Exact dispersion relations for harmonic waves in an infinite one-dimensional medium consisting of plane parallel alternating layers of two homogeneous isotropic elastic materials were derived in [20]. Their exact dispersion curves compare well with the "effective stiffness" theory they developed for the lowest vibrational modes over a wide range of wave numbers. Using a transfer matrix formalism and bypassing the use of Floquet theory, "pseudo-"stop bands and pass bands were computed in [3] for finite, periodically layered media. They showed that for a finite system containing at least ten cells, the characteristics of the second stop band compare well with that predicted in an infinite medium [11], [12] for a 2-2 composite consisting of ceramic and polymer constituents. This problem was further examined in [7], where it was shown that, in some instances, only one or two unit cells could be sufficient to depict the "frequency bandedness" seen in the infinite medium. Dispersion effects in finite periodic structures, which include viscous damping and the use of genetic algorithms for tailoring their frequency response characteristics, are also considered in [8].

Interestingly, the transfer matrix formalism has been successfully used for some time by geophysicists (e.g., [21], [5], [16], [1]), and for finite, layered Goupillaud-type (equal travel time) media [4], also known as the so-called communication matrix approach [19], [22], [9]. These works are not usually cited in prior work by the "bandgap" community, but are included here to emphasize their importance in providing insight and a framework for the analysis of dispersion effects in periodic elastic media.

Returning our attention once again to infinite media, [11] and [12] study the dispersion relation in an infinite strip of a periodically repeated cell with length or period a. According to their model, the cell is composed of two homogeneous elastic materials: the filler (f) and the matrix material (m). These materials are symmetrically arranged with respect to the center of the unit cell as shown in Figure 1.

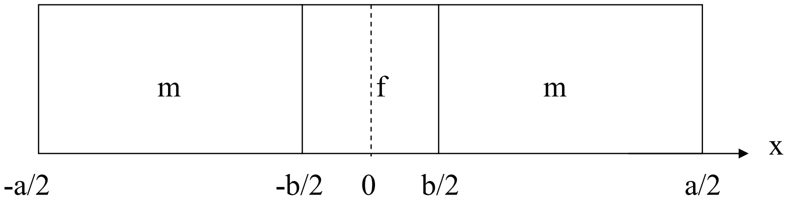

FIG. 1. *Symmetric unit cell made of two materials, used in* [11], [12].

The material density ρ and elastic modulus η are piecewise constant functions, taking constant values with subscripts f and m in the filler and matrix material regions, respectively. The density ρ and the elastic modulus η vary periodically along the strip with position x and period a,

$$\begin{cases} \rho(x+a) = \rho(x), \\ \eta(x+a) = \eta(x). \end{cases}$$

Figure 2 displays the density function within a single (unit) cell, assuming that $\rho_f \leq \rho_m$. Since the cell is periodically repeated in the infinite strip, the density graph shown in Figure 2 is also periodically repeated.

The general model was considered in [18], where each unit cell of the periodic layered structure contains several sublayers of arbitrary lengths and materials. They were

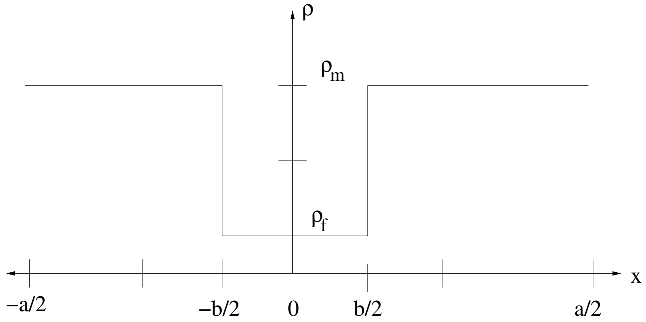

FIG. 2. *Density in a symmetric unit cell made of two materials.*

able to successfully derive the dispersion relation using the transfer matrix method, while involving very long explicit formulas.

In this paper, we generalize the work of [11], [12] and develop recursive dispersion relation formulas for a general cell configuration. The recursive formulas are easy to implement and, through several numerical experiments using Maple [15], successfully corroborate the results of [18].

Unlike the (two-material) symmetric cell configuration studied in [11], [12], the implicit dispersion relation for a general cell configuration appears to be more complex. The process of deriving an implicit recursive dispersion relation involves the construction of basic solutions in the unit cell, which provides more insight on how the properties of such solutions relate to the cell configuration. This is demonstrated through two approaches, which we identify as the central expansion approach and the quasi-symmetric limiting approach.

As shown in [11], [12], we begin with the wave equation with periodic coefficients η and ρ, described by

$$\frac{\partial[\eta\frac{\partial U}{\partial x}]}{\partial x} = \rho\frac{\partial^2 U}{\partial t^2}. \tag{1}$$

Using separation of variables, we assume that the displacement $U(x,t)$ can be expressed as

$$U(x,t) = u(x)\phi(t), \tag{2}$$

and (1) reduces to the second order ordinary differential equation with periodic coefficients,

$$\frac{d}{dx}\left[\eta\frac{du}{dx}\right] + \rho\omega^2 u = 0. \tag{3}$$

According to the Floquet theory, for a fixed ω, the solution $u(x)$ in (3) is of the form

$$u(x) = \upsilon(x)e^{iqx}, \tag{4}$$

where $\upsilon(x)$ is a periodic function with the same period a as the coefficients η and ρ. Due to the quasi-periodic recursive relation that follows from (4), we have

$$u(x+a) = u(x)e^{iqa},$$

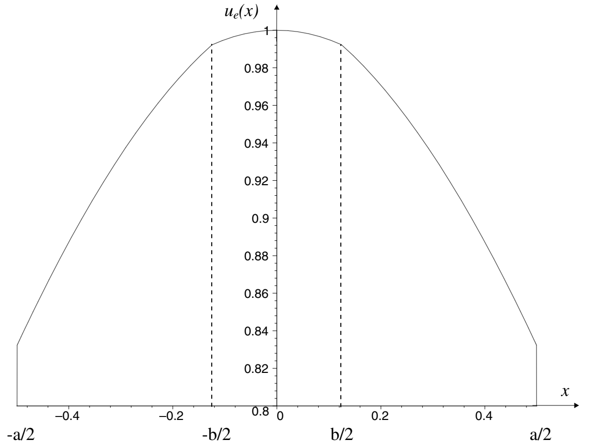

FIG. 3. *Even eigenfunction in a symmetric cell of two materials and three layers.*

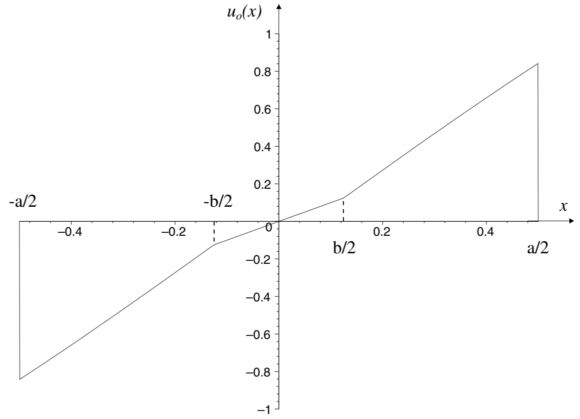

FIG. 4. *Odd eigenfunction in a symmetric cell of two materials and three layers.*

and the problem of finding the solution $u(x)$ along the strip is reduced to the single unit cell $-a/2 \le x \le a/2$, where the following quasi-periodic boundary conditions apply:

$$\left\{ \begin{aligned} u(a/2) &= u(-a/2)e^{iqa}, \\ u'(a/2) &= u'(-a/2)e^{iqa}. \end{aligned} \right. \tag{5}$$

The solution of (3) in the unit cell, subject to the boundary conditions (5), is then expressed as a linear combination of two eigenfunctions/linearly independent solutions of (3). For convenience, the two eigenfunctions are chosen to be even $u_e(x)$ and odd $u_o(x)$ functions along the symmetric cell studied in [11], [12]; see Figures 3 and 4. The solution of (3),

$$u(x) = u_e(x) + Cu_o(x), \tag{6}$$

satisfies the quasi-periodic boundary conditions (5) if

$$C = i\frac{u_e(a/2)}{u_o(a/2)}\tan\frac{qa}{2} \quad \text{and} \quad C = -i\frac{u_e'(a/2)}{u_o'(a/2)}\cot\frac{qa}{2}. \tag{7}$$

According to [11], [12], the compatibility of the two relations above results in the implicit form of the dispersion relation,

$$\boxed{\frac{u_e(a/2)}{u_o(a/2)}\tan\frac{qa}{2} = -\frac{u_e'(a/2)}{u_o'(a/2)}\cot\frac{qa}{2}.} \tag{8}$$

Further simplifications imply the following equivalent forms:

$$\tan^2\left(\frac{qa}{2}\right) = -\frac{u_e'(a/2)u_o(a/2)}{u_o'(a/2)u_e(a/2)}$$

or

$$\boxed{\cos(qa) = \frac{u_o'(a/2)u_e(a/2) + u_e'(a/2)u_o(a/2)}{u_o'(a/2)u_e(a/2) - u_e'(a/2)u_o(a/2)}}. \tag{9}$$

The dispersion relation is then obtained after the construction of the even and odd eigenfunctions $u_e(x)$ and $u_o(x)$ in the unit cell, and their substitution into (8) or (9). As discussed in [11], [12], due to (4), it is only necessary to consider the wave number q limited to the domain $0 \leq q \leq \pi/a$. The dispersion relation graph displays a banded frequency spectrum, comprising bands which transmit Floquet waves and no pass bands which do not.

2. Generalized form of the dispersion relation. In this section, we derive the dispersion relation for a general (unit) cell configuration, made of an arbitrary number of layers and materials. The steps involved are summarized below, and are generalizations of the work of [11], [12] discussed earlier. Through the rest of the paper, the interval of the unit cell with length a is $[-b, d]$. Here $0 < b, d < a$, and $b+d = a$. In the special case of a symmetric cell configuration seen before, $b = d = \frac{a}{2}$.

(i) The application of Floquet's theorem for (3), with ρ and η corresponding to the general (unit) cell configuration, yields two quasi-periodic conditions,

$$\begin{cases} u(x+a) = u(x)e^{iqa}, \\ u'(x+a) = u'(x)e^{iqa}. \end{cases}$$

Evaluating the conditions above at $x = -b$, we obtain the generalization of the boundary conditions (5),

$$\begin{cases} u(d) = u(-b)e^{iqa}, \\ u'(d) = u'(-b)e^{iqa}. \end{cases} \tag{10}$$

(ii) The solution $u = u(x)$ of (3) and (10) may be written in a general form similar to (6) as

$$u = C_1u_1 + C_2u_2. \tag{11}$$

Here $u_1 = u_1(x)$ and $u_2 = u_2(x)$ are two eigenfunctions/linearly independent solutions of (3), to be constructed later, while the constants C_1 and C_2 are unknown. For a symmetric cell configuration, such as the one studied in [11], [12], u_1 and u_2 become even and odd functions.

(iii) As a generalization of (7), after substituting (11) into the quasi-boundary conditions (10), we obtain a linear homogeneous system of equations for the unknowns C_1 and C_2,

$$\left\{\begin{aligned} &(u_1(d) - u_1(-b)e^{iqa})\, C_1 + (u_2(d) - u_2(-b)e^{iqa})\, C_2 = 0, \\ &(u_1'(d) - u_1'(-b)e^{iqa})\, C_1 + (u_2'(d) - u_2'(-b)e^{iqa})\, C_2 = 0. \end{aligned}\right. \tag{12}$$

(iv) Seeking a nontrivial/nonzero solution, we set the determinant of the system (12) to zero, a condition which replaces the compatibility conditions used earlier in (7)–(8) by [11], [12]. This yields the $\omega = \omega(q)$ relation of the form

$$\boxed{\begin{aligned} &(u_1(d) - u_1(-b)e^{iqa})(u_2'(d) - u_2'(-b)e^{iqa}) \\ &= (u_1'(d) - u_1'(-b)e^{iqa})(u_2(d) - u_2(-b)e^{iqa}). \end{aligned}} \tag{13}$$

Equation (13) represents the dispersion relation for a general cell configuration in its implicit complex form.

(v) After a few manipulations of (13), using the property of the Wronskian $W(x)$ discussed below, we obtain the dispersion relation in its implicit real form. The Wronskian $W(x)$ of $u_1(x)$ and $u_2(x)$, two linearly independent solutions of the differential equation (3), is given by

$$W(x) = u_1(x)u_2'(x) - u_1'(x)u_2(x).$$

It directly follows from (3) that

$$\frac{d}{dx}[\eta(x)W(x)] = 0,$$

and therefore,

$$W(x) = \frac{C}{\eta(x)},$$

where C is a constant. Assuming that $\eta(-b) = \eta(d)$, one deduces that $W(-b) = W(d)$. Returning our attention to (13), after multiplying and reorganizing the terms, we obtain

$$W(d) - J(-b, d)e^{iqa} + W(-b)e^{i2qa} = 0, \tag{14}$$

where $J(-b, d) = u_1(-b)u_2'(d) + u_1(d)u_2'(-b) - u_1'(-b)u_2(d) - u_1'(d)u_2(-b)$.

Under the assumption that $\eta(-b) = \eta(d)$, one deduces that $W(-b) = W(d)$ and the relation (14) becomes

$$W(-b)[e^{iqa} + e^{-iqa}] = J(-b, d).$$

From here the dispersion relation is expressed in its implicit real form as

$$2\cos(qa) = \frac{J(-b, d)}{W(-b)},$$

or equivalently

$$\boxed{2\cos(qa) = \frac{u_1(-b)u_2'(d) + u_1(d)u_2'(-b) - u_1'(-b)u_2(d) - u_1'(d)u_2(-b)}{u_1(-b)u_2'(-b) - u_1'(-b)u_2(-b)}.} \tag{15}$$

Further simplifications follow if $u_1(x)$ and $u_2(x)$ are chosen to satisfy $u_1(-b) = u_2'(-b) = 1$ and $u_1'(-b) = u_2(-b) = 0$. Then $W(-b) = 1$ and the implicit dispersion relation,

$$2\cos(qa) = \frac{J(-b,d)}{W(-b)},$$

takes the form

$$2\cos(qa) = u_1(d) + u_2'(d).$$

Similar arguments can be found in [14].

A simplified form of (15) used to express the dispersion relation for the (two-material) symmetric cell configuration was derived in [11], [12] and given by (9). Indeed, when $b = d = \frac{a}{2}$, we obtain

$$(16)\qquad 2\cos(qa) = \frac{u_1(-\frac{a}{2})u_2'(\frac{a}{2}) + u_1(\frac{a}{2})u_2'(-\frac{a}{2}) - u_1'(-\frac{a}{2})u_2(\frac{a}{2}) - u_1'(\frac{a}{2})u_2(-\frac{a}{2})}{u_1(-\frac{a}{2})u_2'(-\frac{a}{2}) - u_1'(-\frac{a}{2})u_2(-\frac{a}{2})}.$$

Due to the symmetry of the cell configuration, u_1 and u_2 become even and odd functions, respectively. This means that

$$\begin{cases} u_1(\frac{a}{2}) = u_1(-\frac{a}{2}), \\ u_1'(\frac{a}{2}) = -u_1'(-\frac{a}{2}) \end{cases} \quad\text{and}\quad \begin{cases} u_2(\frac{a}{2}) = -u_2(-\frac{a}{2}), \\ u_2'(\frac{a}{2}) = u_2'(-\frac{a}{2}). \end{cases}$$

After substituting these relations into (16) and replacing $u_1 = u_e$ and $u_2 = u_o$, we obtain the dispersion relation (9), as seen before in [11], [12].

As a conclusion, relation (15) subject to the boundary requirement $\eta(-b) = \eta(d)$ represents the generalized form of the dispersion relation (9) derived in [11], [12]. This is also confirmed by our numerical experiments with the choice of the unit cell boxed in Figure 5, with border layers occupied by the same material, ensuring the same value for $\eta(x)$ and therefore the same value for $W(x)$ along the border layers.

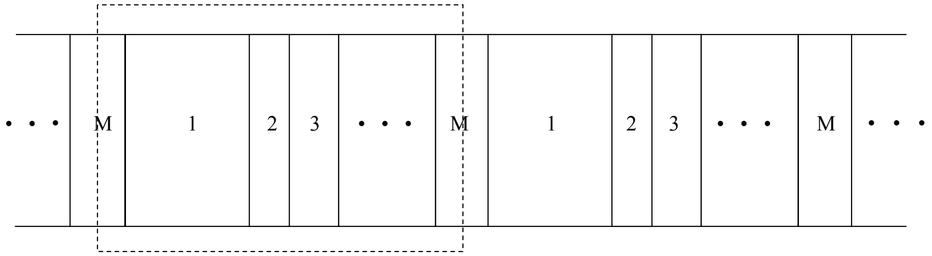

FIG. 5. *Unit cell selection in a periodic medium with a general cell configuration.*

3. Recursive formula of the dispersion relation using the central expansion approach. In order to develop the generalized dispersion relation (15), we need to find two eigenfunctions $u_1(x)$ and $u_2(x)$ of (3) in a unit cell of our choice. The unit cell of choice, used in the central expansion approach, is shown in the last diagram of Figure 6. This is obtained after shifting and renumbering the general cell

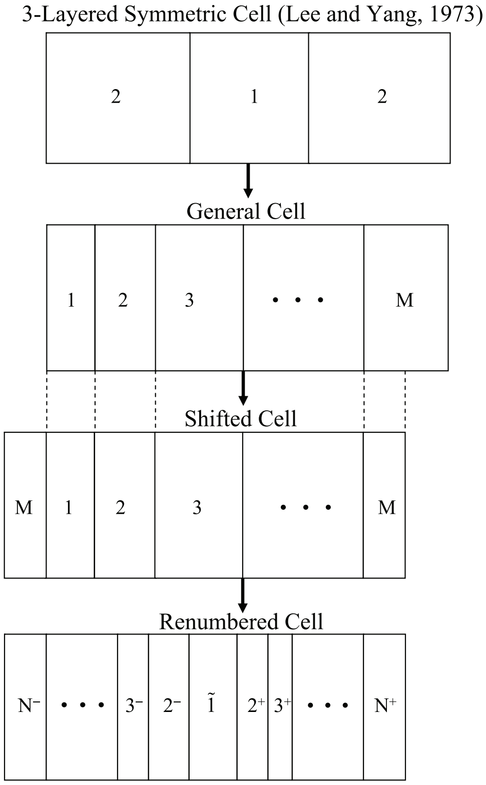

FIG. 6. *The stages of development of the central expansion approach for a given general cell configuration of M-layers. Here $N^+ = N^- = N$, where $N = \lceil \frac{M}{2} \rceil + 1$ or $N = \lceil \frac{M}{2} \rceil$.*

of M-layers. The purpose of the shifting is to have the border layers made of the same material to ensure that $\eta(-b) = \eta(d)$, which implies that $W(-b) = W(d)$ and therefore (15) holds. The purpose of the renumbering is to create a central layer in the cell similar to the three-layered symmetric cell configuration previously studied in [11], [12]. In the renumbered scheme, $N = \lceil \frac{M}{2} \rceil + 1$, unless the cell already has an odd number of layers M and the border layers are made of the same material, in which case $N = \lceil \frac{M}{2} \rceil$. The $(-)$ and $(+)$ superscripts on the renumbered cell diagram of Figure 6 are used for the layers numbered $2, 3, \ldots, N$ to indicate, respectively, their left and right positions with respect to the central layer. The central layer is marked $\tilde{1}$ to distinguish it from the layers on the other diagrams marked 1.

As a result, we may follow the method of [11], [12]. We begin with the solution in the central layer of the cell and expand it to the right and left layers using the continuity conditions of stress and displacement at the layer interfaces. Indeed, in a given layer of the cell, with constant material properties ρ and η and wave speed $c = \sqrt{\eta/\rho}$, the solution of (3) is of the form

$$u(x) = A \cos\left(\frac{\omega}{c} x\right) + B \sin\left(\frac{\omega}{c} x\right). \tag{17}$$

In the notation that follows $\rho_j^{\pm}$, $\eta_j^{\pm}$, and wave speed $c_j^{\pm} = \sqrt{\eta_j^{\pm}/\rho_j^{\pm}}$ indicate the corresponding values for the jth layer, $j = 2, \ldots, N$, located to the right ($(+)$ superscript) or left ($(-)$ superscript) of the central layer with $j = 1$.

As indicated in [11], [12], it is convenient to choose the two eigenfunctions $u_1(x)$ and $u_2(x)$ to be even and odd functions in the central layer,

$$u_1(x) = \cos\left(\frac{\omega}{c_1}x\right), \ -b_1 < x < d_1, \tag{18}$$

$$u_2(x) = \sin\left(\frac{\omega}{c_1}x\right), \ -b_1 < x < d_1. \tag{19}$$

The expansion of these solutions to the right and left layers would be of the form (17), and the eigenfunction $u_1(x)$ along the unit cell $[-b, d]$ can be given as

$$u_1(x) = \begin{cases} A_N^+ \cos\left(\frac{\omega}{c_N^+}(x - d_{N-1})\right) + B_N^+ \sin\left(\frac{\omega}{c_N^+}(x - d_{N-1})\right) & \text{for } d_{N-1} \le x \le d_N, \\ \vdots & \\ A_3^+ \cos\left(\frac{\omega}{c_3^+}(x - d_2)\right) + B_3^+ \sin\left(\frac{\omega}{c_3^+}(x - d_2)\right) & \text{for } d_2 \le x \le d_3, \\ A_2^+ \cos\left(\frac{\omega}{c_2^+}(x - d_1)\right) + B_2^+ \sin\left(\frac{\omega}{c_2^+}(x - d_1)\right) & \text{for } d_1 \le x \le d_2, \\ \cos\left(\frac{\omega}{c_1}x\right) & \text{for } -b_1 \le x \le d_1, \\ A_2^- \cos\left(\frac{\omega}{c_2^-}(x + b_1)\right) + B_2^- \sin\left(\frac{\omega}{c_2^-}(x + b_1)\right) & \text{for } -b_2 \le x \le -b_1, \\ A_3^- \cos\left(\frac{\omega}{c_3^-}(x + b_2)\right) + B_3^- \sin\left(\frac{\omega}{c_3^-}(x + b_2)\right) & \text{for } -b_3 \le x \le -b_2, \\ \vdots & \\ A_N^- \cos\left(\frac{\omega}{c_N^-}(x + b_{N-1})\right) + B_N^- \sin\left(\frac{\omega}{c_N^-}(x + b_{N-1})\right) & \text{for } -b_N \le x \le -b_{N-1}. \end{cases} \tag{20}$$

Using vector notation we denote

$$v_j^\pm = \begin{bmatrix} A_j^\pm \\ B_j^\pm \end{bmatrix}$$

for $j = 1, \ldots, N$.

The coefficients in (20), derived by the continuity conditions at the layer interfaces, are given by the recursive relations

$$v_{j+1}^\pm = M_j^\pm v_j^\pm, \tag{21}$$

where the matrix $M_j^\pm$ and the constant parameters are, respectively, given by

$$M_j^\pm = \begin{bmatrix} \cos\lambda_j^\pm & \pm\sin\lambda_j^\pm \\ \mp p_j^\pm \sin\lambda_j^\pm & p_j^\pm \cos\lambda_j^\pm \end{bmatrix} \tag{22}$$

and

$$\begin{cases} \lambda_j^+ = \frac{\omega}{c_j^+}(d_j - d_{j-1}), \ \lambda_j^- = \frac{\omega}{c_j^-}(b_j - b_{j-1}), \ p_j^\pm = \frac{\eta_j^\pm c_{j+1}^\pm}{\eta_{j+1}^\pm c_{j+1}^\pm}, \\ v_1^\pm = \begin{bmatrix} A_1^\pm \\ B_1^\pm \end{bmatrix} = \begin{bmatrix} 1 \\ 0 \end{bmatrix}, \ d_0 = 0, \ b_0 = 0 \end{cases} \tag{23}$$

for $j = 1, \dots, N-1$. Here A_n^+ and B_n^+ are the coefficients of the eigenfunction $u_1(x)$ along the nth right layer, while A_n^-, B_n^- are the coefficients along the nth left layer. The layer interfaces are located at $-b = -b_N < -b_{N-1} < \cdots < -b_n < \cdots < -b_1 < d_1 < \cdots < d_n < \cdots < d_{N-1} < d_N = d$. Here $b_1 = d_1$, $b + d = a$ and $b_n > 0$, $d_n > 0$ for $n = 1, 2, \dots, N$. Notice that the eigenfunction $u_1(x)$ is even in the central layer, but it does not necessarily remain even after it expands to the other layers of the cell; see Figure 7. The cell in Figure 7 is composed of five layers. Notice that at the layer interfaces, $u_1(x)$ develops corners, as expected from the stress continuity condition.

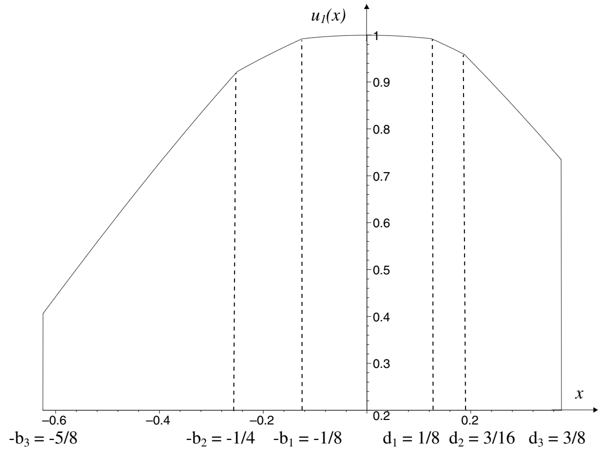

FIG. 7. *Eigenfunction $u_1(x)$ in a nonsymmetric cell of three materials and five layers. Additional parameters involved in* (20) *are* $\omega = c_1 = c_2^\pm = c_3^\pm = 1$, $p_1^\pm = \frac{\eta_1}{\eta_2} = 4$, *and* $p_2^\pm = \frac{\eta_2}{\eta_3} = 2$.

Similarly, we determine the eigenfunction $u_2(x)$ in the unit cell $[-b, d]$ as

$$u_2(x) = \begin{cases} A_N^{*+} \cos\left(\frac{\omega}{c_N^+}(x - d_{N-1})\right) + B_N^{*+} \sin\left(\frac{\omega}{c_N^+}(x - d_{N-1})\right) & \text{for } d_{N-1} \le x \le d_N, \\ \vdots & \\ A_3^{*+} \cos\left(\frac{\omega}{c_3^+}(x - d_2)\right) + B_3^{*+} \sin\left(\frac{\omega}{c_3^+}(x - d_2)\right) & \text{for } d_2 \le x \le d_3, \\ A_2^{*+} \cos\left(\frac{\omega}{c_2^+}(x - d_1)\right) + B_2^{*+} \sin\left(\frac{\omega}{c_2^+}(x - d_1)\right) & \text{for } d_1 \le x \le d_2, \\ \sin\left(\frac{\omega}{c_1}x\right) & \text{for } -b_1 \le x \le d_1, \\ A_2^{*-} \cos\left(\frac{\omega}{c_2^-}(x + b_1)\right) + B_2^{*-} \sin\left(\frac{\omega}{c_2^-}(x + b_1)\right) & \text{for } -b_2 \le x \le -b_1, \\ A_3^{*-} \cos\left(\frac{\omega}{c_3^-}(x + b_2)\right) + B_3^{*-} \sin\left(\frac{\omega}{c_3^-}(x + b_2)\right) & \text{for } -b_3 \le x \le -b_2, \\ \vdots & \\ A_N^{-} \cos\left(\frac{\omega}{c_N^-}(x + b_{M-1})\right) + B_N^{-} \sin\left(\frac{\omega}{c_N^-}(x + b_{N-1})\right) & \text{for } -b_N \le x \le -b_{N-1}. \end{cases}$$

(24)

Using vector notation we denote $v_j^{*\pm} = \left[\begin{smallmatrix} A_j^{*\pm} \\ B_j^{*\pm} \end{smallmatrix}\right]$ for $j = 1, \dots, N$. The coefficients of (24) are defined by the same recursive relations described in (21),

$$v_{j+1}^{*\pm} = M_j^{\pm} v_j^{*\pm}, \tag{25}$$

with

$$v_1^{*\pm} = \begin{bmatrix} A_1^{*\pm} \\ B_1^{*\pm} \end{bmatrix} = \begin{bmatrix} 0 \\ 1 \end{bmatrix}. \tag{26}$$

The matrix $M_j^{\pm}$ and the constant parameters d_0, b_0, $\lambda_j^{\pm}$, and $p_j^{\pm}$ for $j = 1, \ldots, N-1$ are given as before in (22)–(23).

Here A_n^{*+} and B_n^{*+} are the coefficients of the eigenfunction $u_2(x)$ along the nth right layer, while A_n^{*-}, B_n^{*-} are the coefficients along the nth left layer. Notice that $u_2(x)$ is odd in the central layer, but it does not necessarily remain odd after it expands to the other layers of the cell; see Figure 8. The cell in Figure 7 is composed of five layers. Notice that at the layer interfaces, $u_2(x)$ develops corners, as expected from the continuity of the stress condition.

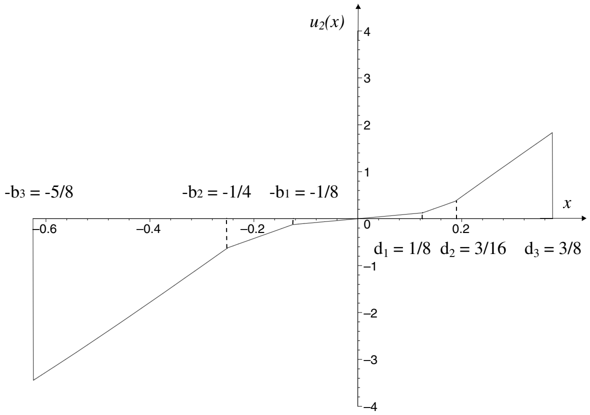

FIG. 8. *Eigenfunction $u_2(x)$ in a nonsymmetric cell of three materials and five layers. Additional parameters involved in* (24) *are $\omega = c_1 = c_2^{\pm} = c_3^{\pm} = 1$, $p_1^{\pm} = \frac{\eta_1}{\eta_2} = 4$, and $p_2^{\pm} = \frac{\eta_2}{\eta_3} = 2$.*

After evaluating $u_1(x)$ and $u_2(x)$ at the boundaries of the cell located at $x = -b$ and $x = d$, and then substituting these expressions into the general implicit formula of the dispersion relation (15), we obtain the following expressions for the numerator and the denominator, respectively:

$$\begin{aligned} &u_1(-b)u_2'(d) + u_1(d)u_2'(-b) - u_2(d)u_1'(-b) - u_2(-b)u_1'(d) \\ &\quad = \frac{\omega}{c_N}(A_N^- B_N^{*+} + A_N^+ B_N^{*-} - A_N^{*+} B_N^- - A_N^{*-} B_N^+)\cos(\lambda_N^+ + \lambda_N^-) \\ &\quad + \frac{\omega}{c_N}(A_N^+ A_N^{*-} - B_N^{*+} B_N^- - A_N^{*+} A_N^{*-} + B_N^{*-} B_N^+)\sin(\lambda_N^+ + \lambda_N^-) \end{aligned} \tag{27}$$

and

$$u_1(-b)u_2'(-b) + u_2(-b)u_1'(-b) = \frac{\omega}{c_N}(A_N^- B_N^{*-} - A_N^{*-} B_N^-). \tag{28}$$

Recall that our leftmost layer is made of the same material as our rightmost layer, and hence $c_N^- = c_N^+ = c_N$.

Substituting (27) and (28) into the general implicit dispersion relation (15), we derive the *recursive formula for the dispersion relation*,

$$\boxed{\begin{aligned}2\cos(qa) = {} & \frac{(A_N^{+}B_N^{*-}+A_N^{-}B_N^{*+}-A_N^{*+}B_N^{-}-A_N^{*-}B_N^{+})\cos(\lambda_N^{+}+\lambda_N^{-})}{A_N^{-}B_N^{*-}-A_N^{*-}B_N^{-}} \\ & + \frac{(A_N^{+}A_N^{*-}-A_N^{-}A_N^{*+}+B_N^{+}B_N^{*-}-B_N^{-}B_N^{*+})\sin(\lambda_N^{+}+\lambda_N^{-})}{A_N^{-}B_N^{*-}-A_N^{*-}B_N^{-}},\end{aligned}} \tag{29}$$

where the coefficients are obtained through the recursive relations involving (21)–(23), (25)–(26), while $\lambda_N^- = \frac{\omega}{c_N^-}(b_N - b_{N-1})$ and $\lambda_N^+ = \frac{\omega}{c_N^+}(d_N - d_{N-1})$. In the numerical experiments included in section 5, the recursive relation generating the coefficients $A_N^{\pm}, B_N^{\pm}, A_N^{*\pm}, B_N^{*\pm}$ of (29) is programmed in Maple [15]. The dispersion relation graph is then obtained using the *implicitplot* Maple command with the wave number q limited to the domain $0 \le q \le \pi/a$.

4. Recursive formula of the dispersion relation using the quasi-symmetric limiting approach. This alternative approach involves the quasi-symmetric cell configuration shown in Figure 9, which preserves the symmetric arrangement of the materials around the filler/central layer, and allows for layers of the same material to have differing lengths.

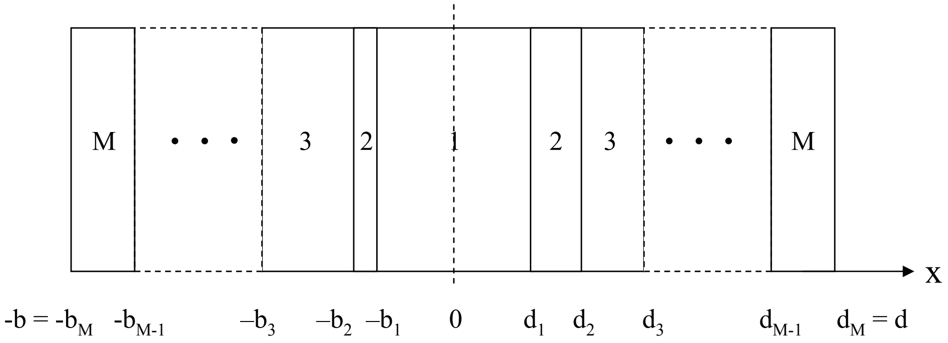

FIG. 9. *Quasi-symmetric configuration of a unit cell made of M materials.*

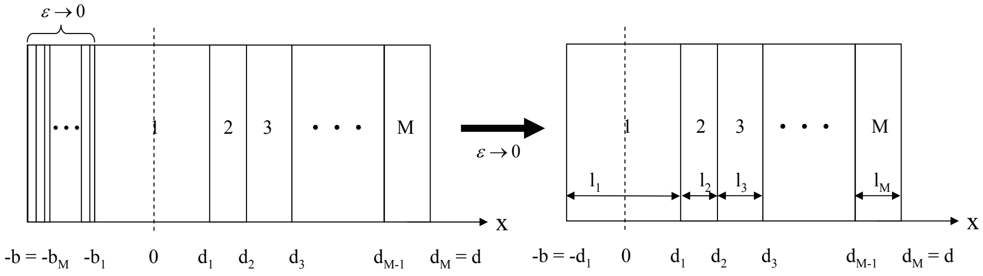

FIG. 10. *Obtaining the general cell configuration as a limiting case of the quasi-symmetric cell configuration.*

The quasi-symmetric limiting approach differs from the central expansion approach in the way the dispersion relation is derived for a general cell configuration with a non-quasi-symmetric configuration. The quasi-symmetric limiting approach views the general cell configuration as a limiting case of the quasi-symmetric configuration when the thickness of the left layer(s) approaches zero; see Figure 10. In the limiting procedure, it is essential to start with a quasi-symmetric and nonsymmetric cell configuration. The same limiting procedure applied to a symmetric cell configuration would fail to produce any results, because in a symmetric cell configuration, as the thicknesses of the left layers approach zero, so do the thicknesses of the corresponding right layers. Thus, the quasi-symmetric nonsymmetric cell configuration is essential, as it allows the layer thicknesses to the left and right of the central layer to be arbitrary, and hence independent. This approach also highlights the fact that the dispersion formula obtained in [11], [12] works for a general symmetric cell configuration but fails once the cell configuration becomes quasi-symmetric. In summary, the quasi-symmetric configuration is a critical configuration to work with, because from there one can recover the dispersion relation for the general cell configuration, something that cannot be achieved from a symmetric configuration. The approach described above is summarized in Figure 11 and discussed in more detail below.

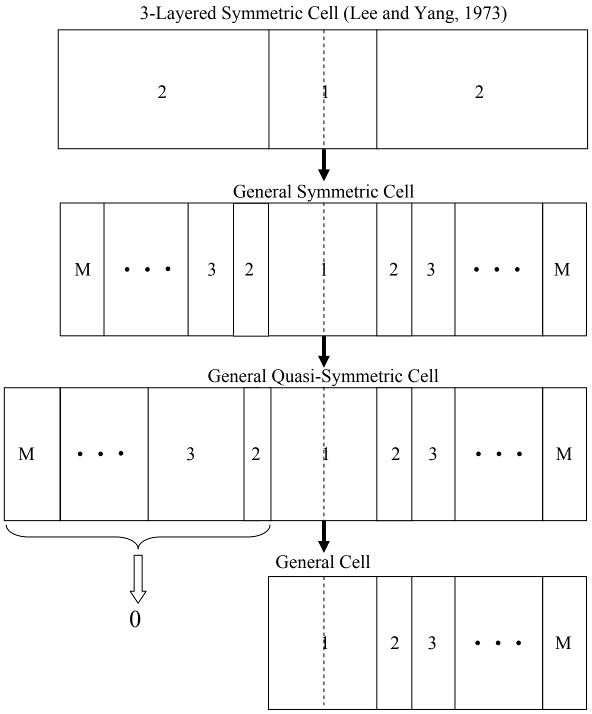

FIG. 11. *The stages of development of the quasi-symmetric limiting approach for a general cell configuration of M-layers.*

The recursive dispersion formula for the quasi-symmetric cell configuration can be derived similarly to that described in the previous section, under the simplifications that $\eta_j^- = \eta_j^+ = \eta_j$, $c_{j+1}^- = c_{j+1}^+ = c_{j+1}$, $p_j^- = p_j^+ = p_j$, and $N = M$ for $j = 1, 2, \ldots, M-1$. With these simplifications, the recursive dispersion formula (29) becomes

$$\boxed{\begin{aligned} 2\cos(qa) = {} & \frac{(A_M^+ B_M^{*-} + A_M^- B_M^{*+} - A_M^{*+} B_M^- - A_M^{*-} B_M^+)\cos(\lambda_M^+ + \lambda_M^-)}{A_M^- B_M^{*-} - A_M^{*-} B_M^-} \\ & + \frac{(A_M^+ A_M^{*-} - A_M^- A_M^{*+} + B_M^+ B_M^{*-} - B_M^- B_M^{*+})\sin(\lambda_M^+ + \lambda_M^-)}{A_M^- B_M^{*-} - A_M^{*-} B_M^-}. \end{aligned}} \tag{30}$$

The coefficients are obtained through the recursive relations involving (21)–(23) and (25)–(26). Notice that $\lambda_M^- = \frac{\omega}{c_M}(b_M - b_{M-1})$, $\lambda_M^+ = \frac{\omega}{c_M}(d_M - d_{M-1})$, while $\lambda_j^- = \frac{\omega}{c_j}(b_j - b_{j-1})$, $\lambda_j^+ = \frac{\omega}{c_j}(d_j - d_{j-1})$, $p_j = \frac{\eta_j c_{j+1}}{\eta_{j+1} c_{j+1}}$ for $j = 1, \ldots, M-1$.

As for the general cell configuration, while the coefficients of (30) with (+) superscript corresponding to the right-hand side layers remain intact, the coefficients of the left-hand side layers with (−) superscript will simplify due to the fact that the left-hand side layers vanish; see Figure 10. From (21)–(23), it follows that the coefficients with (−) superscript related to the eigenfunction $u_1(x)$ along the left layers are given by

$$(31)\qquad \begin{cases} A_{j+1}^- = A_j^- \cos(\lambda_j^-) - B_j^- \sin(\lambda_j^-), \\ B_{j+1}^- = p_j(B_j^- \cos(\lambda_j^-) + A_j^- \sin(\lambda_j^-)), \\ A_1^- = 1,\ B_1^- = 0,\ j = M-1, \ldots, 1. \end{cases}$$

In the limiting case, as $(b_j - b_{j-1})$ approaches zero, so does $\lambda_j = \frac{\omega}{c_j}(b_j - b_{j-1})$ for $j = M, \ldots, 2$. As a result, the recursive relation (31) becomes

$$(32)\quad \begin{cases} A_M^- = A_{M-1}^- = \cdots = A_j^- = \cdots = A_2^-, \\ B_M^- = p_{M-1}B_{M-1}^- = \cdots = p_{M-1}p_{M-2} \cdot p_j B_j^- = \cdots = p_{M-1}p_{M-2} \cdots p_2 B_2^-. \end{cases}$$

Furthermore, considering that $p_j = \frac{\eta_j c_{j+1}}{\eta_{j+1} c_j}$, $\lambda_1^+ = \lambda_1^- = \lambda_1$ (central layer), $A_1^- = 1$, and $B_1^- = 0$, the relations (32) become

$$(33)\quad \begin{cases} A_M^- = A_{M-1}^- = \cdots = A_j^- = \cdots = A_2^- = \cos(\lambda_1), \\ B_M^- = \dfrac{\eta_{M-1} c_M}{\eta_M c_{M-1}} B_{M-1}^- = \cdots = \dfrac{\eta_j c_M}{\eta_M c_j} B_j^- = \cdots = \dfrac{\eta_2 c_M}{\eta_M c_2} B_2^- = \dfrac{\eta_1 c_M}{\eta_M c_1} \sin(\lambda_1). \end{cases}$$

As a result, the coefficients A_M^-, B_M^-, and similarly A_M^{*-} and B_M^{*-}, simplify to

$$(34)\qquad A_M^- = \cos(\lambda_1) \quad \text{and} \quad B_M^- = \frac{\eta_1 c_M}{\eta_M c_1} \sin(\lambda_1),$$

$$(35)\qquad A_M^{*-} = -\sin(\lambda_1) \quad \text{and} \quad B_M^{*-} = \frac{\eta_1 c_M}{\eta_M c_1} \cos(\lambda_1).$$

The parameters to be used in numerical experiments (see Figure 10 and Figure 14) are

$$d_0 = 0, \quad d_1 = l_1/2, \quad d_j = l_1/2 + \sum_{h=2}^{j} l_h, \quad b_0 = 0, \quad b_j = l_1/2, \quad j = 1, 2, \ldots, M,$$

that is,

$$\lambda_1^+ = \lambda_1^- = \lambda_1 = \frac{\omega l_1}{2c_1}, \quad \lambda_j^+ = \lambda_j = \frac{\omega l_j}{c_j}, \quad \lambda_j^- = 0, \quad j = 1, 2, \ldots, M.$$

Finally, by substituting (34) and (35) in the recursive dispersion relation (30) for the quasi-symmetric configuration, we obtain the recursive dispersion relation (36) for the general configuration of the unit cell made of M layers/materials.

$$(36)\quad \boxed{\begin{aligned} 2\cos(qa) = \tfrac{c_1 \eta_M}{c_M \eta_1}\big[&(A_M^+ \tfrac{\eta_1 c_M}{\eta_M c_1} \cos\lambda_1 + \cos\lambda_1 B_M^{*+} - A_M^{*+} \tfrac{\eta_1 c_M}{\eta_M c_1} \sin\lambda_1 + \sin\lambda_1 B_M^+) \cos(\lambda_M) \\ &+ (-A_M^+ \sin\lambda_1 - \cos\lambda_1 A_M^{*+} + B_M^+ \tfrac{\eta_1 c_M}{\eta_M c_1} \cos\lambda_1 - B_M^{*+} \tfrac{\eta_1 c_M}{\eta_M c_1} \sin\lambda_1) \sin(\lambda_M)\big]. \end{aligned}}$$

Here the coefficients with a (+) superscript are generated using the recursive relations (21)–(23) and (25)–(26). In summary, we established in (36) a recursive dispersion relation for the general configuration of the unit cell made of M layers/materials. This formula was obtained by considering the quasi-symmetric cell configuration as an essential intermediate step. For cell configurations that are already quasi-symmetric or symmetric, the recursive dispersion relation expressed by (30) is more suitable, as it involves fewer recursive steps.

5. Numerical results: Comparison of the central expansion approach with the method by Shen and Cao given in [18].

5.1. Three-material cell ($M = 3$). We consider a cell composed of three distinct materials: concrete, nickel alloy, and steel. The lengths of the layers are 0.2 m, 0.25 m, and 0.3 m, respectively. The general cell diagram in Figure 6 illustrates the unit cell used in [18] for $M = 3$. In the central expansion approach, a shifting and renumbering of the layers in the original cell takes place. The resulting cell is illustrated by the renumbered cell diagram given in Figure 6 with $N = \lceil \frac{M}{2} \rceil + 1 = \lceil \frac{3}{2} \rceil + 1 = 3$, hence the need for a fake interface. As a result, the cell to be used with the central expansion approach has five layers and the materials for each layer are steel, nickel, concrete, concrete, and steel. Notice the introduction of a fake interface on the original layer of concrete. The material parameters (elastic modulus and density) are given in the appendix.

The two graphs of the dispersion relation obtained using the central expansion approach given in (29), and Shen and Cao's formulas in [18], overlap in Figure 12, demonstrating the consistency between the two methods. The recursive relation generating the coefficients $A_N^{\pm}, B_N^{\pm}, A_N^{*\pm}, B_N^{*\pm}$ of (29) is programmed in Maple [15]. The dispersion relation graph is then obtained using the *implicitplot* Maple command. Determining more accurately the values of the circular frequency ω for a given value of q, including the band ends with $qa = 0$ or $qa = \pi$, is a difficult root-finding problem. As discussed in [11], [12], due to (4), it is only necessary to consider the wave number q limited to the domain $0 \leq q \leq \pi/a$. As seen in Figure 12, the dispersion relation graph displays a banded frequency spectrum using the reduced zone scheme for the wave number q, with the circular frequency ω in the ordinate. The banded frequency spectrum is composed of pass or propagating bands and stop bands. Over the interval $0 \leq q \leq \pi/a$, bands of permissible frequencies appear, separated by forbidden bands (creating bandgaps), at which frequencies no Floquet waves can be propagated. This band structure of pass and nonpass bands shows the dispersive properties of the medium. Similar comments can be made for the other dispersion relation graphs.

5.2. Four-material cell ($M = 4$). Similarly, we consider a cell composed of four distinct materials: steel, aluminum, concrete, and nickel alloy. The lengths of the layers are 0.15 m, 0.1 m, 0.4 m, and 0.2 m, respectively. As before, the general cell diagram in Figure 6 illustrates the unit cell used in [18], when $M = 4$. The cell used for the central expansion approach is illustrated by the renumbered cell diagram given in Figure 6 with $N = \lceil \frac{M}{2} \rceil + 1 = \lceil \frac{4}{2} \rceil + 1 = 3$. Notice that unlike the three-material case, in this case we do not need to add a fake interface because the number of layers after the shift is already odd. The materials for each of the five layers are nickel alloy, steel, aluminum, concrete, and nickel alloy. We plot the dispersion relation using both methods, as shown in Figure 13. Notice again how well the two graphs overlap.

6. Numerical results: Quasi-symmetric limiting approach.

6.1. Comparison of the quasi-symmetric limiting approach with the method by Shen and Cao in [18]. Here we consider a unit cell composed of five layers arranged in a general configuration, shown in Figure 14. We choose aluminum as material 1, nickel alloy as material 2, concrete as materials 3 and 5, and steel as material 4, with the following layer thicknesses: $l_1 = 0.1$ m, $l_2 = 0.05$ m, $l_3 = 0.4$ m, $l_4 = 0.2$ m, and $l_5 = 0.25$ m. The material parameters (elastic modulus and density) can be found in the appendix. The two graphs displaying the dispersion relation using the quasi-symmetric limiting approach given in (36), and Shen and Cao's formulas in [18], overlap in Figure 15.

6.2. Comparison of both of our approaches with experimental results: A simplified one-dimensional model. The dispersion relation and sound attenuation through three-dimensional structures composed of periodically arranged cubic cells were experimentally measured in [13]. The cubic single cell consisted of a 1 cm diameter spherical core made of lead, coated with a 2.5 mm layer of silicone rubber. The coated spheres were periodically arranged in a $8 \times 8 \times 8$ cubic crystal with lattice constant of 1.55 cm, and with epoxy as the surrounding matrix material. The cross section of the cell is displayed on the upper part of Figure 16. The one-dimensional, three-material symmetric cell model, shown in the lower part of Figure 16, may be viewed, as suggested by Wang et al. [23], as a simplified one-dimensional counterpart of the three-dimensional structure studied in [13]. In our one-dimensional model, lead is considered as material 1, silicone rubber as material 2, and epoxy as material 3 with the following layer lengths: 1 cm (central), with 0.25 cm and 0.025 cm on each side. The material parameters (elastic modulus and density) are included in the appendix. Our intent here is to illustrate the fact that our dispersion relations correctly predict bandgaps due to a so-called localized resonance phenomenon that has been observed in three-dimensional ternary systems [13]; the localized resonance

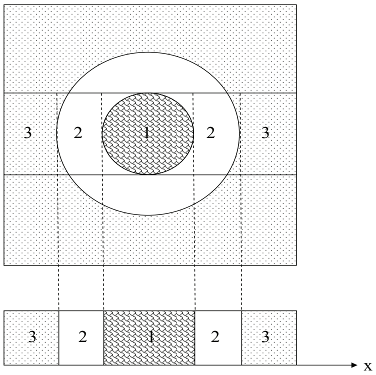

FIG. 16. *One-dimensional unit cell motivated from the three-dimensional cubic structure (cross section) studied in* [13].

can reduce the magnitude of the bandgap by two orders of magnitude relative to that caused by Bragg scattering, and this observation has spurred renewed interest by the acoustic bandgap community for design of acoustic attenuators. In [6], Bragg's law $f = n * v/2a$, for example, predicts a scattering frequency of about 62.5 KHz using steel scatterers embedded in an epoxy matrix with a lattice constant of 20 mm. Here, v is the longitudinal wave speed of the matrix, and a is the distance between the centers of the scatterers ($n = 1, 2, 3, \ldots$).

Liu et al. [13] measured acoustic transmission T as a function of frequency (250 Hz to 1600 Hz) by placing a receiving transducer at the center of their sonic crystals with an external sound source. The lowest values of T correspond to wave frequencies that are attenuated by the structure, whereas the highest values of T correspond to wave frequencies that easily propagate throughout the structure. Their experiments reveal that peak transmission frequencies are located at $f = 600$ Hz and $f = 1600$ Hz. Between these two frequencies, the transmission coefficient is low. The few measurements made for low frequency ($f \simeq 300$ Hz) suggest that waves with low frequencies easily propagate through the structure.

Due to the symmetric cell configuration of the one-dimensional simplified model given in Figure 16, the central expansion approach and the quasi-symmetric limiting approach share the same dispersion relation formula (29). The graph in Figure 17 displays the dispersion relation predicted by (29) and obtained using the *implicitplot* Maple command. Here we use frequency f on the ordinate instead of the circular frequency ω. Determining more accurately the values of the frequency f for a given value of q, including the band ends with $qa = 0$ or $qa = \pi$, is a difficult root-finding problem. As seen in Figure 17, between the frequency range of 0–2000 Hz, the graph exhibits a pass band for low frequencies under 140 Hz, and what appear to be four additional narrow pass bands centered approximately at $f = 873$, $f = 950$, $f = 1353$, and $f = 1907$ Hz. Closer inspection of an expanded view of the second pass band shows that it is centered at $f = 873.5$ Hz (Figure 18). Expanded views of the third and fourth bands (not shown here) located at approximately 950 Hz and 1353 Hz are essentially flat to within numerical roundoff, hence the group velocity at these frequencies is zero, i.e., $v_g = \frac{df}{dq} = 0$.

In conclusion, our one-dimensional model appears to qualitatively predict the acoustic response of the three-dimensional ternary structure, with the two narrow pass

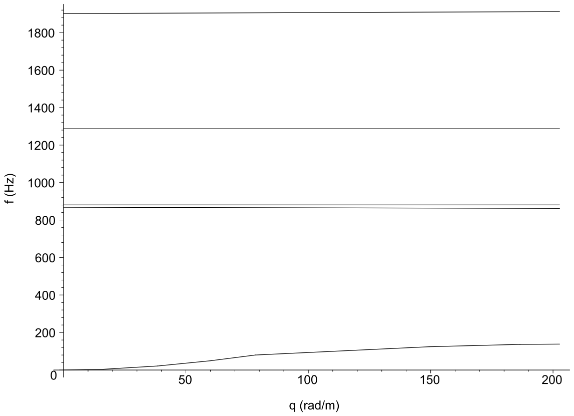

Fig. 17. *Graph of the dispersion relation for one-dimensional symmetrical cell model motivated from the three-dimensional model of* [13]*, using the reduced zone scheme for the wave number q.*

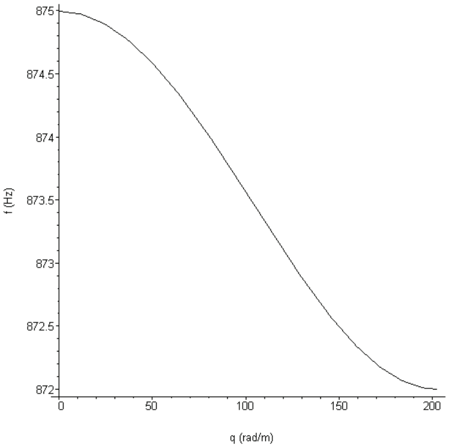

Fig. 18. *Expanded view of the second pass band illustrated in Figure* 17.

bands corresponding to the peaks and the two large bandgaps corresponding to the ranges of frequencies that are highly attenuated. Our numerical simulations predict bandgaps with a lattice constant two orders of magnitude smaller than the relevant wavelength, suggesting a so-called localized resonance phenomenon already observed in three-dimensional ternary systems [13]. However, the locations of the bandgaps do not match those that are experimentally observed. This is to be expected, considering the fact that our band structure equations are derived for infinite one-dimensional periodic elastic media whereas the experiments in [13] were conducted on a finite three-dimensional structure, with bandgaps only partially developed.

Appendix. The following are the elastic modulus η and density ρ of the materials selected for the numerical experiments:

1. Concrete: $\eta = 33 \cdot 10^9$ Pa and $\rho = 2400$ kg/m^3.
2. Steel: $\eta = 210 \cdot 10^9$ Pa and $\rho = 7800$ kg/m^3.
3. Aluminum: $\eta = 69 \cdot 10^9$ Pa and $\rho = 2710$ kg/m^3.

4. Nickel Alloy: $\eta = 214 \cdot 10^9$ Pa and $\rho = 8130$ kg/m^3.
5. Lead: $\eta = 40.8 \cdot 10^9$ Pa and $\rho = 11600$ kg/m^3.
6. Silicone rubber: $\eta = 117500$ Pa and $\rho = 1300$ kg/m^3.
7. Epoxy: $\eta = 4.4 \cdot 10^9$ Pa and $\rho = 1180$ kg/m^3.

Acknowledgment. The authors would like to acknowledge the two reviewers of this paper for their valuable suggestions and constructive comments.

THE SUPPRESSION OF FOUR-WAVE MIXING BY RANDOM DISPERSION[*]

RUDY L. HORNE[†], CHRISTOPHER K. R. T. JONES[‡], AND TOBIAS SCHÄFER[§]

Abstract. Pairwise interactions of optical pulses lead to the creation of four-wave mixing (FWM) products in the presence of periodic damping and amplification. In this manuscript, we examine how these FWM products grow in the presence of small to moderate random dispersion. Namely, we show that (i) the growth of the FWM products in the presence of white noise is inversely proportional to the noise strength $\bar{D}$, confirmed by both analytical and numerical results; (ii) the FWM products as a function of $\bar{D}$ obey a gamma-type probability distribution function; and (iii) the presence of either white or Ornstein–Uhlenbeck (OU) noise has a similar influence on the growth of these FWM products. This work shows that small random dispersion can effectively mitigate the deleterious effects of FWM in wavelength-division–multiplexed optical communications systems for either sech-type or Gaussian-type input pulses.

Key words. four-wave mixing, random dispersion, resonance condition, noise strength

1. Introduction.

In optical fiber transmission systems, there has been a great push to increase the throughput in both single and multiple channel fiber lines. One technique employed is wavelength-division multiplexing (WDM). This technique allows for the propagation of multiple pulses on different channels along a single fiber line. Problems arise when pulses from one channel interact with pulses from a different channel. Indeed, these pulse interactions create by-products that interfere with other pulses within the fiber line. In this manuscript, we examine these by-products from pairwise collisions of optical pulses in different channels under the influence of random system noise.

One of the most common scenarios of pulse interactions is that of pairwise interactions. In this case, two pulses from different frequency channels come together and interact (i.e., collide) with one another by virtue of their different speeds. In linear systems, this type of interaction is described by a superposition of waves. In nonlinear systems (i.e., WDM optical fiber systems), however, these pairwise interactions result in the creation of by-products (known as four-wave mixing (FWM) products) that can interfere with the propagation of other pulses in the fiber system. These products result from a resonance that is excited due to the nonlinearity of the index of refraction, the so-called Kerr nonlinearity. In this paper, we study what happens when random noise is added to the system and how this affects the growth of these by-products.

The model equation that describes pulse propagation in optical fibers is the nonlinear Schrödinger (NLS) equation with periodic damping and amplification. In this work, we use the NLS equation to derive a linear partial differential equation which models the evolution of the FWM growth. This model is then used to determine an analytical expression for the energy (L^2-norm) of the FWM growth in the presence of random dispersion. This result is compared with calculation of the energy of the FWM products via simulations of the NLS equation. These simulations are done in the presence of white noise as well as for Ornstein–Uhlenbeck (OU) noise. We then numerically show the probability distribution function associated with the energy of the FWM growth.

2. Motivation and paper outline. Pairwise nonlinear interactions between pulses in different frequency channels give rise to several effects. Two major effects are (i) collision-induced timing jitter, which results in permanent frequency shifts between colliding pulses (see [20, 3, 13]), and (ii) FWM product generation and growth that results in a permanent waveform that may interact with other optical pulses (see [5, 19, 11, 6]).

Fiber impurities, mostly due to fiber construction and implementation, can be viewed as small random perturbations to the fiber. In the past, these perturbations have often been considered a negative effect on the optical system in that they lead to pulse distortions or even pulse destruction: solitons [2] and dispersion-managed solitons [1, 17, 21] broaden under the influence of random perturbations until they disintegrate. Fortunately, these effects take place over very large distances, and that is why it is possible to use these solitons as bit carriers in terrestrial communication networks. In this paper, we adopt an entirely different point of view by showing that, with respect to other phenomena, namely FWM growth and deterministic resonances, random variations of the dispersion profile can have a beneficial impact concerning pulse interactions. The central issue we address is how random dispersion affects FWM growth. In previous work [12], we showed that FWM products are reduced in the presence of random dispersion. The numerical results presented in [12] showed that weak random dispersion reduces FWM product growth. This reduction can be compared with other methods such as dispersion management (see [9, 16, 15, 7]). We also showed that the resonance condition associated with FWM growth is affected by the presence of random dispersion. In this manuscript, we continue our investigation of FWM product production in the presence of random dispersion. We show that the energy associated with the FWM products (i.e., the L^2-norm associated with the FWM products) gives rise to an integral which one can analyze asymptotically. This asymptotic treatment allows us to give a quantitative comparison between the analytical treatment of the FWM growth and Monte Carlo simulations of the full NLS equation with random dispersion.

The outline for this manuscript is as follows. In the first two sections, we outline the derivation of a linear PDE which describes the FWM growth associated with pairwise collisions of optical fibers. This linear PDE is further reduced to a linear ODE which is used throughout the analysis. Next, we use the linear ODE model to derive an expression for the L^2-norm associated with FWM growth in the presence of random dispersion. This analysis shows that the energy of the FWM products depends inversely on the noise strength, $\bar{D}$. This result is verified via simulations of the full NLS equation for these FWM products in the third section. We consider both white and OU noise. In the fourth section, we give a numerical description of the probability distribution function associated with the energies for these FWM products. Finally, we summarize these results and state some conclusions.

3. FWM growth model.

3.1. Derivation of the FWM growth model: The NLS equation. We begin this analysis with the NLS equation, which includes varying dispersion, damping, and amplification:

$$iE_z + \frac{\beta(Z)}{2} E_{TT} + \gamma |E|^2 E = -i\alpha E. \tag{3.1}$$

$E(Z,T)$ is the envelope of the electric field, where Z and T are the propagation and time variables measured in km and ps, respectively; $\beta(Z)$ is the variable dispersion profile; and the loss and damping/amplification coefficients are given by γ and α.

Let us introduce the dimensionless variables $\zeta = Z/z_*$, $\tau = T/t_*$, $|\beta_{\text{av}}|$, and $Q(\zeta,\tau) = E(Z,T)/\sqrt{P_*}$, where z_*, t_*, $|\beta_{\text{av}}|$, and P_* denote the characteristic length scale, characteristic time scale, the average dispersion value, and the peak power, respectively. We define length scales associated with the dispersion ($z_{\beta_{\text{av}}}$) and the nonlinearity (z_{NL}) given by $z_{\beta_{\text{av}}} = t_*/|\beta_{\text{av}}|$ and $z_{NL} = 1/\gamma P_*$. We also define the dimensionless amplifier spacing, $z_a = L_a/z_*$, where L_a is the physical amplifier spacing taken to be 40km. Under this change of variables, (3.1) becomes

$$iQ_\zeta + \frac{z_* d(\zeta)}{2 z_{\beta_{\text{av}}}} Q_{\tau\tau} + \frac{z_*}{z_{NL}} |Q|^2 Q = -i\Gamma Q, \tag{3.2}$$

where $\Gamma = z_*\alpha$ and $d(Z) = \beta(Z) z_{\beta_{\text{av}}}/{t_*}^2$. A more convenient form of (3.2) is found with a further change of variables and matching certain parameters.

Setting $Q(\zeta,\tau) = \sqrt{g(\zeta)}\, u(\zeta,\tau)$ and taking $z_* = z_{\beta_{\text{av}}} = z_{NL}$, one determines the following form of the NLS equation:

$$iu_z + \frac{d(z)}{2} u_{tt} + g(z)|u|^2 u = 0. \tag{3.3}$$

Here, we have relabeled our variables $(\zeta,\tau) \longrightarrow (z,t)$, $g(z)$ is an exponential function with period z_a (nonlinear coefficient), and $d(z)$ is the dispersion profile of the form $d(z) = d_{\text{av}} + F(z)$, where, d_{av} is the average dispersion and $F(z)$ is either some prescribed function or a white noise process. Throughout this paper, we work with (3.3) and take $F(z)$ to be a white noise process. If one sets $g(z) = 1$ and $F(z) = 0$, (3.3) supports soliton solutions of the form

$$u(z,t) = A\text{sech}[A(t - \Omega d_{\text{av}} z + T)] \exp[i(A^2 - \Omega^2)z/2] \exp(i\Omega t). \tag{3.4}$$

Here, A is the pulse amplitude, $\Omega = \pi c t_* \Delta\lambda/\lambda^2$ is the frequency offset, c is the speed of light, t_* is the characteristic time scale, λ is the wavelength of the soliton, $\Delta\lambda$ is the channel spacing, and T is the timing offset for the soliton pulse. We also take typical parameter values as follows: $L_a = 40\text{km}$, $z_* = 400\text{km}$, $\lambda = 1550\text{nm}$, $\alpha = 0.025\text{km}^{-1}$, and $P_* = 2\text{mW}$, which implies that $z_a = L_a/z_* = 0.1$ and $\Gamma = 10.0$. Also, the characteristic time $t_* = \tau_{pulse}/1.763$, where the number 1.763 denotes the full-width half maximum of the ideal soliton and τ_{pulse}= 28ps. We note that $\Omega = 3.9$ corresponds to a channel spacing of $\Delta\lambda = 0.62\text{nm}$.

3.2. Derivation of the FWM growth model: Model equation. We briefly outline the derivation of the model PDE that describes the growth of the FWM products. The presentation given in this section is a brief summary of work done in [11].

We assume that our pulses can be written as a sum of the two interacting pulses and the FWM products [4, 11]:

$$u(z,t) \simeq u_1(z,t) + u_2(z,t) + u_{\text{fwm}}(z,t). \tag{3.5}$$

Upon substitution of (3.5) into (3.3), one derives the following linear PDE:

$$iq_z + \frac{d(z)}{2} q_{tt} = -g(z) {u_2}^2 {u_1}^*. \tag{3.6}$$

Here, we have that $q(z,t) \equiv u_{221}(z,t)$ is the FWM product growth associated with frequency 3Ω, $u_j(z,t)$ are the input pulses, $d(z)$ is the dispersion profile, which is some prescribed function, and $g(z)$ is the periodic damping and amplification.

We note that on the right-hand side (RHS) of (3.6) the forcing term has a rapidly varying piece which we now factor out in the form

$$q(z,t) = Q(z,t) \exp\left(3i\Omega t - i\frac{\Omega^2}{2}\int_0^z \, d(z')dz'\right). \tag{3.7}$$

Plugging this into our linear PDE for $q(z,t)$, one derives the following equation for $Q(z,t)$:

$$iQ_z + \frac{d(z)}{2}(Q_{tt} + 6i\Omega Q_t - 2(2\Omega)^2 Q) = -g(z) {u_{20}}^2 {u_{10}}^*, \tag{3.8}$$

where

$$ {u_{20}}^2 {u_{10}}^* \equiv {u_2}^2 {u_1}^* \exp\left(-3i\Omega t + i\frac{\Omega^2}{2}\int_0^z \, d(z')dz'\right) \tag{3.9}$$

and $g(z)$ is as described in (3.3). We note that for the case of initially well-separated pulses, $\Delta\Omega = 2\Omega \gg 1$, where 2Ω is the difference in the frequency offset for the two pulses. For this case, one notes that in (3.8) we have $(2\Omega)^2|Q| \gg |Q_t|, |Q_{tt}|$. Here, we have assumed that our input pulses are well separated (i.e., $(2\Omega) \gg 1$). Typical values for this case occur when $\Omega \geq 2$ (see [20]), which is the case of interest throughout this manuscript. This allows us to further reduced our model FWM equation to the form

$$iQ_z - d(z)(2\Omega)^2 Q = -g(z) u_{20}^2 u_{10}^*. \tag{3.10}$$

In this model, the input pulses on the right-hand side of (3.10) can be either classical solitons or Gaussian-type pulses. Equation (3.10) is the FWM growth model used in the analysis throughout this manuscript. In the next section, we incorporate noise into the dispersion coefficient, $d(z)$ in (3.10), and analyze the FWM growth in this case via its L^2-norm.

