FIBER DYNAMICS IN TURBULENT FLOWS: SPECIFIC TAYLOR DRAG*

NICOLE MARHEINEKE[†] AND RAIMUND WEGENER[‡]

Abstract. In [N. Marheineke and R. Wegener, *SIAM J. Appl. Math.*, 66 (2006), pp. 1703–1726], an aerodynamic force concept for a general air drag model based on a stochastic k-ϵ description for a turbulent flow field is derived. The turbulence effects on the dynamics of a long, slender, elastic fiber are specifically modeled by a correlated random Gaussian force and in its asymptotic limit on a macroscopic fiber scale by Gaussian white noise with flow-dependent amplitude. The present paper states quantitative similarity estimates and numerical comparisons for the choice of a Taylor drag model in a given application.

Key words. flexible fibers, k-ϵ turbulence model, fiber-turbulence interaction scales, air drag, random Gaussian aerodynamic force, white noise, stochastic differential equations, ARMA process

1. Introduction.

The understanding of the motion of long flexible fibers suspended in highly turbulent air flows is of great interest for textile manufacturing in the melt-spinning process of nonwoven materials. Disregarding the fiber's influence on the flow, the authors of [13] stated a stochastic partial differential system that describes the dynamics of a single slender elastic fiber in a turbulent flow. The turbulence effects are modeled by a correlated Gaussian aerodynamic force. Applying a global-from-local force concept for general air drag models, we can derive these effects, particularly, on the basis of homogeneous Gaussian fields for the randomly fluctuating local velocity components of the flow. Their construction satisfies the requirements of the stochastic k-ϵ turbulence model and Kolmogorov's universal equilibrium theory on local isotropy. On macroscopic scales, white noise with flow-dependent amplitude turns out be a good approximation for the original correlated force according to $\mathcal{L}^2$- and $\mathcal{L}^\infty$-similarity estimates. In the following, we show the applicability of this general force concept under conditions of a real melt-spinning process by choosing an empirically motivated Taylor drag; see Figure 1. Then, the simplified force model satisfies the demands of accuracy on the relevant fiber scale while drastically facilitating the numerical computations at the same time.

For convenience we start with a brief summary of the models for fiber dynamics and aerodynamic force. Dimensional analysis of turbulence and fiber behavior reveals the characteristic interaction scales for our application in section 2. On the fiber macroscale the mean flow dominates the swinging of the fiber, whereas the energy-bearing turbulent vortices of the mesoscale cause the entanglement and fine-loop forming on the fiber that are crucial for the quality of the resulting nonwoven materials. The interest in a macroscopic description of the fiber dynamics justifies

the use of the simplified force model, as it contains all crucial correlation information of the mesoscale according to the stated quantitative similarity estimates. From the choice of the Taylor drag model, we derive a linear drag operator and thus the concrete correlated and uncorrelated global forces in section 3. Their effects on the fiber dynamics are numerically compared in section 4 by using an introduced curvature measure which yields very convincing results.

1.1. General aerodynamic force model. In the following, we recall the basic models from [13] that are crucial for the description of the fiber dynamics in a turbulent flow. Consider a single long flexible fiber that is fixed at one end and suspended in a subsonic highly turbulent air flow with small pressure gradients and Mach number Ma $< 1/3$. Let l denote the fiber length and d its diameter with aspect ratio $d/l \ll 1$. Whereas the fiber influence on the turbulence is negligibly small due to the slender geometry, the turbulent flow essentially determines the dynamics of the fiber. The motion is modeled by a system of stochastic partial differential equations with algebraic constraint of inextensibility that is deduced from the dynamical Kirchhoff–Love equations for a Cosserat rod being capable of large, geometrically nonlinear deformations,

$$\rho A\, \partial_{tt}\mathbf{r}(s,t) = \partial_s[T(s,t)\, \partial_s\mathbf{r}(s,t)] - EI\, \partial_{ssss}\mathbf{r}(s,t) + \rho A\, \mathbf{g} + \mathbf{f}^{air}(\mathbf{r}(.),s,t), \tag{1.1}$$

$$\|\partial_s\mathbf{r}(s,t)\|_2 = 1, \tag{1.2}$$

with Dirichlet boundary conditions at the fixed end, Neumann at the free end, and the position of rest as the initial condition. Here, $\mathbf{r} : [0,l] \times \mathbb{R}_0^+ \to \mathbb{R}^3$ might be interpreted as the center line of the fiber with arc-length s and time t; its constant line weight is denoted by ρA. The internal line forces stem from bending stiffness indicated by Young's modulus E and moment of inertia I as well as from traction. In this spirit, the Lagrangian multiplier $T : [0,l] \times \mathbb{R}_0^+ \to \mathbb{R}$ can be viewed as the modified tractive force $T = T_t + EI\|\partial_{ss}\mathbf{r}\|_2^2$ containing tension T_t and curvature $\|\partial_{ss}\mathbf{r}\|_2^2$ due to bending. The external line forces acting on the fiber arise from gravity $\mathbf{g}$ and aerodynamics $\mathbf{f}^{air}$.

The aerodynamic force term acts as the additive Gaussian noise in (1.1) due to the applied general global-from-local force concept that is based on the stochastic k-ϵ description of the underlying turbulent flow. In particular, we consider here a correlated Gaussian aerodynamic force $\mathbf{f}_{cc}^{air}$ and its uncorrelated asymptotic limit on macroscopic scales $\mathbf{f}_{uc}^{air}$,

$$\mathbf{f}_{cc}^{air}(\mathbf{r}(.),s,t) = \mathbf{f}(\bar{\mathbf{v}}(s,t),\partial_s\mathbf{r}(s,t)) + \mathbf{L}^{\mathbf{f}}(s,t)\ \frac{\int_{N(\mathbf{r}(.),s,t)} \mathbf{w}_f^{\sigma,\tau}(s,t)\,d\mathcal{W}_{\sigma,\tau}}{(\int_{N(\mathbf{r}(.),s,t)} d\sigma\,d\tau)^{1/2}}, \tag{1.3}$$

$$\mathbf{f}_{uc}^{air}(\mathbf{r}(.),s,t) = \mathbf{f}(\bar{\mathbf{v}}(s,t),\partial_s\mathbf{r}(s,t)) + \mathbf{L}^{\mathbf{f}}(s,t)\ \mathbf{D}^{s,t}\ \mathbf{p}(s,t), \tag{1.4}$$

which depend on the chosen air drag model $\mathbf{f} : \mathbb{R}^3 \times \mathbb{R}^2 \to \mathbb{R}^3$ and its respective linear drag operator $\mathbf{L}^{\mathbf{f}}$. A feasible air drag model is prescribed as a function of the mean relative velocity between fluid and fiber, i.e., $\bar{\mathbf{v}}(s,t) = \bar{\mathbf{u}}(\mathbf{r}(s,t),t) - \partial_t\mathbf{r}(s,t)$, and the fiber tangent $\partial_s\mathbf{r}(s,t)$. In analogy to the k-ϵ turbulence model, the forces are split into a deterministic part $\bar{\mathbf{f}}$, resulting from the mean flow velocity $\bar{\mathbf{u}} : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^3$, and a stochastic part $\mathbf{f}'$ coming from the turbulent fluctuations that are characterized by the turbulent kinetic energy $k : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^+$ and the dissipation rate $\epsilon : \mathbb{R}^3 \times \mathbb{R}_0^+ \to \mathbb{R}^+$. In (1.3) the random fluctuations are modeled as Ito-integral over a family of locally isotropic, homogeneous, incompressible Gaussian velocity fields along the fiber $\{(\mathbf{w}_f^{\sigma,\tau})_{s,t},\ (s,t) \in [0,l] \times \mathbb{R}_0^+),\ (\sigma,\tau) \in [0,l] \times \mathbb{R}_0^+\}$, where $(\mathcal{W}_{\sigma,\tau},\ (\sigma,\tau) \in [0,l] \times \mathbb{R}_0^+)$ denotes a Wiener process (Brownian motion). The underlying fiber region $N(\mathbf{r}(.),s,t) = \{(\sigma,\tau) \in [0,l] \times \mathbb{R}_0^+ \mid \|\mathbf{r}(s,t) - \mathbf{r}(\sigma,\tau) - \bar{\mathbf{u}}(\mathbf{r}(s,t),t)(t-\tau)\|_2 \leq l_{\mathrm{T}} \wedge |t-\tau| \leq t_{\mathrm{T}}\}$ is determined by the turbulent large-scale length l_{T} and time t_{T}. Moreover, the construction of the correlation tensors $\boldsymbol{\gamma}_0^{\sigma,\tau}(s_1-s_2,\ t_1-t_2) := \mathbb{E}[\mathbf{w}_f^{\sigma,\tau}(s_1,t_1) \otimes \mathbf{w}_f^{\sigma,\tau}(s_2,t_2)]$ corresponding to the centered velocity fields complies with the requirements of the k-ϵ model, Kolmogorov's universal equilibrium theory on local isotropy, as well as Taylor's hypothesis of frozen turbulence pattern, by choosing the following energy spectra $E^{\sigma,\tau} \in \mathcal{C}^2(\mathbb{R}_0^+)$:

$$E^{\sigma,\tau}(\kappa) = \begin{cases} K^{\sigma,\tau}\ \kappa_1^{-5/3}\ \sum_{j=4}^{6} a_j\,(\frac{\kappa}{\kappa_1})^j, & \kappa < \kappa_1, \\ K^{\sigma,\tau}\ \kappa^{-5/3}, & \kappa_1 \leq \kappa \leq \kappa_2, \\ K^{\sigma,\tau}\ \kappa_2^{-5/3}\ \sum_{j=7}^{9} b_j\,(\frac{\kappa}{\kappa_2})^{-j}, & \kappa > \kappa_2, \end{cases} \tag{1.5}$$

$$\int_0^\infty E^{\sigma,\tau}(\kappa)\,d\kappa = k(\mathbf{r}(\sigma,\tau),\tau), \qquad \int_0^\infty E^{\sigma,\tau}(\kappa)\,\kappa^2\,d\kappa = \frac{\epsilon(\mathbf{r}(\sigma,\tau),\tau)}{2\nu} \tag{1.6}$$

with viscosity ν, Kolmogorov constant $K^{\sigma,\tau} = C_{\mathrm{K}}\ \epsilon(\mathbf{r}(\sigma,\tau),\tau)^{2/3}$, and further prescribed constant fitting parameters a_j, b_j. In contrast, in (1.4) the integral effects of the localized random fluctuations are incorporated into the amplitude $\mathbf{D}^{s,t}$ of the Gaussian white noise $(\mathbf{p}_{s,t},\ (s,t) \in [0,l] \times \mathbb{R}_0^+)$, i.e., the $\mathbb{R}^3$-valued random variable $\lim_{(\triangle s,\triangle t)\to\mathbf{0}} \sqrt{\triangle s \triangle t}\,\mathbf{p}(s,t) \sim \mathcal{N}(\mathbf{0},\mathbf{I})$ is centered, reduced, and normally distributed. In particular,

$$\mathbf{D}^{s,t} = \left(\frac{2\pi}{\bar{v}_{\mathrm{n}}(s,t)}\ \int_0^\infty \frac{E^{s,t}(\kappa)}{\kappa^2}\,d\kappa\right)^{1/2} \quad \mathbf{P}_{\mathbf{t},\mathbf{n}(s,t)} \tag{1.7}$$

is proportional to the projector $\mathbf{P}_{\mathbf{t},\mathbf{n}}$ onto the plane spanned by fiber tangent $\mathbf{t} = \partial_s\mathbf{r}$ and normal $\mathbf{n} = (\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t})/\|\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t}\|_2$, where $\bar{v}_{\mathrm{n}} = \bar{\mathbf{v}} \cdot \mathbf{n}$. Note that the existence of the amplitude in (1.7), and thus of the uncorrelated force in (1.4), presupposes the linear independence of fiber tangent and mean relative velocity.

2. Fluid-fiber interaction scales. The handling of fiber-turbulence interaction is very difficult, as it is governed by many complex factors, including nature of the flow field, turbulent length scales, and size and behavior of the fiber. The applicability of the uncorrelated aerodynamic force $\mathbf{f}_{uc}^{air}$ particularly depends on the characteristic

Table 1
Typical fiber and flow parameter values in melt-spinning processes.

Fiber			
Diameter	d	$3.0 \cdot 10^{-5}$	m
Length	l	2.5	m
Line weight	ρA	$9.0 \cdot 10^{-7}$	kg/m
Bending stiffness	EI	$4.7 \cdot 10^{-10}$	Nm^2
Absolute velocity	W	$1.0 \cdot 10^{1}$	m/s
Acceleration of gravity	g	9.81	m/s^2
Suspended height	H	1	m

Flow			
Density	ρ^{air}	1.22	kg/m^3
Absolute mean velocity	$\bar{u}$	$1.0 \cdot 10^{2}$	m/s
Turbulent kinetic energy	k	$1.0 \cdot 10^{2}$	m^2/s^2
Dissipation rate	ϵ	$1.0 \cdot 10^{5}$	m^2/s^3
Viscosity	ν	$1.5 \cdot 10^{-5}$	m^2/s

interaction scales of the considered fiber-flow problem. In a typical melt-spinning process, fiber and flow are specified by the parameter values of Table 1. These yield the following quantitative scales and similarity estimates between the correlated and uncorrelated force by using dimensional analysis.

2.1. Turbulence scales. Turbulence is characterized by its wide range of length and time scales. As their significance plays a decisive role in the coming analysis, we focus on them and their interpretation.

Due to the underlying k-ϵ turbulence model, we already distinguish between the length and time scales of the mean motion and those of the fluctuations. The mean motion and its scales are derived from the boundary conditions (geometry) and the absolute mean flow velocity $\bar{u}$. On the other hand, the fluctuations might be interpreted as the turbulent effects of overlapping vortices of different sizes that are indicated by the turbulent kinetic energy k, dissipation rate ϵ, and viscosity ν. The smallest, viscously determined vortices are given by the Kolmogorov scales

$$\eta = \left(\frac{\nu^3}{\epsilon}\right)^{1/4}, \qquad t_{\mathrm{K}} = \left(\frac{\nu}{\epsilon}\right)^{1/2}.$$

Apart from that, the local correlation tensor $\boldsymbol{\gamma}_0$ [12, 13] provides additional information about the size of the present turbulent structures. The structures in the dissipation area (small lengths, thus high frequencies) are determined by the run of the one-dimensional longitudinal correlation function $c_1(z) = 2/z^3 \int_0^\infty \partial_\kappa(E(\kappa)/\kappa) \sin(\kappa z)\, d\kappa$, $z \in \mathbb{R}_0^+$ around the origin and hence by k and ϵ; see (1.6). For $z \ll 1$, $c_1(z) = 2/3k - \epsilon/(30\,\nu)\, z^2 + \mathcal{O}(z^4)$ then describes a parabola that intersects the z-axis at the dissipation length λ_{T}, i.e., $c_1(\lambda_{\mathrm{T}}) = 0$. Thus,

$$\lambda_{\mathrm{T}} = \left(\frac{20k\nu}{\epsilon}\right)^{1/2}$$

represents the turbulent fine or microscale for the decay of the correlations.

In contrast, the large, macro, or integral scale

$$\Lambda_{\mathrm{T}} = \frac{\int_0^\infty \mathrm{tr}\boldsymbol{\gamma}_0(z)\, dz}{\mathrm{tr}\boldsymbol{\gamma}_0(0)} = \frac{\pi}{2}\, \frac{\int_0^\infty E(\kappa)/\kappa\, d\kappa}{\int_0^\infty E(\kappa)\; d\kappa}$$

characterizes the mean coherence scale independently of longitudinal and lateral correlations and can be interpreted as the typical size of the energy-bearing vortices. In this context, the turbulent length proposed by the k-ϵ model,

$$l_{\mathrm{T}} = \frac{k^{3/2}}{\epsilon},$$

can be understood as the leading order term of Λ_{T}; compare with the modeled energy spectrum of (1.5). The energy spectrum gives

$$\Lambda_{\mathrm{T}} = \frac{\pi\, C_{\mathrm{K}}}{2} \frac{\epsilon^{2/3}}{k} \left(A_1 \kappa_1^{-5/3} + B_1 \kappa_2^{-5/3} \right),$$

where κ_1 and κ_2 with $\kappa_2 > \kappa_1 > 0$ are the solutions of the nonlinear system

$$\begin{aligned} A_k \kappa_1^{-2/3} + B_k \kappa_2^{-2/3} &= \frac{k}{C_{\mathrm{K}} \epsilon^{2/3}} = f_k, \\ A_\epsilon \kappa_1^{4/3} + B_\epsilon \kappa_2^{4/3} &= \frac{\epsilon^{1/3}}{2 C_{\mathrm{K}} \nu} = f_\epsilon = \frac{f_k}{\delta^2}, \end{aligned} \tag{2.1}$$

stemming from (1.6). After nondimensionalizing, $\delta = (2k\nu/\epsilon)^{1/2} \sim \mathcal{O}(\lambda_{\mathrm{T}})$ with $\lambda_{\mathrm{T}}/H \ll 1$ turns out to be small, whereas the other coefficients $A_i, B_i, f_k \sim \mathcal{O}(1)$. Thereby, $A_i, B_i, i = 1, k, \epsilon$, denote linear combinations of the fitting parameters arising in (1.5), and $C_{\mathrm{K}} = 0.5$ is the Kolmogorov constant. Substituting $x_i = \kappa_i^{2/3}$, $i = 1, 2$, we write $x_1 = f_k/A_k - B_k/A_k\, x_2$. Inserting this expression into (2.1) yields a 4th order equation for x_2 that has two complex as well as two real solutions—a negative and a positive. The feasible positive solution can be expanded in δ as $x_2 = x_2^{(1)} \delta + x_2^{(3)} \delta^3 + \mathcal{O}(\delta^4)$, which results directly in a δ-series for Λ_{T},

$$\Lambda_{\mathrm{T}} = F_1\, l_{\mathrm{T}} + \mathcal{O}(\delta) \qquad \text{with } F_1 = \frac{\pi}{2} \frac{A_1}{C_{\mathrm{K}}^{3/2} A_k^{5/2}} \approx 1.05. \tag{2.2}$$

In spite of the use of A_i in (2.2), the magnitude of F_1 can be treated as independent of the differentiability order of the underlying chosen energy model. An ansatz for a smoother energy spectrum, $E \in \mathcal{C}^l(\mathbb{R}_0^+)$, $l \geq 3$, certainly contains more fitting parameters, but their influence cancels out in the definition of F_1. In this work, we refer to l_{T} as the turbulent large-scale length.

Concerning the turbulent time scale for the decay of the energy-bearing vortices, the length l_{T} and velocity scale $u_{\mathrm{T}} = k^{1/2}$ of the k-ϵ model imply

$$t_{\mathrm{T}} = \frac{k}{\epsilon}.$$

As this scale does not take into account the advective influence of the mean flow, we suggest additionally

$$t_{\mathrm{A}} = \frac{l_{\mathrm{T}}}{\bar{u}} = \frac{k^{3/2}}{\epsilon\, \bar{u}}.$$

Moreover, the amplitude $\mathbf{D}$ of the uncorrelated force in (1.7) might also be expressed by k and ϵ, since it contains a moment of the energy spectrum. In our case, we get $\int_0^\infty E(\kappa)/\kappa^2\, d\kappa = C_{\mathrm{K}} \epsilon^{2/3} (A_2 \kappa_1^{-8/3} + B_2 \kappa_2^{-8/3})$, where $A_2, B_2 \sim \mathcal{O}(1)$

are linear combinations of the fitting parameters. Following the approach above and introducing the small parameter δ, the expansion for the energy moment reads

$$\int_0^\infty \frac{E(\kappa)}{\kappa^2}\,d\kappa = F_2\,\frac{k^4}{\epsilon^2} + \mathcal{O}(\delta) \qquad \text{with } F_2 = \frac{A_2}{C_{\mathrm{K}}^3\,A_k^4} \approx 0.80. \tag{2.3}$$

In leading order, the amplitude is consequently given by

$$\mathbf{D}^{(0)} = \left(\frac{2\pi F_2}{\bar{v}_{\mathrm{n}}}\right)^{1/2} \frac{k^2}{\epsilon} \quad \mathbf{P}_{\mathbf{t},\mathbf{n}}\,. \tag{2.4}$$

Thus, the resulting correlations along the fiber $(\mathbf{D}^{(0)})^2\,\delta_0(s)\,\delta_0(t)$ can be interpreted as being proportional to the turbulent energy k acting over the mean coherence length l_{T} and over the characteristic turbulent fiber time $\tau_{\mathrm{T}}^f = l_{\mathrm{T}}/\bar{v}_{\mathrm{n}}$ that depends on the geometrical relation between fiber orientation and mean relative velocity.

2.2. Fiber scales. For a better understanding of the fiber behavior in the turbulent flow, dimensional analysis is applied on the fiber system (1.1), (1.2). Therefore, we introduce a dimensionless zooming parameter $h = L/H$ as a ratio of the typical varying length of interest $L \in [0, l]$ and the fixed height of the suspended fiber H, where l denotes the fiber length.

Apart from H, the problem contains nine parameters: diameter d, line weight ρA, bending stiffness EI, fiber velocity W, acceleration of gravity g, flow density ρ^{air}, mean flow velocity $\bar{u}$, mean relative velocity between flow and fiber $\bar{v}$, and kinetic turbulent energy k. The number of parameters can be reduced to four dimensionless:

$$\mathrm{Fr} = \frac{W^2}{g\,H}, \quad \mathrm{Gr} = \frac{\rho A\,g\,H^3}{EI}, \quad \bar{\mathrm{P}} = \frac{d\,\rho^{air}\,H^3\,\bar{v}^2}{EI}, \quad \mathrm{P}' = \frac{d\,\rho^{air}\,H^3\,k^{1/2}\,\bar{v}}{EI}.$$

The Froude number Fr states the ratio of kinetic and gravitational potential energy, the dimensionless gravity Gr the ratio of gravitational and flexural energies, and the dimensionless mean $\bar{\mathrm{P}}$ and fluctuating aerodynamic force P' the ratio of aerodynamic and flexural energies. Introducing dimensionless variables gives

$$\begin{aligned} \mathbf{r}(s,t) &= H\; r^*(s^*,t^*), & T_t(s,t) &= \frac{EI}{L\,H}\; T_t^*(s^*,t^*), \\ \bar{\mathbf{f}}(s,t) &= d\,\rho^{air}\left(\frac{\bar{v}}{h}\right)^2 \bar{\mathbf{f}}^*(s^*,t^*), & \mathbf{f}'(s,t) &= d\,\rho^{air} k^{1/2}\left(\frac{\bar{v}}{h}\right) \mathbf{f}'^*(s^*,t^*), \end{aligned}$$

with $s = L\,s^*$ and $t = (L/W)\,t^*$. Here, two different scalings are used for fiber curve $\mathbf{r}$ and arc-length s, $\mathbf{r}$ is scaled by the suspended height of the fiber H, and s by the typical length of interest L. This choice is motivated by our interest in the whole spatial domain of the fiber line while zooming in on certain fiber lengths. This allows us to investigate the characteristic fiber behavior, e.g., bending, loop forming, crimping or stiffness, arising on typical scales. Hence, the interplay of the fixed outer H and the varying inner length L appears also in the factor of the tension part T_t. The bending part is treated separately due to the composed structure of T. For the scaling of the aerodynamic force $\mathbf{f}^{air}$, it is sufficient to utilize its proportionality to the dynamic pressure, since $\|\mathbf{f}^{air}\|_2 \sim d\rho^{air}\|\mathbf{v}\|_2^2$ in the following. Thereby, the deterministic force part $\bar{\mathbf{f}}$ is based on the quadratic mean relative velocity, and the stochastic part $\mathbf{f}'$ on the product of mean relative velocity and flow fluctuations that are expressed by $k^{1/2}$.

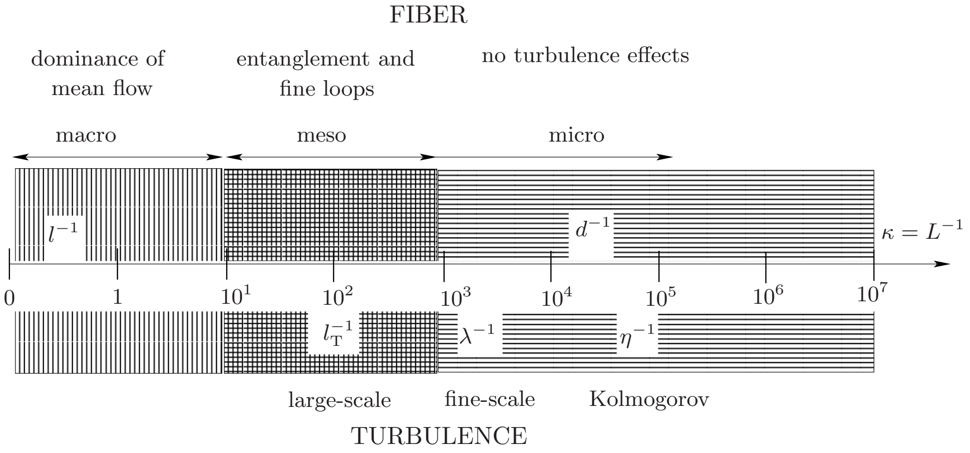

FIG. 2. *Scales of fiber-turbulence interactions in melt-spinning processes (cf. Tables* 1 *and* 2*).*

The magnitude of the mean relative velocity $\bar v$ depends particularly on the direction of mean flow and fiber velocity according to

$$\bar{\mathbf{v}}(s,t) = \|\bar u\,\bar{\mathbf{u}}^* - W/h\;\partial_{t^*}\mathbf{r}^*\|_2\;\bar{\mathbf{v}}^*(s^*,t^*) = (\bar v/h)\,\bar{\mathbf{v}}^*(s^*,t^*). \tag{2.5}$$

It is minimal if $\bar{\mathbf{u}}^\star$ and $\partial_{t^\star}\mathbf{r}^\star$ are similarly directed, and maximal if they are opposite directed; thus $\bar v \in [\,|h\bar u - W|,\,|h\bar u + W|\,]$. The time scaling in (2.5) that is chosen with respect to the fiber dynamics of the typical length L incorporates here the zooming ratio h into the definition of $\bar v$. Then, the dimensionless fiber system reads

$$\begin{aligned}\mathrm{Fr}\,\mathrm{Gr}\,\partial_{tt^\star}\mathbf{r}^\star =&\ \partial_{s^\star}\big((h^{-1}\,T_t^\star + h^{-4}\,\|\partial_{ss^\star}\mathbf{r}^\star\|_2^2)\,\partial_{s^\star}\mathbf{r}^\star\big) - h^{-2}\,\partial_{ssss^\star}\mathbf{r}^\star - h^2\,\mathrm{Gr}\,\mathbf{e_3}\\ &+\bar{\mathrm{P}}\,\bar{\mathbf{f}}^\star + h\,\mathrm{P}'\,\mathbf{f}'^\star,\\ (\partial_{s^\star}\mathbf{r}^\star)^2 =&\ h^2.\end{aligned}$$

For a melt-spinning process, the typical fiber and flow parameter values listed in Table 1 yield

$$\mathrm{Fr}\sim 10^1,\quad \mathrm{Gr}\sim 10^4,\quad \bar{\mathrm{P}}\sim\begin{cases}10^8-10^9, & h\sim 1,\\ 10^6-10^7, & h\ll 1,\end{cases}\qquad \mathrm{P}'\sim\begin{cases}10^7-10^8, & h\sim 1,\\ 10^6-10^7, & h\ll 1,\end{cases}$$

where the aerodynamic similarity quantities $\bar{\mathrm{P}}$ and P' are roughly estimated by means of the range of $\bar v$. Varying the length of interest L and thus the zooming parameter $h = L/H$ reveals three characteristic scales for the fiber-turbulence problem in the technical application that are worth considering in more detail; cf. Figure 2. In the following we suppress the superscript * to keep the expressions short.

Macroscale: $1 \geq h > 10^{-1}$.

$$\mathrm{Fr}\,\mathrm{Gr}\,\partial_{tt}\mathbf{r} = -h^2\,\mathrm{Gr}\,\mathbf{e_3} + \bar{\mathrm{P}}\,\bar{\mathbf{f}} + h\,\mathrm{P}'\,\mathbf{f}'.$$

Over the whole length of the fiber l, the fiber dynamics is caused by the external forces. In particular, the mean flow affects the fiber swinging.

Mesoscale: $10^{-1} \geq h > 10^{-3}$.

$$\mathrm{Fr}\,\mathrm{Gr}\,\partial_{tt}\mathbf{r} = \partial_s\big((h^{-1}T_t + h^{-4}\|\partial_{ss}\mathbf{r}\|_2^2)\,\partial_s\mathbf{r}\big) - h^{-2}\,\partial_{ssss}\mathbf{r} + \bar{\mathrm{P}}\,\bar{\mathbf{f}} + h\,\mathrm{P}'\,\mathbf{f}'.$$

Table 2

Overview of turbulence and fiber scales as well as dimensionless numbers for the fiber-turbulence problem deduced from the typical parameter values in melt-spinning processes (cf. Table 1).

Turbulence scales			
Large length scale	l_{T}	$1.0 \cdot 10^{-2}$	m
Fine length scale	λ_{T}	$5.4 \cdot 10^{-4}$	m
Kolmogorov length scale	η	$1.4 \cdot 10^{-5}$	m
Turbulent time scale	t_{T}	$1.0 \cdot 10^{-3}$	s
Advection time scale	t_{A}	$1.0 \cdot 10^{-4}$	s

Fiber scale			
Typical length of interest	L	$[0, 2.5]$	m

Dimensionless numbers of fiber-turbulence problem			
Zooming ratio	h	$[0, 2.5]$	
Froude number	Fr	10^1	
Gravity number	Gr	10^4	
Mean force number	$\bar{\mathrm{P}}$	$[10^8 - 10^9]$, $h \sim 1$,	$[10^6 - 10^7]$, $h \ll 1$
Fluctuating force number	P'	$[10^7 - 10^8]$, $h \sim 1$,	$[10^6 - 10^7]$, $h \ll 1$
Spatial smoothing parameter	α_s	10^{-2}	
Temporal smoothing parameter	α_t	10^{-3}	

This fiber scale coincides with the turbulent large-scale l_{T} of the energy-bearing vortices. Here, the inner and outer forces acting on the fiber balance each other. But the fluctuating part of the aerodynamic force $\mathbf{f}'$ causes entanglement and fine-loop forming which crucially determine the fiber dynamics.

Microscale: $h \leq 10^{-3}$.

$$\partial_s(h^{-4}\|\partial_{ss}\mathbf{r}\|_2^2\,\partial_s\mathbf{r}) = \mathbf{0}, \qquad \mathrm{Fr}\,\mathrm{Gr}\,\partial_{tt}\mathbf{r} = -h^{-2}\,\partial_{ssss}\mathbf{r} + \bar{\mathrm{P}}\,\bar{\mathbf{f}}.$$

The inner forces, in particular the bending stiffness, dominate the total fiber behavior. In contrast, the effects of the fine-scale λ_{T} and Kolmogorov vortices of size η are irrelevant for the fiber dynamics; here $\eta < d$ (cf. Tables 1 and 2).

The time scales of the problem provide no further information, as they are related to the length scales using the reciprocal of the fiber velocity W as a proportionality factor. Due to its inertia, the fiber shows thus no reaction to turbulent structures decaying faster than $t_{inertia} = h_{micro}H/W \sim 10^{-4}$ s, which includes the whole fine-scale turbulence. The natural decay of the large-scale vortices in contrast is indicated by $t_{\mathrm{T}} \sim 10^{-3}$ s and, under consideration of advection, by the mean flow by $t_{\mathrm{A}} \sim 10^{-4}$ s.

Summing up, fine-scale vortices do not affect a fiber in the melt-spinning process because of bending stiffness of the fiber. Thus, their influence (correlations) might be neglected in the model of the stochastic aerodynamic force. In contrast, the turbulent large-scale vortices cause entanglement and loop-forming, which play a decisive role in the fiber behavior. But instead of resolving their effects explicitly, it is sufficient to model them on the macroscale, as our interest focuses exclusively on a macroscopic description for the fiber dynamics. This motivates the idea of approximating the correlated force by an integrated—still correlated—force. In the following, the introduced uncorrelated aerodynamic force $\mathbf{f}_{uc}^{air}$ of (1.4) that contains the mean turbulent coherences (integral correlations) turns out to satisfy the stated demands on approximability.

2.3. Quantitative similarity estimates. To justify the applicability of the uncorrelated force as a substitute for the original correlated force in our problem, we analyze its approximation properties by means of the similarity estimates taken from [13].

Similarity estimates (see [13]). *Let $\alpha_s, \alpha_t \in \mathbb{R}_0^+$ be spatial and temporal smoothing parameters of the fiber-flow problem. Define $\mathcal{E}(\kappa_1,\kappa_2) := \int_{\mathbb{R}} E(\|\kappa_1,\kappa_2,l\|_2)/(\kappa_1,\kappa_2,l)^2\,dl$ with $\mathcal{E}_0 := \mathcal{E}(0,0)$ and $\mathcal{S} := \sup_{\boldsymbol{\kappa}\in[0,1]^2}\|\nabla_{\boldsymbol{\kappa}}\mathcal{E}(\kappa_1,\kappa_2)\|_2$. Then, the approximability of the correlated by the uncorrelated aerodynamic force given in* (1.3), (1.4) *is expressed by the following estimates:*

$\mathcal{L}^2$-similarity:

$$\mathcal{I}_{\mathcal{L}^2} \leq \frac{\sqrt{\alpha_s\,\alpha_t}}{\sqrt{6}\,\pi\,\bar{v}_{\mathrm{n}}}\sqrt{\mathcal{S}^2\left(\alpha_s^2\left(1+\frac{\bar{v}_{\mathrm{t}}^2}{\bar{v}_{\mathrm{n}}^2}\right)+\frac{\alpha_t^2}{\bar{v}_{\mathrm{n}}^2}\right)+\frac{8\mathcal{E}_0^2}{3\pi}\left(\alpha_s^3+\frac{\alpha_t^3}{(\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|)^3}\right)}; \tag{2.6}$$

$\mathcal{L}^\infty$-similarity:

$$\begin{aligned}\mathcal{I}_{\mathcal{L}^\infty} \leq \frac{\sqrt{2}\,\alpha_s\,\alpha_t}{\pi^2\,\bar{v}_{\mathrm{n}}}\Bigg[&\mathcal{S}\left(\alpha_s\left(1+\frac{\bar{v}_{\mathrm{t}}}{\bar{v}_{\mathrm{n}}}\right)\left(\frac{c}{2}+\ln\left(\frac{1}{\alpha_s}\right)\right)+\frac{\alpha_t}{\bar{v}_{\mathrm{n}}}\left(\frac{c}{2}+\ln\left(\frac{\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|}{\alpha_t}\right)\right)\right)\\ &+\mathcal{E}_0\left(\alpha_s+\frac{\alpha_t}{\bar{v}_{\mathrm{n}}+|\bar{v}_{\mathrm{t}}|}\right)\Bigg],\end{aligned} \tag{2.7}$$

where $\bar{v}_{\mathrm{t}}$, $\bar{v}_{\mathrm{n}}$ are the tangential and normal component of the mean relative velocity with respect to the $(\mathbf{t},\bar{\mathbf{v}})$-induced fiber basis of section 1.1 *and $c = \int_0^1 (1-\cos\iota)/\iota\,d\iota$.*

The limit $\alpha_i \to 0$, $i = s,t$, describes the smoothing over the whole $\mathbb{R}^2$. This is unrealistic, as the fiber length l prescribes a natural upper bound for the spatial smoothing parameter α_s. Thus, $\alpha_s = l_{\mathrm{T}}/l$ is certainly a reasonable value for the macroscopic description of the turbulent flow effects on the fiber. The temporal flow and fiber scales are related to the spatial ones by the respective velocities $\bar{u}$ and W, which motivates the choice of $\alpha_t = t_{\mathrm{A}}W/l = \alpha_s W/\bar{u}$.

Inserting the typical parameter values of Tables 1 and 2 yields for the dimensionless smoothing values $\alpha_s \sim 10^{-2}$ and $\alpha_t \sim 10^{-3}$ as well as for the quantities $\mathcal{S}$ and $\mathcal{E}_0$ in standard international units (SI-units) $\mathcal{S} \sim 1$ $[m^5/s^2]$ and $\mathcal{E}_0 \sim k^4/\epsilon^2 \sim 10^{-2}$ $[m^4/s^2]$ according to (2.3). The order of the relative velocity can be approximated by $\bar{v} \sim 10^2$ which implies $|\bar{v}_{\mathrm{t}}| \in [0,10^2]$ and $\bar{v}_{\mathrm{n}} \in [0,10^2]$. Thus, quantitative similarity estimates in SI-units depend drastically on the relation between fiber direction $\mathbf{t} = \partial_s\mathbf{r}$ and mean relative velocity $\bar{\mathbf{v}}$, as they are expressed by

$$\mathcal{I}_{\mathcal{L}^2}^2 \lesssim 10^{-10}\,\bar{v}_{\mathrm{n}}^{-2} + 10^{-6}\,\bar{v}_{\mathrm{n}}^{-4}, \qquad \mathcal{I}_{\mathcal{L}^\infty} \lesssim 10^{-8}\,\bar{v}_{\mathrm{n}}^{-1} + 10^{-6}\,\bar{v}_{\mathrm{n}}^{-2}$$

with $\mathbf{n} = (\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t})/\|\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t}\|_2$. In the case of $\mathbf{t} \perp \bar{\mathbf{v}}$, we have $\bar{v}_{\mathrm{n}} \sim 10^2$ such that $\mathcal{I}_{\mathcal{L}^2} \lesssim 10^{-7}$ and $\mathcal{I}_{\mathcal{L}^\infty} \lesssim 10^{-10}$ indicate very good approximation properties. But even for smaller normal velocity components—down to $\bar{v}_{\mathrm{n}}^{crit} \sim 10^{-1}$—the uncorrelated force is a good substitute for the correlated one, since the deviations are little, i.e., $\mathcal{I}_{\mathcal{L}^2} \lesssim 10^{-1}$, $\mathcal{I}_{\mathcal{L}^\infty} \lesssim 10^{-4}$. In fact, $\bar{v}_{\mathrm{n}} \sim 1$ in general, and the events $\bar{v}_{\mathrm{n}} < \bar{v}_{\mathrm{n}}^{crit}$ might be viewed as elements of a nullset, because the perturbing influence of turbulence and fiber inertia prevents the fiber from moving continuously within the mean streamlines. However, further numerical realization also requires their treatment, so in section 3.3 we will deal with the arising singularity for $\bar{v}_{\mathrm{n}} \to 0$ which results from the definition of the force amplitude $\mathbf{D}$, (1.7).

3. Air drag model and its consequences.

The numerical simulations of the fiber dynamics imposed by the correlated and/or uncorrelated aerodynamic force rely essentially on the choice of an appropriate air drag model $\mathbf{f}$ and the derivation of the corresponding linear drag operator $\mathbf{L}^{\mathbf{f}}$. We particularly distinguish between linear and quadratic drag relations and discuss their applicability as well as their consequences for our application.

3.1. Choice of drag model.

Stokes drag for turbulent flow. For slow viscous flows with $Re < 1$, Cox [4] has developed an insightful analytical series approximation for the force distribution along the length l of a straight fiber. As the Reynolds number based on the fiber diameter d approaches zero, the drag force per unit length along the fiber is proportional to the relative velocity between fluid and fiber $\mathbf{v}(s,t) = \mathbf{u}(\mathbf{r}(s,t),t) - \partial_t \mathbf{r}(s,t)$ at fiber point s and time t. So,

$$\mathbf{f}(\mathbf{v},\mathbf{t}) = \mathbf{C}^{drag}(\mathbf{t})\ \mathbf{v}, \qquad \mathbf{C}^{drag}(\mathbf{t}) = c_{\mathrm{t}}\, \mathbf{t}\otimes\mathbf{t} + c_{\mathrm{n}}\, (\mathbf{I} - \mathbf{t}\otimes\mathbf{t}) \tag{3.1}$$

gives the linear Stokes drag relation, where the drag tensor $\mathbf{C}^{drag}$ depends on the fiber orientation $\mathbf{t} = \partial_s \mathbf{r}$ in the surrounding flow. From the Stokes flow approximation, Keller and Rubinow [10] have determined the drag coefficients $c_{\mathrm{n}}, c_{\mathrm{t}}$ up to leading order for smooth ellipsoidal filaments which also conform for small surface variations [1]. Götz and Unterreiter [7], in contrast, have derived an integral equation model for the drag force by applying a matching principle to the asymptotic expansions of the flow field around slender ellipsoidal and cylindrical fibers of circular cross sections in the framework of Stokes' and Oseen's equations. Then with $\mu = \rho^{air}\nu$,

$$c_{\mathrm{n}}^{ellipsoid} = \frac{8\pi\mu}{Re}\left(\ln\left(\frac{2l}{d}\right) + \frac{1}{2}\right)^{-1}, \qquad c_{\mathrm{t}}^{ellipsoid} = \frac{4\pi\mu}{Re}\left(\ln\left(\frac{2l}{d}\right) - \frac{1}{2}\right)^{-1},$$
$$c_{\mathrm{n}}^{cylinder} = \frac{8\pi\mu}{Re}\left(\ln\left(\frac{4l}{d}\right) - \frac{1}{2}\right)^{-1}, \qquad c_{\mathrm{t}}^{cylinder} = \frac{4\pi\mu}{Re}\left(\ln\left(\frac{4l}{d}\right) - \frac{3}{2}\right)^{-1}.$$

However, there is no slender-body theory that is strictly valid for the turbulent flow with high Re that is of interest here, $Re \approx 200$. In the analysis of turbulence effects on particles, a linear Stokes drag has successfully been applied to predict particle motions in turbulent flows [15, 16, 18, 20]. Drag relations based on empirical correlations have also been used [3, 14] as well as a modified Stokes drag that takes into account particle oscillations [9]. As a necessary simplification, the form of the drag force, (3.1), on the fiber under creeping flow conditions is assumed to be retained for high Re turbulent flows. But (3.1) has been derived for a small Reynolds number flow. Thus, it is only valid for infinitely thin, small fibers with $d \leq \eta$ and $l \leq \eta$. Anyhow, the relation is conferrable to longer fibers suspended in turbulent flow by imposing the free-draining approximation, which has been used to model flexible fiber motion [17] and polymer dynamics [6]. In this model, the fiber is considered to be composed of a series of elements of length Δ_l, where $\Delta_l \leq \eta$. Each element meets the necessary conditions for (3.1) to be valid. Assuming hydrodynamic independence of each element allows (3.1) to be applied to all elements and thus to the entire fiber.

Taylor drag. For high Reynolds number flow indicated by $Re \in (20, 10^6)$, Taylor [19] has investigated the behavior of drag forces experimentally. Thereby, he has discovered the nonlinear relation between drag and angle of attack α between the flow direction and center line of an immersed straight slender body as well as the influence of the surface roughness on the drag, which Lee [11] has applied successfully to long, flexible fibers within a carding process.

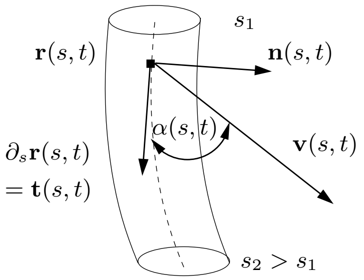

FIG. 3. *Drag-relevant angle* $\alpha \in [0,\pi]$ *enclosed by relative velocity* $\mathbf{v}$ *and fiber tangent* $\partial_s\mathbf{r}$.

As the drag force $\mathbf{f}$ lies in the plane spanned by the fiber tangent and the relative velocity, it can be split into a tangential $\mathbf{f_t}$ and a normal component $\mathbf{f_n}$ with respect to the fiber orientation, i.e., $\mathbf{t} = \partial_s\mathbf{r}$, $\mathbf{n} = (\mathbf{v} - (\mathbf{v}\cdot\mathbf{t})\mathbf{t})/\|\mathbf{v} - (\mathbf{v}\cdot\mathbf{t})\mathbf{t}\|_2$; cf. Figure 3. Then

$$\mathbf{f}(\mathbf{v},\mathbf{t}) = \mathbf{f_n}(\mathbf{v},\mathbf{t}) + \mathbf{f_t}(\mathbf{v},\mathbf{t}), \tag{3.2}$$

where

$$\mathbf{f_n} = 0.5\,\rho^{air}\,d\,\mathbf{v}^2\,\left(\sin^2\alpha + 4\sqrt{\frac{\sin^3\alpha}{Re}}\right)\,\mathbf{n}, \tag{3.3}$$

$$\mathbf{f_t} = 0.5\,\rho^{air}\,d\,\mathbf{v}^2\,\left(5.4\,\cos\alpha\sqrt{\frac{\sin\alpha}{Re}}\right)\,\mathbf{t}, \tag{3.4}$$

with $\sin\alpha = (\mathbf{v}\cdot\mathbf{n})/\|\mathbf{v}\|_2$, $\cos\alpha = (\mathbf{v}\cdot\mathbf{t})/\|\mathbf{v}\|_2$, and $Re = dv/\nu$, respectively. Equations (3.3), (3.4) suggest that a straight fiber with smooth surface does not feel any drag when it is aligned parallel to the direction of the incoming flow. This does not correspond to the experiments in [19] revealing that for small α, $\alpha \to 0$, $\mathbf{f_t}$ can be approximated by $\mathbf{f_t}(\alpha^\circ = \pi/36)$. In contrast, for a rough surface this situation of zero drag does not appear because the Taylor expression reads

$$\mathbf{f} = 0.5\,\rho^{air}\,d\,\mathbf{v}^2\,\left[\left(\sin^2\alpha + \frac{4\sin\alpha}{\sqrt{Re}}\right)\,\mathbf{n} + \cos\alpha\,\mathbf{t}\right]. \tag{3.5}$$

For technical reasons, we rewrite (3.3)–(3.5) as

$$\mathbf{f_n} = 0.5\,\rho^{air}\,d\,c_{\mathrm{n}}\,\|\mathbf{v_n}\|_2\,\mathbf{v_n}, \qquad \mathbf{f_t} = 0.5\,\rho^{air}\,d\,c_{\mathrm{t}}\,\|\mathbf{v_t}\|_2\,\mathbf{v_t} \tag{3.6}$$

with the empirical drag coefficients for smooth, resp., rough, fibers

$$\begin{aligned} c_{\mathrm{n}}^{smooth} &= 1 + 4\sqrt{\nu/(d\|\mathbf{v_n}\|_2)}, & c_{\mathrm{t}}^{smooth} &= 5.4\sqrt{\nu\|\mathbf{v_n}\|_2/(d\|\mathbf{v_t}\|_2^2)}, \\ c_{\mathrm{n}}^{rough} &= 1 + 4\sqrt{\nu\|\mathbf{v}\|_2/(d\|\mathbf{v_n}\|_2^2)}, & c_{\mathrm{t}}^{rough} &= \|\mathbf{v}\|_2/\|\mathbf{v_t}\|_2. \end{aligned} \tag{3.7}$$

The high Reynolds number flow and the presence of very small vortices indicated by the relation $\eta < d$ in our application conflicts with the use of the heuristic linear Stokes drag. Hence, we determine the aerodynamic forces on the smooth polymer fiber under consideration by means of the empirically motivated nearly quadratic Taylor drag (3.6), (3.7), although this concept is examined only for high Re, but still laminar inflow regime. Additionally, to exclude the zero drag in the case of parallelism of $\mathbf{t}$ and $\mathbf{v}$, we suggest a slight modification of the drag coefficient c_{t}^{smooth} that provides more realistic results. As a smooth fiber lying parallel to the direction of the relative velocity experiences the same tangential drag force as one being rotated by α°, and as $\mathbf{v_n} = \mathbf{v} - (\mathbf{v}\cdot\mathbf{t})\mathbf{t}$, we define

$$\mathbf{v}_{\mathbf{n}}^{\circ} := \begin{cases} \mathbf{v_n}, & c^\circ \geq \|\mathbf{v_t}\|_2/\|\mathbf{v}\|_2, \\ \mathbf{v} - \mathrm{sgn}(\mathbf{v}\cdot\mathbf{t})c^\circ\|\mathbf{v}\|_2\,\mathbf{t} & \text{else} \end{cases} \tag{3.8}$$

with $c^\circ = \cos\alpha^\circ$. Here, the sign function, $\mathrm{sgn}(x) = 1$ if $x \geq 0$, $\mathrm{sgn}(x) = -1$ else, includes equal and opposite directed vectors $\mathbf{t}$ and $\mathbf{v}$. We have $\|\mathbf{v}_{\mathbf{n}}^{\circ}\|_2 = 0$ if and only if $\|\mathbf{v}\|_2 = 0$. Setting

$$c_{\mathrm{t}}^{smooth} = 5.4\sqrt{\nu\|\mathbf{v}_{\mathbf{n}}^{\circ}\|_2/(d\|\mathbf{v_t}\|_2^2)} \tag{3.9}$$

thus yields a reasonable tangential drag model that is not only continuous but proves to also be differentiable.

3.2. Linear drag operator. Proceeding with the derivation of the linear drag operator $\mathbf{L^f}$, we consider a generalized linearization approach for the modified Taylor drag model $\mathbf{f}$,

$$\mathbf{f}(\bar{\mathbf{v}} + \mathbf{u}', \mathbf{t}) \approx \mathbf{f}(\bar{\mathbf{v}}, \mathbf{t}) + \mathbf{L^f}(\bar{\mathbf{v}}, \mathbf{t}, k)\ \mathbf{u}', \tag{3.10}$$

with mean relative velocity between fluid and fiber $\bar{\mathbf{v}}$ and random Gaussian fluctuation of the flow velocity $\mathbf{u}'$. In the context of (1.3), (1.4), the first term represents the deterministic part of the aerodynamic forces and the second term the stochastic one.

Model for linear drag operator. *Let* $\mathbf{f} : \mathbb{R}^3 \times \mathbb{R}^2 \to \mathbb{R}^3$ *be the modified Taylor drag model of* (3.6)–(3.9). *Then construct the linear drag operator* $\mathbf{L^f}$ *as continuous composition*

$$\mathbf{L^f}(\bar{\mathbf{v}}, \mathbf{t}, k) = \begin{cases} \nabla_{\mathbf{v}}\mathbf{f}(\bar{\mathbf{v}}, \mathbf{t}), & \varpi > 1, \\ \\ (1-\varpi)\left(a_{\mathrm{n}_0}(k)\ (\mathbf{I} - \mathbf{P_t}) + \ a_{\mathrm{t}_0}(k)\ \mathbf{P_t}\right) & \\ \quad +\varpi\ \nabla_{\mathbf{v}}\mathbf{f}(\varpi^{-1}\,\bar{\mathbf{v}}, \mathbf{t}), & \varpi \leq 1, \end{cases} \tag{3.11}$$

with $\varpi = \|\bar{\mathbf{v}}\|_2\,(2k)^{-1/2}$. *The parameters are given by*

$$a_{\mathrm{n}_0}(k) = \left(2a_{\mathrm{n}_1}^2 k + 5\sqrt{2^5}/\sqrt{3^{3/2}\pi}\,\mathrm{gam}(5/4)a_{\mathrm{n}_1}a_{\mathrm{n}_2}k^{3/4} + 16/\sqrt{3\pi}\,a_{\mathrm{n}_2}^2 k^{1/2}\right)^{1/2}, \tag{3.12}$$

$$a_{\mathrm{t}_0}(k) = \sqrt{8/(3\pi)^{1/2}}\,a_{\mathrm{t}}k^{1/4} \tag{3.13}$$

with $a_{\mathrm{n}_1} = 0.5\rho^{air}d$, $a_{\mathrm{n}_2} = \rho^{air}\sqrt{d\nu}$, $a_{\mathrm{t}} = 1.35a_{\mathrm{n}_2}$, $c^\circ = \cos\alpha^\circ$, *and gamma function* gam.

Let the projectors on fiber tangent $\mathbf{t} = \partial_s\mathbf{r}$, normal $\mathbf{n} = (\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t})/\|\bar{\mathbf{v}} - (\bar{\mathbf{v}}\cdot\mathbf{t})\mathbf{t}\|_2$, and binormal $\mathbf{b} = \mathbf{t}\times\mathbf{n}$ be described by $\mathbf{P}_{[\mathbf{x},\mathbf{y}]} = \mathbf{x}\otimes\mathbf{y}$. In particular, we abbreviate $\mathbf{P_x} := \mathbf{P}_{[\mathbf{x},\mathbf{x}]}$ and $\mathbf{P}_{\mathbf{x},\mathbf{y}} := \mathbf{P_x} + \mathbf{P_y}$, $\mathbf{x}, \mathbf{y} \in \mathbb{R}^3$. Then, the operator $\nabla_{\mathbf{v}}\mathbf{f}$ resulting from (3.6)–(3.9) reads

$$\begin{aligned} \nabla_{\mathbf{v}}\mathbf{f}(\bar{\mathbf{v}}, \mathbf{t}) = {} & (a_{\mathrm{n}_1}\|\bar{\mathbf{v}}_{\mathbf{n}}\|_2 + 2a_{\mathrm{n}_2}\|\bar{\mathbf{v}}_{\mathbf{n}}\|_2^{1/2})\ \mathbf{P}_{\mathbf{n},\mathbf{b}} + \ (a_{\mathrm{n}_1}\|\bar{\mathbf{v}}_{\mathbf{n}}\|_2 + a_{\mathrm{n}_2}\|\bar{\mathbf{v}}_{\mathbf{n}}\|_2^{1/2})\ \mathbf{P_n} \\ & + 2a_{\mathrm{t}}\|\bar{\mathbf{v}}_{\mathbf{n}}^{\circ}\|_2^{1/2}\ \mathbf{P_t} + \ a_{\mathrm{t}}\|\bar{\mathbf{v}}_{\mathbf{n}}^{\circ}\|_2^{-1/2}(\bar{\mathbf{v}}\cdot\mathbf{t})\,\mathbf{P}_{[\mathbf{t},\,\bar{\mathbf{v}}_{\mathbf{n}}^{\circ}\|\bar{\mathbf{v}}_{\mathbf{n}}^{\circ}\|^{-1}]} \\ & + \chi(\bar{\mathbf{v}}, \mathbf{t})\,a_{\mathrm{t}}\|\bar{\mathbf{v}}_{\mathbf{n}}^{\circ}\|_2^{-3/2}\,c^\circ(c^\circ - \|\bar{\mathbf{v}}_{\mathbf{t}}\|_2\|\bar{\mathbf{v}}\|_2^{-1})(\|\bar{\mathbf{v}}_{\mathbf{t}}\|_2^2\ \mathbf{P_t} + (\bar{\mathbf{v}}\cdot\mathbf{t})\|\bar{\mathbf{v}}_{\mathbf{n}}\|_2\ \mathbf{P}_{[\mathbf{t},\mathbf{n}]}). \end{aligned}$$

Although the use of the indicator function $\chi(\bar{\mathbf{v}},\mathbf{t}) = 1$ for $(\|\bar{\mathbf{v}}_{\mathbf{t}}\|_2\|\bar{\mathbf{v}}\|_2^{-1}) \geq c^\circ$ and $\chi(\bar{\mathbf{v}},\mathbf{t}) = 0$ else, the introduction of $\mathbf{v}_{\mathbf{n}}^\circ$ in (3.8) yields a continuous Gâteaux derivative. In the limit to $\mathbf{t}\|\bar{\mathbf{v}}$, additionally it stays bounded, which is a big difference from an ansatz based on Taylor's original zero drag model with missing tangential component.

The Gâteaux derivative $\nabla_{\mathbf{v}}\mathbf{f}(\bar{\mathbf{v}},\mathbf{t})\,\mathbf{u}'$ is a good representative for the stochastic part in (3.10) if the mean relative velocity is much higher than the fluctuations that are characterized by the turbulent kinetic energy k, i.e., $\|\bar{\mathbf{v}}\|_2^2 \gg \mathbb{E}[\mathbf{u}'^2] = 2k$. In contrast, in case of $\bar{\mathbf{v}} = \mathbf{0}$ it would provide a zero drag since

$$\mathbf{f}(\bar{\mathbf{v}}+\mathbf{u}',\mathbf{t})|_{\bar{\mathbf{v}}=\mathbf{0}} = \mathbf{f}(\mathbf{0},\mathbf{t}) + \nabla_{\mathbf{v}}\mathbf{f}(\mathbf{0},\mathbf{t})\,\mathbf{u}' + \mathcal{O}((\mathbf{u}')^2) = \mathbf{0} + \mathcal{O}((\mathbf{u}')^2),$$

which is absurd, as the velocity fluctuations affect the fiber though vanishing mean relative velocity

$$\mathbf{f}(\mathbf{u}',\mathbf{t}) = (a_{\mathrm{n}_1}\|\mathbf{u}'_{\mathbf{n}}\|_2 + 2a_{\mathrm{n}_2}\|\mathbf{u}'_{\mathbf{n}}\|_2^{1/2})\;\mathbf{u}'_{\mathbf{n}} + 2a_{\mathrm{t}}\|\mathbf{u}'_{\mathbf{n}}{}^{\circ}\|_2^{1/2}\;\mathbf{u}'_{\mathbf{t}}. \tag{3.14}$$

Note that in (3.14) the direction $\mathbf{n}$ is exceptionally determined by $\mathbf{u}'$, i.e., $\mathbf{u}'_{\mathbf{n}} = \mathbf{u}' - \mathbf{u}'_{\mathbf{t}}$. The fact that the expectations of drag and velocity fluctuations are equal, i.e., $\mathbb{E}[\mathbf{f}(\mathbf{u}',\mathbf{t})] = \mathbb{E}[\mathbf{u}'] = \mathbf{0}$, motivates the stated extension of the linearized approach for $\bar{\mathbf{v}} = \mathbf{0}$. Keeping the directional vectors $\mathbf{u}'_{\mathbf{n}}, \mathbf{u}'_{\mathbf{t}}$, the coefficients with the specific norms are replaced by the respective averaged quantity expressed by the kinetic energy k such that the variance is correctly reproduced. Therefore abbreviate $\mathbf{f} := \mathbf{f}(\mathbf{u}',\mathbf{t})$ and consider

$$\begin{aligned}\mathbb{E}[\mathbf{f}\otimes\mathbf{f}] = {} & \mathbb{E}[(\mathbf{f}\cdot\mathbf{t})^2]\,\mathbf{t}\otimes\mathbf{t} + \mathbb{E}[(\mathbf{f}\cdot\mathbf{n_1})^2]\,\mathbf{n_1}\otimes\mathbf{n_1} + \mathbb{E}[(\mathbf{f}\cdot\mathbf{n_2})^2]\,\mathbf{n_2}\otimes\mathbf{n_2}\\ & + \mathbb{E}[(\mathbf{f}\cdot\mathbf{t})\;\;(\mathbf{f}\cdot\mathbf{n_1})]\;\;(\mathbf{t}\otimes\mathbf{n_1} + \mathbf{n_1}\otimes\mathbf{t})\\ & + \mathbb{E}[(\mathbf{f}\cdot\mathbf{t})\;\;(\mathbf{f}\cdot\mathbf{n_2})]\;\;(\mathbf{t}\otimes\mathbf{n_2} + \mathbf{n_2}\otimes\mathbf{t})\\ & + \mathbb{E}[(\mathbf{f}\cdot\mathbf{n_1})\,(\mathbf{f}\cdot\mathbf{n_2})]\;\;(\mathbf{n_1}\otimes\mathbf{n_2} + \mathbf{n_2}\otimes\mathbf{n_1})\end{aligned}$$

with arbitrarily chosen orthogonal normal vectors $\mathbf{n_1}, \mathbf{n_2}$. The mixed expectations vanish thereby due to the independence and odd appearance of the underlying velocity components, as for $\mathbb{E}[\mathbf{f}]$ above. Because of the identical distribution of the drag in the normal plane, we have $\mathbb{E}[(\mathbf{f}\cdot\mathbf{n_1})^2] = \mathbb{E}[(\mathbf{f}\cdot\mathbf{n_2})^2]$ such that it is sufficient to consider $\mathbb{E}[(\mathbf{f}\cdot\mathbf{n})^2]$. Using $\mathbb{E}[\mathbf{u}'^2] = 2k$ and the identical distribution of the velocity components yields their variance $\mathbb{E}[(\mathbf{u}'\cdot\mathbf{e})^2] = \sigma^2 = 2k/3$ with unit vector $\mathbf{e}$. The general (centered) moments are prescribed by the gamma function according to $\mathbb{E}[|\mathbf{u}'\cdot\mathbf{e}|^{2m}] = (2\pi\sigma^2)^{-1/2}\int x^{2m}e^{-x^2/(2\sigma^2)}\,dx = (2\sigma^2)^m\,\mathrm{gam}(m+1/2)/\sqrt{\pi}$, $m\in\mathbb{R}^+$. Then

$$\begin{aligned}\mathbb{E}[(\mathbf{f}\cdot\mathbf{t})^2] &= 4a_{\mathrm{t}}^2\,\mathbb{E}[|\mathbf{u}'\cdot\mathbf{n}^\circ|]\,\mathbb{E}[(\mathbf{u}'\cdot\mathbf{t})^2] = (a_{\mathrm{t}_0}(k)\,\sigma)^2,\\ \mathbb{E}[(\mathbf{f}\cdot\mathbf{n})^2] &= a_{\mathrm{n}_1}^2\mathbb{E}[(\mathbf{u}'\cdot\mathbf{n})^4] + 4a_{\mathrm{n}_1}a_{\mathrm{n}_2}\mathbb{E}[|\mathbf{u}'\cdot\mathbf{n}|^{7/2}] + 4a_{\mathrm{n}_2}^2\mathbb{E}[|\mathbf{u}'\cdot\mathbf{n}|^3] = (a_{\mathrm{n}_0}(k)\,\sigma)^2\end{aligned}$$

by means of (3.12), (3.13) such that

$$\mathbf{f}_0(\mathbf{u}',\mathbf{t},k) := a_{\mathrm{n}_0}(k)\,\mathbf{u}'_{\mathbf{n}} + a_{\mathrm{t}_0}(k)\,\mathbf{u}'_{\mathbf{t}} = a_{\mathrm{n}_0}(k)\,(\mathbf{u}'-\mathbf{u}'_{\mathbf{t}}) + a_{\mathrm{t}_0}(k)\,\mathbf{u}'_{\mathbf{t}}$$

describes a Gaussian random variable that has the same stochastic parameters, i.e., expectation and variance, as the original drag of (3.14). Moreover, it is linear in $\mathbf{u}'$, although we suggest that its coefficients depend on k. But the turbulent kinetic energy has to be viewed as an input parameter for the generation of the flow fluctuations in the context of this work. Hence, $\mathbf{L}^{\mathbf{f}}(\bar{\mathbf{v}},\mathbf{t},k) = a_{\mathrm{n}_0}(k)\,(\mathbf{I}-\mathbf{P_t}) + a_{\mathrm{t}_0}(k)\;\mathbf{P_t}$ is taken as the drag operator in the case $\bar{\mathbf{v}} = \mathbf{0}$.

For the secant complement that combines the two determined drag operators, all functional dependencies of ϖ might be imaginable, e.g., squared, linear, or quadratic in $\|\bar{\mathbf{v}}\|_2$. But because of the lack of information about this intermediate domain, i.e., $\|\bar{\mathbf{v}}\|_2^2 \in (0, 2k)$, they are mathematically and physically as less motivated as our proposed linear ansatz in (3.11).

3.3. Technical modification of force amplitude. Since the defined drag operator $\mathbf{L}^{\mathbf{f}}$ has a finite, nonvanishing limit for $\bar{v}_{\mathrm{n}} \to 0$, it is unable to balance the arising singularity of the force amplitude in (1.7),

$$\mathbf{D} = \left(\frac{2\pi}{\bar{v}_{\mathrm{n}}}\int_0^\infty \frac{E(\kappa)}{\kappa^2}d\kappa\right)^{1/2} \mathbf{P_{t,n}} \overset{(2.4)}{\approx} \left(\frac{2\pi F_2}{\bar{v}_{\mathrm{n}}}\right)^{1/2}\frac{k^2}{\epsilon}\;\mathbf{P_{t,n}}.$$

Consequently, the uncorrelated aerodynamic force $\mathbf{f}_{uc}^{air}$ diverges in the case of the linear dependence of $\mathbf{t}$ and $\bar{\mathbf{v}}$, whereas the correlated force $\mathbf{f}_{cc}^{air}$ stays bounded, as we have already seen in the similarity estimates (2.6), (2.7). Although the occurrence of this single discrepancy is negligibly small, the further numerical realization requires its handling. Thus, we suggest a slight technical modification of the amplitude that has no influence on the proved approximation quality of the uncorrelated force. Replace $\mathbf{D}$ by

(3.15)
$$\breve{\mathbf{D}} = (2\pi F_2)^{1/2}\,\frac{k^2}{\epsilon}\begin{cases} \bar{v}_{\mathrm{n}}^{-1/2}\;\mathbf{P_{t,n}}, & \omega > 1, \\[2ex] (1-\omega)\,(\bar{v}_{\mathrm{n}}^{crit})^{-1/2}\;(\mathbf{P_t} + (\mathbf{I}-\mathbf{P_t})/2) + \omega\,\bar{v}_{\mathrm{n}}^{-1/2}\;\mathbf{P_{t,n}}, & \omega \le 1, \end{cases}$$

with $\omega = \bar{v}_{\mathrm{n}}/\bar{v}_{\mathrm{n}}^{crit}$; then

$$\lim_{\bar{v}_{\mathrm{n}}\to 0}\mathbf{f}_{uc}^{air} = \mathbf{f} + \left(\frac{2\pi F_2}{\bar{v}_{\mathrm{n}}^{crit}}\right)^{1/2}\frac{k^2}{\epsilon}\begin{cases} l^{||}\,\mathbf{P_t}\,\mathbf{p}, & \varpi > 1, \\[2ex] ((1-\varpi)\,(a_{\mathrm{n}_0}(k)/2\;(\mathbf{I}-\mathbf{P_t}) + \;a_{\mathrm{t}_0}(k)\;\mathbf{P_t}) \\ \qquad +\varpi\, l^{||}\,\mathbf{P_t})\;\mathbf{p}, & \varpi \le 1, \end{cases}$$

coincides with the limit of the correlated force regarding the formal structure of the terms. Here, the deterministic force part given by the modified Taylor drag of (3.6) and (3.9) reads $\mathbf{f} = \mathbf{f_t}$ for $\|\bar{\mathbf{v}}\|_2 \neq 0$ and $\mathbf{f} = \mathbf{0}$ else, and furthermore

$$l^{||} := a_{\mathrm{t}}\left(2\bar{v}_{\mathrm{n}}^{\circ\,1/2} + \frac{\bar{v}_{\mathrm{t}}}{\bar{v}_{\mathrm{n}}^{\circ\,1/2}} + \frac{(c^{\circ\,2}-c^{\circ})\bar{v}_{\mathrm{t}}^2}{\bar{v}_{\mathrm{n}}^{\circ\,3/2}}\right)$$

with $\bar{v}_{\mathrm{n}}^{\circ} = (1-\mathrm{sgn}(\bar{\mathbf{v}}\cdot\mathbf{t})c^{\circ})\|\bar{\mathbf{v}}\|_2 < \infty$. The modification in (3.15) can be interpreted as cutting the amplitude $\mathbf{D}$ at the critical velocity $\bar{v}_{\mathrm{n}} = \bar{v}_{\mathrm{n}}^{crit}$ and matching it continuously with a linear extension. As the underlying $(\mathbf{t},\bar{\mathbf{v}})$-induced set $\{\mathbf{t},\mathbf{n},\mathbf{b}\}$ loses its basis properties in the limit $\bar{v}_{\mathrm{n}} = 0$, we distinguish between the tangential and the remaining projectors and introduce the normal independent splitting $(\mathbf{P_t}+(\mathbf{I}-\mathbf{P_t})/2)$ instead of the original $(\mathbf{P_t}+\mathbf{P_n})$. Thus, the direction of $\mathbf{f}_{uc}^{air}$ is no longer specified by the mean relative velocity for $\varpi \to 0$, as already indicated by $\mathbf{f}_{cc}^{air}$.

The needed technical modification of the amplitude reveals the deficiency of the modeled fluctuation velocity fields $\mathbf{w}_f^{\sigma,\tau}$ whose dynamics is based on a locally frozen turbulence pattern. Hence, the fiber experiences no temporal change of the correlations if it moves within the mean streamlines, i.e., $\bar{v}_\mathrm{n} = 0$. Alternatively to the modification, one might question the underlying concept of frozen turbulence that neglects the natural decay of vortices because of its large time t_T and slow turbulent velocity scale $u_\mathrm{T} = k^{1/2}$ in comparison to the advection scales of the mean flow t_A, $\bar{u}$. However, for a fiber suspended in turbulence, the actual temporal change of the experienced turbulent coherences is prescribed by the velocity $v_\mathrm{T}^f = \max\{\bar{v}_\mathrm{n}, u_\mathrm{T}\}$. This could be incorporated into the definition of the flow-dependent force amplitude $\check{\mathbf{D}}$ by substituting $\bar{v}_\mathrm{n}^{crit}$ with u_T. Then the characteristic turbulent fiber time reads $\tau_\mathrm{T}^f = \min\{l_\mathrm{T}/\bar{v}_\mathrm{n}, t_\mathrm{T}\}$. The consequences of the choice of the parameter $\bar{v}_\mathrm{n}^{crit}$ are illustrated in the numerical results of the next section.

4. Numerical simulations. The input flow data for the following numerical simulations of the fiber dynamics stem from k-ϵ computations of FLUENT 6.1 that have been adapted with user-specific procedures to reflect the realistic turbulent flow behavior of a melt-spinning process. The implementation of the fiber system (1.1), (1.2) is based on a standard method of lines. The use of spatial finite differences of higher order thereby yields the appropriate approximation of the algebraic constraint (1.2). The time integration is realized by a semi-implicit Euler method, where an adaptive time step control ensures stability and accuracy. The arising nonlinear system of equations is iteratively solved by a modified Newton–Raphson method. As the Jacobian matrices show a band structure, the computational effect of an iteration step is proportional to the number of fiber points. Note that the aerodynamic forces are explicitly included. Their quality depends crucially on the available flow data that are linearly interpolated on the spatial and temporal fiber grid.

In the following, we briefly present the numerical algorithms for the realization of the correlated and uncorrelated aerodynamic forces before we compare their effects on the fiber dynamics by means of an introduced curvature measure.

4.1. Algorithms. Let $I_m^n = \{l \in \mathbb{N}_0 \mid m \leq l \leq n\}$. Let the spatial and temporal fiber discretization be given by $s_i = i\Delta s$ and $t_j = t_{j-1} + \Delta t_{j-1}$, $t_0 = 0$ with fixed space increment Δs, and adaptive time step Δt_j, $(i,j) \in I_0^n \times I_0^m$. Then denote the respective function values at the fiber point s_i at time t_j with subscript $_i$ and superscript ^{j}, e.g., $\mathbf{r}_i^j = \mathbf{r}(s_i, t_j)$.

The numerical generation of the correlated aerodynamic force $\mathbf{f}_{cc}^{air}$ utilizes autoregressive moving average (ARMA) processes [2] for the centered, homogeneous, independent, local fluctuation velocity fields $\mathbf{w}_f^{\sigma,\tau}$ along the fiber, whereas the implementation of the uncorrelated force $\mathbf{f}_{uc}^{air}$ is exclusively based on Gaussian white noise $\mathbf{p}$,

$$\lim_{(\Delta s, \Delta t_j)\to\mathbf{0}} (\Delta s \Delta t_j)^{1/2}\, \mathbf{p}_i^j \sim \mathcal{N}(\mathbf{0}, \mathbf{I}).$$

ALGORITHM 4.1 (computation of correlated force). *Choose l_T and t_T as characteristic turbulent large scales of the problem. Consider a fixed fiber and a time point that is indicated by the index tuple $(i,j) \in I_0^n \times I_0^m$.*

1. *Determine its corresponding index set N_i^j,*

$$N_i^j = \left\{ (\phi, \tau) \mid \left\| \mathbf{r}_i^j - \mathbf{r}_\phi^\tau - \bar{\mathbf{u}}_i^j \sum_{q=1}^{j-\tau} \Delta t_{j+1-q} \right\|_2 \leq l_\mathrm{T} \wedge \sum_{q=1}^{j-\tau} \Delta t_{j+1-q} \leq t_\mathrm{T} \right\}$$

with feasible tuples $(\phi, \tau) \in (I_0^n \times I_0^{j-1}) \cup (I_0^i \times I_j^j)$.

2. *Compute the centered, homogeneous, local fluctuations* $(\mathbf{w}^{\boldsymbol{\ell}}_f)^j_i$ *for all* $\boldsymbol{\ell} = (\ell_1, \ell_2) \in N^j_i$. *For this purpose, consider a fixed* $\boldsymbol{\ell}$*:*
   (a) *Set the turbulent fine-scale length* $\lambda^{\boldsymbol{\ell}}_{\mathrm{T}} = (20k^{\boldsymbol{\ell}}\nu/\epsilon^{\boldsymbol{\ell}})^{1/2}$.
   (b) *Determine the correlation index set* $(J^{\boldsymbol{\ell}})^j_i$,

$$(J^{\boldsymbol{\ell}})^j_i = \left\{ (\phi, \tau) \mid \left\| \mathbf{r}^j_i - \mathbf{r}^\tau_\phi - \bar{\mathbf{u}}^{\boldsymbol{\ell}} \sum_{q=1}^{j-\tau} \Delta t_{j+1-q} \right\|_2 \leq \lambda^{\boldsymbol{\ell}}_{\mathrm{T}} \right\}$$

with feasible tuples

$$(\phi, \tau) \in \begin{cases} I^{i-1}_{\ell_1} \times I^{\ell_2}_{\ell_2}, & \ell_2 = j,\ \ell_1 < i, \\ (I^n_{\ell_1} \times I^{\ell_2}_{\ell_2}) \cup (I^{i-1}_0 \times I^j_j), & \ell_2 = j-1, \\ (I^n_{\ell_1} \times I^{\ell_2}_{\ell_2}) \cup (I^n_0 \times I^{j-1}_{\ell_2+1}) \cup (I^{i-1}_0 \times I^j_j), & \ell_2 < j-1, \\ \emptyset & \textit{otherwise}. \end{cases}$$

   (c) *If* $(J^{\boldsymbol{\ell}})^j_i \neq \emptyset$, *then*:
      i. *Define a bijective mapping* $\rho : \{1, \ldots, |(J^{\boldsymbol{\ell}})^j_i|\} \to (J^{\boldsymbol{\ell}})^j_i$ *and set* $\rho(0) = (i, j)$.
      ii. *Consider the vectorial ARMA process*

$$(\mathbf{w}^{\boldsymbol{\ell}}_f)^j_i = (\mathbf{w}^{\boldsymbol{\ell}}_f)_{\rho(0)} = \sum_{q=1}^{|(J^{\boldsymbol{\ell}})^j_i|} \mathbf{A}_q (\mathbf{w}^{\boldsymbol{\ell}}_f)_{\rho(q)} + (\boldsymbol{\xi}^{\boldsymbol{\ell}})^j_i \tag{4.1}$$

with unknown coefficients $\mathbf{A}_q \in \mathbb{R}^{3\times3}$ *and noise* $(\boldsymbol{\xi}^{\boldsymbol{\ell}})^j_i \sim \mathcal{N}(\mathbf{0}, \mathbf{K})$ *that is assumed to be independent of* $(\mathbf{w}^{\boldsymbol{\ell}}_f)_{\rho(q)}$.
      iii. *Define* $\mathbf{C}_{(p,q)} := \mathbb{E}[(\mathbf{w}^{\boldsymbol{\ell}}_f)_{\rho(p)} \otimes (\mathbf{w}^{\boldsymbol{\ell}}_f)_{\rho(q)}]$ *for* $p, q = 0, \ldots, |(J^{\boldsymbol{\ell}})^j_i|$ *by means of the correlation tensor* $\boldsymbol{\gamma}^{\boldsymbol{\ell}}_0$ *in the canonical basis representation. Then particularly,* $\mathbf{C}_{(p,p)} = \boldsymbol{\gamma}^{\boldsymbol{\ell}}_0(\mathbf{0})$ *and* $\mathbf{C}_{(p,q)} = \mathbf{C}_{(q,p)}$ *hold.*
      iv. *Approximate the lateral correlation function of* $\boldsymbol{\gamma}^{\boldsymbol{\ell}}_0$ *by* $c^{\boldsymbol{\ell}}_1(z) = 2k^{\boldsymbol{\ell}}/3 - \epsilon^{\boldsymbol{\ell}} z^2/(30\nu)$, *i.e.,* $\boldsymbol{\gamma}^{\boldsymbol{\ell}}_0(\mathbf{z}) = (c_1(z) + z\partial_z c_1(z)/2)\mathbf{I} - \partial_z c_1(z)/(2z)\mathbf{z} \otimes \mathbf{z}$, $z = \|\mathbf{z}\|_2$ [13].
      v. *Compute the coefficients* $\mathbf{A}_q$ *by solving*

$$\sum_{q=1}^{|(J^{\boldsymbol{\ell}})^j_i|} \mathbf{C}_{(p,q)}\ \mathbf{A}_q = \mathbf{C}_{(p,0)}, \qquad p = 0, \ldots, |(J^{\boldsymbol{\ell}})^j_i| - 1. \tag{4.2}$$

      vi. *Calculate the covariance* $\mathbf{K}$ *of the noise term* $(\boldsymbol{\xi}^{\boldsymbol{\ell}})^j_i$ *from*

$$\begin{aligned} \mathbf{K} = {} & \mathbf{C}_{(0,0)} - \sum_{p=1}^{|(J^{\boldsymbol{\ell}})^j_i|} \mathbf{A}_p \mathbf{C}_{(p,p)} \mathbf{A}^T_p \\ & - \sum_{p=1}^{|(J^{\boldsymbol{\ell}})^j_i|-1} \sum_{q=p+1}^{|(J^{\boldsymbol{\ell}})^j_i|} \mathbf{A}_p \mathbf{C}_{(p,q)} \mathbf{A}^T_q - \sum_{p=1}^{|(J^{\boldsymbol{\ell}})^j_i|-1} \sum_{q=p+1}^{|(J^{\boldsymbol{\ell}})^j_i|} \mathbf{A}_q \mathbf{C}_{(q,p)} \mathbf{A}^T_p. \end{aligned}$$

vii. *Generate the correlated noise term* $(\boldsymbol{\xi}^{\boldsymbol{\ell}})_i^j = (\xi_1, \xi_2, \xi_3)$ *according to its covariance* $\mathbf{K} = (K_{pq})_{p,q=1,2,3}$ *and the ansatz*

$$\begin{aligned} &\xi_1 \sim \mathcal{N}(0, K_{11}), \\ &\xi_2 = \alpha\xi_1 + \xi_2', \\ &\xi_3 = \beta_1\xi_1 + \beta_2\xi_2 + \xi_3', \end{aligned} \tag{4.3}$$

where the parameters α, β_1, β_2 *and the independent random numbers* ξ_2', ξ_3' *are prescribed by*

$$\begin{aligned} &\alpha = K_{22}/K_{12} \ \textit{and} \ \sum_{q=1}^{2} K_{pq}\,\beta_q = K_{p3} \ \textit{for}\ p = 2, 3, \\ &\xi_2' \sim \mathcal{N}(0, K_{22} - \alpha^2 K_{11}), \\ &\xi_3' \sim \mathcal{N}(0, K_{33} - \beta_1^2 K_{11} - \beta_2^2 K_{22} - 2\beta_1\beta_2 K_{12}). \end{aligned}$$

viii. *Plug the determined coefficients* $\mathbf{A}_q$ *of* (4.2) *and the correlated noise* $(\boldsymbol{\xi}^{\boldsymbol{\ell}})_i^j$ *of* (4.3) *into the ARMA process* (4.1).

else, $(J^{\boldsymbol{\ell}})_i^j = \emptyset$*:*

Set

$$(\mathbf{w}_f^{\boldsymbol{\ell}})_i^j = \left(\frac{2k^{\boldsymbol{\ell}}}{3}\right)^{1/2} (\boldsymbol{\xi}^{\boldsymbol{\ell}})_i^j \qquad \textit{with}\ (\boldsymbol{\xi}^{\boldsymbol{\ell}})_i^j \sim \mathcal{N}(\mathbf{0}, \mathbf{I}). \tag{4.4}$$

3. *Determine the correlated aerodynamic force*

$$(\mathbf{f}_{cc}^{air})_i^j = \mathbf{f}(\bar{\mathbf{v}}_i^j, \mathbf{t}_i^j) + \mathbf{L}^{air}(\bar{\mathbf{v}}_i^j, \mathbf{t}_i^j, k_i^j)\ |N_i^j|^{-1/2} \sum_{\boldsymbol{\ell}\in N_i^j} (\mathbf{w}_f^{\boldsymbol{\ell}})_i^j. \tag{4.5}$$

ALGORITHM 4.2 (computation of uncorrelated force). *Consider a fixed fiber and a time point that is indicated by the index tuple* $(i, j) \in I_0^n \times I_0^m$. *Set* $\varpi_i^j = \|\bar{\mathbf{v}}_i^j\|_2/(2k_i^j)^{1/2}$, $\omega_i^j = (\bar{v}_{\rm n})_i^j/\bar{v}_{\rm n}^{crit}$ *and let the projectors* $\mathbf{P}$ *depend on space and time discretization. Then, the uncorrelated aerodynamic force is determined by*

$$(\mathbf{f}_{uc}^{air})_i^j = \mathbf{f}(\bar{\mathbf{v}}_i^j, \mathbf{t}_i^j) + \sqrt{\frac{2\pi F_2}{\Delta s \Delta t_j}}\ \frac{(k_i^j)^2}{\epsilon_i^j \sqrt{(\bar{v}_{\rm n})_i^j}}\ \boldsymbol{\phi}_i^j, \tag{4.6}$$

where

$$\boldsymbol{\phi}_i^j = \begin{cases} \nabla_{\mathbf{v}} \mathbf{f}(\bar{\mathbf{v}}_i^j, \mathbf{t}_i^j)\ \mathbf{P}_{(\mathbf{t},\mathbf{n})_i^j}\ \boldsymbol{\xi}_i^j, & \varpi_i^j > 1, \omega_i^j > 1, \\ \nabla_{\mathbf{v}} \mathbf{f}(\bar{\mathbf{v}}_i^j, \mathbf{t}_i^j)\ \Big[(1-\omega_i^j)\sqrt{\omega_i^j}\ \big(\mathbf{P}_{\mathbf{t}_i^j} + (\mathbf{I} - \mathbf{P}_{\mathbf{t}_i^j})/2\big) + \omega_i^j\, \mathbf{P}_{(\mathbf{t},\mathbf{n})_i^j}\Big]\ \boldsymbol{\xi}_i^j, & \\ & \varpi_i^j > 1, \omega_i^j \le 1, \\ \big[(1-\varpi_i^j)\ \big(a_{\mathrm{t}_0}(k_i^j)\ \mathbf{P}_{\mathbf{t}_i^j} + a_{\mathrm{n}_0}(k_i^j)\ \mathbf{P}_{\mathbf{n}_i^j}\big) & \\ \quad + \varpi_i^j\ \nabla_{\mathbf{v}} \mathbf{f}((\varpi_i^j)^{-1}\, \bar{\mathbf{v}}_i^j, \mathbf{t}_i^j)\ \mathbf{P}_{(\mathbf{t},\mathbf{n})_i^j}\big]\ \boldsymbol{\xi}_i^j, & \varpi_i^j \le 1, \omega_i^j > 1, \\ \Big[\big[(1-\varpi_i^j)\, a_{\mathrm{t}_0}(k_i^j)\ \mathbf{I} + \varpi_i^j\ \nabla_{\mathbf{v}} \mathbf{f}((\varpi_i^j)^{-1}\, \bar{\mathbf{v}}_i^j, \mathbf{t}_i^j)\big](1-\omega_i^j)\sqrt{\omega_i^j}\ \mathbf{P}_{\mathbf{t}_i^j} & \\ \quad + (1-\varpi_i^j)\, a_{\mathrm{t}_0}(k_i^j)\, \omega_i^j\ \mathbf{P}_{\mathbf{t}_i^j} & \\ \quad + \big[(1-\varpi_i^j)\, a_{\mathrm{n}_0}(k_i^j)\ \mathbf{I} + \varpi_i^j\ \nabla_{\mathbf{v}} \mathbf{f}((\varpi_i^j)^{-1}\, \bar{\mathbf{v}}_i^j, \mathbf{t}_i^j)\big], & \\ \qquad \Big[(1-\omega_i^j)\sqrt{\omega_i^j}\ (\mathbf{I} - \mathbf{P}_{\mathbf{t}_i^j})/2 + \omega_i^j\ \mathbf{P}_{(\mathbf{t},\mathbf{n})_i^j}\Big] g\Big]\ \boldsymbol{\xi}_i^j, & \varpi_i^j \le 1, \omega_i^j \le 1, \end{cases}$$

and $\boldsymbol{\xi}_i^j \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$; *i.e., the components* $(\xi_l)_i^j \sim \mathcal{N}(0,1)$, $l = 1,2,3,$ *are independent and normally distributed.*

Regarding memory and computational effort, Algorithm 4.1 is extremely costly. Apart from the two searching procedures in steps 1 and 2(b), it requires in general the solving of $|N|$ linear systems of $3|J|$ equations for each fiber and time point specified by (i,j), step 2(c)v. Thereby, the cardinal numbers $|N|$ and $|J|$ depend not only on the fiber dynamics at (i,j), but also crucially on the spatial and temporal grid size, which should be chosen to be a compromise between computational capacity and desirable accuracy of the correlation structures to be realized. The required $3|N|$ Gaussian deviates for step 2(c)vii are here generated by the Box–Muller method [5]. In comparison to Algorithm 4.1, Algorithm 4.2 is obviously enormously cheaper and faster. Its evaluation is independent of the chosen discretization and needs only three Gaussian deviates per fiber and time point.

In case of large-scale resolution, where $N_i^j = \{(i,j)\}$ and $(J^{\boldsymbol{\ell}})_i^j = \emptyset$ for all (i,j) in Algorithm 4.1, the correlated aerodynamic force $\mathbf{f}_{cc}^{air}$ is obviously approximated numerically by the uncorrelated $\mathbf{f}_{uc}^{air}$, since (4.4), (4.5) correspond to the white noise approach of Algorithm 4.2 with $\Delta s \sim l_{\mathrm{T}}$ and $\Delta t \sim t_{\mathrm{T}}$ in (4.6). But, also for fine-scale resolution, the respective numerical representatives match very well as far as their effects on the fiber dynamics are concerned. To show the statistical coincidence of their influence, we analyze the imposed fiber dynamics by means of a curvature measure in the following. Thereby, we restrict the comparison exemplarily on a fixed appropriate fiber discretization because of the extremely long run-time and the enormous memory demands of Algorithm 4.1.

4.2. Results. Simulating the motion of an inextensible slender fiber swinging freely in a turbulent flow field, we show the similarity of the macroscopic effects on the fiber that are caused by the correlated and uncorrelated force model. For this purpose, we introduce the following curvature measure.

DEFINITION 4.1 (curvature measure). *Let* $\mathbf{r}_i^j$, $(i,j) \in \mathcal{I}_0^n \times \mathcal{I}_0^m$, *be the spatially and temporally discretized fiber line that is imposed by the aerodynamic forces according*

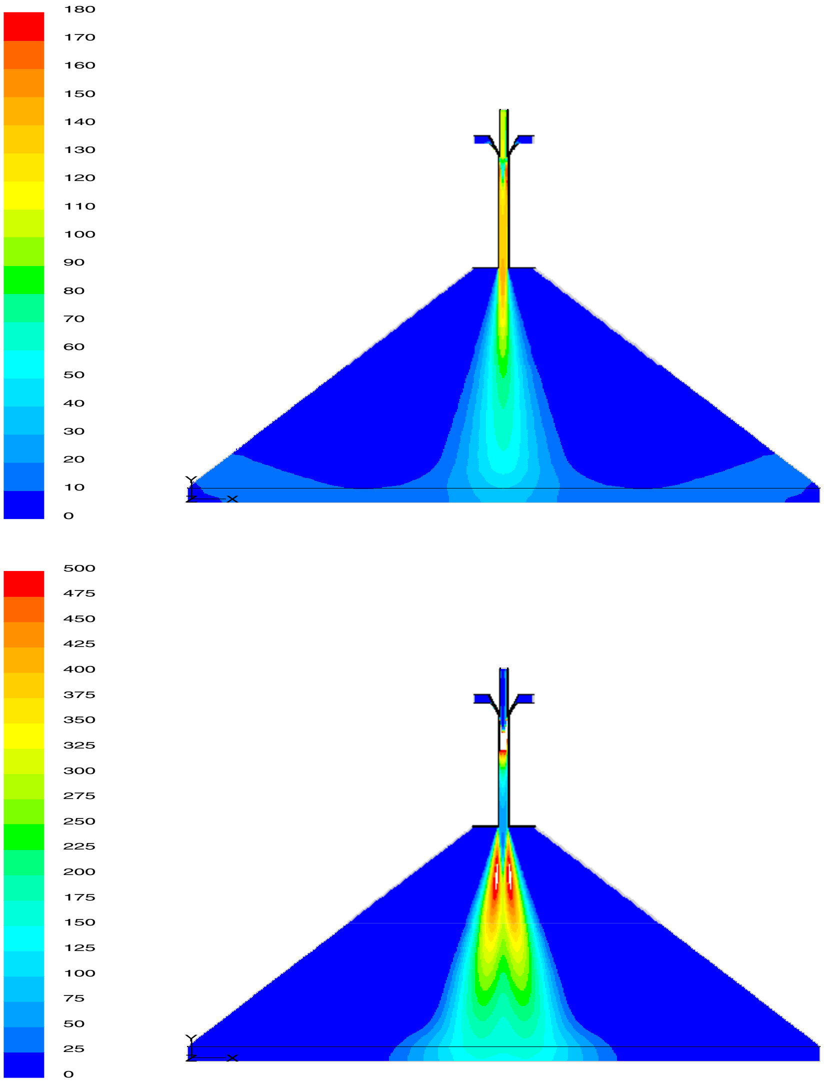

FIG. 4. *k-ϵ simulation results for turbulent flow. Top to bottom: Stationary two-dimensional vertical mean stream $\|\bar{\mathbf{u}}\|_2$, kinetic energy k in SI-units.*

to (1.1), (1.2). *Then, its* curvature measure *at time t_j is defined by*

$$\mathcal{K}^j = \frac{1}{n-1} \sum_{i=1}^{n-1} \|\Delta_{ss} \mathbf{r}_i^j\|_2$$

using the central difference $\Delta_{ss}\mathbf{r}_i^j = (\mathbf{r}_{i+1}^j - 2\mathbf{r}_i^j + \mathbf{r}_{i-1}^j)/\Delta s^2$.

Evaluating the fiber line over a certain time interval gives statistically comparable parameters for $\mathcal{K}$, i.e., its mean μ and its standard deviation σ.

Apart from the similarity, the curvature measure states the significance of the turbulent aerodynamic force for entanglement and loop-forming of the fiber. To illustrate

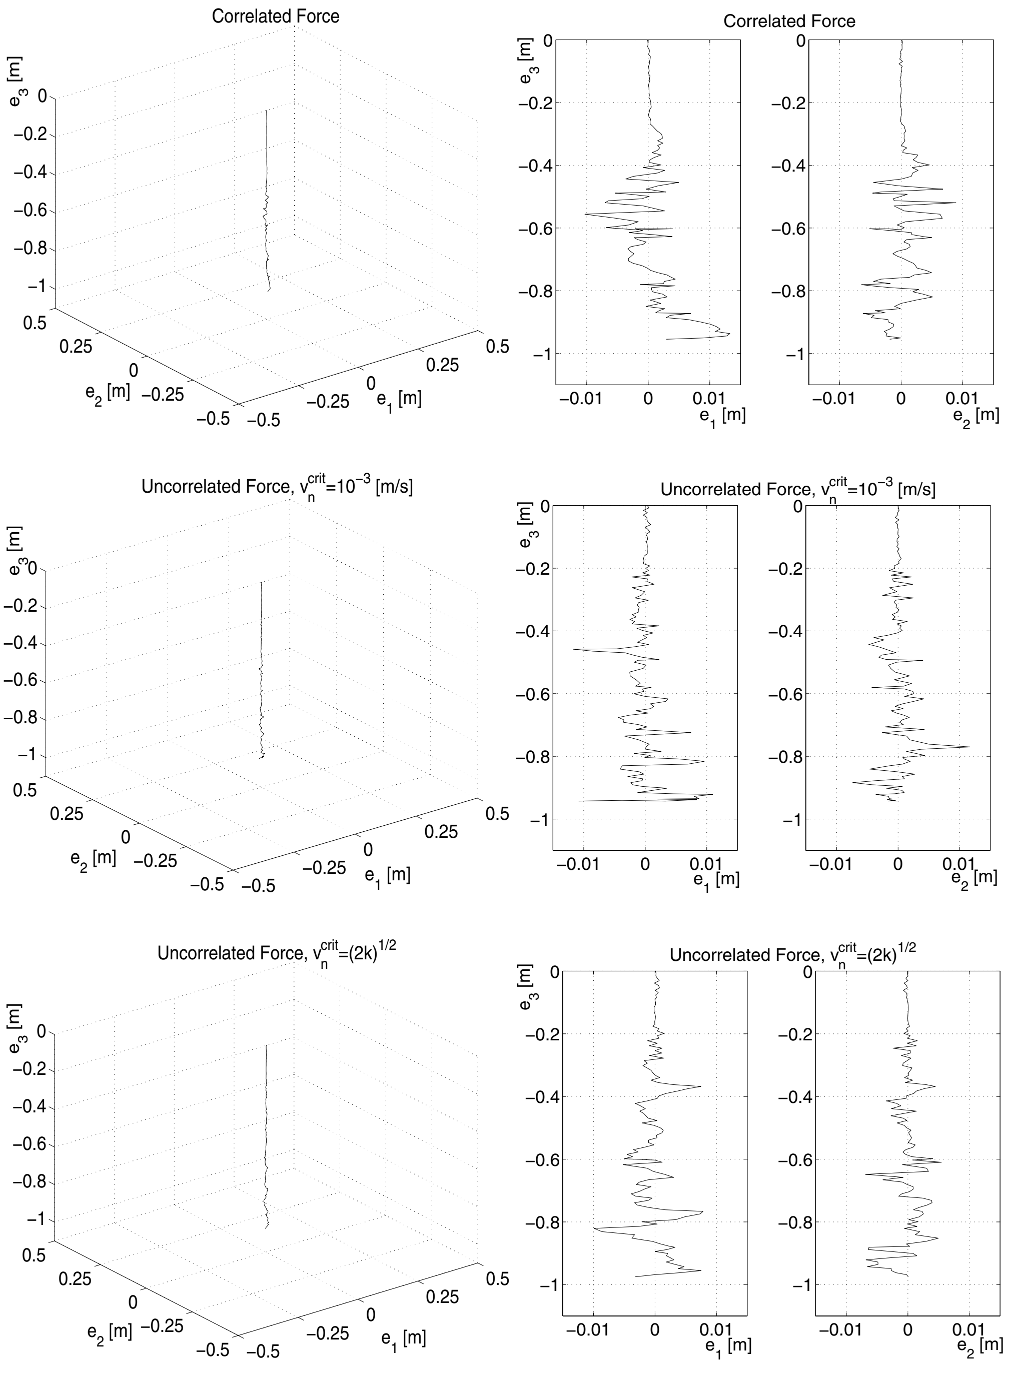

FIG. 5. *From top to bottom: Fiber exposed to* $\mathbf{f}_{cc}^{air}$ *and* $\mathbf{f}_{uc}^{air}$ *with* $\bar{v}_{\mathrm{n}}^{crit} = 10^{-3}$ *m/s, resp.,* $\bar{v}_{\mathrm{n}}^{crit} = (2k)^{1/2}$*. Left: Instantaneous fiber dynamics. Right: Two-dimensional projections zoomed in.*

these effects, we consider a fiber of length $l = 1$ m and material properties according to Table 1 that is initially hanging in the symmetry axis of a stationary, vertically directed two-dimensional mean flow field $\bar{\mathbf{u}}$ (cf. Figure 4). The turbulent fluctuations

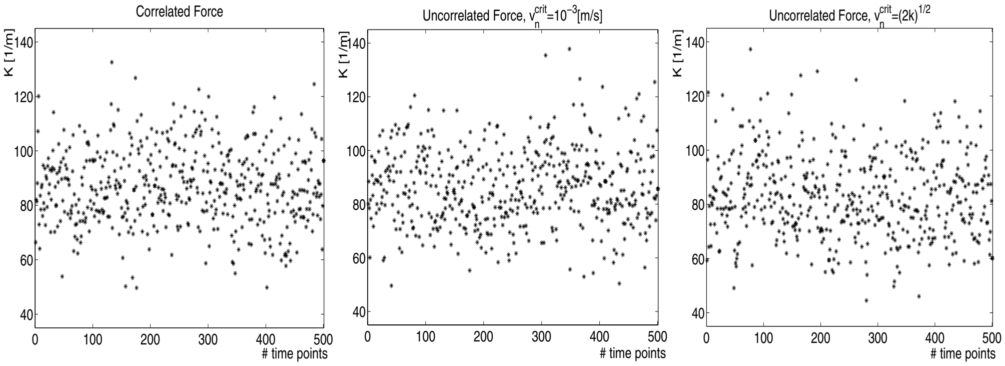

Fig. 6. *Curvature measures $\mathcal{K}$ over 500 time points for fiber exposed to stochastic forces for $5 \cdot 10^{-2}$ s. From left to right: Results for $\mathbf{f}_{cc}^{air}$, $\mathbf{f}_{uc}^{air}$ with $\bar{v}_{\mathrm{n}}^{crit} = 10^{-3}$ m/s, resp., $\bar{v}_{\mathrm{n}}^{crit} = (2k)^{1/2}$.*

are prescribed by the stationary kinetic energy k and dissipation rate ϵ. Then, the resulting deterministic force part $\overline{\mathbf{f}}$ is mainly vertically directed and the stochastic part $\mathbf{f}'$ is determined almost exclusively by the small horizontal fiber oscillations. Hence, if the turbulent influence is neglected, the fiber is not excited out of its position of rest. It has the characteristic curvature properties $\mu = 0$ and $\sigma = 0$ which will prescribe our reference state. The used underlying flow data represent a realistic turbulent stream, as might be expected in the deposition region of a melt-spinning process; see the parameter values in Tables 1 and 2. Note that the illustrated geometry in Figure 4 is distorted in width to stress the flow behavior around the symmetry axis, $\mathbf{e_3}$-axis.

Exposing the fiber to the stochastic force models, we obtain the representatives of a momentary fiber position that are visualized in Figure 5. Apart from the correlated force, we distinguish hereby between the uncorrelated force effects by choosing two variants for $\bar{v}_{\mathrm{n}}^{crit}$, i.e., $\bar{v}_{\mathrm{n}}^{crit} = 10^{-3}$ m/s and $\bar{v}_{\mathrm{n}}^{crit} = (2k)^{1/2}$. At first glance, the behavior of the fibers seems to be straightforward and meaningless due to the chosen draw ratio of meters. But, indeed, all three representatives show similar curvatures, which becomes evident by zooming into the two-dimensional fiber projections; see Figure 5 (right). Near the mounting, they hang down almost straight for the first $2 \cdot 10^{-1}$ m before they start to form loops. The observed oscillations then have a typical range of 10^{-3} up to 10^{-2} m, which corresponds with our asymptotic analysis of section 2.2; see Figure 2. Considering the respective fiber motions for a period of $5 \cdot 10^{-2}$ s, we provide further results by the curvature measures $\mathcal{K}$ that are plotted and statistically evaluated for comparable samples of 500 time points; see Figure 6 and Table 3. Thereby, all temporal evolutions turn out to be normally distributed. The mean curvature measure of the uncorrelated force, $\bar{v}_{\mathrm{n}}^{crit} = 10^{-3}$ m/s, differs less than 1% from that of the correlated force. Also, the standard deviations fit very well, and we obtain differences of only 2%. This shows very good agreement. This choice of $\bar{v}_{\mathrm{n}}^{crit}$ overcomes simply the singularity stemming from the underlying correlated frozen turbulence pattern and therefore yields better approximation properties than the other variant that additionally incorporates the decay of the vortices.

Summing up, the uncorrelated force model is undeniably a good substitute for the correlated one on the macroscopic fiber scale. Leading to a statistically similar fiber behavior, it requires—instead of days—only a few minutes of computational time for the simulation of $5 \cdot 10^{-2}$ s real time motion. Thus, it makes long-time fiber studies possible, which is essential for practical application. Note that for the computation

Table 3
Statistic parameters for the curvature measures $\mathcal{K}$ of Figure 6.

Stochastic force	Correlated	Uncorrelated		Without
		$\bar{v}_{\mathrm{n}}^{crit} = 10^{-3}$[m/s]	$\bar{v}_{\mathrm{n}}^{crit} = (2k)^{1/2}$	
$\mathcal{K}$ [1/m]				
μ	86.93 (100%)	86.33 (−0.69%)	82.99 (−4.53%)	0

CPU-time	Days	∼4.5 min	∼4 min	∼1.5 min

of the deterministic reference case, Algorithm 4.2 is not needed. Moreover, due to the absence of stochastic forces, a larger (adaptive) time step can be used. The increase of Δt by one order, up to $\Delta t \sim 10^{-5}$ s, together with the skipping of Algorithm 4.2, leads to the bisection of the CPU-time observed in Table 3. Thus, it takes only 1.5 min CPU-time instead of 4 min as in the turbulent cases. All calculations have been performed on an Intel Xeon processor, 2.8 GHz.

5. Conclusions. In [13], a general aerodynamic force concept is derived on the basis of a stochastic k-ϵ turbulence model for the flow field. The turbulence effects on the dynamics of a long slender elastic fiber are modeled by a correlated Gaussian force and in its asymptotic limit on a macroscopic fiber scale by Gaussian white noise with flow-dependent amplitude. Choosing a specific Taylor drag model, this paper has shown the applicability of the force concept for the handling of the complex fiber-turbulence interactions as they occur in a typical melt-spinning process of nonwoven materials. Moreover, it has stated the very good theoretical and numerical approximation properties of the uncorrelated force. The introduction of the uncorrelated aerodynamic force changes the character of the perturbation term into a localized linear integrator such that the fiber dynamics is described by a system of partial differential equations with additive Gaussian white noise. This enables not only a theoretical analysis but also an efficient numerical realization. Adapting the fiber system with appropriate boundary and initial conditions, the FIber DYnamics Simulation Tool (FIDYST) [8] developed at Fraunhofer ITWM, Kaiserslautern, applies the presented algorithm to simulate the turbulent deposition region of melt-spinning processes with hundreds of individual endless fibers. The simulation results are validated with experimental data. However, note that for this purpose, further aspects have to be taken into account, such as fiber-fiber interactions, sticky fiber bunches, conveyor belt effects, or the affection of the turbulence by higher concentrated fiber curtains.

ANISOTROPY RECONSTRUCTION FROM WAVE FRONTS IN TRANSVERSELY ISOTROPIC ACOUSTIC MEDIA[*]

JOYCE R. MCLAUGHLIN[†], DANIEL RENZI[†], AND JEONG-ROCK YOON[‡]

Abstract. This paper considers an inverse problem for a transversely isotropic three-dimensional acoustic medium, where there is one preferred direction called the fiber direction along which the wave propagates fastest and there is no preferred wave propagation direction in the isotropic plane, which is the plane orthogonal to the fiber direction. In this medium the parameters to be recovered are (1) the wave speed for a wave propagating in the direction along the fiber; (2) the wave speed for a wave propagating in any direction which is orthogonal to the fiber direction; and (3) the unit fiber direction itself. So four scalar functions are to be recovered. The data are the positions of four distinct wave fronts as the corresponding waves propagate through the medium. The mathematical relation, which is the Eikonal equation, between the wave front locations and the four unknown functions, is nonlinear. Here it is established, perhaps surprisingly, that corresponding to the given data set, there can be up to four possible solution quadruples. We present and implement an algorithm to compute each of the possible solutions and show our selection criteria to obtain the correct solution. The Eikonal equation, which relates the wave front positions to the unknown functions, is the same equation obtained for the horizontally polarized shear wave (SH wave) which propagates in a linear elastic system.

Key words. elastography, inverse problem, arrival time, anisotropic wave equation, transversely isotropic medium, fiber direction

1. Introduction.

Motivated by wave propagation directional dependence in tissue, the goal of this paper is to identify directionally dependent stiffness properties from multiple wave fronts. The wave propagation model is an anisotropic wave equation, where the medium has one preferred direction, which we designate as the *fiber direction*, where it has a faster wave speed and the waves propagating in the plane orthogonal to this preferred direction are slower and exhibit no directional dependence. Our goal is the recovery of the unit fiber direction and the ratio of each of two distinct stiffness coefficients to the density. The square roots of these two ratios define the wave speed in the fiber direction and in the plane orthogonal to the fiber. We show that in three dimensions there can be up to four discrete solution triples of two wave speeds and the fiber direction, from four distinct wave fronts. The fact that there is a discrete set of solutions is a direct result of the nonlinear relations, governed by the Eikonal equation, between wave front directions, wave speeds, and the fiber direction.

Shear stiffness recovery has been of interest for about 15 years, and several experiments are being investigated as follows:

(1) tissue that is compressed as stiff tissue compresses less [4, 17];
(2) single frequency excitation, where stiff tissue exhibits low amplitude and stiffness characteristics can be recovered from amplitude variations [8, 15, 19, 20];
(3) crawling or holographic waves, which are produced with excitations at two nearby frequencies, and where phase wave speed can be recovered [14, 22];
(4) interior radiation force excitation at a single point produced by a single ultrasound beam [16];
(5) interior radiation force excitation produced with two ultrasound beams whose excitation frequency difference is in the KHz range [7];
(6) tissue surface line sources, or *supersonic imaging* that effectively produce line sources orthogonal to the tissue surface and produce propagating waves with identifiable fronts [2, 3]; the propagating front locations can be utilized to recover tissue properties.

In each of the above six cases the goal is to image either (a) shear wave speed which is roughly 3 m/sec in normal isotropic tissue and can more than double in abnormal tissue; or (b) shear stiffness which can increase more than four times in abnormal tissue. The goal is to identify abnormal inclusions, which are tumors.

Here we utilize the supersonic imaging experiment, in which a line source is approximated by a set of interior radiation force pushes, produced by focused ultrasound beams all at the same frequency, and made successively along a line. This effectively induces a conical wave in three dimensions whose angle with the line of the source is determined by how fast the succession of pushes is made and whether or not the pushes begin deep in the tissue and move successively toward the surface or vice versa; see Figure 1.1.

Our goal in this paper is to recover anisotropic tissue properties. Our motivations are (a) that some normal, e.g., muscle, tissue is anisotropic and so mathematical models must include this property; and (b) that it has been conjectured [18, 21] that benign and cancerous tumors may have their own distinguishing anisotropic properties. If indeed the latter conjecture is true, the recovery of anisotropic tumor properties could be of considerable medical importance.

To give some background about what is known in the isotropic case, for contrast with the anisotropic case, we recall that previously we established uniqueness

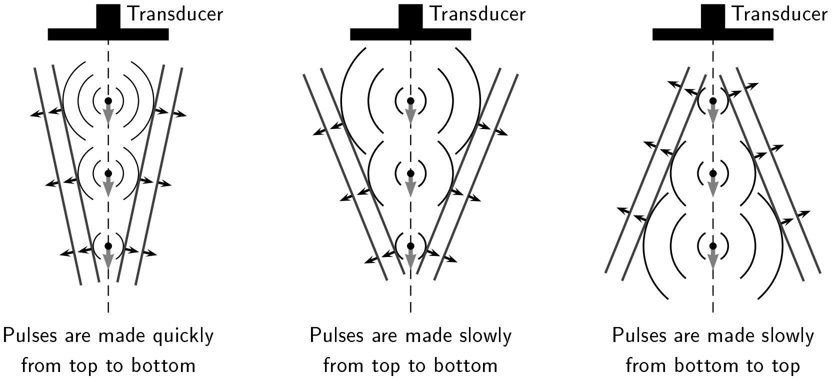

FIG. 1.1. *Illustration of three possible conical wave fronts (two-dimensional view) produced by a succession of interior radiation force pushes. A transducer focuses ultrasound beams to produce interior radiation force pushes and changes focal depth successively, either from top to bottom or vice versa.*

results [10, 11], and the *arrival time algorithm* [10, 12, 13], to reconstruct wave speed in isotropic media. There we showed that the positions of one propagating front established the wave speed uniquely, and that there is at most one pair of the shear stiffness μ and the density ρ, corresponding to a given single displacement data as a function of space and time, provided the medium is initially at rest. In this paper, we establish that four distinct wave fronts in three dimensions yield up to four triples: two distinguishing wave speeds and a fiber direction. We note also that if we are given one of the possible triples and the solution of the anisotropic wave equation (as opposed to only the wave front positions), then also there is at most one density ρ corresponding to that triple.

Our paper is organized as follows. In section 2 we establish that our model has finite propagation speed, that Lipschitz continuous fronts, defined by their arrival times, satisfy an anisotropic Eikonal equation, and we refer to our very recent result that establishes that arrival times are actually Lipschitz continuous; in section 3 we give our analysis that there can be up to four discrete solution triples corresponding to four distinct wave fronts; and in section 4 we show numerical results that includes recoveries of an anisotropic inclusion embedded in an isotropic background.

2. Anisotropic acoustic models. We consider anisotropic models, where the wave speed represented by $\sqrt{c_{44}/\rho}$ in one preferred direction, which we call the fiber direction, $\vec{f}$, is larger than the wave speed $\sqrt{c_{66}/\rho}$ in the plane orthogonal to the fiber direction. In this plane, which we call the isotropic plane, the wave speed is independent of direction. Our language and notation here are consistent with SH-wave propagation in incompressible transversely isotropic linear elastic models, which we will consider in a later paper.

Let Ω be a bounded $\mathcal{C}^2$ open connected subset in $\mathbb{R}^n$ for $n = 2, 3$. Assume

$$\begin{aligned} &\rho \in \mathcal{C}^0(\bar{\Omega}),\ M \in \left[\mathcal{C}^1(\bar{\Omega})\right]^{n\times n} \text{ is a symmetric matrix function, and} \\ &\exists \alpha_0 > 0 \text{ such that } \rho(x) \ge \alpha_0, \quad \vec{v}\cdot M(x)\vec{v} \ge \alpha_0|\vec{v}|^2 \quad \forall x \in \bar{\Omega},\ \forall \vec{v} \in \mathbb{R}^n. \end{aligned} \tag{2.1}$$

Then our anisotropic wave propagation model is

$$\nabla\cdot(M\nabla u) = \rho u_{tt} \quad \text{in } \Omega\times(0,T) \tag{2.2}$$

with homogeneous initial condition, $u(x,0) = u_t(x,0) = 0$ in Ω, and the boundary condition is either Dirichlet or Neumann; $u|_{\partial\Omega\times(0,T)} = g$ or $(\nu\cdot M\nabla u)|_{\partial\Omega\times(0,T)} = h$, where ν is the unit outward normal to $\partial\Omega$. This is an anisotropic extension of the frequently used isotropic elastography model; see [1]. We refer the reader to [6] for techniques to establish existence and uniqueness for the initial-boundary value problem associated with (2.2).

Remark 1. In terms of the SH-wave motivated assumptions mentioned above, the stiffness matrix M is represented by

$$M = c_{66}I + (c_{44} - c_{66})\vec{f}\otimes\vec{f}, \tag{2.3}$$

where $|\vec{f}| = 1$, $c_{44} > c_{66} > 0$ in $\bar{\Omega}$, and I and $\otimes$ denote the identity matrix and tensor product, respectively. Here our assumption that $c_{44} > c_{66}$ is natural since in biological tissue, e.g., muscle tissue, the wave speed is fastest in the direction aligned with the fibers [9].

Since our medium is initially at rest, the wave propagates into the medium from the boundary with a propagating front. In our next two theorems, following [10, 11], we establish that the wave whose propagation is governed by the above model has (1) finite propagation speed, and (2) an arrival time, which we assume to be Lipschitz continuous, that, under this assumption, satisfies the Eikonal equation.

THEOREM 2. *Assume ρ and M satisfy* (2.1). *Let $u \in H^2(\Omega \times (0,T))$ be a solution of* (2.2). *Then for any open ball $B_\epsilon(x_0) \subset \Omega$, u has a finite propagation speed in $B_\epsilon(x_0) \times (0,T)$ with the maximum speed*

$$c = \sup_{x \in B_\epsilon(x_0)} \sqrt{\sigma_M(x)/\rho(x)},$$

where $\sigma_M(x)$ is the largest eigenvalue of $M(x)$.

The proof of the above theorem is along the same lines as that in the isotropic case (Theorem 3.4 in [11]), once we redefine the energy by

$$e(s) := \frac{1}{2} \int_{C_s} \left\{ \rho |u_t|^2 + \nabla u \cdot M \nabla u \right\} dx, \quad C_s := B_{\epsilon - cs}(x_0) \times \{t = t_0 + s\}.$$

So we omit the proof.

As in [10] we define the *arrival time*, $\hat{T}(x)$, of the wave as

$$\hat{T}(x) := \inf\{t \in (0,T) : |u(x,t)| > 0\}, \quad x \in \Omega_{u \neq 0}, \tag{2.4}$$

where $\Omega_{u\neq 0} := \{x \in \Omega\ : u(x,t) \neq 0 \text{ for some } t \in (0,T)\}$, and we assume the solution u of (2.2) is continuous. If $\hat{T} \in \mathcal{C}^1(\Omega)$, then existing unique continuation results would apply to show that the arrival time, $\hat{T}$, satisfies the Eikonal equation given below. Since our target medium is inhomogeneous, we then expect waves originating at more than one point on the boundary to arrive simultaneously at the same interior points of Ω. In this case, $\hat{T}(x)$ could have *kinks* or at least be nondifferentiable there. Hence we assume $\hat{T}(x)$ is Lipschitz continuous and establish the following theorem.

THEOREM 3. *Assume $\rho \in \mathcal{C}^1(\bar{\Omega})$ in addition to* (2.1). *Let $u \in H^2(\Omega \times (0,T)) \cap \mathcal{C}^0(\Omega \times (0,T))$ be a solution of* (2.2) *with $u(x,0) = u_t(x,0) = 0$ in Ω, and either of the following Dirichlet or Neumann boundary conditions: $u|_{\partial\Omega \times (0,T)} = g$ or $(\nu \cdot M\nabla u)|_{\partial\Omega\times(0,T)} = h$. Suppose further that the arrival time $\hat{T} : \Omega_{u\neq 0} \to [0,T]$ is Lipschitz continuous. Then $\hat{T}$ satisfies the Eikonal equation*

$$\rho = \nabla \hat{T} \cdot M \nabla \hat{T} \quad a.e.\ in\ \Omega_{u\neq 0}. \tag{2.5}$$

In particular, when M is given in the form of (2.3), *our Eikonal equation becomes*

$$\frac{1}{|\nabla \hat{T}|^2} = \frac{c_{66}}{\rho} + \left(\frac{c_{44}}{\rho} - \frac{c_{66}}{\rho}\right) \left| \frac{\nabla \hat{T}}{|\nabla \hat{T}|} \cdot \vec{f} \right|^2. \tag{2.6}$$

Proof. Since $\hat{T}$ is Lipschitz continuous, $\nabla \hat{T}$ is well defined almost everywhere. Note that (2.5) is merely a necessary condition for $t = \hat{T}(x)$ to be a characteristic surface with respect to the hyperbolic equation $\rho u_{tt} = \nabla \cdot (M \nabla u)$. If we suppose that $t = \hat{T}(x)$ is a noncharacteristic surface, we can draw a contradiction, as done in Theorem 2.10 in [10], which is based on Theorem 3.6 in [5] and a lemma on page 544 of [6]. See [10] for the details. □

Remark 4. In fact, $\hat{T}$ according to the definition (2.4) may be discontinuous even if the solution u is infinitely smooth. However, in this paper we adopt this definition to make arguments simpler and clearer. Modifying the definition of arrival time by

$$\hat{T}(x) := \inf\{t \in (0,T] : ||u||_{L^2(V\times(0,t))} > 0\ \forall \text{ open } V \subset \Omega \text{ with } x \in V\}, \quad x \in \Omega \setminus \Omega_E,$$

where $\Omega_E := \bigcup\{V \subset \Omega$ is an open set satisfying $||u||_{L^2(V\times(0,T))} = 0\}$, we have recently established that $\hat{T} : \Omega \setminus \Omega_E \to (0, T]$ is actually Lipschitz continuous. This result will be addressed soon.

Note that in the anisotropic case, the wave does not always propagate in the direction orthogonal to the wave front (*group* or *ray* velocity is not always the same as *phase* velocity). Nevertheless, under the assumption that $\hat{T}(x)$ is Lipschitz continuous, the phase wave speed, $c(x)$, in the direction orthogonal to the front, satisfies

$$c(x)|\nabla\hat{T}| = 1, \qquad c(x) = c\left(x, \nabla\hat{T}\right), \tag{2.7}$$

and can be determined by the methods given in [10, 12, 13]. In later sections, we will assume that this speed, $c(x)$, has been determined from $\hat{T}$ so when we solve the inverse problem,

$$\text{find } (c_{66}/\rho, c_{44}/\rho, \vec{f}) \text{ from multiple arrival times,}$$

we will assume we know both $\hat{T}(x)$ and $c(x)$.

Remark 5. In a later paper we will consider a transversely isotropic elastic medium. Note that then (2.6) will be the Eikonal equation with M defined as in (2.3), satisfied by the SH-wave phase $\psi(x)$ in a geometric optics expansion, $\vec{u} = \vec{a}e^{i\omega(t-\psi(x))}$, where $\vec{a} = \vec{a}_0 + \frac{1}{i\omega}\vec{a}_1 + \frac{1}{(i\omega)^2}\vec{a}_2 + \cdots$ is an asymptotic series with $\omega \gg 1$.

3. Reconstruction using four measurements.

Having established the intrinsically nonlinear Eikonal equations (2.6) and (2.7) in section 2, we address the utilization of these equations to recover the three unknown quantities $(c_{66}/\rho, c_{44}/\rho, \vec{f})$ from wave fronts $\hat{T}$. Since $|\vec{f}| = 1$, this means that in three dimensions we have four scalar functions to recover. It is natural then to investigate the inverse problem,

$$\text{find } \left(\frac{c_{66}}{\rho}, \frac{c_{44}}{\rho}, \vec{f}\right) \text{ from four distinct wave fronts } \{\hat{T}_j\}_{j=1}^4. \tag{3.1}$$

Perhaps surprisingly, our analysis establishes that we can have a finite discrete (up to four) set of triples that correspond to given four distinct propagating wave fronts. We make this statement more precise below.

Let $\{\hat{T}_j\}_{j=1}^4$ be four given arrival time data. Define the unit wave normal and the corresponding phase wave speed by $\vec{n}_j := \nabla\hat{T}_j/|\nabla\hat{T}_j|$ and $c_j := 1/|\nabla T_j|$, respectively. Recall c_j can be estimated by solving (2.7) based on the methods given in [10, 12, 13]. Then the Eikonal equation (2.6) becomes

$$c_j^2 = \tilde{c}_{66} + (\tilde{c}_{44} - \tilde{c}_{66})|\vec{f}\cdot\vec{n}_j|^2, \quad j = 1, 2, 3, 4, \tag{3.2}$$

where we define $\tilde{c}_{66} := c_{66}/\rho$ and $\tilde{c}_{44} := c_{44}/\rho$ for convenience. As described in section 2, we are assuming $\tilde{c}_{44} > \tilde{c}_{66}$, which is a reasonable assumption, as the fiber in biological tissue is normally stiffer than the background matrix. Thus $\tilde{c}_{44}$ and $\tilde{c}_{66}$ are the upper and lower bounds of all possible c_j^2, respectively. So we can define $d_j := \sqrt{c_j^2 - \tilde{c}_{66}} \geq 0$ and $\vec{g} := \sqrt{\tilde{c}_{44} - \tilde{c}_{66}}\vec{f} \neq 0$, and from (3.2) we establish linear relations for $\vec{g}$,

$$\vec{g}\cdot\vec{n}_j = \pm d_j, \quad j = 1, 2, 3, 4. \tag{3.3}$$

Then our task is to determine $(\tilde{c}_{66}, \vec{g})$ from the data $\{(\vec{n}_j, c_j)\}_{j=1}^4$. Once we determine $\tilde{c}_{66}$, knowing $\vec{g}$ is equivalent to knowing $\tilde{c}_{44}$ and $\vec{f}$, since $\tilde{c}_{44} = \tilde{c}_{66} + |\vec{g}|^2$ and $\vec{f} = \vec{g}/|\vec{g}|$.

In this section, we will show that $\tilde{c}_{66}$ is a root of a fourth order polynomial $p(x)$ (Theorem 13), and hence we may have four possible $\tilde{c}_{66}$. For each $\tilde{c}_{66}$, we have a *generic* uniqueness to determine $\vec{g}$ (Corollary 20) and an explicit formula for $\vec{g}$ (Theorem 14). So we will have at most four possible solutions $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$. Since $\tilde{c}_{66}$ can be a multiple root of $p(x)$, despite the generic uniqueness, it may look like we have multiple $\tilde{c}_{44}$ and $\vec{f}$ corresponding to a single $\tilde{c}_{66}$ (Theorems 15 and 17). However, to realize this special case, the data $\{(\vec{n}_j, c_j)\}_{j=1}^4$ must satisfy one of a very special set of conditions (3.10)–(3.12) that are unlikely to occur in the actual experiments.

3.1. Coordinate system and data preparation. For convenience, we assume we have a *well prepared* data set, defined below, and fix an appropriate coordinate system, defined as follows.

DEFINITION 6. *We define two concepts for our data and a coordinate system.*

(a) *Data* $\{(\vec{n}_j, c_j)\}_{j=1}^4$ *are called compatible if* $c_1 > c_2 > c_3 > c_4 > 0$ *and all of the following are not vanishing:*

$$\widehat{D}_1 := \det(\vec{n}_2, \vec{n}_3, \vec{n}_4), \quad \widehat{D}_2 := \det(\vec{n}_1, \vec{n}_3, \vec{n}_4),$$
$$\widehat{D}_3 := \det(\vec{n}_1, \vec{n}_2, \vec{n}_4), \quad \widehat{D}_4 := \det(\vec{n}_1, \vec{n}_2, \vec{n}_3),$$

where det *denotes the determinant of a matrix consisting of three vectors. This means that at any given point the normals to any three of the four wave fronts are linearly independent.*

(b) *Data* $\{\vec{n}_j, c_j\}_{j=1}^4$ *are called well prepared if they are compatible and* $\vec{n}_3$, $\vec{n}_4$ *are oriented so that* $\widehat{D}_3 > 0$ *and* $\widehat{D}_4 > 0$.

(c) *For convenience, set the coordinate system* $\{\vec{e}_1, \vec{e}_3, \vec{e}_3\}$ *utilizing* $\vec{n}_1$ *and* $\vec{n}_2$ *by*

$$\vec{e}_1 := \vec{n}_1, \quad \vec{e}_2 := \frac{\vec{n}_2 - (\vec{n}_1 \cdot \vec{n}_2)\vec{n}_1}{|\vec{n}_1 \times \vec{n}_2|}, \quad \vec{e}_3 := \frac{\vec{n}_1 \times \vec{n}_2}{|\vec{n}_1 \times \vec{n}_2|}.$$

Since $-\vec{n}_3$ and $-\vec{n}_4$ also satisfy (3.3), any compatible data can be processed into well prepared data. For well prepared data, we have

$$\vec{n}_1 = \vec{e}_1, \qquad \vec{n}_2 = (\vec{n}_1 \cdot \vec{n}_2)\vec{e}_1 + |\vec{n}_1 \times \vec{n}_2|\vec{e}_2,$$
$$\vec{n}_3 = (\vec{n}_1 \cdot \vec{n}_3)\vec{e}_1 + \frac{(\vec{n}_1 \times \vec{n}_2) \cdot (\vec{n}_1 \times \vec{n}_3)\vec{e}_2}{|\vec{n}_1 \times \vec{n}_2|} + \frac{\widehat{D}_4 \vec{e}_3}{|\vec{n}_1 \times \vec{n}_2|} =: \alpha_3 \vec{e}_1 + \beta_3 \vec{e}_2 + \gamma_3 \vec{e}_3,$$
$$\vec{n}_4 = (\vec{n}_1 \cdot \vec{n}_4)\vec{e}_1 + \frac{(\vec{n}_1 \times \vec{n}_2) \cdot (\vec{n}_1 \times \vec{n}_4)\vec{e}_2}{|\vec{n}_1 \times \vec{n}_2|} + \frac{\widehat{D}_3 \vec{e}_3}{|\vec{n}_1 \times \vec{n}_2|} =: \alpha_4 \vec{e}_1 + \beta_4 \vec{e}_2 + \gamma_4 \vec{e}_3.$$

Here we have $\gamma_3, \gamma_4 > 0$.

3.2. Lemmas based on two or three measurements. Two lemmas using only two or three measurements are presented to show what information can be obtained with the limited data sets.

LEMMA 7 (two measurements). *Using only two data* $\{(\vec{n}_j, c_j)\}_{j=1}^2$, $\tilde{c}_{66}$ *can be any arbitrary number in* $(0, c_2^2]$, *and the first two components of* $\vec{g} = \vec{g}(\tilde{c}_{66})$ *are determined up to four possibilities in terms of* $\tilde{c}_{66}$ *and the measured data*:

$$(\vec{g} \cdot \vec{e}_1, \vec{g} \cdot \vec{e}_2) = \pm \left(d_1, \frac{-d_2 - d_1(\vec{n}_1 \cdot \vec{n}_2)}{|\vec{n}_1 \times \vec{n}_2|} \right) \quad or \quad \pm \left(d_1, \frac{d_2 - d_1(\vec{n}_1 \cdot \vec{n}_2)}{|\vec{n}_1 \times \vec{n}_2|} \right),$$

where $d_1 = \sqrt{c_1^2 - \tilde{c}_{66}}$ *and* $d_2 = \sqrt{c_2^2 - \tilde{c}_{66}}$.

Proof. From (3.3) for $j = 1, 2$ we have $\vec{g} \cdot \vec{e}_1 = \vec{g} \cdot \vec{n}_1 = \pm d_1$ and

$$\pm d_2 = \vec{g} \cdot \vec{n}_2 = \vec{g} \cdot \left[(\vec{n}_1 \cdot \vec{n}_2)\vec{e}_1 + |\vec{n}_1 \times \vec{n}_2| \vec{e}_2 \right] = (\vec{n}_1 \cdot \vec{n}_2)(\vec{g} \cdot \vec{e}_1) + |\vec{n}_1 \times \vec{n}_2|(\vec{g} \cdot \vec{e}_2).$$

Thus we get $\vec{g} \cdot \vec{e}_2 = \frac{\pm d_2 - (\vec{n}_1 \cdot \vec{n}_2)(\vec{g} \cdot \vec{e}_1)}{|\vec{n}_1 \times \vec{n}_2|}$, which completes the proof. □

LEMMA 8 (three measurements). *Using only three data* $\{(\vec{n}_j, c_j)\}_{j=1}^3$, $\tilde{c}_{66}$ *can be any arbitrary number in* $(0, c_3^2]$, *and* $\vec{g} = \vec{g}(\tilde{c}_{66})$ *is determined up to four possibilities in terms of* $\tilde{c}_{66}$ *and the measured data*:

$$\vec{g}_1 = d_1\vec{e}_1 + \eta\vec{e}_2 + \tfrac{1}{\gamma_3}(d_3 - \omega)\vec{e}_3, \qquad \vec{g}_2 = -d_1\vec{e}_1 - \eta\vec{e}_2 + \tfrac{1}{\gamma_3}(d_3 + \omega)\vec{e}_3,$$
$$\vec{g}_3 = d_1\vec{e}_1 + \tilde{\eta}\vec{e}_2 + \tfrac{1}{\gamma_3}(d_3 - \tilde{\omega})\vec{e}_3, \qquad \vec{g}_4 = -d_1\vec{e}_1 - \tilde{\eta}\vec{e}_2 + \tfrac{1}{\gamma_3}(d_3 + \tilde{\omega})\vec{e}_3,$$

where $d_j = \sqrt{c_j^2 - \tilde{c}_{66}}$ *for* $j = 1, 2, 3$, $\eta = \frac{-d_2 - d_1(\vec{n}_1 \cdot \vec{n}_2)}{|\vec{n}_1 \times \vec{n}_2|}$, $\tilde{\eta} = \frac{d_2 - d_1(\vec{n}_1 \cdot \vec{n}_2)}{|\vec{n}_1 \times \vec{n}_2|}$, $\omega = d_1\alpha_3 + \eta\beta_3$, *and* $\tilde{\omega} = d_1\alpha_3 + \tilde{\eta}\beta_3$. *Note that* $\vec{g}_k \cdot \vec{n}_3 = d_3 > 0$, $k = 1, 2, 3, 4$.

Proof. From (3.3) for $j = 3$ we get $\pm d_3 = \vec{g} \cdot \vec{n}_3 = \alpha_3(\vec{g} \cdot \vec{e}_1) + \beta_3(\vec{g} \cdot \vec{e}_2) + \gamma_3(\vec{g} \cdot \vec{e}_3)$. From Lemma 7 we get

$$\vec{g} \cdot \vec{e}_3 = \begin{cases} \frac{1}{\gamma_3}(\pm d_3 - \alpha_3 d_1 - \beta_3\eta) = \frac{1}{\gamma_3}(\pm d_3 - \omega) & \text{if } (\vec{g} \cdot \vec{e}_1, \vec{g} \cdot \vec{e}_2) = (d_1, \eta), \\ \frac{1}{\gamma_3}(\pm d_3 + \alpha_3 d_1 + \beta_3\eta) = \frac{1}{\gamma_3}(\pm d_3 + \omega) & \text{if } (\vec{g} \cdot \vec{e}_1, \vec{g} \cdot \vec{e}_2) = -(d_1, \eta), \\ \frac{1}{\gamma_3}(\pm d_3 - \alpha_3 d_1 - \beta_3\tilde{\eta}) = \frac{1}{\gamma_3}(\pm d_3 - \tilde{\omega}) & \text{if } (\vec{g} \cdot \vec{e}_1, \vec{g} \cdot \vec{e}_2) = (d_1, \tilde{\eta}), \\ \frac{1}{\gamma_3}(\pm d_3 + \alpha_3 d_1 + \beta_3\tilde{\eta}) = \frac{1}{\gamma_3}(\pm d_3 + \tilde{\omega}) & \text{if } (\vec{g} \cdot \vec{e}_1, \vec{g} \cdot \vec{e}_2) = -(d_1, \tilde{\eta}). \end{cases}$$

Thus we have eight possibilities:

$$\begin{pmatrix} \vec{g} \cdot \vec{e}_1 \\ \vec{g} \cdot \vec{e}_2 \\ \vec{g} \cdot \vec{e}_3 \end{pmatrix} = \begin{pmatrix} d_1 \\ \eta \\ \frac{d_3 - \omega}{\gamma_3} \end{pmatrix}, \begin{pmatrix} -d_1 \\ -\eta \\ \frac{d_3 + \omega}{\gamma_3} \end{pmatrix}, \begin{pmatrix} d_1 \\ \tilde{\eta} \\ \frac{d_3 - \tilde{\omega}}{\gamma_3} \end{pmatrix}, \begin{pmatrix} -d_1 \\ -\tilde{\eta} \\ \frac{d_3 + \tilde{\omega}}{\gamma_3} \end{pmatrix},$$
$$\begin{pmatrix} d_1 \\ \eta \\ \frac{-d_3 - \omega}{\gamma_3} \end{pmatrix}, \begin{pmatrix} -d_1 \\ -\eta \\ \frac{-d_3 + \omega}{\gamma_3} \end{pmatrix}, \begin{pmatrix} d_1 \\ \tilde{\eta} \\ \frac{-d_3 - \tilde{\omega}}{\gamma_3} \end{pmatrix}, \begin{pmatrix} -d_1 \\ -\tilde{\eta} \\ \frac{-d_3 + \tilde{\omega}}{\gamma_3} \end{pmatrix}.$$

Since the second line is the same as the first line with opposite sign, which gives the same fiber direction ($\vec{g}$ and $-\vec{g}$) in transversely isotropic media, we select the first line that satisfies $\vec{g} \cdot \vec{n}_3 = d_3 > 0$, and label the four triples in that line as $\vec{g}_1$, $\vec{g}_2$, $\vec{g}_3$, $\vec{g}_4$. □

Remark 9. Note that $(\vec{g}_1 \cdot \vec{n}_k)_{k=1}^3 = (d_1, -d_2, d_3)$, $(\vec{g}_2 \cdot \vec{n}_k)_{k=1}^3 = (-d_1, d_2, d_3)$, $(\vec{g}_3 \cdot \vec{n}_k)_{k=1}^3 = (d_1, d_2, d_3)$, and $(\vec{g}_4 \cdot \vec{n}_k)_{k=1}^3 = (-d_1, -d_2, d_3)$.

3.3. Four measurements.

In the previous subsection, we showed that from three measurements, $\tilde{c}_{66}$ is a continuous parameter that can be anything in $(0, c_3^2]$ and our solution $(\tilde{c}_{66}, \vec{g})$ can be any of four continuous families

$$\{(\tilde{c}_{66}, \vec{g}_k(\tilde{c}_{66})) : \tilde{c}_{66} \in (0, c_3^2]\}_{k=1}^4.$$

But in this subsection we will show that for four measurements the set of possible $\tilde{c}_{66}$ becomes discrete, with a maximum number of at most four, and will provide an explicit formula for $\vec{g}$ corresponding to each $\tilde{c}_{66}$.

LEMMA 10. *For* $\{\vec{g}_k\}_{k=1}^4$ *in Lemma* 8, *we get*

$$\vec{g}_1 \cdot \vec{n}_4 = \frac{d_1\widehat{D}_1 + d_2\widehat{D}_2 + d_3\widehat{D}_3}{\widehat{D}_4}, \quad \vec{g}_2 \cdot \vec{n}_4 = \frac{-d_1\widehat{D}_1 - d_2\widehat{D}_2 + d_3\widehat{D}_3}{\widehat{D}_4},$$
$$\vec{g}_3 \cdot \vec{n}_4 = \frac{d_1\widehat{D}_1 - d_2\widehat{D}_2 + d_3\widehat{D}_3}{\widehat{D}_4}, \quad \vec{g}_4 \cdot \vec{n}_4 = \frac{-d_1\widehat{D}_1 + d_2\widehat{D}_2 + d_3\widehat{D}_3}{\widehat{D}_4}.$$

Proof. Because all of the others are analogous, we will show only the first case. From Lemma 8, we have

$$\vec{g}_1 \cdot \vec{n}_4 = d_1\alpha_4 + \eta\beta_4 + \frac{d_3\gamma_4}{\gamma_3} - \frac{\omega\gamma_4}{\gamma_3} = \frac{d_1\alpha_4\gamma_3 + \eta\beta_4\gamma_3 - \omega\gamma_4}{\gamma_3} + \frac{d_3\widehat{D}_3}{\widehat{D}_4}.$$

Since $d_1\vec{e}_2 - \eta\vec{e}_1 = \frac{d_1\vec{n}_2 + d_2\vec{n}_1}{|\vec{n}_1 \times \vec{n}_2|} = \frac{\gamma_3(d_1\vec{n}_2 + d_2\vec{n}_1)}{\widehat{D}_4}$, we get

$$\begin{aligned}\frac{d_1\alpha_4\gamma_3 + \eta\beta_4\gamma_3 - \omega\gamma_4}{\gamma_3} &= \frac{d_1(\alpha_4\gamma_3 - \alpha_3\gamma_4) - \eta(\beta_3\gamma_4 - \beta_4\gamma_3)}{\gamma_3} \\ &= \frac{(d_1\vec{e}_2 - \eta\vec{e}_1)\cdot(\vec{n}_3 \times \vec{n}_4)}{\gamma_3} = \frac{d_1\widehat{D}_1 + d_2\widehat{D}_2}{\widehat{D}_4},\end{aligned}$$

which completes the proof. □

THEOREM 11. *Let well prepared data $\{\vec{n}_j, c_j\}_{j=1}^4$ be given. Then $\tilde{c}_{66} \in (0, c_4^2]$ is the first function, c_{66}/ρ, in the solution of the inverse problem* (3.1) *if and only if $\tilde{c}_{66}$ satisfies one of the following eight equations*:

$$\pm d_1\widehat{D}_1 \pm d_2\widehat{D}_2 + d_3\widehat{D}_3 \pm d_4\widehat{D}_4 = 0, \qquad d_j := \sqrt{c_j^2 - \tilde{c}_{66}} \geq 0. \tag{3.4}$$

Proof. If $\tilde{c}_{66} \in (0, c_4^2]$ is a solution, then there exist $\vec{g}$ and $\{d_j \geq 0\}_{j=1}^4$ that satisfy (3.3). By Lemma 8, $\vec{g}$ should be one of $\{\vec{g}_k\}_{k=1}^4$, and by Remark 9 we have $(\vec{g}\cdot\vec{n}_1, \vec{g}\cdot\vec{n}_2, \vec{g}\cdot\vec{n}_3, \vec{g}\cdot\vec{n}_4) = (\pm d_1, \pm d_2, d_3, \pm d_4)$. Thus we have $AX = 0$, where

$$A := \begin{pmatrix} \vec{n}_1 & \mp d_1 \\ \vec{n}_2 & \mp d_2 \\ \vec{n}_3 & -d_3 \\ \vec{n}_4 & \mp d_4 \end{pmatrix}, \qquad X := \begin{pmatrix} \vec{g} \\ 1 \end{pmatrix}.$$

For X to be a nontrivial solution, we must get $0 = \det A = \mp d_1\widehat{D}_1 \pm d_2\widehat{D}_2 - d_3\widehat{D}_3 \pm d_4\widehat{D}_4$, which proves the necessity. For sufficiency, from Remark 9 we know that all four of the $\vec{g}_k$ in Lemma 8 already satisfy (3.3) for $j = 1, 2, 3$ for any $\tilde{c}_{66} \in (0, c_3^2]$. In addition, if $\tilde{c}_{66}$ satisfies one of (3.4), then $\tilde{c}_{66} \leq c_4^2$, and one of $\vec{g}_k \cdot \vec{n}_4$ in Lemma 10 satisfies $\vec{g}_k \cdot \vec{n}_4 = \pm d_4$. So these particular $\vec{g}_k$ and $\tilde{c}_{66}$ satisfy (3.3) for $j = 1, 2, 3, 4$. Therefore $\tilde{c}_{66}$ is the first function in a solution of (3.1). □

LEMMA 12. *Let $\Pi(a, b, c, d)$ be the alternating product*

$$\Pi(a, b, c, d) := \prod_{i,j,\ell \in \{0,1\}} \Big((-1)^i a + (-1)^j b + c + (-1)^\ell d \Big).$$

Then we have $\Pi(a, b, c, d) = (A_4 + A_2)^2(A_4 - A_2)^2 + 4(A_1 - A_3)(A_1 A_4^2 - A_3 A_2^2)$, where $A_1 = a^2 + b^2$, $A_2 = a^2 - b^2$, $A_3 = c^2 + d^2$, $A_4 = c^2 - d^2$.

Proof. The proof can be easily shown by tedious calculation. □

THEOREM 13 (determination of $\tilde{c}_{66}$). *$\tilde{c}_{66}$ satisfies one of* (3.4) *if and only if $\tilde{c}_{66} \in (0, c_4^2]$ is a root of $p(x) := \Pi(\hat{d}_1\widehat{D}_1, \hat{d}_2\widehat{D}_2, \hat{d}_3\widehat{D}_3, \hat{d}_4\widehat{D}_4)$, where $\hat{d}_j = \hat{d}_j(x) := \sqrt{c_j^2 - x}$. Here $p(x)$ becomes a fourth order polynomial*

$$p(x) = (l_4 + l_2)^2(l_4 - l_2)^2 + 4(l_1 - l_3)(l_1 l_4^2 - l_3 l_2^2), \qquad l_j := l_j(x) = a_j x - b_j, \tag{3.5}$$

where $a_1 = \widehat{D}_1^2 + \widehat{D}_2^2$, $a_2 = \widehat{D}_1^2 - \widehat{D}_2^2$, $a_3 = \widehat{D}_3^2 + \widehat{D}_4^2$, $a_4 = \widehat{D}_3^2 - \widehat{D}_4^2$, $b_1 = c_1^2\widehat{D}_1^2 + c_2^2\widehat{D}_2^2$, $b_2 = c_1^2\widehat{D}_1^2 - c_2^2\widehat{D}_2^2$, $b_3 = c_3^2\widehat{D}_3^2 + c_4^2\widehat{D}_4^2$, and $b_4 = c_3^2\widehat{D}_3^2 - c_4^2\widehat{D}_4^2$.

Proof. By definition, $p(x) = \Pi(\hat{d}_1\widehat{D}_1, \hat{d}_2\widehat{D}_2, \hat{d}_3\widehat{D}_3, \hat{d}_4\widehat{D}_4)$ is simply a product of the following eight factors:

$$\pm\hat{d}_1\widehat{D}_1 \pm \hat{d}_2\widehat{D}_2 + \hat{d}_3\widehat{D}_3 \pm \hat{d}_4\widehat{D}_4.$$

Since $d_j = \hat{d}_j(\tilde{c}_{66})$, the fact that $\tilde{c}_{66}$ satisfies one of (3.4) is equivalent to finding a root of $p(x)$. Moreover, using Lemma 12 with $A_j = -l_j(x)$, we can easily show that $p(x)$ is the fourth order polynomial given in (3.5). □

Since $p(x)$ is a fourth order polynomial, we have at most four possible $\tilde{c}_{66}$, and each $\tilde{c}_{66}$ satisfies at least one of (3.4), or equivalently, one of the following four equations:

$$(d_1\widehat{D}_1 + d_2\widehat{D}_2 + d_3\widehat{D}_3)^2 = d_4^2\widehat{D}_4^2, \tag{3.6}$$

$$(d_1\widehat{D}_1 + d_2\widehat{D}_2 - d_3\widehat{D}_3)^2 = d_4^2\widehat{D}_4^2, \tag{3.7}$$

$$(d_1\widehat{D}_1 - d_2\widehat{D}_2 + d_3\widehat{D}_3)^2 = d_4^2\widehat{D}_4^2, \tag{3.8}$$

$$(d_1\widehat{D}_1 - d_2\widehat{D}_2 - d_3\widehat{D}_3)^2 = d_4^2\widehat{D}_4^2. \tag{3.9}$$

Each equation corresponds to a product of two equations in (3.4). So we obtain the following theorem, which provides the corresponding $\vec{g}$ (i.e., $\tilde{c}_{44}$ and $\vec{f}$) for each case when $\tilde{c}_{66}$ solves one of the above four equations.

THEOREM 14 (determination of $\vec{g}$). *Let $\tilde{c}_{66} \in (0, c_4^2]$ be a root of $p(x)$ given in* (3.5). *Then $\tilde{c}_{66}$ satisfies at least one of* (3.6)–(3.9), *and for each case the corresponding $\vec{g}$ is determined by*

$$\vec{g} = \begin{cases} \vec{g}_1 & \textit{if and only if } \tilde{c}_{66} \textit{ satisfies } (3.6), \\ \vec{g}_2 & \textit{if and only if } \tilde{c}_{66} \textit{ satisfies } (3.7), \\ \vec{g}_3 & \textit{if and only if } \tilde{c}_{66} \textit{ satisfies } (3.8), \\ \vec{g}_4 & \textit{if and only if } \tilde{c}_{66} \textit{ satisfies } (3.9), \end{cases}$$

where $\{\vec{g}_k\}_{k=1}^4$ are defined as in Lemma 8.

Proof. By Remark 9, (3.3) is already satisfied for $j = 1, 2, 3$. For $j = 4$, i.e., $\vec{g} \cdot \vec{n}_4 = \pm d_4$, it is easily checked by Lemma 10 for each case. □

Later we will show that *generically* only one of (3.6)–(3.9) is satisfied for each $\tilde{c}_{66}$, and hence the maximum number of possible solutions $(\tilde{c}_{66}, \vec{g})$ will be at most four.

3.4. Multiple $\vec{g}$ for a single $\tilde{c}_{66}$. Throughout the rest of the paper we will assume that the data sets are well prepared. We define three special types of data allowing multiple $\vec{g}$ corresponding to a single $\tilde{c}_{66}$:

$$\begin{gathered} |\widehat{D}_1| < |\widehat{D}_2|, \quad \widehat{D}_3 < \widehat{D}_4, \quad c_1^2\widehat{D}_1^2 < c_2^2\widehat{D}_2^2, \quad c_3^2\widehat{D}_3 < c_4^2\widehat{D}_4^2, \\ (c_4^2\widehat{D}_4^2 - c_3^2\widehat{D}_3^2)(\widehat{D}_2^2 - \widehat{D}_1^2) = (c_2^2\widehat{D}_2^2 - c_1^2\widehat{D}_1^2)(\widehat{D}_4^2 - \widehat{D}_3^2), \end{gathered} \tag{3.10}$$

$$\begin{gathered} |\widehat{D}_1| < \widehat{D}_3, \quad |\widehat{D}_2| < \widehat{D}_4, \quad c_1^2\widehat{D}_1^2 < c_3^2\widehat{D}_3^2, \quad c_2^2\widehat{D}_2 < c_4^2\widehat{D}_4^2, \\ (c_4^2\widehat{D}_4^2 - c_2^2\widehat{D}_2^2)(\widehat{D}_3^2 - \widehat{D}_1^2) = (c_3^2\widehat{D}_3^2 - c_1^2\widehat{D}_1^2)(\widehat{D}_4^2 - \widehat{D}_2^2), \end{gathered} \tag{3.11}$$

$$\begin{gathered} |\widehat{D}_1| < \widehat{D}_4, \quad |\widehat{D}_2| < \widehat{D}_3, \quad c_1^2\widehat{D}_1^2 < c_4^2\widehat{D}_4^2, \quad c_2^2\widehat{D}_2 < c_3^2\widehat{D}_3^2, \\ (c_3^2\widehat{D}_3^2 - c_2^2\widehat{D}_2^2)(\widehat{D}_4^2 - \widehat{D}_1^2) = (c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2)(\widehat{D}_3^2 - \widehat{D}_2^2). \end{gathered} \tag{3.12}$$

First, note that we should have $\tilde{c}_{66} < c_4^2$ in order to have more than one $\vec{g}$: the reason is that if $d_4 = \sqrt{c_4^2 - \tilde{c}_{66}} = 0$, then by Theorem 14 at least two of (3.6)–(3.9) are satisfied, implying that at least one of $d_1\widehat{D}_1$, $d_2\widehat{D}_2$, $d_3\widehat{D}_3$ is zero, which is a contradiction. In the following theorem we will see that each of (3.10)–(3.12) actually enforces $\tilde{c}_{66} < c_4^2$.

THEOREM 15 (two $\vec{g}$ for a single $\tilde{c}_{66}$).

(a) *Both* $\vec{g}_1$ *and* $\vec{g}_2$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.10) *and* $\widehat{D}_1\widehat{D}_2 < 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_2\widehat{D}_2 = -d_1\widehat{D}_1$ *and* $d_4\widehat{D}_4 = d_3\widehat{D}_3$.
Both $\vec{g}_3$ *and* $\vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.10) *and* $\widehat{D}_1\widehat{D}_2 > 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_2\widehat{D}_2 = d_1\widehat{D}_1$ *and* $d_4\widehat{D}_4 = d_3\widehat{D}_3$.
For the above two cases,

$$\tilde{c}_{66} = \frac{c_2^2\widehat{D}_2^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_2^2 - \widehat{D}_1^2} = \frac{c_4^2\widehat{D}_4^2 - c_3^2\widehat{D}_3^2}{\widehat{D}_4^2 - \widehat{D}_3^2} \in (0, c_4^2).$$

(b) *Both* $\vec{g}_1$ *and* $\vec{g}_3$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.11) *and* $\widehat{D}_1 < 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_3\widehat{D}_3 = -d_1\widehat{D}_1$ *and* $d_4\widehat{D}_4 = \pm d_2\widehat{D}_2$.
Both $\vec{g}_2$ *and* $\vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.11) *and* $\widehat{D}_1 > 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_3\widehat{D}_3 = d_1\widehat{D}_1$ *and* $d_4\widehat{D}_4 = \pm d_2\widehat{D}_2$.
For the above two cases,

$$\tilde{c}_{66} = \frac{c_3^2\widehat{D}_3^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_3^2 - \widehat{D}_1^2} = \frac{c_4^2\widehat{D}_4^2 - c_2^2\widehat{D}_2^2}{\widehat{D}_4^2 - \widehat{D}_2^2} \in (0, c_4^2).$$

(c) *Both* $\vec{g}_1$ *and* $\vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.12) *and* $\widehat{D}_2 < 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_3\widehat{D}_3 = -d_2\widehat{D}_2$ *and* $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$.
Both $\vec{g}_2$ *and* $\vec{g}_3$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.12) *and* $\widehat{D}_2 > 0$
$\Leftrightarrow$ $\tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_3\widehat{D}_3 = d_2\widehat{D}_2$ *and* $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$.
For the above two cases,

$$\tilde{c}_{66} = \frac{c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2} = \frac{c_3^2\widehat{D}_3^2 - c_2^2\widehat{D}_2^2}{\widehat{D}_3^2 - \widehat{D}_2^2} \in (0, c_4^2).$$

Proof. Because all of the others are analogous, we will show only (c). For $\vec{g}_1$ and $\vec{g}_4$ to be the solutions, from Theorem 14 $\tilde{c}_{66}$ must satisfy (3.6) and (3.9). Since $d_1\widehat{D}_1 \neq 0$, we must have $d_3\widehat{D}_3 = -d_2\widehat{D}_2$, and so $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$. For $\vec{g}_2$ and $\vec{g}_3$ to be the solutions, from Theorem 14 $\tilde{c}_{66}$ must satisfy (3.7) and (3.8). Since $d_1\widehat{D}_1 \neq 0$, we must have $d_3\widehat{D}_3 = d_2\widehat{D}_2$, and so $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$.

Now we will show that the data satisfy (3.12) and $\widehat{D}_2 \lessgtr 0$, respectively, if $\tilde{c}_{66} \in (0, c_4^2)$ solves $d_3\widehat{D}_3 = \mp d_2\widehat{D}_2$ and $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$. First note that $\widehat{D}_2 \lessgtr 0$, respectively, since $d_2, d_3 > 0$. For both cases, we get

$$\widehat{D}_3^2(c_3^2 - \tilde{c}_{66}) = d_3^2\widehat{D}_3^2 = d_2^2\widehat{D}_2^2 = \widehat{D}_2^2(c_2^2 - \tilde{c}_{66}),$$
$$\widehat{D}_4^2(c_4^2 - \tilde{c}_{66}) = d_4^2\widehat{D}_4^2 = d_1^2\widehat{D}_1^2 = \widehat{D}_1^2(c_1^2 - \tilde{c}_{66}),$$

and thus we should have $\tilde{c}_{66} = \frac{c_3^2\widehat{D}_3^2 - c_2^2\widehat{D}_2^2}{\widehat{D}_3^2 - \widehat{D}_2^2} = \frac{c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2}$. So we have

$$(c_3^2\widehat{D}_3^2 - c_2^2\widehat{D}_2^2)(\widehat{D}_4^2 - \widehat{D}_1^2) = (c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2)(\widehat{D}_3^2 - \widehat{D}_2^2).$$

Moreover, since $d_1 > d_2 > d_3 > d_4$, we get $|\widehat{D}_1| < \widehat{D}_4$ and $|\widehat{D}_2| < \widehat{D}_3$. From $\tilde{c}_{66} > 0$, we also get $c_1^2\widehat{D}_1 < c_4^2\widehat{D}_4^2$ and $c_2^2\widehat{D}_2^2 < c_3^2\widehat{D}_3^2$.

Finally, we will show $\tilde{c}_{66} \in (0, c_4^2)$, and it solves $d_3\widehat{D}_3 = \mp d_2\widehat{D}_2$, $d_4\widehat{D}_4 = \pm d_1\widehat{D}_1$ if the data satisfy (3.12) and $\widehat{D}_2 \lesseqgtr 0$, respectively. Set $\tilde{c}_{66} := \frac{c_3^2\widehat{D}_3^2 - c_2^2\widehat{D}_2^2}{\widehat{D}_3^2 - \widehat{D}_2^2} = \frac{c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2} > 0$. Since $c_1^2 > c_4^2$, we get $\tilde{c}_{66} = \frac{c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2} < \frac{c_4^2\widehat{D}_4^2 - c_4^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2} = c_4^2$. Thus $\tilde{c}_{66} \in (0, c_4^2)$ and solves $d_3^2\widehat{D}_3^2 = d_2^2\widehat{D}_2^2$ and $d_4^2\widehat{D}_4^2 = d_1^2\widehat{D}_1^2$. Since $\widehat{D}_2 \lesseqgtr 0$, $\tilde{c}_{66}$ solves $d_3\widehat{D}_3 = \mp d_2\widehat{D}_2$, respectively, and $d_4^2\widehat{D}_4^2 = d_1^2\widehat{D}_1^2$. □

In each case in (3.10)–(3.12), the fourth order polynomial $p(x)$ for $\tilde{c}_{66}$ in Theorem 13 is now further simplified. We will use the following theorem to show the generic uniqueness of $\vec{g}$ in Corollary 20.

THEOREM 16. *In each case in* (3.10)–(3.12), $p(x)$ *in Theorem* 13 *becomes*

$$p(x) = \begin{cases} \left((\widehat{D}_2^2 - \widehat{D}_1^2)x - (c_2^2\widehat{D}_2^2 - c_1^2\widehat{D}_1^2)\right)^2 q_1(x) & \textit{if the data satisfy } (3.10), \\ \left((\widehat{D}_3^2 - \widehat{D}_1^2)x - (c_3^2\widehat{D}_3^2 - c_1^2\widehat{D}_1^2)\right)^2 q_2(x) & \textit{if the data satisfy } (3.11), \\ \left((\widehat{D}_4^2 - \widehat{D}_1^2)x - (c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2)\right)^2 q_3(x) & \textit{if the data satisfy } (3.12), \end{cases}$$

where q_1, q_2, *and* q_3 *are second order polynomials.*

Proof. Because all of the others are analogous, we will show only the case (3.11). First note that

$$\widehat{D}_1^2 = \frac{a_1 + a_2}{2}, \quad \widehat{D}_2^2 = \frac{a_1 - a_2}{2}, \quad \widehat{D}_3^2 = \frac{a_3 + a_4}{2}, \quad \widehat{D}_4^2 = \frac{a_3 - a_4}{2},$$

$$c_1^2\widehat{D}_1^2 = \frac{b_1 + b_2}{2}, \quad c_2^2\widehat{D}_2^2 = \frac{b_1 - b_2}{2}, \quad c_3^2\widehat{D}_3^2 = \frac{b_3 + b_4}{2}, \quad c_4^2\widehat{D}_4^2 = \frac{b_3 - b_4}{2},$$

and define

$$A := \frac{a_4 + a_3 - a_2 - a_1}{2} = \widehat{D}_3^2 - \widehat{D}_1^2 > 0, \quad B := \frac{b_4 + b_3 - b_2 - b_1}{2} = c_3^2\widehat{D}_3^2 - c_1^2\widehat{D}_1^2 > 0.$$

Since we can show $(a_4 - a_2)(b_3 - b_1) = (a_3 - a_1)(b_4 - b_2)$ from (3.11), we also get $A(b_3 - b_1) = B(a_3 - a_1)$ and $A(b_4 - b_2) = B(a_4 - a_2)$. Thus we get

$$A(l_1(x) - l_3(x)) = (a_1 - a_3)(Ax - B), \qquad A(l_2(x) - l_4(x)) = (a_2 - a_4)(Ax - B).$$

Hence the polynomial in (3.5) becomes

$$p(x) = C_2^2(Ax - B)^2(l_4 + l_2)^2 - 4C_1(Ax - B)Q(x),$$

where $C_1 = \frac{a_3 - a_1}{A}$, $C_2 = \frac{a_4 - a_2}{A}$, and

$$\begin{aligned} Q(x) &= l_1 l_4^2 - l_3\left[l_4 - C_2(Ax - B)\right]^2 \\ &= (l_1 - l_3)l_4^2 - l_3(Ax - B)\left[-2l_4C_2 + C_2^2(Ax - B)\right] \\ &= (Ax - B)\left[2C_2l_3l_4 - C_1l_4^2 - C_2^2l_3(Ax - B)\right] \\ &= (Ax - B)\left[2C_2l_3l_4 - C_1l_4^2 + C_2l_3(l_2 - l_4)\right] = (Ax - B)\left[C_2l_3(l_4 + l_2) - C_1l_4^2\right]. \end{aligned}$$

Hence we get $p(x) = (Ax - B)^2 q_2(x)$, where q_2 is a second order polynomial given by $q_2(x) = C_2^2(l_4 + l_2)^2 + 4C_1^2l_4^2 - 4C_1C_2l_3(l_2 + l_4)$. □

For three possible $\vec{g}$ corresponding to a single $\tilde{c}_{66}$, we consider another special type of data that satisfies

$$\begin{gathered}|\widehat{D}_1| < |\widehat{D}_2| < \widehat{D}_3 < \widehat{D}_4, \quad c_1^2\widehat{D}_1^2 < c_2^2\widehat{D}_2^2 < c_3^2\widehat{D}_3 < c_4^2\widehat{D}_4^2, \\ \text{and there exists a single } K := \frac{c_j^2\widehat{D}_j^2 - c_i^2\widehat{D}_i^2}{\widehat{D}_j^2 - \widehat{D}_i^2} \in (0, c_4^2) \quad \forall j > i.\end{gathered} \tag{3.13}$$

Note that (3.13) implies $\{(x_j, y_j) = (\widehat{D}_j^2, c_j^2\widehat{D}_j^2)\}$ are on a single straight line with slope $K > 0$. From Theorem 15, we can easily prove the following theorem, showing exactly when we shall get three $\vec{g}$ corresponding to a single $\tilde{c}_{66}$.

THEOREM 17 (three $\vec{g}$ for a single $\tilde{c}_{66}$).

(a) $\vec{g}_1, \vec{g}_2, \vec{g}_3$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.13), $\widehat{D}_1 < 0$, *and* $\widehat{D}_2 > 0$ $\Leftrightarrow \tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_4\widehat{D}_4 = d_3\widehat{D}_3 = d_2\widehat{D}_2 = -d_1\widehat{D}_1$.

(b) $\vec{g}_1, \vec{g}_2, \vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.13), $\widehat{D}_1 > 0$, *and* $\widehat{D}_2 < 0$ $\Leftrightarrow \tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_4\widehat{D}_4 = d_3\widehat{D}_3 = -d_2\widehat{D}_2 = d_1\widehat{D}_1$.

(c) $\vec{g}_1, \vec{g}_3, \vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.13), $\widehat{D}_1 < 0$, *and* $\widehat{D}_2 < 0$ $\Leftrightarrow \tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_4\widehat{D}_4 = d_3\widehat{D}_3 = -d_2\widehat{D}_2 = -d_1\widehat{D}_1$.

(d) $\vec{g}_2, \vec{g}_3, \vec{g}_4$ *are solutions* $\Leftrightarrow$ *the data satisfy* (3.13), $\widehat{D}_1 > 0$, *and* $\widehat{D}_2 > 0$ $\Leftrightarrow \tilde{c}_{66} \in (0, c_4^2)$ *and it solves* $d_4\widehat{D}_4 = d_3\widehat{D}_3 = d_2\widehat{D}_2 = d_1\widehat{D}_1$.

In each case, we should have $\tilde{c}_{66} = K \in (0, c_4^2)$ *as given in* (3.13).

As in Theorem 16, the fourth order polynomial $p(x)$ for $\tilde{c}_{66}$ in Theorem 13 is also further simplified when the data satisfy (3.13). The following theorem will also be used to show the generic uniqueness of $\vec{g}$ in Corollary 20.

THEOREM 18. *If the data satisfy* (3.13), $p(x)$ *in Theorem* 13 *becomes*

$$p(x) = (x - K)^3 \left(\Pi(\widehat{D}_1, \widehat{D}_2, \widehat{D}_3, \widehat{D}_4)x - \frac{\Pi(c_1\widehat{D}_1, c_2\widehat{D}_2, c_3\widehat{D}_3, c_4\widehat{D}_4)}{K^3} \right),$$

where $K \in (0, c_4^2)$ *is given as in* (3.13).

Proof. Since $a_2, a_4, a_1 - a_3 < 0$ and $K = \frac{b_2}{a_2} = \frac{b_4}{a_4} = \frac{b_1 - b_3}{a_1 - a_3}$, we get

$$l_2(x) = a_2 l(x), \quad l_4(x) = a_4 l(x), \quad l_1(x) - l_3(x) = (a_1 - a_3)l(x),$$

where $l(x) := x - K$. Hence the polynomial in (3.5) becomes $p(x) = [l(x)]^3 Q(x)$, where

$$Q(x) = (a_4^2 - a_2^2)^2 l(x) + 4(a_1 - a_3)(a_4^2 l_1(x) - a_2^2 l_3(x)).$$

Here $Q(x)$ is definitely a linear function, and from

$$\begin{aligned} Q'(0) &= (a_4^2 - a_2^2)^2 + 4(a_1 - a_3)(a_1 a_4^2 - a_3 a_2^2) = \Pi(\widehat{D}_1, \widehat{D}_2, \widehat{D}_3, \widehat{D}_4), \\ Q(0) &= -K(a_4^2 - a_2^2)^2 + 4(a_1 - a_3)(a_2^2 b_3 - a_4^2 b_1) \\ &= -\frac{(b_4^2 - b_2^2)^2 + 4(b_1 - b_3)(b_1 b_4^2 - b_3 b_2^2)}{K^3} = -\frac{\Pi(c_1\widehat{D}_1, c_2\widehat{D}_2, c_3\widehat{D}_3, c_4\widehat{D}_4)}{K^3}, \end{aligned}$$

we conclude $Q(x) = \Pi(\widehat{D}_1, \widehat{D}_2, \widehat{D}_3, \widehat{D}_4)x - \frac{1}{K^3}\Pi(c_1\widehat{D}_1, c_2\widehat{D}_2, c_3\widehat{D}_3, c_4\widehat{D}_4)$. □

Remark 19. From Theorem 17 we can easily prove that the four $\vec{g}_1$, $\vec{g}_2$, $\vec{g}_3$, $\vec{g}_4$ cannot all be solutions at the same time for a single $\tilde{c}_{66}$: If so, then $d_1\widehat{D}_1 = 0$, which is a contradiction.

3.5. Generic uniqueness of $\vec{g}$ for a single $\tilde{c}_{66}$. In this subsection we show that *generically* only one of (3.6)–(3.9) is satisfied for each root $\tilde{c}_{66} \in (0, c_4^2]$ of $p(x)$, and hence generically the maximum number of possible solutions $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$ is at most four.

Corollary 20.

(a) *Let $\tilde{c}_{66} \in (0, c_4^2]$ be a root of $p(x)$ in* (3.5) *and m be its multiplicity. If we denote by $G(\tilde{c}_{66})$ the number of possible $\vec{g}$ corresponding to this $\tilde{c}_{66}$, then* $1 \le G(\tilde{c}_{66}) \le \min(m, 3)$.

(b) *The number of all possible $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$ is less than or equal to the number of* (*multiply counted*) *roots of $p(x)$ in $(0, c_4^2]$, which cannot exceed four.*

(c) *Unless the data satisfy one of the special conditions* (3.10)–(3.12), *there exists only one $\vec{g}$ corresponding to a single $\tilde{c}_{66}$. So in this case, the number of all possible $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$ is exactly the same as the number of (not multiply counted) roots of $p(x)$ in $(0, c_4^2]$, which cannot exceed four.*

Proof. We first prove (a). For any root $\tilde{c}_{66}$, at least one of (3.6)–(3.9) is satisfied, so by Theorem 14 we have $G(\tilde{c}_{66}) \ge 1$. Also Remark 19 says that $G(\tilde{c}_{66}) \le 3$. Hence it suffices to show $G(\tilde{c}_{66}) \le m$ for $m = 1, 2$. For a simple root ($m = 1$), if $G(\tilde{c}_{66}) \ge 2$, then by Theorems 15 and 16 we get $m \ge 2$, which is a contradiction. So we should have $G(\tilde{c}_{66}) \le 1$. For a double root ($m = 2$), if $G(\tilde{c}_{66}) \ge 3$, then by Theorems 17 and 18 we get $m \ge 3$, which is a contradiction. So we should have $G(\tilde{c}_{66}) \le 2$. (b) is straightforward from (a), and so is (c) from Theorems 14 and 15. □

From all the above, we can summarize our algorithm as follows:

1. Make the compatible data to be well prepared.
2. Determine possible $\tilde{c}_{66} \in (0, c_4^2]$ by finding roots of the fourth order polynomial $p(x)$ in (3.5).
3. For each $\tilde{c}_{66} \in (0, c_4^2]$ obtained above, check which one among (3.6)–(3.9) is satisfied.
4. For each case, use Theorem 14 to determine $\vec{g}$ (equivalently, $\tilde{c}_{44}$ and $\vec{f}$).

Remark 21. If we use all of the information about the solution u of (2.2) (as opposed to only the wave front positions $\hat{T}$), which is actually measured in experiments, then we can apply the same arguments of section 5 in [11]. That is, for one of the possible triples $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$ given there corresponds at most one density ρ corresponding to that triple under the Neumann boundary condition (for the Dirichlet boundary condition, ρ needs to be specified on the boundary). Therefore, in this case, we have at most four possibilities in determining four parameters $(\rho, c_{66}, c_{44}, \vec{f})$ from the data set $\{u_j(x,t) \mid x \in \Omega,\ t \in (0,T)\}_{j=1}^4$.

3.5.1. Examples. Here a complete set of examples is presented showing that sometimes there exist no solution, a unique solution, two solutions, three solutions, or four solutions. Here we converted the final solution into the standard coordinate system to represent $\vec{f}$.

Example 22 (no solution). Consider the following well prepared data:

$$\vec{n}_1 = (1, 0, 0), \quad \vec{n}_2 = \left(-\frac{1}{\sqrt{2}}, -\frac{1}{\sqrt{2}}, 0\right), \quad \vec{n}_3 = (0, 0, -1), \quad \vec{n}_4 = \left(0, \frac{1}{2}, -\frac{\sqrt{3}}{2}\right)$$

with $c_1^2 = 9$, $c_2^2 = 3$, $c_3^2 = \frac{5}{2}$, and $c_4^2 = 1$. Then the fourth order polynomial for $\tilde{c}_{66}$ is given by $p(x) = \frac{1}{65536}(18145 + 34592x + 21440x^2 + 7168x^3 + 1024x^4)$, which has no root in $(0, c_4^2]$. Hence there exists no solution matching the data.

Example 23 (unique solution). Consider the same $\vec{n}_j$ as in Example 22 with $c_1^2 = 8$, $c_2^2 = 7$, $c_3^2 = 2$, and $c_4^2 = 1$. Then $p(x) = \frac{1}{64}(-188 + 252x + 53x^2 - 18x^3 + x^4)$, which has only one root $\tilde{c}_{66} = \frac{1}{2}(9 - \sqrt{137 - 32\sqrt{6}}) \approx 0.6719$ in $(0, c_4^2]$. Since $\tilde{c}_{66}$ satisfies (3.7), from Theorem 14 we get the unique solution given by

$$\begin{pmatrix} \tilde{c}_{66} \\ \tilde{c}_{44} \\ \vec{f} \end{pmatrix} \approx \begin{pmatrix} 0.6719 \\ 10.0514 \\ (-0.8839, -0.2777, -0.3763) \end{pmatrix}.$$

Example 24 (two solutions). Consider the same $\vec{n}_j$ as in Example 22 with $c_1^2 = 9$, $c_2^2 = 5$, $c_3^2 = 4$, and $c_4^2 = 3$. Since these data satisfy none of (3.10)–(3.12), only one of $\vec{g}$ will correspond to each root of the fourth order polynomial given by

$$p(x) = \tfrac{1}{4096}(481 - 1488x + 1264x^2 - 384x^3 + 64x^4).$$

This polynomial has two roots $\xi_1 \approx 0.5194$ and $\xi_2 \approx 1.2439$ in $(0, c_4^2]$, where $\tilde{c}_{66} = \xi_1$ satisfies (3.7) and $\tilde{c}_{66} = \xi_2$ satisfies (3.8). So by Theorem 14, we get two solutions:

$$\begin{pmatrix} \tilde{c}_{66} \\ \tilde{c}_{44} \\ \vec{f} \end{pmatrix} \approx \begin{pmatrix} 0.5194 \\ 12.4873 \\ (-0.8418, -0.0235, -0.5393) \end{pmatrix}, \quad \begin{pmatrix} 1.2439 \\ 42.2907 \\ (0.4347, -0.8625, -0.2591) \end{pmatrix}.$$

Example 25 (three solutions). Consider the same $\vec{n}_j$ as in Example 22 with $c_1^2 = 3$, $c_2^2 = \frac{5}{3}$, $c_3^2 = \frac{4}{3}$, and $c_4^2 = \frac{5}{4}$. Since these data satisfy (3.12) and $\widehat{D}_2 > 0$, by Theorem 15(c) we get two solutions $\vec{g}_2$ and $\vec{g}_3$ for $\tilde{c}_{66} = \frac{c_4^2\widehat{D}_4^2 - c_1^2\widehat{D}_1^2}{\widehat{D}_4^2 - \widehat{D}_1^2} = \frac{2}{3}$. Moreover, we have $p(x) = \frac{1}{576}(3x-2)^2\left[x - \left(\sqrt{2} - \frac{1}{6}\right)\right]\left[x + \left(\sqrt{2} + \frac{1}{6}\right)\right]$, which has another root $\tilde{c}_{66} = \sqrt{2} - \frac{1}{6} \approx 1.2476$ in $(0, c_4^2]$ satisfying (3.6). So we get three solutions:

$$\begin{pmatrix} \tilde{c}_{66} \\ \tilde{c}_{44} \\ \vec{f} \end{pmatrix} \approx \begin{pmatrix} 0.6667 \\ 3.6795 \\ (-0.8800, 0.0653, -0.4704) \end{pmatrix}, \quad \begin{pmatrix} 1.2476 \\ 3.2525 \\ (0.9349, -0.2883, -0.2069) \end{pmatrix},$$

$$\begin{pmatrix} 0.6667 \\ 12.3205 \\ (0.4475, -0.8617, -0.2392) \end{pmatrix}.$$

Example 26 (four solutions). Consider the following well prepared data:

$$\vec{n}_1 = (0,0,1), \quad \vec{n}_2 = \left(0, \frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}\right), \quad \vec{n}_3 = \left(-\frac{\sqrt{3}}{2}, \frac{1}{2}, 0\right), \quad \vec{n}_4 = (-1,0,0)$$

with $c_1^2 = 11$, $c_2^2 = 10$, $c_3^2 = 9.9$, and $c_4^2 = 9.8$. Since these data satisfy none of (3.10)–(3.12), only one of $\vec{g}$ corresponds to each root of

$$p(x) = \frac{1}{160000}(14055561 - 6614520x + 1150900x^2 - 88000x^3 + 2500x^4).$$

This polynomial has four roots $\xi_1 \approx 6.2722$, $\xi_2 \approx 9.4936$, $\xi_3 \approx 9.6576$, and $\xi_4 \approx 9.7766$ in $(0, c_4^2]$, where $\tilde{c}_{66} = \xi_1$ satisfies (3.8), and $\tilde{c}_{66} = \xi_2$ satisfies (3.7), and $\tilde{c}_{66} = \xi_3$ and

$\tilde{c}_{66} = \xi_4$ satisfy (3.9). From Theorem 14, we get four solutions:

$$\begin{pmatrix} \tilde{c}_{66} \\ \tilde{c}_{44} \\ \vec{f} \end{pmatrix} \approx \begin{pmatrix} 6.2722 \\ 14.8371 \\ (-0.6418, 0.1900, 0.7430) \end{pmatrix}, \quad \begin{pmatrix} 9.4936 \\ 16.2959 \\ (0.2122, 0.8564, -0.4706) \end{pmatrix},$$

$$\begin{pmatrix} 9.6576 \\ 11.2520 \\ (-0.2989, 0.2622, -0.9176) \end{pmatrix}, \quad \begin{pmatrix} 9.7766 \\ 11.2149 \\ (-0.1275, 0.3649, -0.9223) \end{pmatrix}.$$

4. Numerical implementation. Here we indicate the success of the approach of using four data sets to solve the inverse problem. That is, find the triple $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$ from four propagating fronts, where the four normals and corresponding (estimated) wave speeds $\{(\vec{n}_j, c_j)\}_{j=1}^{4}$ are compatible; that is, the wave speeds are all different and any three normals are linearly independent (see Definition 6(a)).

Furthermore, since we develop our theory under the assumption that the medium properties may not be symmetric about the image plane, we calculate the three-dimensional wave front in the neighborhood of the image plane. Our supersonic excitations are assumed to be slightly out of the image plane to easily achieve the linear independence mentioned above, and we expect that this configuration could be realizable with a full planar array of transducers for three-dimensional imaging or three lines of closely spaced transducers in a so-called $2\frac{1}{2}$-dimensional imaging setting (see Figure 4.1(a)). For this synthetic data experiment we calculate the wave fronts using a first order anisotropic Eikonal solver based on fast marching methods with code developed at Rensselaer.

The successive supersonic imaging pushes to create the approximate line sources are made at a sweeping speed faster than the background shear wave speed and indicated by the multiple of the background shear wave speed (Mach number); hence the label *supersonic* (see [3]). The background wave speed is indicated in each of the labeled figures and also is given in our text description below. In our examples, the

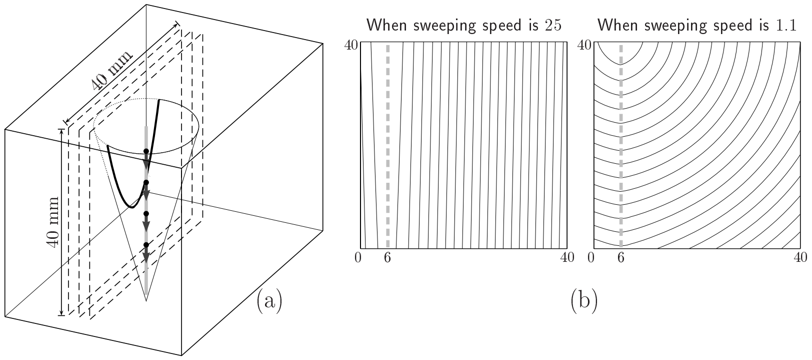

FIG. 4.1. (a) *Configuration: Data are collected on three consecutive image planes (dashed lines) by either a full planar array or three parallel, closely spaced linear arrays. Supersonic excitations are slightly off the imaging planes (gray line). A generated conical wave front yields parabolic intersections with each image plane. The shapes of parabola depend on the location and the sweeping speed of supersonic excitations.* (b) *Observed conical wave fronts on the central image plane, when the supersonic excitation line is* 8*mm away from the central image plane and* 6*mm away from the left side.*

pushes are either made slowly from top to bottom (1.1 sweeping speed), slowly from bottom to top (-1.1 sweeping speed), fast from top to bottom (25 sweeping speed), or fast from bottom to top (-25 sweeping speed). Each set of pushes produces a conical wave front in three dimensions whose intersection with the image plane is generally a parabola but looks like a straight line for high sweeping speeds like ± 25. See Figure 4.1(b).

We show two numerical reconstructions. For the first we have uniform anisotropy, where the fiber direction is out of the image plane; see Figure 4.2. The uniform anisotropic cube is 40 mm on a side with two excitation lines for the pushes, each being 6 mm from the outside edge; note that the excitation lines are at different distances from the image plane with one 8 mm from the image plane and the other 12 mm from the image plane. We take separately the two sweeping speeds, ± 1.1, yielding four propagating fronts. It is assumed that $\sqrt{\tilde{c}_{66}} = 1$, $\sqrt{\tilde{c}_{44}} = 2$. Setting up the three orthogonal coordinates with the x coordinate out of the plane, we show our results for $\sqrt{\tilde{c}_{44}}$, $\sqrt{\tilde{c}_{66}}$, the wave speeds along and across the fiber direction, respectively, and the squares of the fiber direction coordinates f_x^2, f_y^2, f_z^2. In addition we exhibit $\sqrt{\tilde{c}_{66}}$, $\sqrt{\tilde{c}_{44}}$, and $\{c_j\}_{j=1}^4$ along the line $z = 25$, $0 < y < 40$.

As we have seen in section 3, sometimes the fourth order polynomial for $\tilde{c}_{66}$ may have multiple roots in $(0, c_4^2]$, which is the source of our nonuniqueness. In this case, we have chosen to select the largest possible root in $(0, c_4^2]$, as in all of our simulations that choice consistently gave the correct recovery. Note that there are artifacts near the projections of the excitation lines, $y = 6$, onto the image plane because the fourth order polynomial is not well defined there (there four wave normals, $\vec{n}_j$, are on one plane perpendicular to our image plane, i.e., $\hat{D}_j = 0$, which yields $p(x) \equiv 0$). But otherwise the recovery is quite acceptable.

For our second simulation the excitation lines are in the same locations, but along one line we take the sweeping speeds ± 1.1, 25, and along the second line the sweeping speed is 25. Here the fiber is again out of the plane but only in the anisotropic cube inclusion with 10mm on each side. The anisotropic inclusion is embedded in an isotropic medium; see Figure 4.3. Again the recovery is quite acceptable; note that in all images of the material properties we observe anisotropic cube edge effects, except in the image for $\sqrt{\tilde{c}_{66}}$.

Here, also in the first simulation, the points where all four wave speeds $\{c_j\}_{j=1}^4$ are so close (using some threshold) are considered as isotropic points. We established a threshold, $\delta = 0.01$ for the first simulation and 0.04 for the second simulation, and consider the points isotropic when $\max\{c_j\}_{j=1}^4 - \min\{c_j\}_{j=1}^4 \leq \delta \max\{c_j\}_{j=1}^4$. For isotropic points, we assign a zero vector to the fiber direction and set $\sqrt{\tilde{c}_{44}} = \sqrt{\tilde{c}_{66}}$. As mentioned before, the fourth order polynomial is not well defined on the excitation lines, which stems from the fact that all four wave speeds are so close there. Because those points are considered as isotropic points, they are buried in the isotropic background in the second simulation, while in the first simulation the *isotropic* excitation line stands out in the anisotropic background. Compare the graphs near $y = 6$ in Figures 4.2 and 4.3.

5. Conclusion.

Here we address the following question: How do we obtain anisotropic medium properties from a set of wave fronts? Our target application is tissue shear stiffness imaging and we assume the medium is three-dimensional. There is a fiber direction along which the wave speed, $\sqrt{\tilde{c}_{44}}$, is faster than in the plane orthogonal to the fiber where the wave speed is $\sqrt{\tilde{c}_{66}}$ and directionally independent in that plane. We show that from four wave fronts, where any three normals at each

point are linearly independent, we can have up to four distinct triples $(\tilde{c}_{66}, \tilde{c}_{44}, \vec{f})$, where $\vec{f}$ is the unit fiber direction. We exhibit examples to show that multiple solutions can occur and show numerical reconstructions with synthetic data. The multiple solutions are a result of the nonlinearity in the Eikonal equation.

From our work to obtain reconstructions we have observed the importance of (1) having well-separated normals to the wave fronts, and that necessitates some normals having out of image plane components; (2) the need for multiple image planes to capture all three components of the normals; and (3) the fact that in a high contrast subregion embedded in a constant medium, initially well-separated normals may align themselves (the angle between their normals becomes smaller) at some points, and at other points the angle may become larger. This angle change may

occur also at points beyond that subregion. The degree of this angle change depends on the wave speed contrast, size of inclusion, and the initial incident directions. This indicates important features in experimental design when wave fronts are used to image anisotropic properties of the kind modeled in this paper.

THE ATOMIC MIX APPROXIMATION FOR CHARGED PARTICLE TRANSPORT[*]

EDWARD W. LARSEN[†] AND LIANG LIANG[†]

Abstract. The classic atomic mix approximation for particle transport in a stochastic spatial medium is accurate when the material chunks in the medium are small compared to a mean free path. In this paper, we show that for charged particle transport in a stochastic medium, the atomic mix approximation is accurate when the chunk sizes are small compared to a *transport* mean free path. For charged particle transport, the transport mean free path is generally several orders of magnitude larger than the mean free path. Therefore, the result obtained in this paper greatly extends the known range of applicability of the atomic mix approximation. Numerical results are given that validate the asymptotic theory, and an application of the theory to a practical problem in radiation oncology is discussed.

Key words. particle transport, random media, asymptotic analysis, homogenization

1. Introduction.

The *atomic mix* approximation is a classic technique in physics and chemistry that has also been used for many years in the particle (radiation) transport community [1]. The underlying (particle transport) problems are described by a linear Boltzmann equation [1, 2, 3, 4], applied to a heterogeneous spatial medium consisting of randomly located "chunks" of two or more materials. If the chunk diameters are small compared to a typical mean free path and the chunks are distributed in a statistically uniform way throughout the system, the atomic mix approximation applies and the highly space-dependent cross sections can be replaced by their volume averages. The resulting approximate "atomic mix" Boltzmann equation, with volume-averaged cross sections, then accurately determines the radiation flux. The approximate atomic mix problem is much simpler than the original problem because (i) it is not necessary to know the detailed structure of the physical system (it is only necessary to know the cross sections and volume fractions of the constituent parts), and (ii) the atomic mix Boltzmann equation with volume-averaged cross sections is much easier to solve than the original Boltzmann equation, with highly space-dependent cross sections.

Recently, Dumas and Golse have proved that the atomic mix approximation is an asymptotic limit of the Boltzmann equation, for stochastic physical systems in which the chunk sizes are small compared to a typical mean free path [5]. (This is the physical regime in which the atomic mix approximation is commonly understood to hold.) More recently, Larsen [6] and Larsen, Vasques, and Vilhena [7] have shown—by a formal asymptotic analysis—that for 1-D (one-dimensional) diffusive stochastic systems the atomic mix approximation is valid when the chunk sizes are *comparable* to a mean free path.

In the present paper, we consider 3-D charged particle transport problems that are dominated by "soft" collision processes in which the particles experience very small changes in direction and energy. We show that for such problems the atomic mix approximation is a formal asymptotic limit of the linear Boltzmann equation in a stochastic medium in which the chunk sizes are small compared to a *transport* mean free path. For charged particle transport, the transport mean free path is usually several orders of magnitude greater than a mean free path. Therefore, the result obtained in this paper greatly extends the known range of applicability of the atomic mix approximation.

Our theoretical approach employs two different asymptotic limits. First, we use an asymptotic approximation developed by Pomraning [8]—valid when the mean free path is small and particles experience very small changes in the direction of flight and energy in a collision—to approximate the soft collision operator by its Fokker–Planck limit [9]. This reduces the original linear Boltzmann equation to a Boltzmann–Fokker–Planck (BFP) equation [10, 11]. Then we apply a generalization of the asymptotic analysis of Dumas and Golse to the BFP equation to show that when chunk sizes are small compared to a transport mean free path, the BFP equation limits to its atomic mix approximation. The resulting atomic mix BFP equation is identical to the equation obtained by (i) formally replacing the original Boltzmann equation by its atomic mix approximation and (ii) applying Pomraning's Fokker–Planck approximation to the resulting atomic mix soft collision operator.

Therefore, the atomic mix BFP equation is an asymptotic limit of *both* the original linear Boltzmann equation *and* its atomic mix approximation. This implies that, for charged particle transport problems in a stochastic medium in which (i) soft collisions dominate hard collisions and (ii) a typical chunk size within the medium is small compared to a transport mean free path, the atomic mix model is an asymptotic approximation to the linear Boltzmann equation.

The remainder of this paper is organized as follows. In section 2 we introduce the original Boltzmann equation and present our formal asymptotic analysis. To validate the predictions of the asymptotic theory, we present in section 3 the results of realistic Monte Carlo simulations of electron beams penetrating random binary systems of water and air. In work presented elsewhere [12], we have used the results in this paper to develop a practical computer model of the human lung, in order to assess the accuracy of certain treatment planning techniques in radiation oncology. This application of the asymptotic theory is discussed in the concluding section 4 of the present paper.

2. Asymptotic analysis.

We consider the following particle transport problem:

$$\begin{aligned}
&\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)+\Sigma(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\Sigma(\boldsymbol{x},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\Psi(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE',\quad \boldsymbol{x}\in V, \qquad (2.1a)
\end{aligned}$$

$$\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)=\Psi^b(\boldsymbol{x},\boldsymbol{\Omega},E),\quad \boldsymbol{x}\in\partial V,\ \ \boldsymbol{\Omega}\cdot\boldsymbol{n}<0. \qquad (2.1b)$$

Our notation is standard:

$$\boldsymbol{x}=(x,y,z)=\text{ position}, \qquad (2.2a)$$

$$\boldsymbol{\Omega}=(\sqrt{1-\mu^2}\cos\gamma,\sqrt{1-\mu^2}\sin\gamma,\mu)=\text{ direction of flight}, \qquad (2.2b)$$

$$E=\text{ energy}, \qquad (2.2c)$$

and

$$\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) = \text{ angular flux (intensity)}, \tag{2.3a}$$

$$\Sigma(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E) = \text{ differential scattering cross section}, \tag{2.3b}$$

$$\begin{aligned}\Sigma(\boldsymbol{x},E) &= \int_0^\infty \int_{4\pi} \Sigma(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\,d\Omega' dE' \\ &= \text{ scattering cross section.}\end{aligned} \tag{2.3c}$$

Problem (2.1) describes a particle transport process within a physical system V. The process is driven by a specified incident angular flux Ψ^b on the outer surface ∂V of V. V is spatially heterogeneous, consisting of a large number of chunks of two or more materials. Also, the scattering process in V is dominated by soft collisions (in which particles experience very small changes in direction of flight and energy), but rare hard collisions (in which the changes in direction of flight and energy are not small) can also occur. To separate these two types of scattering events, we use $\mu_0 = \boldsymbol{\Omega}'\cdot\boldsymbol{\Omega}$ = scattering cosine and write

$$\Sigma(\boldsymbol{x},\mu_0,E'\to E) = \Sigma_h(\boldsymbol{x},\mu_0,E'\to E) + \Sigma_r(\boldsymbol{x},\mu_0,E'\to E), \tag{2.4}$$

where Σ_h = differential scattering cross section for hard collisions and Σ_r = differential scattering cross section for soft collisions (also called the "restricted" differential scattering cross section). We define

$$\begin{aligned}\Sigma_h(\boldsymbol{x},E) &= \int_0^\infty \int_{4\pi} \Sigma(\boldsymbol{x},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E\to E')\,d\Omega' dE' \\ &= \text{ hard scattering cross section,}\end{aligned} \tag{2.5a}$$

$$\begin{aligned}\Sigma_r(\boldsymbol{x},E) &= \int_0^\infty \int_{4\pi} \Sigma(\boldsymbol{x},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E\to E')\,d\Omega' dE' \\ &= \text{ soft (restricted) scattering cross section,}\end{aligned} \tag{2.5b}$$

and clearly,

$$\Sigma(\boldsymbol{x},E) = \Sigma_h(\boldsymbol{x},E) + \Sigma_r(\boldsymbol{x},E). \tag{2.5c}$$

We also define the *phase function* for hard collisions:

$$p_h(\boldsymbol{x},\mu_0,E'\to E) = \frac{\Sigma_h(\boldsymbol{x},\mu_0,E'\to E)}{\Sigma_h(\boldsymbol{x},E')}\ , \tag{2.6a}$$

which by (2.5a) and (2.6a) satisfies

$$\int_0^\infty \int_{4\pi} p_h(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\,d\Omega dE = 1. \tag{2.6b}$$

Introducing (2.4)–(2.6) into (2.1a), we obtain

$$\begin{aligned}\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) &+ \Sigma_h(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) \\ &= \int_0^\infty \int_{4\pi} \Sigma_h(\boldsymbol{x},E')p_h(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\Psi(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE' \\ &\qquad + L_r\Psi(\boldsymbol{x},\boldsymbol{\Omega},E),\end{aligned} \tag{2.7a}$$

where L_r is the *restricted collision operator:*

$$\begin{aligned} L_r\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) = \int_0^\infty \int_{4\pi} &\Sigma_r(\boldsymbol{x},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\Psi(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE' \\ &-\Sigma_r(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E). \end{aligned} \tag{2.7b}$$

To this point we have made no approximations; (2.7) are equivalent to the original Boltzmann equation (2.1a).

Now we make our first approximation. Because soft collisions generate very small changes in direction of flight and energy, the restricted (soft) differential scattering cross section $\Sigma_t(\boldsymbol{x},\mu_0,E'\to E)$ is very highly peaked near $\mu_0\approx 1$ and $E'\approx E$. In this situation, Pomraning [8] has shown that L_r is asymptotically approximated by the Fokker–Planck operator:

$$\begin{aligned} L_r\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) &\approx L_{FP}\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) \\ &= \frac{\Sigma_{r,tr}(\boldsymbol{x},E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) \\ &\quad + \frac{\partial}{\partial E}S_r(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E), \end{aligned} \tag{2.8}$$

where

$$\begin{aligned} \Sigma_{r,tr}(\boldsymbol{x},E) &= \int_0^\infty\int_{4\pi}(1-\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega})\Sigma_r(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E\to E')\,d\Omega' dE' \\ &= \text{ restricted transport cross section,} \end{aligned} \tag{2.9a}$$

$$\begin{aligned} S_r(\boldsymbol{x},E) &= \int_0^\infty\int_{4\pi}(E-E')\Sigma_r(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E\to E')\,d\Omega' dE' \\ &= \text{ restricted stopping power.} \end{aligned} \tag{2.9b}$$

Introducing (2.8)–(2.9) into (2.7a) and using the boundary condition (2.1b), we obtain the following BFP problem:

$$\begin{aligned} \boldsymbol{\Omega}\cdot\boldsymbol{\nabla}\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) &+ \Sigma_h(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) \\ &= \int_0^\infty\int_{4\pi}\Sigma_h(\boldsymbol{x},E')p_h(\boldsymbol{x},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\Psi(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE' \\ &\quad + \frac{\Sigma_{r,tr}(\boldsymbol{x},E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) \\ &\quad + \frac{\partial}{\partial E}S_r(\boldsymbol{x},E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E), \quad \boldsymbol{x}\in V, \end{aligned} \tag{2.10a}$$

$$\Psi(\boldsymbol{x},\boldsymbol{\Omega},E) = \Psi^b(\boldsymbol{x},\boldsymbol{\Omega},E), \quad \boldsymbol{x}\in\partial V, \ \ \boldsymbol{\Omega}\cdot\boldsymbol{n}<0. \tag{2.10b}$$

The BFP equation is well known in the literature [10, 11]. It provides an accurate way to simulate transport problems in which soft collisions dominate but rare hard collisions can also occur. The advantage of the BFP equation (2.10a) over the Boltzmann equation (2.1a) is that the BFP equation contains neither a large scattering cross section nor a highly peaked differential scattering cross section. (Hard collisions, which produce large changes of direction and energy loss, have a relatively smooth differential scattering cross section.) Also, because the soft differential scattering cross section is highly peaked near $\mu_0 \approx 1$, (2.9a) and (2.5b) imply

$$\Sigma_{r,tr}(\boldsymbol{x}, E) \ll \Sigma_r(\boldsymbol{x}, E) < \Sigma(\boldsymbol{x}, E). \tag{2.11}$$

Here Σ^{-1} is the mean free path (the mean distance between collisions), and $\Sigma_{r,tr}^{-1}$ is the (restricted) transport mean free path (the mean distance a particle must travel for its direction of flight to change by an $O(1)$ amount). Equation (2.11) implies that the restricted transport mean free path is much larger than the mean free path.

The restricted stopping power $S_r(\boldsymbol{x}, E)$ has units of MeV/cm and the interpretation

$$\begin{aligned} S_r(\boldsymbol{x}, E)ds = {} & \text{the energy loss that a particle at } (\boldsymbol{x}, E) \text{ experiences} \\ & \text{through soft collisions while traveling a distance } ds. \end{aligned} \tag{2.12a}$$

Therefore, the function

$$T(\boldsymbol{x}, E) = \frac{S_r(\boldsymbol{x}, E)}{E} \tag{2.12b}$$

has units of cm^{-1} and the interpretation

$$\begin{aligned} T(\boldsymbol{x}, E)ds = {} & \text{the fractional energy loss that a particle at } (\boldsymbol{x}, E) \text{ experiences} \\ & \text{through soft collisions while traveling a distance } ds. \end{aligned} \tag{2.12c}$$

Now we write the functions $\Sigma_h(\boldsymbol{x}, E)$, $\Sigma_{r,tr}(\boldsymbol{x}, E)$, and $T(\boldsymbol{x}, E)$ in a useful dimensionless form. These functions are highly space-dependent, due to the assumption that the physical system V consists of a large number of "chunks" of two or more materials. We define a characteristic length λ_{ch} by

$$\lambda_{ch} = \text{ typical width of a chunk in } V, \tag{2.13}$$

and we introduce the dimensionless spatial variable

$$\boldsymbol{y} = \frac{\boldsymbol{x}}{\lambda_{ch}} \ . \tag{2.14}$$

In terms of $\boldsymbol{y}$, a typical chunk width is $O(1)$.

We also define the characteristic lengths λ_h, $\lambda_{r,tr}$, and λ_r by

$$\frac{1}{\lambda_h} = \text{ typical value of } \Sigma_h(\boldsymbol{x}, E), \tag{2.15a}$$

$$\frac{1}{\lambda_{r,tr}} = \text{ typical value of } \Sigma_{r,tr}(\boldsymbol{x}, E), \tag{2.15b}$$

$$\frac{1}{\lambda_r} = \text{ typical value of } T(\boldsymbol{x}, E). \tag{2.15c}$$

These characteristic lengths have straightforward physical interpretations: λ_h is the typical distance a particle must travel to experience a hard collision; $\lambda_{r,tr}$ is the typical distance a particle must travel for its direction of flight to be altered through soft collisions only by an $O(1)$ amount; and λ_r is the typical distance that a particle must travel to lose an $O(1)$ fraction of its energy through soft collisions. We make the following assumptions:

$$\text{A1}: \qquad \frac{\lambda_h}{\lambda_{r,tr}} = O(1), \quad \frac{\lambda_r}{\lambda_{r,tr}} = O(1), \qquad \varepsilon \equiv \frac{\lambda_{ch}}{\lambda_{r,tr}} \ll 1. \tag{2.16}$$

Thus, λ_h, $\lambda_{r,tr}$, and λ_r are comparable to each other and large compared to λ_{ch}. Physically, this implies that a typical chunk width is small (O(ε)) compared to the distances over which the effect of hard collisions, soft angular deflections, and soft energy loss are $O(1)$. Alternatively, when a particle travels across a typical chunk, the effects of hard collisions, soft angular deflections, and soft energy loss are small ($O(\varepsilon)$).

Since λ_h, $\lambda_{r,tr}$, and λ_r are comparable, the dimensionless functions

$$\sigma_h(\boldsymbol{y}, E) \equiv \lambda_{r,tr}\Sigma_h(\lambda_{ch}\boldsymbol{y}, E) = \lambda_{r,tr}\Sigma_h(\boldsymbol{x}, E), \tag{2.17a}$$

$$\sigma_{r,tr}(\boldsymbol{y}, E) \equiv \lambda_{r,tr}\Sigma_{r,tr}(\lambda_{ch}\boldsymbol{y}, E) = \lambda_{r,tr}\Sigma_{r,tr}(\boldsymbol{x}, E), \tag{2.17b}$$

$$t(\boldsymbol{y}, E) \equiv \lambda_{r,tr}T(\lambda_{ch}\boldsymbol{y}, E) = \lambda_{r,tr}T(\boldsymbol{x}, E) = \lambda_{r,tr}\frac{S(\boldsymbol{x}, E)}{E} \tag{2.17c}$$

are $O(1)$ in magnitude and vary by $O(1)$ amounts when $\boldsymbol{y}$ varies by an $O(1)$ amount. Introducing (2.17) into the BFP equation (2.10a), we obtain

$$\begin{aligned}
&\boldsymbol{\Omega} \cdot \boldsymbol{\nabla}\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E) + \frac{1}{\lambda_{r,tr}}\sigma_h(\boldsymbol{y}, E)\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E) \\
&\quad = \frac{1}{\lambda_{r,tr}}\int_0^\infty \int_{4\pi} \sigma_h(\boldsymbol{y}, E')p_h(\boldsymbol{y}, \boldsymbol{\Omega} \cdot \boldsymbol{\Omega}', E' \to E)\Psi(\boldsymbol{x}, \boldsymbol{\Omega}', E')\, d\Omega' dE' \\
&\qquad + \frac{\sigma_{r,tr}(\boldsymbol{y}, E)}{2\lambda_{r,tr}}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu} + \frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E) \\
&\qquad + \frac{1}{\lambda_{r,tr}}\frac{\partial}{\partial E}Et(\boldsymbol{y}, E)\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E).
\end{aligned} \tag{2.18}$$

Now we express Ψ in terms of dimensionless spatial variables. Two fundamental length scales are present in (2.18): λ_{ch} = a typical chunk width, and $\lambda_{r,tr}$ = a typical restricted transport cross section. In (2.14), we defined the "fast" dimensionless spatial variable $\boldsymbol{y} = \boldsymbol{x}/\lambda_{ch}$, which describes $O(1)$ variations in the problem data that take place over the length scale of a chunk width. We now define the "slow" dimensionless spatial variable

$$\boldsymbol{z} = \frac{\boldsymbol{x}}{\lambda_{r,tr}}, \tag{2.19}$$

which describes $O(1)$ variations in Ψ that take place on the length scale of a restricted transport mean free path, and we assume that Ψ is a function of both $\boldsymbol{y}$ and $\boldsymbol{z}$:

$$\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E) = \psi(\boldsymbol{y}, \boldsymbol{z}, \boldsymbol{\Omega}, E). \tag{2.20a}$$

Then

$$\boldsymbol{\Omega} \cdot \boldsymbol{\nabla}\Psi(\boldsymbol{x}, \boldsymbol{\Omega}, E) = \boldsymbol{\Omega} \cdot \boldsymbol{\nabla}_y\psi(\boldsymbol{y}, \boldsymbol{z}, \boldsymbol{\Omega}, E)\frac{1}{\lambda_{ch}} + \boldsymbol{\Omega} \cdot \boldsymbol{\nabla}_z\psi(\boldsymbol{y}, \boldsymbol{z}, \boldsymbol{\Omega}, E)\frac{1}{\lambda_{r,tr}}\ . \tag{2.20b}$$

Introducing (2.20) into (2.18), multiplying by $\lambda_{r,tr}$, and using ε defined in (2.16), we obtain

$$\begin{aligned}
&\frac{1}{\varepsilon}\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_y\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)+\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_z\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)+\sigma_h(\boldsymbol{y},E)\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\sigma_h(\boldsymbol{y},E')p_h(\boldsymbol{y},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega}',E')\,d\Omega' dE'\\
&\qquad+\frac{\sigma_{r,tr}(\boldsymbol{y},E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}Et(\boldsymbol{y},E)\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E).
\end{aligned}\tag{2.21}$$

Equation (2.21) is mathematically equivalent to the BFP equation (2.10).

Now we derive the leading-order term in a formal asymptotic solution of (2.21) for $\varepsilon \ll 1$. To do this, we assume that $\boldsymbol{y}$ and $\boldsymbol{z}$ are independent spatial variables, we introduce the ansatz

$$\psi(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)=\sum_{n=0}^{\infty}\varepsilon^n\psi_n(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)\tag{2.22}$$

into (2.21), and we equate the coefficients of different powers of ε.

The first $[O(1/\varepsilon)]$ equation in the resulting asymptotic hierarchy is

$$\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_y\psi_0(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)=0,\tag{2.23}$$

which requires that ψ_0 be independent of the fast spatial variable $\boldsymbol{y}$ in the direction of flight $\boldsymbol{\Omega}$. The general solution of (2.23) is

$$\psi_0(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)=\tilde{\psi}_0[\boldsymbol{y}-(\boldsymbol{y}\cdot\boldsymbol{\Omega})\boldsymbol{\Omega},\boldsymbol{z},\boldsymbol{\Omega},E],\tag{2.24}$$

where $\tilde{\psi}_0$ is arbitrary. Thus, the leading-order term ψ_0 in the asymptotic expansion can exhibit fast spatial dependence in directions orthogonal to $\boldsymbol{\Omega}$. A less general solution of (2.23) is

$$\psi_0(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)=\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E),\tag{2.25}$$

which has *no* fast spatial variation. In the following, we assume that (2.25) holds, rather than the more general (2.24), and we systematically derive an equation for $\hat{\psi}_0$ in (2.25). To accomplish this we make an additional assumption A2, stated below, which places a condition on the randomness of the media and is consistent with (2.25). If A2 is not satisfied, then there may be circumstances in which the more general (2.24) might hold. We discuss this in more detail in the final paragraph of this section.

Assuming that ψ_0 is given by (2.25), where $\hat{\psi}_0$ is undetermined, the next $(O(1))$ equation in the asymptotic hierarchy becomes

$$\begin{aligned}
&\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_y\psi_1(\boldsymbol{y},\boldsymbol{z},\boldsymbol{\Omega},E)+\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_z\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)+\sigma_h(\boldsymbol{y},E)\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\sigma_h(\boldsymbol{y},E')p_h(\boldsymbol{y},\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega}',E')\,d\Omega' dE'\\
&\qquad+\frac{\sigma_{r,tr}(\boldsymbol{y},E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}Et(\boldsymbol{y},E)\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E).
\end{aligned}\tag{2.26}$$

Integrating this equation over the line $\boldsymbol{y}+s\boldsymbol{\Omega}$, $-R \le s \le R$, using

$$\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_y\psi_1(\boldsymbol{y}+s\boldsymbol{\Omega},\boldsymbol{z},\boldsymbol{\Omega},E) = \frac{d}{ds}\psi_1(\boldsymbol{y}+s\boldsymbol{\Omega},\boldsymbol{z},\boldsymbol{\Omega},E),$$

and then dividing by $2R$, we obtain

$$\begin{aligned}
&\frac{1}{2R}\left[\psi_1(\boldsymbol{y}+R\boldsymbol{\Omega},\boldsymbol{z},\boldsymbol{\Omega},E)-\psi_1(\boldsymbol{y}-R\boldsymbol{\Omega},\boldsymbol{z},\boldsymbol{\Omega},E)\right]\\
&\quad+\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_z\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)+\left[\frac{1}{2R}\int_{-R}^{R}\sigma_h(\boldsymbol{y}+s\boldsymbol{\Omega},E)\,ds\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\left[\frac{1}{2R}\int_{-R}^{R}\sigma_hp_h(\boldsymbol{y}+s\boldsymbol{\Omega},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\,ds\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega}',E')\,d\Omega'dE'\\
&\qquad+\frac{1}{2}\left[\frac{1}{2R}\int_{-R}^{R}\sigma_{r,tr}(\boldsymbol{y}+s\boldsymbol{\Omega},E)\,ds\right]\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}E\left[\frac{1}{2R}\int_{-R}^{R}t(\boldsymbol{y}+s\boldsymbol{\Omega},E)\,ds\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E).
\end{aligned}\tag{2.27}$$

Now we let $R\to\infty$. Using the assumption that ψ_1 is bounded, and introducing the notation

$$\langle f\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y}) = \lim_{R\to\infty}\frac{1}{2R}\int_{-R}^{R}f(\boldsymbol{y}+s\boldsymbol{\Omega})\,ds,\tag{2.28}$$

which denotes averaging over the infinite line passing through the point $\boldsymbol{y}$ in the direction $\boldsymbol{\Omega}$, we obtain

$$\begin{aligned}
&\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_z\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)+\langle\sigma_h\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y},E)\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\langle\sigma_hp_h\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega}',E')\,d\Omega'dE'\\
&\qquad+\frac{1}{2}\langle\sigma_{r,tr}\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y},E)\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}E\langle t\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y},E)\,\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E).
\end{aligned}\tag{2.29}$$

Now we make another fundamental assumption:

(2.30) A2 : *Each line-averaged quantity in* (2.29) *equals its volume average.*

More explicitly, if we define the volume average

$$\overline{\sigma}_h(E) = \lim_{R\to\infty}\frac{3}{4\pi R^2}\int_{|\boldsymbol{y}|\le R}\sigma_h(\boldsymbol{y},E)\,dy,\tag{2.31}$$

then we assume

$$\langle\sigma_h\rangle_{\boldsymbol{\Omega}}(\boldsymbol{y},E) = \overline{\sigma}_h(E),\tag{2.32}$$

and similarly for the other line averages in (2.29). Assumption A2 places constraints on the uniformity and isotropicity of the randomness in the physical system. These constraints are not true for all heterogeneous systems. For example, they are not true for certain $\boldsymbol{\Omega}$ for crystalline systems in which the spatial heterogeneities are small but spatially periodic. However, for the randomized media considered in this paper, it is reasonable to assume that A2 is satisfied. Equation (2.29) then becomes

$$\begin{aligned}
&\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_z\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)+\overline{\sigma}_h(E)\,\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\overline{\sigma_h p_h}\,(\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\,\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega}',E')\,d\Omega' dE'\\
&\qquad+\frac{\overline{\sigma}_{r,tr}(E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}E\overline{t}(E)\,\hat{\psi}_0(\boldsymbol{z},\boldsymbol{\Omega},E).
\end{aligned}\tag{2.33}$$

Finally, we convert (2.33) back to the original independent variables. We define

$$\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)=\hat{\psi}_0\left(\frac{\boldsymbol{x}}{\lambda_{r,tr}},\boldsymbol{\Omega},E\right),\tag{2.34}$$

and we use (2.17) to obtain

$$\frac{1}{\lambda_{r,tr}}\,\overline{\sigma}_h(E)=\overline{\Sigma}_h(E)=\text{ volume average of }\Sigma_h(\boldsymbol{x},E),\tag{2.35a}$$

$$\begin{aligned}
\frac{1}{\lambda_{r,tr}}\,\overline{\sigma_h p_h}(\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)&=\overline{\Sigma}_h(\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\\
&=\text{ volume average of }\Sigma_h(\boldsymbol{x},\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E),
\end{aligned}\tag{2.35b}$$

$$\frac{1}{\lambda_{r,tr}}\,\overline{\sigma}_{r,tr}(E)=\overline{\Sigma}_{r,tr}(E)=\text{ volume average of }\Sigma_{r,tr}(\boldsymbol{x},E),\tag{2.35c}$$

$$\frac{1}{\lambda_{r,tr}}\,E\overline{t}(E)=\overline{S}_r(E)=\text{ volume average of }S_r(\boldsymbol{x},E).\tag{2.35d}$$

Introducing (2.34) and (2.35) into (2.33), we obtain that the solution $\psi(\boldsymbol{x},\boldsymbol{\Omega},E)$ of (2.1) has the asymptotic approximation

$$\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)=\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)+O(\varepsilon),\tag{2.36}$$

where $\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)$ satisfies the BFP problem:

$$\begin{aligned}
&\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}_x\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)+\overline{\Sigma}_h(E)\,\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)\\
&\quad=\int_0^\infty\int_{4\pi}\overline{\Sigma}_h\,(\boldsymbol{\Omega}'\cdot\boldsymbol{\Omega},E'\to E)\,\Psi_0(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE'\\
&\qquad+\frac{\overline{\Sigma}_{r,tr}(E)}{2}\left[\frac{\partial}{\partial\mu}(1-\mu^2)\frac{\partial}{\partial\mu}+\frac{1}{1-\mu^2}\frac{\partial^2}{\partial\gamma^2}\right]\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)\\
&\qquad+\frac{\partial}{\partial E}\overline{S}_r(E)\,\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E),
\end{aligned}\tag{2.37a}$$

$$\Psi_0(\boldsymbol{x},\boldsymbol{\Omega},E)=\Psi^b(\boldsymbol{x},\boldsymbol{\Omega},E),\quad \boldsymbol{x}\in\partial V,\ \ \boldsymbol{\Omega}\cdot\boldsymbol{n}<0.\tag{2.37b}$$

Equations (2.37) are the atomic mix approximation to the BFP equation (2.10), with the boundary condition (2.1b). We note that (2.37b) is the same as the original boundary condition (2.1b). This is because we tacitly assumed that the prescribed incident flux Ψ^b varies spatially on the slow spatial scale of $\lambda_{r,tr}$, not on the fast spatial scale of λ_{ch}.

To summarize: we have formally shown that by separating the hard and soft collision operators, and requiring the soft collision operator to be sufficiently peaked for $\mu_0 \approx 1$ and $E \approx E'$, one can asymptotically approximate the Boltzmann equations (2.1) by the BFP equations (2.10). Also, if (A1) the characteristic lengths defined by (2.13) and (2.15) satisfy (2.16), and (A2) the average of the problem data over any line equals the volume average, then the BFP equations (2.10) are asymptotically approximated by the atomic mix BFP equations (2.37).

Now let us formally consider the atomic mix model of (2.1):

$$\begin{aligned} &\boldsymbol{\Omega}\cdot\boldsymbol{\nabla}\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)+\overline{\Sigma}(E)\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)\\ &\quad=\int_0^\infty\int_{4\pi}\overline{\Sigma}(\boldsymbol{\Omega}\cdot\boldsymbol{\Omega}',E'\to E)\Psi(\boldsymbol{x},\boldsymbol{\Omega}',E')\,d\Omega' dE',\quad \boldsymbol{x}\in V, \end{aligned} \tag{2.38a}$$

$$\Psi(\boldsymbol{x},\boldsymbol{\Omega},E)=\Psi^b(\boldsymbol{x},\boldsymbol{\Omega},E),\quad \boldsymbol{x}\in\partial V,\ \boldsymbol{\Omega}\cdot\boldsymbol{n}<0. \tag{2.38b}$$

If we split the scattering operator in (2.38a) into the hard and soft collision operators and asymptotically apply the Fokker–Planck approximation, just as was done to (2.1a), we will obtain exactly (2.37a).

Therefore, under the assumptions described above, (2.37) is an asymptotic limit of *both* the Boltzmann equations (2.1) *and* their atomic mix version, (2.38). This implies that the atomic mix (2.38) asymptotically approximates the original Boltzmann equations (2.1). This is the main result of this paper.

We note that (2.33) is consistent with the assumption (2.25) that the leading-order term in the asymptotic expansion is independent of the fast spatial variable $\boldsymbol{y}$. (None of the cross sections in (2.33) depend on $\boldsymbol{y}$. This follows from assumption A2, (2.31), that any line average of each cross section must equal its volume average.) If for a specified problem assumption A2 is not valid, then the cross sections in (2.28) depend on $\boldsymbol{y}$, and it seems inevitable that $\hat{\psi}_0$ will also depend on $\boldsymbol{y}$. In this case, the much more complicated (2.24) should be used as the solution of (2.23). We will not consider this here because the application that we intend for the preceding asymptotic theory satisfies A2.

3. Numerical results. To test the asymptotic theory, we have devised and run a set of computer experiments using the Monte Carlo code PENELOPE [13]. We consider a sequence of 6.0 cm deep targets consisting of small droplets of water randomly mixed in air. The volume fraction occupied by the water droplets is 0.201. In the first set of experiments, a circular (radius = 1.0 cm) 2.0 MeV monodirectional electron beam is normally incident on these targets. The electrons enter the targets and deposit energy, slowing down to 0.1 MeV, at which point their remaining energy is deposited locally. The asymptotic theory predicts that as the water droplets decrease in size, the dose deposited by the electron beam will limit to the dose deposited in the homogenized (atomic mix) target.

To predict the size of the water droplets for which the atomic mix approximation becomes accurate, let us consider Figure 1, which provides data for electrons with energies between 0.1 MeV and 10.0 MeV in water. (All the data shown in Figure 1 was taken from PENELOPE.) In this figure, the quantities $\Sigma_{r,tr}^{-1}(E)$ = transport mean free path, $T^{-1}(E) = E/S(E)$ = *restricted range* (the distance a particle with energy E would travel while slowing down through soft collisions to zero energy if its stopping power while slowing down were equal to $S(E)$), $\Sigma_h^{-1}(E)$ = hard mean

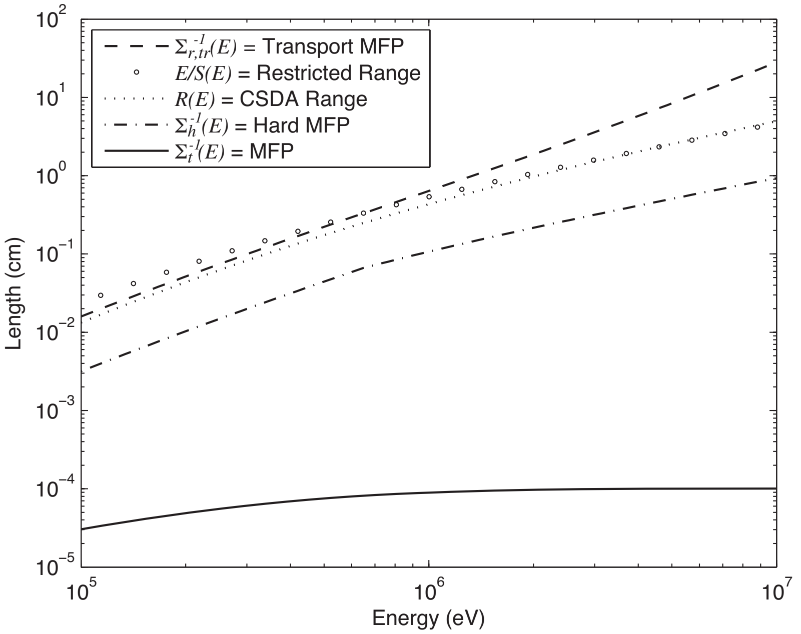

FIG. 1. *Transport MFP, restricted range, CSDA range, hard MFP, and MFP of electrons in water.*

free path, and $\Sigma_t^{-1}(E)$ = mean free path are plotted for water at normal density (1.0 gm/cm^{-1}). Also plotted in Figure 1 is the *continuous slowing down approximation (CSDA) range* $R(E)$, defined by

$$R(E) = \int_0^E \frac{dE'}{S(E')}; \tag{3.1}$$

this is the pathlength that a particle with energy E will travel while slowing down through soft collisions to zero energy. $R(E)$ is included in Figure 1 because it provides an alternate way to measure the distance in which O(1) changes in energy occur. Figure 1 shows that $R(E)$ and $T^{-1}(E)$ are comparable, and that there is a clear separation between the electron mean free path and the more "macroscopic" transport and hard mean free paths.

The asymptotic theory predicts that the atomic mix approximation is accurate if the chunk sizes lie below the transport mean free path (MFP), restricted range, and hard MFP curves in Figure 1. Interpreting this literally would place an upper limit on the chunk size of about $\lambda_{ch} = 3 \times 10^{-3}$ cm. However, the definition of the hard mean free path is somewhat arbitrary. (This definition depends on parameters chosen to run the PENELOPE simulation; the distinction between hard and soft collisions is not well defined.) Also, for most of the energy range of the electrons, the transport MFP, CSDA range, and hard MFP lie well above $\lambda_{ch} = .003$ cm. A less conservative upper bound on the chunk size is $\lambda_{ch} = .01$ cm, which is just below the minimum values of $\Sigma_{r,tr}^{-1}(E)$ and $T^{-1}(E)$.

For the given electron beam, we ran a series of simulations in which the (uniform) diameter of the droplets (λ_{ch}) was set to $\lambda_{ch} = 0.1, 0.05$, and 0.01 cm. We also

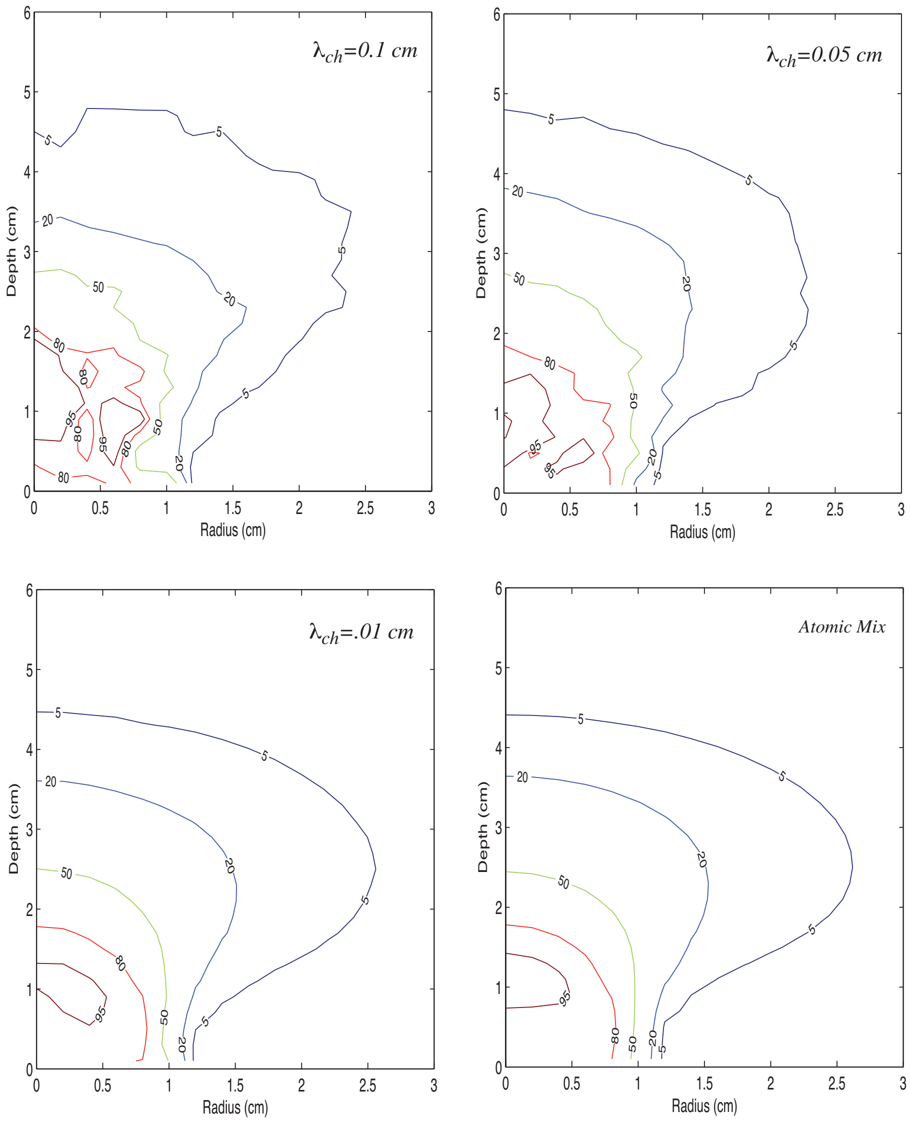

FIG. 2. 2.0 *MeV electron beam contour plots.*

simulated the homogenized (atomic mix) target. The results of these experiments are shown in Figure 2, which depicts isodose contours, normalized so that the maximum dose is unity.

This figure shows that as the chunk sizes decrease from $\lambda_{ch} = 0.1$ cm to 0.01 cm, the dose contours limit very well to the atomic mix result. The only significant difference between the $\lambda_{ch} = 0.01$ cm and atomic mix plots occurs on the 95% isodose contour, within 1.0 cm of the boundary. All of our electron beam simulations indicate such a phenomenon. The flux gradients are steep in these boundary locations, and $\lambda_{ch} = 0.01$ cm is not quite small enough for the atomic mix approximation to be valid there.

In the second set of simulations, a circular (radius = 1.0 cm) 3.4 MeV photon beam is normally incident on the same targets as above. (The energy of the photon beam was selected so that the electrons produced by Compton scattering would have roughly the same energy range as in the electron beam experiments.) These simulations have two Boltzmann equations: one for the photons and one for the electrons. The source term for the photon Boltzmann equation is the prescribed incident photon boundary flux. The source term for the electron Boltzmann equation is a volumetric term, proportional to the rate at which photons Compton scatter. The photon mean free path is on the order of cm, so the atomic mix approximation of these problems easily applies to the photon Boltzmann equation. The relevant electron data is shown in Figure 1, so as before, we predict that the atomic mix approximation for the electron Boltzmann equation should be accurate when the chunk sizes are about 0.01 cm or less.

The results (contour plots) of the photon beam experiments are depicted in Figure 3. The four plots in this figure exhibit the same trends as in Figure 2; as the chunk sizes decrease to about 0.01 cm, the contour plots converge to the contour plot for the atomic mix approximation. The only noteworthy difference is that the boundary effects seen in Figure 2 are not significant in Figure 3. This is likely because, in the photon beam experiments, electrons are produced by the Compton scattering of photons, and hence the electron "source" for the Figure 3 problems is much more spatially distributed than in Figure 2.

Figures 2 and 3 are typical. (We ran multiple realizations for each plot shown in the figures.) They indicate that when the chunk sizes become sufficiently small, the atomic mix limit is attained, and that the asymptotic theory well predicts the chunk sizes ($\lambda_{ch} \approx 0.01$ cm) for which the atomic mix approximation becomes accurate. Figure 1 shows that this size is about two orders of magnitude greater than a typical electron mean free path.

4. Discussion. We have presented a formal asymptotic theory and accompanying numerical results showing that the atomic mix approximation for charged particle transport is valid for physical systems in which (i) soft collisions dominate, (ii) a typical chunk size is small compared to a transport mean free path, and (iii) the average of any cross section over a line equals its volume average. The asymptotic theory uses earlier work by Pomraning [1] and Dumas and Golse [5]. The Monte Carlo results, generated by PENELOPE [13], are consistent with the asymptotic theory.

This work was motivated by the problem of theoretically assessing certain treatment planning procedures used in radiation oncology (radiation cancer therapy). In this field of medicine, carefully sculpted beams of high-energy photons and electrons coverage inside a patient, with the intent of sterilizing a malignant tumor [14, 15, 16]. (Photon beams also produce electrons, through Compton scattering, and these electrons deposit all the dose.) To model radiation beams penetrating the lung, standard computer codes model the lung as a union of homogenized subvolumes of about 75% air and 25% tissue (water), each subvolume having its own density, which is obtained from computerized tomography (CT) scans [17, 18, 19]. (Thus, the atomic mix approximation is used in each subvolume.) The proper resolution (size) of the subvolumes is a matter of debate.

However, the lung is an extraordinarily complex organ, with a complicated hierarchy of structures ranging from the principal bronchi (about 2 cm in diameter) to the alveoli (about 10^{-4} cm in diameter) [20, 21]. The mean free path of photons is on the order of several cm, so the atomic mix model for the entire lung is acceptable for

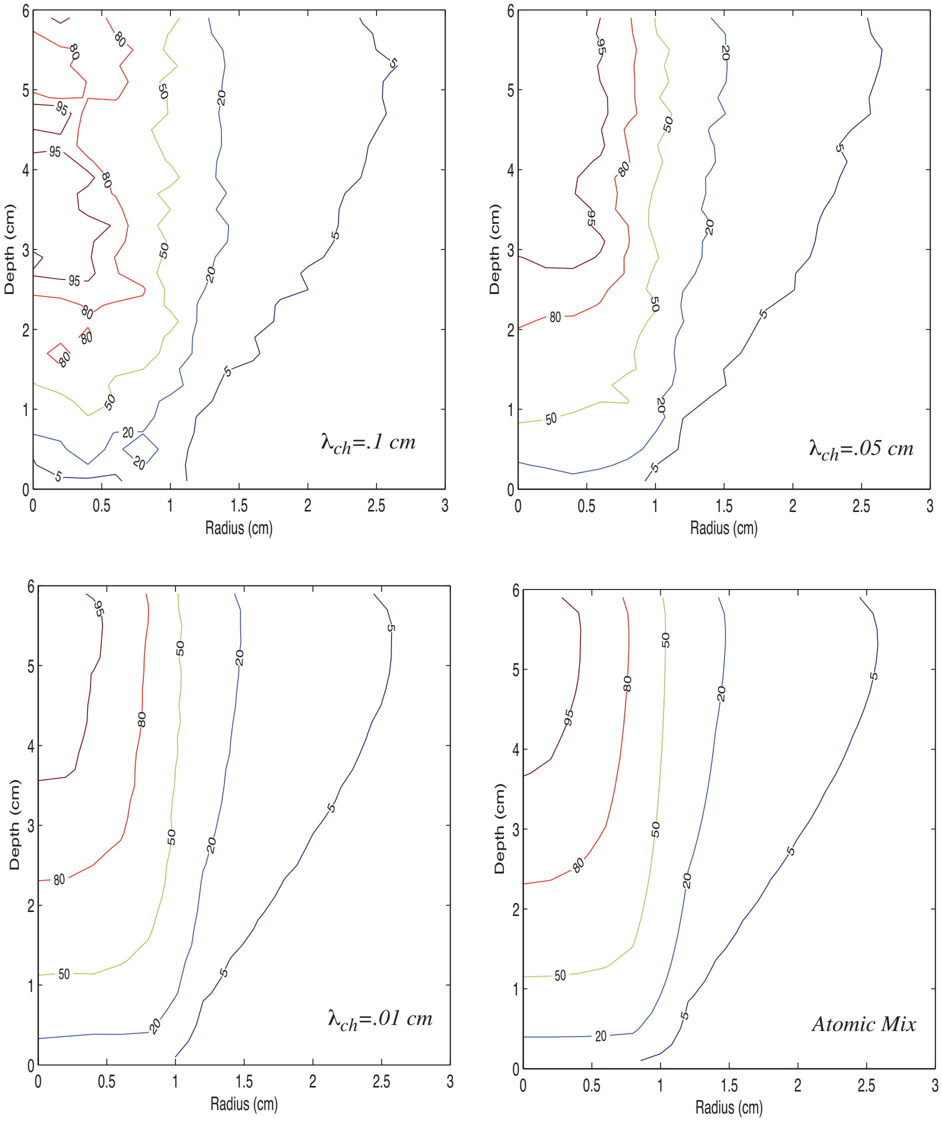

FIG. 3. 3.4 *MeV photon beam contour plots.*

photons. The results of this paper show that for random 75% air–25% water systems with uniformly sized "chunks" of water, the atomic mix approximation (i) is accurate with chunk sizes less than about 0.01 cm in diameter, but (ii) may be inaccurate when the chunk sizes are larger. Since the human lung contains structures with a large hierarchy of sizes, this result cannot be directly used to predict an optimal CT resolution for treatment planning.

However, the work in this paper suggests a way to examine this problem: first, construct a lung model in which all structures larger than a specified critical size are explicitly included and all structures less than the critical size are approximated by atomic mix [12]. (The critical size is chosen as large as possible so that it does not significantly affect Monte Carlo calculations of dose.) Then, compare Monte Carlo simulations of this first model to Monte Carlo simulations of a second CT model, obtained by homogenizing the first model over the user-prescribed CT subvolumes. The differences in dose for the two models are due to the partitioning of the lung into subvolumes. These differences will diminish as the subvolumes become smaller.

We have used PENELOPE to run realistic Monte Carlo simulations on our lung models and have found that $\lambda_{cr} = 0.05$ cm is an acceptable critical value. A detailed description of our lung model and preliminary results of comparisons with CT resolutions are given in [12]. We have found that for large CT resolutions, significant errors in predicted dose can occur, especially for narrow beams that pass through one or more "large" structures.

To conclude, we note from Figure 1 that a typical electron mean free path in tissue is about 10^{-4} cm. If it were necessary to explicitly model all lung structures comparable to or greater than this size, then all structures within the lung would have to be treated explicitly; this would be nearly an impossible computational task. Therefore, the atomic mix result developed in this paper is a crucial theoretical element in the strategy of using Monte Carlo techniques to assess the accuracy of existing treatment planning methods for the lung.

We plan to continue this work—in particular, to more fully assess the accuracy of different CT resolutions—and to report our results in future publications.

Acknowledgments. The authors gratefully thank Indrin Chetty for his encouragement and support.

STOCHASTIC DYNAMICS OF LONG SUPPLY CHAINS WITH RANDOM BREAKDOWNS*

P. DEGOND† AND C. RINGHOFER‡

Abstract. We analyze the stochastic large time behavior of long supply chains via a traffic flow random particle model. As items travel on a virtual road from one production stage to the next, random breakdowns of the processors at each stage are modeled via a Markov process. The result is a conservation law for the expectation of the part density which holds on time scales which are large compared to the mean up and down times of the processors.

1. Introduction.

Traffic flow models for supply chains model the flow of items through the chain as conservation laws for an item density ρ, depending on time and a stage variable x. Stage $x = 0$ denotes the raw material, stage $x = 1$ denotes the finished product, and the interval $[0, 1]$ models the intermediate stages of the production process and plays the role of the "road" in traffic flow theory. Traffic models have been used to model supply chains in [1, 2, 13, 5, 8] and, more recently, to optimize them in [6, 7, 9].

In previous work [3] we developed a traffic flow model for a chain of suppliers with a given capacity and throughput time. It is of the form

$$\partial_t \rho(x,t) + \partial_x F(x,t) = 0, \quad F(x,t) = \min\{\mu(x), V(x)\rho\}. \tag{1.1}$$

Here x denotes a continuous supplier index, i.e., the stage of the process. $\rho(x,t)$ denotes the density of parts in the supply chain. To compute the number of parts, i.e., the work in progress (WIP) $W_{ab}(t)$ in a certain subset of processors, corresponding to an interval (a,b) at a given time t, we have to compute $W_{ab}(t) = \int_a^b \rho(x,t)\ dx$. As long as the processors run below capacity, the movement of parts is given by the velocity V. So $\frac{dx}{V(x)}$ is proportional to the throughput time of the processor occupying the infinitesimal interval dx. The processors are assumed to have a finite capacity, meaning that they cannot process more that $\mu(x)dt$ parts in any infinitesimal time interval dt. So the variables in (1.1) have units of parts/stage for ρ, parts/time for μ, and stage/time for V. We prescribe a general, time-dependent influx of the form

$$F(0,t) = \lambda(t) \tag{1.2}$$

for the conservation law (1.1).

Equation (1.1) is derived rigorously in [3] from a discrete recursion for the times each part arrives at each processor and from a limiting process for the number of parts and the number of processors $M \to \infty$. However, this recursion relation is completely deterministic, and the supply chain is therefore assumed to work like an automaton. The goal of this paper is to include random behavior of the processors, i.e., random breakdowns and random repair times, into the model. We model the breakdown of processors by setting the capacity $\mu(x)$ to zero. Thus, the model we consider consists of (1.1), where $\mu = \mu(x,t)$ is a time-dependent random variable. To be more precise, we assume $\mu(x,t)$ to be piecewise constant in space and of the form

$$\mu(x,t) = \sum_{m=0}^{M-1} \mu_m(t)\chi_{[\gamma_m,\gamma_{m+1})}(x), \tag{1.3}$$

where $0 = \gamma_0 < \cdots < \gamma_M = 1$ denotes a partition of the stage interval $[0,1]$, corresponding to M processors, and the functions $\mu_m(t),\ m = 0,\dots,M-1$, take on values of either $\mu_m(t) = 0$ or $\mu_m = c_m$, where c_m denotes the capacity of the processor in the case when it is running. We assume that the on/off switches are exponentially distributed in time; that is, we assume mean up and down times τ_m^{up} and τ_m^{down} and generate the random signal $\mu_m(t)$ by the following algorithm:

- Assuming that at time t processor m has just switched from the off state to the on state, choose Δt_{up}^m and Δt_{down}^m randomly from the distributions $d\mathcal{P}[\Delta t_{up}^m = s] = \frac{1}{\tau_m^{up}}\exp(-\frac{s}{\tau_m^{up}})ds$ and $d\mathcal{P}[\Delta t_{down}^m = s] = \frac{1}{\tau_m^{down}}\exp(-\frac{s}{\tau_m^{down}})ds$.
- Set $\mu_m(s) = c_m$ for $t < s < t + \Delta t_{up}^m$ and $\mu_m(s) = 0$ for $t + \Delta t_{up}^m < s < t + \Delta t_{up}^m + \Delta t_{down}^m$.
- At $t = t + \Delta t_{up}^m + \Delta t_{down}^m$ the processor is turned on again and we repeat the above process.

In this way we generate M random time-dependent signals which produce the random capacity $\mu(x,t)$ according to (1.3). For each realization of this process, we solve one realization of the conservation law (1.1), thereby modeling the random breakdown of elements in the chain. To illustrate this, Figure 1.1 shows one realization of one of the signals, namely $\mu_1(t)$, switching between $\mu_1 = c_1$ and $\mu_1 = 0$, and one realization of the solution of the corresponding conservation law. Note that the conservation law (1.1) exhibits, despite its simple form, a rather interesting feature. Since the flux function F is uniformly bounded from above by $\mu(x,t)$, it will necessarily become discontinuous if the flux coming from the left exceeds this value. This can be the case if $\mu(x,t)$ is discontinuous in the stage variable x, which will certainly occur if $\mu(x,t)$ is generated randomly by the algorithm above. Since mass has to be conserved, the discontinuity in the fluxes has to be compensated by δ-functions in the density ρ. The temporary buildup of these δ-functions is what is observed in Figure 1.1.

The goal of this paper is to derive an evolution equation for the expectation $\langle\rho(x,t)\rangle$ of the density ρ given by the stochastic process above. This provides us with a rather inexpensive way to estimate the behavior of long supply chains, with random breakdowns of individual processors, by solving directly one rather simple conservation law for the expectation. The main result of the present paper is that the expectation $\langle\rho(x,t)\rangle$ satisfies an initial boundary value problem for a conservation law of the form

(1.4)

$$\text{(a) } \partial_t\langle\rho(x,t)\rangle + \partial_x F_E(\bar\tau, C, V, \langle\rho\rangle) = 0, \quad F_E(\bar\tau, C, V, \langle\rho\rangle) = \bar\tau C\left[1 - \exp\left(-\frac{V\langle\rho}{C}\right)\right],$$

$$\text{(b) } F_E|_{x=0} = \lambda(t), \quad \langle\rho(x,0)\rangle = 0,$$

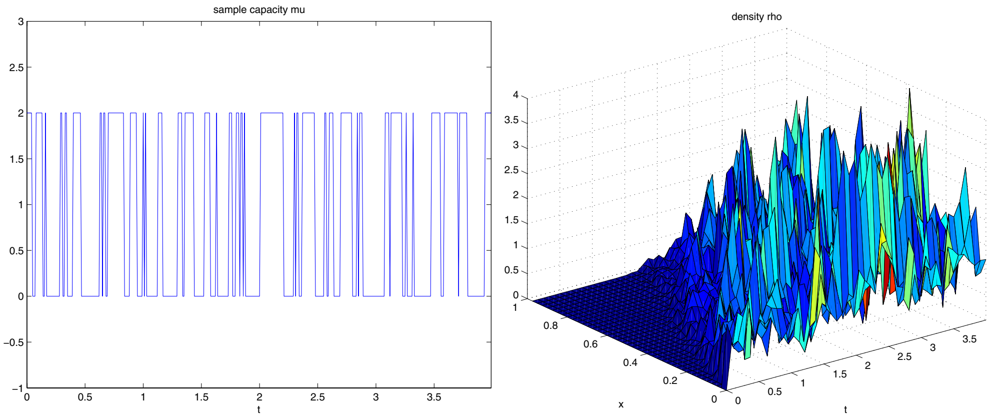

FIG. 1.1. *Left panel: One realization of the random capacity $\mu_1(t)$ of the first processor. Right panel: Density ρ from one realization of the conservation law* (1.1) *with random capacities.*

where the piecewise constant functions $\bar{\tau}$ and C are given by

$$\bar{\tau}(x) = \sum_{m=0}^{M-1} \chi_{[\gamma_m,\gamma_{m+1})}(x) \frac{\tau_m^{up}}{\tau_m^{up} + \tau_m^{down}}, \quad C(x) = \sum_{m=0}^{M-1} \chi_{[\gamma_m,\gamma_{m+1})}(x) c_m. \tag{1.5}$$

The result is derived in a limiting regime for large time scales and many parts and processors. So, it holds when the behavior of the chain, given by the stochastic version of (1.1), is considered on a time scale where a large number of parts arrive and the on/off switches of the processors occur very frequently. Similar models have been used on a heuristic basis, in the context of clearing functions, in [11, 14]. Our result basically states two facts as follows:

- For a large number of parts, the function $\min\{\mu, V\rho\}$ is, under the expectation, replaced by the function $\mu[1 - \exp(-\frac{V\rho}{\mu})]$, which has the same limiting behavior for large and small densities (the limits $\rho \to 0$ and $\rho \to \infty$).
- The effect of the random on/off switches can be incorporated into the model by replacing μ by the on-capacity c and multiplying the whole flux function by the average time $\frac{\tau^{up}}{\tau^{up}+\tau^{down}}$ the processor is on.

This paper is organized as follows. We prove the validity of the limiting equation (1.4) in a somewhat roundabout way. We first discretize one realization of (1.1) by a particle method, using the Lagrangian formulation of (1.1). Then we take the appropriate limits. So, section 2 is devoted to the formulation of the particle method. The limiting behavior is derived in section 3. In section 4 we verify our results numerically and demonstrate the basic premise of the method, namely, that we can accurately model the large time behavior of long chains with the mean field equation (1.4). The proofs of section 3 are given in the appendix.

2. Particle formulation. As mentioned in the introduction, we will derive the main result of this paper, the conservation law (1.4) for the expectation $\langle\rho\rangle$, from a particle discretization of (1.1) in Lagrangian coordinates. Since we are going to employ a mean field theory approach to the particle model in the next section, it is essential that the particle formulation of (1.1) is invariant under permutations of the particles. This will require some special considerations, and therefore we derive first a particle formulation of the deterministic problem, i.e., for one fixed realization of the random capacities $\mu(x, t)$. In section 2.2 we will then generalize this formulation to the random case.

2.1. The deterministic case. First, we reformulate problem (1.1) in Lagrangian coordinates. The transformation from Eulerian to Lagrangian coordinates is given in the usual manner by

$$\text{(2.1)} \qquad \text{(a) } \rho(x,t) = \int \delta(x - \xi(y,t))\ dy, \quad \text{(b) } \rho(\xi(y,t),t) = -\frac{1}{\partial_y \xi(y,t)},$$

where $\xi(y,t)$ denotes the position of a particle with continuous index y at time t. The derivative $\partial_y \xi = -\frac{1}{\rho}$ denotes the specific volume of the flow, i.e., the infinitesimal distance between two neighboring particles, and the minus sign indicates that we number the particles, at least initially, in order of their arrival, i.e., $y_1 < y_2 \Rightarrow \xi(y_1) > \xi(y_2) \Rightarrow \partial_y \xi < 0$ holds. Note, that (2.1)(b) holds only in the absence of caustics, that is, as long as the particles stay ordered and do not overtake one another, whereas (2.1)(a) also holds in the presence of caustics. Using the transformation (2.1), we see the conservation law (1.1) becomes

$$\text{(2.2)} \qquad \partial_t \xi(y,t) = v(\xi,t) = \min\left\{\frac{\mu(\xi,t)}{\rho(\xi,t)}, V(\xi)\right\}$$

and reduces to a parameterized ordinary differential equation (ODE) for the trajectories $\xi(y,t)$. We consider a particle discretization of one realization of the stochastic version of the conservation law (1.1) by replacing $\rho(x,t)$ by the measure corresponding to N particles

$$\text{(2.3)} \qquad \rho(x,t) \approx \Delta y \sum_{n=1}^{N} \delta(x - \xi_n(t))$$

(where we choose the symbol Δy for the particle weight so as to be notationally consistent with (2.1)) and solve the system of ODEs

$$\text{(2.4)} \qquad \partial_t \xi_n(t) = v_n, \quad v_n \approx \min\left\{\frac{\mu(\xi_n)}{\rho(\xi_n)}, V(\xi_n)\right\}.$$

The following three aspects are still missing in the consistent formulation of the particle method (2.4):

- We have to decide on an appropriate weight Δy of each particle.
- We have to define initial conditions for the trajectories ξ_n to reproduce the boundary condition (1.2) of the conservation law.
- We still have to define how to compute the density $\rho(x,t)$ at $x = \xi_n$ from the particle ensemble.

To address the first issue, we assume that we start from an empty system. In this case, the total mass over all time is given by the integral over the influx $\Lambda = \int_0^\infty \lambda(t)\ dt$, which we assume to be finite. To match this total mass Λ to the total mass in (2.3), we set $\Delta y = \frac{\Lambda}{N}$.

To address the second issue, we note that the flux F of the Lagrangian formulation (2.2) is given by

$$F(x,t) = \int \delta(x - \xi(y,t)) v(\xi)\ dy \ \Rightarrow\ \lambda(t) = F(0,t) = \int \delta(\xi(y,t)) v(\xi)\ dy;$$

defining the initial condition $\xi(y, a(y)) = 0$ for the particles in the Lagrangian formulation (2.2) implies

$$\text{(2.5)} \qquad \lambda(t) = \int \delta(t - a(y))\ dy \ \Rightarrow\ a^{-1}(t) = \int_0^t \lambda(s)\ ds.$$

Thus, the arrival times $a(y)$ have to be chosen as the functional inverse of the monotone antiderivative of the influx function $\lambda(t)$, i.e., $a(y) = t \iff y = \int_0^t \lambda(s)\, ds$ has to hold. In the deterministic case, treated in [3], this implies that the arrivals $a(y)$ satisfy the ODE

$$\frac{da(y)}{dy} = \frac{1}{\lambda(a(y))}, \quad a(0) = 0.$$

2.2. The random case. We now consider the stochastic process for the computation of the capacity variables $\mu_m(t)$ in (1.3). The assumption of an exponential distribution of the up and down times τ_m^{up} and τ_m^{down} implies a Markov process. This means that at each infinitesimal time, we can decide whether to switch the processor from on to off and back with a constant frequency $\omega_m(\mu) = \frac{1}{\tau_m^{up/down}}$. Thus, the evolution of $\mu_m(t)$ can be expressed by the process

$$\text{(2.6)} \quad \text{(a) } \mu_m(t + \Delta t) = (1 - r_m)\mu_m(t) + r_m(c_m - \mu_m(t)), \quad r_m = 0 \text{ or } r_m = 1,$$

$$\text{(b) } \mathcal{P}[r_m = 1] = \Delta t \omega_m(\mu_m(t)), \quad \mathcal{P}[r_m = 0] = 1 - \Delta t \omega_m(\mu_m(t)).$$

This means that at each infinitesimal time step Δt, we flip a coin and decide whether to switch, based on the probability $\Delta t \omega_m$, with the frequency ω_m given by

$$\omega_m(0) = \frac{1}{\tau_m^{down}}, \quad \omega_m(c_m) = \frac{1}{\tau_m^{up}}.$$

It is a standard exercise in the analysis of Monte Carlo methods (cf. [10]) that this algorithm results in exponentially distributed up and down times with means τ_m^{up} and τ_m^{down}.

Remark. Note that the assumption of exponentially distributed up and down times $\tau_m^{up}, \tau_m^{down}$ allows us to formulate the on/off switches as the Markov process (2.6). For a general probability distribution, the decision whether to turn the processor on or off at each time step depends on the time it has been in its present state (i.e., its history), leading to a model that is nonlocal in time. The case of a general distribution of up and down times will be the subject of a subsequent paper.

The motion of the particles ξ_n is now discretized in time, which leads to the following time-discrete version of (2.4):

$$\text{(2.7)} \qquad \xi_n(t + \Delta t) = \xi_n(t) + \Delta t v_n(\overrightarrow{\xi}(t), \overrightarrow{\mu}(t)),$$

where the velocities v_n depend on the whole particle ensemble $\overrightarrow{\xi} = (\xi_1, \dots, \xi_N)$ and, in addition, on the random capacity vector $\overrightarrow{\mu}(t) = (\mu_1, \dots, \mu_M)$. We still have to define a way to compute the density $\rho(\xi_n, t)$ from the particle ensemble $\overrightarrow{\xi}$. As stated before, the density ρ is given, in terms of the particle formulation, as the inverse of the specific volume, i.e., the distance of two neighboring particles. Formulating this in a way that is invariant under permutation of the particle index, we set

$$\text{(2.8)} \qquad \frac{1}{\rho(\xi_n, t)} = \min \left\{ \frac{\xi_k - \xi_n}{\Delta y} : \ \xi_k > \xi_n \right\}.$$

Note that if the particles stay in descending order, this reduces to $\frac{1}{\rho} = \frac{\xi_{n-1} - \xi_n}{\Delta y}$, which would be just the difference approximation to (2.1). The significance of the formula

(2.8) lies in the fact that it is also valid if particles pass each other and the descending order is destroyed. Therefore, we choose the velocities $v_n(\overrightarrow{\xi}, \overrightarrow{\mu})$ as

$$(2.9) \qquad v_n(\overrightarrow{\xi}(t), \overrightarrow{\mu}(t)) = \min\left\{V(\xi_n),\ \frac{\mu(\xi_n,t)}{\Delta y}(\xi_k - \xi_n) :\ \xi_k > \xi_n\right\},$$
$$\mu(\xi_n, t) = \sum_m \chi_m(\xi_n)\mu_m(t).$$

Turning to the boundary condition, we replace the influx density $\lambda(t)$ in (2.5) by a measure of the form

$$(2.10) \qquad \lambda(t) \approx \Delta y \sum_{n=1}^{N} \delta(t - a_n) = \frac{\Lambda}{N} \sum_{n=1}^{N} \delta(t - a_n).$$

The goal here is again to formulate (2.10) in such a way that the resulting particle method is invariant under permutations of the particle index n. We do so by randomizing (2.10), and we choose identically distributed random arrival times for each particle, according to the probability distribution $\frac{\lambda}{\Lambda}$. So, we have

$$(2.11) \qquad \xi_n(a_n) = 0, \quad d\mathcal{P}[a_n = t] = \frac{\lambda(t)}{\Lambda}dt, \quad \Lambda = \int_0^\infty \lambda(t)\ dt.$$

Equations (2.6)–(2.7), together with the definitions (2.9) and the initial condition (2.11), give a complete set of rules to advance the particle positions $\overrightarrow{\xi}$ and the capacities $\overrightarrow{\mu}$ from one time step to the next, and these rules are independent under permutations of the particle index. We will reformulate the system once more, to essentially replace the boundary condition (1.2) by an initial condition. This is really a technicality, and the reason for it is that, in the next section, we will derive equations for the probability density of the particle ensemble. To this end it is notationally more convenient to deal with a fixed number of particles in the system, instead of particles which enter at random times a_n. So, instead of imposing the condition $\xi_n(a_n) = 0$, we move the particles with an arbitrary, constant, and deterministic velocity—say $V(0)$—as long as $\xi_n(t) < 0$ holds, and start them out at $\xi_n(0) = -V(0)a_n$. Obviously $\xi_n(t) = V(0)(t - a_n)$ will hold for $\xi_n < 0$ and the particle will arrive at $\xi_n = 0$ at the correct time.

So, in summary, the stochastic particle system, which will be analyzed in the next section, is of the following form.

Start out at $t = 0$ with

$$(2.12) \qquad \text{(a) } \mu_m(0) = c_m,\ m = 0, \dots, M-1,$$
$$\text{(b) } \xi_n(0) = -V(0)a_n,\ n = 1, \dots, N, \quad d\mathcal{P}[a_n = t] = \frac{\lambda(t)}{\Lambda}dt.$$

To move particle positions $\overrightarrow{\xi}$ and capacities $\overrightarrow{\mu}$ for one time step Δt, compute

$$(2.13) \quad \text{(a) } \mu_m(t + \Delta t) = (1 - r_m)\mu_m(t) + r_m(c_m - \mu_m(t)), \quad r_m = 0 \textit{ or } r_m = 1,$$
$$\text{(b) } \mathcal{P}[r_m = 1] = \Delta t\omega_m(\mu_m(t)), \quad \mathcal{P}[r_m = 0] = 1 - \Delta t\omega_m(\mu_m(t)),$$

$$\text{(c) } \xi_{\mathrm{n}}(\mathrm{t}+\Delta\mathrm{t}) = \xi_n(t) + \Delta t v_n(\overrightarrow{\xi}(t), \overrightarrow{\mu}(t)),$$

$$\text{(d) } v_n(\overrightarrow{\xi}(t), \overrightarrow{\mu}(t)) = \begin{pmatrix} & V(0) & \xi_n < 0 \\ \min\{V(\xi_n), & \frac{\mu(\xi_n,t)}{\Delta y}(\xi_k - \xi_n): \quad \xi_k > \xi_n\} & \xi_n \geq 0 \end{pmatrix},$$

$$\text{(e) } \mu(\xi_n, t) = \sum_m \chi_m(\xi_n)\mu_m(t).$$

Remark. We assume in (2.12) for simplicity that all the processors in the beginning are on.

3. The evolution of the expectation.

3. The evolution of the expectation. This section is devoted to the derivation of main result (1.4) from the particle model (2.12)–(2.13). There are three steps involved. In section 3.1 we derive a high dimensional Boltzmann-type equation for the joint probability density of the particle positions $\overrightarrow{\xi}$ and the capacity variables $\overrightarrow{\mu}$ of the previous section. In section 3.2, we then reduce the dimensionality of the problem by employing a type of mean field theory for the conditional probability of the particle positions for a given realization of the capacities. In section 3.3 we compute averages over time scales which are much longer than the mean on/off switching times τ_m^{up} and τ_m^{down}. At leading order when the particle number tends to infinity, this procedure leads to an evolution equation for the probability $p(x,t)$ that an arbitrary particle in (2.13) is at position x at time t. Up to a multiplicative constant, p can be identified with the expectation $\langle\rho\rangle$ in (1.4).

3.1. The probability distribution. We now derive the evolution equation for the probability distribution

$$F(X, Z, t)dXZ = d\mathcal{P}[\overrightarrow{\xi}(t) = X, \overrightarrow{\mu}(t) = Z],$$

where the particle ensemble $\overrightarrow{\xi} = (\xi_1, \ldots, \xi_N)$ is at the N-dimensional position $X = (x_1, \ldots, x_N)$, while the processor capacities $\overrightarrow{\mu} = (\mu_1, \ldots, \mu_m)$ are in the state $Z = (z_1, \ldots, z_m)$. We have the following theorem.

THEOREM 3.1. *Let the evolution of particles $\overrightarrow{\xi}$ and capacities $\overrightarrow{\mu}$ be given by* (2.12) *and* (2.13)*. Then, in the limit $\Delta t \to 0$ the joint probability distribution $F(X, Z, t)$ satisfies the initial value problem for the Boltzmann equation*

$$\text{(3.1)} \qquad \text{(a) } \partial_t F + \sum_n \partial_{x_n}[v_n(X, Z, t)F] = \int Q(Z, Z')F(X, Z', t)\; dZ',$$

$$\text{(b) } F(X, Z, 0) = (\Lambda V(0))^{-N}\left[\prod_{n=1}^{N} \lambda\left(-\frac{x_n}{V(0)}\right)\right]\left[\prod_{m=0}^{M-1} \delta(z_m - c_m)\right],$$

with the integral kernel Q given by

$$\text{(3.2)} \qquad \text{(a) } Q(Z, Z') = \sum_m q_m(z_m, z'_m)\prod_{k\neq m} \delta(z'_k - z_k),$$

$$\text{(b) } q_m(z_m, z'_m) = \omega_m(z'_m)[\delta(c_m - z'_m - z_m) - \delta(z'_m - z_m)].$$

Proof. The proof of Theorem 3.1 consists of summing up over all the possibilities of choosing the random variables r_m in (2.13), and it is an exercise in multidimensional Taylor expansion. It is deferred to the appendix.

In terms of the probability distribution $F(X, Z, t)$, the expectation $\langle \rho(x, t) \rangle$ in (1.4) is then given by

$$\langle \rho(x,t) \rangle = \Delta y \sum_{n=1}^{N} \int \delta(x - \xi_n(t)) F(\overrightarrow{\xi}, Z, t) \; d\overrightarrow{\xi} dZ = \Delta y \sum_{n=1}^{N} p_n(x,t), \tag{3.3}$$

with $p_n(x,t) = \int F(\xi_1, \ldots, \xi_{n-1}, x, \xi_{n+1}, \ldots, \xi_N, Z, t) \; d\xi_1, \ldots, \xi_{n-1}, \xi_{n+1}, \ldots, \xi_N \; dZ$ being the probability density that particle number n is at position x at time t. The density $F(X, Z, t)$ is of course of too high a dimension to be of practical use, and the goal of the next two sections is therefore to reduce the dimensionality of the problem.

3.2. Molecular chaos and mean field theory. Since the joint probability F in (3.1) depends on the capacity variables Z as well, the usual assumption of statistical independence (cf. [4]) has to be slightly modified. We first define the probability for the capacity variables Z as $G(Z,t) = \int F(X, Z, t) \; dX$. Integrating out X in (3.1) gives the initial value problem

$$\text{(a) } \partial_t G = \int Q(Z, Z') G(Z', t) \; dZ', \quad \text{(b) } G(Z, 0) = \prod_{m=0}^{M-1} \delta(z_m - c_m) \tag{3.4}$$

for G. Note that we obtain a closed equation for G, which is an expression of the fact that the capacities $\overrightarrow{\mu}$ evolve independently of the particles. Moreover, the individual capacities μ_m evolve independently of each other. This can be seen by the fact that (3.4) has a solution of the form $G(Z,t) = \prod_{m=0}^{M-1} g_m(z_m, t)$, where the individual probability densities $g_m(z_m, t)$, for the state z_m of the processor m at time t, satisfy the Boltzmann equation

$$\partial_t g_m(z,t) = \int q_m(z, z') g_m(z', t) \; dz', \tag{3.5}$$

with the kernels q_m given by (3.2)(b). We now define the conditional probability density $F^c(X, Z, t) dX = d\mathcal{P}[\overrightarrow{\xi} = X \mid \overrightarrow{\mu} = Z]$, which is the probability of the particle ensemble $\overrightarrow{\xi}$ for a given realization of the $\overrightarrow{\mu}$. The conditional probability density is defined by

$$F^c(X, Z, t) = \frac{F(X, Z, t)}{G(Z, t)}, \quad G(Z, t) = \int F(X, Z, t) \; dX. \tag{3.6}$$

Note that the definition (3.6) implies that $F^c(X, Z, t) dX$ is a probability measure for every fixed Z, i.e., $\int F^c(X, Z, t) \; dX = 1 \; \forall Z$ holds. Using the definition of F^c, (3.1) becomes

$$\partial_t [G F^c] + \sum_n \partial_{x_n} [v_n(X, Z, t) G F^c] = \int Q(Z, Z') F^c(X, Z', t) G(Z', t) \; dZ'. \tag{3.7}$$

The standard molecular chaos assumption employed in particle physics (cf. [4]) now takes the form that *for a given fixed realization of the* $\overrightarrow{\mu}$ the different ξ_n are independently and identically distributed, i.e., that

$$F^c(X, Z, t) = \prod_n f^c(x_n, Z, t), \qquad \int f^c(x, Z, t) \; dx = 1 \; \forall Z, t$$

holds. The molecular chaos assumption implies therefore the ansatz

$$F(X,Z,t) = G(Z,t)\prod_n f^c(x_n,Z,t)$$

for the joint probability F in (3.1). $f^c(x,Z,t)$ is the conditional probability density that any of the identical particles is at position x at time t for a given state Z of the processors. To obtain an evolution equation for $f^c(x,Z,t)$, we integrate (3.7) with respect to the variables $x_2 \dots x_N$ and obtain

$$(3.8)\partial_t[Gf^c(x_1,Z,t)] + \partial_{x_1}\left[Gf^c(x_1,Z,t)\int v_1(X,Z)\prod_{n=2}^{N} f^c(x_n,Z,t)dx_2\dots x_N\right]$$
$$= \int dZ'Q(Z,Z')f^c(x_1,Z')G(Z').$$

To close (3.8) we have to compute the average mean field velocity $u(x_1,Z,f^c)$, given by

$$u(x_1,Z,f^c) = \int v_1(X,Z)\prod_{n=2}^{N} f^c(x_n,Z,t)dx_2\dots x_N,$$

asymptotically for large N. To this end, we recall from (2.13)(d) that for $x_1 \in [\gamma_m,\gamma_{m+1})$, the interval corresponding to processor number m, the velocity $v_1(X,Z)$ is given by

$$v_1(X,Z) = \min\left\{V(x_1),\ \frac{z_m}{\Delta y}(x_k - x_1):\ x_k > x_1\right\}.$$

Theorem 3.2 gives the asymptotic form of the mean field velocity $u(x_1,Z,f^c)$ in the limit for a large number of independent particles ($N \to \infty$).

THEOREM 3.2. *For a given probability measure $f(x)$ and for given constants V and z,*

$$(3.9)\qquad \lim_{N\to\infty \Delta y\to 0}\int \min\left\{V, \frac{z}{\Delta y}(x_k - x_1):\ x_k > x_1\right\}\prod_{n=2}^{N} f(x_n)\ dx_2\dots x_N$$
$$= \frac{z}{\Lambda f(x_1)}\left[1 - \exp\left(-\frac{\Lambda V f(x_1)}{z}\right)\right]$$

holds where $\Lambda = N\Delta y$ is fixed.

Proof. The proof is deferred to the appendix.

Thus, in the mth cell $[\gamma_m,\gamma_{m+1})$, we have that the average mean field velocity is asymptotically given by (3.9) and can therefore be expressed by the piecewise constant function

$$(3.10)\qquad \text{(a) } u(x_1,Z,f^c) = \sum_{m=0}^{M-1} u_m(x_1,z_m,f^c)\chi_{[\gamma_m,\gamma_{m+1})}(x_1),$$
$$\text{(b) } u_m(x_1,z_m,f^c) = \frac{z_m}{\Lambda f^c}\left[1 - \exp\left(-\frac{\Lambda V(x_1)f^c}{z_m}\right)\right].$$

Therefore (3.8) reduces, under the molecular chaos assumption of many independently distributed particles, to the mean field Boltzmann equation

$$(3.11)\qquad \partial_t[Gf^c] + \partial_{x_1}[u(x_1,Z,f^c)Gf^c] = \int dZ'Q(Z,Z')f^c(x_1,Z')G(Z'),$$

with the mean field velocity u given by (3.10). The molecular chaos ansatz is compatible with the initial condition (3.1)(b) for the probability density $F(X,Z,t)$. Using (3.1)(b), we obtain the initial conditions

$$f^c(x_1,Z,0)=\frac{1}{\Lambda V(0)}\lambda\left(-\frac{x_1}{V(0)}\right),\quad G(Z,0)=\prod_{m=0}^{M-1}\delta(z_m-c_m) \tag{3.12}$$

for the evolution equations (3.11) and (3.4). Note that G still independently satisfies (3.4). This is essential, since it guarantees that $f^c(x_1,Z,t)dx_1$ is a probability measure, i.e., $\int f^c(x_1,Z,t)\ dx_1=1\ \forall Z,t$ holds.

The probability density $p_n(x,t)$ of particle number n being at position x at time t in (3.3) is, under the molecular chaos assumption, of the form

$$p_n(x,t)=p(x,t)=\int f^c(x,Z,t)G(Z,t)\ dZ\ \forall n.$$

Since all the p_n's are now identical, the expectation $\langle\rho\rangle$ is, according to (3.3), given by

$$\langle\rho(x,t)\rangle=\Lambda p(x,t).$$

So, the expectation $\langle\rho\rangle$ can be identified with the probability p up to the multiplicative constant Λ, giving the total mass in the system. To obtain the evolution equation (1.4) for the expectation $\langle\rho\rangle$ and the probability density p, we still have to average out somehow the dependence of the conditional probability density f^c on the processor-state variables $Z=(z_0,\dots,z_{M-1})$. The evolution equation for p—and also for $\langle\rho\rangle$—is obtained by integrating out the Z-variable in (3.11). This gives

$$\partial_t p(x,t)+\partial_x[pU(x,t,p)]=0,\quad pU(x,t,p)=\int u(x,Z,f^c)G(Z,t)f^c(x,Z,t)\ dZ. \tag{3.13}$$

Because of the initial condition (3.12) for the conditional probability density f^c, the conservation law (3.13) is subject to the initial condition

$$p(x,0)=\frac{1}{\Lambda V(0)}\lambda\left(-\frac{x}{V(0)}\right). \tag{3.14}$$

Note that f^c still depends on all the capacity variables Z. Therefore (3.13) has to be closed somehow by expressing f^c in terms of p. In section 3.3 this closure is achieved by considering a large time regime.

3.3. The large time regime. First, we note that in the setting of section 2.2 the capacities μ_m can assume only two discrete values, namely $\mu_m=0$ and $\mu_m=c_m$. Therefore the probabilities $g_m(z_m,t)$ in (3.5) are concentrated on these values, and we have an exact solution of (3.5) given by

$$g_m(z,t)=g_m^0(t)\delta(z)+g_m^1(t)\delta(z-c_m).$$

Inserting this into (3.5) and using the form of the integral kernels q_m in (3.2)(b) gives

$$\begin{aligned}&\delta(z)\partial_t g_m^0(t)+\delta(z-c_m)\partial_t g_m^1(t)=q_m(z,0)g_m^0(t)+q_m(z,c_m)g_m^1(t)\\&\quad=[-\omega_m(0)\delta(z)+\omega_m(0)\delta(c_m-z)]g_m^0(t)+[-\omega_m(c_m)\delta(c_m-z)+\omega_m(c_m)\delta(z)]g_m^1(t).\end{aligned}$$

Comparing the coefficients of $\delta(z)$ and $\delta(z-c_m)$, we obtain that $g_m^{0,1}(t)$ are given as solutions of the ODE system

(3.15)
$$\partial_t g_m^0 = -\omega_m(0)g_m^0(t) + \omega_m(c_m)g_m^1(t), \quad \partial_t g_m^1 = \omega_m(0)g_m^0(t) - \omega_m(c_m)g_m^1(t),$$

which preserves the property of $g_m(z,t)dz$ being a probability measure, i.e., $g_m^0 + g_m^1 = 1 \ \forall t$ holds. We now consider a regime where the on/off switches of the processors occur very frequently compared to the overall time scale, i.e., $\tau_m^{up/down} \ll 1$, $\omega_m = \frac{1}{\tau_m} \gg 1$. Thus we rescale the mean up and down times $\tau_m^{up/down}$ as well as the frequencies ω_m in (3.2) by $\tau_m^{up/down} \to \varepsilon\tau_m^{up/down}$ and $\omega_m \to \frac{1}{\varepsilon}\omega_m$. Rescaling the collision kernel Q in (3.11) correspondingly gives the system

$$\partial_t[Gf^c] + \partial_x[u(x,Z,f^c)Gf^c] = \frac{1}{\varepsilon}\int Q(Z,Z')f^c(x,Z',t)G(Z',t)\,dZ', \tag{3.16}$$

with the rescaled collision kernel Q given, according to (3.2), by

$$\text{(a) } Q(Z,Z') = \sum_m q_m(z_m,z_m')\prod_{k\neq m}\delta(z_k'-z_k), \tag{3.17}$$
$$\text{(b) } q_m(z_m,z_m') = \omega_m(z_m')[\delta(c_m - z_m' - z_m) - \delta(z_m' - z_m)].$$

From the above derivation, we have that the probability density $G(Z,t)$ of the processor status factors into M independent densities, supported on $z_m = 0$ and $z_m = c_m$, satisfying the rescaled version of (3.15). Thus, we have

$$\text{(a) } G(Z,t) = \prod_{m=1}^M g_m(z_m,t), \quad g_m(z,t) = g_m^0(t)\delta(z) + g_m^1(t)\delta(z-c_m), \tag{3.18}$$
$$\text{(b) } \varepsilon\partial_t g_m^0 = -\omega_m(0)g_m^0(t) + \omega_m(c_m)g_m^1(t), \quad \varepsilon\partial_t g_m^1 = \omega_m(0)g_m^0(t) - \omega_m(c_m)g_m^1(t),$$

where the small parameter ε denotes the ratio of $\tau^{up/down}$ to the overall time scale. The ODE system (3.18)(b) has two distinct eigenvalues, namely zero and $-\frac{\omega_m(0)+\omega_m(c_m)}{2\varepsilon}$. This, together with the condition that $g_m^0 + g_m^1 = 1 \ \forall t$ holds, implies that the $g_m^{0,1}$ will converge exponentially on an $O(\frac{t}{\varepsilon})$ time scale towards their steady state

$$g_m^0(\infty) = \frac{\omega_m(c_m)}{\omega_m(0)+\omega_m(c_m)}, \quad g_m^1(\infty) = \frac{\omega_m(0)}{\omega_m(0)+\omega_m(c_m)}. \tag{3.19}$$

Therefore, we can, up to exponentially small terms, replace $G(Z,t)$ by $G(Z,\infty)$ in (3.16). Note that $G(Z,\infty)$ is a steady state of (3.4) and therefore satisfies

$$\int dZ'\ Q(Z,Z')G(Z',\infty) = 0 \ \forall Z. \tag{3.20}$$

Replacing $G(Z,t)$ by $G(Z,\infty)$ in (3.16), we obtain

$$\text{(a) } G(Z,\infty)\{\partial_t[f^c] + \partial_x[u(x,Z,f^c)f^c]\} = \frac{1}{\varepsilon}\mathbf{Q_G}[f^c], \tag{3.21}$$
$$\text{(b) } \mathbf{Q_G}[f^c] = \int dZ' Q(Z,Z')f^c(x,Z')G(Z',\infty).$$

Expanding the conditional probability density f^c formally in powers of ε gives that, in zeroth order, $\mathbf{Q_G}[f^c] = 0$ holds. Note that, because of (3.20), functions f^c which are independent of Z are automatically in the kernel of the collision operator $\mathbf{Q_G}$ in (3.21). Theorem 3.3 states that the kernel of the collision operator consists essentially of only such functions.

THEOREM 3.3. *Any element of the kernel of the collision operator* $\mathbf{Q_G}$ *defined in* (3.21)(b) *is constant on the vertices of the hypercube* $\prod_{m=0}^{M-1}[0, c_m]$. *So* $\mathbf{Q_G}[f] = 0$ *implies that*

$$f(z_1 \dots c_m \dots z_M) - f(z_1 \dots 0 \dots z_M) = 0 \ \forall m, \ \forall Z = (z_0, \dots, z_{M-1}) \in \prod_m \{0, c_m\} \tag{3.22}$$

holds.

Proof. The proof is deferred to the appendix.

Theorem 3.3 allows us to compute the macroscopic velocity $U(x, t, p)$ in the evolution equation for the probability p in (3.13) in terms of p itself. Since in zeroth order $\mathbf{Q_G}[f^c] = 0$ has to hold, $f^c(x, Z, t)$ has to be constant on the hypercube vertices $Z \in \prod_{m=0}^{M-1}\{0, c_m\}$. In (3.13) we have to compute the flux as

$$\begin{aligned} &\text{(a) } pU(x, t, p) = \int u(x, Z, f^c) G(Z, \infty) f^c(x, Z, t) \ dZ, \\ &\text{(b) } p(x, t) = \int f^c(x, Z, t) \ dZ. \end{aligned} \tag{3.23}$$

Because of (3.18), $G(Z, \infty)$ is concentrated on the vertices $\prod_{m=0}^{M-1}\{0, c_m\}$, where f^c is constant. Therefore the integral in (3.23)(a) factors, and we obtain

$$U(x, t, p) = U(x, p) = \int u(x, Z, p) G(Z, \infty) \ dZ. \tag{3.24}$$

The derivation above actually computes the zero order term in a Chapman–Enskog procedure for the Boltzmann equation (3.21). The next term would produce a diffusive $O(\varepsilon)$ correction. However, this diffusive correction represents really only a small correction since the mean velocity U of the zero order term is nonzero; i.e., we are still in a primarily hyperbolic instead of a diffusive regime. We now have, in the large time limit, closed (3.13) for the probability density $p(x, t)$ that any of the identical particles is at position x at time t. Since this density is up to the multiplicative constant Λ identical to the expectation $\langle \rho \rangle$, i.e., $\langle \rho \rangle = \Lambda p$ holds, we also obtain a closed form equation for the expectation. This equation is of the form

$$\partial_t \langle \rho(x, t) \rangle + \partial_x \left[\langle \rho \rangle U \left(x, \frac{\langle \rho \rangle}{\Lambda} \right) \right] = 0. \tag{3.25}$$

Using the initial condition (3.14) for the probability density p, we obtain that the conservation law (3.25) is subject to the initial condition

$$\langle \rho(x, 0) \rangle = \frac{1}{V(0)} \lambda \left(-\frac{x}{V(0)} \right). \tag{3.26}$$

We have now assembled all the ingredients for the main result announced in (1.4). Computing $U(x, p)$ in (3.24), using the form (3.10) of the mean field velocity $u(x, Z, f^c)$, we have that in the interval $[\gamma_m, \gamma_{m+1})$, corresponding to the mth processor,

$$U(x, p) = \int \frac{z_m}{\Lambda p} \left[1 - \exp\left(-\frac{\Lambda p V(x)}{z_m} \right) \right] G(Z, \infty) \ dZ, \quad x \in [\gamma_m, \gamma_{m+1}),$$

holds. Using the fact that $G(Z,\infty)$ factors into a product of the g_m, and integrating out all variables, except z_m, we obtain

$$U(x,p) = \int \frac{z_m}{\Lambda p}\left[1 - \exp\left(-\frac{\Lambda p V(x)}{z_m}\right)\right] g_m(z_m,\infty)\, dz_m, \quad x \in [\gamma_m, \gamma_{m+1}).$$

Using the formulas (3.18) and (3.19) for $g_m(z,\infty)$, we integrate with respect to z_m and replace p by $\frac{\langle\rho\rangle}{\Lambda}$, obtaining for the velocity $U(x,\frac{\langle\rho\rangle}{\Lambda})$ in (3.25)

(3.27)
$$U\left(x,\frac{\langle\rho\rangle}{\Lambda}\right) = \frac{\omega_m(0)}{\omega_m(0)+\omega_m(1)}\frac{c_m}{\langle\rho\rangle}\left[1-\exp\left(-\frac{\langle\rho\rangle V(x)}{c_m}\right)\right] \text{ for } x \in [\gamma_m,\gamma_{m+1}),$$

which yields the flux function $F_E = \langle\rho\rangle U(x,\frac{\langle\rho\rangle}{\Lambda})$ in (1.4)(a), since $\frac{\omega_m(0)}{\omega_m(0)+\omega_m(1)} = \frac{\tau_m^{up}}{\tau_m^{up}+\tau_m^{down}}$ holds. Note that the ratio $\frac{\tau_m^{up}}{\tau_m^{up}+\tau_m^{down}}$ is not affected by the rescaling of the mean up and down times $\tau_m^{up/down}$ used in this section. Finally, we remove the technicality of formulating the conservation law as a pure initial value problem, which was used solely to keep the total mass constant in time and to define probability densities. For $x<0$ the velocities of the particles defined in section 2.2 are constantly equal to $V(0)$, and therefore also $U(x,p)=V(0)$ for $x<0$ will hold. The resulting one way wave equation can be solved exactly and, using the initial condition (3.26), we have

$$\langle\rho(x,t)\rangle = \langle\rho(x-tV(0),0)\rangle = \frac{1}{V(0)}\lambda\left(t-\frac{x}{V(0)}\right) \text{ for } x<0.$$

Because of flux continuity,

$$F_E|_{x=0+} = \langle\rho\rangle U\left(x,\frac{\langle\rho\rangle}{\Lambda}\right)|_{x=0+} = V(0)\langle\rho(0-,t)\rangle = \lambda(t)$$

has to hold, which yields the boundary condition (1.4)(b). The boundary condition (1.4)(b) has to be interpreted in the following way. The flux function at influx $F_E|_{x=0+} = \langle\rho\rangle U|_{x=0+}$ is, because of (3.27), bounded from above by the quantity $\frac{\tau_0^{up}c_0}{\tau_0^{up}+\tau_0^{down}}$. If the influx $\lambda(t)$ exceeds this value, as is possible in the transient regime, this results in a flux discontinuity, and correspondingly in a δ-function concentration of the expected density $\langle\rho\rangle$ at the influx boundary at $x=0$.

Remarks.

- Equation (1.4)(a) says that the whole flux (and not just the capacity c_m) is multiplied with the effective up-time $\frac{\tau_m^{up}}{\tau_m^{up}+\tau_m^{down}}$ of processor m. This is reasonable, since even for an empty system $\langle\rho\rangle \ll 1$, the flow will be slowed by shutting down the processors.
- A somewhat puzzling fact is that (1.4) does not reduce to the deterministic conservation law (1.1) in the limit $\tau^{down} \to 0$, i.e., in the case when the processors are always on. The explanation is that the derivation of (1.4) is based on the assumption of molecular chaos for the individual particles, and this assumption is apparently not valid for the deterministic system.
- More precisely, it is the frequent on and off switches *of many or all of the processors* which create the conditions of molecular chaos and the resulting approximate statistical independence of the states. Numerical experiments (not included here) have shown that the presented theory is not applicable;

cf. the case when only one processor switches and the other processors are simply in the on state all the time. (So $\tau_m^{down} = 0$ holds for all but one of the processors.)

