilde{z}|^2dxds\right]. \tag{3.17}$$

Recalling that $v=\theta\tilde{w}$, by (2.5), we get

$$\frac{1}{C}\theta^2(|\nabla\tilde{w}|^2+\varsigma^2\kappa^2\varphi^2|\tilde{w}|^2)\le|\nabla v|^2+\varsigma^2\kappa^2\varphi^2v^2\le C\theta^2(|\nabla\tilde{w}|^2+\varsigma^2\kappa^2\varphi^2|\tilde{w}|^2). \tag{3.18}$$

By the choice of $\widehat{\psi}$, one can check that $\frac{\partial\widehat{\psi}}{\partial\nu}<0$ on $\partial\Omega$. Therefore, by (3.16) and noting (3.17)–(3.18), we end up with

$$\begin{aligned}&\varsigma\kappa^2\int_{-b}^{b}\int_{\Omega}\theta^2\varphi|\nabla\tilde{w}|^2dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_{\Omega}\theta^2\varphi^3|\tilde{w}|^2dxds\\&\le C\left(\int_{-b}^{b}\int_{\Omega}\theta^2\left|\tilde{z}\right|^2dxds+\varsigma\kappa^2\int_{-b}^{b}\int_{\omega}\theta^2\left|\tilde{z}\right|^2dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_{\omega}\theta^2\varphi^3|\tilde{w}|^2dxds\right).\end{aligned}\tag{3.19}$$

Next, we apply Theorem 2.2 with $m=d+1$, $x_{d+1}=s$, $(a^{ij})_{1\le i,j\le d+1}=\left(\begin{smallmatrix}\mathcal{M}&0\\0&1\end{smallmatrix}\right)$, u replaced by $\tilde{z}$, and the weight function θ as the above. In this case, for any fixed $b_1\in(0,b)$, by (2.8), recalling again (3.7) for the definition of ψ and (3.5) for the positive constant h, we conclude that there is a constant $\kappa_1\ge\kappa_0$ such that for any $\kappa\ge\kappa_1$, one can find a constant $\varsigma_1\ge\varsigma_0$ so that, for any $\varsigma\ge\varsigma_1$, the following estimates hold uniformly for $(x,s)\in(\Omega\times(-b,b))\setminus(\omega_0\times(-b_1,b_1))$:

$$\begin{aligned}\sum_{i,j=1}^{d+1}c^{ij}p_ip_j&\ge\varsigma\varphi\Big[\kappa^2(|\nabla\psi|^2+|\partial_s\psi|^2)+O(\kappa)\Big](|\nabla p|^2+|\partial_sp|^2)\\&\ge\frac{h^2}{2}\varsigma\kappa^2\varphi(|\nabla p|^2+|\partial_sp|^2),\end{aligned}\tag{3.20}$$

$$B=2\varsigma^3\kappa^4\varphi^3(|\nabla\psi|^2+|\partial_s\psi|^2)^2+\varsigma^3\varphi^3O(\kappa^3)+O_\kappa(\varsigma^2)\ge h^4\varsigma^3\kappa^4\varphi^3,$$

where $p = \theta\tilde{z}$. Using (3.20) and the second equation in (3.13), similar to the proof of (3.16), one obtains

(3.21)
$$\begin{aligned}
&\frac{1}{C}\left\{\varsigma\kappa^2\int_{-b}^{b}\int_\Omega \varphi(|\nabla p|^2+|\partial_s p|^2)dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_\Omega \varphi^3|p|^2dxds\right\}\\
&\leq \int_{-b}^{b}\int_\Omega \theta^2\left|\phi f+2\partial_s\phi\partial_s z+z\partial_s^2\phi-\tilde{z}-\tilde{w}\right|^2dxds\\
&\quad+\frac{\varsigma\kappa}{||\widehat{\psi}\,||_{L^\infty(\Omega)}}\int_{-b}^{b}\int_{\partial\Omega}\varphi\frac{\partial\widehat{\psi}}{\partial\nu}\left|\frac{\partial p}{\partial\nu_{\mathcal{M}}}\right|^2d(\partial\Omega)ds\\
&\quad+C\left\{\varsigma\kappa^2\int_{-b_1}^{b_1}\int_{\omega_0}\theta^2\varphi(|\nabla\tilde{z}|^2+|\partial_s\tilde{z}|^2)dxds+\varsigma^3\kappa^4\int_{-b_1}^{b_1}\int_{\omega_0}\theta^2\varphi^3|\tilde{z}|^2dxds\right\}.
\end{aligned}$$

By the second equation in (3.13), similar to (3.17), one has

(3.22)
$$\begin{aligned}
&\int_{-b_1}^{b_1}\int_{\omega_0}\theta^2\varphi(|\nabla\tilde{z}|^2+|\partial_s\tilde{z}|^2)dxds\\
&\leq C\left[\varsigma\kappa^2\int_{-b}^{b}\int_\omega\theta^2\varphi^2|\tilde{z}|^2dxds+\int_{-b}^{b}\int_\omega\theta^2\left|\phi f+2\partial_s\phi\partial_s z+z\partial_s^2\phi-\tilde{w}\right|^2dxds\right].
\end{aligned}$$

Now, similar to (3.19), from (3.21) and (3.22), it follows that

$$\begin{aligned}
&\varsigma\kappa^2\int_{-b}^{b}\int_\Omega\theta^2\varphi(|\nabla\tilde{z}|^2+|\partial_s\tilde{z}|^2)dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_\Omega\theta^2\varphi^3|\tilde{z}|^2dxds\\
&\leq C\Bigg\{\varsigma\kappa^2\int_{-b}^{b}\int_\Omega\theta^2\left|\phi f+2\partial_s\phi\partial_s z+z\partial_s^2\phi\right|^2dxds+\int_{-b}^{b}\int_\Omega\theta^2\left|\tilde{w}\right|^2dxds\\
&\quad+\varsigma\kappa^2\int_{-b}^{b}\int_\omega\theta^2\left|\tilde{w}\right|^2dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_\omega\theta^2\varphi^3|\tilde{z}|^2dxds\Bigg\}.
\end{aligned}\tag{3.23}$$

Combining (3.19) and (3.23), we find that for any ς and κ large enough,

$$\begin{aligned}
&\int_{-b}^{b}\int_\Omega\theta^2\varphi(|\nabla\tilde{z}|^2+|\partial_s\tilde{z}|^2)dxds+\varsigma^2\kappa^2\int_{-b}^{b}\int_\Omega\theta^2\varphi^3|\tilde{z}|^2dxds\\
&\quad+\varsigma^3\kappa^4\int_{-b}^{b}\int_\Omega\theta^2\varphi|\nabla\tilde{w}|^2dxds+\varsigma^5\kappa^6\int_{-b}^{b}\int_\Omega\theta^2\varphi^3|\tilde{w}|^2dxds\\
&\leq C\Bigg(\int_{-b}^{b}\int_\Omega\theta^2\left|\phi f+2\partial_s\phi\partial_s z+z\partial_s^2\phi\right|^2dxds+\varsigma^3\kappa^4\int_{-b}^{b}\int_\omega\theta^2\left|\tilde{z}\right|^2dxds\\
&\quad+\varsigma^5\kappa^6\int_{-b}^{b}\int_\omega\theta^2\varphi^3|\tilde{w}|^2dxds\Bigg).
\end{aligned}\tag{3.24}$$

Recall that $\tilde{z} = \Delta\tilde{w} - \tilde{w}$. Therefore, (3.24) leads to

$$\begin{aligned} & \varsigma^2\kappa^2 \int_{-b}^{b}\int_{\Omega} \theta^2\varphi^3|\Delta\tilde{w}|^2 dxds \\ & \leq C\Bigg[\int_{-b}^{b}\int_{\Omega} \theta^2(|f|^2 + \left|2\partial_s\phi\partial_s z + z\partial_s^2\phi\right|^2) dxds \\ & \qquad + \varsigma^3\kappa^4 \int_{-b}^{b}\int_{\omega} \theta^2\varphi^3|\Delta\tilde{w}|^2 dxds + \varsigma^5\kappa^6 \int_{-b}^{b}\int_{\omega} \theta^2\varphi^3|\tilde{w}|^2 dxds \Bigg]. \end{aligned} \tag{3.25}$$

Step 4. *Completion of the proof.* Denote $c_0 = 2 + e^{\kappa} > 1$, and recall (3.6) for $b_0 \in (1, b)$. Fixing the parameter κ in (3.25), by (3.9), using (3.8) and (3.11), one finds

$$\begin{aligned} & \varsigma^2 e^{2\varsigma c_0} \int_{-1}^{1}\int_{\Omega} |\Delta w|^2\, dxds \\ & \leq Ce^{C\varsigma}\left[\int_{-b}^{b}\int_{\Omega} |f|^2 dxds + \int_{-b}^{b}\int_{\omega} (|w|^2 + |\Delta w|^2) dxds \right] \\ & \quad + Ce^{2\varsigma(c_0-1)} \int_{(-b,-b_0)\cup(b_0,b)} \int_{\Omega} \left|2\partial_s\phi\partial_s(\Delta w - w) + (\Delta w - w)\partial_s^2\phi\right|^2 dxds. \end{aligned} \tag{3.26}$$

From (3.26), one concludes that there exists $\varepsilon_0 > 0$ such that the desired inequality (3.2) holds for $\varepsilon \in (0, \varepsilon_0]$, which, in turn, implies that it holds for any $\varepsilon > 0$. This completes the proof of Theorem 3.1. □

4. Quantitative unique continuation for Kirchhoff plate. This section shows the following quantitative unique continuation for solutions of (1.1).

Theorem 4.1. *Suppose that* Ω *is connected. Then, for any nonempty open subset* ω *of* Ω *and any* $\beta \in (0,1)$, *there exists a time* $T > 0$ *such that the solution* u *of* (1.1) *satisfies*

$$\|(u_0,u_1)\|_{H^2(\Omega)\times H^1(\Omega)}^2 \leq e^{C\left[\frac{\|(u_0,u_1)\|_{\mathcal{H}}}{\|(u_0,u_1)\|_{H^2(\Omega)\times H^1(\Omega)}}\right]^{1/\beta}} \int_0^T \int_{\omega} |u\,(x,t)|^2\, dxdt \qquad \forall\ (u_0,u_1) \in \mathcal{H}\setminus\{0\}. \tag{4.1}$$

Remark 4.1. *Estimate* (4.1) *is equivalent to*

$$\|(u_0,u_1)\|_{H^2(\Omega)\times H^1(\Omega)}^2 \leq \frac{C}{\ln^{2\beta}\left(1 + \frac{\|(u_0,u_1)\|_{\mathcal{H}}^2}{\|u\|_{L^2(\omega\times(0,T))}^2}\right)} \|(u_0,u_1)\|_{\mathcal{H}}^2 \tag{4.2}$$

or, equivalently,

$$\|(u_0,u_1)\|_{H^2(\Omega)\times H^1(\Omega)}^2 \leq Ce^{C/\mu} \int_0^T\int_{\omega} |u\,(x,t)|^2\, dxdt + \mu^{2\beta}\, \|(u_0,u_1)\|_{\mathcal{H}}^2 \quad \forall\, \mu > 0. \tag{4.3}$$

This kind of interpolation estimate or logarithmic dependence continuous inequality has already appeared in [14, 20] in the framework of boundary control and stabilization for hyperbolic equations.

In order to prove Theorem 4.1, we need the following known result from [14, p. 473].

PROPOSITION 4.2. *For any $N \in \mathbb{N}$, the function*

$$F(z) \triangleq \frac{1}{2\pi} \int_{\mathbb{R}} e^{iz\tau} e^{-\tau^{2N}} d\tau \tag{4.4}$$

is holomorphic in $\mathbb{C}$ and there exist four positive constants A, c_0, c_1, and c_2 such that

$$\begin{cases} |F(z)| \leq A e^{c_0 |\operatorname{Im} z|^{\alpha}}, \\ |\operatorname{Im} z| \leq c_2 |\operatorname{Re} z| \Longrightarrow |F(z)| \leq A e^{-c_1 |z|^{\alpha}}, \end{cases}$$

where $\alpha = \frac{2N}{2N-1}$.

Proof of Theorem 4.1. Fix any nonempty open subset ω_1 of ω such that $\overline{\omega_1} \subset \omega$. We claim that it suffices to show that

$$\begin{aligned} \|(u_0, u_1)\|^2_{H^2(\Omega)\times H^1(\Omega)} &\leq C e^{C/\mu} \int_0^T \int_{\omega_1} \left[|u(x,t)|^2 + |\Delta u(x,t)|^2 \right] dxdt \\ &\quad + \mu^{2\beta} \|(u_0, u_1)\|^2_{\mathcal{H}} \qquad \forall \mu > 0. \end{aligned} \tag{4.5}$$

To see this, we choose a cut-off function $\varrho \in C_0^{\infty}(\omega)$ such that $\varrho = 1$ in ω_1 and $0 \leq \varrho \leq 1$ in ω. Then, for any $\mu > 0$,

$$\begin{aligned} &\int_0^T \int_{\omega_1} \left[|u(x,t)|^2 + |\Delta u(x,t)|^2 \right] dxdt \leq \int_0^T \|\varrho u(\cdot,t)\|^2_{H^2(\mathbb{R}^d)} dt \\ &\leq C \left[\frac{1}{\mu^2} \int_0^T \|\varrho u(\cdot,t)\|^2_{L^2(\mathbb{R}^d)} dt + \mu \int_0^T \|\varrho u(\cdot,t)\|^2_{H^3(\mathbb{R}^d)} dt \right] \\ &\leq C \left[\frac{1}{\mu^2} \int_0^T \int_{\omega} |u(x,t)|^2 dxdt + \mu \|(u_0, u_1)\|^2_{\mathcal{H}} \right]. \end{aligned} \tag{4.6}$$

Combining (4.5) and (4.6), we arrive at (4.3). By Remark 4.1, this yields the desired inequality (4.1).

We now prove (4.5) and divide the proof into three steps.

Step 1. *Reducing the problem to a fourth order elliptic-like equation.* Let $\beta \in (0,1)$, and choose $N \in \mathbb{N}$ such that $0 < \beta + \frac{1}{2N} < 1$. Let $\gamma = \frac{1}{\alpha} = 1 - \frac{1}{2N} > \beta$. Recall the definition of $F(z)$ in (4.4) and the constant $C_0 > 0$ in Theorem 3.1 (with ω replaced by ω_1). By Proposition 4.2, for any $\lambda \geq 1$, the holomorphic function

$$F_{\lambda}(z) \triangleq \lambda^{\gamma} F(\lambda^{\gamma} z) \equiv \frac{1}{2\pi} \int_{\mathbb{R}} e^{iz\tau} e^{-\left(\frac{\tau}{\lambda^{\gamma}}\right)^{2N}} d\tau \tag{4.7}$$

satisfies

$$\begin{cases} |\operatorname{Im} z| \leq 2 \Longrightarrow |F_{\lambda}(z)| \leq A \lambda^{\gamma} e^{2^{\alpha} c_0 \lambda}, \\ |\operatorname{Im} z| \leq 2 \text{ and } \frac{2}{c_2} \leq |\operatorname{Re} z| \Longrightarrow |F_{\lambda}(z)| \leq A \lambda^{\gamma} e^{-c_1 \lambda |\operatorname{Re} z|^{\alpha}}. \end{cases} \tag{4.8}$$

In what follows, we fix a time T satisfying

$$T > 8 \max\left(2, \frac{2}{c_2}, \sqrt[\alpha]{\frac{1 + 2^{\alpha} c_0 C_0}{c_1}} \right). \tag{4.9}$$

For any $\Phi = \Phi(t) \in C_0^\infty(0,T) \subset C_0^\infty(\mathbb{R})$ and any solution u of (1.1), following [14], we introduce the following *Fourier–Bros–Iagolnitzer transformation* of u:

$$W_{\ell_0,\lambda}(x,s) = \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell)\Phi(\ell)u(x,\ell)d\ell, \qquad s, \ell_0 \in \mathbb{R}. \tag{4.10}$$

Clearly, $\partial_s^2 F_\lambda(\ell_0 + is - \ell) = -\partial_\ell^2 F_\lambda(\ell_0 + is - \ell)$. Hence

$$\begin{aligned}
&\partial_s^2 (I-\Delta) W_{\ell_0,\lambda}(x,s)\\
&= -\int_{\mathbb{R}} \partial_\ell^2 F_\lambda(\ell_0 + is - \ell)\Phi(\ell)(I-\Delta)u(x,\ell)d\ell\\
&= -\int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell)\left[\Phi''(\ell)(I-\Delta)u(x,\ell) + 2\Phi'(\ell)\partial_t (I-\Delta)u(x,\ell)\right]d\ell\\
&\quad -\int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell)\Phi(\ell)\partial_t^2 (I-\Delta)u(x,\ell)d\ell.
\end{aligned} \tag{4.11}$$

Since u is a solution of (1.1), it follows from (4.11) that $W_{\ell_0,\lambda}$ satisfies the following fourth order elliptic-like equation with multiple characteristics:

$$\begin{cases}
-\partial_s^2 W_{\ell_0,\lambda}(x,s) + \Delta^2 W_{\ell_0,\lambda}(x,s) + \partial_s^2 \Delta W_{\ell_0,\lambda}(x,s)\\
\quad = \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell)\left[\Phi''(\ell)(I-\Delta)u(x,\ell) + 2\Phi'(\ell)\partial_t (I-\Delta)u(x,\ell)\right]d\ell,\\
\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (x,s) \in \Omega \times \mathbb{R},\\
W_{\ell_0,\lambda}(x,s) = \Delta W_{\ell_0,\lambda}(x,s) = 0, \qquad (x,s) \in \partial\Omega \times \mathbb{R},\\
W_{\ell_0,\lambda}(x,0) = (F_\lambda * \Phi u(x,\cdot))(\ell_0), \qquad x \in \Omega.
\end{cases} \tag{4.12}$$

On the other hand, we have

$$\begin{aligned}
&\|\Phi\Delta u(x,\cdot)\|_{L^2\left(\frac{T}{2}-1,\frac{T}{2}+1\right)}\\
&\le \|\Phi\Delta u(x,\cdot) - F_\lambda * \Phi\Delta u(x,\cdot)\|_{L^2\left(\frac{T}{2}-1,\frac{T}{2}+1\right)} + \|F_\lambda * \Phi\Delta u(x,\cdot)\|_{L^2\left(\frac{T}{2}-1,\frac{T}{2}+1\right)}\\
&\le \|\Phi\Delta u(x,\cdot) - F_\lambda * \Phi\Delta u(x,\cdot)\|_{L^2(\mathbb{R})} + \left(\int_{T/2-1}^{T/2+1} |\Delta W_{t,\lambda}(x,0)|^2 dt\right)^{1/2}.
\end{aligned}$$

Denote by $\mathcal{F}(f)$ the Fourier transform of f. Therefore, using Parseval's equality and the fact that $\mathcal{F}(F_\lambda)(\tau) = e^{-\left(\frac{\tau}{\lambda^\gamma}\right)^{2N}}$, one finds

$$\begin{aligned}
&\|\Phi\Delta u(x,\cdot) - F_\lambda * \Phi\Delta u(x,\cdot)\|_{L^2(\mathbb{R})} = \frac{1}{\sqrt{2\pi}}\left\|\mathcal{F}\Big(\Phi\Delta u(x,\cdot) - F_\lambda * \Phi\Delta u(x,\cdot)\Big)\right\|_{L^2(\mathbb{R})}\\
&= \frac{1}{\sqrt{2\pi}}\left(\int_{\mathbb{R}}\left|\left(1 - e^{-\left(\frac{\tau}{\lambda^\gamma}\right)^{2N}}\right)\mathcal{F}\Big(\Phi\Delta u(x,\cdot)\Big)(\tau)\right|^2 d\tau\right)^{1/2}\\
&\le C\left(\int_{\mathbb{R}}\left|\frac{\tau}{\lambda^\gamma}\mathcal{F}\Big(\Phi\Delta u(x,\cdot)\Big)(\tau)\right|^2 d\tau\right)^{1/2} \le \frac{C}{\lambda^\gamma}\|\partial_t(\Phi\Delta u(x,\cdot))\|_{L^2(\mathbb{R})}.
\end{aligned}$$

Hence,

$$\begin{aligned}&\int_{T/2-1}^{T/2+1} |\Phi(t)\Delta u(x,t)|^2\,dt \\ &\le C\left[\frac{1}{\lambda^{2\gamma}}\left\|\partial_t\left(\Phi\Delta u(x,\cdot)\right)\right\|_{L^2(\mathbb{R})}^2 + \int_{T/2-1}^{T/2+1}|\Delta W_{t,\lambda}(x,0)|^2\,dt\right].\end{aligned} \tag{4.13}$$

For any $t\in\left(\frac{T}{2}-1,\frac{T}{2}+1\right)\subset\mathbb{R}$, by Cauchy's integral theorem (in the theory of complex variable functions) and Hölder's inequality, we deduce that

$$\begin{aligned}|\Delta W_{t,\lambda}(x,0)| &\le \frac{1}{\pi}\int_{|\ell_0-t|\le 1}\int_{|s|\le 1}|\Delta W_{\ell_0,\lambda}(x,s)|\,dsd\ell_0 \\ &\le \frac{2}{\pi}\left(\int_{|\ell_0-t|\le 1}\int_{|s|\le 1}|\Delta W_{\ell_0,\lambda}(x,s)|^2\,dsd\ell_0\right)^{1/2}.\end{aligned}$$

Hence

$$\begin{aligned}\int_{T/2-1}^{T/2+1}|\Delta W_{t,\lambda}(x,0)|^2\,dt &\le \frac{4}{\pi^2}\int_{T/2-1}^{T/2+1}dt\int_{|\ell_0-t|\le 1}\int_{|s|\le 1}|\Delta W_{\ell_0,\lambda}(x,s)|^2\,dsd\ell_0 \\ &\le \frac{4}{\pi^2}\int_{T/2-1}^{T/2+1}dt\int_{T/2-2}^{T/2+2}d\ell_0\int_{|s|\le 1}|\Delta W_{\ell_0,\lambda}(x,s)|^2\,ds \\ &\le \frac{8}{\pi^2}\int_{T/2-2}^{T/2+2}d\ell_0\int_{|s|\le 1}|\Delta W_{\ell_0,\lambda}(x,s)|^2\,ds.\end{aligned} \tag{4.14}$$

Noticing that

$$\int_\Omega \left\|\partial_t\left(\Phi\Delta u(x,\cdot)\right)\right\|_{L^2(\mathbb{R})}^2 dx \le C\left\|(u_0,u_1)\right\|_{\mathcal{H}}^2,$$

combining (4.13) and (4.14), we get

$$\begin{aligned}&\int_{T/2-1}^{T/2+1}\int_\Omega |\Phi(t)\Delta u(x,t)|^2\,dxdt \\ &\le C\left[\frac{1}{\lambda^{2\gamma}}\left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 + \int_{T/2-2}^{T/2+2}d\ell_0\int_{|s|\le 1}\int_\Omega|\Delta W_{\ell_0,\lambda}(x,s)|^2\,dxds\right].\end{aligned} \tag{4.15}$$

Step 2. *The estimate on* $\int_{T/2-2}^{T/2+2}d\ell_0\int_{|s|\le 1}\int_\Omega|\Delta W_{\ell_0,\lambda}(x,s)|^2\,dxds$. We now fix any $\Phi=\Phi(t)\in C_0^\infty(0,T)$ satisfying $0\le\Phi\le 1$ in $(0,T)$ and $\Phi\equiv 1$ on $\left[\frac{T}{4},\frac{3T}{4}\right]$.

Applying Theorem 3.1 (with ω replaced by ω_1) to $W_{\ell_0,\lambda}$, we obtain that for all $\varepsilon>0$,

$$\begin{aligned}&\int_{|s|\le 1}\int_\Omega|\Delta W_{\ell_0,\lambda}(x,s)|^2\,dxds \\ &\le e^{-2/\varepsilon}\int_{|s|\le 2}\int_\Omega\left[|\Delta W_{\ell_0,\lambda}(x,s)|^2+|\partial_s\Delta W_{\ell_0,\lambda}(x,s)|^2\right]dxds \\ &+\ C_0e^{C_0/\varepsilon}\int_{|s|\le 2}\int_{\omega_1}\left[|W_{\ell_0,\lambda}(x,s)|^2+|\Delta W_{\ell_0,\lambda}(x,s)|^2\right]dxds\end{aligned} \tag{4.16}$$

$$+ C_0 e^{C_0/\varepsilon} \int_{|s|\leq 2} \int_\Omega \Big| \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell) \Big[\Phi''(\ell) \left(I - \Delta\right) u(x,\ell) + 2\Phi'(\ell) \partial_t \left(I-\Delta\right) u(x,\ell) \Big] d\ell \Big|^2 dxds.$$

Using the first conclusion in (4.8), we deduce that

$$\begin{aligned}
&\int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 2} \int_\Omega \left[\left|\Delta W_{\ell_0,\lambda}(x,s)\right|^2 + \left|\partial_s \Delta W_{\ell_0,\lambda}(x,s)\right|^2 \right] dxds \\
&= \int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 2} \int_\Omega \left[\left| \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell) \Phi(\ell) \Delta u(x,\ell) d\ell \right|^2 \right. \\
&\qquad \left. + \left| \partial_s \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell) \Phi(\ell) \Delta u(x,\ell) d\ell \right|^2 \right] dxds \\
&\leq \int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 2} \int_\Omega \left[\left| \int_0^T \left(A\lambda^\gamma e^{2^\alpha c_0 \lambda} \right) \left|\Delta u(x,\ell)\right| d\ell \right|^2 \right. \\
&\qquad \left. + \left| \int_0^T \left(A\lambda^\gamma e^{2^\alpha c_0 \lambda} \right) \left|\Delta \partial_\ell u(x,\ell) + \Phi'(\ell) \Delta u(x,\ell)\right| d\ell \right|^2 \right] dxds \\
&\leq C\lambda^{2\gamma} e^{2^{\alpha+1} c_0 \lambda} \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 .
\end{aligned} \tag{4.17}$$

Similarly,

$$\begin{aligned}
&\int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 2} \int_{\omega_1} \left[\left|W_{\ell_0,\lambda}(x,s)\right|^2 + \left|\Delta W_{\ell_0,\lambda}(x,s)\right|^2 \right] dxds \\
&\leq C\lambda^{2\gamma} e^{2^{\alpha+1} c_0 \lambda} \int_0^T \int_{\omega_1} \left[\left|u(x,t)\right|^2 + \left|\Delta u(x,t)\right|^2 \right] dxdt.
\end{aligned} \tag{4.18}$$

Further, by the choice of Φ, it is obvious that

$$\operatorname{supp}\left(\partial_t^2 \Phi\right) \subset \operatorname{supp}\left(\partial_t \Phi\right) \subset K \triangleq \left[0, \frac{T}{4}\right] \bigcup \left[\frac{3T}{4}, T\right].$$

Let $K_0 = \left[\frac{3T}{8}, \frac{5T}{8}\right]$. Then dist $(K, K_0) = \frac{T}{8}$. The choice of T in (4.9) implies $T > 16$ and $T > 16/c_2$. Hence, $\left(\frac{T}{2} - 2, \frac{T}{2} + 2\right) \subset K_0$, and

$$|\ell_0 - \ell| \geq \frac{T}{8} \geq \frac{2}{c_2} \qquad \forall\ (\ell_0, \ell) \in K_0 \times K.$$

Therefore, using the second conclusion in (4.8), we deduce that

$$\begin{aligned}
&\int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 2} \int_\Omega \left| \int_{\mathbb{R}} F_\lambda(\ell_0 + is - \ell) \Big[\Phi''(\ell) \left(I-\Delta\right) u(x,\ell) \right. \\
&\qquad \left. +2\Phi'(\ell) \partial_t \left(I-\Delta\right) u(x,\ell) \Big] d\ell \right|^2 dxds \\
&\leq C \int_{K_0} d\ell_0 \int_{|s|\leq 2} \int_\Omega \left| \int_K \left(A\lambda^\gamma e^{-c_1 \lambda |\ell_0 - \ell|^\alpha} \right) \Big(\left|\left(I-\Delta\right) u(x,\ell)\right| \right.
\end{aligned} \tag{4.19}$$

$$+ \left|\partial_t \left(I-\Delta\right) u(x,\ell)\right|\Big) d\ell\Big|^2 dxds$$

$$\leq C \left|A\lambda^{\gamma} e^{-c_1\lambda(\mathrm{dist}(K,K_0))^{\alpha}}\right|^2 \int_\Omega \left|\int_K [\left|\left(I-\Delta\right) u(x,\ell)\right| + \left|\partial_t \left(I-\Delta\right) u(x,\ell)\right|] \, d\ell\right|^2 dx$$

$$\leq C\lambda^{2\gamma} e^{-2c_1\lambda\left(\frac{T}{8}\right)^{\alpha}} \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 .$$

Combining (4.17)–(4.19), we arrive at

$$\begin{aligned}&\int_{T/2-2}^{T/2+2} d\ell_0 \int_{|s|\leq 1} \int_\Omega \left|\Delta W_{\ell_0,\lambda}(x,s)\right|^2 dxds \\ &\leq C\lambda^{2\gamma} \Bigg\{ e^{2^{\alpha+1}c_0\lambda} e^{-2/\varepsilon} \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 + e^{-2c_1\lambda\left(\frac{T}{8}\right)^{\alpha}} e^{C_0/\varepsilon} \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 \\ &\qquad + e^{2^{\alpha+1}c_0\lambda} e^{C_0/\varepsilon} \int_0^T \int_{\omega_1} \left[\left|u(x,t)\right|^2 + \left|\Delta u(x,t)\right|^2\right] dxdt \Bigg\}.\end{aligned} \tag{4.20}$$

Step 3. *Choice of* ε *and completion of the proof.* We deduce from (4.15) and (4.20) that

$$\begin{aligned}&\int_{T/2-1}^{T/2+1} \int_\Omega \left|\Phi(t)\Delta u(x,t)\right|^2 dxdt \\ &\leq C \Bigg\{ \left[\frac{1}{\lambda^{2\gamma}} + \lambda^{2\gamma} e^{2^{\alpha+1}c_0\lambda} e^{-2/\varepsilon} + \lambda^{2\gamma} e^{-2c_1\lambda\left(\frac{T}{8}\right)^{\alpha}} e^{C_0/\varepsilon}\right] \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 \\ &\qquad + \lambda^{2\gamma} e^{2^{\alpha+1}c_0\lambda} e^{C_0/\varepsilon} \int_0^T \int_{\omega_1} \left[\left|u(x,t)\right|^2 + \left|\Delta u(x,t)\right|^2\right] dxdt \Bigg\}.\end{aligned} \tag{4.21}$$

We now choose

$$\varepsilon = \frac{1}{2^{\alpha+1}c_0\lambda}. \tag{4.22}$$

Recall the choice of T in (4.9), which gives $-c_1\left(\frac{T}{8}\right)^{\alpha} + 2^{\alpha}c_0C_0 \leq -1$. Hence

$$e^{-2c_1\lambda\left(\frac{T}{8}\right)^{\alpha}} e^{C_0/\varepsilon} = \exp\left\{2\left[-c_1\left(\frac{T}{8}\right)^{\alpha} + 2^{\alpha}c_0C_0\right]\lambda\right\} \leq e^{-2\lambda}. \tag{4.23}$$

Combining (4.21)–(4.23), we deduce that, for all $\lambda \geq 1$,

$$\begin{aligned}&\int_{T/2-1}^{T/2+1} \int_\Omega \left|\Delta u(x,t)\right|^2 dxdt = \int_{T/2-1}^{T/2+1} \int_\Omega \left|\Phi(t)\Delta u(x,t)\right|^2 dxdt \\ &\leq \frac{C}{\lambda^{2\gamma}} \left\|(u_0,u_1)\right\|_{\mathcal{H}}^2 + Ce^{C\lambda} \int_0^T \int_{\omega_1} \left[\left|u(x,t)\right|^2 + \left|\Delta u(x,t)\right|^2\right] dxdt.\end{aligned} \tag{4.24}$$

Finally, by means of the energy method, it is easy to show that

$$\left\|(u_0,u_1)\right\|_{H^2(\Omega)\times H^1(\Omega)}^2 \leq C \int_{T/2-1}^{T/2+1} \int_\Omega \left|\Delta u(x,t)\right|^2 dxdt. \tag{4.25}$$

Combining (4.24) and (4.25), it is easy to conclude that, for any $\mu \in (0,1)$,

$$\begin{aligned} &\|(u_0,u_1)\|^2_{H^2(\Omega)\times H^1(\Omega)} \\ &\leq Ce^{C/\mu}\int_0^T\int_{\omega_1}\left[|u(x,t)|^2+|\Delta u(x,t)|^2\right]dxdt + C\mu^{2\beta}\|(u_0,u_1)\|^2_{\mathcal{H}}. \end{aligned} \tag{4.26}$$

Note that this inequality is trivially true for any $\mu \geq 1$ and for some $C > 1$. Consequently, inequality (4.5) holds true for all $\mu > 0$. This completes the proof of Theorem 4.1. □

5. Observability estimates for Kirchhoff plate. The purpose of this section is to establish two observability estimates which quantify the unique continuation property of (1.1) saying that if its solution u satisfies $\partial_t\Delta u = 0$ in $\omega \times (0,T)$, then $(u_0,u_1) = 0$. Due to the finite speed of propagation, the time $T > 0$ has to be chosen large enough.

First, when GCC is assumed, we have the following estimate.

THEOREM 5.1. *Under GCC, for any $T \geq T_0$, the solution u of* (1.1) *satisfies*

$$E(u,0) \leq C\int_0^T\int_\omega |\partial_t\Delta u(x,t)|^2\,dxdt \qquad \forall\,(u_0,u_1)\in\mathcal{H}. \tag{5.1}$$

Proof. Under GCC, it follows from [2, 3] that for any $g \in L^2(\Omega\times(0,T_0))$ and any $(\chi_0,\chi_1)\in H_0^1(\Omega)\times L^2(\Omega)$, the solution χ of the wave equation

$$\begin{cases} \partial_t^2\chi - \Delta\chi = g & \text{in } \Omega\times(0,T_0), \\ \chi = 0 & \text{on } \partial\Omega\times(0,T_0), \\ \chi(\cdot,0)=\chi_0, \quad \partial_t\chi(\cdot,0)=\chi_1 & \text{in } \Omega \end{cases} \tag{5.2}$$

satisfies the following observability estimate:

$$\|(\chi_0,\chi_1)\|^2_{H_0^1(\Omega)\times L^2(\Omega)} \leq C\left[\int_0^{T_0}\int_\omega|\partial_t\chi(x,t)|^2\,dxdt + \int_0^{T_0}\int_\Omega|g(x,t)|^2\,dxdt\right]. \tag{5.3}$$

Note that the solution u of (1.1) solves

$$\begin{cases} \partial_t^2(I-\Delta)u - \Delta(I-\Delta)u = -\Delta u & \text{in } \Omega\times\mathbb{R}, \\ (I-\Delta)u = 0 & \text{on } \partial\Omega\times\mathbb{R}, \\ (I-\Delta)u(\cdot,0) = (I-\Delta)u_0, \quad \partial_t(I-\Delta)u(\cdot,0) = (I-\Delta)u_1 & \text{in } \Omega. \end{cases} \tag{5.4}$$

Applying estimate (5.3) to system (5.4) (with $\chi = (I-\Delta)u$ and $g = -\Delta u$), we conclude that

$$\begin{aligned} E(u,0) &\leq C\left[\int_0^{T_0}\int_\omega|\partial_t(I-\Delta)u(x,t)|^2\,dxdt + \int_0^{T_0}\int_\Omega|\Delta u(x,t)|^2\,dxdt\right] \\ &\leq C\left[\int_0^{T_0}\int_\omega|\partial_t\Delta u(x,t)|^2\,dxdt + \|(u_0,u_1)\|^2_{H^2(\Omega)\times H^1(\Omega)}\right]. \end{aligned} \tag{5.5}$$

However, by (5.5) and using the classical uniqueness-compactness argument (e.g., [15]), it follows that

$$\|(u_0,u_1)\|^2_{H^2(\Omega)\times H^1(\Omega)} \leq C\int_0^{T_0}\int_\omega |\partial_t \Delta u\,(x,t)|^2\, dxdt. \tag{5.6}$$

Therefore, combining (5.5) and (5.6), we deduce the desired estimate (5.1). This completes the proof of Theorem 5.1. □

Next, when GCC is not assumed, we have the following weaker estimate.

THEOREM 5.2. *Suppose that Ω is connected. Then, for any nonempty open subset ω of Ω, any $\beta \in (0,1)$, and the time $T > 0$ given in Theorem 4.1, the solution u of (1.1) satisfies*

$$\begin{aligned} E(u,0) \leq Ce^{C/\mu}\int_0^T\int_\omega |\partial_t u\,(x,t)|^2\, dxdt + \mu^{2\beta}\,\|(u_0,u_1)\|^2_{D(\mathcal{A})} \\ \forall\,(u_0,u_1)\in D(\mathcal{A})\setminus\{0\}, \quad \forall\,\mu>0, \end{aligned} \tag{5.7}$$

and

$$\begin{aligned} E(u,0) \leq Ce^{C/\mu}\int_0^T\int_\omega |\partial_t \Delta u\,(x,t)|^2\, dxdt + \mu^{2\beta}\,\|(u_0,u_1)\|^2_{D(\mathcal{A}^3)} \\ \forall\,(u_0,u_1)\in D(\mathcal{A}^3)\setminus\{0\}, \quad \forall\,\mu>0. \end{aligned} \tag{5.8}$$

Proof. By (4.3) in Remark 4.1, one sees that the solution u of system (1.1) satisfies

$$\int_0^T\int_\Omega |\Delta u\,(x,t)|^2\, dxdt \leq Ce^{C/\mu}\int_0^T\int_\omega |u\,(x,t)|^2\, dxdt + \mu^{2\beta}\,\|(u_0,u_1)\|^2_{\mathcal{H}} \quad \forall\,\mu>0, \tag{5.9}$$

and

$$\int_0^T\int_\Omega |u\,(x,t)|^2\, dxdt \leq Ce^{C/\mu}\int_0^T\int_\omega |u\,(x,t)|^2\, dxdt + \mu^{2\beta}\,\|(u_0,u_1)\|^2_{\mathcal{H}} \quad \forall\,\mu>0. \tag{5.10}$$

It remains to apply (5.9) (resp., (5.10)) with u replaced by $\partial_t u$ (resp., $\partial_t\Delta u$) to get the desired estimate (5.7) (resp., (5.8)) by using the following inequality:

$$E\,(u,0) \leq C\int_0^T\int_\Omega |\partial_t \Delta u\,(x,t)|^2\, dxdt,$$

which, in turn, follows from the usual energy method. □

6. Proof of Theorems 1.1 and 1.2. We begin with the proof of Theorem 1.2. Recall that the functions $v^{(j)}$ and $U^{(j)}$, defined, respectively, in (1.4) and (1.5), depend only on $\partial_t\Delta u\,(x,T-t)\cdot 1_{|\omega}$. Let

$$w^{(j)}(x,t) = \begin{cases} v^{(0)}(x,t) - u(x,T-t), & j=0, \\ v^{(j)}(x,t) - w^{(j-1)}(x,T-t), & j>0, \end{cases} \quad \text{for } (x,t)\in Q. \tag{6.1}$$

Clearly, $w^{(j)} = U^{(j)}$ in $\omega\times(0,T)$. Also, it is easy to check that $w^{(j)}$ solves

$$\begin{cases} \partial_t^2 w^{(j)} + \Delta^2 w^{(j)} - \partial_t^2\Delta w^{(j)} + \partial_t\Delta w^{(j)}\cdot 1_{|\omega} = 0 & \text{in } Q, \\ w^{(j)} = \Delta w^{(j)} = 0 & \text{on } \Sigma. \end{cases} \tag{6.2}$$

By (6.1) and the third equation in system (1.4), noticing the conservative law (1.3), we deduce that

$$\left\{\begin{array}{ll} E(w^{(j)},0)=E(w^{(j-1)},T), & j>0,\\ E(w^{(0)},0)=E(u,T)=E(u,0). & \end{array}\right. \tag{6.3}$$

First, applying the standard energy method to system (6.2), it follows that

$$E(w^{(j)},T)-E(w^{(j)},0)+\int_0^T\int_\omega\left|\partial_t\Delta w^{(j)}\,(x,t)\right|^2dxdt=0 \qquad \forall\, T>0. \tag{6.4}$$

By (5.8) in Theorem 5.2 and using a well-known perturbation argument (e.g., [16, section 5]), we conclude that the solution $w^{(j)}$ of (6.2) satisfies, for any $\mu>0$,

$$E(w^{(j)},0)\le Ce^{C/\mu}\int_0^T\int_\omega\left|\partial_t\Delta w^{(j)}(x,t)\right|^2dxdt+\mu^{2\beta}\left\|\left(w^{(j)}(\cdot,0),\ \partial_t w^{(j)}(\cdot,0)\right)\right\|^2_{D(\mathcal{A}^3)}. \tag{6.5}$$

Combining (6.4)–(6.5) and the first line in (6.3), it follows that, for any $\mu>0$,

$$E(w^{(j)},0)\le Ce^{C/\mu}\Big[E(w^{(j)},0)-E(w^{(j+1)},0)\Big]+\mu^{2\beta}\left\|\left(w^{(j)}(\cdot,0),\ \partial_t w^{(j)}(\cdot,0)\right)\right\|^2_{D(\mathcal{A}^3)}. \tag{6.6}$$

In view of the dissipation law for system (6.2), noticing again (6.1) and the third equation in system (1.4), one has

$$\left\|\left(w^{(2j+1)}(\cdot,T),\ \partial_t w^{(2j+1)}(\cdot,T)\right)\right\|_{D(\mathcal{A}^3)}\le C\left\|\left(w^{(2j)}(\cdot,T),\ \partial_t w^{(2j)}(\cdot,T)\right)\right\|_{D(\mathcal{A}^3)}. \tag{6.7}$$

Therefore, by (6.6)–(6.7) and denoting $M\overset{\triangle}{=}\sup_{j>0}\left\|\left(w^{(2j)}(\cdot,T),\ \partial_t w^{(2j)}(\cdot,T)\right)\right\|^2_{D(\mathcal{A}^3)}$, we conclude that

$$E(w^{(j)},0)\le Ce^{C/\mu}\Big[E(w^{(j)},0)-E(w^{(j+1)},0)\Big]+\mu^{2\beta}M \quad \forall\,\mu>0. \tag{6.8}$$

Now, by (6.8) and similar to Remark 4.1, one deduces that the solution $w^{(j)}$ of (6.2) satisfies

$$\frac{E\left(w^{(j)},0\right)}{M}\le C\ln^{-2\beta}\left(1+\frac{M}{E\left(w^{(j)},0\right)-E\left(w^{(j+1)},0\right)}\right). \tag{6.9}$$

Let

$$\alpha_n=\frac{E\left(w^{(n)},0\right)}{M}.$$

Then,

$$\alpha_{n+1}=\frac{E\left(w^{(n+1)},0\right)}{M}=\frac{E\left(w^{(n)},T\right)}{M}\le\alpha_n. \tag{6.10}$$

Combining (6.9) and (6.10), we obtain

$$\alpha_{n+1}\le C\ln^{-2\beta}\left(1+\frac{1}{\alpha_n-\alpha_{n+1}}\right) \qquad \forall\, n\in\mathbb{N}. \tag{6.11}$$

Similar to [14, 27], starting from (6.11), one deduces that

$$\alpha_{n+1} \leq C \ln^{-2\beta}(1+n) \qquad \forall\, n \in \mathbb{N}, \tag{6.12}$$

which gives

$$\frac{E\left(w^{(2N)}, T\right)}{M} \leq C \ln^{-2\beta}(1+2N). \tag{6.13}$$

Now it remains to compute $w^{(2N)}(\cdot, T)$. By induction, it is easy to verify that, for any $N \geq 1$,

$$w^{(2N)}(\cdot, t) = \sum_{k=1}^{N} \left[v^{(2k)}(\cdot, t) - v^{(2k-1)}(\cdot, T-t) \right] + v^{(0)}(\cdot, t) - u(\cdot, T-t).$$

Therefore,

$$w^{(2N)}(\cdot, T) = \sum_{k=0}^{N} v^{(2k)}(\cdot, T) - u_0, \quad \partial_t w^{(2N)}(\cdot, T) = \sum_{k=0}^{N} \partial_t v^{(2k)}(\cdot, T) + u_1. \tag{6.14}$$

Finally, by (6.13)–(6.14) and $J_3 < +\infty$, one arrives at the desired estimate (1.7).

Similarly, the proof of Theorem 1.1 follows from (6.3), (6.14), and Theorem 5.1. □

ELECTRICAL IMPEDANCE TOMOGRAPHY BY ELASTIC DEFORMATION*

H. AMMARI[†], E. BONNETIER[‡], Y. CAPDEBOSCQ[§], M. TANTER[†], AND M. FINK[†]

Abstract. This paper presents a new algorithm for conductivity imaging. Our idea is to extract more information about the conductivity distribution from data that have been enriched by coupling impedance electrical measurements to localized elastic perturbations. Using asymptotics of the fields in the presence of small volume inclusions, we relate the pointwise values of the energy density to the measured data through a nonlinear PDE. Our algorithm is based on this PDE and takes full advantage of the enriched data. We give numerical examples that illustrate the performance and the accuracy of our approach.

Key words. electrical impedance tomography, elastic perturbation, asymptotic formula, reconstruction, substitution algorithm, 0-Laplacian

1. Introduction.

The electrical impedance tomography (EIT) technique has been an active research topic since the early 1980s. In EIT, one measures the boundary voltages due to multiple injection currents to reconstruct images of the conductivity distribution. This problem is known to be ill-posed [1] due to the fact that boundary voltages are not very sensitive to local changes of the conductivity distribution.

Medical imaging has been one of the important application areas of EIT. Indeed, biological tissues have different electrical properties that change with cell concentration, cellular structure, and molecular composition. Such changes of electrical properties are the manifestations of structural, functional, metabolic, and pathological conditions of tissues and thus provide valuable diagnostic information.

For practitioners, the practicality of EIT is of great interest: It is a low cost and portable technology which can be used for real time monitoring. However, it suffers from poor spatial resolution and accuracy, a well-known feature of inverse problems. This motivated us to look for a new way of incorporating more information in EIT data, without altering the cost and portability of the data acquisition, which would yet improve the resolution of the reconstructed images.

The classical image reconstruction algorithms view EIT as an optimization problem. An initial conductivity distribution is iteratively updated so as to minimize the difference between measured and computed boundary voltages. This kind of method was first introduced in EIT by Yorkey, Webster, and Tompkins [43]. Numerous variations and improvements followed, which include utilization of a priori information,

and various forms of regularization [42, 19]. This approach is quite greedy in computational time yet produces images with poor accuracy and spatial resolution.

In the 1980s, Barber and Brown [14] introduced a back-projection algorithm that was the first fast and efficient algorithm for EIT, although it provides images with very low resolution. Since this algorithm is inspired from computed tomography, it can be viewed as a generalized Radon transform method [39].

A third technique is dynamical electrical impedance imaging, developed by the Rensselaer impedance tomography group [24] to produce images of changes in conductivity due to cardiac or respiratory functions. Its main idea consists in viewing the conductivity as the sum of a static term (the background conductivity of the human body) plus a perturbation (the change of conductivity caused by respiration or by heart beats). The mathematical problem here is to visualize the perturbation term by an EIT system. Although this algorithm provides accurate images if the initial guess of the background conductivity is good, its resolution does not completely satisfy practitioners especially when screening for breast cancer (see also [25]).

Recently, a commercial system called TransScan TS2000 (TransScan Medical, Ltd, Migdal Ha'Emek, Israel) was released for adjunctive clinical uses with X-ray mammography in the diagnosis of breast cancer. Interestingly, the TransScan system is similar to the frontal plane impedance camera that initiated EIT research early in 1978. The mathematical model of the TransScan can be viewed as a realistic or practical version of the general EIT system, so any theory developed for this model can be applied to other areas in EIT, especially to detection of anomalies. In the TransScan, a patient holds a metallic cylindrical reference electrode, through which a constant voltage of 1 to 2.5 V, with frequencies spanning 100 Hz–100 KHz, is applied. A scanning probe with a planar array of electrodes, kept at ground potential, is placed on the breast. The voltage difference between the hand and the probe induces a current flow through the breast, from which information about the impedance distribution in the breast can be extracted.

Using a simplified dipole method, Assenheimer et al. [13] and Scholz [40] gave a physical interpretation of the white spots in TransScan images.

More recently, taking advantage of the smallness of the anomalies to be detected, Ammari et al. [11] analyzed trans-admittance data for the detection of breast cancer using the TransScan system. Their model assumes that breast tissues can be considered homogeneous, at least near the surface, where the planar array of electrodes is attached, and that the lesion to be detected is located near the surface. In [11], the authors developed better ways of interpreting TransScan images which improve accuracy. They also derived a multifrequency approach to handle the case where the background conductivity is inhomogeneous and not known a priori.

This latter work relies on asymptotic expansions of the fields when the medium contains inclusions of small volume, a technique that has proven useful in many other contexts. Such asymptotics have been investigated in the case of the conduction equation [23, 22, 17, 6, 20, 18, 21], the operator of elasticity [5, 10], and the Helmholtz equation or the Maxwell system [44, 12, 9]. See the books [7, 8] and their lists of references. The remarkable feature of this technique is that it allows a stable and accurate reconstruction of the location and of the geometric features of the inclusions, even for moderately noisy data.

Since all the present EIT technologies are practically applicable only in feature extraction of anomalies, improving EIT calls for innovative measurement techniques that incorporate structural information. A very promising direction of research is the recent magnetic resonance imaging technique, called current density imaging, which measures the internal current density distribution. See the breakthrough work by Seo and his group [36, 37, 32]. However, this technique has a number of disadvantages, among which are the lack of portability and a potentially long imaging time. Moreover, it uses an expensive magnetic resonance imaging scanner.

The aim of this paper is to propose another mathematical direction for future EIT research in view of biomedical applications, without eliminating the most important merits of EIT (real time imaging, low cost, and portability). Our method is based on the simultaneous measurement of an electric current and of acoustic vibrations induced by ultrasound waves. Its intrinsic resolution depends on the size of the focal spot of the acoustic perturbation, and thus our method should provide high resolution images.

Let us now formulate our problem. We first recall that, in mathematical terms, EIT consists in recovering the conductivity map of a d dimensional body Ω, where d is the dimension of the ambient space, from measuring the voltage response to one or several currents applied on the boundary. In practice, a set of electrodes is attached to the body. One or several currents ϕ_i, $1 \leq i \leq I$, are applied to one or several electrodes, and the corresponding voltage potentials f_i, $1 \leq i \leq I$, are recorded on the others. Denoting by $\gamma(x)$ the unknown conductivity, the voltage potential u_i solves the conduction problem

$$(1.1) \qquad \left\{ \begin{aligned} \nabla_x \cdot (\gamma(x) \nabla_x u_i) &= 0 \quad \text{in } \Omega, \\ \gamma(x) \frac{\partial u_i}{\partial n} &= \phi_i \quad \text{on } \partial\Omega. \end{aligned} \right.$$

The problem of impedance tomography is the inverse problem of recovering the coefficients γ of the elliptic conduction PDE, knowing one or more current-to-voltage pairs $(\phi_i,\, f_i := u_i|_{\partial\Omega})$.

The core idea of our approach is to extract more information about the conductivity from data that has been enriched by coupling the electric measurements to localized elastic perturbations. More precisely, we propose to perturb the medium during the electric measurements by focusing ultrasonic waves on regions of small diameter inside the body. Using a simple model for the mechanical effects of the ultrasound waves, we show that the difference between the measurements in the unperturbed and perturbed configurations is asymptotically equal to the pointwise value of the energy density at the center of the perturbed zone. In practice, the ultrasounds impact a spherical or ellipsoidal zone of a few millimeters in diameter. The perturbation should thus be sensitive to conductivity variations at the millimeter scale, which is the precision required for breast cancer diagnosis.

By scanning the interior of the body with ultrasound waves, given an applied current ϕ_i, we obtain data from which we can compute $\mathcal{S}_i(x) := \gamma(x)|\nabla u_i(x)|^2$ in an interior subregion of Ω. The new inverse problem is now to reconstruct γ knowing $\mathcal{S}_i$ for $i = 1, \ldots, I$.

The goal of this work is threefold: First, we show that taking measurements while perturbing the medium with ultrasound waves is asymptotically equivalent to measuring $\mathcal{S}_i$. To this end, we consider the zone ω deformed by the ultrasound wave as a small volume perturbation of the background potential γ. We then relate the difference between the perturbed and unperturbed potentials on the boundary to the conductivity at the center of ω asymptotically as $|\omega| \to 0$. This is our main idea: the ultrasound waves create localized perturbations that allow us, using the method of asymptotic expansions of small volume inclusions, to probe *within* the medium.

Second, noting that the potential u_i satisfies the nonlinear PDE (the 0-Laplacian)

$$\left\{ \begin{aligned} \nabla_x \cdot \left(\frac{\mathcal{S}_i(x)}{|\nabla u_i|^2} \nabla u_i \right) &= 0 \quad \text{in } \Omega, \\ \frac{\mathcal{S}_i(x)}{|\nabla u_i|^2} \frac{\partial u_i}{\partial n} &= \phi_i \quad \text{on } \partial\Omega, \end{aligned} \right. \tag{1.2}$$

we propose a numerical method to compute solutions $\tilde{u}_i$ to (1.2) and then an approximate conductivity $\tilde{\gamma} = \mathcal{S}_i/|\nabla \tilde{u}_i|^2$, using two currents (i.e., $I = 2$). Recall that an appropriate choice of ϕ_i ensures that $\nabla u_i \neq 0$ for all $x \in \Omega$. See [2, 3, 41, 26].

Third, our algorithm, as the one originally developed in [33] for current density imaging, requires data measured with two boundary currents for which the flux densities (the gradient of the voltage potentials) are locally orthogonal (or try to be). We show numerically that this algorithm is able to capture details of the conductivity map up to the precision of the underlying finite element mesh and thus proves very effective.

The paper is organized as follows. In the next section, we describe the physical model and the collection of experimental data on the boundary. Section 3 explains how, given a current ϕ_i, the values of $\mathcal{S}_i(x)$ can be approximated using this data. In section 4, we describe the numerical method for reconstruction of γ using two applied currents. Numerical examples that illustrate the performance and the accuracy of this method are presented in that section. The paper ends with a short discussion.

2. Impedance tomography perturbed by ultrasound waves.

2.1. Description of the experiment. The goal of the experiment is to obtain an impedance map inside a solid with millimetric precision.

An object (a domain Ω) is electrically probed: one or several currents are imposed on the surface and the induced potentials are measured on the boundary (see Figure 1). At the same time, a spherical region of a few millimeters in the interior of Ω is mechanically excited by focused acoustic waves.

The measurements are made as the focus of the ultrasounds scans the entire domain. Several sets of measurements can be obtained by varying the ultrasound waves amplitudes and the applied currents. Several teams have been able to obtain ultrasonic waves focusing in very small regions deep inside the tissues [16, 31]. The support of the focal spot is better represented by an ellipsoid, but the locus of the most intense area can be, in a first approximation, represented by a sphere. The experiment is successful if, for each focal point, a difference in the boundary voltage potential can be measured between the potential corresponding to an unperturbed medium and the potential corresponding to the perturbed one.

2.2. Physical modeling of the effect of ultrasonic waves on the conductivity. We chose to model the effect of the pressure wave in the simplest way. For what follows, there are two crucial points. The first one is that the local conductivity is affected by the pressure wave. The second one is that, at least for acoustic waves of moderate amplitude, the conductivity perturbation depends continuously on the amplitude of the wave—and therefore, in a first approximation, linearly. The fact that acoustic waves affect the conductivity has been known for a long time [35]. In the context of biomedical imaging, the idea of exploiting this property dates from the early 1970s [27]. For focused waves, this is much more recent. In [30, 31] it is established experimentally for moderate and high intensity waves. The experiments show that only the *local* conductivity is affected.

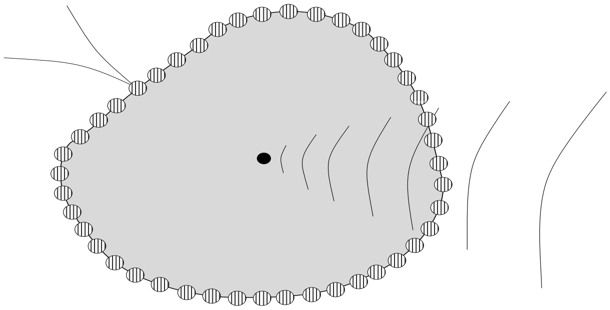

FIG. 1. *The experimental setup.*

Below is an attempt to justify these experimental findings. Within each (small) spherical volume, the conductivity is assumed to be constant per volume unit. At a point $x \in \Omega$, within a ball B of volume V_B, the electric conductivity γ is defined in terms of a density ρ as

$$\gamma(x) = \rho(x) V_B.$$

The ultrasonic waves induce a small elastic deformation of the sphere B. If this deformation is isotropic, the material points of B occupy a volume V_B^p in the perturbed configuration, which at first order is equal to

$$V_B^p = V_B \left(1 + 3\frac{\Delta r}{r}\right),$$

where r is the radius of the ball B and Δr is the variation of the radius due to the elastic perturbation. As Δr is proportional to the amplitude of the ultrasonic wave, we obtain a proportional change of the deformation. Using two different ultrasonic waves with different amplitudes but with the same focal spot, it is therefore easy to compute the ratio V_B^p/V_B for a given perturbation. We are merely pointing out that if $f(x) = a(1 + x * b)$, one can evaluate a and b in terms of $f(x_1)$, $f(x_2)$, x_1, and x_2. As a consequence, the perturbed electrical conductivity γ^p satisfies

$$\forall\, x \in \Omega, \quad \gamma^p(x) = \rho(x) V_B^p \;=\; \gamma(x)\nu(x), \tag{2.1}$$

where $\nu(x) = V_B^p/V_B$ is a known function.

2.3. Mathematical modeling of the effect of ultrasonic waves on the conductivity. We denote by u the voltage potential induced by a current ϕ, in the absence of ultrasonic perturbations. It is given by

$$\left\{ \begin{array}{r} \nabla_x \cdot (\gamma(x) \nabla_x u) = 0 \quad \text{in } \Omega, \\ \gamma(x) \frac{\partial u}{\partial n} = \phi \quad \text{on } \partial\Omega, \end{array} \right. \tag{2.2}$$

with the normalization condition $\int_{\partial\Omega} u = 0$. We assume that the conductivity γ is bounded above and below by positive constants

$$0 < c < \gamma(x) < C < +\infty \quad \text{a.e. } x \in \Omega.$$

Further, we suppose that the conductivity γ is known close to the boundary of the domain so that ultrasonic probing is limited to interior points x such that

$$\text{dist}(x, \partial\Omega) \geq d_0,$$

where d_0 is very large compared to the radius of the focal spot of the ultrasonic perturbation. We denote the corresponding open set Ω_1. We denote by $u_\omega(x)$, $x \in \Omega$, the voltage potential induced by a current ϕ, in the presence of ultrasonic perturbations localized in a domain ω of volume $|\omega|$. The voltage potential u_ω is a solution to

$$\left\{ \begin{array}{c} \nabla_x \cdot (\gamma_\omega(x) \nabla_x u_\omega(x)) = 0 \quad \text{in } \Omega, \\ \gamma(x) \frac{\partial u_\omega}{\partial n} = \phi \quad \text{on } \partial\Omega, \end{array} \right. \tag{2.3}$$

with the notation

$$\gamma_\omega(x) = \gamma(x) \left[1 + \mathbf{1}_\omega(x) \left(\nu(x) - 1 \right) \right],$$

where $\mathbf{1}_\omega$ is the characteristic function of the domain ω. In the next section, we show how comparing u_ω and u on $\partial\Omega$ provides information about the conductivity.

3. Asymptotic recovery of the conductivity. As the zone deformed by the ultrasound wave is small, we can view it as a small volume perturbation of the background conductivity γ, and we seek an asymptotic expansion of the boundary values of $u_\omega - u$.

For $x \in \mathbb{R}^d$, we note that $x = (x_1, \dots, x_d)$. For each $i = 1, \dots, d$, let ζ_ω^i be the solution to

$$\left\{ \begin{array}{l} \nabla_x \cdot \left(\gamma_\omega(x) \nabla_x \zeta_\omega^i \right) = \nabla_x \cdot (\gamma(x) \nabla_x x_i) \quad \text{in } \Omega, \\ \gamma(x) \frac{\partial \zeta_\omega^i}{\partial n} = \gamma(x) \frac{\partial x_i}{\partial n} \quad \text{on } \partial\Omega, \quad \text{with } \int_\Omega \zeta_\omega^i = 0. \end{array} \right.$$

Corresponding to ζ_ω^i, we define $\zeta^i = x_i - c_i$, where c_i is a constant, in the unperturbed case.

The following proposition is a variant of a compactness result proved in [20]. In contrast to previous work, the proof we give here requires only boundedness of the conductivity γ_ω.

PROPOSITION 3.1. *Consider a sequence of sets* $\omega \subset\subset \Omega$, *such that* $\frac{1}{|\omega|} \mathbf{1}_\omega$ *converges in the sense of measures to a probability measure* $d\mu$ *as* $|\omega|$ *tends to zero. Then, the correctors* $\frac{1}{|\omega|} \mathbf{1}_\omega \frac{\partial \zeta_\omega^i}{\partial x_j}$ *converge in the sense of measures to* M, *where* $M \in L^2(\Omega, d\mu)$ *is a matrix-valued function.*

Furthermore, the correctors $\left(\zeta_\omega^i \right)$ *satisfy*

$$\|\nabla(\zeta_\omega^i - \zeta^i)\|_{L^2(\Omega)^d} \le C|\omega|^{1/2} \text{ and } \|\zeta_\omega^i - \zeta^i\|_{L^2(\Omega)} \le C|\omega|^{\frac{1}{2}+\kappa},$$

where the constants $\kappa > 0$ *and* $C > 0$ *depend only on* Ω_1, $\sup_\Omega |\gamma_\omega|$, *and* $\inf_\Omega |\gamma_\omega|$.

Proof. The bounds on $\nabla \left(\zeta_\omega^i - \zeta^i \right)$ and $\left(\zeta_\omega^i - \zeta^i \right)$ are a direct consequence of Lemma A.1 if we remark that, inside the domain Ω, $\zeta_\omega^i - \zeta^i$ satisfies

$$\nabla_x \cdot \left(\gamma_\omega(x) \nabla_x \left(\zeta_\omega^i - \zeta^i \right) \right) = -\nabla_x \cdot \left(\mathbf{1}_\omega \left(\gamma_\omega - \gamma \right) \nabla_x x_i \right) \quad \text{in } \Omega.$$

As for the existence of a limit (and its additional properties) we refer the reader to [20]. □

One of the key elements of our method is the following representation formula.

PROPOSITION 3.2. *Assume that* $u \in W^{2,\infty}(\omega)$. *Then,*

$$\int_{\partial\Omega} (u_\omega - u) \, \phi \, d\sigma = |\omega| \int_\Omega (\gamma_\omega(x) - \gamma(x)) \, M_\omega \nabla u \cdot \nabla u \, dx + O(|\omega|^{1+\kappa}).$$

The exponent κ depends only on Ω_1, $\sup_\Omega |\gamma_\omega|$, and $\inf_\Omega |\gamma_\omega|$. The remainder term has the form

$$\left|O(|\omega|^{1+\kappa})\right| \leq C\,|\omega|^{1+\kappa} \|\nabla u\|_{L^\infty(\omega)^d} \|\nabla^2 u\|_{L^\infty(\omega)^{d\times d}},$$

where C depends only on Ω_1, $\sup_\Omega |\gamma_\omega|$, and $\inf_\Omega |\gamma_\omega|$. Finally, the matrix-valued function M_ω is given by

$$\left(M_\omega\right)_{ij}(x) = \frac{1}{|\omega|}\mathbf{1}_\omega(x)\frac{\partial}{\partial x_j}\zeta^i_\omega(x) \qquad a.e.\ x \in \Omega_1.$$

This is, globally, not a new result. This representation formula and the proof presented were already obtained by Capdeboscq and Vogelius in [20, Theorem 1]. Compared to Theorem 1 in [20], the regularity required on u is investigated more in depth. Note that, globally, u satisfies the minimal requirement $u \in H^1(\Omega)$. Additional regularity on u is required only within ω (in particular, the quality of the representation formula is not affected). We also note that if ω is a disk in the two-dimensional case, then (see, for instance, [22])

$$M_\omega = \frac{1}{|\omega|}\mathbf{1}_\omega(x)\frac{\nu-1}{\nu+1}I_2,$$

where I_2 is the unit matrix. The following corollary holds.

Corollary 3.3. *Assume that the dimension $d = 2$, that the perturbed area ω is a disk centered at z, and that $u \in W^{2,\infty}(\omega)$. Then, we have*

$$\begin{aligned}\int_{\partial\Omega}(u_\omega - u)\phi\,d\sigma &= \int_\omega \gamma(x)\frac{\left(\nu(x)-1\right)^2}{\nu(x)+1}\nabla u\cdot\nabla u\,dx + O(|\omega|^{1+\kappa})\\ &= |\nabla u(z)|^2\int_\omega \gamma(x)\frac{\left(\nu(x)-1\right)^2}{\nu(x)+1}\,dx + O(|\omega|^{1+\kappa}).\end{aligned}$$

Therefore, if γ is $\mathcal{C}^{0,2\alpha}(\omega)$, with $0 \leq \alpha \leq \kappa \leq \frac{1}{2}$, we have

$$\gamma(z)\,|\nabla u(z)|^2 = \mathcal{S}(z) + O(|\omega|^\alpha) \qquad (or\ o(1)\ if\ \alpha = 0), \tag{3.1}$$

where the function $\mathcal{S}(z)$ is defined by

$$\mathcal{S}(z) = \left(\int_\omega \frac{\left(\nu(x)-1\right)^2}{\nu(x)+1}\,dx\right)^{-1}\int_{\partial\Omega}(u_\omega - u)\phi\,d\sigma. \tag{3.2}$$

We emphasize that $\mathcal{S}(z)$ represents a known function, as the second term on the right-hand side of (3.2) is exactly the measured data.

Proof of Proposition 3.2. This proof follows the proof of Lemma 2 in [20]. First, in (3.3) we establish that the boundary data is related to an integral on ω, involving $(\gamma_1 - \gamma_0)\nabla u_\omega$. Then, in (3.7) we show that almost everywhere $(\gamma_1 - \gamma_0)\nabla u_\omega$ can be estimated by a quantity involving ∇u and the polarization tensor. Finally, in (3.8) we show that by approximation this representation formula leads to the desired result.

Integrating (2.2) against U_ω, the solution of (2.3), and vice-versa, we obtain after an integration by parts

$$\int_{\partial\Omega} u_\omega\phi\,d\sigma = \int_\Omega \gamma\nabla u_\omega\cdot\nabla u\,dx \text{ and } \int_{\partial\Omega} u\phi\,d\sigma = \int_\Omega \gamma_\omega\nabla u_\omega\cdot\nabla u\,dx.$$

Consequently,

$$\int_{\partial\Omega} (u_\omega - u)\, \phi \, d\sigma = \int_\Omega (\gamma - \gamma_\omega)\, \nabla u_\omega \cdot \nabla u \, dx \\ = \int_\omega (\gamma - \gamma_\omega)\, \nabla u_\omega \cdot \nabla u \, dx. \tag{3.3}$$

Notice that $u_\omega - u$ satisfies a homogeneous Neumann boundary condition and verifies

$$\nabla \cdot (\gamma_\omega \nabla (u_\omega - u)) = -\nabla \cdot (\mathbf{1}_\omega (\gamma_\omega - \gamma) \nabla u) \text{ in } \Omega.$$

Since $u \in W^{1,\infty}(\omega)$, we can again invoke Lemma A.1 to obtain that

$$\|\nabla(u_\omega - u)\|_{L^2(\Omega)^d} \leq C|\omega|^{1/2} \|\nabla u\|_{L^\infty(\omega)^d} \text{ and } \|u_\omega - u\|_{L^2(\Omega)} \leq C|\omega|^{1/2+\kappa} \|\nabla u\|_{L^\infty(\omega)^d},$$

where the constants C, κ depend only on Ω_1, $\sup_\Omega |\gamma_\omega|$, and $\inf_\Omega |\gamma_\omega|$. For all $\theta \in W^{1,\infty}(\Omega)$, we now compute

$$\begin{aligned} \int_\Omega \gamma_\omega \nabla (u_\omega - u) \cdot \nabla \zeta_\omega^i \, \theta \, dx &= \int_\Omega \gamma_\omega \nabla \left((u_\omega - u)\theta \right) \cdot \nabla \zeta_\omega^i \, dx \\ &\quad - \int_\Omega \gamma_\omega (u_\omega - u) \nabla \theta \cdot \nabla \zeta_\omega^i \, dx \\ &= \int_\Omega \gamma \nabla \left((u_\omega - u)\theta \right) \nabla \zeta^i \, dx + r_1 \\ &= \int_\Omega \gamma \nabla (u_\omega - u) \nabla \zeta^i \, \theta \, dx + r_2. \end{aligned} \tag{3.4}$$

The remainder term is given by

$$\begin{aligned} r_2 &= \int_\Omega \gamma (u_\omega - u) \nabla \theta \nabla \zeta^i \, dx - \int_\Omega \gamma_\omega (u_\omega - u) \nabla \theta \nabla \zeta_\omega^i \, dx \\ &= O(\|u_\omega - u\|_{L^2(\Omega)} \|\nabla \zeta - \nabla \zeta_\omega\|_{L^2(\Omega)^d}) \\ &= O(|\omega|^{1+\kappa}). \end{aligned}$$

Here, by $O(|\omega|^{1+\kappa})$ we denote a quantity that is bounded by $C\|\nabla u\|_{L^\infty(\omega)^d} \|\nabla \theta\|_{L^\infty(\Omega)^d} \cdot |\omega|^{1+\kappa}$, where C depends only on Ω_1, $\sup_\Omega |\gamma_\omega|$, and $\inf_\Omega |\gamma_\omega|$.

We shall consider both terms of identity (3.4) independently. On one hand, we have

$$\begin{aligned} \int_\Omega \gamma_\omega \nabla (u_\omega - u) \cdot \nabla \zeta_\omega^i \, \theta \, dx &= \int_\Omega \gamma_\omega \nabla (u_\omega - u) \cdot \nabla \left(\zeta_\omega^i \theta \right) dx \\ &\quad - \int_\Omega \gamma_\omega \nabla (u_\omega - u) \cdot \nabla \theta \, \zeta_\omega^i \, dx \\ &= \int_\omega (\gamma - \gamma_\omega) \nabla u \cdot \nabla \left(\zeta_\omega^i \theta \right) dx \\ &\quad - \int_\Omega \gamma_\omega \nabla (u_\omega - u) \cdot \nabla \theta \, \zeta^i \, dx + O\left(|\omega|^{1+\kappa} \right) \\ &= \int_\omega (\gamma - \gamma_\omega) \nabla u \cdot \nabla \zeta_\omega^i \, \theta \, dx \\ &\quad + \int_\Omega (\gamma \nabla u - \gamma_\omega \nabla u_\omega) \cdot \nabla \theta \, \zeta^i \, dx + O\left(|\omega|^{1+\kappa} \right). \end{aligned} \tag{3.5}$$

On the other hand, we have

$$\begin{aligned}\int_\Omega \gamma\nabla(u_\omega - u)\cdot\nabla\zeta^i\,\theta\,dx &= \int_\Omega \gamma\nabla(u_\omega - u)\cdot\nabla\left(\zeta^i\theta\right)dx\\ &\quad - \int_\Omega \gamma\nabla(u_\omega - u)\cdot\nabla\theta\,\zeta^i\,dx\\ &= \int_\omega (\gamma-\gamma_\omega)\nabla u_\omega\cdot\nabla\zeta^i\,\theta\,dx\\ &\quad + \int_\Omega (\gamma\nabla u - \gamma_\omega\nabla u_\omega)\cdot\nabla\theta\,\zeta^i\,dx.\end{aligned}\tag{3.6}$$

Inserting identities (3.5) and (3.6) into (3.4), we have obtained that, for all $i = 1,\dots,d$,

$$\int_\omega (\gamma-\gamma_\omega)\frac{\partial u_\omega}{\partial x_i}\,\theta\,dx = \sum_{j=1}^d \int_\omega (\gamma-\gamma_\omega)\,\frac{\partial u}{\partial x_j}\cdot\frac{\partial}{\partial x_j}\zeta^i_\omega\,\theta\,dx + O(|\omega|^{1+\kappa}),\tag{3.7}$$

with

$$\left|O(|\omega|^{1+\kappa})\right| \le C\,|\omega|^{1+\kappa}\|\nabla u\|_{L^\infty(\omega)^d}\|\nabla\theta\|_{L^\infty(\Omega)^d},$$

where C is a constant that depends only on Ω_1, $\sup_\Omega|\gamma_\omega|$, and $\inf_\Omega|\gamma_\omega|$. Let us now conclude the proof of Proposition 3.2. For each $i = 1,\dots,d$, choose $\theta_i = \frac{\partial}{\partial x_i}u * \eta_\epsilon$ in $\omega_\epsilon = \{x \in \omega \text{ s.t. } \operatorname{dist}(x,\partial\omega) > \epsilon\}$, where η is the standard mollifier. Let θ_ϵ be defined as

$$\theta_\epsilon = \left(\frac{\partial}{\partial x_1}u*\eta_\epsilon,\dots,\frac{\partial}{\partial x_d}u*\eta_\epsilon\right).$$

Using for each $i = 1,\dots,d$ the test function θ_i in (3.7) and summing over i, we obtain

$$\int_\omega (\gamma-\gamma_\omega)\nabla u_\omega\cdot\theta_\epsilon\,dx = |\omega|\int_\omega (\gamma-\gamma_\omega)\nabla u\cdot(M_\omega\theta_\epsilon)\,dx + O(|\omega|^{1+\kappa}),\tag{3.8}$$

where

$$O(|\omega|^{1+\kappa}) \le C\|\nabla u\|_{L^\infty(\omega)^d}\|\nabla\theta_\epsilon\|_{L^\infty(\omega)^d} \le C\|\nabla u\|_{L^\infty(\omega)^d}\|\nabla^2 u\|_{L^\infty(\omega)^d}.$$

By passing to the limit in ϵ and using (3.3), the proof of the proposition is complete. □

4. Reconstruction using the 0-Laplacian formulation. In view of deriving an approximation for the conductivity γ inside Ω_1, we introduce the following equation:

$$\begin{cases}\nabla\cdot\left(\dfrac{\mathcal{S}(x)}{|\nabla u|^2}\nabla u\right) = 0 & \text{in } \Omega,\\[2ex] \dfrac{\mathcal{S}(x)}{|\nabla u|^2}\dfrac{\partial u}{\partial n} = \phi & \text{on } \partial\Omega.\end{cases}\tag{4.1}$$

We emphasize that $\mathcal{S}$ is a known function, constructed from the measured data (3.2). Consequently, all the parameters entering (4.1) are known.

Our approach uses measurements $\mathcal{S}_1$ and $\mathcal{S}_2$ obtained using two distinct currents, ϕ_1 and ϕ_2. We choose this pair of current patterns to have $\nabla u_1 \times \nabla u_2 \neq 0$ for all $x \in \Omega$, where u_i, $i = 1, 2$, is the solution to (1.1). See [41, 26] for numerical evidence of the possibility of such a choice and [4] for a rigorous proof. The key question of course is whether such a choice of currents can be made simply by imposing appropriate boundary voltages, independently of the unknown conductivity. This issue will be discussed at length in a future work [19].

We start from an initial guess for the conductivity γ and solve the corresponding Dirichlet conductivity problem

$$\begin{cases} \nabla \cdot (\gamma \nabla u_0) = 0 & \text{in } \Omega, \\ u_0 = \psi & \text{on } \partial\Omega. \end{cases}$$

The data ψ is the Dirichlet data measured as a response to the current ϕ (say, $\phi = \phi_1$) in absence of elastic deformation.

The discrepancy between the data and our guessed solution is

$$\epsilon_0 := \frac{\mathcal{S}(x)}{|\nabla u_0|^2} - \gamma. \tag{4.2}$$

We then introduce a corrector, u_c, computed as the solution to

$$\begin{cases} \nabla \cdot (\gamma \nabla u_c) = -\nabla \cdot (\varepsilon_0 \nabla u_0) & \text{in } \Omega, \\ u_c = 0 & \text{on } \partial\Omega \end{cases}$$

and update the conductivity

$$\gamma := \frac{\mathcal{S}(x) - 2\gamma \nabla u_c \cdot \nabla u_0}{|\nabla u_0|^2}.$$

We iteratively update the conductivity, alternating directions (i.e., with $\phi = \phi_2$).

To study the efficiency of this approach, we have tested this method on various problems and domains, using the PDE solver FreeFem++ [28]. We present here one such test. The domain Ω is a disk of radius 8 centered at the origin, which contains three inclusions, an ellipse, an L-shaped domain, and a triangle, so as to image a convex object, a nonconvex object, and an object with a smooth boundary.

The background conductivity is equal to 0.5; the conductivity takes the values 2 in the triangle, 0.75 in the ellipse, and 2.55 in the L-shaped domain (see Figure 2). We purposely chose values corresponding to small and large contrasts with the background. Note that our approach is perturbative; thus the smaller the contrast, the easier the detection. If the contrast is small, both a small volume fraction approximation and a small amplitude approximation are valid: then the accuracy of a first order approximation such as the one performed here is increased. The choice of a significant contrast was not made to highlight the objects but rather to make the reconstruction more challenging.

Figure 3 shows the result of the reconstruction when perfect measures (with "infinite" precision) are available. In that case, the size of the spot is infinitesimal, that is, at least as small as the mesh size. We use two different boundary potentials, $\psi = x/|x|$ and $\psi = y/|y|$. The initial guess is depicted on the left: it is equal to 1 inside the disk of radius 6 centered at the origin, and it is equal to the supposedly

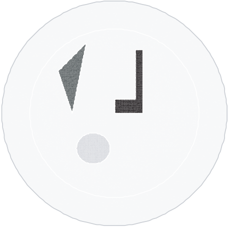

FIG. 2. *Conductivity distribution.*

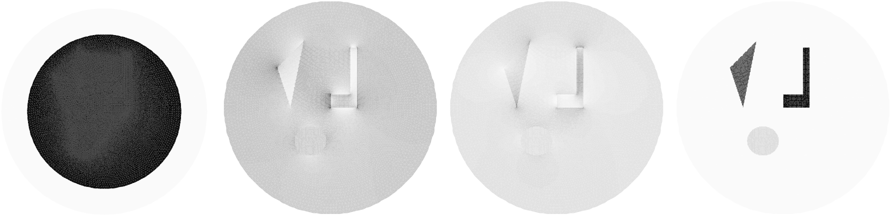

FIG. 3. *Reconstruction test. From left to right, the initial guess, the collected data* $\mathcal{S}$ *(*$x/|x|$ *and* $y/|y|$*), and the reconstructed conductivity.*

known conductivity $\gamma = 0.5$ near the boundary (outside the disk of radius 6). The two central pictures represent the collected data, $\mathcal{S}(x)$ for $\psi = x/|x|$ on the left and $\mathcal{S}(x)$ for $\psi = y/|y|$ on the right. Given the values of the contrast, we remark that although one can "see" the triangle and the L-shaped inclusions on these plots, the circle is hardly noticeable. On the far right, the reconstructed conductivity is represented: it perfectly matches the target.

In Figure 4, the error is represented as a function of the number of iterations. The dotted curve is a plot of the (intrinsic) error estimator $\max_{x\in\Omega} \epsilon_n(x)$, given by (4.2). The curve with diamond symbols depicts the L^1-norm $a_1(n)$ of the true error between the reconstructed conductivity $\tilde{\gamma}$ and the original one:

$$a_1(n) := \int_\Omega |\tilde{\gamma} - \gamma|\, dx.$$

Note that the abscissa is represented in logarithmic scale; thus the convergence seems exponential.

The other two curves correspond to the same computations, but four directions are used instead of two: $x/|x|$, $y/|y|$, $(x+y)/|x+y|$, $(x-y)/|x-y|$. Note that this does not require more measurements because of the linear dependence on the boundary condition; it is merely a change in the algorithm. The same level of error for ϵ_n is reached in 45 iterations instead of 222. The same experiment, with a contrast 5 times smaller, converges in less than ten iterations.

We also considered imperfect data. In Figure 5 we follow the same procedure but now assume that the data was measured at the nodes of a regular mesh on the disk, with 50, 100, 200, and 400 boundary points. To give an idea of the scale of the mesh compared to the objects, the projections of the conductivity that we wish to recover are represented in the left column. The two central columns depict the collected data. The column on the far right shows the obtained reconstructions.

To accelerate the computations, we used the four direction variant of the algorithm. The error as a function of the iterations is represented in Figure 6. The curves

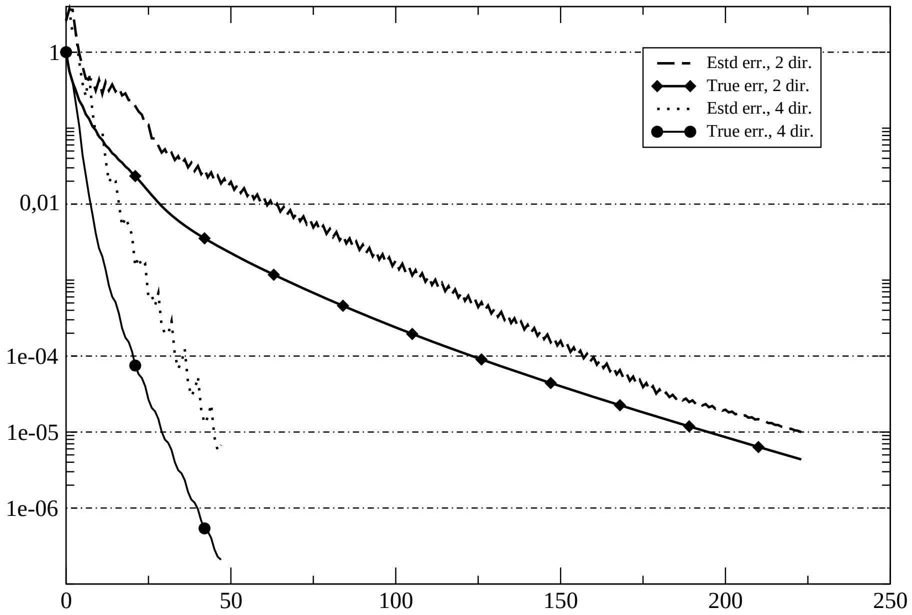

FIG. 4. *Convergence results. The curve labeled "Estd err., 2 dir." (resp., "True err., 2 dir.") corresponds to the estimated error (resp., true error) when two directions are used. The curves "Estd err., 4 dir." and "True err., 4 dir." are the errors computed when four directions are used.*

with symbols represent the L^1-norm of the true error, whereas the dashed line is the L^2-norm of the estimated error ϵ for the most precise mesh. Although the estimated error does not decrease noticeably, the true error does. The reconstructed image is obtained after ten iterations and does not change noticeably henceforth. This calls for further refinements of the algorithm, such as adapted stepsizes and adapted meshes. Improvements are indeed possible and will be the subject of a future publication [19]. As it stands, the algorithm already provides reconstructions comparable in accuracy to those of projected conductivity. Naturally, the sharp corners are easily localized, but the smooth elliptic shape is also accurately reconstructed, even at the coarsest scale.

5. Concluding remarks. We have proposed a new technique for conductivity imaging, which consists in perturbing the medium during the electric measurements, by focusing ultrasonic waves on regions of small diameter inside the body. We derived an approximation of the conductivity using small volume asymptotics and obtained a nonlinear PDE for the potential, in terms of the measured data. Based on this PDE, we proposed a new algorithm for the reconstruction of the conductivity distribution which proves remarkably accurate.

Motivated by the practical limitations of EIT, we intend to pursue the present investigation in the following directions:

(i) Study the reconstruction capabilities of this method when only partial data, measured on a small portion Γ of the boundary, is available.

(ii) Study the dependence of the algorithm on the global geometry of Ω.

(iii) Study the sensitivity of the method to limitations on the intensities of the applied voltages, as electrical safety regulations limit the amount of the total current that patients can sustain.

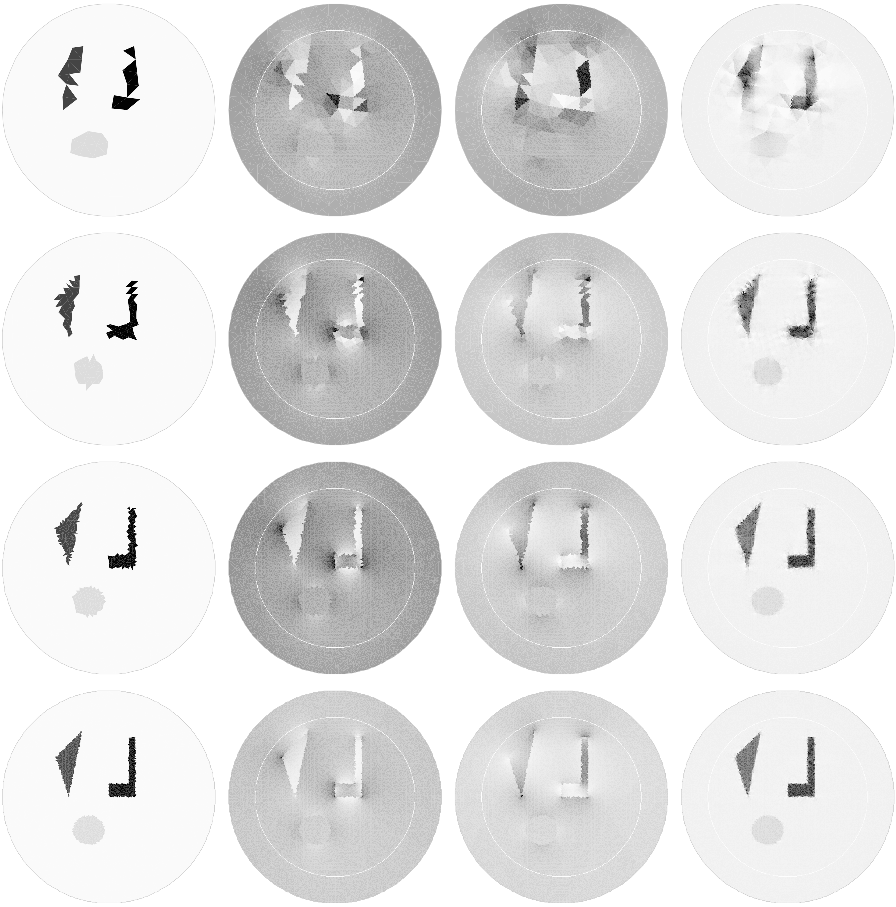

FIG. 5. *Reconstruction tests. From top to bottom, using a regular mesh with* 50*,* 100*,* 200*, and* 400 *boundary points. From left to right, the initial guess, the collected data $\mathcal{S}$ (for $x/|x|$ and $y/|y|$), and the reconstructed conductivity.*

Moreover, we also intend to address some of the mathematical questions raised by this imaging approach, among which are the uniqueness for solutions to the PDE (1.2), the uniqueness of the inverse problem of recovering the conductivity distribution with two measurements, and the convergence analysis of the reconstruction algorithm.

Appendix. Useful estimate.

LEMMA A.1. *Let $a \in L^\infty(\Omega)$ be a positive function satisfying $C_0 > a > c_0 > 0$, and let $F \in L^\infty(\Omega)^d$. Let V be a closed subset of $H^1(\Omega)$ such that*

$$H^1_0(\Omega) \subset V \subset H^1(\Omega).$$

Assume that $\phi \in V$ is such that

$$\nabla \cdot (a\nabla\phi) = \nabla \cdot (\mathbf{1}_\omega(x)F) \text{ in } \Omega. \tag{A.1}$$

Suppose that Ω contains a subset of $\Omega' \subset \Omega$ of class $\mathcal{C}^2$, such that dist$(\Omega', \partial\Omega) > d_0 > 0$, and such that $\omega \subset \Omega'$, or alternatively that Ω is a cube and that ϕ is periodic

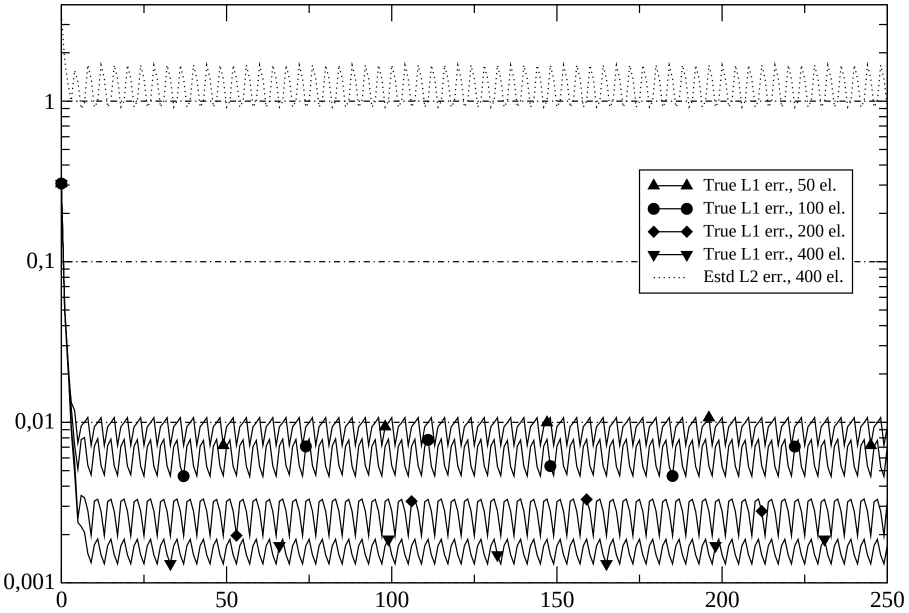

FIG. 6. *Convergence results. The curves labeled "True L1 err." correspond to the L^1 norm of the discrepancy between the real and reconstructed conductivity. The curve labeled "Estd L2 err., 400 el." represents the estimated error for the regular mesh designed with* 400 *boundary points.*

on that cube. Then,

$$\|\nabla\phi\|_{L^2(\Omega)^d} \leq \frac{1}{\sqrt{c_0}}|\omega|^{1/2}\|F\|_{L^\infty(\Omega)^d}. \tag{A.2}$$

Furthermore, there exist $\kappa > 0$ and $C > 0$, two positive constants depending only on Ω', d_0, c_0, and C_0, such that

$$\|\phi\|_{L^2(\Omega)} \leq C|\omega|^{\frac{1}{2}+\kappa}\|F\|_{L^\infty(\Omega)^d}. \tag{A.3}$$

At this point, let us emphasize the fact that the background is not required to be smooth. The proof uses Meyers's theorem [38].

Proof. We shall now prove Lemma A.1 for $V = H^1(\Omega)$ or $V = H_0^1(\Omega)$. Integrating (A.1) against ϕ, we obtain

$$\int_\Omega a\nabla\phi\cdot\nabla\phi\,dx = \int_\Omega \mathbf{1}_\omega F\cdot\nabla\phi\,dx.$$

Thus, using the Cauchy–Schwarz inequality, we get (A.2). Define $\psi \in H^1(\Omega)$ as the unique solution to

$$-\nabla\cdot(a\nabla\psi) = \phi \text{ in } \Omega,$$
$$\psi = 0 \text{ on } \partial\Omega.$$

Choose $f \in \mathcal{C}_0^\infty(\Omega)$ to be a cut-off function such that $f \equiv 1$ on Ω' and $0 \leq f \leq 1$. According to Meyers's theorem [38] (see also [15, pp. 35–45]), there exists an $\eta > 0$ depending only on Ω, c_0, C_0, and f such that $\psi \in W^{1,2+\eta}(\Omega')$, and we have

$$\|\nabla(\psi f)\|_{L^{2+\eta}(\Omega)} \leq C\,\|\phi\|_{L^{2+\eta}(\Omega)}.$$

Using the Gagliardo–Nirenberg inequality,

$$\begin{aligned}\|\phi\|_{L^{2+\eta}(\Omega)} &\leq C\,\|\phi\|^{\alpha}_{L^2(\Omega)}\,\|\nabla\phi\|^{1-\alpha}_{L^2(\Omega)^d} \text{ with } \alpha = \frac{\eta}{2+\eta}\\ &\leq C\,\|\phi\|^{\alpha}_{L^2(\Omega)}\,|\omega|^{\frac{1}{2+\eta}}\,.\end{aligned}$$

We then compute

$$\begin{aligned}\int_\Omega \phi^2\,dx &= \int_\Omega a\nabla\psi\cdot\nabla\phi\,dx\\ &= \int_\Omega \mathbf{1}_\omega F\cdot\nabla\psi\,dx\\ &\leq \|F\|_{L^\infty(\Omega)}\int_\Omega |\mathbf{1}_\omega\nabla\psi|\,dx.\end{aligned}$$

Using Hölder's inequality, we then obtain

$$\begin{aligned}\int_\Omega \phi^2\,dx &\leq \|F\|_{L^\infty(\Omega)}\,|\omega|^{\frac{1+\eta}{2+\eta}}\,\|\nabla(f\psi)\|_{L^{2+\eta}(\Omega)}\\ &\leq C\,\|F\|_{L^\infty(\Omega)}\,|\omega|\,\|\phi\|^{\alpha}_{L^2(\Omega)}\,.\end{aligned}$$

Consequently,

$$\|\phi\|_{L^2(\Omega)} \leq C\,\|F\|_{L^\infty(\Omega)}\,|\omega|^{\frac{1}{2}+\frac{\eta}{2(4+\eta)}}\,,$$

and therefore, choosing $\kappa = \frac{\eta}{2(4+\eta)}$ concludes the proof. □

EFFECTIVE TRANSPORT EQUATIONS AND ENHANCED BACKSCATTERING IN RANDOM WAVEGUIDES[*]

JOSSELIN GARNIER[†] AND KNUT SØLNA[‡]

Abstract. In this paper we derive a general system of transport equations for the moments of reflected and transmitted mode amplitudes in a randomly perturbed waveguide, in a regime where backscattering is significant. The derivation is based on a limit theorem for the system of coupled differential equations for the mode amplitudes, in the limit where the amplitude of the random fluctuations of the medium is small, the correlation lengths in the transverse and longitudinal directions are of the same order of the wavelength, and the waveguide is long. Using this system we derive several results in specific regimes, including the enhanced backscattering phenomenon for the reflected wave: when an incoming monochromatic wave with a specific incidence angle is present, the mean reflected power has a local maximum in the backward direction twice as large as the mean reflected power in the other directions.

Key words. acoustic waveguides, random media, asymptotic analysis

1. Introduction.

This paper is devoted to the analysis of wave propagation in a random waveguide. We use a separation of scales technique introduced by Papanicolaou and his co-authors. Although this technique was originally introduced for wave propagation in one-dimensional random media [1], it has been shown recently that it is possible to extend the technique to three-dimensional random media in the context of waveguides [5, 7, 6]. By writing the coupled mode equations for the complex mode amplitudes, diffusion approximation theorems can be applied, leading to differential equations driven by Brownian motions whose solutions are Itô diffusion processes. In [5, 6, 7] the analysis was restricted to the forward scattering approximation, where the conversion from forward-going to backward-going modes is neglected. This regime is characterized by the equipartition of energy: the mean transmitted mode powers become uniformly distributed when the waveguide is long enough. In this paper, we revisit this analysis in the general case and take into account backscattering. We derive a system of transport equations for the moments of the reflected and transmitted mode amplitudes in the regime where the fluctuations of the random medium have a small amplitude and a correlation length of the same order as the typical wavelength. This allows us to exhibit the enhanced backscattering phenomenon: when a monochromatic input mode is applied, the mean reflected mode powers become uniformly distributed, except for the mode corresponding to the backward direction, where the mean reflected power is twice the mean power of the other modes. This phenomenon, also known as weak localization, is well referenced in the physical literature and it has been observed in several experimental contexts, such as in optics with

powder suspensions [17, 15], with biological tissues [18], and with ultracold atoms [11] as well as in acoustics [14]. The physical analysis of the weak localization is based on diagrammatic expansions [16], where interference effects between direct and reverse paths play a crucial role. Here we give a mathematical derivation of this phenomenon by an asymptotic analysis in the context of random waveguides. We also compute the second moments of the reflected mode powers and show that these quantities are not statistically stable in the sense that their fluctuations are of the same order as their mean values. This means that it is necessary to average the reflected power to detect the enhanced backscattering. This point was already mentioned in the physical literature, and we give here a quantitative analysis of this phenomenon.

2. Propagation in a random waveguide.

We consider wave propagation in a waveguide where the medium parameters have small random perturbations. Many modern applications involve propagation in waveguides [3, 4, 13]. We will here describe the problem in a scaling regime where the radius of the waveguide is of the order of a few wavelengths and with the medium parameters varying randomly in the longitudinal and transversal directions with a correlation length on the order of the wavelength. This scaling regime was also considered in [5, 7, 6]. The analysis could be generalized to other scaling limits whenever diffusion approximation theorems can be applied.

We consider linear acoustic waves propagating in three spatial dimensions:

$$\rho(\mathbf{x}, z)\frac{\partial \mathbf{u}}{\partial t} + \nabla p = \mathbf{0}, \quad \frac{1}{K(\mathbf{x}, z)}\frac{\partial p}{\partial t} + \nabla \cdot \mathbf{u} = 0 \quad \text{for } \mathbf{x} \in \mathcal{D} \text{ and } t, z \in \mathbb{R}, \tag{2.1}$$

where p is the pressure field, $\mathbf{u}$ is the velocity field, ρ is the density of the medium, K is the bulk modulus, and $(\mathbf{x}, z) = (x, y, z)$ stands for the space coordinates. The cross section of the waveguide is denoted by $\mathcal{D}$, and we shall use Dirichlet boundary conditions

$$p(t, \mathbf{x}, z) = 0 \qquad \text{for } \mathbf{x} \in \partial\mathcal{D} \text{ and } z \in \mathbb{R}. \tag{2.2}$$

The direction of propagation along the waveguide axis is z and the transverse coordinates are denoted by $\mathbf{x} \in \mathcal{D}$. The random part of the waveguide occupies the region $z \in [0, L/\varepsilon^2]$ and is embedded in between two homogeneous waveguide sections. Inside the perturbed waveguide the bulk modulus is randomly varying, and we assume for simplicity that the density is homogeneous:

$$\frac{1}{K(\mathbf{x}, z)} = \begin{cases} \frac{1}{\bar{K}}\left(1 + \varepsilon\nu(\mathbf{x}, z)\right) & \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in [0, L/\varepsilon^2], \\ \frac{1}{\bar{K}} & \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in (-\infty, 0) \cup (L/\varepsilon^2, \infty), \end{cases} \tag{2.3}$$

$$\rho(\mathbf{x}, z) = \bar{\rho} \quad \text{for} \quad \mathbf{x} \in \mathcal{D}, \quad z \in (-\infty, \infty). \tag{2.4}$$

It is possible to take into account a randomly varying density; this complicates the algebra but leads to the same general system of transport equations for the moments of reflected and transmitted mode amplitudes. Such a generalization was carried out in the case of randomly layered media in [5, section 17.3]. Here ε is a small parameter and $\nu(\mathbf{x}, z)$ is a zero-mean random process that describes the random medium fluctuations that are mixing in the z-direction. This weakly heterogeneous regime can be encountered, for instance, in underwater acoustics [4, 8].

2.1. Waveguide modes. In a homogeneous waveguide $\nu = 0$, the complex amplitude of a monochromatic wave $p(t, \mathbf{x}, z) = \hat{p}(\omega, \mathbf{x}, z)e^{-i\omega t}$ at frequency ω satisfies the time-harmonic form of the wave equation (Helmholtz equation):

$$\partial_z^2 \hat{p} + \Delta_\perp \hat{p} + k^2(\omega)\hat{p} = 0. \tag{2.5}$$

Here $\Delta_\perp$ is the transverse Laplacian, $k(\omega) = \omega/\bar{c}$ is the wavenumber, and $\bar{c} = \sqrt{\bar{K}/\bar{\rho}}$ is the homogenized wave speed. The monochromatic wave can be decomposed in terms of normal modes which are the (normalized in $L^2(\mathcal{D})$) solutions of the eigenvalue problem

$$-\Delta_\perp \phi_j(\mathbf{x}) = \lambda_j \phi_j(\mathbf{x}), \ \mathbf{x} \in \mathcal{D}, \qquad \phi_j(\mathbf{x}) = 0, \ \mathbf{x} \in \partial\mathcal{D},$$

for $j = 1, 2, \ldots$. The eigenvalues are positive and nondecreasing, and we assume for simplicity that they are simple, so we have $0 < \lambda_1 < \lambda_2 < \cdots$. The eigenmodes are real and form an orthonormal set

$$\int_{\mathcal{D}} \phi_j(\mathbf{x})\phi_l(\mathbf{x})\, d\mathbf{x} = \delta_{jl}.$$

For a given frequency ω, there exists a unique integer $N(\omega)$ such that $\lambda_{N(\omega)} \le k^2(\omega) < \lambda_{N(\omega)+1}$, with the convention that $N(\omega) = 0$ if $\lambda_1 > k^2(\omega)$. The modal wavenumbers $\beta_j(\omega)$ for $1 \le j \le N(\omega)$ are defined by

$$\beta_j(\omega) = \sqrt{k^2(\omega) - \lambda_j}\,. \tag{2.6}$$

The solutions $\hat{p}_j(\omega, \mathbf{x}, z) = \phi_j(\mathbf{x})e^{\pm i\beta_j(\omega)z}$, $j = 1, \ldots, N(\omega)$, of the wave equation (2.5) are the propagating waveguide modes. For $j > N(\omega)$ we define the modal wavenumbers by $\beta_j(\omega) = [\lambda_j - k^2(\omega)]^{1/2}$, and the corresponding solutions $\hat{q}_j(\omega, \mathbf{x}, z) = \phi_j(\mathbf{x})e^{\pm\beta_j(\omega)z}$ of the wave equation (2.5) are the evanescent modes.

From now on we consider the perturbed waveguide as described by (2.3)–(2.4). We expand the time-harmonic field inside the randomly perturbed waveguide in terms of the transverse eigenmodes of the unperturbed waveguide:

$$\hat{p}(\omega, \mathbf{x}, z) = \sum_{j=1}^{N(\omega)} \phi_j(\mathbf{x})\hat{p}_j(\omega, z) + \sum_{j=N(\omega)+1}^{\infty} \phi_j(\mathbf{x})\hat{q}_j(\omega, z), \tag{2.7}$$

where $\hat{p}_j$ is the amplitude of the jth propagating mode and $\hat{q}_j$ is the amplitude of the jth evanescent mode. For $1 \le j \le N(\omega)$, let $\hat{a}_j(\omega, z)$ and $\hat{b}_j(\omega, z)$ represent the amplitudes of the forward- and backward-propagating modes, with the forward direction referring to the z-direction. They are given by

$$\hat{p}_j(\omega, z) = \frac{1}{\sqrt{\beta_j(\omega)}}\left(\hat{a}_j(\omega, z)e^{i\beta_j(\omega)z} + \hat{b}_j(\omega, z)e^{-i\beta_j(\omega)z}\right), \tag{2.8}$$

$$\frac{d\hat{p}_j(\omega, z)}{dz} = i\sqrt{\beta_j(\omega)}\left(\hat{a}_j(\omega, z)e^{i\beta_j(\omega)z} - \hat{b}_j(\omega, z)e^{-i\beta_j(\omega)z}\right). \tag{2.9}$$

We next make a change of the z variable by introducing the rescaled processes $\hat{a}_j^\varepsilon(\omega, z)$, $\hat{b}_j^\varepsilon(\omega, z)$, $j = 1, \ldots, N(\omega)$, given by

$$\hat{a}_j^\varepsilon(\omega, z) = \hat{a}_j\left(\omega, \frac{z}{\varepsilon^2}\right), \qquad \hat{b}_j^\varepsilon(\omega, z) = \hat{b}_j\left(\omega, \frac{z}{\varepsilon^2}\right). \tag{2.10}$$

By projecting the wave equation (2.5) on the transverse eigenmodes and by expressing the amplitudes of the evanescent modes in terms of the amplitudes of the propagating modes [5, 6], we obtain the following mode coupling equations for the amplitude processes $\hat{a}^\varepsilon(\omega,z)=(\hat{a}^\varepsilon_j(\omega,z))_{j=1,\dots,N(\omega)}$ and $\hat{b}^\varepsilon(\omega,z)=(\hat{b}^\varepsilon_j(\omega,z))_{j=1,\dots,N(\omega)}$:

$$\frac{d\hat{a}^\varepsilon}{dz}=\left[\frac{1}{\varepsilon}\mathbf{H}^{(aa)}+\mathbf{G}^{(aa)}\right]\left(\omega,\frac{z}{\varepsilon^2}\right)\hat{a}^\varepsilon+\left[\frac{1}{\varepsilon}\mathbf{H}^{(ab)}+\mathbf{G}^{(ab)}\right]\left(\omega,\frac{z}{\varepsilon^2}\right)\hat{b}^\varepsilon, \tag{2.11}$$

$$\frac{d\hat{b}^\varepsilon}{dz}=\left[\frac{1}{\varepsilon}\overline{\mathbf{H}^{(ab)}}+\overline{\mathbf{G}^{(ab)}}\right]\left(\omega,\frac{z}{\varepsilon^2}\right)\hat{a}^\varepsilon+\left[\frac{1}{\varepsilon}\overline{\mathbf{H}^{(aa)}}+\overline{\mathbf{G}^{(aa)}}\right]\left(\omega,\frac{z}{\varepsilon^2}\right)\hat{b}^\varepsilon, \tag{2.12}$$

with the two-point boundary conditions

$$\hat{a}^\varepsilon_j(\omega,0)=0,\quad \hat{b}^\varepsilon_j(\omega,L)=\hat{b}^{\mathrm{inc}}_j(\omega), \tag{2.13}$$

which correspond to a left-propagating wave incoming from the right homogeneous waveguide. The matrices $\mathbf{G}$ describe coupling via evanescent modes [5]. The $N(\omega)\times N(\omega)$ coupling matrices have entries of form

$$H^{(aa)}_{jl}(\omega,z)=\frac{ik^2(\omega)}{2}\frac{C_{jl}(z)}{\sqrt{\beta_j\beta_l(\omega)}}e^{i(\beta_l(\omega)-\beta_j(\omega))z}, \tag{2.14}$$

$$G^{(aa)}_{jl}(\omega,z)=\frac{ik^4(\omega)}{4}\sum_{l'>N(\omega)}\int_{-\infty}^{\infty}\frac{C_{jl'}(z)C_{ll'}(z+s)}{\sqrt{\beta_j\beta_{l'}^2\beta_l(\omega)}}e^{i\beta_l(\omega)(z+s)-i\beta_j(\omega)z-\beta_{l'}(\omega)|s|}\,ds,$$

$$H^{(ab)}_{jl}(\omega,z)=-e^{-2i\beta_j(\omega)z}\overline{H^{(aa)}_{jl}(\omega,z)},\quad G^{(ab)}_{jl}(\omega,z)=-e^{-2i\beta_j(\omega)z}\overline{G^{(aa)}_{jl}(\omega,z)}, \tag{2.15}$$

$$C_{jl}(z)=\int_{\mathcal{D}}\phi_j(\mathbf{x})\phi_l(\mathbf{x})\nu(\mathbf{x},z)\,d\mathbf{x} \tag{2.16}$$

for $j,l=1,\dots,N(\omega)$.