4. FWM growth and random dispersion.

4.1. Random dispersion in an optical fiber. In this paper, we take the dispersion, $d(z)$, to have the following form:

$$d(z) = d_{av} + \xi(z), \tag{4.1}$$

where $\xi(z)$ is a white noise process with

$$\langle \xi(z) \rangle = 0 \qquad \text{and} \qquad \langle \xi(z)\xi(z') \rangle = \bar{D}\ \delta(z - z'). \tag{4.2}$$

The noise strength, $\bar{D}$, is taken to be small (i.e., $0 < \bar{D} \ll 1$) for our problem of interest. We consider small to moderate noise strength so as to not destroy the input pulses. Since the input soliton pulses decay slowly on the length scale, $z_{degr} = 1/\bar{D}$ (see [8]), we work with distances on the order of $z \ll z_{degr}$. Also, we take the RHS of (3.8) as independent of the randomness given by (4.1)–(4.2). We assume that, to leading order, the input pulses are roughly fixed relative to the input noise. We now present an analysis for the growth of FWM products as a function of the noise strength $\bar{D}$ and the frequency offset Ω.

4.2. FWM growth: Analytical results.

In this section, we derive an equation which captures the behavior of the FWM products in the presence of a white noise process. These results will be shown to be in quantitative agreement with what is seen numerically.

We restate the reduced model equation for FWM growth:

$$iQ_z - d(z)(2\Omega)^2 Q = -g(z){u_{20}}^2{u_{10}}^*. \tag{4.3}$$

Here, $u_{j0}(z,t)$ denotes the form of the input pulse for j = 1,2. Our input pulses can have one of the following forms:

- Sech-type input pulse:

$$u_{j0}(z,t) = A_j \operatorname{sech}[A_j(t - \Omega_j d_{av} z - T_j)] \exp[i({A_j}^2 - {\Omega_j}^2)z/2] e^{i\Omega_j t}, \tag{4.4}$$

  where $\Omega_2 = -\Omega_1 \equiv \Omega$ and $T_1 = -T_2 \equiv T_0$. We take $A_1 = A_2 \equiv A$ unless otherwise specified in this manuscript.

- Gaussian-type input pulse:

$$u_{j0}(z,t) = \frac{\alpha_j}{\sqrt{2\pi\beta_j}} \exp[-(t - \Omega_j d_{av} z - T_j)^2/2\beta_j] \exp[i({\alpha_j}^2 - {\Omega_j}^2)z/2] e^{i\Omega_j t}, \tag{4.5}$$

  where $\Omega_2 = -\Omega_1 \equiv \Omega$ and $T_1{=}-T_2 \equiv T_0$. Similar to the case for sech-type pulses, we take $\alpha_1{=}\alpha_2 \equiv \alpha$ and $\beta_1{=}\beta_2 \equiv \beta$ unless otherwise specified.

We note that, strictly speaking, the input pulses given by (4.4)–(4.5) should incorporate randomness via the dispersion within the argument of the input pulses. For the distances discussed in this manuscript ($z \ll z_{degr}$), the pulses are roughly fixed relative to the random dispersion.

Also, for either type of input pulses, the pairwise collision will occur at the point

$$z_{\text{collision}} \equiv z_{coll} = \frac{T_1 - T_2}{d_{av}(\Omega_2 - \Omega_1)} = \frac{T_0}{d_{av}\Omega} \neq 0. \tag{4.6}$$

The collision point is a function of the timing and frequency offsets, and all results are derived with this in mind. We also note that this analysis applies to complete collisions (i.e., initially well-separated input pulses). If the input pulses are not well separated, then the collision is an incomplete collision, which leads to much larger inelastic effects (see [18, 13]).

Going back to (4.3) and solving for $Q(z,t)$ yields

$$Q(z,t) = ie^{-i(2\Omega)^2 \int_0^z d(z')dz'} \int_0^z dz'\ g(z'){u_{20}}^2{u_{10}}^*(z',t)e^{i(2\Omega)^2 \int_0^{z'} d(s)ds}, \tag{4.7}$$

where $\int_0^z d(z')dz' = d_{av}z + W(z)$ with $W(z) \equiv \int_0^z \xi(s)ds$. We recall that $g(z)$ is a periodic function in z and therefore is expressible as a Fourier series:

$$g(z) = \sum_{m=-\infty}^{\infty} g_m \, e^{-i2\pi m z/z_a}, \qquad g_m = \frac{\Gamma z_a}{\Gamma z_a - im\pi}, \tag{4.8}$$

where z_a is the dimensionless amplifier spacing. Plugging (4.8) into (4.7), one finds

$$Q(z,t) = ie^{-i(2\Omega)^2 \int_0^z \, d(z')dz'} \sum_{m=-\infty}^{\infty} g_m \, I_m(z,t), \tag{4.9}$$

where the integral within the sum is given as

$$I_m(z,t) \equiv \int_0^z dz' \, e^{i\psi_m z'} e^{i(2\Omega)^2 W(z')} [u_{20}^2 u_{10}^*](z',t) = \int_0^z dz' \, e^{i\chi_m(z')} [u_{20}^2 u_{10}^*](z',t). \tag{4.10}$$

Here, $\psi_m \equiv \bar{\lambda}^2/2 + (2\Omega)^2 \, d_{av} - 2\pi m/z_a$ is a resonance condition which determines where the largest FWM products are produced as a function of Ω for $m = 1, 2, 3, \ldots$ (see [11, 4]), $\bar{\lambda}$ is a parameter (usually the amplitude) which depends on the form of the input pulses, and $W(z') = \int_0^{z'} \xi(s')ds'$. Here, $W(z)$ is a normally distributed random variable with

$$\langle W(z) \rangle = 0 \qquad \text{and} \qquad \langle W^2(z) \rangle = \bar{D}z. \tag{4.11}$$

Upon examination of the argument of the $\exp[i\chi_m(z')]$ term in the integrand of $I_m(z,t)$, it is clear that the resonance condition is modified in the presence of the random variable $W(z)$:

$$\chi_m(z') \equiv \psi_m z' + (2\Omega)^2 W(z') = \left(\frac{\lambda^2}{2} + (2\Omega)^2 d_{\mathrm{av}} - \frac{2\pi m}{z_a} \right) z' + (2\Omega)^2 W(z'). \tag{4.12}$$

Equation (4.12) implies that the resonance condition is affected by the random variable $W(z')$. If one views $\chi_m(z')$ as a random function, then one can determine that $\langle \chi_m(z') \rangle = \psi_m z'$ since $\langle W(z') \rangle = 0$. In this work, we present a general analysis of how the size of the FWM products is affected by randomness. We see this through examination of the quantity $\langle |Q(z,t)|^2 \rangle$.

Now, going back to (4.9)–(4.10), one finds

$$|Q(z,t)|^2 = \sum_{m,n=-\infty}^{\infty} g_m \, g_n^* \, I_m(z,t) I_n{}^*(z,t). \tag{4.13}$$

At this point, we can determine the L^2-norm of $Q(z,t)$ (i.e., $\int_{-\infty}^{\infty} |Q(z,t)|^2 dt$). This is done by interchanging the integral and summand as follows:

$$\int_{-\infty}^{\infty} |Q(z,t)|^2 dt = \sum_{m,n=-\infty}^{\infty} g_m \, g_n^* \int_{-\infty}^{\infty} I_m(z,t) I_n{}^*(z,t) dt. \tag{4.14}$$

As concerns the growth of the FWM products, we are interested in the quantity $\langle \int_{-\infty}^{\infty} |Q(z,t)|^2 dt \rangle$. For our problem, the randomness comes in only through the z-dependence, so t can be treated as a parameter relative to the averaging over z. We have that

$$\left\langle \int_{-\infty}^{\infty} |Q(z,t)|^2 dt \right\rangle = \int_{-\infty}^{\infty} \langle |Q(z,t)|^2 \rangle dt, \tag{4.15}$$

which tells us that the quantity of interest is $\langle |Q(z,t)|^2\rangle$. Using (4.14), we have

$$\langle |Q(z,t)|^2\rangle = \sum_{m,n=-\infty}^{\infty} g_m\ g_n^*\ \langle I_m(z,t) I_n{}^*(z,t)\rangle. \tag{4.16}$$

Again, $I_m(z,t)$ has the form

$$I_m(z,t) \equiv \int_0^z dz'\ f(z',t)\ e^{i\psi_m z'}\ e^{i(2\Omega)^2 W(z')}, \tag{4.17}$$

where

$$f(z,t) \equiv [u_{20}^2 u_{10}^*](z,t)\ e^{-i(A^2-\Omega^2)z/2} \quad \text{and} \quad \psi_m \equiv (2\Omega)^2 d_{av} + \frac{\lambda^2}{2} - \frac{2\pi m}{z_a}. \tag{4.18}$$

By examination of the product of the integrals $I_n(z,t)\ I_m{}^*(z,t)$ and using (4.17), we find

$$I_m(z,t)\ I_n{}^*(z,t) = \int_0^z \int_0^z f(s,t) f(s',t)\ e^{i\psi_m s} e^{-i\psi_n s'} e^{i(2\Omega)^2[W(s)-W(s')]}\ ds\ ds'. \tag{4.19}$$

Here, the region of integration corresponds to integrating over the square box: $0 \le s, s' \le z$. Defining the variable $\tilde{W} \equiv W(s) - W(s')$, it is well known that $\tilde{W}$ is also a normally distributed random variable with mean and variance given by (see [10])

$$\langle \tilde{W}\rangle = 0 \qquad \text{and} \qquad \langle \tilde{W}^2\rangle = \bar{D}\ |s-s'|. \tag{4.20}$$

Using elementary calculus and the fact that $\langle e^{k\tilde{W}}\rangle = e^{\frac{k^2\langle \tilde{W}^2\rangle}{2}}$ for $\tilde{W}$ normally distributed with zero mean and k as some constant value, one finds

$$\begin{aligned} \langle I_m(z,t)\ I_n{}^*(z,t)\rangle &= \int_0^z \int_0^z ds' ds\ f(s,t) f(s',t)\ e^{i\psi_m s}\ e^{-i\psi_n s'}\ e^{-(2\Omega)^4 \bar{D}|s-s'|} \\ &= \sum_{j=1}^{4} \int\int_{R_j} ds' ds\ f(s,t) f(s',t)\ e^{i\psi_m s}\ e^{-i\psi_n s'}\ e^{-(2\Omega)^4 \bar{D}|s-s'|}. \end{aligned} \tag{4.21}$$

Here, R_j denotes the following regions of integration: (i) R_1: $0 \le s, s' \le z_{coll}$, (ii) R_2: $0 \le s \le z_{coll}$ and $z_{coll} \le s' \le z$, (iii) R_3: $z_{coll} \le s, s' \le z$, and (iv) R_4: $z_{coll} \le s \le z$ and $0 \le s' \le z_{coll}$. Again, z_{coll} is the collision point of the two pulses (either sech-type or Gaussian-type) stated in (4.6).

We can evaluate each of the integrals in (4.21) with the use of the following transformation:

$$u = s' - s, \quad v = s + s' \quad \Longrightarrow \quad s' = \frac{u+v}{2}, \quad s = \frac{v-u}{2}. \tag{4.22}$$

Applying (4.22) to the regions R_j for $j = 1, 2, 3, 4$, we convert (4.21) into

$$\langle I_m(z,t)\ {I_n}^*(z,t)\rangle$$

$$= \int_0^{z_{coll}} du\, G_1(u)\ \cos\left[\frac{(\psi_m+\psi_n)u}{2}\right] e^{-xu} + \frac{1}{2}\int_0^{z-z_{coll}} du\, F_1(u) e^{-i(\psi_m+\psi_n)u/2} e^{-xu}$$

$$+ \frac{1}{2}\int_0^{z_{coll}} du\, F_1(u) e^{i(\psi_m+\psi_n)u/2} e^{-xu} + \int_0^{z-z_{coll}} du\, G_2(u)\cos\left[\frac{(\psi_m+\psi_n)u}{2}\right] e^{-xu}$$

$$+ \frac{1}{2}\int_{z_{coll}}^{z} du\, F_2(u) e^{-i(\psi_m+\psi_n)u/2} e^{-xu} + \frac{1}{2}\int_{z-z_{coll}}^{z} du\, F_2(u) e^{i(\psi_m+\psi_n)u/2} e^{-xu}$$

$$+ \frac{1}{2}\int_{z-z_{coll}}^{z_{coll}} du\, K_1(u) e^{-i(\psi_m+\psi_n)u/2} e^{-xu} + \frac{1}{2}\int_{z_{coll}}^{z-z_{coll}} du\, K_2(u) e^{i(\psi_m+\psi_n)u/2} e^{-xu}, \tag{4.23}$$

where the parameter $x \equiv (2\Omega)^4\ \bar{D}$, $z \geq z_{coll}$, and the quantities $G_1(u)$, $G_2(u)$, $F_1(u)$, $F_2(u)$, $K_1(u)$, and $K_2(u)$ are defined below:

$$G_1(u) \equiv \int_u^{2z_{coll}-u} dv\ H(u,v), \qquad G_2(u) \equiv \int_{2z_{coll}+u}^{2z-u} dv\ H(u,v),$$

$$F_1(u) \equiv \int_{2z_{coll}-u}^{2z_{coll}+u} dv\ H(u,v), \qquad F_2(u) \equiv \int_u^{2z-u} dv\ H(u,v),$$

$$K_1(u) \equiv \int_{2z_{coll}-u}^{2z-u} dv\ H(u,v), \qquad K_2(u) \equiv \int_u^{2z_{coll}+u} dv\ H(u,v). \tag{4.24}$$

The quantity $H(u,v)$ incorporates information about the two pulses:

$$H(u,v) \equiv f\left(\frac{v+u}{2},\ \ t\right)\ f\left(\frac{v-u}{2},\ \ t\right)\ e^{i(\psi_m-\psi_n)v/2}. \tag{4.25}$$

Typical values for our problem of interest are $\Omega \simeq 3.9$ and $0.005 \leq \bar{D} \leq 0.03$ (corresponding to 0.5% to 3% of variation with respect to the average dispersion set to $d_{av} = 1.0$), which corresponds to a large x value (i.e., $x \gg 1$). One can apply Laplace's method to examine each of the integrals in (4.23) for large x. If one takes $z \longrightarrow \infty$, the resulting asymptotic integral is given by

$$\lim_{z\longrightarrow\infty}\ \langle I_m(z,t)\ {I_n}^*(z,t)\rangle$$

$$\simeq \frac{1}{(2\Omega)^4\bar{D}}\ \left[\int_0^{\infty} dv\ H(u=0,\ v)\ +\ \frac{1}{2}\ \int_{z_{coll}}^{3z_{coll}} dv\ H(u=z_{coll},\ v)\right]. \tag{4.26}$$

Again, we note that this analysis applies to either sech-type or Gaussian-type pulses. One can bound each of the integrals in (4.26) and then show that the quantity $\langle I_m(z,t){I_n}^*(z,t)\rangle$ decays like $1/(2\Omega)^4\bar{D}$, where Ω is the frequency offset and $\bar{D}$ represents the noise strength arising from the random dispersion given in (4.1) and (4.2). In the next section, we compare (4.26) with numerical integration of (3.3), which is the full NLS equation with periodic damping and amplification, to show quantitative agreement between the two approaches.

4.3. FWM growth: Numerical results for white noise process. In the previous section, we showed analytically that the dominant contribution to the L^2-norm for FWM growth in the presence of a random dispersive term decayed like $1/(2\Omega)^4\bar{D}$,

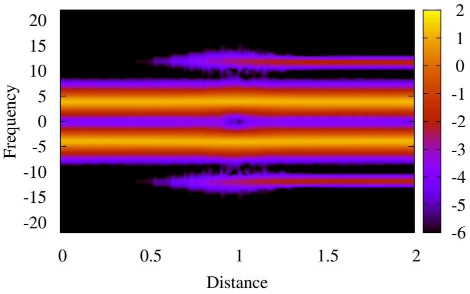

Fig. 1. *Contour plot of the spectrum of a signal for a pairwise interaction of sech-type pulses in the absence of noise in the dispersion coefficient: The dispersion here is simply a constant function (i.e., $d(z) = 1.0$) to show the presence of FWM growth side-bands. The color corresponds to the logarithm of the amplitude.*

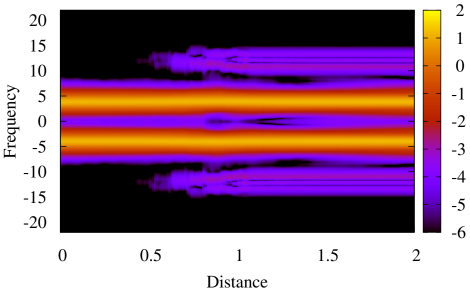

Fig. 2. *Contour plot of the spectrum of a signal for a pairwise interaction of sech-type pulses in the presence of white noise. The noise strength is given by $\bar{D} = 0.03$. The color corresponds to the logarithm of the amplitude, indicating that the side-bands are smoothed out and overall much weaker than in the system without noise.*

where Ω and $\bar{D}$ represent the frequency offset and noise strength, respectively. Again, the FWM growth results from a pairwise collision of either sech- or Gaussian-type pulses (see (4.4)–(4.5)) and is best observed in the frequency domain.

We chose to examine the pairwise interaction of sech-type pulses. The reason for this choice was simply one of convenience for the numerics. All of the results presented here can be applied to Gaussian-type pulses without loss of the basic features concerning FWM products. In Figure 1, we show the frequency spectrum for the propagating signal, which consists of two interacting pulses that are well separated in the frequency domain, in the absence of dispersive noise. Due to the interaction, they develop FWM that occurs as side-bands in the frequency domain. The simulation clearly shows how these bands are first created and then persist. This simulation was obtained by solving (3.3) using a standard second-order split-step method.

Running the same simulation as shown in Figure 1 but allowing for small randomness in the dispersion coefficient $d(z)$ (see (4.1)–(4.2)), considerable suppression of the FWM products arises. In Figure 2, the noise strength is chosen to be $\bar{D} = 0.03$

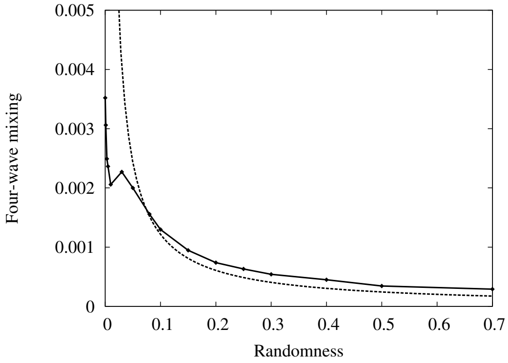

Fig. 3. *This is a plot of* $R = ||u_{FWM}||^2/||u_{sol}||^2$ *versus* $\bar{D}$*, where* R *is the ratio of the FWM energy* ($||u_{FWM}||^2$) *to one of the input sech-type pulse's energy* ($||u_{sol}||^2$) *and* $\bar{D}$ *is the noise strength parameter. The solid line is obtained by integration of the full NLS equation for* 1000 *Monte Carlo simulations at each* $\bar{D}$ *value, taking* $z = 2.5$ *dimensionless units. The dashed line represents the result obtained using* (4.15), (4.16)*, and* (4.26).

and shows that the amplitude of the side-bands is much lower. This indicates that the four-wave products are reduced in a noisy system. In our simulations, we use a standard split-step algorithm in order to integrate the full NLS equation (3.3). At each step in the evolution variable z, we randomly draw a number that approximates the white noise in the dispersion term. In order to model the white noise effectively, this random number is drawn from a normal distribution with the variance $\sigma^2 = \bar{D}/dz$ at each evolution step dz.

In section 4.2 we derived an expression for the L^2-norm for the FWM products given in (4.15), (4.16), and (4.26). In Figure 3, we plot the L^2-norm of the FWM products (relative to the L^2-norm of one of the sech-type pulses) versus the noise strength $\bar{D}$, given the soliton parameters $\Omega = 3.9$ and $T_0 = 4.0$. The plot is generated by solving the full NLS equation for propagation of the pulses to some finite distance along the fiber after the collision ($z = 2.5$ dimensionless units, where the collision occurs at $z_{coll} = 1.027$). A certain distance after the collision of the pulses (at $z = 2.5$ dimensionless units), we measure the value $R = ||u_{FWM}||^2/||u_{sol}||^2$ for a fixed noise strength $\bar{D}$. Figure 3 tells us the value of R for a range of $\bar{D}$ values, averaging the Monte Carlo simulations for 1000 realizations per run in z per $\bar{D}$ value. We compare the numerical results obtained by integration of the full NLS equation with the sum that arises from solving the linear PDE model for the FWM growth (see (4.16)). This figure shows that the FWM growth decays like $1/(2\Omega)^4\bar{D}$, which is shown in both numerical simulations as well as from the analytical results.

The sum in (4.16) was evaluated using twenty terms, with the asymptotic formula given by (4.26). From (4.23)–(4.26), it is clear that the dominant terms arise when the indices m and n are equal. Since we are dealing with sech-type (or Gaussian-type) pulses, the contributions to (4.16) can be shown numerically to be small as m and n become large. Practically speaking, twenty terms give sufficient accuracy (up to at least five digits of numerical accuracy).

In this section, we have shown both numerically and analytically that the FWM products decay inversely with the noise strength parameter $\bar{D}$. This confirms the initial evidence of this phenomenon seen in [12]. Another question to be asked is What is the probability distribution function of the R value (ratio of L^2-norms) associated

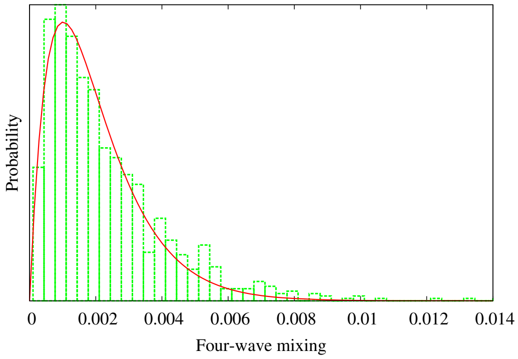

FIG. 4. *This is a plot of the probability distribution function versus* $R = ||u_{FWM}||^2/||u_{sol}||^2$ *given* $\bar{D} = 0.03$ *and* $\Omega = 3.9$.

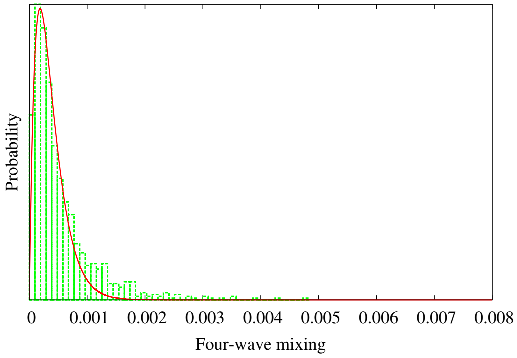

FIG. 5. *This is a plot of the probability distribution function versus* $R = ||u_{FWM}||^2/||u_{sol}||^2$ *given* $\bar{D} = 0.30$ *and* $\Omega = 3.9$.

with these FWM products? We show some numerical results and propose a model for the probability distribution function.

4.4. FWM growth and its probability distribution function. In the previous section, we found that qualitatively the FWM products decrease like $1/(2\Omega)^4\bar{D}$ (see (4.26)). Indeed, we can numerically determine the probability distribution function of the FWM products for a set value of the noise strength $\bar{D}$. Once this is done, we can determine a best fit curve for the probability distribution function associated with the ratio of L^2-norms for the FWM products.

We begin by solving the NLS equation (3.3), where $g(z)$ is a periodic function, $d(z)$ is given by (4.1)–(4.2), and sech-type input pulses are used as given in (4.4). We numerically integrate the NLS equation for 1000 Monte Carlo simulations, setting the appropriate constants Ω, T_0, and $\bar{D}$. Once the histogram is numerically calculated, we fit this curve to a gamma-type probability distribution function.

In Figures 4 and 5, we plot histograms of the probability distribution functions as functions of R for different $\bar{D}$ values. These figures are obtained upon numerical integration of the full NLS equation (3.3) for $\Omega \simeq 3.9$, $\bar{D} = 0.03$, and $\bar{D} = 0.30$ for 1000 Monte Carlo simulations. The results in these figures confirm what was predicted in Figure 3; as we increase the value of the noise strength $\bar{D}$, there is a significant

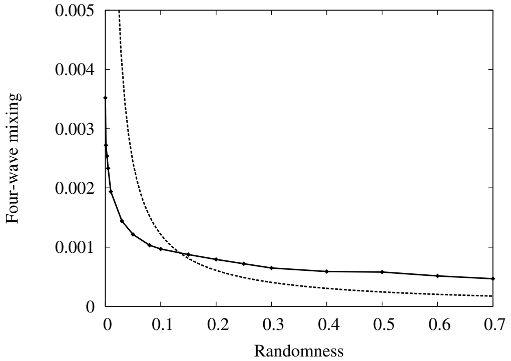

FIG. 6. *This is a plot of $R = ||u_{FWM}||/||u_{sol}||$ versus the noise strength parameter $\bar{D}$ in the presence of OU noise in the dispersive term. The solid line is obtained by integration of the full NLS equation for* 1000 *Monte Carlo simulations for a fixed $\bar{D}$ value for $z = 2.5$ dimensionless units. reduction in the FWM products. These probability distribution functions also give us an indication of how the values of R are distributed for a given Ω and $\bar{D}$. From Figures 4 and 5, it appears that the results in these figures are best approximated by a Gamma-type distribution. By fitting the data using a least-squares approach, one can show that the probability distribution function is approximated by

$$f(x) = \alpha x e^{-\beta x}, \tag{4.27}$$

where $\alpha \approx 9.2356 \times 10^5$ and $\beta \approx 986.315$ when $\bar{D} = 0.03$, and $\alpha \approx 2.42866 \times 10^7$ and $\beta \approx -5366.57$ for 0.30, respectively. Here, x represents the binning of the R values, and β, n, and m depend on the noise strength $\bar{D}$.

4.5. FWM: Numerical results for a correlated noise process. In section 4.3, we showed that the FWM growth is inversely proportional to the noise strength $\bar{D}$ in the presence of a white noise process in the dispersion coefficient. Indeed, the results displayed in Figure 3 summarized both the numerical and analytical results derived for the case of white noise in the dispersive term. A question that we raise is Is the FWM growth affected in a similar manner for different types of noise processes? We briefly give some numerical results for the case of OU noise. In this case, $\xi(z)$ in (4.1) is created by solving the corresponding stochastic equation:

$$d\xi(z) = -k\xi(z)dz + \sqrt{\bar{D}_{OU}}dW, \tag{4.28}$$

where $\bar{D}_{OU}$ is the appropriately scaled diffusion constant for the OU process and k^{-1} is the correlation length (see [10]).

Figure 6 is a plot of the L^2-norm of the FWM products, relative to the L^2-norm of one of the input pulses, versus the noise strength, $\bar{D}$. This plot was generated in a similar manner to that of Figure 3. We solve the full NLS equation for propagation of the pulses to some finite distance along the fiber after the collision ($z = 2.5$ dimensionless units). After this, we measure the value of $R = ||u_{FWM}||^2/||u_{sol}||^2$ (the ratio of the L^2-norm of the FWM product and one of the input pulses) at $z = 2.5$ for a fixed noise strength $\bar{D}$. Again, we determine the values of R for a range of $\bar{D}$ values, averaging the Monte Carlo simulations for 1000 simulations per run in z per $\bar{D}$ value. We plot the analytical result determined for the white noise process to show that, qualitatively, the FWM products decay inversely to the noise strength $\bar{D}$. For the case of short-correlated noise in the form of an OU process, the effect of the noise on the FWM differs slightly from the white noise case (again, see Figure 3), but we again see an efficient suppression of the FWM product.

5. Summary of results and conclusions. In this manuscript, we have examined how randomness in the dispersion term affects the growth of FWM products. We have shown that in the presence of a white-noise process, the decay of the L^2-norm for the FWM products is proportional to $1/(2\Omega)^4\bar{D}$, where Ω is the frequency offset of the input pulse and $\bar{D}$ is the noise strength parameter. We have confirmed this result in two ways: (i) by the development of an analytical model that describes the FWM growth and (ii) using Monte Carlo simulations on the full NLS equation. We have also given a qualitative description for the probability distribution function associated with the FWM products for a fixed noise strength. Furthermore, we have shown that, qualitatively, these results are the same when the white-noise process is replaced by an Ornstein-Uhlenbeck process.

SPECTRUM OF A LINEARIZED AMPLITUDE EQUATION FOR ALTERNANS IN A CARDIAC FIBER*

SHU DAI† AND DAVID G. SCHAEFFER†

Abstract. Under rapid periodic pacing, cardiac cells typically undergo a period-doubling bifurcation in which action potentials of short and long duration alternate with one another. If these action potentials propagate in a fiber, the short-long alternation may suffer reversals of phase at various points along the fiber, a phenomenon called (spatially) discordant alternans. Either stationary or moving patterns are possible. Using a weak approximation, Echebarria and Karma proposed an equation to describe the spatiotemporal dynamics of small-amplitude alternans in a class of simple cardiac models, and they showed that an instability in this equation predicts the spontaneous formation of discordant alternans. To study the bifurcation, they computed the spectrum of the relevant linearized operator numerically, supplemented with partial analytical results. In the present paper we calculate this spectrum with purely analytical methods in two cases where a small parameter may be exploited: (i) small dispersion or (ii) a long fiber. From this analysis we estimate the parameter ranges in which the phase reversals of discordant alternans are stationary or moving.

1. Introduction.

Alternans, a period-doubling bifurcation of action potential durations in rapidly paced cardiac cells, has been implicated as a precursor of ventricular fibrillation [6, 5, 10, 2]. When such action potentials propagate in tissue, their short-long alternation may suffer reversals of phase; such *discordant* alternans pose even higher arrythmogenic risks. Since ventricular fibrillation accounts for 1/6 of all deaths in the USA [1, 7], great importance attaches to understanding these phenomena.

Echebarria and Karma [3] proposed a weakly nonlinear description of the one-dimensional evolution of discordant alternans in cardiac models[1] for which each action potential duration (APD) is a function of only the previous diastolic interval (DI). To set the context, suppose a cardiac fiber of length L is stimulated periodically at its $x = 0$ end, say with period B (mnemonic for basic cycle length, which has the acronym BCL). It is assumed that each stimulus successfully generates an action potential that propagates down the fiber. Let $A_k(x)$ be the duration of the kth action potential at the position x along the fiber. For slow stimulation, say $B > B_{\text{crit}}$, the propagating action potentials become identical after a transient: i.e., $\lim_{k\to\infty} A_k(x)$ exists and is independent of x. In studying pacing with $B < B_{\text{crit}}$, Echebarria and

[1] No cardiology background is required to read this paper if (1.2) is accepted as a given. An appendix, written primarily for mathematicians, reviews the context in which (1.2) arises.

Karma make the ansatz

$$A_k(x) = A_{\text{crit}} - \delta A + (-1)^k a(x,t), \tag{1.1}$$

where A_{crit} is the APD when pacing with period $B = B_{\text{crit}}$, δA is the average shortening of APD resulting from decreasing B below B_{crit}, and $a(x,t)$ is the amplitude of alternans, assumed slowly varying. Because of this slow-variation assumption, one may study the evolution of a with respect to a continuous time t that interpolates between the times $t = kB$, $k = 0, 1, 2, \ldots$, when stimuli are applied. Nondimensionalizing the time by B_{crit}, they derive the evolution equation for $a(x,t)$:

$$\partial_t a = \sigma a + \xi^2 \partial_{xx} a - w \partial_x a - \frac{1}{\Lambda} \int_0^x a(x',t)dx' - ga^3, \tag{1.2}$$

where σ is the bifurcation parameter, which is dimensionless and proportional to $B_{\text{crit}} - B$; Λ, w, and ξ are all positive parameters in units of length, which are derived from the equations of the cardiac model; and the nonlinear term $-ga^3$ limits growth after the onset of linear instability. Boundary conditions

$$\partial_x a(0,t) = 0, \quad \partial_x a(L,t) = 0 \tag{1.3}$$

are imposed on (1.2).

Of course, $a \equiv 0$ is a solution of (1.2)–(1.3), but it loses stability as σ increases. Bifurcation analysis of this equation requires knowing the eigenvalues Ω_n of the linear operator that maps a function $a(x)$ to

$$\xi^2 \partial_{xx} a - w \partial_x a - \frac{1}{\Lambda} \int_0^x a(x',t)dx', \tag{1.4}$$

subject to Neumann boundary conditions. All of these eigenvalues lie in the (stable) left-half plane. The eigenvalue(s) with the largest real part, say $\Omega_{\max}$, determines the character of the solution of (1.2) at the onset of bifurcation—a stationary pattern if $\Omega_{\max}$ is real, a moving pattern if it is complex.

In this paper we extend the results of [3] by calculating the spectrum of (1.4) with purely analytical means in two limiting cases: small dispersion and a long fiber. In particular, it follows from our analysis that in a long fiber $\Omega_{\max}$ is real if, modulo terms that are $\mathcal{O}(L^{-2})$,

$$\Lambda^{-1} \le C \frac{w^3}{\xi^4}, \tag{1.5}$$

where

$$C = \frac{1}{64}\left(71 + 17\sqrt{17}\right) \approx 2.205, \tag{1.6}$$

and $\Omega_{\max}$ is complex otherwise.

2. The eigenvalue problem.

Let us begin by nondimensionalizing (1.4). The parameters ξ, w, and Λ, like L, all have the units of length. Thus we define a set of new parameters

$$\bar{w} = w/\xi, \qquad \bar{\Lambda} = \Lambda/\xi, \qquad \bar{L} = L/\xi, \tag{2.1}$$

and (1.4) can be written as

$$\frac{d^2a}{d\bar{x}^2} - \bar{w}\frac{da}{d\bar{x}} - \bar{\Lambda}^{-1}\int_0^{\bar{x}} a(\bar{x}')d\bar{x}', \tag{2.2}$$

where $\bar{x} = x/\xi$. For further scaling, we define

$$\bar{\bar{x}} = \bar{w}\cdot\bar{x}, \qquad \bar{\bar{L}} = \bar{w}\cdot\bar{L}, \qquad \bar{\bar{\Lambda}} = \bar{\Lambda}\cdot\bar{w}^3 \tag{2.3}$$

and an operator

$$\mathscr{L} = \frac{d^2a}{d\bar{\bar{x}}^2} - \frac{da}{d\bar{\bar{x}}} - \bar{\bar{\Lambda}}^{-1}\int_0^{\bar{\bar{x}}} a(\bar{\bar{x}}')d\bar{\bar{x}}'. \tag{2.4}$$

One observes that (1.4) equals $\bar{w}^2\cdot\mathscr{L}a$.

The analysis in sections 2–4 below uses dimensionless variables, but we nonetheless *shall omit all the bars* in (2.4). Suppose that $a(x)$ is an eigenfunction of (2.4) with eigenvalue Ω: i.e.,

$$\mathscr{L}a = \Omega\, a, \quad \text{with} \quad \mathrm{a}'(0) = 0, \quad \mathrm{a}'(\mathrm{L}) = 0. \tag{2.5}$$

To eliminate the integral term in (2.4), we differentiate this equation (but not the boundary conditions (B.C.)) with respect to x to obtain

$$\begin{cases} a''' - a'' - \Lambda^{-1}a = \Omega\, a', \\ a'(0) = 0, \\ a'(L) = 0, \\ a''(0) = \Omega\, a(0). \end{cases} \tag{2.6}$$

The additional B.C. comes from evaluating the eigenvalue equation, before differentiation, at $x = 0$. A function of the form $a(x) = e^{\kappa x}$ satisfies the ODE in (2.6) if

$$\kappa^3 - \kappa^2 - \Omega\kappa - \Lambda^{-1} = 0. \tag{2.7}$$

If $\kappa_1, \kappa_2, \kappa_3$ are the roots of (2.7), then this equation may be reformulated as

$$1 = \kappa_1 + \kappa_2 + \kappa_3, \tag{2.8}$$

$$\Omega = -(\kappa_1\kappa_2 + \kappa_2\kappa_3 + \kappa_3\kappa_1), \tag{2.9}$$

$$\Lambda^{-1} = \kappa_1\kappa_2\kappa_3. \tag{2.10}$$

Assuming that the roots κ_1, κ_2, κ_3 are distinct, we seek a solution of (2.6) of the form $a(x) = \sum_1^3 C_i e^{\kappa_i x}$. The three B.C.s in (2.6) give a homogeneous linear system for the unknown coefficients C_i. For this system to possess a nontrivial solution, we need

$$\det\begin{pmatrix} \kappa_1 & \kappa_2 & \kappa_3 \\ \kappa_1 e^{\kappa_1 L} & \kappa_2 e^{\kappa_2 L} & \kappa_3 e^{\kappa_3 L} \\ \Omega - \kappa_1^2 & \Omega - \kappa_2^2 & \Omega - \kappa_3^2 \end{pmatrix} = 0. \tag{2.11}$$

Thus $\Omega \in \mathbb{C}$ is an eigenvalue of $\mathscr{L}$ if there exist a triple κ_1, κ_2, κ_3, no two of them equal, such that the four equations (2.8)$-$(2.11) are satisfied.

If $\Lambda^{-1} > 0$ so that each root κ_i is nonzero, (2.11) may be reformulated as follows. By (2.7), $\Omega - \kappa_i^2 = -\kappa_i - \Lambda^{-1}\kappa_i^{-1}$. Substituting this expression into the third row of (2.11) and manipulating the determinant, we obtain

$$\det\begin{pmatrix} 1 & 1 & 1 \\ e^{\kappa_1 L} & e^{\kappa_2 L} & e^{\kappa_3 L} \\ \kappa_1^{-2} & \kappa_2^{-2} & \kappa_3^{-2} \end{pmatrix} = 0. \tag{2.12}$$

Let us rule out possible multiple roots. First regarding a triple root, which by (2.8) must be $\kappa_1 = \kappa_2 = \kappa_3 = \frac{1}{3}$: In this case the general solution to (2.6) is of the form $a(x) = (C_0 + C_1 x + C_2 x^2)\, e^{x/3}$, and the only possible eigenvalue is $\Omega = -\frac{1}{3}$ by (2.9). Substituting $a(x)$ and Ω into (2.6), we find that there is no nontrivial solution and hence no eigenvalue. Now we assume $\kappa_1 = \kappa_2 \neq \kappa_3$ in (2.8)−(2.10), and therefore the general solution to (2.6) is $a(x) = C_1 e^{\kappa_1 x} + C_2 x e^{\kappa_1 x} + C_3 e^{\kappa_3 x}$. Inserting $a(x)$ into the boundary conditions in (2.6) and considering (2.8)−(2.10) with $\kappa_2 = \kappa_1$, we find that the existence of a nontrivial solution requires κ_1 to satisfy both of the following equations,

$$\kappa_1 L(4\kappa_1^2 - 3\kappa_1 - 1) + 2(1 - 2\kappa_1)^2 \cdot \left[e^{(1-3\kappa_1)L} - 1\right] = 0, \tag{2.13}$$

$$-2\kappa_1^3 + \kappa_1^2 = \Lambda^{-1} > 0, \tag{2.14}$$

and the possible eigenvalue is then given by

$$\Omega = 3\kappa_1^2 - 2\kappa_1. \tag{2.15}$$

Note that (2.13) only has isolated complex roots since its left-hand side is a holomorphic function. Thus (2.13)−(2.15) can provide only isolated eigenvalues in the Λ^{-1}-Ω plane, and a perturbation of the parameter Λ^{-1} will lead to the case when all κ_j's are different. So the case $\kappa_1 = \kappa_2 \neq \kappa_3$ can be obtained as limit of the case of distinct roots. In the analysis below we will see that the roots remain separated for Λ^{-1} small or L large.

3. Small dispersion:[2] $\Lambda^{-1} \ll 1$.

If $\Lambda^{-1} = 0$, then $\mathscr{L}$ has eigenvalues

$$\Omega_0^{(0)} = 0, \tag{3.1}$$

with the solution of (2.8)−(2.10) given by $\kappa_j = 0,\ 0,\ 1$, and

$$\Omega_n^{(0)} = -\frac{1}{4} - \left(\frac{\pi n}{L}\right)^2, \qquad n = 1, 2, \ldots, \tag{3.2}$$

with $\kappa_j = 0,\ \frac{1}{2} \pm \frac{in\pi}{L}$. We seek the first term in an expansion of Ω_n in powers of Λ^{-1}.

3.1. Perturbation of Ω_n, $n \geq 1$.

We prove that for Λ^{-1} small,

$$\Omega_n(\Lambda) = \Omega_n^{(0)} + \Omega_n^{(1)}\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}), \tag{3.3}$$

where $\Omega_n^{(0)}$ is given by (3.2) and

$$\Omega_n^{(1)} = -\frac{2}{1 + 4\pi^2 n^2 L^{-2}}. \tag{3.4}$$

[2] We remind the reader that in this section and the next, Λ and L, without bars, refer to the dimensionless parameters defined by (2.3).

By the implicit function theorem, we may expand the solution of (2.8)–(2.10) and (2.12) as

$$\left\{\begin{aligned} &\kappa_{1,2} = \frac{1}{2} \pm \frac{in\pi}{L} + b_{1,2}\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}),\\ &\kappa_3 = 0 + b_3\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}),\\ &\Omega_n = \Omega_n^{(0)} + \Omega_n^{(1)}\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}). \end{aligned}\right. \tag{3.5}$$

Substituting into (2.8)−(2.10), we find from the $\mathcal{O}(\Lambda^{-1})$ terms

$$\left\{\begin{aligned} &b_1 + b_2 + b_3 = 0,\\ &\Omega_n^{(1)} = -\frac{b_1+b_2}{2} + \frac{in\pi}{L}(b_1 - b_2) - b_3,\\ &b_3 = \left(\frac{1}{4} + \frac{n^2\pi^2}{L^2}\right)^{-1}. \end{aligned}\right. \tag{3.6}$$

Substituting into (2.12), we find that the leading order term $\mathcal{O}(\Lambda^2)$ vanishes identically; from the next order term $\mathcal{O}(\Lambda)$ we deduce that $b_1 = b_2$. The relation (3.4) follows from this equation and (3.6).

3.2. Perturbation of $\boldsymbol{\Omega_0}$. We prove that for Λ^{-1} small,

$$\Omega_0(\Lambda) = \Omega_0^{(1)}\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}), \tag{3.7}$$

where

$$\Omega_0^{(1)} = -\left(1 - \frac{L}{\exp(L) - 1}\right). \tag{3.8}$$

The expression analogous to (3.5) is complicated by the fact that, for $\Lambda^{-1} = 0$, $\kappa_1 = \kappa_2 = 0$ is a double root of (2.8)–(2.10). Thus we seek a Puisseux expansion

$$\left\{\begin{aligned} &\kappa_{1,2} = a_{1,2}\Lambda^{-1/2} + b_{1,2}\Lambda^{-1} + \mathcal{O}(\Lambda^{-3/2}),\\ &\kappa_3 = 1 + b_3\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}),\\ &\Omega_0 = \Omega_0^{(1)}\Lambda^{-1} + \mathcal{O}(\Lambda^{-2}). \end{aligned}\right. \tag{3.9}$$

First we substitute into (2.8)–(2.10); from the vanishing of the first two terms in the expansions we deduce

$$\left\{\begin{aligned} &a_1 + a_2 = 0,\\ &b_1 + b_2 + b_3 = 0,\\ &\Omega_0^{(1)} = -a_1a_2 - (b_1 + b_2),\\ &a_1a_2 = 1,\\ &a_1b_2 + a_2b_1 = 0. \end{aligned}\right. \tag{3.10}$$

Note that the equation $a_1 + a_2 = 0$ arises from the leading term of both (2.8) and (2.9). These equations imply that

$$\left\{\begin{aligned} &a_{1,2} = \pm i,\\ &b_2 = b_1,\\ &b_3 = -2b_1,\\ &\Omega_0^{(1)} = -1 - 2b_1. \end{aligned}\right. \tag{3.11}$$

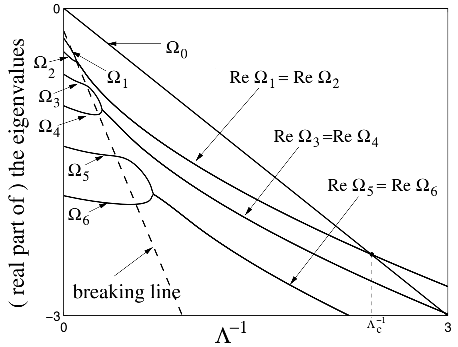

FIG. 1. *The evolution of the real parts of the first seven eigenvalues $\Omega_0, \Omega_1, \ldots, \Omega_6$ versus Λ^{-1}, assuming $L = 15$. The dashed line is the* breaking line *described in* (4.26)*, the estimate for where the eigenvalues $\Omega_1, \Omega_2, \ldots$ become complex. Λ_c^{-1} is the crossover point such that if $\Lambda^{-1} > \Lambda_c^{-1}$, the eigenvalue which has largest real part, $\Omega_{\max}$, is complex.*

Then we substitute (3.11) into the determinant (2.11). The leading term in the resulting expansion, which is $\mathcal{O}(\Lambda^{-1})$, vanishes. Requiring the $\mathcal{O}(\Lambda^{-3/2})$ term to vanish yields the claim (3.8), even though we do not yet know the b_j's.

Incidentally, if desired, the b_j's may be determined by substituting (3.4) into (3.6), yielding

$$b_1 = b_2 = -\frac{L}{2(\exp(L) - 1)} = -\frac{b_3}{2}. \tag{3.12}$$

4. A long fiber:[3] ***L* ≫ 1.** To analyze larger values of Λ^{-1}, where the expansion of section 3 loses accuracy, we need to require that $L \gg 1$. When Λ^{-1} is small, all eigenvalues are real and ordered by their index: i.e.,

$$\Omega_0 > \Omega_1 > \Omega_2 > \cdots . \tag{4.1}$$

As Λ^{-1} increases, some of the eigenvalues become complex. As this occurs we still retain the ordering

$$\text{Re } \Omega_1 \geq \text{Re } \Omega_2 > \text{Re } \Omega_3 \geq \text{Re } \Omega_4 > \text{Re } \Omega_5 > \cdots . \tag{4.2}$$

However, Ω_0 remains real,[4] and although its position in the sequence (4.2) varies with Λ^{-1}, we retain the index zero. This behavior is illustrated in Figure 1, where we have set $L = 15$.

4.1. Computation of $\mathbf{\Omega_0}$. We shall prove that, provided L is sufficiently large, the operator $\mathscr{L}$ has a real eigenvalue

$$\Omega_0 = -\Lambda^{-1} + \mathcal{O}(e^{-L}). \tag{4.3}$$

Note that this result is consistent with (3.8). Recall from section 3.2 that, in solving (2.8)–(2.10) for small nonzero Λ^{-1}, we found that $\kappa_{1,2}$ became a complex-conjugate

[3] We remind the reader that in this section, Λ and L, without bars, refer to the dimensionless parameters defined by (2.3).

[4] This statement breaks down if Λ^{-1} becomes exceedingly large, contradicting our implicit assumption that $\Lambda^{-1} \ll L$.

pair while κ_3 remained real. Thus for general Λ^{-1} we assume

$$\kappa_{1,2} = \mu \pm i\nu. \tag{4.4}$$

Then (2.8) implies

$$\kappa_3 = 1 - 2\mu. \tag{4.5}$$

We use (2.9)–(2.11) to solve for μ, ν, and Ω as follows. Dividing the middle row of (2.11) by $e^{\kappa_3 L}$, we rewrite this equation as

$$\det \begin{pmatrix} \kappa_1 & \kappa_2 & \kappa_3 \\ \kappa_1 e^{(\kappa_1 - \kappa_3)L} & \kappa_2 e^{(\kappa_2 - \kappa_3)L} & \kappa_3 \\ \Omega_0 - \kappa_1^2 & \Omega_0 - \kappa_2^2 & \Omega_0 - \kappa_3^2 \end{pmatrix} = 0. \tag{4.6}$$

Now provided

$$\mu < \frac{1}{3}, \tag{4.7}$$

we have for the 2,1- and 2,2-entries of this determinant

$$|e^{(\kappa_j - \kappa_3)L}| = e^{-(1-3\mu)L} \ll 1, \tag{4.8}$$

since $L \gg 1$. Thus neglecting these entries and recalling (4.4)–(4.5), we conclude

$$\Omega_0 = -(\mu^2 + \nu^2) + \mathcal{O}(e^{-(1-3\mu)L}). \tag{4.9}$$

On the other hand, we substitute (4.4)–(4.5) into (2.9) to find

$$\Omega_0 = -(\mu^2 + \nu^2) - 2\mu(1 - 2\mu). \tag{4.10}$$

Comparing (4.9) and (4.10), we deduce

$$\mu(1 - 2\mu) = \mathcal{O}(e^{-(1-3\mu)L}). \tag{4.11}$$

By (4.7), we have $1 - 2\mu > 1/3 > 0$, so dividing (4.11) by $1 - 2\mu$, we obtain

$$\mu = \mathcal{O}(e^{-(1-3\mu)L}). \tag{4.12}$$

Thus assumption (4.7) is consistent and, moreover,

$$\mu = \mathcal{O}(e^{-(1-3\mu)L}) = \mathcal{O}(e^{-L}). \tag{4.13}$$

Returning to (4.9), we conclude that

$$\Omega_0 = -\nu^2 + \mathcal{O}(e^{-L}). \tag{4.14}$$

But substituting (4.4)–(4.5) into (2.10) and working with (4.13), we see

$$\Lambda^{-1} = \nu^2 + \mathcal{O}(e^{-L}). \tag{4.15}$$

The claim (4.3) follows on eliminating ν from (4.14)–(4.15).

As one might expect with an exponentially small error, (4.3) agrees extremely well with the numerical results. Indeed the graph of (4.3) cannot be distinguished visually from the graph of Ω_0 in Figure 1.

Incidentally, the eigenfunction associated with Ω_0 exhibits unusual behavior for a one-dimensional eigenvalue problem—the number of its zeros or nodes changes as Λ^{-1} varies. Specifically, modulo terms that are exponentially small (outside of a boundary layer near $x = L$), the nondimensionalized eigenfunction is just $\cos(x/\sqrt{\Lambda})$.

4.2. Later eigenvalues, real case. In this subsection, we characterize a range of Λ^{-1}, as this parameter increases from 0, in which the eigenvalue Ω_n is real. Continuing the structure of the roots κ_j inherited from small Λ^{-1}, we assume

$$\kappa_{1,2} = \mu \pm i\nu \tag{4.16}$$

and invoke (2.8) to conclude

$$\kappa_3 = 1 - 2\mu. \tag{4.17}$$

We shall solve (2.12) for ν and substitute the result into (2.9)–(2.10) to obtain a parametric representation of the curve $\Omega = \Omega_n(\Lambda^{-1})$ in the Λ^{-1}, Ω-plane, with μ as the parameter. (It is not practical to solve explicitly for Ω_n as a function of Λ^{-1}.)

Let us divide the second row of the determinant (2.12) by $\exp(\mu L)$, obtaining

$$\det \begin{pmatrix} 1 & 1 & 1 \\ e^{i\nu L} & e^{-i\nu L} & e^{(1-3\mu)L} \\ \kappa_1^{-2} & \kappa_2^{-2} & \kappa_3^{-2} \end{pmatrix} = 0. \tag{4.18}$$

If

$$\mu > \frac{1}{3}, \tag{4.19}$$

then for large L we may neglect the 2, 3-entry of this determinant, so that the equation reduces to

$$e^{2i\nu L} = \frac{\kappa_2^2(\kappa_1^2 - \kappa_3^2)}{\kappa_1^2(\kappa_2^2 - \kappa_3^2)} + \mathcal{O}(e^{-(3\mu-1)L}). \tag{4.20}$$

Equation (4.20) suggests that $\nu L = \mathcal{O}(1)$ or

$$\nu = \mathcal{O}(L^{-1}). \tag{4.21}$$

Assuming this and recalling (4.19), we see that the right-hand side of (4.20) equals $1 + \mathcal{O}(L^{-1})$. Solving (4.20), we find

$$\nu = n\pi \cdot L^{-1} + \mathcal{O}(L^{-2}), \qquad n = 1, 2, \ldots, \tag{4.22}$$

confirming our assumption (4.21). On the other hand, substituting (4.16)–(4.17) into (2.8)–(2.9), we find

$$\begin{cases} \Lambda^{-1} = (1-2\mu)(\mu^2 + \nu^2), \\ \Omega_n = 3\mu^2 - 2\mu - \nu^2. \end{cases} \tag{4.23}$$

Substituting (4.22) into (4.23), we obtain the parametric representation

$$\begin{cases} \Lambda^{-1} = (1-2\mu) \cdot (\mu^2 + n^2\pi^2 L^{-2}) + \mathcal{O}(L^{-3}), \\ \Omega_n = 3\mu^2 - 2\mu - n^2\pi^2 L^{-2} + \mathcal{O}(L^{-3}). \end{cases} \tag{4.24}$$

Note from (4.24) that $\Lambda^{-1} = 0$ occurs when $\mu = 1/2$. (This may also be seen by solving (2.8)–(2.11) directly when $\Lambda^{-1} = 0$, which avoids the $\mathcal{O}(L^{-3})$ error in (4.24).) Recalling (4.19), we conclude that

$$1/3 < \mu \leq 1/2 \tag{4.25}$$

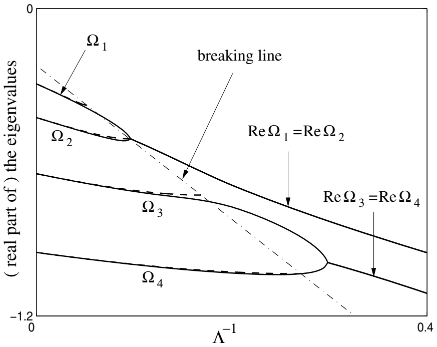

FIG. 2. *A comparison between the computations (solid lines) and the theoretical approximations given by* (4.24) *(dashed lines) of the eigenvalues* $\Omega_1, \ldots, \Omega_4$ *while they are real. The approximation terminate at the breaking line, given by* (4.26)*. The dimensionless cable length* L *is* 15.

is the relevant parameter range in (4.24). At the lower end of the range, the points (Λ^{-1}, Ω) in (4.24) all lie along the line

$$\Omega = -3\Lambda^{-1} - 2/9, \tag{4.26}$$

which we call the *breaking line*. This may be seen, avoiding the $\mathcal{O}(L^{-3})$-errors, by setting $\mu = 1/3$ in (4.23) and eliminating ν^2.

The approximations (4.24), for $n = 1, 2, 3, 4$ and for μ satisfying (4.25), are graphed in Figure 2, along with the computed eigenvalues. As the figure emphasizes, the asymptotics underlying (4.24) break down as $\mu \to 1/3$. More precisely, for μ near $1/3$, exceedingly large values of L are needed to make (4.24) accurate, and increasingly so as n becomes large.

Incidentally, note that for $\Lambda^{-1} = 0$,

$$\frac{d\,\Omega_n}{d\Lambda^{-1}} = \frac{d\,\Omega_n/d\mu}{d\Lambda^{-1}/d\mu}\Big|_{\mu=\frac{1}{2}} = -\frac{2}{1 + 4n^2\pi^2L^{-2}}, \tag{4.27}$$

which is consistent with (3.4), even without the $\mathcal{O}(L^{-3})$-errors in (4.24).

4.3. Later eigenvalues, complex case. Motivated by the numerical results, when the above asymptotics break down we look for complex eigenvalues. Let us define

$$\mu = \frac{1}{2}\ \mathrm{Re}\ (\kappa_1 + \kappa_2), \tag{4.28}$$

$$\nu = \frac{1}{2}\ \mathrm{Im}\ (\kappa_1 + \kappa_2). \tag{4.29}$$

Then

$$\kappa_{1,2} = \mu + i\nu \pm \delta, \tag{4.30}$$

where δ, possibly complex, is to be determined, and (2.8) implies that

$$\kappa_3 = 1 - 2(\mu + i\nu). \tag{4.31}$$

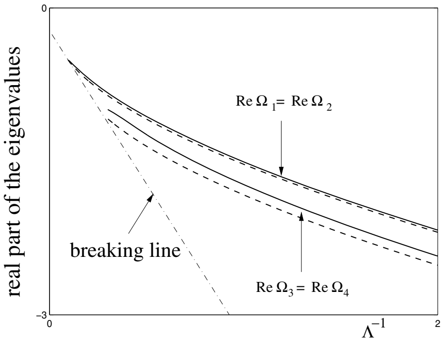

FIG. 3. *A comparison between the computations (solid lines) and the theoretical approximations given by* (4.36), (4.40) *(dashed lines) of the real parts of the eigenvalues* $\Omega_1, \ldots, \Omega_4$ *while they are complex. The dimensionless cable length* L *is* 15.

Even in the complex case, we continue to assume (4.19). Thus, asymptotically for large L, the determinant equation (2.12) may be simplified to

$$e^{2\,\delta L} = \frac{\kappa_2^2(\kappa_1^2-\kappa_3^2)}{\kappa_1^2(\kappa_2^2-\kappa_3^2)} + \mathcal{O}(e^{-(3\mu-1)L}). \tag{4.32}$$

As above, we solve (4.32) to obtain

$$\delta = in\pi\cdot L^{-1} + \mathcal{O}(L^{-2}), \quad n = 1, 2, \ldots. \tag{4.33}$$

We determine the real parameter ν from the condition that Λ^{-1} must be real: i.e., by equation (2.10)

$$\text{Im }(\kappa_1\kappa_2\kappa_3) = 0, \tag{4.34}$$

and from this we deduce that

$$\nu = \pm\Big\{\mu(3\mu-1) + n^2\pi^2L^{-2} + \mathcal{O}(L^{-3})\Big\}^{1/2}. \tag{4.35}$$

Substituting into (2.9)–(2.10), we obtain a parametric representation of Ω versus Λ^{-1}. Specifically, adjusting indices to account for the fact that (4.35) has two solutions, we find

$$\Lambda^{-1} = \mu(4\mu-1)^2 + 4\mu\cdot n^2\pi^2L^{-2} + \mathcal{O}(L^{-3}), \tag{4.36}$$

$$\Omega_{2n} = (\mu+i\nu)(3\mu+3i\nu-2) - n^2\pi^2L^{-2} + \mathcal{O}(L^{-3}), \tag{4.37}$$

$$\Omega_{2n-1} = \overline{\Omega}_{2n}, \tag{4.38}$$

where ν is given by (4.35) and

$$1/3 < \mu < \infty. \tag{4.39}$$

By substituting $\mu = 1/3$ into (4.36), (4.37) we see that these approximations terminate at the breaking line (4.26). Several of them are graphed in Figure 3, along with the computed eigenvalues. Incidentally, note that the real parts of the eigenvalues may be written more simply, without ν:

$$\text{Re }\Omega_{2n-1} = \text{Re }\Omega_{2n} = -\mu(6\mu - 1) - 4n^2\pi^2L^{-2} + \mathcal{O}(L^{-3}). \tag{4.40}$$

To explore the transition between the real and complex cases, we substitute the limiting value $\mu = 1/3$ into (4.24) and (4.36), (4.37). For the even-index eigenvalues, both the real and complex cases give same result,

$$\Lambda^{-1} = \frac{1}{27} + \frac{1}{3}\left(\frac{2n\pi}{L}\right)^2 + \mathcal{O}(L^{-3}), \tag{4.41}$$

$$\Omega_{2n} = -\frac{1}{3} - \left(\frac{2n\pi}{L}\right)^2 + \mathcal{O}(L^{-3}), \tag{4.42}$$

which of course lies on the breaking line (4.26). For odd-index eigenvalues, there is an $\mathcal{O}(L^{-2})$ jump between the results of substituting $\mu = 1/3$ into (4.24) and into (4.36), (4.37). Hints of this behavior may be seen in Figure 2—the asymptotic approximation of Ω_{2n} in the real case continues to be defined closer to the actual transition to complex eigenvalues than that of Ω_{2n-1}. Incidentally, (4.41) may be used to estimate the largest value of Λ^{-1} at which Ω_{2n-1} and Ω_{2n} are still real.

Let us relate these formulae to a result of Echebarria and Karma [4]. Invoking considerations of group velocity and bifurcation theory, those authors argue that, at the onset of instability, the complex wave number ($\kappa = \mu + i\nu$ in our notation) ought to satisfy

$$2\kappa^3 - \kappa^2 + \frac{1}{\Lambda} = 0. \tag{4.43}$$

(This relation is equivalent to their equation (56) written in our notation.) Now to leading order (4.35), (4.36) assert that

$$\nu^2 = \mu(3\mu - 1), \quad 16\mu^3 - 8\mu^2 + \mu = \Lambda^{-1}. \tag{4.44}$$

It may be checked that these two real equations are equivalent to the single complex equation (4.43). Thus we have given an independent derivation of (4.43) that does not rely on computing group velocities for waves that grow exponentially in space and that accounts explicitly for boundary conditions on a (long) finite-length cable.

5. Discussion and conclusion.

Let us summarize the asymptotic results from section 4 regarding the eigenvalues of the linear operator of (1.4), which is $\bar{w}^2\mathscr{L} = (w^2/\xi^2)\cdot\mathscr{L}$. For this task, and for the remainder of the paper, we shall undo the scaling (2.1) and (2.3) and return to the dimensional parameters. We found the following:

- Ω_0 is always real, given by

$$\Omega_0 = -\frac{\xi^2}{w\Lambda} + \mathcal{O}(e^{-wL/\xi^2}). \tag{5.1}$$

- For $n \geq 1$, Ω_n is real if Λ^{-1} is below a threshold. Equation (4.41) estimates that the threshold for Ω_{2n-1} and Ω_{2n} to become complex is

$$\frac{w^3}{27\xi^4} + \frac{w}{3}\left(\frac{2n\pi}{L}\right)^2 + \mathcal{O}(L^{-3}). \tag{5.2}$$

- In the real case, the relation between Λ^{-1} and Ω_n is given parametrically by

$$\text{(5.3)} \qquad \begin{cases} \Lambda^{-1} = \xi^{-2}(w - 2\mu\xi) \cdot (\mu^2 + n^2\pi^2\xi^2 L^{-2}) + \mathcal{O}(L^{-3}), \\ \Omega_n = 3\mu^2 - 2\mu w/\xi - n^2\pi^2\xi^2 L^{-2} + \mathcal{O}(L^{-3}), \end{cases}$$

  where $w/3\xi < \mu \leq w/2\xi$.
- In the complex case, the relation between Λ^{-1} and the real parts of Ω_{2n-1}, Ω_{2n} is given parametrically by
  (5.4)

$$\begin{cases} \Lambda^{-1} = \mu\xi^{-1}(4\mu - w/\xi)^2 + 4\mu\xi \cdot n^2\pi^2 L^{-2} + \mathcal{O}(L^{-3}), \\ \text{Re } \Omega_{2n-1} = \text{Re } \Omega_{2n} = -\mu(6\mu - w/\xi) - 4n^2\pi^2\xi^2 L^{-2} + \mathcal{O}(L^{-3}), \\ \text{Im } \Omega_{2n-1} = -\text{Im } \Omega_{2n} = 2(3\mu - w/\xi)\Big[\mu(3\mu - w/\xi) + n^2\pi^2\xi^2 L^{-2}\Big]^{1/2} + \mathcal{O}(L^{-3}), \end{cases}$$

  where $w/3\xi < \mu < \infty$.

Consider bifurcation of (1.2) from the zero solution as σ increases. An eigenvalue of the linearization crosses into the (unstable) right-half plane when $\sigma = \text{Re } \Omega_{\max}$, where $\Omega_{\max}$ is the eigenvalue of (1.4) with the (algebraically) largest real part. If Λ^{-1} is small, Ω_0 is the largest eigenvalue, its associated eigenfunction is real, and a time-independent stationary-wave solution of (1.2) appears at the bifurcation. However, Ω_0 decreases more rapidly with Λ^{-1} than later eigenvalues, which, moreover, become complex. Thus, when Λ^{-1} is sufficiently large, say $\Lambda^{-1} > \Lambda_c^{-1}$, $\Omega_{\max}$ will be complex, and time-oscillatory traveling-wave solutions will appear at the bifurcation (see [4] for more details). To estimate the crossover value Λ_c^{-1}, we consider the equation $\Omega_0 = \text{Re } \Omega_1$. Recalling (5.1), we may rewrite this equation to leading order as

$$\text{(5.5)} \qquad -\frac{\xi^2}{w\Lambda} = \text{Re } \Omega_1.$$

Substituting the first and second equations of (5.4) into the left and right sides of (5.5), respectively, we obtain the quadratic equation

$$8\mu^2 - 7(w/\xi) \cdot \mu + (w/\xi)^2 = 0$$

for the value of μ associated with the crossover. We select the root $\mu = (7+\sqrt{17})w/16\xi$ that satisfies $\mu > w/3$ and substitute into (4.36) to obtain the leading order estimate

$$\text{(5.6)} \qquad \Lambda_c^{-1} \approx \frac{71 + 17\sqrt{17}}{64} \cdot \frac{w^3}{\xi^4}.$$

By carrying $\mathcal{O}(L^{-2})$ terms in the above calculation, one may extend this estimate to next order,

$$\text{(5.7)} \qquad \Lambda_c^{-1} = \frac{w^3}{\xi^4}\left\{\frac{71 + 17\sqrt{17}}{64} + \frac{(7 + \sqrt{17})\pi^2}{2} \cdot \left(\frac{wL}{\xi^2}\right)^{-2}\right\} + \mathcal{O}(L^{-3}).$$

Figure 4 shows a comparison between the computational result for Λ_c^{-1} and theoretical approximations (5.6) and (5.7) for various (large) cable lengths L. Observe that the computational value is between the values of (5.6) and (5.7). For L smaller than shown in the figure, the graph of Λ_c^{-1} changes character. A hint of such behavior may be gleaned from the fact that the approximation (5.7) blows up as L^{-2} as L

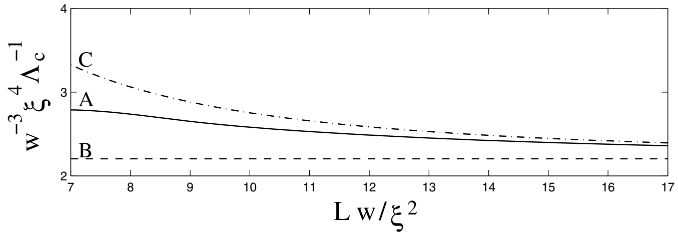

FIG. 4. *A comparison among the computational result (curve A) for Λ_c^{-1}, the theoretical leading order approximation* (5.6) *(line B), and the second order approximation* (5.7) *(curve C). The x-axis is the cable length L scaled by w/ξ^2, and y-axis is the critical value Λ_c^{-1} scaled by $w^{-3}\xi^4$. With these scalings, the curves are independent of ξ and w.*

TABLE 1

Results of two simulations: two-current model and Noble's model. w, ξ, L have units of length in cm*; Λ and Λ_c have units of inverse length in* cm^{-1}.