- Note that we have made the somewhat arbitrary choice of first applying the molecular chaos assumption in section 3.2 and then carrying out the asymptotics for large time scales; we could have reversed the order by carrying out the large time scale asymptotics on the full equation (3.1) and then making the assumption of molecular chaos on the manifold of the slow dynamics, i.e., on the kernel of the collision operator on the right-hand side of (3.1).

4. Numerical experiments. We now turn to numerically verifying the validity of the approximate conservation law (1.4) for the expectation $\langle\rho(x,t)\rangle$. We do so by comparing the average over realizations of the numerical solution of (1.1) to the solution of (1.4). So, we first generate M random signals $\mu_m(t), \mu = 0, \dots, M-1$, as depicted in Figure 1.1, and compute the corresponding time-dependent capacity function $\mu(x,t)$ according to (1.3). For a given realization of $\mu(x,t)$, the conservation law (1.1) is then solved by a standard Godunov method (see [3] for details and cf. [12] for details on the Godunov method). This process is repeated many times for different realizations, and one approximation to the expectation $\langle\rho(x,t)\rangle$ is obtained by calculating averages over different realizations. We compare this approximation to the direct solution of the conservation law (1.4), also obtained by a Godunov method. It should be pointed out that the Godunov method reduces to simple upwinding in all cases, since the velocities always stay nonnegative. We employ only a first order Godunov scheme since the individual realizations will develop δ-function concentrations as soon as the processors are turned off and μ becomes zero in certain intervals. The convergence of the first order Godunov method in this case is analyzed and documented in [3], whereas the convergence properties of higher order methods are not so obvious. In all the example below we consider a chain of 40 processors ($M = 40$) which are located in the stage interval $x \in [0,1]$. For simplicity, we assume that all processors have identical throughput times. This allows us to choose a constant velocity $V(x) = 1$ in (1.1) and (1.4) by choosing an appropriate time scale. Thus, $T = 1$ is the throughput time of a part through the whole chain if all processors run below capacity, and $T = \frac{1}{40}$ is the throughput time of an individual processor in this case. We set $\tau_m^{up} = \tau_m^{down} = \frac{1}{20}\ \forall m$. The processors run, on average, only half the time, and we are in the large time scale regime of section 3.3 since $\varepsilon = \frac{1}{20} \ll 1$ holds.

Experiment 1. In the first experiment we consider $M = 40$ identical processors with a peak capacity $c_m = 2,\ m = 0, \dots, 39$. Thus, the flux function F_E in (1.4) is bounded by the effective capacity $\frac{c\tau^{up}}{\tau^{up}+\tau^{down}} = 1$. We start with an empty system $\rho(x,0) = 0$ and use a constant influx $\lambda(t) = 0.5$, well below the effective capacity. Figure 4.1 shows the expectation $\langle\rho(x,t)\rangle$ computed by averaging 200 realizations of (1.1) and by solving (1.4). Note that we obtain a good *quantitative* agreement in the size of the steady state distribution as well as in the transient behavior, i.e., the velocity of the wave propagating from $x = 0$ to $x = 1$. From (1.4) we deduce that the steady state density $\langle\rho(x,\infty)\rangle$ is given by the equation $F_E(\frac{1}{2}, 2, 1, \langle\rho(x,\infty)\rangle) = \lambda$ or $1 - e^{-\langle\rho(x,\infty)\rangle/2} = 0.5$.

Experiment 2. In the second experiment we keep the setup of the first experiment but introduce a bottleneck in processors 11–20. The peak capacities c_m are shown in Figure 4.2. Note that, because of our choice of mean up and down times τ_m^{up} and τ_m^{down}, the effective capacities are half the peak capacities shown in Figure 4.2. We choose a constant influx $\lambda = 0.27$. Again, Figure 4.3 shows the expectation $\langle\rho(x,t)\rangle$

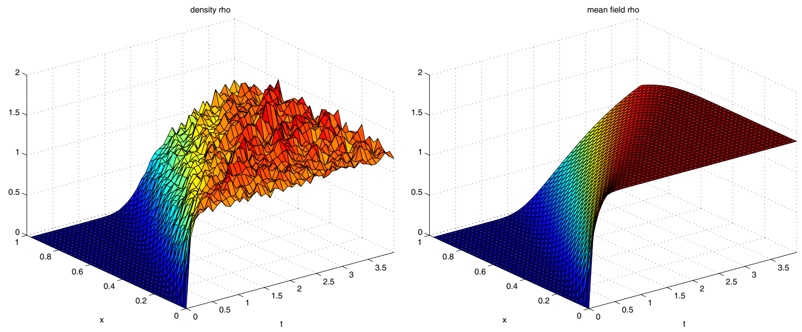

FIG. 4.1. *Experiment* 1. *Left panel: Density ρ from the deterministic conservation law* (1.1) *with random capacities and constant influx $\lambda = 0.5$. Averaged over* 200 *realizations. computed by averaging 200 realizations of (1.1) and by solving (1.4).

Experiment 3. The promise of conservation law models for supply chains lies in their ability to provide a relatively inexpensive way to model the *transient* behavior of supply chains *far from steady state regimes*. Therefore, we perform the third experiment for a regime which is truly far from equilibrium. We keep the setup from

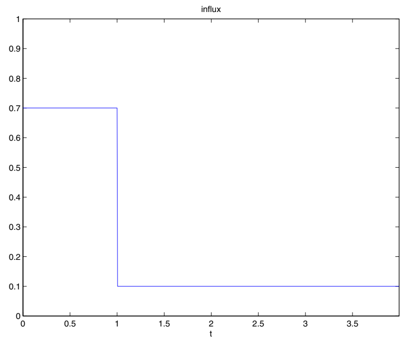

FIG. 4.4. *Experiment* 3. *Transient influx density.*

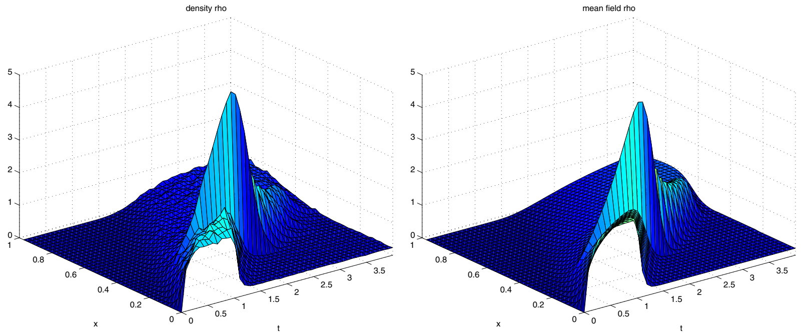

FIG. 4.5. *Experiment* 3. *Left panel: Density ρ from the deterministic conservation law* (1.1) *with random capacities and transient influx,* 40 *cells, and bottleneck in cells* 11–20. *Averaged over* 500 *realizations. the second experiment but use a transient influx density, shown in Figure 4.4. Note that the initial influx density $\lambda = 0.7$ is below the effective capacity $\frac{c_m \tau_m^{up}}{\tau_m^{up}+\tau_m^{down}}$ for most processors but exceeds the effective capacity for the bottleneck processors for $m = 11, \dots, 20$. Beyond $t = 1$ the transient influx $\lambda(t)$ is then well below the effective capacity for all processors. Thus, we will see a wave propagating through the first 10 processors $0 < x < 0.25$, the buildup of queues in the next 10 bottleneck processors $0.25 < x < 0.5$, and relaxation towards steady state after $t = 1$. Figure 4.5 shows the expectation $\langle\rho(x, t)\rangle$ computed by averaging 500 realizations of (1.1) and by solving (1.4). We observe again that the size of the peaks (the maximal queue length in front of the processors) as well as their location in the (x, t) plane (the transient response) are given accurately by the mean field model (1.4).

5. Appendix.

We start by proving the evolution equation (3.1) for the joint probability density $F(X, Z, t)$ of the particle positions and processor states.

Proof of Theorem 3.1. Once the random variables r_m in (2.6) are chosen, the rest of the evolution is completely deterministic. Summing up over all possible choices of the vector $R = (r_1, \dots, r_M)$ and weighting them with their probabilities gives

$$F(X, Z, t + \Delta t) = \int F(X', Z', t) \prod_n \delta(x'_n + \Delta t v_n(X', Z') - x_n)$$
$$\cdot \prod_m [\delta((1 - r_m)z'_m + r_m(c_m - z'_m) - z_m)]$$
$$\cdot \prod_m [\delta(r_m - 1)\Delta t \omega_m(z'_m) + \delta(r_m)(1 - \Delta t \omega_m(z'_m))] dX' dZ' dR.$$

We formulate the above relation weakly in X by integrating against a test function $\psi(X)$:

$$(5.1) \int \psi(X)F(X, Z, t + \Delta t)\ dX = \int dX'Z'R\ F(X', Z', t)\psi(X' + \Delta t V(X', Z'))$$
$$\cdot \prod_m [\delta((1 - r_m)z'_m + r_m(c_m - z'_m) - z_m)]$$
$$\cdot \prod_m [\delta(r_m - 1)\Delta t \omega_m(z'_m) + \delta(r_m)(1 - \Delta t \omega_m(z'_m))],$$

where the vector V denotes $(v_1, \dots, v_N)$. We Taylor-expand the terms on the right-hand side of (5.1) in Δt up to first order and obtain, after some calculus,

$$\int \psi(X)F(X, Z, t + \Delta t)\ dX$$
$$= \int dX\ F(X, Z, t)\psi(X) + \Delta t \int dX' F(X', Z, t)V(X', Z) \cdot \nabla_X \psi(X')$$
$$+ \Delta t \int dXZ'F(X, Z', t)\psi(X)Q(Z, Z'),$$

with the integral kernel Q given by (3.2). Letting $\Delta t \to 0$, we see this gives the weak form of

$$\partial_t F + \sum_n \partial_{x_n}[v_n(X, Z, t)F] = \int dZ' Q(Z, Z')F(X, Z'). \qquad \square$$

We now proceed to prove the form of the mean field velocity $u(x_1, Z, f^c)$ in (3.10); i.e., we prove Theorem 3.2. To prove Theorem 3.2 we will need the following auxiliary lemma, giving the expectation of the minimum of m independent random numbers, which are equidistributed in the interval $[0, 1]$.

LEMMA. *Let $\omega_1, \dots, \omega_m$ be m independent random numbers, uniformly distributed in the interval $[0, 1]$; then the expectation of the random function $\min\{\omega_1, \dots, \omega_m\}$ is given by*

$$(5.2)$$
$$E_m = \int \min\{\omega_k :\ k = 1, \dots, m\} \prod_{k=1}^m \chi_{(0,1)}(\omega_k)\ d\omega_1 \dots \omega_m = \frac{1}{m+1}, \quad m = 1, 2, \dots,$$

where $\chi_{(0,1)}$ denotes the usual indicator function on the interval $[0, 1]$.

Proof. The proof is based on induction in m. We denote by $R_m(s)$ the antiderivative of the probability density of the function $\min\{\omega_k :\ k = 1, \dots, m\}$, where $\omega_1, \dots, \omega_m$ are m random variables, uniformly distributed in $[0, 1]$. So we have

$$R'_m(s)ds = d\mathcal{P}[\min\{\omega_k :\ k = 1, \dots, m\} = s], \quad R_m(0) = 0,\ R_m(1) = 1,$$

and derive a formula for R_m recursively. The derivative $R'(s)$ is given by

$$\begin{aligned}
R'_m(s) &= \int_{[0,1]^m} \delta(s - \min\{\omega_1, \dots, \omega_m\}) d\omega_1 \dots \omega_m \\
&= \int_{[0,1]^m} \delta(s - \min\{\min\{\omega_1, \dots, \omega_{m-1}\}, \omega_m\}) d\omega_1 \dots \omega_m \\
&= \int_{[0,1]^2} \delta(s - \min\{r, \omega_m\}) R'_{m-1}(r)\ dr\omega_m \\
&= \int_{[0,1]^2} [H(r - \omega_m)\delta(s - \omega_m) + H(\omega_m - r)\delta(s - r)] R'_{m-1}(r)\ dr\omega_m \\
&= \int_0^1 H(r - s) R'_{m-1}(r)\ dr + R'_{m-1}(s) \int_0^1 H(\omega_m - s)\ d\omega_m.
\end{aligned}$$

Computing these integrals gives, because of $R_{m-1}(1) = 1$, the recursion

$$R'_m(s) = 1 - R_{m-1}(s) + (1 - s)R'_{m-1}(s) = \frac{d}{ds}[s + (1 - s)R_{m-1}(s)],$$

and because of $R_m(0) = 0,\ \forall m$ we obtain the recursive formula

$$R_m(s) = s + (1 - s)R_{m-1}(s), \quad R_1(s) = s. \tag{5.3}$$

Solving the recursion (5.3) via induction gives $R_m(s) = 1 - (1 - s)^m,\ m = 1, 2, \dots$. The expectation E_m is now given by

$$E_m = \int_0^1 sR'_m(s)\ ds = 1 - \int_0^1 R_m(s)\ ds = \int_0^1 (1 - s)^m\ ds = \frac{1}{m + 1}. \qquad \square$$

With the aid of the above lemma we are able to prove the mean field result of Theorem 3.2.

Proof of Theorem 3.2. In order to prove (3.9), we have to compute the limit of the quantity

$$u(x_1, z, V, f) = \int \min\left\{V, \frac{z}{\Delta y}(x_k - x_1),\ x_k > x_1,\ k = 2 \dots N\right\} \prod_{n=2}^{N} f(x_n)\ dx_2 \dots x_n$$

as $N \to \infty,\ \Delta y \to 0$ with $N\Delta y = \Lambda$ remaining constant, for a given probability measure f and constants z and V. u can be interpreted as the expectation of the quantity $\min\{V, \frac{z}{\Delta y}(x_k - x_1),\ x_k > x_1,\ k = 2 \dots N\}$, where $x_2, \dots, x_N$ are random variables independently and identically distributed according to the measure $f(x)$. We note that the variable x_k contributes only to the minimum if $x_1 < x_k < x_1 + \frac{\Delta y V}{z}$ holds. For any $k = 2, \dots, N$ let $\Delta y \bar{p}$ denote the probability that $x_k \in (x_1, x_1 + \frac{\Delta y V}{z})$ holds. Clearly, $\bar{p}$ is given by

$$\bar{p} = \frac{1}{\Delta y} \int_{x_1}^{x_1 + \frac{\Delta y V(x)}{z}} f(s)\ ds = \frac{V f(x_1)}{z} + O(\Delta y),$$

and the probability that none of the $x_k,\ k = 2, \dots, N$, is in the interval, i.e., the probability that $u = V$ holds, is given by $(1 - \Delta y \bar{p})^{N-1}$. We now compute the probability

p_m that of the $N-1$ variables $x_2, \ldots, x_N$ precisely $m \geq 1$ lie in the interval. p_m is given by

$$p_m = \binom{N-1}{m} (\Delta y \bar{p})^m [1 - \Delta y \bar{p}]^{N-1-m} \ , \tag{5.4}$$

where the binomial coefficient denotes the number of possible ways to choose m variables, and the other terms denote the probabilities that, for such a choice, the chosen m lie in the interval and the others do not. In the case that precisely m variables lie in the interval, their probability distribution can be replaced by the conditional probability, given that we already know that they are in the interval. This conditional probability is given by

$$q(s)ds = d\mathcal{P}\left[x_k = s \mid x_k \in \left(x_1, x_1 + \frac{\Delta y V}{z}\right)\right]$$

or

$$q(s) = \chi_{[x_1, x_1 + \frac{\Delta y V}{z}]}(s) \frac{f(s)}{\Delta y \bar{p}} \ . \tag{5.5}$$

Thus we obtain

$$u(x_1, z, V, f) = p_0 V + \sum_{m=1}^{N-1} p_m \frac{z}{\Delta y} \int \min\{s_k - x_1 : \ k = 1, \ldots, m\} \prod_{k=1}^{m} q(s_k) \ ds_1 \ldots s_m.$$

Substituting $s_k = x_1 + \frac{\Delta y V}{z} \omega_k$ in the integral gives

$$\begin{aligned} u(x_1, z, V, f) = p_0 V + \sum_{m=1}^{N-1} p_m V \int \min\{\omega_k : \ k = 1, \ldots, m\} \\ \cdot \prod_{k=1}^{m} \left[\frac{\Delta y V}{z} q\left(x_1 + \frac{\Delta y V}{z} \omega_k\right)\right] \ d\omega_1 \ldots \omega_m. \end{aligned}$$

Computing the probability density according to (5.5) gives

$$\frac{\Delta y V}{z} q\left(x_1 + \frac{\Delta y V}{z} \omega_k\right) = \frac{V}{z} \chi_{[0,1]}(\omega_k) \frac{f(x_1 + \frac{\Delta y V}{z} \omega_k)}{\bar{p}} = \chi_{[0,1]}(\omega_k) + O(\Delta y).$$

Thus, the ω_k are up to order $O(\Delta y)$ uniformly distributed in $[0, 1]$, and we have

$$u(x_1, z, V, f) = p_0 V + \sum_{m=1}^{N-1} p_m V [E_m + O(\Delta y)], \tag{5.6}$$

with the integral E_m given by

$$E_m = \int \min\{\omega_k : \ k = 1, \ldots, m\} \prod_{k=1}^{m} \chi_{(0,1)}(\omega_k) \ d\omega_1 \ldots \omega_m.$$

E_m is the expectation of the minimum of m uniformly distributed random variables and, according to the auxiliary lemma (5.2), $E_m = \frac{1}{m+1}$ holds.

Using this result in (5.6) gives

$$u(x_1, z, V, f) = V \sum_{m=0}^{N-1} p_m \left[\frac{1}{m+1} + O(\Delta y) \right].$$

Because of (5.4) we have that $\sum_{m=0}^{N-1} p_m = 1$ holds. Therefore, the $O(\Delta y)$ term can be neglected, although it appears inside the summation, and we have

$$(5.7) \qquad u(x_1, z, V, f) = V \sum_{m=0}^{N-1} \frac{1}{m+1} \binom{N-1}{m} (\Delta y \bar{p})^m (1 - \Delta y \bar{p})^{N-1-m} + O(\Delta y).$$

A simple application of the binomial theorem yields that

$$\sum_{m=0}^{N-1} \frac{1}{m+1} \binom{N-1}{m} a^m b^{N-1-m} = \frac{(a+b)^N - b^N}{Na} \quad \forall a, b$$

holds. With the obvious choice of a and b, we obtain from (5.7)

$$u(x_1, z, V, f) = V \frac{1 - (1 - \Delta y \bar{p})^N}{N \Delta y \bar{p}} + O(\Delta y) = V \frac{1 - e^{-\Lambda \bar{p}}}{\Lambda \bar{p}} + O(\Delta y).$$

(Remember $\Lambda = N\Delta y = \text{const}$ holds!) Together with $\bar{p} = \frac{Vf(x_1)}{z} + O(\Delta y)$, this gives (3.9). □

Finally, we prove the structure of the kernel of the collision operator $\mathbf{Q_G}$ in Theorem 3.3.

Proof of Theorem 3.3. From (3.17) we have that the collision kernel Q of the operator $\mathbf{Q_G}$ is of the form

$$Q(Z, Z') = \sum_m q_m(z_m, z'_m) \prod_{k \neq m} \delta(z_k - z'_k),$$
$$q_m(z_m, z'_m) = \omega_m(z'_m)[\delta(c_m - z_m - z'_m) - \delta(z'_m - z_m)].$$

At the same time, we have from (3.18) that the steady state $G(Z, \infty)$ of the processor state distribution is supported only on the hypercube $\prod_{m=0}^{M-1} \{0, c_m\}$. So $G(Z, \infty)$ is of the form

$$G(Z, \infty) = \prod_m g_m(z_m), \quad g_m(z_m) = g_m^0 \delta(z_m) + g_m^1 \delta(z_m - c_m).$$

Inserting this into the definition (3.21)(b) of the collision operator $\mathbf{Q_G}$ gives

$$\mathbf{Q_G}[f] = \sum_m \int q_m(z_m, z'_m)[g_m^0 \delta(z'_m) + g_m^1 \delta(z'_m - c_m)] f(Z') \prod_{k \neq m} \delta(z_k - z'_k) g_k(z'_k)\, dZ'.$$

Integrating out all variables except z'_m in each term of the sum above yields

$$\begin{aligned}\mathbf{Q_G}[f] &= \sum_m \int q_m(z_m, z'_m)[g_m^0 \delta(z'_m) + g_m^1 \delta(z'_m - c_m)] f(z_1 \dots z'_m \dots z_M)\, dz'_m \prod_{k \neq m} g_k(z_k) \\ &= \sum_m [q_m(z_m, 0) g_m^0 f(z_1 0 z_M) + q_m(z_m, c_m) g_m^1 f(z_1 \dots c_m \dots z_M)] \prod_{k \neq m} g_k(z_k).\end{aligned}$$

Using the form (3.17)(b) of the individual kernels q_m gives

$$\mathbf{Q_G}[f] = \sum_m \{\omega_m(0)[\delta(c_m - z_m) - \delta(z_m)]g_m^0 f(z_1 \dots 0 \dots z_M) \\ +\omega_m(c_m)[\delta(z_m) - \delta(c_m - z_m)]g_m^1 f(z_1 \dots c_m \dots z_M)\} \times \prod_{k \neq m} g_k(z_k) \ .$$

Using the form (3.19) of the coefficients $g_m^0(\infty)$ and $g_m^1(\infty)$ of the steady distribution, and collecting terms, gives

$$\mathbf{Q_G}[f] = \sum_m \frac{\omega_m(0)\omega_m(c_m)}{\omega_m(0) + \omega_m(c_m)}[\delta(c_m - z_m) - \delta(z_m)] \\ \cdot[f(z_1 \dots 0 \dots z_M) - f(z_1 \dots c_m \dots z_M)] \prod_{k \neq m} g_k(z_k) \ .$$

Therefore $\mathbf{Q_G}[f]$ can vanish identically $\forall Z$ only if

$$f(z_1 \dots c_m \dots z_M) - f(z_1 \dots 0 \dots z_M) = 0 \ \forall m, \ \forall Z \in \prod_m \{0, c_m\}$$

holds. $\square$

CREEP, RECOVERY, AND WAVES IN A NONLINEAR FIBER-REINFORCED VISCOELASTIC SOLID[*]

M. DESTRADE[†] AND G. SACCOMANDI[‡]

Abstract. We present a constitutive model capturing some of the experimentally observed features of soft biological tissues: nonlinear viscoelasticity, nonlinear elastic anisotropy, and nonlinear viscous anisotropy. For this model we derive the equation governing rectilinear shear motion in the plane of the fiber reinforcement; it is a nonlinear partial differential equation for the shear strain. Specializing the equation to the quasi-static processes of creep and recovery, we find that usual (exponential-like) time growth and decay exist in general, but that for certain ranges of values for the material parameters and for the angle between the shearing direction and the fiber direction, some anomalous behaviors emerge. These include persistence of a nonzero strain in the recovery experiment, strain growth in recovery, strain decay in creep, disappearance of the solution after a finite time, and similar odd comportments. For the full dynamical equation of motion, we find kink (traveling wave) solutions which cannot reach their assigned asymptotic limit.

Key words. fiber reinforcement, nonlinear creep and recovery, traveling waves

1. Introduction.

Many biological, composite, and synthetic materials must be modeled as fiber-reinforced nonlinearly elastic solids. Hence, the anisotropy due to the presence of collagen fibers in many biological materials has been studied extensively within the constitutive context of fiber-reinforced materials by several authors (see, for example, Humphrey (2002) and the references therein.) In nonlinear elasticity, the macroscopic response of an anisotropic material is given in terms of a strain-energy function, which itself depends on a set of independent deformation invariants. This formulation captures a great variety of phenomena related to the behavior of fiber-reinforced materials, e.g., the examination of fiber instabilities, using loss of ellipticity (see Merodio and Ogden (2002), (2003), and the references therein).

Generally speaking, a reinforcement is added to a given material with the aim of avoiding a possible failure under operating conditions. Therefore it is important to develop a detailed study showing how to introduce reinforcements into a material in order to control the possible development of a boundary layer structure. Our goal here is to provide a first step in this direction. We make several simplifications and ad hoc assumptions. First, we limit ourselves to the consideration of *only one fiber direction* and second, we consider a *one-dimensional motion* in the bulk of an infinite body. Here the motion is linearly polarized in a direction normal to the plane containing the direction of propagation and the direction of the fibers. We acknowledge that more complex anisotropies, geometries, and couplings arise in biomechanical applications. For instance, the mechanics of the aorta involves two families of parallel fibers, triaxial motions, and blood flow/arterial wall coupling. However, we argue that some

major characteristics of biological soft tissues are encompassed in the choices of transverse isotropy, of infinite extent, and of a motion governed by an ordinary differential equation. Indeed the anisotropy due to the presence of one family of parallel fibers complicates the governing equations to an extent which is only marginally less than that due to the presence of two families of parallel fibers. Also, soft biological tissues are nearly incompressible, and a (compressive) longitudinal wave is difficult to observe; it thus make sense to focus on transverse shear motions, which are useful in imaging technologies. Our third assumption is that the elastic strain energy is the sum of an isotropic part and an anisotropic part (called a *reinforcing model*), in order to model an isotropic base material augmented by a uniaxial reinforcement in the *fiber direction.* Albeit strong, this constitutive assumption is now common and used by many authors (e.g., Triantafyllidis and Abeyaratne (1983), Qiu and Pence (1997), Merodio and Ogden (2002)). Finally, we assume that the solid is viscoelastic, and here we assume not only Newtonian viscosity (proportional to the stretching tensor) but also fiber-oriented (anisotropic) viscosity. That latter assumption is strong but can be removed from our calculations by taking a constant to be zero. We believe that it might be useful in modeling the well-documented physiological effect of stretching training in sport medicine, which is that it affects the viscosity of tendon structures but not their elasticity (Taylor et al. (1990); Kubo, Kanehisa, and Fukunaga (2002)).

We divide the article into the following sections. Section 2 presents the constitutive model and the derivation of the equation governing the rectilinear shear motion. As expected, this equation is nonlinear in the shear strain: it is a second-order partial differential equation, with cubic nonlinearity. To initiate its resolution, we first look at the quasi-static experiment of recovery in section 3. Then we have a first-order ordinary differential equation, and we find that it can lead to unusual behaviors when certain conditions (strong anisotropy, large angle between the shearing direction and the fibers) are met. The same is true of the case of creep, treated in section 4. Basically, it turns out that the nonlinearity introduces ranges of material parameters and angles for which an expected behavior—say, strain growth in creep—can be turned on its head, and lead to strain decay with time in creep, say. In the course of the investigation we develop synthetic tools of analysis which highlight the boundaries of these ranges. They also guide us for the resolution of the full dynamical equation of motion, which we tackle in section 5 for traveling wave solutions. Again the solution may behave in an unexpected way, provided that the anisotropy is strong enough and the fibers are in compression. Finally, section 6 recaps the results and puts them into a wider context.

2. Basic equations.

2.1. The viscoelastic anisotropic model.

We describe the motion of a body by a relation $\mathbf{x} = \mathbf{x}(\mathbf{X}, t)$, where $\mathbf{x}$ denotes the current coordinates of a point occupied by the particle of coordinates $\mathbf{X}$ in the reference configuration at the time t.

We introduce $\mathbf{F} = \partial\mathbf{x}/\partial\mathbf{X}$, the deformation gradient, and $\mathbf{C} = \mathbf{F}^{\mathrm{T}}\mathbf{F}$, the right Cauchy–Green strain tensor. We focus on *incompressible materials* for which all admissible deformations must be isochoric, or equivalently, for which the relation $\det \mathbf{F} = 1$ must hold at all times.

The body is reinforced with one family of parallel fibers. Our first assumption is that the unit vector $\mathbf{a}_0$, giving the fiber direction in the reference configuration, is independent of $\mathbf{X}$. The stretch along the fiber direction is $\sqrt{\mathbf{a}_0 \cdot \mathbf{C}\mathbf{a}_0} = \sqrt{\mathbf{a} \cdot \mathbf{a}}$, where $\mathbf{a} = \mathbf{F}\mathbf{a}_0$.

We may now introduce the elastic part of our constitutive model. We consider the so-called *standard reinforcing model*, which is a quite simple generalization to anisotropy of the neo-Hookean model (Triantafyllidis and Abeyaratne (1983); Qiu and Pence (1997)). For the standard reinforcing model, the strain-energy density is given by

$$W = \frac{\mu}{2}\left[(I_1-3)+\gamma_0(I_4-1)^2\right], \quad \text{where } I_1 = \text{tr } \mathbf{C},\ I_4 = \mathbf{a}_0\cdot\mathbf{C}\mathbf{a}_0 = \mathbf{a}\cdot\mathbf{a}. \tag{2.1}$$

Here $\mu > 0$ is the infinitesimal shear modulus of the isotropic neo-Hookean matrix, $\gamma_0 > 0$ is the *elastic anisotropy parameter*, and the invariant I_4 measures the squared stretch in the fiber direction. Mechanical tests show that the neo-Hookean strain energy function $\mu(I_1-3)/2$ fits uniaxial data rather well for arteries (Gundiah, Ratcliffe, and Pruitt (2007)), while the anisotropic term $\gamma_0(I_4-1)^2$ is adequate to describe a reinforced material which penalizes deformation in the fiber direction (Merodio and Ogden (2003)).

The spatial velocity gradient $\mathbf{L}(\mathbf{X},t)$ associated with a motion is defined as $\mathbf{L} =$ grad $\mathbf{v}$, where $\mathbf{v} = \partial\mathbf{x}/\partial t$ is the velocity, and the stretching tensor $\mathbf{D}$ is defined as $\mathbf{D} = \frac{1}{2}(\mathbf{L}+\mathbf{L}^{\mathrm{T}})$. For incompressible materials, tr $\mathbf{D} = 0$ at all times. Newtonian viscous fluids possess a constitutive term in the form $2\nu\mathbf{D}$, where ν is a constant. For our special solid, we modulate the Newtonian viscosity with an anisotropic term, by replacing ν with $\nu[1+\gamma_1(I_4-1)]$, where $\gamma_1 > 0$ is the *viscous anisotropy parameter.* We show in the course of the paper that this simple choice of anisotropic viscosity captures the essential characteristics of attenuation in soft biological fibrous tissues. According to Baldwin et al. (2006), ultrasonic measurements of freshly excised myocardium show that "the attenuation coefficient was found to increase as a function of frequency in an approximately linear manner and to increase monotonically as a function of angle of insonification from a minimum perpendicular to a maximum parallel relative to the direction of the myofibers."

We are now ready to give the complete Cauchy stress tensor of our viscoelastic, transversally isotropic material as

$$\mathbf{T} = -p\mathbf{I} + \mu[\mathbf{B} + \gamma_0(I_4-1)\mathbf{a}\otimes\mathbf{a}] + 2\nu[1+\gamma_1(I_4-1)]\mathbf{D}, \tag{2.2}$$

where the p is the yet indeterminate Lagrange multiplier introduced by the incompressibility constraint, and $\mathbf{B} = \mathbf{F}\mathbf{F}^{\mathrm{T}}$ is the left Cauchy–Green tensor.

2.2. Shear motion. We take a fixed orthonormal triad of vectors ($\mathbf{i}$, $\mathbf{j}$, $\mathbf{k}$), and call X, Y, Z the reference coordinates; hence $\mathbf{X} = X\mathbf{i} + Y\mathbf{j} + Z\mathbf{k}$. The triad is such that the unit vector in the fiber direction lies in the XY plane; hence,

$$\mathbf{a}_0 = \cos\theta\mathbf{i} + \sin\theta\mathbf{j} \tag{2.3}$$

(say), where $\theta \in [0,\pi]$ is the angle between the X-axis and the fibers.

We then consider the *rectilinear shearing motion*,

$$x = X + u(Y,t), \quad y = Y, \quad z = Z, \tag{2.4}$$

where the antiplane displacement u is real and finite. Then the components of the gradient of deformation $\mathbf{F}$ and of its inverse are given by

$$\mathbf{F} = \begin{bmatrix} 1 & U & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \mathbf{F}^{-1} = \begin{bmatrix} 1 & -U & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{2.5}$$

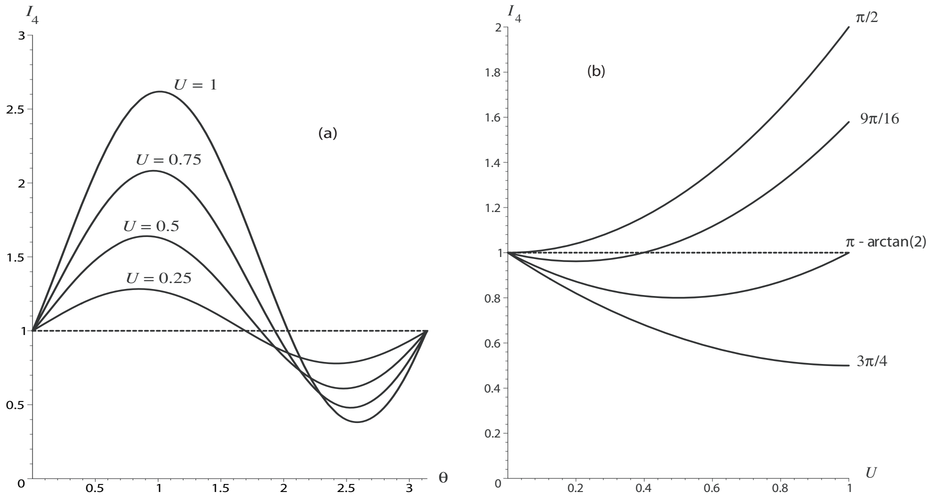

FIG. 2.1. *Variations of the squared stretch in the fiber direction*: (a) *with the angle and* (b) *with the shear. When $I_4 > 1$, the fibers are in extension; when $I_4 < 1$, they are in compression.*

where $U = \partial u/\partial Y$ is the *amount of shear*. The left and right Cauchy–Green tensors are thus

$$\mathbf{B} = \begin{bmatrix} U^2+1 & U & 0 \\ U & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \qquad \mathbf{C} = \begin{bmatrix} 1 & U & 0 \\ U & U^2+1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \tag{2.6}$$

respectively, from which the expressions of the invariants I_1 and I_4 follow,

$$I_1 = 3 + U^2, \quad I_4 = 1 + U \sin 2\theta + U^2 \sin^2\theta. \tag{2.7}$$

Figure 2.1(a) shows the variations of I_4 with θ for several values of U between 0 and 1. When $I_4 > 1$ the fibers are in extension, and when $I_4 < 1$ they are in compression; the figure shows that this latter behavior occurs in a smaller and smaller angular range, but is more and more pronounced, as the amount of shear is increased. Conversely, Figure 2.1(b) shows the variations of I_4 with U for several values of θ; when $0 < \theta < \pi/2$, the fibers are always in extension, and when $\pi - \tan^{-1}(2) = 2.034 < \theta < \pi$, they are always in compression for $0 \leq U \leq 1$. We refer to the paper by Qiu and Pence (1997) for similar figures and closely related discussions.

In the deformed configuration, we find that $\mathbf{a} = (\cos\theta + U\sin\theta)\mathbf{i} + \sin\theta\mathbf{j}$. The remaining tensors required to compute the Cauchy stress tensor (2.2) are

$$\mathbf{a} \otimes \mathbf{a} = \begin{bmatrix} (\cos\theta + U\sin\theta)^2 & (\cos\theta + U\sin\theta)\sin\theta & 0 \\ (\cos\theta + U\sin\theta)\sin\theta & \sin^2\theta & 0 \\ 0 & 0 & 0 \end{bmatrix} \tag{2.8}$$

and

$$\mathbf{D} = \frac{1}{2}\begin{bmatrix} 0 & U_t & 0 \\ U_t & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}, \tag{2.9}$$

so that the nonzero components of $\mathbf{T}$ are $T_{33} = -p + \mu$ and

$$\begin{aligned} &T_{11} = -p + \mu(1 + U^2) + \mu\gamma_0(I_4 - 1)(\cos\theta + U\sin\theta)^2, \\ &T_{22} = -p + \mu + \mu\gamma_0(I_4 - 1)\sin^2\theta, \\ &T_{12} = \mu U + \mu\gamma_0(I_4 - 1)(\cos\theta + U\sin\theta)\sin\theta + \nu[1 + \gamma_1(I_4 - 1)]U_t. \end{aligned} \tag{2.10}$$

Now the equations of motion div $\mathbf{T} = \rho\mathbf{x}_{tt}$ reduce to the two scalar equations $-p_x + T_{12,y} = \rho u_{tt}$ and $-p_y + T_{22,y} = \rho u_{tt}$. Differentiating the former with respect to y and the latter with respect to x, and eliminating p_{xy}, we arrive at a single governing equation for the rectilinear shear motion:

$$\begin{aligned} \rho U_{tt} = \mu U_{yy} &+ \mu\gamma_0 \sin^2\theta \left[U(2\cos\theta + U\sin\theta)(\cos\theta + U\sin\theta)\right]_{yy} \\ &+ \nu U_{tyy} + \nu\gamma_1 \sin\theta \left[UU_t(2\cos\theta + U\sin\theta)\right]_{yy}. \end{aligned} \tag{2.11}$$

Using the scalings $\tilde{t} = \mu t/\nu$ and $\tilde{y} = y/L$ (where L is a characteristic length to be specified later on a case-by-case basis), we write this equation in dimensionless form as

$$\begin{aligned} \varepsilon U_{\tilde{t}\tilde{t}} = U_{\tilde{y}\tilde{y}} &+ \gamma_0 \sin^2\theta \left[U(2\cos\theta + U\sin\theta)(\cos\theta + U\sin\theta)\right]_{\tilde{y}\tilde{y}} \\ &+ U_{\tilde{t}\tilde{y}\tilde{y}} + \gamma_1 \sin\theta \left[UU_t(2\cos\theta + U\sin\theta)\right]_{\tilde{y}\tilde{y}}, \end{aligned} \tag{2.12}$$

where $\varepsilon = \rho\mu L^2/\nu^2$. This is the main equation of our study. For convenience we drop the tildes in the remainder of the paper. We also introduce the functions

$$\begin{aligned} &f(\gamma_0, U, \theta) = 1 + \gamma_0 \sin^2\theta(2\cos\theta + U\sin\theta)(\cos\theta + U\sin\theta), \\ &g(\gamma_1, U, \theta) = 1 + \gamma_1 U\sin\theta(2\cos\theta + U\sin\theta), \end{aligned} \tag{2.13}$$

so that (2.13) is now

$$\varepsilon U_{tt} = \left[Uf(\gamma_0, U, \theta) + U_t g(\gamma_1, U, \theta)\right]_{yy}. \tag{2.14}$$

3. Nonlinear anisotropic recovery. Our first investigation is placed in the quasi-static approximation, where we study the influence of elastic anisotropy and viscous anisotropy on the classic experiment of viscous *recovery*. We imagine that the material is sheared and that at $t = 0$ the shear stress is removed: $T_{12}(0) = 0$. Here the characteristic length L is the displacement at $t = 0$ from which the material will relax to the unstressed state.

In the quasi-static case, we neglect the inertia term of (2.13) and may thus integrate it twice to give the following first-order ordinary differential equation:

$$Uf(\gamma_0, U, \theta) + U_t g(\gamma_1, U, \theta) = 0. \tag{3.1}$$

Here we take the constants of integration to be zero, according to the context of recovery, as explained above. We then solve the equation as

$$\int \frac{g(\gamma_1, U, \theta)}{Uf(\gamma_0, U, \theta)} \mathrm{d}U = -t + \text{const.}, \tag{3.2}$$

where the constant is computed so that $U(0) = 1$.

When $\theta = 0$, the fibers are not active with respect to the deformation, and we recover the classical result of isotropic viscoelastic recovery: $U(t) = \mathrm{e}^{-t}$.

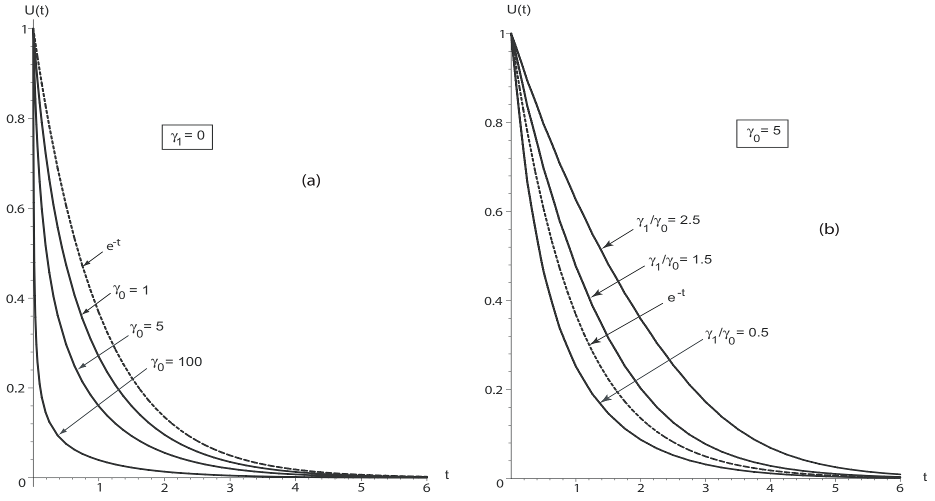

FIG. 3.1. *Time recovery function when* $\theta = \pi/2$: (a) $\gamma_1 = 0$ *and* $\gamma_0 = 1$, 5, 100; (b) $\gamma_0 = 5$ *and* $\gamma_1 = 0.5$, 1.5, 2.5. *The recovery function for an isotropic solid is also plotted (dotted curve).*

When $\theta = \pi/2$, the anisotropic effects are at their strongest. In that case the integral above has a compact expression, and we find

$$U\left[\frac{1+\gamma_0 U^2}{1+\gamma_0}\right]^{\frac{1}{2}\left(\frac{\gamma_1}{\gamma_0}-1\right)} = \mathrm{e}^{-t}. \tag{3.3}$$

We now take $\gamma_1 = 0$ (no anisotropic viscosity) and $\gamma_0 = 1, 5, 100$ (recall that the fibers are inextensible in the limit $\gamma_0 \to \infty$). Figure 3.1(a) shows that as the anisotropic effect becomes more pronounced, the recovery is quicker; in other words, the influence of elasticity becomes stronger as γ_0 increases. Then we fix γ_0 at 5, for instance, and look at the role played by the anisotropic viscosity, by taking in turn $\gamma_1/\gamma_0 = 0.5$, 1.5, 2.5. We find in Figure 3.1(b) that, as expected, the viscous recovery is slower as γ_1 increases.

When $\theta \neq 0$, $\theta \neq \pi/2$, other behaviors arise, which call for a detailed analysis. In particular, the exponential, or near-exponential, decay toward zero as $t \to \infty$ is not necessarily ensured, especially when the anisotropic effects are strong and the fibers are oriented at a large angle $\theta > \pi/2$. Clearly, $U_t = 0$ when $f = 0$, according to (3.2). Also, $U_t < 0$ when f and g are of the same sign, and $U_t > 0$ when f and g are of opposite signs. These two functions are quadratic in U. If they have no real roots in U, then they are both of the positive sign and $U_t < 0$. (This is clearly the case in the region $0 < \theta < \pi/2$.) If they have real roots, then they may change sign, and U might be an *increasing* function of t. This happens for f and for g when $\pi/2 < \theta < \pi$ and

$$\gamma_0 \geq \frac{4}{\cos^2\theta \sin^2\theta}, \quad \gamma_1 \geq \frac{1}{\cos^2\theta}, \tag{3.4}$$

respectively. In Figure 3.2, the region C corresponds to the first inequality, where the delimiting curve has a vertical asymptote at $\theta = \pi/2$, a vertical asymptote at $\theta = \pi$, and a minimum at $\theta = \pi/4$, $\gamma_0 = 16$; we recall that Qiu and Pence (1997) showed that

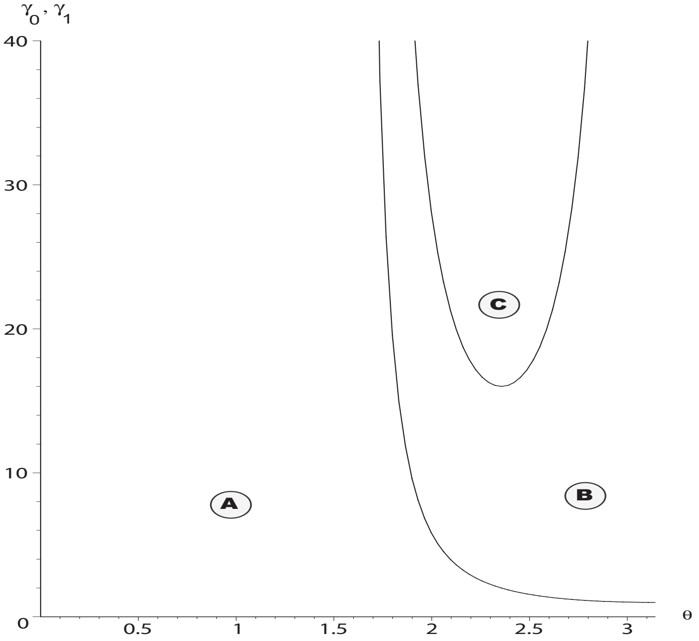

FIG. 3.2. *Recovery: regions where the sign of U_t may change.*

when $\gamma_0 > 16$, "simple shear at certain fiber orientations involves negative shear stress in the shearing direction for certain positive shears." The region B corresponds to the second inequality, where the delimiting curve has a vertical asymptote at $\theta = \pi/2$ and an horizontal asymptote at $\gamma_1 = 1$. In the region A, neither inequality is satisfied.

3.1. Weak anisotropy. First, we take both γ_0 and γ_1 in region A. This is the simplest case because f and g are then both positive, and so U_t is always negative (damped recovery). We took several representative examples in this region (say, $\theta = \pi/4$, $\gamma_0 = 20$, $\gamma_1 = 1$) and checked, through integration and implicit plotting, that the graphs are indeed of the same nature as those in Figure 3.1.

3.2. Strong elastic anisotropy. Second, we take γ_1 in region A, by fixing it at $\gamma_1 = 1$, say. In that region, $g > 0$ always, and thus the sign of U_t is the opposite of the sign of f. Then we take $\gamma_0 = 20$, which is above the minimum of region C. In Figure 3.3, we plot the locus for the values of U as functions of θ such that $f(20, U, \theta) = 0$. Outside the resulting oval shape, $f > 0$, and inside, $f < 0$. We also plotted the line $U = 1$, which intersects the oval at $\theta_{\text{min}} = 2.136$ and $\theta_{\text{max}} = 2.221$. Recall that $U(0) = 1$.

When $\theta > \theta_{\text{max}}$, $U(t)$ starts at 1 and decreases because $f > 0$ so that $U_t < 0$; as U decreases toward 0, U_t tends to zero according to $(3.2)_1$, but takes an infinite time to do so, according to $(3.2)_2$; hence $U = 0$ is a horizontal asymptote and the recovery is "classical"; see plot (i) in Figure 3.3, traced at $\theta = 2.4$ (notice, however, that the recovery is not exponential because the second derivative of U clearly changes sign as t increases, in contrast with e^{-t}, traced in dotted lines).

When $\theta_{\text{min}} < \theta < \theta_{\text{max}}$, $U(t)$ starts at 1 and then grows until it hits the upper side of the oval, taking an infinite time to do so; then this upper bound gives a horizontal asymptotic value, *above the initial value* (see plot (ii) in Figure 3.3), traced at $\theta = 2.2$.

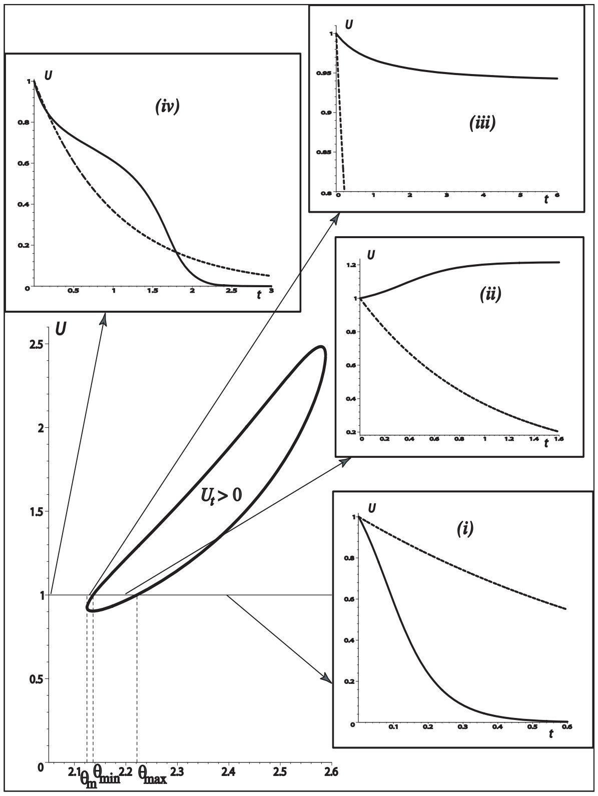

Fig. 3.3. *Types of time recovery functions for $\gamma_0 = 20$, $\gamma_1 = 1$ (strong elastic anisotropy). The amount of shear U starts at 1 for $t = 0$. Outside the oval shape, $U_t < 0$ and U decreases as in* (i) *and* (iv): *decay toward zero*; *and in* (iii): *decay toward a value > 0. Inside the oval shape, $U_t > 0$ and U increases as in* (ii): *growth toward a value > 1. The recovery function e^{-t} for an isotropic solid is also plotted (dotted curves).*

When $\theta_{\mathrm{m}} < \theta < \theta_{\min}$, where $\theta_{\mathrm{m}} = 2.124$ is the angle at which the oval plot has a vertical tangent, $U(t)$ starts at 1 and then decreases until it hits the upper side of the oval, below 1 but above 0; then this lower bound gives a horizontal asymptotic value, *above zero* (see plot (iii) in Figure 3.3), traced at $\theta = 2.125$.

Finally, when $\theta < \theta_{\mathrm{m}}$, $U(t)$ starts at 1 and then decreases until zero; then this lower bound gives zero as a horizontal asymptotic value (see plot (iv) in Figure 3.3), traced at $\theta = 2.05$. Notice that the second derivative changes signs three times as t increases.

3.3. Strong viscous anisotropy. Third, we take γ_0 outside the C region, by fixing it at $\gamma_0 = 1$, say. In that region, $f > 0$ always, and thus the sign of U_t is the opposite of the sign of g. Then we allow γ_1 to be in region B, and thus allow g (and U_t) to change sign with increasing θ, by taking $\gamma_1 = 3.0$, say. In Figure 3.4, we plotted the values of U as functions of θ such that $g(3, U, \theta) = 0$ and obtained the thick-line shape. Outside the shape, $g > 0$, and inside, $g < 0$. We also plotted the horizontal line $U = 1$, which intersects the shape at $\theta_{\min} = 2.356$ and $\theta_{\max} = 2.820$, and the vertical line $\theta = \theta_{\mathrm{m}} = 2.186$, which is tangent to the shape.

Now when $\theta < \theta_{\mathrm{m}}$ or $\theta > \theta_{\max}$, $U(t)$ starts at 1 and decreases until zero; as $U \to 0$, the denominator in the integral tends to zero, indicating that it takes an

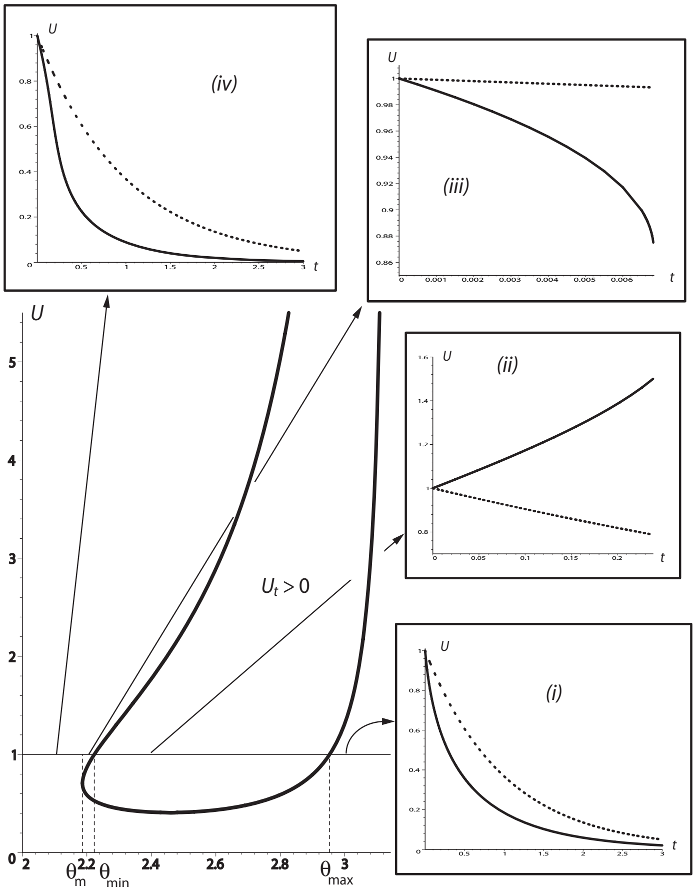

FIG. 3.4. *Types of time recovery functions for $\gamma_0 = 1$, $\gamma_1 = 2$ (strong viscous anisotropy). The amount of shear U starts at 1 for $t = 0$. Outside the thick-line shape, $U_t < 0$ and U decreases toward zero as in* (i) *and* (iv)*. Inside the thick-line shape, $U_t > 0$ and U increases rapidly as in* (ii)*, until it ceases to exist. There is also an angular region $\theta_m < \theta < \theta_{min}$ where U decreases rapidly until it ceases to exist*; *see* (iii)*. The recovery function e^{-t} for an isotropic solid is also plotted (dotted curves).*

infinite time to do so; hence, zero is a horizontal asymptote in these cases. To draw Figure 3.4(i) we took $\theta = 3.0$, and for Figure 3.4(iv) we took $\theta = 2.1$; both graphs show a somewhat classical decay with time.

However, when $\theta_{\min} < \theta < \theta_{\max}$, $U(t)$ starts at 1 and then *grows* because $U_t > 0$ inside the thick line shape. Eventually U hits the upper face of the shape, where $g = 0$; then by (3.1), either $Uf = 0$ or $U_t \to \infty$. Clearly, the first possibility is excluded because $U \neq 0$ when it is larger than 1, and $f \neq 0$ when γ_0 is outside the C region. It follows that U grows and hits the upper face of the shape with a vertical asymptote after a finite time (and then stops because it cannot increase further since $U_t < 0$ outside the shape, it cannot remain constant since $U_t \neq 0$ on the shape, and it cannot decrease since $U_t > 0$ inside the shape). Figure 3.4(ii) shows such behavior for $U(t)$, traced at $\theta = 2.4$.

Finally, when $\theta_{\rm m} < \theta < \theta_{\min}$, $U(t)$ decays from 1 until it hits the shape from above after a finite time; see Figure 3.4(iii), traced at $\theta = 2.2$. Notice how quickly the final value is reached, compared to the isotropic exponential recovery.

3.4. Strong elastic and viscous anisotropies. In the case where both γ_0 and γ_1 are in the region C, any combination and overlaps of the thick curves presented in Figures 3.3 and 3.4 may arise. The tools presented in the two previous subsections are easily transposed to those possibilities. A special situation arises when the locus of $f = 0$ intersects the locus of $g = 0$; then, the numerator and the denominator in (3.2) may have a common factor so that the integrand simplifies and a regular behavior may appear. This situation is, however, too special to warrant further investigation, and we do not pursue this line of enquiry.

4. Nonlinear anisotropic creep. Our second investigation is again placed in the quasi-static approximation, where we now study the influence of elastic anisotropy and viscous anisotropy on the classic experiment of viscous *creep*. As the resulting analysis is similar to that conducted for recovery, we simply outline the main results.

We imagine that the material is sheared and that the shear stress is maintained: $T_{12}(\infty) \neq 0$. Here the characteristic length L is an asymptotic value of the displacement. We neglect the inertial term of (2.13) and integrate it twice to give the ordinary differential equation

$$U f(\gamma_0, U, \theta) + U_t g(\gamma_1, U, \theta) = \text{const.}, \tag{4.1}$$

where we took the constant of the first integration to be zero and the constant of the second integration to correspond to the applied (constant) shear stress, as is usual in the creep problem. More specifically, this constant is taken so that $U(\infty) = 1$, and so is equal to $f(\gamma_0, 1, \theta)$; it follows that the equation above can be written as

$$h(\gamma_0, U, \theta)(U - 1) + g(\gamma_1, U, \theta)U_t = 0, \tag{4.2}$$

where h is defined by

$$\begin{aligned} h(\gamma_0, U, \theta) &= [U f(\gamma_0, U, \theta) - f(\gamma_0, 1, \theta)]/(U - 1) \\ &= 1 + \gamma_0 \sin^2\theta[1 + \cos^2\theta + (U + 1)\sin\theta(U \sin\theta + 3\cos\theta)]. \end{aligned} \tag{4.3}$$

We then solve the equation as

$$\int \frac{g(\gamma_1, U, \theta)}{(U - 1)h(\gamma_0, U, \theta)} \mathrm{d}U = -t + \text{const.}, \tag{4.4}$$

where the constant is computed so that $U(0) = 0$. Hence the equations governing creep are almost identical to those governing recovery, with the difference that f is now replaced by h.

Here we are mostly concerned with the question of how, if at all, a state of shear can be reached such that, once removed, the unusual recovery behaviors of the previous section emerge. Thus we concentrate on strong anisotropic effects, with emphasis on strong elastic anisotropy (where the new function h is involved). We traced the regions where g and h, and thus U_t, may change signs and found that the resulting graph is similar to that of Figure 3.2, with the main difference that the minimum of region C is now located at $\theta = 3\pi/4$ and $\gamma_0 = 4$. Thus unusual behavior in creep may occur at much lower levels of elastic anisotropy than in recovery (where the minimum is at $\gamma_0 = 16$). We recall that Qiu and Pence (1997) showed that when $\gamma_0 > 4$, "simple shear at certain fiber orientations involves a nonmonotonic relation between the shear stress in the shearing direction and the amount of shear."

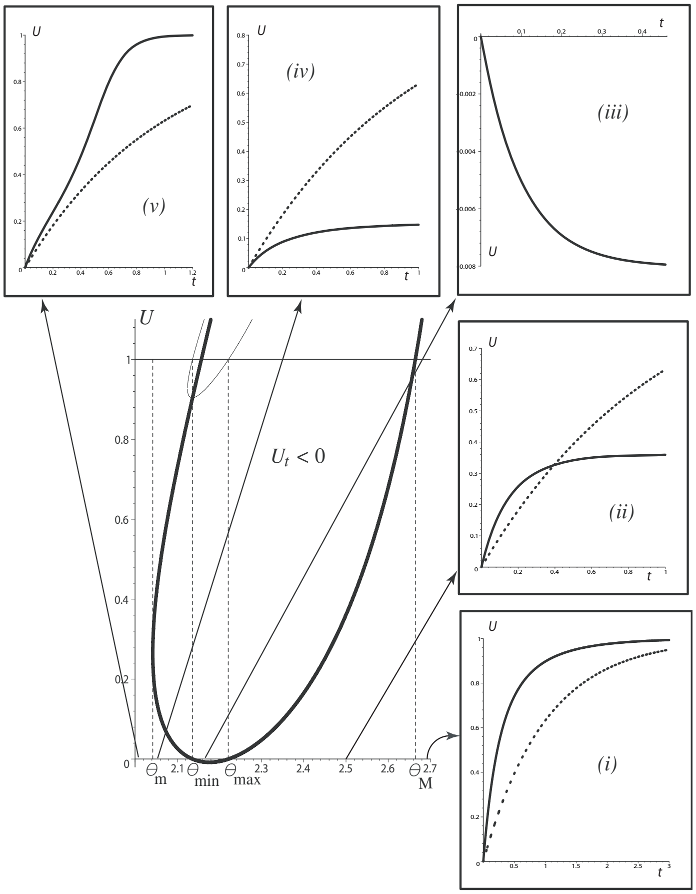

FIG. 4.1. *Types of time creep functions for $\gamma_0 = 20$, $\gamma_1 = 1$ (strong elastic anisotropy). The amount of shear U starts at* 0 *for $t = 0$. Outside the thick-line shape, $U_t > 0$ and U increases as in* (i) *and* (v)*: growth toward* 1*, and as in* (ii) *and* (iv)*: growth toward a value below* 1*. Inside the thick-line shape, U decreases as in* (iii)*: decay toward a negative value. The creep function $1 - e^{-t}$ for an isotropic solid is also plotted (dotted curves).*

4.1. Strong elastic anisotropy. We begin with the case where h plays a major role, that is, when γ_0 is greater than 4. For the purpose of direct comparison with the recovery problem, we take $\gamma_0 = 20$ and $\gamma_1 = 1$, as in section 3.2. Figure 4.1 displays the curve where $h(20, U, \theta) = 0$. Outside the thick-line curve, $U_t > 0$, and inside, $U_t < 0$. The curve intersects the line $U = 0$ twice, at $\theta_{\min} = 2.136$ and at $\theta_{\max} = 2.221$. These are the values at which $f = 0$ intersects $U = 1$ in section 3.2 (see the thin-line shape), because by (4.3), $h(20, 0, \theta_{\min}) = f(20, 1, \theta_{\min}) = 0$ and similarly $h(20, 0, \theta_{\max}) = f(20, 1, \theta_{\max}) = 0$. We also display the vertical lines $\theta = \theta_M = 2.664$, where $h = 0$ intersects $U = 1$, and $\theta = \theta_m = 2.042$, where $h = 0$ has a vertical tangent. Recall that for creep, $U(0) = 0$.

When $\theta > \theta_{\mathrm{M}}$, $U(t)$ starts at 0 and grows toward 1; then U_t tends to zero according to (4.2) but takes an infinite time to do so; hence $U = 1$ is a horizontal asymptote and the creep is "classical." See plot (i) in Figure 4.1, traced at $\theta = 2.7$ (the exponential creep function of isotropic visco-elasticity $(1 - \mathrm{e}^{-t})$ is shown by the dotted line).

When $\theta_{\max} < \theta < \theta_{\mathrm{M}}$ or when $\theta_{\mathrm{m}} < \theta < \theta_{\min}$, $U(t)$ starts at 0 and then grows until it hits the oval shape, taking an infinite time to do so; then this upper bound gives a horizontal asymptotic value, *below* 1; see plot (ii) in Figure 4.1, traced at $\theta = 2.5$, and plot (iv), traced at $\theta = 2.05$.

When $\theta_{\text{min}} < \theta < \theta_{\text{max}}$, $U(t)$ starts at 0 inside the oval shape, and thus it *decreases* until it hits the lower side of the shape, taking an infinite time to do so; then this lower bound gives a horizontal asymptotic value, *below* 0; see plot (iii) in Figure 4.1, traced at $\theta = 2.17$.

Finally, when $\theta < \theta_{\text{m}}$, $U(t)$ can again grow toward 1; see plot (v) in Figure 4.1, traced at $\theta = 2.0$. Notice, however, that the concavity of the curve changes as t increases.

4.2. Strong viscous anisotropy. Here we remark that the function governing the strength of the viscous anisotropy, namely g, is the same for creep as it is for recovery. Thus, the region where U_t might change sign because of strong viscous anisotropy is the region B of Figure 3.1. Also, the locus of points where $g = 0$ is typically displayed by the thick-line shape of Figure 3.4, and because $g(\gamma_1, 0, \theta) = 1 > 0$ always, this curve never crosses the abscissa $U = 0$. It follows that there is only one situation where viscous anisotropy leads to anomalous creep, when $\theta_{\text{min}} < \theta < \theta_{\text{max}}$; then $U(t)$ starts at zero and grows toward the thick-line shape, which it reaches after a finite time with a vertical asymptote.

4.3. Prestretch and nonlinear anisotropic creep. Here we show how anomalous creep can be avoided (amplified) by stretching (compressing) the solid prior to the shear. Hence, instead of (2.4), we consider the motion

$$x = \lambda^{-\frac{1}{2}} X + \lambda u(Y,t), \quad y = \lambda Y, \quad z = \lambda^{-\frac{1}{2}} Z. \tag{4.5}$$

The following decomposition of the associated deformation gradient shows that the solid is stretched by a ratio λ in the Y direction:

$$\mathbf{F} = \mathbf{F_2}\mathbf{F_1}, \quad \text{where} \quad \mathbf{F_2} = \begin{bmatrix} 1 & U & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}, \quad \mathbf{F_1} = \begin{bmatrix} \lambda^{-\frac{1}{2}} & 0 & 0 \\ 0 & \lambda & 0 \\ 0 & 0 & \lambda^{-\frac{1}{2}} \end{bmatrix}. \tag{4.6}$$

(Note that $\mathbf{F_2}\mathbf{F_1} \neq \mathbf{F_1}\mathbf{F_2}$.) The kinematic quantities of section 2.2 are modified accordingly. In particular,

$$I_4 = \lambda^{-1}\cos^2\theta + \lambda^2\sin^2\theta + U\lambda^{\frac{1}{2}}\sin 2\theta + U^2\lambda^2\sin^2\theta. \tag{4.7}$$

The end result is that the differential equation governing creep is changed from (4.2) to

$$h^\lambda(\gamma_0, U, \theta)(U-1) + g^\lambda(\gamma_1, U, \theta)U_t = 0, \tag{4.8}$$

where h^λ and g^λ are defined by

$$\begin{aligned} h^\lambda(\gamma_0, U, \theta) = \lambda^2 \{ 1 + \gamma_0 \sin^2\theta [& 2\lambda^2\sin^2\theta + 3\lambda^{-1}\cos^2\theta - 1 \\ & + (U+1)\sin\theta(U\sin\theta + 3\cos\theta)] \}, \end{aligned}$$

$$g^\lambda(\gamma_1, U, \theta) = 1 + \gamma_1(\lambda^{-1}\cos^2\theta + \lambda^2\sin^2\theta - 1 + U\lambda^{\frac{1}{2}}\sin 2\theta + U^2\lambda^2\sin^2\theta). \tag{4.9}$$

Figure 4.2 shows the loci of $h^\lambda = 0$ in the case of a strong elastic anisotropy ($\gamma_0 = 30$,

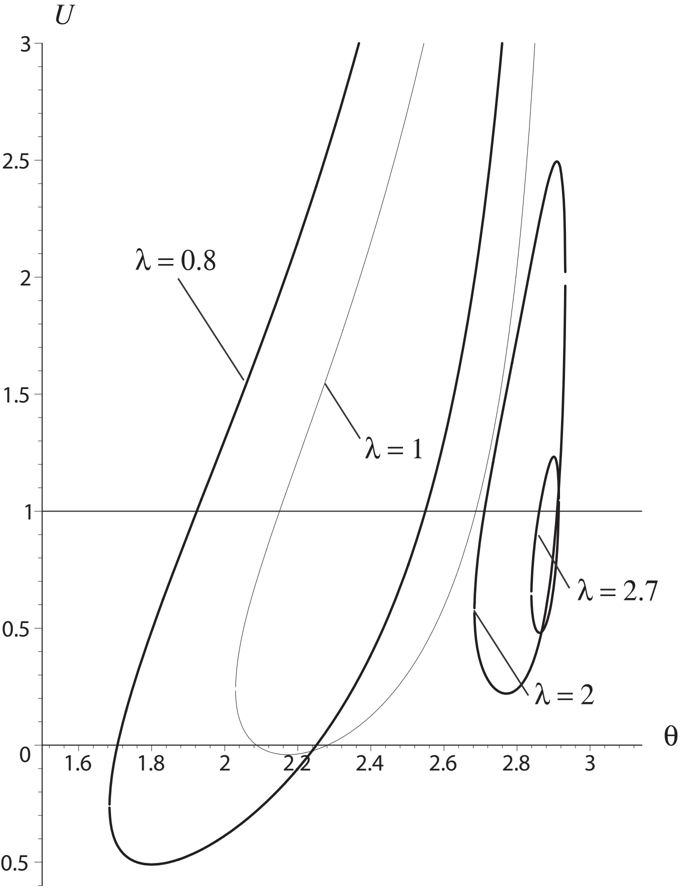

FIG. 4.2. *Effect of prestretch on time creep functions for $\gamma_0 = 30$, $\gamma_1 = 1$ (strong elastic anisotropy). The amount of shear U starts at 0 for $t = 0$. Inside the thick-line shapes, U decreases; this situation may arise when the solid is not prestretched ($\lambda = 1$) or when it is compressed ($\lambda = 0.8$). Outside the thick-line shapes, $U_t > 0$ and U increases; this situation may arise when the solid is in extension ($\lambda = 2$, $\lambda = 2.7$).*

$\gamma_1 = 1$), for several values of λ. The figure clearly shows that the prestretch λ can be used to control the shape of these curves: if the solid is put in compression first, and sheared for creep next, then the region of potential anomalous creep is increased; if it is put under tension, then the area of the region rapidly decreases and eventually disappears altogether.

5. Nonlinear traveling waves. So far we have looked at how the presence of elastic and viscous fibers affects some quasi-static processes. Typically, creep and recovery connect one state of constant shear (initial) to another (final). Now we examine another class of solutions connecting two constant states of shear, this time *dynamically*, by looking for traveling wave (kink) solutions.

The mathematical theory of one-dimensional transverse traveling waves in isotropic viscoelastic materials with a Kelvin–Voigt type of constitutive equation is well grounded; see, for example, Nishihara (1995) for a clear and complete mathematical approach, or Jordan and Puri (2005) for a specific and explicit example. A traveling wave is a solution to the equations of motion in the form

$$U(Y,t) = U(\xi), \qquad \xi = Y - ct, \tag{5.1}$$

where c is the constant speed; also, U is such that

$$\lim_{\xi \to -\infty} U(\xi) = U_L, \qquad \lim_{\xi \to \infty} U(\xi) = U_R, \tag{5.2}$$

where U_L and U_R are distinct constants. In what follows, we focus on the case where $U_L = 0$, $U_R = 1$. This case is general up to a rigid translation. Here we take the displacement corresponding to U_R as the characteristic length L.

Substituting (5.1) into (3.2), we obtain

$$\varepsilon c^2 U'' = (Uf - cU'g)'', \tag{5.3}$$

and then by integration,

$$cU'g = \left(f - \varepsilon c^2\right) U + \text{const.} \tag{5.4}$$

By the requirement $U_L = 0$, the constant must be zero. By the requirement $U_R = 1$, we have

$$f(\gamma_0, 1, \theta) = \varepsilon c^2. \tag{5.5}$$

This equation prompts three remarks.

First, we must ensure that $f(\gamma_0, 1, \theta) > 0$. Recall that, according to (2.13),

$$f(\gamma_0, 1, \theta) = 1 + \gamma_0 \sin^2\theta(2\cos\theta + \sin\theta)(\cos\theta + \sin\theta), \tag{5.6}$$

and so

$$\partial f(\gamma_0, 1, \theta)/\partial\theta = \gamma_0 \sin\theta(4\cos^3\theta + 9\sin\theta\cos^2\theta - 3\sin^3\theta). \tag{5.7}$$

In Figure 5.1(a) we plot the variations of $[f(\gamma_0, 1, \theta) - 1]/\gamma_0$ with θ, as well as those of its derivative with respect to θ (scaled to 1/8). Clearly, the function (5.6), viewed as a function of θ, has an absolute minimum and an absolute maximum. The minimum is at $\hat{\theta}$, say, such that $\tan\hat{\theta}$ is that root of the cubic $4 + 9x - 3x^3 = 0$ corresponding to $\pi/2 < \hat{\theta} < \pi$; numerically, $\hat{\theta} = 2.1777$. Then, solving $f(\gamma_0, 1, \hat{\theta}) = 0$ for γ_0, we find that $f(\gamma_0, 1, \theta) > 0$ when $0 < \gamma_0 < \hat{\gamma_0} = 18.490$; and that when $\gamma_0 > \hat{\gamma_0}$, there appears a range for θ where $f(\gamma_0, 1, \theta) > 0$ is not insured. Placing ourselves outside that possibility, we deduce from (5.5) that, for a given γ_0 and a given θ, the wave travels with speed

$$c = \pm\sqrt{f(\gamma_0, 1, \theta)/\varepsilon}. \tag{5.8}$$

This is of course expressed in the dimensionless variables of length$/L$ and time$\times\mu/\nu$. Turning back, if required, to physical variables, we would find that the wave travels with the dimensional speed $\sqrt{\mu f(\gamma_0, 1, \theta)/\nu}$.

The second remark is that, according to (5.5) and (5.6), the wave (when it exists) travels with maximum speed at the angle $\tilde{\theta}$, say, such that $\tan\tilde{\theta}$ is that root of the cubic $4 + 9x - 3x^3 = 0$ corresponding to $0 < \tilde{\theta} < \pi/2$; numerically, $\tilde{\theta} = 1.0910$. Hence the directions of extremal speeds of propagation are always the same, whatever the values of the constitutive parameters μ, γ_0, and γ_1. This observation indicates the way for

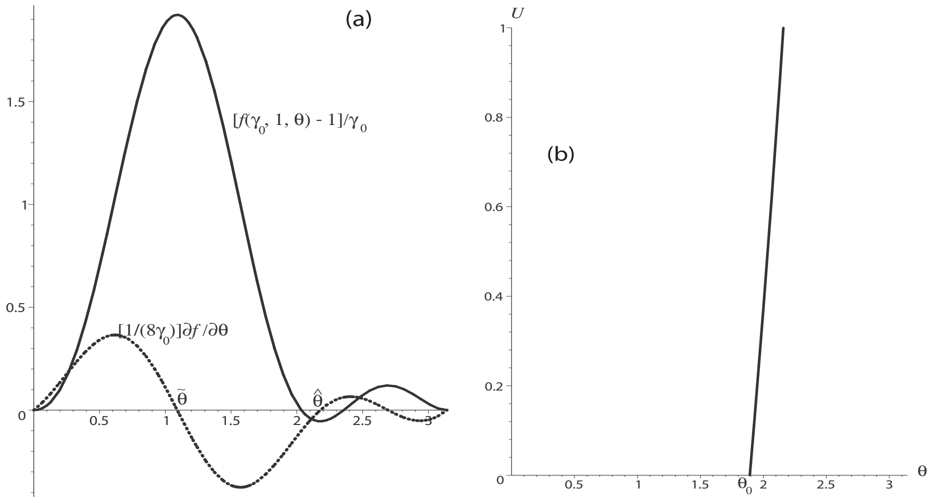

FIG. 5.1. (a) *Variations with* θ *of* $[f(\gamma_0, 1, \theta) - 1]/\gamma_0$ *and of its derivative, showing an absolute minimum at* $\hat{\theta} = 2.1777$. (b) *Variations of* $-3/\tan\theta - 1$ *with* θ, *crossing the abscissa line at* $\theta_0 = 1.8926$.

an acoustic determination of the fiber orientation: if an experimental measurement of the shear wave speed can be made in every direction of a fiber-reinforced viscoelastic nonlinear material, then the fibers are at an angle $\hat{\theta}$ from the direction of the slowest wave and at an angle $\tilde{\theta}$ from the direction of the fastest wave. We recall that for waves in an *isotropic* deformed neo-Hookean material, Ericksen (1953) found that the fastest waves propagate along the direction of greatest initial stretch.

The third remark is that when (5.5) holds,

$$f(\gamma_0, U, \theta) - \varepsilon c^2 = \gamma_0 U(U-1)\sin^3\theta\,[U\sin\theta + 3\cos\theta + \sin\theta]\,. \tag{5.9}$$

Then the separation of variables, followed by integration of the first-order differential equation (5.4), leads to

$$\int \frac{g(\gamma_1, U, \theta)}{U(U-1)\sin^3\theta[U\sin\theta + 3\cos\theta + \sin\theta]}\mathrm{d}U = \frac{\gamma_0}{c}\xi + \text{const.}, \tag{5.10}$$

where the constant of integration is arbitrary; without loss of generality, we take it to be such that $U(0) = 1/2$.

Clearly, critical issues arise when either the numerator or the denominator change signs (because then U' changes sign, and it might not be possible to find a solution satisfying the requirements (5.2)). We may take care of the numerator's sign by considering only elastic anisotropy ($\gamma_0 \neq 0$) and discarding viscous anisotropy ($\gamma_1 = 0$); then $g = 1$. For the denominator, however, we note that $U\sin\theta + 3\cos\theta + \sin\theta$ can change sign for certain ranges of U and θ. Figure 5.1(b) shows the curve $U = -3/\tan\theta - 1$; on its left side, the denominator is positive; on its right side, it is negative. Accordingly, the wave connects 0 to 1 (see Figure 5.2(a)) or is unable to do so (see Figure 5.2(b)). In that latter case, the wave front grows toward an asymptotic value which is less than 1; a second solution exists (dotted curve) with 1 as an asymptotic value, but in the $\xi \to -\infty$ direction.

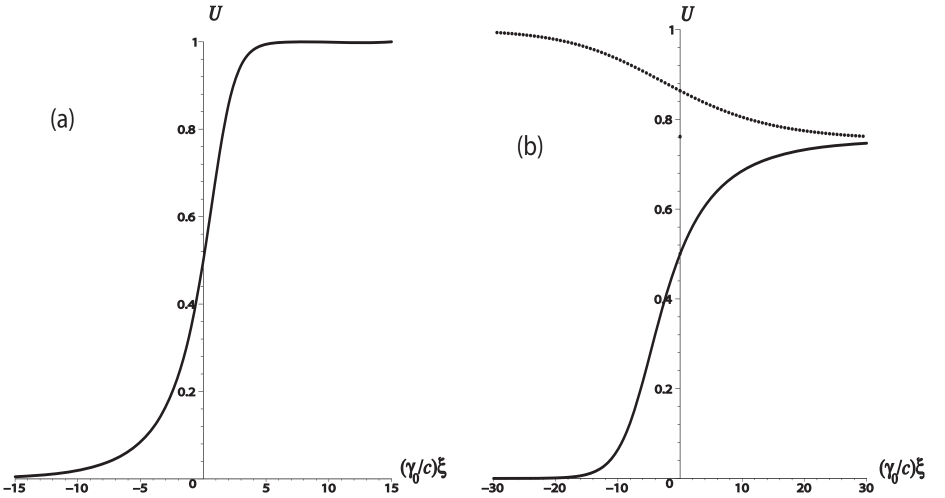

FIG. 5.2. *Traveling wave solution for anisotropic elasticity* ($\gamma_1 = 0$): (a) *at* $\theta = 1.8$, (b) *at* $\theta = 2.1$.

As a final remark, we note that when γ_1 is large enough to allow for the possibility that $g = 0$ (strong viscous anisotropy), then a "singular barrier" arises; see Pettet, McElwain, and Norbury (2000).

6. Discussion.

In the course of this investigation on nonlinear anisotropic creep, recovery, and waves for fiber-reinforced nonlinear elastic materials, we unearthed some complex mechanical responses. For some range of the constitutive parameters and for some angle ranges of the fiber arrangement, we saw that unusual and possibly aberrant behaviors can emerge.

From a mathematical point of view, we gave a detailed explanation of the reasons for these behaviors, by linking them to the singularities of the determining equations for the amount of shear.

From the mechanical point of view, we pointed out that nonstandard behaviors always occur when the angle between the fiber family and the direction of shear is such that the fibers are compressed; see Figure 2.1. It has been widely demonstrated that several types of instabilities may develop in the case of fiber contraction; see the detailed studies by Triantafyllidis and Abeyaratne (1983), Qiu and Pence (1997), Merodio and Ogden (2002), (2003), (2005a), (2005b), or Fu and Freidin (2004). For example, Merodio, Saccomandi, and Sgura (2007) recently investigated a nonhomogeneous rectilinear shear static deformation for the standard reinforcing model (2.1) and found nonregular solutions (that is, deformations characterized by a discontinuous amount of shear) in fiber-contracted materials.

From a numerical point of view, we recall that a simple model, together with a simple class of solutions, allows a step-by-step control of the simulations. It would indeed be hard to detect nonstandard behaviors by relying solely on a complex numerical finite element method (omitting to conduct a simple analytical methodology such as the one presented in this paper). For example, Holzapfel and Gasser (2001) present a detailed computational study of some viscoelastic fiber-reinforced nonlinear materials, but use values for the material parameters and for the angles which place their simulations outside the problematic ranges. Other studies are placed in the framework of linear models (even for polymeric materials; see Liu, Kasyanov, and Schoephoerster (2007)), which fail to capture nonstandard behaviors.

From an experimental point of view, our results suggest some simple yet revealing protocols. In particular, it would be most valuable to investigate the existence and the persistence of asymptotic residual shear strains, sustained after the shear stress is removed, at levels not only below the value at initial time but also above (as in section 3). So far we have identified only reports of experimental results concerned with elastomeric materials reinforced with *inextensible* fibers (and therefore with a ratio between the shear modulus of the bulk matrix and that of the fibers of several orders of magnitude), or concerned with moderate angles between the direction of shear and the fiber direction.

From a biomechanical point of view, the results have meaningful implications for biological soft tissues. First, the model captures adequately the elastic and the viscous anisotropies of biological materials (Baldwin et al. (2006), Taylor et al. (1990)). Second, although anomalous creep behaviors might preclude anomalous recovery behaviors, it is still useful to study the latter, because they might nonetheless arise in vivo following a stress-driven fiber orientation remodeling (Hariton et al. (2006)). Third, the effect of the prestretch on nonstandard behaviors is significant theoretically (section 4.3) as well as practically. (In vivo experiments show that large static prestretches of tendons reduce the risk of unexpected behaviors; see Kubo, Kanehisa, and Fukunaga (2002).) Finally, the results of the traveling wave study (section 5) may eventually lead to an acoustic (elastographic) determination of the fiber angle in soft tissues, through an efficient, simple, and noninvasive investigation.

Obviously, our results must be improved, and several directions are possible. Hence, two families of fibers have to be considered to give a better comparison with in vivo results for soft tissues. Also, the more realistic models of fiber reinforcements (such as the one proposed by Horgan and Saccomandi (2005) and by Gasser, Ogden, and Holzapfel (2006)) must be incorporated into the present study, to identify with a greater precision the range of parameters for which strange behaviors may occur.

ACTIVATION THROUGH A NARROW OPENING[*]

A. SINGER[†] AND Z. SCHUSS[‡]

Abstract. The escape of a Brownian motion through a narrow absorbing window in an otherwise reflecting boundary of a domain is a rare event. In the presence of a deep potential well, there are two long time scales, the mean escape time from the well and the mean time to reach the absorbing window. We derive a generalized Kramers formula for the mean escape time through the narrow window.

Key words. stochastic differential equations, exit problem, narrow escape, mixed boundary value problem

1. Introduction.

Kramers' theory [12], [6] concerns the thermal activation of a Brownian particle over a high potential barrier. It assumes that the barrier height is much larger than the thermal energy. Its application to the theory of chemical kinetics [20] gives the activation rate of the stochastic dynamics of a reactant molecule over a potential barrier ΔE as the Arrhenius law

$$k = Ae^{-\Delta E/k_BT}, \tag{1.1}$$

where A is a function of temperature, friction, and the potential landscape. A similar, but different situation arises, if the chemical reaction can be described as the diffusion of a Brownian particle through a small opening in the boundary of a domain, whose remaining boundaries are practically reflecting. Such a situation can occur, if the reflecting boundaries are due to a high potential barrier with a small opening, whose energy is not necessarily much higher than the thermal energy. This can happen, for example, if the reflecting boundaries are due to a dielectric barrier, as in biological membranes, and the small opening is a protein channel embedded in an otherwise impenetrable membrane [7]. The small absorbing window setup is also a model for the forward rate of chemical reactions, in which there are small binding sites for the diffusing reacting molecule in the boundary of the domain [9]. The same setup also describes the process of trafficking receptors on biological membranes [8]. The escape of a free Brownian motion (without drift) through a small window was discussed in [17], [18], [19]. Here we consider the narrow escape problem for a Brownian motion in a field of force. The closely related problem of computing the principal eigenvalue of the Laplace operator for mixed boundary conditions on large and small pieces of the boundary was considered in [22], [23], [24], [11] (see section 6 for discussion).

We derive an Arrhenius-like formula (1.1) for the activation rate through narrow openings. Specifically, we consider the diffusion of a Brownian particle in a potential

field in a bounded domain Ω, where activation occurs if the particle goes through a small opening $\partial\Omega_a$ in the boundary $\partial\Omega$ of the domain. We assume that the remaining boundary $\partial\Omega_r$ reflects the Brownian trajectories. We find the dependence of the rate constant on the potential, specific geometry of the opening and on the volume or surface area of the domain. As in Kramers' theory, we obtain different rate constants for low and high barriers. The activation rates for the different geometries are summarized in (4.6)–(4.13).

2. Formulation. As in classical theories [12], [6], [20], our point of departure is the Langevin dynamics in $\mathbb{R}^n$ $(n = 2, 3)$,

$$m\ddot{\boldsymbol{x}} + \eta\dot{\boldsymbol{x}} + \nabla\Phi(\boldsymbol{x}) = \sqrt{2\eta k_B T}\dot{\boldsymbol{w}}, \tag{2.1}$$

where m is the mass, η is the friction coefficient, $\Phi(x)$ is the potential, T is temperature, k_B is Boltzmann's constant, and $\dot{\boldsymbol{w}}$ is a vector of n independent δ-correlated Gaussian white noises. In the Smoluchowski (Kramers) limit of large friction, the Langevin dynamics (2.1) reduces to the Smoluchowski equation [16], [4], [6]

$$\dot{\boldsymbol{x}} + \frac{1}{\gamma}\nabla\phi(\boldsymbol{x}) = \sqrt{\frac{2k_B T}{m\gamma}}\,\dot{\boldsymbol{w}}, \tag{2.2}$$

where $\gamma = \eta/m$ is the dynamics viscosity and $\phi = \Phi/m$ is the potential per unit mass.

The motion of the Brownian particle is confined to a bounded domain Ω, whose boundary $\partial\Omega$ is reflecting, but for a small absorbing window $\partial\Omega_a$ $(\partial\Omega = \partial\Omega_a \cup \Omega_r)$. The assumption that the window is small means that

$$\delta = \left(\frac{|\partial\Omega_a|}{|\partial\Omega|}\right)^{1/(n-1)} \ll 1 \tag{2.3}$$

(δ is a small parameter).

The probability density function (pdf) $p_\delta(\boldsymbol{x}, t)$ of finding the Brownian particle at location $\boldsymbol{x}$ at time t satisfies the Fokker–Planck equation

$$\gamma\frac{\partial p_\delta}{\partial t} = \varepsilon\Delta p_\delta + \nabla\cdot(p_\delta\nabla\phi) \equiv \mathcal{L}_\delta p_\delta, \tag{2.4}$$

with the initial condition

$$p_\delta(\boldsymbol{x}, 0) = p_0(\boldsymbol{x}), \tag{2.5}$$

and the mixed Dirichlet–Neumann boundary conditions for $t > 0$

$$p_\delta = 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_a, \tag{2.6}$$

$$\varepsilon\frac{\partial p_\delta}{\partial n} + p_\delta\frac{\partial\phi}{\partial n} = 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_r, \tag{2.7}$$

where $\varepsilon = k_B T/m$, $\boldsymbol{n}$ is the unit outer normal at the boundary, and $p_0(\boldsymbol{x})$ is the initial pdf (e.g., $p_0(\boldsymbol{x}) = \frac{1}{|\Omega|}$ for a uniform distribution). The function

$$u_\delta(\boldsymbol{x}) = \int_0^\infty p_\delta(\boldsymbol{x}, t)\,dt, \tag{2.8}$$

which is the mean time the particle spends at $\boldsymbol{x}$ before it escapes through the narrow window, is the solution of the boundary value problem

$$\mathcal{L}_\delta u_\delta = -\gamma p_0 \quad \text{for} \quad \boldsymbol{x} \in \Omega, \tag{2.9}$$

$$u_\delta = 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_a, \tag{2.10}$$

$$\varepsilon \frac{\partial u_\delta}{\partial n} + u_\delta \frac{\partial \phi}{\partial n} = 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_r. \tag{2.11}$$

The function $g_\delta = u_\delta e^{\phi/\varepsilon}$ is the solution of the adjoint problem

$$\mathcal{L}_\delta^* g_\delta = -\gamma p_0 e^{\phi/\varepsilon} \quad \text{for} \quad \boldsymbol{x} \in \Omega, \tag{2.12}$$

$$\begin{aligned} \frac{\partial g_\delta(\boldsymbol{x})}{\partial n} &= 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_r, \\ g_\delta(\boldsymbol{x}) &= 0 \quad \text{for} \quad \boldsymbol{x} \in \partial\Omega_a. \end{aligned} \tag{2.13}$$

Equation (2.12) can be written in the divergence form

$$\nabla \left(e^{-\phi/\varepsilon} \nabla g_\delta \right) = -\frac{\gamma p_0}{\varepsilon}. \tag{2.14}$$

The adjoint operators $\mathcal{L}_\delta$ and $\mathcal{L}_\delta^*$, defined by (2.4), (2.9), (2.10), (2.11), and (2.12), (2.13), respectively, have biorthogonal systems of normalized eigenfunctions, $\{\psi_i(\boldsymbol{x},\delta)\}$ and $\{\varphi_i(\boldsymbol{x},\delta)\}$ $(i = 0, 1, \ldots)$, and we can expand

$$p_\delta(\boldsymbol{x}, t) = \sum_{i=0}^{\infty} a_i(\delta) \psi_i(\boldsymbol{x}, \delta) e^{-\lambda_i(\delta) t/\gamma}, \tag{2.15}$$

where $\lambda_i(\delta)$ are the eigenvalues of $\mathcal{L}_\delta$. The $a_i(\delta)$ are the Fourier coefficients of the initial function $p_0(\boldsymbol{x})$. In the limit $\delta \to 0$ the Dirichlet part of the boundary conditions, (2.6), is dropped, so that $\lambda_0(\delta) \to 0$ (the first eigenvalue of the problem (2.4), (2.7) with $\partial\Omega_r = \partial\Omega$), with the normalized eigenfunction

$$\psi_0(\boldsymbol{x}, 0) = \frac{\exp\{-\phi(\boldsymbol{x})/\varepsilon\}}{\displaystyle\int_\Omega \exp\{-\phi(\boldsymbol{x})/\varepsilon\}\, d\boldsymbol{x}}, \tag{2.16}$$

and $a_0(\delta) \to 1$. It follows from (2.8) and (2.15) that for all $\boldsymbol{x} \in \Omega$

$$u_\delta(\boldsymbol{x}) = \gamma \sum_{i=0}^{\infty} \frac{a_i(\delta)\psi_i(\boldsymbol{x},\delta)}{\lambda_i(\delta)} \to \infty \quad \text{as} \quad \delta \to 0. \tag{2.17}$$

In particular, the first passage time $\tau_\delta = \inf\{t > 0 \mid \boldsymbol{x}(t) \in \partial\Omega_a\}$ diverges. That is, $\lim_{\delta\to 0} \tau_\delta = \infty$ on almost every trajectory $\boldsymbol{x}(t)$. Obviously, the mean first passage time,

$$\langle \tau_\delta \rangle = \int_\Omega u_\delta(\boldsymbol{x})\, d\boldsymbol{x} = \gamma \sum_{i=0}^{\infty} \frac{a_i(\delta)}{\lambda_i(\delta)}, \tag{2.18}$$

also diverges as $\delta \to 0$. It is the purpose of this paper to find the orders of magnitude of $u_\delta(\boldsymbol{x})$ and $\langle \tau_\delta \rangle$ for small δ.

3. The Neumann function. The Neumann function for Ω is the solution of the boundary value problem

$$\begin{aligned} \Delta_{\boldsymbol{y}} N(\boldsymbol{x},\boldsymbol{y}) &= -\delta(\boldsymbol{x}-\boldsymbol{y}) \quad \text{for} \quad \boldsymbol{x},\boldsymbol{y}\in\Omega, \\ \frac{\partial N(\boldsymbol{x},\boldsymbol{y})}{\partial n_{\boldsymbol{y}}} &= -\frac{1}{|\partial\Omega|} \quad \text{for} \quad \boldsymbol{x}\in\Omega,\ \boldsymbol{y}\in\partial\Omega, \end{aligned} \tag{3.1}$$

with $N(\boldsymbol{x},\boldsymbol{y})$ fixed at a given point, to ensure uniqueness. Using Green's identity and the boundary conditions (2.10)–(2.11) and (3.1) gives

$$\begin{aligned} &\int_\Omega N(\boldsymbol{x},\boldsymbol{y})\Delta_{\boldsymbol{y}} u_\delta(\boldsymbol{y})\,d\boldsymbol{y} \\ &= \int_\Omega u_\delta(\boldsymbol{y})\Delta_{\boldsymbol{y}} N(\boldsymbol{x},\boldsymbol{y})\,d\boldsymbol{y} + \int_{\partial\Omega}\left(N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}} - u_\delta(\boldsymbol{y})\frac{\partial N(\boldsymbol{x},\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\right)dS_{\boldsymbol{y}} \\ &= -u_\delta(\boldsymbol{x}) + \int_{\partial\Omega_a} N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\,dS_{\boldsymbol{y}} - \frac{1}{\varepsilon}\int_{\partial\Omega_r} N(\boldsymbol{x},\boldsymbol{y})u_\delta(\boldsymbol{y})\frac{\partial\phi(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\,dS_{\boldsymbol{y}} \\ &\quad + \frac{1}{|\partial\Omega|}\int_{\partial\Omega_r} u_\delta(\boldsymbol{y})\,dS_{\boldsymbol{y}}. \end{aligned} \tag{3.2}$$

On the other hand, (2.9) gives

$$\begin{aligned} &\int_\Omega N(\boldsymbol{x},\boldsymbol{y})\Delta_{\boldsymbol{y}} u_\delta(\boldsymbol{y})\,d\boldsymbol{y} \\ &\quad = \int_\Omega N(\boldsymbol{x},\boldsymbol{y})\left[-\frac{\gamma p_0}{\varepsilon} - \frac{1}{\varepsilon}\nabla\cdot(u_\delta\nabla\phi)\right]d\boldsymbol{y} \\ &\quad = -\frac{\gamma}{\varepsilon}\int_\Omega N(\boldsymbol{x},\boldsymbol{y})p_0(\boldsymbol{y})\,d\boldsymbol{y} - \frac{1}{\varepsilon}\int_\Omega \nabla_{\boldsymbol{y}}\cdot[N(\boldsymbol{x},\boldsymbol{y})u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})]\,d\boldsymbol{y} \\ &\qquad + \frac{1}{\varepsilon}\int_\Omega u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}N(\boldsymbol{x},\boldsymbol{y})\,d\boldsymbol{y} \\ &\quad = -\frac{\gamma}{\varepsilon}\int_\Omega N(\boldsymbol{x},\boldsymbol{y})p_0(\boldsymbol{y})\,d\boldsymbol{y} - \frac{1}{\varepsilon}\int_{\partial\Omega_r} N(\boldsymbol{x},\boldsymbol{y})u_\delta(\boldsymbol{y})\frac{\partial\phi(\boldsymbol{y})}{\partial n}\,dS_{\boldsymbol{y}} \\ &\qquad + \frac{1}{\varepsilon}\int_\Omega u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}N(\boldsymbol{x},\boldsymbol{y})\,d\boldsymbol{y}. \end{aligned} \tag{3.3}$$

Combining (3.2) and (3.3) yields

$$\begin{aligned} &-u_\delta(\boldsymbol{x}) + \frac{1}{|\partial\Omega|}\int_{\partial\Omega_r} u_\delta(\boldsymbol{y})\,dS_{\boldsymbol{y}} + \int_{\partial\Omega_a} N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\,dS_{\boldsymbol{y}} \\ &= -\frac{\gamma}{\varepsilon}\int_\Omega N(\boldsymbol{x},\boldsymbol{y})p_0(\boldsymbol{y})\,d\boldsymbol{y} + \frac{1}{\varepsilon}\int_\Omega u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}N(\boldsymbol{x},\boldsymbol{y})\,d\boldsymbol{y}. \end{aligned} \tag{3.4}$$

In view of (2.17), the integral $\int_\Omega N(\boldsymbol{x},\boldsymbol{y})p_0(\boldsymbol{y})\,d\boldsymbol{y}$ can be neglected to leading order, because it is uniformly bounded for smooth initial distributions[1] p_0 as $\delta\to 0$, while all other terms in (3.4) are unbounded. For $\boldsymbol{x}\in\Omega$, at a distance $O(1)$ away from the window, the Neumann function is uniformly bounded.

[1] For nonsmooth p_0 the integral is not uniformly bounded. For example, for $p_0 = \delta(\boldsymbol{x}-\boldsymbol{x}_0)$ we have $\int_\Omega N(\boldsymbol{x},\boldsymbol{y})p_0(\boldsymbol{y})\,d\boldsymbol{y} = N(\boldsymbol{x},\boldsymbol{x}_0)$, which becomes singular as $\boldsymbol{x}\to\boldsymbol{x}_0$. However, this is an integrable singularity, and as such it does not affect the leading order asymptotics in δ.

Note that integrating (2.14) and using the boundary conditions (2.13), we obtain the compatibility condition

$$\int_{\partial\Omega_a} \frac{\partial u_\delta}{\partial n}\, dS = -\frac{\gamma}{\varepsilon}. \tag{3.5}$$

Because of the fact that the normal derivative $\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}$ is negative on $\partial\Omega_a$, (3.5) implies that $\int_{\partial\Omega_a} N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\, dS_{\boldsymbol{y}}$ is uniformly bounded. It follows that for $\boldsymbol{x} \in \Omega$, at a distance $O(1)$ (with respect to δ) away from the window, the integral equation (3.4) is to leading order

$$u_\delta(\boldsymbol{x}) \sim \frac{1}{|\partial\Omega|}\int_{\partial\Omega} u_\delta(\boldsymbol{y})\, dS_{\boldsymbol{y}} - \frac{1}{\varepsilon}\int_\Omega u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot\nabla N(\boldsymbol{x},\boldsymbol{y})\, d\boldsymbol{y}, \tag{3.6}$$

which is the integral representation of the boundary value problem $\mathcal{L}_\delta u_\delta = 0$ with the no flux boundary condition (2.11) on the entire boundary (i.e., with $\partial\Omega_r = \partial\Omega$), whose solution is the Boltzmann distribution

$$u_\delta(\boldsymbol{x}) \sim C_\delta e^{-\phi(\boldsymbol{x})/\varepsilon}. \tag{3.7}$$

Equation (3.7) represents the averaged time the particle spent at a point $\boldsymbol{x}$ at a distance $O(1)$ away from the absorbing window prior to absorption.

Due to the absorbing boundary condition (2.10), (3.4) reduces to

$$\begin{aligned}\int_{\partial\Omega_a} & N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\, dS_{\boldsymbol{y}} \\ &= \left\{\frac{-1}{|\partial\Omega|}\int_{\partial\Omega_r} u_\delta(\boldsymbol{y})\, dS_{\boldsymbol{y}} + \frac{1}{\varepsilon}\int_\Omega u_\delta(\boldsymbol{y})\nabla_{\boldsymbol{y}}\phi(\boldsymbol{y})\cdot\nabla_{\boldsymbol{y}}N(\boldsymbol{x},\boldsymbol{y})\, d\boldsymbol{y}\right\}(1+o(1))\end{aligned} \tag{3.8}$$

for all $\boldsymbol{x} \in \partial\Omega_a$. Substituting (3.7) into (3.8) yields an integral equation for the flux $\frac{\partial u_\delta}{\partial n}$ into the absorbing window,

$$\int_{\partial\Omega_a} N(\boldsymbol{x},\boldsymbol{y})\frac{\partial u_\delta(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\, dS_{\boldsymbol{y}} = -C_\delta e^{-\phi(\boldsymbol{x})/\varepsilon}(1+o(1)) \quad \text{for} \quad \delta \ll 1. \tag{3.9}$$

If $\phi(\boldsymbol{x})$ does not change much in the window, we can use the constant approximation $\phi(\boldsymbol{x}) \approx \phi(\text{window}) = \phi_0$.

In three dimensions

$$N(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{4\pi|\boldsymbol{x}-\boldsymbol{y}|} + v_S(\boldsymbol{x},\boldsymbol{y}), \tag{3.10}$$

where v_S is a regular harmonic function [10], and so the leading order contribution to (3.9) is due to the singular part of the Neumann function. Thus the leading order approximation $\frac{\partial u_0}{\partial n}$ to the absorption flux is the solution of

$$\frac{1}{2\pi}\int_{\partial\Omega_a} \frac{\partial u_0(\boldsymbol{y})}{\partial n_{\boldsymbol{y}}}\frac{dS_{\boldsymbol{y}}}{|\boldsymbol{x}-\boldsymbol{y}|} = -C_\delta e^{-\phi_0/\varepsilon}. \tag{3.11}$$

Note that the singularity of the Neumann function at the boundary is twice as large as it is inside the domain, due to the contribution of the regular part (the "image charge"). For that reason the factor $\frac{1}{4\pi}$ in (3.10) was replaced by $\frac{1}{2\pi}$.

4. Narrow escape. von Helmholtz [21] (see also Rayleigh [1] and others, e.g., [13]) solved the integral equation (3.11) analytically for the case of an elliptical absorbing window $\partial\Omega_a$,

$$\frac{\partial u_0(y_1,y_2)}{\partial n} = -\frac{C_\delta e^{-\phi_0/\varepsilon}}{\sqrt{1-\frac{y_1^2}{a^2}-\frac{y_2^2}{b^2}}}, \tag{4.1}$$

where a and b are the ellipse semiaxes, and $\boldsymbol{y} = (y_1, y_2)$ are local Cartesian coordinates in the ellipse. The value of the constant C_δ is calculated using the compatibility condition (3.5) to be

$$C_\delta = \frac{\gamma K(e)}{2\pi\varepsilon a} e^{\phi_0/\varepsilon}, \tag{4.2}$$

where e is the eccentricity of the ellipse and $K(\cdot)$ is the complete elliptic integral of the first kind. In a three-dimensional domain, the averaged time spent at point $\boldsymbol{x}$ before escape through an elliptical absorbing window is given by (see (3.7))

$$u_\delta(\boldsymbol{x}) \approx \frac{\gamma K(e)}{2\pi\varepsilon a} \exp\left\{\frac{\phi_0-\phi(\boldsymbol{x})}{\varepsilon}\right\}. \tag{4.3}$$

Equations (2.18) and (4.3) now give the mean escape time as

$$\langle\tau_\delta\rangle = \frac{\gamma K(e) e^{\phi_0/\varepsilon}}{2\pi\varepsilon a} \int_\Omega \exp\left\{-\frac{\phi(\boldsymbol{x})}{\varepsilon}\right\} d\boldsymbol{x}. \tag{4.4}$$

If the barrier is sufficiently high, we evaluate the integral in (4.4) by the Laplace method, assuming that ϕ has a single global minimum ϕ_m at $\boldsymbol{x}_m$,

$$\int_\Omega \exp\left\{-\frac{\phi(\boldsymbol{x})}{\varepsilon}\right\} d\boldsymbol{x} \approx \frac{(2\pi\varepsilon)^{n/2}}{\prod_{i=1}^{n}\omega_i} \exp\left\{-\frac{\phi_m}{\varepsilon}\right\}, \tag{4.5}$$

where ω_i are the frequencies at the minimum $\boldsymbol{x}_m$. For reactions that consist in passing through a small elliptical window (assuming no returns are possible), the reaction rate is the modified Kramers formula

$$\kappa_\delta = \frac{1}{\langle\tau_\delta\rangle} \sim \frac{a\omega_1\omega_2\omega_3}{\sqrt{2\pi\varepsilon}\,\gamma K(e)}\, e^{-\Delta E/\varepsilon}, \tag{4.6}$$

where $\Delta E = \phi_0 - \phi_m$. In the special case of a circular window, we obtain

$$\kappa_\delta \sim \frac{4a\omega_1\omega_2\omega_3}{(2\pi)^{3/2}\gamma\sqrt{\varepsilon}}\, e^{-\Delta E/\varepsilon}, \tag{4.7}$$

where a is the radius of the window. Note that ΔE is not the barrier height. We conclude that the activation rate is of Arrhenius form and has two contributions. The first is due to the potential, while the second is due to geometry of the absorbing window alone. Unlike the free diffusion case [17], [18], [19], geometrical properties of the domain, such as its volume, are not included in the leading order asymptotics of the reaction rate.

Second, in the limit of large ε, the power series approximation

$$e^{-(\phi(\boldsymbol{x})-\phi_0)/\varepsilon}=1-\frac{\phi(\boldsymbol{x})-\phi_0}{\varepsilon}+\frac{(\phi(\boldsymbol{x})-\phi_0)^2}{2\varepsilon^2}\cdots$$

in (4.4) gives

$$k\sim\frac{2\pi\varepsilon a}{\gamma K(e)|\Omega|}\left(1-\frac{\langle\phi\rangle-\phi_0}{\varepsilon}+O\left(\varepsilon^{-2}\right)\right)^{-1}, \tag{4.8}$$

where $\langle\phi\rangle=\frac{1}{|\Omega|}\int_\Omega\phi(\boldsymbol{x})\,d\boldsymbol{x}$ is the spatial average of the potential. The rate can also be rewritten into an Arrhenius form as

$$k\sim\frac{2\pi\varepsilon a}{\gamma K(e)|\Omega|}\,e^{-\langle\Delta E\rangle/\varepsilon}, \tag{4.9}$$

where $\langle\Delta E\rangle=\phi_0-\langle\phi\rangle$. In the case of large ε the reaction rate depends not merely on the geometry of the window but also on the geometry of the domain itself through its volume. Large ε means that the motion is diffusion limited; therefore, fine details of the potential are less important and the spatial averaged potential has only an $O(\varepsilon^{-1})$ effect.

Finally, we give rate functions for small and large ε for several geometries. For the case of diffusion in a ball of radius R, the results of [17] show that

$$\begin{aligned} k&\sim\frac{4\varepsilon a}{\gamma|\Omega|}\left[1+\frac{a}{R}\ln\frac{R}{a}+O\left(\frac{a}{R}\right)\right]^{-1}e^{-\langle\Delta E\rangle/\varepsilon}\quad\text{for}\quad\varepsilon\gg\Delta E,\\ k&\sim\frac{4\varepsilon a\omega_1\omega_2\omega_3}{\gamma(2\pi)^{3/2}}\left[1+\frac{a}{R}\ln\frac{R}{a}+O\left(\frac{a}{R}\right)\right]^{-1}e^{-\Delta E/\varepsilon}\quad\text{for}\quad\varepsilon\ll\Delta E.\end{aligned} \tag{4.10}$$

We conjecture that the second order term is $O(\delta\ln\delta)$ also for a general three-dimensional domain, though we were unable to prove it so far.

In two dimensions the singularity of the Neumann function is logarithmic, and so the leading order approximation to the activation rate is

$$\begin{aligned} k&\sim\frac{\pi\varepsilon}{\gamma|\Omega|}\frac{e^{-\langle\Delta E\rangle/\varepsilon}}{\left[\ln\frac{1}{\delta}+O(1)\right]}\quad\text{for}\quad\varepsilon\gg\Delta E,\\ k&\sim\frac{\varepsilon\sqrt{\omega_1\omega_2}}{2\gamma}\frac{e^{-\Delta E/\varepsilon}}{\left[\ln\frac{1}{\delta}+O(1)\right]}\quad\text{for}\quad\varepsilon\ll\Delta E.\end{aligned} \tag{4.11}$$

The remainder $O(1)$ is important, because in real life applications even if δ is small, $\ln\frac{1}{\delta}$ is not necessarily large. In [18], [19] we have calculated the $O(1)$ term for diffusion in a circular disk, in a circular annulus, and on a sphere. These results extend in a straightforward way to domains that can be mapped conformally onto these shapes (e.g., all simply connected planar domains).

If the boundary of the absorbing window contains a singular point of $\partial\Omega$, such as a corner or a cusp, the order of magnitude of the activation rate may change. Thus, if the window is at a corner of angle α, then the rate is [19]

$$
\begin{aligned}
k &\sim \frac{\alpha\varepsilon}{\gamma|\Omega|}\frac{e^{-\langle\Delta E\rangle/\varepsilon}}{\left[\ln\dfrac{1}{\delta}+O(1)\right]} \quad \text{for} \quad \varepsilon \gg \Delta E,\\
k &\sim \frac{\alpha\varepsilon\sqrt{\omega_1\omega_2}}{2\pi\gamma}\frac{e^{-\Delta E/\varepsilon}}{\left[\ln\dfrac{1}{\delta}+O(1)\right]} \quad \text{for} \quad \varepsilon \ll \Delta E.
\end{aligned}
\tag{4.12}
$$

If the absorbing window is near a cusp, then $\langle\tau_\delta\rangle$ grows algebraically rather than logarithmically. For example, in the domain bounded between two tangent circles, the activation rate is

$$
\begin{aligned}
k &\sim \frac{(d^{-1}-1)\varepsilon}{\gamma|\Omega|}\left[\delta+O(\delta^2)\right]e^{-\langle\Delta E\rangle/\varepsilon} \quad \text{for} \quad \varepsilon \gg \Delta E,\\
k &\sim \frac{(d^{-1}-1)\varepsilon\sqrt{\omega_1\omega_2}}{2\pi\gamma}\left[\delta+O(\delta^2)\right]e^{-\Delta E/\varepsilon} \quad \text{for} \quad \varepsilon \ll \Delta E,
\end{aligned}
\tag{4.13}
$$

where $d<1$ is the ratio of the radii.

5. Deep well—a Markov chain model. The modified Kramers formulas (4.6) or (4.11) can be explained by coarse-graining the diffusive motion into a simplified 3-state Markov model, when the domain contains a deep well $\Omega_W \subset \Omega$. The three states of the Markov process are (i) state W—the trajectory is trapped in the deep well; (ii) state D—the trajectory diffuses in the domain $\Omega_D = \Omega - \Omega_W$, outside the well; (iii) state A—the trajectory is absorbed into the small hole. Once the trajectory is absorbed into the small hole, its motion is terminated, and so A is a terminal state of the Markov chain. For simplicity, we assume $\Omega \subset \mathbb{R}^2$.

Not all transition times between the different states are finite with probability 1, and so not all mean transition times are finite. The particle leaves the well to the outer in finite mean time, that is,

$$
\Pr\{\tau_{W\to D}<\infty\}=1, \quad \mathbb{E}\tau_{W\to D}<\infty. \tag{5.1}
$$

For small ε, the mean time spent in the well, $\mathbb{E}\tau_{W\to D}$, is exponentially large and is given by [14]

$$
\mathbb{E}\tau_{W\to D} \sim \frac{2\pi\sqrt{\dfrac{\partial^2\phi(x_S)}{\partial s^2}}}{\sqrt{-\dfrac{\partial^2\phi(x_S)}{\partial\nu^2}}\sqrt{H(x_W)}}\exp\left\{\frac{\phi(x_S)-\phi(x_W)}{\varepsilon}\right\}, \tag{5.2}
$$

where ν and s are the distance to and arclength on $\partial\Omega_W$, respectively, x_W is the deepest point of the well, x_S is the point on $\partial\Omega_W$, where ϕ achieves its minimum, and H is the Hessian of ϕ.

The time $\tau_{D\to W}$, however, is not finite with probability 1, because there is a finite probability $\Pr\{\tau_{D\to A}<\tau_{D\to W}\}$ of termination at A without returning to W, and there is no return from A to W. Consequently, $\mathbb{E}\tau_{D\to W}=\infty$. However, $\mathbb{E}\tau_{D\to A}$ and $\mathbb{E}[\tau_{D\to W} \mid \tau_{D\to W}<\tau_{D\to A}]$ are finite. For small ε,δ, the conditional mean time $\mathbb{E}[\tau_{D\to W} \mid \tau_{D\to W}<\tau_{D\to A}]$ is asymptotically the same as $\mathbb{E}\tau_{D\to W}$ for a problem without the small absorbing window, because the conditioning changes the drift only near A, to repel the trajectory from the window, and so the effect on the conditional mean time is small, regardless of whether this mean time is long or short. The transition probabilities from the outer domain to the absorbing window and to the well are

$$\Pr\{\tau_{D\to A}<\tau_{D\to W}\}\sim\frac{\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]}{\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]+\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]},$$
$$\Pr\{\tau_{D\to W}<\tau_{D\to A}\}\sim\frac{\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]}{\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]+\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]},\tag{5.3}$$

respectively. The conditional mean transition time $\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]$ from Ω_D to Ω_W is similar to (5.2),

$$\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]\sim\frac{2\pi\sqrt{\dfrac{\partial^2\phi(x_S)}{\partial s^2}}}{\sqrt{-\dfrac{\partial^2\phi(x_S)}{\partial\nu^2}}\sqrt{H(x_D)}}\exp\left\{\frac{\phi(x_S)-\phi(x_D)}{\varepsilon}\right\},\tag{5.4}$$

where x_D is the deepest point of the potential in the outer domain, $\phi(x_W)<\phi(x_D)<\phi(x_S)$. The mean transition time $\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]$ from Ω_D to the absorbing window is given by (4.11)

$$\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]\sim\frac{2\gamma\ln\delta^{-1}}{\varepsilon\sqrt{H(x_D)}}\exp\left\{\frac{\phi_0-\phi(x_D)}{\varepsilon}\right\}.\tag{5.5}$$

If we assume that the effect of the small window on the mean escape time, $\ln\delta^{-1}$ (or $1/\delta$ in three dimensions), is larger than that of the energy barrier, $\exp\{[\phi_0-\phi(x_S)]/\varepsilon\}$, then, according to our assumption that the potential is relatively flat outside the deep well, $\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]\ll\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]$, and so (5.3) implies

$$\Pr\{\tau_{D\to A}<\tau_{D\to W}\}\sim\frac{\mathbb{E}[\tau_{D\to W}\mid\tau_{D\to W}<\tau_{D\to A}]}{\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]}.\tag{5.6}$$

The mean absorption times $\mathbb{E}\tau_{i\to A}$ are finite for $i=D,W$. They satisfy the renewal equations

$$\mathbb{E}\tau_{D\to A}=\Pr\{\tau_{D\to A}<\tau_{D\to W}\}\mathbb{E}\left[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}\right]$$
$$\qquad+\Pr\{\tau_{D\to W}<\tau_{D\to A}\}\mathbb{E}\tau_{W\to A},\tag{5.7}$$
$$\mathbb{E}\tau_{W\to A}=\mathbb{E}\tau_{W\to D}+\mathbb{E}\tau_{D\to A}\tag{5.8}$$

(see [15]). Adding (5.7) and (5.8), and dividing by $\Pr\{\tau_{D\to A}<\tau_{D\to W}\}=1-\Pr\{\tau_{D\to W}<\tau_{D\to A}\}$, we obtain

$$\mathbb{E}\tau_{W\to A}=\mathbb{E}\left[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}\right]+\frac{\mathbb{E}\tau_{W\to D}}{\Pr\{\tau_{D\to A}<\tau_{D\to W}\}}.\tag{5.9}$$

Both $\mathbb{E}[\tau_{D\to A}\mid\tau_{D\to A}<\tau_{D\to W}]$ and $1/\Pr\{\tau_{D\to A}<\tau_{D\to W}\}$ have the same order of magnitude as functions of δ; however, $\mathbb{E}\tau_{W\to D}$ is exponentially large. Therefore,

$$\mathbb{E}\tau_{W\to A}\sim\frac{\mathbb{E}\tau_{W\to D}}{\Pr\{\tau_{D\to A}<\tau_{D\to W}\}}.\tag{5.10}$$

Now, by (5.8), we have

$$\mathbb{E}\tau_{D\to A} \sim \mathbb{E}\tau_{W\to D}\left(\frac{1}{\Pr\{\tau_{D\to A} < \tau_{D\to W}\}} - 1\right) \sim \frac{\mathbb{E}\tau_{W\to D}}{\Pr\{\tau_{D\to A} < \tau_{D\to W}\}}, \tag{5.11}$$

because $\Pr\{\tau_{D\to A} < \tau_{D\to W}\} \to 0$ as $\delta \to 0$. The meaning of (5.10) and (5.11) is that for each realization of the Markov chain, e.g., $DWDWDWDWDWDWDWDA$, the number of visits in state D is larger by 1, or equal to the number of visits at state W. The mean time that the particle spends at state W is exponentially larger than the mean time spent at state D. Therefore, the mean time to absorption is approximately the average number of visits at state D times the average time of a single visit in the deep well. The average number of visits in state D prior to absorption is $1/\Pr\{\tau_{D\to A} < \tau_{D\to W}\}$, as in a geometric distribution, and (5.10) follows. We conclude that

$$\mathbb{E}\tau_{D\to A} \sim \mathbb{E}\tau_{W\to A}; \tag{5.12}$$

i.e., the initial state (or location) of the particle has no (leading order) significance for the mean absorption time $\langle\tau_\delta\rangle$, which by (5.6) and (5.10) is

$$\langle\tau_\delta\rangle \sim \mathbb{E}\tau_{W\to A} \sim \frac{\mathbb{E}\tau_{W\to D}}{\Pr\{\tau_{D\to W} < \tau_{D\to A}\}}. \tag{5.13}$$

Substituting (5.2), (5.4)–(5.6) into (5.13) yields

$$\langle\tau_\delta\rangle = \frac{2\gamma \ln\dfrac{1}{\delta}}{\varepsilon\sqrt{H(x_W)}} \exp\left\{\frac{\phi_0 - \phi(x_W)}{\varepsilon}\right\}, \tag{5.14}$$

in agreement with (4.11).

6. Summary and discussion.

The narrow escape problem of a Brownian particle through a small absorbing window in an otherwise reflecting boundary was discussed in [8], [17], [18], and [19]. Here we solve the narrow escape problem for a Brownian particle in a force field. In cases where there is a deep potential well inside the domain, there are two time scales in the problem, the mean time to escape the well and the mean time to reach the small window. We give explicit asymptotic expressions for the mean escape time when the time scales are comparable and in the case where one is much longer than the other.

Matched asymptotics of two- and three-dimensional problems [22], [23], [24], [11] yield the leading term in the expansion of the principal eigenvalue in three dimensions and a full expansion in two dimensions. For the special case of the mixed Neumann problem with a small Dirichlet window in the boundary, the leading term obtained in [17], [18], [19] can be obtained by the application of the matched asymptotics expansion to this problem. In this paper we generalize the method of [17], [18], [19] to obtain the leading term for the corresponding boundary value problem for the Fokker–Planck operator, though matched asymptotics can be applied to this problem as well. The advantage of our method, as demonstrated in [17], is that it reveals the order of magnitude of the second term in three dimensions, while the matched asymptotics method does not indicate this in a simple way. In the particular case of a ball with a small Dirichlet cap, the application of the special functions method of Collins [2], [3] gave in [17] the unexpected estimate on the remainder term $O(\delta^2 \log\delta)$

to the expected leading term $O(\delta)$. Another advantage of the present method is the Helmholtz integral equation (3.11) for the flux and capacity of the small window. This equation is easier to solve numerically than the mixed Neumann–Dirichlet problem for a half space, as required in the boundary layer equation of the matched asymptotics expansion.

A SPATIO-TEMPORAL DESIGN PROBLEM FOR A DAMPED WAVE EQUATION[*]

FAUSTINO MAESTRE[†], ARNAUD MÜNCH[‡], and PABLO PEDREGAL[†]

Abstract. We analyze in this work a spatio-temporal optimal design problem governed by a linear damped one-dimensional wave equation. The problem consists of simultaneously seeking the spatio-temporal layout of two isotropic materials and the static position of the damping set in order to minimize a functional depending quadratically on the gradient of the state. The lack of classical solutions for this kind of nonlinear problem is well known. We examine a well-posed relaxation by using the representation of a two-dimensional divergence-free vector as a rotated gradient. We transform the original optimal design problem into a nonconvex vector variational problem. By means of gradient Young measures we compute an explicit form of the *"constrained quasi convexification"* of the cost density. Moreover, this quasi convexification is recovered by first order laminates which give the optimal distribution of materials and damping set at every point. Finally, we analyze the relaxed problem, and some numerical experiments are performed. The novelty here lies in the optimization with respect to two independent subdomains, and our contribution consists of understanding their mutual interaction.

1. Introduction—Problem statement.

Let us consider the following damped wave equation posed in $(0,T)\times\Omega$:

$$
(1.1)\quad \begin{cases} u_{tt}-\nabla_x([\alpha\mathcal{X}_{\omega_1}+\beta(1-\mathcal{X}_{\omega_1})]u_x)+d(x)\mathcal{X}_{\omega_2}u_t=0 & \text{in}\quad (0,T)\times\Omega,\\ u=0 & \text{on}\quad (0,T)\times\partial\Omega,\\ u(0,x)=u_0(x),\ u_t(0,x)=u_1(x) & \text{in}\quad \Omega, \end{cases}
$$

for any bounded interval Ω of $\mathbb{R}$ and any positive time T. $\mathcal{X}_{\omega_1}$ and $\mathcal{X}_{\omega_2}$ designate respectively the characteristic function of two subsets $\omega_1\subset\Omega\times(0,T)$ and $\omega_2\subset\Omega$, both of positive Lebesgue measure $|\omega_1|$ and $|\omega_2|$. We assume that $0<\alpha<\beta$ and that the damping potential $d\in L^\infty(\Omega;\mathbb{R}^+)$ is such that $d(x)\geq d>0$ for all $x\in\omega_2$. Finally, we assume that the initial data (u_0,u_1) are in $H_0^1(\Omega)\times L^2(\Omega)$ and are independent of ω_1,ω_2, and d. System (1.1) is then well posed, and there exists a unique weak solution such that $u\in C\left([0,T];H_0^1(\Omega)\right)\cap C^1\left([0,T];L^2(\Omega)\right)$ (see [16]).

As is well known, system (1.1) models the stabilization of an elastic string made of two materials α and β located on ω_1 and $((0,T)\times\Omega))\backslash\omega_1$, respectively, by an internal dissipative mechanism located on ω_2. The unknown $u(t,x)$ represents the transversal displacement of the string at the point x and at time t, while u_0 and u_1 designate the initial position and velocity, respectively.

Following similar works [9, 15], we address the very important question of determining the best space-time layout of materials α and β in $\Omega\times(0,T)$ and the best space distribution of damping material in order to minimize some cost depending on the square of the gradient of the underlying state u. Precisely, introducing the functions $a_\alpha, a_\beta \in L^\infty((0,T)\times\Omega;\mathbb{R}^\star_+)$ and

$$a(t,x,\mathcal{X}_{\omega_1}) = \mathcal{X}_{\omega_1} a_\alpha(t,x) + (1-\mathcal{X}_{\omega_1})a_\beta(t,x), \tag{1.2}$$

we consider the following nonlinear optimal shape design problem:

$$\text{(P)} \quad \inf_{\mathcal{X}_{\omega_1},\mathcal{X}_{\omega_2}} I(\mathcal{X}_{\omega_1},\mathcal{X}_{\omega_2}) = \int_0^T\int_\Omega (u_t^2 + a(t,x,\mathcal{X}_{\omega_1})|u_x|^2)dxdt \tag{1.3}$$

subject to

$$\begin{cases} u \text{ fulfills (1.1)}, \\ \mathcal{X}_{\omega_1} \in L^\infty(\Omega\times(0,T);\{0,1\}), \quad \mathcal{X}_{\omega_2} \in L^\infty(\Omega;\{0,1\}), \\ \displaystyle\int_\Omega \mathcal{X}_{\omega_1}(t,x)dx \le L_\alpha|\Omega| \quad \forall t\in(0,T), \;\; L_\alpha\in(0,1), \\ \displaystyle\int_\Omega \mathcal{X}_{\omega_2}(x)dx \le L_d|\Omega|, \quad L_d\in(0,1). \end{cases} \tag{1.4}$$

The constraint $(1.4)_3$ requires that for all $t\in(0,T)$ the volume fraction of the α-material be lower than L_α given in $(0,1)$. The constraint $(1.4)_4$ requires that the volume fraction of the damping material be lower than L_d given in $(0,1)$.

Optimal design problems in conductivity and elasticity have been extensively studied in the last decade from various perspectives (e.g., the homogenization approach [1, 24], shape derivative [6, 7], topological derivative [27], variational formulation [5, 26], simulation-oriented approaches [4, 12], etc). Under the hyperbolic laws, much less is known. A pioneer work in this direction is [18], where the author analyzes the hyperbolic G-closure for a similar optimal control problem (see also [17] for a general report on dynamic materials). On the other hand, an interesting analysis for optimal control problems under the wave equation in greater dimensions is described in [8], where the control is a time dependent coefficient. Let us also mention [3], where the authors examine time-harmonic solutions of the wave equation, prove a relaxation result for the corresponding design problem, and obtain existence of classical solutions for some particular cases. Finally, shape analysis for noncylindrical evolution problems is considered in [7] (and the references therein).

More recently, a one-dimensional (1-D) hyperbolic optimal control design problem with designs depending both on x and t has been addressed in [20]. This corresponds to the problem (P) with $\omega_2=\emptyset$ and a minimization with respect to ω_1 only. A full relaxation of the associated problem is given and numerically justified if the gap $\beta-\alpha>0$ is large enough. On the other hand, the pure damping case (corresponding to $\omega_1=\emptyset$ and a minimization with respect to ω_2 only) has been studied similarly in [13, 21, 22]. Once again, it appears that the well-posed character of the problem relies on the amplitude of the function d. In this work, we aim at mixing these two cases and minimize I with respect to ω_1 and ω_2 simultaneously. In this respect, we derive and analyze a well-posed relaxation of (P). The approach is based on an equivalent variational reformulation of the original problem as a nonconvex vector variational problem: following [2, 26], we transform our scalar problem with differential constraints into a vector variational problem with integral constraints (where the state equation is implicit in the new cost function). It is well known that the nonexistence of optimal solutions for vector variational problems is related to the lack of quasi convexity of the cost functional I (see [11]). Therefore, by using gradient Young measures as generalized solutions of variational problems, we compute an explicit relaxation of the original problem in the form of a relaxed (quasi-convexified) variational problem.

To the knowledge of the authors, this work is the first considering a bidesign problem. Our contribution consists, first, of adapting relaxation techniques in this case, and then, of studying the interaction between the two optimal designs ω_1 and ω_2.

The rest of the paper is organized as follows. In section 2, we describe in detail the equivalent variational reformulation (denoted by (VP)) as well as a general relaxation result when integrands are not continuous and may take on infinite values abruptly. Section 3 presents the computation of the constrained quasi convexification of the underlying integrand of (VP). The first part is concerned with the computation of a lower bound—the constrained polyconvexification—by using in a fundamental way the weak continuity of the determinant. The second part is concerned with the search for laminates furnishing the precise value of the lower bound in an attempt to show equality of the three convex hulls (poly-, quasi-, and rank one convex hulls). This provides the well-posed relaxation (RP) stated in Theorem 3.4. In addition, the optimal Young measure permits us to describe precisely the optimal microstructure (see Theorem 3.5). Section 4 is devoted to the analysis of the relaxed formulation. In section 5, we present some numerical experiments which justify the introduction of the relaxed formulation (RP) and present a simple penalization technique to obtain some elements of a minimizing sequence for (P) from the relaxed optimal solution of (RP).

2. Variational reformulation and relaxation.

In order to apply suitable results of calculus of variations [11, 25], we first reformulate the problem (P) into a classical vector variational one. To this end, following [2, 19, 26], we use a characterization of divergence-free vector fields. Precisely, since the subset ω_2 is time independent, the state equation of system (1.1) can be written as

$$div(u_t + d(x)\mathcal{X}_{\omega_2}u,\ -[\alpha\mathcal{X}_{\omega_1} + \beta(1-\mathcal{X}_{\omega_1})]u_x) = 0, \tag{2.1}$$

where the operator div is defined as $div = (\partial_t, \nabla_x)$. Then, under the hypothesis of simple-connectedness of Ω and from the characterization of the 2-D divergence-free vector fields (see, for instance, [14], Chapter I), there exists a potential $v \in H^1(\Omega \times (0,T))$ such that the above formula is equivalent to the pointwise constraint

$$\begin{pmatrix} u_t \\ -(\alpha\mathcal{X}_{\omega_1} + \beta(1-\mathcal{X}_{\omega_1}))u_x \end{pmatrix} - R\nabla v = -d(x)\mathcal{X}_{\omega_2}\bar{u}, \tag{2.2}$$

where

$$\bar{u} = \begin{pmatrix} u \\ 0 \end{pmatrix}, \quad \nabla v = \begin{pmatrix} v_t \\ v_x \end{pmatrix}, \quad R = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}. \tag{2.3}$$

R is the counterclockwise $\pi/2$-rotation in the (x,t)-plane. We then introduce the vector field $U = (u,v) \in (H^1(\Omega \times (0,T)))^2$ and the manifolds $\Lambda_{\gamma,\lambda}$ as follows:

$$\Lambda_{\gamma,\lambda} = \{A \in M^{2\times 2} : M_{-\gamma}A^{(1)} - RA^{(2)} = \lambda e_1\}, \quad \gamma = \alpha, \beta, \text{ and } \lambda \in \mathbb{R},$$

where $A^{(i)}$, $i = 1,2$, stands for the ith row of the matrix and

$$M_{-\gamma} = \begin{pmatrix} 1 & 0 \\ 0 & -\gamma \end{pmatrix}, \quad e_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix}. \tag{2.4}$$

It is clear that we can identify the design variable $(\mathcal{X}_{\omega_1}, \mathcal{X}_{\omega_2})$ with the vector field $U = (u,v)$; conversely, a pair $U = (u,v)$ which verifies (2.2) determines characteristic functions $(\mathcal{X}_{\omega_1}, \mathcal{X}_{\omega_2})$, so that we can consider the new design variables $U = (u,v)$, where $U : \mathbb{R}^2 \to \mathbb{R}^2$ and $\nabla U(t,x) \in \mathbb{R}^{2\times 2}$. Then, for any 2×2 matrix $A = (a_{ij})_{(1\le i,j\le 2)}$, we consider the following three functions:

$$W(t,x,U,A) = \begin{cases} a_{11}^2 + a_\alpha(t,x)a_{12}^2 & \text{if } A \in \Lambda_{\alpha,0} \cup \Lambda_{\alpha,-d(x)U^{(1)}}, \\ a_{11}^2 + a_\beta(t,x)a_{12}^2 & \text{if } A \in (\Lambda_{\beta,0} \cup \Lambda_{\beta,-d(x)U^{(1)}}) \\ & \qquad \setminus(\Lambda_{\alpha,0} \cup \Lambda_{\alpha,-d(x)U^{(1)}}), \\ +\infty & \text{else,} \end{cases}$$

$$V_\alpha(t,x,U,A) = \begin{cases} 1 & \text{if } A \in \Lambda_{\alpha,0} \cup \Lambda_{\alpha,-d(x)U^{(1)}}, \\ 0 & \text{if } A \in (\Lambda_{\beta,0} \cup \Lambda_{\beta,-d(x)U^{(1)}}) \setminus (\Lambda_{\alpha,0} \cup \Lambda_{\alpha,-d(x)U^{(1)}}), \\ +\infty & \text{else,} \end{cases}$$

$$V_d(t,x,U,A) = \begin{cases} 1 & \text{if } A \in (\Lambda_{\beta,-d(x)U^{(1)}} \cup \Lambda_{\alpha,-d(x)U^{(1)}}), \\ 0 & \text{if } A \in (\Lambda_{\beta,0} \cup \Lambda_{\alpha,0}) \setminus (\Lambda_{\beta,-d(x)U^{(1)}} \cup \Lambda_{\alpha,-d(x)U^{(1)}}), \\ +\infty & \text{else.} \end{cases}$$

Then, noting that

$$\{x \in \Omega, \mathcal{X}_{\omega_1}(x,t) = 1\} = \{x \in \Omega, V_\alpha(t,x,U,\nabla U) = 1\} \quad \forall t \in (0,T) \tag{2.5}$$

and

$$\{x \in \Omega, \mathcal{X}_{\omega_2}(x) = 1\} = \{x \in \Omega, V_d(t,x,U,\nabla U) = 1 \quad \forall t \in (0,T)\}, \tag{2.6}$$

the optimization problem (P) is equivalent to the following vector variational problem:

$$\text{(VP)} \quad m = \inf_U \int_0^T \int_\Omega W(t,x,U(t,x),\nabla U(t,x))dxdt \tag{2.7}$$

subject to

(2.8)
$$\begin{cases} U = (U^{(1)}, U^{(2)}) \in H^1((0,T)\times\Omega)^2, \\ U^{(1)}(0,x) = u_0(x), \ U_t^{(1)}(0,x) = u_1(x) \quad \text{in} \quad \Omega, \\ U^{(1)} = 0 \quad \text{in} \quad (0,T)\times\partial\Omega, \\ \displaystyle\int_\Omega V_\alpha(t,x,U(t,x),\nabla U(t,x))dx \le L_\alpha|\Omega| \quad \forall t \in [0,T], \\ \displaystyle\int_\Omega V_d(t,x,U(t,x),\nabla U(t,x)) \times V_d(0,x,U(0,x),\nabla U(0,x))dx \le L_d|\Omega| \quad \forall t \in [0,T]. \end{cases}$$

Therefore, this procedure transforms the scalar dynamical problem (P), with differentiable, integrable, and pointwise constraints, into a nonconvex vector variational problem (VP) with only pointwise and integral constraints.

We are now going to analyze the nonconvex vector problem (VP) by seeking its relaxation. We use Young measures (see [25]) as a main tool in the computation of the suitable density for the relaxed problem. Let us recall the following definition.

Definition 2.1. *The constrained quasi convexification of the functional W is defined as*

$$CQW(t,x,U,A,s,r) = \inf_{\nu} \left\{ \int_{M^{2\times 2}} W(t,x,U,A) d\nu(A) : \nu \in \mathcal{A} \right\}, \tag{2.9}$$

where

$$\begin{aligned} \mathcal{A} = \Big\{ &\nu : \nu \textit{ is a homogeneous } H^1\textit{-Young measure}, \\ &F = \int_{M^{2\times 2}} A d\nu(A), \int_{M^{2\times 2}} V_\alpha(t,x,U,A) d\nu(A) = s, \\ &\int_{M^{2\times 2}} V_d(t,x,U,A) d\nu(A) = r \quad \forall t \in [0,T] \Big\}. \end{aligned} \tag{2.10}$$

We then introduce the following minimization problem:

$$\text{(RP)} \quad \overline{m} = \inf_{(U,s,r)} \int_0^T \int_\Omega CQW(t,x,U(t,x),\nabla U(t,x),s(t,x),r(x)) dx dt \tag{2.11}$$

subject to

$$\begin{cases} U = (U^{(1)}, U^{(2)}) \in H^1((0,T)\times\Omega)^2, \\ U^{(1)}(0,x) = u_0(x), \ U_t^{(1)}(0,x) = u_1(x) \quad \text{in} \quad \Omega, \\ U^{(1)} = 0, \quad \text{in} \quad (0,T)\times\partial\Omega, \\ 0 \le s(t,x) \le 1, \quad \displaystyle\int_\Omega s(t,x) dx \le L_\alpha |\Omega| \quad \forall t \in [0,T], \\ 0 \le r(x) \le 1, \quad \displaystyle\int_\Omega r(x) dx \le L_d |\Omega|. \end{cases} \tag{2.12}$$

The functions s and r denote the pointwise volume fraction associated with the α-material and the damping set, respectively.

Then, the following relaxation result (initially obtained in the elliptic case in [2, 26]) can be proved: (RP) is a full relaxation of (VP) in the sense of the following theorem.

Theorem 2.2. *Assume that the initial data of system* (1.1) *have the regularity*

$$(u_0, u_1) \in (H^2(\Omega) \cap H_0^1(\Omega)) \times H_0^1(\Omega). \tag{2.13}$$

Then, problem (RP) *is well posed and the following equality holds:*

$$m = \overline{m} \quad (\textit{i.e.}, \inf(\text{VP}) = \min(\text{RP})). \tag{2.14}$$

Moreover, the minimum (U,s,r) codifies (in the sense of Young measures) the optimal microstructures of the original optimal design problem.

Remark 2.3. In order to represent the limit of the cost function I associated with a minimizing sequence, say $\{\mathcal{X}_{\omega_1,j}, \mathcal{X}_{\omega_2,j}\}_j$, through its associated Young measure, we need equi-integrability for the sequence $|u_{t,j}|^2 + a(t,x,\mathcal{X}_{\omega_1,j})|\nabla u_j|^2$ (see [25]). Equation (2.13) is a sufficient condition to get this equi-integrability. We refer to [22, 23] for the details.

Therefore, Theorem 2.2 reduces the determination of a relaxed formulation to the computation of the constrained quasi convexification CQW associated with W.

3. Constrained quasi convexification.

In this section, we solve the optimization problem (2.9), leading for all (U,F,s,r) to the value of $CQW(t,x,U,F,s,r)$. The main difficulty is that we do not know explicitly the set of the admissible measures $\mathcal{A}$ defined in (2.10). We then follow the same strategy as in [26]. Consider two classes of a family of probability measures $\mathcal{A}_\star, \mathcal{A}^\star$ such that

$$\mathcal{A}_\star \subset \mathcal{A} \subset \mathcal{A}^\star.$$

We first calculate the minimum over the greater class of probability measures $\mathcal{A}^\star$, and then we check that the optimal value is attained by at least one measure over the narrower class $\mathcal{A}_\star$. This fact tells us that the optimal value so achieved is the same in $\mathcal{A}$, and hence we will have in fact computed the exact value $CQW(t,x,U,F,s,r)$.

Following [26], we choose $\mathcal{A}^\star$ as the set of polyconvex measures, which are not necessarily gradient Young measures, and therefore obtain a lower bound (the constrained polyconvexification). The main property of these measures is that they commute with the determinant. This constraint can be imposed in a more-or-less manageable way. We also choose $\mathcal{A}_*$ as the class of *laminates* which is a subclass of the gradient Young measures. By working with this class, we would get an upper bound (the constrained rank one convexification).

In what follows, in order to simplify the expression, we note $\Lambda_{\gamma,1}$ for $\Lambda_{\gamma,-d(x)U^{(1)}}$.

3.1. Lower bound: Polyconvexification.

We compute the constrained polyconvexification defined as follows.

Definition 3.1. *The constrained polyconvexification CPW of the functional W is given by the following minimization problem:*

$$CPW(U,F,s,r) = \min_\nu \left\{ \int_{M^{2\times 2}} W(U,A)d\nu(A) : \nu \in \mathcal{A}^\star \right\}, \tag{3.1}$$

where

$$\begin{aligned} \mathcal{A}^\star(F,s,r) = \Big\{ \nu :& \nu \textit{ is a homogeneous Young measure,} \\ & \nu \textit{ commutes with the determinant,} \\ & F = \int_{M^{2\times 2}} A d\nu(A), \\ & s = \int_{M^{2\times 2}} V_\alpha(U,A)d\nu(A), \quad r = \int_{M^{2\times 2}} V_d(U,A)d\nu(A) \Big\}. \end{aligned} \tag{3.2}$$

In this respect, we exploit that ν belongs to the class $\mathcal{A}^\star$. First, from the volume constraints $(3.2)_4$, the measure ν has the following decomposition:

$$\nu = s(r\nu_{\alpha,1} + (1-r)\nu_{\alpha,0}) + (1-s)(r\nu_{\beta,1} + (1-r)\nu_{\beta,0}) \tag{3.3}$$

with $\operatorname{supp}(\nu_{\gamma,\lambda}) \subset \Lambda_{\gamma,\lambda}, \gamma = \alpha, \beta,\ \lambda = 0, 1$. Therefore, if we introduce

$$F^{\gamma,\lambda} = \int_{\Lambda_{\gamma,\lambda}} A d\nu_{\gamma,\lambda}, \quad \gamma = \alpha, \beta,\ \lambda = 0, 1,$$

then the first moment constraint $(3.2)_3$ leads to the following expression:

$$F = s(rF^{\alpha,1} + (1-r)F^{\alpha,0}) + (1-s)(rF^{\beta,1} + (1-r)F^{\beta,0}). \tag{3.4}$$

Now, from the property $F^{\gamma,\lambda} \in \Lambda_{\gamma,\lambda}$, we have, for $\gamma = \alpha, \beta$,

$$\begin{cases} F^{\gamma,0}_{11} + F^{\gamma,0}_{22} = 0, \\ -F^{\gamma,0}_{21} - \gamma F^{\gamma,0}_{12} = 0, \end{cases} \quad \text{and} \quad \begin{cases} F^{\gamma,1}_{11} + F^{\gamma,1}_{22} = \lambda, \\ -F^{\gamma,1}_{21} - \gamma F^{\gamma,1}_{12} = 0. \end{cases} \tag{3.5}$$

Substituting (3.5) into the system (3.4), we obtain a noncompatible system on $F^{\gamma,\lambda}$ unless the condition

$$F_{11} + F_{22} = r\lambda \tag{3.6}$$

holds. Assuming henceforth this compatibility condition, (3.4)–(3.6) lead to

$$\begin{cases} F^{\alpha,1}_{11} = c_1, \quad F^{\alpha,0}_{11} = c_2, \quad F^{\beta,0}_{11} = c_3, \quad F^{\alpha,1}_{12} = c_4, \quad F^{\beta,1}_{12} = c_5, \\ F^{\beta,1}_{11} = \dfrac{F_{11} - rsc_1 - s(1-r)c_2 - (1-s)(1-r)c_3}{(1-s)r}, \\ F^{\alpha,0}_{12} = \dfrac{F_{21} + \beta F_{12} - (\beta-\alpha)rsc_4}{(1-r)s(\beta-\alpha)} \equiv f_4(c_4), \\ F^{\beta,0}_{12} = \dfrac{-F_{21} - \alpha F_{12} - (\beta-\alpha)r(1-s)c_5}{(1-r)(1-s)(\beta-\alpha)} \equiv f_5(c_5), \end{cases} \tag{3.7}$$

where $c_i \in \mathbb{R}$, $i = 1, \ldots, 5$, are parameters.

On the other hand, if we take a matrix $A = (a_{ij})_{(1 \le i,j \le 2)} \in \Lambda_{\gamma,\lambda}$ with $\gamma = \alpha, \beta$ and $\lambda = 0, 1$, then the equality

$$\det A = -A^{(1)} M_{-\gamma} A^{(1)} - \lambda A^{(1)} e_1$$

and the constraint on the commutation yield

$$\begin{aligned} \det F &= \int_{M^{2\times 2}} \det A d\nu(A) \\ &= -S_1 + \lambda r(sF^{\alpha,1}_{11} + (1-s)F^{\beta,1}_{11}) + \alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) \\ &\qquad + \beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0}), \end{aligned} \tag{3.8}$$

where

$$S_{\gamma,\lambda} = \int_{\Lambda_{\gamma,\lambda}} a^2_{12} d\nu_{\gamma,\lambda}(A), \quad \gamma = \alpha, \beta, \lambda = 1, 0, \quad S_1 = \int_{M^{2\times 2}} a^2_{11} d\nu(A). \tag{3.9}$$

Similarly, the cost function can be written as

$$\int_{M^{2\times 2}} W(U, A) d\nu(A) = S_1 + a_\alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) + a_\beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0}). \tag{3.10}$$

Finally, using Jensen's inequality, we obtain

$$S_{\gamma,\lambda} = \int_{\Lambda_{\gamma,\lambda}} a_{12}^2 d\nu_{\gamma,\lambda} \geq \left| \int_{\Lambda_{\gamma,\lambda}} a_{12} d\nu_{\gamma,\lambda} \right|^2 = |F_{12}^{\gamma,\lambda}|^2 \tag{3.11}$$

and

$$S_1 \geq \left| \int_{M^{2\times 2}} a_{11} d\nu(A) \right|^2 = |F_{11}|^2.$$

As a conclusion, from (3.8), (3.10), (3.11), the polyconvexification problem (3.1) is reduced to the following mathematical programming problem:

$$\text{(MPP)} \quad \min_{(S_1, S_{\gamma,\lambda}, c_i)} \quad S_1 + a_\alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) + a_\beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0})$$

subject to

$$\begin{cases} \det F = \lambda r(sF_{11}^{\alpha,1} + (1-s)F_{11}^{\beta,1}) - S_1 \\ \qquad\qquad + \alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) + \beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0}), \\ S_{\gamma,\lambda} \geq (F_{12}^{\gamma,\lambda})^2, \quad \gamma = \alpha, \beta, \quad \lambda = 0, 1; \qquad S_1 \geq (F_{11})^2. \end{cases}$$

The resolution of this problem leads to the following expression of CPW.

Proposition 3.2. *The polyconvexification* (3.1) *is explicitly given by*

$$CPW(U, F, s, r) = \begin{cases} |F_{11}|^2 + \dfrac{a_\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 \\ \quad + \dfrac{a_\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21}|^2 & \text{if } \psi(F, s, r) = 0, \\ +\infty & \text{else,} \end{cases} \tag{3.12}$$

where

$$\begin{aligned} \psi(F, s, r) = -\det F - |F_{11}|^2 + \lambda r F_{11} + \frac{\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 \\ + \frac{\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21}|^2. \end{aligned} \tag{3.13}$$

Proof. From (3.7), we obtain that

$$r(sF_{11}^{\alpha,1} + (1-s)F_{11}^{\beta,1}) = F_{11} - s(1-r)c_2 - (1-s)(1-r)c_3. \tag{3.14}$$

Consequently, the problem is

$$\min_{(S_1, S_{\gamma,\lambda}, c_i)} \quad S_1 + a_\alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) + a_\beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0})$$

subject to

$$\begin{cases} \det F = \lambda\big(F_{11} - s(1-r)c_2 - (1-s)(1-r)c_3\big) - S_1 \\ \qquad\qquad + \alpha s(rS_{\alpha,1} + (1-r)S_{\alpha,0}) + \beta(1-s)(rS_{\beta,1} + (1-r)S_{\beta,0}), \\ S_{\alpha,1} \geq c_4^2, \quad S_{\beta,1} \geq c_5^2, \quad S_{\alpha,0} \geq f_4^2(c_4), \quad S_{\beta,0} \geq f_5^2(c_5), \quad S_1 \geq (F_{11})^2. \end{cases} \tag{3.15}$$

Since a_α and a_β are positive, the minimum is obtained when the equalities hold in $(3.15)_2$ with a suitable choice of the constant c_2 and c_3 in $(3.15)_1$. Therefore, the minimum is

$$|F_{11}^2| + a_\alpha s(rc_4^2 + (1-r)f_4^2(c_4)) + a_\beta(1-s)(rc_5^2 + (1-r)f_5^2(c_5)). \tag{3.16}$$

The minimization of $(rc_4^2 + (1-r)f_4^2(c_4))$ with respect to c_4 leads to

$$c_4 = \frac{1}{s(\beta-\alpha)}(\beta F_{12} + F_{21}) = F_{12}^{\alpha,1} \tag{3.17}$$

and then

$$(rc_4^2 + (1-r)f_4^2(c_4)) = \left(\frac{1}{s(\beta-\alpha)}(\beta F_{12} + F_{21})\right)^2 = c_4^2 = S_{\alpha,1}. \tag{3.18}$$

Similarly, we obtain

$$c_5 = -\frac{1}{(1-s)(\beta-\alpha)}(\alpha F_{12} + F_{21}) = F_{12}^{\beta,1}. \tag{3.19}$$

Then, writing $\det F = F_{11}F_{22} - F_{12}F_{21} = -F_{11}^2 + \lambda r F_{11} - F_{12}F_{21}$ from (3.6), the relation $(3.15)_1$ becomes

$$\begin{aligned}\lambda r F_{11} - F_{12}F_{21} = \lambda\Bigg(F_{11} - s(1-r)c_2 - (1-s)(1-r)c_3\Bigg) + \frac{\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 \\ + \frac{\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21}|^2\end{aligned}$$

and implies the equality $\lambda(1-r)F_{11} = \lambda(1-r)(sc_2 + (1-s)c_3)$, and then $(sc_2 + (1-s)c_3) = F_{11}$. This leads to the expression of CPW. Moreover, note that since $c_2 = F_{11}^{\alpha,0}$ and $c_3 = F_{11}^{\beta,0}$, the relation $F_{11} = sF_{11}^{\alpha,0} + (1-s)F_{11}^{\beta,0}$ implies

$$F_{11}^{\alpha,0} = F_{11}^{\beta,0} = F_{11}, \tag{3.20}$$

and then, from $(3.15)_2$,

$$F_{11}^{\alpha,1} = F_{11}^{\beta,1} = F_{11}. \qquad \square \tag{3.21}$$

Remark 3.3. From (3.6), $-\det F - |F_{11}|^2 + \lambda r F_{11}$ is simply $F_{12}F_{21}$ and

$$\begin{aligned}\psi(F,s,r) &= F_{12}F_{21} + \frac{\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 + \frac{\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21}|^2 \\ &= \frac{1}{s(1-s)(\beta-\alpha)^2}\Big[F_{21} + F_{12}(\alpha s + \beta(1-s))\Big]\Big[\alpha\beta F_{12} + F_{21}(\alpha(1-s) + \beta s)\Big]\end{aligned} \tag{3.22}$$

does not depend explicitly on r.

The polyconvexification CPW gives a lower bound of the constrained quasi convexification. In the next section, we prove that this bound is in fact attained.

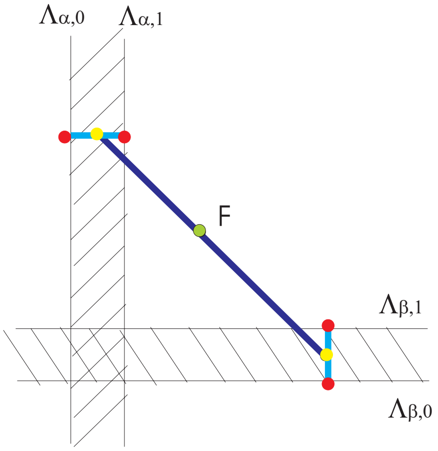

Fig. 3.1. *Geometrical decomposition of F.*

3.2. Upper bound: Searching laminates. In order to prove that the lower bound given by the polyconvexification is in fact the optimal value, we now search a measure ν in the class $\mathcal{A}_\star$ of laminates which recover it. Precisely, we exhibit a ν with the decomposition (3.3) and first moment F which satisfies a rank one condition.

First, from the optimality conditions (3.5), (3.17), (3.21) and the strict convexity of the square function, we deduce that

$$\nu^{(11)} = \delta_{F_{11}} \quad \text{and} \quad \nu^{(12)}_{\gamma,\lambda} = \delta_{F_{12}^{\gamma,\lambda}},$$

and therefore

$$\nu_{\gamma,\lambda} = \delta_{F^{\gamma,\lambda}} \qquad \text{with } \gamma = \alpha, \beta,\ \lambda = 0, 1,$$

where the matrices $F^{\gamma,\lambda}$ are

$$F^{\gamma,1} = \begin{pmatrix} F_{11} & y_\gamma \\ -\gamma y_\gamma & -F_{11} - \lambda \end{pmatrix}, \qquad F^{\gamma,0} = \begin{pmatrix} F_{11} & y_\gamma \\ -\gamma y_\gamma & -F_{11} \end{pmatrix}$$

with $\gamma = \alpha, \beta$ and

$$y_\alpha \equiv \frac{1}{s(\beta - \alpha)}(\beta F_{12} + F_{21}), \qquad y_\beta \equiv \frac{-1}{(1-s)(\beta - \alpha)}(\alpha F_{12} + F_{21}). \tag{3.23}$$

The unique possible measure ν which admits the decomposition (3.3) is then (geometrically; see Figure 3.1)

$$\nu = s(r\delta_{F^{\alpha,1}} + (1-r)\delta_{F^{\alpha,0}}) + (1-s)(r\delta_{F^{\beta,1}} + (1-r)\delta_{F^{\beta,0}}). \tag{3.24}$$

Let us now check that ν is actually a laminate; i.e., we check that there is a rank one connection between the support of deltas. On the one hand, for $\gamma = \alpha, \beta$, the relation

$$F^{\gamma,1} - F^{\gamma,0} = \begin{pmatrix} 0 & 0 \\ 0 & -\lambda \end{pmatrix} = b \otimes e_2 \ \text{ with } \ b = (0, -\lambda), e_2 = (0, 1)$$

indicates that the direction of lamination of the set of damping has to be with normal e_2. On the other hand, the relation

$$\begin{aligned}(rF^{\alpha,1}+(1-r)F^{\alpha,0})-(rF^{\beta,1}+(1-r)F^{\beta,0}) &= \begin{pmatrix} 0 & y_\alpha - y_\beta \\ \beta y_\beta - \alpha y_\alpha & 0 \end{pmatrix} \\ &= (0, y_\alpha - y_\beta)\otimes e_1 + (\alpha y_\alpha - \beta y_\beta, 0)\otimes e_2 \end{aligned} \tag{3.25}$$

implies that ν is a laminate if and only if

$$\det\begin{pmatrix} 0 & y_\alpha - y_\beta \\ \beta y_\beta - \alpha y_\alpha & 0 \end{pmatrix} = 0 \quad \Longleftrightarrow \quad (y_\alpha - y_\beta)(\beta y_\beta - \alpha y_\alpha) = 0.$$

Furthermore, from (3.22) and (3.23), we obtain that

$$\psi(F,s,r) = s(1-s)(\alpha y_\alpha - \beta y_\beta)(y_\alpha - y_\beta). \tag{3.26}$$

Consequently, the above rank one condition is equivalent to $\psi(F,s,r)=0$, which is precisely the necessary condition for the polyconvexification to be finite (see Proposition 3.2). We then conclude that ν is a first order laminate, i.e., belongs to the class $\mathcal{A}_\star$. Then, we remark that the conditions $y_\alpha - y_\beta = 0$ and $\alpha y_\alpha - \beta y_\beta = 0$ are not compatible because they imply $y_\alpha = y_\beta = 0$ and then $F_{12} = F_{21} = 0$. We conclude that the direction of lamination of the α or β material is $e_2 = (0,1)$ if $y_\alpha - y_\beta = 0$ or $e_1 = (1,0)$ if $\beta y_\beta - \alpha y_\alpha = 0$.

In conclusion, for the measure (3.24), the quasi convexification CQW defined by (2.9) coincides with CPW. Moreover, this provides an explicit expression of the full relaxation problem (2.11) stated in the following paragraph.

3.3. Well-posed full relaxation (RP). From Proposition 3.2 and by setting $\lambda = -d(x)U^{(1)}(t,x) = -d(x)u(t,x)$ and $F = \nabla U$ in (3.6), we obtain that the optimization problem

$$\text{(RP)} \quad \min_{U,s,r} \ \hat{I}\ (U) = \int_0^T \int_\Omega CQW(t,x,U(t,x),\nabla U(t,x),s(t,x),r(x))\,dxdt \tag{3.27}$$

subject to

$$\begin{cases} U=(u,v)\in (H^1([0,T]\times\Omega))^2, \quad \psi(t,x,\nabla U(t,x),s(t,x),r(x))=0, \\ u_t + v_x = d(x)r(x)u(t,x) \quad \text{in} \quad \Omega\times(0,T), \\ U^{(1)}(0,x)=u_0(x),\ U_t^{(1)}(0,x)=u_1(x) \quad \text{in} \quad \Omega, \\ U^{(1)}=0 \quad \text{in} \quad \partial\Omega\times[0,T], \\ 0\le s(t,x)\le 1, \quad \displaystyle\int_\Omega s(t,x)\,dx \le L_\alpha|\Omega| \quad \forall t\in[0,T], \\ 0\le r(x)\le 1, \quad \displaystyle\int_\Omega r(x)\,dx \le L_d|\Omega|, \end{cases}$$

where

(3.28)

$$CQW(U,F,s,r) = |F_{11}|^2 + \frac{a_\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 + \frac{a_\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21})|^2$$

and

$$\psi(F,s,r) = -\det F - |F_{11}|^2 + \lambda r F_{11} + \frac{\alpha}{s(\beta-\alpha)^2}|\beta F_{12} + F_{21}|^2 + \frac{\beta}{(1-s)(\beta-\alpha)^2}|\alpha F_{12} + F_{21}|^2 \tag{3.29}$$

for any

$$F = \begin{pmatrix} F_{11} & F_{12} \\ F_{21} & F_{22} \end{pmatrix}, \quad s, r \in \mathbb{R},$$

is a full well-posed relaxation of (VP) in the following sense.

THEOREM 3.4. *The variational problem* (RP) *is a relaxation of the initial optimization problem* (VP) *in the sense that*

(a) *the infima of both problems coincide;*

(b) *there are optimal solutions for the relaxed problem;*

(c) *these solutions codify (in the sense of the Young measures) the optimal microstructures of the original optimal design problem (see Theorem* 3.5*).*

Moreover, we can compute explicitly optimal microstructures, as follows.

THEOREM 3.5. *Optimal Young measures leading to the relaxed formulation are always first order laminates, which can be given in a completely explicit form:*

- *for the damping case the optimal microstructures are*

  $$r(x)\delta_1 + (1 - r(x))\delta_0 \tag{3.30}$$

  with normal direction of lamination $e_2 = (0,1)$*;*
- *for the material case, the optimal microstructures are always*

  $$s(x,t)\delta_\alpha + (1 - s(x,t))\delta_\beta \tag{3.31}$$

  with normal direction of lamination $e_2 = (0,1)$ *(if* $y_\alpha - y_\beta = 0$*) or* $e_1 = (1,0)$ *(if* $\alpha y_\alpha - \beta y_\beta = 0$*), depending on each point.*

Remark 3.6.

- The direction of lamination of the set of damping equal to $e_2 = (0,1)$ is in full agreement with the time independence of the subset ω_2, support of the dissipative term.
- It is interesting to note the influence of the damping term $\mathcal{X}_{\omega_2} d(x) u_t$ on the order of the laminates associated with the optimal Young measure. Without this damping term (i.e., when $\omega_2 = \emptyset$), the analysis of the relaxation of (P) (see [20]) reveals that the constrained quasi convexification is recovered by either first- or second order laminates, obtained when $\psi(\nabla U, s) \le 0$ and $\psi(\nabla U, s) > 0$, respectively. Here, even for arbitrarily small positive value of $||d||_{L^\infty(\Omega)}$ or $|\omega_2|$, the optimal laminates are always of first order, obtained on the set $\psi(\nabla U, s) = 0$. This clearly highlights the smoother effect of this term.

4. Interpretation of the relaxed problem (RP) in terms of u.

The quasiconvexified density depends on the gradient of U, verifies pointwise constraints, and may take the value $+\infty$ abruptly. For these reasons, the numerical approximation of the problem (RP) is not standard and is a priori tricky. In this section, taking advantage of the compatibility conditions, we analyze more deeply the relaxed formulation (RP) and eliminate the auxiliary variable $v = U^{(2)}$ introduced in section 2.

From the relation (3.26), the set $\{F; \psi(F,s)=0\}$ is decomposed into two disjoint sets, $\{F; y_\alpha - y_\beta = 0\}$ and $\{F; \alpha y_\alpha - \beta y_\beta = 0\}$. Then, noticing that

$$\begin{cases} y_\alpha - y_\beta = 0 \iff F_{21} + F_{12}(\alpha s + \beta(1-s)) = 0, \\ \alpha y_\alpha - \beta y_\beta = 0 \iff F_{21} + F_{12}\dfrac{1}{\alpha^{-1}s + \beta^{-1}(1-s)} = 0, \end{cases} \tag{4.1}$$

we may eliminate the variable F_{21} (i.e., v_t) and write the quasi-convexified in terms of F_{11} and F_{12} only, as follows:

$$CQW(U,F,s,r) = \begin{cases} |F_{11}|^2 + (a_\alpha s + a_\beta(1-s))|F_{12}^2| & \text{if } y_\alpha - y_\beta = 0, \\ |F_{11}|^2 + \frac{a_\alpha \beta^2 s + a_\beta \alpha^2(1-s)}{(\alpha(1-s)+\beta s)^2}|F_{12}^2| & \text{if } \alpha y_\alpha - \beta y_\beta = 0, \\ +\infty & \text{else.} \end{cases} \tag{4.2}$$

We can now invoke the following lemma (we refer to [12] for the proof).

Lemma 4.1. *For all $s \in (0,1)$ and $0 < \alpha < \beta$, we have*

$$\begin{aligned} &\frac{a_\beta}{a_\alpha} \le \frac{2\beta}{\alpha+\beta} \implies a_\alpha s + a_\beta(1-s) \le \frac{a_\alpha \beta^2 s + a_\beta \alpha^2(1-s)}{(\alpha(1-s)+\beta s)^2}, \\ &\frac{a_\beta}{a_\alpha} \ge \frac{\alpha+\beta}{2\alpha} \implies a_\alpha s + a_\beta(1-s) \ge \frac{a_\alpha \beta^2 s + a_\beta \alpha^2(1-s)}{(\alpha(1-s)+\beta s)^2}. \end{aligned} \tag{4.3}$$

We are thus led to introducing the following problem:

$$(\widetilde{\mathrm{RP}}) : \inf_{s,r} \tilde{I}(s,r) = \int_0^T \int_\Omega \Big(u_t(t,x)^2 + G(s) u_x(t,x)^2 \Big) dxdt \tag{4.4}$$

subject to

$$\begin{cases} u_{tt} - \nabla_x(H(s)u_x) + d(x)r(x)u_t = 0 & \text{in} \quad (0,T)\times\Omega, \\ u = 0 & \text{on} \quad (0,T)\times\partial\Omega, \\ u(0,x) = u_0(x),\ u_t(0,x) = u_1(x) & \text{in} \quad \Omega, \\ 0 \le s(t,x) \le 1, \quad \int_\Omega s(t,x)\,dx \le L_\alpha|\Omega| & \text{in} \quad [0,T]\times\Omega, \\ 0 \le r(x) \le 1, \quad \int_\Omega r(x)\,dx \le L_d|\Omega| & \text{in} \quad \Omega, \end{cases} \tag{4.5}$$

where

$$G(s) = a_\alpha s + a_\beta(1-s), \quad H(s) = \alpha s + \beta(1-s) \quad \text{if} \quad \frac{a_\beta}{a_\alpha} \le \frac{2\beta}{\alpha+\beta}, \tag{4.6}$$

and

$$G(s) = \frac{a_\alpha \beta^2 s + a_\beta \alpha^2(1-s)}{(\alpha(1-s)+\beta s)^2}, \quad H(s) = \frac{1}{\alpha^{-1}s + \beta^{-1}(1-s)} \quad \text{if} \quad \frac{a_\beta}{a_\alpha} \ge \frac{\alpha+\beta}{2\alpha}. \tag{4.7}$$

We assume henceforth that the positive functions a_α and a_β fulfill, for all $x \in \Omega$, either the property $a_\beta/a_\alpha \le 2\beta/(\alpha+\beta)$ or $a_\beta/a_\alpha \ge (\alpha+\beta)/2\alpha$.

Problem $(\widetilde{\mathrm{RP}})$ with (4.6) (resp., (4.7)) is obtained from (RP) assuming that CQW is given by $(4.2)_1$ (resp., $(4.2)_2$), then putting $F = \nabla U$ and $\lambda = -d(x)u(t,x)$, and finally by eliminating the auxiliary variable v. Note that in the first case, H is the *arithmetic* mean of (α, β), while in the second case, H is the *harmonic* mean.

Moreover, one cannot affirm, a priori, that problem $(\widetilde{\mathrm{RP}})$ is equivalent to (RP) because the pair $U = (u, v)$ which solves (RP) does not necessarily fulfill for all $(t,x) \in (0,T) \times \Omega$ the relation $v_t + u_x(\alpha s + \beta(1-s)) = 0$ (i.e., $y_\alpha - y_\beta = 0$; see (4.1) with $F = \nabla U$) or for all (t,x) the relation $v_t + u_x(\alpha^{-1}s + \beta^{-1}(1-s))^{-1} = 0$ (i.e., $\alpha y_\alpha - \beta y_\beta = 0$). However, we may conjecture this equivalence thanks to the following property.

Lemma 4.2. *The equality* $\inf(\widetilde{\mathrm{RP}}) = \min(\mathrm{RP})$ *holds.*

Proof. Let us consider the first case in Lemma 4.1, i.e., $a_\alpha/a_\beta \leq 2\beta/(\alpha+\beta)$, leading to the arithmetic situation (4.6). In this case, $(\widetilde{\mathrm{RP}})$ is simply derived from (VP) by replacing the set of characteristic functions $\mathcal{X}_{\omega_1} \in L^\infty((0,T) \times \Omega, \{0,1\})$ by the larger set of density functions $s \in L^\infty((0,T) \times \Omega, (0,1))$. Therefore $\inf(\widetilde{\mathrm{RP}}) \leq \inf(\mathrm{VP})$, and the conclusion follows from $\min(\mathrm{RP}) = \inf(\mathrm{VP})$ (see Theorem 2.2) and $\min(\mathrm{RP}) \leq \inf(\widetilde{\mathrm{RP}})$. In the harmonic situation, we obtain the result using the same arguments and Lemma 4.1. □

We have transformed the problem (RP) into the problem $(\widetilde{\mathrm{RP}})$, where the auxiliary variable v does not occur anymore and is much easier to solve numerically. We observe, however, that, since $(\widetilde{\mathrm{RP}})$ is not convex, one cannot ensure the existence of solutions. The next section aims at investigating the numerical resolution of $(\widetilde{\mathrm{RP}})$.

5. Numerical analysis of the relaxed problem.

We address in this section the numerical resolution of the problem $(\widetilde{\mathrm{RP}})$ in the quadratic case for which $(a_\alpha, a_\beta) = (1,1)$ and in the compliance case for which $(a_\alpha, a_\beta) = (\alpha, \beta)$. We first describe an algorithm of minimization and then present some numerical experiments. In order to simplify the presentation, we replace the volume constraint inequalities $(4.5)_4$ and $(4.5)_5$ by constraint equalities.

5.1. Algorithm of minimization.

We present the resolution of the relaxed problem $(\widetilde{\mathrm{RP}})$ using a gradient descent method. In this respect, we compute the first variation of the cost function with respect to s and r.

For any $\eta \in \mathbb{R}^+$, $\eta \ll 1$, and any $s_1 \in L^\infty((0,T) \times \Omega)$, we associate with the perturbation $s^\eta = s + \eta s_1$ of s the derivative of $\widetilde{I}$ with respect to s in the direction s_1 as follows:

$$\frac{\partial \widetilde{I}(s,r)}{\partial s} \cdot s_1 = \lim_{\eta \to 0} \frac{\widetilde{I}(s + \eta s_1, r) - \widetilde{I}(s,r)}{\eta}.$$

Theorem 5.1. *If* $(u_0, u_1) \in (H^2(\Omega) \cap H_0^1(\Omega)) \times H_0^1(\Omega)$, *then the first derivative of* $\widetilde{I}$ *with respect to* s *in any direction* s_1 *exists and takes the form*

$$\frac{\partial \widetilde{I}(s,r)}{\partial s} \cdot s_1 = \int_0^T \int_\Omega \Big(G_{,s}(s) u_x^2 + H_{,s}(s) u_x p_x \Big) s_1 \, dxdt, \tag{5.1}$$

where u *is the solution of* (4.5) *and* p *is the solution in* $C^1([0,T]; H_0^1(\Omega)) \cap C^1([0,T]; L^2(\Omega))$ *of the adjoint problem*

$$\begin{cases} p_{tt} - \nabla_x(H(s)p_x) - d(x)r(x)p_t = u_{tt} + \nabla_x(G(s)u_x) & \textit{in} \quad (0,T) \times \Omega, \\ p = 0 & \textit{on} \quad (0,T) \times \partial\Omega, \\ p(T,x) = 0, \quad p_t(T,x) = u_t(T,x) & \textit{in} \quad \Omega. \end{cases} \tag{5.2}$$

Similarly, the first derivative of $\widetilde{I}$ with respect to r in any direction $r_1 \in L^\infty(\Omega)$ is given by

$$\frac{\partial \widetilde{I}(s,r)}{\partial r} \cdot r_1 = \int_\Omega d(x) r_1(x) \int_0^T u_t(t,x) p(t,x) dt dx. \tag{5.3}$$

Proof. We introduce the Lagrangian

$$\mathcal{L}(s,\phi,\psi) = \int_0^T \int_\Omega (\phi_t^2 + G(s)\phi_x^2)\, dxdt + \int_0^T \int_\Omega \Big[\phi_{tt} - \nabla_x (H(s)\phi_x) + d(x) r \phi_t\Big] \psi \, dxdt$$

for any $s \in L^\infty((0,T) \times \Omega)$, $\phi \in C([0,T]; H^2(\Omega) \cap H_0^1(\Omega)) \cap C^1([0,T]; H_0^1(\Omega))$, and $\psi \in C([0,T]; H_0^1(\Omega)) \cap C^1([0,T]; L^2(\Omega))$ and then write formally that

$$\frac{d\mathcal{L}}{ds} \cdot s_1 = \frac{\partial}{\partial s} \mathcal{L}(s,\phi,\psi) \cdot s_1 + \left\langle \frac{\partial}{\partial \phi} \mathcal{L}(s,\phi,\psi), \frac{\partial \phi}{\partial s} \cdot s_1 \right\rangle + \left\langle \frac{\partial}{\partial \psi} \mathcal{L}(s,\phi,\psi), \frac{\partial \psi}{\partial s} \cdot s_1 \right\rangle .$$

The first term is

$$\frac{\partial}{\partial s} \mathcal{L}(s,\phi,\psi) \cdot s_1 = \int_0^T \int_\Omega \Big(G_{,s}(s)\phi_x^2 + H_{,s}(s) \phi_x \psi_x \Big) s_1 \, dxdt \tag{5.4}$$

for any s, ϕ, ψ, whereas the third term is equal to zero if $\phi = u$ is the solution of (4.5). We then determine the solution p so that, for all $\phi \in C([0,T]; H^2(\Omega) \cap H_0^1(\Omega)) \cap C^1([0,T]; H_0^1(\Omega))$, we have

$$\left\langle \frac{\partial}{\partial \phi} \mathcal{L}(s,\phi,p), \frac{\partial \phi}{\partial s} \cdot s_1 \right\rangle = 0,$$

which leads to the formulation of the adjoint problem (5.2). Next, writing that $\widetilde{I}(s) = \mathcal{L}(s,u,p)$, we obtain (5.1) from (5.4). The relation (5.3) is obtained in a similar way. □

In order to take into account the volume constraint on s and r, we introduce the Lagrange multipliers $\gamma_s \in L^\infty((0,T); \mathbb{R})$, $\gamma_r \in \mathbb{R}$ and the functional

$$\widetilde{I}_\gamma(s,r) = \widetilde{I}(s,r) + \int_0^T \gamma_s(t) \int_\Omega s(t,x) dx dt + \gamma_r \int_\Omega r(x) dx.$$

Using Theorem 5.1, we then obtain easily that the first derivatives of $\widetilde{I}_\gamma$ are

$$\frac{\partial \widetilde{I}_\gamma(s,r)}{\partial s} \cdot s_1 = \int_0^T \int_\Omega (G_{,s}(s) u_x^2 + H_{,s}(s) u_x p_x) s_1 \, dxdt + \int_0^T \gamma_s(t) \int_\Omega s_1 dx dt,$$
$$\frac{\partial \widetilde{I}_\gamma(s,r)}{\partial r} \cdot r_1 = \int_\Omega d(x) r_1(x) \int_0^T u_t p \, dxdt + \gamma_r \int_\Omega r_1(x) dx,$$

which lets us define the following descent directions, respectively:

$$s_1(t,x) = -(G_{,s}(s) u_x^2 + H_{,s}(s) u_x p_x + \gamma_s(t)) \quad \forall (t,x) \in (0,T) \times \Omega, \tag{5.5}$$

and

$$r_1(t,x) = -\Big(d(x) \int_0^T u_t(t,x) p(t,x) dt + \gamma_r \Big) \quad \forall x \in \Omega. \tag{5.6}$$

Consequently, for any function $\eta_s \in L^\infty(\Omega \times (0,T), \mathbb{R}^+)$ with $||\eta_s||_{L^\infty((0,T)\times\Omega)}$ small enough, we have $\widetilde{I}_\gamma(s+\eta_s s_1, r) \leq \widetilde{I}_\gamma(s,r)$. The multiplier function γ_s is then determined so that, for any function $\eta_s \in L^\infty((0,T)\times\Omega, \mathbb{R}^+)$, $||s+\eta_s s_1||_{L^1(\Omega)} = L_\alpha|\Omega|$ for all $t \in (0,T)$, leading to

$$\gamma_s(t) = \frac{(\int_\Omega s(t,x)dx - L_\alpha|\Omega|) - \int_\Omega \eta_s(t,x)(G_{,s}(s)u_x^2 + H_{,s}(s)u_x p_x)\,dx}{\int_\Omega \eta_s(t,x)dx}. \tag{5.7}$$

Finally, the function η_s is chosen so that $s+\eta s_1 \in [0,1]$ for all $(t,x) \in (0,T)\times\Omega$. A simple and efficient choice consists of taking $\eta_s(t,x) = \varepsilon s(t,x)(1-s(t,x))$ for all $(t,x) \in (0,T)\times\Omega$ with ε small and positive.

Similarly, the choice

$$\gamma_r = \frac{(\int_\Omega r(x)dx - L_d|\Omega|) - \int_\Omega \eta_r(x)d(x)\int_0^T u_t(t,x)p(t,x)\,dtdx}{\int_\Omega \eta_r(x)dx} \tag{5.8}$$

with $\eta_r(x) = \varepsilon r(x)(1-r(x))$ for all $x \in \Omega$ permits us to ensure the condition $||r + \eta_r r_1||_{L^1(\Omega)} = L_d|\Omega|$.

The descent algorithm to solve numerically the relaxed problem $(\widetilde{\mathrm{RP}})$ may be structured as follows.

Let $\Omega \subset \mathbb{R}$, $(u_0,u_1) \in (H^2(\Omega)\cap H_0^1(\Omega)) \times H_0^1(\Omega)$, $L_\alpha, L_d \in (0,1)$, $T>0$, $0<\alpha<\beta$, $a_\beta, a_\alpha \in L^\infty((0,T)\times\Omega; \mathbb{R}_+^\star)$, and $\varepsilon < 1$, $\varepsilon_1 \ll 1$ be given;

- Initialization of the densities $s^0 \in L^\infty((0,T\times\Omega;]0,1[)$ and $r^0 \in L^\infty(\Omega;]0,1[)$;
- For $k \geq 0$, iteration until convergence (i.e., $|\widetilde{I}_\gamma(s^{k+1},r^{k+1}) - \widetilde{I}_\gamma(s^k,r^k)| \leq \varepsilon_1|\widetilde{I}_\gamma(s^0,r^0)|$) as follows:
  - Compute the solution u_{s^k,r^k} of (4.5) and then the solution p_{s^k,r^k} of (5.2), both corresponding to $(s,r) = (s^k,r^k)$.
  - Compute the descent direction s_1^k defined by (5.5), where the multiplier γ^k is defined by (5.7). Similarly, compute the descent direction r_1^k defined by (5.6), where the multiplier γ^k is defined by (5.8).
  - Update the density s^k in $(0,T)\times\Omega$ and the density r^k in Ω:

    $$s^{k+1} = s^k + \varepsilon s^k(1-s^k)s_1^k, \quad r^{k+1} = r^k + \varepsilon r^k(1-r^k)r_1^k$$

    with $\varepsilon \in \mathbb{R}^+$ small enough to ensure the decrease of the cost function, $s^{k+1} \in L^\infty((0,T)\times\Omega, [0,1])$ and $r^{k+1} \in L^\infty(\Omega, [0,1])$.

5.2. Numerical experiments. In this section, we present some numerical simulations for $\Omega = (0,1)$ in the quadratic case—$(a_\alpha, a_\beta) = (1,1)$—and in the compliance case—$(a_\alpha, a_\beta) = (\alpha,\beta)$. Recalling the assumption $0<\alpha<\beta$, these two cases fall into the arithmetic (see (4.6)) and harmonic (4.7) cases, respectively. From a numerical viewpoint, we highlight that the numerical resolution of the descent algorithm is a priori delicate in the sense that the descent direction depends on the derivative of u and p, both solutions of a wave equation with space and time coefficients only in $L^\infty((0,T)\times\Omega; \mathbb{R}_+^\star)$. To the knowledge of the authors, there does not exist any numerical analysis for this kind of equation. We use a C^0-finite element approximation for u and p with respect to x and a finite difference centered approximation with respect to t. Moreover, we add a vanishing viscosity and dissipative term of the type $(\beta-\alpha)\epsilon^2 \mathrm{div}(H(s)u_{xtt})$ with ϵ of order h—the space discretization parameter. This term has the effect of regularizing the descent term (5.5) and leading to a convergent algorithm. Finally, this provides an implicit and unconditionally stable scheme, consistent with (4.5) and (5.2), and of order two in time and space.

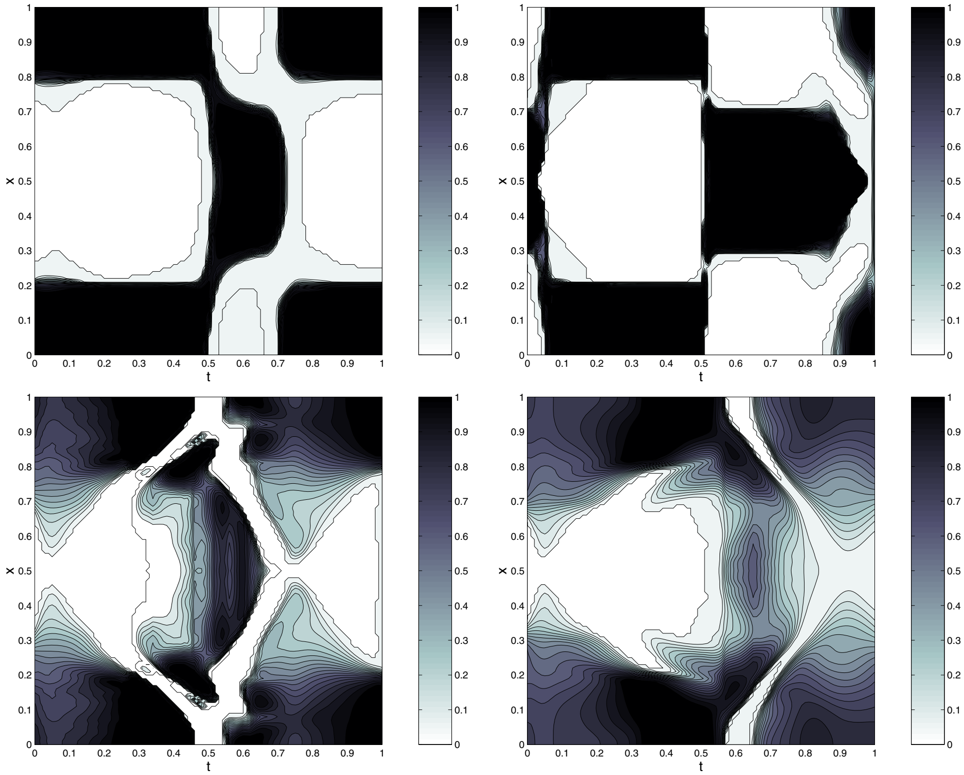

FIG. 5.1. $(a_\alpha, a_\beta) = (\alpha, \beta)$. *Optimal density* s^{lim} *on* $(0,T) \times \Omega$ *for* $(\alpha, \beta, d) = (1, 1.1, 1)$ *(top left),* $(\alpha, \beta, d) = (1, 1.1, 10)$ *(top right),* $(\alpha, \beta, d) = (1, 4, 1)$ *(bottom left), and* $(\alpha, \beta, d) = (1, 4, 10)$ *(bottom right).*

In what follows, we treat the following simple and smooth initial conditions on $\Omega = (0, 1)$:

$$u_0(x) = \sin(\pi x), \quad u_1(x) = 0, \tag{5.9}$$

and $\alpha = 1$. Results are obtained with $h = \Delta t = 10^{-2}$ (Δt designates the time discretization parameter), $\varepsilon_1 = 10^{-5}$, $L_\alpha = 2/5$, $L_d = 1/5$, $T = 1$, $s^0(t, x) = L_\alpha$ on $[0, T] \times \Omega$, $r^0(x) = L_d$ on Ω, and $\varepsilon = 10^{-2}$ (see the algorithm).

We highlight that the gradient algorithm may lead to local minima of $\widetilde{I}$ with respect to s and r. For this reason, we consider constant initial density s^0 and r^0 as indicated above, which does not privilege any location for ω_1 and ω_2.

We discuss the result obtained with respect to the value of β and of the damping function $d(x) = d\mathcal{X}_\Omega$ assumed constant in Ω: precisely, for $(\beta, d) = (1.1, 1)$, $(\beta, d) = (1.1, 10)$, $(\beta, d) = (4, 1)$, and $(\beta, d) = (4, 10)$.

5.2.1. The compliance case—$(a_\alpha, a_\beta) = (\alpha, \beta)$. The compliance choice is the most usual one, because the corresponding cost function I (see (1.3)) coincides with the energy of the vibrating membrane described by system (1.1). This case falls into the harmonic situation (4.7), $G(s) = H(s) = (\alpha^{-1}s + \beta^{-1}(1-s))^{-1}$, and we get easily that $G_{,s}(s) = (\alpha - \beta)G^2(s)/(\alpha\beta)$. We present some results obtained with the following data: Figures 5.1 and 5.2 depict the iso-values of the optimal density

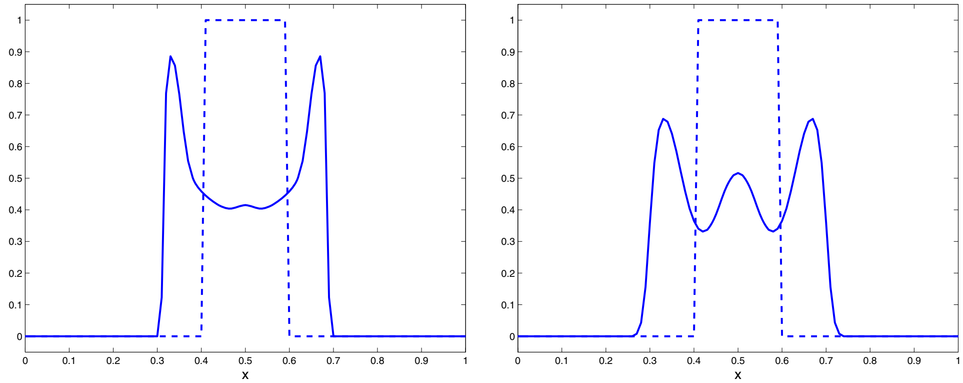

FIG. 5.2. $(a_\alpha, a_\beta) = (\alpha, \beta)$. *Solid line: Optimal density* r^{lim} *for* $(\alpha, \beta, d) = (1, 1.1, 10)$ *(left) and* $(\alpha, \beta, d) = (1, 4, 10)$ *(right). Dashed line: Optimal density* $r^{lim} = \mathcal{X}_{[0.4,0.6]}$ *for* $(\alpha, \beta, d) = (1, 1.1, 1)$ *and* $(\alpha, \beta, d) = (1, 4, 1)$.

s^{lim} and r^{lim}, respectively (obtained at the convergence of the descent algorithm). In agreement with [20] (case $\omega_2 = \emptyset$) and [22] (case $\omega_1 = \emptyset$), results depend qualitatively on the gap $\beta - \alpha$ and d. When $\beta - \alpha$ and d are small enough (function of the data of the problem), here $(\alpha, \beta, d) = (1, 1.1, 1)$, we observe that the optimal densities are characteristic functions. In this case, problem $(\widetilde{\mathrm{RP}})$ coincides with the original problem (P) (we check that when $s^{lim} \in L^\infty((0, T) \times \Omega, \{0, 1\})$, i.e., $s^{lim} = \mathcal{X}_{\omega_1}$, then $H(s^{lim}) = \alpha s^{lim} + \beta(1 - s^{\mathrm{lim}}) = \alpha \mathcal{X}_{\omega_1} + \beta(1 - \mathcal{X}_{\omega_1}))$. The original problem is therefore well posed in the class of characteristic function: $\mathcal{X}_{\omega_1} = s^{lim} \in L^\infty((0, T) \times \Omega; \{0, 1\})$ and $\mathcal{X}_{\omega_2} = r^{lim} \in L^\infty(\Omega; \{0, 1\})$.

Precisely, $r^{lim} = \mathcal{X}_{[1/2 - L_d/2, 1/2 + L_d/2]} = \mathcal{X}_{[0.4,0.6]}$, and the optimal position for the damping zone is—as expected according to the symmetry of u_0—the centered one: $\omega_2 = [0.4, 0.6]$. Moreover, the optimal distribution of (α, β)-material is time dependent (see Figure 5.1(top left)), and we observe that the weaker material α (black zone on the figure) is located, for each time t, on the point (x, t) where the amplitude of $u(x, t)$ is the lowest: on the extremities of Ω at time $t = 0$, and on the middle at time $t \approx 0.5$.

If now we consider a larger gap $\beta - \alpha$, for instance $(\alpha, \beta, d) = (1, 4, 1)$, the limit density s^{lim} is no longer a characteristic function and takes values in $(0, 1)$, highlighting microstructure (Figure 5.1(bottom left)). This suggests that the initial problem (P) is not well posed in the class of characteristic functions and does not coincide with the relaxed problem $(\widetilde{\mathrm{RP}})$. This also fully justifies the search and introduction of a relaxed well-posed formulation. We observe also that this gap is not enough larger to influence the density r^{lim}: we still have $r^{lim} = \mathcal{X}_{[0.4,0.6]}$.

Similarly, when we increase the value of the damping function d (and therefore the dissipation of the system), the limit density r^{lim} is no longer a characteristic function (see Figure 5.2 for $(\alpha, \beta, d) = (1, 1.1, 10)$ (left) and $(\alpha, \beta, d) = (1, 4, 10)$ (right)) but remains symmetric with respect to $x = 1/2$. The optimal domain is no longer the centered position but an infinite union of disjoint intervals (see section 5.2.3). This damping term with $d = 10$ changes significantly the dynamic of u and perturbs the optimal dynamical distribution of (α, β)-material (see Figure 5.1(right)). For $(\alpha, \beta, d) = (1, 1.1, 10)$, the function s^{lim} remains a characteristic function.

Finally, we plot the integrand of the cost function $\widetilde{I}$, i.e., the energy $E(t) \equiv \int_\Omega (|u_t|^2 + G(s^{lim})|u_x|^2) dx$ with respect to time (Figure 5.3). Although the system is

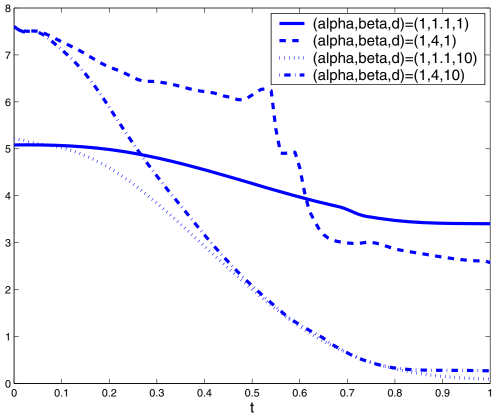

FIG. 5.3. $(a_\alpha, a_\beta) = (\alpha, \beta)$. *Evolution of* $\int_\Omega (|u_t|^2 + G(s^{lim})|u_x|^2)dx$ *versus* $t \in [0, T]$.

not necessarily dissipative when $\omega_2 = \emptyset$—we have the relation

$$\begin{aligned}\frac{dE(t)}{dt} &= 2\int_\Omega H_t(s)u_x^2 dx - 2\int_\Omega d(x)r(x)u_t^2 dx \\ &= 2\alpha\beta(\alpha-\beta)\int_\Omega \frac{s_t}{(\alpha(1-s)+\beta s)^2}u_x^2 dx - 2\int_\Omega d(x)r(x)u_t^2 dx\end{aligned} \tag{5.10}$$

—we observe that the optimal (α, β)-distribution leads to a dissipative system and that the dissipation is monotonous with respect to $(\beta - \alpha)$.

5.2.2. The quadratic case—$(a_\alpha, a_\beta) = (1, 1)$. This case falls in the arithmetic situation (see (4.6)), and the relaxed problem $(\widetilde{\mathrm{RP}})$ is then simply derived from the original one by replacing $(\mathcal{X}_{\omega_1}, \mathcal{X}_{\omega_2})$ by (s, r).

Once again, the optimal distribution of (α, β) and damping material strongly depends on the gap of the coefficients. Moreover, the numerical results still suggest that the original problem is not well posed if these gaps exceed critical values depending on the data (see Figure 5.4). The main difference with respect to the compliance case is observed for $(\alpha, \beta, d) = (1, 4, 10)$: it appears that the density r^{lim} is a characteristic function: $r^{lim} = \mathcal{X}_{[0.4,0.6]}$ (see Figure 5.5). A greater value of d (for instance, $d = 15$) is necessary to obtain values in $(0, 1)$. This phenomenon is due to the dissipative effect of the optimal (α, β)-distribution and highlights the interaction between s and r (or equivalently between ω_1 and ω_2).

Contrary to the compliance case where the density varies somewhat smoothly (see Figure 5.1), we observe in the bottom two panels in Figure 5.4 some high oscillations of the optimal density s with respect to both t and x (especially with $(\alpha, \beta, d) = (1, 4, 10)$). Due to the nonconvexity of the functional $\tilde{I}(s, r)$ with respect to s in the quadratic case, we recall that we do not know a priori whether the problem $(\widetilde{\mathrm{RP}})$ defined by (4.4) is well posed: we can only ensure that $\inf(\widetilde{\mathrm{RP}}) = \min(\mathrm{RP})$ (Lemma 4.2). The situation is different in the compliance case because $\tilde{I}$ is convex. Therefore, these oscillations may be related to the possible ill-posedness of $(\widetilde{\mathrm{RP}})$. These oscillations may also be caused, at least partially, by the numerical sensitivity of the approximation, as discussed above. Figure 5.6 depicts the evolution of the energy for the different values of α, β, and d.

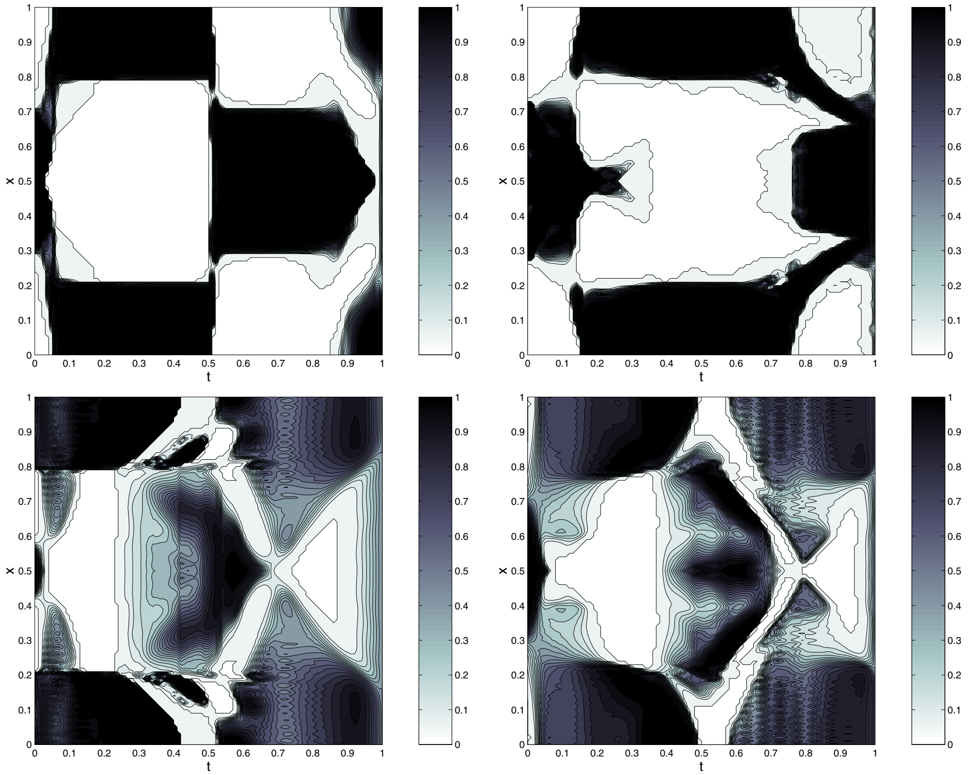

FIG. 5.4. $(a_\alpha, a_\beta) = (1, 1)$. *Optimal density* $s^{lim}(t, x)$ *on* $\Omega \times (0, T)$ *for* $(\alpha, \beta, d) = (1, 1.1, 1)$ *(top left),* $(\alpha, \beta, d) = (1, 1.1, 10)$ *(top right),* $(\alpha, \beta, d) = (1, 4, 1)$ *(bottom left), and* $(\alpha, \beta, d) = (1, 4, 10)$ *(bottom right).*

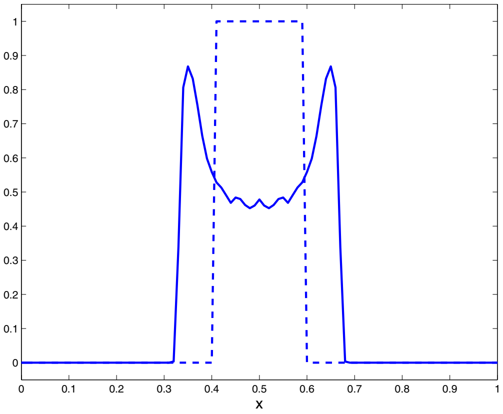

FIG. 5.5. $(a_\alpha, a_\beta) = (1, 1)$. *Solid line: Optimal density* r^{lim} *for* $(\alpha, \beta, d) = (1, 1.1, 10)$*. Dashed line: Optimal density* $r^{lim} = \mathcal{X}_{[0.4,0.6]}$ *for* $(\alpha, \beta, d) = (1, 1.1, 1)$*,* $(\alpha, \beta, d) = (1, 4, 1)$*, and* $(\alpha, \beta, d) = (1, 4, 10)$.

5.2.3. Extraction of a minimizing sequence $(\mathcal{X}_{\omega_1^k}, \mathcal{X}_{\omega_2^k})$ from the optimal density (s^{lim}, r^{lim}). Once we have the optimal microstructure of the (α, β)-material and damping material codified by the optimal density s and r, it remains

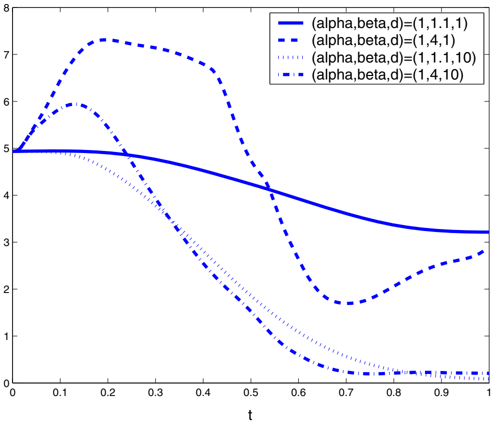

FIG. 5.6. $(a_\alpha, a_\beta) = (1, 1)$. *Evolution of* $\int_\Omega (|u_t|^2 + G(s^{lim})|u_x|^2)dx$ *versus* $t \in [0, T]$.

(from a practical viewpoint) to extract from (s^{lim}, r^{lim}), a sequence of characteristic functions $(\mathcal{X}_{\omega_1^k}, \mathcal{X}_{\omega_2^k})$ such that $\lim_{k\to\infty} \widetilde{I}(\mathcal{X}_{\omega_1^k}, \mathcal{X}_{\omega_2^k}) = \widetilde{I}(s^{lim}, r^{lim})$.

Recalling that $r^{lim}(x)$ is the volume fraction of the damping material at point x, we proceed as follows. Let us decompose the interval Ω into $M > 0$ nonempty subintervals such that $\Omega = \cup_{j=1,M}[x_j, x_{j+1}]$. Then, we associate with each interval $[x_j, x_{j+1}]$ the mean value $m_j \in [0, 1]$ defined by

$$m_j = \frac{1}{x_{j+1} - x_j} \int_{x_j}^{x_{j+1}} r^{lim}(x)dx \tag{5.11}$$

and the division into two parts

$$[x_j, (1 - m_j)x_j + m_j x_{j+1}] \cup [(1 - m_j)x_j + m_j x_{j+1}, x_{j+1}]. \tag{5.12}$$

Finally, we introduce the function r_M^{pen} in $L^\infty(\Omega, \{0, 1\})$ by

$$r_M^{pen}(x) = \sum_{j=1}^{M} \mathcal{X}_{[x_j,(1-m_j)x_j+m_j x_{j+1}]}(x). \tag{5.13}$$

We easily check that $||r_M^{pen}||_{L^1(\Omega)} = ||r^{lim}||_{L^1(\Omega)}$ for all $M > 0$. The bivalued function r_M^{pen} takes more advantage of the information codified in the density r^{lim}. Similarly, using that $s(t, x)$ is the volume fraction of the α-material at point (t, x), we associate with s^{lim} a sequence of bivalued functions $s_N^{pen} \in L^\infty((0, T) \times \Omega, \{0, 1\})$ (see [20]).

For $(\alpha, \beta, d) = (1, 4, 10)$ and $(a_\alpha, a_\beta) = (\alpha, \beta)$, Figure 5.7 represents the function $r_{M=30}^{pen}$ associated with the density r^{lim} of Figure 5.2(right). Similarly, Figure 5.8 represents the function $s_{N=30}^{pen}$ associated with the optimal density s^{lim} of Figure 5.1(bottom right). Finally, we report in Table 5.1 values of $\widetilde{I}(s_N^{pen}, r_M^{pen})$ for several values of N and M. For $M = N = 40$, we obtain $\widetilde{I}(s_{40}^{pen}, r_{40}^{pen}) \approx 2.9803$ which is very near from the minimal value $I(s^{lim}, r^{lim}) \approx 2.9116$. These numerical results suggest the efficiency of this procedure to build optimal domains ω_1, ω_2 composed of a finite number of disjoints components and arbitrarily near the optimal distributions.

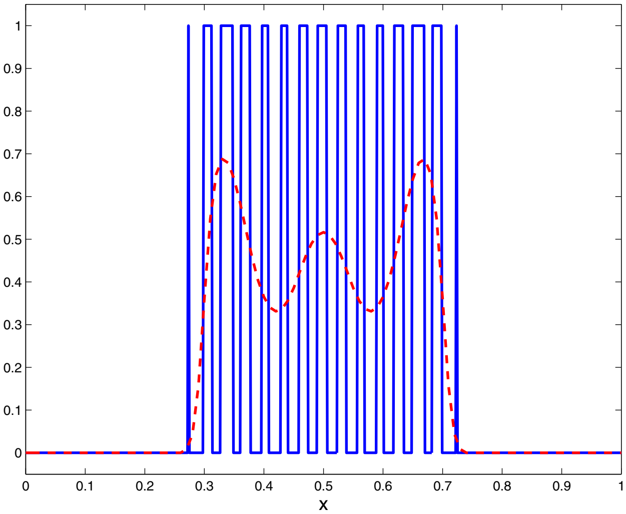

FIG. 5.7. $(a_\alpha, a_\beta) = (\alpha, \beta)$. *Characteristic function associated with the optimal density* r^{lim} *for* $(\alpha, \beta, d) = (1, 4, 10)$. $\widetilde{I}(s^{lim}, r^{lim}) \approx 2.9116$. $\widetilde{I}(s^{lim}, r^{pen}_{M=30}) \approx 3.0360$.

6. Concluding remarks and perspectives. We have analyzed the response of a 1-D damped string with respect to the spatio-temporal distribution of its longitudinal stiffness. The relaxed formulation highlights the smoothing effect of the damping term on the optimal spatio-temporal layout. Moreover, the numerical experiments indicate the strong dependence of the optimal distribution on the initial data (u_0, u_1). In order to get free of this dependence, it would be interesting to consider, for instance, an inf-sup problem of the form

$$\inf_{\mathcal{X}_{\omega_1},\mathcal{X}_{\omega_2}} \sup_{(u_0,u_1)\in H_0^1(\Omega)\times L^2(\Omega)} I(\mathcal{X}_{\omega_1}, \mathcal{X}_{\omega_2}, u_0, u_1), \tag{6.1}$$

where I designates the cost function (1.3). Another approach may consist of averaging the cost function over all initial data of unit energy (we refer to [10] in a similar context). Finally, at the numerical level, it seems important to investigate the numerical approximation of the fully relaxed problem (RP) and compare it with the simplified formulation $(\widetilde{\text{RP}})$. These aspects will be addressed in the near future.

ON POPULATION RESILIENCE TO EXTERNAL PERTURBATIONS[*]

LIONEL ROQUES[†] AND MICKAËL D. CHEKROUN[‡]

Abstract. We study a spatially explicit harvesting model in periodic or bounded environments. The model is governed by a parabolic equation with a spatially dependent nonlinearity of Kolmogorov–Petrovsky–Piskunov type, and a negative external forcing term $-\delta$. Using sub- and supersolution methods and the characterization of the first eigenvalue of some linear elliptic operators, we obtain existence and nonexistence results as well as results on the number of stationary solutions. We also characterize the asymptotic behavior of the evolution equation as a function of the forcing term amplitude. In particular, we define two critical values δ^* and δ_2 such that, if δ is smaller than δ^*, the population density converges to a "significant" state, which is everywhere above a certain small threshold, whereas if δ is larger than δ_2, the population density converges to a "remnant" state, everywhere below this small threshold. Our results are shown to be useful for studying the relationships between environmental fragmentation and maximum sustainable yield from populations. We present numerical results in the case of stochastic environments.

Key words. reaction-diffusion, heterogeneous media, harvesting models, stochastic environments, periodic environments

1. Introduction.

Overexploitation has led to the extinction of many species [4]. Traditionally, models of ordinary differential equations (ODEs) or difference equations have been used to estimate the maximum sustainable yields from populations and to perform quantitative analysis of harvesting policies and management strategies [17]. Ignoring age or stage structures as well as delay mechanisms, which will not be treated by the present paper, the ODEs models are generally of the type

$$\frac{dU}{dt} = F(U) - Y(U), \tag{1.1}$$

where U is the population biomass at time t, $F(U)$ is the growth function, and $Y(U)$ corresponds to the harvest function. In these models, the most commonly used growth function is logistic, with $F(U) = U(\mu - \nu U)$ (see [5], [25], [35]), where $\mu > 0$ is the intrinsic growth rate of the population and $\nu > 0$ models its susceptibility to crowding effects.

Different harvesting strategies $Y(U)$ have been considered in the literature and are used in practical resource management. A very common one is the *constant-yield harvesting* strategy, where a constant number of individuals are removed per unit of time: $Y(U) = \delta$, with δ a positive constant. This harvesting function naturally appears when a quota is set on the harvesters [31], [32], [38]. Another frequently used harvesting strategy is the *proportional harvesting* strategy (also called *constant-effort*

harvesting), where a constant proportion of the population is removed. It leads to a harvesting function of the type $Y(U) = \delta U$.

Much less has been done in this field using reaction-diffusion models (but see [23], [26], [29]). The aim of this paper is to perform an analysis of some harvesting models, within the framework of reaction-diffusion equations.

One of the most celebrated reaction-diffusion models was introduced by Fisher [15] and Kolmogorov, Petrovsky, and Piskunov [22] in 1937 (we call it the Fisher-KPP model). Since then, it has been widely used to model spatial propagation or spreading of biological species into homogeneous environments (see books [25], [28], and [40] for a review). The corresponding equation is

$$u_t = D\nabla^2 u + u(\mu - \nu u), \tag{1.2}$$

where $u = u(t, x)$ is the population density at time t and space position x, D is the diffusion coefficient, and μ and ν still correspond to the *constant* intrinsic growth rate and susceptibility to crowding effects. In the 1980s, this model was extended to heterogeneous environments by Shigesada, Kawasaki, and Teramoto [37]. The corresponding model (which we call the *SKT model* in this paper) is of the type

$$u_t = D\nabla^2 u + u(\mu(x) - \nu(x)u). \tag{1.3}$$

The coefficients $\mu(x)$ and $\nu(x)$ now depend on the space variable x and can therefore include some effects of environmental heterogeneity. More recently, this model revealed that the heterogeneous character of the environment plays an essential role in species persistence, in the sense that for different spatial configurations of the environment a population can survive or become extinct, depending on the habitat spatial structure [8], [12], [34], [36].

As mentioned above, the combination of a harvesting model with a Fisher-KPP population dynamics model, leading to an equation of the form $u_t = D\nabla^2 u + u(\mu - \nu u) - Y(x, u)$, has been considered in recent papers, either using a spatially dependent proportional harvesting term $Y(x, u) = q(x)u$ in [26], [29], or a spatially dependent and time-constant harvesting term $Y(x) = h(x)$ in [23]. In these papers, the models were considered in bounded domains with Dirichlet (lethal) boundary conditions.

Here we study a population dynamics model of the SKT type, with a spatially dependent harvesting term $Y(x, u)$:

$$u_t = D\nabla^2 u + u(\mu(x) - \nu(x)u) - Y(x, u). \tag{1.4}$$

We mainly focus on a "quasi-constant-yield" case, where the harvesting term depends on u only for very low population densities (ensuring the nonnegativity of u). We consider two types of domains and boundary conditions. In the first case, the domain is bounded with Neumann (reflective) boundary conditions; this framework is often more realistic for modeling species that cannot cross the domain boundary. In the second case, we consider the model (1.4) in the whole space $\mathbb{R}^N$ with periodic coefficients. This last situation, though technically more complex, is useful, for instance, for studying spreading phenomena [7], [9], and for studying the effects of environmental fragmentation, independently of the boundary effects. Lastly, note that the effects of variability in time of the harvesting function will be investigated in a forthcoming publication [13].

In section 2, we define a quasi-constant-yield harvesting reaction-diffusion model. We prove, on a firm mathematical basis, existence and nonexistence results for the equilibrium equations, as well as results on the number of possible stationary states. We also characterize the asymptotic behavior of the solutions of (1.4). In section 3, we illustrate the practical usefulness of the results of section 2, by studying the effects of the amplitude of the harvesting term on the population density in terms of environmental fragmentation. Lastly, in section 4, we give new results for the proportional harvesting case $Y(x,u) = q(x)u$.

2. Mathematical analysis of a quasi-constant-yield harvesting reaction-diffusion model.

For the sake of readability, the proofs of the results of section 2 are postponed to section 2.5.

2.1. Formulation of the model.

In this paper, we consider the model

$$u_t = D\nabla^2 u + u(\mu(x) - \nu(x)u) - \delta h(x)\rho_\varepsilon(u), \quad (t,x) \in \mathbb{R}_+ \times \Omega. \tag{2.1}$$

The function $u = u(t,x)$ denotes the population density at time t and space position x. The coefficient D, assumed to be positive, denotes the diffusion coefficient. The functions $\mu(x)$ and $\nu(x)$ respectively stand for the spatially dependent intrinsic growth rate of the population, and for its susceptibility to crowding effects. Two different types of domains Ω are considered: either $\Omega = \mathbb{R}^N$ or Ω is a smooth bounded and connected domain of $\mathbb{R}^N$ $(N \geq 1)$. We qualify the first case as the *periodic case*, and the second one as the *bounded case*. In the periodic case, we assume that the functions $\mu(x)$, $\nu(x)$, and $h(x)$ depend on the space variables in a periodic fashion. For that, let $L = (L_1, \ldots, L_N) \in (0,+\infty)^N$. We recall the following definition.

Definition 2.1. *A function g is said to be* L-periodic *if $g(x+k) = g(x)$ for all $x = (x_1, \ldots, x_N) \in \mathbb{R}^N$ and $k \in L_1\mathbb{Z} \times \cdots \times L_N\mathbb{Z}$.*

Thus, in the periodic case, we assume that μ, ν, and h are L-periodic. In the bounded case we assume that Neumann boundary conditions hold: $\frac{\partial u}{\partial n} = 0$ on $\partial\Omega$, where n is the outward unit normal to $\partial\Omega$. The period cell C is defined by

$$C := (0, L_1) \times \cdots \times (0, L_N)$$

in the periodic case, and in the bounded case we set

$$C := \Omega,$$

for the sake of simplicity of some forthcoming statements.

We furthermore assume that the functions μ and ν satisfy

$$\mu, \nu \in L^\infty(\Omega) \quad \text{and} \quad \exists\ \underline{\nu}, \overline{\nu} \in \mathbb{R} \text{ s.t. } 0 < \underline{\nu} < \nu(x) < \overline{\nu} \quad \forall\ x \in \Omega. \tag{2.2}$$

Regions with higher values of $\mu(x)$ and lower values of $\nu(x)$ will be qualified as being *more favorable*, while, on the other hand, regions with lower $\mu(x)$ and higher $\nu(x)$ values will be considered as being *less favorable* or, equivalently, *more hostile*.

The last term in (2.1), $\delta h(x)\rho_\varepsilon(u)$, corresponds to a quasi-constant-yield harvesting term. Indeed, the function ρ_ε satisfies

$$\rho_\varepsilon \in C^1(\mathbb{R}),\ \rho_\varepsilon' \geq 0,\ \rho_\varepsilon(s) = 0\ \forall s \leq 0 \quad \text{and} \quad \rho_\varepsilon(s) = 1\ \forall s \geq \varepsilon, \tag{2.3}$$

where ε is a nonnegative parameter. With such a harvesting function, the yield is constant in time whenever $u \geq \varepsilon$, while it depends on the population density when $u < \varepsilon$. In what follows, the parameter ε is taken to be very small. As we prove in the next sections, there are many situations where the solutions of the model always remain larger than ε. For these reasons, we qualify our model as a *quasi-constant-yield harvesting SKT model*, the "dominant" regime being the constant-yield one. Note that the function ρ_ε ensures the nonnegativity of the solutions of (2.1). From a biological point of view, ε can correspond to a threshold below which harvesting is progressively abandoned. Considering constant-yield harvesting functions without this threshold value would be unrealistic since it would lead to harvest on zero-populations.

Finally, we specify that $\delta \geq 0$ and that h is a function in $L^\infty(\Omega)$ such that

$$\exists\, \alpha > 0 \text{ with } \alpha \leq h(x) \leq 1\, \forall x \in \Omega. \tag{2.4}$$

We call h the *harvesting scalar field*, and δ designates in this way the amplitude of this field.

Before starting our analysis of this model, we consider the no-harvesting case, i.e., when $\delta = 0$. We recall the main known results in this case. These results will indeed be necessary for the analysis of the quasi-constant-yield harvesting SKT model.

2.2. The no-harvesting case. When $\delta = 0$ in (2.1), our model reduces to the SKT model described by (1.3). The behavior of the solutions of this model has been extensively studied in [8] and [9].

Results are formulated in terms of first (smallest) eigenvalue λ_1 of the Schrödinger operator $\mathcal{L}_\mu$ defined by

$$\mathcal{L}_\mu \phi := -D\nabla^2 - \mu(x)I,$$

with either periodic boundary conditions (on the period cell C) in the periodic case or Neumann boundary conditions in the bounded case. This operator is the linearized one of the full model around the trivial solution. Recall that λ_1 is defined as the unique real number such that there exists a function $\phi > 0$, the first eigenfunction, which satisfies

$$\begin{cases} -D\nabla^2\phi - \mu(x)\phi = \lambda_1\phi \quad \text{in } C, \\ \phi > 0 \quad \text{in } C, \qquad \|\phi\|_\infty = 1, \end{cases} \tag{2.5}$$

with either periodic or Neumann boundary conditions, depending on Ω. The function ϕ is uniquely defined by (2.5) [7] and belongs to $W^{2,\tau}(C)$ for all $1 \leq \tau < \infty$ (see [1] and [2] for further details). We set

$$\underline{\phi} := \min_{x \in C} \phi(x).$$

We recall that a stationary state p of (1.3) satisfies the equation

$$-D\nabla^2 p = p(\mu(x) - \nu(x)p). \tag{2.6}$$

The following result on the stationary states of (2.6) is proved in [8].

Theorem 2.2. (i) *If* $\lambda_1 < 0$, *then* (2.6) *admits a unique nonnegative*, *nontrivial*, *and bounded solution*, p_0.

(ii) *If* $\lambda_1 \geq 0$, *the only nonnegative and bounded solution of* (2.6) *is* 0.

Moreover, in the periodic case, the solution p_0 is L-periodic. Throughout this paper, p_0 always denotes the stationary solution given by Theorem 2.2.i.

In order to emphasize that this solution can be "far" from 0 (see Definition 2.5 and the commentary following (2.10)), we give a lower bound for p_0.

Proposition 2.3. *Assume that* $\lambda_1 < 0$; *then* $p_0 \geq \frac{-\lambda_1 \underline{\phi}}{\overline{\nu}}$ *in* Ω.

The asymptotic behavior of the solutions of (1.3) is also detailed in [8]. It is proved that $\lambda_1 < 0$ is a necessary and sufficient condition for species persistence, whatever the initial population u^0 is, as follows.

THEOREM 2.4. *Let u^0 be an arbitrary bounded and continuous function in Ω such that $u^0 \geq 0$, $u^0 \not\equiv 0$. Let $u(t,x)$ be the solution of* (1.3), *with initial datum $u(0,x) = u^0(x)$.*

(i) *If $\lambda_1 < 0$, then $u(t,x) \to p_0(x)$ in $W^{2,\tau}_{loc}(\Omega)$ for all $1 \leq \tau < \infty$ as $t \to +\infty$ (uniformly in the bounded case).*

(ii) *If $\lambda_1 \geq 0$, then $u(t,x) \to 0$ uniformly in Ω as $t \to +\infty$.*

The situation (i) corresponds to persistence, while in the case (ii) the population tends to extinction. In what follows, unless otherwise specified, we therefore always assume that $\lambda_1 < 0$, so that the population survives, at least when there is no harvesting. We are now in position to start our main analysis of steady states and related asymptotic behavior of the solutions of (2.1).

2.3. Stationary states analysis. As is classically demonstrated in finite dimensional dynamical systems theory and many problems in the infinite dimensional setting (see, e.g., [39]), the asymptotic behavior of the solutions of (2.1) is governed in part by the steady states and their relative stability properties. In that respect, we study in this section the positive stationary solutions of (2.1), namely the solutions of

$$-D\nabla^2 p_\delta = p_\delta(\mu(x) - \nu(x)p_\delta) - \delta h(x)\rho_\varepsilon(p_\delta), \quad x \in \Omega, \tag{2.7}$$

in the periodic and bounded cases. When needed, we may write $(2.7, \delta)$ instead of (2.7).

Note that, provided $p_\delta \geq \varepsilon$ in Ω, p_δ is equivalently a solution of the simpler equation

$$-D\nabla^2 p_\delta = p_\delta(\mu(x) - \nu(x)p_\delta) - \delta h(x), \quad x \in \Omega. \tag{2.8}$$

This last equation has been analyzed in the case of Dirichlet boundary conditions in [29], in the particular case of constant coefficients μ and ν.

Because of the type of harvesting function considered here, we are led to introduce the following definition.

DEFINITION 2.5. *Set $\varepsilon_0 := \frac{\varepsilon}{\underline{\phi}} \geq \varepsilon$. We say that a nonnegative function σ is* remnant *whenever $\max_C \sigma < \varepsilon_0$, whereas it is* significant *if it is a bounded function satisfying $\min_C \sigma \geq \varepsilon_0$.*

Remark 1. The concepts of remnant and significant solutions, as well as the harvesting term $\delta h(x)\rho_\varepsilon(u)$, are not classical. In order to clarify these notions, we present in Figure 1 a short graphical study of the nonspatial model

$$\frac{dU}{dt} = U(\mu - \nu U) - \delta\rho_\varepsilon(U) =: k(U), \quad t \in \mathbb{R}_+, \tag{2.9}$$

with constant coefficients $\mu, \nu > 0$.

Since ε_0 is assumed to be small in our model, the remnant solutions of (2.7) correspond to very low population densities. On the other hand, significant solutions are everywhere above ε_0. In particular, a constant yield is ensured in that case. In contrast to the ODE case, stationary solutions which are neither remnant nor significant may exist, as outlined in the next theorems. However, as we will see while studying the long-time behavior of the solutions of the model (2.1), they are of less importance (see Theorem 2.11 and section 3). The threshold ε_0 is different from ε

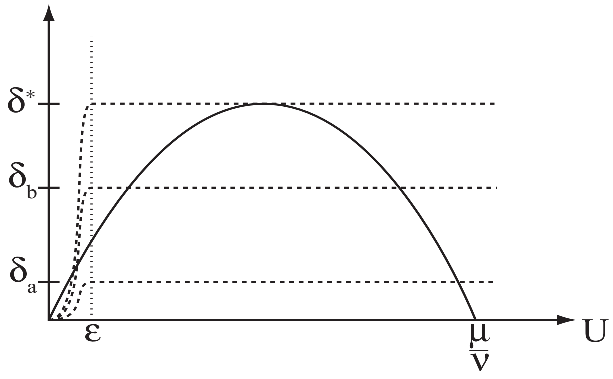

FIG. 1. *The logistic growth function $U \mapsto U(\mu - \nu U)$ (solid line), and the harvesting function $U \mapsto \delta\rho_\varepsilon(U)$ for three values of δ (dashed lines). The abscissae of the points of intersection of the solid and dashed lines correspond, respectively, to remnant (if smaller than ε) and significant (if strictly larger than ε) stationary solutions of* (2.9). *We observe that the number of significant solutions is as follows: one if $\delta < k(\varepsilon)$ (case $\delta = \delta_a$); two if $k(\varepsilon) \le \delta < \mu^2/(4\nu)$ (case $\delta = \delta_b$); one if $\delta = \mu^2/(4\nu)$ (case $\delta = \delta^*$); zero if $\delta > \mu^2/(4\nu)$. The number of nonzero remnant solutions is zero or more if $\delta \le k(\varepsilon)$ (depending on the shape of ρ_ε); one or more if $\delta > k(\varepsilon)$, since, from* (2.3), *$\rho'_\varepsilon(0) = 0$. We assumed here that $\varepsilon_0 = \varepsilon$.*

in general. We had to define remnant and significant functions using ε_0 for technical reasons (see the proof of Theorem 2.10.ii, equation (2.27)). Since ε is assumed to be very small, it has no implication on the biological interpretation of our results. Moreover, most of our results still work when ε_0 is replaced by ε.

Let us now start our analysis of (2.7). In what follows, we always assume that

$$\varepsilon_0 < \frac{-\lambda_1 \underline{\phi}}{4\overline{\nu}}, \tag{2.10}$$

so that, in particular, from Proposition 2.3, the solution p_0 of (2.6) is significant.

We begin by proving that there exists a threshold δ^* such that, if the amplitude δ is below δ^*, (2.7) admits significant solutions, while it does not in the other case.

THEOREM 2.6. *Assume that $\lambda_1 < 0$; then there exists $\delta^* \ge 0$ such that*

(i) *if $\delta \le \delta^*$, there exists at least a positive significant solution $p_\delta \le p_0$ of* (2.7);

(ii) *if $\delta > \delta^*$, there is no positive significant solution of* (2.7).

Remark 2. There is no positive bounded solution of (2.7) whenever $\lambda_1 \ge 0$.

Under stronger hypotheses, we are able to prove that (2.7) admits *at most* two significant solutions. In order to state this result, we need some definitions. Let G be the space defined by

$$G := H^1(C) \tag{2.11}$$

in the bounded case, and by

$$G := H^1_{per} = \left\{\psi \in H^1_{loc}(\mathbb{R}^N) \text{ such that } \psi \text{ is L-periodic}\right\} \tag{2.12}$$

in the periodic case. Let us define the standard Rayleigh quotient: for all $\psi \in G$, $\psi \not\equiv 0$, and for all $\sigma \in L^\infty(C)$,

$$\mathcal{R}_\sigma(\psi) := \frac{\int_C D|\nabla\psi|^2 - \sigma(x)\psi^2}{\int_C \psi^2}. \tag{2.13}$$

According to the Courant–Fischer theorem (see, e.g., [6]), the second smallest eigenvalue λ_2 of the operator $\mathcal{L}_\mu$ can be characterized by

$$\lambda_2 = \min_{E_k \subset G, \dim(E_k)=2} \max_{\psi \in E_k,\ \psi \not\equiv 0} \mathcal{R}_\mu(\psi). \tag{2.14}$$

This characterization is equivalent to the classical one given in [18].

We are now in position to state the following theorem.

Theorem 2.7. *Assume that* $\lambda_1 < 0 \leq \lambda_2$; *then, in the bounded case,* (2.7) *admits at most two significant solutions. In the periodic case,* (2.7) *admits at most two* L'*-periodic significant solutions for all* $L' \in (0, +\infty)^N$. *Moreover, under these hypotheses, if two solutions* $p_{1,\delta}$ *and* $p_{2,\delta}$ *exist, they are ordered in the sense that, for instance,* $p_{1,\delta} < p_{2,\delta}$ *in* Ω.

Remark 3. Similar methods also allow us to assess a result on the number of solutions of (2.8). Indeed, if $\lambda_1 < 0 \leq \lambda_2$, then we obtain that (2.8) admits at most two nonnegative bounded (and periodic in the periodic case) solutions. If these solutions exist, they are ordered.

In the periodic case, Theorem 2.7 also gives some information on the periodicity of the significant solutions of (2.7), which are actually found to have the same periodicity as the coefficients of (2.7), as seen in the next result.

Corollary 2.8. *Assume that* $\lambda_1 < 0 \leq \lambda_2$. *Then, in the periodic case, the significant periodic solutions of* (2.7) *are L-periodic.*

The fact that $\lambda_1 < 0$ is directly related to the instability of the trivial solution in the SKT model. The additional condition $\lambda_2 \geq 0$ in this theorem is linked to the existence of a stable manifold or center manifold of the steady state 0 of the SKT model, in some appropriate functional spaces (see [39]). Therefore, the assumptions of Theorem 2.7, and the Krein Rutmann theory, allow us to conclude that under these assumptions the unstable manifold of 0 is of dimension equal to *one* or equivalently the stable manifold is of codimension 1. Such results on multiplicity of solutions of elliptic nonlinear equations with a source or sink term have been investigated in the past and are known nowadays as being of Ambrosetti-problem type. These results also involve manifolds of codimension 1 (in the functional space of forcing) and first and second eigenvalues (for the Laplace operator only) (see [27] for a survey of these results).

In any event, Theorem 2.7 relies on the assumption that $\lambda_2 \geq 0$. In the next proposition, we give conditions under which λ_2 may become positive.

Proposition 2.9. (i) *In the bounded case, if C is a (smooth) domain with diameter* $d := \max_{x,y \in C} \|x - y\|_{\mathbb{R}^N}$, $\lambda_2(C) \geq D(\frac{\pi}{d})^2 - \max_C \mu$.

(ii) *In the periodic case,* $\lambda_2(C) \geq D(\frac{\pi}{L_d})^2 - \max_C \mu$, *where* L_d *denotes the length of the longest diagonal of the period cell* C.

For instance, when $C = [0,1] \times [0,1]$, we have $d = L_d = \sqrt{2}$; thus, for $D = 1$ and $\max_C \mu = 4$, we get $\lambda_2 > 0.9$. However, this lower bound is far from being optimal. Indeed, in all our computations of section 3, and under the same hypothesis on C and D, we always had $\lambda_2 > 0$, while $\max_C \mu = 10$. Sharper lower bounds for λ_2 can be found in [11]; however, those bounds are also more sensitive to the geometry of the domain and thus less general. They are therefore not detailed here.

We now introduce a result which is important for more applied ecological questions. Indeed, one of the main drawbacks of Theorem 2.6 is that it gives no computable bound for δ^*. Obtaining information on the value of δ^* is precious for ecological questions such as the study of the relationships between δ^* and the environmental heterogeneities. The next theorem states some computable estimates of δ^*.

Let us define

$$\delta_1 := \frac{\lambda_1^2 \underline{\phi}}{\overline{\nu}(1+\underline{\phi})^2} \quad \text{and} \quad \delta_2 := \frac{\lambda_1^2}{4\alpha\underline{\nu}}. \tag{2.15}$$

Note that neither δ_1 nor δ_2 depend on δ and ε.

THEOREM 2.10. (i) *If $\lambda_1 < 0$ and $\delta \leq \delta_1$, then there exists a positive significant (and L-periodic in the periodic case) solution p_δ of* (2.7) *such that $p_\delta \geq -\frac{\lambda_1 \underline{\phi}}{\overline{\nu}(1+\underline{\phi})}$.*

(ii) *If $\lambda_1 < 0$ and $\delta > \delta_2$, the only possible positive bounded solutions of* (2.7) *are remnant.*

The lower bound of part (i), for p_δ, does not depend on ε. Thus, there is a clear distinction between the remnant and significant solutions. Note that, of course, $\delta_1 \leq \delta_2$.

The formulae (2.15) allow numerical evaluations. An important quantity to compute is the size of the gap $\delta_2 - \delta_1$ and its fluctuations in terms of environmental configurations. This question is addressed in section 3 through a numerical study.

2.4. Asymptotic behavior. In this section, we prove that the quantity δ^* in fact corresponds to a maximum sustainable yield, in the sense that when δ is smaller than δ^*, the population density $u(t,x)$ converges to a significant stationary state of (2.1) as $t \to \infty$, whereas when δ is larger than δ^*, the population density converges to a stationary state which is not significant. In fact, when δ is larger than the quantity δ_2 defined by (2.15) we even prove that the population converges to a remnant stationary state of (2.1).

We assume here that the harvesting starts on a stabilized population governed by the standard SKT model with $\delta = 0$. From Theorem 2.4, this means that we study the behavior of the solutions $u(t,x)$ of our model (2.1), starting with the initial datum $u(0,x) = p_0(x)$. Since we have assumed that $\lambda_1 < 0$, it follows from Theorem 2.2, Proposition 2.3, and (2.10) that p_0 is well defined and significant.

Let us describe, with the next theorem, the long-time behavior of the population density.

THEOREM 2.11. *Let $u(t,x)$ be the solution of* (2.1) *with initial datum $u(0,x) = p_0(x)$. Then u is nonincreasing in t and the following hold:*

(i) *If $\delta \leq \delta^*$, $u(t,x) \to p_\delta(x)$ uniformly in Ω as $t \to +\infty$, where p_δ is the maximal significant solution of* (2.7). *Moreover, p_δ is L-periodic in the periodic case.*

(ii) *If $\delta > \delta^*$, then the function $u(t,\cdot)$ converges uniformly in Ω to a solution of* (2.7) *which is not significant.*

(iii) *If $\delta > \delta_2$, the function $u(t,\cdot)$ converges uniformly in Ω to a remnant solution of* (2.7).

Remark 4. If, in addition, we assume that $\lambda_2 \geq 0$, then Theorem 2.7 says that, whenever $\delta \leq \delta^*$, (2.1) admits at most two significant stationary states (which are periodic stationary states in the periodic case). In that case, the stationary state p_δ selected at large times is the higher one. If we do not assume that $\lambda_2 \geq 0$, this stationary state can still be defined as "the maximal one" that can be constructed by a sub- and supersolution method (see [3]).

From the above theorem, we observe that, whenever $\delta \leq \delta^*$, the solution $u(t,x)$ of (2.1), with initial datum p_0, remains significant for all times $t \geq 0$. This ensures a constant yield in time and justifies the name of the model.

Similar results could be obtained for a wider class of initial data. Indeed, with similar methods, the convergence of $u(t,x)$ to a significant solution of (2.7) can be obtained whenever $\delta \leq \delta^*$ for all bounded and continuous initial data $u(0,x)$ which are larger than the smallest significant solution of (2.7). In particular, when $u(0,x)$ is larger than the maximal significant solution of (2.7), $u(t,x)$ converges to this maximal significant solution as $t \to +\infty$. A more detailed analysis of the basin of attraction related to the maximal significant solution will be further investigated in the forthcoming paper [13].

Theorem 2.11 shows that the practical determination of δ^* is directly linked to the size of the gap $\delta_2 - \delta_1$. As we will see in section 3, this gap (δ_1, δ_2) can be very narrow in certain situations. In those cases, the numerical computation of δ_1 and δ_2 therefore gives a sharp localization of the maximum sustainable quota $\delta^* \in [\delta_1, \delta_2]$, which can be of nonnegligible ecological interest.

2.5. Proofs of the results of section 2.

Proof of Proposition 2.3. Let ϕ be defined by (2.5), with the appropriate boundary conditions. Set $\kappa_0 := \frac{-\lambda_1}{\nu}$. Then the function $\kappa_0\phi$ satisfies

$$\begin{aligned}-D\nabla^2(\kappa_0\phi) - \mu(x)\kappa_0\phi + \nu(x)(\kappa_0\phi)^2 &= \lambda_1\kappa_0\phi + \nu(x)(\kappa_0\phi)^2 \\ &= \kappa_0\phi(\lambda_1 + \nu(x)\kappa_0\phi) \leq 0.\end{aligned}$$

Thus $\kappa_0\phi$ is a subsolution of (2.6) satisfied by p_0. Since for $M \in \mathbb{R}$ large enough M is a supersolution of (2.6), it follows from the uniqueness of the positive bounded solution p_0 of (2.6) that $p_0 \geq \kappa_0\phi \geq \frac{-\lambda_1\phi}{\nu}$. □

Before proving Theorem 2.6, we begin with the following lemma.

LEMMA 2.12. *For all $\delta > 0$, if p_δ is a nonnegative bounded solution of* (2.7), *then* $p_\delta \leq p_0$.

Proof of Lemma 2.12. Assume that there exists $x_0 \in \Omega$ such that $p_\delta(x_0) > p_0(x_0)$. The function p_δ satisfies

$$-D\nabla^2 p_\delta - p_\delta(\mu(x) - \nu(x)p_\delta) = -\delta h(x)\rho_\varepsilon(p_\delta) \leq 0,$$

and thus p_δ is a subsolution of (2.6) satisfied by p_0. Since for $M \in \mathbb{R}$ large enough M is a supersolution of (2.6), we can apply a classic iterative method to infer the existence of a solution p_0' of (2.6) (with Neumann boundary conditions in the bounded case since both p_δ and M satisfy Neumann boundary conditions) such that $p_\delta \leq p_0' \leq M$. In particular, $p_0'(x_0) > p_0(x_0)$, which is in contradiction with the uniqueness of the positive bounded solution of (2.6). □

Proof of Theorem 2.6. Let us define

$$\delta^* := \sup\{\delta \geq 0, (2.7) \text{ admits a significant solution}\}.$$

For $\delta = 0$, we know from Proposition 2.3 that p_0 is a significant solution of (2.7). Moreover, for δ large enough, the nonexistence of significant solutions of (2.7) is a direct consequence of the maximum principle (it is also a consequence of the proof of Theorem 2.10.ii). Thus δ^* is well defined and bounded.

Assume that $\delta^* > 0$, and let us prove that $(2.7, \delta^*)$ admits a significant solution. By definition of δ^*, there exists a sequence $(p_{\delta_k})_{k\in\mathbb{N}}$ of solutions of $(2.7, \delta_k)$ with $0 < \delta_k \leq \delta^*$ and $\delta_k \to \delta^*$ as $k \to +\infty$. Moreover, from Lemma 2.12, $\varepsilon_0 \leq p_{\delta_k} \leq p_0$ for all $k \geq 0$. Thus, from standard elliptic estimates and Sobolev injections, the sequence $(p_{\delta_k})_{k\in\mathbb{N}}$ converges (up to the extraction of some subsequence) in $W^{2,\tau}_{loc}$, for all $1 \leq \tau < \infty$, to a significant solution p_{δ^*} of $(2.7, \delta^*)$.

Now, let $0 \leq \delta < \delta^*$. Then

$$-D\nabla^2 p_{\delta^*} - p_{\delta^*}(\mu(x) - \nu(x)p_{\delta^*}) + \delta h(x) = (\delta - \delta^*)h(x) < 0,$$

and thus p_{δ^*} is a subsolution of $(2.7, \delta)$. Since p_0 is a supersolution of $(2.7, \delta)$, and $p_{\delta^*} \leq p_0$, a classical iterative method gives the existence of a significant solution p_δ of $(2.7, \delta)$ (with Neumann boundary conditions in the bounded case since both p_0 and p_δ satisfy Neumann boundary conditions). This concludes the proof of Theorem 2.6. □

Proof of Theorem 2.7. As a preliminary, we prove that if two solutions exist, then they cannot intersect. Let $p_{1,\delta}$ and $p_{2,\delta}$ be two significant solutions of (2.7). In the bounded case, we assume that $p_{1,\delta}$ and $p_{2,\delta}$ satisfy Neumann boundary conditions. In the periodic case, we assume that there exists $\mathrm{L}' \in (0, +\infty)^N$ such that $p_{1,\delta}$ and $p_{2,\delta}$ are L'-periodic, and then denote the period cell by C'. Let us set $q_\delta := p_{2,\delta} - p_{1,\delta}$. Then q_δ verifies

$$-D\nabla^2 q_\delta - [\mu(x) - \nu(x)(p_{1,\delta} + p_{2,\delta})]q_\delta = 0; \tag{2.16}$$

thus, setting $\rho(x) := \mu(x) - \nu(x)(p_{1,\delta} + p_{2,\delta})$, we obtain

$$-D\nabla^2 q_\delta - \rho(x)q_\delta = 0, \tag{2.17}$$

with the same boundary conditions that were satisfied by $p_{1,\delta}$ and $p_{2,\delta}$.

Let $\widehat{\lambda_1}$ and $\widehat{\lambda_2}$ be respectively the first and second eigenvalues of the operator $\mathcal{L}_\rho := -D\nabla^2 - \rho I$. Let $\mathcal{R}_\sigma(\phi)$, be defined by (2.13). Since $\rho(x) < \mu(x) - 2\underline{\nu}\varepsilon_0$ for all $x \in \Omega$, we get

$$\mathcal{R}_\rho(\varphi) \geq \mathcal{R}_\mu(\varphi) + 2\underline{\nu}\varepsilon_0$$

for all $\varphi \in G'$, where $G' := H^1(C)$ in the bounded case and

$$G' := H^1_{per} = \left\{\varphi \ \in \ H^1_{loc}(\mathbb{R}^N) \text{ such that } \varphi \text{ is L}'\text{-periodic}\right\}$$

in the periodic case. Thus, by the classical min-max formula (2.14), it follows that

$$\widehat{\lambda_2} \geq \lambda_2 + 2\underline{\nu}\varepsilon_0 > 0. \tag{2.18}$$

Furthermore, from (2.17), 0 is an eigenvalue of the operator $\mathcal{L}_\rho$. Thus, (2.18) implies that $\widehat{\lambda_1} = 0$. As a consequence, q_δ is a principal eigenfunction of the operator $\mathcal{L}_\rho$. The principal eigenfunction characterization thus implies that q_δ has a constant sign. Finally, we get that $p_{1,\delta}$ and $p_{2,\delta}$ do not intersect each other.

Let us now prove that (2.7) admits at most two significant solutions. Arguing by contradiction, we assume that there exist three significant (L'-periodic in the periodic case, for some $\mathrm{L}' \in (0, +\infty)^N$) solutions $p_{1,\delta}$, $p_{2,\delta}$, and $p_{3,\delta}$ of (2.7). From the above result, we may assume, without loss of generality, that $p_{3,\delta} > p_{2,\delta} > p_{1,\delta} > \varepsilon_0$. Set $q_{2,1} := p_{2,\delta} - p_{1,\delta}$ and $q_{3,2} := p_{3,\delta} - p_{2,\delta}$; then these functions satisfy the equations

$$-D\nabla^2 q_{2,1} - \rho_{2,1}(x)q_{2,1} = 0 \tag{2.19}$$

and

$$-D\nabla^2 q_{3,2} - \rho_{3,2}(x)q_{3,2} = 0, \tag{2.20}$$

with $\rho_{2,1} := \mu(x) - \nu(x)(p_{1,\delta} + p_{2,\delta})$ and $\rho_{3,2} := \mu(x) - \nu(x)(p_{2,\delta} + p_{3,\delta})$. Moreover, $q_{2,1} > 0$ and $q_{3,2} > 0$. Thus 0 is the first eigenvalue of the operators $\mathcal{L}_{\rho_{2,1}} := -D\nabla^2 - \rho_{2,1}I$ and $\mathcal{L}_{\rho_{3,2}} := -D\nabla^2 - \rho_{3,2}I$ with either Neumann or L′-periodic boundary conditions.

From the strong maximum principle (see, e.g., [18]) (together with Hopf's lemma in the bounded case, and using the L′-periodicity of $q_{3,2}$ in the periodic case), we obtain the existence of $\theta > 0$ such that $q_{3,2} > \theta$. Since the operator $\mathcal{L}_{\rho_{3,2}}$ is self-adjoint, we have the following formula for its first eigenvalue $\widehat{\lambda_1}^{3,2}$:

$$\widehat{\lambda_1}^{3,2} = \min_{\varphi \in G'} \mathcal{R}_{\rho_{3,2}}(\varphi).$$

Thus

$$\begin{aligned}\widehat{\lambda_1}^{3,2} = \min_{\varphi \in G'} \left\{ \mathcal{R}_{\rho_{2,1}}(\varphi) + \frac{\int_C \nu(p_{3,\delta} - p_{1,\delta})\varphi^2}{\int_C \varphi^2} \right\} &\geq \min_{\varphi \in G'} \left\{ \mathcal{R}_{\rho_{2,1}}(\varphi) \right\} + \underline{\nu}\theta \\ &\geq \widehat{\lambda_1}^{2,1} + \underline{\nu}\theta,\end{aligned}$$

where $\widehat{\lambda_1}^{2,1}$ is the first eigenvalue of the operator $\mathcal{L}_{\rho_{2,1}}$. Since the first eigenvalues of the operators $\mathcal{L}_{\rho_{2,1}}$ and $\mathcal{L}_{\rho_{3,2}}$ are both 0, we deduce that $0 \geq 0 + \underline{\nu}\theta > 0$, hence a contradiction. □

Proof of Corollary 2.8. Let p_δ be a significant L′-periodic solution of (2.7), and let $k \in \prod_{i=1}^N L_i\mathbb{Z}$. From the L-periodicity of (2.7), $p_\delta(\cdot + k)$ is also a solution of (2.7). By periodicity of p_δ, the functions p_δ and $p_\delta(\cdot + k)$ intersect each other. Thus, from Theorem 2.7, since p_δ and $p_\delta(\cdot + k)$ are both L′-periodic, $p_\delta \equiv p_\delta(\cdot + k)$. Therefore, p_δ is an L-periodic function. □

Proof of Proposition 2.9. In the bounded case, let $\tilde{C}$ be the convex hull of the set C. It was proved in [30] that the second Neumann eigenvalue of the Laplace operator $-D\nabla^2$ on $\tilde{C}$ was larger than $D(\frac{\pi}{d})^2$. Since $C \subset \tilde{C}$, we have $H^1(C) \subset H^1(\tilde{C})$. Using formula (2.14), we thus obtain that the second eigenvalue of $\mathcal{L}_\mu$ in the bounded case satisfies $\lambda_2 \geq D(\frac{\pi}{d})^2 - \max_C \mu$. This proves part (i) of Proposition 2.9.

In the periodic case, since H^1_{per} can be seen as a subset of $H^1(C)$, it follows from (2.14) that

$$\lambda_2 \geq \min_{E_k \subset H^1(C), \dim(E_k)=2} \ \max_{\psi \in E_k,\ \psi \not\equiv 0} \mathcal{R}_\mu(\psi). \tag{2.21}$$

The period cell C is convex but not smooth enough to assert that the right-hand side of (2.21) is equal to the second eigenvalue in the bounded case. Let L_d be the longest diagonal of C. Then C is included in a ball B_{L_d} of diameter L_d. Thus, from formula (2.14), the right-hand side of (2.21) is larger than the second eigenvalue of $\mathcal{L}_\mu$ on B_{L_d}. From (i), the conclusion of (ii) follows. □

Proof of Theorem 2.10*, part* (i). Let λ_1 and ϕ be defined by (2.5), and let κ be a nonnegative real number such that $\kappa > \varepsilon_0$. Then we have

$$\begin{aligned}-D\nabla^2(\kappa\phi) - \kappa\phi(\mu(x) - \kappa\phi\nu(x)) + \delta h(x)\rho_\varepsilon(\kappa\phi) &\leq \lambda_1\kappa\phi + \kappa^2\phi^2\nu(x) + \delta \\ &\leq \kappa\phi(\lambda_1 + \kappa\phi\nu(x)) + \delta \\ &\leq \max_{\tau \in I}\{\tau(\lambda_1 + \tau\overline{\nu})\} + \delta,\end{aligned} \tag{2.22}$$

where $I = \{\kappa\phi(x),\, x \in C\}$. Setting $g(\tau) := \tau(\lambda_1 + \tau\overline{\nu})$, since $\|\phi\|_\infty = 1$, and since g is a convex function, it follows from (2.22) that

$$-D\nabla^2(\kappa\phi) - \kappa\phi(\mu(x) - \kappa\phi\nu(x)) + \delta h(x)\rho_\varepsilon(\kappa\phi) \leq \max\{g(\kappa), g(\kappa\underline{\phi})\} + \delta. \tag{2.23}$$

Let us take κ_0 be such that $g(\kappa_0) = g(\kappa_0\underline{\phi})$, namely $\kappa_0 = -\frac{\lambda_1}{\underline{\nu}(1+\underline{\phi})}$ (note that $\kappa_0\phi > \varepsilon$). We get

$$-D\nabla^2(\kappa_0\phi) - \kappa_0\phi(\mu(x) - \kappa_0\phi\nu(x)) + \delta h(x) \leq -\frac{\lambda_1^2\underline{\phi}}{\underline{\nu}(1+\underline{\phi})^2} + \delta \leq 0, \tag{2.24}$$

from the hypothesis on δ of Theorem 2.10.i. Therefore, $\kappa_0\phi$ is a subsolution of (2.7) with either L-periodic or Neumann boundary conditions. Moreover, if M is a large enough constant, M is a supersolution of (2.7) with L-periodic or Neumann boundary conditions. Thus, it follows from a classical iterative method that there exists a solution $\underline{p_\delta}$ of (2.7), with the required boundary conditions, and which satisfies $\kappa_0\phi \leq \underline{p_\delta \leq M}$ in Ω. Moreover, in the periodic case, since $\kappa_0\phi$ and M are L-periodic and since (2.7) is also L-periodic, it follows that p_δ is L-periodic. Theorem 2.10.i is proved. □

Proof of Theorem 2.10, *part* (ii). Assume that $\lambda_1 < 0$, $\delta > \delta_2$, and that there exists a positive bounded solution p_δ of (2.7) which is not remnant; i.e.,

$$\exists\ x_0 \text{ with } p_\delta(x_0) \geq \varepsilon_0. \tag{2.25}$$

Since ϕ is bounded from below away from 0 and p_δ is bounded, we can define

$$\gamma^* = \inf\{\gamma > 0,\ \gamma\phi > p_\delta \text{ in } \Omega\} > 0. \tag{2.26}$$

It follows from the definition of γ^* that $\gamma^*\phi \geq p_\delta$ in Ω, and in particular, $\gamma^*\phi(x_0) \geq p_\delta(x_0) \geq \varepsilon_0$. Since $\|\phi\|_\infty = 1$, we get $\gamma^* \geq \varepsilon_0$. Thus,

$$\gamma^*\phi \geq \varepsilon_0\underline{\phi} = \varepsilon, \tag{2.27}$$

which implies $\rho_\varepsilon(\gamma^*\phi) = 1$. Thus, $h(x)\rho_\varepsilon(\gamma^*\phi) \geq \alpha$, and we get

$$-D\nabla^2(\gamma^*\phi) - \gamma^*\phi(\mu(x) - \gamma^*\phi\nu(x)) + \delta h(x)\rho_\varepsilon(\gamma^*\phi) \geq \gamma^*\phi(\lambda_1 + \gamma^*\phi\nu(x)) + \delta\alpha$$

on Ω. Moreover, since $\gamma^*\phi > 0$ and $\nu \geq \underline{\nu}$, we have $\gamma^*\phi(\lambda_1 + \gamma^*\phi\nu(x)) \geq -\frac{\lambda_1^2}{4\underline{\nu}}$. Using the fact that $\delta > \delta_2 = \frac{\lambda_1^2}{4\alpha\underline{\nu}}$, we thus get

$$-D\nabla^2(\gamma^*\phi) - \gamma^*\phi(\mu(x) - \gamma^*\phi\nu(x)) + \delta h(x)\rho_\varepsilon(\gamma^*\phi) \geq -\frac{\lambda_1^2}{4\underline{\nu}} + \delta\alpha > 0 \tag{2.28}$$

on Ω. Therefore, $\gamma^*\phi$ is a supersolution of (2.7). Set $z := \gamma^*\phi - p_\delta$. From the definition of γ^*, we know that $z \geq 0$ and that there exists a sequence $(x_n)_{n\in\mathbb{N}}$ in Ω such that $z(x_n) \to 0$ as $n \to +\infty$.

In the bounded case, up to the extraction of some subsequence, $x_n \to \overline{x} \in \Omega$ as $n \to +\infty$. By continuity, $z(\overline{x}) = 0$. Moreover, subtracting (2.7) from (2.28), we get

$$-D\nabla^2 z + [\nu(x)(\gamma^*\phi + p_\delta) + \chi(x) - \mu(x)]z > 0 \quad \text{in } \Omega, \tag{2.29}$$

where the function χ is defined by $\chi(x) = \delta h(x)\frac{\rho_\varepsilon(\gamma^*\phi(x)) - \rho_\varepsilon(p_\delta(x))}{\gamma^*\phi(x) - p_\delta(x)}$ whenever $\gamma^*\phi(x) - p_\delta(x) \neq 0$, and $\chi(x) = \rho_\varepsilon'(p_\delta(x))$ otherwise. Since ρ_ε is C^1, χ is bounded. Thus $b(x) := \nu(x)(\gamma^*\phi + p_\delta) + \chi(x) - \mu(x)$ is a bounded function. Using the strong elliptic maximum principle, we deduce from (2.29) that $z \equiv 0$. Thus $\gamma^*\phi \equiv p_\delta$ is a positive solution of (2.7). It is in contradiction with (2.28).

In the periodic case, we must also consider the situation where the sequence $(x_n)_{n\in\mathbb{N}}$ is not bounded. Let $(\overline{x}_n) \in \overline{C}$ be such that $x_n - \overline{x}_n \in \prod_{i=1}^N L_i\mathbb{Z}$. Up to the extraction of some subsequence, we can assume that there exists $\overline{x}_\infty \in \overline{C}$ such that $\overline{x}_n \to \overline{x}_\infty$ as $n \to +\infty$. Set $\phi_n(x) = \phi(x + x_n)$ and $p_{\delta,n}(x) = p_\delta(x + x_n)$. From standard elliptic estimates and Sobolev injections, it follows that (up to the extraction of some subsequence) $p_{\delta,n}$ converge in $W^{2,\tau}_{loc}$, for all $1 \leq \tau < \infty$, to a function $p_{\delta,\infty}$ satisfying

$$-\nabla^2(Dp_{\delta,\infty}) - p_{\delta,\infty}(\mu(x + \overline{x}_\infty) - p_{\delta,\infty}\nu(x + \overline{x}_\infty)) + \delta h(x + \overline{x}_\infty)\rho_\varepsilon(p_{\delta,\infty}) = 0$$

in $\mathbb{R}^N$, while $\gamma^*\phi_n$ converges to $\gamma^*\phi_\infty := \gamma^*\phi(\cdot + \overline{x}_\infty)$, and

$$-\nabla^2(D\gamma^*\phi_\infty) - \gamma^*\phi_\infty(\mu(x + \overline{x}_\infty) - \gamma^*\phi_\infty\nu(x + \overline{x}_\infty)) + \delta h(x + \overline{x}_\infty)\rho_\varepsilon(\gamma^*\phi_\infty) > 0$$

in $\mathbb{R}^N$. Let us set $z_\infty(x) := \gamma^*\phi_\infty(x) - p_{\delta,\infty}(x)$. Then $z_\infty(x) = \lim_{n\to+\infty} z(x + x_n)$, and therefore $z_\infty \geq 0$ and $z_\infty(0) = 0$. Moreover, there exists a bounded function b_∞ such that

$$-D\nabla^2 z_\infty + b_\infty z_\infty > 0 \quad \text{in } \mathbb{R}^N. \tag{2.30}$$

It then follows from the strong maximum principle that $z_\infty \equiv 0$, and we again obtain a contradiction. Finally, we necessarily have $p_\delta \leq \varepsilon_0$, and the proof of Theorem 2.10.ii is complete. □

Proof of Theorem 2.11, *part* (i). Assume that $\delta \leq \delta^*$. Let p_δ be the unique maximal significant solution defined in the proof of Theorem 2.10.i. Then, from Lemma 2.12,

$$p_\delta(x) \leq p_0(x) = u(0, x) \quad \forall x \in \Omega, \tag{2.31}$$

which implies

$$p_\delta(x) \leq u(t, x) \quad \text{in } \mathbb{R}_+ \times \Omega, \tag{2.32}$$

since p_δ is a stationary solution of (2.1). Moreover, since p_0 is a supersolution of (2.7), u is nonincreasing in time t, and standard parabolic estimates imply that u converges in $W^{2,\tau}_{loc}(\Omega)$, for all $1 \leq \tau < \infty$, to a bounded stationary solution u_∞ of (2.1). Furthermore, from (2.32) we deduce that $p_\delta \leq u_\infty \leq p_0$. Since p_δ is the maximal positive solution of (2.7), it follows that $u_\infty \equiv p_\delta$. Moreover, in the periodic case, since p_0 and (2.1) are L-periodic, $u(t, x)$ is also L-periodic in x. Therefore the convergence is uniform in Ω. Part (i) of Theorem 2.11 is proved. □

Proof of Theorem 2.11, *parts* (ii) *and* (iii). Assume that $\delta > \delta^*$. Since 0 is a stationary solution of (2.1) and $u(0, x) = p_0 > 0$, we obtain that $u(t, x) > 0$ in $\mathbb{R}^+ \times \Omega$, and again, from standard parabolic estimates, we know that u converges in $W^{2,\tau}_{loc}(\Omega)$ (for all $1 \leq \tau < \infty$) to a bounded stationary solution $\underline{u_\infty} \geq 0$ of (2.1) as $t \to +\infty$. Moreover, in the periodic case, from the L-periodicity of the initial data and of (2.1), we know that $u(t, \cdot)$ and $\underline{u_\infty}$ are L-periodic. Therefore the convergence is uniform in Ω. It follows from Theorem 2.6.ii that $\underline{u_\infty}$ cannot be a significant solution of (2.7). Moreover, if $\delta > \delta_2$, Theorem 2.10.ii ensures that $\underline{u_\infty}$ is a remnant solution of (2.7). □

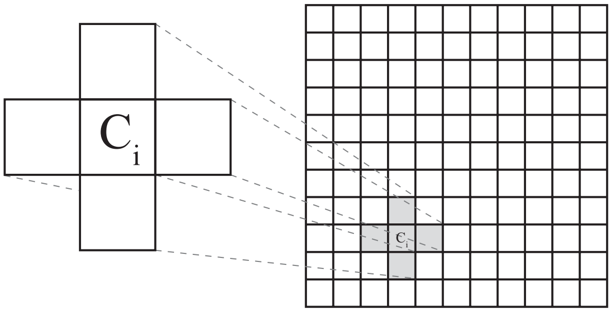

FIG. 2. *The* 4*-neighborhood system*: *an element* C_i *of* C *and its four neighbors.*

3. Numerical investigation of the effects of environmental fragmentation. We propose here to apply the results of section 2, on the estimation of the maximum sustainable yield, to the study of the effects of environmental fragmentation. A theoretical investigation of the relationships between maximum sustainable yield and fragmentation is difficult to achieve (see Remark 5). To overcome this difficulty, we propose a numerical study in the case of stochastic environments. First, we show that the gap $\delta_2 - \delta_1$, obtained from (2.15) and Theorem 2.10, remains small whatever the degree of fragmentation is. This gap corresponds to the numerical values of the harvesting quota δ for which we do not know whether the population density will converge to a significant or a remnant solution of the stationary equation (2.7). Second, we show that there is a monotone increasing relationship between the maximal sustainable yield δ^* and the habitat aggregation.

Remark 5. In a periodic environment, a simple way of changing the degree of fragmentation without changing the relative spatial pattern (favorable area/unfavorable area ratio) is to modify the size of the period cell C. Assume that $\mu(x) = \eta(\frac{x}{L})$, for some 1-periodic function η with positive integral and for some $L > 0$. This means that the environment consists of square cells of side L. Setting $\lambda_{1,L} := \lambda_1$ and $\phi_L := \phi$, we then have $-D\Delta\phi_L - \eta\left(\frac{x}{L}\right)\phi_L = \lambda_{1,L}\phi_L$ on $[0,L]^N$. The function $\psi_L(x) := \phi_L(Lx)$ thus satisfies $-D\Delta\psi_L - L^2\eta(x)\psi_L = L^2\lambda_{1,L}\psi_L$ in $[0,1]^N$, with 1-periodicity. From the Rayleigh formula we thus obtain

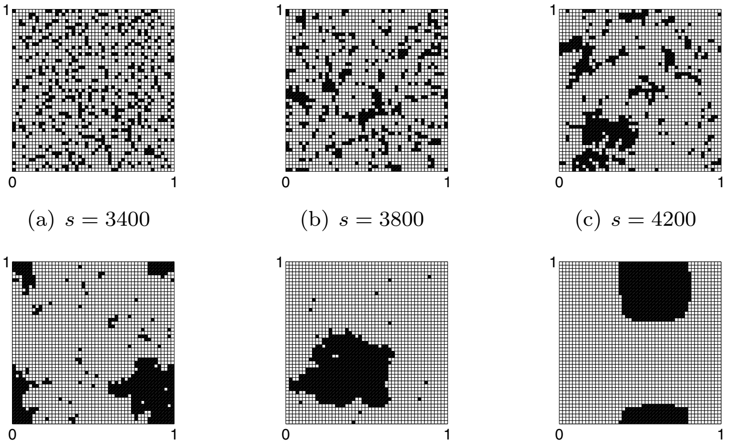
$$\lambda_{1,L} = \min_{\psi \in H^1_{per}} \frac{D}{L^2} \frac{\int_{[0,1]^N} |\nabla\psi|^2}{\int_{[0,1]^N} \psi^2} - \frac{\int_{[0,1]^N} \eta\psi^2}{\int_{[0,1]^N} \psi^2};$$

therefore $\lambda_{1,L} < 0$ (since $\psi \equiv 1 \in H^1_{per}$), and $\lambda_{1,L}$ decreases with L. It implies that δ_2 increases with L. The relationship between δ_1 and L is less clear since $\underline{\phi_L} = \min_C \phi_L$ may not always be an increasing function of L.

In order to lessen the boundary effects and to focus on fragmentation, we place ourselves in the periodic case. For our numerical computations, we assume that the environment is made of two components, favorable and unfavorable regions. This is expressed in the model (2.1) through the coefficient $\mu(x)$, which takes two values μ^+ or μ^-, depending on the space variable x. We also assume that

$$\mu^+ > \mu^-, \quad \nu(x) \equiv 1, \quad h(x) \equiv 1, \text{ and } D = 1.$$

Using a stochastic model for landscape generation [34], we built 2000 samples of binary environments, on the two-dimensional period cell $C = [0,1]^2$, with different



(a) $s = 3400$ (b) $s = 3800$ (c) $s = 4200$

(d) $s = 4600$ (e) $s = 4800$ (f) $s = 4900$

FIG. 3. *Some samples of the landscapes used for the computations of δ_1 and δ_2, with different values of the habitat aggregation index s. The black areas correspond to more favorable environment, where $\mu(x) = \mu^+$.*

degrees of fragmentation. In all these environments, the favorable region, where $\mu(x) = \mu^+$, occupies 20% of the period cell. The environmental fragmentation is defined as follows. We discretize the cell C into $n_C = 50 \times 50$ equal squares C_i. The lattice made of the cells C_i is equipped with a 4-neighborhood system $V(C_i)$ (see Figure 2), with toric conditions. On each cell C_i, we assume that the function μ takes either the value μ^+ or μ^-, while the number $n_+ = \text{card}\{i,\ \mu \equiv \mu^+ \text{ on } C_i\}$ is fixed to $n_C \times \frac{20}{100} = 500$. For each landscape sample $\omega = (\mu(C_i))_{i=1,\dots,n_C}$, we set $s(\omega) = \frac{1}{2}\sum_{C_i \subset C}\sum_{C_j \in V(C_i)} \mathbb{1}\{\mu(C_j) = \mu(C_i)\}$, the number of pairs of neighbors (C_i, C_j) such that μ takes the same value on C_i and C_j ($\mathbb{1}\{\cdot\}$ is the indicator function). The number $s(\omega)$ is directly linked to the environmental fragmentation: a landscape pattern is all the more aggregated as $s(\omega)$ is high, and all the more fragmented as $s(\omega)$ is small (Figure 3). Thus, we shall refer to s as the "habitat aggregation index."

Remark 6. There exist several ways of obtaining hypothetical landscape distributions. The commonest are neutral landscape models, originally introduced by Gardner et al. [16]. They can include parameters which regulate the fragmentation [20]. We preferred to use a stochastic landscape model presented in [34], since it allows an exact control of the favorable and unfavorable surfaces and is therefore well adapted for analyzing the effects of fragmentation per se. This model is inspired from statistical physics. The number of pairs of similar neighbors s is controlled during the process of landscape generation. This quantity can be measured a posteriori on the landscape samples. Other measures of fragmentation could have been used, such as fractal dimension (see [24]). For a discussion on the different ways of measuring habitat fragmentation in real-world situations, the interested reader can refer to [14].

For our computations, we took $\mu^+ = 10$ and $\mu^- = 0$, and we computed the corresponding values of λ_1^i, δ_1^i, and δ_2^i on each landscape sample ω^i of aggregation index s^i, for $i = 1, \dots, 2000$. The eigenvalues λ_1^i were computed with a finite elements method. We fitted the data sets $\{(s^i, \delta_1^i)\}_{i=1,\dots,2000}$ and $\{(s^i, \delta_2^i)\}_{i=1,\dots,2000}$ using ninth degree polynomials (it is enough to assess whether the relations between s and δ_1, δ_2 tend to be monotonic or not). The resulting fitted curves $\delta_{1,f}$ and $\delta_{2,f}$ are presented

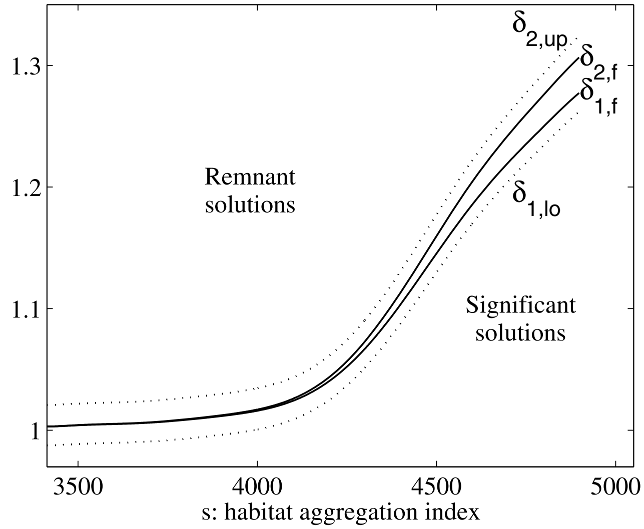


FIG. 4. *Solid lines*: $\delta_{1,f}$ *and* $\delta_{2,f}$ *correspond respectively to the data sets* $\{(s^i,\delta_1^i)\}_{i=1,\dots,2000}$ *and* $\{(s^i,\delta_2^i)\}_{i=1,\dots,2000}$, *fitted with ninth degree polynomials. Dashed lines*: $\delta_{1,lo}$ *is a lower prediction bound for new observations of* δ_1, *and* $\delta_{2,up}$ *an upper prediction bound for new observations of* δ_2, *with in both cases a certainty level of* 99%.

in Figure 4. Under the assumption of normally distributed values of δ_1 and δ_2 for fixed s values, we computed a lower prediction bound ($\delta_{1,lo}$) for new observation of δ_1 and an upper prediction bound for δ_2 ($\delta_{2,up}$), with a level of certainty of 99%. Thus, given a configuration ω, with a fixed value of s, when δ is smaller than $\delta_{1,lo}$ we take a 0.5% chance of being above δ_1, while when δ is larger than $\delta_{2,up}$ we take a 0.5% chance of being below δ_2. The small thickness of the intervals $(\delta_{1,lo},\delta_{2,up})$ emphasizes the quality of the relationship between the habitat aggregation index s and the maximum sustainable yield $\delta^* \in [\delta_1,\delta_2]$. This also indicates that the criteria of Theorems 2.10 and 2.11 are close to being optimal, at least in some situations.

Furthermore, as we can observe, the values of δ_1 and δ_2 tend to increase as s increases, and thus as the environment aggregates. Since $\delta^* \in [\delta_1,\delta_2]$, we deduce from the computations presented in Figure 4 that δ^* tends to increase with environmental aggregation.

These tests were performed for particular values of μ^+ and μ^-. However, the thickness of the interval (δ_1,δ_2) can be determined for all values of μ^+,μ^- without further numerical computations, provided that $\mu^+-\mu^-=10$. Indeed, let us set $B:=\mu^+-\mu^-$. For a fixed value of B, let $\mu_0(x)$ be a given L-periodic function in $L^\infty(\mathbb{R}^N)$ taking only the two values $\mu_0^+=B$ and $\mu_0^-=0$. Let $\lambda_{1,0}$ be the first eigenvalue of the operator $-\nabla^2-\mu_0 I$ on C, with L-periodicity conditions, ϕ_0 the associated eigenfunction with minimal value $\underline{\phi_0}$, and

$$\delta_{1,0}:=\frac{\lambda_{1,0}^2\underline{\phi_0}}{(1+\underline{\phi_0})^2} \quad \text{and} \quad \delta_{2,0}:=\frac{\lambda_{1,0}^2}{4}.$$

We have the following proposition.

PROPOSITION 3.1. *Assume that* $\mu(x)=\mu_0(x)+\mu^-$, *with* $\mu^->\lambda_{1,0}$. *Let* δ_1 *and* δ_2 *be defined by* (2.15). *Then we have* $\delta_2-\delta_1=(1-\frac{\mu^-}{\lambda_{1,0}})^2(\delta_{2,0}-\delta_{1,0})$.

This result also indicates that the information on δ^* is all the more precise as the growth rate function takes low values. However, the "relative thickness" of the interval (δ_1, δ_2), compared to δ_1, $\frac{\delta_2-\delta_1}{\delta_1}$, does not depend on μ^-, as can be easily seen.

Proof of Proposition 3.1. The relation $\lambda_1[\mu(x)] = \lambda_{1,0} - \mu^-$ is a direct consequence of the uniqueness of the first eigenvalue λ_1. We assume that $\mu^- > \lambda_{1,0}$, so that $\lambda_1[\mu(x)] < 0$. From the uniqueness of the eigenfunction ϕ associated with λ_1, ϕ does not depend on μ^-. Therefore, δ_1 and δ_2 satisfy $\delta_1 = \frac{(\lambda_{1,0}-\mu^-)^2 \underline{\phi_0}}{(1+\underline{\phi_0})^2}$ and $\delta_2 = \frac{(\lambda_{1,0}-\mu^-)^2}{4}$. The result immediately follows. □

4. A few comments on the proportional harvesting model. In this model, the population density u is governed by the equation

$$u_t = D\nabla^2 u + u(\mu(x) - \nu(x)u) - q(x)u, \quad x \in \Omega, \tag{4.1}$$

with L-periodicity of the functions $\mu(x)$, $\nu(x)$, and $q(x)$ in the periodic case, and with Neumann or Dirichlet boundary conditions in the bounded case. Setting

$$\tau(x) := \mu(x) - q(x),$$

this model becomes equivalent to the SKT model (1.3). Hence, many properties of the solutions of this model are described in the existing literature. In particular the existence, nonexistence, and uniqueness results of Theorems 2.2 and 2.4 apply. The condition $\lambda_1[\mu(x) - q(x)] < 0$ is therefore necessary and sufficient for species persistence. Furthermore, the theoretical results of [8], [12], [33], [34] on the effects of habitat arrangement on species persistence are also true for this model.

For instance, when the function $\mu(x)$ is constant, with $\mu(x) \equiv \mu_1 > 0$, and if the domain Ω is convex and symmetric with respect to each axis $\{x_1 = 0\}, \dots, \{x_N = 0\}$, the next result is a straightforward consequence of the paper [8].

THEOREM 4.1. (i) *In the periodic case,* $\lambda_1[\mu_1 - q_k^*(x)] \le \lambda_1[\mu_1 - q(x)]$.

(ii) *In the bounded Dirichlet case,* $\lambda_1[\mu_1 - q_k^*(x)] \le \lambda_1[\mu_1 - q(x)]$.

(iii) *In the bounded Neumann case, if* Ω *is a rectangle,* $\lambda_1[\mu_1 - q_k^\sharp(x)] \le \lambda_1[\mu_1 - q(x)]$.

Here q_k^* denotes the symmetric decreasing Steiner rearrangement of the function q with respect to the variable x_k, and $q_k^\sharp$ denotes the monotone rearrangement of q with respect to x_k (see [8] and [10] for the definition of these rearrangements). These rearrangements of a function q preserve not only its mean value, but also its distribution function. This means that if, for instance, q corresponds to a "patch" function taking the values q_1, q_2, and q_3 in some regions A_1, A_2, and A_3, respectively, with $A_1 + A_2 + A_3 = |C|$, then the areas of the regions where the rearranged functions q^* and $q^\sharp$ take the values q_1, q_2, and q_3 remain equal to A_1, A_2, and A_3, respectively.

Theorem 4.1 combined with Theorem 2.4 says that the spatially rearranged harvesting strategies are better for species survival. This result can be helpful from a resource management point of view. Indeed, the authorities can rearrange the position of the harvested areas in order to improve the chances of population persistence. The result of Theorem 4.1 shows that, in the framework of these models, the creation of a large reserve gives persistence more chances than the creation of several small reserves, and is in accordance with the former results of [23] and [26] in the Dirichlet case. See Figure 5 for some illustrations in the bounded case with Dirichlet and Neumann boundary conditions.

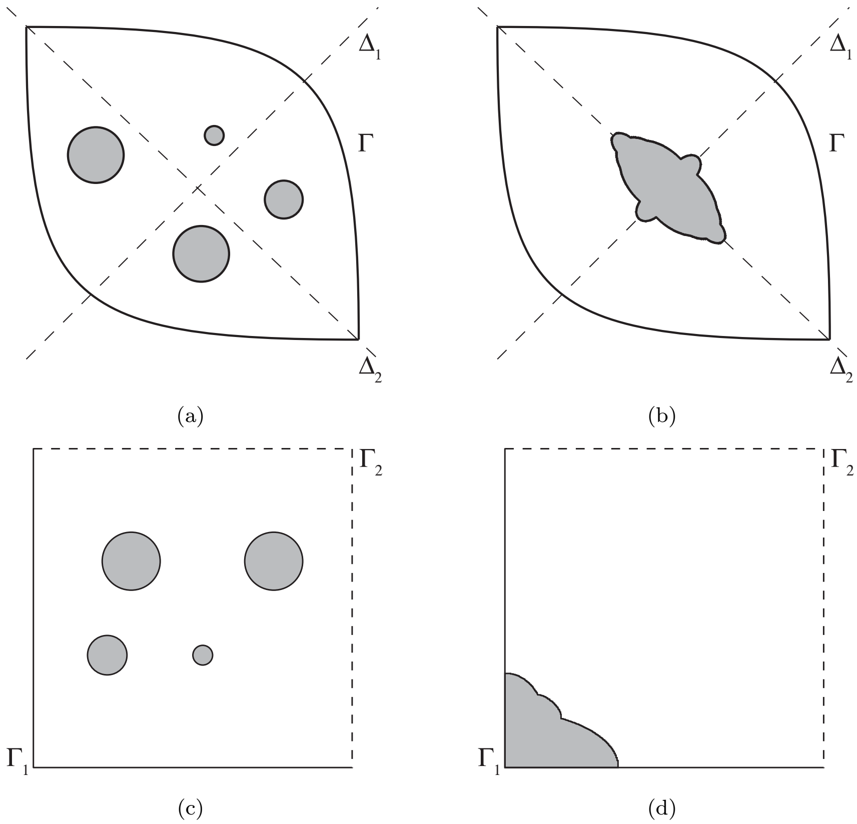

FIG. 5. *Examples of applications of Theorem* 4.1.ii–iii *to reserves management. In panels* (a) *and* (b), *the boundary* Γ *of* Ω *is lethal (Dirichlet boundary conditions).* (a) *The initial effort function* $q(x)$ *takes two values,* $q^+ > 0$ *in the white area, and* $q^- = 0$ *in the shadowed regions, which correspond to reserves.* (b) *Position of the reserves after a symmetric decreasing Steiner rearrangement along the* Δ_1 *and* Δ_2 *axes, successively. The rearranged configuration* (b) *always give more chances of species persistence. In panels* (c) *and* (d), *the boundary* Γ *is divided into two parts*: $\Gamma = \Gamma_1 \cup \Gamma_2$. Γ_1 *is represented with a solid line and can correspond to a coast, while* Γ_2 *is represented with a dashed line and can correspond to a nonphysical limit that the species cannot cross (Neumann boundary conditions).* (c) *The effort function* $q(x)$ *again takes two values,* $q^+ > 0$ *in the white area, and* $q^- = 0$ *in the reserves.* (d) *Position of the reserves after monotone rearrangement along the horizontal and vertical axes, successively. The chances of persistence are better in the rearranged configuration* (d).

5. Discussion. We have proposed a model for the study of populations in heterogeneous environments, for populations submitted to an external negative forcing term. This forcing term could be regarded as a "quasi-constant-yield" harvesting, depending only on the population density u when u is below a certain small threshold ε. The introduction of such a threshold ε was necessary for ensuring the nonnegativity of the solutions of our model, and therefore its actuality.

We carried out new mathematical results on the elliptic equation satisfied by the stationary states of the model, and on the associated parabolic equation. Both qualitative and quantitative results were obtained.

From the qualitative point of view, we described the behavior of the model solutions in terms of the harvesting amplitude δ. Two main types of stationary solutions were found: the remnant solutions, always below a small threshold ε_0 and therefore close to 0, and the significant solutions, always above this threshold, thus ensuring a time-constant yield. We discussed the maximum number of significant stationary solutions, which we found equal to 2, under a hypothesis of positivity of the second eigenvalue λ_2 of a linear operator. We further investigated the long-time behavior of the solution of our model, starting from a nonharvested population at equilibrium. We found a critical value δ^* of the harvesting term amplitude, below which the population density tends over time to a significant stationary solution, and above which it converges to a stationary solution which is not significant. We also established quantitative formulae for some lower and upper bounds for δ^*: δ_1 and δ_2, respectively. The threshold δ_2 has the additional property that, whenever the amplitude δ is above δ_2, the population density decreases to a remnant stationary solution.

The quantitative aspects of our study mainly consisted of discussing the effect of environmental fragmentation on these thresholds δ_1 and δ_2, and therefore on the interactions between environmental fragmentation and maximum sustainable yield. Namely, when computing the values of δ_1 and δ_2 on 2000 samples of stochastically obtained patchy environments, with different levels of fragmentation, we found an increasing relationship between these two coefficients and an environmental aggregation index s. This indicates that, for given areas of favorable and unfavorable regions, the harvesting quota that a species can sustain, while ensuring a time-constant yield, is higher when the favorable regions are aggregated.

The reader may note that, in our model, the species mobility was not affected by the environmental heterogeneity. Such a dependence could be modeled by using a more general dispersion term, of the form $\nabla \cdot (A(x)\nabla u)$, instead of $D\nabla^2 u$, where $A(x)$ stands for the diffusion matrix (see [8], [36]). In fact, most of our results still work when the matrix A is of class $C^{1,\alpha}$ (with $\alpha > 0$) and uniformly elliptic, i.e., when there exists $\tau > 0$ such that $A(x) \geq \tau I_N$ for all $x \in \Omega$. Indeed, Theorems 2.2, 2.4, 2.7, 2.10, and 2.11 remain true under this more general assumption. However, the effects of environmental heterogeneity may differ, depending on the way $A(x)$ and $\mu(x)$ are correlated (see [21]). In the proportional harvesting case, the results of section 4 on the effects of the arrangements of the harvested regions may also not be valid with this dispersion term. However, in situations where $A(x)$ takes low values (slow motion) when $q(x)$ is low ("reserves"; see section 4), as underlined in [33], a simultaneous rearrangement of the functions $A(x)$ and $q(x)$ would lead to lower λ_1 values and therefore to higher chances of species survival.