2.2. Channel coupled wave approximation. We use an invariant imbedding step to convert the boundary value problem to an initial value problem with the objective being to characterize the reflected and transmitted wave fields. Accordingly we introduce the $N(\omega)\times N(\omega)$ reflection and transmission matrices $\boldsymbol{\mathcal{R}}^\varepsilon$ and $\boldsymbol{\mathcal{T}}^\varepsilon$ by

$$\hat{b}^\varepsilon(\omega,0)=\boldsymbol{\mathcal{T}}^\varepsilon(\omega,z)\hat{b}^\varepsilon(\omega,z),\qquad \hat{a}^\varepsilon(\omega,z)=\boldsymbol{\mathcal{R}}^\varepsilon(\omega,z)\hat{b}^\varepsilon(\omega,z). \tag{2.17}$$

Using (2.11)–(2.12) we find that these matrices solve the problems

$$\frac{d}{dz}\boldsymbol{\mathcal{R}}^\varepsilon=\mathbf{H}^{b,\varepsilon}+\mathbf{H}^{a,\varepsilon}\boldsymbol{\mathcal{R}}^\varepsilon-\boldsymbol{\mathcal{R}}^\varepsilon\overline{\mathbf{H}^{a,\varepsilon}}-\boldsymbol{\mathcal{R}}^\varepsilon\overline{\mathbf{H}^{b,\varepsilon}}\boldsymbol{\mathcal{R}}^\varepsilon, \tag{2.18}$$

$$\frac{d}{dz}\boldsymbol{\mathcal{T}}^\varepsilon=-\boldsymbol{\mathcal{T}}^\varepsilon\left(\overline{\mathbf{H}^{a,\varepsilon}}+\overline{\mathbf{H}^{b,\varepsilon}}\boldsymbol{\mathcal{R}}^\varepsilon\right), \tag{2.19}$$

where we defined

$$\mathbf{H}^{a,\varepsilon}(\omega,z)=\frac{1}{\varepsilon}\mathbf{H}^{(aa)}\left(\omega,\frac{z}{\varepsilon^2}\right)+\mathbf{G}^{(aa)}\left(\omega,\frac{z}{\varepsilon^2}\right),$$

$$\mathbf{H}^{b,\varepsilon}(\omega,z)=\frac{1}{\varepsilon}\mathbf{H}^{(ab)}\left(\omega,\frac{z}{\varepsilon^2}\right)+\mathbf{G}^{(ab)}\left(\omega,\frac{z}{\varepsilon^2}\right),$$

and where $\boldsymbol{\mathcal{R}}^\varepsilon(\omega,z)$ and $\boldsymbol{\mathcal{T}}^\varepsilon(\omega,z)$ take initial values at $z=0$

$$\boldsymbol{\mathcal{T}}^\varepsilon(\omega,0)=\mathbf{I},\quad \boldsymbol{\mathcal{R}}^\varepsilon(\omega,0)=\mathbf{0}. \tag{2.20}$$

We remark that energy conservation leads to the reflection-transmission conservation relation

$$\boldsymbol{\mathcal{R}}^{\varepsilon\dagger}\boldsymbol{\mathcal{R}}^{\varepsilon}+\boldsymbol{\mathcal{T}}^{\varepsilon\dagger}\boldsymbol{\mathcal{T}}^{\varepsilon}=\mathbf{I}, \tag{2.21}$$

where the sign † stands for the conjugate transpose [5].

The initial value problem (2.18) is a stochastic Riccati matrix equation, and it can be analyzed in the limit $\varepsilon \to 0$ using the theory of diffusion approximations [5, 10]. The matrix $\mathbf{H}^{(aa)}$ contains rapidly varying phase factors and is centered with respect to the randomness that fluctuates on the scale ε^2 and is mixing in the z-direction. In this white-noise scaling regime we can then identify the corresponding infinitesimal generator and the associated white-noise model that describes the joint law of the transmission and reflection matrices in the limit $\varepsilon \to 0$.

3. The reflected wave field.

We consider the problem of characterizing the modal distribution of the reflected or transmitted waves. We consider in this section the reflected waves, and we will address the transmitted waves in section 4.

3.1. The moments of the reflected time-harmonic field.

We first consider the time-harmonic reflected field for a single frequency ω. We can compute the limit of the moments of the reflection matrix by using the diffusion approximation theory.

PROPOSITION 3.1. *Let* $\mathbf{p}=\{(j_1,l_1),\dots,(j_{|\mathbf{p}|},l_{|\mathbf{p}|})\}\in\{1,\dots,N(\omega)\}^{2|\mathbf{p}|}$ *denote a multi-index (*$|\mathbf{p}|$ *is the number of index pairs in* $\mathbf{p}$*). We introduce the moments of elements* $\mathcal{R}^{\varepsilon}_{jl}$ *of the reflection matrix:*

$$\mathcal{M}^{\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,z)=\mathbb{E}\Big[\prod_{(j,l)\in\mathbf{p}}\mathcal{R}^{\varepsilon}_{jl}(\omega,z)\prod_{(m,n)\in\mathbf{q}}\overline{\mathcal{R}^{\varepsilon}_{mn}(\omega,z)}\Big].$$

These moments converge as $\varepsilon\to 0$ *to the solution* $\mathcal{M}_{\mathbf{p},\mathbf{q}}$ *of the system*

$$\frac{d\mathcal{M}_{\mathbf{p},\mathbf{q}}}{dz}=D_{\mathbf{p},\mathbf{q}}(\omega)\mathcal{M}_{\mathbf{p},\mathbf{q}}+\big[\mathcal{S}_{\omega}(\mathcal{M})\big]_{\mathbf{p},\mathbf{q}}, \tag{3.1}$$

with the initial conditions

$$\mathcal{M}_{\mathbf{p},\mathbf{q}}(\omega,z=0)=\mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|). \tag{3.2}$$

Here we have defined the linear operator $\mathcal{S}_\omega$*,*

$$\begin{aligned}
\big[\mathcal{S}_{\omega}(\mathcal{M})\big]_{\mathbf{p},\mathbf{q}} &= -\sum_{(j,l)\in\mathbf{p}} d^{(1)}_{jl}\mathcal{M}_{\mathbf{p}|\{(j,l)|(l,j)\},\mathbf{q}}-\sum_{(j,l)\in\mathbf{q}} d^{(1)}_{jl}\mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l,j)\}}\\
&-\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} d^{(2)}_{jl}\mathcal{M}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(l,\tilde{l})\},\mathbf{q}}+d^{(2)}_{\tilde{j}\tilde{l}}\mathcal{M}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(\tilde{l},l)\},\mathbf{q}}\\
&-\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} d^{(1)}_{j\tilde{l}}\mathcal{M}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(\tilde{l},l)\},\mathbf{q}}+d^{(1)}_{\tilde{j}l}\mathcal{M}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(l,\tilde{l})\},\mathbf{q}}\\
&-\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} \Big[d^{(5)}_{jl}+d^{(5)}_{\tilde{j}\tilde{l}}+d^{(1)}_{j\tilde{j}}+d^{(1)}_{l\tilde{l}}\Big]\mathcal{M}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\},\mathbf{q}}\\
&-\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} d^{(2)}_{jl}\mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(l,\tilde{l})\}}+d^{(2)}_{\tilde{j}\tilde{l}}\mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(\tilde{l},l)\}}
\end{aligned}$$

$$
\begin{aligned}
&- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} d^{(1)}_{j\tilde{l}} \mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(\tilde{l},l)\}} + d^{(1)}_{\tilde{j}l} \mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(l,\tilde{l})\}} \\
&- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} \left[d^{(5)}_{jl} + d^{(5)}_{\tilde{j}\tilde{l}} + d^{(1)}_{j\tilde{j}} + d^{(1)}_{l\tilde{l}} \right] \mathcal{M}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\}} \\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} d^{(3)}_{jl\tilde{j}\tilde{l}} \mathcal{M}_{\mathbf{p}|(j,l),\mathbf{q}|(\tilde{j},\tilde{l})} \\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} \sum_{k=1\neq j}^{N} \left[d^{(4)}_{jk\tilde{j}} \mathcal{M}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(k,\tilde{l})\}} + d^{(4)}_{jk\tilde{l}} \mathcal{M}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k)\}} \right] \\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} \sum_{k=1\neq l}^{N} \left[d^{(4)}_{lk\tilde{l}} \mathcal{M}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k)\}} + d^{(4)}_{lk\tilde{j}} \mathcal{M}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(k,\tilde{l})\}} \right] \\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} \sum_{k_1,k_2=1}^{N} d^{(2)}_{k_1k_2} \mathcal{M}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k_1),(k_2,\tilde{l})\}} \\

We will discuss applications of this proposition in the next sections, but we first give a generalization of the result for the two-frequency case. The proof of Proposition 3.1 is a simplified version of the proof of the next proposition, so we shall present it only for this second proposition.

3.2. The transport equations for the two-frequency moments. We have the following result, which is proved in Appendix A. We use the same notation as in Proposition 3.1.

PROPOSITION 3.2. *We introduce the moments of elements $\mathcal{R}^\varepsilon_{jl}$ of the reflection matrix at two nearby frequencies:*

$$\mathcal{U}^\varepsilon_{\mathbf{p},\mathbf{q}}(\omega, h, z) = \mathbb{E}\left[\prod_{(j,l)\in\mathbf{p}} \mathcal{R}^\varepsilon_{jl}(\omega + \varepsilon^2 h/2, z) \prod_{(m,n)\in\mathbf{q}} \overline{\mathcal{R}^\varepsilon_{mn}(\omega - \varepsilon^2 h/2, z)} \right], \tag{3.7}$$

where we set $\mathcal{R}^\varepsilon_{jl}(\omega \pm \varepsilon^2 h/2, z) = 0$ if j or l is larger than $N(\omega \pm \varepsilon^2 h/2)$. The family of Fourier transforms (in h)

$$\mathcal{W}^\varepsilon_{\mathbf{p},\mathbf{q}}(\omega, \tau, z) = \frac{1}{2\pi} \int e^{-ih[\tau - \phi_{\mathbf{p},\mathbf{q}}(\omega)z]} \mathcal{U}^\varepsilon_{\mathbf{p},\mathbf{q}}(\omega, h, z)\, dh \tag{3.8}$$

converges as $\varepsilon \to 0$ to the solution $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ of the system of transport equations

$$\frac{\partial \mathcal{W}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi_{\mathbf{p},\mathbf{q}}(\omega) \frac{\partial \mathcal{W}_{\mathbf{p},\mathbf{q}}}{\partial \tau} = D_{\mathbf{p},\mathbf{q}}(\omega) \mathcal{W}_{\mathbf{p},\mathbf{q}} + \left[\mathcal{S}_\omega(\mathcal{W})\right]_{\mathbf{p},\mathbf{q}}, \tag{3.9}$$

with the initial conditions

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega, \tau, z = 0) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\delta(\tau). \tag{3.10}$$

The coefficient $\phi_{\mathbf{p},\mathbf{q}}(\omega)$ is defined by

$$\phi_{\mathbf{p},\mathbf{q}}(\omega) = \frac{1}{2} \sum_{(j,l)\in\mathbf{p}} \left(\beta'_j(\omega) + \beta'_l(\omega)\right) + \frac{1}{2} \sum_{(j,l)\in\mathbf{q}} \left(\beta'_j(\omega) + \beta'_l(\omega)\right), \tag{3.11}$$

with $\beta'_j(\omega) = d\beta_j(\omega)/d\omega$, while the coefficient $D_{\mathbf{p},\mathbf{q}}(\omega)$ and the operator $\mathcal{S}_\omega$ are given in Proposition 3.1.

The set of transport equations (3.9) describes accurately the reflected wave field, and it is the key tool in analyzing various applications with waves in random waveguides. The corresponding transport equations in the layered case with one-dimensional medium variations were first obtained in [1]. They have played a crucial role in the analysis of a wide range of applications, and they have been generalized to describe a wide range of propagation scenarios in [5]. The transport equations given in Proposition 3.2 provide a rigorous tool for studying qualitatively and quantitatively the multiple scattering effects in a nonlayered random medium.

Remark. The convergence of $\mathcal{W}^\varepsilon$ and the existence and uniqueness of the solution $\mathcal{W}$ to the system of transport equations (3.9) are established in the space $\mathcal{C}([0,L],S'_H)$, where S'_H is a generalization of the space of distributions introduced in [12] to study the analogous problem with $N=1$ (randomly layered media). The space S'_H can be identified as the dual of the space S_H of the test functions $\lambda = (\lambda_{\mathbf{p},\mathbf{q}}(\tau))_{\mathbf{p}\in\{1,\dots,N(\omega)\}^{2|\mathbf{p}|},\mathbf{q}\in\{1,\dots,N(\omega)\}^{2|\mathbf{q}|},\tau\in\mathbb{R}}$, where the $\lambda_{\mathbf{p},\mathbf{q}}(\tau)$ are infinitely differentiable in τ and are rapidly decaying as functions of τ, $|\mathbf{p}|$ and $|\mathbf{q}|$. The convergence of $\mathcal{M}^\varepsilon$ in Proposition 3.1 is established in the space $\mathcal{C}([0,L],S'_M)$, where S'_M is the dual of the space S_M of the test sequences $\lambda = (\lambda_{\mathbf{p},\mathbf{q}})_{\mathbf{p}\in\{1,\dots,N(\omega)\}^{2|\mathbf{p}|},\mathbf{q}\in\{1,\dots,N(\omega)\}^{2|\mathbf{q}|}}$ which are rapidly decaying in $|\mathbf{p}|$ and $|\mathbf{q}|$.

3.3. Interpretation of the transport equations. We make the five following observations regarding the system of transport equations.

(1) By integrating the solution of the system of transport equations in τ, it is straightforward to see that the integral quantity is the solution of the system (3.1). This shows that we have

$$\mathcal{M}_{\mathbf{p},\mathbf{q}}(\omega,z) = \int \mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z)\,d\tau. \tag{3.12}$$

Therefore, the following remarks stated in terms of the family $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ hold true for the family of moments $\mathcal{M}_{\mathbf{p},\mathbf{q}}$ as well.

(2) Consider the set of moments $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ such that $|\mathbf{p}|-|\mathbf{q}|=c$ with c a nonzero integer. These moments form a closed subfamily with each member satisfying a zero initial condition. Therefore, these moments vanish and only moments having the same number of conjugated and unconjugated terms $|\mathbf{p}|=|\mathbf{q}|$ survive in the limit $\varepsilon\to 0$.

(3) Consider the case when

$$C_{jl}(z)\equiv 0 \quad \text{for} \quad j\neq l. \tag{3.13}$$

This corresponds to the situation where modes with different modal wavenumbers are not coupled. This is the case particularly when the inhomogeneities of the waveguide do not have lateral variations $\nu(\mathbf{x},z)=\nu(z)$. It then follows that

$$\widetilde{\Gamma}_{jl}(\omega) = \widetilde{\Gamma}_j^{(0)}(\omega)\mathbf{1}_{j=l}, \qquad \widetilde{\Gamma}_j^{(0)}(\omega) = \frac{k^4(\omega)}{2\beta_j^2(\omega)}\int_{-\infty}^{\infty}\mathbb{E}[\nu(0)\nu(s)]\,ds, \tag{3.14}$$

$$\Gamma_{jl}(\omega) = \Gamma_j^{(0)}(\omega)\mathbf{1}_{j=l}, \qquad \Gamma_j^{(0)}(\omega) = \frac{k^4(\omega)}{4\beta_j^2(\omega)}\int_0^{\infty}\mathbb{E}[\nu(0)\nu(s)]e^{i2\beta_j(\omega)s}\,ds. \tag{3.15}$$

This simplification gives $d_{jl}^{(1)}=0$, $d_{jl}^{(2)}=2\Gamma_j^{(0)}\mathbf{1}_{j=l}$, $d_{jl\tilde{j}\tilde{l}}^{(3)}=2\Gamma_j^{(0)}\mathbf{1}_{j=l=\tilde{j}=\tilde{l}}$, $d_{j\tilde{j}k}^{(4)}=2\widetilde{\Gamma}_j^{(0)}\mathbf{1}_{j=\tilde{j}=k}$, and $d_{k_1k_2}^{(5)}=0$. The analysis of the system shows that the solution has the form

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z) = \begin{cases} W_{p_1}^{(1)}*\cdots*W_{p_N}^{(N)}(\omega,\tau,z) \text{ if } \mathbf{p}=\mathbf{q}=\{(1,1)^{p_1},\dots,(N,N)^{p_N}\}, \\ 0 \text{ otherwise,}\end{cases}$$

where $*$ stands for the convolution in τ and for each $j=1,\dots,N$ the family $(W_p^{(j)})_{p\in\mathbb{N}}$ is the solution of the closed system of transport equations

$$\frac{\partial W_p^{(j)}}{\partial z} + 2p\beta'_j(\omega)\frac{\partial W_p^{(j)}}{\partial \tau} = 2p^2\Re\left[\Gamma_j^{(0)}(\omega)\right]\left(W_{p+1}^{(j)}+W_{p-1}^{(j)}-2W_p^{(j)}\right), \tag{3.16}$$

with the initial conditions $W_p^{(j)}(\omega,\tau,z=0)=\mathbf{1}_0(p)\delta(\tau)$. We therefore obtain that the backward and forward jth modes are uncoupled from the other modes, but their moments are coupled together according to the system that governs the propagation of one-dimensional waves in random media [1]. This is not qualitatively surprising, but this analysis shows that a sufficient criterion for this reduction is (3.13).

(4) If the two-point statistics of the process $\nu(\mathbf{x},z)$ are such that

$$\Gamma_{jl}(\omega)\equiv 0 \quad \text{for all} \quad j,l=1,\dots,N(\omega), \tag{3.17}$$

then $d^{(2)}=d^{(3)}=d^{(5)}=0$. Consequently there is coupling in the system of transport equations only for indices $(\mathbf{p},\mathbf{q})$ and $(\mathbf{p}',\mathbf{q}')$ such that $|\mathbf{p}|=|\mathbf{p}'|$ and $|\mathbf{q}|=|\mathbf{q}'|$. Since the initial conditions are zero for all nonempty indices $(\mathbf{p},\mathbf{q})$, the moments $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ are zero as soon as $|\mathbf{p}|$ or $|\mathbf{q}|$ is positive. In other words, $\mathcal{R}_{jl}^{\varepsilon}\to 0$ for all $j,l=1,\dots,N$ in distribution as $\varepsilon\to 0$. This shows that the forward scattering approximation is valid as soon as the condition (3.17) is fulfilled. This approximation is frequently used in the literature; it consists in neglecting coupling between forward- and backward-propagating modes, while retaining the coupling between forward-going modes and the implicit coupling to the evanescent modes. Here we give the necessary and sufficient condition (3.17) for the validity of this approximation.

(5) In the full system (2.18) we do not have“reciprocity” in that in general $\mathcal{R}_{jl}^{\varepsilon}\neq\mathcal{R}_{lj}^{\varepsilon}$ because of the coupling with the evanescent modes modeled by the matrices $\mathbf{G}$. However, the following symmetry relation is satisfied:

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}=\mathcal{W}_{\tilde{\mathbf{p}},\tilde{\mathbf{q}}}$$

for $\tilde{\mathbf{p}}_n=(l_n,j_n)$ with $\mathbf{p}_n=(j_n,l_n)$ and $\tilde{\mathbf{q}}$ correspondingly defined. This means that reciprocity is satisfied in the limit $\varepsilon\to 0$, and this follows from the following observations:

- The initial condition in (3.10) depends on the multi-index only through $|\mathbf{p}|$ and $|\mathbf{q}|$.
- The coupling matrices $\mathbf{G}^{(aa)}$ and $\mathbf{G}^{(ab)}$ in (2.18) affect only the diagonal coefficients $D_{\mathbf{p},\mathbf{q}}$ in a symmetric way in the problem for $\mathcal{W}_{\mathbf{p},\mathbf{q}}$.
- We have the symmetry relations

$$\left(\mathbf{H}^{(aa)}\right)^T=-\overline{\mathbf{H}^{(aa)}},\quad \left(\mathbf{H}^{(ab)}\right)^T=\mathbf{H}^{(ab)}$$

in the coupling matrices in (2.18).

3.4. Enhanced backscattering. In this section we consider the case where the forward coupling is strong while the coupling between the forward- and backward-going modes is weak. As seen above, the forward scattering approximation consists in neglecting completely the latter coupling, and it is valid when the matrix Γ is zero. Here we assume that Γ is not zero but Γ is small compared to $\widetilde{\Gamma}$. This allows us to simplify significantly the system of transport equations and to present very interesting results. In particular, we show in the following proposition that the enhanced backscattering phenomenon extensively discussed in the physical literature can be exhibited from the particular structure of the reflected time-harmonic wave field.

We denote by $\mathcal{P}_{jl}$ the mean reflected power of the mode j when the input wave is a mode l:

$$\mathcal{P}_{jl}^{(1)}(\omega,z)=\mathcal{M}_{(j,l),(j,l)}(\omega,z)=\lim_{\varepsilon\to 0}\mathbb{E}[|\mathcal{R}_{jl}^{\varepsilon}(\omega,z)|^2],\qquad j,l=1,\dots,N(\omega),$$

for a random waveguide with length z.

Proposition 3.3. *If the matrix norm of $\Re[\Gamma(\omega)]$ is small compared to $1/L$ and the positive spectral gap* (3.20) *of the operator $\mathcal{L}_\omega$ in* (3.18) *below, which is defined in terms of $\widetilde{\Gamma}(\omega)$, is large compared to $1/L$, then the mean reflected mode powers are*

$$\mathcal{P}_{jl}^{(1)}(\omega, L) = \begin{cases} P_0(\omega) & \text{if } j \neq l, \\ 2P_0(\omega) & \text{if } j = l, \end{cases}$$

where $P_0(\omega)$ is given by

$$P_0(\omega) = \frac{2}{N(\omega)(N(\omega)+3)}\left[\sum_{j\neq l}\Re[\Gamma_{jl}(\omega)] + 2\sum_{j}\Re[\Gamma_{jj}(\omega)]\right]L.$$

The first condition "$\Re[\Gamma(\omega)L] \ll 1$" means that the coupling between backward- and forward-going modes is weak. The second condition about the spectral gap means that the coupling between forward-going modes is strong (as well as the coupling between backward-going modes). The most striking result of this proposition is that, if the incident wave is a pure mode l, then the mean reflected power of the lth mode $\mathcal{P}_{ll}^{(1)}$ is twice the mean reflected power of any other mode $\mathcal{P}_{jl}^{(1)}$, $j \neq l$.

First, this result shows that the reflected wave has a memory of the initial conditions. This is in contrast to the transmitted wave field in the same regime, where the equipartition of energy means that the mean transmitted mode powers acquire a uniform distribution over the modes, independently of the initial conditions (see section 4.4).

Second, since a mode corresponds to a particular wavevector angle, this result means that we observe a uniform mean reflected power in all outgoing directions, except in the backscattered direction (corresponding to the input one), where we observe twice as much power. The physical reason for this enhancement of backscattered power is the constructive interference between the direct and reverse paths in the backscattering direction. Enhanced backscattering was first predicted in three-dimensional random media in [2] and was detected by several groups [9, 15, 17]. It is also referred to as the weak localization effect. The most popular techniques amongst physicists for analyzing the weak localization effect, and more generally for taking into account interference effects, are based on diagrammatic expansions [16]. Here we give a mathematical derivation of this phenomenon in the context of random waveguides.

Proof. The initial conditions for the solution $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ of the system of transport equations is zero as soon as $|\mathbf{p}| > 0$ or $|\mathbf{q}| > 0$. Since the coupling terms from $|\mathbf{p}|$ to $|\mathbf{p}| \pm 1$ and from $|\mathbf{q}|$ to $|\mathbf{q}| \pm 1$ are proportional to $\Re(\Gamma)$, this shows that the only coefficients $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ of order $\Re(\Gamma)$ are the ones with $|\mathbf{p}| = 1$ and $|\mathbf{q}| = 1$. Up to terms of higher order, we find that

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z) = \begin{cases} \delta(\tau) & \text{if } \mathbf{p} = \mathbf{q} = \emptyset, \\ W_{jl}(\omega,\tau,z) & \text{if } \{\mathbf{p} = (j,l),\ \mathbf{q} = (j,l)\} \text{ or } \{\mathbf{p} = (j,l),\ \mathbf{q} = (l,j)\}, \\ 0 & \text{otherwise,} \end{cases}$$

where W_{jl} is the solution of

$$\frac{\partial W_{jl}}{\partial z} + \left[\beta_j'(\omega) + \beta_l'(\omega)\right]\frac{\partial W_{jl}}{\partial \tau} = (\mathcal{L}_\omega W)_{jl} + 2\Re\left[\Gamma_{jl}(\omega)\right]\delta(\tau),$$

with the initial conditions $W_{jl}(\omega,\tau,z) = 0$. Here $\mathcal{L}_\omega$ is the linear operator from $\mathbb{R}^{N\times N}$ into $\mathbb{R}^{N\times N}$ defined by

$$(3.18)\qquad (\mathcal{L}_\omega \mathcal{P})_{jl} = \begin{cases} \displaystyle\sum_{k\neq j} \tilde{\gamma}_{jk}(\mathcal{P}_{kl} - \mathcal{P}_{jl}) + \sum_{k\neq l} \tilde{\gamma}_{kl}(\mathcal{P}_{jk} - \mathcal{P}_{jl}) - 2\tilde{\gamma}_{jl}\mathcal{P}_{jl} & \text{if } j \neq l, \\ \displaystyle 2\sum_{k\neq j} \tilde{\gamma}_{jk}(2\mathcal{P}_{jk} - \mathcal{P}_{jj}) & \text{if } j = l, \end{cases}$$

where $\tilde{\gamma}_{jl}(\omega) = 2\Re[\widetilde{\Gamma}_{jl}(\omega)]$. By integrating in τ and using (3.12), we obtain the system for the mean reflected powers

$$(3.19)\qquad \frac{d\mathcal{P}^{(1)}_{jl}}{dz} = (\mathcal{L}_\omega \mathcal{P}^{(1)})_{jl} + 2\Re\big[\Gamma_{jl}(\omega)\big].$$

Interpreting $\mathcal{L}_\omega$ as an $N^2(\omega) \times N^2(\omega)$ matrix acting on $N^2(\omega)$-dimensional vectors, it is straightforward to check that the vector $\mathcal{P}^*(\omega)$ defined by

$$\mathcal{P}^*_{jl}(\omega) = \begin{cases} \dfrac{1}{\sqrt{N(\omega)(N(\omega)+3)}} & \text{if } j \neq l, \\ \dfrac{2}{\sqrt{N(\omega)(N(\omega)+3)}} & \text{if } j = l \end{cases}$$

is a unit eigenvector of $\mathcal{L}_\omega$ associated with the eigenvalue zero. Additionally, using the positivity of the matrix $\Re(\widetilde{\Gamma})$ and the Perron–Frobenius theorem, one can show that zero is a simple eigenvalue and all other eigenvalues are negative. Let us denote by $\lambda^{(N^2)}(\omega) \leq \cdots \leq \lambda^{(2)}(\omega) < 0$ these eigenvalues and by $\mathcal{Q}^{(N^2)}(\omega), \dots, \mathcal{Q}^{(2)}(\omega)$ the corresponding unit eigenvectors. The spectral gap mentioned in the proposition is $|\lambda^{(2)}(\omega)|$, which is also given by

$$(3.20)\qquad |\lambda^{(2)}(\omega)| = \inf_{\mathcal{P}\in\mathbb{R}^{N^2(\omega)},\, \langle \mathcal{P},\mathcal{P}^*(\omega)\rangle = 0} \frac{-\langle \mathcal{P}, \mathcal{L}_\omega \mathcal{P}\rangle}{\langle \mathcal{P},\mathcal{P}\rangle},$$

where $\langle \cdot,\cdot\rangle$ denotes the scalar product in $\mathbb{R}^{N^2(\omega)}$. The integration of (3.19) gives

$$(3.21)\qquad \mathcal{P}^{(1)}_{jl}(\omega,z) = \mathcal{P}^*_{jl}\,\langle \mathcal{P}^*, 2\Re(\Gamma)\rangle\, z + \sum_{k=2}^{N^2} \mathcal{Q}^{(k)}_{jl} \left\langle \mathcal{Q}^{(k)}, 2\Re(\Gamma)\right\rangle \frac{\exp(\lambda^{(k)} z) - 1}{\lambda^{(k)}}.$$

If $|\lambda^{(2)}|z$ is much larger than 1, then the first term of the right-hand side is much larger than the other terms. This gives the desired result. □

3.5. Fluctuation theory for the reflected mode powers. The previous section describes the mean reflected powers. It is important to study the fluctuations of the reflected powers in order to predict under which conditions the enhanced backscattering can be observed. Propositions 3.1–3.2 allow us to study the fluctuations of the reflected mode powers by looking at their second moments:

$$\mathcal{P}^{(2)}_{jl,mn}(\omega,z) = \lim_{\varepsilon\to 0} \mathbb{E}\left[|\mathcal{R}^\varepsilon_{jl}(\omega,z)|^2 |\mathcal{R}^\varepsilon_{mn}(\omega,z)|^2\right].$$

We investigate the asymptotic correlation matrix (of size $N^2(\omega) \times N^2(\omega)$) of the reflected mode powers:

$$\begin{aligned} \mathrm{Cor}_{jl,mn}(\omega) &= \lim_{\varepsilon\to 0} \frac{\mathbb{E}\left[|\mathcal{R}^\varepsilon_{jl}(\omega,L)|^2 |\mathcal{R}^\varepsilon_{mn}(\omega,L)|^2\right] - \mathbb{E}\Big[|\mathcal{R}^\varepsilon_{jl}(\omega,L)|^2\Big]\mathbb{E}\Big[|\mathcal{R}^\varepsilon_{mn}(\omega,L)|^2\Big]}{\mathbb{E}\Big[|\mathcal{R}^\varepsilon_{jl}(\omega,L)|^2\Big]\mathbb{E}\Big[|\mathcal{R}^\varepsilon_{mn}(\omega,L)|^2\Big]} \\ &= \frac{\mathcal{P}^{(2)}_{jl,mn}(\omega,L) - \mathcal{P}^{(1)}_{jl}(\omega,L)\mathcal{P}^{(1)}_{mn}(\omega,L)}{\mathcal{P}^{(1)}_{jl}(\omega,L)\mathcal{P}^{(1)}_{mn}(\omega,L)}. \end{aligned}$$

Proposition 3.4. *If the matrix norm of $\Re[(\Gamma(\omega)]$ is small compared to $1/L$ and the positive spectral gap of the operator $\mathcal{L}_\omega^{(2)}$ given in* 1–7 *below, which is defined in terms of $\widetilde{\Gamma}(\omega)$, is large compared to $1/L$, then the second moments of the reflected mode powers satisfy*

$$\lim_{N(\omega)\to\infty} \mathrm{Cor}_{jl,mn}(\omega) = \begin{cases} 0 \textit{ if } (j,l) \neq (m,n) \textit{ and } (j,l) \neq (n,m), \\ 1 \textit{ if } (j,l) = (m,n) \textit{ or } (j,l) = (n,m). \end{cases}$$

The result for $(j,l) \neq (m,n)$ shows that the reflected mode powers are asymptotically uncorrelated as $N \to \infty$. The result for $(j,l) = (m,n)$ shows that they are not statistically stable quantities as $N \to \infty$, since their normalized variances are equal to one. This means that the fluctuations of the reflected mode powers are of the same order as their mean values. This implies that it is necessary to perform an averaging in order to observe the enhanced backscattering. This averaging can be done by a summation of the reflected mode powers over different experiments with different realizations of the random medium, or with the same realization of the random medium but with different frequencies of the input monochromatic wave.

Another interesting point is that the normalized variances of the background reflected powers (i.e., $\mathrm{Cor}_{jl,jl}$ for $j \neq l$) are asymptotically equal to one and equal to the normalized variance of the backscattered reflected power (i.e., $\mathrm{Cor}_{jj,jj}$).

Proof. We apply the same strategy as in the proof of Proposition 3.3. Once again, the fundamental argument is that the coupling terms from $|\mathbf{p}|$ to $|\mathbf{p}| \pm 1$ are proportional to $\Re(\Gamma)$. Therefore, the lowest order terms in $\Re(\Gamma)$ of the coefficients $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ with $|\mathbf{p}| = |\mathbf{q}| = 2$ are

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z) = \begin{cases} W_{jl,mn}(\omega,\tau,z) \text{ if } & \begin{array}{l} \mathbf{p} = \{(j,l),(m,n)\} \text{ and } \mathbf{q} = \{(j,l),(m,n)\} \\ \text{or } \{(l,j),(m,n)\} \text{ or } \{(j,l),(n,m)\} \\ \text{or } \{(l,j),(n,m)\}, \end{array} \\ 0 \text{ otherwise,} & \end{cases}$$

where $W_{jl,mn}$ is the solution of

$$\frac{\partial W_{jl,mn}}{\partial z} + (\beta_j' + \beta_l' + \beta_m' + \beta_n') \frac{\partial W_{jl,mn}}{\partial \tau} = (\mathcal{L}_\omega^{(2)} W)_{jl,mn} + 2\Re(\Gamma_{jl}) W_{mn} + 2\Re(\Gamma_{mn}) W_{jl},$$

with the initial conditions $W_{jl,mn}(\omega,\tau,z=0) = 0$. Here $\mathcal{L}_\omega^{(2)}$ is the linear operator from $\mathbb{R}^{N^2\times N^2}$ into $\mathbb{R}^{N^2\times N^2}$ defined by the following:

1. If $j = l = m = n$,

$$(\mathcal{L}_\omega^{(2)} \mathcal{P}^{(2)})_{jj,jj} = \sum_{k\neq j} \tilde{\gamma}_{jk} [16 \mathcal{P}^{(2)}_{jk,jj} - 4\mathcal{P}^{(2)}_{jj,jj}],$$

where $\tilde{\gamma}_{jl}(\omega) = 2\Re[\widetilde{\Gamma}_{jl}(\omega)]$.

2. If $j = l = m \neq n$,

$$(\mathcal{L}_\omega^{(2)} \mathcal{P}^{(2)})_{jj,jn} = \sum_{k\neq j} \tilde{\gamma}_{jk} [4\mathcal{P}^{(2)}_{jk,jn} - 2\mathcal{P}^{(2)}_{jj,jn}] + \sum_{k\neq j} \tilde{\gamma}_{jk} [\mathcal{P}^{(2)}_{jj,kn} - \mathcal{P}^{(2)}_{jj,jn}]$$
$$+ \sum_{k\neq m} \tilde{\gamma}_{nk} [\mathcal{P}^{(2)}_{jj,jk} - \mathcal{P}^{(2)}_{jj,jn}] - 6\tilde{\gamma}_{jn} \mathcal{P}^{(2)}_{jj,jn}.$$

A formula of the same form holds true if $j = l = n \neq m$ or $j \neq l = m = n$ or $l \neq j = m = n$.

3. If $j = l \neq m = n$,

$$(\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jj,nn} = \sum_{k\neq j}\tilde{\gamma}_{jk}[4\mathcal{P}^{(2)}_{jk,nn} - 2\mathcal{P}^{(2)}_{jj,nn}] + \sum_{k\neq n}\tilde{\gamma}_{nk}[4\mathcal{P}^{(2)}_{jj,kn} - 2\mathcal{P}^{(2)}_{jj,nn}].$$

4. If $j = m \neq l = n$,

$$(\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jl,jl} = \sum_{k\neq j}\tilde{\gamma}_{jk}[4\mathcal{P}^{(2)}_{kl,jl} - 2\mathcal{P}^{(2)}_{jl,jl}] + \sum_{k\neq l}\tilde{\gamma}_{lk}[4\mathcal{P}^{(2)}_{jk,jl} - 2\mathcal{P}^{(2)}_{jl,jl}] - 4\tilde{\gamma}_{jl}\mathcal{P}^{(2)}_{jl,jl}.$$

A formula of the same form holds true if $j = n \neq l = m$.

5. If $j = l \neq m \neq n$,

$$\begin{aligned}(\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jj,mn} = {} & \sum_{k\neq j}\tilde{\gamma}_{jk}[4\mathcal{P}^{(2)}_{jk,mn} - 2\mathcal{P}^{(2)}_{jj,mn}] + \sum_{k\neq m}\tilde{\gamma}_{mk}[\mathcal{P}^{(2)}_{jj,kn} - \mathcal{P}^{(2)}_{jj,mn}] \\ & + \sum_{k\neq n}\tilde{\gamma}_{nk}[\mathcal{P}^{(2)}_{jj,mk} - \mathcal{P}^{(2)}_{jj,mn}] - 2\tilde{\gamma}_{mn}\mathcal{P}^{(2)}_{jj,mn}.\end{aligned}$$

A formula of the same form holds true if $m = n \neq j \neq l$.

6. If $j = m \neq l \neq n$,

$$\begin{aligned}(\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jl,jn} = {} & \sum_{k\neq j}\tilde{\gamma}_{jk}[\mathcal{P}^{(2)}_{kl,jn} - \mathcal{P}^{(2)}_{jl,jn}] + \sum_{k\neq l}\tilde{\gamma}_{lk}[\mathcal{P}^{(2)}_{jk,jn} - \mathcal{P}^{(2)}_{jl,jn}] \\ & + \sum_{k\neq j}\tilde{\gamma}_{jk}[\mathcal{P}^{(2)}_{jl,kn} - \mathcal{P}^{(2)}_{jl,jn}] + \sum_{k\neq n}\tilde{\gamma}_{nk}[\mathcal{P}^{(2)}_{jl,jk} - \mathcal{P}^{(2)}_{jl,jn}] \\ & - 2\left[\tilde{\gamma}_{jl} + \tilde{\gamma}_{jn} + \tilde{\gamma}_{ln}\right]\mathcal{P}^{(2)}_{jl,jn}.\end{aligned}$$

A formula of the same form holds true if $j = n \neq l \neq m$ or $l = m \neq j \neq n$ or $l = n \neq j \neq m$.

7. In the other cases,

$$\begin{aligned}(\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jl,mn} = {} & \sum_{k\neq j}\tilde{\gamma}_{jk}[\mathcal{P}^{(2)}_{kl,mn} - \mathcal{P}^{(2)}_{jl,mn}] + \sum_{k\neq l}\tilde{\gamma}_{lk}[\mathcal{P}^{(2)}_{jk,mn} - \mathcal{P}^{(2)}_{jl,mn}] \\ & + \sum_{k\neq m}\tilde{\gamma}_{mk}[\mathcal{P}^{(2)}_{jl,kn} - \mathcal{P}^{(2)}_{jl,mn}] + \sum_{k\neq n}\tilde{\gamma}_{nk}[\mathcal{P}^{(2)}_{jl,mk} - \mathcal{P}^{(2)}_{jl,mn}] \\ & - 2\left[\tilde{\gamma}_{jl} + \tilde{\gamma}_{mn}\right]\mathcal{P}^{(2)}_{jl,mn}.\end{aligned}$$

By integrating in τ, we find the system for the second moments of the reflected powers:

$$\frac{d\mathcal{P}^{(2)}_{jl,mn}}{dz} = (\mathcal{L}_\omega^{(2)}\mathcal{P}^{(2)})_{jl,mn} + 2\Re(\Gamma_{jl})\mathcal{P}^{(1)}_{mn} + 2\Re(\Gamma_{mn})\mathcal{P}^{(1)}_{jl}. \tag{3.22}$$

Interpreting $\mathcal{L}_\omega^{(2)}$ as an $N^4(\omega) \times N^4(\omega)$ matrix acting on $N^4(\omega)$-dimensional vectors, it is possible to check that the vector $\mathcal{P}^{(2),*}(\omega)$ defined by

$$\mathcal{P}^{(2),*}_{jl,mn} = \frac{1}{\sqrt{T^*}}\begin{cases} 8 & \text{if } j = l = m = n, \\ 4 & \text{if } j = l \neq m = n, \\ 2 & \text{if } \left|\begin{array}{l} j = m \neq l = n \text{ or } j = n \neq l = m \text{ or } j = l \neq m \neq n \\ \text{ or } j \neq l \neq m = n \text{ or } j = l = m \neq n \text{ or } j = l = n \neq m \\ \text{ or } j \neq l = m = n \text{ or } l \neq j = m = n, \end{array}\right. \\ 1 & \text{otherwise} \end{cases}$$

is the unit eigenvector of $\mathcal{L}_\omega^{(2)}$ associated with the eigenvalue zero, where $T^* = N^4+6N^3+15N^2+42N$. The other eigenvalues are negative. As a result, taking into account the expression in (3.21) for $\mathcal{P}^{(1)}$, the integration of (3.22) gives

$$\frac{1}{z^2}\mathcal{P}^{(2)}_{jl,mn}(\omega,z) \overset{z\to\infty}{\longrightarrow} \mathcal{P}^{(2),*}_{jl,mn} \sum_{\tilde{j},\tilde{l},\tilde{m},\tilde{n}=1}^{N} \mathcal{P}^{(2),*}_{\tilde{j}\tilde{l},\tilde{m}\tilde{n}} \left(\Re(\Gamma_{\tilde{j}\tilde{l}})\mathcal{P}^*_{\tilde{m}\tilde{n}} + \Re(\Gamma_{\tilde{m}\tilde{n}})\mathcal{P}^*_{\tilde{j}\tilde{l}}\right) \langle \mathcal{P}^*, 2\Re(\Gamma)\rangle\,,$$

which in turn gives the result of the proposition. □

4. The transmitted wave field.

We consider the problem of characterizing the distribution of the transmitted field.

4.1. The moments of the transmitted time-harmonic field.

We consider the time-harmonic transmitted field for a frequency ω. We can compute the limit of moments of the transmission matrix as in the case of the reflection matrix. We use the same notation as in Proposition 3.1.

Proposition 4.1. *We introduce the joint moments of elements of the reflection matrix along with a pair of elements of the transmission matrix:*

(4.1)
$$\mathcal{M}^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,z;j_1,j_2) = \mathbb{E}\left[\mathcal{T}^\varepsilon_{j_1l_1}(\omega,z)\overline{\mathcal{T}^\varepsilon_{j_2l_2}(\omega,z)} \prod_{(j,l)\in\mathbf{p}} \mathcal{R}^\varepsilon_{jl}(\omega,z) \prod_{(m,n)\in\mathbf{q}} \overline{\mathcal{R}^\varepsilon_{mn}(\omega,z)}\right]$$

for $\mathbf{t}=(l_1,l_2)$. The family of moments $\mathcal{M}^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}$ converges as $\varepsilon\to 0$ to the solution $\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ of the system

$$\frac{d\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}}{dz} = D^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} + \left[\mathcal{S}_\omega(\mathcal{M})\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} + \left[\mathcal{Z}_\omega(\mathcal{M})\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}\,, \tag{4.2}$$

with the initial conditions $\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,z=0;j_1,j_2) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\mathbf{1}_{j_1}(l_1)\mathbf{1}_{j_2}(l_2)$. The linear operator $\mathcal{Z}_\omega$ is defined by

$$\begin{aligned}
\left[\mathcal{Z}_\omega(\mathcal{M})\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} &= \sum_{k=1}^{N} d^{(4)}_{l_1kl_2}\mathcal{M}^{(k,k)}_{\mathbf{p},\mathbf{q}} \\
&+ \sum_{k_1,k_2=1}^{N} d^{(2)}_{k_1k_2}\mathcal{M}^{(k_1,k_1)}_{\mathbf{p}\cup\{(k_2,l_1)\},\mathbf{q}\cup\{(k_2,l_2)\}} + d^{(5)}_{k_1k_2}\mathcal{M}^{(k_2,k_1)}_{\mathbf{p}\cup\{(k_1,l_1)\},\mathbf{q}\cup\{(k_2,l_2)\}} \\
&- \sum_{(j,l)\in\mathbf{p}} d^{(6)}_{l_1j}\mathcal{M}^{(j,l_2)}_{\mathbf{p}|\{(j,l)|(l_1,l)\},\mathbf{q}} + d^{(6)}_{l_1l}\mathcal{M}^{(l,l_2)}_{\mathbf{p}|\{n|(j,l_1)\},\mathbf{q}} \\
&+ \sum_{(j,l)\in\mathbf{q}} \sum_{k=1}^{N} d^{(4)}_{jkl_1}\mathcal{M}^{(k,l_2)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(k,l)\}} + d^{(4)}_{lkl_1}\mathcal{M}^{(k,l_2)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k)\}} \\
&- \sum_{(j,l)\in\mathbf{q}} d^{(6)}_{jl_2}\mathcal{M}^{(l_1,j)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l_2,l)\}} + d^{(6)}_{ll_2}\mathcal{M}^{(l_1,l)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,l_2)\}} \\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{k=1}^{N} d^{(4)}_{jkl_2}\mathcal{M}^{(l_1,k)}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}} + d^{(4)}_{lkl_2}\mathcal{M}^{(l_1,k)}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}} \\
&- \sum_{(j,l)\in\mathbf{p}} d^{(2)}_{jl}\mathcal{M}^{(j,l_2)}_{\mathbf{p}|\{(j,l)|(l,l_1)\},\mathbf{q}} + d^{(5)}_{jl}\mathcal{M}^{(l,l_2)}_{\mathbf{p}|\{(j,l)|(j,l_1)\},\mathbf{q}}
\end{aligned}$$

$$
\begin{aligned}
&- \sum_{(j,l)\in\mathbf{q}} d^{(2)}_{jl}\mathcal{M}^{(l_1,j)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l,l_2)\}} + d^{(5)}_{jl}\mathcal{M}^{(l_1,l)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,l_2)\}}\\
&+ \sum_{(j,l)\in\mathbf{q}} \sum_{k_1,k_2=1}^{N} d^{(2)}_{k_1k_2}\mathcal{M}^{(k_1,l_2)}_{\mathbf{p}\cup\{(k_2,l_1)\},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}}\\
&+ \sum_{(j,l)\in\mathbf{q}} \sum_{k_1,k_2=1}^{N} d^{(5)}_{k_1k_2}\mathcal{M}^{(k_2,l_2)}_{\mathbf{p}\cup\{(k_1,l_1)\},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}}\\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{k_1,k_2=1}^{N} d^{(2)}_{k_1k_2}\mathcal{M}^{(l_1,k_1)}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}\cup\{(k_2,l_2)\}}\\
&+ \sum_{(j,l)\in\mathbf{p}} \sum_{k_1,k_2=1}^{N} d^{(5)}_{k_1k_2}\mathcal{M}^{(l_1,k_2)}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}\cup\{(k_1,l_2)\}}.
\end{aligned}
$$

The coefficient $D^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)$ *is defined by*

$$
\begin{aligned}
D^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = D_{\mathbf{p},\mathbf{q}} &+ i\left(\kappa_{l_1}-\kappa_{l_2}\right) - \Gamma_{kl_1} - \overline{\Gamma_{kl_2}} - \sum_{k=1}^{N}\Big(\widetilde{\Gamma}_{kl_1} + \widetilde{\Gamma}_{l_2k} - 2\check{\Gamma}_{l_1l_2}\mathbf{1}_{l_1\neq l_2}\Big)\\
&- 2\sum_{(j,l)\in\mathbf{p}}\big(\check{\Gamma}_{jl_1}\mathbf{1}_{j\neq l_1} + \check{\Gamma}_{ll_1}\mathbf{1}_{l\neq l_1} - \check{\Gamma}_{jl_2}\mathbf{1}_{j\neq l_2} - \check{\Gamma}_{ll_2}\mathbf{1}_{l\neq l_2}\big)\\
&+ 2\sum_{(j,l)\in\mathbf{q}}\big(\check{\Gamma}_{jl_1}\mathbf{1}_{j\neq l_1} + \check{\Gamma}_{ll_1}\mathbf{1}_{l\neq l_1} - \check{\Gamma}_{jl_2}\mathbf{1}_{j\neq l_2} - \check{\Gamma}_{ll_2}\mathbf{1}_{l\neq l_2}\big).
\end{aligned}
$$

The coefficient $d^{(6)}(\omega)$ *is given by*

$$
d^{(6)}_{jl}(\omega) = 2\Re\big[\widetilde{\Gamma}_{jl}(\omega)\big].
$$

The linear operator $\mathcal{S}_\omega$ *and the coefficients* $D_{\mathbf{p},\mathbf{q}}(\omega)$*,* $\kappa_l(\omega)$*, and* $d^{(j)}(\omega)$*,* $j=1,\ldots,5$*, are defined in Proposition* 3.1*.*

4.2. Transmission transport equations. We consider here the two-frequency statistics of the transmitted field. We have the following result that is proved in Appendix B.

PROPOSITION 4.2. *We introduce the joint moments of elements of the reflection matrix at two nearby frequencies along with a pair of elements of the transmission matrix:*

$$
\begin{aligned}
(4.3)\quad \mathcal{U}^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z;j_1,j_2) = \mathbb{E}\Bigg[&\mathcal{T}^{\varepsilon}_{j_1l_1}(\omega+\varepsilon^2h/2,z)\overline{\mathcal{T}^{\varepsilon}_{j_2l_2}(\omega-\varepsilon^2h/2,z)}\\
&\times\prod_{(j,l)\in\mathbf{p}}\mathcal{R}^{\varepsilon}_{jl}(\omega+\varepsilon^2h/2,z)\prod_{(m,n)\in\mathbf{q}}\overline{\mathcal{R}^{\varepsilon}_{mn}(\omega-\varepsilon^2h/2,z)}\Bigg]
\end{aligned}
$$

for $\mathbf{t}=(l_1,l_2)$*. The family of Fourier transforms*

$$
(4.4)\qquad \mathcal{W}^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2) = \frac{1}{2\pi}\int e^{-ih[\tau-\phi_{\mathbf{p},\mathbf{q}}(\omega)z]}\mathcal{U}^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z;j_1,j_2)\,dh
$$

converges as $\varepsilon\to0$ *to the solution* $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ *of the system of transport equations*

$$
(4.5)\qquad \frac{\partial\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)\frac{\partial\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}}{\partial\tau} = D^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} + \big[\mathcal{S}_\omega(\mathcal{W})\big]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} + \big[\mathcal{Z}_\omega(\mathcal{W})\big]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}},
$$

with the initial conditions $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z=0;j_1,j_2) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\mathbf{1}_{j_1}(l_1)\mathbf{1}_{j_2}(l_2)\delta(\tau)$. *The coefficient* $\phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)$ *is given by*

$$\phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega) = \phi_{\mathbf{p},\mathbf{q}}(\omega) + \frac{\beta'_{l_1}(\omega)+\beta'_{l_2}(\omega)}{2}. \tag{4.6}$$

This generalized set of transport equations describes accurately the transmitted wave field and is the key tool in analyzing various applications with wave propagation in random waveguides. The corresponding transport equations in the layered case are presented in [5].

4.3. Interpretation of the transmission transport equations. We make the following observations regarding the system of transport equations.

(1) By integrating the solution of the system of transport equations in τ, it is straightforward to see that the integral quantity is the solution of the system (4.2). This shows that we have

$$\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,z;j_1,j_2) = \int \mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2)\,d\tau. \tag{4.7}$$

Therefore, the following remarks stated in terms of the family $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ hold true for the family of moments $\mathcal{M}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ as well.

(2) Consider the set of moments $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ such that $|\mathbf{p}|-|\mathbf{q}|=c$ with c a nonzero integer. These moments form a closed subfamily with each member satisfying a zero initial condition. Therefore, these moments vanish, and again only moments having the same number of conjugated and unconjugated terms survive in the small ε limit.

(3) Consider the case (3.13) when $C_{jl}\equiv 0$ for $j\neq l$, as described under (3) in section 3.3. Recall that this corresponds to the situation where modes with different modal wavenumbers are not coupled, which is the case particularly when the inhomogeneities of the waveguide do not have lateral variations. The analysis of the system in (4.2) then shows that the solution has the form

$$\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2) = W^{(1)}_{p_1} * \cdots * W^{(l-1)}_{p_{l-1}} * V^{(l)}_{p_l} * W^{(l+1)}_{p_{l+1}} * \cdots * W^{(N)}_{p_N}(\omega,\tau,z)$$

if $\mathbf{t}=(j_1,j_2)=(l,l)$ and $\mathbf{p}=\mathbf{q}=\{(1,1)^{p_1},\dots,(N,N)^{p_N}\}$, and $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2)=0$ otherwise. For each j, $(W^{(j)}_p)_{p\in\mathbb{N}}$ is given by (3.16) and for each l, $(V^{(l)}_p)_{p\in\mathbb{N}}$ is the solution of the closed system of transport equations

$$\frac{\partial V^{(l)}_p}{\partial z} + (2p+1)\beta'_l(\omega)\frac{\partial V^{(l)}_p}{\partial \tau} = 2\Re\big[\Gamma^{(0)}_l(\omega)\big]\Big[(p+1)^2(V^{(l)}_{p+1}-V^{(l)}_p) + p^2(V^{(l)}_{p-1}-V^{(l)}_p)\Big],$$

with the initial conditions $V^{(l)}_p(\omega,\tau,z=0)=\mathbf{1}_0(p)\delta(\tau)$. We therefore obtain that the backward and forward jth modes are uncoupled from the other modes, but they are coupled together according to the system that governs the propagation of one-dimensional waves in random media [1].

4.4. Forward scattering approximation. To contrast with the fully coupled case discussed above, we address in this section the forward scattering approximation analyzed in detail in [5, 7]. As shown above, this approximation is valid when Γ is zero or very small (in the sense that $\Re(\Gamma)L \ll 1$). The system of transport equations of Proposition 4.2 can be dramatically simplified, since only the terms $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ with $\mathbf{p}=\mathbf{q}=\emptyset$ contribute at the leading order, and these terms satisfy a closed system of transport equations as described in the following proposition.

Proposition 4.3. *If $\Gamma(\omega) = \mathbf{0}$, then the (transformed) autocorrelation function of the transmission coefficients at two nearby frequencies,*

$$\mathcal{V}_{jl}^{\varepsilon}(\omega, \tau, z) = \frac{1}{2\pi} \int e^{-ih[\tau - \beta_l'(\omega) z]} \mathbb{E}\left[\mathcal{T}_{jl}^{\varepsilon}(\omega + \varepsilon^2 h/2, z) \overline{\mathcal{T}_{jl}^{\varepsilon}(\omega - \varepsilon^2 h/2, z)} \right] dh,$$

has a limit as $\varepsilon \to 0$:

$$\lim_{\varepsilon \to 0} \mathcal{V}_{jl}^{\varepsilon}(\omega, \tau, z) = \mathcal{V}_{jl}(\omega, \tau, z).$$

For any fixed $l \in \{1, \ldots, N(\omega)\}$, the subfamily $(\mathcal{V}_{jl}(\omega, \tau, z))_{j=1,\ldots,N(\omega)}$ is the solution of the system of transport equations

$$\frac{\partial \mathcal{V}_{jl}}{\partial z} + \beta_j'(\omega) \frac{\partial \mathcal{V}_{jl}}{\partial \tau} = \sum_{n \neq j} 2\Re\big[\widetilde{\Gamma}_{jn}(\omega)\big] \left(\mathcal{V}_{nl} - \mathcal{V}_{jl}\right), \tag{4.8}$$

with the initial conditions $\mathcal{V}_{jl}(\omega, \tau, z = 0) = \delta(\tau) \mathbf{1}_l(j)$. Here $\widetilde{\Gamma}(\omega)$ is given by (3.4).

Let us introduce the mean transmitted power of the mode j when the input wave is a mode l:

$$\mathcal{P}_{jl}^{(t)}(\omega, z) = \mathcal{M}_{\emptyset,\emptyset}^{(l,l)}(\omega, \tau, z; j, j) = \lim_{\varepsilon \to 0} \mathbb{E}\left[|\mathcal{T}_{jl}^{\varepsilon}(\omega, z)|^2 \right].$$

The next proposition shows the equipartition of energy of the transmitted wave.

Proposition 4.4. *If $\Gamma(\omega) = \mathbf{0}$, then the mean transmitted powers converge to the uniform distribution, that is,*

$$\mathcal{P}_{jl}^{(t)}(\omega, z) \overset{z \to \infty}{\longrightarrow} \frac{1}{N(\omega)},$$

uniformly in j, l and exponentially in z.

Proof. By integrating (4.8) in τ, we get that, for any fixed l, the subfamily $(\mathcal{P}_{jl}^{(t)}(\omega, z))_{j=1,\ldots,N(\omega)}$ is the solution of the linear system

$$\frac{\partial \mathcal{P}_{jl}^{(t)}}{\partial z} = \sum_{n=1}^{N(\omega)} \mathcal{L}_{jn}^{(t)}(\omega) \mathcal{P}_{nl}^{(t)}, \tag{4.9}$$

starting from $\mathcal{P}_{jl}^{(t)}(\omega, z = 0) = \mathbf{1}_l(j)$. Here $\mathcal{L}^{(t)}(\omega)$ is the $N(\omega) \times N(\omega)$ matrix

$$\mathcal{L}_{jn}^{(t)}(\omega) = \begin{cases} 2\Re\big[\widetilde{\Gamma}_{jn}(\omega)\big] & \text{if } j \neq n, \\ -2 \sum_{m \neq j} 2\Re\big[\widetilde{\Gamma}_{jm}(\omega)\big] & \text{if } j = n. \end{cases}$$

Using the positivity of the coefficients $\Re[\widetilde{\Gamma}_{jn}]$ and the Perron–Frobenius theorem, we find that the matrix $\mathcal{L}^{(t)}$ has zero as an isolated eigenvalue, and all other eigenvalues are negative. It is straightforward to check that the eigenvector corresponding to the zero eigenvalue is the uniform vector, which establishes the proposition. □

Appendix A. Derivation of channel reflection-transport equations.

A.1. Propagator equations. We prove here Proposition 3.2. Note first that we can write the first equation in (2.18) in the form

$$\frac{d}{dz} \boldsymbol{\mathcal{R}}^{\varepsilon} = -\boldsymbol{\Phi}^{\varepsilon} \overline{\mathbf{H}^{a,\varepsilon}} + \boldsymbol{\mathcal{R}}^{\varepsilon} \overline{\boldsymbol{\Phi}^{\varepsilon}} \mathbf{H}^{a,\varepsilon} \boldsymbol{\mathcal{R}}^{\varepsilon} + \mathbf{H}^{a,\varepsilon} \boldsymbol{\mathcal{R}}^{\varepsilon} - \boldsymbol{\mathcal{R}}^{\varepsilon} \overline{\mathbf{H}^{a,\varepsilon}}, \tag{A.1}$$

where $\mathbf{\Phi}^\varepsilon(\omega, z)$ is the $N(\omega) \times N(\omega)$ diagonal matrix with diagonal entries:

$$\Phi^\varepsilon_{jj}(\omega, z) = e^{-2i\beta_j(\omega)z/\varepsilon^2}.$$

Our objective is now to compute cross moments of reflection matrix entries using diffusion approximation, and we remark that the phase factors in $\mathbf{\Phi}^\varepsilon$ then act as decoupling terms, decoupling the entries in (A.1). We introduce the quantities $U^\varepsilon_{\mathbf{p},\mathbf{q}}$ that give high-order products of elements $\mathcal{R}^\varepsilon_{jl}$ of the reflection matrix at two nearby frequencies:

$$U^\varepsilon_{\mathbf{p},\mathbf{q}}(\omega, h, z) = \prod_{(j,l)\in\mathbf{p}} \mathcal{R}^\varepsilon_{jl}(\omega + \varepsilon^2 h/2, z) \prod_{(m,n)\in\mathbf{q}} \overline{\mathcal{R}^\varepsilon_{mn}(\omega - \varepsilon^2 h/2, z)}. \tag{A.2}$$

It now follows from (2.18) that the $U^\varepsilon_{\mathbf{p},\mathbf{q}}$'s solve evolution equations of the form

$$\frac{\partial U^\varepsilon_{\mathbf{p},\mathbf{q}}}{\partial z} = \left[\mathcal{H}^\varepsilon_U(U^\varepsilon)\right]_{\mathbf{p},\mathbf{q}}. \tag{A.3}$$

Here $\left[\mathcal{H}^\varepsilon_U(U^\varepsilon)\right]_{\mathbf{p},\mathbf{q}}$ is a finite sum of $U^\varepsilon_{\mathbf{p}^{(1)},\mathbf{q}^{(1)}}, \dots, U^\varepsilon_{\mathbf{p}^{(m)},\mathbf{q}^{(m)}}$, where the multi-indices $\mathbf{p}^{(1)}, \mathbf{q}^{(1)}, \dots, \mathbf{p}^{(N)}, \mathbf{q}^{(N)}$ are obtained from $\mathbf{p}$ and $\mathbf{q}$ by one or two replacements. We have explicitly

$$\begin{aligned}\left[\mathcal{H}^\varepsilon_U(U^\varepsilon)\right]_{\mathbf{p},\mathbf{q}} = &\sum_{(j,l)\in\mathbf{p}} U^\varepsilon_{\mathbf{p}|(j,l),\mathbf{q}} \\ &\times \left\{ H^{b,\varepsilon}_{jl} - \sum_{k_1,k_2=1}^{N} \mathcal{R}^\varepsilon_{jk_1} \overline{H^{b,\varepsilon}_{k_1k_2}} \mathcal{R}^\varepsilon_{k_2l} + \sum_{k=1}^{N} \left[H^{a,\varepsilon}_{jk} \mathcal{R}^\varepsilon_{kl} - \mathcal{R}^\varepsilon_{jk} \overline{H^{a,\varepsilon}_{kl}} \right] \right\}_{\omega+h\varepsilon^2/2} \\ &\quad + \sum_{(j,l)\in\mathbf{q}} U^\varepsilon_{\mathbf{p},\mathbf{q}|(j,l)} \\ &\overline{\times \left\{ H^{b,\varepsilon}_{jl} - \sum_{k_1,k_2=1}^{N} \mathcal{R}^\varepsilon_{jk_1} \overline{H^{b,\varepsilon}_{k_1k_2}} \mathcal{R}^\varepsilon_{k_2l} + \sum_{k=1}^{N} \left[H^{a,\varepsilon}_{jk} \mathcal{R}^\varepsilon_{kl} - \mathcal{R}^\varepsilon_{jk} \overline{H^{a,\varepsilon}_{kl}} \right] \right\}}_{\omega-h\varepsilon^2/2},\end{aligned}$$

which can also be written as

$$\begin{aligned}\left[\mathcal{H}^\varepsilon_U(U^\varepsilon)\right]_{\mathbf{p},\mathbf{q}} = &\sum_{(j,l)\in\mathbf{p}} \Bigg\{ H^{b,\varepsilon}_{jl} U^\varepsilon_{\mathbf{p}|(j,l),\mathbf{q}} - \sum_{k_1,k_2=1}^{N} \overline{H^{b,\varepsilon}_{k_1k_2}} U^\varepsilon_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}} \\ &+ \sum_{k=1}^{N} \left[H^{a,\varepsilon}_{jk} U^\varepsilon_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}} - \overline{H^{a,\varepsilon}_{kl}} U^\varepsilon_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}} \right] \Bigg\}_{\omega+h\varepsilon^2/2} \\ &+ \sum_{(j,l)\in\mathbf{q}} \Bigg\{ \overline{H^{b,\varepsilon}_{jl}} U^\varepsilon_{\mathbf{p},\mathbf{q}|(j,l)} - \sum_{k_1,k_2=1}^{N} H^{b,\varepsilon}_{k_1k_2} U^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}} \\ &+ \sum_{k=1}^{N} \left[\overline{H^{a,\varepsilon}_{jk}} U^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(k,l)\}} - H^{a,\varepsilon}_{kl} U^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k)\}} \right] \Bigg\}_{\omega-h\varepsilon^2/2}.\end{aligned} \tag{A.4}$$

Next we observe that

$$
\begin{aligned}
H_{jl}^{a,\varepsilon}\,|_{\omega\pm\varepsilon^2 h/2} &\sim \alpha_{jl}^{\varepsilon}\,(\omega,h,z)\, e^{i(\beta_l(\omega)-\beta_j(\omega))z/\varepsilon^2} e^{\pm i(\beta_l'(\omega)-\beta_j'(\omega))zh/2}\\
&\equiv \alpha_{jl}^{\pm,\varepsilon}\,(\omega,h,z)\, e^{i(\beta_l(\omega)-\beta_j(\omega))z/\varepsilon^2},\\
H_{jl}^{b,\varepsilon}\,|_{\omega\pm\varepsilon^2 h/2} &\sim -\overline{\alpha_{jl}^{\varepsilon}\,(\omega,h,z)} e^{-i(\beta_l(\omega)+\beta_j(\omega))z/\varepsilon^2} e^{\mp i(\beta_l'(\omega)+\beta_j'(\omega))zh/2}\\
&\equiv \widetilde{\alpha}_{jl}^{\pm,\varepsilon}\,(\omega,h,z)\, e^{-i(\beta_l(\omega)+\beta_j(\omega))z/\varepsilon^2}
\end{aligned}
$$

as $\varepsilon \to 0$ for

$$
\begin{aligned}
\alpha_{jl}^{\varepsilon}(\omega,h,z) &= \frac{ik^2(\omega)}{2\varepsilon}\frac{C_{jl}\left(\frac{z}{\varepsilon^2}\right)}{\sqrt{\beta_j\beta_l(\omega)}}\\
&\quad + \frac{ik^4(\omega)}{4}\sum_{l'>N(\omega)}\int_{-\infty}^{\infty}\frac{C_{jl'}\left(\frac{z}{\varepsilon^2}\right)C_{ll'}\left(\frac{z}{\varepsilon^2}+s\right)}{\sqrt{\beta_j\beta_{l'}^2\beta_l(\omega)}} e^{i\beta_l(\omega)s-\beta_{l'}(\omega)|s|}\,ds.
\end{aligned}
$$

Using this notation, we get from (A.4)

$$
\begin{aligned}
\left[\mathcal{H}_U^{\varepsilon}(U^{\varepsilon})\right]_{\mathbf{p},\mathbf{q}} = \sum_{(j,l)\in\mathbf{p}} &\left\{\widetilde{\alpha}_{jl}^{+,\varepsilon} U^{\varepsilon}_{\mathbf{p}|(j,l),\mathbf{q}} e^{-i(\beta_l+\beta_j)z/\varepsilon^2}\right.\\
&+\sum_{k=1}^{N}\left[\alpha_{jk}^{+,\varepsilon}U^{\varepsilon}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}}e^{i(\beta_k-\beta_j)z/\varepsilon^2} - \overline{\alpha_{kl}^{+,\varepsilon}}U^{\varepsilon}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}}e^{i(\beta_k-\beta_l)z/\varepsilon^2}\right]\\
&\left.-\sum_{k_1,k_2=1}^{N}\overline{\widetilde{\alpha}_{k_1k_2}^{+,\varepsilon}}U^{\varepsilon}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}}e^{i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2}\right\}\\
&\qquad + \sum_{(j,l)\in\mathbf{q}}\left\{\overline{\widetilde{\alpha}_{jl}^{-,\varepsilon}}U^{\varepsilon}_{\mathbf{p},\mathbf{q}|(j,l)}e^{i(\beta_j+\beta_l)z/\varepsilon^2}\right.\\
&+\sum_{k=1}^{N}\left[\overline{\alpha_{jk}^{-,\varepsilon}}U^{\varepsilon}_{\mathbf{p},\mathbf{q}|\{(j,l)|(k,l)\}}e^{i(\beta_j-\beta_k)z/\varepsilon^2} - \alpha_{kl}^{-,\varepsilon}U^{\varepsilon}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k)\}}e^{i(\beta_l-\beta_k)z/\varepsilon^2}\right]\\
&\left.-\sum_{k_1,k_2=1}^{N}\widetilde{\alpha}_{k_1k_2}^{-,\varepsilon}U^{\varepsilon}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}}e^{-i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2}\right\},
\end{aligned}
\tag{A.5}
$$

where the β_j's are evaluated at ω.

A.2. The homogeneous propagator equations. In order the eliminate the h-dependence in the coefficients of (A.5), we now introduce the transformation

$$
V^{\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z) = \frac{1}{2\pi}\int e^{-ih[\tau-\phi_{\mathbf{p},\mathbf{q}}(\omega)z]}U^{\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z)\,dh,
\tag{A.6}
$$

where $\phi_{\mathbf{p},\mathbf{q}}(\omega)$ is given by (3.11). We then obtain from (A.5) that V^{ε} solves the infinite-dimensional system of partial differential equations

$$
\frac{\partial V^{\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi_{\mathbf{p},\mathbf{q}}(\omega)\frac{\partial V^{\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial \tau} = \left[\mathcal{H}_V^{\varepsilon}(V^{\varepsilon})\right]_{\mathbf{p},\mathbf{q}},
$$

with the initial conditions $V^{\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z=0) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\delta(\tau)$. The source term now has the form

$$\begin{aligned}\big[\mathcal{H}^\varepsilon_V(V^\varepsilon)\big]_{\mathbf{p},\mathbf{q}} = \sum_{(j,l)\in\mathbf{p}} \Bigg\{ & -\overline{\alpha^\varepsilon_{jl}} V^\varepsilon_{\mathbf{p}|(j,l),\mathbf{q}} e^{-i(\beta_j+\beta_l)z/\varepsilon^2} \\ & + \sum_{k_1,k_2=1}^{N} \alpha^\varepsilon_{k_1k_2} V^\varepsilon_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}} e^{i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2} \\ & + \sum_{k=1}^{N} \alpha^\varepsilon_{jk} V^\varepsilon_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}} e^{i(\beta_k-\beta_j)z/\varepsilon^2} \\ & - \sum_{k=1}^{N} \overline{\alpha^\varepsilon_{kl}} V^\varepsilon_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}} e^{i(\beta_k-\beta_l)z/\varepsilon^2} \Bigg\} \\ + \sum_{(j,l)\in\mathbf{q}} \Bigg\{ & -\alpha^\varepsilon_{jl} V^\varepsilon_{\mathbf{p},\mathbf{q}|(j,l)} e^{i(\beta_j+\beta_l)z/\varepsilon^2} \\ & + \sum_{k_1,k_2=1}^{N} \overline{\alpha^\varepsilon_{k_1k_2}} V^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}} e^{-i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2} \\ & + \sum_{k=1}^{N} \overline{\alpha^\varepsilon_{jk}} V^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(k,l)\}} e^{i(\beta_j-\beta_k)z/\varepsilon^2} \\ & - \sum_{k=1}^{N} \alpha^\varepsilon_{kl} V^\varepsilon_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k)\}} e^{i(\beta_l-\beta_k)z/\varepsilon^2} \Bigg\}, \end{aligned} \tag{A.7}$$

where the β_j's are evaluated at ω.

A.3. Transport equations. We next apply the diffusion approximation to get transport equations for the moments; see [5] for background material on and related to applications of the diffusion approximation theory. Observe that the function $\mathcal{H}^\varepsilon_V$ is linear and the random coefficients are rapidly fluctuating. Those coefficients whose amplitudes are of order ε^{-1} are centered and fluctuate on the scale ε^2; moreover, they are assumed to be rapidly mixing, giving a white-noise scaling situation. We can thus apply diffusion approximation results to obtain transport equations for the moments $\mathbb{E}[V^\varepsilon_{\mathbf{p},\mathbf{q}}]$ in the limit $\varepsilon \to 0$:

$$\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z) = \lim_{\varepsilon\to 0} \mathbb{E}[V^\varepsilon_{\mathbf{p},\mathbf{q}}(\omega,\tau,z)].$$

We then obtain from (A.7) that $\mathcal{W}_{\mathbf{p},\mathbf{q}}$ solves the infinite-dimensional system of partial differential equations

$$\frac{\partial \mathcal{W}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi_{\mathbf{p},\mathbf{q}}(\omega) \frac{\partial \mathcal{W}_{\mathbf{p},\mathbf{q}}}{\partial \tau} = i\Big[\sum_{(j,l)\in\mathbf{p}} \big(\kappa_j+\kappa_l\big) - \sum_{(j,l)\in\mathbf{q}} \big(\kappa_j+\kappa_l\big)\Big]\mathcal{W}_{\mathbf{p},\mathbf{q}} + \big[\mathcal{H}(\mathcal{W})\big]_{\mathbf{p},\mathbf{q}},$$

with the initial conditions $\mathcal{W}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z=0) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\delta(\tau)$, and where we defined $\kappa_l(\omega)$ (which is real) by (3.6). The source term now takes the form

$$\big[\mathcal{H}(\mathcal{W})\big]_{\mathbf{p},\mathbf{q}} = \sum_{k=1}^{6} \mathcal{I}_k, \tag{A.8}$$

and we next identify the coupling terms $\mathcal{I}_k$. We remark that in applying the diffusion approximation there is no coupling between terms that contain phase modulation of the type $\exp[i(\beta_j-\beta_l)z/\varepsilon^2]$ with terms that contain phase modulation of the type $\exp[i(\beta_m+\beta_n)z/\varepsilon^2]$ since the rapid phases then cannot cancel. There are eight terms in the expression for $\mathcal{H}_V^\varepsilon$ in (A.7); we label the first four associated with the multi-index $\mathbf{p}$ by $1_p, \dots, 4_p$ and the last by four by $1_q, \dots, 4_q$. First we consider the cross interaction of the terms 1_p and 2_p and also the corresponding combination 1_q and 2_q that is associated with complex conjugate coefficients. We label their contribution by the term $\mathcal{I}_1$, which is given by

$$\begin{aligned}\mathcal{I}_1 = &- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} 2\Re\big(\Gamma_{jl}\big)\Big(\mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(l,\tilde{l})\},\mathbf{q}} + \mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\},\mathbf{q}}\mathbf{1}_{j\neq l}\Big)\\ &- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} 2\Re\big(\Gamma_{\tilde{j}\tilde{l}}\big)\Big(\mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(\tilde{l},l)\},\mathbf{q}} + \mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(l,\tilde{j}),(\tilde{l},j)\},\mathbf{q}}\mathbf{1}_{\tilde{j}\neq\tilde{l}}\Big)\\ &- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} 2\Re\big(\Gamma_{jl}\big)\Big(\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},j),(l,\tilde{l})\}} + \mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\}}\mathbf{1}_{j\neq l}\Big)\\ &- \sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} 2\Re\big(\Gamma_{\tilde{j}\tilde{l}}\big)\Big(\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(j,\tilde{j}),(\tilde{l},l)\}} + \mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(l,\tilde{j}),(\tilde{l},j)\}}\mathbf{1}_{\tilde{j}\neq\tilde{l}}\Big)\\ &- \sum_{(j,l)\in\mathbf{p}}\sum_{k=1}^{N}\left(\Gamma_{jk}+\Gamma_{lk}\right)\mathcal{W}_{\mathbf{p},\mathbf{q}} - \sum_{(j,l)\in\mathbf{q}}\sum_{k=1}^{N}\left(\overline{\Gamma_{jk}}+\overline{\Gamma_{lk}}\right)\mathcal{W}_{\mathbf{p},\mathbf{q}},\end{aligned}$$

where Γ is defined by (3.5).

Next we consider the cross interaction of the terms 1_p and 2_p with the terms 1_q and 2_q. We label their contribution by the term $\mathcal{I}_2$, which is given by

$$\begin{aligned}\mathcal{I}_2 = &\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} 2\Re\big(\Gamma_{jl}\big)\mathcal{W}_{\mathbf{p}|(j,l),\mathbf{q}|(\tilde{j},\tilde{l})}\mathbf{1}_{(j,l)\cong(\tilde{j},\tilde{l})}\\ &+ \sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\sum_{k_1,k_2=1}^{N} 2\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k_1),(k_2,\tilde{l})\}}\\ &+ \sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\sum_{k_1,k_2=1}^{N} 2\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k_2),(k_1,\tilde{l})\}}\mathbf{1}_{k_1\neq k_2},\end{aligned}$$

where $(j,l) \cong (\tilde{j},\tilde{l})$ if $(j,l) = (\tilde{j},\tilde{l})$ or $(j,l) = (\tilde{l},\tilde{j})$.

We have completed the analysis of the terms associated with phase modulation of the form $\exp[i(\beta_j+\beta_l)z/\varepsilon^2]$ and consider now terms associated with phases of the form $\exp[i(\beta_j-\beta_l)z/\varepsilon^2]$. Consider first the interaction of the terms 3_p, 4_p, 3_q, and 4_q with themselves. We label this contribution by $\mathcal{I}_3$, which is given by

$$\begin{aligned}\mathcal{I}_3 = &-\Big\{2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}}\Big[\check{\Gamma}_{j\tilde{j}}+\check{\Gamma}_{l\tilde{l}}\Big] + \sum_{(j,l)\in\mathbf{p}}\sum_{k=1}^{N}\Big[\overline{\widetilde{\Gamma}_{jk}}+\overline{\widetilde{\Gamma}_{lk}}\Big]\Big\}\mathcal{W}_{\mathbf{p},\mathbf{q}}\\ &- 2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}}\Big[\mathbf{1}_{j\neq\tilde{j}}\Re\big(\widetilde{\Gamma}_{j\tilde{j}}\big)+\mathbf{1}_{l\neq\tilde{l}}\Re\big(\widetilde{\Gamma}_{l\tilde{l}}\big)\Big]\,\mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\},\mathbf{q}}\\ &-\Big\{2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}}\Big[\check{\Gamma}_{j\tilde{j}}+\check{\Gamma}_{l\tilde{l}}\Big] + \sum_{(j,l)\in\mathbf{q}}\sum_{k=1}^{N}\Big[\widetilde{\Gamma}_{jk}+\widetilde{\Gamma}_{lk}\Big]\Big\}\mathcal{W}_{\mathbf{p},\mathbf{q}}\\ &- 2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}}\Big[\mathbf{1}_{j\neq\tilde{j}}\Re\big(\widetilde{\Gamma}_{j\tilde{j}}\big)+\mathbf{1}_{l\neq\tilde{l}}\Re\big(\widetilde{\Gamma}_{l\tilde{l}}\big)\Big]\,\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{j},l),(j,\tilde{l})\}},\end{aligned}$$

where $\check{\Gamma}$ and $\widetilde{\Gamma}$ are defined by (3.3)–(3.4).

Next, we deal with the cross interaction between the terms 3_p and 4_p and correspondingly between 3_q and 4_q. We label this contribution by $\mathcal{I}_4$ and obtain

$$\begin{aligned}\mathcal{I}_4 = &-\Big\{\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{p}} 2\check{\Gamma}_{j\tilde{l}}\Big\}\mathcal{W}_{\mathbf{p},\mathbf{q}} - \sum_{(j,l)\in\mathbf{p}} 2\Re\big(\widetilde{\Gamma}_{jl}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(l,j)\},\mathbf{q}}\mathbf{1}_{j\neq l}\\
&-2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} \Re\big(\widetilde{\Gamma}_{j\tilde{l}}\big)\mathbf{1}_{j\neq\tilde{l}}\mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{l},l),(\tilde{j},j)\},\mathbf{q}}\\
&-2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{p}} \Re\big(\widetilde{\Gamma}_{\tilde{j}l}\big)\mathbf{1}_{\tilde{j}\neq l}\mathcal{W}_{\mathbf{p}|\{(j,l),(\tilde{j},\tilde{l})|(l,\tilde{l}),(j,\tilde{j})\},\mathbf{q}}\\
&-\Big\{\sum_{(j,l)\in\mathbf{q}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}} 2\check{\Gamma}_{j\tilde{l}}\Big\}\mathcal{W}_{\mathbf{p},\mathbf{q}} - \sum_{(j,l)\in\mathbf{q}} 2\Re\big(\widetilde{\Gamma}_{jl}\big)\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l,j)\}}\mathbf{1}_{j\neq l}\\
&-2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} \Re\big(\widetilde{\Gamma}_{j\tilde{l}}\big)\mathbf{1}_{j\neq\tilde{l}}\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(\tilde{l},l),(\tilde{j},j)\}}\\
&-2\sum_{\{(j,l),(\tilde{j},\tilde{l})\}\in\mathbf{q}} \Re\big(\widetilde{\Gamma}_{\tilde{j}l}\big)\mathbf{1}_{\tilde{j}\neq l}\mathcal{W}_{\mathbf{p},\mathbf{q}|\{(j,l),(\tilde{j},\tilde{l})|(l,\tilde{l}),(j,\tilde{j})\}}.\end{aligned}$$

Now we consider the cross interaction between the terms 3_p and 3_q and correspondingly between 4_p and 4_q. We label this contribution by $\mathcal{I}_5$ and obtain

$$\begin{aligned}\mathcal{I}_5 = &\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\left[2\check{\Gamma}_{\tilde{j}j}\mathcal{W}_{\mathbf{p},\mathbf{q}} + \sum_{k=1\neq j}^{N} 2\Re\left[\widetilde{\Gamma}_{jk}\right]\mathcal{W}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(k,\tilde{l})\}}\mathbf{1}_{j=\tilde{j}}\right]\\
&+\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\left[2\check{\Gamma}_{\tilde{l}l}\mathcal{W}_{\mathbf{p},\mathbf{q}} + \sum_{k=1\neq l}^{N} 2\Re\big(\widetilde{\Gamma}_{lk}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k)\}}\mathbf{1}_{l=\tilde{l}}\right].\end{aligned}$$

Finally, we analyze the cross interaction between the terms 3_p and 4_q and correspondingly between 4_p and 3_q. We label this contribution by $\mathcal{I}_6$ and obtain

$$\begin{aligned}\mathcal{I}_6 = &\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\left[2\check{\Gamma}_{j\tilde{l}}\mathcal{W}_{\mathbf{p},\mathbf{q}} + \sum_{k=1\neq j}^{N} 2\Re\big(\widetilde{\Gamma}_{jk}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(\tilde{j},k)\}}\mathbf{1}_{j=\tilde{l}}\right]\\
&+\sum_{(j,l)\in\mathbf{p}}\sum_{(\tilde{j},\tilde{l})\in\mathbf{q}}\left[2\check{\Gamma}_{l\tilde{j}}\mathcal{W}_{\mathbf{p},\mathbf{q}} + \sum_{k=1\neq l}^{N} 2\Re\big(\widetilde{\Gamma}_{lk}\big)\mathcal{W}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}|\{(\tilde{j},\tilde{l})|(k,\tilde{l})\}}\mathbf{1}_{l=\tilde{j}}\right].\end{aligned}$$

We can now assemble the terms in the source term $\mathcal{H}$ for the transport equation, and this completes the proof of Proposition 3.2.

Appendix B. Derivation of channel transmission-transport equations. We consider next the wave field that has been transmitted through the waveguide and develop a family of transport equations that generalize those we derived above for the characterization of the reflected field. The transmitted field can be characterized by the transmission operator in (2.17). Recall that the transmission and reflection matrices solve (2.18). In order to obtain a closed system of transport equations, we introduce the quantities

$$U^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z;j_1,j_2) = \mathcal{T}^{\varepsilon}_{j_1l_1}(\omega+\varepsilon^2h/2,z)\overline{\mathcal{T}^{\varepsilon}_{j_2l_2}(\omega-\varepsilon^2h/2,z)}U^{\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z)$$

for $\mathbf{t} = (l_1, l_2)$. Then we find, using (A.3),

$$\begin{aligned}\frac{\partial U^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial z} &= \left[\mathcal{H}^\varepsilon_U(U^{\mathbf{t},\varepsilon})\right]_{\mathbf{p},\mathbf{q}} \\ &\quad - U^\varepsilon_{\mathbf{p},\mathbf{q}}\left\{\overline{\mathcal{T}^\varepsilon_{j_2 l_2}}\right\}_{\omega-h\varepsilon^2/2}\left\{\sum_{k_1=1}^N \mathcal{T}^\varepsilon_{j_1k_1}\left(\overline{H^{a,\varepsilon}_{k_1l_1}}+\sum_{k_2=1}^N \overline{H^{b,\varepsilon}_{k_1k_2}}\mathcal{R}^\varepsilon_{k_2l_1}\right)\right\}_{\omega+h\varepsilon^2/2} \\ &\quad - U^\varepsilon_{\mathbf{p},\mathbf{q}}\left\{\mathcal{T}^\varepsilon_{j_1 l_1}\right\}_{\omega+h\varepsilon^2/2}\left\{\sum_{k_1=1}^N \overline{\mathcal{T}^\varepsilon_{j_2k_1}}\left(H^{a,\varepsilon}_{k_1l_2}+\sum_{k_2=1}^N H^{b,\varepsilon}_{k_1k_2}\overline{\mathcal{R}^\varepsilon_{k_2l_2}}\right)\right\}_{\omega-h\varepsilon^2/2},\end{aligned}$$

with $\mathcal{H}^\varepsilon_U$ defined in (A.5). We remark that the family of coefficients $U^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega, h, z; j_1, j_2)$ for fixed j_1 and j_2 form a closed subfamily, which allows us to rewrite the previous system as

$$\text{(B.1)}\qquad \frac{\partial U^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial z} = \left[\mathcal{H}^\varepsilon_U(U^{\mathbf{t},\varepsilon})\right]_{\mathbf{p},\mathbf{q}} + \left[\mathcal{H}^{\varepsilon,1}_U(U^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} + \left[\mathcal{H}^{\varepsilon,2}_U(U^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}},$$

$$\left[\mathcal{H}^{\varepsilon,1}_U(U^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = -\sum_{k=1}^N\left(\left\{\overline{H^{a,\varepsilon}_{kl_1}}\right\}_{\omega+h\varepsilon^2/2}U^{(k,l_2),\varepsilon}_{\mathbf{p},\mathbf{q}} + \left\{H^{a,\varepsilon}_{kl_2}\right\}_{\omega-h\varepsilon^2/2}U^{(l_1,k),\varepsilon}_{\mathbf{p},\mathbf{q}}\right),$$

$$\begin{aligned}\left[\mathcal{H}^{\varepsilon,2}_U(U^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = -\sum_{k_1,k_2=1}^N &\left(\left\{\mathcal{R}^\varepsilon_{k_2l_1}\overline{H^{b,\varepsilon}_{k_1k_2}}\right\}_{\omega+h\varepsilon^2/2}U^{(k_1,l_2),\varepsilon}_{\mathbf{p},\mathbf{q}}\right. \\ &\qquad\left. + \left\{\overline{\mathcal{R}^\varepsilon_{k_2l_2}}H^{b,\varepsilon}_{k_1k_2}\right\}_{\omega-h\varepsilon^2/2}U^{(l_1,k_1),\varepsilon}_{\mathbf{p},\mathbf{q}}\right).\end{aligned}$$

B.1. Homogeneous propagator equations in the transmission case. In order the eliminate the h-dependence in the coefficients of (B.1), we introduce the transformation

$$\text{(B.2)}\qquad V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2) = \frac{1}{2\pi}\int e^{-ih[\tau-\phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)z]}U^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,h,z;j_1,j_2)\,dh,$$

with $\phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)$ defined in (4.6). We then obtain from (B.1) that $V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}$ solves the infinite-dimensional system of partial differential equations

$$\text{(B.3)}\qquad \frac{\partial V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)\frac{\partial V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}}{\partial \tau} = \left[\widetilde{\mathcal{H}}^\varepsilon_V(V^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}},$$

with the initial conditions $V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z=0;j_1,j_2) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\mathbf{1}_{j_1}(l_1)\mathbf{1}_{j_2}(l_2)\delta(\tau)$. We decompose the source term as

$$\text{(B.4)}\qquad \widetilde{\mathcal{H}}^\varepsilon_V = \mathcal{H}^\varepsilon_V + \mathcal{H}^{\varepsilon,1}_V + \mathcal{H}^{\varepsilon,2}_V,$$

with $\mathcal{H}^\varepsilon_V$ defined in (A.7) and the specific transmission source terms given by

(B.5)

$$\left[\mathcal{H}^{\varepsilon,1}_V(V^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = -\sum_{k=1}^N\left[\overline{\alpha^\varepsilon_{kl_1}}V^{(k,l_2),\varepsilon}_{\mathbf{p},\mathbf{q}}e^{i(\beta_k-\beta_{l_1})z/\varepsilon^2} + \alpha^\varepsilon_{kl_2}V^{(l_1,k),\varepsilon}_{\mathbf{p},\mathbf{q}}e^{i(\beta_{l_2}-\beta_k)z/\varepsilon^2}\right],$$

$$\begin{aligned}\left[\mathcal{H}^{\varepsilon,2}_V(V^\varepsilon)\right]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = \sum_{k_1,k_2=1}^N &\left[\alpha^\varepsilon_{k_1k_2}V^{(k_1,l_2),\varepsilon}_{\mathbf{p}\cup\{(k_2,l_1)\},\mathbf{q}}e^{i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2}\right. \\ \text{(B.6)}\qquad &\left. + \overline{\alpha^\varepsilon_{k_1k_2}}V^{(l_1,k_1),\varepsilon}_{\mathbf{p},\mathbf{q}\cup\{(k_2,l_2)\}}e^{-i(\beta_{k_1}+\beta_{k_2})z/\varepsilon^2}\right],\end{aligned}$$

where the β_j's are evaluated at ω.

B.2. Transport equations. We now apply the diffusion approximation to get transport equations for the above modified moments that are relevant in the transmission case. That is, we deduce transport equations for the moments $\mathbb{E}[V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}]$ in the limit $\varepsilon \to 0$:

$$\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2) = \lim_{\varepsilon\to 0} \mathbb{E}[V^{\mathbf{t},\varepsilon}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z;j_1,j_2)].$$

We then obtain from (B.3) that $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$ solves the infinite-dimensional system of partial differential equations

$$\frac{\partial \mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}}{\partial z} + \phi^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega)\frac{\partial \mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}}{\partial \tau} = i\Big[\kappa_{l_1} - \kappa_{l_2} + \sum_{(j,l)\in\mathbf{p}}\big(\kappa_j+\kappa_l\big) - \sum_{(j,l)\in\mathbf{q}}\big(\kappa_j+\kappa_l\big)\Big]\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}$$
$$+ \big[\mathcal{H}(\mathcal{W}^{\mathbf{t}})\big]_{\mathbf{p},\mathbf{q}} + \big[\mathcal{H}^1(\mathcal{W})\big]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}},$$

with the initial conditions $\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}(\omega,\tau,z=0;j_1,j_2) = \mathbf{1}_0(|\mathbf{p}|)\mathbf{1}_0(|\mathbf{q}|)\mathbf{1}_{j_1}(l_1)\mathbf{1}_{j_2}(l_2)\delta(\tau)$. The source term $\mathcal{H}$ is defined in (A.8), and the specific transmission source term has the form

$$\big[\mathcal{H}^1(\mathcal{W})\big]^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} = \sum_{k=1}^{4}\widetilde{\mathcal{I}}_k, \tag{B.7}$$

and we next identify the coupling terms $\widetilde{\mathcal{I}}_k$.

First, we consider the terms that correspond to the interaction of the terms $\mathcal{H}^{\varepsilon,1}_V$ in (B.5) with themselves. This contribution is

$$\widetilde{\mathcal{I}}_1 = 2\sum_{k=1}^{N}\Re\big(\widetilde{\Gamma}_{kl_1}\big)\mathcal{W}^{(k,k)}_{\mathbf{p},\mathbf{q}}\mathbf{1}_{l_1=l_2} - \sum_{k=1}^{N}\Big[\widetilde{\Gamma}_{kl_1} + \widetilde{\Gamma}_{l_2k} - 2\check{\Gamma}_{l_1l_2}\Big]\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}}\mathbf{1}_{l_1\neq l_2}.$$

Then, we consider the cross interaction of the terms in $\mathcal{H}^{\varepsilon,2}_V$ in (B.5). This gives the contribution

$$\widetilde{\mathcal{I}}_2 = 2\sum_{k_1,k_2=1}^{N}\Re\big(\Gamma_{k_1k_2}\big)\Big[\mathcal{W}^{(k_1,k_1)}_{\mathbf{p}\cup\{(k_2,l_1)\},\mathbf{q}\cup\{(k_2,l_2)\}} + \mathcal{W}^{(k_2,k_1)}_{\mathbf{p}\cup\{(k_1,l_1)\},\mathbf{q}\cup\{(k_2,l_2)\}}\mathbf{1}_{k_2\neq k_1}\Big].$$

The terms in $\mathcal{H}^{\varepsilon,1}_V$ interact with those in $\mathcal{H}^{\varepsilon}_V$ having phase modulations of the form $\exp[i(\beta_j-\beta_l)z/\varepsilon^2]$, giving the following contribution to the diffusion approximation:

$$\begin{aligned}
\widetilde{\mathcal{I}}_3 = {} & -2\sum_{(j,l)\in\mathbf{p}}\big[\check{\Gamma}_{jl_1}\mathbf{1}_{j\neq l_1} + \check{\Gamma}_{ll_1}\mathbf{1}_{l\neq l_1} - \check{\Gamma}_{jl_2}\mathbf{1}_{j\neq l_2} - \check{\Gamma}_{ll_2}\mathbf{1}_{l\neq l_2}\big]\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} \\
& + 2\sum_{(j,l)\in\mathbf{q}}\big[\check{\Gamma}_{jl_1}\mathbf{1}_{j\neq l_1} + \check{\Gamma}_{ll_1}\mathbf{1}_{l\neq l_1} - \check{\Gamma}_{jl_2}\mathbf{1}_{j\neq l_2} - \check{\Gamma}_{ll_2}\mathbf{1}_{l\neq l_2}\big]\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} \\
& - 2\sum_{(j,l)\in\mathbf{p}}\Big[\Re\big(\widetilde{\Gamma}_{l_1j}\big)\mathcal{W}^{(j,l_2)}_{\mathbf{p}|\{(j,l)|(l_1,l)\},\mathbf{q}} + \Re\big(\widetilde{\Gamma}_{l_1l}\big)\mathcal{W}^{(l,l_2)}_{\mathbf{p}|\{(j,l)|(j,l_1)\},\mathbf{q}}\Big] \\
& + 2\sum_{(j,l)\in\mathbf{q}}\sum_{k=1}^{N}\Big[\Re\big(\widetilde{\Gamma}_{jk}\big)\mathcal{W}^{(k,l_2)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(k,l)\}}\mathbf{1}_{j=l_1} + \Re\big(\widetilde{\Gamma}_{lk}\big)\mathcal{W}^{(k,l_2)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,k)\}}\mathbf{1}_{l=l_1}\Big] \\
& - 2\sum_{(j,l)\in\mathbf{q}}\Big[\Re\big(\widetilde{\Gamma}_{jl_2}\big)\mathcal{W}^{(l_1,j)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l_2,l)\}} + \Re\big(\widetilde{\Gamma}_{ll_2}\big)\mathcal{W}^{(l_1,l)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,l_2)\}}\Big] \\
& + 2\sum_{(j,l)\in\mathbf{p}}\sum_{k=1}^{N}\Big[\Re\big(\widetilde{\Gamma}_{kj}\big)\mathcal{W}^{(l_1,k)}_{\mathbf{p}|\{(j,l)|(k,l)\},\mathbf{q}}\mathbf{1}_{j=l_2} + \Re\big(\widetilde{\Gamma}_{kl}\big)\mathcal{W}^{(l_1,k)}_{\mathbf{p}|\{(j,l)|(j,k)\},\mathbf{q}}\mathbf{1}_{l=l_2}\Big].
\end{aligned}$$

Finally, we consider the cross interaction of the terms in $\mathcal{H}_V^{\varepsilon,2}$ with those in $\mathcal{H}_V^{\varepsilon}$. This gives the contribution

$$\begin{aligned}
\widetilde{\mathcal{I}}_4 = & -\sum_{k=1}^{N}\Gamma_{kl_1}\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} - 2\sum_{(j,l)\in\mathbf{p}}\Re\big(\Gamma_{jl}\big)\Big[\mathcal{W}^{(j,l_2)}_{\mathbf{p}|\{(j,l)|(l,l_1)\},\mathbf{q}} + \mathcal{W}^{(l,l_2)}_{\mathbf{p}|\{(j,l)|(j,l_1)\},\mathbf{q}}\mathbf{1}_{j\neq l}\Big] \\
& -\sum_{k=1}^{N}\overline{\Gamma_{kl_2}}\mathcal{W}^{\mathbf{t}}_{\mathbf{p},\mathbf{q}} - 2\sum_{(j,l)\in\mathbf{q}}\Re\big(\Gamma_{jl}\big)\Big[\mathcal{W}^{(l_1,j)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(l,l_2)\}} + \mathcal{W}^{(l_1,l)}_{\mathbf{p},\mathbf{q}|\{(j,l)|(j,l_2)\}}\mathbf{1}_{j\neq l}\Big] \\
& + 2\sum_{(j,l)\in\mathbf{q}}\sum_{k_1,k_2=1}^{N}\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}^{(k_1,l_2)}_{\mathbf{p}\cup\{(k_2,l_1)\},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}} \\
& + 2\sum_{(j,l)\in\mathbf{q}}\sum_{k_1,k_2=1}^{N}\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}^{(k_2,l_2)}_{\mathbf{p}\cup\{(k_1,l_1)\},\mathbf{q}|\{(j,l)|(j,k_1),(k_2,l)\}}\mathbf{1}_{k_1\neq k_2} \\
& + 2\sum_{(j,l)\in\mathbf{p}}\sum_{k_1,k_2=1}^{N}\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}^{(l_1,k_1)}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}\cup\{(k_2,l_2)\}} \\
& + 2\sum_{(j,l)\in\mathbf{p}}\sum_{k_1,k_2=1}^{N}\Re\big(\Gamma_{k_1k_2}\big)\mathcal{W}^{(l_1,k_2)}_{\mathbf{p}|\{(j,l)|(j,k_1),(k_2,l)\},\mathbf{q}\cup\{(k_1,l_2)\}}\mathbf{1}_{k_1\neq k_2}.
\end{aligned}$$

We can now assemble the terms in the source term $\mathcal{H}^1$ for the transport equation, and this completes the proof of Proposition 4.2.

COMPETITIVE EXCLUSION OF MICROBIAL SPECIES FOR A SINGLE NUTRIENT WITH INTERNAL STORAGE*

SZE-BI HSU† AND TING-HAO HSU†

Dedicated to Professor Hal Smith on the occasion of his 60*th birthday*

Abstract. We study a chemostat model that describes competition between n microbial species for a single-limited resource based on storage. The model incorporates internal resource storage variables that serve the direct connection between species growth and external resource availability. Mathematical analysis for the global dynamics of the model is carried out by using the fluctuating method. It is shown that the competitive exclusion principle holds for the limiting system of the model. The species with the smallest ambient nutrient concentration wins the competition. We extend the result of competitive exclusion in the paper [H. L. Smith and P. Waltmam, *SIAM J. Appl. Math.*, 54 (1994), pp. 1113–1131] from two species to n species.

Key words. chemostat, single-limited resource, competition, competitive exclusion, fluctuating lemma

1. Introduction.

One of the basic hypotheses in the mathematical modeling of competition of microorganisms for a single-limited nutrient in a continuous culture [JM], [HHW], [T], [FS], [AM], [SW2] is that the rate of consumption of the nutrient and the rate of growth of the organism are directly proportional [M]: (rate of growth of organism)= y (rate of consumption of nutrient); y is called the yield constant and is determined over a finite period of time by

$$y = \frac{\text{weight of organism formed}}{\text{weight of the nutrient used}}.$$

In phytoplankton ecology, it has long been known that the yield can vary depending on the growth rate [D], [G1], [G2], [CM], [CN1], [CN2]. Droop [D] was the first to give a variable yield model or so-called *internal storage* model. He proposed the idea that the organism consumes the nutrient and converts the nutrient into internal storage (cell quota). When the internal storage is below the minimum cell quota, the organism ceases to grow. If the cell quota is above the minimum cell quota, then the growth rate increases with the cell quota. Furthermore, the nutrient uptake rate increases with nutrient concentration and decreases with cell quota. The model of growth with one limiting nutrient incorporating these relations has been tested in both constant and fluctuating environments [G3], [NG], [SC]. Thus the variable yield models are well supported experimentally.

In [SW1], the authors studied the competition between two species competing for a single-limited resource with internal storage. They applied the method of a monotone dynamical system [S] to show that the competitive exclusion principle holds.

*Received by the editors August 22, 2007; accepted for publication (in revised form) March 4, 2008; published electronically June 6, 2008. This work was supported by the National Council of Science, Republic of China, NSC 95-2115-M-007-008.

†Department of Mathematics, National Tsing-Hua University, Hsinchu 300, Taiwan (sbhsu@math.nthu.edu.tw, g933245@alumni.nthu.edu.tw).

When the number of species is greater than two, the method of the monotione dynamical system no longer works. In this paper we shall rigorously prove that the competitive exclusion principle also holds for the competition between n microbial species; $n \geq 2$ for a single-limited resource with internal storage. The result is similar to that of the classical simple chemostat model [HHW]: the species with the smallest ambient nutrient concentration wins the competition.

In section 2, we present the mathematical model and state the main results. In section 3 we give the proof of the main theorem. The main tools in the proof are the conservation principle, which allows the reduction of the $(2n+1)$-dimensional system of ordinary differential equations to a $(2n)$-dimensional system; the fluctuating method [HHG, WX], which provides tools to determine the global behavior of the $(2n)$-dimensional reduced system; and finally, results on the asymptotically autonomous system due to Thieme [Th], which show that the $(2n+1)$-dimensional system and the reduced $(2n)$-dimensional system have the same global asymptotic behavior. In section 4, we discuss the updated mathematical models of microorganisms competing for multiple nutrients in phytoplankton ecology. Several open problems are presented for future research.

2. The model and main result. The model of n species, $n \geq 2$, competing for a single-limited resource with internal storage in a chemostat, takes the form

$$\begin{aligned}
&S'(t) = (S^{(0)} - S(t))D - \sum_{i=1}^{n} x_i(t) f_i(S(t), Q_i(t)),\\
&x_i'(t) = [\mu_i(Q_i(t)) - D]x_i(t),\\
&Q_i'(t) = f_i(S(t), Q_i(t)) - \mu_i(Q_i(t))Q_i(t),\\
&S(0) \geq 0,\ x_i(0) > 0,\ Q_i(0) \geq Q_{\min,i}, \quad i = 1, 2, \ldots, n.
\end{aligned} \tag{2.1}$$

Here $S(t)$ denotes the concentration of the external limiting resource in the chemostat at time t, $x_i(t)$ denotes the concentration of species i at time t, $Q_i(t)$ represents the average amount of stored nutrient per cell of species i at time t, $\mu_i(Q_i)$ is the growth rate of species i as a function of cell quota Q_i, $f_i(S, Q_i)$ is the per capita uptake rate of species i as a function of resource concentration S and cell quota Q_i, $S^{(0)}$ is the input concentration, D is the dilution rate of the chemostat, and $Q_{\min,i}$ denotes the threshold cell quota below which no growth of species i occurs. The growth $\mu_i(Q_i)$ takes the forms [D, G1, G2, CN1, CN2]

$$\begin{aligned}
\mu_i(Q_i) &= \mu_{i\infty}\left(1 - \frac{Q_{\min,i}}{Q_i}\right),\\
\mu_i(Q_i) &= \mu_{i\infty}\frac{(Q_i - Q_{\min,i})_+}{K_i + (Q_i - Q_{\min,i})_+},
\end{aligned}$$

where $Q_{\min,i}$ is the minimum cell quota necessary to allow cell division, $(Q_i - Q_{\min,i})_+$ is the positive part of $(Q_i - Q_{\min,i})$, and $\mu_{i\infty}$ is the maximal growth rate of the species. According to Grover [G2],

$$\begin{aligned}
f_i(S, Q_i) &= \rho_i(Q_i)\frac{S}{a_i + S},\\
\rho_i(Q_i) &= \rho_{\max}^{\text{high}} - (\rho_{\max}^{\text{high}} - \rho_{\max}^{\text{low}})\frac{Q_i - Q_{\min,i}}{Q_{\max,i} - Q_{\min,i}},
\end{aligned}$$

where $Q_{\min,i} \le Q_i \le Q_{\max,i}$. Cunningham and Nisbet [CN1, CN2], Klausmeier and Litchman [KL], and Klausmeier, Litchman, and Levin [KLL] took $\rho_i(Q_i)$ to be a constant.

Motivated by these examples, we assumed that $\mu_i(Q_i)$ is defined and continuously differentiable for $Q_i \ge P_i > 0$ and satisfies

$$\mu_i(Q_i) \ge 0,\ \mu_i'(Q_i) > 0 \text{ and continuous for } Q_i \ge P_i,\ \mu_i(P_i) = 0. \tag{2.2}$$

In both examples above, $P_i = Q_{\min,i}$. We assume that $f_i(S, Q_i)$ is continuous differentiable for $S > 0$ and $Q_i \ge P_i$ and satisfies

$$f_i(0, Q_i) = 0,\ \frac{\partial f_i}{\partial S} > 0,\ \frac{\partial f_i}{\partial Q_i} \le 0. \tag{2.3}$$

In particular, $f_i(S, Q_i) > 0$ when $S > 0$.

From (2.2) and (2.3), it follows that $Q_i' \ge 0$ if $Q_i = P_i$ and the interval of Q_i values $[P_i, \infty)$ is positively invariant under the dynamics of (2.1). Therefore, we assume that the initial values satisfy

$$x_i(0) > 0,\ Q_i(0) \ge P_i,\ S(0) \ge 0,\ i = 1, 2, \ldots, n. \tag{2.4}$$

Assume that the equilibrium E takes the form

$$E = (S, x_1, Q_1, \ldots, x_n, Q_n).$$

Then we have the following steady states.

(i) The washout steady state

$$E_0 = (S^{(0)}, 0, Q_1^0, 0, Q_2^0, \ldots, 0, Q_n^0)$$

always exists. Here Q_i^0 is the unique solution of

$$f_i(S^{(0)}, Q_i) - Q_i \mu_i(Q_i) = 0. \tag{2.5}$$

(ii)

$$\begin{aligned}
E_1 &= (\lambda_1, x_1^*, Q_1^*, 0, \hat{Q}_2^1, 0, \hat{Q}_3^1, \ldots, 0, \hat{Q}_n^1),\\
E_2 &= (\lambda_2, 0, \hat{Q}_1^2, x_2^*, Q_2^*, 0, \hat{Q}_3^2, \ldots, 0, \hat{Q}_n^2),\\
&\ \ \vdots\\
E_n &= (\lambda_n, 0, \hat{Q}_1^n, 0, \hat{Q}_2^n, \ldots, 0, \hat{Q}_{n-1}^n, x_n^*, Q_n^*).
\end{aligned}$$

The equilibrium E_i corresponds to the presence of the ith population and the absence of the others. The parameters $\lambda_i, Q_i^*, x_i^*, \hat{Q}_j^i$, $j \ne i$, satisfy

$$\mu_i(Q_i^*) = D, \tag{2.6}$$

$$f_i(\lambda_i, Q_i^*) = \mu_i(Q_i^*) Q_i^* = D Q_i^*, \tag{2.7}$$

$$x_i^* = \frac{(S^{(0)} - \lambda_i) D}{f_i(\lambda_i, Q_i^*)} = \frac{S^{(0)} - \lambda_i}{Q_i^*}, \tag{2.8}$$

$$f_j(\lambda_j, \hat{Q}_j^i) = \mu_j(\hat{Q}_j^i) \hat{Q}_j^i, \quad j \ne i. \tag{2.9}$$

The steady state E_i exists if and only if the equation $\mu_i(Q_i) = D$ has a unique solution Q_i^* and

$$f_i(S^{(0)}, Q_i^*) > DQ_i^*.$$

Lemma 2.1. *The solutions $S(t), x_1(t), Q_1(t), \ldots, x_n(t), Q_n(t)$ of system* (2.1) *are positive and bounded for all $t \geq 0$. Furthermore,*

$$S(t) + \sum_{i=1}^{n} Q_i(t)x_i(t) = S^{(0)} + O(e^{-Dt}),\ t \to \infty, \tag{2.10}$$

and there exist $\gamma_i > P_i$, $t_0 > 0$ such that $Q_i(t) \geq \gamma_i$ for all $t \geq t_0$, for $i = 1, 2, \ldots, n$.

The above lemma is a statement that system (2.1) is as "well behaved" as one that is intuited from the biological problem. Equation (2.10) is the conservation principle. Therefore, all solutions of (2.1) asymptotically approach

$$S(t) + \sum_{i=1}^{n} Q_i(t)x_i(t) = S^{(0)} \tag{2.11}$$

as $t \to \infty$. Consequently, as a first step in the analysis of (2.1), we consider the restriction of (2.1) to the exponentially attracting invariant subset given by (2.11). Dropping S from (2.1) and letting $U_i = Q_i x_i$, $1 \leq i \leq n$, we obtain the following system:

$$\begin{aligned}
&U_i'(t) = f_i\left(S^{(0)} - \sum_{i=1}^{n} U_i(t),\ Q_i(t)\right)\frac{U_i(t)}{Q_i(t)} - DU_i(t),\\
&Q_i'(t) = f_i\left(S^{(0)} - \sum_{i=1}^{n} U_i(t),\ Q_i(t)\right) - \mu_i(Q_i(t))Q_i(t),\\
&U_i(0) > 0,\ Q_i(0) \geq P_i, \quad 1 \leq i \leq n,\ \sum_{i=1}^{n} U_i(0) \leq S^{(0)}.
\end{aligned} \tag{2.12}$$

We note that $U_i(t)$ is the total amount of stored nutrient of the ith species at time t. In the next section, we shall study the reduced limiting system (2.12). The relevant domain for (2.12) is

$$\Omega = \left\{(U_1, Q_1, \ldots, U_n, Q_n) \in \mathbb{R}^{2n} : \begin{array}{l} \sum_{i=1}^{n} U_i \leq S^{(0)},\ U_k \geq 0, \\ Q_k \geq P_k,\ k = 1, 2, \ldots, n \end{array}\right\}, \tag{2.13}$$

which is positively invariant under (2.12).