Name of model	w	ξ	L	Λ^{-1}	Λ_c^{-1}	Observed alternans
Two-current	0.034	0.310	25	0.206	0.011	Traveling
Noble	0.045	0.180	20	0.020	0.198	Stationary

tends to zero. We plan to investigate these phenomena more thoroughly in a future publication.

Table 1 summarizes the results of two simulations that illustrate the different behavior that occurs for $\Lambda^{-1} > \Lambda_c^{-1}$ and $\Lambda^{-1} < \Lambda_c^{-1}$. The two-current model [8], a simplified cardiac model similar in spirit to the FitzHugh–Nagumo model, is discussed in the appendix of this paper. The Noble model [9] was an early attempt to adapt a Hodgkin–Huxley-type model to cardiac cells. Because realism was attempted, this model is substantially more complicated than the two-current model. The key behavior relevant here is that the conduction-velocity curve is exceptionally flat at the critical diastolic interval, which makes $\Lambda^{-1} = 2c'/c^2$ small [3]. Simulations with the Noble model are presented in [4].

Appendix: Alternans. In this appendix we illustrate the phenomena of alternans in the context of a simple cardiac model [8], which is similar in spirit to the FitzHugh–Nagumo equation. A single heart cell in this model is described by two dimensionless functions of time, a scaled voltage v and a gate h that satisfy a set of ODEs

$$\frac{dv}{dt} = J_{\text{ion}}(v,h) + J_{\text{stim}}(t), \tag{A.1}$$

where the ionic current is

$$J_{\text{ion}}(v,h) = \frac{h}{\tau_{\text{in}}}v^2(1-v) - \frac{v}{\tau_{\text{out}}} \tag{A.2}$$

and $J_{\text{stim}}(t)$ is an external current applied repeatedly in brief pulses (cf. (A.4) below), and

$$\frac{dh}{dt} = \begin{cases} -\dfrac{h}{\tau_{\text{close}}} & \text{if } v > v_{\text{crit}}, \\[2ex] \dfrac{1-h}{\tau_{\text{open}}} & \text{if } v < v_{\text{crit}}. \end{cases} \tag{A.3}$$

Table 2
Representative values for the parameters in the two-current model.

τ_{in}	τ_{out}	τ_{open}	τ_{close}	v_{crit}	K	L
0.2ms	7ms	50ms	130ms	0.05	$0.4\ \text{cm}^2 \cdot \text{s}^{-1}$	25cm

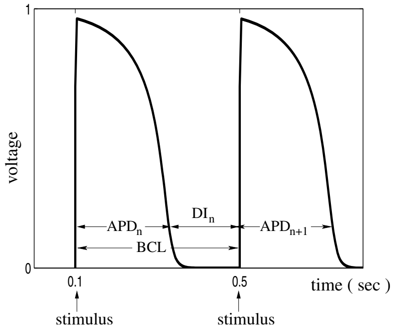

Fig. 5. *An illustration of the solution to ODE system* (A.1)–(A.3) *with parameters given in Table* 2*, assuming a periodic stimulus with period* $BCL = 400$ *ms.*

Representative values for the parameters in these equations are given in Table 2; note that K is the diffusion coefficient that appears in the PDE (A.11).

In the absence of a stimulus current, i.e., $J_{\text{stim}} = 0$, (A.1)–(A.3) have a stable equilibrium at $(v, h) = (0, 1)$. Suppose that this equilibrium is perturbed by a sequence of stimuli, applied with period B, say

$$J_{\text{stim}}(t) = \begin{cases} v_{\text{stim}}/\delta & \text{if } 0 < t < \delta \quad (\text{mod } B), \\ 0 \quad \text{otherwise}, \end{cases} \tag{A.4}$$

where $\delta \ll \tau_{\text{in}}$ and v_{stim} is not excessively small. Provided that this pacing is not too rapid, the stimuli produce action potentials as illustrated in Figure 5; i.e., each stimulus, although very brief, triggers an extended rise in the voltage, after which the voltage decays. Let the APD (A_n) and DI (D_n) be defined as in the figure; note that $A_n + D_n = B$, where B is the period or basic cycle length.

In [8] it is shown that, under the assumption

$$\tau_{\text{in}} \ll \tau_{\text{out}} \ll \tau_{\text{open}},\ \tau_{\text{close}}, \tag{A.5}$$

these variables approximately satisfy

$$A_{n+1} = F(D_n), \tag{A.6}$$

where

$$F(D_n) = \tau_{\text{close}} \ln \left\{ \frac{1 - (1 - h_{\text{min}})\, e^{-D_n/\tau_{\text{open}}}}{h_{\text{min}}} \right\}, \tag{A.7}$$

with $h_{\text{min}} = 4\tau_{\text{in}}/\tau_{\text{out}}$. Since $D_n = B - A_n$, the sequence A_n is determined by iteration of a one-dimensional map,

$$A_{n+1} = F(B - A_n). \tag{A.8}$$

Provided that B is not too small, a sequence generated by (A.8) converges to a stable fixed point $A_*(B)$. However, for B smaller than some critical value, B_{crit}, the fixed point loses its stability and we have a period-doubling bifurcation of A_n to a response called *alternans*. Let A_{crit} be the fixed point solution to (A.8) for $B = B_{\text{crit}}$, and define $D_{\text{crit}} = B_{\text{crit}} - A_{\text{crit}}$. Recognizing that $|F'(D_{\text{crit}})| = 1$ is the condition for bifurcation, we find

$$D_{\text{crit}} = \tau_{\text{open}} \ln\left\{(1 - h_{\min})\left(1 + \frac{\tau_{\text{close}}}{\tau_{\text{open}}}\right)\right\}, \tag{A.9}$$

and thus

$$A_{\text{crit}} = F(D_{\text{crit}}) = \tau_{\text{close}} \ln\left\{\frac{\tau_{\text{close}}}{(\tau_{\text{open}} + \tau_{\text{close}})h_{\min}}\right\}. \tag{A.10}$$

In a homogenized cardiac fiber, say $0 < x < L$, (A.1) is augmented by a diffusion term to obtain a PDE

$$\partial_t v = K\partial_{xx} v + J_{\text{ion}}(v, h) + J_{\text{stim}}(x, t); \tag{A.11}$$

equation (A.3) does not acquire any additional terms, but the t-derivative must be reinterpreted as a partial derivative. The stimulus current is applied locally near one end of the fiber and vanishes elsewhere. No-flux boundary conditions are imposed at both ends of the fiber:

$$\partial_x v(0, t) = \partial_x v(L, t) = 0. \tag{A.12}$$

The action potentials stimulated near $x = 0$ propagate along the fiber. The traveling speed c, or the conduction velocity (CV) of a periodic wave train, depends on the DI D,

$$c = c(D) \approx \sqrt{\frac{K \cdot h_{\text{init}}}{2\tau_{\text{in}}}}\left(1 - \frac{3h_{\min}}{4h_{\text{init}}}\right), \tag{A.13}$$

where

$$h_{\text{init}}(D) = 1 - (1 - h_{\min})e^{-D/\tau_{\text{open}}}. \tag{A.14}$$

If the BCL of the stimuli is sufficiently small (i.e., if the pacing frequency is high enough), alternans will appear along the cable.

Let $A_k(x)$ denote the duration of the kth action potential at position x. Assume that $A_k(x)$ has the form (1.1) in section 1. Echebarria and Karma [4] derived the approximate equation (1.2) to describe the evolution of the amplitude of alternans. The parameters Λ, w, ξ that appear in (1.2) are estimated by

$$\begin{cases} \Lambda^{-1} = c'/c^2, \\ w = 2K/c, \\ \xi = \sqrt{K \cdot A_{\text{crit}}}, \end{cases} \tag{A.15}$$

where c and $c' = \frac{dc}{dD}$ in (A.15) are both evaluated at the critical value $D = D_{\text{crit}}$. Note that D_{crit} and A_{crit} are given by (A.9), (A.10). Evaluating $c(D_{\text{crit}})$ by substituting

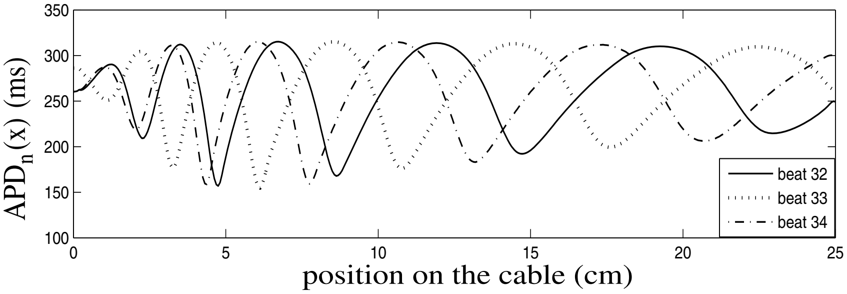

FIG. 6. *Simulation of the PDE* (A.11) *with parameters given in the Table* 2*, assuming a periodic stimulus with period $BCL = 343$ ms. The x-axis is the position on the cable, the y-axis is $A_n(x)$ for the values of n listed above. As predicted by using* (5.7)*, the pattern is propagating.*

the parameters of Table 2 into (A.13), we compute w and ξ as given in Table 1. On the other hand, by differentiating (A.13), we obtain

$$c' = \frac{dc}{dD} = \frac{1 - h_{\min}}{\tau_{\text{open}}}\sqrt{\frac{K}{2\tau_{\text{in}}}} \cdot \left(\frac{1}{2}h_{\text{init}}^{-1/2} + \frac{3}{8}h_{\min}h_{\text{init}}^{-3/2}\right)\ e^{-D/\tau_{\text{open}}}, \tag{A.16}$$

and after substituting we find Λ^{-1} as given in Table 1. The simulation shown in Figure 6 were performed on a cable of length 25 cm, which corresponds to a scaled dimensionless length of

$$\bar{\bar{L}} = wL/\xi^2 = 8.84. \tag{A.17}$$

For this length, the (dimensionless) critical value Λ_c^{-1}(computed numerically—curve A in Figure 4) equals 2.67, which in dimensional units gives the value listed in Table 1. Since $\Lambda^{-1} > \Lambda_c^{-1}$, the modulation equation predicts that alternans will appear in traveling patterns. The behavior is observed in the simulation of Figure 6, which shows $A_n(x)$ for several beats about halfway through the transient to steady state.

TRANSONIC SHOCK FORMATION IN A RAREFACTION RIEMANN PROBLEM FOR THE 2D COMPRESSIBLE EULER EQUATIONS[*]

JAMES GLIMM[†], XIAOMEI JI[‡], JIEQUAN LI[§], XIAOLIN LI[¶], PENG ZHANG[‖], TONG ZHANG[**], AND YUXI ZHENG[††]

Abstract. It is perhaps surprising for a shock wave to exist in the solution of a rarefaction Riemann problem for the compressible Euler equations in two space dimensions. We present numerical evidence and generalized characteristic analysis to establish the existence of a shock wave in such a 2D Riemann problem, defined by the interaction of four rarefaction waves. We consider both the customary configuration of waves at the right angle and also an oblique configuration for the rarefaction waves. Two distinct mechanisms for the formation of a shock wave are discovered as the angle between the waves is varied.

Key words. 2D Riemann problem, gas dynamics, shock waves, generalized characteristic analysis, front tracking method

1. Introduction.

Shock reflection in gas dynamics has long been an open problem. Two-dimensional (2D) Riemann problems have been proposed for the compressible Euler equations as a general approach to the shock reflection problem [20]. Numerical simulations for this type of data have been performed by Chang, Chen, and Yang [1, 2], Schulz-Rinne, Collins, and Glaz [17], Lax and Liu [11, 16], Kurganov and Tadmor [10], and Li, Zhang, and Yang [13], among others. General patterns of shock reflections have been revealed, some cases of which are accessible to analytical treatment.

The initial data of a general Riemann problem is constant along radial directions from an origin and is piecewise constant as a function of angle. We consider the special case with initial data of piecewise constant solutions joined by four forward rarefaction waves; see section 2. For this case, the solution was conjectured to be continuous; see [1, 2, 17, 11, 13]. From the point of view of physically motivated wave interactions, arbitrary angles between waves may be considered, and special solutions (stationary wave interactions) in general will occur at angles other than 90°; see [8]. From the point of view of defining a Riemann solution for a finite difference mesh, we might consider a variety of meshes with different angles between the cell edges. In accordance with both points of view, we consider the oblique four-wave Riemann problem. We perform refined numerical experiments, using the FronTier code developed at the AMS department of SUNY Stony Brook, and obtain resolved numerical solutions. This code uses a five point vectorized split MUSCL scheme [5] as a shock capturing algorithm. It is second order accurate for smooth solutions and first order accurate near shock waves. We solve the full compressible Euler equations in the original x, y, t coordinates, not in self-similar coordinates, so the numerics are actually very well documented in previous literature [5] and [6]. Our main result is the existence of a shock wave, established numerically by several different criteria, for a 2D Riemann problem with four rarefaction waves in both the 90° case and the oblique case. The possibility of shock formation indicates the deep sophistication of this seemingly easy problem. We formulate plausible structures for the solution via the method of generalized characteristic analysis (i.e., the analysis of characteristics, shocks, and sonic curves or the law of causality). In section 2, we formulate the problem under study and discuss an algorithm for the construction of characteristics in the numerical solutions. The existence of shock waves is established by multiple criteria used in our numerical studies to indicate the presence of shock waves. Specifically, we consider

1. plots of density and pressure on a curve through the shocks;
2. nontangential termination of characteristics at the shock front;
3. convergence of characteristics of the same family at the local shock front;
4. pattern recognition software for automated shock wave detection;
5. stability of the above criteria under mesh refinement.

In section 3, we summarize numerical results for several cases. In section 4, we study the 90° case, and in section 5, we consider the oblique case and numerically prove the convergence of very weak shock. In section 6, we present related evidence for shock formation in the case of two backward and two forward rarefaction waves. In section 7, we discuss the physical mechanism that leads to the shock formation in the present problem and summarize results testing the stability of the numerical solutions.

2. The problem formulation and its characteristic curves. We consider the Euler equations

$$\begin{aligned} &\rho_t + \nabla \cdot (\rho U) = 0, \\ &(\rho U)_t + \nabla \cdot (\rho U \otimes U) + \nabla p = 0, \\ &(\rho E)_t + \nabla \cdot ((\rho E + p)U) = 0 \end{aligned} \tag{2.1}$$

for the variables (ρ, U, E), where ρ is the density, $U = (u, v)$ is the velocity, p is the pressure, $E = \frac{1}{2}|U|^2 + e$ is the specific total energy, and e is the specific internal energy. We consider a polytropic gas with pressure p defined by the equation

$$e = \frac{p}{(\gamma - 1)\rho} \ .$$

For more details, see the books by Li, Zhang, and Yang [13] or Zheng [21].

We solve the full compressible flow equations (2.1) in the original x, y, t coordinates. Our numerical studies are based on (2.1), using the MUSCL algorithm [5] as implemented in the FronTier code. This code uses a five point vectorized split MUSCL scheme [5] as a shock capturing algorithm. It is the second order accurate for smooth solutions and the first order accurate near shock waves. Both the MUSCL algorithm and FronTier code have been extensively verified for shock capturing simulations, for example in [5] and [6]. Shock jump conditions for (2.1) can be found in standard textbooks, for example in [3]. The numerical verification of these jump conditions is addressed in section 5.

Because (2.1) and the initial data are both self-similar, the solution is also, and we introduce the self-similar coordinate system $(\xi, \eta) = (\frac{x-x_0}{t}, \frac{y-y_0}{t})$ centered at the point (x_0, y_0). In these coordinates, the system (2.1) takes the form

$$\begin{aligned} &-\xi\rho_\xi - \eta\rho_\eta + (\rho u)_\xi + (\rho v)_\eta = 0, \\ &-\xi(\rho u)_\xi - \eta(\rho u)_\eta + (\rho u^2 + p)_\xi + (\rho uv)_\eta = 0, \\ &-\xi(\rho v)_\xi - \eta(\rho v)_\eta + (\rho v^2 + p)_\eta + (\rho uv)_\xi = 0, \\ &-\xi(\rho E)_\xi - \eta(\rho E)_\eta + (\rho u(E + \tfrac{p}{\rho}))_\xi + (\rho v(E + \tfrac{p}{\rho}))_\eta = 0. \end{aligned} \tag{2.2}$$

Let $\eta = \eta(\xi)$ be a smooth discontinuity with limit states (ρ_1, u_1, v_1, p_1) and (ρ_0, u_0, v_0, p_0) on both sides. The Rankine–Hugoniot relation for (2.2) is derived in [13, pp. 218–219]. By definition, Riemann initial data is constant along radial directions from an origin (x_0, y_0) and piecewise constant as a function of angle. The initial data for (2.1) become boundary data at infinity for (2.2). We use the self-similar formulation (2.2) for the analysis of numerical solutions of (2.1). We specialize to a four-rarefaction wave Riemann problem.

As a special case we consider first the case of four rectangularly oriented waves, representing boundary conditions at infinity for the self-similar Euler equations (2.2) satisfying conditions of four forward rarefaction waves, denoted configuration A in [13, p. 237]. We next consider the case of four constant states joined by forward rarefaction waves that form angles different from 90°, as in Figure 1. Such a problem is called *an oblique four-wave Riemann problem*, in contrast to the rectangular four-wave Riemann problem discussed in [20]. Our initial data is located as indicated in Figure 1 in the initial plane:

$$(\rho, u, v, p) = (\rho_i, u_i, v_i, p_i), \quad i = 1, 2, 3, 4. \tag{2.3}$$

Let R_{ij} denote the forward rarefaction wave, which is a 1D rarefaction wave, connecting contiguously constant states (ρ_i, u_i, v_i, p_i) and (ρ_j, u_j, v_j, p_j). R_{12} is parallel to the positive y-axis, and R_{41} is parallel to the positive x-axis as before, but the angle between R_{23} and the negative x-axis is allowed to be a variable θ in $(0, \pi/4)$. To

FIG. 1. *The initial data for an oblique four-wave Riemann problem.*

simplify the analysis, we impose symmetry about the line $x = y$. We choose the angle between R_{34} and the negative y-axis to be the same θ, so that the angle between R_{23} and R_{34} is equal to $\frac{\pi}{2} - 2\theta$. Let w represent the velocity component that is perpendicular to the line of discontinuity, and w' represent the velocity component parallel to it. At an interface $(i, j) \in \{(1, 2), (2, 3), (3, 4), (4, 1)\}$, a forward planar rarefaction wave R_{ij} is described by the formula in [11],

$$w_i - w_j = \frac{2\gamma^{\frac{1}{2}}}{\gamma - 1}\left(\left(\frac{p_i}{\rho_i}\right)^{\frac{1}{2}} - \left(\frac{p_j}{\rho_j}\right)^{\frac{1}{2}}\right) , \qquad w'_i = w'_j \ , \frac{p_i}{p_j} = \left(\frac{\rho_i}{\rho_j}\right)^{\gamma} . \tag{2.4}$$

For each R_{ij}, the compatibility conditions derived from (2.4), using the normal and tangential components of $u_i, v_j, i, j = 1, 2, 3, 4$, along R_{ij}, are

$$(\rho_3^{(\gamma-1)/2} - \rho_4^{(\gamma-1)/2}) \cos\theta - (\rho_2^{(\gamma-1)/2} - \rho_3^{(\gamma-1)/2}) \sin\theta + (\rho_1^{(\gamma-1)/2} - \rho_2^{(\gamma-1)/2}) = 0; \tag{2.5}$$

$$(\rho_2^{(\gamma-1)/2} - \rho_3^{(\gamma-1)/2}) \cos\theta - (\rho_3^{(\gamma-1)/2} - \rho_4^{(\gamma-1)/2}) \sin\theta - (\rho_1^{(\gamma-1)/2} - \rho_4^{(\gamma-1)/2}) = 0. \tag{2.6}$$

We limit ourselves to the initially symmetric case $\rho_2 = \rho_4$ and $u_1 = v_1$. Then the two compatibility conditions merge to yield

$$\rho_2^{(\gamma-1)/2}(\cos\theta + \sin\theta + 1) = \rho_1^{(\gamma-1)/2} + \rho_3^{(\gamma-1)/2}(\sin\theta + \cos\theta). \tag{2.7}$$

For any fixed $\rho_1, p_1, u_1, v_1, \rho_3$, and θ, we find ρ_2 from the compatibility condition (2.7) and other initial values from (2.4) and symmetry. We consider a fixed polytropic index $\gamma = 1.4$. The computational domain is a square $[0, 1] \times [0, 1]$. We perform numerical experiments with varying Riemann initial data. We draw both families of (pseudo) characteristic curves corresponding to $\lambda_\pm$ in [13],

$$\frac{d\eta}{d\xi} = \lambda_\pm(\xi, \eta) \equiv \frac{(u - \xi)(v - \eta) \pm c[(u - \xi)^2 + (v - \eta)^2 - c^2]^{1/2}}{(u - \xi)^2 - c^2} , \tag{2.8}$$

where c is the sonic speed, $\xi = \frac{x - x_0}{T_0}$, $\eta = \frac{y - y_0}{T_0}$, T_0 is fixed, and $x_0 = y_0 = 0.5$ is the center of the computational domain. By the definition in [13], the pseudo-Mach number is

$$M = \frac{[(u - \xi)^2 + (v - \eta)^2]^{1/2}}{c} . \tag{2.9}$$

The $M = 1$ contour, as understood here, indicates both sonic points and shock points, where M jumps from a value less than 1 to a value greater than 1. The sonic curve is thus a subset of the $M = 1$ contour line. We notice $\lambda_+ = \lambda_-$ on the sonic curve.

We discuss the algorithm for characteristics. The characteristic curves starting at the top boundary of the rectangular domain belong to the family λ_+, while the characteristic curves from the right boundary of the rectangular domain belong to λ_-. To draw the $\lambda_\pm$ characteristics, we assume that the numerical solution of the Euler equations is defined on a rectangular grid. We extend this solution to the entire computational domain for a discrete time $t = T_0$, using linear interpolation. Thus $\lambda_\pm$ become globally defined functions. Starting at the the right boundary, we solve for λ_- to obtain the pseudocharacteristic curves, using the Runge–Kutta scheme. The solution for λ_- is continued up to the sonic curve. For the reflected characteristics $\lambda_\pm(\xi, \eta)$ at the sonic curve, we repeat the above processes. Since these characteristics are reflections of the previously constructed family, we use bilinear interpolation to obtain initial states at the point on the $M = 1$ contour where an incoming characteristic has terminated. We solved all singularities in the characteristic equations (2.8) numerically. Since the main point of this paper is to establish the existence of a shock wave, we list here criteria that we use for this purpose.

The most sensitive of our measures for existence of a shock wave is the fact that a shock will appear when the two families of $\lambda_\pm$ characteristics are not parallel at the $M = 1$ contour line. The existence of a point on the $M = 1$ contour line with λ_+ not parallel to λ_- contradicts (2.8) if the point is a sonic point, i.e., a point at which the solution is continuous. We thus plot $\lambda_- - \lambda_+$ versus the angle around the $M = 1$ contour, where the shock is identified as the locus of points on the contour with $\lambda_- - \lambda_+ > 0$. The end points of the shock are identified relative to figures showing characteristics.

A second test for existence of a shock is to show convergence of nearby characteristics of a common family, so that they meet on the $M = 1$ contour.

As a third test, we plot ρ versus distance along a streamline. By definition in [13], pseudostream curves satisfy $\frac{d\eta}{d\xi} = \lambda_0 = \frac{v-\eta}{u-\xi}$. The solution to (2.1) is called a compression wave if $(1, u, v) \cdot (\rho_t, \rho_x, \rho_y) > 0$; otherwise it is called an expansion wave. We notice the fact

$$(2.10) \qquad (u - \xi, v - \eta) \cdot (\partial_\xi, \partial_\eta) = t(1, u, v) \cdot (\partial_t, \partial_x, \partial_y) = t\frac{d}{dt},$$

where $\frac{d}{dt}$ is evaluated along the trajectories of gas particles in (t, x, y)-space. All pseudostream curves point to the center of the subsonic domain. Moreover, we have

$$\begin{aligned}
\frac{d\rho(\xi,\eta)}{dt} &= \frac{\partial\rho}{\partial\xi} \cdot \frac{\partial\xi}{\partial t} + \frac{\partial\rho}{\partial\eta} \cdot \frac{\partial\eta}{\partial t} \\
&= \frac{\partial\rho}{\partial\xi} \cdot \left(\frac{\partial\rho}{\partial x}\frac{dx}{dt} - \frac{x}{t^2}\right) + \frac{\partial\rho}{\partial\eta} \cdot \left(\frac{\partial\rho}{\partial y}\frac{dy}{dt} - \frac{y}{t^2}\right) \\
&= \frac{\partial\rho}{\partial\xi} \cdot \left(\frac{u}{t} - \frac{\xi}{t}\right) + \frac{\partial\rho}{\partial\eta} \cdot \left(\frac{v}{t} - \frac{\eta}{t}\right) \\
&= \frac{1}{t}\left(u - \xi, v - \eta\right) \cdot (\rho_\xi, \rho_\eta) \\
&= \frac{1}{t}\frac{d\rho(\xi,\eta)}{ds}\ ,
\end{aligned}$$

Table 1
Table of simulation cases studied in this paper.

Three cases	90°	Weakly oblique rarefaction	Oblique rarefaction
Initial conditions	$\rho_1 = 1.0, p_1 = 0.444, u_1 = v_1 = 0.0, \rho_3 = 0.15$		
θ values	$\theta = 0°$	$6° \leq \theta \leq 8°$	$\theta > 8°$
Shock case	Weak shock	Weak shock	Shock
Mesh size $\Delta x = \Delta y$	$\frac{1}{3200}, \frac{1}{1600}$	$\frac{1}{5600}, \frac{1}{3200}, \frac{1}{1600}, \frac{1}{800}$	$\frac{1}{800}$

where in the last term, $\frac{d\rho(\xi,\eta)}{ds}$ is the directional derivative of the density ρ along the pseudostream curve. According to (2.10), a positive value for this derivative indicates a compression or a shock, and a jump indicates a shock.

We also plot pressure along a ray passing through the $M = 1$ contour. A sharp jump in pressure is a sign of a possible shock.

Finally, we use the wave detection filter, or automated shock detection capability in the FronTier code, to locate shock waves in [19]. This software examines numerical discontinuities in the solutions and determines whether they correspond to a particular type of traveling wave. Such discontinuities are organized into curves, which then correspond to the location of a shock wave. The shock jump conditions are included in the Rankine–Hugoniot relation. These jump conditions are verified to confirm that the shock waves detected by the wave filter indeed satisfy the required conditions. Numerical solutions show stability of the above shock criteria under mesh refinement.

Our major point is the consistency of these tests, each reaching the same conclusion: shocks exist in the interior nonconstant domain in the 2D rarefaction Riemann problems studied here. We find two distinct mechanisms for shock formation. For the 90° case, the interaction of two rarefaction waves of the same family and parallel at infinity leads to a pressure drop larger than that due to either taken singly. Thus the interaction seems to "overrarefy," leading to low pressure states incompatible with pressures given at infinity due to the same rarefactions considered individually. A shock wave results from the joining of these high and lower pressure regions. It is the interaction of rarefaction R_{41}, R_{23}, R_{34}, and R_{12}, including the interaction of characteristics from constant states adjacent to them, which produce this result. A second mechanism arises in the case of a (sufficiently) large oblique angle between the rarefaction waves. In this case, the rarefactions R_{41} and R_{12} are reflected from the sonic curve. The sonic curve has extended ears to facilitate this reflection. The reflected wave becomes a compression and breaks into a shock at the $M = 1$ contour, at points that would otherwise be sonic but actually lie on a shock front.

3. Numerical results. We summarize our further refined numerical results in this section. We fix the computational time $T_0 = 0.375$ and let the initial values be p_1, ρ_1, $u_1 = v_1 = 0$, ρ_3 and determine all initial values with different θ. We list the cases to be considered in Table 1. We denote by $C_i(u_i, v_i, c_i)$, $i = 1, 2, 3, 4$, the sonic circles of constant states i, $i = 1, 2, 3, 4$, where u_i, v_i, $i = 1, 2, 3, 4$, are initial velocities and $c_i = \left(\frac{\gamma p_i}{\rho_i}\right)^{\frac{1}{2}}$, $i = 1, 2, 3, 4$, are initial sound speeds.

A. Weak shock case for $\theta = 0$ (90° case). The 90° case is shown in Figure 2 with results consistent with on both coarse and refined grids. The λ_--characteristic lying at the upper boundary of R_{41} coming from infinity penetrates the rarefaction wave $R_{12}(CQ)$ and continues through the constant state 2 (QR) and the rarefaction wave $R_{23}(RF)$, reaching the constant state 3, and meets the sonic circle $C_3(u_3, v_3, c_3)$ tangentially at A. See the strict proof in [13, p. 238]. The bottom boundary of R_{23} (FT) hits the $M = 1$ contour at T. The top boundary of $R_{23}(RV)$ hits the

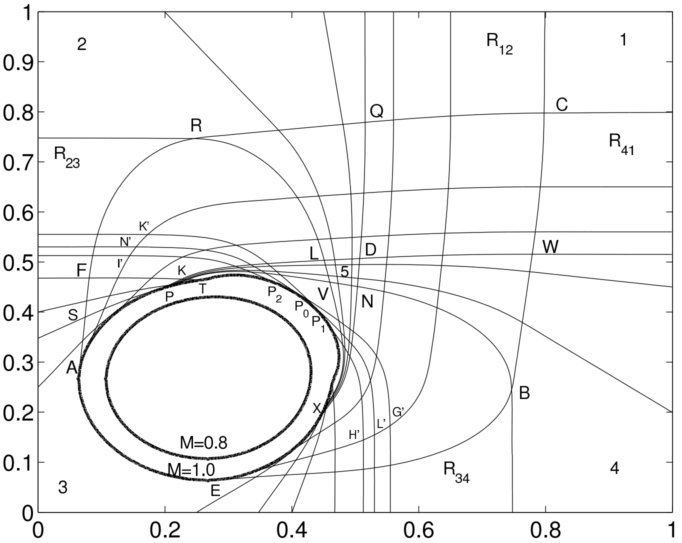

Fig. 2. *Case A: Some pseudocharacteristic curves (light) and Mach number contours (bold) marked with $M = 1.0$ and $M = 0.8$ at $\theta = 0$.*

$M = 1$ contour at X, and a weak shock appears on the larger arc AE (toward the first quadrant), where A, E are symmetric points relative to reflection about the axis $\xi = \eta$. The smaller arc AE (toward the third quadrant) is an arc of the sonic circle C_3. Numerical evidence supports weak shocks on both sides of the sonic circle. The shocks and the numerical evidence for them are stronger on the side nearer the origin. We will discuss these points in detail later.

B. Weak shock case: numerical solutions with $\theta \in [6°, 8°]$. We obtain weak shock cases for $\theta \in [6°, 8°]$. See Figures 3 and 17 for the cases $\theta = 6.5°$ and $\theta = 8°$. In Figure 3, both the upper boundaries FS of R_{41} and GS of R_{23} are parallel, tangential to the sonic curve at S. SA is tangential to the sonic circle C_3 at A, which is a reflection of the λ_+-characteristic curve GS. SK, which is the reflection of the λ_--characteristic curve FS, terminates on a shock. The weak shock appears on the arc $AT \bigcup BR \bigcup UE$, where A, E are symmetric points regarding the axis $\xi = \eta$, and the smaller arc AE is the arc of sonic circle C_3.

C. Strong shock case: numerical solutions with $\theta > 8°$. We increase the value of θ, and we observe a shock wave which is sharply defined and with little numerical oscillation. The shock wave lies in the interior, nonconstant domain between R_{23} and R_{34} and constant states adjacent to them whose structure is similar to case B. See Figure 4. Furthermore, we find that the strength of the shock wave becomes stronger as we increase θ or decrease ρ_3 while keeping the other parameters constant. The numerical oscillations between R_{23} and R_{34} attenuate or even vanish as the strength of the shock wave intensifies. In summary, numerical solutions show the existence of shock waves in the interaction of four rarefaction waves and constant states.

4. Shock formation in the 90° case. A constructive analysis of some of the major ideas of this paper is found in [7], where we study the Riemann problem for the Hamilton–Jacobi equations as a simpler problem, developing a number of ideas needed here. These equations can be regarded as a generalization of Burgers' equation to high dimensions. The analysis there follows a constructive point of view and thus

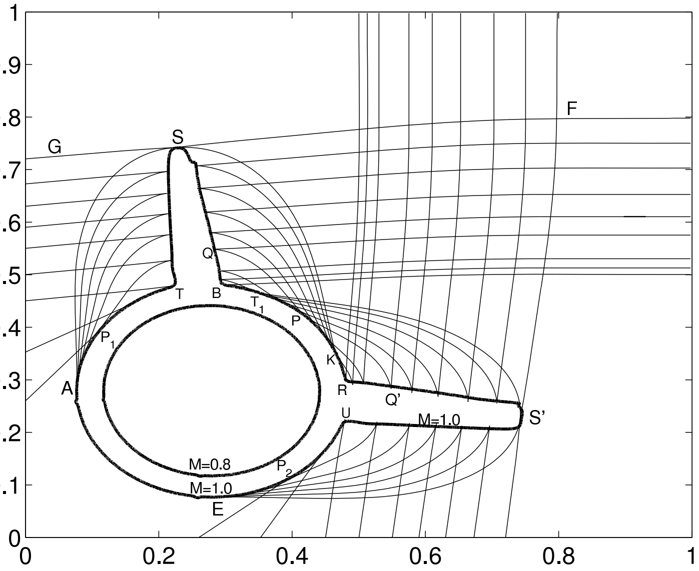

FIG. 3. *Case B: Some pseudocharacteristic curves (light) with $\theta = 6.5°$ and Mach number contours (bold) marked with $M = 1.0$ and $M = 0.8$.*

emphasizes ideas such as generalized characteristics, the propagation of the Riemann solution inward from data located at infinity, and a sonic curve as discussed in the present paper. We discuss in this section the shock formation in the 90° case. We analyze the mechanism for shock formation caused by the interaction of rarefaction waves R_{12}, R_{23}, R_{34}, and R_{41}, including the interaction of R_{41} and characteristics from constant state $3, 4, 5$ adjacent to them. We use numerical methods and generalized characteristic analysis.

4.1. A numerical study of the 90° case. In Figure 2, the characteristic WP along the bottom boundary of R_{41} meets the characteristics SP from constant state 3 at P. The intersection point P is located on the $M = 1$ contour. If P were a sonic point, then we would have $\lambda_+(P) = \lambda_-(P)$. However, we show numerically in Figures 5 and 6 that P cannot be a sonic point because the characteristics are not parallel at P. The numerical results in Figure 5 show that at the common point P of the

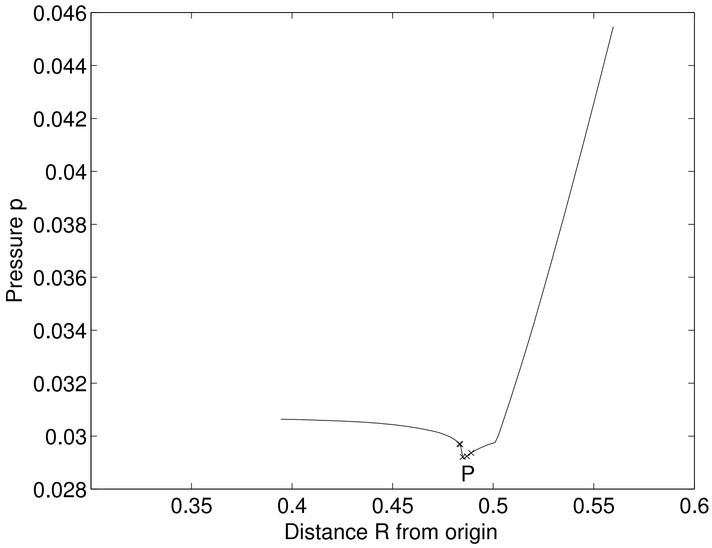

FIG. 7. *Pressure vs. distance along OP for the $90°$ case. The downward jump at the point P is a shock front. The crosses mark cell center locations near the shock front.*

two characteristic curves, $\lambda_+(P) < 0.4$, $\lambda_-(P) > 0.5$, and $\lambda_+(P) \neq \lambda_-(P)$, indicating that P is not sonic. Thus the termination of the λ_+ characteristic and the beginning of the λ_- characteristic must lie on a shock curve. We have two characteristics $N'P_0$ and $L'P_0$ meet at P_0 on $\xi = \eta$, but they are not parallel. Similarly, $G'P_2$ and $I'P_2$ meet at P_2 nontangentially, $H'P_1$ and $K'P_1$ meet at P_1 nontangentially. P_0, P_1, P_2 are located on a shock front. An enlarged view of the nontangential and nonparallel termination of the characteristic curves at the shock front is shown in Figure 6. We plot pressure versus the distance $R = (x^2 + y^2)^{\frac{1}{2}}$ along the straight line OP in Figure 7, where O is the center of subsonic domain in $[0,1] \times [0,1]$. The downward jump in the pressure is a shock front, and P is shown in Figure 2. The curve indicates that values at individual mesh points mean the shock. The crosses marked along this plot indicate pressure values at individual mesh points along the curve, in a neighborhood of the shock. They serve to show that the shock front jump is about one mesh block wide, as is typical for a numerically captured shock. In Figure 8, we represent shock strength by the difference in characteristics $\lambda_-(X) - \lambda_+(X)$ versus the angle plotted along the $M = 1$ contour to show shock existence. The angle between the ray from O and the positive x-axis is denoted by ϕ.

4.2. Generalized characteristic analysis in the 90° case. Let us recall [20]. We use the method of generalized characteristic analysis to indicate the plausible structure of the solution in the 90° case. The values imposed at infinity are given by (2.1) for the self-similar system (2.2). We first construct the solution in the far field (neighborhood of the infinity), which is comprised of four forward planar rarefaction waves R_{12}, R_{23}, R_{34}, and R_{41}, in addition to the constant states (ρ_i, u_i, v_i, p_i), $i = 1, 2, 3, 4$. We extend the four forward rarefaction waves inward from the far field till they interact, as denoted by regions in Figure 2. We find the boundary of the interaction domain, which consists of $CQRFSAEBWC$ in Figure 2, where the arc AE is an arc of sonic circle C_3 and K is the intersection point of the bottom boundaries of R_{23} and R_{41}.

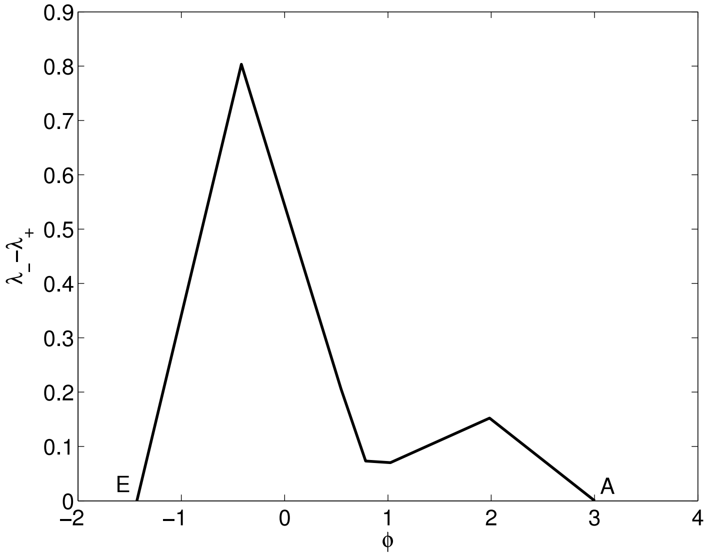

FIG. 8. *$\lambda_- - \lambda+$ vs. the angle ϕ along the $M = 1$ contour in the* 90° *case. This plot shows the shock existence; the endpoints E and A of the shock wave are as shown in Figure* 2.

Then we solve the first Goursat problem with characteristic segments CQ and CW, employing the result in [12, 15], and obtain a continuous (pseudosupersonic) solution inside the domain enclosed by the characteristic segments CQ, QD, DW, and WC. Second, we solve the Goursat problem with characteristic segments QR and QD. The solutions are still continuous in the domain $QRLD$. We continue by solving the third Gousat problem with support DL and DN. In [14], they are straight support. Then we get the continuous solutions in the domain $DLVN$. The wave R_{41} penetrates R_{12} and then R_{23} to emerge as a simple wave $RFKL$ by [14], which is adjacent to the constant state 2 and constant state 5 and located in the supersonic domain without shock wave.

We prove rigorously that two subcases possibly happen: either P_3 is greater than P_5 or P_5 is greater than P_3 in [15], where P_3 and P_5 are pressures in constant state 3 and 5. This inverted pressure profile $P_3 > P_5$ is surprising, because one would expect that pressure would be expansive in the interaction of four forward rarefaction waves. However, the inverted pressure profile is the direct result of the interaction of two waves R_{41} and R_{12}. Why is the pressure drop in the interaction region larger than the combined drop across each of the individual waves? Intuitively or based on physics, it is not easy to see whether the pressure would go up along a characteristic curve to end on a sonic point, or go down to zero to end on a vacuum. In [15], it has been proven rigorously that the pressure in the interaction region approaches zero along any characteristics, which form a hyperbolic domain determined completely by the data on the characteristic boundaries. Once the participating rarefaction waves are relatively large, the binary interaction will produce a vacuum. The pressure satisfies $P_1 > P_2 = P_4 > P_3$ and continues to drop in the simple wave interaction zone $RFKL$, which is proved in [13], to result in an even lower pressure value at K, where K is shown in Figures 2 and 6. From the numerical results, we note that the sonic boundary AP is a free boundary, as the hyperbolic domain of determinacy of the Goursat problem AFT does not include AP; see Figure 6. Thus the elliptic

region influences the solution there. Numerical results show that a global minimum for the pressure in the whole space $[0, 1] \times [0, 1]$ occurs in the domain KPT. The high pressure in the subsonic domain, adjacent to the low pressure in the neighboring domain KPT and FAT, forces the shock wave to occur.

Figures 9 and 10 show the variation of density ρ along the pseudostream curve I,

and the shock wave caused by compression waves with high pressure in the subsonic domain pushing the expansion wave in the supersonic domain. In Figure 10, s denotes the distance along the pseudostream curve.

5. Shock formation in the oblique rarefaction case.

5.1. Numerical results. In the oblique wave interaction case at $\theta = 6.5°$, two reflected characteristic curves $QP, Q'P$ in Figure 11 meet at $P|_{X=0.42}$ on the 45° diagonal line. The intersection point P is located on the $M = 1$ contour. If P were a sonic point, then we would have $\lambda_+(P) = \lambda_-(P)$. However, we show numerically in Figure 11 that P cannot be a sonic point because the characteristics are not parallel at P. At the common point P of the two plots, $\lambda_+(P) < -1$, and $\lambda_-(P) > -1, \lambda_+(P) \neq \lambda_-(P)$, indicating that P is not sonic. Thus the termination of the λ_+ characteristics and the beginning of the λ_- characteristics must be on shock. The plots for two computations, showing the level of mesh refinement, are indistinguishable. In Figure 12, we show shock strength by the difference $\lambda_-(X) - \lambda_+(X)$ in the direction of characteristics versus the angle around the $M = 1$ contour. See Figure 3 for locations of the points A, T, B, R, U, E. The plot demonstrates shock existence. The angle between the ray from O (the center of subsonic domain) and the positive x-axis is denoted by ϕ. We show further details of the nontangential termination of the characteristic curves at the shock front in Figure 13. The characteristic curves terminate nontangentially and are not parallel to each other. We find numerically that the reflected simple wave is a compressive wave and forms a weak shock. See Figure 14, where the characteristic distance denotes the "shock distance." The separation distance, i.e., the normal separation between two neighboring characteristics, is plotted versus the length along the reflected characteristics. The plot also shows the occurrence of the shock.

We plot pressure p against the distance from the origin $R = (x^2 + y^2)^{\frac{1}{2}}$ along the 45° diagonal line in Figures 15 and 16. Under refinement of the mesh, the oscillations

get weaker and the shock becomes sharper. The circles and crosses are located at mesh block centers, for cells within the shock profile. The trend of convergence of shocks in each plot in Figure 15 is clear and sufficient: the shock wave here is very weak, but its strength is not decreasing as the mesh is refined; the shock will be stable even with extremely fine meshes.

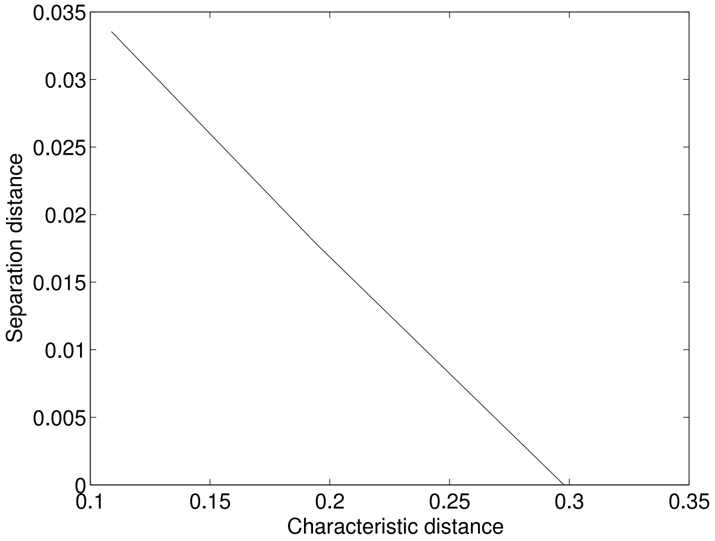

FIG. 14. *Plot of separation between neighboring characteristics vs. distance along characteristics with $\theta = 6.5^\circ$ in case B. This plot shows shock formation.*

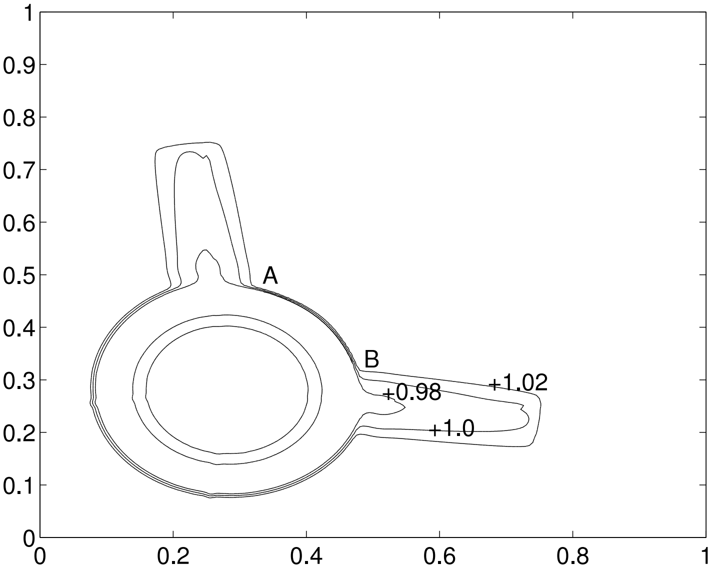

Fig. 17. *Comparison of wave filter shock location A, B and pseudo-Mach number contour plots at $\theta = 8^\circ$ with an 800×800 mesh.*

We use the wave filter embedded in the FronTier code. The wave filter is an automated pattern recognition algorithm which locates shock waves, rarefaction waves, and contact discontinuities in numerical solutions of the Euler equations for compressible fluids on the basis of detecting a local jump in the solution which satisfies the Rankine–Hugoniot relations. The shock wave as determined by this wave filter program is shown in Figure 17 by the curve AB. Note that the labeled Mach number contours $M = 0.98$ and $M = 1.02$ in Figure 17 and $M = 0.96$ and $M = 1.02$ in Figure 18 coincide on the curve AB, indicating that they are shock fronts. These curves match the pseudo-Mach number contours well.

5.2. Generalized characteristic analysis. We use the method of generalized characteristic analysis to indicate the plausible structure of the solution to our problem for $\theta > 8^\circ$ based on numerical results in section 5.1. We retain the notation from [20]. We discuss causal relationships and decompose the boundary value problem into three subproblems based on the features of the characteristics. The analysis consists of the following steps. The first is a classical rarefaction Goursat problem which has been solved analytically in [12, 15]. The second is a degenerate Goursat problem, whose solution is proved to be a simple wave in [14]. The last is a pseudotransonic boundary value problem with free boundaries consisting of interior sonic curves and shocks. The mathematical proof for the structure of this last subproblem is open. The problem involves collisions of rarefaction waves with sonic curves which produce compressive waves upon reflection, which may then form shocks. We outline the boundary of the domain of interaction for the initial four rarefaction waves in both cases above.

Step 5.2.1. *The constant states and simple waves in the far field.* As in [20], we transform problem (2.1) and (2.3) into a boundary value problem for the self-similar system (2.2) with values imposed at infinity,

$$\lim_{\xi^2+\eta^2\to\infty} (\rho, u, v, p)(\xi, \eta) = (\rho_i, u_i, v_i, p_i), \quad i = 1, 2, 3, 4, \tag{5.1}$$

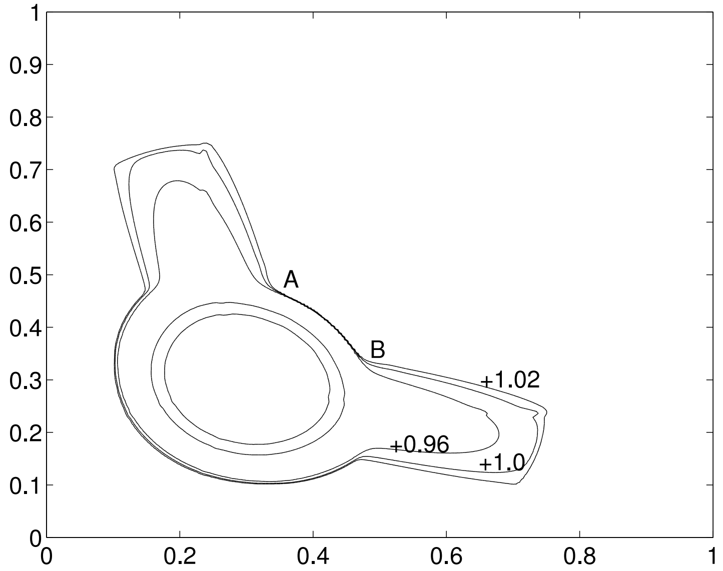

FIG. 18. *Comparison of wave filter shock location A, B and pseudo-Mach number contour plots at $\theta = 22.5^\circ$.*

in which the limiting direction is consistent with the data sector in (2.3). We first construct the solution in the far field (neighborhood of the infinity), which is comprised of four forward planar rarefaction waves R_{12}, R_{23}, R_{34}, and R_{41}, besides the constant states (ρ_i, u_i, v_i, p_i), $i = 1, 2, 3, 4$. We extend the four forward rarefaction waves inward from the far field till they interact, denoted by regions as in Figure 19. We find the boundary of the interaction domain, as in [20], which consists of the characteristic segments PQ, QR, ST, TU, $U'T'$, $T'S'$, $R'Q'$, $Q'P$ and arcs of sonic circles RS, UU', $S'R'$. See Figure 19.

Step 5.2.2. *Simple wave solutions after interaction of planar rarefaction waves.* The two rarefaction waves R_{12} and R_{41} start to interact at P. We use the result in [12, 15] to solve the Goursat problem with the boundary values supported on the characteristic curves PQ and PQ', and obtain a continuous (pseudosupersonic) solution inside the domain enclosed by the characteristic segments PQ, QP', $P'Q'$, and $Q'P$.

Then we proceed to solve the Goursat problem with the boundary data supported on QR and QP'. Since the state (ρ_2, u_2, v_2, p_2) is constant, we use the result in [14, Theorem 7]: *Adjacent to a constant state is a simple wave in which (ρ, u, v, p) are constant along a family of wave characteristics which are thus straight.* This fact indicates that the solution is a simple wave, denoted by R_{25}, in the angular domain between QR and QP'. We note that the simple wave R_{25} just covers the region of the curvilinear quadrilateral $QRWP'$ from the theory of characteristics, where RW is the λ_+-characteristic curve from the point R and can be regarded as the reflection of the λ_--characteristic curve at that point. Also note that the point R on the sonic curve C_2 is degenerate. It has the following interesting properties: It is of Tricomi type from the side of R_{25}, but of Keldysh type from the side of the constant state (ρ_2, u_2, v_2, p_2). A point on a sonic curve is said to have a Tricomi type if the characteristics are nontangential to the sonic curve. It is called Keldysh type if the characteristics are

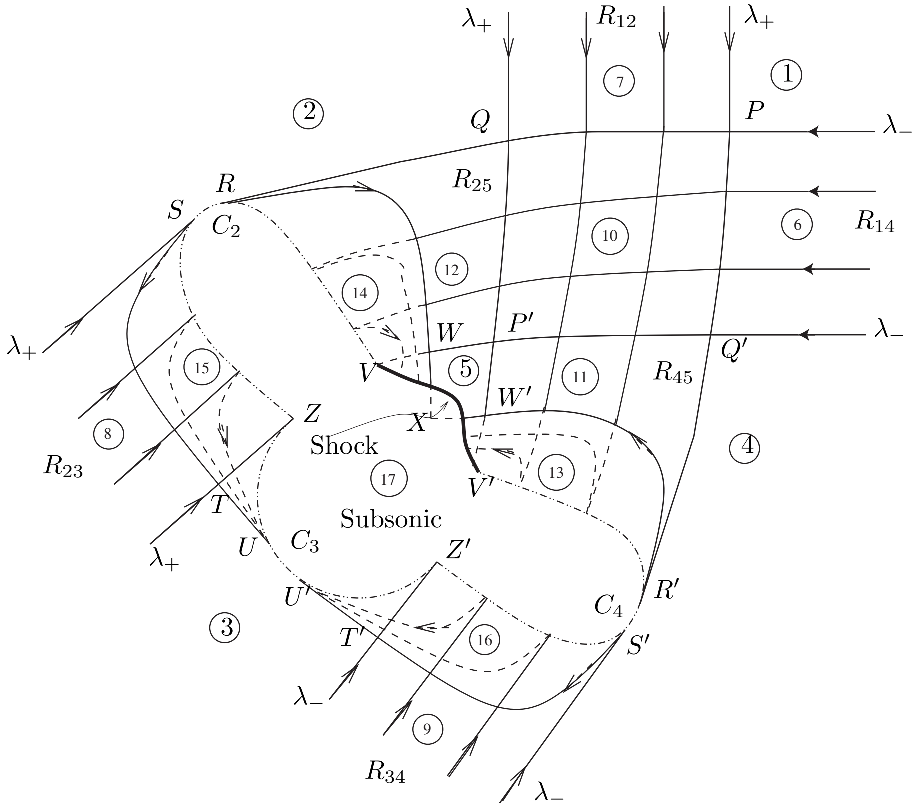

FIG. 19. *Generalized characteristic analysis for the case of four forward rarefactions in a* 2D *Riemann problem.*

tangential to the sonic curve.

We continue to solve the Goursat problem with the support of two straight characteristic curves $P'W$ and $P'W'$. Obviously, the solution is a constant state (ρ_5, u_5, v_5, p_5) with boundary $P'WXW'$. The point X must be outside the sonic circle of the state (ρ_5, u_5, v_5, p_5).

Step 5.2.3. *Plausible solution structure in intersecting supersonic regions with the transonic boundary.* After the above three Goursat problems, we reach the boundary $RWXW'R'$.

Now we consider the problem of the pseudotransonic flow with the boundary $RSTUU'T'S'R'W'XWR$. It is reasonable to assume a priori that the family of the λ_--characteristic curves of the simple wave R_{25} extends to the sonic curve RV and reflect off it as a family of λ_+-characteristic curves. Here the extension of R_{25} is not a simple wave because the solution must vary along both λ_- and λ_+ characteristics. The solution is jointly determined by the subsonic domain and the supersonic domain. These reflected λ_+-characteristic curves reach a curved boundary WV, which forms another degenerate Goursat problem with the support of a straight λ_+-characteristic line $WX$and a curved λ_--characteristic line WV. This degenerate Goursat problem has a simple wave solution whose data are on the left boundary QP' since adjacent to the WX side is the constant state (ρ_5, u_5, v_5, p_5). The numerical results indicate that this reflected simple wave is a compressive wave and forms a shock with starting

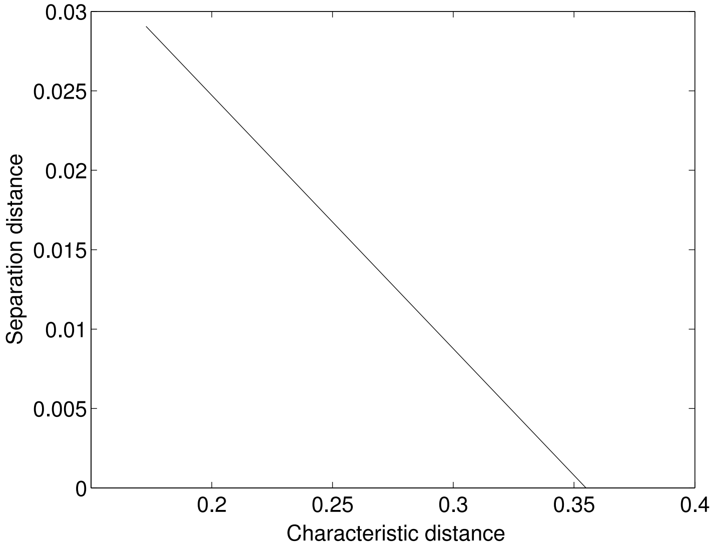

FIG. 20. *Plot of separation distance between neighboring characteristics starting on the sonic curve vs. distance along characteristics with $\theta = 22.5°$.*

point V. See Figure 20, where characteristic distance denotes the shock distance, i.e., the length of the reflected characteristics, and separation distance is the normal separation between two neighboring characteristics. This plot shows the occurrence of the shock. The shock borders the constant domain (ρ_5, u_5, v_5, p_5). By symmetry, this structure is repeated across the symmetric axis with starting point V' of another shock in the primed variables $W'V'X$.

We analyze the numerical results in Figures 21 and 22, which show the variation of density ρ along pseudostream curves I and II, presenting regions corresponding to expansion and compression waves. The arrows on the stream curves indicate the direction of particle motions. In Figure 22, the distance s denotes the distance along pseudostream curves, standing at the data beginning and ending on the pseudostream curves I and II.

The structure of the solution for the reflected characteristic curves R_{23} in Figure 19 is clarified, where the family of λ_+-characteristic curves coming from R_{23} collide with a Tricomi-type pseudosonic curve SZ and are reflected to form a weak shock wave ZU, which resembles the 90° case.

6. Shock formation for two backward and two forward rarefaction waves.

For the case of two backward and two forward rarefaction waves, there are two symmetric transonic shocks in the solution, as shown in [1, 2, 17, 11, 13]; see Figure 23. The mechanism of shock formation is the same as was discussed for the case of four forward rarefaction waves in Figure 19, because the part of Figure 23 upper-right to $\xi + \eta = u_2 + v_2$ has the same structure as that of the corresponding part of Figure 19.

7. Conclusion.

We discuss numerical simulations showing two distinct mechanisms for shock formation and supporting theoretical conjectures based on generalized characteristic analysis regarding mathematical mechanism in the 90° case and the oblique rarefaction case. We also discover that the same mathematical mechanism as in the oblique rarefaction case occurs for the shock formation for two forward and two backward rarefaction waves.

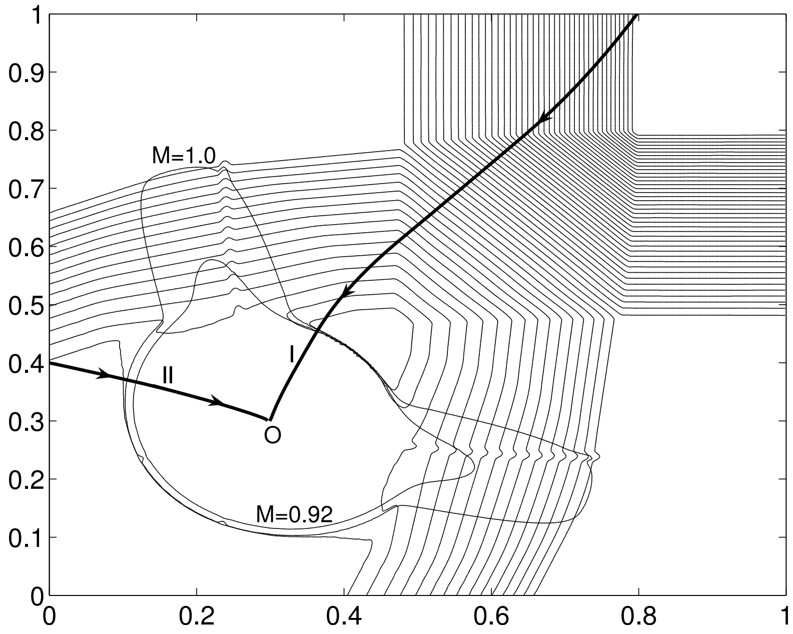

Fig. 21. *Density contours (light); two Mach contours (light) with $M = 1$, $M = 0.92$; and two pseudostream curves I, II (bold), which cut through the weak shock waves and shock waves in the neighborhood of the $M = 1$ contour shown at $\theta = 22.5°$.*

For the 90° case, the interaction of two rarefaction waves of the same family and parallel at infinity leads to a pressure drop larger than that due to enter taken singly. Thus the interaction seems to "overrarefy," leading to low pressure states incompatible with pressures given at infinity due to the same rarefactions considered individually. A shock wave results from the joining of these high and lower pressure regions. It is the interaction of rarefaction R_{41}, R_{23}, R_{34}, and R_{12}, including the interaction of R_{41} and characteristics from constant state 3 below R_{23}, which produces this result.

The shock formation for the oblique case has a possible physical mechanism similar to one found in stationary flow, which is illustrated schematically in Figure 24, associated with the numerical result in Figure 4. Basically, a rarefaction reflection reflects at a sonic boundary; the reflected wave is a compression, which may in time break and become a shock. For the steady transonic small disturbance equation, shock reflection on a sonic curve is illustrated in Cole and Cook [4]; see the shock formation over an airfoil in Figure 5.4.13, p. 314 there. The structure of shock formation from the reflection of rarefaction waves on a sonic curve was suggested by Guderly [9]; for the 2D steady irrotational isentropic flow, they put forward a concept of shock formation from reflection of characteristics on a sonic curve. When a supersonic bubble appears on the top of an airfoil in an ambient subsonic domain, a family of characteristics are generated in the bubble from the surface of the airfoil, and they hit the rear portion of the sonic curve and are reflected downstream to form a compressive wave, which then forms a shock wave within the bubble. The subsonic region plays the role of a permeable obstacle which declines streamlines towards the airfoil and causes compressive waves. This is similar to the way a concave wall does in the classical problem of supersonic flow over a smooth rigid wall. We point out

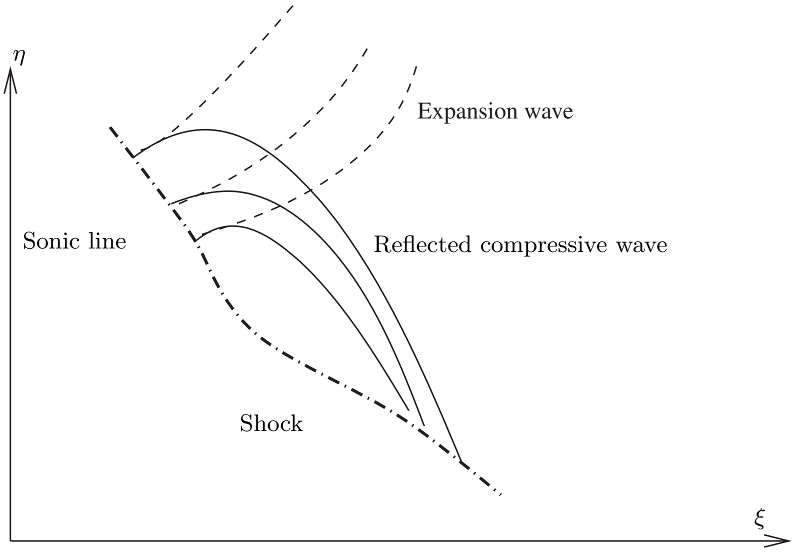

FIG. 24. *Shock formation from the reflection of rarefaction wave on a sonic curve.*

that the bump on the wall of the flow channel causes the shock formation naturally in Cole and Cook [4], where it has an important application in the study of a flow over an airplane wing. Furthermore, this formation of shocks seems to be the fundamental mechanism for the Guderly reflection pattern in Tesdall and Hunter [18].

For waves interacting with a sufficiently large oblique angle in the third quadrant, the sonic curve has an exaggerated nonconvex shape (rabbit ears). The curve extends into the rarefaction waves and interacts with them. The rarefactions are reflected as compression waves along these rabbit ears, in the sense that along this part of the sonic curve there are impinging λ_+ and λ_- characteristics. The characteristics coming from infinity are part of the rarefaction wave, while the reflected ones, as stated, are compressions. On the side facing the first quadrant, these compressions have sufficient travel distance to break and form a shock wave, centered at the 45° line, where it crosses the $M = 1$ contour. On the side facing the third quadrant, due to the angle between the waves at infinity, there is a very weak shock on this side of the $M = 1$ contour, which can be analogously interpreted in Figure 11 of [3, p. 390], where stationary flow is in nozzles and jets. Very likely these characteristics would have an envelope if they were not intercepted by a shock front. To prevent the envelope singularity, an "intercepting" shock is therefore necessary. The reason for the reflected wave to be a compression is illustrated by similarity to a related problem in aerodynamics, as discussed in the literature and explained in [4] and [9].

The Riemann problem is typically unstable in that it is a locus of bifurcation for the Riemann data. Even in one dimension, the isolated jump discontinuity holds only at time zero and (for gas dynamics) the solution at all positive times has three traveling waves.

However, it is stable in the sense of preservation of structure upon variation of initial (Riemann) conditions. In this sense, our analysis deals with representative variation of the initial conditions but does not explore the complete 7D space of nearby initial conditions numerically. This numerical stability analysis was conducted for the full Euler equations (2.1) rather than for the self-similar equations (2.2). No non–

self-similar solutions were observed in the variations of initial data. We have studied systematically a variation of the angle between two of the four initial rarefaction waves. As this angle is modified sufficiently, we find a jump to a new solution branch, with a distinct mechanism (in a detailed sense) for the shock formation. Although it is conceptually possible to allow an arbitrary number of waves, at arbitrary angles in the 2D Riemann problem formulation, the case of four waves is the case most commonly considered.