EFFECTS OF GENERAL INCIDENCE AND POLYMER JOINING ON NUCLEATED POLYMERIZATION IN A MODEL OF PRION PROLIFERATION*

MEREDITH L. GREER†, P. VAN DEN DRIESSCHE‡, LIN WANG§, AND G. F. WEBB¶

Abstract. Two processes are incorporated into a new model for transmissible prion diseases. These are general incidence for the lengthening process of infectious polymers attaching to and converting noninfectious monomers, and the joining of two polymers to form one longer polymer. The model gives rise to a system of three ordinary differential equations, which is shown to exhibit threshold behavior dependent on the value of the parameter combination giving the basic reproduction number $\mathcal{R}_0$. For $\mathcal{R}_0 < 1$, infectious polymers die out, whereas for $\mathcal{R}_0 > 1$, the system is locally asymptotic to a positive disease equilibrium. The effect of both general incidence and joining is to decrease the equilibrium value of infectious polymers and to increase the equilibrium value of normal monomers. Since the onset of disease symptoms appears to be related to the number of infectious polymers, both processes may significantly inhibit the course of the disease. With general incidence, the equilibrium distribution of polymer lengths is obtained and shows a sharp decrease in comparison to the distribution resulting from mass action incidence. Qualitative global results on the disease free and disease equilibria are proved analytically. Numerical simulations using parameter values from experiments on mice (reported in the literature) provide quantitative demonstration of the effects of these two processes.

1. Introduction.

Prion diseases, though widely studied at many levels, continue to challenge understanding. A prion is an infectious protein. Several prion diseases are known, or suspected, to be transmissible, both via ingestion and iatrogenically; as a group, they are thus referred to as transmissible spongiform encephalopathies (TSEs). Examples include scrapie, which affects sheep and goats; bovine spongiform encephalopathy (BSE), which affects cows; chronic wasting disease (CWD), which affects mule deer and elk; and variant Cruetzfeldt–Jakob disease (vCJD), which affects humans [8, 9]. Additionally, mice and hamsters in laboratory experiments can be infected with scrapie [30].

Though incidence of vCJD in humans has declined to just a few new cases per year [36] and BSE incidence also appears to be declining [23], prion diseases warrant ongoing study for reasons that include the following. First, there may be previously unrecognized routes of infection: new research shows that prions can bind to some soils and cause infection via inoculation with those soils [17], indicating that graz-

ing animals may acquire TSEs despite having safely prepared feed. Second, prions are extremely difficult to destroy, remaining infective despite heat or radiation that would inactivate other known infectious agents [1, 5]. Third, prion replication offers a new frontier in scientific understanding: protein-only replication cannot depend on nucleic acids, but must occur somehow for TSEs to spread. Comprehending how this replication works may provide great insight to other biological processes.

A specific naturally occurring protein is vulnerable to infection by prions; it is therefore known as prion protein. In its noninfectious form prion protein is denoted by $\mathrm{PrP^C}$, and in its infectious form it is denoted by $\mathrm{PrP^{Sc}}$; see, for example, [22] for discussion of this notation. The forms differ only in the folding of the protein [27]. Humans, cows, sheep, and other animals susceptible to TSEs produce $\mathrm{PrP^C}$ normally [4]. There is evidence both that an accumulation of $\mathrm{PrP^{Sc}}$ may be toxic [24, 21] and that a lack of $\mathrm{PrP^C}$ may leave the brain overly susceptible to stress [29]. Either or both of these may lead to symptoms associated with TSEs. In the case of transmissible prion disease, some portion of $\mathrm{PrP^{Sc}}$ is introduced into the system, and this $\mathrm{PrP^{Sc}}$ can cause more infectious protein to be made. Though the mechanism for such protein replication is not fully understood, nucleated polymerization is a likely candidate [15, 18].

Nucleated polymerization involves $\mathrm{PrP^{Sc}}$ attaching to $\mathrm{PrP^C}$ and converting it to $\mathrm{PrP^{Sc}}$. While proteins usually exist as individual units, also known as monomers, it appears that $\mathrm{PrP^{Sc}}$ benefits from aggregating in some way [11, 16]. Aggregation confers greater stability, and may even be necessary to maintain the alternate protein folding. We assume within this paper that these aggregates have a linear form [18, 26], and we typically refer to the aggregates as polymers. In our nucleated polymerization model, each polymer may attach at either end to a $\mathrm{PrP^C}$ monomer, quickly converting it to the infectious form of $\mathrm{PrP^{Sc}}$. Since the polymer has thus increased its length by one unit of protein, we refer to this process as *lengthening*. Nucleated polymerization also involves polymer *splitting*. We assume a minimum viable polymer length, so that when polymer splitting results in pieces below the minimum length, these pieces must break apart into their component units of $\mathrm{PrP^C}$. Additionally, our model includes polymer *joining*, in which two $\mathrm{PrP^{Sc}}$ polymers join together to form one longer polymer.

Models of nucleated polymerization for $\mathrm{PrP^C}$ monomers and $\mathrm{PrP^{Sc}}$ polymers containing a discrete number of monomers are formulated and analyzed in [20] and [22]. Based on these, a model with continuous polymer length is introduced in [13] and further analyzed in [12, 14, 28]. All these models assume mass action incidence for the lengthening process of infectious polymers attaching to $\mathrm{PrP^C}$ units. We generalize this form of incidence in a way that reduces lengthening when the total amount of infectious protein becomes large in proportion to the number of polymers. Some research [24] has indicated that only truncated forms of polymers are able to lengthen this way; it is also possible that polymers within a specific range of lengths are able to lengthen at the fastest rate, but that all polymers are capable of lengthening [31]. Our general incidence term captures these features by reducing the rate of lengthening when total $\mathrm{PrP^{Sc}}$ mass is large relative to the total number of $\mathrm{PrP^{Sc}}$ polymers. That is, we reduce the rate of lengthening as the average polymer length becomes greater. In addition, our model is the first to include polymer joining. Joining is implied by the fact that large fibrils or aggregates of $\mathrm{PrP^{Sc}}$ are observed in late stages of disease [2, 10].

We start in section 2 by incorporating the processes of general incidence and polymer joining into an ordinary differential equation (ODE) for the number of monomers, coupled with a partial integro-differential equation for the density of polymers depending on polymer length. Under some assumptions, this system is converted to a system of three ODEs, which is analyzed in section 3. Numerical simulations for parameters obtained from experimental data on mice [30] are presented in section 4, and we conclude in section 5 with a discussion.

2. Model formulation. A core model of nucleated polymerization exists in [12, 13, 14, 28] with some extensions in [32]. We continue to use the same variables and parameters and introduce two new parameters, ω and η, to account for general incidence and polymer joining, respectively:

- $V(t)$ is the number of $\mathrm{PrP^C}$ monomers at time t;
- $u(x,t)$ is the density of $\mathrm{PrP^{Sc}}$ polymers of length x at time t;
- x_0 is the lower bound for polymer length; that is, polymers have length x with $x_0 < x < \infty$;
- $U(t) = \int_{x_0}^{\infty} u(x,t)dx$ is the number of $\mathrm{PrP^{Sc}}$ polymers at time t;
- $P(t) = \int_{x_0}^{\infty} xu(x,t)dx$ is the number of $\mathrm{PrP^{Sc}}$ monomers comprising polymers at time t;
- $W(t) = P(t) - x_0U(t)$ is the number of $\mathrm{PrP^{Sc}}$ units not accounted for within the minimal polymer lengths;
- λ is the source rate for naturally produced $\mathrm{PrP^C}$ monomers;
- γ is the metabolic degradation rate for $\mathrm{PrP^C}$;
- τ is a rate associated with lengthening of $\mathrm{PrP^{Sc}}$ polymers by attaching to and converting $\mathrm{PrP^C}$ monomers;
- ω is a parameter associated with polymer lengthening;
- $\beta(x)$ is the length-dependent rate of polymer breakage;
- $\kappa(x,y)$ is the probability, when a polymer of length y breaks, that one of the two resulting polymers has length x;
- $\mu(x)$ is the length-dependent metabolic degradation rate of $\mathrm{PrP^{Sc}}$ polymers;
- η is the rate at which $\mathrm{PrP^{Sc}}$ polymers join together.

All parameters are assumed to be positive with the exception of ω and η, which may also be zero.

2.1. PDE model. Our model, incorporating both general incidence and polymer joining into the model formulated and discussed in [12, 13, 14, 28], has monomer dynamics governed by

$$V'(t) = \lambda - \gamma V(t) - \frac{\tau V(t)U(t)}{1+\omega P(t)} + 2\int_0^{x_0} x \int_{x_0}^{\infty} \beta(y)\kappa(x,y)u(y,t)dydx \tag{2.1}$$

with $V'(t) = \frac{dV}{dt}$, and polymer dynamics given by

$$\begin{aligned} u_t(x,t) + \frac{\tau V(t)}{1+\omega P(t)}u_x(x,t) &= -(\mu(x)+\beta(x))u(x,t) + 2\int_x^{\infty} \beta(y)\kappa(x,y)u(y,t)dy \\ &\quad + \eta\int_{x_0}^{x} u(x-y,t)u(y,t)dy - 2\eta u(x,t)\int_{x_0}^{\infty} u(y,t)dy, \end{aligned} \tag{2.2}$$

subject to nonnegative initial conditions and the boundary condition

$$u(x_0,t) = 0. \tag{2.3}$$

We write the polymer lengthening term in (2.1) in the general form $\frac{\tau V(t)U(t)}{1+\omega P(t)}$. Note that in the case $\omega = 0$ this is a mass action term. Otherwise, as $P(t)$ becomes large there is a saturation effect, with the result that less lengthening occurs overall. This matches the in vitro observations of [24, 31].

The polymer joining term $\eta\int_{x_0}^{x} u(x-y,t)u(y,t)dy$ introduces the joining parameter η and indicates that a new polymer of length x results from the joining of two smaller polymers of lengths $x-y$ and y. Note that the upper integration limit can be written as x or $x-x_0$ with identical results, as there are zero polymers of length less than x_0. Changing the form of the integration limit does not affect analysis of the model. The last term $2\eta u(x,t)\int_{x_0}^{\infty} u(y,t)dy$ describes the loss of a polymer of length x when it joins with another polymer, of any length, to create a larger polymer. Symmetry mandates the factor 2.

Note that with mass action incidence and no polymer joining, i.e., $\omega = 0$ and $\eta = 0$, our model reduces to that in [12, 13, 14, 28]. For this case, a model with bounded $\beta(x)$, $\mu(x)$, and a general kernel $\kappa(x,y)$ is analyzed in [32].

2.2. Conversion to ODEs. Under an assumption of equidistributed splitting, a system of three ODEs in V, U, and P can be obtained from (2.1) and (2.2). Equidistributed splitting means that splitting is equally likely wherever two protein units have joined together; hence the splitting rate $\beta(x)$ is proportional to polymer length x, i.e., $\beta(x) = \beta x$. The accompanying splitting kernel is then

$$\kappa(x,y) = \begin{cases} 1/y & \text{if} \quad y > x_0 \ \text{ and } \ 0 < x < y, \\ 0 & \text{if} \quad y \le x_0 \ \text{ or } \ y \le x. \end{cases}$$

We make the additional assumption that polymer metabolic degradation occurs at a constant rate, i.e., $\mu(x) = \mu$. A form of the PDEs that assumes mass action and no polymer joining was converted to ODEs in [28] by integrating (2.2), and integrating the product of x and (2.2), over $[x_0,\infty)$. Proceeding similarly, the general incidence term is independent of x and converts analogously. The joining integral $\int_{x_0}^{\infty} u(x,t)\int_{x_0}^{\infty} u(y,t)dydx$ simplifies to $U^2(t)$. The remaining joining integral from (2.2) gives

$$\begin{aligned}\int_{x_0}^{\infty}\int_{x_0}^{x} u(y,t)u(x-y,t)\,dy\,dx &= \int_{x_0}^{\infty}\int_{0}^{x-x_0} u(x-z,t)u(z,t)\,dz\,dx \\ &= \int_{0}^{\infty}\int_{z+x_0}^{\infty} u(x-z,t)u(z,t)\,dx\,dz \\ &= \int_{0}^{\infty}\int_{x_0}^{\infty} u(w,t)u(z,t)\,dw\,dz \\ &= U^2(t).\end{aligned}$$

The resulting system of equations is

$$\begin{aligned} U' &= \beta P - \mu U - 2\beta x_0 U - \eta U^2, \\ V' &= \lambda - \gamma V - \frac{\tau V U}{1+\omega P} + \beta x_0^2 U, \\ P' &= \frac{\tau V U}{1+\omega P} - \mu P - \beta x_0^2 U. \end{aligned} \tag{2.4}$$

It is useful to have equations for infectious polymers, noninfectious monomers, and infectious monomers comprising polymers. To use analysis appropriate for compartmental models, we replace the U equation with an equation for $x_0 U$, and the

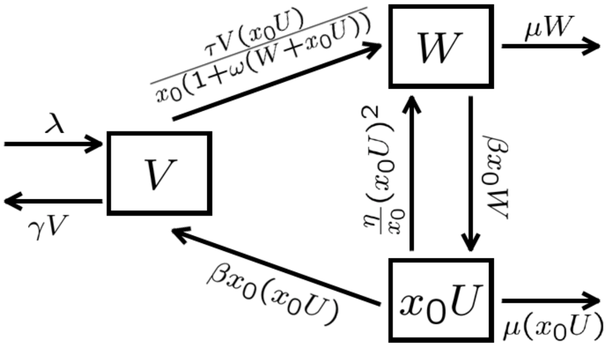

FIG. 1. *Compartmental diagram of system* (2.5).

P equation with an equation for $W = P - x_0U$. The x_0U compartment contains all PrP^{Sc} units that make up the minimum lengths of the polymers. The W compartment contains all additional PrP^{Sc} units. The resulting system of equations is

$$\begin{aligned}
(x_0U)' &= \beta x_0 W - \mu(x_0U) - \beta x_0(x_0U) - \frac{\eta}{x_0}(x_0U)^2,\\
V' &= \lambda - \gamma V - \frac{\tau V(x_0U)}{x_0(1+\omega(W+x_0U))} + \beta x_0^2 U,\\
W' &= \frac{\tau V(x_0U)}{x_0(1+\omega(W+x_0U))} - (\mu+\beta x_0)W + \frac{\eta}{x_0}(x_0U)^2.
\end{aligned} \tag{2.5}$$

The compartmental diagram of this system appears in Figure 1.

3. Model analysis.

3.1. Nondimensionalization.

To facilitate analysis, rewrite the ODE system (2.5) in a nondimensionalized form. Let $\alpha = \mu + \beta x_0$ and $T = \alpha t$. Rewrite $U(t) = \frac{\alpha}{\tau}\mathcal{X}(T)$, $V(t) = \frac{\alpha^2}{\beta\tau}\mathcal{Y}(T)$, and $W(t) = \frac{\alpha^2}{\beta\tau}\mathcal{Z}(T)$. Define $\sigma = \frac{\beta\lambda\tau}{\alpha^3}$, $\rho = \frac{\gamma}{\alpha}$, $\delta = \frac{\beta x_0}{\alpha}$, $\nu = \frac{\omega\alpha^2}{\beta\tau}$, and $\phi = \frac{\eta}{\tau}$. Then

$$\begin{aligned}
\mathcal{X}' &= \mathcal{Z} - \mathcal{X} - \phi\mathcal{X}^2,\\
\mathcal{Y}' &= \sigma - \rho\mathcal{Y} - \frac{\mathcal{X}\mathcal{Y}}{1+\nu(\mathcal{Z}+\delta\mathcal{X})} + \delta^2\mathcal{X},\\
\mathcal{Z}' &= \frac{\mathcal{X}\mathcal{Y}}{1+\nu(\mathcal{Z}+\delta\mathcal{X})} - \mathcal{Z} + \delta\phi\mathcal{X}^2,
\end{aligned} \tag{3.1}$$

with $\mathcal{X}' = \frac{d\mathcal{X}}{dT}$. The nondimensionalization process reduces the number of parameters from eight to five. Note that $\delta = \frac{\beta x_0}{\beta x_0 + \mu} \in (0,1)$. Setting $\nu = 0$ simplifies the incidence term to mass action, whereas setting $\phi = 0$ simplifies the model to the case with no polymer joining.

In all that follows, disease is assumed to be initially present; thus the nonnegative initial conditions for the nondimensional system are $\mathcal{X}(0) \geq 0$, $\mathcal{Y}(0) \geq 0$, $\mathcal{Z}(0) \geq 0$, with $\mathcal{X}(0) + \mathcal{Z}(0) > 0$.

PROPOSITION 3.1. *Let $\nu, \phi \geq 0$, $\sigma, \rho > 0$, and $\delta \in (0,1)$. For each $(\mathcal{X}(0), \mathcal{Y}(0), \mathcal{Z}(0)) \in \mathbb{R}^3_+$ the system* (3.1) *has a unique bounded solution in $\mathbb{R}^3_+$ defined for all $T \geq 0$.*

Proof. Let $F : \mathbb{R}^3_+ \to \mathbb{R}^3_+$ be given by

$$\begin{aligned} F((\mathcal{X},\mathcal{Y},\mathcal{Z})) &= (F_1, F_2, F_3) \\ &= \left(\mathcal{Z} - \mathcal{X} - \phi\mathcal{X}^2, \sigma - \rho\mathcal{Y} - \frac{\mathcal{X}\mathcal{Y}}{1+\nu(\mathcal{Z}+\delta\mathcal{X})} + \delta^2\mathcal{X}, \frac{\mathcal{X}\mathcal{Y}}{1+\nu(\mathcal{Z}+\delta\mathcal{X})} - \mathcal{Z} + \delta\phi\mathcal{X}^2\right), \end{aligned}$$

and observe that F is Lipschitz continuous on bounded sets of $\mathbb{R}^3_+$. For $T \geq 0$ and $(\mathcal{X},\mathcal{Y},\mathcal{Z}) \in \mathbb{R}^3_+$, it follows that $F_1 \geq 0$ when $\mathcal{X} = 0$, $F_2 \geq 0$ when $\mathcal{Y} = 0$, and $F_3 \geq 0$ when $\mathcal{Z} = 0$. Thus by Corollary A.5 in [35] there exists a unique nonnegative solution to (3.1) in $\mathbb{R}^3_+$ for $T \in [0,\infty)$. Since

$$\begin{aligned} \frac{d}{dT}(\delta\mathcal{X}(T) + \mathcal{Y}(T) + \mathcal{Z}(T)) &= \sigma - (1-\delta)\delta\mathcal{X}(T) - \rho\mathcal{Y}(T) - (1-\delta)\mathcal{Z}(T) \\ &\leq \sigma - \theta(\delta\mathcal{X}(T) + \mathcal{Y}(T) + \mathcal{Z}(T)), \end{aligned}$$

where $\theta = \min\{1-\delta, \rho\} > 0$, it follows that $\delta\mathcal{X}(T) + \mathcal{Y}(T) + \mathcal{Z}(T) \leq \max\{\frac{\sigma}{\theta}, \delta\mathcal{X}(0) + \mathcal{Y}(0) + \mathcal{Z}(0)\} = M$. Thus the existence of a unique global nonnegative bounded solution is proved. □

3.2. Computing and interpreting $\mathcal{R}_0$. The disease free equilibrium (DFE) for this nondimensionalized general model of nucleated polymerization is $(\bar{\mathcal{X}}, \bar{\mathcal{Y}}, \bar{\mathcal{Z}}) = (0, \frac{\sigma}{\rho}, 0)$. Note that in the absence of disease, $\bar{\mathcal{Y}}$ is stable. The DFE may be used to find the basic reproduction number $\mathcal{R}_0$, which indicates the average number of new infections caused by a single infective introduced to an entirely susceptible population. One technique [37] examines the infective compartments, in this case the equations within (3.1) for $\mathcal{X}$ and $\mathcal{Z}$. The Jacobian J of the $(\mathcal{X},\mathcal{Z})$ system about the DFE is apportioned into two matrices F and G such that $J = F - G$, where F contains all elements resulting from new infections and G contains all remaining movement between compartments. Then $\mathcal{R}_0$ is the spectral radius of the matrix FG^{-1}. For the model given in (3.1),

$$F = \begin{bmatrix} 0 & 0 \\ \frac{\sigma}{\rho} & 0 \end{bmatrix}, \qquad G = \begin{bmatrix} 1 & -1 \\ 0 & 1 \end{bmatrix},$$

and the spectral radius of FG^{-1} is $\frac{\sigma}{\rho}$. Hence $\mathcal{R}_0 = \frac{\sigma}{\rho}$. The next result follows from Theorem 2 of [37].

LEMMA 3.2. *If* $\mathcal{R}_0 < 1$, *then the DFE of* (3.1) *is locally asymptotically stable*; *if* $\mathcal{R}_0 > 1$, *then the DFE is unstable.*

In the biological variables,

$$\mathcal{R}_0 = \frac{\beta\lambda\tau}{\gamma(\beta x_0 + \mu)^2}. \tag{3.2}$$

The same $\mathcal{R}_0$ results from the model of nucleated polymerization in which the lengthening mechanism proceeds according to mass action and polymer joining does not occur [28]. This result makes it clear that general incidence and joining do not affect the potential success of infection via nucleated polymerization. However, as shown later, the inclusion of a generalized incidence term and polymer joining does affect the distribution of polymer lengths as time progresses during disease and alters the disease equilibrium.

3.3. Global stability of the DFE. Assuming that $\rho \geq 1$, the DFE of the general model of nucleated polymerization given in (3.1) is globally attractive for $\mathcal{R}_0 \leq 1$ and globally asymptotically stable (GAS) for $\mathcal{R}_0 < 1$. The assumption that $\rho \geq 1$ is justified biologically; see data in section 4. To show the DFE results, first consider the model in the case with $\nu = 0$, that is, where polymer lengthening occurs via mass action.

LEMMA 3.3. *If $\mathcal{R}_0 \leq 1$, then the DFE $(\bar{\mathcal{X}}, \bar{\mathcal{Y}}, \bar{\mathcal{Z}}) = (0, \frac{\sigma}{\rho}, 0)$ of the system*

$$\begin{aligned} \mathcal{X}' &= \mathcal{Z} - \mathcal{X} - \phi\mathcal{X}^2, \\ \mathcal{Y}' &= \sigma - \rho\mathcal{Y} - \mathcal{X}\mathcal{Y} + \delta^2\mathcal{X}, \\ \mathcal{Z}' &= \mathcal{X}\mathcal{Y} - \mathcal{Z} + \delta\phi\mathcal{X}^2 \end{aligned} \tag{3.3}$$

is globally attractive.

Proof. Consider the Liapunov function

$$\Phi = \frac{1}{2}(\mathcal{Y} - \bar{\mathcal{Y}})^2 + k_1(\mathcal{X} + \mathcal{Z})$$

with $k_1 = (2 - \delta^2 - \bar{\mathcal{Y}})$. Since both $\delta < 1$ and $\bar{\mathcal{Y}} = \mathcal{R}_0 \leq 1$, then $k_1 > 0$. This Liapunov function is the same as that used by [28] for the nondimensionalized model with mass action and no joining. Its derivative given by

$$\Phi' = -\rho(\mathcal{Y} - \bar{\mathcal{Y}})^2 - \phi(1-\delta)k_1\mathcal{X}^2 - \mathcal{X}[(\mathcal{Y} - 1)^2 + (1 - \delta^2)(1 - \bar{\mathcal{Y}})]$$

is nonpositive for $\mathcal{R}_0 \leq 1$. Also $\Phi' = 0$ only if $\mathcal{Y} = \bar{\mathcal{Y}}$ and $\mathcal{X} = 0$. Thus by LaSalle's invariance principle [19] the DFE $(0, \frac{\sigma}{\rho}, 0)$ of (3.3) is globally attractive. □

THEOREM 3.4. *Assume $\rho \geq 1$. If $\mathcal{R}_0 \leq 1$, then the DFE $(\bar{\mathcal{X}}, \bar{\mathcal{Y}}, \bar{\mathcal{Z}}) = (0, \frac{\sigma}{\rho}, 0)$ of the system* (3.1) *is globally attractive. If $\mathcal{R}_0 < 1$, then the DFE is GAS.*

Proof. From systems (3.1) and (3.3), create the equivalent respective systems

$$\begin{aligned} \mathcal{X}' &= \mathcal{Z} - \mathcal{X} - \phi\mathcal{X}^2, \\ \mathcal{Z}' &= \frac{\mathcal{X}(\mathcal{Y} + \mathcal{Z}) - \mathcal{X}\mathcal{Z}}{1 + \nu(\mathcal{Z} + \delta\mathcal{X})} - \mathcal{Z} + \delta\phi\mathcal{X}^2, \\ (\mathcal{Y} + \mathcal{Z})' &= \sigma - \rho(\mathcal{Y} + \mathcal{Z}) + (\rho - 1)\mathcal{Z} + \delta^2\mathcal{X} + \delta\phi\mathcal{X}^2, \end{aligned} \tag{3.4}$$

and (with $\nu = 0$)

$$\begin{aligned} \mathcal{X}' &= \mathcal{Z} - \mathcal{X} - \phi\mathcal{X}^2, \\ \mathcal{Z}' &= \mathcal{X}(\mathcal{Y} + \mathcal{Z}) - \mathcal{X}\mathcal{Z} - \mathcal{Z} + \delta\phi\mathcal{X}^2, \\ (\mathcal{Y} + \mathcal{Z})' &= \sigma - \rho(\mathcal{Y} + \mathcal{Z}) + (\rho - 1)\mathcal{Z} + \delta^2\mathcal{X} + \delta\phi\mathcal{X}^2, \end{aligned} \tag{3.5}$$

subject to the same nonnegative initial conditions. Since $\rho \geq 1$, system (3.5) is K-monotone. Then $\nu \geq 0$, $\delta \in (0,1)$, $\mathcal{X} \geq 0$, and $\mathcal{Z} \geq 0$ imply by a standard comparison theorem given in [34, Appendix B1] that $(\mathcal{X}, \mathcal{Z}, \mathcal{Y} + \mathcal{Z})_{(3.4)} \leq (\mathcal{X}, \mathcal{Z}, \mathcal{Y} + \mathcal{Z})_{(3.5)}$. Let $\mathcal{R}_0 \leq 1$. Since by Lemma 3.3, the DFE of (3.5) is globally attractive, and by Proposition 3.1, $\mathcal{X} \geq 0$ and $\mathcal{Z} \geq 0$, it follows that $\mathcal{X} \to 0$ and $\mathcal{Z} \to 0$ for system (3.4). From the second equation of (3.1), the theory of asymptotically autonomous systems [6] shows that $\mathcal{Y} \to \frac{\sigma}{\rho}$. The global asymptotic stability result then follows from Lemma 3.2. □

In order to use the comparison theorem to show that the DFE of system (3.1) is GAS, it is required that $\rho \geq 1$ in Theorem 3.4. Next we apply the Liapunov method to establish that the DFE is GAS without assuming that $\rho \geq 1$ but at a cost: $\mathcal{R}_0$ is required to be less than $1-\delta^2$.

THEOREM 3.5. *The DFE of system* (3.1) *is GAS if* $\mathcal{R}_0 \leq 1-\delta^2$.

Proof. Define

$$\Phi = \mathcal{Y} - \bar{\mathcal{Y}} \ln(\mathcal{Y}/\bar{\mathcal{Y}}) + \mathcal{Z} + \mathcal{X}.$$

Notice that $\sigma = \rho\bar{\mathcal{Y}}$. The derivative of Φ along the solution of system (3.1) is given by

$$\begin{aligned}\Phi' &= -\rho\frac{(\mathcal{Y}-\bar{\mathcal{Y}})^2}{\mathcal{Y}} - (1-\delta)\phi\mathcal{X}^2 - \delta^2\bar{\mathcal{Y}}\frac{\mathcal{X}}{\mathcal{Y}} + \mathcal{X}\left(\delta^2 + \frac{\bar{\mathcal{Y}}}{1+\nu(\mathcal{Z}+\delta\mathcal{X})} - 1\right)\\ &\leq -\rho\frac{(\mathcal{Y}-\bar{\mathcal{Y}})^2}{\mathcal{Y}} - (1-\delta)\phi\mathcal{X}^2 - \delta^2\bar{\mathcal{Y}}\frac{\mathcal{X}}{\mathcal{Y}} + \mathcal{X}\left(\delta^2 + \bar{\mathcal{Y}} - 1\right).\end{aligned}$$

This shows that Φ' is nonpositive for $\mathcal{R}_0 = \frac{\sigma}{\rho} = \bar{\mathcal{Y}} < 1-\delta^2$ and $\Phi' = 0$ only if $\mathcal{Y} = \bar{\mathcal{Y}}$ and $\mathcal{X} = 0$. Again, by LaSalle's invariance principle and Lemma 3.2, the DFE is GAS. □

3.4. Existence and stability of the EE. We now consider an endemic equilibrium (EE) with disease present, i.e., $\mathcal{X} > 0$, $\mathcal{Y} > 0$, $\mathcal{Z} > 0$.

LEMMA 3.6. *If* $\mathcal{R}_0 > 1$, *then system* (3.1) *has a unique EE. If* $\phi = 0$, *then that EE is given by* $(\mathcal{X}^*, \mathcal{Y}^*, \mathcal{Z}^*) = \left(\frac{\sigma-\rho}{\rho\nu(1+\delta)+(1-\delta^2)}, \frac{\sigma\nu(1+\delta)+(1-\delta^2)}{\rho\nu(1+\delta)+(1-\delta^2)}, \frac{\sigma-\rho}{\rho\nu(1+\delta)+(1-\delta^2)}\right)$. *If* $\mathcal{R}_0 < 1$, *then* (3.1) *has no EE.*

Proof. If $\phi > 0$, then system (3.1) cannot be solved explicitly for the EE. However, for $\phi \geq 0$, at equilibrium, $\mathcal{Z}$ and $\mathcal{Y}$ can be expressed in terms of $\mathcal{X}$ by

$$\begin{aligned}\mathcal{Z} &= \mathcal{X} + \phi\mathcal{X}^2,\\ \mathcal{Y} &= \frac{1}{\rho}\left[\sigma - \mathcal{X}(1+\phi\mathcal{X}) + \delta\mathcal{X}(\phi\mathcal{X}+\delta)\right]\\ &= \left[1+\nu\mathcal{X}(1+\delta+\phi\mathcal{X})\right]\left[1+\phi\mathcal{X}(1-\delta)\right],\end{aligned}\tag{3.6}$$

and $\mathcal{X}$ satisfies the cubic equation

$$\begin{aligned}0 &= \rho\nu\phi^2(1-\delta)\mathcal{X}^3 + \left[\rho\nu\phi + \rho\nu\phi(1-\delta^2) + \phi(1-\delta)\right]\mathcal{X}^2\\ &\quad + \left[\rho\nu(1+\delta) + \rho\phi(1-\delta) + (1-\delta^2)\right]\mathcal{X} + \rho - \sigma.\end{aligned}\tag{3.7}$$

Since the first three coefficients of (3.7) are positive and the constant term is negative for $\mathcal{R}_0 > 1$, there is a unique positive root. The expressions in (3.6) show that unique positive equilibrium values for $\mathcal{Y}$ and $\mathcal{Z}$ result from the unique positive $\mathcal{X}$; hence there is a unique EE $(\mathcal{X}^*, \mathcal{Y}^*, \mathcal{Z}^*)$ for $\mathcal{R}_0 > 1$. If $\phi = 0$, then the solution of (3.7) is given explicitly as $\mathcal{X}^* = \frac{\sigma-\rho}{\rho\nu(1+\delta)+(1-\delta^2)}$, giving $\mathcal{Y}^*$ and $\mathcal{Z}^*$ from (3.6) as in the lemma statement. If $\mathcal{R}_0 < 1$, then (3.7) has no positive root, and hence there is no EE. □

The proof of the following result is standard, using the Routh–Hurwitz conditions. For details, see Appendix A.

THEOREM 3.7. *If* $\mathcal{R}_0 > 1$, *then the unique EE of system* (3.1) *is locally asymptotically stable.*

Remark 3.8. If $\mathcal{R}_0 > 1$ and $\rho \geq 1$, then every solution of (3.1) approaches either the EE or the DFE.

Proof. Consider the equivalent system $(\mathcal{X}, \mathcal{Z}, \mathcal{Y}+\mathcal{Z})$ of (3.1), namely (3.4). This equivalent system's matrix of partial derivatives has the sign pattern

$$\begin{bmatrix} - & + & 0 \\ + & - & + \\ + & * & - \end{bmatrix}$$

in the case when $\rho \geq 1$ (where $*$ is $+$ or 0), indicating an irreducible cooperative system. Then by Theorems 2.3.2 and 4.1.2 on respective pages 18 and 57 of [33], the system exhibits monotone dynamical flow and solutions must approach an equilibrium. □

The system equivalent to (3.1) has only two possible equilibria: the DFE $(0, 0, \frac{\sigma}{\rho})$ and the EE $(\mathcal{X}^*, \mathcal{Z}^*, \mathcal{Y}^* + \mathcal{Z}^*)$ from Lemma 3.6. If $\mathcal{R}_0 \geq 1$, then by Lemma 3.2, the DFE is unstable, and by Theorem 3.7, the EE is locally asymptotically stable. These facts together with numerical simulations (see section 4) indicate that the EE is GAS if $\mathcal{R}_0 > 1$ and $\rho \geq 1$, but we do not have a proof.

A Liapunov function argument is used in section 3.4 of [28] to prove a global asymptotic stability result in the case $\omega = \eta = 0$.

3.5. Effects of ν and ϕ on the EE. The nucleated polymerization model with mass action and without polymer joining has been well studied in earlier work [12, 13, 14, 28]. It is useful to understand the effects of positive values of ν and ϕ on the EE of model (3.1). By taking partial derivatives of (3.6) and (3.7) and using parameter relationships at the EE, the following signs are determined. (For selected details, see Appendix B.)

Proposition 3.9. *At the EE of* (3.1), *for* $\mathcal{R}_0 > 1$, $\frac{\partial \mathcal{X}^*}{\partial \nu} < 0$, $\frac{\partial \mathcal{Y}^*}{\partial \nu} > 0$, *and* $\frac{\partial \mathcal{Z}^*}{\partial \nu} < 0$.

Proposition 3.10. *At the EE of* (3.1), *for* $\mathcal{R}_0 > 1$, $\frac{\partial \mathcal{X}^*}{\partial \phi} < 0$ *and* $\frac{\partial \mathcal{Y}^*}{\partial \phi} > 0$.

3.6. Summary of ODE results for biological variables. The previous results are now summarized in terms of the original biological variables in system (2.5). Recall that $\mathcal{X}$, $\mathcal{Y}$, and $\mathcal{Z}$ in (3.1) are respectively proportional to $x_0 U$ (the number of PrP$^{\mathrm{Sc}}$ units in the minimum lengths of the polymers), V (the number of PrP$^{\mathrm{C}}$ monomers), and W (the PrP$^{\mathrm{Sc}}$ units not accounted for within the minimum lengths of the polymers), all satisfying system (2.5). With nonnegative initial conditions, system (2.5) has a unique bounded solution in $\mathbb{R}^3_+$ defined for all $t \geq 0$. The basic reproduction number $\mathcal{R}_0$ is given by (3.2). The DFE $(x_0 U, V, W) = (0, \frac{\lambda}{\gamma}, 0)$ is globally attractive if $\gamma \geq \beta x_0 + \mu$ and $\mathcal{R}_0 \leq 1$ and is GAS if $\mathcal{R}_0 < 1$. If $\mathcal{R}_0 > 1$ and $\gamma \geq \beta x_0 + \mu$, then the unique EE $(x_0 U^*, V^*, W^*)$ demonstrated in Lemma 3.6 is locally asymptotically stable in $\mathbb{R}^3_+ \setminus [\{0\} \times \mathbb{R}_+ \times \{0\}]$. For $\mathcal{R}_0 > 1$, at the EE, $\frac{\partial (x_0 U^*)}{\partial \omega} < 0$, $\frac{\partial V^*}{\partial \omega} > 0$, $\frac{\partial W^*}{\partial \omega} < 0$, $\frac{\partial (x_0 U^*)}{\partial \eta} < 0$, and $\frac{\partial V^*}{\partial \eta} > 0$. The sign of $\frac{\partial W^*}{\partial \eta}$ is undetermined in general, since the sign of $\frac{\partial \mathcal{Z}^*}{\partial \phi}$ is unknown.

We can also interpret the results in terms of P (the number of PrP$^{\mathrm{Sc}}$ monomer units comprising the polymers) from (2.4). At the DFE, $P = 0$, and at the EE, $P^* = W^* + x_0 U^*$. By adding the second and third equations in (2.4), it follows that $\frac{\partial P^*}{\partial \omega} < 0$ and $\frac{\partial P^*}{\partial \eta} < 0$ at the EE. The ratio $\frac{P}{U}$ gives the mean polymer length. Dividing the last equation of (2.4) by U and differentiating with respect to η, it is seen that $\frac{d}{d\eta}\left(\frac{P^*}{U^*}\right) > 0$ at the EE.

3.7. A solution of the PDE system in the case of general incidence. Returning to (2.1) and (2.2), consider the case of general incidence but no joining, i.e., $\eta = 0$. The corresponding system of ODEs given in system (2.4), again with $\eta = 0$, has EE from Lemma 3.6 given by the following:

$$\begin{aligned} U^* &= \frac{\beta\gamma(\beta x_0+\mu)^2 - \beta^2\lambda\tau}{(2\beta x_0+\mu)[\omega\gamma(\beta x_0+\mu)^2+\beta\mu\tau]}, \\ V^* &= \frac{(\beta x_0+\mu)^2(\omega\lambda+\mu)}{\omega\gamma(\beta x_0+\mu)^2+\beta\mu\tau}, \\ P^* &= \frac{\gamma(\beta x_0+\mu)^2-\beta\lambda\tau}{\omega\gamma(\beta x_0+\mu)^2+\beta\mu\tau}. \end{aligned} \tag{3.8}$$

To find an equilibrium distribution of polymer lengths, set $\frac{\partial}{\partial t}u(x,t) = 0$ in (2.2). Compute the derivative with respect to x of the rest of (2.2), substituting in values of U^*, V^*, and P^* from (3.8) to obtain

$$\frac{d^2}{dx^2}[u(x)] + \frac{\beta(\beta x+\mu)}{(\beta x_0+\mu)^2}\,\frac{d}{dx}[u(x)] + \frac{3\beta^2}{(\beta x_0+\mu)^2}u(x) = 0. \tag{3.9}$$

The boundary condition $u(x_0) = 0$, first given in (2.3), can be used to find solutions to (3.9) of the form

$$u(x) = Ce^{-\frac{\beta(x-x_0)(\beta x+\beta x_0+2\mu)}{2(\beta x_0+\mu)^2}}(x-x_0)(\beta x+\beta x_0+2\mu). \tag{3.10}$$

Note that from (2.2) with $x = x_0$,

$$\frac{d}{dx}[u(x)] = 2\beta U^*\left(\frac{1+\omega P^*}{\tau V^*}\right). \tag{3.11}$$

Substitute into (3.11) values of U^*, V^*, and P^* from (3.8). Then compute the derivative of (3.10) and set it equal to (3.11) to find

$$C = \frac{\beta^3(\beta\lambda\tau - \gamma(\beta x_0+\mu)^2)}{(\beta x_0+\mu)^3(2\beta x_0+\mu)[\omega\gamma(\beta x_0+\mu)^2+\mu\beta\tau]}.$$

The equilibrium solution from (3.10), denoted by $u^*(x)$, is thus

$$u^*(x) = \left(e^{-\frac{\beta(x-x_0)(\beta x+\beta x_0+2\mu)}{2(\beta x_0+\mu)^2}}\right)\frac{\beta^3(x-x_0)(\beta x+\beta x_0+2\mu)[\beta\lambda\tau(1-1/\mathcal{R}_0)]}{(\beta x_0+\mu)^3(2\beta x_0+\mu)[\omega\gamma(\beta x_0+\mu)^2+\mu\beta\tau]}, \tag{3.12}$$

where $\mathcal{R}_0$ is given in (3.2). Note that the numerator of $u^*(x)$ requires $x > x_0$ and $\mathcal{R}_0 > 1$. The denominator of $u^*(x)$ shows that an increase in ω decreases the number of polymers of length x at steady state for all viable lengths x.

From (3.10), it can be seen that the value of x at which $u^*(x)$ achieves its maximum is independent of ω and is given by

$$x = (\sqrt{3}-1)\frac{\mu}{\beta} + \sqrt{3}\,x_0. \tag{3.13}$$

However, from (3.12), the magnitude of this maximum decreases as ω increases.

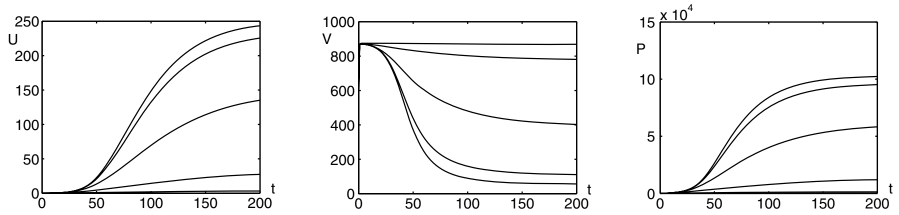

FIG. 2. *Varying $\omega = 0, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}$ for populations $U(t)$, $V(t)$, and $P(t)$ with $x_0 = 6$, $\lambda = 4400$, $\gamma = 5$, $\tau = 0.3$, $\mu = 0.04$, $\beta = 10^{-4}$, $\eta = 0$. Range of ω runs top to bottom on U and P graphs, bottom to top on V graph.*

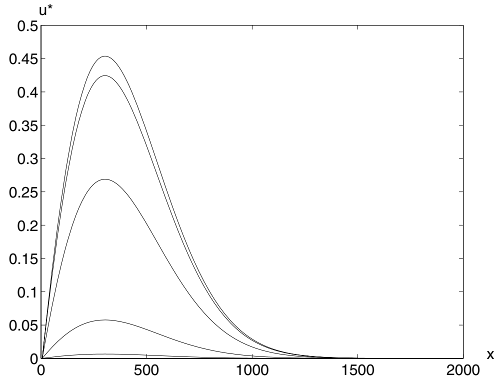

FIG. 3. *Steady-state polymer distribution $u^*(x)$ with $x_0 = 6$, $\lambda = 4400$, $\gamma = 5$, $\tau = 0.3$, $\mu = 0.04$, $\beta = 10^{-4}$, $\eta = 0$, and $\omega = 0, 10^{-5}, 10^{-4}, 10^{-3}, 10^{-2}$. Range of ω runs from top curve to bottom on graph.*

4. Numerical simulations. To complement the previous analytical results, we present some numerical simulations. All simulations shown, unless otherwise noted, use the same parameters as in [14], namely $x_0 = 6/(\text{SAF/sq})$, $\lambda = 4400/\text{day}$, $\gamma = 5/\text{day}$, $\tau = 0.3/(\text{SAF/sq} * \text{day})$, $\mu = 0.04/\text{day}$, and $\beta = 10^{-4}(\text{SAF/sq})/\text{day}$, giving $\rho \approx 2 \times 10^5 > 1$. These parameters follow from data and observations in [3, 7, 20, 25, 30]. Some broader ranges include that $x_0 \approx 6$–30 [20], PrP$^{\text{C}}$ has a half-life of 3–6 hours [3, 7, 25] and hence $\gamma \approx 3$–$5/\text{day}$, $\mu \ll \gamma$ [20, 25], and $\lambda \approx 10^3$–$10^4/\text{day}$ [20]. The units SAF/sq are a measure of scrapie-associated fibrils counted in spleens of Compton white mice that had been given intracerebral injections of the 139A scrapie strain [30]. Note that the above parameter set gives $\mathcal{R}_0 \approx 16$. We vary values of ω and η to investigate the changes introduced by these parameters.

First consider general incidence. The effects of the parameter ω on U, V, and P, discussed in section 3.6, are shown in Figure 2. Additionally, the equilibrium solution for $u(x)$ found in (3.12) allows a comparison of steady-state polymer distributions, given differing values of ω. This appears in Figure 3, computed from (3.12). Note that, for all values of ω, the maximum value of $u(x)$ occurs at $x \approx 303$, as can be computed from (3.13).

Next consider joining. Section 3.6 describes the effects of η on the EE of system (2.4), shown numerically in Figure 4. As discussed in section 3.6, the sign of $\frac{\partial \mathcal{Z}^*}{\partial \phi}$ is undetermined; hence the sign of $\frac{\partial W^*}{\partial \eta}$ is also undetermined. It turns out that most parameter combinations, but not all, support $\frac{\partial \mathcal{Z}^*}{\partial \phi} < 0$. The opposite can occur in the

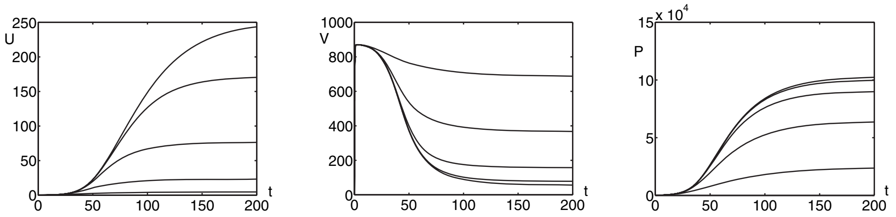

FIG. 4. *Varying $\eta = 0, 10^{-4}, 10^{-3}, 10^{-2}, 10^{-1}$ for populations $U(t)$, $V(t)$, and $P(t)$ with $x_0 = 6$, $\lambda = 4400$, $\gamma = 5$, $\tau = 0.3$, $\mu = 0.04$, $\beta = 10^{-4}$, $\omega = 0$. Range of η runs top to bottom on U and P graphs, bottom to top on V graph.*

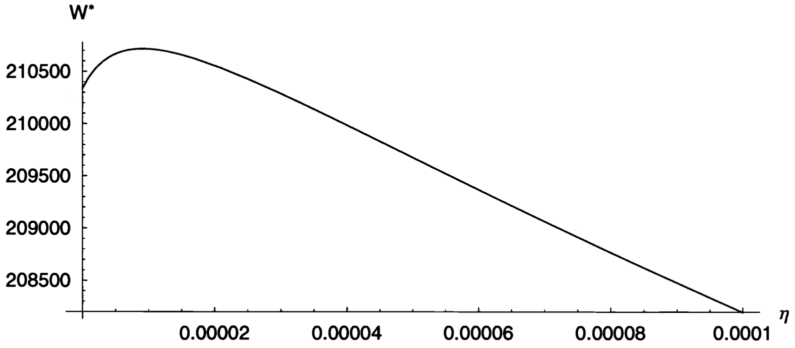

FIG. 5. *Dependence of W^* on η with $x_0 = 6$, $\lambda = 4400$, $\gamma = 5$, $\tau = 0.3$, $\mu = 0.02$, $\beta = 10^{-4}$, $\omega = 0$.*

case that $\delta \to 1$, which is possible in the case that μ is small or βx_0 is large. A brief explanation appears in Appendix C. Even so, it appears that $\frac{\partial \mathcal{Z}^*}{\partial \phi} > 0$ for only small values of ϕ. This effect is demonstrated in Figure 5 for $\frac{\partial W^*}{\partial \eta}$, which is proportional to $\frac{\partial \mathcal{Z}^*}{\partial \phi} > 0$. The parameters used in Figure 5 are the same as those listed above, but with smaller μ, namely $\mu = 0.02$, and $\omega = 0$.

Last, combine general incidence with joining. Lemma 3.2, Theorem 3.7, and Remark 3.8 together suggest that the EE of system (3.1) is GAS. Numerical simulations such as those shown in Figure 6 support this suggestion. The pair of surfaces in this figure show long-term equilibrium values of U and P, denoted U_∞ and P_∞, as both ω and η vary. For all shown pairs of ω and η values, both U_∞ and P_∞ remain positive, indicating (as a consequence of Remark 3.8) that they correspond to U^* and P^*. The shown ranges for ω and η correspond to the lower range of values used in Figures 2, 3, 4, and 5. Similar graphs generated using higher values of ω and η also result in positive values of U_∞ and P_∞. The parameter values used for x_0, λ, γ, τ, μ, and β are the same as those given at the beginning of this section.

Figures 2, 3, and 4 were computed using MATLAB, with `ode15s` for Figures 2 and 4. Figures 5 and 6 were computed using Mathematica.

5. Biological interpretation and discussion. We now discuss the analytical results and numerical simulations (for the assumed parameter values) in terms of prion biology. From sections 3.2 and 3.3, the system (2.4) always has a DFE $(U, V, P) = (0, \frac{\lambda}{\gamma}, 0)$, which attracts all solutions if $\gamma \geq \mu + \beta * x_0$ and $\mathcal{R}_0 = \frac{\beta\lambda\tau}{\gamma(\beta x_0 + \mu)^2} \leq 1$. This is the only equilibrium for $\mathcal{R}_0 < 1$, but for $\mathcal{R}_0 > 1$ there is a unique EE (U^*, V^*, P^*), with $P^* = W^* + x_0 U^*$ and $V^* \leq \lambda/\gamma$, as can be seen from (3.6). This equilibrium

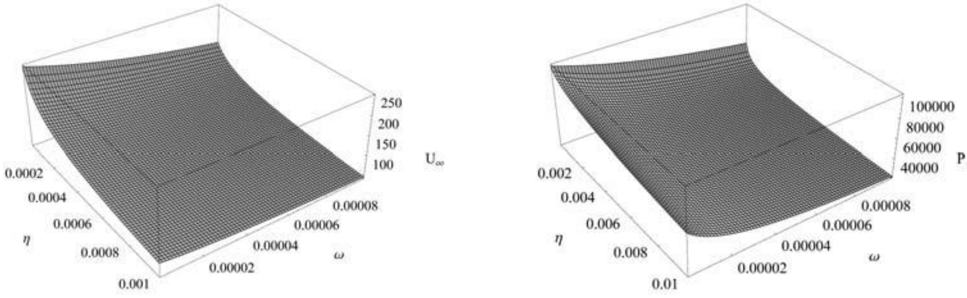

FIG. 6. *Long-term values U_∞ and P_∞ as η and ω vary. In both graphs $x_0 = 6$, $\lambda = 4400$, $\gamma = 5$, $\tau = 0.3$, $\mu = 0.04$, and $\beta = 10^{-4}$. On the U_∞ graph, $10^{-6} < \eta < 10^{-3}$, $10^{-6} < \omega < 10^{-4}$, and $50 < U_\infty < 250$. On the P_∞ graph, $10^{-6} < \eta < 10^{-2}$, $10^{-6} < \omega < 10^{-4}$, and $20,000 < P_\infty < 100,000$.*

is given explicitly by (3.8) in the case of no joining, and with joining it can be found from the solution of a cubic (see Lemma 3.6). If $\mathcal{R}_0 > 1$, then this EE is locally asymptotically stable.

From section 3.6, both increased ω and increased η cause U^* to decrease. The change related to ω indicates that as the total population of PrP$^{\text{Sc}}$ has a greater effect on general incidence, the total number of polymers at the EE decreases. For the parameters used, if $\omega \geq 10^{-3}$, then the values of (U^*, V^*, P^*) are close to those at the DFE, as seen in Figure 2. The change related to η indicates that a higher rate of polymer joining results in fewer total polymers at the EE. Increased ω and increased η cause V^* to increase. Hence the same biological changes cause both a decrease in PrP$^{\text{Sc}}$ polymers and an increase in PrP$^{\text{C}}$ at the EE. Additionally, increased ω and increased η cause the equilibrium value P^* of total PrP$^{\text{Sc}}$ to decrease. If η increases, then at the EE the mean polymer length $\frac{P^*}{U^*}$ increases, with $\ln P^*$ decreasing more slowly than $\ln U^*$.

The effects on W^* are more complicated. Increased ω, that is, increased dependence of incidence on the total PrP$^{\text{Sc}}$ population, decreases W^*. On the other hand, an increased rate of polymer joining has a variable effect on W^*. Differing parameter combinations can cause W^* to either increase or decrease with a positive change in η; see Figure 5. That noted, it is also true that most viable parameter combinations cause W^* to decrease when η increases.

Recall that the form of $\mathcal{R}_0$ given in (3.2) is the same with either mass action or our general incidence term, and with or without polymer joining. Despite the inability of ω and η to affect disease persistence, however, each of these parameters has a demonstrable effect on the steady-state values of U, V, and P. Also, increasing ω clearly decreases the number of polymers of each possible length, with the maximum for $\omega = 10^{-4}$ being about half the maximum for $\omega = 0$; see Figure 3. From data given by Rubenstein et al. [30], the onset of symptoms of scrapie can be estimated [14] to occur as $U(t)$ reaches a critical value of 130 SAF/sq. From Figures 2 and 4, the inclusion of general incidence or joining may result in U^* less than this critical value, while V^* remains closer to its DFE value. Thus, if the effects of prion diseases are caused by either an excess of PrP$^{\text{Sc}}$ or a lack of PrP$^{\text{C}}$ [24, 29], then changing the EE by increasing ω or η may be enough to delay or prevent the onset of disease symptoms.

Appendix A. Proof of Theorem 3.7. Consider a system equivalent to (3.1), namely, the system given by (3.4). Setting each of the derivatives to zero gives

$$\begin{aligned}\mathcal{Z}^* &= \mathcal{X}^* + \phi(\mathcal{X}^*)^2,\\ \frac{(\mathcal{Y}+\mathcal{Z})^* - \mathcal{Z}^*}{1+\nu(\mathcal{Z}^*+\delta\mathcal{X}^*)} &= 1 + \phi(1-\delta)\mathcal{X}^*.\end{aligned}$$

Set $q = 1 + \phi(1-\delta)\mathcal{X}^*$ and $r = 1 + \nu\mathcal{X}^*(1+\delta+\phi\mathcal{X}^*)$. Then the Jacobian of (3.4) at the unique EE is given by

$$\begin{bmatrix} -1-2\phi\mathcal{X}^* & 1 & 0 \\ 2\phi\delta\mathcal{X}^* + q - \dfrac{\nu\delta q\mathcal{X}^*}{r} & -1 - \dfrac{\mathcal{X}^*(1+\nu q)}{r} & \dfrac{\mathcal{X}^*}{r} \\ \delta^2 + 2\phi\delta\mathcal{X}^* & \rho - 1 & -\rho \end{bmatrix}.$$

The Jacobian yields the characteristic equation

$$z^3 + c_1 z^2 + c_2 z + c_3 = 0$$

with

$$\begin{aligned} c_1 &= \rho + 2 + 2\phi\mathcal{X}^* + \frac{\mathcal{X}^*(1+\nu q)}{r},\\ c_2 &= \phi\mathcal{X}^*(1-\delta) + 2\rho(1+\phi\mathcal{X}^*) + \frac{[2(1+\phi\mathcal{X}^*) + (\rho+1+\delta+2\phi\mathcal{X}^*)\nu q]\mathcal{X}^*}{r},\\ c_3 &= (1+2\phi\mathcal{X}^*)\left(\rho + \frac{\rho\nu q\mathcal{X}^*}{r} + \frac{\mathcal{X}^*}{r}\right) - \rho\left(1 + \phi(1+\delta)\mathcal{X}^* - \frac{\delta\nu q\mathcal{X}^*}{r}\right)\\ &\quad - \frac{\mathcal{X}^*}{r}(\delta^2 + 2\phi\delta\mathcal{X}^*). \end{aligned}$$

Notice that $0 < \delta < 1$ and $\mathcal{X}^* > 0$ when $\mathcal{R}_0 > 1$. Clearly $c_1 > 0$ and $c_2 > 0$. Additionally,

$$c_3 > (1+2\phi\mathcal{X}^*)\left(\rho + \frac{\mathcal{X}^*}{r}\right) - \rho(1+\phi(1+\delta)\mathcal{X}^*) - \frac{\mathcal{X}^*}{r}(\delta^2 + 2\phi\delta\mathcal{X}^*) > 0.$$

Rewriting c_3 as

$$c_3 = \frac{\mathcal{X}^*}{r}[1 + 2\phi\mathcal{X}^* - (\delta^2 + 2\phi\delta\mathcal{X}^*)] + \frac{\rho\nu q\mathcal{X}^*}{r}(1 + 2\phi\mathcal{X}^* + \delta) + \rho\phi\mathcal{X}^*(1-\delta),$$

it can be shown that

$$c_1\, c_2 > \frac{\mathcal{X}^*}{r}(2 + 2\phi\mathcal{X}^*) + \frac{\rho\nu q\mathcal{X}^*}{r}(2 + 2\phi\mathcal{X}^*) + \rho(2 + 2\phi\mathcal{X}^*) > c_3.$$

Hence the Routh–Hurwitz conditions are satisfied and the proof is complete. □

Appendix B. Selected proofs of Propositions 3.9 and 3.10. Differentiate (3.7) implicitly to give $\frac{\partial\mathcal{X}^*}{\partial\nu} < 0$, then compute from (3.6) that

$$\frac{\partial\mathcal{Y}^*}{\partial\nu} = -\frac{\partial\mathcal{X}^*}{\partial\nu}(1-\delta^2) - 2\phi\mathcal{X}^*\frac{\partial\mathcal{X}^*}{\partial\nu}(1-\delta) > 0.$$

Differentiate (3.7) implicitly to obtain

$$\frac{\partial \mathcal{X}^*}{\partial \phi} = \frac{-2\nu\rho\phi(1-\delta)(\mathcal{X}^*)^3 - [\nu\rho + \nu\rho(1-\delta^2) + 1 - \delta](\mathcal{X}^*)^2 - \rho(1-\delta)\mathcal{X}^*}{3\nu\rho\phi^2(1-\delta)(\mathcal{X}^*)^2 + 2[\nu\rho\phi + \nu\rho\phi(1-\delta^2) + \phi(1-\delta)]\mathcal{X}^* + \nu\rho(1+\delta) + \rho\phi(1-\delta) + 1 - \delta^2},$$

which shows that $\frac{\partial \mathcal{X}^*}{\partial \phi} < 0$. Next compute $\rho\frac{\partial \mathcal{Y}^*}{\partial \phi}$ and divide by $(1-\delta) > 0$ to find

$$\frac{\rho}{1-\delta}\frac{\partial \mathcal{Y}^*}{\partial \phi} = -2\phi\mathcal{X}\frac{\partial \mathcal{X}^*}{\partial \phi} - (\mathcal{X}^*)^2 - \frac{\partial \mathcal{X}^*}{\partial \phi}(1+\delta).$$

Substitute $\frac{\partial \mathcal{X}^*}{\partial \phi}$ from above, and write the full right-hand side over a common denominator. The resulting numerator can be simplified to give

$$\begin{aligned}&\nu\rho\phi^2(1-\delta)(\mathcal{X}^*)^4 + 2\nu\rho\phi(1-\delta^2)(\mathcal{X}^*)^3 + \rho\phi(1-\delta)(\mathcal{X}^*)^2\\ &\quad + \nu\rho(1-\delta^2)(1+\delta)(\mathcal{X}^*)^2 + \rho(1-\delta^2)\mathcal{X}^*.\end{aligned}$$

The numerator is seen to be strictly positive, over a positive denominator, and hence $\frac{\partial \mathcal{Y}^*}{\partial \phi} > 0$.

Appendix C. Computing values of ϕ for which $\frac{\partial \mathcal{Z}^*}{\partial \phi} > 0$. Given the EE expressions for $\mathcal{X}^*$ and $\mathcal{Z}^*$ in (3.6) and (3.7), clearly $\frac{\partial \mathcal{Z}^*}{\partial \phi} > 0$ requires that

$$\frac{\partial \mathcal{X}^*}{\partial \phi} > \frac{-(\mathcal{X}^*)^2}{2\phi\mathcal{X}^* + 1},$$

where $\frac{\partial \mathcal{X}^*}{\partial \phi}$ is given by

$$\frac{\partial \mathcal{X}^*}{\partial \phi} = \frac{-2\rho\nu\phi(1-\delta)(\mathcal{X}^*)^3 - [\rho\nu + \rho\nu(1-\delta^2) + (1-\delta)](\mathcal{X}^*)^2 - \rho(1-\delta)\mathcal{X}^*}{3\rho\nu\phi^2(1-\delta)(\mathcal{X}^*)^2 + 2[\rho\nu\phi + \rho\nu\phi(1-\delta^2) + \phi(1-\delta)]\mathcal{X}^* + \rho\nu(1+\delta) + \rho\phi(1-\delta) + 1 - \delta^2}.$$

Letting $\delta \approx 1$,

$$\frac{\partial \mathcal{X}^*}{\partial \phi} \approx -\frac{\rho\nu(\mathcal{X}^*)^2}{2\rho\nu\phi\mathcal{X}^* + 2\rho\nu} > -\frac{\rho\nu(\mathcal{X}^*)^2}{2\rho\nu\phi\mathcal{X}^* + \rho\nu} = -\frac{(\mathcal{X}^*)^2}{2\phi\mathcal{X}^* + 1}.$$

Hence for δ near 1, there are likely to be ranges of ϕ values for which $\frac{\partial \mathcal{Z}^*}{\partial \phi} > 0$.

A HIERARCHY OF DIFFUSIVE HIGHER-ORDER MOMENT EQUATIONS FOR SEMICONDUCTORS*

ANSGAR JÜNGEL[†], STEFAN KRAUSE[‡], and PAOLA PIETRA[§]

Abstract. A hierarchy of diffusive partial differential equations is derived by a moment method and a Chapman–Enskog expansion from the semiconductor Boltzmann equation assuming dominant collisions. The moment equations are closed by employing the entropy maximization principle of Levermore. The new hierarchy contains the well-known drift-diffusion model, the energy-transport equations, and the six-moments model of Grasser et al. It is shown that the diffusive models are of parabolic type. Two different formulations of the models are derived: a drift-diffusion formulation, allowing for a numerical decoupling, and a symmetric formulation in generalized dual-entropy variables, inspired by nonequilibrium thermodynamics. An entropy inequality (or H-theorem) follows from the latter formulation.

Key words. semiconductor Boltzmann equation, moment method, Chapman–Enskog expansion, entropy maximization, energy-transport model, higher-order moments

1. Introduction.

The semiconductor Boltzmann equation is of fundamental importance for the modeling of classical transport of charged carriers in solids. Its solution is the microscopic distribution function $f(x, p, t)$ depending on the spatial variable x, the (crystal) momentum p, and the time t. Macroscopic quantities, such as the particle density, current density, and energy density, can be computed from certain integrals over the momentum space, which are called moments. Since the numerical solution of the Boltzmann equation, by direct or Monte Carlo methods, is extremely time consuming and not suitable to simulate real problems in semiconductor production mode, approximate models have been derived, consisting of evolution equations for a certain number of moments of the distribution function.

The idea of the moment method is to multiply the Boltzmann equation by certain weight functions depending only on the momentum variable and to integrate over the momentum space. This leads (for a finite number of weight functions) to the so-called moment equations which are generally not closed; i.e., there are more moments than equations. This is called the closure problem. In order to obtain a closed set of equations, additional information is needed. Here we use a diffusion scaling and follow the approach of Müller and Ruggeri [45] or Levermore [41], who closed the

set of equations (essentially) by taking that distribution function in the definition of the moments, which maximizes the kinetic entropy under the constraints of given moments. This approach was first used in [18]. For a more recent reference, see [12]. In the context of semiconductor problems, entropy maximization has been introduced in [3] (see also [2] for a complete list of references). We derive for the first time diffusive moment models of arbitrary order and for collision operators under abstract hypotheses.

Depending on the number of moments, one obtains a hierarchy of macroscopic equations. The lowest-order model is the standard drift-diffusion model, consisting of the mass conservation equation and a constitutive equation for the current density [44]. This model is often used in device simulations at an industrial level, but it cannot cope with hot-electron or high-field phenomena, occurring in modern ultrasmall devices. Hence, higher-order moments of the distribution function need to be included leading to hydrodynamic or diffusive systems of equations.

First we review the hydrodynamic-type models which are mathematically hyperbolic conservation laws [41]. These models are derived from the Boltzmann equation in the hydrodynamic scaling. As a closure condition, an expansion of the distribution function around a heated Maxwellian using Hermite polynomials [24, 46] or using Grad's expansion [42] has been employed, which gives the so-called hydrodynamic equations [8], consisting of conservation laws for mass, momentum, and energy. The equations may also be closed using the entropy maximization principle. When 13 moments are taken into account, so-called extended hydrodynamic models have been derived [1, 4]. Hydrodynamic models of arbitrary order have been obtained in [49, 53, 54]. Finally, we mention that recently this approach has been generalized to (extended) quantum hydrodynamic models, which are obtained starting from the Wigner equation [17, 37].

Performing the diffusion limit in the Boltzmann equation, combined with the moment method, leads to diffusion-type moment equations. With the moments 1 and $\varepsilon(p)$, where $\varepsilon(p)$ is the carrier kinetic energy, energy-transport models [52] can be derived [6, 7]. These models consist of conservation laws of mass and energy and constitutive relations for particle and energy fluxes. They have been widely studied in the engineering as well as in the mathematical literature (see, e.g., [5, 11, 30, 43, 48, 55] for some engineering and [6, 13, 15, 22, 31, 32, 34] for some mathematical references). Energy-transport equations allow for the modeling of hot-electron effects. However, for ultrasmall devices, the numerical results are not sufficiently accurate compared to Monte Carlo simulations of the Boltzmann equation.

Improved accuracy has been obtained by including further moments of the distribution function leading, for instance, to the six-moments model of Grasser et al. [27] (also see [51]). The six-moments model consists of conservation laws for mass, energy, and the so-called kurtosis and constitutive equations for the corresponding three fluxes. Compared to the extended hydrodynamic models, the advantage of this model is that it constitutes a system of parabolic equations instead of hyperbolic ones, which simplifies the numerical discretization and solution considerably. Up to now, the employed closure in the literature is only heuristic, and the determination of the flux relations is based on approximations [30]. Our approach does not need any approximation and works for general collision operators (under some conditions) and general nonparabolic band structures.

More precisely, we derive, under suitable assumptions (see (H1)–(H4) below), diffusive higher-order moment models of the form

$$\partial_t m_i + \mathrm{div} J_i - i J_{i-1} \cdot \nabla V = W_i, \quad i = 0, \ldots, N,$$

where m_i are the moments (m_0 being the particle density and m_1 the energy density), J_i are the fluxes, V is the electric potential, and W_i are the averaged inelastic scattering terms (with $W_0 = 0$). The fluxes are given by

$$J_i = -\sum_{j=0}^{N} \big(D_{ij} \nabla \lambda_j + j D_{i,j-1} \nabla V \lambda_j \big),$$

where D_{ij} are the diffusion coefficients, coming from the dominant scattering processes, and λ_i are the Lagrange multipliers, coming from the constrained entropy maximization problem. The moments m_i depend nonlinearly on the Lagrange multipliers λ_j. Besides our derivation, the main results of this paper are as follows:

- The diffusion matrix (D_{ij}) is symmetric and positive definite under some topological assumptions on the semiconductor band structure, and the dependence of the moments m_i on λ_j is monotone in the sense of operators. Thus, the evolution problem is of parabolic type.
- The flux equations can be written equivalently in the drift-diffusion form

  $$J_i = -\nabla d_i - F_i(d) d_i \nabla V, \quad i = 0, \ldots, N,$$

  where $d_i = D_{i0}$ and $F_i(d)$ are nonlinear functions of $d = (d_0, \ldots, d_N)$ (see section 4.1 for details). This formulation allows for a numerical decoupling and the use of local Slotboom variables for designing a discretization scheme (see [15] and Remark 4.2 below).
- The convective parts including the electric field $-\nabla V$ can be eliminated by introducing generalized dual-entropy variables $\nu = (\nu_0, \ldots, \nu_N)$, depending on the Lagrange multipliers and the electric potential, such that

  $$\partial_t \rho_i(\nu) + \mathrm{div} F_i = g_i, \quad F_i = -\sum_{j=0}^{N} C_{ij} \nabla \nu_j,$$

  where ρ_i depends on ν, g_i depends on W_j and $\partial_t V$, and the new diffusion matrix (C_{ij}) is symmetric and positive definite (see section 4.2 for details). This formulation is useful for the numerical discretization of the equations employing standard (mixed) finite elements [23]. Moreover, it extends the dual-entropy notion known in nonequilibrium thermodynamics [19, 40].
- We are able to recover many well known diffusion models, such as the drift-diffusion, energy-transport, and six-moments models of Grasser et al. Compared to [29], no approximation of the highest-order moment is needed.

The originality of this paper consists in the facts (i) that we present for the first time a complete hierarchy of diffusion moment models for general collision operators, (ii) that we present a unifying approach of the derivation of these models, and (iii) that the derived models have very pleasant features useful for the mathematical analysis and the numerical discretization of the equations.

The paper is organized as follows. In section 2 we state our assumptions on the band structure and the collision operator, and we derive the model equations by a Chapman–Enskog expansion. Furthermore, some properties and several examples of the diffusion matrix are given. In section 3 we show that the drift-diffusion, energy-transport, and six-moments models can be recovered from the general theory. Section 4 is devoted to the drift-diffusion and dual-entropy formulation. We conclude in section 5. Finally, in the appendix some technical results are proved.

2. Derivation of the model equations. Let $B \subset \mathbb{R}^3$ be the first Brillouin zone of the semiconductor crystal under consideration. The set B is symmetric with respect to the origin; hence, we can identify it with the three-dimensional torus. We assume throughout this paper that all variables and functions are scaled. The evolution of the charged particles in the semiconductor is described by a distribution function $f(x,p,t) \geq 0$ depending on time $t > 0$ and space-crystal momentum variables $(x,p) \in \Omega \times B$, where $\Omega \subset \mathbb{R}^3$ is the semiconductor domain. The distribution function $f = f_\alpha$ is assumed to satisfy the (dimensionless) semiconductor Boltzmann equation in diffusion scaling:

$$\alpha^2 \partial_t f_\alpha + \alpha\big(u \cdot \nabla_x f_\alpha + \nabla_x V \cdot \nabla_p f_\alpha\big) = Q(f_\alpha); \tag{2.1}$$

i.e., we change the space and time scale according to $x \to x/\alpha$ and $t \to t/\alpha^2$, where the Knudsen number α is the ratio of the (optical) phonon energy and the typical kinetic energy of an electron (see [6] for details of the scaling). The Knudsen number is assumed to be small compared to one (like in [6]). The group velocity $u = u(p)$ is defined by $u = \nabla_p \varepsilon(p)$, where $\varepsilon(p)$ is the kinetic carrier energy given by the band structure of the semiconductor crystal. The function $V = V(x,t)$ denotes the electric potential which is assumed to be given or to be determined from the Poisson equation

$$\lambda^2 \Delta V = \int_B f dp - C(x),$$

where $\lambda > 0$ is the (scaled) Debye length and $C(x)$ the doping profile, modeling fixed charged background ions in the semiconductor crystal.

Below, we will perform the (formal) asymptotic limit $\alpha \to 0$. This limit avoids any assumption on the distribution function (unlike in [25]), but, on the other hand, we need some hypotheses on the collision operator. More specifically, we assume that the collision operator can be decomposed into two parts: a dominant part and a small part

$$Q(f) = Q_1(f) + \alpha^2 Q_2(f).$$

This decomposition has been justified in [6, 20], for instance. We will suppose (see section 2.2) that the kernel of Q_1 consists of generalized Maxwellians introduced in section 2.1 and that the moments of $Q_1(f)$ vanish. These assumptions are well known in this context, and they are necessary to perform the diffusion limit $\alpha \to 0$.

In order to specify our assumptions on the collision operator, we need the so-called generalized Maxwellian introduced in the following subsection.

2.1. Entropy maximization. We define the (scaled) relative entropy for $f(x, p, t)$ by

$$H(f)(x,t) = -\int_B f(\log f - 1 + \varepsilon(p))dp.$$

Here and in the following, we consider only scaled quantities. The generalized Maxwellian is defined as the maximizer of a certain constrained extremal problem. In order to define this problem, let scalar *weight functions* $\kappa(p) = (\kappa_0(p), \ldots, \kappa_N(p))$ and *moments* $m(x,t) = (m_0(x,t), \ldots, m_N(x,t))$ be given. In [54], also vector-valued weight functions are considered. We impose the following assumptions on κ_i and ε.

(H1) Let $N \geq 1$. The weight functions $\kappa_i(p)$ $(i = 0, \ldots, N)$ and the kinetic energy $\varepsilon(p)$ are smooth and even in p. Moreover, $\kappa_0 = 1$ and $\kappa_1 = \varepsilon$.

The case $N = 0$ is treated in section 3.

Example 2.1. Examples for the weight functions are

$$\kappa^{(1)} = (1, \varepsilon, \varepsilon^2, \varepsilon^3 \dots), \quad \kappa^{(2)} = (1, \varepsilon, |u|^2, \varepsilon|u|^2, |u|^4, \varepsilon|u|^4, \dots). \tag{2.2}$$

The kinetic energy may be given, for instance, in the parabolic band approximation, by $\varepsilon(p) = \frac{1}{2}|p|^2$. Clearly, in this case $\kappa^{(1)}$ and $\kappa^{(2)}$ coincide (up to multiplicative factors). A more refined model is the Kane dispersion relation, which takes into account the nonparabolicity at higher energies, $\varepsilon(1 + \delta\varepsilon) = \frac{1}{2}|p|^2$, where $\delta > 0$ is the nonparabolicity parameter. In terms of ε, we have

$$\varepsilon(p) = \frac{|p|^2}{1 + \sqrt{1 + 2\delta|p|^2}} = \frac{1}{2\delta}\big(\sqrt{1 + 2\delta|p|^2} - 1\big). \tag{2.3}$$

If $\delta = 0$, we recover the parabolic band approximation. The above examples for $\kappa^{(i)}$ and ε satisfy (H1).

We recall that, instead of Kane's dispersion relation, also the approximation $a\varepsilon(p)^b = |p|^2/2$ has been suggested, where the parameters a and b are fitted for different energy ranges [9] (see the discussion in [30, sect. IV]).

We set $\langle g \rangle = \int_B g(p)dp$ for a function $g(p)$, and we call the expression $\langle \kappa_i f \rangle$ the *ith moment* of f. Then we consider the constrained maximization problem

$$H(f^*) = \max\Big\{H(f) : \langle \kappa f(x, \cdot, t) \rangle = m(x, t) \text{ for } x \in \Omega,\ t > 0\Big\}. \tag{2.4}$$

The solution of this problem, if it exists, is given by

$$f^*(x, p, t) = \exp\big(\widetilde{\lambda}(x, t) \cdot \kappa(p) - \varepsilon(p)\big),$$

where $\widetilde{\lambda} = (\widetilde{\lambda}_0, \dots, \widetilde{\lambda}_N)$ are the Lagrange multipliers. Defining $\lambda_1 = \widetilde{\lambda}_1 - 1$ and $\lambda_i = \widetilde{\lambda}_i$ for all $i \neq 1$, we have the more compact formulation

$$f^*(x, p, t) = e^{\lambda(x,t) \cdot \kappa(p)}.$$

Remark 2.2. We notice that the mathematical solution of (2.4) is quite delicate. In [33], it has been shown that (2.4) can be uniquely solved whenever the multipliers $\widetilde{\lambda} = \widetilde{\lambda}(m)$ can be found. However, there are situations for which problem (2.4) has no solution. This is the case if the momentum space is unbounded and the polynomial weight functions have superquadratic growth at infinity [21, 35]. When the constraint of the highest degree is relaxed (as an inequality instead of an equality), the constrained maximization problem is always uniquely solvable [50]. In particular, the maximization problem can be uniquely solved if one of the following conditions holds:

1. General band structure: B is a bounded set and $\kappa = (1, \varepsilon, \varepsilon^2, \dots)$.
2. Kane's nonparabolic band approximation: $B = \mathbb{R}^3$ and $\kappa = (1, \varepsilon, \varepsilon^2)$, where ε is given by (2.3). Notice that $\varepsilon(p)$ grows linearly with p at infinity such that $\kappa_i(p)$ is at most quadratic.
3. Kane's nonparabolic band approximation: $B = \mathbb{R}^3$ and $\kappa = (1, \varepsilon, |u|^2, \varepsilon|u|^2, |u|^4, \varepsilon|u|^4, \dots)$, where ε is given by (2.3) [38]. Notice that the velocity $u = \nabla_p \varepsilon$ is bounded, and, therefore, $\kappa_i(p)$ is at most quadratic.
4. Parabolic band approximation: $B = \mathbb{R}^3$ and $\kappa = (1, |p|^2/2)$.

Given a function $f(x,p,t)$ with moments $m_i = \langle \kappa_i f \rangle = \int_B \kappa_i f dp$, we call the maximizer of (2.4) the *generalized Maxwellian* with respect to f, $f^* = M_f$. In view of the above comments, there are Lagrange multipliers λ_i such that

$$M_f = e^{\lambda \cdot \kappa}. \tag{2.5}$$

By definition, M_f and f have the same moments; i.e., $\langle \kappa_i M_f \rangle = \langle \kappa_i f \rangle = m_i$.

Below, we employ M_f to close the moment equations. This closure implicitly assumes nondegenerate Boltzmann statistics. For degenerate Fermi–Dirac statistics in the context of the energy-transport model, we refer to [6, 7]. Furthermore, it has been found that in certain semiconductor devices a mixture of hot and cold electrons exists, and a superposition of two (Maxwellian-type) distribution functions has been proposed as a closure [28].

Notice that generally the integrals relating the Lagrange multipliers and the moments cannot be solved analytically, so a numerical approach becomes necessary. However, in the case of the parabolic band energy-transport model (see Example 3.4), the integrals can be computed analytically. Moreover, for the fourth-order moment model (see Example 4.4), we show below that the function $\lambda \mapsto m$ is invertible. We also mention the approach of [4] where the exponentials in the integrals are expanded around the thermal equilibrium.

2.2. Assumptions on the collision operators. With the above definition of the generalized Maxwellian, we can state the following hypotheses on the collision operators.

(H2) For all functions $f(p)$ and all $i = 0, \ldots, N$, $\langle \kappa_i Q_1(f) \rangle = 0$. Furthermore, the null space $N(Q_1)$ of Q_1 consists of generalized Maxwellians, $N(Q_1) = \{f : f = M_f\}$.

(H3) For all functions $f(p)$, it holds that $\langle Q_2(f) \rangle = 0$.

These hypotheses express the collisional invariants. For instance, for elastic collisions, since $\kappa_0 = 1$ and $\kappa_1 = \varepsilon$ by (H1), we have mass and energy conservation:

$$\langle Q_1(f) \rangle = 0, \quad \langle \varepsilon Q_1(f) \rangle = 0.$$

Additionally, we suppose for Q_1 conservation properties for all moments with respect to the chosen weight functions. This assumption is rather strong; however, it is satisfied, for instance, for relaxation-time operators (see Example 2.3). Hypothesis (H3) simply expresses mass conservation for the collision operator Q_2, which is physically reasonable.

In [6], based on [20], the energy-transport model is derived by assuming that Q_1 represents elastic scattering and Q_2 includes inelastic and electron-electron scattering terms. There may be two criticisms: First, the elastic scattering is assumed to be of order one, but it can be seen from physics that elastic scattering gives only a small contribution to the total scattering rate. Second, there are no first-order scattering terms. For a derivation of the energy-transport model including first-order collision terms, we refer to [16]. In this paper, we follow a more formal approach: We derive diffusive models under the above assumptions on the collision operators which may not need to be specified; only some properties are assumed. A refinement of this argument may be the subject of future work. In the following example, we present some simple collision operators satisfying the above hypotheses.

Example 2.3. (i) Consider the relaxation-time operator

$$Q_1(f) = \frac{1}{\tau}(M_f - f), \tag{2.6}$$

where $\tau > 0$ is the (possibly space- and time-dependent) relaxation time. This collision operator satisfies $\langle \kappa_i Q_1(f) \rangle = 0$ for all f (since f and M_f have the same moments), and its null space consists of the functions $f = M_f$. Thus, Q_1 satisfies (H2).

(ii) Let $N = 1$ and $\kappa = (1, \varepsilon)$, and define the collision operator

$$Q_1(f) = Q_{\mathrm{imp}}(f) + Q_{\mathrm{ee}}(f)$$

as the sum of the impurity scattering operator Q_{imp} and the electron-electron binary collision operator Q_{ee},

$$\begin{aligned} Q_{\mathrm{imp}}(f)(p) &= \int_B \phi_{\mathrm{imp}}(p,p')\delta(\varepsilon' - \varepsilon)(f' - f)dp', \\ Q_{\mathrm{ee}}(f)(p) &= \int_B \phi_{\mathrm{ee}}(p,p',p_1,p_1')\delta(\varepsilon' + \varepsilon_1' - \varepsilon - \varepsilon_1)\delta_p(p' + p_1' - p - p_1) \\ &\quad \times (f'f_1' - ff_1)dp_1 dp' dp_1', \end{aligned}$$

where ϕ_{imp}, $\phi_{\mathrm{ee}} > 0$ are transition rates, δ_p is the periodized delta distribution, and $f' = f(p')$, $f_1 = f(p_1)$, $f_1' = f(p_1')$ (see [7]). It has been shown in [7] that $\langle \kappa_i Q_1(f) \rangle = 0$ and that the kernel of Q_1 consists of the functions $M_f = e^{\lambda_0 + \lambda_1 \varepsilon}$; i.e., Q_1 satisfies (H2) for $N = 1$.

(iii) Inelastic scattering may come from phonon collisions modeled by, for instance,

$$Q_{\mathrm{ph}}(f)(p) = \int_B \big(s_{\mathrm{ph}}(p,p')f' - s_{\mathrm{ph}}(p',p)f\big)dp',$$

where $s_{\mathrm{ph}}(p,p') = \phi_{\mathrm{ph}}(p,p')[(N_{\mathrm{ph}}+1)\delta(\varepsilon - \varepsilon' + \varepsilon_{\mathrm{ph}}) + N_{\mathrm{ph}}\delta(\varepsilon - \varepsilon' - \varepsilon_{\mathrm{ph}})]$ and $\varepsilon' = \varepsilon(p')$ [6]. The number N_{ph} is the phonon occupation number, and $\varepsilon_{\mathrm{ph}}$ is the phonon energy. An elementary computation shows that $\langle Q_{\mathrm{ph}}(f) \rangle = 0$; i.e., Q_{ph} satisfies (H3).

2.3. Chapman–Enskog expansion.

First we derive the balance equations.

PROPOSITION 2.4. *Let* (H1)–(H3) *hold, and let f_α be a solution to the Boltzmann equation* (2.1). *We assume that the formal limits $F = \lim_{\alpha \to 0} f_\alpha$ and $G = \lim_{\alpha \to 0}(f_\alpha - M_{f_\alpha})/\alpha$ exist. Then the moments $m_i = \langle \kappa_i M_F \rangle$ and the fluxes $J_i = \langle u \kappa_i G \rangle$ and $I_i = \langle \nabla_p \kappa_i G \rangle$ are solutions of*

$$\partial_t m_i + \mathrm{div} J_i - \nabla V \cdot I_i = W_i, \quad i = 0, \ldots, N, \tag{2.7}$$

where $W_i = \langle \kappa_i Q_2(F) \rangle$ are the averaged inelastic collision terms, $W_0 = 0$, and the divergence and gradient are to be taken with respect to x.

We notice that the definition of the moments is consistent with the notations in section 2.1 since $\langle \kappa_i M_F \rangle = \langle \kappa_i F \rangle$.

Proof. We multiply the Boltzmann equation (2.1) by the weight functions κ_i, integrate over the Brillouin zone B, and integrate by parts in the term involving the electric potential:

$$\alpha^2 \partial_t \langle \kappa_i f_\alpha \rangle + \alpha\big(\mathrm{div}_x \langle u \kappa_i f_\alpha \rangle - \nabla_x V \cdot \langle \nabla_p \kappa_i f_\alpha \rangle\big) = \langle \kappa_i Q_1(f_\alpha) \rangle + \alpha^2 \langle \kappa_i Q_2(f_\alpha) \rangle \tag{2.8}$$

for $i = 0, \ldots, N$. Next, we perform the following Chapman–Enskog expansion (see, e.g., [10]):

$$f_\alpha = M_{f_\alpha} + \alpha g_\alpha. \tag{2.9}$$

This equation in fact defines g_α, and, by assumption, $G = \lim_{\alpha \to 0} g_\alpha$. The generalized Maxwellian M_{f_α} is an even function in p, by hypothesis (H1), whereas $p \mapsto u(p)\kappa_i(p)$

and $p \mapsto \nabla_p \kappa_i(p)$ are odd functions in p. Therefore, $\langle u\kappa_i M_{f_\alpha}\rangle = 0$, $\langle \nabla_p \kappa_i M_{f_\alpha}\rangle = 0$. Then, substituting (2.9) into the moment equations (2.8), observing that the moments of $Q_1(f_\alpha)$ vanish by (H2), and dividing the resulting equation by α^2, we obtain

$$\partial_t \langle \kappa_i M_{f_\alpha}\rangle + \alpha \partial_t \langle \kappa_i g_\alpha\rangle + \mathrm{div}_x \langle u\kappa_i g_\alpha\rangle - \nabla_x V \cdot \langle \nabla_p \kappa_i g_\alpha\rangle = \langle \kappa_i Q_2(f_\alpha)\rangle.$$

Performing the formal limit $\alpha \to 0$ in this equation leads to

$$\partial_t \langle \kappa_i M_F\rangle + \mathrm{div}_x \langle u\kappa_i G\rangle - \nabla_x V \cdot \langle \nabla_p \kappa_i G\rangle = \langle \kappa_i Q_2(F)\rangle. \tag{2.10}$$

These are the balance equations (2.7). □

Remark 2.5. For $i = 0$, we have $I_0 = 0$ and $W_0 = 0$ such that the first balance equation just expresses mass conservation:

$$\partial_t m_0 + \mathrm{div} J_0 = 0. \tag{2.11}$$

Example 2.6. The integrals I_i can be expressed in terms of the fluxes J_i for special choices of the weight functions. For instance, if we choose $\kappa = (1, \varepsilon, \varepsilon^2, \dots)$ (see (2.2)), we obtain $\nabla_p \kappa_i = iu\varepsilon^{i-1}$ for $i \geq 1$ and $\nabla_p \kappa_0 = 0$, and thus $I_i = iJ_{i-1}$ for all $i \geq 0$ (for $i = 0$, we have $I_0 = 0$). In this situation the balance equations become

$$\partial_t m_i + \mathrm{div} J_i - i\nabla V \cdot J_{i-1} = W_i. \tag{2.12}$$

If we choose $\kappa = \kappa^{(2)}$ in (2.2), we cannot express I_i in terms of the integrals $J_0, \dots, J_N$ since, for instance, $\nabla_p \kappa_2 = \nabla_p |u|^2 = \varepsilon'' u$, where ε'' is the Hessian of $\varepsilon(p)$, and this cannot be written in general as a function of $|u|^{2j}$ and $\varepsilon |u|^{2j}$.

Next, we specify the flux equations J_i. For this, we need to determine G. We will see that this is equivalent to solving the operator equation $LG = H$, where $L = DQ_1(M_F)$ is the Fréchet derivative of Q_1 at $M_F = e^{\lambda \cdot \kappa} > 0$ and $H = u \cdot \nabla_x M_F + \nabla_x V \cdot \nabla_p M_F$. We introduce the Hilbert space $L^2(B)$ with the scalar product

$$(g_1, g_2)_F = \int_B g_1 g_2 M_F^{-1} dp$$

and the corresponding norm $\|\cdot\|_F$. In order to solve the equation $LG = H$, we impose the following hypothesis on the operator L.

(H4) The linear operator $L = DQ_1(M_F)$ is continuous, closed, and symmetric on $L^2(B)$, and its null space is spanned by M_F.

An example of an operator Q_1 satisfying (H4) is presented in [6, sect. 3.2].

By the Fredholm alternative, the linear, continuous, and closed operator L on the Hilbert space $L^2(B)$ satisfies the following property: The equation $LG = H$ is solvable if and only if $H \in N(L^*)^\perp$ and its solution is unique in $N(L^*)^\perp$. As L is assumed to be symmetric, $LG = H$ is solvable if and only if $H \in N(L)^\perp$ and the solution is unique in $N(L)^\perp$. Since the null space of L consists of the generalized Maxwellians, $LG = H$ is solvable if and only if $0 = (H, M_F)_F = \int_B H dp$.

Proposition 2.7. *Let* (H1)–(H4) *hold. Then the fluxes of Proposition* 2.4 *can be written as*

$$J_i = -\sum_{j=0}^{N} \big(D_{ij} \nabla \lambda_j + E_{ij} \nabla V \lambda_j \big), \quad i = 0, \dots, N, \tag{2.13}$$

where the diffusion matrices $D_{ij} \in \mathbb{R}^{3\times 3}$ and the matrices $E_{ij} \in \mathbb{R}^{3\times 3}$ are defined by

$$D_{ij} = -\langle \kappa_i u \otimes \phi_j \rangle, \quad E_{ij} = -\langle \kappa_i u \otimes \psi_j \rangle, \tag{2.14}$$

respectively, and $\phi_j = (\phi_{j1}, \phi_{j2}, \phi_{j3})$ *and* $\psi_j = (\psi_{j1}, \psi_{j2}, \psi_{j3})$ *are the (unique) solutions in* $N(L)^\perp$ *of the operator equations*

$$L\phi_{jk} = u_k \kappa_j M_F, \quad L\psi_{j\ell} = \frac{\partial \kappa_j}{\partial p_\ell} M_F, \quad j = 0, \ldots, N, \; k, \ell = 1, 2, 3. \tag{2.15}$$

Proof. Inserting the Chapman–Enskog expansion (2.9) into the Boltzmann equation (2.1), expanding formally the collision operator

$$Q_1(f_\alpha) = Q_1(M_{f_\alpha}) + \alpha D Q_1(M_{f_\alpha}) g_\alpha + O(\alpha^2),$$

and dividing the resulting equation by α, we obtain

$$\begin{aligned} &\alpha \partial_t (M_{f_\alpha} + \alpha g_\alpha) + u \cdot \nabla_x (M_{f_\alpha} + \alpha g_\alpha) + \nabla_x V \cdot \nabla_p (M_{f_\alpha} + \alpha g_\alpha) \\ &\quad = \alpha^{-1} Q_1(M_{f_\alpha}) + D Q_1(M_{f_\alpha}) g_\alpha + O(\alpha). \end{aligned}$$

By (H2), we have $Q_1(M_{f_\alpha}) = 0$. Hence, the formal limit $\alpha \to 0$ gives

$$u \cdot \nabla_x M_F + \nabla_x V \cdot \nabla_p M_F = D Q_1(M_F) G = LG. \tag{2.16}$$

Now let $j \in \{0, \ldots, N\}$ be fixed. The operator equations (2.15) are solvable in $L^2(B)$ since $u_k \kappa_j M_F$ and $(\partial \kappa_j / \partial p_\ell) M_F$ are odd functions in p, and hence, their integrals over B vanish. The unique solution G in $N(L)^\perp$ is given by

$$G = \sum_{j=0}^N \big(\phi_j \cdot \nabla_x \lambda_j + \nabla_x V \cdot \psi_j \lambda_j \big),$$

since, observing $\nabla_x M_F = \sum_j \nabla_x \lambda_j \kappa_j M_F$ and $\nabla_p M_F = \sum_j \lambda_j \nabla_p \kappa_j M_F$, we have

$$\begin{aligned} LG &= \sum_{j=0}^N \big(L\phi_j \cdot \nabla_x \lambda_j + \nabla_x V \cdot L\psi_j \lambda_j \big) = \sum_{j=0}^N \big(\kappa_j u \cdot \nabla_x \lambda_j + \nabla_x V \cdot \nabla_p \kappa_j \lambda_j \big) M_F \\ &= u \cdot \nabla_x M_F + \nabla_x V \cdot \nabla_p M_F. \end{aligned}$$

Hence, since $J_i = \langle u \kappa_i G \rangle$, we obtain (2.13). □

Example 2.8. In the case of the relaxation-time operator of Example 2.3(i), the function G can be found explicitly. Indeed, from Chapman–Enskog expansion (2.9) and Boltzmann equation (2.1), we derive

$$\begin{aligned} g_\alpha &= \frac{1}{\alpha}(f_\alpha - M_{f_\alpha}) = -\frac{\tau}{\alpha} Q_1(f_\alpha) \\ &= -\tau \alpha (\partial_t f_\alpha - Q_2(f_\alpha)) - \tau (u \cdot \nabla_x f_\alpha + \nabla_x V \cdot \nabla_p f_\alpha), \end{aligned}$$

and the formal limit $\alpha \to 0$ gives

$$G = -\tau \big(u \cdot \nabla_x M_F + \nabla_x V \cdot \nabla_p M_F \big) = -\tau \sum_{j=0}^N \big(\kappa_j u \cdot \nabla_x \lambda_j + \nabla_x V \cdot \nabla_p \kappa_j \lambda_j \big) M_F.$$

Thus, the solutions ϕ_j and ψ_j of (2.15) are

$$\phi_j = -\tau u \kappa_j M_F, \quad \psi_j = -\tau \nabla_p \kappa_j M_F. \tag{2.17}$$

Lemma 2.9. *Let $\kappa_i = \varepsilon^i$, $i = 0, \ldots, N$. Then the coefficients E_{ij} in* (2.14) *can be expressed in terms of D_{ij}:*

$$E_{ij} = jD_{i,j-1}, \quad E_{i0} = 0, \quad j = 1, \ldots, N. \tag{2.18}$$

Proof. The assumption $\kappa_i = \varepsilon^i$ gives $\nabla_p \kappa_{i+1} = (i+1)\varepsilon^i \nabla_p \varepsilon = (i+1)u\varepsilon^i$ and hence $L\psi_{i+1} = \nabla_p \kappa_{i+1} M_F = (i+1)L\phi_i$. By the unique solvability in $N(L)^\perp$, $\psi_{i+1} = (i+1)\phi_i + cM_F$ for all $i \geq 0$ and $\psi_0 = cM_F$, where c is a constant vector. Therefore,

$$E_{ij} = -\int_B \kappa_i u \otimes \psi_j dp = -j\int_B \varepsilon^i u \otimes \phi_{j-1} dp = jD_{i,j-1},$$

proving the lemma. □

2.4. Properties of the diffusion matrix. The diffusion matrix $D = (D_{ij})$ defined in (2.14) is symmetric; this expresses the Onsager principle [40].

Lemma 2.10. *The matrices $D = (D_{ij})$, $E = (E_{ij}) \in \mathbb{R}^{3(N+1)\times 3(N+1)}$ are symmetric in the sense that*

$$D_{ij}^\top = D_{ji}, \quad E_{ij}^\top = E_{ji} \quad \textit{for all } i, j = 0, \ldots, N.$$

Proof. We write $D_{ij} = (D_{ij}^{k\ell}) \in \mathbb{R}^{3\times 3}$. Since L is symmetric on $L^2(B)$, we have

$$\begin{aligned} D_{ij}^{k\ell} &= -(u_k \kappa_i M_F, \phi_{j\ell})_F = -(L\phi_{ik}, \phi_{j\ell})_F = -(\phi_{ik}, L\phi_{j\ell})_F \\ &= -(\phi_{ik}, u_\ell \kappa_j M_F)_F = D_{ji}^{\ell k}. \end{aligned}$$

The symmetry of E is proven in a similar way. □

Under additional assumptions on the derivative of the dominant collision operator and on the band structure, we can show that the diffusion matrix is positive definite.

(H5) Let the operator $-L = -DQ_1(M_F)$ be coercive on $N(L)^\perp$; i.e., there exists a constant $\mu > 0$ such that, for all $g \in N(L)^\perp$,

$$(-Lg, g)_F \geq \mu \|g\|_F^2.$$

Example 2.11. We claim that the relaxation-time operator (2.6) satisfies (H5) if the weight functions $\kappa_0, \ldots, \kappa_N$ are linearly independent. Let $g \in N(L)^\perp$. We show first that $M_g \in N(L)$. It is sufficient to prove that $M_{M_g} = M_g$. For this, let $M_g = e^{\lambda\cdot\kappa}$ and $M_{M_g} = e^{\widetilde{\lambda}\cdot\kappa}$. Since the moments of M_g and M_{M_g} coincide by construction, we have

$$\int_B \kappa(e^{\lambda\cdot\kappa} - e^{\widetilde{\lambda}\cdot\kappa})dp = 0 \quad \text{and} \quad \int_B (\lambda\cdot\kappa - \widetilde{\lambda}\cdot\kappa)(e^{\lambda\cdot\kappa} - e^{\widetilde{\lambda}\cdot\kappa})dp = 0.$$

By the strict monotonicity of $x \mapsto e^x$, the integrand vanishes, and, therefore, $(\lambda - \widetilde{\lambda})\cdot \kappa = 0$. Since $\kappa_0, \ldots, \kappa_N$ are linearly independent, $\lambda = \widetilde{\lambda}$. Hence, $M_{M_g} = M_g$, which proves that $M_g \in N(L)$. This property gives

$$(-Lg, g)_F = -\frac{1}{\tau}(M_g - g, g)_F = -\frac{1}{\tau}(M_g, g)_F + \frac{1}{\tau}\|g\|_F^2 = \frac{1}{\tau}\|g\|_F^2.$$

Lemma 2.12. *Let* (H5) *hold, and let $\{u_k\kappa_i : k = 1, 2, 3, i = 0, \ldots, N\}$ be linearly independent functions in p. Then the diffusion matrix $D = (D_{ij})$ is positive definite; i.e., for all $\xi_0, \ldots, \xi_N \in \mathbb{R}^{N+1}$, $(\xi_0, \ldots, \xi_N) \neq 0$,*

$$\sum_{i,j=0}^N \xi_i^\top D_{ij} \xi_j > 0.$$

The proof of the lemma can be found in the appendix. The diffusion matrices D_{ij} can be simplified under additional assumptions.

PROPOSITION 2.13. *Let $\kappa_i = \varepsilon^i$, $i = 0, \dots, N$ and $Q_1(f) = (M_f - f)/\tau$. Then the diffusion coefficients can be written as*

$$D_{ij} = \frac{\tau}{3} \int_B e(\tfrac{1}{2}|p|^2)^{i+j} e'(\tfrac{1}{2}|p|^2)^2 |p|^2 \exp\left(\sum_{k=0}^N \lambda_k e(\tfrac{1}{2}|p|^2)^k \right) dp\, I,$$

where $\varepsilon(p) = e(\frac{1}{2}|p|^2)$ and I is the unit matrix in $\mathbb{R}^{3\times 3}$.

Clearly, we may identify the matrix D_{ij} with its diagonal elements and obtain the $(N \times N)$ matrix $D = (D_{ij})$.

Proof. Since the collision operator Q_1 is assumed to be a relaxation-time operator, the solution of the operator equation (2.15) is equal to $\phi_j = -\tau u \kappa_j M_F = -\tau \varepsilon^j \nabla_p \varepsilon M_F$ (see (2.17)). Thus, by definition (2.14),

$$D_{ij} = -\int_B \varepsilon^i \nabla_p \varepsilon \otimes \phi_j dp = \tau \int_B \varepsilon^{i+j} \nabla_p \varepsilon \otimes \nabla_p \varepsilon M_F dp.$$

Since $\nabla_p \varepsilon(p) = p e'(\frac{1}{2}|p|^2)$, we obtain

$$D_{ij} = \tau \int_B e(\tfrac{1}{2}|p|^2)^{i+j} e'(\tfrac{1}{2}|p|^2)^2 p \otimes p M_F dp.$$

The function $p \mapsto p \otimes p$ is odd in every off-diagonal element such that the above integral vanishes except for the diagonal elements. Since each diagonal element has the same value and $M_F = e^{\lambda \cdot \kappa}$, the expression for D_{ij} is proven. ◻

The diffusion coefficients can be further simplified under additional assumptions on the energy band structure. We consider three examples.

Example 2.14 (monotone energy band). Let the assumption of Proposition 2.13 hold. We suppose additionally that $e(\frac{1}{2}|p|^2)$ is strictly monotone in $|p|$ and that $e(0) = 0$ and $e(\infty) = \infty$. This allows us to choose $B = \mathbb{R}^3$. Then, with spherical coordinates (ρ, θ, ϕ), for $i, j = 0, \dots, N$,

$$D_{ij} = \frac{\tau}{3} \int_0^{2\pi} \int_0^{\pi} \int_0^{\infty} e(\tfrac{1}{2}\rho^2)^{i+j} e'(\tfrac{1}{2}\rho^2)^2 \rho^4 \exp\left(\sum_{k=0}^N \lambda_k e(\tfrac{1}{2}\rho^2)^k \right) \sin\theta d\rho d\theta d\phi.$$

Now we perform the change of variables $\varepsilon = e(\frac{1}{2}\rho^2)$, setting $\gamma(\varepsilon) = \rho^2$. Then $d\rho = (\gamma'(\varepsilon)/2\sqrt{\gamma(\varepsilon)}) d\varepsilon$ such that

$$D_{ij} = \frac{8\pi\tau}{3} \int_0^{\infty} \varepsilon^{i+j} \frac{\gamma(\varepsilon)^{3/2}}{\gamma'(\varepsilon)} \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k \right) d\varepsilon. \tag{2.19}$$

In the special case $N = 1$, the same diffusion coefficients have been derived in [6, equations (3.36), (4.17)]. Notice that the above transformation allows us to simplify the expression for the moments:

$$\begin{aligned} m_i &= \int_B e(\tfrac{1}{2}|p|^2)^i \exp\left(\sum_{k=0}^N \lambda_k e(\tfrac{1}{2}|p|^2)^k\right) dp \\ &= 4\pi \int_0^\infty e(\tfrac{1}{2}\rho^2)^i \exp\left(\sum_{k=0}^N \lambda_k e(\tfrac{1}{2}|p|^2)^k\right) \rho^2 d\rho \\ &= 2\pi \int_0^\infty \varepsilon^i \sqrt{\gamma(\varepsilon)}\gamma'(\varepsilon) \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k\right) d\varepsilon, \end{aligned} \tag{2.20}$$

where $i = 0, \ldots, N$.

Example 2.15 (nonparabolic band approximation). In the case of Kane's nonparabolic band approximation (2.3), we can further simplify the integrals (2.19) and (2.20). Since $\gamma(\varepsilon) = |p|^2 = 2\varepsilon(1+\delta\varepsilon)$ and $\gamma'(\varepsilon) = 2(1+2\delta\varepsilon)$, we compute

$$D_{ij} = \frac{8\sqrt{2}\pi}{3}\tau \int_0^\infty \varepsilon^{i+j+3/2} \frac{(1+\delta\varepsilon)^{3/2}}{1+2\delta\varepsilon} \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k\right) d\varepsilon,$$

$$m_i = 4\sqrt{2}\pi \int_0^\infty \varepsilon^{i+1/2}(1+\delta\varepsilon)^{1/2}(1+2\delta\varepsilon) \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k\right) d\varepsilon, \quad i,j = 0,\ldots,N.$$

Example 2.16 (parabolic band approximation). Setting $\delta = 0$ in the formulas of Example 2.15, we obtain

$$D_{ij} = \frac{8\sqrt{2}\pi}{3}\tau \int_0^\infty \varepsilon^{i+j+3/2} \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k\right) d\varepsilon,$$

$$m_i = 4\sqrt{2}\pi \int_0^\infty \varepsilon^{i+1/2} \exp\left(\sum_{k=0}^N \lambda_k \varepsilon^k\right) d\varepsilon, \quad i,j = 0,\ldots,N.$$

3. Examples.

In this section we derive the diffusive models for $N = 0$, leading to the drift-diffusion equations, the case $N = 1$, leading to the energy-transport model, and $N = 2$, leading to a higher-order model.

3.1. Drift-diffusion equations.

We consider the case $N = 0$. Then $\kappa_0(p) = 1$, and the generalized Maxwellian reads $M_F = e^{\lambda_0 - \varepsilon(p)}$. The balance equation is given by (2.11). We need to compute the flux J_0 since, in section 2.3, the case $N = 0$ was excluded. For this, we have to solve $LG = u \cdot \nabla_x \lambda_0 M_F + \nabla_x V \cdot \nabla_p M_F = u \cdot \nabla_x(\lambda_0 - V)M_F$. Let ϕ_0 be the unique solution in $N(L)^\perp$ of $L\phi_0 = uM_F$. It is not difficult to check that $G = \nabla_x(\lambda_0 - V)\cdot\phi_0$ solves the above operator equation. This shows that

$$J_0 = \langle uG\rangle = \langle u \otimes \phi_0\rangle \nabla_x(\lambda_0 - V).$$

The flux can be written in terms of the particle density m_0. Indeed, since

$$m_0 = \int_B M_F dp = Ae^{\lambda_0}, \quad \text{where } A = \int_B e^{-\varepsilon(p)} dp > 0,$$

we obtain $\nabla_x \lambda_0 = (\nabla_x m_0)/m_0$ and, hence,

$$J_0 = -D_0(\nabla_x m_0 - m_0 \nabla_x V), \quad \text{where } D_0 = -\frac{1}{m_0}\int_B u \otimes \phi_0 dp.$$

This gives the well-known drift-diffusion equations for the particle density $n = m_0$ and the current density $J = J_0$:

$$\partial_t n + \mathrm{div} J = 0, \quad J = D_0(\nabla n - n\nabla V).$$

We specify the diffusion matrix D_0 and the relation between m_0 and λ_0 in the following example.

Example 3.1. Under the assumptions of Example 2.14, we obtain for the expressions for $D_0 = D_{00}/m_0$ and m_0:

$$D_0 = \frac{8\pi}{3}\,\frac{\tau}{m_0}\,e^{\lambda_0}\int_0^\infty \varepsilon^{3/2}\frac{\gamma(\varepsilon)^{3/2}}{\gamma'(\varepsilon)}e^{-\varepsilon}d\varepsilon,$$
$$m_0 = 2\pi\, e^{\lambda_0}\int_0^\infty \sqrt{\gamma(\varepsilon)}\gamma'(\varepsilon)e^{-\varepsilon}d\varepsilon.$$

For nonparabolic bands $\gamma(\varepsilon) = 2\varepsilon(1+\delta\varepsilon)$, this becomes

$$D_0 = \frac{8\sqrt{2}\pi}{3}\,\frac{\tau}{m_0}\,e^{\lambda_0}\int_0^\infty \varepsilon^{3/2}\frac{(1+\delta\varepsilon)^{3/2}}{1+2\delta\varepsilon}e^{-\varepsilon}d\varepsilon, \tag{3.1}$$

$$m_0 = 4\sqrt{2}\pi\, e^{\lambda_0}\int_0^\infty \varepsilon^{1/2}(1+\delta\varepsilon)^{1/2}(1+2\delta\varepsilon)e^{-\varepsilon}d\varepsilon, \tag{3.2}$$

and, for parabolic bands, the formulas simplify to

$$m_0 = 4\sqrt{2}\pi\, e^{\lambda_0}\int_0^\infty \varepsilon^{1/2}e^{-\varepsilon}d\varepsilon = 4\sqrt{2}\pi\, e^{\lambda_0}\Gamma(\tfrac{3}{2}) = (2\pi)^{3/2}e^{\lambda_0}, \tag{3.3}$$

$$D_0 = \frac{8\sqrt{2}\pi}{3}\,\frac{\tau}{m_0}\,e^{\lambda_0}\int_0^\infty \varepsilon^{3/2}e^{-\varepsilon}d\varepsilon = \frac{4\tau}{3\sqrt{\pi}}\Gamma(\tfrac{5}{2}) = \tau, \tag{3.4}$$

where Γ is the Gamma function satisfying $\Gamma(\frac{1}{2}) = \sqrt{\pi}$ and $\Gamma(x+1) = x\Gamma(x)$. The expressions (3.3) and (3.4) coincide with the standard drift-diffusion model; see, for instance, [36, 44].

3.2. Energy-transport equations. We take $N = 1$ and $\kappa = (1, \varepsilon)$. Then $M_F = e^{\lambda_0+\lambda_1\varepsilon}$. The balance equations are, according to Proposition 2.4 and Example 2.6,

$$\partial_t m_0 + \mathrm{div} J_0 = 0, \quad \partial_t m_1 + \mathrm{div} J_1 - \nabla V\cdot J_0 = W_1. \tag{3.5}$$

The diffusion coefficients D_{ij} are, by (2.14),

$$D_{00} = -\langle u\otimes\phi_0\rangle,\ D_{01} = -\langle u\otimes\phi_1\rangle,\ D_{10} = -\langle \varepsilon u\otimes\phi_0\rangle,\ D_{11} = -\langle \varepsilon u\otimes\phi_1\rangle,$$

and the coefficients E_{ij} can be expressed in terms of D_{ij}, according to (2.18),

$$E_{00} = E_{10} = 0, \quad E_{01} = D_{00}, \quad E_{11} = D_{01}.$$

Notice that $D_{01} = D_{10}$ since $\langle u\otimes\phi_1\rangle = (L\phi_0, \phi_1)_F = (\phi_0, L\phi_1)_F = \langle \varepsilon u\otimes\phi_0\rangle$. Then the particle and energy current densities (2.13) can be written as follows:

$$J_0 = -D_{00}(\nabla\lambda_0 + \nabla V\lambda_1) - D_{01}\nabla\lambda_1, \tag{3.6}$$

$$J_1 = -D_{10}(\nabla\lambda_0 + \nabla V\lambda_1) - D_{11}\nabla\lambda_1, \tag{3.7}$$

and the moments are given by

$$m_0 = e^{\lambda_0} \int_B e^{\lambda_1 \varepsilon(p)} dp, \quad m_1 = e^{\lambda_0} \int_B \varepsilon(p) e^{\lambda_1 \varepsilon(p)} dp. \tag{3.8}$$

Equations (3.5)–(3.8) are called the energy-transport model.

Notice that, in [47], a related energy-transport model based on entropy maximization has been derived. More precisely, the model is derived through the relaxation-time limit from the hydrodynamic equations which have been found by a moment method employing the entropy maximization principle. Moreover, an assumption of small anisotropy for the Maxwellian has been used. Depending on the concrete scattering terms, the diffusion coefficients seem to be different compared to our model, but there are similar properties (such as positive definiteness of the diffusion matrix).

Example 3.2 (monotone energy band). In the situation of Example 2.14, we can make the above expressions more explicit. As we have assumed that the constrained maximization problem (2.4) is solvable, the integral expressions defining the moments have to exist. Consequently, we must have $\lambda_1 < 0$ in order to guarantee integrability of $M_F = e^{\lambda_0 + \lambda_1 \varepsilon(p)}$ in $B = \mathbb{R}^3$. Thus, we can define $T = -1/\lambda_1$, and we call $T > 0$ the particle temperature. Formulas (2.19) and (2.20) give

$$\begin{aligned} D_{ij} &= \frac{8\pi}{3} \tau e^{\lambda_0} \int_0^\infty \varepsilon^{i+j} \frac{\gamma(\varepsilon)^{3/2}}{\gamma'(\varepsilon)} e^{-\varepsilon/T} d\varepsilon, \\ m_i &= 2\pi e^{\lambda_0} \int_0^\infty \varepsilon^i \sqrt{\gamma(\varepsilon)} \gamma'(\varepsilon) e^{-\varepsilon/T} d\varepsilon, \quad i, j = 0, 1. \end{aligned}$$

Example 3.3 (nonparabolic band approximation). For nonparabolic bands according to (2.3), i.e., $\gamma(\varepsilon) = 2\varepsilon(1 + \delta\varepsilon)$, we can specify the above formulas, as in Example 2.15:

$$\begin{aligned} D_{ij} &= \frac{8\sqrt{2}\pi}{3} \tau e^{\lambda_0} \int_0^\infty \varepsilon^{i+j+3/2} \frac{(1+\delta\varepsilon)^{3/2}}{1 + 2\delta\varepsilon} e^{-\varepsilon/T} d\varepsilon, \\ m_i &= 4\sqrt{2}\pi e^{\lambda_0} \int_0^\infty \varepsilon^{i+1/2} (1+\delta\varepsilon)^{1/2} (1 + 2\delta\varepsilon) e^{-\varepsilon/T} d\varepsilon, \quad i = 0, 1. \end{aligned}$$

These expressions coincide with those in [15].

Example 3.4 (parabolic band approximation). For $\delta = 0$, the integrals of the previous example can be computed explicitly. Since

$$m_i = 4\sqrt{2}\pi e^{\lambda_0} \int_0^\infty \varepsilon^{i+1/2} e^{-\varepsilon/T} d\varepsilon = 4\sqrt{2}\pi e^{\lambda_0} T^{i+3/2} \Gamma(i + \tfrac{3}{2}), \tag{3.9}$$

we compute the moments

$$m_0 = (2\pi)^{3/2} T^{3/2} e^{\lambda_0}, \quad m_1 = \tfrac{3}{2} (2\pi)^{3/2} T^{5/2} e^{\lambda_0} = \tfrac{3}{2} m_0 T.$$

Calling $n = m_0$ the particle density, $m_1 = \frac{3}{2} nT$ can be interpreted as the electron energy with the temperature T. The diffusion coefficients become

$$D_{ij} = \frac{8\sqrt{2}\pi}{3} \tau e^{\lambda_0} \int_0^\infty \varepsilon^{i+j+3/2} e^{-\varepsilon/T} d\varepsilon = \frac{8\sqrt{2}\pi}{3} \tau e^{\lambda_0} T^{i+j+5/2} \Gamma(i + j + \tfrac{5}{2}),$$

and, computing the Gamma functions, we derive for $D = (D_{ij})$

$$D = \tau n T \begin{pmatrix} 1 & \frac{5}{2}T \\ \frac{5}{2}T & \frac{35}{4}T^2 \end{pmatrix}.$$

The relaxation time τ may be defined as the inverse of the (averaged) collision rate which generally depends on the energy. For instance, we may take

$$\tau = \tau_0 \left(\frac{\langle M_F \rangle}{\langle \varepsilon M_F \rangle} \right)^{\beta},$$

where $\tau_0 > 0$ and $\beta \in \mathbb{R}$ [52]. Then $\tau = \tau_0(m_0/m_1)^\beta = (\frac{2}{3})^\beta \tau_0 T^{-\beta}$, and the diffusion matrix can be written as

$$D = \left(\frac{2}{3}\right)^{\beta} \tau_0 m_0 T^{1-\beta} \begin{pmatrix} 1 & \frac{5}{2}T \\ \frac{5}{2}T & \frac{35}{4}T^2 \end{pmatrix}.$$

We observe that D is very similar to the matrix derived in [15] for $\beta = 1$, but the coefficients are different. The matrix of [15] can be obtained if the relaxation time depends on the microscopic kinetic energy, $\tau = \tau(\varepsilon) = \varepsilon_0/\varepsilon$ for some $\varepsilon_0 > 0$, such that

$$D_{ij} = \frac{8\sqrt{2}\pi}{3} e^{\lambda_0} \int_0^\infty \tau(\varepsilon) \varepsilon^{i+j+3/2} e^{-\varepsilon/T} d\varepsilon = \frac{8\sqrt{2}\pi\varepsilon_0}{3} e^{\lambda_0} T^{i+j+3/2} \Gamma(i+j+\tfrac{3}{2}),$$

which gives the matrix

$$D = \frac{2}{3}\varepsilon_0 n \begin{pmatrix} 1 & \frac{3}{2}T \\ \frac{3}{2}T & \frac{15}{4}T^2 \end{pmatrix}.$$

3.3. Fourth-order moment equations. Finally, we consider the case $N = 2$ and $\kappa = (1, \varepsilon, \varepsilon^2)$. The coefficients are taken from Example 2.15, which uses the hypotheses of Proposition 2.13. The balance equations are given by (2.7), which, taking into account Example 2.6, read as

$$\partial_t m_0 + \mathrm{div} J_0 = 0, \tag{3.10}$$

$$\partial_t m_1 + \mathrm{div} J_1 - \nabla V \cdot J_0 = W_1, \tag{3.11}$$

$$\partial_t m_2 + \mathrm{div} J_2 - 2\nabla V \cdot J_1 = W_2, \tag{3.12}$$

where W_i are the averaged inelastic collision terms (see Proposition 2.4), and the fluxes are given by (2.13):

$$J_i = -D_{i0}(\nabla\lambda_0 + \nabla V \lambda_1) - D_{i1}(\nabla\lambda_1 + 2\nabla V \lambda_2) - D_{i2}\nabla\lambda_2, \quad i = 0, 1, 2.$$

The diffusion coefficients are expressed as in Example 2.15 with $N = 2$. In the limiting case $\delta \to 0$ we obtain the parabolic band approximation, which allows for a more explicit formulation of the fourth-order model. Since the parabolic band approximation cannot be taken directly in the case $N = 2$ (the entropy maximization problem may be unsolvable; see Remark 2.2), we derive the model for $\delta = 0$ by taking formally the limit $\delta \to 0$ in the expressions for D_{ij} and m_i in Example 2.15. This leads to

(3.13)

$$m_i = 4\sqrt{2}\pi e^{\lambda_0} \int_0^\infty \varepsilon^{i+1/2} e^{\lambda_1\varepsilon+\lambda_2\varepsilon^2} d\varepsilon, \quad D_{ij} = \frac{8\sqrt{2}\pi}{3} \tau e^{\lambda_0} \int_0^\infty \varepsilon^{i+j+3/2} e^{\lambda_1\varepsilon+\lambda_2\varepsilon^2} d\varepsilon,$$

where $i, j = 0, 1, 2$. We argue as in Example 3.2 to conclude that $\lambda_2 < 0$ must hold. Notice that we can express the diffusion coefficients in terms of the moments:

$$D_{ij} = \frac{2\tau}{3} m_{i+j+1}. \tag{3.14}$$

The moments m_j for $j \geq 3$ are defined as above. In section 4 we discuss several reformulations of this model and compare it with higher-order models in the literature.

4. Properties of the model equations. We suppose that (H1)–(H5) hold and that the weight functions are given by $\kappa_i = \varepsilon^i$, $i = 0, \ldots, N$. Then, by (2.12), (2.13), and (2.18), the higher-order moment model can be written as

$$\partial_t m_i + \mathrm{div} J_i - iJ_{i-1} \cdot \nabla V = W_i, \quad J_i = -\sum_{j=0}^N \left(D_{ij}\nabla\lambda_j + jD_{i,j-1}\nabla V \lambda_j\right), \tag{4.1}$$

where $i = 0, \ldots, N$, $D_{i,-1} = 0$, and the moments m_i and the Lagrange multipliers λ_j are related by the formula

$$m_i = \int_B \varepsilon(p)^i \exp\left(\sum_{j=0}^N \varepsilon(p)^j \lambda_j\right) dp. \tag{4.2}$$

In this section we show that these equations can be written in two different ways, which allows us to recover some important properties of the model.

4.1. Drift-diffusion formulation. We can write the fluxes in a drift-diffusion formulation which allows a numerical decoupling of the stationary higher-order moment model.

Proposition 4.1. *Let* (H1)–(H5) *and the assumptions of Lemma* 2.12 *hold, and let $\kappa_i = \varepsilon^i$ for $i = 0, \ldots, N$. Then we can write*

$$J_i = -\nabla d_i - F_i(d) d_i \nabla V,$$

where $d_i = D_{i0}$, $d = (d_0, \ldots, d_N)^\top$, and

$$F_i(d) = \sum_{j=1}^N j \frac{D_{i,j-1}}{D_{i0}} \lambda_j, \quad i = 0, \ldots, N.$$

The Lagrange multipliers λ_j are implicitly given by the values of d_i:

$$d_i = -\langle \varepsilon^i u \otimes \phi_0 \rangle, \quad L\phi_0 = ue^{\lambda\cdot\kappa}.$$

The operator L is the linearization of the dominant collision operator; see (H4). *The mapping $d = d(\lambda)$ can be inverted since* $\det d'(\lambda) = \det D > 0$.

Proof. We claim that the first sum in the second equation in (4.1) equals ∇D_{0i}. Indeed, from

$$L(\nabla\phi_{jk}) = u_k\varepsilon^j \sum_{\ell=0}^{N} \nabla\lambda_\ell \varepsilon^\ell M_F = \sum_{\ell=0}^{N} \nabla\lambda_\ell u_k \varepsilon^{j+\ell} M_F = L\left(\sum_{\ell=0}^{N} \nabla\lambda_\ell \phi_{j+\ell,k}\right)$$

and the unique solvability in $N(L)^\perp$, we obtain the relation

$$\nabla\phi_j = \sum_{\ell=0}^{N} \nabla\lambda_\ell \phi_{j+\ell} + cM_F,$$

where c is a constant vector. Hence, by (2.14), setting $j = 0$,

$$\nabla D_{i0} = -\langle \varepsilon^i u \otimes \nabla\phi_0 \rangle = -\sum_{\ell=0}^{N} \nabla\lambda_\ell \langle \varepsilon^i u \otimes \phi_\ell \rangle = -\sum_{\ell=0}^{N} \nabla\lambda_\ell D_{i\ell}.$$

Then (4.1) becomes

$$J_i = -\nabla D_{i0} - D_{i0}\nabla V \sum_{j=0}^{N} j\, \frac{D_{i,j-1}}{D_{i0}} \lambda_j,$$

showing the first assertion.

It remains to show that the determinant of the matrix $d'(\lambda)$ is positive. Since

$$L\Big(\frac{\partial\phi_{jk}}{\partial\lambda_\ell}\Big) = u_k\varepsilon^j \frac{\partial M_F}{\partial\lambda_\ell} = u_k\varepsilon^{j+\ell} M_F = L\phi_{j+\ell,k},$$

which gives $\partial\phi_0/\partial\lambda_\ell = \phi_\ell + cM_F$ and thus

$$\frac{\partial D_{i0}}{\partial\lambda_\ell} = -\Big\langle \varepsilon^i u \otimes \frac{\partial\phi_0}{\partial\lambda_\ell} \Big\rangle = -\langle \varepsilon^i u \otimes \phi_\ell \rangle = D_{i\ell}, \tag{4.3}$$

the Jacobian of $d(\lambda)$ consists of the elements $\partial d_i/\partial\lambda_j = \partial D_{i0}/\partial\lambda_j = D_{ij}$. The matrix $D = (D_{ij})$ is positive definite (see Lemma 2.12), and we have $\det d'(\lambda) = \det D > 0$. □

Remark 4.2. The decoupling of the higher-order moment model can be done as follows. Under the assumptions of the above proposition, the stationary model reads

$$\mathrm{div} J_i = i\nabla V \cdot J_{i-1} + W_i, \quad J_i = -\nabla d_i - F_i(d) d_i \nabla V, \quad i = 0, \ldots, N.$$

We assume that V is given, and $W_i = W_i(d, V)$ may depend on d and V. We also write $J_i = J_i(d, V)$. During the iteration procedure, we may "freeze" the nonlinearities: Let $\widetilde{d}$ be given (e.g., from the previous iteration step), and consider the system

$$\mathrm{div} J_i(d, V) = i\nabla V \cdot J_{i-1}(d, V) + W_i(\widetilde{d}, V), \quad J_i(d, V) = -\nabla d_i - F_i(\widetilde{d}) d_i \nabla V.$$

This system is decoupled since each equation is a scalar elliptic differential equation for d_i. Furthermore, the linear equations can by "symmetrized" by local Slotboom variables as described, for instance, in [15] to treat the convective part $F_i(\widetilde{d}) d_i \nabla V$. Finally, the "symmetrized" equations can be numerically discretized by mixed finite elements [15, 32]. We will numerically explore this idea for a higher-order moment model in a future paper.

Example 4.3 (energy-transport model). In the case of the energy-transport equations ($N = 1$), the functions $F_i(\lambda)$ in Proposition 4.1 simplify. Introducing the particle temperature $T = -1/\lambda_1$ as in Example 3.2, we obtain $F_0(d) = F_1(d) = \lambda_1 = -1/T$ and hence

$$J_i = -\nabla d_i + \frac{d_i}{T}\nabla V, \quad i = 0, 1.$$

The temperature is implicitly defined through the relation

$$f(T) = \frac{d_1}{d_0} = \frac{D_{10}}{D_{00}} = \frac{\langle \varepsilon u \otimes \phi_0\rangle}{\langle u \otimes \phi_0\rangle},$$

where ϕ_0 solves $L\phi_0 = uM_F$. A similar expression has been given in [15] but only in the case of monotone energy bands. For given d_0 and d_1, this defines T uniquely since $f'(T) = \det D/(Td_0)^2 > 0$. In order to check this derivative, we first compute

$$L\Big(\frac{\partial \phi_0}{\partial T}\Big) = \frac{\partial}{\partial T}(ue^{\lambda_0 - \varepsilon/T}) = \frac{1}{T^2}\varepsilon u M_F = \frac{1}{T^2}L\phi_1.$$

Hence, $\partial\phi_0/\partial T = \phi_1/T^2 + cM_F$, where c is a constant. Thus, since $\langle \varepsilon u \otimes \phi_0\rangle = D_{10} = D_{01} = \langle u \otimes \phi_1\rangle$ and $D_{11} = \langle \varepsilon u \otimes \phi_1\rangle$,

$$\begin{aligned} f'(T) &= \frac{1}{T^2 d_0^2}\big(\langle \varepsilon u \otimes \phi_1\rangle\langle u \otimes \phi_0\rangle - \langle \varepsilon u \otimes \phi_0\rangle\langle u \otimes \phi_1\rangle\big) \\ &= \frac{1}{T^2 d_0^2}(D_{11}D_{00} - D_{10}D_{01}) = \frac{\det D}{T^2 d_0^2} > 0. \end{aligned}$$

Example 4.4 (fourth-order model). We take $N = 2$ and assume the parabolic band approximation. The functions $F_i(d)$ read as follows:

$$F_i(d) = \lambda_1 + 2\frac{d_{i+1}}{d_i}\lambda_2, \quad i = 0, 1, 2.$$

Notice that, by (3.14), $d_i = (2\tau/3)m_{i+1}$. Moreover, integration by parts gives, using (3.13),

$$\begin{aligned} m_i &= -4\sqrt{2}\pi e^{\lambda_0}\int_0^\infty \frac{2}{2i+3}\varepsilon^{i+3/2}(\lambda_1 + 2\lambda_2\varepsilon)e^{\lambda_1\varepsilon + \lambda_2\varepsilon^2}\,d\varepsilon \\ &= -\frac{2}{2i+3}(\lambda_1 m_{i+1} + 2\lambda_2 m_{i+2}) = -\frac{3}{(2i+3)\tau}(\lambda_1 d_i + 2\lambda_2 d_{i+1}). \end{aligned} \tag{4.4}$$

Hence,

$$F_i(d) = \frac{1}{d_i}(\lambda_1 d_i + 2\lambda_2 d_{i+1}) = -\frac{(2i+3)\tau}{3}\,\frac{m_i}{d_i},$$

and the fluxes become, for constant relaxation time,

$$J_i = -\nabla d_i - F_i(d)d_i\nabla V = -\frac{2}{3}\tau\Big(\nabla m_{i+1} - \frac{2i+3}{2}m_i\nabla V\Big), \quad i = 0, 1, 2. \tag{4.5}$$

Together with the balance equations (2.12), we obtain a system of three equations for the unknowns m_0, m_1, and m_2. If τ depends on x or t, the variables are τm_0, τm_1, and τm_2. In the expression for J_2, the moment m_3 is needed. However, it can be computed from m_0, m_1, and m_2 using the relation

$$m_3 = -\frac{1}{2\lambda_2}\Big(\frac{5}{2}m_1 + \lambda_1 m_2\Big), \tag{4.6}$$

which comes from (4.4), where λ_1, λ_2 are functions of $m = (m_0, m_1, m_2)$. The fourth-order model with the above current relations can be also seen as a system of parabolic equations in the variables m_1, m_2, and m_3; the particle density m_0 is then a function of m_1, m_2, and m_3.

It remains to show that the function $m(\lambda)$, with $\lambda = (\lambda_0, \lambda_1, \lambda_2)$, can be inverted. This comes from the fact that the matrix $m'(\lambda) = (m_{i+j})_{i,j} \in \mathbb{R}^{3\times 3}$ is positive definite (and hence, its determinant is positive) since it is equal to the Hessian of the strictly convex function

$$\lambda \mapsto m_0 = 4\sqrt{2}\pi\tau \int_0^\infty \varepsilon^{1/2} e^{\lambda_0 + \lambda_1\varepsilon + \lambda_2\varepsilon^2} d\varepsilon.$$

The final fourth-order model consists of the balance equations (3.10)–(3.12) and the current relations (4.5) in the variables m_1, m_2, and m_3.

Remark 4.5. Grasser et al. have derived a related fourth-order model, called the six-moments transport equations (see (124)–(129) in [29]). The model equations are given by (3.10)–(3.12) and (4.5), where

$$m_0 = n, \quad m_1 = \frac{3}{2}nT, \quad m_2 = \frac{5\cdot 3}{4}nT^2\beta_n. \tag{4.7}$$

Here the variables are the particle density n, the electron temperature T, and the kurtosis β_n. This notation is inspired from the energy-transport model in the parabolic band approximation (see Example 3.4), where $m_2 = \frac{15}{4}nT^2$ (see (3.9)). In this sense, β_n measures the deviation from the heated Maxwellian $M_F = e^{\lambda_0 - \varepsilon/T}$. More generally, the kurtosis is defined by

$$\beta_n = \frac{3}{5}\,\frac{m_0 m_2}{m_1^2}.$$

By the Cauchy–Schwarz inequality

$$\begin{aligned} m_1^2 &= 32\pi^2 e^{2\lambda_0}\left(\int_0^\infty \varepsilon^{1/4}\varepsilon^{5/4} e^{\lambda_1\varepsilon + \lambda_2\varepsilon^2} d\varepsilon\right)^2 \\ &\le 32\pi^2 e^{2\lambda_0}\int_0^\infty \varepsilon^{1/2} e^{\lambda_1\varepsilon + \lambda_2\varepsilon^2} d\varepsilon \int_0^\infty \varepsilon^{5/2} e^{\lambda_1\varepsilon + \lambda_2\varepsilon^2} d\varepsilon = m_0 m_2, \end{aligned}$$

we obtain the restriction $\beta_n \ge 3/5$.

Grasser et al. [29] define heuristically m_3 in terms of the lower-order moments by setting

$$m_3 = \frac{7\cdot 5\cdot 3}{8}nT^2\beta_n^c, \tag{4.8}$$

where the constant exponent c is fitted from Monte Carlo simulations of the Boltzmann equation, computing the numerical moment m_3^{MC}. It has been found that the choice

$c = 3$ gives the smallest deviation of the ratio m_3^{MC}/m_3 from the desired value of one [29].

In the model derived in Example 4.4, m_3 is implicitly defined in terms of the lower-order moments; see (4.6). Using notation (4.7) and setting $\lambda_1 = -1/T$ as in the energy-transport equations, we obtain from (4.6)

$$m_3 = -\frac{15}{8}\frac{(1-\beta_n)nT}{\lambda_2}.$$

The expression (4.8) is obtained by setting $\lambda_2 = -(1-\beta_n)/7T^2\beta_n^c$. Since it should hold that $\lambda_2 < 0$, we conclude the restriction $\beta_n \leq 1$. Together with the above condition, the kurtosis has to satisfy the inequality $3/5 \leq \beta_n \leq 1$ [26]. Clearly, $\beta_n = 1$ corresponds to the energy-transport case for which $\lambda_2 = 0$.

Thus, the model of Grasser et al. is contained in our model hierarchy with the heuristic choice $\lambda_2 = -(1-\beta_n)/7T^2\beta_n^c$.

4.2. Dual-entropy variable formulation. It is well known from nonequilibrium thermodynamics that the electric force terms in (4.1) can be removed by employing so-called dual-entropy variables [19, 40]. Here we extend this methodology to higher-order moment models by defining the (generalized) dual-entropy variables $\nu = (\nu_0, \ldots, \nu_N)^\top$ by $\lambda = P\nu$, where $\lambda = (\lambda_0, \ldots, \lambda_N)^\top$ are the Lagrange multipliers (or the primal entropy variables), and the transformation matrix $P = (P_{ij}) \in \mathbb{R}^{(N+1)\times(N+1)}$ is defined by

$$P_{ij} = (-1)^{i+j}\binom{j}{i}a_{ij}V^{j-i} \quad \text{with} \quad a_{ij} = \begin{cases} 1 & \text{if } i \leq j, \\ 0 & \text{if } i > j, \end{cases}$$

where $i, j = 0, \ldots, N$. The dual-entropy formulation "symmetrizes" the system of equations [13]. It is well known that the existence of such variables is equivalent to the existence of an entropy functional [14, 39].

PROPOSITION 4.6. *Define the dual-entropy variables $\nu = (\nu_0, \ldots, \nu_N)^\top$, the transformed moments $\rho = (\rho_0, \ldots, \rho_N)^\top$, and the thermodynamic fluxes $F = (F_0, \ldots, F_N)^\top$ by*

$$\lambda = P\nu, \quad \rho = P^\top m, \quad \textit{and} \quad F = P^\top J,$$

respectively. Then the model equations (4.1) can be equivalently written as

$$\partial_t\rho_i + \mathrm{div}F_i = (P^\top W + V^{-1}\partial_t VRm)_i, \quad F_i = -\sum_{j=0}^{N} C_{ij}\nabla\nu_i,$$

where $W = (0, W_1, \ldots, W_N)^\top$, $R = (R_{ij})$ is given by $R_{ij} = (i-j)P_{ji}$, and the new diffusion matrix $C = (C_{ij})$ is defined by $C = P^\top DP$.

The proposition is proved in the appendix. Notice that the new diffusion matrix C is symmetric and positive definite if and only if D is symmetric and positive definite (see Lemma 2.12).

Example 4.7 (energy-transport model). The transformation matrix P and its inverse Q read in the case $N = 1$ as

$$P = \begin{pmatrix} 1 & -V \\ 0 & 1 \end{pmatrix}, \quad Q = \begin{pmatrix} 1 & V \\ 0 & 1 \end{pmatrix}.$$

Defining the chemical potential μ by $\lambda_0 = \mu/T$, where $T = -1/\lambda_1 > 0$ is the particle temperature, the dual-entropy variable $\nu = Q\lambda$ becomes (see, e.g., [13, 40])

$$\nu_0 = \lambda_0 + V\lambda_1 = \frac{\mu - V}{T}, \quad \nu_1 = \lambda_1 = -\frac{1}{T}.$$

The quantity $\mu - V$ is known as the *electrochemical potential.*

Example 4.8 (fourth-order model). For $N = 2$, the transformation matrix is given by

$$P = \begin{pmatrix} 1 & -V & V^2 \\ 0 & 1 & -2V \\ 0 & 0 & 1 \end{pmatrix}.$$

Introducing the chemical potential and the temperature as in the previous example and the *second-order temperature* θ as in [27] by $\lambda_2 = -1/\theta T$, the dual-entropy variables are

$$\nu_0 = \frac{\mu - V}{T} - \frac{V^2}{\theta T}, \quad \nu_1 = -\frac{1}{T} - \frac{2V}{\theta T}, \quad \nu_2 = -\frac{1}{\theta T}.$$

The dual-entropy formulation allows us to prove entropy dissipation. We define the relative entropy H_0 by

$$H_0(t) = -\int_{\mathbb{R}^3} (m \cdot (\lambda - \bar\lambda) - m_0 + \bar m_0) dx \le 0,$$

where $\lambda = (\lambda_0, \dots, \lambda_N)^\top$, $m = (m_0, \dots, m_N)^\top$, $\bar\lambda = (V, -1, 0, \dots, 0)^\top$, and $\bar m_0 = m_0(\bar\lambda)$ are the equilibrium values (since $e^{\bar\lambda \cdot \kappa} = e^{V - \varepsilon}$ is the equilibrium distribution function in the presence of an electric field). Notice that, in the situation of Example 3.4 (i.e., $N = 1$), the relative entropy becomes

$$H = -\int_{\mathbb{R}^3} \Big(n\Big(\ln n - \frac{3}{2}\ln T - \frac{5}{2} - V\Big) + \frac{3}{2}nT + e^V \Big) dx.$$

PROPOSITION 4.9. *Assume that*

$$\int_{\mathbb{R}^3} W \cdot (\lambda - \bar\lambda) dx \le 0. \tag{4.9}$$

Then any (smooth) solution λ to the higher-order moment equations (4.1) *satisfies the entropy inequality*

$$-\frac{dH}{dt} + \int_{\mathbb{R}^3} \sum_{i,j=0}^{N} C_{ij} \nabla\nu_i \cdot \nabla\nu_j dx \le 0.$$

The second integral on the left-hand side is called *entropy dissipation.* Clearly, it is nonnegative if the diffusion matrix D is positive (semi)definite. Thus, the entropy is nondecreasing in time.

Proof. We introduce the relative entropy density $h(\lambda) = -m \cdot (\lambda - \bar\lambda) + m_0 - \bar m_0$. The moments are given by (4.2) such that $\partial m_0/\partial\lambda_i = m_i$, from which we obtain

$$\frac{\partial h}{\partial \lambda_i} = -\frac{\partial m}{\partial \lambda_i} \cdot (\lambda - \bar\lambda) - m_i + \frac{\partial m_0}{\partial \lambda_i} = -\frac{\partial m}{\partial \lambda_i} \cdot (\lambda - \bar\lambda)$$

and

$$\partial_t m \cdot (\lambda - \bar{\lambda}) = \sum_{i=0}^{N} \frac{\partial m}{\partial \lambda_i} \cdot (\lambda - \bar{\lambda}) \partial_t \lambda_i = -\sum_{i=0}^{N} \frac{\partial h}{\partial \lambda_i} \partial_t \lambda_i = -\partial_t h(\lambda). \tag{4.10}$$

The balance equations (4.1) are formally equivalent to (A.2); multiplying the latter equations by $\nu_i - \bar{\nu}_i$, where $\bar{\nu} = Q\bar{\lambda}$, and summing over $i = 0, \ldots, N$, it follows that

$$(P^\top \partial_t m)^\top (\nu - \bar{\nu}) + (\mathrm{div} F)^\top (\nu - \bar{\nu}) = (P^\top W)^\top (\nu - \bar{\nu}).$$

Integrating over x and employing the definition $\nu = Q\lambda$ gives

$$\int_{\mathbb{R}^3} \partial_t m^\top PQ(\lambda - \bar{\lambda}) dx + \int_{\mathbb{R}^3} \sum_{i,j=0}^{N} \mathrm{div}(C_{ij} \nabla \nu_j)(\nu_i - \bar{\nu}_i) dx = \int_{\mathbb{R}^3} W^\top PQ(\lambda - \bar{\lambda}) dx.$$

Finally, integrating by parts in the second integral, taking into account that $\nabla \bar{\nu} = 0$, and using (4.10) yields

$$-\int_{\mathbb{R}^3} \partial_t h(\lambda) dx + \int_{\mathbb{R}^3} \sum_{i,j=0}^{N} C_{ij} \nabla \nu_i \cdot \nabla \nu_j dx = \int_{\mathbb{R}^3} W^\top (\lambda - \bar{\lambda}) dx \le 0,$$

which proves the lemma. □

In [7, Lem. 4.11], it has been shown that assumption (4.9) on W holds for an inelastic phonon collision operator, in the case of the energy-transport model. This hypothesis also holds if

$$W_i = -\frac{1}{\tau_1}(m_i - \bar{m}_i), \quad \text{where } \bar{m}_i = m_i(\bar{\lambda}),$$

since

$$W \cdot (\lambda - \bar{\lambda}) = -\frac{1}{\tau_1} \int_B (e^{\kappa \cdot \lambda} - e^{\kappa \cdot \bar{\lambda}})(\kappa \cdot \lambda - \kappa \cdot \bar{\lambda}) dp \le 0.$$

5. Conclusions. In this paper, we have derived a new hierarchy of diffusive models from the semiconductor Boltzmann equation by using a moment method and a Chapman–Enskog expansion, based on the entropy maximization principle of Levermore. The hierarchy contains well-known transport models, such as the drift-diffusion equations, the energy-transport equations, and a variant of the six-moments model of Grasser et al. Some features of the new models are (formally) shown: The diffusion matrix is positive definite, the flux equations can be written in a drift-diffusion form suitable for numerical discretizations, and the convective parts due to the electric field can be eliminated by employing generalized dual-entropy variables.

We mention some limitations of this model hierarchy. First, one may criticize hypothesis (H2) in which we require that all moments of the dominant part of the collision operator vanish. The hypothesis is clearly satisfied by a relaxation-type operator as shown in section 2.2, but it is not clear whether more realistic scattering operators satisfy this hypothesis. Second, numerical experiments have to show whether realistic simulation results for the higher-order models applied to small-channel devices can be obtained and whether the numerical effort is moderate compared to other (hydrodynamic or diffusive) models.

An important question is how many moments are actually needed in order to obtain accurate numerical results. In this direction, we mention the works of Schmeiser and Zwirchmayr [49] and of Struchtrup [54] for hyperbolic transport equations. In [54] the number of moments could be significantly reduced by a proper construction of moments.

In a future work, we intend to implement the fourth-order moment model using a mixed finite-element method and to compare the numerical results with those from the (similar) six-moments model of Grasser et al. [28]. Moreover, we intend to extend the hierarchy of diffusive models to Fermi–Dirac statistics (see, for instance, [6]). We expect that the decoupled drift-diffusion formulation has the potential to keep the computational cost down.

Appendix. We present the technical proofs of some results.

Proof of Lemma 2.12. The proof is inspired from the proof of Proposition IV.6 in [6]. We write as above $D_{ij} = (D_{ij}^{k\ell})$ and $\xi_i = (\xi_{ik})$. Let $(\xi_0, \dots, \xi_N) \neq 0$. Then, by the definition of the matrices D_{ij},

$$\sum_{i,j=0}^{N} \xi_i^\top D_{ij} \xi_j = \sum_{i,j=0}^{N} \sum_{k,\ell=1}^{3} \xi_{ik} D_{ij}^{k\ell} \xi_{j\ell} = -\sum_{i,j=0}^{N} \sum_{k,\ell=1}^{3} \int_B \xi_{ik} \kappa_i u_k \phi_{j\ell} \xi_{j\ell} dp.$$

Since $\kappa_i u_k M_F = L\phi_{ik}$, we obtain

$$\begin{aligned}\sum_{i,j=0}^{N} \xi_i^\top D_{ij} \xi_j &= -\sum_{i,j=0}^{N} \sum_{k,\ell=1}^{3} \int_B \xi_{ik} L\phi_{ik} \phi_{j\ell} \xi_{j\ell} M_F^{-1} dp \\ &= \sum_{i,j=0}^{N} \sum_{k,\ell=1}^{3} \big(- L(\xi_{ik}\phi_{ik}), \xi_{j\ell}\phi_{j\ell} \big)_F \\ &= \left(-L \left(\sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik}\phi_{ik} \right), \sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik}\phi_{ik} \right)_F .\end{aligned}$$

As $\phi_{ik} \in N(L)^\perp$, assumption (H5) and the boundedness of L (with constant $c_L > 0$) give

$$\begin{aligned}\sum_{i,j=0}^{N} \xi_i^\top D_{ij} \xi_j &\geq \mu \left\| \sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik}\phi_{ik} \right\|_F^2 \geq \frac{\mu}{c_L^2} \left\| L \left(\sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik}\phi_{ik} \right) \right\|_F^2 \\ &= \frac{\mu}{c_L^2} \left\| \sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik} u_k \kappa_i M_F \right\|_F^2 = \frac{\mu}{c_L^2} \int_B \left| \sum_{i=0}^{N} \sum_{k=1}^{3} \xi_{ik} u_k \kappa_i \right|^2 M_F dp > 0,\end{aligned}$$

since the functions $u_k\kappa_i$ are linearly independent.

Proof of Proposition 4.6. First, we prove some properties of the transformation matrix P which is needed in the proof of the proposition.

LEMMA A.1. (i) *The matrix $Q = (Q_{ij})$ given by $Q_{ij} = \binom{j}{i} a_{ij} V^{j-i}$ is the inverse of P.*

(ii) *For all i, $j = 0, \dots, N$,*

$$\sum_{k=0}^{N} (j-k) P_{ik} Q_{kj} = -\sum_{k=0}^{N} (j-k) Q_{ik} P_{kj} = j\delta_{i,j-1} V,$$

where $j\delta_{i,j-1} = 0$ for $j = 0$.

(iii) *For all* $i = 0, \dots, N-1$, $j = 1, \dots, N$,

$$-jP_{i,j-1} + (i+1)P_{i+1,j} = 0.$$

Proof. (i) By the definition of the coefficients a_{ij}, we have $\sum_k P_{ik}Q_{kj} = 0$ for all $i > j$. Let $i < j$. Then

$$\begin{aligned}\sum_{k=0}^{N} P_{ik}Q_{kj} &= \sum_{k=i}^{j}(-1)^{i+k}\binom{k}{i}\binom{j}{k}V^{j-i} = V^{j-i}\sum_{k=i}^{j}(-1)^{i+k}\binom{j}{i}\binom{j-i}{k-i} \\ &= V^{j-i}\binom{j}{i}\sum_{\ell=0}^{j-i}(-1)^{\ell}\binom{j-i}{\ell} = 0.\end{aligned}$$

Furthermore, for $i = j$, we obtain

$$\sum_{k=0}^{N} P_{ik}Q_{ki} = \sum_{k=i}^{i}(-1)^{i+k}\binom{k}{i}\binom{i}{k} = 1.$$

(ii) The definition of a_{ij} yields $\sum_k (j-k)P_{ik}Q_{kj} = 0$ for $i \geq j$. Next, let $i < j-1$. Then

$$\begin{aligned}\sum_{k=0}^{N}(j-k)P_{ik}Q_{kj} &= V^{j-i}\sum_{k=i}^{j-1}(j-k)(-1)^{i+k}\binom{k}{i}\binom{j}{k} \\ &= V^{j-i}\sum_{k=i}^{j-1}(-1)^{i+k}j\binom{j-1}{i}\binom{j-1-i}{k-i} \\ &= jV^{j-i}\binom{j-1}{i}\sum_{\ell=0}^{j-1-i}(-1)^{\ell}\binom{j-1-i}{\ell} = 0.\end{aligned}$$

If $i = j-1$, then

$$\sum_{k=0}^{N}(j-k)P_{ik}Q_{kj} = V\sum_{k=j-1}^{j-1}(j-k)(-1)^{j-1+k}\binom{k}{j-1}\binom{j}{k} = V\binom{j-1}{j-1}\binom{j}{j-1} = jV.$$

The second equality is shown in a similar way.

(iii) For $i \geq j$ we have $P_{i,j-1} = 0$ and $P_{i+1,j} = 0$. If $i < j$, then

$$-jP_{i,j-1} + (i+1)P_{i+1,j} = (-1)^{i+j+1}V^{j-1-i}\Big(-j\binom{j-1}{i} + (i+1)\binom{j}{i+1}\Big) = 0.$$

This proves the lemma. □

Now we proceed to the proof of Proposition 4.6. First we show the relation for the new fluxes. Employing the definitions $C = P^{\top}DP$ and $\nu = Q\lambda$ and the property

$QP = I$ (I being the identity matrix), we obtain

$$\begin{aligned}\sum_{j=0}^{N} C_{ij}\nabla\nu_j &= \sum_{j,k,\ell,n=0}^{N} P_{ki}D_{k\ell}P_{\ell j}\nabla(Q_{jn}\lambda_n)\\ &= \sum_{j,k,\ell,n=0}^{N} P_{ki}D_{k\ell}(P_{\ell j}Q_{jn}\nabla\lambda_n + P_{\ell j}\nabla Q_{jn}\lambda_n)\\ &= \sum_{k,\ell=0}^{N} P_{ki}D_{k\ell}\nabla\lambda_\ell + \sum_{k,\ell,n=0}^{N} P_{ki}D_{k\ell}\left(\sum_{j=0}^{N}(n-j)P_{\ell j}Q_{jn}\right)V^{-1}\nabla V\lambda_n,\end{aligned}$$

since $\nabla Q_{jn} = (n-j)V^{-1}\nabla V Q_{jn}$. Now, using Lemma A.1(ii),

$$\begin{aligned}\sum_{j=0}^{N} C_{ij}\nabla\nu_j &= \sum_{k,\ell=0}^{N} P_{ki}D_{k\ell}\nabla\lambda_\ell + \sum_{k,\ell,n=0}^{N} P_{ki}D_{k\ell}n\delta_{\ell,n-1}\nabla V\lambda_n\\ &= \sum_{k,n=0}^{N} P_{ki}(D_{kn}\nabla\lambda_n + nD_{k,n-1}\nabla V\lambda_n) = -\sum_{k=0}^{N} P_{ki}J_k = -F_i.\end{aligned}$$

Next we compute the transformed balance equations. By the definition of F_i,

$$\begin{aligned}\mathrm{div}F_i &= \sum_{j=0}^{N}\mathrm{div}(P_{ji}J_j) = \sum_{j=0}^{N}(P_{ji}\mathrm{div}J_j + \nabla P_{ji}\cdot J_j)\\ &= \sum_{j=0}^{N} P_{ji}(\mathrm{div}J_j - jJ_{j-1}\cdot\nabla V) + \sum_{j=0}^{N}(\nabla P_{ji}\cdot J_j + jP_{ji}J_{j-1}\cdot\nabla V).\end{aligned}\tag{A.1}$$

We show that the second sum vanishes. Observing that $\nabla P_{ji} = (i-j)V^{-1}\nabla V P_{ji}$, we find that

$$A := \sum_{j=0}^{N}(\nabla P_{ji}\cdot J_j + jP_{ji}J_{j-1}\cdot\nabla V) = \sum_{j=0}^{N}\big((i-j)P_{ji}V^{-1}\nabla V\cdot J_j + jP_{ji}J_{j-1}\cdot\nabla V\big).$$

Since the first sum can be rewritten, by Lemma A.1(ii), as

$$\begin{aligned}&\sum_{j=0}^{N}(i-j)P_{ji}V^{-1}\nabla V\cdot J_j = \sum_{j,k=0}^{N}(i-k)\delta_{jk}P_{ki}V^{-1}J_j\cdot\nabla V\\ &\quad= \sum_{j,k,\ell=0}^{N}(i-k)P_{j\ell}Q_{\ell k}P_{ki}V^{-1}J_j\cdot\nabla V = \sum_{j,\ell=0}^{N}\left(\sum_{k=0}^{N}(i-k)Q_{\ell k}P_{ki}\right)P_{j\ell}V^{-1}J_j\cdot\nabla V\\ &\quad= -\sum_{j,\ell=0}^{N} i\delta_{\ell,i-1}P_{j\ell}J_j\cdot\nabla V = -\sum_{j=0}^{N} iP_{j+1,i}J_j\cdot\nabla V,\end{aligned}$$

we obtain

$$A = \sum_{j=0}^{N-1}(-iP_{j,i-1} + (j+1)P_{j+1,i})J_j\cdot\nabla V = 0,$$

using Lemma A.1(iii). Hence, with the balance equations (4.1), (A.1) becomes

$$\mathrm{div} F_i = \sum_{j=0}^{N} P_{ji}(-\partial_t m_j + W_j). \tag{A.2}$$

We employ the definition $\rho = P^\top m$ to rewrite the first sum:

$$\begin{aligned}\sum_{j=0}^{N} P_{ji}\partial_t m_j &= \sum_{j=0}^{N}\big(\partial_t(P_{ji}m_j) - \partial_t P_{ji} m_j\big) \\ &= \partial_t \rho_i - V^{-1}\partial_t V \sum_{j=0}^{N}(i-j)P_{ji}m_j = \partial_t\rho_i - V^{-1}\partial_t V\sum_{j=0}^{N} R_{ij}m_j.\end{aligned}$$

This finishes the proof. □

A DIRICHLET-INTEGRAL–BASED DUAL-ACCESS COLLOCATION-KERNEL APPROACH TO POINT SOURCE GRAVITY-FIELD MODELING[*]

ALAN RUFTY[†]

Abstract. Problems in $\mathbb{R}^3$ are addressed where the scalar potential of an associated vector field satisfies Laplace's equation in some unbounded external region and is to be approximated by unknown (point) sources contained in the complimentary subregion. Two specific field geometries are considered: $\mathbb{R}^3$ half-space and the exterior of an $\mathbb{R}^3$ sphere, which are the two standard settings for geophysical and geoexploration gravitational problems. For these geometries it is shown that a new type of kernel space exists, which is labeled a Dirichlet-integral dual-access collocation-kernel space (DIDACKS) and which is well suited for many applications. The DIDACKS examples studied are related to reproducing kernel Hilbert spaces, and they have a replicating kernel (as opposed to a reproducing kernel) that has the ubiquitous form of the inverse of the distance between a field point and a corresponding source point. Underpinning this approach are three basic mathematical relationships of general interest. Two of these relationships—corresponding to the two geometries—yield exact closed-form inner products and thus exact linear equation sets for the corresponding point source strengths of various types (i.e., point mass, point dipole, and/or point quadrupole sets) at specified source locations. The given field is reconstructed not only in a point collocation sense, but also in a (weighted) field-energy error-minimization sense.

Key words. Laplace's equation, inverse problem, reproducing kernels, fundamental solutions, point collocation, point source

1. Introduction.

The goal of this article is to set forth a mathematical framework for the approximation of $\mathbb{R}^3$ harmonic fields in unbounded domains by point sources contained inside the complimentary region. The proposed Dirichlet-integral dual-access collocation-kernel (DIDACK) approach has a mathematically and physically well-motivated underpinning. The associated space (DIDACKS) has certain similarities to reproducing kernel Hilbert space (RKHS) but is distinct from it. Two concrete $\mathbb{R}^3$ geometries are considered: (A) The harmonic field region consisting of a half-space (denoted Ω_1). (B) The harmonic field region consisting of the exterior of a sphere (denoted Ω_0). Within this geometric context, the developed formalism easily handles various combinations of diverse types of point sources (such as point masses, point mass dipoles, or point mass quadrupoles); moreover, for a set of specified source locations the formalism yields closed-form linear equation sets that simultaneously minimize the volume integrals of (weighted) field energy densities (i.e., (weighted) Dirichlet integrals).

Techniques introduced here can either be applied directly or adapted for use in many mathematical and physical areas. Examples on the mathematical side include

potential theory, point source elliptic boundary value modeling (i.e., method of fundamental solutions), fast multipole techniques, radial-basis function techniques, RKHS techniques, geophysical collocation (GC) techniques, and standard energy minimization–based techniques (such as Galerkin and Raleigh–Ritz-based approaches). Also see [22]. Examples on the physical side include geoexploration (where gravity is often used to locate oil or other minerals), geophysics, and magnetostatics (for a survey of these three areas, see [12, 25, 23, 4]), as well as general electromagnetic source analysis, electrostatics, and hydrostatics (for the physical significance of these three areas, and of field energy with regards to them, see [3]). Also somewhat similar mathematical structures arise in many other areas such as biophysical or biomedical engineering (where, for example, electric dipole models are used in electrocardiographical (ECG) modeling and current dipole models are used in electroencephalography (EEG) [2]).

While these diverse candidate application areas exist, DIDACKS theory was developed to handle gravitational problems, and all of the author's direct numerical experience with it is in this arena; hence, gravitation is the application setting considered here. Geophysical gravitation has an easily understood notation and a readily accessible mature literature [10, 19]. (Note that [10] is based on the earlier book [9], which, in turn, was largely based on [8].) Geophysical gravitation also has a direct historical association with potential theory (for example, Gauss played a very significant role in the history of geophysics [10, p. 1]).

A family of significant and challenging problems (including representative geophysical inverse source problems) is associated with geophysical gravitation. In addition to Laplacian inverse source theory, where the goal is to determine source strength, geophysical gravitation has two separate problem categories that point sources can be used in: field modeling and field estimation. For gravitational modeling problems the field is assumed to be known throughout the region of interest, and a more compact, but accurate, representation is desired. For estimation problems it is assumed that values are known accurately at a certain number of points in the field region and that one wants to predict gravity values over some part of this field region. Besides combinations of point sources, other techniques (such as GC) exist for treating gravitational field modeling and field estimation problems. As currently understood, each of these approaches has certain advantages on its own home ground, and the application areas where they all can be considered direct competitors is somewhat limited. In a wider mathematical context, since the fundamental solutions used here are reinterpreted as kernels and satisfy a generalized collocation property, the DIDACKS modeling and estimation approaches described here can also be considered harmonic interpolation and extrapolation techniques, respectively. GC and its extensions are thus the family of approaches that are mathematically closest to DIDACKS theory.

With minor differences these gravitation ($\vec{G}$) problems use the same standard notation and techniques employed in electrostatics, where $\vec{E}$ is the field [11], and so this arena should be readily accessible to all interested applied mathematicians, physicists, and engineers. (Within this electrostatic context the formalism developed here handles multiple types of point sources—such as point charges, electrostatic dipoles, or electrostatic quadrupoles.) Thus, although the notation used in the first four sections is specialized to the gravitational setting, the intrusion of this setting is otherwise minimal in these sections. In fact, the required mathematical background for this "core part of the article" is limited to classical $\mathbb{R}^3$ potential theory [13, 11] and a basic understanding of functional analysis, as utilized in approximation theory. Because no previous geophysical background is presupposed in these first four sections of the paper, the relevant overall geophysical and point mass modeling context is supplied in section 5. Since GC is the most commonly used approach for regional gravitational data processing and estimation it is briefly described at the end of section 5. While a knowledge of neither RKHS nor GC is a necessity in these first five sections, a better understanding of both these areas is presupposed in section 6, which describes the mathematical connections, noted above, of DIDACKS theory to other kernel-based approaches. GC, which is often called least-squares collocation, is an RKHS-based approach that differs from standard collocation techniques utilized by applied mathematicians in several relevant ways and, as such, may not be familiar to many readers. Moritz [19] provides a readily accessible treatment of both RKHS and GC theory; nevertheless, the thrust of section 6 should be directly accessible to those familiar with only standard RKHS theory ([17], [1], or [27] (which contains [1])).

On a first reading, the first four sections of the article should probably be considered only from a mathematical perspective. One implicit, but strong, motivation exists for limiting the level of this core material—there is often a given mathematical level of sophistication from which certain research results tend to emerge, and the same results may not be apparent at either a higher or lower level of mathematical sophistication. The first four sections and the geophysical applications setting given in section 5 are aimed at this default level of sophistication; however, there are open-ended physical and mathematical foundational issues associated with DIDACKS theory implicitly touched on in the last half of section 2 that may be of primary interest to only the type two and type four readers/researchers mentioned below. Other readers may wish to simply skip this material in the second half of section 2 on a first reading. From a general reader's perspective, it is still worth noting that a central theme that emerges from DIDACKS theory is that well-known kernels (such as the fundamental solutions studied here) can be regarded as part of a new kernel setting, and taking this perspective seriously seems to imply not only applied research but also new mathematical results, of which the relationships given below are only one example. To see that all of the various mathematical, applied, and physical facets of DIDACKS theory hang together as a whole and then to envision what the research possibilities are is surely not an easy task, but the material itself can be approached in a step-by-step way and, when this is done, even cross-fertilization and educational possibilities emerge. Given all of this, it is useful to set the stage for the rest of the paper by taking a step back and previewing the basic mathematical relationships that produce closed-form inner products. Closed-form (weighted) energy inner products are the cornerstone of both the theory and application of the whole approach.

Basic DIDACKS relationships in $\mathbb{R}^3$. The DIDACKS approach was conceived and is best understood on its own merits as a new self-consistent mathematical theory that is independent of the geophysical connections just indicated and, as noted above, it is this exposition that occupies the first four sections. Underpinning this mathematical side of the DIDACKS approach are three intrinsically interesting relationships that will now be briefly surveyed. First consider the notation employed. For overall accessibility, for consistency with the geophysical and electrostatic literature, and to avoid various possible notational conflicts, preference is given to a pedestrian but unambiguous notation: Cartesian coordinates are used and overset arrows employed to denote $\mathbb{R}^3$ vectors, $\vec{X} = (x, y, z)^T \in \mathbb{R}^3$ (for superscript $T :=$ transpose), while for $n \neq 3$, n-dimensional vectors and matrices are denoted by lower- and uppercase bold letters, respectively. R_0 is used to denote the radius of the sphere associated with Ω_0 that is centered over the origin: $\Omega_0 := \{\vec{X} \in \mathbb{R}^3 \mid |\vec{X}| \geq \mathrm{R}_0\}$. Likewise for the half-space case, the origin is chosen in the plane $\partial\Omega_1 := \{\vec{X} \in \mathbb{R}^3 \mid z = 0\}$ so that $\Omega_1 := \{\vec{X} \in \mathbb{R}^3 \mid z \geq 0\}$. (Observe that the overall shape of the subscripts here matches that of the associated boundary.) Frequently these two settings will be denoted by a subscript j (for example, Ω_j), where $j = 0$ or 1 is always implied.

Temporarily leaving aside the issue of admissible functions, these relationships can be compactly stated in terms of a Dirichlet integral over some connected but possibly unbounded region Ω, which is usually denoted by $\mathrm{D}[v,\, w] = \iiint_\Omega \vec{\nabla} v \cdot \vec{\nabla} w \; dV$ for admissible harmonic functions $v(\vec{X})$ and $w(\vec{X})$, or in terms of the more inclusive concept of a weighted Dirichlet integral for the region Ω denoted by $\mathrm{D}[v,\, w,\, \mu,\, \Omega]$, where $\mu = \mu(\vec{X})$ is the weighting function so that $\mathrm{D}[v,\, w,\, \mu,\, \Omega] := \iiint_\Omega \mu\, \vec{\nabla} v \cdot \vec{\nabla} w \; dV$. Clearly $\mathrm{D}[v,\, w,\, 1,\, \Omega] = \mathrm{D}[v,\, w]$. Let $\ell^{-1} := 1/|\vec{X} - \vec{X}'|$, where $\vec{X} \in \Omega_j$ and $\vec{X}'$ is in the corresponding closed source region $:= \Omega_{S_j} \subset \Omega'_j :=$ compliment of Ω_j. (By convention, generally primed variables occur in Ω'_j and unprimed ones in Ω_j.) Then the first two relations give the replication (or generalized collocation) properties of the DIDACKS kernel ℓ^{-1}:

$$\mathrm{D}[w,\, \ell^{-1},\, 1,\, \Omega_1] \,=\, 2\pi\, w(x',\, y', -z') \tag{1.1}$$

and

$$\mathrm{D}[w,\, \ell^{-1},\, \mu_0,\, \Omega_0] \,=\, 2\pi\, |\vec{P}|\; w(\vec{P})/\mathrm{R}_0^2, \tag{1.2a}$$

with $\mu_0 = 1/r$ $(r := |\vec{X}|)$ and where

$$\vec{P} = \left(\frac{\mathrm{R}_0^2}{|\vec{X}'|^2} \right) \vec{X}'. \tag{1.2b}$$

Finally the third relationship ties the unweighted Dirichlet integral over Ω_0 to the weighted integral given on the left-hand side (LHS) of (1.2a) and can be written as

$$\mathrm{D}[v,\, w,\, 1,\, \Omega_0] = \mathrm{R}_0 \cdot \mathrm{D}[v,\, w,\, \mu_0,\, \Omega_0] + (2\pi \mathrm{R}_0) \cdot (v,\, w)_\sigma, \tag{1.3a}$$

where the surface inner product on the right-hand side (RHS) here is defined as

$$(v,\, w)_\sigma := (1/4\pi) \iint_\sigma v(r, \theta,\, \phi)\, w(r, \theta,\, \phi)\, d\,\sigma \tag{1.3b}$$

and where, as in [9] and [10], σ and $d\,\sigma$ have the following meaning when associated with the integral of $f(\vec{X})$:

$$\iint_\sigma f(r, \theta,\, \phi)\, d\,\sigma \;:= \int_{\phi=0}^{2\pi} \int_{\theta=0}^{\pi} [f(r,\, \theta,\, \phi)]\Big|_{r=R_0} \sin\,\theta \;\, d\,\theta\, d\,\phi \tag{1.4}$$

for standard spherical coordinates r, θ, ϕ. (Occasionally the limits implicit in (1.4) will be stated explicitly for emphasis.) Due to the way r dependence enters in (1.4) it can be used to derive expressions that are otherwise not obvious, as will be apparent in what follows.

Clearly (1.1) and (1.2a) give a means of performing closed-form inner products based on the Dirichlet integral, while (1.3a) links the weighted Dirichlet inner product to the unweighted one over Ω_0. The general approximation and functional analysis framework for these relationships is given in section 2. The derivation of (1.1) is given in section 3, and that of (1.2a) and (1.3a) in section 4. In order to understand the connections of these relationships to the applications described in section 5 and to put them in proper historical context, it is useful to briefly consider the history of these relationships. Originally (1.2a) and (1.3a) were discovered in a different form by the author in the early 1980s—namely, (4.8) and (4.3), where the "integral norm" introduced in section 4 is used in place of the weighted Dirichlet integral. The history of these relationships in this form and of their application from inception to the mid-1990s can be found in [21]. The germane part of this internal history is summarized and updated in section 5. As an aside, although (1.1) is not explicitly mentioned in [21], the derivation here of (1.1) given in section 3 is the one originally found by the author in the early 1980s. The direct relationship of the integral norm to the weighted Dirichlet norm (4.13) is new. Also unless otherwise noted, the presentation itself (including various terms and concepts) is completely new here. Finally, while the general DIDACKS technique is a synthesis of several results that seem to have been overlooked by the broader scientific community, for any mathematical approach that directly touches on harmonic analysis, RKHS theory, and gravimetric inverse source theory either precedents or specialized parallel lines of development would seem to be a necessity. The known ones for $\mathbb{R}^3$ DIDACKS theory are addressed in section 6. In one way or another all of the discussions of section 6 pertain to the second DIDACKS relation in weighted Dirichlet form, (1.2a). As discussed there, (1.2a) should clearly be viewed as going back to Krarup in [15], since he derived it there in a directly equivalent form. Aside from the author's work, there are no known instances of (1.1) and (1.3a), or for that matter for the second DIDACKS relation expressed in the integral norm form (4.8).

Four types of readers. To motivate a further exploration of the paper's scope and limits it is useful to envision the possible reactions of four typical classes of readers to the above relations. First, consider an applied mathematician, physicist, engineer, or other scientist who may be familiar with the material in the first four chapters of [11], but is not yet a seasoned practitioner and may benefit by consulting [17], [19], or [13]. (The physical and historical importance of Dirichlet integrals and of the associated Dirichlet principle may be obtained from other sources [3, 18, 6].) This reader may find all three of the above field energy expressions somewhat surprising: (1.1) and (1.2a) because they allow for the closed-form evaluation of volume integrals, and (1.3a) since it allows for an unusual reexpression of the volume field energy. This reader may also observe that (1.1) and (1.2a) appear to have some connection to Green's functions and the method of images [11] and may recognize (1.2b) as the coordinate transformation part of a Kelvin transformation [13, 14]. These particular connections arise from the nature of Green's functions for Ω_j, but the most direct explanation requires some knowledge of RKHS theory. First, as noted in [3], the existence of a closed-form reproducing kernel occurs when closed-form expressions for both Neumann and Dirichlet Green's functions exist. Second, for the cases studied here a dual-action collocation kernel (DACK) arises from the result of a reflection, (1.1), or Kelvin transformation, (1.2b), applied to a reproducing kernel of the right form for the relevant geometry.

Second, while the possible reactions of any number of specialists might also be examined, consider a reader who has a particular interest in integral kernels or RKHS theory. For various reasons this reader may also find the above relationships somewhat surprising. This reader might, for example, observe that ℓ^{-1} plays the role of a kernel and then recall that a symmetric reproducing kernel (SRK) of the form $|\vec{X} - \vec{Y}|^{-1}$ for $\vec{X}$ and $\vec{Y}$ both in the same region cannot exist, since a SRK must be bounded and this kernel is not. Here $\vec{X}'$ is a fixed interior point and $\vec{X}$ is in the exterior region, so ℓ^{-1} is bounded, which is a very different situation and implies a change of perspective. This in itself could raise further questions since although DACKs are not reproducing kernels they have some properties analogous to them. In the previous paragraph the kernels studied here were linked to reproducing kernels, but it is unclear whether minimum norm DACKs can arise in other ways. Moreover, consideration of DACKs as a separate class of kernels also raises the question as to how they fit into our current overall understanding of kernel structures. These and other issues of a general nature are outside the scope of the present article, but some specific topics that might interest the second type of reader, such as the exact definition of the replication and generalized collocation property mentioned above, are addressed in section 2.

Third, consider a reader who is very applications- and results-oriented. Such a reader may be disappointed to discover that there is not a table containing numerical examples and results; however, a discussion of point mass and point dipole DIDACKS results and their associated applications settings can be found in section 5, where global nonlinear least-squares (NLLSQ) results are emphasized. Due to the variety and nature of regional gravity data, as well as other issues [21], no known easily replicated example provides generic benchmark results, which is normally an expectation for these tabulated examples. Moreover, point source fitting problems are part of a general class of problems that are "notoriously" ill-conditioned and problematic [4, pp. 214–222] so that each problem encountered should be tackled on its own terms, which means that one or two simple table examples cannot serve to provide adequate implementation guidance. Unfortunately, a thorough discussion of associated implementation strategies is outside the scope of the present article. Also observe that a concrete example provides a replication check that can serve as a consistency test for implementors, but this point is largely superfluous here since the DIDACKS approach exhibits the generalized collocation property with respect to point sources, and thus, when implemented correctly, any point mass or dipole fit replicates the point field data that was used to produce it in the first place to within allowed round-off error, and thus any implementation serves as its own self-consistency test.

Fourth and finally, consider a reader whose primary interest is in the theory and application of Laplacian inverse source theory. Since there are many shared implementation pitfalls common to both point source field modeling and inverse source estimation problems, the comments just made in the last paragraph are also relevant in this context. While specific mathematical tools and implementation strategies are not discussed here, readers with solid applications experience should be able to make direct use of the formalism presented. These readers may also be interested in the topic of continuous parameterized distributions, which is raised in section 2. Finally, it is worth noting that other source region shapes can be entertained within the contexts of the two considered geometries, since the only real requirement is that source regions be bounded and contained within the compliment of the unbounded harmonic field region.

2. Generalized linear least-squares setting. This section addresses the generalized linear least-squares (GLLSQ) plan of approach and the associated functional space setting. There are numerous approaches closely aligned to the GLLSQ method adopted here, such as the Galerkin and Raleigh–Ritz-based techniques mentioned in the introduction; however, the acronym GLLSQ is introduced to imply an implicit change of perspective. In particular, connections to generalized collocation, as discussed later in the section and explicitly formalized by the GLLSQ collocation condition, are implied as well as an approach that is distinct from the usual linear least-squares (LLSQ) ones where sampling and discretization are introduced. Connections to GC are also implied.

Both LLSQ and GLLSQ approaches minimize some cost function $\Phi' = \|v - w\|^2$, where for the problems of interest $v(\vec{X})$ is a point source potential model and $w(\vec{X})$ is some given canonical (or truth) reference potential. For a point mass fit with N_k point masses, v has the form

$$v(\vec{X}) = G \sum_{k=1}^{N_k} \frac{m_k}{|\vec{X} - \vec{X}'_k|} \ , \tag{2.1}$$

where G is the Newtonian gravitational constant $\approx 6.6742 \times 10^{-11}\mathrm{m}^3\mathrm{s}^{-2}\mathrm{kg}^{-1}$ [10, p. 3]. As previously noted, $\vec{X} \in \Omega_j$ and $\vec{X}'_k \in \Omega_{S_j}$, which is a bounded and closed subregion of the open region Ω'_j, so that the (kernel) basis functions occurring in (2.1) are always bounded. Further $\vec{X}'_{k'} \neq \vec{X}'_k$ for all $k' \neq k$ is always assumed.

Five conventions are adopted here. First, in physics texts the potential function v is interpreted as potential energy, and (2.1) has a negative sign since all gravitational bodies attract and the resulting force is given by the negative of the gradient of the potential. In geophysics these sign conventions are different and consistent with (2.1), but in either case this should cause little difficulty since in fitting problems all that is required is that the overall sign conventions for v and w be consistent. Second, it is assumed that gravitational force is always acting on a unit test mass [10, p. 4], and thus it will be treated as having the units of acceleration [10, p. 45]. Third, physical geodesists distinguish between gravity field quantities, which include the effects of the Earth's rotation, and gravitational quantities like (2.1), which do not [10, p. 44]. This is a distinction physicists generally do not make, since rotational effects can be easily tracked and accounted for as required. The physicist's lead is followed here, and this distinction is ignored. Fourth, both positive and negative masses will be considered a possibility, since this is the usual convention adopted in point mass fitting approaches. Specifically, for gravity modeling and estimation problems each m_k can clearly be viewed as a mathematical parameter that can assume either sign. This convention also allows for the ready adaptation of material developed here to other areas where both signs can occur. (Even regional geoexploration inverse mass density estimation problems can be handled by assuming that all smoothed density estimates are with respect to an average or ambient density.) Fifth, it is useful to introduce scaled versions of the above potential functions in order to absorb the factor of G: $V = v/G$ and $W = w/G$. Thus the cost function to be minimized becomes (with $\Phi := \Phi'/G^2$)

$$\Phi = \|V - W\|^2 = \|V\|^2 - 2\,(V, W) + \|W\|^2 \ . \tag{2.2}$$

(Notice that scaling a cost function leaves the minima unchanged.)

Next consider the philosophy behind the norm selection process. As discussed later in section 5, the minimization philosophy of matching the observations as closely as possible has generally been chosen for point mass fitting problems. This philosophy is, however, not necessarily sound in all or even most cases. For modeling problems a reference model, which is assumed to be accurate, is given, and one wishes to match this reference as closely as possible in some physical sense. Here the desire is to minimize the possible error differences that will result when this given reference model is replaced by a new point mass (or point source) model, which invariably occurs in some sort of software emulation of a physical situation. Thus instead of "matching the observables as closely as possible," a sounder strategy is to "minimize the type of errors that will lead to the greatest errors in the end product." From Newton's second law, since these end-product errors here are most often the direct result of gravity errors it is clear that the difference in the given gravity reference field and the developed point mass gravity model should be minimized, say in a squared residual sense at a large number of appropriate sample points. As this distribution of sample points becomes uniformly dense over the entire global region of interest, the following key integral condition results:

$$\text{Minimize } \Phi = \iiint_{\Omega_j} |\vec{\nabla} V - \vec{\nabla} W|^2 \, dV \; = \; \mathrm{D}[W-V,\, W-V,\, 1,\, \Omega_j] \; . \tag{2.3}$$

Temporarily leaving aside fundamental issues, such as how to turn the RHS of (2.3) into a proper norm structure, consider the general form of the linear equation sets that result from minimizing this type of cost function. For concreteness consider the minimization process in $\mathbb{R}^3$ half-space (Ω_1). Since the RHS of (2.3) is already proportional to the field energy, it is natural to consider the half-space ($j = 1$) energy norm:

$$\|V - W\|^2_{\mathrm{E}_1} := \frac{1}{8\pi} \iiint_{\Omega_1} |\vec{\nabla} V - \vec{\nabla} W|^2 \; dV \tag{2.4}$$

(a factor of 8π has been inserted since it often occurs for various field energy expressions in appropriate units). Because $\|V - W\|^2_{\mathrm{E}_1} = \|V\|^2_{\mathrm{E}_1} + \|W\|^2_{\mathrm{E}_1} - 2(V,\, W)_{\mathrm{E}_1}$, the energy inner-product

$$(V,\, W)_{\mathrm{E}_1} := \mathrm{D}[V,\, W,\, 1,\, \Omega_1]/8\pi$$

is also needed. In particular, if V is specified through (2.1), with $\ell_k := |\vec{X} - \vec{X}'_k|$, and if W is an appropriate reference field, then

$$\|V - W\|^2_{\mathrm{E}_1} = \|W\|^2_{\mathrm{E}_1} - 2\sum_{k=1}^{N_k} m_k (\ell_k^{-1},\, W)_{\mathrm{E}_1} + \sum_{k=1}^{N_k}\sum_{k'=1}^{N_k} m_k\, m_{k'} (\ell_k^{-1}, \ell_{k'}^{-1})_{\mathrm{E}_1} . \tag{2.5}$$

Taking the partial of (2.5) with respect to $m_{k''}$ (for $k'' = 1,\, 2,\, 3,\, \ldots,\, N_k$), setting the result to zero, then dividing by two yields a linear equation set that can be easily inverted for the mass values, provided that $(\ell_k^{-1},\, \phi)_{\mathrm{E}_1}$ can be easily computed for $\phi = W$ and $\phi = 1/\ell_{k'}$. The relationship which makes this possible is (1.1). By introducing $T_{k,k'} = (\ell_k^{-1}, \ell_{k'}^{-1})_{\mathrm{E}_1}$ and $A_k = (W, \ell_k^{-1})_{\mathrm{E}_1}$, the linear equation set can be written as

$$\sum_{k'=1}^{N_k} T_{k,k'}\, m_{k'} = A_k . \tag{2.6}$$

For the spherical exterior, matters proceed in much the same fashion except that a weight function, $\mu_0 = 1/r$, must be introduced into (2.3). Not only is this weighting required to turn ℓ_k^{-1} into a replicating kernel, but since regions closer to the Earth's surface are normally of greater interest for geophysical applications than regions further away, it is also desirable.

Obviously with regards to applications, (2.6) is pivotal and, as such, warrants at least an informal examination. Before proceeding it is useful to clarify the differences between reproducing, replication, and generalized collocation kernels. When a kernel, like ℓ_k^{-1}, is not symmetric since its arguments are in different domains and there is a relationship such as (1.1) or (1.2a) that allows for closed-form inner-product expressions, it will be called a replication kernel and be said to have the point replication property. Since reproducing kernels are necessarily symmetric they cannot be considered replicating kernels, so this terminology distinguishes replication and reproducing kernels. Alternatively, the term *generalized collocation property* will be taken to be a generalization of a point data and/or collocation matching condition, and as such includes the possibility of not only reproducing kernels but also replicating kernels. As discussed below, it also allows for the possibility that resulting inner products may be obtainable by numerical means (after assuming that an underlying replication property also holds)—so long as the resulting inner products, A_k, occurring on the RHS of (2.6) can be matched. (The A_k's may also represent empirically obtained data.)

As a concrete example of situations where numerical integration frequently enters, consider fits based on the continuous analogue of (2.1) where the potential is due to some parameterized density function ρ:

$$V(\vec{X}) = \iiint_{\Omega_S} \frac{\rho(\vec{X}', \alpha)}{|\vec{X} - \vec{X}'|}\, dV'. \tag{2.7}$$

Here $\alpha = (\alpha_1, \alpha_2, \alpha_3, \ldots, \alpha_{N_k})^T$. If ρ consists of a linear superposition of density basis functions ψ_k (i.e., $\rho = \sum_{k=1}^{N_k} \alpha_k \psi_k(\vec{X}')$), then minimizing $\|W - V\|^2$ yields a linear equation set similar to (2.6), where the A_k's and $T_{k,k'}$'s must generally be computed numerically; however, when (1.1) or (1.2a) is used, then great simplifications result and continuous distributions are tractable. Besides parameterized volume distributions, parameterized surface and line distributions are also obviously possible. One interesting choice for volume density basis functions ψ_k is the use of finite element method (FEM) basis functions. Thus consider the case where $\vec{q}_k'$ are taken to be a set of node points over Ω_S and where the $\psi_k(\vec{X}')$ are chosen to be a set of localized FEM basis functions with the property that $\psi_{k'}(\vec{q}_k') = 1$ if $k' = k$ and $\psi_{k'}(\vec{q}_k') = 0$ otherwise. The α_k determined directly from the analogue of (2.6) then represent the density strengths at the node points $\vec{q}_k'$.

Any additional structure that can help to clarify the possibilities inherent in (2.6) is desirable. Toward that end, briefly consider a suggestive theorem from RKHS theory. When a reproducing kernel, with specified kernel points $\vec{Q}_k \in \Omega$ replacing the values of $\vec{X}_k'$ in (2.1), is used for a basis functions expansion of V that is analogous to (2.1), and when (2.2) is replaced by the corresponding cost function based on the reproducing kernel norm, then minimization of this cost function results in a closed-form linear equation set that is just like (2.6)—except that the inner products corresponding to A_k take on the simpler form $W(\vec{Q}_k)$. This type of reproducing kernel fit also satisfies a minimum norm collocation property: the function with the smallest associated norm that matches the prescribed data set (i.e., the values $W(\vec{Q}_k)$) is the one which results from solving the analogue of (2.6) [19, pp. 207–220]. This minimum norm property is a well-known functional analysis result [17], and it insures that a reproducing kernel fit will simultaneously match the given point data and minimize both $\|V\|$ and $\|V - W\|$ for the associated norm. This fact is of interest here since it strongly suggests that if a replicating kernel expansion for V is used in (2.6), then generally any specified values for A_k are recovered and that D[V, V, 1, Ω_1] or D[V, V, μ_0, Ω_0] also is simultaneously minimized. While this may fail to happen due to auxiliary restrictions placed on the basis functions or on the overall space of admissible functions, the main way that it can fail to happen is if the kernel basis functions themselves are not linearly independent. These possibilities are not usually addressed in connection with general discussions of the minimum norm collocation property, but in many settings linear independence may not always be transparent, especially if combinations resulting from linear operators acting on kernel basis functions are allowed. (These possibilities can be seen from, among other things, the consequences of the fact that various restricted classes of functions, such as polynomials of fixed degree, may have a reproducing kernel.) When (2.6) is invertible the source parameters (m_k) are uniquely determined, and in some sense one can say that the solution to the inverse point source problem has been obtained. To preserve and extend these inverse source interpretational possibilities, the conservative stance is adopted here of requiring that all admitted basis function sets be invertible and that the solutions to (2.6) replicate the specified A_k values. This condition is called the generalized linear least squares collocation (GLLSQC) condition. There are two obvious ways to enforce this condition: either on a computational case-by-case basis or by proving general theoretical results about classes of particular basis functions. While it is not comparatively well known outside geophysics, a demonstration exists that shows that point mass basis functions are independent in $\mathbb{R}^n$ for finite $n > 1$ [24]. Thus, in a theoretical sense the GLLSQC condition holds for point mass fits, but on a case-by-case basis some care is generally required in solving (2.6) due to ill-conditioning. (As a matter of practice, either a singular value decomposition or a Householder triangulation algorithm implemented to an appropriate number of significant digits should be used.) Finally, it should be readily apparent that while continuous distributions may well satisfy the GLLSQC condition, counterexamples can be easily constructed, with perhaps the simplest example resulting from the consideration of several concentric homogenous spherical shells.

With regard to the overall functional analysis setting, the standard course taken nowadays is to adopt some type of general Banach space setting (such as one type or another of Sobolev space), where the completeness of Cauchy sequences is presupposed. The limit of sequences of functions composed from basis functions that satisfy the GLLSQC condition may not satisfy it; hence, admitting limits of sequences can lead to unwanted interpretational difficulties here. Obviously, to solve (2.6) it is only necessary that a finite linear span of basis functions be admitted, which requires only an inner-product structure. In accord with the conservative stance outlined above, a structured pre-Hilbert space setting is adopted since a pre-Hilbert space setting presupposes an inner-product structure, but it does not make the usual assumptions about admissible sequences of functions. (This way of specifying functions of interest is somewhat dated, but prior to the mid-1950s it was the prevailing way of addressing Dirichlet inner-product spaces and was used, for example, in [3].) The adjective "structured" here means that further auxiliary conditions are imposed on the class of admissible functions. One such condition is that any set of basis functions considered must satisfy the GLLSQC condition stated above. Another requirement is that all functions, f, must be harmonic over Ω_j (including $\partial\Omega_j$). Additional structure is needed to insure that (weighted) Dirichlet integrals over unbounded domains can be regarded as defining a positive definite norm. This can be accomplished by assuming one (or all) of the following four largely equivalent requirements:

(i) $\mathrm{D}[f,\, f,\, 1,\, \Omega_j]$ is bounded, and f tails off at least as fast as $1/r$ as $r \longrightarrow \infty$.

(ii) The first Sobolev norm of f over Ω_j is bounded:

$$\mathrm{D}[f,\, f,\, 1,\, \Omega_j] + \iiint_{\Omega_j} |f|^2 \, dV < \infty.$$

(iii) f is a potential function generated by a (well-behaved) localized source distribution in $\Omega_{S_j} \subset \Omega_j' \setminus \partial\Omega_j'$.

(iv) A well-behaved series representation for f always exists in the form of a spherical harmonic expansion of f in powers of $1/r$, for the exterior of some sphere contained inside Ω_j'.

Notice that (i) is the historical approach [3] and that (ii) is equivalent to (i) for $\Omega_j = \Omega_0$ since both the integrals occurring in the first Sobolev norm must be separately bounded. Also for all f not identically zero, $0 < \mathrm{D}[f,\, f,\, \mu_0,\, \Omega_0] < \mathrm{D}[f,\, f,\, 1,\, \Omega_0]/R_0$, where positivity can be easily proved using several standard properties of harmonic functions. (Specifically, if $|f| \neq 0$ at some point in Ω_0, then taking the line integral of $\vec{\nabla} f$ from this point to a point at infinity, one can infer that $|\vec{\nabla} f| > 0$ for at least one point along this line. Then from the mean-value theorem and the maximum-modulus theorem, $\vec{d} \cdot \vec{\nabla} f > 0$ must occur throughout some neighborhood near $\partial\Omega_0$ for one fixed direction $\vec{d}$ or another, and from this it follows immediately that $\mathrm{D}[f,\, f,\, \mu_0,\, \Omega_0] > 0$.) It is clear that (iii) and (iv) are largely equivalent to (i) or (ii) (although (iii) and (iv) do not require harmonicity as a separate condition). Requirement (iii) is more or less tantamount to the assumption that a collection of point sources is being modeled.

3. Half-space ($\boldsymbol{\Omega_1}$) relationships. For the class of admissible functions just described with bounded source region, the following half-space analogue of Poisson's solution to the Dirichlet boundary value problem holds [5, p. 268]:

$$W(\vec{X}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \frac{W(x'', y'', 0)\, z \; dx''\, dy''}{[(x - x'')^2 + (y - y'')^2 + z^2]^{3/2}}, \tag{3.1}$$

where $z > 0$ and $\vec{X}'' \in \partial\Omega_1$. Using the facts that the surface integral at infinity is zero for the unbounded region Ω_1, that $\partial/\partial n := -\partial/\partial z$, and that $dS = dx\, dy$ for the boundary plane ($\partial\Omega_1$) and applying Green's first identity[1] yields

$$\begin{aligned}(\ell_k^{-1},\, W)_{\mathrm{E}_1} &= \frac{1}{8\pi} \iiint_{\Omega_1} \vec{\nabla}\ell_k^{-1} \cdot \vec{\nabla} W \; dV \\ &= -\frac{1}{8\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \left[W \frac{\partial}{\partial z} \frac{1}{|\vec{X} - \vec{X}_k'|} \right] \Bigg|_{z=0} dx\, dy.\end{aligned} \tag{3.2}$$

Next observe that

$$\left[\frac{\partial}{\partial z} \frac{1}{|\vec{X} - \vec{X}_k'|} \right] \Bigg|_{z=0} = \frac{z_k'}{[(x - x_k')^2 + (y - y_k')^2 + (z_k')^2]^{3/2}}\ , \tag{3.3}$$

where $z_k' < 0$. Combining (3.1), (3.2), and (3.3) produces

$$(\ell_k^{-1},\, W)_{\mathrm{E}_1} = W(x_k',\, y_k',\, -z_k')/4, \tag{3.4}$$

[1] $\iiint_\Omega (\phi \nabla^2 \psi + \vec{\nabla}\psi \cdot \vec{\nabla}\phi)\; dV = \iint_{\partial\Omega} \phi \frac{\partial \psi}{\partial n}\, dS.$

Table 3.1
Point data/source correspondences for $\mathbb{R}^3$ half-space.

Observation type	Source type	Invariance property
Potential	Point mass	Scalar
Gravity	Point dipole	Vector
Gravity gradient	Point quadrupole	2nd rank tensor

which shows (1.1). This relation can be used to evaluate the terms $T_{k,k'}$ and A_k occurring in (2.6):

$$T_{k,k'} = \frac{1}{4\sqrt{(x'_k - x'_{k'})^2 + (y'_k - y'_{k'})^2 + (z'_k + z'_{k'})^2}}\,, \quad A_k = \frac{W(x'_k,\, y'_k,\, |z'_k|)}{4}\,. \tag{3.5}$$

Two final points are relevant. First, dipole and other higher order multipoles can also be easily fit. In general, potentials for these point sources can be written as $\sum_k \sum_i S_{ki}\mathcal{L}_{ki}({\ell_k}^{-1})$, where S_{ki} are the associated source strengths and the $\mathcal{L}_{ki}$ are appropriate linear differential operators that can be expressed as a sum of partials of various orders with respect to x, y, or z. For example, an electrostatic or point mass dipole term is proportional to $\vec{D}_k \cdot \vec{\nabla}\ell_k^{-1}$. Since $\vec{\nabla}\ell_k^{-1} = -\vec{\nabla}'_k \ell_k^{-1}$, where $\vec{\nabla}'_k := (\partial/\partial x'_k,\, \partial/\partial y'_k,\, \partial/\partial z'_k)^T$, and components of $\vec{X}'_k$ serve only as parameters when they occur inside the inner product here, all $\vec{X}$ dependent derivative factors operating on ℓ_k^{-1} that occur inside inner-products can be replaced with $\vec{X}'_k$ derivative factors; hence, these differential operators can be moved inside or outside the inner-products entirely as desired so that all required inner products for $T_{k,k'}$ and A_k can be easily evaluated in closed form. For half-space, these possibilities and the associated measurable point quantities are displayed in Table 3.1. Analogous possibilities exist for the spherical exterior case.

Second, to improve the condition number of the matrix $\boldsymbol{T}$ in (2.6), it is often desirable to use normalized basis functions $\hat{\varphi}_k$ in place of ℓ_k^{-1}:

$$\hat{\varphi}_k := \frac{\widetilde{N}_k}{\ell_k}\,, \quad \text{where} \quad \widetilde{N}_k := \frac{1}{\|\ell_k^{-1}\|} \tag{3.6}$$

in the general norm setting. Introducing $\widetilde{T}_{k,k'} := (\hat{\varphi}_k,\, \hat{\varphi}_{k'}) = \widetilde{N}_k\, \widetilde{N}_{k'}\, T_{k,k'}$, $\tilde{A}_k := (W,\, \hat{\varphi}_k) = \widetilde{N}_k\, A_k$, and $\widetilde{m}_k := m_k/\widetilde{N}_k$ allows (3.5) to be reexpressed as

$$\sum_{k'=1}^{N_k} \widetilde{T}_{k,k'}\, \widetilde{m}_{k'} = \tilde{A}_k. \tag{3.7}$$

For the $\mathbb{R}^3$ half-space energy norm

$$\begin{aligned} \widetilde{N}_k &= 2^{\frac{3}{2}}\sqrt{|z'_k|}\,, \\ \widetilde{T}_{k,k'} &= \frac{2\sqrt{z'_k z'_{k'}}}{\sqrt{(x'_k - x'_{k'})^2 + (y'_k - y'_{k'})^2 + (z'_k + z'_{k'})^2}}\,, \\ \tilde{A}_k &= \frac{\sqrt{|z'_k|}}{\sqrt{2}}\, W(x'_k\; y'_k,\, -z'_k)\,, \end{aligned} \tag{3.8}$$

so that (3.7) can easily be inverted to determine the values of $\widetilde{m}_k$ and thus m_k. While the use of normalized basis functions is not always required for point mass fits, their use in mixed type point source fits is always highly recommended due to the diverse associated physical scales that occur there and the attendant large condition numbers for $\boldsymbol{T}$. (An experiment was performed on the results from one of the global NLLSQ combined point mass/dipole fits discussed in section 5. At the specified source locations a linear fit was done both with and without normalized basis functions. The ratio of the two resulting condition numbers was over 10^{20}.)

4. Spherical exterior ($\boldsymbol{\Omega_0}$) relationships. The goal of this section is the derivation of the two relevant spherical exterior DIDACKS relationships, (1.2a) and (1.3a). Matters are more complex for this case than they were for the half-space case, but all of the supporting issues raised in sections 2 and 3 can obviously be carried over here, so they are not repeated.

Let f and g be two admissible functions as discussed in section 2 and consider the integral norm [21]:

$$(f,\, g)_{\mathrm{I}} := -\frac{R_0^2}{4\pi}\iint_\sigma \mathcal{D}_r(rf\,g)\;d\,\sigma = -\frac{R_0^2}{4\pi}\iint_\sigma \big[\mathcal{D}_r(f\,r\,g)\big]\Big|_{r=R_0} d\,\sigma, \tag{4.1}$$

where $\mathcal{D}_r := \frac{\partial}{\partial\, r}$. The last expression on the RHS here follows from the evaluation convention of (1.4). The label "integral norm" was chosen by the author since, as discussed below, the integrals required for point mass fitting in Ω_0 can be evaluated in closed form and there is little chance of confusing this norm with the usual norm of square integrable functions.

Applying Green's first identity to the Ω_0 energy inner-product and noting that the surface integral at infinity vanishes, while $dS = R_0^2\, d\,\sigma$ and $\partial\,/\partial\, n := -\mathcal{D}_r$ for the bounding inner exterior surface of Ω_0, yields

$$\begin{aligned}(f,\, g)_{\mathrm{E}_0} &:= \frac{1}{8\pi}\iiint_{\Omega_0} \vec{\nabla} f\cdot\vec{\nabla} g\;dV \\ &= -\frac{R_0^2}{8\pi}\iint_\sigma g\,\mathcal{D}_r f\;d\,\sigma = -\frac{R_0^2}{16\pi}\iint_\sigma \big[\mathcal{D}_r(fg)\big]\Big|_{r=R_0} d\,\sigma.\end{aligned} \tag{4.2}$$

From (4.1) and (4.2) it follows immediately that

$$(f,\, g)_{\mathrm{I}} = 4\,R_0(f,\, g)_{\mathrm{E}_0} - R_0^2(f,\, g)_\sigma. \tag{4.3}$$

After the second DIDACKS relation, (1.2a), is addressed, it will be shown that the integral norm is proportional to the weighted Dirichlet integral, which will complete the proof of the third DIDACKS relation, (1.3a).

First, observe that the following two equations can be shown through a relatively straightforward evaluation of their respective LHS and RHSs:

$$\left[\frac{r}{\ell_k}\right]\Bigg|_{r=R_0} = \frac{R_0^2}{r_k'}\left[\frac{1}{|\vec{X}-\vec{P}_k|}\right]\Bigg|_{r=R_0} \tag{4.4}$$

and

$$\left[\mathcal{D}_r\left(\frac{r}{\ell_k}\right)\right]\Bigg|_{r=R_0} = -\frac{R_0^2}{r_k'}\left[\mathcal{D}_r\,\frac{1}{|\vec{X}-\vec{P}_k|}\right]\Bigg|_{r=R_0}, \tag{4.5}$$

where $\vec{P}_k$ is given by (1.2b) with $\vec{X}'_k = \vec{X}'$ and $r'_k := |\vec{X}'_k|$. Employing (4.4) and (4.5) yields

$$\begin{aligned}(4.6)\qquad -\frac{R_0^2}{4\pi}\iint_\sigma \left[\mathcal{D}_r\left(\frac{rW}{\ell_k}\right)\right]\bigg|_{r=R_0} d\sigma \\ = -\frac{R_0^4}{4\pi r'_k}\iint_\sigma \left[\frac{(\mathcal{D}_r W)}{|\vec{X}-\vec{P}_k|} - W\,\mathcal{D}_r\,\frac{1}{|\vec{X}-\vec{P}_k|}\right]\bigg|_{r=R_0} d\sigma.\end{aligned}$$

Recall that W is harmonic for $r > R_0$. Applying Green's second identity[2] to (4.6) yields

$$-\frac{R_0^2}{4\pi}\iint_\sigma \left[\mathcal{D}_r\left(\frac{rW}{\ell_k}\right)\right]\bigg|_{r=R_0} d\sigma = -\frac{R_0^2}{4\pi r'_k}\iiint_{\Omega_0} W\,\nabla^2\left(\frac{1}{|\vec{X}-\vec{P}_k|}\right) dV.$$

Then using $\nabla^2(1/|\vec{X}-\vec{P}_k|) = -4\pi\delta(\vec{X}-\vec{P}_k)$, where δ is the Dirac delta function [11, p. 35], gives

$$(4.7)\qquad -\frac{R_0^2}{4\pi}\iint_\sigma \left[\mathcal{D}_r\left(\frac{rW}{\ell_k}\right)\right]\bigg|_{r=R_0} d\sigma = \frac{R_0^2}{r'_k} W\left(\vec{P}_k\right)$$

or finally, with $P_k = |\vec{P}_k|$:

$$(4.8)\qquad \left(\ell_k^{-1},\, W\right)_{\mathrm{I}} = P_k\, W\left(\vec{P}_k\right).$$

Various other ways exist to prove (4.8). One way is to substitute spherical harmonic expansions for W and ℓ_k^{-1} into the LHS of (4.7). A second way is to first observe that $(\ell_k^{-1}, \ell_{k'}^{-1})_{\mathrm{I}}$ can be evaluated in closed form by using spherical coordinates on the LHS of (4.7). Next, this result can be generalized by substituting the integral form of Poisson's equation (not Poisson's integral) for W into the LHS of (4.8) and then reintroducing the closed-form expression just obtained for $(\ell_k^{-1}, \ell_{k'}^{-1})_{\mathrm{I}}$, which results in the RHS of (4.8) reexpressed in terms of the integral form of Poisson's equation. As previously noted, these various steps were the ones originally followed by the author and account for the nomenclature. Other proofs have also been discovered.

This leaves the proof of the relationship between the weighted Dirichlet integral and the integral norm. Recalling the limit convention implicit for integration over σ, (1.4), and expanding the RHS of (4.1) yields

$$(4.9)\qquad (f,\, g)_{\mathrm{I}} = -\frac{R_0^2}{4\pi}\iint_\sigma f\,g\;d\sigma - \frac{R_0^2}{4\pi}\iint_\sigma r\mathcal{D}_r(f\,g)\;d\sigma.$$

Next temporarily ignore the common factor of $R_0^2/4\pi$ and consider the two integrals on the RHS of (4.9). Using the fact that $\mathcal{D}_r f = (\vec{X}/r)\cdot\vec{\nabla} f$, the first integral on the RHS of (4.9) can be written as

$$\begin{aligned}(4.10)\qquad -\iint_\sigma f\,g\,d\sigma &= \iint_\sigma \left\{\int_{r=R_0}^\infty \mathcal{D}_r\,(f\,g)\,dr\right\} d\sigma = \iiint_{\Omega_0} r^{-2}\,\mathcal{D}_r\,(f\,g)\;dV \\ &= \iiint_{\Omega_0} (g\,r^{-3})\,(\vec{X}\cdot\vec{\nabla} f)\;dV + \iiint_{\Omega_0} (f\,r^{-3})\,(\vec{X}\cdot\vec{\nabla} g)\;dV.\end{aligned}$$

[2] $\iint_{\partial\Omega}\left(\phi\frac{\partial\psi}{\partial n} - \psi\frac{\partial\phi}{\partial n}\right) dS = \iiint_\Omega(\phi\nabla^2\psi - \psi\nabla^2\phi)\;dV.$

Green's second identity in the following form will be useful in reexpressing the second term on the RHS of (4.9):

$$\iiint_{\Omega_0} \vec{\nabla}\psi\cdot\vec{\nabla}\phi \; dV = -\iint_{\sigma} r^2\,\psi\,(\mathcal{D}_r\phi)\,d\sigma, \tag{4.11}$$

where ϕ is harmonic in Ω_0, but ψ need not be, and both must vanish sufficiently fast as $r \longrightarrow \infty$. Using this identity at the appropriate place twice in the following expression (first with $\psi = f/r$ and $\phi = g$ and then with f and g reversed), the second term on the RHS of (4.9) can be rewritten as

$$\begin{aligned} &-\iint_{\sigma} r f\,(\mathcal{D}_r g)\,d\,\sigma - \iint_{\sigma} r\,g\,(\mathcal{D}_r f)\,d\,\sigma \\ &\quad = \iiint_{\Omega_0} \vec{\nabla} g\cdot\vec{\nabla}\,(f/r)\;\; dV + \iiint_{\Omega_0} \vec{\nabla} f\cdot\vec{\nabla}\,(g/r)\;\; dV. \end{aligned} \tag{4.12}$$

Finally using $\vec{\nabla}(f/r) = r^{-1}\vec{\nabla} f - r^{-3}\vec{X} f$ in (4.12) and substituting this result along with (4.10) into (4.9) produces

$$(f,\, g)_{\mathrm{I}} = \frac{R_0^2}{2\pi}\iiint_{\Omega_0} r^{-1}\,\vec{\nabla} f\cdot\vec{\nabla} g \; dV. \tag{4.13}$$

With the aid of (4.3), (4.8), and (4.13), the second and third DIDACKS relationship (i.e., (1.2a) and (1.3a)) follow immediately. From (4.13) and the discussion at the end of section 2 the integral norm is positive definite.

DIDACKS dipole and other higher order multipole implementations differ for the half-space and spherical settings in one significant way. While closed-form expressions for all the required inner-products for an integral-norm point-mass fit can be evaluated just as discussed in section 3, for higher order multipole fits all the derivatives of the potential for all the lower orders are also required in the spherical case because taking partials with respect to the components of $\vec{X}'_k$ yields additional terms on the RHS of (4.8). This means, for example, that a dipole fit requires not only point gravity information, but point potential information as well. It is thus natural in this case to perform not only a point dipole fit, but a combined point mass/dipole fit. With this understanding the spherical case analogue of Table 3.1 is readily obtained.

When an integral norm higher order multipole fit is desired and the lower order derivatives of W are not available, then it still may be possible to do the fit [21]. For example, if a dipole fit is desired and information about W is not available, but the gradient of W is known along various intersecting lines, then potential data in the form $W(\vec{X}) = W_0 + \delta W(\vec{X})$, where W_0 is an unknown constant, can be assumed anywhere along these lines since the form of $\delta W(\vec{X})$ can be found by numerical line integration. For any assumed trial value of W_0, a DIDACKS fit can be performed. The results of this fit can then, in turn, be substituted into a standard LLSQ type of cost function that is the analogue of (5.1) and is based on minimizing gravity computations at various sample points. If gravity data itself is plentiful, then an outer-loop optimization process can be based on minimizing this new cost function, where W_0 is treated as an unknown NLLSQ parameter. In this outer-loop process sample point gravity differences are minimized throughout the fit region of interest (which may be only a small part of Ω_0). When its choice is not obvious, R_0 can also be treated as a parameter and optimized in the same fashion.

5. Broader point mass fitting context. The goal of this section is to illuminate certain aspects of relevant geophysics and point mass fitting background material by way of a brief synopsis (as such, this section is somewhat subjective). Before considering the associated geophysical context it is useful to clarify the distinction between NLLSQ and GLLSQ or LLSQ problems and to briefly consider how the pertinent DIDACKS applications history fits into these categories. In what follows, the distinction between GLLSQ and LLSQ is generally dropped and only the acronym LLSQ is used, so that both classes can be referred to jointly. If all the source locations are known, then linear equation sets result for the source strengths, and in the DIDACKS approach these linear equation sets are exact due to (1.1) and (1.2a). Alternatively, if both the locations and strengths are to be determined, then an NLLSQ problem results since source locations enter as nonquadratic parameters in the cost function. While only LLSQ problems have been addressed so far in this article, accurate low degree and order spherical harmonic (tesseral) NLLSQ fits have been obtained by the author, and this was, in fact, the first area of DIDACKS applications in the early 1980s [21]. These NLLSQ fits are discussed further below. While rather varied approaches have been used by different researchers for point mass–based geoexploration inverse source applications, for the gravity modeling and estimation problems dealt with here far fewer point mass–based approaches have been employed; nevertheless, not only have the associated research efforts been internationally diverse, but the corresponding literature is also extensive, so that only a small part of it can be considered here (see [26] for additional history and references). LLSQ and NLLSQ point mass gravity models can also be produced to serve as synthetic gravity models with realistic attributes, but DIDACKS applications in this area have not been considered, so these applications are not discussed below. Finally, two conventions are adopted in the remainder: (a) a spherical harmonic expansion to degree and order N will be called an $N \times N$ field or expansion, and (b) both field modeling and estimation problems will be referred to as field reconstruction problems.

Next, consider the relevant geophysical aspects. Approximately a quarter of a century ago one could divide the Earth's gravity field into three parts corresponding to their respective data sources:

(I) Global spherical harmonic field data derived directly from satellite tracking data and historically considered accurate to around the degree and order 8 to 12 range. Here this part of the field is called "low degree and order," and it is taken to be 12×12 and below.

(II) An intermediate field taken here to be the part above 12×12 and below 120×120, which before the evolution of more advanced radar equipped satellites could not be accurately determined.

(III) Regional measurements of geophysical surface quantities known as gravity anomaly and vertical deflections. (These data sets contain part (I) and (II) contributions unless they are factored out.)

Parts (I) and (II) together will be taken as comprising the global part of the gravity field. As discussed below, much higher accuracy is desirable for part (I) than part (II) or part (III) data. Currently very accurate spherical harmonic expansions to a much higher degree and order are available on the Internet, so the distinction between the above three data sets is not as distinct as it once was, but to understand the context of the methods discussed in this section it is useful to keep this historical data partition in mind. (Expansions beyond 360×360 are common, and the recent Gravity Recovery and Climate Experiment (GRACE) [10, 20] has already established new global gravity accuracy benchmarks up through 110×110.)

Next consider the origins of part (III) data. Regional data measurements are often made at sea, and it is in this context that the concepts of gravity anomaly and vertical deflection components are best understood. Suppose that the Earth were composed of a homogenous liquid with the same overall mass and volume; then due to rotational effects it would take on an ellipsoidal shape. Geophysicists set up a mathematical model of this configuration that they call the reference ellipsoid. The associated field is called the normal gravity field and is the predominant part of the field. If transient effects (like tides and ocean waves) are accounted for, then under the influence of gravity the oceans form an equal-potential surface (otherwise water would flow from one part to another until an equilibrium was reestablished). If normal gravity is subtracted off and if these transient effects are properly taken into account, then the measurement taken by a gravimeter on a ship is called the gravity anomaly, Δg, and it is a scalar since the measurement is taken along a plumb line. The angular displacement of this plumb line from the vertical is called vertical deflection, which can be resolved into north-south and east-west components. Due to the equipotential effect just noted, this measurement is displaced from the specified reference ellipsoid by a distance that is called the geoid height, but the measurement is recorded as if it had been made at a point on the reference ellipsoid itself [10]. Geoid height and scalar potential values are connected by Bruns formula [10]. Geoid height itself can be determined by a radar-equipped satellite that has a known location. Gravity anomaly is typically measured in units of milligal, where 1 milligal $= 1 \times 10^{-5}\text{m/s}^2$. A 1 milligal error is considered more-or-less acceptable for regional gravity anomaly data processing [10, p. 274], and various underpinning geophysical relationships are derived with an inherent approximation consistent with this 1 milligal requirement [9, 10]. Much higher accuracy is desirable for part (I) than part (II) or part (III) data since gravitational effects are cumulative for most uses and since low degree and order errors tend not to cancel out. GRACE and other modern fields have error levels considerably under a milligal for part (I) data, and for this part of the field it is also desirable to have point mass models with errors somewhat under a milligal.

Historically, there have been three primary motivations for performing NLLSQ fits to the low degree and order spherical harmonic part of the Earth's gravity field: (a) to find a more efficient computational scheme for gravity evaluations, (b) to gain some insight into the distribution of matter in the Earth's interior, (c) to conduct goal-oriented pure research. Due to the computational ease and speed of low degree and order spherical harmonic gravity evaluations that has resulted from computer hardware and software advances, (a) has long ceased to be a realistic reason for using point mass fits, and this point is totally irrelevant now. Other measurement programs and advances have also emerged to address the issues raised by (b), but in fact it was never clear that the small number of point masses used in NLLSQ fits could provide truly significant mantle or deep core density information, which leaves only (c). NLLSQ point mass fitting presents a very challenging problem that can conceivably serve as a sort of test bed for developing techniques to tackle other ill-conditioned problematic NLLSQ problems; moreover, aside from these NLLSQ aspects, it is an intrinsically interesting potential theory problem that has associated cross-fertilization possibilities.

The first step in attacking any LLSQ or NLLSQ problem is to set up a cost function. A commonly chosen minimization philosophy for the NLLSQ point mass fitting problem is that of matching the observed quantities as closely as possible. Since there is a classical result in geophysics (Stokes' integral) that says that if the gravity anomaly is known over the entire reference ellipsoid, then the external field quantities can be reconstructed, standard approaches to performing global NLLSQ low degree and order point mass fits often have been based on matching the gravity anomaly at N_i different sample points, $\vec{X}_i$, specified on the reference surface. This technique will be called the "classical point mass" approach. If $\Delta g_{PM}(\vec{X}_i)$ denotes the anomaly generated by a collection of N_k point masses and $\Delta g_{ref}(\vec{X}_i)$ represents the truth anomaly value at the same point, this classical NLLSQ point mass approach can be framed through the requirement that the following cost function be minimized:

$$\Phi = \sum_{i=1}^{N_i} \left(\Delta g_{PM}(\vec{X}_i) - \Delta g_{ref}(\vec{X}_i) \right)^2 , \tag{5.1}$$

where $N_i \gg N_k$. The usual prescribed number of point masses, N_k, is approximately 50 for an NLLSQ 9×9 fit, while $N_k \approx 80$ for a 12×12 fit. The resulting gravity anomaly error standard deviations (sigma) achieved by applying this classical point mass fitting approach has typically been from 3/4 to several milligals. These approaches normally have a much more sizable error in the smaller degree and order terms than is desirable.

The global NLLSQ point mass fitting problem itself is inherently nonlinear, and the point masses must be quite deep to obtain good results, which heightens numerical difficulties and associated convergence problems. Given this state of affairs, coupled with the facts that the smaller degree and order errors cannot be easily removed using this classical approach and that it contains inherent sampling and discretization error, there is an error floor of around 2/3 milligal that these approaches historically have not been able to overcome. While the associated regional LLSQ approaches that have been tried are remarkably diverse, far fewer low degree and order NLLSQ approaches have been employed—nevertheless the diversity of attempted NLLSQ point mass approaches in the literature is much wider than the above discussion indicates, but still the accuracy levels and deficiencies of the classical point mass approach presented above are thought to be representative of these other existing NLLSQ attempts as well. In section 2 it was argued that the usual philosophy of matching measured quantities is not the correct one and that an energy basis or weighted energy basis is clearly called for in approaching both LLSQ and NLLSQ gravity modeling problems.

As noted above, accurate global NLLSQ low degree and order spherical harmonic point mass fits using the DIDACKS approach were first obtained almost a quarter of a century ago by the author, and in the past as better spherical harmonic data has became available more accurate fits have been obtained [21]. This has been an ongoing effort, and the current NLLSQ 50 point mass fit to the 9×9 part of a recent field has a sigma error of about 0.035 milligal, while the corresponding error in an NLLSQ 80 point mass fit to the 12×12 part of the field is 0.030 milligal. As one might expect, additional masses here can offer marked improvements in accuracy but at a loss of efficiency. Combined point mass/dipole fits (cf. section 4), which are combinations of point masses and dipoles at the same location, have also been performed over the years [21]. Only about half as many of these combined point sources are required for an accurate NLLSQ fit: 22 for a 9×9 field and 35 for a 12×12 field. These NLLSQ DIDACKS fits have all been based on the integral norm introduced in section 4. Besides the basic DIDACKS formalism, these fits also use additional specialized NLLSQ techniques developed by the author to handle the existence of numerous false minima at various physical scales.

While the fits should be feasible, neither LLSQ nor NLLSQ DIDACKS fits to the complete global intermediate part of the field (part (II)) have been attempted, although efficient and accurate DIDACKS fits for various regional and local gravity modeling and estimation problems using both LLSQ and partial NLLSQ implementations have been obtained by the author [21]. Regional point mass gravity field reconstruction (part (III)) based on the "classical point mass" approach epitomized by (5.1) has also often been successfully done over the years by various researchers; however, some have reported disappointing results. This is not surprising since considerable patience is often required in order to obtain the best or even good results with the DIDACKS approach due to source placement issues. Thus while both DIDACKS and the classical point mass fitting approach can be viewed as alternatives to GC for regional applications, they both clearly share the same sensitivity to and dependence on point mass placement. This sensitivity to point mass placement is also apparent from the low degree and order NLLSQ DIDACKS results, since NLLSQ iterations have obviously reduced the errors by several orders of magnitude over those of initial trial configurations. GC is designed to not be as sensitive to the placement of the kernel measurement points (which is the corresponding placement issue for it), and thus GC generally requires less patience and skill. Alternative part (II) and (III) grid-based point mass approaches are referenced and discussed in [26].

It is thus useful to briefly describe GC in order to compare and contrast it with the DIDACKS approach. Unlike DIDACKS, GC theory generally assumes that all available data is used. GC as commonly practiced differs from standard collocation techniques utilized by applied mathematicians in five basic ways:

1. An SRK basis is assumed, and emphasis is primarily focused on a statistical (covariance) interpretation given to these kernels.
2. Laplace's equation in $\mathbb{R}^3$ is always assumed to hold over the region of interest.
3. This field region is assumed to be either half-space or the exterior of a sphere (but the half-space setting is used only occasionally for localized regional distributions, so it is not stressed).
4. The study of kernels is broken down into the standard empirically modeled statistical covariance kernels and analytical collocation (where closed-form kernels are studied)—analytical collocation is generally used only when the functional form of the kernel is understood to be a workable representation of the statistical covariance function.
5. Field measurement errors are allowed.

Practitioners of GC have cataloged most, if not all, useful kernel possibilities allowed by these five differences. The main interpretational basis of GC is the GC or minimum norm property, previously mentioned in connection with the GLLSQC condition in section 2: under the assumption of errorless measurements, from all possible candidate functions that reproduce the given point measurements, GC selects the one that is smoothest—that is, the one with the smallest norm, where the norm is determined by the underlying covariance function [19, pp. 207–220]. It is this minimum norm property, in concert with the emphasis on statistical covariance functions indicated by the first point above, that makes GC approaches less sensitive to kernel point placement issues; however, as indicated above, this also implies a corresponding loss of fitting responsiveness, and thus, for example, it would be hard to argue that GC is capable of the overall level of economy and efficiency indicated above for the NLLSQ DIDACKS low degree and order tesseral fits. Further observe that, just as in RKHS theory, GC also satisfies a least-squares norm property [19], but in practice this property is usually ignored by physical geodesists.

For LLSQ gravity reconstruction problems GC has historically been the first procedure of choice, and for these problems one could argue that when good covariance data is available, these techniques are safe and easy to use; however, as classically practiced, GC techniques do have notable limitations, which are not shared by the DIDACKS approach:

(A) NLLSQ applications cannot be treated.

(B) GC techniques are customarily applicable only to the Earth's gravitational field environment since they require covariance information that is often available only in this context.

(C) The application of GC requires a certain level of familiarity, and thus it is almost never adapted to problems outside the geophysical realm, even when appropriate covariance data can be gathered. (There are, however, various other areas that use somewhat related kernel techniques [22].)

(D) Inverse source estimation problems cannot be entertained.

In summary, for gravity reconstruction problems with accurate selected data sets where either approach can be used, results using the DIDACKS approach can be either much better or much worse than one might normally expect with GC approaches, since the ingenuity, implementation skill, and patience of the practitioner have a much more significant bearing on the outcome for DIDACKS approaches. GC is and probably will always remain the primary mathematical tool employed for raw gravity data processing and related uses where efficiency is not the primary concern, since its behavior in these arenas is well understood and it can handle measurement errors naturally.

6. Mathematical connections to geophysical collocation. As indicated in section 1, (1.2a) can be related to a line of preexisting research performed by Krarup in conjunction with his studies of GC [15]. Also an independent parallel line of point source research exists that maintains direct connections to GC itself and can be considered a direct outgrowth of Krarup's original work. This alternative collocation-based point source scheme is briefly considered after the connections of DIDACKS theory to Krarup's work are addressed. Since this alternative scheme and Krarup's work are primarily based on GC for spherical exteriors, only this geometry will be considered in what follows.

Krarup first introduced the weighted integral occurring on the RHS of (4.13) in conjunction with his study of GC [15, pp. 62–65]. The SRK corresponding to this norm (the "Krarup kernel," K_{κ}) has the form

$$K_{\kappa}(\vec{P},\, \vec{Q}) = \frac{R_0}{\sqrt{R_0^2 - 2\,\vec{P}\cdot\vec{Q} + (P\,Q/R_0)^2}}\ , \tag{6.1}$$

which Krarup and his followers extensively studied and applied. In (6.1), $Q = |\vec{Q}|$. To understand how point mass fitting enters, observe that this SRK can be recast in the form $R_0^2/(P|\vec{Q}-\vec{X}'|)$, or $|\vec{X}'|/|\vec{Q}-\vec{X}'|$ since $\vec{X}' = \vec{P}R_0^2/P^2$, which is proportional to a point mass potential at a fixed location. Making the ansatz $\vec{X}' \longrightarrow \vec{X}'_k$ and $\vec{Q} \longrightarrow \vec{X}$ allows one to transform a collocation fit into a point mass fit if the mass locations are restricted to be at a fixed depth $r'_k = |\vec{X}'_k| =$ constant, where r'_k is simply treated as an overall constant of proportionality. The relevant history of this and related ideas is briefly touched on below. Here one possible next step, which Krarup and his followers did not apparently take since it entails abandoning symmetric kernel forms altogether, is to generalize this procedure to independent variable depths by absorbing the factors

$P_k := R_0^2/r'_k$ and R_0 into each of the collocation fitting parameters separately and then reinterpreting the resulting collocation fit as a point mass fit, which yields a fit based on (1.2a) as the end product.

Conversely, DIDACKS point mass fits based on the integral norm can be reinterpreted as collocation fits [21]. The resulting fits are based on what is called the reciprocal distance covariance function [19, p. 182], which corresponds to R_0^2/PQ times the Krarup kernel specified by (6.1). Notice that while the integral norm can be reexpressed in terms of the "Krarup norm" by (4.13), it is useful to retain the integral norm as a distinct entity specified by (4.1) since (a) it is a surface integral rather than a volume integral, (b) there are some consequences of this form, such as (4.3), that are not apparent from the weighted Dirichlet integral form itself, and (c) the Krarup norm is associated exclusively with the Krarup kernel in SRK form and is primarily linked to GC theory where, as previously noted, the goals and practices are quite different.

As summarized in [16] and as just indicated, starting in the early 1980s a distinct line of point source research based on Krarup's original work above was developed by Marchenko and others (see [7]). This research is based on maintaining connections to symmetric global GC covariance kernel forms. For the spherical case, assuming the usual GC covariance properties, the general form of the allowed global covariance kernel, $C(\vec{P}, \vec{Q})$, can be written as

$$C(\vec{P}, \vec{Q}) = \sum_{n=0}^{\infty} k_n \left(\frac{R_0^2}{PQ}\right)^{n+1} \mathrm{P}_n(\cos\psi)\,, \quad \text{where} \quad \cos\psi = (\vec{P}\cdot\vec{Q}/P\,Q)\,, \tag{6.2}$$

where the P_n are standard (unnormalized) Legendre polynomials and the k_n are constants [19, p. 181]. Here, as before, R_0 is the radius of the spherical region. Mathematically, a kernel specified by (6.2) can, in general, be simply considered an SRK with an added layer of statistical interpretation. Solving (1.2b) for $\vec{X}' = \vec{X}'(\vec{P})$ and substituting the result into (6.2) yields a kernel that is a function of one interior point and one exterior point. For certain applications, when (6.2) is reexpressed in terms of a smaller radius $R_B < R_0$, the resulting sphere is known as a Bjerhammar sphere. For particular choices of k_n if (6.2) can be rewritten as a closed-form expression and if this expression has the correct form, such as (6.1), then the result can be reexpressed as a point mass or other linear combinations of point or line source potentials. As just noted in connection with (6.1), additional parameters will occur in the resulting expressions that do not appear in the source potentials themselves, but if the locations of the sources are restricted, these parameters can be explained away as common constant factors. A Bjerhammar sphere is generally used since it allows for an independent adjustment of the overall depth of the interior source points. By maintaining connections to the symmetric kernel forms that are allowed by (6.2), a statistical covariance interpretation is possible.

As one might expect there are notable differences between this approach and DIDACKS since this alternative approach adopts the basic philosophy of maintaining connections to GC and DIDACKS does not. In particular for a specified domain, from RKHS theory one can deduce that the choice of inner product (or norm) and reproducing kernel must be in one-to-one correspondence [19]; hence, the choice of multipole form to be fit and norm are directly linked. A list of known covariance kernel and multipole point source correspondences for this approach can be found in [16]. For example, in [7] some of the consequences of the Krarup norm choice, along with its half-space approximation, are examined for point mass fits. By employing (6.2), this approach allows for an underpinning statistical covariance interpretation, which is important for many geophysical applications; nevertheless, implicitly retaining symmetric kernel forms also adds a layer of additional complexity, which has the effect of greatly complicating the theory and of limiting the possible choices of dipole and higher multipole forms. For uses outside geophysics there are also clearly interpretational difficulties that limit its use.

In DIDACKS theory all attempts at retaining connections to SRKs are dropped, and the primary emphasis is placed on the (weighted) energy or integral norm and the associated kernel form ℓ^{-1}. As noted earlier, this makes consideration of dipoles and higher multipoles trivial since the required inner products are readily obtained. Moreover, since the DIDACKS approach maintains the same norm choice for all source types there are few interpretational issues—especially with regards to multipole fits of all orders. The types of geophysical areas where one of these two approaches or GC should be preferred over the others clearly warrant further study and consideration since, to date, there have been no researchers proficient in applying all three algorithms. (While GC has had many practitioners and this alternative collocation based approach has had a few practitioners, so far DIDACKS development and use has been limited to the author's involvement.)

MOISTURE TRANSPORT AND DIFFUSIVE INSTABILITY DURING BREAD BAKING[*]

H. HUANG[†], P. LIN[‡], AND W. ZHOU[§]

Abstract. In this paper we study multiphase models for simultaneous heat and mass transfer processes during bread baking. Our main objective is to provide an explanation and a remedy to the observed erroneous and/or divergent results associated with an instantaneous phase change model used in the literature. We propose a reaction-diffusion model based on the Hertz–Knudsen equation, where phase change is not instantaneous but determined by an evaporation/condensation rate. A splitting scheme is designed for the reaction-diffusion model so that a link between these two models can be established and the nonintuitive numerical instability associated with the instantaneous phase change model can be identified and eliminated. The evaporation/condensation rate is estimated by comparing results of the reaction-diffusion model with experimental observations reported in the literature. For evaporation/condensation rate beyond the estimated value, oscillatory solution with multiple regions of dry and two-phase zones is observed. We show that these are caused by an instability intrinsic to the model (which we call diffusive instability) using linear stability analysis and numerical tests.

Key words. diffusive instability, finite difference method, heat and mass transfer, linear stability analysis, multiphase modeling, phase change, reaction-diffusion equation

1. Introduction.

The bread baking process is difficult to model, partly due to the fact that simultaneous heat and mass transfer are involved during the process. During baking, heat transfer in dough is a combination of conduction/radiation from band or tins to the dough surface, convection from air to the dough surface in the absence of baking tins, conduction in the continuous liquid/solid phase of the dough, and evaporation-condensation in the gas phase of the dough.

De Vries, Sluimer, and Bloksma [9] described a 4-step mechanism for the heat transport inside dough: (1) water evaporates at the warmer side of a gas cell that absorbs latent heat of evaporation; (2) water vapor then migrates through the gas phase; (3) when meeting the cooler side of the gas cell, water vapor condenses and becomes liquid; (4) finally, heat and water are transported by conduction and diffusion through the gluten gel to the warmer side of the next cell. The water diffusion mechanism becomes important to heat transfer, because dough tends to be a poor conductor that limits the heat transfer rate via conduction.

The above described mechanism of diffusion, together with evaporation and condensation in dough, was subsequently adopted by Tong and Lund [22] and Thorvalds-

son and Janestad [20]. With this mechanism, liquid water moved towards the loaf center as well as the surface by evaporation and condensation, reducing the partial water vapor pressure due to the temperature gradient. As a result, crumb temperature change was accelerated.

In the model by Zanoni, Peri, and Pierucci [23], an evaporation front inside the dough was assumed to always be at 100°C. This evaporation front progressively advanced towards the center as the bread's temperature increased. Crust was formed in the bread portion above the evaporation front. With similar parameters, Zanoni, Peri, and Pierucci [24] developed a 2-dimensional axisymmetric heat diffusion model. The phenomena were described separately for the upper and lower parts (crust and crumb). The upper part (crust) temperature was determined by equations including heat supply by convection, conductive heat transfer towards the inside, and convective mass transfer towards the outside. The lower part (crumb) temperature was determined by Fourier's law. In addition to the Cartesian coordinate models, a 1-dimensional cylindrical coordinate model was also established by De Vries, Sluimer, and Bloksma [9].

Among the various models, the internal evaporation-condensation mechanism well explains the fact that heat transfer in bread during baking is much faster than that described by the conduction alone in dough/bread. It also supports the observation that there is an increase in the liquid water content at the center of the bread during the early stage of baking (Thorvaldsson and Skjoldebrand [21]) rather than a monotonous decrease resulted from having liquid water diffusion and surface evaporation only. Therefore, a promisingly good model for bread baking might be a multiphase model which consists of three partial differential equations for the simultaneous heat transfer, liquid water diffusion, and water vapor diffusion, respectively, together with two algebraic equations describing water evaporation and condensation in the gas cells. Indeed, Thorvaldsson and Janestad [20] used this multiphase model to describe a 1-dimensional case where a baking tin was absent.

In [20], a slab of bread crumb being baked in a conventional oven was considered. Their model assumes that vapor and liquid water diffuse separately and phase change (evaporation and condensation) occurs instantaneously; i.e., vapor content V is directly proportional to saturated vapor content V_s at any given time, provided that there is enough liquid water available. The authors showed reasonably good agreement between the numerical results predicted by the model and their experimental measurements. However, further investigations using the same model revealed that instability occurs as time step size was refined [18, 25].

Zhou [25] demonstrated that numerically solving the model equations presented a big challenge. Although various schemes of finite difference methods and finite element methods were applied, the corresponding solutions were all shown to be highly sensitive to the time step size, and satisfactory results were yielded only over a limited range of time step sizes. Erroneous and/or divergent results were produced when the time step size was either too small or too large. While it is reasonable to expect that large time steps may lead to instability, failure of the numerical methods due to small time step sizes is nonintuitive.

The main objective of this paper is to provide an explanation as well as a remedy to this highly nonintuitive outcome of the instantaneous phase change model proposed in [20]. In order to identify the source of instability in the instantaneous phase change model, we construct a reaction-diffusion model by assuming that phase change follows a modified Hertz–Knudsen equation, which can be derived using statistical mechanics principles [13]. We show that the two models are related from a numerical point of view when a special time stepping scheme is used for the reaction-diffusion model.

The instantaneous phase change model is equivalent to the reaction-diffusion model with a variable evaporation rate reciprocal to the time step size. Therefore, reducing the time step size in the instantaneous phase change model increases the evaporation rate in the reaction-diffusion model.

The reaction-diffusion model allows us to study the effects of the evaporation rate in more detail by separating two types of instabilities, i.e., instability associated with a particular numerical scheme and diffusive instability associated with the model. Combining numerical tests and linear stability analysis, we show that diffusive instability is an intrinsic feature of the model, which does not disappear as time step size is reduced. As a result, the two-phase region where vapor and liquid water coexist may become unstable. For the parameter values used in [20, 18, 25], the constant state solution in the two-phase region is linearly unstable even though the solution is stable when phase change and diffusion are considered separately. Furthermore, the rate of growth depends on the evaporation rate. A larger evaporation rate leads to faster growth of the disturbances. Oscillation in solutions can occur in the two-phase region before the dry region completely takes over.

We show that the reaction-diffusion model does not lead to numerical instability when sufficiently small time step size is used. For the instantaneous phase change model, reducing the time step size is equivalent to increasing the evaporation rate while keeping the product of time step size and evaporation rate fixed. Therefore, systematic refinement of the time step size induces faster growth of error, which eventually causes numerical instability observed in the computations in [18, 25].

In order to put the problem we study in this paper in a broader context, we shall give a brief overview of some relevant applications whose mathematical description has certain similarity to the bread baking models discussed here. A general feature of these problems is the coupling of thermal diffusion and phase change. We refer the readers to [3, 5, 6, 7, 10] for treatments of phase change and heat transfer phenomena in general. A closely related application is given in [16, 15], where a moisture transport model for the wetting and cooking of a cereal grain is considered. The temperature is decoupled from the moisture model, and it is used as a parameter in their model. In [12, 11], the condensed phase combustion or gasless combustion is considered. The model has applications in synthesizing certain ceramics and metallic alloys and involves a reaction-diffusion system for temperature and fuel concentration, where the diffusion coefficient of fuel concentration is set to be zero. In [2], a model for the aggregate alkali reaction in fluid leaching processes, which is similar to the gasless combustion problem, is studied numerically. All these models are similar to the one studied in [20, 18, 25], with some differences in the way the phase change is handled and in the parameters and coefficients. Numerical techniques used in those studies are also similar, where either finite difference and finite element methods or pseudospectral methods are used for spatial discretization.

The rest of the paper is organized as follows. In section 2, we describe a reaction–diffusion model based on the Hertz–Knudsen equation. The relationship between our model and the instantaneous phase change model is explored in section 2.2 when numerical procedure is discussed. Numerical results for the reaction-diffusion model are given in section 2.3. In section 3 we carry out linear stability analysis of our new model. We finish the paper with a conclusion and a short discussion on future directions in section 4.

2. A reaction-diffusion model. Following [20, 18, 25] we assume that the bread slab can be treated as a 1-dimensional homogeneous porous medium ($0 < x <$

L) with density ρ, specific heat capacity c_p, and thermal conductivity k. While in reality both c_p and k depend on water content, they are assumed to be constants in [20], where density ρ is given as a linear function of the liquid water content. The main variables are temperature T, liquid water content W, and water vapor content V inside the bread with respect to the total weight (both are dimensionless variables defined as the percentage of liquid water and vapor mass with respect to that of the mixture including the bread). Thus the total vapor and liquid water masses per unit of volume can be computed as ρV and ρW, respectively. Vapor and liquid water can be generated via evaporation and condensation, respectively, determined by the saturated vapor concentration V_s (or saturation pressure P_s), which is temperature dependent. Vapor and liquid water can also be transported via diffusion, with coefficients D_v and D_w, respectively.

The governing equations for T, V, and W are

$$\rho c_p \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k \frac{\partial T}{\partial x}\right) + \lambda \Gamma, \tag{2.1}$$

$$\frac{\partial V}{\partial t} = \frac{\partial}{\partial x}\left(D_v \frac{\partial V}{\partial x}\right) - \frac{\Gamma}{\rho}, \tag{2.2}$$

$$\frac{\partial W}{\partial t} = \frac{\partial}{\partial x}\left(D_w \frac{\partial W}{\partial x}\right) + \frac{\Gamma}{\rho}. \tag{2.3}$$

Here Γ is the rate of the phase change (mass per unit volume per unit time), given by the modified Hertz–Knudsen equation (see [13], where this equation is used for studying evaporation phenomena)

$$\Gamma = E(1-\phi)\sqrt{\frac{M}{2\pi R}}\frac{(P_v - cP_s)}{\sqrt{T}}, \tag{2.4}$$

where E is the condensation/evaporation rate, ϕ is the porosity of the bread slab, M is the molecular weight of water and R is the universal gas constant, P_v and P_s are the vapor pressure and saturation pressure, and c is a phase change constant. For simplicity we have included the pore surface area in E, which is inversely proportional to the pore size of the porous sample. Even for a unit pore surface, the value of evaporation rate E is subject to debate [13]. In this study, we estimate the value of E by comparing numerical results of the current model with experimental observations [20]. We also use the fitted saturated vapor pressure data [19] by an exponential function

$$P_s = P_{s,0}\exp[\kappa(T - T_0)] - P_{s,1}. \tag{2.5}$$

Assuming the ideal gas law,

$$P_v = \frac{R\rho V T}{\phi M}, \quad P_s = \frac{R\rho V_s T}{\phi M}, \tag{2.6}$$

we can rewrite (2.4) as

$$\Gamma = \frac{E(1-\phi)\rho}{\phi}\sqrt{\frac{RT}{2\pi M}}\left(V - cV_s\right). \tag{2.7}$$

It is worth noting that evaporation can occur only when there exists a sufficient amount of liquid water. Thus, if $V < cV_s$ and $W = 0$, then no evaporation occurs and $\Gamma = 0$.

As in [20, 18, 25], we assume that initially the bread has certain moisture content W_0 (liquid water) at room temperature T_0. At time zero, the bread is placed in an oven preheated at temperature T_a by a radiator with temperature T_r. The boundary conditions are mixed conditions at $x = 0$:

$$-k\frac{\partial T}{\partial x} = h_r(T_r - T) + h_c(T_a - T), \tag{2.8a}$$

$$-\frac{\partial V}{\partial x} = h_v(V_a - V), \tag{2.8b}$$

$$-\frac{\partial W}{\partial x} = h_w(W_a - W), \tag{2.8c}$$

and they are symmetric conditions at $x = L$:

$$\frac{\partial T}{\partial x} = \frac{\partial V}{\partial x} = \frac{\partial W}{\partial x} = 0. \tag{2.8d}$$

Here h_r, h_c, h_v, and h_w are the radiative and convective heat transfer coefficients and the vapor and liquid water mass transfer coefficients, respectively. V_a and W_a are the vapor and liquid water content in the oven air.

Finally, some of the coefficients are estimated experimentally and following expressions [20] will be used in this paper. The diffusion coefficient for water D_w is approximated as a constant, while for vapor diffusion, we have $D_v = \bar{D}_v T^2$. Heat transfer coefficients depend on temperature and sometimes water content, and they are approximated by $h_v = \bar{h}_v T^{-3}$, $h_w = \bar{h}_{w0}T + \bar{h}_{w1}W + \bar{h}_{w2}TW + \bar{h}_{w3}W^2$, and $h_r = \sigma(T_r^2 + T^2)(T_r + T)/(\epsilon_p^{-1} + \epsilon_r^{-1} - 2 + F_{sp}^{-1})$, where F_{sp} is the shape factor and ϵ_p and ϵ_r are the emissivities of the bread and radiator, respectively. Finally, the density of the mixture is approximated by $\rho = \bar{\rho}_0 + \bar{\rho}W$. The readers are referred to [20] for more details on relevant parameter values.

2.1. Nondimensionalization. We now proceed to nondimensionalize the governing equations by choosing the following scaling:

$$\theta = \frac{T - T_0}{\bar{T}}, \quad \tau = \frac{t}{\bar{t}}, \quad \xi = \frac{x}{L}, \quad \rho' = \frac{\rho}{\bar{\rho}}.$$

Here $T_0 = 298$ K is the initial temperature and $\bar{T} = T_r - T_0$ is the difference between the radiator and initial temperature. We choose the diffusive time scale for the temperature equation

$$\bar{t} = \frac{\bar{\rho} c_p L^2}{k}.$$

Drop the prime for simplicity and we have the following equations:

$$\theta_\tau = \frac{1}{\rho}\theta_{\xi\xi} + S, \tag{2.9}$$

$$V_\tau = D_1[(\theta + \theta_0)^2 V_\xi]_\xi - \alpha S, \tag{2.10}$$

$$W_\tau = D_2 W_{\xi\xi} + \alpha S, \tag{2.11}$$

where the nondimensional density is given as $\rho = W + \rho_0$ with $\rho_0 = \bar{\rho}_0/\bar{\rho}$. The other dimensionless parameters are defined as

$$D_1 = \frac{\bar{D}_v \bar{\rho} \bar{T}^2 c_p}{k}, \quad D_2 = \frac{D_w \bar{\rho} c_p}{k}, \quad \alpha = \frac{\bar{T} c_p}{\lambda}.$$

When there is sufficient amount of liquid water, the source term for phase change is given by

$$S = \beta\sqrt{\theta + \theta_0}\,(V - cV_s)\,, \tag{2.12}$$

where

$$\beta = \lambda E(1-\phi)\frac{\bar{\rho}L^2}{\phi k}\sqrt{\frac{R}{2\pi M\bar{T}}},$$

and the saturated vapor content is

$$V_s = \frac{V_{s,0}e^{\gamma\theta} - V_{s,1}}{(\rho_0 + W)(\theta + \theta_0)},$$

with parameters

$$V_{s,0} = \frac{P_{s,0}M}{\bar{\rho}\bar{T}R}, \quad V_{s,1} = \frac{P_{s,1}M}{\bar{\rho}\bar{T}R}, \quad \gamma = \kappa\bar{T}.$$

The boundary conditions at $x = 0$ ($\xi = 0$) and $x = L$ ($\xi = 1$) are nondimensionalized similarly. At $\xi = 0$, we have

$$\theta_\xi = (h_3 + h_4)(\theta - 1), \tag{2.13a}$$

$$V_\xi = h_1(V - V_a), \tag{2.13b}$$

$$W_\xi = h_2(W - W_a), \tag{2.13c}$$

where

$$\begin{aligned} h_1 &= h_v L, \\ h_2 &= h_w L, \\ h_3 &= \frac{\sigma\bar{T}^3 L}{k}\frac{[(1+\theta_0)^2 + (\theta+\theta_0)^2](\theta + 1 + 2\theta_0)}{\epsilon_p^{-1} + \epsilon_r^{-1} - 2 + F_{sp}^{-1}}, \\ h_4 &= \frac{h_c L}{k}. \end{aligned}$$

Here we have assumed that the air temperature T_a equals the radiator temperature T_r. At $\xi = 1$, we have

$$\theta_\xi = V_\xi = W_\xi = 0. \tag{2.13d}$$

2.2. Numerical method. We now turn our attention to numerical procedures by describing a splitting scheme for the reaction-diffusion model (cf. [4]). We will revisit the instantaneous phase change model and establish a connection between our model and the instantaneous phase change model. Numerical solutions of our new model will be presented at the end of the section.

2.2.1. Reaction-diffusion model. Splitting scheme. We adopt a splitting method for the reaction-diffusion model by separating diffusion from phase change (reaction) and solving the equations in two steps.[1] We first solve the vapor and liquid

[1] From the numerical method point of view, there is also a benefit to using the splitting. Since we can obtain an explicit relation between W and V in the phase change stage, W can be computed using V without treating the source term S in the W equation (or with that relation the source term in the W equation can be written in terms of W and is dissipative). As a result, the algorithm is more stable. We note that time splitting schemes have been used in the literature for reaction-diffusion equations, and we refer interested readers to [1, 8] and the references therein.

water equations by

$$V_\tau = -\alpha S, \tag{2.14}$$

$$W_\tau = \alpha S. \tag{2.15}$$

The second equation for liquid water can be replaced by an algebraic constraint

$$V + W = V^0 + W^0,$$

where V^0 and W^0 are the values at the beginning of the splitting step. Diffusion of vapor and liquid water as well as temperature are solved in the second step by

$$\theta_\tau = \frac{1}{\rho_0 + W}\theta_{\xi\xi} + S, \tag{2.16}$$

$$V_\tau = D_1[(\theta + \theta_0)^2 V_\xi]_\xi, \tag{2.17}$$

$$W_\tau = D_2 W_{\xi\xi}. \tag{2.18}$$

Time stepping scheme. The numerical procedure in semidiscrete form can be described as follows.

1. Vapor content is first solved using

$$\frac{V^c - V^{(n)}}{\Delta\tau} = -\alpha S_1, \tag{2.19a}$$

   where

$$S_1 = \beta\sqrt{\theta^{(n)} + \theta_0}(\bar{V} - cV_s^{(n)}). \tag{2.19b}$$

   Here superscript c denotes the solution updated due to phase change alone and $\bar{V}$ is the arithmetic average, i.e.,

$$\bar{V} = \frac{V^c + V^{(n)}}{2}. \tag{2.20}$$

2. Evaporation can occur only if there exists a sufficient amount of the liquid water. In other words, liquid water content must remain nonnegative. If the available water $W^{(n)}$ is less than the amount $V^c - V^{(n)}$ computed by (2.19), then the amount of liquid water becomes zero. Otherwise, it is given by $W^{(n)} - V^c + V^{(n)}$. Therefore,

$$W^c = \max\{W^{(n)} + V^{(n)} - V^c, 0\}. \tag{2.21}$$

3. As a consequence, vapor content needs to be corrected using the constraint

$$V^c = W^{(n)} + V^{(n)} - W^c. \tag{2.22}$$

4. To account for the possibility of running out of liquid water, phase change needs to be corrected using

$$S_2 = \frac{W^c - W^{(n)}}{\alpha\Delta\tau}. \tag{2.23}$$

5. $V^{(n+1)}$ and $W^{(n+1)}$ are updated using the diffusion equations

$$\frac{V^{(n+1)} - V^c}{\Delta\tau} = D_1[(\theta^{(n)} + \theta_0)^2 V_\xi^{(n+1)}]_\xi, \tag{2.24}$$

$$\frac{W^{(n+1)} - W^c}{\Delta\tau} = D_2 W_{\xi\xi}^{(n+1)}. \tag{2.25}$$

6. Temperature is solved by

$$\frac{\theta^{(n+1)} - \theta^{(n)}}{\Delta\tau} = \frac{1}{\rho_0 + W^{(n+1)}} \theta_{\xi\xi}^{(n+1)} + S_2, \tag{2.26}$$

where the rate of phase change S_2 is given by (2.23).

The time discretizations described above are standard, and it is straightforward to verify that the scheme is consistent and formally the order of accuracy is $\Delta\tau$ for reasonably chosen $\bar{V}$, such as the arithmetic average used in this paper.

2.2.2. Instantaneous phase change model in [20]. The instantaneous phase change model used and studied in [20, 18, 25] is essentially a discrete time model which can be described as follows (in the nondimensional form).

1. Vapor and water contents are solved using

$$V^* = \min\{cV_s^{(n)}, V^{(n)} + W^{(n)}\}, \quad W^* = V^{(n)} + W^{(n)} - V^* \tag{2.27a}$$

or

$$W^* = \max\{W^{(n)} + V^{(n)} - cV_s^{(n)}, 0\}, \quad V^* = V^{(n)} + W^{(n)} - W^*. \tag{2.27b}$$

2. Rate of phase change is computed using

$$S_1 = \frac{W^* - W^{(n)}}{\alpha\Delta\tau}. \tag{2.28}$$

3. Vapor content due to diffusion is updated by

$$\frac{V^{**} - V^*}{\Delta\tau} = D_1[(\theta^{(n)} + \theta_0)^2 V_\xi^{**}]_\xi. \tag{2.29}$$

4. Vapor and water contents are updated again using

$$V^{(n+1)} = \min\{cV_s^{(n)}, V^{**} + W^*\}, \quad W^{**} = V^{**} + W^* - V^{(n+1)} \tag{2.30a}$$

or

$$W^{**} = \max\{W^* + V^{**} - cV_s^{(n)}, 0\}, \quad V^{(n+1)} = V^{**} + W^* - W^{**}. \tag{2.30b}$$

5. Rate of additional phase change is computed using

$$S_2 = \frac{W^{**} - W^*}{\alpha\Delta\tau}. \tag{2.31}$$

6. $W^{(n+1)}$ is updated using the diffusion equations

$$\frac{W^{(n+1)} - W^{**}}{\Delta\tau} = D_2 W_{\xi\xi}^{(n+1)}. \tag{2.32}$$

7. Temperature is solved by

$$\frac{\theta^{(n+1)} - \theta^{(n)}}{\Delta\tau} = \frac{1}{\rho_0 + W^{(n+1)}} \theta_{\xi\xi}^{(n+1)} + S_1 + S_2. \tag{2.33}$$

2.2.3. Simplified instantaneous phase change model. The rate of phase change given by (2.31) is typically small compared to that from (2.28). Therefore, we can simplify the model by eliminating steps (2.30) and (2.31) and using the following procedure.

1. Vapor and water contents are solved using

$$W^* = \max\{W^{(n)} + V^{(n)} - cV_s^{(n)}, 0\}, \quad V^* = V^{(n)} + W^{(n)} - W^*. \tag{2.34}$$

2. Rate of phase change is computed using

$$S = \frac{W^* - W^{(n)}}{\alpha\Delta\tau}. \tag{2.35}$$

3. Vapor content due to diffusion is updated by

$$\frac{V^{(n+1)} - V^*}{\Delta\tau} = D_1[(\theta^{(n)} + \theta_0)^2 V_\xi^{(n+1)}]_\xi. \tag{2.36}$$

4. $W^{(n+1)}$ is updated using

$$\frac{W^{(n+1)} - W^*}{\Delta\tau} = D_2 W_{\xi\xi}^{(n+1)}. \tag{2.37}$$

5. Temperature is solved by

$$\frac{\theta^{(n+1)} - \theta^{(n)}}{\Delta\tau} = \frac{1}{\rho_0 + W^{(n+1)}}\theta_{\xi\xi}^{(n+1)} + S. \tag{2.38}$$

2.2.4. Model comparison. Note that the diffusion part of the reaction-diffusion model (2.24)–(2.26) is the same as that for the simplified instantaneous model (2.36)–(2.38). The only difference between the reaction-diffusion model and the instantaneous phase change model lies in the way the phase change is computed, or more precisely the way vapor content is computed. We now show that the two models are related to each other in the following sense.

In the instantaneous phase change model, assuming there is a sufficient amount of water,[2] we set

$$V^* = cV_s. \tag{2.39}$$

Again assuming there is a sufficient amount of water, using the reaction-diffusion model and $\bar{V}$ defined in (2.20), we obtain

$$V^c - V^{(n)} = -\nu(V^c + V^{(n)} - 2cV_s^{(n)}),$$

where

$$\nu = \frac{\Delta\tau\alpha\beta\sqrt{\theta + \theta_0}}{2}.$$

When $\nu = 1$, or

[2] When all the available water is evaporated, it is straightforward to show that the two models are equivalent since $V^c = V^* = V^{(n)} + W^{(n)}$ and $W^c = W^* = 0$.

$$\beta = \frac{2}{\Delta\tau\alpha\sqrt{\theta+\theta_0}}, \tag{2.40}$$

we obtain

$$V^c = cV_s^{(n)}.$$

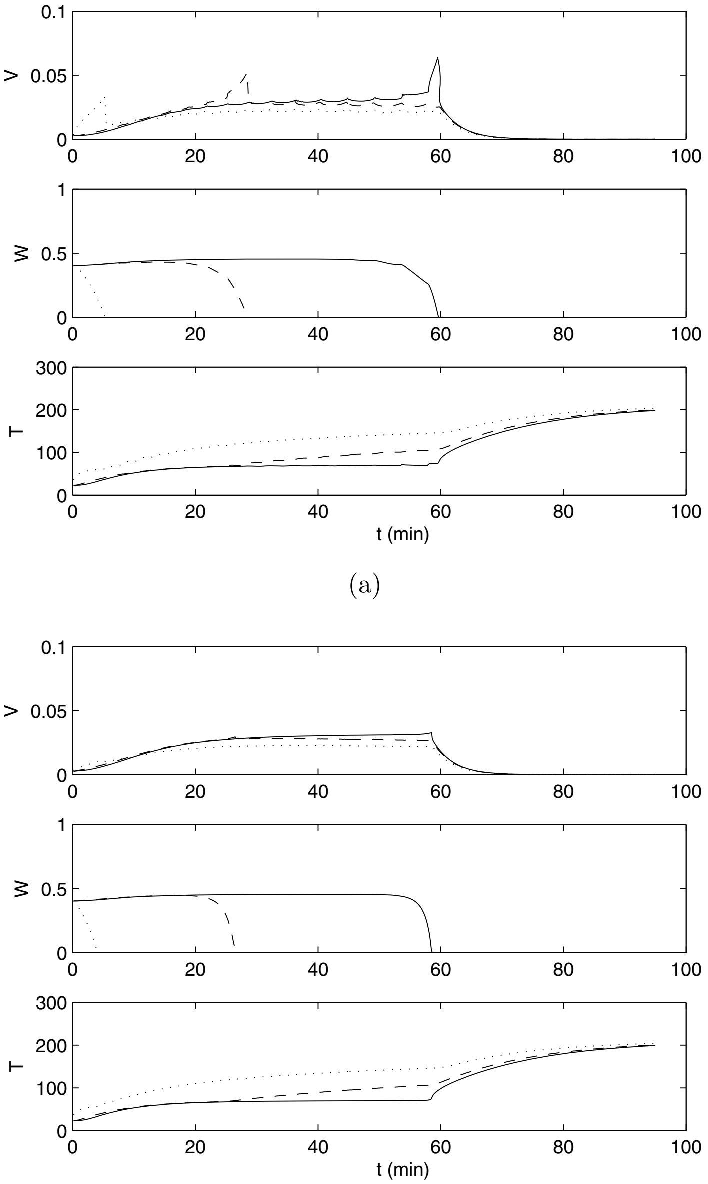
Therefore, the instantaneous phase change model is numerically equivalent to the reaction-diffusion model with a variable β inversely proportional to the time step size $\Delta\tau$. This suggests that the instantaneous phase change model can be viewed as an *inconsistent* discretization of the reaction-diffusion model, which provides a possible explanation for the observed divergence in the numerical solution as $\Delta\tau \to 0$.

2.3. Numerical results. The numerical solutions are obtained using parameter values given in [20, 25]. The corresponding dimensionless parameters are $D_1 = 4.37$, $D_2 = 1.9\times10^{-3}$, $h_1 = 5.05(\theta+\theta_0)^{-3}$, $h_2 = 2.6\times10^{-3}\theta+2.7\times10^{-3}W-7.4\times10^{-4}\theta W-7.7\times10^{-3}W^2$, $h_3 = 5.13\times10^{-2}(\theta+1+2\theta_0)[(1+\theta_0)^2+(\theta+\theta_0)^2]$, $h_4 = 7.14\times10^{-2}$, $V_{s,0} = 3.51\times10^{-5}$, $V_{s,1} = 1.45\times10^{-5}$, $\alpha = 0.286$, $\beta = 1.735\times10^5 E$, $\gamma = 9.662$, $\rho_0 = 5.99\times10^{-1}$, $\theta_0 = 1.61$.

To simulate the moisture transport during bread baking we need to determine the evaporation or condensation rate E or its nondimensionalized quantity β. This is done by choosing its value so that the numerical solution matches the experimental results in [20]. The estimated value is $\beta = 781$ and the corresponding evaporation rate is $E = 4.5\times10^{-3}$. In Figure 2.1, the numerical results based on this evaporation rate is given for two time step sizes $\Delta t = 10$ and 0.2 seconds using a coarse grid (16 grid points in x) and a fine grid (128 grid points in x), respectively. The numerical procedure remains stable as the time step size is reduced for a fixed grid size in x, contrary to the instantaneous phase change model. We note that the nonsmoothness of the solution in Figure 2.1(a) is due to the coarse spatial and temporary grids used in the computation. When we refine the spatial grid, solution becomes smooth, as shown in Figure 2.1(b).

Recall from (2.40) that reducing time step size in the instantaneous phase change model is equivalent to increasing the value of E in the reaction-diffusion model. Therefore, it will help us to understand the mechanism of the instability associated with the instantaneous phase change model by carrying out computations using a larger value of E. In Figure 2.2, computational results using the reaction-diffusion model with $E = 0.0045$ and $E = 0.045$ are presented. Here we plot the snapshots of water content at various times in order to show what can happen with the model if we increase E. The results are obtained using 128 grid points for the x variable and a time step size of 0.2 seconds. We have also done further refinement tests, but the results remain virtually the same, indicating convergence of the numerical solutions. Since evaporation rate is independent of the time step size, we can use a much smaller time step size while keeping the evaporation rate unchanged, which is not possible for the instantaneous phase change model. From Figure 2.2, it can be seen that the solution for the larger evaporation rate starts to oscillate. However, this is not due to numerical instability.

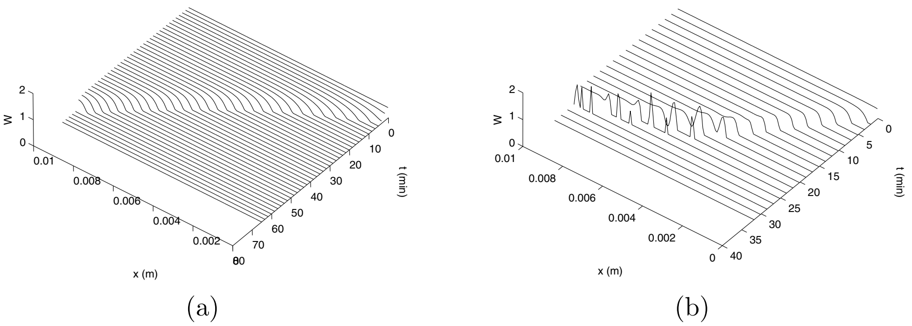
We have also experimented with the instantaneous phase change model, and the results confirmed the observations in [18, 25]. Instead of repeating those results here, we refer interested readers to [18, 25] for more details. In the next section we will provide an explanation for the observed oscillation in the solution of the reaction-diffusion model associated with relatively large value of E (or small $\Delta\tau$ in the instantaneous phase change model when the numerical procedure is still stable).



(a)

(b)

Fig. 2.1. *Computational results of V, W, and T obtained by using the reaction-diffusion model:* (a) *Time and spatial step sizes are $\Delta t = 10$ seconds and $\Delta x = 2^{-4} \times 10^{-2}$ cm;* (b) *Time and spatial step sizes $\Delta t = 0.1$ seconds and $\Delta x = 2^{-8} \times 10^{-2}$ cm. Here the dotted lines represent the quantities at the surface of the slab ($x = 0$), the dashed lines are for those located in the middle of the domain ($x = L/2$), and the solid lines represent the values at the center of the slab ($x = L$). The time is measured in minutes in order to compare our results with those from previous studies in* [20, 18, 25].



(a) (b)

FIG. 2.2. *Snapshots of the water content computed using the reaction-diffusion model for two values of the evaporation constant:* (a) $E = 0.0045$*;* (b) $E = 0.045$*. For the smaller value of* E*, the water content remains monotonic in* x *and the interface between the dry and wet regions is clearly defined. For the larger value of* E*, disturbance from the interface grows and eventually leads to multiple dry-wet regions.*

3. Linear stability analysis. We now turn our attention to the stability of the solution of the nondimensional model (2.9)–(2.11) near a steady state in an infinite domain. It is easy to see that the constant state V_0, W_0, and $\theta = 0$ satisfies the equations as long as

$$V_0 = \frac{c\,(V_{s,0} - V_{s,1})}{\theta_0(\rho_0 + W_0)}.$$

To examine the stability of this constant state solution, we carry out linear stability analysis by assuming that

$$\theta = \hat{\theta}\exp(s\tau + im\xi), \quad V = V_0 + \hat{v}\exp(s\tau + im\xi), \quad W = W_0 + \hat{w}\exp(s\tau + im\xi).$$

The equations for $\hat{\theta}$, $\hat{v}$, and $\hat{w}$ are

$$s\hat{\theta} = -\frac{m^2}{\rho_0 + W_0}\hat{\theta} + \bar{\beta}\left(-V_1\hat{\theta} + \hat{v} + \frac{V_0}{\rho_0 + W_0}\hat{w}\right), \tag{3.1}$$

$$s\hat{v} = -\theta_0^2 D_1 m^2 \hat{v} - \alpha\bar{\beta}\left(-V_1\hat{\theta} + \hat{v} + \frac{V_0}{\rho_0 + W_0}\hat{w}\right), \tag{3.2}$$

$$s\hat{w} = -D_2 m^2 \hat{w} + \alpha\bar{\beta}\left(-V_1\hat{\theta} + \hat{v} + \frac{V_0}{\rho_0 + W_0}\hat{w}\right), \tag{3.3}$$

where $\bar{\beta} = \sqrt{\theta_0}\beta$ and

$$V_1 = \frac{c\,(V_{s,0} - V_{s,1})}{\theta_0(\rho_0 + W_0)} - \frac{cV_{s,0}\gamma}{\theta_0(\rho_0 + W_0)}.$$

Rearranging (3.1)–(3.3) in the matrix form, we obtain

$$M\mathbf{y} = s\mathbf{y},$$

where

$$\mathbf{y} = \begin{pmatrix} \hat{\theta} \\ \hat{v} \\ \hat{w} \end{pmatrix}, \quad M = \begin{pmatrix} -\frac{m^2}{\rho_0+W_0} - \bar{\beta}V_1 & \bar{\beta} & \bar{\beta}\frac{V_0}{\rho_0+W_0} \\ \alpha\bar{\beta}V_1 & -\theta_0^2 D_1 m^2 - \alpha\bar{\beta} & -\alpha\bar{\beta}\frac{V_0}{\rho_0+W_0} \\ -\alpha\bar{\beta}V_1 & \alpha\bar{\beta} & -D_2 m^2 + \alpha\bar{\beta}\frac{V_0}{\rho_0+W_0} \end{pmatrix}. \tag{3.4}$$

3.1. A special case. We want to find out whether instability would occur in this system. This requires us to find eigenvalues of (3.4). To avoid complicated calculations we consider a special case where the linearized diffusion coefficients for temperature and liquid water are the same, i.e.,

$$\frac{1}{\rho_0 + W_0} = \theta_0^2 D_1. \tag{3.5}$$

For our choice of parameters in this bread-baking problem these two coefficients are of similar sizes. Therefore, we expect that this assumption would not change the nature of the stability of the system. Under this assumption the eigenvalues satisfy the following equation:

$$\begin{aligned}(\theta_0^2 D_1 m^2 + s)\Bigg[s^2 + \left(D_2 m^2 + \theta_0^2 D_1 m^2 + \bar{\beta} V_1 + \alpha\bar{\beta} - \frac{\alpha\bar{\beta}V_0}{\rho_0 + W_0}\right) s \\ + D_2 m^2(\theta_0^2 D_1 m^2 + \bar{\beta}V_1 + \alpha\bar{\beta}) - \frac{\alpha\bar{\beta}V_0}{\rho_0 + W_0}\theta_0^2 D_1 m^2\Bigg] = 0.\end{aligned} \tag{3.6}$$

3.1.1. Reaction-only. When there is no diffusion, we have $m = 0$, and the eigenvalues are $s_1 = s_2 = 0$ and

$$s_3 = -\alpha\bar{\beta} - \left(\frac{V_1}{V_0} - \frac{\alpha}{\rho_0 + W_0}\right)\bar{\beta}V_0.$$

For our problem, $\alpha = 0.2864$, $\gamma = 9.662$, $\rho_0 = 0.5986$, $\theta_0 = 1.6116$, and $W_0 = 0.4$. Thus, $s_3 < 0$ and the constant solution is stable.

3.1.2. Reaction-diffusion. We can easily see that the eigenvalue associated with the first factor of (3.6) is negative. Note that the coefficient of s in the second factor is

$$C_1 = D_2 m^2 + \theta_0^2 D_1 m^2 + \bar{\beta}V_1 + \alpha\bar{\beta} - \frac{\alpha\bar{\beta}V_0}{\rho_0 + W_0} > 0.$$

The signs of two eigenvalues associated with the second factor are determined by the sign of the coefficient of s^0:

$$C_0 = D_2 m^2(\theta_0^2 D_1 m^2 + \bar{\beta}V_1 + \alpha\bar{\beta}) - \frac{\alpha\bar{\beta}V_0}{\rho_0 + W_0}\theta_0^2 D_1 m^2$$

since the eigenvalues from the second factor are given by $-C_1 \pm \sqrt{C_1^2 - 4C_0}$. So if $C_0 < 0$ and $C_1^2 > 4C_0$, we will have a positive eigenvalue which indicates instability of the system. If D_2 is comparable to D_1, then C_0 will be positive and both eigenvalues will be negative and the system is stable. Since in our case D_2 is much smaller than D_1, C_0 will be negative if m is not sufficiently large, in which case we will have one positive eigenvalue which leads to instability.

Remark. It is interesting to note that in this case diffusion is actually destabilizing. The instability discussed here is conceptually related to Turing instability or diffusive instability observed in pattern formation, crystal, and tumor growth; cf. [17, 14]. However, the mathematical model and the nonlinearity related to bread baking are quite different from those applications.

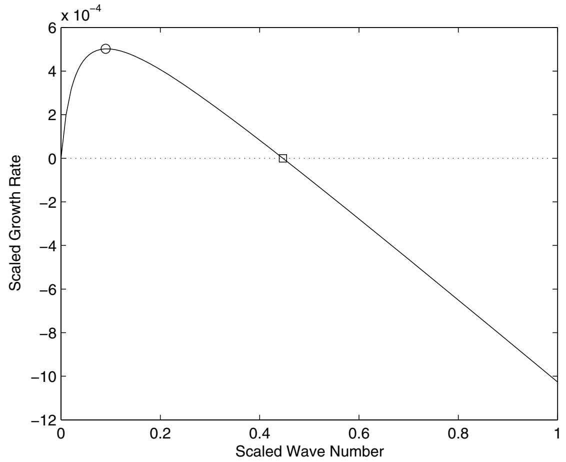


FIG. 3.1. *Plot of the normalized eigenvalue $\bar{s}$ vs. the normalized wave number $\bar{m}$. The circle indicates the most unstable wave number, $\bar{m}_{max} = 0.09$. The square indicates the upper limit of the unstable modes, $\bar{m}_b = 0.4469$.*

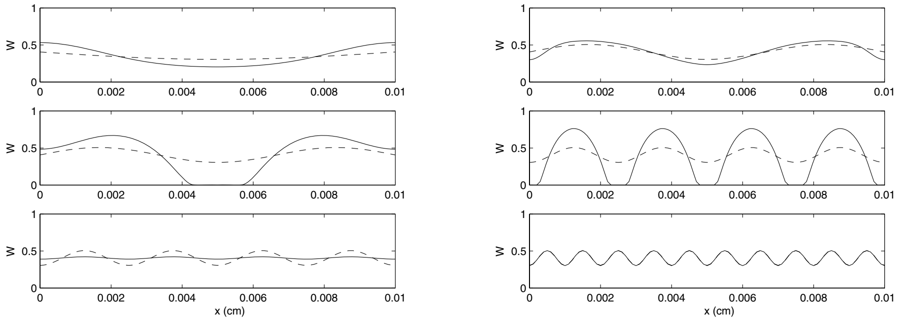
3.2. The general case. In the case when diffusion coefficients for temperature and vapor are not the same, analytical expression can still be obtained. However, it is too complicated to provide useful insights. We can, nevertheless, find the eigenvalues numerically by using the MATLAB routine `eig.m`. Again, for relevant parameter values, two of the three eigenvalues have nonpositive real parts. The real part of the third eigenvalue is plotted in Figure 3.1, where both the wave number and the eigenvalue are normalized as $\bar{s} = s/\bar{\beta}$ and $\bar{m} = m^2/\bar{\beta}$. It can be seen that there exists a range of wave numbers between zero and a finite value, indicated by the square in the figure, within which the perturbation will grow. Larger wave number disturbances beyond the critical wave number will decay. Furthermore, there exists a wave number which grows the fastest, indicated by the circle in the figure. Finally, the range of unstable frequencies increases linearly with $\sqrt{\bar{\beta}}$ and the growth rate increases linearly with $\bar{\beta}$. Therefore, a larger evaporation rate E (implies a larger $\bar{\beta}$) leads to a wider range of unstable modes and faster growth rates for all the unstable modes.

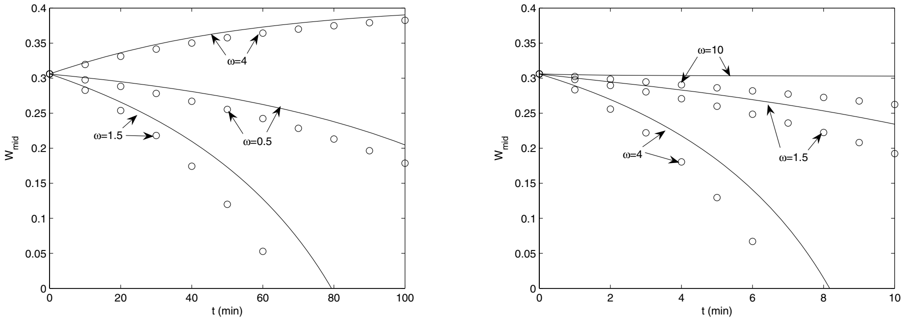
We now verify the results of the linear stability analysis by solving the reaction-diffusion model with Dirichlet conditions which permit the constant solutions $\theta = 0$, $V = V_0$, and $W = W_0$. In Figure 3.2(a), computed liquid water content at the end of 100 minutes is shown. The solutions are obtained by superimposing a small disturbance in the form of $\epsilon \cos[m(\xi - 0.5)]$ to a constant liquid water content W_0 with $m = 2\pi\omega$, $\omega = 0.5$, 1.5, and 4, and $\epsilon = 0.1$. The evaporation rate is $E = 0.0045$ and the range of unstable frequencies is $0 < \omega < 2.9738$. The most unstable mode is given by $\omega \approx 1.3345$, and the rate of growth is approximately $\exp\left(3.5056 \times 10^{-4} t\right)$ measured in dimensionless time. The results show that even though the disturbances with wave numbers below $\omega \approx 3$ grow with time, it takes a relatively long period of time (on the scale of 80 minutes for the fastest growing mode) to develop. On the other hand, the evaporation of all the liquid water takes about 60 minutes (Figures 2.1 and 2.2(a)). Therefore, all liquid water in the bread would have already evaporated before the instability develops and takes effect.

In Figure 3.2(b), computed liquid water content at the end of 10 minutes is shown



(a) (b)

FIG. 3.2. *Computational results of liquid water content subjected to disturbances.* (a) $E = 0.0045$ *with* $\omega = 0.5$, 1.5, *and* 4. (b) $E = 0.045$ *with* $\omega = 1.5$, 4, *and* 10. *The dashed lines indicate the initial states and the solid lines are the final solutions.*



(a) (b)

FIG. 3.3. *Damping rates for* (a) $E = 0.0045$ *and* (b) $E = 0.045$. *The liquid water content in the middle of the domain where the growth is the fastest is plotted for wave numbers* $\omega = 0.5$, 1.5, *and* 4 *in* (a) *and* $\omega = 1.5$, 4, *and* 10 *in* (b). *The circles are predictions by the linear stability analysis.*

for a larger evaporation rate $E = 0.045$, subjected to the same small disturbances. In this case, the range of unstable frequencies is $0 < \omega < 9.4$. The most unstable mode is given by $\omega \approx 4.22$, and the rate of growth is approximately $\exp\left(3.5056 \times 10^{-3} t\right)$ in dimensionless time. Compared to the previous case, this leads to a more rapid growth for the most unstable mode, on the order of 10 minutes in dimensional time, while it takes about 30 minutes for all the liquid water to evaporate (cf. Figure 2.2(b), where the effect of the instability is clearly visible).

The difference in the growth rates for the same disturbance under the two evaporation rates can be seen in Figure 3.3, where liquid water content in the middle of the domain is plotted. The prediction using linear stability analysis is also plotted. Note that the linear stability analysis is valid only near the constant state. Nevertheless, the two sets of data are not too far off. Thus, subject to random perturbation, the initially constant solution in the two-phase region will become unstable. The fastest growing mode eventually causes a multiple region of dry and two-phase zones, as shown in Figure 2.2.

Remark. From the analysis we see that this diffusive instability occurs for any positive β (or E). However, for relatively small β computational results in the previous section are satisfactory. One reason is that the positive eigenvalue is small as β is relatively small and the disturbances grow slowly. In addition, the oscillation (diffusive instability) is visible only when the wave length of the unstable modes is shorter than the domain size in x. This explains why no oscillation is observed in the case of the smaller β (or E).

4. Conclusion. The work in this paper is motivated by the simulation results in [18, 25], based on a multiphase model for bread baking proposed in [20]. This model allows simultaneous heat, vapor, and liquid water transfer by assuming that the phase change is instantaneous. However, previous studies [18, 25] showed that this model produces reasonable solutions only for specific choices of spatial and time step sizes. Reducing spatial and time step sizes usually leads to numerical instability and causes the solution to blow up.

By constructing a reaction-diffusion model and establishing a link between our model and the model in [20], we have identified the source of the instability associated with the model in [20]. We have shown that the instability observed in [18, 25] is a combination of two factors: the numerical instability as well as a diffusive instability. Using our reaction-diffusion model, we showed that the numerical instability can be eliminated by using a sufficiently small time step. This is due to the fact that the reaction-diffusion model separates the numerical instability from the diffusive instability. The diffusive instability, on the other hand, is an intrinsic feature of the model, as demonstrated by linear stability analysis and numerical tests. For relatively large evaporation rate, diffusive instability leads to an oscillatory solution with multiple regions of dry and two-phase zones.

Our analysis of the reaction-diffusion model also reveals that diffusive instability is related to the value of the evaporation rate, which is affected by the properties of the porous medium, such as the surface area of the pore space. This suggests that the phenomenon related to diffusive instability may be realized in the physical process of bread baking. Further experimental investigation is necessary to validate and improve our model for bread baking. On the other hand, the model itself is quite general and may be applicable to similar problems with simultaneous heat and mass transfer processes.

Finally, we wish to point out that a consistent instantaneous phase change model may be derived based on our reaction-diffusion model, using asymptotic analysis and β^{-1} as a small parameter, and this will be pursued in a future study.

Acknowledgments. We would like to thank the referees for many constructive suggestions which have helped to improve the quality of our manuscript. We also wish to acknowledge beneficial discussions with Dr. Jonathan Wylie during the preparation of the manuscript.

STATISTICAL RECONSTRUCTION OF VELOCITY PROFILES FOR NANOPARTICLE IMAGE VELOCIMETRY*

CHRISTEL HOHENEGGER[†] AND PETER J. MUCHA[‡]

Abstract. Velocities and Brownian effects at nanoscales near channel walls can be measured experimentally in an image plane parallel to the wall by evanescent wave illumination techniques [R. Sadr, M. Yoda, Z. Zheng, and A. T. Conlisk, *J. Fluid Mech.*, 506 (2004), pp. 357–367], but the depth of field in this technique is difficult to modify. Assuming mobility of spherical particles dominated by hydrodynamic interaction between particle and wall, the out-of-plane dependence of the mobility and in-plane velocity are clearly coupled. We investigate such systems computationally, using a Milstein algorithm that is both weak- and strong-order 1. In particle image velocimetry (PIV), image pairs are cross-correlated to approximate the mean displacement of n matched particles between two windows. For comparison, we demonstrate that a maximum likelihood algorithm can reconstruct the out-of-plane velocity profile, as specified velocities at multiple points, given known mobility dependence and perfect mean measurements. We then test this reconstruction for noisy measurements as might be encountered in experimental data. Physical parameters are chosen to be as close as possible to the experimental parameters while we consider three types of velocity profiles (linear, parabolic, and exponentially decaying).

Key words. stochastic differential equations, maximum likelihood estimate, particle image velocimetry, velocity profile, wall effects

1. Introduction.

Fluid velocities in a channel can be measured by illumination and imaging of tracer particles under the assumption that they follow the flow, with corrections possibly applied for effects including, e.g., the near-wall relationship between particle translation and rotation [6]. For laser-Doppler velocimetry, Fuller et al. [3] showed that it is possible to reconstruct the velocity gradient in a laminar flow using light-scattering spectroscopy. This requires the knowledge of the intensity function and the technical capacity of turning the sample to get a proper angle of illumination. At microscales, Meinhart et al. (see [15], [11], [10]) developed an illumination technique, particle image velocimetry (PIV), to replace spectroscopy, where the tracers are illuminated using multiple laser sheets and the velocity profile is computed as means over successive windows using cross-correlation techniques. Again the sample has to be properly illuminated so that particles remain in the focal plane. If it is possible to turn the sample, all components of the mean velocity profile can be obtained.

At nanoscales, including the near-wall region of microchannels, Sadr, Li, and Yoda [12] and Sadr et al. [14] extend PIV to flows illuminated with evanescent waves generated by total internal reflection at the wall. Image pairs are captured on a cam-

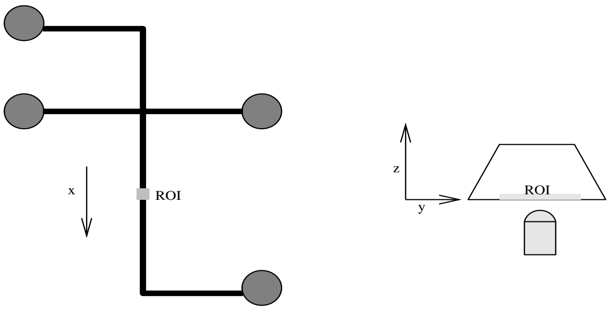

FIG. 1.1. *Experimental setup: Region of interest, flow direction, and wall location.*

era with a time interval ∼ 2ms, and in-image-plane mean velocities are obtained using cross-correlation techniques. Figure 1.1 illustrates the experimental setup around the region of interest and some of the inherent experimental restrictions. While Sadr, Li, and Yoda [12] show that Brownian diffusion can cause additional errors in the measurements as particles drop in and out of the imaged window, only limited information about the velocity along or dependence on the out-of-plane coordinate has been experimentally accessed recently from the brightness of the images and the decay of the illumination function [6], [7], [9]. Questions remain about the accuracy and range of validity of processing based on image intensity, especially in the presence of the highly heterogeneous distribution of fluorescent dye on the tracer particle surfaces, while background noise pollutes the images causing reconstruction of velocity profile based solely on intensity to be extremely challenging (see Li, Sadr, and Yoda [9]).