Lemma 2.2. *Let $(S(t), x_1(t), Q_1(t), \ldots, x_n(t), Q_n(t))$ be the system of* (2.1). *For $1 \leq i \leq n$, if one of the following cases holds:*

(i) *$\mu_i(Q_i) < D$ for all $Q_i \in [P_i, \infty)$,*

(ii) (2.6) *holds with $f_i(S, Q_i^*) < \mu_i(Q_i^*)Q_i^*$ for all $S \in [0, S^{(0)}]$,*

(iii) (2.6) *and* (2.7) *hold with $S^{(0)} < \lambda_i$,*

then

$$\lim_{t\to\infty} x_i(t) = 0.$$

In the first two cases, we denote $\lambda_i = +\infty$.

This lemma states that if the maximal growth rate of the ith organism is less than the dilution rate D or if the input concentration $S^{(0)}$ is too small, then the ith organism will die out as time becomes large. Note that the resulting behavior is competition independent.

Our basic hypothesis is

$$(\mathrm{H_n}) \qquad \begin{aligned} &0 < \lambda_1 < \lambda_2 \leq \cdots \leq \lambda_n, \\ &\lambda_1 < S^{(0)}. \end{aligned}$$

For an equilibrium $E = (S, x_1, Q_1, \ldots, x_n, Q_n)$ of system (2.1), we denote

$$\hat{E} = (U_1, Q_1, \ldots, U_n, Q_n)$$

as the corresponding equilibrium of system (2.12).

Lemma 2.3. *Let* $(\mathrm{H_n})$*hold; then the equilibrium* $\hat{E}_1$ *is locally asymptotically stable and the rest of the equilibria* $\hat{E}_0, \hat{E}_2, \ldots, \hat{E}_n$ *are saddles if they exist. Furthermore, if* $S^{(0)} > \lambda_i,\ i = 1, 2, \ldots, n,$ *then the stable manifolds of* $\hat{E}_0$ *and* $\hat{E}_k,\ k = 2, 3, \ldots, n,$ *are*

$$M^+(\hat{E}_0) = \{(0, Q_1, 0, Q_2, \ldots, 0, Q_n) : P_i < Q_i,\ i = 1, 2, \ldots, n\}$$

and

$$M^+(\hat{E}_k) = \left\{(0, Q_1, \ldots, 0, Q_{k-1}, U_k, Q_k, , \ldots, U_n, Q_n) : \begin{array}{c} P_i < Q_i,\ i = 1, 2, \ldots, n, \\ U_i > 0,\ i = k, k+1, \ldots, n \end{array}\right\}.$$

The following is our main theorem.

Theorem 2.4. *Let* $(\mathrm{H_n})$*hold. The solution of* (2.1) *satisfies*

$$\begin{aligned} &\lim_{t \to \infty} (S(t), x_1(t), Q_1(t), x_2(t), Q_2(t), \ldots, x_n(t), Q_n(t)) = E_1 \\ &= (\lambda_1, x_1^*, Q_1^*, 0, \hat{Q}_2^1, 0, \hat{Q}_3^1, \ldots, 0, \hat{Q}_n^1), \end{aligned}$$

where $Q_1^*,\ \lambda_1,\ x_1^*,\ \hat{Q}_j^1,\ j = 2, 3, \ldots, n,$ *satisfy*

$$\begin{aligned} &\mu_1(Q_1^*) = D, \\ &f_1(\lambda_1, Q_1^*) = DQ_1^*, \\ &x_1^* = \frac{S^{(0)} - \lambda_1}{Q_1^*}, \\ &f_j(\lambda_1, \hat{Q}_j^1) = \mu_j(\hat{Q}_j^1)\hat{Q}_j^1,\ j = 2, \ldots, n. \end{aligned}$$

This theorem states that under the hypothesis $(\mathrm{H_n})$only one species survives, the one with the lowest value of λ_i, and gives the limiting nutrient concentrations.

3. Proofs.

From the differential inequality [H2], the proof of Lemma 3.1 is easy, and so we omit it.

Lemma 3.1. *Let* $x : \mathbb{R}_+ \to [a, \infty),\ y : \mathbb{R}_+ \to [b, \infty),$ *and* $g : [a, \infty) \times [b, \infty) \to \mathbb{R}$ *be continuously differentiable and satisfy*

$$x'(t) \leq g(x(t), y(t)),\ t \geq 0.$$

Suppose

$$\frac{\partial g}{\partial x}(x,y) < 0,\ \frac{\partial g}{\partial y}(x,y) > 0,$$

and suppose that for each $y \in [b,\infty)$ there exists a unique solution $x^* = x^*(y) \in [a,\infty)$ of $g(x,y) = 0$. If $\limsup_{t\to\infty} y(t) \le \alpha$, then

$$\limsup_{t\to\infty} x(t) \le x^*(\alpha).$$

Proof of Lemma 2.1. From (2.2), (2.3), and (2.4), it is easy to verify that the solutions $S(t), Q_i(t), x_i(t)$, $1 \le i \le n$, are positive for all $t \ge 0$. The first equation of (2.1) gives

$$S' \le (S^{(0)} - S)D;$$

then obviously we have

$$\limsup_{t\to\infty} S(t) \le S^{(0)}. \tag{3.1}$$

For $i = 1, 2, \ldots, n$, consider the differential equation of Q_i in (2.1):

$$Q_i' = f_i(S, Q_i) - \mu_i(Q_i)Q_i.$$

From (2.2), (2.3), (3.1), and Lemma 3.1 it follows that

$$\limsup_{t\to\infty} Q_i(t) \le Q_i^0, \tag{3.2}$$

where $Q_i^0 > P_i$ is defined in (2.5).

Let $T = S + \sum_{i=1}^n Q_i x_i$. Then T satisfies

$$T' = (S^{(0)} - T)D.$$

Therefore,

$$T = S^{(0)} + O(e^{-Dt}) \text{ as } t \to \infty. \tag{3.3}$$

Thus the conservation principle (2.10) holds.

Next we show that there exist $\gamma_i > P_i$ and $t_0 > 0$ such that $Q_i(t) \ge \gamma_i$ for $t \ge t_0$. We show $S(t)$ is bounded below by a constant $\gamma > 0$. Let $U_i = x_i Q_i$. Rewrite the first equation in (2.1) as

$$S' + \left(D + \sum_{i=1}^n \frac{U_i}{Q_i}\frac{f_i(S,Q_i)}{S}\right) S = S^{(0)}D.$$

Then from (3.3), (2.3) it follows that

$$S' + \left[D + S^{(0)}\left(\max_{1\le i\le n}\frac{1}{P_i}\right)\cdot \max_{\substack{1\le i\le n\\ 0\le S\le S^{(0)}}} \frac{\partial f_i}{\partial S}(S,P_i)\right] S \ge S^{(0)}D.$$

Then there exists $\gamma > 0$ such that $S(t) \ge \gamma$, $t \ge t_0$.

From (2.1), we have

$$Q_i' = f_i(S, Q_i) - \mu_i(Q_i)Q_i \geq f_i(\gamma, Q_i) - \mu(Q_i)Q_i.$$

Then it follows that $Q_i(t) \geq \gamma_i$ for $t \geq t_0$, where γ_i satisfies

$$f_i(\gamma, \gamma_i) = \mu(\gamma_i)\gamma_i,\ \gamma_i > P_i.$$

For each $1 \leq i \leq n$, we have

$$x_i(t) = U_i(t)/Q_i(t) \leq T(t)/P_i \leq (S^{(0)} + \varepsilon)/P_i \text{ for } t \text{ large.}$$

Consequently, the solution

$$(S(t), x_1(t), Q_1(t), \ldots, x_n(t), Q_n(t))$$

is bounded for $t \geq 0$. □

Proof of Lemma 2.2. Suppose case (i) holds. Then

$$\mu_i(Q_i^0) < D, \tag{3.4}$$

where Q_i^0 is defined in (2.5). In case (ii) or (iii), we have

$$f_i(S^{(0)}, Q_i^*) < \mu_i(Q_i^*)Q_i^*.$$

Since $g_i(Q) = f_i(S^{(0)}, Q) - \mu_i(Q)Q$ is strictly decreasing in Q, from (2.5) it follows that $Q_i^* > Q_i^0$. Thus from (2.2) we obtain (3.4) again.

To complete the proof, it remains to show that the inequality (3.4) implies that $\lim_{t\to\infty} x_i(t) = 0$. Let $\eta = (D - \mu_i(Q_i^0))/2$. Since $\mu_i(Q_i)$ is increasing in Q_i, there exists $\delta > 0$ such that

$$\mu_i(Q_i) \leq \mu_i(Q_i^0) + \eta = D - \eta \quad \text{whenever } Q_i \leq Q_i^0 + \delta.$$

By (3.2) there exists $t_\delta > 0$ such that

$$Q_i(t) < Q_i^0 + \delta \text{ for all } t \geq T_\delta > 0.$$

It follows that

$$\begin{aligned} x_i(t) &= x_i(T_\delta) \exp\left(\int_{T_\delta}^t (\mu_i(Q_i(\tau)) - D)\, d\tau\right) \\ &\leq x_i(T_\delta)e^{-\eta(t-T_\delta)} \to 0 \text{ as } t \to \infty. \end{aligned}$$ □

Proof of Lemma 2.3. Assume that the equilibrium $\hat{E}$ takes the form

$$\hat{E} = (U_1, Q_1, \ldots, U_n, Q_n).$$

Let the variational matrix evaluated at $\hat{E}$ be $J(\hat{E}) = (a_{ij})_{i,j=1}^{2n}$.

Let $\hat{E} = \hat{E}_0$. Then it is easy to verify that the eigenvalues of $J(\hat{E}_0)$ are $a_{11}, a_{22}, \ldots, a_{2n,2n}$, where

$$a_{2i-1,2i-1} = \mu_i(Q_i^0) - D,$$

$$a_{2i,2i} = \frac{\partial f_i}{\partial Q_i}(S^{(0)}, Q_i^0) - \mu_i'(Q_i^0)Q_i^0 - \mu_i(Q_i^0) < 0,\ i = 1, 2, \ldots, n. \tag{3.5}$$

From (2.3), (2.5), and (2.7) we have $S^{(0)} > \lambda_i$ if and only if $Q_i^0 > Q_i^*$. Therefore,

$$a_{1,1} > \mu_1(Q_1^*) - D = 0,$$

and consequently $\hat{E}_0$ is unstable. Furthermore, it is a saddle since (3.5) holds. It is easy to verify that if $S^{(0)} > \lambda_i$, $i = 1, 2, \ldots, n$, then $a_{2i-1,2i-1} > 0$, $i = 1, 2, \ldots, n$, and $\hat{E}_0$ is a saddle point with n-dimensional stable manifold

$$M^+(\hat{E}_0) = \left\{(0, Q_1, 0, Q_2, \ldots, 0, Q_n) : P_i < Q_i,\ i = 1, 2, \ldots, n\right\}.$$

Let $\hat{E} = \hat{E}_k$, $1 \le k \le n$. Then for $i \ne k$,

$$\begin{aligned} a_{2i-1,2i-1} &= \mu_i(\hat{Q}_i^k) - D, \\ a_{2i,2i} &= \frac{\partial f_i}{\partial Q_i}(\lambda_k, \hat{Q}_i^k) - \hat{Q}_i^k \mu_i'(\hat{Q}_i^k) - \mu_i(\hat{Q}_i^k) < 0. \end{aligned}$$

It is easy to verify that the set of eigenvalues of $J(\hat{E}_k)$ is the union of

$$\{a_{2i-1,2i-1}, a_{2i,2i} : 1 \le i \le n, i \ne k\}$$

and the set of eigenvalues of M_k, where

$$M_k = \begin{pmatrix} -\frac{\partial f_k}{\partial S} x_k^* & -f_k(\lambda_k, Q_k^*)\frac{x_k^*}{Q_k^*} + \frac{\partial f_k}{\partial Q_k} x_k^* \\ -\frac{\partial f_k}{\partial S} & \frac{\partial f_k}{\partial Q_k} - \mu_k' Q_k^* - \mu_k \end{pmatrix}.$$

Since

$$\begin{aligned} \operatorname{trace}(M_k) &= -\frac{\partial f_k}{\partial S} x_k^* + \frac{\partial f_k}{\partial Q_k} - \mu_k' Q_k^* - \mu_k < 0, \\ \det(M_k) &= \frac{\partial f_k}{\partial S} x_k^* \mu_k' Q_k^* > 0, \end{aligned}$$

the eigenvalues of M_k have negative real part.

Consider $\hat{E} = \hat{E}_1$. The assumption $(\mathrm{H_n})$implies that

$$\hat{Q}_i^1 < Q_i^*, \quad i = 2, \ldots, n. \tag{3.6}$$

Therefore, from (3.6) it follows that

$$a_{2i-1,2i-1} = \mu_i(\hat{Q}_i^1) - D < \mu_i(Q_i^*) - D = 0, \quad i = 2, \ldots, n,$$

and consequently $\hat{E}_1$ is locally asymptotically stable.

Consider $\hat{E} = \hat{E}_k$, $k \in \{2, \ldots, n\}$. The assumption $(\mathrm{H_n})$implies that $\lambda_1 < \lambda_k$. Then from (2.3) we have

$$\begin{aligned} &f_1(\lambda_1, \hat{Q}_1^k) < f_1(\lambda_k, \hat{Q}_1^k) = \mu_1(\hat{Q}_1^k)\hat{Q}_1^k, \\ &f_1(\lambda_1, \hat{Q}_1^k) - \mu_1(\hat{Q}_1^k)\hat{Q}_1^k < 0 = f_1(\lambda_1, Q_1^*) - \mu_1(\hat{Q}_1^*)Q_1^*. \end{aligned}$$

Thus

$$Q_1^* < \hat{Q}_1^k.$$

Therefore,

$$a_{1,1} = \mu_1(\hat{Q_1^k}) - D > \mu_1(Q_1^*) - D = 0,$$

and consequently $\hat{E}_k$ is unstable. Furthermore, from (3.5) it is a saddle . Similarly, it is easy to verify that if $S^{(0)} > \lambda_i$, $i = 1, 2, \ldots, n$, then $a_{2i-1,2i-1} > 0$, $i = 1, 2, \ldots, k-1$, and $\hat{E}_k$ is a saddle point with a $(2n+1-k)$-dimensional stable manifold. From the results of [SW1] and induction on n, it follows that

$$M^+(\hat{E}_k) = \left\{ (0, Q_1, \ldots, 0, Q_{k-1}, U_k, Q_k, \ldots, U_n, Q_n) : \begin{array}{l} P_i < Q_i, \\ i = 1, 2, \ldots, n \end{array} \right\}. \qquad \square$$

We note now the following lemma.

Lemma 3.2 (see [C]). *Let $f(t) \in C^2[t_0, \infty)$. If $f(t) \to$ constant and $|f''(t)|$ is bounded for $t \geq t_0$, then*

$$\lim_{t\to\infty} f'(t) = 0.$$

The following is the so-called fluctuating lemma, which will be used to prove our main result.

Lemma 3.3 (see [HHG]). *Let $f : \mathbb{R}_+ \to \mathbb{R}$ be a differentiable function. If*

$$\liminf_{t\to\infty} f(t) < \limsup_{t\to\infty} f(t),$$

then there are sequences $\{t_m\} \nearrow \infty$ and $\{\tau_m\} \nearrow \infty$ such that for all m

$$f'(t_m) = 0, \quad f(t_m) \to \limsup_{t\to\infty} f(t) \text{ as } m \to \infty,$$
$$f'(\tau_m) = 0, \quad f(\tau_m) \to \liminf_{t\to\infty} f(t) \text{ as } m \to \infty.$$

Now we prove our main result.

Lemma 3.4. *Let $S(t) = S^{(0)} - \sum_{i=1}^n U_i(t)$. Consider the solution*

$$(U_1(t), Q_1(t), \ldots, U_n(t), Q_n(t))$$

of the reduced system (2.12) with initial conditions $U_i(0) > 0, Q_i(0) \geq P_i$, $1 \leq i \leq n$, $S(0) \geq 0$. Suppose $\lim_{t\to\infty} S(t)$ does not exist; then $\limsup_{t\to\infty} S(t) \leq \lambda_j$ for some $j \in \{1, 2, \ldots, n\}$.

Proof. Since $\lim_{t\to\infty} S(t)$ does not exist, it follows that

$$\liminf_{t\to\infty} S(t) < \limsup_{t\to\infty} S(t).$$

From Lemma 3.3, there exists $\{t_m\} \nearrow \infty$ such that

$$S'(t_m) = 0 \quad \text{and} \quad S(t_m) \to \limsup_{t\to\infty} S(t) \text{ as } m \to \infty. \tag{3.7}$$

Since

$$S'(t) = -(U_1'(t) + \cdots + U_n'(t)),$$

for each t_m there exists $j_m \in \{1, 2, \ldots, n\}$ such that

$$U_{j_m}'(t_m) \leq 0, \quad m = 1, 2, \ldots.$$

We may choose a subsequence $\{\bar{t}_m\}$ of $\{t_m\}$ such that

$$U_j'(\bar{t}_m) \le 0$$

for some $j \in \{1, 2, \ldots, n\}$ and for all m. Thus without loss of generality we may assume that

$$U_j'(t_m) \le 0$$

for some $j \in \{1, 2, \ldots, n\}$ and for all m. Thus

$$f_j(S(t_m), Q_j(t_m)) \le DQ_j(t_m).$$

Let $\gamma_S = \limsup_{t\to\infty} S(t)$ and $\gamma_Q = \limsup_{t\to\infty} Q_j(t)$. Let $\{\tilde{t}_m\}$ be a subsequence of $\{t_m\}$ such that $\lim_{m\to\infty} Q_j(\tilde{t}_m) = \bar{Q}_j$. Then $\bar{Q}_j \le \limsup_{t\to\infty} Q_j(t) = \gamma_Q$, and from the above inequality we have $f_j(\gamma_S, \bar{Q}_j) \le D\bar{Q}_j$. Since $f_j(\gamma_S, Q_j) - DQ_j$ is strictly decreasing in Q_j, then $f_j(\gamma_S, \gamma_Q) - D\gamma_Q < f_j(\gamma_S, \bar{Q}_j) - D\bar{Q}_j \le 0$. Thus we have

$$f_j(\gamma_S, \gamma_Q) < D\gamma_Q. \tag{3.8}$$

Consider the differential equation of Q_j in (2.1):

$$Q_j' = f_j(S, Q_j) - \mu_j(Q_j)Q_j. \tag{3.9}$$

From (3.1), (2.3), and Lemma 3.1 it follows that

$$\gamma_Q = \limsup_{t\to\infty} Q_j(t) \le K^{(0)}, \tag{3.10}$$

where

$$f_j(S^{(0)}, K^{(0)}) - \mu_j(K^{(0)})K^{(0)} = 0. \tag{3.11}$$

If $\lambda_j > S^0$, from (3.1) the assertion of the lemma holds. Thus we assume that $\lambda_j \le S^0$. From (2.3) and (3.11) it follows that

$$f_j(\lambda_j, K^{(0)}) - \mu_j(K^{(0)})K^{(0)} \le 0.$$

Compare the above inequality with (2.7):

$$f_j(\lambda_j, Q_j^*) - \mu_j(Q_j^*)Q_j^* = 0. \tag{3.12}$$

From (2.2), (2.3), (3.11), and (3.12) it follows that

$$K^{(0)} \ge Q_j^*. \tag{3.13}$$

Let $L^{(1)}$ satisfy

$$f_j(L^{(1)}, K^{(0)}) - DK^{(0)} = 0. \tag{3.14}$$

Then from (2.3), (3.10) we have

$$0 = f_j(L^{(1)}, K^{(0)}) - DK^{(0)} \le f_j(L^{(1)}, \gamma_Q) - D\gamma_Q.$$

From (2.3), (3.8) it follows that

$$f_j(L^{(1)}, \gamma_Q) \ge D\gamma_Q \ge f_j(\gamma_S, \gamma_Q),$$

$$\gamma_S \le L^{(1)}. \tag{3.15}$$

Since $K^{(0)} \ge Q_j^*$, from (3.14) and (2.3) it follows that

$$f_j(L^{(1)}, Q_j^*) - DQ_j^* \ge 0.$$

From (3.12) we have

$$L^{(1)} \ge \lambda_j.$$

On the other hand, the inequality $K^{(0)} \ge Q_j^*$ implies that

$$f_j(L^{(1)}, K^{(0)}) = DK^{(0)} = \mu_j(Q_j^*)K^{(0)} \le \mu_j(K^{(0)})K^{(0)} = f_j(S^{(0)}, K^{(0)}).$$

Thus we have

$$S^{(0)} \ge L^{(1)} \ge \lambda_j. \tag{3.16}$$

By (3.9), (3.15), and Lemma 3.1, we have

$$\limsup_{t\to\infty} Q_j(t) \le K^{(1)}, \tag{3.17}$$

where

$$f_j(L^{(1)}, K^{(1)}) = \mu_j(K^{(1)})K^{(1)}. \tag{3.18}$$

Since $\lambda_j \le L^{(1)}$, it follows that

$$f_j(\lambda_j, K^{(1)}) - \mu_j(K^{(1)})K^{(1)} \le 0.$$

By (3.12), we have

$$K^{(1)} \ge Q_j^*.$$

Since $S^{(0)} \ge L^{(1)}$, from (3.11), (3.16), and (3.18) it follows that

$$K^{(0)} \ge K^{(1)} \ge Q_j^*. \tag{3.19}$$

Inductively we construct two sequences $\{L^{(m)}\}_{m=1}^{\infty}$ and $\{K^{(m)}\}_{m=1}^{\infty}$ satisfying

$$\begin{aligned} &S^{(0)} \ge L^{(1)} \ge L^{(2)} \ge \cdots \ge \lambda_j,\\ &K^{(0)} \ge K^{(1)} \ge K^{(2)} \ge \cdots \ge Q_j^*, \end{aligned}$$

and for any $m = 1, 2, \dots,$

$$\begin{aligned} &\limsup_{t\to\infty} S(t) \le L^{(m)},\\ &\limsup_{t\to\infty} Q_j(t) \le K^{(m)}, \end{aligned} \tag{3.20}$$

$$\begin{aligned} &f_j(L^{(m+1)}, K^{(m)}) = DK^{(m)},\\ &f_j(L^{(m)}, K^{(m)}) = \mu_j(K^{(m)})K^{(m)}. \end{aligned} \tag{3.21}$$

Let $L = \lim_{m\to\infty} L^{(m)}$ and $K = \lim_{m\to\infty} K^{(m)}$. Then from (3.21) it follows that

$$f_j(L, K) = DK,$$
$$f_j(L, K) = \mu_j(K)K.$$

Thus $K = Q_j^*$ and $L = \lambda_j$. By (3.20) it follows that

$$\limsup_{t\to\infty} S(t) \le \lambda_j,$$
$$\limsup_{t\to\infty} Q_j(t) \le Q_j^*.$$

Hence we complete the proof of Lemma 3.4. □

THEOREM 3.5. *Let* ($\mathrm{H_n}$)*hold. Then the solution*

$$(U_1(t), Q_1(t), \ldots, U_n(t), Q_n(t))$$

of the reduced system (2.12) *in the relevant domain* Ω *(see* (2.13)*) satisfies*

$$\lim_{t\to\infty}(U_1(t), Q_1(t), \ldots, U_n(t), Q_n(t)) = \hat{E}_1 = (U_1^*, Q_1^*, 0, \hat{Q}_2^1, \ldots, 0, \hat{Q}_n^1). \tag{3.22}$$

Proof. Let $S(t) = S^{(0)} - \sum_{i=1}^n U_i(t)$. If $\lim_{t\to\infty} S(t)$ exists, we claim that $\lim_{t\to\infty} S(t) = \lambda_1$. Let $\lim_{t\to\infty} S(t) = c$.

If $c > \lambda_1$, then for $\varepsilon > 0$ small there exists $T_\varepsilon > 0$ such that

$$Q_1' > f_1(\lambda_1 + \varepsilon, Q_1) - \mu_1(Q_1)Q_1 \text{ for t} \ge \mathrm{T}_\varepsilon.$$

Thus $Q_1(t) \ge Q_1^* + \eta$, $\eta > 0$ small, $t \ge T_\varepsilon$. Hence

$$\frac{x_1'}{x_1} = \mu_1(Q_1) - D \ge \mu_1(Q_1^* + \eta) - D > 0.$$

Then $x_1(t)$ is unbounded for $t \ge T_\varepsilon$. This is in contradiction to Lemma 2.1.

If $c < \lambda_1$, then for $2 \le i \le n$, by the differential equation of Q_i in (2.1) and Lemma 3.1, we have $\limsup_{t\to\infty} Q_1(t) < Q_1^*$ and $\limsup_{t\to\infty} Q_i(t) < \hat{Q}_i^1$ for $2 \le i \le n$. Hence from (3.6), $\lim_{t\to\infty} x_i(t) = 0$, $1 \le i \le n$, and $\lim_{t\to\infty} S(t) = S^{(0)} < \lambda_1$. This is in contradiction to ($\mathrm{H_n}$).

Obviously from Lemma 3.2, $\lim_{t\to\infty} S(t) = \lambda_1$ implies

$$\lim_{t\to\infty} Q_i(t) = \hat{Q}_i^1,\ \lim_{t\to\infty} x_i(t) = 0,\ 2 \le i \le n,$$
$$\lim_{t\to\infty} Q_1(t) = Q_1^*,\ \lim_{t\to\infty} x_1(t) = x_1^*.$$

Thus the trajectory $(U_1(t), Q_1(t), \ldots, U_n(t), Q_n(t))$ tends to $\hat{E}_1$ as $t \to \infty$.

If $\lim_{t\to\infty} S(t)$ does not exist, then $\limsup_{t\to\infty} S(t) > \liminf_{t\to\infty} S(t)$. From Lemma 3.4, we have $\limsup_{t\to\infty} S(t) \le \lambda_j$ for some $j \in \{1, 2, \ldots, n\}$. From ($\mathrm{H_n}$), we have

$$\limsup_{t\to\infty} S(t) \le \lambda_n.$$

Assume that (2.6) and (2.7) hold. Consider the differential equation of Q_n in (2.1):

$$Q_n' = f_n(S, Q_n) - \mu_n(Q_n)Q_n.$$

From Lemma 3.1 it follows that

$$\limsup_{t\to\infty} Q_n(t) \le \tilde{Q}_n,$$

where $\tilde{Q}_n$ satisfies

$$f_n(\lambda_n, \tilde{Q}_n) = \mu_n(\tilde{Q}_n)\tilde{Q}_n.$$

From (2.7) it follows that $\tilde{Q}_n = Q_n^*$. Thus

$$\limsup_{t\to\infty} Q_n(t) \le Q_n^*. \tag{3.23}$$

Let

$$\kappa_n = \liminf_{t\to\infty} Q_n(t).$$

If $\kappa_n = Q_n^*$, then $\lim_{t\to\infty} Q_n(t) = Q_n^*$. From (3.23) and Lemma 3.2, we have $\lim_{t\to\infty} S(t) = \lambda_n$, which contradicts the assumption that $\lim_{t\to\infty} S(t)$ does not exist. Hence we have $\kappa_n < Q_n^*$. Let

$$y_0 = (U_1(0), Q_1(0), \dots, U_n(0), Q_n(0)),\ U_i(0) > 0,\ Q_i(0) \ge P_i(0) \text{ for } 1 \le i \le n.$$

Next we claim that the ω-limit set $\omega(y_0)$ satisfies

$$\omega(y_0) \cap (\{(U_1, Q_1, \dots, U_n, Q_n) : U_n = 0\} \setminus M) \ne \emptyset, \tag{3.24}$$

where

$$M := \left(M^+(\hat{E}_0) \bigcup M^+(\hat{E}_2) \bigcup \cdots \bigcup M^+(\hat{E}_n)\right);$$

$M^+(\hat{E})$ denotes the stable manifold of the equilibrium $\hat{E}$. First we prove that

$$\omega(y_0) \setminus M \ne \emptyset.$$

If not, then $\omega(y_0) \subseteq M$. It is easy to show that $\omega(y_0) \ne \{\hat{E}_0\}$. If $\hat{E}_0 \in \omega(y_0)$, then from the Butler–McGhee lemma [BFW], there exists a point

$$q \in \left(M^+(\hat{E}_0) \setminus \{\hat{E}_0\}\right) \bigcap \omega(y_0).$$

Then the negative orbit $O^-(q) \subseteq \omega(y_0)$. But from Lemma 2.3, either $O^-(q)$ is unbounded or $(0, P_1, 0, P_2, \dots, 0, P_n) \in O^-(q)$. This contradicts Lemma 2.1. Assume that $\hat{E}_k \in \omega(y_0)$ for some $k \in \{2, \dots, n\}$. Obviously $\omega(y_0) \ne \{\hat{E}_k\}$. If $\hat{E}_k \in \omega(y_0)$, then from the Butler–McGhee lemma, there exists a point $q \in (M^+(\hat{E}_k) \setminus \{\hat{E}_k\}) \bigcap \omega(y_0)$. Then from the Lemma 2.3 the negative orbit $O^-(q)$ is unbounded, or $\hat{E}_0 \in O^-(q)$, or $(0, P_1, \dots, 0, P_{k-1}, U_k, P_k, \dots, U_n, P_n) \in O^-(q)$ for some $U_k, \dots, U_n$. For any one of the three cases, we obtain a contradiction.

Since $y_0 \notin M$, we may choose

$$\bar{y}_0 = (\bar{U}_1(0), \bar{Q}_1(0), \dots, \bar{U}_n(0), \bar{Q}_n(0)) \in (\omega(y_0) \setminus M). \tag{3.25}$$

Consider the solution of (2.12):

$$y(t, \bar{y}_0) = (U_1(t; \bar{y}_0), Q_1(t; \bar{y}_0), \dots, U_n(t; \bar{y}_0), Q_n(t; \bar{y}_0)).$$

From (3.23) and the positive invariance of $\omega(y_0)$, we have

$$Q_n(t, \bar{y}_0) \le Q_n^*, \quad t \ge 0.$$

Thus

$$\mu_n(Q_n(t; \bar{y}_0)) - D \le 0, \quad t \ge 0. \tag{3.26}$$

Let

$$\eta = D - \mu_n\left(\frac{Q_n^* + \kappa_n}{2}\right) > 0$$

and

$$\Lambda(t) = \left\{\tau \ : \ 0 \le \tau \le t, \ Q_n(\tau; \bar{y}_0) \le \frac{Q_n^* + \kappa_n}{2}\right\}, \quad t \ge 0.$$

Then

$$\mu_n\left(Q_n(\tau, \bar{y}_0)\right) - D < -\eta, \quad \tau \in \Lambda(t).$$

Since $Q_n'(t; \bar{y}_0)$ is uniformly bounded for $t \in [0, \infty)$, $Q_n(t; \bar{y}_0)$ is uniformly continuous on $[0, \infty)$. Let $\{\tau_m\} \nearrow \infty$ satisfies $Q_n(\tau_m; \bar{y}_0) \to \kappa_n$ as $m \to \infty$. Then given

$$\varepsilon = \frac{Q_n^* + \kappa_n}{2} - \kappa_n > 0,$$

there exists $\delta = \delta(\varepsilon) > 0$ such that

$$|Q_n(\tau; \bar{y}_0) - \kappa_n| < \varepsilon \text{ whenever } |\tau - \tau_m| < \delta.$$

Hence

$$Q_n(\tau; \bar{y}_0) < \kappa_n + \varepsilon = \frac{Q_n^* + \kappa_n}{2} \qquad \text{for } -\delta < \tau - \tau_m < \delta,$$

and therefore

$$|\Lambda(t)| \to +\infty \text{ as } t \to \infty.$$

Since

$$x_n'(t; \bar{y}_0) = (\mu_n(Q_n(t; \bar{y}_0)) - D)x_n(t; \bar{y}_0),$$

it follows that

$$\begin{aligned} x_n(t; \bar{y}_0) &= x_n(0; \bar{y}_0) \exp\left(\int_0^t (\mu_n(Q_n(\tau; \bar{y}_0)) - D)\, d\tau\right) \\ &\le x_n(0; \bar{y}_0) \exp\left(\int_{\Lambda(t)} (\mu_n(Q_n(\tau; \bar{y}_0)) - D)\, d\tau\right) \\ &\le x_n(0; \bar{y}_0) e^{-\eta|\Lambda(t)|} \to 0 \text{ as } t \to \infty. \end{aligned}$$

Therefore,

$$\begin{aligned}\limsup_{t\to\infty} U_n(t;\bar{y}_0) &\leq \left(\limsup_{t\to\infty} x_n(t;\bar{y}_0)\right)\left(\limsup_{t\to\infty} Q_n(t;\bar{y}_0)\right)\\ &\leq \left(\limsup_{t\to\infty} x_n(t;\bar{y}_0)\right) Q_n^* = 0.\end{aligned}$$

Hence

$$\omega(\bar{y}_0) \subseteq \{(U_1, Q_1, \ldots, U_n, Q_n) \in \Omega : U_n = 0\}.$$

Since $\bar{y}_0 \notin M$ by (3.25), it follows that

$$\omega(\bar{y}_0) \cap (\{(U_1, Q_1, \ldots, U_n, Q_n) \in \Omega : U_n = 0\} \setminus M) \neq \emptyset.$$

By the invariance of ω-limit sets, we have

$$\omega(\bar{y}_0) \subseteq \omega(y_0).$$

It follows that

$$\omega(y_0) \cap (\{(U_1, Q_1, \ldots, U_n, Q_n) \in \Omega : U_n = 0\} \setminus M) \neq \emptyset.$$

Continuing the above arguments, we consider the systems (2.12) with $1 \leq i \leq n-1$. Then from the positive invariance of the ω-limit set,

$$\omega(y_0) \cap (\{(U_1, Q_1, \ldots, U_n, Q_n) \in \Omega : U_{n-1} = U_n = 0\} \setminus M) \neq \emptyset.$$

Inductively we have

$$\omega(y_0) \cap (\Gamma \setminus M) \neq \emptyset,$$

where

$$\Gamma = \{(U_1, Q_1, \ldots, U_n, Q_n) \in \Omega : U_2 = U_3 = \cdots = U_n = 0\}.$$

In particular,

$$\omega(y_0) \cap (\Gamma \setminus \{\hat{E}_0\}) \neq \emptyset.$$

It is easy to verify that

$$\omega(\Gamma \setminus \{\hat{E}_0\}) = \{\hat{E}_1\}.$$

Consequently, we have

$$\hat{E}_1 \in \omega(y_0).$$

By Lemma 2.3, the assumption $(\mathrm{H_n})$implies that $\hat{E}_1$ is asymptotically stable. Thus

$$\omega(y_0) = \{\hat{E}_1\}.$$

That is,

$$\lim_{t\to\infty} (U_1(t), Q_1(t), \ldots, U_n(t), Q_n(t)) = \hat{E}_1.$$

The above equality contradicts the assumption that $\lim_{t\to\infty} S(t)$ does not exist. Thus $\lim_{t\to\infty} S(t)$ exists, and we complete the proof of Theorem 3.5. $\square$

Proof of Theorem 2.4. From Lemma 2.1 all solutions of the system (2.1) with initial conditions $S(0) > 0, x_i(0) > 0, Q_i(0) \geq P_i$ asymptotically approach

$$S + \sum_{i=1}^{n} U_i = S^{(0)}$$

as $t \to \infty$. Hence the system (2.12) is the reduced limiting system of (2.1). To apply Theorem 4.2 of [Th], we note that the equilibria of (2.12) are isolated invariant sets of (2.12) and by Theorem 3.5, every solution of (2.12) converges to the equilibrium $\hat{E}_1 = (U_1^*, Q_1^*, 0, \hat{Q}_2^1, \dots, 0, \hat{Q}_n^1)$. Furthermore, we conclude from [Th, Theorem 4.2], that every solution of (2.1) converges to the equilibrium

$$E_1 = (\lambda_1, x_1^*, Q_1^*, 0, \hat{Q}_2^1, 0, \hat{Q}_3^1, \dots, 0, \hat{Q}_n^1). \qquad \square$$

4. Discussion. It is well known that the competitive exclusion principle holds for microorganisms competing for a single-limited nutrient in a chemostat when the yields of organisms are assumed to be fixed constants [HHW], [H1]. In phytoplankton ecology, it has long been known that yield is not constant and it can vary depending on the growth rate [D]. This led to the formulation of the variable-yield model, or the internal storage model. In this paper we proved that the competitive exclusion principle also holds for the variable-yield model in the case of a single-limited nutrient. Mathematically we extend the result of competitive exclusion in [SW1] from two species to arbitrary n species. Biologically the internal storage model with one limiting nutrient has been tested successfully in both constant and fluctuating environments [G3], [SC]. It is more realistic than the constant-yield model.

However, organisms require multiple nutrients to live and reproduce. In phytoplankton ecology, there are many studies in the competition of species for multiple nutrients. Narang and Pilyugin [NP] studied the dynamics of microbial growth by constructing some new physiological models. In [LC] Legović and Cruzado proposed an internal storage model of one species consuming multiple complementary nutrients in a continuous culture. Then in [LLSK] Leenheer et al. proved the global stability for the above model by the method of monotone dynamical systems. Li and Smith [LS1] studied the internal storage model for two species competing for two complementary nutrients. By using the method of monotone dynamical systems, they established the global dynamics of the model. It is shown that basically the model exhibits the familiar Lotka–Volterra alternatives: competitive exclusion, stable coexistence, and bistability. In phytoplankton ecology, many people studied the competition of organisms for multiple complementary nutrients by using the internal storage model. In [KL] Klausmeier and Litchman studied phytoplankton growth and stoichiometry under multiple nutrient limitation. In [KLL] Klausmeier, Litchman, and Levin studied the case of two species and two essential nutrients and suggested experimental tests for the model. In [LKMSF] the authors studied the multiple-nutrient, multiple-group model for phytoplankton communities and listed many biological parameters in the internal storage model.

We conjecture that for the internal storage model there are at most two species that survive for the case of n organisms competing for two complementary nutrients. We note that even in the classical model of fixed yields, the conjecture is still unsolved [LS2]. It is also interesting to compare the mathematical analysis results of the internal storage model to those of the classical constant-yield model in the case of three or more complementary nutrients [PH]. These will be the subject of our work in the future.

Acknowledgments. We are grateful to two anonymous referees for their careful reading and helpful suggestions which led to an improvment of our original manuscript.

EXISTENCE, UNIQUENESS, AND A CONSTRUCTIVE SOLUTION ALGORITHM FOR A CLASS OF FINITE MARKOV MOMENT PROBLEMS*

LAURENT GOSSE† AND OLOF RUNBORG‡

Abstract. We consider a class of finite Markov moment problems with an arbitrary number of positive and negative branches. We show criteria for the existence and uniqueness of solutions, and we characterize in detail the nonunique solution families. Moreover, we present a constructive algorithm to solve the moment problems numerically and prove that the algorithm computes the right solution.

Key words. finite Markov moment problem, inverse problems, exponential transform

DOI. 10.1137/070692510

1. Introduction.

We aim at inverting a moment system often associated with the prestigious name of Markov. The original form of the problem is the following. Given a *finite set of moments* m_k for $k = 1, \dots, K$, find a bounded measurable *density* function f satisfying

$$m_k = \int_{\mathbb{R}} x^{k-1} f(x)dx, \qquad 0 \le f \le 1, \qquad k = 1, \dots, K. \tag{1.1}$$

The condition for the existence of solutions $f(x)$ to this problem is classical [1, 2]. In general, solutions are not unique, unless more conditions are given, e.g., based on entropy minimization [3, 4] or L^∞-minimization [19, 18]. A typical result is that the unique solution for even K is piecewise constant, taking values in $\{0, 1\}$. More precisely, if $K = 2n$, then f is of the form

$$f(x) = \sum_{j=1}^{n} \chi_{[y_i, x_i]}(x), \tag{1.2}$$

where $\chi_I(x)$ is the characteristic function for the interval I and

$$y_1 < x_1 < y_2 < x_2 < \cdots < y_n < x_n. \tag{1.3}$$

See Theorem 6.1 and consult, e.g., [5, 8, 17, 23, 25] for general background on moment problems.

A reduced form of the finite moment problem is to search for solutions to (1.1) which are precisely of the form (1.2), (1.3). One then obtains an algebraic problem for the branch values,

$$m_k = \frac{1}{k} \sum_{j=1}^{n} x_j^k - y_j^k, \qquad k = 1, \dots, K = 2n. \tag{1.4}$$

‡Department of Numerical Analysis, CSC, KTH, 10044 Stockholm, Sweden (olofr@nada.kth.se).

Finding $\{x_j\}$ and $\{y_j\}$ from $\{m_k\}$ is an ill-conditioned problem when the branch values of the solution come close to each other; the Jacobian of the problem is a Vandermonde matrix, and iterative numerical resolution routines require extremely good starting guesses when the matrix degenerates. For less than four moments, a direct method based on solving polynomial equations was presented in [21]. Routines based on the simplex algorithm were proposed in [19]. Another algorithm was presented by Koborov, Sklyar, and Fardigola in [16, 24] in the slightly modified setting where f takes values in $\{-1,1\}$ instead of $\{0,1\}$. It consists of solving a sequence of high degree polynomial equations, constructed through a rather intricate process with unclear stability properties. In [14] we showed that this algorithm can be drastically simplified and adapted to (1.4). Later, in [15], we also gave a direct proof that the simplified algorithm indeed computes the correct solution, relying on the classical Newton identities and Toeplitz matrix theory.

The moment problem has many applications in, for instance, probability and statistics [10, 7] but also in areas like wave modulation [6, 22] and "shape from moments" inverse problems [11]. Our own motivation comes from a quite different field, namely, multiphase geometrical optics [3, 4, 12, 13, 14, 21]. In this application one needs to solve a system of nonlinear hyperbolic conservation laws. To evaluate the flux function in the PDEs a system like (1.4) must be solved. In a finite difference method this means that the system must be inverted once for every point in the computational grid repeatedly in every timestep. It is thus important that the inversion can be done quickly and accurately; this difficulty has been a bottleneck in computations. In [14] we used the simplified algorithm mentioned above for numerical implementation inside a shock-capturing finite difference solver. It is our aim here to develop better algorithms and understanding to open the way for the processing of intricate wave-fields with large K and thus complement the seminal paper [4], where the multiphase geometrical optics PDEs were first proposed.

In this paper we are concerned with a generalization of (1.4). In the geometrical optics application, the number of moments K is typically not even, and one can have a variable number of positive (x_k) and negative (y_k) branches. We thus consider the problem

$$m_k = \sum_{j=1}^{n_x} x_j^k - \sum_{j=1}^{n_y} y_j^k, \qquad k = 1, \dots, K, \tag{1.5}$$

where $n_x + n_y = K$ but where n_x and n_y are not necessarily equal. We study existence and uniqueness of solutions to this problem (Theorem 4.1). In particular, we are interested in how and when uniqueness is lost. For these cases we characterize the family of solutions that exists. The reason is to understand what happens numerically close to degenerate solutions, which is an important feature in the application we have in mind: In the exact solution to the multiphase geometrical optics PDEs, the moment problem is typically degenerate for large domains; the numerical approximation is almost degenerate.

We also give constructive algorithms to solve (1.5) and prove that they generate the right solution (Theorem 2.1). In a future paper we will study the numerical stability of these algorithms. Experimentally we note, for instance, that to compute the next moment, Algorithm 3 is much more stable than Algorithm 1. The difficulty lies in understanding perturbations around degenerate solutions, which is where the algorithms are most unstable. For this the insights of this paper will be of importance.

Remark 1. *The problem* (1.5) *can be cast in the form of* (1.1) *if one demands that the density function $f(x)$ be of the form*

$$f(x) = \sum_{j=1}^{n_x} \operatorname{sgn}(x_j)\,[H(x) - H(x - |x_j|)] - \sum_{j=1}^{n_y} \operatorname{sgn}(y_j)\,[H(x) - H(x - |y_j|)]\,, \tag{1.6}$$

and we rescale the moments $m_k \to k m_k$. For the case $n_x = n_y = n$ and $K = 2n$ with interlaced branch values (1.3)*, this reduces to* (1.2)*.*

This paper is organized as follows. In section 2 we present the algorithms for solving (1.5). Notation and various ways of describing a solution are subsequently introduced in section 3. Next we derive conditions for existence and uniqueness of solutions in section 4 and also discuss various properties of the solution, particularly when it is not unique. A theorem proving the correctness of the algorithms is proved in section 5. Finally, in section 6, we give additional properties of the elements of our algorithms and use these to relate our results back to the classical Markov theory.

2. Algorithms.

In this section we detail the algorithms that we propose for solving (1.5). The solution that we obtain is what we call the *minimal degree solution*, meaning that when the solution is not unique as many branch values as possible are zero. See section 4 for a precise definition. The algorithms are as follows; they may fail in case there is no solution to (1.5).

Algorithm 1 (computing $\{x_j\}$ and $\{y_j\}$).

1. *Construct the sequence $\{a_k\}$ as follows. Set $a_0 = 1$ and $a_k = 0$ for $k < 0$. For $1 \le k \le K$, let the elements be given as the solution to*

$$\begin{pmatrix} 1 & & & \\ -m_1 & 2 & & \\ \vdots & \ddots & \ddots & \\ -m_{K-1} & \dots & -m_1 & K \end{pmatrix} \begin{pmatrix} a_1 \\ a_2 \\ \vdots \\ a_K \end{pmatrix} = \begin{pmatrix} m_1 \\ m_2 \\ \vdots \\ m_K \end{pmatrix}. \tag{2.1}$$

2. *Construct the matrix $A_1 \in \mathbb{R}^{n_x \times n_x}$ as*

$$A_1 = \begin{pmatrix} a_{n_y} & a_{n_y-1} & \cdots & a_{n_y-n_x+1} \\ a_{n_y+1} & a_{n_y} & \cdots & a_{n_y-n_x+2} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n_y+n_x-1} & a_{n_y+n_x-2} & \cdots & a_{n_y} \end{pmatrix}.$$

   Compute the rank of A_1. Let $\tilde{n}_x = \operatorname{rank} A_1$ and $\tilde{n}_y = n_y - n_x + \tilde{n}_x$.

3. *Construct the matrices $\tilde{A}_0, \tilde{A}_1 \in \mathbb{R}^{\tilde{n}_x \times \tilde{n}_x}$ as*

$$\tilde{A}_0 = \begin{pmatrix} a_{\tilde{n}_y+1} & a_{\tilde{n}_y} & \cdots & a_{\tilde{n}_y-\tilde{n}_x+2} \\ a_{\tilde{n}_y+2} & a_{\tilde{n}_y+1} & \cdots & a_{\tilde{n}_y-\tilde{n}_x+3} \\ \vdots & \vdots & \ddots & \vdots \\ a_{\tilde{n}_y+\tilde{n}_x} & a_{\tilde{n}_y+\tilde{n}_x-1} & \cdots & a_{\tilde{n}_y+1} \end{pmatrix},$$

$$\tilde{A}_1 = \begin{pmatrix} a_{\tilde{n}_y} & a_{\tilde{n}_y-1} & \cdots & a_{\tilde{n}_y-\tilde{n}_x+1} \\ a_{\tilde{n}_y+1} & a_{\tilde{n}_y} & \cdots & a_{\tilde{n}_y-\tilde{n}_x+1+1} \\ \vdots & \vdots & \ddots & \vdots \\ a_{\tilde{n}_y+\tilde{n}_x-1} & a_{\tilde{n}_y+\tilde{n}_x-2} & \cdots & a_{\tilde{n}_y} \end{pmatrix}.$$

4. *Solve the generalized eigenvalue problem*

$$\tilde{A}_0\boldsymbol{v} = x\tilde{A}_1\boldsymbol{v} \tag{2.2}$$

to get the $\{x_j\}$ *values of the minimal degree solution to* (1.5)*.*

5. *To compute the* $\{y_j\}$ *values, the same process is used with* m_k *replaced by* $-m_k$ *and the roles of* n_x *and* n_y *interchanged.*

An alternative to Algorithm 1 is as follows.

ALGORITHM 2 (computing $\{x_j\}$ and $\{y_j\}$).

1. *Construct the matrices* $\tilde{A}_0$ *and* $\tilde{A}_1$ *as in steps* 1–3 *in Algorithm* 1*.*
2. *Denote the first column vector in* $\tilde{A}_0$ *by* $\tilde{\boldsymbol{a}}_0$ *by and solve*

$$\tilde{A}_1\boldsymbol{c}' = -\tilde{\boldsymbol{a}}_0, \qquad \boldsymbol{c}' = (c_1, c_2, \dots, c_{\tilde{n}_x})^T. \tag{2.3}$$

3. *Construct the polynomial*

$$P(z) = c_{\tilde{n}_x} + c_{\tilde{n}_x-1}z + \cdots + c_1 z^{\tilde{n}_x-1} + z^{\tilde{n}_x}.$$

The roots of $P(z)$ *are the* $\{x_j\}$ *values of the minimal degree solution to* (1.5) *(possibly together with some zeros).*

4. *To compute the* $\{y_j\}$ *values, the same process is used with* m_k *replaced by* $-m_k$ *and the roles of* n_x *and* n_y *interchanged.*

REMARK 2. *We note that the values of* a_k *in the definition* (2.1) *are independent of* K*, since the system matrix is triangular. We therefore consider the sequence without reference to* K *in any other respect than the fact that we are only able to compute elements with* $k \leq K$ *when we are given* K *moments. The largest index of the* a_k*-sequence appearing in the matrix* A_1 *is* $n_y + n_x - 1 < K$*. In the matrices* $\tilde{A}_0, \tilde{A}_1$ *it is* $\tilde{n}_y + \tilde{n}_x = n_y - n_x + 2\tilde{n}_x \leq n_y + n_x = K$*. Hence all three matrices can be constructed from the first* K *moments. Some properties of the* A_1 *matrix are detailed in section* 6*.*

Sometimes one is not interested in finding the individual $\{x_j\}$ and $\{y_j\}$ branch values but just wants the higher moments, defined as

$$m_k = \sum_{j=1}^{n_x} x_j^k - \sum_{j=1}^{n_y} y_j^k, \tag{2.4}$$

but now for $k > K$, *given* a solution $\{x_j\} \cup \{y_j\}$ to (1.5). (That this is well defined is shown later in Theorem 4.1.) For this case there is another algorithm which has empirically proven to be more stable than first computing $\{x_j\}$ and $\{y_j\}$ from Algorithm 1 or 2 and then entering the values into (2.4). We stress that this is precisely what is needed in order to compute K-multivalued solutions of the inviscid Burgers equation in geometrical optics, following the ideas of [4].

ALGORITHM 3 (computing m_{K+1}).

1. *Construct the* A_1 *matrix as in steps* 1–2 *of Algorithm* 1*.*
2. *Let*

$$\boldsymbol{a}_0 = (a_{n_y+1}, a_{n_y+2}, \dots, a_{n_y+n_x})^T \in \mathbb{R}^{n_x},$$

and let $\bar{\boldsymbol{c}} = (c_1, c_2, \dots, c_{n_x})^T$ *be one solution to*

$$A_1\bar{\boldsymbol{c}} = -\boldsymbol{a}_0. \tag{2.5}$$

3. *The next moment is given by*

$$m_{K+1} = -(K+1)\sum_{j=1}^{n_x} c_j a_{K+1-j} - \sum_{j=1}^{K} m_j a_{K+1-j}.$$

We recall that Algorithm 1 has been shown to be numerically efficient in the paper [14]. The justification of these algorithms is given in section 5, where we show the following theorem.

THEOREM 2.1. *If a solution to* (1.5) *exists, then the following hold.*

(i) *In Algorithm* 1, *the matrix* $\tilde{A}_1$ *is nonsingular. The generalized eigenvalue problem in* (2.2) *is well defined and the generalized eigenvalues (counting algebraic multiplicity) are the* $\{x_j\}$*-values of the minimal degree solution to* (1.5) *plus* $\tilde{n}_x - D_{\min}$ *zeros. (See* (3.7) *for the definition of* $D_{\min}$*.)*

(ii) *In Algorithm* 2, $\boldsymbol{c}'$ *is well defined,*

$$P(z) = \det(zI - \tilde{A}_1^{-1}\tilde{A}_0), \tag{2.6}$$

and the roots of $P(z)$ *are the* $\{x_j\}$*-values of the minimal degree solution to* (1.5) *plus* $\tilde{n}_x - D_{\min}$ *zeros.*

(iii) *In Algorithm* 3, *the computed moment satisfies*

$$m_{K+1} = \sum_{j=1}^{n_x} x_j^{K+1} - \sum_{j=1}^{n_y} y_j^{K+1}$$

for all solutions $\{x_j\} \cup \{y_j\}$ *to* (1.5).

We postpone the proof of Theorem 2.1 to section 5. We just note here that the last point in Algorithms 1 and 2 can easily be explained by the symmetry of the problem. Indeed, the negative of (1.5),

$$-m_k = \sum_{j=1}^{n_y} y_j^k - \sum_{j=1}^{n_x} x_j^k, \qquad k = 1, \dots, K,$$

is of the same form as (1.5) itself, with the roles of n_x, $\{x_j\}$ and n_y, $\{y_j\}$ interchanged.

3. Preliminaries.

We will use three different ways of describing the solution to (1.5). First, we have a set of numbers $\{x_j\}_{j=1}^{n_x}$ and $\{y_j\}_{j=1}^{n_y}$, solving (1.5). We call those numbers branch values. Second, we have a pair of polynomials (p, q) of degrees at most n_x and n_y, respectively, in the z variable. Third, we have a pair of coefficient vectors $\boldsymbol{c} = (c_0, \dots, c_{n_x})^T \in \mathbb{R}^{n_x+1}$ and $\boldsymbol{d} = (d_0, \dots, d_{n_x})^T \in \mathbb{R}^{n_y+1}$. These three representations are related as

$$p(z) = (1 - x_1 z)\cdots(1 - x_{n_x} z) = c_0 + c_1 z + \cdots + c_{n_x-1} z^{n_x-1} + c_{n_x} z^{n_x} \tag{3.1}$$

and

$$q(z) = (1 - y_1 z)\cdots(1 - y_{n_y} z) = d_0 + d_1 z + \cdots + d_{n_y-1} z^{n_y-1} + d_{n_y} z^{n_y}. \tag{3.2}$$

It is clear that there is a one-to-one correspondence between these ways of describing the solution if we disregard the ambiguity in the ordering of the numbers $\{x_j\}$ and $\{y_j\}$. Generally, we will use the notation $\mathrm{Deg}(p)$ to denote the degree of a polynomial p, and, for a given coefficient vector $\boldsymbol{c}$, we systematically write P_c to denote the corresponding polynomial (3.1).

DEFINITION 3.1. *We call the pair of polynomials* (p, q) a (polynomial) solution *to* (1.5) *if the following hold.*

1. *The degrees of p and q are at most n_x and n_y:*

$$\text{(3.3)} \qquad \mathrm{Deg}(p) \le n_x, \qquad \mathrm{Deg}(q) \le n_y.$$

2. *They are normalized to one at the origin:*

$$\text{(3.4)} \qquad p(0) = q(0) = 1.$$

3. *Their roots $\{\tilde{x}_j\}$ and $\{\tilde{y}_j\}$ satisfy*

$$\text{(3.5)} \qquad m_k = \sum_{j=1}^{\mathrm{Deg}(p)} \tilde{x}_j^{-k} - \sum_{j=1}^{\mathrm{Deg}(q)} \tilde{y}_j^{-k}, \qquad k = 1, \dots, K.$$

We note that the roots cannot be zero because of (3.4).

Next, we have the following.

Definition 3.2. *A pair of vectors*

$$\boldsymbol{c} = (c_0, \dots, c_{n_x})^T \in \mathbb{R}^{n_x+1} \textit{ and } \boldsymbol{d} = (d_0, \dots, d_{n_y})^T \in \mathbb{R}^{n_y+1}$$

is said to be a (coefficient) solution *to* (1.5) *if the corresponding pair* (P_c, P_d) (3.1)–(3.2) *realizes a polynomial solution to* (1.5).

The number of branch values is always n_x and n_y, respectively. Some of them may be zero, and they do not need to be distinct. The number of nonzero branch values is $\mathrm{Deg}(p)$ and $\mathrm{Deg}(q)$, respectively. The degree of a solution can then also be defined.

Definition 3.3. *The* degree *of a solution to* (1.5) *is the number of nonzero x_j-values. This number is equivalent to* $\mathrm{Deg}(p)$.

Given any polynomial pair satisfying (3.4), we say that it generates the moment sequence $\{m_k\}$ if m_k is given by (3.5) for all k. In turn, each sequence of moments $\{m_k\}$ generates the corresponding $\{a_k\}$ sequence through (2.1). We define the big matrix

$$A = \begin{pmatrix} a_{n_y+1} & a_{n_y} & \cdots & a_{n_y-n_x+1} \\ a_{n_y+2} & a_{n_y+1} & \cdots & a_{n_y-n_x+2} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n_y+n_x} & a_{n_y+n_x-1} & \cdots & a_{n_y} \end{pmatrix} \in \mathbb{R}^{n_x \times (n_x+1)}.$$

We let the columns of A be denoted $\boldsymbol{a}_0, \dots, \boldsymbol{a}_{n_x}$, and we note that

$$\text{(3.6)} \qquad A = \begin{pmatrix} | & & | \\ \boldsymbol{a}_0 & \cdots & \boldsymbol{a}_{n_x} \\ | & & | \end{pmatrix} = \begin{pmatrix} & & | \\ & A_0 & \boldsymbol{a}_{n_x} \\ & & | \end{pmatrix} = \begin{pmatrix} | & & \\ \boldsymbol{a}_0 & A_1 & \\ | & & \end{pmatrix}.$$

Hence A_0 and A_1 constitute the first and last n_x columns of A, respectively. When $\boldsymbol{a}_0 \in \operatorname{range} A_1$ and $\boldsymbol{a}_0 \neq 0$, let

$$\text{(3.7)} \qquad D_{\min} = \operatorname{argmin}_{j>0} \boldsymbol{a}_0 \in \operatorname{span}\{\boldsymbol{a}_1, \dots, \boldsymbol{a}_j\},$$

and set $D_{\min} = 0$ if $\boldsymbol{a}_0 = 0$. Moreover, define

$$\text{(3.8)} \qquad D_{\max} = D_{\min} + n_x - \operatorname{rank} A_1.$$

4. Existence and uniqueness of solutions.

In this section we prove results on the existence and uniqueness of solutions to (1.5). We aim at establishing the following theorem.

Theorem 4.1.

(i) *There exists a solution to* (1.5) *if and only if*

$$\boldsymbol{a}_0 \in \operatorname{range}(A_1). \tag{4.1}$$

(ii) *If d is the degree of a solution to* (1.5)*, then $D_{\min} \le d \le D_{\max}$.*

(iii) *When* (4.1) *holds, there is a unique solution (p^*, q^*) of minimal degree $D_{\min}$. For this solution, $x_j \neq y_i$ for all indices i, j representing nonzero branch values. Moreover,* $\operatorname{Deg}(q^*) \le n_y - n_x + \operatorname{rank} A_1$ *with equality if* $D_{\min} < \operatorname{rank} A_1$.

(iv) *When* (4.1) *holds, a polynomial pair (p, q) is a solution if and only if $p = p^* r$ and $q = q^* r$, where $r(z)$ is a polynomial satisfying $r(0) = 1$ and* $\operatorname{Deg}(r) \le D_{\max} - D_{\min}$.

(v) *The minimal degree solution is the only solution to* (1.5) *if and only if the matrix A_1 is nonsingular.*

(vi) *Let $\{x_j\}$ and $\{y_j\}$ be a solution to* (1.5)*. Then the higher moments defined in* (2.4) *are well defined.*

Let us proceed with several remarks.

Remark 3. *In particular, it follows from* (i) *that there exists a solution as soon as the matrix A_1 is nonsingular.*

Remark 4. *Since* (1.5) *is a system of polynomial equations of degree K, one could expect there to be a finite number of solutions, typically K solutions. However, because of the special structure of the equations there is either one unique solution (when A_1 is nonsingular) or infinitely many solutions (when A_1 is singular).*

Remark 5. *The form $(p^* r, q^* r)$ of solutions can also be stated as follows: All solutions have a core set of values $\{x_j\}$, $j = 1, \ldots, \operatorname{Deg}(p^*) = D_{\min}$, and $\{y_i\}$, $i = 1, \ldots, \operatorname{Deg}(q^*)$, corresponding to nonzero branch values of the minimal degree solution, where $x_j \neq y_i$ for all those i, j. One can then add an optional set of nonzero branch values $\{x_{D_{\min}+j}\}$ and $\{y_{\operatorname{Deg}(q^*)+j}\}$ for $j = 1, \ldots, D_{\max} - D_{\min}$ such that $x_{D_{\min}+j} = y_{\operatorname{Deg}(q^*)+j}$.*

To prove this theorem we first establish some utility results in the next subsection. We then derive different ways of characterizing the solution in section 4.2 which are subsequently used to prove Theorem 4.1 in section 4.3.

4.1. Utility results.

We start with a useful lemma on Taylor coefficients for a product of functions.

Lemma 4.2. *Suppose f, g, and h are analytic functions in a neighborhood of zero satisfying $f(z) = g(z)h(z)$. Let f have the Taylor expansion*

$$f(z) = \sum_{k=0}^{\infty} f_k z^k,$$

and let $\{g_k\}$ and $\{h_k\}$ be the corresponding coefficients for $g(x)$ and $h(x)$, respectively. Then

$$f_k = \sum_{j=0}^{k} g_j h_{k-j}. \tag{4.2}$$

Proof. Since the functions are analytic, the coefficients are given as

$$f_k = \frac{1}{k!}\frac{d^k}{dz^k}f(z)\Big|_{z=0} = \frac{1}{k!}\frac{d^k}{dz^k}g(z)h(z)\Big|_{z=0} = \frac{1}{k!}\sum_{j=0}^{k} c_{jk}g^{(j)}(0)h^{(k-j)}(0),$$

where $c_{jk} = k!/j!(k-j)!$ are the binomial coefficients. But $g^{(j)}(0) = j!g_j$ and $h^{(k-j)}(0) = (k-j)!h_{k-j}$, and therefore (4.2) follows. □

REMARK 6. *The discrete convolution* (4.2) *is, in fact, precisely an elementwise description of multiplication of a lower triangular $k \times k$ Toeplitz matrix by a vector. In the notation of* [15], *it would read $\boldsymbol{f} = \mathcal{T}(\boldsymbol{g})\boldsymbol{h}$.*

As was already known by Markov, the exponential transform of the moment sequence plays an important role in the analysis of these problems; see, e.g., [1, 2]. We show here that $\{a_k\}$ is a version of the exponential transform of $\{m_k\}$.

LEMMA 4.3. *Suppose $\{m_k\}$ is generated by the polynomials $p(z)$ and $q(z)$ and $\{a_k\}$ is generated by $\{m_k\}$. Let $m(z)$ be defined as*

$$m(z) = m_1 z + \frac{1}{2}m_2 z^2 + \frac{1}{3}m_3 z^3 + \cdots . \tag{4.3}$$

Then, if (3.4) *holds,*

$$e^{m(z)} = \frac{q(z)}{p(z)} = a_0 + a_1 z + a_2 z^2 + \cdots , \tag{4.4}$$

written as its Taylor expansion around $z = 0$.

Proof. Let us first show that $m(z)$ is a well-defined analytic function at zero. We have

$$\begin{aligned} m(z) &= \textstyle\sum_{k=0}^{\infty} \frac{m_k z^k}{k} \\ &= \textstyle\sum_{k=0}^{\infty}\sum_{j=1}^{n_x} \frac{x_j^k z^k}{k} - \sum_{k=0}^{\infty}\sum_{j=1}^{n_y} \frac{y_j^k z^k}{k} \\ &= -\textstyle\sum_{j=1}^{n_x} \log(1 - x_j z) + \sum_{j=1}^{n_y} \log(1 - y_j z). \end{aligned}$$

The last step is allowed when $|z| < 1/\max_{ij}(|x_j|, |y_i|)$, which is true for small enough z since $p(0) \neq 0$. This also shows that the function is analytic at zero. Moreover,

$$e^{m(z)} = \frac{\prod_{j=1}^{n_y}(1 - y_j z)}{\prod_{j=1}^{n_x}(1 - x_j z)} = \frac{q(z)}{p(z)}.$$

Finally, setting $a(z) := \exp(m(z))$ and differentiating gives

$$za'(z) = zm'(z)a(z),$$

where all three functions are analytic at zero. Let $a(z)$ have the Taylor coefficients $\{\tilde{a}_k\}$. Then $za'(z) = \tilde{a}_1 z + 2\tilde{a}_2 z^2 + 3\tilde{a}_3 z^3 \cdots$ and clearly $zm'(z) = m_1 z + m_2 z^2 + \cdots$. By Lemma 4.2, for $k \geq 1$,

$$k\tilde{a}_k = \sum_{j=1}^{k} m_j \tilde{a}_{k-j}.$$

Since $\tilde{a}_0 = q(0)/p(0) = 1$, we see that a_k and $\tilde{a}_k$ satisfy the same nonsingular linear system of equations (2.1), and therefore $a_k = \tilde{a}_k$, showing (4.4). □

We now have the following basic characterization of a solution.

LEMMA 4.4. *Suppose $p(z)$ and $q(z)$ are two polynomials satisfying* (3.3), (3.4)*. They form a polynomial solution to* (1.5) *if and only if their quotient has the Taylor expansion around $z = 0$*

$$\frac{q(z)}{p(z)} = a_0 + a_1 z + \cdots + a_K z^K + O\left(z^{K+1}\right), \tag{4.5}$$

where $\{a_k\}$ is generated by $\{m_k\}$. Moreover, if (p,q) is a solution, then $(\bar{p},\bar{q})$ is also a solution if and only if the pair satisfies (3.3), (3.4)*, and $\bar{p}/\bar{q} = p/q$, where these fractions are defined.*

Proof. Let $\{\tilde{m}_k\}$ be generated by p and q, and suppose (4.5) holds. Then, as in the proof of Lemma 4.3 for $1 \le k \le K$,

$$ka_k = \sum_{j=1}^{k} \tilde{m}_j a_{k-j}.$$

Since $\{m_k\}$ satisfy the linear system (2.1), we have after subtraction

$$m_n - \tilde{m}_n = -\sum_{k=1}^{n-1} (m_k - \tilde{m}_k) a_{n-k}, \qquad m_1 = \tilde{m}_1,$$

for $n = 2, \ldots, K$. By induction $\tilde{m}_k = m_k$ for $1 \le k \le K$, showing that (p,q) solves (1.5). On the other hand, if (p,q) is a solution, then (4.5) must hold by (4.4) in Lemma 4.3.

For the last statement, the "if" part is obvious since both pairs then satisfy (4.5). To show the "only if" part, suppose both (p,q) and $(\bar{p},\bar{q})$ are solutions. By definition they satisfy (3.3), (3.4), and by (4.5),

$$\frac{\bar{q}(z)}{\bar{p}(z)} - \frac{q(z)}{p(z)} = \frac{\bar{q}(z)p(z) - \bar{p}(z)q(z)}{\bar{p}(z)p(z)} = O(z^{K+1}).$$

Since $\bar{p}(0)p(0) = 1$, we must have that $(\bar{q}(z)p(z) - \bar{p}(z)q(z))/z^{K+1}$ is bounded as $z \to 0$. But since the degree of $\bar{q}p - \bar{p}q$ is at most $K = n_x + n_y$, this is possible only if it is identically zero. Hence $\bar{q}(z)p(z) = \bar{p}(z)q(z)$, which concludes the proof. □

4.2. Characterization of the solution. In this section we show three propositions that characterize solutions to (1.5) in terms of polynomials, coefficient vectors, and the column vectors of the A matrix in (3.6). We start by expressing the uniqueness properties of the solution in terms of its polyomial representation.

PROPOSITION 4.5. *Suppose the pairs (p,q) and $(\bar{p},\bar{q})$ are both polynomial solutions to* (1.5)*. Then the following hold.*

(i) $\mathrm{Deg}(p) - \mathrm{Deg}(q) = \mathrm{Deg}(\bar{p}) - \mathrm{Deg}(\bar{q})$.

(ii) *If $\mathrm{Deg}(\bar{p}) \le \mathrm{Deg}(p)$, and if there is no polynomial $r(z)$ such that $p = \bar{p}r$, then there is another solution $(\tilde{p},\tilde{q})$ with $\mathrm{Deg}(\tilde{p}) < \mathrm{Deg}(p)$. In particular, if $\mathrm{Deg}(p) = \mathrm{Deg}(\bar{p})$ but $p \ne \bar{p}$, there is such a lower degree solution.*

(iii) *If $\mathrm{Deg}(\bar{p}) \le \mathrm{Deg}(p)$, any polynomial pair $(\bar{p}r, \bar{q}r)$ is a solution if $r(z)$ is a polynomial satisfying $r(0) = 1$ and $\mathrm{Deg}(r) \le \mathrm{Deg}(p) - \mathrm{Deg}(\bar{p})$. In particular, if $\mathrm{Deg}(\bar{p}) \le m \le \mathrm{Deg}(p)$, there is a solution $(\tilde{p},\tilde{q})$ with $\mathrm{Deg}(\tilde{p}) = m$.*

Proof.

(i) The statement follows directly from Lemma 4.4, since $\bar{q}p = \bar{p}q$ implies that

$$\mathrm{Deg}(\bar{q}) + \mathrm{Deg}(p) = \mathrm{Deg}(\bar{p}) + \mathrm{Deg}(q).$$

(ii) We let

$$p(z) = r_p(z)\bar{p}(z) + s_p(z), \qquad q(z) = r_q(z)\bar{q}(z) + s_q(z)$$

be the unique polynomial decomposition of (p, q) such that r_p, r_q, s_p, s_q are polynomials, $\mathrm{Deg}(s_p) < \mathrm{Deg}(\bar{p})$, and $\mathrm{Deg}(s_q) < \mathrm{Deg}(\bar{q})$. Since $\bar{p}q = p\bar{q}$ by Lemma 4.4, we get

$$\bar{p}\bar{q}(r_q - r_p) = \bar{q}s_p - \bar{p}s_q.$$

Unless $r_q = r_p$, the degree of the left-hand side is at least $\mathrm{Deg}(\bar{p}) + \mathrm{Deg}(\bar{q})$, while the degree of the right-hand side is at most

$$\max\left(\mathrm{Deg}(\bar{q}) + \mathrm{Deg}(s_p),\ \mathrm{Deg}(\bar{p}) + \mathrm{Deg}(s_q)\right) < \mathrm{Deg}(\bar{q}) + \mathrm{Deg}(\bar{p}).$$

Hence, $r_q = r_p$ and $\bar{q}s_p = \bar{p}s_q$. Since $\bar{q}, \bar{p} \not\equiv 0$, it follows that s_p and s_q are either both zero or both nonzero. Suppose $s_p \not\equiv 0$ and $s_q \not\equiv 0$. Write $s_p(z) = z^{m_p}\tilde{s}_p(z)$ and $s_q(z) = z^{m_q}\tilde{s}_q(z)$, where $\tilde{s}_p(0) \neq 0$ and $\tilde{s}_q(0) \neq 0$. Since

$$z^{m_p}\tilde{s}_p(z)\bar{q}(z) = z^{m_q}\tilde{s}_q(z)\bar{p}(z)$$

and also $\bar{q}(0) = \bar{p}(0) = 1$, the lowest degree term in the left- and right-hand side polynomials are z^{m_p} and z^{m_q}, respectively, and therefore $m_p = m_q$. Consequently,

$$\tilde{s}_p(z)\bar{q}(z) = \tilde{s}_q(z)\bar{p}(z)$$

and $\tilde{s}_p(0) = \tilde{s}_q(0)$. We can then take $\tilde{p}(z) = \tilde{s}_p(z)/\tilde{s}_p(0)$ and $\tilde{q}(z) = \tilde{s}_q(z)/\tilde{s}_q(0)$. They satisfy

$$\tilde{p}(z)\bar{q}(z) = \tilde{q}(z)\bar{p}(z), \qquad \tilde{p}(0) = \tilde{q}(0) = 1,$$

while $\mathrm{Deg}(\tilde{p}) = \mathrm{Deg}(\tilde{s}_p) \leq \mathrm{Deg}(s_p) < \mathrm{Deg}(p)$ and similarly $\mathrm{Deg}(\tilde{q}) < \mathrm{Deg}(q) \leq n_y$. Hence $(\tilde{p}, \tilde{q})$ is a polynomial solution by Lemma 4.4. It has degree strictly less than (p, q), which shows the first statement in (ii). If $\mathrm{Deg}(p) = \mathrm{Deg}(\bar{p})$ and $p \neq \bar{p}$, then there is no $r(z)$ satisfying the requirements, showing the second statement in (ii).

(iii) We finally let $r(z)$ be any polynomial with $\mathrm{Deg}(r) \leq \mathrm{Deg}(p) - \mathrm{Deg}(\bar{p})$ and $r(0) = 1$. We then set $\tilde{p} = \bar{p}r$ and $\tilde{q} = \bar{q}r$. These polynomials trivially satisfy (3.4) and (4.5). Since $\mathrm{Deg}(\tilde{p}) = \mathrm{Deg}(r) + \mathrm{Deg}(\bar{p}) \leq \mathrm{Deg}(p) \leq n_x$ and

$$\mathrm{Deg}(\tilde{q}) = \mathrm{Deg}(r) + \mathrm{Deg}(\bar{q}) \leq \mathrm{Deg}(p) - \mathrm{Deg}(\bar{p}) + \mathrm{Deg}(\bar{q}) = \mathrm{Deg}(q) \leq n_y,$$

they also satisfy (3.3) and thus are a polynomial solution by Lemma 4.4. In particular, we can take $r(z)$ of degree m. □

A solution to (1.5) can also be characterized in terms of the coefficient vectors. We have the following proposition.

PROPOSITION 4.6. *The pair* $\boldsymbol{c} = (c_0, \ldots, c_{n_x})^T \in \mathbb{R}^{n_x+1}$ *and* $\boldsymbol{d} = (d_0, \ldots, d_{n_y})^T \in \mathbb{R}^{n_y+1}$ *is a coefficient solution to* (1.5) *if and only if*

(i) $c_0 = 1$,

(ii) $\boldsymbol{c}$ *is in the null-space of* A, *and*

(iii)

$$d_k = \sum_{j=0}^{\min(k,n_x)} c_j a_{k-j}, \qquad k = 0, \dots, n_y. \tag{4.6}$$

Proof. Suppose first that $\boldsymbol{c}$ is in the null-space of A, $c_0 = 1$, and $\{d_k\}$ is given by (4.6). Extend the coefficient sequences by setting $c_k = 0$ for $k > n_x$ and $d_k = 0$ for $k > n_y$. Since $\boldsymbol{c}$ is in the null-space of A, we get $\sum_{j=0}^{k} c_j a_{k-j} = 0$ when $n_y + 1 \leq k \leq n_x + n_x = K$, and in conclusion

$$d_k = \sum_{j=0}^{k} c_j a_{k-j}, \qquad k = 0, \dots, K. \tag{4.7}$$

Upon noting that $\{c_k\}_{k=0}^{\infty}$ and $\{d_k\}_{k=0}^{\infty}$ are the Taylor coefficients of P_c and P_d, and since $P_c(0) = c_0 = 1$, $P_d(0) = d_0 = a_0 c_0 = 1$, Lemma 4.2 shows that

$$P_d(z) = P_c(z) \left[a_0 + a_1 z + \cdots + a_K z^K + O\left(z^{K+1}\right) \right], \tag{4.8}$$

and by Lemma 4.4 we have that (P_c, P_d) is a solution to (1.5). Conversely, if (P_c, P_d) is a solution, then $c_0 = P_c(0) = 1$, and by Lemma 4.2 we get that (4.7) holds. For $k = n_y + 1, \dots, K$ this also implies that $\boldsymbol{c}$ is in the null-space of A. □

The final proposition of this section relates the degree of the solution to the column vectors of A and the linear spaces they span.

PROPOSITION 4.7. *Let* $V_j = \operatorname{span}\{\boldsymbol{a}_1, \dots, \boldsymbol{a}_j\}$ *and* $V_j^0 = \operatorname{span}\{\boldsymbol{a}_0, \dots, \boldsymbol{a}_j\}$. *Set* $V_0 = V_{-1}^0 = \emptyset$. *Then the following hold.*

(i) *There is a solution if and only if* $\boldsymbol{a}_0 \in V_{n_x} = \operatorname{Range}(A_1)$.

(ii) *There is a solution of degree* $j \geq 0$ *if and only if*

$$\boldsymbol{a}_0 \in V_j \quad \textit{and} \quad \boldsymbol{a}_j \in V_{j-1}^0. \tag{4.9}$$

(iii) *When* $\boldsymbol{a}_0 \in V_{n_x}$, *then*

$$\boldsymbol{a}_0 \in V_d, \qquad V_d^0 = V_d$$

if and only if $d \geq D_{\max}$.

(iv) *When* $\boldsymbol{a}_0 \in V_{n_x}$, *the vectors*

$$\boldsymbol{a}_1, \dots, \boldsymbol{a}_{D_{\min}}$$

(when $D_{\min} > 0$*),*

$$\boldsymbol{a}_{D_{\max}+1}, \dots, \boldsymbol{a}_{n_x}$$

(when $D_{\max} < n_x$*) are all linearly independent. Moreover,*

$$\boldsymbol{a}_j \in V_{D_{\min}}, \quad V_j = V_{D_{\min}}, \qquad j = D_{\min}, \dots, D_{\max}.$$

Proof.

(i) By Proposition 4.6 there exists a solution to (1.5) if and only if there is a coefficient vector $\boldsymbol{c} = (1, \boldsymbol{c}')^T$ in the null-space of A, i.e.,

$$A\boldsymbol{c} = A_1\bar{\boldsymbol{c}} + \boldsymbol{a}_0 = 0.$$

But such a vector $\bar{\boldsymbol{c}}$ exists if and only if $\boldsymbol{a}_0$ is in the range of A_1. This shows (i).

(ii) Again by Proposition 4.6 there is a solution of degree j if and only if there is a vector $\boldsymbol{c} = (c_0, c_1, \ldots, c_j, 0, \ldots, 0)^T$ such that

$$0 = A\boldsymbol{c} = c_0\boldsymbol{a}_0 + c_1\boldsymbol{a}_1 + \cdots + c_j\boldsymbol{a}_j, \tag{4.10}$$

with $c_j \neq 0$ and $c_0 = 1$. For $j = 0$ this is clearly equivalent to $\boldsymbol{a}_0 = 0$ or $\boldsymbol{a}_0 \in V_0 = V^0_{-1}$. For $j > 0$ the existence of c_j-coefficients satisfying (4.10) is equivalent to the left condition in (4.9). Moreover, if $\boldsymbol{a}_j \neq V^0_{j-1} = \operatorname{span}\{\boldsymbol{a}_0, \ldots, \boldsymbol{a}_{j-1}\}$, then we must have $c_j = 0$ to satisfy (4.10), and $\boldsymbol{c}$ cannot represent a solution of degree j. On the other hand, if $c_j = 0$ and $\boldsymbol{a}_j = c'_0\boldsymbol{a}_0 + \cdots + c'_{j-1}\boldsymbol{a}_{j-1}$ for some nonzero coefficients c'_k, then $\boldsymbol{a}_0 + c''_1\boldsymbol{a}_1 + \cdots + c''_{j-1}\boldsymbol{a}_{j-1} + \boldsymbol{a}_j = 0$, with $c''_k = (1 + c'_0)c_k - c'_k$, represents a solution of degree j. This shows (ii).

(iii) The statement is obvious in case $D_{\min} = 0$. If $D_{\min} > 0$, there are scalars such that

$$\boldsymbol{a}_0 = v_1\boldsymbol{a}_1 + \cdots + v_{D_{\min}}\boldsymbol{a}_{D_{\min}}, \tag{4.11}$$

by (3.7). Hence, $\boldsymbol{a}_0 \in V_{D_{\min}}$ and since the V_j spaces are nested, $V_j \subset V_{j+1}$, we have $\boldsymbol{a}_0 \in V_d$ for $d \geq D_{\min}$. Moreover, the minimal property of $D_{\min}$ ensures that $v_{D_{\min}} \neq 0$ in (4.11), so that $\boldsymbol{a}_0 \notin V_d$ when $d < D_{\min}$.

(iv) To show that when $D_{\min} > 0$ the vectors $\boldsymbol{a}_1, \ldots, \boldsymbol{a}_{D_{\min}}$ are linearly independent, we use (4.11) and note that $P_c(z)$ with $\boldsymbol{c} = (1, -v_1, \ldots, -v_{D_{\min}}, 0, \ldots, 0)^T$ is a polynomial solution to (1.5). Suppose now that there are nonzero coefficients c'_j such that

$$c'_1\boldsymbol{a}_1 + \cdots + c'_{D_{\min}}\boldsymbol{a}_{D_{\min}} = 0.$$

Then $P_{c'}$ with $\boldsymbol{c}' = (1, c'_1 - v_1, \ldots, c_{D_{\min}} - v_{D_{\min}}, 0, \ldots, 0)^T$ is another polynomial solution to (1.5). Moreover, by the minimality property of $D_{\min}$ we must have $c_{D_{\min}} - v_{D_{\min}} \neq 0$ and therefore $\operatorname{Deg}(P_c) = \operatorname{Deg}(P_{c'}) = D_{\min}$. But by (ii) in Proposition 4.5 this implies that there is yet another solution $P_{c''}$ of degree strictly less than $D_{\min}$. Hence, there are coefficients c''_j such that

$$\boldsymbol{a}_0 + c''_1\boldsymbol{a}_1 + \cdots + c''_d\boldsymbol{a}_d = 0,$$

with $d < D_{\min}$, contradicting (3.7). The vectors must therefore be linearly independent.

Suppose $D^* \geq D_{\min}$ is the highest degree of an existing solution. Since $P_c(z)$ is a solution of degree $D_{\min}$, we get from (iii) in Proposition 4.5 that there are solutions of all intermediate degrees $D_{\min}, \ldots, D^*$. Hence, from (ii), $\boldsymbol{a}_j \in V^0_{j-1}$ for $j = D_{\min}, \ldots, D^*$, and, from (iii), $\boldsymbol{a}_j \in V_{j-1}$ for $j = D_{\min}+1, \ldots, D^*$. Noting that if $\boldsymbol{a}_{j+1} \in V_j$, then $V_j = V_{j+1}$, we can conclude inductively that $V_{D_{\min}} = \cdots = V_{D^*}$ and $\boldsymbol{a}_j \in V_{D_{\min}}$ for $j = D_{\min}, \ldots, D^*$. We now have three different cases.

1. If $D^* = n_x$, then $V_{D_{\min}} = V_{n_x}$, and by (3.8) we get $D^* = \operatorname{rank} A_1 - D_{\min} + D_{\max} = \dim V_{n_x} - D_{\min} + D_{\max} = \dim V_{D_{\min}} - D_{\min} + D_{\max} = D_{\max}$ since either $\boldsymbol{a}_1, \dots, \boldsymbol{a}_{D_{\min}}$ are linearly independent or $D_{\min} = 0$ and $V_{D_{\min}} = \emptyset$. This shows (iv) for $D^* = n_x$.
2. If $D^* < n_x$ and $D_{\min} = 0$, then $V_{D_{\min}} = V_{D^*} = \emptyset$, and

   $$V_{n_x} = \operatorname{span}\{\boldsymbol{a}_{D^*+1}, \dots, \boldsymbol{a}_{n_x}\}. \tag{4.12}$$

   Suppose there are nonzero coefficients α_k such that

   $$\alpha_{D^*+1}\boldsymbol{a}_{D^*+1} + \cdots + \alpha_{n_x}\boldsymbol{a}_{n_x} = 0,$$

   and let k^* be the highest index of all nonzero coefficients, $\alpha_{k^*} \neq 0$. Then $\boldsymbol{a}_{k^*} \in V^0_{k^*-1}$ and there is a solution of degree k^* by (ii), which is in contradiction to the definition of D^*. Hence, the vectors in (4.12) must be linearly independent and

   $$D^* = n_x - \dim V_{n_x} = D_{\min} + n_x - \operatorname{rank} A_1 = D_{\max},$$

   showing (iv) for this case.
3. If $D^* < n_x$ and $D_{\min} > 0$, we have

   $$V_{n_x} = \operatorname{span}\{\boldsymbol{a}_1, \dots, \boldsymbol{a}_{D_{\min}}, \boldsymbol{a}_{D^*+1}, \dots, \boldsymbol{a}_{n_x}\}. \tag{4.13}$$

   Suppose there are nonzero coefficients α_k such that

   $$\alpha_1\boldsymbol{a}_1 + \cdots + \alpha_{D_{\min}}\boldsymbol{a}_{D_{\min}} + \cdots + \alpha_{D^*+1}\boldsymbol{a}_{D^*+1} + \cdots + \alpha_{n_x}\boldsymbol{a}_{n_x} = 0.$$

   Since $\boldsymbol{a}_1, \dots, \boldsymbol{a}_{D_{\min}}$ are linearly independent, at least one α_k with $k > D^*$ must be nonzero. By the same argument as above in case 2 we then get a contradiction, and the vectors in (4.13) must be linearly independent. Hence,

   $$D^* = D_{\min} + n_x - \dim V_{n_x} = D_{\min} + n_x - \operatorname{rank} A_1 = D_{\max},$$

   showing this final case. □

4.3. Proof of Theorem 4.1. To prove Theorem 4.1, we essentially have to combine the results from Propositions 4.5 and 4.7. The statement (i) is given directly by (i) in the latter. For the remaining points we have the following.

(ii) From (ii) in Proposition 4.7 we see that $\boldsymbol{a}_0 \in V_d$ and $\boldsymbol{a}_d \in V^0_{d-1}$. It follows from (iii) in Proposition 4.7 that $d \geq D_{\min}$. On the other hand, if $D_{\max} < n_x$ and $d > D_{\max}$, it says that $V^0_{d-1} = V_{d-1}$. Hence, $\boldsymbol{a}_d \in V_{d-1}$, which contradicts the linear independence of $\boldsymbol{a}_{D_{\max}}, \dots, \boldsymbol{a}_{n_x}$ established in point (iv) of Proposition 4.7.

(iii) We note that by (3.7) there are scalars $v_1, \dots, v_{D_{\min}}$ such that

$$\boldsymbol{a}_0 = v_1\boldsymbol{a}_1 + \cdots + v_{D_{\min}}\boldsymbol{a}_{D_{\min}}. \tag{4.14}$$

Hence, $\boldsymbol{a}_0 \in V_{D_{\min}}$, and since $v_{D_{\min}} \neq 0$, we also have $\boldsymbol{a}_{D_{\min}} \in V^0_{D_{\min}}$. By (ii) in Proposition 4.7 there is thus a solution of degree $D_{\min}$ which we denote (p^*, q^*). Since $\boldsymbol{a}_1, \dots, \boldsymbol{a}_{D_{\min}}$ are linearly independent by (iii) in Proposition 4.7, the coefficients in (4.14) are unique, and therefore the $D_{\min}$-degree solution is also unique. Moreover, suppose that $x_j = y_i = x^* \neq 0$ for some i, j. Then p^* and q^* would have a common factor $(1-zx^*)$, and by Lemma 4.4 $\bar{p}(z) := p^*(z)/(1-zx^*)$ and $\bar{q}(z) := q^*(z)/(1-zx^*)$ would also be a solution. But this is impossible since $\operatorname{Deg}(\bar{p}) < \operatorname{Deg}(p^*) = D_{\min}$. By (iv), shown below, a solution is given by (p^*r, q^*r), where $r(0) = 1$ and $\operatorname{Deg}(r) = D_{\max} - D_{\min}$. Hence $n_y \geq \operatorname{Deg}(q^*r) = \operatorname{Deg}(q^*) + n_x - \operatorname{rank} A_1$. Suppose finally that $D_{\min} < \operatorname{rank} A_1$ and that $\operatorname{Deg}(q^*) < n_y - n_x + \operatorname{rank} A_1$. Let $\operatorname{Deg}(r) = D_{\max} + 1 - D_{\min}$. Then (p^*r, q^*r) is still a solution by Lemma 4.4 since (p^*, q^*) is a solution, $\operatorname{Deg}(p^*r) = D_{\max} + 1 = n_x + D_{\min} + 1 - \operatorname{rank} A_1 \leq n_x$, and

$$\operatorname{Deg}(q^*r) < n_y - n_x + \operatorname{rank} A_1 + D_{\max} + 1 - D_{\min} = n_y + 1.$$

This contradicts (ii) and therefore $\operatorname{Deg}(q^*) = n_y - n_x + \operatorname{rank} A_1$, concluding the proof of (iii).

(iv) We first note that there exists a solution of degree $D_{\max}$ by Proposition 4.7 since, if $D_{\max} > D_{\min}$, we have $\boldsymbol{a}_0 \in V^0_{D_{\max}-1}$ and $\boldsymbol{a}_{D_{\max}} \in V_{D_{\min}} = V_{D_{\max}-1} = V^0_{D_{\max}-1}$. Hence, (iii) in Proposition 4.5 shows that any polynomial pair of the stated type is a solution. On the other hand, if the polynomial solution is not of this type, then (ii) in Proposition 4.5 says there is a solution of degree strictly less than $D_{\min}$, contradicting (ii) above.

(v) We suppose first that A_1 is nonsingular. Then $\operatorname{rank} A_1 = n_x$ so that $D_{\min} = D_{\max}$ and the uniqueness is given by (iii) above. If, on the contrary, A_1 is singular, then $D_{\max} > D_{\min}$, and since we can then pick infinitely many polynomials $r(z)$ in (iv), we have infinitely many solutions.

(vi) This is a consequence of (iv). The solution can be represented by (p^*r, q^*r) for some polynomial $r(z)$ with $r(0) = 1$. Let $1/x_j$ for $j = 1, \ldots, D_{\min}$ and $1/y_j$ for $j = 1, \ldots, \operatorname{Deg}(q^*)$ be the roots of $p^*(z)$ and $q^*(z)$, respectively. Let $1/z_j$ for $j = 1, \ldots, \operatorname{Deg}(r)$ be the roots of $r(z)$. Then

$$m_k = \sum_{j=1}^{D_{\min}} x_j^k + \sum_{j=1}^{\operatorname{Deg}(r)} z_j^k - \sum_{j=1}^{\operatorname{Deg}(q^*)} y_j^k - \sum_{j=1}^{\operatorname{Deg}(r)} z_j^k = \sum_{j=1}^{D_{\min}} x_j^k - \sum_{j=1}^{\operatorname{Deg}(q^*)} y_j^k,$$

which is independent of $r(z)$ and uniquely determined because (p^*, q^*) is unique.

5. Proof of Theorem 2.1.

We can now use the results in section 4 to prove Theorem 2.1.

(i)–(ii) To show the statements about Algorithms 1 and 2 we consider the reduced problem

$$m_k = \sum_{j=1}^{\tilde{n}_x} \tilde{x}_j^k - \sum_{j=1}^{\tilde{n}_y} \tilde{y}_j^k, \qquad k = 1, \ldots, \tilde{K}, \tag{5.1}$$

where $\tilde{n}_x = \operatorname{rank} A_1 \leq n_x$, $\tilde{n}_y = n_y - n_x + \tilde{n}_x \leq n_y$, and $\tilde{K} = \tilde{n}_x + \tilde{n}_y \leq K$. The moments m_k in the left-hand side are the same as in (1.5). First, we consider the minimal solution (p^*, q^*) of (1.5). By (iv) in Proposition 4.7 we must have $\operatorname{Deg}(p^*) = D_{\min} \leq \operatorname{rank} A_1 = \tilde{n}_x$. Moreover, by (iii) in Theorem 4.1,

$$\operatorname{Deg}(q^*) \leq n_y - n_x + \operatorname{rank} A_1 = \tilde{n}_y.$$

It follows from Lemma 4.4 that (p^*, q^*) is also a solution to (5.1). Second, let $(\tilde{p}^*, \tilde{q}^*)$ be the minimal degree solution to (5.1). Then by (iv) in Theorem 4.1 there is a polynomial $r(z)$ with $r(0) = 1$ such that $p^* = \tilde{p}^* r$ and $q^* = \tilde{q}^* r$. But then $(\tilde{p}^*, \tilde{q}^*)$ is also a solution to (1.5) by Lemma 4.4. By the uniqueness of the minimal degree solution of (1.5) it follows that $r \equiv 1$ and $p^* = \tilde{p}^*$, $q^* = \tilde{q}^*$. Suppose now that there is another polynomial $r(z)$ with $r(0) = 1$, $\mathrm{Deg}(r) > 0$ such that $(p^* r, q^* r)$ is a solution to (5.1). Then $\mathrm{Deg}(p^* r) = D_{\min} + \mathrm{Deg}(r) \le \tilde{n}_x = \operatorname{rank} A_1$. Hence, $D_{\min} < \operatorname{rank} A_1$, and therefore by (iii) in Theorem 4.1 we have $\mathrm{Deg}(q^*) = n_y - n_x + \operatorname{rank} A_1 = \tilde{n}_y$. Thus, $\mathrm{Deg}(q^* r) > \tilde{n}_y$, which is impossible if $(p^* r, q^* r)$ is a solution. Hence, (p^*, q^*) is the unique solution to (5.1), and therefore $\tilde{A}_1$ is nonsingular by (v) in Theorem 4.1.

Since $\tilde{A}_1$ is invertible, the generalized eigenvalue problem (2.2) and $\boldsymbol{c}'$ are well defined. Moreover, we can construct $\tilde{A}_1^{-1} \tilde{A}_0$. By (2.3),

$$\tilde{A}_1^{-1} \tilde{A}_0 = \begin{pmatrix} -c_1 & 1 & 0 & \cdots & 0 \\ -c_2 & 0 & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \ddots & \vdots \\ -c_{\tilde{n}_x - 1} & 0 & 0 & \ddots & 1 \\ -c_{\tilde{n}_x} & 0 & 0 & \cdots & 0 \end{pmatrix},$$

which is a companion matrix. It is well known that for those matrices the elements in the first column are the coefficients of its characteristic polynomial. This is shown as follows: let M_{ij} be the minor of $V := zI - \tilde{A}_1^{-1} \tilde{A}_0$, i.e., the determinant of the matrix obtained by removing row i and column j. Then, the determinant can be expanded by minors, for any j:

$$\det(V) = \sum_{i=1}^{\tilde{n}_x} (-1)^{i+j} v_{ij} M_{ij}, \qquad V = \{v_{ij}\}.$$

Taking $j = 1$, we get $M_{i,1} = \det(\mathrm{diag}(z, \ldots, z, -1, \ldots, -1))$ with $i - 1$ occurrences of -1, so that $M_{i,1} = z^{\tilde{n}_x - i} (-1)^{i-1}$. Therefore,

$$\begin{aligned} \det(V) &= (-1)^2 (c_1 + z) M_{1,1} + \textstyle\sum_{i=2}^{\tilde{n}_x} (-1)^{i+1} c_i M_{i,1} \\ &= c_1 z^{\tilde{n}_x - 1} + z^{\tilde{n}_x} + \textstyle\sum_{i=2}^{\tilde{n}_x} c_i z^{\tilde{n}_x - i} \\ &= P(z), \end{aligned}$$

which is exactly (2.6). This shows that the results of Algorithms 1 and 2 are identical, since the generalized eigenvalues in (2.2) are exactly the roots of $P(z)$.

It remains to show what the roots are. Let $\tilde{A} = [\tilde{a}_0 \ \tilde{A}_1]$ be the A matrix related to (5.1). Clearly, $\boldsymbol{c} = (1, \boldsymbol{c}'^T)^T$ is in the null-space of $\tilde{A}$, and hence $P_c(z)$ is the unique solution to (5.1). But for $z \neq 0$,

$$\begin{aligned} P(z) &= c_{\tilde{n}_x} + c_{\tilde{n}_x - 1} z + \cdots + c_1 z^{\tilde{n}_x - 1} + z^{\tilde{n}_x} \\ &= z^{\tilde{n}_x} \left(\frac{c_{\tilde{n}_x}}{z^{\tilde{n}_x}} + \frac{c_{\tilde{n}_x - 1}}{z^{\tilde{n}_x - 1}} + \cdots + \frac{c_1}{z} + 1 \right) \\ &= z^{\tilde{n}_x} P_c(1/z) \\ &= z^{\tilde{n}_x} (1 - x_1/z)(1 - x_2/z) \cdots (1 - x_{D_{\min}}/z) \\ &= z^{\tilde{n}_x - D_{\min}} (z - x_1)(z - x_2) \cdots (z - x_{D_{\min}}), \end{aligned}$$

which extends to $z = 0$ by continuity. This concludes the proof of points (i) and (ii).

(iii) Let (p, q) be a polynomial solution to (1.5) and $\boldsymbol{c}$ the corresponding coefficient solution. From Lemma 4.3 we have

$$q(z) = p(z)e^{m(z)},$$

where $m(z)$ is defined in (4.3). For the $(K+1)$th Taylor coefficient of the left- and right-hand sides we have by Lemmas 4.3 and 4.2

$$0 = \sum_{j=0}^{n_x} c_j a_{K+1-j} \quad \Rightarrow \quad a_{K+1} = -\sum_{j=1}^{n_x} a_{K+1-j} c_j, \tag{5.2}$$

since the kth Taylor coefficient of q and p is zero for $k > n_x$ and $k > n_y$, respectively. Finally, the last row of (2.1) extended to size $K+1$ gives

$$m_{K+1} = (K+1)a_{K+1} - \sum_{j=1}^{K} m_j a_{K+1-j}.$$

Together the last two equations show point (iii).

6. Properties of A_1 and Markov's theorem. We now look in more detail at the structure of the A_1 matrix. In particular, we look at the implications of $A_1 R$ being positive definite. Then we get an explicit simplified formula for the matrix, and our results also shed some light on the relationship of our results to the classical Markov theorem on the existence and uniqueness of solutions to the finite moment problem (1.1) discussed in the introduction. For this we need to define the matrix

$$R = \begin{pmatrix} & & 1 \\ & \cdots & \\ 1 & & \end{pmatrix}$$

and note that left (right) multiplication by R reverses the order of rows (columns) of a matrix. In our notation we can then formulate Markov's theorem as follows.

THEOREM 6.1 (Markov). *Suppose $K = 2n$ is even and $n = n_x = n_y$. There is a unique piecewise continuous function $f(x)$ satisfying*

$$m_k = k \int_{\mathbb{R}} x^{k-1} f(x) dx, \qquad 0 \le f \le 1, \qquad k = 1, \dots, K, \tag{6.1}$$

if $A_1 R$ is symmetric positive definite and the matrix

$$\begin{pmatrix} \boldsymbol{a}_0 & A_1 \\ a_{K+1} & \boldsymbol{a}_0^T \end{pmatrix} \tag{6.2}$$

is singular. This f is of the form in (1.2), (1.3).

REMARK 7. *The theorem does not rule out other forms of $f(x)$ a priori, and without the second condition in* (6.2) *such solutions are indeed possible. It considers only the case $n_x = n_y$, i.e., problem* (1.4), *and says nothing about the possibility of other solution types, e.g., when the $\{x_j\}$ and $\{y_j\}$ are not interlaced as in* (1.3).

We start by introducing some new notation that will be used throughout this section. If $\{x_j\}$ and $\{y_j\}$ are a solution of (1.5) and (p, q) is the corresponding polynomial solution as defined in (3.1), (3.2), we can introduce the new polynomials $p_r(z) = z^{n_x} p(1/z)$ and $q_r(z) = z^{n_y} q(1/z)$ to describe the solution. Defining them by continuity at $z = 0$, we have

$$p_r(z) = (z - x_1) \cdots (z - x_{n_x}), \qquad q_r(z) = (z - y_1) \cdots (z - y_{n_y}). \tag{6.3}$$

Furthermore, we assume that the number of *distinct* roots of p_r (x_j-branch values) is $\tilde{n}$. We also order the roots such that we can write

$$p_r(z) = (z - x_1)^{1+\eta_1} (z - x_2)^{1+\eta_2} \cdots (z - x_{\tilde{n}})^{1+\eta_{\tilde{n}}},$$

where $1 + \eta_j$ is the multiplicity of the root x_j, so that

$$n_x = \mathrm{Deg}(p_r) = \tilde{n} + \sum_{\ell=1}^{\tilde{n}} \eta_\ell.$$

We start the analysis with a lemma giving explicit expressions for the a_k-values.

LEMMA 6.2. *For $k \geq 0$,*

$$a_{n_y - n_x + 1 + k} = \sum_{j=1}^{\tilde{n}} \frac{1}{\eta!} \lim_{z \to x_j} \frac{d^{\eta_j}}{dz^{\eta_j}} \frac{(z - x_j)^{1+\eta_j} z^k q_r(z)}{p_r(z)}. \tag{6.4}$$

Proof. This result follows from an application of the residue theorem in complex analysis as follows. Let C_r be the circle in the complex plane with radius r. Since the roots of $p(z)$ are nonzero, the function q/p is analytic within and on C_ε if ε is taken small enough, and the Cauchy integral formula gives

$$a_k = \begin{cases} \frac{1}{k!} \frac{d^k}{dz^k} \frac{q(z)}{p(z)} \Big|_{z=0}, & k \geq 0, \\ 0, & k < 0, \end{cases} = \frac{1}{2\pi i} \oint_{C_\varepsilon} \frac{q(z)}{p(z) z^{k+1}} dz.$$

Setting

$$f(z) := \frac{q_r(z)}{p_r(z)} = \frac{z^{n_y - n_x} q(1/z)}{p(1/z)} \tag{6.5}$$

and changing variable $z \to 1/z$, we get

$$a_{n_y - n_x + 1 + k} = \frac{1}{2\pi i} \oint_{C_\varepsilon} \frac{q(z)}{p(z) z^{n_y - n_x + k + 2}} dz = \frac{1}{2\pi i} \oint_{C_\varepsilon} \frac{f(1/z)}{z^{k+2}} dz = \frac{1}{2\pi i} \oint_{C_{1/\varepsilon}} z^k f(z) dz.$$

Hence, $a_{n_y - n_x + 1 + k}$ is given by the sum of the residues of $z^k f(z)$ (assuming we take small enough ε). By (6.5) and the restriction $k \geq 0$ we see that its poles are located at the x_j-values and they have multiplicities $1 + \eta_j$ at x_j. Then (6.4) follows from the residue formula for a pole of a function $g(z)$ at z^* with multiplicity $\eta + 1$,

$$\mathrm{Res}(g, z^*) = \frac{1}{\eta!} \lim_{z \to z^*} \frac{d^\eta}{dz^\eta} (z - z^*)^{1+\eta} g(z). \qquad \square$$

When the branch values $\{x_j\}$ are *distinct*, the expression for the a_k elements simplifies. They can then be expressed as sums of the powers of $\{x_j\}$ in a way similar to the moments m_k, but with weights different from one. We can also give a more concise description of the matrices A_0 and A_1, which can be factorized into a product of Vandermonde and diagonal matrices. More precisely, we let V be the Vandermonde matrix

$$V = \begin{pmatrix} 1 & 1 & \cdots & 1 \\ x_1 & x_2 & \cdots & x_{n_x} \\ x_1^2 & x_2^2 & \cdots & x_{n_x}^2 \\ \vdots & \cdots & \cdots & \vdots \\ x_1^{n_x-1} & x_2^{n_x-1} & \cdots & x_{n_x}^{n_x-1} \end{pmatrix}$$

and introduce the diagonal matrices

$$W = \begin{pmatrix} w_1 & & \\ & \ddots & \\ & & w_{n_x} \end{pmatrix}, \qquad X = \begin{pmatrix} x_1 & & \\ & \ddots & \\ & & x_{n_x} \end{pmatrix},$$

where w_j are the weights defined as

$$w_j = \frac{q_r(x_j)}{p_r'(x_j)}. \tag{6.6}$$

(Note that p_r has only simple roots when $\{x_j\}$ are distinct, so $p_r'(x_j) \neq 0$.) Then we can show the following.

PROPOSITION 6.3. *If $\{x_j\}$ are distinct, then for $k \geq 0$,*

$$a_{n_y-n_x+1+k} = \sum_{j=1}^{n_x} w_j x_j^k \tag{6.7}$$

and

$$A_1 R = VWV^T, \qquad A_0 R = VWXV^T. \tag{6.8}$$

Proof. When $\{x_j\}$ are distinct, $\eta_j = 0$ for all j and the expression (6.4) for the x_j-residue simplifies to

$$\lim_{z \to x_j} \frac{(z - x_j) z^k q_r(z)}{p_r(z)} = \frac{x_j^k q_r(x_j)}{p_r'(x_j)}.$$

This shows (6.7). For (6.8) we set $b_k = a_{n_y-n_x+1+k}$. Then

$$A_{1-r} R = \begin{pmatrix} b_r & b_{r+1} & \cdots & b_{r+n_x} \\ b_{r+1} & b_{r+2} & \cdots & b_{r+n_x+1} \\ \vdots & \vdots & \ddots & \vdots \\ b_{r+n_x} & b_{r+n_x+1} & \cdots & b_{r+2n_x} \end{pmatrix} \in \mathbb{R}^{n_x \times n_x}, \qquad r = 0, 1.$$

From (6.7) we then have, for $k \geq 0$,

$$\begin{pmatrix} b_k \\ b_{k+1} \\ \vdots \\ b_{k+n_x} \end{pmatrix} = \sum_{j=1}^{n_x} w_j \begin{pmatrix} x_j^k \\ x_j^{k+1} \\ \vdots \\ x_j^{k+n_x} \end{pmatrix} = \sum_{j=1}^{n_x} w_j x_j^k \begin{pmatrix} 1 \\ x_j \\ \vdots \\ x_j^{n_x} \end{pmatrix} = V \begin{pmatrix} w_1 x_1^k \\ w_2 x_2^k \\ \vdots \\ w_{n_x} x_{n_x}^k \end{pmatrix} = VW \begin{pmatrix} x_1^k \\ x_2^k \\ \vdots \\ x_{n_x}^k \end{pmatrix}.$$

Consequently,

$$A_{1-r}R = VW \begin{pmatrix} x_1^r & x_1^{r+1} & \dots & x_1^{r+n_x} \\ x_2^r & x_2^{r+1} & \dots & x_2^{r+n_x} \\ \vdots & \vdots & \ddots & \vdots \\ x_{n_x}^r & x_{n_x}^{r+1} & \dots & x_{n_x}^{r+n_x} \end{pmatrix} = VWX^rV^T,$$

which concludes the proof. □

We now consider the implications of a positive definite A_1R. It turns out that this is a necessary and sufficient condition to guarantee both distinct $\{x_j\}$-values and positive weights. We get the following theorem.