Acknowledgment. Discussions with John Hunter and Wancheng Sheng were very helpful.

FILTERS. THE NUMBER OF CHANNELS THAT CAN CLOG IN A NETWORK*

GUIDO KAMPEL† AND GUILLERMO H. GOLDSZTEIN†

Abstract. We model filters as two-dimensional networks of channels. As a suspension (fluid with particles) flows through the filter, particles clog channels. We assume that there is no flow through clogged channels. In this paper, we compute a sharp upper bound on the number of channels that can clog before fluid can no longer flow through the filter.

Key words. filters, porous media, networks, clogging, planar graphs, Euler formula

1. Introduction.

A porous medium is a material that contains relatively small spaces filled with fluid embedded in a solid matrix. These fluid-filled spaces are called pores. A porous material is said to be permeable if fluid can flow through its pores from one end to an opposite end of the material. Filters are examples of porous materials.

Fluid suspensions (or suspensions, for short) are fluids with small solid particles in them. According to their size and properties, these particles are called fines or colloids. As a suspension flows through a permeable porous material, some fines are trapped within the material. In fact, the function of the filters we consider in this paper is to *clean* suspensions by capturing most particles bigger than a certain size.

The removal of particles from fluid suspensions is of importance in a wide range of industrial and technological applications such as waste water treatment [18] and other filtration processes [4, 31]. Our studies are motivated by the filters used in the process known as deep bed filtration. As a suspension flows through a filter composed of granular or fibrous materials, fines or colloidal particles penetrate the filter and deposit at various depths [32]. As a result, the fluid suspension is cleaner when it exits the filter (i.e., it exits the filter with many fewer solid particles than it originally had when it entered the filter).

Theoretical models to study transport in porous media can be classified as either macro-scale [5, 15, 22, 23, 24, 26, 32] or pore-scale [9, 19, 28] models. Within the latter group, the class of network models, in which the pore space is modeled as a network of channels, is very popular. Network models provide flexibility in modeling different geometries of pore space while keeping the computational cost low. Our work belongs to this class of models.

Network models to study transport in porous media were introduced by Fatt in 1956 [10, 11, 12]. Donaldson, Baker, and Carrol in 1977 [8] were the first to use networks to study particle transport within porous media. The clogging of particles has been studied in networks with different geometries including bundles of parallel tubes [8], square networks [14, 16, 21], triangular networks [3, 25], cubic networks

[2, 17, 29], bubble models [6, 20], and the so-called three-dimensional physically representative networks [1, 30].

Consider a filter that is a network of channels. As a suspension flows through the filter, particles clog channels. Assume that the suspension cannot flow through clogged channels. In this work, channels that are not clogged are called open. Note that there can be flow only through channels that are part of a percolating path of open channels, i.e., a path of channels that are not clogged connecting one side of the filter with the opposite side. As channels clog, some percolating paths of open channels are broken. Thus, suspension stops flowing not only through the clogged channels, but also through other channels, i.e., those that are no longer part of a percolating path of open channels. Thus, the filter will stop being permeable after not all, but only a number, of its channels clog. In this paper we find an upper bound of this number. Our upper bound is a function of the geometry of the network. In particular, we are able to identify the filter geometries for which the largest fraction of channels may be clogged before the filter ceases to be permeable. Our results suggest that filters with these geometries may have longer lives than others.

Our work is novel. Most of the work that can be found in the literature consists of simulations of the suspension dynamics within the medium. Our work is an analysis that is independent of the dynamics; it depends only on the topology of the network. On the other hand, our work has connections to, but also key differences from, the theory of bond percolation [13, 27]. In percolation theory, channels or edges are removed randomly and independently of each other. Here, channels clog, but neither randomly nor independently of each other; the order in which they clog is important. Nevertheless, we are able to use graph theory techniques that are also used in percolation theory.

We remark that in this paper we assume the porous media to be two-dimensional. Extensions to three-dimensional media, which could lead to results more relevant to real applications, are currently being pursued and will be presented elsewhere. We also acknowledge that our work ignores the dynamics and does not resolve the mechanisms of clogging, which would involve a variable flow-field, drag forces, and particle-solid interaction forces that are all part of a well-developed filtration theory.

This paper is organized as follows. In section 2, we describe the filters as networks. In section 3, we review the basics of graph theory that are needed in the rest of this paper. In section 4, we obtain our upper bound. In section 5, we show that our upper bound is sharp. In section 6, we consider large filters and obtain an alternative description of our bound in terms of the average degree of the network. In section 7, we consider a special class of filters for which our bound is realized. In section 7, we also consider some examples and obtain some conclusions.

2. The model.

We model filters as two-dimensional networks of channels as we illustrate in Figure 1. The pores are the interiors of the channels. Our filters have a bottom boundary at $y = y_b$ and a top boundary at $y = y_t$.

In our model, channels are either open or clogged. Suspension can flow only through open channels. There is no flow through clogged channels. Within an open channel, suspension flows from the end with higher pressure to the opposite end. If both ends are at the same pressure, there is no flow within the channel.

We assume that suspension can flow into the filter only through the bottom boundary and can flow out of the filter only through the top boundary. Both fluid and particles are incompressible, and thus a volume of suspension enters the filter through the bottom boundary at the same rate it exits the filter through the top boundary.

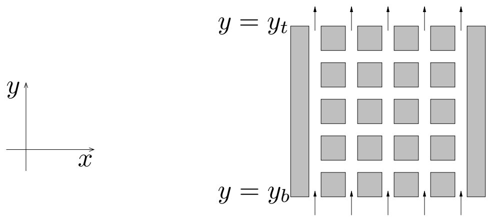

Fig. 1. *As illustrated in the left figure, we use the standard notation of x-axis and y-axis for the horizontal and vertical axes, respectively. The right figure shows a network of channels. The arrows indicate the direction of the flow.*

We assume that the bottom boundary is held at constant pressure $p = p_b$ and the top boundary at $p = p_t$, where $p_b > p_t$. Note that the filter is permeable if and only if there is a path of open channels connecting the bottom boundary with the top boundary. Due to the difference in pressure between the top and bottom boundaries, there is flow through the filter if and only if the filter is permeable.

We assume that initially all the channels are open. As suspension flows through the filter, particles are trapped, causing channels to clog; i.e., channels change from open to clogged. Eventually, the filter is no longer permeable. Note that an open channel can clog only if there is flow through it. For any given filter, we will find an upper bound on the number of channels that may clog under the assumption that different channels do not clog simultaneously.

Assumptions 2.1. *For future reference, we list here the key assumptions of our model:*

1. *Channels are either open or clogged.*
2. *There is no flow through clogged channels.*
3. *Suspension can only flow into the filter through the bottom boundary and out of the filter through the top boundary.*
4. *Fluid and particles are incompressible.*
5. *Initially all the channels are open.*
6. *An open channel may clog if there is flow through it.*
7. *An open channel does not clog if there is no flow through it.*
8. *Different channels do not clog simultaneously.*

3. Review of concepts in graph theory.

In this section we review concepts of graph theory that we need in the rest of the paper. More details on graph theory can be found in [7].

A *graph G* consists of a nonempty set of elements, called *vertices* or *nodes*, and a list of unordered pairs of these elements, called *edges*. It is convenient and a common practice to draw graphs in the plane. Each node is a different point in the plane, and each edge a line joining its two nodes without intersecting any other node. If e is an edge joining the two nodes a and b, we say that a and b are the end points of e and that e connects a and b. For convenience we take e (the drawing of e really) to be a closed set; i.e., e includes its end points. If $a = b$, i.e., the end points of an edge e are the same, we say that e is a loop. In a graph, two different edges do not have the same pair of end points. We have a *multigraph* when this restriction is removed; i.e., in a multigraph, two different edges can have the same end points.

We say that two nodes a and b are connected if there exists a sequence of nodes $n_0, n_1, \ldots, n_k$ such that $a = n_0$, $b = n_k$ and for each $1 \leq i \leq k$ there exists an edge e_i

that connects n_{i-1} and n_i. In this case, the alternating sequence of nodes and edges $n_0, e_1, n_1, e_2, n_2, \dots, e_k, n_k$ forms a *walk* between a and b or simply a *walk*. We say that $a = n_0$ and $b = n_k$ are the end points of the walk. If $n_i \neq n_j$ for all $i \neq j$, we say that the walk is a *path*. If $n_0 = n_k$ and $n_i \neq n_j$ for $i < j$ except when $(i, j) = (0, k)$, we say that the walk is a *cycle*. We will identify each walk with the curve in the plane formed by its edges.

Let G be a multigraph. S is a *submultigraph* of G if S is a multigraph and S is included in G, i.e., every node of S is also a node of G and every edge of S is also an edge of G.

A multigraph is *connected* if there is a walk between any pair of its nodes, and *disconnected* otherwise. Every multigraph is the disjoint union of connected submultigraphs. Each of these submultigraphs is called a *connected component* of the multigraph.

A multigraph is *planar* if it can be drawn in the plane in such a way that any two different edges may intersect at only one or two of their end points. Any such drawing is a *plane drawing* of the multigraph. In this paper we will need to consider only planar multigraphs. We identify each planar multigraph with one of its plane drawings. In the rest of this paper, any multigraph that we mention or consider is a planar multigraph.

A multigraph divides the plane into regions called *faces*. More precisely, the faces are the connected components of what is left from the plane once we remove the multigraph from the plane. In other words, the faces are the connected components of the set of points in the plane that do not belong to any edge of the multigraph. Note that the faces are open sets. Any finite multigraph has an unbounded face surrounding it, called the *infinity face*.

Note that the boundary of any bounded face contains a cycle. Thus, a connected multigraph with no cycles has only one face, the infinity face.

Let G be a multigraph. We denote by n_G its number of nodes, by e_G its number of edges, by f_G its number of faces, and by ℓ_G its number of connected components. The well-known *Euler formula* states that

$$n_G + f_G = e_G + \ell_G + 1. \tag{3.1}$$

The degree of a node n, which we denote by d_n, is the number of edges that have n as an end point, where the loops are counted twice. The average degree of a multigraph G, which we denote by d_G, is defined as the average of the degrees of the nodes of G, $d_G = n_G^{-1} \sum d_n$, where the sum is over all nodes n and n_G is the number of nodes of G. Note that

$$d_G = 2\frac{e_G}{n_G}, \tag{3.2}$$

where e_G is the number of edges of G. An example of a multigraph that is actually a graph is shown in Figure 2.

4. Upper bound on the number of clogged channels.

4.1. Microstructure of the filters. To each filter we associate a multigraph in a natural way. The edges are the channels and the nodes the end points of the edges.

Recall that the bottom and top boundaries of the filter are located at $y = y_b$ and $y = y_t$, respectively. Thus, the multigraph is included in $y_b \leq y \leq y_t$. Note that there

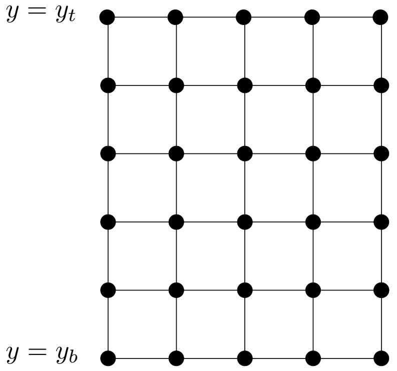

FIG. 2. *Multigraph G. The black small circles are the nodes of the multigraph G and the solid lines its edges.*

are nodes in the bottom and top boundaries. For convenience, we also include edges in $y = y_b$ connecting the nodes in the bottom boundary. In other words, there is a path of edges in $y = y_b$ connecting the leftmost node in the bottom boundary with the rightmost node in that boundary. Analogously, we include edges in $y = y_t$ so that there is a path of edges in $y = y_t$ connecting the leftmost node in the top boundary with the rightmost node in that boundary.

We consider filters with a finite number of channels, and thus our multigraphs are finite multigraphs; i.e., they contain a finite number of nodes and edges. As an example, in Figure 2 we show the multigraph G associated with the filter of Figure 1.

DEFINITION 4.1. *We say that a node is an exterior node if it is located at $y = y_b$ or $y = y_t$. Otherwise, we say that the node is an interior node.*

We also say that an edge is an exterior edge if it is included in $\{y = y_b\} \cup \{y = y_t\}$. Otherwise, we say that the edge is an interior edge.

Note that, by construction, each exterior node is the end point of at least one interior edge.

4.2. Clogged edges. The suspension enters the network through exterior nodes at $y = y_b$ and exits the network through exterior nodes at $y = y_t$.

We say that an edge is clogged if the corresponding channel is clogged. Note that the exterior edges were included for convenience; they do not correspond to any channel. Thus, we assume that there is no flow within them and that they never clog; i.e., they are always open.

As we said in section 2, we assume that initially all the edges are open and that, as suspension flows through the filter, edges clog, but different edges do not clog simultaneously.

We study our filter at a fixed time. In other words, when we say that an edge is clogged, we mean that the edge is clogged at that fixed time. Analogously, when we say that an edge is open, we mean open at that fixed time.

4.3. Mass conservation. In this subsection we introduce a definition and an observation that we will need later in the paper. This observation is a consequence of the law of mass conservation. Here, as in the rest of this section, G is a fixed multigraph that corresponds to one of our filters, such as the one in Figure 2.

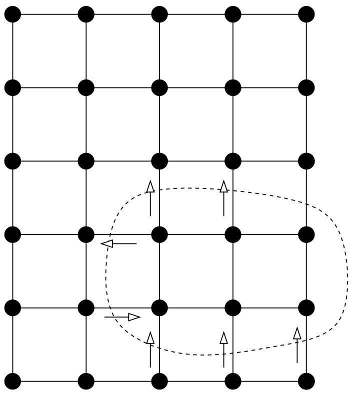

FIG. 3. *Ω is the bounded open set whose boundary, $\partial\Omega$, is in dashed lines. An arrow next to an edge that intersects $\partial\Omega$ indicates the direction of the flow within that edge. No arrow next to an edge that intersects $\partial\Omega$ indicates that there is not flow through that edge. E_Ω^{in} is the set of edges that have arrows next to them pointing into Ω. E_Ω^{out} is the set of edges that have arrows next to them pointing out of Ω.*

DEFINITION 4.2. *Let Ω be an open bounded set of $\mathbb{R}^2$ such that $\bar{\Omega}$, the closure of Ω, does not intersect any exterior edge of G, and $\partial\Omega$, the boundary of Ω, does not contain any node of G. We define*

$$E_\Omega = \{\textit{edges in } G \textit{ with exactly one end point in } \Omega\}, \tag{4.1}$$

$$E_\Omega^{\mathrm{in}} = \{e \in E_\Omega : \textit{suspension flows through } e \textit{ into } \Omega\}, \tag{4.2}$$

and

$$E_\Omega^{\mathrm{out}} = \{e \in E_\Omega : \textit{suspension flows through } e \textit{ out of } \Omega\}. \tag{4.3}$$

In Figure 3 we illustrate these definitions.

Since there may be some edges without flow through them, the union of E_Ω^{in} and E_Ω^{out} need not be E_Ω. In particular, clogged edges in E_Ω are neither in E_Ω^{in} nor in E_Ω^{out}. Note that there may also be open edges E_Ω without flow through them. Thus, there may be open edges in E_Ω that are in neither E_Ω^{in} nor E_Ω^{out}. Note also that E_Ω^{in} and E_Ω^{out} are disjoint sets.

OBSERVATION 4.1. *Let Ω be an open bounded set of $\mathbb{R}^2$ such that $\bar{\Omega}$ does not intersect any of the exterior edges of G and $\partial\Omega$ does not contain any node of G. Then we have the following:*

1. *The rate at which suspension flows into Ω through the edges in E_Ω^{in} is equal to the rate at which suspension flows out of Ω through the edges in E_Ω^{out}.*
2. *Let $e \in E_\Omega$. If all the other edges in E_Ω are clogged, then there is no flow through e.*
3. *If E_Ω is not empty, then at least one of the edges in E_Ω is not clogged.*

Proof. Suspension can flow into the filter only through its bottom boundary (i.e., the exterior nodes at $y = y_b$) and out of the filter only through its top boundary. Thus, since Ω does not contain any of the exterior nodes, there are neither mass sources nor mass sinks within Ω. This, together with the fact that the suspension is incompressible, implies point 1.

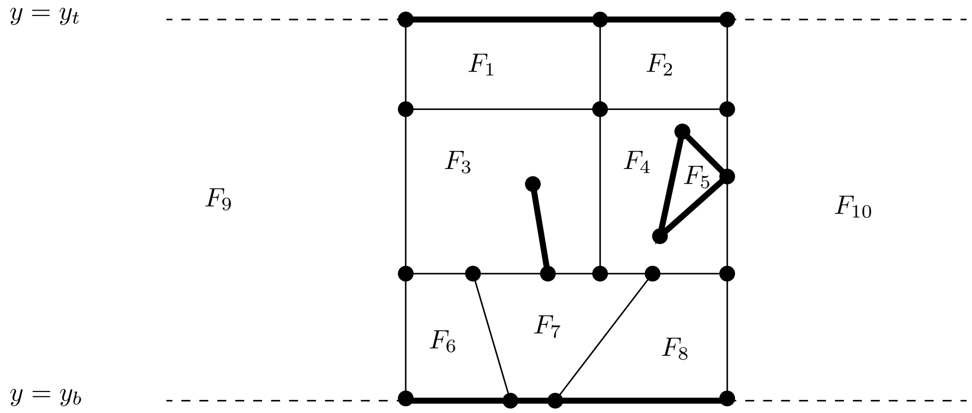

FIG. 4. *Example of a multigraph G. The edges of G are the thin and thick solid lines. The dashed lines are not part of G. F_i ($1 \leq i \leq 10$) are the connected components of $\{y_b < y < y_t\} - G$. The edges in thick solid lines are not contained in any percolating path. The edges in thin solid lines are contained in percolating paths. There can be flow only through the thin edges.*

Let e be an edge in E_Ω. If there is flow through e into Ω, point 1 implies that there should be flow out of Ω through some edge in E_Ω other than e. This is a contradiction since all the edges in E_Ω other than e are clogged. Thus, there is no flow through e into Ω. A similar argument shows that there is no flow through e out of Ω either, which proves point 2.

We prove point 3 by contradiction. Assume that all the edges in E_Ω are clogged. Let e be the edge in E_Ω that clogged last. Once the other edges were clogged, there was no more flow through e, and thus e could not have clogged, because our model assumes that an open edge does not clog if there is no flow through the edge. □

4.4. $C^\star$, a multigraph associated with the clogged edges. In this subsection we construct a multigraph $C^\star$ that is associated with the set of clogged edges.

We first note that the bounded connected components of the set $\{y_b < y < y_t\} - G$ are the bounded faces of G. In addition, $\{y_b < y < y_t\} - G$ has two unbounded connected components, one to the left of G and the other to its right. An example is shown in Figure 4, where the edges of G are the thin and thick solid lines. The dashed lines are not part of G. F_i ($1 \leq i \leq 10$) are the connected components of $\{y_b < y < y_t\} - G$. While F_i for $1 \leq i \leq 8$ are the bounded faces of G, F_9 and F_{10} are not faces of G.

Before proceeding with the construction of $C^\star$ we first need some preliminary definitions and observations.

DEFINITION 4.3. *We say that a path $P = n_0, e_1, n_1, \ldots, e_r, n_r$ in G is a percolating path if n_0 is a bottom exterior node, n_r is a top exterior node, and $n_1, \ldots, n_{r-1}$ are interior nodes.*

OBSERVATION 4.2. *Let e be an edge in G. If there is no percolating path that contains e, then e never clogs.*

The claim of Observation 4.2 is illustrated in Figure 4. Let e be an edge of G. If there is no percolating path that contains e, then the pressures at the end points of e are equal, which implies that there is no flow through e, and thus e can never clog.

Note that all percolating paths split the strip $\{y_b \leq y \leq y_t\}$ into two connected components, one to the right of the path and the other to its left.

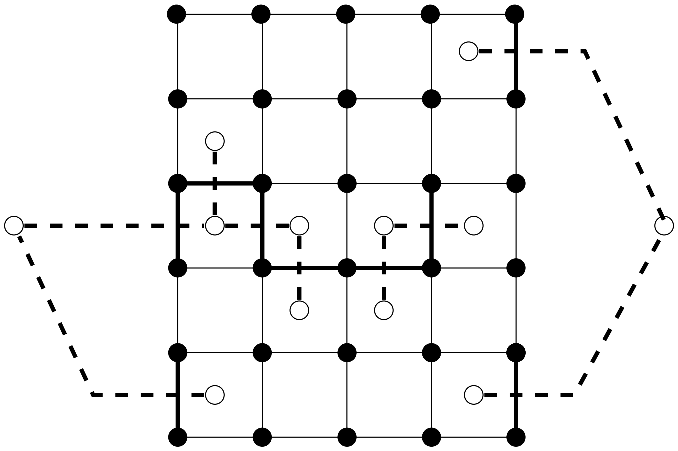

Fig. 5. *The clogged edges are thick solid lines. The open edges are in thin solid lines. The thick dashed lines are the edges in $C^\star$. The white circles are the nodes of $C^\star$.*

Definition 4.4. *Let P be a percolating path. We say that a set S is to the right of P if S is included in the closure of the right connected component of $\{y_b \leq y \leq y_t\} - P$. Analogously, S is to the left of P if S is included in the closure of the left connected component of $\{y_b \leq y \leq y_t\} - P$.*

For example, the set F_{10} in Figure 4 is to the right of any percolating path of the graph of that figure.

Observation 4.3. *Let P be a percolating path and F a connected component of $\{y_b < y < y_t\} - G$. Then F is either to the right of P or to the left of P.*

While obvious, the last observation leads to the next one that will be key in our construction of $C^\star$.

Observation 4.4. *Let e be an edge in G. If there is a percolating path that contains e, then e is in the boundary of two connected components of $\{y_b < y < y_t\} - G$.*

We are now ready to start our construction of a drawing of $C^\star$.

Select a point inside each connected component of the set $\{y_b < y < y_t\} - G$. We call this set of points $\mathcal{N}^\star$.

For each edge of G that is clogged, we draw exactly one edge of $C^\star$ as follows. Let e be a clogged edge of G. Observations 4.2 and 4.4 imply that e is included in the boundary of two connected components of $\{y_b < y < y_t\} - G$. Let $a^\star$ and $b^\star$ be the points of $\mathcal{N}^\star$ that are included in these components. We draw exactly one edge $e^\star$ of $C^\star$ connecting $a^\star$ and $b^\star$ in such a way that $e^\star$ intersects e in exactly one point, $e^\star$ does not intersect any other edge of G, and $e^\star \in \{y_b < y < y_t\}$. We say that $e^\star$ is the edge of $C^\star$ associated with e. This construction is carried out in such a way that edges of $C^\star$ may intersect only at their end points. The nodes of $C^\star$ are the end points of the edges in $C^\star$. Note that the set of nodes of $C^\star$ is a subset of $\mathcal{N}^\star$.

In Figure 5 we show an example of a set of clogged edges and the associated $C^\star$. The clogged edges are the thick solid lines, and the edges of $C^\star$ are the dashed lines. The white circles are the nodes of $C^\star$.

4.5. Bounding the number of clogged edges. The next sequence of observations will allow us to bound the number of clogged edges.

Observation 4.5. *The number of clogged edges is equal to the number of edges in $C^\star$.*

This last observation is an immediate consequence of the definition of $C^\star$.

Observation 4.6. *$C^\star$ does not have any bounded faces.*

Proof. The proof proceeds by contradiction. Assume that Ω is a bounded face of $C^\star$. From the definition of $C^\star$, the edges of G that intersect $C^\star$ are clogged. Thus, all the edges of G that intersect $\partial\Omega$ are clogged. Note also that $\bar{\Omega}$, the closure of Ω, does not intersect any of the exterior edges of G; $\partial\Omega$, the boundary of Ω, does not contain any node of G; and the number of edges of G that intersect $\partial\Omega$ is positive.

The above paragraph is in contradiction of point 3 of Observation 4.1. Thus, $C^\star$ does not have any bounded faces. □

As a consequence, the only face of $C^\star$ is its unbounded face. Thus, we have the following.

Observation 4.7. *$C^\star$ has only one face.*

Due to the definition of $C^\star$, we also have the following observation.

Observation 4.8. *Let $n_{C^\star}$ be the number of nodes of $C^\star$. Then, $n_{C^\star} \leq f_G + 1$, where f_G is the number of faces of G.*

We are now ready to bound the number of clogged edges. Let $n_{C^\star}$, $e_{C^\star}$, $f_{C^\star}$, and $\ell_{C^\star}$ be the number of nodes, edges, faces, and connected components of $C^\star$. Euler's formula implies

$$e_{C^\star} = n_{C^\star} + f_{C^\star} - \ell_{C^\star} - 1. \tag{4.4}$$

From Observation 4.7 we have $f_{C^\star} = 1$. Thus, (4.4) reduces to

$$e_{C^\star} = n_{C^\star} - \ell_{C^\star}. \tag{4.5}$$

As a consequence, using Observation 4.8, we have

$$e_{C^\star} \leq f_G + 1 - \ell_{C^\star}, \tag{4.6}$$

where f_G is the number of faces of G. Finally, since $\ell_{C^\star} \geq 1$ and $e_{C^\star}$ is the number of clogged edges, we obtain our bound, which we summarize in the following theorem.

Theorem 4.5. *Let G be a multigraph that corresponds to one of our filters. Then,*

$$\#\{\textit{clogged edges}\} \leq \#\{\textit{faces of } G\}. \tag{4.7}$$

5. Optimality of the bound.

As always, G is the multigraph of one of our filters.

Definition 5.1. *We say that $e_1, e_2, \ldots, e_s$ is a feasible clogging sequence or (for short) feasible sequence if, for each $1 \leq i \leq s$, there is flow through the edge e_i when $e_1, e_2, \ldots, e_{i-1}$ are clogged and all the other edges are open. We say that s is the length of the sequence.*

Recall that an edge can clog only when suspension flows through it. Thus, if q edges clogged, and the ith edge that clogged was e_i, then $e_1, e_2, \ldots, e_q$ is a feasible sequence of edges. Note that the bound of section 4 is actually a bound on the length of feasible sequences of edges.

While there are many feasible sequences that make the filter nonpermeable, only one actually realizes. The flow conditions, conductivity of the channels, as well as other factors determine the feasible sequence that realizes, which generally has fewer edges than other feasible clogging sequences. It is not our goal to find the sequence that realizes. In this section we show that, if every interior edge of G is contained in a

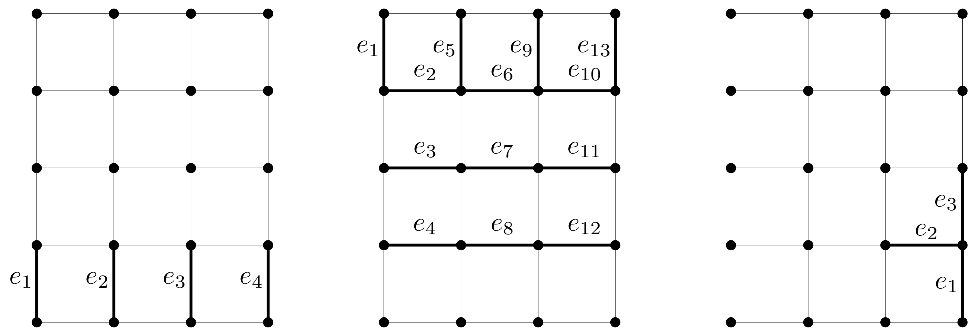

Fig. 6. *The sequences $e_1, \ldots, e_r$ in the left and middle figures ($r = 4$ in the left figure and $r = 13$ in the middle figure) are two feasible sequences of edges that make the filter nonpermeable. Note that the number of faces of the graph is 13. Thus, the sequence of the middle figure is of maximum length. Our work does not predict whether the sequence in the left figure, the one in the middle, or another sequence is realized; thus, we can predict only that the sequence that realizes has length less than or equal to 13. The sequence in the right figure is not feasible. Once e_1 and e_2 clog, there is no more flow through e_3, and thus it cannot clog.*

percolating path, our bound is sharp in the sense that there exists a feasible sequence of edges whose length is equal to our bound, the number of faces of G (the right-hand side of (4.7)). However, it should be noted that the length of the feasible sequence that actually realizes and makes the filter nonpermeable may be smaller. In other words, while the length of the longest feasible sequence of edges is an upper bound on the number of channels that actually clog, these numbers may not be equal. Illustrative examples are given in Figure 6. We will come back to this issue in section 7.

Let e be an interior edge of G. As illustrated in Figure 4 and previously discussed, if there is no percolating path that contains e, then the pressure at the end points of e are equal, which implies that there is no flow through e and thus that e can never clog. Removing first all such edges from G, then all the exterior edges, then the nodes that are left isolated, and finally adding new exterior edges as necessary leads to a new multigraph $\tilde{G}$ for which the bound will be attained. Note that the flow in G is exactly equal to the flow in $\tilde{G}$. There is no flow within edges of G that do not belong to $\tilde{G}$.

5.1. Leftmost percolating paths.

Observation 5.1. *Let $P = n_0, e_1, n_1, \ldots, e_r, n_r$ be a percolating path. Let e be an edge to the left of P. If e is included in a percolating path, then there exists a percolating path R such that P and e are to the right of R.*

Proof. Assume that e is not in P, since otherwise the observation is trivially true by selecting $R = P$. Let Q be a percolating path that contains e. Let $\bar{Q}$ be the largest path that satisfies (1) $\bar{Q}$ is included in Q, (2) $\bar{Q}$ contains e, (3) $\bar{Q}$ is to the left of P, and (4) $\bar{Q}$ may intersect P only at the end points of $\bar{Q}$.

If $\bar{Q} = Q$, as in Figure 7(a), select $R = Q$. Note that e and P are to the right of R. Otherwise, $\bar{Q}$ intersects P. In this case, $\bar{Q} \cap P$ splits P into two or three connected sections. Replacing one of these connected sections with $\bar{Q}$ leads to the percolating path R we are looking for. If $\bar{Q}$ contains a bottom exterior node, as in Figure 7(b), we replace the section of P that has a bottom exterior node. If $\bar{Q}$ contains a top exterior node, as in Figure 7(c), we replace the section of P that has a top exterior node. If $\bar{Q}$ does not contain any exterior node, as in Figure 7(d), we replace the section of P

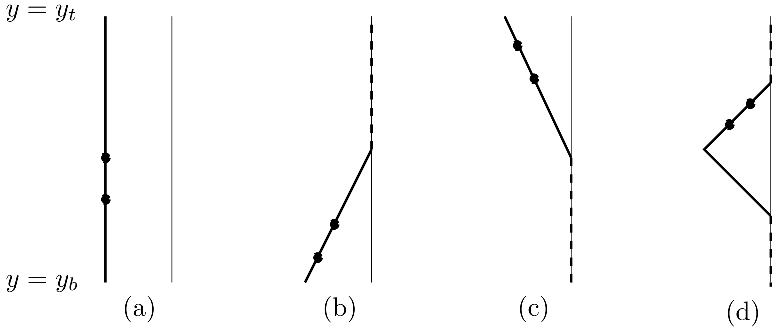

FIG. 7. *The four different possibilities of Observation* 5.1. *We do not show all the multigraph* G*, only* e*,* $\bar{Q}$*, and* P*. The edge* e *is the segment between the solid small circles.* P *is the thin solid vertical line,* $\bar{Q}$ *the thick solid line, and* R *the union of* $\bar{Q}$ *and the dashed lines.*

without exterior nodes. □

This last observation and the fact that each exterior node is the end point of an interior edge lead to the following.

OBSERVATION 5.2. *If every interior edge in* G *is included in a percolating path, then there is a unique percolating path* P *in* G *such that* G *is to the right of* P*. We call* P *the leftmost percolating path of* G*.*

5.2. A feasible sequence of maximum length. The first edge. Assume that every interior edge in G is included in a percolating path. Our goal is to construct a feasible sequence of edges $e_1, e_2, \ldots, e_N$ of maximum length. Let P be the leftmost percolating path of G. In this subsection we identify $\bar{P}$, a subpath of P, from which e_1 will be selected. The selection of $\bar{P}$ is done with care so that the rest of the sequence, $e_2, \ldots, e_N$, can be constructed inductively, as we will do in the next subsection.

OBSERVATION 5.3. *Assume that every interior edge in* G *is included in a percolating path of* G*. Let* P *be the leftmost percolating path of* G*. Assume that there are no bounded faces* F *of* G *such that* $\partial F \cap P$ *contains an edge. Then* $P = G$*.*

Proof. The proof is by contradiction. Assume $P \neq G$. Then there exists an edge in G not in P. In fact, since every exterior node is the end point of an interior edge, we have that there exists an interior edge e in G such that e is not in P. Let Q be a percolating path in G containing e. Note that there is a nonempty open bounded Ω enclosed by P, Q, $y = y_b$, and $y = y_t$. Note also that at least one edge of P is in the boundary of Ω. The closure of Ω is the union of the closure of the bounded faces of G included in Ω. Thus, there exists F, a bounded face of G, such that $\partial F \cap P$ contains an edge. This is a contradiction, which proves the observation. □

OBSERVATION 5.4. *Assume that every interior edge in* G *is included in a percolating path of* G*. Let* F *be a bounded face of* G*. Then,* $\partial F \cap \{y = y_b\}$ *is connected, and* $\partial F \cap \{y = y_t\}$ *is also connected.*

Proof. Assume that $\partial F \cap \{y = y_b\}$ is not connected. Then, as illustrated in Figure 8, there is a path $\bar{Q}$ that is included in ∂F such that $\bar{Q} \cap \{y = y_b\}$ are the end points of $\bar{Q}$, the edges in $\bar{Q}$ are interior edges, and none of them is included in a percolating path of G, which contradicts our assumption. Thus, $\partial F \cap \{y = y_b\}$ is connected. Analogously, $\partial F \cap \{y = y_t\}$ is also connected. □

OBSERVATION 5.5. *Assume that every interior edge in* G *is included in a percolating path of* G*. Let* P *be the leftmost percolating path of* G*. Assume that* G *has a*

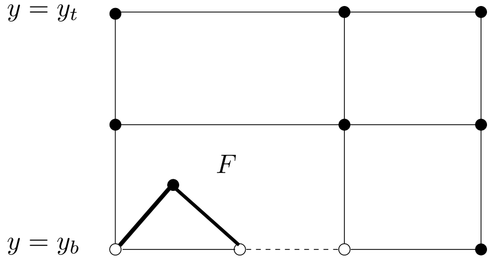

FIG. 8. *Multigraph G. $\partial F \cap \{y = y_b\}$ is the edge in dashed line and the white nodes, which is a disconnected set. The thick solid line is $\bar{Q}$. The edges in $\bar{Q}$ are not included in any percolating path of G.*

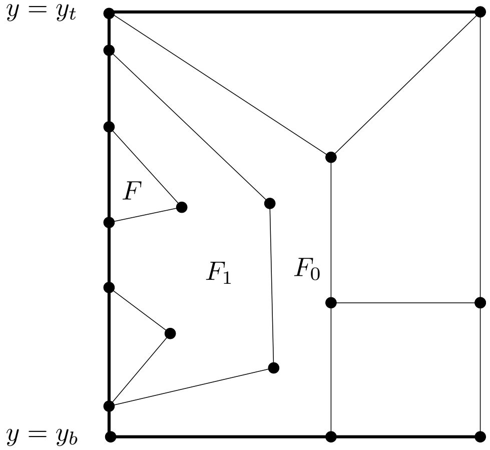

FIG. 9. *Multigraph G. The edges of the path S are in thick lines. Example of a sequence $F_0, F_1, F_2 = F$ constructed as in Observation* 5.5.

bounded face. Then, there exists F, a bounded face of G, such that

1. *$\partial F \cap P$ contains an edge, and*
2. *$\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ is connected.*

Proof. Let S be the path that results from the following steps. We start at the rightmost exterior node of the bottom boundary and walk left along that boundary toward the path P. We continue walking through P to the top boundary. We then walk right along the top boundary and end the path at the rightmost exterior node of the top boundary (see Figure 9).

Since G has a bounded face, $P \neq G$, and thus, from Observation 5.3, there exists F_0, a bounded face of G, such that $\partial F_0 \cap P$ contains an edge. Let $S_{F_0} = \partial F_0 \cap S$ and $\tilde{S}_{F_0}$ be the smallest path included in S that contains S_{F_0}. Recall that paths are connected. Thus, if $\tilde{S}_{F_0} = S_{F_0}$, then $F = F_0$ is a face we are looking for.

We next show that $P \cap \tilde{S}_{F_0} \subseteq S_{F_0}$ implies that $\tilde{S}_{F_0} = S_{F_0}$. Assume that $P \cap \tilde{S}_{F_0} \subseteq S_{F_0}$. If both $\partial F_0 \cap \{y = y_b\}$ and $\partial F_0 \cap \{y = y_t\}$ are empty sets, then $\tilde{S}_{F_0} = P \cap \tilde{S}_{F_0} \subseteq S_{F_0}$. Assume now that $\partial F_0 \cap \{y = y_b\}$ is nonempty. Thus, $\tilde{S}_{F_0}$ contains the exterior node of P in the bottom boundary, and since $P \cap \tilde{S}_{F_0} \subseteq S_{F_0}$, that exterior node is also in S_{F_0}. Thus, $\{y = y_b\} \cap S_{F_0} = \partial F_0 \cap \{y = y_b\}$ also contains that exterior node and, given that $\partial F_0 \cap \{y = y_b\}$ is connected due to Observation 5.4,

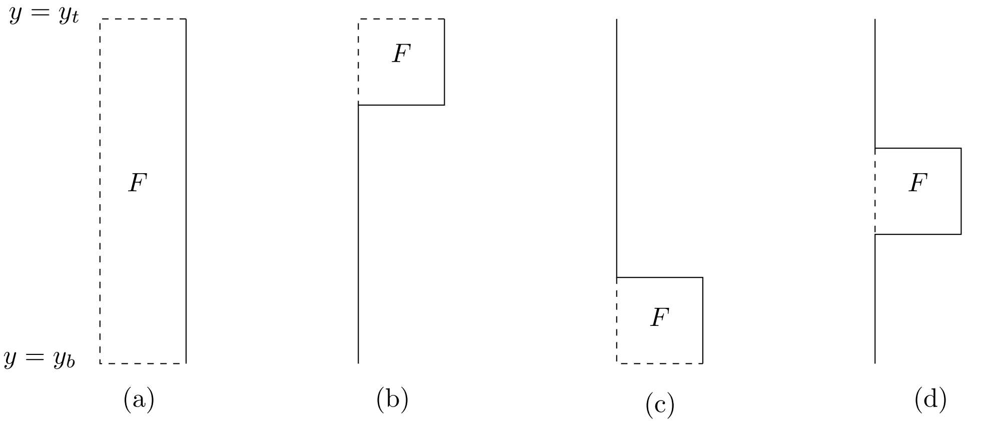

FIG. 10. *Four different possibilities of F from Observation 5.6 and Theorem 5.2. The solid line is the percolating path S of Observation 5.6. The left vertical line is P. $P \cap S$ is in solid line, and the section of P that does not intersect S is in dashed line. The dashed horizontal lines are the sections of the top and bottom boundary that are to the left of S.*

we have that $\{y = y_b\} \cap \tilde{S}_{F_0} \subseteq S_{F_0}$. This argument applied to the top boundary leads to $\tilde{S}_{F_0} = (P \cup \{y = y_t\} \cup \{y = y_b\}) \cap \tilde{S}_{F_0} \subseteq S_{F_0}$ if $(P \cap \tilde{S}_{F_0}) \subseteq S_{F_0}$.

We are left to show that the observation is true when $\tilde{S}_{F_0} \neq S_{F_0}$ (see Figure 9), and so we now assume $\tilde{S}_{F_0} \neq S_{F_0}$. Given the above paragraph, we have that $\tilde{S}_{F_0} - S_{F_0}$ intersects P in at least one edge, say e. As illustrated in Figure 10, we can select F_1, a bounded face of G, such that ∂F_1 contains e. Let $S_{F_1} = \partial F_1 \cap S$ and $\tilde{S}_{F_1}$ be the smallest path included in S that contains S_{F_1}. If $\tilde{S}_{F_1} = S_{F_1}$, then $F = F_1$ is a face we are looking for. Otherwise, we note that $\tilde{S}_{F_1}$ is included in a connected component of $\tilde{S}_{F_0} - S_{F_0}$, and thus $\tilde{S}_{F_1} \subsetneq \tilde{S}_{F_0}$. As a consequence, since G is a finite multigraph, repeating this procedure as many times as necessary, we will find the face F that we are looking for (see Figure 9). □

Assume that every interior edge in G is included in a percolating path. Let F be a bounded face of G that satisfies the conditions of Observation 5.5. Let $\tilde{P} = P \cap \partial F$, where P is the leftmost percolating path of G. In the next subsection we will show how to construct a feasible sequence of edges $e_1, e_2, \ldots, e_N$ of maximum length where e_1 will be selected from $\tilde{P}$.

5.3. Feasible sequence of edges of maximal length.

OBSERVATION 5.6. *Assume that every interior edge in G is included in a percolating path. Let P be the leftmost percolating path of G. Assume that G has a bounded face. Let F be a face of G such that (1) $\partial F \cap P$ contains an edge, and (2) $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ is connected.*

Then, for every interior edge e in G not in $\partial F \cap P$ there exists a percolating path Q of G such that Q contains e and Q does not have any edge in $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$.

Proof. Let S_1 be the section of P that does not intersect ∂F, i.e., $S_1 = P - \partial F$. Let S_2 be the section of ∂F that intersects neither P nor the boundaries, i.e., $S_2 = \partial F - (P \cup \{y = y_t\} \cup \{y = y_b\})$. Let S be the percolating path that results from walking along $S_1 \cup S_2$ (see Figure 10). Note that every edge in G not in $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ is to the right of S.

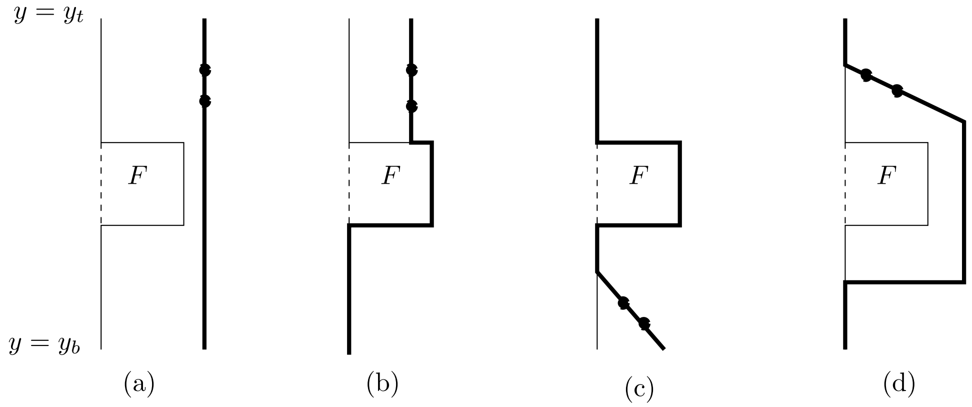

Fig. 11. *Four different possibilities of the percolating path Q, in thick solid lines, from Observation* 5.6. *The edge e is between the solid small circles. The left vertical line is P.*

Let e be an interior edge in G not in $\partial F \cap P$. Let R be a percolating path of G that contains e. Let $\bar{Q}$ be the largest subpath of R that contains e such that $\bar{Q}$ may only intersect S at the end points of $\bar{Q}$. As illustrated in Figure 11, we can construct a percolating path Q that contains $\bar{Q}$, may contain sections of S, but does not contain any edge outside $\bar{Q} \cup S$. Thus, Q contains e and does not have any edge in $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$. □

Observation 5.7. *Assume that every interior edge in G is included in a percolating path of G. Let P be the leftmost percolating path of G. Assume that G has a bounded face. Let F be a bounded face of G such that* (1) *$\partial F \cap P$ contains an edge, and* (2) *$\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ is connected. Let G' be the multigraph that results from first removing from G the edges in $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ and then removing the nodes that are left isolated. Then the following hold:*

1. *Every interior edge in G' is included in a percolating path in G'.*
2. *$f_{G'} = f_G - 1$; i.e., the number of faces of G' is equal to the number of faces of G minus one.*
3. *G' is the multigraph of one of our filters.*

Proof. Point 1 is an immediate consequence of Observation 5.6.

Point 2 results from the simple facts that (1) all the bounded faces of G' are bounded faces of G, (2) the only bounded face of G that is not a face of G' is F, and (3) both G and G' (as well as any multigraph) have only one unbounded face. (Note that G' results from removing the dashed lines in Figure 10.)

Point 3 is also clear. □

Theorem 5.2. *If every interior edge in G is included in a percolating path of G, then there exists a feasible sequence of edges of length f_G. Thus, our bound is optimal for this class of filters.*

Proof. We will prove the theorem by induction on f_G. First note that $f_G = 1$ if and only if G is a percolating path. In this case, any edge of G forms a feasible sequence of edges of length $f_G = 1$.

Assume now that $f_G > 1$. Let P be the leftmost percolating path of G. Note that P cannot be equal to G, since otherwise f_G would be equal to one.

Let F be a bounded face of G such that (1) $\partial F \cap P$ contains an edge, and (2) $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ is connected. Such a face exists by the observations of this section. Let e_1 be any edge in $\partial F \cap P$.

Let G' be the multigraph that results from first removing from G the edges in $\partial F \cap (P \cup \{y = y_t\} \cup \{y = y_b\})$ and then removing the nodes that are left isolated. From Observation 5.7, every interior edge in G' is included in a percolating path in G', $f_{G'} = f_G - 1$, and G' is the multigraph of one of our filters.

By inductive hypothesis there exists in G' a feasible sequence of edges of length $f_{G'} = f_G - 1$. For convenience, call one such sequence $e_2, \ldots, e_{f_G}$. From the observations of this section, it follows that $e_1, e_2, \ldots, e_{f_G}$ is a feasible sequence of edges in G, which proves the theorem. □

6. The bound in terms of the average degree of G for large filters. As always, G is a multigraph of one of our filters. We assume in this section that every interior edge of G is contained in a percolating path. We recall that f_G, e_G, and n_G are the numbers of faces, edges, and nodes of G, respectively. We also recall that d_G, the average degree of G, is given by $d_G = 2e_G/n_G$ (see (3.2)).

Assume that the number of edges is large, i.e., $e_G \gg 1$. In this case, the Euler formula $f_G + n_G = e_G + \ell_G + 1$ reduces to $f_G + n_G \approx e_G$ since $\ell_G = 1$. Thus, from (3.2), we have $f_G + 2e_G/d_G \approx e_G$. This leads to the following observation.

OBSERVATION 6.1. *If $e_G \gg 1$ and $d_G \neq 2$, then our bound* (4.7) *reads*

$$\#\{\textit{clogged edges}\} \lesssim \frac{d_G - 2}{d_G} e_G. \tag{6.1}$$

In particular, if every interior edge of G is contained in a percolating path, the number of edges in a feasible sequence of edges with maximum length is asymptotically $((d_G - 2)/d_G)e_G$.

In many situations of interest, G is a graph; i.e., no two edges have the same end points. For example, if all the edges in a multigraph are straight segments, then the multigraph is really a graph. It is a well-known fact from graph theory that, if G is a planar graph, the average degree of G is bounded by 6, i.e., $d_G \leq 6$. This leads to the following observation.

OBSERVATION 6.2. *If G is a graph and $e_G \gg 1$, then*

$$\#\{\textit{clogged edges}\} \lesssim \frac{2}{3} \#\{\textit{all edges}\}. \tag{6.2}$$

A natural goal is to design filters that use as much of the pore space as possible to trap particles before the filter ceases to be permeable. Thus, of particular interest is to know the proportion of channels that are clogged when the filter ceases to be permeable. The last observation provides a bound on this quantity whenever G is a graph.

As particular examples, consider the graphs of Figure 12. At this point do not make a distinction between solid and dashed edges. In the large filter limit, i.e., the distance between the top and bottom boundaries is much larger than the length of the edges, the graph with square bounded faces satisfies $d_G \approx 4$, and thus, for this graph, (6.1) implies $\#\{\text{clogged edges}\} \lesssim e_G/2$. For the graph with triangle bounded faces, we have $d_G \approx 6$ and thus $\#\{\text{clogged edges}\} \lesssim 2e_G/3$. For the graph with hexagonal bounded faces, we have $d_G \approx 3$ and thus $\#\{\text{clogged edges}\} \lesssim e_G/3$.

7. A subclass of filters and examples. In this section, we consider filters in which every interior edge is included in a percolating path. We have shown that, for this kind of filters, our bound is sharp; i.e., there is a feasible sequence of edges whose number of edges or length is equal to our bound, i.e., the number of faces of

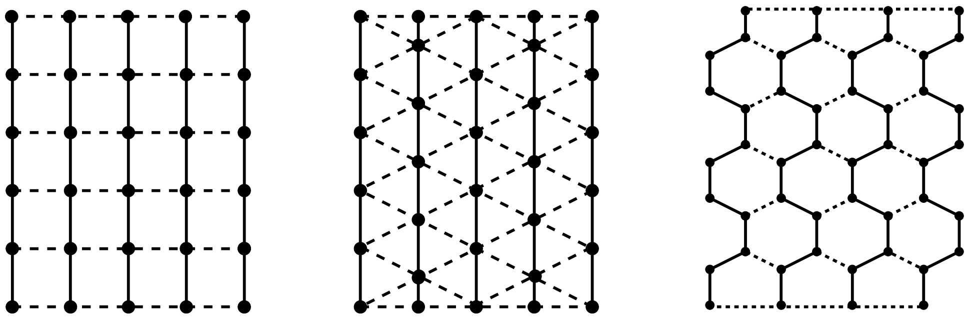

FIG. 12. *Multigraphs with geometries of class $\mathcal{A}$. The percolating paths P_i are in solid lines. The crossing paths $H_{i,j}$ are in dashed lines.*

the multigraph (see the right-hand side of (4.7)). However, in general, there are many feasible sequences of edges that make the filter nonpermeable, and the length of most of them is less than our bound. Thus, the feasible sequence of edges that is realized, i.e., the sequence of edges that actually clog and make the filter nonpermeable, which depends on the flow conditions as well as the width of the channels, is, in general, much shorter than the feasible sequences of edges with maximum length.

In this section, we will restrict our attention to a subclass of filters for which we will show how to select the width of the channels so that, as the suspension flows, the feasible sequence of edges that is realized and makes the filter nonpermeable will indeed have maximum length.

7.1. Subclass of filters. The geometries.

DEFINITION 7.1. *We say that a multigraph G that corresponds to one of our filters has geometry of class $\mathcal{A}$ if there is a nonnegative integer r and a sequence of disjoint percolating paths $P_0, P_1, \ldots, P_r$ in G such that, for each i, $0 \leq i < r$, the following hold:*

1. *P_i is to the left of P_{i+1}.*
2. *There are positive integers s_i such that P_i and P_{i+1} are joined by $s_i + 1$ paths that may have only end points in common; i.e., for each j, $0 \leq j \leq s_i$, there is a path $H_{i,j}$ such that (1) $H_{i,j} \cap P_i$ is an end point of $H_{i,j}$, (2) $H_{i,j} \cap P_{i+1}$ is the other end point of $H_{i,j}$, and (3) H_{i,j_1} and H_{i,j_2} may intersect at their end points only if $j_1 \neq j_2$.*
3. *G is the union of the percolating paths P_i $(0 \leq i \leq r)$ and the "crossing" paths $H_{i,j}$ $(0 \leq i < r,\ 0 \leq j \leq s_i)$.*

For convenience, we assume that the paths $H_{i,j}$ are labeled in such a way that $H_{i,j+1}$ is above $H_{i,j}$ $(0 \leq i < r,\ 0 \leq j < s_i)$. More precisely, $H_{i,j+1}$ is in the closure of the bounded region whose boundary is included in $\{y = y_t\} \cup P_i \cup P_{i+1} \cup H_{i,j}$. Note that $H_{i,0}$ is included in the bottom boundary and H_{i,s_i} is included in the top boundary.

Examples of multigraphs that have the geometry of class $\mathcal{A}$ are shown in Figure 12. The percolating paths P_i are in solid lines. The crossing paths $H_{i,j}$ are in dashed lines.

7.2. Subclass of filters. The width of the channels. The physical mechanisms that lead to the clogging of channels may be complex and depend on the particular problem under consideration. Here we will assume the following simple rules. Each channel is either thin or thick. Thick channels never clog, and thin channels eventually clog if there is flow through them.

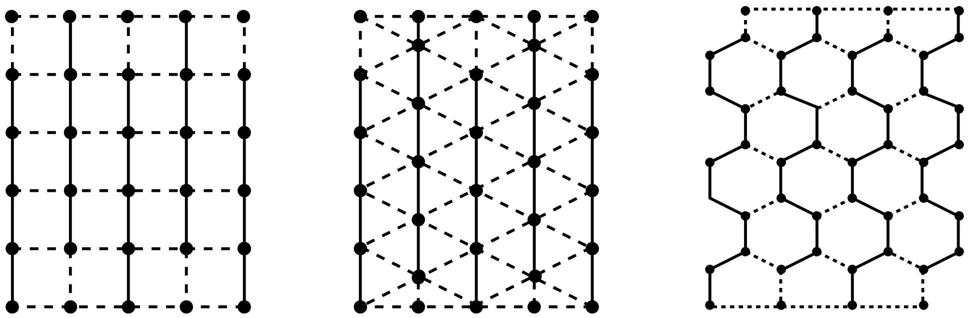

FIG. 13. *Multigraphs of Figure* 12. *The thick edges are in solid lines. Thin edges in dashed lines.*

We now select the thin and thick edges. Let G be a multigraph that has geometry of class $\mathcal{A}$. Let $P_0, P_1, \ldots, P_r$ be the percolating paths as in Definition 7.1. Every percolating path is split into subpaths by the crossing paths. For i even, let $\bar{P}_i$ be the subpath of P_i that contains an exterior node at the top boundary. For i odd, let $\bar{P}_i$ be the subpath of P_i that contains an exterior node at the bottom boundary. One edge in each of the subpaths $\bar{P}_i$ for any i is selected to be thin. One edge in each of the crossing paths $H_{i,j}$ is also selected to be thin. Every other edge is chosen thick. In Figure 13 we show the multigraphs of Figure 12, but now the thick edges are in solid lines and the thin edges in dashed lines.

DEFINITION 7.2. *We say that a multigraph G that corresponds to one of our filters is of class $\mathcal{A}$ if G has geometry of class $\mathcal{A}$ and the width of the edges of G are selected as described above.*

7.3. The bound realizes for filters of class $\mathcal{A}$. We now show that, for the filters considered in this section, i.e., with multigraph of class $\mathcal{A}$, the bound realizes; i.e., the number of edges that actually clog is equal to our bound, the number of faces of the multigraph of the filter. We show this in two steps. We first show that in each of the paths $\bar{P}_i$ the thin edge clogs, and in each of the paths $H_{i,j}$ not included in the top or bottom boundaries, i.e., $H_{i,j}$ for $1 \leq j < s_i$, the thin edge also clogs. Then, we show that the number of these paths is equal to the number of faces of the multigraph of the filter.

OBSERVATION 7.1. *In each of the paths $\bar{P}_i$ ($0 \leq i \leq r$) the thin edge clogs, and in each of the paths $H_{i,j}$ not included in the top or bottom boundaries ($0 \leq i < r$, $1 \leq j < s_i$) the thin edge clogs.*

Proof. We first note that there is no percolating paths with all thick edges. Thus, the filter eventually ceases to be permeable.

Let e_i be the thin edge in $\bar{P}_i$. All the other edges in P_i are thick, and thus they never clog. As a consequence, while e_i is open, the filter is permeable. Thus, e_i eventually clogs.

Let $H_{i,j}$ be one of the crossing paths not included in the top or bottom boundaries, i.e., $1 \leq j < s_i$. We connect one end point of $H_{i,j}$ to a bottom exterior node and the other to a top exterior node with paths of thick edges as follows. Let Q be the subpath of P_i that has an exterior node as an end point, shares the other end point with $H_{i,j}$, and all the edges in Q are thick. Let R be the subpath of P_{i+1} that has an exterior node as an end point, shares the other end point with $H_{i,j}$, and all the edges in R are thick. From the discussion of sections 7.1 and 7.2, it is clear that Q and R are well defined. It is also clear that the union of Q, R, and $H_{i,j}$ forms a percolating

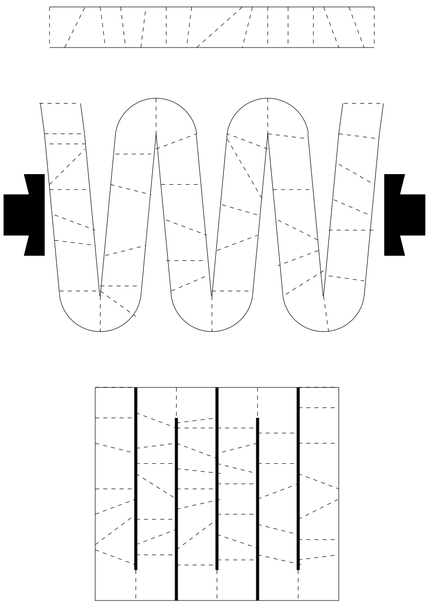

FIG. 14. *Building a filter of class $\mathcal{A}$. In the top figure we start with a thin filter with thin channels. In the middle figure we fold the thin filter. The bottom figure shows the resulting filter after folding and compressing. The thick edges are in solid thick lines. The thin edges are in dashed lines.*

path whose only thin edge is the one in $H_{i,j}$. Due to the same argument of the last paragraph, this implies that the thin edge in $H_{i,j}$ eventually clogs. ∎

OBSERVATION 7.2. *The number of the paths $\bar{P}_i$ ($0 \leq i \leq r$) and $H_{i,j}$ not included in the top or bottom boundaries ($0 \leq i < r$, $1 \leq j < s_i$) is equal to f_G, the number of faces of G.*

Proof. We first note that the number of the paths $\bar{P}_i$ ($0 \leq i \leq r$) and $H_{i,j}$ not included in the top or bottom boundaries ($0 \leq i < r$, $1 \leq j < s_i$) is equal to $1 + r + \sum_{i=0}^{r-1}(s_i - 1) = 1 + \sum_{i=0}^{r-1} s_i$. Thus our goal reduces to showing that $f_G = 1 + \sum_{i=0}^{r-1} s_i$.

Let $0 \leq i < r$ and $1 \leq j \leq s_i$. If we remove from the plane the paths P_i, $H_{i,j-1}$, P_{i+1}, and $H_{i,j}$, we are left with one bounded and one unbounded connected component. Let $F_{i,j}$ be the bounded component. It is clear that the bounded faces of G are $F_{i,j}$ for $0 \leq i < r$ and $1 \leq j \leq s_i$. Therefore, $f_G = 1 + \sum_{i=0}^{r-1} s_i$, which completes the proof. ∎

7.4. Building filters of class $\mathcal{A}$ from thin filters. We now discuss a possible means, at least theoretically, to construct filters of class $\mathcal{A}$.

We start with a thin filter with thin channels. By a thin filter we mean that the corresponding graph is the union of disjoint percolating paths connecting the top and bottom boundaries. An example is shown in the top figure of Figure 14.

Next, we fold the thin filter as shown in the middle figure of Figure 14. As we compress the folded filter from the sides, the spaces between folds become the thick channels, and we are left with the new filter shown in the bottom figure of Figure 14. The applied pressure in the folding step should be high, but not so high so the new pore space, the thick channels, are in fact thicker than the channels in the original thin filter before folding. The resulting filter is a filter of class $\mathcal{A}$.

Note that the above discussion suggests a way to construct filters of *long life* even if the original thin filter does not strictly satisfy the condition of having the corresponding graph be the union of disjoint percolating paths.

7.5. Further comments on filters of class $\mathcal{A}$. As channels clog, the permeability of the filter decreases. This is unavoidable. Nevertheless, we expect that this decrease in permeability will be relatively slow (as compared with other filters) for filters of class $\mathcal{A}$, because the suspension can flow with relative ease along the thick channels and, as shown in the proof of Observation 7.1, this family of filters has lots of percolating paths where all but one edge are thick.

SHORT WAVE STABILITY FOR INVISCID SHEAR FLOW*

MICHAEL RENARDY†

Abstract. We consider the linear stability of inviscid shear flows. While it is well known that discontinuous velocity profiles lead to short wave instabilities and ill-posedness, known examples of instability for smooth profiles have a short wave cutoff; i.e., there is a critical wave number beyond which no unstable eigenvalues exist. This paper proves a result to this effect under suitable assumptions on the base flow profile.

Key words. hydrodynamic stability, Rayleigh equation, inviscid shear flow

AMS subject classification. 76E05

DOI. 10.1137/080720905

1. Introduction.

The linear stability of inviscid shear flows has been studied extensively over the past century. I refer to [1, 2, 3] for reviews. Discontinuous velocity profiles lead to the Kelvin–Helmholtz instability which has unbounded growth rates in the limit of high wave numbers. In contrast, the instabilities in shear flows with smooth velocity profiles appear to be long wave instabilities. That is, there is cutoff at some maximal wave number α_m such that there are no unstable eigenvalues for $\alpha > \alpha_m$.

Although all known examples appear to satisfy this, I have not been able to find a proof in the literature. Almost half a century ago, Howard [4] proved such a result for a special case. He assumes that all inflection points of the base flow profile U occur at the same value U_i and that $U''/(U - U_i)$ is bounded and of one sign.

The objective of this paper is to prove the nonexistence of unstable eigenvalues for large α in more general velocity fields. In the proof, it turns out that the crucial difficulty for the analysis occurs at critical points of U rather than inflection points. A critical point of U is a point where $U' = 0$.[1]

We shall need the following assumptions:

1. All critical points are isolated. Moreover, in a neighborhood of each critical point y_c, $U''(y)(U(y) - U(y_c))$ is nonnegative.
2. If y_c is a critical point, and $U(y) = U(y_c)$, then y is also a critical point.

The first assumption is satisfied for all analytic velocity profiles. I suspect that the second assumption is not necessary, but I do not know how to avoid it in the proof. Even if the second assumption does not hold, it will be shown that growth rates of unstable modes must approach zero at an exponential rate as $\alpha \to \infty$.

2. Proof of short wave stability.

Our goal is the following result.

Theorem 2.1. *Let $U(y)$ be an analytic function defined for $y \in [0, 1]$. Moreover, assume U has the following property: If $U'(y_0) = 0$ for some $y_0 \in [0, 1]$, then $U'(y) = 0$*

[1] This usage of the word “critical”, which is common in calculus of variations, should not be confused with a totally unrelated usage of the same word, which also occurs in hydrodynamic stability studies.

for every y with $U(y) = U(y_0)$. Then there exists α_0 such that, for $\alpha > \alpha_0$, all eigenvalues c of the Rayleigh equation (*equation* (21.17) *in* [2]),

$$(U(y) - c)(\psi''(y) - \alpha^2\psi(y)) - U''(y)\psi(y) = 0, \tag{2.1}$$

with boundary condition $\psi(0) = \psi(1) = 0$ are real.

The assumptions allow, for instance, monotone velocity profiles, profiles with a single maximum or minimum, and periodic profiles with one maximum and minimum.

For the proof, let us assume c is an eigenvalue which is not real. We can write the equation in the form

$$\psi'' - \alpha^2\psi = \frac{U''}{U - c}\psi. \tag{2.2}$$

We multiply by the conjugate of ψ and integrate, which yields

$$\int_0^1 |\psi'|^2 + \alpha^2|\psi|^2\,dy = -\int_0^1 \frac{U''(y)(U(y) - \bar{c})}{|U(y) - c|^2}|\psi|^2\,dy. \tag{2.3}$$

With $c = c_r + ic_i$, this yields the two separate equations

$$\begin{aligned}\int_0^1 |\psi'|^2 + \alpha^2|\psi|^2\,dy &= -\int_0^1 \frac{U''(y)(U(y) - c_r)}{(U(y) - c_r)^2 + c_i^2}|\psi|^2\,dy,\\ 0 &= \int_0^1 \frac{U''(y)}{(U(y) - c_r)^2 + c_i^2}|\psi|^2\,dy.\end{aligned} \tag{2.4}$$

The overall strategy of the proof is to show that, for large α, contributions to the right-hand side of the first equation in (2.4) are either negative or not large enough to balance the left-hand side. Clearly, we have

$$\left|\frac{U''(y)(U(y) - c_r)}{(U(y) - c_r)^2 + c_i^2}\right| \ll \alpha^2 \tag{2.5}$$

unless $U(y) - c_r$ is small of order α^{-2}. To focus the discussion further, we divide the points in $[0, 1]$ into the following two categories:

1. y is a regular point if $U'(y) \neq 0$.
2. y is a critical point if $U'(y) = 0$.

Since we assumed U to be analytic, all but finitely many points are regular. We shall call y a δ-regular point if the distance from the nearest critical point is at least δ.

The next lemma will be used repeatedly in what follows.

LEMMA 2.2. *Let $x_0 \in [0, 1]$, and for given $u \in L^2[0, 1]$, let*

$$Lu(x) = \frac{1}{x - x_0}\int_{x_0}^{x} u(\xi)\,d\xi. \tag{2.6}$$

Then the operator L is a bounded mapping from $L^2[0, 1]$ into itself.

This result follows immediately from Theorem 11.8 in [5], but for the sake of keeping this paper self-contained, I shall give the proof.

Let $v(x) = Lu(x)$. We have $u = ((x - x_0)v)'$, and hence $2uv - v^2 = ((x - x_0)v^2)'$ (in particular, this implies that $(x - x_0)v^2$ is continuous, since $2uv - v^2$ is integrable). Consequently,

$$\int_0^1 2uv\,dx = (1 - x_0)v(1)^2 + x_0v(0)^2 + \int_0^1 v^2\,dx, \tag{2.7}$$

which implies $\|v\| \leq 2\|u\|$. Here and in what follows, $\|\cdot\|$ refers to the norm in $L^2(0,1)$.

We shall begin with an estimate for regular points.

Lemma 2.3. *Let z be a 2δ-regular point, and let $c_r = U(\tilde{z})$ where $|z-\tilde{z}| < \delta/2$. Then there is a constant C, depending on δ but not on z and c, such that*

$$\left| \int_{z-\delta}^{z+\delta} \frac{U''(y)(U(y)-c_r)}{(U(y)-c_r)^2+c_i^2} |\psi|^2 \, dy \right| \leq C(\|\psi\|^2 + \|\psi\|^{1/2}\|\psi'\|^{3/2}). \tag{2.8}$$

If z is close to the boundary, the interval $[z-\delta,\ z+\delta]$ may not be contained in $[0,1]$. In this case, however, we can simply extend ψ by zero outside of $[0,1]$. Due to the boundary condition $\psi(0)=\psi(1)=0$, this continuation is still in H^1.