Another dominant difficulty of these measurements arises from the nonconstant diffusion tensor induced by the proximity of the wall. Both the in-plane and out-of-plane diffusion components strongly depend on the distance from the wall (see Figure 2.1(a)). While this dependence is well understood in terms of the hydrodynamic interaction between particle and wall [1], the effect of such diffusion on the resulting measurements has been only recently addressed experimentally (see, e.g., [14]). Meanwhile, significant effort has been put into extending the range of validity of particle image velocimetry (PIV) and particle tracking velocimetry (PTV) to smaller ranges of particles. For example, Guasto, Huang, and Breuer [4] use a statistical approach assuming nearly constant diffusion to eliminate experimental noise (drop-in/-out, mismatch, particles blinking) and obtain a distribution of velocities. Using a similar idea with nonconstant diffusion, Jin et al. (see [6], [7]) notice in their attempts to assess slip at the wall that a nonnegligible difference exists between the apparent measured mean velocities and the imposed shear rate. Interpretations of such studies are further complicated by the measured velocities representing those across a spatially extended region away from the wall, typically with little mechanism for modifying the extent of such a region.

In this work, we show that it is possible to reconstruct the out-of-plane dependence of the in-plane velocity component as a collection of velocities at specified out-of-plane distances (typically five points), based solely on in-plane images. The unique assumption leading to the statistical reconstruction of the out-of-plane component concerns the out-of-plane distribution of the particles between two window measurements. For simplicity, here we assume that the computational and observational domains are the same, thereby eliminating errors due to particle drop-in/-out for this proof-of-principle demonstration.

The next two sections present the particle model incorporating the most important parameters from the experiments and its numerical simulation with a strong order 1 scheme. In the fourth section we develop the algorithm for the perfect case, in which the mean displacements are known exactly. The reconstruction is illustrated for three different specified velocity test profiles (see Figure 2.1(b)): a linear profile, a parabolic profile, and a profile exponentially decaying to the bulk velocity. In the fifth section we extend the idea to noisy mean displacements obtained through the consideration of a measurement error similar to the one reported for cross-correlation from simulated images (PIV techniques). Finally, we discuss the limitations of the model and its possible improvement.

2. Particle model. We test the algorithmic reconstruction on a simple stochastic model of particle motion. Each particle is assumed to have a fixed radius a ($a = 50\,\mathrm{nm}$ in the demonstrations here), and the hydrodynamic interaction between the wall and a particle is captured by the model for mobility in terms of the out-of-plane coordinate perpendicular to the wall, z. We ignore particle-particle hydrodynamic interactions, which are relatively small for the dilute particle volume fractions of the experiments. The tracer particles are dragged along with the fluid flow; additional interactions between particles and the wall are feasible but not included here.

We consider a system of n ($n = 64$) Brownian particles obeying Stokes drag relations, linearly dependent on the velocity. For time steps Δt bigger than the force relaxation time, Ermak and McCammon [2] show that the displacement Δr_i can be expressed as

$$\Delta r_i = \sum_{j=1}^{3n} \frac{\partial D_{ij}}{\partial r_j} \Delta t + \sum_{j=1}^{3n} \frac{D_{ij} F_j}{k\Theta} \Delta t + W_i(\Delta t), \quad i = 1, \ldots, 3n, \tag{2.1}$$

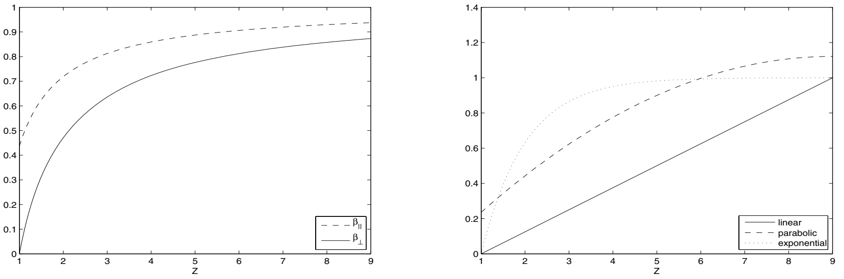
where $W_i(\Delta t)$ is a random displacement with a Gaussian distribution function whose average value is zero and whose variance-covariance matrix is $2\mathbf{D}\Delta t$, $\mathbf{D}$ is the diffusion tensor, $\mathbf{F}$ are the external forces, k is the Boltzmann constant, and Θ is the temperature. The Brownian displacement can be expressed as [2]

$$W_i(\Delta t) = \sum_{j=1}^{i} \sigma_{ij} dW_j, \quad \sigma = \sqrt{\mathbf{2D}}, \quad dW_j = \mathcal{N}(0, \Delta t), \quad j = 1, \ldots, 3n, \tag{2.2}$$

where $\mathcal{N}(\mu, \sigma^2)$ indicates Gaussian random variables of mean μ and variance σ^2.

While we ignore particle-particle interactions, hindered Brownian diffusion due to hydrodynamic particle-wall interactions is an important effect for the near-wall conditions in the experiments. A first approximation of the nonconstant diffusion tensor is obtained by the methods of image singularities for Stokes flows, valid for particle center-to-wall distances, z, that are large compared to the particle radius, a. For our model system here, we include for simplicity only the lowest-order a/z corrections for diffusion components parallel to the planar wall but instead employ the Bevan–Prieve relation [1] for the out-of-plane diffusion perpendicular to the wall, both because of its experimental verification and because it includes the physically impermeable property that the diffusion coefficient goes to zero for a spherical particle touching the wall ($z = a$):

$$\mathbf{D} = \frac{k\Theta}{6\pi\mu a} \begin{pmatrix} 1 - \frac{9}{16}\frac{a}{z} & 0 & 0 \\ 0 & 1 - \frac{9}{16}\frac{a}{z} & 0 \\ 0 & 0 & \frac{6z^2 - 10az + 4a^2}{6z^2 - 3az - a^2} \end{pmatrix} = D_\infty \beta(z), \tag{2.3}$$



(a) Components of $\beta(\frac{z}{a})$

(b) Velocity profiles $\gamma(\frac{z}{a})$

FIG. 2.1. (a) *Dimensionless diffusion coefficients perpendicular $\beta_\perp$ and parallel $\beta_{||}$ to the wall.* (b) *Dimensionless velocity profiles γ for the linear, parabolic, and exponentially decaying test cases.*

for the three components of each individual particle, where $D_\infty = k\Theta/(6\pi\mu a)$ is the Stokes–Einstein relation in the bulk limit far from the wall, the z-component is along the direction perpendicular to the wall, and z is the distance between the center of the particle and the wall.

Here we consider a simulated channel of height H with three different test flows $u_\infty \gamma(z)\mathbf{e_x}$ with "bulk velocity" u_∞, as might be encountered in shear flow, pressure-driven flow, and electroosmotically pumped flow, respectively: linear flow $\gamma(z) = \frac{1}{H-a}(z-a)$, parabolic flow $\gamma(z) = \frac{4}{(2H-a)^2} z(2H-z)$, and an exponentially decaying profile $\gamma(z) = 1 - \exp(1 - z/a)$ (Figure 2.1(b)). For simplicity, we consider the above flows to be the force-free velocity profiles of the tracer particles themselves, with the hydrodynamic balance given for the external forces on the particles $\mathbf{F} = k\Theta\mathbf{D}^{-1} u_\infty \gamma(z)\mathbf{e_x}$. In the physical experiments, additional corrections are required to relate the force-free velocities of the tracers to those of the underlying flow (see, e.g., [6]); we assume such corrections can be imposed if the particle velocities are accurately measured, proceeding with simulations of imposed particle velocities whose velocity profiles we will reconstruct. Here we include only flow along one (x) of the two in-plane directions parallel to the wall, but since the statistical reconstructions below will not process any displacements along the other in-plane direction (y), the methods presented here can be equivalently applied to measure any in-plane flow profile dependent on the out-of-plane (z-) direction.

Our model stochastic ODE Langevin equation for the displacement of an individual particle is then

$$dx = u_\infty \gamma(z)\, dt + \sqrt{2D_\infty \beta_{||}(z)}\, dW_1, \tag{2.4}$$

$$dy = \sqrt{2D_\infty \beta_{||}(z)}\, dW_2, \tag{2.5}$$

$$dz = D_\infty \frac{d\beta_\perp(z)}{dz}\, dt + \sqrt{2D_\infty \beta_\perp(z)}\, dW_3. \tag{2.6}$$

Letting T be the time elapsed between two PIV-window observed images, we set T and the radius a as the characteristic time and length scales, respectively. Letting $x = aX$, $y = aY$, $z = aZ$, and $t = T\tau$ define the dimensionless variables, the resulting dimensionless parameters are $\Pi_1 = \frac{u_\infty T}{a}$ and $\Pi_2 = \frac{D_\infty T}{a^2}$. For our tests reported here, we select $T = 2^{-9}$s, giving $\Pi_2 = 4$ at $\Theta = 300$, with u_∞ selected to give $\Pi_1 = 3$, of a scale typical to those of the experiments. Our dimensionless Langevin model, with $d\mathbf{W} = \mathcal{N}(0, d\tau)$, becomes

$$dX = \Pi_1 \gamma(aZ)\, d\tau + \sqrt{2\Pi_2 \beta_{||}(aZ)} dW_X, \tag{2.7}$$

$$dY = \sqrt{2\Pi_2 \beta_{||}(aZ)}\, dW_Y, \tag{2.8}$$

$$dZ = \Pi_2 \frac{d\beta_\perp(aZ)}{dZ}\, d\tau + \sqrt{2\Pi_2 \beta_\perp(aZ)}\, dW_Z. \tag{2.9}$$

3. Numerical simulation. Equations (2.7), (2.8), and (2.9) form a system of stochastic differential equations of the form $d\mathbf{X} = \mathbf{f}(\mathbf{X}, t)d\tau + \mathbf{g}(\mathbf{X}, t)d\mathbf{W}$. We solve it with a Milstein scheme of weak and strong order of convergence one. The coupling of the system through the Z-component yields a nondiagonal noise in the stochastic differential equation sense. The resulting Milstein scheme is given by [8] (see also [5]):

$$X_{j+1} = X_j + f_{1,j}\Delta\tau + g_{11,j}\Delta W_{1,j} + \frac{1}{2} g_{11,j} \left.\frac{dg_{11}(z)}{dZ}\right|_{Z=Z_j} I_{(3,1)}, \tag{3.1}$$

$$Y_{j+1} = Y_j + f_{2,j}\Delta\tau + g_{22,j}\Delta W_{2,j} + \frac{1}{2} g_{22,j} \left.\frac{dg_{22}(Z)}{dZ}\right|_{Z=Z_j} I_{(3,2)}, \tag{3.2}$$

$$Z_{j+1} = Z_j + f_{3,j}\Delta\tau + g_{33,j}\Delta W_{3,j} + \frac{1}{2} g_{33,j} \left.\frac{dg_{33}(Z)}{dZ}\right|_{Z=Z_j} \Big((\Delta W_{3,j})^2 - \Delta\tau\Big), \tag{3.3}$$

where $f_{i,j} = f_i(Z_j)$, $g_{ii,j} = g_{ii}(Z_j)$, and $I_{(3,i)}$ $(i = 1, 2)$ are the double Itô stochastic integrals defined as $I_{(3,i)} = \int_{t_k}^{t_{k+1}} \int_{t_k}^{t_{k+1}} dW_3 dW_i$. Since $I_{(3,i)}$ has no closed analytical solution, we approximate $I_{(3,i)}$ as the solution of a stochastic differential system:

$$I_{(3,i)} = X_i(t_{k+1}), \quad \text{where} \quad \begin{cases} dX_i = X_3 dW_i, & X_i(t_k) = 0, \\ dX_3 = dW_3, & X_3(t_k) = 0. \end{cases} \tag{3.4}$$

Equation (3.4) is solved using Euler–Maruyama steps, the stochastic equivalent of a forward Euler step, with strong order of convergence $\frac{1}{2}$. To ensure convergence to an accurate solution for the entire system, we choose $\Delta\tau = 2^{-10}$ in (3.1)–(3.3), resolving each Itô integral $I_{(3,i)}$ with 2^{10} time steps in (3.4).

4. Reconstruction with perfect means. We start our proof-of-principle calculations by statistically reconstructing velocity profiles based on perfectly observed mean displacements. By this we mean that the true position of each particle is known and the mean displacement of the n particles between two image-pair windows is computed exactly. Cross-correlation processing of image pairs in PIV extracts, up to various sources of error, the mean displacement of the "matched" particles—those that contribute to both images. If the true displacement of each particle could be experimentally determined, as in particle tracking, then the same reconstruction ideas below do apply, but our various tests indicated that such particle tracking does not improve the results, and may even require greater quantities of data than statistical reconstruction based on mean displacements, presumably because of the statistical reliance below on clearly characterized Brownian displacements.

Let $f_{\Delta X}$ be the probability distribution function of a displacement ΔX. From (2.7) the X-displacement depends on the Z-position. Therefore we define $f_{\Delta X|Z}$ to be the probability density function of ΔX given Z. Then

$$f_{\Delta X} = \int f_{\Delta X|Z} f_Z dZ, \tag{4.1}$$

where f_Z is the probability density function of particles in Z. Because we restrict ourselves to the case where the computation and observation domain are the same, we make the following assumption about the Z distribution:

$$f_Z = \frac{a}{H-a}\chi_{[1,H/a]}, \tag{4.2}$$

where χ_I is the characteristic function on an interval I.

Next we make a fundamental simplifying modeling assumption for the reconstruction: that the particle displacements over the time T between two consecutive windows can be approximated by an Euler step of the form

$$\Delta X \approx \Pi_1\gamma(aZ) + \sqrt{2\Pi_2\beta_{||}(aZ)}dW \quad \text{with } dW = \mathcal{N}(0,1), \tag{4.3}$$

where $\gamma(aZ)$ is the unknown velocity profile. From (4.3) we conclude that

$$f_{\Delta X|Z} = \frac{1}{2\sqrt{\pi\Pi_2\beta_{||}(aZ)}}e^{-\frac{(\Delta X-\Pi_1\gamma(aZ))^2}{4\Pi_2\beta_{||}(aZ)}}. \tag{4.4}$$

Finally, using (4.1), (4.2), and (4.4) we find that

$$f_{\Delta X} = \frac{a}{2\sqrt{\pi\Pi_2}(H-a)}\int_1^{\frac{H}{a}} \frac{1}{\sqrt{\beta_{||}(aZ)}}e^{-\frac{(\Delta X-\Pi_1\gamma(aZ))^2}{4\Pi_2\beta_{||}(aZ)}} dZ. \tag{4.5}$$

Let $\overline{\Delta X}$ be the mean displacement of n matched particles over a window and let f_S be the probability density function of $n\overline{\Delta X}$. Now let f be the joint probability density function of N measured $n\overline{\Delta X}$. A standard result of probability, together with the assumption of independence between two windows measurement, yields

$$f_S = f_{\Delta X} * \cdots * f_{\Delta X} \quad \text{and} \quad f = \prod_{i=1}^{N} f_S, \tag{4.6}$$

where $*$ denotes the convolution. This independence assumption is, of course, incorrect, since consecutive $\overline{\Delta X}$ displacements are correlated by the continuity-in-time of the particles z positions; we nevertheless proceed under this modeling assumption, counting on the effect of the correlations to be sufficiently small.

Figure 4.1 compares the histogram of a $n\overline{\Delta X}$ data set with $Z \in [1, H/a]$ for the parabolic test profile with the probability density function obtained with (4.5) (dashed line). The integral in (4.5) is computed with a Gauss–Legendre quadrature formula under the assumption of a uniform z-distribution. This demonstrates the reasonable validity of assumption (4.3). Going even further, the dotted line in Figure 4.1 represents the probability density function obtained by fitting the data set $n\overline{\Delta X}$ for $Z \in [1, H/a]$ by a single Gaussian. The differences between the integrated Gaussian (dashed line) and the fitted Gaussian (dotted line) are minimal in the height and location of the peak. These minimal distinctions make the desired optimization highly sensitive. Despite these expected difficulties, we nevertheless continue both with our assumption (4.3) and the fundamental ideas of the velocity profile reconstruction.

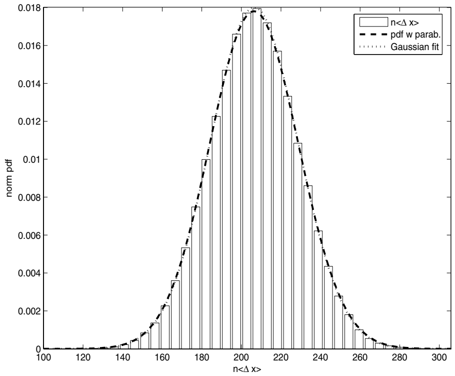


FIG. 4.1. *Comparison of the parabolic profile between the histogram of the distribution of* $n\overline{\Delta X}$*, the probability density function* (4.5)*, and a fitted Gaussian.*

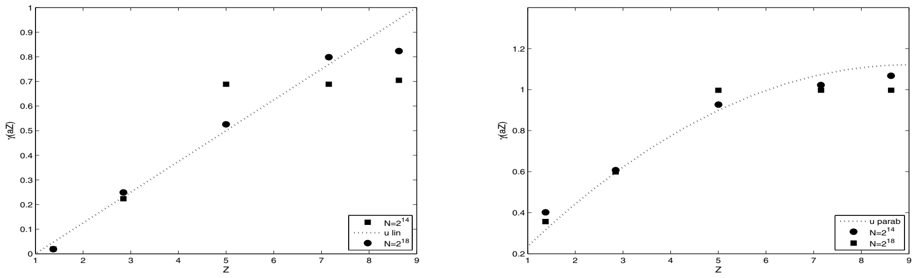
Given N measured mean values $n\overline{\Delta X}$, Π_1, Π_2, and $\beta_{||}(aZ)$, the maximum likelihood estimate of $\gamma(aZ)$ is the value of $\gamma(aZ)$ that makes the observed means most likely. Led by the independence assumption, we define the log-likelihood function

$$\phi(\{\gamma_j\}_{j=1}^{M}) = -\ln f \overset{(4.6)}{=} -\sum_{i=1}^{N} \ln f_S(n\overline{\Delta X}), \tag{4.7}$$

where M is the number of discrete points Z at which we estimate γ. The most likely values for γ_j, $j = 1, \ldots, M$, are obtained by minimizing the log-likelihood function ϕ (4.7) of the M variables $\gamma_1, \ldots, \gamma_M$ for a data set $n\overline{\Delta X}$ of size N.

The statistical reconstruction problem has thus been reduced to two numerical algorithms. First, we evaluate the probability density function f_S in (4.6) by repeated convolution of the probability density function $f_{\Delta X}$ as in (4.5), computing the integral by Gauss–Legendre quadrature for given γ_j values at the Legendre collocation points $Z_j \in [1, H/a]$ for $j = 1, \ldots, M$. We subsequently minimize the function ϕ (4.7) with a direct simplex algorithm penalizing solutions that do not produce an increasing sequence, since we know that the velocity profile is increasing to the bulk velocity away from the wall. We also experimented with the alternative scheme of minimizing ϕ over low-order polynomials for $\gamma(aZ)$ but did not obtain results any more promising than those presented below. Not surprisingly, the minimization routine is highly sensitive to the choice of the initial guess. Therefore, when reconstructing velocity values for a small number of points M, we first search the M-dimensional space for a suitable initial guess by evaluating the function at a fixed number of increasing grid points. When reconstructing velocity values at M points for M larger (say, $M \geq 7$), we interpolate the initial guess from the reconstructed velocity values for smaller M.

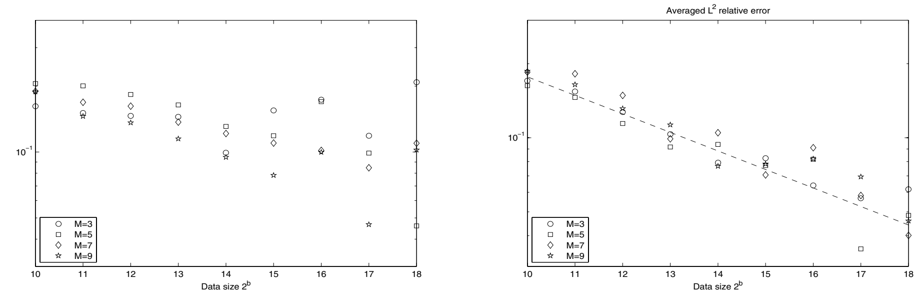
Figure 4.2 illustrates the reconstruction for the linear and parabolic profiles at five points ($M = 5$) for two different data sizes. Since the accuracy of the reconstructed points does not appear to improve when N increases from 2^{14} to 2^{18}, we are motivated to instead consider breaking one block of data up into separate reconstructions over each of B blocks of size 2^b. Figure 4.3 contains semilog plots of the L^2 relative error of the reconstructed γ_j, $j = 1, \ldots, M$, with respect to the true $\gamma(aZ_j)$, $j = 1, \ldots, M$, for individual blocks, the errors averaged over the number of blocks B for four different values of M (3, 5, 7, and 9 points). For the linear profile on the left, we observe the same behavior as in Figure 4.2, namely, that increasing the data size does not



(a) Linear profile

(b) Parabolic profile

FIG. 4.2. *Velocity profile reconstruction at $M = 5$ points for the linear and parabolic test profiles with data set sizes $N = 2^{14}$ and $N = 2^{18}$.*



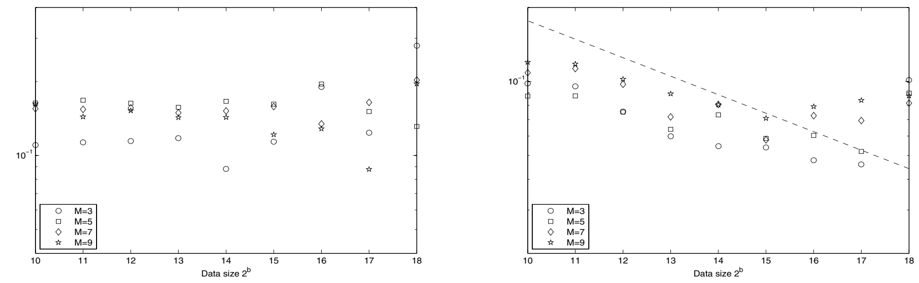
(a) Linear profile

(b) Parabolic profile

FIG. 4.3. *L^2 relative error averaged over the number of blocks B of size 2^b at $M = 3$, $M = 5$, $M = 7$, $M = 9$.*

predictably improve the accuracy of the reconstruction after some point. For the parabolic profile on the right, we find a decay of the relative error in the function of the data size b which appears to be roughly $(2^b)^{-1/4}$ up to another apparent stagnation of the decaying error for data sizes larger than 2^{14} or 2^{15}. We next consider the plot of the L^2-norm of the relative error of the block-averaged reconstructed values $\overline{\gamma_j} = \frac{1}{B}\sum_{k=1}^{B}\gamma_j^k$, $j = 1, \ldots, M$ (where γ_j^k is the reconstructed value at Z_j for the block B_k), with respect to the true $\gamma(aZ_j)$, $j = 1, \ldots, M$ (Figure 4.4). We deduce from the relative errors of the block-averaged values, especially for the parabolic test profile, that errors can be reduced by such averaging over a limited number of blocks. As above, the parabolic profile follows a decay close to $(2^b)^{-1/4}$ up to 2^{15}. We do not at present have any explanation for this particular power law of decay. We conclude that the best reconstruction on a data set of the size $N = 2^{18}$ will be achieved when the average of the reconstructed profile is done over 8 or 16 blocks. We also notice that increasing the number of discrete points to $M = 7$ or $M = 9$ does not produce significantly different normed errors but provides more detail about the calculated profile at the cost of a lengthier computation.

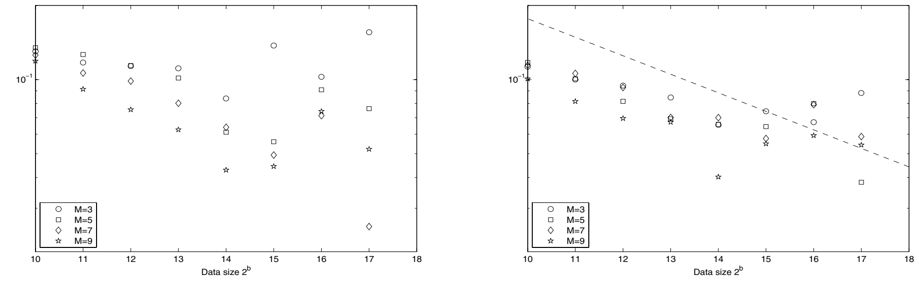
In practice, of course, the goal of the reconstruction is to obtain an approximation of the velocity profile, the true profile being unknown. So, finally, we compare the L^1-norm of the variance of the reconstructed profiles from the individual blocks, plotted



(a) Linear profile

(b) Parabolic profile

FIG. 4.4. *L^2 relative error with γ averaged over the number of blocks B of size 2^b at $M = 3$, $M = 5$, $M = 7$, $M = 9$.*



(a) Linear profile

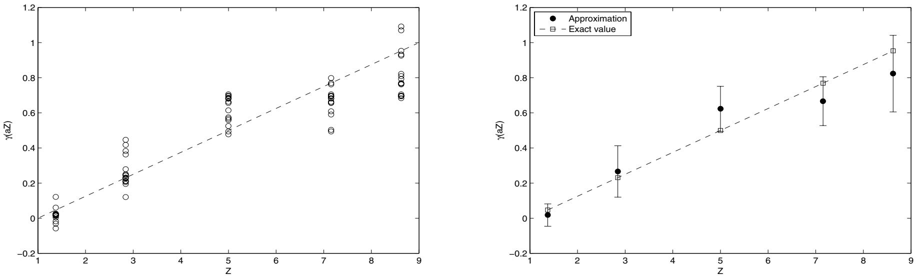
(b) Parabolic profile

FIG. 4.5. *L^1-norm of the variance of γ averaged over the number of blocks B at $M = 3, 5, 7, 9$ for the linear and parabolic profile.*

versus the exponent b in the block size 2^b. Again, we note for both the linear and the parabolic profiles that the variance increases for data sizes bigger than 2^{15}. That is, the L^1-norm of the variance of reconstructed values from individual data blocks appears to trend very similarly to the true L^2-norm errors, and so we propose using the former as a stand-in for the latter in deciding how to block-divide the data in the present setting. Figure 4.5 thereby confirms that a better result can be both obtained and recognized here when averaging over $B = 8$ or $B = 16$ blocks corresponding to blocks of size 2^{15} or 2^{16}. We remark that there are numerous sources of error in the present reconstruction, including errors in the numerical integration, the numerical convolution, and the minimization itself.

Using the result of the block-averaging technique investigated in the previous three error plots (Figures 4.3, 4.4, and 4.5) we can now reconstruct the velocity profile at five points, $M = 5$, for the linear case with $B = 16$ blocks. In Figure 4.6 we examine both the spread of the values obtained for each block and the average $\overline{\gamma_j}$, $j = 1, \ldots, M$, and standard deviation (plotted as 90% confidence interval error bars for the block reconstruction values).

Finally, we apply the block-averaging technique on the parabolic (Figure 4.7(a)) and exponentially decaying (Figure 4.7(b)) test velocity profiles at $M = 5$ points and $B = 16$ blocks. During our proof-of-principle calculations, we sometimes encountered



(a) Scatter plot

(b) Errorbar plot

data sets for which the reconstruction performed particularly poorly, as evidenced by clear jumps in the reconstructed values as might suggest discontinuous velocity profiles. Such poorly performing data was a simple consequence of the state of the random number generator in the simulations; presumably similarly quirky experimental data is not wholly uncommon, and so such reconstructions must therefore, of course, always be questioned, particularly if they indicate highly unlikely results. Finally, we additionally remark that the near-wall region velocity profile is usually assumed to be linear or parabolic, and the exponential case is experimentally unlikely for the present purposes except when the imaged region is large compared to the scale of electroosmotic layers.

To conclude this section we plot the averaged reconstructed mean $\overline{\gamma_j}$, $j = 1, \ldots, M$ (full symbols), compared to their true values (open symbols) at three ($M = 3$) and seven ($M = 7$) points for both the linear (square) and the parabolic (circle) test profiles together in the same figure (Figure 4.8). Figures 4.7 and 4.8 clearly demonstrate that we are able to statistically reconstruct the main behaviors of and distinguish between different profiles (linear, parabolic, and exponentially decaying test profiles) using multiple collocation points ($M = 3, 5, 7$) across the measured region.

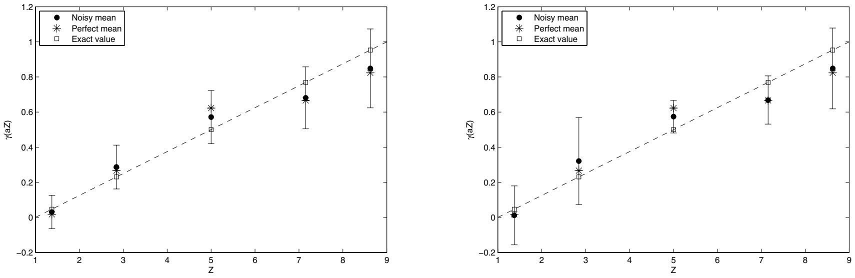
5. Reconstruction with cross-correlated velocities. In the previous section we used perfect mean displacements between two image windows. In this section, first we describe the idea behind PIV approximate mean measurements and then how they influence the reconstruction algorithm.

PIV is an illumination technique combined with image processing to obtain components of the mean velocity by measuring the mean displacement over a lag time. At microscales, the sample is illuminated with laser sheets and cross-correlation techniques (see [15], [11], [10]) producing a three-dimensional velocity profile. In nano-PIV (nPIV), total internal reflection fluorescence microscopy is used to image tracer particles [12], [14]. When light undergoes total internal reflection for angle of incidence larger than the critical angle, an evanescent wave is created and propagates parallel to the interface with an exponentially decaying intensity. Zettner and Yoda [16] report errors in the approximation of the mean of the order of 10%, while Sadr, Li, and Yoda [13] estimate that nPIV leads to an error of about 6% in the approximation of the mean x-displacement. We remark that for the well-established technique of μPIV, Meinhart, Wereley, and Santiago [11] conclude that the ensemble-averaged displacements lie within 2% of their true values.

The parameters in our computer simulations are chosen to closely match experimental parameters [12]: the sizes of the region of interest are $\delta x = 25\,\mu\text{m}$, $\delta y = 5\,\mu\text{m}$, and $\delta z = 450\,\text{nm}$, the radius of a particle is $a = 50\,\text{nm}$, and the number of particles is 64. We note that both background image noise and particle drop-in/-out between the two images also degrade the PIV measurement, but we ignore both effects here for simplicity. Therefore the particles are uniformly distributed in the z-direction between two measurements. Once the image matrix is generated, the approximate x- and y-displacement over a window is determined using cross-correlation [15], [11], [10]. The cross-correlation function is the two-dimensional discrete convolution of two image matrices. The location of the maximum peak of the cross-correlation function gives the mean x- and y-displacement between two windows. To gain subpixel accuracy, a Gaussian surface fitting algorithm with 8 to 11 neighbors is typically used.

Because the previously described technique requires significant experimental agility in the choice of the size of the window over which the displacements are obtained and in the ratio of overlapping of the windows, a threshold criteria for eliminating bad displacement vectors has to be adopted (see [7]). Instead of using a computer



(a) PIV data with 5% relative error (b) PIV data with 10% relative error

analogue to PIV techniques with a threshold which will lead to the generation of more data, here we mimic the effect of these additional experimental errors by adding normally distributed relative errors with standard deviations of 5% and 10% with respect to the overall mean of the perfect mean displacements from our simulations. Then we apply the statistical reconstruction algorithm at $M = 5$ with averaging over $B = 16$ blocks on those two distinct noisy data sets to obtain the results of Figure 5.1 for the linear case and Figure 5.2 for the parabolic test profile. The increasing spread in the extent of the confidence intervals with increasing measurement error demonstrated in Figures 5.1 and 5.2 shows that, while error in the measurement of the mean x-displacement on the scale of that described in the PIV literature definitely affects the reconstructed results and confidence intervals, even at 10% relative errors the reconstructed values are promising. Moreover, if experimental uncertainties can be reduced to about 5%, as pursued in the literature [12], [14], then the block-averaging statistical reconstruction here appears to perform essential as well as with perfectly measured displacements, as illustrated in both Figures 5.1(a) and 5.2(a). We remark that the approximation at the last point Z_M is the worst. This might be caused by some numerical artifacts imposed by the artificial upper wall elastic boundary condition, but we have not been able to pinpoint it precisely so far. However, since the goal is to obtain a better approximation of the velocity profile in the very near-wall region, this is not a major drawback.

6. Discussion. We have successfully demonstrated that it is possible to use the correlation between unknown velocity profiles $\gamma(aZ)$ and known wall-hindered diffusion coefficient $D(z)$ to reconstruct the velocity values with reasonable precision at multiple collocation points within the depth of an imaged window, reconstructing the out-of-plane z-dependence using only measured in-plane displacements, with examples from three basic test flows (linear, parabolic, and exponentially decaying).

We emphasize that all previously reported experimental values, except the recently developed multilayer nPIV (see [9]), obtain a single value for the velocity over the entire region of observation, namely the mean located in the center of the field of focus. The present reconstruction algorithm, approximating the behavior of the deterministic velocity at M (typically $M = 3, 5, 7$) points scattered over the imaged region, is thus a significant improvement.

The reconstruction uses block averaging, and the error plots have demonstrated that it is better to approximate the profile individually over data set blocks of size 2^{14} and to average the result over 8 or 16 consecutive blocks than processing all of our simulated data at once. Importantly, this is computationally fast: the mimimum of the likelihood function ϕ in (4.7) is found in less than 30 minutes on a desktop machine. In contrast, each Milstein-scheme simulation used to generate data here required on the order of 10 days on the same processor. This reconstruction does not use any information about the intensity function and offers an alternative approach to the recently developed multilayer PIV techniques [6], [9] which attempt to infer distance from the wall from image intensities. An interesting direction for future development is the possibility of combining the imperfect (from polydispersity) out-of-plane intensity information with the present statistical method.

The amount of data used in the reconstruction process may seem staggering, but a comparison with data actually captured in experiments indicates that such data sets can be achieved in a reasonable time. For example, Guasto, Huang, and Breuer [4] track over 140000 single quantum dots from 900 image pairs to obtain a single approximation over the entire region. Li, Sadr, and Yoda [9] cite a framing rate of about 26Hz leading to a sequence of 100 frames of about 30 particles recorded within 5 seconds. Keeping the same interframe ratio, it will take between 20 minutes and 4 hours to obtain the necessary 2^{18} frames. Moreover, Li et al. report using in their computer simulated multilayer nPIV 2000 frames with 120 particles and 3 windows for each one of their three layers. In other words they use, after having thrown away an unquantified amount of bad data, about 2^{14} mean displacements for 2^7 particles.

The present demonstration assumes that the particles are uniformly distributed between two measurements; once the computational and observation domain are no longer the same, the uniform distribution assumption will be broken due to particle drop-in and drop-out from the window between two measurements. Provided that this distribution can be computed a priori [13], the reconstruction is simply modified to include the nonuniform probability density function of matched particles. The present results are, of course, only a computer-simulated proof of concept, and more physical effects need to be included for proper use on experimental data, perhaps including the effects of background noise in the images, particle polydispersity, and particles dropping in and out of the field of vision.

Acknowledgments. The authors would like to thank Minami Yoda, Haifeng Li, and Reza Sadr in the Woodruff School of Mechanical Engineering at the Georgia Institute of Technology for providing the experimental problem and for fruitful discussions.

COUPLED FORWARD-ADJOINT MONTE CARLO SIMULATIONS OF RADIATIVE TRANSPORT FOR THE STUDY OF OPTICAL PROBE DESIGN IN HETEROGENEOUS TISSUES[*]

CAROLE K. HAYAKAWA[†], JEROME SPANIER[‡], AND VASAN VENUGOPALAN[†]

Abstract. We introduce a novel Monte Carlo method for the analysis of optical probe design that couples a forward and an adjoint simulation to produce spatial-angular maps of the detected light field within the tissue under investigation. Our technique utilizes a generalized reciprocity theory for radiative transport and is often more efficient than using either forward or adjoint simulations alone. For a given probe configuration, the technique produces rigorous, transport-based estimates of the joint probability that photons will both visit any specified target subvolume and be detected. This approach enables the entire tissue region to be subdivided into a collection of target subvolumes to provide a phase-space map of joint probabilities. Such maps are generated efficiently using only one forward and one adjoint simulation for a given probe configuration. These maps are used to identify those probe configurations that best interrogate targeted subvolumes. Inverse solutions in a layered tissue model serve to illustrate and reinforce our analysis.

Key words. Monte Carlo methods, radiative transfer, inverse problems, biological applications

1. Introduction.

The use of light for noninvasive, in vivo determination of optical and physiological properties of tissue volumes is established for a host of applications in biomedical optics. In some cases, other imaging modalities, such as x-ray, ultrasound, or MRI, are used in conjunction with optical techniques to identify heterogeneous tissue regions that require further analysis. Knowledge of this structural information can provide information critical to the design of optical probes to target these regions effectively or to provide information regarding both the target region and its surroundings.

With these goals in mind, much effort has been expended in improving the design of optical probes. For example, there have been attempts to enhance the light delivered to specific tissue regions by varying source and detector characteristics such as orientation, size, angle of emission (for sources), angle of acceptance (for detectors), source-detector (s-d) separation, and/or distance between the target volume and the source/detector [6, 8, 14, 16, 21, 22, 31]. These optical probes are configured in an attempt to enhance the light that is both delivered to the targeted volume and subsequently detected at the tissue surface. Clearly, detailed knowledge of the spatial-angular distribution of the detected light field for a given probe configuration would serve to assess the effectiveness of these approaches and provide a basis to compare competing probe designs.

Previous studies of radiative transfer in tissue from source to detector have been based mainly on the diffusion approximation to the radiative transport equation [3, 7, 15, 17]. However, the validity of diffusion-based models is compromised when (a) s-d separations are small or (b) the tissue absorption is comparable to or greater than scattering. While analytic [27] and specific Monte Carlo [2] approaches have been investigated, it is unclear how these methodologies would extend to heterogeneous media. Moreover, conventional Monte Carlo simulations provide results with large uncertainties in the detected signals due to the small detector sizes often used in optical probes.

To address this problem in the context of radiative transport, we have developed a novel Monte Carlo method that produces phase-space maps to provide quantitative measures of the ability for a given probe configuration to detect light delivered to specific regions within the tissue. This general approach can be applied to complex, heterogeneous media. The method makes use of coupled forward-adjoint simulations to estimate the joint probability of both visitation of a target region and subsequent detection at the tissue surface. Bayes's theorem [12] is used to decompose this joint probability into the product of an absolute and a conditional probability. These two probabilities are then estimated using separate and efficient simulations. In cases for which the targeted volume is large compared to both source and detector volumes, the gains in efficiency over the use of either a forward or an adjoint simulation alone can be substantial.

In this paper, we describe the foundations of our method as well as its operational details. We then apply the method to investigate how a layered epithelial tissue is interrogated by optical probe designs in which we allow variation in s-d separation. Forward and adjoint simulations are generated for various probe configurations. The simulation results are used to produce maps that provide both qualitative and quantitative information regarding the phase-space distribution of the detected light. This information provides a basis for the comparison of prospective probe designs to determine the merits of each. Accurate recovery of optical properties from heterogeneous tissues via inverse solutions serves to confirm the comparative analysis of candidate probe designs as evaluated by the coupled forward-adjoint Monte Carlo simulations.

2. Method. To determine the probability of detecting light that has visited a targeted volume, one could utilize a conventional Monte Carlo simulation in which one follows photon trajectories from the source to a target volume and then tallies the final photon weight for those photons that are subsequently detected. Alternatively, one could use an adjoint Monte Carlo simulation, in which one follows backward-propagating photons from the detector to the target volume, and then to the source. However, when the source and detector are each small relative to the target volume, sole use of a forward or adjoint simulation engenders low signal-to-noise ratios (SNRs). Such a situation is exceedingly common in biomedical optics.

Our approach is to break the problem into two components and determine separately (a) the probability of source to target trajectories, $P(V)$ ("target visitation"), and (b) the probability of detection conditioned by target visitation, $P(D|V)$ ("detection given target visitation"). The combination of these two probabilities using Bayes's theorem provides the rigorous joint transport probability of "target visitation and detection":

$$P(V \cap D) = P(V) \cdot P(D|V). \tag{2.1}$$

We use a conventional Monte Carlo simulation to determine $P(V)$. However, for

$P(D|V)$, we utilize an adjoint simulation to combat the inherently low SNR in its estimation in the reverse direction. This is done by modifying a generalized reciprocity principle [5, 19, 25, 29] to convert $P(D|V)$ to a coupled forward-adjoint computation at the surface of the target volume.

In the next section, we describe our application of coupled forward-adjoint Monte Carlo methods for the determination of $P(V \cap D)$. This includes a review of classical reciprocity theory and basic equations. We then describe generalized reciprocity, for which classical reciprocity is a special case. Finally, we develop our extension of generalized reciprocity theory to arrive at an estimate of $P(V \cap D)$. This will set the stage for the application of this methodology to problems in biomedical optics.

3. Coupled forward-adjoint Monte Carlo methods.

A series of publications [5, 19, 20, 25, 24, 30, 29] has developed and described the "midway" forward-adjoint coupling method to increase the efficiency of estimating detector responses in radiative transport problems. The idea is to simulate both forward and adjoint Monte Carlo transport and combine the tallies from each at an intermediate surface to estimate the total system response. The midway method is made rigorous by appealing to a generalized reciprocity theory for transport equations [19, 20, 29, 30]. The midway method has been shown to be particularly efficient in problems that involve deep penetration and/or complex streaming pathways taken by the radiation as it moves from source(s) to detector(s) [19, 20, 24, 25].

We modify the midway method in order to apply it to the estimation of the conditional probability $P(D|V)$. Photons are launched at a physical source and are propagated until they exit the phase space. At each interaction within the tissue, the photon weight is reduced according to its survival probability, a technique sometimes referred to as "absorption weighting" [23]. Only photon trajectories that have intersected the target volume $\mathbb{V}$ contribute to the estimate of $P(V)$. These "visiting" photons generate an induced source internal to $\mathbb{V}$ that produces a surface source on $\partial\mathbb{V}$. This surface source is then paired with the adjoint flux on $\partial\mathbb{V}$ in a bilinear integration that produces an estimate of $P(D|V)$. The product of the two probabilities $P(V)$ and $P(D|V)$ then provides the probability that photons will both visit and subsequently be detected from subvolumes within the phase space. We use this product to provide quantitative information to assess the characteristics of potential probe designs.

3.1. Classical reciprocity.

We begin with the integro-differential form of the radiative transport equation (RTE) assumed to hold in the interior of a closed, bounded subset $\mathbb{D}$ of $\mathbb{R}^3$:

$$\nabla \cdot \mathbf{\Omega}\, \Phi(\mathbf{r}, \mathbf{\Omega}) + \mu_t(\mathbf{r})\Phi(\mathbf{r}, \mathbf{\Omega}) = \mu_s(\mathbf{r}) \int_{4\pi} f(\mathbf{\Omega'} \to \mathbf{\Omega})\Phi(\mathbf{r}, \mathbf{\Omega'})\, d\mathbf{\Omega'} + Q(\mathbf{r}, \mathbf{\Omega}), \tag{3.1}$$

where $\Phi(\mathbf{r}, \mathbf{\Omega})$ is the photon flux, $\mu_t(\mathbf{r}) = \mu_s(\mathbf{r}) + \mu_a(\mathbf{r})$ is the total attenuation coefficient, $\mu_s(\mathbf{r})$ is the scattering coefficient, $\mu_a(\mathbf{r})$ is the absorption coefficient, $f(\mathbf{\Omega'} \to \mathbf{\Omega})$ is the single scattering phase function, and $Q(\mathbf{r}, \mathbf{\Omega})$ is an internal (volumetric) source function, with $\mathbf{r} = (x, y, z)$ and $\mathbf{\Omega} = (\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta)$ representing position and unit direction vectors, respectively. A unique solution $\Phi(\mathbf{r}, \mathbf{\Omega})$ is assured for all $\mathbf{r} \in \mathbb{D}$, $\mathbf{\Omega} \in S^2$ by specifying the photon flux $\Phi_{\text{inc}}(\mathbf{r}, \mathbf{\Omega})$ incident on $\partial\mathbb{D}$ from outside the tissue. We introduce an abbreviated form of (3.1):

$$\nabla \cdot \mathbf{\Omega}\Phi + \mathcal{B}\Phi = Q, \tag{3.2}$$

where $\mathcal{B}$ denotes the transport operator less the divergence term.

A typical optical probe is an instrument that both introduces light at the tissue boundary and collects light reemitted from the boundary using or more detectors positioned at fixed distances from the source. Assuming that there are no other (external) sources of light, the unique solution Φ of this RTE can be written as a superposition of the photon fluxes produced by the internal source Q and the boundary source Q_s defined by

$$Q_s(\mathbf{r}_s, \mathbf{\Omega}) = -\mathbf{\Omega} \cdot \mathbf{n}_s \Phi_{\text{inc}}(\mathbf{r}_s, \mathbf{\Omega}) \quad \text{for } \mathbf{r}_s \in \partial\mathbb{D},\ \mathbf{\Omega} \cdot \mathbf{n}_s < 0, \tag{3.3}$$

where $\mathbf{n}_s$ is the outward-pointing unit normal at r_s:

$$\begin{aligned} \Phi(\mathbf{r}, \mathbf{\Omega}) = &\int_{\mathbb{D}\times S^2} G[(\mathbf{r}_0, \mathbf{\Omega}_0) \to (\mathbf{r}, \mathbf{\Omega})] Q(\mathbf{r}_0, \mathbf{\Omega}_0)\, d\mathbf{r}_0\, d\mathbf{\Omega}_0 \\ &+ \int_{\partial\mathbb{D}\times S^2} G_s[(\mathbf{r}_0, \mathbf{\Omega}_0) \to (\mathbf{r}, \mathbf{\Omega})] \Phi_{\text{inc}}(\mathbf{r}_s, \mathbf{\Omega}_s)\, d\mathbf{r}_0\, d\mathbf{\Omega}_0, \end{aligned} \tag{3.4}$$

where G is the volume Green's function and G_s is the surface Green's function for the problem. An alternate, equivalent representation that uses only the volume Green's function is

$$\Phi(r, \Omega) = \int_{\mathbb{D}\times S^2} G[(\mathbf{r}_0, \mathbf{\Omega}_0) \to (\mathbf{r}, \mathbf{\Omega})] Q(\mathbf{r}_0, \mathbf{\Omega}_0)\, d\mathbf{r}_0\, d\mathbf{\Omega}_0, \tag{3.5}$$

where the second term in (3.4) is replaced by the boundary condition

$$\Phi(\mathbf{r}_s, \mathbf{\Omega}_s) = Q_s(\mathbf{r}_s, \mathbf{\Omega}_s) \tag{3.6}$$

and Q_s is defined as in (3.3) [4]. The relationship (3.3) and the equivalence between the representations (3.4) and (3.5) together with (3.6) will be utilized in section 3.3.

The response of either a virtual or a physical detector can then be described in terms of a linear functional of Φ:

$$I = \int_{\mathbb{D}\times S^2} Q^* \Phi\, d\mathbf{r}\, d\mathbf{\Omega}, \tag{3.7}$$

where Q^* characterizes the detector position, size, and acceptance angle. Both the source function Q and detector function Q^* may be described mathematically using characteristic functions associated with the source and detector. For example, if the tissue $\mathbb{D}$ is assumed to occupy the half space characterized in rectangular coordinates by $z > 0$, and a fiber-optic laser source of radius q and unit strength is normally incident at $(0, 0, 0)$, we have

$$Q_s(x_s, y_s, 0, \mathbf{\Omega}) = \begin{cases} 1, & \begin{array}{l} x_s^2 + y_s^2 \le q^2 \quad \text{and} \\ -1 \le \mathbf{n}_{\mathbb{D}} \cdot \mathbf{\Omega} < -\cos\theta_Q, \end{array} \\ 0 & \text{otherwise,} \end{cases} \tag{3.8}$$

where $\mathbf{n}_{\mathbb{D}}$ denotes the outward-pointing unit normal at the bounding surface $z = 0$ and the source is confined to an emission angle θ_Q. A similar description characterizes a typical fiber-optic detector placed elsewhere on the tissue surface $z = 0$, except that it collects light that scatters *into* the half space $z < 0$ at location $(X_{Q^*}, Y_{Q^*}, 0)$ within the detector radius q^* and acceptance angle θ_{Q^*}. Specifically,

$$Q_s^*(x_s, y_s, 0, \mathbf{\Omega}) = \begin{cases} 1, & \begin{array}{l} (x_s - X_{Q^*})^2 + (y_s - Y_{Q^*})^2 \le (q^*)^2 \quad \text{and} \\ 1 \ge \mathbf{n}_{\mathbb{D}} \cdot \mathbf{\Omega} > \cos\theta_{Q^*}, \end{array} \\ 0 & \text{otherwise.} \end{cases} \tag{3.9}$$

It is well known that classical reciprocity theory also permits the detector response I to be expressed as a linear functional of the solution to the RTE that is adjoint to (3.1) [23]:

(3.10)
$$-\nabla \cdot \mathbf{\Omega}\, \Phi^*(\mathbf{r}, \mathbf{\Omega}) + \mu_t(\mathbf{r})\Phi^*(\mathbf{r}, \mathbf{\Omega}) = \mu_s(\mathbf{r}) \int_{4\pi} f(\mathbf{\Omega} \to \mathbf{\Omega}')\Phi^*(\mathbf{r}, \mathbf{\Omega}')\, d\mathbf{\Omega}' + Q^*(\mathbf{r}, \mathbf{\Omega})$$

and

$$I = \int_{\mathbb{D}\times S^2} Q\Phi^*\, d\mathbf{r}\, d\mathbf{\Omega}. \tag{3.11}$$

Upon comparing the detector response representations (3.7) and (3.11), we notice that the roles of the source function Q and detector function Q^* are interchanged in this statement of reciprocity, so that Q acts as a "detector" function for the adjoint formulation and Q^* plays the role of a "source" function for the adjoint equation.

Using operator notation, (3.10) can be written as

$$-\nabla \cdot \mathbf{\Omega}\Phi^* + \mathcal{B}^*\Phi^* = Q^*, \tag{3.12}$$

where $\mathcal{B}^*$ is the operator adjoint to $\mathcal{B}$. For (3.11) to be valid, it is also understood that the boundary condition satisfied by Φ^* on $\partial\mathbb{D}$ is dual to that specified for Φ. For example, in our application $\partial\mathbb{D}$ is the surface of the tissue that is composed of the source region A_Q, the detector region A_{Q^*}, and the complement of these two regions $\partial\mathbb{D}\backslash(A_Q \cup A_{Q^*})$. Here we assume for simplicity that both the source emission angle and the detector acceptance angle are fully open; i.e., $\cos\theta_Q = \cos\theta_{Q^*} = 0$. For this case, the boundary condition at $z = 0$ satisfied by Φ is

$$\Phi(x_s, y_s, 0, \mathbf{\Omega}) = Q_s(x_s, y_s, 0, \mathbf{\Omega}) \quad \text{for } (x_s, y_s) \in A_Q, \tag{3.13}$$

where the right-hand side is defined by (3.8) with $\cos\theta_Q = 0$. The dual boundary condition for Φ^* becomes

$$\Phi^*(x_s, y_s, 0, \mathbf{\Omega}) = Q_s^*(x_s, y_s, 0, \mathbf{\Omega}) \quad \text{for } (x_s, y_s) \in A_{Q^*}, \tag{3.14}$$

where the right-hand side is defined by (3.9) with $\cos\theta_{Q^*} = 0$. From (3.13) and (3.14) we have $\Phi\Phi^* = 0$ on $\partial\mathbb{D}$ establishing that the boundary conditions are dual to each other. Note that (3.13) and (3.14) are incomplete statements of the boundary conditions for $\mathbf{r} \in \partial\mathbb{D}\backslash(A_Q \cup A_{Q^*})$, as they do not include the full range of $\mathbf{\Omega}$. The missing conditions for our case accommodates a tissue-air refractive index mismatch using the Fresnel relations for unpolarized light [28]. This results in a mixed boundary condition comprised of a linear combination of reflecting and nonreentrant conditions, each component of which leads to duality as shown by Aronson [1].

The duality of the governing equations and boundary conditions enables a detector response to be computed *either* in the context of forward Monte Carlo sampling *or* adjoint Monte Carlo sampling via this "classical" reciprocity for the RTE. Usually one of these formulations will lead to a more efficient simulation than the other. However, many problems in biomedical optics utilize *both* small sources *and* small detectors, making *neither* formulation efficient.

However, we can improve the efficiency of classical reciprocity by utilizing a midway surface between source and detector. The midway method combines forward and adjoint sampling that characterizes those photons that have migrated from source to detector through a separating midway surface. Application of generalized reciprocity to the estimation of $P(D|V)$ using this midway method will then lead us to our final evaluation of $P(V \cap D)$. In section 3.2 we explain generalized reciprocity and the midway method. In section 3.3 we extend these ideas to compute the joint probability of visitation and detection $P(V \cap D)$.

3.2. Generalized reciprocity. Let us first consider $\mathbb{V}_M$ to be an arbitrary closed, bounded subset of $\mathbb{D}$ and $\partial\mathbb{V}_M$ its surface. Multiplying (3.2) by Φ^* and (3.12) by Φ, subtracting the latter product from the former, and integrating the difference over all locations and directions within V_M, we get

$$\int_{\mathbb{V}_M \times S^2} \nabla \cdot \mathbf{\Omega}\Phi\Phi^* \, d\mathbf{r} \, d\mathbf{\Omega} = \int_{\mathbb{V}_M \times S^2} [Q\Phi^* - Q^*\Phi] \, d\mathbf{r} \, d\mathbf{\Omega}. \tag{3.15}$$

Use of Green's theorem to replace the volume integral on the left-hand side of (3.15) by a surface integral leads to

$$\int_{\partial\mathbb{V}_M \times S^2} \mathbf{n}_M \cdot \mathbf{\Omega}\Phi\Phi^* \, d\mathbf{r} \, d\mathbf{\Omega} = \int_{\mathbb{V}_M \times S^2} [Q\Phi^* - Q^*\Phi] \, d\mathbf{r} \, d\mathbf{\Omega}, \tag{3.16}$$

where $\mathbf{n}_M$ is the outward-pointing unit vector normal to $\partial\mathbb{V}_M$. Equation (3.16) is often referred to as the global reciprocity theorem [30]. Note that if $\mathbb{V}_M = \mathbb{D}$ and the boundary conditions at the air-tissue interface cause the integral on the left-hand side to vanish (as is the case in our problem), we then arrive at the "classical" statement of reciprocity:

$$\int_{\mathbb{V}_M \times S^2} [Q\Phi^* - Q^*\Phi] \, d\mathbf{r} \, d\mathbf{\Omega} = 0. \tag{3.17}$$

While (3.16) is valid generally, it becomes particularly useful when $\mathbb{V}_M$ encloses *either* the source *or* the detector region. The surface of $\mathbb{V}_M$, $\partial\mathbb{V}_M$, can then be identified as a "midway" surface between source and detector. In this case, every photon that is detected from the source *must* intersect the midway surface.

The function $\Phi\Phi^*$ that occurs in (3.16) has been called a "contributon" response function [5, 19, 20, 24, 25, 29, 30] and used to define a unit of information that characterizes transport from source to detector. The integral of this function appearing on the left-hand side of (3.16) plays a similar role here. It captures the flow of information across the boundary of the midway volume $\mathbb{V}_M$.

If $\mathbb{V}_M$ encloses the source region as shown in Figure 3.1(a) and $Q^* = 0$ in $\mathbb{V}_M$, the left-hand side of (3.16) is positive and equals $\int_{\mathbb{V}_M \times S^2} Q\Phi^*$, which is the adjoint representation of the detector response. If $\mathbb{V}_M$ encloses the detector region, and $Q = 0$ in $\mathbb{V}_M$, the left-hand side of (3.16) is negative and equals $-\int_{\mathbb{V}_M \times S^2} Q^*\Phi$, which is the forward representation of the detector response. Reversing the sense of $\mathbf{n}_M$ by replacing the outward-pointing unit normal with the inward-pointing unit normal changes the sign in the surface integral on the left-hand side of (3.16) and also reverses the sense of enclosure. That is, if $\mathbb{V}_M$ is treated as an enclosure for the source, then $\mathbf{n}_M$ points outward. However, if the complement of $\mathbb{V}_M$ in $\mathbb{D}$, $\mathbb{D}\backslash\mathbb{V}_M$, is treated as an enclosure for the detector, then $\mathbf{n}_M$ points inward.

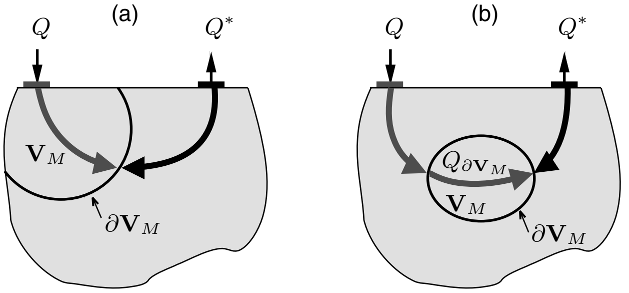

FIG. 3.1. *Geometry of* (a) *generalized reciprocity with the midway surface* $\partial\mathbf{V}_M$ *enclosing the physical source, and* (b) *an extension to generalized reciprocity with an induced boundary source* $Q_{\partial\mathbf{V}_M}$ *out of* $\mathbf{V}_M$ *used to compute conditional probabilities.*

In many situations, this midway surface method proves to be more efficient than using either the forward or adjoint simulation alone [19, 20]. The gains in efficiency will largely be the consequence of the relatively larger "size" of $\mathbb{V}_M$ compared with either the size of the source region, where $Q \neq 0$, or of the detector region, where $Q^* \neq 0$. Here "size" is to be interpreted in a probability sense as opposed to a strict physical size. More precisely, the relevant condition is that the probability of reaching $\mathbb{V}$ from either the source or detector should be larger than the corresponding probabilities in the reverse directions.

3.3. Probability of visitation and detection. The probe design problem requires an understanding of more than the *total* system response at the detector from the original optical source. It requires, in addition, knowledge of the detector response due *only* to those photons that have visited a targeted tissue region $\mathbb{V}$. For our application, $\mathbb{V}$ is a region that encloses *neither* the source *nor* the detector. Thus, to make use of generalized reciprocity, we treat $\mathbb{V}$ as a region that generates a secondary or "virtual" source, induced by the original physical source. This construct allows us to decompose the problem into two subproblems. The first problem deals only with the estimation of $P(V)$ and is handled using conventional Monte Carlo simulation. The second problem handles the estimation of $P(D|V)$ and will be accomplished by a suitable application of the generalized reciprocity relation (3.16).

Accordingly, the midway volume $\mathbb{V}_M$ can be considered as an arbitrary volume enclosing neither source nor detector with surface $\partial\mathbb{V}_M$. A possible geometry is shown in Figure 3.1(b). This arbitrary volume $\mathbb{V}_M$ is one at whose boundary, $\partial\mathbb{V}_M$, information will be collected from both forward and adjoint photons for the estimation of $P(V)$ and $P(D|V)$, respectively. We estimate the first factor of (2.1), $P(V)$, by launching photons from the original source Q characterized in (3.8) and, for those photons that enter $\mathbb{V}_M$, tally the entering weight of each photon. These photons produce estimates of $P(V)$ and generate samples drawn from an induced source $Q_{\partial\mathbb{V}_M}$ impinging on $\partial\mathbb{V}_M$ from *inside* $\mathbb{V}_M$. The boundary surface $\partial\mathbb{V}_M$ then defines the surface for the midway method applied to the problem of estimating the conditional probability, $P(V|D)$.

The details of the required computation deserve elaboration. Denote $\Phi(\mathbf{r}, \mathbf{\Omega})$ as the solution of the boundary-value problem of (3.1) with source described as in (3.8), and let $\Phi_{\mathbb{V}_M}(\mathbf{r}, \mathbf{\Omega})$ denote the restriction of $\Phi(\mathbf{r}, \mathbf{\Omega})$ to $\mathbf{r} \in \mathbb{V}_M$. The photon flux $\Phi_{\partial\mathbb{V}_M}(\mathbf{r}, \mathbf{\Omega})$ for $\mathbf{r} \in \partial\mathbb{V}_M$, $\mathbf{\Omega} \cdot \mathbf{n}_{\partial\mathbb{V}} < 0$, where $\mathbf{n}_{\partial\mathbb{V}}$ = unit normal out of $\mathbb{V}_M$ (*into* $\mathbb{D}\backslash\mathbb{V}$) then generates a boundary source $Q_{\partial\mathbb{V}_M}(\mathbf{r}_s, \mathbf{\Omega}_s) = -\Omega_s \cdot \mathbf{n}_{\partial\mathbb{V}_M} \Phi_{\partial\mathbb{V}_M}(\mathbf{r}_s, \mathbf{\Omega}_s)$ on

$\partial\mathbb{V}_M$. If we merely replace the source function Q by the source function $Q_{\partial\mathbb{V}}(\mathbf{r},\boldsymbol{\Omega})$ and repeat the derivation that led to (3.16), we obtain

$$\int_{\partial\mathbb{V}_M\times S^2}\mathbf{n}_{\partial\mathbb{V}_M}\cdot\boldsymbol{\Omega}\Phi_{\mathbb{V}_M}\Phi^*\,d\mathbf{r}\,d\boldsymbol{\Omega}=\int_{\mathbb{V}_M\times S^2}\left[Q_{\partial\mathbb{V}_M}\Phi^*-Q^*\Phi_{\mathbb{V}_M}\right]d\mathbf{r}\,d\boldsymbol{\Omega}. \tag{3.18}$$

We replace $Q^*(\mathbf{r},\boldsymbol{\Omega})$ by $Q^*(\mathbf{r},-\boldsymbol{\Omega})$ to generate an adjoint flux, $\Phi^*(\mathbf{r},-\boldsymbol{\Omega})$, *inside* the tissue. This, of course, reverses the direction in the arguments of Q^* and Φ^* in (3.18), which then reads

$$\begin{aligned}&\int_{\partial\mathbb{V}_M\times S^2}\mathbf{n}_{\partial\mathbb{V}_M}\cdot\boldsymbol{\Omega}\Phi_{\mathbb{V}_M}(\mathbf{r},\boldsymbol{\Omega})\Phi^*(\mathbf{r},-\boldsymbol{\Omega})\,d\mathbf{r}\,d\boldsymbol{\Omega}\\&\qquad=\int_{\mathbb{V}_M\times S^2}\left[Q_{\partial\mathbb{V}_M}(\mathbf{r},\boldsymbol{\Omega})\Phi^*(\mathbf{r},-\boldsymbol{\Omega})-Q^*(\mathbf{r},-\boldsymbol{\Omega})\Phi_{\mathbb{V}_M}(\mathbf{r},\boldsymbol{\Omega})\right]d\mathbf{r}\,d\boldsymbol{\Omega}\\&\qquad=\int_{\mathbb{V}_M\times S^2}Q_{\partial\mathbb{V}_M}(\mathbf{r},\boldsymbol{\Omega})\Phi^*(\mathbf{r},-\boldsymbol{\Omega})\,d\mathbf{r}\,d\boldsymbol{\Omega}\end{aligned} \tag{3.19}$$

since $Q^*=0$ inside $\mathbb{V}_M$. Estimation of (3.19) is performed using an adjoint simulation and provides the detected response due to the induced source $Q_{\partial\mathbb{V}_M}$, or $P(D|V)$.

The forward simulation of photons exiting an arbitrary target volume $\mathbb{V}_M$ is used to determine $P(V)$ and is matched with the adjoint simulation estimate of $P(D|V)$ at $\partial\mathbb{V}_M$. The joint probability of visitation and detection $P(V\cap D)$ (see (2.1)) is formed by the product of these two factors. The resulting probability characterizes a three body system involving radiative transport from (a) the original source Q to (b) the target volume $\mathbb{V}_M$ and finally to (c) the detector. In what follows, we shall refer to joint probability of visitation and detection of the target volume, $P(V\cap D)$, as *interrogation* of the target volume.

4. Implementation.

Monte Carlo simulations of both the forward RTE equation (3.1) and the adjoint RTE (3.10) are quite conventional [10, 26]. Photon and adjoint photon biographies are generated by alternately sampling from exponential distributions representing intercollision distances and angular deflections sampled from the Henyey–Greenstein phase function [11, 28]. The resulting random walks are followed until they escape the tissue phase space.

We utilize our coupled forward-adjoint methodology to create quantitative maps of the entire tissue that illustrate how the light interrogates various regions in the tissue. We shall refer to these maps as "interrogation maps." To create such maps, the tissue is subdivided into a finite number of voxels, each treated as a target volume $\mathbb{V}$. The matching of photon trajectories between the forward simulation and the adjoint simulation occurs at the boundary of each voxel. The integration shown on the left-hand side of (3.19) requires the pairing of estimates of the photon current $J=\mathbf{n}_{\partial\mathbb{V}_M}\cdot\boldsymbol{\Omega}\tilde{\Phi}$ from the forward simulation with the estimation of the photon flux Φ^* from the adjoint simulation. Upon exiting a voxel $\mathbb{V}$, both the location and orientation of the photon's track are assigned to one of $N_{\partial\mathbb{V}}\cdot N_\mu\cdot N_\phi$ spatial-angular bins:

$$\Delta_{ijk}:\begin{cases}\mathbf{r}\in\partial\mathbb{V}_i, & i=1,\ldots,N_{\partial\mathbb{V}},\\ \frac{2(j-1)}{N_\mu}<(\mu+1)\le\frac{2j}{N_\mu}, & j=1,\ldots,N_\mu,\\ \frac{2\pi(k-1)}{N_\phi}<\phi\le\frac{2\pi k}{N_\phi}, & k=1,\ldots,N_\phi.\end{cases} \tag{4.1}$$

Each solid angle bin is determined by $\mu=\cos\theta$ and ϕ, where θ is the polar angle and ϕ is the azimuthal angle. The north pole for the directional system is taken to be the outward-pointing normal on each voxel side. Trajectories in the forward simulation that *exit* bin Δ_{ijk} are matched with trajectories in the adjoint simulation that *enter* the same angular bin. We determine $P(V \cap D)$ for each voxel $\mathbb{V}$ by summing the product of the tallies of the forward and adjoint photons in the matched spatial-angular pairs over all bins:

$$P(V \cap D) = \sum_{i}^{N_{\partial \mathbb{V}}} \sum_{j}^{N_\mu} \sum_{k}^{N_\phi} J_{ijk} \Phi^*_{ijk} \Delta \partial \mathbb{V}_i \Delta \mu_j \Delta \phi_k. \tag{4.2}$$

In (4.2), J_{ijk} is estimated by tallying the photon weight w_{ijk} per unit area and solid angle upon exiting the voxel surface

$$J_{ijk} = \frac{1}{N_F} \sum_{n=1}^{N_F} \frac{w^{(n)}_{ijk}}{\Delta \partial \mathbb{V}_i \Delta \mu_j \Delta \phi_k}, \tag{4.3}$$

where N_F is the number of photons launched in the forward simulation. The adjoint simulation converts the adjoint current to an adjoint flux via the relation

$$\Phi^*_{ijk} = \frac{J^*_{ijk}}{\mu_j}, \tag{4.4}$$

where μ_j is the polar cosine of the entering photon. The weight w^*_{ijk} of each adjoint photon entering the voxel surface is then used in the estimate of the adjoint current

$$J^*_{ijk} = \frac{1}{N_A} \sum_{n=1}^{N_A} \frac{w^{*(n)}_{ijk}}{\Delta \partial \mathbb{V}_i \Delta \mu_j \Delta \phi_k}, \tag{4.5}$$

where N_A is the total number of adjoint photons launched. For simplicity, we use uniform spatial and angular bins. In practice, however, we anticipate the need to utilize finer binning closer to the tissue surface and at other locations where the distribution of the light field either is highly anisotropic or possesses large spatial gradients. Sufficiently deep in the tissue, where the flux is expected to be nearly isotropic, a coarse uniform angular grid should suffice.

The variance of our $P(V \cap D)$ estimates is derived as specified in the midway method literature [20]. Specifically, the relative variances of the forward current J_{ijk} and the adjoint flux Φ^*_{ijk} are determined by

$$r^2[J_{ijk}] = \frac{\sum_{n=1}^{N_F} \left[w^{(n)}_{ijk} \right]^2}{\left[\sum_{n=1}^{N_F} w^{(n)}_{ijk} \right]^2} - \frac{1}{N_F} \tag{4.6}$$

and

$$r^2[\Phi^*_{ijk}] = \frac{1}{\mu_j^2} \left\{ \frac{\sum_{n=1}^{N_A} \left[w^{*(n)}_{ijk} \right]^2}{\left[\sum_{n=1}^{N_A} w^{*(n)}_{ijk} \right]^2} - \frac{1}{N_A} \right\}, \tag{4.7}$$

respectively. Since the quantities of J_{ijk} and Φ^*_{ijk} are estimated from forward and adjoint random walks that are sampled independently, a first-order approximation of the relative variance of their product is provided by the sum of their relative variances

$$r^2[J_{ijk} \Phi^*_{ijk}] \approx r^2[J_{ijk}] + r^2[\Phi^*_{ijk}]. \tag{4.8}$$

The variance of $P(V \cap D)$ is obtained by summing the variances of the products over all bins:

$$\sigma^2[P(V \cap D)] = \sum_i^{N_{\partial\mathbb{V}}} \sum_j^{N_\mu} \sum_k^{N_\phi} r^2[J_{ijk}\Phi^*_{ijk}]J^2_{ijk}\Phi^{*2}_{ijk}. \tag{4.9}$$

Note that (4.9) provides the variance for *each* target volume. For a fixed number of launched (forward and adjoint) photons, an increase in $N_{\partial\mathbb{V}}$, N_μ, and N_ϕ results in an increase in $r^2[J_{ijk}\Phi^*_{ijk}]$ because there are fewer photons per bin and will tend to increase the relative error in the estimate for each bin. While an increase in the number of bins will tend to increase the variance $\sigma^2[P(V \cap D)]$, it will also reduce the discretization error. Optimal choices for $N_{\partial\mathbb{V}}$, N_μ, and N_ϕ vary depending on the precise location of the voxel in the tissue. For the purposes of the results presented in this initial study, we chose uniform spatial and angular binning. An analysis of the optimal binning allocation strategy is beyond the scope of this paper and, in any event, will be highly problem-dependent.

As a means to eliminate the discretization error, we investigated a method proposed by Cramer [5] in which two sets of trajectories are launched at the voxel boundary in *exactly* opposite directions. Each set is then followed until possible detection at the source or detector. However, due to the small size of the fiber-optic source and detector and the large number of target volumes treated in our application, this method was not particularly efficient and was not employed in this study.

Note that while we are summing over all spatial-angular bins in this study, we could easily provide maps containing information for photons entering and exiting at *any* particular set of orientations or locations. This more refined information would enable an evaluation of the impact of angular variations in the light distribution on the conditional system response. Such angular detail will be especially important for voxels in regions in which the light field is highly anisotropic, for example, in the proximity of collimated sources or interfaces of refractive index mismatch.

5. Numerical results. We apply our methodology to a test case depicting epithelial tissue consisting of a thin upper cellular layer ($0 < z < 0.5$ mm) situated above a much thicker structural (stromal) layer ($z > 0.5$ mm). The goal of this study is to assess the effect of probe s-d separation on the interrogation of each layer. We first examine the forward problem; that is, we generate $P(V \cap D)$ spatial-angular maps for normal tissue. We refer to this as our "background" tissue problem. The purpose of these maps is to indicate the effectiveness of a given probe configuration to detect and isolate transformations in each of the layers associated with the formation of precancerous tissue. Simulated data of measured reflectance is then generated that contains information characterizing physiologically relevant changes in one or both layers. This measured data is then used to predict changes in the layered optical properties via an inverse solution that employs a special perturbation and differential Monte Carlo optimization method developed previously [9, 10]. For our particular study in epithelial tissue, we will discuss possible relationships between the information provided by the $P(V \cap D)$ maps and the quality of the inverse solution results.

5.1. Background tissue forward problem. We first consider a homogeneous background tissue with a refractive index $n = 1.4$ and optical properties typical of normal stromal tissue [13] at an optical wavelength of 849 nm: $\mu_a = 0.034$/mm, $\mu_s = 6.11$/mm, $g = 0.9$. Here g is the average cosine of the Henyey–Greenstein single-scattering phase function commonly used for tissue [28]. The probe configurations considered consist of both source and detector oriented normal to the tissue surface with s-d separations ranging from 1–3 mm. The source and detector have emission and acceptance angles $\theta_Q = \theta_{Q^*} = 15.3°$ relative to their central axis and are 200 μm in radius. To efficiently present the $P(V \cap D)$ results, which constitute a three-dimensional data set, we sum the results of (4.2) along the y-axis and project them onto the x-z plane in 0.1 mm × 0.1 mm pixels, each of which represents a different target volume $\mathbb{V}$.

Figure 5.1 displays the interrogation $P(V \cap D)$ maps for the background tissue. In this analysis, we compare probe features consisting of s-d separations of 1, 2, and 3 mm. In these plots, the color of every voxel represents the absolute (unscaled) conditional probability of detection (conditioned by visiting the voxel in question). We shall refer to this quantity as the "conditional system response." To enable the visualization of a greater dynamic range in $P(V \cap D)$, the colors are represented on a log scale with a spectrum ranging from large (red (10^{-8})) to small (blue (10^{-11})) probability. A dashed white line at a $z = 0.5$ mm delineates the interface between the two layers of interest. Note that in each of these maps, we display the conditional system response for each voxel. The database so constructed provides the raw material for the analysis of competing probe configurations.

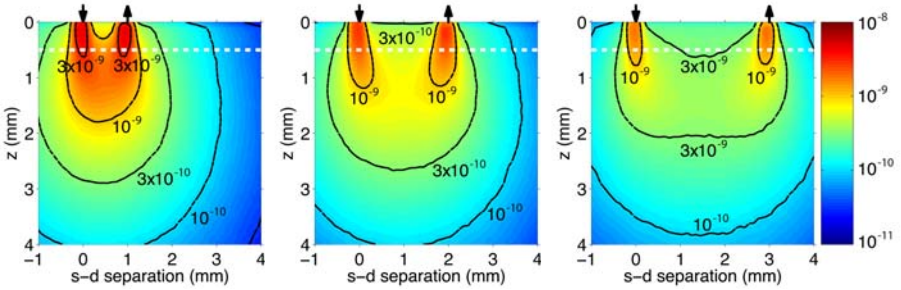

FIG. 5.1. *Interrogation map of the background problem for s-d separations of* 1, 2, *and* 3 *mm (left to right).*

The results of Figure 5.1 can be normalized by the sum of $P(V \cap D)$ over the whole domain $\mathbb{D}$ to produce a true probability density function which we will refer to as an "interrogation density function":

$$p_{V \cap D} = \frac{P(V \cap D)}{\int_{\mathbb{D}} P(V \cap D)}. \tag{5.1}$$

Equation (5.1) provides an appropriate function to assess how a particular region of interest is interrogated. This normalized function allows different probe configurations to be compared on an equivalent basis. For example, we can integrate $p_{V \cap D}$ over the top layer $\mathbb{T}$ or bottom layer $\mathbb{B}$, resulting in $\int_{\mathbb{T}} p_{V \cap D}$ and $\int_{\mathbb{B}} p_{V \cap D}$, respectively. This will provide the relative contribution from each layer to the detected signal in the form of a probability.

Figure 5.2 presents the integration of $p_{V \cap D}$ over the top and bottom layers as a function of s-d separation. These results reveal that roughly four times as much detected signal has interrogated the bottom layer as opposed to the top layer. The bottom layer probabilities increase by 4.5% (from 0.805 to 0.841) as the s-d separation increases from 1 to 3 mm, revealing that the larger s-d separations are more effective in interrogating the bottom layer than the smaller ones. Recall that by "interrogate"

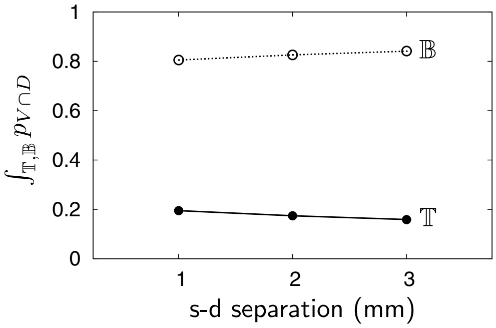

FIG. 5.2. *Interrogation density function* (5.1) *integrated over the top* $\mathbb{T}$ *and bottom* $\mathbb{B}$ *layers as a function of s-d separation.*

we mean that the light both has visited the region and is subsequently detected. This is not surprising, as the detected photons using probes with larger s-d separations will possess longer trajectories that will typically penetrate deeper into the tissue. Consistent with this bottom layer analysis, the top layer probabilities decrease by nearly 20% (from 0.195 to 0.159) as the s-d separation increases from 1 to 3 mm, indicating that the smaller s-d separations provide a considerable improvement in the interrogation of the top layer. This information drawn from our transport model assists in the design of probes for the accurate recovery of optical properties in each layer.

We next solve the inverse problem using similar probe configurations to verify the expected correlation between information given by our $P(V \cap D)$ maps and the ability of specific probe designs to determine optical property changes in one of the layers.

5.2. Perturbed tissue inverse problem. Here we discuss the impact of the interrogation maps on the accurate recovery of optical properties. To utilize information gained from our $P(V \cap D)$ maps, which are generated for various s-d separations, probes with similar features are employed for the recovery of optical properties. However, for the purpose of performing a two-parameter inverse solution, at least two detectors are required. To perform the inversion, we choose to employ six detectors to make the inverse solution more robust with respect to signal noise in the measured reflectance signal. These detectors are 200 μm in diameter and are positioned adjacent to each other to form a linear detector array that spans 1.2 mm. We solve the inverse problem with this detector array immediately adjacent to the source, resulting in s-d separations that span [0–1.2] mm. We also consider the quality of the inverse problem results in seven other configurations by moving the detector array progressively away from the source in increments of 0.2 mm. This provides measurements with eight distinct ranges of s-d separations: [0–1.2] mm, [0.2–1.4] mm, [0.4–1.6] mm, [0.6–1.8] mm, [0.8–2.0] mm, [1.0–2.2] mm, [1.2–2.4] mm, and [1.4–2.6] mm. These configurations of six detectors with a single source provide a spatially resolved measurement of reflected light. Clearly, the progressive movement of the detector array away from the source results in the interrogation of deeper layers, as already seen in Figure 5.2.

We examine two test cases that represent transformations in each layer typical of optical properties changes occurring from the development of precancer: (a) an increase in optical absorption within the lower layer due to the recruitment of increased blood flow and (b) an increase in optical scattering within the upper layer due to local cellular transformations. Simulated spatially resolved reflectance data are generated using two-region Monte Carlo simulations with 2% Gaussian noise added. Our method to determine μ_a and μ_s uses starting values taken from our background (homogeneous) case. Perturbation and differential Monte Carlo methods [9, 10, 18] are used in a two-parameter optimization algorithm to determine the changes to these optical properties, $\hat{\mu}_a = \mu_a + \delta\mu_a$ and $\hat{\mu}_s = \mu_s + \delta\mu_s$, prescribed in one of the layers that best fit the simulated measured data. The solution identifies the layer optical properties that best match the measured data in the least squares sense. Details of the inverse solution method are described elsewhere [9, 10, 18].

5.2.1. Bottom layer $\boldsymbol{\mu_a}$ perturbation. In our first test case we consider a 200% increase to μ_a relative to the background optical properties in the bottom layer. All other optical properties are held fixed. This results in the following set of optical properties: $\mu_s = 6.11$/mm, $\mu_a = 0.034$ in the top layer and $\hat{\mu}_s = 6.11$/mm, $\hat{\mu}_a = 0.068$/mm in the bottom layer. Our two-parameter inverse solution seeks to identify and decouple both $\hat{\mu}_s$ and $\hat{\mu}_a$ successfully.

Figure 5.3 displays the recovered optical properties in the bottom layer as a function of the separation between the source and the linear array of detectors. Error bars representing one standard deviation confidence intervals are shown. The solid and dashed horizontal lines represent the true $\hat{\mu}_s$ and $\hat{\mu}_a$ values in the bottom layer, respectively. The $\hat{\mu}_s$ recovery for all ranges of s-d separation is excellent. The quality of the $\hat{\mu}_a$ estimates improves as the s-d separation increases, as is evidenced by more accurate mean values and smaller confidence intervals. This is consistent with the improved interrogation of the bottom layer at larger s-d separations as predicted by Figure 5.2.

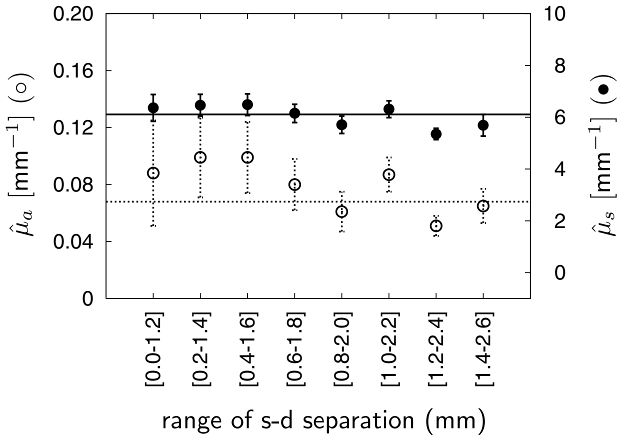

FIG. 5.3. *Recovered bottom layer absorption* (○) *and scattering* (●) *coefficients due to a* 200% μ_a *perturbation in the bottom layer as a function of the range of s-d separations provided by the detector array.*

While the inverse solution results are consistent with the features shown in Figures 5.1 and 5.2, it must be noted that these interrogation maps were generated from the background, not the perturbed system. To focus on changes in the interrogation provided by the perturbed system, we examine a map that displays the relative difference in the interrogation of the perturbed tissue as compared to the background problem (shown in Figure 5.1). Figure 5.4 provides this result, specifically a map of

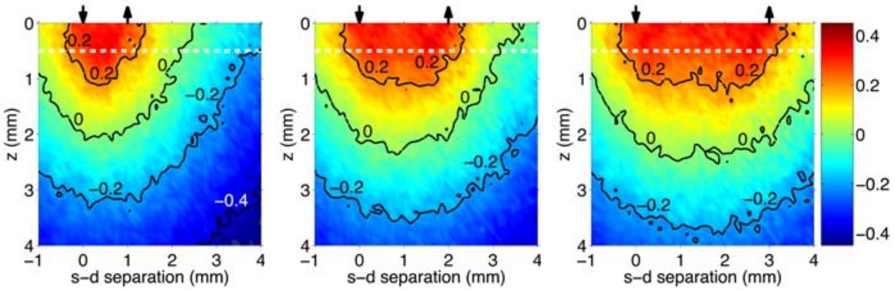

FIG. 5.4. *Plots of the relative difference between the interrogation density function for a* 200% μ_a *perturbation in the bottom layer and the background system for s-d separations of* 1, 2, *and* 3 *mm (left to right).*

$[(\hat{p}_{V\cap D} - p_{V\cap D})/p_{V\cap D}]$ for s-d separations of 1, 2, and 3 mm.

These maps display regions in which the relative difference between the interrogation of the perturbed and background medium is zero (green (0 contour)), increasingly negative (deeper blues (−0.2, −0.4 contours)), and increasingly positive (yellow-orange-red (0.2, 0.4 contours)). Negative values indicate diminished interrogation in the perturbed medium relative to the background system, while positive values indicate enhanced interrogation.

From these maps we observe that the enhancement of interrogation penetrates deeper into the bottom layer with increasing s-d separation. This is consistent with the improved inverse solution results at larger s-d separation. However, this interrogation at larger s-d separation is offset by the increased absorption in the bottom layer of the perturbed system, which depletes the detected signal. This may explain why the $\hat{\mu}_s$ predictions do not improve markedly.

To understand the contributions from each layer, we integrate the data in Figure 5.4 over the top and bottom layers, $(\int_{\mathbb{T}} \hat{p}_{V\cap D} - \int_{\mathbb{T}} p_{V\cap D})/\int_{\mathbb{T}} p_{V\cap D}$ and $(\int_{\mathbb{B}} \hat{p}_{V\cap D} - \int_{\mathbb{B}} p_{V\cap D})/\int_{\mathbb{B}} p_{V\cap D}$, respectively. From these results (shown in Figure 5.5) we see that the probability of interrogating the bottom layer is degraded slightly in the perturbed medium due to the increased absorption in that layer. Despite the detrimental effect of the increased bottom layer absorption, interrogation of the bottom layer still improves with increases of the s-d separation. This again is consistent with the inverse results shown in Figure 5.3. Figure 5.5 also displays the integrated top layer results. Although these results are not pertinent to the bottom layer inverse problem considered here, they may shed light on other inverse problems in which determination of top layer optical properties is desired within a system that is simultaneously undergoing a change in the bottom layer absorption. All top layer values are positive, indicating improved interrogation in this layer of the perturbed medium compared to the background medium due to the increased absorption in the bottom layer.

5.2.2. Top layer $\boldsymbol{\mu_s}$ perturbation. We now examine a second test case involving a 120% increase in μ_s in the top layer relative to the background value. All other optical properties in both layers are held fixed. This results in the following set of optical properties: $\hat{\mu}_s = 7.332$/mm, $\hat{\mu}_a = 0.034$/mm in the top layer and $\mu_s = 6.11$/mm, $\mu_a = 0.034$/mm in the bottom layer. Figure 5.6 displays the recovered optical properties in the top layer as a function of the separation between the source and the linear array of detectors. The results show improved estimates in the mean values of $\hat{\mu}_s$ as well as smaller confidence intervals when the linear detector array is closer to

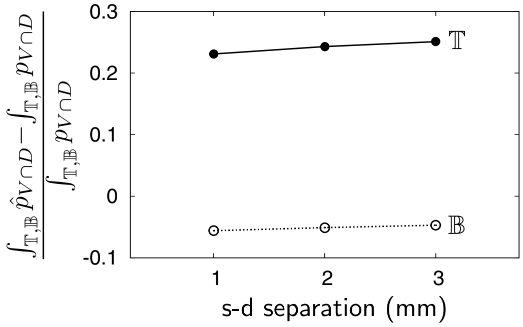

FIG. 5.5. *Relative difference between the interrogation density function for a 200% μ_a perturbation in the bottom layer versus the background, integrated over the top $\mathbb{T}$ and bottom $\mathbb{B}$ layers as a function of s-d separation.*

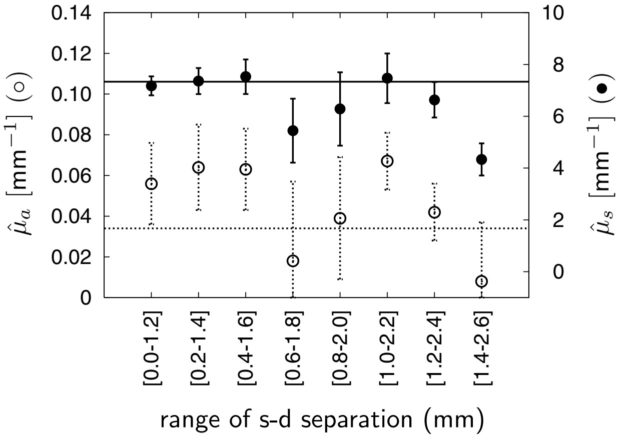

FIG. 5.6. *Recovered top layer absorption (○) and scattering (●) coefficients due to a 120% μ_s perturbation in the top layer as a function of the range of s-d separations provided by the detector array.*

the source. This is in line with the results shown in Figure 5.2 that showed improved interrogation of the top layer at the smaller s-d separations. The recovered mean values of $\hat{\mu}_a$ display no correlation with s-d separation.

For this case it is also useful to examine plots of the relative difference between the perturbed and background medium which are shown in Figure 5.7. The increased scattering in the top layer of the perturbed medium results in enhanced interrogation of this layer. This is especially true when the s-d separation is small, as evidenced by the deep red colors (0.2 contour) in the top layer. However, this enhancement dissipates rapidly as the s-d separation increases and indicates that the increased scattering in the top layer plays a diminishing role in the detected signal. This is easily discerned by focusing attention on the top layer and noticing that while this area is primarily red (0.2 contour) at small s-d separations, it rapidly changes to orange, yellow, and green (0.1 and 0 contours) at larger separations. Moreover, for even larger separations (not shown), this region changes to blue (−0.2 contour). This illustrates that as the s-d separation increases, the increased scattering in the top layer no longer provides an enhanced interrogation of the top layer. This occurs because the photon pathlengths between source and detector increase for larger s-d separations,

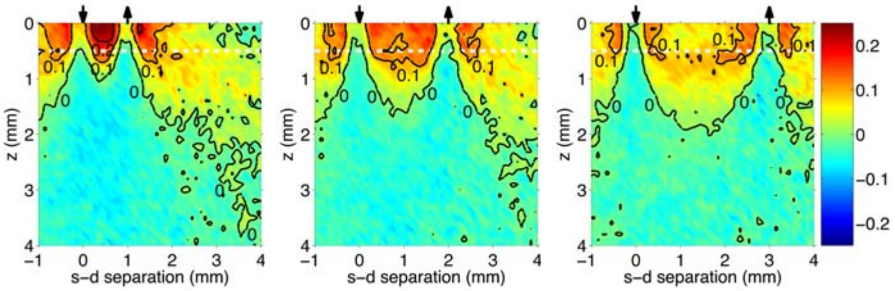

FIG. 5.7. *Plots of the relative difference between the interrogation density function for a* 120% μ_s *perturbation in the top layer and the background system for s-d separations of* 1, 2, *and* 3 *mm (left to right).*

resulting in the depletion of the detected signal by absorption in the top layer. This is the principal cause for the lack of significant improvement in the $\hat{\mu}_a$ predictions with increasing s-d separation shown in Figure 5.6.

The relative difference maps integrated over each layer are shown in Figure 5.8. These plots confirm that the integrated sampling of the top layer is enhanced in the perturbed medium but that this enhancement decreases rapidly with increasing s-d separation. Again, while the integrated bottom layer results are not directly relevant to our top layer inversion, it is interesting to observe that the increased scattering in the top layer has a diminishing effect on the bottom layer interrogation as the s-d separation increases.

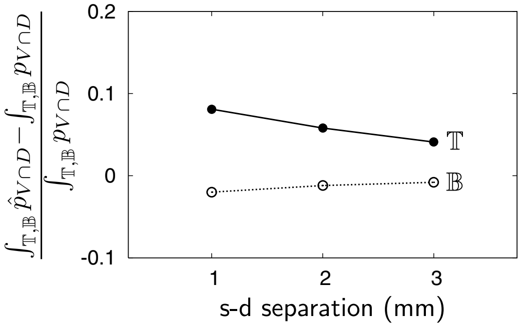

FIG. 5.8. *Relative difference between the interrogation density function for a* 120% μ_s *perturbation in the top layer versus the background, integrated over the top* $\mathbb{T}$ *and bottom* $\mathbb{B}$ *layers as a function of s-d separation.*

It is important to note that for a given medium, the $P(V \cap D)$ maps (Figures 5.1, 5.4, and 5.7) for *all* s-d separations were created from a *single* forward and a *single* adjoint Monte Carlo simulation. To achieve this degree of computational efficiency, we have made use of the symmetry of the layered problem and the probe configuration. This enables the application of linear superposition to align the two simulations for *any* selected s-d separation for the generation of the resulting $P(V \cap D)$ maps. While the use of the coupled forward-adjoint Monte Carlo technique is already more efficient than conventional Monte Carlo simulation, use of symmetry further enhances the computational efficiency of our methodology. A study of the comparative efficiency of conventional Monte Carlo simulation and the coupled forward-adjoint technique developed here is beyond the scope of this paper.

6. Summary and conclusions. We have developed a transport-based technique that determines the joint probability that photons will visit any tissue subvolume and subsequently be detected. Calculation of this conditional system response (system interrogation) is based on an extension of classical reciprocity theory for radiative transport that couples the responses of forward and adjoint Monte Carlo simulations at the boundary of any designated tissue subvolume. These maps of conditional response provide insight as to how s-d configurations affect the spatial distribution of tissue interrogation. While our maps that display the conditional system response were integrated over all angles, it is important to reiterate that angle-specific $P(V \cap D)$ maps can also be generated easily and will be of interest for many applications.

We then applied this computational methodology using data descriptive of a two-layer epithelial/stromal tissue and produced $P(V \cap D)$ maps for varying s-d separations. Moreover, we provided evidence that the maps produced by our coupled forward-adjoint Monte Carlo method provide useful and reliable guidelines for the choice of preferred probe designs, as measured by the successful recovery of optical properties from selected tissue regions.

In biomedical optics applications, the tissue volume targeted for further examination is typically large compared to both the source and detector. In these cases, the coupled forward-adjoint Monte Carlo approach will be especially advantageous from a computational efficiency standpoint. Use of variance reduction methods applied to both forward and adjoint simulations will further increase the efficiency of this new computational method.

IDENTIFYING SCATTERING OBSTACLES BY THE CONSTRUCTION OF NONSCATTERING WAVES[*]

D. RUSSELL LUKE[†] AND ANTHONY J. DEVANEY[‡]

Abstract. There are many methods for identifying the shape and location of scatterers from far field data. We take the view that the connections between algorithms are more illuminating than their differences, particularly with regard to the linear sampling method [D. Colton and A. Kirsch, *Inverse Problems*, 12 (1996), pp. 383–393], the point source method [R. Potthast, *Point Sources and Multipoles in Inverse Scattering Theory*, Chapman & Hall, London, UK, 2001], and the MUSIC algorithm [A. J. Devaney, *IEEE Trans. Antennas and Propagation*, 53 (2005), pp. 1600–1610]. Using the first two techniques we show that, for a scatterer with Dirichlet boundary conditions, there is a nontrivial incident field that does not generate a scattered field. This incident field, written as an expansion of eigenfunctions of the far field operator, is used in the MUSIC algorithm to image the shape and location of the obstacle as those points z where the incident field is orthogonal to the far field pattern due to a point source located at z. This has two intriguing applications, one for inverse scattering and the other for signal design. Numerical examples demonstrate these ideas.

Key words. inverse scattering, MUSIC, linear sampling, point source method

1. Introduction.

The inverse scattering literature abounds with methods to determine the shape of scatterers from far field data. Of principal concern here are the MUSIC algorithm [11], the linear sampling method [7], the point source method [26], and the connections between these methods. The connection between the MUSIC algorithm and Kirsch's factorization method [17] has been detailed by Cheney [5] and Kirsch [18] for scattering from point-like inhomogeneities. More recent studies [1, 16, 12, 13] approach an application of the MUSIC algorithm to scatterers of some specified size, relative to the wavelength, and are based on the finite-dimensional multistatic response matrix for point-like scatterers. Our results complement those of Hazard and Ramdani [15], although they were concerned with the mathematical justification of the decomposition of time-reversal operator (DORT) method [27]. The DORT method also relies on the asymptotic behavior of the time-reversal operator as the scatterers become small. Our goal here is to provide an analysis in the continuum of the inverse problem of determining geometric information about scatterers of arbitrary size and shape that are illuminated by fields of arbitrary frequency.

Our central result, Theorem 3.1, is built upon the linear sampling method of Colton and Kirsch [7] and shows that, on the boundary of a scatterer with Dirichlet boundary conditions, there is a nontrivial incident field that has an arbitrarily small far field pattern. With the help of the point source method of Potthast [26], we show in Corollary 3.2 that such an incident field does not generate a scattered field. Theorem 3.5 combines these results as the foundation for a MUSIC algorithm [11] for determining the shape and location of an obstacle. The technique indicates intriguing

possibilities for the construction of *nonscattering fields* that might be used to shield obstacles from interrogating waves.

To our knowledge the analysis presented here shows for the first time the feasibility of the MUSIC algorithm for determining the shape and location of Dirichlet obstacles without dependence on the size of the obstacle or the frequency of the incident field. The next section introduces our notation and the background for our main theoretical results presented in section 3. Practical implementations of a MUSIC-type algorithm are discussed in section 4. We illustrate the effectiveness of the algorithm with two examples presented in section 5.

2. Scattering background. We consider acoustic scattering of small-amplitude, monochromatic, time-harmonic waves from one or more impenetrable, sound-soft obstacles embedded in an isotropic homogeneous medium. The obstacles are identified by the domain $\Omega \subset \mathbb{R}^m$, $m = 2$ or 3. The domain Ω is assumed to be bounded with a simply connected exterior and C^2 boundary $\partial\Omega$ and the unit outward normal ν. The governing equation is the Helmholtz equation

$$\left(\triangle + k^2\right) v(x) = 0, \quad x \in \Omega^o \subset \mathbb{R}^m, \tag{2.1}$$

where $\triangle$ denotes the Laplacian, $k \geq 0$ is the wavenumber, $\Omega^o := \mathbb{R}^m \backslash \overline{\Omega}$, and the closure of the open exterior is denoted by the complement of Ω, that is, Ω^c. The surface of the obstacle is assumed to be perfectly absorbing or *sound-soft*. This is modeled with Dirichlet boundary conditions: $v = f$ on $\partial\Omega$, where f is continuous on $\partial\Omega$.

2.1. General incident fields. Let

$$v = v^i + v^s, \tag{2.2}$$

where the total field $v : \Omega^c \to \mathbb{C}$ solves (2.1) on Ω^o with boundary data

$$v(x) := 0 \quad \text{for } x \in \partial\Omega. \tag{2.3}$$

The incident field $v^i : \mathbb{R}^m \to \mathbb{C}$ solves (2.1) on $\mathbb{R}^m$. The scattered field $v^s : \Omega^c \to \mathbb{C}$ solves (2.1) on Ω^o with boundary data

$$v^s(x) = -v^i(x) \quad \text{for } x \in \partial\Omega \tag{2.4}$$

and

$$r^{\frac{m-1}{2}}\Big(\frac{\partial}{\partial r} - ik\Big)v^s(x) \to 0, \quad r = |x| \to \infty, \tag{2.5}$$

uniformly in all directions.

By Green's formula we can express the scattered field on Ω^o by the boundary integral

$$v^s(x) = \int_{\partial\Omega} \left\{ \frac{\partial\Phi(x,y)}{\partial\nu(y)} v^s(y) - \Phi(x,y) \frac{\partial v^s}{\partial\nu}(y) \right\} ds(y), \tag{2.6}$$

where $x \in \Omega^o$ and $\Phi(x,y)$ is the outgoing free-space fundamental solution to (2.1), also referred to as Green's function. As $|x| \to \infty$ one can see that the scattered field has the behavior

$$v^s(x) \;=\; \frac{e^{ik|x|}}{|x|^{\frac{(m-1)}{2}}} \left\{ v^\infty(\widehat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \to \infty, \tag{2.7}$$

where the function v^∞ is the far field pattern on the unit sphere $\mathbb{S} := \{\widehat{x} \in \mathbb{R}^m \mid |\widehat{x}| = 1\}$ given by

$$v^\infty(\widehat{x}) = \beta \int_{\partial\Omega} \left(\frac{\partial e^{-\mathrm{i}k\widehat{x}\cdot y}}{\partial\nu}(y) v^s(y) - e^{-\mathrm{i}k\widehat{x}\cdot y} \frac{\partial v^s}{\partial\nu}(y) \right) ds(y) \tag{2.8}$$

for $\widehat{x} \in \mathbb{S}$ with

$$\beta = \begin{cases} \frac{e^{\mathrm{i}\frac{\pi}{4}}}{\sqrt{8\pi k}}, & m = 2, \\ \frac{1}{4\pi}, & m = 3, \end{cases} \qquad k > 0. \tag{2.9}$$

We define next the Herglotz wave operator $\mathcal{H} : L^2(\mathbb{S}) \to H^1_{loc}(\mathbb{R}^m)$ by

$$(\mathcal{H}g)(x) := \int_{\mathbb{S}} e^{-ik\widehat{\eta}\cdot x} g(-\widehat{\eta}) ds(\widehat{\eta}), \quad x \in \mathbb{R}^m. \tag{2.10}$$

The corresponding Herglotz wave function is denoted $v_g(x) := (\mathcal{H}g)(x)$. Here H^1 denotes the Sobolev space of order 1. The signs in our definition are not standard, but they are chosen to assure consistency between the directions of incident waves and measurement points on the far field sphere. The physical interpretation of the signs is more apparent in a limited aperture setting [20].

LEMMA 2.1 (Herglotz wave functions). *Herglotz wave functions $v_g(x) := (\mathcal{H}g)(x)$ with $g \in L^2$ are dense with respect to the $H^1(\Omega)$-norm in the space of solutions to the Helmholtz equation.*

Proof. The proof is found in Theorem 2.3 of [10]. See also [9, Theorem 2.3]. □

By Lemma 2.1 and the trace theorems for elliptic equations [23], we can construct the density g_z such that $v_{g_z}(x) \approx \Phi(x,z)$ and $\frac{\partial v_{g_z}}{\partial\nu}(x) \approx \frac{\partial\Phi(x,z)}{\partial\nu}$ on $\partial\Omega$ arbitrarily closely for $z \in \Omega^o$ with respect to the $H^{1/2}$- and $H^{-1/2}$-norms, respectively. By (2.6) and (2.8), for $z \in \Omega^o$ we have

$$\begin{aligned} v^s(z) &= \int_{\partial\Omega} \left\{ \frac{\partial\Phi(z,y)}{\partial\nu(y)} v^s(y) - \Phi(z,y) \frac{\partial v^s}{\partial\nu}(y) \right\} ds(y) \\ &\approx \int_{\partial\Omega} \left\{ \frac{\partial v_{g_z}(y)}{\partial\nu(y)} v^s(y) - v_{g_z}(y) \frac{\partial v^s}{\partial\nu}(y) \right\} ds(y) \\ &= \int_{\mathbb{S}} \int_{\partial\Omega} \left\{ \frac{\partial e^{ik(-\widehat{x})\cdot y}}{\partial\nu(y)} v^s(y) - e^{ik(-\widehat{x})\cdot y} \frac{\partial v^s}{\partial\nu}(y) \right\} ds(y) g_z(-\widehat{x}) ds(\widehat{x}) \\ &= \frac{1}{\beta} \int_{\mathbb{S}} v^\infty(\widehat{x}) g_z(-\widehat{x}) ds(\widehat{x}). \end{aligned} \tag{2.11}$$

Note that the boundary of the scatterer is no longer involved in the expression for the scattered field. Moreover, the above approximation does not depend on the boundary condition. At each point $z \in \Omega^o$, by the correct choice of the density g_z, we can, in principle, reconstruct the scattered field. In the case of obstacles with Dirichlet boundary conditions, knowing the scattered field allows one to determine the shape and location of the scatterer as the zeros of the total field, or by constructing an indicator function for the scatterer via the eigenfunction expansion theorem [21]. The problem, however, is that the accuracy of this reconstruction depends on finding a density g that approximates the fundamental solution on the boundary of the scatterer, which we do not know! The point source method is concerned mainly with strategies for constructing the density g (see, for example, [24, 25, 26, 20]). Note also that the density g must contain information about the *evanescent* fields in v^s since none of this information is present in the far field pattern v^∞.

2.2. Plane wave scattering. There are two ways to view the last integral in (2.11) that distinguish many numerical methods in inverse scattering. By the first interpretation the last integral in (2.11) is an integral operator with the far field pattern v^∞ as a kernel. By the second interpretation, the kernel of the operator is the density g, and the operator acts on the far field data v^∞. These two different approaches are best illustrated by considering the case of scattering from incident plane waves

$$u^i(x;\widehat{\eta}) := e^{ik(\widehat{\eta})\cdot x}, \tag{2.12}$$

where the incident field is parameterized by the direction of propagation $\widehat{\eta} \in \mathbb{S}$. The corresponding scattered field and far field patterns are denoted $u^s(x;\widehat{\eta})$ and $u^\infty(\widehat{x},\widehat{\eta})$.

When the scattering is from an incident plane wave with direction $\widehat{\eta}$, we define the *far field operator* $\mathcal{F} : L^2(\mathbb{S}) \to L^2(\mathbb{S})$:

$$\mathcal{F}f(\widehat{x}) := \int_{\mathbb{S}} u^\infty(\widehat{x},\widehat{\eta}) f(\widehat{\eta})\ ds(\widehat{\eta}). \tag{2.13}$$

This operator corresponds to the view of (2.11) as an integral operator with the data u^∞ as the kernel. In this case (2.11) becomes

$$u^s(z;\widehat{\eta}) \approx \frac{1}{\beta}\int_{\mathbb{S}} u^\infty(\widehat{x},\widehat{\eta}) g_z(-\widehat{x}) ds(\widehat{x}) = \frac{1}{\beta}\int_{\mathbb{S}} u^\infty(-\widehat{\eta},-\widehat{x}) g_z(-\widehat{x}) ds(\widehat{x}), \tag{2.14}$$

where the last equality follows from the reciprocity relation

$$u^\infty(\widehat{x},\widehat{\eta}) = u^\infty(-\widehat{\eta},-\widehat{x}). \tag{2.15}$$

The fact that $(\mathcal{F}g_z)(-\widehat{\eta}) \approx \beta u^s(z,\widehat{\eta})$ is a coincidence of having selected the correct function g_z to operate on.

By the second interpretation the last integral in (2.11) is an integral operator with the density g_z as a kernel: $\mathcal{A}_{g_z} : L^2(\mathbb{S}) \to \mathbb{X}(z)$, defined as

$$\mathcal{A}_{g_z} f(z) := \frac{1}{\beta}\int_{\mathbb{S}} g_z(\widehat{x}) f(\widehat{x})\ ds(\widehat{x}). \tag{2.16}$$

Here we have left the image space $\mathbb{X}$ ambiguous because the dependence of the kernel of $\mathcal{A}_{g_z}$ on the points z is not specified. Acting on the far field pattern corresponding to an incident plane wave with direction $\widehat{\eta}$, the operator $\mathcal{A}_{g_z}$ can be seen to be a *backpropagation operator* that propagates the far field back to the scattered field at $z \in \Omega^o$. We will occupy ourselves mostly with the latter interpretation, but our principal tool will be the far field operator of the first interpretation.

Lemma 2.2 (far field operator). *The far field operator $\mathcal{F} : L^2(\mathbb{S}) \to L^2(\mathbb{S})$ is compact. $\mathcal{F}$ is injective with dense range if and only if there does not exist a Dirichlet eigenfunction for Ω which is a Herglotz wave function.*

Proof. Compactness follows from the fact that the kernel is continuous. For the remainder of the statement see [8, Corollary 3.18]. □

The far field operator has a useful factorization in terms of a Herglotz wave function and the mapping of radiating solutions to the Helmholtz equation from the boundary data to the far field pattern, denoted by $\mathcal{B}$.

Lemma 2.3 ($\mathcal{B}$). *Assume that k^2 is not an eigenvalue of $-\triangle$ in Ω. The mapping of radiating solutions to the Helmholtz equation from the boundary data to the far field* *pattern,* $\mathcal{B}: H^{1/2}(\partial\Omega) \to L^2(\mathbb{S})$, *is a compact, injective bounded linear operator with dense range and* range$\mathcal{B}$ = range$(\mathcal{F}^*\mathcal{F})^{1/4}$, *where* $\mathcal{F}^*$ *denotes the adjoint of the far field operator. Moreover, the far field pattern of the outgoing fundamental solution to the Helmholtz equation,* $\Phi^\infty(\cdot; z)$, *is in the range of* $\mathcal{B}$ *if and only if* $z \in \Omega$.

Proof. For the proof, see [17, Theorem 3.6] and [17, Theorem 3.7]. See also [4]. □

For any incident wave v^i restricted to $\partial\Omega$ we have $-\mathcal{B}v^i = v^\infty$, and, in particular, incident fields that can be written as superpositions of plane waves, $v^i = \mathcal{H}g$, yield the desired factorization

$$-\mathcal{B}\mathcal{H}g = \mathcal{F}g. \tag{2.17}$$

We slightly abuse the notation since, by our definitions of $\mathcal{H}$ and v^i, we need to include a trace operator restricting them to the boundary $\partial\Omega$. This should be clear from the context.

3. Nonscattering fields.

The next theorem, modeled after the linear sampling method of [4], shows that there is a nontrivial density $\widehat{g}$ that converges to the null space of the far field operator.

Theorem 3.1 (normalized linear sampling). *Let* Ω *be a domain with smooth boundary and assume that* k^2 *is not a Dirichlet eigenvalue for* $-\triangle$ *on* Ω. *If* $z \in \Omega$, *then for every* $\epsilon > 0$ *there exists a solution* g_z *to*

$$\|\mathcal{F}g_z(\cdot) - \Phi^\infty(\cdot; z)\|_{L^2(\mathbb{S})} < \epsilon \tag{3.1a}$$

such that

$$\lim_{z \overset{\Omega}{\to} \partial\Omega} \|\mathcal{F}\widehat{g}_z\|_{L^2(\mathbb{S})} = 0 \quad \textit{and} \quad \lim_{z \overset{\Omega}{\to} \partial\Omega} \left\|\mathcal{H}\widehat{g}_z - \frac{f_z}{\|g_z\|_{L^2(\mathbb{S})}}\right\|_{H^{1/2}(\partial\Omega)} = 0, \tag{3.1b}$$

where

$$\widehat{g}_z := \frac{g_z}{\|g_z\|_{L^2(\mathbb{S})}} \quad \textit{and} \quad f_z \quad \textit{solves} \quad \mathcal{B}f_z(\cdot) = -\Phi^\infty(\cdot; z). \tag{3.1c}$$

Here $\overset{\Omega}{\to}$ *indicates that the limit is taken by points from within* Ω.

Proof. Our proof is modeled after that of [6, Theorem 2.2]. Since $-\Phi^\infty(\cdot; z) \in$ range$(\mathcal{B})$, by Lemma 2.3 there is a solution f_z to

$$\mathcal{B}f_z(\cdot) = -\Phi^\infty(\cdot; z). \tag{3.2}$$

By Lemma 2.1 and the trace theorem [23], since k^2 is not a Dirichlet eigenvalue for the negative Laplacian on Ω, the Herglotz wave operator is injective with dense range in $H^{1/2}(\partial\Omega)$. Hence for any $\epsilon' > 0$ there is a solution $g_z \in L^2(\mathbb{S})$ to

$$\|\mathcal{H}g_z - f_z\|_{H^{1/2}(\partial\Omega)} \leq \epsilon' \tag{3.3}$$

and hence

$$\left\|\mathcal{H}\widehat{g}_z - \frac{f_z}{\|g_z\|_{L^2(\mathbb{S})}}\right\|_{H^{1/2}(\partial\Omega)} \leq \frac{\epsilon'}{\|g_z\|_{L^2(\mathbb{S})}}. \tag{3.4}$$

Then by the continuity of $\mathcal{B}$ and the factorization (2.17) we have

$$\left\|-\mathcal{F}\widehat{g}_z(\cdot) + \frac{\Phi^\infty(\cdot; z)}{\|g_z\|_{L^2(\mathbb{S})}}\right\| = \left\|\mathcal{B}\mathcal{H}\widehat{g}_z - \mathcal{B}\frac{f_z}{\|g_z\|_{L^2(\mathbb{S})}}\right\|_{H^{1/2}(\partial\Omega)} \leq \frac{\epsilon}{\|g_z\|_{L^2(\mathbb{S})}}, \tag{3.5}$$

where ϵ' is small enough that $C\epsilon' < \epsilon$, where C is the norm of $\mathcal{B}$. Now as $z \to \partial\Omega$, we have $f_z(x) \to -\Phi(x,z)$ for $x \in \partial\Omega$; hence $\|f_z\|_{H^{1/2}(\partial\Omega)} \to \infty$ as $z \to \partial\Omega$. Since f_z is approximated by $\mathcal{H}g_z$, it then follows that $\|\mathcal{H}g_z\|_{H^{1/2}(\partial\Omega)} \to \infty$ as $z \to \Omega$. Note also that $\|\mathcal{H}g_z\|_{H^{1/2}(\partial\Omega)} \le \|\mathcal{H}g_z\|_{H^1(\Omega)}$; thus by the Cauchy–Schwarz inequality we have $\|g_z\|_{L^2(\mathbb{S})} \to \infty$ as $z \to \partial\Omega$. In light of (3.5) this yields

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} \left\| -\mathcal{F}\widehat{g}_z(\cdot) + \frac{\Phi^\infty(\cdot;z)}{\|g_z\|_{L^2(\mathbb{S})}} \right\| = \lim_{z \xrightarrow{\Omega} \partial\Omega} \|\mathcal{F}\widehat{g}_z\| = 0,$$

while by (3.4) we have

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} \left\| \mathcal{H}\widehat{g}_z - \frac{f_z}{\|g_z\|_{L^2(\mathbb{S})}} \right\|_{H^{1/2}(\partial\Omega)} = 0.$$

This completes the proof. □

Note that we make no statement about the behavior of $f_z/\|g_z\|_{L^2(\mathbb{S})}$ as $z \xrightarrow{\Omega} \partial\Omega$; hence it is unclear from (3.1b) what the behavior of $\mathcal{H}g_z$ is in the limit as $z \xrightarrow{\Omega} \partial\Omega$. It is an open problem to characterize the rate at which $\|g_z\| \to \infty$ and $\|f_z\| \to \infty$.

Since the far field pattern is zero if and only if there is no scattered field, the above theorem implies that the incident Herglotz wave function $\mathcal{H}\widehat{g}_z$ does not scatter in the limit as $z \to \partial\Omega$. That is, the following corollary holds.

COROLLARY 3.2 (nonscattering incident fields). *Fix any $\epsilon > 0$ and let g_z satisfy* (3.1a) *with*

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} \|\mathcal{F}\widehat{g}_z\|_{L^2(\mathbb{S})} = 0 \quad \text{and} \quad \lim_{z \xrightarrow{\Omega} \partial\Omega} \left\| \mathcal{H}\widehat{g}_z - \frac{f_z}{\|g_z\|_{L^2(\mathbb{S})}} \right\|_{H^{1/2}(\partial\Omega)} = 0,$$

where

$$\widehat{g}_z := \frac{g_z}{\|g_z\|_{L^2(\mathbb{S})}} \quad \text{and} \quad f_z \quad \text{solves} \quad \mathcal{B}f_z(\cdot) = -\Phi^\infty(\cdot;z).$$

Then the scattered field, $v^s_{\widehat{g}_z}$, corresponding to the incident Herglotz wave function $v^i_{\widehat{g}_z} = \mathcal{H}\widehat{g}_z$, has the behavior

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} v^s_{\widehat{g}_z}(x) = 0 \quad \text{for} \quad x \in \Omega^o, \qquad \text{while} \qquad \lim_{x \xrightarrow{\Omega^o} \partial\Omega} \lim_{z \xrightarrow{\Omega} \partial\Omega} v^i_{\widehat{g}_z}(x) = 0.$$

Our proof relies on the backpropagation interpretation of (2.11) that is central to the point source method.

LEMMA 3.3 (backpropagation). *Assume that k^2 is not a Dirichlet eigenvalue of $-\triangle$ on Ω and let $x \in \Omega^o$. Given any $\delta' > 0$, there exists an $\epsilon'(x) > 0$ such that for all $p_x \in L^2(\mathbb{S})$ satisfying*

$$\left\| \Phi(\cdot,x) - \mathcal{H}p_x(\cdot) \right\|_{H^{1/2}(\partial\Omega)} < \epsilon'(x) \tag{3.6}$$

one has

$$\left| u^s(x,\widehat{\eta}) - (\mathcal{A}_{p_x}u^\infty)(x,\widehat{\eta}) \right| < \delta', \tag{3.7}$$

where $\mathcal{A}_{p_x}$ is defined by (2.16).

Proof. The proof is a special case of [26, Theorem 5.1.2]. See also [20, Theorem 1]. □

Proof of Corollary 3.2. To show the first limit we construct a backpropagation operator $\mathcal{A}_{p_x}$ to approximate $v^s_{\widehat{g}_z}$. For $\delta' > 0$ and $x \in \Omega^o$, by Lemma 3.3 there is an $\epsilon'(x) > 0$ such that $p_x \in L^2(\mathbb{S})$ satisfying (3.6) also satisfies (3.7). The existence of such a p_x follows from the denseness of the Herglotz wave operator. Next denote

$$v^\infty_{\widehat{g}_z} := \mathcal{F}\widehat{g}_z, \tag{3.8}$$

where $\widehat{g}_z$ is the density in Theorem 3.1. By [8, Lemma 3.16] the scattered field corresponding to $v^\infty_{\widehat{g}_z}$ is

$$v^s_{\widehat{g}_z}(x) = \int_{\mathbb{S}} u^s(x; -\widehat{\eta})\widehat{g}_z(-\widehat{\eta})\ ds(\widehat{\eta}); \tag{3.9}$$

hence by (2.16), (3.9), and the Cauchy–Schwarz inequality

(3.10)

$$\begin{aligned}
&\left|v^s_{\widehat{g}_z}(x) - (\mathcal{A}_{p_x} v^\infty_{\widehat{g}_z})(x)\right| \\
&\quad = \left| \int_{\mathbb{S}} u^s(x; -\widehat{\eta})\widehat{g}_z(-\widehat{\eta})\ ds(\widehat{\eta}) - \frac{1}{\beta}\int_{\mathbb{S}} p_x(\widehat{y}) \left(\int_{\mathbb{S}} u^\infty(\widehat{y}; -\widehat{\eta})\widehat{g}_z(-\widehat{\eta})\ ds(\widehat{\eta}) \right)\ ds(\widehat{y}) \right| \\
&\quad = \left| \int_{\mathbb{S}} \widehat{g}_z(-\widehat{\eta}) \left(u^s(x; -\widehat{\eta}) - \frac{1}{\beta}\int_{\mathbb{S}} p_x(\widehat{y}) u^\infty(\widehat{y}; -\widehat{\eta})\ ds(\widehat{y}) \right)\ ds(\widehat{\eta}) \right| \\
&\quad < C\delta' \|\widehat{g}_z\|_{L^2(\mathbb{S})} = C\delta',
\end{aligned}$$

where C is the surface area of the unit sphere. For x and δ' fixed, $\mathcal{A}_{p_x}$ is bounded and linear, independent of $\widehat{g}_z$; thus, since $\lim_{z \xrightarrow{\Omega} \partial\Omega} \|v^\infty_{\widehat{g}_z}\|_{L^2(\mathbb{S})} = 0$, it follows that $\lim_{z \xrightarrow{\Omega} \partial\Omega} |\mathcal{A}_{p_x} v^\infty_{\widehat{g}_z}(x)| = 0$. Hence by (3.10) and the triangle inequality,

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} \left|v^s_{\widehat{g}_z}(x) - (\mathcal{A}_{p_x} v^\infty_{\widehat{g}_z})(x)\right| = \lim_{z \xrightarrow{\Omega} \partial\Omega} |v^s_{\widehat{g}_z}(x)| < C\delta' \tag{3.11}$$

for arbitrary $\delta' > 0$, which completes the proof of the first statement.

To see the corresponding incident field behavior, note that the total field $v^i_{\widehat{g}_z} + v^s_{\widehat{g}_z}$ is continuous and since Ω has Dirichlet boundary conditions,

$$(v^i_{\widehat{g}_z} + v^s_{\widehat{g}_z})(x) = 0 \quad \text{for} \quad x \in \partial\Omega.$$

Thus, given any $\epsilon'' > 0$, there is a $\rho > 0$ such that for all $z \in \Omega$ and $x \in \Omega^o$ with dist $(x, \Omega) < \rho$, we have

$$|v^i_{\widehat{g}_z}(x) + v^s_{\widehat{g}_z}(x)| < \frac{\epsilon''}{2}.$$

Now, since $\lim_{z \xrightarrow{\Omega} \partial\Omega} |v^s_{\widehat{g}_z}| = 0$ pointwise, we have by the triangle inequality, $|v^i_{\widehat{g}_z}(x)| \leq \epsilon''$ for arbitrary $\epsilon'' > 0$ and x near enough to $\partial\Omega$. This completes the proof. □

Remark 3.4. By Theorem 3.1, the fact that $\lim_{x \xrightarrow{\Omega^o} \partial\Omega} \lim_{z \xrightarrow{\Omega} \partial\Omega} v^i_{\widehat{g}_z}(x) = 0$ implies that the gradient of this field is the sole contribution to the $H^{1/2}$-norm on $\partial\Omega$. Also note that we have made no assumptions about the frequency or the size of the scatterers, other than to assume that the wavenumber is not a Dirichlet eigenvalue for the scatterer.

Following [15] we interpret the integral operator on the right-hand side of (2.14) as a time-reversal operator for the multistatic data of an antenna array arranged on the aperture $\mathbb{S}$ emitting time-harmonic fields. A transducer located at $r\widehat{\eta}$ for $r \gg 1$ emits a spherically spreading field $\Phi(r\widehat{\eta}, x)$ which, in the region of the scatterer Ω, is approximately the plane wave $u^i(x, -\widehat{\eta})$. The resulting scattered field is measured in the far field at the antenna element located at $r\widehat{x}$. The recorded data $u^\infty(\widehat{x}, -\widehat{\eta})$ is reversed, or backpropagated, in order to reconstruct the scattered field around the obstacle. This multistatic data array is thus the discrete realization of the far field operator $\mathcal{F}$. The connection between the MUSIC algorithm and Kirsch's factorization method for scattering from an inhomogeneous medium has been detailed in [5, 18]. We will have more to say about the discrete operator in section 4.2, where we investigate the spatial resolution as a function of the far field sampling frequency and the number of incident fields.

Denote the singular system of $\mathcal{F}$ by $(\sigma_n, \xi_n, \psi_n)$, where

$$\mathcal{F}\xi_n = \sigma_n\psi_n \quad \text{and} \quad \mathcal{F}^*\psi_n = \sigma_n\xi_n \tag{3.12}$$

with singular values $|\sigma_n| > |\sigma_m|$ for $m > n$, and left and right singular functions ψ_n and ξ_n, respectively. Then, by (2.14), for the correct g_z we have

$$\mathcal{F}^* u^s(z, \cdot) \approx \Psi\Sigma\Xi^* g_z,$$

where Ψ and Ξ are the singular operators corresponding to ψ_n and ξ_n, respectively, and Σ is a diagonal operator with the singular values σ_n on the diagonal.

By Lemma 2.2, $\mathcal{F}$ has at most a countable number of discrete eigenvalues with zero as the only possible cluster point. In fact, zero is an eigenvalue if and only if k^2 is an eigenvalue of the negative Laplacian on the interior of Ω with corresponding eigenfunction a Herglotz wave function. Such k, if they exist, form a discrete set [23]. Thus, the null space of $\mathcal{F}$ is almost always trivial, though the eigenvalues decay exponentially by the analyticity of the kernel of $\mathcal{F}$.

The MUSIC algorithm is based on the observation that the set of Green's functions

$$\Phi^\infty(\widehat{\eta}; z) := \lim_{r\to\infty} \Phi(r\widehat{\eta}, z) = \beta e^{\mathrm{i}k(-\widehat{\eta})\cdot z}, \tag{3.13}$$

for z near $\partial\Omega$ and all $\widehat{\eta} \in \mathbb{S}$, are nearly orthogonal to the *noise subspace* of $\mathcal{F}$. We discuss what we mean by the noise subspace in more detail in the next section. In precise terms we have the following theorem.

THEOREM 3.5 (MUSIC). *Let Ω be a domain with smooth boundary and assume that k^2 is not a Dirichlet eigenvalue for the negative Laplacian on Ω. Let $(\sigma_n, \xi_n, \psi_n)$, $n \in \mathbb{N}$, be the singular system for the far field operator $\mathcal{F}$ with $|\sigma_n| \le |\sigma_m|$ for $n > m$. Given any $\gamma > 0$, there is a vector $a \in l^2$ with $\|a\|_2 = 1$ and $\rho > 0$ such that for any $x \in \Omega^o$ satisfying* dist $(x, \Omega) < \rho$ *we have*

$$\sum_{n=1}^{\infty} \left| a_n \langle \xi_n, \Phi^\infty(\cdot; x)\rangle_{L^2(\mathbb{S})} \right| < \gamma. \tag{3.14}$$

Proof. Let g_z and $\widehat{g}_z$ satisfy (3.1a)–(3.1b). By Corollary 3.2, there are $\delta > 0$ and $\rho > 0$ such that

$$|v^i_{\widehat{g}_z}(x)| < \gamma \quad \text{whenever} \quad \text{dist}\,(z, \partial\Omega) < \delta \ (z \in \Omega) \quad \text{and} \quad \text{dist}\,(x, \Omega) < \rho \ (x \in \Omega^o). \tag{3.15}$$

The density $\widehat{g}_z$ can be written as a linear combination of the singular functions ξ_n [8, Theorem 4.8]:

$$\widehat{g}_z = \sum_{n=1}^{\infty} \widehat{a}_n \xi_n, \qquad \text{where} \qquad \widehat{a}_n = \frac{1}{\sigma_n}(\widehat{G}_z, \psi_n) \qquad \text{and} \qquad \widehat{G}_z := \mathcal{F}\widehat{g}_z. \tag{3.16}$$

This and (3.15) yield

$$\left| \sum_n \widehat{a}_n \left\langle \xi_n, u^i(x, -\cdot) \right\rangle \right| < \gamma \qquad \text{for } \operatorname{dist}(x, \Omega) < \rho. \tag{3.17}$$

Next, we construct a new density $\widetilde{g}_z$ from $\widehat{g}_z$ by rotating the coefficients $\widehat{a}_n$ in the complex plane in such a way that the sum corresponding to (3.17) is of the magnitudes of the individual terms. Define

$$\widetilde{g}_z = \sum_{n=1}^{N} \widetilde{a}_n \xi_n, \qquad \text{where} \quad \widetilde{a}_n := e^{\mathrm{i}\theta_n} \widehat{a}_n \text{ for } \theta_n := -\left(\arg(\left\langle \xi_n,\ u^i(x, -\cdot) \right\rangle) + \arg(\widehat{a}_n)\right). \tag{3.18}$$

Note first that $\|\widetilde{g}_z\|_{L^2(\mathbb{S})} = \|\widetilde{g}_z\|_{L^2(\mathbb{S})}$ and $\|\mathcal{F}\widetilde{g}_z\|_{L^2(\mathbb{S})} = \|\mathcal{F}\widehat{g}_z\|_{L^2(\mathbb{S})}$. As in the proof of Corollary 3.2 we construct a backpropagation operator $\mathcal{A}_{p_x}$ to approximate $v^s_{\widetilde{g}_z}$. For $\delta' > 0$ and $x \in \Omega^o$, by Lemma 3.3 there is an $\epsilon'(x) > 0$ such that $p_x \in L^2(\mathbb{S})$ satisfying (3.6) also satisfies (3.7). Next denote

$$v^{\infty}_{\widetilde{g}_z} := \mathcal{F}\widetilde{g}_z.$$

Again by [8, Lemma 3.16] the scattered field corresponding to $v^{\infty}_{\widetilde{g}_z}$ is

$$v^s_{\widetilde{g}_z}(x) = \int_{\mathbb{S}} u^s(x; -\widehat{\eta}) \widetilde{g}_z(-\widehat{\eta})\ ds(\widehat{\eta}); \tag{3.19}$$

hence by (2.16), (3.19), and the Cauchy–Schwarz inequality,

$$\begin{aligned} &\left| v^s_{\widetilde{g}_z}(x) - (\mathcal{A}_{p_x} v^{\infty}_{\widetilde{g}_z})(x) \right| \\ &\quad = \left| \int_{\mathbb{S}} \widetilde{g}_z(-\widehat{\eta}) \left(u^s(x; -\widehat{\eta}) - \frac{1}{\beta} \int_{\mathbb{S}} p_x(\widehat{y}) u^{\infty}(\widehat{y}; -\widehat{\eta})\ ds(\widehat{y}) \right)\ ds(\widehat{\eta}) \right| \\ &\quad < C\delta' \|\widetilde{g}_z\|_{L^2(\mathbb{S})} = C\delta', \end{aligned} \tag{3.20}$$

where C is the surface area of the unit sphere. For x and δ' fixed, $\mathcal{A}_{p_x}$ is bounded and linear, independent of $\widetilde{g}_z$; thus, since $\lim_{z \xrightarrow{\Omega} \partial\Omega} \|v^{\infty}_{\widetilde{g}_z}\|_{L^2(\mathbb{S})} = \lim_{z \xrightarrow{\Omega} \partial\Omega} \|v^{\infty}_{\widehat{g}_z}\|_{L^2(\mathbb{S})} = 0$, it follows that $\lim_{z \xrightarrow{\Omega} \partial\Omega} |\mathcal{A}_{p_x} v^{\infty}_{\widetilde{g}_z}(x)| = 0$. Hence by (3.20) and the triangle inequality,

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} \left| v^s_{\widetilde{g}_z}(x) - (\mathcal{A}_{p_x} v^{\infty}_{\widetilde{g}_z})(x) \right| = \lim_{z \xrightarrow{\Omega} \partial\Omega} |v^s_{\widetilde{g}_z}(x)| < C\delta' \tag{3.21}$$

for arbitrary $\delta' > 0$.

As in the proof of Corollary 3.2, the corresponding incident field behavior follows from the continuity of the total field and the fact that Ω has Dirichlet boundary conditions; that is, $|v^i_{\widetilde{g}_z}(x)| \leq \epsilon''$ for arbitrary $\epsilon'' > 0$ and x near enough to $\partial\Omega$. In summary, the scattered and incident fields corresponding to the density $\widetilde{g}_z$ have the behavior

$$\lim_{z \xrightarrow{\Omega} \partial\Omega} v^s_{\widetilde{g}_z}(x) = 0 \quad \text{for } x \in \Omega^o \qquad \text{and} \qquad \lim_{x \xrightarrow{\Omega^o} \partial\Omega} \lim_{z \xrightarrow{\Omega} \partial\Omega} v^i_{\widetilde{g}_z}(x) = 0;$$

hence given any $\gamma > 0$, there are $\delta > 0$ and $\rho > 0$ such that $\left|\sum_n \widetilde{a}_n \left\langle \xi_n(\cdot), u^i(x, -\cdot)\right\rangle\right| < \gamma$ whenever dist $(z, \partial\Omega) < \delta$ $(z \in \Omega)$ and dist $(x, \Omega) < \rho$ $(x \in \Omega^o)$. But by our construction of $\widetilde{a}_n$ the summands are all nonnegative real numbers; that is,

$$\sum_n \left|\widetilde{a}_n \left\langle \xi_n(\cdot), u^i(x, -\cdot)\right\rangle\right| < \gamma \quad \text{for dist } (x, \Omega) < \rho. \tag{3.22}$$

Finally, recalling that $u^i(x, -\widehat{\eta}) = \frac{1}{\beta}\Phi^\infty(\widehat{\eta}; x)$, after normalization of the coefficients $\widetilde{a}_n$ the result (3.14) follows. □

Remark 3.6. Inequality (3.17) alone could be used for imaging with the MUSIC methodology; however, the contrast of the resulting images is not strong enough for adequate results. In other words, x need not be very close to Ω in order to satisfy (3.17), and the resulting image does not have a sharp cutoff near the boundary.

4. Practical implementation.

4.1. The MUSIC algorithm. Theorem 3.1 only states that *there exists* a density $\widehat{g}_z$ that can be used to construct nonscattering incident fields; it does not, however, suggest *how* one might calculate such a density. Arens [3] has shown that for a sound-soft scatterer as we have here a regularization strategy such as Tikhonov regularization or spectral cutoff gives rise to a density with the desired properties. In other words, if at a point $z \in \Omega$ we solve (3.1a) using Tikhonov or spectral cutoff regularization, then the corresponding density $\widehat{g}_{\alpha,z}$ can be used to construct an incident field satisfying Corollary 3.2 in the limit as the regularization parameter $\alpha \to 0$. There are two reasons why this is impractical: first, we do not know where the scatterer lies, and second, we do not know about the behavior of $\widehat{g}_z$ for points $z \in \Omega^o$. Note, however, that the location of point z in the computation of the density $\widehat{g}_z$ is arbitrary, so long as it is not in the exterior of Ω. This suggests that the orthogonality of $\widehat{g}_z$ with the fundamental solution far fields $\Phi^\infty(\cdot; x)$ expressed in (3.14) is a phenomenon more intimately tied to the spectrum of the far field operator $\mathcal{F}$ than to the particular density $\widehat{g}_z$. Indeed, as (3.1b) shows, the desired density is in the "noise space" of $\mathcal{F}$. Denote the noise subspace of $\mathcal{F}$ by $\mathcal{N}_\gamma$ corresponding to the span of the singular functions ξ_n with singular values $|\sigma_n| < \gamma$ for $n > N_\gamma$. In the numerical experiments detailed below we take $\widehat{g}$ to be simply a linear combination of the elements $\xi_n \in \mathcal{N}_\gamma$ for a large enough cutoff.

In the conventional MUSIC application one usually works with the MUSIC γ-pseudospectrum defined by

$$\mathcal{P}(x) := \frac{1}{\sum_{n>N_\gamma} \left|a_n \langle \xi_n(\cdot), \Phi^\infty(\cdot; x)\rangle_{L^2(\mathbb{S})}\right|} \geq \frac{1}{\gamma}. \tag{4.1}$$

This is what is usually imaged as a function of x. Note that for $x \in \Omega^o$, we have $\mathcal{P}(x) \to \infty$ as $x \to \partial\Omega$, yielding the image of the support of the obstacle as the points where $\mathcal{P}(x)$ is large.

Our focus thus far has been on finding the location and shape of the scatterer, but the fact that the constructed incident field is arbitrarily small at the boundary of the scatterer opens the door to the construction of fields that *avoid* certain obstacles that one might like to protect, while targeting others. In other words, the constructed incident field $v^i_{\widehat{g}_z}$ effectively *does not scatter.* In order to illustrate this point, in our numerical experiments, instead of the usual MUSIC implementation, we show the *inverse* of the γ-pseudospectrum.

4.2. Resolution analysis. The analysis above is in the continuum. In any practical application one will sample the far field at a finite number of discrete points $\widehat{x}_i$ for a finite number of incident fields with direction $\widehat{\eta}_j$; that is, the far field operator $\mathcal{F}$ given by (2.13) is replaced with the discrete multistatic response matrix $F \in \mathbb{C}^{M\times N}$. In this section we apply sampling criteria derived from the physical optics approximation in order to estimate how many incident fields and far field measurements one needs in order to achieve a specified spatial resolution. Other approaches are presented in [2, 16].

The criteria we develop are based on the physical optics approximation which is valid for very large wavenumbers k. The technique discussed above is not dependent on the wavenumber. Indeed, it works especially well at small wavenumbers in the *resonance region* for the scatterer, that is, where the wavelength is on the order of the scatterer. Our estimates for sampling rates are overestimates in the sense that the spatial resolution predicted from a particular sampling rate in the far field is not as fine as what is actually achieved. The analysis of this section thus provides lower bounds on the predicted spatial resolution from a given sampling rate.

To begin, we recall the physical optics, or Kirchhoff approximation. Our treatment is standard (see [8, 19]), with the exception that our derivation also holds in $\mathbb{R}^2$. The calculation follows [20] where $\mathbb{R}^2$ and $\mathbb{R}^3$ are considered, but is short enough to include here. For very large wavenumbers, that is, very small wavelengths relative to the curvature of the obstacle, the face upon which the incident field impinges is nearly planar. As such, we can then approximate the normal derivative of the scattered field by the normal derivative of the incident field. Define Ω_+ to be the illuminated side of the scattering domain $\Omega_+ := \{x \in \partial\Omega \mid \langle \nu(x), \widehat{\eta}\rangle < 0\}$. The shadow of the scattering domain, Ω_-, is defined as $\Omega_- := \partial\Omega \setminus \overline{\Omega_+}$. The physical optics approximation for the scattered field is written

$$\frac{\partial u^s(x,\widehat{\eta})}{\partial\nu(x)} \approx \begin{cases} \frac{\partial u^i(x,\widehat{\eta})}{\partial\nu(x)}, & x \in \Omega_+, \\ -\frac{\partial u^i(x,\widehat{\eta})}{\partial\nu(x)}, & x \in \Omega_-, \end{cases} \qquad k \gg 0. \tag{4.2}$$

This leads to the physically intuitive approximation that the normal derivative of the total field is twice the normal derivative of the incident field on the illuminated side and zero on the shadow of the scatterer.

Together with the representation for the scattered field [8, Theorem 3.12],

$$u^s(x,\widehat{\eta}) = -\int_{\partial\Omega} \Phi(x,y)\frac{\partial u(y,\widehat{\eta})}{\partial\nu(y)}ds(y) \tag{4.3}$$

for $x \in \Omega^o$, the Kirchhoff approximation yields

$$u^s(x,\widehat{\eta}) \approx -2\int_{\partial\Omega_+} \Phi(x,y)\frac{\partial}{\partial\nu(y)}u^i(y,\widehat{\eta})\; ds(y), \tag{4.4}$$

and

$$u^\infty(\widehat{x},\widehat{\eta}) \approx -2\beta\int_{\partial\Omega_+} e^{-iky\cdot\widehat{x}}\frac{\partial}{\partial\nu(y)}u^i(y,\widehat{\eta})\; ds(y) = -2ik\beta\int_{\partial\Omega_+} e^{iky\cdot(\widehat{\eta}-\widehat{x})}\widehat{\eta}\cdot\nu(y)\; ds(y). \tag{4.5}$$

Similarly, on the shadow region we have

$$u^\infty(\widehat{x},-\widehat{\eta}) \approx 2\beta\int_{\partial\Omega_-} e^{-iy\cdot\widehat{x}}\frac{\partial}{\partial\nu(y)}u^i(y,-\widehat{\eta})\; ds(y) = 2ik\beta\int_{\partial\Omega_-} e^{-iky\cdot(\widehat{\eta}+\widehat{x})}\widehat{\eta}\cdot\nu(y)\; ds(y). \tag{4.6}$$

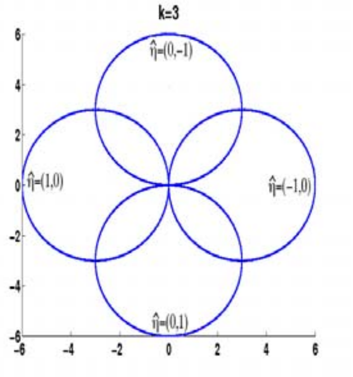

FIG. 1. *Sampling in the Fourier domain of the scatterer* Ω *corresponding to the geometry of the far field pattern in* $\mathbb{R}^2$*. The far field data are depicted here with wavenumber* $k = 3$ *at four incident fields with directions* $\widehat{\eta} = (-1,0), (0,-1), (1,0)$*, and* $(0,1)$*. For each fixed* $\widehat{\eta}$ *the far field samples are depicted here as a continuum on a full aperture* $\mathbb{S}$*.*

The divergence theorem together with (4.5)–(4.6) yields

$$\begin{aligned} u^\infty(\widehat{x},\widehat{\eta}) + \overline{u^\infty(-\widehat{x},-\widehat{\eta})} &\approx -2ik\beta \int_{\partial\Omega} e^{iky\cdot(\widehat{\eta}-\widehat{x})}\widehat{\eta}\cdot\nu(y)ds(y) + R(\widehat{x},\widehat{\eta}) \\ &= 2\beta k^2(1-\widehat{\eta}\cdot\widehat{x}) \int_{\Omega} e^{ikz\cdot(\widehat{\eta}-\widehat{x})}\,dz + R(\widehat{x},\widehat{\eta}) \\ &= 2(2\pi)^{m/2}\beta k^2(1-\widehat{\eta}\cdot\widehat{x})\widehat{\mathcal{X}_\Omega}(k(\widehat{x}-\widehat{\eta})) + R(\widehat{x},\widehat{\eta}), \end{aligned} \tag{4.7}$$

where $\widehat{\mathcal{X}_\Omega}$ is the Fourier transform on $\mathbb{R}^m (m = 2 \text{ or } 3)$ of the indicator function of the obstacle and

$$R(\widehat{x},\widehat{\eta}) = 4ik\mathrm{Im}(\beta) \int_{\partial\Omega_-} e^{iky\cdot(\widehat{\eta}-\widehat{x})}\widehat{\eta}\cdot\nu(y)ds(y). \tag{4.8}$$

In most discussions of the physical optics approximation (see, for example, [19]) the setting is $\mathbb{R}^3$, and here the remainder term does not appear since by (2.9) $\mathrm{Im}(\beta) = \mathrm{Im}(1/(4\pi)) = 0$. In $\mathbb{R}^2$, however, β is complex-valued, which gives rise to the unusual remainder term in the calculations above.

The connection to the Fourier transform above allows us to estimate the sampling requirements for the scatterer via the Whittaker–Shannon sampling theorem. Our data, the far field pattern, are in the so-called Fourier or frequency domain of the scatterer. These data lie on circles in the Fourier domain of the scatterer centered at the point $-k\widehat{\eta}$, where $\widehat{\eta}$ is the direction of the incident field. This is depicted in Figure 1.

For our purposes it is not necessary to carry out a detailed sampling calculation for the geometry shown in Figure 1—an estimate based on sampling on a rectangular grid suffices. Our discussion of the sampling theory is terse; interested readers are referred to [14] for more details. We consider a cubic lattice of samples of some smooth function φ on $\mathbb{R}^m$ defined by

$$\varphi_s := \mathrm{comb}\left(\frac{x}{\Delta x}\right)\varphi(x), \tag{4.9}$$

where Δx is distance between the samples and comb (x) is the m-dimensional "comb" function

$$\text{comb }(x) := \sum_{|n|=-\infty}^{\infty} \delta(x-n)$$

for n a multi-index depending on the dimension $m = 2$ or 3. By the convolution theorem, the Fourier spectrum of the sampled function is

$$\widehat{\varphi}_s(\xi) = (\Delta x)^m \,\text{comb }(\Delta x \xi) * \widehat{\varphi}(\xi),$$

where ξ is the Fourier dual variable to x and $*$ denotes convolution. It can be shown [14, eq. (2–53)] that the sampled Fourier spectrum has the explicit representation

$$\widehat{\varphi}_s(\xi) = \sum_{|n|=-\infty}^{\infty} \widehat{\varphi}\left(\xi - \frac{n}{\Delta x}\right), \tag{4.10}$$

where, again, n is a multi-index. If we assume that φ is bandlimited, then $\widehat{\varphi}$ has compact support. Suppose $\widehat{\varphi}$ is supported on the cube $\mathcal{R}$. If the sample spacing $1/\Delta x$ is large enough that for all $\xi \in \mathcal{R}$

$$\widehat{\varphi}\left(\xi - \frac{n}{\Delta x}\right) = \widehat{\varphi}_s\left(\xi\right),$$

then by (4.10) the sampled Fourier spectrum is just a periodic extension of the true Fourier spectrum; hence we can reconstruct φ exactly from the spectrum of the sampled function. If r is the length of the *smallest* cube that supports the spectrum of φ, then the sampled spectrum will exactly represent the true spectrum as long as

$$\Delta x \leq \frac{1}{2r}.$$

When equality holds, the sampling is said to be at the Nyquist frequency. At the Nyquist frequency, we have the Whittaker–Shannon sampling theorem

$$\varphi(x) = \sum_{|n|=-\infty}^{\infty} \varphi\left(\frac{n}{2r}\right) \text{sinc }\left(2r\left(x - \frac{n}{2r}\right)\right), \tag{4.11}$$

where sinc is the m-dimensional sinc function.

Let us suppose that the smallest feature of our scatterer is $1/M$ of the size of the illuminating wavelength. By the Whittaker–Shannon sampling theorem, a sampling rate of at least $1/(2M)$ in the physical domain represents a highest frequency component of M in each direction and thus $2M$ sample points on a Cartesian grid along each dimension in the Fourier domain. In Figure 1 we see that the "frequency domain" is covered by circles of radius k centered at $-k\widehat{\eta}$. The gaps in the frequency domain are determined by the smallest sampling rate with respect to either the direction of incidence $\widehat{\eta}$ or the far field samples $\widehat{x}$. Suppose that the far field is sampled at infinitesimal intervals and the directions of incidence are sampled at $4N$ points evenly distributed on $[-\pi, \pi]$. The largest gap in the frequency domain for this sampling geometry is bounded above by $2\pi k\sqrt{2}/N$. In order to achieve the same resolution as could be achieved by sampling on the Cartesian grid, N must be chosen so that

$$\frac{2\pi\sqrt{2}}{N} \leq \frac{1}{M}. \tag{4.12}$$

This yields a conservative lower bound on the sampling frequency N of the far field pattern and incident field directions needed to achieve a desired spatial resolution $1/M$ relative to the wavelength of the illuminating field. Since this analysis is based on the physical optics approximation, we expect these sampling requirements in the far field to be greater than what will actually be needed to resolve the scatterers. This is illustrated in section 5.

5. Examples.

5.1. An infinite cylinder. As a first example we consider scattering from an infinite cylinder over which the field satisfies homogeneous Dirichlet conditions. While this example is didactic it has the advantage that the fields have explicit formulations. Taking advantage of radial symmetry, we parameterize directions on the unit sphere $\mathbb{S}$ by the angles α, where α_i is the direction of the incident field and α_0 is the observation point on the far field sphere. The incident and scattered fields can be represented in series of Bessel and Hankel functions, respectively. Let b be the cylinder radius, and let J_n and H_n^+ denote Bessel and Hankel functions of the first kind, respectively; then

$$u^\infty(\alpha_0, \alpha_i) = -\sum_{n=-\infty}^{\infty} \frac{J_n(kb)}{H_n^+(kb)} e^{in(\alpha_i - \alpha_0)}. \tag{5.1}$$

It is easy to verify that the singular system $\{\psi_n, \xi_n, \sigma_n\}$ is, in this case, given by

$$\begin{aligned} \psi_n(\alpha_0) &= \frac{1}{\sqrt{2\pi}} e^{\pm in\alpha_0}, \quad \xi_n(\alpha_i) = \frac{e^{i\phi_n}}{\sqrt{2\pi}} e^{\pm in\alpha_i}, \\ \sigma_n &= \left| \frac{J_n(kb)}{H_j(kb)} \right|, \end{aligned} \tag{5.2}$$

where $\phi_n = \text{Arg}\,[J_n(kb)/H_n(kb)]$ and the plus sign gives one of the two singular vectors and the minus sign the second for each singular value σ_n.

For the density

$$g = \sum_n^\infty a_n \xi_n(\widehat{\eta})$$

we construct the incident Herglotz wave function

$$\begin{aligned} v_g^i(x) &:= \int_{\mathbb{S}} g(-\widehat{\eta}) u^i(x, -\widehat{\eta})\ ds(\widehat{\eta}) = \sum_n^\infty a_n v_n(x), \qquad \text{where} \\ v_n(x) &= \int_{\mathbb{S}} \xi_n(-\widehat{\eta}) u^i(x, -\widehat{\eta})\ ds(\widehat{\eta}). \end{aligned} \tag{5.3}$$

By (3.12), the corresponding far field is given by

$$v_g^\infty(\widehat{x}) := \int_{\mathbb{S}} g(-\widehat{\eta}) u^\infty(\widehat{x}, -\widehat{\eta})\ ds(\widehat{\eta}) = \sum_n^\infty a_n (\mathcal{F}\xi_n)(\widehat{x}) = \sum_n^\infty a_n \sigma_n \psi_n(\widehat{x}). \tag{5.4}$$

For this simple geometry, the incident and scattered fields have explicit formulations. The scattered field corresponding to v_g^i has the representation

$$v_g^s = \sum_n a_n \sigma_n v_n^s(x), \qquad \text{where} \qquad v_n^s(x) = \int_{\mathbb{S}} \xi_n(-\widehat{\eta}) u^s(x, -\widehat{\eta}) ds(\widehat{\eta}) \tag{5.5}$$

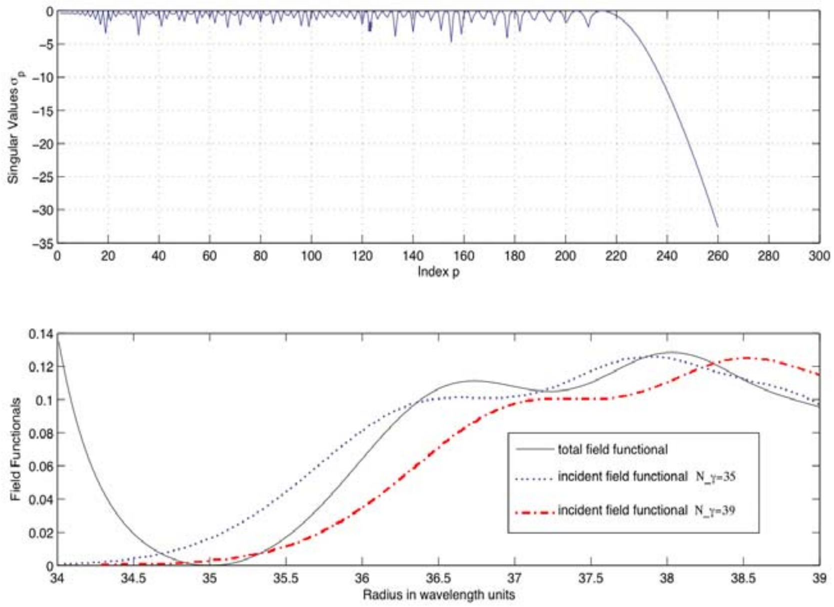

FIG. 2. *Top: Plot of the singular values $\sigma_n = |J_n(kb)/H_n(kb)|$ with $k = 1$ for a cylinder having radius $b = 35$. Bottom: Plots of the left-hand side of* (5.8) *and the right-hand side of this equation for $N_\gamma = 35$, for $\overline{N} = N_\gamma + 20$, and for $b = 35$. Also shown is a plot of the right-hand side of this equation for the case where $N_\gamma = 39$.*

and u^s is the scattered field corresponding to an incident plane wave. In cylindrical polar coordinates, $x = (r, \theta)$, this simplifies to

$$v_n^i(r,\theta) = \sqrt{2\pi} i^n J_n(kr) e^{\pm in\theta}, \tag{5.6}$$

$$v_n^s(r,\theta) = \sqrt{2\pi} e^{i\phi_n} i^n H_n^+(kr) e^{\pm in\theta}. \tag{5.7}$$

For details see [22].

For a Dirichlet obstacle, the total field is zero on the boundary, and, by Theorem 3.5, the incident field constructed from the finite collection of singular functions from N_γ to $\overline{N}$ is approximately zero:

$$\begin{aligned} &\lim_{r\to b} \sum_{n=N_\gamma}^{\overline{N}} \left| J_n(kr) - \frac{J_n(kb)}{H_n(kb)} H_n(kr) \right|^2 \\ &\approx \lim_{r\to b} \sum_{n=N_\gamma}^{\overline{N}} |J_n(kr)|^2 \approx 0 \end{aligned} \tag{5.8}$$

with $\overline{N} > N_\gamma$ and N_γ such that $\sigma_n < \gamma$, for all $n > N_\gamma$.

We present a plot of the singular values $\sigma_n = |J_n(kb)/H_n(kb)|$ using unit wavelength ($k = 2\pi$) and cylinder radius $b = 35\lambda = 35$ in the top of Figure 2. It is clear from this figure that the cutoff $N_\gamma \approx [kb] \approx 220$, where $[x]$ indicates the nearest integer approximation of x. In the bottom of the figure we show plots of the sums on

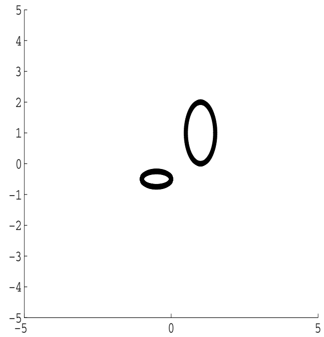

FIG. 3. *Sound-soft obstacles to be recovered.*

the left- and right-hand sides of (5.8) for the cases where $N_\gamma = [kb]$, $N_\gamma = [kb] + 4$, and $\overline{N} = N_\gamma + 20$. The boundary of the cylinder is identified by where the incident field amplitude falls below a chosen cutoff. If this cutoff is chosen to be .02, then one would estimate the radius of the cylinder to be about 35 for the case $N_\gamma = 35$, while one would estimate the radius to be 36 for the case $N_\gamma = 39$. We obtained similar results for other choices of the cylinder radius b. We observed in our experiments that the sharpness of the zero of the constructed incident field at the boundary depends on the cutoff N_γ. The closer N_γ is to the optimal cutoff, kb, the higher the contrast.

5.2. Two ellipses. Our second example is of two ellipses in $\mathbb{R}^2$ shown in Figure 3. We use potential theoretic techniques to calculate the far field pattern for an incident plane wave. We introduce the acoustic single- and double-layer operators given, respectively, by

$$(S\varphi)(x) := 2\int_{\partial\Omega} \varphi(y)\Phi(x,y)\; ds(y), \quad x \in \partial\Omega,$$

$$(K\varphi)(x) := 2\int_{\partial\Omega} \varphi(y)\frac{\partial\Phi(x,y)}{\partial\nu(y)}\; ds(y), \quad x \in \partial\Omega, \tag{5.9}$$

where Φ is the two-dimensional outgoing free-space fundamental solution to the Helmholtz equation, a zeroth-order Hankel function of the first kind. It can be shown [8] that, if the potential φ satisfies the integral equation

$$(I + K - \mathrm{i}S)\varphi(\cdot;\widehat{\eta}) = -u^i(\cdot;\widehat{\eta}), \tag{5.10}$$

then the scattered and far fields are given by

$$u^s(x,\widehat{\eta}) = \int_{\partial\Omega} \left(\frac{\partial\Phi(x,y)}{\partial\nu(y)} - \mathrm{i}\Phi(x,y)\right)\varphi(y;\widehat{\eta})\; ds(y), \quad x \in \Omega^o, \tag{5.11a}$$

$$u^\infty(\widehat{x};\widehat{\eta}) = \beta\int_{\partial\Omega} \left(\frac{\partial e^{-\mathrm{i}\kappa\widehat{x}\cdot y}}{\partial\nu(y)} - \mathrm{i}e^{-\mathrm{i}\kappa\widehat{x}\cdot y}\right)\varphi(y;\widehat{\eta})\; ds(y), \quad \widehat{x} \in \mathbb{S}. \tag{5.11b}$$

We do not use a sophisticated quadrature rule to resolve the point source on the boundary. This introduces a numerical error of about 10% which has the advantage of introducing noise into our calculations, albeit systematic noise.

For $x \in \mathbb{R}^2$ fixed, we calculate the nonscattering incident field v_g^i shown in Figures 4–6 as

$$v_g^i(x) = \sum_{n=N_\gamma}^{\overline{N}} |v_n^i(x)|, \tag{5.12}$$

where v_n^i is given by (5.3). The corresponding scattered field is $v_g^s = \sum_{n=N_\gamma}^{\overline{N}} \sigma_n v_n^s(x)$ for v_n^s given by (5.5) with u^s given by (5.11a).

To illustrate the resolution limits we sample the far field at $\overline{N} = 16$, 32, 64, and 128 points uniformly distributed over $\mathbb{S}$ with 16, 32, 64, and 128 incident field directions, respectively, also uniformly distributed over $\mathbb{S}$. The wavenumber is $k = 3$, and the smaller ellipse has minor axis of radius 0.25. By the resolution analysis of section 4.2, our smallest physical feature is 1/6 the illuminating wavelength, which according to (4.12) suggests that we need to sample the far field at $N \geq 2\pi\sqrt{2}(6) \approx 53$ points with more than 53 incident directions. This is more than is actually required, as an examination of the singular values of the far field operator shows. In Figure 4 we show the magnitude of the constructed incident field for $\overline{N} = 32$ through 128 with $N_\gamma = \overline{N} - 12$. This value of N_γ was chosen based on the decay of the singular values shown in the left column of Figure 4. The singular values decay rapidly after the 7th singular value as predicted by the eventual exponential decay of the singular values of the far field operator. They flatten out, however, beyond the 20th singular value because of the error, or noise, in our calculation of the far field pattern. In other words, the 20th and higher singular vectors of the far field operator appear to be in the noise subspace. For a sampling rate of 32, we have $N_\gamma = \overline{N} - 12 = 20$, and our constructed incident field then consists of all available singular vectors in the noise subspace. For higher sampling rates of 64 and 128 there is not a significant difference in resolution when only the last 12 singular vectors are used.

The case $\overline{N} = 16$ shown in Figure 5 illustrates the reduction in resolution that results from constructing the incident field from singular vectors that are not in the noise subspace of $\mathcal{F}$. In Figure 5(b) we used the 12 smallest singular vectors to construct the incident field. As Figure 5(a) shows, most of these are still well within the signal subspace of the far field operator. With only the last 4 singular vectors we are able to achieve remarkably good results, as demonstrated in Figure 5(c).

To illustrate the relative robustness of the method with respect to the choice of the cutoff N_γ, so long as it is above the critical cutoff, in Figure 6 we show the constructed incident field with $N_\gamma = 25, 78$, and 124. The incident fields are not normalized in order to gauge the relative contrast between the images.

To verify that the constructed scattered field, v_g^s, is indeed small outside the scatterer, we show in Figure 7 the computed scattered field using (5.5). The constructed scattered field is $O(10^{-13})$ around the scatterer and decays to zero rapidly away from the scatterer. The corresponding incident field, in contrast, is at least $O(10^{-4})$ on the exterior of the scatterer. This demonstrates Corollary 3.2.

6. Conclusion. Our main results, Theorem 3.1, Corollary 3.2, and Theorem 3.5, show that there is a density $\widehat{g}$ that approaches, nontrivially, the null space of the far field operator corresponding to some fixed, smooth scatterers. A superposition of plane waves weighted by such a density is a nonscattering incident field for these scatterers. The density can be constructed from the singular functions of the far field operator and the nonscattering phenomenon understood as the orthogonality of the singular functions to the far field pattern of a point source with sources located on

the boundary of the scatterer. Our statement of Theorem 3.1 also raises unanswered questions about the rate of blowup of the densities in the linear sampling method.

The point source method of Potthast [24, 25] rests on the approximation of the scattered field u^s by computing the correct density for the construction of a *backpropagation* operator (2.16). As already noted, constructing such a density is a nontrivial task since this requires some knowledge of the boundary of the scatterer which we assume is unknown. The linear sampling method approaches the problem of finding the shape and location of the scatterer by looking for points where the fundamental solution far field pattern is not in the range of the far field operator, but still, one must solve an ill-posed linear integral equation at each point in some computational domain. One of the disadvantages of the linear sampling methodology, however, is that, since it is not constructive, it provides very little information about numerical

algorithms. Any numerical implementation will involve some sort of regularization strategy. The actual behavior of regularized solutions, or indeed any indication that a particular regularization strategy will deliver the desired behavior, remains open with the exception of the analysis of [3].

Our numerical experiments indicate, however, that particular details about implementing the linear sampling or point source methods are somewhat beside the point: it is not necessary to create an approximate domain as with the point source method, nor is it necessary to solve many ill-posed linear integral equations as in the linear sampling method. We need only work with incident plane waves and the known singular functions of the far field operator. This remains to be proved. We believe that

the answer lies with a closer examination of the connections between linear sampling and the factorization method as detailed in [3]. This is the subject of future research.

These results have intriguing implications for inverse scattering and signal design. The method works very much like the linear sampling method for inverse scattering in that the proposed incident field is constructed from the measured far field data and the scatterer is identified by those points in the domain where the incident field (and scattered field) is small. For signal design the method opens the door to the possibility of constructing signals that avoid certain known obstacles while irradiating others. Our application of the linear sampling method to the MUSIC algorithm is novel and clarifies the connections between many different inverse scattering approaches.

CONVECTIVE STABILIZATION OF A LAPLACIAN MOVING BOUNDARY PROBLEM WITH KINETIC UNDERCOOLING[*]

UTE EBERT[†], BERNARD MEULENBROEK[‡], AND LOTHAR SCHÄFER[§]

Abstract. We study the shape stability of disks moving in an external Laplacian field in two dimensions. The problem is motivated by the motion of ionization fronts in streamer-type electric breakdown. It is mathematically equivalent to the motion of a small bubble in a Hele–Shaw cell with a regularization of kinetic undercooling type, namely, a mixed Dirichlet–Neumann boundary condition for the Laplacian field on the moving boundary. Using conformal mapping techniques, linear stability analysis of the uniformly translating disk is recast into a single PDE which is exactly solvable for certain values of the regularization parameter. We concentrate on the physically most interesting exactly solvable and nontrivial case. We show that the circular solutions are linearly stable against smooth initial perturbations. In the transformation of the PDE to its normal hyperbolic form, a semigroup of automorphisms of the unit disk plays a central role. It mediates the convection of perturbations to the back of the circle where they decay. Exponential convergence to the unperturbed circle occurs along a unique slow manifold as time $t \to \infty$. Smooth temporal eigenfunctions cannot be constructed, but excluding the far back part of the circle, a discrete set of eigenfunctions does span the function space of perturbations. We believe that the observed behavior of a convectively stabilized circle for a certain value of the regularization parameter is generic for other shapes and parameter values. Our analytical results are illustrated by figures of some typical solutions.

Key words. moving boundaries, kinetic undercooling, Laplacian growth, streamer discharges, convective stabilization

1. Introduction.

1.1. Problem formulation in physical and mathematical context.

The mathematical model considered in this paper is motivated by the physics of electric breakdown of simple gases like nitrogen or argon [1, 2, 3, 4, 5]. During the initial "streamer" phase of spark formation, a weakly ionized region extends in a strong externally applied electric field. As the ionized cloud is electrically conducting, it screens the electric field from its interior by forming a thin surface charge layer. This charged layer moves by electron drift within the local electric field and creates additional ionization, i.e., additional electron-ion pairs, by collisions of fast electrons with neutral molecules. We here approximate the ionized and hence conducting bulk of the streamer as equipotential. In the nonionized and hence electrically neutral region outside the streamer, the electric field obeys the Laplace equation. The thin surface charge layer can be approximated as an interface which moves according to

the electric field extrapolated from the neutral region onto the interface. We therefore are concerned with a typical moving boundary problem.

Such moving boundary problems occur in various branches of physics, chemistry, or biology. The most extensively studied examples are viscous fingering observed in two-fluid flows [6] or the Stefan problem of solidification from an undercooled melt [7]. Other physical phenomena like the motion of voids in current carrying metal films [8] lead to similar mathematical models [9].

We here discuss the streamer model in two spatial dimensions, where in the simplest "unregularized" version the basic equations coincide with those describing the motion of a small bubble in a liquid streaming through a Hele–Shaw cell [10, 11, 12, 13], which is a special case of two-fluid flow. The unregularized streamer model has been discussed in [4, 14]. Restriction to two dimensions in space allows us to use standard conformal mapping techniques [6, 15] to reduce the moving boundary problem to the analysis of the time dependence of the conformal map that maps the unit disk to the exterior of the streamer.

It is well known that unregularized moving boundary problems of this type are mathematically ill posed [15], in the sense that the moving interface generically develops cusps within finite time which leads to a breakdown of the model. To suppress such unphysical behavior, the models are regularized by imposing nontrivial boundary conditions on the interface. For viscous fingering typically some curvature correction to the interfacial energy is considered. For the streamer problem a mixed Dirichlet–Neumann boundary condition can be derived [14, 16] by analyzing the variation of the electric potential across the screening layer. Such a boundary condition is well known from the Stefan problem, where it is termed "kinetic undercooling." It rarely has been considered for Hele–Shaw-type problems. There are strong hints [15, 17, 18, 19] but no clear proof that it suppresses cusp formation. In particular, it has been shown that an initially smooth interface stays smooth for some finite time interval.

Here we consider the linear stability of uniformly translating circles in a Laplacian potential φ that approaches a constant slope $\varphi \propto x$ far from the circle; this means that the electric field $\mathbf{E} = -\nabla\varphi$ is constant far from the circle. Though this field breaks radial symmetry, uniformly translating circles are exact solutions of the regularized problem [14]. However, perturbations of these circles do not simply grow or decay locally as on a planar front or on circles in a radially symmetric force field [17, 18], but are also convected along the boundary; this convection turns out to be a determining part of the dynamics. Though physical streamers are elongated objects frequently connected to an electrode, the front part of a streamer is well approximated by a circular shape. Since it is this part that determines the dynamics, our analysis should be relevant also for more realistic shapes like fingers where no closed analytical solutions of the regularized uniformly translating shape are known [19]. In what follows we will use the term "streamer" to denote the translating circles, being aware that this is a slight abuse of the term.

1.2. Overview of content and structure of the paper. Regularization of the streamer model introduces some parameter ϵ that measures the effective width of the interface relative to the typical size of the ionized region. The regularized problem allows for a class of solutions of the form of uniformly translating circles, and linear stability analysis of these solutions can be reduced to solving a single PDE. For the special case $\epsilon = 1$, the general solution of this PDE can be found analytically, as we briefly discussed in [14]. The present paper is restricted to this special case as well.

The main results of the letter [14] are the following: The dynamics of infinitesimal perturbations is governed by a subgroup of the automorphisms of the unit disk. Generically, these automorphisms convect the perturbations to the back of the moving body. Initially, perturbations might grow, but they decay exponentially for $t \to \infty$. Furthermore, this final convergence back to the unperturbed circle follows some universal slow manifold.

The present paper contains a detailed derivation, discussion, and extension of the results presented in [14]. Furthermore, the analyticity and completeness of temporal eigenfunctions and the Fourier decomposition of perturbations are discussed, limit cases of the dynamics are worked out analytically, and results are demonstrated in a set of figures.

In detail, the time evolution determined by a PDE is often analyzed in terms of temporal eigenfunctions. For the present problem in a space of functions representing smooth initial perturbations of the moving circle, no such eigenfunctions exist. They can be constructed only if we allow for singularities on the boundary. We find here that a subset of these functions with time dependence $e^{-n\tau}$, $n \in \mathbf{N}_0$, is intimately related to the asymptotic convergence of the perturbations. These functions show singularities only at the backside of the circle, and the front part of any smooth perturbation can be expanded in this set of functions. The spatial domain of convergence of this expansion increases with time and, asymptotically for $t \to \infty$, it covers almost the whole streamer. In this restricted sense these eigenfunctions form a complete set.

These results dealing with infinitesimal perturbations, of course, do not imply the asymptotic stability of the circular shape against finite perturbations. To solve this problem, the full nonlinear theory must be considered. Nevertheless, a first hint might be gained by considering the evolution of a finite perturbation under the linearized dynamics. Due to the conformal mapping involved, the absence of cusps under this evolution is not a completely trivial question. We show here that for a large range of smooth initial conditions, the shape of the streamer stays smooth under the linearized dynamics.

All the present work deals with the exactly solvable case $\epsilon = 1$, whereas the physically most interesting case is $\epsilon \ll 1$. We believe, however, that the features we could identify explicitly for $\epsilon = 1$ are generic for all $\epsilon > 0$. In particular, the subgroup of automorphisms of the unit circle leads to the basic mechanism of convective stabilization, it is for all $\epsilon > 0$ intimately related to the characteristic curves of the PDE, and it also governs the dynamics in another exactly solvable case, namely, for $\epsilon = \infty$. Furthermore, it can be shown [20] that the temporal eigenvalues $\lambda_n(\epsilon)$ emerging from $\lambda_n(1) = -n$ stay negative for all $\epsilon > 0$, which also indicates that the circle might be asymptotically stable for arbitrary $\epsilon > 0$.

This paper is organized as follows. In section 2 we introduce the model, and the linear stability analysis of translating circles is carried through in section 3. These two sections are extended versions of [14]. Analytical results based on the PDE of linear stability analysis are derived in section 4, in particular, center of mass motion, internal motion, (non)analyticity and completeness of eigenfunctions, intermediate growth and asymptotic decay of perturbations, Fourier representation, and motion of nonanalytical points in the complex plane of the conformal map. These dynamic features are illustrated by explicit examples in section 5. The appendix contains a discussion of the case $\epsilon = \infty$.

2. Physical model and conformal mapping approach.

2.1. The model. We assume the ionized bulk of the streamer to be a compact, simply connected domain $\bar{\mathcal{D}}_i$ of the (x, y)-plane (see Figure 2.1). Outside the streamer,

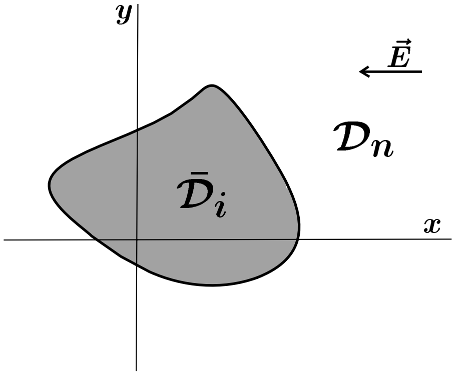

FIG. 2.1. *Geometry of the streamer model; $\vec{E}$ is the constant far field.*

i.e., in the open domain $\mathcal{D}_n$, there are no charges and the electric potential obeys the Laplace equation

$$\Delta\varphi = 0 \quad \text{for } (x, y) \in \mathcal{D}_n. \tag{2.1}$$

The streamer moves in an external electric field that becomes homogeneous far from the ionized body; therefore the electric potential φ at infinity obeys the boundary condition

$$\varphi \to E_0 x + \text{const} \quad \text{for } \sqrt{x^2 + y^2} \to \infty. \tag{2.2}$$

This condition excludes a contribution to φ diverging as $\ln(x^2 + y^2)$, which implies that the total charge due to the sum of all electrons and ions vanishes within $\bar{\mathcal{D}}_i$ and that the far field has the form

$$\vec{E} = -\nabla\varphi \to -E_0\hat{\mathbf{x}},$$

where $\hat{\mathbf{x}}$ is the unit vector in the x-direction. On the surface of the streamer we impose the boundary condition

$$\varphi = \ell\, \hat{\mathbf{n}} \cdot \nabla\varphi, \tag{2.3}$$

where $\hat{\mathbf{n}}$ is the unit vector normal to the surface pointing into $\mathcal{D}_n$. Here as well as in (2.4) below it is understood that the surface is approached from $\mathcal{D}_n$. As mentioned in the introduction, this boundary condition results from the analysis of the variation of the potential across the interface, and the length parameter ℓ can be interpreted as the effective thickness of the screening layer. The case $\ell = 0$ corresponds to the unregularized case with a pure Dirichlet condition on the moving boundary. Dynamics is introduced via the relation

$$v_n = \hat{n} \cdot \nabla\varphi, \tag{2.4}$$

which holds on the boundary and determines its normal velocity v_n. This defines our model. For further discussion of its physical background, we refer to [1, 2, 3, 4, 5, 16]. Now obviously, E_0 can be absorbed into a rescaling of the potential φ and of the time scale inherent in the velocity v_n; therefore we henceforth take $E_0 = 1$. Clearly the model defined here is most similar to a model of the motion of a small bubble in a Hele–Shaw cell [11, 12], except that the boundary condition (2.3) is of the form of a kinetic undercooling condition [17, 18].

2.2. Conformal mapping. A standard approach to such moving boundary problems proceeds by conformal mapping [6, 14]. We identify the (x, y)-plane with the closed complex plane $z = x + iy$, and we define a conformal map $f(\omega, t)$ that maps the unit disk $\mathcal{U}_\omega$ in the ω-plane to $\mathcal{D}_n$ in the z-plane, with $\omega = 0$ being mapped on $z = \infty$:

$$z = f(\omega, t) = \frac{a_{-1}(t)}{\omega} + \hat{f}(\omega, t), \quad a_{-1}(t) > 0. \tag{2.5}$$

Here the function $\hat{f}$ is holomorphic for $\omega \in \mathcal{U}_\omega$, and we assume that the derivatives ∂_ω^n of all orders n exist on the unit circle $\partial\mathcal{U}_\omega$. This restricts our analysis to smooth boundaries of the streamer. (Weaker assumptions on boundary behavior will be discussed briefly in section 4.8.) We recall that the closed physical boundary can now be retrieved as $x_\alpha(t) = \Re f(e^{i\alpha}, t)$ and $y_\alpha(t) = \Im f(e^{i\alpha}, t))$, where the interface parametrization with the real variable $\alpha \in [0, 2\pi[$ is fixed by the conformal map.

By virtue of (2.1), the potential φ restricted to $\mathcal{D}_n$ is a harmonic function; therefore it is the real part of some analytic function $\tilde{\Phi}(z, t)$, which under the conformal map (2.5) transforms into

$$\Phi(\omega, t) = \tilde{\Phi}\left(f(\omega, t)\right) = \frac{a_{-1}(t)}{\omega} + \hat{\Phi}(\omega, t). \tag{2.6}$$

Here the holomorphic function $\hat{\Phi}$ obeys the same conditions as $\hat{f}$ above. The pole results from the boundary condition (2.2) with $E_0 = 1$ and (2.5).

Conditions (2.3) and (2.4) take the form

$$|\omega\partial_\omega f|\, \Re[\Phi] = -\ell\, \Re\left[\omega\partial_\omega\Phi\right] \quad \text{for } \omega \in \partial\mathcal{U}_\omega, \tag{2.7}$$

$$\Re\left[\frac{\partial_t f}{\omega\partial_\omega f}\right] = \frac{\Re\left[\omega\partial_\omega\Phi\right]}{|\omega\partial_\omega f|^2} \quad \text{for } \omega \in \partial\mathcal{U}_\omega. \tag{2.8}$$

Equations (2.5)–(2.8) form the starting point of our analysis.

3. Linear stability analysis of translating circles.

3.1. Uniformly translating circles. A simple solution of (2.7), (2.8) takes the form

$$\left\{ \begin{aligned} f^{(0)}(\omega, t) &= \frac{R}{\omega} + \frac{2R}{R + \ell}\, t, \\ \Phi^{(0)}(\omega, t) &= R\left[\frac{1}{\omega} - \frac{R - \ell}{R + \ell}\,\omega\right]. \end{aligned} \right. \tag{3.1}$$

In physical coordinates x and y, it describes circles of radius $R > 0$ centered at $x(t) = v_0 t$ and moving with velocity $v_0 = 2R/(R + \ell)$ in direction $\hat{\mathbf{x}}$. Thus the point $\omega = 1$ maps to a point at the front, and the point $\omega = -1$ maps to a point at the back of the streamer. These points will play a crucial role in our analysis.

We note that the one-parameter family (3.1) of solutions parametrized by R, which is found in the regularized model, is a subset of the two-parameter family found in the unregularized case $\ell = 0$. As is well known, for $\ell = 0$ all ellipses with one axis parallel to $\hat{\mathbf{x}}$ are uniformly translating solutions [10].

3.2. Derivation of the operator $\mathcal{L}_\epsilon$ for linear stability analysis. We now derive the equation governing the evolution of infinitesimal perturbations of the circles

(3.1). In general, the parameter R can become time dependent. We use the ansatz

$$\left\{\begin{aligned} f(\omega,t) &= \frac{R(t)}{\omega} + x(t) + \eta\,\beta(\omega,t)\,, \\ \Phi(\omega,t) &= R(t)\left[\frac{1}{\omega} - \frac{R(t)-\ell}{R(t)+\ell}\,\omega + \eta\,\chi(\omega,t)\right], \\ \partial_t x(t) &= \frac{2R(t)}{R(t)+\ell}, \quad R(t)>0, \end{aligned}\right. \tag{3.2}$$

where β and χ are holomorphic functions of ω and where η is a small parameter. However, working to first order in η it is found that R stays constant. This results from the fact that the dynamics embodied in (2.8) strictly conserves the area $|\bar{\mathcal{D}}_i|$ of the streamer, which in this context is equivalent to the temporal conservation of the zero order Richardson moment [13, 15, 21], but integrated over the complement of $\mathcal{D}_n$. In terms of the mapping f, the conserved area $\left|\bar{\mathcal{D}}_i\right|$ can be written as

$$\begin{aligned} \left|\bar{\mathcal{D}}_i\right| &= \left|\int_0^{2\pi} d\alpha\left(\Re\left[f(e^{i\alpha},t)\right] - x(t)\right)\partial_\alpha \Im\left[f(e^{i\alpha},t)\right]\right| \\ &= \pi R^2(t) - \eta^2\int_0^{2\pi} d\alpha\,\Re\left[\beta(e^{i\alpha},t)\right]\partial_\alpha\Im\left[\beta(e^{i\alpha},t)\right]. \end{aligned} \tag{3.3}$$

Now introducing the time independent length R_0 through $\left|\bar{\mathcal{D}}_i\right| = \pi R_0^2$, we find $R(t) = R_0 + \mathcal{O}(\eta^2)$, which proves that R is time independent within linear perturbation theory. In what follows we will use R_0 as our length scale, introducing

$$\epsilon = \frac{\ell}{R_0} \quad \text{and} \quad \tau = \frac{2}{1+\epsilon}\frac{t}{R_0}, \tag{3.4}$$

and rescaling f and Φ by factors $1/R_0$. We note that within a dimensionless time interval τ of order unity, the streamer moves a distance of the order of its size.

With the thus simplified ansatz (3.2), equations (2.7) and (2.8) evaluated to first order in η take the form

$$\left\{\begin{aligned} &\Re\left[\omega(\partial_\omega - \partial_\tau)\beta - \frac{1+\epsilon}{2}\omega\partial_\omega\chi\right] = 0, \\ &\Re\left[\epsilon(\omega^2+1)\omega\partial_\omega\beta - (1+\epsilon)(1+\epsilon\omega\partial_\omega)\chi\right] = 0, \end{aligned}\right. \qquad \text{for } \omega \in \partial\mathcal{U}_\omega. \tag{3.5}$$

Since β and χ are holomorphic for $\omega \in \mathcal{U}_\omega$, these equations imply

$$\left\{\begin{aligned} &\omega(\partial_\omega - \partial_\tau)\beta - \frac{1+\epsilon}{2}\omega\partial_\omega\chi = 0, \\ &\epsilon(\omega^2+1)\omega\partial_\omega\beta - (1+\epsilon)(1+\epsilon\omega\partial_\omega)\chi = ia(t), \end{aligned}\right. \qquad \text{for } \omega \in \mathcal{U}_\omega, \tag{3.6}$$

where $a(t)$ is some real function of time. χ is eliminated by substituting the expressions for $\partial_\omega\chi$ and $\partial_\omega^2\chi$ from the first equation and its derivative into the second equation differentiated with respect to ω. This yields

$$\mathcal{L}_\epsilon\beta = 0, \tag{3.7}$$

where $\mathcal{L}_\epsilon$ is the operator

$$\mathcal{L}_\epsilon = \frac{\epsilon}{2}\,\partial_\omega\,(\omega^2-1)\omega\,\partial_\omega + \epsilon\,\omega\partial_\omega\partial_\tau + (1+\epsilon)\,\partial_\tau - \partial_\omega. \tag{3.8}$$

3.3. Normal form of $\mathcal{L}_\epsilon$ and induced automorphisms of the unit disk. It is instructive to transform $\mathcal{L}_\epsilon$ to the normal form of a hyperbolic differential operator. We introduce

$$T = \tanh \frac{\tau}{2}, \tag{3.9}$$

mapping the time interval $\tau \in [0, \infty[$ to $T \in [0, 1[$, and

$$\zeta = \frac{\omega + T}{1 + \omega T}, \tag{3.10}$$

to find

$$\mathcal{L}_\epsilon = \epsilon h(\zeta, T)\partial_T \partial_\zeta + \frac{\partial h(\zeta, T)}{\partial T} \partial_\zeta + (1 + \epsilon)\partial_T, \tag{3.11}$$

$$h(\zeta, T) = \frac{\omega}{\partial_\zeta \omega} = \frac{(\zeta - T)(1 - T\zeta)}{1 - T^2}. \tag{3.12}$$

This identifies the manifolds $T = \text{const}$ or $\zeta = \text{const}$ as the characteristic manifolds of our problem for all $\epsilon \neq 0$.

As function of the "time-like" parameter T, $0 \leq T < 1$, the transformation $\zeta = \zeta(\omega, T)$ in (3.10) represents a semigroup of automorphisms of the unit disk, with fixed points

$$\zeta = \omega = \pm 1.$$

For $T \to 1$, corresponding to $\tau \to \infty$, all points $\omega \neq -1$ are mapped into $\zeta = +1$, so that the large time behavior of any perturbation is governed by this attractive fixed point.

3.4. Analytical solutions of (3.7) for special values of ϵ. The general solution of (3.7) can be found analytically for the special values $\epsilon = 0$, $\epsilon = \pm 1$, and $\epsilon = \infty$. In the unregularized case $\epsilon = 0$, evidently any function

$$\beta(\omega, \tau) = \tilde{\beta}(\omega + \tau)$$

is a solution, and any singularity of $\tilde{\beta}$ found in the strip

$$0 < \Re[\omega] < \infty, \quad -1 \leq \Im[\omega] \leq 1,$$

will lead to a breakdown of perturbation theory within finite time. This is the fingerprint of the ill-posedness of the problem for $\epsilon = 0$.

For $\epsilon = -1$, $\beta(\omega, \tau)$ generically for all $\tau > 0$ has a logarithmic singularity at $\omega = -T(\tau)$. We recall that negative values of $\epsilon = \ell / R_0$ imply negative thickness of the screening layer and thus are of no physical interest.

The case $\epsilon = +1$ is discussed in detail in the remainder of the paper. Though a regularization length ℓ identical to the object size R_0 is somewhat artificial, it is accessible to rigorous analytical treatment and, as explained in section 1.2, we expect it to reveal generic features of the behavior for all $\epsilon > 0$.

This is supported by the results for $\epsilon = \infty$ which show essentially the same features as the results for $\epsilon = 1$ below. Though the limit $\epsilon \to \infty$ is physically absurd when applied to streamers, it is worth studying with respect to the properties of the operator $\mathcal{L}_\epsilon$, and we present a short discussion in the appendix.

4. Strong screening: Analytical results for $\epsilon = 1$.

4.1. Analytical solution of the general initial value problem. With the form (3.11) of $\mathcal{L}_\epsilon$, the PDE (3.7) for $\epsilon = 1$ reduces to

$$\partial_T \left(2 + h(\zeta, T)\partial_\zeta\right) \beta = 0, \tag{4.1}$$

showing that the function

$$G(\zeta) = \left(2 + h(\zeta, T)\partial_\zeta\right) \beta \tag{4.2}$$

is independent of T. To determine β, we use (3.12), $h(\zeta, T) = \omega/\partial_\zeta\omega$, to find

$$\left(2 + \omega\partial_\omega\right) \beta(\omega, \tau) = G(\zeta), \quad \zeta = \zeta(\omega, T(\tau)). \tag{4.3}$$

The solution regular at $\omega = 0$ takes the form

$$\beta(\omega, \tau) = \int_0^\omega \frac{x\,dx}{\omega^2}\, G\left(\frac{x + T(\tau)}{1 + xT(\tau)}\right). \tag{4.4}$$

A second independent solution is singular in $\omega = 0$:

$$\beta_{\text{sing}}(\omega, \tau) \equiv \frac{1}{\omega^2}. \tag{4.5}$$

The function G in the regular solution (4.4) is determined by the initial condition $\beta(\omega, 0)$ through

$$G(\omega) = \left(2 + \omega\partial_\omega\right) \beta(\omega, 0). \tag{4.6}$$

It thus is holomorphic for ω in the unit disk $\mathcal{U}_\omega$, and all derivatives exist on $\partial\mathcal{U}_\omega$, since we assume the initial surface to be smooth. Equation (4.4) then shows that $\beta(\omega, \tau)$ inherits these properties for all $\tau < \infty$.

4.2. Automorphism of the unit disk and a bound on the perturbation. It is now clear that the automorphisms $\zeta(\omega, T)$ of $\mathcal{U}_\omega$ from (3.12) contain the basic dynamics, and, as shown in the appendix, this also holds for $\epsilon = \infty$. This is to be contrasted to the unregularized case $\epsilon = 0$, where the dynamics amounts to a translation of the unit disk. With the present dynamics, in the course of time larger and larger parts $\mathcal{U}(\delta)$ of the unit disk $\mathcal{U}_\omega$ are mapped to an arbitrarily small neighborhood $|\zeta - 1| < \delta$ of the attractive fixed point $\zeta = 1$. According to (4.4) and (4.6), the initial condition in the neighborhood $|\omega - 1| < \delta$ then determines the evolution of $\beta(\omega, \tau)$ in all $\mathcal{U}(\delta)$. As a consequence, any pronounced structure found initially near ω_0, $|\omega_0 - 1| > \delta$, is convected towards $\omega = -1$. Quantitatively this behavior is embodied in (4.17) below, and explicit examples will be presented in section 5; see, in particular, Figure 5.4(b).

For the further discussion we normalize $G(\omega)$ so that

$$\max_{|\omega|=1} |G(\omega)| = 1. \tag{4.7}$$

Equations (4.4), (4.7) yield a bound on $\beta(\omega, \tau)$:

$$|\beta(\omega, \tau)| \leq \frac{1}{2}, \quad |\omega| \leq 1, \quad 0 \leq T \leq 1. \tag{4.8}$$

Thus the perturbation can shift the position of the streamer by at most $\eta/2$, and therefore it cannot affect the asymptotic velocity of the propagation.

4.3. Center of mass motion for $0 \le \tau < \infty$. In precise terms the position of the streamer can be defined as the center of mass

$$z_{\mathrm{cm}} = x_{\mathrm{cm}} + iy_{\mathrm{cm}} = \frac{1}{|\bar{\mathcal{D}}_i|} \int_{\mathcal{D}_i} dx\, dy\, (x + iy), \tag{4.9}$$

where the integral is related to the first order Richardson moment. Evaluating (4.9) and (4.4), we find to first order in η

$$z_{\mathrm{cm}} = \tau + \eta\, \beta(0, \tau), \tag{4.10}$$

$$\beta(0, \tau) = \frac{G(T(\tau))}{2}. \tag{4.11}$$

Here τ is the uniform translation of the unperturbed circle. The additional center of mass motion (4.11) for all times is explicitly given by the initial condition $\beta(\omega, 0)$ through (4.6) and the transformed time variable $T(\tau)$ from (3.9); for $\tau \to \infty$, it approaches $\beta(0, \tau) \to G(1)/2$.

4.4. Internal motion: Convergence along a universal slow manifold for $\tau \to \infty$. We now concentrate on the perturbation of the circular shape, given by

$$\tilde{\beta}(\omega, \tau) = \beta(\omega, \tau) - \beta(0, \tau). \tag{4.12}$$

The explicit expression

$$\tilde{\beta}(\omega, \tau) = \int_0^1 d\rho\, \rho \left[G\left(\frac{\rho\omega + T}{1 + \rho\omega T} \right) - G(T) \right] \tag{4.13}$$

yields

$$\lim_{\tau \to \infty} \tilde{\beta}(\omega, \tau) = 0 \tag{4.14}$$

for arbitrary G, i.e., for arbitrary initial condition (4.6). Thus the shape perturbation converges to zero as $\tau \to \infty$, and the circular shape is linearly stable.

We note that this holds despite the fact that the limits $\omega \to -1$ and $\tau \to \infty$ (i.e., $T \to 1$) do not commute:

$$\lim_{T \to 1} \lim_{\omega \to -1} G(\zeta(\omega, T)) = G(-1),$$
$$\lim_{\omega \to -1} \lim_{T \to 1} G(\zeta(\omega, T)) = G(+1).$$

This peculiar behavior near the backside of the streamer, at $\omega = -1$, shows up only in the rate of convergence.

Investigating the rate of convergence for $\tau \to \infty$, we first exclude a neighborhood of $\omega = -1$ and expand G in the integral (4.13) as

$$G\left(\frac{\rho\omega + T}{1 + \rho\omega T} \right) = G(T) + (1 - T^2)\, \frac{\rho\omega}{1 + \rho\omega T}\, G'(T) + \mathcal{O}(1 - T^2)^2,$$
$$\text{where } G'(\omega) = \partial_\omega G(\omega).$$

With

$$1 - T^2 = 4e^{-\tau} + \mathcal{O}(e^{-2\tau}),$$

the integral yields

$$\frac{\tilde{\beta}(\omega,\tau)}{G'(1)} = \frac{4}{\omega^2}\left[\ln(1+\omega) - \omega + \frac{\omega^2}{2}\right]e^{-\tau} + \mathcal{O}(e^{-2\tau}), \tag{4.15}$$

valid for

$$|1+\omega| \gg |\omega| e^{-\tau}.$$

Thus outside the immediate neighborhood of $\omega = -1$, the shape for all smooth initial conditions with $G'(1) \neq 0$ converges exponentially in time as $e^{-\tau}$ along a universal path in function space, given in (4.15). For $G'(1) = 0$ the first nonvanishing term in the expansion of G dominates the convergence.

To analyze the neighborhood of $\omega = -1$ we take the limit $\tau \to \infty$, with

$$s = (1+\omega)e^{\tau} \tag{4.16}$$

fixed. We find

$$\begin{aligned}\frac{\tilde{\beta}(\omega,\tau)}{G'(1)} &= 4\left(\ln(2+s) - \tau\right)e^{-\tau} \\ &\quad + \Bigg\{ 2G'(1) + 4\ln\left(\frac{2+s}{4}\right)\left(G'\left(\frac{s-2}{s+2}\right) - G'(1)\right) \\ &\quad + (2+s)\left(G(1) - G\left(\frac{s-2}{s+2}\right)\right) - 4\int_0^{4/(2+s)} dy \ln y \, G''(1-y)\Bigg\} \frac{e^{-\tau}}{G'(1)} \\ &\quad + \mathcal{O}\left(\tau e^{-2\tau}\right).\end{aligned} \tag{4.17}$$

In terms of ω, the first contribution on the right-hand side takes the form

$$4\left(\ln(2+s) - \tau\right)e^{-\tau} = 4e^{-\tau}\ln\left(2e^{-\tau} + 1 + \omega\right),$$

which shows that a logarithmic cut of $\tilde{\beta}(\omega,\tau)$ reaches $\omega = -1$ for $\tau \to \infty$, but with a prefactor vanishing exponentially in that limit. We thus have found a weak anomaly of the asymptotic relaxation near $\omega = -1$: In a spatial neighborhood of order $e^{-\tau}$ the exponential relaxation is modified by a factor τ. Furthermore, as mentioned above, all the initial structure of $\beta(\omega, 0)$ is compressed into that region. This is obvious from the occurrence of $G\left(\frac{s-2}{s+2}\right)$ etc. in (4.17).

To summarize, we have found that the shape of the interface for $\tau \to \infty$ converges to the circle along a universal slow manifold (4.15), except for a weak anomaly (4.17) at the backside at $\omega = -1$.

4.5. (Non)analyticity of temporal eigenfunctions. In many cases, a full dynamical solution for arbitrary initial values cannot be found, and rather temporal eigenfunctions are searched for. However, in the present problem, functions $\beta(\omega,\tau)$ resulting from smooth initial conditions cannot exhibit exponential behavior in time for all τ, $0 \leq \tau < \infty$. This is seen easily by introducing

$$G(x) = \hat{G}\left(\frac{x-1}{x+1}\right), \tag{4.18}$$

writing $G(\zeta)$ in the equivialent form

$$G\left(\frac{\omega+T}{1+\omega T}\right)=\hat{G}\left(\frac{\omega-1}{\omega+1}\,e^{-\tau}\right), \tag{4.19}$$

and substituting this form into (4.4). Postulating strict exponential time behavior $\beta\sim e^{-\lambda\tau}$, one finds

$$\beta(\omega,\tau)\propto e^{\lambda\tau}\,\beta_\lambda(\omega),\quad \beta_\lambda(\omega)=\int_0^1 d\rho\,\rho\left(\frac{\omega\rho-1}{\omega\rho+1}\right)^\lambda. \tag{4.20}$$

Any eigenfunction $\beta_\lambda(\omega,0)$ with $\lambda\neq 0$ clearly is singular at $\omega=+1$, at $\omega=-1$, or at both points. It therefore conflicts with smooth initial conditions. On the other hand, omitting a neighborhood of $\omega=-1$, eigenfunctions exist for all $-\lambda\in\mathbf{N}_0$.

4.6. Completeness of the eigenfunctions near $\omega = 1$. In some neighborhood of $\omega=1$, we can even show that any regular solution $\beta(\omega,\tau)$ can be expanded in terms of the "eigenfunctions" $\beta_{-n}(\omega)$, $n\in\mathbf{N}_0$. This results from the Taylor expansion

$$\hat{G}(y)=\sum_{n=0}^{\infty}\hat{g}_n y^n, \tag{4.21}$$

which by assumption converges in a disk of radius $\hat{r}>0$. Rewriting (4.4) as

$$\begin{aligned}\beta(\omega,\tau)&=\int_0^1\frac{x\,dx}{\omega^2}\,G\left(\frac{x+T}{1+xT}\right)-\int_\omega^1\frac{x\,dx}{\omega^2}\,G\left(\frac{x+T}{1+xT}\right)\\&=\frac{M(T)}{\omega^2}-\sum_{n=0}^{\infty}\hat{g}_n\,e^{-n\tau}\int_\omega^1\frac{x\,dx}{\omega^2}\left(\frac{1-x}{1+x}\right)^n\end{aligned} \tag{4.22}$$

and $\beta_{-n}(\omega)$ in a similar form as

$$\beta_{-n}(\omega)=\frac{M_n}{\omega^2}-\int_\omega^1\frac{x\,dx}{\omega^2}\left(\frac{1-x}{1+x}\right)^n, \tag{4.23}$$

we find

$$\beta(\omega,\tau)=\frac{M(T)}{\omega^2}+\sum_{n=0}^{\infty}\hat{g}_n\left[\beta_{-n}(\omega)-\frac{M_n}{\omega^2}\right]e^{-n\tau}. \tag{4.24}$$

Provided that $e^{-\tau}<\hat{r}$, we can separate the sum into the contribution $\propto 1/\omega^2$ and the rest. Since both $\beta(\omega,\tau)$ and $\beta_{-n}(\omega)$ are regular at $\omega=0$, the contributions $\propto 1/\omega^2$ have to cancel, which yields the final result

$$\beta(\omega,\tau)=\sum_{n=0}^{\infty}\hat{g}_n\,\beta_{-n}(\omega)\,e^{-n\tau}. \tag{4.25}$$

This result is valid for $e^{-\tau}<\hat{r}$ in the disk

$$\left|\frac{1-\omega}{1+\omega}\right|e^{-\tau}<\hat{r}.$$

It generalizes the asymptotic result (4.15). Indeed, the universal shape relaxation found in (4.15) together with the center of mass relaxation (4.11) precisely follows the slowest eigenfunction from (4.21) with $\lambda=-n=-1$. Furthermore this result shows that the range of validity of the expansion (4.25) increases with τ and asymptotically covers the whole complex plane except for the special point $\omega=-1$.

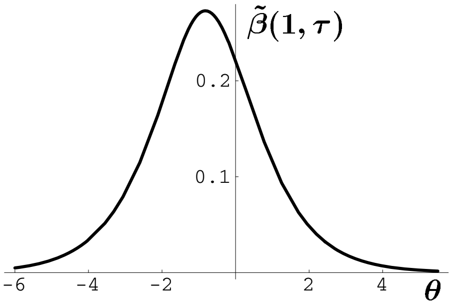

FIG. 4.1. *$\tilde{\beta}(e^{i\alpha},\tau)$ from (4.27) for $\alpha = 0$ as a function of subtracted time $\theta = \tau - \ln 2k$.*

4.7. Intermediate temporal growth and coupling of Fourier modes. Having found that the space of regular functions does not allow for strictly exponential time behavior, we now consider the typical time variation of smooth perturbations. Before the exponential relaxation sets in, such perturbations typically will grow, and this growth can be quite dramatic. As an illustration we consider a perturbation defined by

$$G(\omega) = \omega^k, \quad k \gg 1,$$

corresponding to initial conditions

$$\beta(\omega, 0) = \frac{\omega^k}{k+2}. \tag{4.26}$$

For $T = 1 - e^{-\theta}/k$, corresponding to times $\tau = \theta + \ln(2k) + \mathcal{O}(1/k)$, we can write

$$G\left(\frac{\omega + T}{1 + \omega T}\right) = \left(\frac{1 - \frac{e^{-\theta}}{1+\omega}\frac{1}{k}}{1 - \frac{\omega e^{-\theta}}{1+\omega}\frac{1}{k}}\right)^k = \exp\left[-e^{-\theta}\frac{1-\omega}{1+\omega}\right]\left(1 + \mathcal{O}\left(\frac{1}{k}\right)\right),$$

where we again exclude some neighborhood of $\omega = -1$. Substituting this expression into (4.13), we find on the unit circle $\omega = e^{i\alpha}$

$$\begin{aligned}&\tilde{\beta}(e^{i\alpha}, \tau)\\ &= \int_0^1 d\rho\, \rho \exp\left[-e^{-\theta}\frac{1 - \rho^2 - 2i\rho\sin\alpha}{1 + \rho^2 + 2\rho\cos\alpha}\right] - \frac{1}{2}\exp\left[-e^{-\theta}\right] + \mathcal{O}\left(\frac{1}{k}\right).\end{aligned} \tag{4.27}$$

Figure 4.1 shows this function, evaluated at $\alpha = 0$ ($\omega = 1$). The behavior is quite peculiar. Up to times of order $\ln k$ the perturbation stays of order $1/k \ll 1$, then it increases roughly exponentially up to values of order 1, and finally it decreases again exponentially, approaching the slow manifold (4.15). Thus for very large k the initial perturbation $\beta(\omega, 0) \sim 1/k$ in some time interval can be amplified by a factor of order k, and (4.27) shows that the leading behavior in that time interval is independent of k.

Closer analysis shows that in terms of a formal Fourier expansion

$$\tilde{\beta}(e^{i\alpha}, \tau) = \sum_{n=1}^{\infty} a_n(\tau) e^{in\alpha}, \tag{4.28}$$

the amplification is carried by the low modes, $n = \mathcal{O}(1)$. As will be illustrated by an explicit example below (cf. Figure 5.2(b)), in such a mode representation the time evolution feeds the strength of the perturbation successively into lower and lower modes. This is equivalent to the observation that the automorphism $e^{i\alpha} \to \zeta(e^{i\alpha}, T)$ drives all the perturbative structure towards $\alpha = \pi$ and smooths the remainder of the interface. Note, however, that, starting with a perturbation $\sim \omega^k$, in the course of time modes $n > k$ are also (weakly) populated to build up a complicated structure near $\omega = -1$. We recall that for the unregularized model $\epsilon = 0$, the time evolution of a perturbation $\propto \omega^k$ populates only modes $k \leq n$ [4].

4.8. Motion of the zeros of $\partial_\omega f$ and cusps. So far we have shown that the propagating circle is linearly stable; i.e., we implicitly considered perturbations of infinitesimal strength η. The full nonlinear evolution of a finite perturbation is beyond the scope of this paper. Still, it clearly is a question of practical interest, whether a finite perturbation evolving under the linearized dynamics for all times satisfies the assumptions underlying the conformal mapping approach. For the mapping to stay conformal, all the zeros of $\partial_\omega f(\omega, \tau)$ must stay outside the unit circle. Thus, here we analyze the roots of the equation

$$0 = \partial_\omega f(\omega, \tau) = -\frac{1}{\omega^2} + \eta\, \partial_\omega \beta(\omega, \tau). \tag{4.29}$$

Using (4.3), (4.4), we can rewrite this equation as

$$2\eta \int_0^1 d\rho\, \rho \left[G\left(\frac{\omega + T}{1 + \omega T} \right) - G\left(\frac{\rho\omega + T}{1 + \rho\omega T} \right) \right] = \frac{1}{\omega}. \tag{4.30}$$

With our normalization (4.7) of G, for all ω in the closed unit disk the left-hand side of this equation is bounded by $2|\eta|$. We conclude that the bound

$$|\eta| < \frac{1}{2} \tag{4.31}$$

guarantees that within the framework of first order perturbation theory the mapping stays conformal for all times. We now will show that in general this bound cannot be improved.

For $\tau \to \infty$, zeros of $\partial_\omega f(\omega, \tau)$ reach $\omega = -1$, which is a consequence of the fact that in this limit an infinitesimally small neighborhood of $\omega = -1$ under the mapping $\omega \to \zeta$ is mapped essentially on the whole complex plane. We now analyze this limit for the simple example $G(\omega) = \omega$. Substituting this form into the asymptotic behavior (4.17) and using the definition (4.16) of s, we find

$$\partial_\omega \beta = \frac{4}{2 + s} + \mathcal{O}(\tau e^{-\tau}).$$

Equation (4.29) reduces to $s = 4\eta - 2$, showing that a zero ω_0 of $\partial_\omega f(\omega, \tau)$ approaches $\omega = -1$ as

$$\omega_0 = -1 + (4\eta - 2) e^{-\tau}.$$

For ω_0 to come from outside the unit circle we clearly must have

$$\Re[\eta] < \frac{1}{2}. \tag{4.32}$$

To get some feeling for the estimate (4.31), we note that for $G(\omega) = \omega^k$ the map initially (for $\tau = 0$) is conformal provided that $|\eta| < 1 + 2/k$. We conclude that under the linearized dynamics a large part of smooth initial conditions relaxes to the circle.

Throughout this section we have assumed the initial boundary to be smooth, so that all derivatives $\partial_\omega^n G(\omega)$ exist on the boundary $|\omega| = 1$. Inspecting the results, it is obvious that this assumption can be considerably relaxed, since only those derivatives which show up explicitly have to exist. Thus, for exponential relaxation (4.15) outside the neighborhood of $\omega = -1$ to prevail, the existence of $\partial_\omega G(\omega)$ is sufficient, which amounts to the condition that the curvature of the initial boundary is well defined. For the circle to be linearly stable, as in (4.14), it is sufficient that $G(e^{i\alpha})$ is bounded and continuous, which implies that the boundary has a well-defined slope.

If the initial boundary shows a cusp, the time evolution sensitively depends on the details. If the cusp is found in the forward direction, so that $G(\omega)$ diverges for $\omega \to 1$, the streamer will be strongly accelerated. In a related model [12], such an effect has been pointed out before. Furthermore, the shape will not relax to a circle, and the conformal map will presumably break down at finite time. If the cusp does not affect the analyticity of $G(\omega)$ near $\omega = 1$, it is convected towards the back and broadened, whereas the front of the streamer approaches the circular shape. Still, however, conformality of the map may break down at finite time.

5. Explicit examples for $\epsilon = 1$.

We here illustrate the general results by some examples.

5.1. The evolution of Fourier perturbations.

We first consider perturbations of the form

$$\beta^{[k]}(\omega, 0) = \frac{\omega^k}{k+2}, \quad \text{i.e., } G(\omega) = \omega^k. \tag{5.1}$$

The integral (4.4) is easily evaluated to yield

$$\begin{aligned}\beta^{[k]}(\omega,\tau) = \frac{1}{2\omega^2 T^2}\Bigg\{ & T^k + \left((T\omega)^2 - 1\right)\zeta^k \\ & + k\left(1 - T^2\right)\left[T^k - (\omega T + 1)\zeta^k + \frac{1 + k + T^2(1-k)}{T^k}\right. \\ & \left.\cdot \left(\ln(1+\omega T) - \sum_{\nu=1}^{k-1} \frac{T^\nu}{\nu}(\zeta^\nu - T^\nu)\right)\right]\Bigg\},\end{aligned} \tag{5.2}$$

where $T = T(\tau)$ and $\zeta = \zeta(\omega, T(\tau))$ are given by (3.9) or (3.10), respectively. In Figure 5.1 we have plotted snapshots of the resulting motion of the interface, determined as

$$z = x + iy = \frac{1}{\omega} + \tau + \eta\,\beta^{[k]}(\omega,\tau), \quad \omega = e^{i\alpha}, \quad 0 \le \alpha \le 2\pi. \tag{5.3}$$

The direction of motion, i.e., the positive x-direction, is downwards. Together with the moving interface, we show the unperturbed circular streamer at different times as gray disks with the center moving according to

$$z_{\mathrm{cm}}(\tau) = \tau + \frac{\eta}{2}\,G(T(\tau)) = \tau + \frac{\eta}{2}\tanh^k \frac{\tau}{2}, \tag{5.4}$$

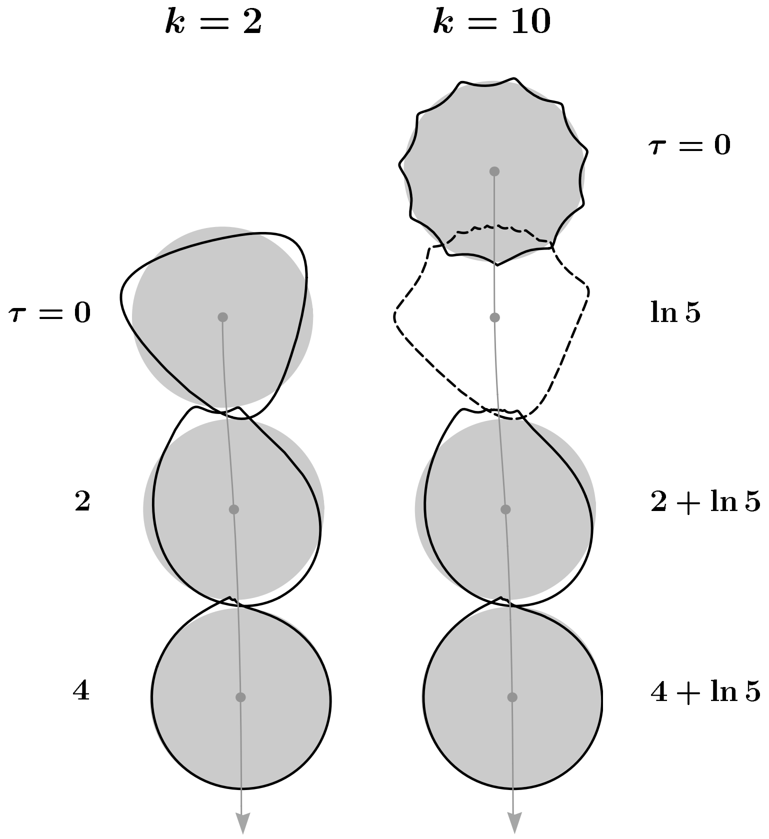

FIG. 5.1. *Snapshots of the evolution of the streamer for $k = 2$ (left column) and $k = 10$ (right column) at the indicated instants of time. The solid lines represent the perturbed interfaces. The gray disks move with the center of mass velocity* (5.4) *of the perturbed circles. One gray disk has been omitted for clarity. See the text for further discussion.*

as predicted for the center of mass motion for the perturbed streamer in (4.10).

In Figure 5.1 we perturbed the circle by $\eta\, \beta^{[k]}$, $k = 2$ or $k = 10$, using the same parameter $\eta = 0.6e^{i\pi/4}$ in both cases. The starting position for $k = 10$ is shifted relative to that for $k = 2$ by a distance corresponding to $\Delta\tau = \ln 5$. As discussed below (4.27), for $1 \ll k_1 < k_2$ we expect

$$\beta^{[k_1]}(\omega, \tau) \approx \beta^{[k_2]}(\omega, \tau + \ln(k_2/k_1)).$$

Figure 5.1 illustrates that such a "universality" for the gross structure holds down to very small k. (Of course the choice of differing values of η would distort the figures and mask this feature.) Basically during time evolution the initial maximum closest to the forward direction is smeared out and builds up the asymptotic circle, whereas all other structures are compressed at the backside. For $k = 10$ the complicated structure at the back is magnified in Figure 5.2(a). Figure 5.2(b) shows the time dependence of the coefficients a_n of the low modes $e^{in\alpha}$ in the expansion (4.28), again for $k = 10$. It illustrates how the strength of the perturbation cascades downwards in n and increases in time, until it is completely absorbed into the lowest mode, i.e., the overall shift of the circle. We should recall, however, that modes $n > k$ are also weakly populated to build up the structure at the back.

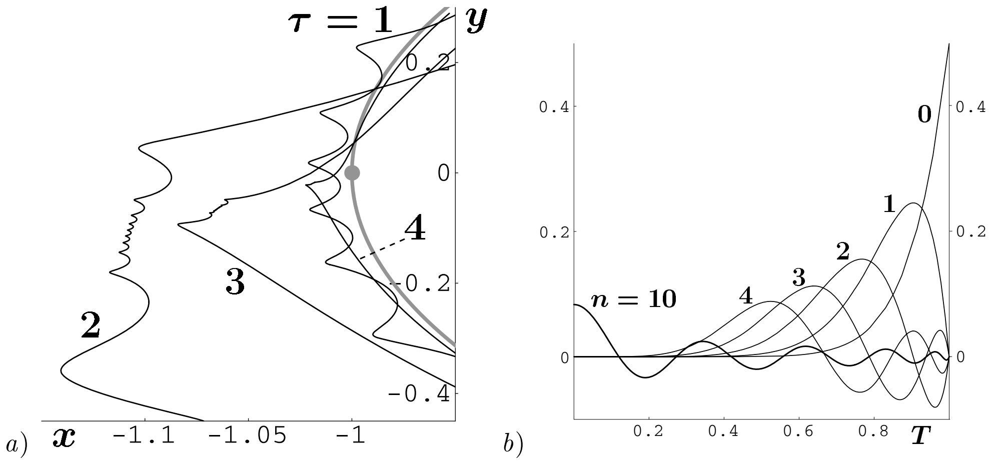

FIG. 5.2. (a) *Magnified plot of the backside of the streamer for $k = 10$, $\eta = 0.6\, e^{i\pi/4}$ (as in the right column of Figure* 5.1*) for the τ values given. The overall motion is subtracted. We observe the compression of the fine structure and the intermediate growth of the perturbation. Asymptotically for $\tau \to \infty$, the structure converges to the gray circle. In the comoving frame, the gray dot marks $x + iy = -1$, which is the point to which the structure finally is contracted. Note that the scale of x is stretched compared to that of y, and that the figure is turned relative to Figure* 5.1. (b) *The amplitudes a_n as in* (4.28) *as a function of T for $k = 10$; the values of n are given.*

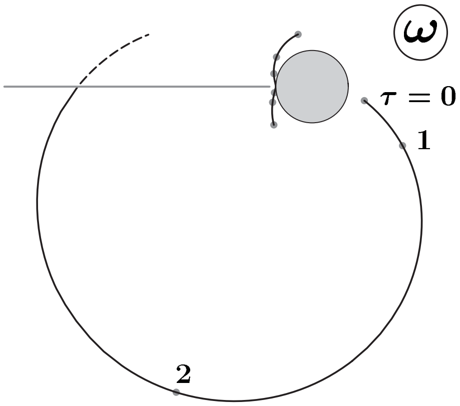

FIG. 5.3. *Motion of the zeros of $\partial_\omega f$ in the ω-plane for $k = 2$ and $\eta = 0.6\, e^{i\pi/4}$ (as in the left column of Figure* 5.1*). The dots give the position for $\tau = 0, 1, 2$. The horizontal line is the cut for $\tau = 2.51$, where one zero enters the second sheet (broken curve). The unit disk is also shown.*

For $k = 2$, Figure 5.3 shows the motion of the zeros of $\partial_\omega f(\omega, \tau)$ in the complex ω-plane, as discussed in section 4.8. It corresponds to the $k = 2$ part of Figure 5.1. Two zeros, which initially are close to the backside of the unit circle, approach $\omega = -1$ for $\tau \to \infty$. They clearly are associated with the two maxima that in the comoving frame are convected towards $z = x + iy = -1$. The third zero, originally found close to $\omega = +1$, after a large excursion leaves the physical sheet at time $\tau \simeq 2.51$. The logarithmic cut is on the negative axes, with the branchpoint $\omega_{\rm bp} = -1/T(\tau)$ reaching $\omega = -1$ for $\tau \to \infty$.

5.2. The evolution of localized perturbations. We finally consider some more localized perturbation, defined by

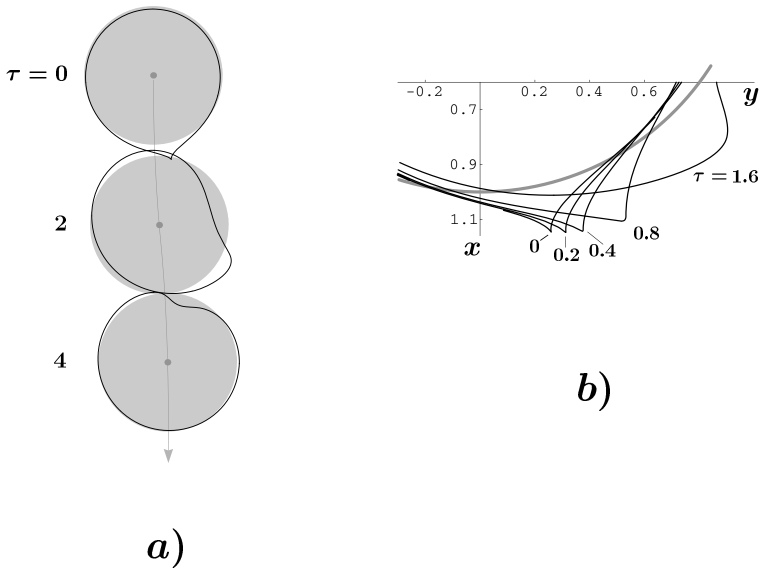

FIG. 5.4. (a) *Time evolution of a localized perturbation as described in the text.* (b) *Evolution of the initial peak for shorter times as indicated. The overall motion of the streamer is subtracted. A part of the asymptotic circle is shown in gray.*

$$G(\omega) = \frac{(1-\gamma)e^{i\alpha_0}}{\omega - \gamma e^{i\alpha_0}}, \quad \gamma > 1, \tag{5.5}$$

corresponding to an initial perturbation

$$\eta\,\beta(\omega,0) = \eta\,\frac{(1-\gamma)\gamma}{\omega^2}\,e^{2i\alpha_0}\left[\ln\left(1 - \frac{\omega}{\gamma}\,e^{-i\alpha_0}\right) - \frac{\omega}{\gamma}\,e^{-i\alpha_0}\right]. \tag{5.6}$$

The result for $\beta(\omega,\tau)$ reads

$$\beta(\omega,\tau) = \frac{(\gamma-1)e^{i\alpha_0}}{\gamma e^{-i\alpha_0} - T(\tau)}\left\{\frac{T(\tau)}{2b(\tau)} - \left(1 - \frac{T(\tau)}{b(\tau)}\right)\frac{\ln(1+b(\tau)\omega) - b(\tau)\omega}{(b(\tau)\omega)^2}\right\}, \tag{5.7}$$

where

$$b(\tau) = \frac{1 - T(\tau)\gamma e^{i\alpha_0}}{T(\tau) - \gamma e^{i\alpha_0}}. \tag{5.8}$$

We note that $b(\tau) \to 1$ for $T(\tau) \to 1$, so that in the large time limit the logarithmic cut reaches $\omega = -1$. As discussed in the context of (4.17), this is a generic feature of the present problem. Our choice of parameters ($\gamma = 1.1$, $\alpha_0 = -\pi/12$, $\eta = 1.5$) almost produces a cusp in the initial condition: The only zero of $\partial_\omega f(\omega, 0)$ is found at $\omega_0 = 1.001\exp(-.243i)$. This zero, however, is driven away from the unit circle and leaves the physical sheet. Another zero, which entered the physical sheet somewhat earlier, for $\tau \to \infty$ reaches $\omega = -1$. Figure 5.4(a) shows snapshots of the time evolution of the perturbed interface in a representation like Figure 5.1. It illustrates how the peak is rapidly smeared out and the interface becomes smooth. Figure 5.4(b) follows the evolution of the peak for short times and shows how it is convected and broadened.

We finally note that, in the special case where the initial peak strictly points in the forward direction ($\alpha_0 = 0$), convection cannot take place. The peak simply is broadened and vanishes, whereas some new peak shows up at the back for intermediate times.

Appendix A. The limit $\epsilon \to \infty$.

For $\epsilon \to \infty$, the PDE (3.7) with the form (3.11) of $\mathcal{L}_\epsilon$ reduces to

$$\Big(h(\zeta, T)\,\partial_\zeta + 1\Big)\,\partial_T\,\hat{\beta}(\zeta, T) = 0, \quad \text{where } \hat{\beta}(\zeta, T) \equiv \beta(\omega, \tau). \tag{A.1}$$

Equation (A.1) allows for a large set of solutions obeying the same initial condition

$$\beta(\omega, 0) = \beta_0(\omega), \tag{A.2}$$

but imposing regularity on the unit disk $\mathcal{U}_\omega$, we single out the simple form

$$\beta(\omega, \tau) = \beta_0(\zeta). \tag{A.3}$$

Thus for $\epsilon = \infty$, the dynamics is simply given by the automorphisms $\omega \longrightarrow \zeta(\omega, T)$. This implies that $\beta(\omega, \tau)$ is bounded uniformly in τ as

$$\big|\beta(\omega, \tau)\big| \le \max_{\omega \in \partial\mathcal{U}_\omega} \big|\beta_0(\omega)\big|, \tag{A.4}$$

so that in contrast to the case $\epsilon = 1$, there is no intermediate growth of the perturbations.

The shift of the center of mass is given by (cf. (4.10))

$$\beta(0, \tau) = \beta_0(T(\tau)) = \beta_0(1) - 2\,\beta_0'(1)\,e^{-\tau} + \mathcal{O}\left(e^{-2\tau}\right), \tag{A.5}$$

and except for the point $\omega = -1$, the shape again converges exponentially in time to the circle along the universal slow manifold

$$\beta(\omega, \tau) - \beta(0, \tau) = \beta_0'(1)\,\frac{4\,\omega}{1 + \omega}\,e^{-\tau} + \mathcal{O}\left(e^{-2\tau}\right); \tag{A.6}$$

cf. (4.15) for $\epsilon = 1$. Again the neighborhood of $\omega = 1$ for time $\tau = 0$, more precisely $\beta_0(1)$ and $\beta_0'(1)$, determines the long time convergence. Since by assumption $\beta_0(\omega)$ is analytical at $\omega = 1$, evidently an eigenfunction expansion in the sense of subsection 4.5 exists.

The only major difference compared to the case $\epsilon = 1$ concerns the point $\omega = -1$. Clearly,

$$\beta(-1, \tau) \equiv \beta_0(-1) \tag{A.7}$$

independently of τ, and indeed for $\tau \to \infty$ the conformality of the mapping breaks down in the neighborhood of $\omega = -1$ since $\partial_\omega \beta(\omega, \tau)\big|_{\omega=-1}$ diverges.

INVERSE SCATTERING IN MULTIMODE STRUCTURES[*]

OLE HENRIK WAAGAARD[†] AND JOHANNES SKAAR[‡]

Abstract. We consider the inverse scattering problem associated with any number of interacting modes in one-dimensional structures. The coupling between the modes is contradirectional in addition to codirectional and may be distributed continuously or in discrete points. The local coupling as a function of position is obtained from reflection data using a layer-stripping-type method, and the separate identification of the contradirectional and codirectional coupling is obtained using matrix factorization. Ambiguities are discussed in detail, and different a priori information that can resolve the ambiguities is suggested. The method is exemplified by applications to multimode optical waveguides with quasi-periodical perturbations.

Key words. inverse scattering, layer-stripping, multimode structures

1. Introduction.

In waveguides that support several modes, scattering, or coupling between the different modes, may appear due to different kinds of perturbations. Possible perturbations are reflectors, gratings, bends, tapering, and other kinds of geometrical or material modulation along the waveguide. The coupling may be both codirectional (coupling between modes that propagate in the same direction) or contradirectional (coupling between modes that propagate in opposite directions). The direct scattering problem of computing the scattered field when the probing waves and the scattering structure are known has been extensively discussed in the literature [24, 38, 21]. The inverse scattering problem associated with two interacting modes is also well understood and has been treated in several contexts since the pioneering work by Gel'fand and Levitan [13], Boutet de Monvel and Marchenko [3], and Kreĭn [22]. In geophysics the so-called dynamic deconvolution or layer-stripping (layer-peeling) methods emerged for the identification of layered-earth models from acoustic scattering data [28, 31, 2, 6, 5]. More recently the inverse scattering methods have been applied to the design and characterization of optical devices involving two interacting modes. Both contradirectional coupling and codirectional coupling have been treated. Optical components based on contradirectional coupling include thin-film filters and fiber Bragg gratings [40, 10, 37, 30, 36, 34], while codirectional coupling is present in, e.g., grating-assisted codirectional couplers and long-period gratings [19, 39, 9, 42, 4]. While the inverse scattering problem associated with two interacting modes is well known, the inverse scattering problem of several, possibly nondegenerate modes (i.e., with different propagation constants) seems unsolved so far. Some work has been done in the case of four degenerate modes, that is, two polarization modes in each direction [35, 41], and several degenerate modes with only contradirectional coupling [1].

On the other hand, several methods for the inverse scattering of acoustic or electromagnetic waves in two or three dimensions have been reported. In particular,

Yagle et al. have developed layer-stripping methods for the multidimensional case [45, 43, 44]. By Fourier transforming the problem with respect to the transversal coordinates, the multidimensional problem may be regarded as one-dimensional with several interacting modes.

In this paper we will extend these lines of thought to cover the general inverse scattering problem associated with any number of interacting modes in one-dimensional, reciprocal structures. In the model (section 2) both codirectional and contradirectional coupling may be present simultaneously. We limit ourselves to the case where the known probing waves and the scattered waves propagate in opposite directions. In other words the scattered wave is considered as a reflection from the unknown structure. A layer-stripping inverse scattering algorithm is presented in section 3. Ambiguities related to the simultaneous presence of co- and contradirectional coupling are discussed in detail. Possible a priori information that can resolve these ambiguities will be suggested. The formalism is particularly useful for the quasi-periodical case (section 4), since only the slowly varying envelope needs to be represented rather than the structure itself, yielding an efficient algorithm. In section 5, the method is applied for the numerical reconstruction of a quasi-periodical waveguide structure. Sections 4 and 5 are exemplified by a multimode fiber Bragg grating: an optical fiber with quasi-periodic refractive index perturbation along the fiber axis, giving rise to both co- and contradirectional coupling. Finally, analogies to the multidimensional case are discussed in section 6.

2. Continuous and discrete coupling model. Consider a structure with P modes propagating in each direction along the x-axis. We visualize the x-axis as being directed to the right and say that the $+x$-direction is the forward direction. The propagation constant of the pth mode is $\pm\beta_p$; i.e., the x-dependence of the complex field associated with mode p is described by the factor $\exp(\pm i\beta_p x)$, where the upper (lower) sign applies to forward (backward) propagating modes. Note that the propagation constants of different modes may or may not be different. The propagation constants are related to frequency through the dispersion relation of the structure. The propagation constants may be expressed as $\beta_p = n_p\omega/c$, where ω is the angular frequency, c is some fixed reference velocity (common for all modes), and n_p accounts for the actual phase velocity. (However, in some cases it may rather be convenient to express the propagation constants in the form $n_p\omega/c - \pi/\Lambda$, where Λ is a constant; see section 4.) For electromagnetic waves, it is natural to set c equal to the vacuum velocity, and consequently we will refer to n_p as the effective index associated with mode p. In principle, the effective indices may be complex and dependent on frequency, meaning that modal loss and dispersion are permitted in the model. However, the dispersion must be limited by relativistic causality in the sense that any signal carried by the modes travels no faster than the vacuum light velocity. Also, the modal field profiles are assumed to have uniform phases such that they can be written real.

Coupling may occur due to a continuous or discrete scattering structure. In the first case, the field is assumed to be governed by the coupled-mode equation

$$\frac{\mathrm{d}\mathbf{E}}{\mathrm{d}x} = i\mathbf{C}\mathbf{E}, \tag{2.1}$$

where $\mathbf{E}$ is a column vector containing the $2P$ mode amplitudes. In the absence of the scattering structure ($\mathbf{C}_{\boldsymbol{\sigma}} = \mathbf{C}_{\boldsymbol{\kappa}} = 0$; see below), the first P elements are the mode amplitudes of the forward propagating modes (propagating in the $+x$-direction) and the last P elements are those of the backward propagating modes. The coupling matrix $\mathbf{C}$ can be decomposed into three contributions:

$$\mathbf{C} = \mathbf{D} + \mathbf{C}_{\boldsymbol{\sigma}} + \mathbf{C}_{\boldsymbol{\kappa}}. \tag{2.2}$$

The contributions can be expressed as 2×2 block matrices consisting of $P \times P$ blocks:

$$\mathbf{D} = \begin{bmatrix} \boldsymbol{\beta} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{\beta} \end{bmatrix}, \tag{2.3a}$$

$$\mathbf{C}_{\boldsymbol{\kappa}} = \begin{bmatrix} \mathbf{0} & \boldsymbol{\kappa} \\ -\boldsymbol{\kappa}^* & \mathbf{0} \end{bmatrix}, \tag{2.3b}$$

$$\mathbf{C}_{\boldsymbol{\sigma}} = \begin{bmatrix} \boldsymbol{\sigma} & \mathbf{0} \\ \mathbf{0} & -\boldsymbol{\sigma}^* \end{bmatrix}, \tag{2.3c}$$

where * denotes complex conjugate. The first term $\mathbf{D}$ describes the frequency dependence due to the propagation of the different modes ("self-coupling") and is independent on x; and $\boldsymbol{\beta} = \mathrm{diag}\{\beta_1, \beta_2, \ldots, \beta_P\}$. Only this term is permitted to be lossy in the model ($\boldsymbol{\beta}$ may be complex). In practice, we should require $\mathrm{Im}\,\beta_p L \lesssim 1$, where L is the total length of the structure; otherwise the field at the far end of the structure may be close to zero (i.e., the mode will be bound at the left interface to the structure, and very little reflection will originate from the far end). The second term $\mathbf{C}_{\boldsymbol{\kappa}}$ describes the coupling between counterpropagating modes, whereas the last term $\mathbf{C}_{\boldsymbol{\sigma}}$ accounts for the coupling between copropagating modes. The coupling coefficients $\boldsymbol{\kappa}$ and $\boldsymbol{\sigma}$ are dependent on x but assumed independent on frequency. As will become clear shortly, the above forms of $\mathbf{C}_{\boldsymbol{\kappa}}$ and $\mathbf{C}_{\boldsymbol{\sigma}}$ are consequences of reciprocity and losslessness. It should be noted that in structures such as long-period gratings, where the coupling is purely codirectional, the coupling is described by $\boldsymbol{\kappa} = \mathbf{0}$ and a $\boldsymbol{\sigma}$ with nonzero off-diagonal elements. The conventional way of describing such structures would be to consider only the upper-left $P \times P$ block of $\mathbf{C}$. The layer-stripping method in section 3 cannot be used to reconstruct such structures since the reflection response is zero.

The coupling region in the waveguide is discretized into N layers, each of thickness $\Delta x = L/N$. If N is sufficiently large so that the matrices in (2.3) can be treated as constants in each layer, we can solve (2.1):

$$\mathbf{E}(x_j + \Delta x) = \exp{(i\mathbf{C}\Delta x)}\mathbf{E}(x_j), \quad x_j = j\Delta x. \tag{2.4}$$

This transfer matrix relation can be used to propagate the fields through the piecewise uniform structure. With the help of the connection between the transfer matrix and the scattering matrix (Appendix B) we can find the reflection and transmission response from the total transfer matrix, obtained as a product of the transfer matrices $\exp{(i\mathbf{C}\Delta x)}$ of each layer (direct scattering).

While direct scattering is achieved straightforwardly using the piecewise-uniform discretization, for inverse scattering it is convenient to push the discretization further, in order to identify the different contributions to the transfer matrix $\exp{(i\mathbf{C}\Delta x)}$. To first order in Δx, we have $\exp(i\mathbf{C}\Delta x) = \exp(i\mathbf{D}\Delta x)\exp(i\mathbf{C}_{\boldsymbol{\kappa}}\Delta x)\exp(i\mathbf{C}_{\boldsymbol{\sigma}}\Delta x)$. For a continuous structure of finite thickness, the bandwidth where the reflection spectrum is significantly different from zero is finite. Thus we need only be concerned with frequencies satisfying $|\omega| \leq \omega_{\mathrm{b}}$ for some positive constant ω_{b}. Note that this model may give entirely incorrect results for $|\omega| > \omega_{\mathrm{b}}$. For instance, if $P = 1$, the reflection spectrum calculated with the discrete model will be periodic with period

$\pi c/(n_1\Delta x)$, while the spectrum associated with a continuous structure tends to zero for large frequencies. For inverse scattering, the reflection spectrum and therefore ω_{b} are known. Therefore, provided Δx is chosen sufficiently small we can approximate each layer by a cascade of three sections: a section with codirectional coupling, a section with contradirectional coupling, and a time-delay section. The physical implication of this factorization is that the mode coupling appears in a discrete point within the layer rather than distributed along the whole layer. The contradirectional section may therefore be pictured as a discrete reflector. The transfer matrix of the jth layer becomes

$$\mathbf{T}_j = \mathbf{T}_{\boldsymbol{Z}}\mathbf{T}_{\boldsymbol{\rho}_j}\mathbf{T}_{\boldsymbol{\Phi}_j}, \tag{2.5}$$

where

(2.6a)

$$\mathbf{T}_{\boldsymbol{Z}} \equiv \exp(i\mathbf{D}\Delta x) = \begin{bmatrix} \boldsymbol{Z}^{-1} & \mathbf{0} \\ \mathbf{0} & \boldsymbol{Z} \end{bmatrix}, \quad \boldsymbol{Z}^{-1} = \exp(i\boldsymbol{\beta}\Delta x),$$

(2.6b)

$$\mathbf{T}_{\boldsymbol{\rho}_j} \equiv \exp(i\mathbf{C}_{\boldsymbol{\kappa}}\Delta x) = \begin{bmatrix} \boldsymbol{t}_j^{-1*} & -\boldsymbol{t}_j^{-1*}\boldsymbol{\rho}_j^* \\ -\boldsymbol{t}_j^{-1}\boldsymbol{\rho}_j & \boldsymbol{t}_j^{-1} \end{bmatrix}, \quad \begin{array}{l} \boldsymbol{\rho}_j = i\tanh[(\boldsymbol{\kappa}^*\boldsymbol{\kappa})^{1/2}\Delta x](\boldsymbol{\kappa}^*\boldsymbol{\kappa})^{-1/2}\boldsymbol{\kappa}^*, \\ \boldsymbol{t}_j = \cosh[(\boldsymbol{\kappa}^*\boldsymbol{\kappa})^{1/2}\Delta x]^{-1}, \end{array}$$

(2.6c)

$$\mathbf{T}_{\boldsymbol{\Phi}_j} \equiv \exp(i\mathbf{C}_{\boldsymbol{\sigma}}\Delta x) = \begin{bmatrix} \boldsymbol{\Phi}_j & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Phi}_j^* \end{bmatrix}, \quad \boldsymbol{\Phi}_j = \exp(i\boldsymbol{\sigma}\Delta x).$$

The form of the matrix in (2.6b) may, for example, be verified by evaluating the power series expansion of the matrix exponential. In principle, it suffices to express (2.6) to first order in Δx; however, the exact form is kept to emphasize the properties of each of the three sections, to ensure that each section is lossless regardless of the value of Δx, and to retain the correspondence to the discrete case (below).

We are now in the position that we can argue for the forms of the coupling matrices (2.3). Note that while we have permitted loss in the propagation section $\boldsymbol{Z}^{-1}$, the coupling sections are assumed lossless. Since the coupling sections also are assumed to be reciprocal, their transfer matrices satisfy (B.10) and (B.11) (Appendix B). Allowing a more general $\mathbf{C}_{\boldsymbol{\kappa}}$ by substituting $\boldsymbol{\kappa}^* \to \boldsymbol{\kappa}_{21}$ into the $(2,1)$ block and expanding $\exp(i\mathbf{C}_{\boldsymbol{\kappa}}\Delta x)$ to first order in Δx, the lossless and reciprocity conditions give $\boldsymbol{\kappa}_{12} = -\boldsymbol{\kappa}^*$ and dictate $\boldsymbol{\kappa}$ to be symmetric. Similarly, we can derive the form of $\mathbf{C}_{\boldsymbol{\sigma}}$ and establish that $\boldsymbol{\Phi}_j$ must be unitary; i.e., $\boldsymbol{\sigma}$ is hermitian.

From the discussion above, each layer is characterized by a unitary codirectional coupling matrix $\boldsymbol{\Phi}_j$ and a discrete reflector. Let superscript T denote transpose and let $\|\cdot\|$ be the usual matrix 2-norm. The discrete reflector satisfies $\boldsymbol{\rho}_j = \boldsymbol{\rho}_j^{\mathrm{T}}$ and $\|\boldsymbol{\rho}_j\| < 1$ and has an associated, positive definite transmission matrix $\boldsymbol{t}_j$ with $\boldsymbol{t}_j^2 = \boldsymbol{I} - \boldsymbol{\rho}_j\boldsymbol{\rho}_j^*$.

So far we have considered a continuous scattering structure and discretized it into a cascade of codirectional coupling, reflection, and pure propagation. Obviously, we can also describe discrete coupling directly. The most general, lossless, reciprocal coupling element can be described as a discrete reflector sandwiched between two codirectional coupling sections (Appendix B). Compared to our discrete model above, there is an extra codirectional coupling section on the right-hand side of the reflector. In the special case where all modes have equal effective index, $\boldsymbol{Z}^{-1} \propto \boldsymbol{I}$, this coupling section commutes with the delay section, and as a result it can be absorbed into the next, adjacent layer on the right-hand side. However, in the general case this extra coupling section does not commute with the delay section and cannot be ignored. For inverse scattering, this coupling section should therefore not be present since it would not be possible to determine the transmission through the layer uniquely from the reflection which prevents unique reconstruction, at least when only using the reflection response as the starting point. Under this assumption, $\boldsymbol{t}_j$ is positive semidefinite and uniquely determined by $\boldsymbol{t}_j^2 = \boldsymbol{I} - \boldsymbol{\rho}_j \boldsymbol{\rho}_j^*$. We restrict ourselves to reflectors that satisfy $\|\boldsymbol{\rho}_j\| < 1$; otherwise the reflector will mask the later part of the structure such that the inverse scattering procedure will not be possible. Also, with two or more layers with $\|\boldsymbol{\rho}_j\| = 1$, the structure may behave as an ideal resonator with bound modes.

Writing out the transfer matrix (2.5) of each layer, we obtain

$$\mathbf{T}_j = \begin{bmatrix} \boldsymbol{Z}^{-1}\boldsymbol{t}_j^{-1*}\boldsymbol{\Phi}_j & -\boldsymbol{Z}^{-1}\boldsymbol{t}_j^{-1*}\boldsymbol{\rho}_j^*\boldsymbol{\Phi}_j^* \\ -\boldsymbol{Z}\boldsymbol{t}_j^{-1}\boldsymbol{\rho}_j\boldsymbol{\Phi}_j & \boldsymbol{Z}\boldsymbol{t}_j^{-1}\boldsymbol{\Phi}_j^* \end{bmatrix} = \begin{bmatrix} \boldsymbol{Z}^{-1}\boldsymbol{K}_j & \boldsymbol{0} \\ \boldsymbol{0} & \boldsymbol{Z}\boldsymbol{K}_j^* \end{bmatrix} \begin{bmatrix} \boldsymbol{I} & -\boldsymbol{\Upsilon}_j^* \\ -\boldsymbol{\Upsilon}_j & \boldsymbol{I} \end{bmatrix}, \tag{2.7}$$

where $\boldsymbol{\Upsilon}_j = \boldsymbol{\Phi}_j^{\mathrm{T}}\boldsymbol{\rho}_j\boldsymbol{\Phi}_j$ and $\boldsymbol{K}_j = \boldsymbol{t}_j^{-1*}\boldsymbol{\Phi}_j$. The transfer matrix can be converted into a scattering matrix (Appendix B):

$$\mathbf{S}_j = \begin{bmatrix} \boldsymbol{\Phi}_j^{\mathrm{T}}\boldsymbol{\rho}_j\boldsymbol{\Phi}_j & \boldsymbol{\Phi}_j^{\mathrm{T}}\boldsymbol{t}_j\boldsymbol{Z}^{-1} \\ \boldsymbol{Z}^{-1}\boldsymbol{t}_j^*\boldsymbol{\Phi}_j & -\boldsymbol{Z}^{-1}\boldsymbol{t}_j^{-1*}\boldsymbol{\rho}_j^*\boldsymbol{t}_j\boldsymbol{Z}^{-1} \end{bmatrix}. \tag{2.8}$$

Thus, $\boldsymbol{\Upsilon}_j$ represents the reflection response from the left of layer j.

The combined transfer matrix describing the total structure with N layers is given by

$$\mathbf{T} = \mathbf{T}_{N-1}\mathbf{T}_{N-2}\cdots\mathbf{T}_1\mathbf{T}_0. \tag{2.9}$$

From this matrix we can determine the reflection and transmission response using (B.3). For example, the reflection response from the left is

$$\boldsymbol{R}(\omega) \equiv \boldsymbol{S}_{11} = -\boldsymbol{T}_{22}^{-1}\boldsymbol{T}_{21}, \tag{2.10}$$

where $\boldsymbol{T}_{kl}$ are the $P \times P$ blocks in $\mathbf{T}$. Assuming $\|\boldsymbol{\rho}_j\| < 1$ for all j, it can be proven by induction that $\boldsymbol{T}_{22}$ is invertible on and above the real frequency axis in the complex ω-plane for any number of layers. Physically this is obvious since $\boldsymbol{T}_{22}^{-1}$ is the transmission response from the right, and therefore it must exist and be causal and stable.

Reciprocity (B.4a) gives $\boldsymbol{R}(\omega) = \boldsymbol{R}(\omega)^{\mathrm{T}}$. Using $\|\boldsymbol{\rho}_j\| < 1$ for all j, it can be shown by induction that $\|\boldsymbol{R}(\omega)\| < 1$ for a passive structure (a passive structure is characterized by $\operatorname{Im}\beta_p \geq 0$ for all p). By causality the reflection response can be written in the form

$$\boldsymbol{R}(\omega) = \int_0^\infty \boldsymbol{h}(t)\exp(i\omega t)\mathrm{d}t, \tag{2.11}$$

where $\boldsymbol{h}(t)$ is called the time-domain impulse response.

When the modes are nondispersive, i.e., $\boldsymbol{\beta}$ is linearly related to frequency, $\boldsymbol{h}(t)$ equals a train of nonequally spaced, weighted delta pulses:

$$\boldsymbol{h}(t) = \sum_{k=0}^{\infty} \boldsymbol{h}^k \delta(t - t^k). \tag{2.12}$$

Here $\boldsymbol{h}^k$ and t^k are the weight and arrival time of the kth pulse, respectively. Substituting (2.12) into (2.11) gives

$$\boldsymbol{R}(\omega) = \sum_{k=0}^{\infty} \boldsymbol{h}^k \exp(i\omega t^k). \tag{2.13}$$

The weights $\boldsymbol{h}^k$ can, in principle, be calculated from $\boldsymbol{R}(\omega)$ using an inverse transform of the form

$$\boldsymbol{h}^k = \lim_{\omega_{\max}\to\infty} \frac{1}{2\omega_{\max}} \int_{-\omega_{\max}}^{\omega_{\max}} \boldsymbol{R}(\omega) \exp(-i\omega t^k) \mathrm{d}\omega. \tag{2.14}$$

The arrival times are determined by the delay from one layer to the next of each mode. Let Δt_p be the delay of mode p through a single layer. A delta pulse at $t = 0$ is incident to the structure on the left-hand side. Consider the reflection from the different layers, as seen from the left-hand side of the structure. From layer 0, the arrival times in all modes will be zero. An impulse in mode p reflected from layer 1 into mode q will arrive at $\Delta t_p + \Delta t_q$. Thus, considering layer 1, the arrival times are any combinations of two unit delays Δt_p. Considering layer 2, the arrival times are any combinations of four unit delays, and so forth.

When the modes are dispersive, the impulse response is no longer a train of delta functions. Nevertheless, for $t = 0$ it can still be written as $\boldsymbol{h}^0\delta(t)$, and the weight $\boldsymbol{h}^0$ can be found from (2.14).

Equation (2.13) clearly demonstrates that, in principle, for a discrete structure the reflection response $\boldsymbol{R}(\omega)$ does not approach zero for large frequencies. Only in the special case where the modal effective indices are rational numbers with common denominator is the reflection spectrum periodic. Fortunately, in practice, it is not necessary to represent the entire bandwidth to enable inverse scattering for a discrete structure. As shown in the next section, what is needed in the layer-stripping algorithm is the zeroth point of the impulse response at time $t = 0$. Since the next nonzero value is for $t = 2\min_p \Delta t_p$,[1] the zeroth point is computed accurately, provided the represented bandwidth $\omega_{\max}$ satisfies $\omega_{\max} \gg 1/\min_p \Delta t_p$. Then, if the true reflection spectrum is multiplied by a smooth window function $W(\omega)$ that goes to zero at $\omega = \pm\omega_{\max}$, the inverse Fourier transform evaluated around zero is approximately $w(t)\boldsymbol{h}^0$, where $w(t)$ is the inverse Fourier transform of $W(\omega)$. Since $w(0)\boldsymbol{h}^0 \approx \frac{1}{2\pi}\int_{-\omega_{\max}}^{\omega_{\max}} W(\omega)\boldsymbol{R}(\omega)\mathrm{d}\omega$, we can find $\boldsymbol{h}^0$ from a measurement of $\boldsymbol{R}(\omega)$ in the bandwidth $(-\omega_{\max}, \omega_{\max})$:

$$\boldsymbol{h}^0 \approx \frac{\int_{-\omega_{\max}}^{\omega_{\max}} W(\omega)\boldsymbol{R}(\omega)\mathrm{d}\omega}{\int_{-\omega_{\max}}^{\omega_{\max}} W(\omega)\mathrm{d}\omega}. \tag{2.15}$$

In many practical cases, the structure to be reconstructed is quasi-sinusoidal. More generally, the structure is often quasi-periodic, and, e.g., the first "Fourier component" is to be reconstructed. In such cases, one can define modal field envelopes which vary slowly with respect to x (compared to a wavelength). Similarly, one can extract slowly varying coupling coefficient envelopes. As a result, all quantities in (2.1) vary slowly with x. The relevant bandwidth in (2.15) will then be centered about a chosen "design frequency" rather than zero. The main advantage of this

[1] For simplicity it is assumed to be a nondispersive structure.

procedure is that it leads to considerably fewer requirements on the spatial resolution and, as a result, efficient inverse scattering. This modification to the model is detailed in section 4.

3. Layer-stripping method. The inverse scattering problem can now be stated as follows: Given a structure consisting of N layers, each layer consists of three sections (sublayers), the first ($\mathbf{\Phi}_j$) responsible for coupling between copropagating modes, the second ($\boldsymbol{\rho}_j$) responsible for coupling between counterpropagating modes, and the third a pure propagating section ($\boldsymbol{Z}^{-1}$). The propagation constants of the involved modes are known and specified in terms of $\boldsymbol{Z}^{-1}$.[2] From a set of excitation-response pairs (that is, $\boldsymbol{R}(\omega)$), we want to reconstruct $\boldsymbol{\rho}_j$ and $\mathbf{\Phi}_j$ for all j.

The structure itself and the medium to the right are assumed to be at rest at time $t = 0$. For incident waves from the left, the reflection response from the structure is described by the matrix $\boldsymbol{R}(\omega)$ of dimension $P \times P$. This matrix can be viewed as the operator which takes the excitation field vector to the reflected field vector. Its columns can be interpreted as the responses for orthonormal excitation basis vectors $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_P$, respectively. Here $\boldsymbol{e}_p$ has only one nonzero element (equal to unity) at position p. Similarly, we can define the forward ($\boldsymbol{u}_j(\omega)$) and backward ($\boldsymbol{v}_j(\omega)$) propagating field matrices as $P \times P$ matrices where the columns are the fields for orthonormal excitations $\boldsymbol{e}_1, \boldsymbol{e}_2, \ldots, \boldsymbol{e}_P$. A subscript j is specified to emphasize that $\boldsymbol{u}_j(\omega)$ and $\boldsymbol{v}_j(\omega)$ are the fields at the beginning (left-hand side) of layer j. The field matrices of layer $j + 1$ are related to the field matrices of layer j by

$$\begin{bmatrix} \boldsymbol{u}_{j+1}(\omega) \\ \boldsymbol{v}_{j+1}(\omega) \end{bmatrix} = \mathbf{T}_j \begin{bmatrix} \boldsymbol{u}_j(\omega) \\ \boldsymbol{v}_j(\omega) \end{bmatrix}, \tag{3.1}$$

where $\mathbf{T}_j$ is given by (2.7).

The layer-stripping algorithm is based on the simple fact that the leading edge of the impulse response is independent on later parts of the structure due to causality. Hence, one can identify the first layer of the structure and subsequently remove its effect using the associated transfer matrix.

For layer 0, we initialize $\boldsymbol{u}_0(\omega) = \boldsymbol{I}$ and $\boldsymbol{v}_0(\omega) = \boldsymbol{R}(\omega)$. We define a local reflection spectrum $\boldsymbol{R}_j(\omega) = \boldsymbol{v}_j(\omega)\boldsymbol{u}_j(\omega)^{-1}$ and the associated impulse response $\boldsymbol{h}_j(t)$ as the response of the structure after removing the first $j-1$ layers. Similarly to the impulse response of the entire structure, $\boldsymbol{h}_j(t)$ contains an isolated delta function at $t = 0$. Due to causality, this pulse is equal to the reflection from the zeroth layer alone. Denoting the weight of this pulse $\boldsymbol{h}_j^0$, we find from (2.8) that

$$\boldsymbol{h}_j^0 = \mathbf{\Upsilon}_j \equiv \mathbf{\Phi}_j^{\mathrm{T}} \boldsymbol{\rho}_j \mathbf{\Phi}_j. \tag{3.2}$$

Note that $\boldsymbol{R}_j(\omega)$ is symmetric for all ω as a result of reciprocity; thus $\boldsymbol{h}_j^0$ is symmetric as well. Writing out (3.1) and (2.7) and substituting $\boldsymbol{v}_j(\omega) = \boldsymbol{R}_j(\omega)\boldsymbol{u}_j(\omega)$, we obtain

$$\boldsymbol{u}_{j+1}(\omega) = \boldsymbol{Z}^{-1}\boldsymbol{K}_j \left[\boldsymbol{I} - \mathbf{\Upsilon}_j^* \boldsymbol{R}_j(\omega)\right] \boldsymbol{u}_j(\omega), \tag{3.3a}$$

$$\boldsymbol{v}_{j+1}(\omega) = \boldsymbol{Z}\boldsymbol{K}_j^* \left[\boldsymbol{R}_j(\omega) - \mathbf{\Upsilon}_j\right] \boldsymbol{u}_j(\omega), \tag{3.3b}$$

[2] The effective indices may contain small, real, unknown parts Δn_p, i.e., $n_p = n_{p,\mathrm{known}} + \Delta n_p$, where $n_{p,\mathrm{known}}$ are known. Provided Δn_p is sufficiently small, the variation of the associated phase factor $\exp(i\omega\Delta n_p \Delta x/c)$ may be small over the relevant bandwidth. In such cases the unknown parts can be absorbed into the $\mathbf{\Phi}_j$'s.

and therefore

$$\boldsymbol{R}_{j+1}(\omega) = \boldsymbol{Z}\boldsymbol{K}_j^* \left[\boldsymbol{R}_j(\omega) - \boldsymbol{\Upsilon}_j\right] \left[\boldsymbol{I} - \boldsymbol{\Upsilon}_j^* \boldsymbol{R}_j(\omega)\right]^{-1} \boldsymbol{K}_j^{-1} \boldsymbol{Z}. \tag{3.4}$$

Provided $\boldsymbol{\Upsilon}_j$ and $\boldsymbol{K}_j$ are known, (3.4) shows that the local reflection spectrum of layer $j+1$ can be calculated directly from the local reflection spectrum of layer j without calculating the fields $\boldsymbol{u}_{j+1}$ and $\boldsymbol{v}_{j+1}$. Note the similarity to the Schur formula used in scalar layer-stripping [6].

To characterize layer j completely and to identify $\boldsymbol{K}_j$, we must determine $\boldsymbol{\rho}_j$ and $\boldsymbol{\Phi}_j$. By counting the available degrees of freedom (in $\boldsymbol{\Upsilon}_j$), we immediately find that this cannot be done uniquely. It is therefore necessary to use a priori information on $\boldsymbol{\rho}_j$ and/or $\boldsymbol{\Phi}_j$. The available information may vary from situation to situation. Here we will consider the following situations, where $\boldsymbol{\rho}_j$ and $\boldsymbol{\Phi}_j$ can be found using the methods in sections A.1 and A.2.

(a) $\boldsymbol{\Phi}_j = \boldsymbol{I}$. In this case there is no codirectional coupling. The identification of the layer is now particularly simple, as $\boldsymbol{\rho}_j = \boldsymbol{\Upsilon}_j$ uniquely. Note that while there is no codirectional coupling, $\boldsymbol{\rho}_j$ describes reflection from all modes into all modes. Thus the different modes may still interact.

(b) $\boldsymbol{\rho}_j$ is diagonal and nonnegative. Now $\boldsymbol{\rho}_j$ is a simple partial reflector which reflects only light into the same mode as the incident field (no reflection into other modes). The coupling between different modes is instead described by $\boldsymbol{\Phi}_j$. Since $\boldsymbol{\Upsilon}_j = \boldsymbol{\Phi}_j^{\mathrm{T}} \boldsymbol{\rho}_j \boldsymbol{\Phi}_j$, $\boldsymbol{\rho}_j$ is found uniquely as the singular value matrix associated with $\boldsymbol{\Upsilon}_j$ up to reordering of the singular values. Once the order of the singular values has been established, the unitary $\boldsymbol{\Phi}_j$ is found uniquely up to the sign of its rows, provided all singular values are distinct and nonzero (see section A.1). When one or more singular values of $\boldsymbol{\Upsilon}_j$ are zero, the corresponding row(s) of $\boldsymbol{\Phi}_j$ cannot be determined uniquely. More precisely, $\boldsymbol{\Phi}_j$ is determined up to a premultiplicative unitary matrix $\boldsymbol{J}$ operating on the associated mode(s). Physically, this is obvious since when a singular value is zero, the associated mode is not reflected from the layer. When two or more nonvanishing singular values are equal, $\boldsymbol{\Phi}_j$ is determined up to a premultiplicative, real unitary $\boldsymbol{J}$ operating on the associated modes. Physically, this means that these modes experience the same reflection, and thus an arbitrary (real) "rotation" of the modes is not detected. In such cases, the unitary section $\boldsymbol{\Phi}_j$, as determined by the method in section A.1, does not necessarily correspond to the physical section. This error will propagate to the next layers according to (3.4).

(c) $\boldsymbol{\Phi}_j$ is symmetric and $\boldsymbol{\rho}_j$ is real and positive semidefinite. A special case in which there are only two degenerate modes in each direction is treated in [41]. The reflector matrix $\boldsymbol{\rho}_j$ can be written $\boldsymbol{P}_j^{\mathrm{T}} \boldsymbol{\Sigma}_j \boldsymbol{P}_j$, where $\boldsymbol{P}_j$ is a real, special unitary matrix and $\boldsymbol{\Sigma}_j$ is diagonal and nonnegative. Since $\boldsymbol{\Upsilon}_j = \boldsymbol{\Phi}_j^{\mathrm{T}} \boldsymbol{\rho}_j \boldsymbol{\Phi}_j = \boldsymbol{\Phi}_j^{\mathrm{T}} \boldsymbol{P}_j^{\mathrm{T}} \boldsymbol{\Sigma}_j \boldsymbol{P}_j \boldsymbol{\Phi}_j$, we find $\boldsymbol{\Sigma}_j$ and $\boldsymbol{P}_j \boldsymbol{\Phi}_j$ as in the previous case, with the identical ambiguity issues. The separate identification of $\boldsymbol{P}_j$ and $\boldsymbol{\Phi}_j$ is accomplished using the factorization method in section A.2, with certain ambiguities related to the sign of the eigenvalues of $\boldsymbol{\Phi}_j$.

The ambiguities when determining $\boldsymbol{\Phi}_j$ in situation (b) are in fact very similar to the well-known ambiguities in the scalar case with a single mode in each direction. In the scalar case any π phase-shift sections between the reflectors cannot be identified since the associated round-trip phase accumulated to and from a reflector becomes 2π. In our multimode case, the sign of the rows of the "phase-delay" section ($\boldsymbol{\Phi}_j$)

between two reflectors cannot be identified. Similarly, in the scalar case, any phase-shift section preceding a zero reflector cannot be determined uniquely. Instead it is chosen arbitrarily (e.g., removed) and attributed to the next layer with a nonzero reflector.

When the structure to be reconstructed is a discretized version of a smooth structure, the smoothness can be used to resolve ambiguites. First we consider situation (b). For small Δx, $\mathbf{\Phi}_j$ is close to identity; thus the sign of the rows of $\mathbf{\Phi}_j$ can be determined uniquely. If $\boldsymbol{\rho}_j$ has distinct eigenvalues, valid for all j, the order of the eigenvalues of $\boldsymbol{\rho}_j$ can be determined from the order of the eigenvalues of $\boldsymbol{\rho}_{j-1}$ using the smoothness of $\boldsymbol{\kappa} = \boldsymbol{\kappa}(x)$. If there are equal eigenvalues for a certain reflector $\boldsymbol{\rho}_j$, or if $\boldsymbol{\rho}_j$ is singular, the ambiguities of $\mathbf{\Phi}_j$ are characterized by the premultiplicative $\boldsymbol{J}$ matrix (section A.1). In other words, the chosen $\mathbf{\Phi}_j$ is related to the corresponding true matrix ($\mathbf{\Phi}_{j,\text{true}}$) by $\mathbf{\Phi}_j = \boldsymbol{J}\mathbf{\Phi}_{j,\text{true}}$. By choosing $\boldsymbol{J}$ such that $\|\mathbf{\Phi}_j - \mathbf{\Phi}_{j-1}\|$ is minimum, the resulting $\boldsymbol{J}$ is close to identity (that is, $\|\boldsymbol{J} - \boldsymbol{I}\| \leq 2\|\mathbf{\Phi}_{j,\text{true}} - \mathbf{\Phi}_{j-1}\|$). Since $\boldsymbol{t}_j$ and $\boldsymbol{Z}^{-1}$ are close to identity as well, the order of three sections $\boldsymbol{J}$, $\boldsymbol{t}_j$, and $\boldsymbol{Z}^{-1}$ can be interchanged (see section 2). Thus the error due to wrong choice of $\mathbf{\Phi}_j$ can be absorbed into $\mathbf{\Phi}_{j+1}$. More generally, provided only a few neighboring layers have singular or degenerate $\boldsymbol{\rho}_j$'s, only the corresponding and following $\mathbf{\Phi}_j$ sections may be determined erroneously, and the determination of the later part of the structure is (approximately) unaffected.

In situation (c), the order of eigenvalues of $\boldsymbol{\rho}_j$ can be determined as in situation (b). However, $\boldsymbol{P}_j\mathbf{\Phi}_j$ is not necessarily close to identity. Nevertheless, the sign of its rows can be determined from $\boldsymbol{P}_{j-1}\mathbf{\Phi}_{j-1}$ if $\boldsymbol{\kappa} = \boldsymbol{\kappa}(x)$ is sufficiently smooth. (Recall that $\boldsymbol{P}_j\mathbf{\Phi}_j$ is unitary, which means that in each row there exists at least one element of magnitude $\geq 1/\sqrt{P}$.) Finally, since $\mathbf{\Phi}_j$ is close to identity, its eigenvalues are close to unity. It follows that the factorization of $\boldsymbol{P}_j\mathbf{\Phi}_j$ into $\boldsymbol{P}_j$ and $\mathbf{\Phi}_j$ is unique (section A.2).

From the discussion above, we summarize the layer-stripping algorithm, analogously to the scalar version described in [6, 5], that can be applied to identify a structure supporting multiple modes:

(1) Initialize $j = 0$. Set $\boldsymbol{R}_j(\omega) = \boldsymbol{R}(\omega)$.

(2) Compute the zeroth weight $\boldsymbol{h}_j^0$ of the impulse response. In practice this is achieved by the substitutions $\boldsymbol{h}^0 \to \boldsymbol{h}_j^0$ and $\boldsymbol{R}(\omega) \to \boldsymbol{R}_j(\omega)$ in (2.15).

(3) Use a model-specific factorization of $\boldsymbol{h}_j^0 = \mathbf{\Phi}_j^{\mathrm{T}}\boldsymbol{\rho}_j\mathbf{\Phi}_j$ to find $\mathbf{\Phi}_j$ and $\boldsymbol{\rho}_j$.

(4) Calculate $\boldsymbol{t}_j = (\boldsymbol{I} - \boldsymbol{\rho}_j\boldsymbol{\rho}_j^*)^{1/2}$ such that the associated eigenvalues are positive, and set $\boldsymbol{K}_j = \boldsymbol{t}_j^{-1}\mathbf{\Phi}_j$.

(5) Calculate the next, local reflection response $\boldsymbol{R}_{j+1}(\omega)$ using (3.4).

(6) If $j < N - 1$, increase j and return to (2).

When the scattering structure is continuous, one can use the true reflection spectrum as input to the layer-stripping algorithm, even though the structure is modeled discrete. This can be justified as follows: The layer thickness Δx is chosen small such that the first order approximations of $\exp(i\mathbf{C}_{\boldsymbol{\kappa}}\Delta x)$ and $\exp(i\mathbf{C}_{\boldsymbol{\sigma}}\Delta x)$ are accurate. (Thus an upper bound on $\|\mathbf{C}_{\boldsymbol{\kappa}}\|$ and $\|\mathbf{C}_{\boldsymbol{\sigma}}\|$ should be known a priori.) Let $\omega \leq \omega_{\text{b}}$ be the bandwidth where the true reflection spectrum is significantly different from zero. For sufficiently small Δx, the first order approximation of $\exp(i\mathbf{D}\Delta x)$ is valid, and the true reflection spectrum is approximately equal to that of the corresponding discrete model in the bandwidth $\omega \leq \omega_{\text{b}}$. In the limit $t \to 0^+$, the (p, q) element of the impulse response of the continuous structure can be calculated exactly from (2.1) using the Born approximation, yielding

$$(3.5)\quad h_{pq}(t=0^+) \equiv \frac{1}{2\pi}\lim_{t\to 0^+}\int_{-\infty}^{\infty} R_{pq}(\omega)\exp(-i\omega t)\mathrm{d}\omega = i\kappa_{pq}^*(x=0^+)c/(n_p+n_q).$$

Here $\kappa_{pq}(x=0^+)$ is the (p,q) element of $\boldsymbol{\kappa}(x)$ at $x=0^+$. For practical computations, the integral in (3.5) must be truncated at $\pm\omega_{\mathrm{b}}$; thus, to find the leading edge of $h_{pq}(t)$, one can take $t=0$ in the integral and multiply the result by a factor of two. (Recall that by causality $\lim_{t\to 0^-} h_{pq}(t)=0$.) Once $\boldsymbol{\kappa}$ for the zeroth layer is found, one can propagate the fields using (3.4). Since we have not identified the codirectional coupling $\boldsymbol{\Phi}_0$ of the zeroth layer, $\boldsymbol{\Phi}_0$ is associated with the next layer. Thus, after the zeroth layer has been stripped off, the leading edge of the impulse response of the remaining structure becomes

$$(3.6)\qquad \boldsymbol{\Phi}_0^{\mathrm{T}}\left[i\kappa_{pq}^*(x=\Delta x^+)c/(n_p+n_q)\right]\boldsymbol{\Phi}_0,$$

where the square bracket denotes a matrix formed by the elements inside. The identification of $\boldsymbol{\Phi}_0$ and $\left[i\kappa_{pq}^*/(n_p+n_q)\right]$ can now be accomplished using the factorization methods described above. The algorithm continues in the same way, until finally the bandwidth of the reflection spectrum of the remaining structure exceeds ω_{b}. This remaining part of the structure can be made arbitrarily thin by choosing a sufficiently small Δx.

The difference between the latter “quasi-continuous” formulation and the discrete algorithm is essentially the factor n_p+n_q and the method for evaluating the leading edge or first point of the impulse response. When the effective indices can be approximated by some number n_0 for all p, $n_p\approx n_0$, one can in fact use the discrete algorithm directly: A periodic extension of the true reflection spectrum outside a principal bandwidth $[-\omega_{\max},\omega_{\max}]$ corresponds then to a discrete model with $\Delta x=\pi c/(2n_0\omega_{\max})$. The first point of the impulse response is calculated by (2.15) using a rectangular window function $W(\omega)$. For a broad class of waveguides of practical interest, the effective indices are similar (see section 4). While the phase relation between the modes, as described by $\boldsymbol{Z}^{-1}$, may still result in a nontrivial multimode coupling, the discrete algorithm gives accurate results. The errors due to this periodic spectrum approximation can be corrected to some extent by including the factor $(n_p+n_q)/(2n_0)$ in the elements on the right-hand side of (2.15). This can be justified, e.g., using the Born approximation.

4. Quasi-sinusoidal coupling structures. Continuous coupling in acoustical, radio frequency, or optical waveguides may be obtained by perturbation of the effective indices n_p associated with each mode. This can be achieved by modulation of the wall profile or waveguide medium properties. As a concrete example, we will discuss fiber Bragg gratings [17], which have attracted large interest recently due to their applications in fiber optical communications and sensors. A fiber grating is formed in an optical fiber by modulating the refractive index of the core periodically or quasi-periodically. The main peak of the reflection spectrum appears for the frequency where the reflection from a crest in the index modulation is in phase with the next reflection. Permanent gratings are fabricated by UV-illumination. In fibers doped with certain dopants such as germanium, the UV-illumination will permanently rise the refractive index of the core. Advanced fabrication methods have made it possible to manufacture complex gratings with varying index modulation amplitude and period. The layer-stripping algorithm is the most widely used method for designing the index profile to obtain a given reflection spectrum [10, 37, 36].

In most cases, the fiber grating is formed in a single-mode fiber, and coupling is considered only between the forward-propagating and backward-propagating fundamental mode. The field matrices $\boldsymbol{u}_j(\omega)$ and $\boldsymbol{v}_j(\omega)$ are then scalar functions. However, in some cases it is not sufficient to consider only one forward-propagating mode and one backward-propagating mode. For instance, a single mode fiber is always slightly birefringent, and the photosensitivity can be polarization-dependent [16]. In this case, two forward-propagating and two backward-propagating polarization modes must be considered. An inverse scattering algorithm that takes into account polarization mode coupling is described in [41]. The coupling between the two polarization modes is described by Jones matrices [20]. Both polarization modes have approximately the same effective index, and so $\boldsymbol{Z}^{-1} = \exp(i\beta\Delta x)\boldsymbol{I}$, where the common propagation constant β is scalar.

In a multimode fiber, the modulation of the refractive index may result in coupling between the fundamental mode and other modes. Each mode has a transversal field profile $\Psi_p(r,\phi)$ which is a solution to the scalar wave equation in polar coordinates r and ϕ [38]:[3]

$$\left\{\nabla_{\mathrm{t}}^2 + k^2(\bar{n}^2(r) - n_p^2)\right\}\Psi_p(r,\phi) = 0. \tag{4.1}$$

Here $\bar{n}(r)$ is the unperturbed, refractive index profile of the fiber, which is assumed to be real, ∇_{t} is the transversal nabla operator, and $k = \omega/c$. The field $\Psi_p(r,\phi)$ and its first derivatives are continuous. For bound modes, the fields are real and orthonormal such that $\int_{A_\infty} \Psi_p(r,\phi)\Psi_q(r,\phi)\mathrm{d}A = \delta(p-q)$, where $\delta(p-q)$ denotes the Kronecker delta, and A_∞ is the entire transversal plane. The effective indices n_p are eigenvalue solutions to (4.1). A mode p is bound when $n_{\mathrm{cl}} < n_p \leq n_{\mathrm{co}}$, where n_{co} and n_{cl} are the refractive indices of the fiber core and cladding, respectively. Ignoring radiation modes, which in the vicinity of the core decay rapidly away from the excitation source, the total electric field $E(r,\phi,x)$ can be written as a superposition of forward- and backward-propagating bound modes:

$$E(r,\phi,x) = \sum_{p=1}^{P}(b_p^+(x) + b_p^-(x))\Psi_p(r,\phi). \tag{4.2}$$

Here $b_p^\pm(x)$ contain all x-dependence including the harmonic propagation factor $\exp(\pm i\beta_p x)$, where $\beta_p = kn_p$.

Coupling between the modes originates from longitudinal modulation of the refractive index. Let the refractive index be perturbed quasi-periodically with a spatial period Λ,

$$n(r,\phi,x) = \bar{n}(r) + \Delta n_{\mathrm{ac}}(r,\phi,x)\cos\left(\frac{2\pi}{\Lambda}x + \theta(x)\right) + \Delta n_{\mathrm{dc}}(r,\phi,x), \tag{4.3}$$

where $\Delta n_{\mathrm{ac}}(r,\phi,x)$, $\Delta n_{\mathrm{dc}}(r,\phi,x)$, and $\theta(x)$ are slowly varying with x over a distance Λ. We assume that $\Delta n_{\mathrm{ac}}(r,\phi,x) \ll \bar{n}$, and $\Delta n_{\mathrm{dc}}(r,\phi,x) \ll \bar{n}$, which is the case for practical fiber gratings. The total electric field must satisfy the scalar wave equation for the perturbed fiber, i.e.,

$$\left\{\nabla_{\mathrm{t}}^2 + \frac{\partial^2}{\partial x^2} + k^2 n^2(r,\phi,x)\right\}E(r,\phi,x) = 0. \tag{4.4}$$

[3] To find the exact electromagnetic modes, the vector wave equation must be solved. However, for weakly guiding waveguides (waveguides with small difference between the refractive index of the core and the cladding), the scalar wave equation can be used. This is the case for most conventional fibers.

We now substitute (4.2) into (4.4), take (4.1) into account, and multiply the resulting equation by $\Psi_q(r,\phi)$. By integration over the entire transversal plane and recalling that the modes are orthonormal, the resulting set of second order differential equations can be decomposed into first order coupled mode equations [38],

$$\frac{\mathrm{d}b_p^+(x)}{\mathrm{d}x} - i\beta_p b_p^+(x) = i\sum_{q=1}^{P} \mathcal{C}_{pq}(x)(b_q^+(x)+b_q^-(x)), \tag{4.5a}$$

$$\frac{\mathrm{d}b_p^-(x)}{\mathrm{d}x} + i\beta_p b_p^-(x) = -i\sum_{q=1}^{P} \mathcal{C}_{pq}(x)(b_q^+(x)+b_q^-(x)), \tag{4.5b}$$

where

$$\mathcal{C}_{pq}(x) = \frac{k}{2n_p}\int_{A_\infty} (n^2(r,\phi,x)-\bar{n}^2(r))\Psi_p(r,\phi)\Psi_q(r,\phi)\mathrm{d}A. \tag{4.6}$$

Note that the frequency dependence of (4.6) can be ignored in practice, since the normalized bandwidth of interest is usually much less than unity, and the field profiles and effective indices are approximately constant in this bandwidth. Also note that since the fiber is assumed to be weakly guiding, n_p can be set equal to n_{co}; thus $\mathcal{C}_{pq} = \mathcal{C}_{qp}$.

In the case of a quasi-periodic structure it is natural to write the coupling coefficient as a quasi-Fourier series:

$$\begin{aligned}\mathcal{C}_{pq}(x) = \sigma_{pq}(x) + \kappa_{pq}(x)\exp\left(i\frac{2\pi}{\Lambda}x\right) + \kappa_{pq}^*(x)\exp\left(-i\frac{2\pi}{\Lambda}x\right)\\ + \sum_{|m|\geq 2}\kappa_{pq}^{(m)}(x)\exp\left(i\frac{2\pi m}{\Lambda}x\right),\end{aligned} \tag{4.7}$$

where the "Fourier coefficients" $\kappa_{pq}(x)$, $\sigma_{pq}(x)$, and $\kappa_{pq}^{(m)}(x)$ are slowly varying over a period Λ. For a fiber grating the index modulation $n(r,\phi,x)-\bar{n}(r)$ is given by (4.3) and is small compared to $\bar{n}(r)$, and so the zeroth and first order Fourier components dominate. Note that $\arg\{\kappa_{pq}(x)\} = \theta(x)$.

The field amplitudes $b_p^{\pm}(x)$ vary rapidly; it is therefore convenient to introduce the slowly varying field envelopes $u_p(x)$ and $v_p(x)$ by setting

$$b_p^+(x) = i^{1/2}u_p(x)\exp\left(i\frac{\pi}{\Lambda}x\right)\exp\left(i\frac{\theta(x)}{2}\right), \tag{4.8a}$$

$$b_p^-(x) = i^{-1/2}v_p(x)\exp\left(-i\frac{\pi}{\Lambda}x\right)\exp\left(-i\frac{\theta(x)}{2}\right). \tag{4.8b}$$

Since an identical phase factor is removed from all modes, the reflection response as calculated from b_p^+ and b_q^- will differ only from that calculated from u_p and v_q by a constant phase factor not dependent on p and q. Inserting (4.7) and (4.8) into (4.5) and ignoring rapidly oscillating terms (since they contribute little to $\mathrm{d}u_p/\mathrm{d}x$ and $\mathrm{d}v_p/\mathrm{d}x$), we obtain an alternative set of coupled-mode equations

$$\frac{\mathrm{d}u_p(x)}{\mathrm{d}x} = i\delta_p u_p(x) - \frac{i}{2}\frac{\mathrm{d}\theta(x)}{\mathrm{d}x}u_p(x) + i\sum_{q=1}^{P}\sigma_{pq}(x)u_q(x) + \sum_{q=1}^{P}|\kappa_{pq}(x)|v_q(x), \tag{4.9a}$$

$$\frac{\mathrm{d}v_p(x)}{\mathrm{d}x} = -i\delta_p v_p(x) + \frac{i}{2}\frac{\mathrm{d}\theta(x)}{\mathrm{d}x}v_p(x) - i\sum_{q=1}^{P}\sigma_{pq}(x)v_q(x) + \sum_{q=1}^{P}|\kappa_{pq}(x)|u_q(x), \tag{4.9b}$$

where $\delta_p = \beta_p - \pi/\Lambda = n_p\omega/c - \pi/\Lambda$ is the wavenumber detuning of mode p. Thus, $-i|\kappa_{pq}(x)|$ is the coupling coefficient between modes p and q propagating in opposite directions, while $\sigma_{pq}(x) - \delta(p-q)(\mathrm{d}\theta(x)/\mathrm{d}x)/2$ is the coupling coefficient between modes p and q in the same direction. With $\boldsymbol{E} = [u_1, u_2, \ldots, u_P, v_1, v_2, \ldots, v_P]^{\mathrm{T}}$ we find that (4.9) coincides with (2.1), where $\sigma_{pq}(x) - \delta(p-q)(\mathrm{d}\theta(x)/\mathrm{d}x)/2$ and $-i|\kappa_{pq}(x)|$ are the (p,q) elements of $\boldsymbol{\sigma}$ and $\boldsymbol{\kappa}$, respectively, and δ_p are the diagonal elements of $\boldsymbol{\beta}$. Note that δ_p do not correspond to the actual propagation constants but rather their detuning from π/Λ. Approximating the effective indices by n_{co}, this means that the bandwidth of interest is not centered about zero but rather about the "design frequency" $\omega_0 \equiv \pi c/(n_{\mathrm{co}}\Lambda)$. The frequency interval of integration in (2.15) should be centered about ω_0. As in the scalar case [36], we also note that, in general, the geometrical phase variation $\theta(x)$ cannot be distinguished from the phase variation associated with the dc index term $\Delta n_{\mathrm{dc}}(r,\phi,x)$.

We observe that $\boldsymbol{\sigma}$ is real and symmetric, and $\boldsymbol{\kappa}$ is imaginary and symmetric. Moreover, it is not difficult to realize that $i\boldsymbol{\kappa}$ is positive semidefinite.[4] Thus $\boldsymbol{\Phi}_j$ defined in (2.6) is unitary and symmetric, and $-\boldsymbol{\rho}_j$ is real and positive semidefinite. It follows that we can use the layer-stripping method together with the factorization approach (c), as given in section 3, to identify the coupling sections $\boldsymbol{\rho}_j$ and $\boldsymbol{\Phi}_j$ (and therefore the coupling matrices $\boldsymbol{\kappa}$ and $\boldsymbol{\sigma}$ as a function of position x). Since $(i\boldsymbol{\Phi}_j)^{\mathrm{T}}(-\boldsymbol{\rho}_j)(i\boldsymbol{\Phi}_j) = \boldsymbol{\Phi}_j^{\mathrm{T}}\boldsymbol{\rho}_j\boldsymbol{\Phi}_j$, the factorization approach gives $-\boldsymbol{\rho}_j$ and $i\boldsymbol{\Phi}_j$.