THEOREM 6.4. *The matrix A_1R is symmetric positive definite if and only if $\{x_j\}$ are distinct and the weights are strictly positive, $w_j > 0$ for $j = 1, \dots, n_x$.*

Proof. We use the same notation as in Lemma 6.2 and set

$$S_j(z) = \frac{1}{\eta_j!}(z - x_j)^{1+\eta_j}\frac{q_r(z)}{p_r(z)}.$$

We note that $S_j(z)$ is smooth and regular close to $z = x_j$. Then, by Lemma 6.2, for $k \geq 0$,

$$a_{n_y-n_x+1+k} = \sum_{j=1}^{\tilde{n}} \lim_{z\to x_j} \frac{d^{\eta_j}}{dz^{\eta_j}} z^k S_j(z).$$

Next, we let $\boldsymbol{v} = (v_1, \dots, v_{n_x})^T$ be an arbitrary vector in $\mathbb{R}^{n_x}$ and recall that $P_v(z)$ is the corresponding $n_x - 1$ degree polynomial

$$P_v(z) = v_1 + v_2 z + \cdots + v_{n_x} z^{n_x-1}.$$

Then

$$\begin{aligned} \boldsymbol{v}^T A_1 R \boldsymbol{v} &= \sum_{j=1}^{n_x}\sum_{k=1}^{n_x} v_j v_k a_{n_y-n_x+j+k-1} = \sum_{j=1}^{n_x}\sum_{k=1}^{n_x}\sum_{\ell=1}^{\tilde{n}} \lim_{z\to x_\ell} \frac{d^{\eta_\ell}}{dz^{\eta_\ell}} z^{j+k-2} S_\ell(z) v_j v_k \\ &= \sum_{\ell=1}^{\tilde{n}} \lim_{z\to x_\ell} \frac{d^{\eta_\ell}}{dz^{\eta_\ell}} S_\ell(z) \sum_{j=1}^{n_x}\sum_{k=1}^{n_x} z^{j+k-2} v_j v_k = \sum_{\ell=1}^{\tilde{n}} \lim_{z\to x_\ell} \frac{d^{\eta_\ell}}{dz^{\eta_\ell}} S_\ell(z) P_v(z)^2. \end{aligned} \tag{6.9}$$

If

$$\tilde{n} + \sum_{j=1}^{\tilde{n}} \lfloor \eta_j/2 \rfloor \leq n_x - 1, \tag{6.10}$$

then we can take

$$P_v(z) = (z - x_1)^{1+\tilde{\eta}_1}(z - x_2)^{1+\tilde{\eta}_2} \cdots (z - x_{\tilde{n}})^{1+\tilde{\eta}_{\tilde{n}}}, \qquad \tilde{\eta}_j = \lfloor \eta_j/2 \rfloor.$$

Since $2(1 + \tilde{\eta}_\ell) = 2 + 2\lfloor \eta_\ell/2 \rfloor \geq 2 + 2(\eta_\ell/2 - 1) > \eta_\ell$ and

$$\left.\left(\frac{d^\ell}{dz^\ell} f(z)(z - z^*)^k\right)\right|_{z=z^*} = 0, \qquad 0 \leq \ell < k,$$

for all smooth enough $f(z)$, we get $\boldsymbol{v}^T A_1 R \boldsymbol{v} = 0$, which contradicts the positivity of $A_1 R$. Hence,

$$\tilde{n} + \sum_{j=1}^{\tilde{n}} \lfloor \eta_j / 2 \rfloor > n_x - 1 = \tilde{n} + \sum_{\ell=1}^{\tilde{n}} \eta_\ell - 1.$$

Since for any integer $n > 0$ we have $\lfloor n/2 \rfloor \leq n - 1$, it follows that all $\eta_\ell = 0$ and $\tilde{n} = n_x$. Hence, if $A_1 R$ is positive definite, then $\{x_j\}$ are distinct.

To show the theorem it is now enough to show that, when $\{x_j\}$ are distinct, $A_1 R$ is positive if and only if the weights are positive. From (6.9) we then have

$$\boldsymbol{v}^T A_1 R \boldsymbol{v} = \sum_{\ell=1}^{n_x} S_\ell(x_\ell) P_v(x_\ell)^2 = \sum_{\ell=1}^{n_x} w_\ell P_v(x_\ell)^2.$$

Clearly, when all $w_\ell > 0$, this expression is positive for $\boldsymbol{v} \neq 0$, and $A_1 R$ is positive definite. To show the converse, we take $P_v(z)$ to be the Lagrange basis polynomials $L_j(z)$ of degree $n_x - 1$ defined as

$$L_j(x_i) = \begin{cases} 1, & i = j, \\ 0, & i \neq j. \end{cases}$$

If $A_1 R$ is positive, then

$$0 < \boldsymbol{v}^T A_1 R \boldsymbol{v} = \sum_{\ell=1}^{n_x} w_\ell L_j(x_\ell)^2 = w_j.$$

This can be done for each j, which concludes the proof. □

We can now relate our conclusions with those in Markov's theorem, Theorem 6.1. We consider all solutions to (1.5) instead of those given by the integral relation (6.1) with a piecewise continuous function $f(x)$. The extra condition (6.2) is then automatically satisfied, and we note that the positivity of $A_1 R$ guarantees a unique solution also in our space of density functions (1.6). We view this as a corollary of Theorems 4.1 and 6.4.

Corollary 6.5. *If there exists a solution to* (1.5)*, then the matrix in* (6.2) *is singular. When $n_x = n_y$, there is a unique solution to* (1.5) *of the form* (1.3) *if and only if $A_1 R$ is symmetric positive definite.*

Proof. We start by proving the singularity of (6.2). By (ii) in Proposition 4.6 a coefficient solution $\boldsymbol{c} = (c_0, \ldots, c_{n_x})^T = (c_0, \bar{\boldsymbol{c}}^T)^T$ satisfies $A\boldsymbol{c} = 0$. Since $A = (\boldsymbol{a}_0 \; A_1)$, it remains to prove that $c_0 a_{K+1} + \boldsymbol{a}_0^T \bar{\boldsymbol{c}} = 0$. This was already proved in (5.2).

Next, we prove the "if" part of the second statement. If $A_1 R$ is symmetric positive definite, it is nonsingular, and by (i), (iii), and (v) in Theorem 4.1, the minimal degree solution exists and is unique and $x_j \neq y_i$ for all i, j. (If $x_j = 0$ for some j, then there is no zero y_i-value since $\mathrm{Deg}(q^*) = n$ by point (iii).) By Theorem 6.4 the corresponding branch values $\{x_j\}$ are distinct. It remains to show that, upon some reordering, the $\{x_j\}$ and $\{y_j\}$ are interlaced as in (1.3).

Order the x_j-values in an increasing sequence and let m_k be the number of y_j-values such that $y_j < x_k$. Clearly, m_k is increasing and $0 \leq m_k \leq n_y$. Moreover, $\mathrm{sgn}(q_r(x_k)) = (-1)^{n_y - m_k}$, and since $\lim_{z\to\infty} p_r'(z) > 0$, we also have $\mathrm{sgn}(p_r'(x_k)) = (-1)^{n_x - k}$. Hence, by also using the fact that $n_y = n_x$,

$$\operatorname{sgn}(w_k) = (-1)^{n_y - m_k + n_x - k} = (-1)^{m_k + k}.$$

We conclude that $m_k + k$ is even, which implies that m_k is, in fact, *strictly* increasing. Then, for $k = 1, \dots, n_x - 1$, we have $m_{k+1} \geq m_k + 1$ and

$$n_x \geq m_{n_x} \geq m_k + n_x - k \quad \Rightarrow \quad m_k \leq k.$$

Similarly, $m_k \geq m_1 + k - 1 \geq k - 1$, so $k - 1 \leq m_k \leq k$, and therefore

$$2k - 1 \leq m_k + k \leq 2k.$$

Finally, since $m_k + k$ is even, we must have $m_k = k$, which implies that the values are interlaced.

We now consider the "only if" part. If there is a solution of the form (1.3), then the $\{x_j\}$-values are obviously distinct and $m_k = k$. By Proposition 6.3 the weights are then given by (6.6) and they are positive since, as above, $\operatorname{sgn}(w_k) = (-1)^{m_k+k} = 1$. It follows from Theorem 6.4 that $A_1 R$ is positive definite. □

7. Outlook.

Several interesting issues may be worth mentioning:

1. Computational complexity in a finite difference implementation: One can consult the article [14], where practical implementation issues and several examples of increasing complexity have been addressed in the context of geometric optics problems. In particular, comparisons with Lagrangian (ray-tracing) solutions are shown.
2. Extension to higher dimensions for the present problem: Nothing seems to exist in this direction at the time being; see, however, the last sections of [20] and the routines based on complex variables in [11, 9] for "shape from moments."
3. A very special case of the trigonometric moment problem can be solved by means of a slight variation of the algorithms presented here, in [14], and in section IV.A of [9]. That is to say, one tries to invert the following set of equations:

$$\sum_{j=0}^{n} \mu_j \exp(ik\lambda_j) = m_k, \qquad k = 0, \dots, n. \tag{7.1}$$

Let us state that in case the $n+1$ real frequencies λ_j are known, the set of complex amplitudes μ_j are found by solving a Vandermonde system:

$$\begin{pmatrix} 1 & \cdots & 1 \\ \exp(i\lambda_0) & \cdots & \exp(i\lambda_n) \\ \vdots & & \vdots \\ \exp(in\lambda_0) & \cdots & \exp(in\lambda_n) \end{pmatrix} \begin{pmatrix} \mu_0 \\ \mu_1 \\ \vdots \\ \mu_n \end{pmatrix} = \begin{pmatrix} m_0 \\ m_1 \\ \vdots \\ m_n \end{pmatrix}.$$

The frequencies can be found through a byproduct of [9, 14] as we state now. Let us suppose n is odd (i.e., the number of equations is even); we form the two matrices

$$A_1 = \begin{pmatrix} m_0 & \cdots & m_{\frac{n-1}{2}} \\ \vdots & & \vdots \\ m_{\frac{n-1}{2}} & \cdots & m_{n-1} \end{pmatrix}, \qquad A_2 = \begin{pmatrix} m_1 & \cdots & m_{\frac{n+1}{2}} \\ \vdots & & \vdots \\ m_{\frac{n+1}{2}} & \cdots & m_n \end{pmatrix},$$

and then the frequencies can be obtained through a generalized eigenvalue problem, $A_1 \boldsymbol{v}_j = \lambda_j A_2 \boldsymbol{v}_j$, $j = 0, \dots, n$. This kind of algorithm can be used to check the accuracy of the classical FFT and will be studied in a forthcoming article.

INCIPIENT DYNAMICS OF SWELLING OF GELS*

HANG ZHANG[†] AND M. CARME CALDERER[†]

Abstract. In this article, we analyze a model of the incipient dynamics of gel swelling and perform numerical simulations. The governing system consists of balance laws for a mixture of nonlinear elastic solid and solvent yielding effective equations for the gel. We discuss the multiscale nature of the problem and identify physically realistic regimes. The mixing mechanism is based on the Flory–Huggins energy. We consider the case that the dissipation mechanism is the solid-solvent friction force. This leads to a system of weakly dissipative nonlinear hyperbolic equations. After addressing the Cauchy problem, we propose physically realistic boundary conditions describing the motion of the swelling boundary. We study the linearized version of the free boundary problem. Numerical simulations of solutions are presented too.

Key words. gel swelling, two-component mixture, polymer-solvent friction, type II diffusion, hyperbolic free boundary problem

1. Introduction.

We present analysis and numerical simulations of a model of the incipient dynamics of polymer gel swelling. The system that we study is derived from the balance laws of a two-component mixture of solid polymer and solvent [3]. The free energy of the system consists of the elastic energy of deformation of the polymer together with the Flory–Huggins free energy of mixing. The dissipation is due to the friction force between polymer and solvent. The resulting balance laws of the mixture form a weakly dissipative hyperbolic system. We formulate the boundary conditions for the swelling boundaries and analyze the free boundary problem for the linearized equations. We discuss numerical simulations of the solutions of the Cauchy problem. The effective equations that we obtain clearly reveal the multiscale nature of the problem and the dynamics associated with the different time scales.

In dimensionless form, the elasticity, Flory–Huggins mixing, and dissipative mechanisms bring four time scales into the problem, with the largest one naturally associated with the friction mechanism: this is the time scale of relaxation to the equilibrium volume fraction, with diffusive dynamics. Indeed, many works on gels focus on the relaxation part of the process. In this article, we address the earlier time scale dynamics and investigate their physical and mathematical significances, with the goal of understanding their individual roles. This allows us to gain information on the start-up of the process and on how the evolution of the swelling surface occurs.

In our applications, we will refer mostly to two classes of materials, entangled linear polymers and polysaccharides. In terms of the physical parameters that characterize them, the dissipation coefficient and elasticity modulus of the latter are several orders of magnitude smaller than their polymeric counterparts.

Our study is motivated by polymeric applications to body implanted devices, such as bone replacement tissue and controlled drug release mechanisms. Predictions

on change in shape from the dry state to saturation may help the manufacturing process. Another related application involving polysaccharides is the study of gel motility phenomena in myxobacteria.

Still a larger time scale would be present if polymer-polymer dissipation were taken into account. Since our numerical simulations focus on the dynamics at the smaller time scales, we neglect the latter dissipation source in the present work.

Another motivation to our work is to gain some understanding of the so-called type II diffusion phenomena [21] and [20]. It has been experimentally observed that the dynamics of interaction between the gel and its surrounding solvent, in the case that the polymer is dry, is very different from the case of partially swollen polymer. Indeed, the latter shows features of standard diffusion. In this work, we argue that type II diffusion is mostly a hyperbolic phenomena and therefore significantly different from standard diffusion.

The model that we study was developed in [3]. It consists of laws of balance of mass, momentum, and energy for two-component systems of nonlinear elastic solid and solvent. Fields of the problem include volume fractions ϕ_1 and ϕ_2, velocity fields $\mathbf{v}_1$ and $\mathbf{v}_2$ for solid and solvent, respectively, and pressure λ, a Lagrange multiplier corresponding to the constraint of $\phi_1 + \phi_2 = 1$. We observe that the continuum theory for a two-component mixture can be used as a tool to obtain governing equations for a third material, the gel, with properties that may be significantly different from those of the individual components. Moreover, the effective equations are formulated in terms of the center of mass velocity $\mathbf{V}$ and the diffusion velocity $\mathbf{U} = \mathbf{v}_1 - \mathbf{v}_2$. The model as formulated allows us to identify regimes associated with the different time scales, with the short times characterizing evolution of the interface between gel and solvent. The friction between polymer and solvent suggests existence of a purely diffusive regime with $\mathbf{V} = 0$. Indeed, considering initial conditions satisfying $\mathbf{V} = 0$, there exists a Lagrange multiplier function that maintains zero center of mass velocity for as long as the solution exists. If polymer-polymer friction is included in the model, either in the form of Newtonian dissipation or as given by a viscoelastic law, another time scale, larger by several orders of magnitude than the diffusive one, is added to the problem. Our model, then, suggests that, upon relaxation to equilibrium of the diffusive velocity and volume fraction, the material subsequently evolves as a viscoelastic fluid with uniform volume fraction, with respect to the transport velocity $\mathbf{V}$.

In one-dimensional geometries, the model reduces to a system of equations for the diffusion velocity of the mixture U and the volume fraction of the polymer ϕ_1. The dependence on the center of mass velocity can be eliminated by imposing transitional invariance of the solutions.

We formulate the one-dimensional problem in Eulerian coordinates, in which case it becomes a free boundary problem. First, we assume that the interface between dry polymer and solvent achieves a balance of force all the time, and that the interface is fully saturated. In our framework, this amounts to neglecting the shortest time scale of the system that causes very rapid saturation of the interface to an equilibrium volume fraction $\phi^* \in (0, 1)$. The value of ϕ^* can itself be determined by the pressure applied to the surrounding solvent [7]. We also assume that the interface moves at the speed of the polymer and formulate an ordinary differential equation for its dynamics. The remaining boundary conditions are formulated in terms of the symmetry of the domain with respect to $x = 0$, implying that $U(0, t) = 0$. We study the free boundary problem for the linearized equations and prove the global existence of solutions $(\phi(x, t), U(x, t), S(t)) \in C^1(\bar{Q}_S \times C^1(\bar{Q}_S \times C^2[0, t_1]))$, where $Q(S) := \{(x, t) : t \geq 0,\ 0 < x < S(t)\}$; we also prove a global bound for $S(t)$, $0 < |S(t) - L| < C$.

The analysis of the free boundary problem precludes the presence of shocks in the system. In a separate section, we consider the Cauchy problem and show that the system is weakly dissipative, as characterized by Dafermos [5]. The existence of an entropy-entropy pair flux allows us to show that the governing system is L^1-stable and, therefore, solutions of bounded variation follow as a consequence of the theorem in [5]. We show that the condition of hyperbolicity is satisfied for the material constants of a linear polymer as shown in Table 1. Consequently, the system remains hyperbolic and weakly dissipative for all time. However, this is not the case for polysaccharide data, where hyperbolicity is lost at a critical volume fraction ϕ_c that may be greater than the saturation value ϕ^*. Thus, the swelling interface may stop propagating before reaching saturation. We interpret such a phenomenon as the onset of deswelling. In the case of myxobacteria, this may suggest a reversal of direction perhaps achieved by deswelling. In this model, the break of hyperbolicity shown by the polysaccharide data occurs because of the small elastic modulus. This provides another motivation to study early dynamics. Indeed, in polysaccharide systems, the regime of relaxation dynamics may not be reached.

Works by Doi and coauthors address steady state solutions as well as relaxation regimes [23], [24], [25], [7], and [27]. Our modeling assumptions involving the free energy, which combines the Flory–Huggins contribution and the rubber elasticity, and the multiscale properties of the system are fully motivated by such works and those by Tanaka and Filmore [19].

This work is also partially inspired by the analysis in [15] of a flow with viscoelastic particles. From another point of view, the system of equations and free boundary problem share mathematical analogies with models of diffusion and transport aiming at including finite speed propagation effects in heat conduction [18].

In section 2 we explain the model, and in section 3, we derive the properties of the one-dimensional system. The Cauchy problem is studied in section 4, and the boundary conditions and the free boundary problem are formulated and studied in section 5. Finally, in section 6, we present numerical simulations for the regularized system.

2. The model.

We use the continuum theory of mixtures of an elastic solid and a solvent as the main tool to derive the governing equations of a gel [22, Chapter 5]. Since the free energy depends explicitly on the volume fraction of the components, the mixture modeling the gel turns out to be of immiscible type. Furthermore, since the intrinsic densities of the components are taken to be constant, the mixture is incompressible.

2.1. Balance of mass, transport and constitutive equations.

We assume that each component occupies a domain $\Omega_a \subset \mathbb{R}^3$, $a = 1, 2$, in the reference configuration (Lagrangian), with a reference volume fraction ϕ_a^R. Here the subindex 1 refers to the polymer, and 2 represents the fluid. In some applications, the reference configuration can be taken to be the initial state of the mixture. It is important to emphasize that the reference domains Ω_a, $a = 1, 2$, will, in general, be distinct. Both components occupy a common domain in the deformed (Eulerian) configuration.

The deformation of each component, polymer and fluid, respectively, is given by sufficiently smooth functions

$$\mathbf{x} = \mathcal{M}(\mathbf{X}, t), \quad \mathbf{X} \in \Omega_1,$$
$$\mathbf{x} = \mathcal{N}(\mathbf{X}, t), \quad \mathbf{X} \in \Omega_2,$$

with $F = \nabla_{\mathbf{X}}\mathcal{M}(\mathbf{X},t)$ denoting the gradient of deformation of the polymer. According to the theory of mixtures, both polymer and fluid may occupy the same region, with volume fractions $\phi_1(\mathbf{x},t)$, $\phi_2(\mathbf{x},t)$, respectively. Here $\mathbf{x} \in \Omega$ represents a point in a fixed region in space. We also assume that no other material or vacuum is present in the region; that is,

$$\phi_1(\mathbf{x},t) + \phi_2(\mathbf{x},t) = 1 \tag{2.1}$$

holds. We let ρ_1 and ρ_2 denote the mass densities of each component, respectively, per unit volume in space. These are related to the *true densities* $(\frac{\text{mass of component}}{\text{volume of component}})$ γ_1 and γ_2 as follows:

$$\rho_1 = \gamma_1\phi_1, \quad \rho_2 = \gamma_2\phi_2.$$

We assume that the mass densities of polymer and fluid are equal, and $\gamma_1 = \gamma_2 = 1$. In this case, the densities and volume fractions coincide:

$$\rho_1 = \phi_1, \quad \rho_2 = \phi_2. \tag{2.2}$$

We introduce the material velocities of polymer and solvent, respectively:

$$\begin{aligned} \tilde{\mathbf{v}}_1(\mathbf{X},t) &= \frac{\partial\mathcal{M}}{\partial t}(\mathbf{X},t), \quad \mathbf{X} \in \Omega_1, \\ \tilde{\mathbf{v}}_2(\mathbf{X},t) &= \frac{\partial\mathcal{N}}{\partial t}(\mathbf{X},t), \quad \mathbf{X} \in \Omega_2. \end{aligned}$$

We denote the corresponding velocity fields

$$\mathbf{v}_1(\mathbf{x},t) = \tilde{\mathbf{v}}_1(\mathcal{M}^{-1}(\mathbf{x},t),t), \quad \mathbf{v}_2(\mathbf{x},t) = \tilde{\mathbf{v}}_2(\mathcal{N}^{-1}(\mathbf{x},t),t), \quad \mathbf{x} \in \Omega. \tag{2.3}$$

We let $\mathcal{T}_1(\mathbf{x},t)$ and $\mathcal{T}_2(\mathbf{x},t)$ denote Cauchy stress tensor of polymer and fluid, respectively. Each one may consist of elastic and dissipative contributions, although in this work we emphasize the former. In addition, we take into account the friction forces $\mathbf{f}_a$, per unit volume, that the polymer exerts upon the fluid, and vice versa. The local forms of the laws of balance of mass and linear momentum are

$$\frac{\partial\phi_1}{\partial t} + (\mathbf{v}_1\cdot\nabla)\phi_1 + \phi_1\nabla\cdot\mathbf{v}_1 = 0, \tag{2.4}$$

$$\frac{\partial\phi_2}{\partial t} + (\mathbf{v}_2\cdot\nabla)\phi_2 + \phi_2\nabla\cdot\mathbf{v}_2 = 0, \tag{2.5}$$

$$\phi_1\frac{\partial\mathbf{v}_1}{\partial t} + \phi_1(\mathbf{v}_1\cdot\nabla)\mathbf{v}_1 = \nabla_{\mathbf{x}}\cdot\mathcal{T}_1 + \mathbf{f}_1, \tag{2.6}$$

$$\phi_2\frac{\partial\mathbf{v}_2}{\partial t} + \phi_2(\mathbf{v}\cdot\nabla)\mathbf{v}_2 = \nabla_{\mathbf{x}}\cdot\mathcal{T}_2 + \mathbf{f}_2. \tag{2.7}$$

Assuming that the second law of thermodynamics holds for all admissible processes [3], we have the following equations for the reversible parts of the stress tensors, $\mathcal{T}_1$ and $\mathcal{T}_2$, and an expression for the friction forces $\mathbf{f}_a$:

$$\mathcal{T}_1 = \phi_1\left\{\frac{\partial\psi_1}{\partial F}F - \left(\phi_1\frac{\partial\psi_1}{\partial\phi_1} + \phi_2\frac{\partial\psi_2}{\partial\phi_1} + \lambda\right)I\right\}, \tag{2.8}$$

$$\mathcal{T}_2 = -\phi_2\left\{\phi_1\frac{\partial\psi_1}{\partial\phi_2} + \phi_2\frac{\partial\psi_2}{\partial\phi_2} + \lambda\right\}I, \tag{2.9}$$

$$\mathbf{f}_1 = \lambda\nabla\phi_1 - \beta(\mathbf{v}_1 - \mathbf{v}_2) = -\mathbf{f}_2, \tag{2.10}$$

where λ is the Lagrange multiplier associated with the constraint (2.1) and $\beta(\phi_1, \phi_2)$ the polymer drag coefficient. The functions ψ_1 and ψ_2 represent the free energies of the polymer and solvent, respectively, giving the total free energy of the mixture, $\Psi \equiv \phi_1\psi_1 + \psi_2\psi_2$. According to the Flory theory of mixtures [8],

$$\Psi = \frac{K_BT}{V_m}\left(\frac{\chi}{2}\phi_1\phi_2 + \frac{1}{N}\phi_1 \log\phi_1 + \phi_2 \log\phi_2\right) + \phi_1 W(F). \tag{2.11}$$

Expressions of the component free energies [9] that yield (2.11) are

$$\psi_1 = \frac{K_BT}{2V_m}\chi\phi_2^2 + \frac{K_BT}{N_1V_m}\log\phi_1 + W(F), \tag{2.12}$$

$$\psi_2 = \frac{K_BT}{2V_m}\chi\phi_1^2 + \frac{K_BT}{N_2V_m}\log\phi_2, \tag{2.13}$$

where $W(F)$ represents the elastic deformation energy which we will assume to be neo-Hookean [1]; that is, $W(F) = \mu \text{trace} FF^T$, with $\mu > 0$.

With these, (2.8) and (2.9) become

$$\mathcal{T}_1 = \frac{K_BT}{N_xV_m}\phi_1\left((\det F)^{\frac{2}{3}} - \left(\frac{1}{2} + \frac{N_x}{N_1}\right) - \chi N_x\phi_1\phi_2\right)\mathbf{I} - \lambda\phi_1\mathbf{I} + 2\mu\phi_1 FF^T, \tag{2.14}$$

$$\mathcal{T}_2 = -\phi_2\left(\frac{K_BT}{N_2V_m} + \frac{K_BT}{V_m}\chi\phi_1\phi_2 + \lambda\right)\mathbf{I}. \tag{2.15}$$

We now list the parameters of the problem:

1. V_m is the volume occupied by one monomer;
2. K_B is the Boltzmann constant, and T is the absolute temperature;
3. N_1, N_2 denote the number of lattice sites occupied by the polymer and the solvent;
4. N_x is the number of monomers between entanglement points;
5. $\frac{\phi_1}{N_xV_m}$ represents the number of entanglement points per unit volume;
6. χ is the Flory interaction parameter;
7. β is the polymer drag coefficient;
8. μ is related to the elastic shear modulus.

Parameter values appropriate to semidry polymers are given in Table 1 [27], [16].

TABLE 1
Data for polymer and polysaccharide.

Parameter	Polymer	Polysaccharide
N_x	20	20
N_1	1000	1000
N_2	1	1
V_m	.1 nm^3	.1 nm^3
χ	.5	.5
T	300° K	300° K
μ	10^4 pNnm^{-2}	10^{-5} pNnm^{-2}
β	2.4×10^{10} pN$s$nm^{-4}	2.4×10^3 pN$s$nm^{-4}

Remark. The approach developed so far is also suitable to account for polymer-polymer friction by postulating a viscoelastic law for the total stress. Let us denote $\tau_1 = \mathcal{T}_1 + \phi_1\lambda$ and $\tau_2 = \mathcal{T}_2 + \phi_2\lambda$, the (reversible) extra stress of polymer and solvent, respectively. Let $\tau_1^{total} = \tau_1 + \tau_1^d$. In the case of Jeffrey's model [2], we have

$$\tau_1^{total} + \xi[\dot{\tau}_1^{total} - (\nabla\mathbf{v}_1)^T\tau_1^{total} - \tau_1^{total}(\nabla\mathbf{v}_1)] = \eta_0\mathbf{D}^1 + \tau_1, \tag{2.16}$$

where $\mathbf{D}_1$ is the strain, $\xi > 0$ denotes a relaxation constant, and $\eta_0 > 0$ is the Newtonian viscosity.

2.2. Governing equations of gels. The governing equations for the individual components give the governing system of the gel. The fields of the gel model consist of

$$\{\mathbf{V}, \mathbf{U}, F, \phi_1, \lambda\},$$

where $\mathbf{V} = \phi_1\mathbf{v}_1 + (1-\phi_1)\mathbf{v}_2$ represents the center of mass velocity and $\mathbf{U} = \mathbf{v}_1 - \mathbf{v}_2$ the diffusion velocity. The total stress $\mathcal{T}$ is defined by

$$\mathcal{T} = \mathcal{T}_1 + \mathcal{T}_2 - (1-\phi_1)\phi_1\mathbf{U}\otimes\mathbf{U}.$$

From (2.4)–(2.10), we derive the governing system for the new variables,

$$\frac{\partial \mathbf{V}}{\partial t} + (\mathbf{V}\cdot\nabla)\mathbf{V} = \nabla\cdot\mathcal{T}, \tag{2.17}$$

$$\begin{aligned}&\frac{\partial \mathbf{U}}{\partial t} + (1-2\phi_1)(\nabla\mathbf{U})\mathbf{U} - (\mathbf{U}\otimes\mathbf{U})\nabla\phi_1 + (\nabla\mathbf{V})\mathbf{U} + (\nabla\mathbf{U})\mathbf{V}\\ &= \frac{1}{\phi_1}\nabla\cdot\mathcal{T}_1 - \frac{1}{1-\phi_1}\nabla\cdot\mathcal{T}_2 - \frac{\beta}{\phi_1(1-\phi_1)}\mathbf{U} + \frac{\lambda\nabla\phi_1}{\phi_1(1-\phi_1)},\end{aligned} \tag{2.18}$$

$$F_t + (\mathbf{V} + (1-\phi_1)\mathbf{U})\cdot\nabla F = \nabla(\mathbf{V} + (1-\phi_1)\mathbf{U})F, \tag{2.19}$$

$$\nabla\cdot\mathbf{V} = 0, \tag{2.20}$$

$$\frac{\partial\phi_1}{\partial t} + ((\mathbf{V} + (1-\phi_1)\mathbf{U})\cdot\nabla)\phi_1 + \phi_1\nabla\cdot(\mathbf{V} + (1-\phi_1)\mathbf{U}) = 0. \tag{2.21}$$

Equation (2.19) is a version of the chain rule relating time derivatives of F with velocity gradients. This equation is required in mixed solid-fluid systems [14]. We note that the first equation gives the balance of linear momentum for the mixture, and the second can be interpreted as giving the evolution of the microstructure of the gel. We now introduce the following tensorial notation:

$$\begin{aligned}\hat{\mathcal{T}} &:= \frac{\mathcal{T}_1}{\phi_1} - \frac{\mathcal{T}_2}{1-\phi_1}\\ &= \frac{K_BT}{V_m}\left[\frac{1}{N_x}(\det F)^{\frac{2}{3}} - \left(\frac{1}{2N_x} + \frac{1}{N_1} - \frac{1}{N_2}\right)\right]I + 2\mu FF^T,\\ \hat{\mathcal{G}} &:= \frac{K_BT}{V_m}\left[\frac{1}{N_x}{\phi_1}^{-1}(\det F)^{\frac{2}{3}} - {\phi_1}^{-1}\left(\frac{1}{2N_x} + \frac{1}{N_1}\right) - \frac{1}{N_2}(1-\phi_1)^{-1} - \chi\right]I\\ &\quad + 2\mu\phi_1^{-1}FF^T.\end{aligned} \tag{2.22}$$

We point out that the first notation represents a relative stress, and the second plays the role of a body force, as indicated by the following calculations:

$$\begin{aligned}&\frac{1}{\phi_1}\nabla\cdot\mathcal{T}_1 - \frac{1}{1-\phi_1}\nabla\cdot\mathcal{T}_2\\ &= \nabla\cdot(\phi_1^{-1}\mathcal{T}_1 - (1-\phi_1)^{-1}\mathcal{T}_2) - (\phi_1^{-2}\mathcal{T}_1 + (1-\phi_1)^{-2}\mathcal{T}_2)\nabla\phi_1\\ &= \nabla\cdot\hat{\mathcal{T}} + \hat{\mathcal{G}}(\nabla\phi_1) - \frac{\lambda\nabla\phi_1}{\phi_1(1-\phi_1)}.\end{aligned}$$

This allows us to rewrite (2.18) as follows:

$$\begin{aligned}&\frac{\partial \mathbf{U}}{\partial t}+(1-2\phi_1)(\nabla\mathbf{U})\mathbf{U}-(\mathbf{U}\otimes\mathbf{U})\nabla\phi_1+(\nabla\mathbf{V})\mathbf{U}+(\nabla\mathbf{U})\mathbf{V}\\ &=\nabla\cdot\hat{\mathcal{T}}+\hat{\mathcal{G}}(\nabla\phi_1)-\frac{\beta}{\phi_1(1-\phi_1)}\mathbf{U}.\end{aligned}\tag{2.23}$$

The governing equations of the gel consist of (2.17), (2.19), (2.20), (2.21), and (2.23). We note that the latter equation does not involve λ explicitly. Indeed, it appears only in the balance of linear momentum of the center of mass (2.17).

We conclude this subsection by discussing two limiting regimes modeled by the previously obtained system. First, let us consider the system obtained by setting $\mathbf{V}=0$. This corresponds to fields initially satisfying $\mathbf{V}=0$ and such that λ solves the equilibrium equation resulting from (2.17). The governing system for $\mathbf{U}$ and ϕ_1 becomes

$$\begin{aligned}&\frac{\partial \mathbf{U}}{\partial t}+(1-2\phi_1)(\nabla\mathbf{U})\mathbf{U}-(\mathbf{U}\otimes\mathbf{U})\nabla\phi_1\\ &=\nabla\cdot\hat{\mathcal{T}}+\hat{\mathcal{G}}(\nabla\phi_1)-\frac{\beta}{\phi_1(1-\phi_1)}\mathbf{U},\\ &F_t+((1-\phi_1)\mathbf{U})\cdot\nabla F=\nabla((1-\phi_1)\mathbf{U})F,\\ &\frac{\partial\phi_1}{\partial t}+(((1-\phi_1)\mathbf{U})\cdot\nabla)\phi_1+\phi_1\nabla\cdot((1-\phi_1)\mathbf{U})=0.\end{aligned}\tag{2.24}$$

This corresponds to purely diffusive regimes where no net motion of the center of mass of the mixture takes place. Of course, this type of regime would not be compatible, for instance, with flow geometries with prescribed nonzero boundary velocity (e.g., shearing flow).

Another regime fully characterized by the single velocity $\mathbf{V}$ can also be obtained from the governing system. Indeed, setting $\mathbf{U}=0$ in (2.17), (2.19), (2.20), (2.21), and (2.23) and accounting for viscoelastic stress, we get

$$\frac{\partial\mathbf{V}}{\partial t}+(\mathbf{V}\cdot\nabla)\mathbf{V}=\nabla\cdot\tau-\nabla\lambda,\tag{2.25}$$

$$\tau+\xi[\dot{\tau}-(\nabla\mathbf{V})^T\tau-\tau(\nabla\mathbf{V})]=\eta_0\mathbf{D}+(\mathcal{T}_1+\mathcal{T}_2),\tag{2.26}$$

$$F_t+\mathbf{V}\cdot\nabla F=(\nabla\mathbf{V})F,\tag{2.27}$$

$$\nabla\cdot\mathbf{V}=0,\tag{2.28}$$

where $\mathcal{T}_1+\mathcal{T}_2$ denotes the total elastic stress of the system (2.14) and (2.15). In terms of dimensional analysis, including a dissipative stress in the system to account for polymer-polymer friction results in an additional time scale $t_v=\frac{\eta_0}{L_0^2\beta}t_0$ much greater than that governing the relaxation of the diffusive velocity $\mathbf{U}$:

$$t_0=\frac{\beta L_0^2V_mN_x}{K_BT}.\tag{2.29}$$

(Here L_0 denotes a typical macroscopic length scale of the problem. The dimensional analysis is presented in a later section.) This is due to the fact that the polymer-polymer viscosity coefficient represented by η_0 is much larger that the polymer-solvent friction coefficient β. Heuristically, we may argue that in a system where both velocities are initially present, $\mathbf{U}$ relaxes to 0 much faster than $\mathbf{V}$. In the largest time scale, the mixture is governed by equations (2.25)–(2.28) of viscoelastic flow, in a regime characterized by transport only.

2.3. Relaxation regimes. Many studies of gels address the relaxation regimes, beyond transient behavior. For instance, such an approach has been used by Doi, Tanaka, and other researchers in many pioneering studies of gel swelling [19], [7]. We now indicate how the proposed equations relate to these earlier models. For this we return to our original component formulation (2.1) and (2.4)–(2.7). Addition of (2.4)–(2.5), together with the constraint equation $\phi_1 + \phi_2 = 1$, yields

$$\nabla \cdot (\phi_1 \mathbf{v}_1 + (1-\phi_1)\mathbf{v}_2) = 0.$$

With the stress tensors of the form (2.8) and (2.9) and setting $\psi_1 = \phi_1 W(F)$ and $\psi_2 \equiv 0$, we get

$$\begin{aligned} \mathcal{T}_1 &= \phi_1 \frac{\partial W}{\partial F} F^T - \phi_1 \lambda, \\ \mathcal{T}_2 &= -\phi_2 \lambda. \end{aligned}$$

The equations of balance of linear momentum become

$$\frac{\partial \mathbf{v}_1}{\partial t} + (\mathbf{v}_1 \cdot \nabla)\mathbf{v}_1 = \nabla \cdot \left(\phi_1 \frac{\partial \psi_1}{\partial F} F^T\right) - \phi_1 \nabla\lambda - \beta(\mathbf{v}_1 - \mathbf{v}_2), \tag{2.30}$$

$$\frac{\partial \mathbf{v}_2}{\partial t} + (\mathbf{v}_1 \cdot \nabla)\mathbf{v}_2 = -\phi_2 \nabla\lambda + \beta(\mathbf{v}_1 - \mathbf{v}_2). \tag{2.31}$$

Moreover, neglecting inertial terms, we get

$$\begin{aligned} &\nabla \cdot (\phi_1 \mathbf{v}_1 + (1-\phi_1)\mathbf{v}_2) = 0, \\ &\nabla \cdot \mathcal{T}_1 + \mathbf{f}_1 = 0, \\ &\nabla \cdot \mathcal{T}_2 + \mathbf{f}_2 = 0. \end{aligned}$$

Taking into account that $\mathbf{f}_1 = \lambda \nabla \phi_1 - \beta(\mathbf{v}_1 - \mathbf{v}_2) = -\mathbf{f}_2$, the previous equations yield

$$\nabla \cdot (\phi_1 \mathbf{v}_1 + (1-\phi_1)\mathbf{v}_2) = 0,$$

$$\nabla \cdot \left(\phi_1 \frac{\partial W(F)}{\partial F} F^T\right) + \phi_1 \nabla\lambda - \beta(\mathbf{v}_1 - \mathbf{v}_2) = 0, \tag{2.32}$$

$$-\phi_2 \nabla\lambda + \beta(\mathbf{v}_1 - \mathbf{v}_2) = 0. \tag{2.33}$$

Addition of (2.32) and (2.33) yields

$$\nabla \cdot \left(\phi_1 \frac{\partial W(F)}{\partial F} F^T - \lambda\right) = 0, \tag{2.34}$$

where $\frac{\partial W(F)}{\partial F}$ is the Piola–Kirchoff stress tensor [10]. Taking into account the balance of mass equation, $\phi_1 \det F = 1$, we rewrite (2.34) as

$$\nabla \cdot \left(\det F^{-1} \frac{\partial W(F)}{\partial F} F^T - \lambda\right) = 0.$$

Note that $\sigma = \det F^{-1} \frac{\partial W(F)}{\partial F} F^T$ is the Cauchy stress tensor. Summarizing,

$$\begin{aligned} &F_t + (\mathbf{v}_1) \cdot \nabla F = \nabla(\mathbf{v}_1)F, \\ &\frac{\partial \phi_1}{\partial t} + (\mathbf{v}_1 \cdot \nabla)\phi_1 + \phi_1 \nabla \cdot \mathbf{v}_1 = 0, \\ &\nabla \cdot (\sigma - \lambda) = 0, \\ &-(1-\phi_1)\nabla \cdot \lambda + \beta(\mathbf{v}_1 - \mathbf{v}_2) = 0, \\ &\nabla \cdot (\phi_1 \mathbf{v}_1 + (1-\phi_1)\mathbf{v}_2) = 0. \end{aligned}$$

We observe that the first equation gives the chain rule, the second corresponds to balance of mass, the third is the force balance, the fourth corresponds to Darcy's law, and the last is the incompressibility condition of the mixture.

Remark. Many analyses found in the literature consider additional linearization of the previous system [23], [24], [25], [26], and [27].

3. One-dimensional geometry. We consider the gel occupying a strip domain

$$\Omega = \{(x, y, z) : -L \leq x \leq L\}$$

in the form of a strip, with $L > 0$ fixed. For instance, this type of geometry may be appropriate in modeling gliding behavior of bacteria by polysaccharide swelling [11]. We seek solutions of the governing system with $x = M(X, t)$, $x = N(X, t)$ denoting the deformation map of the polymer and the fluid, respectively. The fields of the problem are taken as follows:

$$\mathbf{V} = (V(x, t), 0, 0), \quad \mathbf{U} = (U(x, t), 0, 0), \quad \phi_1 = \phi_1(x, t), \quad \lambda = \lambda(x, y, z, t). \tag{3.1}$$

The deformation gradient matrix is

$$F = \mathrm{diag}(g(x, t), 1, 1), \quad \text{with} \tag{3.2}$$

$$g(x, t) = \frac{\partial M(X, t)}{\partial X}|_{X=M^{-1}(x,t)} = \det F. \tag{3.3}$$

The equation of balance of mass for the polymer in Lagrangian form is

$$\phi_1(x, t) \det F(x, t) = \alpha, \tag{3.4}$$

$$g(x, t) = \alpha \phi_1(x, t)^{-1}, \tag{3.5}$$

where $0 \leq \alpha \leq 1$ is a parameter of the problem. It represents the volume fraction of dry polymer in the reference configuration. For the deformation gradient F given in (3.2) and (3.5), we calculate

$$\begin{aligned}\mathcal{T}_1 = \frac{K_B T}{N_x V_m}\left(\alpha^{\frac{2}{3}}\phi_1^{\frac{1}{3}} - \left(\frac{1}{2} + \frac{N_x}{N_1}\right)\phi_1 - \chi N_x \phi_1(1 - \phi_1)\right)\mathbf{I} - \lambda\phi_1\mathbf{I} \\ + 2\mu\phi_1 \,\mathrm{diag}(1, 1, \alpha^2\phi_1^{-2}).\end{aligned}$$

$\mathcal{T}_2$ is as in (2.15). The second and third component equations in (2.17) give $\lambda = \lambda(x, t)$ (independent of y and z). Moreover, the equation $\nabla \cdot \mathbf{V} = 0$ together with (3.1a) gives $V = V(t)$. Prescribing $V(0) = 0$, $V(t) = 0$, $t > 0$ follows, provided that $\nabla \cdot \mathcal{T} = 0$ holds. The latter determines λ in terms of ϕ_1 and U, up to a constant. Moreover, ϕ_1 and U satisfy the equations

$$\frac{\partial \phi_1}{\partial t} + \frac{\partial(\phi_1(1 - \phi_1)U)}{\partial x} = 0, \tag{3.6}$$

$$\frac{\partial U}{\partial t} + \frac{\partial}{\partial x}\left(\frac{1}{2}U^2(1 - 2\phi_1) - G(\phi_1)\right) = -\frac{\beta}{\phi_1(1 - \phi_1)}U, \tag{3.7}$$

where

$$\begin{aligned}G(\phi_1) = \frac{K_B T}{V_m N_x}\left(-\frac{1}{2}\alpha^{2/3}\phi_1^{-\frac{2}{3}} - \left(\frac{1}{2} + \frac{N_x}{N_1}\right)\log\phi_1\right) \\ + \mu\alpha^2\phi_1^{-2} - \frac{K_B T \chi}{V_m}\phi_1 + \frac{K_B T}{N_2 V_m}\log(1 - \phi_1).\end{aligned} \tag{3.8}$$

The sign of $G'(\phi_1)$ is very relevant to the forthcoming analysis. Indeed, the condition $G'(\phi_1) < 0$ will be needed to guarantee hyperbolicity of the governing system, and therefore is a requirement for the propagation of the swelling front towards the solvent region. It turns out that $G'(\phi_1) < 0$ holds for polymer data. However, in the case of polysaccharides with data as previously given, there is a quantity $\phi_c = \phi_c(\mu)$, $0 < \phi_c < 1$, such that $G'(\phi_c) = 0$. This may be interpreted in terms of the onset of deswelling, observed in bacteria motility phenomenon [11]; it may also be associated with volume phase transitions observed in systems with a small elastic shear modulus [13].

We assume that, initially, the polymer occupies the strip $-L < x < L$, and the solvent is in the region $|x| > L$. At a later time $t > 0$, the gel occupies the region $-S(t) < x < S(t)$, where $x = S(t)$ denotes the position of the interface between the gel and the pure solvent. We look for symmetric solutions about the origin, $x = 0$, i.e., $\phi_1(x) = \phi_1(-x)$ and $U(-x) = -U(x)$, $x \in (-S(t), S(t))$. Therefore, it is sufficient to solve the problem for $x > 0$ only. Thus, we assume that (3.6) and (3.7) hold for $x \in (0, S(t))$, $t > 0$, for the fields (ϕ_1, U). Equation (2.7) for the incompressible inviscid solvent $\phi_2 = 1$ holds in the region $x > S(t)$. This implies that

$$v = 0, \quad \lambda = -\frac{K_B T}{V_m N_2} + c, \tag{3.9}$$

where c is a constant. In addition, we choose c so that the pressure in the fluid region takes a prescribed value, p_0; that is, $\lambda = p_0$, $x > S(t)$.

The boundary conditions of the problem consist of symmetry conditions at $x = 0$ and balance of forces at the interface $x = S(t)$. The former reduce to

$$\frac{\partial \phi_1}{\partial x}(0, t) = 0, \quad U(0, t) = 0. \tag{3.10}$$

Letting $-$ and $+$ denote the left and right limit at $S(t)$, respectively, we formulate boundary conditions. We first establish balance of forces

$$(\mathcal{T}_1 + \mathcal{T}_2)^-_{11} = (\mathcal{T}_2)^+_{11}. \tag{3.11}$$

Also, following Yamaue and Doi [24], we propose the following constitutive equation that expresses the degree of permeability of the interface. For a given $P > 0$, we assume that

$$\lambda^- - \lambda^+ = P. \tag{3.12}$$

Using the expressions of $\mathcal{T}_i$, $i = 1, 2$, and substituting (3.12) into (3.11) yields

$$\begin{aligned} P = {} & \frac{K_B T}{N_x V_m}\left(\alpha^{\frac{2}{3}}(\phi_1^-)^{\frac{1}{3}} - \left(\frac{1}{2} + \frac{N_x}{N_1}\right)\phi_1^-\right) - \chi\frac{K_B T}{V_m}\phi_1^-(1 - \phi_1^-) - \frac{K_B T}{N_x V_2}(1 - \phi_1^-) \\ & + 2\mu\alpha^2(\phi_1^-)^{-1} + \frac{K_B T}{N_2 V_m}. \end{aligned} \tag{3.13}$$

If the interface is fully permeable, then the pressure is continuous and $P = 0$ holds. In the case of charged polymers the discontinuity of λ is related to the net surface charge. Here, we take the point of view of P being a parameter of the problem. In particular, we observe from (3.13) that prescribing P allows us to the determine the saturation value $\phi_1^- \equiv \phi^*$. This, in turn, motives the definition of the interface as the location $x = S(t)$ with $\phi_1(S(t), t) = \phi^*$ that moves with the speed of the polymer. Specifically, the dynamics of the interface are described by the following equations:

$$\frac{dS}{dt}(t) = (1 - \phi_1(S(t), t))U(S(t), t), \tag{3.14}$$

$$S(0) = L, \tag{3.15}$$

$$\phi_1(S(t), t) = \phi^*. \tag{3.16}$$

The problem reduces to three equations, (3.6), (3.7), and (3.14), for the unknowns (ϕ_1, U, S), with boundary conditions (3.10) and (3.16) and initial conditions (3.15) and

$$\phi_1(x, 0) = \phi^0(x), \quad U(x, 0) = 0, \quad x \in (0, L). \tag{3.17}$$

We conclude this section by listing the time scales of the problem. Let L_0 denote a typical length; in polymer experiments, this would be of the order of centimeters. We find the following time constants:

$$t_0 = \frac{\beta L_0^2 V_m N_x}{K_B T}, \quad t_1 = \frac{\beta L_0^2 V_m}{K_B T \chi},$$
$$t_2 = \frac{\beta L_0^2 V_m N_2}{K_B T}, \quad t_3 = \frac{\beta L_0^2}{\mu}.$$

Comparing the time constants, we observe that

$$t_0 = \frac{N_x}{\chi} t_1, \quad t_1 = \frac{1}{\chi N_2} t_2, \quad t_2 = \frac{\mu N_2 V_m}{K_B T} t_3.$$

For the data in (1), we have that

$$t_2 \sim 10^{-1} t_3.$$

The previous data reflect the relative orders of magnitude of the time scales in polymer applications. The largest time constant is t_0, and t_2 is the smallest. Many works on gels focus on the time scale t_0 corresponding to the relaxation regime. In our work, we study the dynamics at the time scale t_2. After (3.6) and (3.7) are scaled to make them nondimensional, G takes the form

$$G(\phi_1) = C_0 \left(-\frac{1}{2} \alpha^{2/3} \phi_1^{-\frac{2}{3}} - \left(\frac{1}{2} + \frac{N_x}{N_1} \right) \log \phi_1 \right)$$
$$+ C_3 \alpha^2 \phi_1^{-2} - C_2 \phi_1 + C_1 \log(1 - \phi_1),$$

with dimensionless parameters

$$C_0 = \frac{\beta^2 L_0^2 V_m N_2^2}{K_B T N_x}, \quad C_1 = \frac{\beta^2 L_0^2 V_m N_2^2 \chi}{K_B T},$$
$$C_2 = \frac{\beta^2 L_0^2 V_m N_2}{K_B T}, \quad C_3 = \frac{\mu \beta^2 L_0^2 V_m^2 N_2^2}{K_B^2 T^2}.$$

The scaled equations and coefficients are employed in the numerical simulations.

4. The Cauchy problem. In this section we consider the Cauchy problem for (3.6) and (3.7) with initial conditions

$$\begin{aligned} U(x,0) &= U_0(x), \\ \phi_1(x,0) &= \phi_0(x). \end{aligned} \tag{4.1}$$

First we show that for the range of physical parameters corresponding to a semidry polymer, the governing system is of hyperbolic type with dissipation. Let us denote

$$\begin{aligned} \mathbf{u} &= (\phi_1, U)^T, \\ \mathbf{F} &= \left[\phi_1(1-\phi_1)U,\ \frac{1}{2}U^2(1-2\phi_1) - G(\phi_1)\right]^T, \\ \mathbf{G} &= \left[0,\ \frac{\beta}{\phi_1(1-\phi_1)}U\right]^T. \end{aligned}$$

The governing system becomes

$$\frac{\partial \mathbf{u}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x}(\mathbf{u}) + \mathbf{G}(\mathbf{u}) = 0. \tag{4.2}$$

The gradient matrix is

$$D\mathbf{F} = \begin{bmatrix} (1-2\phi_1)U & \phi_1(1-\phi_1) \\ -U^2 - G'(\phi_1) & (1-2\phi_1)U \end{bmatrix}.$$

Eigenvalues λ_i, $i = 1, 2$, of $D\mathbf{F}$ are

$$\begin{aligned} \lambda_1 &= (1-2\phi_1)U + \sqrt{-\phi_1(1-\phi_1)(U^2 + G'(\phi_1))}, \\ \lambda_2 &= (1-2\phi_1)U - \sqrt{-\phi_1(1-\phi_1)(U^2 + G'(\phi_1))}. \end{aligned}$$

They are real and distinct provided that

$$U^2 + G'(\phi_1) < 0$$

holds. The hyperbolic region in the space (ϕ_1, U) consists of the points between the graphs of $U = \pm\hat{U}(\phi_1)$, with $\hat{U}(\phi_1) = \sqrt{|G'(\phi_1)|}$. The right eigenvectors of $D\mathbf{F}$ are

$$\mathbf{r}_1 = \begin{bmatrix} \sqrt{\frac{\phi_1(1-\phi_1)}{|U^2+G'(\phi_1)|}} \\ 1 \end{bmatrix}, \quad \mathbf{r}_2 = \begin{bmatrix} -\sqrt{\frac{\phi_1(1-\phi_1)}{|U^2+G'(\phi_1)|}} \\ 1 \end{bmatrix}.$$

Let

$$V = \begin{bmatrix} \sqrt{\frac{\phi_1(1-\phi_1)}{|U^2+G'(\phi_1)|}} & -\sqrt{\frac{\phi_1(1-\phi_1)}{|U^2+G'(\phi_1)|}} \\ 1 & 1 \end{bmatrix}, \quad V^{-1} = \begin{bmatrix} \frac{1}{2}\sqrt{\frac{|U^2+G'(\phi_1)|}{\phi_1(1-\phi_1)}} & \frac{1}{2} \\ -\frac{1}{2}\sqrt{\frac{|U^2+G'(\phi_1)|}{\phi_1(1-\phi_1)}} & \frac{1}{2} \end{bmatrix}.$$

The characteristic coordinates $\mathbf{w} = V^{-1}\mathbf{u}$ give

$$w_1 = \frac{1}{2}\left(\sqrt{\frac{\phi_1}{1-\phi_1}|U^2 + G'(\phi_1)|} + U\right), \quad w_2 = \frac{1}{2}\left(-\sqrt{\frac{\phi_1}{1-\phi_1}|U^2 + G'(\phi_1)|} + U\right).$$

Let us define the pair of functions,

$$\eta(\phi_1, U) = -\int_\phi G(\rho)\,d\rho + \frac{1}{2}\phi_1(1-\phi_1)U^2, \quad q = \phi_1(1-\phi_1)U\left[-G(\phi_1) + \frac{1}{2}U^2(1-2\phi_1)\right].$$

Lemma 4.1. *The functions* (η, q) *form an entropy-flux pair for the hyperbolic system.*

Proof. We need to find $B = (B_1(\phi_1, U, x, t), B_2(\phi_1, U, x, t))$ such that

$$B = D\eta,$$
$$BD\mathbf{F} = Dq,$$

where $D = (\partial_{\phi_1}, \partial_U)^T$. It is easy to verify that

$$\begin{aligned} D\eta &= \left(\frac{1}{2}\phi_1(1-\phi_1)U^2 - G, \phi_1(1-\phi_1)U\right), \\ Dq &= \left(\left(\frac{1}{2}\phi_1(1-\phi_1)U^2 - G\right)((1-2\phi_1)U - (U^2+G')\phi_1(1-\phi_1)U),\right. \\ &\qquad \left.\left(\frac{1}{2}\phi_1(1-\phi_1)U^2 - G\right)\phi_1(1-\phi_1) + \phi_1(1-\phi_1)(1-2\phi_1)U^2\right). \end{aligned}$$

Choosing $B = (\frac{1}{2}\phi_1(1-\phi_1)U^2 - G,\ \phi_1(1-\phi_1)U)$, a direct calculation gives

$$BD\mathbf{F} = Dq.$$

Hence, (η, q) is an entropy-flux pair. □

We now introduce the concept of L^1-stability [4]. The Cauchy problem (3.6)–(3.7), (4.1) is said to be L^1*-stable* at an equilibrium state $U = \hat{U}$ and $\phi_1 = \hat{\phi}$ if there are positive numbers r and b such that any admissible bounded variation (BV) solution $U(x,t)$ and $\phi_1(x,t)$ of (3.6)–(3.7), (4.1) defined on any time interval $[0,T)$, $0 < T \le \infty$, and taking values in the ball $B_r(\hat{\phi}, \hat{U})$ of R^2 satisfies the inequality

(4.3)
$$\int_\infty^\infty |\phi_1(x,t) - \hat{\phi}| + |U(x,t) - \hat{U}|\,dx \le b\int_\infty^\infty |U_0(x) - \hat{U}| + |\phi_0(x) - \hat{\phi}|\,dx, \quad 0 \le t < T.$$

Lemma 4.2. *The Cauchy problem* (3.6)–(3.7)*,* (4.1) *is* L^1*-stable at the equilibrium state* $U = 0$*,* $\phi = \phi^*$*.*

Proof. From Lemma 4.1 and the form of the entropy function, we see that $\eta(\phi_1, U)$ is C^1 near the equilibrium $U = 0$, $\phi = \phi^*$. Thus, there are constants $r > 0$ sufficiently small and $d > 0$ such that

$$d^{-\frac{1}{2}}(|\phi - \phi^*| + |U|) \le |\eta(\phi_1, U)| \le d^{\frac{1}{2}}(|\phi - \phi^*| + |U|)$$

holds for any $(\phi, U) \in B_r(\phi^*, 0)$. Moreover, the entropy production is nonnegative; i.e.,

$$B\mathbf{G} = \beta U^2 \ge 0.$$

Hence, by an argument similar to [4], the L^1-stability is readily established. So, there exist r and d such that any admissible BV solution $U(x,t)$ and $\phi_1(x,t)$ of (3.6)–(3.7), (4.1) satisfies (4.3) with $\hat{U} = 0$ and $\hat{\phi} = \phi^*$. □

We next derive the linearization of the governing system about the equilibrium solution, $U = 0$ and $\phi_1 = \phi^*$, where $\phi^* \in (0,1)$ denotes the saturation volume fraction. We calculate

$$\begin{aligned}
&D\mathbf{F}(\mathbf{u}_e) = \begin{bmatrix} 0 & \phi^*(1-\phi^*) \\ -G'(\phi^*) & 0 \end{bmatrix},\\
&2\lambda_1 = \sqrt{\phi^*(1-\phi^*)|G'(\phi^*)|}, \quad 2\lambda_2 = -\sqrt{\phi^*(1-\phi^*)|G'(\phi^*)|},\\
&\mathbf{r}_1 = \left[\sqrt{\frac{\phi^*(1-\phi^*)}{|G'(\phi^*)|}}, 1\right]^T, \quad \mathbf{r}_2 = \left[-\sqrt{\frac{\phi^*(1-\phi^*)}{|G'(\phi^*)|}}, 1\right]^T,\\
&V = \begin{bmatrix} \sqrt{\frac{\phi^*(1-\phi^*)}{|G'(\phi^*)|}} & -\sqrt{\frac{\phi^*(1-\phi^*)}{|G'(\phi^*)|}} \\ 1 & 1 \end{bmatrix}.
\end{aligned}$$

We also calculate

$$\begin{aligned}
&DG(\mathbf{u}^*) = \begin{bmatrix} 0 & 0 \\ 0 & \frac{\beta}{\phi^*(1-\phi^*)} \end{bmatrix},\\
&R = V^{-1}(DG)V = \frac{\beta}{2\phi^*(1-\phi^*)} \begin{bmatrix} 1 & 1 \\ 1 & 1 \end{bmatrix}, \qquad (4.4)\\
&\mathbf{w} = V^{-1}\mathbf{u}.
\end{aligned}$$

The resulting linear diagonal system is

$$\frac{\partial \mathbf{w}}{\partial t} + \operatorname{diag}(\lambda_1, \lambda_2)\frac{\partial \mathbf{w}}{\partial x} + R\mathbf{w} = 0.$$

We recall that a matrix A is strictly diagonally dominant if

$$A_{ii} - \sum_{i \neq j} |A_{ij}| \geq 0, \quad i, j = 1, 2, \ldots, n.$$

It is easy to check that the matrix R defined by (4.4) has positive entries in the principal diagonal and is diagonally dominant. However, since it is not strictly diagonally dominant, the exponential decay property of $TV_x\phi_1$ and TV_xU established in Theorem 2 of [6] cannot be asserted here. This prevents us from obtaining asymptotic stability of solutions with respect to time.

Since the Cauchy problem (3.6)–(3.7) with initial condition (4.1) is L^1-stable and R is diagonally dominant, the results proved by Dafermos [5] on existence and decay of BV solutions of weakly dissipative hyperbolic systems apply as follows.

Theorem 4.3. *Let r, b be defined in* (4.3). *Consider integrable initial data (ϕ_0, U_0) taking values in $B_r(\phi^*, 0)$. Let*

$$\sigma = \int_{-\infty}^{\infty} |U_0(x)| + |\phi_0(x) - \phi^*|\, dx$$

and

$$\omega = TV_{(-\infty,\infty)}|U_0(x)| + TV_{(-\infty,\infty)}|\phi_0(x)|$$

over $(-\infty, \infty)$. Then there are positive constants σ_0, ω_0, a, and μ such that, when $\sigma < \sigma_0$ and $\omega < \omega_0$, there exists an admissible global BV solution $U(x,t)$, $\phi_1(x,t)$ to *the Cauchy problem* (3.6)–(3.7) *with* (4.1)*, taking values in* $B_r(\phi^*, 0)$*. Furthermore, for each fixed* $t \in (0, \infty)$*,* $(\phi_1(x,t), U(\cdot,t))$ *is integrable and has bounded variation over* $(-\infty, \infty)$*:*

$$\int_{-\infty}^{\infty} |\phi_1(x,t) - \phi^*| + |U(x,t)|\, dx \leq b\sigma,$$

$$TV_{(-\infty,\infty)}|U(\cdot,t)| + TV_{(-\infty,\infty)}|\phi_1(\cdot,t) - \phi^*| \leq a\omega e^{-\mu t} + a\sigma.$$

Next we discuss the free boundary problem for the linearized system.

5. Analysis of the free boundary problem.

We now analyze a free boundary problem for (3.6) and (3.7). We consider the boundary and initial conditions given by (3.10), (3.16), (3.14), (3.15), and (3.17).

Also, since $\phi_1(x,0)$ is the initial volume fraction, we have the bound $0 < \phi_1(x,0) < 1$ for any $0 \leq x \leq L$. We consider the linearization of the above equations and boundary conditions with respect to the equilibrium pair $(\phi^*, 0)$.

5.1. Linearization and hyperbolicity condition.

We linearize (3.6) and (3.7) with respect to $\phi = \phi^*$ and $U = 0$, set $\bar{\phi} = \phi_1 - \phi^*$, and write the resulting system as follows:

$$\begin{aligned} &\frac{\partial \bar{\phi}}{\partial t} + \phi^*(1-\phi^*)\frac{\partial \bar{U}}{\partial x} = 0, \\ &\frac{\partial \bar{U}}{\partial t} - G'(\phi^*)\frac{\partial \bar{\phi}}{\partial x} = -\frac{\beta}{\phi^*(1-\phi^*)}\bar{U}. \end{aligned} \tag{5.1}$$

The linearized free boundary conditions (3.10), (3.16), (3.14), (3.15), and (3.17) become

$$\begin{aligned} &S'(t) = \bar{U}(S(t),t)(1-\phi^*), \\ &S(0) = L, \\ &\bar{\phi}(S(t),t) = 0, \\ &\bar{U}(0,t) = 0, \qquad t \in [0,T], \\ &\bar{\phi}(x,0) = \phi_0(x) - \phi^*, \qquad x \in [0,L], \\ &\bar{U}(x,0) = \bar{U}_0(x), \qquad x \in [0,L]. \end{aligned} \tag{5.2}$$

Because $0 < \phi_0 < 1$, we have $-\phi^* < \bar{\phi} < 1 - \phi^*$. Let us recall that $G'(\phi^*) < 0$, which ensures hyperbolicity. Let $\Gamma = G'(\phi^*)$. We make the following change of variables:

$$\begin{aligned} &\bar{\phi} = \sqrt{-\Gamma}(p+q), \\ &\bar{U} = \sqrt{\phi^*(1-\phi^*)}(p-q). \end{aligned} \tag{5.3}$$

Then the system (5.1) and (5.2) changes to the following equivalent system of equations:

$$p_t + \lambda_v p_x = -\frac{\beta}{2\phi^*(1-\phi^*)}(p-q), \tag{5.4}$$

$$q_t - \lambda_v q_x = \frac{\beta}{2\phi^*(1-\phi^*)}(p-q) \tag{5.5}$$

with free boundary conditions

$$\begin{aligned}
&S'(t) = (1-\phi^*)\sqrt{\phi^*(1-\phi^*)}(p(S(t),t) - q(S(t),t)),\\
&S(0) = L,\\
&p(S(t),t) + q(S(t),t) = 0, \qquad t \in [0,T],\\
&p - q = 0, \qquad t \in [0,T],\\
&p(x,0) = p_0(x), \qquad x \in [0,L],\\
&q(x,0) = q_0(x), \qquad x \in [0,L],
\end{aligned} \tag{5.6}$$

where $\lambda_v = \sqrt{-\Gamma\phi^*(1-\phi^*)}$.

5.2. Free boundary problem for the linearized system. A free boundary problem analogous to the present one is studied in [28]. However, the proof of the theorem relies on the assumption that the speed U is strictly positive at $x = 0$. Here, we generalize the global existence result to the case $U = 0$ at $x = 0$. We first point out that the local existence of solution stated next follows from the theorem in [12].

Theorem 5.1. *Let $0 < \phi^* < 1$, $\Gamma < 0$ be constant. Suppose that $p_0(x), q_0(x) \in C^1[0,L]$ satisfy compatibility conditions at $(0,0)$ and $(L,0)$. Let*

$$|p_0(L)| < \frac{\sqrt{-\Gamma}}{2(1-\phi^*)}. \tag{5.7}$$

Then there is a $t_0 > 0$ such that the free boundary problem (5.4), (5.5), and (5.6) has a unique solution $(p(x,t), q(x,t), S(t)) \in C^1(\bar{Q}_{S,t_0}) \times C^1(\bar{Q}_{S,t_0}) \times C^2[0,t_0]$, where

$$Q_{S,t_0} = \{(x,t),\ 0 < x < S(t),\ 0 < t < t_0\},$$

and t_0 depends on $S(0)$, $S'(0)$, $\|p_0(x)\|_{C^1[0,L]}$, and $\|q_0(x)\|_{C^1[0,L]}$.

In order to prove global existence of solutions, we will use the lemmas stated next. The proof of Lemma 5.2 makes use of the approach presented in [28].

Lemma 5.2 (see [28]). *Let $(\bar{\phi}, \bar{U}, S)$ be a C^1 solution of (5.1) and (5.2), and define p, q as in (5.3). Also, suppose that p_0 satisfies (5.7). Then*

$$|S'| < \lambda_v, \quad |p(S(t),t)| < \frac{\sqrt{-\Gamma}}{2(1-\phi^*)}, \quad |q(S(t),t)| < \frac{\sqrt{-\Gamma}}{2(1-\phi^*)}$$

hold for $t \in (0,t_0)$.

Proof. We proceed by contradiction. First, since $S'(0) > \lambda_v$, we suppose that there exists $0 < \hat{t} \le t_0$ such that

$$\lim_{t\to\hat{t}^-} S'(t) = \lambda_v \quad \text{and} \quad S'(t) < \lambda_v \quad \text{for } 0 < t < \hat{t}$$

holds. This implies that $S'(t)$ reaches its maximum as t approaches $\hat{t}$, and, consequently,

$$\lim_{t\to\hat{t}^-} S''(t) \ge 0.$$

This together with boundary condition (5.2a) yields

$$\lim_{t\to\hat{t}^-} \frac{d}{dt}\bar{U}(S(t),t) = \lim_{t\to\hat{t}^-} \frac{\partial U}{\partial x}\lambda_v + \frac{\partial U}{\partial t} \ge 0 \quad \text{at } (S(\hat{t}),\hat{t}). \tag{5.8}$$

On the other hand, because of boundary condition (5.2c), $\bar{\phi} \equiv 0$ on $(S(t), t)$ follows, and therefore

$$\frac{d}{dt}\bar{\phi}(S(t), t) = \frac{\partial \bar{\phi}}{\partial x}\lambda_v + \frac{\partial \bar{\phi}}{\partial t} = 0 \quad \text{on } (S(t), t). \tag{5.9}$$

Multiplying (5.1a) by $\frac{\sqrt{-\Gamma}}{\sqrt{\phi^*(1-\phi^*)}}$, adding the result to (5.1b), and taking limits as $x \to S(t)$ and $t \to \hat{t}^-$, we get

$$\frac{\sqrt{-\Gamma}}{\sqrt{\phi^*(1-\phi^*)}}\left(\frac{\partial \bar{\phi}}{\partial x}\lambda_v + \frac{\partial \bar{\phi}}{\partial t}\right) + \frac{\partial U}{\partial x}\lambda_v + \frac{\partial U}{\partial t} + \frac{\beta \lambda_v}{\phi^*(1-\phi^*)^2} = 0. \tag{5.10}$$

By application of (5.9), this reduces to

$$\frac{\partial U}{\partial x}\lambda_v + \frac{\partial U}{\partial t} = -\frac{\beta \lambda_v}{\phi^*(1-\phi^*)^2} < 0,$$

which contradicts inequality (5.8). We can follow the analogous argument in the case that

$$\lim_{t \to \hat{t}^-} S'(t) = -\lambda_v \quad \text{and} \quad S'(t) > -\lambda_v \quad \text{for } 0 < t < t_0.$$

Therefore,

$$|S'(t)| < \lambda_v = \sqrt{-\Gamma \phi^*(1-\phi^*)}$$

holds. This inequality together with boundary conditions (5.6a) and (5.6c) yields that the two remaining conclusions of the lemma hold. □

Lemma 5.3 (see [28]). *Let* $(\bar{\phi}, \bar{U}, S) \in C^1(Q_{S,t_0}) \times C^1(Q_{S,t_0}) \times C^2[0, t_0]$ *be a solution of the system* (5.1) *satisfying boundary conditions* (5.2). *Also, suppose that* $\max\{\|p_0\|_{L^\infty}, \|q_0\|_{L^\infty}\} \leq C_0 < \frac{\sqrt{-\Gamma}}{2(1-\phi^*)}$. *Then* $|p(x,t)| \leq C_0$ *and* $|q(x,t)| \leq C_0$ *for* $x \in Q_{S,t_0}$, *where* Q_{S,t_0} *is defined in Theorem* 5.1.

Proof. Arguing by contradiction, suppose otherwise; that is, there exist $\epsilon > 0$, $(x^*, t^*) \in Q_{S,t_0}$, such that

$$\begin{aligned} &|p(x^*, t^*)| = \max\{|p(x^*, t^*)|, |q(x^*, t^*)|\} = C_0 + \epsilon, \\ &\max\{|p(x,t)|, |q(x,t)|\} < C_0 + \epsilon \quad \text{for any fixed } t < t^*. \end{aligned}$$

First, notice that $S(t^*) > 0$, because, otherwise, if $S(t^*) = 0$, we can apply the boundary conditions at $x = 0$ and $x = S(t)$ to conclude that $p = q = 0 \leq C_0$. For $0 < x^* \leq S(t)$, there exists $\delta > 0$ such that $x^* - \lambda_v \delta > 0$ and $t^* - \delta > 0$. Integrating on characteristics, we have

$$\begin{aligned} p(x^*, t^*) = {}& e^{-\frac{\beta}{2\phi^*(1-\phi^*)}\delta} p(x^* - \lambda_v \delta, t^* - \delta) \\ &+ \int_0^\delta \frac{\beta}{2\phi^*(1-\phi^*)} e^{-\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - \delta)} q(x^* + (\tau - \delta), t^* + (\tau - \delta))\, \mathrm{d}\tau. \end{aligned}$$

With the help of the mean value theorem, we get the estimate

$$\begin{aligned} |p(x^*, t^*)| \leq {}& e^{-\frac{\beta}{2\phi^*(1-\phi^*)}\delta} |p(x^* - \lambda_v \delta, t^* - \delta)| \\ &+ |q(x^* + (\theta - \delta), t^* + (\theta - \delta))|(1 - e^{-\frac{\beta}{2\phi^*(1-\phi^*)}\delta}) \\ \leq {}& \max\{|p(x^* - \lambda_v \delta, t^* - \delta)|, |q(x^* + (\theta - \delta), t^* + (\theta - \delta))|\} \\ < {}& C_0 + \epsilon. \end{aligned}$$

This is a contradiction to the statement $|p(x^*, t^*)| = C_0 + \epsilon$. Now, if $x^* = 0$, there exist $0 < \delta < t^*$ such that $0 < \lambda_v \delta < S(t)$; applying the boundary condition $p(0, t^*) = q(0, t^*)$ yields

$$\begin{aligned}|p(0,t^*)| = |q(0,t^*)| &\le \max\{|q(\lambda_v\delta, t^* - \delta)|, |p(\lambda_v(\delta-\theta), t-(\delta-\theta))|\}\\ &< C_0 + \delta,\end{aligned}$$

where $0 < \theta < \delta$. This is again a contradiction to $|p(x^*, t^*)| = C_0 + \epsilon$. Hence $|p(x,t)| \le C_0$. We can follow an analogous argument in the case that $|q(x^*, t^*)| = \max\{|p(x^*, t^*)|, |q(x^*, t^*)|\} = C_0 + \epsilon$. □

Remark. Note that we can choose C_0 so that $\max\{\|\phi_0\|_{L^\infty}, \|U_0\|_{L^\infty}\} < \min\{\phi^*, 1 - \phi^*\}$. Hence $\bar{\phi}$ is always bounded by $\min\{\phi^*, 1-\phi^*\}$.

LEMMA 5.4. *Under the assumption of Lemma* 5.3 *and* $\int_0^L \bar{\phi}_0\,dx + \phi^* L > 0$, *there exist* $C > 0$ *and* $\eta > 0$ *such that*

$$C \ge S(t) \ge \eta > 0,$$

where η *depends on* C_0, p_0, q_0, ϕ^*, *and* Γ.

Proof. Integrating $\frac{\partial \bar{\phi}}{\partial t} + \phi^*(1-\phi^*)\frac{\partial \bar{U}}{\partial x} = 0$ with respect to x at fixed t, we get

$$\int_0^{S(t)} \frac{\partial \bar{\phi}}{\partial t}\,\mathrm{d}x + \phi^*(1-\phi^*)\bar{U}(S(t),t) = \phi^*(1-\phi^*)\bar{U}(0,t).$$

By applying boundary conditions (5.2a) and (5.2d), we get

$$\int_0^{S(t)} \frac{\partial \bar{\phi}}{\partial t}\,\mathrm{d}x + \phi^* S'(t) = 0.$$

Moreover, using the boundary condition $\bar{\phi}(S(t),t) = 0$, we get

$$\frac{d}{dt}\left\{\int_0^{S(t)} \bar{\phi}\,\mathrm{d}x + \phi^* S\right\} = 0.$$

Integration with respect to t gives

$$\int_0^{S(t)} \bar{\phi}\,\mathrm{d}x + \phi^* S - \int_0^L \bar{\phi}_0\,\mathrm{d}x - \phi^* L = 0.$$

Following Lemma 5.3, we can choose C_0 such that

$$\|\bar{\phi}\|_{L^\infty} < 2\sqrt{-\Gamma}C_0 \le \min\{\phi^*, 1-\phi^*\} - \epsilon.$$

Hence

$$S(t) \ge \frac{1}{2\sqrt{-\Gamma}C_0 + \phi^*}\left(\int_0^L \bar{\phi}_0\,\mathrm{d}x + \phi^* L\right) > 0,$$

and

$$S(t) \le \frac{1}{-2\sqrt{-\Gamma}C_0 + \phi^*}\left(\int_0^L \bar{\phi}_0\,\mathrm{d}x + \phi^* L\right). \qquad \square$$

LEMMA 5.5. *Then under the assumption of Lemma* 5.3,

$$|p_x(x,t)| \le C_3, \quad |q_x(x,t)| \le C_3$$

for $0 < t < t_0$*, where* C_3 *depends on* $\|p_0\|_{C^1[0,L]}$, $\|p_0\|_{C^1[0,L]}$*, and* C_0.

Proof. First, let us suppose that $t_0 < t_1 = \frac{L}{2\lambda_v}$ as in Figure 1. Differentiating (5.4) and (5.5) with respect to x yields

$$p_{xt} + \lambda_v p_{xx} = -\frac{\beta}{2\phi^*(1-\phi^*)}(p_x - q_x), \tag{5.11}$$

$$q_{xt} - \lambda_v q_{xx} = \frac{\beta}{2\phi^*(1-\phi^*)}(p_x - q_x) \tag{5.12}$$

and boundary condition

$$p_x + q_x = 0 \quad \text{at } x = 0, \tag{5.13}$$

$$(2(1-\phi^*)p - \sqrt{-\Gamma})p_x + (2(1-\phi^*)p + \sqrt{-\Gamma})q_x = 0 \quad \text{at } x = S(t). \tag{5.14}$$

Now, for fixed $0 < t < t_0$, define

$$\begin{aligned} A(t) &= \|p_x(x,t)\|_{L^\infty[0,S(t)]}, \\ B(t) &= \|q_x(x,t)\|_{L^\infty[0,S(t)]}, \\ C(t) &= \max\{A(t), B(t)\}, \\ C_1 &= \max\left\{\|p_{0x}\|_{L^\infty[0,L]}, \|q_{0x}\|_{L^\infty[0,L]}\right\}. \end{aligned}$$

If $(x,t) \in \Omega_3$, integrating along the characteristics of (5.11) and (5.12) yields

$$\begin{aligned} q_x(x,t) &= e^{-\frac{\beta}{2\phi^*(1-\phi^*)}(t-t_0)} q_x(S(t_0), t_0) \\ &\quad + \int_{t_0}^{t} \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} p_x(S(t_0) - \lambda_v(\tau - t_0), \tau)\, \mathrm{d}\tau, \end{aligned} \tag{5.15}$$

$$\begin{aligned} p_x(S(t_0), t_0) &= e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t_0} p_x(S(t_0) - \lambda_v t, 0) \\ &\quad + \int_{0}^{t_0} \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t_0)} q_x(S(t_0) - \lambda_v(t_0 - \tau), \tau)\, \mathrm{d}\tau. \end{aligned} \tag{5.16}$$

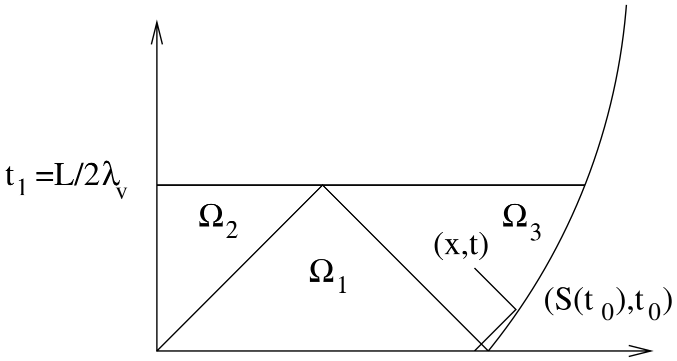

FIG. 1.

From the boundary condition (5.14), we have

$$q_x = \frac{\sqrt{-\Gamma} - 2(1-\phi^*)p}{2(1-\phi^*)p + \sqrt{-\Gamma}} p_x.$$

It follows from Lemma 5.3 that $|p(x,t)| \leq C_0 <$ const. Hence

$$\begin{aligned} |q_x| &\leq \left| \frac{\sqrt{-\Gamma} - 2(1-\phi^*)p}{2(1-\phi^*)p + \sqrt{-\Gamma}} \right| |p_x| \\ &\leq \left| \frac{\sqrt{-\Gamma} + 2(1-\phi^*)C_0}{\sqrt{-\Gamma} - 2(1-\phi^*)C_0} \right| |p_x| = C_2 |p_x|, \end{aligned}$$

where $C_2 := |\frac{\sqrt{-\Gamma}+2(1-\phi^*)C_0}{\sqrt{-\Gamma}-2(1-\phi^*)C_0}| > 1$. Combining (5.15) and (5.16) gives

$$|q_x(x,t)| \leq C_1 C_2 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + C_2 \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau.$$

For $(x,t) \in \Omega_1 \cup \Omega_2$, we have the estimate

$$|q_x(x,t)| \leq C_1 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau.$$

Hence

$$B(t) \leq C_1 C_2 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + C_2 \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau$$

holds. Now, for $(x,t) \in \Omega_2$, we have the following relations:

$$\begin{aligned} p_x(x,t) &= e^{-\frac{\beta}{2\phi^*(1-\phi^*)}\frac{x}{\lambda_v}} p_x\left(0, t - \frac{x}{\lambda_v}\right) \\ &\quad + \int_{t-\frac{x}{\lambda_v}}^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} q_x\left(\lambda_v\left(\tau - t + \frac{x}{\lambda_v}\right), \tau\right) \mathrm{d}\tau, \\ q_x\left(0, t - \frac{x}{\lambda_v}\right) &= e^{-\frac{\beta}{2\phi^*(1-\phi^*)}(t - \frac{x}{\lambda_v})} q_x\left(\lambda_v\left(t - \frac{x}{\lambda_v}\right), 0\right) \\ &\quad + \int_0^{t-x/\lambda_v} \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - (t - \frac{x}{\lambda_v}))} p_x\left(\lambda_v\left(t - \frac{x}{\lambda_v} - \tau\right), \tau\right) \mathrm{d}\tau. \end{aligned}$$

Application of the boundary condition (5.13) to the previous expression yields the estimate

$$|p_x(x,t)| \leq C_1 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau.$$

For $(x,t) \in \Omega_1 \cup \Omega_3$, we get

$$|p_x(x,t)| \leq C_1 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau.$$

Hence,

$$C(t) \leq C_1 C_2 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} + C_2 \int_0^t \frac{\beta}{2\phi^*(1-\phi^*)} e^{\frac{\beta}{2\phi^*(1-\phi^*)}(\tau - t)} C(\tau)\, \mathrm{d}\tau.$$

By Gronwall's inequality, we have

$$C(t) \leq C_1 C_2 e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t} e^{C_2(1-e^{-\frac{\beta}{2\phi^*(1-\phi^*)}t})} =: C_3.$$

Note that C_3 has a bound depending only on C_1, C_2, and t_0. Now for $t_0 > t_1$, we take the value of the solution at $t = t_1$ as initial condition and extend the estimate up to $t_1 + \frac{S(t_1)}{2\lambda_v}$. Since $S(t_1) > \eta > 0$, we can extend the estimate up to t_0. This completes the proof of the lemma. □

LEMMA 5.6. *Under the assumption of Lemma* 5.3, *there exists* $\epsilon > 0$ *such that*

$$|S'(t)| \leq \lambda_v(1-\epsilon).$$

Proof. Suppose that for any positive constant $\epsilon > 0$, there exist $0 < t^* \leq \min\{t_0, t_1\}$ and $0 < \delta < \epsilon$ such that $|S'(t^*)| = \lambda_v(1-\delta)$. Thus, we have

$$\begin{aligned} &\frac{\partial\bar{\phi}}{\partial x}\lambda_v(1-\delta) + \frac{\partial\bar{\phi}}{\partial t} = 0 \quad \text{on } (S(t), t), \\ &\lim_{t\to t^*} \frac{\partial U}{\partial x}\lambda_v(1-\delta) + \frac{\partial U}{\partial t} \geq 0. \end{aligned} \tag{5.17}$$

By following arguments analogous to those in the derivation of (5.10) and using (5.17), we have

$$\lambda_v\delta\left(\frac{\lambda_v}{\phi^*(1-\phi^*)}\frac{\partial\bar{\phi}}{\partial x} + \frac{\partial\bar{U}}{\partial x}\right) \leq -\frac{\beta}{\phi^*(1-\phi^*)}\frac{\lambda_v(1-\delta)}{1-\phi^*}. \tag{5.18}$$

By Lemma 5.5, $|p_x| \leq C_3$ and $|q_x| \leq C_3$, and thus $\bar{\phi}_x$ and $\bar{U}_x$, as linear combinations of p_x and q_x, are also bounded by a constant. Hence, $\frac{\lambda_v}{\phi^*(1-\phi^*)}\frac{\partial\bar{\phi}}{\partial x} + \frac{\partial\bar{U}}{\partial x} > -C$ holds, where $C = (\frac{\lambda_v}{\phi^*(1-\phi^*)} + 1)C_3$. Thus, letting $(x,t) \to (x^*, t^*)$ and using (5.18) and (5.17), we get

$$-\delta\lambda_v C + \frac{\beta(1-\delta)}{1-\phi^*} \leq 0,$$

which implies

$$\delta \geq \frac{\beta}{C(1-\phi^*)\lambda_v + \beta} > 0.$$

This contradicts inequality (5.18). □

We now state the following theorem on global existence. It also states that the interface remains bounded and cannot collapse to a point.

THEOREM 5.7. *Let the assumptions of Theorem* 5.1 *hold. Let* $\delta > 0$ *be such that*

$$\max\{\|p_0\|_{L^\infty}, \|q_0\|_{L^\infty}\} < \delta.$$

Then for any $t > 0$, *there exists a unique solution*

$$(U(x,\tilde{t}), \phi_1(x,\tilde{t}), S(\tilde{t})) \in C^1(\bar{Q}_{S,t}) \times C^1(\bar{Q}_{S,t}) \times C^2[0,t],$$

where $Q_{S,t} = \{(x,\tilde{t}),\ 0 < x < S(t),\ 0 < \tilde{t} < t\}$. *Moreover, there exist* η *and* μ *such that*

$$\mu_1 > S(\tilde{t}) > \eta > 0.$$

Proof. Because the transformation (5.3) is nonsingular, there exists $\delta > 0$ such that if

$$\max\{|p(x,t)|, |q(x,t)|\} < \delta < \frac{\sqrt{-\Gamma}}{2(1-\phi^*)},$$

then $|\phi| < \max\{\phi^*, 1-\phi^*,\}$ holds. Now, define t_{max} to be the maximum time of the local solution to (5.1) with (5.2). First, let us suppose that $t_{max} \leq t_1 = \frac{L}{2\lambda_v}$. By Lemma 5.6, $|S'(t)| \leq \lambda_v(1-\epsilon)$, with $\epsilon > 0$ depending on $\max\{\|p_0\|_{C^1}, \|q_0\|_{C^1}\}$. From Lemmas 5.3 and 5.5, we have that

$$\lim_{t\to t_{max}} \|p(x,t)\|_{C^1} < C_3,$$
$$\lim_{t\to t_{max}} \|q(x,t)\|_{C^1} < C_3.$$

On the other hand, by Lemma 5.4, there exists $\eta > 0$ such that $S(t) \geq \eta > 0$ for $0 < t < t_{max}$. Then by the local existence theorem, we can extend the solution beyond t_{max}; hence we have $t_{max} \geq t_1$. Now, taking $\{\bar{\phi}(x,t_1), U(x,t_1), S(t_1)\}$ as initial condition, we can extend the solution up to time $\frac{L}{2\lambda_v} + \frac{S(t_1)}{2\lambda_v}$. Note that $S(t) > \eta$, and therefore we can further extend the solution up to $\frac{L}{2\lambda_v} + m\frac{S(t_1)}{2\lambda_v}$ for any $m \in \mathbb{Z}^+$. Hence, the solution exists for all $t > 0$. □

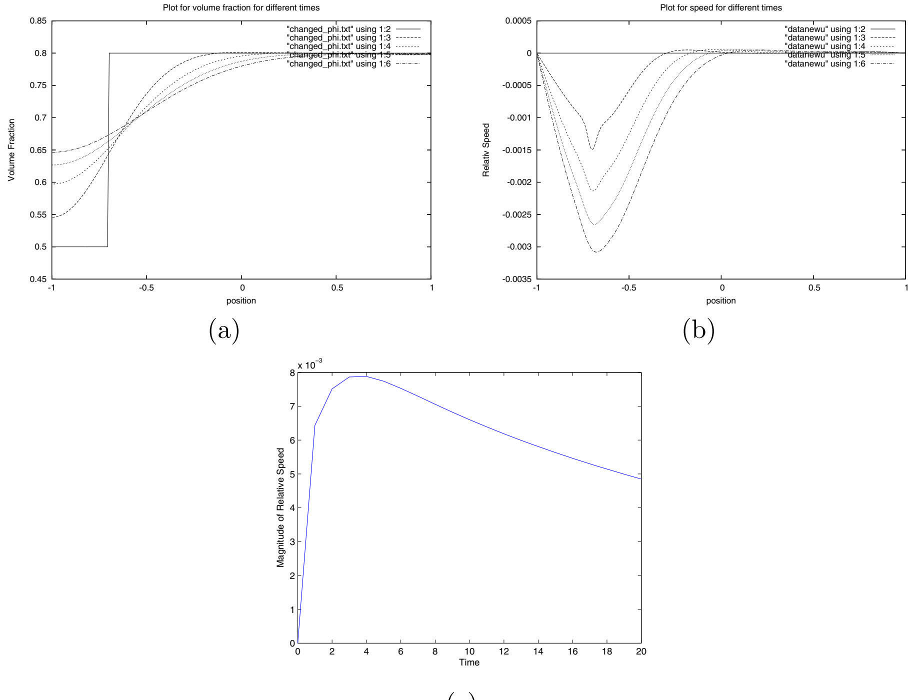
6. Numerical simulations. Based on the theoretical study, the following simulations are carried out for the Cauchy problem, with periodic boundary conditions. In order to achieve numerical stability, an artificial dissipation of form $\gamma\triangle^2\phi_1$ is added to the balance of mass equation, with $\gamma > 0$ small. Data are taken from Table 1.

It is well known that the value of β may be very sensitive to the volume fraction of the polymer. We consider the following expression for β [20]:

$$\beta(\phi_1) = (1-\phi_1)\phi_1^{\frac{2\gamma}{(3\gamma-1)}},$$

where $\gamma = 1/2$ for a Θ-solvent and $\gamma = 3/5$ for a good solvent [27]. Since we are interested in initial behavior where ϕ_1 jumps from 0 to 1, near the initial location of the interface between solvent and dry polymer, effectively, β is considerably smaller than the constant value in Table 1. The time and length scales of the calculations are taken to be $10^{-7}s$ and $10^{-5}m$, respectively. We take the polymer domain as the strip $(-1,3)$ centered at $x = 1$. Because of the symmetry of the problem, we show only the strip $(-1,1)$. We use the spectral method [17] to solve the nonlinear equation recursively; the result is shown in Figure 2. We observe that initially, the diffusive velocity builds up quickly, and the volume fraction changes rapidly. However, after a short initial time interval, the diffusive velocity decays, and the polymer volume fraction tends to an equilibrium saturation value.

7. Conclusion. We have analyzed the model developed in [3] for a two-component mixture of elastic solid and solvent and obtained effective equations for gels. We investigate the multiple time scales of the system and characterize the corresponding dynamics. We argue that studying early dynamics provides information on the evolution of swelling fronts and also gives a mathematical characterization of type II diffusion in polymers. We consider one-dimensional geometries and study the corresponding Cauchy problem, by applying the theory of Dafermos [5] on weakly dissipative hyperbolic systems. This allows us to establish existence and asymptotic



(a)

(b)

(c)

FIG. 2. (a) *polymer profile,* (b) *speed profile,* (c) *maximum relative velocity U versus time.*

properties of the solution of the Cauchy problem. We interpret the breakdown of the hyperbolicity condition, occurring at critical volume fractions for polysaccharide data, as an onset of deswelling. We formulate and study the free boundary problem for the linearized system and prove existence and uniqueness of solutions. This provides direct information on interface evolution; in particular, we show that the strip domain cannot collapse to a point. Follow-up studies address the nonlinear free boundary problem by combining estimates of the Cauchy problem with the information on the solution of the linearized problem.

Acknowledgments. The authors wish to thank Hans Weinberger, Suping Lyu, and Brandon Chabaud for many fruitful discussions. Both authors also thank Jie Shen for help and advice on the numerical study of the problem.

A MATHEMATICAL MODEL FOR THE CONTROL AND ERADICATION OF A WOOD BORING BEETLE INFESTATION*

STEPHEN A. GOURLEY† AND XINGFU ZOU‡

Abstract. We propose a mathematical model for an infestation of a wooded area by a beetle species in which the larva develop deep in the wood of living trees. Due to the difficulties of detection, we presume that only a certain proportion of infested trees will be detected and that detection, if it happens, will occur only after some delay, which could be long. An infested tree once detected is immediately cut down and burned. The model is stage structured and contains a second time delay, which is the development time of the beetle from egg to adult. There is a delicate interplay between the two time delays due to the possibility in one case for a larva to mature even in a tree destined for destruction. We present conditions sufficient for infestation eradication and discuss the significance of the conditions, particularly in terms of the proportion of infested trees that need to be detected and removed. If the infestation is successfully eradicated, there are always a number of trees that completely escape infestation, and we compute lower bounds and an approximation for this number. Finally, we present the results of some numerical simulations.

1. Introduction.

In this paper we present a mathematical model of a possible strategy for the control of an infestation of wood boring beetles in which the larvae are burrowed deep in the wood of trees so that they are well protected from natural enemies but still have some intrinsic death rate. Our model also incorporates removal of trees that have been diagnosed as infested. Our work has been motivated in large part by recent infestations in parts of the US and Canada of *Anoplophora glabripennis*, commonly known as the Asian longhorned beetle (ALB), which attacks hardwood trees. Maple, willow, and elm constitute especially good hosts. Birch, ash, poplar, and numerous other tree species can also host this pest. The ALB has been intercepted at ports and warehouses all over North America, and it is believed that the pest entered the US (later spreading to Canada) in wooden packing crates used for imports from China. The beetle is native to China and Korea, and in China has caused major damage to poplar plantations with significant economic loss [6]. So far in North America the pest has affected only urban and suburban areas, but the potential impact of the ALB on the millions of acres of hardwood forests in the US and Canada could be devastating. It has been estimated that 1.2 billion trees could be at risk if the ALB were to become established in North America (see Nowak et al. [13] for a further discussion of the potential impact). Since the ALB species is not native to North America, it has no known natural enemies there (in fact, even in China it has few natural enemies).

*Received by the editors November 8, 2006; accepted for publication (in revised form) March 17, 2008; published electronically June 25, 2008. This research was partially supported by NSERC and NCE-MITACS of Canada and by PREA of Ontario.

‡Department of Applied Mathematics, University of Western Ontario, London, ON, Canada N6A 5B7 (xzou@uwo.ca).

The first time the ALB was found in North America seems to have been in Brooklyn, NY in 1996. Since then, the species has been found infesting trees in several US cities, including New York and Chicago, and it was found in Toronto, Canada for the first time in 2003.

Currently, the only known effective method of control of the ALB is to cut down, chip, and burn infested trees. Chemical controls are of limited potential because the larvae are deep within the tree and no effective chemical controls are yet available, though the effectiveness of certain insecticides is being investigated. It is current practice to establish quarantines around known infested areas and to monitor potential host trees within a certain distance of an infested area. Adult beetles are poor fliers but can fly short distances up to a few hundred yards to other neighboring trees, though in fact an adult often remains on the same host tree from which it emerged. ALB infested trees once removed are always replaced with a nonhost species. Other measures currently used for control include inspection of imports and the imposition of regulations on wooden packing material used for imports.

The ALB is a large beetle (up to 1.5 in long) which is easy to recognize. Adults are active from late spring to fall, when they perish. However, a large proportion of the life cycle of the beetle is spent in the larval stage deep within a tree, and this makes the detection of ALB activity more difficult. ALB larval activity on a tree is usually spotted either by inspectors or by members of the public. Warning signs of a tree being infested include exit holes (typically the diameter of a dime), oozing sap, sawdust accumulation, and unseasonable yellowing or drooping of leaves. The females prefer to lay their eggs in the upper canopy of a tree, though the lower trunk and branches can become affected if the upper canopy has been damaged by previous ALB activity. Preference for the upper canopy means that detection is more likely if inspectors are able to inspect it, for example, by climbing the tree. This slows down and increases the expense of systematically searching for ALB in a wooded area with the consequence of trees potentially missing detection. We shall aim to include these factors in the models we present in this paper. Since at present ALB affects only urban or suburban areas of North America, an infested tree probably stands a reasonable chance of being diagnosed as such, though possibly not until some time after the laying of eggs. An infested tree, if detected, will always be cut down and burned, but if not detected, the tree may survive several more years. Its death in this case will be due to the weakening of the tree and disruption of sap flow caused by the tunneling due to the larvae.

Adult ALB of both sexes are promiscuous, mating repeatedly and with different partners, according to greenhouse experiments reported in Morewood et al. [11]. The female will chew through the bark on the upper trunk and lay an egg. A single female can lay from 35 to 90 eggs during her lifetime of one season. The egg hatches after 1–2 weeks and the larva burrows deep into the tree, where it is very well protected from natural enemies, so there is a high probability of survival to maturity (this probability does depend to some extent on the tree species; see Morewood et al. [12]). Later in its development the larva enters the pupa stage, and finally the adult emerges from the tree. The whole duration from egg to adult lasts about one year but can be as long as 18 months. Adult emergence creates visible exit holes, which can sometimes be seen with binoculars, though the holes are not the only or necessarily the earliest sign of tree infestation.

In our models we shall deal with the issue of infested tree detection by supposing that there is a time delay σ between the time a tree becomes infested and the subsequent detection of ALB activity on the tree. To allow for the difficulties of detection we assume that only a certain fraction λ of infested trees is detected and then immediately removed. Such a fraction might well be close to 1, if the infestation is confined to a small suburban wooded area, but is likely to be much smaller if ALB infestation were to develop in a wilderness area. The models include a second time delay τ which models the developmental time of the beetle from egg to adult. As we shall see, there is a delicate interplay between the two delays σ and τ for reasons that will be explained early in the next section.

Subsection 2.1 deals with the case when $\sigma < \tau$ and presents the model for this case together with a detailed derivation. Positivity of solutions is established, which is not at all obvious from the appearance of the model equations. Then, sufficient conditions are presented for infestation eradication and a lower bound is given for the final number of susceptible trees.

Subsection 2.2 addresses the case $\sigma > \tau$. The model equations for this case look similar to those for the $\sigma < \tau$ case, but there are subtle differences, and a different strategy is required to establish positivity of solutions. For this case we again present an inequality that is sufficient for infestation eradication. Subsection 2.3 deals with the case when $\lambda = 1$. In subsection 2.4 we present a Laplace transform analysis that enables us to calculate analytically the final number of susceptible trees in the case when the number of adult beetles is small throughout the course of the infestation.

In some parameter regimes the infestation is not eradicated but instead all trees become infested, with the number of susceptible trees tending to zero (we shall see, however, that if the infestation is eradicated, there are always some trees that escape infestation). In situations in which eradication has not been achieved, the beetle numbers typically evolve to a periodic cycle in a forest in which all trees end up being infested. In reality the goal, of course, is to prevent this from happening and aim for eradication, but without necessarily requiring the detection and removal of every single infested tree.

2. Model derivation and analysis.

Let $T_s(t)$ and $T_i(t)$ denote, respectively, the numbers of susceptible and infested trees. Trees can survive about 4 years of infestation before they die; this is somewhat longer than the timescale on which we would want to remove infested trees, so disease-induced death of infested trees is neglected. It is also reasonable to neglect natural mortality of trees which occurs on an even longer timescale (e.g., of 100 years or more for maple trees). The quantities $L(t)$ and $A(t)$ denote the numbers of larval and adult beetles.

The model we shall develop involves two time delays. We shall let σ denote the amount of time that elapses between the instant that a tree becomes infested and the subsequent instant at which there is a probability λ of its being removed and burnt as a consequence (i.e., a fraction $\lambda \in [0, 1]$ of trees that become infested are removed σ time units later). We shall let τ denote the time it takes between the laying of an egg and subsequent emergence of an adult beetle, i.e., the duration of the larval stage, which in this paper is understood to include all pre-adult stages. It will be clear that the cases $\sigma < \tau$ and $\sigma > \tau$ have to be dealt with separately. For example, if $\sigma < \tau$, then the period between time of infection of a tree and its subsequent removal (if it is removed) is not long enough to allow any larva to mature; however, a larva can still mature if it is fortunate enough to be in a host tree that is not removed. On the other hand if $\sigma > \tau$, then it is possible for larvae to complete their development into maturity and escape as adult beetles even if all infested trees are removed.

2.1. The case $\sigma < \tau$. For the case when $\sigma < \tau$, we propose the following model:

$$\frac{dT_s(t)}{dt} = -\beta A(t)T_s(t), \tag{2.1}$$

$$\frac{dT_i(t)}{dt} = \beta A(t)T_s(t) - \lambda\beta A(t-\sigma)T_s(t-\sigma), \tag{2.2}$$

$$\begin{aligned}\frac{dL(t)}{dt} &= T_i(t)B(A(t)) - \mu_L L(t) - \lambda\beta A(t-\sigma)T_s(t-\sigma)\int_0^\sigma B(A(t-a))e^{-\mu_L a}\,da\\ &- e^{-\mu_L\tau}B(A(t-\tau))\left[T_i(t-\tau) - \lambda\beta\int_0^\sigma A(\tilde{a}+t-\tau-\sigma)T_s(\tilde{a}+t-\tau-\sigma)\,d\tilde{a}\right],\end{aligned} \tag{2.3}$$

$$\begin{aligned}\frac{dA(t)}{dt} &= e^{-\mu_L\tau}B(A(t-\tau))\left[T_i(t-\tau) - \lambda\beta\int_0^\sigma A(\tilde{a}+t-\tau-\sigma)T_s(\tilde{a}+t-\tau-\sigma)\,d\tilde{a}\right]\\ &\quad - \mu_A A(t).\end{aligned} \tag{2.4}$$

Here, all parameters are nonnegative with $\lambda \in [0,1]$. We justify each equation in (2.1)–(2.4) below.

Susceptible trees are converted to infested trees via contact with adult beetles, and it is assumed that the rate at which this occurs is given by the law of mass action (equation (2.1)). There is no term reflecting regeneration of trees, partly because this would occur on a relatively slow timescale and partly because tree replanting would be of some nonsusceptible species and might not take place at all while the infestation is still present.

The second term in the right-hand side of (2.2) represents the cutting down (and subsequent burning) of infested trees. It is assumed that when a tree becomes infested, it may be recognized and diagnosed as such but only after some time delay σ, which models the time taken for the tree to begin exhibiting telltale signs. A fraction $\lambda \in [0,1]$ of trees which become infested are later cut down, so that at time t the rate of cutting down of infested trees is λ times the infection rate at the earlier time $t-\sigma$.

The first term in the right-hand side of (2.3) is the birth rate, assumed proportional to the total number of infested hosts (recall that a tree is considered infested after contact with an adult beetle) and also to $B(A(t))$, where the function $B(\cdot)$ is the number of eggs laid per unit time per tree. We assume that all eggs hatch successfully, but some of the larvae may die in the tree at a rate μ_L. Of course, larvae may also die due to trees being cut down and burned. The rate at which this happens is evidently related to the total cutting down rate of infested and dead trees and is computed as follows:

$$\underbrace{\lambda\beta A(t-\sigma)T_s(t-\sigma)}_{\text{rate of tree removal}}\underbrace{\int_0^\sigma B(A(t-a))e^{-\mu_L a}\,da}_{\text{larvae per tree}}.$$

The last term in (2.3), which also appears in (2.4), is the rate at time t at which larvae mature into adult beetles. We next provide a rigorous derivation of this term, which is essentially the birth rate at the earlier time $t-\tau$ (τ being the length of the maturation period), modified to allow for natural mortality and mortality due to tree removal. Death of adult beetles is modeled by the last term in (2.4).

To derive the maturation term for the case when $\sigma < \tau$, let $b(t,a)$ denote the density of beetles at time t of age a. Larval beetles and adult beetles are, respectively, those of age less than τ and greater than τ so that

$$L(t) = \int_0^\tau b(t,a)\,da, \qquad A(t) = \int_\tau^\infty b(t,a)\,da. \tag{2.5}$$

It is larval beetles that are affected by removal of trees, but we must note that, since we assume $\sigma < \tau$ here, the larvae that are removed due to tree removal will have age up to at most σ. Any older larvae will necessarily be in trees that escaped removal. We model this as follows using von Foerster age-structured equations:

$$\frac{\partial b}{\partial t} + \frac{\partial b}{\partial a} = -\mu_L b(t,a) - \lambda\beta A(t-\sigma)T_s(t-\sigma)B(A(t-a))e^{-\mu_L a}, \qquad a < \sigma, \tag{2.6}$$

$$\frac{\partial b}{\partial t} + \frac{\partial b}{\partial a} = -\mu_L b(t,a), \qquad \sigma < a < \tau. \tag{2.7}$$

The explanation for the last term in the right-hand side of (2.6) is as follows. It is the rate at which larvae of age a are removed due to tree removal, and is therefore the rate of tree removal $\lambda\beta A(t-\sigma)T_s(t-\sigma)$, times the larvae density of age a per tree that is thus removed, which will be the birth rate per tree at time $t-a$ times the probability of survival to age a, i.e., $B(A(t-a))e^{-\mu_L a}$.

For adult beetles,

$$\frac{\partial b}{\partial t} + \frac{\partial b}{\partial a} = -\mu_A b(t,a), \qquad a > \tau. \tag{2.8}$$

Differentiating the expression for $A(t)$ in (2.5) gives

$$\frac{dA}{dt} = b(t,\tau) - \mu_A A, \tag{2.9}$$

assuming that $b(t,\infty) = 0$. We shall find $b(t,\tau)$ in terms of the birth rate $b(t,0)$ by integrating (2.6) and (2.7) along characteristics. Since we previously defined $B(A(t))$ as the number of eggs laid per unit time per tree, the birth rate $b(t,0)$ is given by

$$b(t,0) = T_i(t)B(A(t)).$$

Define

$$b_\zeta(a) = b(a+\zeta, a).$$

Then, for $a \le \sigma$,

$$\begin{aligned}\frac{db_\zeta(a)}{da} &= \left[\frac{\partial b}{\partial t} + \frac{\partial b}{\partial a}\right]_{t=a+\zeta}\\ &= -\mu_L b_\zeta(a) - \lambda\beta A(a+\zeta-\sigma)T_s(a+\zeta-\sigma)B(A(\zeta))e^{-\mu_L a}.\end{aligned}$$

Solving this for $b_\zeta(a)$ leads to

(2.10)

$$b(t,a) =$$

$$e^{-\mu_L a}B(A(t-a))\left[T_i(t-a) - \lambda\beta\int_0^a A(\tilde a + t - a - \sigma)T_s(\tilde a + t - a - \sigma)\,d\tilde a\right], \quad a \le \sigma.$$

For ages a between σ and τ, an easier calculation involving (2.7) shows that

$$b(t,a) = b(t-(a-\sigma),\sigma)e^{-\mu_L(a-\sigma)},$$

and $b(t-(a-\sigma),\sigma)$ can be found from (2.10) giving that, for $\sigma \le a \le \tau$,

$$b(t,a) = e^{-\mu_L a}B(A(t-a))\left[T_i(t-a) - \lambda\beta\int_0^\sigma A(\tilde{a}+t-a-\sigma)T_s(\tilde{a}+t-a-\sigma)\,d\tilde{a}\right]. \tag{2.11}$$

This expression looks rather like the corresponding one for $a \le \sigma$ (expression (2.10)), but note that the upper limit on the integral is now σ rather than a. This difference is very important. Putting $a = \tau$ into (2.11) gives an expression for $b(t,\tau)$, which we insert into (2.9), thereby completing the derivation of (2.4).

The expression for $b(t,\tau)$ is those larvae of age τ and represents the rate at which larval beetles become adult beetles (the adult recruitment rate). Expression (2.11) with $a=\tau$ shows that this is basically the birth rate at the earlier time $t-\tau$ (corrected for larval mortality) minus those larvae that would have made it to adulthood but were removed and destroyed with their host tree (the integral term represents accumulated removal of trees that could have hosted the larvae we are discussing, i.e., trees that became infested at times between $t-\tau-\sigma$ and $t-\tau$). An alternative viewpoint is that the term in square brackets in (2.11) (with $a=\tau$) is the "effective" number of host trees at time $t-\tau$ when the eggs are laid since, in this $\sigma<\tau$ regime, those trees that are removed might as well not have been there in the first place.

The derivation of the larval equation (2.3) is by differentiation of the expression for $L(t)$ in (2.5), breaking the integral up into the $a<\sigma$ and $a \in (\sigma,\tau)$ contributions, and using (2.6) and (2.7).

As we are considering the $\sigma<\tau$ situation, in which it is impossible for a larva to complete its development in a tree that gets removed, we should expect that when $\lambda = 1$ (i.e., every tree that becomes infested is later removed), the maturation rate $b(t,\tau)$ should be zero. When (and only when) $\lambda=1$, the number of infested trees at time t is given by

$$T_i(t) = \int_{t-\sigma}^t \beta A(\xi)T_s(\xi)\,d\xi.$$

Therefore, indeed, $b(t,\tau)=0$ when $\lambda=1$, for $\sigma<\tau$.

2.1.1. Initial data and positivity. The initial data for system (2.1), (2.2), (2.3), (2.4) has the form

$$\begin{aligned}
T_s(t) &= T_s^0(t) \ge 0, \qquad t\in[-\tau-\sigma,0],\\
A(t) &= A^0(t) \ge 0, \qquad t\in[-\tau-\sigma,0],\\
T_i(t) &= \beta\int_{-\sigma}^0 A^0(t+\xi)T_s^0(t+\xi)\,d\xi, \qquad t\in[-\tau,0],\\
L(0) &= \int_{-\tau}^0 B(A^0(\xi))e^{\mu_L\xi}T_i(\xi)\,d\xi\\
&\quad -\lambda\beta\int_0^\sigma\int_{-\tau}^{-a} B(A^0(\xi))A^0(a+\xi-\sigma)T_s^0(a+\xi-\sigma)e^{\mu_L\xi}\,d\xi\,da,
\end{aligned} \tag{2.12}$$

where $T_s^0(t)$ and $A^0(t)$ are prescribed continuous functions. The last two conditions in (2.12) are compatibility conditions, by which we mean that the initial data for T_i

and L is not arbitrary but is computed from the prescribed nonnegative initial data for T_s and A. For example, the larvae present at time $t = 0$ are the offspring of the adults at earlier times, and the modeling described thus far in this paper leads to the expression in (2.12) for $L(0)$. The initial data (2.12) including the compatibility conditions is the only ecologically relevant initial data.