Clearly, there is a lower bound for U' on the set of all δ-regular points. Let $q(\delta)$ be this lower bound. Then we have $|U(y)-c_r| \geq q(\delta)\delta/2$ if $|y-\tilde{z}| > \delta/2$. In this range of y, we can therefore estimate the integrand by

$$\frac{2\max|U''|}{\delta q(\delta)}|\psi|^2. \tag{2.9}$$

Hence we only need to concern ourselves with

$$\int_{\tilde{z}-\delta/2}^{\tilde{z}+\delta/2} \frac{U''(y)(U(y)-c_r)}{(U(y)-c_r)^2+c_i^2}|\psi|^2 \, dy. \tag{2.10}$$

In this integral, we set

$$\psi(y) = \psi(\tilde{z}) + (y-\tilde{z})\chi(y) \tag{2.11}$$

and

$$|\psi(y)|^2 = |\psi(\tilde{z})|^2 + (y-\tilde{z})(\psi(y)\bar{\chi}(y) + \chi(y)\bar{\psi}(\tilde{z})). \tag{2.12}$$

According to Lemma 2.2 above, we have $\|\chi\| \leq 2\|\psi'\|$, and from the trace theorem (see (3.18) in [5]) we have $|\psi(\tilde{z})|^2 \leq C(\|\psi\|^2 + \|\psi\|\|\psi'\|)$ for some constant C. Moreover,

$$\frac{U''(y)(U(y)-c_r)(y-\tilde{z})}{(U(y)-c_r)^2+c_i^2} \tag{2.13}$$

is bounded. Consequently, we find

$$\begin{aligned} &\left| \int_{\tilde{z}-\delta/2}^{\tilde{z}+\delta/2} \frac{U''(y)(U(y)-c_r)(y-\tilde{z})}{(U(y)-c_r)^2+c_i^2}(\psi(y)\bar{\chi}(y) + \chi(y)\bar{\psi}(\tilde{z}))\, dy \right| \\ &\quad \leq C(\delta)(\|\psi\|\|\chi\| + |\psi(\tilde{z})|\|\chi\| \leq C(\delta)(\|\psi\|^2 + \|\psi'\|^{3/2}\|\psi\|^{1/2}). \end{aligned} \tag{2.14}$$

It remains to estimate

$$|\psi(\tilde{z})|^2 \left| \int_{\tilde{z}-\delta/2}^{\tilde{z}+\delta/2} \frac{U''(y)(U(y)-c_r)}{(U(y)-c_r)^2+c_i^2}\, dy \right|. \tag{2.15}$$

In this last integral, we substitute $U(y)$ as a new variable to obtain the new integral

$$\int_{U(\tilde{z}-\delta/2)}^{U(\tilde{z}+\delta/2)} \frac{U''(y(U))(U-c_r)}{U'(y(U))[(U-c_r)^2+c_i^2]}\, dU. \tag{2.16}$$

The interval of integration contains the symmetric interval $|U - c_r| < \delta q(\delta)/2$, and outside this interval, the integrand is bounded by a constant $C(\delta)$. Next, we write

$$\frac{U''(y(U))}{U'(y(U))} = \frac{U''(\tilde{z})}{U'(\tilde{z})} + (U - c_r)S(U), \tag{2.17}$$

where $S(U)$ is a continuous function. By symmetry, we then find

$$\int_{c_r-\delta q(\delta)/2}^{c_r+\delta q(\delta)/2} \frac{U''(y(U))(U - c_r)}{U'(y(U))[(U - c_r)^2 + c_i^2]}\, dU = \int_{c_r-\delta q(\delta)/2}^{c_r+\delta q(\delta)/2} \frac{(U - c_r)^2 S(U)}{(U - c_r)^2 + c_i^2}\, dU. \tag{2.18}$$

The integrand in the latter integral is bounded by a constant. This completes the proof of Lemma 2.3.

We next consider the neighborhood of a critical point.

LEMMA 2.4. *There exist $\epsilon > 0$ and $K > 0$ such that, if y_0 is in an ϵ-neighborhood of a critical point y_c, and $c_r = U(y_0)$, then*

$$\int_0^1 \frac{U''(y)(U(y) - c_r)}{(U(y) - c_r)^2 + c_i^2} |\psi|^2\, dy \geq -K\|\psi\|^2. \tag{2.19}$$

We exploit the second equation of (2.4) to obtain that

$$\int_0^1 \frac{U''(y)(U(y) - c_r)}{(U(y) - c_r)^2 + c_i^2} |\psi|^2\, dy = \int_0^1 \frac{U''(y)(U(y) - U(y_c))}{(U(y) - c_r)^2 + c_i^2} |\psi|^2\, dy. \tag{2.20}$$

All values of y where $U(y) = U(y_c)$ are critical points, and there is a finite number of these. Each of them has a neighborhood on which $U''(y)(U(y) - U(y_c))$ is nonnegative. If we choose ϵ small enough, then $|U(y) - c_r|$ has a positive lower bound outside these neighborhoods. The lemma follows.

To prove the theorem, we need to bound the right-hand side in the first equation of (2.4). Lemma 2.3 gives a bound of the form

$$C(\|\psi\|^2 + \|\psi\|^{1/2}\|\psi'\|^{3/2}) \tag{2.21}$$

in the neighborhood of regular points. Lemma 2.4 gives an upper bound of the form $K\|\psi\|^2$ in the neighborhood of critical points. By combining the two, we find that the right-hand side in the first equation of (2.4) cannot balance the left-hand side if α is large and ψ is nontrivial, which is the desired result.

We note that the assumption of analyticity was used only to ensure that the number of critical points is finite and that $(U(y) - U(y_c))U''(y)$ is nonnegative in a neighborhood of each critical point.

Without the assumption that U assumes its critical values only at critical points, we can still prove that the growth rate of unstable modes must tend to zero at an exponential rate as $\alpha \to \infty$.

THEOREM 2.5. *Let U be any analytic function on $[0, 1]$. Then there exists a function $s(\alpha)$, with $s(\alpha) \to 0$ for $\alpha \to \infty$, such that, if c is a nonreal eigenvalue of the Rayleigh equation, and α is sufficiently large, then there exists a critical point y_c with $|c - U(y_c)| \leq s(\alpha)$. Moreover, there exist constants C and k such that $|\alpha c_i| \leq C|c - U(y_c)| \exp(-k|\alpha|)$.*

The first statement, that c_r must be close to a critical value of U when α is large, follows from the proof of the previous theorem. Now let ρ be a nonnegative function which vanishes in an ϵ-neighborhood of the critical points but is equal to 1 at distance more than 2ϵ from the critical points. We multiply the Rayleigh equation by $\rho\bar{\psi}$ and integrate. The result is

$$\int_0^1 \rho(|\psi'|^2 + \alpha^2|\psi|^2)\,dy = -\int_0^1 \frac{U''(y)(U(y)-\bar{c})}{|U(y)-c|^2}\rho|\psi|^2\,dy - \int_0^1 \rho'\psi'\bar{\psi}\,dy. \tag{2.22}$$

With the help of Lemma 2.3, this yields the estimate

$$\int_0^1 \rho(|\psi'|^2 + \alpha^2|\psi|^2)\,dy \le C(\|\psi\|^2 + \|\psi\|^{1/2}\|\psi'\|^{3/2}). \tag{2.23}$$

Now let y_c be a critical point, and let χ be a smooth function which is equal to 1 in an ϵ-neighborhood of y_c and has support in a 2ϵ-neighborhood of y_c. We can choose ϵ such that $U''(U - U(y_c))$ is nonnegative on the support of χ. We shall also assume that $c_r = U(y_1)$, where y_1 is within $\epsilon/2$ of y_c. We multiply the Rayleigh equation by $\chi\bar{\psi}$ and integrate. The result is

$$\int_0^1 \chi(|\psi'|^2 + \alpha^2|\psi|^2)\,dy = -\int_0^1 \frac{U''(y)(U(y)-\bar{c})}{|U(y)-c|^2}\chi|\psi|^2\,dy - \int_0^1 \chi'\psi'\bar{\psi}\,dy. \tag{2.24}$$

Taking the imaginary part of this identity, we conclude that

$$|c_i|\left|\int_0^1 \frac{U''}{|U-c|^2}\chi|\psi|^2\,dy\right| \le \left|\int_0^1 \chi'\psi'\bar{\psi}\,dy\right|. \tag{2.25}$$

For large α, the solutions of the Rayleigh equation have exponential asymptotics as long as we stay away from points where $U - c$ is small (see Theorem 26.3 in [6]). Since the support of χ' is separated from the points where $|U - c|$ is small, we can conclude that there is a bound of the form

$$\left|\int_0^1 \chi'\psi'\bar{\psi}\,dy\right| \le C\exp(-k(\epsilon)|\alpha|)\|\psi\|^2. \tag{2.26}$$

Next, we consider the real part of (2.24), which we write in the form

$$\begin{aligned}&\int_0^1 \chi\left(|\psi'|^2 + \alpha^2|\psi|^2 + \frac{U''(U-U(y_c))}{|U-c|^2}|\psi|^2\right)\,dy\\ &= \int_0^1 \frac{U''(c_r - U(y_c))}{|U-c|^2}\chi|\psi|^2 - \chi'\,\mathrm{Re}\,(\psi'\bar{\psi})\,dy.\end{aligned} \tag{2.27}$$

We can now use (2.25) and (2.26) to bound the right-hand side by

$$C\left(1 + \frac{|c_r - U(y_c)|}{|c_i|}\right)\exp(-k(\epsilon)|\alpha|)\|\psi\|\|\psi'\|. \tag{2.28}$$

By combining this result with (2.23), we conclude that we have a bound of the form

$$\|\psi'\|^2 + \alpha^2\|\psi\|^2 \le \frac{|c_r - U(y_c)|\exp(-k(\epsilon)|\alpha|)}{|c_i|}\|\psi\|\|\psi'\|. \tag{2.29}$$

This is not possible if $|\alpha c_i| \gg |c_r - U(y_c)|\exp(-k(\epsilon)|\alpha|)$.

STEADY AND INTERMITTENT SLIPPING IN A MODEL OF LANDSLIDE MOTION REGULATED BY PORE-PRESSURE FEEDBACK[*]

DAVID G. SCHAEFFER[†] AND RICHARD M. IVERSON[‡]

Abstract. This paper studies a parsimonious model of landslide motion, which consists of the one-dimensional diffusion equation (for pore pressure) coupled through a boundary condition to a first-order ODE (Newton's second law). Velocity weakening of sliding friction gives rise to nonlinearity in the model. Analysis shows that solutions of the model equations exhibit a subcritical Hopf bifurcation in which stable, steady sliding can transition to cyclical, stick-slip motion. Numerical computations confirm the analytical predictions of the parameter values at which bifurcation occurs. The existence of stick-slip behavior in part of the parameter space is particularly noteworthy because, *unlike stick-slip behavior in classical models*, here it arises in the absence of a reversible (elastic) driving force. Instead, the driving force is static (gravitational), mediated by the effects of pore-pressure diffusion on frictional resistance.

Key words. Hopf bifurcation, landslide, pore pressure, stick-slip

DOI. 10.1137/07070704X

1. Introduction.

Landslides exhibit a great diversity of movement styles and rates, including steady creeping slip, intermittent rapid slip, and catastrophic avalanching. Recently Iverson [4, 5] introduced a new theoretical model that in numerical simulations exhibits all these behaviors as a consequence of pore-pressure feedback. Most intriguing is the transition between steady and intermittent slip. In this paper we analyze this transition as a bifurcation problem.

As sketched in Figure 2.1, consider a block of porous soil on a rigid planar slope that is inclined at an angle θ. If there is no liquid in the pores of the soil, then friction can support its weight at rest provided μ_0, the coefficient of static friction, is greater than $\tan\theta$. If, however, water pressure acting on the base of the block is sufficiently large, the block will begin to slide. Suppose that it slides rigidly except for a zone of intense shearing at its base. If the soil in the basal shear zone is compacted, the governing equations admit a solution with steady sliding, due to the following sequence of physical effects:

> As the basal zone shears, it dilates; this expansion creates new pore space, thereby reducing the fluid pressure in the expanding pores; in consequence, the normal traction on the soil matrix is increased; and increased friction between the soil and the base can balance the driving and resisting forces, leading to steady creep as water pressure is restored by steady diffusion from the overlying slide block.

If friction is rate-independent, this steady creeping motion is stable. However, even a small amount of rate softening in the friction law is sufficient to destabilize steady

motion through a Hopf bifurcation. This bifurcation is the primary focus of the present paper.

Hopf bifurcation explains the origin of oscillatory behavior in the system. Intermittent behavior—brief periods of rapid slipping alternating with comparatively long periods with no slipping—arises from the singular behavior of friction at zero velocity. Specifically, the resisting frictional force jumps to a static value dictated by the ambient pore pressure. The block then remains stationary while diffusion brings pore pressure back up to a level where friction can no longer balance gravity.

The outline of this paper is as follows. In section 2 we introduce the equations of Iverson's model, nondimensionalize them, and linearize them around the steady-state solution. Mathematically, provided the block velocity is positive, this model may be described as a parabolic PDE for the pore pressure coupled through a boundary condition to an ODE for the block velocity. In section 3 the linearized equations are solved by separation of variables, leading to a trancendental equation for eigenvalues. In section 4 we extract the condition for bifurcation by analyzing the eigenvalue equation. In section 5 we summarize the results of supporting computations, which agree well with the theoretical predictions. In section 6 we present a concluding discussion regarding our findings. Finally, in an appendix we provide a mathematical proof omitted from the main text.

Mathematically, this model is interesting in that time-periodic behavior appears in a problem governed by the (scalar) diffusion equation (of course, coupled to an ODE through a boundary condition). Physically, the model is important because it provides a parsimonious mathematical description of diverse landslide behavior that has not been rigorously analyzed until now.

2. Governing equations.

2.1. Dimensional formulation. As indicated in Figure 2.1, consider a block of soil of porosity ϕ, height H_s, and density ρ_s, which is defined as the mass of solid grains per unit total volume (i.e., the porosity is factored into ρ_s). The block is saturated with pore water of density ρ_w to a height H_w that does not change with time.[1]

Suppose this system is supported by a planar slope inclined at an angle θ. Using coordinates aligned with the slope, we describe this system by the pore pressure $p(y,t)$, the traction $\tau_x(t), \tau_y(t)$ exerted by the supporting plane on the solid matrix (effective stress at the base), and, assuming the block slides as a rigid unit over a shearing basal zone, the velocity $v_x(t), v_y(t)$ of the block. The motion is assumed to be one-dimensional in that all variables are independent of the tangential coordinate x, but it is two-dimensional in that the block is allowed to move in the normal direction as well as the tangential—indeed, dilatancy of the shearing basal zone requires this.

Let us decompose the total pore pressure into a hydrostatic component plus the excess pore pressure associated with dilation,

$$p_{\text{tot}}(y,t) = p_{\text{hydro}}(y) + p_{\text{ex}}(y,t),$$

[1] The assumption that H_w is constant is not strictly satisfied owing to small fluxes of water to and from the basal shear zone. Changes in H_w can be estimated from simple mass-balance considerations. On this basis we estimate that such changes are less than 1%. We exclude such changes from our model, however, not only for the sake of simplicity, but also because rigorous assessment of changes in water-table height requires consideration of hysteretic, nonlinear processes associated with variably saturated groundwater flow [2].

Incidentally, the model can easily be modified to allow for flux of water into the soil beneath the shear zone as well as flux into the soil above the shear zone. Computations with these options did not differ qualitatively from those reported here.

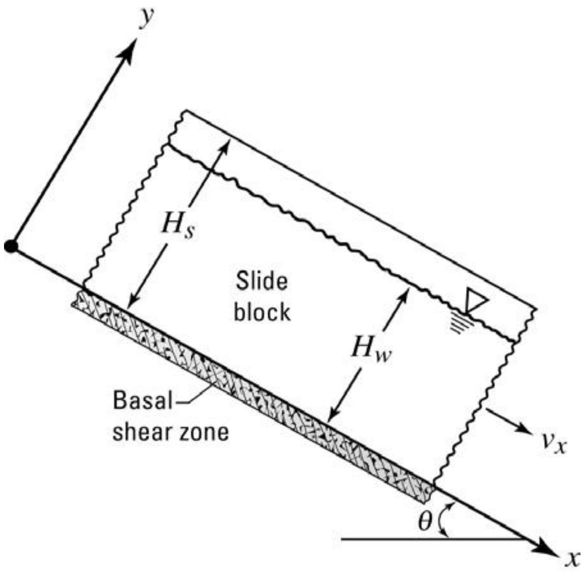

FIG. 2.1. *Schematic of landslide block.*

where

$$p_{\text{hydro}}(y) = \rho_w g \cos\theta(H_w - y). \tag{2.1}$$

Following arguments summarized by Iverson [5], we suppose the excess pore pressure evolves diffusively,

$$\partial_t p_{\text{ex}} = D\partial_{yy} p_{\text{ex}}, \qquad 0 < y < H_w, \tag{2.2}$$

with boundary conditions

$$\begin{array}{lrcl} \text{(a)} & p_{\text{ex}}(H_w, t) & = & 0, \\ \text{(b)} & \partial_y p_{\text{ex}}(0, t) & = & (\rho_w g/K) v_y(t), \end{array} \tag{2.3}$$

where D is the saturated hydraulic diffusivity, K is the saturated hydraulic conductivity below the water table, and g is the acceleration of gravity. Typical values for these parameters, and for others below, are given in Table 2.1. Equation (2.3)(b) follows from Darcy's law [2]: the excess-pressure gradient at the boundary of the shear zone is proportional to the fluid flux through the boundary that is needed to fill the volume vacated through dilatancy.

In Iverson's model, the behavior of the basal zone is characterized simply by two constitutive equations: (i) dilatancy,

$$v_y = \psi v_x, \tag{2.4}$$

where ψ is the angle of dilatancy, and (ii) friction,

$$\begin{array}{lccccccc} \text{either} & v_x & = & 0 & \text{and} & |\tau_x| & < & \mu_0 \tau_y, \\ \text{or} & \tau_x & = & -\mu(v_x)\tau_y & \text{and} & v_x & \geq & 0, \end{array} \tag{2.5}$$

where $\mu(v_x)$ is a rate-softening coefficient of friction,

$$\mu(v_x) = \mu_0[1 - a \sinh^{-1}(v_x/2v_{\text{ref}})], \tag{2.6}$$

Parameter values in the model.

Parameter	Definition	Units	Plausible values	Values used in computations
a	Rate-dependence coefficient in friction rule	—	0 — 0.05	0.02, 0.04
D	Hydraulic diffusivity of soil	m^2/s	10^{-8} — 1	10^{-8} — 3×10^{-1}
g	Acceleration of gravity	$\mathrm{m/s}^2$	9.8	9.8
H_s	Thickness of soil block	m	0.1 — 100	0.65
H_w	Height of water table	m	0 — 100	0.3701
K	Hydraulic conductivity of soil	m/s	10^{-11} — 1	2×10^{-9} — 2×10^{-1}
v_{ref}	Reference slip rate in friction rule	m/s	10^{-4} — 1	7×10^{-4} — 4×10^{-1}
θ	Slope angle	radians	0.1 — 0.8	0.5411
μ_0	Static friction coefficient of soil	—	0.2 — 1.2	0.8693
ρ_w	Mass density of pore water	$\mathrm{kg/m}^3$	900 — 1100	1000
ρ_s	Bulk density of dry soil	$\mathrm{kg/m}^3$	1000 — 2200	1600
ϕ	Porosity of soil block	—	0.2 — 0.6	0.4
ψ	Dilatancy angle of shearing soil	radians	-0.2 — 0.2	0.1047

v_{ref} being a reference velocity. Regarding dilatancy, we take ψ to be constant. Under continued shearing, ψ will in fact converge to zero as the soil tends to a critical state. However, as shown in the landslide experiments of [6], the evolution to critical state occurs only when displacement magnitudes greatly exceed those appearing during the processes considered here. Equation (2.6) is a three-parameter representation of rate-weakening friction that we use instead of a more complicated, rate-and-state friction model, which typically employs six parameters. Because of its simplicity, we are able to explore the full relevant parameter space. However, investigation of the model with a rate-and-state friction law remains a task for future research.

Finally, the system is completed by Newton's equations of motion for the block. For this system, the mass per unit area of slope is $\rho_s H_s + \phi\rho_w H_w$. Thus, for the tangential component of the motion we have

$$(\rho_s H_s + \phi\rho_w H_w)\partial_t v_x = (\rho_s H_s + \phi\rho_w H_w) g \sin\theta + \tau_x. \tag{2.7}$$

Regarding the normal component, we are assuming the dilatancy ψ is small, and therefore, in light of (2.4), we may neglect acceleration in the y-direction; thus Newton's equation reduces to force balance. According to Terzaghi's effective-stress principle (e.g., see [2]), the effective normal traction exerted by the slope on the solid matrix is the total stress reduced by the pore pressure at the base; in symbols,

$$\tau_y = (\rho_s H_s + \phi\rho_w H_w) g \cos\theta - p_{\mathrm{tot}}(0,t).$$

On substitution of (2.1), we obtain our last equation,

$$\tau_y = [\rho_s H_s - (1-\phi)\rho_w H_w] g \cos\theta - p_{\mathrm{ex}}(0,t). \tag{2.8}$$

This formulation differs from that of Iverson [5] in two main respects:

- Most importantly, here we allow for rate-softening friction.
- Our assumptions on the imposed pore pressure are more restrictive: specifically, in the notation of (8) of Iverson [5], we assume that $\beta = \cos\theta$ and $W = 0$. Physically, these assumptions imply that there is no flux of groundwater normal to the water table, except for the flux caused by shear-zone dilation.

Provided

$$(\rho_s H_s + \phi\rho_w H_w)\sin\theta \le \mu_0\left[\rho_s H_s - (1-\phi)\rho_w H_w\right]\cos\theta, \tag{2.9}$$

the above equations have a solution with $p_{\mathrm{ex}} = 0$ and $v = 0$: i.e., friction is sufficient to resist the pull of gravity. We study the case where (2.9) is violated.

2.2. Nondimensionalization. We nondimensionalize (2.2)–(2.8) by defining

$$t = \frac{t^{(\mathrm{dim})}}{H_w^2/D}, \quad y = \frac{y^{(\mathrm{dim})}}{H_w}, \quad v = \frac{v_x^{(\mathrm{dim})}}{K}, \quad p = \frac{p_{\mathrm{ex}}^{(\mathrm{dim})}}{\rho_w g H_w}, \quad \tau = \frac{\tau^{(\mathrm{dim})}}{\rho_s g H_s}, \tag{2.10}$$

where the superscript *dim* indicates the dimensional version of a variable. We will eliminate $v_y^{(\mathrm{dim})}$ from the equations, so we do not define a scaled version of this variable; however, we nondimensionalize both components of τ. As in Iverson [5], we have used the diffusive time scale to nondimensionalize t; however, our nondimensionalization of v differs from that of [5]. We also define two dimensionless constants that will appear in the nondimensionalized equations below,

$$\varepsilon = \frac{K/g}{H_w^2/D} \qquad \text{and} \qquad M = \frac{\rho_w H_w}{\rho_s H_s}. \tag{2.11}$$

The first, which according to Table 2.1 is very small, is the ratio of the acceleration time scale to the diffusive time scale; the second is ϕ^{-1} times the ratio of fluid mass to solid mass.

The evolution of the nondimensionalized pressure is governed by

$$\begin{array}{llcll} \text{(a)} & \partial_t p & = & \partial_{yy} p, & 0 < y < 1, \\ \text{(b)} & p(1,t) & = & 0, & \\ \text{(c)} & \partial_y p(0,t) & = & \psi v(t). & \end{array} \tag{2.12}$$

In nondimensional variables, the friction relation (2.5) does not change, except that the rate-softening coefficient in (2.6) must be rescaled to give

$$\mu(v) = \mu_0\left[1 - a\sinh^{-1}\left(\frac{K}{2v_{\mathrm{ref}}}v\right)\right]. \tag{2.13}$$

Newton's equations for the motion of the block scale to

$$\begin{array}{llcl} \text{(a)} & \varepsilon\,\partial_t v & = & \sin\theta - (1+\phi M)^{-1}\tau_x, \\ \text{(b)} & \tau_y & = & [1-(1-\phi)M]\cos\theta - Mp_{\mathrm{ex}}(0,t). \end{array} \tag{2.14}$$

In nondimensional variables, the no-motion condition (2.9) may be rewritten as

$$\tan\theta \le A_1\mu_0, \tag{2.15}$$

where A_1 is the first of two mass ratios defined in (2.17) below. If (2.15) is violated and hence $v > 0$, then (2.5) and (2.14)(b) may be combined to solve for τ_x. On substitution into (2.14)(a), we obtain

$$\varepsilon\,\partial_t v = \sin\theta - \mu(v)\left(A_1\cos\theta - A_2 p(0,t)\right), \tag{2.16}$$

where

$$A_1 = \frac{1-(1-\phi)M}{1+\phi M}, \qquad A_2 = \frac{M}{1+\phi M}. \tag{2.17}$$

As long as $v > 0$, the motion is described by (2.12), (2.16).

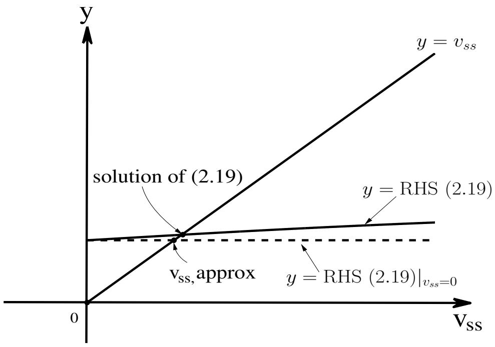

FIG. 2.2. *Graphical solution of* (2.19).

2.3. A steady solution and linearization of the equations. Henceforth we assume that

$$(2.15) \text{ is violated and } \psi > 0.$$

Let us look for a steady-state solution $p_{\mathrm{ss}}(y), v_{\mathrm{ss}}$ of the equations of motion. It follows from (2.12) that

$$p_{\mathrm{ss}}(y) = \psi v_{\mathrm{ss}}(y-1), \tag{2.18}$$

and this relation may be substituted into (2.16) to obtain an implicit equation for v_{ss},

$$v_{\mathrm{ss}} = (A_2\psi)^{-1}\left[\frac{\sin\theta}{\mu(v_{\mathrm{ss}})} - A_1\cos\theta\right]. \tag{2.19}$$

If the friction coefficient is independent of velocity, then this equation is in fact a formula for v_{ss}. Even with rate-softening friction, for parameter values such as in Table 2.1, the right-hand side (RHS) of (2.19) is a slowly varying function of v_{ss} (see Figure 2.2). For example, defining

$$v_{\mathrm{ss,approx}} = (A_2\psi)^{-1}\left[\frac{\sin\theta}{\mu_0} - A_1\cos\theta\right] \tag{2.20}$$

as the solution of (2.19) in the rate-independent case, we may see that

$$\frac{\mu(v_{\mathrm{ss,approx}})}{\mu_0} = 1 - \mathcal{O}\left(\frac{a}{\psi}\frac{K}{v_{\mathrm{ref}}}\right),$$

and, unless ψ is extremely small, we have

$$\frac{a}{\psi}\frac{K}{v_{\mathrm{ref}}} \ll 1. \tag{2.21}$$

Thus, assuming $\psi > 0$ is not too small, we conclude that (2.19) has a unique solution close to $v_{\mathrm{ss,approx}}$.

Incidentally, there is a second solution of (2.19) at very large values of v_{ss}. To see this, observe from (2.13) that $\mu(v)$ vanishes when $v \approx (v_{\mathrm{ref}}/K)e^{1/a}$. Since $\mu(v_{\mathrm{ss}})$ occurs in the denominator, the RHS of (2.19) blows up as v tends to $(v_{\text{ref}}/K)e^{1/a}$, giving rise to a second intersection with the linear function on the left-hand side (LHS). This second steady-state solution of (2.19), for which the velocity is very large indeed, is always unstable, but it can be involved in the steady-state bifurcation of (2.12), (2.16) at extreme parameter values. For clarity, we shall refer to the first solution, given approximately by (2.20), as the *physical* steady state. Referring to the figure and comparing the derivatives of both sides of (2.19), we conclude that at the physical steady state

$$\frac{\sin\theta\,|\mu'(v_{\text{ss}})|}{A_2\psi\,\mu^2(v_{\text{ss}})} < 1. \tag{2.22}$$

To linearize (2.12), (2.16) near the (physical) steady-state solution, we define incremental variables $\overline{p}, \overline{v}$ by

$$p(y,t) = p_{\text{ss}}(y) + \overline{p}(y,t), \qquad v(t) = v_{\text{ss}} + \overline{v}(t).$$

Equations (2.12) are already linear, so we find trivially that

$$\begin{array}{lrcll} \text{(a)} & \partial_t\overline{p} & = & \partial_{yy}\overline{p}, & 0 < y < 1, \\ \text{(b)} & \overline{p}(1,t) & = & 0, & \\ \text{(c)} & \partial_y\overline{p}(0,t) & = & \psi\overline{v}(t), & \end{array} \tag{2.23}$$

and on linearizing (2.16) and simplifying using (2.19) we obtain

$$\varepsilon\partial_t\overline{v} = B_1\overline{p}(0,t) + B_2,\overline{v}, \tag{2.24}$$

where

$$B_1 = A_2\,\mu(v_{\text{ss}}) \quad \text{and} \quad B_2 = \sin\theta\,|\mu'(v_{\text{ss}})|/\mu(v_{\text{ss}}). \tag{2.25}$$

Since $\mu'(v_{\text{ss}}) < 0$, we have used the absolute value to emphasize that $B_2 > 0$.

3. Derivation of the eigenvalue equation. We seek a solution of the linearized equations (2.23), (2.24) with exponential time dependence $e^{-\lambda t}$ (note the minus sign). Using separation of variables, we derive from (2.23)(a),(b) that

$$\overline{p}(y,t) = P\sin[\sqrt{\lambda}(1-y)]e^{-\lambda t}, \qquad \overline{v}(t) = Ve^{-\lambda t},$$

where P and V are constants. Substitution of these formulas into (2.23)(c), (2.24) yields the 2×2 homogeneous linear system

$$\begin{bmatrix} \sqrt{\lambda}\cos\sqrt{\lambda} & \psi \\ B_1\sin\sqrt{\lambda} & \varepsilon\lambda + B_2 \end{bmatrix} \begin{bmatrix} P \\ V \end{bmatrix} = 0. \tag{3.1}$$

This system has a nonzero solution if and only if the determinant of the coefficient matrix vanishes, which leads to the trancendental equation for the decay rate λ,

$$\frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} = \varepsilon C_1\lambda + C_2, \tag{3.2}$$

where

$$C_1 = 1/B_1\psi, \qquad C_2 = B_2/B_1\psi. \tag{3.3}$$

Recalling (2.25), (2.22), we see that

$$C_2 < 1. \tag{3.4}$$

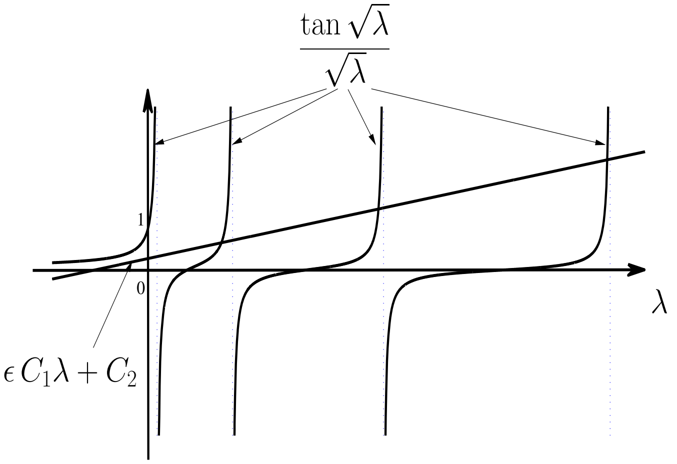

FIG. 4.1. *Graphical determination of the real solutions of* (3.2). *In the figure shown,* $\varepsilon C_1 = 0.02$ *and* $C_2 = 0.3$. *As indicated by* (4.9), *the two complex solutions of* (3.2) *lie in the unstable half-plane,* $\{\mathrm{Re}\,\lambda < 0\}$.

4. Analysis of the eigenvalue equation.

4.1. Introduction. As illustrated in Figure 4.1, (3.2) has an infinite sequence of positive roots. Since these eigenvalues are all in the stable half plane, they do not require further attention. It is not obvious, but (3.2) has two other, possibly complex, roots, which are the focus of the present section.

As a function of a complex variable, $(\tan\sqrt{\lambda})/\sqrt{\lambda}$ is a meromorphic function: i.e., apart from a sequence of poles on the positive real axis, it is single-valued and analytic in the entire plane. Although neither the numerator nor the denominator of this expression is single-valued, the quotient avoids this difficulty. Of course, we use the same branch of $\sqrt{\lambda}$ in the numerator and the denominator so that

$$\lim_{\lambda\to 0}\frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} = 1.$$

To be specific, let us choose the branch

$$\sqrt{\lambda} = |\lambda|^{1/2}\, e^{i(\arg\lambda)/2}, \tag{4.1}$$

where $\arg\lambda$ satisfies

$$0 \le \arg\lambda < 2\pi.$$

The analysis of the complex roots of (3.2) is based on the simple behavior of $\tan\sqrt{\lambda}$ away from the positive real axis, as articulated in the following proposition.

PROPOSITION 4.1. *Let* Λ *be a wedge in* $\mathbb{C}$ *excluding the positive real axis, say,*

$$\Lambda = \{\lambda \in \mathbb{C} : \delta < \arg\lambda < 2\pi - \delta\}, \tag{4.2}$$

where $0 < \delta < \pi/2$. *Then, as* $|\lambda| \to \infty$ *in* Λ,

$$\tan\sqrt{\lambda} = i + \mathcal{O}(e^{-\delta\sqrt{|\lambda|}/2}). \tag{4.3}$$

Proof. By manipulating the definition of $\tan z$, we deduce that

$$\tan z = i\,\frac{1-e^{2iz}}{1+e^{2iz}}. \tag{4.4}$$

Now $|e^{2iz}| = e^{-2\operatorname{Im} z}$, so taking $z=\sqrt{\lambda}$ we see that

$$\tan\sqrt{\lambda} = i + \mathcal{O}(e^{-2\operatorname{Im}\sqrt{\lambda}}).$$

By (4.1), $\operatorname{Im}\sqrt{\lambda} = |\lambda|^{1/2}\sin(\arg\lambda/2)$. To complete the proof, we estimate $\arg\lambda$ with (4.2) and use the fact that $\sin(\delta/2)\geq\delta/4$. □

4.2. The rate-independent case ($C_2 = 0$). When friction is independent of velocity, the coefficient C_2 in (3.2) vanishes. In the appendix we prove that in this case (3.2) has no zeros in the left half plane: i.e., the steady solution is stable. Since the proof sheds little light on the Hopf bifurcation, we do not include it here. It is instructive, however, to locate the two complex eigenvalues.

Suppose $C_2 = 0$. By (4.3), for large $|\lambda|$ away from the positive real axis, (3.2) may be rewritten, approximately, as

$$e^{i[\pi-\arg\lambda]/2} = \varepsilon C_1|\lambda|^{3/2}e^{i\arg\lambda}.$$

Equating magnitudes we find that $|\lambda| = (\varepsilon C_1)^{-2/3}$, and then equating arguments we find the two approximate roots of (3.2):

$$\lambda = e^{i\pi/3}(\varepsilon C_1)^{-2/3},\quad e^{5i\pi/3}(\varepsilon C_1)^{-2/3}. \tag{4.5}$$

By (4.3) the error in this estimate is exponentially small in ε. Since $\operatorname{Re}\lambda \gg 1$, the associated eigenfunctions decay rapidly in time.

4.3. The rate-dependent case: Steady-state bifurcation. If C_2 assumes positive values, the complex[2] eigenvalues (4.5) can cause the linearized equations (2.23), (2.24) to lose stability if they cross into the left half plane. As we shall see in the next subsection, for physical parameter values, (2.23), (2.24) lose stability through a Hopf bifurcation: i.e., the complex eigenvalues cross the imaginary axis as a pair of complex conjugates. However, for mathematical completeness, we also ask when real solutions of (3.2) cross the imaginary axis. Indeed, one may see by inspection that $\lambda = 0$ is a root of (3.2) iff $C_2 = 1$. If one forces C_2 to its limiting value unity (cf. (3.4)), then the two solutions of (2.19) merge and annihilate one another at a steady-state bifurcation of limit-point type [3].

4.4. The rate-dependent case: Hopf bifurcation.

(a) *Main calculations.* Figure 4.2 shows a curve Γ in the $(\varepsilon C_1, C_2)$-plane that separates the infinite strip

$$\{(\varepsilon C_1, C_2)\ :\ 0<\varepsilon C_1<\infty,\ 0<C_2<1\}$$

into two regions in which (2.23), (2.24) are stable or unstable. This curve has the parametric representation

$$\varepsilon C_1 = \frac{2}{\mu^3}\,\frac{1-2e^{-\mu}\sin\mu - e^{-2\mu}}{1+2e^{-\mu}\cos\mu + e^{-2\mu}}, \tag{4.6}$$

[2] We shall refer to these roots of (3.2) as *complex* eigenvalues even though, for extreme parameter values, they may actually become real.

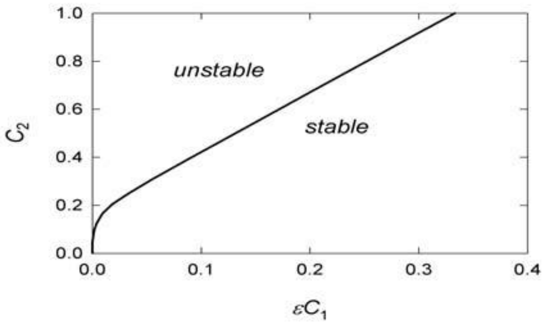

FIG. 4.2. *Graph of the Hopf bifurcation curve* Γ *defined parametrically by* (4.6), (4.7).

$$C_2 = \frac{1}{\mu}\,\frac{1 + 2e^{-\mu}\sin\mu - e^{-2\mu}}{1 + 2e^{-\mu}\cos\mu + e^{-2\mu}}, \tag{4.7}$$

where $0 \le \mu < \infty$. In the following proposition we show that (2.23), (2.24) undergo Hopf bifurcation when C_1, C_2 lies on Γ.

PROPOSITION 4.2. *If* $\varepsilon C_1, C_2$ *lie on* Γ, *then the complex eigenvalues of* (3.2) *are pure imaginary.*

Proof. Suppose (3.2) has a root on the positive imaginary axis, say, at $\lambda = i\mu^2/2$, where $\mu \ge 0$. Then $\sqrt{\lambda} = (1+i)\mu/2$. Equating real and imaginary parts of (3.2), we conclude that

$$\varepsilon C_1 = \frac{2}{\mu^2}\,\mathrm{Im}\left\{\frac{\tan[(1+i)\mu/2]}{(1+i)\mu/2}\right\}, \qquad \varepsilon C_2 = \mathrm{Re}\left\{\frac{\tan[(1+i)\mu/2]}{(1+i)\mu/2}\right\}. \tag{4.8}$$

We claim that

$$\tan[(1+i)\mu/2] = \frac{2e^{-\mu} + i(1 - e^{-2\mu})}{1 + 2e^{-\mu}\cos\mu + e^{-2\mu}},$$

which may be proved by recalling (4.4), multiplying and dividing by the complex conjugate of the denominator, and simplifying. Equations (4.6), (4.7) result on multiplying by $[(1+i)\mu/2]^{-1} = (1-i)/\mu$ and substituting into (4.8). □

By examining the Taylor series expansions of the numerators in (4.6), (4.7), we see that

$$\lim_{\mu\to 0} \varepsilon C_1 = 1/3, \qquad \lim_{\mu\to 0} C_2 = 1,$$

which is behavior that may be seen in Figure 4.2. At the other extreme, $\mu \gg 1$, or equivalently $\varepsilon C_1 \ll 1$, the exponentials in (4.6), (4.7) may be neglected, so that it is possible to eliminate μ and obtain a relation between the C's that characterizes Hopf bifurcation:

$$C_2 = \left(\frac{\varepsilon C_1}{2}\right)^{1/3}, \tag{4.9}$$

both sides of the equation being small. The proof of the proposition shows that at parameter values given by (4.6), (4.7), the complex eigenvalues of (2.23), (2.24) are $\pm i\mu^2/2$, and in the asymptotic range the complex eigenvalues are approximately $\pm iC_2^{-2}/2$. In particular, the bifurcating periodic solutions have periods approximately equal to

$$\frac{2\pi}{|\lambda|} \approx 4\pi C_2^2. \tag{4.10}$$

Our simulations below confirm the accuracy of this prediction.

It is natural to undo the nondimensionalization of the equations to seek a prediction for the period of oscillations of landslide motion in the field. However, the enormous ranges of D, K, and v_{ref} in Table 2.1 diminish the value of this exercise. Specifically, one obtains oscillation periods ranging from about 10^{-7} to 10^3 seconds. At the small end, these periods will be unobservable by conventional measurement techniques. At the upper end, these periods are similar to those sometimes observed in the field and also observed in the landslide experiments of Iverson et al. [6].

(b) *Numerical limitations.* Provided $\varepsilon C_1 \ll 1$, (4.9) characterizes the loss of stability in the PDE (2.23), (2.24) through Hopf bifurcation. However, this relation is not accurate for numerical simulations if

$$\varepsilon C_1 \leq \mathcal{O}(h^3), \tag{4.11}$$

where h is the mesh size. To motivate this assertion, first recall that the eigenvalues of the PDE at the bifurcation point have absolute value

$$\mu^2/2 = 1/(2C_2^2) = 2^{-1/3}(\varepsilon C_1)^{-2/3} \gg 1.$$

On the other hand, the largest eigenvalue of the discretization is $\mathcal{O}(h^{-2})$, and moreover the large eigenvalues of the discretization do not approximate eigenvalues of the PDE. These two observations warn of a mismatch if

$$(\varepsilon C_1)^{-2/3} \geq \mathcal{O}(h^{-2}),$$

which is equivalent to (4.11).

Let us illustrate this phenomenon for a second-order explicit discretization of the PDE. (In the simulations below, we used the Crank–Nicholson method, for which the analysis is similar in spirit but more technical in detail.) For a positive integer N, let $h = 1/N$ be the mesh size in discretizing space, and let

$$y_n = 1 - nh, \quad n = 0, 1, \ldots, N+1.$$

Consider the semidiscrete approximation for the pressure equation (2.23),

(4.12)

$$\begin{array}{llcll}
\text{(a)} & \partial_t p_n & = & h^{-2}\left[p_{n+1} - 2p_n + p_{n-1}\right], & n = 1, 2, \ldots, N, \\
\text{(b)} & p_0 & = & 0, & \\
\text{(c)} & (2h)^{-1}\left[p_{N-1} - p_{N+1}\right] & = & \psi v, &
\end{array}$$

and for the velocity equation (2.24),

$$\varepsilon \partial_t v = B_1 p_N + B_2 v. \tag{4.13}$$

As with the PDE, we look for solutions of (4.12), (4.13) such that $p_n(t)$ and $v(t)$ have exponential time dependence $e^{-\lambda t}$. It follows from (4.12)(a),(b) that

$$p_n(t) = Pe^{-\lambda t}(z^n - z^{-n}), \qquad n = 0, 1, \ldots, N+1,$$

$$v(t) = Ve^{-\lambda t},$$

where

$$\lambda = \frac{z - 2 - z^{-1}}{h^2}. \tag{4.14}$$

Substituting into (4.12)(c), (4.13), we obtain a solution provided

$$\det \begin{bmatrix} (2h)^{-1}(z - z^{-1}) & \psi \\ B_1 & B_2 - \varepsilon h^{-2}(z - 2 - z^{-1}), \end{bmatrix} = 0, \tag{4.15}$$

where we have divided the first column of this determinant by z^N.

We analyze the Hopf bifurcation in this system as with the PDE: i.e., we ask when there is a solution z of (4.15) such that λ, computed according to (4.14), lies on the imaginary axis, say, $\lambda = i\mu$. We consider only the asymptotic range $\mu \gg 1$. Hence $z \gg 1$, and we may solve (4.14) for z approximately by neglecting z^{-1}; i.e.,

$$z = 2 + i\mu h^2.$$

Substituting this approximation into (4.15) and solving for B_i from (3.3), we rewrite (4.15) as

$$\det \begin{bmatrix} h^{-1} + i\mu h/2 & \psi \\ 1/(\psi C_1) & C_2/C_1 - i\varepsilon\mu \end{bmatrix} = 0. \tag{4.16}$$

From the vanishing of the imaginary part of this equation, we conclude that

$$C_2 = \frac{2}{h^2}\, \varepsilon C_1, \tag{4.17}$$

which is the relation that characterizes Hopf bifurcation at large eigenvalues in the discretization; thus, (4.17) replaces (4.8) when discretization effects invalidate the latter.

5. Supporting computations.

5.1. Methods. To test our bifurcation predictions and examine details of the dynamics described by (2.2) and (2.7), we solved discretized versions of the equations numerically. Values of most parameters used in the computations were fixed to match those of physical landslide experiments in which both quasi-steady sliding and stick-slip behavior were observed [6], whereas values of K, D, and v_{ref} were modified systematically to make computational transects of the εC_1-C_2 parameter space (Table 2.1). Specifically, values of ε were manipulated by adjusting the values of K and D in accordance with values appropriate for diverse soils; then, while holding εC_1 essentially constant, C_2 was increased incrementally through a plausible range by adjusting v_{ref}. As C_2 increased, bifurcation was detected as a transition from convergent oscillations (leading to a stable steady state) to divergent oscillations (leading to repetitive stick-slip cycles) in the v-p phase plane, a result described in more detail below.

With few exceptions, the value of the rate-weakening friction parameter a used in all computations was 0.02, consistent with observations in rate-controlled shear tests with many soil-like materials [8, 12]. To attain values of C_2 large enough to cause bifurcation when $\varepsilon C_1 > 0.1$, however, it was necessary to increase a to 0.04. Such large values of a, C_2, and εC_1 are atypical and perhaps even physically implausible, but mathematically they characterize the upper fringes of the εC_1-C_2 parameter space.

Our computational algorithm employed an explicit fourth-order Runge–Kutta method to solve the ODE (2.7) and the Crank–Nicholson method to solve the PDE (2.2) [9] in an operator-splitting scheme. First a Runge–Kutta time step Δt was taken to advance the slide-block velocity $v_x(t)$ while holding the excess basal pore pressure $p_{\text{ex}}(0, t)$ constant; then using the new $v_x(t)$ to update the basal boundary condition (2.3b) a Crank–Nicholson time step Δt was taken to advance the pore-pressure diffusion solution $p_{\text{ex}}(y, t)$. The updated pore-pressure solution provided the basal pore pressure necessary to take the next Runge–Kutta step. Refinement of this scheme by using the mean $v_x(t)$ between successive time steps to update (2.3b) and then recompute $p_{\text{ex}}(y, t)$ using this mean yielded solutions that differed negligibly from those of the basic scheme, provided that time steps were sufficiently small. Therefore, we used the basic scheme for all computations reported in this paper.

Our discretization of (2.2) and (2.7) used times steps with a size Δt suitable for resolving slide-block acceleration, which had an intrinsic timescale K/g typically much smaller than that of pore-pressure diffusion (i.e., $\varepsilon \ll 1$). In trial calculations we initially set $\Delta t = (K/g) \sin \theta$, the time necessary for the block to accelerate from 0 to K in the absence of friction and pore-pressure feedback. Subsequent trials showed that when friction and feedback were present, $\Delta t \gg (K/g) \sin \theta$ could generally be used with negligible loss of accuracy. Therefore, we consistently employed $\Delta t = 0.0002s$ to produce all computational results reported in this paper, although we regularly checked these results against those obtained using smaller time steps. Also, for the sake of consistency, our spatial discretization of (2.2) employed $h = 0.001$ for all results reported here, except for trials exploring finite-h effects.

In all computations we used $H_w = 0.3701m$, a value 1% larger than the static limiting equilibrium value that applies when (2.9) reduces to an equality for the parameter values listed in Table 2.1. As indicated by (2.1), fixing the initial value of H_w also fixed the background pore-pressure distribution $p_{\text{hydro}}(y)$. An initial excess pore-pressure distribution could be specified by (2.18), using (2.20) as an estimate for the steady-state velocity. In practice, during production runs, we iterated (2.19) one or more times to improve the initial estimate (2.20), in order to hasten convergence to the steady state.

5.2. Results. Our computational results are summarized in Figure 5.1, a graph that depicts theoretical bifurcation curves and computed bifurcation points in the εC_1-C_2 parameter space. The broad range of values spanned by this parameter space reflects the broad range of K and D values that are physically plausible for diverse soils (e.g., [2]), and it illustrates the wide scope of the bifurcation phenomenon.

We determined all bifurcation points shown in Figure 5.1 to at least two significant digits. At this level of precision, the computed bifurcation points lie exactly on the theoretical Hopf-bifurcation curve Γ (solid line in Figure 5.1), provided the simulation is not polluted by finite-h effects. When $\varepsilon C_1 \leq \mathcal{O}(h^3)$, numerical effects determine the location of the bifurcation point, and it may be seen from the figure that the bifurcation is accurately described by (4.17) (dashed line in Figure 5.1).

The physical character of the Hopf bifurcation is illustrated by phase portraits depicting coevolution of $v_x(t)$ and $p_{\text{ex}}(0, t)$. Figure 5.2 shows typical phase portraits

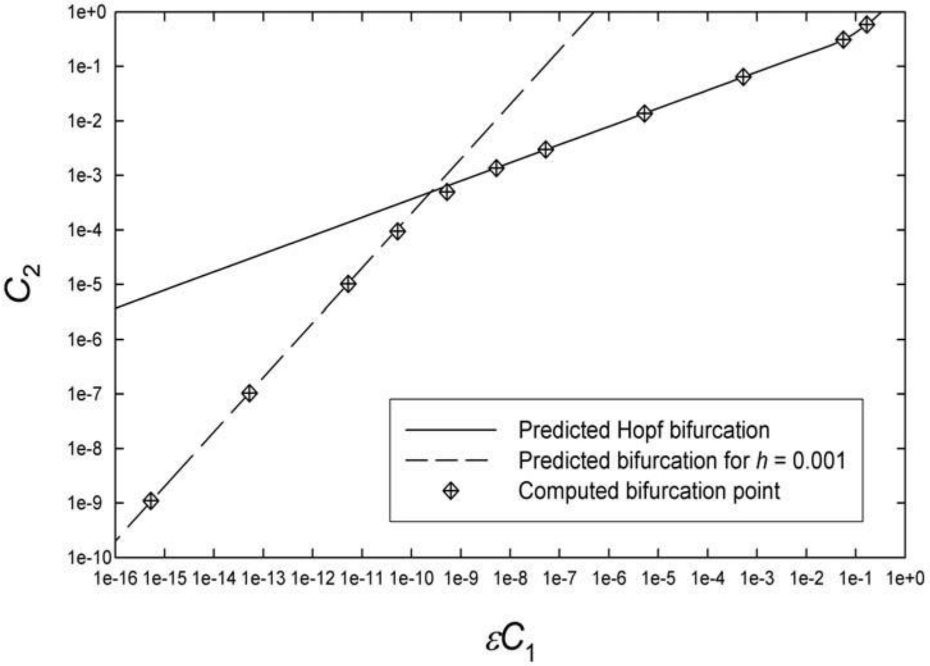

FIG. 5.1. *Comparison of computed bifurcation points with the Hopf bifurcation curve* Γ *predicted by* (4.6), (4.7) *(solid line), and the finite-h limit* (4.17) *for the case in which* $h = 0.001$ *(dashed line).*

for C_2 near the bifurcation point. The bifurcation is subcritical—when $C_2 > C_{2\text{Hopf}}$, the solution evolves to a periodic solution whose amplitude does not tend to zero as $C_2 \to C_{2\text{Hopf}}$. (Note that Figures 5.2B and 5.2C have different scales.) As expected, the evolution toward or away from the steady state slows down as the bifurcation point is approached [11].

For the parameter values used in making Figure 5.2, (4.10) predicts that near the bifurcation point, the period of oscillations is 0.325 s. By comparision, the oscillations depicted in Figure 5.2C have a computed period of 0.336 s. The fairly large discrepancy between these two numbers is related to the fact that the bifurcation is subcritical. Strictly speaking, (4.10) predicts the period of the small-amplitude, unstable orbits close to the bifurcation point, while Figure 5.2C shows a moderate-amplitude, stable orbit to which the solution jumps when C_2 exceeds $C_{2\text{Hopf}}$. A better comparison is provided by the nearly periodic, decaying solution shown in Figure 5.2B, in which the numerically estimated period is 0.324 s.

During part of the periodic orbits in Figures 5.2C and 5.2D, the velocity vanishes. This stick-slip behavior occurs because the nonlinearity limiting growth of the oscillations is a nonsmooth one, i.e., the discontinuous behavior of friction at $v = 0$. In no instance did oscillations persist without stick-slip behavior.

Transitions in phase-portrait behavior for other values of εC_1 were qualitatively similar to those illustrated in Figure 5.2 except for unphysically large values of εC_1: i.e., near the end of Γ at the point $(1/3, 1)$. In the latter case, the large-time orbit differs from Figure 5.2 in that the block "sticks" during a large fraction of the period, even immediately after bifurcation.

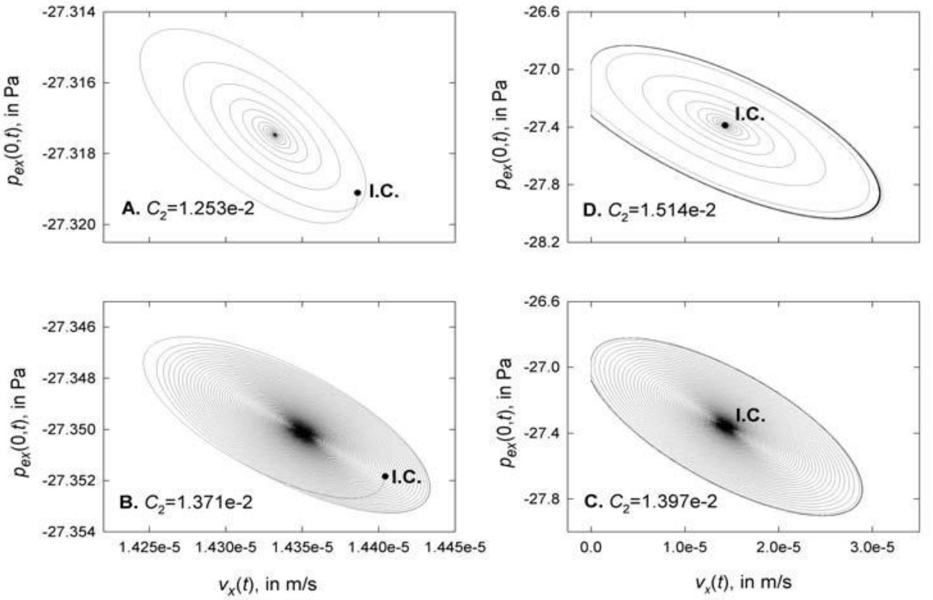

FIG. 5.2. *Examples of computed orbits in the* v_x, p_{ex} *phase plane for a case in which* $\varepsilon C_1 = 5.256\times10^{-6}$ *and* $C_{2Hopf} = 1.380\times10^{-2}$. *These computations used* $K = 2\times10^{-4}$ *m/s,* $D = 1\times10^{-3}$ *m*^{2}*/s,* $a = 0.02$, *and values of* v_{ref} *ranging from* 2.4×10^{-3} *to* 2.9×10^{-3} *m/s to obtain varying values of* C_2. *All other parameters were held fixed at the values listed in Table* 2.1. *The point marked "I.C." indicates the initial condition used in each computation. Note that the value of* C_2 *increases moving counterclockwise in the figure from frames* A *through* D. *In frame* B, C_2 *is just below critical, while in frame* C, *it is just above. Incidentally, in frame* D, *motion along the portion of the trajectory where* $v \equiv 0$, *which is governed by diffusion alone, is slower than along the remainder of the trajectory, and this effect is more pronounced if* C_2 *is further from the bifurcation point.*

6. Concluding discussion. Hopf bifurcation occurs in solutions of equations that provide a parsimonious model of landslide motion regulated by dilatancy, pore-pressure feedback, and rate-weakening friction. The bifurcation is manifested as an abrupt transition (thus, the bifurcation is subcritical) from stable, steady, downslope motion to periodic motion characterized by repetitive stick-slip cycles. The existence of stick-slip behavior in this system is noteworthy because, unlike classical models that exhibit stick-slip, our model includes no elastic element that exerts a variable and reversible driving force. (The archetype model for stick-slip behavior is a rate-weakening friction block pulled along a plane by an elastic spring.) Instead, in our model, the driving force is the steady pull of gravity, and the frictional resisting force is mediated by pore-pressure diffusion. Effects of pore-pressure diffusion have also been studied in the context of stick-slip models that include an elastic driving element [10], but to our knowledge no previous model has duplicated ours in omitting elastic forces while retaining the capacity for stick-slip behavior.

Analysis and computations show that the Hopf bifurcation leading to stick-slip behavior in our model is precisely governed by the parameters εC_1 and C_2, although decomposition of these parameters into their physical components shows that their variation depends mostly on variations in ε and the velocity ratio K/v_{ref}. Physically, the timescale ratio ε specifies the relative speeds at which the landslide characteristically moves and excess pore pressure characteristically diffuses, whereas K/v_{ref}

specifies the degree to which rate-weakening friction affects landslide motion. For relevant parameter values (Table 2.1), $\varepsilon \ll 1$ applies almost universally, indicating that pore-pressure diffusion is a relatively slow process that serves to regulate the inherently faster process of landslide motion. Also, for relevant parameter values, $K/v_{\text{ref}} \ll 1$ is typical, although K/v_{ref} values of order 1 or larger are possible (see Table 2.1). For $K/v_{\text{ref}} \ll 1$, the characteristic slip velocity $v_x = \mathcal{O}(K)$ is small. Taking the limit $v_{\text{ss}} = 0$ and then combining (3.3), (2.25), and (2.6), we calculate that

$$C_2 = \frac{\sin\theta}{\psi A_2}\,\frac{aK}{2\mu_0 v_{\text{ref}}},$$

which shows that, for $K/v_{\text{ref}} \ll 1$, increases in K/v_{ref} produce increases in C_2 and hence decreases in stability. This is the behavior typically observed in our computations. By contrast, if K/v_{ref} becomes comparable to or greater than 1, increases in K/v_{ref} can produce decreases in C_2 and hence *increases* in stability. Physically, this behavior reflects the fact that friction, which decreases logarithmically at large velocities, becomes increasingly insensitive to v as slip rates grow large.

Another important observation regarding the physics described by our model concerns the consistent manner in which orbits in the v_x-p_{ex} phase plane are skewed. As shown in Figure 5.2, the minimum $p_{\text{ex}}(0,t)$ always lags the maximum $v_x(t)$ by less than one quarter of an orbit cycle, irrespective of whether orbits diverge unstably or converge to a fixed point. Similar orbit skewness is exhibited in all of our computational results. However, as $\varepsilon C_1 \to 0$ the orbit skewness gradually diminishes, so that orbits become almost symmetrical about the line $v_x = v_{\text{ss}}$ and the phase lag approaches 1/4-cycle. This skewness of the orbits is a consequence of inertia. To illustrate this, observe that $\varepsilon C_1 \to 0$ if, for example, $K \to 0$; it follows from (2.10) that the dimensional steady-state velocity tends to zero as $K \to 0$, and hence inertial effects will disappear in this limit.

Finally, we emphasize that two key effects are not included in our model: (i) parameter evolution (e.g., dilatancy evolution) and (ii) a rate-and-state friction law in which the friction coefficient evolves with time [1, 10]. Such effects could lead to other kinds of instabilities, including a possibly more complex bifurcation than what we have analyzed.

Appendix.

PROPOSITION A.1. *If $C > 0$, the function*

$$f(\lambda) \equiv \frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} - C\lambda$$

has no zeros in the closed left half plane $\{\lambda : \operatorname{Re}\lambda \le 0\}$.

Proof. For any $R > 0$, let Ω_R be the half disk

$$\{\lambda : \operatorname{Re}\lambda < 0,\ |\lambda| < R\},$$

inside which f is analytic. According the principle of the argument [7, Chapter 4, section 4], provided f is nonzero on $\partial\Omega_R$, the number of zeros of f in Ω_R equals the variation of $\arg f$ around the boundary. It is obvious that $\operatorname{Re}(-C\lambda) \ge 0$ on $\partial\Omega_R$. We claim that, no matter how large R may be,

$$\operatorname{Re}\frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} > 0 \qquad \text{on } \partial\Omega_R.$$

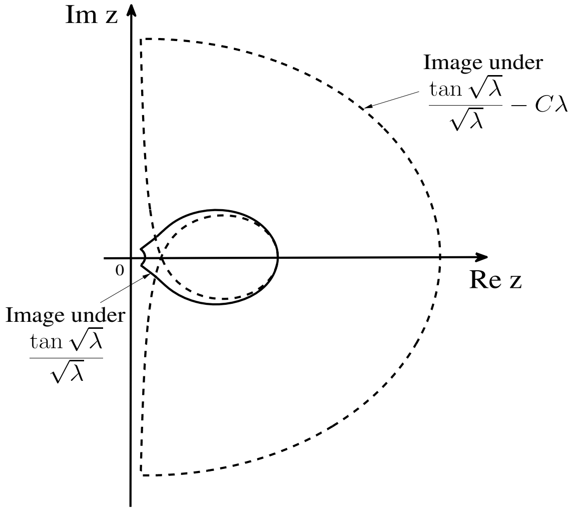

FIG. A.1. *Images of the semicircle $\partial\Omega_R$ in the complex plane under two mappings (see the appendix). The radius $R = 100$, and the constant $C = 0.02$.*

Thus, the variation of the argument of f around $\partial\Omega_R$ is zero, and this proves the result.[3]

Let us prove the claim. For λ on the semicircle $\{\lambda : \operatorname{Re}\lambda \le 0, |\lambda| = R\}$, we invoke the asymptotic form (4.3) and observe that

$$\operatorname{Re}\frac{i}{\sqrt{\lambda}} = |\lambda|^{-1/2}\cos\left(\frac{\pi - \arg\lambda}{2}\right) > 0;$$

the reason for the inequality is that $-\pi/4 \le (\pi - \arg\lambda)/2 \le \pi/4$. For λ on the imaginary axis, since $f(\overline{\lambda}) = \overline{f(\lambda)}$, it suffices to restrict our attention to $\{\operatorname{Im}\lambda \ge 0\}$. Along the nonnegative imaginary axis we may parametrize $\sqrt{\lambda}$ as

$$\sqrt{\lambda} = (1+i)t, \qquad t \ge 0.$$

Substituting into (4.4), we find

$$\frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} = \frac{i}{(1+i)t}\,\frac{1 - e^{2i(1+i)t}}{1 + e^{2i(1+i)t}}.$$

Multiplying both the numerator and the denominator by the complex conjugate of the denominator and collecting terms, we calculate that

$$\operatorname{Re}\frac{\tan\sqrt{\lambda}}{\sqrt{\lambda}} = p(t)\,\frac{\sinh 2t + \sin 2t}{t} > 0,$$

where the positive factor

$$p(t) = \left|1 + e^{2i(1+i)t}\right|^{-2}$$

comes from the modulus squared of the denominator. This proves the proposition. □

[3] The reader may find it interesting to consult Figure A.1, which shows the image of $\partial\Omega_R$ under $(\tan\sqrt{\lambda})/\sqrt{\lambda}$ and under f.

A CONTINUUM THEORY OF CHIRAL SMECTIC C LIQUID CRYSTALS[*]

MARIA-CARME CALDERER[†] AND SOOKYUNG JOO[‡]

Abstract. We formulate a nonlinear continuum theory of flow of chiral smectic C liquid crystals (C*) involving molecular director, layer order parameter, polarization vector, flow velocity, and hydrostatic pressure fields. In addition to chiral orientational ordering, smectic C* phases also present positional ordering, with molecular centers of mass arranged in one dimensional layers. The nonzero tilt angle of the molecular director with respect to the layer normal together with the chirality is responsible for the ferroelectric nature of the phase. This results in a stronger coupling with applied electric fields than the dielectric nematic. We apply the model to study the molecular reorientation dynamics in homeotropic geometry under the influence of an applied electric field. The switching process between states with opposite polarization is understood by the traveling wave solution of the system. We prove existence and uniqueness of the traveling wave and show that the predicted switching time is smaller than that when the flow effect is neglected. We also obtain bounds on the speed of switching and an optimality condition on the parameters of the problem. Numerical simulations confirm the predictions of the analysis.

Key words. continuum theory, smectic liquid crystals, molecular reorientation dynamics, ferroelectric liquid crystals, traveling wave

1. Introduction.

We develop a model of smectic C* liquid crystals accounting for elastic, hydrodynamic, and electrostatic effects. The free energy includes the Oseen–Frank energy of nematic liquid crystals, the smectic C energy of the form proposed by Chen and Lubensky, and the ferroelectric electrostatic energy. We apply the governing equations to study the switching dynamics, in homeotropic geometry, between two states with opposite electric polarization. We apply a variational method to characterize the speed of the switching traveling wave and show that the predicted speed is greater than in the approach that neglects flow. We also obtain an optimality condition of the speed in terms of the parameters of the problem. We perform numerical simulations to illustrate the dynamics of switching. A main feature of our work is the study of the backflow effect due to the spontaneous polarization of the liquid crystal.

Liquid crystal phases form when a material has a degree of positional or orientational ordering yet stays in a liquid state. In the nematic state, molecules tend to align themselves along a preferred direction with no positional order of centers of mass. The unit vector field $\mathbf{n}$, nematic director, represents the average direction of molecular alignment. Moreover, if the liquid crystal is chiral, $\mathbf{n}$ follows a helical pattern with temperature-dependent pitch. Upon lowering the temperature, or increasing concentration, according to whether the liquid crystal is thermotropic or lyotropic, the nematic liquid crystal experiences a transition to the smectic A phase

with molecules arranged along equally spaced layers. The molecules tend to align themselves along the direction perpendicular to the layers. Upon transition to the lower temperature smectic C phase, a symmetry break occurs, with molecules making a nonzero tilt angle with the layer normal. Values of the tilt angle α are found to be between 20 and 35 degrees and depend on the material and temperature.