For a fiber grating it is usually reasonable to assume that the ac and dc index modulations can be written in the forms $\Delta n_{\mathrm{ac}}(r,\phi,x) = \Delta n(r,\phi)\Delta n_{\mathrm{ac}}(x)$ and $\Delta n_{\mathrm{dc}}(r,\phi,x) = \Delta n(r,\phi)\Delta n_{\mathrm{dc}}(x)$, respectively. Here $\Delta n(r,\phi)$ accounts for the transversal variation of the index modulation profile, and $\Delta n_{\mathrm{ac}}(x)$ and $\Delta n_{\mathrm{dc}}(x)$ are the ac and dc modulations as a function of x. As before, we assume that the index modulation and $n_{\mathrm{co}} - n_{\mathrm{cl}}$ are small, yielding

$$\boldsymbol{\kappa}(x) = -i\frac{\Delta n_{\mathrm{ac}}(x)}{2}\boldsymbol{\eta}, \tag{4.10a}$$

$$\boldsymbol{\sigma}(x) = \Delta n_{\mathrm{dc}}(x)\boldsymbol{\eta} - \frac{1}{2}\frac{\mathrm{d}\theta(x)}{\mathrm{d}x}\boldsymbol{I}, \tag{4.10b}$$

where $\boldsymbol{\eta}$ is independent on x. The elements of $\boldsymbol{\eta}$ are

$$\eta_{pq} = k\int_{A_\infty} \Delta n(r,\phi)\Psi_p\Psi_q \mathrm{d}A. \tag{4.11}$$

When the mode profiles and $\Delta n(r,\phi)$ are known, this means that the entire coupling matrix $\boldsymbol{\kappa}(x)$ is determined from only a single nonvanishing element. For $\boldsymbol{\sigma}$, two elements are needed (including at least one diagonal element). Note that, in this case, it is indeed possible to distinguish between the dc index modulation $\Delta n_{\mathrm{dc}}(x)$ and the geometrical phase variation $\mathrm{d}\theta(x)/\mathrm{d}x$ using information contained in $\boldsymbol{\sigma}$.

For characterization of multimode gratings, measurements of the reflection from every mode to every mode are required. Executing such a measurement is not trivial. Reference [33] describes using an auxiliary long-period grating (LPG), i.e., a grating with purely codirectional coupling, to characterize another interrogated LPG. With the auxiliary LPG, both modes were excited. Due to the difference in propagation

[4] The real matrix given by the elements $\Psi_p\Psi_q$ is clearly positive semidefinite, since $\sum_{p,q} a_p\Psi_p\Psi_q a_q = (\sum_p \Psi_p a_p)^2 \geq 0$ for any real a_p. For a fiber grating $\Delta n_{\mathrm{ac}}(r,\phi,x) \geq 0$ for all r and ϕ; thus $|\kappa_{pq}(x)|$ adopts the positive semidefinite property from $\Psi_p\Psi_q$.

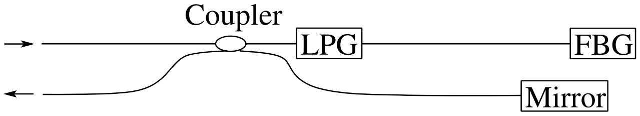

Fig. 4.1. *Measurement setup for characterization of multimode gratings.*

constant, the difference in delay between the modes was large enough to separate the response from the two modes in the time domain. Figure 4.1 shows how this method can be adopted to characterization of multimode fiber Bragg gratings (FBGs) using optical frequency domain reflectometry [12]. Here light is coupled into the fundamental mode of the input fiber and the wavelength of the highly coherent source is swept. The coupler splits the light equally into the two fibers. The LPG couples light from the fundamental modes into the other modes so that the total optical power is distributed between all modes. The light returned by the FBG will again propagate through the LPG, and some light from each mode will be coupled back into the fundamental mode. The mirror reflects only the fundamental mode, and at the coupler the reflected light from the mirror interferes with the light in the fundamental mode out of the LPG. If the fiber between the LPG and FBG is so long that the difference in the delay between the modes is larger than the length of the impulse response of the grating, the individual elements of the reflection matrix will be separable in the time domain, provided that there is no degenerated modes.

5. Numerical example. A potential application of the multimode layer-stripping method is to characterize coupling from the core mode to cladding modes in a single mode fiber. Cladding modes are bound not within the core of the fiber but by the cladding/air boundary [8]. A single mode fiber may support as many as 100 cladding modes. The power in these modes will eventually be lost to the environment. The core-cladding mode coupling can be seen clearly in the transmission spectra of strong gratings. For chirped gratings [26] and chirped, sampled gratings [27], the bandwidth may become larger than the separation in resonant wavelength between the core-core mode coupling and the core-cladding mode coupling. Then the core-cladding mode coupling will interfere with the reflection spectrum associated with the core mode [11]. This unwanted coupling is often handled by writing the grating in fibers with depressed cladding modes [7]. There has also been some attempts to take into account the core-cladding mode coupling in the design of the grating [23, 14]. Here direct scattering is treated with multiple mode coupling, but the inverse scattering has so far been purely single-mode. The layer-stripping algorithm described in section 3 can be used for characterization of such coupling and possibly for design. In contrast to the methods in [23, 14], multiple modes can be taken into account in the inverse scattering part of an iterative design process.

A simpler, but nevertheless interesting, problem is to characterize coupling in an optical fiber with a few bound modes. Here we will present a numerical experiment simulating a grating in a fiber with $n_{\text{co}} = 1.452$, $n_{\text{cl}} = 1.437$, and core radius $r_{\text{co}} = 5\ \mu\text{m}$. By solving the eigenvalue equation for a circular fiber [38], we find that this fiber supports four modes: LP_{01}, LP_{11}, LP_{21}, and LP_{02} at the design wavelength $\lambda_0 = 1.55\ \mu\text{m}$. Here the index l in LP_{lm} means that the transversal field profile can be written in the form $f_{lm}(r)\cos(l\phi)$. In the further discussion, these modes are denoted 1 to 4 in the order indicated above. The eigenvalue equation gives the modal indices $n_1 = 1.449$, $n_2 = 1.444$, $n_3 = 1.439$, and $n_4 = 1.437$. We assume that the refractive index is modulated uniformly in the core of the fiber but not at all in the cladding. This is quite realistic since, during fabrication, the fiber usually is made sensitive to UV exposure only in the core. By evaluating (4.11), we find that there will be no coupling between modes with different azimuthal indices l:

$$\boldsymbol{\eta} = \frac{2\pi}{\lambda_0} \begin{bmatrix} 0.957 & 0 & 0 & -0.116 \\ 0 & 0.874 & 0 & 0 \\ 0 & 0 & 0.707 & 0 \\ -0.116 & 0 & 0 & 0.491 \end{bmatrix}. \tag{5.1}$$

There is no coupling to or from modes 2 and 3; thus the grating profile can be found by applying a scalar layer-stripping method separately to the responses associated with these modes. On the other hand, modes 1 and 4 are coupled, so that the multimode layer-stripping method must be applied when using the associated responses as a starting point.

Defining the nominal mode index $n_0 = (n_1 + n_4)/2$, the grating period is set to $\Lambda = \lambda_0/(2n_0)$. The length of the grating is $L = 20$ mm, and $\Delta n_{\mathrm{ac}}(x)$ has the form of a raised cosine window with maximum value $1 \cdot 10^{-3}$. Furthermore, $\Delta n_{\mathrm{dc}}(x)$ is chosen as a sine-modulated Gaussian window with a full-width-at-half-maximum of 7 mm and a maximum value $5 \cdot 10^{-4}$; the period of the sine modulation is 4 mm. The grating is chirped by varying the grating phase according to

$$\frac{\mathrm{d}\theta}{\mathrm{d}x} = \frac{\pi}{8} \cdot 10^4 \left(x - \frac{L}{2} \right) \mathrm{m}^{-1}. \tag{5.2}$$

The reflection matrix as a function of frequency detuning is generated using the piecewise uniform approximation (section 2) with $\Delta x = 10$ μm, which gives $N = 2000$. Zero detuning is taken to be the frequency $f_0 = c/\lambda_0$. Figure 5.1(a) shows the resulting reflection matrix spectrum. The maximum values are $[|R_{11}|, |R_{22}|, |R_{33}|, |R_{44}|, |R_{14}|]_{\max} = [99.6, 99.6, 97.0, 83.0, 28.3]\%$. Note that the large chirp has resulted in significant spectral overlap between the different elements.

The reflection matrix is applied as input to the layer-stripping method. As the modal indices are similar in magnitude, we use the discrete algorithm directly, and $\boldsymbol{\Upsilon}_j$ is calculated by taking into account the factor $(n_p + n_q)/(2n_0)$ as discussed in section 3. Moreover, $\boldsymbol{\kappa}(x)$ and $\boldsymbol{\sigma}(x)$ are calculated by inverting the expressions for $\boldsymbol{\rho}_j$ and $\boldsymbol{\Phi}_j$ in (2.6b) and (2.6c), respectively. Figure 5.1(b) shows $\Delta n_{\mathrm{ac}}(x)$ along with its reconstructed version. The reconstructed $\Delta n_{\mathrm{ac}}(x)$ is calculated by a least square fit to (4.10a) using the diagonal elements of the reconstructed $\boldsymbol{\kappa}(x)$. We find that the error in reconstructed profile is less that $4 \cdot 10^{-6}$ m^{-1}. Also shown is the ac modulation profile calculated using scalar layer-stripping on R_{11}. Due to the strong coupling between mode 1 and 4, the scalar layer-stripping method does not reconstruct the profile accurately. Figures 5.1(c) and (d) show that it is possible to separate the dc index variations $\Delta n_{\mathrm{dc}}(x)$ from the grating phase gradient $\mathrm{d}\theta(x)/\mathrm{d}x$. The separation is based on a least square fit to (4.10b) using the diagonal elements of $\boldsymbol{\sigma}(x)$. The error in reconstructed $\Delta n_{\mathrm{dc}}(x)$ is less than $6 \cdot 10^{-5}$ m^{-1}, while the error in reconstructed $\mathrm{d}\theta(x)/\mathrm{d}x$ is less than 300 m^{-1}. Errors are mainly due to the finite Δx in addition to the fact that the reflection matrix spectrum of the discretized structure is strictly nonperiodic (see the last paragraph of section 3).

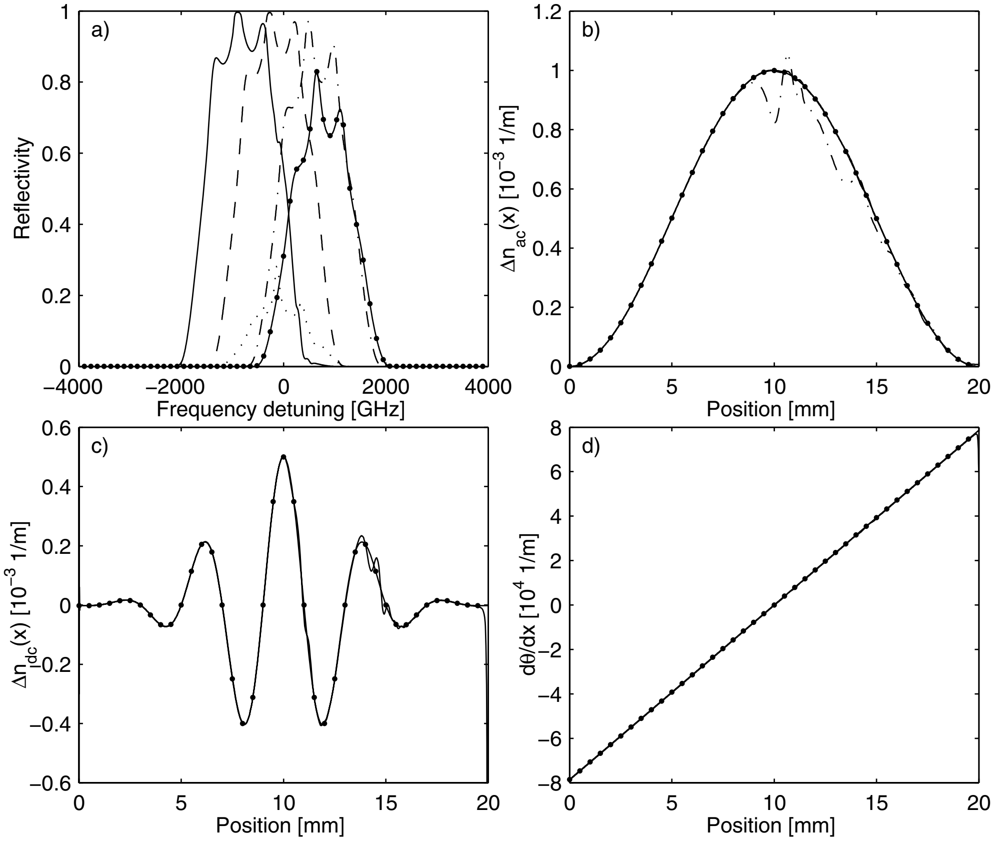

FIG. 5.1. (a) *Magnitude of the reflection spectrum* $|R_{11}|$ *(solid curve),* $|R_{22}|$ *(dashed curve),* $|R_{33}|$ *(dashed-dotted curve),* $|R_{44}|$ *(solid point-marked curve), and* $|R_{14}| = |R_{41}|$ *(dotted curve).* (b) *Reconstructed longitudinal ac modulation* $\Delta n_{\mathrm{ac}}(x)$ *(solid curve), actual ac modulation (solid point-marked curve), and ac modulation calculated using scalar layer-stripping on* R_{11} *(dashed-dotted curve).* (c) *Reconstructed longitudinal dc modulation* $\Delta n_{\mathrm{dc}}(x)$ *(solid curve) and actual dc modulation (solid point-marked curve).* (d) *Reconstructed grating phase gradient* $\mathrm{d}\theta/\mathrm{d}x$ *(solid curve) and actual grating phase gradient (solid point-marked curve).*

6. Analogies to three-dimensional inverse scattering. An important inverse scattering problem is the three-dimensional problem associated with the Schrödinger equation [25]

$$\left\{\nabla^2 + k^2 - V(x,y,z)\right\}\psi(x,y,z;k) = 0, \tag{6.1}$$

where $\psi(x,y,z,k)$ is the wave function and $V(x,y,z)$ is a smooth and nonnegative potential with compact support. In particular, solutions to this problem are applicable to inverse seismic scattering. This problem has been solved using a generalized Marchenko method in [25] and [32], while layer-stripping solutions are suggested in [45] and [43]. Note the close resemblance between (6.1) and (4.4), indicating that a similar method as that in section 4 can be used.

We express the solution as a superposition of the eigenmodes of the Schrödinger equation with $V(x,y,z) = 0$. Writing $\psi(x,y,z;k) = \Psi(y,z;k_y,k_z)\exp(ik_x x)$, these eigenmodes are given by

$$\Psi(y,z;k_y,k_z) = \exp(i(k_y y + k_z z)), \tag{6.2}$$

where k_y and k_z are the wavenumbers in the y-direction and z-direction, respectively, and $k^2 = k_x^2 + k_y^2 + k_z^2$.

In a discrete model, the wavenumbers k_y and k_z can, for example, be discretized in equal intervals Δk, such that $k_y = p\Delta k$ and $k_z = q\Delta k$. In the yz-plane, this means that only a principal range $(-\pi/\Delta k, \pi/\Delta k)$ is considered, and the fields are extended periodically outside this range. The integers p and q are the modal indices satisfying $p^2 + q^2 \leq (k/\Delta k)^2$ for propagating (not evanescent) modes. The modal field profiles are written in normalized form $\Psi_{pq}(y,z) = (\Delta k/2\pi)\Psi(y,z;p\Delta k, q\Delta k)$. The total field $\psi(x,y,z;k)$ is expressed as the superposition

$$\psi(x,y,z;k) = \sum_{p,q} (b_{pq}^{+}(x) + b_{pq}^{-}(x))\Psi_{pq}(y,z), \tag{6.3}$$

where $b_{pq}^{\pm}(x)$ includes all x-dependence of the fields, and ± indicate the sign of k_x, i.e., the propagation direction of the mode.

As in section 4, we insert (6.3) into (6.1), multiply by $\Psi_{pq}^{*}(y,z)$, and integrate over the principal range of the yz-plane. This leads to the coupled mode equations

$$\frac{\mathrm{d}b_{pq}^{+}(x)}{\mathrm{d}x} - ik_{x,pq}b_{pq}^{+}(x) = i\sum_{r,s} \mathcal{C}_{pq,rs}(x)(b_{rs}^{+}(x) + b_{rs}^{-}(x)), \tag{6.4a}$$

$$\frac{\mathrm{d}b_{pq}^{-}(x)}{\mathrm{d}x} + ik_{x,pq}b_{pq}^{-}(x) = -i\sum_{r,s} \mathcal{C}_{pq,rs}(x)(b_{rs}^{+}(x) + b_{rs}^{-}(x)), \tag{6.4b}$$

where the coupling coefficients are given by

$$\begin{aligned} \mathcal{C}_{pq,rs}(x) &= -\frac{1}{2k_x}\int \Psi_{pq}^{*}(y,z)V(x,y,z)\Psi_{rs}(y,z)\mathrm{d}y\mathrm{d}z \\ &= -\frac{1}{2k_x}\left(\frac{\Delta k}{2\pi}\right)^2 \int V(x,y,z)\exp\left[i\Delta k((r-p)y + (s-q)z)\right]\mathrm{d}y\mathrm{d}z, \end{aligned} \tag{6.5}$$

and $k_{x,pq} = [k^2 - (\Delta k)^2(p^2+q^2)]^{1/2}$. We restrict ourselves to the situation where $V(x,y,z)$ is known to be quasi-periodic along the x-direction. Then an expansion of $\mathcal{C}_{pq,rs}(x)$ as in (4.7) together with the transformation (4.8) can be used, resulting in the exact same problem as that described in section 4. Thus the layer-stripping method in section 3 can be applied. The required input data is the reflection into all plane waves upon excitation of the different plane waves onto the plane $x = 0$. The scattering potential $V(x,y,z)$ is found from the inverse of (6.5).

There are two complications. First, in order to use the factorization methods developed in section 3, we must ensure that reciprocity implies symmetric scattering matrices. This is guaranteed when the mode profiles can be written real. Thus we define real mode fields by the transformation

$$\begin{bmatrix} \boldsymbol{\Psi}_{++} \\ \boldsymbol{\Psi}_{-+} \\ \boldsymbol{\Psi}_{+-} \\ \boldsymbol{\Psi}_{--} \end{bmatrix} \rightarrow \mathbf{M} \begin{bmatrix} \boldsymbol{\Psi}_{++} \\ \boldsymbol{\Psi}_{-+} \\ \boldsymbol{\Psi}_{+-} \\ \boldsymbol{\Psi}_{--} \end{bmatrix}, \quad \mathbf{M} = \frac{1}{2}\begin{bmatrix} \boldsymbol{I} & \boldsymbol{I} & \boldsymbol{I} & \boldsymbol{I} \\ -i\boldsymbol{I} & +i\boldsymbol{I} & -i\boldsymbol{I} & +i\boldsymbol{I} \\ i\boldsymbol{I} & -i\boldsymbol{I} & +i\boldsymbol{I} & +i\boldsymbol{I}- \\ \boldsymbol{I} & \boldsymbol{I} & \boldsymbol{I} & -\boldsymbol{I} \end{bmatrix}. \tag{6.6}$$

Here $\boldsymbol{\Psi}_{++}$ denotes a column vector containing the modal field amplitudes Ψ_{pq} with positive p and q, $\boldsymbol{\Psi}_{-+}$ denotes a column vector containing the modal field amplitudes with negative p and positive q, and so forth. The dimension of the identity matrices in the blocks of $\mathbf{M}$ corresponds to the dimension of $\mathbf{\Psi}_{++}$. If $\mathcal{C}$ denotes the matrix formed by the elements $\mathcal{C}_{pq,rs}$, the coupling matrix transforms $\mathcal{C} \to \mathbf{M}^*\mathcal{C}\mathbf{M}^{\mathrm{T}}$. Inspection of (6.5) shows that the transformed $-\mathcal{C}$ is real and positive semidefinite (recall that $V(x,y,z) \geq 0$), thus enabling the factorization method in section 3.

Second, the causality argument of the layer-stripping method works only when the coupling matrix $\mathcal{C}$ is independent on frequency. Equation (6.5) shows that this condition can be justified only when the relevant frequency band is narrow. Therefore the structure must, in addition to being quasi-periodic along the x-direction, vary slowly along the transversal direction. The variation must be sufficiently slow such that the modes with $(p^2+q^2)\Delta k^2 \ll k^2$ contain sufficient information about the transversal dependence, and the other modes may be neglected.

7. Conclusion. A layer-stripping method for the inverse scattering of multimode structures has been proposed. Ambiguities related to factorization of each layer's response into codirectional and contradirectional coupling have been discussed. When there is no codirectional coupling, the ambiguities disappear. Also, when the structure to be reconstructed is smooth, there are important cases with simultaneous co- and contradirectional coupling that can be reconstructed uniquely, provided the reflector eigenvalues are nonzero and nondegenerate. Applications to quasi-periodical structures and analogies to multidimensional inverse scattering have been discussed.

Appendix A. Matrix factorizations.

A.1. Takagi factorization of complex symmetric matrices. Any complex symmtric matrix $\boldsymbol{\Upsilon}$ can be written

$$\boldsymbol{\Upsilon} = \boldsymbol{U}^{\mathrm{T}}\boldsymbol{\Sigma}\boldsymbol{U}, \tag{A.1}$$

where $\boldsymbol{U}$ is unitary and $\boldsymbol{\Sigma}$ is diagonal and nonnegative (see, e.g., [18, Chapter 4.4]). Equation (A.1) is called Takagi factorization.

A constructive proof, suitable for implementation, can be given as follows: Singular value decomposition yields

$$\boldsymbol{\Upsilon} = \boldsymbol{V}_1\boldsymbol{\Sigma}\boldsymbol{V}_2, \tag{A.2}$$

where $\boldsymbol{V}_{1,2}$ are unitary, and $\boldsymbol{\Sigma}$ is diagonal and nonnegative. Using $\boldsymbol{\Upsilon} = \boldsymbol{\Upsilon}^{\mathrm{T}}$ and $(\boldsymbol{\Upsilon}\boldsymbol{\Upsilon}^\dagger)^{\mathrm{T}} = \boldsymbol{\Upsilon}^\dagger\boldsymbol{\Upsilon}$ we find that $\boldsymbol{W}\boldsymbol{\Sigma} = \boldsymbol{\Sigma}\boldsymbol{W}^{\mathrm{T}} = \boldsymbol{\Sigma}\boldsymbol{W}$, where $\boldsymbol{W} \equiv \boldsymbol{V}_2^*\boldsymbol{V}_1$. Thus, provided $\boldsymbol{\Upsilon}$ is nonsingular, $\boldsymbol{W}$ is symmetric. Then $\sqrt{\boldsymbol{W}}$ can be chosen such that it commutes with $\boldsymbol{\Sigma}$ and is symmetric, and we obtain $\boldsymbol{\Upsilon} = \boldsymbol{V}_2^{\mathrm{T}}\boldsymbol{W}\boldsymbol{\Sigma}\boldsymbol{V}_2 = (\sqrt{\boldsymbol{W}}\boldsymbol{V}_2)^{\mathrm{T}}\boldsymbol{\Sigma}\sqrt{\boldsymbol{W}}\boldsymbol{V}_2$, or

$$\boldsymbol{\Upsilon} = \boldsymbol{U}^{\mathrm{T}}\boldsymbol{\Sigma}\boldsymbol{U}, \tag{A.3}$$

where $\boldsymbol{U} \equiv \sqrt{\boldsymbol{W}}\boldsymbol{V}_2$ is unitary and $\boldsymbol{\Sigma}$ is diagonal and positive.

If $\boldsymbol{\Upsilon}$ is singular, we write

$$\boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\Sigma}' & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{bmatrix} \qquad \text{and} \qquad \boldsymbol{W} = \begin{bmatrix} \boldsymbol{W}_{11} & \boldsymbol{W}_{12} \\ \boldsymbol{W}_{21} & \boldsymbol{W}_{22} \end{bmatrix}, \tag{A.4}$$

where we have arranged $\boldsymbol{\Sigma}$ so that the zero singular values are the last ones, $\boldsymbol{\Sigma}'$ is a diagonal matrix with the nonzero singular values, and $\boldsymbol{W}_{11}$ has the same dimension as $\boldsymbol{\Sigma}'$. We now find $\boldsymbol{\Sigma}'\boldsymbol{W}_{11} = \boldsymbol{W}_{11}\boldsymbol{\Sigma}'$, $\boldsymbol{W}_{12} = \boldsymbol{W}_{21} = \mathbf{0}$, and $\boldsymbol{W}_{11} = \boldsymbol{W}_{11}^{\mathrm{T}}$. The commutation relations do not provide any information on $\boldsymbol{W}_{22}$. Choose $\sqrt{\boldsymbol{W}}$ such that

$$\sqrt{\boldsymbol{W}} = \begin{bmatrix} \sqrt{\boldsymbol{W}_{11}} & \mathbf{0} \\ \mathbf{0} & \sqrt{\boldsymbol{W}_{22}} \end{bmatrix}, \tag{A.5}$$

where $\sqrt{\boldsymbol{W}_{11}}$ is symmetric and $\sqrt{\boldsymbol{W}_{11}}$ and $\boldsymbol{\Sigma}'$ commute. Write $\boldsymbol{\Upsilon} = \boldsymbol{U}_1^{\mathrm{T}} \boldsymbol{\Sigma} \boldsymbol{U}_2$, with

$$\boldsymbol{U}_1 = \sqrt{\boldsymbol{W}}^{\mathrm{T}} \boldsymbol{V}_2 = \begin{bmatrix} \boldsymbol{U}' \\ \boldsymbol{U}_1'' \end{bmatrix}, \tag{A.6}$$

$$\boldsymbol{U}_2 = \sqrt{\boldsymbol{W}} \boldsymbol{V}_2 = \begin{bmatrix} \boldsymbol{U}' \\ \boldsymbol{U}_2'' \end{bmatrix}. \tag{A.7}$$

The matrices $\boldsymbol{U}_1''$ and $\boldsymbol{U}_2''$ are the rows of $\boldsymbol{U}_1$ and $\boldsymbol{U}_2$ that correspond to the zero singular values, and they do not give any contribution to $\boldsymbol{\Upsilon}$. We may therefore replace the rows $\boldsymbol{U}_1''$ by $\boldsymbol{U}_2''$, which gives $\boldsymbol{U}_1 = \boldsymbol{U}_2 = \boldsymbol{U}$.

The matrix $\boldsymbol{\Sigma}$ is unique up to reordering of the singular values. When the order of the singular values is established, $\boldsymbol{U}$ is unique up to the replacement $\boldsymbol{J}\boldsymbol{U} \to \boldsymbol{U}$, where $\boldsymbol{J}$ is a unitary matrix satisfying $(\boldsymbol{J}\boldsymbol{U})^{\mathrm{T}} \boldsymbol{\Sigma} \boldsymbol{J} \boldsymbol{U} = \boldsymbol{U}^{\mathrm{T}} \boldsymbol{\Sigma} \boldsymbol{U}$. This leads to $\boldsymbol{J}^{\mathrm{T}} \boldsymbol{\Sigma} \boldsymbol{J} = \boldsymbol{\Sigma}$. Assuming the singular values are sorted in, say, descending order, we find that $\boldsymbol{J}$ is a unitary block-diagonal matrix, where each block has a dimension equal to the number of corresponding repeated singular values. For zero singular values, the corresponding block in $\boldsymbol{J}$ is an arbitrary unitary matrix. For repeated nonzero singular values, the corresponding block in $\boldsymbol{J}$ is real. For a distinct, nonzero singular value, the corresponding block of $\boldsymbol{J}$ is either 1 or −1.

A.2. Factorization of a unitary matrix into a symmetric matrix and an orthogonal matrix. A unitary matrix $\boldsymbol{U}$ can be factorized into $\boldsymbol{U} = \boldsymbol{P}\boldsymbol{\Phi}$, where $\boldsymbol{P}$ is a real unitary matrix (orthogonal matrix) and $\boldsymbol{\Phi}$ is a symmetric unitary matrix (see, e.g., [18, Chapter 3.4]). A constructive proof, suitable for implementation, can be given as follows. First we note that the symmetric unitary matrix $\boldsymbol{\Phi}$ can be factorized into $\boldsymbol{\Phi} = \boldsymbol{P}_1 \boldsymbol{D} \boldsymbol{P}_1^{\mathrm{T}}$, where $\boldsymbol{D}$ is a diagonal unitary matrix and $\boldsymbol{P}_1$ is a real unitary matrix (a simple, constructive proof for this particular spectral decomposition is given in [18, Chapter 4.4]). Thus, an equivalent problem is to show that

$$\boldsymbol{U} = \boldsymbol{P}_2 \boldsymbol{D} \boldsymbol{P}_1^{\mathrm{T}}, \tag{A.8}$$

where $\boldsymbol{P}_2 = \boldsymbol{P}\boldsymbol{P}_1$. The decomposition in (A.8) is very similar to singular value decomposition of real matrices, except that $\boldsymbol{D}$ may have complex elements.

The matrix $\boldsymbol{U}^{\mathrm{T}}\boldsymbol{U}$ is unitary and symmetric; thus we can write

$$\boldsymbol{U}^{\mathrm{T}}\boldsymbol{U} = \boldsymbol{P}_1 \boldsymbol{\Lambda} \boldsymbol{P}_1^{\mathrm{T}}, \tag{A.9}$$

where $\boldsymbol{P}_1$ is a real unitary matrix and $\boldsymbol{\Lambda}$ is a diagonal unitary matrix. Define

$$\boldsymbol{P}_2 = \boldsymbol{U} \boldsymbol{P}_1 \boldsymbol{D}^*, \tag{A.10}$$

where the diagonal matrix $\boldsymbol{D}$ is a solution to $\boldsymbol{D}^2 = \boldsymbol{\Lambda}$. The matrix $\boldsymbol{P}_2$ is unitary since it is produced by multiplication of unitary matrices; thus $\boldsymbol{P}_2^* \boldsymbol{P}_2^{\mathrm{T}} = \boldsymbol{I}$. The matrix is also real since

$$\boldsymbol{P}_2^{\mathrm{T}} \boldsymbol{P}_2 = \boldsymbol{D}^* \boldsymbol{P}_1^{\mathrm{T}} \boldsymbol{U}^{\mathrm{T}} \boldsymbol{U} \boldsymbol{P}_1 \boldsymbol{D}^* = \boldsymbol{D}^* \boldsymbol{P}_1^{\mathrm{T}} \boldsymbol{P}_1 \boldsymbol{D}^2 \boldsymbol{P}_1^{\mathrm{T}} \boldsymbol{P}_1 \boldsymbol{D}^* = \boldsymbol{I}, \tag{A.11}$$

which gives $\boldsymbol{P}_2 = (\boldsymbol{P}_2^*\boldsymbol{P}_2^{\mathrm{T}})\boldsymbol{P}_2 = \boldsymbol{P}_2^*(\boldsymbol{P}_2^{\mathrm{T}}\boldsymbol{P}_2) = \boldsymbol{P}_2^*$.

From (A.10) we therefore conclude that the decomposition in (A.8), with real unitary $\boldsymbol{P}_1$ and $\boldsymbol{P}_2$ and diagonal $\boldsymbol{D}$, is always possible. It follows that any unitary matrix can be written $\boldsymbol{U} = \boldsymbol{P}\boldsymbol{\Phi}$, where $\boldsymbol{P}$ is real and unitary, and $\boldsymbol{\Phi}$ is symmetric and unitary. Note that any global phase of $\boldsymbol{P}$ can instead be assigned to $\boldsymbol{\Phi}$, and so without loss of generality we can assume that $\boldsymbol{P}$ is special ($\det \boldsymbol{P} = 1$ and $\det \boldsymbol{\Phi} = \det \boldsymbol{U}$).

Since $\boldsymbol{D}$ is calculated from $\boldsymbol{D}^2 = \boldsymbol{\Lambda}$, the signs of its elements are arbitrary. The ambiguities when determining $\boldsymbol{P}_1$ in (A.9) give rise to ambiguities in $\boldsymbol{P}$ and $\boldsymbol{\Phi}$. The possible $\boldsymbol{P}$ and $\boldsymbol{\Phi}$ can be expressed as $\boldsymbol{P} = \boldsymbol{U}\boldsymbol{P}_1\boldsymbol{J}\boldsymbol{D}^*\boldsymbol{J}^{\mathrm{T}}\boldsymbol{P}_1^{\mathrm{T}}$ and $\boldsymbol{\Phi} = \boldsymbol{P}_1\boldsymbol{J}\boldsymbol{D}\boldsymbol{J}^T\boldsymbol{P}_1^{\mathrm{T}}$ for a real unitary $\boldsymbol{J}$ that commutes with $\boldsymbol{D}^2$. Here $\boldsymbol{P}_1$ is fixed. If the signs of the elements of $\boldsymbol{D}$ are known to be such that any equal elements of $\boldsymbol{D}^2$ correspond to equal elements of $\boldsymbol{D}$, then $\boldsymbol{J}$ commutes with $\boldsymbol{D}$ and can be ignored.

Appendix B. Linear, reciprocal, and lossless components.

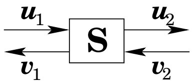

FIG. B.1. *A linear component with P input and P output modes on each side.*

Consider a linear component with P input and P output modes on the left-hand side and P input and P output modes on the right-hand side; see Figure B.1. The component is completely characterized by the $(2P\times 2P)$-dimensional scattering matrix $\mathbf{S}$ which relates the input and output fields:

$$\begin{bmatrix}\boldsymbol{v}_1\\ \boldsymbol{u}_2\end{bmatrix} = \mathbf{S}\begin{bmatrix}\boldsymbol{u}_1\\ \boldsymbol{v}_2\end{bmatrix} = \begin{bmatrix}\boldsymbol{S}_{11} & \boldsymbol{S}_{12}\\ \boldsymbol{S}_{21} & \boldsymbol{S}_{22}\end{bmatrix}\begin{bmatrix}\boldsymbol{u}_1\\ \boldsymbol{v}_2\end{bmatrix}. \tag{B.1}$$

The field vectors that propagate to the right and left are denoted $\boldsymbol{u}$ and $\boldsymbol{v}$, respectively, and the subscripts 1 and 2 indicate the left- and right-hand sides of the component. The scattering matrix is a block matrix; the blocks $\boldsymbol{S}_{11}$ and $\boldsymbol{S}_{22}$ are the reflection from the left- and right-hand sides of the device, respectively, and $\boldsymbol{S}_{21}$ and $\boldsymbol{S}_{12}$ the transmission through the device from the left and right, respectively. These blocks have the dimension $P \times P$.

There exists a similar relation, a transfer matrix relation, that connects the fields on the left-hand side to the fields on the right-hand side:

$$\begin{bmatrix}\boldsymbol{u}_2\\ \boldsymbol{v}_2\end{bmatrix} = \mathbf{T}\begin{bmatrix}\boldsymbol{u}_1\\ \boldsymbol{v}_1\end{bmatrix}. \tag{B.2}$$

Comparing (B.1) and (B.2) we find the blocks of $\mathbf{T}$:

$$\mathbf{T} = \begin{bmatrix}\boldsymbol{S}_{21} - \boldsymbol{S}_{22}\boldsymbol{S}_{12}^{-1}\boldsymbol{S}_{11} & \boldsymbol{S}_{22}\boldsymbol{S}_{12}^{-1}\\ -\boldsymbol{S}_{12}^{-1}\boldsymbol{S}_{11} & \boldsymbol{S}_{12}^{-1}\end{bmatrix}. \tag{B.3}$$

To describe a device with a transfer matrix, $\boldsymbol{S}_{12}$ must be invertible; that is, the transmission from the right cannot be zero for any input field vector. Thus, ideal mirrors, for example, cannot be described by a transfer matrix.

Provided the mode profiles can be written real, reciprocity means that the scattering matrix is symmetric [29, 15], i.e.,

$$\boldsymbol{S}_{11} = \boldsymbol{S}_{11}^{\mathrm{T}}, \tag{B.4a}$$

$$\boldsymbol{S}_{22} = \boldsymbol{S}_{22}^{\mathrm{T}}, \tag{B.4b}$$

$$\boldsymbol{S}_{21} = \boldsymbol{S}_{12}^{\mathrm{T}}. \tag{B.4c}$$

Moreover, the lossless condition is expressed as the unitarity condition $\mathbf{S}^{\dagger}\mathbf{S} = \mathbf{I}$:

$$\boldsymbol{S}_{11}^{\dagger}\boldsymbol{S}_{11} + \boldsymbol{S}_{21}^{\dagger}\boldsymbol{S}_{21} = \boldsymbol{I}, \tag{B.5a}$$

$$\boldsymbol{S}_{12}^{\dagger}\boldsymbol{S}_{12} + \boldsymbol{S}_{22}^{\dagger}\boldsymbol{S}_{22} = \boldsymbol{I}, \tag{B.5b}$$

$$\boldsymbol{S}_{12}^{\dagger}\boldsymbol{S}_{11} + \boldsymbol{S}_{22}^{\dagger}\boldsymbol{S}_{21} = \mathbf{0}. \tag{B.5c}$$

With (B.4) in mind, we introduce Takagi factorization of $\boldsymbol{S}_{11}$ and $-\boldsymbol{S}_{22}$ (see section A.1):

$$\boldsymbol{S}_{11} = \boldsymbol{\Phi}_{\mathrm{l}}^{\mathrm{T}}\boldsymbol{\rho}\boldsymbol{\Phi}_{\mathrm{l}}, \tag{B.6a}$$

$$\boldsymbol{S}_{22} = \boldsymbol{\Phi}_{\mathrm{r}}(-\boldsymbol{\rho}')\boldsymbol{\Phi}_{\mathrm{r}}^{\mathrm{T}}, \tag{B.6b}$$

$$\boldsymbol{S}_{21} = \boldsymbol{\Phi}_{\mathrm{r}}\boldsymbol{t}'\boldsymbol{\Phi}_{\mathrm{l}}. \tag{B.6c}$$

Here $\boldsymbol{\Phi}_{\mathrm{l}}$ and $\boldsymbol{\Phi}_{\mathrm{r}}$ are unitary matrices, $\boldsymbol{\rho}$ and $\boldsymbol{\rho}'$ are diagonal and nonnegative, and $\boldsymbol{t}' = \boldsymbol{\Phi}_{\mathrm{r}}^{\dagger}\boldsymbol{S}_{21}\boldsymbol{\Phi}_{\mathrm{l}}^{\dagger}$. By substituting into (B.5) and using (B.4) we obtain

$$\boldsymbol{t}'^{\dagger}\boldsymbol{t}' = \boldsymbol{I} - \boldsymbol{\rho}^{2}, \tag{B.7a}$$

$$\boldsymbol{t}'\boldsymbol{t}'^{\dagger} = \boldsymbol{I} - \boldsymbol{\rho}'^{2}, \tag{B.7b}$$

$$\boldsymbol{\rho}' = \boldsymbol{t}'\boldsymbol{\rho}\boldsymbol{t}'^{*-1}. \tag{B.7c}$$

Introducing the singular value decomposition $\boldsymbol{t}' = \boldsymbol{U}'\boldsymbol{t}\boldsymbol{V}'$, we obtain from (B.7a) that $\boldsymbol{t}^{2} = \boldsymbol{V}'(\boldsymbol{I} - \boldsymbol{\rho}^{2})\boldsymbol{V}'^{\dagger}$, which means $\boldsymbol{t} = \boldsymbol{V}'\sqrt{\boldsymbol{I} - \boldsymbol{\rho}^{2}}\boldsymbol{V}'^{\dagger}$. Backsubstitution shows that $\boldsymbol{t}'$ can be written $\boldsymbol{t}' = \boldsymbol{U}\sqrt{\boldsymbol{I} - \boldsymbol{\rho}^{2}}$ for a unitary $\boldsymbol{U}$; thus (B.7c) reduces to $\boldsymbol{\rho}' = \boldsymbol{U}\boldsymbol{\rho}\boldsymbol{U}^{\mathrm{T}}$. With these properties, it is straightforward to show that (B.6) can be written

$$\boldsymbol{S}_{11} = \boldsymbol{\Phi}_{\mathrm{l}}^{\mathrm{T}}\boldsymbol{\rho}\boldsymbol{\Phi}_{\mathrm{l}}, \tag{B.8a}$$

$$\boldsymbol{S}_{22} = \boldsymbol{\Phi}_{\mathrm{r}}(-\boldsymbol{\rho})\boldsymbol{\Phi}_{\mathrm{r}}^{\mathrm{T}}, \tag{B.8b}$$

$$\boldsymbol{S}_{21} = \boldsymbol{S}_{12}^{\mathrm{T}} = \boldsymbol{\Phi}_{\mathrm{r}}\boldsymbol{t}\boldsymbol{\Phi}_{\mathrm{l}}, \tag{B.8c}$$

where $\boldsymbol{U}$ has been absorbed into $\boldsymbol{\Phi}_{\mathrm{r}}$, $\boldsymbol{\Phi}_{\mathrm{r}}\boldsymbol{U} \to \boldsymbol{\Phi}_{\mathrm{r}}$, and

$$\boldsymbol{t} = \sqrt{\boldsymbol{I} - \boldsymbol{\rho}^{2}}. \tag{B.9}$$

Note that (B.7) implies that $\|\boldsymbol{\rho}\| \leq 1$.

Equations (B.8) and (B.9) can be interpreted as follows: The component can be viewed as a discrete reflector sandwiched between two unitary transmission sections. The discrete reflector provides coupling between equal modes that propagate in opposite directions, and the unitary sections provide coupling between different modes in the same direction. For the discrete reflector, the reflection response from the left and right is $\boldsymbol{\rho}$ and $-\boldsymbol{\rho}$, respectively, and the transmission is $\boldsymbol{t}$. For the two unitary sections, there are no reflections, and the transmission responses from the left are $\boldsymbol{\Phi}_{\mathrm{l}}$ and $\boldsymbol{\Phi}_{\mathrm{r}}$, while the transmission responses from the right are $\boldsymbol{\Phi}_{\mathrm{l}}^{\mathrm{T}}$ and $\boldsymbol{\Phi}_{\mathrm{r}}^{\mathrm{T}}$. Note that this interpretation is consistent with the reciprocity and lossless conditions (B.4) and (B.5) for each of the three sections separately. By inspection, we find that (B.8) is invariant if $\boldsymbol{P}\boldsymbol{\rho}\boldsymbol{P}^{\mathrm{T}} \to \boldsymbol{\rho}$, $\boldsymbol{P}\boldsymbol{t}\boldsymbol{P}^{\mathrm{T}} \to \boldsymbol{t}$, $\boldsymbol{P}\boldsymbol{\Phi}_{\mathrm{l}} \to \boldsymbol{\Phi}_{\mathrm{l}}$, and $\boldsymbol{\Phi}_{\mathrm{r}}\boldsymbol{P}^{\mathrm{T}} \to \boldsymbol{\Phi}_{\mathrm{r}}$, where $\boldsymbol{P}$ is a real unitary matrix. Here $\boldsymbol{P}$ represents an arbitrary rotation of the eigenaxes of the reflector ($\boldsymbol{\rho}$ and $\boldsymbol{t}$ are now real and positive semidefinite).

Using (B.8), the transfer matrix (B.3) can be written

$$\mathbf{T} = \begin{bmatrix} \boldsymbol{A}^* & \boldsymbol{B}^* \\ \boldsymbol{B} & \boldsymbol{A} \end{bmatrix}, \tag{B.10}$$

where the blocks $\boldsymbol{A} = \boldsymbol{\Phi}_r^* \boldsymbol{t}^{-1} \boldsymbol{\Phi}_l^*$ and $\boldsymbol{B} = -\boldsymbol{\Phi}_r^* \boldsymbol{t}^{-1} \boldsymbol{\rho} \boldsymbol{\Phi}_l$ satisfy

$$\boldsymbol{A}^\dagger \boldsymbol{A} - \boldsymbol{B}^{\mathrm{T}} \boldsymbol{B}^* = \boldsymbol{I}, \tag{B.11a}$$

$$\boldsymbol{A}\boldsymbol{B}^{\mathrm{T}} - \boldsymbol{B}\boldsymbol{A}^{\mathrm{T}} = \mathbf{0}, \tag{B.11b}$$

$$\boldsymbol{A}^{\mathrm{T}} \boldsymbol{B}^* - \boldsymbol{B}^\dagger \boldsymbol{A} = \mathbf{0}. \tag{B.11c}$$

FILTERED BACKPROJECTION INVERSION OF THE CONE BEAM TRANSFORM FOR A GENERAL CLASS OF CURVES[*]

ALEXANDER KATSEVICH[†] AND MIKHAIL KAPRALOV[†]

Abstract. We extend a cone beam transform inversion formula, proposed earlier for helices by one of the authors, to a general class of curves. The inversion formula remains efficient, because filtering is shift-invariant and is performed along a one-parametric family of lines. The conditions that describe the class are very natural. Curves C are smooth, without self-intersections, have positive curvature and torsion, do not bend too much, and do not admit lines which are tangent to C at one point and intersect C at another point. The notions of PI lines and PI segments are generalized, and their properties are studied. The domain U is found, where PI lines are guaranteed to be unique. Results of numerical experiments demonstrate very good image quality.

Key words. shift-invariant filtering, theoretically exact, PI lines

1. Introduction.

Image reconstruction from projections is important both in pure mathematics (as a problem of integral geometry) and in applications (as a problem of computed tomography (CT)). Cone beam CT is one of the most common medical imaging modalities. Here one recovers a function $f(x), x \in \mathbb{R}^3$, knowing the integrals of f along lines that intersect a curve C. The curve C is usually called a source trajectory. The ever-increasing needs of medical imaging require the development of inversion algorithms for more and more general source trajectories.

A number of theoretically exact algorithms have been proposed in the past several years. They can be classified into three groups: filtered backprojection (FBP) algorithms, slow-FBP algorithms, and backprojection filtration (BPF) algorithms. Slow-FBP and BPF algorithms are quite flexible, allow some transverse data truncation, and can be used for virtually any complete source trajectory [20, 19, 27, 21, 25, 23, 26]. FBP algorithms are less flexible, but they are by far the fastest and have been developed for a range of source trajectories. They include constant pitch helix [9, 12, 13, 15], dynamic pitch helix [7, 6], circle-and-line [11], circle-and-arc [14, 3], circle-and-helix [2], and saddle [22]. A very nice FBP algorithm was recently proposed by Pack and Noo [20]. It applies to almost any reasonable source trajectory. However, it sometimes leads to excessive detector requirements. The problem is that the algorithm is too general and does not take the geometry of the curve into account. Significant progress has also been achieved in the development of quasi-exact algorithms [1, 16].

With one exception, FBP algorithms have been proposed only for certain types of well-defined trajectories: helices, saddles, etc. There is no FBP algorithm developed specifically for a general class of curves. Ideally, such a class would be described only in terms of some basic geometric properties (e.g., smoothness, curvature, etc.) rather than specifying the types of curves (helices, etc.). In this paper we develop a theoretically exact shift-invariant FBP algorithm for a wide class of source trajectories.

The conditions describing our class are very natural. We consider curves C that are smooth, have no self-intersections, have positive curvature and torsion, do not bend too much, and do not admit lines which are tangent to C at one point and intersect C at another point. Our algorithm applies to any curve with these properties. The inversion algorithm of this paper is a generalization of the formula proposed for constant- and variable-pitch helices in [9, 12, 7].

The importance of our results is twofold. First, the algorithm can be used in a variety of applications. For example, in electron-beam CT/micro-CT there arise source trajectories that can be described as helices with variable radius and pitch [24]. The FBP algorithms of [9, 12, 7] do not work for such curves, but the new algorithm can easily handle them. Second, the results have theoretical value as well. They provide a deeper understanding of the available algorithms, put them into the context of a more general approach, and demonstrate which geometrical properties the curve is required to have for an efficient FBP algorithm to apply.

The paper is organized as follows. In section 2 we define PI lines for general curves, describe precisely the class of curves considered in the paper, and study properties of their PI segments. In section 3 we find the set U where PI lines are guaranteed to be unique. The result is based on the notions of maximal and minimal PI lines. These critical PI lines can be viewed as a generalization of the axial direction for regular helices. Also we find the special planes, such that the stereographic projection of C onto these planes has very useful properties. In section 4 we study more properties of the PI segments of C. Then the inversion formula is given. Finally, the results of numerical experiments are presented in section 5.

2. PI lines and their properties. The objective of this section is to define PI lines for a general class of smooth curves and study their properties. Let C be a smooth curve:

$$I := [a, b] \ni s \to y(s) \in \mathbb{R}^3, \ |\dot{y}(s)| \neq 0. \tag{2.1}$$

Here and below, the dot above a variable denotes differentiation with respect to s. Define the functions

$$\Phi(s, s_0) := [y(s) - y(s_0), \dot{y}(s), \ddot{y}(s)], \ Q(s, s_0) := [y(s) - y(s_0), \dot{y}(s_0), \dot{y}(s)], \tag{2.2}$$

where $[e_1, e_2, e_3] := e_1 \cdot (e_2 \times e_3)$ denotes the scalar triple product of three vectors. If C is a helix, then Φ and Q are precisely the functions that have been introduced under the same names in [7]. Similarly to [7], it turns out later that Φ is intimately related to the convexity of the projection of C onto a detector plane (cf. (4.6) below), and Q is related to the uniqueness of PI lines (cf. Definitions 2.1 and 2.2, (3.6), and the proof of Proposition 3.3). Given any $s_0, s_1 \in I$, $H(s_0, s_1)$ denotes the line segment with the endpoints $y(s_0), y(s_1) \in C$.

Definition 2.1. *Pick two points $y(s_0), y(s_1) \in C$, $s_0 < s_1$. The line segment $H(s_0, s_1)$ is called a PI segment if $Q(s_0, q) \neq 0$ for any $q \in (s_0, s_1)$.*

Definition 2.2. *Pick two points $y(s_0), y(s_1) \in C$, $s_0 < s_1$. The line segment $H(s_0, s_1)$ is called a maximal PI segment if $Q(s_0, s_1) = 0$, but $Q(s_0, q) \neq 0$ for any $q \in (s_0, s_1)$.*

If C is a helix, Definition 2.1 gives the usual PI segments $H(s, q), 0 < q - s < 2\pi$, and Definition 2.2 gives the maximal PI segments $H(s, s + 2\pi)$.

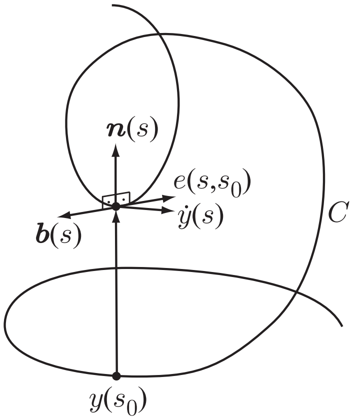

Fig. 1. *Critical case.*

Next we discuss how a smooth curve bends. Consider two points: $y(s_0), y(s) \in C$. Assume $y(s_0)$ is fixed, and $y(s)$ moves along C. The line segment joining $y(s_0)$ and $y(s)$ rotates about the instantaneous axis $e(s,s_0) = (y(s) - y(s_0)) \times \dot{y}(s)/|(y(s) - y(s_0)) \times \dot{y}(s)|$. The point $y(s)$ rotates also about the instantaneous axis, which is obtained by finding the circle of curvature of C at $y(s)$ (also known as the osculating circle). The corresponding axis of rotation is $\mathbf{b}(s)$, i.e., the binormal vector. If $s \to s_0$, then $e(s,s_0) \to \mathbf{b}(s)$. Thus, the difference in directions of the two vectors can measure how much the curve bends between the two points. The maximum possible "bent" occurs when the two axes point in the opposite directions: $e(s,s_0) = -\mathbf{b}(s)$ (see Figure 1).

For the convenience of the reader we recall the definitions of the curvature κ and torsion τ of a smooth curve:

$$\kappa(s) := \frac{|\dot{y}(s) \times \ddot{y}(s)|}{|\dot{y}(s)|^3}, \quad \tau(s) := \frac{[\dot{y}(s), \ddot{y}(s), \dddot{y}(s)]}{|\dot{y}(s) \times \ddot{y}(s)|^2}. \tag{2.3}$$

Now we can formulate the main assumptions on the curve C.

C1. C is smooth, and the curvature and torsion of C are positive;

C2. C does not self-intersect within any PI segment (or a maximal PI segment) of C;

C3. given any PI segment (or a maximal PI segment) $H(s_0,s)$ of C, there is no line tangent to C at $y(s_1)$ and intersecting C at $y(s_2)$, with $s_1, s_2 \in [s_0, s]$, $s_1 \neq s_2$;

C4. C does not bend too much; i.e., given any PI segment (or a maximal PI segment) $H(s_0,s)$ of C, one has $e(s_1,s_2) \neq -\mathbf{b}(s_2)$ for any $s_1, s_2 \in [s_0, s]$, $s_1 \neq s_2$.

If a curve satisfies conditions C1–C4, then its PI segments have a number of nice properties.

Proposition 2.3. *Let C be a curve which satisfies conditions* C1–C4*, and let $H(s_0,s_1)$ be its (possibly maximal) PI segment. Then for any $s,q \in [s_0,s_1]$ one has $\Phi(s,q) > 0$ if $s > q$ and $\Phi(s,q) < 0$ if $s < q$.*

Proof. By shrinking the PI line if necessary, the proposition follows if we show that $\Phi(s,s_0) \neq 0$ for any $s \in (s_0,s_1]$ and $\Phi(s,s_1) \neq 0$ for any $s \in [s_0,s_1)$. We prove only the first statement, because the proof of the second one is analogous.

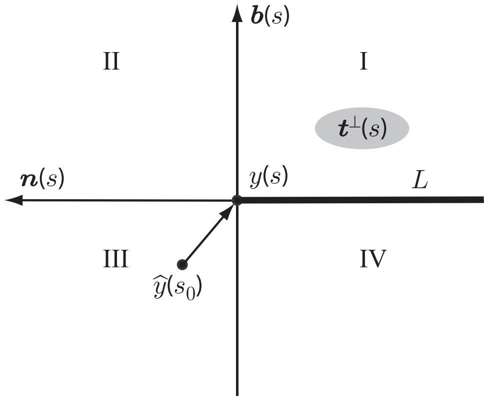

FIG. 2. *Projection of $y(s_0)$ onto the plane through $y(s)$ with normal vector $\dot{y}(s)$.*

Let us assume that the parameterization of $y(s)$ is natural, i.e., $|\dot{y}(s)| \equiv 1$. For convenience, recall the Frenet–Serret formulas:

$$\begin{bmatrix} \dot{\mathbf{t}} \\ \dot{\mathbf{n}} \\ \dot{\mathbf{b}} \end{bmatrix} = \begin{bmatrix} 0 & \kappa & 0 \\ -\kappa & 0 & \tau \\ 0 & -\tau & 0 \end{bmatrix} \begin{bmatrix} \mathbf{t} \\ \mathbf{n} \\ \mathbf{b} \end{bmatrix}, \tag{2.4}$$

where $\mathbf{t}(s), \mathbf{n}(s), \mathbf{b}(s)$ are the unit tangent and the normal and binormal vectors, respectively, $\kappa(s)$ is the curvature, and $\tau(s)$ is the torsion of the source trajectory (cf. (2.3)). Using (2.4), we get

$$\begin{aligned} \Phi(s, s_0) = [y(s) - y(s_0), \dot{y}(s), \ddot{y}(s)] &= \kappa(s)[y(s) - y(s_0), \mathbf{t}(s), \mathbf{n}(s)] \\ &= \kappa(s)\mathbf{b}(s) \cdot (y(s) - y(s_0)). \end{aligned} \tag{2.5}$$

Since we are interested in the sign of $\Phi(s, s_0)$ and $\kappa(s) > 0$, we determine the sign of

$$\begin{aligned} \mathbf{b}(s) \cdot (y(s) - y(s_0)) &= \int_{s_0}^{s} (\mathbf{b}(t) \cdot (y(t) - y(s_0)))'_t \, dt \\ &= -\int_{s_0}^{s} \tau(t)\mathbf{n}(t) \cdot (y(t) - y(s_0))dt. \end{aligned} \tag{2.6}$$

Let $\mathbf{t}^{\perp}(s)$ denote the plane passing through $y(s)$ and perpendicular to $\mathbf{t}(s)$. We assume that $\mathbf{n}(s)$ and $\mathbf{b}(s)$ are the coordinate axes on the plane, and $y(s)$ is the origin (see Figure 2).

Let $\Pi_{osc}(s)$ denote the osculating plane of C at $y(s)$. Recall that $\Pi_{osc}(s)$ contains $y(s)$ and is parallel to $\dot{y}(s)$ and $\ddot{y}(s)$. If $y(s_0)$ projects onto the ray $L := y(s) - \lambda\mathbf{n}(s), \lambda > 0$, then $y(s_0)$ belongs to $\Pi_{osc}(s)$. Moreover, the two rotation axes—one determined by rotation of $y(s)$ around $y(s_0)$ and the other, $\mathbf{b}(s)$, determined by rotation of $y(s)$ relative to the intrinsic center of rotation—are parallel and point in opposite directions. This is prohibited by the assumption that the curve does not bend too much (see C4), so $y(s_0)$ never projects onto L.

Let $\hat{y}(s_0)$ denote the projection of $y(s_0)$ onto $\mathbf{t}^{\perp}(s)$. The Taylor series expansions show that $\tau > 0$ and $\kappa > 0$ imply

$$\mathbf{n}(t) \cdot (y(s) - y(s_0)) < 0, \ \mathbf{b}(s) \cdot (y(s) - y(s_0)) > 0, \tag{2.7}$$

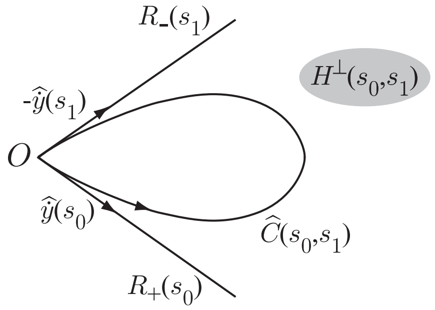

FIG. 3. *Illustration of the containment property: orthogonal projection onto $H^\perp(s_0,s_1)$.*

for $s-s_0>0$ small enough. Hence, initially $\hat{y}(s_0)$ is located in the third quadrant (see Figure 2). Suppose now s increases. If $\hat{y}(s_0)$ appears in the third quadrant, then $\mathbf{n}(t)\cdot(y(t)-y(s_0))<0$. So $\mathbf{b}(s)\cdot(y(s)-y(s_0))$ increases and $\hat{y}(s_0)$ moves down and does not cross the $\mathbf{n}$-axis. If $\hat{y}(s_0)$ appears in the fourth quadrant, then $\mathbf{n}(t)\cdot(y(t)-y(s_0))>0$ and $\mathbf{b}(s)\cdot(y(s)-y(s_0))$ decreases. This implies that in the fourth quadrant $\hat{y}(s_0)$ moves up. However, our assumption precludes $\hat{y}(s_0)$ from crossing L. Consequently, $\hat{y}(s_0)$ never crosses the $\mathbf{n}$-axis and $\Phi(s,s_0)>0$ for any $s\in(s_0,s_1]$. □

Let $H(s_0,s_1)$ be a PI segment (possibly maximal) and $C(s_0,s_1)$ the corresponding curve segment. Project $C(s_0,s_1)$, $\dot{y}(s_0)$, and $\dot{y}(s_1)$ orthogonally onto a plane perpendicular to $H(s_0,s_1)$. Such a plane is denoted $H^\perp(s_0,s_1)$. The corresponding projections are denoted $\hat{C}(s_0,s_1)$, $\hat{\dot{y}}(s_0)$, and $\hat{\dot{y}}(s_1)$, respectively (see Figure 3). Let O be the projection of $H(s_0,s_1)$. Because of condition C3, the vectors $\hat{\dot{y}}(s_0)$ and $\hat{\dot{y}}(s_1)$ determine two rays:

$$\begin{aligned} R_+(s_0,s_1) &:= \{x\in H(s_0,s_1)^\perp : x=O+\lambda\hat{\dot{y}}(s_0),\lambda\ge 0\},\\ R_-(s_0,s_1) &:= \{x\in H(s_0,s_1)^\perp : x=O+\lambda(-\hat{\dot{y}}(s_1)),\lambda\ge 0\}. \end{aligned}\tag{2.8}$$

PROPOSITION 2.4. *Let C be a curve which satisfies conditions* C1–C4. *If $H(s_0,s_1)$ is a (possibly maximal) PI segment of C, then one has the following:*

1. *$\hat{C}(s_0,s_1)$ is contained inside the wedge with vertex O and formed by the rays $R_+(s_0,s_1)$ and $R_-(s_0,s_1)$;*
2. *$\hat{C}(s_0,s_1)$ is smooth, and no line through O is tangent to $\hat{C}(s_0,s_1)$ at an interior point;*
3. *if $H(s_0,s_1)$ is not maximal, the angle between $R_+(s_0,s_1)$ and $R_-(s_0,s_1)$ is less than π. If $H(s_0,s_1)$ is maximal, the angle between the rays equals π;*
4. *no line through O intersects the interior of $\hat{C}(s_0,s_1)$ at more than one point.*

The property of C described in statement (1) of the proposition is important for us, so it will be given the name *containment property.* In other words, statement (1) says that PI segments of curves which satisfy conditions C1–C4 have the containment property.

Proof. To show that $\hat{C}(s_0,s_1)$ is contained inside the wedge, we first consider $\hat{C}(s_0,s_1)$, where $s_1=s_0+\epsilon$ for some $0<\epsilon\ll 1$. As is easily seen, containment follows from the two inequalities:

$$\begin{aligned} &[y(t)-y(s_0),y(s_1)-y(s_0),\dot{y}(s_0)]>0\ \forall t\in(s_0,s_1),\\ &[y(t)-y(s_0),y(s_1)-y(s_0),\dot{y}(s_1)]>0\ \forall t\in(s_0,s_1). \end{aligned}\tag{2.9}$$

To prove the first inequality introduce the function

$$\Psi(s_1,t) := \left[\frac{y(t)-y(s_0)-\dot y(s_0)(t-s_0)}{(t-s_0)^2}, \frac{y(s_1)-y(s_0)-\dot y(s_0)(s_1-s_0)}{(s_1-s_0)^2}, \dot y(s_0)\right]. \tag{2.10}$$

By using the Taylor series expansions we see that $\Psi(s_1,t)$ is smooth and bounded on compact sets. Notice also that

$$\Psi(s_1,s_1)=0,\ \Psi_t'(s_1,t)<\infty. \tag{2.11}$$

Hence $\Psi(s_1,t)/(s_1-t)$ is bounded as well, which implies

$$\begin{aligned}&[y(t)-y(s_0), y(s_1)-y(s_0), \dot y(s_0)]\\ &\qquad = \frac{(t-s_0)^2(s_1-s_0)^2(s_1-t)}{12}([\dot y(s_0), \ddot y(s_0), \dddot y(s_0)] + o(1)) > 0,\end{aligned} \tag{2.12}$$

where $o(1)\to 0$ as $s_1\to s_0$. We used the argument based upon the function Ψ, because we needed an asymptotic result that holds when $t\to s_0$ and when $t\to s_1$. The second inequality in (2.9) can be proven for small $s_1-s_0>0$ in a similar fashion.

Suppose now that s_1-s_0 is not necessarily small. Note that $\hat C(s_0,s_1)$ is tangent to the rays $R_+(s_0,s_1)$ and $R_-(s_0,s_1)$ at the point O of order precisely one. Consider, for example, the ray $R_+(s_0,s_1)$. To determine the order of tangency we need to find the asymptotics of the first expression in (2.9) as $t\to s_0$, with s_0 and s_1 fixed. We have

$$\begin{aligned}&[y(t)-y(s_0), y(s_1)-y(s_0), \dot y(s_0)]\\ &\qquad = [\ddot y(s_0), y(s_1)-y(s_0), \dot y(s_0)]\frac{(t-s_0)^2}{2} + O\left((t-s_0)^3\right)\\ &\qquad = -\Phi(s_0,s_1)\frac{(t-s_0)^2}{2} + O\left((t-s_0)^3\right).\end{aligned} \tag{2.13}$$

Similarly,

$$[y(t)-y(s_0), y(s_1)-y(s_0), \dot y(s_1)] = \Phi(s_1,s_0)\frac{(t-s_1)^2}{2} + O\left((t-s_1)^3\right),\ t\to s_1. \tag{2.14}$$

By Proposition 2.3, $\Phi(s_0,s_1)<0$, $\Phi(s_1,s_0)>0$, and the desired assertion follows.

Suppose $C(s_0,s_1)$ does not have the containment property. Assume, for example, that the first inequality in (2.9) is violated. A violation of the other inequality can be considered analogously. From (2.13) and Proposition 2.3, the inequality holds for some $t>s_0$, where $t-s_0$ is sufficiently small. Thus there exists $t\in(s_0,s_1)$ such that

$$[y(t)-y(s_0), y(s_1)-y(s_0), \dot y(s_0)] = 0. \tag{2.15}$$

Let us show that (2.15) defines t as a function of s_1. Formally differentiating (2.15) with respect to s_1 gives

$$\frac{dt}{ds_1} = -\frac{[y(t)-y(s_0), \dot y(s_1), \dot y(s_0)]}{[\dot y(t), y(s_1)-y(s_0), \dot y(s_0)]}. \tag{2.16}$$

The denominator in (2.16) does not vanish. Otherwise, from the linear independence of $\dot y(s_0)$ and $y(s_1)-y(s_0)$ (property C3) and (2.15) we get $Q(t,s_0)=[y(t)-$

$y(s_0), \dot{y}(s_0), \dot{y}(t)] = 0$. Since $H(s_0, s_1)$ is a PI line, this is a contradiction. Thus (2.15) does define t as a function of s_1, and $C(s_0, s_1)$ does not have the containment property for all s_1 in an open set. Hence we can consider the function $t(s)$ for some $s \le s_1$ using the fact that $Q(t, s_0) \neq 0$ for $t \in (s_0, s_1)$. As s decreases from s_1 towards s_0, one of the following must happen:

(a) $s, t \to s^* \neq s_0$. Replacing s_1 with s and t with $t(s)$ in (2.15) gives $Q(s^*, s_0) = [y(s^*)-y(s_0), \dot{y}(s_0), \dot{y}(s^*)] = 0$, which contradicts the assumption that $H(s_0, s_1)$ is a PI line.

(b) $t \to s_0$, $s \to s^* > s_0$. From (2.15), $\Phi(s_0, s^*) = [y(s_0)-y(s^*), \dot{y}(s_0), \ddot{y}(s_0)] = 0$, which contradicts Proposition 2.3.

Note that $s, t \not\to s_0$ because of (2.12). Thus the containment property is established.

To prove the second statement we argue by contradiction. Suppose there exists $t \in (s_0, s_1)$, where either $\hat{C}(s_0, s_1)$ is nonsmooth or where the line through O and $\hat{y}(t)$ is tangent to $\hat{C}(s_0, s_1)$. Here $\hat{y}(t)$ is the projection of $y(t)$ onto $H^{\perp}(s_0, s_1)$. In both cases

$$[y(s_1) - y(s_0), \dot{y}(t), y(t) - y(s_0)] = 0. \tag{2.17}$$

Just as in the proof of statement (1), (2.17) defines t as a function of s_1. Differentiating (2.17) with respect to s_1 gives

$$\frac{dt}{ds_1} = -\frac{[\dot{y}(s_1), \dot{y}(t), y(t) - y(s_0)]}{[y(s_1) - y(s_0), \ddot{y}(t), y(t) - y(s_0)]}. \tag{2.18}$$

The denominator in (2.18) does not vanish. Otherwise, together with (2.17) this gives $\Phi(t, s_0) = [y(t) - y(s_0), \dot{y}(t), \ddot{y}(t)] = 0$, which contradicts Proposition 2.3. Here we have used the fact that $y(s_1)-y(s_0)$ and $y(t)-y(s_0)$ are not parallel (cf. (2.9)). Hence we can consider the function $t(s)$ for some $s \le s_1$ using the fact that $\Phi(t, s_0) \neq 0$ for $t \in (s_0, s_1]$. As s decreases from s_1 towards s_0, one of the following must happen:

(a) $s, t \to s^* \neq s_0$. Replacing s_1 with s and t with $t(s)$ in (2.17) gives $[y(s^*) - y(s_0), \dot{y}(s^*), \ddot{y}(s^*)] = 0$, which contradicts Proposition 2.3.

(b) $t \to s_0$, $s \to s^* > s_0$. Then (2.17) implies $[y(s^*) - y(s_0), \dot{y}(s_0), \ddot{y}(s_0)] = 0$, which is again a contradiction.

(c) $s, t \to s_0$. Now (2.17) implies $[\dot{y}(s_0), \ddot{y}(s_0), \dddot{y}(s_0)] = 0$, i.e., $\tau(s_0) = 0$. This contradicts the assumption $\tau(s_0) > 0$.

Our argument proves that (2.17) does not happen, so statement (2) is established.

To prove statement (3), first consider $H(s_0, q)$ for $q - s_0 > 0$ sufficiently small. As follows from statements (1) and (2), $\hat{C}(s_0, q)$ is contained between the rays $R_+(s_0, q)$ and $R_-(s_0, q)$, which are close to each other. As q increases towards s_1, the two rays cannot collapse into one. Because of the containment, $\hat{C}(s_0, q)$ is always located between the rays. So if the two rays collapse into one for some $q > s_0$, then $C(s_0, q)$ is a planar curve, which contradicts the assumption $\tau > 0$. Hence $Q(s_0, s_1) = 0$ if and only if $R_+(s_0, s_1)$ and $R_-(s_0, s_1)$ point in opposite directions (see Figure 5).

Statements (1)–(3) imply that (i) whenever a line through O intersects $\hat{C}(s_0, s_1)$, then all of the intersection points (IPs) are on one side of O and (ii) neither $R_+(s_0, s_1)$ nor $R_-(s_0, s_1)$ intersects the interior of $\hat{C}(s_0, s_1)$. By (i) we can replace "line" with "ray" in statement (4). Suppose there is a ray γ with a vertex at O, which intersects $\hat{C}(s_0, s_1)$ at two interior points. Clearly, by rotating γ around O towards either $R_+(s_0, s_1)$ or $R_-(s_0, s_1)$ we can make the two IPs collide. As soon as the IPs collide, we get a ray tangent to $\hat{C}(s_0, s_1)$ at an interior point, which contradicts statement (2). □

Corollary 2.5. *No plane intersects $C(s_0, s_1)$ at more than three points.*

Proof. Suppose there is a plane Π that has at least four IPs with $C(s_0, s_1)$: $s_0 \le t_1 < t_2 < t_3 < t_4 \le s_1$. Consider $C(t_1, t_4)$, and project it onto the plane perpendicular to $H(t_1, t_4)$ (as was done in the proof of Proposition 2.4). As before, let O denote the projection of $H(t_1, t_4)$. The projection of Π gives the line through O which intersects $\hat{C}(t_1, t_4)$ at least at two points, which contradicts statement (3) of Proposition 2.4. □

Corollary 2.6. *Pick any $x \in H(s_0, s_1)$ and $s \in (s_0, s_1)$. Consider a plane Π rotating around the line through x and $y(s)$. The number of IPs of Π and $C(s_0, s_1)$ changes from one to three when Π passes through $H(s_0, s_1)$.*

Proof. Consider the critical case when Π contains $H(s_0, s_1)$. As follows from Proposition 2.4, the vectors $\dot{y}(s_0)$ and $-\dot{y}(s_1)$ point into the opposite half-planes relative to Π. Hence, a small rotation of Π around $\beta(s, x)$ in one direction gives one IP and in the opposite direction three IPs. See section 4 in [15] for more details. □

3. Establishing uniqueness of PI lines.

To establish uniqueness of PI lines, we generalize the standard argument from helices [17, 8, 7] to general curves.

Fix some reconstruction point $x \in \mathbb{R}^3 \setminus C$. For each $s \in I$, fix a vector $N(s)$, $|N(s)| \equiv 1$ (a specific $N(s)$ will be chosen later). Define the functions $q(s)$ and $\lambda(s)$ so that $q(s) > s$, $H(s, q(s))$ is a PI segment, $0 < \lambda(s) < 1$, and the point

$$x(s) := y(s) + \lambda(s)(y(q(s)) - y(s)) \in H(s, q(s)) \tag{3.1}$$

has the property

$$x(s) - x \parallel N(s). \tag{3.2}$$

We assume that the functions $q(s)$ and $\lambda(s)$ with the required properties exist. Later (see (3.11) and the proof of Proposition 3.3) we find an open set U such that for any $x \in U$ the functions $q(s)$ and $\lambda(s)$ do exist.

Condition (3.2) means that the parallel projection of $x(s)$ onto the plane through x with normal vector $N(s)$ coincides with x. Note that the vector-valued function $N(s)$ is determined independently of $q(s)$ and $\lambda(s)$. A similar idea is used in proving the uniqueness of PI lines for the standard helix, the difference being that the vector $N(s)$ is constant and directed along the axis of the helix.

Figure 4 illustrates the setup: The functions $q(s)$ and $\lambda(s)$ are defined in such a way as to ensure that the parallel projection of $x(s)$ onto the plane through x with normal $N(s)$ always coincides with x. Denote $\Delta y(s) := y(q(s)) - y(s)$. Thus,

$$\varepsilon(s) := N(s) \cdot \{(y(s) + \lambda(s)\Delta y(s)) - x\} \tag{3.3}$$

is the signed distance from $y(s) + \lambda(s)\Delta y(s)$ to x, i.e., $\varepsilon(s) = 0$ if and only if the chord $H(s, q(s))$ passes through x. We are interested in calculating $\varepsilon'(s)$.

Combining (3.1)–(3.3) gives

$$y(s) + \lambda(s)(y(q(s)) - y(s)) = x + \varepsilon(s)N(s). \tag{3.4}$$

Differentiate (3.4) with respect to s:

$$\dot{y}(s) + \lambda'(s)\Delta y(s) + \lambda(s)(\dot{y}(q(s))q'(s) - \dot{y}(s)) = \varepsilon'(s)N(s) + \varepsilon(s)\dot{N}(s). \tag{3.5}$$

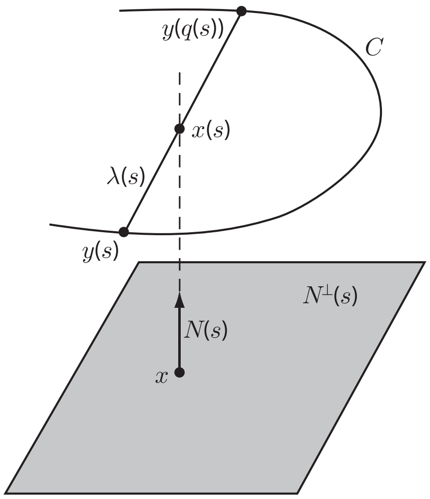

FIG. 4. *Parallel projection onto the plane $N^{\perp}(s)$ through x.*

Computing the dot product of (3.5) with $\Delta y(s)\times\dot y(q)$ on both sides gives the following expression:

$$\begin{aligned}&\varepsilon'(s)=A(s)+\varepsilon(s)B(s),\\ &A(s):=-(1-\lambda(s))\frac{Q(s,q(s))}{[N(s),\Delta y(s),\dot y(q(s))]},\ B(s):=-\frac{[\dot N(s),\Delta y(s),\dot y(q(s))]}{[N(s),\Delta y(s),\dot y(q(s))]},\end{aligned}\tag{3.6}$$

where we have used (2.2).

The goal is to obtain the uniqueness of PI lines. We start by choosing a vector $N(s)$ in such a way as to ensure that the denominator in (3.6) is never zero as long as $H(s,q(s))$ is a PI line. Denote the supremum (respectively, infimum) of all q such that $H(s,q)$ is a PI line by $q_{max}(s)$ (respectively, $q_{min}(s)$). Since $I=[a,b]$ is a compact interval, $q_{max}(s)$ and $q_{min}(s)$ are well-defined.

Now we study the properties of the function $q_{max}(s)$. Pick any $s_0\in(a,b)$ such that $q_{max}(s_0)<b$. Consider the equation

$$Q(q_{max}(s),s)=[y(q_{max}(s))-y(s),\dot y(s),\dot y(q_{max}(s))]=0\tag{3.7}$$

for s in a neighborhood of s_0. In particular, $q_{max}(s)$ satisfies (3.7) when $s=s_0$. Formally differentiating (3.7) with respect to s gives

$$q'_{max}(s_0)=-\frac{[y(q_{max}(s_0))-y(s_0),\ddot y(s_0),\dot y(q_{max}(s_0))]}{[y(q_{max}(s_0))-y(s_0),\dot y(s_0),\ddot y(q_{max}(s_0))]}.\tag{3.8}$$

By assumption C2, $y(q_{max}(s_0))-y(s_0)$ and $\dot y(s_0)$ are not parallel. Hence, if the denominator in (3.8) is zero, together with (3.7) this implies

$$[y(q_{max}(s_0))-y(s_0),\dot y(q_{max}(s_0)),\ddot y(q_{max}(s_0))]=0,\tag{3.9}$$

which contradicts Proposition 2.3. By the implicit function theorem, in a neighborhood of the point $(s_0,q_{max}(s_0))$ there exists a locally unique solution $q(s)$ to (3.7), and this solution satisfies $q(s_0)=q_{max}(s_0)$. By construction, $q(s)<b$ in a neighborhood of s_0. Clearly, $q_{max}(s)$ is continuous at s_0. Otherwise we can find $s_j\to s_0$ such that

$q_j := q_{max}(s_j) \not\to q_{max}(s_0)$. Thus we can choose a subsequence q_{j_k} which converges to some $\bar{q} \neq q_{max}(s_0)$. By the definition of q_{max}, $q_{max}(s_j) \leq q(s_j) < b$, so $Q(q_j, s_j) = 0$. By the continuity of Q, $Q(\bar{q}, s_0) = 0$. Since $\bar{q} \neq q_{max}(s_0)$, by the definition of q_{max} we must have $\bar{q} > q_{max}(s_0)$. This is a contradiction, because, by using the continuity of $q(s)$, there must exist K such that $q_{max}(s_{j_k}) > q(s_{j_k})$ for all $k > K$.

Using (3.7) and assumption C2 gives $\dot{y}(q_{max}(s_0)) = c_1\dot{y}(s_0) + c_2(y(q_{max}(s_0)) - y(s_0))$, $c_1 \neq 0$. Substituting into (3.8) we obtain after simple transformations: $q'_{max}(s_0) = -c_1^2\Phi(s_0, q_{max}(s_0))/\Phi(q_{max}(s_0), s_0)$. By Proposition 2.3, $q'_{max}(s_0) > 0$.

Our argument implies that the function $q_{max}(s)$ has the following properties: (1) $q_{max}(s)$ is continuous on $[a, b]$. If $q_{max}(a) < b$, then there exists $s^*_{max} \in (a, b)$ such that (2) $q_{max}(s) \in C^\infty([a, s^*_{max}])$, $q_{max}(s) < b$ and $q'_{max}(s) > 0$ on $[a, s^*_{max})$, and $q_{max}(s) \equiv b$ on $[s^*_{max}, b)$, and (3) to compute $q_{max}(s)$ on $[a, s^*_{max}]$ we can find $q_{max}(s_0)$ at any $s_0 \in [a, s^*_{max}]$ and then extend it to the entire interval by solving (3.7).

Properties of $q_{min}(s)$ are completely analogous: (1) $q_{min}(s)$ is continuous on $[a, b]$. If $q_{min}(b) > a$, then there exists $s^*_{min} \in (a, b)$ such that (2) $q_{min}(s) \in C^\infty([s^*_{min}, b])$, $q_{min}(s) > a$ and $q'_{min}(s) > 0$ on $(s^*_{max}, b]$, and $q_{min}(s) \equiv a$ on $(a, s^*_{min}]$, and (3) to compute $q_{min}(s)$ on $[s^*_{min}, b]$ we can find $q_{min}(s_0)$ at any $s_0 \in [s^*_{min}, b]$ and then extend it to the entire interval by solving (3.7) (with q_{max} replaced by q_{min}).

From the monotonicity of $q_{max}(s)$ we immediately obtain the following.

PROPOSITION 3.1. *Pick any $s_0 \in [a, b)$. If $s, q \in (s_0, q_{max}(s_0)]$ and $s \neq q$, then $H(s, q)$ is a PI line.*

Proposition 3.1 is a generalization of a similar property for helices: Any line segment connecting two different points within one turn of a helix is a PI line [4, 5, 7]. Note also the following immediate corollary to Proposition 3.1: $q_{min}(q_{max}(s_0)) = s_0$ if $q_{max}(s_0) < b$.

Define

$$(3.10)\quad N_{max}(s) := \frac{y(q_{max}(s)) - y(s)}{|y(q_{max}(s)) - y(s)|},\ N_{min}(s) := \frac{y(q_{min}(s)) - y(s)}{|y(q_{min}(s)) - y(s)|},\ s \in (a, b).$$

Thus, $N_{max}(s)$ (respectively, $N_{min}(s)$) is the unit vector along $H(s, q_{max}(s))$ (respectively, $H(q_{min}(s), s)$).

PROPOSITION 3.2. *Pick any $t \in (s, q_{max}(s))$. One has $[y(t) - y(s), \dot{y}(t), N_{max}(s)] \neq 0$, and the curve segments $C(s, t)$ and $C(t, q_{max}(s))$ are located on opposite sides of the plane containing $H(s, q_{max}(s))$ and $y(t)$. Similarly, pick any $t \in (q_{min}(s), s)$. One has $[y(t) - y(s), \dot{y}(t), N_{min}(s)] \neq 0$, and the curve segments $C(t, s)$ and $C(q_{min}(s), t)$ are located on opposite sides of the plane containing $H(q_{min}(s), s)$ and $y(t)$.*

Proof. We prove only the statements concerning $q_{max}(s)$. The other half of the proposition is completely analogous.

The assertion $[y(t) - y(s), \dot{y}(t), N_{max}(s)] \neq 0$ follows immediately from statement (2) of Proposition 2.4 (see also its proof). This proposition also implies that any line which contains O and passes between the rays $R_+(s, q_{max}(s))$ and $R_-(s, q_{max}(s))$ divides $\hat{C}(s, q_{max})$ into two segments located in the opposite half-planes (see Figure 5). This means that the curve segments $C(s, t)$ and $C(t, q_{max}(s))$ are located on opposite sides of the plane containing $H(s, q_{max}(s))$ and $y(t)$. □

Next we determine the region where PI lines, if exist, are unique. Even though the curve C is well-behaved locally, very little can be said about the global behavior of C. So we choose a "local" piece of C: $I_0 := [a_0, b_0] \subset (a, b)$. The word local is made precise later. For each $s \in I_0$ consider the curve $\hat{C}(s, q_{max})$ in the plane $N^\perp_{max}(s)$. By construction, $\hat{C}(s, q_{max})$ is closed. Let $Cyl_{max}(s)$ be the infinite open cylinder with

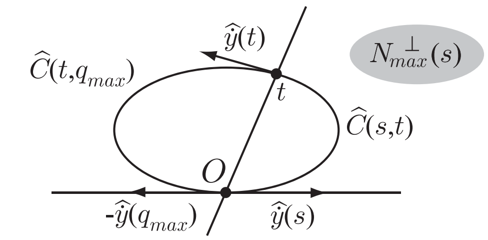

FIG. 5. *Projection onto the plane $N_{max}(s)^{\perp}$ in the case $q_{max}(s) < b$.*

axis $N_{max}(s)$, whose base is the interior of $\hat{C}(s, q_{max})$. In the same fashion we define the cylinders $Cyl_{min}(s)$ using $\hat{C}(q_{min}, s)$ and $N_{min}(s)$. Define U as the intersection of all such open cylinders:

$$U := \cap_{s\in I_0} \left(Cyl_{min}(s) \cap Cyl_{max}(s)\right). \tag{3.11}$$

If the curve turns too much, U can be empty. As an example, imagine a "slinky" toy. Locally it looks like a section of a helix. However if the slinky twists too much and the interval I_0 is sufficiently large, there can be no x that belongs to all of the cylinders. We assume that a sufficiently "local" piece of C is taken, so $U \neq \varnothing$. In other words, the only condition we assume for the interval I_0 is that the set U defined by (3.11) be nonempty. Note that in the case of a helix all cylinders $Cyl_{min}(s)$ and $Cyl_{max}(s)$ are identical, so (3.11) gives the usual domain inside the helix.

PROPOSITION 3.3. *Pick $x \in U$. If x admits a PI line, it is unique in the sense that there is no other PI line with an end point inside I_0.*

Proof. Choose $N(s) := N_{max}(s)$ in (3.2). Since $x \in U$, x projects along $N(s)$ into the interior of $\hat{C}(s, q_{max}(s))$ for any $s \in I_0$. Hence the functions $q(s)$ and $\lambda(s)$ and the map $s \to x(s)$ (cf. (3.1), (3.2)) are well-defined on I_0. By Proposition 3.2, $[\Delta y(s), \dot{y}(q(s)), N(s)] \neq 0$ for any $s \in I_0$. By Proposition 3.1, $H(s, q(s))$ are PI segments, so $Q(s, q(s)) \neq 0$ on I_0. By construction, $\lambda(s) < 1$ on I_0.

Our argument implies that $A(s)$ (cf. (3.6)) is bounded away from zero and of constant sign on I_0. Consider now $B(s)$ (cf. (3.6)). As we already know, the denominator is bounded away from zero. Differentiating (3.10) gives

$$\begin{aligned}\dot{N}_{max}(s) = &\frac{1}{|y(q_{max}(s)) - y(s)|}\\ &\times \left\{[\dot{y}(q_{max}(s))q'_{max}(s) - \dot{y}(s)] - N\left(N \cdot [\dot{y}(q_{max}(s))q'_{max}(s) - \dot{y}(s)]\right)\right\}.\end{aligned} \tag{3.12}$$

By assumption C1, C has no self-intersections, so $|y(q_{max}) - y(s)|$ is bounded away from zero. From (3.8) and the subsequent discussion, it follows that $q'_{max}(s)$ is bounded away from zero. Hence, $\dot{N}_{max}(s)$ is bounded, and $B(s)$ is bounded as well.

From the properties of $A(s)$ and $B(s)$ we get that $\varepsilon(s)$ cannot have more than one root on I_0. This follows immediately from the fact that the signs of $\varepsilon'(s)$ and $A(s)$ in a neighborhood of any s where $\varepsilon(s) = 0$ are the same. Hence x cannot have more than one PI segment with $s_b(x) \in I_0$.

Choosing $N(s) := N_{min}(s)$ in (3.2) and repeating the same argument gives that x cannot have more than one PI segment with $s_t(x) \in I_0$. □

4. Reconstruction algorithm. In order to derive an inversion formula we need to study the curve C some more.

Proposition 4.1. *Let $H(s_0, s_1)$ be a (possibly maximal) PI segment of C. Then $\hat{C}(s_0, s_1)$ has everywhere nonvanishing curvature.*

Proof. Recall that $\hat{C}(s_0, s_1)$ is smooth by Proposition 2.4. Pick any $t \in (s_0, s_1)$. Up to a nonzero factor the curvature of $\hat{C}(s_0, s_1)$ at the point t is given by $[y(s_1) - y(s_0), \dot{y}(t), \ddot{y}(t)]$. Using (2.2) we see that this expression equals $\Phi(t, s_0) - \Phi(t, s_1)$. Since $s_0 < t < s_1$, Proposition 2.3 gives the desired result. We can think of $\Phi(t, s)$ as a signed "distance" from $y(s)$ to $\Pi_{osc}(t)$, so Proposition 2.3 also gives that the line segment $H(s_0, s_1)$ intersects $\Pi_{osc}(t)$ for any $t \in (s_0, s_1)$. □

Corollary 4.2. *Let $H(s_0, s_1)$ be a (possibly maximal) PI segment of C. For any $x \in H(s_0, s_1)$ and $t \in (s_0, s_1)$, the vectors $\dot{y}(t)$ and $x - y(t)$ are not collinear.*

Proof. By Proposition 2.3, $\hat{C}(s_0, q_{max}(s_0))$ is strictly convex. $x \in H(s_0, s_1)$ implies that x projects into the domain bounded by $\hat{C}(s_0, q_{max}(s_0))$. Thus $\dot{y}(t)$ and $x - y(t)$ are not collinear. □

Proposition 4.3. *Let $H(s_0, s_1)$ be a (possibly maximal) PI segment of C. For any $x \in H(s_0, s_1)$ there exists the unique $s^*(x) \in (s_0, s_1)$ such that $x \in \Pi_{osc}(s^*(x))$.*

Proof. As follows from the proof of Proposition 4.1, $\Pi_{osc}(t)$ intersects $H(s_0, s_1)$ for any $t \in [s_0, s_1]$. Hence we can write

$$y(s_0) + \lambda(t)(y(s_1) - y(s_0)) = y(t) + a(t)\dot{y}(t) + b(t)\ddot{y}(t) \tag{4.1}$$

for some scalar functions λ, a, and b. Differentiate (4.1) with respect to t, multiply the resulting equation by $\dot{y}(t) \times \ddot{y}(t)$, and solve for λ':

$$\lambda'(t) = b(t)\frac{[\dot{y}(t), \ddot{y}(t), \dddot{y}(t)]}{[y(s_1) - y(s_0), \dot{y}(t), \ddot{y}(t)]}. \tag{4.2}$$

Since the torsion of C is nonzero, the numerator in (4.2) does not vanish. From the proof of Proposition 4.1, the denominator in (4.2) is nonzero. By Corollary 4.2, $b(t) \neq 0, t \in (s_0, s_1)$. Hence $\lambda(t)$ is a smooth monotone function on $[s_0, s_1]$. Obviously, $\Pi_{osc}(s_0)$ (respectively, $\Pi_{osc}(s_1)$) intersects $H(s_0, s_1)$ at $y(s_0)$ (respectively, $y(s_1)$). Thus $\lambda(s_0) = 0$, $\lambda(s_1) = 1$, and the proposition is proven. □

Due to the containment property (statement (1) of Proposition 2.4), the curve $C(s, q_{max}(s))$ (respectively, $C(s, q_{min}(s))$) is on one side of the plane passing through $y(s)$ and parallel to $\dot{y}(s)$ and $N_{max}(s)$ (respectively, $N_{min}(s)$). This makes it very convenient to project $C(s, q_{max}(s))$ (respectively, $C(s, q_{min}(s))$) onto a plane parallel to $\dot{y}(s)$ and $N_{max}(s)$ (respectively, $N_{min}(s)$). The corresponding projections turn out to be smooth. Let $DP_+(s)$ (respectively, $DP_-(s)$) denote a plane not passing through $y(s)$ and parallel to $\dot{y}(s)$ and $N_{max}(s)$ (respectively, $N_{min}(s)$). We think of $DP_+(s)$ and $DP_-(s)$ as detector planes, so they are chosen on the same side of $y(s)$ as the set U. More precisely, the rays with vertex $y(s)$ passing through U intersect $DP_+(s)$ and $DP_-(s)$. The stereographic projection of $C(s, q_{max}(s))$ onto $DP_+(s)$ is denoted Γ_+, while the stereographic projection of $C(q_{min}(s), s)$ onto $DP_-(s)$ is denoted Γ_-.

Proposition 4.4. *Γ_+ and Γ_- are smooth and have nonvanishing curvature at every point.*

Proof. We consider only Γ_+. The statement about Γ_- is proven analogously. Suppose, for simplicity, that the origin is at $y(s)$ and the equation of $DP_+(s)$ is $x_3 = 1$. Thus, x_1 and x_2 are the coordinates on $DP_+(s)$. Let $x_1(t)$ and $x_2(t)$ be the coordinates of the projection of $y(t), t \in (s, q_{max}(s))$, onto $DP_+(s)$. Then

$$x_1(t) = \frac{y_1(t)}{y_3(t)},\ x_2(t) = \frac{y_2(t)}{y_3(t)}. \tag{4.3}$$

Applying (2.3) to a planar curve gives

$$\kappa(t) = \frac{\dot{x}_1^2}{(\dot{x}_1^2+\dot{x}_2^2)^{3/2}}\left(\frac{\dot{x}_2}{\dot{x}_1}\right)'. \tag{4.4}$$

Differentiating (4.3) gives

$$\begin{aligned}\left(\frac{\dot{x}_2}{\dot{x}_1}\right)' &= \left(\frac{\dot{y}_2y_3-\dot{y}_3y_2}{\dot{y}_1y_3-\dot{y}_3y_1}\right)'\\ &= \frac{(\ddot{y}_2y_3-\ddot{y}_3y_2)(\dot{y}_1y_3-\dot{y}_3y_1)-(\dot{y}_2y_3-\dot{y}_3y_2)(\ddot{y}_1y_3-\ddot{y}_3y_1)}{(\dot{x}_1y_3^2)^2}\\ &= \frac{1}{(\dot{x}_1y_3^2)^2}\begin{vmatrix} y_1 & y_2 & y_3\\ \dot{y}_1 & \dot{y}_2 & \dot{y}_3\\ \ddot{y}_1 & \ddot{y}_2 & \ddot{y}_3\end{vmatrix}.\end{aligned} \tag{4.5}$$

Substituting (4.5) into (4.4) and using (4.3) (recall that $y(s)=0$ is the origin) gives the curvature of Γ_+:

$$\kappa(t) = \frac{\Phi(t,s)}{y_3^4(t)\,(\dot{x}_1^2(t)+\dot{x}_2^2(t))^{3/2}}. \tag{4.6}$$

By the properties of $C(s,q_{max}(s))$ mentioned prior to this proposition, $y_3(t)\neq 0, t\in (s,q_{max}(s))$. Also, $y_3(s)=0$, and, if $H(s,q_{max}(s))$ is maximal, $y_3(q_{max}(s))=0$. It remains to show that $\dot{x}_1^2(t)+\dot{x}_2^2(t)\neq 0$. This would also imply that Γ_+ is smooth. We argue by contradiction. Suppose $\dot{x}_1(t)=\dot{x}_2(t)=0$. Then $\dot{y}_2y_3=\dot{y}_3y_2$, $\dot{y}_1y_3=\dot{y}_3y_1$. Consequently, $y(t)\times\dot{y}(t)$ is parallel to the x_3-axis. Thus, either both $y(t)$ and $\dot{y}(t)$ are parallel to $DP_+(s)$ or $y(t)$ and $\dot{y}(t)$ are parallel to each other. Both cases are impossible because of the convexity of $\hat{C}(s,q_{max}(s))$ (cf. Proposition 4.1). Since $\Phi(t,s)\neq 0$ for $t\in[s,q_{max}(s)]$ (cf. Proposition 2.3), the desired assertion is proven. □

Denote $L_0^+ := DP_+(s)\cap\Pi_{osc}(s)$. It is clear that L_0^+ is an asymptote of Γ_+: $\text{dist}(\hat{y}(t),L_0^+)\to 0$ as $t\to s^+$. Similarly, $L_0^- := DP_-(s)\cap\Pi_{osc}(s)$ is an asymptote of Γ_-: $\text{dist}(\hat{y}(t),L_0^-)\to 0$ as $t\to s^-$.

Fix $x\in U$, which admits a PI line. Let $I_{PI}(x)=[s_b(x),s_t(x)]$ be the PI interval of x. Let $\hat{x}$ denote the projection of x onto a detector plane. Frequently it is convenient to identify detector planes by introducing systems of coordinates that depend smoothly on s. This allows one to identify all $DP_+(s)$ and, separately, all $DP_-(s)$. Since $x\in U$, x does not belong to any plane passing through $y(s)$ and parallel to $DP_+(s)$ or $DP_-(s)$, where $s\in I_{PI}(x)$. Hence Propositions 4.3 and 3.3 immediately imply the following statement.

Corollary 4.5. *As s moves along $I_{PI}(x)$, the point $\hat{x}$ traces smooth curves on $DP_+(s)$ and $DP_-(s)$. $\hat{x}$ is between $\Gamma_+(s)$ and L_0^+ on $DP_+(s)$ if and only if $s\in(s_b(x),s^*(x))$, and $\hat{x}$ is between L_0^- and $\Gamma_-(s)$ on $DP_-(s)$ if and only if $s\in(s^*(x),s_t(x))$.*

Loosely speaking, Corollary 4.5 can be stated as follows: $\hat{x}$ is between $\Gamma_+(s)$ and $\Gamma_-(s)$ if and only if $s\in I_{PI}(x)$.

Following [9, 12], choose any $\psi\in C^\infty(\mathbb{R}^+)$ with the properties

$$\begin{aligned}&\psi(0)=0;\ 0<\psi'(t)<1,\, t\geq 0,\\ &\psi'(0)=0.5;\ \psi^{(2k+1)}(0)=0,\, k\geq 1.\end{aligned} \tag{4.7}$$

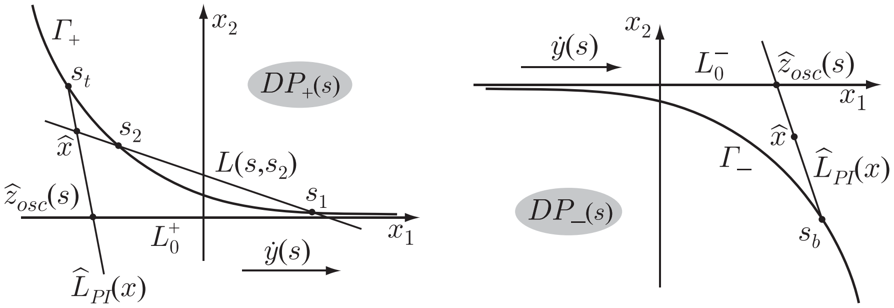

FIG. 6. *Detector planes $DP_+(s)$ (left panel) and $DP_-(s)$ (right panel).*

Suppose s, s_1, and s_2 are related by

$$s_1 = \begin{cases} \psi(s_2 - s) + s, & s_2 \geq s, \\ \psi(s - s_2) + s_2, & s_2 < s. \end{cases} \tag{4.8}$$

From (4.7), $s_1 = s_1(s, s_2)$ is a C^∞ function of s and s_2. Conditions (4.7) are easy to satisfy. One can take, for example, $\psi(t) = t/2$, and this leads to

$$s_1 = (s + s_2)/2. \tag{4.9}$$

Denote also

$$\begin{gathered} u(s, s_2) = \frac{(y(s_1) - y(s)) \times (y(s_2) - y(s))}{|(y(s_1) - y(s)) \times (y(s_2) - y(s))|} \operatorname{sgn}(s_2 - s), \\ q_{min}(s) < s_2 < q_{max}(s), s_2 \neq s, \\ u(s, s_2) = \frac{\dot{y}(s) \times \ddot{y}(s)}{|\dot{y}(s) \times \ddot{y}(s)|}, \ s_2 = s. \end{gathered} \tag{4.10}$$

In the same way as in [12], we prove that $u(s, s_2)$ is a C^∞ vector function of its arguments. Let $\Pi(s, s_2)$ be the plane through $y(s)$, $y(s_2)$, and $y(s_1(s, s_2))$. The intersection of $\Pi(s, s_2)$ with $DP_+(s)$ if $s < s_2 < q_{max}(s)$ or with $DP_-(s)$ if $q_{min}(s) < s_2 < s$ is called a filtering line and denoted $L(s, s_2)$.

Fix $x \in U$, which admits a PI line, and $s \in I_{PI}(x)$. Find $s_2 \in I_{PI}(x)$ such that $\Pi(s, s_2)$ contains x. More precisely, we have to solve for s_2 the following equation:

$$(x - y(s)) \cdot u(s, s_2) = 0, \ s_2 \in I_{PI}(x). \tag{4.11}$$

Recall that $\dot{y}(s)$ is parallel to $DP_+(s)$ and $DP_-(s)$. For convenience, we choose the x_1- and x_2-axes so that

1. $\dot{y}(s)$ and the x_1-axis are parallel and point in the same direction;
2. the equation of $\Pi_{osc}(s)$ is $x_2 = 0$;
3. on $DP_+(s)$, Γ_+ is located in the half-plane $x_2 > 0$;
4. on $DP_-(s)$, Γ_- is located in the half-plane $x_2 < 0$.

Figure 6 illustrates the two detector planes.

The advantage of planes $DP_+(s)$ and $DP_-(s)$ is that the segments $C(s, q_{max}(s))$ and $C(q_{min}(s), s)$ are projected onto them as continuous curves with positive curvature. If C is a helix, the two segments become the usual 2π-segments $C(s, s+2\pi)$ and $C(s - 2\pi, s)$. This makes it very convenient when describing how to choose filtering lines in a shift-invariant FBP algorithm. On the other hand, the disadvantage is that the two segments are projected onto two different planes. This makes it difficult to adapt the proofs from [12, 9] to the present more general situation. Fortunately, the difficulty can be resolved. Given $x \in U$ with the PI interval $I_{PI}(x) = [s_b(x), s_t(x)]$, we can find a family of "detector planes" such that for any $s \in I_{PI}(x)$ the entire PI segment of x, $C(s_b(x), s_t(x))$, projects onto them in exactly the same way as in the case of a regular constant-pitch helix. There is no guarantee that the larger segment $C(q_{min}(s), q_{max}(s))$ (which is equivalent to two adjacent turns of a helix) projects well onto the planes, but this is not needed.

Let $DP(s), s \in I_{PI}(x)$, be a plane not passing through $y(s)$ and parallel to $\dot{y}(s)$ and $N_{max}(s_b(x))$. Using the convexity of $\hat{C}(s_b(x), s_t(x)) \subset \hat{C}(s_b(x), q_{max}(s_b(x)))$ (cf. Proposition 4.1 and Figure 5) and repeating the proof of Proposition 4.4, we establish that the stereographic projection of $C(s_b(x), s_t(x))$ onto $DP(s)$ has all of the usual properties as in the constant-pitch helix case. More precisely, the projections of $C(s_b(x), s)$ and $C(s, s_t(x))$ are concave down and up, respectively, they share the usual asymptote $DP(s) \cap \Pi_{osc}(s)$, they are located on the opposite sides of the latter, etc. Thus, using the same argument as in [12, 7], we immediately obtain the following result.

Proposition 4.6. *The solution s_2 to* (4.11) *exists, is unique, and depends smoothly on s.*

The following result shows that filtering lines are shared by sufficiently many points $x \in U$. The planes $DP(s)$ used for the proof of Proposition 4.6 are selected separately for each x, so they do necessarily work for all x in a large subset of U. Thus we have to go back to the planes $DP_+(s)$ and $DP_-(s)$.

Proposition 4.7. *All $x \in U$ that project onto any line $L(s, s_2), s < s_2 < q_{max}(s)$, on $DP_+(s)$ to the left of s_2 or onto $L(s, s_2), q_{min}(s) < s_2 < s$, on $DP_-(s)$ to the right of s_2 share $L(s, s_2)$ as their filtering line.*

Proof. We consider only the case when $s_2 > s$, i.e., $\hat{x} \in DP_+(s)$. The other case can be considered analogously. We have $s_t(x) \in \Gamma_+$. By Corollary 4.5, $\hat{x}$ appears between L_0^+ and Γ_+. From the proof of Proposition 4.1, $\Pi_{osc}(s)$ intersects the PI segment of x, $H(s_b(x), s_t(x))$. Let $z_{osc}(s)$ denote the point of intersection. Let $\Pi_{max}(s)$ be the plane through $y(s)$ and parallel to $\dot{y}(s)$ and $N_{max}(s)$. Our first goal is to show that the line segment $[z_{osc}(s), y(s_t(x))]$ lies on one side of $\Pi_{max}(s)$ and, therefore, projects well onto $DP_+(s)$. Let $z_{max}(s)$ denote the intersection of the line through $L_{PI}(x)$ and $\Pi_{max}(s)$. Clearly, $z_{osc}(s) = z_{max}(s)$ when $s = s_b(x)$. From the proof of Proposition 4.3, $z_{osc}(s)$ moves toward $y(s_t(x))$ along $L_{PI}(x)$ as s increases from $s_b(x)$ to $s_t(x)$. From the convexity of $\hat{C}(s, q_{max}(s))$ (cf. Figure 5), it is easy to obtain that in a neighborhood of $s = s_b(x)$ the point $z_{max}(s)$ moves away from $H(s_b(x), s_t(x))$ as s increases. If for some $s \in (s_b(x), s_t(x))$ the points $z_{osc}(s)$ and $y(s_t(x))$ are on opposite sides of $\Pi_{max}(s)$, then the point $z_{max}(s)$ enters the line segment $[z_{osc}(s), y(s_t(x))]$ for some $s = s_0 \in (s_b(x), s_t(x))$. Hence, either (i) $z_{osc}(s_0) = z_{max}(s_0)$ or (ii) $y(s_t(x)) = z_{max}(s_0)$. From Proposition 2.3, $[y(q_{max}(s_0)) - y(s_0), \dot{y}(s_0), \ddot{y}(s_0)] \neq 0$, so (i) implies that $z_{osc}(s_0) - y(s_0)$ and $\dot{y}(s_0)$ are collinear, which contradicts Corollary 4.2. In case (ii), $y(s_t(x)) \in \Pi_{max}(s_0)$, which contradicts the containment property.

Hence $\hat{L}_{PI}(x)$, the projection of $H(s_b(x), s_t(x))$ onto $DP_+(s)$, intersects L_0^+. More precisely, the projection of the line segment $[z_{osc}(s), y(s_t(x))] \subset L_{PI}(x)$ is a continuous line segment that connects Γ_+ and L_0^+ (see Figure 6). Note that Proposition 4.3 implies $x \in [z_{osc}(s), y(s_t(x))]$ if $s < s^*(x)$. It turns out that $\hat{L}_{PI}(x)$ does not intersect Γ_+ at any point other than $s_t(x)$. Suppose there is an additional intersection point t. Thus the plane through $y(s)$ and $H(s_b(x), s_t(x))$ intersects $C_{PI}(x)$ at four points: $s_b(x), t, s,$

and $s_t(x)$, and this contradicts Corollary 2.5. Here $C_{PI}(x)$ is the section of the curve corresponding to the parametric interval $I_{PI}(x)$, i.e., $C_{PI}(x) := C(s_b(x), s_t(x))$.

If x projects onto $L(s, s_2)$ to the left of s_2, we make two observations: (i) $\hat{x}$ is between L_0^+ and Γ_+ on $DP_+(s)$, and (ii) $s_2 < s_t(x)$ (due to the properties of $\hat{L}_{PI}(x)$ that we just established). From (i) and Corollary 4.5, $s \in I_{PI}(x)$. From (ii), $s_2 \in (s, s_t(x))$, so by (i) $s_2 \in I_{PI}(x)$. By construction, s_2 was chosen to satisfy $(x - y(s)) \cdot u(s, s_2) = 0$. We have just shown that $s, s_2 \in I_{PI}(x)$. This proves that $L(s, s_2)$ is the filtering line for x. □

By Proposition 4.7, our construction defines $s_2 := s_2(s, x)$ and, consequently, $u(s, x) := u(s, s_2(s, x))$. Let $D_f(s, \Theta) = \int_0^\infty f(y(s) + t\Theta)dt$, $|\Theta| = 1$, denote the cone beam transform of f. The main result of the paper is the following theorem.

THEOREM 4.8. *Let C be a curve* (2.1)*, which satisfies conditions* C1–C4. *Let $I_0 \subset I$ be an interval such that the set U defined by* (3.11) *is nonempty. For any $f \in C_0^\infty(U)$ and $x \in U$ which admits a PI line such that $I_{PI}(x) \subset I_0$, one has*

$$f(x) = -\frac{1}{2\pi^2} \int_{I_{PI}(x)} \frac{1}{|x - y(s)|} \int_0^{2\pi} \frac{\partial}{\partial q} D_f(q, \Theta(s, x, \gamma)) \bigg|_{q=s} \frac{d\gamma}{\sin\gamma} ds, \tag{4.12}$$

where $\beta(s, x) = (x - y(s))/|x - y(s)|$, $e(s, x) := \beta(s, x) \times u(s, x)$, and $\Theta(s, x, \gamma) := \cos\gamma\beta(s, x) + \sin\gamma e(s, x)$.

Proof. Corollaries 2.5, 2.6, and 4.5 and Propositions 4.1, 4.3, 4.4, and 4.6 imply that locally, i.e., in a neighborhood of $I_{PI}(x)$, the curve C behaves in essentially the same way as the usual helix. Hence the same argument as in [12, 7] can be used to prove that (4.12) holds. For the convenience of the reader we recall the key steps in the proof. Fix $x \in U$ such that $I_{PI}(x) \subset I_0$ and $s \in I_{PI}(x)$. Suppose $s < s^*(x)$ (cf. Proposition 4.3). Consider the detector plane $DP(s)$ introduced prior to Proposition 4.6. Let d_0 be the unit vector perpendicular to $DP(s)$ and pointing from the source position $y(s)$ towards the detector. By the choice of U and the detector plane, this implies $\beta(s, x) \cdot d_0 > 0$ and $\dot{y}(s) \cdot d_0 = 0$. In the same way as in [10] we show that the stereographic projection of all of the relevant vectors onto $DP(s)$ preserves the sign of dot products. Let Π be a generic plane containing x and $y(s)$. By Corollary 2.5, there can be only either one or three IPs in the set $\Pi \cap C_{PI}(x)$. If s is the only IP or the middle of the three IPs, then the slope of the line $\Pi \cap DP(s)$ on $DP(s)$ is greater than the slopes of L_0 $(= \Pi_{osc}(s) \cap DP(s))$ and the filtering line through $\hat{x}$. Recall that the filtering line intersects the projection of $C(s, s_t(x))$ onto $DP(s)$ twice, and the projected curve is convex. Hence the IP s gets weight 1. Since $s < s^*(x)$, the only remaining alternative is that s is the smallest of the three IPs. In this case s gets weight 1 or -1 depending on the location of $\Pi \cap DP(s)$ relative to the filtering line through $\hat{x}$. Using exactly the same argument as in section 3 of [12], we prove that the largest of the three IPs gets weight -1 or 1, respectively. Hence the inversion formula (4.12) is exact. □

Proposition 4.7 implies that (4.12) is of the efficient shift-invariant FBP form. This means that filtering in (4.12) is convolution-based and is performed along a one-parametric family of lines.

5. Numerical experiments.

Numerical experiments are conducted using flat detector geometry. The simulation parameters are summarized in Table 1. The detector is located at the distance of 600 mm from the axis of rotation opposite to the source position. The algorithm is implemented in the native coordinates following [18]. The clock phantom (see, e.g., [7]) is chosen for reconstructions. The background cylinder is at 0 HU, the spheres are at 1000 HU, and the air is at -1000 HU.

Table 1
Simulation parameters.

Parameter	Value	Units
Views per rotation	1000	
Number of detector columns	1101	
Number of detector rows	111	
Actual detector pixel size	1 × 1	mm^2
Isocenter to detector distance	600	mm

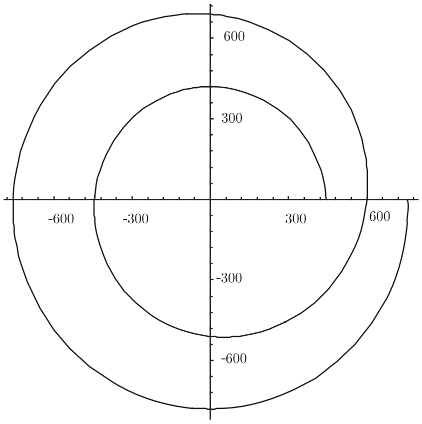

Fig. 7. *Projection of the source trajectory in* (5.1) *onto the xy-plane.*

Two source trajectories have been used. The first one is a variable radius helix given by the formula:

$$y(s) = \left(R(s)\cos s, R(s)\sin s, \frac{h_0}{2\pi}s \right), \;\; R(s) = R(1 + 0.3\sin(s/3)), \tag{5.1}$$

where $R = 600$ mm, and the table feed per turn is $h_0 = 35$ mm. The projection of this trajectory onto the plane $x_3 = 0$ for $s \in [-2\pi, 2\pi]$ is shown in Figure 7.

Because of the variable radius, detector usage is different for different source positions. The detector parameters given in Table 1 were chosen so as to accommodate all source positions. The horizontal size of the detector varied from 894 to 1098 mm; the average was 945 mm. The vertical size of the detector varied from 49 to 75 mm; the average was 59 mm. These values were calculated for the segment of the trajectory necessary to reconstruct the clock phantom.

The boundary of the set U is calculated according to (3.11). The cross section of the boundaries of cylinders $Cyl_{min}(s)$ and $Cyl_{max}(s)$ with the plane $x_3 = 0$ is shown in Figure 8 (left panel). The solid circle of radius $r = 240$ mm shows the boundary of the clock phantom, and the dashed circle is of the maximum radius $r \approx 374$ mm that fits inside the cross section of U. The result of reconstruction is shown in Figure 9. Here and in the experiment below we use voxels of size 1mm in each direction.

The second experiment is carried out using the variable-radius and variable-pitch helix given by:

$$y(s) = \left(R(s)\cos s, R(s)\sin s, \frac{h(s)}{2\pi}s \right), \;\; h(s) = h_0\left(1 + \frac{\sin(s/2)}{s}\right). \tag{5.2}$$

Here $R(s)$ and h_0 are the same as in (5.1). Because of the variable radius/variable pitch, detector usage is different for different source positions. The horizontal size

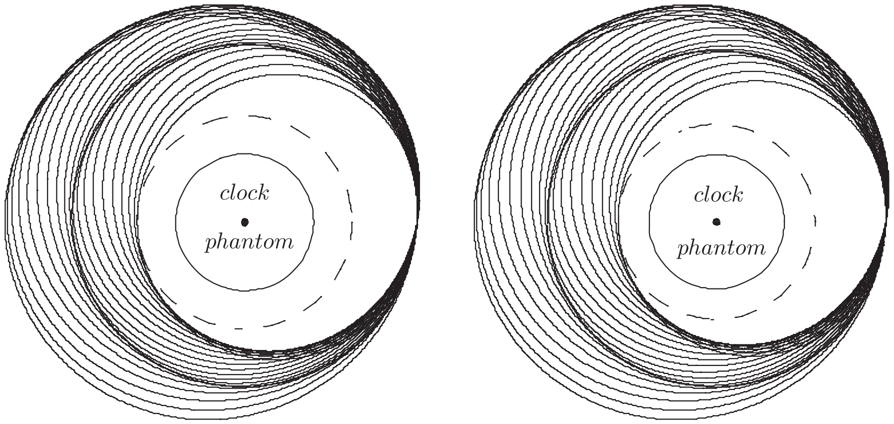

Fig. 8. *Cross section of boundaries of cylinders $Cyl(s)$ from* (3.11) *for trajectory* (5.1) *(left panel) and trajectory* (5.2) *(right panel).*

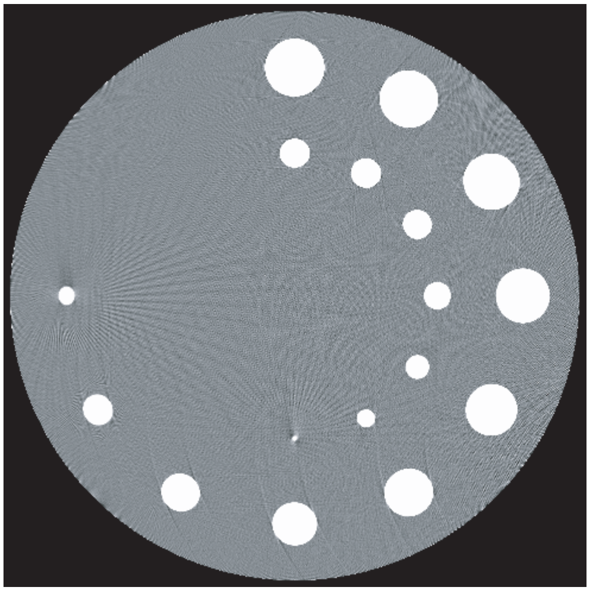

Fig. 9. *Reconstruction of the clock phantom from trajectory* (5.1)*: slice $x_3 = 0$, $WL = 0$* HU*, $WW = 100$* HU*.*

of the detector varied from 894 to 1098 mm; the average was 945 mm. The vertical size of the detector varied from 38 to 88 mm; the average was 71 mm. These values were calculated for the segment of the trajectory necessary to reconstruct the clock phantom. The cross section of the boundaries of cylinders $Cyl_{min}(s)$ and $Cyl_{max}(s)$ with the plane $x_3 = 0$ is shown in Figure 8 (right panel). Again, the solid circle of radius $r = 240$ mm shows the boundary of the clock phantom, and the dashed circle is of the maximum radius $r \approx 348$ mm that fits inside the cross section of U. The results of the reconstruction are shown in Figure 10.

EXPLOITING HISTORY-DEPENDENT EFFECTS TO INFER NETWORK CONNECTIVITY[*]

DUANE Q. NYKAMP[†]

Abstract. We present an approach to distinguish between causal connections and common input connections among nodes in a network. By modeling how the activity of a node depends on its own recent history, we demonstrate how this history dependence predicts different patterns of activity depending on the nature of the network connectivity. In particular, a causal connection between a pair of observed nodes can be distinguished from common input connections that originate from nodes whose activity remains unobserved. This work builds on previous results where this same distinction was made based on modeling how the activity of a node depends on measured external variables such as stimuli. The results have a potentially broad range of application as the analysis can be based on a fairly generic class of models.

1. Introduction.

The determination of causal connections among nodes within a network is a difficult challenge. This challenge is magnified in the presence of hidden nodes, the effects of which can mimic the presence of causal connections among the set of measured nodes. For example, the connection from a hidden node onto two measured nodes could introduce correlations in the activity of the measured nodes that resemble the effect of a causal connection between the measured nodes (see Figure 1).

We have recently introduced [14, 13, 12] an approach for identifying causal connections in the presence of hidden nodes that is based on modeling the relationship between the activity of nodes and measurable external variables, such as those representing a stimulus. In the original formulation of this approach, the activity of any node could be only weakly dependent on the history of its activity. However, in general, the activity of a node could depend strongly on the recent activity of that node. For example, this approach was originally designed for neuronal networks, and the spiking activity of a neuron is strongly modulated by that neuron's spike history. After firing a spike, a neuron cannot immediately fire a second spike due to its refractory period. Some neurons tend to fire spikes in bursts so that, once the refractory period is over, the probability of firing a spike is transiently much higher than baseline. These history-dependent effects were neglected in our original formulation.

We have now discovered that, if one models how the activity of a node depends on its recent history, one's ability to distinguish causal connections within a network is enhanced. The reason that modeling history dependence can help determine causal connections is caricatured in Figure 2. For the purpose of illustration, imagine that the nodes are neurons and that the measured activity is the times of the neurons' output spikes. Moreover, imagine that neuron 1 tends to fire spikes in pairs (note the

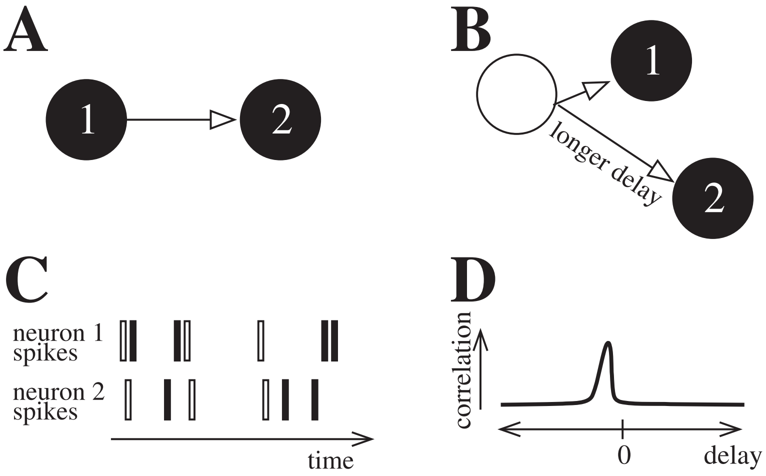

Fig. 1. *The effect of hidden nodes (unfilled circle) can be to mimic causal connections among measured nodes (filled circles).* (A) *A causal connection from measured node* 1 *onto measured node* 2*.* (B) *A common connection from a hidden node onto two measured nodes, where the connection onto measured node* 2 *has a longer delay.* (C) *Both the common input configuration (A) and the causal connection configuration (B) produce similar correlations in the activity of the measured nodes. For concreteness, let the nodes be neurons whose activity is a sequence of spike times illustrated by the temporal sequence of rectangles. Both the networks (A and B) will increase the probability that neuron* 2 *will fire a spike immediately after neuron* 1*. (These spike combinations are highlighted by the unfilled rectangles.)* (D) *Schematic of the correlation induced by either network (A or B). Neuron* 2 *is highly likely to fire a spike a certain delay after neuron* 1 *fires. There is a peak in the correlation measured at that delay. (We arbitrarily use a negative delay when neuron* 2 *follows neuron* 1*.) Since both the common input (A) and the causal connection (B) configurations induce similar correlations in the activity of the measured nodes, our goal is to distinguish which configuration underlies the measured activity of the two nodes.*

pairs of closely spaced spikes in the output of neuron 1 in the right panels of Figure 2). We argue that neuron 2 should respond differently to the spike pairs depending on whether the network contains a causal connection (Figure 2(A)) or common input connections (Figure 2(B)).

To further simplify the situation, imagine that the spike trains of neither neuron 2 nor the hidden neuron have a significant dependence on their history. Then, as portrayed in Figure 2(A), if neuron 1 has a causal connection onto neuron 2, neuron 2 will respond equally well to both spikes in the spike pairs emitted by neuron 1. Neuron 2 will receive both spikes in the pair as inputs, so neuron 2 will be likely to fire a spike immediately after both of these inputs. On the other hand, in the common input configuration of Figure 2(B), neuron 2 does not receive neuron 1's spike pairs as inputs. When the hidden neuron fires a single spike, it may elicit a spike pair from neuron 1. However, neuron 2 just receives the single input from the hidden neuron, so neuron 2 will not be driven to fire twice. When looking at just the spike trains of neuron 1 and 2, it may appear, for example, that neuron 2 is responding to just the first spike of each pair from neuron 1 and ignoring the second spike. The key intuition to gain from this example is that, for the common input configuration, it looks as though neuron 2 does not respond to spikes that can be predicted by the history dependence of neuron 1.

Of course, any real situation will be far more complicated than this exaggerated example. For instance, all of the nodes could have a strong history dependence to their activity, which will confound the simple reasoning given above. Moreover,

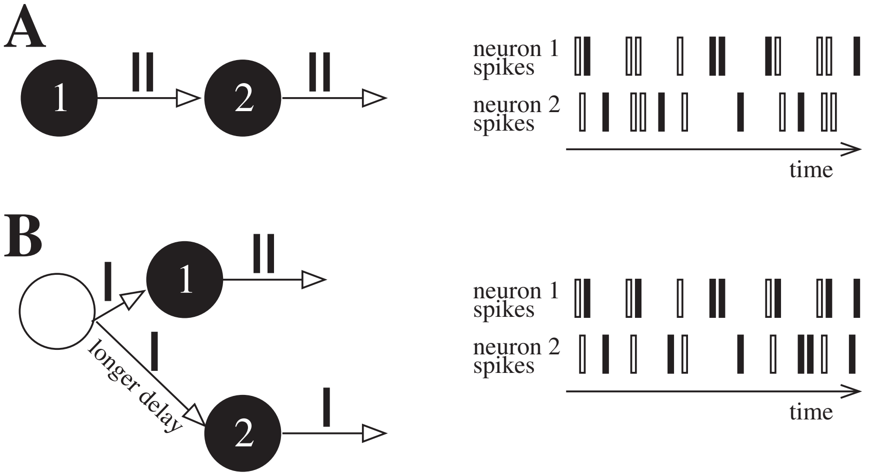

FIG. 2. *Illustration of the different effects of history dependence based on the underlying circuitry. Nodes are spiking neurons as in Figure* 1. *For this illustration, we assume neuron* 1*'s activity is strongly dependent on its spiking history; it is highly likely to fire spikes in pairs. We also assume that the spikes of neuron* 2 *and the unmeasured neuron are largely independent of their respective history.* (A) *In a causal connection configuration, neuron* 2 *may respond to all of neuron* 1*'s spikes. As schematized on the left, when neuron* 1 *fires a pair of spikes (black rectangles), neuron* 2 *is likely to spike after each one and so may spike twice. The right panel illustrates a possible temporal sequence of spikes from both neurons. Spike combinations where neuron* 2 *fires immediately after neuron* 1 *are highlighted by unfilled rectangles. Neuron* 2 *is highly likely to spike both after the first spike and after the second spike in each spike pair from neuron* 1. (B). *In a common input configuration, neuron* 2 *does not receive the spike pairs from neuron* 1. *Since a single spike from the hidden neuron can evoke the spike pair from neuron* 1, *neuron* 2 *receives only one input that is correlated with the spike pair from neuron* 1. *If the connection from the hidden neuron onto neuron* 2 *has a slightly longer delay than the connection onto neuron* 1, *neuron* 2 *will be likely to fire immediately after the first spike in each pair from neuron* 1. *It will not be likely to spike after the second spike of the pair, as illustrated in the right panel.*

the influence of the connections between a pair of nodes will typically be weaker than illustrated here, as input received via any one connection will be just one small influence on a node bathed with inputs from other nodes in the network. Hence, exploiting such history-dependent effects to infer connectivity requires some form of analysis that can synthesize the various ways in which internode connectivity and intranode history-dependent effects interact to influence nodes' activities. Nonetheless, the mathematical analysis we present will confirm that intuition gleaned from this exaggerated example does apply to the more complex situation (see section 3.4.1).

This paper presents a mathematical analysis through which one can employ a model of history-dependent effects to develop estimates of the network connectivity among measured nodes. In section 2, we describe the class of models that we consider. In section 3, we present the analysis to determine the connectivity. We demonstrate the results applied to simulated networks in section 4 and discuss the results in section 5.

2. The history-dependent model.

We present our model and analysis in fairly abstract terms. As detailed in [14], we employ a modular approach where the details of the single-node model are ignored in the network analysis. To employ the results to analyze a particular dataset, one must select an appropriate model, the form of which can be "plugged into" the network analysis.

2.1. The general model formulation. The model is formulated in discrete time. Let R_s^i be a random variable that represents the activity of node s at time point i. Since our examples will involve models of neurons, we will assume that R_s^i is a discrete random variable. However, the analysis proceeds analogously for a continuous random variable. Ignoring the activity of other nodes for a moment, the probability distribution of R_s^i will depend both on the history of node s and on some measurable external variables. Let $\mathbf{R}_s^{<i}$ be the vector of the history of the activity of node s (i.e., the vector with values of R_s^k for $k < i$). Denote the external variable vector by $\mathbf{X}$. The vector $\mathbf{X}$ could represent any quantity or set of quantities whose values are known and that modulate the activity of the nodes. For example, in neuroscience applications, $\mathbf{X}$ could correspond to a sequence of stimuli or a sequence of animal positions. (See [14] for a discussion on external variables. Note that $\mathbf{X}$ could depend on time, although the notation does not make that explicit.)

The activity of a given node on the network also depends on activity of other nodes. We denote the network connectivity by $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$, which indicates the magnitude of the effect of the activity of node $\tilde{s}$ at time $\tilde{\imath}$ (i.e., $R_{\tilde{s}}^{\tilde{\imath}}$) on the activity of node s at time i (i.e., R_s^i). We assume that all connections are causal so that $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i} = 0$ for $\tilde{\imath} \geq i$. We model the effect of $R_{\tilde{s}}^{\tilde{\imath}}$ on the probability distribution of R_s^i as a function of the product $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i} R_{\tilde{s}}^{\tilde{\imath}}$. Moreover, we simply linearly sum the coupling effects from all nodes and previous time steps, modeling the total coupling effect of all nodes on the probability distribution of R_s^i as a function of the sum

$$\sum_{\tilde{s}\neq s} \sum_{\tilde{\imath}<i} \bar{W}_{\tilde{s},s}^{\tilde{\imath},i} R_{\tilde{s}}^{\tilde{\imath}}.$$

To summarize, we model the probability distribution of R_s^i as a parametric function of the history $\mathbf{R}_s^{<i}$ of node s, the external variables $\mathbf{X}$, and the past activity of all nodes as

$$\Pr(R_s^i = r_s^i \,|\, \mathbf{R}^{<i} = \mathbf{r}^{<i}, \mathbf{X} = \mathbf{x}) = P_s\left(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, \sum_{\tilde{s}\neq s} \sum_{\tilde{\imath}<i} \bar{W}_{\tilde{s},s}^{\tilde{\imath},i} r_{\tilde{s}}^{\tilde{\imath}}; \bar{\theta}_s^i \right), \tag{2.1}$$

where P_s is some discrete probability distribution in its first argument and $\bar{\theta}_s^i$ is a vector of parameters. The quantity $\mathbf{R}^{<i}$ (without a subscript) is the history of all nodes, i.e., has components $R_{\tilde{s}}^k$ for all $\tilde{s}$ and all $k < i$. If $\mathbf{R}$ represents all of the activity of all nodes (i.e., has components $R_{\tilde{s}}^k$ for all $\tilde{s}$ and k), then, by Bayes' law, the probability distribution of $\mathbf{R}$, given the value of the external variable vector $\mathbf{X}$, is

$$\begin{aligned} \Pr(\mathbf{R} = \mathbf{r} \,|\, \mathbf{X} = \mathbf{x}) &= \prod_s \prod_i \Pr(R_s^i = r_s^i \,|\, \mathbf{R}^{<i} = \mathbf{r}^{<i}, \mathbf{X} = \mathbf{x}) \\ &= \prod_s \prod_i P_s\left(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, \sum_{\tilde{s}\neq s} \sum_{\tilde{\imath}<i} \bar{W}_{\tilde{s},s}^{\tilde{\imath},i} r_{\tilde{s}}^{\tilde{\imath}}; \bar{\theta}_s^i \right). \end{aligned} \tag{2.2}$$

To obtain (2.2), we exploited the fact that nodes influence each other only through causal connections. Hence, conditioned on the history $\mathbf{R}^{<i}$ of the network and the external variables, the activities R_s^i of nodes in a single time step i are independent. (In other words, we assume the time bins are small enough so that interactions involve a delay of at least one time bin.)

2.2. Assumptions required for analysis. With the exception of the linear coupling among nodes, (2.2) is a fairly generic description of a network in discrete time. (Recall that the equations could be trivially modified to allow the activity R_s^i to be a continuous random variable.) However, to proceed with our analysis we make a few strong assumptions about the network. These assumptions are similar to those detailed in [14]. (The biggest difference is that here we make no assumptions about the dependence of a node on its own history.) For this reason, we present only a brief discussion of these assumptions here and refer the reader to the more detailed discussion in the former article.

First, we assume that an algorithm exists to fit the activity of a single node to the same parametric model with the coupling factors $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ set to zero. Note that this particular assumption is only about choice of models; it is not an assumption about the network activity. We assume that, from measurements of the activity of just a single node s (i.e., of the vector $\mathbf{R}_s$ composed of R_s^i for all i), one has an algorithm to determine effective parameters θ_s^i by fitting the averaged model[1]

$$\Pr(\mathbf{R}_s = \mathbf{r}_s \,|\, \mathbf{X} = \mathbf{x}) = \prod_i P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, 0; \theta_s^i\big). \tag{2.3}$$

Although the activity of all other nodes $R_{\tilde{s}}^{\tilde{\imath}}$ is ignored in this fitting procedure, we view the R_s^i as really generated from the full network via model (2.2). Therefore, the effective parameters θ_s^i do include the averaged effects of the coupling from other nodes. Our analysis will rely heavily on these effective parameters; hence, the results depend on having chosen a good model P_s and fitting algorithm so that the averaged model (2.3) captures key elements of the activity of each node. This assumption puts stringent limits on the model P_s. For example, one cannot use detailed biophysical models, as all of the parameters of such models cannot be determined by $\mathbf{R}_s$ and $\mathbf{X}$ alone. Neither could one allow the θ_s^i to be independent for each time i. (See [14] for more details.)

Second, we assume that the coupling $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ is weak so that we can expand the full model (2.2) in a Taylor series in $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ and retain terms only through second order. Since we assume that P_s is C^2 in its fourth argument, our analysis will have an error that is $O(\bar{W}^3)$. As detailed in [14], the assumption has the following important consequences: The average coupling strength must scale like $1/N$, where N is the network size; the identity of the nodes that appear in (2.2) must be regarded as "lumped" models that already incorporate effects of nodes projecting to them; and the network topology is highly simplified, as the second order Taylor series will represent combinations of at most two edges of the network graph. If the actual connectivity is too strong to strictly justify this assumption, the resulting connectivity estimates may need to be reinterpreted as an effective connectivity (see the discussion in section 5).

Third, once we have calculated θ_s^i by fitting the averaged model (2.3), we assume that the model is constructed so that we can calculate $P_s(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i)$ for any value of w. This is a strong assumption on the allowed form of the model function P_s, as the averaged model (2.3) is not based on $P_s(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i)$ for any nonzero w. This assumption also implies that we can calculate $\frac{\partial}{\partial w} P_s(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i)$ and

[1] The probability of the left-hand side of model (2.3) is the marginal distribution of the probability of the left-hand side of model (2.2), averaged over the activity of all other nodes.

$\frac{\partial^2}{\partial w^2} P_s(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i)$. In fact, this assumption implies that these derivatives must be equivalent to derivatives with respect to some function of $\mathbf{r}_s^{<i}$, $\mathbf{x}$, and θ_s^i.

Last, unless one could repeatedly sample the activity of the nodes from the same time points, one couldn't hope to be able to determine arbitrary connectivity $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ that varies freely with the time point. (This is the same reason θ_s^i cannot be allowed to vary freely with the time point, as mentioned above.) When we actually implement the approach, we will eventually (see section 3.3.3) allow $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ to depend on $\tilde{\imath}$ and i only through the delay $i - \tilde{\imath}$. (One could also allow the coupling to adapt slowly with time.) During most of our analysis, we will keep the notation where $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ varies freely with the time point, as it adds no complexity to the equations.

3. The analysis. We begin by giving a short overview of the analysis. We operate under the assumption that model (2.2) gives the true probability distribution of the activity $\mathbf{R}$ of the entire network. However, we assume that one can observe just a small number of nodes with indices q in some subset $\mathcal{Q}$. We denote by $\mathbf{R}_\mathcal{Q}$ the activity of all of these measured nodes. (The components of $\mathbf{R}_\mathcal{Q}$ are a subset of those of $\mathbf{R}$.)

The first step of the analysis will be to derive an expression for the probability distribution of the activity of just the measured nodes. We will derive an expression for this probability, which we denote by $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$, by taking the expression for $\Pr(\mathbf{R}|\mathbf{X})$ given in (2.2) and averaging it over the activity of all hidden nodes. This step will rely heavily on the weak coupling assumption described above.

The resulting expression for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ will depend on all of the unknown parameters $\bar{\theta}_s^i$ and $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$. Given that many nodes remain hidden, we don't have any hope of obtaining estimates of the original parameters $\bar{\theta}_s^i$. However, we do, by assumption, have an algorithm for determining the effective parameters θ_q^i of any measured node q by fitting the averaged model (2.3) to the activity of that measured node. To take advantage of this information, our second step will be to derive an expression for the original parameters $\bar{\theta}$ in terms of the effective parameters θ.

Our third step is to combine the results of steps one and two to arrive at an expression for the probability distribution $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ of the measured node activity in terms of the effective parameters. With one further approximation, we can group all of the effects of the hidden nodes into a small number of parameters. In the end, our expression for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ will contain just two sets of unknown parameters: the effective causal connection parameters (which we'll denote by an unbarred W) and the effective common input parameters (which we'll denote by U). Given a measurement of the activity of the measured nodes, we use our expression for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ to compute maximum likelihood estimates of the W and U. The effective causal connection W will be our estimate of the connectivity among the measured nodes.

3.1. Step one: Average for measured node probability distribution. Our first step is to average the full model (2.2) over all possible values of the activity of hidden nodes to obtain an expression for the probability distribution of measured node activity. Before we compute the average, we use the weak coupling assumption described in section 2.2 to simplify (2.2).

We invoke the weak coupling assumption to expand the full model (2.2) as a Taylor series in $\bar{W}$. To simplify the presentation, we define the following shorthand notation for the probability distribution of the activity of node s (over all time points

i) that would result if all coupling was set to zero:

$$\bar{P}_s = \prod_i P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, 0; \bar{\theta}_s^i, \big). \tag{3.1}$$

Similarly, we define shorthand notation for the derivatives of $\bar{P}_s$ with respect to the $r_{\tilde{s}}^{\tilde{\imath}}$ for $\tilde{s} \neq s$:

$$\frac{\partial \bar{P}_s}{\partial r_{\tilde{s}}^{\tilde{\imath}}} = \frac{\partial}{\partial r_{\tilde{s}}^{\tilde{\imath}}} \left(\prod_i P_s \left(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath} < i} \bar{W}_{\acute{s},s}^{\acute{\imath},i} r_{\acute{s}}^{\acute{\imath}}; \bar{\theta}_s^i \right) \right) \Bigg|_{\{r_{\acute{s}}^{\acute{\imath}}=0 | \acute{s} \neq s\}},$$

$$\frac{\partial^2 \bar{P}_s}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1} \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} = \frac{\partial^2}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1} \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} \left(\prod_i P_s \left(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath} < i} \bar{W}_{\acute{s},s}^{\acute{\imath},i} r_{\acute{s}}^{\acute{\imath}}; \bar{\theta}_s^i \right) \right) \Bigg|_{\{r_{\acute{s}}^{\acute{\imath}}=0 | \acute{s} \neq s\}}. \tag{3.2}$$

Since the $\bar{W}$ appear only in the combination $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i} r_{\tilde{s}}^{\tilde{\imath}}$, we can write our Taylor series in $\bar{W}$ as though it were a Taylor series in the $r_{\tilde{s}}^{\tilde{\imath}}$. This notation will turn out to be more convenient for the analysis because the key factors of $r_{\tilde{s}}^{\tilde{\imath}}$ will be written out explicitly. Note that, for each node s, we make no assumptions about the effect of its own history $\mathbf{r}_s^{<i}$ and do *not* expand out this history dependence in a Taylor series.

Using the above shorthand notation, the Taylor series of (2.2) is

$$\begin{aligned} \Pr(\mathbf{R} = \mathbf{r} | \mathbf{X} = \mathbf{x}) = \prod_s \bar{P}_s &+ \sum_{\substack{s_1, \tilde{s}_1 \\ \tilde{s}_1 \neq s_1}} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} \prod_{\substack{s_2 \\ s_2 \neq s_1}} \bar{P}_{s_2} \\ &+ \frac{1}{2} \sum_{\substack{s_1, \tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s_1, \tilde{s}_2 \neq s_1}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1} \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} r_{\tilde{s}_1}^{\tilde{\imath}_1} r_{\tilde{s}_2}^{\tilde{\imath}_2} \prod_{\substack{s_2 \\ s_2 \neq s_1}} \bar{P}_{s_2} \\ &+ \frac{1}{2} \sum_{\substack{s_1, s_2, \tilde{s}_1, \tilde{s}_2 \\ s_2 \neq s_1, \tilde{s}_1 \neq s_1 \\ \tilde{s}_2 \neq s_2}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1}} \frac{\partial \bar{P}_{s_2}}{\partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} r_{\tilde{s}_1}^{\tilde{\imath}_1} r_{\tilde{s}_2}^{\tilde{\imath}_2} \prod_{\substack{s_3 \\ s_3 \neq s_1 \\ s_3 \neq s_2}} \bar{P}_{s_3} + O(\bar{W}^3). \end{aligned} \tag{3.3}$$

Note that the derivative $\partial \bar{P}_s / \partial r_{\tilde{s}}^{\tilde{\imath}}$ corresponds to the effect of a connection from node $\tilde{s}$ onto node s. If we wrote out the derivative explicitly, it would contain a sum of terms involving $\bar{W}_{\tilde{s},s}^{\tilde{\imath},i}$ for all $i > \tilde{\imath}$. It represents the change in the distribution of all R_s^i for $i > \tilde{\imath}$ given a change in $R_{\tilde{s}}^{\tilde{\imath}}$ (calculated at $R_{\tilde{s}}^{\tilde{\imath}} = 0$).

We can now write down an expression for the activity of all measured nodes by averaging over all possible values of the activity of the hidden nodes. As mentioned above, let $\mathcal{Q}$ denote the set of node indices corresponding to all measured nodes. Similarly, let $\mathcal{P}$ denote the set of node indices corresponding to all hidden nodes. Then $\mathcal{Q} \cup \mathcal{P}$ corresponds to the entire network. To simplify the notation, we will make the following notational conventions. We will use the index s and its variants to index all nodes in the network; i.e., we implicitly assume that $s \in \mathcal{Q} \cup \mathcal{P}$. We will use the indices p and q (and their variants) to index hidden and measured nodes, respectively; i.e., we implicitly assume that $p \in \mathcal{P}$ and $q \in \mathcal{Q}$. Last, we let $\mathbf{R}_{\mathcal{Q}}$ and $\mathbf{R}_{\mathcal{P}}$ represent all measured node activity R_q^i and all hidden node activity R_p^i, respectively.

To derive an expression for the probability distribution of all measured activity, we average (3.3) over all possible values of $\mathbf{R}_{\mathcal{P}}$. The probability distribution of $\mathbf{R}_{\mathcal{Q}}$ is therefore

$$\begin{aligned}
\Pr(\mathbf{R}_{\mathcal{Q}} = \mathbf{r}_{\mathcal{Q}} | \mathbf{X} = \mathbf{x}) &= \sum_{\mathbf{r}_{\mathcal{P}}} \Pr(\mathbf{R} = \mathbf{r} | \mathbf{X} = \mathbf{x}) \\
&= \sum_{\mathbf{r}_{\mathcal{P}}} \prod_{s} \bar{P}_s + \sum_{\mathbf{r}_{\mathcal{P}}} \sum_{\substack{s_1, \tilde{s}_1 \\ \tilde{s}_1 \neq s_1}} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} \prod_{\substack{s_2 \\ s_2 \neq s_1}} \bar{P}_{s_2} \\
&\quad + \frac{1}{2} \sum_{\mathbf{r}_{\mathcal{P}}} \sum_{\substack{s_1, \tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s_1, \tilde{s}_2 \neq s_1}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1} \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} r_{\tilde{s}_1}^{\tilde{\imath}_1} r_{\tilde{s}_2}^{\tilde{\imath}_2} \prod_{\substack{s_2 \\ s_2 \neq s_1}} \bar{P}_{s_2} \\
&\quad + \frac{1}{2} \sum_{\mathbf{r}_{\mathcal{P}}} \sum_{\substack{s_1, s_2, \tilde{s}_1, \tilde{s}_2 \\ s_2 \neq s_1, \tilde{s}_1 \neq s_1 \\ \tilde{s}_2 \neq s_2}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{s_1}}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1}} \frac{\partial \bar{P}_{s_2}}{\partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} r_{\tilde{s}_1}^{\tilde{\imath}_1} r_{\tilde{s}_2}^{\tilde{\imath}_2} \prod_{\substack{s_3 \\ s_3 \neq s_1 \\ s_3 \neq s_2}} \bar{P}_{s_3} + O(\bar{W}^3),
\end{aligned} \tag{3.4}$$

where the sum over $\mathbf{r}_{\mathcal{P}}$ indicates a sum over all possible values of the hidden node activity.

It turns out that we can explicitly compute the sum over $\mathbf{r}_{\mathcal{P}}$. Note that the value r_s^i of a given random variable can appear in (3.4) either explicitly or in the probability distribution $\bar{P}_s$ (or its derivatives). It is not hidden in any other factors. Therefore, to compute a sum over all possible values of the activity of a node indexed by some s, we can factor out everything except one factor of $\bar{P}_s$ (or a derivative of $\bar{P}_s$) and a polynomial in the r_s^i. Hence, we need to derive expressions for the average of such quantities.

The average of a polynomial in the r_s^i multiplied by the undifferentiated $\bar{P}_s$ will simply be the expected value of that polynomial, under the probability distribution $\bar{P}_s$ with the W argument set to zero. Taking the average of expressions involving the derivatives of $\bar{P}_s$ is more complicated. In Appendix A.1, we outline how to compute such averages. The important point is that one can compute these averages explicitly in terms of the model parameters and the probability distributions $P_s(\cdot)$. We end up with the lengthy expression for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ given by (A.5).

3.2. Step two: Original parameters in terms of effective parameters. One of the assumptions given in section 2.2 is the existence of an algorithm to calculate the effective parameters θ_s^i by fitting the averaged model (2.3) to the activity of node s (while ignoring the activity of all other nodes). Hence, we can regard the effective parameters θ_q^i as known for all measured nodes $q \in \mathcal{Q}$. In the previous step, we obtained an expression for the probability distribution of the measured node activity $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ in terms of the unknown original model parameters $\bar{\theta}_s^i$. In this second step of the analysis, we will derive a relationship between the effective parameters θ_s^i and the original paramters $\bar{\theta}_s^i$. This relationship will allow us to rewrite our equation for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ in terms of the effective parameters.

We define equivalent shorthand notation for expressions involving the effective parameters as we did for expressions involving the original model parameters. We define P_s to be the probability distribution that we fit from the averaged model (2.3):

$$P_s = \prod_i P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, 0; \theta_s^i,\big) = \Pr(\mathbf{R}_s = \mathbf{r}_s \,|\, \mathbf{X} = \mathbf{x}). \tag{3.5}$$

We then define the derivatives P_s just as we did for $\bar{P}_s$:

$$\frac{\partial P_s}{\partial r^{\tilde{\imath}}_{\tilde{s}}} = \frac{\partial}{\partial r^{\tilde{\imath}}_{\tilde{s}}} \left(\prod_i P_s \left(r^i_s, \mathbf{r}^{<i}_s, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath} < i} \bar{W}^{\acute{\imath},i}_{\acute{s},s} r^{\acute{\imath}}_{\acute{s}}; \theta^i_s \right) \right) \Bigg|_{\{r^{\acute{\imath}}_{\acute{s}}=0 | \acute{s} \neq s\}} \tag{3.6}$$

and analogously for the second derivatives. We also define the expected values:

$$E_0(g(\mathbf{R})) = \sum_{\mathbf{r}} g(\mathbf{r}) \prod_s P_s, \tag{3.7a}$$

$$E_0 \left(\frac{\partial R^i_s}{\partial R^{\tilde{\imath}}_{\tilde{s}}} \right) = \frac{\partial}{\partial r^{\tilde{\imath}}_{\tilde{s}}} E(R^i_s | \mathbf{R}^{<i} = \mathbf{r}^{<i}) \Bigg|_{\{\mathbf{r}_{\acute{s}}=\mathbf{0} | \acute{s} \neq s\}} = \sum_{\mathbf{r}_s} r^i_s \frac{\partial P_s}{\partial r^{\tilde{\imath}}_{\tilde{s}}}. \tag{3.7b}$$

These expected values are analogous to the barred versions given in Appendix A.1 ((A.2) and (A.4)) except that they are based on the averaged model (2.3). We assume that the chosen model and fitting algorithm for θ^i_s results in the averaged model (2.3) being a good approximation. Then (3.7a) does indeed represent the expected value of any function for the activity. For example, $E_0(R^i_s)$ is the expected value of the activity of node s at time i. We will also use the statistic $E_0(R^{i_1}_s R^{i_2}_s) - E_0(R^{i_1}_s) E_0(R^{i_2}_s)$, which represents the covariance of the activity of node s at the times i_1 and i_2.

The derivative of (3.7b) represents how the average activity of node s at time i changes with the activity of node $\tilde{s}$ at time $\tilde{\imath}$. (Since we assume causal connections, this is nonzero only if $\tilde{\imath} < i$.) See Appendix A.1 for further discussion on the properties of such derivatives.

Although we know the effective parameters only for measured nodes, we can still define the (unknown) effective parameters for hidden nodes using the averaged model (2.3). Using effective parameters for all nodes will simplify the form of our equation for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$.

It turns out that we have already done much of the work toward deriving an equation for effective parameters in step one, above. In that first step, we derived an expression for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$, which is the marginal distribution (of the full distribution $\Pr(\mathbf{R}|\mathbf{X})$ given by model (2.2)) for the activity of a set of measured nodes. The averaged model (2.3) is based on $\Pr(\mathbf{R}_s|\mathbf{X})$, which we can regard as the marginal distribution for the activity of a single node. If we replace the set $\mathcal{Q}$ of measured nodes in (A.5) with just the single node s, then (A.5) becomes the marginal distribution for the activity of a single node. In this way, we obtain an expression for $\Pr(\mathbf{R}_s|\mathbf{X})$ in terms of the original model parameters. Given the definition (2.3) of the effective parameters, we have obtained an expression for the effective parameters θ in terms of the original model parameters $\bar{\theta}$.

However, we need to go the other direction: to transform expressions involving the original model parameters $\bar{\theta}$ in terms of the effective parameters θ. Using the procedure outlined in Appendix A.2, we can solve for the original uncoupled probability $\bar{P}_s$ (which is a function of the $\bar{\theta}^i_s$) in terms of the effective probability P_s (which is a function of the θ^i_s). We obtain the following relationship:

$$\begin{aligned} \bar{P}_s = P_s &- \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}) \\ &- \frac{1}{2} \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1} \partial r^{\tilde{\imath}_2}_{\tilde{s}_1}} [E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1} R^{\tilde{\imath}_2}_{\tilde{s}_1}) - E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}) E_0(R^{\tilde{\imath}_2}_{\tilde{s}_1})] \end{aligned}$$

$$\begin{aligned}
&-\sum_{\substack{\tilde{s}_1\\ \tilde{s}_1\neq s}}\sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_2<\tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} E_0\left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{s}_1}}{\partial R^{\tilde{\imath}_2}_s}\right)[r^{\tilde{\imath}_2}_s - E_0(R^{\tilde{\imath}_2}_s)]\\
&+\frac{1}{2}\sum_{\substack{\tilde{s}_1,\tilde{s}_2\\ \tilde{s}_1\neq s,\tilde{s}_2\neq s}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}\partial r^{\tilde{\imath}_2}_{\tilde{s}_2}} E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{s}_2}) + O(\bar{W}^3). \qquad (3.8)
\end{aligned}$$

Each term on the right-hand side of (3.8) has a significant meaning and illustrates the process of approximating a full network (2.2) by an averaged model (2.3). The sum on the first line is simply the change in the probability distribution of node s caused by the average effect of connections from other nodes $\tilde{s}_1$. Intuitively, this change is the average activity of node $\tilde{s}_1$ times the effect of node $\tilde{s}_1$ on the probability distribution of node s (i.e., the derivative of P_s). Since the effective distribution P_s includes the average influence of connections from other nodes, this term must be subtracted from P_s to regain the original uncoupled distribution $\bar{P}_s$.

The term from the second line accounts for second-order effects from a connection from node $\tilde{s}_1$. First consider the case where $\tilde{\imath}_1 = \tilde{\imath}_2$. Now imagine that the effect of the connection from node $\tilde{s}_1$ onto node s lasts multiple time steps.[2] Then the connection from node $\tilde{s}_1$ will introduce correlations in the activity of node s. (Recall how common input from a node onto two different nodes can introduce correlations between those two nodes. The effect of the second line of (3.8) is identical except that in this case we have "common input" onto the same node but at different times, which creates correlations within that one node's activity.) This correlation will be proportional to the variance of $R^{\tilde{\imath}_1}_{\tilde{s}_1}$.

The case with $\tilde{\imath}_1 \neq \tilde{\imath}_2$ is similar. If $R^{\tilde{\imath}_1}_{\tilde{s}_1}$ is correlated with $R^{\tilde{\imath}_2}_{\tilde{s}_1}$ (due to the history dependence of the activity of node $\tilde{s}_1$), then the combined effect of the activity of node $\tilde{s}_1$ at times $\tilde{\imath}_1$ and $\tilde{\imath}_2$ will induce correlations in the activity of node s. This correlation will be proportional to the covariance of $R^{\tilde{\imath}_1}_{\tilde{s}_1}$ and $R^{\tilde{\imath}_2}_{\tilde{s}_1}$.

The reason this source of correlation must be subtracted from P_s in the second line of (3.8) is as follows. When fitting the averaged model (2.3) for node s, one is averaging over the activity of all other nodes, including node $\tilde{s}_1$. The induced correlations due to the connection from node $\tilde{s}_1$ will still be present in the activity of node s. Hence, the averaged model P_s (and its parameters θ_s) will take into account this additional correlation, and the additional correlation will appear in the averaged model as part of the history dependence of node s. However, the original uncoupled model represented by $\bar{P}_s$ (and its parameters $\bar{\theta}_s$) will not include effects due to coupling from other nodes. This history dependence of $\bar{P}_s$ would not include these additional correlations due to the connection from node $\tilde{s}_1$. Hence, the effect of these correlations must be subtracted from the effective distribution P_s to regain the original distribution $\bar{P}_s$, as is done in the second line of (3.8).

The term from the third line of (3.8) is similar in that it accounts for additional correlations in the activity of node s due to connections involving other nodes. In this case, the correlations are induced by indirect connections from node s onto itself via one of the other nodes $\tilde{s}_1$. This effect has three components as shown by the three factors. The right factor is the deviation of the activity of node s at time $\tilde{\imath}_2$

[2] Since P_s, as defined in (3.5), models the activity of node s for all time steps, the derivative $\partial^2 P_s/(\partial r^{\tilde{\imath}_1}_{\tilde{s}_1})^2$ includes the effects of $R^{\tilde{\imath}_1}_{\tilde{s}_1}$ on the activity of node s at all times. In particular, this derivative captures how the activity of node $\tilde{s}_1$ at a single time point $\tilde{\imath}_1$ can influence the activity of node s at two different times, thus causing correlations in the activity of node s at those two times.

from its expected activity as predicted by the averaged model (2.3). The middle factor is the effect of the activity of node s at time $\tilde{\imath}_2$ on the activity of node $\tilde{s}_1$ at time $\tilde{\imath}_1$. The left factor is the effect of the activity of node $\tilde{s}_1$ at time $\tilde{\imath}_1$ on the probability distribution of node s. The resulting correlation in the activity of node s from this chain of connection would be included in the history dependence of the effective distribution P_s. But, since these correlations depend on connections, their effect would not be included in the original uncoupled distribution $\bar{P}_s$. Hence, their effect must be subtracted from P_s to regain the original distribution $\bar{P}_s$.

The sum from the last line of (3.8) is simply a second-order effect of single connections onto node s. Equation (3.8) is accurate up to second order in $\bar{W}$. The sum of the first line is only a first-order approximation of the change in P_s due to the average effect of connections from other nodes. The addition of the last line gives the correct second-order approximation.

3.3. Step three: Measured node distribution in terms of effective parameters.

Our third step is to derive an expression for the probability distribution $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ of the measured node activity in terms of the effective parameters θ_s^i. Once we have written down an initial form of this distribution, we can simplify it by grouping the effects of hidden nodes into two sets of parameters: an effective causal connection W and an effective common input U. Then, by making one further assumption, we can sufficiently reduce the degrees of freedom within W and U so that computing their solution becomes tractable.

3.3.1. The initial form of the measured node probability distribution.

In the first step of our analysis, we obtained a lengthy expression for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$, the probability distribution of the measured node activity. (It is given by (A.5) in Appendix A.1.) However, this expression is in terms of the original model parameters $\bar{\theta}_s^i$ which remain unknown. As outlined in Appendix A.3, we rewrite this expression in terms of the effective parameters. Appendix A.4 describes how we transform the result into the form of a true probability (which we need since we wish to use it to develop maximum likelihood estimates of network parameters). We show in Appendix A.4 that this step requires one small deviation from a true second-order approximation, so we will use the $\approx$ symbol in our result. We also use the shorthand notation[3]

$$\begin{aligned} P_s^i &= P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, 0; \theta_s^i\big), \\ \frac{\partial P_s^i}{\partial w} &= \frac{\partial}{\partial w} P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i\big)\Big|_{w=0}. \end{aligned} \tag{3.9}$$

In the end, we obtain the following expression for the probability distribution of the measured nodes' activity:

$$\Pr(\mathbf{R}_\mathcal{Q} = \mathbf{r}_\mathcal{Q}|\mathbf{X} = \mathbf{x}) \approx \prod_q \prod_i P_q\big(r_q^i, \mathbf{r}_q^{<i}, \mathbf{x}, \widetilde{W}_q^i; \theta_q^i\big) + O(\bar{W}^3), \tag{3.10a}$$

[3] Note the subtle difference between the new notation P_s^i and $\partial P_s^i/\partial w$ (defined by (3.9)) on one hand and the similar notation P_s and $\partial P_s/\partial r_{\tilde{s}}^{\tilde{\imath}}$ (defined by (3.5) and (3.6)) on the other hand. One key difference is that the new notation contains a superscript i, which means it refers to the distribution of the activity of node s just at time point i.

where

$$
\begin{aligned}
\widetilde{W}_q^i = {} & \sum_{\substack{\tilde q\\ \tilde q\neq q}} \sum_{\substack{\tilde\imath_1\\ \tilde\imath_1<i}} \bar W^{\tilde\imath_1,i}_{\tilde q,q}[r^{\tilde\imath_1}_{\tilde q} - E_0(R^{\tilde\imath_1}_{\tilde q})] \\
& + \sum_{\substack{p,\tilde q\\ \tilde q\neq q}} \sum_{\substack{\tilde\imath_1,\tilde\imath_2\\ \tilde\imath_2<\tilde\imath_1<i}} \bar W^{\tilde\imath_1,i}_{p,q} E_0\left(\frac{\partial R_p^{\tilde\imath_1}}{\partial R_{\tilde q}^{\tilde\imath_2}}\right)[r_{\tilde q}^{\tilde\imath_2} - E_0(R_{\tilde q}^{\tilde\imath_2})] \\
& + \sum_{\substack{p,\tilde q\\ \tilde q\neq q}} \sum_{\substack{\tilde\imath_1,\tilde\imath_2,\tilde\imath_3\\ \tilde\imath_2<\tilde\imath_3<i\\ \tilde\imath_1<i}} \bar W^{\tilde\imath_1,i}_{p,q}\bar W^{\tilde\imath_2,\tilde\imath_3}_{p,\tilde q} \frac{\partial P^{\tilde\imath_3}_{\tilde q}}{\partial w}\frac{1}{P^{\tilde\imath_3}_{\tilde q}}[E_0(R_p^{\tilde\imath_1}R_p^{\tilde\imath_2}) - E_0(R_p^{\tilde\imath_1})E_0(R_p^{\tilde\imath_2})] \\
& + \sum_{\substack{p,\tilde q\\ \tilde q<q}} \sum_{\substack{\tilde\imath_1,\tilde\imath_2\\ \tilde\imath_1,\tilde\imath_2<i}} \bar W^{\tilde\imath_1,i}_{p,q}\bar W^{\tilde\imath_2,i}_{p,\tilde q} \frac{\partial P^{i}_{\tilde q}}{\partial w}\frac{1}{P^{i}_{\tilde q}}[E_0(R_p^{\tilde\imath_1}R_p^{\tilde\imath_2}) - E_0(R_p^{\tilde\imath_1})E_0(R_p^{\tilde\imath_2})] \\
& - \sum_{\substack{\tilde q\\ \tilde q\neq q}} \sum_{\substack{\tilde\imath_1,\tilde\imath_2,\tilde\imath_3\\ \tilde\imath_2<\tilde\imath_3<i\\ \tilde\imath_1<i}} \bar W^{\tilde\imath_1,i}_{\tilde q,q}\bar W^{\tilde\imath_2,\tilde\imath_3}_{\tilde q,q} \frac{\partial P^{\tilde\imath_3}_{q}}{\partial w}\frac{1}{P^{\tilde\imath_3}_{q}}[E_0(R_{\tilde q}^{\tilde\imath_1}R_{\tilde q}^{\tilde\imath_2}) - E_0(R_{\tilde q}^{\tilde\imath_1})E_0(R_{\tilde q}^{\tilde\imath_2})] \\
& - \sum_{\substack{\tilde q\\ \tilde q\neq q}} \sum_{\substack{\tilde\imath_1,\tilde\imath_2\\ \tilde\imath_2<\tilde\imath_1<i}} \bar W^{\tilde\imath_1,i}_{\tilde q,q} E_0\left(\frac{\partial R_{\tilde q}^{\tilde\imath_1}}{\partial R_{q}^{\tilde\imath_2}}\right)[r_{q}^{\tilde\imath_2} - E_0(R_{q}^{\tilde\imath_2})]. \qquad \text{(3.10b)}
\end{aligned}
$$

Though this expression is somewhat lengthy, each line of (3.10b) represents the effect of a connection or combination of connections on the probability distribution of the measured nodes' activity. Just as we did for the single-node results (3.8), we briefly describe the effects of the connections as embedded in (3.10).

The sum from the first line of (3.10b) represents a direct causal connection from measured node $\tilde q$ onto measured node q. The second line represents an indirect causal connection from measured node $\tilde q$ onto measured node q via a hidden node p. Both lines describe a change in the distribution of the activity of node q due to a deviation in the activity of node $\tilde q$ from that predicted by the averaged model.

The third and fourth lines are the common input onto measured nodes q and $\tilde q$ from a hidden node p. The common input effect is proportional to the (unknown) (co)variance of the activity of node p (compare to the second line of (3.8)). We separated out the common input that reaches nodes q and $\tilde q$ simultaneously (fourth line of (3.10b)). We arbitrarily put this common input effect into the $\widetilde{W}_q$ of the node with the higher index (as we restrict the sum to $\tilde q < q$). The goal of this analysis will be to distinguish the common input from the third line from the causal connections of the first two lines. (We will assume any correlations at zero delay are due to the common input described on the fourth line.)

The fifth and sixth lines of (3.10b) involve only measured nodes. These lines are similar to the second and third lines of (3.8), and their presence in (3.10) has a similar origin. When the effective parameters of node q were determined, the activity of node $\tilde q$ was ignored. Nonetheless, connections from node $\tilde q$ onto node q still influenced the activity of node q. As we described in the context of (3.8), the activity of node $\tilde q$ could induce correlations in the activity of node q if it had connections onto node q that lasted multiple time steps. Similarly, node $\tilde q$ could induce correlations in node q via an indirect connection from node q onto itself through node $\tilde q$.

If the network contains such a pattern of connections, the effective distribution P_q of node q would already contain such correlations as part of the history dependence of the model. Hence, the probability distribution of $R_{\mathcal{Q}}$ in (3.10) would contain these correlations in the activity of node q even if all $\bar{W}$ were zero. However, these correlations in the activity of node q were caused by connections (i.e., nozero $\bar{W}$) between node q and $\tilde{q}$, as described above. When these individual connections are added to (3.10) via the direct causal connections of the first line of (3.10b), the resulting correlations in the activity of node q will have been added to (3.10) twice. To correct for this, we need to explicitly subtract them off via the fifth and sixth lines of (3.10b).

3.3.2. Grouping the effects of hidden nodes. Once the effective parameters θ_q^i have been determined for all measured nodes q, the only unknowns in (3.10) are the connectivity factor $\bar{W}$ and all expressions involving hidden nodes p. We group these unknowns into two expressions:

$$\begin{aligned} W^{i_2,i_1}_{q_2,q_1} &= \bar{W}^{i_2,i_1}_{q_2,q_1} + \sum_{p} \sum_{\substack{\tilde{i} \\ i_1>\tilde{i}>i_2}} \bar{W}^{\tilde{i},i_1}_{p,q_1} E_0\left(\frac{\partial R_p^{\tilde{i}}}{\partial R_{q_2}^{i_2}}\right), \\ U^{i_2,i_1}_{q_2,q_1} &= \sum_{p} \sum_{\substack{\tilde{i}_1,\tilde{i}_2 \\ \tilde{i}_1<i_1,\tilde{i}_2<i_2}} \bar{W}^{\tilde{i}_1,i_1}_{p,q_1} \bar{W}^{\tilde{i}_2,i_2}_{p,q_2} [E_0(R_p^{\tilde{i}_1} R_p^{\tilde{i}_2}) - E_0(R_p^{\tilde{i}_1}) E_0(R_p^{\tilde{i}_2})], \end{aligned} \tag{3.11}$$

defined for $q_2 \neq q_1$. The causal connection factor $W^{i_2,i_1}_{q_2,q_1}$ is the effective causal connection from node q_2 onto node q_1. It includes an indirect causal connection via a hidden node p. The direct and indirect causal connections are lumped together as we cannot distinguish between them. The common input factor $U^{i_2,i_1}_{q_2,q_1}$ is the effective common input from hidden nodes that arrives at node q_2 at time i_2 and at node q_1 and time i_1. Both $W^{i_2,i_1}_{q_2,q_1}$ and $U^{i_2,i_1}_{q_2,q_1}$ include sums over arbitrary hidden nodes. Although we cannot resolve the individual contributions of the hidden nodes, we will be able to solve for these effective parameters.

We also rewrite the expression for the expected value of the derivative to pull out the hidden factor of $\bar{W}$ contained in it. From the definition (3.7) as well as the definitions of the derivatives (3.6) and (3.9), we write[4]

$$\begin{aligned} E_0\left(\frac{\partial R_s^i}{\partial R_{\tilde{s}}^{\tilde{i}}}\right) &= \sum_{\mathbf{r}_s} r_s^i \frac{\partial P_s}{\partial r_{\tilde{s}}^{\tilde{i}}} = \sum_{\mathbf{r}_s} r_s^i \sum_{\substack{i_2 \\ \tilde{i}<i_2\leq i}} \bar{W}^{\tilde{i},i_2}_{\tilde{s},s} \frac{\partial P_s^{i_2}}{\partial w} \frac{1}{P_s^{i_2}} \prod_{i_3} P_s^{i_3} \\ &= \sum_{\substack{i_2 \\ \tilde{i}<i_2\leq i}} \bar{W}^{\tilde{i},i_2}_{\tilde{s},s} E_0\left(R_s^i \frac{\partial P_s^{i_2}}{\partial w} \frac{1}{P_s^{i_2}}\right). \end{aligned} \tag{3.12}$$

With these definitions of W and U, $\widetilde{W}_q^i$ becomes

$$\begin{aligned} \widetilde{W}_q^i = {} & \sum_{\substack{\tilde{q} \\ \tilde{q}\neq q}} \sum_{\substack{\tilde{i} \\ \tilde{i}<i}} W^{\tilde{i},i}_{\tilde{q},q} [r_{\tilde{q}}^{\tilde{i}} - E_0(R_{\tilde{q}}^{\tilde{i}})] \\ & + \sum_{\substack{\tilde{q} \\ \tilde{q}\neq q}} \sum_{\substack{\tilde{i} \\ \tilde{i}<i}} U^{\tilde{i},i}_{\tilde{q},q} \frac{\partial P_{\tilde{q}}^{\tilde{i}}}{\partial w} \frac{1}{P_{\tilde{q}}^{\tilde{i}}} + \sum_{\substack{\tilde{q} \\ \tilde{q}<q}} U^{i,i}_{\tilde{q},q} \frac{\partial P_{\tilde{q}}^{i}}{\partial w} \frac{1}{P_{\tilde{q}}^{i}} \end{aligned}$$

[4] One subtlety in (3.12) is the fact that we restrict $i_2 \leq i$. If $i_2 > i$, then the term disappears due to a similar argument as underlying the identities in (A.3).

$$-\sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}}\sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2,\tilde{\imath}_3\\ \tilde{\imath}_2<\tilde{\imath}_3<i\\ \tilde{\imath}_1<i}} W_{\tilde{q},q}^{\tilde{\imath}_1,i}W_{\tilde{q},q}^{\tilde{\imath}_2,\tilde{\imath}_3}\frac{\partial P_q^{\tilde{\imath}_3}}{\partial w}\ \frac{1}{P_q^{\tilde{\imath}_3}}[E_0(R_{\tilde{q}}^{\tilde{\imath}_1}R_{\tilde{q}}^{\tilde{\imath}_2})-E_0(R_{\tilde{q}}^{\tilde{\imath}_1})E_0(R_{\tilde{q}}^{\tilde{\imath}_2})]$$

$$-\sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}}\sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2,\tilde{\imath}_3\\ \tilde{\imath}_2<\tilde{\imath}_3\leq\tilde{\imath}_1<i}} W_{q,\tilde{q}}^{\tilde{\imath}_2,\tilde{\imath}_3}W_{\tilde{q},q}^{\tilde{\imath}_1,i}E_0\left(R_{\tilde{q}}^{\tilde{\imath}_1}\frac{\partial P_{\tilde{q}}^{\tilde{\imath}_3}}{\partial w}\frac{1}{P_{\tilde{q}}^{\tilde{\imath}_3}}\right)[r_q^{\tilde{\imath}_2}-E_0(R_q^{\tilde{\imath}_2})]. \tag{3.13}$$

Note that, according to (3.12), the quantity $E_0\big(\partial R_{\tilde{s}}^{\tilde{\imath}}/\partial R_s^i\big)$ is $O(\bar{W})$. Hence, the definition (3.11) of W shows that W is a first-order approximation to $\bar{W}$ (i.e., $W_{\tilde{q},q}^{\tilde{\imath},i} = \bar{W}_{\tilde{q},q}^{\tilde{\imath},i}+O(\bar{W}^2)$). This means that, in terms that are quadratic in $\bar{W}$, we can replace $\bar{W}$ with W and still maintain our second-order approximation (as the error is cubic in $\bar{W}$). This allowed us to write (3.13) in terms of just the effective W.

Our expression for the probability distribution $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ of the measured activity is now (3.10a) combined with (3.13). Given the effective parameters θ_q^i, we can calculate the P_q^i and the $\partial P_q^i/\partial w$ via (3.9). We can also calculate, in principle, all of the expressions involving $E_0(\cdot)$ using the definitions in (3.7). (We estimate these via Monte Carlo simulations, as described in Appendix C.) Therefore, the only remaining unknown factors are the causal connection factors W and the common input factors U.

3.3.3. A further assumption for a tractable solution. Our goal is to estimate W and U by finding their values that maximize our approximation of the probability distribution of measured activity. In other words, we seek maximum likelihood estimators of W and U. However, there are still too many unknowns to make the solution tractable, as we still have more unknowns than we would have data points (we have only one measurement of activity per measured node per time point).[5] To reduce the number of unknowns, we assume that W and U depend only on the difference between their temporal indicies, i.e.,

$$W_{q_1,q_2}^{i-j,i}=W_{q_1,q_2}^{j} \qquad \text{and} \qquad U_{q_1,q_2}^{i-j,i}=U_{q_1,q_2}^{j}. \tag{3.14}$$

(One could presumably weaken this assumption by allowing W and U to change slowly over time at the cost of additional computational complexity and increased data requirements.)

This assumption for W has no hidden surprises, as it is equivalent to assuming that the underlying connectivity $\bar{W}$ depends only on the difference in temporal indicies.[6] However, this assumption for U is more significant than may appear at first glance. It turns out that this assumption is really about the hidden nodes and affects how one can interpret the meaning of W and U.

To demonstrate this, we rewrite the definition of U from (3.11) using the index j to indicate the difference between temporal indices:

$$U_{q_2,q_1}^{i_1-j_1,i_1} = \sum_{p}\sum_{\substack{j_2,j_3\\ j_2>0,j_3>0}} \bar{W}_{p,q_1}^{i_1-j_2,i_1}\bar{W}_{p,q_2}^{i_1-j_1-j_3,i_1-j_1}[E_0(R_p^{i_1-j_2}R_p^{i_1-j_1-j_3})-E_0(R_p^{i_1-j_2})E_0(R_p^{i_1-j_1-j_3})].$$

[5] Perhaps one could solve for W and U in full generality if one could repeatedly sample from a small number of time bins and one assumed that the $\bar{W}$ could vary over the time bins but were identical for each repetition.

[6] The effect of the connectivity, however, could vary with time, as each $P_s(\cdot)$ could change with time.

Our assumption on $U_{q_2,q_1}^{i_1-j_1,i_1}$ is that it is independent of i_1. If the $\bar{W}$ depend only on the difference in temporal indices, the only place on the right-hand side where i_1 doesn't immediately drop out is in the (co)variance of activity of the hidden node p. Hence, by insisting that $U_{q_2,q_1}^{i_1-j_1,i_1}$ be independent of i_1, we are really approximating the covariance of each hidden node p as though it were independent of time bin i_1. Equivalently, we could view this approximation as replacing the covariance of node p with its average over all time bins i_1.

As detailed in [14], such an approximation leads to a certain degree of ambiguity in the identification of causal connections, which we refer to as *subpopulation ambiguity.* This ambiguity contains subtleties that are out of the scope of this article and are discussed extensively in [14]. We illustrate the basic consequences of the ambiguity with simulation results (see section 4.4). Note also that, as described in [14], this ambiguity is already present in many experimental contexts (such as those commonly used in neuroscience); hence, in those contexts, this approximation does not add additional ambiguity.

Putting this all together, our procedure to construct the causal connections among measured nodes is as follows. For each measured node indexed by $q \in \mathcal{Q}$, determine the effective parameters θ_q^i by fitting the averaged model (2.3) to the external variables $\mathbf{X}$ and the activity R_q^i of node q. (We assume such an algorithm for determining the θ_q^i is known.) Then determine the effective causal connections W_{q_1,q_2}^j and the effective common input U_{q_1,q_2}^j from the external variables and the activity $\mathbf{R}_\mathcal{Q}$ of all measured nodes by finding the values of W_{q_1,q_2}^j and U_{q_1,q_2}^j that maximize the log-likelihood modeled by the equation

$$\log \Pr(\mathbf{R}_\mathcal{Q} = \mathbf{r}_\mathcal{Q} | \mathbf{X} = \mathbf{x}) = \sum_q \sum_i \log P_q\big(r_q^i, \mathbf{r}_q^{<i}, \mathbf{x}, \widetilde{W}_q^i; \theta_q^i\big), \tag{3.15a}$$

where

$$\begin{aligned}\widetilde{W}_q^i = &\sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}} \sum_{\substack{j\\ j>0}} W_{\tilde{q},q}^j [r_{\tilde{q}}^{i-j} - E_0(R_{\tilde{q}}^{i-j})] \\ &+ \sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}} \sum_{\substack{j\\ j>0}} U_{\tilde{q},q}^j \frac{\partial P_{\tilde{q}}^{i-j}}{\partial w} \frac{1}{P_{\tilde{q}}^{i-j}} + \sum_{\substack{\tilde{q}\\ \tilde{q}<q}} U_{\tilde{q},q}^0 \frac{\partial P_{\tilde{q}}^i}{\partial w} \frac{1}{P_{\tilde{q}}^i} \\ &- \sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}} \sum_{\substack{j_1,j_2,j_3\\ j_1,j_2,j_3>0}} W_{\tilde{q},q}^{j_1} W_{\tilde{q},q}^{j_2} \frac{\partial P_q^{i-j_3}}{\partial w} \frac{1}{P_q^{i-j_3}} [E_0(R_{\tilde{q}}^{i-j_1} R_{\tilde{q}}^{i-j_3-j_2}) - E_0(R_{\tilde{q}}^{i-j_1}) E_0(R_{\tilde{q}}^{i-j_3-j_2})] \\ &- \sum_{\substack{\tilde{q}\\ \tilde{q}\neq q}} \sum_{\substack{j_1,j_2,j_3\\ j_1,j_2>0\\ j_3\geq 0}} W_{q,\tilde{q}}^{j_2} W_{\tilde{q},q}^{j_1} E_0\bigg(R_{\tilde{q}}^{i-j_1} \frac{\partial P_{\tilde{q}}^{i-j_1-j_3}}{\partial w} \frac{1}{P_{\tilde{q}}^{i-j_1-j_3}}\bigg) [r_q^{i-j_1-j_3-j_2} - E_0(x R_q^{i-j_1-j_3-j_2})].\end{aligned} \tag{3.15b}$$

Unfortunately, especially with the terms that are quadratic in W, one cannot be certain that the log-likelihood is free of nonglobal local maxima. So, in general, one needs to be aware that one could get trapped in such a local maximum in the process of looking for the global maximum. The likelihood surface may be better behaved if one ignores the quadratic terms (the final two terms in (3.15b)). We next present an example probability distribution P_s where the likelihood surface has no nonglobal local maxima in the absence of the quadratic terms. We use that fact to find a local maximum of the full log-likelihood that, at least in our tests, gives good results.

3.4. Special case: A Poisson distribution. We present a special case of the results when the activity of each node at each time step is drawn from a Poisson distribution. We use such a distribution because, for small time bins, the averaged model approximates a generic history-dependent point process [4, 5], which one can use to model the spike times of a neuron. Moreover, the results with the Poisson distribution illustrate how history dependence can distinguish common input from causal connections, as discussed below. We use the Poisson model when we demonstrate the results via simulations.

Since we assume that R^i_s, the activity of node s at time bin i, is a Poisson random variable, we simply need to specify its mean. We can write the probability distribution of R^i_s as

$$P_s(r^i_s, \mathbf{r}^{<i}_s, \mathbf{x}, w; \theta^i_s) = \Gamma(r^i_s, \lambda_s(\mathbf{r}^{<i}_s, \mathbf{x}, w; \theta^i_s)), \tag{3.16a}$$

where

$$\Gamma(n, \lambda) = \frac{1}{n!}\lambda^n e^{-\lambda}. \tag{3.16b}$$

The function $\lambda_s(\mathbf{r}^{<i}_s, \mathbf{x}, w; \theta^i_s)$ defines how the expected value of R^i_s depends on the history $\mathbf{r}^{<i}_s$ of node s, the external variables $\mathbf{x}$, and the total input w from other neurons. We rewrite the log-likelihood (3.15) as

$$\log \Pr(\mathbf{R}_\mathcal{Q} = \mathbf{r}_\mathcal{Q} | \mathbf{X} = \mathbf{x}) = \sum_{q,i} r^i_q \log \lambda_q(\mathbf{r}^{<i}_q, \mathbf{x}, \widetilde{W}^i_q; \theta^i_q) - \sum_{q,i} \lambda_q(\mathbf{r}^{<i}_q, \mathbf{x}, \widetilde{W}^i_q; \theta^i_q) + C, \tag{3.17a}$$

where

$$\begin{aligned}\widetilde{W}^i_q = {} & \sum_{\substack{\tilde{q} \\ \tilde{q} \neq q}} \sum_{\substack{j \\ j>0}} W^j_{\tilde{q},q}[r^{i-j}_{\tilde{q}} - E_0(\lambda_{\tilde{q}}(\mathbf{R}^{<i-j}_{\tilde{q}}, \mathbf{x}, 0; \theta^{i-j}_{\tilde{q}}))] \\ & + \sum_{\substack{\tilde{q} \\ \tilde{q} \neq q}} \sum_{\substack{j \\ j>0}} U^j_{\tilde{q},q}[r^{i-j}_{\tilde{q}} - \lambda_{\tilde{q}}(\mathbf{r}^{<i-j}_{\tilde{q}}, \mathbf{x}, 0; \theta^{i-j}_{\tilde{q}})] \frac{\partial_w \lambda_{\tilde{q}}(\mathbf{r}^{<i-j}_{\tilde{q}}, \mathbf{x}, 0; \theta^{i-j}_{\tilde{q}})}{\lambda_{\tilde{q}}(\mathbf{r}^{<i-j}_{\tilde{q}}, \mathbf{x}, 0; \theta^{i-j}_{\tilde{q}})} \\ & + \sum_{\substack{\tilde{q} \\ \tilde{q} < q}} U^0_{\tilde{q},q}[r^i_{\tilde{q}} - \lambda_{\tilde{q}}(\mathbf{r}^{<i}_{\tilde{q}}, \mathbf{x}, 0; \theta^i_{\tilde{q}})] \frac{\partial_w \lambda_{\tilde{q}}(\mathbf{r}^{<i}_{\tilde{q}}, \mathbf{x}, 0; \theta^i_{\tilde{q}})}{\lambda_{\tilde{q}}(\mathbf{r}^{<i}_{\tilde{q}}, \mathbf{x}, 0; \theta^i_{\tilde{q}})} \\ & + \text{quadratic terms.}\end{aligned} \tag{3.17b}$$

The constant $C = -\sum_{q,i} \log((r^i_q)!)$ can be ignored since we simply want to maximize (3.17) over W and U with everything else fixed. We use the notation $\partial_w \lambda_{\tilde{q}}(\mathbf{r}^{<i-j}_{\tilde{q}}, \mathbf{x}, w; \theta^{i-j}_{\tilde{q}})$ for the partial derivative of $\lambda_{\tilde{q}}(\cdot)$ with respect to w.

The quadratic terms are the last two lines of (3.15b); we gain no insight by rewriting them in terms of the Poisson distribution. As detailed in section 3.3.1, they are needed to have a correct second-order expression. However, they don't directly contribute to the distinction between causal connections and common input.

3.4.1. Different effects of causal connections and common input. From (3.17), we see two important differences in the way that the causal connections W and the common input U affect the probability distribution $\Pr(R_{\mathcal{Q}}|\mathbf{X})$ of the measured node activity. Our ability to successfully distinguish causal connections from common input connections is based on these two differences.

The first difference is that the common input terms have an additional $\partial_w \lambda_{\tilde{q}}/\lambda_{\tilde{q}}$ factor. In previous work [14], this factor was the only difference that appeared because the analysis did not exploit history-dependent effects. As detailed in [14], this difference alone can distinguish causal connections from common input in many cases. Even if one did not model history-dependent effects, the relationship among external variables (such as a stimulus) and the activity of measured nodes would distinguish common input from causal connection, and this difference is captured by the $\partial_w \lambda_{\tilde{q}}/\lambda_{\tilde{q}}$ factor.

The second difference in the way W and U appear in (3.17) is due to the history-dependent effects. This second difference is the focus of this paper. It turns out that this difference is exactly what we observed in the exaggerated example presented in the introduction and illustrated in Figure 2. For both the causal connection W term and the common input U term of (3.17b), a certain quantity is subtracted from the activity $r_{\tilde{q}}^{i-j}$. The difference between these quantities can distinguish a causal connection from common input. In what follows, we will show that the key difference is that the activity predicted by a node's history dependence is subtracted only from the common input term.

Equation (3.17) shows that a causal connection from node $\tilde{q}$ onto node q induces a change in the probability distribution of node q proportional to the deviation of the activity of node $\tilde{q}$ from that predicted by the averaged model (2.3). That is, in the causal connection term (first line of (3.17b)), a contribution is added to $\widetilde{W}_q^i$ when the measured activity of node $\tilde{q}$ (i.e., $r_{\tilde{q}}^{i-j}$) differs from its expected value $E_0(R_{\tilde{q}}^{i-j}) = E_0(\lambda_{\tilde{q}}(\mathbf{R}_{\tilde{q}}^{<i-j}, \mathbf{x}, 0; \theta_{\tilde{q}}^{i-j}))$ given by the averaged model.

An important point is that, once the effective parameters ($\theta_{\tilde{q}}^{\tilde{\imath}}$ for all $\tilde{\imath}$) have been determined, this expected value $E_0(R_{\tilde{q}}^{i-j})$ does not depend on the actual history $\mathbf{r}_{\tilde{q}}^{<i-j}$ of node $\tilde{q}$. This expected value is an average over all possible histories of node $\tilde{q}$, given the effective parameters and the external variables.[7] For example, imagine that $R_{\tilde{q}}^i$ corresponds to the number of spikes of neuron $\tilde{q}$ in time bin i (with a sufficiently small time bin so that $R_{\tilde{q}}^i > 1$ with vanishingly small probability). Imagine, moreover, that (similar to neuron 1 in Figure 2) neuron $\tilde{q}$ tended to spike in pairs so that if it spiked in time bin $i-1$ but not in time bin $i-2$, it was very likely to spike in time bin i: $\Pr(R_{\tilde{q}}^i = 1 | R_{\tilde{q}}^{i-1} = 1 \ \& \ R_{\tilde{q}}^{i-2} = 0) \approx 1$. If one used an appropriate model, then the averaged model (2.3) would capture this tendency to fire in pairs once the parameters $\theta_{\tilde{q}}$ were fit to the spikes $\mathbf{R}_{\tilde{q}}$ of neuron $\tilde{q}$. Even so, the expected value $E_0(R_{\tilde{q}}^i)$ would not depend on the presence or absence of spikes in the previous two time bins; it is independent of the specific history of node $\tilde{q}$. Even if $r_{\tilde{q}}^{i-1} = 1$ and $r_{\tilde{q}}^{i-2} = 0$, the expected value $E_0(R_{\tilde{q}}^i)$ would not be close to one. If indeed $r_{\tilde{q}}^i = 1$, then both the spike at time bin $i-1$ and the spike at time bin i would contribute equally to the causal connection term in the first line of (3.17b).[8]

[7] We calculate this value via Monte Carlo. We repeatedly generate a realization of the activity of node $\tilde{q}$ for all time points according to the averaged model (2.3). The average activity at each time point i over many such realizations is our estimate of $E_0(R_{\tilde{q}}^i)$. See Appendix C.

[8] One would get a similar result if neuron $\tilde{q}$ had a *refractory period* where, for example, it could not spike in time i if it spiked in time bin $i-1$: $\Pr(R_{\tilde{q}}^i = 1 | R_{\tilde{q}}^{i-1} = 1) = 0$. Even if neuron $\tilde{q}$ did spike at time bin $i-1$, the presence of the refractory period would not affect $E_0(R_{\tilde{q}}^i)$.

We contrast this observation with the common input term from the second line of (3.17b). In the common input term, the activity $r_{\tilde{q}}^{i-j}$ of node $\tilde{q}$ is subtracted by the mean $\lambda_{\tilde{q}}$ of the Poisson distribution, given the specific history $\mathbf{r}_{\tilde{q}}^{<i-j}$ measured from node $\tilde{q}$. Unlike the causal connection term, this quantity is the expected value of $R_{\tilde{q}}^{i-j}$, *conditioned on the measured history* $\mathbf{r}_{\tilde{q}}^{<i-j}$: $\lambda_{\tilde{q}}(\mathbf{r}_{\tilde{q}}^{<i-j}, \mathbf{x}, 0; \theta_{\tilde{q}}^{i-j}) = E_0(R_{\tilde{q}}^{i-j} \,|\, \mathbf{R}_{\tilde{q}}^{<i-j} = \mathbf{r}_{\tilde{q}}^{<i-j})$. This is still an expected value based on the averaged model, but it is not an average over all possible histories of node $\tilde{q}$. As above, imagine that node $\tilde{q}$ was a neuron that tended to fire pairs of spikes and that one used a model that accurately captured this firing pattern. Then, if $r_{\tilde{q}}^{i-1} = 1$ and $r_{\tilde{q}}^{i-2} = 0$, the expected value $\lambda_{\tilde{q}}(\mathbf{r}_{\tilde{q}}^{<i}, \mathbf{x}, 0; \theta_{\tilde{q}}^{i})$ would be close to one because the model predicts that neuron $\tilde{q}$ should immediately fire a second spike. If indeed $r_{\tilde{q}}^{i} = 1$, this spike would have little contribution to the second line of (3.17b) as $r_{\tilde{q}}^{i} - \lambda_{\tilde{q}}(\mathbf{r}_{\tilde{q}}^{<i}, \mathbf{x}, 0; \theta_{\tilde{q}}^{i})$ would be small.

Equation (3.17) therefore demonstrates that the intuition we gain from the exaggerated example of Figure 2 is applicable to the more realistic situation we used to derive (3.17). For example, although it isn't intuitively obvious what should happen when all nodes have strong history dependence, (3.17) shows that one may estimate the connectivity even in that case, provided one has a model through which one can accurately capture the history dependence of the measured nodes.

3.4.2. Tractable computation of maximum likelihood estimators. In order to efficiently compute maximum likelihood estimators of W and U, we'd like to make sure that any local maxima of the log-likelihood (3.17) are indeed global maxima. As discussed below, if one ignores the quadratic terms in (3.17b), one can develop a condition on the form of λ_s to ensure all local maxima are global maxima. One can then use the solution to the reduced problem (without quadratic terms) to guide the search for a solution to the full problem.

If we ignore the quadratic terms from (3.17b), then $\widetilde{W}_q^i$ is linear in W and U, and the log-likelihood (3.17) has the same form of dependence on W and U as discussed in [14]. Since concavity is preserved under addition and $r_q^i \geq 0$, the log-likelihood will be concave in W and U if $\lambda_q(\mathbf{r}_q^{<i}, \mathbf{x}, w; \theta_q^i)$ is convex in w and $\log \lambda_q(\mathbf{r}_q^{<i}, \mathbf{x}, w; \theta_q^i)$ is concave in w. Reference [17] describes this condition in a more general setting and outlines the ensuing requirements on λ_q, such as the fact that λ_q must be monotonically increasing in w and must grow at least linearly in w. If the log-likelihood is concave in W and U, there can be no nonglobal local maxima.

We base our search for a maximizer of the full log-likelihood (3.17) on the maximizer for reduced log-likelihood (ignoring the quadratic terms of (3.17b)). We form a homotopy from the reduced problem to the full problem by multiplying the quadratic terms by some number $\gamma \in [0, 1]$. After maximizing the reduced log-likelihood ($\gamma = 0$), we form a series of log-likelihoods with increasing γ. For each problem, we use the maximizer of the previous problem as the initial condition. We end up with a maximizer of the full log-likelihood ($\gamma = 1$). Although we cannot guarantee that we have found a global maximizer, we have achieved good results using this algorithm in our simulation tests. (To calculate the maximizer for a given γ, we iterate to a critical point of (3.17) using a modified version of Powell's hybrid method as implemented in the GNU Scientific Library [6].)

4. Results.

4.1. Overview of simulations. To test the performance of our analysis, we simulated small networks of simplified neurons responding to a stimulus $\mathbf{X}$. Our goal is to demonstrate that we can distinguish the common input and causal connection networks schematized in Figure 1, under the condition that the common input neuron is unmeasured.

4.1.1. The stimulus. The external variables $\mathbf{X}$ represented the same one-dimensional (i.e., constant along vertical lines) visual stimulus as detailed in [14]. This stimulus was a movie of a sequence of sinusoidal gratings $\mathbf{I}^k$ with wave number k. The jth line of $\mathbf{I}^k$ was $I_j^k = \operatorname{cas}(2\pi kj/N_0)$, where $\operatorname{cas} x = \cos x + \sin x$, $N_0 = 100$, and $0 \leq j \leq N_0 - 1$. Every 10 simulated milliseconds, a new image was selected, with replacement, from the set composed of the $\mathbf{I}^k$ and $-\mathbf{I}^k$, for $k = -10, -9, \dots, 9, 10$. The movie was one simulated minute long.

4.1.2. The simulated neurons. In the simulated networks, we let each neuron be a generalized linear model (also called a linear-nonlinear model). We discretized time into $\Delta t_{\text{sim}} = 0.5$ ms time bins. In each time bin i, we let the probability that a neuron spiked be a linear function of its spiking history, the stimulus $\mathbf{X}$, and previous spikes of other neurons, composed with a half-squaring nonlinearity,

$$\begin{aligned} &\Pr(R_p^i = 1 | \mathbf{R}^{<i} = \mathbf{r}^{<i}, \mathbf{X} = \mathbf{x}) \\ &\qquad = A \Delta t_{\text{sim}} \left[\sum_{j>0} \bar{h}^j_{\text{hist},p} r_p^{i-j} + \bar{\mathbf{h}}^i_{\text{ext},p} \cdot \mathbf{x} + \sum_{q \neq p} \sum_{j>0} \bar{W}^j_{q,p} r_q^{i-j} + \bar{y}_p \right]_+^2, \end{aligned} \tag{4.1}$$

where $[y]_+^2 = y^2$ if $y > 0$ and is zero otherwise. The activity variable $R_p^i = 1$ if neuron p spiked in time bin i and $R_p^i = 0$ otherwise. We set $A = 0.01$ ms^{-1}. The value of the threshold parameters $\bar{y}_p$, coupling parameters $\bar{W}^j_{q,p}$, and other parameters that appear below are given in the context of specific simulations. If (4.1) resulted in a probability greater than one, it was truncated to one.

The linear kernel $\bar{\mathbf{h}}_{\text{hist},p}$ specified the spike-history dependence of neuron p. We included a refractory period of length τ_p^{ref} by setting $\bar{h}^j_{\text{hist},p} = -100$ for $j \Delta t_{\text{sim}} \leq \tau_p^{\text{ref}}$. (Since -100 was much larger in magnitude than other parameters in (4.1), $\Pr(R_p^i = 1)$ was zero for an interval of τ_p^{ref} after each spike.) After the refractory period, we let the history-dependent term transiently increase the probability of a spike by setting

$$\bar{h}^j_{\text{hist},p} = a_{\text{hist},p} e^{-j \Delta t_{\text{sim}} / \tau_{\text{hist},p}} \qquad \text{for } j \Delta t_{\text{sim}} > \tau_p^{\text{ref}}.$$

As our purpose is to demonstrate the effect of history dependence, we included strong history dependence in each model neuron, setting $a_{\text{hist},p}$ relatively large and positive. Hence, the history-dependence term created a tendency for spikes to occur in bursts, leading to significant peaks in autocorrelation, such as shown in Figure 3.

We used the same spatiotemporal kernels $\bar{\mathbf{h}}_{\text{ext},p}$ as in [14], retaining the convention that $\bar{\mathbf{h}}^i_{\text{ext},p}$ was the kernel $\bar{\mathbf{h}}_{\text{ext},p}$ shifted for time point i. For line $j = 0, 1, \dots, N_0$ and temporal index t, we used the form

$$\bar{h}_{\text{ext},p}(j,t) = (t - b_p) \exp\left(-\frac{t - b_p}{\tau_{\text{ext},p}} - \frac{(j-c)^2}{2\sigma_p^2} \right) \cos(2\pi f_p (j - c) + \phi_p)$$

for $t > b_p$ and $\bar{h}_{\text{ext},p}(j,t) = 0$ otherwise [10]. To center the kernels on the image, we set $c = (N_0 - 1)/2$. The vector $\bar{\mathbf{h}}_{\text{ext},p}$ corresponded to $\bar{h}_{\text{ext},p}(j, k\Delta t_{\text{sim}})$ for integer k with $k \Delta t_{\text{sim}} < 200$ ms. We normalized $\bar{\mathbf{h}}_{\text{ext},p}$ so that the standard deviation of $\bar{\mathbf{h}}^i_{\text{ext},p} \cdot \mathbf{X}$ was equal to the parameter $a_{\text{ext},p}$; hence, $a_{\text{ext},p}$ specified how strongly neuron p responded to the stimulus.

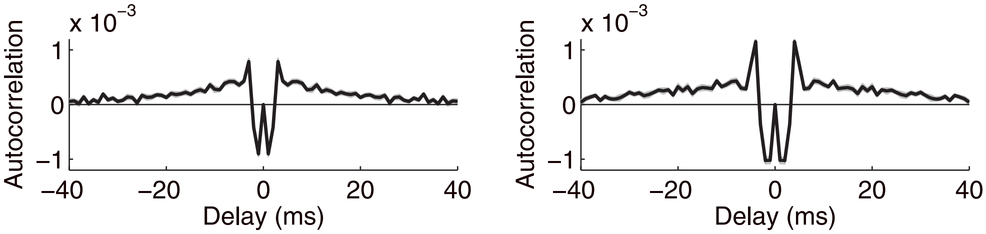

FIG. 3. *Examples of the large autocorrelations due strong history dependence included in simulated models. The autocorrelation of neuron* p *at delay* j *is* $\langle R_p^i R_p^{i-j}\rangle - \langle\langle R_p^i|\mathbf{X}\rangle\langle R_p^{i-j}|\mathbf{X}\rangle\rangle$*, where* $\langle\cdot|\mathbf{X}\rangle$ *indicates averaging over all repeats of the stimulus and* $\langle\cdot\rangle$ *indicates averaging over all time points. Shown are the autocorrelations from neuron* 1 *(left) and neuron* 2 *(left) in the simulation of Figure* 4(A)*. Autocorrelation at zero delay has been truncated to zero.*

We used interneuronal coupling of the form

$$\bar{W}_{pq}^j = B_{pq}\frac{j\Delta t_{\mathrm{sim}} - d_{pq}}{\tau_w^2}\exp\left(-\frac{j\Delta t_{\mathrm{sim}} - d_{pq}}{\tau_W}\right)$$

for $j\Delta t_{\mathrm{sim}} > d_{pq}$ and $\bar{W}_{pq}^j = 0$ otherwise. Hence, d_{pq} represented the delay and B_{pq} the strength of the connection. For all connections, we set the time scale to $\tau_W = 0.5$ ms.

4.1.3. The model used in the analysis. We also used a generalized linear model (or linear-nonlinear model) for the analysis. (In [14], we test an earlier version of the analysis for stronger deviations from the simulated model.) In the analysis, we uses a temporal discretization of $\Delta t = 1$ ms.

We modeled the activity of each neuron in time bin i as a Poisson distribution (section 3.4) with the expected value given by

$$(4.2)\quad \lambda_s(\mathbf{r}_s^{<i}, \mathbf{x}, w; \theta_s^i) = A_s \log\left(1 + \exp\left[\sum_{j>0} h_{\mathrm{hist},s}^j r_s^{i-j} + \mathbf{h}_{\mathrm{ext},s}^i \cdot \mathbf{x} + w + y_s\right]\right).$$

The parameters θ_s^i correspond to A_s and y_s, as well as the parameters within $\mathbf{h}_{\mathrm{hist},s}$ and $\mathbf{h}_{\mathrm{ext},s}$. We used this form of the nonlinearity so that λ_s would be convex and $\log\lambda_s$ would be concave, a requirement for tractable numerical computations discussed in section 3.4.2 and [17]. We discuss how to determine the parameters θ_s^i in Appendix B.

4.2. Distinguishing common input from direct connection. We simulated two networks analogous to those schematized in Figure 1. In the first network, neuron 2 had a direct connection onto neuron 1. In the second network, a third, unmeasured neuron had a direct connection onto both neurons 1 and 2, with a longer delay onto neuron 1. In both cases, the spikes of neuron 1 were correlated with a delayed version of the spikes of neuron 2.

We simulated the response of each network to ten repetitions of the minute-long movie described above. Then we set the thresholds $\bar{y}_p$ so that each neuron spiked approximately 1,000 times during each presentation of the movie, obtaining approximately 10,000 spikes per neuron. The spikes from the third, common input neuron were discarded, as we treated that neuron as an unmeasured neuron.

Since we analyze just the spikes of two neurons, we will plot both the causal connection factor W and the common input factor U as a function of the delay j

defined as spike time of neuron 1 minus spike time of neuron 2. Hence, our plots will use the convention

$$W^j = \begin{cases} W_{12}^{-j} & \text{for } j < 0, \\ 0 & \text{for } j = 0, \\ W_{21}^{j} & \text{for } j > 0, \end{cases}$$

$$U^j = \begin{cases} U_{12}^{-j} & \text{for } j \leq 0, \\ U_{21}^{j} & \text{for } j > 0. \end{cases}$$

As shown in Figure 4, we were able to successfully distinguish the common input network from the direct connection network, despite the fact that the correlations between neurons 1 and 2 looked the same in both cases. The causal connection measure W was positive in the direct connection network; the common input measure U was positive in the common input network.

Section 3.4.1 outlines two differences between causal connections and common input that our analysis exploits to make this distinction. Only one of those differences was due exclusively to the history-dependence modeling that is the focus of this paper. To test the relative importance of the history-dependent factor, we reanalyzed the simulation of Figure 4 while ignoring any history-dependent effects. We set $\mathbf{h}_{\text{hist},p}$ in (4.2) to zero, essentially reverting our analysis back to an earlier version [14]. In this case, we model the expected activity of a node as independent of its measured history (conditioned on the external variables $\mathbf{X}$), so we remove the difference between the causal connection and common input terms of (3.17b) that is attributed to this history dependence.

The results after ignoring history-dependent effects (not shown) differed only slightly from the results when employing the full model. As in Figure 4, W was positive in the direct connection network, and U was positive in the common input network. Note that the simulations were generated with strong history dependence (yielding autocorrelations as in Figure 3). The fact that we achieved good results even while assuming no history dependence indicates that the analysis is at least somewhat robust to deviations from model assumptions.

4.3. Improvement from modeling history dependence. Although the above results do indicate that the analysis that includes history dependence can succeed in distinguishing causal connections from common input, we wish to demonstrate that we have gained analytic power from our history-dependent modeling. Adding history-dependent effects to our modeling introduced significant complexity compared to an earlier version of the analysis [14]. To justify such complexity, we must demonstrate an improved ability to distinguish connectivity.

One limitation of earlier versions [13, 14] of this analysis is that they require that the neural activity be strongly related to measurable external variables (such as stimuli) in a manner that one can capture with a model. In many experimental contexts, such as when recording from brain areas that are not closely linked to a stimulus, such a strong relationship between external variables and neuronal activity may not be available. In such cases, the earlier versions of the analysis may not apply. On the other hand, if such neurons have a strong history dependence that can be captured by a model, the additional handle provided by history-dependent modeling may allow one to apply the analysis to these systems.

To demonstrate how the history-dependent modeling can improve the results, we repeated the simulation of Figure 4 but weakened the relationship between the

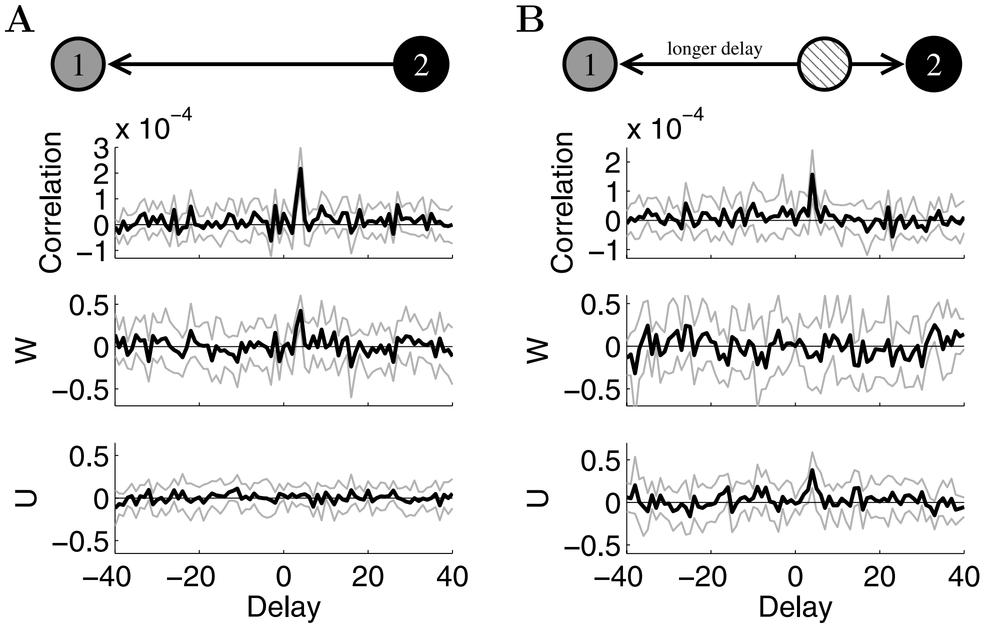

FIG. 4. *Successfully distinguishing a causal connection from common input.* (A) *Results from analyzing a network where neuron* 2 *has a direct connection onto neuron* 1*, as schematized at top. The correlation (shuffle-corrected correlogram or covariogram* [19, 1, 16]*) at delay* j *is* $\langle R_1^i R_2^{i-j}\rangle - \langle\langle R_1^i|\mathbf{X}\rangle\langle R_2^{i-j}|\mathbf{X}\rangle\rangle$*, where the averaging* $\langle\cdot\rangle$ *is defined as in Figure* 3*. The direct connection leads to a peak in the correlation at a positive delay. The causal connection measure* W *(but not the common input measure* U*) has a positive peak at the same delay, indicating the presence of a causal connection from neuron* 2 *onto neuron* 1*. (At the peak,* W *was seven standard errors from zero.) Thin gray lines indicate a bootstrap estimate of three standard errors, calculated by resampling from the set of stimulus repetitions* 50 *times. Simulation parameters:* $a_{\text{hist},1} = 1.2$, $a_{\text{hist},2} = 1.5$, $\tau_{\text{hist},1} = 10$ ms, $\tau_{\text{hist},2} = 12$ ms, $\bar{y}_1 = 0.5$, $\bar{y}_2 = 0.7$, $b_1 = b_2 = 0$, $a_{\text{ext},1} = a_{\text{ext},2} = 1$, $\tau_{\text{ext},1} = 40$ ms, $\tau_{\text{ext},2} = 50$ ms, $\sigma_1 = 10$, $\sigma_2 = 15$, $f_1 = 0.08$, $f_2 = 0.04$, $\phi_1 = 0$, $\phi_2 = 2\pi/3$, $B_{21} = 1.2$, $d_{21} = 3$, $B_{11} = B_{12} = B_{22} = 0$. (B) *Results from analyzing a network where an unmeasured neuron (hatched circle in schematic at top) has a connection onto neuron* 1 *and onto neuron* 2*. Since the connection onto neuron* 1 *has a longer delay, there is a peak in the correlation at a positive delay that is indistinguishable from a peak in correlation due to a direct connection from neuron* 2 *onto neuron* 1*. Only* U*, and not* W*, has a positive peak at the same delay, indicating that the correlation was due to common input rather than any causal connection from neuron* 2 *onto neuron* 1*. (At the peak,* U *was five standard errors from zero.) Most parameters as in panel A. Exceptions and additional parameters (the unmeasured neuron is indexed by* 3*):* $a_{\text{hist},3} = 1.0$, $\tau_{\text{hist},3} = 6$ ms, $\bar{y}_2 = 0.6$, $\bar{y}_3 = 0.8$, $b_3 = 0$, $a_{\text{ext},3} = 1$, $\tau_{\text{ext},3} = 45$ ms, $\sigma_3 = 20$, $f_3 = 0.06$, $\phi_3 = 4\pi/3$, $d_{31} = 4$, $d_{32} = 0$, $B_{31} = B_{32} = 4.5$, $B_{ij} = 0$ *for all other* i *and* j*.*

neuronal activity and the stimulus. We reduced the magnitude of the external variable terms $\mathbf{h}_{\text{ext},p} \cdot \mathbf{X}$ by a factor of 5 (reducing their standard deviation $a_{\text{ext},p}$ from 1 to 0.2). As this greatly increased the difficulty of the network analysis, we also doubled the simulation length to 20 simulated minutes (20 repeats of the movie), obtaining around 20,000 spikes from each neuron.

The results of the analysis based on the full model (4.2) are shown in Figure 5. Despite the weak dependence on the stimulus, the analysis was still able to determine which network contained the causal connection and which network contained common input.

In this case, since the neurons' activities were only weakly related to the stimulus, the history-dependent effects played a bigger role in determining the connectivity. To

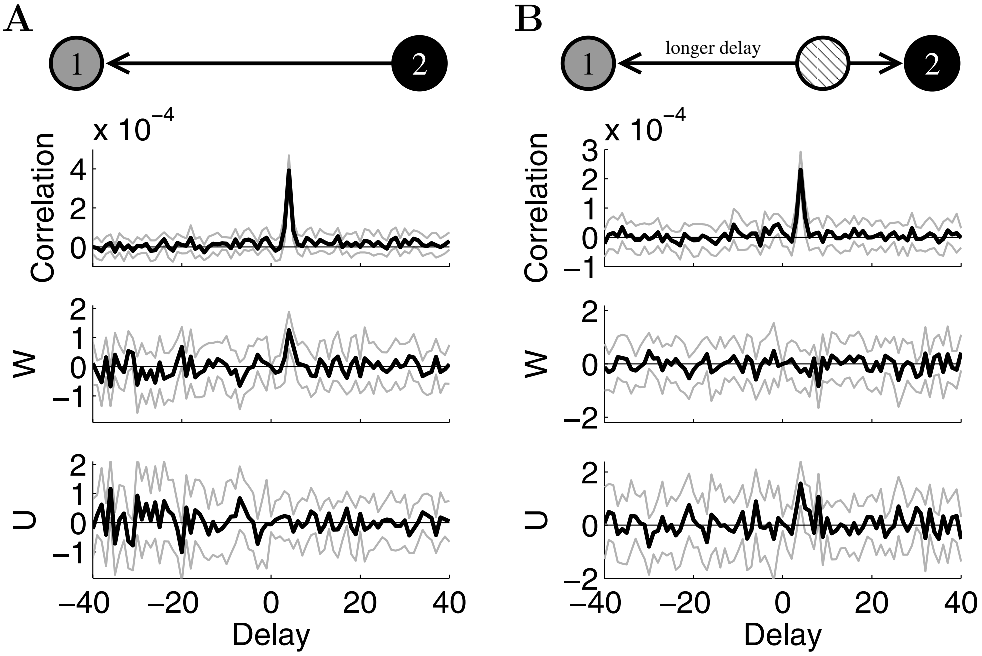

FIG. 5. *Determining circuitry even when neuronal activity is only weakly related to the stimulus. The same networks as in Figure* 4 *were simulated, except that the magnitude of the stimulus input was decreased by a factor of* 5 *and the simulation length was doubled. The causal connection network was still distinguished from the common input network, primarily due to exploitation history-dependent effects (cf. Figure* 6*, where these effects were ignored). Panels as in Figure* 4*.* (A) *The causal connection measure W has a peak at the same delay as the correlation, indicating the correlation was due to a causal connection from neuron* 2 *onto neuron* 1*. (At the peak, W was six standard errors from zero.) Parameters as in Figure* 4(A)*, except that $a_{\text{ext},1} = a_{\text{ext},2} = 0.2$, $\bar{y}_1 = 1.1$, and $\bar{y}_2 = 1.1$.* (B) *The common input measure U has a peak at the same delay as the correlation, indicating the correlation was due to common input. (At the peak, U was five standard errors from zero.) Parameters as in Figure* 4(B)*, except that $a_{\text{ext},1} = a_{\text{ext},2} = a_{\text{ext},3} = 0.2$, $\bar{y}_1 = 1.0$, $\bar{y}_2 = 1.0$, $\bar{y}_3 = 1.2$, and $B_{31} = B_{32} = 4$.*

demonstrate the role of the history-dependent model, we reanalyzed the simulation results of Figure 5 while ignoring history-dependent effects (as above, we set $\mathbf{h}_{\text{hist},p}$ in (4.2) to zero). This time, the analysis was unable to make a clear distinction between the direct connection network and the common input network, as shown in Figure 6. In the direct connection network of Figure 6(A), both W and U were positive so that the result was ambiguous. In the common input network of Figure 6(B), only U was positive at the delay corresponding to the correlation, but U was barely above the noise, and the result was much weaker than in Figure 5(B). (If we quadrupled the simulation to 80 simulated minutes, then the network analysis was able to determine the connectivity even with ignoring history-dependent effects.)

4.4. Subpopulation ambiguity. In section 3.3.3, we described an assumption we made about the hidden nodes in order to complete our analysis. We briefly mentioned that this assumption resulted in a certain degree of ambiguity in the identity of causal connections. This ambiguity is described in detail in [14], where we refer to it as *subpopulation ambiguity.*

The nature of the subpopulation ambiguity is illustrated by Figure 7. Here we repeated the simulation of the common input network of Figure 4(B), except we

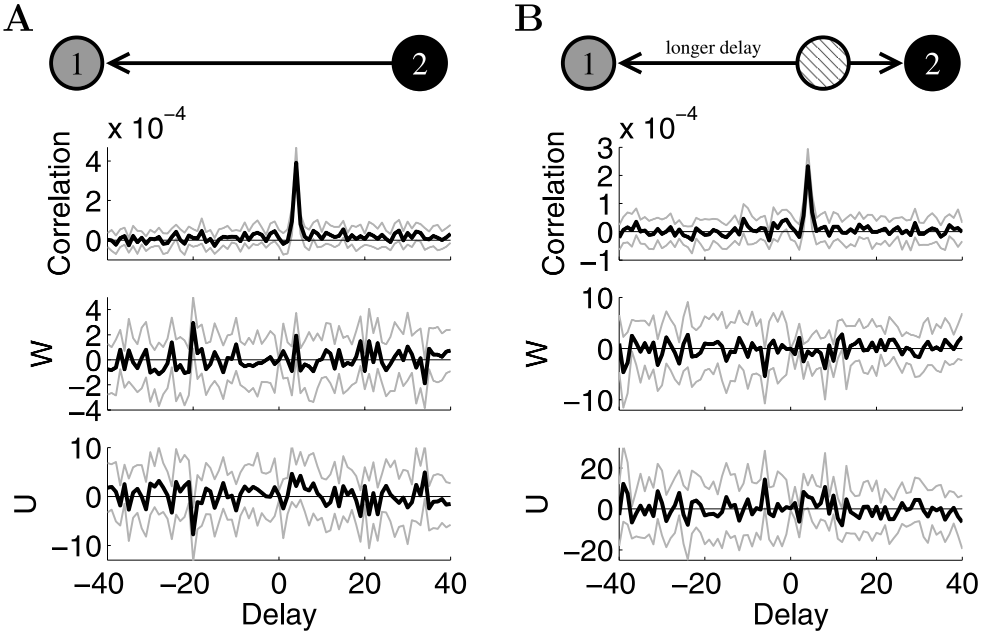

FIG. 6. *Reanalyzing the simulations of Figure* 5 *while ignoring all history-dependent effects. The history kernel* $\mathbf{h}_{\text{hist}}$ *of* (4.2) *was set to zero, so the analysis could not exploit the differences between causal connection and common input networks that are caused by history dependence. In this case, since the neural activity was only weakly related to the stimulus, the analysis failed to cleanly distinguish the circuitry. Panels as in Figure* 4. (A) *The causal connection measure* W *did have a (small) positive peak at the delay of the peak in the correlation. However, the common input measure* U *also had a positive peak at that delay, so that the identity of the causal connection could not be clearly determined. (At the peak* W *was three standard errors and* U *was over two standard errors from zero.)* (B) *Only the causal connection measure* U *had a peak at the delay of the correlation peak, so the results do correctly point to the presence of common input. However, the peak in* U *at that delay is small (though it was three standard errors from zero), especially compared to Figure* 5(B), *indicating that ignoring history dependence hampered the ability to determine circuitry.*

changed the kernel $\bar{\mathbf{h}}_{\text{ext},3}$ of the unmeasured neuron first to match the kernel $\bar{\mathbf{h}}_{\text{ext},2}$ of neuron 2 and then to match the kernel $\bar{\mathbf{h}}_{\text{ext},1}$ of neuron 1. As shown in Figure 7(A), the analysis misidentifies the common input as a causal connection when the kernel of the unmeasured common input neuron matched neuron 2. The analysis does not have any trouble correctly identifying the common input when the kernel of the unmeasured common input neuron matched neuron 1, as shown in Figure 7(B).

We argue that the misidentification in Figure 7(A) merely introduces a relatively modest ambiguity into the interpretation of the results. Clearly, one cannot justify a strict interpretation that the peak in W always indicates a causal connection from neuron 2 itself onto neuron 1. However, note that in the network of Figure 7(A) there is a causal connection from the unmeasured neuron onto neuron 1 and that this unmeasured neuron has similar properties to neuron 2 (one might use the language that the unmeasured neuron has a *receptive field* that is similar to that of neuron 2). Hence, one can make a looser interpretation of the peak in W to indicate the presence of a causal connection onto neuron 1 from some neuron with properties (or receptive field) similar to neuron 2.

In experiments where one measures only the spike times of individual neurons, neurons are identified only by their properties, such as the relationship between their

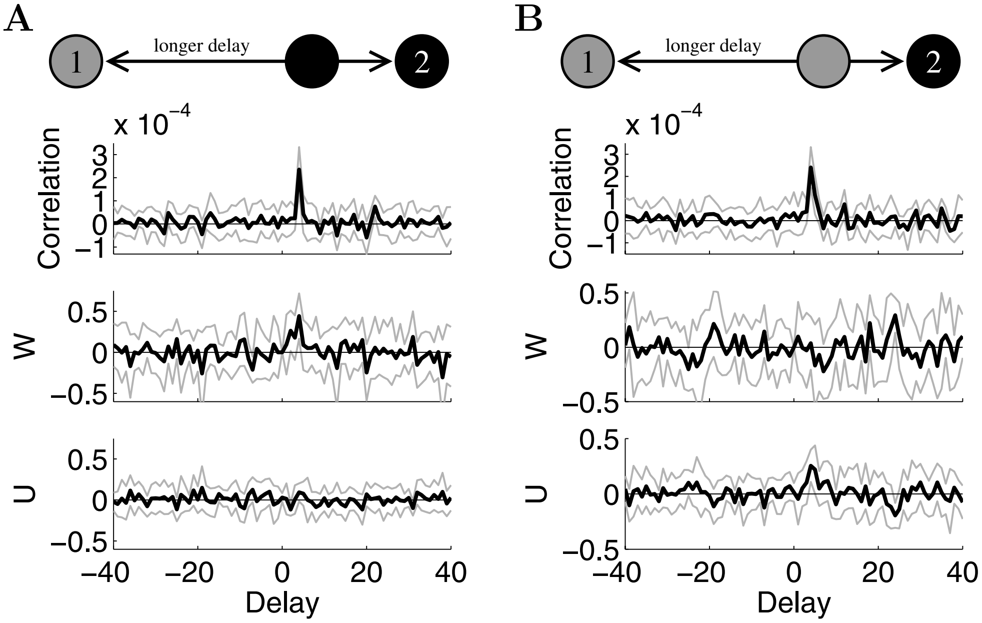

FIG. 7. *An illustration of the subpopulation ambiguity in the identification of the individual neurons involved in a connection. Note that, in both networks shown, the delays are set up so that the correlations mimic a connection from neuron* 2 *onto neuron* 1*. Hence neuron* 1 *and neuron* 2 *do not play symmetric roles. Panels as in Figure* 4. (A) *When the unmeasured neuron has similar properties as neuron* 2 *(as schematized by the black circles at top), the causal connection factor W has a peak at the delay of the correlation peak, incorrectly indicating a connection from neuron* 2 *onto neuron* 1*. (At the peak, W is four standard errors from zero.) However, there is a connection onto neuron* 1 *from a neuron similar to neuron* 2 *(a black neuron in the schematic). Hence, W must be interpreted as indicating a causal connection onto neuron* 1 *from a neuron with properties similar to those of neuron* 2*. Parameters as in Figure* 4(B)*, except that $\bar{y}_1 = 0.4$, $\bar{y}_2 = 0.5$, $\bar{y}_3 = 0.9$, $b_2 = 1$ ms, $\tau_{\text{ext},3} = 50$ ms, $\sigma_3 = 16$, $f_3 = 0.038$, and $\phi_3 = 2\pi/3$.* (B). *When the unmeasured neuron has properties similar to neuron* 1 *(as schematized by the gray circles at top), the results correctly indicate a common input connection as U has a positive peak at the delay of the correlation peak. (At the peak, U is five standard errors from zero.) In this case, it is important that the analysis obtained the correct results, as there is no connection from a neuron similar to neuron* 2 *(a black neuron in the schematic) onto a neuron similar to neuron* 1 *(a gray neuron). Parameters as in Figure* 4(B)*, except that $\bar{y}_1 = 0.4$, $\bar{y}_2 = 0.5$, $\bar{y}_3 = 0.7$, $b_1 = 5$ ms, $\tau_{\text{ext},3} = 40$ ms, $\sigma_3 = 11$, $f_3 = 0.078$, and $\phi_3 = 0$.*

spikes and external variables or stimuli. In this case, if two neurons had similar properties (such as the unmeasured neuron and neuron 2 in Figure 7(A)), those two neurons would be indistinguishable. Hence, it would not make a difference if one concluded that neuron 2 had a connection onto neuron 1 or concluded that an unmeasured neuron with similar properties had a connection onto neuron 1. In either case, the conclusion would be that a neuron with the properties of neuron 2 had a connection onto a neuron with the properties of neuron 1.

In Figure 7(B), there is no connection from a neuron with properties similar to neuron 2 onto a neuron with properties similar to neuron 1. Even with the looser interpretation of the causal connection W, this network cannot be identified as having a causal connection. It is critical that the analysis correctly identified the correlation as arising from common input.

In [14], we refer to a group of neurons with similar properties as a *subpopulation* of neurons. Since the identity of the presynaptic neuron involved in a connection is narrowed down only to an individual member within a supopulation, we use the language that our analysis can determine connectivity only with subpopulation ambiguity. In using such a term, one must be careful to recognize that one is not assuming connections between groups of neurons but only ambiguity in the identity of individual neurons. See [14] for more details, including more intuition behind the subpopulation ambiguity.

5. Discussion. The present work represents a continuation of our development of methods to determine the pattern of causal connections among measured neurons while controlling for the effects of unmeasured neurons [14, 13, 12]. We have successfully eliminated the limitation of earlier versions that the activity of a neuron could depend only weakly on its history. In the process, we have discovered that one can exploit such history dependence to increase one's ability to distinguish common input from causal connections.

Although the analysis involved a fair number of technical manipulations, it turns out that the intuition developed in the introduction does hold for the class of models we consider. In the common input configuration (Figure 2(B)), but not in the causal connection configuration (Figure 2(A)), spikes that can be accounted for by the first neuron's history dependence do not influence the second neuron's spiking probability (see (3.17)). This difference is exploited by our analysis in order to distinguish common input from causal connections.

Successfully exploiting history dependence requires a strong dependence on history in a manner that one can capture by a model. In our simulations, we included such history dependence and demonstrated that we could use it to improve our estimates of connectivity. It is well known that the spike times of neurons are not well approximated by a Poisson process [23, 21] and hence contain history dependence. However, it remains unclear if this history dependence is sufficiently strong and if it can be sufficiently well modeled to aid in the determination of connectivity.

The analysis was justified by a weak coupling assumption (section 2.2) where the original coupling $\bar{W}$ was assumed to be a small parameter. However, even if the original coupling $\bar{W}$ were large and only the perturbation $\widetilde{W}$ due to coupling (see (3.15b)) were small, the analysis might still indicate the effective connectivity of the network. To interpret the analysis under these conditions, one could reinterpret the likelihood equation (3.15) as a perturbation off the effective models (2.3) rather than off the original network (2.2). In this case, one cannot assume that the causal connectivity obtained with W actually corresponds to the underlying connectivity of the network. Such a reinterpretation of W as an effective connectivity would allow application of the results to networks where the weak coupling assumption cannot be justified.

Although the analysis depends on selecting appropriate single-neuron models of the form (2.3), flexibility is given by the modular approach [14] employed in our analysis. One can develop additional single-neuron models and include them in the analysis without modification of the network analysis. In the simulation tests, we used only generalized linear models. Such a model of the dependence of neural activity on spiking history is, of course, only roughly approximated by such a model. One future goal is to implement more sophisticated models of history dependence, such as a stochastic integrate-and-fire model [18]. Paninski, Pillow, and Simoncelli have already developed efficient numerical schemes for determining the parameters of the stochastic integrate-and-fire model [18], and the model does fit into the formalism of (2.3). Such a model may more closely approximate history dependence observed in biological neurons.

Although there is a large literature focused on analyzing interactions among neurons [19, 1, 16, 2, 3, 11, 25, 15, 7, 20, 18, 24, 9], we are aware of only one other attempt to explicitly control for the effects of common input from *unmeasured* sources. Kulkarni and Paninski [9] have recently developed an expectation-maximization algorithm for fitting a neuronal model that contains a latent noise source that could correspond to such unmeasured common input. In their approach, the common input (i.e., latent noise) is assumed to be a Gaussian process (justified by thinking of the common input as a sum of a large number of small inputs). Hence, in place of a point process model (2.2) for a network containing unmeasured neurons, their model is a doubly stochastic process or Cox process [22]. As their approach differs significantly from ours, one future task will be to compare the results of the two methods to understand their relative strengths and weaknesses.

Earlier versions of our analysis relied exclusively on models of the relationship between neuron spikes and external variables such as stimuli. As we have demonstrated via simulations, modeling history-dependent effects may allow one to apply the analysis even in cases where the activity of neurons is not strongly related to external variables. Especially with the implementation of more sophisticated models of history dependence, our analysis may become applicable to a large variety of neuronal systems (or other networks), regardless of whether or not they are strongly linked to a stimulus or other external variable.

Appendix A. Calculations underlying analysis.

A.1. Averaging over hidden node activity. We outline how to simplify (3.4) for the probability distribution $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ of measured node activity $\mathbf{R}_\mathcal{Q}$ by explicitly computing the averages over hidden node activity $\mathbf{R}_\mathcal{P}$. We argued in the context of (3.4) that the value r_s^i of any random variable appears in (3.4) only as a polynomial in r_s^i times $\bar{P}_s$ (or times a derivative of $\bar{P}_s$).

Expressions involving the undifferentiated $\bar{P}_s$ are simple. Let a sum over $\mathbf{r}_s$ denote the sum over all possible values of the activity $\mathbf{r}_s$ (i.e., r_s^i for all i) of a given node s. Then, since $\bar{P}_s$ is shorthand for a probability distribution in the $\mathbf{r}_s$, we can conclude that

$$\text{(A.1)}\quad \sum_{\mathbf{r}_s} \bar{P}_s = 1, \qquad \sum_{\mathbf{r}_s} r_s^i \bar{P}_s = \bar{E}_0(R_s^i), \qquad \text{and} \qquad \sum_{\mathbf{r}_s} r_s^{i_1} r_s^{i_2} \bar{P}_s = \bar{E}_0(R_s^{i_1} R_s^{i_2}).$$

$\bar{E}_0(\cdot)$ denotes the expected value under the probability distribution defined by the P_s with W arguments set to zero, i.e., for any function g of the activity of nodes,

$$\text{(A.2)}\qquad \bar{E}_0(g(\mathbf{R})) = \sum_{\mathbf{r}} g(\mathbf{r}) \prod_s \prod_i P_s\big(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, 0; \bar{\theta}_s^i\big).$$

(The sum over $\mathbf{r}$ indicates the sum over all possible values of the activity of all nodes.) Note that $\bar{E}_0(R_s^i)$ is not the expected value of R_s^i under model (2.2); it is the expected value of R_s^i only if the coupling happened to be zero.

The expressions involving the derivatives of $\bar{P}_s$ are more subtle. First, note that, for any node s,

$$\sum_{\mathbf{r}_s} \prod_i P_s \left(r_s^i, \mathbf{r}_s^{<i}, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath} < i} \bar{W}_{\acute{s},s}^{\acute{\imath},i} r_{\acute{s}}^{\acute{\imath}}; \bar{\theta}_s^i \right) = 1$$

independent of any value of the $r^{\tilde{\imath}}_{\tilde{s}}$ for $\tilde{s} \neq s$. (The case when all $r^{\tilde{\imath}}_{\tilde{s}} = 0$ for $\tilde{s} \neq s$ was the first identity of (A.1).) So, if we differentiate with respect to any $r^{\tilde{\imath}}_{\tilde{s}}$ with $\tilde{s} \neq s$, we will get zero:

$$\sum_{\mathbf{r}_s} \frac{\partial}{\partial r^{\tilde{\imath}}_{\tilde{s}}} \left(\prod_i P_s \left(r^i_s, \mathbf{r}^{<i}_s, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath} < i} \bar{W}^{\acute{\imath},i}_{\acute{s},s} r^{\acute{\imath}}_{\acute{s}}; \bar{\theta}^i_s \right) \right) = 0.$$

In particular, this derivative is zero if we set all $r^{\tilde{\imath}}_{\tilde{s}} = 0$ for $\tilde{s} \neq s$, so that

$$\text{(A.3)} \qquad \sum_{\mathbf{r}_s} \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}}_{\tilde{s}}} = 0, \qquad \text{and} \qquad \sum_{\mathbf{r}_s} \frac{\partial^2 \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1} \partial r^{\tilde{\imath}_2}_{\tilde{s}_1}} = 0.$$

On the other hand,

$$E(R^i_s | \{\mathbf{R}^{<i}_{\acute{s}} = \mathbf{r}^{<i}_{\acute{s}}\}_{\acute{s} \neq s}) = \sum_{\mathbf{r}_s} r^i_s \prod_{\acute{\imath}_1} P_s \left(r^{\acute{\imath}_1}_s, \mathbf{r}^{<\acute{\imath}_1}_s, \mathbf{x}, \sum_{\acute{s} \neq s} \sum_{\acute{\imath}_2 < \acute{\imath}_1} \bar{W}^{\acute{\imath}_2,\acute{\imath}_1}_{\acute{s},s} r^{\acute{\imath}_2}_{\acute{s}}; \bar{\theta}^{\acute{\imath}_1}_s \right)$$

does depend on the values of the $r^{\tilde{\imath}}_{\tilde{s}}$ for $\tilde{s} \neq s$ and $\tilde{\imath} < i$. Due to network connections, the expected value of R^i_s could indeed depend on the value of the past activity of another node. So, if we differentiate with respect to any $r^{\tilde{\imath}}_{\tilde{s}}$, we won't necessarily get zero. Denote this derivative, once we set all $r^{\tilde{\imath}}_{\tilde{s}} = 0$ for $\tilde{s} \neq s$, as

$$\text{(A.4)} \qquad \bar{E}_0 \left(\frac{\partial R^i_s}{\partial R^{\tilde{\imath}}_{\tilde{s}}} \right) = \frac{\partial}{\partial r^{\tilde{\imath}}_{\tilde{s}}} E(R^i_s | \{\mathbf{R}^{<i}_{\acute{s}} = \mathbf{r}^{<i}_{\acute{s}}\}_{\acute{s} \neq s}) \Big|_{\{\mathbf{r}_{\acute{s}} = \mathbf{0} | \acute{s} \neq s\}} = \sum_{\mathbf{r}_s} r^i_s \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}}_{\tilde{s}}}.$$

The notation captures that this expression represents how a change in the activity of node $\tilde{s}$ at time $\tilde{\imath}$ affects the average activity of node s at time i. This is nonzero, of course, only if $\tilde{\imath} < i$. Note that this expression doesn't depend on $R^{\tilde{\imath}}_{\tilde{s}}$, as the derivative is calculated around $R^{\tilde{\imath}}_{\tilde{s}} = 0$. Note also that this expression need not be zero even if $R^{\tilde{\imath}}_{\tilde{s}}$ does not directly influence R^i_s, i.e., if $\bar{W}^{\tilde{\imath},i}_{\tilde{s},s} = 0$. Because we have allowed R^i_s to depend arbitrarily on its history $R^{i_2}_s$ for $i_2 < i$, this derivative could be nonzero just because $\bar{W}^{\tilde{\imath},i_2}_{\tilde{s},s} \neq 0$.

We use the identities in (A.1), (A.3), and (A.4) to simplify all of the sums over $\mathbf{r}_{\mathcal{P}}$ in the marginal distribution of $\mathbf{R}_{\mathcal{Q}}$ given in (3.4). To use these identities, we need to distinguish all of the subsets of the various s indicies that could correspond to a hidden node. We do this by enumerating all of the possible ways in which each s index could be either a hidden or a measured node, as well as all of the possible ways in which hidden node indices in a given term could correspond to the same node. Hence each term in (3.4) will be expanded into many different terms.

However, due to the identities in (A.3), most terms involving derivatives of hidden nodes disappear. Recall that a derivative of $\bar{P}_s$ represents a connection onto node s. A connection onto a hidden node p should not directly affect the marginal distribution of the measured nodes $R_{\mathcal{Q}}$; such a connection should have an effect only through a connection from that hidden node onto a measured node. Indeed, the only place where derivatives of hidden nodes survive is in the last term:

$$\frac{1}{2} \sum_{\mathbf{r}_{\mathcal{P}}} \sum_{\substack{s_1, s_2, \tilde{s}_1, \tilde{s}_2 \\ s_2 \neq s_1, \tilde{s}_1 \neq s_1 \\ \tilde{s}_2 \neq s_2}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{s_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} \frac{\partial \bar{P}_{s_2}}{\partial r^{\tilde{\imath}_2}_{\tilde{s}_2}} r^{\tilde{\imath}_1}_{\tilde{s}_1} r^{\tilde{\imath}_2}_{\tilde{s}_2} \prod_{\substack{s_3 \\ s_3 \neq s_1 \\ s_3 \neq s_2}} \bar{P}_{s_3}.$$

If we set s_1 to a hidden node $s_1 = p_1$, then by identity (A.4), the term will survive only if $\tilde{s}_2$ also corresponds to the same hidden node $\tilde{s}_2 = p_1$ and if $\tilde{\imath}_2$ corresponds to an earlier time $\tilde{\imath}_2 < \tilde{\imath}_1$. If we then tried to set s_2 to another hidden node $s_2 = p_2$, we would need the contradictory condition of $\tilde{\imath}_2 > \tilde{\imath}_1$ for the term to survive. In this case, we must set s_2 to a measured node $s_2 = q_2$. Hence, with these substitutions, the term represents the cascade of the effect of a connection from node $\tilde{s}_2$ (which could be hidden or measured) onto hidden node p_1 combined with the effect of a connection from hidden node p_1 onto measured node q_2. (We must double the effect of this term because we could swap s_1 and s_2 and obtain the same result.)

In all other cases, only the effects of connections onto measured nodes survive. The connections from measured and hidden nodes must still be distinguished. We describe this process in [14] as identifying all possible subnetworks of two or fewer edges. When this process is completed, we end up with the following lengthy expression:

$$
\begin{aligned}
\Pr(\mathbf{R}_{\mathcal{Q}} = \mathbf{r}_{\mathcal{Q}} | \mathbf{X} = \mathbf{x}) = {} & \prod_{q} \bar{P}_q + \sum_{\substack{q_1, \tilde{q}_1 \\ q_1 \neq \tilde{q}_1}} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}} r^{\tilde{\imath}_1}_{\tilde{q}_1} \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \sum_{q_1, \tilde{p}_1} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{p}_1}) \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \frac{1}{2} \sum_{\substack{q_1, \tilde{q}_1, \tilde{q}_2 \\ q_1 \neq \tilde{q}_1, q_1 \neq \tilde{q}_2}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1} \partial r^{\tilde{\imath}_2}_{\tilde{q}_2}} r^{\tilde{\imath}_1}_{\tilde{q}_1} r^{\tilde{\imath}_2}_{\tilde{q}_2} \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \sum_{\substack{q_1, \tilde{q}_1, \tilde{p}_2 \\ q_1 \neq \tilde{q}_1}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1} \partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} r^{\tilde{\imath}_1}_{\tilde{q}_1} \bar{E}_0(R^{\tilde{\imath}_2}_{\tilde{p}_2}) \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \frac{1}{2} \sum_{q_1, \tilde{p}_1, \tilde{p}_2} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1} \partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{p}_1} R^{\tilde{\imath}_2}_{\tilde{p}_2}) \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \sum_{\substack{q_1, \tilde{p}_1, \tilde{p}_2 \\ \tilde{p}_1 \neq \tilde{p}_2}} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} \bar{E}_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{p}_1}}{\partial R^{\tilde{\imath}_2}_{\tilde{p}_2}} \right) \bar{E}_0(R^{\tilde{\imath}_2}_{\tilde{p}_2}) \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \sum_{q_1, \tilde{p}_1, \tilde{q}_2} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} \bar{E}_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{p}_1}}{\partial R^{\tilde{\imath}_2}_{\tilde{q}_2}} \right) r^{\tilde{\imath}_2}_{\tilde{q}_2} \prod_{\substack{q_2 \\ q_2 \neq q_1}} \bar{P}_{q_2} \\
& + \frac{1}{2} \sum_{\substack{q_1, \tilde{p}_1, q_2, \tilde{p}_2 \\ q_2 \neq q_1}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} \frac{\partial \bar{P}_{q_2}}{\partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{p}_1} R^{\tilde{\imath}_2}_{\tilde{p}_2}) \prod_{\substack{q_3 \\ q_3 \neq q_1, q_3 \neq q_2}} \bar{P}_{q_3} \\
& + \sum_{\substack{q_1, \tilde{q}_1, q_2, \tilde{p}_2 \\ q_2 \neq q_1, q_1 \neq \tilde{q}_1}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}} \frac{\partial \bar{P}_{q_2}}{\partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} r^{\tilde{\imath}_1}_{\tilde{q}_1} \bar{E}_0(R^{\tilde{\imath}_2}_{\tilde{p}_2}) \prod_{\substack{q_3 \\ q_3 \neq q_1, q_3 \neq q_2}} \bar{P}_{q_3} \\
& + \frac{1}{2} \sum_{\substack{q_1, \tilde{q}_1, q_2, \tilde{q}_2 \\ q_2 \neq q_1, q_1 \neq \tilde{q}_1 \\ q_2 \neq \tilde{q}_2}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial \bar{P}_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}} \frac{\partial \bar{P}_{q_2}}{\partial r^{\tilde{\imath}_2}_{\tilde{q}_2}} r^{\tilde{\imath}_1}_{\tilde{q}_1} r^{\tilde{\imath}_2}_{\tilde{q}_2} \prod_{\substack{q_3 \\ q_3 \neq q_1, q_3 \neq q_2}} \bar{P}_{q_3} + O(\bar{W}^3).
\end{aligned}
\tag{A.5}
$$

A.2. Obtaining an effective parameter equation. We obtained (A.5) for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ by averaging the full model (2.2) over the activity of all hidden nodes. The averaged model (2.3) is equivalent to the full model (2.2) averaged over the activity of all nodes except for a single node s. Hence, the averaged model (2.3) must be equal to (A.5) for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$ where the set $\mathcal{Q}$ of measured nodes is replaced by the single node s.

Given definition (3.5) for the effective probability distribution P_s, we obtain

$$\begin{aligned}
P_s &= \Pr(\mathbf{R}_s = \mathbf{r}_s|\mathbf{X} = \mathbf{x}) \\
&= \bar{P}_s + \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}) \\
&\quad + \frac{1}{2} \sum_{\substack{\tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s, \tilde{s}_2 \neq s}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1} \partial r^{\tilde{\imath}_2}_{\tilde{s}_2}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{s}_1} R^{\tilde{\imath}_2}_{\tilde{s}_2}) \\
&\quad + \sum_{\substack{\tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s, \tilde{s}_2 \neq s \\ \tilde{s}_1 \neq \tilde{s}_2}} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} \bar{E}_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{s}_1}}{\partial R^{\tilde{\imath}_2}_{\tilde{s}_2}} \right) \bar{E}_0(R^{\tilde{\imath}_2}_{\tilde{s}_2}) \\
&\quad + \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} \bar{E}_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{s}_1}}{\partial R^{\tilde{\imath}_2}_{s}} \right) r^{\tilde{\imath}_2}_s + O(\bar{W}^3),
\end{aligned} \tag{A.6}$$

where we simply replaced all variations of q in (A.5) with s and replaced the $\tilde{p}$ in (A.5) with the corresponding $\tilde{s}$. Equation (A.6) relates the effective parameters θ (hidden in P) to the original model parameters $\bar{\theta}$ (hidden in $\bar{P}$). Since, by assumption, we have an algorithm to determine the effective parameters θ (at least for measured nodes), we want to be able to rewrite everything in terms of the effective parameters. To accomplish this, we need an expression for the original model parameters $\bar{\theta}$ in terms of the effective parameters θ.

Recall that each derivative with respect to r implicitly includes a factor of $\bar{W}$. Hence (A.6) shows that P_s deviates from $\bar{P}_s$ by an amount that is $O(\bar{W})$. Since we are computing only a second-order approximation in $\bar{W}$, we can replace $\bar{P}_s$ with P_s in any terms that are second-order in $\bar{W}$ (i.e., contain two derivatives with respect to r) without affecting the order of our approximation. Similarly expressions with E_0 differ by the equivalent expressions with $\bar{E}_0$ by an amount that is $O(\bar{W})$ (compare (3.7) with (A.2) and (A.4)), so we can also replace $\bar{E}_0$ with E_0 in terms that are second-order in $\bar{W}$. Then (A.6) becomes (after solving for $\bar{P}_s$)

$$\begin{aligned}
\bar{P}_s &= P_s - \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1} \frac{\partial \bar{P}_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} \bar{E}_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}) \\
&\quad - \frac{1}{2} \sum_{\substack{\tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s, \tilde{s}_2 \neq s}} \sum_{\tilde{\imath}_1, \tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1} \partial r^{\tilde{\imath}_2}_{\tilde{s}_2}} E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1} R^{\tilde{\imath}_2}_{\tilde{s}_2}) \\
&\quad - \sum_{\substack{\tilde{s}_1, \tilde{s}_2 \\ \tilde{s}_1 \neq s, \tilde{s}_2 \neq s \\ \tilde{s}_1 \neq \tilde{s}_2}} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} E_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{s}_1}}{\partial R^{\tilde{\imath}_2}_{\tilde{s}_2}} \right) E_0(R^{\tilde{\imath}_2}_{\tilde{s}_2}) \\
&\quad - \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\substack{\tilde{\imath}_1, \tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} E_0 \left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{s}_1}}{\partial R^{\tilde{\imath}_2}_{s}} \right) r^{\tilde{\imath}_2}_s + O(\bar{W}^3).
\end{aligned} \tag{A.7}$$

To write the right-hand side of (A.7) solely in terms of effective parameters θ, we need to change only the sum from the first line. Since this sum is $O(\bar{W})$, we need approximations to $\partial \bar{P}_s / \partial r_{\tilde{s}_1}^{\tilde{\imath}_1}$ and $\bar{E}_0(R_{\tilde{s}_1}^{\tilde{\imath}_1})$ that are accurate to first order in $\bar{W}$. We start with the first-order approximation of $\bar{P}_s$ (the first line of (A.7)):

$$\bar{P}_s = P_s - \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1} \frac{\partial P_s}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1}} E_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) + O(\bar{W}^2). \tag{A.8}$$

Here we could replace $\bar{P}_s$ and $\bar{E}_0$ with P_s and E_0 in the terms that are first-order in $\bar{W}$, since we are computing only a first-order approximation.

When we differentiate $\bar{P}_s$ with respect to $r_{\tilde{s}_2}^{\tilde{\imath}_2}$, we are, by (3.6), essentially differentiating with respect to the $\bar{W}_{\tilde{s}_2,s}^{\tilde{\imath}_2,i}$. Hence, if we differentiate the left-hand side of (A.8) with respect to $r_{\tilde{s}_2}^{\tilde{\imath}_2}$, we need to differentiate only those terms on the right-hand side of (A.8) that are functions of P_s or $\bar{P}_s$. We obtain the following expression for the derivative $\partial \bar{P}_s / \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}$ in terms of effective parameters:

$$\frac{\partial \bar{P}_s}{\partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} = \frac{\partial P_s}{\partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} - \sum_{\substack{\tilde{s}_1 \\ \tilde{s}_1 \neq s}} \sum_{\tilde{\imath}_1} \frac{\partial^2 P_s}{\partial r_{\tilde{s}_1}^{\tilde{\imath}_1} \partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} E_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) + O(\bar{W}^2). \tag{A.9}$$

To find an expression for $\bar{E}_0(R_{\tilde{s}_1}^{\tilde{\imath}_1})$ in terms of effective parameters, we simplify its definition based on (A.2) to

$$\bar{E}_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) = \sum_{\mathbf{r}_{\tilde{s}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} \bar{P}_{\tilde{s}_1}.$$

We similarly simplify the definition of $E_0(R_{\tilde{s}_1}^{\tilde{\imath}_1})$ (based on (3.7a)) to

$$E_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) = \sum_{\mathbf{r}_{\tilde{s}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} P_{\tilde{s}_1}.$$

Then, by using (A.8) along with (3.7b), we can write $\bar{E}_0(R_{\tilde{s}_1}^{\tilde{\imath}_1})$ as

$$\begin{aligned}
\bar{E}_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) &= \sum_{\mathbf{r}_{\tilde{s}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} \bar{P}_{\tilde{s}_1} \\
&= \sum_{\mathbf{r}_{\tilde{s}_1}} r_{\tilde{s}_1}^{\tilde{\imath}_1} P_{\tilde{s}_1} - \sum_{\mathbf{r}_{\tilde{s}_1}} \sum_{\substack{\tilde{s}_2 \\ \tilde{s}_2 \neq \tilde{s}_1}} \sum_{\tilde{\imath}_2} r_{\tilde{s}_1}^{\tilde{\imath}_1} \frac{\partial P_{\tilde{s}_1}}{\partial r_{\tilde{s}_2}^{\tilde{\imath}_2}} E_0(R_{\tilde{s}_2}^{\tilde{\imath}_2}) + O(\bar{W}^2) \\
&= E_0(R_{\tilde{s}_1}^{\tilde{\imath}_1}) - \sum_{\substack{\tilde{s}_2 \\ \tilde{s}_2 \neq \tilde{s}_1}} \sum_{\substack{\tilde{\imath}_2 \\ \tilde{\imath}_2 < \tilde{\imath}_1}} E_0\left(\frac{\partial R_{\tilde{s}_1}^{\tilde{\imath}_1}}{\partial R_{\tilde{s}_2}^{\tilde{\imath}_2}} \right) E_0(R_{\tilde{s}_2}^{\tilde{\imath}_2}) + O(\bar{W}^2).
\end{aligned} \tag{A.10}$$

We substitute (A.9) and (A.10) into the first line of (A.7) and obtain the following second-order expression of $\bar{P}_s$ in terms of effective parameters:

$$\begin{aligned}\bar{P}_s =&P_s - \sum_{\substack{\tilde{s}_1\\ \tilde{s}_1\neq s}} \sum_{\tilde{\imath}_1} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}} E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1})\\ &- \frac{1}{2} \sum_{\substack{\tilde{s}_1,\tilde{s}_2\\ \tilde{s}_1\neq s,\tilde{s}_2\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{s}_1}\partial r^{\tilde{\imath}_2}_{\tilde{s}_2}} [E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}R^{\tilde{\imath}_2}_{\tilde{s}_2}) - 2E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{s}_2})]\\ &- \sum_{\substack{\hat{s}_2\\ \hat{s}_2\neq s}} \sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_2<\tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\hat{s}_2}} E_0\left(\frac{\partial R^{\tilde{\imath}_1}_{\hat{s}_2}}{\partial R^{\tilde{\imath}_2}_{s}}\right)[r^{\tilde{\imath}_2}_s - E_0(R^{\tilde{\imath}_2}_s)].\end{aligned}$$

Since for $\tilde{s}_1 \neq \tilde{s}_2$, $E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1}R^{\tilde{\imath}_2}_{\tilde{s}_2}) = E_0(R^{\tilde{\imath}_1}_{\tilde{s}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{s}_2})$, we can simplify this expression to obtain (3.8).

A.3. Measured node activity in terms of effective parameters. Equation (A.5) for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$, the probability distribution of the measured node activity, is given in terms of the original model parameters $\bar{\theta}$. Our next step is to use (3.8) to rewrite (A.5) in terms of effective parameters θ.

First, we rewrite (3.8) to replace the sums over all nodes in the network by two sums: one over the measured nodes and one over the hidden nodes. Recall that we use q (and its variants) to denote measured node indices and p (and its variants) to denote hidden node indices (i.e., implicitly restrict $q \in \mathcal{Q}$ and $p \in \mathcal{P}$).

$$\begin{aligned}\bar{P}_s = P_s &- \sum_{\substack{\tilde{q}_1\\ \tilde{q}_1\neq s}} \sum_{\tilde{\imath}_1} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}} E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1}) - \sum_{\substack{\tilde{p}_1\\ \tilde{p}_1\neq s}} \sum_{\tilde{\imath}_1} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})\\ &- \frac{1}{2} \sum_{\substack{\tilde{q}_1\\ \tilde{q}_1\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}\partial r^{\tilde{\imath}_2}_{\tilde{q}_1}} [E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1}R^{\tilde{\imath}_2}_{\tilde{q}_1}) - E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{q}_1})]\\ &- \frac{1}{2} \sum_{\substack{\tilde{p}_1\\ \tilde{p}_1\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}\partial r^{\tilde{\imath}_2}_{\tilde{p}_1}} [E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1}R^{\tilde{\imath}_2}_{\tilde{p}_1}) - E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_1})]\\ &- \sum_{\substack{\tilde{q}_1\\ \tilde{q}_1\neq s}} \sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_2<\tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}} E_0\left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{q}_1}}{\partial R^{\tilde{\imath}_2}_{s}}\right)[r^{\tilde{\imath}_2}_s - E_0(R^{\tilde{\imath}_2}_s)]\\ &- \sum_{\substack{\tilde{p}_1\\ \tilde{p}_1\neq s}} \sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_2<\tilde{\imath}_1}} \frac{\partial P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}} E_0\left(\frac{\partial R^{\tilde{\imath}_1}_{\tilde{p}_1}}{\partial R^{\tilde{\imath}_2}_{s}}\right)[r^{\tilde{\imath}_2}_s - E_0(R^{\tilde{\imath}_2}_s)]\\ &+ \frac{1}{2} \sum_{\substack{\tilde{q}_1,\tilde{q}_2\\ \tilde{q}_1\neq s,\tilde{q}_2\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}\partial r^{\tilde{\imath}_2}_{\tilde{q}_2}} E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{q}_2})\\ &+ \sum_{\substack{\tilde{q}_1,\tilde{p}_2\\ \tilde{q}_1\neq s,\tilde{p}_2\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}\partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_2})\\ &+ \frac{1}{2} \sum_{\substack{\tilde{p}_1,\tilde{p}_2\\ \tilde{p}_1\neq s,\tilde{p}_2\neq s}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_s}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}\partial r^{\tilde{\imath}_2}_{\tilde{p}_2}} E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_2}) + O(\bar{W}^3).\end{aligned}\tag{A.11}$$

The first term on the right-hand side of (A.5) for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ is $\prod_q \bar{P}_q$. This is the only term that is zeroth-order in $\bar{W}$ and so is the only term where we need a second-order conversion from original paremeters $\bar{\theta}$ to effective parameters θ. We derive a second-order approximation of $\prod_q \bar{P}_q$ by taking the product of (A.11) (ignoring terms that are third- or higher-order in $\bar{W}$) and substitute this expression into (A.5). We use a first-order approximation of $\bar{P}_s$, $\bar{E}_0(R_s^i)$ (A.10), and $\partial \bar{P}_s / \partial r_{\tilde{s}}^{\tilde{\imath}}$ (A.9) to rewrite the first-order terms of (A.5) in terms of effective parameters. After simplification, (A.5) becomes

$$
\begin{aligned}
\Pr(\mathbf{R}_\mathcal{Q} = \mathbf{r}_\mathcal{Q}|\mathbf{X} = \mathbf{x}) = {} & \prod_q P_q + \sum_{\substack{q_1,\tilde{q}_1\\ q_1\neq\tilde{q}_1}} \sum_{\tilde{\imath}_1} \frac{\partial P_{q_1}}{\partial r_{\tilde{q}_1}^{\tilde{\imath}_1}} [r_{\tilde{q}_1}^{\tilde{\imath}_1} - E_0(R_{\tilde{q}_1}^{\tilde{\imath}_1})] \prod_{\substack{q_2\\ q_2\neq q_1}} P_{q_2} \\
& + \sum_{\substack{q_1,\tilde{p}_1,\tilde{q}_2\\ \tilde{q}_2\neq q_1}} \sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_1>\tilde{\imath}_2}} \frac{\partial P_{q_1}}{\partial r_{\tilde{p}_1}^{\tilde{\imath}_1}} E_0\left(\frac{\partial R_{\tilde{p}_1}^{\tilde{\imath}_1}}{\partial R_{\tilde{q}_2}^{\tilde{\imath}_2}}\right) [r_{\tilde{q}_2}^{\tilde{\imath}_2} - E_0(R_{\tilde{q}_2}^{\tilde{\imath}_2})] \prod_{\substack{q_2\\ q_2\neq q_1}} P_{q_2} \\
& + \frac{1}{2} \sum_{\substack{q_1,\tilde{p}_1,q_2\\ q_2\neq q_1}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial P_{q_1}}{\partial r_{\tilde{p}_1}^{\tilde{\imath}_1}} \frac{\partial P_{q_2}}{\partial r_{\tilde{p}_1}^{\tilde{\imath}_2}} [E_0(R_{\tilde{p}_1}^{\tilde{\imath}_1} R_{\tilde{p}_1}^{\tilde{\imath}_2}) - E_0(R_{\tilde{p}_1}^{\tilde{\imath}_1}) E_0(R_{\tilde{p}_1}^{\tilde{\imath}_2})] \prod_{\substack{q_3\\ q_3\neq q_1, q_3\neq q_2}} P_{q_3} \\
& - \frac{1}{2} \sum_{\substack{q_1,\tilde{q}_1\\ q_1\neq\tilde{q}_1}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_{q_1}}{\partial r_{\tilde{q}_1}^{\tilde{\imath}_1} \partial r_{\tilde{q}_1}^{\tilde{\imath}_2}} [E_0(R_{\tilde{q}_1}^{\tilde{\imath}_1} R_{\tilde{q}_1}^{\tilde{\imath}_2}) - E_0(R_{\tilde{q}_1}^{\tilde{\imath}_1}) E_0(R_{\tilde{q}_1}^{\tilde{\imath}_2})] \prod_{\substack{q_2\\ q_2\neq q_1}} P_{q_2} \\
& - \sum_{\substack{q_1,\tilde{q}_1\\ \tilde{q}_1\neq q_1}} \sum_{\substack{\tilde{\imath}_1,\tilde{\imath}_2\\ \tilde{\imath}_1>\tilde{\imath}_2}} \frac{\partial P_{q_1}}{\partial r_{\tilde{q}_1}^{\tilde{\imath}_1}} E_0\left(\frac{\partial R_{\tilde{q}_1}^{\tilde{\imath}_1}}{\partial R_{q_1}^{\tilde{\imath}_2}}\right) [r_{q_1}^{\tilde{\imath}_2} - E_0(R_{q_1}^{\tilde{\imath}_2})] \prod_{\substack{q_2\\ q_2\neq q_1}} P_{q_2} \\
& + \frac{1}{2} \sum_{\substack{q_1,\tilde{q}_1,q_2,\tilde{q}_2\\ q_2\neq q_1,\tilde{q}_1\neq q_1\\ \tilde{q}_2\neq q_2}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial P_{q_1}}{\partial r_{\tilde{q}_1}^{\tilde{\imath}_1}} \frac{\partial P_{q_2}}{\partial r_{\tilde{q}_2}^{\tilde{\imath}_2}} [r_{\tilde{q}_1}^{\tilde{\imath}_1} - E_0(R_{\tilde{q}_1}^{\tilde{\imath}_1})][r_{\tilde{q}_2}^{\tilde{\imath}_2} - E_0(R_{\tilde{q}_2}^{\tilde{\imath}_2})] \prod_{\substack{q_3\\ q_3\neq q_1, q_3\neq q_2}} P_{q_3} \\
& + \frac{1}{2} \sum_{\substack{q_1,\tilde{q}_1,\tilde{q}_2\\ q_1\neq\tilde{q}_1,q_1\neq\tilde{q}_2}} \sum_{\tilde{\imath}_1,\tilde{\imath}_2} \frac{\partial^2 P_{q_1}}{\partial r_{\tilde{q}_1}^{\tilde{\imath}_1} \partial r_{\tilde{q}_2}^{\tilde{\imath}_2}} [r_{\tilde{q}_1}^{\tilde{\imath}_1} - E_0(R_{\tilde{q}_1}^{\tilde{\imath}_1})][r_{\tilde{q}_2}^{\tilde{\imath}_2} - E_0(R_{\tilde{q}_2}^{\tilde{\imath}_2})] \prod_{\substack{q_2\\ q_2\neq q_1}} P_{q_2} + O(\bar{W}^3).
\end{aligned}
$$

(A.12)

A.4. Transforming back to probability distribution. Equation (A.12) is a second-order approximation to a probability distribution, but it is not exactly a probability distribution. Since we wish to use $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ to compute maximum likelihood estimators of coupling parameters (i.e., find values of certain parameters that maximize $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$), we need to use an expression for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$ that is a true probability distribution. For most terms of (A.12), one can simply reverse the Taylor expansion to pull terms back into the product of P_q.

However, one cannot simply reverse the Taylor expansion for the common input terms, i.e., the third line (common input from a hidden node onto two measured nodes) and the fourth line ("common input" from a measured node onto a single measured node). For those two terms, we'll need to tease apart the effects from different time points. We use the notation defined in (3.9) for P_s^i, the probability distribution at a single time point i (as well as its second derivative, defined analogously by (3.9)). We rewrite the derivatives with respect to r in terms of the P_s^i and its derivatives. We also separate out the common input effects at a single time point, rewriting the third and fourth lines of (A.12) as[9]

$$
\begin{aligned}
&+\frac{1}{2}\sum_{\substack{q_1,\tilde{p}_1,q_2\\ q_2\neq q_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\frac{\partial P_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{p}_1}}\frac{\partial P_{q_2}}{\partial r^{\tilde{\imath}_2}_{\tilde{p}_1}}[E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1}R^{\tilde{\imath}_2}_{\tilde{p}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_1})]\prod_{\substack{q_3\\ q_3\neq q_1,q_3\neq q_2}}P_{q_3}\\
&-\frac{1}{2}\sum_{\substack{q_1,\tilde{q}_1\\ q_1\neq\tilde{q}_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\frac{\partial^2 P_{q_1}}{\partial r^{\tilde{\imath}_1}_{\tilde{q}_1}\partial r^{\tilde{\imath}_2}_{\tilde{q}_1}}[E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1}R^{\tilde{\imath}_2}_{\tilde{q}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{q}_1})]\prod_{\substack{q_2\\ q_2\neq q_1}}P_{q_2}\\
&=\sum_{\substack{q_1,\tilde{p}_1,q_2\\ q_2\neq q_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\sum_{\substack{\hat{\imath}_1,\hat{\imath}_2\\ \hat{\imath}_2<\hat{\imath}_1}}\bar{W}^{\tilde{\imath}_1,\hat{\imath}_1}_{\tilde{p}_1,q_1}\bar{W}^{\tilde{\imath}_2,\hat{\imath}_2}_{\tilde{p}_1,q_2}\frac{\partial P^{\hat{\imath}_1}_{q_1}}{\partial w}\frac{\partial P^{\hat{\imath}_2}_{q_2}}{\partial w}[E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1}R^{\tilde{\imath}_2}_{\tilde{p}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_1})]\frac{\prod_{q_3}P_{q_3}}{P^{\hat{\imath}_1}_{q_1}P^{\hat{\imath}_2}_{q_2}}\\
&+\frac{1}{2}\sum_{\substack{q_1,\tilde{p}_1,q_2\\ q_2\neq q_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\sum_{\hat{\imath}_1}\bar{W}^{\tilde{\imath}_1,\hat{\imath}_1}_{\tilde{p}_1,q_1}\bar{W}^{\tilde{\imath}_2,\hat{\imath}_1}_{\tilde{p}_1,q_2}\frac{\partial P^{\hat{\imath}_1}_{q_1}}{\partial w}\frac{\partial P^{\hat{\imath}_1}_{q_2}}{\partial w}[E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1}R^{\tilde{\imath}_2}_{\tilde{p}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{p}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{p}_1})]\frac{\prod_{q_3}P_{q_3}}{P^{\hat{\imath}_1}_{q_1}P^{\hat{\imath}_1}_{q_2}}\\
&-\sum_{\substack{q_1,\tilde{q}_1\\ q_1\neq\tilde{q}_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\sum_{\substack{\hat{\imath}_1,\hat{\imath}_2\\ \hat{\imath}_2<\hat{\imath}_1}}\bar{W}^{\tilde{\imath}_1,\hat{\imath}_1}_{\tilde{q}_1,q_1}\bar{W}^{\tilde{\imath}_2,\hat{\imath}_2}_{\tilde{q}_1,q_1}\frac{\partial P^{\hat{\imath}_1}_{q_1}}{\partial w}\frac{\partial P^{\hat{\imath}_2}_{q_1}}{\partial w}[E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1}R^{\tilde{\imath}_2}_{\tilde{q}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{q}_1})]\frac{\prod_{q_3}P_{q_3}}{P^{\hat{\imath}_1}_{q_1}P^{\hat{\imath}_2}_{q_1}}\\
&-\frac{1}{2}\sum_{\substack{q_1,\tilde{q}_1\\ q_1\neq\tilde{q}_1}}\sum_{\tilde{\imath}_1,\tilde{\imath}_2}\sum_{\hat{\imath}_1}\bar{W}^{\tilde{\imath}_1,\hat{\imath}_1}_{\tilde{q}_1,q_1}\bar{W}^{\tilde{\imath}_2,\hat{\imath}_1}_{\tilde{q}_1,q_1}\frac{\partial^2 P^{\hat{\imath}_1}_{q_1}}{\partial w^2}[E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1}R^{\tilde{\imath}_2}_{\tilde{q}_1})-E_0(R^{\tilde{\imath}_1}_{\tilde{q}_1})E_0(R^{\tilde{\imath}_2}_{\tilde{q}_1})]\frac{\prod_{q_3}P_{q_3}}{P^{\hat{\imath}_1}_{q_1}}.
\end{aligned}
$$

The last line in the above equation corresponds to the second-order effect of a single connection between two measured nodes. For this term, we cannot reverse the Taylor expansion to fold the term back into the product of the P_q and create a probability distribution. However, this term represents a second-order effect that is not summed over all nodes of the network (it is simply summed over the measured nodes, which we view as a small subset). If we modify our weak coupling assumption to allow us to ignore second-order terms that are not summed over all nodes, we can neglect this last term. Since we no longer have exactly a second-order approximation in $\bar{W}$, we denote the approximation by $\approx$.

With this approximation, we can reverse the Taylor expansion of the remaining terms of (A.12) and obtain (3.10) for $\Pr(\mathbf{R}_{\mathcal{Q}}|\mathbf{X})$, which is written as a probability distribution in terms of effective parameters.

Appendix B. Estimation of single-node parameters. We sketch our algorithm for determining the single-node parameters θ^i_s of model (4.2) that we used to analyze the results of our simulations. The parameters θ^i_s correspond to A_s, y_s, $\mathbf{h}_{\text{hist},s}$, and $\mathbf{h}_{\text{ext},s}$. We calculated maximum likelihood estimators of these parameters from measurements of R^i_s, the spikes of neuron s, and the stimulus $\mathbf{X}$.

We chose our form (4.2) of $\lambda_s(\cdot)$ so that $\lambda_s(\cdot)$ is convex and $\log\lambda_s(\cdot)$ is concave as a function of y_s, $\mathbf{h}_{\text{hist},s}$, and $\mathbf{h}_{\text{ext},s}$. In this way, for a fixed A_s, the log-likelihood surface (logarithm of (2.3)) is free of nonglobal local maxima [17], and we could use standard gradient ascent algorithms to find the maximum, conditioned on a value of A_s. (We used the Polak–Ribiere conjugate gradient algorithm as implemented in the GNU Scientific Library [6].)

[9] Note that all of the probabilities P^i_q that appear in a denominator are also a factor in the corresponding numerator. If a P^i_q that appears in a denominator were to be zero, one could still define the ratio by canceling the factor in the numerator.

Before calculating these maximum likelihood estimators, we calculated the absolute refractory period τ_s^{absref} as the minimum number of $\Delta t = 1$ ms time bins observed between spikes. Then, so that our model predicts absolutely no firing for τ_s^{absref} time steps after each spike, we set $h^i_{\text{hist},s} = -10^{100}$ for $i \leq \tau_s^{\text{absref}}$. To reduce the dimension of the parameter space, we restricted the remainder of the history kernel $\mathbf{h}_{\text{hist},s}$ to be in the subspace spanned by the vectors

$$B^k_{s,1}(i) = \sin\left(\pi k \left[2\frac{i-\tau_s^{\text{absref}}}{\tau_{s,1}} - \left(\frac{i-\tau_s^{\text{absref}}}{\tau_{s,1}}\right)^2\right]\right)$$

for $0 < i - \tau_s^{\text{absref}} < \tau_{s,1}$ and $B^k_{s,1}(i) = 0$ otherwise. (These vector are not orthogonal, so we applied Gram–Schmidt orthonormalization to obtain basis vectors.) We set $\tau_{s,1} = 60 - \tau_s^{\text{absref}}$ time bins. These basis vectors are analagous to those used in [8]; they can represent fine temporal structure for the time immediately after the spike but are smoother for longer time scales. We used 29 basis vectors $1 \leq k \leq 29$ (viewing the 30th basis vector as capturing the absolute refractory period).

We similarly reduced the dimension of $\mathbf{h}_{\text{ext},s}$ by using basis vectors that are a product of a Hartley basis function in space (to match the stimulus) and temporal basis functions similar to the $B^k_{s,1}$. The basis function indexed by k and l evaluated at time bin i and space bin j was based on

$$B^{k,l}_{s,2}(i,j) = \operatorname{cas}(2\pi l j/N_0) \sin\left(\pi k \left[2i/\tau_{s,2} - (i/\tau_{s,2})^2\right]\right)$$

for $0 < i < \tau_{s,2}$ and $B^{k,l}_{s,2}(i,j) = 0$ otherwise (again, we obtained orthogonal basis functions through Gram–Schmidt orthonormalization). As in the definition of the stimulus (section 4.1.1), $\operatorname{cas} x = \cos x + \sin x$ and $N_0 = 100$. We set $\tau_{s,1} = 200$ time bins. We used the 210 basis vectors $-10 \leq l \leq 10$ and $1 \leq k \leq 10$.

As mentioned above, we calculated y_0 and the coefficients of the basis functions to maximize the log-likelihood, given a fixed value of A_s. This defines all parameters as a function of A_s. We then search for a value of A_s that maximizes the log-likelihood while keeping the other parameters set at this function of A_s. We use this procedure since the log-likelihood surface may not be well-behaved as a function of A_s.

Recall that the causal connection measure W and the common input measure U are maximum likelihood estimators based on (3.15), which depends on these values of θ^i_s. To reduce bias at this stage, we calculate the θ^i_s using cross-validation. We divided the data into 4 segments. For each time bin i from one of these segments, we calculated the parameters θ^i_q using only the data in the other 3 segments. (For computation efficiency, we don't recalculate A_s four times but base A_s from calculations using all of the data.)

Appendix C. Monte Carlo estimates of single-node expected values. The estimation of connectivity parameters is based on (3.15) for $\Pr(\mathbf{R}_\mathcal{Q}|\mathbf{X})$, the probability distribution of measured node activity. Once the effective parameters θ_q of the measured nodes have been estimated, the only unknown quantities in (3.15) are the causal connection W and common input U parameters. However, some of the known quantities are given as expected values of functions of the measured node activities as predicted by the averaged model (2.3). Although these expected values are completely determined by the averaged model and the known effective parameters θ_q, computing them explicitly would be impractical, as one would need to enumerate all possible sequences of the history of each node and average over them all.[10] Instead, for each measured node, we use the averaged model (2.3) to randomly generate sequences of activity in order to estimate these expected values using Monte Carlo.

There are three different expected values that appear in (3.15b). They are the average activity $E_0(R_q^i)$ at a given time bin, the second moment $E_0(R_q^i R_q^{i-j})$, and the expected value involving the derivative $E_0(R_q^i(\partial P_q^{i-j}/\partial w)/P_q^{i-j})$. To estimate these expected values via Monte Carlo, we randomly generate a sequence $\mathbf{R}_q$ of the activity of the node from the averaged model (2.3). Then, at each time point i (ignoring initial time points for which we don't have enough preceeding history), we make a sample estimate of each expected value, as described below. We repeat this process 1000 times, setting our final estimates to be averages of these 1000 samples.

To compute the average activity $E_0(R_q^i)$, we could simply record the sampled R_q^i and average these. However, we improve our estimate by taking advantage of the fact that we have an analytic expression for the mean of R_q^i conditioned on the history $\mathbf{R}_q^{<i}$ (for the Poisson distribution it is simply $\lambda_q(\mathbf{R}_q^{<i}, \mathbf{x}, 0; \theta_q^i)$). Our estimate of $E_0(R_q^i)$ is the average of such conditioned means.

In our examples, we use the Poisson distribution (section 3.4) for the probability distribution $P_q(R_q^i, \mathbf{R}_q^{<i}, \cdot)$ of R_q^i conditioned on the history $\mathbf{R}_q^{<i}$. However, one must remember that R_q^i no longer has a probability distribution of the form $P_q(R_q^i, \mathbf{R}_q^{<i}, \cdot)$ once one averages over all possible histories. Since R_q^i does not have a Poisson distribution, one must resist the urge to estimate the variance $E_0((R_q^i)^2) - E_0(R_q^i)E_0(R_q^i)$ as being equal to the mean $E_0(R_q^i)$. Instead, one must calculate $E_0((R_q^i)^2)$ in the same manner as that described above for calculating $E_0(R_q^i)$. Since we have an analytic formula for the second moment of R_q^i conditioned on this history $\mathbf{R}_q^{<i}$ (for the Poisson distribution, it is $\lambda_q^2 + \lambda_q$), we can estimate $E_0((R_q^i)^2)$ as the average of such conditioned second moments. To estimate $E_0(R_q^i R_q^{i-j})$ (for $j > 0$), we take our analytic expression for the average of R_q^i conditioned the history $\mathbf{R}_q^{<i}$, multiply it by the sampled value of R_q^{i-j}, and average over all samples.

For the derivative term, $E_0(R_q^i(\partial P_q^{i-j}/\partial w)/P_q^{i-j})$, we first look at the $j = 0$ case. We can rewrite it as

$$E_0\left(R_q^i \frac{\partial P_q^i}{\partial w}\frac{1}{P_q^i}\right) = \sum_{\mathbf{r}_q^{<i+1}} r_q^i \frac{\partial P_q^i}{\partial w}\frac{1}{P_q^i}\prod_{\tilde{\imath}\le i} P_q^{\tilde{\imath}} = \sum_{\mathbf{r}_q^{<i+1}} r_q^i \frac{\partial P_q^i}{\partial w}\prod_{\tilde{\imath}<i} P_q^{\tilde{\imath}}, \tag{C.1}$$

where the sum is over all possible values of the r_q^k for $k \le i$. At least for the Poisson distribution, we can calculate an analytic expression[11] for $\sum_{r_q^i} r_q^i \partial P_q^i/\partial w$, and we take the average of that quantity over all samples. For $j > 0$, the term is

$$E_0\left(R_q^i \frac{\partial P_q^{i-j}}{\partial w}\frac{1}{P_q^{i-j}}\right) = \sum_{\mathbf{r}_q^{<i+1}} r_q^i \frac{\partial P_q^{i-j}}{\partial w}\frac{1}{P_q^{i-j}}\prod_{\tilde{\imath}\le i} P_q^{\tilde{\imath}}. \tag{C.2}$$

[10] Hence, the computational cost would increase exponentially in length of the history that could affect the activity.

[11] For the Poisson distribution, $\sum_{r_q^i} r_q^i \partial P_q^i/\partial w = \partial_w \lambda_q(\mathbf{r}_q^{<i}, \mathbf{x}, 0; \theta_q^i)$.

In this case, we take the average value of R_q^i conditioned on the sampled history and multiply it by $(\partial P_q^{i-j}/\partial w)/P_q^{i-j}$. We average this quantity over all samples.[12]

INVERSION OF SPHERICAL MEANS AND THE WAVE EQUATION IN EVEN DIMENSIONS[*]

DAVID FINCH[†], MARKUS HALTMEIER[‡], AND RAKESH[§]

Abstract. We establish inversion formulas of the so-called filtered back-projection type to recover a function supported in the ball in even dimensions from its spherical means over spheres centered on the boundary of the ball. We also find several formulas to recover initial data of the form $(f, 0)$ (or $(0, g)$) for the free space wave equation in even dimensions from the trace of the solution on the boundary of the ball, provided that the initial data has support in the ball.

Key words. spherical means, thermoacoustic tomography, wave equation

1. Introduction and statement of results.

The problem of determining a function from a subset of its spherical means has a rich history in pure and applied mathematics. Our interest in the subject was provoked by the new medical imaging technologies called thermoacoustic and photoacoustic tomography. The idea behind these [10, 16] is to illuminate an object by a short burst of radiofrequency or optical energy which causes rapid (though small in magnitude) thermal expansion which generates an acoustic wave. The acoustic wave can be measured on the periphery or in the exterior of the object. The inverse problem we consider is to find the distribution of the absorbed energy throughout the body. This is of interest, since the amount of energy absorbed at different points may be diagnostic of disease or indicative of uptake of probes tagged to metabolic processes or gene expression [9]. For a more thorough discussion of the modeling and biomedical applications, the reader is referred to the recent survey [17]. If the illuminating energy is impulsive in time, the propagation may be modeled as an initial value problem for the wave equation. The problem of recovering the initial data of a solution of the wave equation from the value of the solution on the boundary of a domain is of mathematical interest in every dimension, but for the application to thermo-/photoacoustic tomography it would appear that the three dimensional case is the only one of interest, since sound propagation is not confined to a lower dimensional submanifold. However, there exist methods of measuring the generated wave field which do not rely on point measurements of the sort that would be generated by an (idealized) acoustic transducer. In particular, integrating line detectors, which have been studied in [3, 14], in effect compute the integral of the acoustic wave field along a specified line. In this paper, we work under the assumption that the speed of sound, c, is constant throughout the body, and since the x-ray transform in a given direction of a solution of the three dimensional wave equation is a solution of the two dimensional wave equation, the problem is

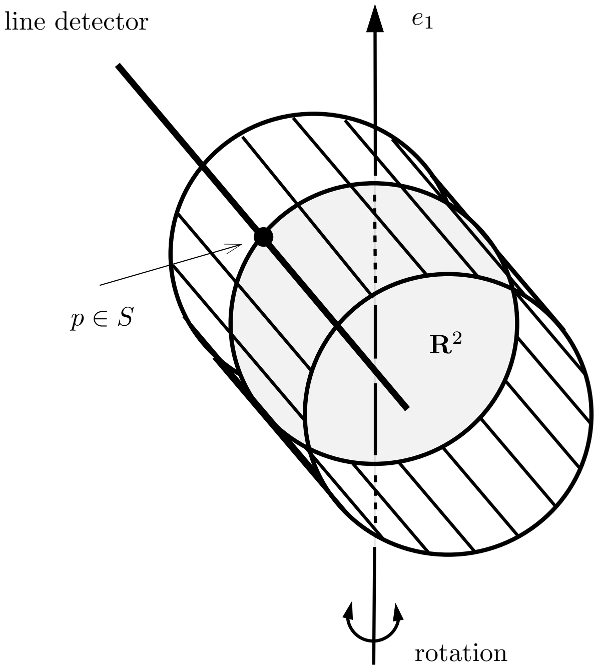

FIG. 1.1. *Principle of thermoacoustic tomography with integrating line detectors. A cylindrical array of line detectors records the acoustic field and is rotated around the axis e_1. For each fixed rotation angle the array outputs the x-ray transform (projection along straight lines) of the trace of the solution of the wave equation restricted to the boundary S of the disk. The initial condition is given by the x-ray transform of the initially induced pressure restricted to lines orthogonal to the base of the cylinder.*

transformed. If a circular array of line detectors is rotated around an axis orthogonal to the direction of the line detectors [7, 14], then for each fixed rotation angle the measurement provides the trace of the solution of the two dimensional wave equation on the circle corresponding to the array. The initial data of this two dimensional problem is the x-ray transform of the three dimensional initial data. If the initial data can be recovered in the disk bounded by the detector array and assuming that the projection of the object to be imaged lies in this disk, then the problem of recovering the three dimensional initial data is reduced to the inversion of the x-ray transform in each plane orthogonal to the axis of rotation. One such two dimensional problem is illustrated in Figure 1.1.