PROPOSITION 1. *Let $\sigma < \tau$ and $\lambda \in [0, 1]$, and let the initial data for system* (2.1), (2.2), (2.3)*,* (2.4) *satisfy* (2.12)*. Let the birth function be bounded and satisfy $B(0) = 0$ and $B(A) > 0$ for $A > 0$. Then all variables in* (2.1)–(2.4) *are defined for all $t > 0$ and are bounded and remain nonnegative for $t > 0$.*

Proof. Existence of solutions follows by the method of steps which, since $\sigma < \tau$ here, is carried out successively on the steps $t \in [0, \sigma]$, $t \in [\sigma, 2\sigma]$, etc. It is easily seen that this works on the subsystem consisting of (2.1), (2.2), and (2.4). For example when $t \in [\sigma, 2\sigma]$, all arguments of the delayed variables in (2.4) remain less than σ. So, local existence is assured for $T_s(t)$, $T_i(t)$, and $A(t)$ (global existence will be shown later). It turns out that $L(t)$ has an explicit expression in terms of these variables (see (2.17) below). Next we shall show that all variables remain nonnegative for as long as they are defined.

It is obvious that $T_s(t) \geq 0$ for all $t > 0$. Next we shall show nonnegativity of $A(t)$. This will be achieved by jointly showing nonnegativity of $A(t)$ and the function $f(t)$ defined by

$$f(t) = T_i(t) - \lambda\beta \int_{t-\sigma}^{t} A(\xi)T_s(\xi)\, d\xi. \tag{2.13}$$

Using (2.2) we find that

$$\frac{df}{dt} = \beta(1 - \lambda)A(t)T_s(t). \tag{2.14}$$

Also, (2.4) can be rewritten in a form involving $f(t)$,

$$\frac{dA(t)}{dt} = e^{-\mu_L \tau} B(A(t - \tau))f(t - \tau) - \mu_A A(t). \tag{2.15}$$

As regards initial conditions for $f(t)$, note that when $t \in [-\tau, 0]$, from (2.12),

$$\begin{aligned} f(t) &= \beta \int_{-\sigma}^{0} A(t + \xi)T_s(t + \xi)\, d\xi - \lambda\beta \int_{t-\sigma}^{t} A(\xi)T_s(\xi)\, d\xi \\ &= (1 - \lambda)\beta \int_{-\sigma}^{0} A(t + \xi)T_s(t + \xi)\, d\xi \geq 0, \end{aligned} \tag{2.16}$$

so $f(t)$ is nonnegative initially. The functions $f(t)$ and $A(t)$ can be viewed as satisfying (2.14) and (2.15), considered here as a coupled system in which $T_s(t)$ is some known nonnegative function. The assumptions on $B(\cdot)$ and the nonnegativity of $f(t)$ and $A(t)$ for $t \leq 0$ allow us to deduce, from Theorem 2.1 on page 81 of Smith [16], that $f(t) \geq 0$ and $A(t) \geq 0$ for all $t > 0$.

From (2.2),

$$\begin{aligned} \frac{dT_i(t)}{dt} &= \beta A(t)T_s(t) - \lambda\beta A(t - \sigma)T_s(t - \sigma) \\ &\geq \beta A(t)T_s(t) - \beta A(t - \sigma)T_s(t - \sigma) = \frac{d}{dt} \int_{t-\sigma}^{t} \beta A(\xi)T_s(\xi)\, d\xi. \end{aligned}$$

Thus $T_i(t) - \int_{t-\sigma}^{t} \beta A(\xi) T_s(\xi)\, d\xi$ is an increasing function of t which, by (2.12), is zero when $t = 0$. Hence

$$T_i(t) \geq \int_{t-\sigma}^{t} \beta A(\xi) T_s(\xi)\, d\xi \geq 0$$

for $t > 0$.

Finally, we address positivity of $L(t)$. The solution of (2.3) subject to the compatibility condition in (2.12) is most easily found from (2.5) with (2.10) and (2.11) and turns out to be

$$\begin{aligned} L(t) \quad = \quad & \int_{t-\tau}^{t} B(A(\xi)) e^{-\mu_L (t-\xi)} T_i(\xi)\, d\xi \\ & - \lambda\beta \int_0^{\sigma} \int_{t-\tau}^{t-a} B(A(\xi)) A(a + \xi - \sigma) T_s(a + \xi - \sigma) e^{-\mu_L (t-\xi)}\, d\xi\, da. \end{aligned} \tag{2.17}$$

Indeed, the most general solution of (2.3), which is linear in $L(t)$, is the above expression plus $C \exp(-\mu_L t)$ for some constant C, and the latter term would have to be set to zero to satisfy (2.12). The state space of initial data in (2.12) is forward invariant in this sense.

Using (2.13) and nonnegativity of $f(t)$, it can be shown that

$$L(t) \geq \int_0^{\sigma} \int_{t-\bar{\xi}}^{t} B(A(\xi)) A(\bar{\xi} + \xi - \sigma) T_s(\bar{\xi} + \xi - \sigma) e^{-\mu_L (t-\xi)}\, d\xi\, d\bar{\xi}.$$

Hence $L(t) \geq 0$. Having shown nonnegativity of each solution variable while it is defined, we may now establish global existence. This can be done by establishing a priori bounds. Indeed, nonnegativity of the variables and (2.1) imply that $T_s(t)$ is decreasing, so that $T_s(t)$ is bounded above and below. Since $df/dT_s = -(1 - \lambda)$, it follows that $f(t)$ is also bounded above and below. It then follows from (2.15), using boundedness of $B(\cdot)$, that $A(t)$ is bounded. Then (2.13) implies that $T_i(t)$ is bounded. Then expression (2.17) shows that $L(t)$ is bounded and the proof is complete. □

2.1.2. Infestation eradication. In this section we present conditions on the parameters which guarantee that for initial data satisfying (2.12) in section 2.1.1 the infestation is eradicated.

THEOREM 1. *Let* $\sigma < \tau$ *and* $\lambda \in [0, 1]$*, and let the initial data for system* (2.1), (2.2), (2.3), (2.4) *satisfy* (2.12)*. Let the birth function satisfy* $B(0) = 0$ *and* $0 < B(A) \leq B'(0)A$ *for* $A > 0$*. Assume further that*

$$(1 - \lambda) e^{-\mu_L \tau} B'(0) \left(T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right) < \mu_A. \tag{2.18}$$

Then the solution of the system satisfies $A(t) \to 0$ *and* $L(t) \to 0$ *as* $t \to \infty$*, so that the infestation is eradicated.*

Furthermore, the final number $T_s(\infty)$ *of susceptible trees is not less than*

$$T_s(0) \exp\left(-\beta \left\{ \frac{A^0(0) + (1-\lambda) e^{-\mu_L \tau} B'(0) \left(T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right) \int_{-\tau}^{0} A^0(\xi)\, d\xi}{\mu_A - (1-\lambda) e^{-\mu_L \tau} B'(0) \left(T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right)} \right\} \right). \tag{2.19}$$

Remark 1. Inequality (2.18) essentially arises from the worst imaginable (but not actually attainable) scenario in which the entire forest becomes infested before the infestation is eradicated. If the infestation is successfully eradicated, there will always be some trees that escape infestation, and (2.19) gives a lower bound for this number of escaped trees. However, in the proof of the theorem we are faced with the difficulty that the number $T_s(\infty)$ is not known exactly. We need an upper bound for the function $f(t)$ defined by (2.13) involving only known quantities, and in achieving this we are forced to use $T_s(\infty) \geq 0$ so that we are effectively considering an extreme but unattained situation. The quantity $T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi$ is the total initial number of trees (susceptible and infested), all of which would end up infested in this worst case scenario. But a fraction $1 - \lambda$ of them is *not* removed. The left-hand side of (2.18) is the per capita maturation rate at large times, being the per capita egg laying rate per tree $B'(0)$, multiplied by the number of infested trees at large times corrected for tree removal, multiplied by the survival probability $e^{-\mu_L \tau}$.

Proof of Theorem 1. From (2.1) and nonnegativity of solutions, $T_s(t)$ is a decreasing nonnegative function which therefore approaches a nonnegative limit as $t \to \infty$.

Recall the function $f(t)$ defined by (2.13). From (2.1) and (2.14) note that

$$\frac{df}{dT_s} = -(1 - \lambda).$$

Hence

$$f(t) = -(1 - \lambda) T_s(t) + T_i(0) - \lambda \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi + (1 - \lambda) T_s(0).$$

Since $T_s(t) \geq 0$,

$$\begin{aligned} f(t) &\leq T_i(0) - \lambda \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi + (1 - \lambda) T_s(0) \\ &= (1 - \lambda) \left[T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right] \qquad \text{using (2.12).} \end{aligned}$$

Using the form of (2.4) involving $f(t)$ (i.e., (2.15)) and the above upper bound for $f(t)$, we obtain

(2.20)
$$\begin{aligned} \frac{dA(t)}{dt} &\leq (1 - \lambda) e^{-\mu_L \tau} B(A(t - \tau)) \left(T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right) - \mu_A A(t) \\ &\leq (1 - \lambda) e^{-\mu_L \tau} B'(0) A(t - \tau) \left(T_s(0) + \beta \int_{-\sigma}^{0} A^0(\xi) T_s^0(\xi)\, d\xi \right) - \mu_A A(t). \end{aligned}$$

Since the right-hand side of this is increasing as a function of the delayed variable $A(t - \tau)$, we may say that $A(t)$ is bounded above by the solution of the differential equation obtained by replacing "$\leq$" by "$=$" and satisfying the same initial data as that for A (see, e.g., Theorem 1.1 on page 78 of Smith [16]). By a straightforward and standard argument involving the characteristic equation of the resulting linear delay equation, utilizing Theorem 5.1 on page 92 of Smith [16] to assure ourselves that the dominant eigenvalue is real, we conclude that $A(t) \to 0$ as $t \to \infty$ under the hypothesis (2.18). The proof that $L(t) \to 0$ follows from (2.3) and the theory of asymptotically autonomous systems (see, e.g., Castillo-Chavez and Thieme [2]). Furthermore since the convergence of $A(t)$ to zero will be exponential, we are assured that $\int_0^\infty A(t)\,dt < \infty$, which is necessary for what follows.

Integrating (2.21) from 0 to ∞ and rearranging gives

$$\int_0^\infty A(t)\,dt \le \frac{A^0(0) + (1-\lambda)e^{-\mu_L\tau}B'(0)\left(T_s(0) + \beta\int_{-\sigma}^0 A^0(\xi)T_s^0(\xi)\,d\xi\right)\int_{-\tau}^0 A^0(\xi)\,d\xi}{\mu_A - (1-\lambda)e^{-\mu_L\tau}B'(0)\left(T_s(0) + \beta\int_{-\sigma}^0 A^0(\xi)T_s^0(\xi)\,d\xi\right)}.$$

Inserting this estimate into

$$T_s(\infty) = T_s(0)\exp\left(-\beta\int_0^\infty A(t)\,dt\right),$$

which follows from (2.1), gives the estimate (2.19). The proof is complete. □

2.2. The case $\boldsymbol{\sigma > \tau}$. If $\sigma > \tau$, then the maturation time for a larva is less than the time that elapses between a tree becoming infested and its possible subsequent removal σ time units later. Thus, if an egg is laid on a particular tree just after that tree became infested, then that larva is not at risk of having its host tree removed and burned. If an egg is laid on a tree that became infested some time ago, such that the tree now has less than τ time units to go before the time at which there is a probability λ of its being removed, that larva could still survive to maturation if its host is not actually removed. These considerations lead us to the following different model equations:

$$\frac{dT_s(t)}{dt} = -\beta A(t)T_s(t), \tag{2.21}$$

$$\frac{dT_i(t)}{dt} = \beta A(t)T_s(t) - \lambda\beta A(t-\sigma)T_s(t-\sigma), \tag{2.22}$$

(2.23)
$$\frac{dL(t)}{dt} = T_i(t)B(A(t)) - \mu_L L(t) - \lambda\beta A(t-\sigma)T_s(t-\sigma)\int_0^\tau B(A(t-a))e^{-\mu_L a}\,da$$
$$- e^{-\mu_L\tau}B(A(t-\tau))\left[T_i(t-\tau) - \lambda\beta\int_0^\tau A(\tilde{a}+t-\tau-\sigma)T_s(\tilde{a}+t-\tau-\sigma)\,d\tilde{a}\right],$$

(2.24)
$$\frac{dA(t)}{dt} = e^{-\mu_L\tau}B(A(t-\tau))\left[T_i(t-\tau) - \lambda\beta\int_0^\tau A(\tilde{a}+t-\tau-\sigma)T_s(\tilde{a}+t-\tau-\sigma)\,d\tilde{a}\right]$$
$$- \mu_A A(t).$$

All parameters are again nonnegative with $\lambda \in [0,1]$.

This system looks very similar to the corresponding system for $\sigma < \tau$ described in subsection 2.1, but there is an important difference: the upper limits in the integrals in (2.23) and (2.24) are τ rather than σ. This is because in this case, we need only break down $b(t,a)$ into two cases: (i) when $a < \tau$, $b(t,a)$ is governed by the PDE in (2.6); and (ii) for $a > \tau$, $b(t,a)$ is governed by the PDE in (2.8). The derivation of (2.23) and (2.24) is similar to but even simpler than that of (2.3) and (2.4).

The first goal for this model is again to prove positivity of the solutions corresponding to the initial compatibility conditions (2.12). First, (2.21) gives $T_s(t) = T_s(0)\exp(-\beta\int_0^t A(\theta)\,d\theta) > 0$ for all $t \geq 0$. In order to obtain the positivity of other variables, we introduce a new variable,

$$\begin{aligned} g(t) &= T_i(t) - \lambda\beta\int_0^{\tau} A(\tilde{a}+t-\sigma)T_s(\tilde{a}+t-\sigma)\,d\tilde{a} \\ &= T_i(t) - \lambda\beta\int_{t-\sigma}^{t+\tau-\sigma} A(\xi)T_s(\xi)\,d\xi. \end{aligned} \tag{2.25}$$

Then we have

$$\frac{dg(t)}{dt} = \beta A(t)T_s(t) - \lambda\beta A(t+\tau-\sigma)T_s(t+\tau-\sigma), \tag{2.26}$$

and the adults equation (2.24) can be rewritten as

$$\frac{dA(t)}{dt} = e^{-\mu_L\tau}B(A(t-\tau))g(t-\tau) - \mu_A A(t). \tag{2.27}$$

Since $g(t)$ does not behave as nicely as the function $f(t)$ in subsection 2.1, we have to tackle positivity via another strategy.

Note that, for $t \in [0, \sigma-\tau]$,

$$\frac{dg(t)}{dt} \geq \beta A(t)T_s(t) - \beta A(t-(\sigma-\tau))T_s(t-(\sigma-\tau)) = \frac{d}{dt}\int_{t-(\sigma-\tau)}^{t} \beta A(\xi)T_s(\xi)\,d\xi,$$

implying that $g(t) - \int_{t-(\sigma-\tau)}^{t} \beta A(\xi)T_s(\xi)\,d\xi$ is increasing on $[0, \sigma-\tau]$. Thus, for $t \in [0, \sigma-\tau]$, we have

$$\begin{aligned} &g(t) - \int_{t-(\sigma-\tau)}^{t} \beta A(\xi)T_s(\xi)\,d\xi \\ &\quad\geq g(0) - \int_{-(\sigma-\tau)}^{0} \beta A(\xi)T_s(\xi)\,d\xi \\ &\quad= T_i(0) - \lambda\int_{-\sigma}^{-(\sigma-\tau)} \beta A(\xi)T_s(\xi)\,d\xi - \int_{-(\sigma-\tau)}^{0} \beta A(\xi)T_s(\xi)\,d\xi \\ &\quad\geq T_i(0) - \int_{-\sigma}^{-(\sigma-\tau)} \beta A(\xi)T_s(\xi)\,d\xi - \int_{-(\sigma-\tau)}^{0} \beta A(\xi)T_s(\xi)\,d\xi \\ &\quad= T_i(0) - \int_{-\sigma}^{0} \beta A(\xi)T_s(\xi)\,d\xi = 0. \end{aligned} \tag{2.28}$$

Hence,

$$g(t) \geq \int_{t-(\sigma-\tau)}^{t} \beta A(\xi)T_s(\xi)\,d\xi \quad \text{for} \quad t \in [0, \sigma-\tau]. \tag{2.29}$$

This implies that if $A(0) > 0$ and $T_s(0) > 0$ (recalling that $A^0(\theta)$ and $T^0(\theta)$ are continuous in (2.12)), then $g(0) > 0$. Let $\delta = \min\{\tau, \sigma-\tau\}$; then either both $A(t)$ and $g(t)$ remain positive on $[0, \delta]$ or $A(t)$ will become negative before $g(t)$. In the latter case, there is a $t_0 \in (0,\delta]$ such that $A(t_0)=0$, $A(t)>0$, and $g(t)>0$ for $t<t_0$. It follows from (2.27) that

$$A'(t_0) = e^{-\mu_L \tau} B(A(t_0-\tau))g(t_0-\tau) > 0,$$

which is impossible. This contradiction shows that $A(t)>0$ and $g(t)>0$ for all $t\in[0,\delta]$. Repeating this process, we can obtain the positivity of $A(t)$ and $T_s(t)$ on $[0,2\delta]$ and, by induction, on $[0,n\delta]$ for all positive integers n, giving the positivity of $A(t)$ and $T_s(t)$ for all $t>0$.

Once we have obtained the positivity of $A(t)$ and $T_s(t)$, the positivity of $T_i(t)$ and $L(t)$ can be obtained in precisely the same way as in subsection 2.1. Therefore, we have obtained the following positivity result for (2.21)–(2.24), parallel to Proposition 1 for (2.1)–(2.4).

Proposition 2. *Let $\sigma>\tau$ and $\lambda\in[0,1]$, and let the initial data for system* (2.21)–(2.24) *satisfy* (2.12) *with $A(0)>0$ and $T_s(0)>0$. Let the birth function satisfy $B(0)=0$ and $B(A)>0$ for $A>0$. Then all variables in* (2.21)–(2.24) *remain nonnegative for $t>0$.*

We next seek conditions under which the infestation will be eradicated. Adding (2.21) and (2.26) gives

$$\frac{d}{dt}[g(t)+T_s(t)] = -\lambda\beta A(t-(\sigma-\tau))T_s(t-(\sigma-\tau)) \le 0.$$

Thus,

$$\begin{aligned} g(t) &\le g(t)+T_s(t) \le g(0)+T_s(0)\\ &= T_i(0) - \lambda\beta\int_{-\sigma}^{-(\sigma-\tau)} A(\xi)T_s(\xi)\,d\xi + T_s(0)\\ &= \beta\int_{-\sigma}^{0} A(\xi)T_s(\xi)\,d\xi - \lambda\beta\int_{-\sigma}^{-(\sigma-\tau)} A(\xi)T_s(\xi)\,d\xi + T_s(0)\\ &= (1-\lambda)\beta\int_{-\sigma}^{-(\sigma-\tau)} A(\xi)T_s(\xi)\,d\xi + \beta\int_{-(\sigma-\tau)}^{0} A(\xi)T_s(\xi)\,d\xi + T_s(0). \end{aligned} \tag{2.30}$$

Therefore, in the case $\sigma>\tau$, if (2.18) is replaced by

(2.31)
$$e^{-\mu_L\tau}B'(0)\left[(1-\lambda)\beta\int_{-\sigma}^{-(\sigma-\tau)} A(\xi)T_s(\xi)\,d\xi + \beta\int_{-(\sigma-\tau)}^{0} A(\xi)T_s(\xi)\,d\xi + T_s(0)\right] < \mu_A,$$

then by an argument similar to that in the proof of Theorem 1, we can conclude that the solution of system (2.21)–(2.24) with the initial compatibility conditions (2.12) satisfies $A(t)\to 0$ and $L(t)\to 0$ as $t\to\infty$; that is, the infestation will be eradicated. We have proved the following theorem.

Theorem 2. *Let $\sigma>\tau$ and $\lambda\in[0,1]$, and let the initial data for system* (2.21), (2.22), (2.23), (2.24) *satisfy* (2.12) *with $T_s(0)>0$ and $A(0)>0$. Let the birth function satisfy $B(0)=0$ and $0<B(A)\le B'(0)A$ for $A>0$. Assume further that* (2.31) *holds. Then the solution of the system satisfies $A(t)\to 0$ and $L(t)\to 0$ as $t\to\infty$ so that the infestation is eradicated.*

As in section 2.1, under the assumptions in Theorem 2 and based on the $T_s(t)$ and $A(t)$ equations (i.e., (2.21) and (2.27)) and the estimate (2.30) for the function

$g(t)$, we can also establish a lower bound for $T_s(\infty)$, the final number of susceptible trees. Indeed, if we denote by M the right-hand side of (2.30), then by an argument similar to that for obtaining the estimate (2.19), we can derive the following lower bound for $T_s(\infty)$:

$$T_s(\infty) \geq T_s(0) \exp \left(-\beta \left\{ \frac{A^0(0) + e^{-\mu_L \tau} B'(0) M \displaystyle\int_{-\tau}^{0} A^0(\xi)\, d\xi}{\mu_A - e^{-\mu_L \tau} B'(0) M} \right\} \right). \tag{2.32}$$

2.3. The case $\boldsymbol{\lambda = 1}$. In this subsection we discuss the situation when $\lambda = 1$, which means that every tree that becomes infested is removed σ time units later. We shall deal with both of the cases $\sigma < \tau$ and $\sigma > \tau$. In either case, the expression

$$T_i(t) = \int_{t-\sigma}^{t} \beta A(\xi) T_s(\xi)\, d\xi \tag{2.33}$$

is available to us, though the implications of this fact for the cases $\sigma < \tau$ and $\sigma > \tau$ are different. Expression (2.33) gives us the total number of infested trees at time t, which, when $\lambda = 1$, is simply the accumulation of all new infestations over the previous σ units of time (the corresponding expression for $T_i(t)$ when $\lambda \neq 1$ appears later (expression (2.39)) and in this case includes trees that became infested before time $t - \sigma$ but escaped detection).

In the case $\sigma < \tau$ the use of expression (2.33) in (2.4) yields $A'(t) = -\mu_A A(t)$ so that $A(t) \to 0$, and the infestation is eradicated. This is hardly surprising since if every infested tree is removed σ time units after the time of infestation, and $\sigma < \tau$, then no larva is being given enough time to mature.

If $\sigma > \tau$, the equation for $A(t)$ is (2.24), and the use of (2.33) leads to

$$\frac{dA(t)}{dt} = e^{-\mu_L \tau} B(A(t-\tau)) \int_{t-\sigma}^{t-\tau} \beta A(\xi) T_s(\xi)\, d\xi - \mu_A A(t). \tag{2.34}$$

We will use this equation to show that the infestation is always eradicated when $\lambda = 1$, regardless of the values of σ and τ. The truth of this result even in the $\sigma > \tau$ case is a little surprising, since this case offers the possibility of some larvae maturing before their host tree is destroyed. However, numerical simulations do show that even though eradication is still the final outcome, there may be a long transient in which the infestation grows worse for a while before dying out.

THEOREM 3. *Let $\lambda = 1$, and consider the system consisting of either* (2.1)–(2.4) *or* (2.21)–(2.24)*, with initial data satisfying* (2.12) *with $T_s(0) > 0$ and $A(0) > 0$. Let the birth function satisfy $B(0) = 0$ and $0 < B(A) \leq B'(0)A$ for $A > 0$. Then the infestation is eradicated, that is, $(T_i(t), L(t), A(t)) \to (0, 0, 0)$ as $t \to \infty$.*

Proof. It is sufficient to show that $A(t) \to 0$. Then $L(t) \to 0$ follows trivially from (2.3) or (2.23) as appropriate, and $T_i(t) \to 0$ follows from (2.33). We have already commented above that if $\sigma < \tau$, then $A(t) \to 0$ trivially; this can be extended to $\sigma = \tau$. So it remains to consider the case $\sigma > \tau$, and it is here that we shall make use of (2.34), which has to be coupled to (2.21). The latter equation, together with nonnegativity of solutions, implies that $T_s(t)$ must decay monotonically to some nonnegative limit as $t \to \infty$. If $T_s(t) \to 0$, then the asymptotic limit of (2.34) is just $A'(t) = -\mu_A A(t)$, and so $A(t) \to 0$. So it remains to consider the case that

$\lim_{t\to\infty} T_s(t) > 0$. If this is so, then from (2.21) it follows that

$$\int_0^\infty A(t)\,dt < \infty. \tag{2.35}$$

If we can show that, additionally,

$$\int_0^\infty |A'(t)|\,dt < \infty, \tag{2.36}$$

then a result from integration theory assures us that $\lim_{t\to\infty} A(t) = 0$. The integral in (2.34) can be expressed in terms of $T_s(t-\tau)$ and $T_s(t-\sigma)$ using (2.21), and the monotonicity properties of $T_s(t)$ therefore assure us of the existence of a finite C such that

$$\left|\int_{t-\sigma}^{t-\tau} \beta A(\xi) T_s(\xi)\,d\xi\right| \le C \quad \text{for all } t \ge 0.$$

Therefore, integration of (2.34) and using the estimate $0 < B(A) \le B'(0)A$ lead to

$$\int_0^\infty |A'(t)|\,dt \le Ce^{-\mu_L\tau}B'(0)\int_{-\tau}^0 A^0(t)\,dt + (Ce^{-\mu_L\tau}B'(0) + \mu_A)\int_0^\infty A(t)\,dt.$$

Hence $\int_0^\infty |A'(t)|\,dt < \infty$. The proof is complete. □

2.4. Approximation of $T_s(\infty)$. In subsections 2.1 and 2.2 we have seen that, under the eradication condition (2.18) for system (2.1)–(2.4), or condition (2.31) for system (2.21)–(2.24), the infestation is eradicated and the beetle does not affect the entire forest, since $A(t) \to 0$ and $T_s(t) \to T_s(\infty) =: T_s^* > 0$. Lower bounds for T_s^* are provided by inequalities (2.19) and (2.32) for models (2.1)–(2.4) and (2.21)–(2.24), respectively. In this subsection we provide an approach for obtaining an approximation for T_s^*. We present our analysis only for (2.21)–(2.24); the analysis for (2.1)–(2.4) is similar.

It is easily seen using (2.26) that the function

$$t \to g(t) - \int_{t-(\sigma-\tau)}^{t} \beta A(\xi) T_s(\xi)\,d\xi$$

is increasing for all $t \ge 0$. But (2.30) implies that this function is bounded from above. Therefore, it has a limit as $t \to \infty$, and thus $g(t)$ also has a limit as $t \to \infty$, since we consider the situation in which $A(t) \to 0$. It follows from (2.25) that $T_i^* := \lim_{t\to\infty} T_i(t)$ also exists and $T_i^* = \lim_{t\to\infty} g(t)$. Now, when t is sufficiently large, $A(t)$ becomes very small, and hence we may study the linearized approximation of (2.27) for small $A(t)$, and also replace $g(t-\tau)$ by its (as yet undetermined) limiting value T_i^* as $t \to \infty$ to obtain

$$\frac{dA(t)}{dt} = e^{-\mu_L\tau}B'(0)T_i^* A(t-\tau) - \mu_A A(t). \tag{2.37}$$

Letting p be the transform variable, the Laplace transform $\bar{A}(p)$ of $A(t)$ is

$$\bar{A}(p) = \frac{A^0(0) + e^{-\mu_L\tau}T_i^* B'(0)e^{-p\tau}\displaystyle\int_{-\tau}^0 A^0(\xi)e^{-p\xi}\,d\xi}{p - e^{-\mu_L\tau}T_i^* B'(0)e^{-p\tau} + \mu_A}.$$

The structure of (2.37) assures us that the dominant eigenvalue of its characteristic equation is real (see Smith [16]). Furthermore, this dominant eigenvalue is negative, since we consider the situation when $A(t) \to 0$, so let it be $-p^*(T_i^*)$, to emphasize the dependence on T_i^*, with $p^*(T_i^*) > 0$. This dominant eigenvalue is also the singularity of $\bar{A}(p)$ of greatest real part. By the inversion formula for Laplace transforms, $A(t)$ can be expressed as a contour integral, which by Cauchy's residue formula can be evaluated as a sum of residues of the poles of $\bar{A}(p)$. We shall include in this calculation only the pole of greatest real part, which is located at $p = -p^*(T_i^*)$, to give

$$\begin{aligned} A(t) &\approx \operatorname{res}\left(\bar{A}(p)e^{pt},\ p = -p^*(T_i^*)\right) \\ &= \frac{e^{-p^*(T_i^*)\,t}\left[A^0(0) + e^{-\mu_L\tau}T_i^*B'(0)e^{p^*(T_i^*)\tau}\displaystyle\int_{-\tau}^{0} A^0(\xi)e^{p^*(T_i^*)\xi}\,d\xi\right]}{1 + \tau e^{-\mu_L\tau}T_i^*B'(0)e^{p^*(T_i^*)\tau}}. \end{aligned}$$

Now, from (2.21),

$$T_s^* = T_s(0)\exp\left(-\beta\int_0^\infty A(t)\,dt\right),$$

giving

$$T_s^* \approx T_s(0)\exp\left(-\frac{\beta\left[A^0(0) + e^{-\mu_L\tau}T_i^*B'(0)e^{p^*(T_i^*)\tau}\displaystyle\int_{-\tau}^{0} A^0(\xi)e^{p^*(T_i^*)\xi}\,d\xi\right]}{p^*(T_i^*)(1 + \tau e^{-\mu_L\tau}T_i^*B'(0)e^{p^*(T_i^*)\tau})}\right). \tag{2.38}$$

The solution of (2.22), subject to the initial value formula for $T_i(0)$ from (2.12), is

$$T_i(t) = \int_{t-\sigma}^{t} \beta A(\xi)T_s(\xi)\,d\xi + (1-\lambda)\int_{-\sigma}^{t-\sigma} \beta A(\xi)T_s(\xi)\,d\xi, \tag{2.39}$$

which states that the number of infested trees at time t is the accumulated total of newly infested trees since time $t-\sigma$, plus the accumulated total over all times prior to $t-\sigma$ that escaped being cut down. Since we consider the case when $A(t) \to 0$, we can use (2.39) to find T_i^* in terms of T_s^* as follows:

$$\begin{aligned} T_i^* &= (1-\lambda)\int_{-\sigma}^{\infty} \beta A(\xi)T_s(\xi)\,d\xi \\ &= (1-\lambda)\left[\int_{-\sigma}^{0} \beta A^0(\xi)T_s^0(\xi)\,d\xi - \int_0^\infty \frac{dT_s(\xi)}{d\xi}\,d\xi\right], \end{aligned}$$

giving

$$T_i^* = (1-\lambda)\left[\int_{-\sigma}^{0} \beta A^0(\xi)T_s^0(\xi)\,d\xi + T_s(0) - T_s^*\right]. \tag{2.40}$$

Recall that $p^*(T_i^*) > 0$ has been defined such that $p = -p^*(T_i^*)$ is the singularity of $\bar{A}(p)$ of greatest real part. Therefore, $p^*(T_i^*)$ satisfies

$$-p^*(T_i^*) - e^{-\mu_L\tau}T_i^*B'(0)e^{p^*(T_i^*)\tau} + \mu_A = 0. \tag{2.41}$$

Equation (2.41) defines $p^*(T_i^*)$ as a function of T_i^*, and then (2.38) and (2.40) are solved simultaneously for T_s^* and T_i^*.

3. Numerical simulations. We have carried out some numerical simulations of our model for both the $\sigma < \tau$ and $\sigma > \tau$ situations. Fortunately, the alternative formulations of the two systems in terms of the functions $f(t)$ and $g(t)$ make the systems easily amenable to simulation using standard software tools for delay equations including those found within MATLAB.

For the $\sigma < \tau$ situation described in subsection 2.1, we simulate the system of three equations consisting of (2.1), (2.14), and (2.15). Note that one of the delays, σ, is not explicitly present in this system. However, σ plays a role through the formula (2.16), which is used to compute the initial data for the variable f from that for A and T_s. We measure time in months, so $\tau = 12$, corresponding to the maturation time of one year. We chose the birth rate function $B(A)$ to have the form $B(A) = b_m A e^{-aA}$, a common choice in the mathematical study of insect infestations, because it reflects the decreasing per capita egg laying rate due to crowding. In this formula the quantity b_m is the egg laying rate per female adult beetle per tree at lower densities without the effects of crowding. We assumed that a single female lays on average about 60 eggs during her life (though estimates vary considerably). She is active only in summer, but we average over a year to arrive at a figure of 5 eggs per female per month. Good data on the survival probability for the larvae are not available, but by being deep inside the trees the larvae are well protected from predators, so if we assume a survival probability of about 0.8, this leads to $\mu_L = 0.0186$. Values for other parameters are shown in the figures. Figures 1 and 2 illustrate two situations in which $\sigma < \tau$. In Figure 1 the infestation is eradicated, whereas in Figure 2 (in which we used a lower number for the probability λ of an infested tree being detected and removed) the number of susceptible trees tends to zero and the entire forest ends up infested, with the number of adult beetles tending to a constant. Other simulations showed a similar outcome but with the number of adults evolving to a periodic cycle. We also noted from our numerical experiments that (2.18) does not appear to be the best possible condition for eradication (i.e., it is sufficient but not necessary).

For the $\sigma > \tau$ situation of subsection 2.2, the appropriate system to simulate is that consisting of (2.21), (2.26), and (2.27). This system involves both delays σ and τ explicitly, with initial data for g calculated from that for A and T_s using (2.25) and the initial data formula for T_i in (2.12). Figure 3 shows a simulation for the $\sigma > \tau$ situation in which the time between tree infestation and tree removal is a little longer than the time taken for a larva to complete its development and mature as an adult beetle. One expects that it will be more difficult to achieve eradication. The simulation shows that it is still possible to do so, but only by detecting and removing 95% of infested trees. Figure 4 shows a situation with $\lambda = 1$, i.e., every infested tree is later destroyed, but with σ chosen to be considerably larger than τ, so that many larvae can complete their maturation and emerge as adults even though their host tree is doomed. With $\lambda = 1$, eradication is the final outcome (Theorem 3) even though $\sigma > \tau$, but the simulation shows a large and destructive transient, with very few susceptible trees remaining after the infestation has died out.

4. Discussion. We have derived a mathematical model to describe the infestation of wood boring beetles with the Asian longhorned beetle (ALB) as a prototype. Two delays are needed for the model. One of these delays, denoted by σ, is the average duration between the time a tree becomes infested and the time the infestation in the tree is detected and the tree removed. The second delay is the maturation delay τ for the beetle. Since the purpose is to examine whether or not the cut-burn

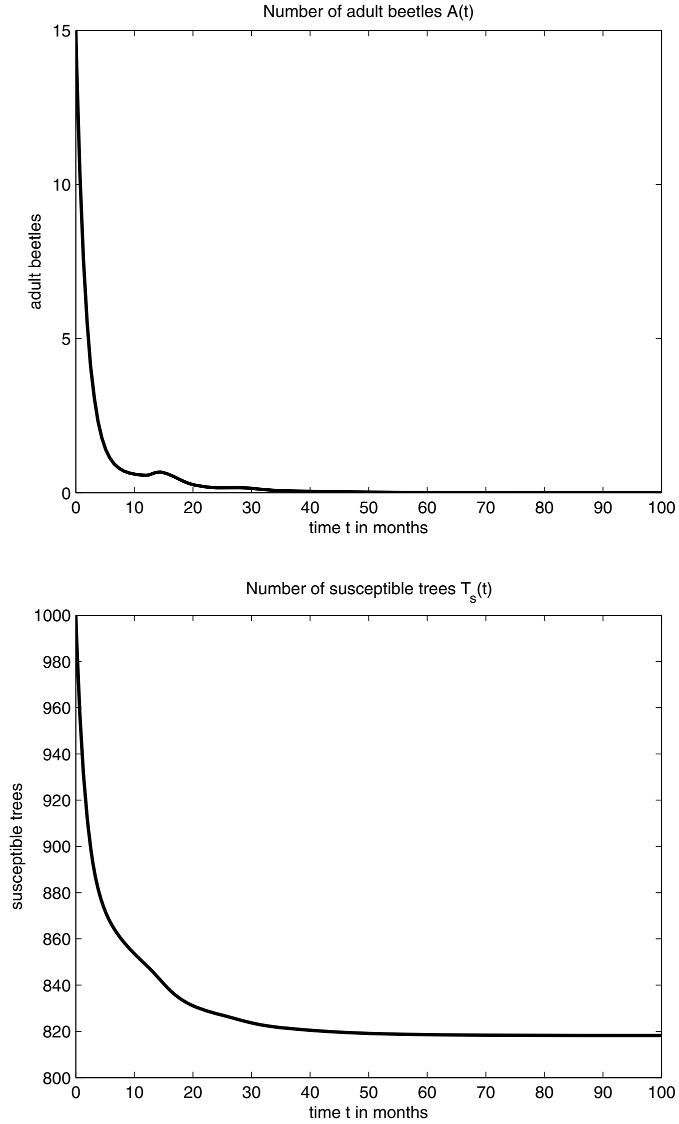

FIG. 1. *The* $\sigma < \tau$ *case: a simulation of* (2.1), (2.14), *and* (2.15). *Parameter values were* $\tau = 12$, $\lambda = 0.9$, $\beta = 0.005$, $\sigma = 3$, $b_m = 0.005$, $a = 0.1$, $\mu_L = 0.0186$, $\mu_A = 0.55$. *For these values,* (2.18) *is satisfied (by a fairly narrow margin) and the infestation is eradicated.*

(or removal) control strategy is successful, we have also incorporated a removal rate $\lambda \in [0, 1]$ into the model. The parameter λ accounts for the possibility that some infested trees might escape detection, which is very likely indeed if ALB activity were to reach wilderness areas, and also permits us to explore the possibility that infestation eradication might be possible without necessarily cutting down and burning every single infested tree. The model assumes different forms depending on whether $\sigma < \tau$ or $\sigma > \tau$, given by (2.1)–(2.4) and (2.21)–(2.24), respectively.

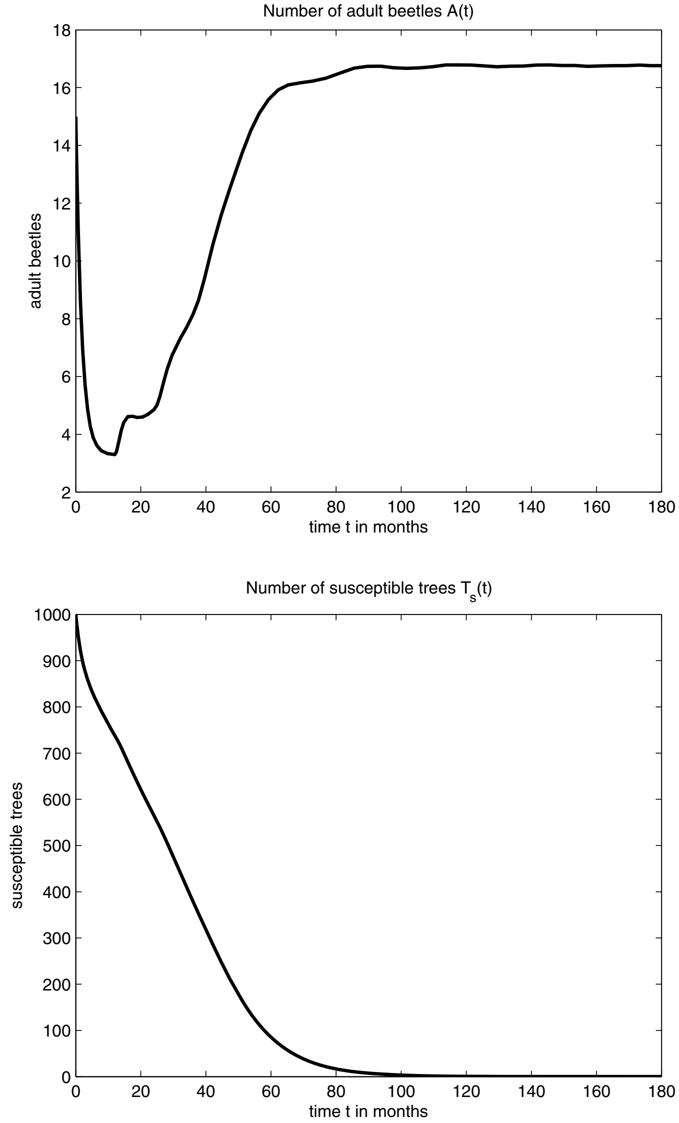

FIG. 2. *The $\sigma < \tau$ case: a simulation of* (2.1), (2.14), *and* (2.15). *Parameter values were $\tau = 12$, $\lambda = 0.4$, $\beta = 0.005$, $\sigma = 3$, $b_m = 0.005$, $a = 0.1$, $\mu_L = 0.0186$, $\mu_A = 0.55$. For these values the infestation takes over the whole forest and the number of adult beetles evolves to a constant.*

By applying the comparison method for delay differential equations, we have obtained some conditions for each of the two model systems that are sufficient for infestation eradication. We have also established lower bounds and even approximations for the remaining number of susceptible trees after eradication of the infestation, and this number has economic significance. We have also conducted some numerical simulations which confirm all the theoretical results.

If $\sigma < \tau$, then a beetle larva cannot complete its maturation in a host tree destined for detection and removal. The eradication condition for this case is (2.18), from which we conclude that if the proportion λ of attacked trees that are detected and removed is sufficiently close to 1, then the control strategy succeeds. Solving (2.18) for λ gives an explicit requirement on λ. In the case $\sigma > \tau$, detection of infestation in a tree is not happening quickly enough and it may be possible for a beetle larva to complete its maturation even in a tree destined for removal, especially if the larva hatched from an egg that was laid soon after the tree became infested. The corresponding model (2.21)–(2.24) is more difficult to analyze, but nevertheless a condition (namely, (2.31)) for eradication of the infestation can be obtained. However, it is more difficult to satisfy the condition. Indeed, if

$$e^{-\mu_L \tau} B'(0) \left[\beta \int_{-(\sigma-\tau)}^{0} A(\xi) T_s(\xi)\, d\xi + T_s(0) \right] < \mu_A, \tag{4.1}$$

then (2.31) will hold if $\lambda \in [0,1]$ is chosen sufficiently close to 1. But if (4.1) does not hold, that is,

$$e^{-\mu_L \tau} B'(0) \left[\beta \int_{-(\sigma-\tau)}^{0} A(\xi) T_s(\xi)\, d\xi + T_s(0) \right] \geq \mu_A, \tag{4.2}$$

then condition (2.31) is never satisfied regardless of the value of $\lambda \in [0,1]$, although we do know from Theorem 3 that the infestation is nevertheless eradicated if $\lambda = 1$. To understand the difference between conditions (2.18) and (2.31), note that condition (2.31) relates to the $\sigma > \tau$ situation, in which the timescale for infestation detection in a tree is longer than the maturation time for the beetle. Naturally, we should expect that infestation eradication should be more difficult in the $\sigma > \tau$ situation than in the $\sigma < \tau$ situation in which, if a tree is found to be infested, then its destruction happens sufficiently quickly so that a larva cannot mature in it. In the $\sigma > \tau$ situation it will be possible for some larvae to mature even in a host tree destined for removal.

Note that σ and λ are the only parameters in the model that are within our control. For example, σ could be decreased by the use of high technology acoustic detectors that can detect larval activity in a tree, and λ, which effectively measures the likelihood of ALB activity being detected in a tree, can be raised by increasing public awareness of the telltale signs of tree infestation. Another related beetle species in Japan has been controlled by the use of fungal bands which contain cultures of insect pathogenic fungi, and there have been trials of the technique on the ALB in Anhui, China (see Hajek et al. [7]). The fungal bands are placed at an approximate height of 2–2.5 m around the trees and infect the adult beetles, which can then transfer the infection during mating, leading to a reduced number of viable eggs. The effectiveness of the technique can be augmented by the use of a chemical attractant. On the use of entomopathogenic nematodes, see also Qin et al. [14].

None of the abovementioned measures is likely to be of much value if ALB were to take hold in wilderness areas. This, of course, highlights the importance of ensuring that the ALB does not become established in North America. Some studies of Keena [8] on the dependence of ALB activity on temperature suggests that the lower 48 states should be able to support beetle survival and reproduction. The numerical simulation work reported in this paper highlights the importance of rapid detection and removal of as many infested trees as possible, and moreover, the simulations demonstrate that if the detection of infestation timescale σ is significantly larger than

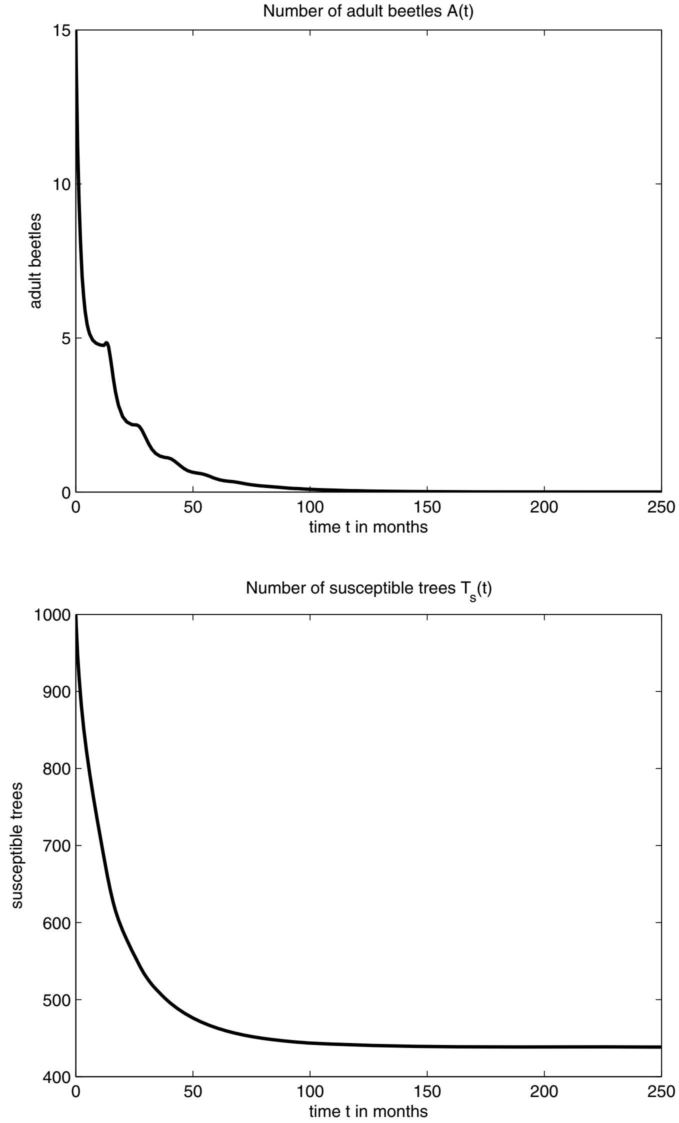

FIG. 3. *The $\sigma > \tau$ case: a simulation of* (2.21), (2.26), *and* (2.27). *Parameter values were $\tau = 12$, $\lambda = 0.95$, $\beta = 0.005$, $\sigma = 14$, $b_m = 0.005$, $a = 0.1$, $\mu_L = 0.0186$, $\mu_A = 0.55$. In this situation it is possible for a larva to complete its maturation in a tree destined for removal. Nevertheless it is possible to achieve eradication, but only with a large proportion of infested trees being detected and removed.*

the beetle maturation delay τ, then even though the infestation can be eradicated, the large transients will result in decimation of the forest.

We point out that although the eradication conditions (2.18) and (2.31) are obtained under the hypothesis $B(A) \leq B'(0)A$ for $A > 0$, this assumption is not crucial. Indeed, if $B(A)$ is continuously differentiable and $B(0) = 0$ (which always holds for all birth functions), then by the mean value theorem one can write

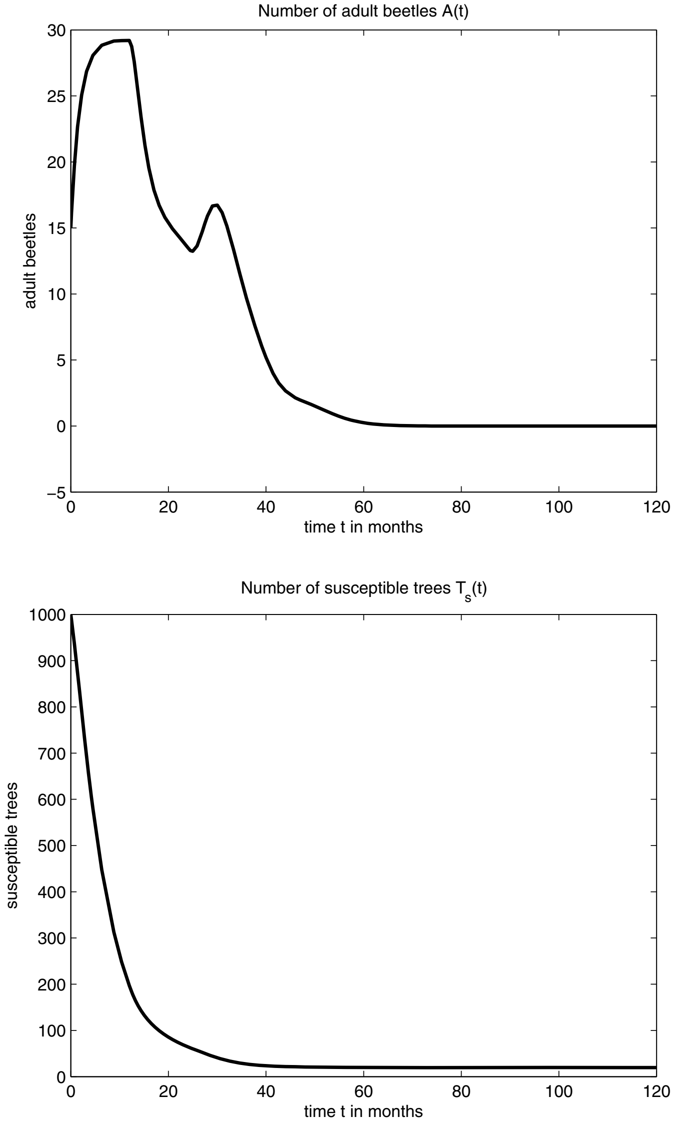

Fig. 4. *The $\sigma > \tau$ case: a simulation of* (2.21), (2.26), *and* (2.27). *Parameter values were $\tau = 12$, $\lambda = 1$, $\beta = 0.005$, $\sigma = 28$, $b_m = 0.005$, $a = 0.1$, $\mu_L = 0.0186$, $\mu_A = 0.55$. In this situation every tree that becomes infested is later destroyed, but with σ considerably larger than τ, many larvae can mature and escape as adults before their host tree is destroyed. Nevertheless the final outcome is still eradication, though only after a very destructive transient in which the infestation gets worse. Note that the final number of susceptible trees is very low, indicating severe destruction of the forest during the course of the infestation.*

$B(A) = B'(\theta)A \le B_m A$, where $B_m = \sup_{\theta \ge 0} B'(\theta)$. Therefore, the results in Theorems 1 and 2 remain true, with $B'(0)$ being replaced by B_m. Obviously the corresponding eradication conditions become more demanding on λ.

Spatial spread is another important issue that we have not considered here in this initial work. It is known that the adults of the ALB can fly, but only short distances between neighboring trees. Of course, the larvae do not disperse at all. The invasion of the ALB from Asia to North America is believed to have been via the use of wooden packing crates and wood products which may contain individuals in premature stages (eggs, larvae, or pupae). This no doubt accounts for the long range transport between continents and between different districts. Short range dispersal of adult beetles could possibly be modeled, as a first approximation, by the incorporation of Fickian diffusion. However, the actual dispersal behavior of the ALB is not so straightforward, and some experimental work reported in Bancroft and Smith [1] suggests a dependence on beetle density, weather conditions, beetle size and tree size, and that a thorough knowledge of dispersal behavior will be beneficial to eradication efforts. Release of the ALB is prohibited in the US, so there is little experimental work documented, but there have been detailed mark and release studies in Gansu Province, China (Smith et al. [17]) at a site chosen for its landscape similarities to those of urban infestations in the US. These studies suggest that dispersal depends on the spacing of suitable host trees, the age of the beetles, availability of host material, and crowding on suitable trees.

A great deal of mathematical work has been carried out on the dispersal behavior of beetles and insect species more generally (see Shigesada and Kawasaki [15], and Kot, Lewis, and van den Driessche [9]), but not specifically on the ALB. In fact, in our future work on the ALB we are considering the use of integrodifference equations that are continuous in space but discrete in time, since the ALB seems to follow a predictable pattern in nonnative habitats of having one generation per year. Discrete time models have been commonly used in the past to model beetle populations. The flour beetle *tribolium* has been particularly well studied due to its high rates of reproduction, short life cycle (4 to 6 weeks from egg to adult), ease of culture, and strong cannibalistic tendencies, which make the beetle suitable for laboratory studies (see Costantino and Desharnais [3]). These characteristics do imply that *tribolium* is very different from the ALB. Cannibalism in particular can affect all pre-adult stages of *tribolium*, including even some callow (not fully sclerotized) adults (see Mertz [10]).

Costantino et al. [4] compared the results of laboratory studies with the predictions of a discrete time model incorporating, unlike the present study, two pre-adult compartments. In the laboratory studies, adult mortality could be manipulated by removing or adding adults, and recruitment by removing or adding younger adults. Under conditions of high adult mortality, quasi-periodic cycles and chaos were observed in the laboratory populations and in the model predictions.

It seems unlikely that a continuous time model such as the one we present here could work satisfactorily for beetle species which have complex dynamics. Discrete time models might in principle be able to address the issue of complex dynamics, but these models have their limitations too. For example, western pine beetle populations can be asynchronous and indistinguishably overlapped because of differential brood development rates in different trees (see DeMars et al. [5]).

When it comes to modeling the eradication of infestation by removal strategy, we may have to consider diffusion of adults which depends on the removal strength (i.e., the parameter $\lambda \in [0,1]$), since when an infected tree is cut, the adult beetles in that tree will all fly to the neighboring trees. In other words, the removal of infested trees will enhance the diffusion of the adults. This will make modeling a more interesting yet more challenging job. We leave such problems for future investigation.

Acknowledgments. We are grateful to the referees for their very useful comments and suggestions.

THE FREDERIKS EFFECT AND RELATED PHENOMENA IN FERRONEMATIC MATERIALS*

V. I. ZADOROZHNII†, T. J. SLUCKIN‡, V. YU. RESHETNYAK†, AND K. S. THOMAS§

Abstract. Using continuum and statistical mechanical theories, we study the switching properties of a ferronematic in a nematic liquid crystal cell subject to homeotropic boundary conditions at the cell and particle walls. An external magnetic field normal to the cell plane is also imposed. At low fields we find thresholdless switching of the nematic director, consistent with experimental data. At higher fields, there are three regimes, depending on the strength of the anchoring interaction between the director and the ferroparticle orientation. For low anchoring strengths, there is an inverse Frederiks effect, and the nematic reorientation reduces and then disappears continuously at a critical magnetic field. At intermediate fields, the degree of reorientation reduces at high fields but remains finite. For high fields, however, the director switching saturates. The dimensionless temperature scale in the problem involves the temperature, the mean nematic elastic constant, the colloidal density, and the cell dimension. If this quantity is sufficiently low, then high magnetic fields can cause magnetic segregation. The segregation order parameter is coupled to the director distortion, and this can change the inverse Frederiks transition into a first order transition, leading to bistability in an intermediate field regime. These features are perturbed but not changed structurally by the effect of a small bias magnetic field (< 10 Oe) normal to the unperturbed director. Subject to suitable choice of parameters, the theory is also quantitatively consistent with the results of the classic experiment of Chen and Amer in 1983.

Key words. liquid crystals, ferronematics, colloids

1. Introduction.

In 1970 Brochard and de Gennes [1] suggested on theoretical grounds that it might be possible to construct magnetic colloids based on a liquid crystal matrix. As a result of the anchoring at the surface of the colloidal particles, magnetic and nematic order in these materials would be coupled. The weak interaction between magnetic fields and nematic order, already exploited by the early liquid crystal pioneers such as Charles Mauguin [2], would then be dramatically increased.

The giant magnetic-nematic coupling might then be fruitfully used in devices controlled by easily accessible magnetic fields (< 10 Oe). These systems, including as they do elements of both ferromagnetism and nematic liquid crystalline behavior, have come to be known as *ferronematics* (FNs). The key relevant properties of a nematic crystal doped with single-domain ferromagnetic particles are (a) the intrinsic high magnetic susceptibility and (b) the uniform molecular reorientation of the entire liquid crystal (LC) matrix, or macroscopic collective behavior [1], in a varying magnetic field.

It was not until 1983 that Chen and Amer [3] were first able to construct a model experimental system. One feature complicating the interpretation of experiments is

the fact that the ferroparticles can coagulate irreversibly. Indeed, subsequent work has continually been hindered for a long time by difficulties in the manufacture of stable reproducible magnetic liquid crystalline colloids.

In the last two decades interest in these materials has grown. Not only do these systems pose interesting physical problems, but also they promise to provide an optical device technology based on magnetic switching [4, 5, 6, 7, 8]. In particular, Buluy et al. [9] have recently synthesized an FN which is stable against colloidal aggregation. This system consists of magnetite particles (Fe_3O_4) coated with oxyethyl-propylene glycol and suspended in 5CB.

The initial continuum theory [1] has been generalized by Burylov and Raikher [10, 11] to the case of a finite anchoring energy of the nematic at the ferroparticle surface. This provided an explanation for the absence of coalignment of the nematic director $\hat{\mathbf{n}}$ and the averaged local magnetization $\mathbf{M}$ in the FN, as had been found experimentally [12]. Experiments, among them one on 8CB-based FN with magnetite particles of nearly spherical shape [6], have subsequently confirmed the generalized theory. The loss of coalignment has been labeled *detachment* in the literature. In this paper we determine some more precise conditions for detachment.

One other important feature which the theory must include is the possibility of *magnetic segregation* [1, 13]. This involves the magnetic colloidal particles migrating toward regions in which the ferronematic coupling energy is minimized. Typically this occurs in the center of the sample, where the nematic director is most free to rotate toward the magnetically favored direction.

However, this tendency to segregate is opposed by entropic forces favoring a uniform colloidal concentration. The balance is subtle and is controlled by the dimensionless temperature, which is typically of order unity. Previous calculations [14] have suggested that this effect can lead to hysteretic effects as a function of magnetic field. The hysteretic effects have been interpreted as the signature of a decoupling of the nematic director and the ferroparticle orientation. In this paper we give a full account of the physics of the ordering process which occurs in a confined ferronematic system within the usual Frederiks geometry.

The plan of the paper is as follows. In section 2 we describe the theoretical model. In section 3 we give an analysis of the basic aspects of the model, specifically confining our interest to the case in which magnetic segregation is absent. Most of this work is analytical, but we conclude this section by presenting the results of some computational solutions of the equations. We also compare the numerical solutions and the analytical approximations; the analysis, even where only approximate, yields surprisingly accurate precisions. In section 4 we extend the model to include the so-called bias field. This is the extra in-plane magnetic field required to stabilize experimentally the systems we are discussing. In section 5 we add a discussion of magnetic segregation. Both bias field and magnetic segregation are important experimentally but might be regarded as complications to the basic underlying mathematical model. In section 6 we give a brief discussion linking our work to some of the available experiments. Finally, in section 7 we draw some conclusions and place our work in a larger context. A brief preliminary report of our work has been published elsewhere [15].

2. Model.

The basic geometry of the problem is shown in Figure 1. The ferroparticles are needle-like monodomain ferrite grains of length L and diameter $d \sim L/7$–$L/3$; they are significantly larger than the nematic molecule size. We consider a cell of thickness D and suppose strong homeotropic nematic anchoring at the cell walls at $z = 0$ and $z = D$.

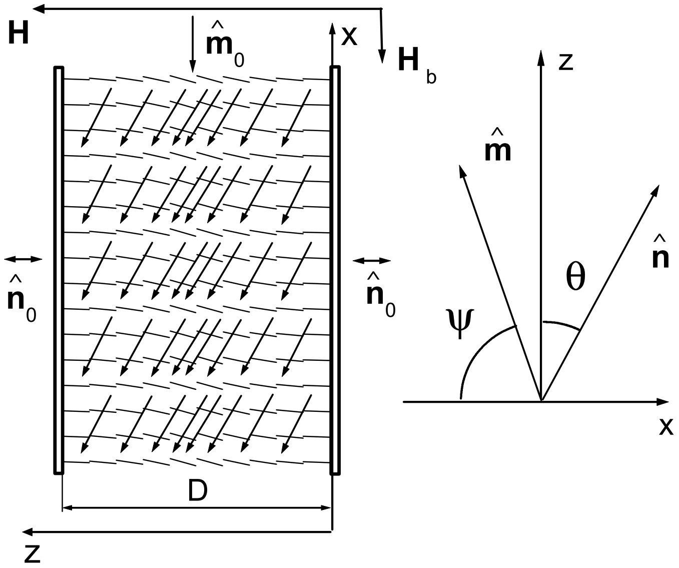

FIG. 1. *Schematic of the FN cell. The total magnetic field is given by* $\mathbf{H}_s = [H_b, 0, H]$, *with* H_b *the bias field and* H *the imposed field. In the left-hand diagram, the magnetic director is marked with an arrow, while the nematic director is marked by a line. The meaning of the angles* ψ, *signifying the deviation of the magnetic director from its original orientation, and* θ, *signifying the nematic deviation, are shown in the right-hand diagram.*

Burylov and Raikher [10, 11] have derived an effective soft homeotropic anchoring energy W_p per colloidal particle due to the nematic-ferroparticle surface interaction. We do not discuss the microscopic derivation of the magnitude of this interaction here but simply note that in our discussion it is a measurable parameter which enters the theory. The existence of this anchoring encourages, but does not oblige, the ferroparticles to orient perpendicular to the (averaged) nematic director. This term changes the physics of the classical nematic liquid crystal.

In addition, the cell may be initially subject to a small *bias* magnetic field $\mathbf{H}_b$ parallel to the cell substrates. In this initial state ferroparticles are homogeneously distributed over the cell volume and their magnetic moments are perpendicular to the unperturbed director $\hat{\mathbf{n}}_0$. $\hat{\mathbf{m}}_0$ is the unit vector in the direction of the sample magnetization at $\mathbf{H} = 0$. The sample is uniform in the x-y direction.

The physical states are defined by a nematic director $\hat{\mathbf{n}}(\mathbf{r})$, a local normalized magnetization $\hat{\mathbf{m}}(\mathbf{r})$, and a local colloidal particle density $\rho(\mathbf{r}) = \frac{f(\mathbf{r})}{\nu}$, with f the local colloidal packing fraction and ν the colloidal particle volume.

The FN equilibrium state at given magnetic field $\mathbf{H}_s = \mathbf{H} + \mathbf{H}_b$ can be determined by minimizing the full free energy functional [10]

$$\begin{aligned}\mathcal{F} = \int_V \Bigg\{ &\frac{1}{2}\left[K_1(\nabla\cdot\hat{\mathbf{n}})^2 + K_2(\hat{\mathbf{n}}\cdot\nabla\times\hat{\mathbf{n}})^2\right.\\ &\left.+ K_3(\hat{\mathbf{n}}\times\nabla\times\hat{\mathbf{n}})^2\right] - \frac{1}{2}\chi_a(\hat{\mathbf{n}}\cdot\mathbf{H}_s)^2 + \frac{fk_BT}{\nu}\ln f\\ &- \bar{M}f(\hat{\mathbf{m}}\cdot\mathbf{H}_s) + fW_p(\hat{\mathbf{n}}\cdot\hat{\mathbf{m}})^2\Bigg\}\,dV \end{aligned} \tag{1a}$$

subject to ferroparticle number conservation

$$\int f\,dV = \bar{f}V, \tag{1b}$$

where K_1, K_2, K_3 are elastic (Frank) constants, χ_a is the anisotropic part of the nematic diamagnetic susceptibility, f and $\bar{f}$ are the local and the mean volume particle fractions, and $\hat{\mathbf{m}}$ is the unit vector in the direction of the sample magnetization $\mathbf{M} = \bar{M}f\hat{\mathbf{m}}$, where normally $\bar{M} = M_s$, the saturation magnetization per unit volume within an individual colloidal particle. In the limit of low applied fields, we shall find, however, that sometimes $\bar{M}$ is reduced from this saturation value by thermal fluctuation effects.

The term in square brackets in (1a) is the Frank–Oseen–Zocher curvature energy. The remaining terms are, respectively, the magnetic energy density, the contribution of the mixing entropy of an ideal ferroparticle solution, the magnetic energy of the colloidal particles, and the anchoring-induced ferronematic interaction [10]. We ignore the ferroparticle magnetic dipole-dipole interaction energy, which disappears at low ferroparticle concentrations. It will be useful to define the quantity $\eta(\mathbf{r}) = \frac{f(\mathbf{r})}{\bar{f}}$. This is the local enhancement (or reduction) of the colloidal density induced by segregation effects. We also suppose the magnetization of the ferroparticles to have reached saturation [10].

In this geometry, the nematic and magnetic distortions are given, respectively, by $\hat{\mathbf{n}} = (\sin\theta, 0, \cos\theta)$ and $\hat{\mathbf{m}} = (-\cos\psi, 0, \sin\psi)$, where $\theta = \theta(z)$ and $\psi = \psi(z)$ are shown in Figure 1. In the simple case when the elastic constants K_1 and K_3 are taken to be equal ($K_1 = K_3 = K$), the free energy functional reduces to

$$\begin{aligned}\mathcal{F} = \int_0^D \Bigg[&\frac{1}{2}K\left(\frac{d\theta}{dz}\right)^2 - \frac{1}{2}\chi_a(H\cos\theta - H_b\sin\theta)^2 \\ &+ \eta(z)\frac{\bar{f}k_BT}{\nu}\ln\eta - \bar{M}\eta(z)\bar{f}(H\sin\psi + H_b\cos\psi) \\ &+ \eta(z)\bar{f}W_p\sin^2(\theta-\psi)\Bigg]\,dz,\end{aligned} \tag{2}$$

subject to the boundary condition $\theta(0) = \theta(D) = 0$ and the constraint $\frac{1}{D}\int_0^D \eta(z)\,dz = 1$.

We may sensibly enquire what conditions are required for (1a) and (2) to hold. This point has been addressed briefly by Burylov and Raikher [10, 11]. However, a detailed discussion of this point goes beyond the scope of this paper. The key point is that it should be possible to define the local magnetic director $\hat{\mathbf{m}}$ as a good macroscopic variable in a continuum theory. This in turn requires that there be effective coupling of the local magnetic directors over length scales larger than the typical interparticle distance. We return to this point briefly in section 6, when we discuss the application of our work to experimental interpretation.

The effective coupling between the magnetic and nematic director will necessarily involve some orientational distortions induced by the colloidal particles over a length scale which may be considerably larger than the individual particle. A sufficient condition for the existence of the director $\hat{\mathbf{m}}$ will be that this distortion region be larger than the typical interparticle distance, so that the distortions induced by neighboring colloidal particles overlap. There will then be an indirect interaction between the magnetic particles, and a locally macroscopic structure. This condition has been termed the requirement for collective behavior [1, 10, 16].

To simplify we initially suppose the following:

(a) There is no bias field. The *raison d'être* of the bias field is to hold $\hat{\mathbf{m}}$ and hence $\hat{\mathbf{n}}$ in the x-z plane. In the absence of the bias field at very low applied fields $\bar{M}/M_s < 1$, but here we shall suppose that this is not the case. We shall discuss the low bias field case (and criteria for determining what is meant by this limit) at the end of the paper.

(b) The direct magnetic-nematic interaction as a result of the anisotropic nematic molecular susceptibility can be ignored as compared to the indirect (but giant) colloidally mediated coupling. Normally, the anisotropic part of the nematic diamagnetic susceptibility is extremely low, for 5CB $\chi_a = 1.7 \times 10^{-7}$ [17]. Thus neglecting the bare magnetic-nematic interaction is a reasonable approximation for the magnetic fields which we shall consider ($H < 200$ Oe), as we will see below.

We now nondimensionalize the problem. Length scales are now measured in units of the cell width D (i.e., z in scaled units is equal to z/D in unscaled units). The scaled free energy is now given by the following formula:

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 + \eta t \ln \eta - \eta h \sin\psi \right. \\ \left. + \eta w \sin^2(\theta - \psi) \right], \tag{3}$$

subject to the constraint $\int_0^1 \eta(z)\, dz = 1$, and with

(a) $h = \bar{f}\bar{M}HD^2/K$ the dimensionless magnetic field;

(b) $w = \bar{f}W_pD^2/K$ the dimensionless coupling (W_p now per unit volume) between the nematic and magnetic orientations; we refer to this quantity as the *ferronematic coupling parameter*; and

(c) $t = k_BT\bar{f}D^2/(\nu K)$ the dimensionless temperature; this is roughly the ratio of the thermal energy of the colloidal particles to the nematic elastic free energy density.

We note that this nondimensionalization scheme differs from that in a number of previous papers [10, 11, 13, 14]. In the previous normalization scheme, it turns out not to be possible to remove the magnetic segregation in a regular way. By contrast, the scheme introduced in our previous letter [15] and further developed here permits a simple limit in which there is no magnetic segregation. This corresponds to an infinite temperature limit with respect to the energy parameter driving the segregation. Segregation can then be considered as a finite temperature perturbation. The natural perturbation parameter is then a nondimensionalized inverse temperature.

Suitable surrogates for the global behaviors of the parameters will be the quantities $\theta_0(h) = \theta\left(h, z = \frac{1}{2}\right)$ and the analogous quantity $\psi_0(h) = \psi\left(h, z = \frac{1}{2}\right)$. We shall also define the degree of segregation in a number of ways. The segregation order parameter $s(h)$ is an integral quantity and is defined by

$$s = -\int_0^1 dz\, \eta(z) \cos 2\pi z. \tag{4}$$

The quantity

$$\eta_0(h) = \eta\left(h, z = \frac{1}{2}\right) \tag{5}$$

is in some respects analogous to $\theta_0(h)$ and $\psi_0(h)$ and measures the ratio of the concentration in the center of the cell to its average value.

3. Unsegregated limit. To begin with we put $t \to \infty$ [18]. The colloidal concentration responds in a Boltzmann-like fashion to its local potential energy. In the infinite temperature limit, therefore, there is no response; the concentration $\eta(z)$ remains constant, and there is no colloidal segregation. Equation (3) and the resulting field theory are both now much simplified.

The theory now reduces to minimizing

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - h\sin\psi + w\sin^2(\theta - \psi)\right]. \tag{6}$$

3.1. Infinitely strong ferronematic coupling. Now $w \to \infty$, which enforces $\theta = \psi$; the nematic director follows the magnetic particle distortion and is always perpendicular to the magnetic particles. The resulting problem is now similar to the classical Frederiks problem but lacks the symmetry-breaking characteristic of this problem. The theory now reduces to

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - h\sin\theta\right]. \tag{7}$$

The Euler–Lagrange equation is

$$\frac{d^2\theta}{dz^2} + h\cos\theta = 0. \tag{8}$$

The *weak field* solution can be calculated by putting $\cos\theta = 1$ in this equation. Substituting $\theta(0) = \theta(1) = 0$ then yields

$$\theta(z) = \frac{h}{2}\, z\,(1 - z). \tag{9}$$

One suitable figure of merit for the total degree of reorientation is $\Theta = \int_0^1 \theta(z)\, dz$. At low fields $\Theta = h/12$; the effect is proportional to the imposed field and is thresholdless. Alternatively, we may choose $\theta_0(h) = \theta\left(h, z = \frac{1}{2}\right)$. From (9), we find $\theta_0(h) = \frac{h}{8}$. Later in this paper we shall find it useful to expand $\theta(h, z) \approx \theta_0(h)\sin\pi z$ in a harmonic approximation. If we minimize the linearized version of (7) within this approximation, we obtain $\theta_0(h) \approx (4/\pi^3)h \approx 0.129h$, rather close to the $\theta_0(h) = 0.125h$, given by (9).

A *strong field* solution can be found using a matched asymptotic expansion method [19]. A high field is here defined by $h \geq 1$ in the absence of any other scale on which to compare it. We omit the details, as only the conclusion is important for the subsequent discussion. There is a boundary region close to the wall, in which the distortion is small but rapidly increases:

$$\theta(z) \approx 1.46h^{1/2}z - 0.5\left(h^{1/2}z\right)^2. \tag{10}$$

This region has thickness $z_0 = 0.46h^{-1/2}$. In the bulk of the cell, the solution for θ is approximately given by

$$\theta(z) = \frac{\pi}{2} - 3.16\exp\left[-\frac{h^{1/2}}{2}\right]\cosh\left[h^{1/2}\left(z - \frac{1}{2}\right)\right]. \tag{11}$$

The key result is that the director distortion saturates. There are boundary regions close to the walls in which the distortion reduces to zero of thickness $z_0 \sim h^{-1/2}$, which become increasingly thin with increasing field. The value of the distortion in the center of the cell becomes increasingly close to saturation, with

$$\theta_0(h) = \frac{\pi}{2} - 3.16 \exp\left[-\frac{h^{1/2}}{2}\right] \tag{12}$$

and

$$\frac{\pi}{2} - \Theta(h) \sim h^{-1/2}. \tag{13}$$

We note that all figures of merit for the total degree of reorientation, including the optical phase lag measured through the cell, *monotonically increase* with magnetic field up to saturation, although this increase does of course slow at high fields.

These results do not, however, carry over exactly into the finite coupling case. This is because the degree to which the saturated alignment of the magnetic director is limited by the degree of coupling between the nematic and the magnetic directors, as we shall see below.

3.2. Finite ferronematic coupling. This corresponds to the more realistic case of finite anchoring at the colloidal particle surface. The appropriate free energy functional is given by (6):

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - h \sin\psi + w \sin^2(\theta - \psi)\right]. \tag{6}$$

The Euler–Lagrange equations corresponding to the free energy (6) are

$$\frac{d^2\theta}{dz^2} - w \sin(2(\theta - \psi)) = 0, \tag{14a}$$

$$h \cos\psi + w \sin(2(\theta - \psi)) = 0. \tag{14b}$$

Equation (14b) is the *bonding equation* of Burylov and Raikher [10, 11]. It is apparent that so long as the ratio $\frac{h}{w} \ll 1$, we can expect that $\theta \approx \psi$. The magnetic and nematic directors will be coaligned (or bonded) in this circumstance. If this condition does not hold, then $\theta \approx \psi$ may still hold, but only if $\cos\psi$ is sufficiently small (i.e., ψ is sufficiently close to $\frac{\pi}{2}$). Much of this paper is concerned with determining the details of when and in what way this relation holds. It ceases to hold with increasing field when h and w are of the same order of magnitude. The magnetic director becomes more aligned with the field, but the nematic director is no longer aligned with it. This phenomenon has been described as *decoupling* by Burylov et al. [13].

3.2.1. Boundary conditions. From a mathematical point of view these equations are slightly peculiar. The strong surface anchoring condition on θ yields $\theta(0) = \theta(1) = \theta_s = 0$. However, the boundary conditions $\psi(0) = \psi(1) = \psi_s$ are not defined explicitly. However, they are implicit in (14b) from the surface condition $\theta = 0$. This yields

$$h \cos\psi_s = w \sin(2\psi_s), \tag{15}$$

which sustains two solutions:

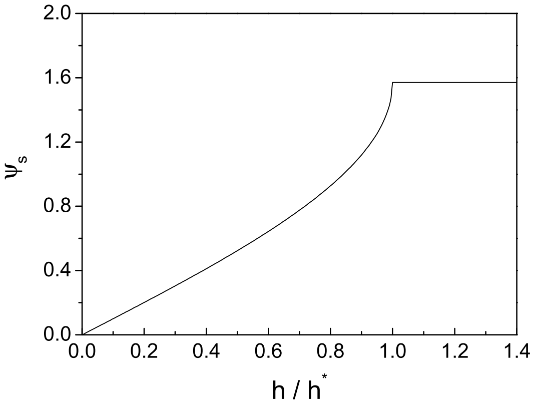

FIG. 2. *Behavior of the displacement of the magnetic director at the surface ψ_s, as a function of scaled magnetic field h. Note the linear behavior at low h, and the sharp singularity at $h = h^*$, at which the ψ_s abruptly saturates.*

(a) $\psi_s = \arcsin(h/2w)$, which is the low magnetic field case. For $h/2w > 1$, however, $\psi_s = \arcsin(h/2w)$ is no longer well defined.

(b) $\psi_s = \pi/2$, which is the high magnetic field case. The surface value of the magnetic angle ψ_s *saturates*.

Thus $\psi_s(h)$ is a monotonic function of h, increasing smoothly from zero at $h = 0$. For low h, $\psi_s \sim h$; the behavior is linear. But there is a change of regime at $h = h^*(w) = 2w$, at which point $\psi_s = \psi(0) = \psi(1)$ saturates. The behavior of ψ_s is shown in Figure 2. The quantity ψ_s saturates abruptly at $h = h^*$. There is strongly discontinuous behavior in the gradient $\frac{d\psi_s}{dh}$ at $h = h^*$. Just below $h = h^*$, we have

$$\psi_s \sim \frac{\pi}{2} - \sqrt{2}\left(1 - \frac{h}{h^*}\right)^{1/2}. \tag{16}$$

Given the coupling between ψ and θ, one might also expect some nonanalytic properties in $\psi(z)$ (and hence in $\theta(z)$) for all z as a function of h. Numerical evidence suggests, however, that the singularity is rounded away from the boundary. We shall return to this problem elsewhere.

3.2.2. Low field properties. We can now expand (6) in powers of small quantities h, θ_0, and γ_0, where

$$\theta(z) \approx \theta_0 \sin \pi z; \quad \psi(z) = \psi_s + \gamma_0 \sin \pi z; \quad \psi_s = \arcsin\left(\frac{h}{2w}\right). \tag{17}$$

The free energy is then given by

$$\begin{aligned} F = \int_0^1 \Bigg\{ & \frac{\pi^2}{2}\,\theta_0^2 \cos^2 \pi z - h \sin\left[\arcsin\frac{h}{2w} + \gamma_0 \sin \pi z\right] \\ & + w \sin^2\left[\arcsin\frac{h}{2w} + (\gamma_0 - \theta_0)\sin \pi z\right]\Bigg\}\, dz. \end{aligned} \tag{18}$$

We now expand the integrand of (18) in a multivariate Taylor series up to second order in θ_0 and γ_0, noting that $\sin\left(\arccos\frac{h}{2w}\right) = \cos\left(\arcsin\frac{h}{2w}\right) = \sqrt{1 - \frac{h^2}{4w^2}}$. Performing the integrals, including those over $\sin \pi z$ and $\sin^2 \pi z$, we obtain the following expansion in θ_0 and γ_0:

(19)

$$F = -\frac{h^2}{4w} - \frac{2h}{\pi}\sqrt{1-\frac{h^2}{4w^2}}\,\theta_0 + \frac{\pi^2}{4}\theta_0^2 + \frac{h^2}{8w}\gamma_0^2 + \frac{w}{2}\left(1-\frac{h^2}{2w^2}\right)(\theta_0-\gamma_0)^2 + O(\theta_0^3,\gamma_0^3).$$

This leads to Lagrange equations

$$\text{(20a)}\qquad \frac{\pi^2}{2}\theta_0 + w\left(1-\frac{h^2}{2w^2}\right)(\theta_0-\gamma_0) - \frac{2h}{\pi}\sqrt{1-\frac{h^2}{4w^2}} = 0,$$

$$\text{(20b)}\qquad \frac{h^2}{4w}\gamma_0 - w\left(1-\frac{h^2}{2w^2}\right)(\theta_0-\gamma_0) = 0.$$

Solving these we find

(21)

$$\theta_0 = \frac{16hw^3}{\pi(4w^3\pi^2+2w^2h^2-\pi^2h^2w-h^4)}\left(1-\frac{h^2}{4w^2}\right)^{3/2} = \frac{4h}{\pi^3} - \frac{\pi^2+4w}{2\pi^5w^2}h^3 + O(h^5)$$

and

$$\text{(22)}\qquad \theta_0-\gamma_0 = \frac{h^3}{\pi^3w^2} + O(h^5).$$

In the limit $\frac{h}{w}\to 0$, as expected, this solution tends to the behavior of the infinitely strong-coupling regime (9). In the very low field regime, the response is as though the torque is acting directly on the nematic director. But this response is modified by a third order term in h. This reduces the response as compared to the infinite coupling case, as one might expect, given that the restoring force on the nematic director acts only through the intermediary effect of the magnetic director.

3.2.3. Infinite field limiting properties. For sufficiently high fields, the minimizer of the free energy (6) with respect to ψ requires that $\psi(z) = \frac{\pi}{2}$ everywhere. Now (6) reduces to

$$\text{(23)}\qquad F \sim \int_0^1 dz\left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 + w\sin^2\left(\theta-\frac{\pi}{2}\right)\right] \sim \int_0^1 dz\left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - w\sin^2\theta\right].$$

This is just the classic Frederiks transition problem, whose solution is well known [20].

The nematic distortion now no longer saturates at high fields. Indeed, for $w \le w_c = \frac{\pi^2}{2}$, $\psi(z) = \frac{\pi}{2}$ everywhere; i.e., the magnetic distortion is *maximal*. But apparently paradoxically the cost of *any* nematic distortion is positive, and hence $\theta(z)\equiv 0$; the nematic distortion is *minimal*.

However, as w increases beyond w_c, the high field nematic distortion increases. In the region $w\sim w_c$, we can again make the approximation $\theta(z) = \theta_0\sin\pi z$, in which case (23) reduces to

$$\text{(24)}\qquad F(\theta_0) \sim \frac{1}{2}\left(\frac{\pi^2}{2}-w\right)\theta_0^2 + \frac{w}{8}\theta_0^4 + \dots .$$

Minimizing this with respect to θ_0 yields

$$\text{(25)}\qquad \theta_0 \approx \sqrt{2}\left(1-\frac{w_c}{w}\right)^{\frac{1}{2}}.$$

Finally for $w \gg w_c$, $\theta(z)\approx\frac{\pi}{2}$ almost everywhere. There is a small healing region close to the boundaries, of dimension $w^{-\frac{1}{2}}$, over which $\theta(z)$ goes from zero to $\frac{\pi}{2}$.

3.2.4. General classification. On the basis of the evidence adduced above, we are now in a position to make a general classification of FN behavior into three regimes. The regimes are as follows.

(a) *Weak ferronematic coupling.* The weak coupling regime is defined by $w \leq w_c = \frac{\pi^2}{2}$. In this regime, as we have shown in section 3.2.2, the initial response $\theta_0(h)$ is proportional to h. We have shown in section 3.2.3 that $\lim_{h\to\infty} \theta_0 \equiv 0$, but in fact the condition is stronger. It will turn out that there is a critical field $h_c(w)$ at which the nematic distortion abruptly *disappears*, so that for $h \geq h_c(w)$, $\theta_0(h) \equiv 0$. In any event, there is a turning point at intermediate h_M, and for $h > h_M$, $\theta_0(h)$ decreases.

(b) *Intermediate ferronematic coupling.* We know from section 3.2.2 that at low fields the nematic response increases, with $\theta_0 \sim h$. If $w > w_c$, but $\left|\left(\frac{w}{w_c}\right) - 1\right| \ll 1$, we also know from section 3.2.3 that $\theta_0(h \to \infty)$ is small. Thus there will be a regime $w_c < w < w_{c2}$ for which necessarily $\theta_0(h)$ reaches a maximum as a function of h before decreasing at high fields. The precise value of w_{c2} remains to be determined.

(c) *Strong ferronematic coupling.* We know from section 3.1 that in the infinite coupling regime $\theta_0(h)$ increases for all h. We thus expect a regime defined by $w > w_{c2}$ for which this behavior is retained.

3.2.5. High field limit. We can now extend the considerations of the infinite field limit to fields which are merely high. In this case, given the considerations of section 3.2.1, this means $h \geq 2w$. The analysis involves constructing a free energy expansion in both nematic and magnetic orientation variables. Specifically, the expansion extends the considerations of (24) involving θ to include departures in ψ from complete alignment.

We recall from section 3.2.1 that for large h, $\psi_s = \frac{\pi}{2}$. Hence $\psi(z) = \frac{\pi}{2} - \gamma(z)$, where the angle $\gamma(z)$ is small and zero at the boundary. Likewise, at least in the weak and intermediate ferronematic coupling regimes discussed in section 3.2.4, the angle $\theta(z)$ may be regarded as small.

The appropriate expansion variables are then γ_0, θ_0, where

$$\psi(z) \approx \frac{\pi}{2} - \gamma(z), \quad \gamma(z) = \gamma_0 \sin \pi z, \quad \theta = \theta_0 \sin \pi z. \tag{26}$$

We shall construct a Landau expansion of F in the high field regime. From (6), we obtain

$$F = F_0 + \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - h\cos\gamma - w\sin^2(\theta+\gamma)\right], \tag{27}$$

where F_0 is a reference free energy defined for $\theta(z) \equiv 0$ and $\psi \equiv \frac{\pi}{2}$. Expanding (27) to fourth order in the angular variables θ_0, γ_0, using the relations (26), yields

$$F - F_0 = \left[\frac{\pi^2}{4}\theta_0^2 + \frac{h}{4}\gamma_0^2 - \frac{1}{2}w\left(\theta_0+\gamma_0\right)^2\right] - \frac{h}{64}\gamma_0^4 + \frac{1}{8}w\left(\theta_0+\gamma_0\right)^4 + \dots. \tag{28}$$

Here we have isolated the crucial terms quadratic in the variables θ_0, γ_0.

Stability is defined by this quadratic term, which can be written as

$$F_Q = \frac{1}{2}\left[w_c\,\theta_0^2 + \frac{h}{2}\gamma_0^2 - w\left(\theta_0+\gamma_0\right)^2\right] = \frac{1}{2}\left[\left(w_c - w\right)\theta_0^2 + \left(\frac{h}{2} - w\right)\gamma_0^2 - 2w\,\theta_0\gamma_0\right], \tag{29}$$

where we have substituted $w_c = \frac{\pi^2}{2}$. We have seen in section 3.2.3 that this is the critical ferronematic coupling beyond which the infinite field nematic distortion no longer vanishes, i.e., $\lim_{h\to\infty} \theta_0 \neq 0$. And indeed, when $\gamma_0 \equiv 0$, then by inspection it is clear that the expression given in (29) is positive definite (and hence $\theta_0 \equiv 0$) if and only if $w < w_c$.

For finite h, $\theta_0 = \gamma_0 = 0$ are minimizers of the free energy expression (28) if and only if the quadratic term (29) is positive definite. This will be the case if

$$w_c - w > 0 \tag{30a}$$

and also if the discriminant of expression (29) is positive:

$$\left(\frac{h}{2} - w\right)(w_c - w) > w^2. \tag{30b}$$

Rearranging (30b), we obtain a condition

$$\frac{h}{2}(w_c - w) - ww_c > 0 \tag{31a}$$

or

$$h^{-1} < h_c^{-1}(w) = \frac{1}{2}(w^{-1} - w_c^{-1}). \tag{31b}$$

The result of this calculation is that in the weak FN coupling limit, i.e., if $w - w_c < 0$, then the magnetic director is completely saturated, the nematic distortion will be zero not only in the limit of infinitely high field but also *for all* fields $h > h_c(w)$, where

$$h_c(w) = \frac{2}{(w^{-1} - w_c^{-1})} = \frac{2ww_c}{(w_c - w)}. \tag{32}$$

Equivalently, the quadratic form (29) is positive definite if both $w_c - w > 0$ and $h - h_c > 0$. Using (29), the free energy (28) can then be recast in a diagonal form in which the change of character at $h = h_c$, $w = w_c$ becomes explicit:

$$\begin{aligned} F - F_0 = \frac{1}{2}\Bigg[&\frac{2w_c^2}{2w_c + h}\left(\theta_0 - \frac{h}{2w_c}\gamma_0\right)^2 + \frac{(h - h_c(w))(w_c - w)}{2w_c + h}(\theta_0 + \gamma_0)^2 \\ &+ \frac{w}{4}(\theta_0 + \gamma_0)^4 - \frac{h}{32}\gamma_0^4\Bigg]. \end{aligned} \tag{33}$$

In all cases of interest there exists a minimizer of $F(\theta_0, \gamma_0)$ such that θ_0, γ_0 are either zero or small. The γ_0^4 term with a negative coefficient is swamped by the $(\gamma_0 + \theta_0)^4$ term.

3.2.6. The weak coupling regime. This is the regime $w < w_c = \frac{\pi^2}{2}$. We have seen that the nematic response increases rapidly at low fields and reaches a maximum. θ_0 then *decreases*, reaching zero at $h_c(w)$, where from (31b)

$$\frac{2}{h_c(w)} = \frac{1}{w} - \frac{1}{w_c}.$$

We describe this transition as an inverse Frederiks transition, because at high fields the nematic director remains undistorted, whereas for lower fields, deviation from the zero field equilibrium occurs. We note also that

$$\lim_{w\to w_c} h_c^{-1}(w) = 0; \quad \frac{h_c(w)}{2w} = \frac{1}{(1-w/w_c)}. \tag{34}$$

The critical field $h_c(w)$ *diverges* as $w \to w_c$, so that for $w > w_c$, the undistorted state no longer exists.

For $h > h_c(w)$ the magnetic director $\hat{\mathbf{m}}$ is completely aligned with the magnetic field, corresponding to $\psi(z) = \pi/2$ everywhere. This magnetic alignment is coupled to the nematic director through the colloidal particles, giving an effective perpendicular field on the nematic of magnitude w. As we have seen above, there is a strong analogy with the conventional Frederiks effect. If w is too low, even at high fields the effective aligning force on the nematic particles cannot overcome the elastic energy of the nematic director. The director thus remains unmoved by the field. The critical value w_c is just that field which corresponds to the Frederiks transition.

We also note that the alignment of the magnetic director ψ_s at the *surface* saturates at $h^*(w) = 2w$. However, *in the bulk* the magnetic saturation occurs only at the higher field $h_c(w) = 2w(1-w/w_c)^{-1} = h^*(w)(1-w/w_c)^{-1}$. The effect of the surface singularities in the response of the bulk system close to $h^*(w)$ is not clear; preliminary evidence suggests that they may be smoothed out. Cells with *weaker* nematic-magnetic coupling saturate at *lower* fields (i.e., more easily) because the saturation is discouraged by the nematic elastic term.

At $h_c(w)$ there is a transition to nonzero values of θ because the magnetic field is no longer sufficiently strong to hold the magnetic director perpendicular to the walls. The magnetic director then orients at some angle to the walls, and this in turn breaks the left-right symmetry to which the nematic director is subject. The nematic director thus follows the distorting magnetic director.

In order to analyze the behavior of ψ and θ just below h_c, it is necessary to analyze (33). The quadratic form in this equation is diagonal. The coefficient of the term

$$\frac{2w_c^2}{2w_c+h}\left(\theta_0 - \frac{h}{2w_c}\gamma_0\right)^2$$

is always positive. Thus, apart from corrections, $\theta(z) = \frac{h}{2w_c}\gamma(z)$, or

$$\gamma_0 = \frac{2w_c}{h}\theta_0. \tag{35}$$

We can now rewrite (33) as an expansion in θ_0 alone. In the spirit of Landau theory, close to $h = h_c(w)$, we replace all values of h by $h_c(w)$ except where the relevant term is $(h - h_c(w))$. After some algebra, we obtain

$$F - F_0 = \frac{w_c^2}{2w}\left[\left(1 - \frac{h_c(w)}{h}\right)\left(1 - \frac{w}{w_c}\right)\theta_0^2 + \frac{1}{4}\left(\frac{w_c}{w}\right)^2\left(1 - \frac{1}{4}\left(1 - \frac{w}{w_c}\right)^3\right)\theta_0^4\right]. \tag{36}$$

We note that the coefficient of the quartic term is always positive, despite the apparent negative term in γ_0^4 in (28). Minimizing (36) with respect to θ_0 yields

$$\theta_0 = \sqrt{2}\frac{w}{w_c}\left(\frac{(1-w/w_c)}{\left[1 - \frac{1}{4}(1-w/w_c)^3\right]}\right)^{1/2}\left[\frac{h_c(w)}{h} - 1\right]^{1/2}, \tag{37}$$

exhibiting the expected square root singularity as function of the field. The transition thus follows the normal paradigm.

As the magnetic field is further reduced, the nematic response increases. However, at very low fields, the magnetic director responds little to the magnetic field. Then finally the nematic response also decreases, in sympathy. The qualitative explanation of this phenomenon is as follows. The degree of distortion is associated with the couple exerted on the nematic director. This is proportional to $\sin 2(\theta - \psi)$. For the undistorted nematic ($\theta = 0$) this has a maximum at $\psi = \pi/4$. We thus expect a maximum in $\theta_0 = \theta(z = 1/2)$ to occur when $\psi \approx \pi/4$.

3.2.7. The intermediate coupling regime. We now discuss the regime for which $\theta_0(h)$ is monotonically decreasing at high h, but $\lim_{h\to\infty} \theta_0 \neq 0$. Now the ferronematic coupling is somewhat larger than in the previous case: $w_c < w < w_{c2}$, where we shall determine w_{c2}.

The Landau expansion again uses (35) connecting γ_0 and θ_0. Re-expanding in terms of the one relevant variable θ_0 yields

$$F \sim w_c \left(1 - \frac{w}{w_c} - \frac{2w}{h}\right)\left(1 + \frac{2w_c}{h}\right)\theta_0^2 + \frac{w}{4}\left(1 + \frac{2w_c}{h}\right)^4 \theta_0^4, \tag{38}$$

where now the γ_0^4 term in (33) is negligibly small at $w \gg \pi^2/6$. Minimizing this function, we obtain the following expression for $\theta_0(h)$:

$$\theta_0^2(h) = 2\frac{\left(1 - \dfrac{w_c}{w} + \dfrac{2w_c}{h}\right)}{\left(1 + \dfrac{2w_c}{h}\right)^3}. \tag{39}$$

We observe that in the limit $h \to \infty$, this expression is consistent with (37). Indeed, we can expand $\theta_0(h)$ in terms of $\theta_0(h = \infty)$, yielding

$$\theta_0^2(h) = \theta_0^2(h = \infty)\frac{\left(1 + \dfrac{2w_c}{h\left(1 - \dfrac{w_c}{w}\right)}\right)}{\left(1 + \dfrac{2w_c}{h}\right)^3}. \tag{40}$$

Expanding this, and taking square roots, we obtain, now to leading order in h^{-1},

$$\theta_0(h) = \theta_0(\infty)\left[1 + \left(\frac{w_c}{h}\right)\left(\frac{1}{1 - \dfrac{w_c}{w}} - 3\right)\right]. \tag{41}$$

This is the key result of this section. It shows that for w such that $\frac{1}{1-w_c/w} > 3$, $\theta_0(h)$ for large fields is an *increasing* function of *inverse* field and hence a *decreasing* function of h. This condition can be rewritten as

$$w_c < w < w_{c2}, \quad w_{c2} = \frac{3}{2}w_c. \tag{42}$$

Equation (42) improves the estimate of w_{c2} given in our previous paper [15].

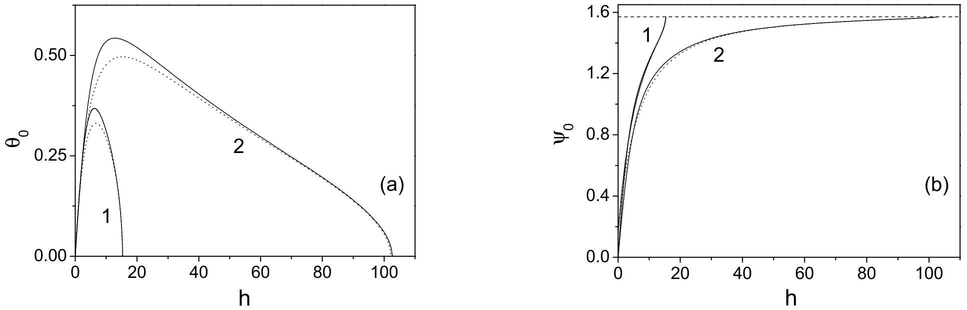

FIG. 3. *Weak coupling ferronematics: Nematic* (a) *and magnetic* (b) *directors as a function of dimensionless external field, in the absence of a bias field. Quantities θ_0 and ψ_0 in the center of the cell are used as surrogates for global behavior. Curve* 1 *corresponds to $w = 3$ and curve* 2 *to $w = 4.5$; $w < w_c \approx 4.93$. The dotted lines have been added to show comparison with the results of the asymptotic calculation* (36) *in section* 3.2.6.

3.2.8. The strong coupling regime. This is the regime $w > w_{c2} = \frac{3}{2}w_c$. We can see from (41) that in this regime, the angle θ_0 *increases* at high field. It is further not clear from the asymptotic analysis whether there is a region of w for which θ_0 is not a monotonic function of h, or whether the maximum in $\theta_0(h)$ disappears exactly at w_{c2}. The numerical results are consistent with the latter hypothesis.

3.3. Numerical results. We have also carried out a numerical minimization of the relevant free energy (3). The method does not involve a direct brute force quadrature-based solution of the resulting Euler–Lagrange equations. Rather we use the existence of a set of first integrals, which allows us to parameterize the solutions in terms of the values of the parameters ψ_0, θ_0, η_0, where these quantities are the values of the relevant parameters in the middle of the cell. These quantities satisfy algebraic self-consistency conditions. The method has been used in previous publications [13, 14]. We shall present a detailed discussion of the merits of this approach elsewhere.

Figures 3–6 illustrate the behavior of weak, intermediate, and strong-coupling FNs in the unsegregated limit. Solid curves are numerical solutions. A comparison of numerical calculations and asymptotic results is given by dotted lines.

Figure 3 shows the *inverse Frederiks transition.* As h increases, the nematic response first increases and then decreases, disappearing at an inverse Frederiks transition at $h = h_c(w)$. The magnetic response is a monotonically increasing function of h but saturates at $h = h_c(w)$ and $\psi_0 = \pi/2$.

The profiles of the nematic and magnetic directors for weak-coupling FNs at low and high fields are shown in Figure 4. These profiles demonstrate that the harmonic approximations for $\theta(z)$ and $\psi(z)$ given in (17) and (26) are extremely good. There is a change of the magnetic director profile shape when h is close to $2w$. Our investigation shows that this change in the profile structure is due to the ambiguity of the dependence of θ (14b) on h or ψ when $\psi_s > \pi/4$ or $h > \sqrt{2}w$, respectively.

Figure 5 also illustrates peculiar changes in the magnetic director behavior with h. For low fields ($h < \sqrt{2}w$) the magnetic profile is concave-down and $\psi_0 - \psi_s > 0$. For high fields the profile is concave-up. In the process of changing the profile from concave-up to concave-down, there is the intermediate concave-convex profile in the narrow interval of h close to $h = 2w$. At a certain value of h in this interval $\psi_0 = \psi_s$ and $\Delta\psi = 0$.

Figure 6 shows the nematic and magnetic response in the intermediate and strong-

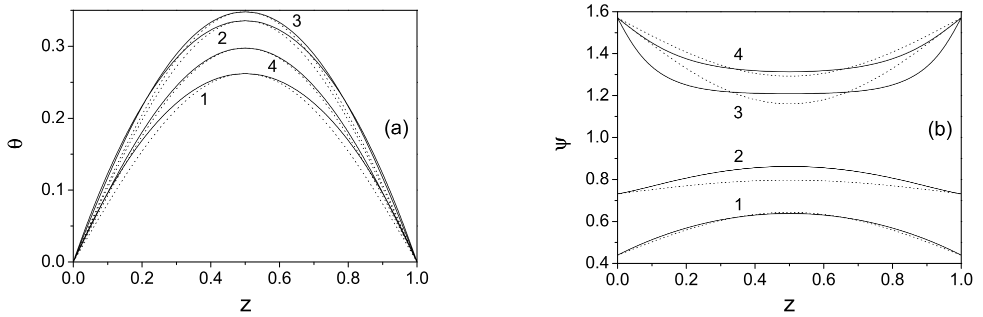

FIG. 4. *Weak coupling ferronematics: Nematic distortion* $\theta(z)$ (a) *and magnetic distortion* $\psi(z)$ (b) *as a function of position for different dimensionless external fields, in the absence of a bias field, with* $w = 3$*,* $w < w_c$*. Curve* 1*,* $h = 2.55$*; curve* 2*,* $h = 4.0$*; curve* 3*,* $h = 8.38$*; curve* 4*,* $h = 10.56$*. Solid curves are numerical solutions. Dotted curves are asymptotic solutions; in curves* 1 *and* 2 *we used the low* h *expansion, and in curves* 3 *and* 4 *we used the high* h *expansion. Note how* $\theta(z)$ *always increases in the center of the cell, but in the weak coupling case* $\psi(z)$ *increases for low* h *but decreases for higher* h*.*

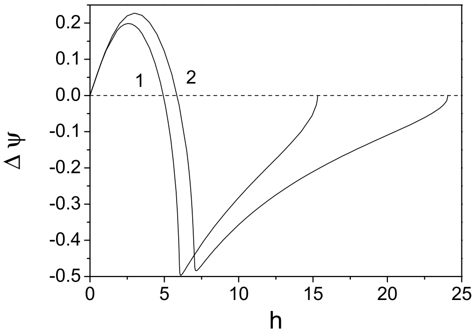

FIG. 5. *Differences between surface and bulk behavior as a function of field* h *for weak ferronematic couplings* $w = 3$ *(curve* 1*) and* $w = 3.5$ *(curve* 2*). The quantity* $\Delta\psi = \psi_0 - \psi_s$ *is the difference between the magnetic distortion at the center of the cell and its value at the surface. Note the discussion in the text.*

coupling regimes. As h increases, the nematic response of the intermediate coupling FN first increases and then decreases, but $\lim_{h\to\infty} \theta_0 = \sqrt{2(1 - w_c/w)} \approx 0.6 \neq 0$. In the strong-coupling regime the nematic response is a monotonically increasing function of h and saturates at high h. The magnetic response is a monotonically increasing function of the field in both regimes.

4. Bias field. Experimentally, the bias field is imposed in order to maintain particles and hence the director in the x-z plane, whereas we simply *assume*, even in the absence of a bias field, that the orientation is maintained in this plane. The zero-bias-field case then becomes the distinguished limit which we have discussed in the last section. *Physically* the important point about the bias field is that the resultant magnetic field is never entirely perpendicular to the cell plane. The consequence of this is that the angle ψ can reach its saturation value of $\pi/2$ only at infinitely high fields (i.e., $h^{-1} \equiv 0$). This contrasts with the zero-bias-field case, for which, as we have seen, at least for $w < w_c$, $\psi \equiv 0$ for $h > h_c(w)$.

For analytical purposes it is convenient to discuss small perturbations from the

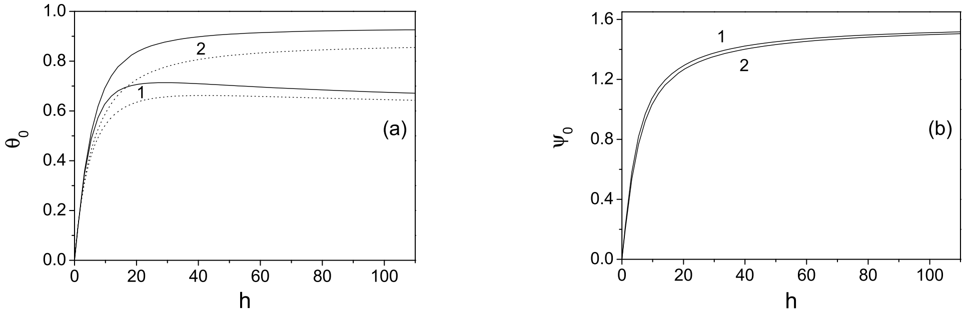

FIG. 6. *Intermediate and strong coupling ferronematics: Nematic* (a) *and magnetic* (b) *directors as a function of dimensionless external field, in the absence of a bias field. (Curve* 1*)* $w = 6$, $w_c < w < 3w_c/2$*, corresponding to intermediate ferronematic coupling; (curve* 2*)* $w = 8$, $w > 3w_c/2$*, corresponding to strong ferronematic coupling. Dotted lines show comparison with the results of the asymptotic calculation which minimizes the free energy* (28)*. This figure is the intermediate and strong FN coupling version of Figure* 3.

zero-bias-field case already considered. It is sensible to scale the bias field, by analogy with other nondimensionalization in the problem, leading to a dimensionless bias field $h_b = \bar{f}\bar{M}H_bD^2/K$. The constant η, high t free energy is now

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 - h\sin\psi - h_b\cos\psi \right.$$
$$\left. + w\sin^2(\theta - \psi)\right]. \tag{43}$$

This is the bias field analogue of (3). The Euler–Lagrange equations now become

$$\frac{d^2\theta}{dz^2} - w\sin(2(\theta - \psi)) = 0, \tag{44a}$$

$$h\cos(\psi) - h_b\sin\psi + w\sin(2(\theta - \psi)) = 0, \tag{44b}$$

where (14a) and (44a) are identical, and (44b) differs from its zero-bias-field analogue (14b) by an extra factor $-h_b\sin\psi$.

The most dramatic effects of the bias field occur in the low w regime. In this regime, when there is no bias field, the magnetic director saturates. The saturation drives the high field absence of nematic director distortion and the inverse Frederiks transition. The bias field destroys the magnetic saturation and thus fundamentally affects the inverse Frederiks effect.

We first discuss the boundary values ψ_s. We recall from section 3.2.1 that in the absence of a bias field, $\psi_s(h)$ is a monotonically increasing function of h, saturating at $\psi_s = \frac{\pi}{2}$ at $h = h^* = 2w$. We shall investigate the behavior of $\gamma_s = \frac{\pi}{2} - \psi_s$, which in the $h_b = 0$ case vanishes identically for $h > 2w$. Combining (44b) and the condition $\theta_s = 0$ yields the bias field analogue of (15):

$$h\cos\psi_s - h_b\sin\psi_s = w\sin 2\psi_s. \tag{45}$$

For $h_b = 0$ there are two regimes separated by a singularity at $h = 2w$. In the $h > 2w$ regime $\psi_s = \pi/2$; $\gamma_s = 0$, whereas for $h < 2w$, $\gamma_s \neq 0$. However, a finite value

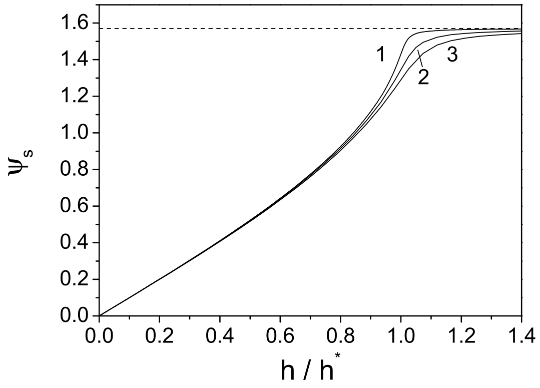

FIG. 7. *Behavior of the magnetic surface director deviation $\psi_s(h)$ as a function of bulk field h for various different values of bias field h_b, with $w = 0.9$, $w < w_c$. Curve* 1: $h_b = 0.01$. *Curve* 2: $h_b = 0.05$. *Curve* 3: $h_b = 0.1$. *Compare to the zero-bias-field case shown in Figure* 2. *Note the rounding of the sharp singularity at $h = h^* = 2w$.*

of h_b rounds this singularity, and the behavior of ψ_s and hence all other quantities can no longer be divided into two distinct regimes. Rewriting (45) in terms of γ_s, we obtain

$$h \sin\gamma_s - h_b \cos\gamma_s = w \sin 2\gamma_s. \tag{46}$$

Linearizing in the regime of small $\gamma_s \ll 1$ yields

$$h\gamma_s - h_b = 2w\gamma_s, \tag{47}$$

yielding

$$\gamma_s = \frac{h_b}{h - 2w}. \tag{48}$$

We plot exact numerical results for $\psi_s(h)$ for a number of different values of h_b in Figure 7. Equation (48) can be regarded as a response by the FN surface to a bias field probe. The unbiased system is unstable with respect to a perturbation of γ_s at $h = 2w$. One should thus expect that the susceptibility of the magnetic director to the small bias field would diverge at $h = 2w$, as indeed occurs (although for fields of this order, the small γ_s approximation no longer holds). The nonzero γ_s is a signature of a nonzero γ_0, and hence of a nonzero θ_0, as we now show.