We consider chiral smectic C liquid crystals and label them C*, according to conventional notation. One relevant feature of liquid crystal molecules that form smectic C* phases is the presence of a *side chain* giving a transverse electric dipole and therefore yielding the polarization field $\mathbf{P}$ of the theory. Level surfaces of the scalar variable ϕ describe smectic layers. A schematic representation of the fields of a smectic C* phase is given in Figure 1, where the normal vector to the layers corresponds to the axis of a cone of semiangle α, with $\mathbf{n}$ being allowed to rotate on the surface. The polarization vector $\mathbf{P}$ is perpendicular to both the layer normal $\nabla\phi$ and the director field [16]. Additional fields of the hydrodynamic theory are the velocity field $\mathbf{u}$ and the hydrostatic pressure p. The latter is the constraint associated with the assumption of fluid incompressibility.

In chiral configurations, since $\mathbf{P}$ rotates with $\mathbf{n}$, the net polarization of the material is zero. Therefore, ferroelectric states correspond to configurations with constant $\mathbf{n}$. The electrostatic effects due to polarization dominate the dielectric effects of standard nematic liquid crystals. Consequently, faster switching devices are achieved with smectic C* liquid crystals.

In this article, we study the transition between states with opposite polarization and determine lower bounds for the speed of the connecting traveling wave. The latter corresponds to a chiral configuration with periodically varying $\mathbf{n}$ and $\mathbf{P}$. The switching takes place upon reversing the direction of the applied electric field. The stability of the polarized states was studied in [23]. The traveling wave of our problem represents the backflow effect, that is, the flow generated by changes in the applied electric field.

The free energy density of the model consists of nematic, smectic C, and electrostatic contributions. The form of the smectic C free energy, $\mathbf{F}_S$, that we study was introduced by Chen and Lubensky in 1976, based on the Landau–de Gennes model for smectic A [6]. They investigated the nematic to smectic phase transition, and it was later used by Renn and Lubensky to predict the twist grain boundary phase in cholesteric smectic [19]. However, the free energy density $\mathbf{F}_S$ is degenerate in that it lacks second order coercivity in the direction $\mathbf{n}$. In order to avoid the anisotropic quartic order derivatives in the Chen–Lubensky model, Luk'yanchuk proposed a modified model [20]. The new model was later used in [13] to rigorously analyze the temperature phase transition from chiral nematic to chiral smectic liquid crystals. The analysis of the ferroelectric smectic C* phases was carried out in [24], where the energy minimizers are further required to satisfy the electrostatic Maxwell equations. The hydrodynamic theory that we propose combines the approaches by Leslie and Ericksen (for details, see [8], [4], and [29]) for nematic and the work by W. E [9] for smectic A liquid crystals. The latter follows the model by Kleman and Parodi [14] also for smectic A phases, where the concepts of permeation force and molecular field were introduced as forces driving smectic A flow. However, since the layer position completely specifies the director field in smectic A, W. E shows that only the permeation force is responsible for the dynamics of smectic A liquid crystals. This is not the case for the smectic C modeling, where both forces are needed to describe the hydrodynamics. We use a variational approach together with the dissipation inequality to determine the elastic and viscous components, respectively, of such forces. Furthermore, the Lorenz force associated with the charge density $-\mathrm{div}\mathbf{P}$ enters the equation of balance of linear momentum.

Leslie, Stewart, and Nakagawa also developed a nonlinear continuum theory for smectic C liquid crystals, using the **c** director, which is the projection of **n** onto the layer, and the unit vector normal to the layers (see [18] and [29]). Their theory is constrained to exclude variations in the layer spacing thickness and changes in tilt with respect to the layer. The nonlinear continuum theory in the present paper is also restricted to the constant tilt angle case, excluding the variation of the tilt angle between the director and the layer normal as in [18]. However, our model allows the variation of the layer spacing thickness.

The second part of the paper is devoted to the study of the switching dynamics of a smectic C* sample confined between parallel bounding planes. We assume that the electric field is applied parallel to the smectic layers. We derive the governing equation of the director and the flow equation in the homeotropic geometry, where the smectic layers are parallel to the bounding plates. When the flow is neglected, the director profile can be understood by the traveling wave solution of the resulting nonlinear reaction diffusion equation (see [7], [21], [25], and [26]). This equation also represents the gradient flow of the energy. One main goal of our work is to study the traveling wave solutions, taking flow and ferroelectric effects into account and estimating the speed of the corresponding traveling wave. The variational characterization of the speed follows the approach in [2] for reaction-diffusion equations. Furthermore, we obtain an optimal lower bound of the speed in terms of the viscous and smectic parameters of the model. Numerical simulations of the problem explore ranges of parameters, from the case in which flow is neglected to cases in which parameters approach the optimal lower bound of the speed. We find a very good agreement with the predictions of the analysis.

Section 2 is devoted to static theory, and dissipation and hydrodynamics are discussed in section 3. The analysis of traveling waves of the switching problem and the corresponding numerical simulations are developed in section 4.

2. Hydrostatic theory.

2.1. Smectic C* free energy. The total free energy density consists of the nematic f_n and smectic f_s parts. The Oseen–Frank energy density for a nematic is given by

$$f_n = \frac{K_1}{2}(\nabla\cdot\mathbf{n})^2 + \frac{K_2}{2}(\mathbf{n}\cdot\nabla\times\mathbf{n}+\tau)^2 + \frac{K_3}{2}|\mathbf{n}\times(\nabla\times\mathbf{n})|^2,$$

where K_1, K_2, and K_3 are the splay, twist, and bend elastic constants, respectively. The parameter τ denotes the cholesteric twist.

In order to associate smectic and nematic structure with a state $(\mathbf{n},\Psi)$, we write

$$\Psi(\mathbf{x}) = \rho(\mathbf{x})e^{i\varphi(\mathbf{x})}.$$

Then the molecular mass density is defined by

$$\delta(\mathbf{x}) = \rho_0(\mathbf{x}) + \frac{1}{2}(\Psi(\mathbf{x})+\Psi^*(\mathbf{x})) = \rho_0(\mathbf{x}) + \rho(\mathbf{x})\cos\varphi(\mathbf{x}),$$

where ρ_0 is a locally uniform mass density, $\rho(\mathbf{x})$ is the mass density of the smectic layers, and φ parametrizes the layers so that $\nabla\varphi$ is the direction of the layer normal.

Now the smectic C energy density is given by

$$f_s = \frac{D}{2}|\mathbf{D}_\mathbf{n}^2\Psi|^2 - \frac{C_\perp}{2}|\mathbf{D}_\mathbf{n}\Psi|^2 + \frac{C_\|}{2}|\mathbf{n}\cdot\mathbf{D}_\mathbf{n}\Psi|^2,$$

where $\mathbf{D}_\mathbf{n} = \nabla - iq\mathbf{n}$, $\mathbf{D}_\mathbf{n}^2 = \mathbf{D}_\mathbf{n}\cdot\mathbf{D}_\mathbf{n}$, and $D, C_\perp, C_\|$ are positive constants. The model for smectic C energy was proposed by Chen and Lubensky [6], but we use the modified model, introduced by Luk'yanchuk [20]. Since we investigate smectic structure far from the nematic–smectic transition, we assume that the magnitude of the smectic order parameter is a constant. We may assume that $\Psi = e^{i\varphi}$. Then f_s becomes

$$\begin{aligned} f_s &= \frac{D}{2}|\nabla\varphi - q\mathbf{n}|^4 + \frac{D}{2}(\Delta\varphi - q\nabla\cdot\mathbf{n})^2 - \frac{C_\perp}{2}|\nabla\varphi - q\mathbf{n}|^2 + \frac{C_\|}{2}(\mathbf{n}\cdot\nabla\varphi - q)^2 \\ &= \frac{D}{2}\left(|\nabla\varphi - q\mathbf{n}|^2 - \frac{C_\perp}{2D}\right)^2 + \frac{C_\|}{2}(\mathbf{n}\cdot\nabla\varphi - q)^2 + \frac{D}{2}(\Delta\varphi - q\nabla\cdot\mathbf{n})^2. \end{aligned}$$

If $\mathbf{n}$ is a constant and φ is linear, then we can see that the energy is minimized if and only if $\mathbf{n}\cdot\nabla\varphi = q$ and $|\nabla\varphi - q\mathbf{n}|^2 = \frac{C_\perp}{2D}$. This corresponds to a uniform smectic C state with tilt angle α, between the director and the layer normal, determined by $\tan^2\alpha = C_\perp/(2Dq^2)$ and layer thickness d satisfying $(\frac{2\pi}{d})^2 = q^2 + \frac{C_\perp}{2D}$.

We get the free energy density

$$f_d = f_n + f_s.$$

Note that there are two constraints:

$$|\mathbf{n}| = 1 \qquad \text{and} \qquad \mathbf{n}\cdot\nabla\varphi = \cos\alpha|\nabla\varphi|. \tag{2.1}$$

We consider the total smectic C free energy density

$$\tilde{f} = f_d + f_l, \tag{2.2}$$

where the last term is present in order to make use of Lagrange multipliers:

$$f_l = \frac{\lambda}{2}(\mathbf{n}\cdot\mathbf{n} - 1) + \beta(\mathbf{n}\cdot\nabla\varphi - \cos\alpha|\nabla\varphi|).$$

2.2. The molecular field and the permeation force. In the nematic, the molecular field can be obtained through the deformation of the director field while the centers of gravity of the molecules are fixed. On the other hand, the directors are parallel to the layer normal in smectic A. As a result, W. E instead discussed the permeation forces, the normal forces acting on layers in [9]. In smectic C, the directors are tilted with respect to the layer normal, and hence both the molecular field and the permeation force need to be discussed. First we obtain the equilibrium conditions in bulk by writing the variation of the total free energy with respect to the director and the layer normal variations, while keeping the material undeformed. Let D be any region inside the liquid crystal. We get

$$\delta\int_D \tilde{f} = \int_D \left(\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\delta(\Delta\varphi) + \frac{\partial\tilde{f}}{\partial(\partial_i\varphi)}\delta(\partial_i\varphi) + \frac{\partial\tilde{f}}{\partial(\partial_i\mathbf{n}_j)}\delta(\partial_i\mathbf{n}_j) + \frac{\partial\tilde{f}}{\partial\mathbf{n}_i}\delta\mathbf{n}_i\right) d\mathbf{x}$$

$$
\begin{aligned}
&= \int_D \left(\partial_i \left[\partial_i \left(\frac{\partial \tilde{f}}{\partial(\Delta\varphi)} \right) - \frac{\partial \tilde{f}}{\partial(\partial_i \varphi)} \right] \delta\varphi + \left[\frac{\partial \tilde{f}}{\partial \mathbf{n}_i} - \partial_j \left(\frac{\partial \tilde{f}}{\partial(\partial_j \mathbf{n}_i)} \right) \right] \delta\mathbf{n}_i \right) d\mathbf{x} \\
&+ \int_{\partial D} \left(\frac{\partial \tilde{f}}{\partial(\Delta\varphi)} \partial_j(\delta\varphi) + \left[\frac{\partial \tilde{f}}{\partial(\partial_j \varphi)} - \partial_j (\frac{\partial \tilde{f}}{\partial(\Delta\varphi)}) \right] \delta\varphi + \frac{\partial \tilde{f}}{\partial(\partial_j \mathbf{n}_i)} \delta\mathbf{n}_i \right) \nu_j \, ds \\
&=: \int_D (-g\delta\varphi - \mathbf{h}_i \delta\mathbf{n}_i) \, d\mathbf{x} + \int_{\partial D} \left(\frac{\partial \tilde{f}}{\partial(\Delta\varphi)} \partial_j(\delta\varphi) - \tau_j \delta\varphi + \pi_{ij} \delta\mathbf{n}_i \right) \nu_j \, ds,
\end{aligned}
$$

where

$$
\begin{aligned}
g &= -\nabla \cdot \tau \\
&= -\nabla \cdot \left[\nabla \left(\frac{\partial f_d}{\partial(\Delta\varphi)} \right) - \frac{\partial f_d}{\partial(\nabla\varphi)} - \beta \left(\mathbf{n} - \cos\alpha \frac{\nabla\varphi}{|\nabla\varphi|} \right) \right], \\
\mathbf{h}_i &= -\frac{\partial f_d}{\partial \mathbf{n}_i} + \partial_j \pi_{ij} - \lambda \mathbf{n}_i - \beta \partial_i \varphi,
\end{aligned}
\tag{2.3}
$$

using the notation

$$
\pi_{ij} = \frac{\partial f_d}{\partial(\partial_j \mathbf{n}_i)}. \tag{2.4}
$$

2.3. The elastic stress. We now calculate the elastic stress associated with the infinitesimal deformation of the body, while holding the location of the layers and the director field fixed. For this, we let

$$
\begin{aligned}
&\mathbf{r}' = \mathbf{r} + \mathbf{u}(\mathbf{r}), \\
&\mathbf{n}'(\mathbf{r}') = \mathbf{n}'(\mathbf{r} + \mathbf{u}) = \mathbf{n}(\mathbf{r}), \\
&\varphi'(r') = \varphi(\mathbf{r} + \mathbf{u}) = \varphi(\mathbf{r}).
\end{aligned}
$$

Using the relations

$$
\frac{\partial r_i'}{\partial r_j} = \delta_{ij} + \frac{\partial u_i}{\partial r_j} \quad \text{and} \quad \frac{\partial r_i}{\partial r_j'} \simeq \delta_{ij} - \frac{\partial(\delta u_i)}{\partial r_j},
$$

we get

$$
\frac{\partial \varphi'}{\partial r_j'} \simeq \frac{\partial \varphi}{\partial r_j} - \frac{\partial \varphi}{\partial r_k} \frac{\partial u_k}{\partial r_j} \quad \text{and} \quad \frac{\partial \mathbf{n}_i'}{\partial r_j'} \simeq \frac{\partial \mathbf{n}_i}{\partial r_j} - \frac{\partial \mathbf{n}_i}{\partial r_k} \frac{\partial u_k}{\partial r_j}.
$$

Hence

$$
\begin{aligned}
\delta(\partial_i \varphi) &\simeq -\frac{\partial \varphi}{\partial r_k} \frac{\partial u_k}{\partial r_i}, \\
\delta(\partial_i \mathbf{n}_j) &\simeq -\frac{\partial \mathbf{n}_j}{\partial r_k} \frac{\partial u_k}{\partial r_i}, \\
\delta(\Delta\varphi) &\simeq -2(\partial_{ik}\varphi)(\partial_i u_k) - (\partial_k \varphi)\Delta u_k.
\end{aligned}
$$

Taking these approximations into account, we now calculate the corresponding variation of the energy of a subdomain D in Ω. For this, we use integration by parts. This gives

$$
\begin{aligned}
\delta\int_D \tilde{f} &= \int_D \left(\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\delta(\Delta\varphi) + \frac{\partial\tilde{f}}{\partial(\partial_i\varphi)}\delta(\partial_i\varphi) + \frac{\partial\tilde{f}}{\partial(\partial_j\mathbf{n}_i)}\delta(\partial_j\mathbf{n}_i)\right) d\mathbf{x}\\
&= \int_D \left(\frac{\partial f_d}{\partial(\Delta\varphi)}\left[-2(\partial_{jk}\varphi)(\partial_j\mathbf{u}_k) - (\partial_k\varphi)(\partial_j^2\mathbf{u}_k)\right]\right) d\mathbf{x}\\
&+ \int_D \left(\left[\frac{\partial f_d}{\partial(\partial_j\varphi)} + \beta\left(\mathbf{n}_j - \cos\alpha\frac{\partial_j\varphi}{|\nabla\varphi|}\right)\right]\left(-(\partial_k\varphi)(\partial_j\mathbf{u}_k)\right)\right) d\mathbf{x}\\
&+ \int_D \left(\frac{\partial f_d}{\partial(\partial_i\mathbf{n}_j)}\left(-(\partial_k\mathbf{n}_i)(\partial_j\mathbf{u}_k)\right)\right) d\mathbf{x} - \int_{\partial D}\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}(\partial_k\varphi)(\partial_j\mathbf{u}_k)\nu_j\, ds\\
&=: \int_D \left(\sigma^d_{kj}(\partial_j\mathbf{u}_k)\right) d\mathbf{x} - \int_{\partial D}\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}(\partial_k\varphi)(\partial_j\mathbf{u}_k)\nu_j\, ds,
\end{aligned}
$$

where

$$
\sigma^d_{kj} = \left[-\frac{\partial f_d}{\partial(\Delta\varphi)}\partial_{jk}\varphi + \tau_j(\partial_k\varphi) - \pi_{ij}(\partial_k\mathbf{n}_i)\right] \tag{2.5}
$$

is the deviatoric part of the stress tensor. To take this incompressibility constraint into account, we modify the previous calculations to include the corresponding Lagrange multiplier term. For this, let us consider the free energy density

$$
f = \tilde{f} - p\nabla\cdot\mathbf{u},
$$

where p is a Lagrange multiplier. This leads to a modified elastic stress

$$
\sigma^e_{kj} = \sigma^d_{kj} - p\delta_{kj}. \tag{2.6}
$$

2.4. The equilibrium equations. By combining all variations from the previous sections, we have the total variation of $\tilde{f}$:

$$
\begin{aligned}
\delta\int_D \tilde{f} = \int_D &\left(\sigma^e_{kj}(\partial_j\mathbf{u}_k) - \mathbf{h}_k\delta\mathbf{n}_k - g\delta\varphi\right) d\mathbf{x}\\
+ \int_{\partial D} &\left(\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\partial_j(\delta\varphi) - \tau_j\delta\varphi + \pi_{kj}\delta\mathbf{n}_k - \frac{\partial\tilde{f}}{\partial(\Delta\varphi)}(\partial_k\varphi)(\partial_j\mathbf{u}_k)\right)\nu_j\, ds.
\end{aligned} \tag{2.7}
$$

By integration by parts, it becomes

$$
\begin{aligned}
\delta\int_D \tilde{f} = \int_D &\left(-\partial_j(\sigma^e_{kj})\mathbf{u}_k - \mathbf{h}_k\delta\mathbf{n}_k - g\delta\varphi\right) d\mathbf{x}\\
+ \int_{\partial D} &\left(\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\partial_j(\delta\varphi) - \tau_j\delta\varphi + \pi_{kj}\delta\mathbf{n}_k\right)\nu_j\, ds\\
+ \int_{\partial D} &\left(\sigma^e_{kj}\mathbf{u}_k - \frac{\partial\tilde{f}}{\partial(\Delta\varphi)}(\partial_k\varphi)(\partial_j\mathbf{u}_k)\right)\nu_j\, ds.
\end{aligned}
$$

Then the hydrostatic equilibrium condition is

$$
\delta\int_D \tilde{f} = 0
$$

for all $D \subseteq \Omega$ and for admissible variations. Taking variations such that $\delta \mathbf{n} = 0$, $\delta\varphi = 0$, and $\mathbf{u}$ and its gradient vanish at the boundary gives the system of partial differential equations

$$\mathbf{h} = 0, \qquad g = 0, \tag{2.8}$$

and

$$\partial_j \sigma_{kj} = 0. \tag{2.9}$$

These, together with two constraint relations (2.1), give the equilibrium equations for smectic C without the external fields. In three dimensions, the system (2.1) and (2.8) consists of six scalar equations for the six unknowns $\mathbf{n}$, φ, λ, and β. Well posedness of this system, in its variational form, was studied in [13] and [24]. Moreover, in [13], the authors performed an extensive phase transition and stability analysis of equilibrium states. In [24], the role of permanent polarization was a main focus of the work.

Notice that the combined system (2.1), (2.8), and (2.9) is overdetermined. This issue in nematic liquid crystals was addressed by Ericksen in [10]. He argues that artificial body forces have to be included in the equations for the system to be closed.

2.5. The balance of torques. We integrate by parts (2.7) to obtain

$$\begin{aligned} \delta \int_D \tilde{f} &= \int_D \left(\sigma^e_{kj}(\partial_j \mathbf{u}_k) - \mathbf{h}_k \delta \mathbf{n}_k - \tau_k \partial_k(\delta\varphi)\right) d\mathbf{r} \\ &\quad + \int_{\partial D} \left(\frac{\partial \tilde{f}}{\partial(\Delta\varphi)} \partial_j(\delta\varphi) + \pi_{kj}\delta\mathbf{n}_k - \frac{\partial \tilde{f}}{\partial(\Delta\varphi)}(\partial_k\varphi)(\partial_j \mathbf{u}_k)\right) \nu_j \, ds. \end{aligned} \tag{2.10}$$

Notice that $\tilde{f}$ is invariant under the rotation of the centers of gravity, the directors, and the layers by the same angle ω. Now the energy is unchanged under the following replacement:

$$\begin{aligned} \mathbf{u}(\mathbf{r}) &= \omega \times \mathbf{r}, \\ \delta\mathbf{n}(\mathbf{r}) &= \omega \times \mathbf{n}, \\ \delta\varphi &= 0, \end{aligned}$$

where ω is the rotation vector. Then we have

$$\partial_j \mathbf{u}_k = \varepsilon_{kpj}\omega_p.$$

Therefore, we have, from (2.10),

$$\begin{aligned} \delta \int_D f_d &= \varepsilon_{kpj}\omega_p \int_D \left[\sigma^d_{kj} - \mathbf{h}_k\mathbf{n}_j + \beta\left(\mathbf{n}_j - \cos\alpha \frac{\partial_j\varphi}{|\nabla\varphi|}\right)\partial_k\varphi - \lambda\mathbf{n}_k\mathbf{n}_j - \beta\partial_k\varphi\mathbf{n}_j\right] d\mathbf{r} \\ &\quad + \omega_p \int_{\partial D}\left(\varepsilon_{kpq}\pi_{kj}\mathbf{n}_q\nu_j - \frac{\partial f}{\partial(\Delta\varphi)}\varepsilon_{kpj}(\partial_k\varphi)\nu_j\right) ds \\ &= \varepsilon_{kpj}\omega_p \int_D \left[\sigma^d_{kj} - \mathbf{h}_k\mathbf{n}_j\right] d\mathbf{r} \\ &\quad + \omega_p \int_{\partial D}\left(\varepsilon_{kpq}\pi_{kj}\mathbf{n}_q\nu_j - \frac{\partial f}{\partial(\Delta\varphi)}\varepsilon_{kpj}(\partial_k\varphi)\nu_j\right) ds = 0. \end{aligned} \tag{2.11}$$

From the equilibrium condition (2.8), we obtain

$$\int_D \varepsilon_{kpj}(\sigma^d_{kj})d\mathbf{r} + \int_{\partial D} \varepsilon_{kpq}\left(\mathbf{s}_k\mathbf{n}_q + (\partial_q\varphi)\,\mathbf{m}_k\right) ds = 0,$$

where $\mathbf{s}_i = \pi_{ij}\nu_j$ and $\mathbf{m}_i = \frac{\partial f}{\partial(\Delta\varphi)}\nu_i$. Using the notation Γ for the antisymmetric part of the elastic stress, we have

$$\varepsilon_{pji}\sigma^d_{ij} = \Gamma_p(\sigma^d), \tag{2.12}$$

and using the fact $\Gamma_p(\sigma^e) = \Gamma_p(\sigma^d)$, we have

$$\int_D \Gamma_p(\sigma^e)\,d\mathbf{r} + \int_{\partial D}(\mathbf{n}\times\mathbf{s} + \nabla\varphi\times\mathbf{m}) = 0. \tag{2.13}$$

From (2.9), we have

$$\begin{aligned} 0 &= \int_D \varepsilon_{jpq}\left(\partial_i(\sigma^e_{ji})\right)\mathbf{r}_q \\ &= \varepsilon_{jpq}\left(-\int_D(\sigma^e_{ji} + \phi_{ji})\partial_i\mathbf{r}_q + \int_{\partial D}(\sigma^e_{ji})\,\mathbf{r}_q\,\nu_i\right) \\ &= -\int_D \varepsilon_{jpi}(\sigma^e_{ji}) + \varepsilon_{jpq}\int_{\partial D}(\sigma^e_{ji})\,\mathbf{r}_q\,\nu_i. \end{aligned}$$

Therefore,

$$\int_D \Gamma_p(\sigma^e)\,d\mathbf{r} = \int_{\partial D}\mathbf{r}\times\mathbf{t}\,d\mathbf{x},$$

where $\mathbf{t}_j = (\sigma^e_{ji})\,\nu_i$. Inserting this equation into (2.13), we finally obtain

$$\int_{\partial D}(\mathbf{r}\times\mathbf{t} + \mathbf{n}\times\mathbf{s} + \nabla\varphi\times\mathbf{m})\,ds = 0. \tag{2.14}$$

This indicates that there are three contributions to these surface torques: mechanical torque (due to the stress tensor), director torque, and layer torque. This is the analogue of the balance of torques in nematic liquid crystals given by equation (3.115) of [8].

3. Hydrodynamic theory.

In this section, we derive the hydrodynamic equations for smectic C liquid crystals following previous work by Ericksen and Leslie (see [8], [4], [29], and [17]) for nematics and work by W. E [9] for smectic A. As we mentioned in the introduction, both the director and the layer functions are hydrodynamic variables.

3.1. Balance laws.

The equations of balance of mass, linear momentum, energy, and angular momentum are given by

$$\frac{d}{dt}\int_D \rho\,d\mathbf{x} = 0, \tag{3.1}$$

$$\frac{d}{dt}\int_D \rho\mathbf{v}_i\,d\mathbf{x} = \int_{\partial D}\sigma_{ij}ds_j, \tag{3.2}$$

$$\frac{d}{dt}\int_D E\,d\mathbf{x} = \int_{\partial D}(\sigma\mathbf{v} + \dot{\varphi}\tau + \dot{\mathbf{n}}\pi)\cdot\,ds - \int_{\partial D}\mathbf{q}\cdot ds, \tag{3.3}$$

$$\frac{d}{dt}\int_D(\mathbf{r}\times\rho\mathbf{v})\,d\mathbf{r} = \int_{\partial D}(\mathbf{r}\times\mathbf{t} + \mathbf{n}\times\mathbf{s} + \nabla\varphi\times\mathbf{m})\,ds, \tag{3.4}$$

where $D \subseteq \Omega$. We neglect body forces for simplicity, but they can easily be included as needed. Here, σ, τ, π, $\mathbf{t}$, $\mathbf{s}$, and $\mathbf{m}$ consist of the equilibrium components obtained in the previous sections and the dissipative components to be calculated next. The energy density in (3.3) is given by $E = \frac{1}{2}|\mathbf{v}|^2 + e$, where e denotes the internal energy per unit mass. The terms on the right-hand side of (3.3) represent the work done by the stress, the layer permeation force, and the director force, respectively, on the material. The vector field $\mathbf{q}$ denotes the heat flux.

Since the above balance laws are valid for any $D \subseteq \Omega$, by the Reynolds transport theorem, (3.1), (3.2), and (3.3) yield

$$\rho_t + \nabla \cdot (\rho \mathbf{v}) = 0 \quad \text{or} \quad \dot{\rho} = -\rho \nabla \cdot \mathbf{v}, \tag{3.5}$$

$$\rho \dot{\mathbf{v}} = \nabla \cdot \sigma \quad \text{or} \quad \rho \dot{\mathbf{v}}_i = \partial_j \sigma_{ij}, \tag{3.6}$$

$$\rho \left(\frac{1}{2}\mathbf{v}^2 + e\right)^{\cdot} = \nabla \cdot (\sigma \mathbf{v} + \dot{\varphi}\tau + \dot{\mathbf{n}}\pi) - \nabla \cdot \mathbf{q}, \tag{3.7}$$

where $\dot{f} = \frac{\partial f}{\partial t} + \mathbf{v} \cdot \nabla f$ is a material derivative. The local form of (3.4) becomes a symmetry relation on constitutive equations, analogous to (2.28) of [10] for the nematic liquid crystal in the static case. It is guaranteed to hold for fields satisfying the balance of linear momentum, provided that the constitutive equations are invariant under rigid body rotations. It will be used later in the connection with the entropy inequality. In this paper, we assume incompressibility of the flow; that is, $\nabla \cdot \mathbf{v} = 0$ holds, and consequently, ρ is constant.

3.2. The entropy inequality. We assume that the second law of thermodynamics in the form of the Clausius–Duhem inequality

$$\rho \dot{S} + \nabla \cdot \left(\frac{\mathbf{q}}{T}\right) \geq 0 \tag{3.8}$$

holds for all processes. Here field S denotes the entropy of the system per unit mass. We use this inequality to determine the forms of the dissipative contribution to stresses and forces [17]. Taking (3.6) into account, we rewrite the balance of energy (3.7) as follows:

$$\rho \dot{e} = -\nabla \cdot \mathbf{q} + Tr(\sigma \nabla \mathbf{v}) + \nabla \cdot (\dot{\varphi}\tau + \dot{\mathbf{n}}\pi).$$

We let

$$H = e - TS \tag{3.9}$$

denote the Helmholtz free energy density. Substituting (3.9) into inequality (3.8), using the balance of energy, and omitting the pure divergence terms, we obtain

$$\begin{aligned} \rho \dot{H} &= \rho(\dot{e} - T\dot{S} - S\dot{T}) \\ &\leq Tr(\sigma \nabla \mathbf{v}) - \nabla \cdot \mathbf{q} + \nabla \cdot \left(\frac{\mathbf{q}}{T}\right) T - \rho S \dot{T} \\ &= Tr(\sigma \nabla \mathbf{v}) - \rho S \dot{T} - \frac{\mathbf{q} \cdot \nabla T}{T}. \end{aligned}$$

Since $H = H(\rho, \mathbf{n}, \nabla \mathbf{n}, \nabla \varphi, \Delta \varphi, T)$,

$$\dot{H} = \frac{\partial H}{\partial T}\dot{T} + \frac{\partial H}{\partial \mathbf{n}}\dot{\mathbf{n}} + \frac{\partial H}{\partial (\nabla \mathbf{n})}(\nabla \mathbf{n})^{\cdot} + \frac{\partial H}{\partial (\nabla \varphi)}(\nabla \varphi)^{\cdot} + \frac{\partial H}{\partial (\Delta \varphi)}(\Delta \varphi)^{\cdot} + \frac{\partial H}{\partial \rho}\dot{\rho}.$$

A direct computation gives

$$\begin{aligned}\nabla\dot{\varphi} &= (\nabla\varphi)^{\cdot} + \nabla\mathbf{v}\nabla\varphi,\\ \nabla\dot{\mathbf{n}} &= (\nabla\mathbf{n})^{\cdot} + \nabla\mathbf{v}\nabla\mathbf{n},\\ \Delta\dot{\varphi} &= (\Delta\varphi)^{\cdot} + 2Tr(\nabla^2\varphi\nabla\mathbf{v}) + \Delta\mathbf{v}\cdot\nabla\varphi.\end{aligned}$$

So, we get

$$\begin{aligned}&Tr(\sigma\nabla\mathbf{v}) - \frac{1}{T}\mathbf{q}\cdot\nabla T - \rho\dot{T}\left(S + \frac{\partial H}{\partial T}\right)\\ &\quad -\rho\frac{\partial H}{\partial\mathbf{n}}\dot{\mathbf{n}} - \rho\frac{\partial H}{\partial(\nabla\mathbf{n})}\{\nabla\dot{\mathbf{n}} - \nabla\mathbf{v}\nabla\mathbf{n}\} - \rho\frac{\partial H}{\partial(\nabla\varphi)}\{\nabla\dot{\varphi} - (\nabla\mathbf{v})(\nabla\varphi)\}\\ &\quad -\rho\frac{\partial H}{\partial(\Delta\varphi)}\left\{\Delta\dot{\varphi} - 2Tr(\nabla^2\varphi\nabla\mathbf{v}) - \Delta\mathbf{v}\cdot\nabla\varphi - \rho\frac{\partial H}{\partial\rho}\dot{\rho}\right\} \geq 0.\end{aligned}$$

Since, in particular, such an inequality holds for all possible choices of $\dot{T}$, we find that $S = -\frac{\partial H}{\partial T}$. For smectic C liquid crystals, we take $\tilde{f} = \rho H$, as in (2.2). Moreover, since the density is constant, the previous inequality becomes

$$\begin{aligned}&Tr\left[\left(\sigma + \frac{\partial\tilde{f}}{\partial(\nabla\mathbf{n})}\nabla\mathbf{n} + \frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\nabla^2\varphi - \nabla\left\{\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\nabla\varphi\right\}\right)\nabla\mathbf{v}\right] - \frac{1}{T}\mathbf{q}\cdot\nabla T\\ &-\left(\frac{\partial\tilde{f}}{\partial\mathbf{n}} - \nabla\frac{\partial\tilde{f}}{\partial(\nabla\mathbf{n})}\right)\dot{\mathbf{n}} - \left(-\nabla\cdot\frac{\partial\tilde{f}}{\partial(\nabla\varphi)} + \Delta\frac{\partial\tilde{f}}{\partial(\Delta\varphi)}\right)\dot{\varphi} \geq 0.\end{aligned}$$

Assuming that the stress consists of elastic and dissipative parts, σ^e (equation (2.6)) and σ^v, respectively, we write

$$\sigma = \sigma^e + \sigma^v.$$

This, together with substituting (2.3), (2.4), and (2.5) into the inequality, gives

$$Tr(\sigma^v\nabla\mathbf{v}) - \frac{1}{T}\mathbf{q}\cdot\nabla T + \mathbf{h}\cdot\dot{\mathbf{n}} + g\dot{\varphi} \geq 0.$$

Let us introduce the notation

$$\begin{aligned}2\sigma^{sym} &= \sigma^v + (\sigma^v)^T,\\ 2D &= \nabla\mathbf{v} + (\nabla\mathbf{v})^T, \qquad 2\mathbf{w} = \nabla\times\mathbf{v}.\end{aligned}$$

We denote $D = (d_{ij})$. From (2.12), we have

$$\Gamma(\sigma) = (\sigma_{32} - \sigma_{23}, \sigma_{13} - \sigma_{31}, \sigma_{21} - \sigma_{12}). \tag{3.10}$$

Therefore,

$$Tr(\sigma^{sym}D) + \Gamma(\sigma^v)\cdot\mathbf{w} + \mathbf{h}\cdot\dot{\mathbf{n}} + g\dot{\varphi} - \frac{1}{T}\mathbf{q}\cdot\nabla T \geq 0. \tag{3.11}$$

Following de Gennes [8], in order to characterize $\Gamma(\sigma^v)$, we need to consider the balance of angular momentum. Using integration by parts, (3.4) becomes

$$\int_D \mathbf{r}\times\rho\dot{\mathbf{v}}\,d\mathbf{r} = \int_D (\Gamma(\sigma) + \mathbf{r}\times(\nabla\cdot\sigma))\,d\mathbf{r} + \int_{\partial D} (\mathbf{n}\times\mathbf{s} + \nabla\varphi\times\mathbf{m})\,ds.$$

By substituting (3.6) into this, we get

$$\int_D \Gamma(\sigma)\,d\mathbf{x} + \int_{\partial D} (\mathbf{n}\times\mathbf{s} + \nabla\varphi\times\mathbf{m})\;ds = 0.$$

Moreover, using (2.11), we now get

$$\int_D \Gamma(\sigma^v)\,d\mathbf{r} = \int_D (-\mathbf{n}\times\mathbf{h})\,d\mathbf{r}, \tag{3.12}$$

which, substituted into the inequality, gives

$$Tr(\sigma^{sym}D) + \mathbf{h}\cdot\mathbf{N} + g\dot{\varphi} - \frac{1}{T}\mathbf{q}\cdot\nabla T \geq 0, \tag{3.13}$$

where $\mathbf{N} = \dot{\mathbf{n}} - \mathbf{w}\times\mathbf{n}$. Observe that $\mathbf{n}\cdot\mathbf{N} = 0$ holds as a result of the constraint $|\mathbf{n}| = 1$.

We conclude this subsection by writing the skew part of the viscous stress. Since (3.12) holds for all $D \subseteq \Omega$, we have

$$\sigma_{ij}^{skw} = \frac{1}{2}\varepsilon_{kji}\Gamma_k = -\frac{1}{2}\varepsilon_{kji}\mathbf{n}_j h_i. \tag{3.14}$$

From now on, we will denote $\mathbf{l} = \nabla\varphi$.

3.3. Coefficients of viscosity. We consider linear dependence of the dissipative forces on their fluxes. We require $\mathbf{q}$ and σ^{sym} to be invariant under the simultaneous transformations $\mathbf{n}\to-\mathbf{n}$ and $\nabla\varphi\to-\nabla\varphi$. We impose that $\mathbf{h}$ and $\dot{\varphi}$ change into $-\mathbf{h}$ and $-\dot{\varphi}$, respectively, under the same transformation. Hence the most general form of the equations is

$$\sigma_{ij}^{sym} = A_{ijk}^1\mathbf{N}_k + A_{ijkm}^2 d_{km}, \tag{3.15}$$

$$\mathbf{h}_i = B_{ij}^1\mathbf{N}_j + B_{ijk}^2 d_{jk}, \tag{3.16}$$

$$\mathbf{q}_i = C_{ij}^3\frac{1}{T}\frac{\partial T}{\partial x_j} + C_i^4 g, \tag{3.17}$$

$$\dot{\varphi} = D_i^3\frac{1}{T}\frac{\partial T}{\partial x_i} + D^4 g, \tag{3.18}$$

where A, B, C, and D are functions of $\mathbf{n}_i$ and $\partial_i\varphi$. The most general form of $\mathbf{h}$ that meets the invariance requirement is

$$\begin{aligned}\mathbf{h} = {}&\beta_1\mathbf{N} + \beta_2(\mathbf{N}\cdot\mathbf{l})\mathbf{l} + \beta_3 D\mathbf{n} + \beta_4 D\mathbf{l} + \beta_5(\mathbf{n}\cdot D\mathbf{l})\mathbf{l}\\ &+ \beta_6(\mathbf{n}\cdot D\mathbf{n})\mathbf{l} + \beta_7(\mathbf{l}\cdot D\mathbf{l})\mathbf{l}.\end{aligned} \tag{3.19}$$

The skew-symmetric part of the viscous stress follows from (3.14) together with (3.19). Writing the symmetric part of the stress tensor explicitly from (3.15) and adding to it the skew part, gives

$$\begin{aligned}\sigma^v = {}&\alpha_1 D + \alpha_2 D\mathbf{n}\otimes\mathbf{n} + \alpha_3\mathbf{n}\otimes D\mathbf{n} + \alpha_4(D\mathbf{l}\otimes\mathbf{l} + \mathbf{l}\otimes D\mathbf{l}) + \alpha_5 D\mathbf{l}\otimes\mathbf{n}\\ &+ \alpha_6\mathbf{n}\otimes D\mathbf{l} + \alpha_7(D\mathbf{n}\otimes\mathbf{l} + \mathbf{l}\otimes D\mathbf{n}) + \alpha_8(\mathbf{l}\cdot D\mathbf{l})\mathbf{l}\otimes\mathbf{n} + \alpha_9(\mathbf{l}\cdot D\mathbf{l})\mathbf{n}\otimes\mathbf{l}\\ &+ \alpha_{10}(\mathbf{n}\cdot D\mathbf{l})\mathbf{l}\otimes\mathbf{l} + \alpha_{11}(\mathbf{l}\cdot D\mathbf{l})\mathbf{n}\otimes\mathbf{n} + \alpha_{12}(\mathbf{n}\cdot D\mathbf{l})\mathbf{l}\otimes\mathbf{n}\\ &+ \alpha_{13}(\mathbf{n}\cdot D\mathbf{l})\mathbf{n}\otimes\mathbf{l} + \alpha_{14}(\mathbf{n}\cdot D\mathbf{n})\mathbf{l}\otimes\mathbf{l} + \alpha_{15}(\mathbf{n}\cdot D\mathbf{l})\mathbf{n}\otimes\mathbf{n}\\ &+ \alpha_{16}(\mathbf{n}\cdot D\mathbf{n})\mathbf{l}\otimes\mathbf{n} + \alpha_{17}(\mathbf{n}\cdot D\mathbf{n})\mathbf{n}\otimes\mathbf{l} + \alpha_{18}(\mathbf{n}\cdot D\mathbf{n})\mathbf{n}\otimes\mathbf{n}\\ &+ \alpha_{19}(\mathbf{l}\cdot D\mathbf{l})\mathbf{l}\otimes\mathbf{l} + \alpha_{20}(\mathbf{l}\otimes\mathbf{N} + \mathbf{N}\otimes\mathbf{l}) + \alpha_{21}\mathbf{N}\otimes\mathbf{n} + \alpha_{22}\mathbf{n}\otimes\mathbf{N}\\ &+ \alpha_{23}(\mathbf{l}\cdot\mathbf{N})\mathbf{l}\otimes\mathbf{l} + \alpha_{24}(\mathbf{l}\cdot\mathbf{N})\mathbf{l}\otimes\mathbf{n} + \alpha_{25}(\mathbf{l}\cdot\mathbf{N})\mathbf{n}\otimes\mathbf{l} + \alpha_{26}(\mathbf{l}\cdot\mathbf{N})\mathbf{n}\otimes\mathbf{n}.\end{aligned} \tag{3.20}$$

We also get

$$
\begin{aligned}
\mathbf{q} &= \frac{1}{T}(\mu_1\partial_i T + \mu_2\mathbf{n}_i\mathbf{n}_j\partial_j T + \mu_3\varphi_i\varphi_j\partial_j T + \mu_4\mathbf{n}_i\varphi_j\partial_j T + \mu_5\mathbf{n}_j\varphi_i\partial_j T)\\
&\quad + (\gamma_1\mathbf{n}_i + \gamma_2\varphi_i)g,\\
\dot\varphi &= \frac{1}{T}(\gamma_1'\mathbf{n}_i\partial_i T + \gamma_2'\varphi\partial_i T) + \gamma_3' g.
\end{aligned}
\tag{3.21}
$$

The viscosity coefficients α, β, γ, μ, and γ' cannot be arbitrarily chosen: they satisfy inequalities that follow from (3.13). Further restrictions result from Onsager's reciprocal relations (see, for instance, [8], [4], and [22]):

$$
\begin{aligned}
&\beta_1 = \alpha_{22} - \alpha_{21}, \qquad \beta_2 = \alpha_{25} - \alpha_{24}, \qquad \beta_3 = \alpha_3 - \alpha_2 = \alpha_{21} + \alpha_{22},\\
&\beta_4 = \alpha_6 - \alpha_5 = 2\alpha_{20}, \qquad \beta_5 = \alpha_{13} - \alpha_{12} = \alpha_{24} + \alpha_{25},\\
&\beta_6 = \alpha_{17} - \alpha_{16} = \alpha_{26}, \qquad \beta_7 = \alpha_9 - \alpha_8 = \alpha_{23},\\
&\gamma_1' = \gamma_1, \qquad \gamma_2' = \gamma_2.
\end{aligned}
\tag{3.22}
$$

We end this section by summarizing the governing equations of the hydrodynamic of smectic C. It consists of 11 equations and 11 unknowns. The latter are the pressure p, the velocity field $\mathbf{v}$, the director $\mathbf{n}$, the layer φ, the temperature T, and Lagrange multipliers λ and β. The equations are as follows:

- balance of linear momentum equation (3.6):

$$\rho\dot{\mathbf{v}} = \nabla\cdot(-pI + \sigma^d + \sigma^v) + \mathbf{f}, \tag{3.23}$$

  where the elastic stress σ^d is given from (2.5), the viscous part σ^v is from (3.20), and $\mathbf{f}$ is an external force;
- molecular field equation:

$$\frac{\partial f_d}{\partial \mathbf{n}_i} - \partial_j\pi_{ij} + \lambda\mathbf{n}_i + \beta\partial_i\varphi + \mathbf{h}_i = 0, \tag{3.24}$$

  where $\mathbf{h}$ is given from (3.19);
- permeation force equation:

$$\dot\varphi = \frac{1}{T}(\gamma_1'\mathbf{n}_i\partial_i T + \gamma_2'\varphi\partial_i T) + \gamma_3' g,$$

  where g is defined in (2.3);
- balance of energy equation:

$$E_t + \nabla\cdot(E\mathbf{v} + \mathbf{q} - \sigma\mathbf{v} - \dot\varphi\tau - \dot{\mathbf{n}}\pi) = 0,$$

  where $\mathbf{q}$ is given from (3.21);
- incompressibility condition:

$$\nabla\cdot\mathbf{v} = 0;$$

- two constraints:

$$|\mathbf{n}| = 1 \qquad \text{and} \qquad \mathbf{n}\cdot\nabla\varphi = \cos\alpha|\nabla\varphi|.$$

In the isothermal case, this reduces to 10 equations and 10 unknowns.

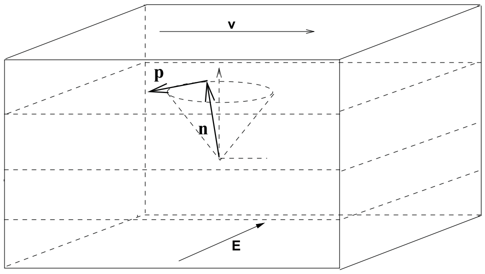

FIG. 1. *Smectic C* liquid crystals in the homeotropic geometry; the polarization is perpendicular to both the layer normal and the director.*

4. Switching dynamics.

4.1. Electrostatic energy. In order to investigate the electric effect, we consider the electric energy [8], [29],

$$f_e = -\int_\Omega \mathbf{D}\cdot d\mathbf{E} = -\int_\Omega (\varepsilon_\perp \mathbf{E} + \varepsilon_a(\mathbf{n}\cdot\mathbf{E})\mathbf{n} + \mathbf{P})\cdot d\mathbf{E}, \tag{4.1}$$

where $\mathbf{E}$ denotes the electric field, $\mathbf{P}$ denotes the ferroelectric polarization, and ε_a represents the dielectric anisotropy. Since chiral smectic C liquid crystals are known to be ferroelectric, they possess a spontaneous polarization $\mathbf{P}$. Dropping the constant term in the electric energy, (4.1) reduces to

$$f_e = -\frac{1}{2}\int_\Omega \varepsilon_a(\mathbf{n}\cdot\mathbf{E})^2\,d\mathbf{x} - \int_\Omega \mathbf{P}\cdot\mathbf{E}\,d\mathbf{x}. \tag{4.2}$$

Since the magnitude of the polarization is small in smectic C* liquid crystals, we assume that it is constant, P_0. Furthermore, since the chiral molecules create a spontaneous polarization within each layer and the polarization is perpendicular to the director (see Figure 1), we write

$$\mathbf{P} = P_0\frac{\nabla\varphi\times\mathbf{n}}{|\nabla\varphi\times\mathbf{n}|}. \tag{4.3}$$

The polarization $\mathbf{P}$ also gives an electrostatic charge density, $-\nabla\cdot\mathbf{P}$. The electrostatic effects of chiral smectic C liquid crystals were studied in [24]. As a result of the electric field, the Lorentz force $\mathbf{f} = (-\nabla\cdot\mathbf{P})\mathbf{E}$ has to be included in (3.23).

4.2. The model. We consider the homeotropic geometry where the liquid crystal is confined between two parallel plates with the smectic layers parallel to the plates (Figure 1). Let

$$\begin{aligned} \mathbf{n} &= (\cos\phi\sin\alpha, \sin\phi\sin\alpha, \cos\alpha),\\ \mathbf{v} &= (v,0,0),\\ \nabla\varphi &= (0,0,k), \end{aligned} \tag{4.4}$$

with $\phi = \phi(z)$, $v = v(z)$, $p = p(x,y,z)$, and α and k constant. We consider the switching dynamics between states with opposite polarization when a uniform electric field is applied in a direction parallel to the layer, i.e., $\mathbf{E} = E_0(0,1,0)$ in (4.2). We also restrict our attention to the case when $\varepsilon_a < 0$, which applies to many smectic C liquid crystals. This tends to align the director and polarization fields along directions perpendicular and parallel to the applied field, respectively. Note that, since $\nabla\cdot\mathbf{P} = 0$, $\mathbf{f}$ in (3.23) vanishes.

The balance of linear momentum (3.23) yields

$$\begin{aligned} \rho v_t &= -\frac{\partial p}{\partial x} + \frac{\partial}{\partial z}(\sigma^d_{13} + \sigma^v_{13}), \\ 0 &= -\frac{\partial p}{\partial y} + \frac{\partial}{\partial z}(\sigma^d_{23} + \sigma^v_{23}), \\ 0 &= -\frac{\partial p}{\partial z} + \frac{\partial}{\partial z}(\sigma^d_{33} + \sigma^v_{33}). \end{aligned} \tag{4.5}$$

The first two equations imply that p is linear on x and y. So, p is of the form

$$p(x,y,z,t) = k_0(t) + k_1(t)x + k_2(t)y + \sigma^d_{33} + \sigma^v_{33}.$$

Hence, (4.5) reduces to

$$\rho v_t = -k_1(t) + \frac{\partial}{\partial z}(\sigma^d_{13} + \sigma^v_{13}).$$

Also, as a result of (4.4), equation (3.24) reduces to a single equation for ϕ. Hence the system of governing equations is

$$\begin{aligned} \rho v_t &= \frac{\partial}{\partial z}\Big[g(\phi)v_z - \eta_3(\sin\phi)\phi_t\Big] - k_1(t), \\ 2\beta_1 \sin^2\alpha\phi_t &= \lambda_1 \sin\phi v_z + 2K\phi_{zz} - 2P_0E_0\sin\phi - |\varepsilon_a|E_0^2\sin^2\alpha\sin 2\phi, \end{aligned} \tag{4.6}$$

where

$$\begin{aligned} &\lambda_1 = \sin\alpha((-\beta_1+\beta_3)\cos\alpha + \beta_4 k), \\ &K = \sin^2\alpha(K_2\sin^2\alpha + K_3\cos^2\alpha), \\ &g(\phi) = \frac{1}{2}(\eta_1 + \eta_2\cos^2\phi), \\ &\eta_1 = \alpha_1 + \alpha_4 k^2(\alpha_2 - \alpha_{21})\cos^2\alpha + (\alpha_5 + \alpha_7 - \alpha_{20})k\cos\alpha, \\ &\eta_2 = \sin^2\alpha\Big(\alpha_3 + \alpha_{22} + k^2(\alpha_{13} + \alpha_{25}) + (\alpha_{15} + 2\alpha_{17} + \alpha_{26})k\cos\alpha \\ &\qquad\qquad +2\alpha_{18}\cos^2\alpha\Big), \\ &\eta_3 = \sin\alpha(\alpha_{20}\,k + \alpha_{21}\cos\alpha), \\ &\frac{\partial p}{\partial x} = k_1(t). \end{aligned}$$

Onsager reciprocal relation (3.22) now gives

$$\lambda_1 = 2\sin\alpha\,(\alpha_{20}k + \alpha_{21}\cos\alpha) = 2\eta_3. \tag{4.7}$$

Note that we may derive the following inequalities from the dissipation inequality (3.13):

$$\beta_1 > 0, \quad g(\phi) > 0, \quad \text{and} \quad \beta_1 g(\phi)\sin^2\alpha - \eta_3^2\sin^2\phi > 0. \tag{4.8}$$

The first inequality can be obtained from the shear flow alignment.

Let $V = v + K(t)/\rho$, where $K(t)$ is an antiderivative of $k_1(t)$. Using (4.7) and new variables

$$\bar{z} = \left(\frac{P_0 E_c}{K}\right)^{\frac{1}{2}} z, \quad \bar{t} = \frac{P_0 E_c}{\beta_1 \sin^2\alpha} t, \quad u = \frac{\beta_1}{\sqrt{K P_0 E_c}} V, \quad \text{and} \quad E_c = \frac{2P_0}{|\varepsilon_a| \sin^2\alpha},$$

the system (4.6) becomes

$$\begin{aligned} \varepsilon u_{\bar{t}} &= \frac{\partial}{\partial \bar{z}} \left(\frac{\sin^2\alpha}{\eta_1} g(\phi)\, u_{\bar{z}} - \frac{\eta_3}{\eta_1} (\sin\phi) \phi_{\bar{t}} \right), \\ \phi_{\bar{t}} &= \frac{\eta_3}{\beta_1} \sin\phi\, u_{\bar{z}} + \phi_{\bar{z}\bar{z}} - e \sin\phi - e^2 \sin 2\phi, \end{aligned} \tag{4.9}$$

where

$$\varepsilon = \frac{\rho K}{\beta_1 \eta_1} \qquad \text{and} \qquad e = E_0/E_c.$$

We may assume that the dimensionless parameter $\varepsilon \ll 1$ since the viscous coefficients are much bigger than the elastic coefficients.

4.3. Traveling wave solution. In this section, we study the traveling wave solutions of system (4.9) to understand the director profile when the electric field is applied. For this, we look for a solution of (4.9) in the form $w(\zeta) = u(\bar{z}, \bar{t})$ and $\theta(\zeta) = \phi(\bar{z}, \bar{t})$, where $\zeta = \bar{z} - c\bar{t}$, such that θ connects two bistable states, $\theta = 0$ and $\theta = \pi$. Then the traveling wave solution is $(w(\zeta), \theta(\zeta)) \in C^2(\mathbb{R}) \times C^2(\mathbb{R})$ and $c \in \mathbb{R}$ satisfying

$$-c\varepsilon\, w' = \left[\frac{\sin^2\alpha}{\eta_1}\, g(\theta) w' + c\frac{\eta_3}{\eta_1} \sin\theta\, \theta' \right]', \tag{4.10}$$

$$-c\, \theta' = \frac{\eta_3}{\beta_1} \sin\theta w' + \theta'' - e\sin\theta - e^2 \sin 2\theta, \tag{4.11}$$

with $w(-\infty) = w'(-\infty) = 0$, $\theta(-\infty) = 0$, and $\theta(\infty) = \pi$. This is consistent with the system approaching an equilibrium state. Here the $'$ denotes the derivative with respect to ζ. Integrating (4.10) and using the relations $w(-\infty) = w'(-\infty) = \theta(-\infty) = 0$, equation (4.10) reduces to

$$-c\varepsilon\, w = \frac{\sin^2\alpha}{\eta_1}\, g(\theta) w' + c\frac{\eta_3}{\eta_1} \sin\theta\, \theta'. \tag{4.12}$$

Substituting this into (4.11), we have

$$\theta'' + ch(\theta)\theta' - e\sin\theta - e^2 \sin 2\theta - c\varepsilon \frac{\eta_3 \sin\theta}{\beta_1 \sin^2\alpha\, g(\theta)} w = 0, \tag{4.13}$$

where

$$0 < h(\theta) := 1 - \frac{\eta_3^2}{\beta_1 \sin^2\alpha} \frac{\sin^2\theta}{g(\theta)} \leq 1. \tag{4.14}$$

Notice that the inequalities follow from (4.8). Introducing the rescaled variable $v = \varepsilon w$, we rewrite the system (4.12) and (4.13) as follows:

$$\begin{aligned} &v' + c\,\varepsilon b(\theta) v + c\,\varepsilon \beta_1 d(\theta) \theta' = 0, \\ &\theta'' + ch(\theta)\theta' + E(\theta) - c\, d(\theta) v = 0, \end{aligned} \tag{4.15}$$

where

$$\begin{aligned} b(\theta) &= \frac{\eta_1}{\sin^2\alpha\, g(\theta)}, \\ E(\theta) &= -e\sin\theta - e^2\sin 2\theta, \\ d(\theta) &= \frac{\eta_3}{\beta_1\sin^2\alpha}\frac{\sin\theta}{g(\theta)}. \end{aligned}$$

If $\theta(\zeta)$ and $v(\zeta)$ are solutions of the system, then so are $\theta(\zeta+\zeta_0)$ and $v(\zeta+\zeta_0)$ for any constant ζ_0. Hence we impose a normalized condition, $\theta(0) = \frac{1}{2}[\theta(-\infty)+\theta(\infty)] = \frac{\pi}{2}$. Using the condition $v(-\infty) = 0$, we solve the first equation for v,

$$v(\varepsilon, c, \theta, \zeta) = -c\varepsilon\beta_1 e^{-c\varepsilon\beta(\zeta)}\int_{-\infty}^{\zeta} d(\theta(s))\theta'(s)e^{c\varepsilon\beta(s)}\,ds,$$

where

$$\beta(\zeta) = \int b(\theta(s))\,ds.$$

Substituting this expression into the second equation of (4.15), we have

$$\theta'' + ch(\theta)\theta' + E(\theta) - c\,d(\theta)v(\varepsilon, c, \theta, \zeta) = 0. \tag{4.16}$$

For $\varepsilon = 0$, equation (4.16) becomes

$$\theta'' + ch(\theta)\theta' + E(\theta) = 0. \tag{4.17}$$

From now on, we will restrict our attention to the case $e > \frac{1}{2}$ so that the term $E(\theta)$ is cubic-like. In fact, if $e > \frac{1}{2}$, the term $E(\theta) = -e\sin\theta(1+2e\cos\theta)$ has an intermediate zero. In this case, (4.17) with a bistable nonlinearity has an increasing traveling wave solution (c_0, θ_0) with $c_0 > 0$ that $\theta_0 \to 0$ as $\zeta \to -\infty$ and $\theta_0 \to \pi$ as $\zeta \to \infty$, thanks to the condition $h(\theta) > 0$ for any θ [15]. Furthermore, we can easily see that [11], [1], from the phase plane analysis, θ_0 satisfies

$$|\theta_0(\zeta) - \pi| \le Ke^{-\mu_1\zeta}, \qquad |\theta_0'(\zeta)| \le Ke^{-\mu_1\zeta}$$

for $\zeta \ge 0$ and for some constant $\mu_1 > 0$, and

$$|\theta_0(\zeta)| \le Ke^{\mu_2\zeta}, \qquad |\theta_0'(\zeta)| \le Ke^{\mu_2\zeta}$$

for $\zeta \le 0$ and for some constant $\mu_2 > 0$.

Motivated by the work in [12], we look for solutions of (4.16) of the form

$$\begin{aligned} \theta &= \theta_0 + s(\zeta, c, \varepsilon), \\ c &= c_0 + \sigma. \end{aligned}$$

Substituting these into (4.16) and letting $r = (s, \sigma)$, we define the operator F:

$$\begin{aligned} F(r;\varepsilon) = \theta_0'' + s'' + (c_0+\sigma)h(\theta_0+s)(\theta_0'+s') + E(\theta_0+s) \\ -(c_0+\sigma)d(\theta_0+s)v(\varepsilon, c_0+\sigma, \theta_0+s). \end{aligned}$$

Note that r satisfies the boundary conditions

$$r(-\infty;\varepsilon) = r(\infty;\varepsilon) = 0. \tag{4.18}$$

For a fixed constant μ satisfying $0 < \mu < \min\{\mu_1, \mu_2\}$, we define the function spaces

$$B^n_\mu(\mathbb{R}) = \left\{ u \in C^n(\mathbb{R}) : \|u\|_{B^n_\mu(\mathbb{R})} \equiv \sum_{i=0}^{n} \sup_{x\in\mathbb{R}} \left| e^{\mu|x|} \left(\frac{d}{dx}\right)^i u(x) \right| < \infty \right\},$$
$$\dot{B}^n_\mu(\mathbb{R}) = \{u \in B^n_\mu(\mathbb{R}) : u(0) = 0\}.$$

Note that the mapping F is differentiable from X into Y, where

$$X = \dot{B}^2_\mu \times \mathbb{R},$$
$$Y = B^0_\mu.$$

The next lemma establishes that F meets the hypotheses of the implicit function theorem.

LEMMA 4.1.

(i) *F is a continuous mapping, and $\|F(r;\varepsilon) - F(r;0)\|_Y \to 0$ as $\varepsilon \to 0$.*

(ii) *F is continuously Fréchet differentiable with respect to r, and*

$$\|F_r(r;\varepsilon)[\tilde{r}] - F_r(r;0)[\tilde{r}]\|_Y \to 0 \text{ as } \varepsilon \to 0.$$

(iii) *$F_r(0;0)$ has a bounded inverse.*

Proof.

(i) We have

$$\begin{aligned}
&|e^{\mu|z|}(F(r;\varepsilon) - F(r;0))| \\
&= e^{\mu|z|} \left| (c_0+\sigma)^2 d(\theta_0+s)\varepsilon\beta_1 g_-(z) \int_{-\infty}^{z} d(\theta_0+s)(\theta_0'+s')g_+(t)e^{\mu|t|}e^{-\mu|t|}\,dt \right| \\
&\le C\varepsilon(c_0+\sigma)\|\theta_0'+s'\|_{B^0_\mu} e^{\mu|z|} \left| \int_{-\infty}^{z} e^{-\mu|t|}dt \right| \\
&\le C\varepsilon(c_0+\sigma)\|\theta_0+s\|_{B^2_\mu},
\end{aligned}$$

where $g_\pm(z) = \exp(\pm\varepsilon(c_0+\sigma)\beta(z))$ and $\beta'(z) = b(\theta_0+s)(z)$. Notice that we used the fact that $\beta(z)$ is increasing.

(ii) Note that

$$\begin{aligned}
&e^{\mu|z|}|F_r(r;\varepsilon)\tilde{r} - F_r(r;0)\tilde{r}| \\
&= e^{\mu|z|}|\tilde{\sigma}d(\theta_0+s)v_\varepsilon(z) - (c_0+\sigma)d'(\theta_0+s)v_\varepsilon(z)\tilde{s} + (c_0+\sigma)d(\theta_0+s)v_\varepsilon'(z)\tilde{s}|,
\end{aligned}$$

where $v_\varepsilon(z) = v(\varepsilon, c_0+\sigma, \theta_0+s, z)$. Since we have

$$v_\varepsilon'(z) = -(c_0+\sigma)\varepsilon b(\theta_0+s)v_\varepsilon(z) - (c_0+\sigma)\varepsilon\beta_1 d(\theta_0+s)(\theta_0'+s'),$$

the rest of the proof follows as in part (i).

(iii) It suffices to show that for any $g \in Y$, the linear problem

$$F_r(0;0)\tilde{r} = g$$

has a unique solution $\tilde{r} \in \dot{B}^2_\mu$ such that

$$\|\tilde{r}\|_{\dot{B}^2_\mu} \le C\|g\|_Y.$$

The above linear problem can be explicitly written as

$$\tilde{s}^{''} + c_0 h(\theta_0)\tilde{s}' + (c_0 h(\theta_0)\theta_0' + E'(\theta_0))\tilde{s} = G, \tag{4.19}$$

where

$$G = g - h(\theta_0)\theta_0'\tilde{\sigma}.$$

The proof of existence and uniqueness of solution of (4.19) satisfying boundary condition (4.18) follows as that of Lemma 3 in [15]. □

The proof of the following theorem uses the implicit function theorem together with Lemma 4.1.

THEOREM 4.2. *For $\varepsilon > 0$ sufficiently small, there exists a unique (up to translation in ζ) $(c_\varepsilon, \theta_\varepsilon, v_\varepsilon)$ satisfying* (4.15) *such that*

$$\|\theta_\varepsilon - \theta_0\|_{B^2_\mu} + \|v_\varepsilon\|_{B^1_\mu} + |c_\varepsilon - c_0| \longrightarrow 0 \qquad \text{as } \varepsilon \to 0.$$

4.4. Speed of the traveling wave. In this section, we study the speed of the traveling front of (4.16). We follow the variational approach in [2] for reaction-diffusion equations.

We first consider front propagation for the reaction-diffusion equation

$$\theta'' + c\theta' = H(\theta), \tag{4.20}$$

where $H(\theta) = e \sin\theta + e^2 \sin 2\theta$. This is the traveling wave equation for a switching problem for smectic C liquid crystals, when flow effects are neglected (see [25], [26]). It is known that there exists a unique heteroclinic solution (c_s, θ_s) of (4.20) such that $\theta(-\infty) = 0$, $\theta(\infty) = \pi$, and $\theta'(\zeta) > 0$ for $|\zeta| < \infty$. This equation can also be obtained from our model by neglecting the flow. The authors of [7] found the explicit wave front solution (θ_s, c_s) of (4.20), given by

$$\theta_s(\zeta) = 2\arctan(e^{\sqrt{2}e\zeta}), \quad c_s = \frac{1}{\sqrt{2}}.$$

Following the work by Benguria and Depassier in [2], we obtain the variational expression of the speed for (4.20):

$$c_s^2 = \max \frac{2\int_0^\pi Hf\,d\theta}{\int_0^\pi \frac{f^2}{f'}d\theta}, \tag{4.21}$$

where the maximum is taken over all positive increasing functions f in $(0, \pi)$. We denote the maximizing function by $\hat{f}$.

With the help of Theorem 4.2, we will investigate c_0, the speed of the traveling wave solution of (4.17). We let θ be a solution of (4.17). The same proof as in [2] leads to the variational principle for the speed of the traveling wave of (4.17). Noting that $0 < h(\theta) \leq 1$,

$$c_0^2 = \max \frac{2\int_0^\pi Hf\,d\theta}{\int_0^\pi \frac{h^2 f^2}{f'}d\theta}, \tag{4.22}$$

where the maximum is taken over all positive increasing functions f in $(0, \pi)$ for which the integrals exist.

Now we compare the speeds c_0 and c_s using (4.21) and (4.22). From (4.22), we get

$$c_0^2 \geq \frac{2\int_0^\pi H\hat{f}d\theta}{\int_0^\pi \frac{h^2\hat{f}^2}{\hat{f}'}d\theta}.$$

Since $0 < h(\theta) \leq 1$, we have

$$h^2(\theta) \leq h(\theta) = 1 - \frac{2\eta_3^2 \sin^2\theta}{\beta_1 \sin^2\alpha\,(\eta_1 + \eta_2\cos^2\theta)} \leq 1 - A\sin^2\theta,$$

where

$$A := \frac{2\eta_3^2}{\beta_1 \sin^2\alpha\,(\eta_1 + \max\{\eta_2, 0\})} \geq 0. \tag{4.23}$$

It follows from (4.14) that $0 \leq A < 1$. In fact, if $\max\{\eta_2, 0\} = 0$, then

$$A = \frac{2\eta_3^2}{\beta_1\eta_1\sin^2\alpha} = 1 - h\left(\frac{\pi}{2}\right) < 1.$$

Also, if $\max\{\eta_2, 0\} = \eta_2$, then

$$A = \frac{2\eta_3^2}{\beta_1\sin^2\alpha(\eta_1 + \eta_2)} \leq 1 - h\left(\frac{\pi}{2}\right) < 1.$$

From (4.21) and (4.22), we have

$$c_0^2 \geq \frac{2\int_0^\pi H\hat{f}d\theta}{\int_0^\pi \frac{\hat{f}^2}{\hat{f}'}d\theta - A\int_0^\pi \frac{\sin^2\theta\,\hat{f}^2}{\hat{f}'}\,d\theta} = \frac{2\int_0^\pi H\hat{f}d\theta}{\int_0^\pi \frac{\hat{f}^2}{\hat{f}'}d\theta(1 - A\cdot M)} = \frac{c_s^2}{1 - A\cdot M}, \tag{4.24}$$

where M is a fixed number given by

$$M = \frac{\int_0^\pi \frac{\sin^2\theta\,\hat{f}^2}{\hat{f}'}\,d\theta}{\int_0^\pi \frac{\hat{f}^2}{\hat{f}'}d\theta}.$$

Notice that $0 < M < 1$ is independent of viscosity coefficients, since $\hat{f}$ is the maximizing function for c_s. We rewrite (4.24) as

$$\left(\frac{c_0}{c_s}\right)^2 \geq \frac{1}{1 - A\cdot M}. \tag{4.25}$$

The inequality (4.25) shows that the switching is faster when the flow is taken into consideration. The value A in (4.23) is the control parameter; i.e., A is the quantity which measures flow effects. If A is close to 1, then flow effects are expected to be strong, and if A is close to 0, then flow effects are weak. In particular, we see that the ratio of c_0 to c_s increases as A approaches 1. In view of this control parameter, the optimal switching time is obtained when $A = 1$. The sufficient condition for this is

$$\eta_2 \leq 0 \qquad \text{and} \qquad 2\eta_3^2 = \beta_1\eta_1\sin^2\alpha.$$

This condition depends only on the viscosity, the tilt angle, and the layer thickness of the material. In [5], the control parameter was also found. Our control parameter A is analogous to that given by Carlsson, Clark, and Zou in [5].