To our knowledge, the first work to tackle the problem of recovering a function from its circular means with centers on a circle was [13], whose author was interested in ultrasound reflectivity tomography. He found an inversion method based on harmonic decomposition and, for each harmonic, the inversion of a Hankel transform. This method has been the basis for most subsequent work on exact inversion of circular means. The inversion of the Hankel transform involves a quotient of a Hankel transform of a harmonic component of the data and a Bessel function. That this quotient be well defined turns out to be a condition on the range of the circular mean transform [2]. See also [1] for range results on the spherical mean transform on functions supported in a ball in all dimensions and [6] for range results for the wave trace map for functions supported in the ball in odd dimensions.

In Finch, Patch, and Rakesh [5], several formulas were found to recover a smooth function f with support in the closure $\overline{B}$ of the open ball $B \subseteq \mathbf{R}^n$ from the trace of the solution of the wave equation on the product $\partial B \times [0, \operatorname{diam}(B)]$, provided that the space dimension is odd. Specifically, if u is the solution of the initial value problem

$$u_{tt} - \Delta u = 0 \quad \text{in } \mathbf{R}^n \times [0, \infty), \tag{1.1}$$

$$u(., t = 0) = f(.), \quad u_t(., t = 0) = 0, \tag{1.2}$$

where f is smooth and has support in the $\overline{B}$, then several formulas were found to recover f from $u(p, t)$ for $p \in S := \partial B$ and $t \in \mathbf{R}^+$.

Finch and Rakesh tried, at that time, to extend the method to even dimensions but did not see a way. Recently, Haltmeier tried numerical experiments using a two dimensional analogue of one of the inversion formulas and found that it gave excellent reconstructions. This prompted our reexamination of the problem. Among the results of this paper is a proof of the validity of this formula.

To describe our results, we introduce some notation. The spherical mean transform $\mathcal{M}$ is defined by

$$(\mathcal{M} f)(x, r) = \frac{1}{|S^{n-1}|} \int_{S^{n-1}} f(x + r\theta) \, dS(\theta) \tag{1.3}$$

for $f \in C^\infty(\mathbf{R}^n)$ and $(x, r) \in \mathbf{R}^n \times [0, \infty)$. In this expression, $|S^{n-1}|$ denotes the area of the unit sphere S^{n-1} in $\mathbf{R}^n$ and $dS(\theta)$ denotes the area measure on the sphere. In general, we write the area measure on a sphere of any radius as dS, except when $n = 2$ when we write ds. We will denote the (partial) derivative of a function q with respect to a variable r by $\partial_r q$, except in a few formulas where the subscript notation q_r is used. At several points we use D_r to denote the operator

$$(D_r u)(r) := \frac{(\partial_r u)(r)}{2r}$$

acting on smooth (even) functions u with compact support. Moreover, r will be used to denote the operator that multiplies a function $u(r)$ by r.

Our first set of results is a pair of inversion formulas for the spherical mean transform in even dimensions. We state and prove these first in dimension two, that is, for the circular mean transform.

Theorem 1.1. *Let $D \subset \mathbf{R}^2$ be the disk of radius R_0 centered at the origin, let $S := \partial D$ denote the boundary circle, and let $f \in C^\infty(\mathbf{R}^2)$ with $\operatorname{supp} f \subset \overline{D}$. Then, for $x \in D$,*

$$f(x) = \frac{1}{2\pi R_0} \Delta_x \int_S \int_0^{2R_0} r \, (\mathcal{M} f)(p, r) \log \left| r^2 - |x - p|^2 \right| dr \, ds(p) \tag{1.4}$$

and

$$f(x) = \frac{1}{2\pi R_0} \int_S \int_0^{2R_0} (\partial_r r \partial_r \mathcal{M} f)(p, r) \log \left| r^2 - |x - p|^2 \right| dr \, ds(p). \tag{1.5}$$

In Theorem 1.1, $\partial_r r \partial_r \mathcal{M} f$ denotes the composition of ∂_r, r, ∂_r, and $\mathcal{M}$ applied to f. The same convention will be used throughout the article to denote the composition of any operators.

While $\mathcal{M} f$ has a natural extension to the negative reals as an even function, we instead take the odd extension in the second variable. In view of the support hypothesis on f, this extension is also smooth. Then formula (1.5) has the following corollary.

COROLLARY 1.2. *With the same hypotheses as in Theorem* 1.1*, and $\mathcal{M} f$ extended as an odd function in the second variable r, f can be recovered for $x \in D$ by*

$$f(x) = \frac{1}{2\pi R_0} \int_S \int_{-2R_0}^{2R_0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{|x-p|-r}\, dr\, ds(p) \tag{1.6}$$

and

$$f(x) = \frac{1}{2\pi R_0} \int_S |x-p| \int_{-2R_0}^{2R_0} \frac{(\partial_r \mathcal{M} f)(p,r)}{|x-p|-r}\, dr\, ds(p), \tag{1.7}$$

where the inner integrals are taken in the principal value sense.

These forms are very close to the standard inversion formula for the Radon transform in the plane [12, eq. (2.5)].

In higher even dimensions we prove a similar pair of results.

THEOREM 1.3. *Let $B \subset \mathbf{R}^n$, $n > 2$ even, be the ball of radius R_0 centered at the origin, let $S := \partial B$ be the boundary of the ball, set*

$$c_n = (-1)^{(n-2)/2} 2((n-2)/2)!\pi^{n/2} = (-1)^{(n-2)/2}[((n-2)/2)!]^2 |S^{n-1}|,$$

and let $f \in C^\infty(\mathbf{R}^n)$ have support in $\overline{B}$. Then, for $x \in B$,

$$f(x) = \frac{1}{c_n R_0} \Delta_x \int_S \int_0^{2R_0} \log\left|r^2 - |x-p|^2\right| (rD_r^{n-2} r^{n-2} \mathcal{M} f)(p,r)\, dr\, dS(p), \tag{1.8}$$

$$f(x) = \frac{2}{c_n R_0} \int_S \int_0^{2R_0} \log\left|r^2 - |x-p|^2\right| (rD_r^{n-1} r^{n-1} \partial_r \mathcal{M} f)(p,r)\, dr\, dS(p). \tag{1.9}$$

Recently, Kunyansky [11] has also established inversion formulas of the filtered back-projection type for the spherical mean transform. His method and results appear to be very different from ours.

For some results, it will be more convenient to use the wave equation (1.1) with initial condition

$$u(.,t=0) = 0, \quad u_t(.,t=0) = f(.). \tag{1.10}$$

It is obvious that the solution of (1.1) with initial values (1.2) is the time derivative of the solution of (1.1) with initial values (1.10). We denote by $\mathcal{P}$ the operator which takes smooth initial data with support in $\overline{B}$ to the solution of (1.1), (1.10) restricted to $S \times [0,\infty)$ and by $\mathcal{W}$ the operator taking f to the solution of (1.1), (1.2) restricted to $S \times [0,\infty)$. These operators are simply related by $\mathcal{W} = \partial_t \mathcal{P}$. An explicit representation for $\mathcal{P}$ comes from the well-known formula [4]

$$u(p,t) = \frac{1}{(n-2)!} \partial_t^{n-2} \int_0^t r(t^2-r^2)^{(n-3)/2} (\mathcal{M} f)(p,r)\, dr, \tag{1.11}$$

giving the solution of the initial value problem (1.1), (1.10), in dimension $n \geq 2$. We denote by $\mathcal{P}^*$ and $\mathcal{W}^* = -\mathcal{P}^* \partial_t$ the formal L^2 adjoints of $\mathcal{P}$ and $\mathcal{W}$ mapping from smooth functions $u \in C^\infty(S \times [0,\infty))$ with sufficient decay in the second variable. An explicit expression for $\mathcal{P}^* u$ will be given in section 3.

We have two types of inversion results for the wave equation. The first type is based on the inversion results for the spherical mean transform, since the spherical mean transform itself can be recovered from the solution of the wave equation by solving an Abel-type equation. In dimension two, this approach yields the following result.

Theorem 1.4. *Let $D \subset \mathbf{R}^2$ be the open disc with radius R_0, and let $S := \partial D$ denote the boundary circle. Then there exists a kernel function $K : [0, 2R_0]^2 \to \mathbf{R}$ such that for any $f \in C^\infty(\mathbf{R}^2)$ with support in $\overline{D}$ and any $x \in D$*

$$f(x) = \frac{1}{R_0 \pi^2} \Delta_x \int_S \int_0^{2R_0} (\mathcal{W} f)(p,t) K(t, |x-p|)\, dt\, ds(p). \tag{1.12}$$

An analytic expression for K will be given in section 3.

Theorem 1.4 provides inversion formulas of the filtered back-projection type for reconstruction of f from $(\mathcal{W} f)(p,t) = (\partial_t \mathcal{P} f)(p,t)$ using only data with $t \in [0, 2R_0]$, despite the unbounded support of $\mathcal{W} f$ and $\mathcal{P} f$ in t.

The second type of inversion results holds in all even dimensions and takes the following form.

Theorem 1.5. *Let f be smooth and supported in closure of the ball B of radius R_0 in $\mathbf{R}^{2m}$, and let $\mathcal{P} f$ and $\mathcal{W} f$ be as above. Then, for $x \in B$,*

$$f(x) = -\frac{2}{R_0} \left(\mathcal{P}^* t \partial_t^2 \mathcal{P} f\right)(x), \tag{1.13}$$

$$f(x) = \frac{2}{R_0} \left(\mathcal{W}^* t \mathcal{W} f\right)(x) = -\frac{2}{R_0} \left(\mathcal{P}^* \partial_t t \partial_t \mathcal{P} f\right)(x). \tag{1.14}$$

We will prove (1.13) in dimension $n = 2m = 2$ directly. The higher dimensional case of (1.13), and (1.14) in all dimensions, are consequences of the following trace identities, relating the L^2 inner product of the initial data to the weighted L^2 inner product of the traces of the solutions of the wave equation.

Theorem 1.6. *Let f, g be smooth and supported in the ball B of radius R_0, in $\mathbf{R}^{2m}$ with $m \geq 1$, let $S := \partial B$, and let u (resp., v) be the solution of the initial value problem* (1.1), (1.10) *with initial value f (resp., g). Then*

$$\int_B f(x) g(x)\, dx = -\frac{2}{R_0} \int_S \int_0^\infty t u_{tt}(p,t) v(p,t)\, dt\, dS(p), \tag{1.15}$$

$$\int_B f(x) g(x)\, dx = \frac{2}{R_0} \int_S \int_0^\infty t u_t(p,t) v_t(p,t)\, dt\, dS(p). \tag{1.16}$$

In the proof of this theorem, (1.15) for $n = 2$ follows from (1.13) for $n = 2$, while (1.15) in higher even dimensions is derived from the $n = 2$ case; (1.16) is a consequence of (1.15) in all dimensions. We remark that these identities were already proved in [5] for odd dimensions, and so they hold for all dimensions.

Section 2 is devoted to the proof of the inversion formulas for the spherical mean transform, that is, Theorems 1.1 and 1.3 and Corollary 1.2. Section 3 treats the wave equation and contains the proofs of Theorems 1.4, 1.5, and 1.6. This is followed by a section reporting on the implementation of the various reconstruction formulas of the preceding sections and results of numerical tests in dimension two.

2. Spherical means. In this section we prove the theorems related to the inversion from spherical means and Corollary 1.2. We begin by establishing an elementary integral identity, which is the key to the results in this paper.

PROPOSITION 2.1. *Let $D \subset \mathbf{R}^2$ be the disk of radius R_0, and let $S = \partial D$ be the boundary circle. Then, for $x, y \in D$ with $x \neq y$,*

$$\int_S \log \left| |x-p|^2 - |y-p|^2 \right| ds(p) = 2\pi R_0 \log|x-y| + 2\pi R_0 \log R_0. \tag{2.1}$$

Proof. Let $x \neq y$ both lie in D, and let I denote the integral on the left-hand side of (2.1). Expanding the argument of the logarithm as

$$\left| |x-p|^2 - |y-p|^2 \right| = 2R_0|x-y| \left| \left(\frac{x+y}{2R_0} - \frac{p}{R_0} \right) \cdot \frac{x-y}{|x-y|} \right|,$$

setting $e := \frac{x-y}{|x-y|}$, and writing $p = R_0\theta$ for $\theta \in S^1$, we have

$$I = 2\pi R_0 \log\left(2R_0|x-y|\right) + R_0 \int_{S^1} \log|e\cdot\theta - a|\, d\theta, \tag{2.2}$$

where

$$a = \frac{x+y}{2R_0} \cdot e = \frac{|x|^2 - |y|^2}{2R_0|x-y|}.$$

We note that $|a| < 1$.

Using the parameterization $\theta = \cos(\phi)e + \sin(\phi)e^{\perp}$, the integral term on the right-hand side of (2.2) has the form

$$R_0 \int_0^{2\pi} \log|\cos\phi - a|\, d\phi.$$

Writing $a = \cos\alpha$ and using the *sum to product* trigonometric identity $\cos\phi - \cos\alpha = -2\sin((\phi+\alpha)/2)\sin((\phi-\alpha)/2)$, this is equal to

$$R_0 \int_0^{2\pi} \left(\log 2 + \log|\sin((\phi+\alpha)/2)| + \log|\sin((\phi-\alpha)/2)|\right) d\phi.$$

By periodicity and two linear changes of variable, this reduces to

$$R_0 \int_0^{2\pi} \left(\log 2 + 2\log|\sin(\phi/2)|\right) d\phi = 2R_0\pi \log 2 + 4R_0 \int_0^{\pi} \log\sin u\, du,$$

which is independent of α and hence of x and y. The latter integral can be found in tables and is equal to $-R_0\pi\log 2$, and so the sum is $-2\pi R_0 \log 2$. Substituting in (2.2) gives the desired result. □

Proposition 2.1 is already enough to establish Theorem 1.1.

Proof of Theorem 1.1. Let $f \in C^\infty(\mathbf{R}^2)$ be supported in $\overline{D}$, and let p be any point in $S = \partial B$. Using the definition of $\mathcal{M} f$ and Fubini's theorem, we have that

$$\int_0^{2R_0} (r\,\mathcal{M} f)(p,r) q(r)\, dr = \frac{1}{2\pi} \int_{\mathbf{R}^2} f(p+z) q(|z|)\, dz \tag{2.3}$$

for any measurable function q, provided that the product of functions on the right-hand side is absolutely integrable. Applying this with $q(r) = \log\left|r^2 - |x-p|^2\right|$ and making the change of variables $y = p + z$ gives

$$\int_S \int_0^{2R_0} (r\,\mathcal{M})(f)(p,r) \log\left|r^2 - |x-p|^2\right| dr\, ds(p)$$
$$= \frac{1}{2\pi} \int_S \int_{\mathbf{R}^2} f(y) \log\left||y-p|^2 - |x-p|^2\right| dy\, ds(p).$$

Fubini's theorem again justifies the change of order of integration in the iterated integral on the right-hand side, and so

$$\frac{1}{2\pi} \int_{\mathbf{R}^2} f(y) \int_S \log\left||y-p|^2 - |x-p|^2\right| ds(p)\, dy$$
$$= \frac{2\pi R_0}{2\pi} \int_{\mathbf{R}^2} f(y)(\log|x-y| + \log R_0)\, dy$$

upon application of (2.1). Recalling that for any constant c, $1/(2\pi)\log|x-y| + c$ is a fundamental solution of the Laplacian in $\mathbf{R}^2$, we have

$$f(x) = \frac{1}{2\pi R_0} \Delta_x \int_S \int_0^{2R_0} (r\,\mathcal{M}\,f)(p,r) \log|r^2 - |x-p|^2|\, dr\, ds(p),$$

which proves (1.4).

The second formula, (1.5), has a similar proof. In this case, we use that the spherical means satisfy the Euler–Poisson–Darboux equation [4]

$$(\partial_r^2\,\mathcal{M}\,f)(x,r) + \frac{1}{r}(\partial_r\,\mathcal{M}\,f)(x,r) = (\Delta\,\mathcal{M}\,f)(x,r) = (\mathcal{M}\,\Delta f)(x,r).$$

The left-hand side of the Darboux equation may be written as $(1/r)(\partial_r r \partial_r\,\mathcal{M}\,f)(x,r)$, and so the expression on the right-hand side of (1.5) may be rewritten as

$$\frac{1}{2\pi R_0} \int_S \int_0^{2R_0} (r\,\mathcal{M}\,\Delta f)(p,r) \log\left|r^2 - |x-p|^2\right| dr\, ds(p). \tag{2.4}$$

Again applying (2.3), now with the function $q(r) = r\log\left|r^2 - |x-p|^2\right|$ and Δf instead of f, interchanging the order of integration and using (2.1) shows that the expression (2.4) is equal to

$$\frac{1}{2\pi} \int_{\mathbf{R}^2} \Delta_y f(y)(\log|x-y| + \log R_0)\, dy = f(x),$$

since no boundary terms arise in view of the support hypothesis on f. □

Proof of Corollary 1.2. Let $x \in D$, and let

$$U(p,x) := \int_0^{2R_0} \left(\partial_r r \partial_r\,\mathcal{M}\,f\right)(p,r) \log\left|r^2 - |x-p|^2\right| dr$$

denote the inner integral in (1.5). Taking the support of f into account, writing the logarithm as

$$\log\left|r^2 - |x-p|^2\right| = \log|r - |x-p|| + \log|r + |x-p||\,,$$

and integrating (1.5) by parts leads to

$$U(p,x) = -P.V.\int_0^\infty \frac{(r\partial_r \mathcal{M} f)(p,r)}{r-|x-p|}\,dr - \int_0^\infty \frac{(r\partial_r \mathcal{M} f)(p,r)}{r+|x-p|}\,dr.$$

Here we have used that the distributional derivative of $\log|r|$ is $P.V.\frac{1}{r}$ as well as an ordinary integration by parts. Therefore (1.5) implies that

$$\begin{aligned} f(x) &= \frac{1}{2\pi R_0}\int_S U(p,x)\,ds(p) \\ &= \frac{-1}{2\pi R_0}\int_S\int_0^{2R_0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{r-|x-p|}\,dr\,ds(p) \\ &\quad - \frac{1}{2\pi R_0}\int_S\int_0^{2R_0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{r+|x-p|}\,dr\,ds(p), \end{aligned} \tag{2.5}$$

where the inner integral of the first term on the right-hand side is taken in the principal value sense. The odd extension of $\mathcal{M} f$, $\mathcal{M} f(p,-r) := -\mathcal{M} f(p,r)$, is smooth on $\mathbf{R}$ since $\mathcal{M} f$ vanishes to infinite order at $r=0$ by the support hypothesis on f and $(r\partial_r \mathcal{M} f)(p,r)$ is an odd function in r. Substituting $r=-r$ into the last integral in (2.5) gives

$$\begin{aligned} f(x) = \frac{-1}{2\pi R_0}&\int_S\int_0^{2R_0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{r-|x-p|}\,dr\,ds(p) \\ - \frac{1}{2\pi R_0}&\int_S\int_{-2R_0}^{0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{r-|x-p|}\,dr\,ds(p) \end{aligned}$$

and hence

$$f(x) = \frac{1}{2\pi R_0}\int_S\int_{-2R_0}^{2R_0} \frac{(r\partial_r \mathcal{M} f)(p,r)}{|x-p|-r}\,dr\,ds(p).$$

This is (1.6). To prove (1.7), it suffices to write

$$\frac{r}{|x-p|-r} = -1 + \frac{|x-p|}{|x-p|-r}$$

in (1.6) and to note that $\int_{-2R_0}^{2R_0}(\partial_r \mathcal{M} f)(p,r)\,dr = 0$ by the support hypothesis on f. □

2.1. Proof of Theorem 1.3. We have found several proofs of Theorem 1.3, the extension of Theorem 1.1 to higher even dimensions. The one we present is based on reduction of the higher dimensional problem to the two dimensional case already established. Another, which is not presented in this article, is based on an extension of (2.1) to higher dimensions.

We first observe that by a dilation, we may reduce the problem to the case when f is supported in the unit ball. Tracing through the formulas (1.8) and (1.9) it is routine to verify that scaling from the unit ball to the ball of radius R_0 introduces a factor of R_0. To simplify notation, we shall now suppose that f is supported in the unit ball B. Let Q and N denote the operators

$$(Qf)(x) = \Delta_x \int_S\int_0^2 (rD_r^{n-2}r^{n-2}\mathcal{M} f)(p,r)\log\left|r^2-|x-p|^2\right|\,dr\,dS(p), \tag{2.6}$$

$$(Nf)(x) = \int_S\int_0^2 (rD_r^{n-1}r^{n-1}\partial_r\mathcal{M} f)(p,r)\log\left|r^2-|x-p|^2\right|\,dr\,dS(p), \tag{2.7}$$

which map $f \in C^\infty(\mathbf{R}^n)$ supported in $\overline{B}$ to constant multiples of the right-hand sides of (1.8) and (1.9). Moreover, $\langle f, g\rangle$ denotes the L^2 product of two functions supported in $\overline{B}$. To establish $Qf = c_n f$ and $Nf = (c_n/2)f$ we will use the following auxiliary results.

Proposition 2.2. *Let f, g be smooth and supported in $\overline{B}$. Then*

$$\int_{\mathbf{R}^n} (Qf)(x)g(x)\,dx = \langle Qf, g\rangle = 2\langle f, Ng\rangle = 2\int_{\mathbf{R}^n} f(x)(Ng)(x)\,dx. \tag{2.8}$$

Proof. Let $F = \mathcal{M}f$ and $G = \mathcal{M}g$. We introduce the temporary notation $\tilde{F}(p,r) = rD_r^{n-2}r^{n-2}F(p,r)$. Using the self-adjointness of Δ, applying Fubini's theorem and an n-dimensional analogue of (2.3), we obtain

$$\begin{aligned}
\langle Qf, g\rangle &= \int_B \left(\int_S \int_0^2 (rD_r^{n-2}r^{n-2}F)(p,r)\log\left|r^2 - |x-p|^2\right| dr\,dS(p)\right)(\Delta_x g)(x)\,dx \\
&= |S^{n-1}| \int_S \int_0^2 \left(\int_0^2 \tilde{F}(p,r)\log\left|r^2 - \bar{r}^2\right| (\mathcal{M}\,\Delta_x g)(p,\bar{r})\bar{r}^{n-1}\,d\bar{r}\right) dr\,dS(p) \\
&= |S^{n-1}| \int_S \int_0^2 \left(\int_0^2 \tilde{F}(p,r)\log\left|r^2 - \bar{r}^2\right| dr\right) (\mathcal{M}\,\Delta_x g)(p,\bar{r})\bar{r}^{n-1}\,d\bar{r}\,dS(p) \\
&= |S^{n-1}| \int_S \int_0^2 \left(\int_0^2 \tilde{F}(p,r)\log\left|r^2 - \bar{r}^2\right| dr\right) \partial_{\bar{r}}\bar{r}^{n-1}\partial_{\bar{r}}G(p,\bar{r})\,d\bar{r}\,dS(p). \qquad (2.9)
\end{aligned}$$

To justify the last equation it is used that G satisfies the Euler–Poisson–Darboux equation and the identity $\bar{r}^{n-1}(\partial_{\bar{r}}^2 + \frac{n-1}{\bar{r}}\partial_{\bar{r}}) = \partial_{\bar{r}}(\bar{r}^{n-1}\partial_{\bar{r}})$. Applying the identities $(D_r^{n-2})^* r\log|r^2 - \bar{r}^2| = (-1)^{n-2}rD_r^{n-2}\log|r^2-\bar{r}^2| = rD_{\bar{r}}^{n-2}\log|r^2-\bar{r}^2|$ in two stages to the last expression, this becomes

$$\begin{aligned}
&|S^{n-1}| \int_S \int_0^2 \left(\int_0^2 r^{n-1}F(p,r)D_{\bar{r}}^{n-2}\log\left|r^2-\bar{r}^2\right| dr\right)\left(\partial_{\bar{r}}\bar{r}^{n-1}\partial_{\bar{r}}G(p,\bar{r})\right) d\bar{r}\,dS(p) \\
&\quad= \int_S \int_0^2 \left(\int_B f(y)D_{\bar{r}}^{n-2}\log\left||y-p|^2 - \bar{r}^2\right| dy\right)\left(\partial_{\bar{r}}\bar{r}^{n-1}\partial_{\bar{r}}G(p,\bar{r})\right) d\bar{r}\,dS(p) \\
&\quad= \int_B \left(\int_S \int_0^2 \log\left||y-p|^2 - \bar{r}^2\right| ((D_{\bar{r}}^*)^{n-2}\partial_{\bar{r}}\bar{r}^{n-1}\partial_{\bar{r}}G)(p,\bar{r})\,d\bar{r}\,dS(p)\right) f(y)\,dy
\end{aligned}$$

after applying Fubini's theorem. This is finally seen to be equal to $\langle f, 2Ng\rangle$ since $(D_{\bar{r}}^{n-2})^*\partial_{\bar{r}} = 2\bar{r}(-1)^{n-2}D_{\bar{r}}^{n-1}$. □

We now look at the spherical means of products

$$f(x) = \rho^k\alpha(\rho)\Phi(\theta), \tag{2.10}$$

where $x = \rho\theta$ with $\rho \geq 0$, $\theta \in S^{n-1}$, Φ is a spherical harmonic of degree k, and $\alpha : \mathbf{R} \to \mathbf{R}$ is an even smooth function supported in $[-1,1]$. Let $F := \mathcal{M}f$ be extended to an even function in the second component, and let $\nu = n + 2k$. Then F satisfies the initial value problem (IVP) for the Euler–Poisson–Darboux equation

$$\left(\partial_r^2 F + \frac{n-1}{r}\partial_r F\right)(x,r) = \Delta_x F(x,r), \qquad (x,r) \in \mathbf{R}^n \times \mathbf{R}, \tag{2.11}$$

$$F(x,0) = \alpha(\rho)\rho^k\Phi(\theta), \quad \partial_r F(x,0) = 0, \qquad x \in \mathbf{R}^n, \tag{2.12}$$

and, conversely, any solution of (2.11), (2.12) is the spherical mean of the initial values. The unique solution of (2.11), (2.12) has the form $F(x,r) = \rho^k A(\rho,r)\Phi(\theta)$, where $A(\rho,r)$ is the solution of the IVP

$$(L_n A)(\rho,r) = \left(\partial_\rho^2 A + \frac{\nu-1}{\rho}\partial_\rho A\right)(\rho,r), \qquad (\rho,r)\in \mathbf{R}^2, \tag{2.13}$$

$$A(\rho,0) = \alpha(\rho), \quad \partial_\rho A(\rho,0) = 0, \qquad \rho \in \mathbf{R}. \tag{2.14}$$

Here $(L_n A)(\rho,r) := (\partial_r^2 A + \frac{n-1}{r}\partial_r A)(\rho,r)$.

We recall that the operator D_r satisfies $L_n D_r = D_r L_{n-2}$ and for any $\mu \in \mathbf{N}$

$$\left(\partial_r^2 + \frac{1-\mu}{r}\partial_r\right)(r^\mu w) = r^\mu \left(\partial_r^2 + \frac{1+\mu}{r}\partial_r\right) w,$$

that is, $L_{2-\mu} r^\mu = r^\mu L_{\mu+2}$. So

$$(L_{2-\mu+2\sigma} D_r^\sigma r^\mu w)(r) = (D_r^\sigma L_{2-\mu} r^\mu w)(r) = (D_r^\sigma r^\mu L_{\mu+2} w)(r). \tag{2.15}$$

If we set $\mu = n-2$ and $\sigma = (n-2)/2$ in (2.15), then $\mu+2 = n$ and $2-\mu+2\sigma = 2$. Therefore

$$(L_2 D_r^{(n-2)/2} r^{n-2} w)(r) = (D_r^{(n-2)/2} r^{n-2} L_n w)(r). \tag{2.16}$$

Now we set

$$H(\rho,r) := \frac{1}{((n-2)/2)!}(D_r^{(n-2)/2} r^{n-2} A)(\rho,r). \tag{2.17}$$

Since $A(\rho,r)$ is even in r and D_r corresponds to differentiation with respect to r^2, $H(\rho,r)$ is even in r. Moreover, by (2.14), $H(\rho,0) = \frac{1}{((n-2)/2)!}A(\rho,0)(D_r^{(n-2)/2} r^{n-2}) = \alpha(\rho)$, and therefore from (2.13) and (2.16) it follows that H is the solution of the IVP

$$\left(\partial_r^2 H + \frac{1}{r}\partial_r H\right)(\rho,r) = \left(\partial_\rho^2 H + \frac{\nu-1}{\rho}\partial_\rho H\right)(\rho,r), \qquad (\rho,r)\in\mathbf{R}^2, \tag{2.18}$$

$$H(\rho,0) = \alpha(\rho), \quad \partial_r H(\rho,0) = 0, \qquad \rho\in\mathbf{R}. \tag{2.19}$$

Proposition 2.3. *Let $A_i(\rho,r)$, $i=1,2$, solve* (2.13) *with $n=2$, subject to initial conditions $A_i(\rho,0) = \alpha_i(\rho)$, $\partial_r A_i(\rho,0) = 0$, where α_i are smooth even functions with support in $[-1,1]$ and $\nu \geq 2$ is even. Then*

$$\int_0^1 \rho^{\nu-1}\alpha_1(\rho)\alpha_2(\rho)\,d\rho = -\int_0^2\int_0^2 rA_1(1,r)\partial_{\bar r}\log|r^2-\bar r^2|\,\bar r(\partial_{\bar r}A_2)(1,\bar r)\,d\bar r\,dr. \tag{2.20}$$

Proof. Let $k = (\nu-2)/2$, and let $\Phi(\theta)$ be a nontrivial real circular harmonic of degree k. Then $F_i(x,r) := A_i(\rho,r)\rho^k\Phi(\theta)$ satisfies (2.11), (2.12) for $n=2$, and so is the circular mean of its initial value, $f_i(x) = \alpha_i(\rho)\rho^k\Phi(\theta)$. By (1.4), $f_1 = \frac{1}{2\pi}Qf_1$, and using (2.9) gives

$$\begin{aligned}\langle f_1, f_2\rangle &= \frac{1}{2\pi}\langle Qf_1, f_2\rangle \\ &= \int_S\int_0^2\int_0^2 rF_1(p,r)\log|r^2-\bar r^2|(\partial_{\bar r}\bar r\partial_{\bar r}F_2)(p,\bar r)\,dr\,d\bar r\,ds(p).\end{aligned}$$

Taking into account the form of F_i and that $\rho = 1$ on S, this may be rewritten as

$$\langle f_1, f_2 \rangle = \int_S \Phi^2(p)\, ds(p) \int_0^2 \int_0^2 rA_1(1,r) \log|r^2 - \bar{r}^2| (\partial_{\bar{r}} \bar{r} \partial_{\bar{r}} A_2)(1,\bar{r})\, dr\, d\bar{r}. \tag{2.21}$$

Appealing to the form of $f_i = F(x,0)$,

$$\begin{aligned} \langle f_1, f_2 \rangle &= \int_0^1 \rho(\rho^k \alpha_1)(\rho^k \alpha_2)\, d\rho \int_S \Phi^2(p)\, ds(p) \\ &= \int_0^1 \rho^{\nu-1} \alpha_1(\rho) \alpha_2(\rho)\, d\rho \int_S \Phi^2(p)\, ds(p). \end{aligned} \tag{2.22}$$

Since $\int_S \Phi^2(p)\, ds(p) \neq 0$, a comparison of (2.21) and (2.22) and an integration by parts on the right-hand side of (2.21) establishes (2.20), which completes the proof. □

Proof of Theorem 1.3. Let $\{\Phi_j\}$ be an orthonormal basis for the spherical harmonics on S^{n-1}, and consider f_i, $i = 1, 2$, of the form (2.10) with $\alpha = \alpha_i$ and $\Phi = \Phi_{j_i}$ of possibly different degrees. Let F_i be the even extensions of $\mathcal{M} f_i$ as above. Then by orthogonality, $\langle f_1, f_2 \rangle = 0$ unless $j_1 = j_2$, in which case

$$\langle f_1, f_2 \rangle = \int_0^1 \rho^{\nu-1} \alpha_1(\rho) \alpha_2(\rho)\, d\rho, \tag{2.23}$$

with $\nu = n + 2k$, where k is the degree of Φ_{j_1}. Evaluating $\langle Qf_1, f_2 \rangle$ by (2.9) and using that $F_i = \rho^{k_i} A_i(\rho, r) \Phi_{j_i}$, we see that it is also zero unless $j_1 = j_2$. In this case we have

$$\begin{aligned} \langle Qf_1, f_2 \rangle &= |S^{n-1}| \int_0^2 \int_0^2 (rD_r^{n-2} r^{n-2} A_1)(1,r) \log|r^2 - \bar{r}^2| \tilde{A}_2(1,\bar{r})\, dr\, d\bar{r} \\ &= |S^{n-1}| \int_0^2 \int_0^2 (D_r^{\frac{n-2}{2}} r^{n-2} A_1)(1,r) (D_r^*)^{\frac{n-2}{2}} (r \log|r^2 - \bar{r}^2|) \tilde{A}_2(1,\bar{r})\, dr\, d\bar{r} \\ &= |S^{n-1}| \int_0^2 \int_0^2 r(D_r^{\frac{n-2}{2}} r^{n-2} A_1)(1,r) D_{\bar{r}}^{\frac{n-2}{2}} \log|r^2 - \bar{r}^2| \tilde{A}_2(1,\bar{r})\, dr\, d\bar{r}, \end{aligned} \tag{2.24}$$

where we have abbreviated $\tilde{A}_2 = \partial_{\bar{r}} \bar{r}^{n-1} \partial_{\bar{r}} A_2$ and used

$$(D_r^{(n-2)/2})^* r \log|r^2 - \bar{r}^2| = (-1)^{(n-2)/2} r D_r^{(n-2)/2} \log|r^2 - \bar{r}^2| = r D_{\bar{r}}^{(n-2)/2} \log|r^2 - \bar{r}^2|.$$

Applying the adjoint (distributional derivative) again in (2.24) and using $\hat{A}_1(r)$ to abbreviate $r(D_r^{\frac{n-2}{2}} r^{n-2} A_1)(1,r)$, which depends only on r,

$$\begin{aligned} \langle Qf_1, f_2 \rangle &= |S^{n-1}| \int_0^2 \int_0^2 \hat{A}_1(r) \log|r^2 - \bar{r}^2| (D_{\bar{r}}^{\frac{n-2}{2}})^* (\partial_{\bar{r}} \bar{r}^{n-1} \partial_{\bar{r}} A_2)(1,\bar{r})\, dr\, d\bar{r} \\ &= |S^{n-1}| \int_0^2 \int_0^2 \hat{A}_1(r) \log|r^2 - \bar{r}^2| (-1)^{\frac{n-2}{2}} (\partial_{\bar{r}} D_{\bar{r}}^{\frac{n-2}{2}} \bar{r}^{n-1} \partial_{\bar{r}} A_2)(1,\bar{r})\, dr\, d\bar{r} \\ &= |S^{n-1}| (-1)^{n/2} \int_0^2 \int_0^2 \hat{A}_1(r) \partial_{\bar{r}} \log|r^2 - \bar{r}^2| (D_{\bar{r}}^{\frac{n-2}{2}} \bar{r}^{n-1} \partial_{\bar{r}} A_2)(1,\bar{r})\, dr\, d\bar{r}. \end{aligned}$$

We now use the following identity, which is readily proved by induction:

$$D_{\bar{r}}^{(n-2)/2} \bar{r}^{n-1} \partial_{\bar{r}} q = \bar{r} \partial_{\bar{r}} D_{\bar{r}}^{(n-2)/2} \bar{r}^{n-2} q$$

taking $q = A_2$, and observe that defining H_i by (2.17) with $A = A_i$, it then holds that

$$\langle Qf_1, f_2\rangle = \gamma_n \int_0^2 \int_0^2 rH_1(1, r)\partial_{\bar{r}} \log |r^2 - \bar{r}^2|\, \bar{r}(\partial_{\bar{r}} H_2)(1, \bar{r})\, dr\, d\bar{r}$$

for $\gamma_n = |S^{n-1}|(-1)^{n/2}[((n-2)/2)!]^2$. By (2.18) and (2.19) the H_i satisfy the hypotheses of Proposition 2.3 with initial data α_i, and so by (2.20) the expression on the right-hand side is equal to

$$-\gamma_n \int_0^1 \rho^{\nu-1}\alpha_1(\rho)\alpha_2(\rho)\, d\rho.$$

Thus we have proved that for f_i of the form above

$$\langle Qf_1, f_2\rangle = (-1)^{(n-2)/2}|S^{n-1}|[((n-2)/2)!]^2\langle f_1, f_2\rangle. \tag{2.25}$$

We note that the constant on the right-hand side is c_n of Theorem 1.3. By linearity and orthogonality of spherical harmonics, this still holds when either f_1 or f_2 is replaced by a finite linear combination of such functions. The set of finite linear combinations of functions of form (2.10) is dense in L^2, and so we have $Qf = c_n f$ in L^2 when f is a finite linear combination of functions of the form (2.10). Now let g be smooth with support in the unit ball. Applying Proposition 2.2, it follows that

$$\langle f, Ng\rangle = (1/2)\langle Qf, g\rangle = (c_n/2)\langle f, g\rangle \tag{2.26}$$

for all f as above. Since (2.26) holds for a dense subset of functions f in $L^2(B)$, it implies that $Ng = (c_n/2)g$ almost everywhere in B. However, Ng is easily seen to be a continuous function, and so $Ng = (c_n/2)g$ holds pointwise in B, which is (1.9). But if N is a multiple of the identity, then so is Q, and the proof is complete. □

3. The wave equation. We begin the analysis of recovery of initial data from the trace of the solution of the wave equation on the lateral boundary of the cylinder. As mentioned in the introduction, we have two types of inversion results. The first, Theorem 1.4, is really a corollary of one of the inversion formulas for circular means from the previous section.

Proof of Theorem 1.4. Let $u(x, t)$ be the solution of the IVP (1.1), (1.2) in dimension two. Then by (1.11),

$$u(p, t) = \partial_t \int_0^t \frac{(r\,\mathcal{M} f)(p, r)}{\sqrt{t^2 - r^2}}\, dr$$

for $p \in S$. We can recover the circular means from u by the standard method of inverting an Abel-type equation. The details are not hard and may be found, for example, in [12]. The result is

$$(\mathcal{M} f)(p, r) = \frac{2}{\pi} \int_0^r \frac{u(p, t)}{\sqrt{r^2 - t^2}}\, dt. \tag{3.1}$$

Inserting (3.1) into the inversion formula (1.4) for $\mathcal{M}$ and applying Fubini's theorem gives, for $x \in D$,

$$\begin{aligned}
f(x) &= \frac{1}{2\pi R_0}\,\Delta \int_S \int_0^{2R_0} (r\,\mathcal{M}\,f)(p,r) \log\left|r^2 - |x-p|^2\right| dr\, ds(p) \\
&= \frac{1}{R_0\pi^2}\,\Delta \int_S \int_0^{2R_0} r \int_0^r \frac{u(p,t)}{\sqrt{r^2-t^2}} \log\left|r^2 - |x-p|^2\right| dt\, dr\, ds(p) \\
&= \frac{1}{R_0\pi^2}\,\Delta \int_S \int_0^{2R_0} u(p,t) \int_t^{2R_0} \frac{r}{\sqrt{r^2-t^2}} \log\left|r^2 - |x-p|^2\right| dr\, dt\, ds(p) \\
&= \frac{1}{R_0\pi^2}\,\Delta \int_S \int_0^{2R_0} u(p,t) K(t, |x-p|)\, dt\, ds(p).
\end{aligned}$$

Since $u(p,t) = (\mathcal{W}\,f)(p,t)$, this is (1.12), with

$$K(t,\bar{r}) := \int_t^{2R_0} \frac{r}{\sqrt{r^2-t^2}} \log\left|r^2 - \bar{r}^2\right| dr. \tag{3.2}$$

The integral in (3.2) can be evaluated exactly. For the sake of completeness, we give the analytic expression. If we substitute $r = \sqrt{t^2+\xi^2}$ into (3.2), then $dr = (\xi/r)\,d\xi$ and thus

$$\begin{aligned}
K(t,\bar{r}) &= \int_0^{\sqrt{4R_0^2-t^2}} \log\left|\xi^2 + (t^2 - \bar{r}^2)\right| d\xi \\
&= \sqrt{4R_0^2 - t^2}\left(-2 + \log|4R_0^2 - \bar{r}^2|\right) + \Gamma(t,\bar{r}),
\end{aligned}$$

where

$$\Gamma(t,\bar{r}) = \begin{cases} \sqrt{\bar{r}^2 - t^2}\log \frac{\sqrt{4R_0^2-t^2}+\sqrt{\bar{r}^2-t^2}}{\sqrt{4R_0^2-t^2}-\sqrt{\bar{r}^2-t^2}}, & t < \bar{r}, \\ 2\sqrt{t^2-\bar{r}^2}\arctan\sqrt{\frac{4R_0^2-t^2}{t^2-\bar{r}^2}}, & t > \bar{r}. \end{cases} \qquad \square$$

For the second type of inversion formula, we start by deriving a representation of the formal adjoint $\mathcal{P}^*$ for $n=2$. For any continuous function $G(p,t)$ on $S \times [0,\infty)$ that has a small amount of decay as $t \to \infty$, by Fubini's theorem, we have

$$\begin{aligned}
\langle \mathcal{P}\,f,\, G\rangle &= \int_S \int_0^\infty (\mathcal{P}\,f)(p,t)\, G(p,t)\, dt\, ds(p) \\
&= \frac{1}{2\pi}\int_S \int_0^\infty G(p,t)\left(\int_0^t \frac{r}{\sqrt{t^2-r^2}} \int_{S^1} f(p + r\omega)\, ds(\omega)\, dr\right) dt\, ds(p) \\
&= \frac{1}{2\pi}\int_S \int_0^\infty \left(\int_0^t \int_{S^1} \frac{f(p+r\omega)}{\sqrt{t^2-r^2}}\, r\, dr\, dS(\omega)\right) G(p,t)\, dt\, ds(p) \\
&= \frac{1}{2\pi}\int_S \int_0^\infty \left(\int_{\mathbf{R}^2} \frac{f(y)}{\sqrt{t^2-|y-p|^2}} \chi(\{|y-p|<t\})\, dy\right) G(p,t)\, dt\, ds(p) \\
&= \frac{1}{2\pi}\int_{\mathbf{R}^2} f(y) \left(\int_S \int_{|y-p|}^\infty \frac{G(p,t)}{\sqrt{t^2-|y-p|^2}}\, dt\, ds(p)\right) dy \\
&= \langle f,\, \mathcal{P}^*\, G\rangle,
\end{aligned}$$

where

$$\left(\mathcal{P}^*\, G\right)(y) := \frac{1}{2\pi}\int_S \int_{|y-p|}^\infty \frac{G(p,t)}{\sqrt{t^2-|y-p|^2}}\, dt\, ds(p). \tag{3.3}$$

The integral in (3.3) will be absolutely convergent for continuous G, provided that G has a small amount of decay as $t \to \infty$, for example, if $G(p,t) = \mathcal{O}(1/t^\alpha)$, as $t \to \infty$, for some $\alpha > 0$.

Next, we note a differentiation formula for the fractional integral appearing in (1.11).

PROPOSITION 3.1. *Let h be differentiable on $[0,\infty)$. Then, for $t > 0$,*

$$\partial_t \int_0^t \frac{r\,h(r)}{\sqrt{t^2-r^2}}\,dr = \frac{1}{t}\int_0^t \frac{r\,(\partial_r r h)(r)}{\sqrt{t^2-r^2}}\,dr. \tag{3.4}$$

Proof. Making the change of variable $r = t\xi$ in the integral on the left-hand side we have to evaluate

$$\partial_t \int_0^1 \frac{\xi}{\sqrt{1-\xi^2}}\, th(t\xi)\,d\xi.$$

Here differentiation under the integral yields $\int_0^1 \frac{\xi}{\sqrt{1-\xi^2}}\,(t\xi h'(t\xi) + h(t\xi))\,d\xi$, which is equal to the expression on the right-hand side after changing back to integration with respect to $r = t\xi$. □

Proof of (1.13) *in Theorem* 1.5 *for* $n = 2$. We compute $(\mathcal{P}^*\, t\partial_t^2\, \mathcal{P}\, f)(x)$ for smooth f supported in $\overline{B}$ and $x \in B$. The function $t\partial_t^2\,\mathcal{P}\, f$ has decay of order $1/t^2$ as $t \to \infty$ and so lies in the domain of $\mathcal{P}^*$. Using the definitions of $\mathcal{P}$ and $\mathcal{P}^*$ and relation (3.4),

$$\begin{aligned}
&(\mathcal{P}^*\, t\partial_t^2\, \mathcal{P}\, f)(x) \\
&\quad = \frac{1}{2\pi}\int_S \int_{|x-p|}^\infty \partial_t^2 \left(\int_0^t \frac{r\,(\mathcal{M}\, f)(p,r)}{\sqrt{t^2-r^2}}\,dr\right) \frac{t\,dt\,ds(p)}{\sqrt{t^2-|x-p|^2}} \\
&\quad = \frac{1}{2\pi}\int_S \int_{|x-p|}^\infty \partial_t \left(\frac{1}{t}\int_0^t \frac{r\,(\partial_r r\,\mathcal{M}\, f)(p,r)}{\sqrt{t^2-r^2}}\,dr\right) \frac{t\,dt\,ds(p)}{\sqrt{t^2-|x-p|^2}}.
\end{aligned}$$

Carrying out the differentiation in t using the chain rule, again using (3.4), and combining terms, the last integral can be rewritten as

$$\frac{1}{2\pi}\int_S \int_{|x-p|}^\infty \left(\int_0^r \frac{r\,(\partial_r r \partial_r r\,\mathcal{M}\, f)(p,r) - r\,(\partial_r r\,\mathcal{M}\, f)(p,r)}{t\sqrt{t^2-|x-p|^2}\sqrt{t^2-r^2}}\,dr\right) dt\,ds(p).$$

Using the identity

$$\partial_r r \partial_r r h - \partial_r r h = \partial_r r(\partial_r r h - h) = \partial_r r r \partial_r h = \partial_r r^2 \partial_r h$$

and applying Fubini's theorem $(\mathcal{P}^*\, t\partial_t^2\, \mathcal{P}\, f)(x)$ is in turn equal to

$$\frac{1}{2\pi}\int_S \int_0^\infty r\,(\partial_r r^2 \partial_r\,\mathcal{M}\, f)(p,r) \left(\int_{\max(|x-p|,r)}^\infty \frac{dt}{t\sqrt{t^2-|x-p|^2}\sqrt{t^2-r^2}}\right) dr\,ds(p).$$

The inner integral evaluates to

$$\frac{1}{2r|x-p|}\log\frac{r+|x-p|}{|r-|x-p||},$$

giving

$$(\mathcal{P}^*\, t\partial_t^2\, \mathcal{P}\, f)(x) = \frac{1}{4\pi}\int_S \left(\int_0^\infty (\partial_r r^2 \partial_r\,\mathcal{M}\, f)(p,r)\log\frac{r+|x-p|}{|r-|x-p||}\,dr\right)\frac{ds(p)}{|x-p|}. \tag{3.5}$$

Treating the inner integral in the principal value sense and integrating by parts, it is equal to the limit as $\varepsilon \to 0$ of boundary terms

$$\left[(r^2\partial_r \mathcal{M} f)(p,r)\log\frac{r+|x-p|}{|x-p|-r}\right]_0^{|x-p|-\varepsilon} + \left[(r^2\partial_r \mathcal{M} f)(p,r)\log\frac{r+|x-p|}{r-|x-p|}\right]_{|x-y|+\varepsilon}^{\infty}$$

plus the term

$$I_\epsilon := -\int_{\mathbf{R}^+\setminus[|x-p|-\varepsilon,|x-p|+\varepsilon]} (r\partial_r \mathcal{M} f)(p,r)\, r\partial_r \log\frac{r+|x-y|}{|r-|x-p||}\,dr.$$

Using that $\mathcal{M} f$ is smooth, flat at $r=0$, and of bounded support in $(0,\infty)$, the limit of the boundary terms is zero. Using the identity

$$r\partial_r \log\frac{r+|x-p|}{|r-|x-p||} = -|x-p|\partial_r \log|r^2-|x-p|^2|,$$

followed by another integration by parts, yields the sum of another pair of boundary terms and

$$I_\epsilon = -|x-p|\int_{R^+\setminus[|x-p|-\varepsilon,|x-p|+\varepsilon]} \left(\partial_r r\partial_r \mathcal{M} f\right)(p,r)\log\left|r^2-|x-p|^2\right|dr.$$

The boundary terms again evaluate to zero as $\varepsilon \to 0$, while the integral I_ϵ converges to

$$-|x-p|\int_0^\infty \left(\partial_r r\partial_r \mathcal{M} f\right)(p,r)\log\left|r^2-|x-p|^2\right|dr.$$

Inserting this into (3.5) and taking into account the support of $\mathcal{M} f$ gives

$$(\mathcal{P}^*\, t\partial_t^2\, \mathcal{P} f)(x) = -\frac{1}{4\pi}\int_S\int_0^{2R_0} \left(\partial_r r\partial_r \mathcal{M} f\right)(p,r)\log\left|r^2-|x-p|^2\right|dr\,ds(p).$$

In view of (1.5) of Theorem 1.1, (1.13) in Theorem 1.5 is proved for $n=2$. □

Proof of Theorem 1.6. Formula (1.15), for $n=2$, is an easy corollary of the result just established. Indeed, for f, g smooth with compact support in the closed disk of radius R_0, then

$$\langle f, g\rangle = -\frac{2}{R_0}\left\langle \mathcal{P}^*\, t\partial_t^2\, \mathcal{P} f,\, g\right\rangle = -\frac{2}{R_0}\left\langle t\partial_t^2\, \mathcal{P} f,\, \mathcal{P} g\right\rangle, \tag{3.6}$$

which is (1.15) for $n=2$, due to the definition of the operator $\mathcal{P}$.

In (1.15), the left-hand side is symmetric in f and g, while the right-hand side is not. Thus there is a companion identity, reversing the roles of u and v on the right-hand side. Taking the difference gives the equation

$$0 = \int_S\int_0^\infty t(u_{tt}v - uv_{tt})\,dt\,ds(p).$$

Integrating by parts (the boundary terms vanish) yields

$$0 = \int_S\int_0^\infty (u_t v - uv_t)\,dt\,ds(p),$$

and another integration by parts proves

$$0 = \int_S \int_0^\infty u_t v \, dt \, ds(p) = \int_S \int_0^\infty u v_t \, dt \, ds(p).$$

Using this and one integration by parts in (1.15) establishes (1.16), which completes the proof of Theorem 1.6 for $n = 2$. The extension to higher (even) dimensions follows almost word for word the proof from [5, section 4.2], where the trace identities in odd dimensions greater than three were proved from the three dimensional case. $\square$

Proof of Theorem 1.5 *for* $n > 2$. Reversing the chain of reasoning in (3.6) proves (1.13) in the L^2 sense from (1.15). Similarly, (1.14) follows from (1.16). However, as both sides are continuous functions when f is smooth, the formulas hold pointwise as well. $\square$

4. Numerical results. In the previous sections, we have established several exact inversion formulas to recover a function f supported in a closed disc $\overline{D}$ from either its spherical means $\mathcal{M} f$ or the trace $\mathcal{W} f$ of the solution of the wave equation with initial data $(f, 0)$. However, those formulas require continuous data, whereas in practical applications only a discrete data set is available. For example, in thermoacoustic tomography (see Figure 1.1) only a finite number of positions of the line detectors and a finite number of samples in time are feasible. In this section we derive discrete *filtered back-projection* (FBP) algorithms with linear interpolation in dimension two and present some numerical results.

The derived FBP algorithms are numerical implementations of discretized versions of (1.4)–(1.7) and (1.12)–(1.14), and the derivation of any of them follows the same line. We shall focus on the implementation of (1.5), assuming uniformly sampled discrete data

$$F^{k,m} := (\mathcal{M} f)(p^k, r^m), \qquad (k, m) \in \{0, \dots, N_\varphi\} \times \{0, \dots, N_r\}\,, \tag{4.1}$$

where $p^k := R_0 \, (\cos(kh_\varphi), \sin(kh_\varphi))$, $r^m := mh_r$, $h_\varphi := 2\pi/(N_\varphi + 1)$, and $h_r := 2R_0/N_r$. In order to motivate the derivation of a discrete FBP algorithm based on (1.5), we introduce the differential operator $\mathcal{D} := \partial_r r \partial_r$ and the integral operator

$$\begin{aligned} &\mathcal{I} : C_0^\infty(S \times [0, 2R_0)) \to C^\infty(S \times [0, 2R_0)), \\ &(\mathcal{I}\, G)(p, \bar{r}) := \int_0^{2R_0} G(p, r) \log |r^2 - \bar{r}^2| \, dr, \end{aligned} \tag{4.2}$$

which both act in the second component, and the so-called *back-projection operator*

$$\begin{aligned} \mathcal{B} : C^\infty(S \times [0, 2R_0)) &\to C^\infty(\overline{D}), \\ (\mathcal{B}\, G)(x) &:= \frac{1}{2\pi R_0} \int_S G(p, |x - p|) \, ds(p) \\ &= \frac{1}{2\pi} \int_0^{2\pi} G(p(\varphi), |x - p(\varphi)|) \, d\varphi, \end{aligned} \tag{4.3}$$

where $p(\varphi) := R_0(\cos\varphi, \sin\varphi)$. Therefore, we can rewrite (1.5) as

$$f = (\mathcal{B} \mathcal{I} \mathcal{D})(\mathcal{M} f). \tag{4.4}$$

In the numerical implementation the operators $\mathcal{B}$, $\mathcal{I}$, and $\mathcal{D}$ in (4.4) are replaced by finite dimensional approximations $\mathbf{B}$, $\mathbf{I}$, and $\mathbf{D}$ (as described below) and (4.4) is approximated by

$$f(x^i) \approx f^i := (\mathbf{B}\,\mathbf{I}\,\mathbf{D}\,\mathbf{F})^i, \quad i \in \{0, \dots, N\}^2\,. \tag{4.5}$$

Here $\mathbf{F} := (F^{k,m})_{k,m}$ with $F^{k,m}$ defined by (4.1), $x^i := -(R_0, R_0) + ih_x$ with $i = (i_1, i_2) \in \{0, N\}^2$, and $h_x := 2R_0/N$. In the following $\mathbf{S}_{\varphi,r}$ and $\mathbf{S}_x$ denote the sampling operators that map $G \in C^\infty(S \times [0, 2R_0])$ and $f \in C^\infty(\overline{D})$ onto their samples, $\mathbf{S}_{\varphi,r}\, G := (G(p^k, r^m))_{k,m}$ and $\mathbf{S}_x\, f := \mathbf{f} := (f(x^i))_i$, where we set $f(x^i) := 0$ if $x^i \notin \overline{D}$. Moreover, $|\cdot|_\infty$ denotes the maximum norm on either $\mathbf{R}^{(N_\varphi+1)\times(N_r+1)}$ or $\mathbf{R}^{(N+1)\times(N+1)}$.

1. The operator $\mathcal{D}$ can be written as $\partial_r + r\partial_r^2$. We approximate $\partial_r G$ with symmetric finite differences $\left(G^{k,m+1} - G^{k,m-1}\right)/(2h_r)$, $\partial_r^2 G$ by $\left(G^{k,m+1} + G^{k,m-1} - 2G^{k,m}\right)/h_r^2$ and the multiplication operator $G \mapsto rG$ by pointwise discrete multiplication $(G^{k,m})_{k,m} \mapsto (r^m G^{k,m})_{k,m}$. This leads to the discrete approximation

   (4.6)
   $$\mathbf{D} : \mathbf{R}^{(N_\varphi+1)\times(N_r+1)} \to \mathbf{R}^{(N_\varphi+1)\times(N_r+1)} : \qquad \mathbf{G} \mapsto \left((\mathbf{D}\,\mathbf{G})^{k,m}\right)_{k,m},$$
   $$(\mathbf{D}\,\mathbf{G})^{k,m} := \frac{1}{h_r}\left(\left(m + \frac{1}{2}\right) G^{k,m+1} + \left(m - \frac{1}{2}\right) G^{k,m-1} - 2mG^{k,m}\right),$$

   where we set $G^{k,-1} := G^{k,N_r+1} := 0$. The approximation of ∂_r with symmetric finite differences is of second order, and therefore $|(\mathbf{S}_{\varphi,r}\,\mathcal{D} - \mathbf{D}\,\mathbf{S}_{\varphi,r})G|_\infty \le C_1 h_r^2$ for some constant C_1, which does not depend on h_r.
2. Next, we define a second order approximation to the integral operator $\mathcal{I}$. This is done by replacing $G(p^k, \cdot)$ in (4.2) by the piecewise linear spline $T^k[G] : [0, 2R_0] \to \mathbf{R}$ interpolating G at the nodes r^m. More precisely,

   $$\mathbf{I} : \mathbf{R}^{(N_\varphi+1)\times(N_r+1)} \to \mathbf{R}^{(N_\varphi+1)\times(N_r+1)} : \quad \mathbf{G} \mapsto \left((\mathbf{I}\,\mathbf{G})^{k,m}\right)_{k,m}$$

   is defined by

   $$(4.7) \qquad T^k[\mathbf{G}](r) := G^{k,m} + \frac{r - r^m}{h_r}(G^{k,m+1} - G^{k,m}), \quad r \in [r^m, r^{m+1}],$$

   and

   (4.8)
   $$\begin{aligned}(\mathbf{I}\,\mathbf{G})^{k,m} &:= \int_0^{2R_0} T^k[\mathbf{G}](r) \log|r^2 - (r^m)^2|\, dr \\ &= \sum_{m'=0}^{N_r-1} G^{k,m'} \left(\int_{r^{m'}}^{r^{m'+1}} \log|r^2 - (r^m)^2|\, dr\right) \\ &\quad + \sum_{m'=0}^{N_r-1} \frac{G^{k,m'+1} - G^{k,m'}}{h_r} \left(\int_{r^{m'}}^{r^{m'+1}} (r - r^{m'}) \log|r^2 - (r^m)^2|\, dr\right).\end{aligned}$$

   For an efficient and accurate numerical implementation it is crucial that the integrals in (4.8) are evaluated analytically. In fact, by straightforward computation it can be verified that

   $$(\mathbf{I}\,\mathbf{G})^{k,m} = \sum_{m'=0}^{N_r-1} a_{m'}^m G^{k,m'} + \frac{1}{h_r}\sum_{m'=0}^{N_r-1} b_{m'}^m \left(G^{k,m'+1} - G^{k,m'}\right),$$

   (4.9)
   $$a_{m'}^m := \Big[(r - r^m)\log|r - r^m| + (r + r^m)\log|r + r^m| - 2r\Big]_{r=r^{m'}}^{r^{m'+1}},$$
   $$b_{m'}^m := -r^{m'} a_{m'}^m + \frac{1}{2}\Big[(r^2 - (r^m)^2)\log|r^2 - (r^m)^2| - r^2\Big]_{r=r^{m'}}^{r^{m'+1}}.$$

Moreover, using the fact that piecewise linear interpolation is of second order [15] and that $r \mapsto \log|r^2 - (r^m)^2|$ is integrable, it can be readily verified that the approximation error satisfies $|(\mathbf{S}_{\varphi,r}\,\mathcal{I} - \mathbf{I}\,\mathbf{S}_{\varphi,r})G|_\infty \le C_2 h_r^2$ with some constant C_2 independent of h_r.

3. Finally, we define a second order approximation to the back-projection (4.3). The discrete back-projection operator $\mathbf{B} : \mathbf{R}^{(N_\varphi+1)\times(N_r+1)} \to \mathbf{R}^{(N+1)\times(N+1)}$ is obtained by approximating (4.3) with the trapezoidal rule and piecewise linear interpolation (4.7) in the second variable,

$$(\mathbf{B}\,\mathbf{G})^i := \frac{1}{N_\varphi + 1} \sum_{k=0}^{N_\varphi} T^k[\mathbf{G}](|x^i - p^k|), \quad x^i \in D, \tag{4.10}$$

and setting $(\mathbf{B}\,\mathbf{G})^i := 0$ for $x^i \notin D$. It is well known [15] that both linear interpolation in r and the trapezoidal rule in φ are second order approximations and therefore $|(\mathbf{S}_x\,\mathcal{B} - \mathbf{B}\,\mathbf{S}_{\varphi,r})G|_\infty \le C_3 \max\left\{h_r^2, h_\varphi^2\right\}$ for some constant C_3.

The discrete FBP algorithm is given by (4.5) with $\mathbf{D}$, $\mathbf{I}$, $\mathbf{B}$ defined in (4.6), (4.9), (4.10) and is summarized in Algorithm 1. Using $f(x^i) = (\mathbf{S}_x\,\mathcal{B}\mathcal{I}\mathcal{D}\,F)^i = (\mathbf{S}_x\,f)^i$ and $f^i = (\mathbf{B}\,\mathbf{I}\,\mathbf{D}\,\mathbf{S}_{\varphi,r}\,F)^i$, the discretization error $|f(x^i) - f^i|$ can be estimated as

$$\begin{aligned} |(\mathbf{S}_x\,\mathcal{B}\mathcal{I}\mathcal{D} - \mathbf{B}\,\mathbf{I}\,\mathbf{D}\,\mathbf{S}_{\varphi,r})F|_\infty &\le |(\mathbf{S}_x\,\mathcal{B} - \mathbf{B}\,\mathbf{S}_{\varphi,r})(\mathcal{I}\mathcal{D}\,F)|_\infty \\ &\quad + |\mathbf{B}(\mathbf{S}_{\varphi,r}\,\mathcal{I} - \mathbf{I}\,\mathbf{S}_{\varphi,r})(\mathcal{D}\,F)|_\infty \\ &\quad + |\mathbf{B}\,\mathbf{I}(\mathbf{S}_{\varphi,r}\,\mathcal{D} - \mathbf{D}\,\mathbf{S}_{\varphi,r})(F)|_\infty. \end{aligned} \tag{4.11}$$

Using the facts that $\mathbf{B}$ and $\mathbf{I}$ are bounded by some constant independent of h_r and that the approximations of $\mathcal{D}$, $\mathcal{I}$, $\mathcal{B}$ with $\mathbf{D}$, $\mathbf{I}$, $\mathbf{B}$ are of second order implies that

$$|\mathbf{S}_x\,f - \mathbf{B}\,\mathbf{I}\,\mathbf{D}\,\mathbf{F}|_\infty \le C \max\left\{h_r^2, h_\varphi^2\right\} \tag{4.12}$$

for some constant C independent of h_r, h_φ. This shows that the derived FBP algorithm has second order accuracy (for exact data).

In the numerical implementation, the coefficients in (4.9) are precomputed and stored. Therefore the numerical effort of evaluating (4.9) is $\mathcal{O}(N_r^2 N_\varphi)$. Moreover, (4.6) requires $\mathcal{O}(N_r N_\varphi)$ operations and the discrete FBP $\mathcal{O}(N^2 N_\varphi)$, since for all $(N+1)^2$ reconstruction points x^i we have to sum over $N_\varphi + 1$ center locations on S. Hence, assuming $N \sim N_r$ and $N \sim N_\varphi$, Algorithm 1 requires $\mathcal{O}(N^3)$ operations and therefore has the same numerical effort as the classical FBP algorithm used in x-ray CT [12]. Analogous to the procedure described above, discrete FBP algorithms were derived using (1.4), (1.6) for inverting $\mathcal{M}$ and (1.12) for inverting $\mathcal{W}$.

In the following we present numerical results of our FBP algorithms for reconstruction of the phantom shown in the left picture in Figure 4.1, consisting of a superposition of characteristic functions and one Gaussian kernel. We calculated the data $\mathcal{M}\,f$ via numerical integration and the operator $\mathcal{W}\,f = \partial_t\,\mathcal{P}\,f$ using (1.11). Subsequently we added 5% uniformly distributed noise to $\mathcal{M}\,f$ and 10% uniformly distributed noise to $\mathcal{W}\,f$. The results for $N = N_\varphi = N_r = 300$ using the algorithms based on (1.4), (1.5), (1.6), and (1.12) are depicted in Figures 4.2, 4.3, and 4.4. All implementations show good results, although no explicit regularization strategy is incorporated in order to regularize the involved (mildly) ill-posed numerical differentiation. In particular, (1.6) and (1.12) appear to be most insensitive to noise. However, for noisy data, the accuracy of FBP algorithms can be further improved by incorporating a regularizing strategy similar to that used in [8]. The derived identities in this article provide the

Algorithm 1 Discrete FBP algorithm with linear interpolation for reconstruction of $\mathbf{f}$ using data $\mathbf{F}$.

A HYBRID LAGRANGIAN MODEL BASED ON THE AW–RASCLE TRAFFIC FLOW MODEL[*]

S. MOUTARI[†] AND M. RASCLE[†]

Abstract. In this paper, we propose a simple fully discrete hybrid model for vehicular traffic flow, for which both the macroscopic and the microscopic models are based on a Lagrangian discretization of the Aw–Rascle (AR) model [A. Aw and M. Rascle, *SIAM J. Appl. Math.*, 60 (2000), pp. 916–938]. This hybridization makes use of the relation between the AR macroscopic model and a *follow-the-leader*-type model [D. C. Gazis, R. Herman, and R. W. Rothery, *Oper. Res.*, 9 (1961), pp. 545–567; R. Herman and I. Prigogine, *Kinetic Theory of Vehicular Traffic*, American Elsevier, New York, 1971], established in [A. Aw, A. Klar, M. Materne, and M. Rascle, *SIAM J. Appl. Math.*, 63 (2002), pp. 259–278]. Moreover, in the hybrid model, the total variation in space of the velocity v is nonincreasing, the total variation in space of the specific volume τ is bounded, and the total variations in time of v and τ are bounded. Finally, we present some numerical simulations which confirm that the models' synchronization processes do not affect the waves propagation.

Key words. traffic flow, hybrid model, Lagrangian discretization, macroscopic model, microscopic model, total variation

1. Introduction.

Most of the vehicular traffic models are either macroscopic [3, 12, 18, 25, 30, 33, 34, 36, 37] or microscopic [15, 22]. When following a macroscopic approach, one focuses on global parameters such as traffic density or traffic flow. In general, from a macroscopic perspective vehicular traffic is viewed as a compressible fluid flow, whereas a microscopic approach describes the behavior of each individual vehicle. Macroscopic models allow one to simulate traffic on large networks but with a poor description of the details. On the other hand, microscopic models can cover such details, but they are intractable on a large network.

However, a typical road transport system or a road network includes obstacles, different road geometries and configurations (intersections, roundabouts, multiple lanes, etc.), as well as control features, such as traffic lights and crossings, which have a nonnegligible impact on traffic in the whole network. Therefore, neither of the two approaches is separately able to capture real traffic dynamics. A natural strategy is therefore to combine macroscopic and microscopic models, depending on the number of details that we need. This *hybrid* approach has recently received a considerable interest in traffic modeling [1, 6, 8, 19, 21, 27, 31]. Indeed, such models enable one to take into account the most important details of the traffic but still allow for descriptions of the traffic on a large network. However, they require strong consistency and compatibility between macroscopic and microscopic models to be coupled [20, 31].

Here, our macroscopic description is based on the Aw–Rascle (AR) model [3], whereas the microscopic model is a *follow-the-leader* (FLM)-type model [15, 22].

In [2], Aw et al. established a connection between the two classes of models. More precisely, the macroscopic model can be viewed as the limit of the time discretization of a microscopic FLM-type model when the number of vehicles increases. This can be done via a (hyperbolic) scaling in space and time (zoom) for which the density and the velocity are invariant.

Our aim in the current work is to propose a simple and fully discrete hybrid model for which both the macroscopic and the microscopic parts are based on the Lagrangian discretization of the AR second order model of traffic flow.

The outline of this paper is as follows: Sections 2 and 3 provide, respectively, some details on the discretizations of the macroscopic and the microscopic models. Section 4 describes the relations between the two models. Section 5 is devoted to the presentation of the hybrid model. In section 6, we establish estimates on the total variation both in space and time for the velocity v and the specific volume τ in Lagrangian coordinates. These estimates are of course the main ingredient for studying the convergence of our hybrid scheme to a suitable initial boundary value problem, which we will investigate in a forthcoming work. Finally, in section 7, some numerical simulations of the hybrid model confirm that this micro-macro description allows for a very nice description in *both* regimes.

2. The AR macroscopic model. We are concerned with the AR macroscopic model of traffic flow. It consists of the conservative form (in Eulerian coordinates) of the two following equations:

$$\begin{cases}\partial_t\rho+\partial_x(\rho v)=0,\\ \partial_t(\rho w)+\partial_x(\rho v w)=0,\end{cases} \tag{2.1}$$

where ρ denotes the fraction of space occupied by cars (a dimensionless local density), v is the macroscopic velocity of cars, and, for instance, $w=v+p(\rho)$. Many other choices could be considered as well. In what follows, we will assume for concreteness that

$$p(\rho)=\begin{cases}\frac{v_{ref}}{\gamma}\left(\frac{\rho}{\rho_m}\right)^{\gamma}, & \gamma>0,\\ -v_{ref}ln\left(\frac{\rho}{\rho_m}\right), & \gamma=0,\end{cases} \tag{2.2}$$

with v_{ref} a given reference velocity and $\rho_m:=\rho_{max}=1$ the maximal density.

Let $\tau=1/\rho$ be the specific volume and denote by (X,T) the Lagrangian "mass" coordinates. We have

$$\partial_x X=\rho,\qquad \partial_t X=-\rho v,\qquad T=t.$$

We recall that ρ is dimensionless; thus $X=\int^x\rho(y,t)dy$ describes the total length occupied by cars up to the point x if they were packed "nose to tail."

The system (2.1) can be rewritten in Lagrangian "mass" coordinates (X,T) as

$$\begin{cases}\partial_T\tau-\partial_X v=0,\\ \partial_T w=0,\end{cases} \tag{2.3}$$

now with $w=v+P(\tau):=v+p\left(\frac{1}{\tau}\right)$ (we set $\tau_m:=\tau_{min}:=\frac{1}{\rho_m}:=\frac{1}{\rho_{max}}=1$).

Away from the vacuum, the system (2.3) is strictly hyperbolic and is equivalent to the system (2.1). Its eigenvalues are

$$\lambda_1=P'(\tau)<0\quad\text{and}\quad\lambda_2=0.$$

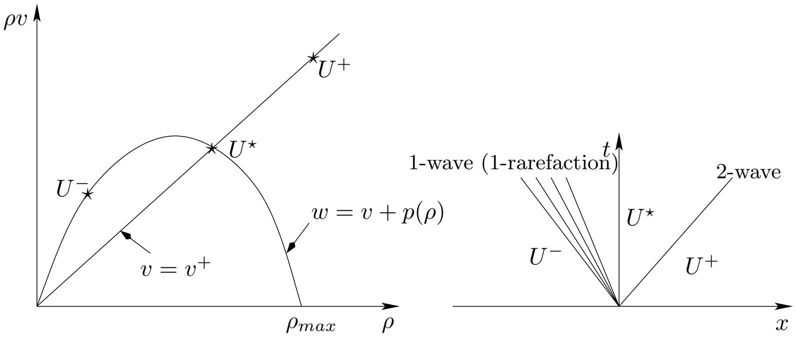

FIG. 2.1. *Riemann problem in $(\rho, \rho v)$ and (x, t) planes.*

Moreover, λ_1 is genuinely nonlinear and λ_2 is linearly degenerate. The Riemann invariants associated with the two eigenvalues λ_1 and λ_2 are v and w, respectively.

2.1. The Riemann solver. Let us consider the following Riemann problem:

$$\begin{cases} \partial_t \tau - \partial_X v = 0, \\ \partial_t w = 0, \end{cases} \tag{2.4}$$

with the initial data

$$\begin{cases} U^+(X,0) = (\tau^+, w^+) & \text{if } X > 0, \\ U^-(X,0) = (\tau^-, w^-) & \text{if } X < 0. \end{cases} \tag{2.5}$$

The natural solution $U(X, t)$ to the Riemann problem (2.4)–(2.5) involves two waves: a rarefaction or a shock wave associated with the first characteristic field λ_1 followed by a contact discontinuity associated with the second one λ_2.

PROPOSITION 2.1. *The solution of the Riemann problem* (2.4)–(2.5) *is constructed as follows. First, we connect U^- with an intermediate state $U^* = (\tau^*, w^*)$ (such that $v^* = w^* - P(\tau^*) = v^+$ and $w^* = w^-$) by a 1-shock wave (if $v^+ < v^-$) or a 1-rarefaction (if $v^+ > v^-$). Then, U^* is connected with U^+ by a 2-contact discontinuity (see Figure* 2.1*).*

Through each wave, the specific volume τ and the velocity v are monotonous functions of X/t. Therefore, away from the vacuum, the solution $U(X, t)$ remains in the bounded invariant region $\mathcal{R}$ defined in (2.6)*, i.e.,*

$$U(X,t) = (\tau, w), \quad \textit{where } \tau = P^{-1}(w - v)$$

and

$$(v, w) \in \mathcal{R} = \{[v^{min}, v^{max}] \times [w^{min}, w^{max}]\} \cap \{w \geq v\}, \tag{2.6}$$

where $v^{min}, w^{min} \geq 0$ and $v^{max}, w^{max} < +\infty$ (see Figure 2.2*).*

In the (w, v) coordinates (see Figure 2.2) we have

$$U^{\pm} = (w^{\pm}, v^{\pm}) \quad \text{and} \quad U^* = (w^-, v^+). \tag{2.7}$$

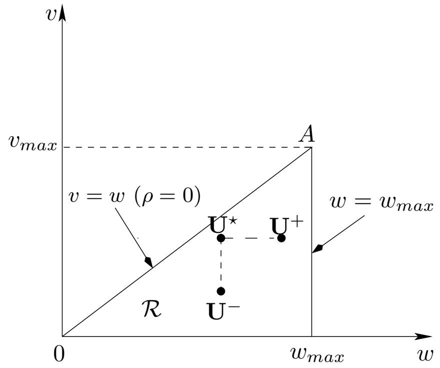

FIG. 2.2. *Riemann problem. The above triangle* $(0, A, w_{max})$ *is an invariant region in the* (w, v) *plane.*

2.2. Lagrangian discretization of the AR macroscopic model. Many approximate methods for (2.3) are based on solutions to the Riemann problem. Here, we are particularly interested in the Godunov scheme. In order to define the Godunov scheme associated with the above Riemann solver, we introduce grid points in space $X_j := j\Delta X$, $j \in \mathbb{Z}$, and in time $t_n = n\Delta t$, $n \in \mathbb{N}$. Let $h := (\Delta X, \Delta t)$ tend to $(0, 0)$, with $r := \frac{\Delta t}{\Delta X} =$ *constant*, and assume that for all $(\Delta X, \Delta t)$ the CFL condition is satisfied:

$$r \sup_{U \in \mathcal{R}} \left(\max_{i=1,2} \{|\lambda_i(U)|\} \right) \leq 1, \tag{2.8}$$

where $\mathcal{R}$ is the invariant region defined in (2.6), containing the initial data $U(x)$ for all $x \in \mathbb{R}$. Moreover, we assume that $\mathcal{R}$ does not touch the vacuum, i.e.,

$$\inf\{w - v,\ (v, w) \in \mathcal{R}\} > 0.$$

Then, the Lagrangian Godunov discretization of the AR macroscopic model (2.3) (see [2] for more details) is given by

$$\begin{cases} \tau_j^{n+1} = \tau_j^n + \frac{\Delta t}{\Delta X} \left(v_{j+1}^n - v_j^n \right), \\ w_j^{n+1} = w_j^n, \end{cases} \tag{2.9}$$

with initial data

$$\begin{cases} \tau_j(0) = \tau_j^0 \geq \frac{1}{\rho_m} = \tau_m = 1, \\ 0 \leq v_j(0) = v_j^0 \leq w_j - P(\tau_m). \end{cases} \tag{2.10}$$

PROPOSITION 2.2. *Starting with arbitrary initial data for the Godunov scheme*

$$U_h(X, 0) = (\tau_h^0, w_h^0),$$

with $(v_h^0 = w_h^0 - P(\tau_h^0), w_h^0) \in \mathcal{R}$ *(defined in* (2.6)*), the solutions*

$$U_h(X, t_n) = (\tau_h^n, w_h^n)$$

constructed by the Godunov scheme satisfy

$$(v_h^n = w_h^n - P(\tau_h^n), w_h^n) \in \mathcal{R}.$$

Therefore, the region $\mathcal{R}$ is also invariant for the Godunov scheme.

Proof. In each cell $I_j = [X_{j-1/2}, X_{j+1/2}]$, the variable w is constant, whereas the velocity and the specific volume τ are monotonous, by Proposition 2.1. Therefore, in each cell, $U(X,t) = (\tau, w)(X,t)$ remains in the same bounded region $\mathcal{R}$, which is thus invariant for the Godunov scheme. □

We are going to use the following results; see [4, Theorem 3.1] and [2, Theorem 1].

PROPOSITION 2.3 (see [4]). *Assume that the sequence v_h^0 is in $BV(\mathbb{R})$; that is, the total variation in space is bounded: there exists a constant $C_0 < +\infty$ such that*

$$TV_X(v_h^0; \mathbb{R}) = \sum_{j\in\mathbb{Z}} \left| v_{j+1}^0 - v_j^0 \right| \leq C_0.$$

Let

$$\tilde{v}_h(X,t) := v_j^n + (t - t_n)(v_j^{n+1} - v_j^n)/\Delta t \tag{2.11}$$

be the linear interpolation in time of v_h on I_j between t_n and t_{n+1} and similarly for $\tilde{\tau}_h$.

Then, for all $n \in \mathbb{N}$, for all $h = (\Delta X, \Delta t)$, we have the following:

(i) *The total variation in X of $v_h(.,t)$ is nonincreasing in time, and the total variation in t of $\tilde{v}_h(.,.)$ is bounded on $\mathbb{R} \times [0,T]$:*

$$\begin{aligned} \sup_{t\geq 0} TV_X(v_h(.,t) &= \sup_{n\in\mathbb{N}} TV_X(v_h^n; \mathbb{R}) \\ &= \sup_{n\in\mathbb{N}} \sum_{j\in\mathbb{Z}} \left| v_{j+1}^n - v_j^n \right| \leq TV_X(v_h^0, \mathbb{R}) \leq C_0, \end{aligned} \tag{2.12}$$

$$TV_t(\tilde{v}_h(.,.); \mathbb{R} \times [t,t']) \leq C \max(|t'-t|, \Delta t) C_0. \tag{2.13}$$

(ii) *The total variation in X of $\tau_h(.,t)$ on $\cup_{j\in\mathbb{Z}} I_j$ and the total variation in t of $\tilde{\tau}_h(.,.)$ on $\mathbb{R} \times [0,\infty]$ are bounded uniformly in h; i.e., there exists a constant C' independent of h such that*

$$\sup_h \sup_{t\geq 0} \sum_{j\in\mathbb{Z}} TV_X(\tau_h(.,t); I_j) \leq C' C_0, \tag{2.14a}$$

$$\forall t \in [0,t'],\ \sup_h TV_t(\tilde{\tau}_h(.,.); \mathbb{R} \times [t,t']) \leq C' \max(|t'-t|, \Delta t) C_0. \tag{2.14b}$$

We recall that I_j is the open interval $\left(X_{j-1/2}, X_{j+1/2}\right)$. Moreover, if we assume that w_h and τ_h are initially in $BV(\mathbb{R})$, then (2.14a) *can be replaced by the stronger result*

$$\sup_h \sup_{t\geq 0} TV_X(\tau_h(.,t); \mathbb{R}) \leq C' C_0. \tag{2.15}$$

3. The microscopic (FLM) model.

The microscopic model that we consider is an FLM-type model [15, 22]. In such a model, the basic idea is that the acceleration at time t depends on the relative speeds of the vehicle and its leading vehicle at time t as well as the distance between the vehicles. Therefore, the dynamics of a vehicle j is given by the two equations

$$\begin{cases} \frac{dx_j}{dt} = v_j, \\ \frac{dv_j}{dt} = P'\left(\frac{x_{j+1}-x_j}{\Delta X}\right)\left(\frac{v_{j+1}-v_j}{\Delta X}\right), \end{cases} \tag{3.1}$$

where $x_j(t)$ and $v_j(t)$ are, respectively, the position and the velocity of the vehicle j at time t, and ΔX is its length. Here, $\rho_j := \frac{\Delta X}{(x_{j+1}-x_j)}$ is the normalized local density (more precisely the fraction of space occupied by a vehicle) of this vehicle. Therefore, the specific volume is $\tau_j = \frac{1}{\rho_j} = \frac{(x_{j+1}-x_j)}{\Delta X}$ and the maximal density $\rho_m = \rho_{max} = \frac{1}{\tau_m} = 1 := \frac{1}{\tau_{min}}$. In this section, contrarily to sections 5 and 6, the car $(j+1)$ is the leader of car j. A prototype is the case where $P(\tau) = p\left(\frac{1}{\tau}\right) = \frac{v_{ref}}{\gamma}\left(\frac{\rho}{\rho_m}\right)^\gamma$ (with v_{ref} a given reference velocity and $\gamma > 0$ a given parameter) and $w_j = v_j + P(\tau_j)$. Then system (3.1) writes

$$\begin{cases} \frac{d\tau_j}{dt} = \frac{(v_{j+1}-v_j)}{\Delta X}, \\ \frac{dw_j}{dt} = 0. \end{cases} \tag{3.2}$$

The explicit first order Euler time discretization (with step Δt of system (3.2) is then

$$\begin{cases} \tau_j^{n+1} = \tau_j^n + \frac{\Delta t}{\Delta X}\left(v_{j+1}^n - v_j^n\right), \\ w_j^{n+1} = w_j^n, \end{cases} \tag{3.3}$$

with

$$v_j^{n+1} = w_j^{n+1} - P(\tau_j^{n+1})$$

and initial conditions

$$\begin{cases} \tau_j(0) = \tau_j^0 \geq \frac{1}{\rho_m} = \tau_m = 1, \\ 0 \leq v_j(0) = v_j^0 \leq w_j - P(\tau_m). \end{cases} \tag{3.4}$$

As in the macroscopic scheme, we can define $(\tilde{\tau}_h, \tilde{v}_h)$ by (2.11). Since system (3.3) is *exactly* the same as (2.9), $\tilde{\tau}_h$ and $\tilde{v}_h$ satisfy the same BV estimates as in Proposition 2.3.

4. Link between the macroscopic and microscopic model: The scaling. We now consider a large number of vehicles on a long stretch of road. Let us now introduce in the AR macroscopic model (2.3) a scaling (zoom) such that the size of the considered domain and the number of vehicles tend to infinity, whereas the vehicle length tends to 0. Let ϵ be the scaling parameter. For some given Eulerian or Lagrangian coordinates (x,t) or (X,t), we consider the rescaled coordinates

$$(x', t') = (\epsilon x, \epsilon t); \qquad (X', t') = (\epsilon X, \epsilon t).$$

Consequently, the length of a vehicle is now $\Delta X' = \epsilon \Delta X$. The parameter ϵ is proportional to the inverse of maximal possible number of vehicles per new unit length. However, in the new coordinates (X', t'), the variable τ (resp., ρ) and the Riemann invariant (v, w) remain unchanged, that is,

$$\tau' = \tau \text{ (resp., } \rho' = \rho), \quad v' = v, \quad w' = w.$$

Thus the system (2.3) becomes

$$\begin{cases} \frac{\partial \tau}{\partial t} = \frac{\partial v}{\partial X'}, \\ \frac{\partial w}{\partial t'} = 0. \end{cases} \tag{4.1}$$

Using the same scaling for the microscopic model, (3.2) now writes

$$\begin{cases} \frac{d\tau_j}{dt'} = \frac{1}{\Delta X'}\left(v_{j+1} - v_j\right), \\ \frac{dw_j}{dt'} = 0. \end{cases} \tag{4.2}$$

Both in the original and in the rescaled coordinates, the standard first order explicit Euler discretization of the microscopic model (3.3) is equivalent to the Godunov discretization (2.9) of the macroscopic model; see (7.1), (7.2), (7.3), and (7.4).

5. Hybrid Lagrangian model.

In order to construct our hybrid Lagrangian model, we want to combine a macroscopic description away from the junctions, traffic lights, etc. and a microscopic view near these obstacles as shown in Figure 5.1.

Thanks to the equivalence established above between the two models, we expect to get rid of the usual compatibility problems encountered when developing a hybrid model.

5.1. Description of the two Lagrangian models.

Since the macroscopic model is shown to be the limit of a large number of vehicles on a long stretch of road (away from the vacuum), we may consider that a Lagrangian macroscopic (moving) cell (or the corresponding moving Eulerian cell) contains a "*long vehicle*" made by juxtaposition of *several (say N) ordinary vehicles*, whereas in the microscopic model, a Lagrangian cell contains a *single ordinary vehicle*, as depicted in Figure 5.1. Obviously macroscopic Lagrangian cells are much larger than microscopic ones. In Eulerian hybrid models (see, e.g., [6, 8, 19, 21, 27, 31]), the "microscopic region" is fixed in Eulerian coordinates. In contrast, here, this "actual microscopic region (AMR)" (see Figure 5.1) is piecewise constant in Lagrangian coordinates. It is moving in Eulerian coordinates and is periodically refreshed in order to *always* contain a *fixed* Eulerian region: the "minimal microscopic region (MMR)" (see Figure 5.1) around the junction, traffic light, etc., in which our description will *always* be microscopic.

5.2. Model synchronization.

In this section we show in detail how to pass from the macroscopic to the microscopic description and vice versa. Here and in the next sections, we order the cells and the cars by calling $(i-1)$ the leader and i the follower.

5.2.1. From the macroscopic to the microscopic model.

When a macroscopic Lagrangian cell enters the MMR, we split the "*long vehicle*" (which is nothing but a juxtaposition of N cars) into N different microscopic cells and uniformly distribute these cars over the length L of the macroscopic cell, as shown in Figure 5.2. Here, all our vehicles are supposed to have the same length. In principle, we could also cover the case of vehicles with different lengths; see Remark 5.1 below.

This splitting does not modify the specific volume τ. Indeed, in the macroscopic

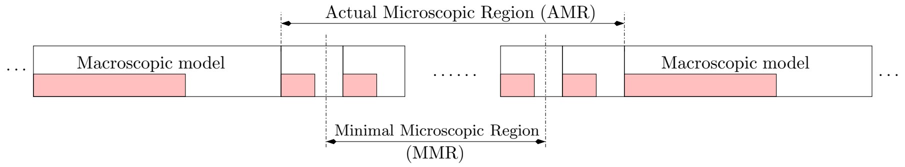

FIG. 5.1. *Hybrid Lagrangian model.*

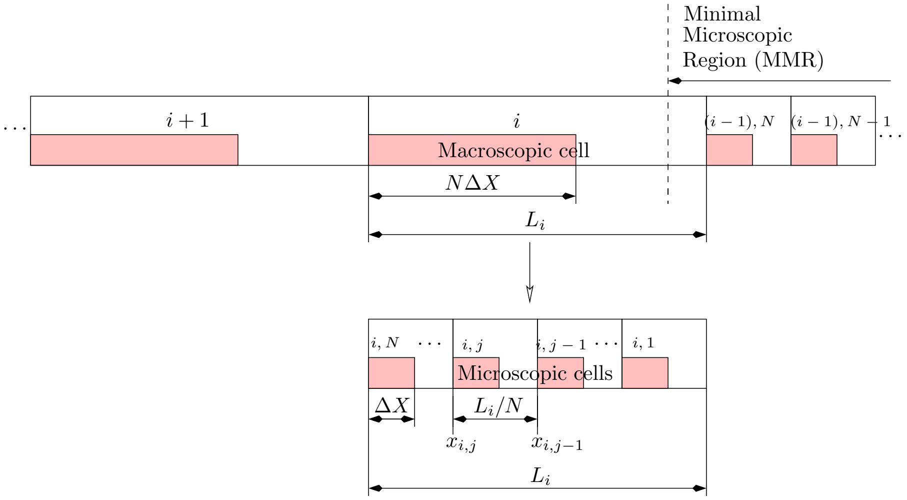

FIG. 5.2. *From the macroscopic to the microscopic model: before (above) and after (below) the synchronization.*

cell i, we have

$$\tau_i = \frac{L_i}{N\Delta X} = \tau_{mac}. \tag{5.1}$$

When this cell i becomes microscopic, the distance between two successive cars (i,j) (the follower) and $(i,j-1)$ (the leader) is

$$(x_{i,j-1} - x_{i,j}) = \frac{L_i}{N}. \tag{5.2}$$

Therefore, the microscopic specific volume in each of these microscopic cells is now

$$\tau_{i,j} = \tau_{mic} = \frac{L_i/N}{\Delta X} = \tau_{mac}. \tag{5.3}$$

So the specific volume does not change when passing from the macroscopic to the microscopic model. Notice that in the Godunov scheme the Lagrangian variable w does not change in time inside a cell i: $w_{i,j}^{n+1} = w_{i,j}^{n}$. Therefore, in the microscopic cells $w_{i,j}$ will be the same as in the macroscopic cell, i.e., $w_{i,j} = w_i$. Consequently, the velocity also does not change:

$$v_{i,j} = w_{i,j} - P(\tau_{i,j}) = w_i - P(\tau_i) = v_i \quad \text{for all microscopic cars } j \text{ in this cell } i.$$

REMARK 5.1. *In the case of vehicles with different lengths, we need to keep the order of vehicles and their respective lengths in each macroscopic cell. Since there is no possibility of overtaking (our model is in principle a one lane model), this order remains constant in time. Let us consider a macroscopic cell i of total length L_i and let $\Delta X_{i,j}$ be the length of the microscopic vehicle j in this cell. When this cell becomes microscopic, we need to distribute uniformly the cars over the length L_i. In the synchronization macro-micro, we distribute uniformly the specific volume among all the vehicles of this cell:*

$$\tau_{i,j} = \tau_{mic} = \frac{x_{i,j-1} - x_{i,j}}{\Delta X_{i,j}} = \tau_i = \frac{L_i}{\sum_{j=1}^{N} \Delta X_{i,j}} = \tau_{mac} \quad \forall\ j = 1, \ldots, N. \tag{5.4}$$

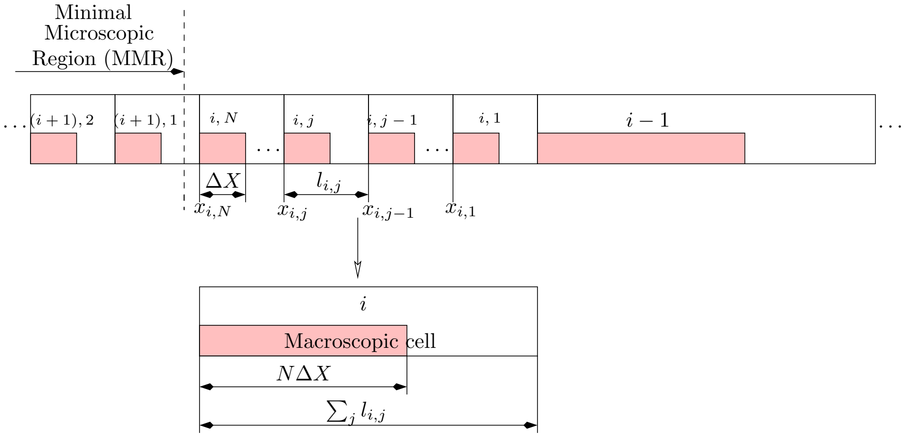

FIG. 5.3. *From the microscopic to the macroscopic model: before (above) and after (below) the synchronization.*

Therefore, we compute the distance $l_{i,j} = (x_{i,j-1} - x_{i,j})$ *for all* $j = 2, \ldots, N$ *by solving the following system:*

$$(5.5) \qquad \begin{cases} \frac{l_{i,j}}{\Delta X_{i,j}} = \frac{l_{i,j-1}}{\Delta X_{i,j-1}} \quad \forall\ j = 1, \ldots, N, \\ \displaystyle\sum_{j=1}^{n} l_{ij} = L_i. \end{cases}$$

5.2.2. From the microscopic to the macroscopic model. When the last (say the (i,N)th) vehicle has completely left the MMR, we do exactly the converse; i.e., we aggregate the N vehicles to form a new macroscopic "*vehicle*." We set $l_{i,j} = x_{ij-1} - x_{i,j}$, with $x_{i,j}$ the position of vehicle (i,j) as indicated in Figure 5.3.

The macroscopic specific volume will be

$$(5.6) \qquad \bar{\tau}_i = \frac{\sum_{j=1}^{N} l_{i,j}}{N\Delta X} = \frac{1}{N}\sum_{j=1}^{N} \frac{l_{i,j}}{\Delta X} = \frac{1}{N}\sum_{j=1}^{N} \tau_{i,j}.$$

The Lagrangian variable $w_{i,j}$ is conserved, since according to subsection 5.2.1 the N vehicles have the same Lagrangian variable $w_{i,j} = w_i$. Thus, averaging in Lagrangian coordinates, we have

$$(5.7) \qquad \frac{1}{N}\sum_{j=1}^{N} w_{i,j} = \frac{1}{N}\sum_{j=1}^{N} w_i = w_i.$$

Therefore, the corresponding macroscopic velocity is $\bar{v}_i = w_i - P(\bar{\tau}_i)$.

In this case, the macroscopic model does not inherit exactly the microscopic parameters but only the average values for τ and w and the above corresponding velocity. In spite of this change of parameters, we will prove in the following section that in the hybrid model the total variation in space of v is nonincreasing, the total variation in space of τ is bounded, and total variations in time of v and τ are bounded.

6. Estimates on the total variation in the hybrid model. In this section, with the above synchronizations between the macroscopic and the microscopic models, we show that in the hybrid model the total variation in space of the velocity v is nonincreasing, the total variation in space of the specific volume τ is bounded, and the total variations in time of v and τ are bounded.

First, the following type of results is classical. Its proof is recalled below for the convenience of the reader.

Lemma 6.1. *Let $U = (u_1, u_2, \dots, u_n) \in \mathbb{R}^n$ and $\bar{u} \in \mathbb{R}$ such that*

$$m = \min_i(u_i) \leq \bar{u} \leq \max_i(u_i) = M.$$

Then,

$$\forall\ \alpha, \beta \in \mathbb{R}, \quad |\alpha - \bar{u}| + |\bar{u} - \beta| \leq |\alpha - u_1| + \sum_{i=1}^{n-1} |u_i - u_{i+1}| + |u_n - \beta|\,. \tag{6.1}$$

Proof.

$$\begin{aligned} |\alpha - \bar{u}| + |\bar{u} - \beta| &= |\alpha - u_1 + u_1 - \bar{u}| + |\bar{u} - u_n + u_n - \beta| \\ &\leq |\alpha - u_1| + |u_1 - \bar{u}| + |\bar{u} - u_n| + |u_n - \beta|\,. \end{aligned} \tag{6.2}$$

Now let us prove that $|u_1 - \bar{u}| + |\bar{u} - u_n| \leq \sum_{i=1}^{n-1} |u_i - u_{i+1}| = TV(u_i)_{i=1,\dots,n}$.

Since the function $\{\bar{u} \longmapsto |u_1 - \bar{u}| + |\bar{u} - u_n|\}$ is convex, its maximum is attained at an extremum point u_k equal to m or M; therefore,

$$\begin{aligned} |u_1 - \bar{u}| + |\bar{u} - u_n| &\leq \max\left(|u_1 - M| + |M - u_n|\,, |u_1 - m| + |m - u_n|\right) \\ &\leq |u_1 - u_k| + |u_k - u_n| \\ &\leq |u_1 - u_2| + \dots + |u_{k-1} - u_k| \\ &\quad + |u_k - u_{k+1}| + \dots + |u_{n-1} - u_n| \\ &= \sum_{i=1}^{n-1} |u_i - u_{i+1}| = TV(u_i)_{i=1,\dots,n}. \qquad \square \end{aligned} \tag{6.3}$$

Let us denote by v_i^n (resp., τ_i^n) and $v_{i,j}^n$ (resp., $\tau_{i,j}^n$), respectively, the macroscopic and the microscopic velocities (resp., specific volumes) at time t_n. At time $t = 0$, the velocities are in $BV(\mathbb{R})$ in both models and therefore in the hybrid one.

According to sections 2 and 3, the results of Proposition 2.3 hold, in both the macroscopic and the microscopic models, away from the synchronized cells. Therefore, we focus on the synchronization process, i.e., when passing from one representation to another.

Passing from a macroscopic cell to several microscopic cells does not change the velocity and the specific volume and therefore does not change their total variation.

On the other hand, when we convert N microscopic cells into a macroscopic one, the total variation of the hybrid model can change. We are going to show that nevertheless the total variation in space of the velocity v is nonincreasing, the total variation in space of the specific volume τ is bounded, and the total variations in time of v and τ are bounded.

Let us denote by TV_X and TV'_X the total variation in space, respectively, before and after this *micro-macro* synchronization. Since inside the synchronized cell (say $\bar{I}_{sync} = \bar{I}_i$), $\bar{\tau} = \frac{1}{N}\sum_j^N \tau_j$, $\bar{v} = w - P(\bar{\tau})$, and P is nonincreasing, we have, by

Lemma 6.1,

$$\begin{aligned} TV'_X(\tau_h(.,t_n),\bar{I}_{sync}) &= \left|\tau^n_{i-1} - \bar{\tau}^n_i\right| + \left|\bar{\tau}^n_i - \tau^n_{i+1,1}\right| \\ &\leq \left|\tau^n_{i-1} - \tau^n_{i,1}\right| + \sum_{j=1}^{N-1} \left|\tau^n_{i,j} - \tau^n_{i,j+1}\right| + \left|\tau^n_{i,N} - \tau^n_{i+1,1}\right| \\ &= TV_X(\tau_h(.,t_n),\bar{I}_{sync}), \end{aligned} \tag{6.4}$$

and similarly

$$\begin{aligned} TV'_X(v_h(.,t_n),\bar{I}_{sync}) &= \left|v^n_{i-1} - \bar{v}^n_i\right| + \left|\bar{v}^n_i - v^n_{i+1,1}\right| \\ &\leq \left|v^n_{i-1} - v^n_{i,1}\right| + \sum_{j=1}^{N-1} \left|v^n_{i,j} - v^n_{i,j+1}\right| + \left|v^n_{i,N} - v^n_{i+1,1}\right| \\ &= TV_X(v_h(.,t_n),\bar{I}_{sync}). \end{aligned} \tag{6.5}$$

Therefore, after any (micro-macro or conversely) synchronization process, the total variation *in space* of v is nonincreasing and the total variation *in space* of τ is bounded:

$$TV'_X(v_h(.,t_n),\bar{I}_{sync}) \leq TV_X(v_h(.,t_n),\bar{I}_{sync}). \tag{6.6}$$

We recall that in each macroscopic cell i, v_h and τ_h are monotonous in time in $[t_n, t_{n+1})$, that is,

$$\min(v^n_i, v^n_{i+1}) \leq v^{n+1}_i \leq \max(v^n_i, v^n_{i+1}), \tag{6.7}$$

and similarly for τ. Therefore, v_h, τ_h and their linear interpolations in time $\tilde{v}_h, \tilde{\tau}_h$ defined in (2.11) satisfy (2.14a) (or (2.15)) and (2.14b); see Proposition 2.3.

Moreover, as we said in sections 3 and 4, the macroscopic and microscopic models are essentially the same. In particular, the same BV estimates hold in microscopic cells for $(\tilde{v}_h, \tilde{\tau}_h)$.

According to the monotonicity property of v (see (6.7)), we have

$$\left|v^{n+1}_i - v^n_{i+1}\right| + \left|v^n_i - v^{n+1}_i\right| = \left|v^n_{i+1} - v^n_i\right|. \tag{6.8}$$

Let us denote, respectively, by $\mathcal{M}^n$ and μ^n the sets of indices of macroscopic cells and discretized macroscopic cells (i.e., split into microscopic cells) at time t_n. Therefore, $\mathcal{M}^n \cup \mu^n = \mathbb{Z}$.

From (6.6) and (6.8) we have

$$TV_X(v_h(.,t_n),\mathbb{R}) \leq TV_X(v_h(.,t_{n-1}),\mathbb{R}) \leq \cdots \leq TV_X(v^0_h,\mathbb{R}) = C_0. \tag{6.9}$$

In each cell I_k, $\tau_h(X,t) = P^{-1}(w_k - v_h(X,t))$, with P^{-1} Lipschitz-continuous. Therefore,

$$TV_X(\tau_h(.,t_n),\{\cup I_k; k \in \mathcal{M}^n \cup \mu^n\}) = \sum_{k\in\mathcal{M}^n\cup\mu^n} TV_X(\tau_h(.,t_n),I_k) \leq C_1 C_0, \tag{6.10}$$

where $C_1 := \left\|(P^{-1})'\right\|_{L^\infty}$.

Now let us study how the total variation in time evolves in our hybrid model:

$$TV_t(\tilde{\tau}_h(.,.);\mathbb{R}\times[t,t']) \leq \sum_{t-\Delta t\leq n\Delta t\leq t'+\Delta t} \left(A_n + B_n + C_n + D_n\right), \tag{6.11}$$

with

$$A_n = \sum_{i \in \mathcal{M}^n \cap \mathcal{M}^{n-1}} \left|\tau_i^n - \tau_i^{n-1}\right| N\Delta X,$$

$$B_n = \sum_{i \in \mu^n \cap \mu^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^n - \tau_{ij}^{n-1}\right| \Delta X,$$

$$C_n = \sum_{i \in \mu^n \cap \mathcal{M}^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^n - \tau_i^{n-1}\right| \Delta X,$$

$$D_n = \sum_{i \in \mathcal{M}^n \cap \mu^{n-1}} \sum_{j=1}^{N} \left|\bar{\tau}_i^n - \tau_{ij}^{n-1}\right| \Delta X.$$

Note that in (6.11) the summation involves all the times $t = n\Delta t$ between times t and t'.

We recall that we have, respectively, in the macroscopic model (see (2.9)) and the microscopic model (see (3.3)) the following:

$$\tau_i^n = \tau_i^{n-1} - \frac{\Delta t}{N\Delta X}\left(v_{i+1}^{n-1} - v_i^n\right) \text{ and} \tag{6.12a}$$

$$\tau_{ij}^n = \tau_{ij}^{n-1} - \frac{\Delta t}{\Delta X}\left(v_{ij+1}^{n-1} - v_{ij}^n\right), \tag{6.12b}$$

$$\begin{aligned} A_n &= \Delta t \sum_{i \in \mathcal{M}^n \cap \mathcal{M}^{n-1}} \left|v_{i+1}^{n-1} - v_i^n\right| \text{ by (6.12a)} \\ &\leq \Delta t \sum_{i \in \mathcal{M}^n \cap \mathcal{M}^{n-1}} \left|v_{i+1}^{n-1} - v_i^{n-1}\right| \text{ due to (6.7)} \\ &\leq \Delta t \sum_{i \in \mathbb{Z}} \left|v_{i+1}^{n-1} - v_i^{n-1}\right| \\ &= \Delta t\ TV_X(v_h(.,t_{n-1}),\mathbb{R}) \leq \Delta t\ TV_X(v_h^0,\mathbb{R}) = \Delta t C_0, \end{aligned}$$

$$\begin{aligned} B_n &= \Delta t \sum_{i \in \mu^n \cap \mu^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^n\right| \text{ by (6.12b)} \\ &\leq \Delta t \sum_{i \in \mu^n \cap \mu^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right| \text{ due to (6.7)} \\ &\leq \Delta t \sum_{i \in \mathbb{Z}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right| \\ &= \Delta t\ TV_X(v_h(.,t_{n-1}),\mathbb{R}) \leq \Delta t\ TV_X(v_h^0,\mathbb{R}) = \Delta t C_0, \end{aligned}$$

$$\begin{aligned} C_n &= \Delta X \sum_{i \in \mu^n \cap \mathcal{M}^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^n - \tau_i^{n-1}\right| \\ &\leq \Delta X \sum_{i \in \mu^n \cap \mathcal{M}^{n-1}} \sum_{j=1}^{N} \left(\left|\tau_{ij}^n - \tau_{ij}^{n-1}\right| + \left|\tau_{ij}^{n-1} - \tau_i^{n-1}\right|\right) \end{aligned}$$

$$
\begin{aligned}
&= \Delta X \sum_{i\in\mu^n\cap\mathcal{M}^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^{n} - \tau_{ij}^{n-1}\right| \text{ (since } \tau_{ij}^{n-1} = \tau_{i}^{n-1}, \\
&\quad \text{according to the macro-micro synchronization process)} \\
&= \Delta t \sum_{i\in\mu^n\cap\mathcal{M}^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n}\right| \\
&\leq \Delta t \sum_{i\in\mu^n\cap\mathcal{M}^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right| \text{ due to (6.7)} \\
&\leq \Delta t \sum_{i\in\mathbb{Z}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right| \\
&= \Delta t \; TV_X(v_h(.,t_{n-1}),\mathbb{R}) \leq \Delta t \; TV_X(v_h^0,\mathbb{R}) = \Delta t C_0,
\end{aligned}
$$

$$
\begin{aligned}
D_n &= \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|\bar{\tau}_{i}^{n} - \tau_{ij}^{n-1}\right| \\
&\leq \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|\bar{\tau}_{i}^{n} - \tau_{ij}^{n}\right| + \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^{n} - \tau_{ij}^{n-1}\right| \\
&=: D_n^1 + D_n^2,
\end{aligned}
$$

$$
\begin{aligned}
D_n^1 &= \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|\bar{\tau}_{i}^{n} - \tau_{ij}^{n}\right| \\
&\leq \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} N \max_{j} \left|\bar{\tau}_{i}^{n} - \tau_{ij}^{n}\right| \\
&\leq N\Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \left|\tau_{ir}^{n} - \tau_{is}^{n}\right|, \\
&\qquad \text{(since } \min_{j}(\tau_{ij}^{n}) = \tau_{is}^{n} \leq \bar{\tau}_{i}^{n} \leq \max_{j}(\tau_{ij}^{n}) = \tau_{ir}^{n}\text{)} \\
&\leq N\Delta X \; TV_X(\tau_h(.,t_n), \cup_{i\in\mathbb{Z}} I_i) \text{ by the same argument as in} \\
&\qquad \text{the proof of Lemma 6.1} \\
&\leq N\Delta X \; TV_X(v_h^0,\mathbb{R}) \left\|(P^{-1})'\right\|_{L^\infty} = N\Delta X C_1 C_0 \text{ due to (6.10),}
\end{aligned}
$$

$$
\begin{aligned}
D_n^2 &= \Delta X \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|\tau_{ij}^{n} - \tau_{ij}^{n-1}\right| \\
&= \Delta t \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n}\right| \\
&\leq \Delta t \sum_{i\in\mathcal{M}^n\cap\mu^{n-1}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right| \text{ due to (6.7)}
\end{aligned}
$$

$$\leq \Delta t \sum_{i\in\mathbb{Z}} \sum_{j=1}^{N} \left|v_{ij+1}^{n-1} - v_{ij}^{n-1}\right|$$
$$= \Delta t \; TV_X(v_h(.,t_{n-1}),\mathbb{R}) \leq \Delta t \; TV_X(v_h^0,\mathbb{R}) = \Delta t C_0.$$

So, $D_n \leq N\Delta X C_1 C_0 + \Delta t C_0$.

Finally, we get

$$TV_t(\tilde{\tau}_h(.,.);\mathbb{R}\times[t,t']) \leq (|t'-t| + 2\Delta t)(N\Delta X C_1 + 4\Delta t)C_0. \tag{6.13}$$

We recall that we study the limit when $\frac{\Delta t}{\Delta X}$ is constant and satisfies the CFL condition (2.8).

In each cell, the specific volume τ_h is monotonous, w_h is constant, and the velocity is

$$v_h = w_h - P(\tau_h),$$

where P is a monotonous Lipschitz continuous function. Therefore, there exists a $C_2 < +\infty$ such that

$$TV_t(\tilde{v}_h(.,.);\mathbb{R}\times[t,t']) \leq (|t'-t| + 2\Delta t)C_2 C_0. \tag{6.14}$$

We summarize the above results in the following.

THEOREM 6.2. *Assume that the sequences* (v_h^0, τ_h^0)*, respectively, the initial data for* v *and* τ *(and therefore for* w*), are in* $BV(\mathbb{R})$*; i.e., there exist some constants* $c_v < +\infty$ *and* $c_\tau < +\infty$ *such that*

$$TV_X(v_h^0;\mathbb{R}) = \sum_{i\in\mathcal{M}^0} \left|v_i^0 - v_{i+1}^0\right| + \sum_{i\in\mu^0}\sum_{j=1}^{N} \left|v_{ij}^0 - v_{ij+1}^0\right| + b_v \leq c_v, \tag{6.15}$$

$$TV_X(\tau_h^0;\mathbb{R}) = \sum_{i\in\mathcal{M}^0} \left|\tau_i^0 - \tau_{i+1}^0\right| + \sum_{i\in\mu^0}\sum_{j=1}^{N} \left|\tau_{ij}^0 - \tau_{ij+1}^0\right| + b_\tau \leq c_\tau, \tag{6.16}$$

where b_v *and* b_τ *are the boundary terms (for instance* $b_v = \sum \left|v_k^0 - v_{lj}^0\right|$ *with* $k \in \mathcal{M}^0$ *and* $l = k \pm 1 \in \mu^0$*).*

Moreover, assume that the CFL condition (2.8) *is satisfied and let* Δt, ΔX*, and* $N\Delta X$ *be constant with* $\frac{\Delta t}{\Delta X}$ = *constant. Then, the following hold:*

(i) *In the macroscopic region* (2.9) *(resp., the microscopic region* (3.3)*), we have the following (see* [2, 4]*):*
  (a) *the total variation in* X *of* $v_h(.,t)$ *(resp., in* t *of* $\tilde{v}_h(.,.)$ *and therefore of* $v_h(.,.)$*) is nonincreasing in time (resp., is bounded on* $\mathbb{R}\times[t,t']$*);*
  (b) *the total variation in* X *of* $\tau_h(.,t)$ *on* $\cup_{j\in\mathbb{Z}} I_j$ *(resp., in* t *of* $\tilde{\tau}_h(.,.)$ *and therefore of* $\tau_h(.,.)$*, on* $\mathbb{R}\times[t,t')$*) is bounded (resp., is bounded).*

(ii) *During the synchronization process, at each time* t_n*, the total variations in* X *of* v_h *and* τ_h *do not increase and their total variations in time are controlled from above.*

(iii) *Therefore, in the whole hybrid model we have the following:*
  (a) *the total variation in* X *of* $v_h(.,t)$ *(resp., in* t *of* $\tilde{v}_h(.,.)$ *and therefore of* $v_h(.,.)$*) is nonincreasing in time thanks to* (6.9) *(resp., is bounded on* $\mathbb{R}\times[t,t']$ *thanks to* (6.14)*);*

(b) *the total variation in X of $\tau_h(.,t)$ on $\cup_{j\in\mathbb{Z}} I_j$ (resp., in t of $\tilde{\tau}_h(.,.)$ and therefore of $\tau_h(.,.)$ on $\mathbb{R}\times[t,t'])$ is bounded thanks to* (6.10) *(resp., is bounded thanks to* (6.13)*).*

We are now in position to establish the convergence of the discrete solution constructed by our hybrid scheme. Let us first recall the following.

Definition 6.3 (see [2, 4]).

(i) *An L^∞ function*

$$U := (\tau, w) : \mathbb{R}\times\mathbb{R}_+ \longrightarrow \mathbb{R}^2$$

is called a weak entropy solution to the Lagrangian system (2.3) *if it is a weak solution (see* (ii)*) and if for any entropy-flux pair $(\eta(\tau,w), q(\tau,w))$ with $\eta(\tau,w)$ convex in τ, and for any $\phi(X,t)\in C_0^\infty(\mathbb{R}\times\mathbb{R}_+)$, $\phi\geq 0$, we have*

$$\int_0^\infty\int_{\mathbb{R}}(\eta(U)\partial_t\phi + q(U)\partial_X\phi)dXdt + \int_{\mathbb{R}}\eta(U_0(X))\phi(X,0)dX \geq 0. \tag{6.17}$$

(ii) *U is called a weak solution to* (2.3) *if the above inequality holds (and therefore is an equality) for the trivial entropy flux pairs $(\eta,q) := (\pm\tau, \mp v)$.*

Adapting the results of [4], it is easy to show that any entropy $\eta(\tau,w)$ is convex in τ if and only if the associated entropy flux $q\equiv q(v)$ is concave (in v), and that there is an associated L^1 contraction principle "à la Kružkov," which implies the uniqueness. Consequently, we obtain the following.

Theorem 6.4.

(i) *The sequence $(U_h = (\tau_h, w_h))$ in the hybrid model (given by the Godunov scheme* (2.9) *of the AR model and the Euler discretization* (3.3) *of the FLM model) is therefore a sequence of approximate weak entropy solutions to* (2.3)*, associated with the initial data $U_h^0 = (\tau_h^0, w_h^0)$.*

(ii) *Consequently, a subsequence (U_h)—in fact, by uniqueness, the whole sequence —converges to the unique weak entropy solution to* (2.3)*, with the same initial data.*

Proof. First, since $\partial_t\tau_h - \partial_X v_h = 0$, for $t_n < t < t_{n+1}$, for any smooth function $\phi(X,t)$ with compact support, we have

$$\begin{aligned}
&\int_0^\infty\int_{\mathbb{R}}(\tau_h\partial_t\phi - v_h\partial_X\phi)(X,t)dXdt + \int_{\mathbb{R}}\tau_h^0(X)\phi(X,0)dX\\
&= \sum_{n\geq 1}\sum_{i\in\mathbb{Z}}\left[\int_{I_i}\tau_h(X,t)\phi(X,t)dX\right]_{t_n^-}^{t_n^+} + \sum_i\int_{I_i}\tau_h^0(X)\phi(X,0)dX\\
&= \sum_{n\geq 1}\sum_{i\in\mathcal{M}^n}\int_{I_i}(\tau_h(X,t_n^-) - \tau_i^n)\phi(X,t_n)dX + \sum_{n\geq 1}\sum_{i\in\mu^n}\sum_{j=1}^N\int_{I_{ij}}(\tau_h(X,t_n^-) - \tau_{ij}^n)\phi(X,t_n)dX\\
&+ \sum_{i\in\mathcal{M}^n\cup\mu^n}\int_{I_i}\tau_h^0(X)\phi(X,0)dX =: A_h.
\end{aligned}$$

Now, since the test function ϕ is C^1 and compactly supported, using a Taylor expansion of ϕ on each interval, we get

$$|A_h| \leq (\Delta X)^2\,\|\partial_X\phi\|_{L^\infty}\sum_{n\geq 0}\sum_{i\in\mathcal{M}^n\cup\mu^n} TV_X(\tau_h(.,t);I_i)$$

$$\leq (\Delta X)^2 \frac{T}{\Delta t} \left\| \partial_X \phi \right\|_{L^\infty} \sup_{n \leq \frac{T}{\Delta t}} \sum_{i \in \mathcal{M}^n \cup \mu^n} TV_X(\tau_h(.,t); I_i)$$
$$\leq \left(\frac{\Delta X}{\Delta t}\right) \Delta X T \left\| \partial_X \phi \right\|_{L^\infty} \sup_{n \leq \frac{T}{\Delta t}} \sum_{i \in \mathcal{M}^n \cup \mu^n} TV_X(\tau_h(.,t); I_i)$$
$$= \left(\frac{\Delta X}{\Delta t}\right)^2 \Delta t T \left\| \partial_X \phi \right\|_{L^\infty} \sup_{n \leq \frac{T}{\Delta t}} \sum_{i \in \mathcal{M}^n \cup \mu^n} TV_X(\tau_h(.,t); I_i).$$

Therefore, thanks to the BV estimates in Theorem 6.2, $|A_h| \longrightarrow 0$ as $\Delta t \longrightarrow 0$ (or $\Delta X \longrightarrow 0$), since $\frac{\Delta X}{\Delta t}$ is constant.

We proceed similarly with the entropy production term. On the one hand, the approximate solutions U_h are weak entropy solutions on any $[t_n, t_{n+1})$, and on the other hand, by Jensen's inequality, any convex entropy does not increase at time t_n in the Godunov averaging step as well as in the *macro-micro* or *micro-macro* synchronization. Consequently, for any entropy $\eta(\tau, w)$ convex with respect to τ, associated with the flux q, for all $\phi \in C_0^\infty(\mathbb{R} \times \mathbb{R}_+)$, $\phi \geq 0$, we have

$$\int_0^\infty \int_{\mathbb{R}} (\eta(U_h)\partial_t \phi + q(U_h)\partial_X \phi)(X,t) dX dt + \int_{\mathbb{R}} \eta(U_h(X,0))\phi(X,0) dX$$
$$\geq \sum_{n \geq 1} \sum_{i \in \mathcal{M}^n} \int_{I_i} (\eta(U_h(X, t_n^-)) - \eta(U_i^n))\phi(X, t_n) dX$$
$$+ \sum_{n \geq 1} \sum_{i \in \mu^n} \sum_{j=1}^{N} \int_{I_{ij}} (\eta(u_h(X, t_n^-)) - \eta(u_{ij}^n))\phi(X, t_n) dX \geq 0. \qquad \square$$

Naturally, the above BV estimates are the crucial ingredient for showing the convergence of such a hybrid scheme to the unique globally defined weak entropy solution of a class of initial boundary value problems for a road with traffic light(s) or a road network in the spirit of [24] or [23]; see also [10]. We will investigate this in a forthcoming work.

7. Numerical simulations.

In this section, we are concerned with the numerical investigation of the hybrid model. We consider the equations given by the explicit Euler time discretization of the microscopic model or equivalently the Godunov discretization of the macroscopic model in Lagrangian mass coordinates, which is itself equivalent to the Godunov discretization in Eulerian coordinates, in Lagrangian (moving) cells. We set the number of vehicles in the macroscopic cell to $N := 10$ and the length of a vehicle to $\Delta X := 5$ m. In order to show how information travels through the different parts of the hybrid model, we have fixed the MMR to a distance of 200 m (i.e., 100 m on both sides of the obstacle), which corresponds to the grey rectangle in Figures 7.1, 7.2, and 7.3. In order to get a better insight into the use of the hybrid model, we consider two scenarios and in each case we compare the densities given by the fully macroscopic model, the hybrid model, and the fully microscopic model.

The vertical line at $x = 0$ in Figures 7.1, 7.2, 7.3, and 7.5 is thickened to emphasize the state of the traffic light.

7.1. Case 1: The same time step in the whole hybrid scheme.

This case corresponds exactly to the assumptions of the theoretical analysis of sections 5 and 6. We consider the same time step for the macroscopic and microscopic parts of the

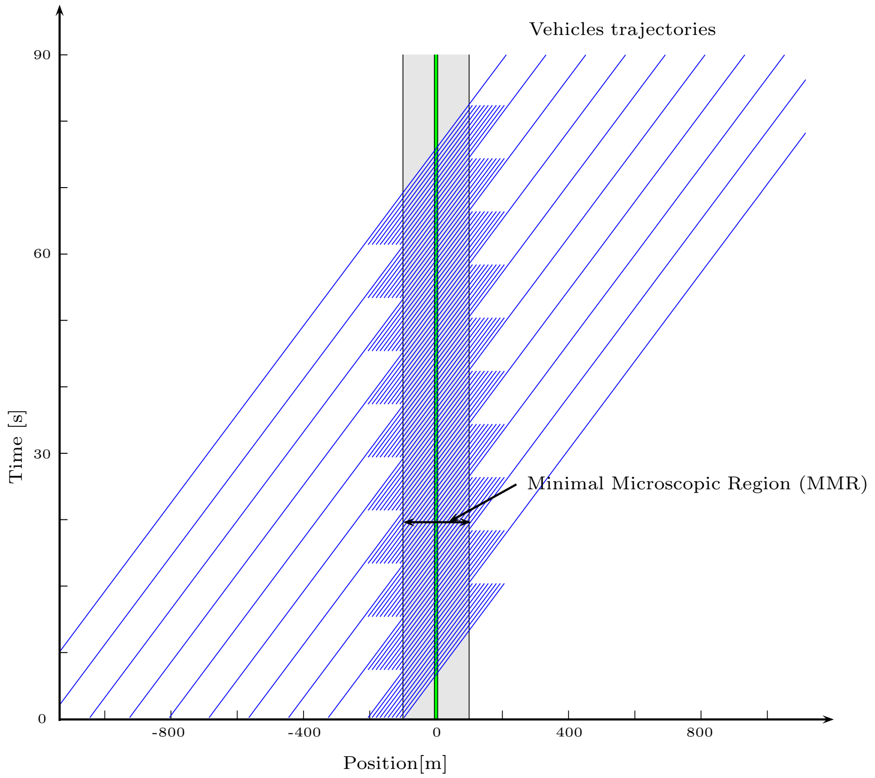

FIG. 7.1. *Case* 1. *The same time step in the microscopic and macroscopic regime: free flow traffic.*

hybrid model. Therefore, at time t_{n+1}, we have

$$\begin{cases} \tau_{ij}^{n+1} = \tau_{ij}^{n} + \frac{\Delta t}{\Delta X}\left(v_{ij-1}^{n} - v_{ij}^{n}\right), \\ w_{ij}^{n+1} = w_{ij}^{n} \end{cases} \tag{7.1}$$

in the microscopic part and

$$\begin{cases} \tau_{i}^{n+1} = \tau_{i}^{n} + \frac{\Delta t}{N\Delta X}\left(v_{i-1}^{n} - v_{ij}^{n}\right), \\ w_{i}^{n+1} = w_{i}^{n} \end{cases} \tag{7.2}$$

in the macroscopic part.

The time step Δt is chosen such that the CFL condition (2.8) is satisfied in both models. Obviously, the more drastic condition is the microscopic one, and thus we also expect too much numerical diffusion in the macroscopic part. For the simulations below the time step Δt is such that the Courant number is equal to 1 in the microscopic part.

The position of the vehicles is computed as follows:

$$x_{ij}^{n+1} = x_{ij}^{n} + \Delta t v_{ij}^{n}, \quad \text{with} \quad v_{ij}^{n} = w_{ij}^{n} - P(\tau_{ij}^{n}), \tag{7.3}$$

$$x_{i}^{n+1} = x_{i}^{n} + \Delta t v_{i}^{n}, \quad \text{with} \quad v_{i}^{n} = w_{i}^{n} - P(\tau_{i}^{n}). \tag{7.4}$$

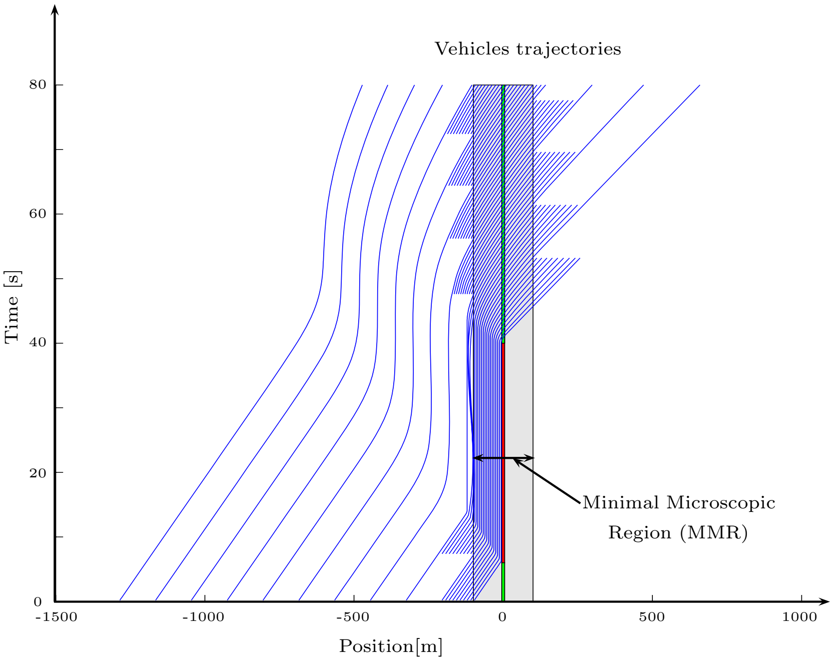

FIG. 7.2. *Case* 1. *The same time step in the microscopic and macroscopic regime: first a shock wave and then a rarefaction fan, both produced in the microscopic region, propagating backward in the macroscopic region.*

First, we simulate the hybrid model in a free flow situation. Trajectories of the "vehicles" in space and time for this case are plotted in Figure 7.1. In Figure 7.2, we plotted the "vehicles" trajectories when a "shock wave" appears at $t = 5$ s, followed by a "rarefaction fan" at $t = 40$ s in the minimal microscopic region (e.g., at a traffic light). Finally, Figure 7.3 shows the vehicles trajectories when a shock wave appears at $t = 40$ s followed by a rarefaction fan at $t = 70$ s, both downstream in the macroscopic regime (typically an incident on a highway). These "shocks" or "rarefaction waves" are produced numerically by forcing the leading vehicle to brake or accelerate. The simulations of these three situations show that the model synchronization does not perturb the wave propagation and allows for a nice description in each regime. In Figure 7.4, for the same situation (first a shock wave and then a rarefaction fan, both downstream of the minimal microscopic region), we plot the density for the fully macroscopic model, the hybrid model, and the fully microscopic model, respectively. The fully microscopic model gives a more precise description (but would be intractable for a large road network). In contrast, the description given by the macroscopic model is rather coarse to describe precisely the details in the minimal microscopic region. We also note that the shock is completely smoothed out by the numerical diffusion since the macroscopic CFL condition is $\frac{1}{10}$. Finally, the hybrid scheme gives an intermediate description, which is precise only in the region in which the details are important, in particular, here in the MMR [−100 m; +100 m].

7.2. Case 2: Different time steps in the hybrid scheme. This case is not exactly covered by the assumptions of sections 5 and 6, even though the same ideas could in principle be extended to this situation. We consider different time steps in the two parts (microscopic part and macroscopic part) of the hybrid scheme, in order

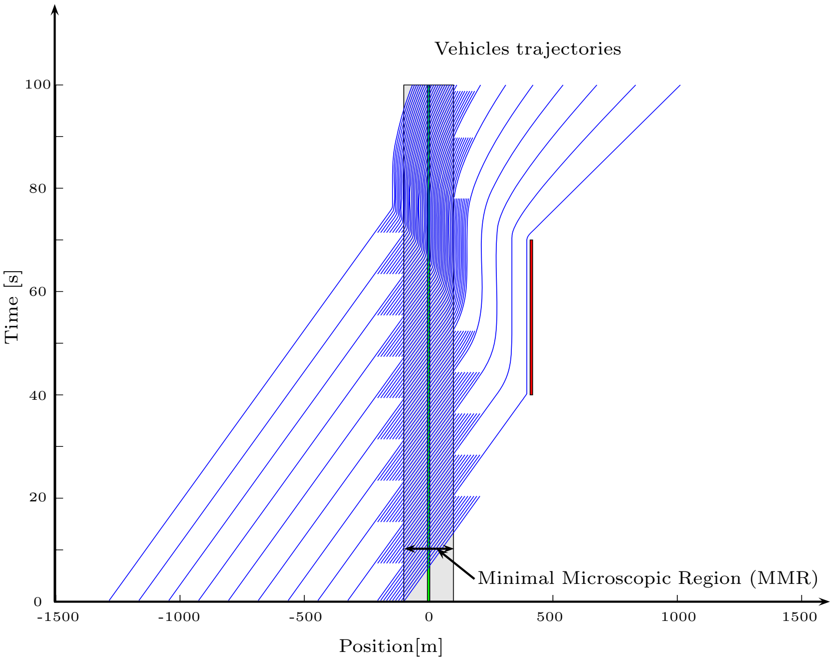

FIG. 7.3. *Case* 1. *The same time step in the microscopic and macroscopic regime: first a shock wave and then a rarefaction fan, both produced in the macroscopic region, propagating backward in the microscopic region.*

to have a Courant number (CFL condition) smaller than 1, but as large as possible in each region. Let $\Delta t_{\rm mic}$ and $\Delta t_{\rm mac}$ be, respectively, the time step in the microscopic part and the macroscopic part. In the microscopic region the updating takes place at each microscopic time $t_{n+1} = t_n + \Delta t_{\rm mic}$, i.e.,

$$\begin{cases} \tau_{ij}^{n+1} = \tau_{ij}^n + \frac{\Delta t_{\rm mic}}{\Delta X}\left(v_{ij-1}^n - v_{ij}^n\right), \\ w_{ij}^{n+1} = w_{ij}^n, \\ x_{ij}^{n+1} = x_{ij}^n + \Delta t_{\rm mic} v_{ij}^n, \\ v_{ij}^{n+1} = w_{ij}^{n+1} - P(\tau_{ij}^{n+1}), \end{cases} \tag{7.5}$$

with $\Delta t_{\rm mic}$ chosen in such a way that the CFL condition (2.8) is satisfied in the microscopic model.

In contrast, in the macroscopic region, the updating takes place at each macroscopic time $\bar{t}_{n+1} = \bar{t}_n + \Delta t_{\rm mac}$, i.e.,

$$\begin{cases} \tau_{i}^{n+1} = \tau_{i}^n + \frac{\Delta t_{\rm mac}}{N\Delta X}\left(v_{i-1}^n - v_{i}^n\right), \\ w_{i}^{n+1} = w_{i}^n, \\ x_{i}^{n+1} = x_{i}^n + \Delta t_{\rm mac} v_{i}^n, \\ v_{i}^{n+1} = w_{i}^{n+1} - P(\tau_{i}^{n+1}), \end{cases} \tag{7.6}$$

with $\Delta t_{\rm mac}$ chosen such that the CFL condition (2.8) is satisfied in the macroscopic model. Moreover, $\Delta t_{\rm mac} = k\Delta t_{\rm mic}$, with $1 < k \leq N$ and in general $k = N$.

One of the severe test cases is to handle the propagation of a strong shock, produced, e.g., at a (red) traffic light. In order to better track the propagation of this

(b)

(c)

FIG. 7.4. *Case* 1. *The same time step in the microscopic and macroscopic regime: first a shock wave and then a rarefaction fan, both downstream from the minimal microscopic region* ([−100 m, 100 m]): (a) *the density in the macroscopic model,* (b) *the density in the hybrid model,* (c) *the density in the microscopic model.*

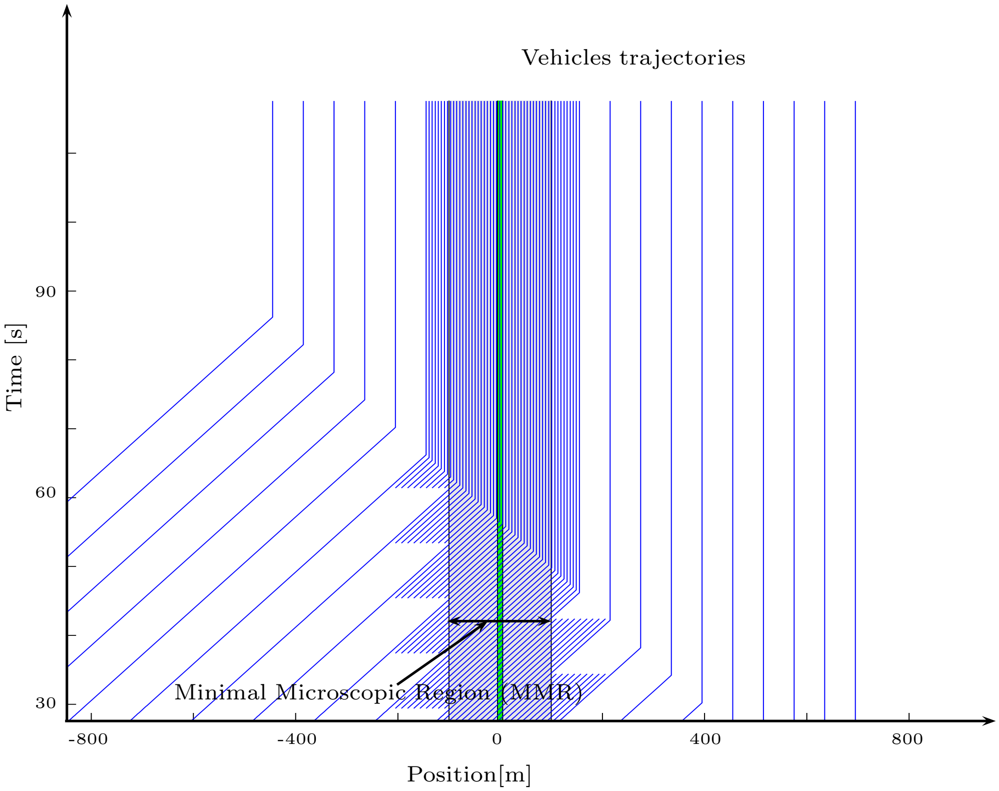

FIG. 7.5. *Case* 2. *Different time steps in the microscopic and macroscopic regime: a shock wave produced in the macroscopic region, propagating backward in the microscopic region.*

strong shock, we could use a front tracking method, which is a completely different numerical strategy. Here, we have used the following numerical procedure: At the macroscopic-microscopic interface, we include the following procedure to treat the case of a strong shock, as it happens at a traffic light. As soon as the last microscopic vehicle of a microscopic cell $(i-1)$ stops, the macroscopic cell i just behind this vehicle is tracked at each microscopic time step, until the time at which the "macroscopic vehicle" in cell i gets nose to tail with the microscopic vehicle ahead. Let t_s be this time. If t_s does not correspond to a macroscopic time, then we shift the macroscopic time step, not only for the macroscopic cell i but, exceptionally, for all the macroscopic cells behind cell i, which are updated at this time t_s using (once) the time step $\tilde{\Delta} t_{\text{mac}} = (t_s - \bar{t}_n)$, where $\bar{t}_n$ is the last macroscopic time before t_s. Thereafter, the time t_s becomes the beginning of the macroscopic time step for the cells behind cell i. We also recall that $\bar{t}_n \leq t_s \leq \bar{t}_n + \Delta t_{\text{mac}} = \bar{t}_{n+1}$.

For the numerical simulations plotted in Figures 7.5 and 7.6, we consider the CFL condition (2.8) with equality in both the microscopic and the macroscopic parts, and we set $\Delta t_{\text{mac}} = N \Delta t_{\text{mic}}$. As in the previous case, the fully microscopic model gives a more precise description (still too heavy for a large road network). In contrast, the description given by the macroscopic scheme is still a bit coarse to describe precisely the details in the MMR, but on the other hand, the shock is now much sharper even on this relatively coarse grid, thanks to the much better macroscopic CFL condition. Finally, the hybrid model gives an intermediate description which is very precise in the

MMR and still tractable elsewhere. Note in particular that the numerical propagation speed of the shock is quite well preserved in each region.

8. Conclusion.

Traffic investigation has simultaneously progressed both on the macroscopic and microscopic front. However, each description has its own limits. The recent success of hybrid models is due to their ability to capture traffic dynamics in a large domain with enough details near the obstacles.

In this paper, we propose a simple hybrid model based solely on a Lagrangian discretization of both the macroscopic and the microscopic models, coupled through Lagrangian interfaces periodically refreshed in order to *always* contain a fixed *Eulerian* region near an obstacle. As shown in the above numerical examples, the waves produced in either region nicely propagate through the other region. In particular, by this construction, the mass is automatically conserved through the interfaces.

This approach, which establishes a link between microscopic and macroscopic models and allows one to carry out simultaneous macro-micro simulations, could be hopefully a promising way to treat road intersections, in particular, on urban road networks.

RESTORATION OF COLOR IMAGES BY VECTOR VALUED BV FUNCTIONS AND VARIATIONAL CALCULUS[*]

MASSIMO FORNASIER[†] AND RICCARDO MARCH[‡]

Abstract. We analyze a variational problem for the recovery of vector valued functions and compute its numerical solution. The data of the problem are a small set of complete samples of the vector valued function and some significant incomplete information where the former are missing. The incomplete information is assumed as the result of a distortion, with values in a lower dimensional manifold. For the recovery of the function we minimize a functional which is formed by the discrepancy with respect to the data and total variation regularization constraints. We show the existence of minimizers in the space of vector valued bounded variation functions. For the computation of minimizers we provide a stable and efficient method. First, we approximate the functional by coercive functionals on $W^{1,2}$ in terms of Γ-convergence. Then we realize approximations of minimizers of the latter functionals by an iterative procedure to solve the PDE system of the corresponding Euler–Lagrange equations. The numerical implementation comes naturally by finite element discretization. We apply the algorithm to the restoration of color images from limited color information and gray levels where the colors are missing. The numerical experiments show that this scheme is very fast and robust. The reconstruction capabilities of the model are shown, also from very limited (randomly distributed) color data. Several examples are included from the real restoration problem of A. Mantegna's art frescoes in Italy.

1. Introduction and examples.

This paper concerns the analysis and the numerical implementation of a variational model for the restoration of vector valued functions. The restoration is obtained from few and sparse *complete* samples of the function and from significant *incomplete* information. The latter is assumed as the result of a nonlinear distortion and with values in a lower dimensional manifold. The applications we consider are in the field of digital signal and image restoration. Therefore, we deal with functional analysis in the space of bounded variation (BV) functions, which are actually considered a reasonable functional model for natural images and signals, usually characterized by discontinuities and piecewise smooth behavior. While in the literature on mathematical image processing mainly real valued BV functions and associated variational problems are discussed (see, for example, [7, 31]), in this contribution we consider vector valued functions.

Since the work of Mumford and Shah [29] and Rudin, Osher, and Fatemi [30], variational calculus techniques have been applied in several image processing problems. We refer the reader to the introductory book [6] for a presentation of this field, more details, and an extended literature.

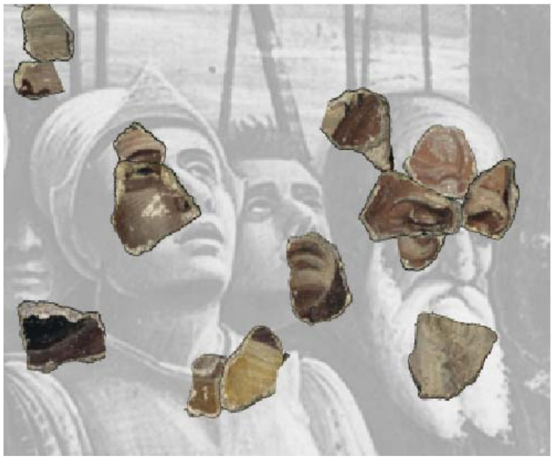

FIG. 1.1. *Fragments of A. Mantegna's frescoes* (1452)*, destroyed by a bombing in the Second World War. Computer based reconstruction by using efficient pattern matching techniques* [24] *is shown.*

Inspired by the fresco problem shown in Figure 1.1, a variational model has been proposed by one of the authors in [21]. The problem consists in recovering color in A. Mantegna's frescoes, which were partially destroyed by a bombing in the Second World War. Pieces of the frescoes with the original colors remain, while black and white photos, taken before the war, of the full frescoes are available. Unfortunately, the surface covered by the original fragments is only 77 m^2, while the original area was of several hundreds. This means that what we can currently reconstruct is just a *fraction* (estimated up to 8%) of what this inestimable artwork was. In particular, for most of the frescoes, the *original color* of the blanks is not known. So, natural questions arise: Is it possible to estimate *mathematically* the original colors of the frescoes by using the known fragments' information and the gray level of the pictures taken before the damage? And, how *faithful* is this estimation?

We now introduce some notations. Let Ω be an open, bounded, and connected subset of $\mathbb{R}^N$, and $D \subset \Omega$. The fresco problem is modeled as the reconstruction/restoration of a vector valued function $u : \Omega \to \mathbb{R}^M$ from a given observed couple of functions $(\bar{u}, \bar{v})$. The observed function $\bar{u}$ is assumed to represent correct information on $\Omega \backslash D$, and $\bar{v}$ is the result of a *nonlinear distortion* $\mathcal{L} : \mathbb{R}^M \to \mathbb{R}$ on D.

In particular, a digital image can be modeled as a function $u : \Omega \subset \mathbb{R}^2 \to \mathbb{R}^3_+$, so that, with each "point" $\mathbf{x}$ of the image, one associates the vector $u(\mathbf{x}) = (r(\mathbf{x}), g(\mathbf{x}), b(\mathbf{x})) \in \mathbb{R}^3_+$ of the color represented by the different channels: red, green, and blue. In particular, a digitalization of the image u corresponds to its sampling on a regular lattice $\tau\mathbb{Z}^2$, $\tau > 0$. Let us again write $u : \mathcal{N} \to \mathbb{R}^3_+$, $u(\mathbf{x}) = (r(\mathbf{x}), g(\mathbf{x}), b(\mathbf{x}))$ for $\mathbf{x} \in \mathcal{N} := \Omega \cap \tau\mathbb{Z}^2$.

Usually the gray level of an image can be described as a submanifold $\mathcal{M} \subset \mathbb{R}^3$ by

$$\mathcal{M} := \mathcal{M}_\sigma = \{\sigma(x) : x = \mathcal{L}(r, g, b) := L(\alpha r + \beta g + \gamma b),\ (r, g, b) \in \mathbb{R}^3_+\},$$

where $\alpha, \beta, \gamma > 0$, $\alpha + \beta + \gamma = 1$, $L : \mathbb{R} \to \mathbb{R}$ is a nonnegative increasing function, and $\sigma : \mathbb{R}_+ \to \mathbb{R}^3_+$ is a suitable section such that $\mathcal{L} \circ \sigma = \mathrm{id}_{\mathbb{R}_+}$. The function L is assumed smooth, nonlinear, and normally nonconvex and nonconcave. For example, Figure 1.2 describes the typical shape of an L function, which is estimated by fitting

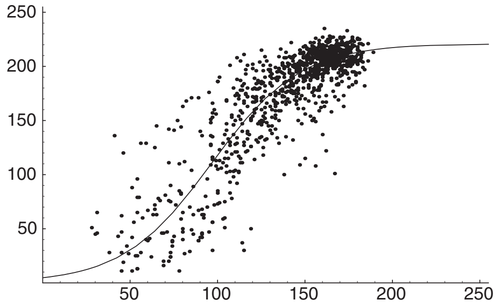

FIG. 1.2. *Estimate of the nonlinear curve L from a distribution of points with coordinates given by the linear combination $\alpha r + \beta g + \gamma b$ of the (red, green, blue) color fragments (abscissa) and by the corresponding underlying gray level of the original photographs dated to* 1920 *(ordinate). The sensitivity parameters α, β, γ to the different frequencies of red, green, and blue are chosen in order to minimize the total variance of the ordinates.*

a distribution of data from the real color fragments in Figure 1.1.

The variational problem proposed in [21] is the following:

$$\arg \inf_{u:\Omega\to\mathbb{R}^M} \Bigg\{ F(u) = \mu \int_{\Omega\setminus D} |u(x) - \bar{u}(x)|^p dx + \lambda \int_D |\mathcal{L}(u(x)) - \bar{v}(x)|^p dx \tag{1.1}$$
$$+ \int_\Omega \sum_{i=1}^M \phi(|\nabla u_i(x)|) dx \Bigg\},$$

where $p \geq 1$. For example, Figure 1.1 illustrates a typical situation where this model applies. In fact, in this case, there is an area $\Omega\setminus D$ of the domain $\Omega \subset \mathbb{R}^2$ of the image, where some fragments with colors are placed and complete information is available, and another area D (which we call the *inpainting region*), where only the gray-level information is known, modeled as the image of $\mathcal{L}$. The solution of the variational problem (1.1) produces in this case a new color image that extends the colors of the fragments in the gray region. Once the extended color image is transformed by means of $\mathcal{L}$, it is constrained to match the known gray level. We can consider this problem as a generalization of the well-known *image inpainting/disocclusion*; see, e.g., [3, 8, 9, 13, 14, 15, 16]. Several heuristic algorithms have been introduced for colorization of gray images; we refer the reader to the recently appeared paper [33] for related literature and to [26] for numerical examples. Nevertheless, our approach is theoretically founded, more general, and fits with many possible applications, for example, the recovery of a transmitted multichannel signal affected by a stationary (nonlinear) distortion.

For $N = p = 2$, we can compute the Euler–Lagrange equations associated with the functional F and obtain

$$0 = -\nabla \cdot \left(\frac{\phi'(|\nabla u_i|)}{|\nabla u_i|} \nabla u_i \right)$$
$$+ 2\mu(u_i - \bar{u}_i)1_{\Omega\setminus D} + 2\lambda(\mathcal{L}(u) - \bar{v}) \frac{\partial \mathcal{L}}{\partial u_i}(u) 1_D := \mathcal{E}_i(\mathcal{L}, u), \tag{1.2}$$

$i = 1, \ldots, M$, where $u = (u_1, \ldots, u_M)$ are the components of the function u. This is a system of coupled second order equations, and the analysis of the solutions itself constitutes a problem of independent interest. By using (1.2) and a finite difference approximation, a steepest-descent algorithm can be formulated as in [21].

Encouraged by the numerical evidence in [21], we discuss the existence of minimizers of the functional F in the context of vector valued BV functions. Our second goal is the formulation of efficient and stable algorithms for the computation of minimizers. Although the steepest-descent scheme recalled above gives appreciable results, it lacks a rigorous analysis and its convergence is usually very slow. For these reasons, we introduce new coercive functionals F_h on $W^{1,2}$ which approximate $\bar{F}$ (the relaxed functional of F with respect to the BV weak-$*$-topology) in terms of Γ-convergence. The computation of minimizers of F_h is performed by an iterative *double-minimization* algorithm; see also [12]. The reconstruction performances are very good, also from very limited (randomly distributed) color data. The virtues of our scheme can be summarized as follows.

1. It is derived as the minimization of a functional and its mathematical analysis and foundations are well described.
2. It implements a total variation (TV) minimization. It is well known [14, 15] that total variation inpainting is affected by two major drawbacks. The first one is that the TV model is only a linear interpolant; i.e., the broken isophotes are interpolated by straight lines. Thus it can generate corners along the inpainting boundary. The second one is that TV often fails to connect widely separated parts of a whole object, due to the high cost in TV measure of making long-distance connections. Due to the constraint on the gray level in the inpainting region, our scheme does not extend isophotes as straight lines and does not violate the *connectivity principle*.
3. As pointed out in [11, 23], while it is relatively easy to recover at higher resolution image portions with relatively uniform color, it might be difficult to recover jumps correctly. Not only should we preserve the morphology and enhance the detail of the discontinuities, but these properties must fit through the different color channels. An incorrect or uncoupled recovery in fact produces "rainbow effects" around jumps. In our functional, the constraint on the gray level in the inpainting region is formulated as a coupled combination of the color channels. In practice, this is sufficient to enforce the correct coupling of the channels at edges.
4. The numerical implementation of our double-minimization scheme is very simple. Its approximation by finite elements comes in a natural way. The scheme is fast and stable.

The paper is organized as follows. In section 2 we introduce the mathematical setting. We recall the main properties of BV functions and a definition of the space of BV functions with vector values. Section 3 is dedicated to results on convex functions and relaxed functionals of measures. In section 4 we collect the assumptions on the nonlinear function $\mathcal{L}$ we will need in our analysis. In section 5 the representation of the relaxed functional $\bar{F}$ of F with respect to the BV topology is given, and the existence and uniqueness of minimizers of $\bar{F}$ are discussed. In section 6 we introduce coercive functionals F_h on $W^{1,2}$ which are shown to Γ-converge to the relaxed functional described above. The double-minimization algorithm to compute minimizers of F_h is illustrated in section 7. Its numerical implementation is presented in section 8. We include several numerical experiments and discuss their results.

2. Vector valued BV functions.

In this section we want to introduce notations and preliminary results concerning vector valued BV functions.

We denote by $\mathcal{L}_N$ (and in the integrals dx) the Lebesgue N-dimensional measure in $\mathbb{R}^N$ and by $\mathcal{H}_\alpha$ the α-dimensional Hausdorff measure. Let Ω be an open, bounded, and connected subset of $\mathbb{R}^N$. With $\mathcal{B}(\Omega)$ we denote the family of Borel subsets of $\Omega \subset \mathbb{R}^N$. For a given vector valued measure $\mu : \mathcal{B}(\Omega) \to \mathbb{R}^M$, we denote by $|\mu|$ its total variation, i.e., the finite positive measure

$$|\mu|(A) := \sup \left\{ \sum_{j=1}^{M} \int_\Omega v_j d\mu_j : v = (v_1, \dots, v_M) \in C_0(A; \mathbb{R}^M), \ \|v\|_\infty \leq 1 \right\},$$

for every open set $A \subset \Omega$, where $C_0(A; \mathbb{R}^M) := \overline{C_c(A; \mathbb{R}^M)}^{\|\cdot\|_\infty}$, i.e., the sup-norm closure of the space of continuous function with compact support in A and vector values in $\mathbb{R}^M$. The set of the signed measures on Ω with bounded total variation is denoted by $\mathcal{M}(\Omega)$, coinciding in fact with the topological dual of $(C_0(A; \mathbb{R}^M), \| \cdot \|_\infty)$. Thus, the usual weak-$*$-topology on $\mathcal{M}(\Omega)$ is the weakest topology that makes the maps $\mu \to \int_\Omega f d\mu$ continuous for every continuous function $f \in C_0(A; \mathbb{R}^M)$. In the following we will make use of the notations $x \wedge y := \inf\{x, y\}$ and $x \vee y := \sup\{x, y\}$ for all $x, y \in \mathbb{R}$.

We say that $u \in L^1(\Omega)$ is a real function of bounded variation if its distributional derivative $Du = (D_{x_1} u, \dots, D_{x_N} u)$ is in $\mathcal{M}(\Omega)$. Then the space of bounded variation functions is denoted by

$$BV(\Omega) := \{u \in L^1(\Omega) : Du \in \mathcal{M}(\Omega)\}$$

and, endowed with the norm $\|u\|_{BV(\Omega)} := \|u\|_1 + |Du|(\Omega)$, is a Banach space [20]. More generally, we are interested in vector valued functions with bounded variation components, whose space is defined by

$$BV(\Omega; \mathbb{R}^M) := \{u = (u_1, \dots, u_M) \in L^1(\Omega; \mathbb{R}^M) : u_i \in BV(\Omega)\}.$$

To this space it will turn out to be convenient to attach the norm $\|u\|_{BV(\Omega;\mathbb{R}^M)} := \|u\|_{L^1(\Omega;\mathbb{R}^M)} + \sum_{i=1}^M |Du_i|(\Omega)$. With a slight abuse of notation, for $u \in BV(\Omega; \mathbb{R}^M)$ we denote

$$|Du| := \sum_{i=1}^{M} |Du_i|, \tag{2.1}$$

which again is a finite positive measure for Ω. The space $(BV(\Omega; \mathbb{R}^M), \| \cdot \|_{BV(\Omega;\mathbb{R}^M)})$ is a Banach space. Of course $BV(\Omega; \mathbb{R}^M) = BV(\Omega)$ for $M = 1$, and our notations are consistent with this case.

The product topology of the strong topology of $L^1(\Omega; \mathbb{R}^M)$ for u and of the weak-$*$-topology of measures for Du_i (for all $i = 1, \dots, M$) will be called the weak-$*$-topology of $BV(\Omega; \mathbb{R}^M)$ or the componentwise BV weak-$*$-topology. In the following, whenever the domain Ω and the dimension M will be clearly understood, we will write L^1 instead of $L^1(\Omega; \mathbb{R}^M)$ and BV instead of $BV(\Omega; \mathbb{R}^M)$.

We further recall the main structure properties of BV functions [1, 2, 20]. If $v \in BV(\Omega)$, then the Lebesgue decomposition of Dv with respect to the Lebesgue measure $\mathcal{L}_N$ is given by

$$Dv = \nabla v \cdot \mathcal{L}_N + D_s v,$$

where $\nabla u = \frac{d(Dv)}{dx} \in L^1(\Omega;\mathbb{R}^N)$ is the Radon–Nikodym derivative of Dv and $D_s v$ is singular with respect to $\mathcal{L}_N$.

For a function $v \in L^1(\Omega)$ one denotes by S_v the complement of the Lebesgue set of v, i.e.,

$$S_v := \{x \in \Omega : v^-(x) < v^+(x)\},$$

where

$$v^+(x) := \inf \left\{ t \in \bar{\mathbb{R}} : \lim_{\epsilon \to 0} \frac{\mathcal{L}_N(\{v > t\} \cap B(x,\epsilon))}{\epsilon^N} = 0 \right\}$$

and

$$v^-(x) := \sup \left\{ t \in \bar{\mathbb{R}} : \lim_{\epsilon \to 0} \frac{\mathcal{L}_N(\{v < t\} \cap B(x,\epsilon))}{\epsilon^N} = 0 \right\}.$$

Then S_v is countably rectifiable, and for $\mathcal{H}_{N-1}$-a.e. $x \in \Omega$ we can define the outer normal $\nu(x)$. We denote by $\tilde{v} : \Omega \setminus S_v \to \mathbb{R}$ the approximate limit of v defined as $\tilde{v}(x) = v^+(x) = v^-(x)$.

Following [1, 20] $D_s v$ can be expressed by $D_s v = C_v + J_v$, where $J_v = (v^+ - v^-)\nu \cdot \mathcal{H}_{N-1}|_{S_v}$ is the *jump part* and C_v is the *Cantor part* of Dv. Therefore, we can express the measure Dv by

$$Dv = \nabla v \cdot \mathcal{L}_N + C_v + (v^+ - v^-)\nu \cdot \mathcal{H}_{N-1}|_{S_v}, \tag{2.2}$$

and its total variation by

$$|Dv|(E) = \int_E |\nabla v| dx + \int_{E \setminus S_v} |C_v| + \int_{E \cap S_v} (v^+ - v^-) d\mathcal{H}_{N-1}, \tag{2.3}$$

for every Borel set E in the Borel σ-algebra $\mathcal{B}(\Omega)$ of Ω. For major details we refer the reader to [1]. By these properties of real BV functions, one obtains the following result for vector valued BV functions.

LEMMA 2.1 (Lebesgue decomposition for vector valued BV functions). *For $u \in BV(\Omega;\mathbb{R}^N)$, the positive measure $|Du|$ as defined in* (2.1) *has the following Lebesgue decomposition:*

$$|Du| = |D_a u| + |D_s u|, \tag{2.4}$$

where $|D_a u| = \sum_{i=1}^M |\nabla u_i| \mathcal{L}_N$ is the absolutely continuous part and $|D_s u| = \sum_{i=1}^M |C_{u_i}| + \sum_{i=1}^M (u_i^+ - u_i^-)\mathcal{H}_{N-1}|_{S_{u_i}}$ is the singular part of $|Du|$ with respect to the Lebesgue measure $\mathcal{L}_N$.

Proof. By definition it is $|Du| = \sum_{i=1}^M |Du_i|$ and by the Lebesgue decomposition (2.3) for each $|Du_i|$ it is $|Du| = \sum_{i=1}^M \left(|\nabla u_i| \mathcal{L}_N + |C_{u_i}| + (u_i^+ - u_i^-)\mathcal{H}_{N-1}|_{S_{u_i}} \right)$. Since $\sum_{i=1}^M |\nabla u_i| \mathcal{L}_N$ is absolutely continuous and $\sum_{i=1}^M |C_{u_i}| + \sum_{i=1}^M (u^+ - u^-)\mathcal{H}_{N-1}|_{S_{u_i}}$ is singular with respect to $\mathcal{L}_N$, one concludes the proof by the uniqueness of the Lebesgue decomposition. □

3. Convex functions and functionals of measures. In the following and throughout the paper we assume that

(A) $\phi : \mathbb{R} \to \mathbb{R}_+$ is an even and convex function, nondecreasing in $\mathbb{R}_+$, such that the following hold:

(i) $\phi(0) = 0$;

(ii) there exist $c > 0$ and $b \geq 0$ such that $cz - b \leq \phi(z) \leq cz + b$ for all $z \in \mathbb{R}$.

Under such conditions the asymptotic recession function ϕ^∞ defined by

$$\phi^\infty(z) := \lim_{y \to \infty} \frac{\phi(yz)}{y}$$

is well defined and bounded. It is $c = \lim_{y\to\infty} \frac{\phi(y)}{y} = \phi^\infty(1)$ and $\phi^\infty(z) = cz \cdot \operatorname{sign}(z)$.

Following [17, 25] we can define convex functions of measures. In particular, if $\mu \in \mathcal{M}(\Omega)$, then we can define

$$\phi(|\mu|) = \phi(|\mu_a|)\mathcal{L}_N + \phi^\infty(1)|\mu_s|,$$

where μ_a and μ_s are the absolutely continuous and singular parts of μ, respectively, with respect to $\mathcal{L}_N$. Therefore, according to Lemma 2.1, if $u \in BV(\Omega; \mathbb{R}^M)$, then

$$\begin{aligned} &\sum_{i=1}^M \phi(|Du_i|) \\ &= \sum_{i=1}^M \phi(|\nabla u_i|)\mathcal{L}_N + \phi^\infty(1) \left(\sum_{i=1}^M |C_{u_i}| + \sum_{i=1}^M (u^+ - u^-)\mathcal{H}_{N-1}|_{S_{u_i}} \right). \end{aligned} \tag{3.1}$$

Definition 3.1. *Let (X, τ) be a topological space satisfying the first axiom of countability and $F : X \to \bar{\mathbb{R}}$. The relaxed functional of F with respect to the topology τ is defined for every $x \in X$ as $\bar{F}(x) := \sup\{G(x) : G$ is τ-lower semicontinuous and $G \leq F\}$. In other words $\bar{F}$ is the maximal τ-lower semicontinuous functional that is smaller than F. We may also write*

$$\bar{F}(u) = \inf_{u^{(n)} \in X,\, u^{(n)} \xrightarrow{\tau} u} \left\{ \liminf_n F(u^{(n)}) \right\}.$$

We have the following result.

Lemma 3.2. *If $u \in BV(\Omega; \mathbb{R}^M)$ and ϕ is as in assumption* (A), *then*

$$\begin{aligned} E(u) &:= \int_\Omega \sum_{i=1}^M \phi(|Du_i|) := \sum_{i=1}^M \phi(|Du_i|)(\Omega) \\ &= \int_\Omega \sum_{i=1}^M \phi(|\nabla u_i|)dx + c \left(\sum_{i=1}^M \int_{\Omega \setminus S_{u_i}} |C_{u_i}| + \int_{S_{u_i}} (u_i^+ - u_i^-) d\mathcal{H}_{N-1} \right) \end{aligned}$$

is lower semicontinuous with respect to the componentwise BV weak-$*$-topology.

Proof. It is known that $u_i \to E_i(u_i) := \int_\Omega \phi(|\nabla u_i|)dx + c(\int_{\Omega\setminus S_{u_i}} |C_{u_i}| + \int_{S_{u_i}} (u_i^+ - u_i^-)d\mathcal{H}_{N-1})$ is lower semicontinuous for the BV weak-$*$-topology on $BV(\Omega)$ [25]. One concludes simply by observing that $E(u) = \sum_{i=1}^M E_i(u_i)$. □

4. Assumptions on the evaluation map $\mathcal{L}$. In the following we assume that

(L1) $\mathcal{L} : \mathbb{R}^M \to \mathbb{R}_+$ is a nondecreasing continuous function in the sense that $\mathcal{L}(x) \leq \mathcal{L}(y)$ for any $x, y \in \mathbb{R}^M$ such that $|x_i| \leq |y_i|$ for any $i \in \{1, \ldots, M\}$;

(L2) $\mathcal{L}(x) \leq a + b|x|^s$ for all $x \in \mathbb{R}^M$ and for fixed $s \geq p^{-1}$, $b > 0$, and $a \geq 0$.

Moreover, one of the two following conditions holds:

(L3-a) $\lim_{x\to\infty} \mathcal{L}(x) = +\infty$;

(L3-b) $\mathcal{L}(x) = \mathcal{L}(x_1, \dots, x_M) = \mathcal{L}((\ell_1 \wedge x_1 \vee -\ell_1), \dots, (\ell_M \wedge x_M \vee -\ell_M))$ for a suitable fixed vector $\ell = (\ell_1, \dots, \ell_M) \in \mathbb{R}^M_+$.

Observe that condition (L3-a) is equivalent to saying that for every $C > 0$ the set $\{\mathcal{L} \le C\}$ is bounded. Therefore, there exists $A \in \mathbb{R}^M$, with $A_i \ge 0$ for any $i \in \{1, \dots, M\}$, such that $\{\mathcal{L} \le C\} \subseteq \prod_{i=1}^M [-A_i, A_i]$.

In the following and throughout the paper D denotes a measurable subset of Ω, and we are given the couple $(\bar{u}, \bar{v})$ of bounded functions such that $\bar{u} : \Omega \setminus D \to \mathbb{R}^M$ and $\bar{v} : D \to \mathbb{R}$.

If condition (L3-a) holds, for any measurable function $u : \Omega \to \mathbb{R}^M$, we define the *truncation or clipping operator* as follows:

$$\text{tr}(u, \bar{u}, \Omega, D)(x) := ((\|\bar{u}_i|\Omega \setminus D\|_\infty \vee A_i) \wedge u_i(x) \vee (-\|\bar{u}_i|\Omega \setminus D\|_\infty \wedge -A_i))_{i=1}^M, \tag{4.1}$$

where $A \in \mathbb{R}^M$ is determined so that $\{\mathcal{L} \le \|\bar{v}|D\|_\infty\} \subseteq \prod_{i=1}^M [-A_i, A_i]$. Analogously we define the truncation operator in the case of condition (L3-b):

$$\text{tr}(u, \bar{u}, \bar{v}, \Omega, D)(x) := ((\|\bar{u}_i|\Omega \setminus D\|_\infty \vee \ell_i) \wedge u_i(x) \vee (-\|\bar{u}_i|\Omega \setminus D\|_\infty \wedge -\ell_i))_{i=1}^M. \tag{4.2}$$

In the case when it is clear which of the conditions (L3-a,b) holds and the set D and the functions $\bar{u}, \bar{v}$ are given, then it will be convenient to use the shorter notation $\hat{u} := \text{tr}(u, \bar{u}, \bar{v}, \Omega, D)$.

For any measurable function $u : \Omega \to \mathbb{R}^M$ we define

$$G_1(u) = \int_{\Omega \setminus D} |u(x) - \bar{u}(x)|^p dx, \tag{4.3}$$

$$G_2(u) = \int_D |\mathcal{L}(u(x)) - \bar{v}(x)|^p dx. \tag{4.4}$$

LEMMA 4.1. *For any $u \in BV(\Omega; \mathbb{R}^M)$ the truncation operator has the property that $\hat{u} \in BV(\Omega; \mathbb{R}^M)$, and*

$$G_i(\hat{u}) \le G_i(u), \quad i = 1, 2, \quad \textit{and } E(\hat{u}) \le E(u). \tag{4.5}$$

Proof. Let us assume that condition (L3-a) holds. If $x \in \Omega \setminus D$, the definition of the truncation operator implies that $|\hat{u}(x) - \bar{u}(x)| \le |u(x) - \bar{u}(x)|$, from which it follows that $G_1(\hat{u}) \le G_1(u)$. If $x \in D$ is such that $u(x) \in \prod_{i=1}^M [-\|\bar{u}_i|\Omega \setminus D\|_\infty \wedge -A_i, \|\bar{u}_i|\Omega \setminus D\|_\infty \vee A_i]$, then $\hat{u}(x) = u(x)$. Otherwise, $x \notin \prod_{i=1}^M [-A_i, A_i]$ and $|u_i(x)| \ge |\hat{u}_i(x)| \ge |\xi_i|$ for any ξ such that $\mathcal{L}(\xi) \le \|\bar{v}|D\|_\infty$ and any $i \in \{1, \dots, M\}$. Therefore, by the monotonicity assumption (L1) $\mathcal{L}(u(x)) \ge \mathcal{L}(\hat{u}(x)) \ge \|\bar{v}|D\|_\infty$, which implies that $|\mathcal{L}(\hat{u}(x)) - \bar{v}(x)| \le |\mathcal{L}(u(x)) - \bar{v}(x)|$ for any $x \in D$, and $G_2(\hat{u}) \le G_2(u)$. The proof is analogous if condition (L3-b) holds.

We now prove the corresponding statement for the functional E. Fix $i \in \{1, \dots, M\}$. By definition of the truncation operator, we have $\hat{u}_i = g_i \circ u_i$, where $g_i : \mathbb{R} \to \mathbb{R}$ is a Lipschitz function such that

$$g_i(t) = \begin{cases} t, & -c_i \le t \le d_i, \\ d_i, & t > d_i, \\ -c_i, & t < -c_i, \end{cases}$$

where $c_i, d_i > 0$ are determined by (4.1), (4.2). Using the chain rule for real valued BV functions (Theorem 3.99 of [2]), we have that $\hat{u} \in BV(\Omega; \mathbb{R}^M)$ and

$$D\hat{u}_i = g_i'(u_i) \nabla u_i \cdot \mathcal{L}_N + g_i'(\tilde{u}_i) C_{u_i} + \left(g_i(u_i^+) - g_i(u_i^-)\right) \nu_i \cdot \mathcal{H}_{N-1}|_{S_{u_i}},$$

where $\tilde{u}_i$ is the approximate limit of u_i. Then $\nabla\hat{u}_i(x) = \nabla u_i(x)$ if $-c_i < u_i(x) < d_i$, and $\nabla\hat{u}_i(x) = 0$ if either $u_i(x) > d_i$ or $u_i(x) < -c_i$. Moreover, by Proposition 3.73(c) of [2] it follows that $\nabla u_i(x) = 0$ for a.e. $x \in \{u_i(x) = d_i\}$ and a.e. $x \in \{u_i(x) = -c_i\}$. Hence $|\nabla\hat{u}_i(x)| \leq |\nabla u_i(x)|$ a.e., so that from assumption (A) of the function ϕ we get

$$\int_\Omega \phi(|\nabla\hat{u}_i|)dx \leq \int_\Omega \phi(|\nabla u_i|)dx. \tag{4.6}$$

Since $u_i^+(x) \geq u_i^-(x)$ for any $x \in S_{u_i}$, by the definition of the function g_i we have

$$S_{\hat{u}_i} \subseteq S_{u_i}, \qquad g_i(u_i^+(x)) - g_i(u_i^-(x)) \leq u_i^+(x) - u_i^-(x) \quad \text{for any } x \in S_{u_i}.$$

Then it follows that

$$\int_{S_{\hat{u}_i}} (\hat{u}_i^+ - \hat{u}_i^-)d\mathcal{H}_{N-1} \leq \int_{S_{u_i}} (u_i^+ - u_i^-)d\mathcal{H}_{N-1}. \tag{4.7}$$

By the definition of g_i we then have $0 \leq g_i'(\tilde{u}_i(x)) \leq 1$ for any $x \in \{x : \tilde{u}_i(x) \neq d_i\} \cap \{x : \tilde{u}_i(x) \neq -c_i\}$. Moreover, by Proposition 3.92(c) of [2], the Cantor part C_{u_i} vanishes on sets of the form $\tilde{u}_i^{-1}(Q)$ with $Q \subset \mathbb{R}$, $\mathcal{H}_1(Q) = 0$. It follows that C_{u_i} vanishes on the set $\{x : \tilde{u}_i(x) = d_i\} \cup \{x : \tilde{u}_i(x) = -c_i\}$, so that we get $|C_{\hat{u}_i}|(\Omega) \leq |C_{u_i}|(\Omega)$, i.e.,

$$\int_{\Omega\setminus S_{\hat{u}_i}} |C_{\hat{u}_i}| \leq \int_{\Omega\setminus S_{u_i}} |C_{u_i}|. \tag{4.8}$$

Collecting the inequalities (4.6)–(4.8) and summing over $i = 1, \dots, M$, we obtain $E(\hat{u}) \leq E(u)$, which concludes the proof. □

REMARK 4.2. *The truncation operator maps C_0^1 functions into $W^{1,q}$; i.e., for any $u \in C_0^1(\Omega;\mathbb{R}^M)$ we have $\operatorname{tr}(u, \bar{u}, \bar{v}, \Omega, D) \in W^{1,q}(\Omega;\mathbb{R}^M)$ for any $1 \leq q \leq \infty$.*

5. Relaxation and existence of minimizers.

The functional F is well defined in $L^\infty(\Omega;\mathbb{R}^M) \cap W^{1,1}(\Omega;\mathbb{R}^M)$. Since this space is not reflexive, and sequences that are bounded in $W^{1,1}$ are also bounded in BV, we extend F to the space $BV(\Omega;\mathbb{R}^M)$ in such a way that the extended functional is lower semicontinuous. By using the relaxation method of the calculus of variations, the natural candidate for the extended functional is the relaxed functional $\bar{F}$ of F with respect to the componentwise BV weak-$*$-topology [6].

In the following, without loss of generality, we set $\mu = \lambda = 1$.

5.1. Relaxation.

We set $X = \{u \in BV(\Omega;\mathbb{R}^M) : \|u_i\|_\infty \leq K_i,\ i = 1, \dots, M\}$, where, for any $i \in \{1, \dots, M\}$, the constant $K_i > 0$ is defined by $K_i = \max\{A_i, \|\bar{u}_i|\Omega\setminus D\|_\infty\}$ if condition (L3-a) holds, and by $K_i = \max\{\ell_i, \|\bar{u}_i|\Omega\setminus D\|_\infty\}$ if condition (L3-b) holds.

The following theorem extends to our case the relaxation result proved in [6, Theorem 3.2.1].

THEOREM 5.1. *The relaxed functional of F in X with respect to the componentwise BV weak-$*$-topology is given by*

$$\bar{F}(u) = \int_{\Omega\setminus D} |u(x) - \bar{u}(x)|^p dx + \int_D |\mathcal{L}(u(x)) - \bar{v}(x)|^p dx$$
$$+ \int_\Omega \sum_{i=1}^M \phi(|\nabla u_i|)dx + c\left(\sum_{i=1}^M \int_{\Omega\setminus S_{u_i}} |C_{u_i}| + \int_{S_{u_i}} (u_i^+ - u_i^-)d\mathcal{H}_{N-1}\right).$$

Proof. Let us define

$$f(u) := \begin{cases} F(u), & u \in X \cap W^{1,1}(\Omega;\mathbb{R}^M), \\ +\infty, & u \in X \setminus W^{1,1}(\Omega;\mathbb{R}^M). \end{cases}$$

Observe that $f(u) = \bar{F}(u)$ for $u \in W^{1,1}(\Omega;\mathbb{R}^M)$.

By property (L2) we have that $G_1(u), G_2(u) < +\infty$ for all $u \in X$. By using Fatou's lemma the functionals G_1 and G_2 are lower semicontinuous with respect to the strong L^1 topology and hence with respect to the componentwise BV weak-$*$-topology. Therefore, by Lemma 3.2, $\bar{F}$ is lower semicontinuous in X with respect to such topology.

Let $\bar{f}$ denote the relaxed functional of f in X with respect to the same topology. Since $\bar{F}(u) \leq f(u)$ for any $u \in X$, and $\bar{f}$ is the greatest lower semicontinuous functional less than or equal to f, we have $\bar{f}(u) \geq \bar{F}(u)$ for any $u \in X$. Then we have to show that $\bar{f}(u) \leq \bar{F}(u)$.

By [17, Theorems 2.2 and 2.3] for any $u \in X$ there exists a sequence $\{u^{(n)}\}_n \subset C_0^\infty(\Omega;\mathbb{R}^M) \cap W^{1,1}(\Omega;\mathbb{R}^M)$ such that $u^{(n)}$ converges to u in the componentwise BV weak-$*$-topology and $E(u) = \lim_n E(u^{(n)})$.

Let us now consider the sequence $\{\hat{u}^{(n)}\}_n$ of the truncated functions. By Lemma 4.1 we have

$$E(u) = \lim_n E(u^{(n)}) \geq \limsup_n E(\hat{u}^{(n)}). \tag{5.1}$$

With similar computations as those in the proof of Lemma 4.1

$$\int_\Omega |\hat{u}^{(n)}(x) - u(x)| dx \leq \int_\Omega |u^{(n)}(x) - u(x)| dx \to 0, \quad n \to \infty.$$

Moreover, since the truncated functions $\hat{u}^{(n)}$ are uniformly bounded in $L^\infty(\Omega;\mathbb{R}^M)$, then $\hat{u}^{(n)}$ converges to u in $L^q(\Omega;\mathbb{R}^M)$ for any $1 \leq q < \infty$.

Now the functional G_1 is continuous with respect to the strong $L^p(\Omega \setminus D;\mathbb{R}^M)$ topology. Moreover, since $\mathcal{L}$ is continuous, the functional G_2 is continuous with respect to the strong $L^q(D;\mathbb{R}^M)$ topology, with $q = sp \geq 1$ (see [19, Chapter 9, Lemma 3.2]).

Then, using (5.1), the continuity properties of G_1 and G_2, and Remark 4.2, we have $\hat{u}^{(n)} \in W^{1,1}(\Omega;\mathbb{R}^M)$, $\bar{F}(\hat{u}^{(n)}) = f(\hat{u}^{(n)})$, and

$$\begin{aligned} \bar{F}(u) = G_1(u) + G_2(u) + E(u) &\geq \lim_n (G_1(\hat{u}^{(n)}) + G_2(\hat{u}^{(n)})) + \limsup_n E(\hat{u}^{(n)}) \\ &\geq \limsup_n f(\hat{u}^{(n)}) \geq \liminf_n f(\hat{u}^{(n)}) \geq \inf_{u^{(n)} \in BV,\, u^{(n)} \overset{BV-w^*}{\to} u} \left\{ \liminf_n f(u^{(n)}) \right\} = \bar{f}(u). \end{aligned}$$

Then we have $\bar{F}(u) = \bar{f}(u)$ and the statement is proved. □

5.2. Existence and uniqueness of minimizers. In this section we shall prove the existence of minimizers of $\bar{F}$ in X and state the conditions for the uniqueness.

THEOREM 5.2. *There exists a solution of the following variational problem:*

$$\min_{u \in X} \left\{ \bar{F}(u) = \int_{\Omega \setminus D} |u(x) - \bar{u}(x)|^p dx + \int_D |\mathcal{L}(u(x)) - \bar{v}(x)|^p dx \right. \\ \left. + \int_\Omega \sum_{i=1}^M \phi(|\nabla u_i|) dx + c \left(\sum_{i=1}^M \int_{\Omega \setminus S_{u_i}} |C_{u_i}| + \int_{S_{u_i}} (u_i^+ - u_i^-) d\mathcal{H}_{N-1} \right) \right\}.$$

In particular, we have

$$\min_{u\in X} \bar{F}(u) = \inf_{u\in X} F(u).$$

Moreover, if $D \subsetneq \Omega$ and G_2 is a strictly convex functional, then the solution is unique.

Proof. Let $\{u^{(n)}\}_n$ be a minimizing sequence in BV. By assumption (A)(ii) in section 3, there exists a constant $C > 0$ such that $|Du^{(n)}|(\Omega) \leq C$ uniformly with respect to n. By Lemma 4.1 we can modify the minimizing sequence by truncation, obtaining a new minimizing sequence $\{\hat{u}^{(n)}\}_n \subset X$. By Lemma 4.1 this sequence is uniformly bounded in $BV(\Omega;\mathbb{R}^M)$, i.e.,

$$\|\hat{u}^{(n)}\|_\infty \leq \max_{i=1,\dots,M} K_i, \qquad |D\hat{u}^{(n)}|(\Omega) \leq C$$

for any n. Therefore, there exists a subsequence $\{\hat{u}^{(n_k)}\}_k$ converging with respect to the componentwise BV weak-$*$-topology to a function $u \in X$. Since the relaxed functional $\bar{F}$ is lower semicontinuous in X with respect to such a topology, we have

$$\bar{F}(u) \leq \liminf_k \bar{F}(u^{(n_k)}).$$

From the compactness and lower semicontinuity properties of $\bar{F}$ it follows that $u \in X$ is a minimizer of $\bar{F}$. Moreover, if $D \subsetneq \Omega$ and G_2 is a strictly convex functional, then $\bar{F}$ is strictly convex and the solution u is unique. Since F is coercive in X, one concludes by an application of [27, Theorem 3.8]. □

6. Approximation by Γ-convergence.

In this section we endow the space X with the L^1 strong topology, and we show that minimizers of $\bar{F}$ can be approximated in X by minimum points of functionals that are defined in $W^{1,2}(\Omega;\mathbb{R}^M)$.

For a positive decreasing sequence $\{\varepsilon_h\}_{h\in\mathbb{N}}$ such that $\lim_{h\to\infty}\varepsilon_h = 0$, and for $\phi \in C^1(\mathbb{R})$, we define

$$(6.1)\quad F_h(u) = \begin{cases} G_1(u) + G_2(u) + \displaystyle\int_\Omega \sum_{i=1}^M \phi_h(|\nabla u_i(x)|)dx, & u \in W^{1,2}(\Omega;\mathbb{R}^M), \\ +\infty, & u \in X \setminus W^{1,2}(\Omega;\mathbb{R}^M), \end{cases}$$

where

$$\phi_h(z) = \begin{cases} \dfrac{\phi'(\varepsilon_h)}{2\varepsilon_h} z^2 + \phi(\varepsilon_h) - \dfrac{\varepsilon_h \phi'(\varepsilon_h)}{2}, & 0 \leq z \leq \varepsilon_h, \\ \phi(z), & \varepsilon_h \leq z \leq \dfrac{1}{\varepsilon_h}, \\ \dfrac{\varepsilon_h \phi'(1/\varepsilon_h)}{2} z^2 + \phi\left(\dfrac{1}{\varepsilon_h}\right) - \dfrac{\phi'(1/\varepsilon_h)}{2\varepsilon_h}, & z \geq \dfrac{1}{\varepsilon_h}. \end{cases}$$

If $z \mapsto \frac{\phi'(z)}{z}$ is continuously decreasing, then $\phi_h(z) \geq \phi(z) \geq 0$ for any h and any z, and $\lim_h \phi_h(z) = \phi(z)$ for any z.

By means of standard arguments we have that for any h the functional F_h has a minimizer in $X \cap W^{1,2}(\Omega;\mathbb{R}^M)$; see, e.g., [31, Proposition 6.1]. Moreover, if $D \subsetneq \Omega$ and G_2 is a strictly convex functional, then the minimizer is unique. The following theorem extends to our case the Γ-convergence result proved in [31, Proposition 6.1]; see also Theorem 3.2.3 of [6]. We do not introduce the concept of Γ-convergence which is used here only as an auxiliary tool. We refer the reader to [27] and the relevant results therein for more details, in particular, [27, Proposition 5.7, Theorem 7.8, Corollary 7.20, Corollary 7.24].

THEOREM 6.1. *Let $\{u^{(h)}\}_h$ be a sequence of minimizers of F_h. Then $\{u^{(h)}\}_h$ is relatively compact in $L^1(\Omega;\mathbb{R}^M)$, each of its limit points minimizes the functional $\bar{F}$, and*

$$\min_{u\in X}\bar{F}(u)=\lim_{h\to\infty}\min_{u\in X\cap W^{1,2}}F_h(u).$$

Moreover, if $D\subsetneq\Omega$ and G_2 is a strictly convex functional, we have

$$\lim_{h\to\infty}u^{(h)}=u^{(\infty)}\ \textit{in } X,\qquad \lim_{h\to\infty}F_h(u^{(h)})=\bar{F}(u^{(\infty)}),\tag{6.2}$$

where $u^{(\infty)}$ is the unique minimizer of $\bar{F}$ in X.

Proof. We define

$$g(u)=\begin{cases} F(u), & u\in X\cap W^{1,2}(\Omega;\mathbb{R}^M),\\ +\infty, & u\in X\setminus W^{1,2}(\Omega;\mathbb{R}^M).\end{cases}$$

Observe that g is the restriction of F to functions $u\in W^{1,2}(\Omega;\mathbb{R}^M)$.

By construction we have that $\{F_h\}_h$ is a decreasing sequence of functionals that converges pointwise to g in $X\cap W^{1,2}(\Omega;\mathbb{R}^M)$. Therefore, by [27, Proposition 5.7], F_h Γ-converges to the relaxed functional $\bar{g}$ of g in X with respect to the $L^1(\Omega;\mathbb{R}^M)$ topology. Then we have to show that $\bar{F}=\bar{g}$.

Let $\{u^{(n)}\}_n\subset X$ be a sequence such that $u^{(n)}\to u$ in $L^1(\Omega;\mathbb{R}^M)$ and $\liminf_n \bar{F}(u^{(n)})<+\infty$. Up to the extraction of a subsequence we may assume that $\liminf_n \bar{F}(u^{(n)})=\lim_n\bar{F}(u^{(n)})$. Then $\bar{F}(u^{(n)})$ is uniformly bounded with respect to n, so that $\{u^{(n)}\}_n$ is uniformly bounded in BV. Then, up to a subsequence, $u^{(n)}$ converges to u in the componentwise BV weak-$*$-topology and, by Theorem 5.1, we have $\liminf_n\bar{F}(u^{(n)})\geq\bar{F}(u)$. Hence $\bar{F}$ is lower semicontinuous in X with respect to the $L^1(\Omega;\mathbb{R}^M)$ topology.

Then, arguing as in the proof of Theorem 5.1, for any function $u\in X$ there exists a sequence of truncated functions $\hat{u}^{(n)}\in W^{1,2}(\Omega;\mathbb{R}^M)\cap X$ such that

$$\hat{u}^{(n)}\to u \text{ in } L^1(\Omega;\mathbb{R}^M)\quad\text{and}\quad \bar{F}(u)\geq\liminf_{n\to\infty}g(\hat{u}^{(n)}).\tag{6.3}$$

Since $g\geq\bar{F}$, property (6.3) implies that $\bar{F}\geq\bar{g}$. Then, by the lower semicontinuity of $\bar{F}$ with respect to the $L^1(\Omega;\mathbb{R}^M)$ topology, we have $\bar{F}=\bar{g}$. Therefore, F_h Γ-converges to $\bar{F}$.

By construction $\phi_h(z)\geq\phi(z)$ for any $z\geq 0$, so that $F_h(u)\geq\bar{F}(u)$ for any h and any $u\in X$. Since $\bar{F}$ is coercive and lower semicontinuous in $L^1(\Omega;\mathbb{R}^M)$, it follows that the sequence $\{F_h\}_h$ is equicoercive in $L^1(\Omega;\mathbb{R}^M)$. In particular, any family $\{u^{(h)}\}_h$ of minimizers of F_h is relatively compact in $L^1(\Omega;\mathbb{R}^M)$. Then, using [27, Theorem 7.8], the limit points of sequences of minimizers of F_h minimize $\bar{F}$ and $\min_{u\in X}\bar{F}(u)=\lim_h\min_{u\in W^{1,2}}F_h(u)$.

Finally, if $D\subsetneq\Omega$ and G_2 is a strictly convex functional, by Theorem 5.2 there exists a unique minimizer of $\bar{F}$ in X. Therefore the limits (6.2) follow from Corollary 7.24 of [27]. □

REMARK 6.2. *So far we have considered evaluation maps $\mathcal{L}:\mathbb{R}^M\to\mathbb{R}$. However, the whole analysis can be generalized to the case $\mathcal{L}:\mathbb{R}^M\to\mathcal{M}$, $\mathcal{L}(x)=$*

$(\mathcal{L}_1(x),\dots,\mathcal{L}_D(x))$, where $\mathcal{M}\subset\mathbb{R}^M$ is a $(D\le M)$-dimensional submanifold. However, for $D=1$ and L usually being an invertible map, it is possible to "reequalize" the gray level so that $\mathcal{L}(x)=\frac{1}{M}(x_1+\cdots+x_M)$. Later in this paper, for simplicity purposes in numerical implementation, we will use such linearization for $\mathcal{L}$.

7. Euler–Lagrange equations and a relaxation algorithm. In this section we want to provide an algorithm to compute efficiently minimizers of the approximating functionals F_h. First, we want to derive the Euler–Lagrange equations associated with F_h. In the following we assume that both ϕ_h and $\mathcal{L}$ are continuously differentiable and that Ω is an open, bounded, and connected subset of $\mathbb{R}^N$ with Lipschitz boundary $\partial\Omega$. Moreover, $p=2$ if $N=1$ and $p=\frac{N}{N-1}$ for $N>1$, $1/p+1/p'=1$. By standard arguments we have the following result.

Proposition 7.1. *If u is a minimizer in $W^{1,2}(\Omega;\mathbb{R}^M)$ of F_h, then u solves the following system of Euler–Lagrange equations:*

$$\begin{cases} 0=-\operatorname{div}\left(\frac{\phi_h'(|\nabla u_i|)}{|\nabla u_i|}\nabla u_i\right)+p|u-\bar{u}|^{p-2}(u_i-\bar{u}_i)1_{\Omega\setminus D}+p|\mathcal{L}(u)\\ \qquad -\bar{v}|^{p-2}(\mathcal{L}(u)-\bar{v})\frac{\partial\mathcal{L}}{\partial u_i}(u)1_D,\\ \frac{\phi_h'(|\nabla u_i|)}{|\nabla u_i|}\frac{\partial u_i}{\partial\nu}=0 \text{ on } \partial\Omega,\quad i=1,\dots,M.\end{cases}$$

The former equalities hold in the sense of distributions and in $L^{p'}(\Omega;\mathbb{R}^M)$.

The previous equations yield a necessary condition for the computation of minimizers of F_h. Again we are not ensured of the uniqueness in general, unless G_2 is strictly convex. The system is composed of M second order *nonlinear* equations which are coupled on terms of order 0. Both the nonlinear term $\operatorname{div}\left(\frac{\phi_h'(|\nabla u_i|)}{|\nabla u_i|}\nabla u_i\right)$ and the coupled terms of order 0 constitute a complication for the numerical solution of these equations.

Based on the work [12, 18, 32], we propose in the following a method to compute efficiently solutions of the Euler–Lagrange equations, which simplifies the problem of the nonlinearity. Since we want to illustrate concrete applications for color image recovery, for simplicity, we limit our analysis to the case $N=p=2$ and $\phi(t)=|t|$ for all $t\in\mathbb{R}$. Let us introduce a new functional given by

$$\mathcal{E}_h(u,w):=2\left(G_1(u)+G_2(u)\right)+\int_\Omega\sum_{i=1}^M\left(w_i|\nabla u_i(x)|^2+\frac{1}{w_i}\right)dx, \tag{7.1}$$

where $u\in W^{1,2}(\Omega;\mathbb{R}^M)$, and $w\in L^2(\Omega;\mathbb{R}^M)$ is such that $\varepsilon_h\le w_i\le\frac{1}{\varepsilon_h}$, $i=1,\dots,M$. While the variable u again is the function to be reconstructed, we call the variable w the *gradient weight*. In the following, since we assume h fixed, we drop the index h from the functional $\mathcal{E}_h$.

For any given $u^{(0)}\in X\cap W^{1,2}(\Omega;\mathbb{R}^M)$ and $w^{(0)}\in L^2(\Omega;\mathbb{R}^M)$ (for example, $w^{(0)}:=1$), we define the following iterative double-minimization algorithm:

$$\begin{cases} u^{(n+1)}=\arg\min\limits_{u\in W^{1,2}(\Omega;\mathbb{R}^M)}\mathcal{E}(u,w^{(n)}),\\ w^{(n+1)}=\arg\min\limits_{\varepsilon_h\le w\le\frac{1}{\varepsilon_h}}\mathcal{E}(u^{(n+1)},w).\end{cases} \tag{7.2}$$

We have the following convergence result.

Theorem 7.2. *The sequence $\{u^{(n)}\}_{n\in\mathbb{N}}$ has subsequences that converge strongly in $L^2(\Omega;\mathbb{R}^M)$ and weakly in $W^{1,2}(\Omega;\mathbb{R}^M)$ to a stationary point $u^{(\infty)}$ of F_h; i.e., $u^{(\infty)}$*

solves the Euler–Lagrange equations in Proposition 7.1. *Moreover, if F_h has a unique minimizer u^*, then $u^{(\infty)} = u^*$ and the full sequence $\{u^{(n)}\}_{n\in\mathbb{N}}$ converges to u^*.*

Proof. Observe that

$$\begin{aligned}\mathcal{E}(u^{(n)}, w^{(n)}) - \mathcal{E}(u^{(n+1)}, w^{(n+1)}) &= \underbrace{\Big(\mathcal{E}(u^{(n)}, w^{(n)}) - \mathcal{E}(u^{(n+1)}, w^{(n)})\Big)}_{A_n} \\ &\quad + \underbrace{\Big(\mathcal{E}(u^{(n+1)}, w^{(n)}) - \mathcal{E}(u^{(n+1)}, w^{(n+1)})\Big)}_{B_n} \geq 0.\end{aligned}$$

Therefore, $\mathcal{E}(u^{(n)}, w^{(n)})$ is a nonincreasing sequence and, moreover, it is bounded from below, since

$$\inf_{\varepsilon_h \leq w \leq 1/\varepsilon_h} \int_\Omega \sum_{i=1}^M \left(w_i |\nabla u_i(x)|^2 + \frac{1}{w_i} \right) dx \geq 0.$$

This implies that $\mathcal{E}(u^{(n)}, w^{(n)})$ converges. Moreover, we can write

$$B_n = \int_\Omega \sum_{i=1}^M c(w_i^{(n)}(x), |\nabla u_i^{(n+1)}(x)|) - c(w_i^{(n+1)}(x), |\nabla u_i^{(n+1)}(x)|) dx,$$

where $c(t, z) := tz^2 + \frac{1}{t}$. By Taylor's formula, we have

$$c(w_i^{(n)}, z) = c(w_i^{(n+1)}, z) + \frac{\partial c}{\partial t}(w_i^{(n+1)}, z)(w_i^{(n)} - w_i^{(n+1)}) + \frac{1}{2}\frac{\partial^2 c}{\partial t^2}(\xi, z)|w_i^{(n)} - w_i^{(n+1)}|^2$$

for $\xi \in \operatorname{conv}(w_i^{(n)}, w_i^{(n+1)})$. By definition of $w_i^{(n+1)}$ and taking into account that $\varepsilon_h \leq w_i^{(n+1)} \leq \frac{1}{\varepsilon_h}$, we have

$$\frac{\partial c}{\partial t}(w_i^{(n+1)}, |\nabla u_i^{(n+1)}(x)|)(w_i^{(n)} - w_i^{(n+1)}) \geq 0,$$

and $\frac{\partial^2 c}{\partial t^2}(t, z) = \frac{2}{t^3} \geq 2\varepsilon_h^3$, for any $t \leq 1/\varepsilon_h$. This implies that

$$\mathcal{E}(u^{(n)}, w^{(n)}) - \mathcal{E}(u^{(n+1)}, w^{(n+1)}) \geq B_n \geq \varepsilon_h^3 \int_\Omega \sum_{i=1}^M |w_i^{(n)}(x) - w_i^{(n+1)}(x)|^2 dx,$$

and since $\mathcal{E}(u^{(n)}, w^{(n)})$ is convergent, we have $\sum_{i=1}^M \int_\Omega |w_i^{(n)}(x) - w_i^{(n+1)}(x)|^2 dx \to 0$ for $n \to \infty$. In fact it holds that

$$\|w_i^{(n)} - w_i^{(n+1)}\|_{L^q} \to 0, \quad i = 1, \ldots, M, \tag{7.3}$$

for $n \to \infty$ and for any $1 \leq q < \infty$. Since $u^{(n+1)}$ is a minimizer of $\mathcal{E}(u, w^{(n)})$, it solves the following system of variational equations:

$$\begin{aligned}\int_\Omega \Big(& w_i^{(n)} \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2(u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ & + 2(\mathcal{L}(u^{(n+1)}(x)) - \bar{v}(x)) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}(x)) 1_D(x) \Big) \varphi_i(x) dx = 0 \end{aligned} \tag{7.4}$$

for $i = 1, \ldots, M$ and for all $\varphi \in W^{1,2}(\Omega; \mathbb{R}^M)$. Therefore, we can write

$$\begin{aligned}\int_\Omega \Big(& w_i^{(n+1)} \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2(u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ & + 2(\mathcal{L}(u^{(n+1)}(x)) - \bar{v}(x)) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}(x)) 1_D(x) \Big) \varphi_i(x) dx \\ & = \int_\Omega (w_i^{(n+1)} - w_i^{(n)}) \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) dx.\end{aligned}$$

For $\frac{1}{q} + \frac{1}{q'} + \frac{1}{2} = 1$, we have

$$\begin{aligned}\Bigg| \int_\Omega \Big(& w_i^{(n+1)} \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2(u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ & + 2(\mathcal{L}(u^{(n+1)}(x)) - \bar{v}(x)) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}(x)) 1_D(x) \Big) \varphi_i(x) dx \Bigg| \\ & \leq \| w_i^{(n+1)} - w_i^{(n)} \|_{L^q} \| \nabla u_i^{(n+1)} \|_{L^{q'}} \| \nabla \varphi_i \|_{L^2}.\end{aligned}$$

Since $u^{(n+1)}$ is a minimizer of $\mathcal{E}(u, w^{(n)})$, we may assume without loss of generality that $\hat{u}_i^{(n+1)} = u_i^{(n+1)}$ for all $i = 1, \ldots, M$, where $\hat{}$ is the truncation operator. Consequently $\|u_i^{(n+1)}\|_\infty \leq C < +\infty$ uniformly with respect to n. We can use the results in [28] to show that there exists $q' > 2$ such that

$$\| \nabla u_i^{(n+1)} \|_{L^{q'}} \leq C < +\infty$$

uniformly with respect to n (see also [4, 5, 12] for similar arguments). Therefore, using (7.3), we can conclude that

$$- \operatorname{div}(w_i^{(n+1)} \nabla u_i^{(n+1)}) + 2 \left((u_i^{(n+1)} - \bar{u}_i) 1_{\Omega \setminus D} + (\mathcal{L}(u^{(n+1)}) - \bar{v}) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}) 1_D \right) \to 0,$$

for $n \to \infty$, in $(W^{1,2}(\Omega; \mathbb{R}^M))'$. This also shows that $\{u^{(n)}\}_n$ is uniformly bounded in $W^{1,2}(\Omega; \mathbb{R}^M)$. Therefore, there exists a subsequence $\{u^{(n_k)}\}_k$ that converges strongly in L^2 and weakly in $W^{1,2}(\Omega; \mathbb{R}^M)$ to a function $u^{(\infty)} \in W^{1,2}(\Omega; \mathbb{R}^M)$. Since $w_i^{(n+1)} = \frac{\phi_h'(|\nabla u_i^{(n+1)}|)}{|\nabla u_i^{(n+1)}|}$, with standard arguments for monotone operators (see the proof of [12, Proposition 3.1] and [10]), we show that in fact

(7.5)
$$- \operatorname{div} \left(\frac{\phi_h'(|\nabla u_i^{(\infty)}|)}{|\nabla u_i^{(\infty)}|} \nabla u_i^{(\infty)} \right) + 2 \left((u_i^{(\infty)} - \bar{u}_i) 1_{\Omega \setminus D} + (\mathcal{L}(u^{(\infty)}) - \bar{v}) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(\infty)}) 1_D \right) = 0,$$

for $i = 1, \ldots, M$, in $(W^{1,2}(\Omega; \mathbb{R}^M))'$. The latter are the Euler–Lagrange equations associated with the functional F_h, and therefore $u^{(\infty)}$ is a stationary point for F_h.

Assume now that F_h has a unique minimizer u^*. Then necessarily $u^{(\infty)} = u^*$. Since every subsequence of $\{u^{(n)}\}_n$ has a subsequence converging to u^*, the full sequence $\{u^{(n)}\}_n$ converges to u^*. □

Since both F_h and $\mathcal{E}_h(\cdot, w)$ admit minimizers, their uniqueness is equivalent to the uniqueness of the solutions of the corresponding Euler–Lagrange equations. If uniqueness of the solution is satisfied, then the algorithm (7.2) can be reformulated equivalently as the following two-step iterative procedure:

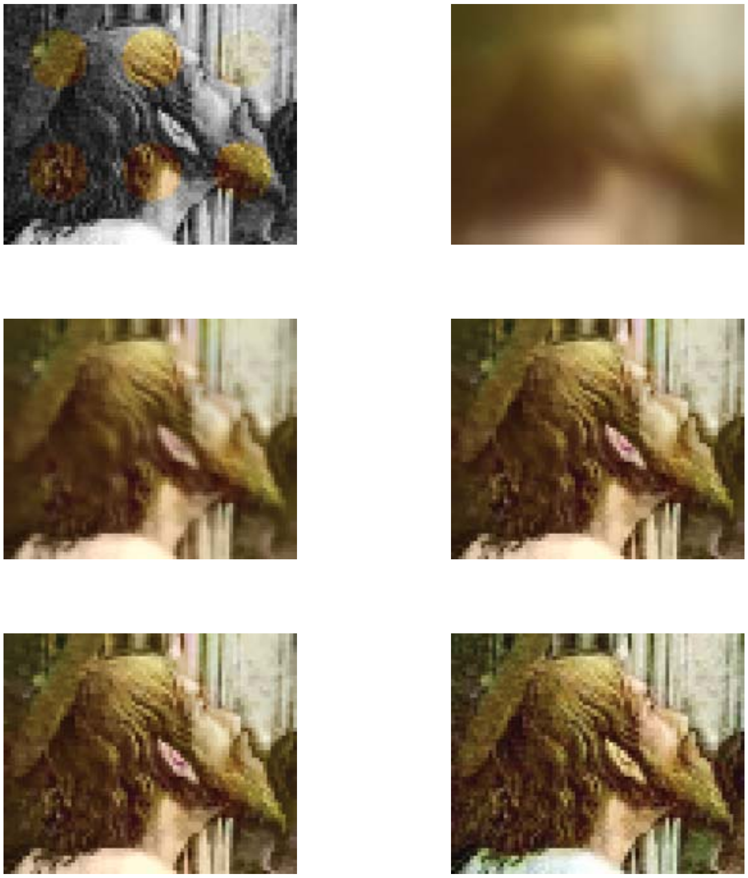

Fig. 7.1. *The datum* $(\bar{u}, \bar{v})$ *is illustrated in the top-left position. The image has dimensions* 64×78 *pixels. The first four iterations of the algorithms are listed from left to right, starting from the first row. The original color image (A. Mantegna's frescoes, photo by Alinari dated to* 1940*) to be reconstructed is illustrated in the bottom-right position. This image serves as a ground truth for the numerical experiments. The parameters we have used are* $\varepsilon_h = 10^{-4}$, $\lambda = \mu = 150$.

- Find $u^{(n+1)}$, which solves

$$\int_\Omega \Big(w_i^{(n)}(x) \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2(u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ + 2(\mathcal{L}(u^{(n+1)}(x)) - \bar{v}(x)) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}(x)) 1_D(x) \Big) \varphi_i(x) dx = 0$$

  for $i = 1, \ldots, M$ and for all $\varphi \in W^{1,2}(\Omega; \mathbb{R}^M)$.
- Compute directly $w^{(n+1)}$ by

$$w_i^{(n+1)} = \varepsilon_h \vee \frac{1}{|\nabla u_i^{(n+1)}|} \wedge \frac{1}{\varepsilon_h}, \quad i = 1, \ldots, M.$$

There are cases for which one can ensure uniqueness of solutions:

1. If G_2 is strictly convex, then the minimizers are unique as well as the solutions of the equations.

2. Modify the equations by again inserting the parameters $\lambda, \mu > 0$:

$$\int_\Omega \Bigg(w_i^{(n)} \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2\mu (u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ + 2\lambda (\mathcal{L}(u^{(n+1)}(x)) - \bar{v}(x)) \frac{\partial \mathcal{L}}{\partial u_i}(u^{(n+1)}(x)) 1_D(x) \Bigg) \varphi_i(x) dx = 0$$

for $i = 1, \ldots, M$ and for all $\varphi \in W^{1,2}(\Omega; \mathbb{R}^M)$. By a standard fixed point argument, it is not difficult to show that for $\mu \sim \lambda \sim \varepsilon_h$ the solution of the previous equations is unique. Unfortunately the condition $\mu \sim \lambda \sim \varepsilon_h$ is acceptable only for those applications where the constraints on the data are weak, for example, when the data are affected by a strong noise.

3. In the following section we illustrate the finite element approximation of the Euler–Lagrange equations. Since we are interested in color image applications, we restrict the numerical experiments to the case $\mathcal{L}(u_1, u_2, u_3) = \frac{1}{3}(u_1 + u_2 + u_3)$. By this choice, the numerical results confirm that the linear systems arising from the finite element discretization are uniquely solvable for a rather large set of possible parameters λ, μ.

8. Numerical implementation and results. In this section we want to present the numerical implementation of the iterative double-minimization algorithm (7.2) for color image restoration. As the second step of the scheme (which amounts to the update of the gradient weight) can be explicitly done once $u^{(n+1)}$ is computed, we are left essentially to provide a numerical implementation of the first step, i.e., the solution of the Euler–Lagrange equations.

8.1. Finite element approximation of the Euler–Lagrange equations. For the solution of the Euler–Lagrange equations we use a finite element approximation. We illustrate the implementation with the concrete aim of the reconstruction of a digital color image supported in $\Omega = [0,1]^2$ from few color fragments supported in $\Omega \setminus D$ and the gray-level information where colors are missing. By the nature of this problem, we can choose a regular triangulation $\mathcal{T}$ of the domain Ω with nodes distributed on a regular grid $\mathcal{N} := \tau \mathbb{Z}^2 \cap \Omega$, corresponding to the pixels of the image. Associated with $\mathcal{T}$ we fix the following finite element spaces:

$$\mathcal{U} = \{u \in C^0(\Omega) : u|T \in \mathbb{P}^1, \, T \in \mathcal{T}\}, \\ \mathcal{V} = \{w \in L^2(\Omega) : w|T \in \mathbb{P}^0, \, T \in \mathcal{T}\}.$$

The space $\mathcal{U}$ induces the finite element space of color images given by

$$U := \{u \in W^{1,2}(\Omega, \mathbb{R}^3) : u_i \in \mathcal{U}, \, i = 1,2,3\}.$$

The space $\mathcal{V}$ induces the finite element space of *gradient weights* given by

$$V := \{w \in L^2(\Omega, \mathbb{R}^3) : w_i \in \mathcal{V}, \, i = 1,2,3\}.$$

In order to avoid the nonlinearity in the coupled terms of order 0, we restrict our functional to the case $\mathcal{L}(u_1, u_2, u_3) = \frac{1}{3}(u_1 + u_2 + u_3)$. For further simplicity we have not considered truncations which in fact are not necessary in practice.

For a given $w^{(n)} \in V$, the first step of our approximation of the double-minimization scheme amounts to the computation of $u^{(n+1)} \in U$, which solves, using (7.4),

$$\int_\Omega \Bigg(w_i^{(n)}(x) \nabla u_i^{(n+1)}(x) \cdot \nabla \varphi_i(x) + 2\mu (u_i^{(n+1)}(x) - \bar{u}_i(x)) 1_{\Omega \setminus D}(x) \\ + \frac{2}{3}\lambda \left(\frac{1}{3}(u_1^{(n+1)}(x) + u_2^{(n+1)}(x) + u_3^{(n+1)}(x)) - \bar{v}(x) \right) 1_D(x) \Bigg) \varphi_i(x) dx = 0 \tag{8.1}$$

for $i = 1, 2, 3$ and for all $\varphi \in U$. To the spaces $\mathcal{U}$ and $\mathcal{V}$ are attached the corresponding nodal bases $\{\varphi_k\}_{k \in \mathcal{N}}$ and $\{\chi_k\}_{k \in \mathcal{N}}$, respectively. Therefore, we also have that

$$U = \left\{ u : u = \left(\sum_{k \in \mathcal{N}} u_{i,k} \varphi_k \right)_{i=1,2,3} \right\}, \quad V = \left\{ w : w = \left(\sum_{k \in \mathcal{N}} w_{i,k} \chi_k \right)_{i=1,2,3} \right\}.$$

With these bases we can construct the following matrices:

$$\mathbf{K}_i^{(n+1)} := \left(\int_\Omega w_i^{(n)}(x) \nabla \varphi_k(x) \cdot \nabla \varphi_h(x) dx \right)_{k,h \in \mathcal{N}}, \tag{8.2}$$

$$\mathbf{M}_{\Omega \setminus D} := \left(2\mu \int_\Omega 1_{\Omega \setminus D}(x) \varphi_k(x) \varphi_h(x) dx \right)_{k,h \in \mathcal{N}}, \tag{8.3}$$

$$\mathbf{M}_D := \left(\frac{2\lambda}{9} \int_\Omega 1_D(x) \varphi_k(x) \varphi_h(x) dx \right)_{k,h \in \mathcal{N}}. \tag{8.4}$$

By these building blocks, we can assemble

$$\mathbf{K}^{(n+1)} := \begin{pmatrix} \mathbf{K}_1^{(n+1)} + \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D & \mathbf{M}_D & \mathbf{M}_D \\ \mathbf{M}_D & \mathbf{K}_2^{(n+1)} + \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D & \mathbf{M}_D \\ \mathbf{M}_D & \mathbf{M}_D & \mathbf{K}_3^{(n+1)} + \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D \end{pmatrix}$$

and

$$\mathbf{M} := \begin{pmatrix} \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D & \mathbf{M}_D & \mathbf{M}_D \\ \mathbf{M}_D & \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D & \mathbf{M}_D \\ \mathbf{M}_D & \mathbf{M}_D & \mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D \end{pmatrix}. \tag{8.5}$$

Furthermore, let us denote the vector of the nodal values of the solution by

$$\mathbf{u}^{(n+1)} = (u_{1,k_1}^{(n+1)}, \dots, u_{1,k_{\#\mathcal{N}}}^{(n+1)}, u_{2,k_1}^{(n+1)}, \dots, u_{2,k_{\#\mathcal{N}}}^{(n+1)}, u_{3,k_1}^{(n+1)}, \dots, u_{3,k_{\#\mathcal{N}}}^{(n+1)})^T \tag{8.6}$$

assembled as a column vector containing the nodal values of each channel in order, where $k_i \in \mathcal{N}$ are nodes which are suitably ordered. In a similar way the nodal values of the data $\bar{u}, \bar{v}$ are assembled in the vector

$$\bar{\mathbf{u}} = (\bar{u}_{1,k_1}, \dots, \bar{u}_{1,k_j}, \bar{v}_{1,k_{j+1}}, \dots, \bar{v}_{1,k_{\#\mathcal{N}}}, \bar{u}_{2,k_1}, \dots, \bar{u}_{2,k_j}, \bar{v}_{2,k_{j+1}}, \dots, \bar{v}_{2,k_{\#\mathcal{N}}}, \\ \bar{u}_{3,k_1}, \dots, \bar{u}_{3,k_j}, \bar{v}_{3,k_{j+1}}, \dots, \bar{v}_{3,k_{\#\mathcal{N}}})^T. \tag{8.7}$$

For the right-hand side we have the additional requirement that $\bar{v}_{i,k} = \bar{v}_{\ell,k}$ for $i \neq \ell$, representing the gray-level values. Moreover, the order of the nodes $\{k_l : l = 1, \dots, \#\mathcal{N}\}$ is such that

$$(\mathbf{M}_{\Omega \setminus D} + \mathbf{M}_D)(\bar{u}_{i,k_1}, \dots, \bar{u}_{i,k_j}, \bar{v}_{i,k_{j+1}}, \dots, \bar{v}_{i,k_{\#\mathcal{N}}})^T = \mathbf{M}_{\Omega \setminus D} \begin{pmatrix} \bar{\mathbf{u}}_\mathbf{i} \\ 0 \end{pmatrix} + \mathbf{M}_D \begin{pmatrix} 0 \\ \bar{\mathbf{v}}_\mathbf{i} \end{pmatrix}.$$

With these notations and conventions, the solution of the system of equations (8.1) is equivalent to the solution of the following algebraic linear system:

$$\mathbf{K}^{(n+1)}\mathbf{u}^{(n+1)} = \mathbf{M}\bar{\mathbf{u}}. \tag{8.8}$$

8.2. Numerical implementation of the double-minimization algorithm. We have now all the ingredients to assemble our numerical scheme into the following algorithm.

Algorithm 1. **DOUBLE_MINIMIZATION**

```
Input:        Data vector $\bar{\mathbf{u}}$, $\varepsilon_h > 0$, initial gradient weight $w^{(0)}$ with $\varepsilon_h \leq w_{i,k}^{(0)} \leq$
              $1/\varepsilon_h$, number $n_{\max}$ of outer iterations.
Parameters:   Positive weights $\lambda, \mu \geq 0$.
Output:       Approximation $u^*$ of the minimizer of $F_h$
$\mathbf{u}^{(0)} := 0$;
$\mathbf{f} := \mathbf{M}\bar{\mathbf{u}}$;
for $n := 0$ to $n_{\max}$ do
    Assemble the matrix $\mathbf{K}^{(n+1)}$ as in (8.2);
    Compute $\mathbf{u}^{(n+1)}$ such that $\mathbf{K}^{(n+1)}\mathbf{u}^{(n+1)} := \mathbf{f}$;
    Assemble the solution $u^{(n+1)} = (\sum_{k\in\mathcal{N}} u_{i,k}^{(n+1)}\varphi_k)_{i=1,2,3}$;
    Compute the gradient $\nabla u^{(n+1)} = (\sum_{k\in\mathcal{N}} u_{i,k}^{(n+1)}\nabla\varphi_k)_{i=1,2,3}$;
    $w_i^{(n+1)} := \varepsilon_h \vee \frac{1}{|\nabla u_i^{(n+1)}|} \wedge \frac{1}{\varepsilon_h}, \quad i = 1, \ldots, M$;
endfor
$u^* := u^{(n+1)}$.
```

8.3. Numerical experiments in color image restoration and results. In this section we show numerical results dealing with applications of the algorithm to color image restoration. We assume as in Figure 1.1 to have available few color fragments of the image and the gray levels of the missing parts. In all the experiments we report, we also furnish a corresponding ground truth image for comparison. The support of the image is $\Omega = [0,1]^2$, where we construct a grid of dimensions $h \times w$, and w and h are the width and height of the image in pixels, respectively. On this grid a regular triangulation is defined. The values of the images are in $[0, 255]$ channelwise.

The algorithm converges to a stationary situation in a limited number of iterations. In our numerical tests 3–4 iterations are sufficient; see Figures 7.1 and 8.4. The quality of the reconstruction increases for increasing the amount of correct color information of the datum. Nevertheless we observe that the geometrical distribution of the color datum is more crucial for a better reconstruction. A remarkable result is illustrated in Figures 8.1 and 8.2. In the bottom-left positions we illustrate data with only 3% of the original color information, randomly distributed. From this very limited complete information the algorithm still produces a rather good reconstruction of the original color images. Let us emphasize this once more:

It is sufficient to have a very limited guess of possible colors which are nicely distributed in the image to recolor all of the image.

This result has a significant impact for several possible applications. Besides the problem of the restoration of the fresco colors (where we have available 8% of the total color surface), we can use this algorithm in old black and white video and image restoration and for extreme compression of color images. For the sake of further reference, in Figure 8.3 we illustrate a comparison between the algorithm proposed in [26] and our reconstruction. In our experiments the results appear visually equivalent, although our method tends to reproduce more accurately the luminosity of the image,

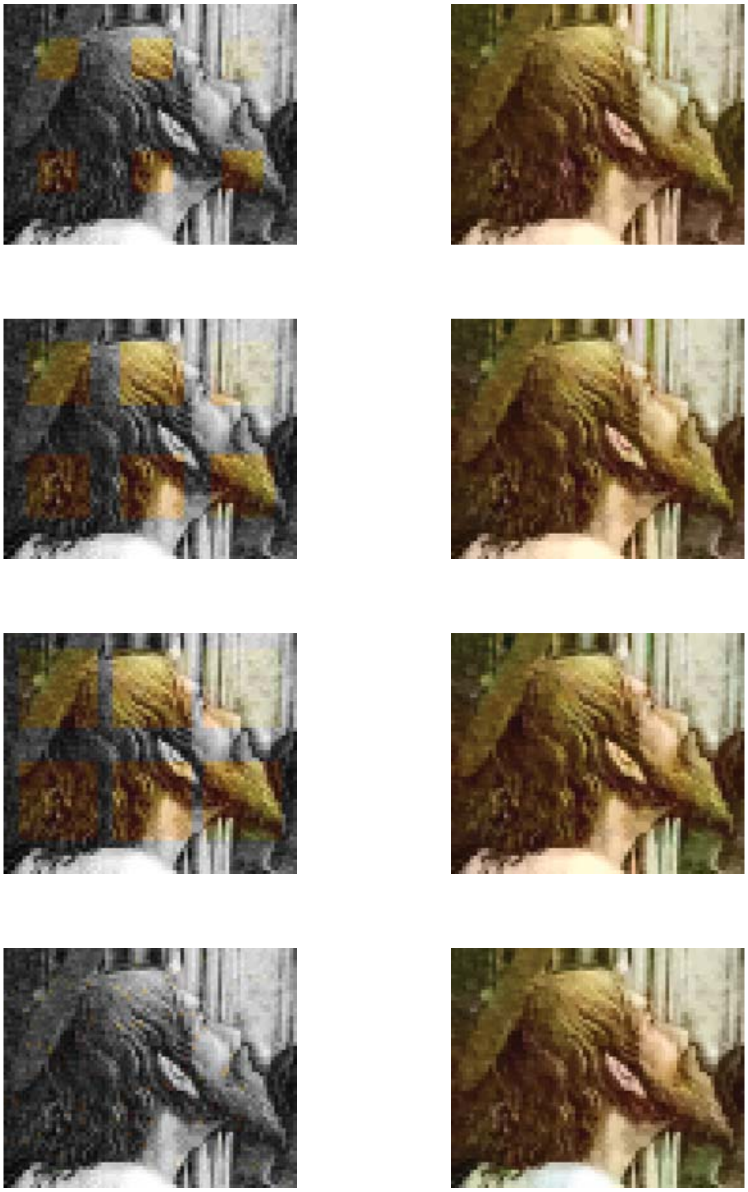

Fig. 8.1. *The first column illustrates a sequence of different data. The second column illustrates the corresponding* 10*th iteration of the algorithm. The original color image to be reconstructed is illustrated in Figure* 7.1 *in the bottom-right position. The parameters we have used are* $\varepsilon_h = 10^{-4}$, $\lambda = \mu = 150$. *In the bottom-left position we illustrate a datum with only* 3% *of the original color information, randomly distributed.*

because of the enforced constraint of the gray-level reproduction in the inpainting region. The method proposed in [26] can perform slightly better pick signal-to-noise ratios (PSNRs), though in most of the cases they do not differ significantly. For a more specific discussion on fidelity in recolorization, we refer the reader to [22]. We

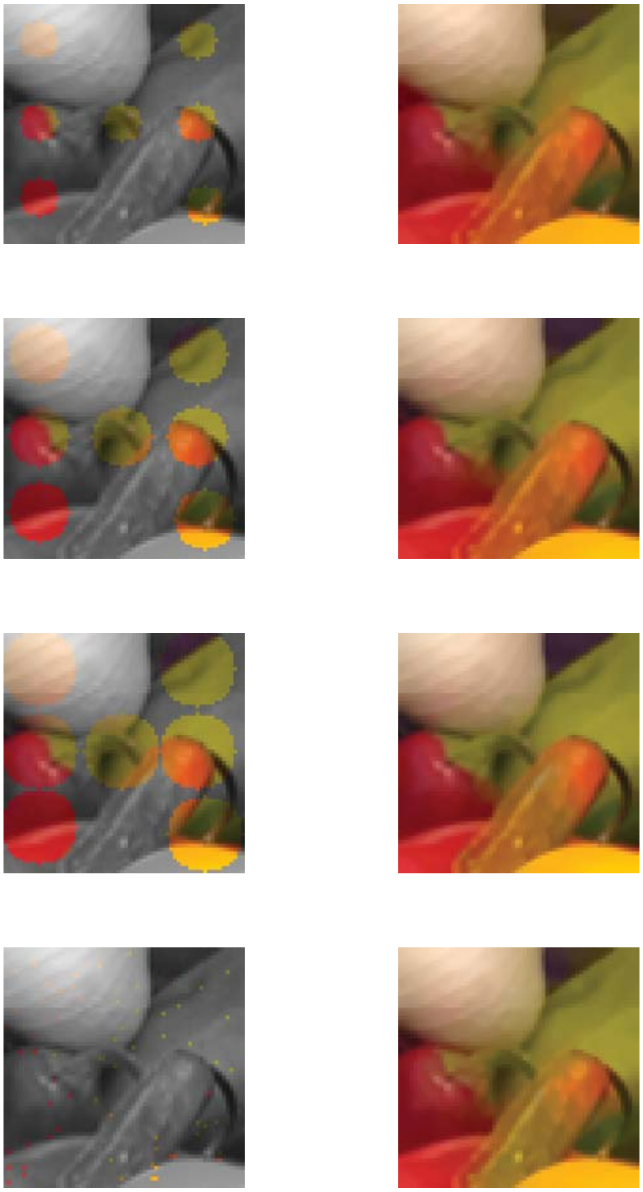

FIG. 8.2. *The first column illustrates a sequence of different data. The second column illustrates the corresponding* 10*th iteration of the algorithm. The parameters we have used are* $\varepsilon_h = 10^{-4}$, $\lambda = \mu = 150$. *In the bottom-left position we illustrate a datum with only* 3% *of the original color information, randomly distributed. conclude with a brief discussion on the parameters $\lambda, \mu, \varepsilon_h$. In Figure 8.4 we show the history of the residual error with respect to the original color image for increasing choices of the parameters λ, μ. These numerical results confirm the regularization effect due to the total variation constraint. The choice of ε_h has a twofold function. It

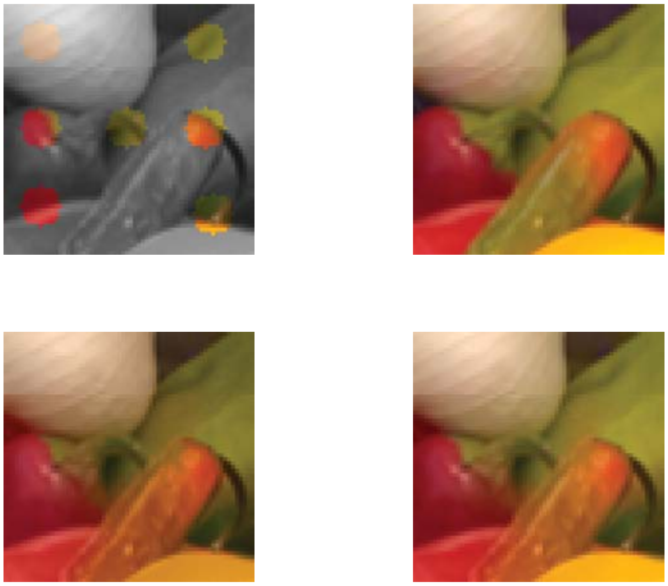

FIG. 8.3. *The figure on the top-left reports the initial data, and on the top-right we have the original image. The figure on the bottom-left is the recolorization by means of the algorithm presented in* [26] *generated by the MATLAB code provided at http://www.cs.huji.ac.il/∼yweiss/Colorization/colorization.zip. On the bottom-right we again report the reconstruction due to our algorithm. The PSNR of a color image u with respect to a ground truth image $\bar{u}$ is defined by PSNR* $= 10\log_{10}\big(\frac{255^2}{\frac{1}{3hw}\sum_{i=1}^{3}\|u_i-\bar{u}_i\|_2^2}\big)$, *where h, w are the height and width of the image, respectively. Although the PSNRs are* 31.61 *dB and* 29.48 *dB, respectively, particularly visible is a more accurate luminosity restoration, e.g., in the yellow region, due to our algorithm.*

serves as a regularization parameter; i.e., the visual smoothness of the reconstruction depends on ε_h. The larger values of ε_h give smoother reconstructed images. This effect is due to the fact that if ε_h gets large, then the corresponding differential operator $\nabla \cdot \big(\frac{\phi_h'(|\nabla u_i|)}{|\nabla u_i|}\nabla u_i\big)$ becomes more and more isotropic. Moreover, since in discrete images the gradients are always bounded, if ε_h is smaller than a threshold $T > 0$ depending on the mesh size τ—in our experiments $T = (255 \max\{h, w\})^{-1}$—then the lower bound on the gradient weight becomes irrelevant in the algorithm. However, the second purpose of this parameter is also for the sake of numerical stability. Depending on the size of the image, this parameter cannot be too small (i.e., minimal); otherwise the corresponding stiffness matrices $\mathbf{K}^{(n)}$ might be significantly ill-conditioned, and suitable preconditioners (multigrid and subspace correction/domain decomposition methods) should be invoked in this case.

ASYMMETRIC CREEPING MOTION OF A RIGID SPINDLE-SHAPED BODY IN A VISCOUS FLUID[*]

M. ZABARANKIN[†]

Abstract. Exact solutions to the three-dimensional problems of asymmetric creeping translation and rotation of a rigid spindle-shaped body in a viscous incompressible fluid have been obtained. In both problems, the velocity field has been represented in the form of Dean and O'Neill, and under certain conditions, the equation of continuity has been reduced to a three-contour equation for an analytic function related to the density in a Fourier integral, representing the pressure in bispherical coordinates. Then, the three-contour equation has been reduced to a Fredholm integral equation of the second kind with a quasi-difference kernel by the complex Fourier transform. As an illustration for the obtained solutions, the pressure at the surface of the body has been calculated and analyzed. The resisting force and torque have been obtained for an arbitrary body of revolution via limits of certain harmonic functions at infinity and, as an example, have been computed for various values of a geometrical parameter of the spindle-shaped body for asymmetric translation and rotation, respectively.

Key words. spindle-shaped body, asymmetric Stokes flow, exact solution, three-contour equation, complex Fourier transform, Fredholm integral equation, Riemann boundary-value problem, drag force, resisting torque

1. Introduction.

This paper presents exact solutions to the three-dimensional (3D) problems of *asymmetric creeping translation* and *rotation* of a rigid spindle-shaped body in a quiescent viscous incompressible fluid. The problems are formulated in the framework of the linearized Navier–Stokes equations that govern slow flows of viscous incompressible fluids and neglect inertial effects:

$$\operatorname{grad}\wp = \mu\,\boldsymbol{\Delta}\mathbf{u}, \qquad \operatorname{div}\mathbf{u} = 0, \tag{1}$$

where $\mathbf{u}$ is the fluid velocity field, $\wp$ is the pressure in the fluid, μ is the shear viscosity, and $\boldsymbol{\Delta}\mathbf{u} \equiv \operatorname{grad}(\operatorname{div}\mathbf{u}) - \operatorname{curl}(\operatorname{curl}\mathbf{u})$. The model (1) describes so-called *Stokes (creeping) flows* and is known as the Stokes equations [7, 10]. We also consider that the velocity field $\mathbf{u}$ and pressure $\wp$ vanish at infinity:

$$\mathbf{u}|_\infty = 0, \qquad \wp|_\infty = 0. \tag{2}$$

Constructing *exact* solutions to the model (1) has been and continues to be one of the central themes in analytical hydrodynamics. Much of the work in this research area has been dedicated to studying Stokes flows due to axially symmetric and asymmetric motions of a rigid body of *revolution*. By asymmetric motion of the body, we will understand translation along and rotation around axes orthogonal to the body's axis of revolution.

The problem of 3D Stokes flows arising from *axially symmetric rotation* of bodies of revolution reduces to finding merely one harmonic function [8] and is the simplest

from this class. On the other hand, the 3D Stokes flow problem corresponding to *axially symmetric translation* of bodies of revolution can be reduced to determining a biharmonic *stream function* [7, 19] and has been solved for *sphere* [17], *prolate* and *oblate spheroids* [12, 7], *circular disk* [12, 7], *spherical cap* [13, 2, 19], *two spheres* [16], *torus* [14, 21], *spindle-shaped body* [15, 23], and *lens-shaped body* [13, 22]. However, it is well known that the stream function approach cannot be extended to solving *asymmetric* 3D Stokes flow problems.

For arbitrary boundary conditions, Dean and O'Neill [3] suggested the solution form

$$\mathbf{u} = \tfrac{1}{2\mu}\,\mathfrak{r}\,\wp + \mathfrak{F}, \tag{3}$$

where $\mathfrak{r}$ is the radius vector and $\mathfrak{F}$ is an arbitrary harmonic vector ($\boldsymbol{\Delta}\mathfrak{F} = 0$). In this case, the continuity equation $\operatorname{div}\mathbf{u} = 0$ reduces to

$$3\wp + (\mathfrak{r}\cdot \operatorname{grad}\wp) + 2\mu \operatorname{div}\mathfrak{F} = 0. \tag{4}$$

The representation (3) was used to construct exact solutions to the Stokes flow problems for the asymmetric translation and rotation of a rigid torus [6, 21] and bispheres (two spheres of equal size) [20].

Let (x, y, z) and (r, φ, z) be systems of Cartesian and cylindrical coordinates with bases $(\mathbf{i}, \mathbf{j}, \mathbf{k})$ and $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$, respectively, which have the same z-axis and are related in an ordinary way, and let S be the surface of the rigid body of revolution, whose axis of revolution (symmetry) coincides with the z-axis. We also introduce the so-called k-harmonic operator, Δ_k, by

$$\Delta_k = \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2} - \frac{k^2}{r^2}.$$

Without loss of generality, we consider the following asymmetric Stokes flow problems (which, to the best of our knowledge, have not been addressed for the spindle-shaped body).

Problem I (asymmetric translation). *Let the body of revolution translate along the x-axis with the constant velocity v_x. Then the vector $\mathbf{u}$ solves* (1) *and* (2) *and satisfies the* no-slip *boundary condition on the body's surface S:*

$$\mathbf{u}|_S = v_x \mathbf{i},$$

which in component form in the cylindrical coordinates is reformulated as

$$u_r|_S = v_x \cos\varphi, \qquad u_\varphi|_S = -v_x \sin\varphi, \qquad u_z|_S = 0. \tag{5}$$

Problem II (asymmetric rotation). *Let the body of revolution rotate around the y-axis with the constant angular velocity ϖ_y. Then the vector $\mathbf{u}$ solves* (1) *and* (2) *and satisfies the* no-slip *boundary condition on the body's surface S:*

$$\mathbf{u}|_S = \left[\varpi_y\,\mathbf{j} \times (x\,\mathbf{i} + z\,\mathbf{k})\right],$$

which in component form in the cylindrical coordinates reduces to

$$u_r|_S = \varpi_y\, z\, \cos\varphi, \qquad u_\varphi|_S = -\varpi_y\, z\, \sin\varphi, \qquad u_z|_S = -\varpi_y\, r\, \cos\varphi. \tag{6}$$

It is seen from the boundary conditions (5) and (6) that in both cases, the pressure $\wp$ and solution form (3) can be represented by

$$\wp(r,\varphi,z) = \mu\,\mathit{\Theta}(r,z)\,\cos\varphi, \tag{7}$$

$$\begin{aligned} u_r(r,\varphi,z) &= u_r^{(1)}(r,z)\cos\varphi = \tfrac{1}{2}\,\left(r\,\mathit{\Theta}(r,z) + \mathit{\Upsilon}(r,z) + \mathit{\Phi}(r,z)\right)\cos\varphi,\\ u_\varphi(r,\varphi,z) &= u_\varphi^{(1)}(r,z)\sin\varphi = \tfrac{1}{2}\,\left(\mathit{\Phi}(r,z) - \mathit{\Upsilon}(r,z)\right)\sin\varphi,\\ u_z(r,\varphi,z) &= u_z^{(1)}(r,z)\cos\varphi = \left(\tfrac{1}{2}\,z\,\mathit{\Theta}(r,z) + \mathit{\Psi}(r,z)\right)\cos\varphi, \end{aligned} \tag{8}$$

where the functions $\mathit{\Theta}$ and $\mathit{\Upsilon}$, $\mathit{\Phi}$, and $\mathit{\Psi}$ are associated with the first harmonics of the pressure $\wp$ and vector-function $\mathfrak{F}$, respectively, and satisfy

$$\Delta_1\,\mathit{\Theta} = 0, \qquad \Delta_0\,\mathit{\Upsilon} = 0, \qquad \Delta_2\,\mathit{\Phi} = 0, \qquad \Delta_1\,\mathit{\Psi} = 0. \tag{9}$$

For (8), (4) reduces to

$$\left(r\frac{\partial}{\partial r} + z\frac{\partial}{\partial z} + 3\right)\mathit{\Theta} + \frac{\partial}{\partial r}\mathit{\Upsilon} + \left(\frac{\partial}{\partial r} + \frac{2}{r}\right)\mathit{\Phi} + 2\,\frac{\partial}{\partial z}\,\mathit{\Psi} = 0. \tag{10}$$

A known approach for solving the problem (2), (8), (9), and (10) for both boundary conditions (5) and (6) is to represent the harmonic functions $\mathit{\Theta}$, $\mathit{\Upsilon}$, $\mathit{\Phi}$, and $\mathit{\Psi}$ in the form of integrals or series in curvilinear coordinates, associated with the geometry of the body of revolution, then to express $\mathit{\Upsilon}$, $\mathit{\Phi}$, and $\mathit{\Psi}$ via $\mathit{\Theta}$ from the corresponding boundary conditions, and finally to substitute the series or integrals representing these functions into (10).

For bispheres and a torus, the function $\mathit{\Theta}$ can be represented in bispherical and toroidal coordinates, respectively, in the form of a series, and by this approach, (10) reduces to a *second-order difference equation* with respect to series coefficients X_k [20, 21, 6]:

$$a_k\,X_{k+1} + b_k\,X_k + c_k\,X_{k-1} = F_k, \qquad k \geq 1, \tag{11}$$

where a_k, b_k, c_k, and F_k are known functions such that $a_k \to 0$, $b_k \to 0$, $c_k \to 0$, and $F_k \to 0$ as $k \to \infty$. In [20, 21, 6], (11), also known as an infinite tridiagonal algebraic system (arising in 3D problems of elastic media [9]), was reduced to finite systems for some large k and solved numerically.

In this paper, we show that for the spindle-shaped body, the described approach reduces (10) to a *three-contour equation* for an analytic function $X(s)$ related to the density in a Fourier integral representing the function $\mathit{\Theta}$ in bispherical coordinates:

$$a(s)\,X(s+1) + b(s)\,X(s) + c(s)\,X(s-1) = F(s), \qquad \operatorname{Re} s = 0, \tag{12}$$

where s is a complex variable and $a(s)$, $b(s)$, $c(s)$, and $F(s)$ are known functions. We obtain (12) under the condition that $X(s)$ is an analytic function in the strip $|\operatorname{Re} s| \leq 1$ and show that this condition holds true for the body with $\eta_0 < 2.103$ (the surface of the spindle-shaped body is determined by fixing the coordinate η in the bispherical coordinates (ξ,η,φ); i.e., $\eta = \eta_0$). Then, we reduce (12) to a three-contour equation with $a(s) = c(s) = 1$, and show that in this special case, the latter reduces to a Fredholm integral equation of the second kind by the complex Fourier transform. As an illustration for the suggested method, we calculate the pressure at the surface of the body in the xz–half-plane ($\varphi = 0$) for various values of η_0 for the asymmetric translation and rotation of the body.

We also derive formulas for the resisting force and torque experienced by an arbitrary rigid body of revolution in asymmetric creeping motion in a viscous incompressible fluid. For the asymmetric translation with the boundary conditions (5), the resisting force is expressed via the limit of the function Θ at $z = 0$ and $r \to \infty$, and for the asymmetric rotation with the boundary conditions (6), the resisting torque is found via the limit of the function Ψ at $z = 0$ and $r \to \infty$. These formulas resemble Payne and Pell's formula for the resisting force for a body of revolution in axially symmetric translation, which is given by the limit of a stream function at infinity; see [7]. Using the derived formulas, we compute the resisting force and torque for the spindle-shaped body for various values of η_0 ($\eta_0 < 2.103$) for the asymmetric translation and rotation, respectively.

The paper is organized into six sections. Section 2 derives formulas for the resisting force and torque for an arbitrary body of revolution slowly moving in the viscous fluid. Section 3 reduces the 3D Stokes flow problems for asymmetric creeping motions of the rigid spindle-shaped body to the Fredholm integral equation of the second kind. Sections 4 and 5 obtain exact solutions to the problems in the cases of asymmetric translation and rotation, respectively, and compute the resisting force and torque for various values of the geometrical parameter η_0. Section 6 concludes the paper. Appendices A and B present proofs for the propositions dealing with computation of the resisting force and torque, respectively.

2. Resisting force and torque.

This section derives the formulas for the resisting force and torque experienced by an arbitrary rigid body of revolution in asymmetric creeping motion in a quiescent viscous incompressible fluid. The formulas resemble the one of Payne and Pell for the resisting force for the body in axially symmetric translation, which is given by the limit of a stream function at infinity; see [13].

2.1. Resisting force.

Proposition 1 (resisting force). *The resisting force for a rigid body of revolution, slowly moving in the fluid, is given by*

$$\mathbf{F} = -\iint_{\widetilde{S}} \left(\mu \left[\mathfrak{n} \times \boldsymbol{\omega}\right] + \wp\, \mathfrak{n}\right) dS, \tag{13}$$

where $\boldsymbol{\omega} = \operatorname{curl} \mathbf{u}$ is the vorticity, $\widetilde{S}$ is an arbitrary smooth surface encompassing the body, and $\mathfrak{n}$ is the outer normal of $\widetilde{S}$.

Proof. The proof is presented in Appendix A.

Let the body whose axis of revolution is determined by the z-axis[1] translate in the fluid along the x-axis. In this case, the velocity field of the fluid satisfies the boundary conditions (5) and can be represented in the form (8).

Theorem 2 (resisting force for asymmetric translation). *In terms of the solution form* (8), *the resisting force for the body having the z-axis of revolution and translating along the x-axis is given by*

$$F_x = -4\pi\mu \lim_{r\to\infty} \left(r^2\, \Theta(r, z)\big|_{z=0} \right). \tag{14}$$

Proof. We calculate the resisting force by formula (13) assuming that the surface $\widetilde{S}$ is a sphere with large radius R_0. Let (R, ϑ, φ) be a system of spherical coordinates

[1] The Cartesian and cylindrical coordinates have the same z-axis.

with the basis $(\mathbf{e}_R, \mathbf{e}_\vartheta, \mathbf{e}_\varphi)$ and relating to the cylindrical coordinates (r, φ, z) in the ordinary way. For the sphere $\widetilde{S}$, we have $dS = R_0^2 \sin\vartheta \, d\vartheta \, d\varphi$, $\mathfrak{r} = R_0 \mathbf{e}_R$, and $\mathfrak{n} = \mathbf{e}_R$, and thus, (13) reduces to

$$\mathbf{F} = -\int_0^{2\pi} \int_0^{\pi} \left(\mu \left[\mathbf{e}_R \times \boldsymbol{\omega}\right] + \wp \, \mathbf{e}_R\right) R_0^2 \sin\vartheta \, d\vartheta \, d\varphi. \tag{15}$$

In the case of the asymmetric translation of the body along the x-axis, the velocity field is given by (8), and consequently, in the spherical coordinates, the vector $\mathbf{u}$ takes the form

$$\begin{aligned} \mathbf{u} = \mathbf{e}_R & \left\{ \tfrac{1}{2} R \, \Theta(R,\vartheta) + \tfrac{1}{2} \left[\varUpsilon(R,\vartheta) + \varPhi(R,\vartheta) \right] \sin\vartheta + \varPsi(R,\vartheta) \cos\vartheta \right\} \cos\varphi \\ & + \mathbf{e}_\vartheta \left\{ \tfrac{1}{2} \left[\varUpsilon(R,\vartheta) + \varPhi(R,\vartheta) \right] \cos\vartheta - \varPsi(R,\vartheta) \cos\vartheta \right\} \cos\varphi \\ & + \mathbf{e}_\varphi \; \tfrac{1}{2} \left(\varPhi(R,\vartheta) - \varUpsilon(R,\vartheta) \right) \sin\varphi, \end{aligned} \tag{16}$$

where the functions Θ, $\varUpsilon$, $\varPhi$, and $\varPsi$ satisfy (9) and can be represented by

(17)

$$\begin{aligned} \Theta(R,\vartheta) &= \sum_{n=1}^{\infty} A_n R^{-n-1} \, \mathrm{P}_n^{(1)}(\cos\vartheta) = -A_1 R^{-2} \sin\vartheta - \tfrac{3}{2} A_2 R^{-3} \sin[2\vartheta] + \mathcal{O}\left(R^{-4}\right), \\ \varUpsilon(R,\vartheta) &= \sum_{n=0}^{\infty} B_n R^{-n-1} \, \mathrm{P}_n(\cos\vartheta) = B_0 R^{-1} + B_1 R^{-2} \cos\vartheta + \mathcal{O}\left(R^{-3}\right), \\ \varPhi(R,\vartheta) &= \sum_{n=2}^{\infty} C_n R^{-n-1} \, \mathrm{P}_n^{(2)}(\cos\vartheta) = \mathcal{O}\left(R^{-3}\right), \\ \varPsi(R,\vartheta) &= \sum_{n=1}^{\infty} D_n R^{-n-1} \, \mathrm{P}_n^{(1)}(\cos\vartheta) = -D_1 R^{-2} \sin\vartheta + \mathcal{O}\left(R^{-3}\right). \end{aligned}$$

Here, $\mathrm{P}_n^{(k)}(\cos\vartheta)$ is the associated Legendre polynomial of the first kind of order n and rank k. For $k = 0$, the superscript is omitted.

Then, substituting (17) into (10), we obtain

$$(A_1 + B_0) \, R^{-2} \, \mathrm{P}_1^{(1)}(\cos\vartheta) + (B_1 - 2D_1) \, R^{-3} \, \mathrm{P}_2^{(1)}(\cos\vartheta) + \mathcal{O}\left(R^{-4}\right) = 0, \tag{18}$$

whence

$$A_1 + B_0 = 0, \qquad B_1 - 2D_1 = 0, \qquad \ldots. \tag{19}$$

For (16) with (17) and (19), the vorticity $\boldsymbol{\omega} = \operatorname{curl} \mathbf{u}$ reduces to

$$\begin{aligned} \boldsymbol{\omega} = A_1 R^{-2} & \left\{ \mathbf{e}_\vartheta \sin\varphi + \mathbf{e}_\varphi \cos\vartheta \cos\varphi \right\} + \tfrac{1}{2} R^{-3} \left\{ \mathbf{e}_R \left(4D_1 \sin\vartheta \sin\varphi\right) \right. \\ & \left. + \mathbf{e}_\vartheta \left(3A_2 - 2D_1\right) \cos\vartheta \sin\varphi - \mathbf{e}_\varphi \left(2D_1 - 3A_2 \cos[2\vartheta]\right) \cos\varphi \right\} + \mathcal{O}\left(R^{-4}\right). \end{aligned} \tag{20}$$

In the case of the asymmetric translation along the x-axis, the resisting force has the component in the direction $\mathbf{i}$ only. We substitute (20) and the function Θ in the form (17) into (15) and obtain

$$F_x = (\mathbf{F} \cdot \mathbf{i}) = 4\pi\mu \, A_1 + \mathcal{O}\left(R_0^{-1}\right), \tag{21}$$

where A_1 can be determined from (17) by

$$A_1 = -\lim_{R \to \infty} \left\{ R^2 \; \Theta(R,\vartheta)\big|_{\vartheta = \frac{\pi}{2}} \right\}.$$

Consequently, passing R_0 to infinity in (21), we obtain (14). □

Obviously, for the translation along any axis orthogonal to the z-axis with the same velocity v_x, the formula for the resisting force will be the same, in particular, $F_y = F_x$.

2.2. Resisting torque.

Proposition 3 (resisting torque). *The resisting torque for a rigid body of revolution, slowly rotating in the fluid, is given by*

$$\mathbf{T} = -\mu \iint_{\widetilde{S}} \left([\mathfrak{n} \times [\mathfrak{r} \times \boldsymbol{\omega}]] + [\mathfrak{n} \times \mathbf{u}] - \tfrac{1}{\mu} \, [\mathfrak{n} \times \mathfrak{r}] \, \wp + (\mathfrak{r} \cdot \boldsymbol{\omega}) \, \mathfrak{n} \right) dS, \tag{22}$$

where $\boldsymbol{\omega} = \operatorname{curl} \mathbf{u}$ *is the vorticity,* $\mathfrak{r}$ *is the radius vector,* $\widetilde{S}$ *is an arbitrary smooth surface encompassing the body, and* $\mathfrak{n}$ *is the outer normal of* $\widetilde{S}$.

Proof. The proof is presented in Appendix B.

Let the body with the z-axis of revolution rotate in the fluid around the y-axis. In this case, the velocity field of the fluid satisfies the boundary conditions (6) and, as in the case of the asymmetric translation along the x-axis, can be represented in the form (8).

Theorem 4 (resisting torque for asymmetric rotation). *In terms of the solution form* (8), *the resisting torque for the body having the z-axis of revolution and rotating around the y-axis is given by*

$$T_y = 8\pi\mu \lim_{r \to \infty} \left(r^2 \, \Psi(r, z) \big|_{z=0} \right). \tag{23}$$

Proof. As in the proof of Theorem 2, let $\widetilde{S}$ be the sphere of large radius R_0, and let (R, ϑ, φ) be the system of the spherical coordinates. For $\widetilde{S}$, we have $dS = R_0^2 \sin\vartheta \, d\vartheta \, d\varphi$, $\mathfrak{r} = R_0 \mathbf{e}_R$, and $\mathfrak{n} = \mathbf{e}_R$, and thus, (22) reduces to

$$\mathbf{T} = -\mu \int_0^{2\pi} \int_0^{\pi} \left(2R_0 \, (\mathbf{e}_R \cdot \boldsymbol{\omega}) \, \mathbf{e}_R - R_0 \, \boldsymbol{\omega} + [\mathbf{e}_R \times \mathbf{u}] \right) R_0^2 \sin\vartheta \, d\vartheta \, d\varphi. \tag{24}$$

In the case of the asymmetric rotation around the y-axis, the resisting torque has the component in the direction $\mathbf{j}$ only. Then, substituting (16), (17), and (20) into (24) and using (19), we obtain

$$T_y = (\mathbf{T} \cdot \mathbf{j}) = -8\pi\mu \, D_1 + \mathcal{O}\left(R_0^{-1}\right), \tag{25}$$

where D_1 can be determined from (17) by

$$D_1 = - \lim_{R \to \infty} \left\{ R^2 \, \Psi(R, \vartheta) \big|_{\vartheta = \frac{\pi}{2}} \right\}.$$

Consequently, passing R_0 to infinity in (25), we obtain (23). □

Obviously, for the rotation around any axis orthogonal to the z-axis with the same angular velocity ϖ_y, the formula for the resisting torque will be the same, in particular, $T_x = T_y$.

3. Fredholm integral equation for asymmetric motion of a rigid spindle-shaped body.

Let (ξ, η, φ) be a system of bispherical coordinates, in which the angular coordinate φ coincides with the one in the cylindrical coordinates (r, φ, z) and coordinates ξ and η are related to r and z by

$$r = c \, \frac{\sin\eta}{\cosh\xi - \cos\eta}, \qquad z = c \, \frac{\sinh\xi}{\cosh\xi - \cos\eta}, \qquad \begin{array}{c} -\infty < \xi < \infty, \\ 0 \le \eta \le \pi, \end{array} \tag{26}$$

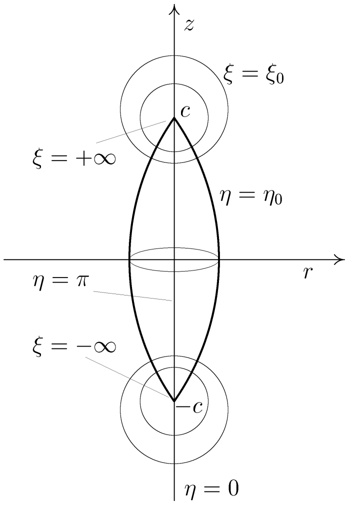

FIG. 1. *The bispherical coordinates and spindle-shaped body.*

where c is a metric parameter of the bispherical coordinates.

The spindle-shaped body is the body of revolution whose surface S is formed by rotating a circle arc around the z-axis[2] and can be described in the bispherical coordinates by fixing the coordinate η, i.e., $\eta = \eta_0$ (see Figure 1). For $\eta_0 = \frac{\pi}{2}$, the surface of the body forms a sphere, and for $\eta_0 < \frac{\pi}{2}$ and $\eta_0 > \frac{\pi}{2}$, the body's shape resembles an "apple" and "lemon," respectively.

For the boundary conditions (5) and (6), the velocity field $\mathbf{u}$ can be represented by (8), where the functions $\varTheta$, $\varUpsilon$, $\varPhi$, and $\varPsi$ satisfy (9) and (10). For convenience, we denote

$$(27)\qquad f_1 = \left(u_r^{(1)} - u_\varphi^{(1)}\right)\Big|_{\eta=\eta_0}, \qquad f_2 = \left(u_r^{(1)} + u_\varphi^{(1)}\right)\Big|_{\eta=\eta_0}, \qquad f_3 = u_z^{(1)}\Big|_{\eta=\eta_0},$$

and reformulate (5) and (6) for $\varTheta$, $\varUpsilon$, $\varPhi$, and $\varPsi$ in a general form:

$$(28)\quad \left(\tfrac{1}{2}\, r\, \varTheta + \varUpsilon\right)\big|_{\eta=\eta_0} = f_1, \quad \left(\tfrac{1}{2}\, r\, \varTheta + \varPhi\right)\big|_{\eta=\eta_0} = f_2, \quad \left(\tfrac{1}{2}\, z\, \varTheta + \varPsi\right)\big|_{\eta=\eta_0} = f_3.$$

For the domain exterior to the spindle-shaped body, i.e., for $\eta \in [0, \eta_0]$, the functions $\varTheta$, $\varUpsilon$, $\varPhi$, and $\varPsi$ can be represented in the bispherical coordinates by Fourier integrals with respect to ξ:

$$(29)\qquad \varTheta(\xi,\eta) = \frac{1}{2\pi i}\sqrt{\cosh\xi - \cos\eta}\int_{-i\infty}^{+i\infty} A(s)\, \mathrm{P}^{(1)}_{-\frac{1}{2}+s}(\cos\eta)\, \mathrm{e}^{-\xi s} ds, \quad \eta \le \eta_0,$$

$$(30)\qquad \varUpsilon(\xi,\eta) = \frac{1}{2\pi i}\sqrt{\cosh\xi - \cos\eta}\int_{-i\infty}^{+i\infty} B(s)\, \mathrm{P}_{-\frac{1}{2}+s}(\cos\eta)\, \mathrm{e}^{-\xi s} ds, \quad \eta \le \eta_0,$$

$$(31)\qquad \varPhi(\xi,\eta) = \frac{1}{2\pi i}\sqrt{\cosh\xi - \cos\eta}\int_{-i\infty}^{+i\infty} C(s)\, \mathrm{P}^{(2)}_{-\frac{1}{2}+s}(\cos\eta)\, \mathrm{e}^{-\xi s} ds, \quad \eta \le \eta_0,$$

[2] The z-axis is the axis of revolution of the spindle-shaped body.

$$\mathit{\Psi}(\xi,\eta)=\frac{1}{2\pi i}\sqrt{\cosh\xi-\cos\eta}\int_{-i\infty}^{+i\infty}D(s)\,\mathrm{P}^{(1)}_{-\frac{1}{2}+s}(\cos\eta)\,\mathrm{e}^{-\xi s}ds,\quad \eta\le\eta_0, \tag{32}$$

where $\mathrm{P}^{(k)}_{-\frac{1}{2}+s}(\cos\eta)$ is the associated Legendre function of the first kind of complex index s and rank k, behaving as $\frac{|\operatorname{Im}s|^k}{\sqrt{2\pi\sin\eta}}\,\mathrm{e}^{\eta|\operatorname{Im}s|}$ at $\operatorname{Re}s=0$ and $|\operatorname{Im}s|\to\infty$; see [1]. For $k=0$, the superscript is omitted.

We assume $A(s)$, $B(s)$, $C(s)$, and $D(s)$ in the corresponding Fourier integrals (29)–(32) to be meromorphic functions in the strip $|\operatorname{Re}s|\le 1$, vanishing as $\mathcal{O}(\mathrm{e}^{-\gamma|\operatorname{Im}s|})$ at $\operatorname{Re}s=0$ and $|\operatorname{Im}s|\to\infty$, where $\gamma>\eta_0$.

Substituting (29)–(32) into (10), where the derivatives of the functions $\mathit{\Theta}$, $\mathit{\Upsilon}$, $\mathit{\Phi}$, and $\mathit{\Psi}$ in (10) are derived similarly to formulas (2.1) and (2.2) in [22], we obtain

$$\begin{aligned} &c\left(\left(s+\tfrac{3}{2}\right)A(s+1)+5A(s)-\left(s-\tfrac{3}{2}\right)A(s-1)\right)+B(s+1)-2B(s)+B(s-1)\\ &\quad-\left(\left(s+\tfrac{5}{2}\right)\left(s+\tfrac{3}{2}\right)C(s+1)-2\left(s^2-\tfrac{9}{4}\right)C(s)+\left(s-\tfrac{5}{2}\right)\left(s-\tfrac{3}{2}\right)C(s-1)\right)\\ &\quad+2\left(\left(s+\tfrac{3}{2}\right)D(s+1)-2s\,D(s)+\left(s-\tfrac{3}{2}\right)D(s-1)\right)=0, \end{aligned} \tag{33}$$

under the condition that

$$\begin{aligned} &\operatorname*{Res}_{0\le\operatorname{Re}s\le1}\left\{\left(\left(s+\tfrac{1}{2}\right)\left(c\,A(s)-\left(s+\tfrac{3}{2}\right)C(s)+2D(s)\right)+B(s)\right)\mathrm{P}^{(1)}_{-\frac{3}{2}+s}(\cos\eta)\right\}=0,\\ &\operatorname*{Res}_{-1\le\operatorname{Re}s\le0}\left\{\left(\left(s-\tfrac{1}{2}\right)\left(c\,A(s)+\left(s-\tfrac{3}{2}\right)C(s)-2D(s)\right)-B(s)\right)\mathrm{P}^{(1)}_{\frac{1}{2}+s}(\cos\eta)\right\}=0, \end{aligned} \tag{34}$$

which follow from the assumption that $A(s)$, $B(s)$, $C(s)$, and $D(s)$ may admit poles in $|\operatorname{Re}s|\le1$.

Let $\mathcal{A}_{[-1,1]}$ define the class of functions *analytic* in the strip $|\operatorname{Re}s|\le1$, i.e., with no poles in $|\operatorname{Re}s|\le1$, and vanishing within the strip at $|s|\to\infty$. Also, to simplify further notation, let

$$\alpha_k(s)=\mathrm{P}^{(k)}_{-\frac{1}{2}+s}(\cos\eta_0),\qquad \beta_k(s)=\mathrm{P}^{(k)}_{-\frac{3}{2}+s}(\cos\eta_0),\qquad \gamma_k(s)=\mathrm{P}^{(k)}_{\frac{1}{2}+s}(\cos\eta_0). \tag{35}$$

We introduce a new function $X(s)$ related to $\mathit{\Theta}(\xi,\eta_0)$ by the complex Fourier transform:

$$X(s)=\frac{1}{2}\int_{-\infty}^{\infty}\frac{\mathit{\Theta}(\xi,\eta_0)\,\mathrm{e}^{\xi s}}{(\cosh\xi-\cos\eta_0)^{\frac{3}{2}}}\,d\xi,\qquad s\in\mathbb{C}, \tag{36}$$

$$\mathit{\Theta}(\xi,\eta_0)=\frac{1}{\pi i}\,(\cosh\xi-\cos\eta_0)^{\frac{3}{2}}\int_{-i\infty}^{+i\infty}X(s)\,\mathrm{e}^{-\xi s}ds. \tag{37}$$

The critical condition for the rest of the analysis is to consider that $X(s)\in\mathcal{A}_{[-1,1]}$. As will be shown in the end of this section, this condition holds true for the spindle-shaped body with $\eta_0<2.103$.

Since $\mathit{\Theta}(\xi,\eta_0)$ is the boundary value for the function $\mathit{\Theta}(\xi,\eta)$, we obtain from (29) that

$$A(s)=\frac{1}{\alpha_1(s)}\int_{-\infty}^{\infty}\frac{\mathit{\Theta}(\xi,\eta_0)\,\mathrm{e}^{\xi s}\,d\xi}{\sqrt{\cosh\xi-\cos\eta_0}}=\frac{1}{\alpha_1(s)}\left(X(s+1)-2X(s)\cos\eta_0+X(s-1)\right). \tag{38}$$

Similarly, from the boundary conditions (28) and representations (30), (31), and (32), we can express the functions $B(s)$, $C(s)$, and $D(s)$ via $X(s)$:

$$\begin{aligned} B(s) &= \frac{1}{\alpha_0(s)}\left(F_1(s) - c\,X(s)\sin\eta_0\right), \\ C(s) &= \frac{1}{\alpha_2(s)}\left(F_2(s) - c\,X(s)\sin\eta_0\right), \\ D(s) &= \frac{1}{\alpha_1(s)}\left(F_3(s) - \tfrac{c}{2}\left(X(s+1) - X(s-1)\right)\right), \end{aligned} \tag{39}$$

where

$$F_j(s) = \int_{-\infty}^{\infty} \frac{f_j(\xi)\,\mathrm{e}^{\xi s}}{\sqrt{\cosh\xi - \cos\eta_0}}\,d\xi, \qquad j = 1, 2, 3. \tag{40}$$

With (38) and (39), equation (33) reduces to a so-called three-contour equation for the function $X(s)$:

$$\begin{aligned} &\left(\sin\eta_0\left(\frac{\left(s+\frac52\right)\left(s+\frac32\right)}{\gamma_2(s)} - \frac{1}{\gamma_0(s)}\right) - \frac{2\left(s+\frac32\right)\cos\eta_0}{\gamma_1(s)} + \frac{2\left(s+\frac52\right)}{\alpha_1(s)}\right)X(s+1) \\ &+ 2\left(\sin\eta_0\left(\frac{1}{\alpha_0(s)} - \frac{\left(s^2-\frac94\right)}{\alpha_2(s)}\right) - \frac{5\cos\eta_0}{\alpha_1(s)} + \frac{\left(s+\frac32\right)}{\gamma_1(s)} - \frac{\left(s-\frac32\right)}{\beta_1(s)}\right)X(s) \\ &+ \left(\sin\eta_0\left(\frac{\left(s-\frac52\right)\left(s-\frac32\right)}{\beta_2(s)} - \frac{1}{\beta_0(s)}\right) + \frac{2\left(s-\frac32\right)\cos\eta_0}{\beta_1(s)} - \frac{2\left(s-\frac52\right)}{\alpha_1(s)}\right)X(s-1) \\ &+ R_1(s+1) + R_2(s) + R(s-1) = 0, \end{aligned} \tag{41}$$

where

$$\begin{aligned} R_1(s) &= \frac{1}{c}\left(\frac{F_1(s)}{\alpha_0(s)} - \frac{\left(s+\frac12\right)\left(s+\frac32\right)F_2(s)}{\alpha_2(s)} + \frac{2\left(s+\frac12\right)F_3(s)}{\alpha_1(s)}\right), \\ R_2(s) &= -\frac{2}{c}\left(\frac{F_1(s)}{\alpha_0(s)} - \frac{\left(s^2-\frac94\right)F_2(s)}{\alpha_2(s)} + \frac{2sF_3(s)}{\alpha_1(s)}\right), \\ R_3(s) &= \frac{1}{c}\left(\frac{F_1(s)}{\alpha_0(s)} - \frac{\left(s-\frac12\right)\left(s-\frac32\right)F_2(s)}{\alpha_2(s)} + \frac{2\left(s-\frac12\right)F_3(s)}{\alpha_1(s)}\right). \end{aligned} \tag{42}$$

The crucial point in the analysis of (41) is to notice that the coefficients at $X(s+1)$ and $X(s-1)$ can be represented as $\widetilde{\mathfrak{D}}(s+1)/\alpha_1(s)$ and $\widetilde{\mathfrak{D}}(s-1)/\alpha_1(s)$, respectively,[3] where the function $\widetilde{\mathfrak{D}}(s)$ is defined by

$$\widetilde{\mathfrak{D}}(s) = \frac{\mathfrak{D}(s)}{\alpha_0(s)\alpha_1(s)\alpha_2(s)} \tag{43}$$

with

$$\begin{aligned} \mathfrak{D}(s) = {}& 2\alpha_1^3(s)\cos^2\eta_0 + \left(s^2-\tfrac14\right)^2\alpha_0^3(s)\sin[2\eta_0] + 2\left(s^2-\tfrac14\right)\alpha_0^2(s)\alpha_1(s)\cos[2\eta_0] \\ &+ 2\left(\left(s^2-\tfrac54\right)\sin^2\eta_0 - 2\right)\alpha_0(s)\alpha_1^2(s)\cot\eta_0. \end{aligned} \tag{44}$$

[3] Noticing this, in fact, requires a great deal of manipulation.

In terms of $\widetilde{\mathfrak{D}}(s)$, the condition (34) is reformulated as

$$\begin{aligned}
&\operatorname*{Res}_{0\le \operatorname{Re} s\le 1}\left\{\left(\frac{2\left(s+\frac{1}{2}\right)X(s-1)}{\alpha_1(s)}+\frac{\left(\widetilde{\mathfrak{D}}(s)-2\left(s+\frac{3}{2}\right)\right)X(s)}{\beta_1(s)}+R_1(s)\right)\right.\\
&\qquad\qquad\qquad\qquad\qquad\left.\times\,\mathrm{P}^{(1)}_{-\frac{3}{2}+s}(\cos\eta)\right\}=0,\\
&\operatorname*{Res}_{-1\le \operatorname{Re} s\le 0}\left\{\left(-\frac{2\left(s-\frac{1}{2}\right)X(s+1)}{\alpha_1(s)}+\frac{\left(\widetilde{\mathfrak{D}}(s)+2\left(s-\frac{3}{2}\right)\right)X(s)}{\gamma_1(s)}+R_3(s)\right)\right.\\
&\qquad\qquad\qquad\qquad\qquad\left.\times\,\mathrm{P}^{(1)}_{\frac{1}{2}+s}(\cos\eta)\right\}=0,
\end{aligned}\tag{45}$$

and the three-contour equation (41) takes the form

$$\widetilde{\mathfrak{D}}(s+1)X(s+1)+\frac{2K(s)\,X(s)}{\alpha_0(s)\alpha_2(s)\beta_1(s)\gamma_1(s)}+\widetilde{\mathfrak{D}}(s-1)X(s-1)=\mathcal{F}(s),\quad \operatorname{Re} s=0,\tag{46}$$

where

$$\begin{aligned}
K(s)=\ &(\beta_1(s)+\gamma_1(s))\left(3\alpha_0(s)\alpha_1(s)\alpha_2(s)-\tfrac{1}{2}\,\mathfrak{D}(s)\right)\\
&+3\alpha_0(s)\beta_1(s)\gamma_1(s)\left(\alpha_1(s)\sin\eta_0-2\alpha_2(s)\cos\eta_0\right)
\end{aligned}$$

and

$$\mathcal{F}(s)=-\alpha_1(s)\left(R_1(s+1)+R_2(s)+R_3(s-1)\right).\tag{47}$$

Now we analyze the condition (45) provided that $X(s)$ is analytic in the strip $|\operatorname{Re} s|\le 1$. Note that (45) holds true if each term in the left-hand sides of equations (45) is analytic in the corresponding strip ($0\le \operatorname{Re} s\le 1$ or $-1\le \operatorname{Re} s\le 0$). However, the converse statement is not correct.

1. We begin with the first terms in the left-hand sides of (45).
   (i) The analyticity of $X(s)$ in $|\operatorname{Re} s|\le 1$ implies that the functions $X(s-1)$ and $X(s+1)$ are analytic in $0\le \operatorname{Re} s\le 1$ and $-1\le \operatorname{Re} s\le 0$, respectively.
   (ii) The function $\alpha_1(s)=\mathrm{P}^{(1)}_{-\frac{1}{2}+s}(\cos\eta_0)$ (as well as $\alpha_2(s)=\mathrm{P}^{(2)}_{-\frac{1}{2}+s}(\cos\eta_0)$) has only "generic"[4] zeros $s=\pm\frac{1}{2}$ in $|\operatorname{Re} s|\le 1$ for all $\eta_0\in(0,\pi)$, which are, however, compensated by zeros $s=\pm\frac{1}{2}$ of the multipliers $\mathrm{P}^{(1)}_{-\frac{3}{2}+s}(\cos\eta)$ and $\mathrm{P}^{(1)}_{\frac{1}{2}+s}(\cos\eta)$ in the strips $0\le \operatorname{Re} s\le 1$ and $-1\le \operatorname{Re} s\le 0$, respectively.
2. We proceed to the second terms in the left-hand sides of (45).
   (i) By the same reasoning as in item 1(ii), we conclude that

$$\mathrm{P}^{(1)}_{-\frac{3}{2}+s}(\cos\eta)\Big/\beta_1(s)\quad\text{and}\quad \mathrm{P}^{(1)}_{\frac{1}{2}+s}(\cos\eta)\Big/\gamma_1(s)$$

[4] Zeros $s=\pm\frac{1}{2}$, which $\alpha_1(s)$, $\alpha_2(s)$, and $\mathfrak{D}(s)$ have for all $\eta_0\in(0,\pi)$, are referred to as "generic," in contrast to "individual" zeros, which depend on η_0.

have no poles for all $\eta_0 \in (0, \pi)$ in $0 \le \operatorname{Re} s \le 1$ and $-1 \le \operatorname{Re} s \le 0$, respectively.
(ii) According to (43) and (44), poles of $\widetilde{\mathfrak{D}}(s)$ are determined by zeros of the product $\alpha_0(s)\,\alpha_1(s)\,\alpha_2(s)$. However, the only zeros $s = \pm\frac{1}{2}$ of $\alpha_1(s)$ and $\alpha_2(s)$ in $|\operatorname{Re} s| \le 1$ (see item 1(ii)) are compensated by zeros $s = \pm\frac{1}{2}$ of multiplicity 2 of $\mathfrak{D}(s)$. Consequently, since the function $\alpha_0(s) = \mathrm{P}_{-\frac{1}{2}+s}(\cos\eta_0)$ has zeros in $|\operatorname{Re} s| \le 1$ for $\eta_0 \ge 2.281$ only, $\widetilde{\mathfrak{D}}(s)$ has no poles in $|\operatorname{Re} s| \le 1$ for $\eta_0 < 2.281$.

3. At last, the functions $R_1(s)$ and $R_3(s)$ in (45) may admit only simple poles $s = \pm\frac{1}{2}$ in $0 \le \operatorname{Re} s \le 1$ and $-1 \le \operatorname{Re} s \le 0$, respectively (because of the corresponding multipliers $\mathrm{P}^{(1)}_{-\frac{3}{2}+s}(\cos\eta)$ and $\mathrm{P}^{(1)}_{\frac{1}{2}+s}(\cos\eta)$). This condition will be verified in sections 4 and 5 for the problems of asymmetric translation and rotation, respectively.

Concluding the analysis of (45), we assume that $\eta_0 < 2.281$ and require the functions $R_1(s)$ and $R_3(s)$ to admit simple poles $s = \pm\frac{1}{2}$ in $|\operatorname{Re} s| \le 1$ only. Consequently, these conditions along with the analyticity of $X(s)$ in $|\operatorname{Re} s| \le 1$ are sufficient for (45) to hold true (however, they may not be necessary).

Finally, introducing a new function

$$\widetilde{X}(s) = \widetilde{\mathfrak{D}}(s) X(s) \tag{48}$$

and denoting

$$\widetilde{K}(s) = \frac{\alpha_1(s)}{\beta_1(s)\gamma_1(s)}\,\frac{K(s)}{\mathfrak{D}(s)}, \tag{49}$$

we obtain

$$\widetilde{X}(s+1) + 2\widetilde{K}(s)\widetilde{X}(s) + \widetilde{X}(s-1) = \mathcal{F}(s), \qquad \operatorname{Re} s = 0. \tag{50}$$

To solve (50), we first need to determine a class of functions for $\widetilde{X}(s)$. The condition $\eta_0 < 2.281$ guarantees that $\widetilde{\mathfrak{D}}(s)$ is analytic in $|\operatorname{Re} s| \le 1$ (see item 2(ii) in the analysis of (45)), and consequently, the analyticity of $\widetilde{\mathfrak{D}}(s)$ and $X(s)$ in $|\operatorname{Re} s| \le 1$ implies that $\widetilde{X}(s)$, defined by (48), is analytic in $|\operatorname{Re} s| \le 1$. Moreover, from (43) and the asymptotic behavior of $\alpha_k(s)$ for $k = 0$, 1 and 2, it follows that $\widetilde{\mathfrak{D}}(s) \to 2\sin^2\eta_0$ at $\operatorname{Re} s = 0$ and $|\operatorname{Im} s| \to \infty$, which, along with $X(s) \to 0$ at $\operatorname{Re} s = 0$ and $|\operatorname{Im} s| \to \infty$, results in having $\widetilde{X}(s) \to 0$ at $\operatorname{Re} s = 0$ and $|\operatorname{Im} s| \to \infty$. Thus, we conclude that

$$X(s) \in \mathcal{A}_{[-1,1]} \quad \text{and} \quad \eta_0 < 2.281 \quad \Longrightarrow \quad \widetilde{X}(s) \in \mathcal{A}_{[-1,1]}.$$

We will seek to find a solution to the three-contour equation (50) in the class $\mathcal{A}_{[-1,1]}$. Although obtaining a closed-form solution to (50) is still an open issue, (50) can be reduced to a Fredholm integral equation of the second kind for the function

$$H(s) = \widetilde{X}(s+1) + \widetilde{X}(s-1). \tag{51}$$

Provided that $\widetilde{X}(s) \in \mathcal{A}_{[-1,1]}$, we apply the complex Fourier transform to (51) and obtain

$$\int_{-i\infty}^{+i\infty} H(\tau)\,\mathrm{e}^{\tau\, t}\,d\tau = 2\cosh t \int_{-i\infty}^{+i\infty} \widetilde{X}(\tau)\,\mathrm{e}^{\tau\, t}\,d\tau,$$

whence $\widetilde{X}(s)$ is expressed via $H(s)$ by the inverse Fourier transform:

$$\widetilde{X}(s) = \frac{1}{4\pi i}\int_{-i\infty}^{+i\infty}\left(\int_{-\infty}^{\infty}\frac{\mathrm{e}^{(\tau-s)\,t}}{\cosh t}\,dt\right)H(\tau)\,d\tau = \frac{1}{4i}\int_{-i\infty}^{+i\infty}\frac{H(\tau)\,d\tau}{\cos\left[\frac{\pi}{2}(\tau-s)\right]}. \tag{52}$$

To show that $\widetilde{X}$, determined by (52), is unique, we need to prove that (51), as an equation with respect to $\widetilde{X}$, has only zero homogeneous solution in the class of functions analytic in the strip $|\operatorname{Re} s| \le 1$ and vanishing within the strip at $|s| \to \infty$.

PROPOSITION 5. *The equation $\widetilde{X}(s+1) + \widetilde{X}(s-1) = 0$ has only zero solution in the class $\mathcal{A}_{[-1,1]}$.*

Proof. This equation reduces to a Riemann boundary-value problem for an analytic function by the conformal mapping $w = -i\cot[\pi s/2]$ of the strip $|\operatorname{Re} s| \le 1$ into the complex plane w with the branch cut along the segment $[-1,1]$; see Figure 2. The lines $s = -1 + i\tau$ and $s = 1 + i\tau$, $\tau \in \mathbb{R}$, correspond to the upper and lower banks of the branch cut with the counterclockwise orientation as shown in Figure 2, and infinite points of the strip $|\operatorname{Re} s| \le 1$, i.e., $|s| \to \infty$, correspond to the points $w = \pm 1$.

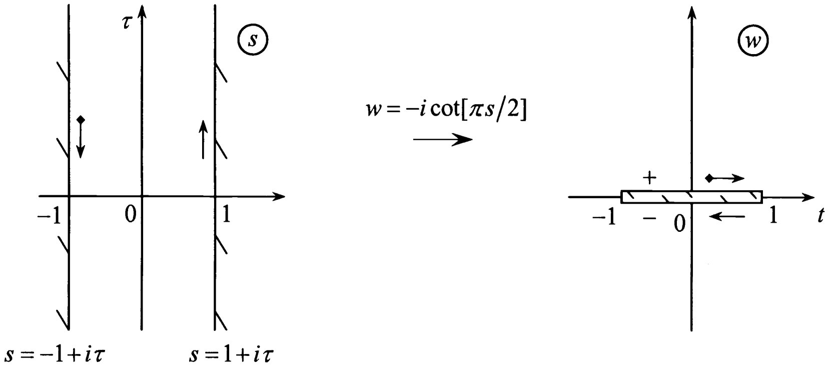

FIG. 2. *The function $w = -i\cot[\pi s/2]$ maps the strip $-1 \le \operatorname{Re} s \le 1$ of the complex plane s into the complex plane w with the branch cut along the segment* $[-1,1]$.

Let $Y(w) = \widetilde{X}(s)$; then $Y^{+}(t) = \widetilde{X}(-1+i\tau)$ and $Y^{-}(t) = \widetilde{X}(1+i\tau)$, $\tau \in \mathbb{R}$, are the boundary values of $Y(w)$ at the upper and lower banks of the branch cut, respectively. Thus, the original equation reduces to $Y^{+}(t) = -Y^{-}(t)$, $t \in [-1,1]$, which is the Riemann boundary-value problem for determining the analytic function $Y(w)$ in the complex plane w with the branch cut along the segment $[-1,1]$. An analytic function that solves this problem and vanishes at $w = \pm 1$ is given by $Y(w) = \sqrt{1-w^2}\,\mathcal{P}_n(w)$, where $\mathcal{P}_n(w)$ is a polynomial of degree n to be determined from the behavior of $Y(w)$ at $|w| \to \infty$; see [5]. But since $\widetilde{X}(s)$ is analytic at $s = 0$, the function $Y(w)$ is bounded at $|w| \to \infty$, and, consequently, $\mathcal{P}_n(w) \equiv 0$, and $Y(w)$ is the zero function. □

Thus, with (51) and (52), the three-contour equation (50) reduces to a Fredholm integral equation of the second kind for $H(s)$:

$$H(s) + \frac{\widetilde{K}(s)}{2i}\int_{-i\infty}^{+i\infty}\frac{H(\tau)\,d\tau}{\cos\left[\frac{\pi}{2}(\tau-s)\right]} = \mathcal{F}(s), \qquad \operatorname{Re} s = 0. \tag{53}$$

The analytic function $\widetilde{X}(s)$ is determined in $|\operatorname{Re} s| \le 1$ by (52), and its value at

TABLE 1
First "individual" zero of $\mathfrak{D}(s)$ for various η_0.

η_0	s_0	η_0	s_0
$\pi/12$	20.33	$7\pi/12$	1.197
$2\pi/12$	10.19	$8\pi/12$	1.005
$3\pi/12$	6.817	2.103[†]	1.000
$4\pi/12$	5.142	$9\pi/12$	0.873
$5\pi/12$	2.153	$10\pi/12$	0.777
$6\pi/12$	1.5	$11\pi/12$	0.696

[†] For $\eta_0 \geq 2.103$, the first "individual" zero lies within the strip $|\operatorname{Re} s| \leq 1$.

the contour $\operatorname{Re} s = 0$ is expressed from (53) by

$$\widetilde{X}(s) = \frac{\mathcal{F}(s) - H(s)}{2\widetilde{K}(s)}, \qquad \operatorname{Re} s = 0. \tag{54}$$

Finally, it follows from (48), along with (54) and (49), that

$$X(s) = \frac{\beta_1(s)\gamma_1(s)}{\alpha_1(s)} \frac{(\mathcal{F}(s) - H(s))}{2K(s)}, \qquad \operatorname{Re} s = 0. \tag{55}$$

Substituting (55) into the inverse Fourier transform (37), we obtain $\Theta(\xi, \eta_0)$.