Analogous results are found for the magnetic and nematic director deviations in the center of the sample. Numerical results are presented in Figure 8.

The results in Figure 8 can be understood semiquantitatively as follows. Using the expansion of (26), we can rewrite the functional (43) in a power law expansion in γ_0 and θ_0, yielding for the relevant terms

$$\begin{aligned} F - F_0 = \frac{1}{2}\Bigg\{ &(w_c - w)\left[\theta_0 - \frac{h_c(w)}{2w}\gamma_0\right]^2 + \frac{1}{2}(h - h_c(w))\gamma_0^2 \\ &- \frac{4}{\pi}h_b\gamma_0 + \frac{w}{4}(\theta_0 + \gamma_0)^4 - \frac{h}{32}\gamma_0^4 + \frac{4}{9\pi}h_b\gamma_0^3\Bigg\}. \end{aligned} \tag{49}$$

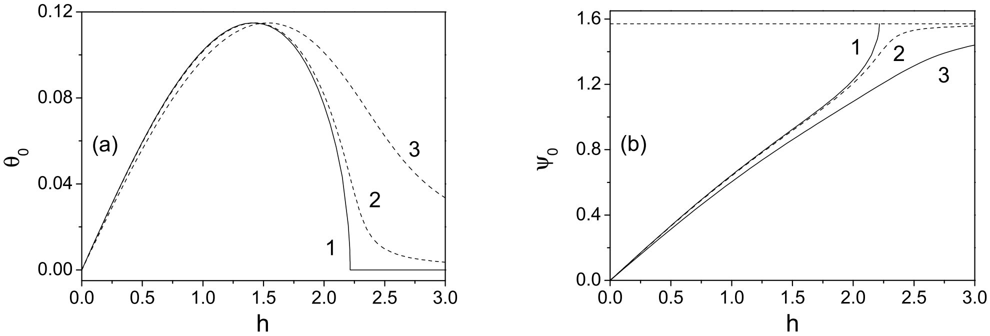

FIG. 8. *Effect of bias field on the bulk distortion in the weak ferronematic coupling regime. In all cases $w = 0.9$, $w < w_c$, and the nematic director* (a) *behavior is shown. Curve* 1*: No bias field* ($h_b = 0$)*. Curves* 2 *and* 3*: Weak bias field* ($h_b = 0.01, 0.1$)*. The re-entrant Frederiks transition is rounded in the presence of a bias field. The analogous curve for the magnetic director* (b) *is monotonic as a function of h, saturates at $\pi/2$ for $h_b = 0$, but merely tends to $\pi/2$ as $h \to \infty$ for $h_b \neq 0$.*

For high fields, the main balance defining γ_0 comes from the linear and quadratic terms; the fourth order terms can be neglected. With this assumption, we minimize (49). This yields $\gamma_0 = (2w_c/h_c(w))\,\theta_0$ for the relationship between γ_0 and θ_0, as well as an equation for $\gamma_0(h)$:

$$\gamma_0 = \frac{4}{\pi(h - h_c(w))} h_b. \tag{50}$$

There is thus no longer an unambiguous distinction between the high field $h > h_c(w)$ regime, for which $\gamma = \theta_0 = 0$, and the low field $h < h_c(w)$ regime, for which $\gamma_0 \neq \theta_0 \neq 0$. In the high field regime both θ and ψ differ from their zero-bias values 0 and $\pi/2$, respectively, by quantities which are proportional to the bias field, and appear for $h \gg h_c(w)$ to be heading for a divergence at $h = h_c^+(w)$. This divergence is, however, prevented by higher order terms in (49) which have been neglected here. On the other hand, there is no qualitative change in the low field response; the magnitude of the response is proportional to h_b.

Taking into account fourth order terms in (49), we find at $h = h_c(w)$

$$\gamma_0 \approx 4w \left[\frac{h_b}{\pi h_c(w)(h_c^3(w) - 2w^3)} \right]^{1/3}. \tag{51}$$

Here the magnitude of the response is proportional to $h_b^{1/3}$.

5. Ferroparticle segregation. In the theory as written so far, the ferroparticle density is kept constant. This corresponds to the limit $\eta = 1$ in (3), which in turn follows in the infinite temperature limit $t \to \infty$. However, inserting a finite value of t permits the ferroparticle density to respond so that more particles can migrate to regions where the ferronematic coupling energy is minimized. Interestingly (and apparently paradoxically) the constant η limit corresponds to inserting an apparently *infinite* rather than a zero term. We note that in the real problem t takes its physical value; it is useful nevertheless to treat it as a variable parameter in the theory.

We recall the figures of merit for the degree of segregation s defined in (4) and η_0 defined in (5) in section 2. Then $s = 0, 1$ are the limits of complete lack of segregation and segregation, respectively. The quantity s is a segregation order parameter, and it possesses a status comparable in the theory to the angular quantities θ_0 and ψ_0. In the low segregation limit we can expand the normalized colloidal density as follows:

$$\eta(z) = 1 - 2s\cos 2\pi z. \tag{52}$$

5.1. Zero bias field. The full free energy is given by (3):

$$F = \int_0^1 dz \left[\frac{1}{2}\left(\frac{d\theta}{dz}\right)^2 + \eta t \ln \eta - \eta h \sin\psi + \eta w \sin^2(\theta - \psi) \right],$$

subject to the constraint $\int_0^1 \eta(z)\,dz = 1$. The Euler–Lagrange equations are now

$$\frac{d^2\theta}{dz^2} - \eta w \sin(2(\theta-\psi)) = 0, \tag{53a}$$

$$h\cos\psi + w\sin(2(\theta-\psi)) = 0, \tag{53b}$$

$$t\ln\eta - \left(h\sin\psi - w\sin^2(\theta-\psi)\right) = \lambda, \tag{53c}$$

where λ is a Lagrange parameter which enforces density conservation. Equation (53a) modifies (14a) to the case in which segregation is allowed; (53b) is in fact identical to (14b) and is unchanged by the addition of segregation while (53c) is a new equation for the self-consistent degree of segregation.

The exact solution for $\eta(z)$ comes from inverting (53c) and enforcing the density conservation condition $\bar{\eta} = 1$. This solution is

$$\eta(z) = \frac{\exp\left\{\left[h\sin\psi - w\sin^2(\theta-\psi)\right]/t\right\}}{\int_0^1 dz \exp\left\{\left[h\sin\psi - w\sin^2(\theta-\psi)\right]/t\right\}}. \tag{54}$$

In general, this solution must be determined self-consistently with solutions for $\psi(z)$ and $\theta(z)$, and the detailed picture is complicated.

However, in the high temperature limit η is always small. We can then describe the degree of segregation using the order parameter s and perturb away from the infinite t solution using (4). In this limit

$$s = -\frac{1}{t}\int_0^1 dz \cos 2\pi z \left[h\sin\psi - w\sin^2(\theta-\psi)\right], \tag{55}$$

where values of θ and ψ are given by the infinite t limit. In general, we expect values of $s(h)$ to peak at intermediate h, for it is in these cases that θ and ψ change most across the cell.

A particularly interesting case occurs for high fields in the low ferronematic coupling $w < w_c$ regime. Here it is possible to include the segregation order parameter s in an extended Landau expansion closely analogous to (28). The parameter s couples to the variables θ_0, ψ_0 in this expansion. We recall (17): in this regime $\psi \approx \frac{\pi}{2} - \gamma_0 \sin\pi z$; $\theta(z) = \theta_0 \sin\pi z$.

We obtain the following free energy:

$$\begin{aligned} F - F_0 = \frac{1}{2}\Bigg\{ & \frac{2w_c^2}{2w_c + h}\left(\theta_0 - \frac{h}{2w_c}\gamma_0\right)^2 + \frac{(h - h_c(w))(w_c - w)}{2w_c + h}(\theta_0 + \gamma_0)^2 \\ & + \frac{w}{4}(\theta_0+\gamma_0)^4 - \frac{h}{32}\gamma_0^4 + 2s^2 t - s\left[w(\theta_0+\gamma_0)^2 - \frac{h}{2}\gamma_0^2\right]\Bigg\}. \end{aligned} \tag{56}$$

Equation (56) is (33) modified by some extra terms in s. The quadratic term in s comes from the $\eta \ln \eta$ term in the free energy (3). The linear term comes from the evident fact that the colloidal density is coupled linearly both to the nematic-magnetic coupling and to the coupling of the magnetic director with the field.

In the high field $h > h_c(w)$ limit there is no structure at all in the infinite t regime, for now $\psi(z) = \pi/2$ and $\theta(z) = 0$. As a result, (54) and (55) show that in this regime $s = 0$ and there is no segregation. However, in the low h limit there is structure in $\psi(z), \theta(z)$ and so $\eta(h) \neq 0$ for $h < h_c(w)$. As a result, the order parameters s and γ_0 couple in a Landau expansion of the free energy of the system close to $h_c(w)$. The coupling is constant, but the stabilizing term in s is proportional to t. It is this fact which gives rise to the general result $s \sim t^{-1}$.

However, the linear coupling between s and quadratic terms in the other order parameters does have profound consequences. This is a consequence of the Halperin–Lubensky–Ma theorem [24]. This theorem states that coupling a critical order parameter to a second noncritical order parameter can under some circumstances drive a continuous phase transition first-order.

To show what happens in this case, we minimize (56). We obtain (35) for the relationship between γ_0 and θ_0, and additional equations for s and γ_0:

$$s = \frac{hh_c}{16tw_c}\left[1 + \frac{4w_c^2 - hh_c}{h(2w_c + h_c)}\left(1 - \frac{h}{h_c}\right)\right]\gamma_0^2, \tag{57}$$

$$\gamma_0^2 = 8\left\{\left[\frac{(2w_c + h)^2}{2w_c(2w_c + h_c)} - \frac{h}{h_c}\right]s + \frac{2w_c + h}{2w_c + h_c}\left(1 - \frac{h}{h_c}\right)\right\}\left[\frac{(2w_c + h)^4}{2w_c^3(2w_c + h_c)} - \frac{h}{h_c}\right]^{-1}. \tag{58}$$

Substituting (35) and (57) into (56), we can evaluate the fourth order term in γ_0 at $h = h_c(w)$:

$$F - F_0 = \left[\frac{h_c^3(w)}{2}\left(\frac{1}{w^3} - \frac{1}{2\,t\,w_c^2}\right) - 1\right]\frac{h_c(w)}{64}\,\gamma_0^4. \tag{59}$$

The key point is that the coupling terms provide a negative definite contribution to the fourth order term. The negative magnitude increases as the coupling (which in this case is the temperature) decreases. Eventually, at a sufficiently low temperature the sign of the γ_0^4 term in the Landau expansion close to $h = h_c(w)$ changes. A negative γ_0^4 term signals that the continuous transition at $h = h_c(w)$ becomes first order.

From (59) we find that the tricritical point (i.e., the point at which the continuous phase transition becomes first order) occurs for

$$t_c(w) = \frac{w^3}{2w_c^2\left(1 - \dfrac{2w^3}{h_c^3(w)}\right)} \approx \frac{w_c}{2}\left(\frac{w}{w_c}\right)^3. \tag{60}$$

We can also look at the properties of $\gamma_0(h)$ and $s(h)$ *below* $h = h_c(w)$ but *above* $t = t_c(w)$. In this region the transition is still continuous but is approaching tricriticality. By substituting (58) into (57) and expanding s in powers of $(h_c(w) - h)$, we find the segregation order parameter

$$s = \frac{2w_c t_c(w)}{h_c^2(w)\,(t - t_c(w))}\,(h_c(w) - h) \tag{61}$$

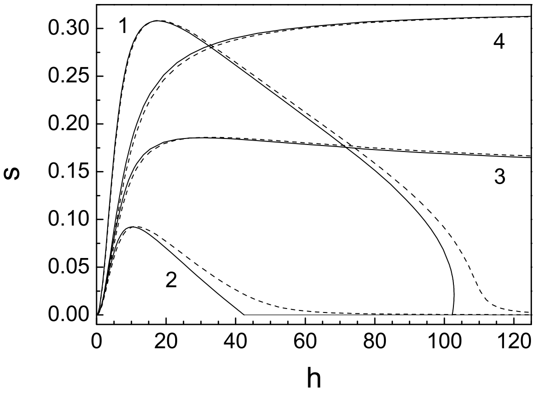

FIG. 9. *Behavior of the segregation order parameter as a function of the dimensionless external field in the three ferronematic coupling regimes. (Curve* 1*) Weak coupling regime;* $w = 4.5$*,* $t = 1.78 < t_c = 1.87$*,* $h_c = 102.1$*. (Curve* 2*) Weak coupling regime;* $w = 4$*,* $t > t_c = 1.32$*,* $h_c = 42.3$*. (Curve* 3*) Intermediate coupling regime;* $w = 5.5$*. (Curve* 4*) Strong coupling regime;* $w = 7$*.* $t = 3.85$ *in curves* 2–4*. Solid curves: No bias field. Dashed curves: Weak bias field;* $h_b = 0.1$ *in curve* 1 *and* $h_b = 0.4$ *in curves* 2–4*.*

in the lowest order approximation. We find that s goes *linearly* with $(h_c(w) - h)$ but that the linear coefficient diverges at the tricritical point.

Likewise, from (57) and (58) we find

$$\gamma_0^2 = \frac{32tw_c^2 t_c(w)}{h_c^4(w)(t - t_c(w))}(h_c(w) - h). \tag{62}$$

Here the characteristic square root behavior for γ_0 is maintained, but the coefficient of proportionality diverges with a square root divergence as the tricritical point is approached.

Beyond the tricritical point (i.e., $t < t_c(w)$), there are solutions for $h > h_c(w)$. These solutions belong to a van der Waals loop. Thus there are two qualitatively different behaviors, separated by a singularity at $t = t_c(w)$, with $w < w_c$. For $t > t_c(w)$ we have the inverse Frederiks transition described in detail in the sections above. For $t < t_c(w)$, on the other hand, the functional dependence of s, θ, and ψ develops a van der Waals loop. These cases are illustrated in Figure 9 (solid curves 2 and 1), where we show curves calculated numerically by minimizing the cell free energy (1a).

To show what happens in the intermediate and strong-coupling regimes, we rewrite (56) in the form

$$\begin{aligned} F - F_0 = \frac{1}{2}\Bigg\{ &\frac{2w_c w}{2w_c + h}\left[\frac{w_c}{w}\left(\theta_0 - \frac{h}{2w_c}\gamma_0\right)^2 - \left(1 + h\frac{w - w_c}{2w_c w}\right)(\theta_0 + \gamma_0)^2\right] \\ &+ \frac{w}{4}(\theta_0 + \gamma_0)^4 - \frac{h}{32}\gamma_0^4 + 2s^2 t + s\left[\frac{h}{2}\gamma_0^2 - w(\theta_0 + \gamma_0)^2\right]\Bigg\}, \end{aligned} \tag{63}$$

where $w > w_c$. We now minimize (63). For $t \gg 1$ this yields (35) for the relationship between γ_0 and θ_0. The equations for s and θ_0 are now

$$s = \frac{1}{4t}\left[w\left(1+\frac{2w_c}{h}\right)^2 - \frac{2w_c^2}{h}\right]\theta_0^2, \tag{64a}$$

$$\theta_0^2 = \frac{2\left(1-\frac{w_c}{w}+\frac{2w_c}{h}\right)\left(1+\frac{2w_c}{h}\right)}{\left(1+\frac{2w_c}{h}\right)^4 - \frac{2w_c^4}{wh^3} - \frac{w}{2t}\left[\left(1+\frac{2w_c}{h}\right)^2 - \frac{2w_c^2}{wh}\right]^2}. \tag{64b}$$

From (64a) and (64b) one can obtain to lowest order in h^{-1}

$$s = \frac{w-w_c}{2t-w}\left[1+\frac{2w_c^2}{wh}\left(\frac{2w}{w-2t} - \frac{w_c}{w_c-w}\right)\right], \tag{65a}$$

$$\theta_0^2 = \frac{4t}{2t-w}\left[\frac{w-w_c}{w} + \frac{2w_c}{wh}\left(5w_c - 2w + \frac{2w_c(2t-w_c)}{w-2t}\right)\right]. \tag{65b}$$

Equations (65a) and (65b) are valid in the high field limit if $t > w - w_c/2$ (by definition, $s \leq 1$). In the limit $t \to \infty$, (65b) reduces to its no-segregation limit (41). It follows from (65b) that the boundary w_{c2} of the intermediate coupling regime at finite temperature reduces to

$$w_{c2}(t) = t + \frac{5}{4}w_c - \frac{1}{4}\left(16t^2 - 8tw_c + 9w_c^2\right)^{1/2} \approx \frac{3}{2}\,w_c\left(1-\frac{w_c}{6t}\right), \tag{66}$$

and this regime takes place at $w_c < w < w_{c2}(t)$. The strong coupling regime should begin at $w_{c2}(t)$. It is seen from (64a) that $s(h)$ has a maximum if $w_c < w_{sc}(t)$, where

$$w_{sc}(t) = \frac{w_c}{4}\left(1+\sqrt{1+\frac{16t}{w_c}}\right). \tag{67}$$

The behavior of the segregation order parameter in the intermediate and strong-coupling regimes is shown in Figure 9 (curves 3 and 4).

5.2. Nonzero bias field. For the nonzero bias field, the free energy can be expressed as

$$\begin{aligned} F - F_0 = \frac{1}{2}\Bigg\{ & \frac{2w_c w}{2w_c+h}\left[\frac{w_c}{w}\left(\theta_0 - \frac{h}{2w_c}\gamma_0\right)^2 - \left(1+h\frac{w-w_c}{2w_c w}\right)(\theta_0+\gamma_0)^2\right] \\ & - \frac{4h_b}{\pi}\,\gamma_0 + \frac{4}{9\pi}h_b\gamma_0^3 - \frac{8h_b}{3\pi}\,\gamma_0 s + \frac{w}{4}(\theta_0+\gamma_0)^4 + 2ts^2 \\ & - w(\theta_0+\gamma_0)^2 s + \frac{h}{2}\,\gamma_0^2 s - \frac{h}{32}\,\gamma_0^4\Bigg\}. \end{aligned} \tag{68}$$

Here (68) is (56) modified by some extra terms in h_b. Minimizing this equation, we obtain (35) for the relationship between γ_0 and θ_0. For high fields we can find the relationship between s and γ_0:

$$s = \frac{1}{8t}\left\{\frac{16}{3\pi}\,h_b\gamma_0 - \left[h - 2w\left(1+\frac{h}{2w_c}\right)^2\right]\gamma_0^2\right\}. \tag{69}$$

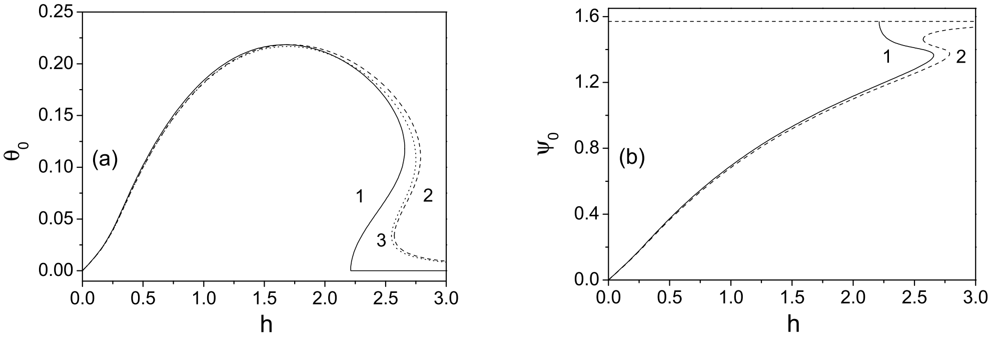

FIG. 10. (a) *Director distortion for weak ferronematic coupling at a finite temperature as a function of the external field, showing the development of a van der Waals loop at the inverse Frederiks transition. In both curves* $t = 0.005$*,* $w = 0.9$ *(*$t < t_c \approx 0.018$*). Curve* 1*: No bias field;* $h_b = 0$*. Curve* 2*: Weak bias field;* $h_b = 0.025$*. The analogous curve for the magnetic director* (b) *is nonmonotonic as a function of* h*, but saturates at* $\pi/2$ *for* $h_b = 0$*, but merely tends to* $\pi/2$ *as* $h \to \infty$ *for* $h_b \neq 0$*. Curve* 3*: The effect of small diamagnetic anisotropy (*$\kappa = \frac{1}{2}\chi_a K/(\bar{f}\bar{M}D)^2 = 0.015$*).*

A solution for θ_0 can be obtained from a cubic equation in which linear and cubic terms play an important role. However, this equation is too complicated and is not presented here.

The dashed curve 2 in Figure 9 shows that the bias field rounds the re-entrant Frederiks transition. The van der Waals loop is retained at the small bias field (not shown in the figure), but no longer occurs at a sufficiently high bias field (dashed curve 1).

We now make remarks concerning the importance of the bias field. The role of the bias field in the x direction is to restrict the nematic and magnetic directors to the x-z plane. In the absence of the bias field but in high applied fields, the system will *choose* a (broken symmetry) plane in which to orient. A detailed analysis requires a full treatment of the local statistical mechanics of the ferronematic ordering and will be discussed elsewhere.

We have analyzed in detail the behavior of a ferronematic system at high dimensionless temperatures ($t \geq 1$). However, our analysis is restricted to a weak bias field and runs into difficulties if the magnetic particles are not well aligned. Our segregation parameter s is a useful tool only for high t.

In experiments, however, it is more common to encounter a low-coupling regime at low t, and it is this regime which is of prime interest for ferronematic applications. However, to investigate the segregation effect we now have to use the quantity η, which can take values much larger than unity. Furthermore, the asymptotic analysis gives little insight into the system properties at large deviations from the initial alignment. We thus resort to numerical studies. Figures 10–13 show aspects of the system behavior in the low-coupling regime at low temperature t for system parameter values in the experimental region.

In Figures 10 and 11 we illustrate the orientational behavior of the nematic and magnetic directors and the quantity η in the varying magnetic field in the middle of the cell. The figures show the development of the van der Waals loop.

We remark that the van der Waals loop, and thus the first order transition between a highly segregated low field phase and a slightly segregated high field case, is retained even when a bias field is introduced. In this case, however, if there is no first order

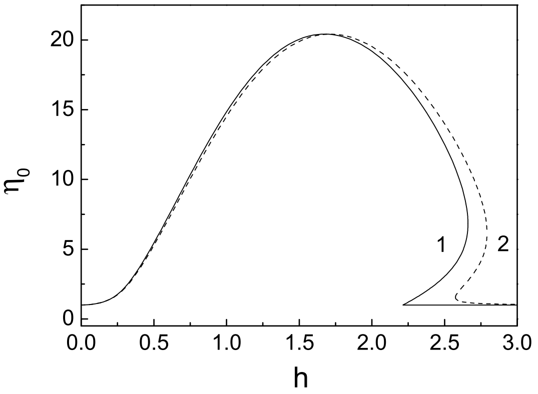

FIG. 11. *Ratio of the local to the mean volume particle fraction for weak ferronematic coupling at a finite temperature as a function of the external field, showing the development of a van der Waals loop at the inverse Frederiks transition. transition, then the continuous transition found in the zero-bias-field case disappears and is replaced by smooth high field behavior (curve 2 in Figures 10 and 11). In fact, we have found numerical evidence for van der Waals loops in previous calculations [14, 15]. This analysis presented here provides for the first time a consistent explanation.

We also show, in Figures 12 and 13, some examples of the profiles of the nematic and magnetic directors and of magnetic colloid concentration profiles through the cell. In these examples the system is in the weak coupling regime; as the field is increased the system exhibits a van der Waals loop and a consequent first order phase. We recall that in this regime, for low fields, the degree of nematic distortion, represented by $\theta(1/2) = \theta_{\max}$, goes through a maximum before tumbling in a discontinuous way and subsequently decreasing to zero in the limit of the high field.

The profile of the magnetic director in Figure 12(a) (given by the angle ψ) shows a change of regime from low fields to high fields. For low fields the profile is concave-down (i.e., $\psi(1/2) > \psi_s$), whereas for high fields it is concave-up ($\psi(1/2) < \psi_s$). We

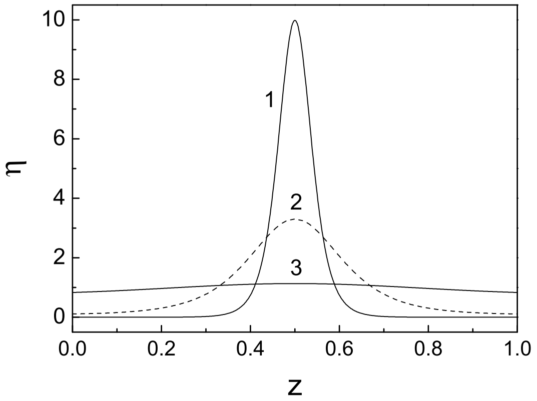

FIG. 13. *Concentration profiles at* $t = 0.005$*,* $w = 0.9$*, and* $h = 2.7$*,* $h_b = 0.025$*. Curves* 1*–*3 *correspond to the upper, middle (unstable), and lower parts of the van der Waals loop, respectively.*

have seen this behavior above in the non-bias-field case in Figure 4(b). The change from concave-down to concave-up profiles occurs near the peaks in $\theta_{\max}$ (Figure 10(a)) and $\eta_{\max}$ (Figure 11) ($h_{\max} = 1.68$). From this figure we note a well-defined intermediate concave-convex profile. The orientational profile of the nematic director θ is concave-down everywhere as a result of the boundary conditions on θ. However, we note that the behavior of $\theta(z)$ is unlike that in conventional nematics. In conventional nematics the nematic director can saturate over most of the cell apart from a region very close to the boundary. Here, however, we see a constant (absolute) *gradient* in θ, apart from very close to the center of the cell, where θ abruptly changes its gradient.

We give here a brief semiquantitative discussion of the changing properties of $\psi(z)$. As h is increased, the magnetic director profile begins to change when $\psi(0) = \psi(1) = \psi_s$ reaches the value $\frac{\pi}{4}$. Using (44b) it can be shown that this occurs at $h^{**} = h_b + \sqrt{2}w$. For $h < h^{**}$, $\frac{d\psi(0)}{dz} > 0$ and ψ increases away from the boundary. At h^{**}, $\frac{d\psi(0)}{dz} = 0$, and for $h > h^{**}$, $\frac{d\psi(0)}{dz} < 0$; ψ now *decreases* away from the boundary. There is then a narrow interval in h over which the turning points in $\psi(z)$ move from the edge of the cell toward its center. In this interval for $0 < z < z_c(h)$, $\frac{d\psi}{dz} < 0$, whereas for $z_c < z < \frac{1}{2}$, $\frac{d\psi}{dz} > 0$, with $\psi(z) = \psi(1-z)$ everywhere. Eventually, for $h > h^{\dagger}$ (which depends in specific cases on h_b), z_c reaches $z_c = \frac{1}{2}$, and for $h > h^{\dagger}$, $\psi(1/2) < \psi_s$, and the behavior of $\psi(z)$ is monotonic in the interval $0 \leq \frac{1}{2}$.[1]

The inverse Frederiks effect can also be interpreted in terms of a force law. The torque of the magnetic particles on the nematic matrix is not a monotonic function of the angle $\alpha = \pi/2 - (\psi - \theta)$ between the directors and reaches its maximum value at $\alpha \approx \pi/4$.

Finally, in this section, we note that it seems likely that the transition to a ferronematically distorted state actually occurs first through a first order transition at lower fields. Physical values of t are lower than unity; the result is that our analysis remains true in the high field limit but is modified in low field limit. Similarly, we

[1] Further computation shows that the change in the profiles $\psi(z)$ is connected with an ambiguity of the dependence $\theta(h,\psi)$ when $\psi_s > \pi/4$ or $h > h_b + \sqrt{2}w$. There are two branches, but only one of these satisfies the boundary condition $\theta_s = 0$. On this branch the angle θ decreases with h and hence with ψ, leading to the inverse Frederiks effect.

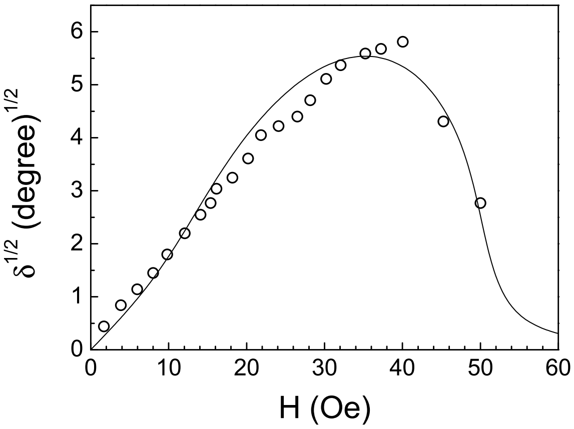

Fig. 14. *Experimental data by Chen and Amer* [3] *of the square root of the phase difference versus the magnetic field strength (open circles) and the theoretical curve obtained by the numerical minimization of the cell free energy equations* (1a) *and* (1b).

find that in dimensionless units the bias field required for the analysis presented here to hold true is $h_b < t$. Unsurprisingly, at low temperatures, a small bias field suffices to saturate the local magnetic order.

Figures 12(b) and 13 show the profiles in the magnetic field range where the van der Waals loop is developed. All profiles are symmetrical due to equal nematic anchoring strengths at the walls of the cell.

6. Experimental considerations. To make contact with the experiment [9, 17, 18, 21], we consider a cell of thickness $D = 125$ μm and suppose magnetic particles of $L = 0.2$ μm, $d = L/3$. Plausible mean packing fractions are in the range $\bar{f} \approx 2 \times 10^{-7} - 6 \times 10^{-5}$, with magnetite particles for which $\bar{M} = 485$ G. The quantity $W_p d$ is a quantity with the dimensions of an anchoring energy W. Naive microscopic theory suggests that this might be expected to be of the same order of magnitude as the anchoring energy at the surface of the colloidal particle. In this spirit, we expect $W_p\, d \approx 10^{-3} - 10^{-1}$ erg/cm^2. Finally, for 5CB at $T = 25^o$C, $K \sim 5.3 \times 10^{-7}$ dyn. The resulting dimensionless quantities are in the range $w \approx 9 \times 10^{-3} - 2.7 \times 10^{2}$ and $t \approx 3.5 \times 10^{-3} - 1$.

To obtain higher temperatures t, in order that real experiments more closely match our ideal systems, it would be necessary to use thicker cells and higher particle concentrations. For example, with a cell of thickness $D = 460$ μm, magnetic particles with $L = 0.15$ μm, $d = L/3$, and a mean volume fraction of $f = 6.9 \times 10^{-6}$ ($c = 2.3 \times 10^{10}$ cm^{-3}), we have $t = 3.85$.

The size and the aspect ratio we consider for the colloidal ferromagnetic particles are consistent with these particles being in a single-domain magnetic state [22]. We suppose that the magnetic grains are coated by suitable surfactant [3, 9, 23] to prevent coagulation. This theoretical idealization has in practice presented problems for experimentalists, but we do not address these here. Finally, we impose homeotropic boundary conditions at the particle surfaces.

We show in Figure 14 a fit of the experimental data by Chen and Amer [3] to our theory. The field-induced molecular reorientation of the FN was found in [3] by measuring the corresponding induced change in phase difference

$$\delta = \frac{2\pi}{\lambda}\int_0^D \left[\frac{n_o n_e}{(n_e^2\cos^2\theta + n_o^2\sin^2\theta)^{1/2}} - n_o\right] dz, \tag{70}$$

where λ is the wavelength of the incident laser beam and n_o, n_e are, respectively, the ordinary and extraordinary refractive indices of the sample. The continuous curve is calculated for $\lambda = 632.8$ nm, the width of an FN cell $D = 337$ μm, $H_b = 0.6$ Oe, $M_s = 340$ G (γ-Fe$_2$O$_3$ magnetic particles), $K_3 = 7.63 \times 10^{-7}$dyn, $K_1 = 6 \times 10^{-7}$dyn, $n_o = 1.5443$, $n_e = 1.7582$, and $\chi_a = 0.97 \times 10^{-7}$ (MBBA, $T = 25^o$C [17]). The parameters of the best fit are $L = 0.47$ μm, $L/d = 7.7$ (close to that in [3]), $W_p\, d = 4.9 \times 10^{-2}$ erg/cm^2, and $\bar{f} = 1.83 \times 10^{-8}$. For the above parameter values, $w \approx 0.22$ (low coupling regime). A clear decrease in δ for $H > 40$ Oe is in agreement with our prediction of an inverse Frederiks effect.

We note [10] that the ferronematic is expected to exhibit collective behavior only for colloidal particle concentrations exceeding a critical value w_{cr}, with $w_{cr} \sim 1/2$. However, our estimate for w is slightly below 1/2. There is thus an apparent paradox that results can be fitted to a model, but only with parameters for which the microscopic foundation of the model is weak. The solution to the paradox is not entirely clear, but it is possible to speculate. Among possible weaknesses in the model are (a) a failure to take account of the polydispersity in size of magnetic particles and (b) the use of a simple phenomenological Rapini–Papoular expression for the anchoring energy [10].

The best fit of the birefringence gives the value of mean particle concentration $\bar{c}$ as about 7% of the total concentration reported in [3]. We speculate that this may be related to a partial coagulation of the magnetic particles during the preparation of the ferronematic, i.e., a formation of large multiparticle aggregates whose total magnetic moment is close to zero [11]. These aggregates would be insensitive to a weak external magnetic field, thus reducing the birefringence effect.

7. Discussion. In this paper we have carried out an exhaustive analysis of the ordering processes which take place in a Frederiks-like cell when the liquid crystal is doped by magnetic colloidal particles. These systems are otherwise known as ferronematics. The original motivation for introducing the magnetic particles is to amplify the otherwise low magnetic response. The magnetic Frederiks transition would then be observable at experimentally accessible fields, and the effect could be utilized in magnetically switched liquid crystal devices.

Our calculations show that the simple amplification picture outlined in the last paragraph is at best a great simplification. The mathematical structure of these ferronematic systems seems extremely simple to formulate. There is also an interesting homogenization problem concerned with determining the magnitude of the effective magnetic-nematic director interaction which we have not addressed here, but which is under study elsewhere [25]. The simple formulation nevertheless exhibits a complex and rich set of behaviors as a function of magnetic field, colloidal particle structure, and colloidal concentration.

Although these behaviors can be analyzed easily using computational solutions, we have sought here where possible to examine the structural predictions of the model using mathematical tools. Without this perspective, the model predictions may look counterintuitive. A particular advantage of the method presented here, as opposed to earlier attempts at the same problem, is a change of scaling. The result of this apparently trivial scaling change is that temperature effects on the colloidal density can be added as a perturbation rather than present themselves as an essential element in the theory.

We find that low magnetic fields do indeed produce a switching analogous to the switching in Frederiks cells in an electric field. However, if the colloidal particles are insufficiently anisotropic, or if their volume fraction is too low, the alignment at low fields is followed by a disorientation process at high fields. In this circumstance, even though the magnetic particles are ordered by the field, the nematic order is dominated by the boundaries at high and low fields, although not at intermediate fields. We have further shown that a first-order disorientation transition is expected as a result of coupling between the orientation and segregation of the magnetic particles into regions where the magnetic force is highest.

The key difference between the ferronematic-induced effects and the direct magnetic effects is the fact that at high fields the magnitude of the ferronematic effects saturates. For very high fields, the director is more strongly tied to the magnetic field than it is to the nematic director. Our treatment completely ignores the direct interaction between the nematic and the magnetic fields. This is normally down by several orders of magnitude, but in the very high field limit, this will no longer be the case. In this very high field limit, our high field asymptotics would need to be modified. In extreme cases, where the direct and induced fields compete, there is further potentially interesting very high field physics. But we anticipate that this will occur at experimentally inaccessible magnetic fields. In any event, we postpone this to future work.

Finally, we note again the paucity of experimental data on these systems. This is a result of the difficulties of aligning magnetic particles themselves at higher temperatures, and also of preventing van der Waals forces from forcing irreversible colloidal aggregation. Attempts in the physics and engineering communities to make progress in this area continue. If these attempts bear fruit, there are further interesting mathematical problems to attack in this area. The most obvious of these is the dynamics of the ordering process itself, which, because of the nature of the couple exerted by the magnetic field on the local dipole moment, could in principle lead to a slow and oscillatory response. We postpone this problem to a future paper.

MODELS OF VIRULENT PHAGE GROWTH WITH APPLICATION TO PHAGE THERAPY*

HAL L. SMITH†

Abstract. We modify existing models of bacteriophage growth on an exponentially growing bacterial population by including (1) density dependent phage attack rates and (2) loss to phage due to adsorption to both infected and uninfected bacteria. The effects of these modifications on key pharmacokinetic parameters associated with phage therapy are examined. More general phage growth models are explored which account for infection-age of bacteria, bacteria-phage complex formation, and decoupling phage progeny release from host cell lysis.

Key words. phage therapy, infection-age structure, multiple adsorptions, bacteria-phage complex, passive therapy, active therapy, proliferation threshold

1. Introduction.

As pathogenic bacteria have increasingly become resistant to our arsenal of antibiotics, there has been renewed interest in the use of bacteriophage to control bacterial infections [13, 11, 12, 14, 15, 23]. Bacteriophage, phage for short, are viruses which prey on bacteria. Almost as soon as they were discovered there was interest in using them to control infections and bacterial contamination. The history of early attempts to use them for such purposes during the last century is fascinating [13, 12, 6]. It is not hard to see the potential in phage therapy, for, unlike chemotherapy, which simply results in the death of a susceptible bacteria, phage therapy results in the death of the host cell and the release of hundreds more lethal phage. The author found the review articles [13, 12] on phage therapy useful.

Mathematical modeling has long played a significant role in the study of phage-bacterial interactions for ecological reasons [2, 22, 17, 9] as well as for medical ones [3, 11, 12, 10, 14, 15, 23]. See also the additional references in these papers. The reasons for this are obvious—among them being the difficulty of carrying out controlled experiments in vivo and the novelty of a self-replicating therapeutic agent.

It will be useful to briefly review the life cycle of a virulent phage and some of the associated terminology for later use. Typically, phage specialize to attack only one or a few strains of a bacterial host whose cell surface contains an appropriate binding site. Phage attach to a preferred binding site and then inject their genetic material, DNA or RNA depending on the phage, and perhaps some enzymes into the cell, which thereafter is called an infected cell. In the case of virulent (also called lytic) phage, the infected host cell machinery is then immediately co-opted to make new phage particles which are subsequently released in a burst when phage enzymes cause the host cell to lyse and the cycle repeats. The latent period is the time between phage-host binding and subsequent release of the phage at cell lysis, usually on the order of 20 minutes to an hour depending on the host-phage system. The burst size, ranging between several to thousands, is a measure of the average number of phage

progeny resulting from a single infected host cell and also depends on the host-phage system.

This paper addresses some issues that seem not to have been explored in the mathematical modeling of bacteriophage growth that may be important in phage therapy. First, one finds that mass action kinetics, e.g., bxv, where x denotes the concentration of uninfected bacteria and v is the concentration of phage, is invariably used to model both the phage attack rate on uninfected bacteria and the rate of loss of free phage due to attachment [9, 10, 14, 15, 23]. Weld, Butts, and Heinemann [23] experimentally measured the "adsorption rate" b in the context of the rate of loss of phage (number of adsorbed phage per free phage per bacterium per minute), found a wide variation of values, and noted that it decreased as the sum of phage and bacterial densities $(x + y + v)$ increased, where y is the density of infected bacteria.

In this paper, we will argue that the phage attack rate and the rate of phage loss due to attachment are distinct. As the former involves attachment and injection of the one primary (first to inject) phage while the latter takes account of all secondary phage that attach to a cell, this should not be unexpected. We propose that the phage attack rate deviates from bxv when phage densities are large due to the higher likelihood of multiple phage binding to a cell between the time of initial binding and lysing and therefore to a lower impact per phage particle. Mathematically, this will be achieved here not by making b dependent on the densities but by adding an extra multiplicative term to the phage attack rate which depends on the phage density. Specifically, our analysis leads to the reduced phage attack rate

$$\frac{bxv}{F_N(cv)}, \quad c = b/\rho, \tag{1.1}$$

where $1/\rho$ denotes the injection time, the time between binding of a phage to a host bacteria and subsequent injection of genetic material into the host, N denotes the number of binding sites for phage per host, and

$$F_N(u) = 1 + \frac{u}{1+u} + \frac{u^2}{(1+u)(2+u)} + \cdots + \frac{u^N}{(1+u)(2+u)\cdots(N-1+u)N}.$$

Observe that $F_N(u) > 1$, so the attack rate is strictly less than bxv. Despite appearances, $F_N(u)$ depends rather weakly on N; $F_3(u)$ is a good approximation of $F_{100}(u)$ on $0 < u < 5$. To lowest order, $F_N(u) \approx 1 + u$, so the effect of the term cv in (1.1) is nonnegligible precisely when $bv \times \frac{1}{\rho}$ is nonnegligible compared to one. bv/ρ gives the number of potential irreversible phage attachments that could be formed with a typical host cell during the injection time. A rough estimate of $c = O(10^{-8})$ for a strain of *E. coli* and phage implies that the term cv in (1.1) is significant when $v \geq O(10^7)$, well within the range used in experimental and theoretical studies.

Second, it seems to us that the rate of loss of phage is underestimated in existing models and moreover that the effect of this underestimation may be significant for bacteriophage therapy. For example, if we assume that a phage cannot detect the state (uninfected or infected) of the host cell to which it binds, then one should not ignore the loss of the phage due to "wasted attacks" on already infected hosts. We take into account that a host cell has a multiplicity of potential phage binding sites on its surface, more than one of which may be simultaneously bound by phage. This leads, with good approximation, to the expression

$$-bv(x + y) \tag{1.2}$$

for the rate of phage loss due to attachment. As a result our model differs from others in the literature in that the phage loss rate due to attachment differs from the phage attack rate on the host.

Finally, most existing models either assume an exponentially distributed latent period [14, 15] leading to ordinary differential equations or assume a fixed-length latent period which results in delay differential equations [9, 10, 23]. Here, in the appendix, we explore a more general model, where infected cells are structured by age-since-injection and where the release rate of phage progeny may be either a continuous "budding off" or an abrupt burst at host lysis typical of virulent phage. We also allow for variable phage progeny size by decoupling cell death from the release of progeny. This structured model may lead to ordinary differential equations, to delay equations, or to more general integro-differential equations depending on whether the infected cell mortality rate is independent of age-since-injection, sharply dependent on it, or a more smooth nonconstant function of it. However, much of our effort is devoted to a delay differential equation model resulting from the assumption of a fixed-length latent period followed by a discrete burst of phage. This model is similar to models considered by Lenski and Levin [10] and by Beretta and Kuang [2] except for the modifications already noted. Our treatment of the initial conditions and their effect during the initial latent period is more natural than in [10, 2], and it facilitates the consideration of a proliferation threshold for phage therapy.

We show that the density dependent attack rate (1.1) and the modified rate of phage loss due to attachment (1.2) result in potentially significant modifications in key pharmacokinetic quantities associated with active phage therapy first identified by Payne and Jansen [14, 15]. Unlike passive therapy which relies on a massive dose of phage to kill bacteria in only one phage generation, active therapy does not need such a large dose since it relies on second and third generation phage for its success. Payne and Jansen argued for the existence of a threshold number of uninfected host cells required to support the amplification in phage numbers from one phage generation to the next (the phage reproductive number exceeds one). This idea has generated some controversy in the field [7, 8, 13, 16] due to a misunderstanding of its meaning. However, it is certainly valid for the mathematical models of phage growth treated in [14, 23]. We derive a threshold condition for phage proliferation which reduces to one comparable to Payne and Jansen's when total bacterial density is not too large but changes character when densities become large.

2. Phage growth on an exponentially growing host population: Fixed-length latent period. In the appendix we derive a general model of phage growth which includes the one described below as a special case. Here, we make the following assumptions:

(a) Bacteria first injected by phage at time $t-\tau$ lyse (die) at time t.

(b) Uninfected host cells grow at rate a; infected cells do not grow.

(c) Free phage, those unattached to host cells, decay or wash out at rate m.

(d) Bacteria are removed by washout or death unrelated to phage at rate p.

(e) Phage do not distinguish between infected and uninfected cells with regard to attachment and injection.

(f) The rate of release of phage progeny from an infected host of infection-age (time since injection) $s \in [0, \tau]$ is $\eta(s)$. In particular, it is independent of the number of phage injections.

In other words, we assume the latent period has duration precisely τ units of time as in [2, 23, 10]; this is relaxed in the more general model in the appendix. As we are primarily motivated by applications to phage therapy where one is interested in treating the initial phase of a bacterial infection which, in the worst case, is characterized by an exponentially growing pathogen, the model equations do not include density effects on host growth such as in [10, 2]. Payne and Jansen [14, 15] assume that infected hosts grow at the same rate as uninfected hosts, but we follow Weld, Butts, and Heinemann [23] and Abedon, Herschler, and Stopar [1], who suggest that infected host cells do not grow. According to (f), the integral

$$L = \int_0^\tau \eta(s)ds$$

gives the phage progeny from an infected host assuming that it survives the latent period. The general release rate $\eta(s)$ easily accommodates both what is sometimes called "budding" of phage progeny from a living host cell as well as a "burst" of phage progeny released at cell lysis. Assumption (e) is used by Schrag and Mittler in [18] in an ecological setting. We are unaware of any evidence supporting or refuting it. Our assumption in (f) that the number of progeny is independent of the number of phage injections is consistent with observations of Stent [20, p. 74], who remarks that "latent period and burst size do not, however, depend in any very striking way on the number of phage particles with which each bacterial cell has been infected." However, he later mentions lysis inhibition that occurs in the infected host of certain T-even phage where superinfection late in the latent stage may substantially prolong the latent stage and enhance the burst size. See also [1]. Hypothesis (d) is rather standard [14, 23].

Let x denote the density of uninfected host bacteria, y the density of phage-infected bacteria, and v phage density. The expression (1.1) is used for the phage attack rate rather than the usual mass action rate bxv for the reasons described in the introduction. The corresponding loss rate for phage due to attachment to host cells is modeled by (1.2) to account for wasted attachments following (e) above. We stress that both these rates are derived in the appendix.

Initial conditions at time $t = 0$ must take account of the infection-age of the infected cells since these cells may have been infected at different times in the past. Moreover, it is reasonable to assume that the initial set of infected cells was obtained in a manner independent of the initial set of uninfected cells and phage. Therefore, we prescribe the initial uninfected host density $x(0)$, the initial phage density $v(0)$, and the initial distribution of infected cells:

$$U_0(s), \ 0 \le s \le \tau,$$

where s denotes the age since infection (injection). Thus, for $0 < c < d < \tau$, $\int_c^d U_0(s)ds$ denotes the number of infected cells with infection-age between c and d. These cells, infected at times between $t = -d$ and $t = -c$, will, if not washed out, lyse at times between $\tau - d$ and $\tau - c$.

In our view, the manner in which initial data are formulated here is more natural than that in [2], where the past history of phage and uninfected host cells are prescribed over a latent period, assuming that the initial population of infected cells at $t = 0$ arises through infection of the initial host population by the initial phage.

For the initial latent period, the equations of the model are given by

$$
\begin{aligned}
&\frac{dx}{dt} = ax - \frac{bxv}{F_N(cv)} - px,\\
&y(t) = \int_0^t \frac{bx(t-s)v(t-s)}{F_N(cv(t-s))} e^{-ps} ds + e^{-pt} \int_0^{\tau - t} U_0(s) ds, \quad 0 \le t \le \tau,\\
&\frac{dv}{dt} = -b(x+y)v - mv + \int_0^t \frac{bx(t-s)v(t-s)}{F_N(cv(t-s))} e^{-ps} \eta(s) ds\\
&\qquad + e^{-pt} \int_0^{\tau - t} U_0(s) \eta(s+t) ds.
\end{aligned} \tag{2.1}
$$

Observe that infected cells at time $t < \tau$ arise either from cells infected after $t = 0$ or from surviving cells from the founding population U_0. The first integral in the equation for y gives the number of cells infected after $t = 0$ which survive washout to be alive at time t. The second gives the survivors from the founding population still alive at time t; clearly these must have had age less than $\tau - t$ in order to be alive at time t. A similar analysis explains the two integrals in the equation for phage: the first integral gives phage progeny issuing from cells infected after $t = 0$, and the second integral gives phage progeny issuing from survivors from the founding population of infected cells.

In all our simulations and in most experimental setups, the founding population of infected cells is taken to vanish, $U_0 = 0$, simplifying the equations during the initial latent period. Indeed, the natural initial conditions for phage therapy correspond to administering a dose of phage to an exponentially growing bacterial population that has not been exposed to phage, and therefore there are initially no infected hosts of any age of infection. This does not mean that our care in formulating the initial conditions is wasted since we will have reason to consider nonzero U_0 in our later discussion related to phage therapy.

After the latent period, the founding population of infected cells have all lysed and the equations are simpler:

$$
\begin{aligned}
&\frac{dx}{dt} = ax - \frac{bxv}{F_N(cv)} - px,\\
&y(t) = \int_{t-\tau}^t \frac{bx(s)v(s)}{F_N(cv(s))} e^{-p(t-s)} ds, \quad t > \tau,\\
&\frac{dv}{dt} = \int_0^\tau e^{-ps} \frac{bx(t-s)v(t-s)}{F_N(cv(t-s))} \eta(s) ds - b(x+y)v - mv.
\end{aligned} \tag{2.2}
$$

Key properties of the function $F_N(u)$ are given in the lemma below, which is proved in the appendix. As Figure 2.1 shows, these functions depend rather weakly on N for small u.

LEMMA 2.1. *The functions* $F_N : [0, \infty) \to [1, \infty)$ *satisfy the following:*

1. $\frac{d}{du} \frac{u}{F_N(u)} > 0$ *and* $\frac{d}{du} F_N(u) > 0$,
2. $\frac{u}{F_N(u)} \to N$ *as* $u \to \infty$, *and*
3. $F_\infty(u) \le F_{N+1} \le F_N(u) \le F_1(u) = 1 + u$,

where

$$
F_\infty(u) = 1 + \sum_{n=1}^{\infty} \prod_{i=1}^{n} \frac{u}{i+u}.
$$

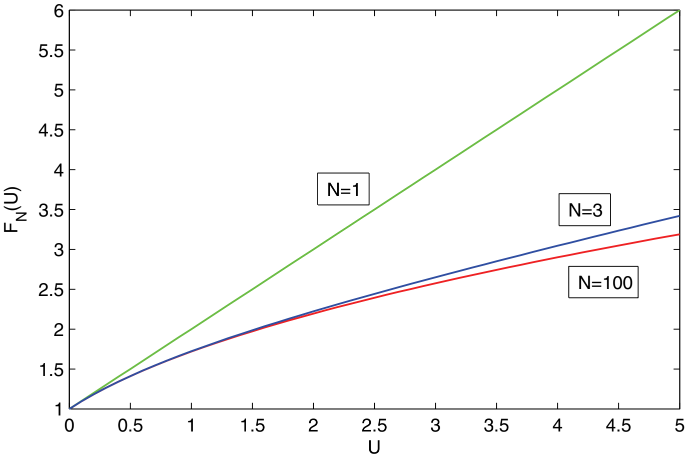

FIG. 2.1. *Plot of $F_N(u)$ versus u for $N = 1, 3, 100$.*

The biological implications of these assertions are not surprising. The fact that $F_N(u) > 1$ for $u > 0$ means that the attack rate (1.1) is smaller than the corresponding mass action rate bxv. According to assertion 3, it increases with N, the number of host binding sites; more sites means the potential for more attached phage, which decreases the time to injection. The first assertions ensure that the phage attack rate increases with increasing phage density v. The second indicates that the maximum effect of phage on the specific growth rate of bacteria (x'/x) is bN/c. Observe that $F_3(2) \approx F_{100}(2) > 2$, so the attack rate is less than half the corresponding mass action rate bxv when $cv > 2$.

For $t > \tau$, the y equation can be differentiated to yield

$$y' = \frac{bxv}{F_N(cv)} - e^{-p\tau}\frac{bx_\tau v_\tau}{F_N(cv_\tau)} - py, \tag{2.3}$$

where $x_\tau = x(t-\tau)$, $v_\tau = v(t-\tau)$. As noted above, the natural initial conditions for phage therapy are to administer a dose of phage to an exponentially growing bacterial population which has not previously been exposed to phage. Thus, $U_0 \equiv 0$ and the differentiated form of the y equation during the initial latent period differs from (2.3) in that the second term is removed.

Well-posedness issues related to our system (2.1)–(2.2) can be treated using results in [5]. Corollary 2.2 of Chapter 12 can be used to prove the existence and uniqueness of a maximally defined continuous solution corresponding to nonnegative initial data if, for example, U_0 is integrable and η is essentially bounded. Easy arguments give that the solution is nonnegative, and prior bounds show that it is globally defined.

If the rate of phage progeny release is highly peaked about the age at lysis τ, it is reasonable to assume that cells produce L-phage exactly on reaching age τ:

$$\eta(s) = L\delta(s-\tau), \tag{2.4}$$

where $\delta(r)$ is the Dirac impulse function with unit mass concentrated at $r = 0$. In that case, the equation for phage simplifies for the latent period to

$$\frac{dv}{dt} = -b(x+y)v - mv + Le^{-pt}U_0(\tau - t), \quad 0 < t \le \tau, \tag{2.5}$$

and thereafter to

$$\frac{dv}{dt} = Le^{-p\tau}\frac{bx_\tau v_\tau}{F_N(cv_\tau)} - b(x+y)v - mv, \quad t > \tau. \tag{2.6}$$

2.1. Remarks on long term dynamics. In contrast to ecologically motivated theoretical studies of phage growth where attention has been paid to long term dynamics [2, 17], there has been very little consideration of long term dynamics of phage growth models aimed at understanding phage therapy [14, 23]. This is probably due to a tacit assumption that the equations are valid only until such time as an immune response is mounted. Indeed, the hypothesis of exponential bacterial growth captures this focus on the short term dynamics.

Returning to the general system (2.1)–(2.2) with budding rate η, if $a > p$, which we assume hereafter, then the trivial equilibrium point $(x, y, v) = (0, 0, 0)$ is an unstable saddle point. For if there are no virus or infected cells, then the uninfected cells grow at the exponential rate $a - p > 0$. If, on the other hand, there are no uninfected cells, then any free virus and infected cells are removed at an exponential rate. Therefore, it is plausible that no solution starting with $x(0) > 0$ can satisfy $x(t) \to 0$, $t \to \infty$. We wish to stress that this fact is common to all models of virulent phage growth in the literature—not just the one treated here. It is possible to overlook this observation on viewing the simulations reported here and in [14, 23]. Below we give a proof which carries over to these other models with only minor changes.

Proposition 2.2. *If $a > p$, then no solution of* (2.2) *with* $x(0) > 0$ *can satisfy* $x(t) \to 0$, $t \to \infty$.

Proof. The assertion is obvious if $bN/c \le a - p$ since then $x'/x \ge 0$. Hereafter, assume that $bN/c > a - p$. If $x(t) \to 0$ as $t \to \infty$ for some nonzero solution of (2.2), then necessarily $y(t) \to 0$ as well. It can then be seen that v must remain bounded. By standard arguments, this and the convergence of $x(t)$ imply that $x'(t) \to 0$ and, therefore, since $x(t) \ne 0$, $v(t) \to V_I > 0$, where V_I is the unique positive root of $\frac{bv}{F_N(cv)} = a - p$ guaranteed by Lemma 2.1. The convergence of $v(t)$ implies $v'(t) \to 0$, but this immediately leads to the contradiction that $v \to 0$. □

Proposition 2.2 does not preclude that bacteria levels fall below a singleton, $x(t) < O(1)$, which means extinction and hence successful treatment. This will be evident in our numerical simulations. Obviously, our deterministic model breaks down at low densities of bacteria, but aside from this therapy can be successful if, even with large initial bacterial populations, there are feasible phage doses that will result in bacteria levels decreasing to a small fraction of pretreatment levels.

Because we assume that bacteria grow exponentially, rather than, say, logistically as in [2] or controlled by nutrient limitation as in [11, 10], there is no "phage-free" equilibrium with host cells at some positive level and no phage or infected cells.

If $\frac{bN}{c} > a - p$ and

$$(a-p)\int_0^\tau e^{-ps}\eta(s)ds > bV_I\left(1 + (a-p)\tau\frac{(1-e^{-p\tau})}{p\tau}\right), \tag{2.7}$$

where the quotient $\frac{(1-e^{-p\tau})}{p\tau} = 1$ when $p = 0$, then there exists a unique positive steady state (X, Y, V). The analytical determination of the stability properties of the positive steady state via linearization is very challenging. See Beretta and Kuang [2] for some partial results. Simulations of our system extending for hundreds of hours, not shown here, are oscillatory in nature and characterized by long periods with cell

Table 2.1
System parameters.

Parameter	Value
a	0.3 /hr

c	$3 \times 10^{-8} ml$
L	150
m	1.8 /hr
p	0
τ	.43 hr
N	100
ρ	30/hr

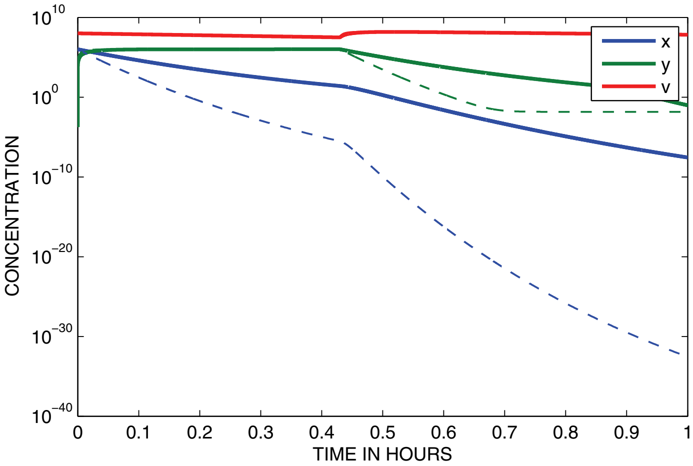

Fig. 2.2. $x(0) = 10^6$, $y(0) = 0$, $v(0) = 10^8$. *Dashed lines correspond to* $c = 0$.

densities well below one cell per milliliter. We conclude that the asymptotic behavior of the model system has limited relevance for phage growth.

2.2. Parameter values for simulations. Measurements of Weld, Butts, and Heinemann [23] found that the adsorption rate for phage T4 growing on an *E. coli* strain averaged 1.5×10^{-8} ml/min, which translates to the per hour rate in Table 2.1. Similar values can be found in [14, 20].

Grayson et al. [4] observe that the waiting time following phage binding to the host for initiation of injection is random, ranging from seconds to minutes. Their data reasonably fit an increasing but saturating exponential function with time constant t_0 which ranges from 79 seconds to 166 seconds. As they find that the injection process takes roughly 10 seconds, it is reasonable to take our injection time $1/\rho$ to be 2 minutes.

This leads to a value $c = b/\rho = 3 \times 10^{-8}$ ml, which means that the term cv appearing in (1.1) is significant; i.e., $cv = O(0.1)$ when $v > 0.3 \times 10^7$. In the numerical simulation shown in Figure 2.2, we take $v(0) = 10^8$ (compare with Payne and Jansen [14] who use even 10^9 initial phage in simulations), so $cv(0) = 3$.

In his monograph, Stent [20] describes experiments of Schlesinger, who measured the "adsorption capacity" of *E. coli* for WLL phage by adding phage to a suspension of bacteria and noting when additional phage could no longer become attached. He found that this threshold occurred at about 300 phage per bacterium. Although the adsorption capacity may differ from the number of binding sites for a variety of reasons, the experiment suggests that the number of binding sites satisfies $N = O(10^2)$. The lack of sensitivity of the attack rate (1.1) to N suggests that $N = 100$ should give sufficient accuracy.

Parameter values used in our simulations are displayed in Table 2.1. Those not described above were taken from [14, 23]. Our simulations are restricted to the special case that a burst of L phage is produced from an infected cell at lysis. Therefore, (2.5) and (2.6) were used. Initial data were taken following Payne and Jansen.

Assuming that $U_0(s) \equiv 0$, the simulated system is

$$\begin{aligned} \frac{dx}{dt} &= ax - \frac{bxv}{F_N(cv)} - px, \\ \frac{dy}{dt} &= \frac{bxv}{F_N(cv)} - H(t-\tau)e^{-p\tau}\frac{bx_\tau v_\tau}{F_N(cv_\tau)} - py, \\ \frac{dv}{dt} &= H(t-\tau)Le^{-p\tau}\frac{bx_\tau v_\tau}{F_N(v_\tau)} - b(x+y)v - mv, \end{aligned} \tag{2.8}$$

where $H(t-\tau)$ denotes the Heaviside function and $y(0) = 0$ (reflecting that $U_0 \equiv 0$) unless mentioned otherwise. Numerical solutions were computed using the dde23 delay differential equation solver on MATLAB.

Thick lines in Figure 2.2 display the time series simulating phage therapy over an hour time frame. A notable feature of the time series is the sharp discontinuity in the derivative of solution components at the time of the first latent period, roughly 26 minutes or 0.43 hours, caused by the burst of fresh phage. Cell concentrations below one cell per milliliter should be viewed as the absence of cells; this occurs for uninfected cells at approximately 0.6 hours. For comparison purposes, the dashed lines show the result of replacing both the attack rate (1.1) and rate of phage loss (1.2) by the traditional mass-action term bxv, keeping initial data the same. Note that the traditional mass-action rate results in a substantially quicker reduction in uninfected hosts over the first two latent periods and a reduction in infected cells over the second latent period. Uninfected cells essentially vanish at 0.2 hours and infected cells at 0.6 hours. Virus levels appear to be affected to a lesser degree. We conclude that the effect of our modifications in phage attack rate and phage loss rate is to significantly lengthen host cell survival, at least for initial data used here. As viral densities appear to be less affected by our modifications, it is probably the case that the modified attack rate is most significant.

3. Implications for phage therapy.

Payne and Jansen [14, 15] discovered some key pharmacokinetic parameters related to in vivo phage therapy against bacterial infection using a very simple model of phage growth. Of course, effects of an immune response to phage and to bacteria are ignored for these calculations, assuming that they kick in at a later time.

As noted above, in the context of our deterministic model, successful phage therapy can at best mean that bacterial levels are driven to a sufficiently low level that the immune system easily finishes them off. Successful phage therapy requires at minimum that uninfected bacterial density decreases. Our equations imply that

$$x' < 0 \Leftrightarrow v > V_I, \tag{3.1}$$

where V_I is the unique positive root of $\frac{bv}{F_N(cv)} = a - p$ (see Lemma 2.1). Payne and Jansen [14] refer to their V_I, obtained by setting $c = 0$ in ours, as the "inundation threshold" value. For the parameter values in Table 2.1, $V_I = 3.3 \times 10^5$.

Note that there is no guarantee, if one starts out with (3.1) holding, that it will continue to hold. In fact, Proposition 2.2 implies that $x' < 0$ cannot hold indefinitely. Therefore, merely arranging for initial phage densities to exceed the inundation threshold does not ensure "successful treatment."

Payne and Jansen identify two phage therapy strategies: passive therapy and active therapy. Passive therapy is the attempt to substantially knock down the bacterial population with the initial dose of phage, ignoring contributing effects of subsequent phage generations. Active therapy, presumably requiring a much smaller initial dose of phage, relies on the proliferation potential of phage reproduction to build up phage densities to levels sufficient to eventually drive down bacterial levels.

3.1. Passive therapy. Payne and Jansen's derivation of an explicit minimal phage dose for successful passive therapy, i.e., reaching $x(t) = O(1)$, in [14] relies on the simplicity of their model. Indeed, there are excellent reasons for simple models, and the ability to perform explicit calculations is one of them. Our model, which includes additional features such as the unproductive loss of phage due to phage attacking uninfected bacteria that are already bound to phage and to wasted phage attacks on infected cells, does not permit easy calculations. These additional features are most likely to be nonnegligible at the required large phage doses used in passive therapy.

It is not clear that the notion of a minimal dose for passive therapy is well defined for our model. Here, we take passive therapy to mean that bacterial density is reduced to a suitably small fraction of its initial size *within the initial latent period*. We take this obviously restrictive view of passive therapy only for analytical convenience; it is not, however, at great variance from the rather subjective definition of passive therapy—not to rely on subsequent generations of phage for success.

It seems obvious on biological grounds that if we fix the initial uninfected bacterial density $x(0)$ and assume as usual that $y(0) = 0$ but vary the initial phage dose $v(0)$, then larger doses will lead to smaller uninfected bacterial levels. However, this is far from obvious from a mathematical viewpoint. The next result establishes this point and provides a theoretical basis for the concept of a minimal dose for passive therapy.

PROPOSITION 3.1. *Let $(x(t), y(t), v(t))$ and $(\bar{x}(t), \bar{y}(t), \bar{v}(t))$ be two solutions of (2.8) with $x(0) = \bar{x}(0)$ and $y(0) = \bar{y}(0) = 0$. If $v(0) < \bar{v}(0)$, then $\bar{x}(t) < x(t)$ and $\bar{x}(t) + \bar{y}(t) < x(t) + y(t)$ on $0 < t \leq \tau$.*

For every $\theta \in (0, 1)$ and every $U > 0$ there exists $V = V(U) > 0$ such that if $(x(t), y(t), v(t))$ is a solution of (2.8) with $x(0) + y(0) \leq U$ and $v(0) \geq V$, then

$$\frac{x(\tau)}{x(0)} \leq e^{(a-p-(bN/c)\theta)\tau}. \tag{3.2}$$

In words, bigger phage doses result in smaller bacteria levels over the first latent period. In addition, *for any* initial bacterial density, there is a phage dose which will reduce bacterial density at the end of the first latent period by a factor that can be taken as close to $e^{(a-p-(bN/c))\tau}$ as desired. Recall that we are assuming $a - p - (bN/c) < 0$. Indeed, for the parameters of Table 2.1 it is approximately -1290. Therefore, $e^{(a-p-(b/c)\theta)\tau} \approx \exp(-1290)$ if $\theta \approx 1$. We do not claim that the required doses are medically feasible or even that there are the required number of phage in the universe. The proof of Proposition 3.1 is provided in the appendix.

3.2. Active therapy. In their consideration of active treatment, Payne and Jansen give an intuitive argument for the existence of a threshold bacterial density such that phage numbers are amplified over each successive phage generation only if bacterial density exceeds threshold. We can apply this intuitive reasoning to our model as well, although we arrive at a somewhat different threshold for phage amplification. According to our delay model, a cohort of y_0 newly infected cells, i.e., $U_0(s) = y_0\delta(s)$, where δ is the Dirac impulse concentrated at zero so all cells have infection-age zero, gives rise to $y_0 Le^{-p\tau}$ phage τ units of time later, when the surviving members of this cohort of the infected host have lysed. These phage survive $\frac{1}{b(x+y)+m}$ hours during which they infect the host at rate $\frac{bx}{F_N(cv)}$ per phage. We conclude that the $y_0 Le^{-p\tau}$ phage produce $Le^{-p\tau}\frac{bx}{(b(x+y)+m)F_N(cv)}y_0$ second generation infected cells. The amplification factor (of y_0) is therefore

$$R_0 = Le^{-p\tau}\frac{bx}{(b(x+y)+m)F_N(cv)}.$$

The condition for amplification of infected cells, and hence the condition for proliferation of phage, is that $R_0 > 1$:

$$Le^{-p\tau}\frac{bx}{(b(x+y)+m)F_N(cv)} > 1. \tag{3.3}$$

Unlike the proliferation threshold derived in [14], ours does not lead to a threshold condition for uninfected bacteria alone. However, as active therapy should not require such large phage doses that cv is significant, it may be reasonable in some cases to assume $cv \ll 1$, in which case $F_N(cv) \approx 1$ and we may ignore this factor. For parameter values in Table 2.1, if $v < 10^7$, this is a good approximation. Immediately below, we assume this approximation is valid.

Our proliferation condition involves both infected and uninfected hosts. If $b(x+y)$ is small relative to m, then we arrive at a threshold bacterial density for phage proliferation that is comparable to the one obtained in [14] and corrects the one given in [23]:

$$x > X_p \approx \frac{m}{bLe^{-p\tau}}. \tag{3.4}$$

However, if $b(x+y)$ is large relative to m, then (3.3) yields a threshold on the fraction of uninfected cells

$$Le^{-p\tau}\frac{x}{x+y} > 1.$$

In summary, the proliferation threshold computed from our model is more complex than that of Payne and Jansen since it involves all three quantities x, y, v. If $cv \ll 1$, it reduces to one similar to theirs, a lower bound on uninfected bacteria, when the total bacterial density is not too large but gives a lower bound for the fraction of uninfected bacteria when the total bacterial density is large. For parameter values in Table 2.1, $\frac{m}{bLe^{-p\tau}} \approx 13,500$; $b(x+y) \ll m$ if $x + y < 10^4$.

We provide two simulations where active therapy can be clearly identified. Initial data in Figure 3.1 yield a value $R_0 \approx 7$ well above unity. Bacteria initially grow before the phage gain control after the initial latent period. Figure 3.2 can be compared to Payne and Jansen's Figure 1(c) in [14], which shows passive therapy. We chose parameter values to correspond to those in that figure: $a = 0.3$, $b = 10^{-6}$, $\tau = 0.83$,

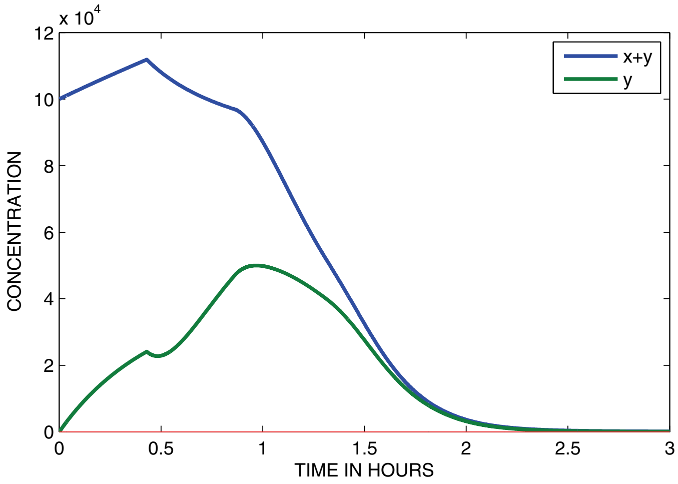

Fig. 3.1. *Active therapy with* $x(0) = 10^5$*,* $v(0) = 10^6$*.*

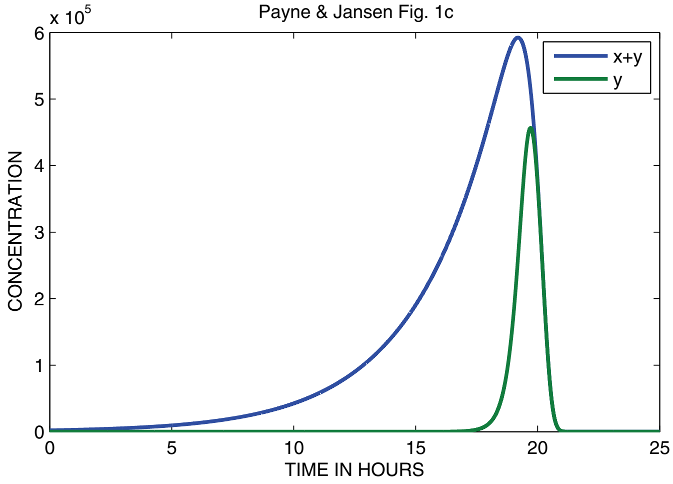

Fig. 3.2. *Compare to* [14, *Figure* 1(c)]*:* $x(0) = 2117$*,* $v(0) = 100$*.*

$L = 100$, $m = 1.8$, $p = 0$ with our value of N, and $c = b/\rho = 0.33 \times 10^{-7}$. Initial data were chosen as in their figure as well except that our starting time corresponds to their t_ϕ. It must be kept in mind that our model differs from theirs in the attack rate as well as our assumption that infected hosts do not grow. Our simulation agrees qualitatively with theirs, although our peak bacterial density exceeds theirs by a factor of three.

3.3. Summary of conclusions for phage therapy. We have explored a mathematical model of virulent phage growth on an exponentially growing bacterial population, system (2.8), which differs from previous models in two ways: (i) the density-dependent phage attack rate (1.1) is used in place of the mass action rate, and (ii) the loss rate of phage due to attachment (1.2) includes all bacterial cells and not just uninfected ones. Our simulations, particularly Figure 2.2, appear to be most strongly influenced by the modification (i), leading to significantly lengthened host cell survival. However, (ii) played a role in the calculation of the proliferation threshold (3.3) for active therapy which has a more complicated character than the simpler one deduced in [14]. Finally, in Proposition 3.1 we established that passive therapy works: for any initial bacterial population there is a phage dose that can reduce the host population to an insignificant fraction of its initial level within the first latent period. Although the dose may be impractically large and the restriction to a single latent period unduly restrictive, our result establishes the principle. It remains to be seen whether any of these effects are important for phage therapy.

In the following appendix, we show how (i) and (ii) arise from a careful modeling of bacteria-phage complexes consisting of a single host and a number of attached phage. The modeling framework we introduce there may be more important in the long run than the conclusions described above since it leads to much more flexibility in modeling phage release and host cell survival.

Appendix. We explore several modeling issues in this appendix which may be of interest for general bacteriophage-host interactions. First, we construct a model where infected hosts are structured by injection-age and where various complexes consisting of a host cell and one or more attached phage are explicitly included. We assume that each cell has a fixed number N of binding sites where host cells can have multiple attached phage. Finally, the age-structured infected cell population is reduced to integro-differential equations. Two cases lead to relatively simple equations: (1) the case where infected cell death rate by lysis is zero until time τ after which it is infinite, equivalent to fixed-length latent period, and (2) the case where the lysis rate is constant meaning an exponentially distributed latent period. The first case leads to the model considered in previous sections, while the second case leads to simpler ordinary differential equations similar to those in [14].

A.1. Phage-host complex formation. We call a host cell infected when a phage has injected genetic material into it; until then it is called uninfected. Furthermore, a phage ceases to exist once it has injected its genetic material.

The time between injection and lysis is on the order of 20 minutes or so, depending on the host-phage system. We will keep track of this "infection age" of infected cells. Denote by $Y(t,s)$ the distribution of infected cells of age s at time t. The integral

$$\int_{a_1}^{a_2} Y(t,s)ds$$

then gives the number of infected (postinjection) cells that were injected between $t-a_1$ and $t-a_2$, and

$$Y = \int_0^\infty Y(t,s)ds$$

gives the size of the infected class of cells.

Assume that each host cell has N potential phage binding sites. Then we partition uninfected host X, infected host Y, and phage V as follows:

$$X(t) = \sum_i C_x^i(t),$$
$$Y(t,s) = \sum_i C_y^i(t,s),$$

$$V(t) = v(t) + \sum_i i \left(C_x^i(t) + \int_0^\infty C_y^i(t,s)ds \right).$$

C_x^i (C_y^i) denotes the concentration of uninfected (infected) cells having i attached phage for $0 \leq i \leq N$, and $v(t)$ denotes the concentration of unadsorbed phage. In the case of infected cells, we stress that the age variable s denotes time since injection and not time in a particular compartment. All sums are over the range $0 \leq i \leq N$.

Recall that a host cell is infected once an attached phage injects, and a phage ceases to exist once it injects.

We assume that a host complex with $i < N$ attached phage may adsorb an additional phage at the rate bvC_z^i, where $z = x, y$. The rate constant b, the adsorption rate, is assumed independent of i and whether the host complex is infected ($z = y$) or uninfected ($z = x$). Let $\nu(s)$ denote the death (lysis) rate of infected cells of age s, and let $\eta(s)$ denote the rate of release of phage from an infected cell of age s. Here, we explore the case that both are independent of the number of attached phage. Recall that ρ is the injection rate; equivalently, $1/\rho$ is the average time between phage binding and subsequent injection of genetic material. The model equations are as follows:

$$\begin{aligned}
X' &= aX - \rho \sum_{i=1}^N iC_x^i - pX,\\
(C_x^i)' &= aC_x^i + bvC_x^{i-1} - (i\rho + bv)C_x^i - pC_x^i,\\
\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial s}\right) C_y^i(t,s) &= bC_y^{i-1}v + (i+1)\rho C_y^{i+1} - (i\rho + bv)C_y^i - (p + \nu(s))C_y^i,\\
C_y^i(t,0) &= \rho(i+1)C_x^{i+1}(t),\\
\text{(A.1)}\left(\frac{\partial}{\partial t} + \frac{\partial}{\partial s}\right) Y(t,s) &= -(\nu(s) + p)Y(t,s),\\
Y(t,0) &= \rho \sum_{i=1}^N iC_x^i(t),\\
v' &= \int_0^\infty Y(t,s)\eta(s)ds - mv\\
&\quad -bv \sum_{i=0}^{N-1} \left(C_x^i + \int_0^\infty C_y^i(t,s)ds \right),
\end{aligned}$$

where $C_x^{N+1} = C_y^{N+1} = 0$ and where for $i = N$ the loss term $-bvC_z^N$, $z = x, y$, in the equations for C_z^N is dropped since all binding sites are filled so no more attachments are allowed.

Some comments are in order as these equations may not at first appear transparent. Uninfected hosts are lost due to injection of a complex $C_x^i(t)$ by one of its attached phage, which then becomes a newly infected host $C_y^{i-1}(t,0)$ with one less attached phage. The rate of injection is $\rho i C_x^i$ since any one of the i attached phage may inject. This accounts for the loss term $-i\rho C_x^i(t)$ in the equation for X and the boundary condition for $C_y^i(t,s)$ and $Y(t,s)$ at $s = 0$. The injection of an infected host simply reduces the number of attached phage by one. Figure A.1 shows the flow between the compartments C_x^i and C_y^i. Free phage are lost due to attachment to host cells.

Initial conditions for (A.1) consist of specifying nonnegative values for $X(0)$, $C_x^i(0)$, $v(0)$ and nonnegative functions $C_y^i(0,s)$ and $Y(0,s) = U_0(s)$ defined for $s \geq 0$.

$$\begin{tikzcd}
C_x^{i-1} \arrow[r, "bv"'] & C_x^{i} \arrow[r, "bv"'] \arrow[dl, "i\rho"'] & C_x^{i+1} \arrow[dl, "(i+1)\rho"'] \\
C_y^{i-1} \arrow[r, shift right, "bv"'] & C_y^{i} \arrow[l, shift right, "i\rho"'] \arrow[r, shift right, "bv"'] & C_y^{i+1} \arrow[l, shift right, "(i+1)\rho"']
\end{tikzcd}$$

FIG. A.1. *Transfer diagram between complexes for* (A.1)*: ρ denotes injection rate, and bv denotes adsorption rate.*

We intend to employ a quasi–steady state analysis in order to remove the equations for the host/phage complexes. Before doing so it is convenient to integrate the equation for C_y^i with respect to infection-age, yielding

$$(C_y^i)' = -\int_0^\infty (\nu(s) + p)C_y^i(t,s)ds - (i\rho + bv)C_y^i + bvC_y^{i-1} + (i+1)\rho(C_y^{i+1} + C_x^{i+1}).$$

Hereafter, unless specifically mentioned, C_y^i denotes

$$C_y^i(t) = \int_0^\infty C_y^i(t,s)ds.$$

We assume that irreversible binding and injection are fast compared to such processes as growth and washout of host and the latent period. Therefore, we ignore these slower processes in the equations for complexes C_x^i and C_y^i in (A.1). Setting the time derivatives to zero in the C_x^i and C_y^i equations yields

$$\begin{aligned}
&0 = bvC_x^{i-1} - (i\rho + bv)C_x^i,\ 1 \le i \le N,\\
&0 = bvC_y^{i-1} + (i+1)\rho(C_x^{i+1} + C_y^{i+1}) - (i\rho + bv)C_y^i,
\end{aligned}$$

where we employ the conventions used in (A.1).

Adding the first N equations for the C_x^i and then adding all $2N$ equations yields

$$\sum_{i=1}^N iC_x^i = bvC_x^0/\rho, \quad C_x^1 + C_y^1 = bv(C_x^0 + C_y^0)/\rho.$$

Then straightforward calculations give the distribution of phage occupancy of host cell binding sites:

$$C_x^i + C_y^i = \frac{(bv/\rho)^i}{i!}(C_x^0 + C_y^0), \tag{A.2}$$

meaning phage are distributed according to a Poisson distribution with parameter (mean and variance) bv/ρ. We also have

$$C_x^i = C_x^0 \prod_{j=1}^i \frac{u}{j+u},\ 1 \le i \le N-1,\ C_x^N = \frac{u}{N}C_x^{N-1},\ u = bv/\rho. \tag{A.3}$$

We must express all quantities in terms of the variables X, Y, v used in (A.1). We summarize the results of doing so below.

Proposition A.1. *The phage attack rate is*

$$-\rho \sum_{i=1}^{N} i C_x^i = -\frac{bvX}{F_N(cv)}, \quad c = b/\rho,$$

where

$$F_N(u) = 1 + \frac{u}{1+u} + \frac{u^2}{(1+u)(2+u)} + \cdots + \frac{u^N}{(1+u)(2+u)\cdots(N-1+u)N}.$$

The rate of loss of free phage due to attachment satisfies

$$-bv \sum_{i=0}^{N-1} (C_x^i + C_y^i) = -bv(X+Y)\left(1 - \frac{\frac{u^N}{N!}}{\sum_{i=0}^{N} \frac{u^i}{i!}}\right),$$

where $Y = Y(t) = \int_0^\infty Y(t,s)ds$.

Proof. In order to relate C_x^0 to X, we use (A.3):

$$\begin{aligned} X &= \sum_i C_x^i \\ &= C_x^0 \left(1 + \frac{u}{1+u} + \frac{u^2}{(1+u)(2+u)} \right. \\ &\qquad \left. + \cdots + \frac{u^N}{(1+u)(2+u)\cdots(N-1+u)N}\right) \\ &= C_x^0 F_N(u). \end{aligned}$$

Similarly, using (A.2),

$$X + Y = \sum_{i=0}^{N} (C_x^i + C_y^i) = (C_x^0 + C_y^0) \sum_{i=0}^{N} \frac{u^i}{i!}.$$

Finally,

$$\begin{aligned} \sum_{i=0}^{N-1} (C_x^i + C_y^i) &= X + Y - (C_x^N + C_y^N) \\ &= (X+Y) - \frac{u^N}{N!}(C_x^0 + C_y^0) \\ &= (X+Y)\left(1 - \frac{\frac{u^N}{N!}}{\sum_{i=0}^{N} \frac{u^i}{i!}}\right) \\ &\approx X + Y. \qquad \square \end{aligned}$$

In view of the above result and the quasi–steady state analysis, our system (A.1) reduces to

$$\begin{aligned} X' &= aX - \frac{bvX}{F_N(cv)} - pX, \\ \left(\frac{\partial}{\partial t} + \frac{\partial}{\partial s}\right) Y(t,s) &= -(\nu(s)+p)Y(t,s), \\ Y(t,0) &= \frac{bvX}{F_N(cv)}, \\ v' &= \int_0^\infty Y(t,s)\eta(s)ds - mv \\ &\quad - bv\left(X(t) + \int_0^\infty Y(t,s)ds\right). \end{aligned} \tag{A.4}$$

Our analysis above shows that the parameter c in (1.1) is given by

$$c = \frac{b}{\rho} = b \times \text{adsorption time.}$$

We may solve for $Y(t,s)$ by integrating along characteristics:

$$Y(t,s) = \left\{ \begin{array}{ll} R(t-s)e^{-ps}e^{-\int_0^s \nu(u)du}, & t > s \\ U_0(s-t)e^{-pt}e^{-\int_{s-t}^s \nu(u)du}, & t < s \end{array} \right\},$$

where $R(t) = \frac{bvX}{F_N(cv)}$. The total infected cell population, $Y(t) = \int_0^\infty Y(t,s)ds$, is easily computed:

$$Y(t) = \int_0^t R(t-s)e^{-ps}e^{-\int_0^s \nu(u)du}ds + \int_0^\infty U_0(s)e^{-pt}e^{-\int_s^{s+t}\nu(u)du}ds.$$

Similarly, for the equation for phage,

$$\begin{aligned} v' = -bv(X+Y) - mv + \int_0^t R(t-s)e^{-ps}\eta(s)e^{-\int_0^s \nu(u)du}ds \\ + e^{-pt}\int_0^\infty U_0(s)\eta(s+t)e^{-\int_s^{t+s}\nu(u)du}ds. \end{aligned}$$

System (A.4) can now be replaced by the equation for X together with the equations above for Y and v. Below we consider two special cases for the lysis rate ν.

A.2. Fixed-length latent period. The special case

$$\nu(s) = \left\{ \begin{array}{ll} 0, & s < \tau \\ \infty, & s > \tau \end{array} \right\}$$

leads to

$$e^{-\int_0^s \nu(u)du} = \chi_{[0,\tau]}(s),\ e^{-\int_s^{s+t}\nu(u)du} = \left\{ \begin{array}{ll} 1, & s+t < \tau \\ 0, & s+t > \tau \end{array} \right\},$$

where, for a set B, $\chi_B(z) = 1$ if $z \in B$; otherwise $\chi_B(z) = 0$.

Hence

$$Y(t) = \int_0^{\min\{t,\tau\}} R(t-s)e^{-ps}ds + \int_0^{\infty} U_0(s)e^{-pt}\chi_{\{s+t<\tau\}}(t,s)ds$$
$$= \int_0^{\min\{t,\tau\}} R(t-s)e^{-ps}ds + \chi_{[0,\tau]}(t)\int_0^{\tau-t} U_0(s)e^{-pt}ds.$$

Equivalently,

$$Y(t) = \left\{ \begin{array}{cc} \int_0^t R(t-s)e^{-ps}ds + \int_0^{\tau-t} U_0(s)e^{-pt}ds, & t<\tau \\ \int_0^\tau R(t-s)e^{-ps}ds, & t>\tau \end{array} \right\}.$$

The equation for phage becomes

$$\begin{array}{c} v' = -bv(X+Y) - mv + \int_0^{\min\{\tau,t\}} R(t-s)e^{-ps}\eta(s)ds \\ + e^{-pt}\chi_{[0,\tau]}(t)\int_0^{\tau-t} U_0(s)\eta(s+t)ds. \end{array}$$

Equivalently,

$$v' = \left\{ \begin{array}{cc} -bv(X+Y) - mv + \int_0^t R(t-s)e^{-ps}\eta(s)ds & \\ + e^{-pt}\int_0^{\tau-t} U_0(s)\eta(s+t)ds, & t<\tau \\ -bv(X+Y) - mv + \int_0^\tau R(t-s)e^{-ps}\eta(s)ds, & t>\tau \end{array} \right\}.$$

If

$$\eta(s) = L\delta(s-\tau),$$

then

$$v' = \left\{ \begin{array}{cc} -bv(X+Y) - mv + Le^{-pt}U_0(\tau-t), & t<\tau \\ -bv(X+Y) - mv + LR(t-\tau)e^{-p\tau}, & t>\tau \end{array} \right\}.$$

These, together with the equation for X from (A.4), are the equations considered in section 2.

A.3. Exponentially distributed latent period. In case of an exponentially distributed latent period, $\nu(s) \equiv \nu$, easy computations yield expressions for the infected:

$$Y(t) = \int_0^t R(s)e^{-(p+\nu)(t-s)}ds + e^{-(p+\nu)t}\int_0^\infty U_0(s)ds$$

or, on differentiation,

$$Y' = -(p+\nu)Y + R(t),\ Y(0) = \int_0^\infty U_0(s)ds.$$

The phage equation becomes

$$v' = -bv(X+Y) - mv + \int_0^t R(s)\eta(t-s)e^{-(p+\nu)(t-s)}ds + e^{-(p+\nu)t}\int_0^\infty U_0(s)\eta(s+t)ds.$$

If $\eta(s) \equiv L\nu$, then v satisfies

$$v' = -bv(X+Y) - mv + \nu L\left(\int_0^t R(s)e^{-(p+\nu)(t-s)}ds + e^{-(p+\nu)t}\int_0^\infty U_0(s)ds\right)$$
$$= -bv(X+Y) - mv + \nu Ly.$$

These, together with the equation for X from (A.4), can be compared to those of Payne and Jansen [14].

A.4. Proof of Lemma 2.1. Straightforward calculation yields that

$$F_{N+1}(u) = F_N(u) - \frac{u^{N+1}}{(1+u)\cdots(N+u)N(N+1)}$$

and that $F_N(u)/u \to 1/N$ as $u \to \infty$.

We show that $\frac{u}{F_N(u)}$ is monotonically increasing by showing it has a positive derivative. Since we may write

$$\frac{u}{F_N(u)} = \frac{u}{F_1(u)} \frac{F_1(u)}{F_2(u)} \cdots \frac{F_{N-1}(u)}{F_N(u)},$$

it suffices to show that $\frac{u}{F_1(u)}$ and $\frac{F_n(u)}{F_{n+1}(u)}$ have positive derivatives for $n \geq 1$. $\frac{u}{F_1(u)} = u/1+u$ is clearly increasing.

$$\begin{aligned} \frac{d}{du}\frac{F_n(u)}{F_{n+1}(u)} &= \frac{d}{du}\frac{F_{n+1}(u)+g(u)}{F_{n+1}(u)} \\ &= \frac{g(u)}{uF_{n+1}(u)}\left(\frac{ug'(u)}{g(u)} - \frac{uF'_{n+1}(u)}{F_{n+1}(u)}\right), \end{aligned}$$

where

$$g(u) = \frac{u^{n+1}}{(1+u)(2+u)\cdots(n+u)(n+1)n}.$$

Straightforward computation gives

$$\frac{ug'(u)}{g(u)} = 1 + \sum_{i=1}^{n} \frac{i}{i+u}$$

and

$$\begin{aligned} uF'_{n+1}(u) = \frac{u}{1+u}\left(\frac{1}{1+u}\right) &+ \frac{u^2}{(1+u)(2+u)}\left(\frac{1}{1+u} + \frac{2}{2+u}\right) + \cdots \\ &+ \frac{u^n}{(1+u)(2+u)\cdots(n+u)}\left(\frac{1}{1+u} + \frac{2}{2+u} + \cdots + \frac{n}{n+u}\right) \\ &+ \frac{u^{n+1}}{(1+u)(2+u)\cdots(n+u)(n+1)}\left(1 + \frac{1}{1+u} + \frac{2}{2+u} + \cdots + \frac{n}{n+u}\right). \end{aligned}$$

On dividing this expression by $F_{n+1}(u)$, we see that it can be viewed as a convex combination of the quantities in parentheses in the previous expression, and therefore it lies between the minimum and maximum of the quantities in parentheses. But the maximum is clearly inside the last parenthesis, which exactly agrees with $\frac{ug'(u)}{g(u)}$. We conclude that

$$\frac{ug'(u)}{g(u)} - \frac{uF'_{n+1}(u)}{F_{n+1}(u)} > 0.$$

A.5. Proof of Proposition 3.1. Setting $u = x + y$ in our system (2.8), we obtain the system

$$\begin{aligned} \frac{dx}{dt} &= ax - \frac{bxv}{F_N(cv)} - px, \\ \frac{du}{dt} &= ax - pu, \quad 0 \le t \le \tau, \\ \frac{dv}{dt} &= -buv - mv. \end{aligned} \tag{A.5}$$

This is a monotone system of differential equations whose forward flow preserves the order relation

$$(\bar{x}, \bar{u}, \bar{v}) \le_K (x, u, v) \Leftrightarrow \bar{x} \le x,\ \bar{u} \le u,\ v \le \bar{v}; \tag{A.6}$$

see [19, Chap. 3, sec. 5]. As the Jacobian matrix on the right-hand side is irreducible, it follows that for $0 < t \le \tau$

$$(\bar{x}(0), \bar{u}(0), \bar{v}(0)) <_K (x(0), u(0), v(0)) \Rightarrow (\bar{x}(t), \bar{u}(t), \bar{v}(t)) \ll_K (x(t), u(t), v(t)),$$

where $<_K$ means at least one strict inequality in (A.6) while $\ll_K$ means all inequalities are strict. The first assertion of Proposition 3.1 is an immediate consequence of the previous inequality.

As for the second assertion of Proposition 3.1, we need some elementary estimates. Inequality $u' \le (a-p)u$ leads to $u(t) \le u(0)e^{(a-p)t}$, so there exists $M \ge 1$ such that $u(t) \le Mu(0)$, $0 \le t \le \tau$. Similarly, $v' \ge -[bMu(0) + m]v$ leads to $v(t) \ge Kv(0)$, $0 \le t \le \tau$, where $K = e^{-(bMu(0)+m)\tau}$. If $0 < \theta < 1$, then

$$\frac{cv}{F_N(cv)} \ge \frac{cKv(0)}{F_N(cKv(0))} \ge \theta N$$

by taking $v(0)$ sufficiently large. Hence, $\frac{x'}{x} \le a - p - (bN/c)\theta$.

TRANSPORT-BASED IMAGING IN RANDOM MEDIA[*]

GUILLAUME BAL[†] AND KUI REN[†]

Abstract. This paper generalizes well-established derivations of the radiative transfer equation from first principles to model the energy density of time-dependent and monochromatic high frequency waves propagating in a random medium composed of localized scatterers. The correlation length of the random scatterers is small compared to the overall distance of propagation so that ensemble averaging may take place. The correlation length may be either comparable to the typical wavelength in the system (the weak-coupling regime) or larger than the wavelength (the low-density regime). The paper also considers the detection and imaging of inclusions buried in highly scattering random media. In such multiple scattering environments, the coherent wave fields may be too weak to be used for imaging purposes. We thus propose to model the inclusions as parameters in the macroscopic radiative transfer equations and consider the imaging problem as an inverse transport problem. Numerical simulations address the domain of validity of the radiative transfer equation and of the imaging method. Wave propagation is solved by using a Foldy–Lax framework, and the forward and inverse transport problems are solved by using a Monte Carlo method. Since the inverse transport problem is ill-posed, the buried inclusions are parameterized by a small number of degrees of freedom, typically their position and a few geometric properties.

Key words. imaging in random media, high frequency waves in random media, inverse problems, radiative transfer equation, Foldy–Lax model

1. Introduction.

The imaging of buried inclusions in random media from acoustic, electromagnetic, or elastic wave measurements has a long history. We refer the reader to, e.g., [2, 9, 15, 21, 30, 28, 36] and their references. Several imaging methods have been proposed based on the type of available data and on the regime of wave propagation.

The most favorable situation occurs when the specific realization of the random medium is explicitly known. We can then use the refocusing properties of time reversed waves to backpropagate measured wave fields numerically through the known random environment. The time reversed waves focus on the location of the buried inclusions and allow for fairly accurate imaging; see, e.g., [12, 14, 24]. Note, however, that even small errors in the assessment of the random medium, such as the mislocation of the random scatterers by an amount comparable to the typical wavelength of the propagating waves, have a very large effect on the refocusing of time reversed waves [13, 31].

In most applications, the random medium is not known, and this lack of knowledge inevitably degrades the quality of the reconstructions. Randomness may then roughly be treated in two different ways. One way is to assume that noise is sufficiently small so that it may be treated perturbatively. Imaging is then performed

by backpropagating appropriately mollified wave field measurements into a homogeneous medium or a medium with smooth variations, whose determination is often an important aspect of the reconstruction. One of the main pitfalls in such reconstructions is that many classical inversion techniques are not statistically stable, i.e., the reconstruction strongly depends on the realization in a given set of random media. We refer the reader to, e.g., [15] for optimal, statistically stable imaging methods in that context. Such methods no longer work adequately when the fluctuations in the random medium increase to a point where the coherent wave field, i.e., the part of the wave field that is not affected by random scattering, becomes too weak. In such regimes of strong scattering, other models are necessary.

The alternative to backpropagation in a homogeneous or smoothly varying medium is to find a model that describes wave scattering in the random medium. In regimes where the wavelength and the correlation length of the random medium are very small compared to the overall distance of propagation, such as in the propagation of light through the atmosphere or of near-infrared photons through human tissues, the kinetic description for wave propagation is extremely accurate [1, 18]. The wave energy density is then modeled quite accurately by a radiative transfer (transport) equation or a diffusion equation.

In this paper, we are interested in the validity of the radiative transfer model in a more intermediate regime, where the fluctuations in the random medium are too strong for imaging methods based on coherent information to work, and where the typical wavelength in the system is smaller, though not orders of magnitude smaller, than the overall distance of propagation. Typically, GHz microwaves with a wavelength of 30 cm propagate over distances of tens or hundreds of meters. The typical random medium we consider here is made of hundreds of scatterers, with a mean separation distance between scatterers comparable to or larger than compared to the wavelength but smaller compared to the overall distance of propagation. Our objective is then to detect and image a—sufficiently large—inclusion buried in the random medium.

When the density of scatterers is sufficiently large so that the coherent wave field is too weak to be useful in imaging, the incoherent part of the wave field, i.e., the part that has interacted with the unknown random medium, can no longer be neglected and needs to be modeled. Such a model has to depend on the regime of wave propagation. In the high frequency regime, when the wavelength is smaller than the propagation distance, the simplest extension of wave propagation in homogeneous domains is arguably the radiative transfer equation. Such an equation models the propagation of the phase-space energy density $a(t, \mathbf{x}, \mathbf{k})$ at time t, position $\mathbf{x}$, and wave number $\mathbf{k}$, and for acoustic waves takes the form

$$\frac{\partial a}{\partial t} + c\hat{\mathbf{k}} \cdot \nabla_{\mathbf{x}} a = \mathcal{Q}a, \qquad \mathcal{Q}a = \int_{\mathbb{R}^d} \sigma(\mathbf{x}, \mathbf{k}', \mathbf{k})(a(t, \mathbf{x}, \mathbf{k}') - a(t, \mathbf{x}, \mathbf{k}))\delta(c|\mathbf{k}'| - c|\mathbf{k}|)d\mathbf{k}', \tag{1}$$

where $\hat{\mathbf{k}} = \mathbf{k}/|\mathbf{k}|$, c is sound speed, and $\sigma(\mathbf{x}, \mathbf{k}, \mathbf{k}')$ is the scattering coefficient, which is inversely proportional to the mean free path, the mean distance between successive interactions of the wave energy with the underlying medium. Note that the radiative transfer equation may be seen as a perturbation of the propagation of high frequency waves in a homogeneous medium, which corresponds to the case $\sigma = 0$. The radiative transfer equation is thus characterized by the following two features: scattering is not sufficiently strong to modify the dispersion relation of high frequency waves; this is the left-hand side in (1). However, because of incoherent interactions with the underlying structure, the—partially incoherent—energy density, rather than the wave field, needs to be modeled, and while the energy density is still transported through the random medium, it does so by possibly changing direction in a way described by the scattering operator on the right-hand side of (1). In that sense, it may be seen as the simplest model for the energy density of high-frequency waves propagating in heterogeneous media.

Radiative transfer equations have also been extensively studied and derived either phenomenologically or from first principles (i.e., starting from a wave equation); see [3, 18, 23, 27, 35, 37, 38]. We derive the equation in the setting of localized (possibly) strong scatterers, adapting techniques in [3, 35] to model the energy density of time-dependent and mono-frequency (monochromatic) waves propagating in such a random medium. The localized scatterers are assumed here to have a Poisson distribution with a correlation length that is either comparable to the wavelength (weak-coupling regime) or much larger than the wavelength (low-density regime). We then propose to assess the range of validity of the radiative transfer model by comparing its predictions with wave field calculations. We use a Foldy–Lax model to compute the wave fields. We demonstrate, based on numerical simulations, that the radiative transfer equations are very accurate, provided that the wave energy measurements are sufficiently stable statistically.

Statistical stability is a cornerstone of the interferometric imaging techniques developed in [15]. Reconstructions based on coherent information are much enhanced when an inversion technique that is carefully calibrated to the random medium and statistically stable is employed. When macroscopic models for the incoherent energy density are used, statistical stability is an absolute prerequisite to any form of imaging. It is impossible, based on one measurement, to image an inclusion whose influence on the detectors is a random variable whose fluctuations cannot be averaged out one way or another (for instance, by collecting measurements on a larger detector). It turns out that in the high frequency limit, wave energy densities are indeed statistically stable for a wide class of random media, in the sense that they converge in probability to their deterministic limit as the wavelength tends to 0. This has been proved in simplified models of wave propagation [6, 8] and has been confirmed by numerical simulations [10, 11].

We present here numerical evidence of the statistical stability of the wave energy density in sufficiently mixing random media with localized scatterers. What we mean by sufficiently mixing is that the density of scatterers is sufficiently high. We demonstrate numerically the physically simple fact that the energy density is more stable statistically when the density of scatterers increases (their correlation length decreases) while their scattering strength decreases in such a way that the mean free path remains constant.

Once we are confident in the radiative transfer equation as a model for the wave energy density, we use the model to image buried inclusions in such random media. We assume here that the random medium is statistically homogeneous, i.e., that its statistics are invariant by spatial translation. We can consider two scenarios. In the first scenario, we measure energy densities in the presence of the inclusion. We thus have to estimate the mean free path of the random medium and image the inclusion at the same time. In such a configuration, the inclusion's influence on available measurements has to be larger than the statistical instability coming from our lack of knowledge of the underlying random medium. In the second scenario, we have access to energy measurements in the presence *and* in the absence of the inclusion. We may thus perform differential measurements. These differential measurements are then proportional to the inclusion. With a kinematic picture in mind, all the instability in the random paths that do not visit the object cancels out in differential measurements, thus allowing us to image much smaller objects. We consider reconstructions under these two scenarios based on forward wave field calculations and inverse transport problems.

The rest of the paper is structured as follows. Section 2 presents our model of random media with localized scatterers and derives the radiative transfer equation from a high frequency acoustic wave equation. Time-dependent and mono-frequency equations are considered. The Foldy–Lax approximation to wave propagation is also presented. The numerical validation of the radiative transfer equations based on Foldy–Lax wave simulations and transport Monte Carlo simulations is presented in section 3. Transport-based imaging of inclusions in random media is then considered in section 4.

2. Radiative transfer models.

In this section, we introduce the microscopic and macroscopic models for the propagation of high frequency waves in random media with localized scatterers.

We start with the acoustic wave equation with sound speed given by the superposition of a constant background sound speed and localized strong fluctuations. In section 2.1, the radiative transfer equation is obtained as the high frequency limit of the energy density of the acoustic waves following methods developed in, e.g., [3, 35]. The corresponding transport equation for mono-frequency (time-harmonic) waves is given in section 2.2. Because the scatterers are localized on a scale much smaller than the wavelength, the wave equation for time-harmonic wave fields is approximated by the Foldy–Lax model, which is recalled in section 2.3.

It remains to address the modeling of the buried inclusions. Extended objects are treated like any other pointlike object in the Foldy–Lax formalism. At the radiative transfer level, we assume that the inclusion is sufficiently large compared to the wavelength so that energy reflects specularly at the inclusion's boundary. Such models are explained in greater detail in section 2.4.

2.1. Derivation of the transport equation.

We consider the propagation of scalar waves in media with, for simplicity, constant density ρ_0 and spatially varied compressibility $\kappa(\mathbf{x})$,

$$\rho_0 \partial_t \mathbf{v} + \nabla p = 0, \quad \kappa(\mathbf{x})\partial_t p + \nabla \cdot \mathbf{v} = 0, \quad p(0,\mathbf{x}) = p_0(\mathbf{x}), \quad \mathbf{v}(0,\mathbf{x}) = \mathbf{v}_0(\mathbf{x}), \tag{2}$$

where $t > 0$ and $\mathbf{x} \in \mathbb{R}^d$ with $d \geq 2$ the spatial dimension. The theories that follow generalize to the context of electromagnetic and elastic waves; see, e.g., [3, 35]. For concreteness, we restrict ourselves to the case of acoustic waves.

In the high frequency regime of interest in this paper, the above equation rescales, after the change of variables $t \mapsto \frac{t}{\varepsilon}$ and $\mathbf{x} \mapsto \frac{\mathbf{x}}{\varepsilon}$, as

$$\rho_0 \varepsilon \partial_t \mathbf{v}_\varepsilon + \varepsilon \nabla p_\varepsilon = 0, \quad \kappa_\varepsilon(\mathbf{x}) \varepsilon \partial_t p_\varepsilon + \varepsilon \nabla \cdot \mathbf{v}_\varepsilon = 0, \tag{3}$$

where the initial conditions $p_\varepsilon(0,\mathbf{x}) = p_{0\varepsilon}(\mathbf{x})$ and $\mathbf{v}_\varepsilon(0,\mathbf{x}) = \mathbf{v}_{0\varepsilon}(\mathbf{x})$ oscillate at the frequency ε^{-1}. The parameter ε thus models the typical wavelength in the system. The wave speed is defined as

$$c_\varepsilon^2(\mathbf{x}) = \frac{1}{\rho_0 \kappa_\varepsilon(\mathbf{x})} = c_0^2(\mathbf{x}) - \sqrt{\varepsilon} V_\varepsilon \left(\frac{\mathbf{x}}{\varepsilon} \right). \tag{4}$$

We retain the scaling $\sqrt{\varepsilon}V_\varepsilon(\frac{\mathbf{x}}{\varepsilon})$ to use the results developed in, e.g., [3, 35]. Neither the amplitude nor the correlation length of the potential V_ε is necessarily of order $O(1)$, however. More precisely, the potential V_ε is chosen as

$$V_\varepsilon(\mathbf{x}) = \varepsilon^{-\frac{(\gamma+2\beta)d}{2}} \sum_j \tau_j V\Big(\frac{\mathbf{x}-\mathbf{x}_j^\varepsilon}{\varepsilon^\beta}\Big), \tag{5}$$

where $\beta > 0$, $\gamma < 1$, where $V(\mathbf{x})$ is a compactly supported nonnegative, uniformly bounded function, where the points $\mathbf{x}_j^\varepsilon(\omega)$ form a Poisson point process of density $\nu_\varepsilon = \varepsilon^{\gamma d} n_0$, and where the coefficients $\tau_j(\omega)$ are square-integrable, mean-zero, independent identically distributed random variables. Here ω is a point in a sufficiently large abstract probability space $(\Omega, \mathcal{F}, P)$.

The sound speed fluctuations are therefore of the form

$$\sqrt{\varepsilon}V_\varepsilon\left(\frac{\mathbf{x}}{\varepsilon}\right) = \varepsilon^{\frac{1-(\gamma+2\beta)d}{2}} \sum_j \tau_j V\Big(\frac{\mathbf{x}-\varepsilon\mathbf{x}_j^\varepsilon}{\varepsilon^{1+\beta}}\Big). \tag{6}$$

We thus conclude that the thickness of the scatterers is $t_\varepsilon = \varepsilon^{1+\beta} \ll \varepsilon$, the correlation length in the medium is $l_\varepsilon = \varepsilon^{1-\gamma}L$ for L a typical distance of propagation, which verifies $l_\varepsilon \gg \varepsilon$ when $0 < \gamma < 1$ and $L = O(1)$, and the density of scatterers is $n_\varepsilon = \varepsilon^{-d}\nu_\varepsilon = \varepsilon^{(\gamma-1)d} n_0 \gg O(1)$.

Note that the Poisson point process allows for the clustering of points $\mathbf{x}_j^\varepsilon$, although the number of points in a given bounded domain is bounded P-a.s. There is therefore a (P-)small subset Ω_ε of Ω, where the above fluctuation is larger than c_0^2, which would result in a negative c_ε^2. The process in (6) thus needs to be modified on Ω_ε, for instance, by setting the fluctuations to 0. We verify, although we shall not present this here, that such modifications of the process in (6) occur on a very small set and that the calculations of the power spectra presented below are not affected by the change.