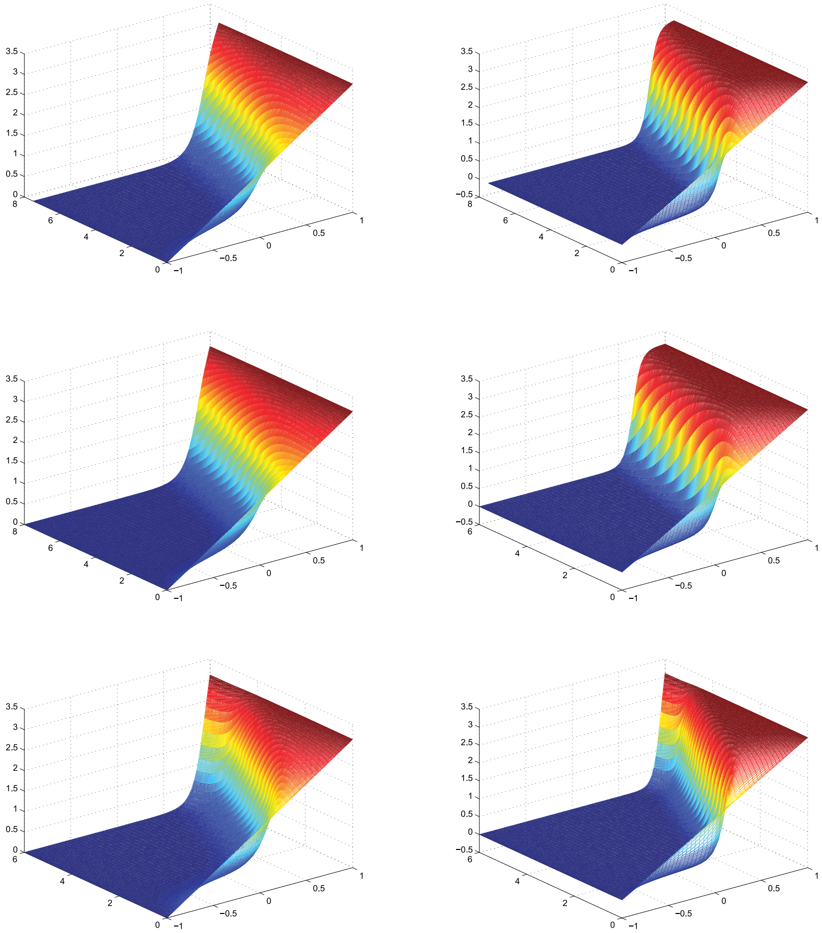

FIG. 2. *Director configuration when the initial condition is the linear function connecting* 0 *and* π. *The applied electric field corresponds to* $e = 0.75$ *on the left column and* $e = 1.3$ *on the right column. The upper row depicts the director profile when flow is neglected, while in the second and third rows the flow effects are included. For simulations in the second row, the control parameter* A *is close to* 0, *while for the third row,* A *is close to* 1.

4.5. Numerical simulation. In order to solve the system (4.9) numerically, we use a second order semi-implicit scheme for time discretization. This scheme requires us to solve two Helmholtz equations at each time step, which we do by means of a spectral Galerkin method (see [27] and [28]). We impose the homogeneous boundary and initial conditions on u and assume strong anchoring conditions for ϕ, i.e., $\phi(0,t) = 0$ and $\phi(L,t) = \pi$, where L is the domain size. From (4.3) and (4.4) we see that the director configurations $\phi = 0$ and $\phi = \pi$ correspond to the polarization pointing in the same and opposite directions as the applied electric field, respectively.

For ε, we simply take $\varepsilon = 10^{-6}$. For the tilt angle and viscosity coefficients appearing in the system, we use $\eta_1 = 3.8$, $\eta_2 = -0.2$, $\beta_1 = 40.9706$, and $\alpha = \pi/8$. This set of parameters, employed in [3], gives a value of the control parameter A in (4.23) of approximately 0.5. In [3], the authors study the macroscopic equations of

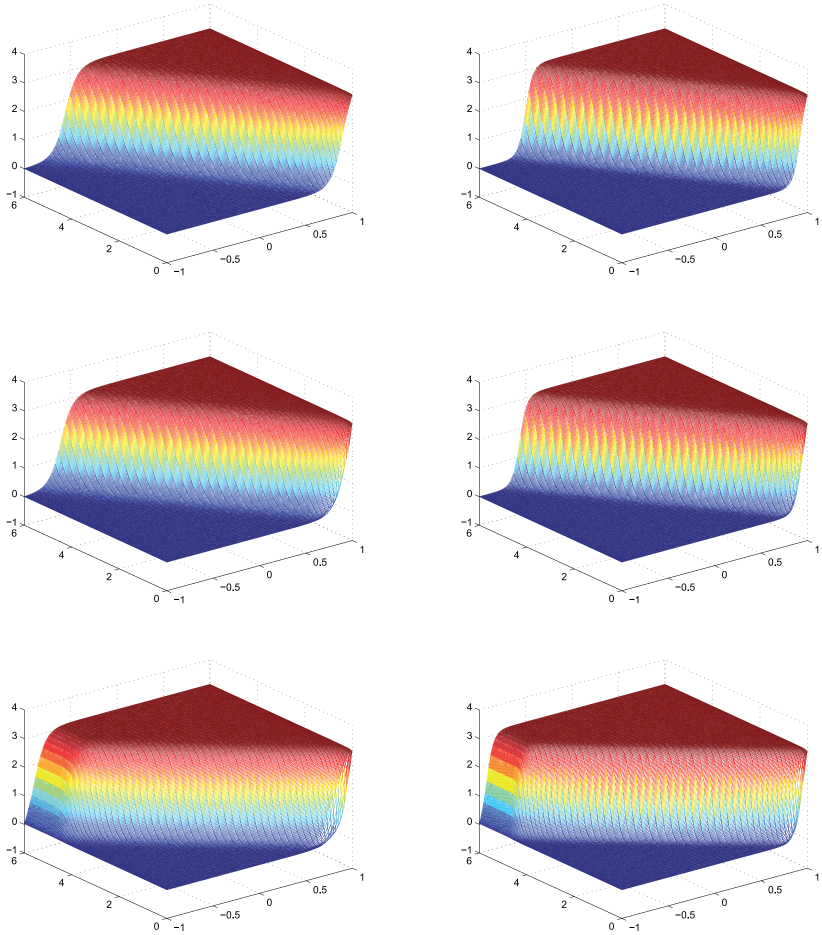

FIG. 3. *Director configuration when the sign of the electric field is reversed at $t = 0$. The arrangement of the simulations in rows and columns follows the analogous criteria to those in Figure* 2.

smectic C* liquid crystals [18] in a homeotropic geometry to investigate the backflow effect upon the removal of a strong electric field. Their approach is based on linear analysis, replacing the nonlinear functions by their initial values. In our simulations, we vary the parameter η_3 in order for A to span the interval $(0, 1)$.

We consider two types of initial conditions for ϕ corresponding to the simulations shown in Figures 2 and 3, respectively. In Figure 2, the initial value ϕ_0 is the linear function connecting two bistable states, 0 and π. When a positive electric field is applied, the molecules start to switch so that the polarization is parallel to the applied field in most of the cell except near the top plate where the strong anchoring condition, $\phi(L, t) = \pi$, is imposed. Figure 2 depicts the director configuration with $e = 0.75$ in the left and $e = 1.3$ in the right columns, respectively. The flow effect is neglected in simulations in the first row, and it is included in the second and third rows. The control parameter A is close to 0 in the middle, while A is close to 1 in the third row. As we may expect from (4.25), the simulations in first and second rows depict almost the same switching time, while the third row describes faster switching dynamics.

In Figure 3, we numerically investigate the switching behavior when the sign of the electric field is alternating, proceeding as follows: we first obtain the director profile of the equilibrium state in a positive electric field and then impose it as an initial condition of the problem with an applied negative electric field. In [21], the authors investigated the switching time for the static model when alternating fields are applied.

The simulations show that the predicted switching process is faster when the flow is taken into consideration. We note that the switching is already faster even with a very small, but nonzero, value of A.

Zou, Clark, and Carlsson in [30] also performed numerical simulations for reorientation dynamics with various boundary conditions, based on the model proposed by Leslie, Stewart, and Nakagawa [18]. In bookshelf geometry, they showed that the switching process is generally faster when backflow is present. They also numerically confirmed that the control parameter found in [5] is a measure of the contribution of the backflow effects. The control parameter in [30] is defined as the average of $1-h(\theta)$ over θ. In the previous section, we also identified an analogous control parameter, which is dependent only on parameters of the problem, but we obtained bounds on it that rigorously allow us to quantify the backflow effects in the switching time. In particular, the upper bound on A yields an optimality condition on the parameters.

5. Conclusion. In this paper, we presented a nonlinear continuum theory of smectic C* liquid crystals. Since the smectic C liquid crystals have molecules tilted with respect to the layers, we use both the director and the layer functions as variables in the hydrodynamic theory. For the general framework, we employed the approach by Ericksen and Leslie for the hydrodynamic theory of the nematic liquid crystals. Also, motivated by the work of W. E on the continuum theory of the smectic A liquid crystals, we obtained the dynamic equations for the director $\mathbf{n}$ and the layer variable φ.

We applied the model to study the switching dynamics between two states with opposite polarization in the homeotropic geometry. Even though there are 22 viscosity coefficients in our hydrodynamic theory, the system of equations reduces to two equations with only four viscosity constants, η_1, η_2, η_3, and β_1. These constants are further constrained by the entropy inequality. We understand the molecular reorientation via the propagation of a traveling wave. We proved the existence and uniqueness of the traveling wave solution and further analyzed the speed of the front. We showed that the flow generally makes the switching faster and that there is a control parameter that determines the importance of the flow effect. This analysis was confirmed by the numerical simulations.

Acknowledgment. We would like to thank Professor Jie Shen of Purdue University for his help on numerical simulations.

OPTIMAL SELLING RULES IN A REGIME-SWITCHING EXPONENTIAL GAUSSIAN DIFFUSION MODEL*

P. ELOE†, R. H. LIU†, M. YATSUKI†, G. YIN‡, and Q. ZHANG§

Abstract. This paper develops optimal selling rules in asset trading using a regime-switching exponential Gaussian diffusion model. The optimization problem is solved by a combined approach of boundary value problems and probabilistic analysis. A system of linear differential equations with variable coefficients and two-point boundary conditions, satisfied by the objective function of the problem, is derived. The existence and uniqueness of the solution are proved. A closed-form solution in terms of Weber functions is obtained for one-dimensional cases. For m-dimensional cases, a stochastic recursive algorithm for numerically searching the optimal value is developed. Numerical results are reported.

Key words. optimal selling rule, Markov chain, regime-switching, Gaussian diffusion, boundary value problem, stochastic recursive algorithm

1. Introduction.

This paper develops an optimal selling rule in asset trading using a regime-switching exponential Gaussian diffusion model for asset price. A selling rule is specified by two threshold levels—an upper level (greater than the purchase price) for the profit target and a lower level (less than the purchase price) for the stop-loss limit. The asset is sold once its price hits either level. Our objective in this study is to obtain a pair of optimal threshold levels that maximize a prespecified objective function which reflects the investment goal and/or risk attitude of investors.

Recently, considerable attention has been drawn to regime-switching models in financial mathematics which aim to include the influence of macroeconomic factors on the individual asset price behavior. In this setting, asset prices are dictated by a number of stochastic differential equations coupled by a finite-state Markov chain, which represents various randomly changing economical factors. Model parameters (drift and volatility coefficients) are assumed to depend on the Markov chain. Regime-switching models have been used in derivative pricing (see Buffington and Elliott [2], Guo [12], Guo and Zhang [13], and Yao, Zhang, and Zhou [22] among others), for interest rates and bond prices (see Bansal and Zhou [1] and Dai, Singleton, and Yang [6] among others), and in modeling commodity and electricity prices (see Clewlow and Strickland [3], Erlwein, Benth, and Mamon [9], Kluge [16], and Lucia and Schwartz [18] among others).

Along another line, Zhang [26] studied an optimal selling rule for stock liquidation using a regime-switching geometric Brownian motion (GBM) model. In [26], a method that combines differential equation with probabilistic analysis was developed;

an analytical solution for the two-regime case was obtained, and optimization techniques for deterministic functions were used to find the optimal thresholds. However, when the number of regimes exceeds two, the analytical solutions are difficult to obtain, and thus the deterministic optimization approaches are not applicable anymore. To find a feasible solution, Yin, Liu, and Zhang [23] took a different approach, namely, using stochastic approximation algorithms. By focusing on threshold-type strategies, recursive algorithms using Monte Carlo simulation were developed in [23]. Convergence and the rates of convergence of the algorithms were proved. The stochastic algorithms were tested by using both simulations and market data (see Yin, Liu, and Zhang [23], and Yin et al. [25] for more details).

In this work, we extend the aforementioned optimal selling rule study for the regime-switching GBM model to a class of regime-switching exponential Gaussian diffusion models that include the GBM and regime-switching GBM models as special cases. The new mathematical model is presented first, and its connection with other models is then noted. An objective function associated with the optimization problem is defined next. Consequently, a system of linear differential equations with two boundary conditions, satisfied by the objective function, is derived. We point out a significant difference between the system considered in this paper and that of Zhang [26]. That is, the coefficients of the differential equations are no longer constant. Therefore, solutions from [26] cannot be used in this paper. We develop a different approach. The existence of a solution to the variable coefficient boundary value problem is proved by adopting a method of upper and lower solutions that use the Green's function of the associated homogeneous system. The uniqueness of the solution is established by applying Dynkin's formula. In addition, a numerical method to construct a sequence of increasing functions (lower solution approximation) and a sequence of decreasing functions (upper solution approximation) is developed. The second part of the paper is concerned with stochastic optimization methods. We develop a recursive algorithm which provides a feasible solution for searching the best selling rules and is particularly applicable to models with large state spaces.

The rest of the paper is organized as follows. Section 2 presents the regime-switching model and the precise formulation of the selling rule problem. The differential equations and boundary values satisfied by the objective function of the optimization problem is derived. Section 3 establishes the existence and uniqueness of the solution to the problem. Section 4 is concerned with stochastic recursive algorithms. The selling rule problem is reformulated as a stochastic optimization problem. A recursive algorithm for searching the optimal thresholds using gradient estimation and projection procedure is developed. Conditions for convergence of the algorithm are provided. Numerical results are reported. Finally, the paper is concluded with further remarks in section 5.

2. Problem formulation. Let $(\Omega, \mathcal{F}, \mathcal{P})$ be the underlying probability space, upon which all stochastic processes are defined. Let $\alpha(t)$ be a continuous-time Markov chain taking values in $\mathcal{M} := \{1, \dots, m\}$, a finite state space. The states represent general market trends and other economic factors (called "state of the world" or "regime") and are labeled by integers 1 to m, where m is the total number of regimes considered for the economy. For example, with $m = 2$, $\alpha(t) = 1$ may stand for an up market and $\alpha(t) = 2$ a down market. Let $B(t)$ be a real-valued standard Brownian motion. Assume that $\alpha(t)$ is independent of $B(t)$.

Let $S(t)$ be the asset price at time $t \geq 0$,

$$S(t) = S_0 \exp(X(t)), \quad t \geq 0, \tag{2.1}$$

where $S_0 > 0$ denotes the asset price at $t = 0$ (i.e., $S(0) = S_0$), and $X(t)$ is the solution of the stochastic differential equation

$$\begin{cases} dX(t) = [b(\alpha(t)) + \mu(\alpha(t))X(t)]dt + \sigma(\alpha(t))dB(t), \\ X(0) = 0. \end{cases} \tag{2.2}$$

Note that the coefficients $b(\alpha(t))$, $\mu(\alpha(t))$, and $\sigma(\alpha(t))$ in (2.2) all depend on $\alpha(t)$, indicating that they can take different values for different regimes. We assume that $b(i) \geq 0$ and $\sigma(i) > 0$ for each $i \in \mathcal{M}$. Before introducing the optimal selling rule problem, we make three remarks regarding the model given by (2.1) and (2.2).

Remark 2.1. Consider a special case in which there is only one state for $\alpha(t)$, i.e., $m = 1$. Then $\alpha(t) = 1$ for all $t \geq 0$. In this case, these is no regime switching, and we can write $b(\alpha(t)) = b$, $\mu(\alpha(t)) = \mu$, and $\sigma(\alpha(t)) = \sigma$, where b, μ, and σ are constants. Then (2.2) becomes an Ornstein–Uhlenbeck process,

$$dX(t) = [b + \mu X(t)]dt + \sigma dB(t). \tag{2.3}$$

In particular, if we assume that $\mu < 0$ and let $\kappa = -\mu$ and $\theta = b/\kappa$, then we have the well-known Vasicek model [21] for interest rates, namely,

$$dr(t) = \kappa[\theta - r(t)]dt + \sigma dB(t),$$

where $r(t) := X(t)$ denotes the instantaneous spot rate at time $t \geq 0$, θ is the mean-reverting level, κ is the rate at which $r(t)$ is pulled back to the level θ, and σ is the volatility of $r(t)$. Also note that the solution of (2.3) is given by

$$X(t) = \frac{b}{\mu}(e^{\mu t} - 1) + \sigma \int_0^t e^{\mu(t-s)} dB(s), \tag{2.4}$$

which is a Gaussian process. Consequently, the asset price $S(t) = S_0 \exp(X(t))$ becomes an exponential Gaussian process. However, when there is more than one state for $\alpha(t)$, i.e., $m \geq 2$, then $X(t)$ will no longer be a Gaussian process. Instead, it is a mixture of m Gaussian processes. We use the term regime-switching exponential Gaussian diffusion model for (2.1) and (2.2) in this paper that generalizes the Ornstein–Uhlenbeck process.

Remark 2.2. Set $\mu(i) \equiv 0$ and let $b(i) = \nu(i) - \frac{1}{2}\sigma^2(i)$ for $i \in \mathcal{M}$ in (2.2). Then the model given by (2.1) and (2.2) is reduced to the regime-switching GBM model considered in [26] with drift $\nu(\alpha(t))$ and volatility $\sigma(\alpha(t))$, i.e.,

$$\frac{dS(t)}{S(t)} = \nu(\alpha(t))dt + \sigma(\alpha(t))dB(t),$$

which includes the commonly used log-normal model as a special case (when $m = 1$). Thus the model we consider in this paper further generalizes the (regime-switching) log-normal model. The selling rule problem for the case of $\mu(i) \equiv 0$ for $i \in \mathcal{M}$ has already been handled in Zhang [26]. In what follows we will focus on $\mu(i) \neq 0$; see also Remark 2.6.

Remark 2.3. Note that if $m = 1$, i.e., without regime switching, then the model given by (2.1) and (2.2) becomes a particular member of the class of affine diffusion models (see Duffie, Filipović, and Schachermayer [8] for definition of affine models). For $m > 1$, the model generalizes the affine model by adding a Markovian regime switching.

To continue our studies, consider a threshold-type selling rule specified by a pair of numbers z_1 and z_2 with $-\infty < z_1 \le 0 \le z_2 < \infty$. Define a stopping time τ by

$$\tau = \inf\{t > 0 : \; X(t) \notin (z_1, z_2)\}. \tag{2.5}$$

Let $S_L = S_0 e^{z_1}$ and $S_U = S_0 e^{z_2}$. Then $0 < S_L \le S_0 \le S_U < \infty$, and τ can be equivalently defined in terms of $S(t)$, i.e.,

$$\tau = \inf\{t > 0 : \; S(t) \notin (S_L, S_U)\}. \tag{2.6}$$

We call τ the selling time and S_L and S_U the lower and upper thresholds, respectively, for asset $S(t)$. That means we sell the asset at time τ either to take a profit (if S_U is reached) or to prevent further loss (if S_L is reached).

The optimal selling rule problem is to find a pair of numbers (z_1, z_2) that maximize the objective function:

$$V(z_1, z_2) = E\left\{\Phi(X(\tau)) \exp(-\rho\tau)\right\}, \tag{2.7}$$

where $\Phi(x)$ is a prespecified utility function and $\rho > 0$ is a discount factor.

Remark 2.4. Depending on the investment purpose and/or the risk attitude of an investor (risk-neutral or risk-averse), an appropriate utility function $\Phi(x)$ can be used in the objective (2.7). For instance, if we choose $\Phi(x) = e^x - 1$, then we can rewrite the objective function (2.7) as

$$V(z_1, z_2) = E\left\{\exp(-\rho\tau)\frac{S(\tau) - S_0}{S_0}\right\},$$

which gives the expectation of the discounted percentage return. By maximizing this objective function, one seeks the maximum percentage return, a common index used in evaluating investment performance.

Remark 2.5. The selling rule problem we consider in this paper is an optimal stopping problem. Note that the objective function (2.7) is determined by the first hitting time τ of process $X(t)$ at the double barriers z_1, z_2. When the log-normal model (without regime-switching) is specified for the underlying asset price, a probabilistic approach can be used to obtain the distribution function of the stopping time τ (see Karatzas and Shreve [15] and Steele [20] for extensive discussions on the probabilistic methods and results), and, consequently, an analytical objective function can be derived. However, when the new regime-switching model is used, it is difficult to obtain the distribution function of τ; thus the "pure" probabilistic approach does not work. We resort to methods of differential equations together with probabilistic approaches to solve the problem.

To proceed, we derive a two-point boundary value problem associated with (2.7). For a given real number z, consider the process $\xi(t)$ that is the solution of

$$d\xi(t) = [b(\alpha(t)) + \mu(\alpha(t))\xi(t)]dt + \sigma(\alpha(t))dB(t), \quad \xi(0) = z.$$

Then $\xi(t) = X(t)$ if $z = 0$. For each $z \in [z_1, z_2]$, define a stopping time:

$$\tau(z) = \inf\{t > 0 : \; \xi(t) \notin (z_1, z_2)\}.$$

Note we use $\tau(z)$ to indicate the z dependence of the stopping time. Let

$$v(z, i) = E\left\{\Phi(\xi(\tau(z))) \exp(-\rho\tau(z)) \middle| \alpha(0) = i, \xi(0) = z\right\}. \tag{2.8}$$

Then the objective function (2.7) can be written in terms of $v(z,i)$ as

$$V(z_1,z_2)=\sum_{i=1}^{m}p_iv(0,i), \tag{2.9}$$

where $p_i = P\{\alpha(0) = i\}$, $i = 1,\dots,m$, assumed given, is the initial probability distribution of the Markov chain $\alpha(\cdot)$.

Let matrix $Q = (q_{ij})_{m\times m}$ be the generator of the Markov chain $\alpha(\cdot)$. From Markov chain theory (see, for example, Yin and Zhang [24]), the entries q_{ij} of Q satisfy (i) $q_{ij} \geq 0$ if $j \neq i$; (ii) $\sum_{j=1}^{m} q_{ij} = 0$ for each $i = 1,\dots,m$. Moreover,

$$\lim_{\Delta t\to 0^+}\frac{P(\Delta t)-I}{\Delta t}=Q, \tag{2.10}$$

where $P(\Delta t) = (p_{ij}(\Delta t))_{m\times m} = (P\{\alpha(\Delta t) = j|\alpha(0) = i\})_{m\times m}$ is the transition probability matrix of $\alpha(\cdot)$, and I denotes the $m \times m$ identity matrix.

Consider a small interval Δt. Since $\xi(t)$ and $\alpha(t)$ are jointly Markovian, it follows that

$$v(z,i)=\sum_{j=1}^{m}E\left\{v(\xi(\Delta t),j)\exp(-\rho\Delta t)\right\}P\{\alpha(\Delta t)=j|\alpha(0)=i\}.$$

Expanding $v(\xi(\Delta t), j) \exp(-\rho\Delta t)$ at 0, using Itô's formula, sending $\Delta t \to 0$, and using the limit (2.10), we obtain the following system of differential equations associated with the value functions $v(z,i)$, $i = 1,\dots,m$:

$$\frac{\sigma^2(i)}{2}\frac{d^2v(z,i)}{dz^2}+[b(i)+\mu(i)z]\frac{dv(z,i)}{dz}-\rho v(z,i)+\sum_{j=1}^{m}q_{ij}v(z,j)=0 \tag{2.11}$$

for $z \in (z_1,z_2)$. The boundary conditions are given by

$$v(z_1,i)=\Phi(z_1),\quad v(z_2,i)=\Phi(z_2). \tag{2.12}$$

If the boundary value problem (2.11) and (2.12) has a smooth solution $v(z,i)$, $i = 1,\dots,m$, then, using Dynkin's formula (see, for example, Oksendal [19]), we can show that it must be given by (2.8), which implies the uniqueness of the solution. Therefore, it is necessary to establish the existence of a C^2 solution to (2.11) and (2.12). This is the task of the next section.

Remark 2.6. While a system of *constant* coefficient linear differential equations was obtained in Zhang [26] based on the regime-switching log-normal model for asset price, what we have here for the new model is a system of differential equations with *variable* coefficients. Therefore, methods used in [26] for constant coefficient systems are not applicable and we need a new approach for the analysis of (2.11) and (2.12). One of the major contributions of this paper (in the next section) is that we employ a new method and successfully prove the existence of a C^2 solution of the variable coefficient boundary value problem (2.11) and (2.12).

In what follows, we use f_x and f_{xx} to denote the first- and second-order derivatives of f with respect to x, respectively, where f is either a real-valued or a vector-valued function of x. Using this notation, we rewrite the system (2.11)–(2.12) in the following matrix form:

$$\begin{cases} AV_{zz}(z)+[B_1+B_0z]V_z(z)+CV(z)=FV(z) & \text{for } z\in(z_1,z_2),\\ V(z_1)=\Phi(z_1)\mathbb{1}_m,\ V(z_2)=\Phi(z_2)\mathbb{1}_m, \end{cases} \tag{2.13}$$

where $V(z) = (v(z,1),\dots,v(z,m))^T$, $1\!\!1_m = (1,\dots,1)^T$, $A = \frac{1}{2}\operatorname{diag}(\sigma^2(1),\dots,\sigma^2(m))$, $B_0 = \operatorname{diag}(\mu(1),\dots,\mu(m))$, $B_1 = \operatorname{diag}(b(1),\dots,b(m))$, $C = Q_d - \rho I = \operatorname{diag}(q_{11}-\rho, \dots, q_{mm}-\rho)$, and $F = Q_d - Q$ where $Q_d = \operatorname{diag}(q_{11},\dots,q_{mm})$.

3. Solution of the boundary value problem.

In this section, we assume that $\mu(i) > 0$ for $i \in \mathcal{M}$. The case of $\mu(i) < 0$ can be handled similarly. We first study the scalar system (the one-dimensional case) and derive an explicit solution. Then we prove the existence of a solution for multidimensional systems, using the one-dimensional result.

When $m = 1$, (2.13) reduces to a second-order scalar linear differential equation subject to two boundary conditions:

$$\left\{\begin{array}{l} \dfrac{\sigma^2}{2}V_{zz}(z) + [b+\mu z]V_z(z) - \rho V(z) = 0 \quad \text{for } z \in (z_1, z_2), \\ V(z_1) = \Phi(z_1),\ V(z_2) = \Phi(z_2), \end{array}\right. \tag{3.1}$$

where $V(z) = v(z,1)$, $\mu = \mu(1)$, $b = b(1)$, and $\sigma = \sigma(1)$. Set $x = \kappa_1 + \kappa_0 z$, where $\kappa_0 = \frac{\sqrt{2\mu}}{\sigma}$ and $\kappa_1 = \frac{b}{\sigma}\sqrt{\frac{2}{\mu}}$. Let $\widetilde{V}(x) = V(z)$. Then (3.1) is transformed into

$$\left\{\begin{array}{l} \widetilde{V}_{xx}(x) + x\widetilde{V}_x(x) - \lambda\widetilde{V}(x) = 0 \quad \text{for } x \in (\kappa_1+\kappa_0 z_1, \kappa_1+\kappa_0 z_2), \\ \widetilde{V}(\kappa_1+\kappa_0 z_1) = \Phi(z_1),\ \widetilde{V}(\kappa_1+\kappa_0 z_2) = \Phi(z_2), \end{array}\right. \tag{3.2}$$

where $\lambda := \rho/\mu$. To solve the homogeneous equation (3.2), we use the following transform:

$$\widetilde{V}(x) = \exp\left(-\frac{x^2}{4}\right) D(x).$$

Then $D(x)$ satisfies

$$D_{xx}(x) + \left[\frac{1}{2} - \frac{x^2}{4} - \bar{\lambda}\right] D(x) = 0, \tag{3.3}$$

where $\bar{\lambda} := 1 + \lambda > 0$. From the results presented in Darling and Siegert [7] and Finch [10], we have the following proposition.

Proposition 3.1. *The function $D^\nu(x)$ defined below (known as the parabolic cylinder function or the Weber function) satisfies the equation*

$$D^\nu_{xx}(x) + \left[\frac{1}{2} - \frac{x^2}{4} + \nu\right] D^\nu(x) = 0, \tag{3.4}$$

where

$$D^\nu(x) = \left\{\begin{array}{ll} \sqrt{\dfrac{2}{\pi}}\exp\left(\dfrac{x^2}{4}\right)\displaystyle\int_0^\infty t^\nu \exp\left(-\frac{t^2}{2}\right)\cos\left(xt - \frac{\pi\nu}{2}\right)dt, & \nu > -1, \\ \dfrac{1}{\Gamma(-\nu)}\exp\left(-\dfrac{x^2}{4}\right)\displaystyle\int_0^\infty t^{-\nu-1}\exp\left(-\frac{t^2}{2} - xt\right)dt, & \nu < 0, \end{array}\right. \tag{3.5}$$

and $\Gamma(\cdot)$ is the Gamma function. The two branches in (3.5) *agree for $-1 < \nu < 0$.*

Comparing (3.3) with (3.4), we see that one solution of (3.3) is given by

$$D(x) = D^{-\bar{\lambda}}(x) = D^{-(1+\lambda)}(x) = \frac{1}{\Gamma(1+\lambda)}\exp\left(-\frac{x^2}{4}\right)\int_0^\infty t^\lambda \exp\left(-\frac{t^2}{2} - xt\right)dt.$$

The second independent solution is given by

$$D(-x) = \frac{1}{\Gamma(1+\lambda)} \exp\left(-\frac{x^2}{4}\right) \int_0^\infty t^\lambda \exp\left(-\frac{t^2}{2} + xt\right) \, dt.$$

It follows that the solution to (3.2) is

$$\widetilde{V}(x) = C_1 \int_0^\infty t^\lambda \exp\left(-\frac{(t+x)^2}{2}\right) \, dt + C_2 \int_0^\infty t^\lambda \exp\left(-\frac{(t-x)^2}{2}\right) \, dt,$$

where C_1 and C_2 are constants to be determined using the given boundary conditions.

Consider the scalar boundary value problem defined below:

$$(3.6) \qquad \begin{cases} D_{xx}(x) + \left[\frac{1}{2} - \frac{x^2}{4} - (1+\gamma)\right] D(x) = 0 \quad \text{for } x \in (x_1, x_2), \\ D(x_1) = 0, \; D(x_2) = 0, \end{cases}$$

where $\gamma > 0$ is a fixed constant. Set

$$D_1(x) = \exp\left(-\frac{x^2}{4}\right) \int_0^\infty t^\gamma \exp\left(-\frac{t^2}{2} - xt\right) \, dt$$

and

$$D_2(x) = \exp\left(-\frac{x^2}{4}\right) \int_0^\infty t^\gamma \exp\left(-\frac{t^2}{2} + xt\right) \, dt.$$

Then D_1 and D_2 form a Descartes system of solutions for the homogeneous equation in (3.6), since $D_1 > 0$, $D_2 > 0$, and $W(D_1, D_2) > 0$ on $[x_1, x_2]$, where

$$W(D_1, D_2) = \det \begin{pmatrix} D_1 & D_2 \\ D_{1,x} & D_{2,x} \end{pmatrix}$$

denotes the Wronskian of D_1 and D_2. Thus, the equation in (3.6) is disconjugate on $[x_1, x_2]$ (see Coppel [5]). This result, coupled with the observation that the boundary conditions in (3.6) (i.e., $D(x_1) = 0$ and $D(x_2) = 0$) are two-point conjugate boundary conditions, implies two immediate corollaries which we shall employ below to establish the existence of a solution of (2.13) and to provide numerical approximations that converge monotonically to the appropriate C^2 solution.

Corollary 3.2. *There exists a Green's function $G(\gamma; x, s)$ for the boundary value problem (3.6) satisfying*

$$G(\gamma; x, s) < 0 \text{ for } (x, s) \in (x_1, x_2) \times (x_1, x_2).$$

Moreover, $G_x(\gamma; x_1, s) < 0$ for $s \in (x_1, x_2)$ and $G_x(\gamma; x_2, s) > 0$ for $s \in (x_1, x_2)$, where G_x denotes the partial derivative of G with respect to x.

Note that the Green's function G plays the role that

$$D(x) = \int_{x_1}^{x_2} G(x, s) f(s) ds$$

is the unique solution of

$$\begin{cases} D_{xx}(x) + \left[\frac{1}{2} - \frac{x^2}{4} - (1+\gamma)\right] D(x) = f(x) \quad \text{for } x \in (x_1, x_2), \\ D(x_1) = 0, \; D(x_2) = 0, \end{cases}$$

where $f(x)$ is a continuous function on $[x_1, x_2]$.

COROLLARY 3.3. *The solution of the boundary value problem*

$$\begin{cases} D_{xx}(x) + \left[\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\gamma)\right] D(x) = 0 \quad \textit{for } x \in (x_1, x_2), \\ D(x_1) > 0,\ D(x_2) > 0 \end{cases}$$

is positive on $[x_1, x_2]$.

Proof. The disconjugacy of $D_{xx}(x) + [\frac{1}{2} - \frac{x^2}{4} - (1+\gamma)]\, D(x) = 0$ on $[x_1, x_2]$ means that any nontrivial solution has at most one root (counting multiplicities) on $[x_1, x_2]$. Since the solution is strictly positive at each boundary, the desired result follows. □

Having done with the one-dimensional case, now we address the existence of a C^2 solution to the m-dimensional ($m > 1$) boundary value system (2.13). To carry out the analysis, the following assumption is needed.

ASSUMPTION 3.4.

$$\frac{\mu(1)}{\sigma^2(1)} = \frac{\mu(2)}{\sigma^2(2)} = \cdots = \frac{\mu(m)}{\sigma^2(m)}$$

and

$$\frac{b^2(1)}{\sigma^2(1)\mu(1)} = \frac{b^2(2)}{\sigma^2(2)\mu(2)} = \cdots = \frac{b^2(m)}{\sigma^2(m)\mu(m)} .$$

THEOREM 3.5. *Under Assumption* 3.4*, there exists a unique* C^2 *solution to the boundary value problem* (2.13)*.*

Proof. We employ the method of upper and lower solutions to obtain existence. Let $x = \kappa_1 + \kappa_0 z$, where $\kappa_0 = \frac{\sqrt{2\mu(i)}}{\sigma(i)}$ and $\kappa_1 = \frac{b(i)}{\sigma(i)}\sqrt{\frac{2}{\mu(i)}}$ are two constants due to Assumption 3.4. For notational brevity, in what follows, we introduce

$$\bar{\kappa}_1 = \kappa_1 + \kappa_0 z_1\ ,\ \bar{\kappa}_2 = \kappa_1 + \kappa_0 z_2. \tag{3.7}$$

Let $\widetilde{V}(x) = V(z)$. Then (2.13) is converted to the following problem:

$$\begin{cases} \widetilde{V}_{xx}(x) + x\widetilde{V}_x(x) - \widetilde{C}\widetilde{V}(x) = \widetilde{F}\widetilde{V}(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ \widetilde{V}(\bar{\kappa}_1) = \Phi(z_1)\mathbb{1}_m,\ V(\bar{\kappa}_2) = \Phi(z_2)\mathbb{1}_m, \end{cases} \tag{3.8}$$

where

$$\widetilde{C} = \operatorname{diag}(\lambda_1, \ldots, \lambda_m),\ \ \lambda_i = \frac{\rho - q_{ii}}{\mu(i)},\ \ i = 1, \ldots, m, \tag{3.9}$$

and

$$\widetilde{F} = \begin{pmatrix} 0 & -q_{12}/\mu(1) & \cdots & -q_{1m}/\mu(1) \\ -q_{21}/\mu(2) & 0 & \cdots & -q_{2m}/\mu(2) \\ \vdots & \vdots & \cdots & \vdots \\ -q_{m1}/\mu(m) & -q_{m2}/\mu(m) & \cdots & 0 \end{pmatrix}. \tag{3.10}$$

Note that $\rho > 0$, $\mu(i) > 0$, and $q_{ii} \le 0$. Hence $\lambda_i > 0$ for $i = 1, \ldots, m$.

We use the (vector) transform $\widetilde{V}(x) = \exp(-\frac{x^2}{4})D(x)$, where

$$D(x) = (D_1(x), \dots, D_m(x))^T.$$

Then (3.8) is transformed into

$$\tag{3.11} \begin{cases} D_{xx}(x) + \bar{C}D(x) = \widetilde{F}D(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ D(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1)\mathbb{1}_m, \;\; D(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\mathbb{1}_m, \end{cases}$$

where

$$\tag{3.12} \bar{C} = \operatorname{diag}\left(\left[\frac{1}{2} - \frac{x^2}{4} - (1+\lambda_1)\right], \dots, \left[\frac{1}{2} - \frac{x^2}{4} - (1+\lambda_m)\right]\right).$$

Note that the left-hand side of the vector equation (3.11) is decoupled and, hence, diagonal. For each $i = 1, \dots, m$, the corresponding homogeneous scalar boundary value problem is given by

$$\tag{3.13} \begin{cases} D_{i,xx}(x) + \left[\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_i)\right] D_i(x) = 0 \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ D_i(\bar{\kappa}_1) = 0, \; D_i(\bar{\kappa}_2) = 0. \end{cases}$$

Let $G(\lambda_i; x, s)$ be the associated Green's function as given by Corollary 3.2. Define

$$G(x,s) = \operatorname{diag}\Big(G(\lambda_1; x, s), \dots, G(\lambda_m; x, s)\Big).$$

Then $G(x,s)$ is a Green's function of the system (3.11).

Next, define a Banach space C_m by

$$C_m[\bar{\kappa}_1, \bar{\kappa}_2] = \Big\{U = (u_1, \dots, u_m)^T : [\bar{\kappa}_1, \bar{\kappa}_2] \to \mathbb{R}^m, u_i \in C[\bar{\kappa}_1, \bar{\kappa}_2], i = 1, \dots, m\Big\}$$

with norm $\|U\| = \max_{1 \le i \le m}\{\|u_i\|_0\}$, where $\|\cdot\|_0$ denotes the usual supremum norm. Consider the partial order on $\mathbb{R}^m$:

$$V \le U \iff v_i \le u_i, \quad i = 1, \dots, m, \text{ where } U, V \in \mathbb{R}^m.$$

Using this partial order, we define a partial order on $C_m[\bar{\kappa}_1, \bar{\kappa}_2]$:

$$V \le U \iff V(x) \le U(x), x \in [\bar{\kappa}_1, \bar{\kappa}_2], \text{ where } U, V \in C_m.$$

Let $D_\Phi \in C_m$ denote the solution of the following homogeneous equation with nonhomogeneous boundary conditions:

$$\tag{3.14} \begin{cases} D_{xx}(x) + \bar{C}D(x) = 0 \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ D(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1)\mathbb{1}_m, \;\; D(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\mathbb{1}_m. \end{cases}$$

The existence of D_Φ is ensured by Corollary 3.3. Define an operator $\mathbf{K}$ on C_m by

$$\tag{3.15} (\mathbf{K}D)(x) = D_\Phi(x) + \int_{\bar{\kappa}_1}^{\bar{\kappa}_2} G(x,s)\widetilde{F}D(s)\,ds,$$

where $\widetilde{F}$ is given by (3.10).

Remark 3.6. Let $\mathbf{K}$ be defined by (3.15). Then $\mathbf{K} : C_m[\bar{\kappa}_1, \bar{\kappa}_2] \longrightarrow C^2_m[\bar{\kappa}_1, \bar{\kappa}_2]$.

The remark follows by standard properties of the diagonal structure of the Green's matrix $G(x, s)$ (see Coddington and Levinson [4, p. 192]). In fact, each scalar-valued function $G(\lambda_i; x, s)$ is continuous on triangles, $x < s$, $s < x$, and satisfies the differential equation

$$D_{i,xx}(x) + \left[\frac{1}{2} - \frac{x^2}{4} - (1 + \lambda_i)\right] D_i(x) = 0$$

on triangles, $x < s$, $s < x$, and

$$\lim_{x \to s^+} G_x(x, s) - \lim_{x \to s^-} G_x(x, s) = 1.$$

If $D \in C_m[\bar{\kappa}_1, \bar{\kappa}_2]$, then it is standard to show that $\mathbf{K}D \in C^2_m[\bar{\kappa}_1, \bar{\kappa}_2]$.

The following remark is also immediate from Corollary 3.2 and (3.15) (see Coddington and Levinson [4, p. 192] and Jackson [14, p. 99]).

Remark 3.7. $D \in C^2_m$ is a solution of the boundary value problem (3.11) if and only if $D \in C_m$ and $\mathbf{K}D = D$.

In view of Corollary 3.2 and (3.10), we have $G(x, s)\widetilde{F} \geq 0$ elementwise. Therefore, $\mathbf{K}$ is a monotonic operator; that is,

$$V \leq U \Longrightarrow \mathbf{K}V \leq \mathbf{K}U, \quad U, V \in C_m.$$

We establish upper and lower solutions of the boundary value problem (3.11), respectively. That is, (see Jackson [14]), we seek $U_0 \in C^2_m$ and $V_0 \in C^2_m$ satisfying

$$V_0 \leq U_0, \quad V_0 \leq \mathbf{K}V_0, \quad \mathbf{K}U_0 \leq U_0, \tag{3.16}$$

and

$$V_0(\bar{\kappa}_i) \leq \exp\left(\frac{(\bar{\kappa}_i)^2}{4}\right) \Phi(z_i) \mathbb{1}_m \leq U_0(\bar{\kappa}_i), \quad i = 1, 2. \tag{3.17}$$

Once we obtain the upper and lower solutions, the proof for existence of a solution is complete. To see this, define a closed and convex region $\Omega \subset C_m$ by

$$D \in \Omega \Longleftrightarrow V_0(x) \leq D(x) \leq U_0(x), \quad \bar{\kappa}_1 \leq x \leq \bar{\kappa}_2 \ .$$

The inequalities (3.16) and (3.17), coupled with the fact that $\mathbf{K}$ is monotone, imply that $\mathbf{K} : \Omega \to \Omega$. Thus, the existence of a solution D, satisfying

$$V_0(x) \leq D(x) \leq U_0(x), \qquad \bar{\kappa}_1 \leq x \leq \bar{\kappa}_2, \tag{3.18}$$

follows as an application of the Schauder fixed point theorem (Jackson [14, p. 102]).

It can be shown, using the definition (3.15) and Corollary 3.2, that V_0 is a lower solution if

$$\begin{cases} V_{0,xx}(x) + \bar{C}V_0(x) \geq \widetilde{F}V_0(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ V_0(\bar{\kappa}_1) \leq \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right) \Phi(z_1)\mathbb{1}_m, \;\; V_0(\bar{\kappa}_2) \leq \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right) \Phi(z_2)\mathbb{1}_m, \end{cases} \tag{3.19}$$

where $\bar{C}$ is the diagonal matrix defined in (3.12). Similarly, U_0 is a upper solution if the above inequalities are reversed, i.e.,

$$\begin{cases} U_{0,xx}(x) + \bar{C}U_0(x) \le \widetilde{F}U_0(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ U_0(\bar{\kappa}_1) \ge \exp\left(\frac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1)\mathbb{1}_m, \;\; U_0(\bar{\kappa}_2) \ge \exp\left(\frac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\mathbb{1}_m. \end{cases} \tag{3.20}$$

Consider the solution D_Φ of (3.14). Since D_Φ satisfies the homogeneous equation (3.14), $0 \ge \widetilde{F}D_\Phi$, and D_Φ satisfies the boundary conditions, it is readily seen that D_Φ satisfies (3.19). Thus we can choose $V_0 = D_\Phi$.

On the other hand, the upper solution can be chosen as $U_0 = (K, \dots, K)^T \in \mathbb{R}^m$, where K is a constant satisfying

$$K \ge \max\left\{\exp\left(\frac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1), \exp\left(\frac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\right\}. \tag{3.21}$$

To show that the so-chosen U_0 is indeed an upper solution, we need only to verify the first inequality in (3.20). In fact, in view of (3.9) and (3.10), substituting the constant vector $(K, \dots, K)^T$ into the inequality yields, for $i = 1, \dots, m$,

$$\frac{1}{2} - \frac{x^2}{4} - (1 + \lambda_i) = \frac{1}{2} - \frac{x^2}{4} - \left(1 + \frac{\rho}{\mu(i)} - \frac{q_{ii}}{\mu(i)}\right) \le -\sum_{j \ne i} \frac{q_{ij}}{\mu(i)},$$

which is true in view of $\sum_{j=1}^m q_{ij} = 0$ and $\mu(i) > 0$. This completes the proof of the existence of a C^2 solution. □

Remark 3.8. Define $V_{k+1} = \mathbf{K}V_k$, $U_{k+1} = \mathbf{K}U_k$, $k = 0, 1, 2 \dots$. Then it follows that

$$V_k \le V_{k+1} \le U_{k+1} \le U_k, \quad k \ge 0.$$

This string of inequalities is immediate from the monotonicity of $\mathbf{K}$. Consequently, there exist functions $\bar{V}, \bar{U}$ such that $\{V_k\} \uparrow \bar{V}$, $\{U_k\} \downarrow \bar{U}$ (pointwise and componentwise) as $k \to \infty$. Moreover, by Dini's theorem, the convergence is uniform in x. So $\bar{V}, \bar{U} \in C_m$. Applying operator (3.15) to V_k (resp., U_k) and letting $k \to \infty$, we have $\mathbf{K}\bar{V} = \bar{V}$ and $\mathbf{K}\bar{U} = \bar{U}$. Therefore, both $\bar{V}$ and $\bar{U}$ are the solutions of (3.11). From Remark 3.6, we know both $\bar{V}$ and $\bar{U}$ are C_m^2 functions. The uniqueness of the solution implies that $\bar{V} = \bar{U}$.

Remark 3.9. From the proof of Theorem 3.5, we also see that the C^2 solution of the system (2.13) (and therefore the objective function (2.9)) is continuous with respect to the boundary points z_1 and z_2.

Now we study the optimality of the objective function (2.9). We make the following assumption on z_1 and z_2; see Zhang [26] for further discussions.

Assumption 3.10.

$$a_1 \le z_1 \le b_1, \quad a_2 \le z_2 \le b_2,$$

where a_1, b_1, a_2, b_2 are prespecified constants satisfying $-\infty < a_1 < b_1 < 0 < a_2 < b_2 < \infty$.

Theorem 3.11. *Under Assumptions* 3.4 *and* 3.10*, the following assertions hold:*

1. *For each $1 \le i \le m$, $v(z, i) \in C^2$ and is the unique solution to* (2.11) *and* (2.12).

2. *For each fixed pair* (z, i)*,* $v(z, i)$ *is a continuous function of* (z_1, z_2) *on* $[a_1, b_1] \times [a_2, b_2]$*.*
3. *There exists an optimal pair* $(z_1^*, z_2^*) \in [a_1, b_1] \times [a_2, b_2]$ *that maximizes the objective function* (2.9)*.*

Proof. Parts 1 and 2 are obtained by Theorem 3.5 together with Dynkin's formula. Part 3 follows from the compactness of $[a_1, b_1] \times [a_2, b_2]$. □

We provide a numerical example to demonstrate the approximation process proposed in Remark 3.8.

Example 3.12. Consider a two-dimensional system ($m = 2$) and construct the two sequences of approximation solutions (upper and lower) by iteratively solving the corresponding boundary value problems. We numerically solve these equations and graphically display the convergence of the two sequences.

When $m = 2$, the system (3.11) can be written componentwise as

$$\tag{3.22} \begin{cases} D_{1,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_1)\right) D_1(x) = -\dfrac{q_{12}}{\mu(1)} D_2(x), \\ D_{2,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_2)\right) D_2(x) = -\dfrac{q_{21}}{\mu(2)} D_1(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ D_i(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right) \Phi(z_1), \quad D_i(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right) \Phi(z_2), \quad i = 1, 2. \end{cases}$$

We first find the solution $D_\Phi = (D_{1,\Phi}, D_{2,\Phi})^T$ of the associated homogeneous equations with nonhomogeneous boundary conditions, i.e.,

$$\tag{3.23} \begin{cases} D_{1,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_1)\right) D_1(x) = 0, \\ D_{2,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_2)\right) D_2(x) = 0 \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ D_i(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right) \Phi(z_1), \quad D_i(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right) \Phi(z_2), \quad i = 1, 2. \end{cases}$$

To make the expression compact, let

$$W_\lambda(x) = \exp\left(-\frac{x^2}{4}\right) \int_0^\infty t^\lambda \exp\left(-\frac{t^2}{2} - xt\right) dt.$$

Then we have

$$\tag{3.24} D_{1,\Phi}(x) = C_1 W_{\lambda_1}(x) + C_2 W_{\lambda_1}(-x),$$

where the two constants C_1, C_2 are determined by the given pair of boundary conditions,

$$C_1 = \frac{W_{\lambda_1}(-\bar{\kappa}_2) \exp\left(\frac{(\bar{\kappa}_1)^2}{4}\right) \Phi(z_1) - W_{\lambda_1}(-\bar{\kappa}_1) \exp\left(\frac{(\bar{\kappa}_2)^2}{4}\right) \Phi(z_2)}{W_{\lambda_1}(\bar{\kappa}_1) W_{\lambda_1}(-\bar{\kappa}_2) - W_{\lambda_1}(-\bar{\kappa}_1) W_{\lambda_1}(\bar{\kappa}_2)},$$

$$C_2 = \frac{W_{\lambda_1}(\bar{\kappa}_1) \exp\left(\frac{(\bar{\kappa}_2)^2}{4}\right) \Phi(z_2) - W_{\lambda_1}(\bar{\kappa}_2) \exp\left(\frac{(\bar{\kappa}_1)^2}{4}\right) \Phi(z_1)}{W_{\lambda_1}(\bar{\kappa}_1) W_{\lambda_1}(-\bar{\kappa}_2) - W_{\lambda_1}(-\bar{\kappa}_1) W_{\lambda_1}(\bar{\kappa}_2)}\ .$$

Replacing λ_1 in the equations for $D_{1,\Phi}$ with λ_2 yields $D_{2,\Phi}$. Thus we obtain an analytical lower solution $V_0 = D_\Phi$.

Starting at $V_0 = (V_{0,1}, V_{0,2})^T$, the approximate sequence $V_k = (V_{k,1}, V_{k,2})^T$, $k \geq 1$, can be constructed by iteratively solving the following two-point boundary value problem:

$$\tag{3.25} \begin{cases} V_{k+1,1,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_1)\right) V_{k+1,1}(x) = -\dfrac{q_{12}}{\mu(1)} V_{k,2}(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ V_{k+1,1}(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1), \quad V_{k+1,1}(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2), \end{cases}$$

$$\tag{3.26} \begin{cases} V_{k+1,2,xx}(x) + \left(\dfrac{1}{2} - \dfrac{x^2}{4} - (1+\lambda_2)\right) V_{k+1,2}(x) = -\dfrac{q_{21}}{\mu(2)} V_{k,1}(x) \quad \text{for } x \in (\bar{\kappa}_1, \bar{\kappa}_2), \\ V_{k+1,2}(\bar{\kappa}_1) = \exp\left(\dfrac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1), \quad V_{k+1,2}(\bar{\kappa}_2) = \exp\left(\dfrac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\ . \end{cases}$$

The same process, starting at the upper solution $U_0 = (K, K)^T$, will produce the other sequence U_k, $k \geq 0$. In view of (3.21), we choose

$$K = \max\left\{\exp\left(\frac{(\bar{\kappa}_1)^2}{4}\right)\Phi(z_1),\ \exp\left(\frac{(\bar{\kappa}_2)^2}{4}\right)\Phi(z_2)\right\}.$$

We used a box method (see Zwillinger [27]) to solve (3.25) and (3.26). Various parameters for the numerical experiment were chosen as follows:

$$\mu(1) = 0.1, \quad \mu(2) = 0.2, \quad b(1) = 0, \quad b(2) = 0, \quad \sigma^2(1) = 0.25, \quad \sigma^2(2) = 0.5,$$

$$Q = (q_{ij}) = \begin{pmatrix} -2 & 2 \\ 3 & -3 \end{pmatrix}, \quad \rho = 1, \quad z_1 = -1, \quad z_2 = 1, \quad \Phi(x) \equiv 1.$$

Figure 1 displays a number of upper and lower approximation solutions. It demonstrates that the upper and lower approximate sequences converge to a common solution, which is the unique solution to the boundary value system.

4. Stochastic optimization method. Except for the special one-dimensional case, it is very difficult to obtain the analytical representation of the objective function (2.7). Thus finding a systematic way of obtaining the optimal threshold values becomes an important task. To search for the optimal thresholds, we develop stochastic recursive approximation algorithms in this section. To this end, we reformulate the task of finding optimal thresholds as a stochastic approximation or stochastic optimization problem. For a general approach to stochastic approximation methods, the reader is referred to Kushner and Yin [17] for an up-to-date account of stochastic approximation.

4.1. Optimization problem and stochastic approximation algorithms. In lieu of using the differential equation method, we convert the optimal stopping problem to a stochastic optimization problem. The rationale is based on using a threshold-type strategy, and the underlying problem can be stated as

$$\tag{4.1} \text{Problem } \mathcal{P}: \begin{cases} \text{Find argmax } \varphi(z) = E\{\Phi(X(\tau))\exp(-\rho\tau)\}, \\ z = (z_1, z_2)^T \in [a_1, b_1] \times [a_2, b_2], \end{cases}$$

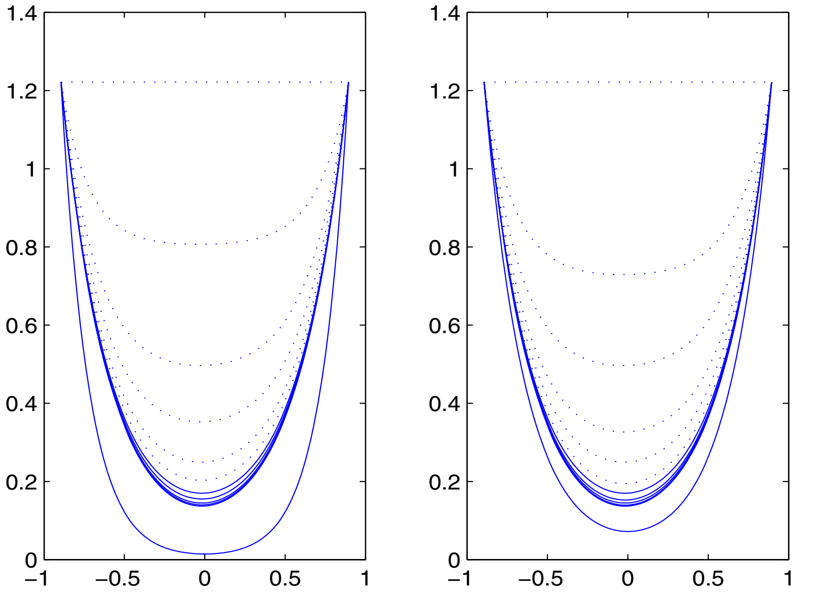

FIG. 1. *Approximation sequences and convergence. The dotted lines are the upper approximation sequences, and the solid lines are the lower approximation sequences. The left graph is for $D_1(x)$, and the right graph is for $D_2(x)$.*

where we use $\varphi(z)$ for the objective function $V(z_1, z_2)$ defined in (2.7), and τ is the stopping time defined by (2.5). Our objective is to find the optimal vector-valued threshold value for the constraint optimization problem $\mathcal{P}$.

To approximate the optimal threshold value $z^* = (z_1^*, z_2^*)^T$, we construct a recursive algorithm

$$z_{n+1} = z_n + \{\text{step size}\} \cdot \{\text{gradient estimate of } \varphi(z)\}, \tag{4.2}$$

where $z_n = (z_{n,1}, z_{n,2})^T$ denote the threshold values at the nth iteration. The step size is typically a decreasing sequence of real numbers satisfying certain conditions.

To implement (4.2), we need to construct gradient estimates of the objective function $\varphi(z)$ either by observing the real data with noisy measurements or by using a simulation. We use ξ to denote the collective random factors (including the Brownian motion, the Markov chain, and other observation noise or simulation of random effects from random seeds) so that each realization of ξ uniquely determines a sample path of the asset price dynamics (2.2) as well as the stopping time τ (2.5) for a fixed value of z. At the nth iteration, suppose the threshold values are $z_n = (z_{n,1}, z_{n,2})^T$. Let $\widetilde{\varphi}(z_n, \xi_n)$ denote the value of the discounted utility function either observed or simulated using the sample path associated with ξ_n. We assume that $E\{\widetilde{\varphi}(z, \xi_n)\} = \varphi(z)$.

Let $\Delta\widetilde{\varphi}(z_n, \xi_n) = (\Delta_1\widetilde{\varphi}(z_n, \xi_n), \Delta_2\widetilde{\varphi}(z_n, \xi_n))^T$ denote the sample path gradient estimates using a finite difference approximation, where, for $i = 1, 2$,

$$\Delta_i\widetilde{\varphi}(z_n, \xi_n) = \frac{\widetilde{\varphi}(z_n + \delta_n e_i, \xi_n) - \widetilde{\varphi}(z_n - \delta_n e_i, \xi_n)}{2\delta_n}, \tag{4.3}$$

$e_1 = (1, 0)^T$ and $e_2 = (0, 1)^T$ are the standard unit vectors, and $\{\delta_n\}$ is a sequence of positive real numbers tending to 0 and satisfying certain conditions.

Remark 4.1. The following points are worth noting.

(1) In (4.3), we use the same sample path generated by ξ_n for calculations of the function $\widetilde{\varphi}$ at different z values. This is because when Monte Carlo simulation is used to calculate a finite difference gradient approximation, using the same random numbers in calculating the two function values can reduce the variance of the estimator (see, for example, Glasserman [11]). The common random number generators can be effectively used in conjunction with stochastic approximation methods; see Kushner and Yin [17, pp. 15, 143].

(2) In the above construction of gradient estimates, instead of one simulation run, we could use multiple replications. We could use (2.2) to generate n_0 independent sample paths of $X(t)$. For each sample path, we find the value of τ, i.e., the first exit time of $X(t)$ from the interval $(z_{n,1}, z_{n,2})$. Then we construct the gradient estimates using n_0 different random seeds and then average them out. In lieu of one replication, we then use the average of n_0 replications as the gradient estimator. The advantage is that the result will be smoother. However, if we deal with real data, this idea cannot be implemented. For simplicity, we do not write the expression but refer the reader to [23] for further details.

The stochastic recursive algorithm (4.2) takes the form

$$z_{n+1} = z_n + \varepsilon_n \Delta\widetilde{\varphi}(z_n, \xi_n), \tag{4.4}$$

where $\{\varepsilon_n\}$ is a sequence of real numbers known as step sizes satisfying $0 \le \varepsilon_n \to 0$ and $\varepsilon_n/\delta_n \to 0$ as $n \to \infty$, and $\sum_n \varepsilon_n = \infty$. To ensure the boundedness of the iterates, similarly to Yin, Liu, and Zhang [23] (see also [17, p. 121]), we use the following modified stochastic approximation algorithm for the constrained problem $\mathcal{P}$:

$$z_{n+1} = \Pi[z_n + \varepsilon_n \Delta\widetilde{\varphi}(z_n, \xi_n)], \tag{4.5}$$

or, in a component form,

$$z_{n+1,i} = \Pi_{[a_i,b_i]}[z_{n,i} + \varepsilon_n \Delta_i \widetilde{\varphi}(z_n, \xi_n)] \quad \text{for} \quad i = 1, 2,$$

where the projection Π is defined as, for each real value x,

$$\Pi_{[a_i,b_i]}(x) = \begin{cases} a_i & \text{if } x < a_i, \\ b_i & \text{if } x > b_i, \\ x & \text{otherwise.} \end{cases}$$

The idea is as follows: For each component i, after the update $z_{n,i} + \varepsilon_n \Delta_i \widetilde{\varphi}(z_n, \xi_n)$ is obtained, we compare this value with the bounds a_i and b_i. If the updated value is smaller than the lower value a_i, reset the value to a_i; if it is greater than the upper value b_i, reset it to b_i; otherwise keep the value as it was. Note that in view of the techniques in [17, Chapter 5], the projection algorithm may be rewritten as

$$z_{n+1} = z_n + \varepsilon_n \Delta\widetilde{\varphi}(z_n, \xi_n) + \varepsilon_n R_n, \tag{4.6}$$

where $\varepsilon_n R_n = z_{n+1} - z_n - \varepsilon_n \Delta\widetilde{\varphi}(z_n, \xi_n)$, known as reflection term, is the minimal force needed to bring the iterates back to the constrained region if they ever escape from there.

In what follows, we present sufficient conditions guaranteeing the convergence of the algorithm. For analysis purposes only, define

$$\begin{aligned} &\psi_n = \Delta\widetilde{\varphi}(z_n, \xi_n) - E_n \Delta\widetilde{\varphi}(z_n, \xi_n), \\ &\zeta_{n,i} = E_n \Delta_i \widetilde{\varphi}(z_n, \xi_n) - [\varphi(z_n + \delta_n e_i) - \varphi(z_n - \delta_n e_i)], \quad i = 1, 2, \\ &b_{n,i} = \frac{\varphi(z_n + \delta_n e_i) - \varphi(z_n - \delta_n e_i)}{2\delta_n} - \frac{\partial \varphi(z_n)}{\partial z^i}, \quad i = 1, 2, \end{aligned} \tag{4.7}$$

where E_n denotes the conditional expectation with respect to $\mathcal{F}_n$, the σ-algebra generated by $\{z_0, \xi_j : j < n\}$, and $\varphi_z(z) = ((\partial/\partial z^1)\varphi(z), (\partial/\partial z^2)\varphi(z))^T$ denotes the gradient of $\varphi(\cdot)$. Above, $\zeta_{n,i}$ and $b_{n,i}$ for $i = 1, 2$ represent the noise and bias, and $\{\psi_n\}$ is a martingale difference sequence. This separation together with the expanded form of the recursion is for analysis purposes. As far as computation is concerned, only (4.5) is needed.

Write $\zeta_n = (\zeta_{n,1}, \zeta_{n,2})^T$ and $\beta_n = (b_{n,1}, b_{n,2})^T$ and note that $\zeta_n = \zeta_n(z_n, \xi_n)$. With the noise $\zeta_n(z_n, \xi_n)$ and the bias β_n defined above, algorithm (4.5) becomes

$$z_{n+1} = z_n + \varepsilon_n \varphi_z(z_n) + \varepsilon_n \frac{\psi_n}{2\delta_n} + \varepsilon_n \beta_n + \varepsilon_n \frac{\zeta_n}{2\delta_n} + \varepsilon_n R_n. \tag{4.8}$$

Denote $t_n = \sum_{i=1}^{n-1} \varepsilon_i$ and

$$m(t) = \begin{cases} n : t_n \le t < t_{n+1}, & t \ge 0, \\ 0, & t < 0. \end{cases}$$

To study the convergence of the algorithm, define a piecewise constant interpolation by $z^0(t) = z_n$ for $t \in [t_n, t_{n+1})$ and $z^n(t) = z^0(t + t_n)$ for $n > 0$. Similarly, define the interpolation for R_n. Let $\{\Delta_n\}$ be a sequence of positive real numbers tending to 0 as $n \to \infty$ such that $\sup_{j \ge n} \varepsilon_j / \Delta_n \to 0$. Select an increasing sequence $n = m_1 < m_2 < \cdots$ such that $\sum_{k=m_l}^{m_{l+1}-1} \varepsilon_k / \Delta_n \to 1$ as $n \to \infty$ uniformly in l. Then we have the following convergence result.

PROPOSITION 4.2. *Assume that $\varphi_{zz}(\cdot)$, the second partial derivative of $\varphi(\cdot)$, is continuous, that $\sup_n E|\widetilde{\varphi}(z, \xi_n)|^2 < \infty$ for each z, that the projected ordinary differential equation*

$$\dot{z}(t) = \varphi_z(z(t)) + r(t), \;\; r(t) \in C(z(t)) \tag{4.9}$$

has a unique solution for each initial condition, and that there is a unique stationary point z_* of (4.9) in $(a_1, b_1) \times (a_2, b_2)$ that is globally asymptotically stable in the sense of Liapunov. In addition, for each z in the constraint set, $\{\zeta_n(z, \xi)\}$ is uniformly integrable, and $\sum_{k=m_l}^{m_{l+1}-1} \varepsilon_k E_{m_l} \zeta(z, \xi_k)/\delta_k \to 0$ in probability. Then $z^n(\cdot)$ converges to $z(\cdot)$, the solution of the projected ordinary differential equation (4.9). Assume that $\{s_n\}$ is a sequence of real numbers satisfying $s_n \to \infty$ as $n \to \infty$. Then $z^n(s_n + \cdot)$ converges to z_* with probability 1.

In Proposition 4.2, $r(t)$ satisfies $R(t) = \int_0^t r(s) ds$, with $R(t)$ being the limit of the interpolation sequence of the projection term R_n. The set $C(z)$ is defined as follows: If z is inside $(a_1, b_1) \times (a_2, b_2)$, then $C(z)$ contains only the zero element. If z is on the boundary, then $C(z)$ is the infinite convex cone generated by the outer normal at z of the faces on which z lies; see [17, section 4.3] for more discussions. The proof of the proposition is based on a combined use of a probabilistic approach and analytic results on differential equations. For explanations on the conditions needed together with a proof, we refer the reader to [23]. In addition to the convergence, we may also study the rates of convergence and obtain large deviation-type bounds as was done in [25]. However, these are not the main concerns of the current paper. We are more interested in the numerical performance of the algorithm, which is discussed next.