Now, based on the obtained solution $\widetilde{X}(s)$, we can establish when $X(s)$ is analytic in $|\operatorname{Re} s| \leq 1$. The analyticity of the ratio $X(s) = \widetilde{X}(s)/\widetilde{\mathfrak{D}}(s)$ is guaranteed by the analyticity of $\widetilde{X}(s)$ and $1/\widetilde{\mathfrak{D}}(s)$. Since both $\mathfrak{D}(s)$ and the multiplier $\alpha_1(s)\,\alpha_2(s)$ in the denominator of $\widetilde{\mathfrak{D}}(s)$ have "generic" zeros $s = \pm\frac{1}{2}$ of multiplicity 2 that compensate each other, poles of $1/\widetilde{\mathfrak{D}}(s)$ are determined only by "individual" zeros of $\mathfrak{D}(s)$. Table 1 presents the first "individual" zero of $\mathfrak{D}(s)$ for various η_0 ($\mathfrak{D}(s)$ is an even function) and shows that $\mathfrak{D}(s)$ has no "individual" zero in the strip $|\operatorname{Re} s| \leq 1$ for $\eta_0 < 2.103$. Consequently, we conclude that

$$\widetilde{X}(s) \in \mathcal{A}_{[-1,1]} \quad \text{and} \quad \eta_0 < 2.103 \quad \Longrightarrow \quad X(s) \in \mathcal{A}_{[-1,1]}.$$

This means that the formula (55) is valid only for $\eta_0 < 2.103$.

In the next sections, we will solve (53) for the asymmetric translation of the spindle-shaped body along the x-axis and for the asymmetric rotation of the body around the y-axis.

4. Asymmetric translation. In the case of the asymmetric translation of the rigid spindle-shaped body in the fluid along the x-axis, the velocity field satisfies the boundary conditions (2) and (5) and is represented in the form (8).

From (5) and (27), we have

$$f_1 = 2v_x, \qquad f_2 = 0, \qquad f_3 = 0.$$

To calculate Fourier integrals (40), we use the representation for the associated Legendre function

$$\mathrm{P}^{(k)}_{-\frac{1}{2}+s}(\cos\eta) = \frac{(2k-1)!!}{2^k\sqrt{2}\,\pi}\cos[\pi s]\int_{-\infty}^{\infty} \frac{\left(\sin^k \eta\right) \mathrm{e}^{\tau s}\, d\tau}{(\cosh\tau + \cos\eta)^{k+\frac{1}{2}}}, \tag{56}$$

where $k \geq 0$ and $(2k-1)!! = \prod_{j=1}^{k}(2j-1)$; see [1]. For $k=0$, we define $(-1)!! = 1$. To simplify further notation, we denote

$$\alpha_0^-(s) = \mathrm{P}_{-\frac{1}{2}+s}(-\cos\eta_0), \qquad \alpha_1^-(s) = \mathrm{P}^{(1)}_{-\frac{1}{2}+s}(-\cos\eta_0).$$

Using (56), we have

$$F_1(s) = v_x\,\frac{2\sqrt{2}\,\pi}{\cos[\pi s]}\,\alpha_1^-(s), \qquad F_2(s) = 0, \qquad F_3(s) = 0,$$

and, consequently, it follows from (42) that

$$R_1(s) = R_3(s) = \frac{v_x}{c}\,\frac{2\sqrt{2}\,\pi}{\cos[\pi s]}\,\frac{\alpha_1^-(s)}{\alpha_0(s)}.$$

For $\eta_0 < 2.103$, the functions $R_1(s)$ and $R_3(s)$ are analytic in $|\operatorname{Re} s| \leq 1$ (zeros $s = \pm\frac{1}{2}$ of $\cos[\pi s]$ are compensated by those of $\alpha_1^-(s)$), and, thus, condition (45) holds true.

Then, with the convolution relationship (see [1])

$$\alpha_0^-(s)\,\alpha_1(s) + \alpha_0(s)\,\alpha_1^-(s) = \frac{2}{\pi}\,\frac{\cos[\pi s]}{\sin\eta_0}, \tag{57}$$

we obtain from (42) and (47) that

$$\mathcal{F}(s) = -\frac{v_x}{c}\,4\sqrt{2}\,\frac{\alpha_1(s)\,(2\alpha_1(s)\sin\eta_0 + \alpha_0(s)\cos\eta_0)}{\left(s^2 - \frac{1}{4}\right)\alpha_0(s)\beta_0(s)\gamma_0(s)}. \tag{58}$$

Thus, the Fredholm integral equation (53) is solved for (58), and the function $\Theta(\xi, \eta_0)$ is determined by (37) with (55).

In the case of a sphere, i.e., $\eta_0 = \frac{\pi}{2}$, equation (53) has the closed-form solution

$$H_{\text{sphere}}(s) = \frac{v_x}{c}\,\frac{6\sqrt{2}}{\mathrm{P}_{-\frac{1}{2}+s}(0)},$$

and, consequently, we obtain

$$X_{\text{sphere}}(s) = -\frac{v_x}{c}\,\frac{\sqrt{2}\left(s^2 - \frac{1}{4}\right)}{\mathrm{P}^{(1)}_{-\frac{1}{2}+s}(0)}, \qquad \Theta_{\text{sphere}}(\xi, \eta_0)\big|_{\eta_0 = \frac{\pi}{2}} = \frac{v_x}{c}\,\frac{3}{2\cosh\xi},$$

and

$$\begin{aligned}
\Theta_{\text{sphere}}(r, z) &= \frac{3}{2} v_x\, c\, \frac{r}{(r^2 + z^2)^{\frac{3}{2}}},\\
\Upsilon_{\text{sphere}}(r, z) &= \frac{3}{2} v_x\, c\, \frac{1}{\sqrt{r^2 + z^2}} + \frac{1}{4} v_x\, c^3\, \frac{2z^2 - r^2}{(r^2 + z^2)^{\frac{5}{2}}},\\
\Phi_{\text{sphere}}(r, z) &= -\frac{3}{4} v_x\, c^3\, \frac{r^2}{(r^2 + z^2)^{\frac{5}{2}}},\\
\Psi_{\text{sphere}}(r, z) &= -\frac{3}{4} v_x\, c^3\, \frac{r\,z}{(r^2 + z^2)^{\frac{5}{2}}}.
\end{aligned}$$

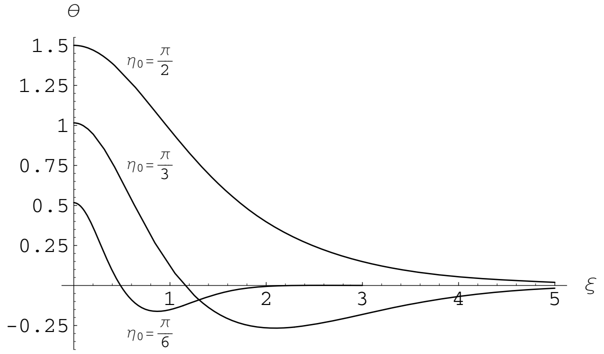

FIG. 3. *Asymmetric translation: the function* $\frac{c}{v_x}\,\Theta(\xi,\eta_0)$ *for* $\eta_0 = \frac{\pi}{6}$, $\frac{\pi}{3}$, *and* $\frac{\pi}{2}$ *("apples").*

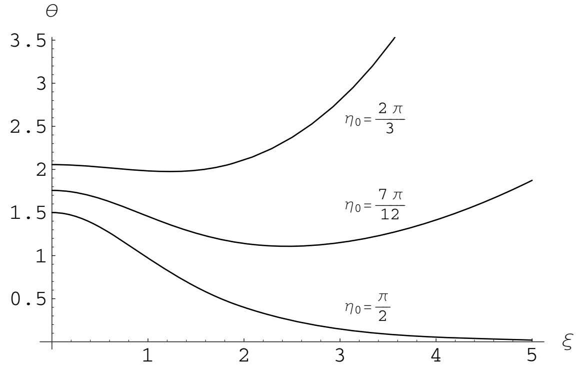

FIG. 4. *Asymmetric translation: the function* $\frac{c}{v_x}\,\Theta(\xi,\eta_0)$ *for* $\eta_0 = \frac{\pi}{2}$, $\frac{7\pi}{12}$, *and* $\frac{2\pi}{3}$ *("lemons").*

The pressure $\wp$ and function Θ are related by (7). Figures 3 and 4 illustrate $\frac{c}{v_x}\,\Theta(\xi,\eta_0)$ as a function of ξ for $\eta_0 = \frac{\pi}{6}, \frac{\pi}{3}, \frac{\pi}{2}, \frac{7\pi}{12}$, and $\frac{2\pi}{3}$. Figures 5 and 6 show epures of the normalized pressures, $\frac{c}{v_x\mu}\,\wp$ and $\frac{c}{2v_x\mu}\,\wp$, at the surface of the rigid spindle-shaped body in the xz–half-plane ($\varphi = 0$) for $\eta_0 = \frac{\pi}{3}$ ("apple") and $\eta_0 = \frac{7\pi}{12}$ ("lemon"), respectively.

In the case of the asymmetric translation along the x-axis, the resisting force is given by (14), which for the function $\Theta(\xi,\eta)$ in the form (29) with (38) reduces to

$$\begin{aligned} F_x &= -2\sqrt{2}\,i\mu c^2 \int_{-i\infty}^{+i\infty} \left(s^2 - \tfrac{1}{4}\right) A(s)\,ds \\ &= -2\sqrt{2}\,i\mu c^2 \int_{-i\infty}^{+i\infty} X(s)\left(\frac{\left(s-\frac{3}{2}\right)\left(s-\frac{1}{2}\right)}{\beta_1(s)} - 2\frac{\left(s^2-\frac{1}{4}\right)\cos\eta_0}{\alpha_1(s)} + \frac{\left(s+\frac{1}{2}\right)\left(s+\frac{3}{2}\right)}{\gamma_1(s)}\right)ds, \end{aligned}$$

where in obtaining the last integral, we used the condition that $X(s)$ has no poles within the strip $|\operatorname{Re} s| \le 1$. This means that the above formula for F_x is valid only for $\eta_0 < 2.103$.

In the case of the *axially symmetric* translation of the spindle-shaped body along the z-axis with the constant velocity v_z (see [15, 23]), the resisting force has the

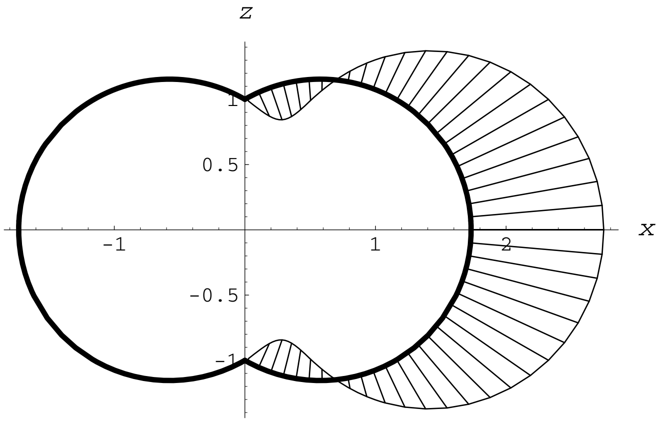

FIG. 5. *Asymmetric translation: epure of the normalized pressure* $\frac{c}{v_x \mu}\,\wp$ *at the surface of the rigid spindle-shaped body in the xz–half-plane* ($\varphi = 0$) *for* $\eta_0 = \frac{\pi}{3}$ *("apple"). At a particular point on the contour, the value of the function is depicted by the length of the outward normal line if the value is positive and by the length of the inward normal line if the value is negative.*

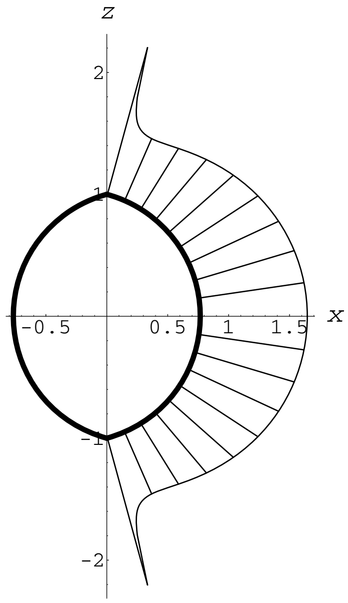

FIG. 6. *Asymmetric translation: epure of the normalized pressure* $\frac{c}{2v_x \mu}\,\wp$ *at the surface of the rigid spindle-shaped body in the xz–half-plane* ($\varphi = 0$) *for* $\eta_0 = \frac{7\pi}{12}$ *("lemon").*

component in the direction $\mathbf{k}$ only, i.e., F_z, which is determined by (see [23])

$$F_z = -4v_z\,\mu\,c\,i\int_{-i\infty}^{+i\infty}\left(\frac{\alpha_2(s)\sin\eta_0}{\mathfrak{D}_0(s)} + \frac{\pi\,\alpha_0^-(s)}{\cos[\pi s]}\right)\frac{ds}{\alpha_0(s)},$$

where $\mathfrak{D}_0(s)$ is the determinant of the axially symmetric translation problem:

$$\mathfrak{D}_0(s) = \left(1+\cos^2\eta_0\right)\alpha_0(s)\alpha_1(s) + \tfrac{1}{2}\,\sin[2\eta_0]\left(\alpha_1^2(s) + \left(s^2 - \tfrac{1}{4}\right)\alpha_0^2(s)\right).$$

Table 2
Normalized resisting forces, d_z and d_x, as functions of η_0.

$2\pi/12$	0.9405	0.8568	$8\pi/12$	1.100	1.213
$3\pi/12$	0.9475	0.8747	$9\pi/12$	1.209	–
$4\pi/12$	0.9585	0.9022	$10\pi/12$	1.430	–
$5\pi/12$	0.9751	0.9423	$11\pi/12$	2.067	–

†The case $\eta_0 = 0$ corresponds to a closed torus (torus with no opening).
‡The value is reported in [19], while 0.9353 and 0.953 are reported in [4] and [18], respectively.
§The value is reported in [11].

Table 2 compares the normalized resisting forces $d_z = \frac{\tan[\eta_0/2]}{6\pi\mu v_z c} F_z$ and $d_x = \frac{\tan[\eta_0/2]}{6\pi\mu v_x c} F_x$ for the spindle-shaped body for the axially symmetric and asymmetric translations, respectively, where $c\,\cot[\eta_0/2]$ determines the radius of the sphere inscribed into “lemon” (the body with $\eta_0 > \frac{\pi}{2}$) or circumscribed about “apple” (the body with $\eta_0 < \frac{\pi}{2}$).

5. Asymmetric rotation. In the case of the asymmetric rotation of the rigid spindle-shaped body in the fluid around the y-axis, the velocity field satisfies the boundary conditions (2) and (6) and is represented in the form (8).

From (6) and (27), we have

$$f_1 = \varpi_y c\,\frac{2\sinh\xi}{\cosh\xi - \cos\eta_0}, \qquad f_2 = 0, \qquad f_3 = -\varpi_y c\,\frac{\sin\eta_0}{\cosh\xi - \cos\eta_0},$$

and using (56), we calculate Fourier integrals (40):

$$F_1(s) = \varpi_y\, c\,\frac{4\sqrt{2}\,\pi\, s}{\cos[\pi s]}\,\alpha_0^-(s), \qquad F_2(s) = 0, \qquad F_3(s) = -\varpi_y\, c\,\frac{2\sqrt{2}\,\pi}{\cos[\pi s]}\,\alpha_1^-(s).$$

It follows from (42) that

$$R_1(s) = \varpi_y\,\frac{4\sqrt{2}\,\pi}{\cos[\pi s]}\left(\frac{s\,\alpha_0^-(s)}{\alpha_0(s)} - \frac{\left(s+\frac{1}{2}\right)\alpha_1^-(s)}{\alpha_1(s)}\right),$$
$$R_3(s) = \varpi_y\,\frac{4\sqrt{2}\,\pi}{\cos[\pi s]}\left(\frac{s\,\alpha_0^-(s)}{\alpha_0(s)} - \frac{\left(s-\frac{1}{2}\right)\alpha_1^-(s)}{\alpha_1(s)}\right).$$

For $\eta_0 < 2.103$, the above functions $R_1(s)$ and $R_3(s)$ admit only simple poles $s = \pm\frac{1}{2}$ in the strip $|\operatorname{Re} s| \le 1$, and consequently, the condition (45) holds true.

Then, with the convolution relationship (57), we obtain from (42) and (47) that

$$\mathcal{F}(s) = \varpi_y\, 8\sqrt{2}\, s\left(\frac{\alpha_1(s)\,(\alpha_0(s)\cos\eta_0 - 2\alpha_1(s)\sin\eta_0)}{\left(s^2-\frac{1}{4}\right)\alpha_0(s)\beta_0(s)\gamma_0(s)} - \frac{2\alpha_2(s)\sin\eta_0}{\beta_1(s)\gamma_1(s)}\right). \tag{59}$$

Thus, the Fredholm integral equation (53) is solved for (59), and the function $\mathit{\Theta}(\xi,\eta_0)$ is determined by (37) with (55).

In the case of a sphere, i.e., $\eta_0 = \frac{\pi}{2}$, expression (59) reduces to zero. Thus, $H_{\text{sphere}} \equiv 0$, $X_{\text{sphere}} \equiv 0$, and $\mathit{\Theta}_{\text{sphere}} \equiv 0$, and the functions $\mathit{\Upsilon}_{\text{sphere}}$, $\mathit{\Phi}_{\text{sphere}}$, and

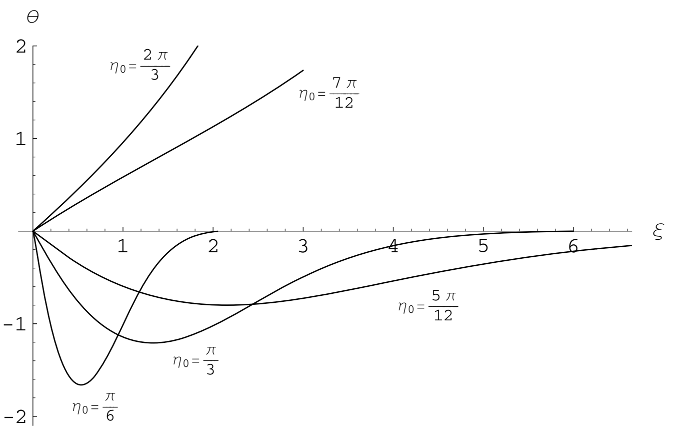

FIG. 7. *Asymmetric rotation: the function* $\frac{1}{\varpi_y}\,\Theta(\xi,\eta_0)$ *for* $\eta_0 = \frac{\pi}{6},\ \frac{\pi}{3},\ \frac{5\pi}{12},\ \frac{7\pi}{12}$*, and* $\frac{2\pi}{3}$.

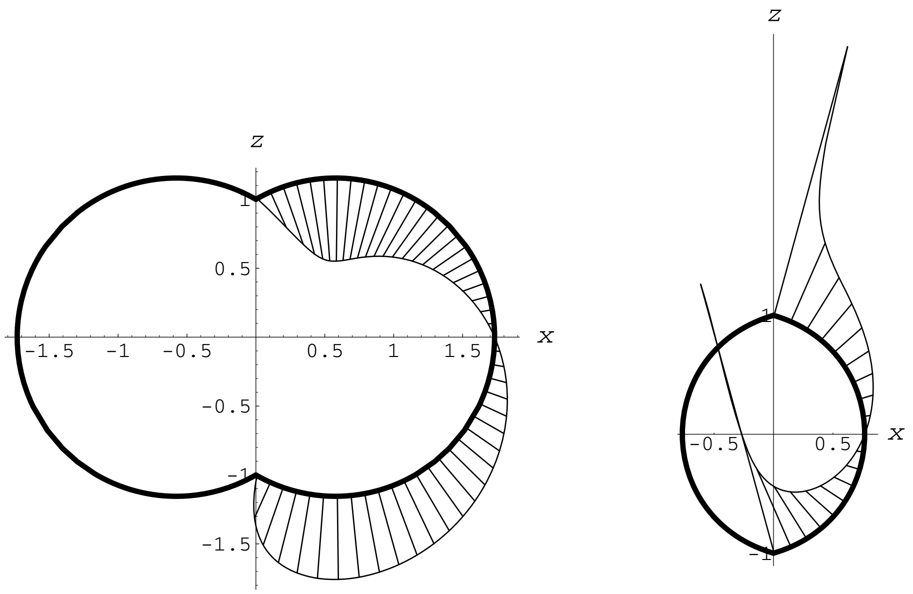

$\eta_0 = \pi/3$

$\eta_0 = 7\pi/12$

FIG. 8. *Asymmetric rotation: epures of the normalized pressure* $\frac{1}{2\varpi_y\mu}\,\wp$ *at the surface of the rigid spindle-shaped body in the xz–half-plane (*$\varphi = 0$*) for* $\eta_0 = \frac{\pi}{3}$ *("apple") and* $\eta_0 = \frac{7\pi}{12}$ *("lemon").*

Ψ_{sphere} take the form

$$\Upsilon_{\text{sphere}} = \varpi_y c^3 \frac{2z}{(r^2+z^2)^{\frac{3}{2}}}, \qquad \Phi_{\text{sphere}} \equiv 0, \qquad \Psi_{\text{sphere}} = -\varpi_y c^3 \frac{r}{(r^2+z^2)^{\frac{3}{2}}}.$$

As in the case of the asymmetric translation, the pressure $\wp$ and function Θ are related by (7). Figure 7 illustrates $\Theta(\xi,\eta_0)$ as a function of ξ for $\eta_0 = \frac{\pi}{6},\ \frac{\pi}{3},\ \frac{5\pi}{12},\ \frac{7\pi}{12}$, and $\frac{2\pi}{3}$. Figure 8 shows epures of the normalized pressure $\frac{1}{2\varpi_y\mu}\,\wp$ at the surface of the rigid spindle-shaped body in the xz–half-plane ($\varphi = 0$) for $\eta_0 = \frac{\pi}{3}$ (“apple”) and $\eta_0 = \frac{7\pi}{12}$ (“lemon”).

For the asymmetric rotation around the y-axis, the torque is represented by (23), which for the function Ψ in the form (32) with (39) reduces to

$$\begin{aligned} T_y &= 4\sqrt{2}\, i\, \mu\, c^2 \int_{-i\infty}^{+i\infty} \left(s^2 - \tfrac{1}{4}\right) D(s)\, ds \\ &= -16\pi\varpi_y \mu\, c^3\, i \int_{-i\infty}^{+i\infty} \frac{\left(s^2 - \frac{1}{4}\right)}{\cos[\pi s]} \frac{\alpha_1^-(s)}{\alpha_1(s)}\, ds \\ &\quad - 4\sqrt{2}\, i\, \mu\, c^3 \sin\eta_0 \int_{-i\infty}^{+i\infty} \frac{s\, \alpha_2(s)}{\beta_1(s)\gamma_1(s)}\, X(s)\, ds, \end{aligned}$$

where in obtaining the last integral, as in the case of deriving the expression for F_x, we used the condition that $X(s)$ has no poles within the strip $|\operatorname{Re} s| \le 1$. This means that the above formula for T_y is valid only for $\eta_0 < 2.103$.

In the case of the *axially symmetric* rotation of a body of revolution around the z-axis with the constant angular velocity ϖ_z, the no-slip boundary condition for the velocity field $\mathbf{u}$ is determined by $\mathbf{u}|_S = [\varpi_z\, \mathbf{k} \times r\, \mathbf{e}_r]$, which in component form reduces to

$$u_r|_S = 0, \qquad u_\varphi|_S = \varpi_z\, r, \qquad u_z|_S = 0.$$

The vector $\mathbf{u}$ that solves (1), (2), and the above boundary condition can be represented by

$$\mathbf{u} = \Omega(r, z)\, \mathbf{e}_\varphi,$$

where Ω satisfies $\Delta_1 \Omega = 0$ (see [8]). In this case, the resisting torque has the component in the direction $\mathbf{k}$ only, i.e., T_z, and similarly to the derivation of the formula (23) for T_y, it can be shown that

$$T_z = -8\pi\mu \lim_{r\to\infty} \left(r^2 \Omega(r, z)\big|_{z=0} \right),$$

which for the spindle-shaped body reduces to

$$T_z = -16\pi\varpi_z \mu\, c^3\, i \int_{-i\infty}^{+i\infty} \frac{\left(s^2 - \frac{1}{4}\right)}{\cos[\pi s]} \frac{\alpha_1^-(s)}{\alpha_1(s)}\, ds.$$

Table 3 shows the normalized torques $t_z = -\frac{\tan^3[\eta_0/2]}{8\pi\mu\varpi_z c^3}\, T_z$ and $t_y = -\frac{\tan^3[\eta_0/2]}{8\pi\mu\varpi_y c^3}\, T_y$ for the rigid spindle-shaped body for the axially symmetric and asymmetric rotations, respectively, where $c \cot[\eta_0/2]$ determines the radius of the sphere inscribed into “lemon” (the body with $\eta_0 > \frac{\pi}{2}$) or circumscribed about “apple” (the body with $\eta_0 < \frac{\pi}{2}$).

6. Conclusions. We have obtained exact solutions to the 3D Stokes flow problems for asymmetric translation and rotation of a rigid spindle-shaped body. Representing the velocity field in the form (3), we have reduced both problems to the three-contour equation (46) for the analytic function $X(s)$, related to the density in the Fourier integral representing the pressure. The equation has been obtained under the condition $\eta_0 < 2.103$ that guarantees the analyticity of $X(s)$ in the strip

TABLE 3
Normalized resisting torques, t_z and t_y, as functions of η_0.

[†] The case $\eta_0 = 0$ corresponds to a closed torus (torus with no opening).
[‡] The value is reported in [4].
[§] The value is reported in [11].

$|\operatorname{Re} s| \leq 1$. This condition follows from the fact that the function $\widetilde{\mathfrak{D}}(s)$ has zeros in $|\operatorname{Re} s| \leq 1$ for $\eta_0 \geq 2.103$. Then, we have reduced (46) to the three-contour equation (50) with the unit coefficients at $\widetilde{X}(s+1)$ and $\widetilde{X}(s-1)$ and finally have reduced the latter to the Fredholm integral equation (53) by the complex Fourier transform. In the case of a sphere, i.e., $\eta_0 = \frac{\pi}{2}$, the integral equation has a closed-form solution for the asymmetric translation and has a zero solution for the asymmetric rotation.

We have derived formulas for the resisting force, $\mathbf{F}$, and torque, $\mathbf{T}$, experienced by a rigid body of revolution in arbitrary slow motion in a viscous incompressible fluid, and have shown that for the asymmetric translation along the x-axis and asymmetric rotation around the y-axis, F_x and T_y can be expressed via the limits of the functions $\Theta(r,z)$ and $\Psi(r,z)$ at infinity. We have computed F_x and T_y for the corresponding asymmetric motions of the spindle-shaped body for various values of η_0 ($\eta_0 < 2.103$) and compared them with F_z and T_z for the axially symmetric translation and rotation of the body, respectively. In the case of "apple" ($\eta_0 < \frac{\pi}{2}$), $F_x < F_z$ and $T_y < T_z$, and in the case of "lemon" ($\eta_0 > \frac{\pi}{2}$), $F_x > F_z$ and $T_y > T_z$; see Tables 2 and 3. Also, F_x and T_y for the spindle-shaped body are in accordance with F_x and T_y for a closed torus.

For both problems of asymmetric motion, we have calculated the pressure at the surface of the spindle-shaped body in the xz–half-plane ($\varphi = 0$) for various values of η_0 ($\eta_0 < 2.103$). It follows from (37) that the function $\Theta(\xi, \eta_0)$, associated with the pressure, is infinite at $\xi \to \pm\infty$ when $X(s)$ has a pole (except $\frac{1}{2}$) with the real part less than $\frac{3}{2}$. Since the poles of $X(s)$ are determined by zeros of $\mathfrak{D}(s)$, we conclude based on Table 1 that in both problems, $\Theta(\xi, \eta_0) \to 0$ for "apples" ($\eta_0 < \frac{\pi}{2}$), and $|\Theta(\xi, \eta_0)| \to \infty$ for "lemons" ($\eta_0 > \frac{\pi}{2}$) when $\xi \to \pm\infty$. This conclusion is supported by numerical calculations; see Figures 3–8. Notably, in the case of *axially symmetric* translation, the pressure at the surface at $\xi \to \pm\infty$ is finite for $\eta_0 \leq \frac{2\pi}{3}$ and is infinite for $\eta_0 > \frac{2\pi}{3}$; see [23].

Obtaining exact solutions for the asymmetric Stokes flow problems for the rigid spindle-shaped body in the case $\eta_0 \geq 2.103$ as well as calculating the corresponding resisting force and torque is still an open issue.

Appendix A. Proof of Proposition 1.

This section proves Proposition 1.

Let (r, φ, z) be a system of cylindrical coordinates with the basis $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$, in which the z-axis determines the body's axis of revolution, and let $\mathfrak{n} = n_r\, \mathbf{e}_r + n_z\, \mathbf{k}$ define the outer normal to the body's surface S, where $n_r = \frac{\partial r}{\partial n}$ and $n_z = \frac{\partial z}{\partial n}$.

By definition, the force, exerted by the fluid on the elementary surface dS with the normal $\mathfrak{n}$, is given by

$$\mathbf{P}_n = 2\mu\,(\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u} + \mu\,[\mathfrak{n}\times\operatorname{curl}\mathbf{u}] - \wp\,\mathfrak{n} \tag{60}$$

(see [19]), and the total force is defined as the integral over the body's surface S:

$$\mathbf{F} = \iint_S \left(2\mu\,(\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u} + \mu\,[\mathfrak{n}\times\operatorname{curl}\mathbf{u}] - \wp\,\mathfrak{n}\right) dS. \tag{61}$$

Let (s,φ,n) be a characteristic coordinate system with the right-handed orthogonal basis $(\mathfrak{s},\mathbf{e}_\varphi,\mathfrak{n})$. Then, in (s,φ,n), the operators $\operatorname{grad}\wp$, $\operatorname{div}\mathbf{u}$, and $\operatorname{curl}\mathbf{u}$ take the form

$$\begin{aligned}
\operatorname{grad}\wp &= \mathfrak{s}\,\frac{\partial\wp}{\partial s} + \mathbf{e}_\varphi\,\frac{1}{r}\,\frac{\partial\wp}{\partial\varphi} + \mathfrak{n}\,\frac{\partial\wp}{\partial n},\\
\operatorname{div}\mathbf{u} &= \frac{1}{r}\,\frac{\partial}{\partial s}\,(r\,u_s) + \frac{1}{r}\,\frac{\partial}{\partial\varphi}\,u_\varphi + \frac{1}{r}\,\frac{\partial}{\partial n}\,(r\,u_n),\\
\operatorname{curl}\mathbf{u} &= \mathfrak{s}\left(\frac{1}{r}\,\frac{\partial}{\partial\varphi}\,u_n - \frac{1}{r}\,\frac{\partial}{\partial n}\,(r\,u_\varphi)\right) + \mathbf{e}_\varphi\left(\frac{\partial}{\partial n}\,u_s - \frac{\partial}{\partial s}\,u_n\right)\\
&\qquad + \mathfrak{n}\left(\frac{1}{r}\,\frac{\partial}{\partial s}\,(r\,u_\varphi) - \frac{1}{r}\,\frac{\partial}{\partial\varphi}\,u_s\right),
\end{aligned} \tag{62}$$

where (u_s,u_φ,u_n) are the components of $\mathbf{u}$ in $(\mathfrak{s},\mathbf{e}_\varphi,\mathfrak{n})$; see [7]. The derivatives $\frac{\partial}{\partial s}$, $\frac{\partial}{\partial\varphi}$, and $\frac{\partial}{\partial n}$ of the unit vectors $\mathfrak{s}$, $\mathbf{e}_\varphi$, and $\mathfrak{n}$ are given by

$$\begin{aligned}
&\tfrac{\partial}{\partial s}\,\mathfrak{s} = 0, && \tfrac{\partial}{\partial\varphi}\,\mathfrak{s} = \tfrac{\partial r}{\partial s}\,\mathbf{e}_\varphi, && \tfrac{\partial}{\partial n}\,\mathfrak{s} = 0,\\
&\tfrac{\partial}{\partial s}\,\mathbf{e}_\varphi = 0, && \tfrac{\partial}{\partial\varphi}\,\mathbf{e}_\varphi = -\tfrac{\partial r}{\partial s}\,\mathfrak{s} - \tfrac{\partial r}{\partial n}\,\mathfrak{n}, && \tfrac{\partial}{\partial n}\,\mathbf{e}_\varphi = 0,\\
&\tfrac{\partial}{\partial s}\,\mathfrak{n} = 0, && \tfrac{\partial}{\partial\varphi}\,\mathfrak{n} = \tfrac{\partial r}{\partial n}\,\mathbf{e}_\varphi, && \tfrac{\partial}{\partial n}\,\mathfrak{n} = 0.
\end{aligned} \tag{63}$$

It can be shown that

$$(\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u} = -\,[\mathfrak{n}\times\operatorname{curl}\mathbf{u}] + \frac{1}{r}\left(\frac{\partial}{\partial\varphi}\,[\mathbf{u}\times\mathfrak{s}] - \frac{\partial}{\partial s}\,(r\,[\mathbf{u}\times\mathbf{e}_\varphi])\right). \tag{64}$$

Indeed, using the formula

$$\operatorname{grad}(\mathfrak{a}\cdot\mathfrak{b}) = (\mathfrak{a}\cdot\operatorname{grad})\,\mathfrak{b} + (\mathfrak{b}\cdot\operatorname{grad})\,\mathfrak{a} + [\mathfrak{a}\times\operatorname{curl}\mathfrak{b}] + [\mathfrak{b}\times\operatorname{curl}\mathfrak{a}]$$

for $\mathfrak{a} = \mathfrak{n}$ and $\mathfrak{b} = \mathbf{u}$, along with the identity $\operatorname{curl}\mathfrak{n} = 0$, we obtain

$$(\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u} = -\,[\mathfrak{n}\times\operatorname{curl}\mathbf{u}] + \operatorname{grad}(\mathfrak{n}\cdot\mathbf{u}) - (\mathbf{u}\cdot\operatorname{grad})\,\mathfrak{n}. \tag{65}$$

Then, using (62) and (63) and the fact that $\operatorname{div}\mathbf{u} = 0$, we have

$$\begin{aligned}
\frac{\partial}{\partial\varphi}\,[\mathbf{u}\times\mathfrak{s}] - \frac{\partial}{\partial s}\,(r\,[\mathbf{u}\times\mathbf{e}_\varphi]) &= \frac{\partial}{\partial\varphi}\,(u_n\,\mathbf{e}_\varphi - u_\varphi\,\mathfrak{n}) + \frac{\partial}{\partial s}\,(r\,(u_n\,\mathfrak{s} - u_s\,\mathfrak{n}))\\
&= \frac{\partial u_n}{\partial\varphi}\,\mathbf{e}_\varphi - \frac{\partial u_\varphi}{\partial\varphi}\,\mathfrak{n} - u_n\left(\frac{\partial r}{\partial s}\,\mathfrak{s} + \frac{\partial r}{\partial n}\,\mathfrak{n}\right) - u_\varphi\,\frac{\partial r}{\partial n}\,\mathbf{e}_\varphi\\
&\quad + \frac{\partial}{\partial s}\,(ru_n)\,\mathfrak{s} - \frac{\partial}{\partial s}\,(ru_s)\,\mathfrak{n}\\
&= r\,\frac{\partial u_n}{\partial s}\,\mathfrak{s} + \frac{\partial u_n}{\partial\varphi}\,\mathbf{e}_\varphi + r\,\frac{\partial u_n}{\partial n}\,\mathfrak{n} - u_\varphi\,\frac{\partial r}{\partial n}\,\mathbf{e}_\varphi\\
&\equiv r\,(\operatorname{grad}(\mathfrak{n}\cdot\mathbf{u}) - (\mathbf{u}\cdot\operatorname{grad})\,\mathfrak{n}).
\end{aligned} \tag{66}$$

The relationship (64) follows from (66) and (65).

Let ℓ denote the contour of the surface S in the rz–half-plane. If ℓ is a closed curve with no intersections, e.g., the body is a torus, then obviously $\iint_S \frac{1}{r}\frac{\partial}{\partial s}\left(r\left[\mathbf{u}\times\mathbf{e}_\varphi\right]\right)dS = 0$, where $dS = r\,ds\,d\varphi$. Otherwise, since the body is bounded, ℓ intersects the z-axis at least twice. Assuming that s varies from the first intersection of the contour ℓ with the z-axis to the last one, and having that at all the intersections $r = 0$, we again obtain $\iint_S \frac{1}{r}\frac{\partial}{\partial s}\left(r\left[\mathbf{u}\times\mathbf{e}_\varphi\right]\right)dS = 0$. Consequently, integrating (64) over the surface S with $dS = r\,ds\,d\varphi$, we have

$$\iint_S (\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u}\,dS = -\iint_S \left[\mathfrak{n}\times\operatorname{curl}\mathbf{u}\right]dS. \tag{67}$$

With (67) and the notation $\boldsymbol{\omega} = \operatorname{curl}\mathbf{u}$, the resisting force (61) reduces to

$$\mathbf{F} = -\iint_S \left(\mu\left[\mathfrak{n}\times\boldsymbol{\omega}\right] + \wp\,\mathfrak{n}\right)dS. \tag{68}$$

Finally, let $\widetilde{S}$ be an arbitrary smooth surface encompassing the body, and let V be the volume between the surfaces S and $\widetilde{S}$ ($\mathfrak{n}$ will denote the outer normal for the corresponding surface). The Stokes equations (1) can be rewritten as

$$\operatorname{grad}\wp = -\mu\operatorname{curl}\left(\operatorname{curl}\mathbf{u}\right), \qquad \operatorname{div}\mathbf{u} = 0. \tag{69}$$

Integrating the first equation in (69) over the volume V and using Gauss's theorem, we obtain

$$\iiint_V \left(\mu\operatorname{curl}\boldsymbol{\omega} + \operatorname{grad}\wp\right)dV = \iint_{\widetilde{S}} \left(\mu\left[\mathfrak{n}\times\boldsymbol{\omega}\right] + \wp\,\mathfrak{n}\right)dS - \iint_S \left(\mu\left[\mathfrak{n}\times\boldsymbol{\omega}\right] + \wp\,\mathfrak{n}\right)dS = 0,$$

which implies the equivalence of (68) and (13), and, thus, the proposition is proved.

Appendix B. Proof of Proposition 3.

This section proves Proposition 3.

As in Appendix A, let (r,φ,z) and (s,φ,n) be the systems of the cylindrical and characteristic coordinates, respectively, and let the z-axis coincide with the body's axis of revolution.

By definition, the resultant torque, exerted on the body, is given by the integral over the body's surface S:

$$\mathbf{T} = \iint_S \left[\mathfrak{r}\times\mathbf{P}_n\right]dS = \iint_S \left[\mathfrak{r}\times\left(2\mu\left(\mathfrak{n}\cdot\operatorname{grad}\right)\mathbf{u} + \mu\left[\mathfrak{n}\times\operatorname{curl}\mathbf{u}\right] - \wp\,\mathfrak{n}\right)\right]dS, \tag{70}$$

where $\mathfrak{r} = r\,\mathbf{e}_r + z\,\mathbf{k}$ is the radius vector and $\mathbf{P}_n$ is determined by (60).

Producing the vectorial product of (64) with $\mathfrak{r}$, we obtain

$$\left[\mathfrak{r}\times(\mathfrak{n}\cdot\operatorname{grad})\,\mathbf{u}\right] = -\left[\mathfrak{r}\times\left[\mathfrak{n}\times\operatorname{curl}\mathbf{u}\right]\right] + \frac{1}{r}\left[\mathfrak{r}\times\left(\frac{\partial}{\partial\varphi}\left[\mathbf{u}\times\mathfrak{s}\right] - \frac{\partial}{\partial s}\left(r\left[\mathbf{u}\times\mathbf{e}_\varphi\right]\right)\right)\right]. \tag{71}$$

With the relationships $\frac{\partial\mathfrak{r}}{\partial\varphi} = r\,\mathbf{e}_\vartheta$ and $\frac{\partial\mathfrak{r}}{\partial s} = \frac{\partial r}{\partial s}\,\mathbf{e}_r + \frac{\partial z}{\partial s}\,\mathbf{k} \equiv \mathfrak{s}$, the second term in the right-hand side in (71) can be represented by

$$\frac{1}{r}\left(\frac{\partial}{\partial\varphi}\left(\left[\mathfrak{r}\times\left[\mathbf{u}\times\mathfrak{s}\right]\right]\right) - \frac{\partial}{\partial s}\left(r\;\left[\mathfrak{r}\times\left[\mathbf{u}\times\mathbf{e}_\varphi\right]\right]\right)\right) - \left(\left[\mathbf{e}_\varphi\times\left[\mathbf{u}\times\mathfrak{s}\right]\right] - \left[\mathfrak{s}\times\left[\mathbf{u}\times\mathbf{e}_\varphi\right]\right]\right),$$

where

$$\begin{aligned}[\mathbf{e}_\varphi \times [\mathbf{u} \times \mathfrak{s}]] - [\mathfrak{s} \times [\mathbf{u} \times \mathbf{e}_\varphi]] &= -\mathfrak{s}\,(\mathbf{u} \cdot \mathbf{e}_\varphi) + \mathbf{e}_\varphi\,(\mathbf{u} \cdot \mathfrak{s}) \\ &= [\mathfrak{n} \times \mathbf{e}_\varphi]\,(\mathbf{u} \cdot \mathbf{e}_\varphi) + [\mathfrak{n} \times \mathfrak{s}]\,(\mathbf{u} \cdot \mathfrak{s}) = [\mathfrak{n} \times \mathbf{u}]\,.\end{aligned}$$

With the last two formulas, the relationship (71) takes the from

$$\begin{aligned}[\mathfrak{r} \times (\mathfrak{n} \cdot \operatorname{grad})\,\mathbf{u}] = &-[\mathfrak{r} \times [\mathfrak{n} \times \operatorname{curl}\mathbf{u}]] - [\mathfrak{n} \times \mathbf{u}] \\ &+ \frac{1}{r}\left(\frac{\partial}{\partial\varphi}\left([\mathfrak{r} \times [\mathbf{u} \times \mathfrak{s}]]\right) - \frac{\partial}{\partial s}\left(r\ [\mathfrak{r} \times [\mathbf{u} \times \mathbf{e}_\varphi]]\right)\right).\end{aligned} \tag{72}$$

By the same reasoning as for integrating (64) over the body's surface S (see Appendix A), we obtain

$$\iint_S [\mathfrak{r} \times (\mathfrak{n} \cdot \operatorname{grad})\,\mathbf{u}]\,dS = -\iint_S \left([\mathfrak{r} \times [\mathfrak{n} \times \operatorname{curl}\mathbf{u}]] + [\mathfrak{n} \times \mathbf{u}]\right) dS. \tag{73}$$

With (73), the torque (70) reduces to

$$\mathbf{T} = -\mu \iint_S \left([\mathfrak{r} \times [\mathfrak{n} \times \operatorname{curl}\mathbf{u}]] + 2\,[\mathfrak{n} \times \mathbf{u}] + \tfrac{1}{\mu}\ [\mathfrak{r} \times \mathfrak{n}]\,\wp\right) dS. \tag{74}$$

Then, for the first equation in (69) and for an arbitrary volume V, we can write

$$\iiint_V \left[\mathfrak{r} \times \left(\operatorname{curl}(\operatorname{curl}\mathbf{u}) + \tfrac{1}{\mu}\ \operatorname{grad}\wp\right)\right] dV = 0. \tag{75}$$

Summing up two formulas

$$\begin{aligned}\operatorname{curl}[\mathfrak{a} \times \mathfrak{b}] &= (\mathfrak{b} \cdot \operatorname{grad})\,\mathfrak{a} - (\mathfrak{a} \cdot \operatorname{grad})\,\mathfrak{b} + \mathfrak{a}\operatorname{div}\mathfrak{b} - \mathfrak{b}\operatorname{div}\mathfrak{a}, \\ \operatorname{grad}(\mathfrak{a} \cdot \mathfrak{b}) &= (\mathfrak{a} \cdot \operatorname{grad})\,\mathfrak{b} + (\mathfrak{b} \cdot \operatorname{grad})\,\mathfrak{a} + [\mathfrak{a} \times \operatorname{curl}\mathfrak{b}] + [\mathfrak{b} \times \operatorname{curl}\mathfrak{a}]\,,\end{aligned}$$

which hold true for arbitrary $\mathfrak{a}$ and $\mathfrak{b}$, and rearranging terms, we obtain

$$\begin{aligned}[\mathfrak{a} \times \operatorname{curl}\mathfrak{b}] = \operatorname{curl}[\mathfrak{a} \times \mathfrak{b}] &+ \operatorname{grad}(\mathfrak{a} \cdot \mathfrak{b}) - 2\,(\mathfrak{b} \cdot \operatorname{grad})\,\mathfrak{a} \\ &- [\mathfrak{b} \times \operatorname{curl}\mathfrak{a}] - \mathfrak{a}\operatorname{div}\mathfrak{b} + \mathfrak{b}\operatorname{div}\mathfrak{a}.\end{aligned} \tag{76}$$

Substituting $\mathfrak{a} = \mathfrak{r}$ and $\mathfrak{b} = \operatorname{curl}\mathbf{u}$ into (76) and using the identities

$$\operatorname{curl}\mathfrak{r} = 0, \qquad \operatorname{div}\mathfrak{r} = 3, \qquad (\mathfrak{b} \cdot \operatorname{grad})\,\mathfrak{r} = \mathfrak{b},$$

we have

$$[\mathfrak{r} \times \operatorname{curl}(\operatorname{curl}\mathbf{u})] = \operatorname{curl}\left([\mathfrak{r} \times \operatorname{curl}\mathbf{u}] + \mathbf{u}\right) + \operatorname{grad}(\mathfrak{r} \cdot \operatorname{curl}\mathbf{u})\,. \tag{77}$$

Let V be the volume between the body's surface S and an arbitrary smooth surface $\widetilde{S}$ encompassing the body, and let $\mathfrak{n}$ be the outer normal to these surfaces. Then, with (77) and the relationship

$$[\mathfrak{r} \times \operatorname{grad}\wp] \equiv \wp\operatorname{curl}\mathfrak{r} - \operatorname{curl}(\mathfrak{r}\,\wp) = -\operatorname{curl}(\mathfrak{r}\,\wp)\,,$$

(75) takes the form

$$\begin{aligned}&\iiint_V \left[\mathfrak{r} \times \left(\operatorname{curl}(\operatorname{curl}\mathbf{u}) + \tfrac{1}{\mu}\ \operatorname{grad}\wp\right)\right] dV \\ &\quad= \iiint_V \left(\operatorname{curl}\left([\mathfrak{r} \times \operatorname{curl}\mathbf{u}] + \mathbf{u} - \tfrac{1}{\mu}\ \mathfrak{r}\,\wp\right) + \operatorname{grad}(\mathfrak{r} \cdot \operatorname{curl}\mathbf{u})\right) dV \\ &\quad= \iint_{S,\,\widetilde{S}} \left(\left[\mathfrak{n} \times \left([\mathfrak{r} \times \operatorname{curl}\mathbf{u}] + \mathbf{u} - \tfrac{1}{\mu}\ \mathfrak{r}\,\wp\right)\right] + (\mathfrak{r} \cdot \operatorname{curl}\mathbf{u})\,\mathfrak{n}\right) dS = 0,\end{aligned} \tag{78}$$

where the surface integral, being the difference between the integrals over the surfaces $\widetilde{S}$ and S, respectively, follows from Gauss's theorem.

Then, for the integrand in (78), we have

$$[\mathfrak{n} \times [\mathfrak{r} \times \operatorname{curl} \mathbf{u}]] + (\mathfrak{r} \cdot \operatorname{curl} \mathbf{u})\, \mathfrak{n} = [\mathfrak{r} \times [\mathfrak{n} \times \operatorname{curl} \mathbf{u}]] + (\mathfrak{n} \cdot \operatorname{curl} \mathbf{u})\, \mathfrak{r}, \tag{79}$$

and with the relationships

$$\frac{\partial r}{\partial s} = \frac{\partial z}{\partial n}, \qquad \frac{\partial r}{\partial n} = -\frac{\partial z}{\partial s},$$

and

$$\frac{\partial \mathfrak{r}}{\partial s} = \frac{\partial r}{\partial s}\, \mathbf{e}_r + \frac{\partial z}{\partial s}\, \mathbf{e}_\varphi \equiv \mathfrak{s}, \qquad \frac{\partial \mathfrak{r}}{\partial \varphi} = r\, \mathbf{e}_\varphi, \qquad \mathfrak{s} = -[\mathfrak{n} \times \mathbf{e}_\varphi],$$

we obtain

$$\begin{aligned}(\mathfrak{n} \cdot \operatorname{curl} \mathbf{u})\, \mathfrak{r} &= \frac{1}{r} \left(\frac{\partial}{\partial s} (r\, u_\varphi) + \frac{\partial}{\partial \varphi} \left(u_z \frac{\partial r}{\partial n} - u_r \frac{\partial z}{\partial n} \right) \right) \mathfrak{r} \\ &= \frac{1}{r} \left(\frac{\partial}{\partial s} \{(r\, u_\varphi)\, \mathfrak{r}\} + \frac{\partial}{\partial \varphi} \left\{ \left(u_z \frac{\partial r}{\partial n} - u_r \frac{\partial z}{\partial n} \right) \mathfrak{r} \right\} \right) \\ &\qquad - \left(u_\varphi\, \mathfrak{s} + \left(u_z \frac{\partial r}{\partial n} - u_r \frac{\partial z}{\partial n} \right) \mathbf{e}_\varphi \right) \\ &= \frac{1}{r} \left(\frac{\partial}{\partial s} \{(r\, u_\varphi)\, \mathfrak{r}\} + \frac{\partial}{\partial \varphi} \left\{ \left(u_z \frac{\partial r}{\partial n} - u_r \frac{\partial z}{\partial n} \right) \mathfrak{r} \right\} \right) + [\mathfrak{n} \times \mathbf{u}]\,.\end{aligned} \tag{80}$$

With (79) and (80), the surface integral over S in (78) takes the form

$$\begin{aligned}&\iint_S \left(\left[\mathfrak{n} \times \left([\mathfrak{r} \times \operatorname{curl} \mathbf{u}] + \mathbf{u} - \tfrac{1}{\mu}\, \mathfrak{r}\, \wp \right) \right] + (\mathfrak{r} \cdot \operatorname{curl} \mathbf{u})\, \mathfrak{n} \right) dS \\ &\qquad = \iint_S \left([\mathfrak{r} \times [\mathfrak{n} \times \operatorname{curl} \mathbf{u}]] + 2\, [\mathfrak{n} \times \mathbf{u}] + \tfrac{1}{\mu}\, [\mathfrak{r} \times \mathfrak{n}]\, \wp \right) dS \\ &\qquad = \iint_{\widetilde{S}} \left(\left[\mathfrak{n} \times \left([\mathfrak{r} \times \operatorname{curl} \mathbf{u}] + \mathbf{u} - \tfrac{1}{\mu}\, \mathfrak{r}\, \wp \right) \right] + (\mathfrak{r} \cdot \operatorname{curl} \mathbf{u})\, \mathfrak{n} \right) dS.\end{aligned} \tag{81}$$

Consequently, (22) follows from (74) and (81), and the proposition is proved.

ON THE EXISTENCE OF SMALL PERIODIC SOLUTIONS FOR THE 2-DIMENSIONAL INVERTED PENDULUM ON A CART*

LUCA CONSOLINI[†] AND MARIO TOSQUES[‡]

Abstract. This paper studies the problem of controlling an inverted pendulum on a cart which has to track a given curve lying on a vertical plane in such a way that the pendulum rod does not overturn. The problem is reduced to finding sufficiently small T-periodic solutions for a special type of mathematical forced pendulum equation.

Key words. inverted pendulum, periodic solutions, tracking control

AMS subject classifications. 65N30, 74K20, 74S05

DOI. 10.1137/070683404

Introduction. This article studies the existence of T-periodic solutions for the equation

$$d\ddot{\theta} = g\sin\theta + \left\langle \begin{pmatrix} \cos(\theta) \\ \sin(\theta) \end{pmatrix}, \ddot{\gamma}(t) \right\rangle, \tag{0.1}$$

which comes out from studying the problem of controlling an inverted pendulum on a cart which has to track a given curve lying on a vertical plane in such a way that the pendulum rod does not overturn (see Figure 1.1); in control theory, (0.1) is usually referred to as the system internal dynamics.

It is shown that there is a constant $k_0 \simeq 0.2672$, independent of the length of the pendulum rod, such that if $\|\ddot{\gamma}\| \leq k_0 g$, where g is the gravity acceleration, then there exist suitable initial conditions such that the functions $\theta(t), \dot{\theta}(t)$ are T-periodic and sufficiently small; in fact, they are uniformly bounded by the maximum norm of the acceleration of the reference trajectory.

The inverted pendulum on a cart is an important benchmark for nonlinear control techniques since it is a nonminimum phase problem and has been widely analyzed in various problems, under different points of view (see, for instance, [2], [3], [10], [6], [1], [8], [5].)

Equation (0.1) is related to the mathematical forced pendulum equation

$$\ddot{\theta} = \sin\theta + h(t),$$

which has been intensively studied in literature (see, for instance, [7] for a detailed survey). Many papers are focused on the existence and the multiplicity of periodic solutions (see, for example, [4], [9], [11]). Differently from these articles, this paper shows the existence of a specific sufficiently small periodic solution (in such a way that the pendulum does not overturn), gives precise bounds on its norm, and proposes a method for computing it. It is shown that the bounding term is directly proportional to the maximum norm of the acceleration of the reference trajectory.

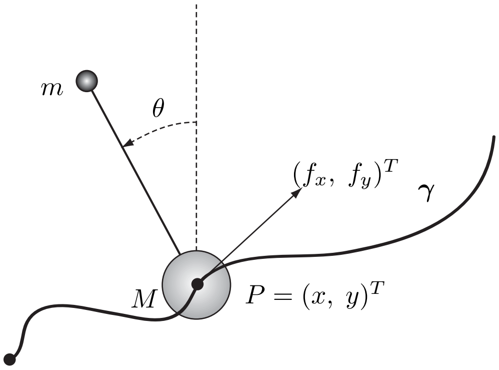

Fig. 1.1. *Inverted pendulum on a cart constrained on a curve.*

In the development of the proof, the problem of finding the right initial state is reformulated as a fixed point problem of a suitable Poincaré map associated to the internal dynamic given by (0.1). The main idea is the following: The inverted pendulum has an unstable equilibrium when the position of the cart is fixed at the origin and the pendulum rod is vertical. This unstable equilibrium corresponds to the null solution of (0.1) which is, trivially, a periodic bounded solution of the zero dynamics. Since any bounded desired reference trajectory may be prolongated to a periodic trajectory, γ may be seen as the value that the family of periodic curves $\{s\gamma\}$ assumes at $s = 1$. By prolongating the trivial null solution with a technique based on the implicit function theorem, we obtain a family of bounded periodic solutions, parameterized by $s \in [0, 1]$. The desired bounded solution is obtained by taking $s = 1$.

The paper is divided as follows. Section 1 presents the problem and section 2 the main results, section 3 contains the proof of the main theorem, and section 4 presents a computational method to drive an inverted pendulum along a given curve which is applied to a periodic spline.

The following notations will be used: For all $a, b \in \mathbb{R}$, $a \wedge b = \min\{a,\ b\}$, $a \vee b = \max\{a,\ b\}$; for all $\theta \in [0, 2\pi[$, $\tau(\theta) = (\cos\theta,\ \sin\theta)^T$; for all $x \in \mathbb{R}^2$, $\arg x = \theta$, where $\theta \in [0, 2\pi[$ is such that $x = \|x\|\tau(\theta)$; for all $x = (x_1, \dots, x_n)^T$, $y = (y_1, \dots, y_n)^T \in \mathbb{R}^n$, $\langle x\,,\, y\rangle = \sum_{i=1}^n x_i y_i$, $\|x\| = \sqrt{\langle x\,,\, x\rangle}$; for all $f : [0, T] \to \mathbb{R}^2$, $\|f\|_\infty = \sup_{x\in[0,T]}\{\|f(x)\|\}$.

1. Problem formulation. Consider an inverted pendulum of mass m linked to a moving cart of mass M through a massless rod of length d; in Figure 1.1 the pendulum is represented as the smaller sphere and the cart as the bigger one. It is supposed that during the motion the control force $f(t) = \binom{f_x(t)}{f_y(t)}$ is applied on it. Let $q = (x, y, \theta) \in \mathbb{R}^3$ be the vector of generalized coordinates, where (x, y) are the coordinates of the center of mass of the moving cart and θ is the angle between the rod and the vertical axis. Given a curve γ, we want to find a control force such that, starting from $\gamma(0)$, the point P can track all of the curve γ and the rod remains close to the vertical. To find the system dynamics, let $L = T - U$ be the Lagrangian, where

$$T = \frac{1}{2}\dot{q}^T H \dot{q}$$

is the kinetic energy, the inertia matrix H is given by

$$H(q) = \begin{pmatrix} M+m & 0 & -md\cos\theta \\ 0 & M+m & -md\sin\theta \\ -md\cos\theta & -md\sin\theta & md^2 \end{pmatrix},$$

and the potential energy U is given by

$$U(q) = (M+m)gy + mgd\cos\theta.$$

The dynamic equations are derived through the Euler–Lagrange equation

$$\frac{d}{dt}\frac{\partial L}{\partial \dot{q}} - \frac{\partial L}{\partial q} = \tau,$$

where $\tau = (f_x,\ f_y,\ 0)^T$ is the vector of generalized forces. The resulting dynamical system has 6 states $(x,\ \dot{x},\ y,\ \dot{y},\ \theta,\ \dot{\theta})$ and is given by

$$\left\{\begin{array}{l} (M+m)\ddot{x} = md(\ddot{\theta}\cos\theta + \dot{\theta}^2\sin\theta) + f_x, \\ (M+m)\ddot{y} = md(\ddot{\theta}\sin\theta + \dot{\theta}^2\cos\theta) - (M+m)g + f_y, \\ d\ddot{\theta} = g\sin\theta + \left\langle \begin{pmatrix} \ddot{x} \\ \ddot{y} \end{pmatrix}, \begin{pmatrix} \cos\theta \\ \sin\theta \end{pmatrix} \right\rangle. \end{array}\right. \tag{1.1}$$

Then let $\gamma = (\gamma_1,\ \gamma_2) \in \mathcal{C}^2([0,T], \mathbb{R}^2)$ be a curve, and if θ is a solution of system

$$\left\{\begin{array}{l} \ddot{\theta} = d^{-1}g\sin\theta + d^{-1}\left\langle \ddot{\gamma}, \begin{pmatrix} \cos\theta \\ \sin\theta \end{pmatrix} \right\rangle, \\ \theta(0) = \theta_0, \\ \dot{\theta}(0) = \dot{\theta}_0, \end{array}\right. \tag{1.2}$$

the control force f given by

$$\left\{\begin{array}{l} f_x = (M+m)\ddot{\gamma_1} - md(\ddot{\theta}\cos\theta + \dot{\theta}^2\sin\theta), \\ f_y = (M+m)\ddot{\gamma_2} - md(\ddot{\theta}\sin\theta + \dot{\theta}^2\cos\theta) + (M+m)g \end{array}\right. \tag{1.3}$$

drives point P along all of the curve γ; that is, the solution of system (1.1), with the initial conditions $(x(0),\ \dot{x}(0))^T = \gamma(0)$, $(y(0), \dot{y}(0))^T = \dot{\gamma}(0)$, $(\theta(0), \dot{\theta}(0)) = (\theta_0, \dot{\theta}_0)$, has the property that $(x(t),\ y(t))^T = \gamma(t)$, for all $t \in [0,T]$. From these remarks, it follows that our problem is solvable if it is possible to find a suitable initial condition $(\theta_0,\ \dot{\theta}_0)$ such that the solution $(\theta,\ \dot{\theta})$ of (1.2) (which is usually referred to as the internal dynamic of the problem) remains uniformly small. Theorem 2.3 exhibits a geometric property on γ for the existence of an initial condition $(\theta_0,\ \dot{\theta}_0)$ for which there exists a periodic solution of system (1.2), which remains uniformly bounded in terms of $\|\ddot{\gamma}\|_\infty$.

2. The main results.

The following theorem gives an answer to our problem.

THEOREM 2.1 (exact tracking). *There exist positive constants $k_0 \geq 0.2672$ and $\omega_0 \leq 1.4302$ rad, independent of d and g, such that for any curve $\gamma \in C^2([0,\ T], \mathbb{R}^2)$ with*

$$\|\ddot{\gamma}\|_\infty \leq k_0 g \tag{2.1}$$

there exist an initial condition $(\theta_0,\ \dot{\theta}_0)^T$ and a control force $f \in C^0([0,T], \mathbb{R}^2)$ such that the solution of (1.1) with initial conditions $(x(0),\ y(0))^T = \gamma(0)$, $(\dot{x}(0), \dot{y}(0))^T = \dot{\gamma}(0)$, $(\theta(0), \dot{\theta}(0)) = (\theta_0, \dot{\theta}_0)$ satisfies the following properties, for all $t \in [0,T]$:

$$\begin{aligned} &(x(t),\ y(t))^T = \gamma(t), \\ &|\theta(t)| \leq \frac{\omega_0}{k_0 g}\|\ddot{\gamma}\|_\infty, \\ &|\dot{\theta}(t)| \leq \frac{(1+k_0)^2}{g(\cos\omega_0 - k)^3}\|\ddot{\gamma}\|_\infty. \end{aligned} \tag{2.2}$$

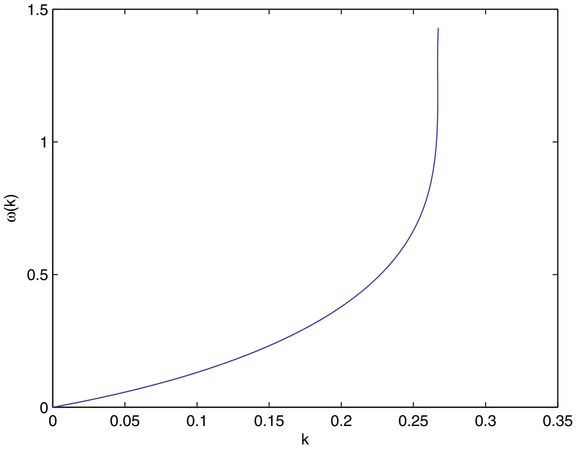

FIG. 2.1. *Function $\omega(k)$.*

In other words the curve is exactly tracked and the internal dynamics of the inverted pendulum remain bounded.

Proof. It follows directly from Theorem 2.3, by the previous considerations, since γ can be always considered the restriction on $[0, T]$ of a C^2-periodic curve. ◻

The following corollary states that it is always possible to find a reparameterization of a regular path γ that allows it to be followed with $\|(\theta, \dot{\theta})\|_\infty$ arbitrarily small.

COROLLARY 2.2 (exact path-following). *Let $\tilde{\gamma} \in C^2([0,\ \Lambda], \mathbb{R}^2)$ be an arc-length parameterized curve (that is, $\|\dot{\tilde{\gamma}}(\lambda)\| = 1$). For any $\sigma > 0$ there exist a bijection $\lambda(t) \in C^2([0,\ T],\ [0, \Lambda])$, an initial condition $(\theta_0,\ \dot{\theta}_0)^T$, and a control force $f \in C^0([0, T], \mathbb{R}^2)$ such that the solution of problem (1.1) with initial conditions $(x(0),\ y(0))^T = \gamma(0)$, $(\dot{x}(0),\ \dot{y}(0))^T = \frac{d(\tilde{\gamma}\circ\lambda)}{dt}(0)$, $(\theta(0),\ \dot{\theta}(0)) = (\theta_0,\ \dot{\theta}_0)$ satisfies the following properties for all $t \in [0,\ T]$:*

$$(x(t),\ y(t))^T = \tilde{\gamma}(\lambda(t)),\ \|(\theta(t),\ \dot{\theta}(t))^T\| \le \sigma.$$

In other words, for any arbitrary small constant σ, the exact path-following problem can always be solved by keeping the internal dynamics bounded by σ.

Proof. Set $\gamma = \tilde{\gamma} \circ \lambda$, where $\lambda(t)$ is a $C^2([0,\ T], [0,\ \Lambda])$ bijection; then

$$\|\ddot{\gamma}(t)\| = \sqrt{\ddot{\lambda}^2 + (\kappa(\lambda(t))\dot{\lambda}^2(t))^2},$$

where $\kappa(\lambda) = \frac{d}{d\lambda} \arg(\dot{\tilde{\gamma}}(\lambda))$ is the curvature of $\tilde{\gamma}(\lambda)$. Note that $\ddot{\lambda}(t)$ is the linear acceleration, and $\kappa(\lambda)\dot{\lambda}^2$ is the centripetal acceleration. Then the results follow directly from Theorem 2.1, choosing the reparameterization $\lambda(t)$ in a suitable way. ◻

THEOREM 2.3 (main theorem). *There exist $\bar{k} > 0$ and a continuous strictly increasing function $\omega : [0, \bar{k}[\to [0, \frac{\pi}{2}]$, with $\omega(0) = 0$ (see Figure 2.1), such that, for any $k \in [0, \bar{k}[$, any $d > 0$, and any periodic curve $\gamma \in C^2(\mathbb{R},\ \mathbb{R}^2)$ of period T with*

$$\|\ddot{\gamma}\|_\infty \le kg, \tag{2.3}$$

there exists an initial condition $(\theta_0,\ \dot{\theta}_0)^T$ *such that the solution of system*

$$\left\{\begin{array}{l}\ddot{\theta} = d^{-1} g \sin\theta + d^{-1}\left\langle \ddot{\gamma}\, ,\, \left(\begin{array}{c}\cos\theta\\ \sin\theta\end{array}\right)\right\rangle,\\ \theta(0)=\theta_0,\\ \dot{\theta}(0)=\dot{\theta}_0,\end{array}\right. \tag{2.4}$$

is periodic of period T*, and for all* $t \in \mathbb{R}$

$$\begin{aligned}|\theta(t)| &\le \frac{\omega(k)}{kg}\|\ddot{\gamma}\|_\infty,\\ |\dot{\theta}(t)| &\le \frac{(1+k)^2}{g(\cos\omega(k)-k)^3}\|\ddot{\gamma}\|_\infty.\end{aligned} \tag{2.5}$$

Furthermore

$$\bar{k} > 0.2672 \text{ and } \omega(0.2672) = 1.4302. \tag{2.6}$$

3. Proof of the main theorem. First of all, we define the function $\omega(k)$. For any $k \ge 0$, set $\mathcal{R}_k = \{(s,\omega) | \cos\omega - sk > 0\}$ and

$$\psi_k(s,\omega) = \frac{k(1+sk)^2}{(\cos\omega - sk)^3}\ \forall (s,\omega)\in\mathcal{R}_k.$$

Let ξ_k be the solution of the differential problem

$$\left\{\begin{array}{l}\dot{\xi}_k(s) = \psi_k(s,\xi_k(s)),\\ \xi_k(0)=0,\end{array}\right. \tag{3.1}$$

defined on the maximal interval of existence $[0,\bar{s}(k)[$. By the definition of ψ_k we get that $\xi_k : [0,\bar{s}(k)[\to [0,\frac{\pi}{2}]$ is strictly increasing, and $\bar{s}(k)$ is a strictly decreasing continuous function such that $\bar{s}(0)=+\infty$, $\bar{s}(k)\le\frac{1}{k}$, if $k>0$. Therefore there exists $\bar{k} : 0<\bar{k}\le 1$ such that $\bar{s}(\bar{k})=1$, and let $\omega : [0,\bar{k}[\to[0,\frac{\pi}{2}]$ be the function defined by $\omega(k)=\xi_k(1)$. By numerical computation it is $\bar{k}>0.2672$ with $\omega(0.2672)=1.4302$. Remark that $0\le 1\le \bar{s}(k)$ for all $k\in[0,\bar{k}[$, since $\bar{s}(k)$ is strictly decreasing and $\bar{s}(\bar{k})=1$. Set $k\in[0,\bar{k}[$, and suppose that $\|\ddot{\gamma}\|_\infty = kg$. For every $\tau, s\in\mathbb{R}$, for all $y\in\mathbb{R}^2$, let $x(t,\tau,s,y)$ be the solution of the problem

$$\left\{\begin{array}{l}\dot{x} = F(t,s,x),\ \forall t\in\mathbb{R},\\ x(\tau)=y,\end{array}\right. \tag{3.2}$$

where $F:\mathbb{R}\times\mathbb{R}\times\mathbb{R}^2\to\mathbb{R}^2$ is the C^2 map defined by

$$F(t,s,x) = \left(x_2,\ d^{-1}g\sin x_1 + s d^{-1}\left\langle \ddot{\gamma}(t)\, ,\, \left(\begin{array}{c}\cos x_1\\ \sin x_1\end{array}\right)\right\rangle\right)^T,\ \forall (t,s,x)\in\mathbb{R}\times\mathbb{R}\times\mathbb{R}^2, \tag{3.3}$$

and remark that, for every $(s,x)\in\mathbb{R}\times\mathbb{R}^2$, the map $t \rightsquigarrow F(t,s,x)$ is periodic of period T and that $(\theta,\dot{\theta})^T$ is a solution of (2.4) if and only if $x=(\theta,\dot{\theta})^T$ is a solution of (3.2) with $s=1$, $\tau=0$, and $y=(\theta_0,\dot{\theta}_0)$. Let $P:\mathbb{R}\times\mathbb{R}\times\mathbb{R}^2\to\mathbb{R}^2$ be the Poincaré map associated to problem (3.2); that is,

$$P(\tau,s,y) = x(T+\tau,\tau,s,y), \tag{3.4}$$

and set $\mathcal{P} : \mathbb{R} \times \mathbb{R} \times \mathbb{R}^2 \to \mathbb{R}^2$ the map defined by

$$\mathcal{P}(\tau, s, y) = P(\tau, s, y) - y.$$

Set $l = d^{-1}g$, and remark that $F(t, 0, x) = (x_2,\ l \sin x_1)^T$. Therefore for all $\tau \in \mathbb{R}$, $x(t, \tau, 0, 0) = 0$, for all $t \in \mathbb{R}$, which is clearly a periodic solution of period T, and therefore

$$\mathcal{P}(\tau, 0, 0) = 0\ \forall \tau \in \mathbb{R}.$$

The following property holds:

$$\partial_y \mathcal{P}(\tau, 0, 0) = \partial_y P(\tau, 0, 0) - I \text{ is invertible } \forall \tau \in \mathbb{R}; \tag{3.5}$$

that is, $\partial_y P(\tau, 0, 0)$ has two eigenvalues different from 1. In fact for all $i = 1, 2$

$$\partial_{y_i} P(\tau, s, y) = \partial_{y_i} x(T + \tau, \tau, s, y),$$

where $\partial_{y_i} x(t, \tau, s, y)$ is the solution ϕ_i of the problem

$$\begin{cases} \dot{\phi}_i = \partial_x F(t, s, x(t, \tau, s, y))\phi_i \ \forall t \in \mathbb{R}, \\ \phi_i(\tau) = e_i \end{cases} \tag{3.6}$$

(where $e_1 = (1, 0)$, $e_2 = (0, 1)$); therefore $\partial_y P(\tau, s, y) = \Phi^y_s(T + \tau, \tau)$, where $\Phi^y_s(t,\ \tau)$ is the matrix solution of system

$$\begin{cases} \dot{\Phi} = \partial_x F(t, s, x(t, \tau, s, y))\Phi \ \forall t \in \mathbb{R}, \\ \Phi(\tau) = I, \end{cases} \tag{3.7}$$

where I is the identity matrix. Since $x(t, \tau, 0, 0) = 0$ for all $t \in \mathbb{R}$, it is $\partial_x F(t, 0, x(t, \tau, 0, 0)) = \left(\begin{smallmatrix} 0 & 1 \\ l & 0 \end{smallmatrix}\right)$ which has the eigenvalues $\sqrt{l}$ and $-\sqrt{l}$ and normalized eigenvectors:

$$W = \frac{1}{\sqrt{l + 1}} \left(\begin{pmatrix} 1 \\ \sqrt{l} \end{pmatrix}, \begin{pmatrix} -1 \\ \sqrt{l} \end{pmatrix} \right).$$

Then $\Phi^0_0(t,\ \tau) = W\left(\begin{smallmatrix} e^{\sqrt{l}t} & 0 \\ 0 & e^{-\sqrt{l}t} \end{smallmatrix}\right)W^{-1}$ for all $t, \tau \in \mathbb{R}$, which implies that for all $t, \tau \in \mathbb{R}$, $\Phi^0_0(t, \tau)$ has the eigenvalues $e^{\sqrt{l}t}$ and $e^{-\sqrt{l}t}$ and constant eigenvectors given by the columns of W; therefore

$$\partial_y \mathcal{P}(\tau, 0, 0) = \Phi^0_0(T + \tau, \tau) - I\ \forall t \in \mathbb{R},$$

and property (3.5) holds. Since $\{(\tau, 0, 0) | 0 \le \tau \le T\}$ is a compact subset of $\mathbb{R}^3$, by the implicit function theorem, we can find $\rho > 0$ and a C^1 map $y : [0, T] \times [-\rho,\ \rho] \to \overline{B((0, 0), \rho)}$ (where $\overline{B((0, 0), \rho)}$ denotes the closed ball in $\mathbb{R}^2$ of center $(0, 0)$ and radius ρ), represented in Figure 3.1, such that

$$\begin{aligned} &y(\tau, 0) = 0\ \forall \tau \in [0, T],\ \mathcal{P}(\tau, s, y(\tau, s)) = 0\ \forall (\tau, s) \in [0, T] \times [-\rho,\ \rho], \\ &\{(\tau, s, y(\tau, s)) | (\tau, s) \in [0, T] \times [-\rho,\ \rho]\} \\ &= \{(\tau, s, y) \in [0, T] \times [-\rho, \rho] \times \overline{B((0, 0), \rho)} \text{ such that } \mathcal{P}(\tau, s, y) = 0\}; \end{aligned} \tag{3.8}$$

that is (as stated in the implicit function theorem), $y(\tau, s)$ is the only solution of $\mathcal{P}(\tau, s, y) = 0$, inside $[0, T] \times [-\rho, \rho] \times \overline{B((0, 0), \rho)}$,

$$\partial_y \mathcal{P}(\tau, s, y(\tau, s)) \text{ is invertible } \forall (\tau, s) \in [0, T] \times [-\rho, \rho]. \tag{3.9}$$

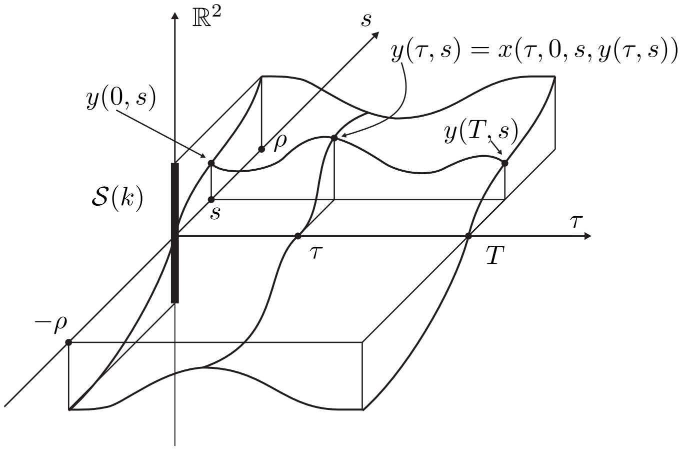

Fig. 3.1. *The implicit function method.*

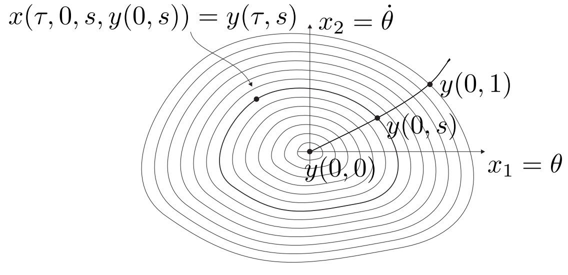

Fig. 3.2. *The family of periodic orbits* $x(t,0,s,y(0,s))$, $0\le s\le 1$.

The aim of the following is to prove that map $y(\tau,s)$ can be prolongated at least to $s=1$ for all $\tau\in[0,T]$, see Figure 3.2. It is used as a maximality procedure that requires the definition of suitable sets and functions, whose use is related to Lemmas 3.1 and 3.2.

Set $\mathcal{S}(k)=\{x=(x_1,x_2)\big||x_1|\le\omega(k)\}$. Let $\bar\rho$ be the supremum of the ρ's such that there exists a unique $y\in C^1([0,T]\times[-\rho,\rho],\ \mathcal{S}(k))$, with the properties (3.8), (3.9). Since it can be supposed that $\overline{B((0,0),\rho)}\subset\mathcal{S}(k)$ unless of decreasing ρ if necessary, we have that $\bar\rho>0$ by the previous step. Then by the definition of $\bar\rho$ we have that there exists a unique $y\in C^1([0,T]\times]-\bar\rho,\bar\rho[,\mathcal{S}(k))$ such that the properties (3.8), (3.9) are verified on $[0,T]\times]-\bar\rho,\bar\rho[$. But by the group property and the periodicity in t of $x(t,0,s,y(0,s))$

$$x(T+\tau,\tau,s,x(\tau,0,s,y(0,s)))=x(T+\tau,0,s,y(0,s))=x(\tau,0,s,y(0,s)),$$

then it is

$$y(\tau,s)=x(\tau,0,s,y(0,s))\ \forall(\tau,s)\in[0,T]\times]-\bar\rho,\bar\rho[,$$

since $y(\tau,s)$ is the only solution y in $\mathcal{S}(k)$ of the equation $y=x(\tau+T,\tau,s,y)$.

Therefore, by the group property, for all $s\in]-\bar\rho,\bar\rho[$, for all $\tau_1,\tau_2\in[0,T]$

$$\begin{aligned}x(t,\tau_1,s,y(\tau_1,s))&=x(t,\tau_1,s,x(\tau_1,0,s,y(0,s)))\\&=x(t,\tau_2,s,x(\tau_2,0,s,y(0,s)))=x(t,\tau_2,s,y(\tau_2,s));\end{aligned}$$

in other words, for all $t \in \mathbb{R}$ for all $s \in]-\bar{\rho}, \bar{\rho}[$, $x(t, \tau, s, y(\tau, s))$ is independent of $\tau \in [0, T]$, and in particular:

$$x(t, \tau, s, y(\tau, s)) = x(t, 0, s, y(0, s)) = y(t, s) \; \forall (t, \tau, s) \in [0, T]^2 \times]-\bar{\rho}, \bar{\rho}[. \tag{3.10}$$

Furthermore (3.8) imply that

$$\partial_y \mathcal{P}(\tau, s, y(\tau, s)) \partial_s y(\tau, s) + \partial_s \mathcal{P}(\tau, s, y(\tau, s)) = 0,$$

which can be rewritten in the form

$$\partial_s y(\tau, s) = \partial_y P(\tau, s, y(\tau, s)) \partial_s y(\tau, s) + \partial_s P(\tau, s, y(\tau, s)) \; \forall (\tau, s) \in [0, T] \times]-\bar{\rho}, \bar{\rho}[, \tag{3.11}$$

since for all $(\tau, s, y) \in \mathbb{R} \times \mathbb{R} \times \mathbb{R}^2$, $\partial_s P(\tau, s, y) = Z_s^y(T + \tau, \tau)$, where $Z_s^y(t, \tau)$ is the solution of the following system:

$$\begin{cases} \dot{Z} = \partial_x F(t, s, x(t, \tau, s, y))Z + \partial_s F(t, s, x(t, \tau, s, y)), \\ Z(\tau) = 0. \end{cases}$$

Therefore (3.11) says that $\partial_s y(\tau, s)$ verifies the following property:

$$\partial_s y(\tau, s) = \Phi_s^{y(\tau,s)}(T + \tau, \tau) \partial_s y(\tau, s) + Z_s^{y(\tau,s)}(T + \tau, \tau) \; \forall (\tau, s) \in [0, T] \times]-\bar{\rho}, \bar{\rho}[. \tag{3.12}$$

Since $x(t, \tau, s, y(\tau, s)) = y(t, s)$ by property (3.10), we can set for all $t \in \mathbb{R}$, for all $s \in]-\bar{\rho}, \bar{\rho}[$, for all $\tau \in [0, T]$, for all $t \in \mathbb{R}$,

$$\begin{cases} \partial_x F(t, s, x(t, \tau, s, y(\tau, s))) = \begin{pmatrix} 0 & 1 \\ f(t, s, y_1(t, s)) & 0 \end{pmatrix} = A_s(t), \\ \partial_s F(t, s, x(t, \tau, s, y(\tau, s))) = \begin{pmatrix} 0 \\ b(t, y_1(t, s)) \end{pmatrix} = B_s(t), \end{cases} \tag{3.13}$$

where

$$\begin{cases} f(t, s, x_1) = d^{-1} \left[g \cos x_1 + s \left\langle \ddot{\gamma}(t), \begin{pmatrix} -\sin x_1 \\ \cos x_1 \end{pmatrix} \right\rangle \right], \\ b(t, x_1) = d^{-1} \left\langle \ddot{\gamma}(t), \begin{pmatrix} \cos x_1 \\ \sin x_1 \end{pmatrix} \right\rangle. \end{cases} \tag{3.14}$$

$A_s(t), B_s(t)$ are periodic of period T, for all $s \in]-\bar{\rho}, \; \bar{\rho}[$, $\ddot{\gamma}(t)$ and $y(t, s)$ being periodic functions of t of period T.

Since the solution of this family of periodic time-varying systems

$$\begin{cases} \dot{\xi} = A_s(t)\xi + B_s(t), \\ \xi(\tau) = z \end{cases}$$

is given by $\xi(t) = \Phi_s(t, \tau)z + \int_\tau^t \Phi_s(t, p)B_s(p)dp$, where $\Phi_s(t, \tau) \triangleq \Phi_s^{y(\tau,s)}(t, \tau)$, property (3.12) can be rewritten in the form: For all $\tau \in [0, T]$, for all $s \in]-\bar{\rho}, \; \bar{\rho}[$

$$\partial_s y(\tau, s) = \Phi_s(T + \tau, \tau) \partial_s y(\tau, s) + \int_\tau^{T+\tau} \Phi_s(T + \tau, p) B_s(p) dp. \tag{3.15}$$

Our aim is to show that $\bar{\rho} \geq 1$. Suppose, by contradiction, that $\bar{\rho} < 1$, and set, for brevity, $f_s(t) = f(t, s, y_1(t, s))$. Since $\|\ddot{\gamma}\|_\infty = kg$ and $l = d^{-1}g$ it is by (3.14) that, for all $s \in]-\bar{\rho}, \bar{\rho}[$, $f_s(t)$ is periodic of period T, and, for all $t \in \mathbb{R}$, for all $s \in]-\bar{\rho}, \; \bar{\rho}[$,

$$f_1(s, k, l) = l(\cos(\|y_1(\cdot, s)\|_\infty) - sk) \leq f_s(t) \leq l(1 + sk) = f_2(s, k, l), \tag{3.16}$$

where $\|y_1(\cdot,s)\|_\infty = \sup_{0\le t\le T}|y_1(t,s)|$. Then for every $s \in]-\bar\rho,\bar\rho[$, we can apply the corollary to Lemma 3.2, with $A(t) = A_s(t)$ and $B(t) = B_s(t)$, (3.38) being verified by (3.15).

Then it is $\|B_s(t)\| \le d^{-1}\|\ddot\gamma\|_\infty = lk$, for all $t \in \mathbb{R}$, for all $s \in]-\bar\rho,\bar\rho[$, and, by (3.39), for all $(\tau,s) \in [0,T]\times]-\bar\rho,\bar\rho[$:

$$(3.17)\qquad |\partial_s y_1(\tau,s)| \le lk\frac{\sqrt{f_2}(1+f_2)}{f_1(1+f_1)}\left(\sqrt{f_1}\wedge\left(\sqrt{f_2}\frac{1+f_1}{1+f_2}\right)\right)^{-1},$$

$$(3.18)\qquad |\partial_s y_2(\tau,s)| \le lk\frac{\sqrt{1+f_2}}{\sqrt{1+f_1}}\frac{f_2}{f_1}\left(\sqrt{f_1}\wedge\left(\sqrt{f_2}\frac{1+f_1}{1+f_2}\right)\right)^{-1}.$$

Because $\frac{1+f_2}{1+f_1} \le \frac{f_2}{f_1}$, $\frac{1+f_1}{1+f_2} \ge \frac{f_1}{f_2}$ since $f_1 \le f_2$,

$$\frac{\sqrt{f_2}(1+f_2)}{f_1(1+f_1)}\left(\sqrt{f_1}\wedge\left(\sqrt{f_2}\frac{1+f_1}{1+f_2}\right)\right)^{-1} \le \frac{f_2^2}{f_1^3},$$

which implies, by (3.17), (3.18), (3.16) that, for all $(\tau,s) \in [0,T]\times]-\bar\rho,\bar\rho[$,

$$(3.19)\qquad |\partial_s y_1(\tau,s)| \le lk\frac{f_2^2}{f_1^3} \le \frac{k(1+sk)^2}{(\cos\|y_1(\cdot,s)\|_\infty - sk)^3} = \psi_k(s,\|y_1(\cdot,s)\|_\infty).$$

Therefore by the definition of ξ_k (see (3.1)) and the comparison lemma, we obtain that

$$(3.20)\qquad \|y_1(\cdot,s)\|_\infty \le \xi_k(s)\ \forall s \in]-\bar\rho,\bar\rho[.$$

Since $\|y_1(\cdot,s)\|_\infty \le \omega(k) = \xi_k(1)$ for all $s \in [-\bar\rho,\ \bar\rho]$,

$$(3.21)\qquad |\partial_s y_1(\tau,s)| \le \frac{k(1+sk)^2}{(\cos\omega(k) - sk)^3} \le \frac{k(1+k)^2}{(\cos\omega(k)-k)^3} = \psi_k(\xi_k(1),1),$$

and

$$(3.22)\qquad |\partial_s y_2(\tau,s)| \le lk\sqrt{\frac{1+f_1}{1+f_2}}\frac{f_2^2}{f_1^3} \le lk\frac{f_2^2}{f_1^3} \le \psi_k(\xi_k(1),1).$$

Remark that $\xi_k(s)$ and $\psi_k(\xi_k(s),s)$ are well defined on 1 since $0 \le k < \bar k$ (see the definition of $\bar k$ at the beginning of the proof). Then by (3.21) and (3.22), for all $\tau \in [0,T]$ the map $s \rightsquigarrow y(\tau,s)$ may be prolongated to a Lipschitz map defined on $[-\bar\rho,\bar\rho]$ and $y(\tau,s) \in S(k)$, $(\tau,s) \in [0,T]\times[-\bar\rho,\ \bar\rho]$. Furthermore $\exists\epsilon > 0:$

$$\|y_1(\cdot,s)\|_\infty \le \omega(k) - \epsilon\ \forall s \in [-\bar\rho,\bar\rho]$$

(by (3.20), since $\xi_k(\bar\rho) < \xi(1) = \omega(k)$, ξ being strictly increasing and $\bar\rho < 1$ by the absurd hypothesis). Moreover, by continuity, $\mathcal{P}(\tau,\pm\bar\rho,y(\tau,\pm\bar\rho)) = 0$ for all $\tau \in [0,T]$, and by (3.27) of Lemma 3.1, $\partial_y\mathcal{P}(\tau,\pm\bar\rho,y(\tau,\pm\bar\rho))$ is invertible for all $\tau \in [0,T]$. Therefore, by applying the implicit function theorem to the curves $\tau \rightsquigarrow y(\tau,\pm\bar\rho)$, the definition of $\bar\rho$ is contradicted.

Then $\bar\rho \ge 1$, and, taking $s = 1$, $\mathcal{P}(0,1,y(0,1)) = 0$; that is, there exists an initial condition $y(0,1)$ such that the solution $x(t,0,1,y(0,1))$ is periodic of period T, with the properties for all $t \in [0,T]$:

$$|x_1(t,0,1,y(0,1))| = |y_1(t,1)| \le \omega(k),$$

$$|x_2(t,0,1,y(0,1))| = |y_2(t,1)| \le \frac{k(1+k)^2}{(\cos\omega(k)-k)^3}.$$

This completes the proof if $\|\ddot{\gamma}\|_\infty = kg$. Suppose now that $\|\ddot{\gamma}\|_\infty < kg$. Remark that for all $\alpha : 0 \leq \alpha \leq 1$, $\omega(\alpha k) \leq \alpha\omega(k)$, and $\frac{\alpha k(1+\alpha k)^2}{(\cos\omega(\alpha k)-\alpha k)^3} \leq \alpha\frac{k(1+k)^2}{(\cos\omega(k)-k)^3}$, which implies (2.5) if $\alpha = \frac{\|\ddot{\gamma}\|_\infty}{kg}$, and the theorem has been proved. □

The following lemma studies the properties of the eigenvalue and eigenvectors of the fundamental matrix Φ associated to an hyperbolic matrix having the form (3.23) with the suitable control (3.24).

LEMMA 3.1. *Let $A(t)$ be the following (2×2) continuous matrix:*

$$A(t) = \begin{pmatrix} 0 & 1 \\ f(t) & 0 \end{pmatrix}, \tag{3.23}$$

where $f : \mathbb{R} \to \mathbb{R}$ is a continuous function such that

$$0 < f_1 \leq f(t) \leq f_2 < +\infty, \tag{3.24}$$

where f_1 and f_2 are given constants.

Set $\tau \geq 0$, and let $\Phi(t)$ be the solution to

$$\begin{cases} \dot{\Phi} = A(t)\Phi \ \forall t \in [0, +\infty[, \\ \Phi(\tau) = I, \end{cases} \tag{3.25}$$

and let, for all $i = 1, 2$, $\mu_i(t)$ and $w_i(t)$ be, respectively, the eigenvalues and the corresponding normalized eigenvectors of $\Phi(t)$ (i.e., for all $i = 1, 2$, $\Phi(t)w_i(t) = \mu_i(t)w_i(t)$ and $\|w_i(t)\| = 1$). Then

$$w_i(t) \in \Sigma_i \ \forall t \geq \tau, \tag{3.26}$$

$$\mu_2(t) \leq e^{-\lambda_0(t-\tau)} < e^{\lambda_0(t-\tau)} \leq \mu_1(t) \ \forall t \geq \tau, \tag{3.27}$$

where Σ_1 and Σ_2 are the cones defined as follows:

$$\Sigma_1 = \left\{ x \in \mathbb{R}^2 | \left\langle x\,, \begin{pmatrix} 1 \\ \sqrt{f_1} \end{pmatrix}^\perp \right\rangle \geq 0, \ \left\langle x\,, \begin{pmatrix} 1 \\ \sqrt{f_2} \end{pmatrix}^\perp \right\rangle \leq 0 \right\},$$

$$\Sigma_2 = \left\{ x \in \mathbb{R}^2 | \left\langle x\,, \begin{pmatrix} 1 \\ -\sqrt{f_1} \end{pmatrix}^\perp \right\rangle \leq 0, \ \left\langle x\,, \begin{pmatrix} 1 \\ -\sqrt{f_2} \end{pmatrix}^\perp \right\rangle \geq 0 \right\},$$

and $\lambda_0(f_1, f_2) = \sqrt{f_1} \wedge (\sqrt{f_2}\frac{1+f_1}{1+f_2})$.

Proof. Clearly it can be assumed that $\tau = 0$. First of all, it is shown that Σ_1 is positively invariant with respect to the vector field $A(t)x$. To this end it is sufficient to show that

$$\left\langle A(t)x\,, \begin{pmatrix} 1 \\ \sqrt{f_1} \end{pmatrix}^\perp \right\rangle \geq 0 \ \forall x \in P_1, \forall t \geq 0,$$

$$\left\langle A(t)x\,, \begin{pmatrix} 1 \\ \sqrt{f_2} \end{pmatrix}^\perp \right\rangle \leq 0 \ \forall x \in P_2, \forall t \leq 0,$$

where $P_1 = \{x \in \mathbb{R}^2 | x_1 \geq 0, \ x_2 \leq x_1\sqrt{f_1}\}$, $P_2 = \{x \in \mathbb{R}^2 | x_1 \geq 0, \ x_2 \geq x_1\sqrt{f_2}\}$.

In fact if $x \in P_1$, then

$$\left\langle A(t)x\,,\begin{pmatrix}1\\ \sqrt{f_1}\end{pmatrix}^{\perp}\right\rangle = \left\langle x\,,\, A^T(t)\begin{pmatrix}-\sqrt{f_1}\\ 1\end{pmatrix}\right\rangle$$
$$= \left\langle\begin{pmatrix}x_1\\ x_2\end{pmatrix}\,,\begin{pmatrix}f(t)\\ -\sqrt{f_1}\end{pmatrix}\right\rangle = x_1 f(t) - x_2\sqrt{f_1} \geq x_1(f(t)-f_1) \geq 0.$$

If $x \in P_2$, then

$$\left\langle A(t)x\,,\begin{pmatrix}1\\ \sqrt{f_2}\end{pmatrix}^{\perp}\right\rangle = x_1 f(t) - x_2\sqrt{f_2} \leq x_1(f(t)-f_2(t)) \leq 0.$$

Therefore Σ_1 is positively invariant with respect to $A(t)x$, and analogously it is proved that Σ_2 is positively invariant with respect to the vector field $-A(-t)x$.

Moreover, for all $i = 1, 2$, the eigenvectors $w_i(t)$ of $\Phi(t)$ satisfy $w_i(t) \in \Sigma_i$ for all $t \geq 0$. In fact set $\alpha_i = \arcsin\frac{\sqrt{f_i}}{\sqrt{1+f_i}}$, $i = 1, 2$, and define the continuous map $G_t : [\alpha_1,\ \alpha_2] \to \mathbb{R}$ by

$$G_t(\alpha) = \arg(\Phi(t)\tau(\alpha)) - \alpha$$

(recall that $\tau(\alpha) = (\cos(\alpha), \sin(\alpha))^T$). Because of the positive invariance of Σ_1, $G_t(\alpha_1) \geq 0$ and $G_t(\alpha_2) \leq 0$; therefore, by Bolzano's theorem there exists $\bar{\alpha} \in [\alpha_1,\ \alpha_2]$ such that $G_t(\bar{\alpha}) = 0$; that is, there exists $\mu(t)$ such that

$$\Phi(t)\tau(\bar{\alpha}(t)) = \mu(t)\tau(\bar{\alpha}(t)),$$

and therefore $w_1(t) = \tau(\bar{\alpha}(t))$ is a normalized eigenvector. Analogously, by using the positive invariance of Σ_2 with respect to $-A(-t)$, it is verified that the other eigenvector $w_2(t)$ of $\Phi(t)$ belongs to Σ_2.

Given any $\bar{x} \in \Sigma_1\backslash\{0\}$, let $x(t) = \Phi(t)\bar{x}$ for all $t \geq 0$. Since $x(t) \in \Sigma_1$, by the positive invariance of Σ_1, there exists functions $\rho(t)$ and $\beta(t)$ such that

$$x(t) = \rho(t)\begin{pmatrix}1\\ \beta(t)\end{pmatrix},\ \rho(t) \geq 0,\ \sqrt{f_1} \leq \beta(t) \leq \sqrt{f_2}\ \forall t \geq 0.$$

Since $\|x(t)\| = \rho(t)\sqrt{1+\beta^2(t)}$ for all t, with $\|x(t)\| > 0$,

$$\frac{d\|x(t)\|}{dt} = \frac{\langle \dot{x}(t)\,,\, x(t)\rangle}{\|x(t)\|} = \frac{\langle A(t)x(t)\,,\, x(t)\rangle}{\rho(t)\sqrt{1+\beta^2(t)}}$$
$$= \frac{\rho(t)\beta(t)}{\sqrt{1+\beta^2(t)}}(1+f(t)) = \|x(t)\|\frac{\beta(t)}{1+\beta(t)^2}(1+f(t)).$$

Since $\sqrt{f_1} \leq \beta(t) \leq \sqrt{f_2}$, for all $t \geq 0$

$$\frac{\beta(t)}{1+\beta^2(t)} \geq \frac{\sqrt{f_1}}{1+f_1} \wedge \frac{\sqrt{f_2}}{1+f_2},$$

and

$$\frac{d\|x(t)\|}{dt} \geq \left(\frac{\sqrt{f_1}}{1+f_1} \wedge \left(\frac{\sqrt{f_2}}{1+f_2}(1+f_1)\right)\right)\|x(t)\|$$
$$= \left(\sqrt{f_1} \wedge \left(\sqrt{f_2}\frac{1+f_1}{1+f_2}\right)\right)\|x\| = \lambda_0(f_1, f_2)\|x\|,$$

and therefore $\|x(t)\| \geq e^{\lambda_0 t}\|x(0)\|$. Finally let $x(t) = \Phi(t)w_1(\tau)$, where $w_1(\tau)$ is the eigenvector of $\Phi(t)$ belonging to Σ_1. Since $w_1(t) \in \Sigma_1$ for all $t \geq 0$, by the previous reasoning,

$$\|x(t)\| \geq e^{\lambda_0 t}\|w(\tau)\|,$$

which implies, since $x(\tau) = \mu_1(\tau)w(\tau)$ for all $\tau \geq 0$ that:

$$\mu_1(t) \geq e^{\lambda_0 t}\ \forall t \geq 0.$$

Therefore (3.27) holds since $\mu_2(t) = \mu_1(t)^{-1}$ is the trace of $A(t) = 0$. □

The following lemma gives an estimate on the fixed points of the solution for a nonhomogeneous time-dependent linear system associated to an hyperbolic matrix $A(t)$ having the form (3.23) with controls (3.24) on the coefficients.

LEMMA 3.2. *Let $A(t)$ be a continuous 2×2 matrix defined on $[0, +\infty[$, satisfying the hypotheses of Lemma 3.1, and let $B(t) \in \mathbb{R}^2$ be a continuous vector on $[0, +\infty[$. Let $\xi \in \mathbb{R}^2$ be such that there exists $\tau \geq 0$ and $T > 0$ for which*

$$\xi = \Phi(T + \tau, \tau)\xi + \int_\tau^{T+\tau} \Phi(T + \tau, p)B(p)dp,$$

where $\Phi(t, \tau)$ is a solution of (3.25). Then

$$(3.28)\qquad \begin{aligned} |\xi_1| &\leq c_1 \frac{1 + e^{-\lambda_0 T}}{\lambda_0}\|B\|_{[\tau,\ T+\tau]}, \\ |\xi_2| &\leq c_2 \frac{1 + e^{-\lambda_0 T}}{\lambda_0}\|B\|_{[\tau,\ T+\tau]}, \end{aligned}$$

where

$$(3.29)\qquad \begin{cases} \lambda_0(f_1, f_2) = \sqrt{f_1} \wedge \left(\sqrt{f_2}\dfrac{1 + f_1}{1 + f_2}\right), \\ c_1(f_1, f_2) = \dfrac{\sqrt{f_2}}{f_1}\dfrac{1 + f_2}{1 + f_1}, \\ c_2(f_1, f_2) = \dfrac{f_2}{f_1}\dfrac{\sqrt{1 + f_2}}{\sqrt{1 + f_1}}, \end{cases}$$

and $\|B\|_{[\tau,T+\tau]} = \max\{\|B(t)\| | \tau \leq t \leq T + \tau\}$.

Proof. Without loss of generality, assume $\tau = 0$, and therefore suppose that ξ satisfies

$$(3.30)\qquad \xi = \Phi(T, 0)\xi + \int_0^T \Phi(T, \tau)B(\tau)d\tau.$$

Set $W(t, \tau) = (w_1(t, \tau), w_2(t, \tau))$, where $w_i(t, \tau)$ are the normalized eigenvectors and $\mu_i(t)$ the eigenvalues of $\Phi(t, \tau)$. Remark that, for any invertible 2×2 matrix $W = (w_1,\ w_2)$,

$$(3.31)\qquad \forall z \in \mathbb{R}^2,\ z = (W^{-1}z)_1 w_1 + (W^{-1}z)_2 w_2,$$

where $(W^{-1}z)_i$ are the components of vector $W^{-1}z$. Therefore

$$\begin{aligned} (I - \Phi(T, 0))\xi &= (I - \Phi(T, 0)) \sum_{i=1}^{2} (W^{-1}(T, 0)\xi)_i w_i(T, 0) \\ &= \sum_{i=1}^{2} (1 - \mu_i(T, 0))(W^{-1}(T, 0)\xi)_i w_i(T, 0), \end{aligned}$$

and moreover

$$\begin{aligned}\int_0^T \Phi(T,\tau)B(\tau)d\tau &= \int_0^T \Phi(T,\tau)\sum_{j=1}^{2}(W^{-1}(T,\tau)B(\tau))_j w_j(T,\tau)d\tau\\ &= \sum_{j=1}^{2}\int_0^T (W^{-1}(T,\tau)B(\tau))_j \mu_j(T,\tau)w_j(T,\tau)d\tau\\ &= \sum_{i=1}^{2}\left(\sum_{j=1}^{2}\int_0^T \mu_j(T,\tau)(W^{-1}(T,\tau)B(\tau))_j\right.\\ &\qquad\left.\cdot\ (W^{-1}(T,0)w_j(T,\tau))_i d\tau\right) w_i(T,0).\end{aligned}$$

Therefore, by (3.30) it follows that

(3.32)

$$(W^{-1}(T,0)\xi)_1 = \sum_{j=1}^{2}\frac{1}{1-\mu_1(T,0)}\int_0^T \mu_j(T,\tau)(W^{-1}(T,\tau)B(\tau))_j(W^{-1}(T,0)w_j(T,\tau))_1 d\tau.$$

Moreover (3.30) can also be written in the form

$$(\Phi(T,0)^{-1}-I)\xi = \int_0^T \Phi(\tau,0)^{-1}B(\tau)d\tau, \tag{3.33}$$

and then we obtain

$$(\Phi(T,0)^{-1}-I)\xi = \sum_{i=1}^{2}(\mu_i(T,0)^{-1}-1)(W^{-1}(T,0)\xi)_i w_i(T,0),$$

$$\begin{aligned}&\int_0^T \Phi(\tau,0)^{-1}B(\tau)d\tau\\ &\quad= \sum_{i=1}^{2}\left(\sum_{j=1}^{2}\int_0^T \mu_j(\tau,0)^{-1}(W^{-1}(\tau,0)B(\tau))_j(W^{-1}(T,0)w_j(\tau,0))_i d\tau\right) w_i(T,0).\end{aligned}$$

Moreover, by (3.33)

(3.34)

$$(W^{-1}(T,0)\xi)_2 = \sum_{j=1}^{2}\frac{\mu_2(T,0)}{1-\mu_2(T,0)}\int_0^T \mu_j(\tau,0)^{-1}(W^{-1}(\tau,0)B(\tau))_j(W^{-1}(T,0)w_j(\tau,0))_2 d\tau.$$

Note that if $w_1 \in \Sigma_1$ and $w_2 \in \Sigma_2$,

$$|(W^{-1}x)_1| \vee |(W^{-1}x)_2| \leq \sqrt{\frac{f_2(1+f_2)}{f_1(1+f_1)}}\|x\|. \tag{3.35}$$

In fact, first of all, we can suppose that $\|x\| = 1$, and then W and x can be written in the following way:

$$W = \begin{pmatrix} \frac{1}{\sqrt{1+a}} & -\frac{1}{\sqrt{1+b}} \\ \frac{\sqrt{a}}{\sqrt{1+a}} & \frac{\sqrt{b}}{\sqrt{1+b}} \end{pmatrix}, \quad x = \begin{pmatrix} \frac{1}{\sqrt{1+c}} \\ \frac{\sqrt{c}}{\sqrt{1+c}} \end{pmatrix},$$

where $f_1 \leq a, b, c \leq f_2$. Then

$$W^{-1}x = \begin{pmatrix} \frac{\sqrt{1+a}}{\sqrt{1+b}} \frac{\sqrt{b}+\sqrt{c}}{\sqrt{a}+\sqrt{b}} \\ \\ \frac{\sqrt{1+b}}{\sqrt{1+c}} \frac{\sqrt{c}-\sqrt{a}}{\sqrt{a}+\sqrt{b}} \end{pmatrix},$$

which implies (3.35), since

$$\frac{\sqrt{1+a}}{\sqrt{1+c}} \vee \frac{\sqrt{1+b}}{\sqrt{1+c}} \leq \frac{\sqrt{1+f_2}}{\sqrt{1+f_1}}, \quad \frac{\sqrt{b}+\sqrt{c}}{\sqrt{a}+\sqrt{b}} \vee \frac{\sqrt{c}-\sqrt{a}}{\sqrt{a}+\sqrt{b}} \leq \frac{\sqrt{f_2}}{\sqrt{f_1}}.$$

Moreover

$$|(W^{-1}B(t))_i| \leq \frac{\sqrt{1+f_2}}{2\sqrt{f_1}} \|B(t)\|, i = 1, 2, \tag{3.36}$$

and for all $z \in \mathbb{R}^2$, for all $i = 1, 2$

$$\begin{aligned} |z_1| &\leq \frac{1}{\sqrt{1+f_1}} (|(W^{-1}z)_1| + |(W^{-1}z)_2|), \\ |z_2| &\leq \frac{\sqrt{f_2}}{\sqrt{1+f_2}} (|(W^{-1}z)_1| + |(W^{-1}z)_2|). \end{aligned} \tag{3.37}$$

Therefore from (3.32), (3.34), (3.35), (3.36), and Lemma 3.1, setting $c = \frac{1}{2} \frac{1+f_2}{f_1} \sqrt{\frac{f_2}{1+f_1}}$,

$$\begin{aligned} &|(W^{-1}(T,0)\xi)_1| \vee (W^{-1}(T,0)\xi)_2| \\ &\leq c\|B\|_{[0,T]} \left\{ \frac{1}{\mu_1(T,0)-1} \left[\mu_1(T,0) \int_0^T \mu_1(\tau,0)^{-1} d\tau \right.\right. \\ &\left.\left. + \int_0^T \mu_2(T,\tau) d\tau \right] \vee \frac{1}{1-\mu_2(T,0)} \left[\mu_2(T,0) \int_0^T \mu_1(\tau,0)^{-1} d\tau + \int_0^T \mu_2(T,\tau) d\tau \right] \right\} \\ &\leq c\|B\|_{[0,T]} \left\{ \frac{1}{\mu_1(T,0)-1} \left[\mu_1(T,0) \int_0^T e^{-\lambda_0 \tau} d\tau \right.\right. \\ &\left.\left. + \int_0^T e^{-\lambda_0 (T-\tau)} d\tau \right] \vee \frac{1}{1-\mu_2(T,0)} \left[\mu_2(T,0) \int_0^T e^{-\lambda_0 \tau} d\tau + \int_0^T e^{-\lambda_0 (T-\tau)} d\tau \right] \right\} \\ &= c\|B\|_{[0,T]} \left(\frac{\mu_1(T,0)+1}{\mu_1(T,0)-1} \vee \frac{\mu_2(T,0)+1}{1-\mu_2(T,0)} \right) (1-e^{-\lambda_0 T}) \\ &\leq c\|B\|_{[0,T]} \frac{1+e^{-\lambda_0 T}}{1-e^{-\lambda_0 T}} \frac{1-e^{-\lambda_0 T}}{\lambda_0}, \end{aligned}$$

which implies the thesis by (3.37). □

COROLLARY 3.3. *Assume that $A(t)$ and $B(t)$ satisfy the hypotheses of Lemma 3.2 and that $A(t)$ and $B(t)$ are periodic of period T. If $\xi \in \mathbb{R}^2$ is such that there exists $\tau \geq 0$ and $T \geq 0$ for which*

$$\xi = \Phi(T+\tau, \tau)\xi + \int_\tau^{T+\tau} \Phi(T+\tau, p) B(p) dp, \tag{3.38}$$

where $\Phi(t,\tau)$ *is a solution of* (3.25), *then*

$$|\xi_i| \le \frac{c_i}{\lambda_0}\|B\|_{[\tau,T+\tau]},\ i=1,2, \tag{3.39}$$

where λ_0 *and* c_i *are given by* (3.29).

Proof. If $A(t)$ is periodic, there exists a periodic and continuous matrix $P(t)$ and a constant matrix E such that $\Phi(t) = P(t)e^{Et}$, which implies that, for all $n \in \mathbb{N}$, $\Phi(T+\tau,\tau)^n = \Phi(nT+\tau,\tau)$ and $\Phi(T+\tau,\tau) = \Phi((n+1)T+\tau, nT+\tau)$. Therefore from (3.38) it follows by induction that:

$$\xi = \Phi(nT+\tau,\tau)\xi + \int_\tau^{nT+\tau} \Phi(T+\tau,p)B(p)dp\ \forall n \in \mathbb{N},$$

which implies (3.39), by (3.28). □

4. A computational method. As can be deduced from section 1 and the proof of Theorem 2.3, the following computational method for finding the control forces to drive the inverted pendulum on a cart along an assigned curve can be stated.

Given a curve $\gamma \in \mathcal{C}^2(\mathbb{R},\ \mathbb{R}^2)$, *the control force* f *is given by* (1.3), *where* θ *is the solution of system* (2.4) *with initial condition* $(\theta_0,\ \dot\theta_0) = y(1)$, $y(s)$ *being the solution of the following differential equation:*

$$\dot y(s) = (I - \Phi(T,s,y(s)))^{-1}Z(T,s,y(s)), \quad y(0)=0,$$

where $\Phi(t,s,y)$ *and* $Z(t,s,y)$ *are, respectively, the solutions of the systems*

$$\begin{cases} \dot\Phi = \partial_x F(t,s,x(t,s,y))\Phi, \\ \Phi(0) = I \end{cases} \quad \textit{and} \quad \begin{cases} \dot Z = \partial_x F(t,s,x(t,s,y))Z + \partial_s F(t,s,x(t,s,y)), \\ Z(0) = 0, \end{cases}$$

$x(t,s,y)$ *being the solution of the system* $\dot x = F(t,s,x)$, *with* $x(0) = y$ *and where* $F(t,s,x) = (x_2,\ d^{-1}(g\sin x_1 + s\left\langle (\cos x_1, \sin x_1)^T,\ \ddot\gamma(t)\right\rangle))^T$.

As an example we apply this method to a periodic curve γ given by a fifth-order spline of period $T = 5s$. This function has a continuous third-order derivative.

The spline γ satisfies the properties

$$\begin{aligned} &\gamma(0) = (0,0),\ \dot\gamma(0) = (0,-1),\ \ddot\gamma(0) = (-1,0),\ \dddot\gamma(0) = (0,0), \\ &\gamma(1) = (-2-2),\ \gamma(2) = (1,-1),\ \gamma(3) = (2,0),\ \gamma(4) = (-2,2), \end{aligned} \tag{4.1}$$

and $\frac{d^i\gamma(5)}{dt^i} = \frac{d^i\gamma(0)}{dt^i}$, for $i = 0,\ldots,3$, and is represented in Figure 4.1; it is $\|\ddot\gamma\|_\infty = 2.2m/s^2$. For numerical computation of γ use, for instance, Matlab Spline Toolbox.

Assume $d = 1$, $g = 9.8\frac{m}{s^2}$. By applying the method outlined above, we can find a control force that drives the pendulum along the spline without overturning. In particular the initial condition for system (2.4) is given by $(\theta_0,\ \dot\theta_0) = (0.0283,\ 0.0030)$, and the couple $(\theta,\ \dot\theta)$ associated to the solution is shown in Figure 4.2; it is $|\theta(t)| \le 0.085$, $|\dot\theta(t)| \le 0.24$; in fact, the pendulum rod remains almost vertical (see Figure 4.3). Remark that the bounds given by Theorem 2.3 are $|\theta(t)| \le 0.4861$, $|\dot\theta(t)| \le 1.1727$. In this example, these bounds may appear very large, but this is justified by the fact that they must apply to any trajectory whose acceleration is bounded by $2.2m/s^2$.

DYNAMICS OF STOICHIOMETRIC BACTERIA-ALGAE INTERACTIONS IN THE EPILIMNION[*]

HAO WANG[†], HAL L. SMITH[‡], YANG KUANG[‡], AND JAMES J. ELSER[§]

Abstract. Bacteria-algae interaction in the epilimnion is modeled with the explicit consideration of carbon (energy) and phosphorus (nutrient). Global qualitative analysis and bifurcation diagrams of this model are presented. We hypothesize that there are three dynamical scenarios determined by the basic reproductive numbers of bacteria and algae. Effects of key environmental conditions are examined through these scenarios and from systematic and extensive simulations. It is also shown that excessive sunlight will destroy bacterial communities. Bifurcation diagrams for the depth of epilimnion mimic the profile of Lake Biwa, Japan. Competition of bacterial strains are modeled to examine Nishimura's hypothesis that in severely P-limited environments such as Lake Biwa, P-limitation exerts more severe constraints on the growth of bacterial groups with higher nucleic acid contents, which allows low nucleic acid bacteria to be competitive.

Key words. stoichiometry, bacteria, cell quota, persistence, competitive system

1. Introduction.

Stoichiometry is the accounting behind chemistry. It deals with the balance of multiple chemical elements in chemical reactions. Many chemical processes are effectively studied and modeled with the applications of some simple yet powerful stoichiometric constraints. Since biomass growth is a biochemical process, ubiquitous and natural stoichiometric constraints may also be useful for modeling species growth and interactions [15, 23, 27, 28]. This concept forms the framework of the newly emerging research area of ecological stoichiometry, the study of the balance of energy and multiple chemical elements in ecological interactions [37].

It is observed that plant quality can dramatically affect the growth rate of herbivorous grazers and may even lead to their extinction. Specifically, if the quantity of an essential element in plant biomass is lower than the minimum threshold for its consumer, then the consumer's growth rate may suffer. This has been shown for both aquatic [30, 37] and terrestrial systems [31]. Stoichiometry-based population models explicitly model the highly varying nutritional quality of plant resources for consumer-resource dynamics.

Solar energy (for producing organic carbon) and nutrients (phosphorus, nitrogen, etc.) are important factors regulating ecosystem characteristics and species density. Phosphorus is often a limiting nutrient for algal production in lakes [11]. For example,

in Lake Biwa, Japan, phosphorus is an extremely limiting element for both algal and bacterial growth. Lake Biwa is a large (surface area, $674km^2$) and deep (maximum depth, $104m$) lake located in the central part of Honshu Island, Japan. Nishimura, Kim, and Nagata [32] used flow cytometry to examine seasonal variations in vertical distributions of bacterioplankton in Lake Biwa. They hypothesized that in severely phosphorus (P)-limited environments such as Lake Biwa, P-limitation exerts more severe constraints on the growth of bacterial groups with higher nucleic acid (HNA) contents, which allows low nucleic acid (LNA) bacteria to be competitive and become an important component of the microbial community. A main purpose of this paper is to examine this hypothesis theoretically.

The interaction between bacteria and algae in pelagic ecosystems is complex [6]. Bacteria are nutrient-rich organisms whose growth is easily limited by nutrient supply and organic matter produced by plants and algae, which have very flexible stoichiometry compared to bacteria [29]. Suspended algae, also called phytoplankton, live in almost all types of aquatic environments. Algae grow in open water by taking up nutrients such as phosphorus and nitrogen from the water and capturing energy from sunlight. Extra energy in the form of organic carbon can be exuded from algae during photosynthesis. Bacteria require dissolved organic carbon (DOC) as a source of energy and carbon. Hence, algae are an important source of DOC to bacteria. However, bacteria and algae compete with each other for phosphorus if bacteria are limited by phosphorus [18].

In temperate lakes, the water column is seasonally separated by a thermocline into two parts, epilimnion and hypolimnion (Figure 1.1). The epilimnion is the upper warmer layer overlying the thermocline. It is usually well mixed. The hypolimnion is the bottom colder layer. The absorption and attenuation of sunlight by the water itself, by dissolved substances, and by algae are major factors controlling the potential photosynthesis and temperature. Solar energy, essential for algae, decreases rapidly with depth. Nutrients are redistributed from epilimnion to hypolimnion as the plankton detritus gradually sinks to lower depths and decomposes; the redistribution is partially offset by the active vertical migration of the plankton and by eddy diffusion across the thermocline [19]. In many lakes, algal DOC exudation is a prime energy source for bacterial growth. To simplify the study of algal stimulation of bacterial growth, we assume below that algal DOC exudation is the only source for bacterial subsistence.

Algae dynamics in a lake system have been modeled by many researchers [2, 8, 9, 20, 21, 22]. Chemostat theory and experiments have been applied frequently to nutrient competition of bacteria [4, 14, 34, 35]. For example, bacteria-algae interaction was modeled by Bratbak and Thingstad [3]. Their work provides a useful framework to develop a more realistic model. In recent years, modeling stoichiometric food web systems has gained much attention [1, 9, 15, 17, 24, 25, 26, 27]. However, these models are not directly applicable to the phytoplankton-bacteria interaction. Our models, motivated by the experiments and hypotheses of Nishimura, Kim, and Nagata [32], can be viewed as an extension as well as a variation of the work of Diehl, Berger, and Wöhrl [9] where they modeled algal growth experiments subject to varying light and nutrient availability, but without bacteria.

In the following, we will model the ecological stoichiometry of bacteria-algae interactions in the epilimnion under the "well mixed" assumption [2, 20, 21]. We perform a global qualitative analysis and present bifurcation diagrams illustrating model behavior. We discuss the implications of these bifurcation diagrams and the basic reproductive numbers of bacteria and algae. Proofs of mathematical results are placed

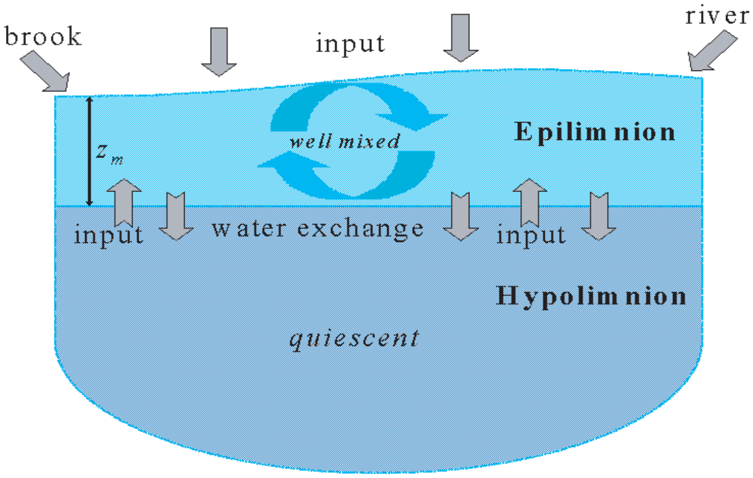

FIG. 1.1. *The cartoon lake system for our mathematical modeling.*

in the appendix. Competing bacterial strains are modeled to test some hypotheses of Nishimura, Kim, and Nagata [32]. A brief discussion section concludes the paper.

2. Modeling bacteria-algae interactions. Our model consists of five highly interconnected nonlinear differential equations, tracking the rates of change for algae, algal cell quota, dissolved mineral phosphorus, heterotrophic bacteria, and dissolved organic carbon (see Table 2.1). The algal growth is assumed to depend on the light intensity and phosphorus availability. This will be modeled according to the Lambert-Beer law and the Droop equation. The rates of change for Q, P, B are modeled according to standard approaches. In addition, algal sinking and water exchange between epilimnion and hypolimnion are included in the model. The challenge is to model the algal exudation of DOC, which is needed in the DOC equation.

According to the Lambert–Beer law, the light intensity at the depth s of a water column with algal abundance A is [20]

$$I(s, A) = I_{in} \exp[-(kA + K_{bg})s].$$

The algal carbon uptake function takes the Monod form $\frac{I(s,A)}{I(s,A)+H}$ [9].

The epilimnion is well mixed overnight [9, 20]. The depth-averaged algal growth function contains the factor (for carbon) [2, 20]

$$h(A) \equiv \frac{1}{z_m} \int_0^{z_m} \frac{I(s, A)}{I(s, A) + H} ds = \frac{1}{z_m(kA + K_{bg})} \ln\left(\frac{H + I_{in}}{H + I(z_m, A)}\right) \tag{2.1}$$

and the Droop term (for phosphorus) $1 - \frac{Q_m}{Q}$, where Q_m is the minimum algal phosphorus cell quota and Q is the actual algal phosphorus cell quota.

Algal sinking takes place at the interface between epilimnion and hypolimnion, and its rate is negatively related to the volume of epilimnion, because with a larger volume there is relatively less proportion of total species abundances or element concentrations for sinking. For convenience, we assume that the algal sinking rate is inversely proportional to the mixing layer depth z_m [2, 9]. D is the water exchange rate across the interface between epilimnion and hypolimnion and between the epilimnion and the inflow and outflow (Figure 1.1). We assume that there is a constant

Table 2.1
Variables in the bacteria-algae system (2.2).

Var.	Meaning	Unit
A	algal carbon density	mgC/m^3
Q	algal cell quota (P:C)	gP/gC $(= mgP/mgC)$
P	dissolved mineral phosphorus concentration	mgP/m^3
B	heterotrophic bacterial abundance	mgC/m^3
C	DOC concentration	mgC/m^3

phosphorus concentration, P_{in}, in the hypolimnion and in the inflow. Using the same reasoning as for algal sinking, we assume the water exchange is inversely proportional to z_m. We assume that bacteria have a fixed stoichiometry, since compared to algae, their elemental composition is relatively constant [29]. We assume that bacterial growth functions for carbon and phosphorus take the Monod form: $f(P) = \frac{P}{K_P+P}$ and $g(C) = \frac{C}{K_C+C}$, where K_P, K_C are half-saturation constants, respectively.

The exudation rate of DOC by algae is the difference between the potential growth rate attained when growth is not P-limited, $\mu_A A \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds$, and the actual growth rate, $\mu_A A(1 - \frac{Q_m}{Q}) \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds$, which gives us the form $\mu_A A \frac{Q_m}{Q} \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds$. This actually assumes that algae always fix carbon at rate $\mu_A A \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds$ and then have to dispose of excessive carbon. As in [9], we assume that the algal phosphorus uptake rate is $\rho(Q,P) = \rho_m(\frac{Q_M-Q}{Q_M-Q_m}) \frac{P}{M+P}$. At the minimum cell quota, the specific phosphorus uptake rate is just a saturating function of P. At the maximum cell quota, there is no uptake. The algal cell quota dilution rate is proportional to the algal growth rate [2].

The above assumptions yield the following bacteria-algae interaction system:

$$\begin{aligned}
\frac{dA}{dt} &= \underbrace{\mu_A A \left(1 - \frac{Q_m}{Q}\right) \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds}_{\text{algal growth limited by nutrient and energy}} - \underbrace{l_m A}_{\text{respiration}} - \underbrace{\frac{\nu + D}{z_m} A}_{\text{sinking and exchange}}, \\
\frac{dQ}{dt} &= \underbrace{\rho(Q,P)}_{\text{replenishment}} \underbrace{- \mu_A Q \left(1 - \frac{Q_m}{Q}\right) \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds}_{\text{dilution due to growth}}, \\
\frac{dP}{dt} &= \underbrace{\frac{D}{z_m}(P_{in} - P)}_{\text{P input and exchange}} - \underbrace{\rho(Q,P)A}_{\text{P consumption by algae}} - \underbrace{\theta \mu_B B f(P) g(C)}_{\text{P consumption by bacteria}}, \\
\frac{dB}{dt} &= \underbrace{\mu_B B f(P) g(C)}_{\text{bacterial growth}} - \underbrace{(\mu_r + \mu_g) B}_{\text{respiration and grazing}} - \underbrace{\frac{D}{z_m} B}_{\text{exchange}}, \\
\frac{dC}{dt} &= \underbrace{\mu_A A \frac{Q_m}{Q} \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds}_{\text{DOC exudation from algae}} - \underbrace{\frac{1}{r} \mu_B B f(P) g(C)}_{\text{DOC consumption by bacteria}} - \underbrace{\frac{D}{z_m} C}_{\text{exchange}}.
\end{aligned} \tag{2.2}$$

In the rest of this paper, we assume the following parameter values (with units and sources given in Table 2.2) for numerical simulations: $I_{in} = 300$, $k = 0.0004$, $K_{bg} = 0.3$, $H = 120$, $z_m = 30$, $Q_m = 0.004$, $Q_M = 0.04$, $\rho_m = 0.2$, $M = 1.5$, $\mu_A = 1$,

Table 2.2
Parameters in bacteria-algae system (2.2).

Par.	Meaning	Value	Ref.
I_{in}	light intensity at surface	$300\mu mol(photons)/(m^2 \cdot s)$	[9]
k	specific light attenuation coeff. of algal biomass	0.0003–$0.0004 m^2/mgC$	[2, 9]
K_{bg}	background light attenuation coefficient	0.3–$0.9/m$	[2, 9]
H	h.s.c.[1] for light-dependent algal production	$120\mu mol(photons)/(m^2 \cdot s)$	[9]
z_m	depth of epilimnion	$> 0m$, $30m$ in Lake Biwa	[32]
Q_m	algal cell quota at which growth ceases	$0.004gP/gC$	[9]
Q_M	algal cell quota at which nutrient uptake ceases	$0.04gP/gC$	[9]
ρ_m	maximum specific algal nutrient uptake rate	0.2–$1gP/gC/day$	[2, 9]
M	h.s.c. for algal nutrient uptake	$1.5mgP/m^3$	[9]
μ_A	maximum algal specific production rate	$1.0/day$	[9]
l_m	algal specific maintenance respiration loss	0.05–$0.13/day$	[2, 9]
ν	algal sinking velocity	0.05–$0.25m/day$	[2, 9]
D	water exchange rate	$0.02m/day$	[2]
P_{in}	phosphorus input	0–$150mgP/m^3$	[2]
K_P	P-dependent h.s.c. for bacterial growth	0.06–$0.4mgP/m^3$	[4]
K_C	C-dependent h.s.c. for bacterial growth	100–$400mgC/m^3$	[5]
μ_B	maximum bacterial growth rate	1.5–$4.0/day$	[4, 5]
θ	bacterial fixed cell quota	0.0063–$0.1585mgP/mgC$	[7, 16]
μ_r	bacterial respiration loss	0.1–$2.5/day$	[5, 13]
μ_g	grazing mortality rate of bacteria	0.06–$0.36/day$	[32]
r	C-dependent yield constant for bacterial growth	0.31–0.75	[10, 13]

[1] "h.s.c." stands for half-saturation constant.

$l_m = 0.1$, $\nu = 0.25$, $D = 0.02$, $P_{in} = 120$, $K_P = 0.06$, $K_C = 100$, $\mu_B = 3$, $\theta = 0.1$, $\mu_r = 0.2$, $\mu_g = 0.1$, $r = 0.5$. These specific values are taken from [2, 9] or selected from within the reasonable ranges (see Table 2.2).

Our first theorem states that there is a bounded set which all solutions of the system (2.2) eventually enter.

Theorem 1. *The system* (2.2) *is dissipative.*

3. Algae dynamics. In order to have a comprehensive understanding of the model (2.2), we study first the algae dynamics without bacteria ($B = 0$):

$$\begin{aligned} \frac{dA}{dt} &= \mu_A A \left(1 - \frac{Q_m}{Q}\right) \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds - l_m A - \frac{\nu + D}{z_m} A \equiv A\Psi(A,Q), \\ \frac{dQ}{dt} &= \rho(Q,P) - \mu_A Q \left(1 - \frac{Q_m}{Q}\right) \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds, \\ \frac{dP}{dt} &= \frac{D}{z_m}(P_{in} - P) - \rho(Q,P)A. \end{aligned} \tag{3.1}$$

From (2.1), we recall that

$$h(A) = \frac{1}{z_m} \int_0^{z_m} \frac{I(s,A)}{I(s,A)+H} ds. \tag{3.2}$$

$h(A)$ is decreasing in A, and $0 < h(A) < 1$. Furthermore, $Ah(A)$ is increasing in A. Biologically meaningful initial conditions are given by $A(0) > 0$, $\;Q_m \le Q(0) \le Q_M$,

$P(0) \geq 0$. We analyze this system on the positively invariant set

$$\Omega = \{(A, Q, P) \in \mathbb{R}^3_+ \mid A \geq 0,\, Q_m \leq Q \leq Q_M,\, P \geq 0\}.$$

Obviously the set where $A = 0$ is invariant for the system. It is easy to see that $Q_m < Q < Q_M$ whenever $Q_m < Q(0) < Q_M$; that is, the cell quota stays within the biologically confined interval.

There can be two types of steady state solutions for system (3.1): the algae extinction steady state $E_0 = (0, \hat{Q}, P_{in})$, where

$$\hat{Q} = \frac{\beta(P_{in})Q_M + \mu_A Q_m h(0)}{\beta(P_{in}) + \mu_A h(0)} > 0 \quad \text{with} \quad \beta(P) = \frac{\rho_m}{Q_M - Q_m}\frac{P}{M + P},$$

and positive steady state(s) $E^* = (\bar{A}, \bar{Q}, \bar{P})$ with $\Psi(\bar{A}, \bar{Q}) = 0$.

The standard computation shows that the basic reproductive number for algae is

$$R_0 = \frac{\mu_A \beta(P_{in})(Q_M - Q_m)h(0)}{(\beta(P_{in})Q_M + \mu_A Q_m h(0))(l_m + \frac{\nu + D}{z_m})} = \frac{\mu_A h(0)(1 - Q_m/\hat{Q})}{l_m + \frac{\nu + D}{z_m}}.$$

Here $h(0) = \frac{1}{z_m K_{bg}} \ln(\frac{H + I_{in}}{H + I_{in}\exp(-z_m K_{bg})})$ is the potential average sunlight intensity in the epilimnion without algal shading. Indeed, R_0 is calculated from $\Psi(0, \hat{Q})$ so that $R_0 > 1 \Leftrightarrow \Psi(0, \hat{Q}) > 0$. R_0 is the average amount of new algae produced by one unit of algae (measured in carbon content) during the algal life span in the epilimnion. It is an indicator of algal viability. Part of Theorem 2 states that R_0 is an indicator for the local stability of E_0.

We observe that increasing sunlight input or phosphorus input enhances algal viability, since $\frac{\partial R_0}{\partial I_{in}} = \frac{\partial R_0}{\partial h(0)}\frac{\partial h(0)}{\partial I_{in}} > 0$ and $\frac{\partial R_0}{\partial P_{in}} = \frac{\partial R_0}{\partial \beta(P_{in})}\frac{\partial \beta(P_{in})}{\partial P_{in}} > 0$. Weakening water exchange enhances algal viability, since $\frac{\partial R_0}{\partial D} < 0$.

Theorem 2 is our main mathematical result. When $R_0 < 1$, we establish the local and global stability of E_0, which is equivalent to saying that algae will die out. It can be shown that there is no positive equilibrium E^* when $R_0 < 1$, in which case the existing results of general competitive systems can be applied to prove the global stability of E_0. When $R_0 > 1$, we prove that E_0 is unstable, algae are uniformly persistent, and there is a unique positive steady state E^*.

Theorem 2. *If $R_0 < 1$, E_0 is locally asymptotically and globally asymptotically stable. $R_0 > 1$ implies that E_0 is unstable, there exists a unique positive equilibrium E^*, and algae uniformly persist: there exists $\epsilon > 0$ such that*

$$\liminf_{t \to \infty} A(t) > \epsilon$$

for all solutions with $A(0) > 0$.

In the following, we show that the global stability of E^* is true in two special cases. It is known that the algal cell quota changes on a much faster timescale than the algal (carbon) biomass and the nutrient [23]. Additionally, since dQ/dt is linear in Q, there is a unique solution to $dQ/dt = 0$. Hence, the fast-slow approximation is achieved by setting $dQ/dt = 0$ and substituting the solution of $dQ/dt = 0$ into the other equations. Then the following theorem holds.

Theorem 3. *E^* is globally asymptotically stable for the planar system obtained from the system* (3.1) *by setting $dQ/dt = 0$, when $R_0 > 1$.*

The next theorem gives a partial result of global stability of E^*.

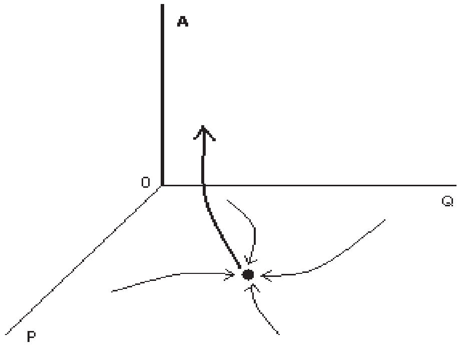

FIG. 3.1. *Algae dynamics phase space when $R_0 > 1$. The algae extinction equilibrium $E_0 = (0, \hat{Q}, P_{in})$ is globally attracting on the subspace $\Omega_2 = \{x \in \Omega \mid A = 0\}$, but is a uniform weak repeller for $\Omega_1 = \{x \in \Omega \mid A \neq 0\}$, and A is persistent in this case.*

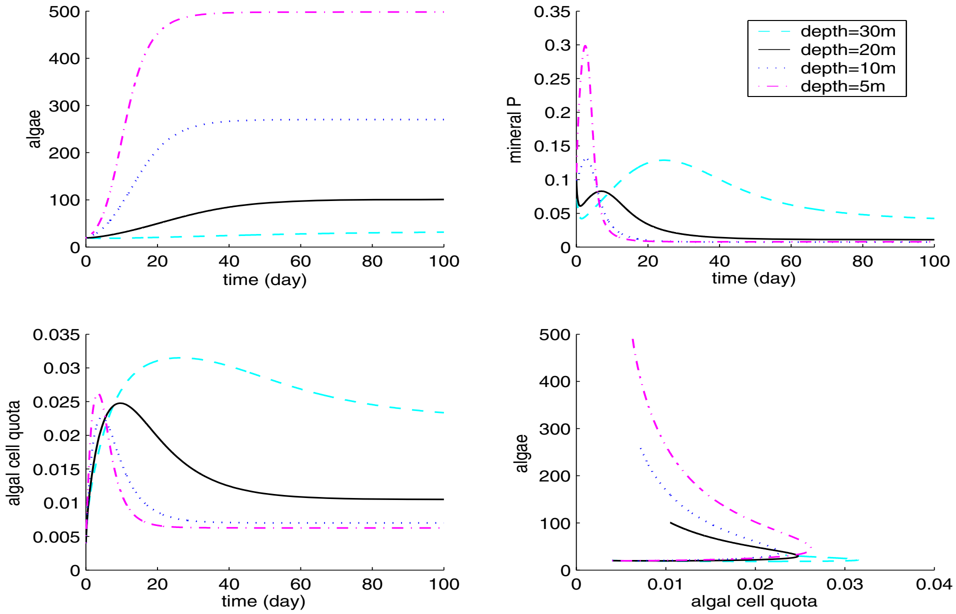

FIG. 3.2. *Algae dynamics without bacteria with respect to different depths of the mixing layer: All the variables approach the positive equilibrium in about two months. The simulation benefited from the explicit expression of $h(A)$ given in* (2.1).

THEOREM 4. *E^* is globally asymptotically stable when $R_0 > 1$ and $l_m = \nu = 0$.*

The property that a locally asymptotically stable (in linear approximation) steady state is globally attracting is an open condition in parameters [36]. Hence, E^* is still globally asymptotically stable for small positive l_m and ν.

Our main mathematical results for the system (3.1) are briefly expressed by the phase space diagram (Figure 3.1) for the case $R_0 > 1$. Typical solutions are simulated in Figure 3.2 for different depths of epilimnion. Algal abundance is negatively related to the depth because the average sunlight intensity in the epilimnion is lower when the epilimnion is deeper. The eventual P concentration is relatively large when the epilimnion is deep, whereas the eventual concentration is small when it is shallow.

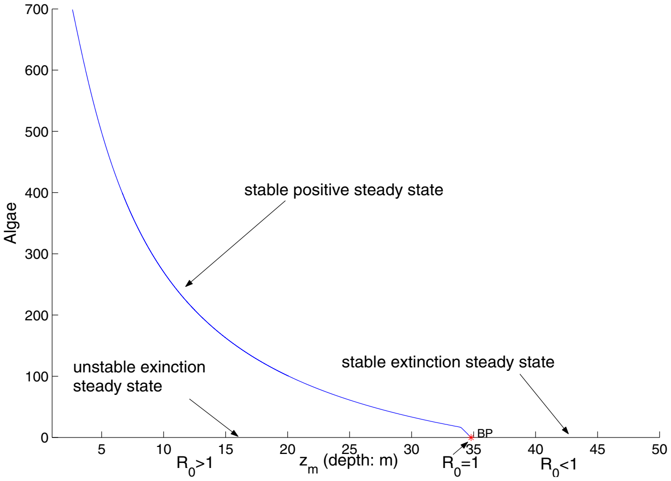

Fig. 3.3. *Bifurcation diagram for algae dynamics without bacteria. The shallower the better for algae in the algae system* (3.1)*. This bifurcation diagram confirms our mathematical findings. When $R_0 > 1$, the algae extinction equilibrium is unstable, and the only positive equilibrium appears to be globally attractive. The branching point occurs at $R_0 = 1$. When $R_0 < 1$, there is no positive equilibrium, and the algae extinction equilibrium is globally attracting. This numerical result is generated by the continuation software "MatCont" in MATLAB.*

Eventual concentrations at the depths $5m, 10m, 20m$ are similar and low, which indicates that P becomes limiting in a shallow epilimnion. In contrast, the algal cell quota is positively related to epilimnion depth. This is due to the fact that the algal cell quota is positively related to the P concentration. Hence, epilimnion depth has two influences on algae in our simulation: It is positively related to P (at least in Figure 3.2) and negatively related to the average sunlight intensity through the average light uptake integral term. In the case of Figure 3.2, if C has a larger effect than P, then algal abundance is negatively related to the depth. It is not clear whether or not algal abundance can be positively related to depth when P is more limited than C in some lakes. The algae-quota phase plane shows that algae and their cell quotas are positively related in the very beginning, but they are negatively related eventually, demonstrating a general phenomenon of "larger quantity leads to lower quality." The bifurcation diagram with respect to the mixing layer depth (Figure 3.3) illustrates that algae love shallower epilimnions and also illustrates our mathematical findings.

4. Bacteria-algae interaction dynamics.

We return to the original bacteria-algae system (2.2). We analyze this system on the positively invariant set

$$\Omega = \{(A, Q, P, B, C) \in \mathbb{R}^5_+ \mid A \geq 0,\ \ Q_m \leq Q \leq Q_M,\ \ P \geq 0, B \geq 0, C \geq 0\}.$$

The system (2.2) may have three types of equilibria: the extinction steady state $e_0 = (0, \hat{Q}, P_{in}, 0, 0)$, the bacteria extinction only steady state $e_1 = (\bar{A}, \bar{Q}, \bar{P}, 0, \bar{C})$, and the coexistence steady state(s) e^* with all components positive (see Figure 4.1). We can calculate the basic reproductive number for bacteria, R_1, by linearizing about e_1. We obtain

$$R_1 = \frac{\mu_B f(\bar{P}) g(\bar{C})}{\mu_r + \mu_g + \frac{D}{z_m}},$$

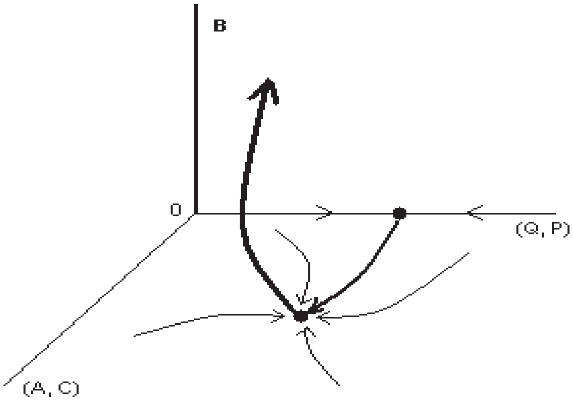

Fig. 4.1. *An abstract phase space diagram for system* (2.2) *when* $R_0 > 1$ *and* $R_1 > 1$. Q, P *are placed on one axis (say x-axis),* A, C *are placed on another axis (say y-axis), and* B *is on the vertical axis (z-axis). Extinction equilibrium* $e_0 = (0, \hat{Q}, P_{in}, 0, 0)$ *is globally attracting on the subspace* $\{x \in \Omega \mid A = B = C = 0\}$*, but is a repeller for* $\Omega_2 = \{x \in \Omega \mid B = 0\}$*. Bacteria extinction only equilibrium* $e_1 = (\bar{A}, \bar{Q}, \bar{P}, 0, \bar{C})$ *is globally attracting on the subspace* Ω_2*, but is a repeller for* $\Omega_1 = \{x \in \Omega \mid B \neq 0\}$*. Bacteria persist, and at least one coexistence equilibrium exists.*

where $\bar{C} = \frac{\mu \bar{A} z_m}{D} \frac{Q_m}{\bar{Q}} h(\bar{A})$ and $\bar{P}$, $\bar{A}$, $\bar{Q}$ are components of E^* in the system (3.1). This number is defined under the assumption $R_0 > 1$. When $R_0 < 1$, we have proved that there is no positive equilibrium in system (3.1), which means at least one of $\bar{P}$, $\bar{A}$, $\bar{Q}$ is undefined or out of the region of interest. Biologically, R_1 is the average biomass of new bacteria produced by one unit of bacterial biomass during the bacterial life span in epilimnion. R_1 should be an indicator for the local stability of e_1; hence, R_1 is an indicator for the bacterial viability when $R_0 > 1$.

A simple sufficient condition for the extinction of both algae and bacteria is given in the next theorem.

Theorem 5. *When* $\mu_A h(0) < \frac{D}{z_m}$ *(* $\Leftrightarrow \frac{\mu_A}{K_{bg}} \ln(\frac{H+I_{in}}{H+I_{in}\exp(-z_m K_{bg})}) < D$ *), both algae and bacteria will die out; i.e.,* $\lim_{t\to\infty} A(t) = \lim_{t\to\infty} B(t) = 0$ *for all nonnegative initial conditions.*

It is easy to observe that $R_0 < \frac{\mu_A h(0)}{D/z_m}$. Hence $\mu_A h(0) < \frac{D}{z_m}$ implies $R_0 < 1$.

Figure 4.2 confirms that both species go extinct when $R_0 < 1$, a weaker condition than the condition $\mu_A h(0) < \frac{D}{z_m}$ in Theorem 5. The line-filled region expands rapidly when the sunlight increases past $800 \mu mol(photons)/(m^2 \cdot s)$. This suggests that high light intensity can negatively affect bacteria, even driving them to extinction due to competition with algae. Hence, the balance of light and nutrient is significant for the lake system, which is in agreement with the “light:nutrient” hypothesis [38].

Branching points in Figures 3.3 and 6.1 are identical, since all of them are determined by the same condition $R_0 = 1$. R_1 does not affect this branching point, since R_1 is defined only if $R_0 > 1$. $R_0 > 1$ implies $R_1 > 1$ in the white region of Figure 4.2. Upon existent mathematical results, we hypothesize that there are three types of dynamics: (1) $R_0 > 1, R_1 > 1$ ensure the persistence of species (white region in Figure 4.2); (2) $R_0 > 1, R_1 < 1$ enable the persistence of algae but the extinction of bacteria (line-filled region in Figure 4.2); (3) $R_0 < 1$ leads to the extinction of all species (grey region in Figure 4.2).

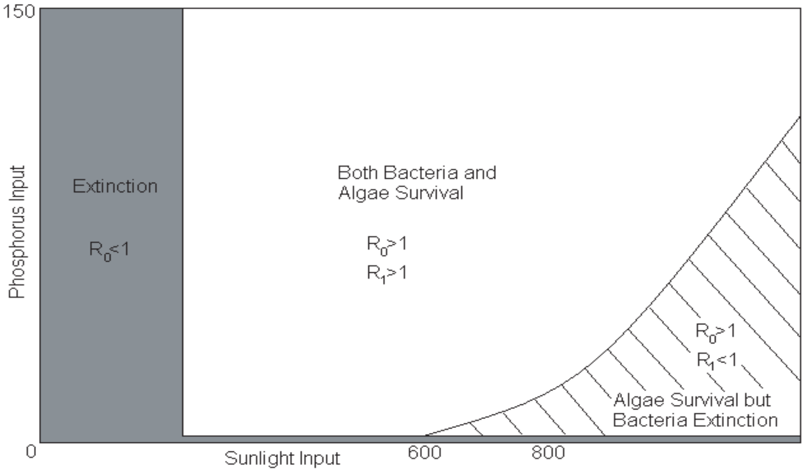

FIG. 4.2. *Regions of P_{in} versus I_{in} for survival and extinction of bacteria and algae. Both algae and bacteria go extinct ($R_0 < 1$) in the grey region. Both algae and bacteria survive ($R_0 > 1, R_1 > 1$) in the white region. Algae survive, but bacteria go extinct ($R_0 > 1, R_1 < 1$) in the line-filled region. We run simulations of the system* (2.2) *for each pair of (I_{in}, P_{in}) and then put the point in the grey region if both A and B go to zero, in the white region if both persist, and in the line-filled region if A persists, but B goes to zero.*

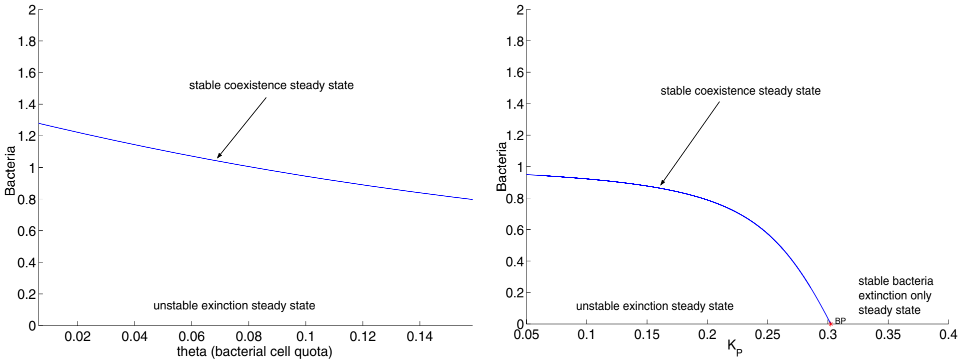
5. Competing bacterial strains. In lake ecosystems, bacteria comprise the most important trophic level for processing dissolved organic matter (DOM) and consume almost half of the primary production [32]. Most existing studies have treated bulk bacterial communities as a homogeneous pool, even though they consist of diverse subgroups that differ in metabolic state, DOM use, growth rate, susceptibility to grazing, and phylogenetic affiliations. One of the challenges for aquatic microbial ecology is to clarify variations and regulation of different bacterial subgroups in order to better understand the internal dynamics of the bacterioplankton "black box."

Growth characteristics and ecological roles of LNA bacteria are controversial. Some previous studies have claimed that LNA bacteria represent less active, dormant, or even dead cells. However, Nishimura, Kim, and Nagata [32] found that the growth rates of LNA bacteria were comparable to or even exceeded HNA bacteria in Lake Biwa. This is probably because LNA bacteria have higher nutrient uptake efficiencies (this means bacteria take up nutrients efficiently even at very low external concentrations, i.e., have a low half-saturation constant for P) and lower requirements for P (this means less P per unit carbon is needed, or a smaller cell quota). An important implication of this scenario is that LNA bacteria, under severe P-limitation conditions, represent an "active" subgroup that outcompetes HNA bacteria and hence may play an important role in the functioning of the microbial loop [32]. In fact, both of these seemingly contradictory statements can be correct under different situations. One of our main motivations for this work is to examine these statements theoretically.

To examine the statement that "LNA bacteria have lower requirements for P," we plot the bifurcation diagram of the bacterial variable with respect to the cell quota parameter θ for the system (2.2). This is done in Figure 5.1(a). Clearly, this figure supports the "P requirement" hypothesis, since a lower bacterial cell quota gives higher bacterial abundance at equilibrium. The second statement, "LNA bacteria have higher nutrient uptake efficiencies," is supported by Figure 5.1(b), which has



(a) Bacteria vs θ: supporting 'P requirement' hypothesis. θ is the bacterial homeostasis cell quota.

(b) Bacteria vs K_P: supporting 'nutrient uptake efficiency' hypothesis. K_P is the P-dependent half-saturation constant for the bacterial growth.

FIG. 5.1. *We examine Nishimura's hypotheses by system* (2.2).

higher sensitivity than Figure 5.1(a). This seems to suggest that "nutrient uptake efficiency" is probably the key factor for LNA bacteria to dominate HNA bacteria near the surface since this is where P is most limiting.

To examine Nishimura's hypothesis, we model the competition of two bacterial strains, HNA bacteria (B_1) and LNA bacteria (B_2), and assume these two strains are heterogeneous in P usage and the maximum growth rate, but homogeneous in C usage. Elser et al. [12], and Sterner and Elser [37] have proposed the "growth rate hypothesis" to explain variation among organisms in biomass C:P and N:P ratios. The growth rate hypothesis states that differences in organismal C:N:P ratios are caused by differential allocations to RNA necessary to meet the protein synthesis demands of rapid rates of biomass growth and development [37, p. 144]. Due to the growth rate hypothesis, the bacterial cell quota is strongly correlated to the maximum growth rate; that is, $\theta_1/\theta_2 = \iota\mu_1/\mu_2$, where ι is a positive constant. For convenience, we assume $\theta_1/\theta_2 = \mu_1/\mu_2$. With these assumptions, the competition system takes the form

$$
\begin{aligned}
\frac{dA}{dt} &= \mu_A A\left(1-\frac{Q_m}{Q}\right)h(A) - l_m A - \frac{\nu + D}{z_m}A,\\
\frac{dQ}{dt} &= \rho(Q,P) - \mu_A Q\left(1-\frac{Q_m}{Q}\right)h(A),\\
\frac{dP}{dt} &= \frac{D}{z_m}(P_{in}-P) - \rho(Q,P)A - [\theta_1\mu_1 B_1 f_1(P) + \theta_2\mu_2 B_2 f_2(P)]g(C),\\
\frac{dB_1}{dt} &= \mu_1 B_1 f_1(P) g(C) - (\mu_r + \mu_g)B_1 - \frac{D}{z_m}B_1,\\
\frac{dB_2}{dt} &= \mu_2 B_2 f_2(P) g(C) - (\mu_r + \mu_g)B_2 - \frac{D}{z_m}B_2,\\
\frac{dC}{dt} &= \mu_A A\frac{Q_m}{Q}h(A) - \frac{1}{r}[\mu_1 B_1 f_1(P) + \mu_2 B_2 f_2(P)]g(C) - \frac{D}{z_m}C,
\end{aligned}
\tag{5.1}
$$

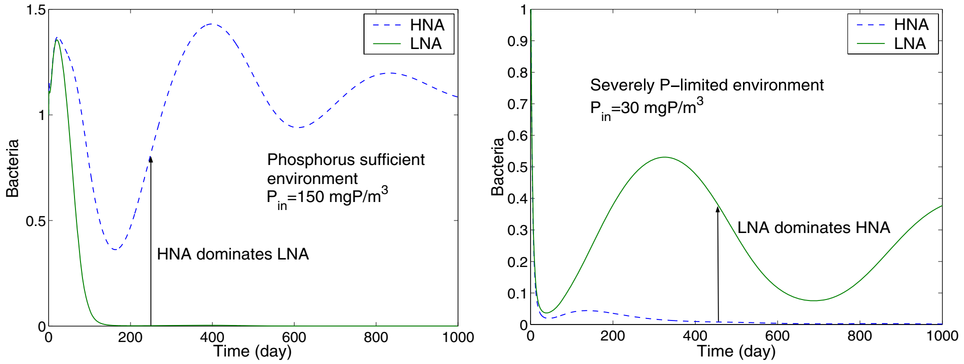


FIG. 5.2. *Under different lake environments, a different bacterial strain dominates.* $\mu_1 = 4, \mu_2 = 2, K_1 = 0.15, K_2 = 0.06, \theta_1 = 0.1, \theta_2 = 0.05$ *with the same units as in Table* 2.2.

where $f_i(P) = \frac{P}{K_i+P}$, $i = 1, 2$. Since the maximum LNA bacteria growth rate is lower and LNA bacteria have higher nutrient uptake efficiencies, it is biologically reasonable to assume that $\mu_1 > \mu_2$, $K_1 > K_2$.

The positivity and dissipativity of the system (5.1) obviously hold, and the proof can be formulated in a fashion similar to that of Theorem 1.

As we can see from Figure 5.2, HNA bacteria grow faster than LNA bacteria whenever P is sufficient, simply because in such situations the maximum HNA bacteria growth rate is greater than that of the LNA bacteria. But LNA bacteria grow faster than HNA bacteria whenever P is severely limited (Figure 5.2), because LNA bacteria have higher nutrient uptake efficiencies and lower requirements for P. Therefore, these seemingly conflicting phenomena can happen under distinct nutrient conditions.

We can seek the expression of the potential positive steady state of the system (5.1). From the bacterial equations, we have

$$\mu_i f_i(P) g(C) = (\mu_r + \mu_g) + \frac{D}{z_m}$$

for the potential positive steady state. Solving it for P, we obtain

$$P = \frac{aK_i}{\mu_i g(C) - a},$$

where $a = (\mu_r + \mu_g) + \frac{D}{z_m}$ is a constant. Assume the system (5.1) has a positive steady state; then $\mu_i g(C) > a$ holds for $i = 1, 2$. For a fixed C level, the P level for the potential positive steady state of that bacterial strain is increasing in K_i, but decreasing in μ_i. Since K_2 is smaller, LNA bacteria have more chance to survive because of the lower level of P required to reach its potential positive steady state level. However, μ_2 is also smaller, which can reduce the LNA bacteria's chance to survive because of the higher level of P required to obtain its potential positive steady state level. In other words, K_i and μ_i work together in a nonlinear fashion. These arguments are only true for the case when a single steady state is globally attractive, in which case only one bacterial strain persists (see Figure 5.2). These bacterial strains may coexist in the form of limit cycles, as periodic solutions are possible even for system (2.2) (for example, Figure 5.3).

6. Discussion. Mechanistically formulated mathematical models of population dynamics are sought after since they often have advantages over phenomenologically derived ad hoc models in generating plausible and verifiable dynamics. However, the challenge of developing a mechanistic and predictive theory for biological systems is daunting. Exciting progress in understanding and modeling ecological systems in the last decade has been achieved through the application of the theory of ecological stoichiometry [37] and the consideration of interactions between nutrient and light availability [8, 9, 20, 21, 22]. Our models (2.2) and (5.1), hybrids of mechanistic and phenomenological derivations and motivated by the experiments and hypotheses of Nishimura, Kim, and Nagata [32], continue this newly established tradition. They can be viewed as an extension as well as a variation of the work of Diehl, Berger, and Wöhrl [9] who modeled algal growth experiments subject to varying light and nutrient availability.

Our preliminary analytical results on system (2.2) demonstrate that it is mathematically interesting, and our extensive bifurcation and numerical simulation work suggests that it is biologically sound.

We leave many mathematical questions open, including the global qualitative result below.

Conjecture. E^* is globally asymptotically stable when $R_0 > 1$.

Theorems 3 and 4, together with the bifurcation diagram (Figure 3.3) and the uniqueness of E^*, support the conjecture. This limiting case global stability result (Theorem 3) for the positive equilibrium suggests that the conjecture is true when the cell quota evolves on a much faster timescale than other variables. Theorem 4 and its extension are pure mathematical results that give more credence to the conjecture.

Obviously, algae are favored by shallow epilimnia, sufficient sunlight, and P inputs, while bacteria are favored by medium depths of epilimnion and sunlight and sufficient P input. With a larger P input, the ecosystem can thrive with more intensive sunlight input. Alternatively, with more intensive sunlight input, the algae-bacteria ecosystem may need more P input to be viable. When the epilimnion is very shallow

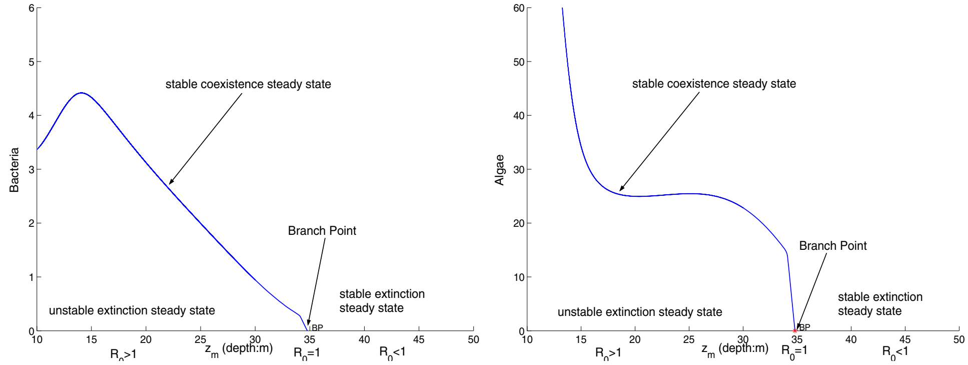

FIG. 6.1. *Bifurcation diagrams of system* (2.2) *with respect to depth of epilimnion.*

($z_m = 1$), the system (2.2) may generate complicated attractors such as that shown in Figure 5.3. It can be said that a shallower epilimnion tends to be more transient and fragile than a deep one.

Bifurcation diagrams of bacteria and algae versus depth are shown in Figure 6.1. From Figures 6.1(a) and (b), we observe that neither algae nor bacteria may survive in a very deep mixing layer ($> 35m$). In Lake Biwa, the northern lake with mean depth $43m$ is much deeper than the southern lake with mean depth $4m$. Our bifurcation diagrams (Figure 6.1) try to mimic bacterial and algal abundances in Lake Biwa from the southern site to the northern site. According to these diagrams, bacteria-to-algae ratios in the south should be smaller than in the north. *This numerical observation may be tested in the field.*

The mathematical study of the more involved system (5.1) is even more complex, and we thus opted to perform only numerical simulations to examine the hypotheses of Nishimura, Kim, and Nagata [32]. Our bifurcation diagrams (Figure 5.1) suggest that higher nutrient uptake efficiencies of LNA bacteria are the key factor for LNA bacteria to dominate HNA bacteria in severely P-limited lakes.

Appendix.

Proof of Theorem 1. Positivity obviously holds for the system. Let $R = AQ + P + \theta B$, which is the total phosphorus in system (2.2). Then

$$\frac{dR}{dt} = \frac{D}{z_m}(P_{in} - R) - \left(l_m + \frac{\nu}{z_m}\right) AQ - \theta(\mu_r + \mu_g)B \leq \frac{D}{z_m}(P_{in} - R),$$

which implies

$$R^\infty = \limsup_{t\to\infty} R(t) \leq P_{in} \qquad \text{and} \qquad R(t) \leq \max\{P_{in}, R(0)\}.$$

Since all the variables are positive and $Q_m \leq Q \leq Q_M$, we have

$$A^\infty = \limsup_{t\to\infty} A(t) \leq \frac{P_{in}}{Q_m} \qquad \text{and} \qquad A(t) \leq \frac{1}{Q_m} \max\{P_{in}, R(0)\}.$$

Noting that

$$\frac{dC}{dt} \leq \mu_A A - \frac{D}{z_m} C \leq \frac{\mu_A}{Q_m} \max\{P_{in}, R(0)\} - \frac{D}{z_m} C,$$

we have

$$C(t) \leq \max\left\{\frac{z_m\mu_A}{DQ_m}\max\{P_{in}, R(0)\}, C(0)\right\} = \max\left\{\frac{z_m\mu_A P_{in}}{DQ_m}, \frac{z_m\mu_A R(0)}{DQ_m}, C(0)\right\}.$$

Hence, for given initial conditions, $C(t)$ is bounded. Therefore, all the variables are bounded. It is easy to show that

$$\limsup_{t\to\infty} C(t) = C^\infty \leq \frac{z_m\mu_A}{D}A^\infty \leq \frac{z_m\mu_A}{D}\frac{P_{in}}{Q_m} = \frac{z_m\mu_A P_{in}}{DQ_m}.$$

Consequently, the bacteria-algae system (2.2) is dissipative, and

$$\wp = \left\{(A, Q, P, B, C) \in \Omega \mid AQ + P + \theta B \leq P_{in}, C \leq \frac{z_m\mu_A P_{in}}{DQ_m}\right\}$$

is a global attracting region for the system. □

Proof of Theorem 2. At E_0, the Jacobian matrix is

$$J(E_0) = \begin{pmatrix} \Psi(0, \hat{Q}) & 0 & 0 \\ + & \lambda_1 & + \\ - & 0 & \lambda_2 \end{pmatrix},$$

where λ_1 and λ_2 are negative numbers. It is easy to see that the eigenvalues of $J(E_0)$ are $\Psi(0, \hat{Q}), \lambda_1$, and λ_2. $R_0 < 1$ implies $\Psi(0, \hat{Q}) < 0$. Hence E_0 is locally asymptotically stable. $R_0 > 1$ implies $\Psi(0, \hat{Q}) > 0$, which implies that E_0 is unstable.

For the case $R_0 > 1$, let $x = (A, Q, P)$ and $x' = F(x)$; then $F : \mathbb{R}^3_+ \longrightarrow \mathbb{R}^3$ is locally Lipschitzian. Let $\Omega_1 = \{(A, Q, P) \in \Omega \mid A \neq 0\}$; $\Omega_2 = \{(A, Q, P) \in \Omega \mid A = 0\}$; then $\Omega = \Omega_1 \cup \Omega_2$, $\Omega_1 \cap \Omega_2 = \emptyset$, with Ω_2 being a closed invariant subset of $\mathbb{R}^3_+$ and Ω_1 positively invariant. E_0 is the only equilibrium in Ω_2. It is easy to show that the solution that starts in Ω_2 converges to $\{E_0\}$.

The singleton set $\{E_0\}$ is a uniform weak repeller for Ω_1 when $R_0 > 1$ and an isolated invariant set in Ω [39]. It is acyclic in Ω_2. Hence Ω_2 is a uniform strong repeller for Ω_1, and there exists an equilibrium $x^* \in \Omega_1$, $F(x^*) = 0$ [40]. The first conclusion implies that A is uniformly persistent.

We are now ready to establish the uniqueness of E^*. E^* satisfies

$$\text{(A.1)} \qquad \mu_A\left(1 - \frac{Q_m}{Q}\right)h(A) - l_m - \frac{\nu + D}{z_m} = 0,$$

$$\text{(A.2)} \qquad \rho(Q, P) - \mu_A Q\left(1 - \frac{Q_m}{Q}\right)h(A) = 0,$$

$$\text{(A.3)} \qquad \frac{D}{z_m}(P_{in} - P) - \rho(Q, P)A = 0.$$

By simple eliminations, we see that

$$P = P_{in} - \frac{z_m}{D}\left(l_m + \frac{\nu + D}{z_m}\right)AQ = P_{in} - \left(\frac{z_m}{D}l_m + \frac{\nu + D}{D}\right)AQ.$$

By substituting this into (A.1), we have

$$\text{(A.4)} \qquad A = \frac{M + P_{in} - \frac{\rho_m}{(l_m + \frac{\nu+D}{z_m})Q}\frac{Q_M - Q}{Q_M - Q_m}P_{in}}{(\frac{z_m}{D}(l_m + \frac{\nu+D}{z_m})Q - \rho_m\frac{z_m}{D}\frac{Q_M - Q}{Q_M - Q_m}} \equiv F(Q).$$

Therefore

$$\Phi(Q) \equiv \Psi(F(Q), Q) = \mu_A \left(1 - \frac{Q_m}{Q}\right) h(F(Q)) - l_m - \frac{\nu + D}{z_m} = 0.$$

We will show that $\Phi(Q) = 0$ has a unique positive solution. To this end, we show that $F(Q)$ is decreasing in Q. Notice that

$$F(x) = \frac{a - (\frac{b}{x} - c)}{dx - (e - fx)} = \frac{(a+c)x - b}{(d+f)x^2 - ex},$$

where

$$a = M + P_{in}, b = \frac{\rho_m}{l_m + \frac{\nu+D}{z_m}} \frac{Q_M}{Q_M - Q_m} P_{in}, c = \frac{\rho_m}{l_m + \frac{\nu+D}{z_m}} \frac{1}{Q_M - Q_m} P_{in},$$

$$d = \frac{z_m}{D}\left(l_m + \frac{\nu + D}{z_m}\right), e = \rho_m \frac{z_m}{D} \frac{Q_M}{Q_M - Q_m}, f = \rho_m \frac{z_m}{D} \frac{1}{Q_M - Q_m}.$$

We have

$$F'(x) = \frac{-(a+c)(d+f)x^2 + 2b(d+f)x - be}{((d+f)x^2 - ex)^2} \equiv \frac{G(x)}{((d+f)x^2 - ex)^2}.$$

Observe that

$$\Delta = [2b(d+f)]^2 - 4(a+c)(d+f)be = 4b(d+f)[b(d+f) - e(a+c)] < 0$$

since $b(d+f) - e(a+c) = -\rho_m \frac{z_m}{D} \frac{Q_M}{Q_M - Q_m} M < 0$. Therefore $G(x) = -(a+c)(d+f)x^2 + 2b(d+f)x - be < 0$. Therefore $F(x)$ is strictly decreasing in x. As a result, the uniqueness of E^* holds.

Assume now that $R_0 < 1$. If we have a positive equilibrium, then $\bar{Q} > \hat{Q}$ since $\Phi(\hat{Q}) = \Psi(0, \hat{Q}) < 0$. Observe that since $\bar{P} < M + \bar{P}$, we need only

$$\left(l_m + \frac{\nu + D}{z_m}\right) \bar{Q} < \rho_m \frac{Q_M - \bar{Q}}{Q_M - Q_m}$$

to guarantee that $\bar{P} > 0$. To ensure $\bar{A} > 0$, due to (A.4), we need the more restrictive condition

$$\left(\frac{z_m}{D} l_m + \frac{\nu + D}{D}\right) \bar{Q} - \rho_m \frac{z_m}{D} \frac{Q_M - \bar{Q}}{Q_M - Q_m} < -M \left(\frac{z_m}{D} l_m + \frac{\nu + D}{D}\right) \bar{Q}/P_{in}.$$

Hence $\bar{A} > 0$ will ensure $\bar{P} > 0$. The previous inequality implies that

$$\bar{Q} < \frac{\beta(P_{in}) Q_M}{\beta(P_{in}) + (l_m + \frac{\nu+D}{z_m})}.$$

Recall that $R_0 < 1$ implies that $\mu_A(1 - Q_m/\hat{Q})h(0) < l_m + \frac{\nu+D}{z_m}$ and

$$\hat{Q} = \frac{\beta(P_{in}) Q_M + \mu_A Q_m h(0)}{\beta(P_{in}) + \mu_A h(0)}.$$

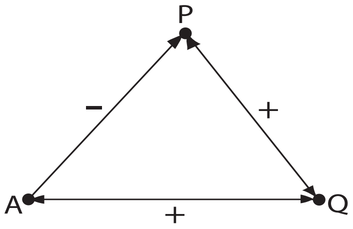

FIG. A.1. *Graph of algae system* (3.1) *to check that the system is competitive. This is observed from the Jacobian matrix of system* (3.1) *in the proof of Theorem* 2.

Hence

$$\bar{Q} - \hat{Q} < \frac{\beta(P_{in})Q_M}{\beta(P_{in}) + (l_m + \frac{\nu+D}{z_m})} - \frac{\beta(P_{in})Q_M + \mu_A Q_m h(0)}{\beta(P_{in}) + \mu_A h(0)}.$$

Simple computation shows that

$$\bar{Q} - \hat{Q} < -\frac{\mu_A h(0) Q_m(\beta(P_{in}) + \mu_A h(0))}{(\beta(P_{in}) + (l_m + \frac{\nu+D}{z_m}))(\beta(P_{in}) + \mu_A h(0))} < 0,$$

a contradiction to $\bar{Q} > \hat{Q}$.

We now proceed to show that E_0 is globally asymptotically stable when $R_0 < 1$. The Jacobian matrix of system (3.1) has the structure

$$J = \begin{pmatrix} * & + & 0 \\ + & * & + \\ - & + & * \end{pmatrix}$$

which is sign-stable for the off-diagonal elements. According to the graph in Figure A.1, every closed loop has an even number of edges with + signs; thus the system (3.1) is *monotone* ([33, p. 50–51]) in Ω with respect to the order defined by

$$K_m = \{(A, Q, P) \in \mathbb{R}^3 \mid A \geq 0, Q \leq 0, P \geq 0\}.$$

An application of monotone dynamical system theory ([33, Prop. 4.3, p. 44]) yields the statement that if system (3.1) has a positive periodic solution in Ω, then it contains an equilibrium in Ω. However, we have shown that there is no positive equilibrium E^* when $R_0 < 1$. Hence system (3.1) has no positive periodic solution in Ω. By the Poincaré–Bendixson theory for the monotone algae system and the local stability of E_0, we see that E_0 is globally asymptotically stable. □

Proof of Theorem 3. An application of the quasi–steady state approximation for the cell quota equation yields

$$\tilde{Q} = \frac{Q_M \beta(P) + Q_m \mu_A h(A)}{\beta(P) + \mu_A h(A)} \equiv \gamma(A, P)$$

which is increasing in both A and P, with $\gamma(A, P) \in (Q_m, Q_M)$. The system (3.1) is then reduced to a two-dimensional system:

$$\text{(A.5)} \qquad \begin{cases} \dfrac{dA}{dt} = \mu_A A \left(1 - \dfrac{Q_m}{\gamma(A, P)}\right) h(A) - l_m A - \dfrac{\nu + D}{z_m} A \equiv F_1(A, P), \\ \dfrac{dP}{dt} = \dfrac{D}{z_m}(P_{in} - P) - \mu_A(\gamma(A, P) - Q_m) h(A) A \equiv F_2(A, P). \end{cases}$$

There are still two equilibria: $\tilde{E}_0 = (0, P_{in})$ and $\tilde{E}^* = (\bar{A}, \bar{P})$. All the theorems above for system (3.1) hold for system (A.5). Choose the Dulac function $\delta(A, P) = 1/A$. Then

$$\begin{aligned}\frac{\partial(\delta F_1)}{\partial A} &= \partial\left[\mu_A\left(1 - \frac{Q_m}{\gamma(A,P)}\right)h(A) - l_m - \frac{\nu + D}{z_m}\right]/\partial A\\ &= \partial\left[\mu_A\frac{(Q_M - Q_m)\beta(P)h(A)}{Q_M\beta(P) + Q_m\mu_A h(A)}\right]/\partial A < 0,\\ \frac{\partial(\delta F_2)}{\partial P} &= \partial\left[\frac{D}{z_m}(P_{in} - P)/A - \mu_A(\gamma(A,P) - Q_m)h(A)\right]/\partial P < 0.\end{aligned}$$

Therefore $\frac{\partial(\delta F_1)}{\partial A} + \frac{\partial(\delta F_2)}{\partial P} < 0$. By the Poincaré–Bendixson theory, the positive equilibrium $\tilde{E}^*$ is globally asymptotically stable for the system (A.5) when $R_0 > 1$. □

Proof of Theorem 4. The system (3.1) satisfies the conservation principle as follows:

$$\begin{aligned}\frac{d(P + AQ)}{dt} &= \frac{D}{z_m}(P_{in} - P) - \left(l_m + \frac{\nu + D}{z_m}\right)AQ\\ &= \frac{D}{z_m}(P_{in} - P) - \frac{D}{z_m}AQ = \frac{D}{z_m}[P_{in} - (P + AQ)];\end{aligned}$$

then, all solutions of system (3.1) asymptotically approach the surface $P + AQ = P_{in}$ as $t \to \infty$. We need only show that E^* is globally asymptotically stable on the surface $P + AQ = P_{in}$, which is the limiting case of system (3.1). The whole system is reduced to be a planar system on the surface; then, we can prove global stability on the surface as Theorem 3 when $R_0 > 1$. According to Smith and Waltman [35], E^* is also globally asymptotically stable for the system (3.1) when $R_0 > 1$. □

For convenience, in the following proofs we use the same notations Ω, Ω_1, Ω_2, $\wp$, F, M, etc. for system (2.2) as we did for system (3.1). Although they are different from those used for system (3.1), they play similar roles for system (2.2).

Proof of Theorem 5. For system (2.2), consider the total carbon $T = A + B/r + C$. Then $\frac{dT}{dt} = \mu_A Ah(A) - \frac{D}{z_m}T - (l_m + \frac{\nu}{z_m})A - \frac{\mu_r + \mu_g}{r}B \leq \mu_A Ah(A) - \frac{D}{z_m}T$, which gives us $\frac{dT}{dt} \leq \mu_A Th(T) - \frac{D}{z_m}T$, since $Ah(A)$ is increasing in A. By the condition $\mu_A h(0) < \frac{D}{z_m}$ and because $h(A)$ is decreasing in A, we have $\mu_A h(T) - \frac{D}{z_m} \leq \mu_A h(0) - \frac{D}{z_m} < 0$, which implies $T \to 0$ as $t \to \infty$. Together with positivity of all the variables, we have $\lim_{t\to\infty} A(t) = \lim_{t\to\infty} B(t) = 0$ for all nonnegative initial conditions; that is, both algae and bacteria go extinct. □

Acknowledgments. We are grateful to the referees for their many helpful and insightful suggestions. We would like to thank Val Smith for introducing the paper of Nishimura, Kim, and Nagata [32] to us, Irakli Loladze for an initial discussion, and James Cotner for comments on the bacterial cell quota. We also thank Sebastian Diehl for his helpful suggestions, and James Grover for his valuable comments on parameter estimations and conclusions.

A DIFFUSION ANALYSIS APPROACH TO TE MODE PROPAGATION IN RANDOMLY PERTURBED OPTICAL WAVEGUIDES*

EMMANUEL PERREY-DEBAIN[†] AND I. DAVID ABRAHAMS[‡]

Abstract. The aim of this work is to model the evolution of the modal distribution of the electromagnetic field as it propagates along a randomly deformed multimode optical waveguide. When the number of guided modes becomes large we can regard the discrete set of modes as a quasi continuum. In some cases, nearest neighbor coupling predominates over other power transfer mechanisms and the coupling process can be ideally described in terms of a diffusion equation. The theory is applied to the propagation of guided transverse electric (TE) field waves in a slab waveguide with parabolic refractive index profile. Numerical simulations are in good agreement with theoretical results, and the error is shown to behave as the inverse of the number of guided modes. The technique allows the prediction of the long-distance modal distribution for a very large number of guided modes within fixed computational resources.

Key words. random waveguide, modal diffusion, optical fiber

1. Introduction.

While more and more sophisticated methods for the manufacture and control of graded index multimode fibers are being implemented, the random variations of the optical and geometrical properties of fibers from the ideal model are impossible to avoid. These small imperfections influence the signal propagation as a result of mode coupling, and their cumulative effects may become important after a long propagation length. Thus, they need to be taken into account when calculating the power attenuation, the signal distortion, and the bandwidth of the fiber [1, 2, 3]. The statistical treatment of wave propagation in random waveguides has been the topic of numerous papers, and a complete survey would merit a separate article; some interesting references can be found in [4].

The most common approach consists in deriving and solving the coupled power equations describing the evolution of the average power carried by the propagating modes. The earliest investigations of mode coupling in optical waveguides were concerned with the excess losses which result from the coupling of guided modes to radiation modes [5, 6]. Rowe and Young [7] showed that when random perturbations are present in a two-mode waveguide, one can derive coupled power equations for the power in each mode. Marcuse [8] generalized this result to any number of guided modes, and an excellent summary of this work can be found in his textbook [9]. When the number of guided modes becomes too large, a direct algebraic treatment of the coupled system is ruled out because of the computational overhead. In some cases,

however, nearest neighbor coupling predominates over other power transfer mechanisms and, within appropriate limits, the coupling process can be ideally described in terms of a diffusion equation in which the mode number is treated as a continuous variable. This idea originated in the mid-seventies for dealing with the specific problem of random bends [10, 11, 12].

The diffusion analysis approach to mode propagation in optical fibers relies on many simplifications and assumptions which render the theory's validity difficult to estimate. Curiously enough, no progress has been made since the mid-seventies and, until recently, Gloge's diffusion theory [10] has been the starting point for evaluating mode conversion in step-index multimode fibers [13, 14]. In this paper (and in a forthcoming article discussing the three-dimensional waveguide [15]), we aim at offering a new contribution to the diffusion approach [16] by treating the problem in a much more rigorous manner. It is found that, for the specific case of a slab waveguide with a parabolic index profile, the coupled power equations system can be approximated as a diffusion equation with an approximation error of order $\mathcal{O}(N^{-1})$, where N is the number of modes. In practice, the theory leads to a numerically tractable problem for predicting the long-distance modal distribution of the transverse electric (TE) field for any waveguide supporting a sufficiently large number of modes. Furthermore, it allows one to identify nondiffusive regimes in which the modal power distribution is not the solution of a diffusion equation and which exhibits irregular behavior.

The structure of the paper is as follows. The statement of the problem is presented in section 2. In section 3, the standard coupled power equations for the slab waveguide are stated, and a continuous model is derived in section 4. We finally compare the theoretical results with numerical solutions of the diffusion equation for various cases in section 5.

2. Problem statement. We aim to study the propagation of a monochromatic TE field $E_Y = E(X,Z)e^{-i\omega t}$ in a weakly guiding two-dimensional dielectric waveguide whose parabolic graded-index profile n is affected by a small random perturbation, say, δn. The field is governed by the time-harmonic wave equation

$$\frac{\partial^2 E}{\partial X^2} + \frac{\partial^2 E}{\partial Z^2} + \kappa^2 n^2(X) E = \kappa^2 \delta n^2(X,Z) E, \tag{2.1}$$

where κ is the vacuum wavenumber, Z is the guide axis, and X is the transverse coordinate. The refractive index of the unperturbed waveguide has the parabolic profile

$$n^2(X) = n_0^2(1 - 2\Delta(X/a)^2) \tag{2.2}$$

in the waveguide region, $|X| \leq a$, and $n^2(X) = n_c^2$ in the infinite cladding, $|X| > a$. The profile height parameter $\Delta = (n_0^2 - n_c^2)/2n_0^2$ is assumed to be small, and backscattering is ignored so that, under appropriate scaling, the problem can be conveniently formulated [4] as the following Schrödinger-type equation for the amplitude $\Psi = Ee^{-i\kappa n_0 Z}$:

$$2i\frac{\partial \Psi}{\partial z} = -\frac{\partial^2 \Psi}{\partial x^2} + v(x)\Psi + \delta v(x,z)\Psi, \tag{2.3}$$

where $z = \sqrt{2\Delta}Z/a$, $x = \sqrt{V}X/a$, and $\delta v = V(n_0^2 - n_c^2)^{-1}\delta n^2$. Here V denotes the usual waveguide parameter $V = \kappa n_0 a\sqrt{2\Delta}$ and v stands for the quadratic potential with finite depth: $v(x) = Vf(\bar{x})$, where $\bar{x} = x/\sqrt{V} = X/a$ and f is the normalized

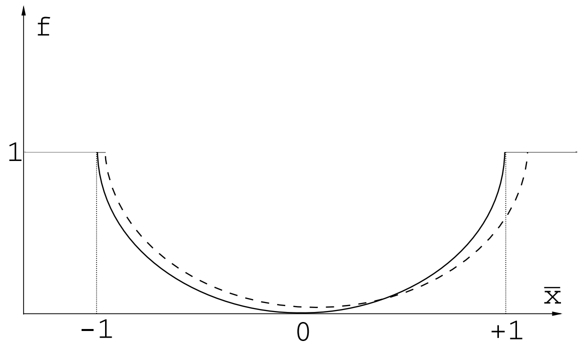

FIG. 2.1. *Profile of the normalized index of refraction; solid line indicates the unperturbed waveguide; dashed line indicates the waveguide under small deformation.*

quadratic profile (see Figure 2.1)

$$f(\bar{x}) = \left\{ \begin{array}{ll} \bar{x}^2, & |\bar{x}| \le 1 \\ 1, & |\bar{x}| > 1 \end{array} \right\}. \tag{2.4}$$

Let us now introduce ϵ, the relative amplitude of the perturbation of the slab profile. We can simulate small deviations from the ideal profile (2.4) as follows:

$$\tilde{f}(\bar{x}, z) = f(\bar{x}) + \delta f(\bar{x}, z) = (1 + \epsilon g_2(z))(\bar{x} + \epsilon g_1(z)/2)^2 + \epsilon g_3(z), \quad a^-(z) \le \bar{x} \le a^+(z).$$

The functions $g_q(z)$'s are random processes with amplitudes that do not exceed unity. In practice, g_1 simulates random oscillations of the center of the waveguide around the optical axis (microbending), g_2 is a random change of waveguide width, and g_3 is a random variation of the average refractive index. Note that the core-cladding interface is perturbed slightly from $\bar{x} = \pm 1$ to $\bar{x} = a^{\pm}(z)$. However, we will be interested in the behavior of the wave field away from the interface and so, as is usual, we will ignore the effects of the core-cladding interface on the mode intercoupling in this article. To first order, we find that the nondimensionalized perturbation to the refractive index is

$$\tilde{f}(\bar{x}, z) - f(\bar{x}) = \delta f(\bar{x}, z) = \epsilon(g_1(z)\bar{x} + g_2(z)\bar{x}^2 + g_3(z)) + O(\epsilon^2). \tag{2.5}$$

We can be more general, and henceforth take $\delta f = \epsilon g$, where the normalized random perturbation g is assumed to have the separable form

$$g(\bar{x}, z) = \sum_{q=1}^{Q} g_q(z)\phi_q(\bar{x}), \tag{2.6}$$

in which the g_q's are real-valued zero-mean, *independent*, stationary, and ergodic processes with respect to the waveguide axis coordinate z, and $\phi_q(\bar{x})$ are *deterministic* functions that can be referred to as the "perturbation modes." These functions are assumed to be sufficiently regular that they can be conveniently formulated as the truncated Taylor series

$$\phi_q(\bar{x}) = \sum_{n=0}^{\eta_q} b_{q,n}\bar{x}^n, \quad \text{where} \quad b_{q,n} = \frac{1}{n!}\left(\frac{d^n\phi_q}{d\bar{x}^n}\right)_{\bar{x}=0}. \tag{2.7}$$

3. Coupled mode theory. We wish to solve the parabolic equation (2.3), given the initial conditions $\Psi(x,0)$ at the input of the waveguide. For sufficiently small perturbations, it is possible to express the field distribution in the waveguide by using standard perturbation theory [17, 18, 19], i.e., Ψ is expanded in the eigenfunction basis of the unperturbed waveguide as

$$\Psi(x,z) = \sum_{\nu} a_{\nu}(z)\psi_{\nu}(x)e^{-i\beta_{\nu}z} + \sum \int a(\beta,z)\psi(\beta,x)e^{-i\beta z}d\beta. \tag{3.1}$$

The first summation extends over all the discrete spectrum of *guided modes* satisfying the eigenmode problem

$$-\frac{d^2\psi_{\nu}}{dx^2} + v(x)\psi_{\nu} = 2\beta_{\nu}\psi_{\nu}, \tag{3.2}$$

with the boundary condition $\psi_{\nu}(x) \to 0$ as $|x| \to \infty$. Eigenvalues of (3.2) are real positive quantities lying in the range $0 < \beta_{\nu} < \beta_c$ ($\beta_c = V/2$ is the cut-off wavenumber). They characterize the number of oscillations of the eigenfunctions along the transverse section of the waveguide. For a very large number of modes ($V \gg 1$), the highly oscillating wavefunction ψ_{ν} are conveniently described by the WKB approximation, and the largest permitted eigenvalue below cut-off can be shown to be approximately given by the upper bound, $\max_{\nu} \beta_{\nu} \approx \beta_c$. The integral in (3.1) extends over modes of the continuum (radiation modes), and the summation sign in front of the integral indicates summation over even and odd modes. These modes are oscillatory solutions of (3.2) and do not have the evanescent behavior (in x) of the guided mode fields. To be consistent with the forward scattering approximation introduced earlier, we restrict the integration domain to small propagation constants: $\beta_c \leq \beta \ll \beta_c/\Delta$. The expansion coefficients $a_{\nu}(z)$ and $a(\beta,z)$ are unknown functions of z. Using orthogonality properties of both guided and radiation modes, (2.3) is transformed into the system of ordinary differential equations

$$\begin{aligned}\frac{da_{\nu}}{dz} &= -i\epsilon\beta_c \sum_{\mu} C_{\nu,\mu}(z)e^{i(\beta_{\nu}-\beta_{\mu})z}a_{\mu}(z)\\ &\quad - i\epsilon\beta_c \sum \int a(\beta,z)C_{\nu}(\beta,z)e^{i(\beta_{\nu}-\beta)z}d\beta,\end{aligned} \tag{3.3}$$

where coupling coefficients are given by the overlap integrals

$$C_{\nu,\mu}(z) = \int_{-\infty}^{\infty} \psi_{\nu}(x)g(\bar{x},z)\psi_{\mu}(x)dx \tag{3.4}$$

and

$$C_{\nu}(\beta,z) = \int_{-\infty}^{\infty} \psi_{\nu}(x)g(\bar{x},z)\psi(\beta,x)dx. \tag{3.5}$$

Though feasible, a numerical solution of the coupled mode system (3.3) can be obtained at a heavy price, which could be well above standard computational resources. In fact, the solution of (3.3) contains more information (i.e., regarding the phase) than is required. It is now well established [9] that, under some additional assumptions, system (3.3) can be averaged over an ensemble of N_w similar waveguide realizations. More precisely, if the guided modes are weakly coupled over a distance which is large compared to the correlation length of the random process g, then the average power $A_\nu(z) = \langle |a_\nu(z)|^2 \rangle = \lim_{N_w \to \infty} \frac{1}{N_w} \sum_{N_w} |a_\nu(z)|^2$ carried by mode ν can be shown to satisfy the system of master equations

$$\frac{1}{\epsilon^2} \frac{dA_\nu}{dz} = \sum_\mu W_{\nu\to\mu}(A_\mu - A_\nu) - \alpha_\nu A_\nu, \tag{3.6}$$

where the transition probability matrix coefficients $W_{\nu\to\mu}$ are given from the spectral density of $C_{\nu,\mu}(z)$ evaluated at the wavenumber spacing $|\beta_\nu - \beta_\mu|$, i.e.,

$$W_{\nu\to\mu} = 2\beta_c^2 \int_0^\infty \langle C_{\nu,\mu}(0) C_{\nu,\mu}(z) \rangle \cos[(\beta_\nu - \beta_\mu)z] dz. \tag{3.7}$$

These are, by definition, positive quantities, and thus $W_{\nu\to\mu} \geq 0$. Note that a similar derivation can be found in the context of quantum mechanics [20] and in acoustics [21]. The power loss coefficients α_ν are positive quantities taking into account the coupling between mode ν to the continuum of radiation modes. A rigorous analysis of the radiation loss is a very difficult task as it requires both an accurate description of the perturbation in the vicinity of the core-cladding interface as well as precise knowledge of the mathematical form for the guided and radiation modes close to cut-off. Nevertheless, for waveguides supporting a sufficiently large number of modes, only highest order modes near cut-off carry nonnegligible energy near the interface and therefore suffer from very high losses. To simplify the analysis we will assume that $\alpha_\nu = \infty$ when $\nu \geq \beta_c$, which means that high order modes carry no power: $A_{\nu \geq \beta_c} = 0$. These assumptions were introduced by Marcuse [11] for the parabolic index fiber and were recently found to be in agreement with measurements carried out by Golowich et al. [3]. Due to the symmetry of the matrix coefficients $W_{\nu\to\mu}$, the solution of (3.6) is given explicitly by

$$\mathbf{A}(z) = \mathbf{U} \exp\bigl(\epsilon^2 \mathbf{\Lambda}\, z\bigr)\, \mathbf{U}^T\, \mathbf{A}(0), \tag{3.8}$$

where vector $\mathbf{A}(z) = (A_1(z), A_2(z), \ldots)^T$, and $\mathbf{A}(0)$ contains the initial conditions at $z = 0$, i.e.,

$$A_\nu(0) = |a_\nu(0)|^2 = \left| \int_{-\infty}^{\infty} \Psi(x, 0) \psi_\nu(x) dx \right|^2. \tag{3.9}$$

The diagonal matrix $(\mathbf{\Lambda})_{i,i} = \lambda_i$, $i = 1, 2, \ldots$, contains the real eigenvalues in descending order, and the column vectors $\mathbf{U}^{(i)} = (U_1^{(i)}, U_2^{(i)}, \ldots)^T$ are the eigenmodes of the real symmetric system with eigenvalues λ_i:

$$\mathbf{W}\mathbf{U}^{(i)} = \lambda_i \mathbf{U}^{(i)}, \tag{3.10}$$

with the cut-off condition that $U_\nu^{(i)} = 0$ when $\nu \geq \beta_c$. Note that the transition probability operator $\mathbf{W}$ is defined, from (3.6), as

$$(\mathbf{W}\mathbf{U}^{(i)})_\nu = \sum_\mu W_{\nu\to\mu} \left(U_\mu^{(i)} - U_\nu^{(i)} \right) - \alpha_\nu U_\nu^{(i)}. \tag{3.11}$$

Due to the special structure of (3.11) and the positivity of the off-diagonal terms, Dozier and Tappert [21] showed that Gerschgorin discs with radius $R_\nu = \sum_{\mu\neq\nu} W_{\nu\to\mu}$

lie in the left part of the complex plane, and hence all eigenvalues, λ_i, are negative. The special case, $\lambda_1 = 0$, can be referred to as the adiabatic case and corresponds to the long-distance solutions $\lim_{z\to\infty} A_\nu(z) = (\sum_\mu 1)^{-1} \sum_\mu A_\mu(0)$, i.e., an equipartition of energy is achieved whatever the initial conditions. This is a consequence of neglecting the radiation loss. This ideal scenario was considered in [21] but is obviously unrealistic in our context as losses from the highest order modes are unavoidable.

4. The continuous model.

4.1. Simplification when $V \gg 1$. Numerical diagonalization of the transition probability operator $\mathbf{W}$ (3.11) becomes impractical for very large V. Nevertheless, progress can be made if we are interested only in the lower $|\lambda_i|$ corresponding to long-distance solutions. To achieve this, we need to find a continuum analogue of (3.10). Let us first observe that in the limit of large V, the set of orthonormal functions ψ_ν satisfying (3.2) are the classical harmonic oscillator bases [18, 20]:

$$\psi_\nu(x) = \frac{1}{\sqrt{\pi^{1/2} 2^\nu \nu!}} H_\nu(x) e^{-x^2/2}, \quad \nu = 0, 1, 2, \ldots, \quad \text{with} \quad \beta_\nu = \nu + 1/2, \tag{4.1}$$

where H_ν denotes the usual Hermite polynomials. These are good approximations to the exact solutions, except for modes near cut-off, $\beta_\nu \approx \beta_c$. We assume that (4.1) is valid for all modes below cut-off; these modes are unaffected by the interface core-cladding as the power carried in this region is negligible and the evaluation of the coupling coefficients can be greatly simplified by extending the perturbation (2.6) over the whole real line as

$$C_{\nu,\mu}(z) = \sum_{q=1}^{Q} \sum_{n=0}^{\eta_q} g_q(z) b_{q,n} \int_{-\infty}^{\infty} \psi_\nu(x) \bar{x}^n \psi_\mu(x)\, dx. \tag{4.2}$$

To make some progress, we can observe that Hermite polynomials fall into the class of orthogonal polynomials satisfying a three-term recurrence relation which, in terms of the normalized function ψ_ν, reads

$$x\psi_\nu(x) = \frac{1}{\sqrt{2}} \left(\sqrt{\nu}\psi_{\nu-1}(x) + \sqrt{\nu+1}\psi_{\nu+1}(x) \right). \tag{4.3}$$

Using purely algebraic arguments, the nth power of the two-term recurrence operator (4.3) is established in [22]. This leads to following result.

LEMMA 4.1. *Given positive integers $(\zeta, n) \in \mathbb{N}^2$, the following integration formula holds:*

$$\int_{-\infty}^{\infty} \psi_\nu(x) x^n \psi_{\nu+\zeta}(x) dx = 2^{-\frac{n}{2}} F_\zeta(\nu) G_{\zeta,n}(\nu), \tag{4.4}$$

where

$$F_\zeta(\nu) = \prod_{l=1}^{\zeta} \sqrt{\nu + l} \quad \text{and} \quad G_{\zeta,n}(\nu) = \sum_{\sigma \in \frac{n-\zeta}{2} \cap \mathbb{N}} \; \sum_{\underline{i}_\sigma \in \mathcal{I}_\sigma^n} \prod_{l=1}^{\sigma} (\nu + 1 + i_l - l) \tag{4.5}$$

and $\mathcal{I}_\sigma^n$ is the set of indices $\underline{i}_\sigma = (i_1, \ldots, i_\sigma) \in \mathbb{N}^\sigma$ associated with the nested sum

$$\sum_{\underline{i}_\sigma \in \mathcal{I}_\sigma^n} = \sum_{i_\sigma=0}^{n-\sigma} \sum_{i_{\sigma-1}=0}^{i_\sigma} \cdots \sum_{i_2=0}^{i_3} \sum_{i_1=0}^{i_2}. \tag{4.6}$$

By common convention, the products above take the value unity when the lower limit exceeds the upper, and the notation $\sum_{\sigma\in\xi\cap\mathbb{N}}$ indicates that σ takes the value of ξ when ξ is an integer, or else the sum is zero. Note that the parameter ν has been written as an argument of F and G because we will soon generalize it to take noninteger values. Several other quantities will soon be defined which will also use this convention.

The result (4.4) shows that, for the ideal modes just described, the coupling coefficients between modes ν and $\nu+\zeta$ (ζ positive) take the form

$$C_{\nu,\nu+\zeta}(z) = \sum_{q=1}^{Q} g_q(z)\Phi_{q,\zeta}(\nu), \tag{4.7}$$

where

$$\Phi_{q,\zeta}(\nu) = F_\zeta(\nu)\sum_{n\geq 0} b_{q,n}(2V)^{-\frac{n}{2}}G_{\zeta,n}(\nu), \tag{4.8}$$

and $b_{q,n}$ is written in (2.7). The factorization of the quantity $F_\zeta(\nu)$ in (4.8) is a key result since it allows us to define the polynomial series w_ζ defined over the real line $\tilde{\nu}\in\mathbb{R}$ as

$$w_\zeta(\tilde{\nu}) = \sum_{q=1}^{Q} \Phi^2_{q,|\zeta|}(\tilde{\nu}-|\zeta|/2)\,\Gamma_q(\zeta), \tag{4.9}$$

where ζ now belongs to the whole integer set, $\zeta\in\mathbb{Z}$, and Γ_q stands for the spectral density function

$$\Gamma_q(\zeta) = 2\int_0^\infty \langle g_q(0)g_q(z)\rangle\cos(\zeta z)dz. \tag{4.10}$$

Finally the transition probability matrix coefficients $W_{\nu\to\nu+\zeta}$ are given from the regular function w_ζ evaluated at the midpoint $\nu+\zeta/2$, i.e.,

$$W_{\nu\to\nu+\zeta} = \beta_c^2\, w_\zeta(\nu+\zeta/2). \tag{4.11}$$

This is a key result of this article; it relates the transition probability matrix to a regular function over continuous arguments. This fact will be used shortly in obtaining a Taylor series expansion.

Let us now introduce η as the maximum exponent in the truncated Taylor expansion (2.7), i.e., $\eta=\max_{1\leq q\leq Q}\{\eta_q\}$. By virtue of (4.5), the transition matrix has a band-diagonal structure: $W_{\nu\to\nu+\zeta}=0$ when $|\zeta|>\eta$, and furthermore the roots of w_ζ are such that

$$W_{\nu\to -1} = \cdots = W_{\nu\to\nu-\eta} = 0. \tag{4.12}$$

Thus, there is no coupling with negative indices and (4.11) is exact for all guided modes. Let us now introduce a real analytic function $\tilde{U}_i$ which interpolates the discrete values of the elements of the column vector $\mathbf{U}^{(i)}$,

$$\tilde{U}_i(\nu) = U_\nu^{(i)} \quad \text{in the interval} \quad 0\leq\nu<\beta_c, \tag{4.13}$$

with the cut-off condition $\tilde{U}_i(\nu)=0$ in the interval $\beta_c\leq\nu\leq\beta_c+\eta$. This last condition does not need to be satisfied for $\nu>\beta_c+\eta$ due to the band-diagonal structure of the transition probability matrix. Similarly, we introduce a regular function $\tilde{\gamma}$ such that $\tilde{\gamma}(\nu) = \alpha_\nu$ (the attenuation factor) for all modes below cut-off $0 \leq \nu < \beta_c$. Note that such interpolating functions exist, and it suffices to consider the Lagrange interpolation polynomial, for instance. We can now exploit the equality (4.11) to give the continuum analogue of (3.11). Direct application of Taylor's theorem for real analytic functions yields the following result.

Lemma 4.2. *Let $\tilde{U}_i(\tilde{\nu})$ be the real analytic function introduced earlier. Then we have*

$$
\begin{aligned}
(\mathbf{W}\mathbf{U}^{(i)})_\nu &= \sum_{\zeta=-\eta}^{\eta} W_{\nu\to\nu+\zeta}\left(\tilde{U}_i(\nu+\zeta) - \tilde{U}_i(\nu)\right) - \tilde{\gamma}(\nu)\tilde{U}_i(\nu) \\
&= \beta_c^2 \frac{d}{d\tilde{\nu}}\left(D(\tilde{\nu})\frac{d\tilde{U}_i}{d\tilde{\nu}}\right)\Bigg|_{\tilde{\nu}=\nu} - \tilde{\gamma}(\nu)\tilde{U}_i(\nu) + \mathcal{R}(\tilde{U}_i)(\nu), \qquad (4.14)
\end{aligned}
$$

where $D(\tilde{\nu}) = \sum_{\zeta=1}^{\eta} \zeta^2 w_\zeta(\tilde{\nu})$ and the residual term $\mathcal{R}(\tilde{U}_i)$ is given by the Taylor series

$$
\mathcal{R}(\tilde{U}_i) = 4\beta_c^2 \sum_{(n,m)\in\mathbb{N}_*^2} \sum_{\zeta=1}^{\eta} \frac{(\zeta/2)^{2(n+m+1)}}{(2n+1)!(2m+1)!} \frac{d^{2m+1}}{d\tilde{\nu}^{2m+1}}\left(w_\zeta \frac{d^{2n+1}\tilde{U}_i}{d\tilde{\nu}^{2n+1}}\right),
$$

where $\mathbb{N}_*^2 = \mathbb{N}^2 \backslash \{(0,0)\}$.

Proof. First, we have the following equality, taking an expansion about the midpoint $\nu + \zeta/2$:

$$
\tilde{U}_i(\nu+\zeta) - \tilde{U}_i(\nu) = \zeta \frac{d\tilde{U}_i}{d\tilde{\nu}}(\nu+\zeta/2) + 2\sum_{n=1}^{\infty} \frac{(\zeta/2)^{2n+1}}{(2n+1)!}\frac{d^{2n+1}\tilde{U}_i}{d\tilde{\nu}^{2n+1}}(\nu+\zeta/2). \qquad (4.15)
$$

Now, functions w_ζ are polynomial series and so, given (4.11), we find

$$
\begin{aligned}
\left(w_\zeta \frac{d\tilde{U}_i}{d\tilde{\nu}}\right)(\nu+\zeta/2) - \left(w_\zeta \frac{d\tilde{U}_i}{d\tilde{\nu}}\right)(\nu-\zeta/2) &= \zeta \frac{d}{d\tilde{\nu}}\left(w_\zeta \frac{d\tilde{U}_i}{d\tilde{\nu}}\right)(\nu) \\
&\quad + 2\sum_{n=1}^{\infty} \frac{(\zeta/2)^{2n+1}}{(2n+1)!}\frac{d^{2n+1}}{d\tilde{\nu}^{2n+1}}\left(w_\zeta \frac{d\tilde{U}_i}{d\tilde{\nu}}\right)(\nu).
\end{aligned}
$$

Repeating this operation for the residual term on the right-hand side of (4.15) yields the expected result. □

The reader's attention is drawn to the fact that the leading term on the right-hand side of (4.14) is just the diffusion operator acting on $\tilde{U}_i$. We comment on this further below.

4.2. Asymptotic series expansion. We are interested in the eigenmode solutions of (3.10) when the number of guided modes is sufficiently large. To do this, we introduce the small parameter $\varepsilon = 1/V$. The asymptotic approach starts by writing every quantity as a power series of ε, and equating coefficients of like powers to yield a hierarchy of equations. Let us first observe that by introducing the normalized variables $u = \beta_c^{-1}\tilde{\nu}$, where $\beta_c^{-1} = 2/V = 2\varepsilon \ll 1$, function w_ζ admits the regular series expansion

$$
w_\zeta(\tilde{\nu}) = W_\zeta^0(u) + \varepsilon W_\zeta^1(u) + \varepsilon^2 W_\zeta^2(u) + \cdots + \varepsilon^\eta W_\zeta^\eta(u), \qquad (4.16)
$$

where

$$W^{\alpha}_{\zeta}(u) = \lim_{\varepsilon \to 0} \frac{1}{\alpha!} \frac{\partial^{\alpha} w_{\zeta}(u\,(2\varepsilon)^{-1})}{\partial \varepsilon^{\alpha}}, \quad \alpha = 0, 1, 2, \dots, \eta, \tag{4.17}$$

are all polynomial series with respect to the continuous variable u. The first two terms are given explicitly by

$$W^{0}_{\zeta}(u) = u^{\zeta} \sum_{q=1}^{Q} \Gamma_q(\zeta)[P^{I}_{q,\zeta}(u)]^2 \tag{4.18}$$

and

$$W^{1}_{\zeta}(u) = u^{\zeta-1} \sum_{q=1}^{Q} \Gamma_q(\zeta) P^{I}_{q,\zeta}(u)[\zeta P^{I}_{q,\zeta}(u) + 4P^{II}_{q,\zeta}(u)], \tag{4.19}$$

where

$$P^{I}_{q,\zeta}(u) = \sum_{\sigma=0}^{\lfloor(\eta_q-\zeta)/2\rfloor} 2^{-n} b_{q,n} C^{n}_{\sigma} u^{\sigma}|_{n=\zeta+2\sigma} \tag{4.20}$$

and

$$P^{II}_{q,\zeta}(u) = \sum_{\sigma=1}^{\lfloor(\eta_q-\zeta)/2\rfloor} 2^{-n} b_{q,n} A^{n}_{\sigma} u^{\sigma}|_{n=\zeta+2\sigma} \tag{4.21}$$

with

$$C^{n}_{\sigma} = \mathrm{card}(\mathcal{I}^{n}_{\sigma}) = \frac{n!}{\sigma!(n-\sigma)!} \quad \text{and} \quad A^{n}_{\sigma} = \sum_{\underline{\mathrm{i}}_{\sigma} \in \mathcal{I}^{n}_{\sigma}} \sum_{l=1}^{\sigma} (1 + i_l - l - n/2 + \sigma).$$

Note that the quantity $\lfloor x \rfloor$ in these equations indicates the floor of x, i.e., the largest integer less than or equal to the real number x, and η_q (from (2.7)) is the maximum value of n with nonzero $b_{q,n}$. The expansion (4.16) suggests writing a solution $\tilde{U}_i(\tilde{\nu})$ in the form of an asymptotic series expansion

$$\tilde{U}_i(\tilde{\nu}) = U_{i,0}(u) + \varepsilon U_{i,1}(u) + \varepsilon^2 U_{i,2}(u) + \cdots \tag{4.22}$$

and

$$\lambda_i = \lambda_{i,0} + \varepsilon \lambda_{i,1} + \varepsilon^2 \lambda_{i,2} + \cdots . \tag{4.23}$$

Similarly, we may assume that

$$\tilde{\gamma}(\tilde{\nu}) = \gamma_0(u) + \varepsilon \gamma_1(u) + \varepsilon^2 \gamma_2(u) + \cdots . \tag{4.24}$$

Substituting these expansions into (3.10) yields a series of diffusion equations (for brevity we restrict ourselves to writing just the leading order and the first order corrections):

$$\frac{d}{du}\left(D_0(u)\frac{dU_{i,0}}{du}\right) - \gamma_0\, U_{i,0} = \lambda_{i,0} U_{i,0}, \tag{4.25}$$

$$\begin{aligned}\frac{d}{du}\left(D_0(u)\frac{dU_{i,1}}{du}\right) - \gamma_0\, U_{i,1} &= \lambda_{i,0} U_{i,1} + \lambda_{i,1} U_{i,0} \\ &\quad + \gamma_1\, U_{i,0} - \frac{d}{du}\left(D_1(u)\frac{dU_{i,0}}{du}\right),\end{aligned} \tag{4.26}$$

where functions

$$D_0(u) = \sum_{\zeta=1}^{\eta} \zeta^2 W_\zeta^0(u) \quad \text{and} \quad D_1(u) = \sum_{\zeta=1}^{\eta} \zeta^2 W_\zeta^1(u) \tag{4.27}$$

can be interpreted as diffusion coefficients controlling the average transfer of modal power at the mode "number" $\tilde{\nu} = \beta_c u$. At subsequent orders, formulae are more complicated due to the presence of the residual term $\mathcal{R}(\tilde{U}_i)$. Each diffusion equation in the family must be solved over the unit interval $[0,1]$ and all have boundary data $U_{i,\alpha}(1) = 0$, $\alpha \in \mathbb{N}$. The boundary condition at the origin emerges naturally after realizing that there is no transfer of modal energy from negative indices; this implies that

$$\left(D_0 \frac{dU_{i,\alpha}}{du} \right)_{u=0} = 0. \tag{4.28}$$

This boundary condition is in fact the continuous analogue of the no-coupling condition (4.12) and is automatically satisfied for any *regular* solution since, by construction (see (4.18)), we have $D_0(0) = 0$.

4.3. Nature of the leading order solution. In this section, we are interested in *regular* solutions of the leading order eigenmode satisfying

$$\frac{d}{du}\left(D_0 \frac{d\varphi}{du} \right) - \gamma_0\, \varphi = \lambda \varphi, \quad \varphi(1) = 0. \tag{4.29}$$

From the remark below (3.11) we also require that $\lambda < 0$. Since $D_0(u)$ is a strictly positive polynomial in $(0,1]$ with $D_0(0) = 0$, (4.29) is a singular Sturm–Liouville eigenvalue problem and $u = 0$ is a singular endpoint. The regularity of the eigensolution therefore depends upon the behavior of $D_0(u)$ as u tends to zero. Fortunately, (4.29) admits exact analytical solutions for monomial perturbations $g(\bar{x}, z) = g_n(z)\bar{x}^n$ (recall that $\bar{x}$ is the scaled transverse coordinate given in section 2 by $\bar{x} = X/a$) because in these cases

$$D_0(u) = d_n u^n \quad \text{with} \quad d_n = 2^{-2n} \sum_{\sigma=0}^{[\frac{n-1}{2}]} (n - 2\sigma)^2 \Gamma_n(n - 2\sigma)(C_\sigma^n)^2 > 0; \tag{4.30}$$

by neglecting the loss term γ_0, it can be shown that the general family of solutions (up to the normalization constant) is

$$\varphi(u) = u^{(1-n)/2} J_{\pm\vartheta}(\omega_{n,i}^{\pm} u^{(2-n)/2}), \quad \vartheta = \frac{n-1}{n-2} \quad (n \geq 3), \tag{4.31}$$

where $\omega_{n,i}^{\pm}$ satisfies $J_{\pm\vartheta}(\omega_{n,i}^{\pm}) = 0$ and $J_{\pm\vartheta}$ is the Bessel function of the first kind of order $\pm\vartheta$. The particular case $n = 3$ yields $\vartheta = 2$ so an additional independent solution is given by $\varphi(u) = u^{-1} Y_2(y_{2,i} u^{-1/2})$, where Y_2 denotes the usual Bessel function of the second kind of order 2 and $y_{2,i}$ are the zeros of Y_2. When $n = 2$, (4.29) is the classical Euler–Cauchy equation with general solution $\varphi(u) = u^r$, where r satisfies the associated characteristic equation $r^2 + r - \lambda/d_2 = 0$. A quick inspection reveals that, as λ is negative, $\mathrm{Re}(r) < 0$. To summarize, for the specific case where the diffusion coefficient has the simple form $D_0(u) = d_n u^n$ and losses are neglected

($\gamma_0 = 0$), solutions of (4.29) are all singular at the origin except when $n = 1$, for which there exists a unique regular solution of the form

$$\varphi(u) = J_0(j_{0,i}\sqrt{u}), \tag{4.32}$$

where $j_{0,i}$ are the zeros of J_0 in ascending order. The other independent solution is $\varphi(u) = Y_0(y_{0,i}\sqrt{u})$, where Y_0 denotes the usual Bessel function of the second kind of order 0 and $y_{0,i}$ are the zeros of Y_0. This result suggests that regular solutions are expected, provided the diffusion coefficient has *linear* behavior as $u \to 0$. This is confirmed by the following proposition.

Lemma 4.3. *There exists a unique power series solution to the Sturm–Liouville problem* (4.29)*, provided $D_0(u) \sim u$ as $u \to 0$, which is equivalent to*

$$\Gamma_q(1)\, b_{q,1}^2 \neq 0, \quad q = 1, \dots, Q. \tag{4.33}$$

Proof. The diffusion coefficient $D_0(u)$ has the general polynomial form

$$D_0(u) = \sum_{n=1}^{\eta} d_n u^n, \tag{4.34}$$

where the first coefficient is explicitly given by $d_1 = \frac{1}{4}\sum_{q=1}^{Q} \Gamma_q(1) b_{q,1}^2$. Without loss of generality, we may assume that $\gamma_0(u)$ has a power series expansion. Substituting the Frobenius–Fuchs series

$$\varphi(u) = u^c \sum_{j=0}^{\infty} a_j u^j, \quad a_0 \neq 0, \tag{4.35}$$

in (4.29) leads to the indicial equation: $d_1 a_0 c^2 = 0$ and the existence of a power series solution is guaranteed if $d_1 \neq 0$, which is equivalent to (4.33) since the Γ_q's are positive functions. Furthermore, the series is unique due to Fuchs' theorem. Note the associated eigenvalues can be checked to be real negative since the regularity of φ implies that

$$\lambda \int_0^1 \varphi^2\, du = -\int_0^1 D_0 \left(\frac{d\varphi}{du}\right)^2 du - \int_0^1 \gamma_0 \varphi^2\, du, \tag{4.36}$$

where all the integrals are positive; the result is apparent by inspection. This is consistent with that found for the discrete eigenvalue problem (3.10).

If $d_1 = 0$ and $d_2 \neq 0$, then the indicial equation becomes

$$c^2 + c - \frac{\lambda + \gamma_0(0)}{d_2} = 0. \tag{4.37}$$

In the limit of large V, the energy carried by the fundamental mode $\nu = 0$ is vanishingly small at the core-cladding interface, so $\lim_{V\to\infty} \tilde{\gamma}(0) = 0$ and therefore $\gamma_0(0) = 0$. Now, given the fact that $\lambda < 0$ and $d_2 > 0$, roots of the quadratic form have strictly negative real part, and this leads to singular solutions. When $d_1 = d_2 = 0$, $u = 0$ is an irregular singular point and there is no series solution. □

In order to give a physical explanation of the condition (4.33), for simplicity let us assume that the waveguide is affected by a single perturbation mode, i.e.,

$g(\bar{x},z) = g_1(z)\phi_1(\bar{x})$. As the number of guided modes tends to infinity, the modal distribution tends to the solution of a diffusion equation provided that (see (4.10))

$$\Gamma_1(1) = 2\int_0^\infty \langle g_1(0)g_1(z)\rangle \cos(z)dz \neq 0 \quad \text{and} \quad b_{1,1} = \left(\frac{d\phi_1}{d\bar{x}}\right)_{\bar{x}=0} \neq 0. \tag{4.38}$$

The first inequality is nothing other than the well-known "resonance" condition [9] to ensure the coupling between two adjacent modes with equal spacing in β space; in other words, the perturbation g_1 must have spatial frequency support at $\beta_{\nu+1}-\beta_\nu = 1$. The second condition means that the perturbation cannot be locally flat in the vicinity of the waveguide axis. If it is, then as $V \to \infty$ the lowest order modes, localized very near the axis, will not "see" any perturbation at all and there will be no coupling and therefore no modal diffusion. This behavior is illustrated numerically in the last section of this paper.

4.4. Regular solution and first order correction. Given a random perturbation satisfying (4.33), we call $\{U_{i,0}\}_{i=1}^\infty$ the set of regular solutions of the self-adjoint eigenvalue problem (4.25). Assuming that the associated eigenvalues are all distinct, the following orthogonality property holds:

$$\int_0^1 U_{i,0}U_{k,0}\, du = \|U_{i,0}\|^2\delta_{i,k}, \tag{4.39}$$

where $\|\cdot\|$ stands for the usual energy norm of $L^2([0,1])$. The orthogonality of the eigenfunctions is in line with the orthogonality of the eigenvectors

$$\mathbf{U}^{(i)} \cdot \mathbf{U}^{(k)} = \delta_{i,k}. \tag{4.40}$$

Let us define vectors $\mathbf{V}_\alpha^{(i)}$, $\alpha = 0,1,2,\ldots$, as the discrete versions of their continuous counterpart: $(\mathbf{V}_\alpha^{(i)})_\nu = U_{i,\alpha}(\nu/\beta_c)$ for all guided modes. Rewriting the perturbation expansion (4.22) in its vectorial form gives

$$\mathbf{U}^{(i)} = \mathbf{V}_0^{(i)} + \varepsilon\mathbf{V}_1^{(i)} + \varepsilon^2\mathbf{V}_2^{(i)} + \cdots. \tag{4.41}$$

According to (4.40), the norm of the leading order solution $\|U_{i,0}\|$ must be chosen such that $\|\mathbf{V}_0^{(i)}\|_2^2 = 1 + \mathcal{O}(\varepsilon)$. This can easily be shown to be satisfied by simply taking

$$\|U_{i,0}\| = \beta_c^{-\frac{1}{2}} = \sqrt{2}\varepsilon^{\frac{1}{2}}. \tag{4.42}$$

The first order correction is explicitly obtained by expanding $U_{i,1}$ in the leading order orthogonal basis $U_{i,0}$, i.e.,

$$U_{i,1}(u) = \sum_{k=1}^\infty v_{i,k}\, U_{k,0}(u). \tag{4.43}$$

Substituting (4.43) into (4.26) and using orthogonality properties yields

$$v_{i,k} = \frac{(2\varepsilon)^{-1}}{\lambda_{i,0} - \lambda_{k,0}} \int_0^1 \left[\frac{d}{du}\left(D_1\frac{dU_{i,0}}{du}\right)U_{k,0} - \gamma_1 U_{i,0}U_{k,0}\right] du, \quad k \neq i, \tag{4.44}$$

and

$$\lambda_{i,1} = (2\varepsilon)^{-1} \int_0^1 \left[\frac{d}{du}\left(D_1 \frac{dU_{i,0}}{du} \right) U_{i,0} - \gamma_1 U_{i,0} U_{i,0} \right] du. \tag{4.45}$$

The diagonal correction terms $v_{i,i}$ stem from the discrete normalization (4.40). To first order, this is equivalent to the condition

$$\|\mathbf{V}_0^{(i)} + \varepsilon \mathbf{V}_1^{(i)}\|_2^2 = 1 + \mathcal{O}(\varepsilon^2). \tag{4.46}$$

The correspondence between the discrete and continuous norms is given by the composite trapezoidal rule:

$$\int_0^{\beta_c} (U_{i,0}(\tilde{\nu}/\beta_c) + \varepsilon U_{i,1}(\tilde{\nu}/\beta_c))^2 \, d\tilde{\nu} = \|\mathbf{V}_0^{(i)} + \varepsilon \mathbf{V}_1^{(i)}\|_2^2 - \frac{1}{2}(U_{i,0}(0) + \varepsilon U_{i,1}(0))^2 + T^{(i)},$$

where the quadrature error $T^{(i)}$ is bounded by

$$|T^{(i)}| \le \frac{\varepsilon}{6} \max_{u \in [0,1]} \left| \frac{d^2 (U_{i,0} + \varepsilon U_{i,1})^2}{du^2}(u) \right|.$$

Thus, due to the normalization (4.42), $T^{(i)} \sim \mathcal{O}(\varepsilon^2)$. Moreover, by construction

$$\int_0^{\beta_c} (U_{i,0}\,(\tilde{\nu}/\beta_c) + \varepsilon U_{i,1}(\tilde{\nu}/\beta_c))^2 \, d\tilde{\nu} = 1 + \varepsilon 2 v_{i,i} + \mathcal{O}(\varepsilon^2),$$

and so the normalization condition (4.46) is satisfied if

$$v_{i,i} = -\frac{\varepsilon^{-1}}{4} U_{i,0}^2(0). \tag{4.47}$$

Note that the orthogonality of the first order eigenvectors is checked in Appendix A, confirming the above analysis.

5. Numerical experiments.

5.1. Linear perturbation. In this section we shall focus on the linear perturbation $g(\bar{x}, z) = g_1(z)\bar{x}$. This arises from random changes in the direction of the waveguide axis. From (4.20)–(4.21), $P_{1,1}^I(u) = 2^{-1}$ and $P_{1,1}^{II}(u) = 0$, which, taking $Q = \eta = 1$ in (4.18), (4.19), and (4.27), leads to the simple form for the diffusion coefficients: $D_0(u) = u\Gamma_1(1)/4$ and $D_1(u) = \Gamma_1(1)/4$. To simplify the analysis, the spectral density of g_1 is chosen so that (see (4.10)) $\Gamma_1(1) = 4$. This choice gives

$$D_0(u) = u \quad \text{and} \quad D_1(u) = 1. \tag{5.1}$$

By neglecting the radiation losses, we get the leading order solution $U_{i,0} \equiv \varphi_i$ (see Appendix B). The leading order eigenvalue is $\lambda_{i,0} = -j_{0,i}^2/4$, and we show in the appendix that the integral (4.45) can be evaluated analytically to yield $\lambda_{i,1} = -\lambda_{i,0}$. However, an analytical form for (4.44) could not be found and so numerical integration has to be performed. To summarize, the eigenvector solution of the original eigenvalue problem (3.10) is, to first order,

$$\mathbf{U}^{(i)} = \mathbf{V}_0^{(i)} + \varepsilon \sum_{k=1}^{\infty} v_{i,k} \mathbf{V}_0^{(k)} + \mathcal{O}(\varepsilon^2), \tag{5.2}$$

Table 5.1
Evolution of the first eigenvalue.

2500	−7.614772	−7.614768

where $(\mathbf{V}_0^{(i)})_\nu = (\varphi_i(\nu/\beta_c))$. The off-diagonal terms are given explicitly by

$$v_{i,k} = \frac{1 - \frac{j_{0,k}}{j_{0,i}} \int_0^1 u^{-1} J_1(\sqrt{u} j_{0,i}) J_1(\sqrt{u} j_{0,k})\, du}{\left(\frac{j_{0,k}^2}{j_{0,i}^2} - 1\right) |J_1(j_{0,i}) J_1(j_{0,k})|} \tag{5.3}$$

and $v_{i,i} = -1/(2J_1^2(j_{0,i}))$. The eigenvalues are, from (4.23), found to be

$$\lambda_i = -\frac{j_{0,i}^2}{4}(1-\varepsilon) + \mathcal{O}(\varepsilon^2). \tag{5.4}$$

In this example, the associated original discrete system (3.10) may be written explicitly as

$$(\nu+1)(U_{\nu+1}^{(i)} - U_\nu^{(i)}) + \nu(U_{\nu-1}^{(i)} - U_\nu^{(i)}) = \lambda_i U_\nu^{(i)}. \tag{5.5}$$

So, mode coupling occurs only between adjacent modes, and the description of the power coupling process in terms of a diffusion equation is clearly validated since (5.5) is nothing but the finite difference discretization of (B.1).

Tables 5.1 and 5.2 display the values of the first two eigenvalues calculated from the original discrete system (5.5) and using the first order approximation (5.4). The number of digits of accuracy given by the continuous model is in agreement with the expected V^{-2} law; recall that the above expressions are correct to $\mathcal{O}(\varepsilon^2)$, $\varepsilon \to 0$, which is equivalent to $\mathcal{O}(V^{-2})$, $V \to \infty$. This is clearly confirmed in Figure 5.1, where the evolution of the quadratic errors (in percentages) for the leading order solutions

$$E_0^{(i)} = 100 \times \|\mathbf{U}^{(i)} - \mathbf{V}_0^{(i)}\|_2$$

and for the first order solutions

$$E_1^{(i)} = 100 \times \|\mathbf{U}^{(i)} - \mathbf{V}_0^{(i)} - \varepsilon \mathbf{V}_1^{(i)}\|_2$$

are plotted against the waveguide parameter V. Note that the first order correction vector $\mathbf{V}_1^{(i)}$ is computed with only the first 30 terms in the infinite sum in (5.2).

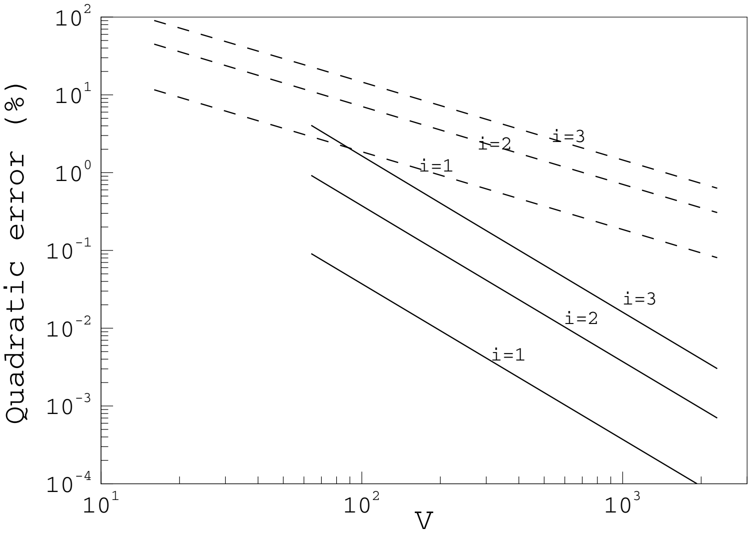

FIG. 5.1. *Error behavior with respect to V for the first three eigenmodes; dashed lines denote leading order solution, and straight lines denote first order solution.*

5.2. General case: The Rayleigh–Ritz method. We consider a random perturbation satisfying (4.33). Regular solutions of the Sturm–Liouville eigenvalue problem (4.25) can be numerically recovered using the Rayleigh–Ritz method [23]. For the sake of notational simplicity, we define the symmetric positive bilinear form

$$\mathcal{A}(\varphi,\varphi') = \int_0^1 \left(D_0(u)\frac{d\varphi}{du}\frac{d\varphi'}{du} + \gamma_0(u)\varphi\varphi' \right) du. \tag{5.6}$$

Solutions of (4.25) are stationary points of the energy functional $\mathcal{E}[U_{i,0}] = \mathcal{A}(U_{i,0}, U_{i,0})$ subject to the normalization constraint $\|U_{i,0}\| = \beta_c^{-\frac{1}{2}}$. The set of functions $\{\varphi_k\}_{k=1}^{\infty}$ forms a complete orthogonal system on $L^2([0,1])$ satisfying the Dirichlet boundary condition at the endpoint $u = 1$ (see Appendix B) and can therefore serve as a natural basis for an approximate solution $U_{i,0}^K$; i.e., we consider the truncated generalized Fourier expansion

$$U_{i,0}^K(u) = \sum_{k=1}^{K} c_{i,k}^K \, \varphi_k(u). \tag{5.7}$$

Following standard variational techniques, the stationary points are reached at the approximate eigenvalue $|\lambda_{i,0}^K| = \beta_c \, \mathcal{E}[U_{i,0}^K]$, where the expansion coefficients $c_{i,k}^K$ satisfy the matrix eigenvalue problem,

$$\sum_{k=1}^{K} c_{i,k}^K \, \mathcal{A}(\varphi_k, \varphi_l) = -\lambda_{i,0}^K \, c_{i,l}^K, \qquad l = 1, 2, \dots, K. \tag{5.8}$$

The symmetry of the bilinear form implies that the basis set $(U_{i,0}^K)_{i=1,\dots,K}$ is orthogonal in $L_2([0,1])$. Furthermore, the true solution is recovered by taking the limit

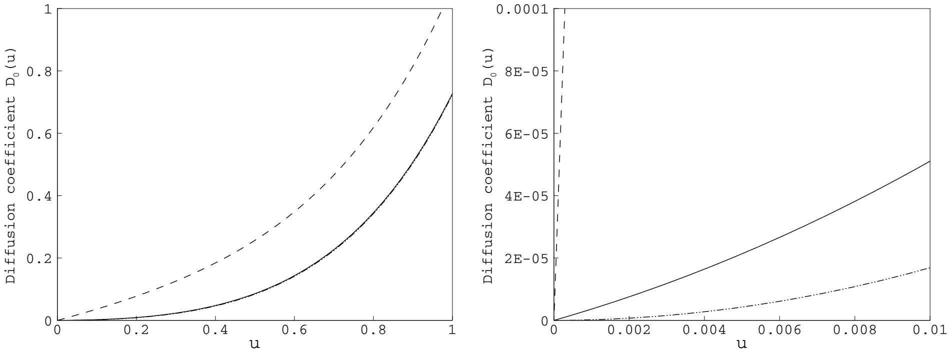

FIG. 5.2. *Leading order diffusion coefficient* $D_0(u)$. *Dashed line:* $\tau = 1$*; continuous line:* $\tau = 0.01$*; dash-dot-dot line:* $\tau = 0.0001$.

$U_{i,0} = \lim_{K\to\infty} U_{i,0}^K$. Similarly, $\lambda_{i,0} = \lim_{K\to\infty} \lambda_{i,0}^K$ and from the Rayleigh–Ritz principle, approximate eigenvalues $|\lambda_{i,0}^K|$ are upper bounds for the true eigenvalues $|\lambda_{i,0}|$ of the infinite-dimensional problem. The convergence of the method depends upon the properties of the perturbation such as its shape and its power spectrum. In most cases of practical interest, lowest order eigenvalues are expected to be obtained at a modest computational price (say $K \le 100$). For the sake of illustration, we consider perturbations given by the general form

$$g(\bar{x}, z) = \tau g_1(z)\bar{x} + \sum_{q=2}^{5} g_q(z)\bar{x}^q. \tag{5.9}$$

In the current analysis, the random functions g_q are assumed to be statistically identical and satisfy the Gaussian distribution: $\langle g_q(0)g_q(z)\rangle = e^{-z^2}$, $q = 1, \dots, 5$, which gives $\Gamma_q(\zeta) = \sqrt{\pi}e^{-\zeta^2/4}$. The corresponding diffusion coefficient is the polynomial of degree 5,

$$D_0(u) = \tau\frac{\sqrt{\pi}e^{-1/4}}{4}u + \sum_{n=2}^{5} d_n u^n. \tag{5.10}$$

The other coefficients are given explicitly in (4.30). In Figure 5.2 are plotted two graphs of D_0 against u for three values of τ. The tiny difference between the two curves $\tau = 0.01$ and $\tau = 0.0001$ can be identified on the magnified figure on the right. When $\tau = 0$, criterion (4.33) is not satisfied and there is no continuous counterpart to the discrete eigenmode. Thus, the coefficient τ can be interpreted as a diffusion parameter and the modal distribution in the waveguide is expected to "lose its regularity" when $\tau \to 0$. This behavior is revealed in Figures 5.3–5.4, where the first and fifth eigenmodes obtained from the discrete system (3.10) and from the continuous model (4.25) are shown. In all cases illustrated we considered $\beta_c = V/2 = 500$ guided modes, and the eigenfunctions $U_{i,0}^K$ are computed with $K = 50$ basis functions. From (4.44), it can be shown that the amplitude of the first order correction terms $v_{i,k}$ will grow as $\tau \to 0$. Thus the leading order solution $U_{i,0}$ will be a good approximation only if the number of guided modes is sufficiently large so that $\varepsilon\|U_{i,1}\| \ll \|U_{i,0}\|$. This explains the discrepancy observed when $\tau = 0.0001$.

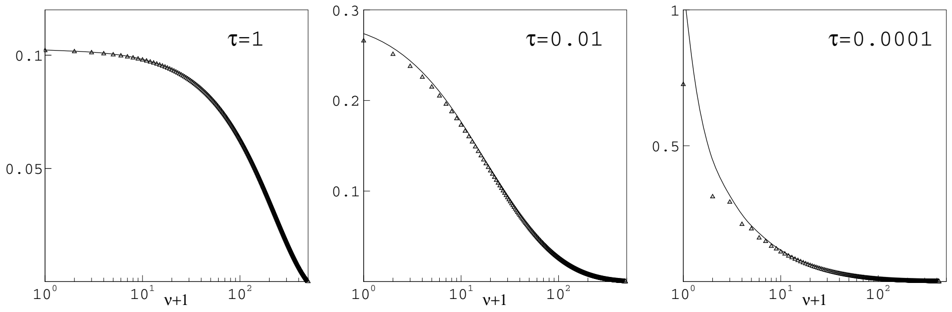

FIG. 5.3. *Influence of the diffusion parameter τ on the "regularity" of the first eigenmode; unbroken line denotes the continuous model $U_{1,0}$, and triangles denote the discrete eigenmode $\mathbf{U}^{(1)}$. Number of guided modes:* 500*.*

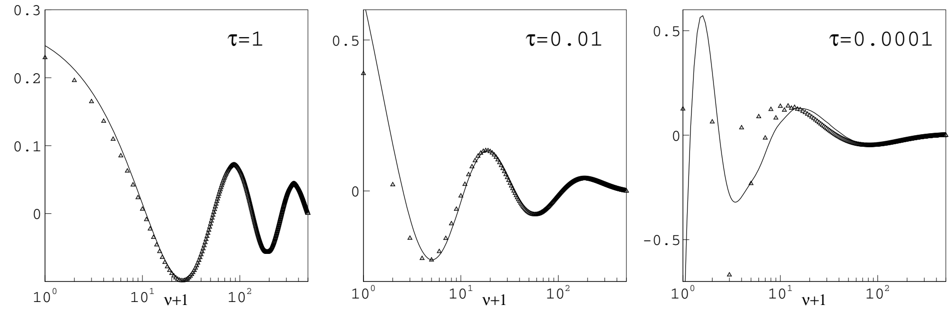

FIG. 5.4. *Influence of the diffusion parameter τ on the "regularity" of the fifth eigenmode; unbroken line denotes the continuous model $U_{5,0}$, and triangles denote the discrete eigenmode $\mathbf{U}^{(5)}$. Number of guided modes:* 500*.*

TABLE 5.3
Long distance power distribution. Fraction of energy carried by the lowest modes ($\beta_c = 500$).

τ	$\nu = 0, 1, \ldots, 10$	$\nu = 0, 1, \ldots, 100$
1	33%	82%
0.01	70%	98%
0.0001	95%	99.8%

The diffusion parameter has noticeable consequences on the modal distribution of $\mathbf{U}^{(1)}$ and therefore the long-distance power distribution

$$\mathbf{A}(z) \approx \mathbf{U}^{(1)} \exp\left(\epsilon^2 \lambda_1 z\right) \left[\mathbf{U}^{(1)}\right]^T \mathbf{A}(0) \quad \text{as} \quad z \to \infty. \tag{5.11}$$

This is clearly illustrated in Figure 5.3, where τ has a significant effect on the modal distribution. Since the fundamental mode $U_{1,0}$ is a positive function in $[0, 1]$ and $\lambda_{1,0} U_{1,0}(0) = \tau(dU_{1,0}/du)_{u=0}$ (see Appendix A), the optical power is likely to be concentrated among the lowest order modes as $\tau \to 0$. This is confirmed in Table 5.3, where the fraction of energy carried by the lowest modes is shown for various values of τ.

6. Conclusion. In this paper we have analyzed the evolution of the modal power distribution of the transverse electric field as it propagates along a multimode slab waveguide with quadratic refractive index profile and with small random deformations. We showed that for waveguides supporting a sufficiently large number of guided modes, the mode coupling mechanism can be ideally described as a diffusion equation. Even for a moderate number of modes, the regular expansion method allows us to obtain very accurate solutions when first order correction terms are taken into account. In practice, the technique described herein provides excellent qualitative predictions for the long-distance modal distribution within fixed computational resources regardless of the number of modes. Furthermore, we were able to identify nearly nondiffusive regimes in which the modal power distribution is not the solution of a diffusion equation and exhibits irregular behavior. In these latter scenarios, we observed strong focusing effects of the wave field in the vicinity of the waveguide axis. Work is almost complete on applying the present technique to three-dimensional fibers of circular cross-section with parabolic index profile [15]. We have good reason to believe that the results demonstrated in this paper could be generalized to other graded-index fibers, and this will be the subject of future work.

Appendix A. Orthogonality of the first order eigenvectors. The purpose of this appendix is to prove that the eigenmodes of the discrete system, taken to first order in ε, are orthogonal to $\mathcal{O}(\varepsilon^2)$. We commence by integrating by parts (4.44). This yields

$$v_{i,j} + v_{j,i} = -\frac{\beta_c D_1(0)}{\lambda_{i,0} - \lambda_{j,0}} \left(\frac{dU_{i,0}}{du} U_{j,0} - \frac{dU_{j,0}}{du} U_{i,0} \right)_{u=0}, \qquad i \neq j. \tag{A.1}$$

Moreover, the eigenvalue equation (4.25), together with $\gamma_0(0) = 0$ and $D_0(0) = 0$, implies

$$\lambda_{i,0} U_{i,0}(0) = \left(\frac{dD_0}{du} \frac{dU_{i,0}}{du} \right) \bigg|_{u=0}, \tag{A.2}$$

and by virtue of (4.20) and (4.21), it can be shown that $W^1_\zeta(0) = (dW^0_\zeta/du)_{u=0}$. Thus, from (4.27),

$$D_1(0) = \frac{dD_0}{du}(0), \tag{A.3}$$

and so we can construct the identity

$$(\lambda_{i,0} - \lambda_{j,0})(U_{i,0}U_{j,0})_{u=0} = D_1(0) \left(\frac{dU_{i,0}}{du} U_{j,0} - \frac{dU_{j,0}}{du} U_{i,0} \right)_{u=0}. \tag{A.4}$$

Therefore, from (A.1) and (A.4) we arrive at the result

$$v_{i,j} + v_{j,i} = -\beta_c (U_{i,0}U_{j,0})_{u=0}. \tag{A.5}$$

Finally, using $\beta_c^{-1} = 2\varepsilon$ and applying the composite trapezoidal rule yields a relationship between the discrete and continuous eigenmode products, namely,

$$\begin{aligned}(\mathbf{V}_0^{(i)} + \varepsilon \mathbf{V}_1^{(i)}) \cdot (\mathbf{V}_0^{(j)} + \varepsilon \mathbf{V}_1^{(j)}) &= \frac{1}{2}(U_{i,0}U_{j,0})_{u=0} + \mathcal{O}(\varepsilon^2) \\ &+ \int_0^{\beta_c} (U_{i,0}(\tilde{\nu}/\beta_c) + \varepsilon U_{i,1}(\tilde{\nu}/\beta_c))(U_{j,0}(\tilde{\nu}/\beta_c) + \varepsilon U_{j,1}(\tilde{\nu}/\beta_c))\, d\tilde{\nu}.\end{aligned} \tag{A.6}$$

This reduces to

$$\begin{aligned}(\mathbf{V}_0^{(i)} + \varepsilon \mathbf{V}_1^{(i)}) \cdot (\mathbf{V}_0^{(j)} + \varepsilon \mathbf{V}_1^{(j)}) &= \varepsilon(v_{i,j} + v_{j,i}) \\ &+ \frac{1}{2}(U_{i,0}U_{j,0})_{u=0} + \mathcal{O}(\varepsilon^2) = \mathcal{O}(\varepsilon^2)\end{aligned} \tag{A.7}$$

by virtue of (A.5) and completes the exercise.

Appendix B. Microbending solution. This appendix proves completeness of the regular orthogonal eigenfunctions satisfying

$$\frac{d}{du}\left(u\frac{d\varphi}{du}\right) = \lambda\varphi, \qquad \varphi(1) = 0, \tag{B.1}$$

together with the normalization condition (4.42), $\|\varphi_i\| = \beta_c^{-\frac{1}{2}}$. We find that (see section 4.3) these functions are

$$\varphi_i(u) = \beta_c^{-\frac{1}{2}} \frac{J_0(j_{0,i}\sqrt{u})}{|J_1(j_{0,i})|}, \tag{B.2}$$

where J_n is the Bessel function of the first kind of order n, $j_{0,i}$ is the location of the ith zero of J_0, and each $\varphi_i(u)$ has the associated eigenvalue $\lambda_{i,0} = -j_{0,i}^2/4$.

B.1. Completeness. By construction, the set of eigenfunctions $\{\varphi_i\}_{i=1}^{\infty}$ defines an orthogonal system on $L^2([0,1])$. The system is complete if the Dalzell-type criterion [24] is satisfied, i.e.,

$$S = 2\beta_c \sum_{i=1}^{\infty} \int_0^1 \left| \int_0^t \varphi_i(u)du \right|^2 dt = 1. \tag{B.3}$$

A straightforward calculation yields

$$S = \sum_{i=1}^{\infty} \frac{8}{3j_{0,i}^2}\left(1 + \frac{4}{j_{0,i}^2}\right). \tag{B.4}$$

Now, let $\alpha \geq 2$ be an integer; then the Cauchy residue theorem gives the identity

$$I_{N,\alpha} = \oint_{C_N} \frac{d\ln J_0(z)}{dz}\frac{dz}{z^\alpha} = 4\pi i \sum_{i=1}^{N} \frac{1}{j_{0,i}^\alpha} + 2\pi i \operatorname{Res}\left\{\frac{d\ln J_0(z)}{z^\alpha dz};\, z = 0\right\}, \tag{B.5}$$

where the closed contour C_N is the circle centered at the origin with radius R_N chosen such that $j_{0,N} < R_N < j_{0,N+1}$. Since $\lim_{N\to\infty} I_{N,\alpha} = 0$, we get, setting respectively $\alpha = 2$ and $\alpha = 4$,

$$\sum_{i=1}^{\infty} \frac{1}{j_{0,i}^2} = \frac{1}{4} \quad \text{and} \quad \sum_{i=1}^{\infty} \frac{1}{j_{0,i}^4} = \frac{1}{32}. \tag{B.6}$$

Substitution of these sums into (B.4) completes the result.

B.2. First order eigenvalues. The first order eigenvalues are specified by (4.45); we can evaluate them as follows. First, multiply (B.1) by $d\varphi/du$ and integrate over 0 to 1 to give

$$\int_0^1 \frac{d\varphi}{du}\frac{d}{du}\left(u\frac{d\varphi}{du}\right)du = \frac{\lambda}{2}\int_0^1 \frac{d\varphi^2}{du}\,du. \tag{B.7}$$

Integrating by parts twice then yields

$$\frac{1}{2}\left(\frac{d\varphi}{du}\right)^2_{u=1} + \frac{1}{2}\int_0^1 \left(\frac{d\varphi}{du}\right)^2 du = -\frac{\lambda}{2}\varphi^2(0). \tag{B.8}$$

Integrating by parts again and using the equality $(d\varphi/du)_{u=0} = \lambda\varphi(0)$ gives finally

$$\int_0^1 \varphi\frac{d^2\varphi}{du^2}\,du = \left(\frac{d\varphi}{du}\right)^2_{u=1} = -\frac{\lambda}{\beta_c}. \tag{B.9}$$

Substituting this into (4.45), using (A.3) and setting $\gamma_1 = 0$ (lossless case), yields

$$\lambda_{i,1} = -\lambda_{i,0}. \tag{B.10}$$

Acknowledgments. The authors are most grateful to Professor John Love (ANU, Australia), Dr. David Allwright and Dr. John Ockendon (OCIAM, University of Oxford, UK), and Dr. Dominic Gallagher and Dr. Tom Felici (Photon Design) for their substantial input to the project.

THE GENERALIZED RIEMANN PROBLEM FOR A SCALAR NONCONVEX CHAPMAN–JOUGUET COMBUSTION MODEL*

WANCHENG SHENG[†], MEINA SUN[†], AND TONG ZHANG[‡]

Abstract. The generalized Riemann problem for a scalar nonconvex Chapman–Jouget combustion model in a neighborhood of the origin ($t > 0$) on the (x, t) plane is considered. Under the entropy conditions, we exhibit the construction of the solutions. It can be observed that, for some cases, there are essential differences between the structures of the perturbed Riemann solutions and the corresponding Riemann solutions. Especially, a strong detonation in the corresponding Riemann solution may turn into a weak deflagration followed by a shock wave after perturbation, which appears in the numerical simulations of Bao and Jin [*J. Comput. Phys.*, 163 (2000), pp. 216–248] and Zhang and Ying [*J. Comput. Math.*, 23 (2005), pp. 337–350].

1. Introduction.

The Chapman–Jouguet (CJ) combustion theory plays an important role in gas dynamics [5], [16], [2]. In Lagrangian coordinates, one-dimensional adiabatic, inviscid flow of combustible ideal gases with an infinite rate of reaction is described by the hyperbolic system of conservation laws

$$\begin{cases} u_t + p_x = 0, \\ \tau_t - u_x = 0, \\ E_t + (pu)_x = 0, \end{cases} \tag{1.1}$$

with reaction equation

$$q(x,t) = \begin{cases} q(x,0), & \sup\limits_{0<y\le t} T(x,y) \le T_i, \\ 0 & \text{otherwise}, \end{cases} \tag{1.2}$$

where $u, p > 0$, $\tau > 0$, T, and $E > 0$ are the velocity, pressure, specific volume, temperature, and specific energy, respectively, and T_i is the ignition temperature. In addition to the kinetic energy $\frac{1}{2}u^2$ and internal energy e, the total energy E also contains the chemical binding energy q:

$$E = \frac{1}{2}u^2 + e + q. \tag{1.3}$$

The internal energy $e = e(T)$ is a known function of T, which satisfies the law of Boyle and Gay-Lussac for ideal gas [5],

$$p\tau = RT, \tag{1.4}$$

or the van der Waals equation of state for van der Waals gas [11],

$$\left(p+\frac{a}{\tau^2}\right)(\tau-b)=RT, \tag{1.5}$$

where R, a, and b are constants. For ideal gas, the equation of state (1.4) is a convex curve in the (p,τ) plane, while for van der Waals gas, the equation of state (1.4) is a nonconvex curve in the (p,τ) plane in some cases.

Because of the difficulty of the combustion problems in gas dynamics, there are few results except for the Riemann problems in [4] (solution involving only detonation), [15] (solution involving only deflagration), and [21]. In [21], all Riemann solutions are obtained for the Riemann problem (1.1), (1.2) and

$$(u,\tau,p,q)\big|_{t=0}=(u^{\pm},\tau^{\pm},p^{\pm},q^{\pm}),\quad \pm x>0. \tag{1.6}$$

Fickett in 1979 [6] and Majda in 1981 [10] proposed the simplest CJ combustion model in Lagrangian coordinates,

$$\begin{cases} (u+q)_t+f(u)_x=0, \\ q(x,t)=\begin{cases} q(x,0), & \sup\limits_{0\le\tau\le t} u(x,\tau)\le u_i, \\ 0 & \text{otherwise}, \end{cases} \end{cases} \tag{1.7}$$

where u is a lumped quantity with some features of density, velocity, pressure or temperature, q denotes the binding energy of the reactive gas, and $f(u)$ represents the flux function. The model (1.7) describes the combustible gas with an infinite rate of reaction, which implies that a gas particle releases all of its binding energy once its temperature exceeds u_i (ignition temperature).

In this paper, the initial value we are interested in is of the form

$$(u,q)(x,0)=(u_0^{\pm}(x),q_0^{\pm}(x)),\quad \pm x>0, \tag{1.8}$$

where $q_0^{\pm}(x)$ equal a constant q_0 for unburnt gas and zero for burnt gas, and $u_0^{\pm}(x)$ are arbitrary smooth functions with the properties

$$\lim_{x\to 0-} u_0^{-}(x)=u^{-},\quad \lim_{x\to 0+} u_0^{+}(x)=u^{+}. \tag{1.9}$$

The corresponding Riemann problem is an initial problem (1.7) with

$$(u,q)\big|_{t=0}=\begin{cases} (u^{-},q_0), & x<0, \\ (u^{+},0), & x>0. \end{cases} \tag{1.10}$$

The initial value problem (1.8) is a perturbation of (1.10) at the neighborhood of the origin. So, we call (1.8) a generalized Riemann problem. Naturally, we would like to know whether or not, in some neighborhood of the origin, the solution for (1.7) and (1.8) is similar to the corresponding Riemann solution. When $f(u)$ is convex, this problem was studied in [14], the results of which show that they are essentially different for some cases. In the present paper, our attention is focused on the nonconvex case. For simplicity, we assume that $f(u)$ is the simplest nonconvex function; i.e.,

(A) $f(u)$ has only one inflection point $\tilde{u}$, and $f'(\pm\infty)=+\infty$.

The case for $f(u)$ with one inflection point and $f'(\pm\infty) = -\infty$ can be treated similarly without substantial difficulties.

To guarantee the uniqueness of the solution, entropy conditions are needed. Here we mention some works on the entropy conditions for the model (1.7). In 1984, Ying and Teng [17] proved the existence and uniqueness of the Riemann solution for the Zeldovich–von Neumann–Döring (ZND) model

$$\begin{cases} (u+q)_t + f(u)_x = 0, \\ q_t = -k\varphi(u)q, \end{cases} \tag{1.11}$$

where k is the rate of reaction for combustible gas and $\varphi(u)$ is the Heaviside function: $\varphi(u) = 0$ as $u \le u_i$, $\varphi(u) = 1$ as $u > u_i$. Furthermore, they obtained limits of the solution as k tends to infinity and defined the limits as an admissible solution of the Riemann problem for (1.7). Based on Ying and Teng's results, Liu and Zhang [9] summarized a set of entropy conditions, including pointwise and global entropy conditions, with which they obtained the uniqueness of the Riemann problem for CJ model (1.7). These results were all obtained under the assumption that $f(u)$ is strictly convex.

Since a genuine two-dimensional conservation law must be nonconvex in certain directions [3], [20] and the van der Waals equation of state is nonconvex in some cases, it is interesting to investigate a scalar combustion model with a nonconvex flux $f(u)$, which is the indispensable preparation for the study of multidimensional combustion problems. There is another motivation to study the nonconvex model (1.7) [12]. A well-known phenomenon in combustion theory is the transition from deflagration to detonation. However, this phenomenon cannot occur in the convex case because detonation and deflagration waves cannot propagate in the same direction (forward or backward). In the nonconvex case, however, this phenomenon can be observed [12].

For the nonconvex system (1.7), Zhang and Zhang [19] gave the entropy restriction that mimics those in [9] and generalizes the classical Oleinik entropy condition for scalar conservation laws when solving the Riemann problem. In 2003, Li and Zhang [8] proved that the Riemann solutions in [19] are the limit of the Riemann solutions for the nonconvex self-similar ZND combustion model

$$\begin{cases} (u+q)_t + f(u)_x = 0, \\ q_t = -\dfrac{k}{t}\varphi(u)q \end{cases} \tag{1.12}$$

as the rate of reaction goes to infinity. However, through the study of the structure stability of combustion solutions, Sheng and Zhang [12] found that their entropy conditions do not guarantee the uniqueness in some cases, which was not discussed in the two papers [19] and [8]. Sheng and Zhang contributed a set of complete entropy conditions by a different method and uniquely constructed the entropy solutions for the Riemann problem (1.7), (1.8), and (1.9). The ignition problem for (1.7) without convexity was investigated in [13].

With the method of characteristic analysis, we constructively obtain the solutions of (1.7) and (1.8), which include all the possibilities in [14] and have more interesting structures. We find that for most of the cases, the combustion waves in the corresponding Riemann solutions are able to retain their forms after perturbation, in the neighborhood of the origin, while for some other cases, the perturbation brings essential changes to the combustion waves. For instance, the perturbation may transform a strong detonation into a weak deflagration followed by a shock wave; see Case 4 in the present paper. This interesting phenomenon also appears in the numerical solutions in [1] and [18]. The phenomenon is unreadable and has puzzled numerical analysts. Our theoretical results give a reasonable explanation for this phenomenon. In fact, error is unavoidable in computation. The error forms a perturbation of the initial data.

This paper is organized as follows. In section 2, we present some preliminaries containing the pointwise and global entropy conditions and elementary waves. Then the construction of the perturbed Riemann solutions and our main results are exhibited in section 3.

2. Preliminaries. Suppose the piecewise smooth vector function (u, q) satisfies (1.7). Then it is easy to show that $q(x, t)$ is piecewise constant, 0 or q_0, and that the smooth solution $u(x, t)$ is a constant or rarefaction wave (R).

A jump of solution $(u, q)(x, t)$ at $x = x(t)$ should satisfy the Rankine–Hugoniot condition

$$\frac{\mathrm{d}x(t)}{\mathrm{d}t} = \frac{[f]}{[u+q]} =: \sigma, \tag{2.1}$$

where $[f] = f(u_r) - f(u_l)$, $u_l = u(x(t) - 0, t)$, $u_r = u(x(t) + 0, t)$, etc.

The following three kinds of noncombustion discontinuities are admissible.

1. $[q] = 0$, $[u] \neq 0 \Rightarrow \sigma = \frac{[f]}{[u]}$ is a generalized shock, which may be classified into
   (a) shock wave (S): $f'(u_r) < \sigma < f'(u_l)$;
   (b) left–contact discontinuity (LC): $f'(u_r) < \sigma = f'(u_l)$;
   (c) right–contact discontinuity (RC): $f'(u_r) = \sigma < f'(u_l)$;
   (d) double–contact discontinuity (DC): $f'(u_r) = \sigma = f'(u_l)$;
2. $[q] \neq 0$, $[u] = 0 \Rightarrow \sigma = 0$ is a contact jump (J);
3. $[q] \neq 0$, $[u] \neq 0$, $\sigma = 0$ is a combination of S and J (SJ),

where the generalized shock and SJ satisfy the Oleinik entropy condition

$$\frac{f(u) - f(u_l)}{u - u_l} \geq \frac{f(u_r) - f(u_l)}{u_r - u_l} \qquad \text{for} \quad (u - u_l)(u - u_r) \leq 0. \tag{2.2}$$

We next investigate the combustion wave, which has nonzero speed $\sigma \neq 0$, and across which q jumps from q_0 to zero. Let u_l and u_r be the limit values of u in the combustion wave front and wave back, respectively, i.e., $q_l > 0 = q_r$ and $u_l \leq u_i < u_r$, which implies $\sigma = \frac{f(u_r) - f(u_l)}{u_r - (u_l + q_0)} < 0$. Then the following six kinds of combustion waves satisfying the pointwise entropy conditions [12] are admissible.

Pointwise entropy conditions.

a. If there exists a $u_R \in [u_l, u_r)$ such that for all $u \in (u_l, u_r)$,

$$\sigma = \frac{f(u_r) - f(u_l)}{u_r - (u_l + q_0)} = \frac{f(u_R) - f(u_l)}{u_R - u_l} \leq \frac{f(u) - f(u_l)}{u - u_l}, \tag{2.3}$$

the discontinuity σ is called deflagration. Furthermore, it can be divided into three subcases:

1. $f'(u_l) = \sigma < f'(u_r)$: CJ deflagration (CJDF);
2. $f'(u_l) > \sigma < f'(u_r)$: weak deflagration (WDF);
3. $f'(u_l) = \sigma = f'(u_r)$: double–contact combustion (DCC).

b. If there exists a $u_R \in [u_r, +\infty)$ satisfying (2.3) for $u \in (u_l, u_R)$, σ is called detonation. Also, it can be divided into three subcases:

4. $f'(u_l) > \sigma = f'(u_r)$: CJ detonation (CJDT);

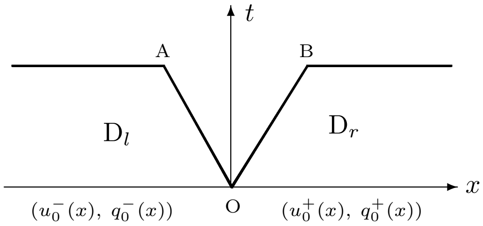

Fig. 1.

5. $f'(u_l) > \sigma > f'(u_r)$: strong detonation (SDT);
6. $f'(u_l) = \sigma > f'(u_r)$: contact detonation (CDT).

For the case that $q_l = 0 < q_r$, $u_l > u_i \geq u_r$, the pointwise entropy conditions for combustion waves can be easily defined by means of transformation $\bar{x} = -x$, $\bar{f} = -f$.

We call R, S, J, SJ, CJDF, WDF, DCC, CJDT, SDT, and CDT elementary waves for (1.7) without convexity.

The aforementioned entropy conditions cannot guarantee the uniqueness and structure stability of the Riemann solutions for (1.7). Hence, global entropy conditions [12] are needed.

Global entropy condition.

If the Riemann problem for (1.7) has several solutions, we choose one which satisfies the following rule:

If $U = \big\{u \;\big|\; \exists u < u_i,$ *such that* $f(u) = f(u + q_0)$ *and* $f'(u + q_0)f'(u_i) > 0\big\} \neq \emptyset$, *take*

$$u_l = \max\big\{u \;\big|\; u \in U\big\};$$

otherwise, take the combustion wave which propagation speed is as low as possible.

Then in the next section, we show that the generalized Riemann problem subject to the above entropy conditions can be solved uniquely.

3. Solutions of the generalized Riemann problem. We will investigate the solutions for the discontinuous initial value problem (1.7), (1.8) in a neighborhood of the origin ($t > 0$) on the (x,t) plane. In fact, in the region where the solution is smooth ($q \equiv$ *const.*), (1.7) reduces to the scalar conservation law $u_t + f(u)_x = 0$, for which the generalized Riemann problem was studied in [3] and the references therein. Hence by [7], the classical solution $(u_l, q_l)(x,t)$ $((u_r, q_r)(x,t))$ can be defined in a strip domain D_l (D_r) for local time. The right boundary of D_l has characteristic OA: $x = \lambda(u^-)t$, and the left boundary of D_r has characteristic OB: $x = \lambda(u^+)t$, where $\lambda(u) = f'(u)$ (see Figure 1).

We will distinguish the different cases according to the different solutions for the corresponding Riemann problem [12]. It is redundant to dwell on all the cases since some of them can be discussed similarly. So we will pick some typical cases and focus our attention on them in the following.

By assumption (A), there are two possibilities: $f'(\tilde{u}) < 0$ or $f'(\tilde{u}) \geq 0$. The latter can be treated as the special case of the former. Therefore, we suppose $f'(\tilde{u}) < 0$ in the following without loss of generality. From $f'(\tilde{u}) < 0$ and $f'(\pm\infty) = +\infty$, we know that there exist u_1 and u_2 such that $f'(u_1) = f'(u_2) = 0$, where $u_1 > \tilde{u} > u_2$. Let u_3, u_4 satisfy $f(u_1) = f(u_3)$, $f(u_2) = f(u_4)$, respectively (Figure 2). For convenience, in the following figures, we denote $(f(u^{\pm}), u^{\pm})$ as $(\pm)$, $(f(u^{\pm}), u^{\pm}{+}q_0)$ as $(\pm')$, $(f(u_i), u_i)$ as (i) in the (f,u) plane, etc.

3.1. Solutions for $u_0^-(x) \leq u_i < u^+$, $q_0^-(x) = q_0 > 0 = q_0^+(x)$. We begin by fixing $u^- \in (u_3, \tilde{u})$. Let u_5 ($\tilde{u} < u_5 < u_1$) satisfy $f'(u_5) = w(u^-, u_5)$, where $w(u,v) = \frac{f(u)-f(v)}{u-v}$. Then our discussion can be divided into the following cases according to the elementary waves in the corresponding Riemann solutions.

Case 1. *The corresponding Riemann problem has noncombustion solution containing no SJ.*

We just consider the case $u_i > u_5$ and $f'(u_i) \geq 0$, for which the Riemann solution consists of a contact jump J for q and RC + R for u. Here "+" means "follows."

When $\dot{u}_0^-(0) > 0$, it is possible to construct a discontinuity without combustion $x = x(t)$ in the domain $\lambda(u_5)t < x < \lambda(u^+)t$ as follows:

$$\left\{ \begin{array}{l} \dfrac{\mathrm{d}x}{\mathrm{d}t} = w(u_l(x,t), u_r(x,t)), \\ x(0) = 0, \end{array} \right. \tag{3.1}$$

where $u_r(x,t)$ is a centered simple wave defined by

$$\frac{x}{t} = \lambda(u_r(x,t)) \quad (u_5 \leq u_r \leq u^+). \tag{3.2}$$

Since $x = x(t)$ satisfies the stability condition at the origin, $\lambda(u_5) = \dot{x}(0) < \lambda(u^-)$, it can be proved by the method used in [3, p. 16] that there exists a solution of (3.1) in the interior of domain $\lambda(u_5)t < x < \lambda(u^+)t$, near the origin.

Conversely, under the condition that there is a discontinuity $x = x(t)$ with $\dot{x}(0) = \lambda(u_5)$ and $\ddot{x}(0) \geq 0$ in the domain $\lambda(u_5)t < x < \lambda(u^+)t$, we now prove that $\dot{u}_0^-(0) \geq 0$. In fact, $\ddot{x}(0)$ can be calculated as follows. Differentiating the first equation in (3.1) with respect to t and letting $t = 0$, one obtains

$$(u^- - u_5)\ddot{x}(0) = (\lambda(u^-) - \dot{x}(0)) \left.\frac{\mathrm{d}u_l}{\mathrm{d}t}\right|_{t=0} - (\lambda(u_5) - \dot{x}(0)) \left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0},$$

where it can be easily checked that

$$\left.\frac{\mathrm{d}u_l}{\mathrm{d}t}\right|_{t=0} = \frac{\partial u_l}{\partial t} + \frac{\partial u_l}{\partial x}\dot{x}(0) = (\lambda(u_5) - \lambda(u^-))\dot{u}_0^-(0).$$

As for $\left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0}$, note that along $x = x(t)$,

$$\lim_{t\to 0} \lambda(u_r(x,t)) = \lim_{t\to 0} \frac{x}{t} = \dot{x}(0) = \lambda(u_5);$$

namely,

$$\lim_{t\to 0} u_r(x(t),t) = u_5.$$

Then from (3.2), we have

$$\lambda'(u_5) \left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0} = \lim_{t\to 0} \frac{t\dot{x}(t) - x(t)}{t^2} = \frac{\ddot{x}(0)}{2}.$$

Thus

$$(u^- - u_5)\ddot{x}(0) = -(\lambda(u^-) - \lambda(u_5))^2 \dot{u}_0^-(0),$$

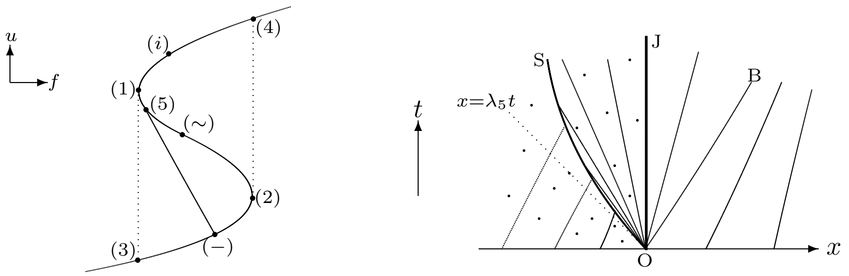

Fig. 2.

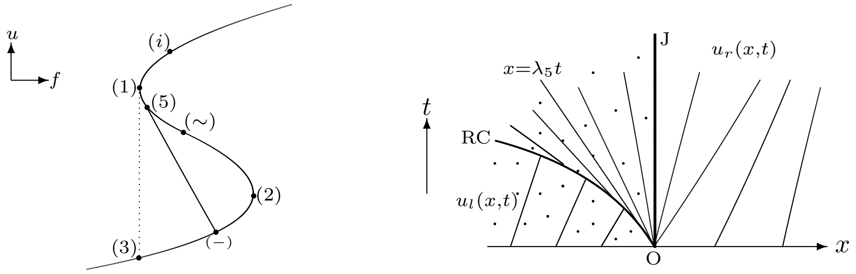

Fig. 3.

which shows that $\ddot{x}(0)$ has the same sign as $\dot{u}_0^-(0)$. It is easily seen that $x = x(t)$ satisfies $\lambda(u_r) < w(u_l, u_r) < \lambda(u_l)$ near the origin, which means that the right–contact discontinuity turns into a shock wave (see Figure 2).

For $\dot{u}_0^-(0) < 0$, it is impossible to construct a solution containing a shock wave, but it is possible to construct an RC $x = x(t)$ such as

$$\left\{\begin{array}{l} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \lambda(\bar{u}) = w(u_l, \bar{u}) \quad \left(-\infty < \dfrac{x}{t} \leq \lambda(u_5)\right), \\ x(0) = 0. \end{array}\right. \tag{3.3}$$

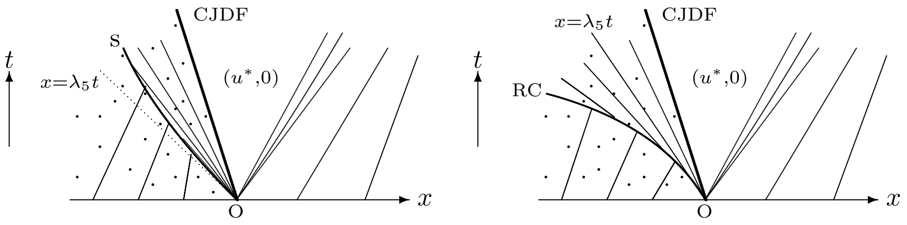
A solution of (1.7) and (1.8) can then be defined, which takes $u_r(x,t)$ on the right-hand side of $x = \lambda(u_5)t$ and $u_l(x,t)$ on the left-hand side of $x = x(t)$ for u, respectively. The characteristic of the solution in the domain $x(t) < x \leq \lambda(u_5)t$ is the tangent of $x = x(t)$ (see Figure 3). Similarly to the case $\dot{u}_0^-(0) > 0$, it can be proved that $\dot{u}_0^-(0) < 0$ is a necessary condition for a solution constructed as above.

Case 2. *A combustion wave CJDF appears in the corresponding Riemann solution:* $u_i > u_5$ *and* $f'(u_i) < 0$.

Since the same discussion as above can be carried out for this case, we omit the details. The solution for $u^+ \geq u^*$ is illustrated in Figure 4, where $u^* > u_i$ satisfies $f'(u_i) = \frac{f(u^*) - f(u_i)}{f(u^*) - (u_i + q_0)}$. The case for $u^+ < u^*$ is the same as for $u^+ \geq u^*$ except that $(u^*, 0)$ and $(u_r, 0)$ are connected by a shock wave instead of a centered simple wave, in which the shock wave satisfies

$$\left\{\begin{array}{l} \dfrac{\mathrm{d}x}{\mathrm{d}t} = w(u^*, u_r(x,t)) \quad \left(\lambda(u^+) \leq \dfrac{x}{t} \leq \lambda(u^*)\right), \\ x(0) = 0. \end{array}\right. \tag{3.4}$$

As we can see, the perturbation has no influence on the CJDF, which goes on to propagate with the speed $f'(u_i)$ in the neighborhood of the origin.



$\dot{u}_0^-(0){>}0$ $\dot{u}_0^-(0){<}0$

FIG. 4.

Case 3. *A combustion wave WDF appears in the corresponding Riemann solution.*

We are concerned with the typical case $u_i = u_5$.

In the case of $\dot{u}_0^-(0) < 0$, it can be proved that the combustion wave WDF turns to CJDF $x = f'(u_i)t$, ahead of which is RC+R lying in the domain $-\infty < \frac{x}{t} \le \lambda(u_i)$. The structure of the solution is similar to that of the case $\dot{u}_0^-(0) < 0$ in Figure 4.

In the case of $\dot{u}_0^-(0) > 0$, the combustion wave WDF remains. Let u^* have the same representation as in Case 2. Then we need to do some analysis for the case $u^+ \ge u^*$, for which the corresponding Riemann solution can be denoted by WDF + $(u^*, 0)$ + R. For any u_l, we may define $\bar{u}(u_l) \in (\tilde{u}, u_5)$, $\hat{u}(u_l) > \bar{u}(u_l)$ such that

$$\begin{cases} w(u_l, \bar{u}) = \lambda(\bar{u}) = \dfrac{f(\hat{u}) - f(u_l)}{\hat{u} - (u_l + q_0)}, \\ \bar{u}(u^- - 0) = u_5, \quad \hat{u}(u^- - 0) = u^*. \end{cases} \tag{3.5}$$

Differentiating the above equations and eliminating $\mathrm{d}\bar{u}$, we finally get, by setting $u_l = u^- - 0$,

$$\left.\frac{\mathrm{d}\hat{u}}{\mathrm{d}u_l}\right|_{u_l = u^- - 0} = \frac{(\lambda(u^-) - \lambda(u_5))(u_5 + q_0 - u^*)}{(\lambda(u^*) - \lambda(u_5))(u_5 - u^-)}. \tag{3.6}$$

Along the WDF $x = x(t)$ with $\dot{x}(0) = \lambda(u_5)$, defined as

$$\begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \lambda(\bar{u}) = \dfrac{f(\hat{u}) - f(u_l)}{\hat{u} - (u_l + q_0)}, \\ x(0) = 0, \end{cases} \tag{3.7}$$

it holds that

$$\left.\frac{\mathrm{d}u_l}{\mathrm{d}t}\right|_{t=0} = (\lambda(u_5) - \lambda(u^-))\dot{u}_0^-(0). \tag{3.8}$$

Therefore,

$$\left.\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\right|_{t=0} = \left.\frac{\mathrm{d}\hat{u}}{\mathrm{d}u_l}\right|_{u_l = u^- - 0} \left.\frac{\mathrm{d}u_l}{\mathrm{d}t}\right|_{t=0} = \frac{(\lambda(u_5) - \lambda(u^-))^2(u_5 + q_0 - u^*)}{(\lambda(u_5) - \lambda(u^*))(u_5 - u^-)}\dot{u}_0^-(0). \tag{3.9}$$

Then for $\ddot{x}(0)$ of the WDF, an easy calculation provides

$$(u^- + q_0 - u^*)\ddot{x}(0) = (\lambda(u^-) - \lambda(u_5)) \left.\frac{\mathrm{d}u_l}{\mathrm{d}t}\right|_{t=0} - (\lambda(u^*) - \lambda(u_5)) \left.\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\right|_{t=0},$$

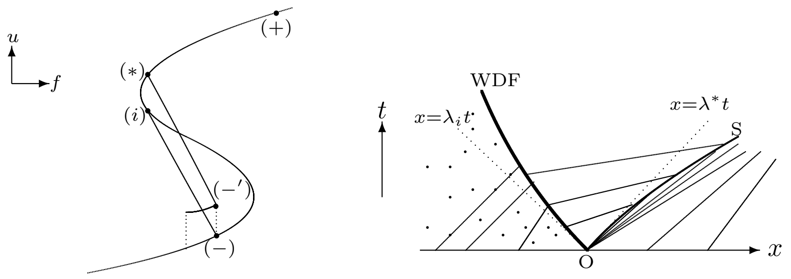


FIG. 5.

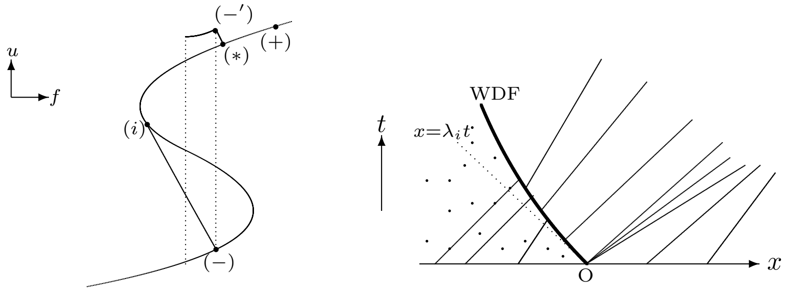

FIG. 6.

which, combined with (3.8) and (3.9), implies

$$\ddot{x}(0) = \frac{(\lambda(u^-) - \lambda(u_5))^2}{u_5 - u^-} \dot{u}_0^-(0) > 0.$$

It is obvious that $\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\Big|_{t=0} > 0$ when $u^* > u_5 + q_0$, which means that the rarefaction wave behind the WDF turns to a shock wave $x = x(t)$ (see Figure 5) determined by

$$(3.10)\qquad \begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = w(\hat{u}, u_r), & \lambda(u^*) \le \dfrac{x}{t} \le \lambda(u^+), \\ \dfrac{x}{t} = \lambda(u_r), & u^* \le u_r \le u^+, \\ x(0) = 0. \end{cases}$$

For $u^* < u_5 + q_0$, i.e., $\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\Big|_{t=0} < 0$, however, the rarefaction wave remains (see Figure 6). For the case $u^+ < u^*$, we can show by similar discussion that the solution is similar to the corresponding Riemann solution consisting of WDF $+ (u^*, 0) +$ S. We omit the details. In the following, we take $u_i \in (u^-, u_5)$ and $u^+ \in (u_i, u_5)$.

Case 4. *A combustion wave SDT appears in the corresponding Riemann solution.*

We discuss the case $f(u^+) < f(u^-)$, $f'(u^+) < f'(u_5)$, and $q_0 \in (0, q_1]$, where $q_1 > 0$ satisfies $f'(u_5) = \frac{f(u^+) - f(u^-)}{u^+ - (u^- + q_1)}$ (see Figure 7).

It is easy to find that the SDT retains its form when $q_0 \in (0, q_1)$. Namely, a strong detonation $x = x(t)$ can be constructed in the interior of the domain AOB satisfying

$$(3.11)\qquad \begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \dfrac{f(u_r) - f(u_l)}{u_r - (u_l + q_0)} & \left(\lambda(u^+) \le \dfrac{x}{t} \le \lambda(u^-)\right), \\ x(0) = 0. \end{cases}$$

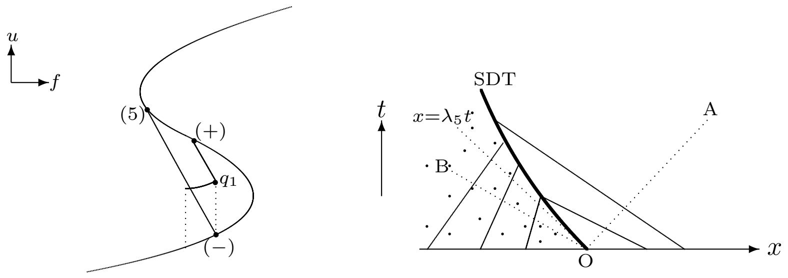

FIG. 7.

Then we consider the complicated case $q_0 = q_1$. According to the Riemann solution, it is possible to define a combustion jump $x = x(t)$ by solving the problem (3.11). Whether an $x = x(t)$ so defined is an SDT depends on whether the stability condition $\lambda(u_r) < \frac{\mathrm{d}x}{\mathrm{d}t} < \lambda(u_l)$ holds for it.

Let $\bar{u}(u_l)$, $\hat{u}(u_l)$ have the same meanings as in Case 3, while $u^* > u_5$ satisfies $f'(u_5) = \frac{f(u^*)-f(u^-)}{f(u^*)-(u^-+q_1)}$, which is different from that in (3.5). In addition, we define $\hat{\hat{u}}(u_l) < \bar{u}(u_l)$ as

$$\begin{cases} \lambda(\bar{u}) = \dfrac{f(\hat{\hat{u}}) - f(u_l)}{\hat{\hat{u}} - (u_l + q_1)}, \\ \hat{\hat{u}}(u^- - 0) = u^+. \end{cases} \tag{3.12}$$

By a calculation similar to that in Case 3, it can be obtained that along $x = x(t)$,

$$\left.\frac{\mathrm{d}\hat{\hat{u}}}{\mathrm{d}t}\right|_{t=0} = -\frac{(\lambda(u^-) - \lambda(u_5))^2(u_5 + q_1 - u^+)}{(\lambda(u^+) - \lambda(u_5))(u_5 - u^-)}\dot{u}_0^-(0).$$

It is easy to see that $x = x(t)$ is an SDT if and only if

$$\left.\frac{\mathrm{d}\hat{\hat{u}}}{\mathrm{d}t}\right|_{t=0} \geq \left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0},$$

which, combined with

$$\left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0} = (\lambda(u_5) - \lambda(u^+))\dot{u}_0^+(0),$$

implies that

$$\frac{(\lambda(u^-) - \lambda(u_5))^2}{u_5 - u^-}\dot{u}_0^-(0) \geq \frac{(\lambda(u^+) - \lambda(u_5))^2}{u_5 + q_1 - u^+}\dot{u}_0^+(0). \tag{3.13}$$

Obviously, (3.13) is satisfied when $\dot{u}_0^-(0) > 0$ and $\dot{u}_0^+(0) < 0$. Moreover, we can derive $\ddot{x}(0) > 0$ for the SDT by the following:

$$(u^- + q_1 - u^+)\ddot{x}(0) = (\lambda(u^+) - \lambda(u_5))^2\dot{u}_0^+(0) - (\lambda(u^-) - \lambda(u_5))^2\dot{u}_0^-(0) > 0.$$

The solution is depicted in Figure 7.