We can now use the methodology developed in [35] to show that the wave energy density is such that

$$\mathcal{E}_\varepsilon(t,\mathbf{x}) - \int_{\mathbb{R}^d} a_\varepsilon(t,\mathbf{x},\mathbf{k})d\mathbf{k} \to 0 \tag{7}$$

in a weak sense (i.e., after integration against a test function in the spatial variables $\mathbf{x}$), where $\mathcal{E}_\varepsilon(t,\mathbf{x})$ is the energy density defined as

$$\mathcal{E}_\varepsilon(t,\mathbf{x}) = \rho_0|\mathbf{v}_\varepsilon|^2(t,\mathbf{x}) + \kappa_\varepsilon(\mathbf{x})p_\varepsilon^2(t,\mathbf{x}), \tag{8}$$

and where $a_\varepsilon(t,\mathbf{x},\mathbf{k})$ is a phase-space energy density, which solves the following radiative transfer equation:

$$\frac{\partial a_\varepsilon}{\partial t} + c_0\hat{\mathbf{k}}\cdot\nabla a_\varepsilon = \int_{\mathbb{R}^d} \sigma_\varepsilon(\mathbf{x},\mathbf{k},\mathbf{q})(a_\varepsilon(\mathbf{x},\mathbf{q}) - a_\varepsilon(\mathbf{x},\mathbf{k}))\delta(c_0|\mathbf{k}| - c_0|\mathbf{q}|)d\mathbf{q}, \tag{9}$$

with appropriate initial conditions, where

$$\sigma_\varepsilon(\mathbf{x},\mathbf{k},\mathbf{q}) = \frac{\pi c_0^2|\mathbf{k}|^2}{2(2\pi)^d}\hat{R}_\varepsilon(\mathbf{k}-\mathbf{q}). \tag{10}$$

Here, $\hat{R}_\varepsilon$ is the power spectrum of the fluctuations V_ε. It is the Fourier transform of the correlation function R_ε of the fluctuations V_ε. They are defined as follows:

$$\begin{aligned} c_0^4 R_\varepsilon(\mathbf{y}) &= \mathbb{E}\{V_\varepsilon(\mathbf{x})V_\varepsilon(\mathbf{x}+\mathbf{y})\}, \\ (2\pi)^d c_0^4 \hat{R}_\varepsilon(\mathbf{p})\delta(\mathbf{p}+\mathbf{q}) &= \mathbb{E}\{\hat{V}_\varepsilon(\mathbf{p})\hat{V}_\varepsilon(\mathbf{q})\}, \end{aligned} \tag{11}$$

where $\hat{V}_\varepsilon(\mathbf{p}) = \int_{\mathbb{R}^d} e^{-i\mathbf{x}\cdot\mathbf{p}} V_\varepsilon(\mathbf{x})d\mathbf{x}$ is the Fourier transform of $V_\varepsilon(\mathbf{x})$. We then have the following result on the asymptotic limit of the power spectrum.

LEMMA 2.1. *Let us assume that $V(\mathbf{x})$ is a nonnegative, integrable, compactly supported function such that $\hat{V}(\mathbf{0}) = c_0^2 L^d$ for some characteristic distance $0 < L = O(1)$, where $\hat{V}(\mathbf{k})$ is the Fourier transform of V. Then we find that the power spectrum $\hat{R}_\varepsilon(\mathbf{k})$ converges in the uniform norm uniformly on compact sets to the limit*

$$\hat{R}_0 = L^{2d}\mathbb{E}\{\tau^2\}n_0. \tag{12}$$

Proof. We calculate that

$$c_0^4 R_\varepsilon(\mathbf{y}) = \varepsilon^{-(\gamma+2\beta)d}\mathbb{E}\{\tau^2\}\mathbb{E}\left\{\sum_{j=1}^\infty V\Big(\frac{\mathbf{x}-\mathbf{x}_\varepsilon^j}{\varepsilon^\beta}\Big)V\Big(\frac{\mathbf{x}+\mathbf{y}-\mathbf{x}_\varepsilon^j}{\varepsilon^\beta}\Big)\right\}.$$

Since V is compactly supported, there is a domain D, at $\mathbf{x}$ and $\mathbf{y}$ fixed, such that the above product vanishes for $\mathbf{x}_j^\varepsilon$ outside of D. The Poisson point process verifies that the number of points on D satisfies a Poisson distribution and that, conditioned on the number of points, these points are uniformly and independently distributed on D. This yields that

$$\begin{aligned} &\mathbb{E}\left\{\sum_{j=1}^\infty V\Big(\frac{\mathbf{x}-\mathbf{x}_\varepsilon^j}{\varepsilon^\beta}\Big)V\Big(\frac{\mathbf{x}+\mathbf{y}-\mathbf{x}_\varepsilon^j}{\varepsilon^\beta}\Big)\right\} \\ &\quad = \sum_{m=0}^\infty e^{-|D|\nu_\varepsilon}\frac{(|D|\nu_\varepsilon)^m}{m!}\sum_{j=1}^m \int_D V\Big(\frac{\mathbf{x}-\mathbf{z}}{\varepsilon^\beta}\Big)V\Big(\frac{\mathbf{x}+\mathbf{y}-\mathbf{z}}{\varepsilon^\beta}\Big)\frac{d\mathbf{z}}{|D|} \\ &\quad = \nu_\varepsilon \int_{\mathbb{R}^d} V\Big(\frac{\mathbf{z}-\mathbf{x}}{\varepsilon^\beta}\Big)V\Big(\frac{\mathbf{z}-\mathbf{x}-\mathbf{y}}{\varepsilon^\beta}\Big)d\mathbf{z}, \end{aligned}$$

where $|D|$ is the Lebesgue measure of D. Now,

$$\begin{aligned} H_\varepsilon(\mathbf{y}) &= \int_D V\Big(\frac{\mathbf{z}-\mathbf{x}}{\varepsilon^\beta}\Big)V\Big(\frac{\mathbf{z}-\mathbf{x}-\mathbf{y}}{\varepsilon^\beta}\Big)d\mathbf{z} = \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d} e^{-i\mathbf{x}\cdot\mathbf{k}}e^{i(\mathbf{x}+\mathbf{y})\cdot\mathbf{k}}\varepsilon^{2\beta d}|\hat{V}(\varepsilon^\beta\mathbf{k})|^2 d\mathbf{k} \\ &= \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d} e^{i\mathbf{y}\cdot\mathbf{k}}\varepsilon^{2\beta d}|\hat{V}(\varepsilon^\beta\mathbf{k})|^2 d\mathbf{k}. \end{aligned}$$

Its Fourier transform is thus given by

$$\hat{H}_\varepsilon(\mathbf{p}) = \varepsilon^{2\beta d}|\hat{V}(\varepsilon^\beta\mathbf{p})|^2 = \varepsilon^{2\beta d}(|\hat{V}(\mathbf{0})|^2 + O(\varepsilon^\beta)),$$

where $O(\varepsilon^\beta)$ means a term of order ε^β in the uniform norm, uniformly bounded on compact sets. This follows, e.g., from the analyticity of $\hat{V}(\mathbf{p})$. Since $\hat{R}_\varepsilon(\mathbf{k})$ is the Fourier transform of $R_\varepsilon(\mathbf{x})$, we find that

$$c_0^4\hat{R}_\varepsilon(\mathbf{k}) = (|\hat{V}(\mathbf{0})|^2 + O(\varepsilon^\beta))\mathbb{E}\{\tau^2\}n_0.$$

This proves the result. □

In the limit $\varepsilon \to 0$, we thus find that a_ε converges to the solution of the following radiative transfer equation:

$$\frac{\partial a}{\partial t} + c_0 \hat{\mathbf{k}} \cdot \nabla a + \Sigma(\mathbf{x}, |\mathbf{k}|) a = \int_{\mathbb{R}^d} \sigma(\mathbf{x}, \mathbf{k}, \mathbf{q}) a(t, \mathbf{x}, \mathbf{q}) \delta(c_0|\mathbf{k}| - c_0|\mathbf{q}|) d\mathbf{q}, \tag{13}$$

where

$$\begin{aligned} \sigma(\mathbf{x}, \mathbf{k}, \mathbf{q}) &= \frac{\pi |\mathbf{k}|^2 L^{2d} c_0^2 \mathbb{E}\{\tau^2\} n_0}{2(2\pi)^d}, \\ \Sigma(\mathbf{x}, |\mathbf{k}|) &= \frac{|S^{d-1}|\pi}{2(2\pi)^d} |\mathbf{k}|^{d+1} L^{2d} c_0 \mathbb{E}\{\tau^2\} n_0. \end{aligned} \tag{14}$$

Here, $|S^{d-1}|$ is the Lebesgue measure of the unit sphere in $\mathbb{R}^d$.

Note that the transport equations generalize to the case where the density of scatterers depends on space. For instance, we may assume that the sound speed fluctuations are of the form

$$\sqrt{\varepsilon} V_\varepsilon \left(\mathbf{x}, \frac{\mathbf{x}}{\varepsilon}\right) = \varepsilon^{\frac{1-(\gamma+2\beta)d}{2}} \sum_j \tau_j \varphi(\mathbf{x}_j^\varepsilon) V\left(\frac{\mathbf{x} - \varepsilon \mathbf{x}_j^\varepsilon}{\varepsilon^{1+\beta}}\right), \tag{15}$$

where $\varphi(\mathbf{x})$ is a deterministic nonnegative function on $\mathbb{R}^d$. In the numerical simulations considered below, $\varphi(\mathbf{x})$ is the indicatrix function of our computational domain. The limit in (12) is then modified as

$$\hat{R}_0(\mathbf{x}) = \varphi^2(\mathbf{x}) L^{2d} \mathbb{E}\{\tau^2\} n_0. \tag{16}$$

The scattering coefficients in (14) also need to be multiplied by $\varphi^2(\mathbf{x})$ and thus become spatially dependent.

2.2. Transport equation in the frequency domain.

The derivation of transport equations for mono-frequency waves cannot be deduced in a straightforward way from that of time-dependent equations. We refer to [17] for a derivation of kinetic models from the Helmholtz equation. We formally generalize these results by adding a scattering operator to the transport equation to model the interaction with the underlying random medium.

The Helmholtz equation for the mono-frequency wave field $u_\varepsilon(\mathbf{x})$ with high frequency $\frac{\omega}{\varepsilon}$ takes the form

$$\varepsilon^2 \Delta u_\varepsilon(\mathbf{x}) + \frac{\omega^2}{c_\varepsilon^2(\mathbf{x})} u_\varepsilon(\mathbf{x}) = \frac{1}{\varepsilon^{\frac{d-1}{2}}} \varphi\Big(\frac{\mathbf{x} - \mathbf{x}_0}{\varepsilon}\Big), \tag{17}$$

where $\varphi(\mathbf{x})$ is a smooth function which localizes in the vicinity of the point $\mathbf{x}_0$. We assume that the density of scatterers vanishes in the vicinity of the source location $\mathbf{x}_0$ so that the dispersion relation is $\omega = c_0|\mathbf{k}|$ locally.

In the absence of scatterers, the results obtained, e.g., in [17] show that there exists a positive bounded measure $a(\mathbf{x}, \mathbf{k})$ such that

$$\lim_{\varepsilon \to 0} |u_\varepsilon(\mathbf{x})|^2 := \nu(\mathbf{x}) = \int_{\mathbb{R}^d} a(\mathbf{x}, \mathbf{k}) d\mathbf{k}, \tag{18}$$

where $\nu(\mathbf{x})$ is a positive measure on $\mathbb{R}^d$. Moreover, the phase-space measure $a(\mathbf{x},\mathbf{k})$ solves the Liouville equation

$$c_0\hat{\mathbf{k}}\cdot\nabla a = Q(\mathbf{x},\mathbf{k}), \tag{19}$$

with the source $Q(\mathbf{x},\mathbf{k})$ given by

$$\begin{aligned} Q(\mathbf{x},\mathbf{k}) &= \frac{c_0^2}{2\omega(2\pi)^{d-1}}\delta(\mathbf{x}-\mathbf{x}_0)\delta\left(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\right)|\hat{\varphi}(\mathbf{k})|^2 \\ &= \frac{c_0^3}{4\omega^2(2\pi)^{d-1}}\delta(\mathbf{x}-\mathbf{x}_0)\delta\left(\frac{\omega}{c_0}-|\mathbf{k}|\right)|\hat{\varphi}(\mathbf{k})|^2. \end{aligned} \tag{20}$$

The above transport equation should be augmented with outgoing radiation conditions, namely, the incoming field $a(\mathbf{x}-t\mathbf{k},\mathbf{k})\to 0$ as $t\to+\infty$.

We briefly recall the derivation of the above equation and explain the scaling for the source term in (17). The regularized Helmholtz equation (17) with constant sound speed may be written as

$$\left(i\varepsilon\alpha+\varepsilon^2\Delta+\frac{\omega^2}{c_0^2}\right)u_\varepsilon = \frac{1}{\varepsilon^{\frac{d-1}{2}}}\varphi\Big(\frac{\mathbf{x}}{\varepsilon}\Big)$$

for some causality-preserving regularization parameter $0<\alpha\ll 1$ that will be sent to 0 eventually, and where we set $\mathbf{x}_0=0$ to simplify the presentation. In the Fourier domain at wave number $\boldsymbol{\xi}/\varepsilon$, this is

$$\hat{u}_\varepsilon\Big(\frac{\boldsymbol{\xi}}{\varepsilon}\Big) = \frac{\varepsilon^d\varepsilon^{-\frac{d-1}{2}}\hat{\varphi}(\boldsymbol{\xi})}{i\varepsilon\alpha+\frac{\omega^2}{c^2}-|\boldsymbol{\xi}|^2}.$$

Let us now introduce the following Wigner transform of u_ε:

$$W_\varepsilon(\mathbf{x},\mathbf{k}) = \frac{1}{(2\pi)^d}\int_{\mathbb{R}^d} u_\varepsilon\left(\mathbf{x}-\frac{\varepsilon\mathbf{y}}{2}\right)u_\varepsilon^*\left(\mathbf{x}+\frac{\varepsilon\mathbf{y}}{2}\right)e^{i\mathbf{k}\cdot\mathbf{y}}d\mathbf{y},$$

which verifies that

$$|u_\varepsilon(\mathbf{x})|^2 = \int_{\mathbb{R}^d} W_\varepsilon(\mathbf{x},\mathbf{k})d\mathbf{k}.$$

We verify that the Fourier transform $\mathbf{x}\to\mathbf{q}$ of W_ε is given by

$$\begin{aligned} \hat{W}_\varepsilon(\mathbf{q},\mathbf{k}) &= \frac{1}{(2\pi\varepsilon)^d}\hat{u}_\varepsilon\Big(\frac{\mathbf{q}}{2}-\frac{\mathbf{k}}{\varepsilon}\Big)\widehat{u_\varepsilon^*}\Big(\frac{\mathbf{q}}{2}+\frac{\mathbf{k}}{\varepsilon}\Big) \\ &= \frac{\varepsilon}{(2\pi)^d}\frac{|\hat{\varphi}(\mathbf{k})|^2}{[i\varepsilon\alpha+\frac{\omega^2}{c_0^2}-|\mathbf{k}+\frac{\varepsilon\mathbf{q}}{2}|^2][-i\varepsilon\alpha+\frac{\omega^2}{c_0^2}-|\mathbf{k}-\frac{\varepsilon\mathbf{q}}{2}|^2]}+l.o.t. \\ &= \frac{\varepsilon}{(2\pi)^d}\frac{|\hat{\varphi}(\mathbf{k})|^2}{\big(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\big)^2-\big(i\varepsilon\alpha-\varepsilon\mathbf{k}\cdot\mathbf{q}\big)^2}+l.o.t. \\ &= \frac{\varepsilon}{(2\pi)^d}\frac{|\hat{\varphi}(\mathbf{k})|^2}{2i\varepsilon\alpha-2\varepsilon\mathbf{k}\cdot\mathbf{q}}\left[\frac{1}{\big(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\big)-i\varepsilon\alpha}-\frac{1}{\big(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\big)+i\varepsilon\alpha}\right]+l.o.t. \\ &= \frac{1}{i(2\pi)^d}\frac{|\hat{\varphi}(\mathbf{k})|^2}{2\alpha+i2\mathbf{k}\cdot\mathbf{q}}2\pi i\delta\left(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\right)+l.o.t. \\ &= \frac{1}{2\alpha+i2\mathbf{k}\cdot\mathbf{q}}\frac{|\hat{\varphi}(\mathbf{k})|^2}{(2\pi)^{d-1}}\delta\left(\frac{\omega^2}{c_0^2}-|\mathbf{k}|^2\right)+l.o.t. \end{aligned}$$

Here, *l.o.t.* refers to terms that tend to 0 in the sense of distributions as $\varepsilon \to 0$. We refer the reader to, e.g., [17] for a more rigorous derivation. This shows that in the limit $\varepsilon \to 0$, we have

$$(2\alpha + i2\mathbf{k}\cdot\mathbf{q})\hat{W}(\mathbf{q},\mathbf{k}) = \frac{|\hat{\varphi}(\mathbf{k})|^2}{(2\pi)^{d-1}}\delta\left(\frac{\omega^2}{c_0^2} - |\mathbf{k}|^2\right).$$

Sending the regularizing parameters $\alpha \to 0^+$ and denoting by $a(\mathbf{x},\mathbf{k})$ the inverse Fourier transform $\mathbf{q} \to \mathbf{x}$ of $\hat{W}$, we obtain the Liouville equation (19).

In the presence of scatterers whose density vanishes at $\mathbf{x} = \mathbf{x}_0$, the radiating source term $Q(\mathbf{x},\mathbf{k})$ is not modified, and propagation in a homogeneous medium is replaced formally by propagation in a scattering medium, as in the preceding section. The phase-space energy density $a(\mathbf{x},\mathbf{k})$ thus solves the following stationary transport equation:

$$(21)\qquad c_0\hat{\mathbf{k}}\cdot\nabla a + \Sigma(\mathbf{x},|\mathbf{k}|)a = \int_{\mathbb{R}^d}\sigma(\mathbf{x},\mathbf{k},\mathbf{q})a(\mathbf{x},\mathbf{q})\delta(c_0|\mathbf{k}| - c_0|\mathbf{q}|)d\mathbf{q} + Q(\mathbf{x},\mathbf{k}).$$

The equation should be augmented with zero-incoming radiation conditions, i.e., $a(\mathbf{x}-t\mathbf{k},\mathbf{k}) \to 0$ as $t \to +\infty$. In practice, we choose the source term $\varphi(\mathbf{x}) = \delta(\mathbf{x})$ so that $\hat{\varphi}(\mathbf{k}) = 1$.

2.3. Foldy–Lax model for point scatterers. The Helmholtz equation (17) is very demanding to solve numerically for the choice of sound speed fluctuations given in (5). Since $\beta > 0$ so that $\varepsilon^\beta \to 0$ as $\varepsilon \to 0$, the localized scatterers are very small compared to the wavelength of the propagating waves. As a consequence, we can replace the localized scatterers by point scatterers. We thus have to solve a Helmholtz equation with randomly distributed point scatterers.

Assuming that the number of scatterers on a given computational domain is N, we obtain that the solution to the Helmholtz equation is given by

$$(22)\qquad u(\mathbf{x}) = u^i(\mathbf{x}) + \sum_{j=1}^{N}\tau_j G_0(\mathbf{x},\mathbf{x}_j)u(\mathbf{x}_j),$$

where $u^i(\mathbf{x})$ is the wave field generated by the source and the Green's function $G_0(\mathbf{x},\mathbf{x}')$ is given by

$$(23)\qquad G_0(\mathbf{x},\mathbf{x}') = \begin{cases} \dfrac{i}{4}H_0^1(k|\mathbf{x}-\mathbf{x}'|), & d = 2,\\ \dfrac{e^{ik|\mathbf{x}-\mathbf{x}'|}}{4\pi|\mathbf{x}-\mathbf{x}'|}, & d = 3,\end{cases}$$

with H_0^1 the 0th order Hankel function of the first kind. When $\mathbf{x} = \mathbf{x}_j$, the above solution needs modification. The Foldy–Lax model [25, 29, 40] removes the singularities in a self-consistent fashion by imposing that

$$(24)\qquad u(\mathbf{x}_j) = u^i(\mathbf{x}_j) + \sum_{\substack{j'=1\\ j'\neq j}}^{N}\tau_{j'}G_0(\mathbf{x}_j;\mathbf{x}_{j'})u(\mathbf{x}_{j'})$$

for $j = 1, \ldots, N$. We thus need to solve the system (24) first, and then we can evaluate the field $u(\mathbf{x})$ at each point $\mathbf{x}$ using (22).

The Foldy–Lax equation (24) can be written in matrix form as

$$\mathbf{H}\mathbf{U} = \mathbf{U}^i, \tag{25}$$

where

$$\mathbf{U} \equiv [u(\mathbf{x}_1), \ldots, u(\mathbf{x}_N)]^{\mathrm{T}}, \qquad \mathbf{U}^i \equiv [u^i(\mathbf{x}_1), \ldots, u^i(\mathbf{x}_N)]^{\mathrm{T}}, \tag{26}$$

and where the complex matrix $\mathbf{H}$ is given by

$$H_{jj'} = \delta_{jj'} - (1 - \delta_{jj'})\tau_{j'} G_0(\mathbf{x}_j, \mathbf{x}_{j'}). \tag{27}$$

For simplicity, let us assume that the strength of the scatterers is given by $\tau_j = \epsilon_j \tau k^2$, where the ϵ_j are independent variables taking the values 1 and -1 with equal probability. This is the setting that we will consider in the next section. We then verify that

$$\Sigma_{2D}(\mathbf{x}) = \frac{k^3\tau^2 n_0}{4}, \qquad \sigma_{2D}(\mathbf{x}, \mathbf{k}, \mathbf{k}') = \frac{k^3\tau^2 n_0}{8\pi} \tag{28}$$

in the two-dimensional case and

$$\Sigma_{3D}(\mathbf{x}) = \frac{k^4\tau^2 n_0}{4\pi}, \qquad \sigma_{3D}(\mathbf{x}, \mathbf{k}, \mathbf{k}') = \frac{k^4\tau^2 n_0}{16\pi^2} \tag{29}$$

in the three-dimensional case. These expressions are consistent with (14), provided that we set $L = 1$ and normalize the sound speed $c_0 = 1$. We shall assume that $L = 1$ and $c_0 = 1$ for the rest of the paper.

2.4. Models for the buried inclusions. We now have to model the buried inclusions, both at the level of the Helmholtz equation and of the radiative transfer equation.

The Foldy–Lax model can be generalized to account for the presence of extended objects. Here, we consider impenetrable objects with vanishing Neumann boundary conditions at the inclusion's boundary for the Helmholtz equation. In this setting, (22) becomes

$$u(\mathbf{x}) = u^i(\mathbf{x}) + \sum_{j=1}^{N} \tau_j G_0(\mathbf{x}; \mathbf{x}_j) u(\mathbf{x}_j) + \sum_{l=1}^{M} \int_{\partial\Omega_l} \mathbf{n}_l \cdot \nabla_{\mathbf{y}} G_0(\mathbf{x}; \mathbf{y}) u(\mathbf{y}) dS(\mathbf{y}), \tag{30}$$

where M is the number of extended objects in the domain and Ω_l is the lth inclusion with sufficiently smooth boundary $\partial\Omega_l$ and outer normal vector $-\mathbf{n}_l$ on the boundary. The Foldy–Lax consistent equation now becomes

$$u(\mathbf{x}_j) = u^i(\mathbf{x}_j) + \sum_{j' \neq j}^{N} \tau_{j'} G_0(\mathbf{x}_j; \mathbf{x}_{j'}) u(\mathbf{x}_{j'}) + \sum_{l=1}^{M} \int_{\partial\Omega_l} \mathbf{n}_l \cdot \nabla_{\mathbf{y}} G_0(\mathbf{x}_j; \mathbf{y}) u(\mathbf{y}) dS(\mathbf{y}) \tag{31}$$

for $j = 1, \ldots, N$.

In order to evaluate wave fields at arbitrary points $\mathbf{x}$, we need to solve (30) for points on the boundary of the extended objects and (31) for $\mathbf{x}_j, j = 1, \ldots, N$. Equations (30) and (31) are the new self-consistent Foldy–Lax multiple scattering equations in the case where extended objects are present.

At the transport level, in order to obtain a contribution of order $O(1)$, we need to assume that the inclusion is comparable in size to the overall distance of propagation. This implies that the extended object is large compared to the wavelength ε so that its boundary may be treated as specularly reflecting. In other words, we assume the following specular reflection:

$$a(\mathbf{x},\mathbf{k}) = a(\mathbf{x},\mathbf{k}-2\mathbf{k}\cdot\mathbf{n}(\mathbf{x})\mathbf{n}(\mathbf{x})), \qquad \mathbf{x}\in\partial\Omega_l. \tag{32}$$

The radiative transfer equation (21) holds outside of the inclusions, i.e., on $\mathbb{R}^d\backslash(\cup_l\Omega_l)$.

3. Numerical validations.

Although radiative transfer equations have been used for a long time to describe the energy density of waves in random media, numerical validations of such models are more recent; see, e.g., [10, 33] for simulations in the time domain. The reason is that the propagation of high frequency waves in highly heterogeneous media is computationally quite expensive. In this section, we compare the energy densities of monochromatic waves based on the Foldy–Lax model with the solution of the corresponding radiative transfer equation.

3.1. The wave and transport solvers.

The Foldy–Lax consistent equations (25) form a system of complex-valued algebraic equations with a dense matrix $\mathbf{H}$. We solve the system by a direct solver that utilizes the LU factorization. In the case where extended objects are present in the domain, we need to solve (30) and (31). We approximate the boundary integrals by standard numerical quadrature rules. Since these integrals are weakly singular, we adopt the kernel splitting method developed in [22] to discretize the integrals.

The random medium is generated by distributing the random scatterers according to a Poisson point process of density n_0. We recall that for a bounded volume element V, the number of points in V has the distribution $\mathbb{P}(N_V = k) = \frac{e^{-n_0|V|}(n_0|V|)^k}{k!}$ for $k \geq 0$, where $|V|$ is the (Lebesgue) measure of V. Once a realization of the number k is chosen, the k points are placed in V using a uniform (normalized Lebesgue) distribution on V. A typical distribution of point scatterers is shown in Figure 1.

The transport equation (21) is solved by the Monte Carlo method [39]. We run enough particles to ensure that the statistical error in the simulation is smaller than any other involved quantity. As in [10], to which we refer the reader for more details, we use as much as possible the same random trajectories in the Monte Carlo simulation for the calculations performed with and without the extended objects. This variance reduction technique is necessary to calculate the influence of the inclusions accurately.

Note that the Foldy–Lax model and the radiative transfer equations work for a given (large) frequency. By varying the frequency in the vicinity of a central frequency, time-domain data may be obtained by inverse Fourier transform. In the rest of the paper, we concentrate on frequency domain calculations.

3.2. Numerical results.

To compare the wave and transport models, we compute the total energy on a fixed array of detectors D; see Figure 1. After appropriate normalization, the energies take the form

$$E_W = \int_D |u(\mathbf{x})|^2 d\mathbf{x} \quad \text{and} \quad E_T = \int_D \int_{S^{d-1}} a(\mathbf{x},\hat{\mathbf{k}})d\hat{\mathbf{k}}d\mathbf{x}, \tag{33}$$

where $u(\mathbf{x})$ is the random solution to the wave equation and $a(\mathbf{x},\hat{\mathbf{k}})$ is the energy density of those waves at position $\mathbf{x}$ propagating in direction $\hat{\mathbf{k}}\in S^{d-1}$, where $d=2$ in all our numerical simulations.

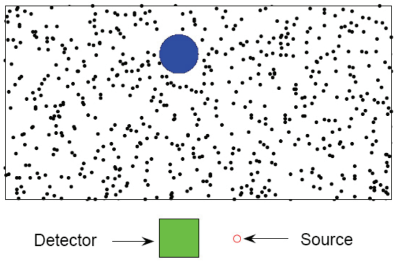

Fig. 1. *Setup for the numerical simulations. The inclusion may be placed inside or outside of the random medium. We show here a typical realization of the distribution of* 1000 *point scatterers.*

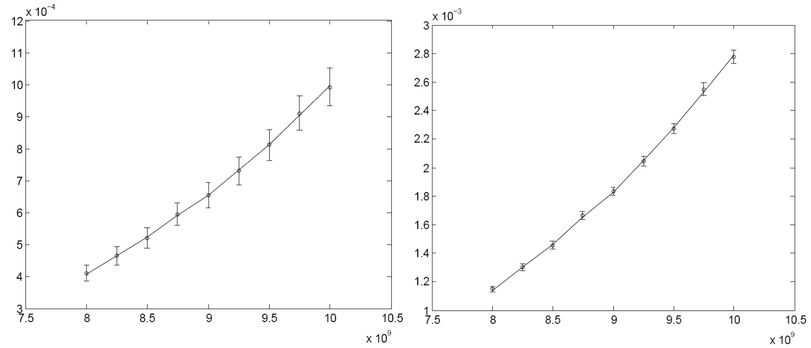

Fig. 2. *Comparison between measured transport and wave data at frequencies between* $\omega = \frac{2\pi}{\lambda}$ *and* 1.25ω *with detectors of size* $40\lambda \times 40\lambda$ *(left) and* $80\lambda \times 80\lambda$ *(right), respectively. Solid line: transport data* E_T*. Circles with error bar: wave data* $\mathbb{E}\{E_W\}$ *and its standard deviation* $\sigma(E_W)$*.*

Since $u(\mathbf{x})$ is a random variable, E_W is also a random variable, which thus depends on the realization of the random medium. Note that E_T, in contrast, is a deterministic quantity. We have therefore two objectives: (i) show that $\mathbb{E}\{E_W\}$ is close to E_T; and (ii) show that the standard deviation $\sigma(E_W)$ of E_W is small. The latter is defined as

$$\sigma(E_W) = \Big(\mathbb{E}\{(E_W - \mathbb{E}\{E_W\})^2\}\Big)^{\frac{1}{2}}. \tag{34}$$

From now on, we use the standard notation σ to denote standard deviations, which should not be confused with the scattering cross-section in (21). We are interested in the behavior of $\sigma(E_W)$ as a function of the mean free path $c_0\Sigma^{-1}$.

Energy measurements and detector size. The first numerical test compares wave and transport data in the absence of any buried inclusion. The setup is as shown in Figure 1. In order to illustrate the behavior of the energy density as a function of frequency, we compare the models for nine frequencies uniformly distributed on $[\omega \;\; 1.25\omega]$, where $\omega = \frac{2\pi}{\lambda}$. The domain of interest is fixed and given by $[0 \;\; 400\lambda] \times [0 \;\; 200\lambda]$. The point source is located at position $(220\lambda, -40\lambda)$. A total of 6000 point scatterers on average (using a Poisson distribution) are randomly distributed in the domain. This corresponds to a correlation length $l_c \approx 3.65\lambda$. The strength of the scatterers is chosen such that the mean free path is equal to 40λ. As the frequency increases, the transport mean free path decreases as the third power of frequency, as can be seen in (28). We show in Figure 2 a comparison between E_W and E_T at different frequencies with two different sizes of the array of detectors. The average

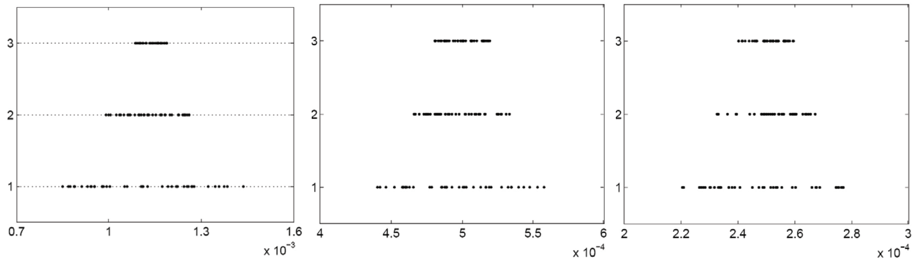

FIG. 3. *Statistical stability of wave data with respect to media properties at three mean free paths:* $c_0\Sigma^{-1} = 30\lambda$ *(left),* $c_0\Sigma^{-1} = 50\lambda$ *(middle), and* $c_0\Sigma^{-1} = 100\lambda$ *(right). Each dot corresponds to the wave energy measured on the array of detectors for one realization with an average of* 6000 *scatterers (top lines labeled* 3*;* $l_c \approx 3.65\lambda$*),* 3000 *scatterers (middle lines labeled* 2*;* $l_c \approx 5.16\lambda$*), and* 1500 *scatterers (bottom lines labeled* 1*;* $l_c \approx 7.30\lambda$*), respectively.*

$\mathbb{E}\{E_W\}$ and standard deviation $\sigma(E_w)$ are calculated based on 40 realizations of the random medium.

We observe that the wave and transport models agree quite well. The ensemble average of the energy density is well captured by the radiative transfer equation. However, radiative transfer models are valid when energy is averaged over a sufficiently large domain compared to the wavelength [4, 8]. When averaging takes place over too small a detector, significant statistical instabilities occur.

These results generalize to the case where an inclusion is present in the random medium. The comparison between the energy densities E_W and E_T is then qualitatively very similar to the case shown in Figure 2.

Statistical stability and density of scatterers. In the next numerical example, we want to address the statistical stability of the transport model with respect to the number of random scatterers. The same average scattering medium, characterized by a given mean free path, may be obtained from a low density of strong scatterers or a high density of weak scatterers in such a way that $\tau^2 n_0$ stays constant. We do not have a theoretical model at present to characterize the statistical stability of the energy E_W when τ and n_0 vary while the product $\tau^2 n_0$ remains constant. Intuitively, however, we expect the random medium to be more mixing, and thus more stable statistically, when the number of scatterers is large simply because the wave fields interact with the underlying structure more often. The following numerical simulations confirm this.

We show in Figure 3 the energy measurements obtained from nine types of random media corresponding to an average of 6000 scatterers ($l_c \approx 3.65\lambda$), 3000 scatterers ($l_c \approx 5.16\lambda$), and 1500 scatterers ($l_c \approx 7.30\lambda$), and to mean free paths $c_0\Sigma^{-1}$ equal to 30λ, 50λ, and 100λ. We observe that, as expected, the standard deviation increases with the correlation length in the medium (as statistical instability increases) and that it increases when the mean free path decreases (as the random medium becomes optically thicker); see the statistics in Table 1.

4. Transport-based imaging in random media. We now examine the capabilities of the radiative transfer model to detect and image inclusions buried in random media. As in the preceding section, all simulations are performed in a two-dimensional setting, which is appropriate for the experimental configuration considered in, e.g., [31]. Note that both the Foldy–Lax model and the Monte Carlo method are independent of dimension, so the proposed numerical method is essentially independent of spatial dimension.

TABLE 1
Average and standard deviation of the wave energy measurements presented in Figure 3.

	$c_0\Sigma^{-1} = 30\lambda$			$c_0\Sigma^{-1} = 50\lambda$			$c_0\Sigma^{-1} = 100\lambda$

As we saw in section 2, the wave energy density is modeled by a radiative transfer equation given by (21) outside of the buried inclusions and by specular reflection conditions (32) at the inclusions' boundary. The inclusions thus become constitutive parameters in the radiative transfer equation, as is the mean free path $c_0\Sigma^{-1}(\mathbf{x})$. In this section, we propose to reconstruct the mean free path and the inclusion in (21)–(32) using energy measurements obtained by solving the Foldy–Lax equations (22)–(24). Although inverse transport models have been used already (see, e.g., [1, 34]), to our knowledge this is the first analysis of reconstructions based on a macroscopic (wavelength-independent) transport model from microscopic (wave- and medium-dependent) wave data.

We consider three slightly different settings as follows: inclusions buried inside a random medium; inclusions separated from the array of detectors by a random medium; and inclusion buried in a random medium and located behind a large blocker that prevents a direct line of sight from the source location. The settings are shown in Figure 4.

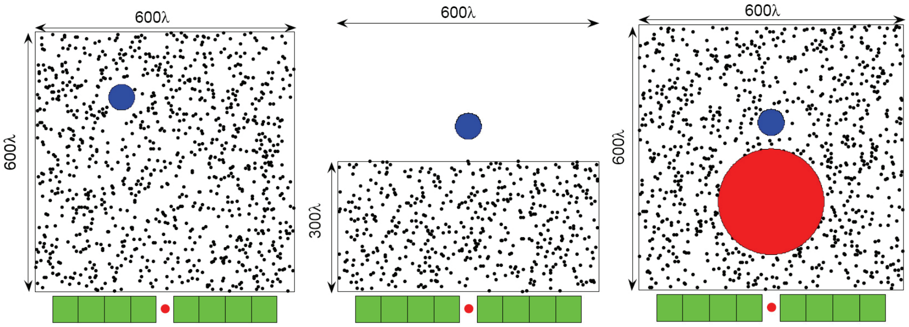

FIG. 4. *Three different setups for the reconstructions: inclusion inside the medium (left), inclusion outside the medium (middle), and inclusion behind a blocker (right). The small circles and the squares represent the source and detector locations, respectively. The small disks are the inclusions to be reconstructed. The large disk represents a blocker, whose location and geometry is assumed to be known.*

The theory of inverse problems for transport equations is relatively well established in the presence of phase-space measurements; see [20]. Here, however, we assume that E_W and E_T are available, not $a(\mathbf{x}, \hat{\mathbf{k}})$ for all $\mathbf{x} \in D$ and $\hat{\mathbf{k}} \in S^{d-1}$. As in reconstructions from knowledge of the Cauchy data in an inverse elliptic problem [26], the recent theoretical result on inverse transport obtained recently in [7] shows that our inverse problem is severely ill-posed. The stability of such inverse problems is notoriously bad, in the sense that noise is drastically amplified during the inversion.

What this means in practice is that the number of degrees of freedom about the random medium and the inclusion that we can possibly retrieve from available data is *small*. The inverse transport problem thus needs to be parameterized. Our choice of a parameterization is the following: we assume that the mean free path $c_0\Sigma^{-1}$ is constant in a rectangular domain, whose geometry is known, and vanishes outside of that domain; and we assume that the inclusion is a disc parameterized by its location $\mathbf{x}$ and its radius R. This hypothesis is slightly relaxed in section 4.3.

4.1. Transport-based imaging method. The reconstruction method for the parameters mentioned above is based on the following least-square minimization procedure. Let $\mathcal{F}$ be the family of parameters we want to reconstruct. We find these parameters by solving the following minimization problem:

$$\mathcal{F}_b = \arg\min_{\mathcal{F}\in\Xi} \mathcal{O}(\mathcal{F}), \tag{35}$$

where $\Xi = [\mathcal{F}_{min}, \mathcal{F}_{max}]$ is a family of a priori box constraints that define a region in which we search for optimal solutions. The objective function that measures the mismatch between measured data and model prediction is given by

$$\mathcal{O}(\mathcal{F}) = \frac{1}{2}\sum_{j=1}^{J} |E_T^j - E_W^j|^2, \tag{36}$$

where E_T^j is the model prediction on detector j, E_W^j the corresponding wave measurement, and J the total number of detectors. We solve this minimization problem by a quasi-Newton minimization algorithm with BFGS updating rules for the Hessian matrix. Box constraints on decision variables are enforced by a gradient projection method. The gradient of the objective function with respect to the parameters to be recovered is calculated by using a finite difference approximation since we have only a few parameters to reconstruct. We refer the interested reader to [16, 32] for details on the BFGS quasi-Newton method and to [34] for an application of the method in inverse transport problems.

In all of the inversions run below, we consider eight detectors of size $62.5\lambda \times 80\lambda$, as depicted in Figure 4. We have mentioned that the energy density was statistically stable only on sufficiently large domains. The size of the detectors thus needs to be sufficiently large to average over local fluctuations. The number of detectors also needs to be sufficiently large to increase the amount of available data. We do not possess a theory for the energy-energy correlations that could guide us in the design of optimal detector arrays. Several scenarios have been tested, and eight is an optimal number of detectors in terms of the statistical stability and the amount of nonredundant information it provides.

The box constraints Ξ have also been chosen to be fairly nonconstraining. For an inclusion of radius $R = 30\lambda$ and location $(300\lambda, 400\lambda)$ in a random medium of size $[0\ 600\lambda]\times[0\ 600\lambda]$, for instance, the constraints on the radius are $R \in [10\lambda, 100\lambda]$ and the constraints on the locations (x, y) are $[50\lambda\ 550\lambda]\times[50\lambda\ 550\lambda]$.

4.2. Imaging under different measurement scenarios. We consider two imaging scenarios: (i) when we have wave energy measurements in the presence of the object; and (ii) when we have energy measurements in the presence *and* in the absence of the inclusion. The former measurements are referred to as *direct* measurements. The latter measurements are referred to as *differential* measurements.

4.2.1. Scenario Ia: Direct measurement. In this first scenario, we are not able to probe the random medium in the absence of an inclusion. We distinguish two subscenarios, which essentially have the same reconstruction capabilities. In scenario Ia, we assume that we have access to measurements in the absence of the inclusion for a given realization of the random medium, which we call medium 1. This allows us to reconstruct the parameters of the random medium, i.e., here the mean free path $c_0\Sigma^{-1}$. We then assume that we have access to measurements in the presence of the inclusion in a medium 2 that is completely uncorrelated to medium 1. This allows us to reconstruct the inclusions' parameters. In scenario Ib, we assume that we have access to the measurements in medium 2 only, and hence in the presence of the inclusion. We have thus to reconstruct all parameters at once. We will present numerical evidence that both scenarios provide very similar reconstruction capabilities. In both cases, the inclusion's influence on the measurements needs to be greater than the noise level coming from our lack of understanding of the specific realization of the random medium. In other words, the inclusion's influence needs be larger than the statistical instability of the radiative transfer model. The reconstruction in scenario Ia is a two-step process, as follows.

Step A. We measure the energy density of waves propagating in one realization of the random medium described above. We then estimate the scattering cross-section Σ by solving the following minimization problem:

$$\Sigma_b = \arg\min_{\Sigma\in\Xi_A} \mathcal{O}(\Sigma), \tag{37}$$

where $\Xi_A = [\Sigma_{min}, \Sigma_{max}]$ is the space in which we seek Σ, and the objective functional is given by

$$\mathcal{O}(\Sigma) = \frac{1}{2}\sum_{j=1}^{J} |E_T^j - E_W^j|^2, \tag{38}$$

where E_T^j is the model prediction detector j, and E_W^j is the corresponding wave energy measurement.

Step B. We now perform the energy measurements in the presence of an inclusion buried in medium 2 uncorrelated with the medium used in Step A. Such a scenario is realistic when we know that medium 2 has statistics similar to medium 1, on which more refined estimates can be obtained before measurements in medium 2 are performed.

We use the scattering coefficient Σ_b (b for best fit) obtained in Step A and image the inclusion from available measurements in medium 2. The position and radius of the inclusion, assumed to be a disc, are obtained by the following minimization:

$$(\mathbf{x}_b, R_b) = \arg\min_{(\mathbf{x},R)\in\Xi_B} \mathcal{O}(\mathbf{x}, R). \tag{39}$$

Here $\mathcal{O}(\mathbf{x}, R)$ is defined as in (36), with E_T^j the transport solutions, with Σ_b the scattering cross-section, and E_W^j the wave energy measurements in medium 2. Here, $\Xi_B \subset \mathbb{R}^{d+1}$ is the constraint set in which the solution $(\mathbf{x}, R)$ is sought.

We show in Figure 5 four typical reconstructions ((A)–(D) from left to right) with this two-step procedure. The reconstructions in (A) and (B) are done for the first configuration in Figure 4, where the medium covers the domain $[0\ 600\lambda]\times[0\ 600\lambda]$ and the inclusion is located inside the medium. A few scatterers around the inclusions are removed from the picture to make the plot clearer. The reconstructions in (C) and (D) are done for the second configuration in Figure 4, where the medium covers the

domain $[0\ 600\lambda]\times[0\ 300\lambda]$ and the inclusion is located outside of the medium. The mean free path (with $c_0 = 1$) for the medium in (A) and (C) is $c_0\Sigma^{-1} = 200\lambda$ and that for the medium in (B) and (D) is $c_0\Sigma^{-1} = 100\lambda$. In all experiments, the correlation length is $l_c \approx 7.75\lambda$, with an average of 6000 rods in experiments (A) and (C) and of 3000 rods in experiments (B) and (D).

The reconstructions are repeated for 40 different realizations of the random medium. The results are presented in Figure 6, where we have plotted the reconstructed locations and radii for the four cases shown in Figure 5. We observe that in all cases, the reconstructions of the inclusion's location are quite accurate. The radii are also good, though not as accurate. Given the smallness (relative to the mean free path) of the inclusions, we do not expect to reconstruct their size very precisely.

We have calculated the first two statistical moments (expectation and standard deviation) of the mean free path, the inclusions' locations (measured by x- and y-coordinates), and the inclusions' radii. The numbers are presented in Table 2. We observe that the reconstruction of the inclusion's location is relatively good, as the variance is quite small. The error in the reconstruction of the inclusion's geometry (i.e., the radius) is, however, significantly larger. The results presented in Table 2 also show that the standard deviations in the x and y variables are somewhat comparable (and on the order of $2-3\lambda$, less than 1% of the distance from the source to the

inclusion). This is an indication that the regime of wave propagation is quite highly mixing so that there is no real privileged direction of propagation.

As we have mentioned in section 3, the statistical stability of the wave energy measurements depends on the number of scatterers for a given mean free path. We now consider the reconstruction of inclusions for two random media with a mean free path equal to $c_0\Sigma^{-1} = 100\lambda$. The first random medium has an average of 6000 point scatterers ($l_c \approx 7.75\lambda$) and the second random medium has an average of 3000 point scatterers ($l_c \approx 10.95\lambda$). The results are presented in Figure 7. We have also calculated the two first statistical moments of the inclusions' location and radius. Results are reported in Table 3. The averaged values are very similar for both reconstructions, which is expected, since radiative transfer is indeed valid for the ensemble averaged energy density. The standard deviation, however, increases when the scatterers become fewer and stronger. In that case, our lack of understanding of the specific realization of the random medium creates large noise in the data, and hence in the reconstructions. Such results are consistent with our numerical analysis of the statistical instability done in section 3.

Let us conclude this section with a remark on the resolution of the method. With random media with 6000 scatterers on average, a mean free path of $c_0\Sigma^{-1} = 100\lambda$ on a square domain of size 600λ, and an inclusion buried 375λ north of the source, we have good reconstructions for radii larger than 20λ. At about 20λ, the "optimal" radius obtained by minimization has a large probability of hitting the box constraints imposed on the radius and is thus meaningless. In the same configuration with a random medium with 3000 scatterers on average, the smallest radius we can confidently reconstruct increases to $R = 30$. These results lead to the following conclusion. Even in the presence of a highly mixing random medium (with 6000 scatterers, which may be large for most practical situations [31]), the inclusion needs to be quite large compared to the wavelength in order for its influence to be larger than

TABLE 3

the statistical instability of the wave energy measurements. In such a context, the only solution to improve resolution is to have access to the measurements of scenario II considered below.

4.2.2. Scenario Ib: Reconstructing all at once. We now consider the setting where Σ and the inclusion's parameters are reconstructed in a single step because we do not possess any a priori knowledge of the statistics of the random medium. Compared to scenario Ib, we have one more parameter to reconstruct, and possibly many more parameters when the power spectrum is spatially dependent. However, the reconstruction of these parameters is more adapted to the random medium 2 than in scenario Ia. Reconstructions are based on minimizing the functional,

$$(\Sigma_b, \mathbf{x}_b, R_b) = \arg \min_{(\Sigma, \mathbf{x}, R) \in \Xi} \mathcal{O}(\Sigma, \mathbf{x}, R), \tag{40}$$

where $\Xi \subset \mathbb{R}^3$ is a set of constraints.

This scenario is of equivalent complexity to the previous one since only one additional parameter is added. Moreover, as long as the inclusion is relatively small compared to the size of the domain, it will not affect the reconstruction of Σ in any significant way.

We show in Figure 8 the same reconstructions under scenario Ib as those obtained under scenario Ia in Figures 5(A) and 5(B). The first two statistical moments of the reconstructed locations and radii are listed in Table 4. We observe that the reconstructed mean free paths, inclusion's positions, and radii are very similar to the parameters reconstructed in Figure 5.

4.2.3. Scenario II: Differential measurement. Scenario II relies on much different measurements. We assume that we have access to wave energy measurements in the presence and in the absence of the inclusion, and in both cases for the *same* realization of the random medium (except at the location of the inclusion, where the

Table 4

	Inclusion			Reconstruction[a]		
	$c_0\Sigma^{-1}$	location	R	$c_0\Sigma_b^{-1}$	location	R
Medium 1	200	(200, 450)	40	200.6 [3.1]	(199.5 [2.6], 450.7 [2.8])	41.5 [5.7]
Medium 2	100	(200, 450)	40	99.0 [5.0]	(199.5 [3.4], 450.1 [3.5])	39.7 [7.0]

random scatterers are suppressed). However, we do not know the random medium and thus have to model it macroscopically using a radiative transfer model. As in the preceding case, the macroscopic model is parameterized by a unique parameter, the mean free path $c_0\Sigma^{-1}$.

As we said earlier, differential measurements allow for much more accurate reconstructions. The reason is that the difference of the two measured energies depends only on the inclusion. Therefore, with a kinematic picture in mind, where wave energy packets are replaced by particles scattering in the random media, all the wave packets that do not interact with the inclusion do not contribute to differential measurements. These wave packets are the largest contributors to the statistical instability of the random medium that hampers reconstructions of small objects in scenario I. The measured wave packets that have interacted with the inclusion are also statistically unstable. However, they are in some sense proportional to the inclusion, and in the absence of external measurement noise, differential measurements allow one to reconstruct arbitrarily small objects. They are not immune to the statistical instability, and a statistical instability in the random medium of 10% may result in an error on the location and radius of the inclusion on the order of 10% as well. However, the limit in the size of the objects that can be reconstructed is governed by external measurement noise and no longer by the statistical instability in the medium. The two-step reconstruction process used in scenario Ia applies here as follows.

Step A. We use the measurements in the absence of an inclusion in the medium to estimate the scattering cross-section of the medium. This is done by minimizing (37) as before.

Step B. Once Σ has been found, we reconstruct the location ($\mathbf{x}$) and the radius (R) of the spherical inclusion by minimizing,

$$(\mathbf{x}_b, R_b) = \arg \min_{(\mathbf{x},R)\in\Xi_B} \delta\mathcal{O}(\mathbf{x}, R), \tag{41}$$

where

$$\delta\mathcal{O}(\mathbf{x}, R) = \frac{1}{2}\sum_{j=1}^{J} |\delta E_T^j - \delta E_W^j|^2. \tag{42}$$

Here, δE_T^j and δE_W^j correspond to the difference of energies with and without the inclusion for the transport model and the wave data, respectively, at detector j. In practice, δE_W is calculated by estimating the difference of the solutions to two Foldy–Lax equations, and δE_W is estimated by Monte Carlo using the variance reduction technique introduced in [10]. The role of this variance reduction is to write the difference δE_W as the expectation of an appropriate process, rather than the difference of two expectations, which requires a huge amount of particles to be accurate. We refer the reader to [10] for additional details.

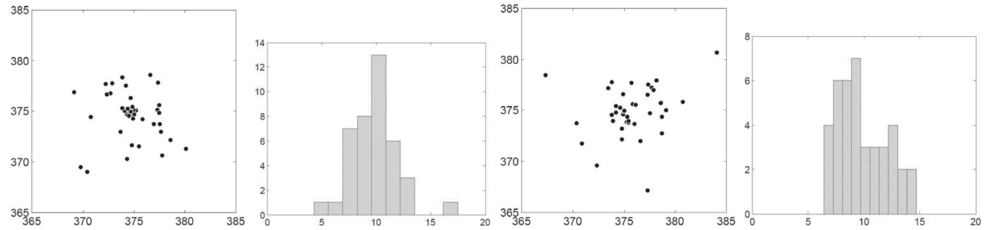

FIG. 9. *Distribution of reconstructed location and radius for* 40 *realizations with differential measurement. Left two plots:* $c_0\Sigma^{-1} = 200\lambda$. *Right two plots:* $c_0\Sigma^{-1} = 100\lambda$.

TABLE 5

Reconstructed mean free paths, locations, and radii based on differential measurements. [a]*Averaged value and standard deviation (numbers in brackets) calculated from* 40 *realizations. All numbers are in units of the wavelength* λ.

	Real			Reconstruction[a]		
	$c_0\Sigma^{-1}$	location	R	$c_0\Sigma_b^{-1}$	location	R
Medium 1	200	(375, 375)	10	199.8 [2.8]	(374.8 [2.4], 374.6 [2.4])	9.9 [2.3]
Medium 2	100	(375, 375)	10	100.1 [3.3]	(375.8 [2.9], 375.0 [2.4])	9.9 [2.2]

Reconstructions based on scenario II have been performed for two different mean free paths $c_0\Sigma^{-1} = 200\lambda$ and $c_0\Sigma^{-1} = 100\lambda$, respectively. The random medium is again formed of an average of 6000 scatterers over $[0\ 600\lambda]\times[0\ 600\lambda]$ so that the correlation length $l_c \approx 7.75\lambda$. The inclusion is located at coordinates $(375\lambda, 375\lambda)$ and has a radius equal to $R = 10\lambda$, which is significantly smaller than what we can reconstruct under scenario I.

We show in Figure 9 the distributions of the reconstructed locations and radii for the two random media.

The averaged value and standard deviation of the mean free path and the inclusion's location and radius are summarized in Table 5. As we can observe, the transport inversion does a relatively good job at locating the inclusion. However, it misses the size of the inclusion by a much larger amount. This is understandable because the specular reflection model may not be totally consistent with the size of an object with radius of order 10λ. For smaller objects, a more accurate radiation model than specular reflection is necessary. We do not consider this issue further here.

Reconstructions based on differential measurement may be used in the monitoring of cluttered areas, where we have access to energy measurements before and after the inclusion is present.

4.3. Imaging the orientation of the inclusions. In the preceding sections, we have obtained satisfactory reconstructions of inclusions based on low-dimensional parameterizations of the inclusion. Since, as we have mentioned in section 4, the inverse transport problem is quite ill-posed, we should not expect to reconstruct any fine geometrical information about the inclusion. To demonstrate this, we consider the reconstruction of half discs from wave energy measurements. Half discs are parameterized by their location, their radius, and the orientation θ of their flat portion (with respect to the x-axis). We use the same minimization techniques as in the preceding sections with this additional parameter θ in the functional in (36) in the case of direct measurements and in (42) in the case of differential measurements.

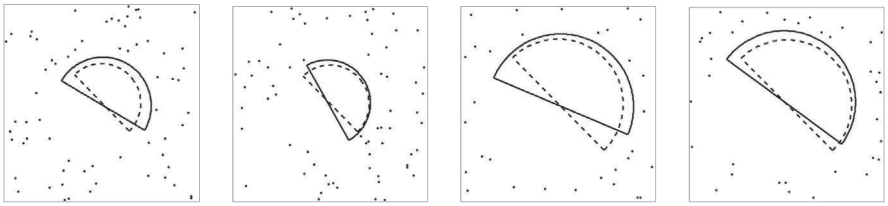

FIG. 10. *Reconstructions of half discs from direct and differential measurements in random media with an average of* 6000 *scatterers and a mean free path* $c_0\Sigma^{-1} = 100\lambda$*. From left to right: A typical reconstruction from differential measurement; an ensemble averaged reconstruction from differential measurement; a typical reconstruction from direct measurement; and an ensemble averaged reconstruction from direct measurement. True inclusions are plotted with dashed lines and reconstructed inclusions with solid lines.*

We show in Figure 10 typical reconstructions obtained from direct and differential measurements. The radius of the inclusion is $R = 30\lambda$ for the case of differential measurement and $R = 50\lambda$ for the case of direct measurement. In both cases, the half disc is centered at position $(375\lambda, 375\lambda)$. The reconstruction of the orientation is relatively accurate. Based on simulations on 20 realizations, the averaged reconstructed angle is 0.68π and the standard deviation is 0.16π for the case with differential measurements. The average angle is 0.81π and the standard deviation is 0.19π for the case with direct measurements. In each case, the exact angle is $\frac{3\pi}{4}$. The standard deviations on the orientation thus correspond to roughly 20% of the error. The reconstruction of the orientation is, however, not as accurate as that of the radius (or equivalently, the volume) and the location of the inclusion. The orientation is a finer geometric property of the inclusion and is thus more difficult to observe. Even with differential measurement, our experience is that we cannot faithfully reconstruct the orientation of half disks with a radius smaller than 25λ. For direct measurement, we can reconstruct the orientation when the radius of the inclusion is larger than 45λ. Below these numbers, the reconstruction of θ becomes extremely noisy.

4.4. Imaging in the presence of blockers.

In all of the above reconstructions, the mean free path is sufficiently small so that the energy leaving the source, hitting the inclusion, and coming back to the detectors without having interacted with the underlying medium, i.e., the energy of the coherent wave field, is relatively small. Inversions based only on the coherent information may thus fail to provide meaningful information about the inclusion. One may, however, use larger wavelengths, which are less affected by the random medium since the mean free path is much larger as the latter scales like λ^3. The assumption in scenarios I and II above is that we have access to wave measurements at frequencies for which there is considerable multiple scattering, i.e., for which the mean free path is relatively small.

There are, however, situations in which the coherent wave field can hardly be used no matter which frequency we consider, for instance, when the inclusion we seek to image is hidden by a large blocker. One can always argue that some energy reaches the hidden inclusion by diffractive effects. Such fields, however, are quite weak according to the geometric theory of diffraction and may well be below noise level as soon as the propagating medium has unknown spatial fluctuations.

In such situations, randomness in the underlying medium may be helpful. In the context considered in this paper of random media with multiple localized scatterers, the wave energy may be modeled by a radiative transfer equation, and both the

Table 6

Reconstructed mean free path, location, and radius in presence of blockers. [a]*Average and standard deviation (numbers in bracket) calculated from* 40 *reconstructions. All numbers are in units of the wavelength* λ.

	Inclusion			Reconstruction[a]		
	$c_0\Sigma^{-1}$	location	R	$c_0\Sigma_b^{-1}$	location	R
Medium 1	100	(300, 380)	40	101.0 [2.9]	(299.9 [2.6], 379.6 [2.9])	39.7 [5.3]
Medium 2	75	(300, 380)	40	74.8 [3.3]	(299.1 [3.1], 379.9 [2.6])	39.0 [5.2]

blocker and the unknown inclusion may be modeled as constitutive parameters in that equation. We consider here a situation where the blocker is large, spherical, and *known*. It is sufficiently large to block direct paths from the source term to the inclusion. The blocker is treated as any other extended inclusion in the Foldy–Lax and transport models.

We consider the setup shown on the right in Figure 4. The blocker is located at $(300\lambda, 200\lambda)$ and its radius is 120λ. The inclusion's center and radius are $(300\lambda, 380\lambda)$ and $R = 40\lambda$. All reconstructions are done based on differential measurements, i.e., under scenario II. The mean free path is estimated in the presence of the known blocker and the inclusion's parameters minimizing (42). Figure 11 shows reconstructions in random media with (theoretical) mean free paths equal to $c_0\Sigma^{-1} = 100\lambda$ and $c_0\Sigma^{-1} = 75\lambda$, respectively. In each case, there would be a number of scatterers equal to 6000 on average if the blocker was filled with scatterers so that $l_c \approx 7.75\lambda$. We are therefore in the more stable of the two random media considered so far.

The average and standard deviations of the reconstructed parameters are shown in Table 6. We observe quite good reconstruction capabilities. The images obtained in the presence of the blocker are of a quality comparable to those obtained in the absence of the blocker. Since the blocker is known and not so large so that no energy radiated from the source can reach the inclusion and come back to the array of detectors, this is consistent with what one expects from theoretical considerations.

5. Conclusions. We have derived a radiative transfer equation to model the energy density of mono-frequency waves propagating in random media composed of localized scatterers. We have shown the validity of the model based on numerical simulations, provided that the medium is sufficiently mixing. In our context, this means that the number of scatterers needs to be sufficiently large so that sufficient mixing occurs. Otherwise, the energy density becomes statistically less stable, i.e., depends more on the realization of the random medium.

When the medium is sufficiently mixing, the radiative transfer model is sufficiently stable for imaging purposes. Inclusions buried in the random medium are modeled as a constitutive parameter in the transport equation. We have shown numerical evidence that the inverse transport method indeed allows for accurate reconstruction of sufficiently large inclusions from wave energy measurements. Because inverse transport problems are quite ill-posed, in the sense that noise may be drastically amplified during the reconstruction, we have parameterized the inclusion by a small number of parameters, typically its location and its radius for spherical inclusions.

For smaller inclusions whose influence falls below the noise level coming from the statistical instability of the random medium, we have shown that differential measurements, i.e., wave energy measurements in the presence and in the absence of the inclusion, allowed for accurate reconstructions. Because the inclusions are modeled by specular reflections of the wave energy at their boundaries, the inverse model works for inclusions that are significantly larger than the wavelengths. For smaller inclusions, the model needs to be modified and the inclusion treated as a point source in the transport model with an appropriate radiation pattern that depends on geometry (an isotropic radiation pattern for a small spherical inclusion).

The imaging methods developed in this paper have been validated with real-world experimental data. The results are reported elsewhere [5].

Acknowledgments. We would like to thank the anonymous referees for their helpful comments on the first draft of this paper.

TIME-LOCAL DISSIPATIVE FORMULATION AND STABLE NUMERICAL SCHEMES FOR A CLASS OF INTEGRODIFFERENTIAL WAVE EQUATIONS[*]

C. CASENAVE[†] AND E. MONTSENY[†]

Abstract. We consider integrodifferential equations of the abstract form $\mathbf{H}(\partial_t)\Phi = \mathbf{G}(\nabla)\Phi + f$, where $\mathbf{H}(\partial_t)$ is a diagonal convolution operator and $\mathbf{G}(\nabla)$ is a linear anti-selfadjoint differential operator. On the basis of an original approach devoted to integral causal operators, we propose and study a time-local augmented formulation under the form of a Cauchy problem $\partial_t\Psi = \mathcal{A}\Psi + \mathcal{B}f$ such that $\Phi = \mathcal{C}\Psi$. We show that under a suitable hypothesis on the symbol $\mathbf{H}(p)$, this new formulation is dissipative in the sense of a natural energy functional. We then establish the stability of numerical schemes built from this time-local formulation, thanks to the dissipation of appropriate discrete energies. Finally, the efficiency of these schemes is highlighted by concrete numerical results relating to a model recently proposed for 1D acoustic waves in porous media.

Key words. integrodifferential equation, partial differential equation, convolution operator, diffusive representation, numerical scheme, Cauchy problem, energy functional, stability condition

1. Introduction.

In many physical problems where accurate dynamic models are required, the contribution of some underlying and more or less ill-known distributed phenomena cannot be neglected. Although the precise local description of such phenomena often appears excessively complex or even, in many cases, out of scope, fortunately most of the time their macroscopic dynamic consequences can be taken into account by means of suitable time-operators of a convolution nature, which in fact summarize the collective contribution of many hidden parameters to the global dynamic behavior of the quantities of interest. In that sense, such *integrodifferential* models therefore conciliate accuracy and simplicity, up to the loss of the so-called time-locality property. In opposition to standard Cauchy problems, for which the future is conditioned by the present only, here all past evolution is involved via the time-convolution. In past years, various problems relating to integrodifferential models have been studied in many fields. As examples we can cite [2, 7, 13, 16] in physics, [6, 9, 12] in mathematical analysis or numerical simulation, [1, 11] in control problems, [3, 10] in electrical engineering, [18] in biology, etc.

In the particular context of partial integrodifferential equations, the crucial problem of numerical simulation is in general quite difficult. This is due in one part to the numerical complexity of quadratures of convolution integrals, which generate highly expensive time discretizations, particularly when long memory components are present. Beyond this first heavy shortcoming, the stability of numerical schemes is in general very difficult to get, namely because standard techniques devoted to (ordinary) partial differential equations such as energy dissipation cannot be used for integrodifferential equations. So, the construction of stable numerical schemes remains an important challenge, and it can be expected that some specific methods

[†] Laboratoire d'Analyse et d'Architecture des Systèmes, LAAS-CNRS, University of Toulouse, 31077 Toulouse, France (casenave@laas.fr, emontseny@laas.fr).

devoted to analysis and approximation of convolution operators should be of great help. This is the topic of the present paper.

In what follows, we consider partial integrodifferential equations of the abstract form

$$\mathbf{H}(\partial_t)\Phi = \mathbf{G}(\nabla)\Phi + f \quad \text{on } (t,x) \in \mathbb{R}_t^{+*} \times \mathbb{R}_x^n, \tag{1.1}$$

where $\mathbf{H}(\partial_t)$ is an invertible[1] diagonal convolution operator, and $\mathbf{G}(\nabla)$ is an anti-selfadjoint linear differential operator. Many propagation phenomena can be modelled following (1.1). As significant examples, we can mention, for example, electromagnetic waves in dissipative media [13], wave propagation in viscoacoustic media [6], etc. In order to illustrate our results, we will consider in particular the following model of 1D acoustic waves in a porous wall proposed in [5]: $(H_1(\partial_t)u, H_2(\partial_t)P)^T = (-\partial_x P, -\partial_x u)^T + f$, where u and P stand for the velocity and the pressure of the gas, and the symbols H_i take the form $H_1(p) = k\,p + a\sqrt{1+b\,p}$, $H_2(p) = k'p + \frac{c\,p^2}{p+a'\sqrt{1+b'p}}$.

On the basis of an original approach devoted to integral causal operators presented in [14, 15] and successfully applied to various integrodifferential problems, namely in [1, 2, 3, 10], we propose and study a new formulation, both equivalent to (1.1) and time-local, written as the following Cauchy problem:

$$\partial_t\Psi = \mathcal{A}\Psi + \mathcal{B}f \quad \text{on } (t,x,\xi) \in \mathbb{R}_t^{+*} \times \mathbb{R}_x^n \times \mathbb{R}_\xi, \quad \Psi(0,.,.) = 0, \tag{1.2}$$

in such a way that the solution of (1.1) is expressed as $\Phi = \mathcal{C}\Psi$. We show in particular that under a natural hypothesis on the symbol $\mathbf{H}(p)$, the formulation (1.2) is dissipative in the sense of an energy functional derived, in some way, from the one of the standard equation $\partial_t\Phi = \mathbf{G}(\nabla)\Phi$. Following a convenient method introduced in [14], straightforward dissipative approximate versions of (1.2) are deduced by simple discretization of the auxiliary variable ξ. We then study numerical schemes based on classical discretizations relating to the variables t, x, and we establish their stability in the sense of adapted energy functionals inherited from the continuous model.

The paper is organized as follows. Section 2 deals with the time-local formulation of (1.1). It begins with a short presentation of the so-called diffusive representation of causal integral operators introduced in [14]; then, the formulation (1.2) is deduced and its dissipativity is established. In section 3, implicit and explicit numerical schemes for (1.2) are stated and studied from the point of view of stability. Finally, the efficiency of these schemes is highlighted in section 4 by means of some numerical simulations.

2. Time-local formulation of integrodifferential equations.

2.1. Time-local realization of causal convolution operators.

In this section, we present a particular case of a methodology called diffusive representation, introduced and developed in [14] in a general framework.

We consider a causal convolution operator denoted by $K(\partial_t)$, that is, for any continuous function $w : \mathbb{R}^+ \to \mathbb{R}$,

$$(K(\partial_t)w)(t) = \int_0^t k(t-s)\,w(s)\,ds = (k * w)(t); \tag{2.1}$$

the function $K = \mathcal{L}k$ (the Laplace transform of k) is called the symbol of operator $K(\partial_t)$.

[1] We implicitly refer to an underlying algebra of causal convolution operators. For example, for a Cauchy problem on $\mathbb{R}_t^+$ with null initial condition, the inverse of $\mathbf{H}(\partial_t) = \partial_t$ is $\partial_t^{-1} : v \mapsto \int_0^t v\,ds$.

Let $w^t(s) = \mathbf{1}_{]0,t]}(s)\, w(s)$, and let $w_t(s) = w^t(t-s)$ be the so-called history of w. From causality of $K(\partial_t)$, we deduce

$$\left(K(\partial_t)(w - w^t)\right)(t) = 0 \ \forall t;$$

then, we have for any continuous function w,

$$(K(\partial_t)w)(t) = \left[\mathcal{L}^{-1}\left(K\,\mathcal{L}w\right)\right](t) = \left[\mathcal{L}^{-1}\left(K\,\mathcal{L}w^t\right)\right](t). \tag{2.2}$$

We then define

$$\Psi_w(t,p) := \mathrm{e}^{pt}\left(\mathcal{L}w^t\right)(p) = \left(\mathcal{L}w_t\right)(-p); \tag{2.3}$$

by computing $\partial_t \mathcal{L} w_t$, and using Laplace inversion and (2.2), the following lemma can be shown.

Lemma 2.1.

1. *The function Ψ_w is a solution of the differential equation*

$$\partial_t \Psi(t,p) = p\,\Psi(t,p) + w, \ \ t > 0, \ \ \Psi(0,p) = 0, \ \ p \in \mathbb{C}. \tag{2.4}$$

2. *There exists $b_0 \in \mathbb{R}$ such that*

$$\forall b \geqslant b_0,\ \left(K(\partial_t)w\right)(t) = \frac{1}{2\mathrm{i}\pi}\int_{b-\mathrm{i}\infty}^{b+\mathrm{i}\infty} K(p)\,\Psi_w(t,p)\,dp. \tag{2.5}$$

Proof.

1. From (2.3), we have $\Psi_w(t,p) := \mathrm{e}^{pt}\int_0^t \mathrm{e}^{-ps}\, w(s)ds$, and so

$$\partial_t \Psi_w(t,p) = p\,\mathrm{e}^{pt}\int_0^t \mathrm{e}^{-ps}\, w(s)ds + \mathrm{e}^{pt}\,\mathrm{e}^{-pt}\, w(t).$$

2. From (2.2), there exists $b_0 \in \mathbb{R}$ such that for any $b \geqslant b_0$,

$$\left(K(\partial_t)w\right)(t) = \frac{1}{2\mathrm{i}\pi}\int_{b-\mathrm{i}\infty}^{b+\mathrm{i}\infty} \mathrm{e}^{pt}\, K(p)\ \left(\mathcal{L}w^t\right)(p)\,dp = \frac{1}{2\mathrm{i}\pi}\int_{b-\mathrm{i}\infty}^{b+\mathrm{i}\infty} K(p)\,\Psi_w(t,p)\,dp. \qquad \square$$

We denote by Ω the holomorphic domain of K. Let γ be a simple arc closed at infinity and included in $\mathbb{C}^- = \mathbb{R}^- + \mathrm{i}\mathbb{R}$. We denote by Ω_γ^+ the exterior domain defined by γ, and denote by Ω_γ^- the complementary of $\overline{\Omega_\gamma^+}$ (see Figure 2.1). By use of standard techniques (Cauchy theorem, Jordan lemma), the following lemma can be shown.

Lemma 2.2. *For $\gamma \subset \Omega$ such that K is holomorphic in Ω_γ^+, if $K(p) \to 0$ when $p \to \infty$ in Ω_γ^+, then, for any closed simple arc $\tilde{\gamma}$ in Ω_γ^+ such that $\gamma \subset \Omega_{\tilde{\gamma}}^-$ (see Figure 2.1),*

$$\left(K(\partial_t)w\right)(t) = \frac{1}{2\mathrm{i}\pi}\int_{\tilde{\gamma}} K(p)\,\Psi_w(t,p)\,dp. \tag{2.6}$$

We now suppose that γ, $\tilde{\gamma}$ are defined by functions of $W^{1,\infty}_{\mathrm{loc}}(\mathbb{R};\mathbb{C})$, also denoted γ, $\tilde{\gamma}$. From classical techniques, the following has been shown in [14].

Theorem 2.3. *Under the hypothesis of Lemma 2.2, if in addition the possible singularities of K on γ are simple poles or branching points in the neighborhood of which $|K \circ \gamma|$ is locally integrable, then*

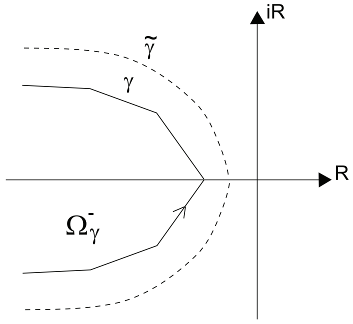

FIG. 2.1. *Example of γ and $\tilde{\gamma}$ arcs.*

1. *with* $\tilde{\nu} = \frac{\tilde{\gamma}'}{2i\pi} K \circ \tilde{\gamma}$ *and* $\tilde{\psi}(t,.) = \Psi_w(t,.) \circ \tilde{\gamma}$,

$$(K(\partial_t)w)(t) = \int_{\mathbb{R}} \tilde{\nu}(\xi)\, \tilde{\psi}(t,\xi)\, d\xi; \tag{2.7}$$

2. *if* $\tilde{\gamma}_n \to \gamma$ *in* $W^{1,\infty}_{\text{loc}}$, *then* $\frac{\tilde{\gamma}_n'}{2i\pi} K \circ \tilde{\gamma}_n \to \nu$ *in the sense of measures;*
3. $\psi(t,.) = \Psi_w(t,.) \circ \gamma$ *is the unique solution of the following Cauchy problem on* $(t,\xi) \in \mathbb{R}^{*+} \times \mathbb{R}$*:*

$$\partial_t \psi(t,\xi) = \gamma(\xi)\, \psi(t,\xi) + w(t),\ \psi(0,\xi) = 0 \tag{2.8}$$

and

$$(K(\partial_t)w)(t) = \langle \nu, \psi(t,.)\rangle\,. \tag{2.9}$$

For convenience in what follows, we will indifferently denote by $\langle \nu, \psi\rangle$ or $\int \nu\, \psi\, d\xi$ the duality product between a continuous function ψ and a measure ν (in particular, for Dirac measures, $\psi(a) = \int \delta_a \psi\, d\xi$).

Remark 1. In the limit case $\gamma(\xi) = -|\xi|$, we have $\Omega^-_\gamma = \varnothing$. The above results remain valid, and we deduce from the symmetry of the problem that there exists a measure μ such that

$$\int_{-\infty}^{+\infty} \nu\, \psi\, d\xi = \int_0^{+\infty} \mu\, \psi\, d\xi.$$

This particular case will be useful in practice when K is holomorphic in $\mathbb{C} \setminus \mathbb{R}^-$.

DEFINITION 2.4 (see [14]). *The measure ν defined in Theorem* (2.3) *is called the γ-symbol of operator $K(\partial_t)$.*

In many cases, the arc γ can be constrained to satisfy a suitable additional condition which makes (2.8) of diffusive type [14]. The main advantage of the input-output formulation (2.8), (2.9) lies in its time-local nature which allows us to use classical methods devoted to Cauchy problems. In particular, stable and efficient schemes for the numerical resolution of (1.1) can be straightforwardly built from discretizations of problem (2.8) following standard techniques. This is the topic of the following sections.

2.2. Application to a class of partial integrodifferential equations. We consider the problem

$$\mathbf{H}(\partial_t)\Phi = \mathcal{G}\Phi + f \quad \text{on } \mathbb{R}_t^+ \times \Omega \quad \Omega \subset \mathbb{R}_x^m, \tag{2.10}$$

where $\Phi = (\Phi_1, \dots, \Phi_M)^T$ is the unknown, $\mathbf{H}(\partial_t)$ is an invertible causal convolution operator of the form

$$\mathbf{H}(\partial_t) = \begin{bmatrix} H_1(\partial_t) & & \\ & \ddots & \\ & & H_M(\partial_t) \end{bmatrix}, \tag{2.11}$$

and $\mathcal{G} = \mathbf{G}(\nabla)$ is a differential operator assumed to be anti-selfadjoint, that is,

$$\mathcal{G}_{ij}^* = -\mathcal{G}_{ji}, \tag{2.12}$$

where $\mathcal{G}_{ij}^*$ is defined by

$$\left(\mathcal{G}_{ij}\, u \middle|\, v\right)_{L^2(\Omega)} = \left(u \,\middle|\mathcal{G}_{ij}^*\, v\right)_{L^2(\Omega)} \quad \forall u, v \in \mathcal{D}(\Omega).$$

As usual, suitable boundary conditions associated with $\mathcal{G}$, not expressed here, can complete the model (2.10). The γ_i-symbols ν_i of operators $H_i(\partial_t)^{-1}$ are assumed to be positive measures. Note that this property appears as physically realistic in the sense of an energy balance, as it will be highlighted later.

By expressing (2.10) under the form $\Phi = \mathbf{H}(\partial_t)^{-1}\left(\mathcal{G}\Phi + f\right)$, we formally deduce from the results of section 2.1, under a suitable hypothesis on $H_i^{-1}(\partial_t)$, the following diffusive time-local formulation of (2.10):

$$\partial_t\psi(t,x,\xi) = \gamma(\xi)\psi(t,x,\xi) + \mathcal{G}\left\langle \nu, \psi(t,x,.)\right\rangle + f(t,x), \quad \psi(0,.) = 0, \tag{2.13}$$

$$\Phi(t,x) = \left\langle \nu, \psi(t,x,.)\right\rangle, \tag{2.14}$$

where $\psi := (\psi_1, \dots, \psi_M)^T$, $\gamma := \mathrm{diag}(\gamma_1, \dots, \gamma_M)$, $\nu := \mathrm{diag}(\nu_1, \dots, \nu_M)$, and $\langle \nu, \psi\rangle := (\langle \nu_1, \psi_1\rangle, \dots, \langle \nu_M, \psi_M\rangle)^T$.

Let us now consider the functional

$$\psi \longmapsto E_\psi = \frac{1}{2}\sum_i \iint \nu_i \left|\psi_i\right|^2 d\xi\, dx = \frac{1}{2}\iint \psi^T \nu\, \overline{\psi}\, d\xi\, dx\,;$$

thanks to the positivity of ν_i, the functional E_ψ is positive. We have the following.

PROPOSITION 2.5. *For any ψ solution of* (2.13)*, and at any t such that $f(t,\cdot) = 0$, the functional E_ψ verifies*

$$\frac{dE_\psi(t)}{dt} \leqslant 0.$$

Proof.

$$\begin{aligned}
\frac{dE_\psi(t)}{dt} &= \frac{1}{2}\left(\iint \left(\partial_t\psi\right)^T \nu\, \overline{\psi}\, d\xi dx + \iint \psi^T \nu\, \overline{\partial_t\psi}\, d\xi dx\right)\\
&= \iint \psi^T \nu \mathrm{Re}(\gamma)\, \overline{\psi}\, d\xi dx + \frac{1}{2}\left(\int \left\langle \nu, \psi\right\rangle^T\, \overline{\mathcal{G}\left\langle \nu, \psi\right\rangle}\, dx + \int \left(\mathcal{G}\left\langle \nu, \psi\right\rangle\right)^T \overline{\left\langle \nu, \psi\right\rangle}\, dx\right)\\
&= \iint \psi^T \nu \mathrm{Re}(\gamma)\, \overline{\psi}\, d\xi dx\\
&\quad + \frac{1}{2}\sum_{i,j}\left[\left(\mathcal{G}_{ij}\left\langle \nu_j, \psi_j\right\rangle \,\middle|\, \left\langle \nu_i, \psi_i\right\rangle\right)_{L^2(\Omega)} + \left(\left\langle \nu_j, \psi_j\right\rangle \,\middle|\, \mathcal{G}_{ji}\langle \nu_i, \psi_i\rangle\right)_{L^2(\Omega)}\right].
\end{aligned}$$

Because $\mathcal{G}$ is anti-selfadjoint, we then have

$$\frac{dE_\psi(t)}{dt} = \iint \psi^T \nu \mathrm{Re}(\gamma)\, \overline{\psi}\, d\xi\, dx = \sum_i \iint \nu_i \mathrm{Re}(\gamma_i)\, |\psi_i|^2\, d\xi \leqslant 0. \qquad \square$$

Therefore, the time-local problem (2.13) is dissipative in the sense of the positive functional E_ψ. At this stage, standard methods of semigroup theory can be investigated to study the well-posedness of this Cauchy problem in the associated energy Hilbert space[19], from which will follow the well-posedness of problem (2.10) as a simple consequence.

In practice, the numerical resolution of problems such as (2.10) presents major difficulties due to the nonlocal nature of $\mathbf{H}(\partial_t)^{-1}$. So, we focus here on the construction and analysis of numerical schemes for (2.13), from which approximate solutions of (2.10) will be directly deduced. We mainly study the stability property, which holds most of the technical difficulties.

3. Numerical schemes for (2.13).

First note that in any case, it follows from (2.14) that, in the sense of suitable topologies not specified here, approximations of a Φ solution of (2.10) will be straightforwardly obtained from discrete approximations $\tilde{\psi}$ of a ψ solution of (2.13) under the generic form,

$$\Phi(t_n, x_k) \simeq \tilde{\Phi}(t_n, x_k) = \sum_l \alpha_l\, \tilde{\psi}(t_n, x_k, \xi_l).$$

So, we build and study some numerical schemes for (2.10). A general technique for ξ-discretization presented in [14] is first introduced, followed by the statement of fundamental properties of generic x-discretizations, inherited from the properties of operator $\mathcal{G}$. Then, we consider different ways of using time discretization which define different classes of implicit and explicit schemes.

3.1. $\boldsymbol{\xi}$-discretization (see [14]).

Consider $\mathcal{K}$ a Hilbert space such that $\psi(t, x, .) \in \mathcal{K}$, and consider $\mathcal{K}_L$ a sequence of subspaces of $\mathcal{K}$ of dimension L such that $\overline{\cup_L \mathcal{K}_L}^{\mathcal{K}} = \mathcal{K}$. Given a mesh $\{\xi_l\}_{l=1:L}$, consistent approximations $\widetilde{\psi}_L \in \mathcal{K}_L$ of ψ are then defined by

$$\widetilde{\psi}_L(\xi) = \sum_{l=1}^{L} \psi(\xi_l) \Lambda_l(\xi),$$

where Λ_l are finite element functions belonging to $\mathcal{K}_L$ in such a way that

$$\left\| \widetilde{\psi}_L - \psi \right\|_{\mathcal{K}} \underset{L\to\infty}{\longrightarrow} 0.$$

We then deduce the finite-dimensional approximate state formulation of (2.13),

$$\partial_t \psi(t, x, \xi_l) = \gamma(\xi_l)\psi(t, x, \xi_l) + \mathcal{G} \sum_j C_j \psi(t, x, \xi_j), \quad l = 1 : L, \tag{3.1}$$

where

$$C_l = \mathrm{diag}(c_{l1}, \ldots, c_{lM}),\ c_{li} := \int \nu_i(\xi)\, \Lambda_l(\xi) d\xi.$$

Note that, in practice, only a few tens of ξ_l are necessary to correctly approximate each operator $H_i(\partial_t)^{-1}$. More details on the ξ-discretization of diffusive state realizations of convolution operators can be found in [14].

In addition, for consistency with positivity of measures ν_i, we will suppose that

$$c_{li} \geqslant 0;$$

this property, which will play a central role, is satisfied namely if $\Lambda_l \geqslant 0$. The energy functional associated with (3.1) is then

$$E_\psi^L(t) = \frac{1}{2}\sum_{i,l}\int c_{li}\,|\psi_i(t,x,\xi_l)|^2\,dx = \frac{1}{2}\sum_{l}\int \psi(t,x,\xi_l)^T C_l\,\overline{\psi(t,x,\xi_l)}\,dx$$

and verifies, in the same way as previously,

$$\begin{aligned} \frac{dE_\psi^L(t)}{dt} &= \sum_l \int \psi(t,x,\xi_l)^T \mathrm{Re}(\gamma(\xi_l))\,C_l\,\overline{\psi(t,x,\xi_l)}\,dx \\ &= \sum_{l,i}\int c_{li}\,\mathrm{Re}(\gamma_i(\xi_l))\;|\psi_i(t,x,\xi_l)|^2\,dx \leqslant 0. \end{aligned} \tag{3.2}$$

3.2. *x*-discretization. In formulation (3.1), $\mathcal{G}_{ij}$ is a differential operator; it is approximate on a mesh $\{x_k\}_{k=1:K} \subset \mathbb{R}^m$ by

$$\left(\mathcal{G}_{ij}\Phi\right)(x_q) \simeq \sum_{k=1}^{K} g_{ij}^{qk}\Phi(x_k) \quad \forall q = 1:K, \tag{3.3}$$

where the coefficients g_{ij}^{qk} define the approximation under consideration (for example, finite differences [17], finite elements, or even more general Galerkin methods up to suitable technical adaptations [4]). By denoting $\widetilde{\Phi} := (\Phi(x_1),\ldots,\Phi(x_K))^T$, (3.3) can be written in a more condensed way, as follows:

$$\left(\left(\mathcal{G}_{ij}\Phi\right)(x_1),\ldots,\left(\mathcal{G}_{ij}\Phi\right)(x_K)\right)^T \simeq G_{ij}\widetilde{\Phi},$$

where we denote by G_{ij} the matrix with terms g_{ij}^{qk}. In what follows, for simplicity $\widetilde{\Phi}$ will be denoted Φ.

Because the operator $\mathcal{G}$ is anti-selfadjoint, it is natural to consider approximations which preserve this property. So the block matrix G with block elements $G_{ij} \in \mathcal{M}_{K,K}(\mathbb{R})$ must be antisymmetric, that is,

$$G_{ij}^T = -G_{ji}. \tag{3.4}$$

In what follows, we will denote by $S_{G_{ij}}$ the quantity

$$S_{G_{ij}} := \max\left(\max_k \sum_q \left|g_{ij}^{qk}\right|, \max_q \sum_k \left|g_{ij}^{qk}\right|\right).$$

The Euclidian scalar product in $\mathbb{C}^K$ and the associated norm will be denoted

$$(X|\,Y) = \sum_{k=1}^{K} X_k\overline{Y_k}, \text{ and } \|X\| = \sqrt{\sum_{k=1}^{K}|X_k|^2}.$$

3.3. Stability analysis for an implicit scheme. We propose the following class of time-implicit schemes, based on a Cranck–Nicholson time discretization:

$$\frac{\psi_i^{n+1}(\xi_l)-\psi_i^n(\xi_l)}{\Delta t} = \gamma_i(\xi_l)\,\frac{\psi_i^{n+1}(\xi_l)+\psi_i^n(\xi_l)}{2} + \sum_{k,j} G_{ik}c_{jk}\,\frac{\psi_k^{n+1}(\xi_j)+\psi_k^n(\xi_j)}{2} + f_i^n, \tag{3.5}$$

where

$$\psi_i^n(\xi_l) = (\psi_i(n\Delta t, x_1, \xi_l), \dots, \psi_i(n\Delta t, x_K, \xi_l))^T$$

and $f_i^n = (f_i(n\Delta t, x_1), \dots, f_i(n\Delta t, x_K))^T$. In a more condensed way, (3.5) can be written

$$\frac{\psi^{n+1}(\xi_l)-\psi^n(\xi_l)}{\Delta t} = \Gamma_l\,\frac{\psi^{n+1}(\xi_l)+\psi^n(\xi_l)}{2} + G\sum_j Q_j\,\frac{\psi^{n+1}(\xi_j)+\psi^n(\xi_j)}{2} + f^n, \tag{3.6}$$

where $\psi^n(\xi_l) = (\psi_1^n(\xi_l)^T, \dots, \psi_M^n(\xi_l)^T)^T$, $f^n = (f_1^{nT}, \dots, f_M^{nT})^T$, $\Gamma_l = \mathrm{diag}(\gamma_i(\xi_l)\, I_K)$, $Q_j = \mathrm{diag}(c_{jk}\, I_K)$, and G is the antisymmetric block matrix defined above.

Let us now consider the quantity

$$E^n = \sum_l \Big(\psi^n(\xi_l)\,\Big|\, Q_l\psi^n(\xi_l)\Big) = \sum_{i,l} c_{li}\,|\psi_i^n(\xi_l)|^2 .$$

Note that, thanks to the positivity of coefficients c_{li}, E^n is an energy candidate for (3.6). We have the following.

THEOREM 3.1. *The implicit scheme* (3.6) *is stable.*

Proof.

$$\begin{aligned}
&E^{n+1} - E^n\\
&= \sum_l \big(Q_l(\psi^{n+1}(\xi_l) + \psi^n(\xi_l))\big|\, \psi^{n+1}(\xi_l) - \psi^n(\xi_l)\big) + \sum_l 2\mathrm{i}\,\mathrm{Im}\big(Q_l\psi^{n+1}(\xi_l)\big|\, \psi^n(\xi_l)\big)\\
&= \sum_l \frac{\Delta t}{2} \big(Q_l(\psi^{n+1}(\xi_l)+ \psi^n(\xi_l))\big|\, \Gamma_l(\psi^{n+1}(\xi_l)+ \psi^n(\xi_l))\big) + \sum_l 2\mathrm{i}\,\mathrm{Im}\big(Q_l\psi^{n+1}(\xi_l)\big|\, \psi^n(\xi_l)\big)\\
&\qquad + \frac{\Delta t}{2}\sum_{l,j} \big(Q_l(\psi^{n+1}(\xi_l) + \psi^n(\xi_l))\big|\, GQ_j(\psi^{n+1}(\xi_j) + \psi^n(\xi_j))\big) .
\end{aligned}$$

Because G is antisymmetric, we have

$$\sum_{l,j} \big(Q_l(\psi^{n+1}(\xi_l) + \psi^n(\xi_l))\big|\, GQ_j(\psi^{n+1}(\xi_j) + \psi^n(\xi_j))\big) = 0,$$

so

$$\begin{aligned}
&E^{n+1} - E^n\\
&= \sum_l \frac{\Delta t}{2} \big(Q_l(\psi^{n+1}(\xi_l)+ \psi^n(\xi_l))\big|\, \Gamma_l(\psi^{n+1}(\xi_l)+ \psi^n(\xi_l))\big) + \sum_l 2\mathrm{i}\,\mathrm{Im}\big(Q_l\psi^{n+1}(\xi_l)\big|\, \psi^n(\xi_l)\big)\\
&= \frac{\Delta t}{2}\sum_{i,l} \gamma_i(\xi_l)c_{li}\,\big|\psi_i^{n+1}(\xi_l) + \psi_i^n(\xi_l)\big|^2 + \sum_l 2\mathrm{i}\,\mathrm{Im}\big(Q_l\psi^{n+1}(\xi_l)\big|\, \psi^n(\xi_l)\big) .
\end{aligned}$$

As $E^{n+1} - E^n$ is real, we have

$$E^{n+1} - E^n = \frac{\Delta t}{2}\sum_{i,l} c_{li}\,\mathrm{Re}(\gamma_i(\xi_l))\ \big|\psi_i^{n+1}(\xi_l) + \psi_i^n(\xi_l)\big|^2 \leqslant 0. \qquad \square$$

3.4. Stability analysis for explicit schemes. In this section, we propose a class of two-step explicit schemes of the form

$$\psi_i^{n+1}(\xi_l) = a_{li}\,\psi_i^{n-1}(\xi_l) + b_{li}\sum_k G_{ik}\sum_j b_{jk}\,\psi_k^n(\xi_j) + b_{li}\,f_i^n, \tag{3.7}$$

where $a_{li} \in \mathbb{C}$, $|a_{li}| < 1$, and $b_{jk} \in \mathbb{R}_+^*$ depend both on time approximation and $\gamma_i(\xi_l)$ choices, and G is the antisymmetric block matrix associated with operator $\mathcal{G}$.

Let us now study the stability of (3.7). We consider the functional

$$E^n = \sum_{i,l} \|\psi_i^n(\xi_l)\|_2^2 + \mathrm{Re}\left(\psi_i^{n+1}(\xi_l)|\psi_i^{n-1}(\xi_l)\right).$$

LEMMA 3.2. *If*

$$\mathrm{Re}(a_{li}) - \frac{b_{li}}{2}\sum_{k,j} b_{jk}S_{G_{ik}} > 0 \quad \forall i,l, \tag{3.8}$$

then there exists $K > 0$ such that

$$E^n \geqslant K\sum_{i,l}\|\psi_i^n(\xi_l)\|^2.$$

Proof. We have

$$E^n = \sum_{i,l}\|\psi_i^n(\xi_l)\|_2^2 + \sum_{i,l}\mathrm{Re}(a_{li})\left\|\psi_i^{n-1}(\xi_l)\right\|_2^2 + \sum_{i,l,k,j} b_{li}b_{jk}\,\mathrm{Re}\left(G_{ik}\,\psi_k^n(\xi_j)|\,\psi_i^{n-1}(\xi_l)\right).$$

Moreover, by using the following relation:

$$\forall\alpha\in\mathbb{R},\ \forall u,v\in\mathbb{C}^K,\quad \alpha\,\mathrm{Re}\,(u|v) = \frac{|\alpha|}{2}(\|u\|^2 + \|v\|^2 - \|u - \mathrm{sign}(\alpha)v\|^2), \tag{3.9}$$

we get

$$\begin{aligned}\mathrm{Re}\left(G_{ik}\,\psi_k^n(\xi_j)|\,\psi_i^{n-1}(\xi_l)\right) \geqslant \sum_{p,q}\frac{|g_{ik}^{pq}|}{2}\left|\psi_k^n(\xi_j,x_q) + \mathrm{sign}(g_{ik}^{pq})\psi_i^{n-1}(\xi_l,x_p)\right|^2 \\ - \frac{S_{G_{ik}}}{2}\left\|\psi_i^{n-1}(\xi_l)\right\|^2 - \frac{S_{G_{ik}}}{2}\|\psi_k^n(\xi_j)\|^2;\end{aligned}$$

so, as $S_{G_{ik}} = S_{G_{ki}}$,

$$\begin{aligned}E^n \geqslant \sum_{i,l}\left(1 - \frac{b_{li}}{2}\sum_{k,j}b_{jk}S_{G_{ik}}\right)\|\psi_i^n(\xi_l)\|^2 + \sum_{i,l}\left(\mathrm{Re}(a_{li}) - \frac{b_{li}}{2}\sum_{k,j}b_{jk}S_{G_{ik}}\right)\left\|\psi_i^{n-1}(\xi_l)\right\|^2 \\ + \sum_{i,j,k,l,p,q} b_{li}b_{jk}\frac{|g_{ik}^{pq}|}{2}\left|\psi_k^n(\xi_j,x_q) + \mathrm{sign}(g_{ik}^{pq})\psi_i^{n-1}(\xi_l,x_p)\right|^2. \qquad \square\end{aligned}$$

Remark 2. Note that condition (3.8) necessarily implies $\mathrm{Re}(a_{li}) > 0$; the hypothesis $|a_{li}| < 1$ is motivated by the term $a_{li}\,\psi_i^{n-1}(\xi_l)$ of (3.7).

Remark 3. Conditions of Lemma 3.2 are necessary conditions that link Δt (in a_{li} and b_{ik}) and the space discretization step (in $S_{G_{ik}}$).

Let us now consider the quantity

$$\mathcal{E}^n = E^n + E^{n-1},$$

which, under the conditions of Lemma 3.2, defines an energy candidate for (3.7). Then, we have the following theorem for stability of the class of explicit schemes (3.7).

THEOREM 3.3. *Under the conditions of Lemma* 3.2, *and if for any* k, j,

(3.10)

$$|a_{jk}|^2+\frac{b_{jk}}{2}\sum_{i,l}\|G_{ik}\|^2\, b_{li}\left(\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|+b_{li}\sum_{p,q}b_{qp}\left(|a_{li}-\overline{a_{jk}}|+|a_{li}-\overline{a_{qp}}|\right)\right)\leqslant 1$$

and

$$\text{(3.11)} \qquad \operatorname{Re}(a_{jk})(|a_{jk}|^2-1)+\frac{b_{jk}}{2}\sum_{i,l}b_{li}\left||a_{jk}|^2+a_{jk}^2-\overline{a_{li}}a_{jk}-1\right|\leqslant 0,$$

then the scheme (3.7) *is stable.*

Proof. After computations and reorganization, we have

$$\begin{aligned}
&\mathcal{E}^{n+1}-\mathcal{E}^n = E^{n+1}-E^{n-1}\\
&=\sum_{i,l}|a_{li}|^2\left\|\psi_i^{n-1}(\xi_l)\right\|^2+\sum_{i,l,k,j}b_{li}b_{jk}\operatorname{Re}\left(a_{li}\psi_i^{n-1}(\xi_l)\right|G_{ik}\,\psi_k^n(\xi_j)\big)\\
&\quad+\sum_{i,l,k,j}b_{li}b_{jk}\operatorname{Re}\left(G_{ik}\,\psi_k^n(\xi_j)\left|\psi_i^{n+1}(\xi_l)\right)+\sum_{i,l}|a_{li}|^2\operatorname{Re}\left(\psi_i^n(\xi_l)\left|\psi_i^{n-2}(\xi_l)\right)\right.\right.\\
&\quad+\sum_{i,l,k,j}b_{li}b_{jk}\operatorname{Re}\left(a_{li}\psi_i^n(\xi_l)\left|G_{ik}\psi_k^{n-1}(\xi_j)\right)+\sum_{i,l,k,j}b_{li}b_{jk}\operatorname{Re}\left(G_{ik}\,\psi_k^{n+1}(\xi_j)\right|\psi_i^n(\xi_l)\right)\\
&\quad-\sum_{i,l}\left(\|\psi_i^{n-1}(\xi_l)\|^2+\operatorname{Re}\left(\psi_i^n(\xi_l)\left|\psi_i^{n-2}(\xi_l)\right)\right)\right..
\end{aligned}$$

As $G_{ik}=-G_{ki}^T$, we have

$$\begin{aligned}
\mathcal{E}^{n+1}-\mathcal{E}^n &= \sum_{i,l}(|a_{li}|^2-1)\left\|\psi_i^{n-1}(\xi_l)\right\|^2+\sum_{i,l}(|a_{li}|^2-1)\operatorname{Re}\left(\psi_i^n(\xi_l)\left|\psi_i^{n-2}(\xi_l)\right)\right.\\
&\quad+\sum_{i,l,k,j}b_{li}b_{jk}(a_{li}-a_{jk})\operatorname{Re}\left((a_{li}-\overline{a_{jk}})\psi_i^n(\xi_l)\right|G_{ik}\psi_k^{n-1}(\xi_j)\big)\\
&=\sum_{i,l}(|a_{li}|^2-1)\left\|\psi_i^{n-1}(\xi_l)\right\|^2+\sum_{i,l}(|a_{li}|^2-1)\operatorname{Re}(a_{li})\left\|\psi_i^{n-2}(\xi_l)\right\|^2\\
&\quad+\sum_{i,l,k,j}b_{li}b_{jk}\operatorname{Re}\left(\left(|a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right)\psi_i^{n-2}(\xi_l)\right|G_{ik}\,\psi_k^{n-1}(\xi_j)\Big)\\
&\quad+\sum_{i,l,k,j,p,q}b_{li}^2b_{jk}b_{qp}\operatorname{Re}\left((a_{li}-\overline{a_{jk}})G_{ip}\psi_p^{n-1}(\xi_q)\right|G_{ik}\psi_k^{n-1}(\xi_j)\big).
\end{aligned}$$

By using (3.9) and the following relation:

$$\operatorname{Re}(\beta u|v)=\frac{1}{2}\left(|\beta|\,\|v\|_2^2+|\beta|\,\|u\|_2^2-\left\|\sqrt{\beta}u+\overline{\sqrt{\beta}}v\right\|_2^2\right),$$

and after reorganization, we obtain

$$\begin{aligned}
&\mathcal{E}^{n+1}-\mathcal{E}^{n}=\sum_{i,l}(|a_{li}|^2-1)\left\|\psi_i^{n-1}(\xi_l)\right\|^2\\
&+\sum_{i,l}\left(\mathrm{Re}(a_{li})(|a_{li}|^2-1)+\frac{b_{li}}{2}\sum\nolimits_{k,j}b_{jk}\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|\right)\left\|\psi_i^{n-2}(\xi_l)\right\|^2\\
&-\frac{1}{2}\sum_{i,l,k,j,p,q}b_{li}^2b_{jk}b_{qp}\left\|\sqrt{a_{li}-\overline{a_{jk}}}G_{ip}\,\psi_p^{n-1}(\xi_q)+\overline{\sqrt{a_{li}-\overline{a_{jk}}}}G_{ik}\psi_k^{n-1}(\xi_j)\right\|^2\\
&-\frac{1}{2}\sum_{i,l,k,j}b_{li}b_{jk}\left\|\sqrt{|a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1}\,\psi_i^{n-2}(\xi_l)+\overline{\sqrt{|a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1}}\,G_{ik}\psi_k^{n-1}(\xi_j)\right\|^2\\
&+\frac{1}{2}\sum_{i,l,k,j}b_{li}b_{jk}\left(\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|+\sum_{p,q}b_{li}b_{qp}(|a_{li}-\overline{a_{jk}}|+|a_{li}-\overline{a_{qp}}|)\right)\left\|G_{ik}\psi_k^{n-1}(\xi_j)\right\|^2.
\end{aligned}$$

By using the property $\left\|G_{ik}\psi_k^{n-1}(\xi_j)\right\|\leqslant\|G_{ik}\|\left\|\psi_k^{n-1}(\xi_j)\right\|$, we then get

$$\begin{aligned}
\mathcal{E}^{n+1}-\mathcal{E}^{n}\leqslant\sum_{k,j}\Bigg(&(|a_{jk}|^2-1)+\frac{b_{jk}}{2}\sum_{i,l}\|G_{ik}\|^2\,b_{li}\Bigg[\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|\\
&+\ b_{li}\sum_{p,q}b_{qp}(|a_{li}-\overline{a_{jk}}|+|a_{li}-\overline{a_{qp}}|)\Bigg]\Bigg)\left\|\psi_k^{n-1}(\xi_j)\right\|^2\\
&+\sum_{i,l}\left(\mathrm{Re}(a_{li})(|a_{li}|^2-1)+\frac{b_{li}}{2}\sum_{k,j}b_{jk}\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|\right)\left\|\psi_i^{n-2}(\xi_l)\right\|^2\\
&-\frac{1}{2}\sum_{i,l,k,j}b_{li}b_{jk}\left\|\sqrt{|a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1}\,\psi_i^{n-2}(\xi_l)+\overline{\sqrt{|a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1}}\,G_{ik}\psi_k^{n-1}(\xi_j)\right\|^2\\
&-\frac{1}{2}\sum_{i,l,k,j,p,q}b_{li}^2b_{jk}b_{qp}\left\|\sqrt{a_{li}-\overline{a_{jk}}}G_{ip}\,\psi_p^{n-1}(\xi_q)+\overline{\sqrt{a_{li}-\overline{a_{jk}}}}G_{ik}\psi_k^{n-1}(\xi_j)\right\|^2.
\end{aligned}$$

So, if for any k,j,

$$|a_{jk}|^2+\frac{b_{jk}}{2}\sum_{i,l}\|G_{ik}\|^2\,b_{li}\left(\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|+b_{li}\sum_{p,q}b_{qp}\,(|a_{li}-\overline{a_{jk}}|+|a_{li}-\overline{a_{qp}}|)\right)\leqslant 1$$

and for any i,l,

$$\mathrm{Re}(a_{li})(|a_{li}|^2-1)+\frac{b_{li}}{2}\sum_{k,j}b_{jk}\left||a_{li}|^2+a_{li}^2-\overline{a_{jk}}a_{li}-1\right|\leqslant 0,$$

then $\mathcal{E}^{n+1}\leqslant\mathcal{E}^{n}$, from which we deduce $E^{n+1}\leqslant E^{n-1}$. Consequently, we have $E^n\leqslant\max(E^0,E^1)$; from Lemma 3.2, the scheme is stable. □

In section 4, where a concrete application is presented, we will consider as follows two particular explicit schemes of the form (3.7), based on two time discretizations (the first one is rather classical, and the second can be expected to be more precise):

• In the first scheme, the time derivative is approximated by centered finite differences; we then get

$$\psi_i^{n+1}(\xi_l)=(1+2\Delta t\,\gamma_i(\xi_l))\,\psi_i^{n-1}(\xi_l)+2\Delta t\sum_k G_{ik}\sum_j c_{jk}\,\psi_k^n(\xi_j)+2\Delta t\,f_i^n,$$

which, after the change of variable $\widetilde{\psi}_i^{n+1}(\xi_l) = \psi_i^{n+1}(\xi_l)\sqrt{\frac{c_{li}}{2\Delta t}}$, is rewritten under the form (3.7) with

$$a_{li} = 1 + 2\,\Delta t\,\gamma_i(\xi_l) \text{ and } b_{jk} = \sqrt{2\,\Delta t\, c_{jk}}. \tag{3.12}$$

• The second scheme is based on another time discretization, described in the appendix and can be considered in the case where $\gamma_i(\xi)$ is real (e.g., $\gamma_i(\xi) = -\xi$). It is written

$$\psi_i^{n+1}(\xi_l) = e^{\gamma_i(\xi_l)2\Delta t}\,\psi_i^{n-1}(\xi_l) + \frac{e^{\gamma_i(\xi_l)2\Delta t} - 1}{\gamma_i(\xi_l)}\left(\sum_k G_{ik}\sum_j c_{jk}\,\psi_k^n(\xi_j) + f_i^n\right); \tag{3.13}$$

after the change of variable $\widetilde{\psi}_i^{n+1}(\xi_l) = \psi_i^{n+1}(\xi_l)\sqrt{\frac{c_{li}\gamma_i(\xi_l)}{e^{\gamma_i(\xi_l)2\Delta_t}-1}}$, (3.13) is rewritten under the form (3.7) with

$$a_{li} = e^{\gamma_i(\xi_l)2\Delta_t} \text{ and } b_{jk} = \sqrt{c_{jk}\,\frac{e^{\gamma_k(\xi_j)2\Delta_t} - 1}{\gamma_k(\xi_j)}}. \tag{3.14}$$

The stability of those particular schemes is obtained as a corollary of the general stability theorem, Theorem 3.3.

COROLLARY 3.4. *Under the conditions of Lemma* 3.2, *and if* Δt *is small enough, the two schemes* (3.7), (3.12) *and* (3.7), (3.14) *are stable.*

Proof. For the first scheme, we have

$$a_{li} = 1 + 2\Delta t\,\gamma_i(\xi_l) \text{ and } b_{jk} = \sqrt{2\Delta t c_{jk}},$$

so that, by supposing Δt small enough, conditions (3.10) and (3.11) are, respectively, equivalent to

$$1 + 4\Delta t\ \mathrm{Re}(\gamma_k(\xi_j)) \leqslant 1 \quad\text{and}\quad 4\Delta t\ \mathrm{Re}(\gamma_k(\xi_j)) \leqslant 0,$$

which are both verified thanks to the property $\mathrm{Re}\,\gamma \subset \mathbb{R}^-$.