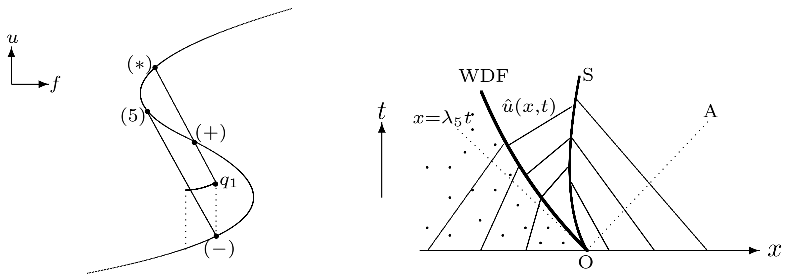

Fig. 8.

Next, let us assume $\dot{u}_0^-(0) > 0$ and $\dot{u}_0^+(0) > 0$. It is certain that the SDT remains when (3.13) is satisfied. Once (3.13) fails to hold, it turns out that the combustion wave SDT turns into a WDF followed by a shock wave (see Figure 8). Now we give the proof for this case.

Due to the entropy conditions, a WDF $x = x^+(t)$ should be constructed in the domain $\lambda(u_5)t \leq x \leq \lambda(u^-)t$, which is determined by (3.7). Then we construct the jump without combustion on the right-hand side of $x = x^+(t)$ as follows:

$$\begin{cases} \dot{x}^-(t) = w(\hat{u}(x,t), u_r(x,t)) \quad \left(x^+(t) \leq \dfrac{x}{t} \leq \lambda(u^-)\right), \\ x^-(0) = 0. \end{cases} \tag{3.14}$$

In order to show the existence of the shock $x = x^-(t)$, we need a certain a priori estimate.

In fact, by (3.7) and (3.14), it can be shown that for any t, t_0 we have

$$\frac{x^-(t) - x^+(t_0)}{t - t_0} = \lambda(\hat{u}(x^-(t),t)) = \lambda(\hat{u}(x^+(t_0),t_0)), \quad t > t_0, \tag{3.15}$$

where

$$\hat{u}(x^-(t),t) = \hat{u}(x^+(t_0),t_0).$$

Differentiating the above equation yields

$$\left.\frac{\mathrm{d}\hat{u}(x^-(t),t)}{\mathrm{d}t}\right|_{t=0} = \left.\frac{\mathrm{d}\hat{u}(x^+(t_0),t_0)}{\mathrm{d}t_0}\right|_{t_0=0} \left.\frac{\mathrm{d}t_0}{\mathrm{d}t}\right|_{t=0}.$$

Noting

$$\left.\frac{\mathrm{d}\hat{u}(x^+(t_0),t_0)}{\mathrm{d}t_0}\right|_{t_0=0} = \frac{(\lambda(u_5) - \lambda(u^-))^2(u_5 + q_1 - u^*)}{(u_5 - u^-)(\lambda(u_5) - \lambda(u^*))}\dot{u}_0^-(0),$$

it follows from (3.15) that $\frac{\mathrm{d}t_0}{\mathrm{d}t}\big|_{t=0} = 1$. Thus we have

$$(u^* - u^+)\ddot{x}^-(0) = (\lambda(u^+) - \lambda(u_5))^2\dot{u}_0^+(0) - \frac{(\lambda(u^-) - \lambda(u_5))^2(u_5 + q_1 - u^*)}{u_5 - u^-}\dot{u}_0^-(0).$$

On the other hand, we get $\ddot{x}^+(0) = \frac{(\lambda(u^-)-\lambda(u_5))^2}{u_5-u^-}\dot{u}_0^-(0)$. Therefore,

$$\ddot{x}^-(0) - \ddot{x}^+(0) = \frac{(\lambda(u^+) - \lambda(u_5))^2}{u^* - u^+}\dot{u}_0^+(0) - \frac{(u_5 + q_1 - u^+)(\lambda(u^-) - \lambda(u_5))^2}{(u_5 - u^-)(u^* - u^+)}\dot{u}_0^-(0) > 0.$$

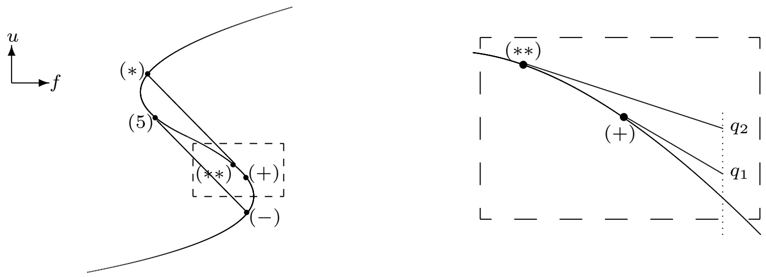

FIG. 9.

Then by virtue of $x^-(0) = x^+(0) = 0$, $\dot{x}^-(0) = \dot{x}^+(0) = \lambda(u_5)$, $\ddot{x}^-(0) > \ddot{x}^+(0) > 0$, it can be proved that there exists a solution $x = x^-(t)$ of (3.14) which takes the value $\hat{u}(x,t)$ on the left-hand side and the value $u_r(x,t)$ on the right-hand side, respectively. Thus we have completed the construction of the solution for this case.

For the remaining cases, $\dot{u}_0^-(0) < 0$ and $\dot{u}_0^+(0) > 0$ or $\dot{u}_0^-(0) < 0$ and $\dot{u}_0^+(0) < 0$, the same discussion as above can be carried out. In brief, the solution of (1.7) and (1.8) may contain an SDT if (3.13) holds; otherwise a WDF followed by a shock may appear.

Remark. In the numerical simulations [18], transition from SDT to WDF followed by a shock is reasonable from the above discussion.

Case 5. *A combustion wave CJDT appears in the corresponding Riemann solution.*

The case $f(u^+) < f(u^-)$, $f'(u^+) > f'(u_5)$, and $q_0 \in [q_1, q_2]$ is considered. Here $q_1, q_2 > 0$ satisfy $f'(u^+) = \frac{f(u^+)-f(u^-)}{u^+-(u^-+q_1)}$, $f'(u_5) = f'(u^{**}) = \frac{f(u^{**})-f(u^-)}{u^{**}-(u^-+q_2)}$, respectively, in which $u^{**} \in (u^+, \tilde{u})$. It is obvious that $q_2 > q_1$ (see Figure 9).

For $q_0 \in [q_1, q_2)$, a discussion similar to that for the convex case shows that the CJDT in the corresponding Riemann solution may either turn into an SDT (if $\dot{u}_0^-(0) > 0$) or retain its form (if $\dot{u}_0^-(0) < 0$).

We now investigate the complex case $q_0 = q_2$. First, we assume $\dot{u}_0^-(0) < 0$. Motivated by the Riemann solution, a CJDT $x = x(t)$ is considered to be constructed in the domain $-\infty < \frac{x}{t} \le \lambda(u_5)$, which is determined by

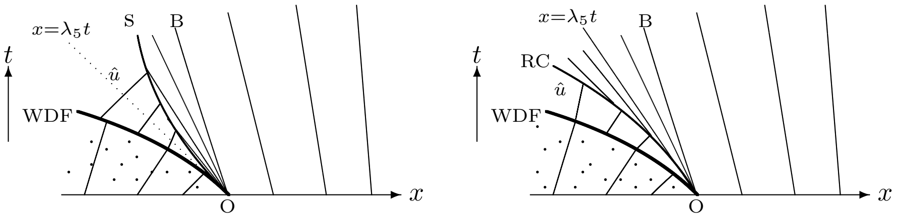
$$\text{(3.16)} \qquad \begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \lambda(\bar{\bar{u}}) = \dfrac{f(\bar{\bar{u}}) - f(u_l)}{\bar{\bar{u}} - (u_l + q_2)}, \\ x(0) = 0, \end{cases}$$

where $\bar{\bar{u}} \in (u^{**}, \tilde{u})$ and $\bar{\bar{u}}(u^- - 0) = u^{**}$. Obviously, such a CJDT occurs if and only if along $x = x(t)$,

$$\text{(3.17)} \qquad \lambda'(u^{**}) \frac{\mathrm{d}\bar{\bar{u}}}{\mathrm{d}t}\bigg|_{t=0} \ge \lambda'(u_5) \frac{\mathrm{d}\bar{u}}{\mathrm{d}t}\bigg|_{t=0},$$

in which $\bar{u}(u_l)$ satisfies the same definition as in Case 3. From (3.5) and (3.16), we derive

$$\begin{aligned} \lambda'(u_5) \frac{\mathrm{d}\bar{u}}{\mathrm{d}u_l}\bigg|_{u_l = u^- - 0} &= \frac{\lambda(u^-) - \lambda(u_5)}{u^- - u_5}, \\ \lambda'(u^{**}) \frac{\mathrm{d}\bar{\bar{u}}}{\mathrm{d}u_l}\bigg|_{u_l = u^- - 0} &= \frac{\lambda(u^-) - \lambda(u_5)}{u^- + q_2 - u^{**}}. \end{aligned}$$



$u_5 + q_2 > u^*$ $u_5 + q_2 < u^*$

FIG. 10.

Then by noting $\frac{\mathrm{d}u_l}{\mathrm{d}t}\big|_{t=0} = (\lambda(u_5) - \lambda(u^-))\dot{u}_0^-(0)$, (3.17) gives

$$u^{**} - u_5 \geq q_1 > 0,$$

from which we find that the construction of the combustion wave CJDT is impossible. Therefore, under the entropy conditions, a WDF $x = x^+(t)$ satisfying (3.7) is to be constructed in the domain $-\infty < \frac{x}{t} \leq \lambda(u_5)$. Now we do some analysis to determine the noncombustion jump behind the WDF. According to (3.9), it holds that along $x = x^+(t)$, $\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\big|_{t=0} > 0$ if $u_5 + q_2 > u^*$, whereas $\frac{\mathrm{d}\hat{u}}{\mathrm{d}t}\big|_{t=0} < 0$ if $u_5 + q_2 < u^*$. Here $u^* > u_5$ satisfies $f'(u_5) = \frac{f(u^*)-f(u^-)}{u^*-(u^-+q_2)} = \frac{f(u^*)-f(u^{**})}{u^*-u^{**}}$. For the case $u_5 + q_2 > u^*$, a shock wave $x = x^-(t)$ should be constructed (see Figure 10) as follows:

$$\begin{cases} \dot{x}^-(t) = w(\hat{u}, u_r) \quad \left(\lambda(u_5) \leq \dfrac{x}{t} \leq \lambda(u^+)\right), \\ \dfrac{x}{t} = \lambda(u_r) \quad (u^{**} \leq u_r \leq u^+), \\ x^-(0) = 0. \end{cases}$$

Furthermore, a computation similar to that in Case 4 results in

$$\ddot{x}^-(0) = \frac{(\lambda(u_5) - \lambda(u^-))^2(u_5 + q_2 - u^*)}{(u_5 - u^-)(u^{**} - u^*)}\dot{u}_0^-(0) > 0.$$

Instead, a right–contact discontinuity $x = x^-(t)$ such as

$$\begin{cases} \dot{x}^-(t) = \lambda(u_m) = w(\hat{u}, u_m) \quad (x^+(t) \leq x \leq \lambda(u_5)t), \\ x^-(0) = 0 \end{cases} \tag{3.18}$$

is constructed for the case $u_5 + q_2 < u^*$, where $u_m \in (u^{**}, \tilde{u})$. In the same way, we can get

$$\ddot{x}^-(0) = \frac{(\lambda(u_5) - \lambda(u^-))^2(u_5 + q_2 - u^*)}{(u_5 - u^-)(u^{**} - u^*)}\dot{u}_0^-(0) < 0.$$

Then by using the fact that $\ddot{x}^+(0) = \frac{(\lambda(u_5)-\lambda(u^-))^2}{u_5-u^-}\dot{u}_0^-(0) < 0$, we have

$$\ddot{x}^-(0) - \ddot{x}^+(0) = -\frac{(\lambda(u_5) - \lambda(u^+))^2(u_5 + q_2 - u^{**})}{(u_5 - u^-)(u^* - u^{**})}\dot{u}_0^-(0) > 0,$$

which, together with $x^-(0) = x^+(0) = 0$ and $\dot{x}^-(0) = \dot{x}^+(0) = \lambda(u_5)$, guarantees the existence of the solution $x = x^-(t)$ to (3.18) (see Figure 10).

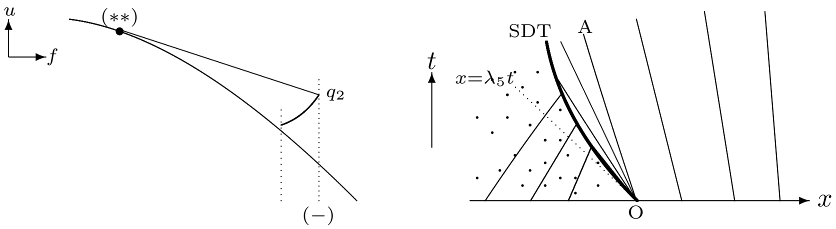


FIG. 11.

Next, we consider the case $\dot{u}_0^-(0) > 0$. It is possible, by the entropy conditions, to define an SDT $x = x(t)$ by solving the following problem:

$$\begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \dfrac{f(u_r) - f(u_l)}{u_r - (u_l + q_2)} & \left(\lambda(u_5) \leq \dfrac{x}{t} \leq \lambda(u^+)\right), \\ x(0) = 0, \end{cases}$$

where $u_r(x,t)$ is a centered simple wave $x = \lambda(u_r)t$ $(u^{**} \leq u_r \leq u^+)$. It can be verified that the sufficient and necessary condition for the appearance of such an SDT is that along $x = x(t)$,

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{f(u_l) - f(u_r)}{u_l + q_2 - u_r}\right)\bigg|_{t=0} \geq \lambda'(u_5)\frac{\mathrm{d}\bar{u}}{\mathrm{d}t}\bigg|_{t=0};$$

namely,

$$\begin{aligned} &[(u^{**} - u^- - q_2)\lambda(u_5) - (f(u^{**}) - f(u^-))]\,\frac{\mathrm{d}u_r}{\mathrm{d}t}\bigg|_{t=0} \\ &\qquad - [(u^{**} - u^- - q_2)\lambda(u^-) - (f(u^{**}) - f(u^-))]\,\frac{\mathrm{d}u_l}{\mathrm{d}t}\bigg|_{t=0} \\ &\geq \frac{(\lambda(u_5) - \lambda(u^-))^2(u^- + q_2 - u^{**})^2}{u_5 - u^-}\,\dot{u}_0^-(0). \end{aligned} \tag{3.19}$$

Note that $f(u^{**}) - f(u^-) = \lambda(u_5)(u^{**} - u^- - q_2)$ and $\frac{\mathrm{d}u_r}{\mathrm{d}t}\big|_{t=0} \neq \infty$; then we find (3.19) is obviously true so that the solution of (1.7) and (1.8) involves an SDT indeed (see Figure 11).

Case 6. *The corresponding Riemann solution is SJ: $x = 0$.*

The case $f(u^+) = f(u^-)$ and $f'(u^+) < f'(u_5)$ is taken into account.

Due to the entropy condition $\lambda(u^+) < w(u^+, u^-) < \lambda(u^-)$, it is possible to construct a shock wave $x = x(t)$ with $\dot{x}(0) = 0$ in the burnt region, which is determined by

$$\begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = w(u_l, u_r) & \left(\lambda(u^+) \leq \dfrac{x}{t} \leq \lambda(u^-)\right), \\ x(0) = 0. \end{cases} \tag{3.20}$$

It is obvious that a solution corresponding to no reaction exists or, equivalently, that a shock wave such as (3.20) forms if and only if along $x = x(t)$,

$$\lambda(u^+)\frac{\mathrm{d}u_r}{\mathrm{d}t}\bigg|_{t=0} \geq \lambda(u^-)\frac{\mathrm{d}u_l}{\mathrm{d}t}\bigg|_{t=0};$$

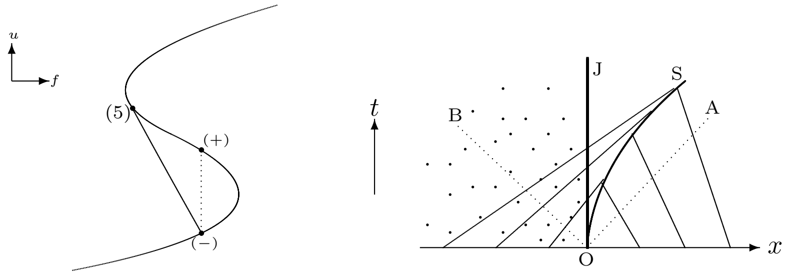

FIG. 12.

namely,

$$(\lambda(u^+))^2\dot{u}_0^+(0) \leq (\lambda(u^-))^2\dot{u}_0^-(0). \tag{3.21}$$

For the case $\dot{u}_0^+(0) < 0$ and $\dot{u}_0^-(0) > 0$, (3.21) obviously holds. So the solution can be denoted by $\mathrm{S}+\mathrm{J}$ (see Figure 12).

For the case $\dot{u}_0^+(0) > 0$ and $\dot{u}_0^-(0) > 0$, we give the discussion in detail. Certainly, burning does not happen, and the solution shown in Figure 12 can be constructed if (3.21) is satisfied. Now we deal with the cases when (3.21) fails, that is, the cases that involve combustion waves.

Suppose the SJ at $t = 0$ becomes an SDT $x = x(t)$ for $t > 0$, in which $x(t)$ with $\dot{x}(0) = 0$, $\ddot{x}(0) < 0$ can be expressed as (3.11). Then we have

$$(u^- + q_0 - u^+)\ddot{x}(0) = (\lambda(u^+))^2\dot{u}_0^+(0) - (\lambda(u^-))^2\dot{u}_0^-(0) > 0,$$

which implies $q_0 < u^+ - u^- =: q_1$. On the other hand, assuming $q_0 \in (0, q_1)$, it can easily be proved that there exists such an SDT as above.

When $q_0 = q_1$, it can be claimed that the SJ turns into either an SDT or a WDF behind which there is a shock wave. In fact, it is easy to show that the combustion wave is an SDT $x = x(t)$ if and only if along $x = x(t)$,

$$\left.\frac{\mathrm{d}\hat{\hat{u}}}{\mathrm{d}t}\right|_{t=0} \geq \left.\frac{\mathrm{d}u_r}{\mathrm{d}t}\right|_{t=0}, \tag{3.22}$$

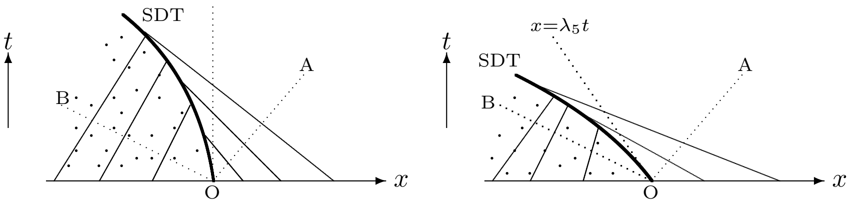
where $\hat{\hat{u}}(u_l)$ satisfies (3.12). With the condition $\dot{x}(0) = 0$, (3.22) is equivalent to

$$\lambda(u^-)(\lambda(u^-) - \lambda(u_5))\dot{u}_0^-(0) \geq \lambda(u^+)(\lambda(u^+) - \lambda(u_5))\dot{u}_0^+(0). \tag{3.23}$$

Thus the SDT with $\dot{x}(0) = 0$ occurs once (3.23) is satisfied. If the SDT has the property $\dot{x}(0+0) = \lambda(u_5)$, (3.22) becomes

$$(\lambda(u^-) - \lambda(u_5))^2\dot{u}_0^-(0) \geq (\lambda(u^+) - \lambda(u_5))^2\dot{u}_0^+(0). \tag{3.24}$$

Therefore we have two possibilities: an SDT with $\dot{x}(0) = 0$ (if (3.23) holds) or an SDT with $\dot{x}(0+0) = \lambda(u_5)$ (if (3.23) fails and (3.24) holds) (see Figure 13). When (3.24) fails to hold, the WDF $x = x^+(t)$ with $\dot{x}^+(0+0) = \lambda(u_5)$ is sure to appear by the entropy conditions. The structure of the solution is similar to that of Figure 8, in which the WDF $x = x^+(t)$ and the shock wave $x = x^-(t)$ also satisfy (3.7) and (3.14), respectively. The discussion on the existence of the shock wave is the same as that in Case 4.



(3.23) holds

(3.24) holds

Fig. 13.

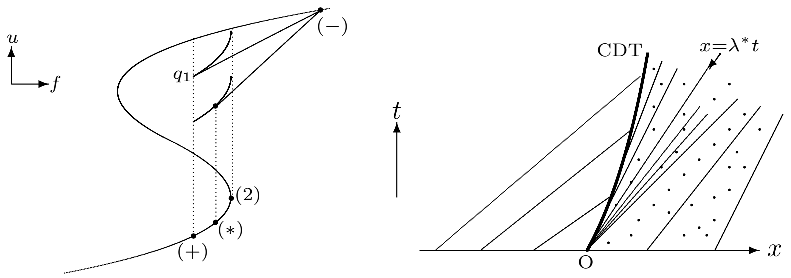


Fig. 14.

When $q_0 \in (q_1, +\infty)$, we can easily find that the perturbation gives rise to WDF + S.

Similarly we deal with the other cases, i.e., $\dot{u}_0^+(0) > 0$ (< 0) and $\dot{u}_0^-(0) < 0$, to obtain that the SJ becomes an SDT ($0 < q_0 < q_1$) or a WDF followed by a shock wave ($q_0 \geq q_1$) if a combustion wave emerges.

Notice that the case $f(u^+) = f(u^-)$, $f'(u^+) > f'(u_5)$ can be treated similarly to the convex case when $q_0 \in (0, q_2)$, where q_2 has the same meaning as in Case 5, while for $q_0 \in [q_2, +\infty)$, the same discussion as above can be carried out. Thus we do not elaborate on it here.

So far we have completed the discussion of all typical cases when the gas is unburnt at the left-hand side of the origin and burnt at the right-hand side at the initial time. Now we turn to the converse case to see what the perturbation will bring.

3.2. Solutions for $u^- > u_i \geq u_0^+(x)$, $q_0^-(x) = 0 < q_0 = q_0^+(x)$. In this subsection, we just mention briefly the cases which differ from those in section 3.1 and the convex ones. In the following, we fix $u^+ \in (-\infty, u_2)$.

Case 7. *A combustion wave CDT appears in the corresponding Riemann solution.*

First, we consider the case $u_i \in [u_2, u^+)$, $f(u^-) > f(u_2)$, and $f'(u^-) > f'(u^+)$. Let $q_1 > 0$ satisfy $f'(u^+) = \frac{f(u^+)-f(u^-)}{u^+ + q_1 - u^-}$ (see Figure 14). Then to ensure the appearance of the CDT, we take $q_0 \in (0, q_1]$. A proof similar to that in Case 1 shows that for $\dot{u}_0^-(0) > 0$, the CDT preserves its form as $x = x(t)$ satisfying

$$
(3.25) \qquad \begin{cases} \dfrac{\mathrm{d}x}{\mathrm{d}t} = \lambda(\bar{u}) = \dfrac{f(u_l) - f(\bar{u})}{u_l - (\bar{u} + q_0)}, \\ x(0) = 0, \\ \dot{x}(0) = \lambda(u^*), \end{cases}
$$

where $\bar{u}(u_l) \in (u^+, u_2)$ with $\bar{u}(u^- - 0) = u^*$ (see Figure 14). And for $\dot{u}_0^-(0) < 0$, the

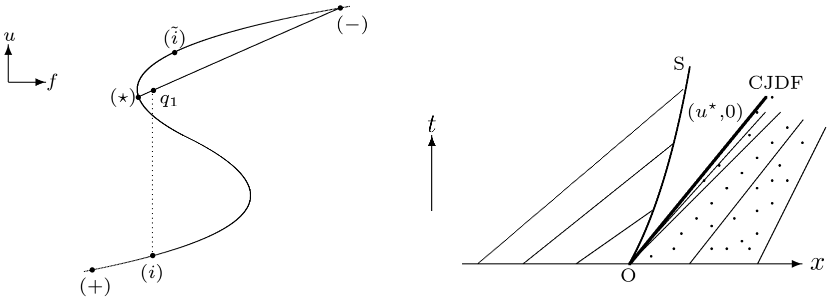

FIG. 15.

CDT changes into an SDT lying in the domain $\lambda(u^*)t \le x \le \lambda(u^-)t$.

Let us consider another case $u_i < u_2$, $f(\tilde{u}_i) \ge f(u_i)$, $u^- > \tilde{u}_i$, and $q_0 = q_2$, in which $q_2 > 0$, $\tilde{u}_i > u_1$ satisfy $f'(u_i) = f'(\tilde{u}_i) = \frac{f(u^-)-f(u_i)}{u^- -(u_i+q_2)}$ (see Figure 15). We also have two possible situations: as above, the CDT becomes an SDT in the domain $\lambda(u_i)t \le x \le \lambda(u^+)t$ provided that $\dot{u}_0^-(0) < 0$, while for $\dot{u}_0^-(0) > 0$, the combustion wave CJDF $x = \lambda(u_i)t$ appears. The state behind the CJDF is $(u^\star, 0)$, which is connected with $(u_r(x,t), 0)$ by a shock wave. Here $u^\star < \tilde{u}_i$, satisfying $f'(u_i) = \frac{f(u^-)-f(u^\star)}{u^- - u^\star} = \frac{f(u_i)-f(u^\star)}{u_i+q_2-u^\star}$ (see Figure 15).

Case 8. *A combustion wave DCC appears in the corresponding Riemann solution.*

From the property of DCC: $\lambda(u_r) = \sigma = \lambda(u_l)$, we easily find that the perturbation cannot affect a combustion wave of this kind, which is able to propagate with the speed at initial time.

We summarize our results in the following.

THEOREM 3.1. *There exists a unique solution to the generalized Riemann problem* (1.7) *and* (1.8). *For most of the cases, the corresponding Riemann solutions are stable, while for some typical cases, a small perturbation of initial data may lead to essential changes to the corresponding Riemann solutions. Especially, a strong detonation in the corresponding Riemann solution may turn into a weak deflagration followed by a shock wave after perturbation, which appears in the numerical simulations.*

ADMISSIBILITY OF A WIDE CLUSTER SOLUTION IN "ANISOTROPIC" HIGHER-ORDER TRAFFIC FLOW MODELS[*]

RUI-YUE XU[†], PENG ZHANG[‡], SHI-QIANG DAI[†], AND S. C. WONG[§]

Abstract. We analytically investigate a wide cluster solution and show that it is not admitted in some of the traffic flow models in the literature. For those traffic flow models that admit the wide cluster solution, the relationship between two important control parameters and the critical densities that divide an equilibrium solution into stable and unstable regions is thoroughly discussed in detail. We find that such wide clusters exist with a free traffic density in an unstable region, and with one or three critical densities. These results are different from the cases in the well-known higher-order traffic flow models of Payne and Whitham [H. J. Payne, "Models of freeway traffic and control," in *Mathematical Models of Public Systems*, A. G. Bekey, ed., Simulation Council Proc. Ser. 1, La Jolla, CA, 1971, pp. 51–61], [G. B. Whitham, *Linear and Nonlinear Waves*, John Wiley and Sons, New York, 1974], Kühne [R. D. Kühne, "Macroscopic freeway model for dense traffic-stop-start waves and incident detection," in *Proceedings of the 9th International Symposium on Transportation and Traffic Theory*, J. Volmuller and R. Hamerslag, eds., VNU Science Press, Utrecht, 1984, pp. 21–42], and Kerner and Konhäuser [B. S. Kerner and P. Konhäuser, *Phys. Rev. E* (3), 50 (1994), pp. 54–83].

1. Introduction.

Lighthill and Whitham [14] and Richards [17] independently proposed a hydrodynamic approach to study the traffic flow problems on a homogeneous highway, which is known in the literature as the first-order LWR model. The model has recently been extended to multilane [4] and multiclass models [3, 9, 10, 25, 31, 30, 32]. To embody the important nonlinear phenomena in traffic flow problems, some classical higher-order traffic flow models were developed [13, 12, 15, 23] and are characterized by their capability to reproduce the stop-and-go waves that are frequently observed on the highways. The formation of clusters is related to the instability of congested traffic, of which the development into free traffic and jams is typical of phase transitions and hystereses [12, 29, 28]. However, Daganzo [5] criticized the "isotropic" nature of these models, following which a stream of so-called anisotropic higher-order models [1, 8, 11, 19, 26, 27] was developed.

Recently, an analytical tool that is based on the weak solution theory was proposed to give a full and concise description of a wide cluster solution in higher-order models. Zhang, Wong, and Dai [33] used the model proposed by Jiang, Wu, and

Zhu [11] to demonstrate the solution procedure. Zhang and Wong [28] further showed that two conservation forms of the Payne–Whitham (PW) models [15, 23] have different cluster solutions that are asymptotic to the solutions of the Kühne [13] and Kerner and Konhäuser (KK) [12] models.

In this paper, we thoroughly investigate the admissibility of a wide cluster solution for several aforementioned "anisotropic" models, using the technique that was developed in [33, 28]. The model equations are introduced in section 2. In section 3, the procedure for solving a wide cluster is briefly discussed. While a criterion is prescribed as an essential condition, the formulations in [26, 27] are excluded from further consideration because they do not admit a wide cluster solution (see section 3.1). Here, we note that cluster solutions were also derived in Greenberg [6], Siebel and Mauser [20], and Wilson and Berg [24]. With two control parameters in the "pressure" $p(\rho) = \alpha(\rho/\rho_m)^\gamma$ of Aw and Rascle [1], the admissible regions of (γ, α) for the wide cluster solution are displayed. The regions of (γ, α) that are related to the stability of an equilibrium solution are also discussed (see section 3.2). It is novel to find that the free traffic flow (the constant flow with the minimal density) of a wide cluster solution is not stable in numerous regions, whereas the jam (the flow with the maximal density in the cluster) together with the whole solution is always stable. In some of these regions, it is evident that a wide cluster solution is admitted with one or three critical densities, which are used to divide equilibrium flows into stable and unstable regions. The results from numerical simulations (see section 4) are in good agreement with all analytical findings.

2. Model equations.

In macroscopic descriptions, vehicles on a highway are analogous to flows in compressible hydrodynamics [14, 17]. We have, by the mass conservation,

$$\rho_t + q_x = 0, \tag{1}$$

where $\rho(x,t)$ is the density, $q(x,t)$ is the flow, and no off- or on-ramp flows are considered along the highway. By defining an average speed $v = q/\rho$, the acceleration is considered in higher-order models. We write the acceleration of the discussed "anisotropic" models in the following mutual form:

$$v_t + vv_x = \frac{v_e(\rho) - v}{\tau} + \rho p'(\rho) v_x, \tag{2}$$

where $p(\rho)$ is the "pressure" with $p'(\rho) > 0$, and $v_e(\rho)$ is the equilibrium speed-density relationship with $v_e'(\rho) < 0$. For the derivation of a stable wide cluster, we assume a nonconvex fundamental diagram $q_e(\rho) = \rho v_e(\rho)$. Precisely, $q_e''(\rho) < 0$ for $0 \le \rho < \rho_I$, and $q_e''(\rho) > 0$ for $\rho_I < \rho \le \rho_m$, where $q_e''(\rho_I) = 0$, and ρ_m is the jam (maximum) density. Furthermore, we assume that $\tau > \tau_0$ for some fixed $\tau_0 > 0$, and thus the relaxation term is bounded. Nevertheless, this model is asymptotic to the LWR model [14, 17] if we allow $\tau \to 0$, which leads to $v \to v_e(\rho)$; see [16].

It is easy to derive the two characteristic speeds of system (1)–(2): $\lambda_1 = v - \rho p'(\rho)$ and $\lambda_2 = v$, which are no greater than the motion speed. Therefore, a perturbation propagates only upstream with respect to the perturbed moving vehicle. This is why the formulation is classified as "anisotropic." In contrast, the two characteristic speeds in the classical models are, respectively, smaller and greater than the traffic speed v, meaning that the perturbation propagates both upstream and downstream.

Several choices of the function $p(\rho)$ are listed in Table 1, corresponding to different

TABLE 1

"Anisotropic" formulations of higher-order traffic flow models, which are distinguished by the "pressure" $p(\rho)$ or the sound speed $c(\rho) = \rho p'(\rho)$, where $T(\rho) = t_r[1 + E/(1+\rho)]$ and constants $c_0, E, t_r > 0$.

Models	$c(\rho)$	$p(\rho)$

Jiang, Wu, and Zhu [11]	c_0	$c_0 \ln \rho$
Zhang [27]	$-\rho\, v_e'(\rho)$	$-v_e(\rho)$
Xue and Dai [26]	$-\rho\, \frac{t_r}{T(\rho)} v_e'(\rho)$	$-\frac{t_r}{T(\rho)} v_e(\rho)$

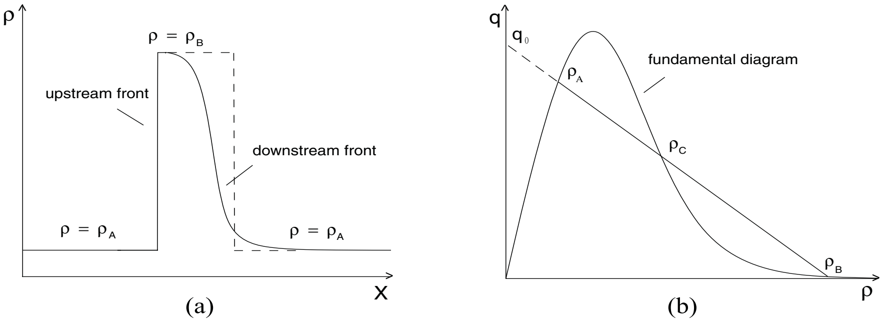

FIG. 1. *Illustration of a wide cluster solution:* (a) *profile of the density distribution;* (b) *phase plot $q = q(\rho)$ in comparison to the fundamental diagram $q = q_e(\rho)$.*

formulations in [1, 11, 26, 27]. We note that Aw and Rascle [1] contained a more general model by assuming an increasing function $p(\rho)$, and that the relaxation term was considered in [16] as an improvement; see also [2, 7] for further development of the Aw and Rascle model. Similarly, we add such a term to the formulation of Zhang [27]; without the term, it is unlikely to derive a wide cluster solution.

3. Admissibility of a wide cluster solution.

The profile of a wide cluster solution is shown in Figure 1(a). The cluster is expected to move backward with a constant velocity $a < 0$, without change in the shape. In other words, we assume a traveling wave solution $\rho(x,t) = \rho(X)$ and $v(x,t) = v(X)$ with $X = x - at$. Following the procedures in [33, 28], we can show that the downstream front is a smooth transition layer and the upstream front is a shock wave.

3.1. The downstream and upstream fronts.

For the downstream front that smoothly links a higher density region $\rho = \rho_B$ to a lower density region $\rho = \rho_A$, $\rho_A < \rho_B$, equations (1) and (2) are applicable. Hence, we replace $\rho(x,t)$ and $v(x,t)$ with $\rho(X)$ and $v(X)$ in the equations, which yields

$$q = a\rho + q_0 \tag{3}$$

and

$$\frac{d\rho}{dX} = g(\rho)\frac{q_e(\rho) - (a\rho + q_0)}{p'(\rho)\rho^2 - q_0}, \tag{4}$$

where the integration constant $q_0 > 0$, and thus the function $g(\rho) = \rho^2(\tau q_0)^{-1} > 0$. Equation (3) suggests a linear relation between the flow q and the density ρ, which is represented by a segment $\overline{AB}$ in Figure 1(b). As we assume that $d\rho/dX|_{\rho=\rho_A} = d\rho/dX|_{\rho=\rho_B} = 0$ (Figure 1(a)), (4) gives

$$(5) \qquad q_e(\rho_A) = a\rho_A + q_0, \quad q_e(\rho_B) = a\rho_B + q_0.$$

This implies that the two constant states ρ_A and ρ_B are in equilibrium (see Figure 1(b)). See [23] for a similar derivation. Let $(\rho_C, q_e(\rho_C))$ be the intersection of the segment $\overline{AB}$ and the fundamental diagram $q = q_e(\rho)$, i.e.,

$$(6) \qquad q_e(\rho_C) = a\rho_C + q_0.$$

It is obvious that the numerator of (4) is positive for $\rho \in (\rho_A, \rho_C)$ and negative for $\rho \in (\rho_C, \rho_B)$ (see Figure 1(b)). Accordingly, a decreasing transition layer ($d\rho/dX < 0$) is guaranteed if and only if

$$(7) \qquad p'(\rho_C)\rho_C^2 - q_0 = 0, \quad (p'(\rho)\rho^2 - q_0)(\rho - \rho_C) > 0 \quad \text{for } \rho \neq \rho_C.$$

Intuitively, we have $q_e'(\rho_C) < a < q_e'(\rho_B)$; see Figure 1(b). This along with (5)–(7) gives $v_e'(\rho_C) + p'(\rho_C) < 0$, and $v_e'(\rho_B) + p'(\rho_B) > 0$. By the linear stability conditions (see section 3.2), the two inequalities imply the following property.

PROPERTY 1. *For the solvability of a transition layer,* (i) ρ_C *must be located in an unstable region, whereas* (ii) ρ_B *must be located in a stable region.*

The two formulations attained by choosing $p(\rho) = -v_e(\rho)$ in [27] and $p(\rho) = -t_r v_e(\rho)/T$ in [26] (see Table 1) are not able to generate a transition layer, because equilibria of [27] and [26] can be easily shown to be uniformly stable and unstable, respectively. This also implies that they are not able to reproduce a wide cluster. For the choice of $p(\rho) = c_0 \ln \rho$ in [11] (see Table 1), the detailed discussion on the solution of a wide cluster was given in [33]. These three models are excluded from the forthcoming discussion.

We also note that Siebel and Mauser [19, 20, 21] adopted a strictly concave flow-density relationship $q_e(\rho) = \rho v_e(\rho)$ with the "pressure" $p(\rho) = -v_e(\rho)$. Although the convective term of their models resembled the model in Zhang [27], Siebel and Mauser introduced a coefficient $\beta(\rho, v)$ in the relaxation term which may change sign to reflect the interaction or difference between the relaxation time and reaction time of drivers. This allowed two critical densities (and thus an unstable regime) which correspond to the roots of the function $\beta(\rho, v)$. Then a traveling wave solution was obtained for this novel formulation [20].

In another development, Greenberg [6] derived the traveling wave solutions (clusters) using Lagrangian coordinates, in which the headway $s = 1/\rho$ and the car index m were taken as solution variables. Conservation across the discontinuous upstream front was also considered in [6], which in essence was similar to our discussion in what follows. Here, we remark that some intrinsic relations were implied in the formulations of Greenberg, Klar, and Rascle [8], Greenberg [6], and Siebel and Mauser [19].

In the forthcoming discussion, we assume that the denominator of (4) is an increasing function of ρ, that is,

$$(8) \qquad (p'(\rho)\rho^2)' \equiv \rho(\rho p(\rho))'' > 0,$$

which is sufficient to ensure the inequality in (7). Essentially, (8) or the convexity of the function $\rho p(\rho)$ was also assumed in [1, 8, 6, 19, 20, 21].

A monotonically increasing and smooth connection from ρ_A to ρ_B is impossible at the upstream front according to (3) and (4) and the detailed discussion in [33, 28]. We consider a shock wave with the following conservation form of (2),

$$\frac{\partial \rho(v+p(\rho))}{\partial t} + \frac{\partial \rho v(v+p(\rho))}{\partial x} = \frac{q_e(\rho)-q}{\tau}, \tag{9}$$

in [1, 16]. It is difficult, if not impossible, to define other conservation forms, except for that defined in [33] in which $c(\rho) = \rho p'(\rho)$ was taken as a constant. We note that different conservation forms result in different values of the characteristic parameters for solving a wide cluster [28].

To deal with the assumed shock that is also a traveling wave with the moving speed $a < 0$, we apply the Rankine–Hugoniot conditions to the conservation system of (1) and (9). This gives two equalities: one is implied in (5) and the other reads

$$a = \frac{q_e(\rho_B)(v_e(\rho_B)+p(\rho_B)) - q_e(\rho_A)(v_e(\rho_A)+p(\rho_A))}{(q_e(\rho_B)+\rho_B p(\rho_B)) - (q_e(\rho_A)+\rho_A p(\rho_A))}, \tag{10}$$

where the constant state $\rho = \rho_A$ (together with $\rho = \rho_B$) can easily be verified to be in equilibrium by (1) and (9). By (5)–(7) and (10) we have five independent algebraic equations to solve for five unknowns: a, ρ_A, ρ_B, ρ_C, and q_0. The solution of this algebraic equation system determines the assumed wide cluster solution.

3.2. Control parameters and solvability of the wide cluster. The speed-density relationship is taken as

$$v_e(\rho) = v_f((1+e^{12.5(\rho/\rho_m - 0.25)})^{-1} - (1+e^{12.5\times 0.75})^{-1}), \tag{11}$$

where v_f is the free-flow speed, ρ_m is the jam density, and the point of inflexion of the fundamental diagram $q_e(\rho) = \rho v_e(\rho)$ is located at $\rho_I \approx 0.333598$. Equation (11) is similar to that in [12] and was also applied in [33]. We take the "pressure" as

$$p(\rho) = \alpha(\rho/\rho_m)^\gamma, \quad \alpha, \gamma > 0. \tag{12}$$

Let $(\rho_0, q_e(\rho_0))$ be an equilibrium point in the fundamental diagram. The linear stability conditions for a constant solution $\rho = \rho_0$ can then be easily determined as $\lambda_1(\rho_0) \le q_e'(\rho_0) \le \lambda_2(\rho_0)$, which implies that the kinematic wave speed lies between the first and second characteristic speeds. See Whitham [23] for the relevant discussion. The inequalities are equivalent to

$$H(\rho_0) \equiv -1 - \frac{v_e'(\rho_0)}{p'(\rho_0)} \le 0, \tag{13}$$

because it is assumed that $p'(\rho_0) > 0$, and the condition of a single point at the boundary with $\rho_0 = 0$ is excluded. Taking the equality of (13) and with two control parameters α and γ, we indicate the solvability of the critical densities and the resultant stable and unstable regions. Hereafter, we denote dimensionless variables by placing a bar over them, such that a density is scaled by ρ_m and a speed (including the parameter α) is scaled by v_f. Using the dimensionless variables, we note that these critical densities and all characteristic parameters of the cluster solution depend on γ and $\bar{\alpha}$ only.

For the case $\gamma > 1$, say $\gamma = 2$ as is applied in the construction of Figure 2(a), monotone changes of the function $H(\rho_0)$ are divided into three intervals. This suggests

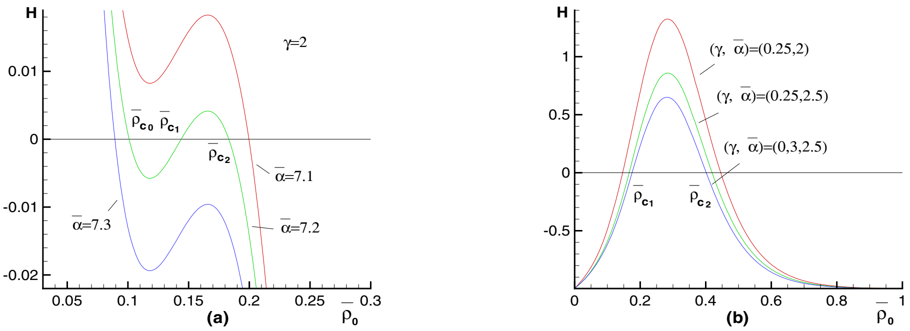

FIG. 2. *Solvability of critical densities and division of stable and unstable regions for an equilibrium constant solution* $\rho = \rho_0$ *for* (a) $\gamma > 1$ *and* (b) $\gamma \leq 1$.

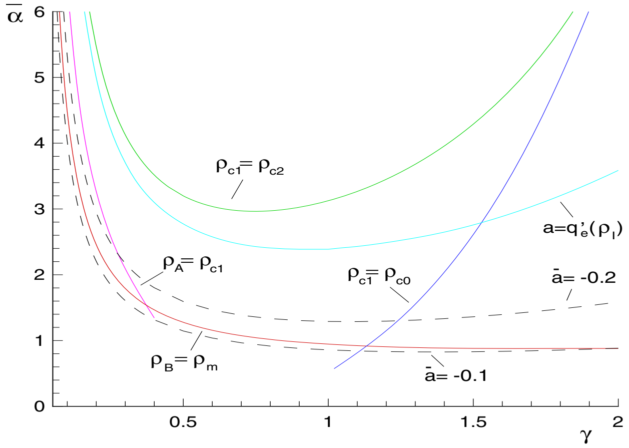

FIG. 3. *Division of the* γ-$\bar{\alpha}$ *plane for the study of a wide cluster solution. The solution exists below the curve* $a = q_e'(\rho_I)$, *and the traveling wave velocity* a *and the height* $\rho_B - \rho_A$ *decrease when* $(\gamma, \bar{\alpha})$ *approaches the curve. The equilibrium density* $\rho = \rho_A$ *of the cluster solution is located in a stable region only for approximately* $\gamma < 0.4$ *and* $(\gamma, \bar{\alpha})$ *in or below the curve* $\rho_A = \rho_{c_1}$.

at most three critical densities, ρ_{c_0}, ρ_{c_1}, and ρ_{c_2}. In this case, say with $\bar{\alpha} = 7.2$ as in the figure, the three critical densities divide the interval $(0, 1]$ into two stable intervals, $[\bar{\rho}_{c_0}, \bar{\rho}_{c_1}]$ and $[\bar{\rho}_{c_2}, 1]$, and two unstable intervals, $(0, \bar{\rho}_{c_0})$ and $(\bar{\rho}_{c_1}, \bar{\rho}_{c_2})$. As $\bar{\alpha}$ decreases (with reference to another curve $H(\bar{\rho}_0)$ for $\bar{\alpha} = 7.1 < 7.2$), $\bar{\rho}_{c_1}$ and $\bar{\rho}_{c_0}$ become identical for some $\bar{\alpha} \in (7.1, 7.2)$. This is to simultaneously have $H(\rho_{c_0}) = 0$ and $H'(\rho_{c_0}) = 0$, which determine a curve that is denoted by $\rho_{c_1} = \rho_{c_0}$ in the γ-$\bar{\alpha}$ coordinate plane (Figure 3). In the region that is below the curve $\rho_{c_1} = \rho_{c_0}$ (Figure 3), the critical densities $\bar{\rho}_{c_0}$ and $\bar{\rho}_{c_1}$ together with the interval $[\bar{\rho}_{c_0}, \bar{\rho}_{c_1}]$ must vanish because $\bar{\alpha}$ becomes smaller; see also the reference curve $H(\bar{\rho}_0)$ for $\bar{\alpha} = 7.1 < 7.2$ in Figure 2(a). In this case, we have an unstable interval $(0, \bar{\rho}_{c_2})$ and a stable interval $[\bar{\rho}_{c_2}, 1]$. Similarly, we can draw a curve $\rho_{c_1} = \rho_{c_2}$ in Figure 3, which is determined by setting $H(\rho_{c_2}) = 0$ and $H'(\rho_{c_2}) = 0$. The critical densities $\bar{\rho}_{c_1}$ and $\bar{\rho}_{c_2}$ along with the interval $(\bar{\rho}_{c_1}, \bar{\rho}_{c_2})$ vanish for $(\gamma, \bar{\alpha})$ in the region that is above this curve (Figure 3). See also the reference curve $H(\bar{\rho}_0)$ for $\bar{\alpha} = 7.3 > 7.2$ in Figure 2(a). In this case, we have an unstable interval $(0, \bar{\rho}_{c_0})$ and a stable interval $[\bar{\rho}_{c_0}, 1]$.

For the case $\bar{\gamma} \leq 1$, monotone changes of the function $H(\rho_0)$ are divided into two intervals. This suggests at most two critical densities $\bar{\rho}_{c_1}$ and $\bar{\rho}_{c_2}$. We define the same curve $\rho_{c_1} = \rho_{c_2}$ as previously discussed, and the curve goes smoothly in the whole region for $\gamma > 1$ and $\gamma \leq 1$ (Figure 3). However, in the region that is above the curve $\rho_{c_1} = \rho_{c_2}$ and for $\gamma \leq 1$, we have an overall stable interval $(0, 1]$.

We now turn our attention to the solvability and the characteristic parameters of the discussed wide cluster, which is related to the critical densities and the division of the stable and unstable intervals through Property 1 and the following discussion. With two control parameters $\bar{\alpha}$ and γ, we note that one equation in addition to (5)–(7) and (10) determines a curve in the γ-$\bar{\alpha}$ coordinate plane implicitly, which is also shown in Figure 3.

Defining the curve $\rho_B = \rho_m$, we can verify that the region below the curve $\rho_B = \rho_m$ suggests that $\rho_B > \rho_m$, by which the wide cluster solution is not collision-free. Therefore, this region is not considered in the forthcoming discussion. Furthermore, we define the curve $a = q_e'(\rho_I)$ ($\approx -0.542579 v_f$). By Figure 1(b), it is evident that the traveling wave speed a reaches its minimum with $\rho_A = \rho_C = \rho_B = \rho_I$ for $(\gamma, \bar{\alpha})$ in this curve. Here, the inequalities

$$\rho_A < \min(\rho_C, \rho_I) < \rho_B \tag{14}$$

are assumed for the wide cluster solution because of the nonconvexity of the function $q_e(\rho)$ (cf. Figure 1(b)). According to Property 1, it is implied that ρ_I is a critical density in the above limiting solution. Actually, we derive the same curve when defining $\rho_{c_2} = \rho_I$. For $(\gamma, \bar{\alpha})$ that is above this curve ($a = q_e'(\rho_I)$ or $\rho_{c_2} = \rho_I$), (5)–(7) and (10) are insolvable. This means that the iteration that is applied to solve these equations is never convergent under the restriction of (14). On the other hand, (5)–(7) and (10) are solvable for $(\gamma, \bar{\alpha})$ that is between the curves $\rho_B = \rho_m$ and $a = q_e'(\rho_I)$. Here, the curve $a = q_e'(\rho_I)$ serves as the other boundary to separate the two regions in which the wide cluster is, respectively, solvable and insolvable.

Let α increase. Then we find that the traveling wave speed a of the wide cluster decreases until a reaches its limiting value in the curve $a = q_e'(\rho_I)$. Two reference curves $\bar{a} = -0.1$ and $\bar{a} = -0.2$ are depicted in Figure 3 to show such a monotonic decreasing property. By the mass conservation at the discontinuous upstream front, a decreasing traveling wave speed usually suggests a drastic drop in the height $\rho_B - \rho_A$ of the wide cluster. The critical density ρ_{c_2} also decreases in this trend, which implies that $\rho_{c_2} > \rho_I$ for $(\gamma, \bar{\alpha})$ below the curve $a = q_e'(\rho_I)$, and $\rho_{c_2} < \rho_I$ for $(\gamma, \bar{\alpha})$ between the curves $a = q_e'(\rho_I)$ and $\rho_{c_1} = \rho_{c_2}$. This seems to suggest that it is essential that there exist a critical density that is greater than the inflexion ρ_I for the solvability of the wide cluster. On the other hand, it is novel that the wide cluster is insolvable even though we do have a critical density $\rho_{c_2} < \rho_I$ that is close to ρ_I.

The foregoing discussion together with Property 1 also suggests the locational relations between the critical densities and the two characteristic densities ρ_C and ρ_B. That is, $\rho = \rho_C$ and $\rho = \rho_B$ (as a constant portion of the wide cluster), respectively, are located in two adjacent unstable and stable intervals that is separated by $\rho_{c_2} > \rho_I$. This fact is also related to the following analytical property.

Property 2. *There is at most one critical density in* $[\rho_I, \rho_m]$.

This property holds simply because a critical density is also the root of the function $\rho^2 p'(\rho) H(\rho)$, and $(\rho^2 p'(\rho) H(\rho))' = -\rho(\rho p(\rho))'' - \rho(\rho v_e(\rho))'' < 0$ in $[\rho_I, \rho_m]$. For the solvability of the wide cluster, we do have such a critical density ρ_{c_2}. Here, it is implied that $\rho_{c_0} \leq \rho_{c_1} < \rho_I$ if the critical density ρ_{c_0} or ρ_{c_1} does exist.

To learn the locational relation between ρ_A and the critical densities, we draw the curve $\rho_A = \rho_{c_1}$ in Figure 3, which exists for $\gamma \leq 0.4$ approximately, where it meets with the curve $\rho_B = \rho_m$. Between the two curves we have $\rho_A \leq \rho_{c_1}$, which suggests that the equilibrium $\rho = \rho_A$ (as a constant portion of the wide cluster) is stable. In other regions where ρ_{c_1} does not vanish, we obviously have $\rho_{c_1} < \rho_A < \rho_I < \rho_{c_2}$, which suggests that $\rho = \rho_A$ is unstable. In the region that is below the curve $\rho_{c_0} = \rho_{c_1}$ for $\gamma > 1$, where ρ_{c_0} and ρ_{c_1} vanish, $\rho = \rho_A < \rho_I < \rho_{c_2}$ still belongs to the unstable region $(0, \rho_{c_2})$.

4. Wide clusters derived from numerical simulation. We write the system of (1) and (9) as the following standard conservation or balance laws:

$$u_t + f(u)_x = s(u), \tag{15}$$

where $u = (\rho, h)^T$, $h = \rho(v + p(\rho))$, $f(u) = (h - \rho p(\rho),\ \rho^{-1}h^2 - hp(\rho))^T$, and $s(u) = (0, \tau^{-1}(q_e(\rho) - h + \rho p(\rho)))^T$. For a numerical simulation, a conservative scheme of system (15) can be written as

$$u_i^{n+1} = u_i^n - \frac{\Delta t^n}{\Delta x}(\hat{f}_{i+1/2}^n - \hat{f}_{i-1/2}^n) + \Delta t^n s(u_i^n),$$

where $\Delta x = L/N$, and N is the grid number of the computational interval $(0, L)$. We apply the Lax–Friedrichs numerical flux:

$$\hat{f}_{i+1/2}^n = \frac{1}{2}(f(u_i^n) + f(u_{i+1}^n) - \mu^n(u_{i+1}^n - u_i^n)), \quad \mu^n = \max_u \max(|\lambda_1|, |\lambda_2|),$$

where $\lambda_{1,2}$ are the two characteristic speeds, and the maximum is taken over u_i^n for all i at time level n. The CFL condition that is necessary for numerical stability turns out to be $\Delta t^n \leq \mu^n \Delta x$; we always take $\Delta t^n = 0.7\mu^n \Delta x$ in numerical simulations. As the grids should be sufficiently refined to obtain the discussed wide cluster solution, we take a large grid number $N = 10000$ in all examples. For illustration purposes, only one state in every 20 grid points is shown in the figures. See [18, 22] for detailed accounts of the Lax–Friedrichs scheme. The reason for the application of this scheme rather than the Godunov or a higher-order scheme was explained in [28].

For an initial constant distribution $\rho(x, 0) = \rho_0$, which is in equilibrium with $v(x, 0) = v_e(\rho(x, 0))$, the small perturbation

$$\rho(x, 0) = \rho_0 + 0.005\rho_0(sgn(0.05 - |x/L - 0.5|) + 1)\sin(20\pi(x/L - 0.5)) \tag{16}$$

induces amplifying oscillations if density ρ_0 is located in an unstable region. Here, we define $sgn(s) = 1$ for $s \geq 0$, and $sgn(s) = -1$ for $s < 0$; the integral average density of $\rho(x, 0)$ over the computational interval $[0, L]$ is not changed by the perturbation. Applying the periodic boundary conditions

$$\rho(0, t) = \rho(L, 0), \quad v(0, t) = v(L, 0), \tag{17}$$

which ensure the conservation of the total vehicles in numerical simulation, the oscillations may evolve into stop-and-go waves or wide clusters in the long run if ρ_0 is sufficiently large. The dynamics of the evolution was well described in the PW [15, 23], Kühne [13], and KK [12] models; see also [28] for more relevant discussion.

As discussed in previous sections, the evolution of the perturbed constant flow $\rho = \rho_0$ is dependent on the control parameters γ and $\bar{\alpha}$, as shown in Figure 3. Our

numerical tests agree well with all these descriptions. In the domain that is on or above the curve $\rho_{c_1} = \rho_{c_2}$ in Figure 3, the perturbation decays with time because the solution $\rho = \rho_0$ is stable if $\bar{\gamma} \leq 1$ or, otherwise, if ρ_0 is greater than ρ_{c_0}, which is usually very small (see Figure 4(a)). In the domain between the curves $\rho_{c_1} = \rho_{c_2}$ and $a = q_e'(\rho_I)$, the perturbation increases with time but a wide cluster solution can never be developed regardless of the length of simulation (see Figure 4(b)). Here and hereafter, for all figures, the related parameters are shown in Table 2 and the variable x is scaled by $\bar{x} = x/L$. Through numerical simulation, we can always derive one or more wide clusters in other domains where the solution is predicted analytically. Two

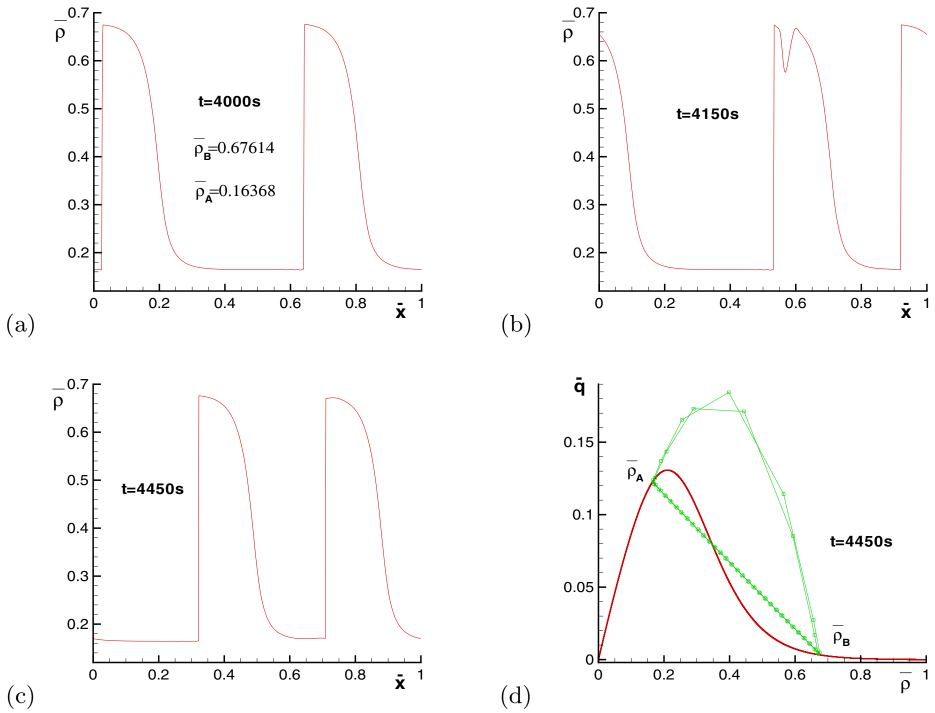

FIG. 5. *Stability test of a wide cluster solution with* $(\gamma, \bar{\alpha}) = (1.5, 1.5)$*,* $\bar{\rho}_0 = 0.33$*, and* $\tau = 10s$*:* (a) *two fully developed clusters;* (b) *density change due to a perturbation to the cluster solution;* (c) *recovery of the cluster solution from the perturbation;* (d) *the fundamental diagram* $(\bar{\rho}, \bar{q}_e(\bar{\rho}))$ *and the phase plot* $(\bar{\rho}, \bar{q})$*.*

such examples are shown in Figures 4(c) and (d).

It is novel that all predicted wide clusters are stable through numerical testing, even though the density $\rho = \rho_A$ of the free traffic is located in an unstable region. It is evident that a stable wide cluster solution exists with one or three critical densities for $\bar{\gamma} > 1$, as predicted analytically in Figure 3. We show a stability test in Figure 5 with $(\bar{\gamma}, \alpha)$ in this region, in which there is only one critical density (see also Table 2). Figure 5(a) shows two wide clusters that are derived at $t = 4000s$. By a perturbation that changes the speed $\bar{v}$ to $\bar{v} \mp 0.1$ for $\bar{x}$ between 0.5 and 0.5 ∓ 0.01, one cluster is found to be slightly distorted at $t = 4150s$. However, it soon recovers, as shown in Figure 5(c). In comparison to the fundamental diagram, we show the phase plot of the solution in Figure 5(d), where the segment $\overline{AB}$ represents the acceleration path of the downstream front. Nevertheless, the deceleration path of the two upstream fronts is now replaced by two curves from A to B. This takes place because a shock profile has to be smoothed by numerical viscosities, which can hardly be avoided in any scheme. The clusters that are shown in all of these figures follow the pattern that is anticipated in Figures 1(a) and (b).

A stable wide cluster solution with a length of unstable equilibrium $\rho = \rho_A$ might be well explained by the stable structure of the upstream front. Actually, the relaxation term of (9) vanishes for solution states on the both sides near the upstream front. Moreover, it is easy to verify that the Lax entropy conditions are satisfied with respect to this discontinuity (see also [6]). When the periodic boundary conditions are applied, a perturbation to $\rho = \rho_A$ (or other solution states) of the wide cluster is expected to be overtaken and thus "absorbed" by the upstream-moving shock. However, an affirmative conclusion could be made only through a rigorous mathematical proof, which is an interesting question for future study.

The parameter values of ρ_A and ρ_B acquired from numerical simulations are also shown in the figures, which are in good agreement with those that are derived from (5)–(7) and (10), and are listed in Table 2. This demonstrates that our numerical solutions converge to the analytical solutions of the described wide cluster.

5. Conclusions and discussions. We have thoroughly investigated the admissibility of a wide cluster solution in "anisotropic" higher-order models, in which the acceleration equation takes the functional form in (2). By this functional form (and also those in [6] and [19]), it appears essential that for the existence of the wide cluster solution the speed-density relationship $v_e(\rho)$ and the "pressure" $p(\rho)$ should be in "conflict" such that there exists an unstable regime in the vicinity of the congestion. Accordingly, it is evident that some formulations that are mentioned in this paper (and probably others) do not admit any wide cluster solution. Even with the functional forms that allow an unstable regime, the "pressure" $p(\rho)$ and the speed-density relationship $v_e(\rho)$ that represents the "force" for relaxation or fluctuation should act "harmoniously" to admit the solution. With reference to Figure 3, this means that a wide cluster is not always ensured or physically sound for all combinations of control parameters $(\gamma, \bar{\alpha})$. The intrinsic relationships between the aforementioned functions or "forces" can be left for future study.

FAST TOMOGRAPHIC RECONSTRUCTION VIA ROTATION-BASED HIERARCHICAL BACKPROJECTION*

ASHVIN GEORGE† AND YORAM BRESLER†

Abstract. We introduce a family of fast algorithms for tomographic backprojection in the parallel-beam geometry. The algorithms reduce the computational cost of backprojecting P projections onto an $N \times N$ pixel image from the conventional $O(N^2P)$ to $O(N^2 \log P)$. The new algorithms aggregate the projections in a hierarchical structure, with images in the hierarchy formed by the rotation and addition of other images made up of fewer projections. While these algorithms are related to existing fast algorithms, this work places them within the signal processing framework, providing a systematic means to optimize and adjust the trade-off between computational cost and accuracy. Rotations are performed separably in order that higher-order interpolators may be used with low computational cost. The same ideas are applied to create a tomographic projection algorithm, which computes projections of an $N \times N$ pixel image onto P view-angles at a cost of $O(N^2 \log P)$.

Key words. radon transform, fast algorithms, backprojection, projection, tomography, separable rotation, spline interpolation

1. Introduction.

The problem of computed tomography in two dimensions is to reconstruct an image from a set of its line-integral projections. In addition to the ubiquitous computed tomography (CT) scanner, other medical applications of tomography are positron emission tomography (PET), single-photon computed tomography (SPECT), and, to a lesser extent, magnetic resonance imaging (MRI). Outside of medical imaging, tomographic imaging is used in security scanning, nondestructive evaluation, transmission electron microscopy (TEM), synthetic aperture radar (SAR), radio astronomy, geophysics, and other areas [14, 5]. The computational cost of the classic method used to estimate the image from its projections—the filtered backprojection (FBP) or convolution backprojection algorithm—is dominated by the step of backprojection. Traditionally, the backprojection of an $N \times N$ pixel image from P projections has a computational complexity of $O(N^2P)$. Fast algorithms exist that achieve $O(N^2 \log P)$ complexity. In practice, the traditional algorithm has been preferred because of the inadequate image quality of the fast algorithms. Our family of algorithms have $O(N^2 \log P)$ complexity and provide image quality comparable to the conventional method.

In medical and security applications, fast backprojection is necessitated by the increasing demand to rapidly process large amounts of data due to (a) the use of larger multirow detectors in CT machines and (b) the use of tomography to image moving objects (such as the beating heart or baggage on a conveyer belt). Another area where fast algorithms are useful is when the data is noisy, sparse, or otherwise degraded and an iterative reconstruction algorithm, involving multiple successive backprojections and reprojections, is used.

1.1. Basics of tomography. A *parallel-beam projection* $\mathcal{P}_\theta f$ of a two-dimensional (2D) image $f(x_1, x_2)$ is the set of all parallel straight-line integrals through the image, oriented at the view-angle θ, i.e., $\mathcal{P}_\theta f(t) \triangleq \int_{-\infty}^{\infty} f(t\cos\theta - s\sin\theta,\, t\sin\theta + s\cos\theta)ds$. The Radon transform is the set of all such projections at view-angles $\theta \in [0, \pi)$. Reconstructing a 2D image from a set of *parallel-beam line-integral projections* is equivalent to inverting the Radon transform.

In practice the set of view-angles is a discrete set. The *discrete-angle Radon transform* $\mathcal{R}$ is defined by $\mathcal{R}f(t,p) \triangleq \mathcal{P}_{\theta_p} f(t)$, where $p = 1, \ldots, P$.

The FBP algorithm [23], based on the continuous inversion formula discovered by Radon as early as 1917 (see [14]), involves first filtering the projections with a linear *ramp* filter (with frequency response $H(\omega) = |\omega|$), and then *backprojecting* those filtered projections $q(t,p)$. The discrete-angle *backprojection* operator $\mathcal{B}_{\vec{\theta}}$ (where the set of view-angles $\vec{\theta} \in [0, \pi]^P$) is defined by

$$(\mathcal{B}_{\vec{\theta}} q)(x_1, x_2) \triangleq \frac{\pi}{P} \sum_{p=1}^{P} q(x_1 \cos\theta_p + x_2 \sin\theta_p, p). \tag{1.1}$$

While backprojection can be defined for arbitrarily spaced view-angles $\vec{\theta} = (\theta_1, \theta_2, \ldots, \theta_P)$, in this definition and the rest of the paper the simplifying assumption is made that the P view-angles are uniformly spaced in some π-length interval, i.e., $\theta_p = \theta_1 + (\pi/P)(p-1)$.

A straightforward implementation of the backprojection equation (1.1) in the discrete domain—reconstructing an $N \times N$ pixel image from P (sampled) projections—has a computational complexity of $O(N^2 P)$ because for each of the $O(N^2)$ points in the output image, $O(P)$ multiplications and additions must be performed to interpolate the sampled projections and evaluate the summation. This is the essence of the traditional, slow algorithm.

1.2. Other fast algorithms. Existing fast algorithms are either FFT-based [28, 17, 24, 1]—exploiting the low complexity of the FFT (fast Fourier transform)—or hierarchical [10, 9, 13, 26, 22, 11, 4]—taking a divide-and-conquer approach directly in the data or image domains..

Most FFT-based algorithms rely on the projection-slice theorem and fast methods to recover the image samples from nonuniformly spaced Fourier samples [16, 21]. Recent versions of these reconstruction algorithms [24] are reported to achieve significant speedup compared to conventional FBP. Andersson's algorithm [1] is conceptually different and interesting (it is based on expressing backprojection, in the log-polar coordinate system, as a convolution that can be implemented in the Fourier domain via an FFT) but appears to be not as computationally competitive in practice. Averbuch et al. [3, 2] define a rapidly computable, invertible Radon transform for *discrete* images, which also makes use of FFTs. Because the projections we consider are approximations to the projections of an underlying *continuous* image, they can be inverted only approximately. While the Averbuch groups' definition of the Radon transform is invertible, their inversion requires an iterative procedure whose complexity, although $O(N^2 \log N)$, has high proportionality constants and is therefore expensive.

Our algorithms fall into the second category. Hierarchical algorithms achieve their low complexity by recursively decomposing the problem of reconstructing an N-by-N image from P projections into smaller problems. This produces an algorithmic tree whose root is the original problem and whose leaves are the smallest problems into which it is decomposed. This hierarchy, when designed correctly, results in a reduction of the complexity of the algorithm from $O(N^2P)$ to $O(N^2 \log P)$, or $O(NP \log N)$, depending on the specific hierarchy chosen.

Basu and Bresler's algorithm [4] performs the dividing-and-conquering in the space domain. It may be classified, therefore, as a decimation-in-space algorithm. It uses the fact, known as the bow-tie result, which allows smaller-sized images to be backprojected from fewer projections. Dividing the image plane into a hierarchy of square subimages leads to a backprojection algorithm of $O(NP \log N)$ complexity.

There are several fast projection and backprojection algorithms [10, 9, 13, 26, 22, 11] that perform the dividing-and-conquering in the projection domain, partitioning and aggregating projections by their view angles. They may, therefore, be classified as decimation-in-angle algorithms. Brady's projection algorithm (see [10, 9]) calculates the discrete Radon transform of an $N \times N$ image (summations along sets of parallel lines through the image) in $O(N^2 \log N)$ time by hierarchically sharing partial sums of projections in similar directions. This hierarchical sharing of partial sums is reversed in Brandt et al.'s [11] and Nilsson's [26] backprojection algorithms. They recognize that images that are backprojected from a limited number of projections at angles close to a common direction may be sampled sparsely along the common direction. Thus the whole backprojected image is recursively constructed, with $O(N^2 \log P)$ complexity, by combining smaller (sparsely sampled) images. Danielsson [13] and Ingerhed [22] apply the hierarchical sharing of similar partial sums to the sinogram domain (similar to the way Brady [9] applies it to the image domain), recognizing that backprojection at a particular pixel in the image is the summation along a sinusoidal trace through the sinogram.

Our algorithm too applies the divide-and-conquer approach in the projection domain. It is most closely related to Brandt's algorithm, but places the idea of projection domain hierarchical backprojection within the framework of signal processing. The signal processing framework allows us to make rigorous the notion of sparsely sampling an image made up of few projections. It also allows for the use of optimizations such as separable image transformations (and consequently recursive infinite impulse response (IIR) filtering), fractional shifting, and integer-factor up-sampling. This improved understanding allows us to make significant improvements in accuracy and computational cost.

Each of the existing fast algorithms processes the data differently and may be therefore more appropriate for particular applications or computer architectures. Memory access, rather than arithmetic cost, can dominate computation on current computing architectures. For practical image sizes our algorithm offers an order of magnitude gain in both arithmetic and memory access over the conventional method for comparable image quality. Our algorithm has some other characteristics that make it particularly attractive compared to existing fast algorithms such as the decimation-in-space [4] and Fourier methods [24, 17]. It allows for the easy sequential processing of projections as they are acquired. The reduction in latency, resulting from the ability to begin computation without waiting for all the projections to be acquired, may be important in real-time imaging. This sequential processing is not as obviously or naturally implementable in the decimation-in-space algorithm, and is particularly difficult in Fourier-based algorithms. The cost of our algorithm also scales with the size of the region on which the reconstruction is performed—even in the case when the region of reconstruction has a nonconvex shape. This is not the case with Fourier-based methods. A comparison of different fast algorithms will require careful and optimized implementation of the algorithms to be compared on the computing architectures of interest. It is left for future work.

1.3. Reprojection. Reprojection, the operation of computing projections at a set of view-angles from a given image, has several applications in imaging including in algorithms for beam-hardening correction, streak suppression, removal of artifacts due to the presence of high-density objects, correction for missing data or partial volume effects, and compensation for attenuation errors (in PET and SPECT). As mentioned before, iterative reconstruction algorithms also involve reprojection (see [8] and the references therein) and make use of the fact that reprojection is the adjoint operation to backprojection [25]. By flow graph transposition [12], fast reprojection algorithms are derived from the fast backprojection algorithms that we introduce.

1.4. Other imaging geometries. The parallel beam tomographic geometry, discussed in this paper, arises in reconstruction problems in MRI and in electron microscopy, and so the algorithm described here can be applied directly to those problems. The algorithm can also be easily extended to the 3D Radon-transform problem (in which integrals are performed on parallel planes rather than lines).

In CT, projection data is usually available not in the parallel-beam, but in the divergent-beam (fan-beam or cone-beam) geometry. Reconstruction algorithms are performed directly on the divergent-beam data, or after it has been rebinned to the parallel-beam configuration [20]. The algorithms presented here can be applied to rebinned data but not (directly) to divergent-beam data.

Fast algorithms for other imaging geometries (most importantly fan-beam and cone-beam) are derived by extending our approach, and the Fourier-domain understanding which leads to the efficient sampling of images made up of few projections, to those geometries. This paper has been restricted to the 2D parallel geometry because this algorithm illustrates most of the important ideas and is a stepping stone for the more general algorithms.

1.5. Brief summary. Following preliminary explanations in section 2, the actual algorithm is presented in section 3. The algorithm involves producing sparsely sampled images from single projections, and then combining them in a hierarchical manner using digital image transformation operations and additions of images. At every stage in the hierarchy (of $\log P$ levels), the number of images decreases by a factor of 3, while the density of samples increases by roughly the same factor. This keeps the cost of each level in the hierarchy $O(N^2)$ and, therefore, the cost of the whole algorithm $O(N^2 \log P)$. This scheme is motivated by Fourier-domain analysis (section 2.2.3), which explains the key idea of the algorithm: how an image backprojected from projections with a small angular range varies slowly in a direction transverse to those angles, and therefore can be sampled sparsely. Additional implementational details of the algorithm are included in section 3.

2. Fast hierarchical backprojection.

2.1. Backprojection as the sum of rotated images. The $O(N^2 \log P)$ hierarchical backprojection algorithms that we introduce are based on the decomposition of backprojection in terms of image rotations.

For convenience denote the P individual filtered projections as $q_p(t) \triangleq q(t,p)$, $p = 1, 2, \dots, P$. Restricting the backprojection operator $\mathcal{B}_{\vec{\theta}}$ (1.1) to a scalar $\theta \in [0, \pi)$, we define the backprojection of a function $q(t)$ at a single-angle θ as $(\mathcal{B}_\theta q)(\vec{x}) \triangleq (\pi/P)q(x_1 \cos\theta + x_2 \sin\theta)$. In particular,

$$(\mathcal{B}_0 q)(\vec{x}) = (\pi/P)q(x_1) = (\pi/P)q([\,1\ 0\,]\vec{x}). \tag{2.1}$$

FIG. 2.1. *Rotation-based backprojection.* (a) *Backprojection as the sum of rotated zero-backprojected images, as in* (2.4). (b) *The hierarchical equivalent of* (a).

It is easy to see that the full backprojection can be written in terms of the single-angle backprojection as

$$(\mathcal{B}_{\vec{\theta}}\{q_p\}_{p=1}^{P})(\vec{x}) = \sum_{p=1}^{P} (\mathcal{B}_{\theta_p} q_p)(\vec{x}). \tag{2.2}$$

Denoting the matrix of rotation by angle θ in the plane by $K_\theta = \left[\begin{smallmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{smallmatrix}\right]$ and defining the rotation-by-θ operator $\mathcal{K}(\theta)$ by $(\mathcal{K}(\theta)f)(\vec{x}) \triangleq f(K_\theta \vec{x})$, we obtain immediately from (2.1) that

$$\mathcal{B}_\theta = \mathcal{K}(-\theta)\mathcal{B}_0. \tag{2.3}$$

Combining (2.2) with (2.3) leads to the starting point of the rotation-based hierarchical algorithm: the backprojection operator is equivalent to the summation of rotated zero-backprojected images, i.e.,

$$\hat{f} = B_{\vec{\theta}}\{q_p\}_{p=1}^{P} = \sum_{p=1}^{P} \mathcal{K}(-\theta_p)\mathcal{B}_0 q_p. \tag{2.4}$$

This is illustrated in Figure 2.1(a).

2.2. Hierarchical backprojection.

2.2.1. From parallel to a tree structure. The rotation of an $M \times N$ discrete-index image can be performed in $O(NM)$ operations [30]. Therefore, the complexity of backprojecting P projections onto an $N \times N$ image, according to Figure 2.1(a), is $P \times O(N^2) = O(N^2 P)$, which is no improvement over the conventional algorithm. The first key to improving the complexity to $O(N^2 \log P)$ is conversion to a hierarchical structure. Because the composition of successive rotations is still a rotation,

$$\mathcal{K}(\theta_1)\mathcal{K}(\theta_2)\ldots\mathcal{K}(\theta_N) = \mathcal{K}(\theta_1 + \theta_2 + \cdots + \theta_N), \tag{2.5}$$

we can rearrange the block diagram in Figure 2.1(a) into a hierarchical tree structure as shown in Figure 2.1(b). The intermediate image in the mth branch of the lth level is denoted as $I_{l,m}$. In the initial level

$$I_{1,m} \triangleq \mathcal{B}_0 q_m, \qquad m = 1, 2, \ldots, 2 \cdot 3^L. \tag{2.6}$$

In levels $l = 2, \ldots, L+1$,

$$\begin{aligned} I_{l,m} = {} & \mathcal{K}(\delta_{l-1,3m-2}) I_{l-1,3m-2} + \mathcal{K}(\delta_{l-1,3m-1}) I_{l-1,3m-1} \\ & + \mathcal{K}(\delta_{l-1,3m}) I_{l-1,3m}, \qquad m = 1, 2, \ldots, 2 \cdot 3^{L-l+1}, \end{aligned} \tag{2.7}$$

and in the final level

$$\hat{f} = I_{L+2,1} = \mathcal{K}(\delta_{L+1,1}) I_{L+1,1} + \mathcal{K}(\delta_{L+1,2}) I_{L+1,2}. \tag{2.8}$$

Even though the above explanation (2.6)–(2.8) describes the hierarchical algorithm for a set of exactly $P = 2 \cdot 3^L$ view-angles (or equivalently $L = \log_3(P/2)$), the algorithm can be generalized to arbitrary numbers and configurations of view-angles. The *ternary* branch (i.e., involving the combination of three images) is particularly efficient since, as is explained later, it eliminates the need for one third of the rotations. The efficient grouping of projections relies on the fact that a set of projections (or images) of any number can always be divided into groups such that all but one of the groups has exactly three members. Consequently a set of an arbitrary number of projections can always be hierarchically combined such that in every level all but one of the branches is ternary. The remaining branch involves the rotation and addition of two images (in the case of a binary branch) or no addition (in the case of a unary branch).

We will say that the hierarchical algorithm of (2.6)–(2.8) displayed in Figure 2.1(b) is correct if it is equivalent to that in Figure 2.1(a), i.e., if $\hat{f}$ in (2.4) and (2.8) coincide for every set of filtered projections $\{q_p\}_{p=1}^{P}$.

Now, for any set of projection angles θ_i, $i = 1, \ldots, P$, the intermediate rotation angles $\delta_{l,m}$ can be chosen so that the hierarchical algorithm is correct. Such a collection $\{\delta_{l,m}\}$ will be called *admissible* (for this set of projection angles). A trivial admissible set is $\delta_{1,i} = -\theta_i$, $i = 1, \ldots, P$, with the remaining $\delta_{l,m} = 0$. However, as we will show, certain other choices are preferable.

This hierarchical structure alone does not guarantee the $O(N^2 \log P)$ computational complexity. In fact, it involves up to $1.5 \times P - 1$ rotation operations—about 50% more than the single-level algorithm of (2.4) and Figure 2.1(a).

The second and essential key to reducing the complexity is to use the extra degrees of freedom provided by the additional rotations to enable sparse sampling of the underlying continuous images. This is possible by selecting the intermediate rotation angles $\{\delta_{l,m}\}$ such that the intermediate images have *low bandwidth.* Understanding and optimizing this procedure involves the interplay between three aspects: (i) the composition of the intermediate images, and the relationships between the angles of their constituent projections and the intermediate rotation angles; (ii) the spectral supports of intermediate images; and (iii) the sampling requirements of the intermediate images, and their effect on the computational requirements. We explore these aspects in the following subsections.

2.2.2. Intermediate images and rotation angles. To help identify the composition of intermediate images, we introduce a notational tool to pick out the angle of the pth projection in an image generated by a weighted backprojection of the form

$$I = \sum_{s \in \mathcal{N}'} \nu_s \mathcal{K}(\phi_s) \mathcal{B}_0 q_s, \tag{2.9}$$

where $\mathcal{N}' \subset \{1, 2, \ldots, P\}$ is an index set and $\nu_s \in \mathbb{R}$ are real weights.

Definition 2.1. *For an image I as in* (2.9) *and $p \in \mathcal{N}'$, the pth-angle extraction operator Φ_p is defined as $\Phi_p(I) \triangleq -\phi_p$.*

The following two properties follow in a straightforward way from Definition 2.1.

Lemma 2.2. *For the pth-angle extraction operator Φ_p:*

(a) $\Phi_p(\mathcal{K}(\theta)I) = \Phi_p(I) - \theta$.

(b) *Suppose that I_1 and I_2 are given by* (2.9) *with $\mathcal{N}' = \mathcal{N}_1$ and $\mathcal{N}' = \mathcal{N}_2$ respectively. If $\mathcal{N}_1 \cap \mathcal{N}_2 = \emptyset$, then*

$$\Phi_p(I_1 + I_2) = \begin{cases} \Phi_p(I_1) & \textit{if } p \in \mathcal{N}_1, \\ \Phi_p(I_2) & \textit{if } p \in \mathcal{N}_2, \\ \textit{undefined} & \textit{if } p \notin (\mathcal{N}_1 \cup \mathcal{N}_2). \end{cases} \tag{2.10}$$

By iterating (2.7) it is easy to see that any intermediate image $I_{l,m}$ is given by

$$I_{l,m} = \sum_{p \in \mathcal{N}_{l,m}} \mathcal{K}(\phi_p) \mathcal{B}_0 q_p \tag{2.11}$$

for some set $\mathcal{N}_{l,m}$ of integer indices and angles $\{\phi_p : p \in \mathcal{N}_{l,m}\}$, which depend on the intermediate rotation angles $\delta_{l,m}$. Furthermore, it follows from (2.7) and (2.8) that for $l = 1, 2, \ldots, L+1$

$$\begin{gathered} \mathcal{N}_{l,m} = \{b, b+1, b+2, \ldots, e\}, \\ \text{where } b = 3^{l-1}(m-1) + 1 \quad \text{and} \quad e = 3^{(l-1)}(m-1) + 3^{l-1}. \end{gathered} \tag{2.12}$$

Combining Lemma 2.2 with (2.11) and (2.12), and denoting by $\lceil x \rceil$ the smallest integer larger than or equal to x, yields the following characterization of the backprojection angles of projections composing intermediate images in Figure 2.1(b).

Lemma 2.3. *Let $I_{l,m}$ be an intermediate image defined recursively by* (2.6)–(2.8). *Then for $l = 1, 2, \ldots, L+1$, $m = 1, 2, \ldots, 2 \cdot 3^{L-l+1}$, and any $p \in \mathcal{N}_{l,m}$, $\Phi_p(I_{l,m}) = -\sum_{i=1}^{l-1} \delta_{i,\mu(p,i)}$, where $\mu(p,l) \triangleq \lceil p/3^{l-1} \rceil$.*

Proof. For the proof, see Appendix A.

In particular, for $l = L+2$, Lemma 2.3 yields a characterization of the admissible set of intermediate rotation angles: $\theta_p = \Phi_p(I_{L+2,1}) = -\sum_{i=1}^{L+1} \delta_{i,\mu(p,i)}$, $p = 1, \ldots, P$. As expected, these conditions impose only P constraints on the up to $1.5P - 1$ free intermediate rotation angles $\{\delta_{l,m}\}$.

The following additional characterization of the intermediate images is useful in optimizing the intermediate rotation angles.

Consider the *virtual* image (i.e., one that is not actually formed) made up of projections indexed by the set $\mathcal{N}_{l,m}$, with each projection backprojected at its nominal view angle θ_p. Denoted $\tilde{I}_{l,m}$, this virtual image is given by

$$\tilde{I}_{l,m} = \sum_{p \in \mathcal{N}_{l,m}} \mathcal{B}_{\theta_p} q_p. \tag{2.13}$$

In general $\tilde{I}_{l,m} \neq I_{l,m}$. Now, by (2.3), we know that

$$\tilde{I}_{l,m} = \sum_{p \in \mathcal{N}_{l,m}} \mathcal{K}(-\theta_p)\mathcal{B}_0 q_p. \tag{2.14}$$

By Definition 2.1,

$$\Phi_p(\tilde{I}_{l,m}) = \theta_p \qquad \text{if } p \in \mathcal{N}_{l,m}. \tag{2.15}$$

Inspection of the block diagram in Figure 2.1(b) suggests that the relative angles between projections in an intermediate image are preserved in the final reconstructed image $\hat{f}$. This fact is captured by the following result.

Proposition 2.4. *If the algorithm of Figure* 2.1(b) *is correct, then for all* l, m *in the algorithm,*

$$I_{l,m} = \mathcal{K}(\alpha_{l,m})\tilde{I}_{l,m} \quad \textit{for some } \alpha_{l,m} \in (-\pi, \pi]. \tag{2.16}$$

Proof. For the proof, see Appendix B.

Because $\tilde{I}_{l,m}$ are virtual images, we call the $\{\alpha_{l,m}\}$ *virtual rotation angles.* They are related to the (actual) intermediate rotation angles of the hierarchical algorithm as follows.

The definition of $\mathcal{N}_{l,m}$ and the definition of the hierarchical algorithm together imply that (for $l = 2, 3, \ldots, L+1$) $\mathcal{N}_{l,m} = \mathcal{N}_{l-1,3m-2} \cup \mathcal{N}_{l-1,3m-1} \cup \mathcal{N}_{l-1,3m}$, and consequently by (2.13),

$$\tilde{I}_{l,m} = \tilde{I}_{l-1,3m-2} + \tilde{I}_{l-1,3m-1} + \tilde{I}_{l-1,3m}. \tag{2.17}$$

By Proposition 2.4,

$$\begin{aligned}\mathcal{K}(-\alpha_{l,m})I_{l,m} = \mathcal{K}(-\alpha_{l-1,3m-2})I_{l-1,3m-2} &+ \mathcal{K}(-\alpha_{l-1,3m-1})I_{l-1,3m-1} \\ &+ \mathcal{K}(-\alpha_{l-1,3m})I_{l-1,3m},\end{aligned}$$

and therefore

$$\begin{aligned}I_{l,m} = \mathcal{K}(\alpha_{l,m} - \alpha_{l-1,3m-2})I_{l-1,3m-2} &+ \mathcal{K}(\alpha_{l,m} - \alpha_{l-1,3m-1})I_{l-1,3m-1} \\ &+ \mathcal{K}(\alpha_{l,m} - \alpha_{l-1,3m})I_{l-1,3m}.\end{aligned}$$

Comparing this to (2.7), it follows that $\delta_{l-1,3m-i} = \alpha_{l,m} - \alpha_{l-1,3m-i}$, i.e.,

$$\delta_{l,3m-i} = \alpha_{l+1,m} - \alpha_{l,3m-i}. \tag{2.18}$$

2.2.3. Optimal rotation angles. The optimal angles $\alpha^*_{l,m}$ are chosen so that the intermediate images can be sparsely sampled. We use a rectangular sampling lattice with sampling intervals Δ_f and Δ_s; i.e., the discrete image $I^d(n_1, n_2) = I(\Delta_f n_1, \Delta_s n_2)$ is a sampled version of the continuous image. We maintain $\Delta_f \leq \Delta_s$ and, in keeping with the terminology of Brandt et al. [11], we call the first (horizontal) coordinate the *fast* direction and the second (vertical) coordinate the *slow* direction. These sampling intervals are chosen to satisfy the *sampling theorem* [15, p. 37] which, as explained in sections 2.2.4 and 3.3.1, dictates how small the sampling intervals need to be to represent an image with a given spectral support.

Equation (2.14) leads us to the spectral support of $\tilde{I}_{l,m}$. It is easy to see that the spectral support of $\mathcal{B}_0 q$ is restricted to the ω_1-axis (because $(\mathcal{B}_0 q)(x_1, x_2) = q(x_1)$

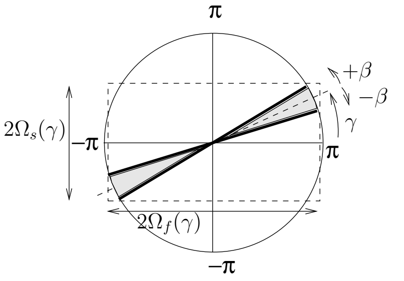

Fig. 2.2. *If the spectral support is the shaded wedge-shaped region within dark lines at angles* $\gamma \pm \beta$*, then the bandwidth in the fast and slow directions,* Ω_f *and* Ω_s*, is as indicated.*

and $\int (\mathcal{B}_0 q)(x_1, x_2) e^{j\omega_2 x_2} dx_2 = 2\pi q(x_1)\delta(\omega_2))$. Furthermore, if q has a bandwidth of π (i.e., its Fourier transform $Q(\omega) = 0$ for $\omega > \pi$), then the 2D spectral support of $\mathcal{B}_0 q$ is exactly $\{(\omega_1, 0) : \omega_1 \leq \pi\}$. It follows from the behavior of the Fourier transform under a spatial linear coordinate transformation ($g(\vec{x}) = f(K_\theta \vec{x}) \implies G(\vec{\omega}) = \frac{1}{|K_\theta|} F(K_\theta^{-T} \vec{\omega}) = F(K_\theta \vec{\omega})$) and (2.14) that the spectral support of $\tilde{I}_{l,m}$ is a wedge-shaped region $\tilde{W}_{l,m}$, as shown in Figure 2.2. In particular, if $\mathcal{N}_{l,m} = \{b, b+1, \ldots, e\}$, the wedge lies between θ_b and θ_e (i.e., $\theta_b = \gamma - \beta$ and $\theta_e = \gamma + \beta$ in Figure 2.2).

By (2.16), $W_{l,m}$, the spectral support of $I_{l,m}$, is also a wedge: in fact, it is just $\tilde{W}_{l,m}$ rotated by $\alpha_{l,m}$. The optimal angle $\alpha^*_{l,m}$ is one that minimizes the bandwidth $\Omega_s \Omega_f$ of $I_{l,m}$, where Ω_s and Ω_f are the bandwidths in slow and fast directions as shown in Figure 2.2. It is easily shown that the optimum virtual rotation angles and corresponding highest frequencies are

$$\alpha^*_{l,m} = \frac{\theta_b + \theta_e}{2}, \qquad \Omega_s(I_{l,m}) = \pi \sin \frac{\theta_e - \theta_b}{2}, \qquad \Omega_f(I_{l,m}) = \pi. \tag{2.19}$$

In view of (2.18), the optimum intermediate rotation angles $\delta^*_{l,m}$ of the hierarchical algorithm are completely determined by $\alpha^*_{l,m}$ as $\delta^*_{l,3m-i} = \alpha^*_{l+1,m} - \alpha^*_{l,3m-i}$.

Though the algorithm can be tailored to arbitrary sets and numbers of projections, we will simplify the description and analysis of the algorithm by assuming exactly $P = 2 \cdot 3^L$ projections uniformly distributed in angle as follows:

$$\theta_i = -\frac{\pi}{4}(1 - 3^{-L}) + \Delta_\theta (i - 1), \qquad i = 1, 2, \ldots, 2 \cdot 3^L,\ \Delta_\theta = \frac{\pi}{2 \cdot 3^L}. \tag{2.20}$$

This choice yields explicit expressions for the optimum rotation angles of the intermediate images. For $l = 2, 3, \ldots, L$,

$$\delta^*_{l,m} = \begin{cases} \Delta_\theta 3^{l-1} & \text{if } m = 1, 4, 7, \ldots, \\ 0 & \text{if } m = 2, 5, 8, \ldots, \\ -\Delta_\theta 3^{l-1} & \text{if } m = 3, 6, 9, \ldots. \end{cases} \tag{2.21}$$

Note that the center image of each triplet in the hierarchy is rotated by 0 radians—a free operation. This is the motivation for the choice of the ternary hierarchy in the common case of uniformly spaced projection angles as in (2.20). Turning now to the last, $l = L + 1$, level in the hierarchy, we again use the 0 radian rotation and another free rotation by $\pi/2$, which merely involves rearrangement (transposition) of pixels.

The algorithm of (2.6)–(2.8) accordingly simplifies to

$$
\begin{aligned}
&I_{l,m} = \mathcal{K}(\Delta_\theta 3^{l-2}) I_{l-1,3m-2} + I_{l-1,3m-1} + \mathcal{K}(-\Delta_\theta 3^{l-2}) I_{l-1,3m} \\
&\qquad \text{for } l = 2, 3, \ldots, L+1 \quad \text{and} \quad m = 1, 2, \ldots, 2 \cdot 3^{L-l+1}, \\
&I_{L+2,1} = I_{L+1,1} + \mathcal{K}(-\pi/2) I_{L+1,2} \qquad \text{and} \qquad \hat{f} = I_{L+2,1}.
\end{aligned} \tag{2.22}
$$

For this algorithm, with the rotation angles chosen per (2.21), substitution of (2.12) into (2.19) yields that the optimum bandwidths of $I_{l,m}$ are

$$
\Omega_s(I_{l,m}) = \pi \sin(\pi(3^{l-1} - 1)/(2P)), \qquad \Omega_f(I_{l,m}) = \pi. \tag{2.23}
$$

These bandwidths will determine the computational requirements and the discretization scheme of the algorithm.

2.2.4. Computational cost. The *sampling theorem* [15, p. 37] dictates how small the sampling intervals need to be in order for the intermediate image $I_{l,m}$ to be recovered from its sampled version $I^d_{l,m}$ (where $I^d_{l,m}(n_1, n_2) = I_{l,m}(n_1 \Delta_f^{l,m}, n_2 \Delta_s^{l,m})$). We combine the criterion of the *sampling theorem* ($\Delta_s < \pi/\Omega_s$ and $\Delta_f < \pi/\Omega_f$) with (2.23) to find the size of the discrete image $I^d_{l,m}$ in the lth level:

$$
\begin{aligned}
\text{size}(I^d_{l,m}) \approx (N/\Delta_s)(N/\Delta_f) &= (N\Omega_s(I_{l,m})/\pi)(N\Omega_f(I_{l,m})/\pi) \\
&= N^2 \sin(\pi(3^{l-1} - 1)/(2P)) \\
&< N^2(\pi 3^{l-1}/(2P)) = O(N^2 3^l/P).
\end{aligned}
$$

In the next section we will show that the cost of rotating a discrete-domain image containing S samples, to a given accuracy, is $O(S)$ arithmetic operations (adds and multiplies). Hence, because $\text{size}(I^d_{l,m}) = O(N^2 3^l/P)$, and because there are $P/3^{l-1}$ images in level l, the arithmetic complexity of the algorithm is

$$
\sum_{l=1}^{L+1} \frac{P}{3^{l-1}} O\left(\frac{N^2 3^l}{P}\right) = O(N^2 \log P). \tag{2.24}
$$

Rather than the number of arithmetic operations, the number of memory accesses or memory bandwidth is often the bottleneck in current computer architectures. Fortunately, the hierarchical algorithm provides a significant improvement in this respect too. In fact, counting the number of arithmetic operations provides a count of the number of memory accesses also, as memory accesses are performed only when arithmetic operations are performed. The number of memory accesses is therefore $O(N^2 \log P)$, which represents an improvement over the $O(N^2 P)$ memory accesses required in the conventional BP algorithm. Finally, a simple analysis shows that, if executed in place, the hierarchical algorithm requires $O(NP)$ memory—the same as the conventional algorithm.

3. Hierarchical backprojection in the discrete domain. We have established that the hierarchical algorithm discussed thus far has the favorable $O(N^2 \log P)$, scaling of the computational cost. However, for fixed N and P, the constants in the cost expression become important and will determine the actual speedup offered by the algorithm. Furthermore, various structural and parametric choices in the discrete index design of the algorithm will determine the trade-off between computation and

FIG. 3.1. *Hierarchical backprojection in the discrete-domain with oversampling. This is a modification of Figure* 2.1(b)*. The modifications include very sparse sampling of the initial zero-backprojected* ($\mathcal{B}_0$) *images, upsampling in the slow direction* ($\uparrow_s$) *at every stage in the hierarchy to increase the density of sampling, and initial up-sampling* $\uparrow_f$ *and final down-sampling* $\downarrow_f$ *in the fast direction to tune the quality of the reconstruction.*

accuracy. We address these issues in this section, describing what we believe is a particularly favorable design.

The block diagram of this digital algorithm is shown in Figure 3.1 for an example with $L = 2$, i.e., for a set of $P = 2 \cdot 3^2 = 18$ projections. The projection view-angles are equally spaced with $\Delta_\theta = \pi/18$. The digital projections $q_p^d[m] = q_p(m\Delta_q)$ are sampled versions of the continuous projections, with uniform sampling interval Δ_q. The digital images $I_{l,m}^d$ are the sampled versions of the underlying continuous images $I_{l,m}$. The operation of sampling a continuous-domain image $I_{l,m}(\vec{x})$ on a rectangular lattice, with sampling periods Δ_1 and Δ_2, is denoted by $\mathcal{D}_{\vec{\Delta}}$, where $\vec{\Delta} = [\Delta_1, \Delta_2]$, and produces the 2D sequence or discrete-domain image $I_{l,m}^d[\vec{m}] = (\mathcal{D}_{\vec{\Delta}} I_{l,m})[\vec{m}] \triangleq I(\Delta_1 m_1, \Delta_2 m_2)$.

Blocks marked $\mathcal{B}_0$ represent the digital zero-angle backprojection operator (see (2.1)) $(B_0 q^d)[\vec{m}] = (\pi/P) q^d[m_1]$. Blocks marked $\mathcal{K}_\delta$ represent the discrete-domain rotation operator. The application of affine coordinate transformations ($(\mathcal{A}f)(\vec{x}) = f(A\vec{x})$, where A is a 2×2 matrix) to digital images is addressed in section 3.1, and a particularly efficient, separable implementation of the digital rotation operator using two shears is described in section 3.2.

The blocks labeled $\uparrow_s U_{l,m}$ represent up-sampling in the slow coordinate by factor $U_{l,m}$ (a digital affine transformation with $A = \left[\begin{smallmatrix} 1 & 0 \\ 0 & 1/U_{l,m} \end{smallmatrix}\right]$). Their role is to adjust the sampling periods $\vec{\Delta}_{l,m}$ of the intermediate images to the increasing slow bandwidth (viz. (2.23)). Section 3.3 explains how $\{U_{l,m}\}$ are determined. Finally, the blocks labeled $\uparrow_f U_{l,m}^f$ and $\downarrow_f U_{l,m}^f$ represent similar up- and down-resampling, respectively, in the fast direction, whose roles are discussed in sections 3.3.1 and 3.4.2.

3.1. Digital affine transformations. Each digital image $f^d[\vec{m}]$ in the algorithm will be considered to be a representation of an underlying continuous image $f_{\vec{\Delta}}^{\psi}(\vec{x})$ with respect to a particular basis function $\psi(\vec{x}) : \mathbb{R}^2 \to \mathbb{R}$ and sampling period $\vec{\Delta} \in \mathbb{R}^2$, the two images being related by

$$f_{\vec{\Delta}}^{\psi}(\vec{x}) \triangleq (E_{\vec{\Delta}}^{\psi} f^d)(\vec{x}) \triangleq \sum_{\vec{n} \in \mathbb{Z}^2} f^d[\vec{n}] \psi\left(\frac{x_1}{\Delta_1} - n_1, \frac{x_2}{\Delta_2} - n_2\right). \tag{3.1}$$

We will say that $f^{\psi}_{\vec{\Delta}}$ is the $\Delta - \psi$ continuous domain extension of f^d, and $E^{\psi}_{\vec{\Delta}}$ is the corresponding extension operator. We assume that $\Psi(\vec{x})$ has a bounded Fourier transform and $f^d \in l_2(\mathbb{Z}^2)$ so that the sum in (3.1) converges in $L_2(\mathbb{R}^2)$. The function ψ is chosen as an interpolant (vanishing on $\mathbb{Z}^2$, except at the origin), so that the digital image coincides with the samples of its $\Delta - \psi$ extension on the rectangular sampling lattice with period $\vec{\Delta}$, i.e.,

$$\mathcal{D}_{\vec{\Delta}} E^{\psi}_{\vec{\Delta}} f^d = f^d \qquad \forall f^d \in l_2. \tag{3.2}$$

With the relationship between digital and continuous-domain images established, we can define an affine transformation of a digital image.

The digital $\Delta - \psi$ affine transformation $\mathcal{A}^{\psi,\vec{\Delta}} : \ell_2(\mathbb{Z}^2) \rightarrow \ell_2(\mathbb{Z}^2)$ corresponding to the continuous affine transformation $\mathcal{A} : L_2(\mathbb{R}^2) \rightarrow L_2(\mathbb{R}^2)$ is defined by

$$\mathcal{A}^{\psi,\vec{\Delta}} f^d \triangleq \mathcal{D}_{\vec{\Delta}} \mathcal{A} E^{\psi}_{\vec{\Delta}} f^d = \mathcal{D}_{\vec{\Delta}} \mathcal{A} f^{\vec{\psi}}_{\vec{\Delta}}. \tag{3.3}$$

In other words, the transformation $\mathcal{A}^{\psi,\vec{\Delta}}$ is defined by applying the continuous affine transformation $\mathcal{A}$ to the $\Delta - \psi$ extension of the digital image, and then resampling. (Recall that $(\mathcal{A}f)(\vec{x}) \triangleq f(A\vec{x})$.) However, because $\mathcal{A}^{\psi,\vec{\Delta}}$ is a mapping between digital images, it is performed purely in the discrete-index domain. Under some additional conditions, we can show that this definition is *consistent*; that is, affine transformation $A^{\psi,\vec{\Delta}}$ yields the same result whether applied in the continuous or digital domain.

Let

$$F^d(\vec{\lambda}) \triangleq \sum_{\vec{n} \in \mathbb{Z}^2} f^d[\vec{n}] e^{-j\vec{\lambda}' \cdot \vec{n}}, \qquad \vec{\lambda} \in \mathbb{R}^2, \tag{3.4}$$

be the discrete-time Fourier transform (DTFT) of f^d. The square $[-\pi, \pi]^2$ is the principal period of $F^d(\lambda)$. If, on $[-\pi, \pi]^2$, $F^d(\lambda)$ vanishes outside a region W, f^d will be called band-limited to W, or $f^d \in B(W)$.

LEMMA 3.1. *Suppose* $f^d \in B(A^{-T}[-\pi, \pi]^2)$ *and* $\Psi(\vec{x}) = \mathrm{Sinc}(\pi x_1)\,\mathrm{Sinc}(\pi x_2)$*; then*

$$E^{\psi}_{\vec{\Delta}} \mathcal{A}^{\psi,\vec{\Delta}} f^d = \mathcal{A} E^{\psi}_{\vec{\Delta}} f^d. \tag{3.5}$$

Proof. For the proof, see Appendix C.

Recall now that the composition property $\mathcal{K}(\theta_1 + \theta_2) = \mathcal{K}(\theta_1)\mathcal{K}(\theta_2)$ of rotation is key to the hierarchical decomposition. The corresponding property for digital affine transformations is established by the following result.

PROPOSITION 3.2. *Let* $\mathcal{A}_1$ *and* $\mathcal{A}_2$ *be affine coordination transformations,* $\mathcal{A}_{21} = \mathcal{A}_2\mathcal{A}_1$*, and* $\mathcal{A}_1^{\psi,\vec{\Delta}}$*,* $\mathcal{A}_2^{\psi,\vec{\Delta}}$*, and* $\mathcal{A}_{2,1}^{\psi,\vec{\Delta}}$ *their corresponding digital versions. Suppose* $f^d \in B(A_1[-\pi, \pi]^2)$ *and* $\Psi(\vec{x}) = \mathrm{Sinc}(\pi x_1)\,\mathrm{Sinc}(\pi x_2)$*. Then*

$$\mathcal{A}_2^{\psi,\vec{\Delta}} \mathcal{A}_1^{\psi,\vec{\Delta}} f^d = \mathcal{A}_{21}^{\psi,\vec{\Delta}} f^d. \tag{3.6}$$

Proof. We have

$$\begin{aligned} \mathcal{A}_2^{\psi,\vec{\Delta}} \mathcal{A}_1^{\psi,\vec{\Delta}} f^d &= \mathcal{D}_{\vec{\Delta}} \mathcal{A}_2 E^{\psi}_{\vec{\Delta}} \mathcal{A}_1^{\psi,\vec{\Delta}} f^d = \mathcal{D}_{\vec{\Delta}} \mathcal{A}_2 \mathcal{A}_1 E^{\psi}_{\vec{\Delta}} f^d \\ &= \mathcal{D}_{\vec{\Delta}} \mathcal{A}_{21} E^{\psi}_{\vec{\Delta}} f^d = \mathcal{A}_{21}^{\psi,\vec{\Delta}} f^d, \end{aligned}$$

where the second equality follows from Lemma 3.1. □

Proposition 3.2 is the basis for converting the continuous-domain hierarchical algorithm of Figure 2.1(b) to the digital algorithm illustrated in Figure 3.1.

In practice, in order to limit computational cost, certain approximations must be made. Instead of the ideal band-limited interpolant $\Psi(\vec{x})$ we use, in (3.1), a $\Psi(\vec{x})$ of finite (usually small) support. This yields, via (3.3), a digital affine transformation with a kernel of small support on $\mathbb{Z}^2$, which is cheap to apply. Because $\Psi(\vec{x})$ is only approximately band-limited, the results in Lemma 3.1 and Proposition 3.2 hold only approximately. However, by using a certain degree of oversampling, the error can be made to fall off exponentially fast with the size of the support of the interpolant. More specifically, assume oversampling by factor $\gamma > 1$, i.e., $\Delta_i = \frac{1}{\gamma}\frac{\pi}{\Omega_i}$, and let $M \times M$ be the size of the support of the interpolant Ψ. Then the interpolation error introduced by (3.1) behaves as $ce^{-\pi M(\gamma-1)/\gamma}$ for some constant c (see [8]).

3.2. Two-shear rotations. The computation is further reduced by implementing each rotation in the algorithm as a cascade of one-dimensional (1D) transformations. We use the well-known decomposition of the rotation matrix

$$K_\theta = S_2^{\tan\theta} S_1^{-\sin\theta\cos\theta} S_c^{\cos\theta}$$

into shears along the fast and slow coordinates, $S_1^\alpha = \left[\begin{smallmatrix} 1 & \alpha \\ 0 & 1 \end{smallmatrix}\right]$, $S_2^\alpha = \left[\begin{smallmatrix} 1 & 0 \\ \alpha & 1 \end{smallmatrix}\right]$, and $S_c^\alpha = \left[\begin{smallmatrix} \alpha & 0 \\ 0 & 1/\alpha \end{smallmatrix}\right]$. The validity of a corresponding decomposition of digital rotation into a cascade of one-dimensional digital shears follows from Proposition 3.2.

Corollary 3.3. *Let* $A_1 = \left[\begin{smallmatrix} 1 & 0 \\ \tan\delta & 1 \end{smallmatrix}\right]$, $A_2 = \left[\begin{smallmatrix} 1 & -\sin\delta\cos\delta \\ 0 & 1 \end{smallmatrix}\right]$, *and* $\Psi(\vec{x}) = \operatorname{Sinc}(\pi x_1)\operatorname{Sinc}(\pi x_2)$, *and suppose that* $f^d \in l_2(\mathbb{Z}^2) \cap B(W)$, *where* $W = \{\vec{\omega} \in [-\pi, \pi]^2 : |\omega_1 + \omega_2 \tan\delta \Delta_1/\Delta_2| \leq \pi\}$. *Then*

$$\mathcal{A}_2^{\psi,\vec{\Delta}} \mathcal{A}_1^{\psi,\vec{\Delta}} f^d = \mathcal{D}_{\vec{\Delta}'} \mathcal{K}(\delta) E_{\vec{\Delta}}^{\psi} f^d, \tag{3.7}$$

where $\vec{\Delta}' = \left[\begin{smallmatrix} \cos\delta & 0 \\ 0 & 1/\cos\delta \end{smallmatrix}\right] \vec{\Delta}$.

Proof. Use Proposition 3.2 to obtain the result. □

The digital shear operations $\mathcal{A}_i^{\psi,\vec{\Delta}}$ are one-dimensional, involving digital filtering of the rows or columns of the digital image individually. This reduces the computational cost (per pixel) of a 2D image rotation using an $M \times M$ kernel $\Psi(\vec{x})$ from $O(M^2)$ to $O(M)$ for the two-shear version.

To further save in computation, we omit the coordinate scaling transformation $S_c^{\cos\theta}$ in the intermediate digital rotations, producing what we call a two-shear rotation. By Corollary 3.3 this implements combined digital rotation and resampling, rather than pure rotation. The δ-rotated image is effectively down-sampled in the fast coordinate and up-sampled in the slow coordinate by a common factor $1/\cos\theta$.

A fractional (noninteger) resampling of the initially backprojected images $\mathcal{B}_0 q_{\theta_p}$ is, therefore, required. Because these initial images are constant in the slow-direction, changing $\Delta_s^{l,m}$ will leave the image unchanged, and, consequently, the resampling in the slow-coordinate is a free operation. But, as displayed in Figure 3.1, in the initial level a fractional up-sampling in the fast direction is required (as $\Delta_f^{l,m} \leq 1.0$).

3.3. Optimum intermediate up-sampling factors.

3.3.1. Necessary sampling intervals. By (2.23), for the optimum rotation-angles the intermediate image bandwidths are $\Omega_s(I_{l,m}) = \pi\sin(\Delta_\theta(3^{l-1}-1)/2)$ and $\Omega_f(I_{l,m}) = \pi$. Therefore, in successive levels of the continuous-domain algorithm, as l increases, the *slow bandwidth* increases. Consequently the slow-sampling period required by the *sampling theorem* [15, p. 37], $\Delta_s^{l,m} < \pi/\Omega_s(I_{l,m})$, decreases. The required slow sampling rate adjustment from level to level is provided by the slow up-sampling operations $\uparrow_s U_{l,m}$ in Figure 3.1. Recall now from section 3.2 that the digital two-shear rotation introduces down-sampling in the slow direction and up-sampling in the fast direction by a factor $1/\cos(\delta_{l,m})$ at each level.

Consequently the sampling periods $\vec{\Delta}_{l,m}$ in adjacent levels of the algorithm, if the algorithm is correct, are related as follows:

$$\Delta_s^{l+1,\lceil m/3\rceil} = \Delta_s^{l,m}/(\kappa_{l,m}U_{l,m}) \quad \text{and} \quad \Delta_f^{l+1,\lceil m/3\rceil} = \kappa_{l,m}\Delta_f^{l,m}, \tag{3.8}$$

where

$$\kappa_{l,m} = \begin{cases} 1 & \text{if } m = 2,5,8,\dots,2\cdot 3^{L-l+1}-1 \text{ (no rotation)},\\ 1/\cos(\Delta_\theta 3^{l-1}) & \text{if } m = 1,3,4,6,\dots,2\cdot 3^{L-l+1} \text{ (rotation by } \pm\Delta_\theta 3^{l-1}). \end{cases} \tag{3.9}$$

Working backwards from $\Delta_s^{L+1,m} = 1$, we find that the slow-sampling period $\Delta_s^{l,m}$ is related to the up-sampling factors $U_{l',m}$ (for $l' > l$) as follows:

$$\Delta_s^{l,m} = \prod_{l'=l}^{L}(U_{l',\mu(l'-l,m)}\kappa_{l',\mu(l'-l,m)}), \tag{3.10}$$

where $\mu(l,m) = \lceil m/3^l\rceil$.

Next, combining equation (3.10) with the sampling condition $\Delta_s^{l,m} \le \pi/\Omega(I_{l,m}) = 1/\sin(\Delta_\theta(3^{l-1}-1)/2)$ provides necessary conditions on the slow direction up-sampling factors $U_{l,m}$.

Consider now the fast sampling interval Δ_f; because $\Omega_f(I_{l,m}) = \pi$ does not change between levels, no change in Δ_f is required to satisfy sampling requirements. However, the change in $\Delta_f^{l,m}$ produced by the two-shear digital rotation has to be accounted for. To avoid the cost of resampling operations in the fast direction of each level, it suffices to up-sample in level $L = 1$ by a factor $U_{1,l}^f$. Working backwards from $\Delta_f^{L+1,m} = 1$ and using (3.8) and (3.9) yields

$$U_{1,l}^f = \prod_{l'=l}^{L}\frac{1}{\kappa_{l',\mu(l'-l,m)}}. \tag{3.11}$$

3.3.2. Optimum slow up-sampling. Next, we formulate the choice of up-sampling factors as an optimization problem. The total computational cost is the sum of the costs of the image transformations and image additions in all branches of the algorithm which are, in turn, proportional to the sizes of the intermediate image. By (3.10), the dimensions of $I_{l,m}^d$ are $N/\Delta_s^{l,m}\times N/\Delta_f^{l,m} = (N/\prod_{l'=l}^{L}(U_{l',\mu(l'-l,m)}\kappa_{l',\mu(l'-l,m)}))$ $\times\, N/\prod_{l'=l}^{L}\kappa_{l',\mu(l'-l,m)}$. So, using 1D digital filters of fixed length M to implement the 1D digital coordinate transformations, the total cost can be shown to be equal to

$$\sum_{l=2}^{L}\sum_{m=1}^{6\cdot 3^{L-l}}\left(\frac{c_{l,m}}{\prod_{l'=l}^{L}U_{l',\mu(l'-l,m)}}\right) + \text{constant}, \tag{3.12}$$

where the constants $c_{l,m}$ depend on the computational costs of the filters used. This expression makes a mildly simplifying assumption. As written, it implies that the number of samples used to represent the (l, m)th image (i.e., the size of the sampled (l, m)th image) is inversely proportional to the slow-sampling interval. The size of the sampled image is equal to the above expression except for small additive constants that are due to the rounding effects that stem from the representation of an image by a whole number of samples and the retaining of a few samples beyond the strict edge of the image. The above expressions are therefore deemed acceptable for the calculation of optimal upsampling factors.

This cost (3.12) is to be minimized by choice of the factors $U_{l,m}$, subject to the sampling constraint derived from (2.23) in section 3.3.1 (i.e., $\Delta_s^{l,m} \leq \pi/\Omega_s(I_{l,m})$).

Practical considerations suggest yet another constraint on the $U_{l,m}$. The coefficients of digital filters implementing digital resampling operations can be either precomputed and stored (at the cost of memory and access time), or computed "on the fly." In the latter case, resampling by integer factors can be implemented more efficiently than that by fractional factors. Consequently, taking advantage of the freedom in selecting the slow up-sampling factors, we restrict them to integers. (No such freedom exists in the choice of fast direction resampling factors, which are fixed by (3.11)—but these fast direction resampling operations contribute a very small fraction of the total cost of the algorithm.)

The problem of minimizing the computational cost is thus equivalent to the following constrained integer optimization problem:

$$\mathcal{U}^* = \arg\min_{\mathcal{U}} \mathcal{J}(\mathcal{U}), \qquad \mathcal{U} = \{U_{l,m} \in \mathbb{N} : l = 2, 3, \ldots, L;\ m = 1, 2, \ldots, 6 \cdot 3^{L-l}\},$$

$$\mathcal{J}(\mathcal{U}) = \sum_{l=2}^{L} \sum_{m=1}^{6\cdot 3^{L-l}} \frac{c_{l,m}}{\prod_{l'=l}^{L} U_{l',\mu(l'-l,m)}}, \qquad \text{where } c_{l,m} \in \mathbb{R},\ \mu(l'-l, m) = \left\lceil m/3^{l'-l} \right\rceil,$$

subject to the constraint that

$$\Delta_s^{l,m} = \prod_{l'=l}^{L} (U_{l',\mu(l'-l,m)} \kappa_{l',\mu(l'-l,m)}) \leq \pi/\Omega_s(I_{l,m}) = 1/\sin(\Delta_\theta(3^{l-1} - 1)/2). \tag{3.13}$$

This optimization problem can be solved cheaply using dynamic programming [19].

3.4. Oversampling. As explained in section 3.1, oversampling the intermediate images will increase accuracy. Applying the oversampling condition uniformly, we require that each image undergoing a digital coordinate transformation be oversampled by at least some specified constant $\gamma > 1$.

3.4.1. Oversampling in the slow direction. The sampling frequency in the slow direction is controlled by the upsampling factors $U_{l,m}$. Upsampling by a factor γ is achieved by simply replacing the constraint (3.13) in the integer optimization problem by $\Delta_s^{l,m} \leq \frac{1}{\gamma}\pi/\Omega_s(I_{l,m})$ for $l = 2, 3, \ldots, L$.

3.4.2. Oversampling in the fast direction. In the fast direction, we simply increase the upsampling factors $U_{1,m}^f$ to incorporate oversampling, and then downsample the image in the fast direction at level L after the last transformation has been performed, to return to the desired sampling scheme (where $\Delta_f = \Delta_s = 1.0$). This modification to the algorithm therefore involves only one additional level of (fractional) x-resampling in level L, as shown in Figure 3.1. Note that though the block diagram shows these last down-sampling operations as separate, they are combined with rotations in four out of the six images in the Lth level for improved computational efficiency. This is achieved by combining the fast-direction shear operation in the decomposed rotation and the fast-direction down-sampling operation.

The exact values of these fast direction resampling fractions is determined both by the parameter γ and the spectral structure of the intermediate images. The γ oversampling condition is that $\Delta_f^{l,m} \leq \frac{1}{\gamma}\pi/\Omega_f(I_{l,m})$ for $l = 2, 3, \ldots, L$. We know that $\Omega_f(I_{l,m}) = \pi$, and $\{\Delta_f^{l,m}\}$ are related to each other strictly according to (3.8), so the largest of these values is $\Delta_f^{L+1,m}$ (as $\kappa_{l,m} \geq 1$). Consequently, the up-sampling factors $U_{l,m}^f$ are modified to $\tilde{U}_{1,m}^f = \gamma U_{1,m}^f$, and new down-sampling is introduced in level L, with down-sampling factors $\tilde{U}_{L+1,m} = \gamma$.

Note that the oversampling condition in the fast direction will not be satisfied for the first-level images, $\mathcal{B}_0 q_{\theta_p}\,|_{p=1,\ldots,P}$ if the input projections are sampled too sparsely (i.e., if $\Delta_q > \frac{1}{\gamma}$).

4. Fast hierarchical reprojection. The reprojection operator is known to be the adjoint of backprojection. Therefore, the fast hierarchical algorithm for reprojection can be derived from the backprojection algorithm by determining the adjoint of the sequence of operations that defines it. Accordingly, as shown in Figure 4.1, the reprojection algorithm may be formally derived from the block-diagrams of the backprojection algorithm (Figure 3.1) by a flow-graph transposition operation, reversing the flow of data [12]. Summation junctions in the backprojection block-diagram are replaced by simple branchings in the reprojection case, affine transforms (rotations by θ) are replaced by their adjoints (rotations by $-\theta$), up-sampling is replaced by down-sampling, and down-sampling by up-sampling, by the same factor. Finally, the zero-angle backprojection is replaced by zero-angle reprojection $\mathcal{P}_0$, where $(\mathcal{P}_0 f)(t) = \int_{-\infty}^{\infty} f(t,s)ds$. In the discrete implementation, it reduces to summation of pixel values along the columns of the image. As in the discrete backprojection algorithm, the rotations are implemented by two-shear rotations. The choice of parameters in the hierarchical reprojection algorithm is guided by the same principles as for the backprojection algorithm.

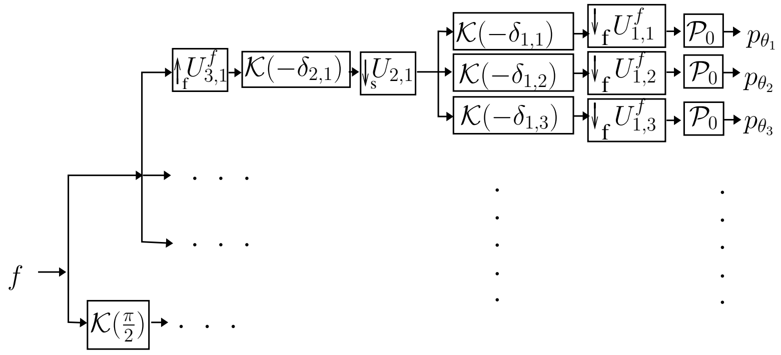

FIG. 4.1. *Ternary hierarchical reprojection. It is formed by a flow-graph transposition (i.e., reversal of the flow of data) of the block-diagram in Figure* 3.1.

5. Numerical experiments. The backprojection algorithms were tested in reconstructing the well-known Shepp–Logan phantom of size 512×512 pixels ($N = 512$).

The sampling-theoretic analysis of tomography [25] dictates that at least $N\pi/2 \approx 805$ projections are needed for reconstruction.

While the description of the algorithm is for $P = 2 \cdot 3^L$ view angles, the hierarchy is easily modified to accommodate $P = 2 \cdot 3^{L-1} \cdot T$ (for some small integers T and L). This is done by modifying the initial level so that it combines projections in groups of T instead of groups of 3.

We analytically generate $P = 1134 = 2 \cdot 3^4 \cdot 7$ projections at equally spaced angles in $(-\pi/4, 3\pi/4)$. (Because of the particular way we implement the digital image transformations, wherein we retain some samples beyond the strict edge of the image, it is cheaper to use a single 7-ary initial level than a ternary level preceded by an initial level with branches of varying branching-factors.) The use of 1134 projections means that there is some oversampling in the angular direction (which is not uncommon in practical systems). With fewer views, the relative acceleration provided by the hierarchical algorithm will be somewhat reduced (and the exact values will be specified later in this section). The projections are sampled with a sample-spacing of one pixel unit (and to simulate real tomographic systems which have detector elements of nonzero width, each projection is analytically convolved with the indicator function of the interval $(-0.5, 0.5)$). The projections are filtered with the well-known Shepp–Logan ramp filter.

The key trade-off in this algorithm is between accuracy, or the quality of the reconstructed image, and computational efficiency. Though visual quality is not easily quantifiable, we choose to measure the quality of the image reconstructed by the fast hierarchical algorithm in a few different ways. As reference images we use both the actual phantom and a reconstruction of the phantom using the conventional method. The conventional method that we use as a reference is pixel-driven backprojection, using linear interpolation between adjacent samples of a projection; cf. [23]. To quantify the difference between our $N \times N$ pixel reconstruction ($\hat{f}[\vec{m}]$) and the reference image ($f_{ref}[\vec{m}]$), we compute both the peak error ($\max_{\vec{m}} |\hat{f}[\vec{m}] - f_{ref}[\vec{m}]|$—the maximum difference between the pixel values of the reconstruction and the reference image) and the RMS (root mean square) error $= \sqrt{\frac{1}{N^2} \sum_{\vec{m}} |\hat{f}[\vec{m}] - f_{ref}[\vec{m}]|^2}$.

The computational cost of the algorithm is measured by counting the number of arithmetic operations—additions and multiplications—involved. By using this measure we can avoid the need to account for differences in processors and programming optimizations that affect the run-time of the particular code implementation. The *acceleration factor* relative to conventional backprojection is defined as the ratio of total operation count (adds + multiplies) for the conventional and the fast algorithm.

The trade-off between accuracy and cost in the fast algorithm is adjusted in two main ways—changing the oversampling parameter and changing the kind of interpolator used. The list of interpolators used is as follows: two FIR (finite impulse response) interpolators—the two-point linear interpolator and the three-point quadratic Schaum [29] interpolator, and three IIR (infinite impulse response) interpolators—Blu's shifted-linear interpolator [6], and Unsers's MOMS (spline) interpolators of quadratic and cubic degree [7].

Figure 5.1 displays the reconstruction of the phantom using the conventional and fast backprojection algorithms. In Figure 5.1(a) is shown the conventional reconstruction, and in Figure 5.1(b) is shown the reconstruction produced by the fast algorithm using the quadratic Schaum interpolator and an oversampling factor of $\gamma = 1.22$ (at an acceleration factor over the conventional algorithm of 9.7). While the pixel values of the phantom lie in the range $[0, 2.0]$, the displayed images in Figure 5.1(a) and (b) use

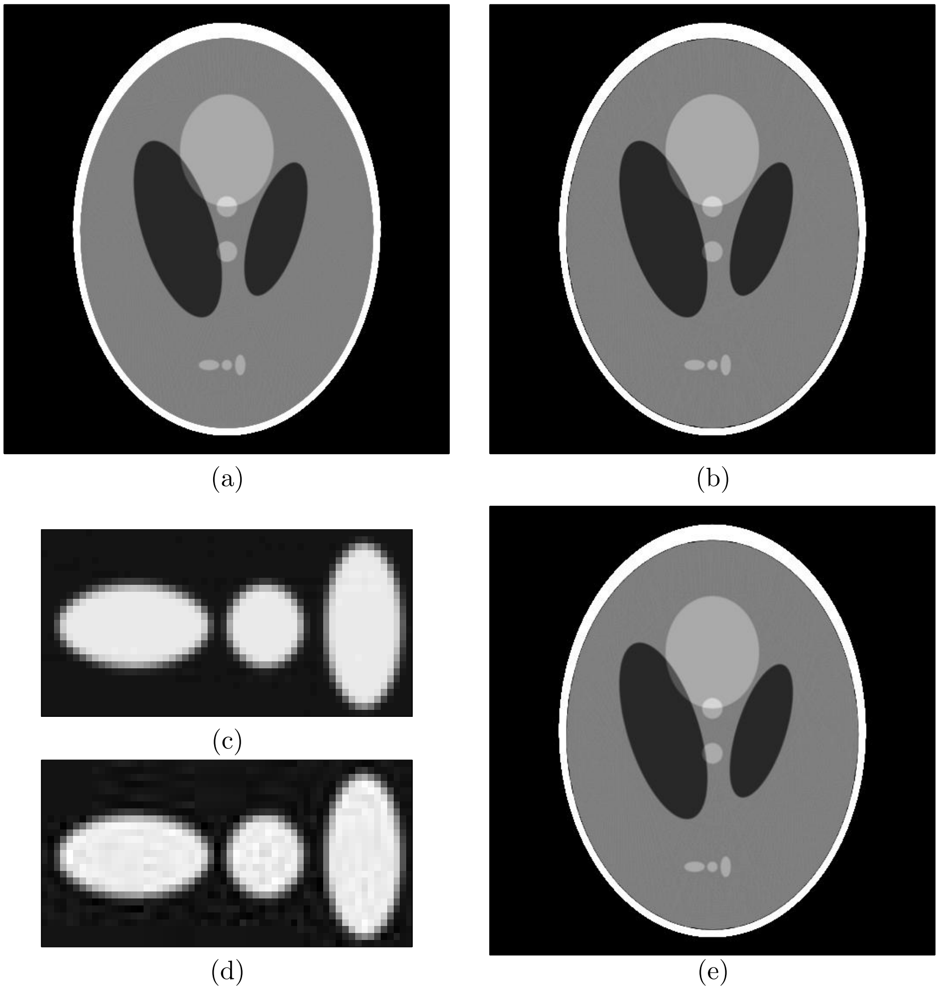

FIG. 5.1. *Sample reconstructions:* (a) *conventional backprojection,* (b) *fast backprojection (using the quadratic Schaum interpolator and oversampling $\gamma = 1.22$). The grayscale window in* (a) *and* (b) *is* $[0.99, 1.05]$*, which is* 3% *of the total range of pixel values.* (c) *Detail of* (a)*, and* (d) *detail of* (b)*. The grayscale window in* (c) *and* (d) *is* $[1.019, 1.031]$*, which is* 0.6% *of the total range of pixel values.* (e) *Fast backprojection (using the quadratic Schaum interpolator and oversampling $\gamma = 1.22$) with additional Kaiser windowing of projections with Kaiser parameter $\beta = 2.0$ (and grayscale window* $[0.99, 1.05]$*).*

a grayscale window of $[0.99, 1.05]$ (3% of the total range of pixel values) to emphasize small differences and assist the comparison of the reconstructions.

As mentioned previously, the relative acceleration is reduced when fewer view angles are used. In comparison to the acceleration of 9.7 achieved when using $P = 1134$ ($= 2 \cdot 3^4 \cdot 7$) projections, under the same conditions of quadratic Schaum interpolator and oversampling of $\gamma = 1.22$, the relative acceleration is 8.7 in the case of $P = 972$ ($= 2 \cdot 3^4 \cdot 6$), and 7.7 in the case of $P = 810$ ($= 2 \cdot 3^4 \cdot 5$).

The close-ups of Figure 5.1(a) and (b) are shown in Figure 5.1(c) and (d) (respectively). The closeups are visually comparable, even with a narrow grayscale window of $[1.019, 1.031]$ (0.6% of the total range of pixel values). The difference between the fast and slow reconstructions is most visible along the inner edge of the skull. The fast reconstruction displays an overshoot along this inner edge that is visible as a dark curve. A profile through the field of view is shown in Figure 5.2. A zoomed-in closeup of the inner edge of the skull is shown in Figure 5.2(b). Here, in addition to the fast algorithm (solid line), conventional algorithm (dashed line), and phantom (circles), is shown a fast reconstruction that uses a Kaiser window [27] (dotted line). The initial ramp filter is modified by a Kaiser window (with Kaiser parameter $\beta = 2.0$) to reduce the overshooting of the fast algorithm. The whole image (from the Kaiser-windowed fast reconstruction) is displayed in Figure 5.1(e). The reconstructions in the rest of this section do not use this Kaiser windowing.

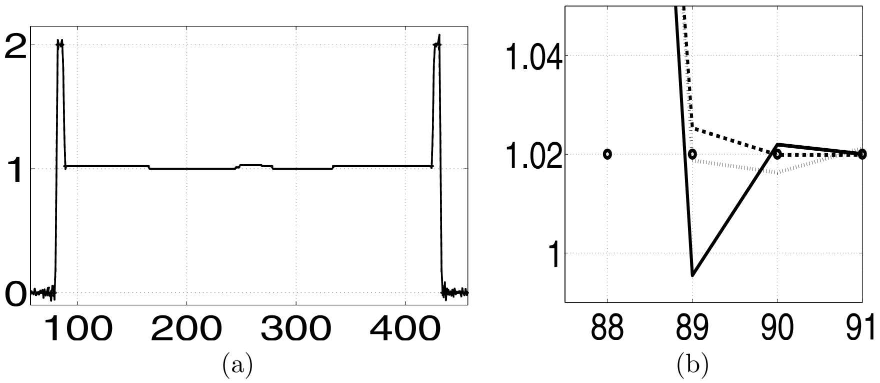

FIG. 5.2. *Profiles through reconstructions.* (a) *A profile of a row (number* 281*) through the conventional reconstruction and the fast reconstruction* without *Kaiser windowing. At this level of detail the differences are hard to see.* (b) *A zoomed in detail of the profile in* (a). *The circles represent the actual values of the phantom, the dashed line is the conventional reconstruction, the solid line is the fast reconstruction, and the dotted line is the fast reconstruction with Kaiser filtering. Notice that that Kaiser filtering reduces overshooting near edges.*

The RMS error of the reconstructions using the fast backprojection versus the acceleration factor over the conventional algorithm is plotted in Figure 5.3(a). The reference image is the original phantom. All five versions of the fast algorithm, each with a different interpolator, are run at different values of the oversampling parameter γ, ranging from 1.0 to 1.82. Data points corresponding to a particular choice of interpolator are connected by a line, and as the oversampling is increased, the cost of the algorithm increases (i.e., the acceleration factor decreases).

As expected, for a given interpolator, as the oversampling (and γ) is increased, the error decreases. For a given oversampling parameter γ, the error of the reconstruction decreases as expected as the complexity of the interpolator is increased—from linear, through shifted-linear, quadratic Schaum, quadratic MOMS, to cubic MOMS. In comparison the RMS error of the conventional algorithm is 0.059 (which is 3% of the maximum pixel value of the image) and is indicated by the horizontal dashed line in Figure 5.3(a).

The peak error of the reconstruction versus the acceleration over the conventional algorithm is plotted in Figure 5.3(b) and (c). Figure 5.3(b) shows the peak error (calculated with respect to the phantom) near the skull, and Figure 5.3(c) shows the peak error (calculated with respect to the conventional reconstruction) far from the skull. The reason for the observed reductions in peak error when oversampling is decreased or when a less complex interpolator is used is the suppression of high-frequency content associated with these choices, which reduces ringing and thereby peak error. The

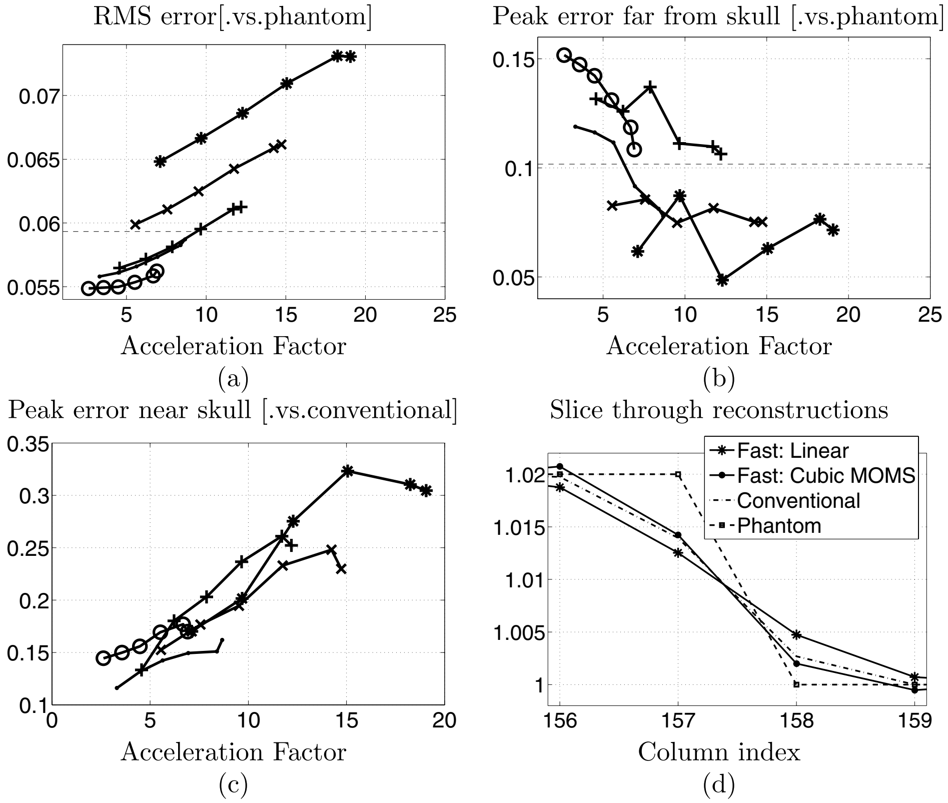

FIG. 5.3. *Comparing reconstructions—Error versus acceleration (*(a), (b), *and* (c)*) and slice profiles* (d). *Error is measured between the reconstruction and a reference image (conventional reconstruction or actual phantom). Acceleration is the cost of the conventional reconstruction divided by the cost of the particular fast reconstruction.* (a) *The RMS error (referenced against phantom),* (b) *the peak error away from the skull (referenced against phantom), and* (c) *the peak error near the skull (referenced against conventional). Interpolation types in* (a), (b), *and* (c): *cubic MOMS* ($\circ$), *quadratic MOMS* ($\cdot$), *quadratic Schaum* ($+$), *shifted linear* ($\times$), *and linear* ($*$). *The oversampling parameter* γ *increases from* 1.0 *to* 1.82*—specifically* $\gamma = 1.00, 1.10, 1.22, 1.37, 1.56$, *and* 1.82. *In* (a) *and* (b) *the horizontal dashed line indicates the error of the conventional reconstruction.* (d) *Profile of row* 256 *of the reconstruction: original phantom (dashed line), conventional reconstruction (dot-dashed line), and fast reconstructions using linear* ($*$) *and cubic-MOMS* ($\bullet$) *interpolation.*

most desirable image quality might therefore not be the set of parameters with the lowest RMS error, but instead one that also has an acceptably low peak error. These curves can be used to select an interpolator and operating point of acceptable quality.

Apart from the error measures described above, the accuracy of the algorithms was adjudged by examining 1D profiles of the reconstructions near the edges of regions in the image. The width of the edge—the number of pixel units taken for the reconstruction to cross from 5% to 95% of the edge-transition (assuming underlying bilinear interpolation)—is calculated by choosing a set of points near the edge of each ellipse making up the phantom, calculating the edge width at each such edge pixel, and averaging the edge width over all the pixels. The edge widths are also calculated using different transition bounds—namely, 10% to 90%, and 20% to 80%. As displayed in Table 5.1, in all cases the edge widths decrease as the complexity of the interpolators is increased from linear (with $\gamma = 1.22$) to shifted-linear, quadratic

Table 5.1

The average edge widths of the reconstructions for different types of interpolators, using three different transition bounds to calculate edges.

Transition Bounds	Conv-enti-onal	Hierarchical (varying interpolators)					
		Linear (γ=1.22)	Shifted-linear (γ=1.0)	Quad Schaum (γ=1.22 with Kaiser)	Quad Schaum (γ=1.22 without Kaiser)	Quad MOMS (γ=1.0)	Cubic MOMS (γ=1.0)
5 to 95 %	2.48	3.36	2.83	2.59	2.27	2.21	2.06
10 to 90 %	1.96	2.62	2.25	2.08	1.85	1.82	1.70
20 to 80 %	1.31	1.73	1.51	1.41	1.26	1.25	1.17
Accel.	1	15.1	14.8	9.7	9.7	8.7	6.9

Schaum (with $\gamma = 1.22$), quadratic MOMS, and cubic MOMS. The Kaiser window increases the edge width (as seen in the case of the quadratic Schaum interpolator). The bottom row displays the acceleration factors of the hierarchical methods. Notice that the fast algorithm, when implemented with interpolators more complex than the quadratic Schaum, achieves a smaller edge width than the conventional algorithm.

The profile of a particular edge for a few representative reconstructions is displayed in Figure 5.3(d). In order of decreasing edge width they are the cubic MOMS, the conventional algorithm, and the linear interpolator. Visually, the edge-transitions are clearly comparable.

6. Conclusions.

Though the rotation-based hierarchical backprojection algorithms presented here are similar to Brandt's multilevel inversion (MI) algorithm [11], there are key differences and improvements.

These algorithms, like MI, involve sampling the intermediate images on rectangular grids, rotated with respect to each other. The sampling criterion in the slow direction explained heuristically in [11, equation 4.1] is equivalent to the sampling criterion derived here (the constraint in (3.13)). While in MI this slow-sampling interval is exactly achieved, we restrict ourselves to computationally efficient integer up-sampling factors in the slow direction and, consequently, satisfy or exceed the sampling criterion in [11]. Brandt et al. also mention “doubling”: they interpolate the projection data at double the original sampling rate to get better accuracy. In our algorithms we introduce variable oversampling in a more structured manner which results in greater flexibility to improve accuracy.

Our choice to perform digital image rotations leads to more performance gains. The decomposition of the rotation operator into shears allows for the intermediate rotations in the algorithm to be implemented as a sequence of 1D digital fractional delays. The separable implementation of the rotation operator allows for the use of digital image transformations and filtering of a higher quality than the bilinear interpolation used by Brandt in the MI algorithm. These higher-quality transformations are possible first because longer FIR filters can be used at low cost when used separably. Furthermore, operations involving IIR filters, such as the shifted-linear and higher-order spline-based filters, can be used (while they could not be used in the non-separable case). Fractional shifts can be efficiently implemented using shift-invariant filters. This also allows for the use of FFT-based shifting.

By analyzing the algorithm within the signal processing framework, we are able to elucidate conditions on the sampling and interpolation of the intermediate images, and optimize various parameters in the algorithm. We are also able to derive a reprojection algorithm which may be designed with the existing machinery of signal processing—optimal low-pass filtering and image transformations. Furthermore, this understanding may be used to derive fast hierarchical algorithms for other tomographic methods whose Fourier-domain behavior is well understood.

Both the backprojection and reprojection algorithms can be adapted to arbitrary numbers of view-angles, not just sets of size $2 \cdot 3^L$. While the ternary branching factor (or radix) is a particularly computationally efficient choice, arbitrary, possibly mixed, radixes may be used. Any number of projections may be processed through a hierarchy consisting of mostly ternary nodes. The algorithm is easily adapted to process projections at nonuniform view-angles. The Fourier-domain analysis dictates the optimal intermediate rotation-angles and the up-sampling factors.

The new family of fast backprojection and reprojection algorithms developed in this paper complements and extends the existing fast algorithms. These algorithms have different tradeoffs between computation and accuracy, and different architectures. A decision as to which of these algorithms is the most effective in any given practical application will require careful comparison of optimized implementations on the computing architectures of interest.

This algorithm can be extended to other projection geometries—the fan-beam [18] and cone-beam, for example—in order to find wider practical application.

Appendix. Proofs of propositions and lemmas.

A. Proof of Lemma 2.3.

Proof (by induction on l). The result is trivially true for $l = 1 : \Phi_p(I_{1,m}) = 0$ for all $p \in N_{1,m} = \{m\}$. Assume that the result is true for $l-1$.

Now consider $p \in \mathcal{N}_{l-1,3m-i}$. By (2.7) and Lemma 2.2, we know that $\Phi_p(I_{l,m}) = \Phi_p(I_{l-1,3m-i}) - \delta_{l-1,3m-i}$. By the inductive hypothesis, we know that $\Phi_p(I_{l-1,3m-i}) = -\sum_{i=1}^{l-2} \delta_{i,\mu(p,i)}$. Equation (2.12) implies that $N_{l-1,3m-i} = \{3^{l-2}(3m-i-1) + k : k = 1, 2, \dots, 3^{l-2}\}$. So $p/3^{l-2} \in \{(3m-i-1) + k/3^{l-2} : k = 1, 2, \dots, 3^{l-2}\}$, and consequently $\mu(p, l-1) \triangleq \lceil p/3^{l-2} \rceil = 3m - i$. Thus $\Phi_p(I_{l,m}) = -\sum_{i=1}^{l-2} \delta_{i,\mu(p,i)} - \delta_{l-1,\mu(p,l-1)} = -\sum_{i=1}^{l-1} \delta_{i,\mu(p,i)}$. $\square$

B. Proof of Proposition 2.4. We will need the following property of the ceiling operator $\lceil . \rceil$.

LEMMA B.1. *Let $x_1, x_2 \in (3^{-k}m, 3^{-k}(m+1)) \subset \mathbb{R}$ for some fixed $k, m \in \mathbb{N}$. Then $\lceil x_1 \rceil = \lceil x_2 \rceil$.*

Proof. Clearly, if $k \geq 0$, the set $\mathbb{Z} = \{3^{-k}3^k p : p \in \mathbb{Z}\} \subseteq \{3^{-k}n : n \in \mathbb{Z}\}$. If there exists $m \in \mathbb{Z}$ such that $x_i \in (3^{-k}m, 3^{-k}(m+1))$ for $i = 1, 2$, then $\lceil x_i \rceil \triangleq \arg\min_{n \in \mathbb{Z}} (n \geq x_i) \geq \arg\min_{y \in \{3^{-k}n : n \in \mathbb{Z}\}} (y \geq x_i) = 3^{-k}(m+1) \implies \lceil x_i \rceil = \lceil (3^{-k}(m+1)) \rceil$; i.e., $\lceil x_1 \rceil = \lceil x_2 \rceil$. $\square$

Proof of Proposition 2.4. Consider a particular l, m in the algorithm described by the block diagram in Figure 2.1(b). By (2.11), $I_{l,m} = \sum_{p \in N_{l,m}} \mathcal{K}(-\Phi_p(I_{l,m}))\mathcal{B}_0 q_p$. Since $\tilde{I}_{l,m} = \sum_{p \in N_{l,m}} \mathcal{K}(-\theta_p)\mathcal{B}_0 q_p$, the statement "there exists a $\alpha_{l,m}$ such that $I_{l,m} = \mathcal{K}(\alpha_{l,m})\tilde{I}_{l,m}$" is equivalent to

$$\sum_{p \in N_{l,m}} \mathcal{K}(-\Phi_p(I_{l,m}))\mathcal{B}_0 q_p = \sum_{p \in N_{l,m}} \mathcal{K}(\alpha_{l,m})\mathcal{K}(-\theta_p)\mathcal{B}_0 q_p = \sum_{p \in N_{l,m}} \mathcal{K}(\alpha_{l,m} - \theta_p)\mathcal{B}_0 q_p.$$

However, because this equality is assumed to hold for any $\{q_p\}_{p=1}^{P}$, it must hold term by term, and is equivalent to the statement that for all $p \in N_{l,m}$, there exists a $\alpha_{l,m}$

such that $-\Phi_p(I_{l,m}) = \alpha_{l,m} - \theta_p$, which is equivalent to

$$\Phi_{p1}(I_{l,m}) - \Phi_{p2}(I_{l,m}) = \theta_{p1} - \theta_{p2} \qquad \forall p1, p2 \in N_{l,m}. \tag{B.1}$$

Hence, we need to prove that the assumption of the proposition implies (B.1). Now, from (2.6)–(2.8) and the definition of Φ_p (Definition 2.1), $\hat{f} = \sum_{p=1}^{P} \mathcal{K}(-\Phi_p(I_{L+2,1}))\mathcal{B}_0 q_p$. But, by an assumption of this proposition—that the final image is correct and equal to that of the nonhierarchical algorithm—$\hat{f} = \sum_{p=1}^{P} \mathcal{K}(-\theta_p)\mathcal{B}_0 q_p$. Hence

$$\Phi_p(I_{L+2,1}) = \theta_p. \tag{B.2}$$

The angle $(\Phi_p(I_{l,m}))$ of a projection in any intermediate image is related to the angle $(\Phi_p(I_{L+2,1}))$ of the same projection in the final image as follows. Using Lemma 2.3, we get

$$\begin{aligned}\Phi_p(I_{L+2,1}) &= -\sum_{i=1}^{L+1} \delta_{i,\mu(p,i)} = -\sum_{i=1}^{l-1} \delta_{i,\mu(p,i)} - \sum_{i=l}^{L+1} \delta_{i,\mu(p,i)} \\ &= \Phi_p(I_{l,m}) - \sum_{i=l}^{L+1} \delta_{i,\mu(p,i)} \qquad \forall p \in N_{l,m},\, \forall l \le (L+2),\end{aligned} \tag{B.3}$$

where $\mu(p,i) = \lceil p/3^{i-1} \rceil$. We also know that if $p \in \mathcal{N}_{l,m} \triangleq \{3^{l-1}(m-1) + k : k = 1, 2, \ldots, 3^{l-1}\}$, as defined in (2.12), then $\frac{p}{3^{i-1}} \subset (3^{l-i}(m-1), 3^{l-i}m]$. So by Lemma B.1, we conclude that for any $p1, p2 \in N_{l,m}$ and $i \ge l$ we have $\mu(p1,i) = \lceil p1/3^{i-1} \rceil = \lceil p2/3^{i-1} \rceil = \mu(p2,i)$. Consequently, using (B.3) and then (B.2),

$$\begin{aligned}\Phi_{p1}(I_{l,m}) - \Phi_{p2}(I_{l,m}) &= \Phi_{p1}(I_{L+2,1}) + \sum_{i=l}^{L+1} \delta_{i,\mu(p1,i)} - \left(\Phi_{p2}(I_{L+2,1}) + \sum_{i=l}^{L+1} \delta_{i,\mu(p2,i)}\right) \\ &= \Phi_{p1}(I_{L+2,1}) - \Phi_{p2}(I_{L+2,1}) = \theta_{p1} - \theta_{p2}.\end{aligned}$$

But this is (B.1), which we have already shown to imply the lemma. □

C. Proof of Lemma 3.1.

Proof. Let $B_2(W)$ denote the space of $L_2(R^2)$ functions bandlimited to $W \subset R^2$, and let $H = \{\vec{\omega} \in \mathbb{R}^2 : |\omega_i| \le \frac{\pi}{\Delta_i}\}$. Then, $E^{\psi}_{\vec{\Delta}} f^d \in B_2(AH) \cap B_2(H)$. To see this note that the Sinc-interpolator Ψ zeroes out the DTFT of f^d outside the principal period $[-\pi, \pi]^2$. Hence, upon coordinate transformation by $\mathcal{A}$, the spectral support is transformed by A^T so that $\mathcal{A}E^{\psi}_{\vec{\Delta}} f^d \in B_2(A^T A^{-T} H) = B_2(H)$. Finally, $E^{\psi}_{\vec{\Delta}} \mathcal{A}^{\psi,\vec{\Delta}} f^d = E^{\psi}_{\vec{\Delta}} \mathcal{D}_{\vec{\Delta}} \mathcal{A} E^{\psi}_{\vec{\Delta}} f^d = \mathcal{A}E^{\psi}_{\vec{\Delta}} f^d$, where the first equality follows from (3.3) and the second from the sampling theorem: $E^{\psi}_{\vec{\Delta}} D_{\vec{\Delta}}$ is an identity on $B_2(H)$. □

A PHASE FIELD METHOD FOR JOINT DENOISING, EDGE DETECTION, AND MOTION ESTIMATION IN IMAGE SEQUENCE PROCESSING*

T. PREUSSER†, M. DROSKE‡, C. S. GARBE§, A. TELEA¶, AND M. RUMPF‡

Abstract. The estimation of optical flow fields from image sequences is incorporated in a Mumford–Shah approach for image denoising and edge detection. Possibly noisy image sequences are considered as input and a piecewise smooth image intensity, a piecewise smooth motion field, and a joint discontinuity set are obtained as minimizers of the functional. The method simultaneously detects image edges and motion field discontinuities in a rigorous and robust way. It is able to handle information on motion that is concentrated on edges. Inherent to it is a natural multiscale approximation that is closely related to the phase field approximation for edge detection by Ambrosio and Tortorelli. We present an implementation for two-dimensional image sequences with finite elements in space and time. This leads to three linear systems of equations, which have to be solved in a suitable iterative minimization procedure. Numerical results and different applications underline the robustness of the approach presented.

1. Introduction.

The task of motion estimation from image sequences, or computing the visual representation as optical flow, is a fundamental problem in computer vision. For a number of applications, a dense motion or optical flow field is desirable, yielding a representation of the motion of observed objects for each pixel of the image sequence. In low-level image processing, the accurate computation of object motion in scenes is a long-standing problem which has been addressed extensively. In particular, global variational approaches initiated by the work of Horn and Schunck [19] are increasingly popular. Initial problems such as the smoothing of discontinuities or high computational cost have been solved successfully [25, 7, 8]. Motion estimation also yields important indicators for the detection and recognition of the observed objects. While a number of techniques first estimate the optical flow field and segment objects later in a second phase [37], an approach of computing motion as well as segmenting objects at the same time is much more appealing. First advances in this direction were investigated in [33, 27, 28, 9, 23, 30]. In particular, Kornprobst et al. [22, 3, 4] have considered piecewise smooth motion patterns on image sequences characterized by piecewise smooth objects. Their results are phrased rigorously on the space of

functions of bounded variation (BV), and they propose suitable approximations for the numerical implementation. Already, in [22] a joint approach for the segmentation of moving objects in front of a still background and the computation of motion velocities has been proposed. For a given intensity function on an image sequence, a total variation (TV) type functional for the motion field—which allows for jumps in the optical flow velocity—is analyzed in [4, 3]. Recently, Papenberg et al. [29] considered another TV regularization of the motion field and optical flow constraints involving higher order gradients.

The idea of combining different image processing tasks into a single model in order to cope with interdependencies has drawn attention in several different fields. In image registration, for instance, a joint discontinuity approach for simultaneous registration, segmentation, and image restoration has been proposed by Droske and Ring [15] and extended in [16] to incorporate phase field approximations. In these approaches, the phase field is used to describe object boundaries, and sharp interfaces of zero width are replaced by diffuse interfaces of finite width ϵ in which the phase field variable continuously changes its value from 0 to 1. This description of object boundaries draws its name from physics, where it is used for modeling solidification of fluids and associated phase boundaries [31, 38]. Kapur, Yezzi, and Zöllei [20] and Unal et al. [35] have combined segmentation and registration by applying geodesic active contours described by level sets in both images. Vemuri et al. have also used a level set technique to exploit a reference segmentation in an atlas [36]. We refer to [14] for further references.

Recently, Keeling and Ring [21] investigated the relation between optimization and optical flow extraction. A first approach which relates optical flow estimation to Mumford–Shah image segmentation was presented by Nesi [26]. Recently, Rathi et al. investigated active contours for joint segmentation and optical flow extraction [32]. Cremers and Soatto [13, 12] presented an approach for joint motion estimation and motion segmentation with one functional. Incorporating results from Bayesian inference, they derived an energy functional, which can be seen as an extension of the well-known Mumford–Shah [24] approach. Their functional involves the length of boundaries separating regions of different motion as well as a “fidelity term” for the optical flow assumption. Brox, Bruhn, and Weickert [7] present a Chan–Vese-type model for piecewise smooth motion extraction. For given fixed image data the decomposition of image sequences into regions of homogeneous motion is encoded in a set of level set functions, and the regularity of the motion fields in these distinct regions is controlled by a TV functional. Our approach is in particular inspired by these investigations.

We combine denoising and edge detection with the estimation of motion. This results in an energy functional, which incorporates fidelity and smoothness terms for both the image sequence and the flow field. Our focus lies in particular on motion information that is concentrated on edges such as in the case of a moving object with sharp edge contours but without shading and texture. To cope with this, we formulate the optical flow equations appropriately in regions away from edges and on the edge set. Moreover, we incorporate an anisotropic enhancement of the flow along the edges of the image in the sense of Nagel and Enkelmann [25]. This effectively allows us to spread motion information from the edge set onto the whole domain of a moving object. The model is implemented using the phase field approximation in the spirit of Ambrosio and Tortorelli's approach [2] for the original Mumford–Shah functional. The identification of edges is phrased in terms of a phase field function; no a priori knowledge of objects is required, as opposed to formulations of explicit contours. *Particular focus is on optical flow constraints which are not only continuously distributed over shaded or textured regions, but also might be concentrated on edges, e.g., in case of moving objects without texture and shading.* In contrast to a level set approach, the built-in multiscale of the phase field model enables a natural cascadic energy relaxation approach and thus an efficient computation. Indeed, no initial guess for the edge set and the motion field will be required. We present here a truly $(d+1)$-dimensional algorithm, considering time as an additional dimension to the d-dimensional image data. This fully demonstrates the conceptual advantages of the joint approach. Nevertheless, a transfer of the method for only two consecutive time frames is possible but not investigated here. The characteristics of our approach are as follows:

- The distinction of smooth motion fields and optical flow discontinuities is directly linked to edge detection, improving the reliability of the motion estimation.
- The denoising and segmentation task will profit from the explicit coupling of the sequence via the assumption of brightness constancy.
- The phase field approximation is expected to converge to a limit problem for vanishing scale parameter, with a strict notion of edges and motion field discontinuities not involving any additional filtering parameter.
- The algorithm is based on an iteration. In each step a set of three relatively simple linear systems have to be solved for the image intensity, the edge description via the phase field, and the motion field, respectively. Only a small number of iterations is required.

This paper is organized as follows: In section 2 Mumford–Shah-type image denoising and edge detection are reviewed, in section 3 we discuss a generalized optical flow equation, and in section 4 the minimization problem is presented. Section 5 shows how to approximate the segmentation in terms of a variational phase field model. Furthermore, we prove existence of solutions of this model and discuss the limit behavior. Section 6 propounds the corresponding Euler–Lagrange equations, which are discretized applying the usual finite element method in section 7. We conclude with the results in section 8. Finally, in the appendix we provide explicit formulas of all matrices and vectors appearing in the implementation to enable readers to reproduce the algorithm.

2. Recalling the Mumford–Shah functional. In their pioneering paper, Mumford and Shah [24] proposed the minimization of the following energy functional:

$$E_{MS}[u,S] = \lambda \int_\Omega (u-u_0)^2 \,\mathrm{d}\mathcal{L} + \frac{\mu}{2}\int_{\Omega\setminus S} |\nabla u|^2 \,\mathrm{d}\mathcal{L} + \nu\mathcal{H}^{d-1}(S), \tag{2.1}$$

where u_0 is the initial image defined on an image domain $\Omega \subset \mathbb{R}^d$ and λ, μ, ν are positive weights. Here, one asks for a piecewise smooth representation u of u_0 and an edge set S, such that u approximates u_0 in the least squares sense, u ought to be smooth apart from the free discontinuity set S, and in addition S should be smooth and thus small with respect to the $(d-1)$-dimensional Hausdorff measure $\mathcal{H}^{d-1}$. Mathematically, this problem has been treated in the space of functions of bounded variation BV, more precisely in the specific subset SBV [1]. In this paper, we will pick up a phase field approximation for the Mumford–Shah functional (2.1) proposed by Ambrosio and Tortorelli [2]. They describe the edge set S by a phase field ζ which is supposed to be small on S and close to 1 apart from edges, i.e., one asks for minimizers of the energy functional

$$E_\epsilon[u,\zeta] = \int_\Omega \lambda(u-u_0)^2 + \frac{\mu}{2}(\zeta^2+k_\epsilon)\,|\nabla u|^2 + \nu\epsilon\,|\nabla\zeta|^2 + \frac{\nu}{4\epsilon}(1-\zeta)^2\,\mathrm{d}\mathcal{L}, \tag{2.2}$$

where ϵ is a scale parameter and $k_\epsilon = o(\epsilon) \ll 1$ a small positive regularizing parameter, which mathematically ensures strict coercivity with respect to u. On edges the weight ζ^2 is expected to vanish. Hence, the second term measures smoothness of u but only away from edges. The last two terms in the integral encode the approximation of the $(d-1)$-dimensional area of the edge set and the strong preference for a phase field value $\zeta \approx 1$ far from edges, respectively. For larger ϵ one obtains coarse, blurred representations of the edge sets and corresponding smoother images u. With decreasing ϵ we successively refine the representation of the edges and include more image details.

3. Generalized optical flow equation. In image sequences we observe different types of motion fields: locally smooth motion visible via variations of object shading and texture in time, or jumps in the motion velocity apparent at edges of objects moving in front of a background. We aim for an identification of corresponding piecewise smooth optical flow fields in piecewise smooth image sequences

$$u : [0,T]\times\Omega \mapsto \mathbb{R}; \quad (t,x) \to u(t,x)$$

for a finite time interval $[0,T]$ and a spatial domain $\Omega \subset \mathbb{R}^d$ with $d = 1,2,3$. In what follows, we assume $\partial\Omega$ to be Lipschitz. The flow fields are allowed to jump on edges in the image sequence. On edges, the derivative Du splits into a singular and a regular part. The regular part is a classical gradient $\nabla_{(t,x)}u$ in space and time, whereas the singular part lives on the singularity set S—the set of edge surfaces in space-time. Time slices of S are the actual image edges at the specific time. We denote by $n_S \in \mathbb{R}^{d+1}$ the normal on S with respect to space-time. The singular part represents the jump of the image intensity on S, i.e., one observes that $D^s u = (u^+ - u^-)n_S$. Here, u^+ and u^- are the upper and lower intensity values on both sides of S, respectively. Now, we suppose that the image sequence u reflects an underlying motion with a piecewise smooth motion velocity v, which is allowed to jump only on S. Thus, S represents object boundaries moving in front of a background, which might as well be in motion. In strict mathematical terms, we suppose that $u, v \in SBV$ (the set of functions of bounded variation and vanishing Cantor part in the gradient) [17, 1]. In this general setting without any smoothness assumption on u and v, we have to ask for a generalized optical flow equation. In fact, away from moving object edges we derive, as usual, from the brightness constancy constraint equation (BCCE) $u(t+s,\, x+s\,v) = $ const on motion trajectories $\{(t+s,\, x+s\,v) \mid s \in [0,T]\}$, that

$$\nabla_{(t,x)}u \cdot w = 0, \tag{3.1}$$

where $w = (1,v)$ is the space-time motion velocity. On edges, the situation is more complex and in general requires prior knowledge. For instance, a white circular disk moving in front of a black background is visually identical to a black mask with a circular hole moving with the same speed on a white background (the aperture problem). Hence, it is ambiguous on which side of the edge $w^\pm$ vanishes and on which side a nontrivial optical flow equation $n_S \cdot w^\pm = 0$ holds. We will not resolve this ambiguity via semantic assumptions. In what follows, we assume instead that locally only one object—in our example either the circle or the mask—is moving on a stationary background. Hence, we rule out that foreground and background are in motion. In other words, our background is that part of the image which is not moving. Then one of the two values of w on both sides of the edge vanishes by assumption, and we can rewrite the optical flow constraint on the edge without identifying foreground or background by

$$n_S \cdot (w^+ + w^-) = 0. \tag{3.2}$$

This in particular includes the case of a sliding motion without any modification of the object overlap, where $n_S \cdot w^+ = n_S \cdot w^- = 0$.

4. Mumford–Shah approach to optical flow. Now, we ask for a simultaneous denoising, segmentation, and flow extraction on image sequences. Hence, we will incorporate the motion field generating an image sequence into a variational method. Let us formulate a corresponding minimization problem in the spirit of the Mumford–Shah model.

Definition 4.1 (Mumford–Shah-type optical flow approach). *Given a noisy initial image sequence $u_0 : D \to \mathbb{R}$ on the space-time domain $D = [0,T] \times \Omega$, we define the energy*

$$\begin{aligned} E_{\mathrm{MSopt}}[u,w,S] = {} & \int_D \frac{\lambda_u}{2}(u-u_0)^2 \,\mathrm{d}\mathcal{L} + \int_{D\setminus S} \frac{\lambda_w}{2}\left(w \cdot \nabla_{(t,x)} u\right)^2 \mathrm{d}\mathcal{L} \\ & + \int_{D\setminus S} \frac{\mu_u}{2}\left|\nabla_{(t,x)} u\right|^2 \mathrm{d}\mathcal{L} + \int_{D\setminus S} \frac{\mu_w}{q}\left|\nabla_{(t,x)} w\right|^q \mathrm{d}L + \nu \mathcal{H}^d(S) \end{aligned} \tag{4.1}$$

for a piecewise smooth image sequence u, and a piecewise smooth motion field $w = (1, v)$ with a joint jump set S. Furthermore, we require the optical flow constraint $n_S \cdot (w^+ + w^-) = 0$ on S from (3.2). *Now, one asks for a minimizer (u, w, S) of the corresponding constraint minimization problem.*

The first and second terms of the energy are fidelity terms with respect to the image intensity and the regular part of the optical flow constraint, respectively. The third and fourth terms encode the smoothness requirement of u and w. Finally, the last term represents the area of the edge surfaces S. The fidelity weights λ_u, λ_w, the regularity weights μ_u, μ_w, and the weight ν controlling the phase field are supposed to be positive and $q \geq 2$. Let us emphasize that, without any guidance from the local time modulation of shading or texture on both sides of an edge, there is still an undecidable ambiguity with respect to foreground and background.

5. Phase field approximation. Similar to the original model for denoising and edge detection (2.1), the above Mumford–Shah approach (4.1) with its explicit dependence on the geometry of the edge set is difficult to implement without any additional strong assumptions either on the image sequence or on the motion field. For a corresponding parametric approach we refer to the recent results by Cremers and Soatto [13, 12]. The level set approach recently presented by Brox, Bruhn, and Weickert [7] does not explicitly encode motion concentrated on edges. We do not aim to impose any additional assumption on the image sequence u and the motion field v and ask for a suitable approximation of the above model. To gain more flexibility and, in addition, to incorporate a simple multiscale into the model, we propose here a phase field formulation (2.2) in the spirit of Ambrosio and Tortorelli [2]. Let us note that in [3] Aubert, Deriche, and Kornprobst already proposed considering this type of phase field approximation for the regularization of the motion field. We introduce an auxiliary variable ζ—the phase field—describing the edge set S. Away from S we aim for $\zeta \approx 1$, and on S the phase field ζ should vanish. As in the original Ambrosio–Tortorelli model, a scale parameter ϵ controls the thickness of the region with small phase field values. We consider the following energy functionals in the Mumford–Shah optical flow model (4.1):

$$E^{\epsilon}_{\mathrm{fid},u}[u] = \int_D \frac{\lambda_u}{2}(u-u_0)^2 \,\mathrm{d}\mathcal{L}, \tag{5.1}$$

$$E^{\epsilon}_{\mathrm{fid},w}[u,w] = \int_D \frac{\lambda_w}{2}\left(w\cdot\nabla_{(t,x)}u\right)^2 \mathrm{d}\mathcal{L}, \tag{5.2}$$

$$E^{\epsilon}_{\mathrm{reg},u}[u,\zeta] = \int_D \frac{\mu_u}{2}(\zeta^2+k_\epsilon)\left|\nabla_{(t,x)}u\right|^2 \mathrm{d}\mathcal{L}, \tag{5.3}$$

$$E^{\epsilon}_{\mathrm{phase}}[\zeta] = \int_D \left(\nu\epsilon\left|\nabla_{(t,x)}\zeta\right|^2 + \frac{\nu}{4\epsilon}(1-\zeta)^2\right)\mathrm{d}\mathcal{L}. \tag{5.4}$$

These energy contributions control the approximation of the initial image u_0 (5.1) and the optical flow constraints (5.2), the regularity of u (5.3), and the shape of the phase field ζ (5.4). Here, as in the original model, $k_\epsilon = o(\epsilon) > 0$ is a "safety" coefficient, which is needed later to establish existence of solutions of our approximate problem. Still missing is a regularity term for the motion field corresponding to the fourth energy term in the Mumford–Shah model (4.1). If we would consider in a straightforward way the integral

$$\tilde{E}^{\epsilon}_{\mathrm{reg},w}[w,\zeta] = \int_D \frac{\mu_w}{2}(\zeta^2+k_\epsilon)\left|\nabla_{(t,x)}w\right|^2 \mathrm{d}\mathcal{L}, \tag{5.5}$$

the motion field will form approximate jumps on S but without any coupling of a concentrated motion constraint on S and the motion field in homogeneous regions on the image sequence. Figure 8.1 clearly outlines this drawback in the case of a circle with constant white image intensity inside moving on a textured background. As an alternative one might want to decouple the scales for image edges and motion edges introducing a second phase field with a much finer scale parameter $\tilde{\epsilon} \ll \epsilon$ for the representation of motion singularities. But this is not very practical, taking into account a suitable discretization on digital images with limited pixel resolution. Here the parameter ϵ is already in the range of the pixel size. Furthermore, in case of finite energy we would obtain motion fields w bounded in $W^{1,2}$, which is not sufficient to ensure compactness of the optical flow integrand in (5.2). Thus, to allow for piecewise smooth motion fields and to enable an extension of motion velocities first concentrated on edges via the variational approach, we consider

$$E^{\epsilon}_{\mathrm{reg},w}[w,\zeta] = \int_D \frac{\mu_w}{q}\left|P_\delta[\zeta]\nabla_{(t,x)}w\right|^q \mathrm{d}\mathcal{L}. \tag{5.6}$$

Here, the following properties are encoded in the operator $P_\delta[\zeta]$:

- Close to the edges, where $\zeta \le \theta^-$ for some θ^- with $0 < \theta^- < 1$, $P_\delta[\zeta]$ should behave like the original edge indicator ζ^2 proposed by Ambrosio and Tortorelli [2].
- Away from the edges, where $\zeta \ge \theta^+$ for $\theta^- < \theta^+ < 1$, $P_\delta[\zeta]$ is expected to be the identity matrix, which enforces an isotropic smoothness modulus for the motion field w.

- In the spirit of the classical approach by Nagel and Enkelmann [25], $P_\delta[\zeta]$ will be an (approximate) projection onto level sets of the phase field function in the intermediate region. These level sets are surfaces approximately parallel to the edge set in space-time. Thus, information on the optical flow is mediated along the edge set, without a coupling across edge surfaces.

An explicit definition for $P_\delta[\zeta]$ fulfilling these properties is

$$P_\delta[\zeta] = \alpha(\zeta^2)\left(\mathbb{1} + k_\epsilon - \beta(\zeta^2)\frac{\nabla_{(t,x)}\zeta}{\left|\nabla_{(t,x)}\zeta\right|_\delta} \otimes \frac{\nabla_{(t,x)}\zeta}{\left|\nabla_{(t,x)}\zeta\right|_\delta}\right),$$

where $|z|_\delta = (|z|^2 + \delta^2)^{\frac{1}{2}}$ represents a regularized normal. Furthermore, $\alpha : \mathbb{R} \to \mathbb{R}_0^+$ and $\beta : \mathbb{R} \to \mathbb{R}_0^+$ are continuous blending functions, with

$$\alpha(s) = \max\left(0, \min\left(1, \frac{s}{\theta^-}\right)\right) + k_\epsilon, \quad \beta(s) = \max\left(0, \min\left(1, 1 - \frac{s}{\theta^+}\right)\right).$$

Concerning algebraic notation, $\nabla_{(t,x)}w(t,x)$ is a $(d+1)^2$ matrix and thus $P_\delta[\zeta]\nabla_{(t,x)}w$ represents the matrix product. We consider the Frobenius norm of matrices, given by $|A| = \sqrt{\operatorname{tr}(A^T A)}$. Suitable choices for the parameters are $\theta^+ = 0.8$ and $\theta^- = 0.0025$. For vanishing ϵ and a corresponding steepening of the slope of u, this operator basically leads to a separated diffusion on both sides of S in the relaxation of the energy.

Let us recall that the energies $E^\epsilon_{\mathrm{reg},u}, E^\epsilon_{\mathrm{phase}}$ and the term $E^\epsilon_{\mathrm{fid},u}$ are identical to those in the original Ambrosio–Tortorelli approach (see above). In addition, we ask for an optical flow field w according to the optical flow constraint encoded in $E^\epsilon_{\mathrm{fid},w}$ (cf. Figure 8.1 for a first test case). At the same time, this term implies a strong coupling of the image intensities along motion trajectories—which turns into a flow-aligned diffusion in the corresponding Euler–Lagrange equations—for the benefit of a more robust denoising and edge detection. Figure 8.2 shows an example where a completely destroyed time step in the image sequence is recovered by this enhanced diffusion along motion trajectories. Due to the regularity energy $E^\epsilon_{\mathrm{reg},w}$ this motion field is isotropically smooth away from the approximate jump set of u, and the smoothness modulus is characterized by a successively stronger anisotropy along level sets of u while approaching the approximate jump set. The energy term $E^\epsilon_{\mathrm{reg},w}$ (5.6) which we consider for the regularization of the motion field is very similar to the corresponding smoothness term in the classical approach by Nagel and Enkelmann [25], where tangential diffusion is steered by the local structure tensor. In the above multiscale approach no additional prefiltering of the image sequence in terms of a structure tensor is required.

The projection operator $P_\delta[\zeta]$ couples the smoothness of the motion field w to the image geometry, which in fact is very beneficial for the purpose of piecewise smooth motion extraction. The reverse coupling, which would try to align tangent spaces of level sets of u to the motion field, is not required and might even be misleading for our actual goal. The optical flow term in the fidelity energy $E^\epsilon_{\mathrm{fid},w}$ already couples image sequence gradients to the motion field in a direct way. Hence, we don't ask for global minimizers of the sum of all energies but formulate the phase field approximation problem as follows.

Definition 5.1 (solution of the phase field model). *Let $u_0 : D \to \mathbb{R}$ be a noisy space-time image, and let $v_\delta \in W^{1,q}(D, \mathbb{R}^d)$ be boundary data for the velocity field. A space-time image $u \in W^{1,2}(D, \mathbb{R})$, a motion field $w = (1, v + v_\delta)$, with $v \in W^{1,q}_0(D, \mathbb{R}^d)$, and a phase field $\zeta \in W^{1,2}(D, \mathbb{R})$ is called a solution of the phase* *field model if u and ζ minimize the restricted energy*

$$E_w[u,\zeta] := E^{\epsilon}_{\mathrm{fid},u}[u] + E^{\epsilon}_{\mathrm{fid},w}[u,w] + E^{\epsilon}_{\mathrm{reg},u}[u,\zeta] + E^{\epsilon}_{\mathrm{phase}}[\zeta] \tag{5.7}$$

for fixed w in $W^{1,2}(D,\mathbb{R}^{d+1})$, and if the motion field w minimizes the global energy

$$E^{\epsilon}_{\mathrm{global}}[u,w,\zeta] = E^{\epsilon}_{\mathrm{fid},u}[u] + E^{\epsilon}_{\mathrm{fid},w}[u,w] + E^{\epsilon}_{\mathrm{reg},u}[u,\zeta] + E^{\epsilon}_{\mathrm{reg},w}[w,\zeta] + E^{\epsilon}_{\mathrm{phase}}[\zeta] \tag{5.8}$$

for fixed $u,\zeta \in W^{1,2}(D,\mathbb{R})$.

In the Mumford–Shah optical flow model (4.1) the edge set S describes the discontinuities of u and w simultaneously. With the splitting introduced in the definition, we obtain a decoupling of the edge sets. Still the flow field w is smoothed along edges of u. But edges in w will not affect the phase field ζ and thus edges of u. Altogether the set of edges of w will be a subset of the edge set of u

REMARK 5.2. *The definition of u and ζ as the minimizer of a restricted functional is not only sound with respect to the applications. Indeed, a simultaneous relaxation of the global energy with respect to all unknowns is theoretically questionable. In fact, $E^{\epsilon}_{\mathrm{reg},w}$ is not convex in ζ, and we cannot expect this energy contribution to be lower semicontinuous on a suitable set of admissible functions. With the above notion of solutions the direct method in the calculus of variations can be applied, and in particular one observes compactness of the sequence of phase fields associated with a minimizing sequence of image sequences and motion fields (cf. the proof below).*

THEOREM 5.3 (existence of solutions). *Suppose that $d+1 < q < \infty$ and $\lambda_u, \lambda_w, \mu_u, \mu_w, \nu, \epsilon > 0$, and let $k_\epsilon > 0$. Then there exists a solution (u,w,ζ) of the phase field problem introduced in Definition* 5.1.

Proof. At first, we rewrite the phase field approach as an energy minimization problem, which later allows us to apply the direct method from the calculus of variations. For fixed w the energy functional $E_w[u,\zeta]$ (5.7) is strictly convex. By the direct method we obtain a unique minimizer. So let us denote by $(u[w],\zeta[w])$ this minimizer in $W^{1,2}(D,\mathbb{R}) \times W^{1,2}(D,\mathbb{R})$ of the quadratic energy functional $E_w[u,\zeta]$ for fixed $u \in W^{1,2}(D,\mathbb{R})$. The minimizing phase field is given as the weak solution of the corresponding Euler–Lagrange equation

$$-\epsilon\Delta\zeta + \frac{1}{4\epsilon}\zeta = f[u,\zeta] := \frac{1}{4\epsilon} - \frac{\mu_u}{2\nu}\left|\nabla_{(t,x)}u\right|^2\zeta. \tag{5.9}$$

Applying the weak maximum principle we observe that $\overline{\zeta} \equiv 1$ is a supersolution and $\underline{\zeta} \equiv 0$ a subsolution. Thus, $\zeta[w]$ is uniformly bounded, i.e., $0 \le \zeta[w] \le 1$.

Given $(u[w],\zeta[w])$ we consider the global energy $E^{\epsilon}_{\mathrm{global}}$ solely as a functional of the motion field $w=(1,v)$:

$$E[w] = E^{\epsilon}_{\mathrm{global}}[u[w],w,\zeta[w]]$$

on the admissible set

$$\mathcal{A} := \{w \mid w = (1, v+v_\delta),\ v \in W^{1,q}_0(D,\mathbb{R}^{d+1})\},$$

and we define $\underline{E} := \inf_{w\in\mathcal{A}} E[w]$. Testing the energy at $u \equiv 0$, $\zeta \equiv 0$, and $w = (1,v_\delta)$ we observe that $\underline{E} \le \frac{\lambda_u}{2}\left|u_0\right|^2_{L^2} + \frac{\mu_w}{q}\left|\nabla_{(t,x)}v_\delta\right|^q_{L^q} < \infty$. Let us consider a minimizing sequence $\left(w^k\right)_{k=1,\dots,\infty}$ in $\mathcal{A}$ with $E[w^k] \to \underline{E}$ for $k \to \infty$. We set $u^k = u[w^k]$ and

$\zeta^k = \zeta[w^k]$ and estimate the energy E_{global} as

$$E_{\mathrm{global}}[u,w,\zeta] \geq \frac{\lambda_u}{4}\left(|u|_{L^2}^2 - 2\,|u_0|_{L^2}^2\right) + \frac{\mu_u k_\epsilon}{2}\left|\nabla_{(t,x)}u\right|_{L^2}^2 + \frac{\mu_w k_\epsilon}{q}\left|\nabla_{(t,x)}w\right|_{L^q}^q + \frac{\nu}{4\epsilon}\left(|\zeta|_{L^2}^2 - 2\mathcal{L}(D)\right) + \nu\epsilon\left|\nabla_{(t,x)}\zeta\right|_{L^2}^2,$$

where $\mathcal{L}(D)$ denotes the Lebesgue measure of D. From this, we deduce that $(u^k)_k$ and $(\zeta^k)_k$ are bounded in $W^{1,2}(D,\mathbb{R})$ and, taking into account the boundary conditions, that $(w^k)_k$ is bounded in $W^{1,q}(D,\mathbb{R})$. Hence, we can extract a weakly converging subsequence again denoted by $(u^k,w^k,\zeta^k)_k$ having the weak limit (u,w,ζ). From the Sobolev embedding theorem and the assumption $q > d+1$ we derive that w^k strongly converges in L^∞. Furthermore, the corresponding sequence $(\zeta^k)_k$ of phase field functions $\zeta^k := \zeta[w^k]$ are weak solutions of $-\epsilon\Delta\zeta^k + \frac{1}{4\epsilon}\zeta^k = f^k$ (cf. (5.9)). From the bounds on ζ^k in L^∞ and on u^k in $W^{1,2}$ we obtain that $f^k = f[u^k,\zeta^k]$ is uniformly bounded in L^1. This observation allows us to apply a compensated compactness result to verify that $\nabla_{(t,x)}\zeta^k$ converges to $\nabla_{(t,x)}\zeta$ a.e. This is proven for the equation $-\Delta\zeta = f$ on the space $W_0^{1,2}$ in [34, Chap. I, Thm. 3.4], but can easily be generalized for equations of type $-\Delta\zeta + \zeta = f$ on $W^{1,2}$. The matrix-valued function $P_\delta[\cdot]$ is continuous and bounded. Hence, we obtain that $P_\delta[\zeta^k] \to P_\delta[\zeta]$ a.e. for $k \to \infty$. For later use, we define the constants $C_u = \sup_{k=1,\dots,\infty}\left|\nabla_{(t,x)}u^k\right|_{L^2}$ and $C_w = \sup_{k=1,\dots,\infty}\max\left\{\left|w^k\right|_{L^\infty}, \left|\nabla_{(t,x)}w^k\right|_{L^q}\right\}$.

Next, we verify that $u = u[w]$ and $\zeta = \zeta[w]$. Indeed, taking into account the lower semicontinuity of E_w and the modulus of continuity with respect to w we can estimate

$$\begin{aligned}
E_w[u,\zeta] &\leq \liminf_{k\to\infty} E_{w^k}[u^k,\zeta^k] \\
&\leq \liminf_{k\to\infty} E_{w^k}[\tilde{u},\tilde{\zeta}] \\
&\leq E_w[\tilde{u},\tilde{\zeta}] + \liminf_{k\to\infty}\left(\left|w^k\cdot\nabla_{(t,x)}\tilde{u}\right|_{L^2}^2 - \left|w\cdot\nabla_{(t,x)}\tilde{u}\right|_{L^2}^2\right) \\
&\leq E_w[\tilde{u},\tilde{\zeta}] + 2C_w\left|\nabla_{(t,x)}\tilde{u}\right|_{L^2}^2 \liminf_{k\to\infty}\left|w - w^k\right|_{L^\infty}
\end{aligned}$$

for any $\tilde{u},\tilde{\zeta} \in W^{1,2}(D,\mathbb{R})$. From the L^∞ convergence of w^k to w, we immediately obtain that $E_w[u,\zeta] \leq E_w[\tilde{u},\tilde{\zeta}]$. Thus, by definition $u = u[w]$ and $\zeta = \zeta[w]$. Based on these preliminaries, we are able to prove weak lower semicontinuity of the energy. For this we assume without loss of generality that

$$E[w^k] \leq \underline{E} + \rho, \quad \left|P_\delta[\zeta^k] - P_\delta[\zeta]\right|_{L^\infty} \leq \rho, \quad \left|w^k - w\right|_{L^\infty} \leq \rho$$

for a fixed and small constant $\rho > 0$. Applying Mazur's lemma we obtain a sequence of convex combinations

$$\left(\sum_{i=1,\dots,k}\lambda_i^k(u^i,w^i,\zeta^i)\right)_k, \quad \text{with} \sum_{i=1,\dots,k}\lambda_i^k = 1, \quad \lambda_i^k \geq 0,$$

converging strongly to (u,w,ζ) in $W^{1,2}(D,\mathbb{R}) \times W^{1,2}(D,\mathbb{R}^{d+1}) \times W^{1,2}(D,\mathbb{R})$. Finally, taking into account convexity properties of the integrands, Fatou's lemma, and the modulus of continuity of $E_{\text{fid},u}$, $E_{\text{fid},w}$, and $E_{\text{reg},w}$ with respect to w and $P_\delta[\zeta]$, respectively, we estimate (using Einstein's summation convention)

$$\begin{aligned}
E[w] &= E_{\text{global}}[u[w], w, \zeta[w]] = E_{\text{global}}[u, w, \zeta]\\
&= \int_D \frac{\lambda_u}{2}\left(\liminf_{k\to\infty} \lambda_i^k u^i - u_0\right)^2 + \frac{\lambda_w}{2}\left|\liminf_{k\to\infty} w \cdot \left(\lambda_i^k \nabla_{(t,x)} u^i\right)\right|^2 \mathrm{d}\mathcal{L}\\
&\qquad + \int_D \frac{\mu_u}{2}(\zeta^2 + k_\epsilon)\left|\liminf_{k\to\infty} \lambda_i^k \nabla_{(t,x)} u^i\right|^2 + \frac{\mu_w}{q}\left|\liminf_{k\to\infty} P_\delta[\zeta]\lambda_i^k \nabla_{(t,x)} w^i\right|^q \mathrm{d}\mathcal{L}\\
&\qquad + \int_D \left(\nu\epsilon\left|\liminf_{k\to\infty} \lambda_i^k \nabla\zeta^i\right|^2 + \frac{\nu}{4\epsilon}\left(1 - \liminf_{k\to\infty} \lambda_i^k \zeta^i\right)^2\right) \mathrm{d}\mathcal{L}\\
&\le \int_D \frac{\lambda_u}{2} \liminf_{k\to\infty} \lambda_i^k \left(\left(u^i - u_0\right)^2 + \frac{\lambda_w}{2}\left|w \cdot \left(\nabla_{(t,x)} u^i\right)\right|^2\right) \mathrm{d}\mathcal{L}\\
&\qquad + \int_D \liminf_{k\to\infty} \lambda_i^k \left(\frac{\mu_u}{2}(\zeta^2 + k_\epsilon)\left|\nabla_{(t,x)} u^i\right|^2 + \frac{\mu_w}{q}\left|P_\delta[\zeta]\nabla_{(t,x)} w^i\right|^q\right) \mathrm{d}\mathcal{L}\\
&\qquad + \int_D \liminf_{k\to\infty} \lambda_i^k \left(\nu\epsilon\left|\nabla_{(t,x)}\zeta^i\right|^2 + \frac{\nu}{4\epsilon}(1 - \zeta^i)^2\right) \mathrm{d}\mathcal{L}\\
&\le \liminf_{k\to\infty} \lambda_i^k E[u^i, w^i] + \frac{\lambda_w}{2} \sup_{i=1,\ldots,\infty} \left(\left|w^i \cdot \nabla_{(t,x)} u^i\right|_{L^2}^2 - \left|w \cdot \nabla_{(t,x)} u^i\right|_{L^2}^2\right)\\
&\qquad + \frac{\mu_w}{q} \sup_{i=1,\ldots,\infty} \left(\left|P_\delta[\zeta^i]\nabla_{(t,x)} w^i\right|_{L^q}^q - \left|P_\delta[\zeta]\nabla_{(t,x)} w^i\right|_{L^q}^q\right)\\
&\le \underline{E} + \lambda_w C_w C_u^2 \sup_{i=1,\ldots,\infty} \left|w^i - w\right|_{L^\infty} + \mu_w C_w^q \sup_{i=1,\ldots,\infty} \left(\left|P_\delta[\zeta^i] - P_\delta[\zeta]\right|_{L^\infty}\right)\\
&\le \underline{E} + \rho + \lambda_w C_w C_u^2 \rho + \mu_w C_w^q \rho.
\end{aligned}$$

This estimate holds for any $\rho \ge 0$. Thus, we obtain $E[w] \le \underline{E}$, which implies that w is a minimizer of the energy E, and hence (u, w, ζ) is a solution of our phase field problem. □

REMARK 5.4. *The above problem formulation is not only sound with respect to the actual modeling, but it will also allow a simple relaxation approach (see below). Indeed, on all tested data sets we obtain convergence in few iterations (*10–15*).*

Applying formal asymptotics, one observes that the phase field approach proposed here indeed converges to the above Mumford–Shah model. For small ϵ we expect a steepening of the gradient u on a stripe of thickness ϵ around the edge set. The phase field ζ will approximate 1 away from a shrinking neighborhood of the edge surface. For $\epsilon \to 0$ we expect to observe convergence of $E_{\text{reg},u}$ and $E_{\text{reg},w}$ to $\int_{D\setminus S} \frac{\mu_u}{2}\left|\nabla_{(t,x)} u\right|^2 + \frac{\mu_w}{q}\left|\nabla_{(t,x)} u\right|^q \mathrm{d}\mathcal{L}$ and of $E^\epsilon_{\text{phase}}$ to $\mathcal{H}^d(S)$. Under these assumptions on the qualitative behavior $\int_D (w \cdot \nabla_{(t,x)} u)^2 \,\mathrm{d}\mathcal{L}$ converges to the second term of E_{MSopt}, whereas on the edge surface one observes a concentration of energy on the jump set and which scales like $O(\epsilon^{-1})$. Thus, we observe that in the limit we reproduce our optical flow constraint $n_S \cdot (w^+ + w^-) = 0$ from the sharp-interface Mumford–Shah approach. A rigorous validation of this limit behavior in terms of Γ-convergence is still open. For results on Γ-convergence for the optical flow problem in the context of TV type models we refer to [4, 22].

6. Variations of the energy and an algorithm. In what follows, we will consider the Euler–Lagrange equations of the above energies. Thus, we need to compute the variations of the energy contributions with respect to the involved unknowns

u, w, ζ. The variation of an energy E in direction ζ with respect to a parameter function z will be denoted by $\langle \delta_z E, \zeta \rangle$. For the ease of implementation we consider the case $q = 2$. Using straightforward differentiation for sufficiently smooth u, w, ζ and initial data u_0 we obtain

$$\begin{aligned}
\langle \delta_u E^\epsilon_{\mathrm{fid},u}[u], \vartheta \rangle &= \int_D \lambda_u (u - u_0)\, \vartheta \, \mathrm{d}\mathcal{L}, \\
\langle \delta_u E^\epsilon_{\mathrm{fid},w}[u, w], \vartheta \rangle &= \int_D \lambda_w (\nabla_{(t,x)} u \cdot w)(\nabla_{(t,x)} \vartheta \cdot w) \, \mathrm{d}\mathcal{L}, \\
\langle \delta_w E^\epsilon_{\mathrm{fid}}[u, w], \psi \rangle &= \int_D \lambda_w (\nabla_{(t,x)} u \cdot w)(\nabla_{(t,x)} u \cdot \psi) \, \mathrm{d}\mathcal{L}, \\
\langle \delta_u E^\epsilon_{\mathrm{reg},u}[u, \zeta], \vartheta \rangle &= \int_D \mu_u (\zeta^2 + k_\epsilon) \nabla_{(t,x)} u \cdot \nabla_{(t,x)} \vartheta \, \mathrm{d}\mathcal{L}, \qquad (6.1)\\
\langle \delta_\zeta E^\epsilon_{\mathrm{reg},u}[u, \zeta], \xi \rangle &= \int_D \mu_u \zeta \left| \nabla_{(t,x)} u \right|^2 \xi \, \mathrm{d}\mathcal{L}, \\
\langle \delta_w E^\epsilon_{\mathrm{reg},w}[w, \zeta], \psi \rangle &= \int_D \mu_w P_\delta[\zeta] \nabla_{(t,x)} w : \nabla_{(t,x)} \psi \, \mathrm{d}\mathcal{L}, \\
\langle \delta_\zeta E^\epsilon_{\mathrm{phase}}[\zeta], \xi \rangle &= \int_D 2\nu\epsilon \nabla_{(t,x)} \zeta \cdot \nabla_{(t,x)} \xi \, \mathrm{d}\mathcal{L} + \int_D \frac{\nu}{2\epsilon} (\zeta - 1) \xi \, \mathrm{d}\mathcal{L}
\end{aligned}$$

for scalar test functions ξ, ϑ and velocity-type test functions ψ with the structure $\psi = (0, \pi)$. Here, we use the notation $A : B := \mathrm{tr}(B^T A)$. Now, summing up the different terms as in (5.7) and integrating by parts, we end up with the system of PDEs

$$-\mathrm{div}_{(t,x)} \left(\frac{\mu_u}{\lambda_u} (\zeta^2 + k_\epsilon) \nabla_{(t,x)} u + \frac{\lambda_w}{\lambda_u} w (\nabla_{(t,x)} u \cdot w) \right) + u = u_0, \tag{6.2}$$

$$-\epsilon \Delta_{(t,x)} \zeta + \left(\frac{1}{4\epsilon} + \frac{\mu_u}{2\nu} \left| \nabla_{(t,x)} u \right|^2 \right) \zeta = \frac{1}{4\epsilon}, \tag{6.3}$$

$$-\frac{\mu_w}{\lambda_w} \mathrm{div}_{(t,x)} \left(P_\delta[\zeta] \nabla_{(t,x)} v \right) + (\nabla_{(t,x)} u \cdot v) \nabla_x u = 0 \tag{6.4}$$

as the Euler–Lagrange equations characterizing the necessary conditions for a solution (u, w, ζ) of the above-stated phase field approach. Let us emphasize that with the full Euler–Lagrange equations, characterizing a global minimizer of the energy would in addition involve variations of $E_{\mathrm{reg},w}$ with respect to ζ. However, as described in section 5, we do not consider this variation, since it would add a coupling of the edges of the flow field to the edges of the image. Thus, the PDE system (6.2)–(6.4) directly corresponds to our notion of solution specified in Definition 5.1.

For Neumann boundary conditions (which we actually consider in the application) the Euler–Lagrange equation in w is not guaranteed to be coercive in $W^{1,q}$. Indeed, the optical flow term $w \cdot \nabla_{(t,x)} u$ represents a pointwise rank-1 condition, and it is not known a priori that "sufficiently many" of these conditions, in the sense of the Lebesgue measure, are assembled in the image while integrating this term. To remedy this degeneracy, we consider a gradient descent of (6.4)

$$\partial_s v - \frac{\mu_w}{\lambda_w} \mathrm{div}_{(t,x)} \left(P_\delta[\zeta] \nabla_{(t,x)} v \right) + (\nabla_{(t,x)} u \cdot w) \nabla_x u = 0. \tag{6.5}$$

Consequently, the matrices resulting from a discretization are well conditioned and the corresponding systems can be solved easily (see section 7).

Inspired by Ambrosio and Tortorelli, we propose the following iterative algorithm for the solution of the phase field problem with $q = 2$:

Step 0. Initialize $u = u_0$, $\zeta \equiv 1$, and $w \equiv (1, 0)$.
Step 1. Solve (6.2) for fixed w, ζ.
Step 2. Solve (6.3) for fixed u, w.
Step 3. Compute one step of the gradient descent (6.5) for fixed u, ζ.
Step 4. Return to Step 1.

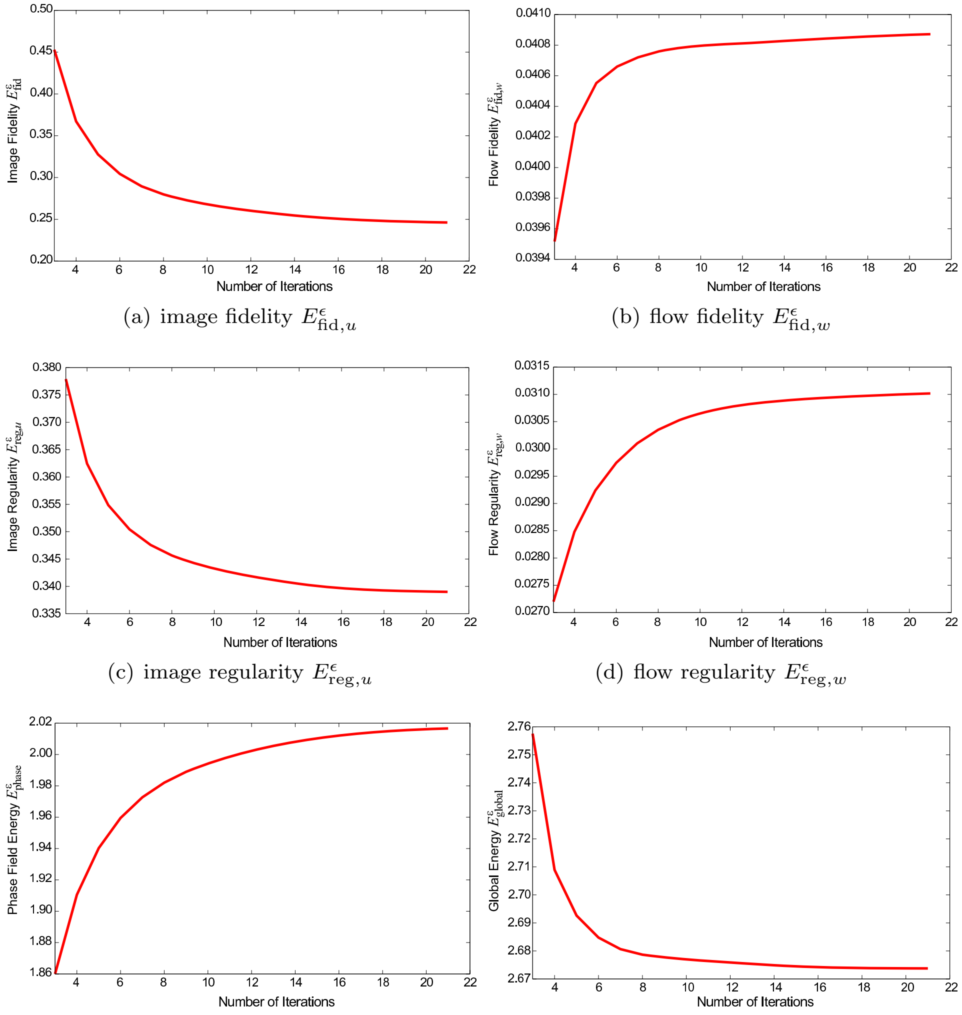
Steps 1 and 2 of the algorithm consist of a consecutive solution of linear PDEs. Let us note that we use a time step control for the gradient descent in Step 3. Alternatively we might iterate first Steps 1 and 2 until convergence, and then in another iteration we would consider the identification of the motion field w. Even though this second variation seems to be closer to our definition of solutions of the phase field problem, the above algorithm converges to the same solution in the applications we have considered. Our algorithm can be seen as a diagonal scheme, where the iteration of Steps 1 and 2 and the gradient descent iteration in Step 3 are intertwined.

7. Finite element discretization. We proceed similarly to the finite element method proposed by Bourdin and Chambolle [5, 6] for the phase field approximation of the Mumford–Shah functional, which is an extension of the approach first presented by Chambolle and Dal Maso [10].

To solve the above system of PDEs we suppose $[0, T] \times \Omega$ to be overlaid by a regular hexahedral grid. In the following, the spatial and temporal grid width are denoted by h and τ, respectively. Hence, image frames are at a distance of τ and pixels of each frame are placed on a regular mesh with grid size h.

On this hexahedral grid we consider the space of piecewise trilinear continuous functions $\mathcal{V}$ and ask for discrete functions $U, Z \in \mathcal{V}$ and $V \in \mathcal{V}^2$, such that discrete and weak counterparts of the Euler–Lagrange equations (6.2), (6.3), and (6.4) are fulfilled. This leads to the solution of systems of linear equations for the vectors of the nodal values of the unknowns U, Z, V. We refer to the appendix for a detailed description of the matrices and the resulting systems of equations. A careful implementation is required to ensure an efficient method. For a time-space volume of K time steps and images of $N \times M$ pixels, the finite element matrices for U and Z have $N\,M\,K\,C$ entries, where $C = 27$ is the number of nonzero entries per row, equal to the number of couplings of a node. The finite element matrix for V has four times more elements, as V is a two-dimensional vector. Data-sets of up to $K = 10$ frames of $N = 500$, $M = 320$ pixels can be treated by standard hardware with less than 1GB memory. The linear systems of equations are solved applying a classical conjugate gradient method. For the pedestrian sequence (Figure 8.5), one such iteration takes 47 seconds on a Pentium IV PC at 1.8 GHz running Linux. The complete method typically converges after 10–15 such iterations. To treat large video sequences, we typically consider a window of $K = 6$ frames, to avoid boundary effects, and then shift this window successively in time.

In Figure 7.1 we have depicted the progression of the various components of the energy $E^\epsilon_{\mathrm{global}}$ for the taxi sequence shown in Figure 8.6. The rapid decay of the global energy in the first steps of the algorithm is clearly visible. While the image fidelity $E^\epsilon_{\mathrm{fid}}$ and its regularity $E^\epsilon_{\mathrm{reg},u}$ decay, the other parts of the energy increase. Obviously this is the case, because we are starting with constant initial values $\zeta = 0$ and $w = (1, 0)$.



(a) image fidelity $E^{\epsilon}_{\mathrm{fid},u}$

(b) flow fidelity $E^{\epsilon}_{\mathrm{fid},w}$

(c) image regularity $E^{\epsilon}_{\mathrm{reg},u}$

(d) flow regularity $E^{\epsilon}_{\mathrm{reg},w}$

(e) phase field energy $E^{\epsilon}_{\mathrm{phase}}$

(f) global energy $E^{\epsilon}_{\mathrm{global}}$

FIG. 7.1. *For the example presented in Figure* 8.6 *(bottom row) we show the progression of the various energy contributions during the solution iteration. The decay of the global energy can be seen in the lower right plot* (f)*.*

8. Results and discussion. We present here several results of the proposed method for two-dimensional image sequences. In the considered examples, the parameter setting $\epsilon = h/4$, $\mu_u = h^{-2}$, $\mu_w = \lambda_u = 1$, $\lambda_w = 10^5 h^{-2}$, and $k_\epsilon = \epsilon$, $\delta = \epsilon$ has proven to give good results. We first consider a simple example of a white disk moving with constant speed $v = (1, 1)$ on a vaguely textured, low-contrast, dark background (Figure 8.1). Let us first consider the top row in Figure 8.1, which corresponds to the energy formulation without the projection component. A limited amount of smoothing results from the regularization energy $E^{\epsilon}_{\mathrm{reg},u}$ (Figure 8.1(a)), which is desirable to ensure robustness in the resulting optical flow term $\nabla_{(t,x)}u \cdot w$ and removes noisy artifacts in real-world videos; see, e.g., Figures 8.4 and 8.5. The phase field clearly captures the moving object's contour. The optical flow is depicted in Figure 8.1(c) by color coding the vector directions as shown by the lower right color wheel. Clearly, the method is able to extract the uniform motion of the disc's boundary, which has a

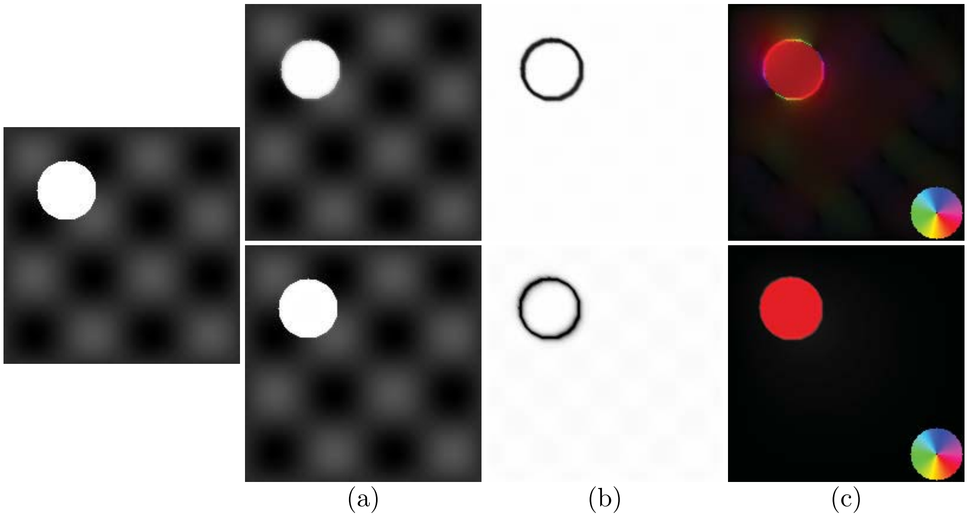


Fig. 8.1. *One frame of the test sequence (left) and corresponding smoothed images* (a)*, phase field* (b)*, optical flow (color coded)* (c)*. Top row: Energy formulation without projection. Bottom row: energy formulation with projection.*

high image contrast. The optical flow information, available only on the motion edges (black in Figure 8.1(b)), is propagated only to a limited extent into the informationless area inside the moving disk. Indeed, we notice that the model with the standard regularity term for w (5.5) is not able to diffuse the optical flow information, concentrated on the motion edges, in order to completely and uniformly fill in the moving circle.

In the bottom row of Figure 8.1, the same example is shown, this time run with the energy formulation including the projection term. We now clearly see a perfect reconstruction of the optical flow (Figure 8.1(c), bottom row) also inside the nontextured moving disc.

In the next example we revisit this simple image sequence of the moving circle. This time we have added noise to the sequence. At the same time we have completely destroyed the information of one frame of the sequence. In Figure 8.2 we show the results for frames 3 and 9–11, where frame 10 has been completely destroyed. From the images we see that the phase field detects the missing circle in the destroyed frame as a temporal edge surface in the sequence. Indeed the ζ drops down to zero in the temporal vicinity of the destroyed frame. This is still visible in the previous and the next time steps, shown in the second and third rows. But it does not hamper the restoration of the correct optical flow field shown in the fourth column. This is due to the anisotropic smoothing of information from the surrounding frames into the destroyed frame. For this example we have chosen $\epsilon = 0.4h$.

Another synthetic example is shown in Figure 8.3. This example is from the publicly available data-set collection at [11]. Here, a textured sphere spins on a textured background (Figure 8.3(a)). Again, the method is able to clearly segment the moving object from the background, even though the object does not change position. We used a phase field parameter $\epsilon = 0.15h$. The extracted optical flow clearly shows the spinning motion (Figure 8.3(d)) and the discontinuous motion field.

A first example on real video data is shown in Figure 8.4. The video shows a table tennis player whose body moves to the right while the hand goes down as he strikes the ball. This motion is well captured in the flow field (Figure 8.4(c)).

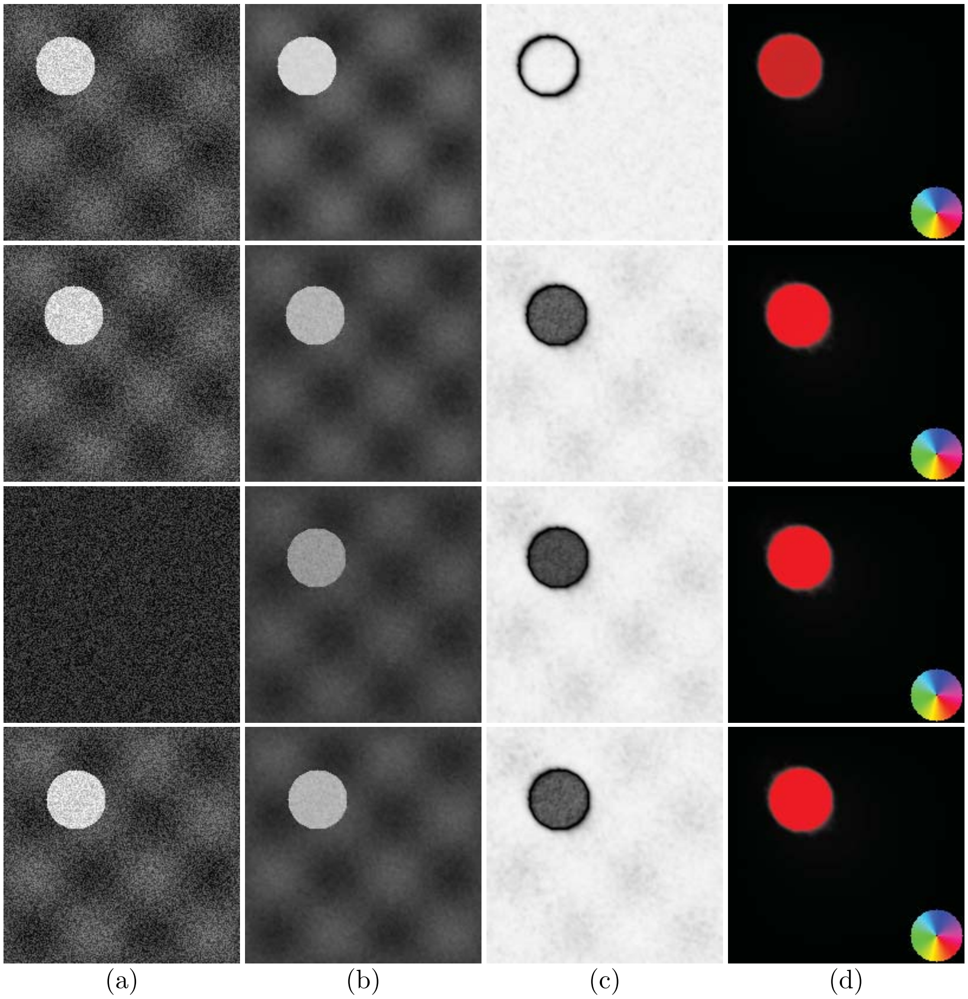

Fig. 8.2. *Noisy test sequence: From top to bottom frames* 3 *and* 9–11 *are shown.* (a) *Original image sequence,* (b) *smoothed images,* (c) *phase field,* (d) *estimated motion (color coded).*

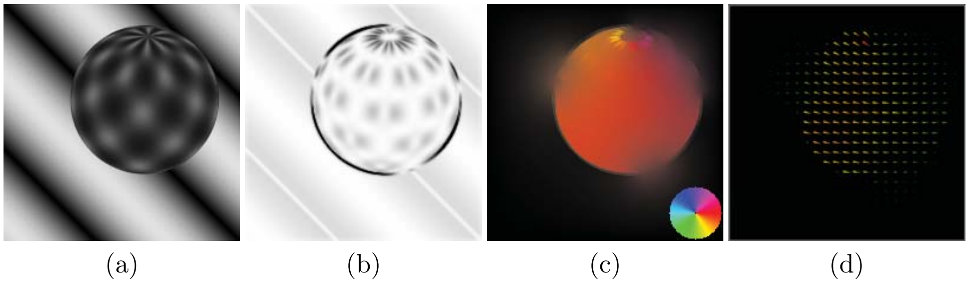

Fig. 8.3. *Rotating sphere: smoothed image* (a), *phase field* (b), *optical flow (color coded)* (c), *optical flow (vector plot, color coded magnitude)* (d).

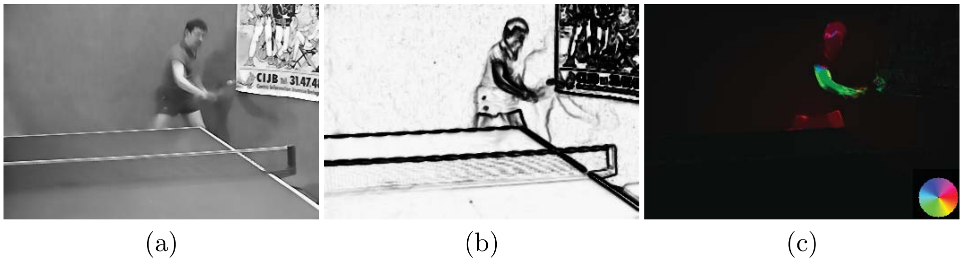
Furthermore, we consider a complex, higher resolution video sequence, taken under outdoor conditions by a monochrome video camera. The sequence shows a group of walking pedestrians (Figure 8.5 (top)). The human silhouettes are well extracted



(a) (b) (c)

and captured by the phase field (Figure 8.5 (middle)). We do not show a vector plot of the optical flow, as it is hard to interpret visually at the video sequence resolution of 640 × 480 pixels. However, the color-coded optical flow plot (Figure 8.5 (bottom)) shows how the method is able to extract the moving limbs of the pedestrians. The overall red and blue color corresponds to the walking directions of the pedestrians. The estimated motion is smooth inside the areas of the individual pedestrians and not smeared across the motion boundaries. In addition, the algorithm nicely segments the different moving persons. The cluttered background poses no big problem to the segmentation, nor do the edges of occluding and overlapping pedestrians, who are moving at almost the same speed.

Finally, let us note a limitation of the approach we have presented above: Let us consider the well-known Hamburg taxi video sequence, which is available from [18]. Figure 8.6 shows the taxi sequence processed both with the classical AT energy component (top row) and with our projection operator (bottom row). The progression of the various energy contributions is shown in Figure 7.1. Here we start with $u = 0$, i.e., a black image, and a zero velocity field $v = 0$. In this sequence, cars of differing image contrasts are moving. When the projection operator P_δ in our model is used (bottom row), only the central, high-contrast moving car is captured. When the operator is not used (top row), motion edges corresponding to low-contrast image edges also determine the phase field; hence the other oppositely moving cars in the bottom part of the image are captured as well and the corresponding optical flow is extracted. For all the cars in this example, the motion field is determined largely by the low-contrast shading and not only by high-contrast image edges, as was the case in the synthetic example in Figure 8.1.

Appendix. Algorithmic building blocks. In this appendix we would like to focus on the discrete version of the Euler–Lagrange equations resulting from (5.7). Let us denote by $\{\Psi_i\}_{i=1,\dots,N}$ the usual nodal basis of $\mathcal{V}$ (cf. section 7). The corresponding basis of the vector-valued discrete functions $\Psi \in \mathcal{V}^2$ is given by $\{\Psi_i e_1\}_i \cup \{\Psi_i e_2\}_i$, where $e_{1,2}$ are the standard basis vectors of $\mathbb{R}^2$: $e_1 = (1, 0)$, $e_2 = (0, 1)$. For any discrete function $Q \in \mathcal{V}$ we denote by $\overline{Q}$ the corresponding nodal vector. For discrete vector-valued functions we order the coefficients such that the e_1 coefficients are followed by the e_2 coefficients. Hence, the systems of discrete equations to be solved in the above algorithm are given in matrix vector notion as follows. We ask for solution vectors $\overline{U}, \overline{Z} \in \mathbb{R}^N$ and $\overline{V} \in \mathbb{R}^{2N}$, such that denoting $\overline{W} = (1, \overline{V})$ we have

$$(\mathbf{L}_u[W,\zeta] + \mathbf{M})\overline{U} = R_u, \tag{A.1}$$

$$(\mathbf{L}_\zeta + \mathbf{M}_\zeta[U])\overline{Z} = R_\zeta, \tag{A.2}$$

$$(\mathbf{L}_w[Z] + \mathbf{M}_w[U])\overline{V} = R_w. \tag{A.3}$$

These systems contain the matrices $\mathbf{L}_u[W,Z], \mathbf{L}_\zeta, \mathbf{M}, \mathbf{M}_\zeta[U] \in \mathbb{R}^{N\times N}$, $\mathbf{L}_w[Z], \mathbf{M}_w[U] \in \mathbb{R}^{2N\times 2N}$, $R_u, R_\zeta \in \mathbb{R}^n$, and finally $R_w \in \mathbb{R}^{2N}$, which can easily be derived from the variations of the energy (5.8). We have

$$\begin{aligned}
(\mathbf{L}_u[W,Z])_{ij} &= \int_D \frac{\mu_u}{\lambda_u}(Z^2 + k_\epsilon)\nabla_{(t,x)}\Psi_i \cdot \nabla_{(t,x)}\Psi_j \\
&\qquad + \frac{\lambda_w}{\lambda_u}(\nabla_{(t,x)}\Psi_i \cdot W)(\nabla_{(t,x)}\Psi_j \cdot W)\,\mathrm{d}\mathcal{L}, \\
\mathbf{M}_{ij} &= \int_D \Psi_i\Psi_j\,\mathrm{d}\mathcal{L}, \\
R_u &= \mathbf{M}\overline{\mathcal{I}_h u_0},
\end{aligned}$$

as well as

$$\begin{aligned}
(\mathbf{L}_\zeta)_{ij} &= \epsilon\int_D \nabla_{(t,x)}\Psi_i \cdot \nabla_{(t,x)}\Psi_j\,\mathrm{d}\mathcal{L}, \\
(\mathbf{M}_\zeta[U])_{ij} &= \int_D \left(\frac{\mu_u}{2\nu}\left|\nabla_{(t,x)}U\right|^2 + \frac{1}{4\epsilon}\right)\Psi_i\Psi_j\,\mathrm{d}\mathcal{L}, \\
(R_\zeta)_i &= \frac{1}{4\epsilon}\int_D \Psi_i\,\mathrm{d}\mathcal{L}
\end{aligned}$$

and

$$\begin{aligned}
(\mathbf{L}_w[Z])_{ikjl} &= \int_D \mu_w P_\delta[Z]\nabla_{(t,x)}\Psi_i \cdot \nabla_{(t,x)}\Psi_j\delta_{kl}\,\mathrm{d}\mathcal{L}, \\
(\mathbf{M}_w[U])_{ikjl} &= \int_D \lambda_w\partial_{x_k}U\partial_{x_l}U\,\Psi_i\Psi_j\,\mathrm{d}\mathcal{L}, \\
(R_w)_{ik} &= -\int_D \lambda_w\partial_t U\partial_{x_k}U\Psi_i\,\mathrm{d}\mathcal{L}.
\end{aligned}$$

Here, δ_{kl} is the usual Kronecker symbol, which is 1 if $k = l$ and otherwise 0. Let us remark that the integrands are piecewise polynomials of degree ≤ 2. We use a suitable quadrature rule on the hexahedra, which ensures exact integration.

HOMOGENEOUS BRANCHED-CHAIN EXPLOSIONS[*]

LUIS L. BONILLA[†], MANUEL CARRETERO[†], AND J. B. KELLER[‡]

Abstract. A model of homogeneous explosions with competing branching and recombination processes due to Kapila is analyzed by singular perturbation methods. In this model, the concentration of radicals is very low during a long induction period that ends with a rapid radical-growth stage in which all the reactants are consumed as the radicals reach their peak concentrations. The sudden jump in radical concentration is then followed by a long period of chain termination. Based on an exact relation between the fuel concentration and a slowly varying combination of fuel and radicals, we find a composite of two matched asymptotic expansions providing very good agreement with the numerical solution. This approximation is compared to another composite obtained by the method of multiple self-adjusting scales. Both approximations seem to be similarly accurate provided the induction time is calculated beyond leading order.

Key words. jump phenomena, chain-branched homogeneous explosions, induction time, matched asymptotic expansions, multiple scale methods

1. Introduction.

Jump phenomena are characterized by large amplitude dynamic responses to small amplitude disturbances and typically involve different time scales: the system may evolve slowly during long time intervals which are separated by fast transition layers during which the system changes abruptly [6, 13]. Polymer flow in a capillary [7], jump-to-contact instabilities in ultra-thin film lubrication [10], vibration in mechanical systems [11], instabilities of the current in semiconductors [2, 12], saltatory motion of wave fronts in discrete systems [4] and branched-chain explosions [8, 9], and overdriven detonations [14] in combustion theory are examples of jump phenomena. Their multilayer structure makes it difficult to find a uniform description of jump phenomena. In [3], we introduced a method of self-adjusting time scales to describe homogeneous branched-chain explosions, whose main ingredient is a fast time scale which is a nonlinear function of one of the system variables. This method is not standard in that it requires two different solvability conditions depending on whether time is smaller or larger than the very large induction time. An approximate solution valid for all times was obtained by patching two different approximations at the induction time.

In this paper, we introduce an alternative method (based on an exact relation between the fuel concentration and a slowly varying combination of fuel and radicals) to approximate the solutions of the explosion problem before and after the induction time, and match them to find a uniform approximation. We also find an exact expression for the induction time in terms of an integral whose leading order approximation

coincides with the induction time provided by the inner expansion. Comparison between our approximate solution and the numerical solution of the model equations shows discrepancies of order ϵ that can be tracked to the fact that the leading order expression for the induction time is not sufficiently accurate. Much better agreement between our theory and the numerical solution of the model is obtained using the numerically calculated integral expression for the induction time. We have also found a matching procedure to improve the method of self-adjusting scales. The resulting composite solution yields a similarly accurate approximation to the numerical solution of the model, provided the induction time is calculated to first order. While the simplicity of the boundary layer method found in this paper makes it preferable, the method of self-adjusting scales may be more widely applicable, in particular when more complex chemical schemes are used.

2. Model problem and solution. A straightforward manipulation of the kinetic rate equations for a homogeneous branched-chain explosion at constant pressure, similar to that presented in [9], leads to the following dimensionless problem [3]:

$$\frac{dx}{dt} = \exp\left[\frac{\beta\theta}{1+\theta}\right] x\, f - \epsilon\, x, \tag{2.1}$$

$$\frac{df}{dt} = -\exp\left[\frac{\beta\theta}{1+\theta}\right] x\, f, \tag{2.2}$$

$$\frac{d\theta}{dt} = q\,\epsilon\, x, \tag{2.3}$$

to be solved with the initial conditions

$$x(0) = \nu, \quad f(0) = 1, \quad \theta(0) = 0. \tag{2.4}$$

Equations (2.1)–(2.3) correspond to a two-step reaction scheme without an initiation stage in which a small amount of intermediate radical X (chain carrier) is present from the beginning. Production of the radical X is enhanced through the chain-branching process F + X → 2X that uses up the fuel F. This process is terminated when the radical X is fully consumed through the production of a product P in the radical recombination reaction X → P. All of the heat is generated through the termination step. The chain-branching rate is assumed to have Arrhenius form with a constant prefactor and constant activation temperature. The termination rate depends only weakly on temperature and we assume that it is constant. In (2.1)–(2.3), $f(t)$ and $x(t)$ are the normalized concentration of fuel and of radical, respectively, and θ is the temperature at time t. The nondimensional parameters q, β, ν, and ϵ represent a heat release, the activation energy of the branching reaction, the initial radical concentration, and a chemical-time ratio, respectively. In realistic applications $q = O(1)$, $\beta = O(1)$, and $0 < \nu \ll \epsilon \ll 1$. See [3] for the specific definitions of the nondimensional variables and parameters we use in terms of dimensional variables, rate constants, heat release, and initial concentrations.

Linear combinations of (2.1)–(2.3) lead to

$$\frac{d}{dt}[\theta + q(x+f)] = 0,$$

an equation that can be readily integrated using the condition (2.4) to give

$$x = 1 + \nu - f - q^{-1}\theta. \tag{2.5}$$

This expression, which replaces (2.3) in the following analysis, reveals in particular that θ reaches a maximum value $\theta = q(1+\nu)$ as radicals and fuel are depleted. On the other hand by adding (2.1) and (2.2), it is easy to see that the sum $x+f$ that appears in (2.5) varies only slowly in time, and would be conserved in the absence of radical recombination, i.e., if $\epsilon = 0$. The use of combined variables of this type is always convenient in combustion problems with multiple chemical scales. For instance, by introducing in this case the alternative variable

$$y = x + f, \tag{2.6}$$

we can isolate the effect of radical branching. The problem reduces then to that of integrating

$$\frac{df}{dt} = -(y - f)\, f\, e^{a(y)}\,, \tag{2.7}$$

$$\frac{dy}{dt} = -\epsilon\,(y - f), \tag{2.8}$$

$$a(y) = \frac{\beta q\,(1 + \nu - y)}{1 + q\,(1 + \nu - y)}\,, \tag{2.9}$$

with initial conditions

$$f(0) = 1, \quad y(0) = 1 + \nu. \tag{2.10}$$

Thus x and θ are given by

$$x = y - f, \tag{2.11}$$

$$\theta = q\,(1 + \nu - y) \tag{2.12}$$

as follows from (2.5) and (2.6).

Equations (2.7) and (2.8) yield

$$\frac{df}{dy} = \frac{f}{\epsilon}\, e^{a(y)}\,, \tag{2.13}$$

which, together with (2.10), lead to the relation

$$f(y) = \exp\left(-\frac{1}{\epsilon}\int_y^{1+\nu} e^{a(s)}\, ds\right)\,. \tag{2.14}$$

By using (2.14) for $f(y)$ in (2.8), we obtain the following integro-differential equation for $y(t)$:

$$\frac{dy}{dt} = -\epsilon\,[y - f(y)] = -\epsilon\left[y - \exp\left(-\frac{1}{\epsilon}\int_y^{1+\nu} e^{a(s)} ds\right)\right]. \tag{2.15}$$

The solution of (2.15) with $y(0) = 1 + \nu$ is given by

$$\epsilon t = \int_y^{1+\nu} \frac{ds}{s - f(s)} = \int_y^{1+\nu} \frac{ds}{s - \exp\left(-\frac{1}{\epsilon}\int_s^{1+\nu} e^{a(r)}\, dr\right)}. \tag{2.16}$$

The solution $y(t)$ can be obtained by evaluating the integral in (2.16) numerically. However, the asymptotic forms of y, both for t large, and for ϵ small and t finite, can be determined analytically.

3. Asymptotic form of $y(t)$ for t large. The integrand in (2.16) becomes infinite, and the integral diverges, when the denominator of the integrand vanishes. This occurs at y_∞, determined by

$$y_\infty = \exp\left(-\frac{1}{\epsilon}\int_{y_\infty}^{1+\nu} e^{a(s)}\,ds\right). \tag{3.1}$$

Thus $t \to \infty$ as $y \to y_\infty$. Note that y_∞ is the exponentially small amount of fuel that remains unused after the termination step causes the radical concentration to become zero. At this point, x, f, and θ in (2.1)–(2.3) have reached their final stationary values, $x = 0$, $f = y_\infty$, and $\theta = q\,(1+\nu-y_\infty)$. To obtain $y(t)$ for t large we note that the denominator in (2.16) can be written as

$$y - f(y) = [1 - f'(y_\infty)]\,(y - y_\infty) + O[(y-y_\infty)^2]. \tag{3.2}$$

We add and subtract from the integrand in (2.16) the reciprocal of the first term on the right-hand side of (3.2). Thus we obtain

$$\epsilon t = \int_y^{1+\nu}\left[\frac{1}{s-f(s)} - \frac{(s-y_\infty)^{-1}}{1-f'(y_\infty)}\right]ds + \int_y^{1+\nu}\frac{(s-y_\infty)^{-1}}{1-f'(y_\infty)}\,ds. \tag{3.3}$$

The second integral in (3.3) can be evaluated explicitly. The first integral has a finite limit as $y \to y_\infty$, which we denote as ϵt_o. Then for t large, (3.3) yields

$$\epsilon t \sim \epsilon t_o + [1 - f'(y_\infty)]^{-1}\ln\left(\frac{1+\nu-y_\infty}{y-y_\infty}\right), \quad t \gg 1. \tag{3.4}$$

Here t_o is defined by

$$\epsilon t_o = \int_{y_\infty}^{1+\nu}\left[\frac{1}{s-f(s)} - \frac{(s-y_\infty)^{-1}}{1-f'(y_\infty)}\right]ds. \tag{3.5}$$

Upon solving (3.4) for y, we get

$$y(t) \sim y_\infty + (1+\nu-y_\infty)\,e^{-\epsilon\,[1-f'(y_\infty)](t-t_o)}, \quad t \gg 1. \tag{3.6}$$

Thus for $t > t_o$, y decays exponentially to the asymptotic value y_∞.

When ϵ is small, (3.1) shows that y_∞ is exponentially small. Then $f'(y_\infty)$ is also exponentially small, and (3.1) becomes simply

$$y(t) \sim (1+\nu)\,e^{-\epsilon\,(t-t_o)}, \quad t \gg 1, \quad \epsilon \ll 1. \tag{3.7}$$

The integral (3.5) for t_o can be evaluated for ϵ small. The result is

$$t_o \sim t_{o,0} = \frac{\ln\nu^{-1}}{1+\nu}, \quad \epsilon \ll 1. \tag{3.8}$$

4. Asymptotic form of $y(t)$ for ϵ small. For ϵ small and $t = O(1)$, we write

$$y(t) = y_0(t) + \epsilon y_1(t) + O(\epsilon^2). \tag{4.1}$$

We use (4.1) in (2.8) and in the initial condition $y(0) = 1+\nu$. Then we equate coefficients of ϵ^0 to get

$$\frac{dy_0}{dt} = 0, \quad y_0(0) = 1+\nu. \tag{4.2}$$

Solving (4.2) gives

$$y_0 = 1 + \nu. \tag{4.3}$$

Now we use (4.1) and (4.3) in (2.8) and in the initial condition with $f(y)$ given by (2.15). From the coefficients of ϵ, we get

$$\frac{dy_1}{dt} = -(1+\nu) + e^{y_1}, \quad y_1(0) = 0. \tag{4.4}$$

Separating variables in (4.4) and integrating them yields

$$t = -\int_0^{y_1} \frac{ds}{1+\nu-e^s} = -\frac{y_1}{1+\nu} + \frac{\ln(1+\nu-e^{y_1})}{1+\nu} - \frac{\ln\nu}{1+\nu}. \tag{4.5}$$

Solving (4.5) for y_1 and exponentiating both sides of the resulting equation yields

$$e^{y_1} = e^{-(1+\nu)t}\nu^{-1}(1+\nu-e^{y_1}). \tag{4.6}$$

Now we solve (4.6) for e^{y_1} and take the logarithm of the result to get

$$y_1 = \ln\left[\frac{1+\nu}{1+\nu e^{(1+\nu)t}}\right]. \tag{4.7}$$

Finally (4.1), (4.3), and (4.7) yield

$$y(t) = 1+\nu+\epsilon\ln\left[\frac{1+\nu}{1+\nu e^{(1+\nu)t}}\right] + O(\epsilon^2). \tag{4.8}$$

5. Matching and the composite expansion. For $t \gg 1$, the inner expansion (4.8) becomes, when (3.8) is used,

$$y(t) \sim 1+\nu-\epsilon\,[(1+\nu)\,(t-t_o)], \quad \epsilon \ll 1, \quad t \gg 1. \tag{5.1}$$

On the other hand, for $\epsilon\,(t-t_o) \ll 1$, the outer expansion (3.7) becomes

$$y(t) \sim (1+\nu) - \epsilon\,(1+\nu)\,(t-t_o), \quad 0 < \epsilon, \quad 0 \le (t-t_o) \ll 1. \tag{5.2}$$

These two expansions match.

A composite expansion can be formed by adding together the inner expansion (4.8) and the outer expansion (3.7), and subtracting the common part, given by the right-hand side of (5.1) or (5.2). However, (5.2) holds only for $\epsilon(t-t_o)$ positive. Therefore we multiply the outer expansion minus its inner form (5.2) by the Heaviside function $H(t-t_o)$. Thus the composite expansion for $\epsilon \ll 1$ is

$$\begin{aligned} y_c(t) \sim{}& 1+\nu-\epsilon\,\ln\left(\frac{1+e^{(1+\nu)\,(t-t_o)}}{1+\nu}\right) \\ &+ H(t-t_o)\left[(1+\nu)\,e^{-\epsilon(t-t_o)} - \{1+\nu-\epsilon\,(1+\nu)\,(t-t_o)\}\right], \end{aligned} \tag{5.3}$$

where t_o is given by (3.8). By inserting this approximate y_c in (2.14), (2.11), and (2.12), we find the approximations for f, x, and θ, respectively:

$$f_c(t) = \exp\left(-\frac{1}{\epsilon}\int_{y_c(t)}^{1+\nu} e^{a(s)}\,ds\right), \tag{5.4}$$

$$x_c(t) = y_c(t) - f_c(t), \tag{5.5}$$

$$\theta_c(t) = q\,[1+\nu-y_c(t)]. \tag{5.6}$$

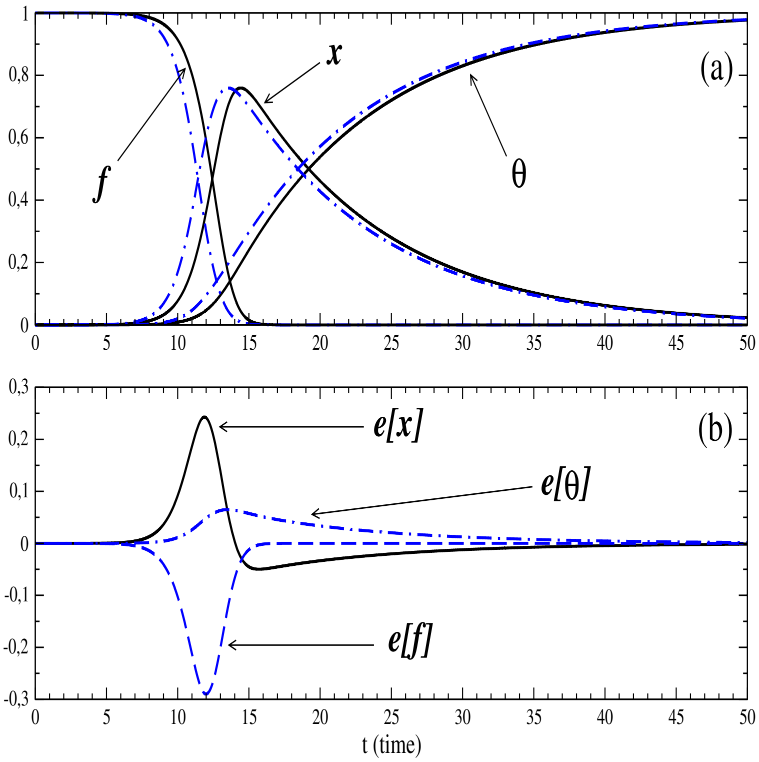

FIG. 1. (a) *Time evolution of* x, f, *and* θ *for* $\epsilon = 0.1$, $\nu = 10^{-5}$, $\beta = 5$, $q = 1$ *obtained by numerical integration of* (2.1) *to* (2.4) *(solid lines), and by using* f_c, x_c, *and* θ_c *in* (5.4), (5.5), *and* (5.6) *(dashed lines).* (b) *Differences* $e[x]$, $e[f]$, *and* $e[\theta]$ *between the approximations* (5.4), (5.5) *and* (5.6), *and the numerical solutions of the model for the same parameter values as in* (a).

The results (5.3) to (5.6) with the approximate induction time (3.8) are compared to the numerical solution of the complete problem in Figure 1. Note that the errors $e[x]$ and $e[f]$ are approximately equal in magnitude: $e[x]+e[f] \approx 0$. Our approximate solutions capture rather well the behavior of the solution of the model equations. However, we observe appreciable differences that are essentially due to the fact that the induction time (3.8) is not a good approximation to the real value. Better agreement with the numerical solution of the model is obtained if an improved induction time is calculated by retaining $O(\epsilon)$ terms in $t_o(\epsilon)$ as defined by (3.5):

$$t_o(\epsilon) = t_{o,0} + \epsilon\, t_{o,1} + O(\epsilon^2), \tag{5.7}$$

$$t_{o,1} = \frac{\ln(\nu^{-1}+1)}{(1+\nu)^2} - \frac{\beta q(1+\nu)-1}{(1+\nu)^2} \int_0^\infty \frac{\sigma\, e^{-\sigma}}{1+\nu-e^{-\sigma}}\, d\sigma, \tag{5.8}$$

where $t_{o,0}$ is given by (3.8). For the parameters used in Figure 1, $t_{o,0} = 11.51$, whereas (5.7) yields $t_o(\epsilon) = 12.01 + O(\epsilon^2)$. We have found that the differences $e[x]$ and $e[f]$ from the numerical solution are still larger than $\epsilon = 0.1$. This means that the induction time is not well resolved even if we keep terms of order ϵ. Therefore we calculate numerically the integral (3.5) and use the resulting value of $t_o \approx 12.31$ in (5.3)–(5.6). The much more satisfactory result is depicted in Figure 2, and we observe that the differences $e[x]$ and $e[f]$ seem now to be of order ϵ^2.

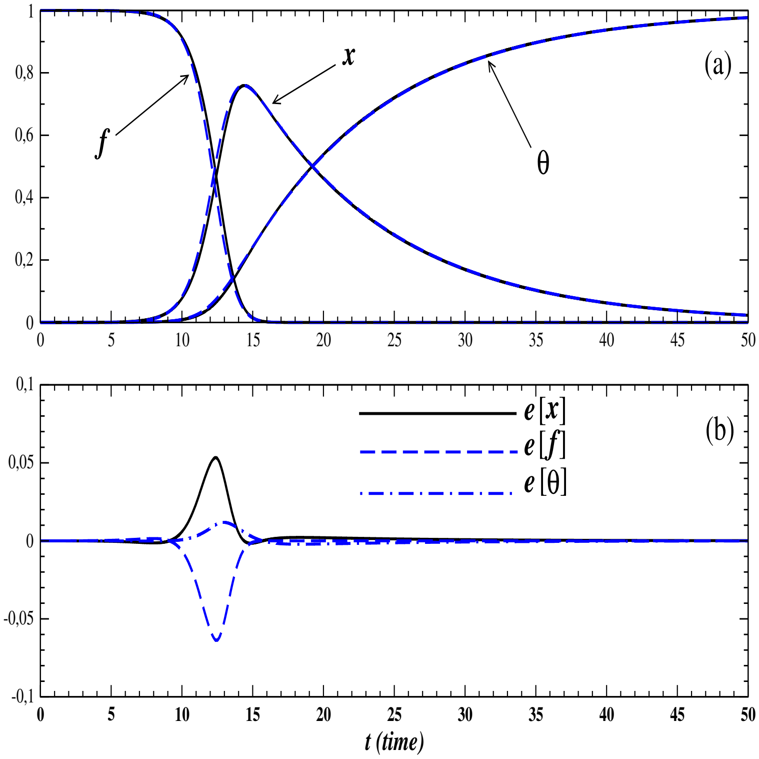

FIG. 2. (a) *Time evolution of x, f, and θ for the same parameter values as in Figure* 1. *The solid lines are the numerical solutions of the model whereas the dashed lines are given by* (5.3)–(5.6) *with t_o given by numerical evaluation of* (3.5). (b) *Differences $e[x]$, $e[f]$, and $e[\theta]$ of the approximations in* (a) *from the numerical solution of the model.*

6. Comparison with the method of self-adjusting time scales. To leading order, the method of self-adjusting scales gave approximated x and f that were somewhat better than (5.3)–(5.5), as a comparison of Figure 1(a) to Figure 3(a) of [3] (both figures have the same parameter values) readily shows. This method used patching of two different asymptotic expansions at the induction time, and this patching implies that the temperature given by the method of self-adjusting scales is a worse approximation than (5.6). In the appendix, we indicate how to improve the method by matching two terms of the expansion valid before the induction time to one term of the expansion for later times. As with the boundary layer method, the quality of the composite expansion given by self-adjusting scales depends on the accuracy with which we calculate the induction time. Inserting the leading order approximation to the induction time, we observe differences of order ϵ between the composite and the numerical solution of the model, similar to those in Figure 1. Calculating the induction time with the method of self-adjusting scales to order ϵ yields a composite expansion whose differences from the numerical solution for x, f, and θ are of order ϵ^2, as shown in Figure 3. Thus, the difference between the composite (5.3) with induction time given by the numerical evaluation of (3.5), and the composite (A.4)–(A.6) (with induction time including terms of order ϵ) given by the method of self-adjusting scales is quite small: see Figures 2(b) and 3(b). To order ϵ, both methods seem to provide similarly accurate approximations although the greater simplicity of the boundary layer method makes it preferable.

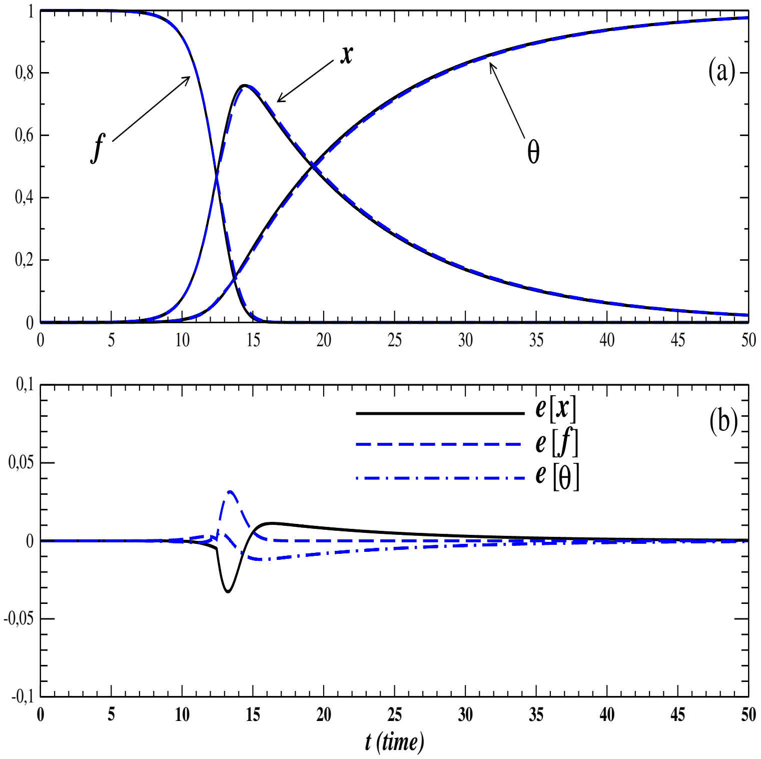

FIG. 3. *Time evolution of x, f, and θ for the same parameter values as in Figure* 1. (a) *Comparison of* (A.3)–(A.6) *(dashed line) to the numerical solution of the model (solid line).* (b) *Differences of the approximations in* (a) *from the numerical solution of the model.*

In more complex models of homogeneous chain-branched explosions, there is an additional induction stage in which radicals are generated by chemical reactions (whose rate constants may contain different Arrhenius factors than those in the branching stage), more than one radical may be acting, etc. Examples are the Blythe, Kapila and Short three-stage branched-chain explosions [1] and the Del Alamo and Williams calculation of ignition times of branched-chain explosions [5]. To extend the ideas in this paper to those more complicated schemes remains a challenge for the future.

Appendix. Matching in the method of self-adjusting scales. We can correct the effects of patching in the method of self-adjusting scales described in [3] by using ideas similar to those used in section 5. For $\tau < \tau_o$ ($\tau = \epsilon t$), the two-term approximation of y before the induction time is

$$y = 1 + \nu - \epsilon \ln\left(\frac{1 + e^{\eta - \eta_o}}{1 + \nu}\right) + o(\epsilon), \tag{A.1}$$

as obtained from (B.24) in [3]. If we let $(\eta - \eta_o) \to +\infty$ in this expression, then we obtain

$$\begin{aligned} y \sim 1 + \nu + \epsilon \ln(1 + \nu) - \epsilon\,(\eta - \eta_o) &= 1 + \nu - (1 + \nu)\tau + \epsilon\tau + \epsilon \ln(1 + \nu^{-1}) \\ &= 1 + \nu - (1 + \nu - \epsilon)[\tau - \epsilon \ln(1 + \nu^{-1})/(1 + \nu - \epsilon)], \end{aligned}$$

where (3.32), (3.36), and (3.42) of [3] have been used. Provided $\tau_o = \epsilon \ln(\nu^{-1}+1)/(1+\nu-\epsilon)$, the previous expression is $y \sim 1+\nu-(1+\nu-\epsilon)(\tau-\tau_o)$. This matches the one-term expansion $y = (1+\nu)\, e^{-(\tau-\tau_o)}$ for $\tau > \tau_o$ [3], except for a higher order term $\epsilon(\tau-\tau_o)$. Thus we obtain the composite expansion:

$$\text{(A.2)} \qquad y_{c,sas} = 1+\nu-\epsilon\,\ln\left(\frac{1+e^{\eta-\eta_o}}{1+\nu}\right) - \{[1+\nu+\epsilon\ln(1+\nu)]\,(1-e^{-(\tau-\tau o)}) \\ -\,\epsilon\,(\eta-\eta_o)\}\,H(\tau-\tau_o), \qquad \tau_o = \frac{\epsilon\ln(1+\nu^{-1})}{1+\nu-\epsilon}.$$

In the method of self-adjusting time scales, the radical concentration is given to leading order by

$$\text{(A.3)} \qquad x = \frac{y}{1+e^{-(\eta-\eta_o)}}, \quad f = y-x, \quad \theta = q(1+\nu-y),$$

according to (3.47), (3.49), and (3.50) of [3].

The composite (A.2)–(A.3) better approximates the temperature and fuel concentration than the leading order approximation of the method of self-adjusting scales with patching, but the differences from the numerical solution of the model are still of order ϵ. Further improvement comes from calculating the induction time better. Equation (B.21) of [3] gives the induction time including first order corrections according to the method of self-adjusting scales:

$$\text{(A.4)} \qquad t_{o,c} = \int_{\ln\nu}^{0} \frac{dh}{1+\nu-\epsilon+\epsilon\,[\beta q\,(1+\nu)-1]\,\ln\left(\frac{1+e^h}{1+\nu}\right)}\,,$$

which is somewhat smaller than τ_o/ϵ (for the parameter values in Figure 1, $\tau_o/\epsilon = 12.79$, $t_{o,c} = 12.44$). By replacing $\epsilon t_{o,c}$ instead of τ_o in (A.2), we obtain a better approximation:

$$\text{(A.5)} \qquad y_{c,sas} = 1+\nu-\epsilon\,\ln\left(\frac{1+e^{\eta-\eta_o}}{1+\nu}\right) - \{[1+\nu+\epsilon\ln(1+\nu)]\,(1-e^{-\epsilon\,(t-to,c)}) \\ -\,\epsilon\,(\eta-\eta_o)\}\,H(t-t_{o,c}),$$

$$\text{(A.6)} \quad t-t_{o,c} = \int_{0}^{\eta-\eta_o} \frac{dh}{1+\nu-\epsilon+\epsilon[q\beta(1+\nu)-1]\,\ln\left(\frac{1+e^h}{1+\nu}\right)}.$$

The relation (A.6) between $\eta-\eta_o$ and $t-t_{o,c}$ is obtained from (B.20) and (B.21) in [3]. Figure 3 shows that the corresponding x, f, and θ in (A.3) provide essentially an approximation of the solution throughout the whole time interval which is accurate to $O(\epsilon^2)$.

SPECTRAL THEORY FOR AN ELASTIC THIN PLATE FLOATING ON WATER OF FINITE DEPTH[*]

CHRISTOPHE HAZARD[†] AND MICHAEL H. MEYLAN[‡]

Abstract. The spectral theory for a two-dimensional elastic plate floating on water of finite depth is developed (this reduces to a floating rigid body or a fixed body under certain limits). Two spectral theories are presented based on the first-order and second-order formulations of the problem. The first-order theory is valid only for a massless plate, while the second-order theory applies for a plate with mass. The spectral theory is based on an inner product (different for the first- and second-order formulations) in which the evolution operator is self-adjoint. This allows the time-dependent solution to be expanded in the eigenfunctions of the self-adjoint operator which are nothing more than the single frequency solutions. We present results which show that the solution is the same as those found previously when the water depth is shallow, and show the effect of increasing the water depth and the plate mass.

Key words. linear water waves, elastic plate, spectral expansion

1. Introduction.

This paper concerns the application of spectral theory to the offshore engineering problem of the linear wave problem in the presence of a floating elastic plate. We show how the time-dependent solution can be expressed as an expansion over the single frequency incoming wave solutions. As well as presenting the theory, we use the derived expressions to make practical calculations of the time-dependent motion of an elastic plate.

The time-dependent linear water wave problem has received considerable attention, and various solution methods have been developed. The simplest method is to use a time stepping method to advance the solution, combined with a solution for the Dirichlet-to-Neumann map [10]. The solution method is numerically demanding, and there will be significant error growth for long time calculations. A more mathematically sophisticated time stepping procedure is based on a kernel function derived from the single frequency solutions. This method is described in detail in [11] and has been recently applied to the solution of the time-dependent motion of a floating elastic plate [7, 19]. This method, while using the single frequency solutions, requires that the solution be stepped forward in time. The convolution of the kernel function is used, and for this reason the method is sometimes called the *memory effect*. This method requires only integration over the wetted surface of the body. There are other methods, including a method based on the time-dependent Green function [18, 22], which also requires time stepping and simultaneous solution of the body equations of motion. The spectral solution presented here is based on the single frequency solutions, but does not require a time stepping solution; instead the solution is calculated for all time using the fast Fourier transform (FFT).

Spectral theory for finite-dimensional or compact operators is well known, for example, the calculation of the modes and frequencies of vibration of an elastic plate. For the operators in linear wave theory, which are self-adjoint but not compact, the spectral theory is much more complicated. This theory has been developed for fixed bodies [1, 20, 3, 4] in infinitely deep water. The focus of these works was on developing the theory, and no calculations were made. Only [12], which considered the problem of a floating massless elastic plate in the case of shallow water (which greatly simplified the equations of motion), has presented any calculations using a spectral method for a linear wave problem. The solution in [12] was found by both a spectral expansion and by Lax–Philips theory. The present work can be seen as an extension of the spectral solution of [12] to the considerably more complicated situation when the water can no longer be approximated as shallow.

The floating elastic plate is a very natural problem to consider when attempting to use spectral theory to make practical calculations of time-dependent motion. The floating elastic plate is amongst the best-studied problems in hydroelasticity and has been used to model floating breakwaters [18], ice floes [17], and very large floating structures [6, 21]. The single frequency (time harmonic) response has been well studied. While more complicated to study than the rigid body, the elastic body reduces to a rigid floating body and to a rigid dock in various limits as the stiffness and mass tend to infinity. Therefore, by providing a solution to the elastic plate problem, we are also providing a solution to the rigid floating body and dock problem. Furthermore, [19] has developed a solution to the time-dependent problem for a floating elastic plate on water of infinite depth.

As mentioned previously, the single frequency response for a floating elastic plate has been well studied. We will give a brief summary of the research in the case of the two-dimensional problem. The problem is mentioned in [18] where a solution for the case of shallow water is presented. The first solutions to the problem, without the assumptions of shallow water or a small plate effect, were by [13] and [15]. These solutions are based on using the Green function methods which had been developed for rigid bodies. The elastic plate problem (because of the assumption of shallow draft) actually has an eigenfunction expansion in the plate covered and non–plate covered regions. This property was exploited by [2] but only for the case of a semi-infinite plate. The matching using inner products was recently considered by [9], and a solution method was derived using residue calculus, but only for a semi-infinite plate. A fast method for multiple plates has recently been developed by [8].

In this paper, we present the time-dependent solution to the floating elastic plate on water of finite depth using spectral theory. The solution is based on finding an inner product in which the non–time-dependent operator which occurs in the time-dependent equation is self-adjoint. We show in section 2 that there are two formulations which can be developed; the first is based on a first-order equation in time and is closely related to the method used in [12]. However, this formulation is valid only for a massless plate. The second formulation is based on the second-order time-dependent equation and does allow for the plate to have mass. The spectral approach that we follow to solve the time-dependent problem has a quite natural physical interpretation: it consists of expanding the time-dependent solution in a basis of time-harmonic solutions. The main difficulty mathematically is to normalize the generalized eigenfunctions (time-harmonic solutions), and we use a perturbation technique based on the generalized eigenfunctions for the pure hydrodynamic problem, that is, in the absence of the plate (section 3). We then have to determine the associated scattered waves in the presence of the plate (section 4): we thus obtain a basis of generalized eigenfunctions for the coupled problem. Finally, we present in section 5 some numerical results: they agree with those found earlier by [12] where the equivalent theory was developed for shallow water, and show the effect of water depth on the time-dependent solution.

2. Statement of the problem and mathematical formulations.

2.1. Governing equations.

The plate is infinite in the y direction, so that only the x and z directions are considered. The x direction is horizontal, the positive z axis points vertically up, and the plate covers the region $-b \leqslant x \leqslant b$. The water is of uniform depth h. The amplitudes are assumed small enough that the linear theory is appropriate, and the plate is sufficiently thin that the shallow draft approximation may be made [21].

The mathematical description of the problem follows from [18]. The kinematic condition is

$$\partial_t \zeta = \partial_n \Phi, \qquad z = 0,$$

where ζ is the displacement of the water surface or the plate (from the shallow draft approximation), ∂_n is the outward normal derivative, and Φ is the velocity potential of the water, which satisfies

$$\begin{aligned} \Delta\Phi &= 0, \qquad -h < z < 0, \\ \partial_n \Phi &= 0, \qquad z = -h. \end{aligned}$$

On the other hand, the dynamic condition obtained by matching the pressure at the free surface is

$$-\rho g \zeta - \rho \partial_t \Phi = \begin{cases} 0, & x \notin (-b, b), \\ D\partial_x^4 \zeta + \rho' d\, \partial_t^2 \zeta, & x \in (-b, b), \end{cases} \qquad z = 0,$$

where D is the bending rigidity of the plate per unit length, ρ is the density of water, ρ' is the density of the plate, d is the plate thickness, and g is the acceleration due to gravity. At the ends of the plate the free edge boundary conditions

$$\lim_{x\downarrow -b} \partial_x^2 \zeta = \lim_{x\uparrow b} \partial_x^2 \zeta = \lim_{x\downarrow -b} \partial_x^3 \zeta = \lim_{x\uparrow b} \partial_x^3 \zeta = 0$$

are applied.

Nondimensional variables are now introduced using a length parameter L for the space variables and $\sqrt{L/g}$ for the time variable. We leave the choice of the length parameter arbitrary, since there are two natural length parameters, the water depth and the characteristic length $(D/\rho g)^{1/4}$. It also means that we can present results in our nondimensional variables in which the plate properties are kept constant and the water depth is varied. Hence the nondimensional surface displacement and velocity potential satisfy the following coupled equations, where the overbar denotes nondimensional variables,

$$\partial_{\bar t} \bar\zeta = \partial_{\bar n} \bar\Phi, \qquad \bar z = 0, \tag{2.1}$$

$$\bar\Delta \bar\Phi = 0, \qquad -\bar h < \bar z < 0, \tag{2.2}$$

$$\partial_{\bar n} \bar\Phi = 0, \qquad \bar z = -\bar h, \tag{2.3}$$

$$-\bar\zeta - \partial_{\bar t} \bar\Phi = \begin{cases} 0, & \bar x \notin (-\bar b, \bar b), \\ \beta \partial_{\bar x}^4 \bar\zeta + \gamma \partial_{\bar t}^2 \bar\zeta, & \bar x \in (-\bar b, \bar b), \end{cases} \qquad \bar z = 0, \tag{2.4}$$

plus the free edge boundary conditions

$$\lim_{\bar{x}\downarrow -\bar{b}} \partial_{\bar{x}}^2 \bar{\zeta} = \lim_{\bar{x}\uparrow \bar{b}} \partial_{\bar{x}}^2 \bar{\zeta} = \lim_{\bar{x}\downarrow -\bar{b}} \partial_{\bar{x}}^3 \bar{\zeta} = \lim_{\bar{x}\uparrow \bar{b}} \partial_{\bar{x}}^3 \bar{\zeta} = 0, \tag{2.5}$$

where $\beta = D/(\rho g h^4)$ and $\gamma = \rho' d/(\rho h)$. Note that if we consider the limit as $\beta \to \infty$, we obtain a rigid floating body (with negligible submergence), and if we consider the limit as $\beta \to \infty$ and $\gamma \to \infty$, then we obtain the dock boundary condition ($\eta = 0$, $\bar{x} \in (-\bar{b}, \bar{b})$). For clarity the overbar is dropped from now on.

Our aim is to exhibit a spectral expansion of the solution to these equations together with suitable initial conditions at time $t = 0$. To do so, we shall rewrite this system in an abstract form which involves a *self-adjoint* operator: such a property is essential for the application of the spectral approach. We propose below two such mathematical formulations corresponding to two different choices of inner products.

2.2. Two component energy inner product for a massless plate. We first introduce an inner product based on the usual mechanical energy, to which both potential and displacement contribute: this energy consists of the kinetic energy of the water ($\propto |\nabla\Phi|^2$), the potential energy of the water ($\propto |\zeta|^2$), and the energy of the plate. This approach is a generalization to finite depth of the inner product used in [12]. As was the case in [12], this inner product is based on the assumption that the plate is massless. This means that we consider only the stiffness of the plate, not its inertia, in calculating the equations of motion. This is obviously an approximation, but it is actually valid for many practical situations. This approximation is discussed in [12] and [14].

The starting point of the abstract formulation lies in the following remark: if we know the velocity potential only at the surface of the water, say $\phi(x,t) = \Phi(x,0,t)$, then (2.2) and (2.3) determine Φ everywhere. Consider then the operator $\mathbf{G}$ which maps ϕ onto $\Phi = \mathbf{G}\phi$: this is the harmonic lifting which solves the boundary value problem

$$\begin{aligned} &\Delta\Phi = 0, && -h < \bar{z} < 0,\\ &\Phi = \phi, && z = 0,\\ &\partial_n \Phi = 0, && z = -h. \end{aligned} \tag{2.6}$$

This operator allows us to rewrite our system (2.1)–(2.5) with $\gamma = 0$ as a problem set only on $z = 0$:

$$\begin{aligned} \partial_t \zeta &= \partial_n \mathbf{G}\phi,\\ -\zeta - \partial_t \phi &= \chi_P \beta \partial_x^4 \zeta, \end{aligned}$$

where χ_P is the characteristic function for the plate covered region $P = (-b, +b)$ (i.e., $\chi_P(x) = 1$ if $x \in P$; else $\chi_P(x) = 0$). The edge conditions (2.5) are omitted for simplicity.

If we combine ζ and ϕ in a two component vector $U(x,t)$ given by

$$U(x,t) = \begin{pmatrix} \phi(x,t) \\ \mathrm{i}\zeta(x,t) \end{pmatrix}, \tag{2.7}$$

the above coupled equations turn into a Schrödinger-type equation

$$i\partial_t U = \mathcal{P}U, \quad \text{with} \quad \mathcal{P} = \begin{pmatrix} 0 & 1 + \chi_P \beta \partial_x^4 \\ \partial_n \mathbf{G} & 0 \end{pmatrix}. \tag{2.8}$$

The problem is to find an inner product $\langle \cdot\,, \cdot \rangle_{\mathcal{V}}$, defining a Hilbert space $\mathcal{V}$, for which $\mathcal{P}$ becomes self-adjoint. We shall actually verify only the symmetry property:

$$\langle \mathcal{P}V, V' \rangle_{\mathcal{V}} = \langle V, \mathcal{P}V' \rangle_{\mathcal{V}}. \tag{2.9}$$

The questions related to the domain of $\mathcal{P}$ are essential in the mathematical definition of self-adjointness but not in the numerical implementation of the method which is the focus of the present work. The works of [1, 20, 3] which are focused on the mathematics do treat the domain rigorously, however only for the case of a rigid body. A mathematically rigorous treatment in the case of an elastic body remains undeveloped.

A convenient way to interpret the symmetry property of $\mathcal{P}$ is to exhibit the associated bilinear form (we should say more precisely "sesquilinear"):

$$\langle \mathcal{P}V, V' \rangle_{\mathcal{V}} = p(V, V'). \tag{2.10}$$

It is then clear that (2.9) holds if $p(\cdot\,, \cdot)$ is symmetric, that is,

$$p(V', V) = \overline{p(V, V')}. \tag{2.11}$$

In order to exhibit $p(\cdot\,, \cdot)$ in our case, first consider the operator $\partial_n \mathbf{G}$ involved in the definition of $\mathcal{P}$. Choose the usual inner product of $L^2(\mathbb{R})$, i.e.,

$$\langle \psi, \psi' \rangle_{\mathbb{R}} = \int_{\mathbb{R}} \psi(x)\, \overline{\psi'(x)}\, dx.$$

From (2.6), Green's formula yields

$$\langle \partial_n \mathbf{G}\psi, \psi' \rangle_{\mathbb{R}} = \int_{\mathbb{R}} \int_{-h}^{0} \nabla(\mathbf{G}\psi) \cdot \overline{\nabla(\mathbf{G}\psi')}\, dx\, dz, \tag{2.12}$$

where the right-hand side clearly defines a positive symmetric form: the operator $\partial_n \mathbf{G}$ is thus positive and self-adjoint in $L^2(\mathbb{R})$. On the other hand, the operator $\beta\partial_x^4$ is positive and self-adjoint in $L^2(P)$. Indeed, if ζ satisfies the edge conditions (2.5), integrating by parts twice gives

$$\langle \beta\partial_x^4 \zeta, \zeta' \rangle_P = \beta \langle \partial_x^2 \zeta, \partial_x^2 \zeta' \rangle_P. \tag{2.13}$$

Then it may seem natural to consider $\mathcal{P}$ in $L^2(\mathbb{R}) \times L^2(\mathbb{R})$. But $\mathcal{P}$ would not be self-adjoint. The symmetry property actually occurs in a subspace, defined by the inner product

$$\langle V, V' \rangle_{\mathcal{V}} = \int_{\mathbb{R}} \int_{-h}^{0} \nabla(\mathbf{G}\psi) \cdot \overline{\nabla(\mathbf{G}\psi')}\, dx\, dz + \langle \xi, \xi' \rangle_{\mathbb{R}} + \beta \langle \partial_x^2 \xi, \partial_x^2 \xi' \rangle_P \tag{2.14}$$

for all complex vector functions

$$V = \begin{pmatrix} \psi \\ \xi \end{pmatrix} \quad \text{and} \quad V' = \begin{pmatrix} \psi' \\ \xi' \end{pmatrix}. \tag{2.15}$$

To see this, we simply have to use (2.12) and (2.13) in the relation

$$\begin{aligned} \langle \mathcal{P}V, V' \rangle_{\mathcal{V}} = \int_{\mathbb{R}} \int_{-h}^{0} & \nabla(\mathbf{G}(1 + \chi_P \beta\partial_x^4)\xi) \cdot \overline{\nabla(\mathbf{G}\psi')}\, dx\, dz \\ & + \langle \partial_n \mathbf{G}\psi, \xi' \rangle_{\mathbb{R}} + \beta \langle \partial_x^2(\partial_n \mathbf{G}\psi), \partial_x^2 \xi' \rangle_P, \end{aligned}$$

which yields

$$\langle \mathcal{P}V, V' \rangle_{\mathcal{V}} = \left\langle (1 + \chi_P \beta \partial_x^4)\xi, \partial_n \mathbf{G}\psi' \right\rangle_{\mathbb{R}} + \left\langle \partial_n \mathbf{G}\psi, (1 + \chi_P \beta \partial_x^4)\xi' \right\rangle_{\mathbb{R}},$$

where ξ is implicitly assumed to satisfy the edge conditions (2.5). The bilinear form on the right-hand side is clearly symmetric, and thus $\mathcal{P}$ is self-adjoint (but not positive).

At least formally, we can express the solution to (2.8) as

$$U(t) = e^{i\mathcal{P}t} U_0 \quad \text{with} \quad U_0(x) = U(x,0) = \begin{pmatrix} \phi_0(x) \\ i\zeta_0(x) \end{pmatrix}, \tag{2.16}$$

where $\exp(i\mathcal{P}t)$ is a unitary operator that we will make explicit by a spectral expansion.

2.3. Single component inner product which allows nonzero mass. In this section we will derive an abstract formulation which allows the case of nonzero mass. The inner product involved in this formulation is not based on the total energy and is closer to the standard L^2 inner product.

We introduce a new variable $\Psi = -\partial_t \Phi$, i.e., the opposite of the acceleration potential. Our system (2.1)–(2.4) then becomes

$$\partial_t^2 \zeta + \partial_n \Psi = 0, \qquad z = 0, \tag{2.17}$$

$$\Delta \Psi = 0, \qquad -h < z < 0, \tag{2.18}$$

$$\partial_n \Psi = 0, \qquad z = -h, \tag{2.19}$$

$$-\zeta + \Psi = \begin{cases} 0, & x \notin (-b,b), \\ \beta \partial_x^4 \zeta + \gamma \partial_t^2 \zeta, & x \in (-b,b), \end{cases} \qquad z = 0. \tag{2.20}$$

Instead of the harmonic lifting $\mathbf{G}$ introduced in the first-order formulation, we consider the operator $\mathbf{H}$ which maps ζ onto Ψ, where the latter solves the boundary value problem

$$\begin{aligned} &\Delta \Psi = 0, \qquad -h < z < 0, \\ &\partial_n \Psi = 0, \qquad z = -h, \\ &-\zeta + \Psi = \begin{cases} 0, & x \notin (-b,b), \\ \beta \partial_x^4 \zeta + \gamma \partial_n \Psi, & x \in (-b,b), \end{cases} \qquad z = 0. \end{aligned}$$

Our system (2.17)–(2.20) thus turns into the following second-order equation:

$$\partial_t^2 \zeta + \partial_n \mathbf{H} \zeta = 0. \tag{2.21}$$

The operator $\partial_n \mathbf{H}$ is positive and self-adjoint in the Hilbert space $\mathcal{H}$ with inner product

$$\langle \zeta, \zeta' \rangle_{\mathcal{H}} = \langle \zeta, \zeta' \rangle_{\mathbb{R}} + \beta \langle \partial_x^2 \zeta, \partial_x^2 \zeta' \rangle_P. \tag{2.22}$$

Indeed, let $\Psi = \mathbf{H}\zeta$ and $\Psi' = \mathbf{H}\zeta'$ for arbitrary ζ and ζ' satisfying (2.5). Using Green's formula and the above definition of $\mathbf{H}$, we have

$$\begin{aligned} &\int_{\mathbb{R}} \int_{-h}^{0} \nabla \Psi \cdot \overline{\nabla \Psi'} \, dx \, dz \\ &\qquad = \langle \partial_n \Psi, \zeta' \rangle_{\mathbb{R}} + \beta \langle \partial_n \Psi, \partial_x^4 \zeta' \rangle_P - \gamma \langle \partial_n \Psi, \partial_n \Psi' \rangle_P \\ &\qquad = \langle \partial_n \Psi, \zeta' \rangle_{\mathbb{R}} + \beta \langle \partial_x^2 (\partial_n \Psi), \partial_x^2 \zeta' \rangle_P - \gamma^{-1} \langle \zeta + \beta \partial_x^4 \zeta - \Psi, \zeta' + \beta \partial_x^4 \zeta' - \Psi' \rangle_P. \end{aligned}$$

Substituting this relation into

$$\langle \partial_n \mathbf{H}\zeta, \zeta' \rangle_{\mathcal{H}} = \langle \partial_n \mathbf{H}\zeta, \zeta' \rangle_{\mathbb{R}} + \beta \langle \partial_x^2 (\partial_n \mathbf{H}\zeta), \partial_x^2 \zeta' \rangle_P$$

yields

$$\langle \partial_n \mathbf{H}\zeta, \zeta' \rangle_{\mathcal{H}} = \int_{\mathbb{R}} \int_{-h}^{0} \nabla(\mathbf{H}\zeta) \cdot \overline{\nabla(\mathbf{H}\zeta')} \, dx \, dz + \gamma^{-1} \langle \zeta + \beta \partial_x^4 \zeta - \mathbf{H}\zeta, \zeta' + \beta \partial_x^4 \zeta' - \mathbf{H}\zeta' \rangle_P .$$

The right-hand side defines a positive symmetric bilinear form, which shows that $\partial_n \mathbf{H}$ is a positive self-adjoint operator in $\mathcal{H}$.

Thanks to this property, we shall construct the spectral expansion of the solution to (2.21) together with the initial conditions

$$\zeta(x,0) = \zeta_0(x) \quad \text{and} \quad \partial_t \zeta(x,0) = \theta_0(x), \tag{2.23}$$

where θ_0 is related to ϕ_0 in (2.16) by the relation $\theta_0 = \partial_n \mathbf{G}\phi_0$. This solution is

$$\zeta(t) = \cos((\partial_n \mathbf{H})^{1/2} t) \, \zeta_0 + (\partial_n \mathbf{H})^{-1/2} \sin((\partial_n \mathbf{H})^{1/2} t) \, \theta_0,$$

or equivalently, in the condensed form

$$\zeta(t) = \mathrm{Re}\{\exp(i(\partial_n \mathbf{H})^{1/2} t)\eta_0\} \quad \text{with} \quad \eta_0 = \zeta_0 - i(\partial_n \mathbf{H})^{-1/2} \theta_0. \tag{2.24}$$

3. Spectral decompositions without the floating plate. We consider in this section the *free* problem associated with our scattering problem, obtained by removing the floating plate. The basic ideas of the spectral approach that we propose for solving the preceding equations are described here. The solution is simply the solution found using the Fourier transform explained in the context of *generalized eigenfunctions* expansion. We will use the normalization results for the simpler free problem to derive the normalization for the problem with the plate.

3.1. Spectral representation for the first-order equation. If we remove the plate, the first-order problem (2.8) then simplifies to

$$i\partial_t U = \tilde{\mathcal{P}} U, \quad \text{with} \quad \tilde{\mathcal{P}} = \begin{pmatrix} 0 & 1 \\ \partial_n \mathbf{G} & 0 \end{pmatrix}, \tag{3.1}$$

where the tilde symbol refers to the free problem. Similarly to $\mathcal{P}$, the operator $\tilde{\mathcal{P}}$ is self-adjoint in the free energy space $\tilde{\mathcal{V}}$ defined by the inner product (see (2.14))

$$\langle V, V' \rangle_{\tilde{\mathcal{V}}} = \int_{\mathbb{R}} \int_{-h}^{0} \nabla(\mathbf{G}\psi) \cdot \overline{\nabla(\mathbf{G}\psi')} \, dx \, dz + \langle \xi, \xi' \rangle_{\mathbb{R}} \tag{3.2}$$

for all V and V' defined by (2.15). The solution to (3.1) can be formally expressed as a function of the initial state $U(0) = U_0$:

$$U(t) = e^{i\tilde{\mathcal{P}} t} U_0. \tag{3.3}$$

Spectral theory offers a way to express $\exp(i\tilde{\mathcal{P}} t)$ by means of the eigenelements of $\tilde{\mathcal{P}}$, that is, the solutions to the eigenvalue problem

$$(\tilde{\mathcal{P}} - \lambda) V = 0 \quad \text{with } V \neq 0 \text{ and } \lambda \in \mathbb{R}. \tag{3.4}$$

For our free problem $\tilde{\mathcal{P}}$ possesses a *continuous spectrum.* (Recall that a point $\lambda \in \mathbb{R}$ belongs to the continuous spectrum if $\mathcal{P} - \lambda$ is injective but not surjective.)

The generalized eigenfunctions of $\tilde{\mathcal{P}}$ can be found easily and are given by

$$\tilde{U}_{\lambda,\kappa}(x) = \exp(i\kappa k(\lambda^2)x) \begin{pmatrix} \lambda^{-1} \\ 1 \end{pmatrix}, \tag{3.5}$$

where $\kappa = \pm 1$ and $k(\lambda^2)$ is the positive root of the dispersion equation

$$k \tanh kh = \lambda^2. \tag{3.6}$$

We can easily show using the well-known orthogonality relation for the Fourier transform that

$$\begin{aligned} \left\langle \tilde{U}_{\lambda,\kappa}, \tilde{U}_{\lambda',\kappa'} \right\rangle_{\tilde{\mathcal{V}}} &= \int_{\mathbb{R}} \int_{-h}^{0} \frac{1}{\lambda\lambda'} \nabla(\mathbf{G}e^{i\kappa kx}) \cdot \overline{\nabla(\mathbf{G}e^{i\kappa' k' x})}\, dx\, dz + \left\langle e^{i\kappa kx}, e^{i\kappa' k' x} \right\rangle_{\mathbb{R}} \\ &= \frac{k \tanh kh}{\lambda\lambda'} \int_{\mathbb{R}} \frac{1}{\lambda\lambda'} e^{i\kappa kx} \overline{e^{i\kappa' k' x}}\, dx + \left\langle e^{i\kappa kx}, e^{i\kappa' k' x} \right\rangle_{\mathbb{R}} \\ &= 4\pi \left| \frac{d\lambda}{dk} \right| \delta_{\kappa\kappa'} \delta\left(\lambda - \lambda'\right). \end{aligned}$$

Note that we have used the property of the free linear waves that

$$\partial_n \mathbf{G} e^{i\kappa kx} = k \tanh kh e^{i\kappa kx}.$$

Therefore the solution to the free Schrödinger-type equation (3.1) for an initial state U_0 is given by

$$U(t) = \frac{1}{4\pi} \int_{\mathbb{R}} e^{i\lambda t} \sum_{\kappa=\pm 1} \langle U_0, \tilde{U}_{\lambda,\kappa} \rangle_{\tilde{\mathcal{V}}} \tilde{U}_{\lambda,\kappa} \left| \frac{dk}{d\lambda} \right| d\lambda. \tag{3.7}$$

3.2. Spectral representation for the second-order equation $\partial_n \mathbf{G}$. On the other hand, the second-order wave equation (2.21) becomes

$$\partial_t^2 \zeta + \partial_n \mathbf{G} \zeta = 0, \tag{3.8}$$

where $\partial_n \mathbf{G}$ is positive and self-adjoint in $L^2(\mathbb{R})$ (see (2.12)). We denote here by ν instead of λ the spectral variable for $\partial_n \mathbf{G}$: from (3.8), it represents a frequency squared, whereas λ stands for a signed frequency in the previous section.

It can easily be shown that the generalized eigenfunctions of $\partial_n \mathbf{G}$ are given by the linear wave solutions for a fixed frequency given by

$$\tilde{\zeta}_{\nu,\kappa}(x) = e^{i\kappa\, k(\nu)x} \quad \text{for } \nu \in \mathbb{R}^+ \text{ and } \kappa = \pm 1, \tag{3.9}$$

where $k(\nu)$ is the positive root of the dispersion equation (3.6). From the properties of the Fourier transform we know that

$$\langle \tilde{\zeta}_{\nu,\kappa}\, , \tilde{\zeta}_{\nu',\kappa'} \rangle_{\mathbb{R}} = 2\pi \frac{d\nu}{dk}\, \delta_{\kappa,\kappa'}\, \delta(\nu - \nu'). \tag{3.10}$$

This means that the solution to (3.8) together with initial conditions of the form (2.23) is

$$\begin{aligned} \zeta(t) &= \mathrm{Re}\{\exp(i(\partial_n \mathbf{G})^{1/2} t)\eta_0\}, \quad \text{where } \eta_0 = \zeta_0 - i(\partial_n \mathbf{H})^{-1/2}\theta_0, \\ &= \mathrm{Re}\left\{ \frac{1}{2\pi} \int_{\mathbb{R}^+} e^{i\sqrt{\nu}t} \sum_{\kappa=\pm 1} \langle \eta_0, \tilde{\zeta}_{\nu,\kappa} \rangle_{\mathcal{H}}\, \tilde{\zeta}_{\nu,\kappa}\, \frac{dk}{d\nu}\, d\nu \right\}. \end{aligned}$$