For the second scheme, we have

$$a_{li} = e^{\gamma_i(\xi_l)2\Delta_t} \text{ and } b_{jk} = \sqrt{c_{jk}\,\frac{e^{\gamma_k(\xi_j)2\Delta_t} - 1}{\gamma_k(\xi_j)}},$$

so if Δt is small enough, then

$$a_{li} \sim 1 + 2\Delta t\,\gamma_i(\xi_l) \text{ and } b_{jk} \sim \sqrt{2\Delta t c_{jk}},$$

and the same analysis as for the first scheme can be made. □

4. Application to a porous wall model.

4.1. Problem under consideration. In the context of aircraft motor noise reduction in the aerospace industry, a specific porous wall was proposed in [5] for absorption of a wide part of the energy of incident acoustic waves. The following frequency model of such a material has been established from analysis of harmonic propagating waves:

$$\text{(4.1)} \qquad \left\{ \begin{array}{l} e\,\mathrm{i}\omega\,\rho_{\text{eff}}\,(\mathrm{i}\omega)\;\hat{u} + \partial_x \hat{P} = 0 \\ e\,\mathrm{i}\omega\,\chi_{\text{eff}}\,(\mathrm{i}\omega)\;\hat{P} + \partial_x \hat{u} = 0 \end{array} \right. \quad \text{with} \quad \left\{ \begin{array}{l} \rho_{\text{eff}}\,(\mathrm{i}\omega) = \rho\,(1 + a\,\frac{\sqrt{1+b\,\mathrm{i}\omega}}{\mathrm{i}\omega}) \\ \chi_{\text{eff}}\,(\mathrm{i}\omega) = \chi\,(1 - \beta\,\frac{\mathrm{i}\omega}{\mathrm{i}\omega + a'\sqrt{1+b'\mathrm{i}\omega}}), \end{array} \right.$$

where $\widehat{u}$ and $\widehat{P}$ designate the Fourier transforms of the velocity and the pressure in the porous medium, e denotes the thickness of the porous wall,[2] $\rho_{\text{eff}}\,(\mathrm{i}\omega)$ and $\chi_{\text{eff}}\,(\mathrm{i}\omega)$ are, respectively, the effective density of Pride, Morgan, and Gangi [16] and the effective compressibility of Lafarge [8], and $\rho = \rho_0\,\alpha_\infty$, $\chi = \frac{1}{P_0}$, $a = \frac{8\mu}{\rho_0 \Lambda^2}$, $a' = \frac{8\mu}{\rho_0 \Lambda'^2}$, $b = \frac{1}{2a}$, $b' = \frac{1}{2a'}$, $0 < \beta = \frac{\gamma - 1}{\gamma} < 1$. The physical parameters ρ_0, P_0, μ, γ, α_∞, Λ, Λ' are, respectively, the density and pressure at rest, the dynamic viscosity, the specific heat ratio, the tortuosity, the high frequency characteristic length of the viscous incompressible problem, and the high frequency characteristic length of the thermal problem. Note that all these parameters are positive by nature.

The aim of this section is to perform temporal simulations of these equations, based on the schemes previously studied. In the time domain, (4.1) can be written (by replacing $p = i\omega$ by ∂_t)

$$\text{(4.2)} \qquad \begin{bmatrix} H_1(\partial_t) & 0 \\ 0 & H_2(\partial_t) \end{bmatrix} \begin{pmatrix} u \\ P \end{pmatrix} = \begin{bmatrix} 0 & -\partial_x \\ -\partial_x & 0 \end{bmatrix} \begin{pmatrix} u \\ P \end{pmatrix}$$

with

$$H_1(p) = e\,\rho\,(p + a\,\sqrt{1 + b\,p}) \text{ and } H_2(p) = e\,p\,\chi\,\left(1 - \beta\,\frac{p}{p + a'\sqrt{1 + b'p}}\right).$$

The analytic continuations of functions $H_1(p)^{-1}$ and $H_2(p)^{-1}$ are clearly decreasing at infinity and holomorphic in $\mathbb{C} \setminus \mathbb{R}^-$. So, from Theorem 2.3, the time-local formulation (2.13) of (4.2) with $\gamma_i(\xi) = -\,|\xi|$ is valid. It takes the form

$$\text{(4.3)} \qquad \left\{ \begin{array}{l} \partial_t \psi(t,x,\xi) = \begin{bmatrix} -\xi & 0 \\ 0 & -\xi \end{bmatrix} \psi(t,x,\xi) + \begin{bmatrix} 0 & -\partial_x \\ -\partial_x & 0 \end{bmatrix} \begin{pmatrix} \langle \nu_1, \psi_1(t,x,.) \rangle \\ \langle \nu_2, \psi_2(t,x,.) \rangle \end{pmatrix}, \\ u = \langle \nu_1, \psi_1(t,x,.) \rangle\,, \\ P = \langle \nu_2, \psi_2(t,x,.) \rangle\,. \end{array} \right.$$

After computations, the γ-symbol ν_i associated with the operator $H_i(\partial_t)^{-1}$ is expressed (δ denotes the Dirac measure)

$$\nu_1(\xi) = \frac{a}{\pi\,e\,\rho}\,\frac{\sqrt{b\,\xi - 1}}{\xi^2 + \frac{a\,\xi}{2} - a^2}\,\mathbf{1}_{\xi > 2a} + k_1\,\delta(\xi - \xi_1),$$

$$\nu_2(\xi) = \frac{a'\,\beta}{\pi\,e\,\chi}\,\frac{\sqrt{b'\,\xi - 1}}{\xi^2\,(1 - \beta)^2 + \frac{a'}{2}\xi - a'^2}\,\mathbf{1}_{\xi > 2a'} + \frac{1}{e\,\chi}\delta(\xi) + k_2\,\delta(\xi - \xi_2)$$

[2] In the model, the unit of length for x is e, so $x \in \,]0,1[$.

with

$$\xi_1 = \frac{a(\sqrt{17}-1)}{4} > 0, \quad \xi_2 = \frac{a'(\sqrt{1+16(1-\beta)^2}-1)}{4(1-\beta)^2} > 0,$$
$$k_1 = \frac{\sqrt{17}-1}{e\,\rho\sqrt{17}} > 0, \quad k_2 = \frac{\beta(\sqrt{1+16(1-\beta)^2}-1)}{e\,\chi(1-\beta)\sqrt{1+16(1-\beta)^2}} > 0.$$

For the ξ-discretization, we consider the classical interpolation functions

$$\Lambda_l(\xi) = \frac{\xi-\xi_{l-1}}{\xi_l-\xi_{l-1}}\mathbf{1}_{[\xi_{l-1},\xi_l]}(\xi) + \frac{\xi_{l+1}-\xi}{\xi_{l+1}-\xi_l}\mathbf{1}_{]\xi_l,\xi_{l+1}]}(\xi),$$

and coefficients c_{li} are computed by a simple quadrature of $\int \nu_i(\xi)\Lambda_l(\xi)d\xi$.

4.2. Numerical schemes. In this example, $\mathcal{G} = \left[\begin{smallmatrix} 0 & -\partial_x \\ -\partial_x & 0 \end{smallmatrix}\right]$. We use centered finite differences to approximate the derivative operator ∂_x, so the matrix of the x-discretization G is given by

$$G = \begin{bmatrix} 0 & G_{12} \\ G_{21} & 0 \end{bmatrix} \text{ with } G_{12} = G_{21} = \frac{1}{2\Delta x}\begin{bmatrix} 0 & -1 & & & \\ 1 & 0 & -1 & & \\ & \ddots & \ddots & \ddots & \\ & & 1 & 0 & -1 \\ & & & 1 & 0 \end{bmatrix}.$$

Note that this matrix is antisymmetric, so that the schemes studied in section 3 can be used. Then, we consider the following:

- the implicit scheme

$$\begin{cases} \dfrac{\psi_1^{n+1}(\xi_l)-\psi_1^n(\xi_l)}{\Delta t} = -\xi_l\dfrac{\psi_1^{n+1}(\xi_l)+\psi_1^n(\xi_l)}{2} + G_{12}\sum_j c_{j2}\dfrac{\psi_2^{n+1}(\xi_j)+\psi_2^n(\xi_j)}{2} + f_1^n, \\ \dfrac{\psi_2^{n+1}(\xi_l)-\psi_2^n(\xi_l)}{\Delta t} = -\xi_l\dfrac{\psi_2^{n+1}(\xi_l)+\psi_2^n(\xi_l)}{2} + G_{21}\sum_j c_{j1}\dfrac{\psi_1^{n+1}(\xi_j)+\psi_1^n(\xi_j)}{2} + f_2^n; \end{cases} \tag{4.4}$$

- the two particular explicit schemes of the form

$$\begin{cases} \psi_1^{n+1}(\xi_l) = a_{l1}\,\psi_1^{n-1}(\xi_l) + b_{l1}\,G_{21}\sum_j b_{j2}\,\psi_2^n(\xi_j) + b_{l1}f_1^n, \\ \psi_2^{n+1}(\xi_l) = a_{l2}\,\psi_2^{n-1}(\xi_l) + b_{l2}\,G_{12}\sum_j b_{j1}\,\psi_1^n(\xi_j) + b_{l2}f_2^n, \end{cases} \tag{4.5}$$

respectively, obtained with

$$a_{li} = 1-2\Delta t\,\xi_l,\ b_{jk} = \sqrt{2\Delta t\,c_{jk}} \quad \text{and} \quad a_{li} = e^{-\xi_l 2\Delta_t},\ b_{jk} = \sqrt{c_{jk}\,\frac{e^{-\xi_j 2\Delta_t}-1}{-\xi_j}}.$$

4.3. Physical interpretation of stability conditions. Obviously, to correctly simulate wave propagation phenomena, explicit schemes must necessarily have a numerical influence velocity at least equal to the maximal velocity of wave fronts in the medium under consideration. When this is not the case, a consistent explicit scheme cannot be convergent and is therefore unstable. So, it can be expected that the stability conditions of section 3.4 applied to (4.5) can be in some way interpreted in terms of high frequency wave velocity. More precisely, is the sufficient stability condition for (4.5) "optimal" in the sense that it is close to the necessary condition mentioned above? This is studied in the present section.

Let us compute the expression of the high frequency wave velocity of model (4.2), denoted by c. We have

$$\left\{\begin{array}{l} u = -H_1(\partial_t)^{-1}\partial_x P, \\ P = -H_2(\partial_t)^{-1}\partial_x u, \end{array}\right. \tag{4.6}$$

so we get $u = H_1(\partial_t)^{-1}H_2(\partial_t)^{-1}\,\partial_x^2 u$. Moreover [14],

$$H_i(\mathrm{i}\omega)^{-1} = \int \frac{\nu_i(\xi)}{\mathrm{i}\omega+\xi}\,d\xi = \frac{1}{\mathrm{i}\omega}\int \frac{\nu_i(\xi)}{1+\frac{\xi}{\mathrm{i}\omega}}\,d\xi, \quad i=1,2.$$

So, when $\omega \to +\infty$,

$$H_i(\mathrm{i}\omega)^{-1} \sim \frac{1}{\mathrm{i}\omega}\int \nu_i(\xi)\,d\xi.$$

The equation $u = H_1(\partial_t)^{-1}H_2(\partial_t)^{-1}\,\partial_x^2 u$ therefore behaves at high frequency as equation $\partial_t^2 u = c^2\,\partial_x^2 u$, with

$$c = \sqrt{\int \nu_1(\xi)\,d\xi \int \nu_2(\xi)\,d\xi}.$$

Similarly, we denote by c_d the high frequency wave velocity of the continuous model obtained after ξ-discretization of (4.2), in which $H_i(\mathrm{i}\omega)$ is replaced by its approximation $\widetilde{H}_i(\mathrm{i}\omega)$ [14] as follows:

$$\widetilde{H}_i(\mathrm{i}\omega)^{-1} = \sum_j \frac{c_{ji}}{\mathrm{i}\omega+\xi_j} = \frac{1}{\mathrm{i}\omega}\sum_j \frac{c_{ji}}{1+\frac{\xi_j}{\mathrm{i}\omega}}, \quad i=1,2. \tag{4.7}$$

We have, when $|\omega| \to +\infty$,

$$\widetilde{H}_i(\mathrm{i}\omega)^{-1} \sim \frac{1}{\mathrm{i}\omega}\sum_j c_{ji},$$

which leads to a high frequency behavior of the form $\partial_t^2 u = c_d^2\,\partial_x^2 u$ with

$$c_d = \sqrt{\sum_j c_{j1}\sum_j c_{j2}}.$$

Thanks to the expression of c_{li}, we then have, if $\widetilde{H}_i^{-1}$ is sufficiently close to H_i^{-1},

$$c_d \simeq c. \tag{4.8}$$

Moreover, $S_{G_{12}} = S_{G_{21}} = \frac{1}{\Delta x}$, so the stability conditions of section 3.4 applied to (4.5) are Δt small enough and

$$\forall (i,k) \in \{(1,2),(2,1)\}, \quad \forall l = 1:L, \quad a_{li} - \frac{b_{li}}{2\Delta x}\sum_j b_{jk} > 0. \tag{4.9}$$

For the first explicit scheme, (4.9) is expressed as

$$\frac{\Delta x}{\Delta t} > v_d := \max_{(i,k)} \max_{l} \frac{\sqrt{c_{li}}}{1-2\Delta t\, \xi_l} \sum_j \sqrt{c_{jk}}, \tag{4.10}$$

where $\frac{\Delta x}{\Delta t}$ is the numerical influence velocity of the scheme. For the second explicit scheme, the order one approximation leads to the same condition. Then, we have the following result:

PROPOSITION 4.1. $v_d \geqslant c_d$.

Proof. Without loss of generality, we can consider that

$$v_d = \max_{(i,k)} \max_{l} \frac{\sqrt{c_{li}}}{1-2\Delta t\, \xi_l} \sum_j \sqrt{c_{jk}} = \max_{l} \frac{\sqrt{c_{l1}}}{1-2\Delta t\, \xi_l} \sum_j \sqrt{c_{j2}}.$$

So we have

$$\begin{aligned} c_d^2 = \sum\nolimits_j c_{j1} \sum\nolimits_j c_{j2} &\leqslant \max_l \sqrt{c_{l1}} \sum\nolimits_j \sqrt{c_{j1}}\, \max_l \sqrt{c_{l2}} \sum\nolimits_j \sqrt{c_{j2}} \\ &\leqslant \max_l \frac{\sqrt{c_{l1}}}{1-2\Delta t\, \xi_l} \sum\nolimits_j \sqrt{c_{j2}}\, \max_l \frac{\sqrt{c_{l2}}}{1-2\Delta t\, \xi_l} \sum\nolimits_j \sqrt{c_{j1}} \\ &\leqslant \left(\max_l \frac{\sqrt{c_{l1}}}{1-2\Delta t\, \xi_l} \right)^2 \left(\sum\nolimits_j \sqrt{c_{j2}} \right)^2 = v_d^2. \qquad \square \end{aligned}$$

As expected, we deduce from (4.10) and Proposition 4.1 that the numerical influence velocity of the scheme necessarily satisfies

$$\frac{\Delta x}{\Delta t} > c_d.$$

The sufficient stability condition (4.10) is of course not necessary. However, in the numerical results of section 4.4, the gap between this condition and the instability of the scheme is small; then, this condition is quasi optimal in this case.

Remark 4. The numerical velocity v_d of (4.5) could also be compared to that of a (theoretical) scheme, in which the variable ξ remains continuous, by considering the continuous equivalent of the quantity $v_d = \max_{(i,k)} \max_l \frac{\sqrt{c_{li}}}{1-2\Delta t\, \xi_l} \sum_j \sqrt{c_{jk}}$ in (4.10). Namely, by supposing by simplicity that ν_i are positive and continuous functions[3] with bounded support, that $\Delta_\xi = \xi_{l+1} - \xi_l$ is constant and with $\Lambda_l = \mathbf{1}_{[\xi_l, \xi_{l+1}]}$, there exists $\nu'_{li} \in [\nu_i(\xi_l), \nu_i(\xi_{l+1})]$ such that $c_{li} = \int_{\xi_l}^{\xi_{l+1}} \nu_i(\xi)\, d\xi = \nu'_{li}\, \Delta\xi$; so,

$$\sqrt{c_{li}} \sum_j \sqrt{c_{jk}} = \sqrt{\nu'_{li}} \sum_j \sqrt{\nu'_{jk}}\, \Delta\xi \simeq \sqrt{\nu'_{li}} \int \sqrt{\nu_k(\xi)}\, d\xi,$$

and therefore, with Δt such that $1 - 2\Delta t\, \xi \geqslant 0$ for any $\xi \in \operatorname{supp} \nu_1 \cup \operatorname{supp} \nu_2$,

$$v_d \simeq \max_{(i,k)} \max_{l} \frac{\sqrt{\nu'_{li}}}{1-2\Delta t\, \xi_l} \int \sqrt{\nu_k(\xi)}\, d\xi \leqslant v := \max_{(i,k)} \sup_{\xi} \frac{\sqrt{\nu_i(\xi)}}{1-2\Delta t\, \xi} \int \sqrt{\nu_k}\, d\xi.$$

Then, similarly to Proposition 4.1, it can be easily shown that $v > c$. Note, however, that besides the boundedness of supp ν_i, which is a quite unrealistic hypothesis, this estimation can be in some cases excessively pessimistic.

[3] Dirac and L^1_{loc} components could be similarly treated up to suitable technical adaptations.

4.4. Numerical results. We give in this section some numerical results obtained with the explicit schemes. The values of parameters are [5]

$$\Lambda = \Lambda' = 0.1\,10^{-3}\,\mathrm{m},\quad \rho_0 = 1.2\,\mathrm{kg.m}^{-3},\quad P_0 = 10^5\,\mathrm{Pa},$$
$$\mu = 1.8\,10^{-5}\,\mathrm{kg.m}^{-1}.\mathrm{s}^{-1},\quad \gamma = 1.4,\ \alpha_\infty = 1.3,\quad e = 5\,10^{-2}\,\mathrm{m}.$$

The frequency responses of the approximations of $H_i(\partial_t)^{-1}$ obtained with (4.7) are given in Figure 4.1. Only 15 (resp., 20) ξ_l are used to approximate $H_1(\partial_t)^{-1}$ (resp., $H_2(\partial_t)^{-1}$) in a range of six decades with good accuracy.

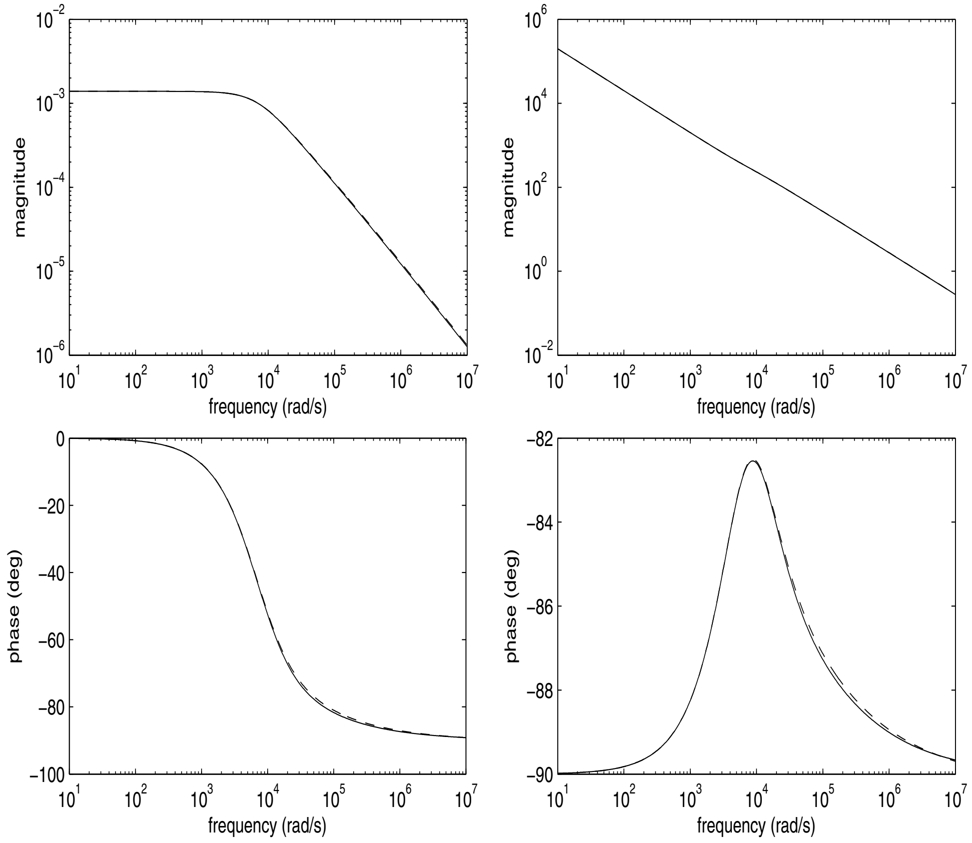

FIG. 4.1. *Exact (—) and approximate (- - -) frequency responses of operators $H_1(\partial_t)^{-1}$ (left) and $H_2(\partial_t)^{-1}$ (right).*

For illustration, the evolution of P obtained from simulation with explicit schemes is shown in Figure 4.2 (the two curves are superposed); the x-domain of (4.2) is $\Omega =]0,1[$ and the boundary conditions are

$$P(t,0) = (1-\cos(2\pi f\,t))\,\mathbf{1}_{[0,\frac{1}{f}]}(t),\qquad u(t,1) = 0,$$

with $f = 5\,kHz$. We can clearly observe the dissipation and dispersion due to operator $\mathbf{H}(\partial_t)$.

In Figure 4.3 we can see, at a particular time, the functions ψ_1 which are involved in the synthesis of u.

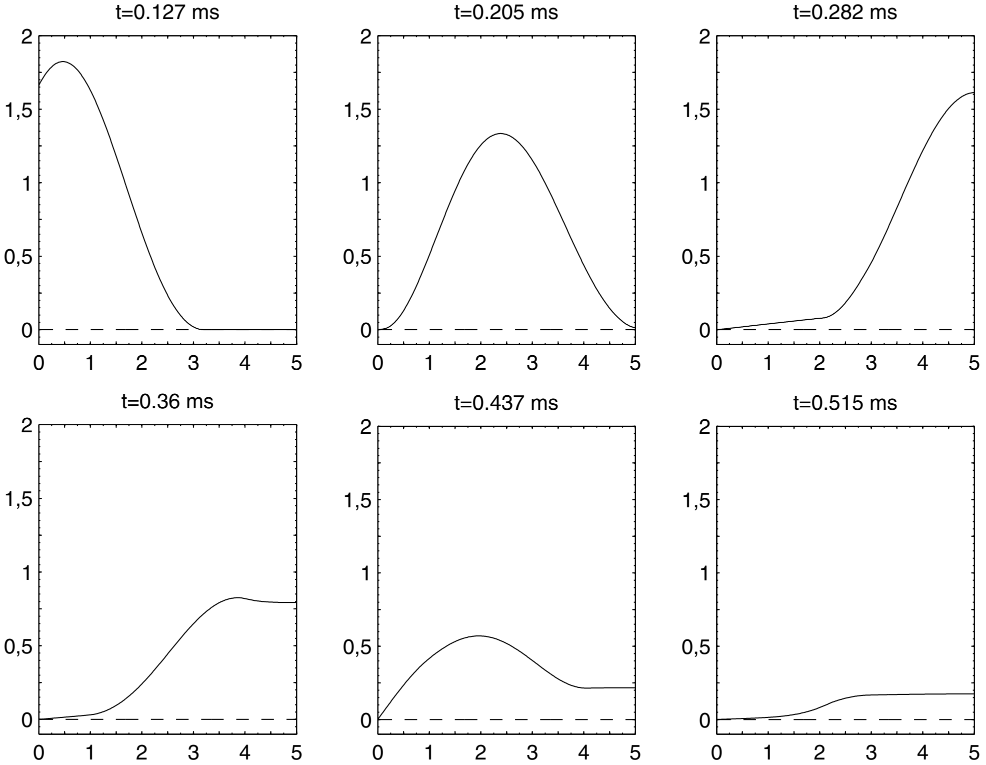

FIG. 4.2. *Evolution of* $\widetilde{P} = \sum_l b_{l2}\psi_2(\xi_l)$ *(N.B.: the unit of length for the x-axis is* $10^{-2}m$*).*

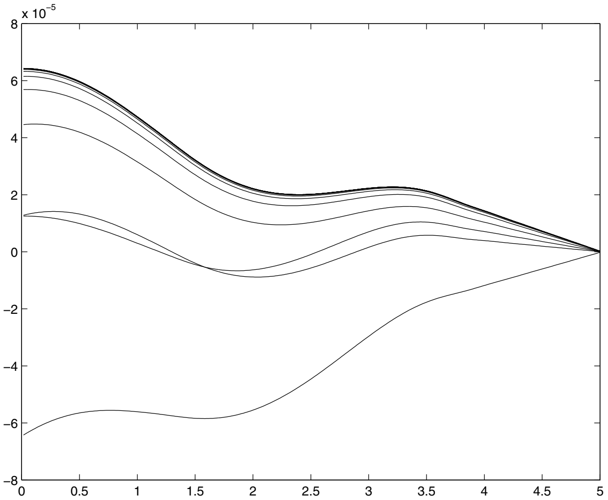

FIG. 4.3. *Functions* $\psi_1(t, ., \xi_l)$, $l = 1 : L$, *at time* $t = 1.3\,ms$.

4.5. Comparison between experimental and theoretical stability conditions. In the case of explicit schemes, the (sufficient) stability conditions are as follows:

Condition 1. Δt small enough.

Condition 2. $a_{li} - \frac{b_{li}}{2\Delta x} \sum_k b_{kj} > 0$.

We propose to compare from numerical simulations the stability condition, Condition 2, with the experimental one. In the same conditions as previously, for different values of $\frac{\Delta t}{\Delta x}$, we test the experimental stability of the schemes and verify whether Condition 2 is satisfied or not. The results are presented in Table 4.1 (resp., in Table 4.2) for the first (resp., the second) scheme. In the two cases, the results confirm that Condition 2 is a sufficient stability condition. We can notice that the interval of $\frac{\Delta t}{\Delta x}$ values, for which the scheme is stable even if Condition 2 is not verified, is small ($1.48\,10^{-4}$ to $1.98\,10^{-4}$); then, this condition is in fact "almost necessary."

Finally, to make the link with section 4.3, we can remark that the experimental stability bounds are intimately linked to propagation velocities. Indeed, the values of velocities defined in section 4.3 are (in length unit e per second)

$$c = 5992,\ c_d = 5038, \text{ and } v_d = 6856,$$

which correspond to the physical values $c = 299.6$ m.s^{-1}, $c_d = 251.9$ m.s^{-1}, and $v_d = 342.8$ m.s^{-1}. We can remark that, as expected, the schemes become unstable when $\frac{\Delta x}{\Delta t} \leqslant \frac{1}{1.98\,10^{-4}} \simeq c_d$, that is, when the numerical propagation velocity is less than the model's one.

TABLE 4.1
First explicit scheme.

Value of $\Delta t/\Delta x$	Condition 2	Stability
$\leqslant 1.4710^{-4}$	verified	yes
from 1.4810^{4} to 1.98710^{-4}	not verified	yes
$\geqslant 1.9810^{-4}$	not verified	no

TABLE 4.2
Second explicit scheme.

Value of $\Delta t/\Delta x$	Condition 2	Stability
$\leqslant 1.4710^{-4}$	verified	yes
from 1.4810^{4} to 1.9810^{-4}	not verified	yes
$\geqslant 1.9910^{-4}$	not verified	no

Appendix A. A particular time discretization. For a linear differential system in $\mathbb{C}^M$,

$$\partial_t \varphi = A\varphi + Bw, \quad \varphi(0) = 0,$$

the solution φ is given by

$$\varphi(t) = \int_0^t e^{A(t-s)} B\, w(s)\, ds.$$

For w constant in $[t - \Delta t, t + \Delta t]$, we have

$$\varphi(t+\Delta t) = \int_0^{t-\Delta t} e^{A(t+\Delta t-s)} B\, w(s)\, ds + \int_{t-\Delta t}^{t+\Delta t} e^{A(t+\Delta t-s)}\, ds B\, w(t) = F\varphi(t-\Delta t) + Gw(t),$$

with $F = e^{2\Delta t A}$ and $G = A^{-1}(e^{2\Delta t A} - I)B$. So we get the following numerical scheme:

$$\varphi^{t+\Delta t} = F\varphi^{t-\Delta t} + Gw^t.$$

Note that this scheme is especially useful in the case where A is diagonal.

AN INTERACTION THEORY FOR SCATTERING BY DEFECTS IN ARRAYS[*]

I. THOMPSON[†] AND C. M. LINTON[†]

Abstract. Wave scattering by an array of bodies that is periodic except for a finite number of missing or irregular elements is considered. The field is decomposed into contributions from a set of canonical problems, which are solved using a modified array scanning method. The resulting interaction theory for defects is very efficient and can be used to construct the field in a large number of different situations. Numerical results are presented for several cases, and particular attention is paid to the amplitude with which surface waves are excited along the array. We also show how other approaches can be incorporated into the theory so as to increase the range of problems that can be solved.

Key words. arrays, defects, scattering, surface waves

1. Introduction.

Wave scattering by arrays of bodies is of fundamental importance in numerous engineering and physics applications. Here we are concerned with the effect of one or more defects in an infinite, periodic array. This problem is of significant current interest in several fields, including elastodynamics [19] and phononic [7, 28] and photonic [1, 26, 5] crystals. The presence of defects leads to a significant increase in difficulty in determining the scattered field, because the geometry is no longer periodic. In particular, Rayleigh–Bloch (RB) surface waves (also known as array guided surface waves) are excited if the array geometry and physical parameters are such that these modes can exist. RB waves propagate without loss along an array, and are evanescent in other directions. They are known to occur in a wide variety of situations [15, 21, 18, 10]. One of the key goals of this article is to develop an efficient and accurate method for the determination of the amplitude with which they are excited. The theory is presented in a form that can be directly interpreted in a number of different physical contexts. These include the acoustic case, in which the wavenumber k is the ratio of the angular frequency ω to the speed of sound c, and the interaction of linear water waves with bottom mounted, surface penetrating cylinders, in which case k is the positive solution to the dispersion relation $k \tanh kh = \omega^2/g$, g being the acceleration due to gravity and h the quiescent fluid depth. For acoustics, Dirichlet and Neumann boundary conditions are used to model sound hard and sound soft bodies, respectively, whereas Neumann conditions are appropriate for solid bodies immersed in water. The method is also applicable in the electromagnetic and elastodynamic cases, provided that the overall vector wave problem decouples into separate scalar components.

Our first step in obtaining the field scattered by a defective array is to decompose the solution into contributions arising from a set of simpler, canonical problems. This is achieved by modifying the field generated when a wave interacts with a periodic

array, so as to eliminate a finite number of elements, or replace these with bodies of different sizes, shapes, or surface compositions. The procedure is independent of the type of wavefunctions used to represent the field (i.e., cylindrical, spherical, etc.) and is therefore presented in a general form in section 2. The canonical problems are independent of the defect configuration and all aspects of the incident field, except the wavenumber; they need not be solved again if these parameters are changed. In order for the decomposition to be useful in a specific case, the relevant canonical problems must be solved accurately and efficiently. The boundary conditions on the surface of the array elements come into play at this stage, and therefore we must apply an appropriate multiple scattering theory. This requires the use of certain results concerning the periodic array, and these are readily available for problems involving cylindrical wavefunctions; a summary is given in section 3. The canonical problems for this case are then solved in section 4 using a special Fourier series. This approach is closely related to the array scanning method [27, 16], which is typically used in problems involving excitation by an aperiodic field, and in particular for the analysis of antenna arrays [3, 4]. The idea is to create a periodic incident field by introducing an array of phase-shifted sources, and then to integrate over a single period of the phase shift so as to eliminate all but one of the sources. The procedure used in section 4 is similar, but its effect is rather different, and we shall refer to it as the "modified array scanning method" (MASM). Instead of eliminating sources, the integration, which must be performed using quadrature, enables us to replace one member of a periodic array with a source. This is the most computationally intensive part of the technique. Nevertheless, important parameters such as RB wave amplitudes can be efficiently calculated to near machine precision. In contrast, other techniques such as the filtering approach used for a related problem in [11] have limited accuracy. Technical details regarding the method used to evaluate the relevant integrals are given in the appendix. This method is chosen for simplicity and is open to improvement.

Considered together, the decomposition into canonical problems and the MASM are similar to the "fictitious source superposition method" which was originally used for a study of photonic crystals with a single defect [26]. This was later extended in [5] to account for situations where more than one defect is present. Our formulation, which is a generalization of earlier work in [22], is rather different and automatically includes the case of multiple defects. Indeed, by first reducing to canonical problems, we obtain an "interaction theory for defects" by means of which the solutions for a wide variety of cases can be constructed at very little computational expense.

A representative sample of the numerical results that can be obtained is given in section 5. We also demonstrate how the methods in sections 2–4 can be combined with other approaches, such as infinite array subtraction [11] and the large array approximation method used in [24], to widen the class of problems that can be considered.

2. General theory.

In this section we will show how the problem of wave scattering by a defective array can be reduced to a set of simpler, canonical problems. This is achieved using a procedure that is independent of the shape of the scatterers and the boundary conditions that are to be applied on their surfaces. We therefore present the theory from a general perspective, although for clarity we deal with the case of a one-dimensional array in the two-dimensional setting. The extensions to higher array dimensions and to three dimensions in space is straightforward, requiring only that scalar indices are replaced by appropriate multi-indices.

Thus, consider an array of scatterers which is periodic, except for a finite number of missing, or possibly irregular, elements. The elements are labeled by an index $p \in \mathbb{Z}$, and the defects correspond to those values for which p is a member of the finite defect set $\mathcal{D}$. If $p \notin \mathcal{D}$, we shall say that scatterer p is regular. A (one-dimensional) lattice of points $\mathbf{r}_p$ is defined so that $\mathbf{r} = \mathbf{r}_p$ lies inside scatterer p if this body is present in the array. The field in the vicinity of each scatterer is then expanded about the point $\mathbf{r} = \mathbf{r}_p$ as a sum of incoming and outgoing wavefunctions. The former are regular for all $\mathbf{r}$, whereas the latter are singular at $\mathbf{r} = \mathbf{r}_p$ and regular elsewhere. The choice of $\mathbf{r}_p$ is of course not unique.

In the region exterior to the scatterers, all wavefields ϕ must satisfy the Helmholtz equation

$$(\nabla^2 + k^2)\phi = 0. \tag{2.1}$$

The array is excited by the incident wave ϕ^{i}, and the total field is obtained by adding the scattered response. Hence,

$$\phi^{\mathrm{t}} = \phi^{\mathrm{i}} + \phi^{\mathrm{s}}, \tag{2.2}$$

where ϕ^{s} can be expanded in the form

$$\phi^{\mathrm{s}}(\mathbf{r}; \mathcal{D}) = \sum_m \sum_p A_m^p(\mathcal{D}) \mathcal{H}_m^p(\mathbf{r}). \tag{2.3}$$

Here, the notation $\mathcal{H}_m^p$ represents an outgoing wavefunction of order m that is singular at $\mathbf{r} = \mathbf{r}_p$ and regular elsewhere. Where no limits are placed on an index it is to be understood that this ranges over all possible values. The radiation condition stipulates that ϕ^{s} cannot include any contributions that are incoming from the far field, or that increase in magnitude as the observer moves toward infinity. Initially, we consider defects that consist of missing scatterers, in which case we must have

$$A_m^p(\mathcal{D}) = 0, \quad p \in \mathcal{D}, \tag{2.4}$$

so that there are no singularities in the field. Later we will show how the theory can be modified to account for irregular scatterers, which is slightly more difficult.

The pivotal idea behind our procedure is to modify $\phi^{\mathrm{s}}(\mathbf{r}, \emptyset)$ (i.e., the scattered field that occurs when there is no defect) by cancelling the singularities at $\mathbf{r} = \mathbf{r}_p$ for each $p \in \mathcal{D}$. The resulting wavefield does not include any radiation from the scatterers for which $p \in \mathcal{D}$, and no longer satisfies the boundary conditions on their surface. In this way, the influence of these array elements is eliminated. The boundary conditions on the surface of the regular scatterers are still satisfied, as is the radiation condition.

At a later stage, it is necessary to apply a multiple scattering theory in order to satisfy the boundary conditions on the scatterer surfaces. This requires that, in some region containing the surface of scatterer p, the total field can be represented in the form

$$\phi^{\mathrm{t}}(\mathbf{r}; \mathcal{D}) = \phi_p^{\mathrm{i}}(\mathbf{r}; \mathcal{D}) + \phi_p^{\mathrm{r}}(\mathbf{r}; \mathcal{D}), \tag{2.5}$$

where

$$\phi_p^{\mathrm{i}}(\mathbf{r}; \mathcal{D}) = \sum_m I_m^p(\mathcal{D}) \mathcal{J}_m^p(\mathbf{r}) \tag{2.6}$$

and

$$\phi_p^{\mathrm{r}}(\mathbf{r};\mathcal{D}) = \sum_m A_m^p(\mathcal{D})\mathcal{H}_m^p(\mathbf{r}). \tag{2.7}$$

Here, $\mathcal{J}_m^p$ represents a regular wavefunction of order m and ϕ_p^{i} is the total field incoming toward the point $\mathbf{r}_p$. It consists of the incident wave and the radiation from all of the other scatterers. The second term on the right-hand side of (2.5) represents the field outgoing from scatterer p. The relationships between the expansions (2.3) and (2.5)–(2.7) can be found in [14, Chapters 2 and 3] for wavefunctions in a number of separable geometries. The crucial point here is the nature of the regions where the series appearing in (2.6) and (2.7) converge and therefore represent valid solutions to the Helmholtz equation. The expansion of the incoming field (2.6) is valid inside a simply connected region that contains the point $\mathbf{r}_p$. In fact, if we are to apply a multiple scattering theory based on the expansions (2.5)–(2.7), this region must contain the whole of scatterer p. Thus, the field incoming toward a particular body can be extended to the entire region inside that body, and there it continues to represent a valid solution to the Helmholtz equation. The same cannot be said for the field radiating from a particular body (equation (2.7)) because $\mathcal{H}_m^p(\mathbf{r})$ is singular at the point $\mathbf{r} = \mathbf{r}_p$. Note that the use of (2.5)–(2.7) to represent the field at the surface of the scatterers imposes a geometrical restriction. For cylindrical and spherical wavefunctions, the maximum distance from $\mathbf{r}_p$ to the surface of scatterer p must be less than $|\mathbf{r}_p - \mathbf{r}_{p\pm 1}|$ [14, sections 2.5, 3.12].

As a starting point, for the case where $\mathcal{D} = \emptyset$, we have

$$\phi^{\mathrm{s}}(\mathbf{r};\emptyset) = \sum_m \sum_p A_m^p(\emptyset)\mathcal{H}_m^p(\mathbf{r}), \tag{2.8}$$

and we will assume that the coefficients $A_m^p(\emptyset)$ are known, since this is a periodic geometry, and so the solution can be obtained relatively easily. Now, construct the field $\phi^{\mathrm{s}}(\mathbf{r};\mathcal{D})$ by writing

$$\phi^{\mathrm{s}}(\mathbf{r};\mathcal{D}) = \phi^{\mathrm{s}}(\mathbf{r};\emptyset) + \psi(\mathbf{r};\mathcal{D}), \tag{2.9}$$

and observe that $\psi(\mathbf{r};\mathcal{D})$ must satisfy the boundary conditions on the regular scatterers because $\phi^{\mathrm{s}}(\mathbf{r};\mathcal{D})$ and $\phi^{\mathrm{s}}(\mathbf{r};\emptyset)$ do so independently. From (2.3), (2.4), and (2.8) we have the explicit representation

$$\psi(\mathbf{r};\mathcal{D}) = \sum_m \sum_{p\notin\mathcal{D}} \left[A_m^p(\mathcal{D}) - A_m^p(\emptyset)\right]\mathcal{H}_m^p(\mathbf{r}) - \sum_m \sum_{p\in\mathcal{D}} A_m^p(\emptyset)\mathcal{H}_m^p(\mathbf{r}). \tag{2.10}$$

By considering the last term on the right-hand side (which is known) as an incident field, and the other terms as the associated scattered response, it is now seen that $\psi(\mathbf{r};\mathcal{D})$ is the total field that occurs when an array with scatterers absent for $p \in \mathcal{D}$ is excited by a distribution of sources located at the points $\mathbf{r} = \mathbf{r}_p$, $p \in \mathcal{D}$. We shall refer to $\mathcal{H}_m^p(\mathbf{r})$ as the source of order m with unit amplitude, located at the point $\mathbf{r} = \mathbf{r}_p$.

Rather than solve for $\psi(\mathbf{r};\mathcal{D})$ directly, we can reduce the problem to a set of simpler, canonical problems by considering each source term in (2.10) separately. Thus, introduce the potential $\psi_n^q(\mathbf{r})$, which represents the total field that occurs when a periodic array has a single element (labeled by q) removed and replaced by a unit source of order n. Crucially, if $q \in \mathcal{D}$, then $\psi_n^q(\mathbf{r})$ satisfies the boundary conditions on the surface of all the regular scatterers. Now $\psi(\mathbf{r}; \mathcal{D})$ clearly consists entirely of waves that are outgoing from the array, and therefore we can expand it into the form

$$\psi_n^q(\mathbf{r}) = \mathcal{H}_n^q(\mathbf{r}) + \sum_m \sum_{p \neq q} C_{m,n}^{p,q} \, \mathcal{H}_m^p(\mathbf{r}). \tag{2.11}$$

Here, we have introduced the convention that the indices to the right of the comma describe the source, in this case referring to order n and position q. It is convenient to simplify such expressions by defining

$$C_{m,n}^{q,q} = \delta_{mn}, \tag{2.12}$$

so that the first term on the right-hand side can be taken inside the series. To avoid any possible misinterpretation, we emphasize that (2.11) does not represent a homogeneous solution to the periodic (i.e., defect-free) array problem because the appropriate boundary condition on the surface of scatterer q is not satisfied.

Next, we represent $\psi(\mathbf{r}; \mathcal{D})$ as a linear combination of the potentials $\psi_n^q(\mathbf{r})$, $q \in \mathcal{D}$; thus

$$\psi(\mathbf{r}; \mathcal{D}) = \sum_n \sum_{q \in \mathcal{D}} a_n^q \psi_n^q(\mathbf{r}). \tag{2.13}$$

If we substitute from (2.11) into (2.13) and rearrange the summations, we obtain

$$\psi(\mathbf{r}; \mathcal{D}) = \sum_m \sum_{p \in \mathcal{D}} a_m^p \mathcal{H}_m^p(\mathbf{r}) + \sum_m \sum_p \sum_n \sum_{\substack{q \in \mathcal{D} \\ q \neq p}} a_n^q C_{m,n}^{p,q} \, \mathcal{H}_m^p(\mathbf{r}). \tag{2.14}$$

Comparing this with (2.10), we find that

$$a_m^p + \sum_n \sum_{\substack{q \in \mathcal{D} \\ q \neq p}} a_n^q C_{m,n}^{p,q} = -A_m^p(\emptyset), \quad p \in \mathcal{D}, \tag{2.15}$$

which is a linear system of equations for the coefficients a_m^p, and

$$\sum_n \sum_{q \in \mathcal{D}} a_n^q C_{m,n}^{p,q} = A_m^p(\mathcal{D}) - A_m^p(\emptyset), \quad p \notin \mathcal{D}, \tag{2.16}$$

which then serves to determine the unknowns $A_m^p(\mathcal{D})$. Equation (2.15) is an "interaction theory for defects," which is similar in nature to the standard interaction theories for multiple bodies. If only a single scatterer is absent from the array, we retrieve $a_m^p = -A_m^p(\emptyset)$ so as to cancel the radiation emanating from $\mathbf{r} = \mathbf{r}_p$, as we should expect. A useful simplification now occurs if the array consists of periodic repetitions of a single body. In this case the potentials ψ_m^p are identical up to a spatial shift, and we need only determine ψ_m^0. In terms of the coefficients $C_{m,n}^{p,q}$, we have

$$C_{m,n}^{p,q} = C_{m,n}^{p-q,0} \tag{2.17}$$

and so there is a single canonical problem to solve for each value of m.

Finally, consider defects consisting of scatterers that are in some way different from the other elements of the array. In this case, the method operates by replacing members of the periodic array for which $p \in \mathcal{D}$ with irregular bodies. In contrast to the case of absent scatterers, $A_m^p(\mathcal{D})$ is generally nonzero for $p \in \mathcal{D}$. The singularities at $\mathbf{r} = \mathbf{r}_p$ are no longer cancelled; instead they are adjusted so that for $p \in \mathcal{D}$, the expansion (2.7) represents a solution to the Helmholtz equation in the region exterior to the new element. Consequently, the point $\mathbf{r} = \mathbf{r}_p$ must lie inside scatterer p for $p \in \mathcal{D}$ (as it does for $p \notin \mathcal{D}$). The field $\psi(\mathbf{r}; \mathcal{D})$ can still be constructed from a linear combination of the solutions to the same canonical problems, but in place of (2.15), we now have

$$a_m^p + \sum_n \sum_{\substack{q \in \mathcal{D} \\ q \neq p}} a_n^q C_{m,n}^{p,q} = A_m^p(\mathcal{D}) - A_m^p(\emptyset), \quad p \in \mathcal{D}. \tag{2.18}$$

Equation (2.16) is unaffected. The presence of the additional unknowns $A_m^p(\mathcal{D})$ on the right-hand side of (2.18) is countered by the need to apply a boundary condition on the surface of the irregular scatterers, and in section 5 we shall see how this works in practice. While it is evident that replacing scatterers is more complicated than eliminating them, the increase in difficulty is marginal. Essentially this is because the extra requirement is to determine the field incoming toward $\mathbf{r} = \mathbf{r}_p$ for $p \in \mathcal{D}$, but this is no more difficult than determining the field incoming toward a regular scatterer, which is always necessary.

A major advantage of this method over a more direct approach is as follows. Had we simply applied an interaction theory to the defective array problem, we would be faced with the inversion of a linear system of equations containing infinite sums over the spatial indices. These have a very slow rate of convergence and present serious difficulties in obtaining accurate results, even with the aid of modern computing power. In contrast, (2.15), (2.16), and (2.18) contain only *finite* spatial sums. The infinite order summation is of less concern, particularly at low frequencies, because as $|m|$ is increased the coefficients A_m^p converge rapidly to zero. Even in cases where the scatterers are almost in contact, the convergence of the order sum is much more rapid than that of the spatial sum; the former can be truncated at a relatively small value of $|m|$. Of course, it remains to solve the canonical problems, and these involve infinite linear systems containing spatial sums. However, these possess symmetries that are not present in the overall problem, and as mentioned earlier, solutions to one set of canonical problems can be used to construct the field for a number of different cases. Thus, the decomposition described above is useful even in problems where the MASM cannot be used effectively.

3. Array problems involving cylindrical wavefunctions. In order to solve the canonical problems that arise in the interaction theory for defects, we must deal with the boundary conditions on the scatterer surfaces. It is therefore necessary to present subsequent material for a specific geometry, and since the theory of linear arrays is well established for the case of cylindrical wavefunctions, this is a natural choice. Here, we collect some results from pre-existing literature in this area that will be needed later. It should be noted that the essential principles upon which the method depends remain unchanged if wavefunctions from another separable geometry are used. We will assume that the scatterers themselves are circular so as to present the theory in the simplest possible form; however we will indicate how scatterers of a different shape can be considered through the incorporation of transfer matrices.

Let all lengths be scaled on the distance between the centers of consecutive lattice points, with these located at $\mathbf{r}_p = (p, 0)$ in the (x, y) plane. According to the chosen scaling, the radius a of the regular scatterers must satisfy the inequality $a \leq 0.5$. The expansion (2.3) now takes the form

$$\phi^{\mathrm{s}}(\mathbf{r}; \mathcal{D}) = \sum_m \sum_p A_m^p(\mathcal{D})\, H_m^{(1)}(kr_p)\mathrm{e}^{\mathrm{i}m\theta_p}, \tag{3.1}$$

where (r_p, θ_p) is a set of polar coordinates with its origin at the center of scatterer p (see Figure 3.1), and $H_m^{(1)}(\cdot)$ denotes a Hankel function of the first kind with order m. This choice of outgoing wavefunction (rather than $H_m^{(2)}(\cdot)$) corresponds to an implicit time-harmonic factor $\mathrm{e}^{-\mathrm{i}\omega t}$. We also have a decomposition of the form (2.5)–(2.7), with

$$\phi_p^{\mathrm{i}}(r_p, \theta_p; \mathcal{D}) = \sum_m I_m^p(\mathcal{D})\, J_m(kr_p)\mathrm{e}^{\mathrm{i}m\theta_p} \tag{3.2}$$

and

$$\phi_p^{\mathrm{r}}(r_p, \theta_p; \mathcal{D}) = \sum_m A_m^p(\mathcal{D})\, H_m^{(1)}(kr_p)\mathrm{e}^{\mathrm{i}m\theta_p}, \tag{3.3}$$

where $J_m(\cdot)$ is the Bessel function of order m. As before, $\phi_p^{\mathrm{i}}(\mathbf{r}; \mathcal{D})$ represents the total field incoming toward scatterer p, and this consists of the incident wave and the radiation from all of the other scatterers. The expansion (3.2) is a valid representation for $\phi_p^{\mathrm{i}}(\mathbf{r}; \mathcal{D})$, provided that $r_p < 1$. In general, a transfer matrix appropriate to the geometry of the scatterers relates the coefficients $I_m^p(\mathcal{D})$ and $A_m^p(\mathcal{D})$, but for circular scatterers, orthogonality leads to a matrix that is diagonal. Consequently, we can write

$$A_m^p(\mathcal{D}) + Z_m I_m^p(\mathcal{D}) = 0, \tag{3.4}$$

where Z_m is a scattering coefficient which is given by

$$Z_m = J_m(ka)/\, H_m^{(1)}(ka) \tag{3.5}$$

for Dirichlet boundary conditions, or

$$Z_m = J_m'(ka)/\, H_m^{(1)\prime}(ka) \tag{3.6}$$

for Neumann conditions. Other expressions for Z_m can be used to model different situations, such as impedance boundary conditions.

Scattering problems of this type can be separated into components that are symmetric and antisymmetric about $y = 0$ by decomposing the incident field ϕ^{i} into an even (subscript "+") and an odd (subscript "−") function of y; thus

$$\phi_{\pm}^{\mathrm{i}}(x, y) = \frac{1}{2}\left[\phi^{\mathrm{i}}(x, y) \pm \phi^{\mathrm{i}}(x, -y)\right]. \tag{3.7}$$

If the array is excited by incident wave $\phi_{\pm}^{\mathrm{i}}(x, y)$, then the resulting coefficients A_m^p and I_m^p satisfy the identity

$$\mathcal{U}_{-m}^p = \pm(-1)^m \mathcal{U}_m^p. \tag{3.8}$$

This often leads to useful simplifications, and also to an increase in performance when inverting linear systems. For brevity, we will give equations for the complete

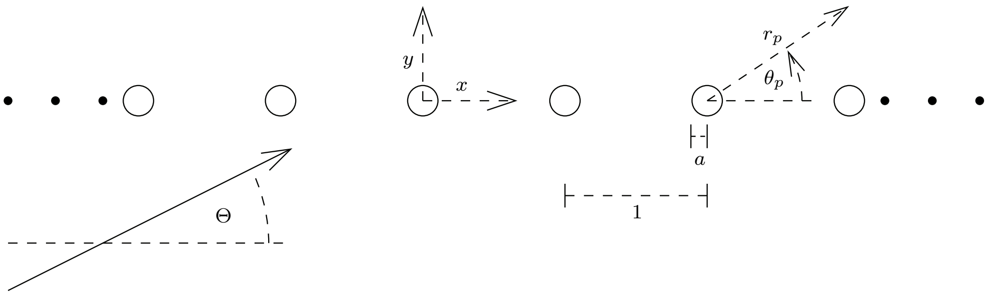

FIG. 3.1. *Schematic diagram of a periodic array with circular scatterers centered at the points* $(p,0)$ *in the* (x,y) *plane, and a plane wave incident at angle* Θ.

wavefield, and it is to be understood that these can always be decomposed in the manner described above.

To conclude this section, we will now review the theory of periodic arrays, starting with the method for obtaining the coefficients $A_m^p(\emptyset)$ in the case where the incident field is the plane wave

$$\phi^{\mathrm{i}}(x,y) = \mathrm{e}^{\mathrm{i}k(x\cos\Theta + y\sin\Theta)}; \tag{3.9}$$

see Figure 3.1. Values for $A_m^p(\emptyset)$ are of course required as a starting point, and the technique used to obtain them provides some motivation for the MASM developed in section 4 to solve the canonical problems. First of all, we require a second set of equations relating the coefficients $A_m^p(\emptyset)$ and $I_m^p(\emptyset)$. This will form a closed system, when combined with (3.4), and can be obtained using Graf's addition theorem [14, section 2.5]. For the specific case under consideration here, we have

$$I_m^p(\emptyset) = \mathrm{i}^m \mathrm{e}^{\mathrm{i}pk\cos\Theta}\mathrm{e}^{-\mathrm{i}m\Theta} + \sum_v \sum_{j\neq p} A_v^j(\emptyset) X_{v-m}^{p-j}\, H_{v-m}^{(1)}(k|p-j|), \tag{3.10}$$

where $X_v^p = \operatorname{sgn}(p)^v$. Given that the only difference between the field at the point (x,y) and that at $(x+j,y)$, $j\in\mathbb{Z}$, is a phase shift due to the incident plane wave, this can be simplified by seeking a solution for which

$$A_m^p(\emptyset) = A_m^0(\emptyset)\mathrm{e}^{\mathrm{i}pk\cos\Theta}. \tag{3.11}$$

Enforcing the boundary conditions via (3.4), and then making use of (3.11), we obtain

$$A_m^0(\emptyset) + Z_m \sum_v A_v^0(\emptyset)\sigma_{v-m}(k\cos\Theta) = -Z_m \mathrm{i}^m \mathrm{e}^{-\mathrm{i}m\Theta}, \tag{3.12}$$

which is a linear system involving only an order sum. The function $\sigma_n(t)$ is a Schlömilch series of order n, i.e.,

$$\sigma_n(t) = \sum_{j=1}^{\infty} \left[\mathrm{e}^{-\mathrm{i}jt} + (-1)^n \mathrm{e}^{\mathrm{i}jt}\right] H_n^{(1)}(kj). \tag{3.13}$$

If the values of k and Θ are such that the Schlömilch series are divergent, the values for $A_m^p(\emptyset)$ can be obtained as in [12]. Note that $\sigma_{-n}(t) = (-1)^n\sigma_n(t)$.

The Schlömilch series is a type of lattice sum, and the capacity to evaluate these accurately and efficiently is crucial to the analysis of wave interactions with arrays.

For the case under consideration here, the well-known Twersky formulae [25, 8] can be used. The singularity structure of $\sigma_n(t)$ must be considered when applying the MASM, and so we note that

$$\sigma_n(t) = b_n(t) + 2(-\mathrm{i})^{n+1}\left[\mu_n^0(t) + \sum_{j=1}^{\infty}\left(\mu_n^j(t) + \mu_{-n}^{-j}(t) - \frac{\delta_{n0}}{\pi j}\right)\right], \tag{3.14}$$

where $b_n(t)$ is an entire function that can be expressed as a finite sum of Bernoulli polynomials, and

$$\mu_n^j(t) = \frac{[t + 2j\pi - \gamma(t+2j\pi)]^n}{k^n\gamma(t+2j\pi)}. \tag{3.15}$$

The function $\gamma(t)$ is defined for real t via

$$\gamma(t) = \begin{cases} \sqrt{t^2-k^2} & : |t| \geq k, \\ -\mathrm{i}\sqrt{k^2-t^2} & : |t| < k. \end{cases} \tag{3.16}$$

For $n = 0$, 1, and 2, the summand in (3.14) is $O(j^{-3})$ as $j \to \infty$; for larger n it is $O(j^{-5})$ or smaller. The rate of convergence can easily be accelerated by expanding the summand in (3.14) for large j. Where derivatives are required, the formula

$$\frac{\mathrm{d}\mu_n^j}{\mathrm{d}t} = \frac{-\mu_n^j(t)}{\gamma(t+2j\pi)}\left[n + \frac{t+2j\pi}{\gamma(t+2j\pi)}\right] \tag{3.17}$$

can be used. The infinite summation in the resulting formula for $\sigma_n'(t)$ has a summand that is $O(j^{-3})$ as $j \to \infty$ for $n = 0$ and $n = 1$, and $O(j^{-5})$ or smaller for larger values of n. Again, the convergence can be accelerated where necessary.

An important property of infinite periodic arrays is their capacity to support RB surface waves in some circumstances. These propagate without loss along the array and decay exponentially in other directions. The presence of RB waves corresponds to the existence of nontrivial homogeneous solutions to the periodic array problem with the form

$$\phi_{RB}^{\mathrm{t}}(\mathbf{r}) = \sum_m \sum_p \widetilde{B}_m \mathrm{e}^{\mathrm{i}p\widetilde{\beta}}\, H_m^{(1)}(kr_p)\mathrm{e}^{\mathrm{i}m\theta_p}, \tag{3.18}$$

where $\widetilde{\beta} \in \mathbb{R}$ is an arbitrary phase shift. The coefficients $\widetilde{B}_m$ satisfy the same system of equations as $A_m^0(\emptyset)$ (i.e., (3.12)), but with the right-hand side set to zero and $k\cos\Theta$ replaced by $\widetilde{\beta}$; thus

$$\widetilde{B}_m + Z_m \sum_v \widetilde{B}_v \sigma_{v-m}(\widetilde{\beta}) = 0, \tag{3.19}$$

in which $\widetilde{B}_m \neq 0$ for at least one m. A straightforward method for finding the appropriate values for $\widetilde{\beta}$ is given in [6]. The associated coefficients $\widetilde{B}_m$ are then normalized so that

$$\sum_m |\widetilde{B}_m|^2 = 1. \tag{3.20}$$

Given the evident 2π-periodicity of the Schlömilch series (3.13), distinct solutions to (3.19) can occur only for $\widetilde{\beta} \in [0, 2\pi)$. Full details of the parameter ranges for which RB modes have been found are given in [23]. Here we summarize the important details.

If the surface of the scatterers is subject to a Dirichlet boundary condition, then RB waves do not occur [2]. On the other hand, if a Neumann boundary condition is in use, then up to two distinct modes are known to exist. One of these is symmetric about $y = 0$; this can occur for scatterers of any size, for a range of wavenumbers $0 < k < k^{\mathrm{s}}_{\max} < \pi$. The other is an antisymmetric mode which exists in the range $k^{\mathrm{a}}_{\min} < k < k^{\mathrm{a}}_{\max} < \pi$, but only if $a \gtrsim 0.403$. The cut-off values depend upon the scatterer radius a. Outside the given ranges for k, the RB wave is replaced by a mode that is evanescent in x. In both the symmetric and antisymmetric cases, the principal value for $\widetilde{\beta}$ lies in the interval (k, π) and corresponds to a right-propagating wave. The associated left-propagating mode has the phase shift $2\pi - \widetilde{\beta}$ in place of $\widetilde{\beta}$ and the coefficient $(-1)^m \widetilde{B}_m$ in place of $\widetilde{B}_m$. As $k \to k_{\max}$, $\widetilde{\beta} \to \pi$, i.e., the RB modes become standing waves. The amplitude with which RB modes are excited is a key parameter in the solution, and obtaining this is a major goal of our analysis. In what follows, we will assume that exactly one type of RB mode occurs (i.e., symmetric or antisymmetric). It is not difficult to modify our subsequent analysis if this is not the case. In a problem where the incident wave has been decomposed using (3.7), there is at most one mode for each component of the solution.

4. Canonical problems.

In order to proceed, we must determine ψ^0_n, i.e., the total field that occurs when scatterer 0 is replaced by a unit source of order n. In this case, we have the expansion

$$\psi^0_n(\mathbf{r}) = \sum_m \sum_p C^{p,0}_{m,n} \, H^{(1)}_m(kr_p) \mathrm{e}^{\mathrm{i}m\theta_p}, \tag{4.1}$$

where

$$C^{0,0}_{m,n} = \delta_{mn}, \tag{4.2}$$

as in (2.12). A useful symmetry relation can be obtained by changing x to $-x$ and y to $-y$ (and therefore $r_p \to r_{-p}$ and $\theta_p \to \pi + \theta_{-p}$) in (4.1). After applying (4.2) and comparing the result to (4.1), we find that

$$C^{-p,0}_{m,n} = (-1)^{m+n} C^{p,0}_{m,n}. \tag{4.3}$$

As before, a linear system for the unknown coefficients can be obtained by locally expanding ψ^0_n about the point $r_p = 0$; thus

$$\psi^0_n(r_p, \theta_p) = \sum_m \Big[K^{p,0}_{m,n} \, J_m(kr_p) + C^{p,0}_{m,n} \, H^{(1)}_m(kr_p) \Big] \mathrm{e}^{\mathrm{i}m\theta_p}. \tag{4.4}$$

An expression for the incoming field coefficients $K^{p,0}_{m,n}$ in terms of the outgoing coefficients $C^{p,0}_{m,n}$ can be deduced from (3.10) by simply omitting the term due to plane wave forcing. We find that

$$K^{p,0}_{m,n} = \sum_v \sum_{j \neq p} C^{j,0}_{v,n} X^{p-j}_{v-m} \, H^{(1)}_{v-m}(k|p-j|), \tag{4.5}$$

and the boundary condition gives

$$C^{p,0}_{m,n} + Z_m K^{p,0}_{m,n} = 0, \quad p \neq 0. \tag{4.6}$$

The MASM can now be used to obtain an expression for $C^{p,0}_{m,n}$. The principal idea is derived from the original array scanning method [27, 16, 23], in which the unknown coefficients are represented as Fourier integrals. First of all, introduce damping by writing

$$k = \mathrm{Re}[k] + \mathrm{i}\epsilon, \tag{4.7}$$

where $\epsilon > 0$. This ensures the convergence of the summations over the spatial index in subsequent equations. Once the solutions are obtained, we can take the limit $\epsilon \to 0$ to retrieve the time-harmonic field. Next, define the function $f_{m,n}(t)$ by writing

$$f_{m,n}(t) = \mathrm{i} \sum_p C^{p,0}_{m,n} \mathrm{e}^{-\mathrm{i}pt}, \tag{4.8}$$

so that we have

$$C^{p,0}_{m,n} = \frac{1}{2\pi \mathrm{i}} \int_0^{2\pi} f_{m,n}(t) \mathrm{e}^{\mathrm{i}pt} \, \mathrm{d}t. \tag{4.9}$$

One motivation for this choice of representation is that the spatial dependence of the integral is such that if we substitute (4.9) into (4.5), the sum over j will become a Schlömilch series as in (3.13). Indeed, combining (4.5), (4.6), and (4.9), we find that

$$\int_0^{2\pi} \left[f_{m,n}(t) + Z_m \sum_v f_{v,n}(t) \sigma_{v-m}(t) \right] \mathrm{e}^{\mathrm{i}pt} \, \mathrm{d}t = 0, \quad p \neq 0. \tag{4.10}$$

A second motivation for (4.8) is that the integration in (4.9) facilitates a simple means by which the left-hand side of (4.10) can be made to vanish for all $p \neq 0$. If we now write

$$f_{m,n}(t) + Z_m \sum_v f_{v,n}(t) \sigma_{v-m}(t) = \mathcal{F}_{m,n}(t), \tag{4.11}$$

then (4.10) becomes

$$\int_0^{2\pi} \mathcal{F}_{m,n}(t) \mathrm{e}^{\mathrm{i}pt} \, \mathrm{d}t = 0, \quad p \neq 0. \tag{4.12}$$

By considering the Fourier series expansions of $\mathcal{F}_{m,n}(t)$, it becomes clear that (4.11) can be satisfied if and only if these functions are constants, which we denote by $\mathcal{F}_{m,n}$. The values for these are fixed by setting $p = 0$ in (4.9) and imposing the requirement (4.2); hence

$$\frac{1}{2\pi \mathrm{i}} \int_0^{2\pi} f_{m,n}(t) \, \mathrm{d}t = \delta_{mn}. \tag{4.13}$$

Note that the system of equations (4.11) contains only an order sum, and also that the source order n does not affect the operator on the left-hand side, which is of exactly the same form as those appearing in (3.12) and (3.19), with the variable t taking the place of the parameters $k \cos \Theta$ and $\widetilde{\beta}$.

In order to determine the coefficients $\mathcal{F}_{m,n}$, we introduce the function $g_{m,n}(t)$ as the solution to the linear system (4.11), but with the right-hand side replaced by δ_{mn}, i.e.,

$$g_{m,n}(t) + Z_m \sum_v g_{v,n}(t) \sigma_{v-m}(t) = \delta_{mn}. \tag{4.14}$$

Since the right-hand side is known, this system of equations can be inverted numerically for any value of t at which both $\sigma_n(t)$ and $g_{v,n}(t)$ are analytic. If (4.14) is multiplied by $\mathcal{F}_{n,u}$ and then summed over all integers n, we see that $g_{m,n}(t)$ is related to $f_{m,n}(t)$ via

$$\sum_v g_{m,v}(t)\mathcal{F}_{v,n} = f_{m,n}(t). \tag{4.15}$$

Integrating (4.15) yields

$$\frac{1}{2\pi \mathrm{i}} \sum_v \mathcal{F}_{v,n} \int_0^{2\pi} g_{m,v}(t)\,\mathrm{d}t = \delta_{mn}, \tag{4.16}$$

in view of (4.13). In principle, therefore, the solutions to the canonical problems are now available—take the limit $\epsilon \to 0$ in (4.7) and then apply quadrature to compute the integrals in (4.16). This latter step is discussed in the appendix. This done, the resulting linear system can be inverted to yield $\mathcal{F}_{m,n}$. However, taking the limit $\epsilon \to 0$ in (4.7) will cause singularities to appear on the real line, and so we must determine the correct indentations for the path of integration.

First, for any $k > 0$, there exists $\lambda \in \mathbb{Z}$ such that $\mathrm{Re}[k_\lambda] \in [0, 2\pi]$, where

$$k_\lambda = k + 2\lambda\pi. \tag{4.17}$$

Equation (3.14) shows that the function $\sigma_n(t)$ has a branch point at $t = k_\lambda$; another is located at $t = 2\pi - k_\lambda$. Note that $\mathrm{Im}[k_\lambda] = \epsilon$, and $\mathrm{Im}[2\pi - k_\lambda] = -\epsilon$. The functions $f_{m,n}(t)$ and $g_{m,n}(t)$ will inherit these singularities via (4.11) and (4.14), respectively. The special case in which $k_\lambda = 2\pi - k_\lambda = \pi$ can be handled by adjusting the path of integration in (4.9) to run from $-\pi$ to π.

A second important possibility is that, after taking the limit $\epsilon \to 0$ in (4.7), there may exist real values of t at which the matrix of known coefficients appearing on the left-hand side of (4.11) and (4.14) is singular. These correspond to the existence of RB waves, as discussed in section 3; at $t = \widetilde{\beta}$ the left-hand side of (4.11) (and also (4.14)) is identical to that of (3.19). In general, the Fredholm alternative permits solutions at $t = \widetilde{\beta}$ and $t = 2\pi - \widetilde{\beta}$ if the functions $f_{m,n}(t)$ and $g_{m,n}(t)$ possess simple poles at these points. Numerical results in [6] show that $\mathrm{d}\widetilde{\beta}/\mathrm{d}k > 0$, and so when we add damping using (4.7) the pole at $t = \widetilde{\beta}$ moves above the real line, and that at $t = 2\pi - \widetilde{\beta}$ moves below. If we now let $\epsilon \to 0$ in (4.7) so as to retrieve the time-harmonic solution, we find that the correct indentations for the path of integration are those shown in Figure 4.1. This is the only configuration that leads to a purely outgoing scattered field in the limit $\sqrt{x^2 + y^2} \to \infty$. The residues at the poles of $f_{m,n}(t)$ determine the amplitudes of any RB waves that are excited, and these make a contribution to $C^{p;0}_{m,n}$ that does not decay in the limit $|p| \to \infty$. We now calculate these, using the method in [23]. First, multiply (4.11) by $t - \widetilde{\beta}$ and then take the limit $t \to \widetilde{\beta}$. The residue of the function $f_{m,n}(t)$ at the pole must satisfy the resulting homogeneous linear system, which is identical to (3.19), and hence

$$\operatorname*{Res}_{t=\widetilde{\beta}} f_{m,n}(t) = c_n \widetilde{B}_m, \tag{4.18}$$

for some constant c_n. Essentially, the coefficients $\widetilde{B}_m$ describe the shape of the RB wave, and c_n is the amplitude. The same procedure can then be applied with $\widetilde{\beta}$

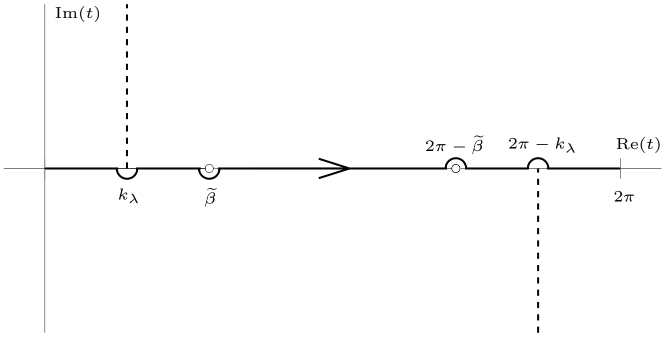

FIG. 4.1. *Singularity structure and indented contour of integration in the t plane. The poles at $t = \widetilde{\beta}$ and $t = 2\pi - \widetilde{\beta}$ do not occur if Dirichlet boundary conditions are imposed on the surface of the regular scatterers, or if $\lambda \neq 0$ (i.e., $k > \pi$).*

replaced by $2\pi - \widetilde{\beta}$, (and $\widetilde{B}_m$ by $(-1)^m \widetilde{B}_m$) and the symmetry relation (4.3) then shows that

$$f_{m,n}(t) = \widehat{f}_{m,n}(t) + c_n \widetilde{B}_m \left[\frac{1}{t - \widetilde{\beta}} - \frac{(-1)^{m+n}}{t + \widetilde{\beta} - 2\pi} \right], \tag{4.19}$$

where $\widehat{f}_{m,n}(t)$ is analytic at $t = \widetilde{\beta}$ and $t = 2\pi - \widetilde{\beta}$. Finally, substitute (4.19) into (4.11), transfer the terms with denominator $t - \widetilde{\beta}$ to the right-hand side, and take the limit $t \to \widetilde{\beta}$ using L'Hôpital's rule as appropriate. We can now apply the Fredholm alternative to the resulting linear system. The left-hand side consists of a singular matrix, multiplied by a vector of bounded functions. Therefore, a solution can exist if and only if the right-hand side is orthogonal to the (nontrivial) solution to the homogeneous adjoint problem [20, eqns. (5.7)–(5.9)]. The latter is easily shown to be $\widetilde{B}_m / Z_m^*$ [23], leading to the following equation for c_n:

$$\sum_m \frac{\widetilde{B}_m^* \mathcal{F}_{m,n}}{Z_m} = c_n \sum_m \widetilde{B}_m^* \sum_v \widetilde{B}_v \sigma'_{v-m}(\widetilde{\beta}). \tag{4.20}$$

Here, the superscript "$*$" denotes the complex conjugate, and the prime a derivative with respect to the argument. The residues of the function $g_{m,n}(t)$ can be calculated in exactly the same way; simply replace f with g in (4.18) and (4.19) and $\mathcal{F}_{m,n}$ with δ_{mn} in (4.20).

The asymptotic behavior of $C_{m,n}^{p,0}$ in the limit $|p| \to \infty$ can be obtained by noting that $f_{m,n}(t)$ is 2π-periodic, this property being inherited from the Schlömilch series via (4.11). Consequently, if the path of integration in (4.9) is closed in the upper half plane, the contributions from $t = \mathrm{i}u$ and $t = 2\pi + \mathrm{i}u$, $u > 0$, cancel each other. Therefore, as $p \to \infty$, we have

$$C_{m,n}^{p,0} \sim c_n \widetilde{B}_m \mathrm{e}^{\mathrm{i}p\widetilde{\beta}} + C_{m,n} \frac{\mathrm{e}^{\mathrm{i}kp}}{p^{3/2}} + O(p^{-5/2}). \tag{4.21}$$

Here, the second term on the right-hand side is the dominant contribution from the branch point at $t = k_\lambda$. The dependence upon p can be deduced by using the method in [12] to show that $f_{m,n}(t)$ remains finite as $t \to k_\lambda$. Given that $t = k_\lambda$ is a branch point of square root type, the result follows. In principle, one can also obtain a formula for the coefficient $C_{m,n}$ using a similar technique, but this is somewhat involved. The behavior of $C^{p,0}_{m,n}$ in the limit $p \to -\infty$ can be deduced by closing the contour of integration in (4.9) in the lower half plane; alternatively, the symmetry relation (4.3) can be used.

A final point concerns the field incoming toward the source, which must be calculated if we are dealing with defects that do not consist of absent scatterers. From (4.4) it is seen that this amounts to finding the value of $K^{0,0}_{m,n}$, which can be achieved by setting $p = 0$ in (4.5). Both the spatial sum and the order sum can be evaluated exactly. Thus, on using (4.9), we have

$$K^{0,0}_{m,n} = \frac{1}{2\pi \mathrm{i}} \int_0^{2\pi} \sum_v f_{v,n}(t)\sigma_{v-m}(t)\ \mathrm{d}t. \tag{4.22}$$

Equation (4.11) reduces this to an integral whose value is known in view of (4.13), the result being

$$Z_m K^{0,0}_{m,n} = -\delta_{mn} - \mathrm{i}\mathcal{F}_{m,n}. \tag{4.23}$$

5. Illustrative results. In this section we present some numerical results for a variety of different situations. We also show how the interaction theory for defects can be combined with the infinite array subtraction technique developed in [11], and the large array approximation used in [24] to validate results, and extend the range of applicability. Particular attention is paid to the determination of the amplitude with which RB waves are excited by the defects. Accurate computation by more direct numerical methods is difficult (see the appendix, and also [11]), but our approach is numerically efficient, and we are able to compute the amplitudes for all possible k and Θ. In view of the number of cases that can be solved, we have not carried out a comprehensive parameter survey, but instead we have attempted to provide a representative sample of the types of result that can be obtained. In performing any such calculations, the rapidly convergent order summations that occur throughout our analysis must be truncated at some suitable value, which depends on the size of ka. This must be chosen to be large enough to yield accurate results, but not so large as to unnecessarily increase program execution time or generate near singular linear systems. The truncation levels used by our numerical codes are the same as those reported in [24]. Unless otherwise stated, Neumann boundary conditions are applied on the surface of the regular scatterers.

5.1. Localized defects. In cases where the defects are confined to a small section of the array, all of the relevant integrals can easily be evaluated by quadrature. The asymptotic behavior of $A^p_m(\mathcal{D})$ for large p can be obtained using (2.16), (2.17), (3.11), and (4.21). A formula for large, negative p can be obtained in a similar way by applying the symmetry relation (4.3) in (2.17). We find that, as $p \to \pm\infty$,

$$A^p_m(\mathcal{D}) \sim A^0_m(\emptyset)\mathrm{e}^{\mathrm{i}kp\cos\Theta} + (\pm 1)^m \Gamma^{\pm} \widetilde{B}_m \mathrm{e}^{\mathrm{i}|p|\widetilde{\beta}} + O(|p|^{-3/2}), \tag{5.1}$$

where

$$\Gamma^{\pm} = \sum_n (\pm 1)^n c_n \sum_{q\in\mathcal{D}} a^q_n \mathrm{e}^{\mp\mathrm{i}q\widetilde{\beta}}. \tag{5.2}$$

The quantity Γ^{+} (Γ^{-}) is the complex amplitude coefficient of the right- (left-) propagating RB wave that is excited by the defect. This depends upon the solutions to

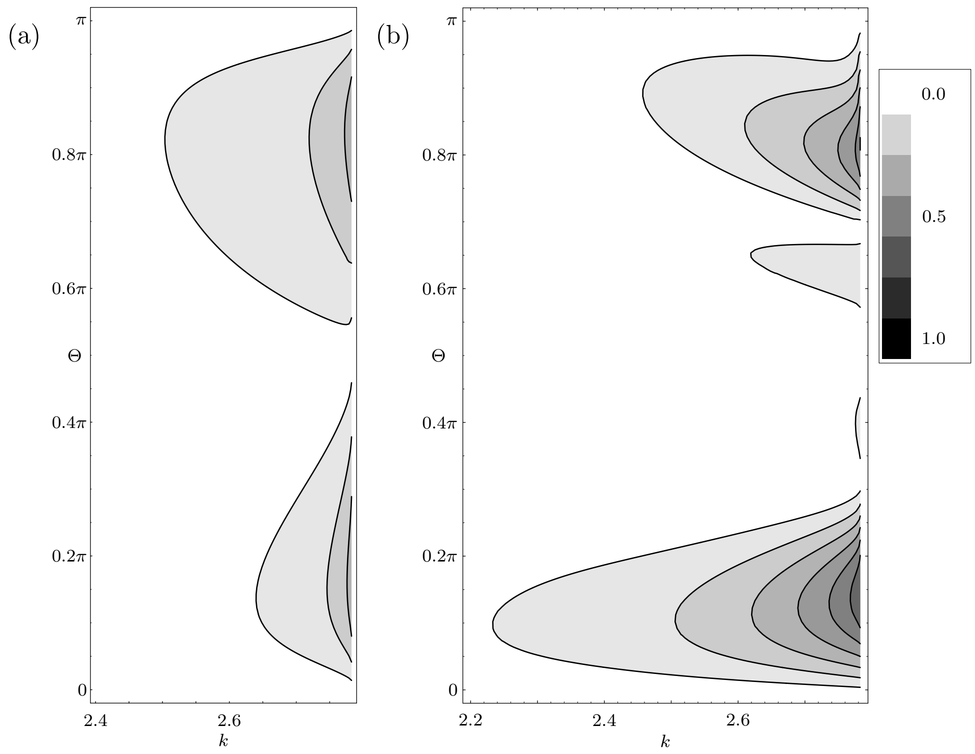

FIG. 5.1. *Contour plots showing the amplitude of the right-propagating RB wave,* $|\Gamma^+|$, *for* $a = 0.25$ *with varying* k *and* Θ. (a) $\mathcal{D} = \{0\}$. (b) $\mathcal{D} = \{0, 1, 2, 3, 4, 5\}$.

the canonical problems and the interactions between the defects via the coefficients c_n, and the sum over $\mathcal{D}$, respectively.

Figure 5.1 shows contour plots of $|\Gamma^+|$ with varying k and Θ, for $a = 0.25$ and two different defect sets: $\mathcal{D} = \{0\}$ and $\mathcal{D} = \{0, 1, 2, 3, 4, 5\}$. Figure 5.2 shows similar plots, but for the antisymmetric RB wave on an array with $a = 0.49$. In all cases, $|\Gamma^-|$ can be deduced by symmetry. The computation time required to obtain data for figures such as these is greatly reduced by the fact that the canonical problems need only be solved once for each value of k. The general trend for the amplitude to increase with k is consistent with the cases of excitation at an array end [11], and by an aperiodic source [23]. The upper limit for k is the cut-off ($k \approx 2.783$ for $a = 0.25$ and $k \approx 2.971$ for the antisymmetric mode on an array with $a = 0.49$), above which the RB waves cease to exist. For all values of k smaller than those shown, the symmetric mode exists but is excited at a very low amplitude. The antisymmetric mode does not exist for $k \lessapprox 1.796$; for intermediate values up to those that are shown in Figure 5.2 the excitation amplitude is small. The dependence of Γ^+ upon the angle of incidence Θ exhibits a number of interesting features. First, the surface wave is cut off completely as $\Theta \to 0$ and $\Theta \to \pi$. In fact, the total field vanishes in these limits, as demonstrated in [12]; the presence of a finite set of defects has no bearing on this. The cut-off at $\Theta = 0$ is sharper in Figures 5.1(b) and 5.2(b) than it is in Figures 5.1(a) and 5.2(a); this is consistent with the case of excitation at the end of a semi-infinite array, where the cut-off disappears, and the amplitude is generally greatest at head-on incidence [11]. The two-peak structure, and the fact that the relative size

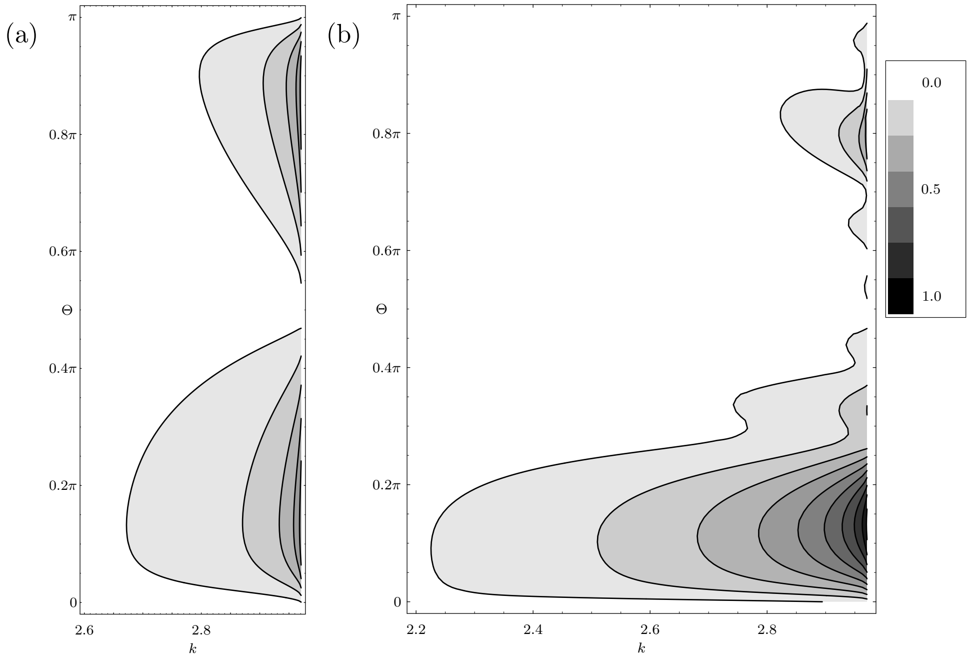

FIG. 5.2. *Contour plots showing the amplitude of the right propagating antisymmetric RB wave,* $|\Gamma^+|$, *for* $a = 0.49$ *with varying* k *and* Θ. (a) $\mathcal{D} = \{0\}$, (b) $\mathcal{D} = \{0, 1, 2, 3, 4, 5\}$.

of the peak at $\Theta \approx 0.8\pi$ is reduced for the larger defect sets, is also consistent with the case of excitation at an end. Finally, note that for the case where $\mathcal{D} = \{0\}$, the amplitude of the symmetric right-propagating RB wave is largest when $\Theta \approx 0.8\pi$, which corresponds to an incident field whose x-component is propagating to the left.

The infinite array subtraction methods introduced in [11] provide a useful means of validating results such as those shown in Figures 5.1 and 5.2. If we write

$$D_m^p(\mathcal{D}) = A_m^p(\mathcal{D}) - A_m^p(\emptyset), \tag{5.3}$$

then, on recalling that $A_m^p(\mathcal{D}) = 0$ for $p \in \mathcal{D}$, it is not difficult to use the results in section 3 to show that the coefficients $D_m^p(\mathcal{D})$ satisfy the linear system of equations

$$\begin{aligned} D_m^p(\mathcal{D}) + Z_m \sum_v \sum_{\substack{j \notin \mathcal{D} \\ j \neq p}} D_v^j(\mathcal{D}) X_{v-m}^{p-j}\, H_{v-m}^{(1)}(k|p-j|) \\ = Z_m \sum_v A_v^0(\emptyset) \sum_{j \in \mathcal{D}} \mathrm{e}^{\mathrm{i}jk\cos\Theta} X_{v-m}^{p-j}\, H_{v-m}^{(1)}(k|p-j|), \quad p \notin \mathcal{D}. \end{aligned} \tag{5.4}$$

Note that the right-hand side has been simplified using (3.4) (with $\mathcal{D} = \emptyset$) and (3.10). If no RB waves are present, then we should expect that $D_p \to 0$ as $|p| \to \infty$. On the other hand, if RB waves are present in the solution, their contribution can be isolated by writing

$$D_m^p(\mathcal{D}) = \begin{cases} \widehat{D}_m^p(\mathcal{D}) + \Gamma^- \mathrm{e}^{-\mathrm{i}p\widetilde{\beta}}(-1)^m \widetilde{B}_m & : p \le p_0, \\ \widehat{D}_m^p(\mathcal{D}) & : p_0 < p < p_1, \\ \widehat{D}_m^p(\mathcal{D}) + \Gamma^+ \mathrm{e}^{\mathrm{i}p\widetilde{\beta}} \widetilde{B}_m & : p \ge p_1, \end{cases} \tag{5.5}$$

where p_0 and p_1 are chosen so that the array is regular for $p \leq p_0$ and $p \geq p_1$. Substituting this into (5.4), we find that the coefficients $\widehat{D}^p_m(\mathcal{D})$ satisfy a linear system which has the same left-hand side as (5.4) and correction terms L^p_m and R^p_m (due to the left- and right-propagating RB waves, respectively) added to the right-hand side. A straightforward calculation shows that

$$L^p_m = \begin{cases} -\Gamma^- Z_m \mathrm{e}^{-\mathrm{i}p\widetilde{\beta}} \sum_v (-1)^v \widetilde{B}_v S^{p-p_0}_{v-m}(\widetilde{\beta}) & : p > p_0, \\ \Gamma^- (-1)^m Z_m \mathrm{e}^{-\mathrm{i}p\widetilde{\beta}} \sum_v \widetilde{B}_v S^{1+p_0-p}_{v-m}(-\widetilde{\beta}) & : p \leq p_0 \end{cases} \tag{5.6}$$

and

$$R^p_m = \begin{cases} -\Gamma^+ Z_m \mathrm{e}^{\mathrm{i}p\widetilde{\beta}} \sum_v \widetilde{B}_v S^{p_1-p}_{m-v}(\widetilde{\beta}) & : p < p_1, \\ \Gamma^+ Z_m \mathrm{e}^{\mathrm{i}p\widetilde{\beta}} \sum_v \widetilde{B}_v S^{1+p-p_1}_{v-m}(-\widetilde{\beta}) & : p \geq p_1, \end{cases} \tag{5.7}$$

where

$$S^p_m(\beta) = \sum_{j \geq p} \mathrm{e}^{\mathrm{i}j\beta} H^{(1)}_m(kj); \tag{5.8}$$

this half range Schlömilch series can be efficiently computed using methods in [8]. The fact that the RB wave is a homogeneous solution to the periodic array problem has been used to simplify L^p_m for $p \leq p_0$ and R^p_m for $p \geq p_1$. If we now solve the linear system for $\widehat{D}^p_m(\mathcal{D})$, the solution will decay as $|p| \to \infty$, but *only* if the correct values for the RB amplitudes Γ^- and Γ^+ are used.

As an example, consider the parameter set $a = 0.25$, $k = 2.5$, $\Theta = 0.1\pi$, and $\mathcal{D} = \{0\}$, which is included in Figure 5.1. Figure 5.3 shows a logarithmic plot of D_p for this case, where

$$D_p = \sum_m \left| D^p_m(\mathcal{D}) \right|^2 . \tag{5.9}$$

This provides a simple measure of the difference between the scattered fields in the periodic and defective array problems. The data are obtained by truncating the system (5.4) at $|p| = 100$. Clearly, D_p does not decay as $|p| \to \infty$; instead it oscillates about a fixed value corresponding to the amplitude of the RB wave. As in Figure 5.1, this is stronger to the left of the defect. The quantity $\widehat{D}_p$ is also plotted in Figure 5.3. This is obtained by replacing $D^p_m(\mathcal{D})$ with $\widehat{D}^p_m(\mathcal{D})$ in (5.9). Values for Γ^- ($\approx 0.07613 + 0.02638\mathrm{i}$) and Γ^+ ($\approx -0.04897 + 0.00176\mathrm{i}$) are obtained using (2.15) and (5.2), with the canonical problems solved using the MASM. These values are then used in (5.6) and (5.7). The fact that $\widehat{D}_p$ decays as $|p|$ is increased confirms that these amplitudes are indeed correct.

5.2. Irregular scatterers. In cases where the defects do not consist of absent scatterers, we must close the system of equations for a^p_m (2.18) by applying boundary conditions on the surface of the irregular array elements. We will assume that the irregular scatterers differ from the other array elements in either size, surface composition, or possibly both. In such cases, we can impose the boundary condition for the

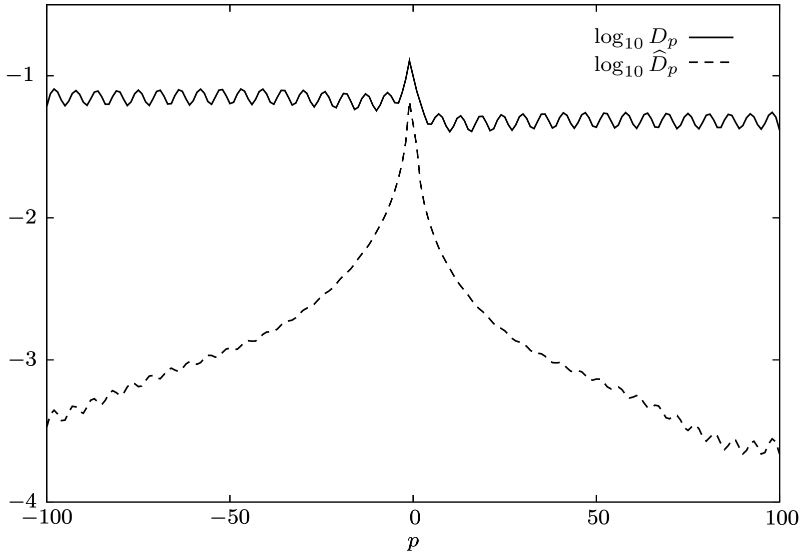

FIG. 5.3. *Logarithmic plot of* D_p *and* $\widehat{D}_p$ *for* $a = 0.25$, $k = 2.5$, $\Theta = 0.1\pi$, *and* $\mathcal{D} = \{0\}$.

irregular scatterers using an equation similar to (3.4), but with a different scattering coefficient $\widehat{Z}_m$; thus

$$A_m^p(\mathcal{D}) + \widehat{Z}_m I_m^p(\mathcal{D}) = 0, \quad p \in \mathcal{D}. \tag{5.10}$$

As before, it is not difficult to incorporate transfer matrices so as to deal with scatterers of a different shape. Equation (5.10) is to be used in conjunction with

$$A_m^p(\mathcal{D}) = A_m^p(\emptyset) + \sum_n \sum_{q\in\mathcal{D}} a_n^q C_{m,n}^{p-q,0}, \tag{5.11}$$

which is obtained from (2.12) and (2.16)–(2.18), and is valid for *all* p. The simplest way to proceed is to deduce an expression for $I_m^p(\mathcal{D})$ from (3.10) by replacing $\emptyset$ with $\mathcal{D}$. If we then use (5.11) to decompose $A_m^p(\mathcal{D})$, the spatial sums in the resulting expression can be evaluated using (3.10) and (4.5), leading to

$$I_m^p(\mathcal{D}) = I_m^p(\emptyset) + \sum_n \sum_{q\in\mathcal{D}} a_n^q K_{m,n}^{p-q,0}. \tag{5.12}$$

The incoming field coefficients $K_{m,n}^{p,0}$ on the right-hand side can then be eliminated using (3.4) (with $\mathcal{D} = \emptyset$), (4.6), and (4.23). This amounts to exploiting the fact that (5.11) decomposes $A_m^p(\mathcal{D})$ into contributions from fields that satisfy the boundary condition for a regular scatterer at $r_p = a$ and contributions for which the local expansion of the incoming field is known from (4.23). We find that

$$-Z_m I_m^p(\mathcal{D}) = A_m^p(\emptyset) + \sum_n \sum_{q\in\mathcal{D}} a_n^q C_{m,n}^{p-q,0} + \mathrm{i} \sum_n a_n^p \mathcal{F}_{m,n}. \tag{5.13}$$

Finally, we can form a closed system for a_m^p by combining (5.13) with (5.10) and (5.11). The resulting expression is

$$-\mathrm{i}\widehat{Z}_m \sum_n a_n^p \mathcal{F}_{m,n} + (Z_m - \widehat{Z}_m) \sum_n \sum_{q\in\mathcal{D}} a_n^q C_{m,n}^{p-q,0} = (\widehat{Z}_m - Z_m) A_m^p(\emptyset), \quad p \in \mathcal{D}. \tag{5.14}$$

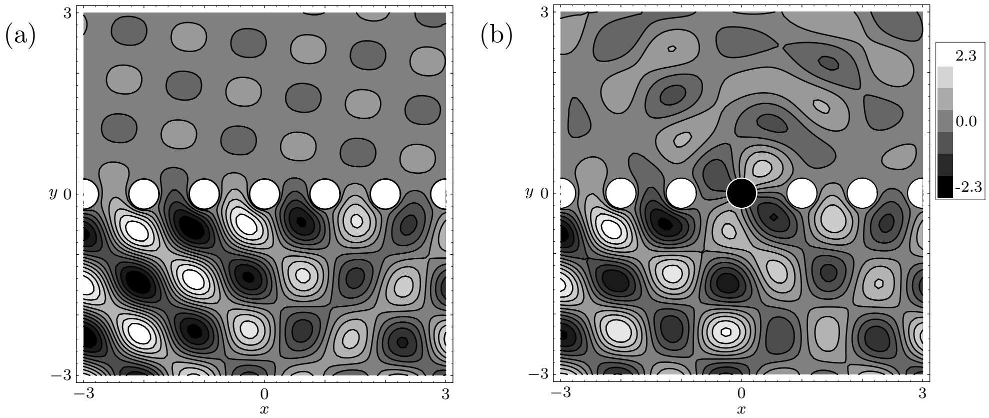

FIG. 5.4. *Contour plots showing* $\mathrm{Re}[\phi^{\mathrm{t}}]$ *for* $a = 0.25$*,* $k = 5.0$*, and* $\Theta = 0.25\pi$*, with Dirichlet boundary conditions applied on the surface of the regular scatterers.* (a) $\mathcal{D} = \emptyset$*.* (b) $\mathcal{D} = \{0\}$*. The defect is a Neumann scatterer, also with* $a = 0.25$*.*

As before, this determines the values of a_m^p; (5.11) can then be used to find values of $A_m^p(\mathcal{D})$ for $p \notin \mathcal{D}$. Note that taking $\widehat{Z}_m = 0$ returns the equation for absent scatterers, and $\widehat{Z}_m = Z_m$ yields $a_m^p = 0$, as we should expect, since then there are no defects.

Figure 5.4 shows contour plots depicting the local effects caused by replacing a single element in a periodic array with an irregular scatterer. The parameters used are $a = 0.25$, $k = 5.0$, and $\Theta = 0.25\pi$, and a Dirichlet boundary condition is applied on the surface of the regular scatterers (shown as white with a black boundary). In Figure 5.4(a), there is no defect, and the quasi-periodic nature of the field is evident. In Figure 5.4(b), the field is modified using the solutions to the canonical source problems, so that the Neumann boundary condition is now satisfied on the surface of scatterer 0 (shown as black with a white boundary). Contour lines intersecting this scatterer do so at a right angle to the surface tangent. The influence of the defect is more significant in the region above the array, because the field in the periodic case is relatively weak here.

For suitable parameters, irregular scatterers also cause RB waves to be excited. Figure 5.5 shows contour plots of $|\Gamma^+|$ for $a = 0.25$ with varying k and Θ, with $\mathcal{D} = \{0\}$ and $\mathcal{D} = \{0, 1, 2, 3, 4, 5\}$. The defects consist of Dirichlet scatterers with radius $a = 0.25$. As before, $|\Gamma^-|$ can be deduced by symmetry. The pattern of behavior here is quite different from the case of absent scatterers shown in Figure 5.1. The main qualitative difference lies in the dependence of $|\Gamma^+|$ upon Θ; there is no longer a second peak at $\Theta \approx 0.8\pi$. Elsewhere, the excitation is generally stronger than it is in the corresponding cases in Figure 5.1.

5.3. Widely spaced defects. If the defects are spread over a large section of the array, the evaluation of (4.9) by quadrature is no longer straightforward. This is because we must calculate values for $C_{m,n}^{p-q,0}$ for all $p, q \in \mathcal{D}$, and if $|p - q|$ is large, the integrals are difficult to compute. There are a number of ways to proceed. One possibility is to adopt a mixed strategy, obtaining $\Gamma^{\pm}$ using the MASM, and then solving for the decaying contributions to $C_{m,n}^{p-q,0}$ using the infinite array subtraction technique discussed in section 5.1. This yields approximate values for *all* of the unknown coefficients, and is therefore a particularly attractive idea if results for a large number of different defect sets are to be computed. Alternatively, we can form

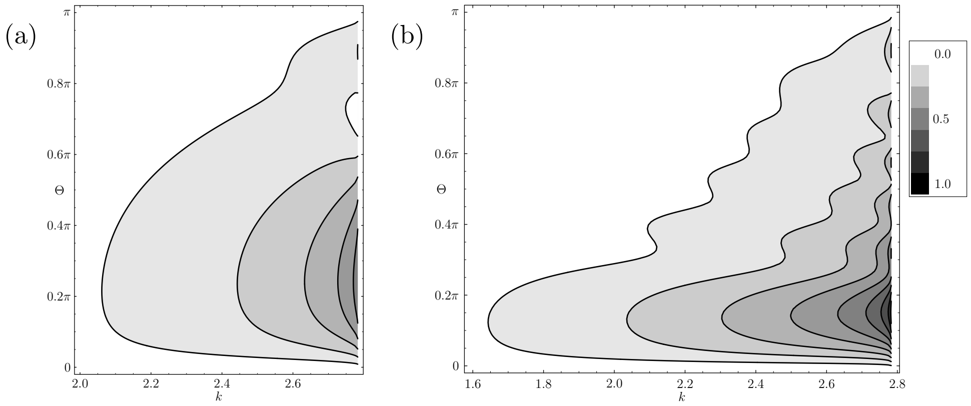

FIG. 5.5. *Contour plots showing the amplitude of the right-propagating RB wave,* $|\Gamma^+|$*, for* $a = 0.25$ *with varying* k *and* Θ*; Dirichlet boundary conditions are applied on the surface of scatterers for which* $p \in \mathcal{D}$*.* (a) $\mathcal{D} = \{0\}$. (b) $\mathcal{D} = \{0, 1, 2, 3, 4, 5\}$.

an approximate interaction theory by neglecting the decaying terms in (4.21) when $p^{3/2} \gg 1$. This approximation was used in generating the data for Figure 5.6; it amounts to assuming that significant interactions between widely spaced defects are caused solely by the RB modes and has been shown to work well in practice in the related case of a long, finite array [24].

The presence of such widely spaced defects in an array can lead to "near-trapping" in the intermediate region. This effect was originally reported in [13] in a study of interactions between water waves and long, finite arrays of bottom-mounted circular cylinders. In this physical context, the force in the x direction exerted on cylinder p by the total field (i.e., the integral of the pressure times the component of the outgoing normal to $r_p = a$ that is parallel to the array), normalized using the force exerted on an isolated cylinder, is given in [9] as

$$X_p = \left| \frac{1}{2Z_1} \left[A_1^p(\mathcal{D}) - A_{-1}^p(\mathcal{D}) \right] \right|. \tag{5.15}$$

Figure 5.6 shows a contour plot of the horizontal force on an array element that is equidistant between two widely spaced defects, each of which consists of a single absent element. The scatterer radius a is 0.25, as in [13] and in the majority of cases in [24]. The wavenumber is varied between 2.7 and the cut-off for RB waves ($k \approx 2.783$), using 1000 data points, and the angle of incidence is varied between 0 and $\pi/2$ using 500 data points. Results for $\Theta > \pi/2$ can be deduced by symmetry. The plot reveals that very large forces occur at certain discrete intervals in k and Θ. The strongest force occurs at a wavenumber that is close to, but not exactly equal to, the cut-off for RB waves. No significant peaks in the force occur for values of k smaller than those shown. The causes of the near-trapping effect are explored in [24] for the case of a finite array; the mechanism here is much the same. Essentially, RB waves generated by one periodicity breaking feature (end or defect) are reflected back by the other. The magnitude of the reflection coefficient increases as $k \to k_{\max}$. Peaks in the force correspond to situations where the interference is predominantly constructive between RB modes excited by the interaction of the incident wave with the defects and those generated by reflection.

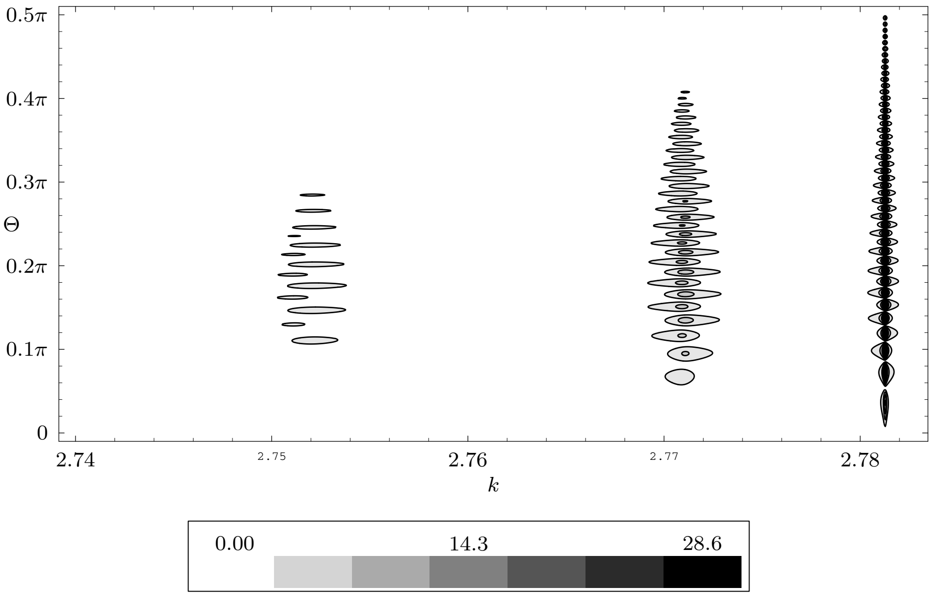

FIG. 5.6. *Contour plot showing the force exerted on scatterer* 51*, with* $a = 0.25$ *and* $\mathcal{D} = \{0, 102\}$*.*

6. Concluding remarks. By reducing the problem of scattering by a defective array to a set of simpler, canonical problems, we have developed an interaction theory for defects in infinite periodic arrays. This is similar in nature to the standard interaction theory for a finite number of bodies. The simplest case is that of an array with one or more absent scatterers. A straightforward extension to the theory that allows irregular scatterers to be considered has also been presented. The MASM is an effective means by which the canonical problems can be solved, and in particular enables important field characteristics such as RB surface wave amplitudes to be efficiently calculated to near machine accuracy. The canonical problems are independent of the defect type and configuration and all aspects of the incident field except the wavenumber, and need not be solved again if these parameters are changed.

Numerical results for various cases have been presented, with particular attention paid to the amplitude with which RB surface waves are excited. The MASM is particularly well-suited to cases in which the defects are localized. For defects that are spread over a larger section of the array, we have shown how other methods such as infinite array subtraction and the large array approximation can be incorporated so as to overcome the difficulties that arise. All of the results that we have presented involve arrays whose elements are circular cylinders. It is not difficult to modify our theory so as to account for other shapes by using transfer matrices. More complicated cases such as fully three-dimensional scattering problems can also be considered, provided that the relevant analogue to the theory of periodic arrays summarized in section 3 is available.

Appendix. Numerical quadrature. The most computationally expensive procedure in applying the interaction theory for defects in arrays is the evaluation of the integrals in (4.16) and (4.9). Quadratures must be performed on a contour whose orientation with respect to the branch points is the same as that shown in Figure 4.1, but in general it is convenient to move the path of integration away from

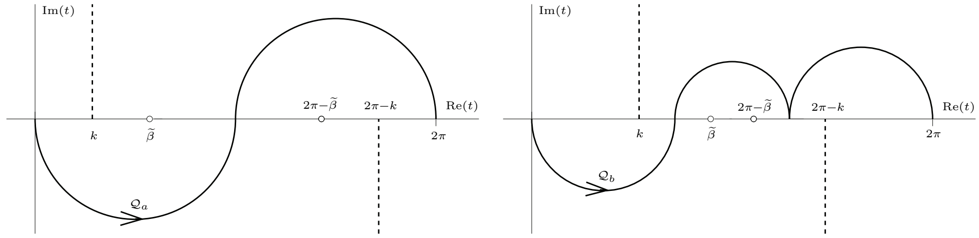

FIG. A.1. *Schematic diagrams of the contours $\mathcal{Q}_a$ and $\mathcal{Q}_b$ used for numerical quadrature.*

the various singularities. Since the residues of the functions $f_{m,m}(t)$ and $g_{m,n}(t)$ can be obtained using (4.20), the orientation with respect to the poles need not be maintained. In choosing an appropriate contour, a number of factors must be taken into consideration. These include the possibility of complex poles, contour length, proximity to the known real line singularities, and the behavior of the exponential term $\mathrm{e}^{\mathrm{i}pt}$ that appears in (4.9). Obviously, the extent to which a computer program can automatically adjust the contour to account for these factors has a significant effect on its overall complexity.

The paths of integration used by our numerical codes when RB modes are present are shown in Figure A.1. These are chosen for their relative simplicity, and we do not claim that they are optimal. For most parameter values, the distance between the two poles is at least as great as the distance between a pole and the nearest branch point, i.e., $2(\pi-\widetilde{\beta}) \geq \widetilde{\beta}-k$, and so we use the contour $\mathcal{Q}_a$, which consists of two semicircular arcs of radius $\pi/2$, centered at $t = \pi/2$ and $t = 3\pi/2$. As $k \to \pi$, $\widetilde{\beta} \to \pi$, and so the two poles move close together. If $2(\pi-\widetilde{\beta}) < \widetilde{\beta}-k$, then we integrate along $\mathcal{Q}_b$, which consists of two semicircular arcs of radius $(\widetilde{\beta}+k)/4$ centered at $t = (\widetilde{\beta}+k)/4$ and $t = 2\pi - (\widetilde{\beta}+k)/4$, and a third arc centered at $t = \pi$ with radius $2\pi - (\widetilde{\beta}+k)$. A residue contribution from the pole at $t = \widetilde{\beta}$ must be included in this case.

To deal with the possibility of complex poles, we introduce the function $d(t)$ as the determinant of the matrix on the left-hand side of (4.11) (also (4.14)), so that poles of $f_m^n(t)$ and $g_m^n(t)$ can occur only at points where $d(t) = 0$. We then numerically apply the principle of the argument [17, page 99] to $\log[d(t)]$ in the finite region(s) of the cut plane enclosed by the original path of integration (Figure 4.1) and the new contour (Figure A.1). Aside from $t = \widetilde{\beta}$ and $t = 2\pi - \widetilde{\beta}$, no poles that interfere with the deformations used here have been found. Additional poles were found on the line $t = \pi + \mathrm{i}u$, $u \in \mathbb{R}$, but only for large values of $|u|$. It should be noted that we have not searched exhaustively across the parameter ranges for a and k. A uniform partition of the contours $\mathcal{Q}_a$ and $\mathcal{Q}_b$ is used by our numerical codes, and the three-point Gaussian formula is applied on each subinterval. In cases involving multiple defects, efficiency can be greatly improved by storing values of $f_{m,n}(t)$ at the partition points used for the largest value of $|p|$ at which the integral in (4.9) must be evaluated and by making repeated use of these.

It is of some interest to compare the accuracy achieved by the MASM with that of the filtering technique [11], which can also be used to solve the canonical problems. The filtering technique requires the truncation and inversion of linear systems involving slowly convergent infinite spatial sums. We should therefore expect the MASM to achieve a superior degree of both accuracy and performance. An ideal parameter

149	0.1361053214	0.0000000039	6.40	90	0.1360096190	0.0542126301	8.55
199	0.1361053214	0.0000000003	8.57	110	0.1361554350	0.1072100718	14.33
249	0.1361053214	0.0000000000	10.72	130	0.1361523637	0.0022557485	21.68
299	0.1361053214	0.0000000000	12.90	150	0.1360562815	0.0705696206	31.55

for comparison is the quantity $|c_n|$, i.e., the amplitude of the RB wave that is excited by a source of order n replacing the scatterer centered at the origin. Table A.1 shows typical performance and accuracy figures that can be achieved by the two methods. The parameters used are $a = 0.25$ and $k = 1$, which lead to $\widetilde{\beta} \approx 2.586$, and the computations are performed using Fortran 2003 on a machine with a 2.5GHz processor. Note that the times given are those required for the simultaneous computation of c_n for all n up to the order truncation. The abbreviation NSI stands for the number of subintervals into which the contour is divided. The value for the spatial index p at which the linear system used in the filtering method is truncated is denoted by SPT. The dependence of computation time upon NSI is clearly linear, whereas increasing SPT leads to a significant decrease in performance. The results obtained by the two methods are in agreement up to the degree of accuracy that can be expected of the filtering method [11]; this requires the inversion of a large linear system of equations and is susceptible to round-off errors. It is clear that the MASM yields far greater accuracy, and is also much more efficient.