4.2. Numerical results.

In this section we provide two numerical examples and compare the results. We study a two-dimensional problem with variable parameters (i.e., regime-dependent parameters) in the first example and constant parameters in

Table 1
Optimal thresholds using the stochastic approximation algorithm.

Initial z	$-0.05, 0.05$	$-0.10, 0.20$	$-0.20, 0.40$	$-0.10, 0.60$	$-0.05, 0.85$
$z^*(n_0 = 100)$	$-0.36, 0.421$	$-0.36, 0.422$	$-0.36, 0.422$	$-0.36, 0.422$	$-0.36, 0.423$
$z^*(n_0 = 10)$	$-0.36, 0.409$	$-0.36, 0.418$	$-0.36, 0.429$	$-0.36, 0.418$	$-0.36, 0.419$
$z^*(n_0 = 1)$	$-0.36, 0.409$	$-0.36, 0.416$	$-0.36, 0.425$	$-0.359, 0.417$	$-0.359, 0.423$

the second. In both cases, the Markov chain $\alpha(t)$ takes two states, whose generator is given by

$$Q = \begin{pmatrix} -6.04 & 6.04 \\ 8.90 & -8.90 \end{pmatrix}.$$

The probability distribution of the initial Markov chain $\alpha(0)$ is given by $p_1 = p_2 = \frac{1}{2}$. We use the utility function $\Phi(x) = e^x - 1$ (see Remark 2.4).

Example 4.3. We choose the following parameter values for the regime-switching model: $\mu(1) = 0.01$, $\mu(2) = 0.02$, $b(1) = b(2) = 0$, $\sigma^2(1) = 0.25$, $\sigma^2(2) = 0.5$, and $\rho = 1$. We first implement the stochastic recursive algorithm developed in section 4.1. For the search region for $z = (z_1, z_2)$, we choose $(z_1, z_2) \in [a_1, b_1] \times [a_2, b_2] = [-0.36, -0.01] \times [0.01, 1.0]$. The sequence $\{\varepsilon_n\}$ for step sizes in (4.4) and the sequence $\{\delta_n\}$ used in the gradient estimation (4.3) are chosen to be $\varepsilon_n = 1/(n + k_0)$ and $\delta_n = 1/(n^{1/6} + k_1)$, respectively, where k_0 and k_1 are some positive integers, e.g., $k_0 = k_1 = 1$. The search stops whenever $\varepsilon_n < 0.001$. In what follows, we use n_0 replications, as presented in Remark 4.1. Table 1 reports the search results by using the stochastic recursive algorithm for five different initial values of z and for three different n_0 for gradient estimation. Note that the last row in the table ($n_0 = 1$) gives the results obtained by using a single path gradient estimate in the recursion.

Next we numerically solve the differential equations (2.11) with boundary conditions (2.12). For this example, they become

$$\text{(4.10)} \qquad \begin{cases} \dfrac{\sigma^2(1)}{2}\dfrac{d^2v(z,1)}{dz^2} + \mu(1)z\dfrac{dv(z,1)}{dz} + (q_{11} - \rho)v(z,1) + q_{12}v(z,2) = 0, \\ \dfrac{\sigma^2(2)}{2}\dfrac{d^2v(z,2)}{dz^2} + \mu(2)z\dfrac{dv(z,2)}{dz} + (q_{22} - \rho)v(z,2) + q_{21}v(z,1) = 0, \\ v(z_1, i) = e^{z_1} - 1, \quad v(z_2, i) = e^{z_2} - 1, \quad i = 1, 2. \end{cases}$$

We use a grid size 0.01 to divide the region $[-0.36, -0.01] \times [0.01, 1.0]$ for (z_1, z_2). This results in 36 points along z_1, 100 points along z_2, and totally 3600 different pairs for (z_1, z_2). For each pair, which specifies the boundary values, a finite difference scheme is used to solve the system (4.10). The objective function $V(z_1, z_2)$ is then calculated by $V(z_1, z_2) = [v(0,1) + v(0,2)]/2$. Figure 2 plots the surface $V(z_1, z_2)$ using the 3600 values. The numerical results show that the maximum value for $V(z_1, z_2)$ is achieved at $(-0.36, 0.41)$ and $(-0.36, 0.42)$. This suggests that the optimal threshold (z_1^*, z_2^*) is very close to these two points. It is consistent with the estimates obtained in Table 1 by using the stochastic optimization algorithms. Note that numerically solving the differential equations is time consuming, while the stochastic recursive algorithms produce the optimal estimates in much less computation. This efficiency becomes more eminent when a small number of sample paths is used in gradient estimation. From Table 1 we notice that even a single sample path yields pretty good approximations to the optimal thresholds.

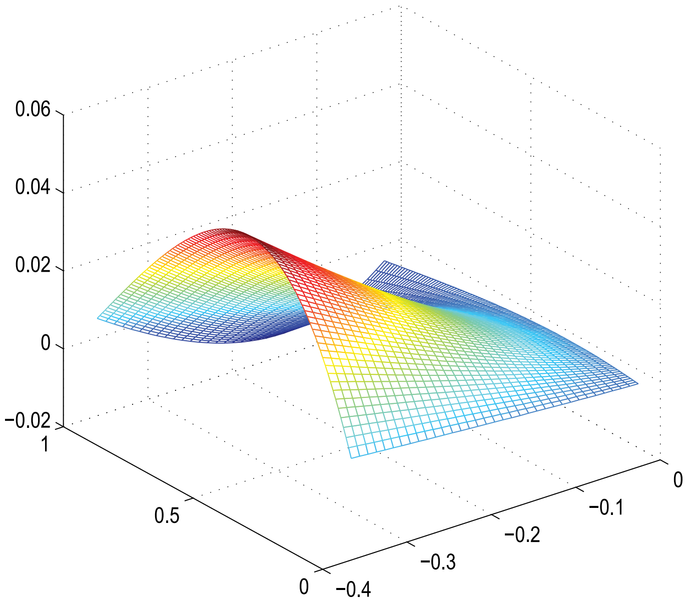

FIG. 2. *Surface of the value function* $V(z_1, z_2)$ *over the region* $(z_1, z_2) \in [-0.36, -0.01] \times [0.01, 1.0]$. *Grid size* 0.01 *is used.*

TABLE 2
Comparison of optimal selling rules in different markets.

	Optimal threshold (z_1^*, z_2^*)	Percentage increase in asset price	Percentage decrease in asset price
Bear market (Case I, Ex. 3)	$(-0.36, 0.33)$	39%	30%
Bull market (Case II, Ex. 3)	$(-0.36, 0.55)$	73%	30%
Mixed market (Ex. 2)	$(-0.36, 0.42)$	52%	30%

Based on the results, we may conclude that the optimal threshold for this specific example is given by $(z_1^*, z_2^*) = (-0.36, 0.42)$ with double-digit precision. This pair of values corresponds to a 52% increase and a 30% decrease in asset price, respectively. Following the selling rule, an investor would sell the asset he or she has bought whenever the price goes up by 52% or down by 30%.

Example 4.4. In this example we assume that the model parameters do not change across regimes, i.e., $\mu(1) = \mu(2) = \mu$, $\sigma(1) = \sigma(2) = \sigma$, while keeping other values the same, as in the last example. We report two cases: one uses regime 1 parameters and another uses regime 2 parameters from Example 4.3.

Case 1. $\mu = 0.01$, $\sigma^2 = 0.25$. The optimal thresholds are $(z_1^*, z_2^*) = (-0.36, 0.33)$, which correspond to a 39% increase and a 30% decrease in asset price.

Case 2. $\mu = 0.02$, $\sigma^2 = 0.50$. The optimal thresholds are $(z_1^*, z_2^*) = (-0.36, 0.55)$, which correspond to a 73% increase and a 30% decrease in asset price.

For comparison, in Table 2, we summarize the results from Examples 4.4 and 4.3. We may call Case 2 in Example 4.4 a bull market since a bigger μ value is used and Case 1 a bear market since a smaller μ value is used. Then we call Example 4.3 a mixed market because of the switching between the two μ numbers. Note that the optimal selling rules change in a manner that agrees with common investment practice. If a 30% drop in asset price is used by investors for the stop-loss limit, then the upper threshold for achieving maximum profit is higher (73%) in the bull market than that in the (more realistic) mixed market (52%), which in turn is higher than that in the bear market (39%).

5. Concluding remarks. In this paper we developed an optimal selling rule using a regime-switching exponential Gaussian diffusion model. The optimal selling can be characterized by two threshold levels. We designed a numerical algorithm for searching these threshold levels.

Note that our results in this paper rely crucially on Assumption 3.4. It is interesting and practically useful to relax these conditions. In addition, we assumed the market mode to be completely observable. In order to apply our results in practice, one needs to estimate the system mode using nonlinear filtering techniques. The Wonham filter, in which the hidden Markov chain $\alpha(t)$ is observed in noise, is a good candidate; it provides sound conditional probability estimates given the stock price up to time t.

Acknowledgment. We thank the reviewers whose comments have improved the exposition of this paper.

FAR FIELD MODELING OF ELECTROMAGNETIC TIME REVERSAL AND APPLICATION TO SELECTIVE FOCUSING ON SMALL SCATTERERS*

X. ANTOINE†, B. PINÇON†, K. RAMDANI†, AND B. THIERRY†

Abstract. A time harmonic far field model for closed electromagnetic time reversal mirrors is proposed. Then, a limit model corresponding to small perfectly conducting scatterers is derived. This asymptotic model is used to prove the selective focusing properties of the time reversal operator. In particular, a mathematical justification of the decomposition of the time reversal operator (DORT) method is given for axially symmetric scatterers.

Key words. electromagnetic scattering, time reversal, far field, small obstacles

DOI. 10.1137/080715779

1. Introduction.

In the last decade, acoustic time reversal has definitely demonstrated its efficiency in target characterization by wave focusing in complex media (see the review papers [13, 15]). In particular, it has been shown that selective focusing can be achieved using the eigenvectors (resp., eigenfunctions) of the so-called time reversal matrix (resp., operator). Known as the DORT method (French acronym for *diagonalization of the time reversal operator*; see [14, 32, 26, 31, 16, 25, 18]), this technique involves three steps. First, an incident wave is emitted in the medium containing the scatterers by the time reversal mirror (TRM). The scattered field is then measured by the mirror and time-reversed (or phase-conjugated in the time harmonic case). Finally, the obtained signal is then re-emitted in the medium. By definition, the time reversal operator $\mathbf{T}$ is the operator describing two successive cycles of emission/reception/time reversal. If the propagation medium is nondissipative, then the operator $\mathbf{T}$ is hermitian, since $\mathbf{T} = \mathbf{F}^*\mathbf{F}$, where $\mathbf{F}$ denotes the far field operator. The DORT method can thus be seen as a singular value decomposition of $\mathbf{F}$. Moreover, in a particular range of frequencies (for which the scatterers can be considered as point-like scatterers), $\mathbf{T}$ has as many significant eigenvalues as there are scatterers in the medium, and the corresponding eigenfunctions generate incident waves that selectively focus on the scatterers. From the mathematical point of view, a detailed analysis of this problem has been proposed for the acoustic scattering problem by small scatterers in the free space in [19] and in a two-dimensional straight waveguide in [29]. Let us emphasize that time reversal has also been intensively studied in the context of random media (see [17] and the references therein).

Recently, electromagnetic focusing using time reversal has been demonstrated experimentally [23] and used for imaging applications [24]. One of the first works dealing with mathematical and numerical aspects of electromagnetic time reversal is the paper [34]. The authors analyze therein the DORT method in the case of a homogeneous

†Institut Elie Cartan Nancy (Nancy-Université, CNRS, INRIA), Université Henri Poincaré, BP 239, 54506, Vandœuvre-lès-Nancy, France, and INRIA (Corida Team), 615 rue du Jardin Botanique, 54600 Villers-lès-Nancy, France (Xavier.Antoine@iecn.u-nancy.fr, Bruno.Pincon@iecn.u-nancy.fr, Karim.ramdani@loria.fr, Bertrand.Thierry@iecn.u-nancy.fr).

medium containing perfectly conducting or dielectric objects of particular shapes (circular rods and spheres). Their method is based on a low frequency approximation of a multipole expansion of the scattered field (i.e., a Fourier–Bessel series involving Hankel functions for circular rods and vector spherical functions for spheres). In [8], the authors proposed an iterative process based on time reversal to determine optimal electromagnetic measurements (i.e., to determine the incident waves maximizing the scattered field). More recently, the DORT method has been used for target localization, especially in the context of imaging [6, 7, 1]. The analysis followed in these works is based on the singular value decomposition of the multistatic response matrix, which corresponds to the case where the mirror is described by a discrete array of transducers (emitters and receivers). In this paper, we propose a time harmonic far field model of electromagnetic time reversal in the case of a continuous distribution of transducers. Only *closed mirrors* (i.e., completely surrounding the scatterers) are considered in this work, and the limited aperture case is not studied. Except for this difference, the present work can be seen as an extension of the results obtained for acoustic time reversal in free space [19] and in straight waveguides [29]. We pay very careful attention to the derivation of the limit scattering model for small perfectly conducting scatterers. The functional framework used hereafter for the far field and the time reversal operators is the one commonly used in inverse electromagnetic scattering theory [11, 5, 20].

We start the paper with a short description in section 2 of the mathematical model of time reversal. In particular, we define the incident field emitted by the TRM (electromagnetic Herglotz waves), the measured fields (the far field pattern), and the time reversal operator. In section 3, we restrict our analysis to the case of small scatterers (of typical size δ). We show that the small scatterers' asymptotics can be deduced from the classical low frequency scattering asymptotics (the Rayleigh approximation) involving the polarization tensors of the scatterers. More precisely, our analysis corresponds to the case where $k\delta$ and δ/d tend simultaneously to 0, where k denotes the wavenumber and d the minimum separation distance between the scatterers. Finally, we study in section 4 the spectral focusing properties of the eigenfunctions of the limit far field operator obtained in section 3. We show that each small scatterer gives rise to at most six distinct eigenvalues (recovering the results obtained in [7, 1] for the case of a discrete TRM). Furthermore, if the polarizability tensors of the scatterers are diagonal (e.g., for axially symmetric scatterers) and under the additional assumption that $kd \to \infty$, we prove that each associated eigenfunction generates an incident wave that selectively focuses on the corresponding scatterer.

2. A far field model for electromagnetic time reversal. In order to obtain an expression of the time reversal operator, we begin this paper by recalling the far field model of electromagnetic scattering. Consider the scattering problem of an incident electromagnetic plane wave by a perfectly conducting bounded obstacle contained in a homogeneous medium. Without loss of generality, we assume that the electric permittivity ε and the magnetic permeability μ are both equal to 1. Let $\mathcal{O}$ be a bounded open subset of $\mathbb{R}^3$ with smooth boundary Γ and outward unit normal $\boldsymbol{\nu}$, and let $\Omega = \mathbb{R}^3 \setminus \overline{\mathcal{O}}$ be the propagation domain. Let $L^2_t(S^2)$ be the space of tangential vector fields of the unit sphere S^2,

$$L^2_t(S^2) = \left\{ \boldsymbol{f} \in \left(L^2(S^2)\right)^3 \mid \forall \boldsymbol{\alpha} \in S^2,\, \boldsymbol{f}(\boldsymbol{\alpha}) \cdot \boldsymbol{\alpha} = 0 \right\},$$

and consider the incident plane wave $(\boldsymbol{E}_I^{\boldsymbol{\alpha},\boldsymbol{f}}, \boldsymbol{H}_I^{\boldsymbol{\alpha},\boldsymbol{f}})$ of direction $\boldsymbol{\alpha} \in S^2$ and electric polarization $\boldsymbol{f} \in L_t^2(S^2)$:

$$\left\{ \begin{array}{l} \boldsymbol{E}_I^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) = \boldsymbol{f}(\boldsymbol{\alpha})\, \mathrm{e}^{ik\boldsymbol{\alpha}\cdot\boldsymbol{x}}, \\ \boldsymbol{H}_I^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) = (\boldsymbol{\alpha} \times \boldsymbol{f}(\boldsymbol{\alpha}))\, \mathrm{e}^{ik\boldsymbol{\alpha}\cdot\boldsymbol{x}}. \end{array} \right. \tag{2.1}$$

Throughout the paper, the time dependence is assumed to be of the form $e^{-i\omega t}$ and will always be implicit. Introducing the wavenumber $k = \omega\sqrt{\varepsilon\mu} = \omega$, the scattered field $(\boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}})$ solves the following exterior boundary value problem:

$$\begin{cases} \operatorname{curl} \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}} = ik\, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}} & (\Omega), \\ \operatorname{curl} \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}} = -ik\, \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}} & (\Omega), \\ \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}} \times \boldsymbol{\nu} = -\boldsymbol{E}_I^{\boldsymbol{\alpha},\boldsymbol{f}} \times \boldsymbol{\nu} & (\Gamma), \\ \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}} \cdot \boldsymbol{\nu} = -\boldsymbol{H}_I^{\boldsymbol{\alpha},\boldsymbol{f}} \cdot \boldsymbol{\nu} & (\Gamma), \\ \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}} \text{ are outgoing.} \end{cases} \tag{2.2}$$

Classically, the outgoing behavior of the scattered field is imposed by one of the two Silver–Müller radiation conditions,

$$\begin{cases} \lim\limits_{|\boldsymbol{x}|\to\infty} \Big(\boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) \times \boldsymbol{x} + |\boldsymbol{x}|\, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) \Big) = 0, \\ \lim\limits_{|\boldsymbol{x}|\to\infty} \Big(\boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) \times \boldsymbol{x} - |\boldsymbol{x}|\, \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x}) \Big) = 0, \end{cases}$$

uniformly in every direction $\boldsymbol{x}/|\boldsymbol{x}| \in S^2$, where $|\,.\,|$ is the Euclidean norm in $\mathbb{R}^3$.

We are now in a position to introduce the far field pattern of the electromagnetic field $(\boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}})$. Its main properties are collected in the next proposition (see [11] for the proofs).

Proposition 2.1. *The scattered field* $(\boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}})$ *has the following asymptotic behavior in the direction* $\boldsymbol{\beta} \in S^2$ *as* $|\boldsymbol{x}| \to \infty$*:*

$$\left\{ \begin{array}{l} \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{\beta}|\boldsymbol{x}|) = \dfrac{e^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|} \boldsymbol{A}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) + O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), \\ \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{\beta}|\boldsymbol{x}|) = \dfrac{e^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|} (\boldsymbol{\beta} \times \boldsymbol{A}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))) + O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right). \end{array} \right.$$

The scattering amplitude $\boldsymbol{A}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))$ *is given for all* $\boldsymbol{\alpha},\boldsymbol{\beta} \in S^2$ *and all* $\boldsymbol{f} \in L_t^2(S^2)$ *by the formula*

$$\boldsymbol{A}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) = -\frac{k^2}{4\pi}\boldsymbol{\beta} \times \int_\Gamma \Big[\boldsymbol{\nu}(\boldsymbol{y}) \times \boldsymbol{H}_T^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{y})\Big] \times \boldsymbol{\beta}\, e^{-ik\boldsymbol{\beta}\cdot\boldsymbol{y}}\, \mathrm{d}\boldsymbol{y}, \tag{2.3}$$

where $\boldsymbol{H}_T^{\boldsymbol{\alpha},\boldsymbol{f}} = \boldsymbol{H}_I^{\boldsymbol{\alpha},\boldsymbol{f}} + \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}}$ *is the total magnetic field. Moreover,* $\boldsymbol{A}(\cdot,\cdot;\cdot)$ *satisfies the reciprocity relation*

$$\boldsymbol{g}(\boldsymbol{\beta}) \cdot \boldsymbol{A}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) = \boldsymbol{f}(\boldsymbol{\alpha}) \cdot \boldsymbol{A}(-\boldsymbol{\beta},-\boldsymbol{\alpha};\boldsymbol{g}(\boldsymbol{\beta})) \tag{2.4}$$

for all $\boldsymbol{\alpha},\boldsymbol{\beta} \in S^2$ *and all* $\boldsymbol{f},\boldsymbol{g} \in L_t^2(S^2)$.

Assume now that the TRM emits a Herglotz wave, i.e., a superposition of plane waves of the form (2.1). More precisely, denote by $(\boldsymbol{E}_I^{\boldsymbol{f}}, \boldsymbol{H}_I^{\boldsymbol{f}})$ the incident Herglotz wave of polarization $\boldsymbol{f} \in L^2_t(S^2)$, defined by

$$\begin{cases} \boldsymbol{E}^{\boldsymbol{f}}_I(\boldsymbol{x}) = \displaystyle\int_{S^2} \boldsymbol{E}^{\boldsymbol{\alpha},\boldsymbol{f}}_I(\boldsymbol{x})\,\mathrm{d}\boldsymbol{\alpha} = \int_{S^2} \boldsymbol{f}(\boldsymbol{\alpha}) e^{ik\boldsymbol{\alpha}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{\alpha}, \\ \boldsymbol{H}^{\boldsymbol{f}}_I(\boldsymbol{x}) = \displaystyle\int_{S^2} \boldsymbol{H}^{\boldsymbol{\alpha},\boldsymbol{f}}_I(\boldsymbol{x})\,\mathrm{d}\boldsymbol{\alpha} = \int_{S^2} (\boldsymbol{\alpha} \times \boldsymbol{f})(\boldsymbol{\alpha}) e^{ik\boldsymbol{\alpha}\cdot\boldsymbol{x}}\,\mathrm{d}\boldsymbol{\alpha}. \end{cases} \tag{2.5}$$

By linearity, Proposition 2.1 yields the following result.

COROLLARY 2.2. *When illuminated by the Herglotz wave* $(\boldsymbol{E}^{\boldsymbol{f}}_I, \boldsymbol{H}^{\boldsymbol{f}}_I)$, *the scattering obstacle generates the diffracted field* $(\boldsymbol{E}^{\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{f}})$, *which admits in the direction* $\boldsymbol{\beta} \in S^2$ *the far field asymptotics*

$$\begin{cases} \boldsymbol{E}^{\boldsymbol{f}}(\boldsymbol{\beta}|\boldsymbol{x}|) = \dfrac{e^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|}\mathbf{F}\boldsymbol{f}(\boldsymbol{\beta}) + O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), \\ \boldsymbol{H}^{\boldsymbol{f}}(\boldsymbol{\beta}|\boldsymbol{x}|) = \dfrac{e^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|}\boldsymbol{\beta} \times \mathbf{F}\boldsymbol{f}(\boldsymbol{\beta}) + O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), \end{cases}$$

where $\mathbf{F}\boldsymbol{f}(\boldsymbol{\beta})$ *is given by*

$$\mathbf{F}\boldsymbol{f}(\boldsymbol{\beta}) = \int_{S^2} \boldsymbol{A}(\boldsymbol{\alpha}, \boldsymbol{\beta}; \boldsymbol{f}(\boldsymbol{\alpha}))\,\mathrm{d}\boldsymbol{\alpha}. \tag{2.6}$$

Using the expression (2.3) of the scattering amplitude, one can show that the far field operator $\mathbf{F} : \boldsymbol{f} \longmapsto \mathbf{F}\boldsymbol{f}$ defined by (2.6) is continuous from $L^2_t(S^2)$ onto itself. Moreover, using the reciprocity relation (2.4), one can show the following result (see [9] for the proof).

PROPOSITION 2.3. *The far field operator* $\mathbf{F} : L^2_t(S^2) \longrightarrow L^2_t(S^2)$ *defined by* (2.6) *is a compact and normal operator. As in the acoustic case, its adjoint is the operator* $\mathbf{F}^* : L^2_t(S^2) \to L^2_t(S^2)$ *defined by*

$$\forall \boldsymbol{f} \in L^2_t(S^2), \qquad \mathbf{F}^*\boldsymbol{f} = \overline{\mathbf{R}\mathbf{F}\overline{\mathbf{R}\boldsymbol{f}}}, \tag{2.7}$$

where $\mathbf{R}$ *is the symmetry operator defined by* $\mathbf{R}\boldsymbol{f}(\boldsymbol{\alpha}) = \boldsymbol{f}(-\boldsymbol{\alpha})$ *for all* $\boldsymbol{\alpha} \in S^2$ *and* $\boldsymbol{f} \in L^2_t(S^2)$.

We are now able to define the time reversal operator $\mathbf{T}$. During the time reversal process, the TRM first emits an incident electromagnetic Herglotz wave $(\boldsymbol{E}^{\boldsymbol{f}}_I, \boldsymbol{H}^{\boldsymbol{f}}_I)$ of polarization $\boldsymbol{f}$. Then the scattering obstacle generates a scattered field $(\boldsymbol{E}^{\boldsymbol{f}}, \boldsymbol{H}^{\boldsymbol{f}})$. The TRM measures and conjugates the corresponding electric far field $\mathbf{F}\boldsymbol{f}$. The resulting field is then used as a polarization $\boldsymbol{g}$ of a new incident Herglotz wave. Therefore, we have

$$\boldsymbol{g} = \overline{\mathbf{R}\mathbf{F}\boldsymbol{f}}, \tag{2.8}$$

where the presence of the symmetry operator is due to the fact that the far field measured in a direction $\boldsymbol{\beta}$ is re-emitted in the opposite direction $-\boldsymbol{\beta}$. The time reversal operator $\mathbf{T}$ is then obtained by iterating this cycle twice:

$$\mathbf{T}\boldsymbol{f} = \overline{\mathbf{R}\mathbf{F}\boldsymbol{g}} = \overline{\mathbf{R}\mathbf{F}\overline{\mathbf{R}\mathbf{F}\boldsymbol{f}}}. \tag{2.9}$$

Thanks to Proposition 2.3, we have shown the following result.

PROPOSITION 2.4. *The time reversal operator* $\mathbf{T}$ *is the compact, self-adjoint, and positive operator given by*

$$\begin{array}{rlcl} \mathbf{T}: & L^2_t(S^2) & \longrightarrow & L^2_t(S^2), \\ & \boldsymbol{f} & \longmapsto & \mathbf{T}\boldsymbol{f} = \mathbf{F}\mathbf{F}^*\boldsymbol{f} = \mathbf{F}^*\mathbf{F}\boldsymbol{f}. \end{array}$$

The nonzero eigenvalues of $\mathbf{T}$ *are exactly the positive numbers*

$$|\lambda_1|^2 \geq |\lambda_2|^2 \geq \cdots > 0,$$

where the sequence $(\lambda_p)_{p\geq 1}$ *denotes the nonzero complex eigenvalues of the normal compact far field operator* $\mathbf{F}$*. Moreover, the corresponding eigenfunctions* $(\boldsymbol{f}_p)_{p\geq 1}$ *of* $\mathbf{F}$ *are exactly the eigenfunctions of* $\mathbf{T}$*.*

3. Scattering by perfectly conducting small scatterers.

In this section, we show that the asymptotics of the electromagnetic scattering problem by small scatterers is closely connected to the classical low frequency scattering (the Rayleigh approximation [21, 12]). In particular, this asymptotics involves the electromagnetic polarizability tensors of the scatterers [30, 2, 3]. The fact that the two limit models are similar is straightforward when the scattering obstacle has only one connected component. As shown in subsection 3.1, this follows from a scaling argument. The proof is less obvious when the obstacle is multiply connected (one can no longer use a unique change of variables to work in a reference domain of fixed size). We study this question using an integral equation approach in subsection 3.2.

3.1. The case of one scatterer.

Let us assume that the perfectly conducting scatterer is of small size δ and that it is obtained from a reference obstacle after a dilation. More precisely, let us set

$$\mathcal{O}^\delta = \{\boldsymbol{x} = \boldsymbol{s} + \delta\boldsymbol{\xi}\ ;\ \boldsymbol{\xi} \in \mathcal{O}\}.$$

Its boundary is denoted by Γ^δ and its exterior by $\Omega^\delta := \mathbb{R}^3 \setminus \overline{\mathcal{O}^\delta}$. Given an incident plane wave $(\boldsymbol{E}_I^{\alpha,\boldsymbol{f}}, \boldsymbol{H}_I^{\alpha,\boldsymbol{f}})$, let $(\boldsymbol{E}^\delta, \boldsymbol{H}^\delta)$ be the solution of the scattering problem by the perfectly conducting obstacle (for the sake of clarity, we drop here the reference to the angle of incidence and to the polarization in the scattered field):

$$\left\{\begin{array}{ll}\operatorname{curl}\boldsymbol{E}^\delta = ik\boldsymbol{H}^\delta & (\Omega^\delta),\\ \operatorname{curl}\boldsymbol{H}^\delta = -ik\boldsymbol{E}^\delta & (\Omega^\delta),\\ \operatorname{div}\boldsymbol{E}^\delta = 0 & (\Omega^\delta),\\ \operatorname{div}\boldsymbol{H}^\delta = 0 & (\Omega^\delta),\\ \boldsymbol{E}^\delta \times \boldsymbol{\nu} = -\boldsymbol{E}_I^{\alpha,\boldsymbol{f}} \times \boldsymbol{\nu} & (\Gamma^\delta),\\ \boldsymbol{H}^\delta \cdot \boldsymbol{\nu} = -\boldsymbol{H}_I^{\alpha,\boldsymbol{f}} \cdot \boldsymbol{\nu} & (\Gamma^\delta),\\ \boldsymbol{E}^\delta,\ \boldsymbol{H}^\delta \text{ outgoing.} & \end{array}\right. \tag{3.1}$$

Introducing the scaled fields

$$\left\{\begin{array}{l}\boldsymbol{e}^\delta(\boldsymbol{\xi}) = \boldsymbol{E}^\delta(\boldsymbol{s} + \delta\boldsymbol{\xi}),\\ \boldsymbol{h}^\delta(\boldsymbol{\xi}) = \boldsymbol{H}^\delta(\boldsymbol{s} + \delta\boldsymbol{\xi}),\end{array}\right. \qquad \boldsymbol{\xi} \in \Omega := \mathbb{R}^3 \setminus \overline{\mathcal{O}},$$

we obtain that

$$\left\{\begin{array}{ll}\operatorname{curl}\boldsymbol{e}^\delta = i\,(k\delta)\,\boldsymbol{h}^\delta & (\Omega),\\ \operatorname{curl}\boldsymbol{h}^\delta = -i\,(k\delta)\,\boldsymbol{e}^\delta & (\Omega),\\ \operatorname{div}\boldsymbol{e}^\delta = 0 & (\Omega),\\ \operatorname{div}\boldsymbol{h}^\delta = 0 & (\Omega),\\ \boldsymbol{e}^\delta \times \boldsymbol{\nu} = -\boldsymbol{e}_I^{\alpha,\boldsymbol{f}} \times \boldsymbol{\nu} & (\Gamma),\\ \boldsymbol{h}^\delta \cdot \boldsymbol{\nu} = -\boldsymbol{h}_I^{\alpha,\boldsymbol{f}} \cdot \boldsymbol{\nu} & (\Gamma),\\ \boldsymbol{e}^\delta,\ \boldsymbol{h}^\delta \text{ outgoing,} & \end{array}\right. \tag{3.2}$$

where $\Gamma = \partial\Omega$ and

$$\begin{cases} \boldsymbol{e}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{\xi}) = \boldsymbol{E}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}+\delta\boldsymbol{\xi}) = \boldsymbol{E}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}) + O(k\delta), \\ \boldsymbol{h}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{\xi}) = \boldsymbol{H}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}+\delta\boldsymbol{\xi}) = \boldsymbol{H}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}) + O(k\delta). \end{cases}$$

When $\delta \to 0$, problem (3.2) appears as a low frequency electromagnetic scattering problem ($k\delta \to 0$) associated with an incident wave that behaves like the constant field $(\boldsymbol{E}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}), \boldsymbol{H}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}))$ asymptotically. The electromagnetic scattering problem for small frequencies has been studied for a long time (see [35, 36, 22, 28]), and the asymptotic behavior of its solution is by now well known (see the reference book [12] for a detailed presentation and [4] for convergence results of higher order terms). In particular, the first order approximation $(\boldsymbol{e}^0, \boldsymbol{h}^0)$ of $(\boldsymbol{e}^\delta, \boldsymbol{h}^\delta)$ (the so-called Rayleigh approximation) is given by the next result, which follows from [12, Chap. 5]).

THEOREM 3.1. *Let $\boldsymbol{\Phi} = (\Phi_1, \Phi_2, \Phi_3)$ and $\boldsymbol{\Psi} = (\Psi_1, \Psi_2, \Psi_3)$ be the vector potentials defined by*

$$\text{(3.3)} \qquad \begin{cases} \Delta\boldsymbol{\Phi} = 0 & (\Omega), \\ \boldsymbol{\Phi} = \boldsymbol{x} + \boldsymbol{c} & (\Gamma), \\ \boldsymbol{\Phi} = O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), & |\boldsymbol{x}| \to \infty, \end{cases}$$

and

$$\text{(3.4)} \qquad \begin{cases} \Delta\boldsymbol{\Psi} = 0 & (\Omega), \\ \dfrac{\partial\boldsymbol{\Psi}}{\partial\boldsymbol{\nu}} = \boldsymbol{\nu} & (\Gamma), \\ \boldsymbol{\Psi} = O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), & |\boldsymbol{x}| \to \infty, \end{cases}$$

where the constant vector $\boldsymbol{c} \in \mathbb{R}^3$ is chosen such that $\int_\Gamma \frac{\partial\boldsymbol{\Phi}}{\partial\boldsymbol{\nu}} = 0$.

Then, as $\delta \longrightarrow 0$, we have

$$\begin{cases} \boldsymbol{e}^\delta \longrightarrow \boldsymbol{e}^0 := -\nabla\boldsymbol{\Phi}\, \boldsymbol{f}(\boldsymbol{\alpha}), \\ \boldsymbol{h}^\delta \longrightarrow \boldsymbol{h}^0 := -\, \nabla\boldsymbol{\Psi}\, (\boldsymbol{\alpha} \times \boldsymbol{f}(\boldsymbol{\alpha})) \end{cases}$$

locally in $H_{\mathrm{curl}}(\Omega)$.

Using the above result, one can easily obtain the asymptotics of the far field associated to $\boldsymbol{E}^\delta$.

COROLLARY 3.2. *Let $(\boldsymbol{E}^\delta, \boldsymbol{H}^\delta)$ be the solution of the scattering problem (3.1). Let $\boldsymbol{\mathcal{P}}$ and $\boldsymbol{\mathcal{M}}$ be, respectively, the electric polarizability and magnetic polarizability tensors defined by (I denotes the identity)*

$$\boldsymbol{\mathcal{P}} = |\mathcal{O}|\, I - \int_\Gamma \boldsymbol{x} \left(\frac{\partial\boldsymbol{\Phi}}{\partial\boldsymbol{\nu}}\right)^T \mathrm{d}\gamma_{\boldsymbol{x}}, \qquad \boldsymbol{\mathcal{M}} = |\mathcal{O}|\, I - \int_\Gamma \boldsymbol{\nu}\boldsymbol{\Psi}^T \,\mathrm{d}\gamma_{\boldsymbol{x}},$$

where the vector potentials $\boldsymbol{\Phi}$ and $\boldsymbol{\Psi}$ are respectively defined by (3.3) *and* (3.4). *Then, the far field $\boldsymbol{A}^\delta(\boldsymbol{\alpha}, \boldsymbol{\beta}; \boldsymbol{f}(\boldsymbol{\alpha}))$ of $\boldsymbol{E}^\delta$, defined by*

$$\boldsymbol{E}^\delta(\boldsymbol{\beta}|\boldsymbol{x}|) = \boldsymbol{A}^\delta(\boldsymbol{\alpha}, \boldsymbol{\beta}; \boldsymbol{f}(\boldsymbol{\alpha})) \frac{\mathrm{e}^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|} + O\left(\frac{1}{|\boldsymbol{x}|^2}\right),$$

admits as $\delta \to 0$ the following asymptotics:

$$\text{(3.5)} \quad \boldsymbol{A}^\delta(\boldsymbol{\alpha}, \boldsymbol{\beta}; \boldsymbol{f}(\boldsymbol{\alpha})) = \frac{(ik\delta)^3}{4\pi}\, \boldsymbol{\beta} \times \Big[\boldsymbol{\beta} \times (\boldsymbol{\mathcal{P}}\boldsymbol{f}(\boldsymbol{\alpha})) - \boldsymbol{\mathcal{M}}(\boldsymbol{\alpha} \times \boldsymbol{f}(\boldsymbol{\alpha}))\Big]\, \mathrm{e}^{ik\,(\boldsymbol{\alpha}-\boldsymbol{\beta})\cdot\boldsymbol{s}} + O(\delta^4).$$

Proof. Following [12], we have

$$\boldsymbol{A}^{\delta}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) = \frac{k^2}{4\pi}\,\boldsymbol{\beta}\times\left\{\boldsymbol{\beta}\times\int_{\Gamma^{\delta}}\left[\boldsymbol{\nu}_{\boldsymbol{x}}\times\left(\boldsymbol{H}^{\delta}(\boldsymbol{x})+\boldsymbol{H}_I^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{x})\right)\right]\,\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{x}}\,\mathrm{d}\gamma_{\boldsymbol{x}}\right\}. \tag{3.6}$$

The change of variables $\boldsymbol{\xi} = (\boldsymbol{x}-\boldsymbol{s})/\delta$ in the above integral shows that

$$\begin{aligned}\boldsymbol{A}^{\delta}(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) = {}&\left(\frac{(k\delta)^2}{4\pi}\,\boldsymbol{\beta}\times\left\{\boldsymbol{\beta}\times\int_{\Gamma}\left[\boldsymbol{\nu}_{\boldsymbol{\xi}}\times\left(\boldsymbol{h}^{\delta}(\boldsymbol{\xi})+\boldsymbol{h}_I^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{\xi})\right)\right]\,\mathrm{d}\gamma_{\boldsymbol{\xi}}\right\}\right)\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{s}}\\&+O(\delta^3).\end{aligned} \tag{3.7}$$

Comparing (3.6) with the term between the parentheses in the above expression, we see that this term is nothing but the electric far field associated to the solution $(\boldsymbol{e}^{\delta},\boldsymbol{h}^{\delta})$ of the low frequency scattering problem (3.2). Consequently, this term can be expressed using the polarizability tensors (see equation (5.158) in [12])

$$\begin{aligned}&\frac{(k\delta)^2}{4\pi}\,\boldsymbol{\beta}\times\left\{\boldsymbol{\beta}\times\int_{\Gamma}\left[\boldsymbol{\nu}_{\boldsymbol{\xi}}\times\left(\boldsymbol{h}^{\delta}(\boldsymbol{\xi})+\boldsymbol{h}_I^{\boldsymbol{\alpha},\boldsymbol{f}}(\boldsymbol{\xi})\right)\right]\,\mathrm{d}\gamma_{\boldsymbol{\xi}}\right\}\\&\qquad=\frac{(ik\delta)^3}{4\pi}\boldsymbol{\beta}\times\left[\boldsymbol{\beta}\times(\boldsymbol{\mathcal{P}}\boldsymbol{f}(\boldsymbol{\alpha}))-\boldsymbol{\mathcal{M}}(\boldsymbol{\alpha}\times\boldsymbol{f}(\boldsymbol{\alpha}))\right]\mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot\boldsymbol{s}}+O\left(\delta^4\right),\end{aligned}$$

where we have used the fact that the incident electromagnetic field $(\boldsymbol{e}_I,\boldsymbol{h}_I)$ converges to the constants $(\boldsymbol{E}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}),\boldsymbol{H}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{s}))=(\boldsymbol{f}(\boldsymbol{\alpha}),\boldsymbol{\alpha}\times\boldsymbol{f}(\boldsymbol{\alpha}))\,\mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot\boldsymbol{s}}$ as δ tends to 0. Plugging the last relation into (3.7) yields (3.5). □

3.2. Multiply connected scatterer. We consider now the case where the scatterer has M connected components:

$$\mathcal{O}^{\delta}=\bigcup_{p=1}^{M}\mathcal{O}_p^{\delta},$$

where each component $\mathcal{O}_p^{\delta}$ is obtained from a reference domain $\mathcal{O}_p$ by a dilation and a translation,

$$\mathcal{O}_p^{\delta}=\{\boldsymbol{x}=\boldsymbol{s}_p+\delta\boldsymbol{\xi}\ ;\ \boldsymbol{\xi}\in\mathcal{O}_p\}.$$

Finally, we denote once again by $\Omega^{\delta}=\mathbb{R}^3\setminus\overline{\mathcal{O}^{\delta}}$ the exterior domain and by $\Gamma^{\delta}=\bigcup_{p=1}^{M}\Gamma_p^{\delta}$ its boundary.

In order to study the asymptotics $\delta\to 0$, we seek an integral representation of the solution $(\boldsymbol{E}^{\delta},\boldsymbol{H}^{\delta})$ of (3.1) in the form

$$\left\{\begin{aligned}\boldsymbol{E}^{\delta}(\boldsymbol{y})&=\delta\,\mathrm{curl}\,\mathrm{curl}\int_{\Gamma^{\delta}}G_k(\boldsymbol{x},\boldsymbol{y})\,\boldsymbol{J}^{\delta}(\boldsymbol{x})\,\mathrm{d}\gamma_{\boldsymbol{x}},\\ \boldsymbol{H}^{\delta}(\boldsymbol{y})&=-\delta\,(ik)\,\mathrm{curl}\int_{\Gamma^{\delta}}G_k(\boldsymbol{x},\boldsymbol{y})\,\boldsymbol{J}^{\delta}(\boldsymbol{x})\,\mathrm{d}\gamma_{\boldsymbol{x}},\end{aligned}\right.\qquad \boldsymbol{y}\in\Omega^{\delta}, \tag{3.8}$$

where $\boldsymbol{J}^{\delta}$ is the (unknown) electric surface current and

$$G_k(\boldsymbol{x},\boldsymbol{y})=\frac{\mathrm{e}^{ik|\boldsymbol{x}-\boldsymbol{y}|}}{4\pi|\boldsymbol{x}-\boldsymbol{y}|}$$

denotes the Green function of $-\Delta-k^2$ in $\mathbb{R}^3$.

Using the identity curl curl $= \nabla \operatorname{div} - \Delta$ and the fact that for $\boldsymbol{x} \neq \boldsymbol{y}$ we have $\Delta G_k(\boldsymbol{x},\boldsymbol{y}) = -k^2\, G_k(\boldsymbol{x},\boldsymbol{y})$, one can show that the electric field can also be written in the form [10, p. 64]

$$\boldsymbol{E}^\delta(\boldsymbol{y}) = \delta \left(k^2 \int_{\Gamma^\delta} G_k(\boldsymbol{x},\boldsymbol{y})\, \boldsymbol{J}^\delta(\boldsymbol{x})\, \mathrm{d}\gamma_{\boldsymbol{x}} + \nabla \int_{\Gamma^\delta} G_k(\boldsymbol{x},\boldsymbol{y}) \operatorname{div}_{\Gamma^\delta} \boldsymbol{J}^\delta(\boldsymbol{x})\, \mathrm{d}\gamma_{\boldsymbol{x}} \right), \tag{3.9}$$

where $\operatorname{div}_{\Gamma^\delta}$ denotes the surface divergence operator on Γ^δ.

The unknown current $\boldsymbol{J}^\delta = (\boldsymbol{J}_1^\delta, \dots, \boldsymbol{J}_M^\delta)$ is uniquely determined by writing the perfectly conducting boundary condition on each scatterer:

$$(\boldsymbol{E}^\delta \times \boldsymbol{\nu})_{|\Gamma_p^\delta} = -(\boldsymbol{E}_I^{\alpha,\boldsymbol{f}} \times \boldsymbol{\nu})_{|\Gamma_p^\delta} \qquad \forall\, p = 1, \dots, M. \tag{3.10}$$

It is well known (see, for instance, [27, Theorem 5.5.1]) that the trace of a potential of the form (3.9) is given by

$$(\boldsymbol{E}^\delta \times \boldsymbol{\nu})_{|\Gamma_p^\delta} = \sum_{q=1}^{M} \delta \left(k^2 S_{pq}^{k,\delta} + T_{pq}^{k,\delta} \right) \boldsymbol{J}_q^\delta,$$

where the integral operators $S_{pq}^{k,\delta} : TH^s(\Gamma_q) \to TH^{s+1}(\Gamma_p)$ and $T_{pq}^{k,\delta} : TH^s(\Gamma_q) \to TH^{s-1}(\Gamma_p)$ ($TH^s(\Gamma_q)$ denotes the Sobolev space of tangent vector fields [27]) are defined for $\boldsymbol{y} \in \Gamma_p$ by

$$\left\{ \begin{array}{lcl} \left(S_{pq}^{k,\delta}\, \boldsymbol{J}_q^\delta\right)(\boldsymbol{y}) & = & \displaystyle\int_{\Gamma_q^\delta} G_k(\boldsymbol{x},\boldsymbol{y}) \left(\boldsymbol{J}_q^\delta(\boldsymbol{x}) \times \boldsymbol{\nu}_{\boldsymbol{y}}\right) \mathrm{d}\gamma_{\boldsymbol{x}}, \\ \left(T_{pq}^{k,\delta}\, \boldsymbol{J}_q^\delta\right)(\boldsymbol{y}) & = & \left(\nabla_{\boldsymbol{y}} \displaystyle\int_{\Gamma_q^\delta} G_k(\boldsymbol{x},\boldsymbol{y}) \operatorname{div}_{\Gamma_q^\delta} \boldsymbol{J}_q^\delta(\boldsymbol{x})\, \mathrm{d}\gamma_{\boldsymbol{x}}\right)_{|\Gamma_p^\delta} \times \boldsymbol{\nu}_{\boldsymbol{y}}. \end{array} \right.$$

For $q \neq p$, the kernels of the above integral operators are infinitely differentiable. The operator S_{pp}^δ is the classical single layer potential and has a singular but integrable kernel. The operator T_{pp}^δ can also be written using a formula involving only integrable kernels (see [27, p. 242]):

$$\begin{aligned} \left(T_{pp}^{k,\delta}\, \boldsymbol{J}_p^\delta\right)(\boldsymbol{y}) = \int_{\Gamma_p^\delta} \Big[& (\nabla_{\boldsymbol{y}} G_k(\boldsymbol{x},\boldsymbol{y}) \times (\boldsymbol{\nu}_{\boldsymbol{y}} - \boldsymbol{\nu}_{\boldsymbol{x}})) \operatorname{div}_{\Gamma_p^\delta} \boldsymbol{J}_p^\delta(\boldsymbol{x}) \\ & - G_k(\boldsymbol{x},\boldsymbol{y}) \operatorname{curl}_{\Gamma_p^\delta} \operatorname{div}_{\Gamma_p^\delta} \boldsymbol{J}_p^\delta(\boldsymbol{x}) \Big]\, \mathrm{d}\gamma_{\boldsymbol{x}}. \end{aligned}$$

In the above relation, $\operatorname{div}_{\Gamma_p^\delta}$ and $\operatorname{curl}_{\Gamma_p^\delta}$ denote, respectively, the surface divergence operator and tangential rotational operator on Γ_p^δ. Then, the integral equation (3.10) reads

$$\sum_{q=1}^{M} \delta \left(k^2 S_{pq}^{k,\delta} + T_{pq}^{k,\delta} \right) \boldsymbol{J}_q^\delta = -(\boldsymbol{E}^{inc} \times \boldsymbol{\nu})_{|\Gamma_p^\delta} \qquad \forall\, p = 1, \dots, M. \tag{3.11}$$

In order to work in a functional framework independent of δ, we introduce the new variables

$$\left\{ \begin{array}{l} \boldsymbol{\xi} = \dfrac{\boldsymbol{x} - \boldsymbol{s}_q}{\delta} \in \mathcal{O}_q, \\ \boldsymbol{\eta} = \dfrac{\boldsymbol{y} - \boldsymbol{s}_p}{\delta} \in \mathcal{O}_p \end{array} \right.$$

and the scaled fields

$$\begin{cases} \boldsymbol{j}_q^{\delta}(\boldsymbol{\xi}) = \boldsymbol{J}_q^{\delta}(\boldsymbol{x}), \\ \mathcal{G}_{pq}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta}) = G_k(\boldsymbol{x},\boldsymbol{y}). \end{cases}$$

With the above notation, we have

$$\left(S_{pq}^{k,\delta}\,\boldsymbol{J}_q^{\delta}\right)(\boldsymbol{y}) := \delta^2\left(\mathcal{S}_{pq}^{k,\delta}\,\boldsymbol{j}_q^{\delta}\right)(\boldsymbol{\eta}) = \delta^2\int_{\Gamma_q}\mathcal{G}_{pq}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\,\left(\boldsymbol{j}_q^{\delta}(\boldsymbol{\xi})\times\boldsymbol{\nu}_{\boldsymbol{\eta}}\right)\,\mathrm{d}\gamma_{\boldsymbol{\xi}}$$

and

$$\begin{aligned} \left(T_{pq}^{k,\delta}\,\boldsymbol{J}_p^{\delta}\right)(\boldsymbol{y}) &= \begin{cases} \left(\nabla_{\boldsymbol{\eta}}\displaystyle\int_{\Gamma_q}\mathcal{G}_{pq}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\,\mathrm{div}_{\Gamma_q}\boldsymbol{j}_q^{\delta}(\boldsymbol{\xi})\,\mathrm{d}\gamma_{\boldsymbol{\xi}}\right)_{|\Gamma_p}\times\boldsymbol{\nu}_{\boldsymbol{\eta}} & \text{for } q\neq p, \\ \displaystyle\int_{\Gamma_q}\Big[\left(\nabla_{\boldsymbol{\eta}}\mathcal{G}_{pp}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\times(\boldsymbol{\nu}_{\boldsymbol{\eta}}-\boldsymbol{\nu}_{\boldsymbol{\xi}})\right)\,\mathrm{div}_{\Gamma_q}\,\boldsymbol{j}_p^{\delta}(\boldsymbol{\xi}) & \\ \qquad\qquad -\,\mathcal{G}_{pp}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\,\mathrm{curl}_{\Gamma_p}\mathrm{div}_{\Gamma_p}\,\boldsymbol{j}_p^{\delta}(\boldsymbol{\xi})\Big]\,\mathrm{d}\gamma_{\boldsymbol{\xi}} & \text{for } q=p \end{cases} \\ &:= \left(\mathcal{T}_{pq}^{k,\delta}\,\boldsymbol{j}_q^{\delta}\right)(\boldsymbol{\eta}). \end{aligned}$$

Consequently, (3.11) can be written

$$\mathcal{B}_{pp}^{k,\delta}\,\boldsymbol{j}_p^{\delta} + \sum_{q\neq p}\mathcal{B}_{pq}^{k,\delta}\,\boldsymbol{j}_q^{\delta} = -(\boldsymbol{e}_I^{\alpha,\boldsymbol{f}}\times\boldsymbol{\nu})_{|\Gamma_p} \qquad \forall\, p=1,\dots,M, \tag{3.12}$$

with

$$\mathcal{B}_{pq}^{k,\delta} = (k\delta)^2\;\delta\,\mathcal{S}_{pq}^{k,\delta} + \delta\,\mathcal{T}_{pq}^{k,\delta} \tag{3.13}$$

and

$$\boldsymbol{e}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{\eta}) = \boldsymbol{E}_I^{\alpha,\boldsymbol{f}}(\boldsymbol{y}).$$

Let us consider first the diagonal terms in (3.12) by investigating the behavior of the kernels involved in the expression of $\mathcal{B}_{pp}^{k,\delta}$ as $\delta\to 0$. Since

$$\begin{cases} \mathcal{G}_{pp}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta}) = \dfrac{1}{\delta}G_{k\delta}(\boldsymbol{\xi},\boldsymbol{\eta}), \\ \nabla_{\boldsymbol{\eta}}\mathcal{G}_{pp}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta}) = \dfrac{1}{\delta}\nabla_{\boldsymbol{\eta}}G_{k\delta}(\boldsymbol{\xi},\boldsymbol{\eta}), \end{cases}$$

we see that

$$\mathcal{B}_{pp}^{k,\delta} = (k\delta)^2\,\widetilde{\mathcal{S}}_{pp}^{k\delta} + \widetilde{\mathcal{T}}_{pp}^{k\delta} := \widetilde{\mathcal{B}}_{pp}^{k\delta},$$

where

$$\begin{cases} \left(\widetilde{\mathcal{S}}_{pp}^{k\delta}\,\boldsymbol{j}_p\right)(\boldsymbol{y}) = \displaystyle\int_{\Gamma_q}G_{k\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\,\left(\boldsymbol{j}_p(\boldsymbol{\xi})\times\boldsymbol{\nu}_{\boldsymbol{\eta}}\right)\,\mathrm{d}\gamma_{\boldsymbol{\xi}}, \\ \left(\widetilde{\mathcal{T}}_{pp}^{k\delta}\,\boldsymbol{j}_q\right)(\boldsymbol{y}) = \displaystyle\int_{\Gamma_q}\Big[(\nabla_{\boldsymbol{\eta}}G_{k\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\times(\boldsymbol{\nu}_{\boldsymbol{\eta}}-\boldsymbol{\nu}_{\boldsymbol{\xi}}))\,\mathrm{div}_{\Gamma_p}\,\boldsymbol{j}_p(\boldsymbol{\xi}) \\ \qquad\qquad\qquad -\,G_{k\delta}(\boldsymbol{\xi},\boldsymbol{\eta})\,\mathrm{curl}_{\Gamma_p}\mathrm{div}_{\Gamma_p}\,\boldsymbol{j}_p(\boldsymbol{\xi})\Big]\,\mathrm{d}\gamma_{\boldsymbol{\xi}}. \end{cases}$$

The crucial point here is that $\widetilde{\mathcal{B}}_{pp}^{k\delta}$ is exactly the operator involved in the integral equation formulation of the simple scattering problem associated with the reference scatterer $\mathcal{O}_p$ at low frequency $k\delta \to 0$. Moreover, since the zero frequency limit exists, $\widetilde{\mathcal{B}}_{pp}^{k\delta} = \mathcal{B}_{pp}^{k,\delta}$ admits a limit $\mathcal{B}_{pp}^{0}$.

Let us consider now the off diagonal terms $\mathcal{B}_{pq}^{k,\delta}$, $q \neq p$. Denote by

$$d = \min_{1 \le p < q \le N} |\boldsymbol{s}_p - \boldsymbol{s}_q| \tag{3.14}$$

the minimal distance between the centers of the obstacles. Using the relation

$$|s_p - s_q + \delta(\boldsymbol{\xi} - \boldsymbol{\eta})| = |s_p - s_q| \left(1 + O\left(\frac{\delta}{d}\right)\right),$$

one can easily check that

$$\left\{\begin{aligned} &\mathcal{G}_{pq}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta}) = G_k(\boldsymbol{s}_q, \boldsymbol{s}_p)\left[1 + O(k\delta) + O\left(\frac{\delta}{d}\right)\right], \\ &\nabla_{\boldsymbol{\eta}}\, \mathcal{G}_{pq}^{k,\delta}(\boldsymbol{\xi},\boldsymbol{\eta}) = G_k(\boldsymbol{s}_q, \boldsymbol{s}_p)\left[O(k\delta) + O\left(\frac{\delta}{d}\right)\right] \end{aligned}\right. \qquad \forall q \neq p.$$

Inserting the above asymptotics into (3.13) shows that

$$\mathcal{B}_{pq}^{k,\delta} = O\left(\frac{\delta}{d}\right)\left[O(k\delta) + O\left(\frac{\delta}{d}\right)\right] \qquad \text{for } q \neq p.$$

Summing up, the behavior of the solution $(\boldsymbol{E}^{\delta}, \boldsymbol{H}^{\delta})$ of (3.1) for small scatterers (namely, for $k\delta \to 0$ and $\delta/d \to 0$) is given by the low frequency limit of the simple scattering problem. Therefore, the multiple scattering effects can be neglected when $k\delta \to 0$ and $\delta/d \to 0$, and the electric far field can be obtained simply by superposition of the far fields given in Corollary 3.2. We have thus proved the following result.

THEOREM 3.3. *Assume that the scatterer has M connected components*

$$\mathcal{O}^{\delta} = \bigcup_{p=1}^{M} \mathcal{O}_p^{\delta},$$

where each component $\mathcal{O}_p^{\delta}$ is obtained from a reference scatterer $\mathcal{O}_p$ (centered at the origin) of smooth boundary Γ_p by a dilation of ratio δ centered at a given point $\boldsymbol{s}_p \in \mathbb{R}^3$:

$$\mathcal{O}_p^{\delta} = \{\boldsymbol{x} = \boldsymbol{s}_p + \delta\boldsymbol{\xi}\ ;\ \boldsymbol{\xi} \in \mathcal{O}_p\}.$$

For all $p = 1, \ldots, M$, let $\boldsymbol{\Phi}_p$ and $\boldsymbol{\Psi}_p$ be the vector potentials defined by

$$\left\{\begin{array}{ll} \Delta\boldsymbol{\Phi}_p = 0 & (\mathbb{R}^3 \setminus \overline{\mathcal{O}_p}), \\ \boldsymbol{\Phi}_p = \boldsymbol{x} + \boldsymbol{c}_p & (\Gamma_p), \\ \boldsymbol{\Phi}_p = O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), & |\boldsymbol{x}| \to \infty, \end{array}\right. \tag{3.15}$$

and

$$\left\{\begin{array}{ll}\Delta\boldsymbol{\Psi}_p = 0 & (\mathbb{R}^3\setminus\overline{\mathcal{O}_p}),\\ \dfrac{\partial\boldsymbol{\Psi}_p}{\partial\boldsymbol{\nu}} = \boldsymbol{\nu} & (\Gamma_p),\\ \boldsymbol{\Psi}_p = O\left(\dfrac{1}{|\boldsymbol{x}|^2}\right), & |\boldsymbol{x}|\to\infty,\end{array}\right. \tag{3.16}$$

where the constant vector $\boldsymbol{c}_p \in \mathbb{R}^3$ *is chosen such that* $\int_{\Gamma_p}\frac{\partial\boldsymbol{\Phi}_p}{\partial\boldsymbol{\nu}} = 0$.

Let $\boldsymbol{\mathcal{P}}_p$ *and* $\boldsymbol{\mathcal{M}}_p$ *be, respectively, the electric polarizability and magnetic polarizability tensors of the reference scatterer* $\mathcal{O}_p$ *(*I *denotes the identity):*

$$\left\{\begin{array}{l}\boldsymbol{\mathcal{P}}_p = |\mathcal{O}_p|\, I - \displaystyle\int_{\Gamma_p}\boldsymbol{x}\left(\frac{\partial\boldsymbol{\Phi}_p}{\partial\boldsymbol{\nu}}\right)^T \mathrm{d}\gamma_{\boldsymbol{x}},\\ \boldsymbol{\mathcal{M}}_p = |\mathcal{O}_p|\, I - \displaystyle\int_{\Gamma_p}\boldsymbol{\nu}\boldsymbol{\Psi}_p^T\,\mathrm{d}\gamma_{\boldsymbol{x}}.\end{array}\right. \tag{3.17}$$

Finally, let $(\boldsymbol{E}^\delta, \boldsymbol{H}^\delta)$ *be the solution of the scattering problem* (3.1) *and* $\boldsymbol{A}^\delta(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))$ *the far field of* $\boldsymbol{E}^\delta$*:*

$$\boldsymbol{E}^\delta(\boldsymbol{\beta}|\boldsymbol{x}|) = \boldsymbol{A}^\delta(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))\frac{\mathrm{e}^{ik|\boldsymbol{x}|}}{ik|\boldsymbol{x}|} + O\left(\frac{1}{|\boldsymbol{x}|^2}\right).$$

Then, as $\delta\to 0$*, we have*

$$\frac{4\pi}{(ik\delta)^3}\boldsymbol{A}^\delta(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) \longrightarrow \boldsymbol{A}^0(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})), \tag{3.18}$$

where

$$\boldsymbol{A}^0(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha})) = \sum_{p=1}^{M}\boldsymbol{\beta}\times\Big[\boldsymbol{\beta}\times(\boldsymbol{\mathcal{P}}_p\boldsymbol{f}(\boldsymbol{\alpha})) - \boldsymbol{\mathcal{M}}_p(\boldsymbol{\alpha}\times\boldsymbol{f}(\boldsymbol{\alpha}))\Big]\mathrm{e}^{ik\,(\boldsymbol{\alpha}-\boldsymbol{\beta})\cdot\boldsymbol{s}_p}. \tag{3.19}$$

The convergence (3.18) *holds uniformly for all* $\alpha,\beta\in S^2$ *and for all wavenumbers* k *and minimal distances* d *(defined by* (3.14)*) satisfying* $k\delta\to 0$ *and* $\delta/d\to 0$.

4. Selective focusing using time reversal. From now on, we assume that $k\delta\to 0$ and $\delta/d\to 0$. According to Theorem 3.3, the eigenfunctions of the far field operator $\mathbf{F}^\delta$ can be approximated by those of the operator $\mathbf{F}^0 : L^2_t(S^2)\to L^2_t(S^2)$ defined by

$$(\mathbf{F}^0\boldsymbol{f})(\boldsymbol{\beta}) = \int_{S^2}\boldsymbol{A}^0(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))\,\mathrm{d}\boldsymbol{\alpha} \qquad \forall\,\boldsymbol{f}\in L^2_t(S^2). \tag{4.1}$$

Substituting the expression (3.19) of $\boldsymbol{A}^0(\boldsymbol{\alpha},\boldsymbol{\beta};\boldsymbol{f}(\boldsymbol{\alpha}))$ into (4.1), we obtain that

$$(\mathbf{F}^0\boldsymbol{f})(\boldsymbol{\beta}) = \sum_{p=1}^{M}\boldsymbol{\beta}\times\Big[\boldsymbol{\beta}\times\Big(\boldsymbol{\mathcal{P}}_p\boldsymbol{E}_I^{\boldsymbol{f}}(\boldsymbol{s}_p)\Big) - \boldsymbol{\mathcal{M}}_p\boldsymbol{H}_I^{\boldsymbol{f}}(\boldsymbol{s}_p)\Big]\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{s}_p}, \tag{4.2}$$

where $(\boldsymbol{E}_I^{\boldsymbol{f}}, \boldsymbol{H}_I^{\boldsymbol{f}})$ denote the electromagnetic Herglotz wave associated to $\boldsymbol{f}$ defined by (2.5). Finally, let us notice that

$$(\mathbf{F}^0\boldsymbol{f})(\boldsymbol{\beta}) = -\sum_{p=1}^{M}\Big[\Delta(\boldsymbol{\beta})\boldsymbol{\mathcal{P}}_p\boldsymbol{E}_I^{\boldsymbol{f}}(\boldsymbol{s}_p) + \boldsymbol{\beta}\times(\boldsymbol{\mathcal{M}}_p\boldsymbol{H}_I^{\boldsymbol{f}}(\boldsymbol{s}_p))\Big]\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{s}_p}, \tag{4.3}$$

where for every

$$\boldsymbol{\alpha} = \begin{bmatrix} \sin\theta\cos\phi \\ \sin\theta\sin\phi \\ \cos\theta \end{bmatrix} \in S^2$$

we have set

$$\Delta(\boldsymbol{\alpha}) = \mathbf{I} - \boldsymbol{\alpha}\boldsymbol{\alpha}^T. \tag{4.4}$$

REMARK 4.1. *Note that formula* (4.2) *shows that the electric far field radiated by the scatterers as their size tends to* 0 *corresponds to the superposition of* M *(uncoupled) electric and magnetic dipoles located at the points* $\boldsymbol{s}_p$ *and associated with the electric and magnetic moments* $\boldsymbol{p}_p = \boldsymbol{\mathcal{P}}_p\, \boldsymbol{E}_I^{\boldsymbol{f}}(\boldsymbol{s}_p)$ *and* $\boldsymbol{m}_p = \boldsymbol{\mathcal{M}}_p\, \boldsymbol{H}_I^{\boldsymbol{f}}(\boldsymbol{s}_p)$.

REMARK 4.2. *Formula* (4.3) *shows that* $\mathbf{F}^0$ *has at most* $6M$ *nonzero eigenvalues, since its range satisfies* $\operatorname{Ran}\mathbf{F}^0 \subset \bigoplus_{1\le p\le M} \left\{ \left(\Delta(\boldsymbol{\beta})\operatorname{Ran}\boldsymbol{\mathcal{P}}_p\right) \oplus \left(\boldsymbol{\beta}\times\operatorname{Ran}\boldsymbol{\mathcal{M}}_p\right)\right\}$.

The aim of this section is twofold: first, to compute approximate eigenfunctions of $\mathbf{F}^0$, and then to prove that these eigenfunctions selectively focus on the scatterers. As we will see, this can be achieved provided the following two assumptions are satisfied:

1. The polarizability tensors $\boldsymbol{\mathcal{P}}_p$ and $\boldsymbol{\mathcal{M}}_p$ are diagonal (in the same basis). This is particularly true for axially symmetric scatterers (see [12, p. 167]).
2. The scatterers are distant enough (well-separated scatterers). More precisely, we assume that $kd \to \infty$, where $d = \min_{1\le p<q\le N} |\boldsymbol{s}_p - \boldsymbol{s}_q|$ is the minimal distance between the obstacles.

From now on, we will assume that these two conditions are satisfied.

THEOREM 4.3. *For* $p \in \{1,\dots,M\}$, *let* $(\boldsymbol{e}_{p,1}, \boldsymbol{e}_{p,2}, \boldsymbol{e}_{p,3})$ *be an orthonormal basis of* $\mathbb{R}^3$ *such that the polarizability tensors* $\boldsymbol{\mathcal{P}}_p, \boldsymbol{\mathcal{M}}_p$ *of the reference scatterer* $\mathcal{O}_p$ *are diagonal:*

$$\boldsymbol{\mathcal{P}}_p = \begin{bmatrix} \lambda_{p,1} & 0 & 0 \\ 0 & \lambda_{p,2} & 0 \\ 0 & 0 & \lambda_{p,3} \end{bmatrix}, \qquad \boldsymbol{\mathcal{M}}_p = \begin{bmatrix} \lambda'_{p,1} & 0 & 0 \\ 0 & \lambda'_{p,2} & 0 \\ 0 & 0 & \lambda'_{p,3} \end{bmatrix}. \tag{4.5}$$

Given $\ell \in \{1,2,3\}$, *define the following elements of* $L^2_t(S^2)$ *(recall that* $\Delta(\boldsymbol{\alpha})$ *is defined by* (4.4)*):*

$$\left\{ \begin{aligned} &\boldsymbol{f}_{p,\ell}(\boldsymbol{\alpha}) = \boldsymbol{\alpha}\times(\boldsymbol{\alpha}\times\boldsymbol{e}_{p,\ell})\,\mathrm{e}^{-ik\,\boldsymbol{\alpha}\cdot\boldsymbol{s}_p} = -\Delta(\boldsymbol{\alpha})\boldsymbol{e}_{p,\ell}\,\mathrm{e}^{-ik\,\boldsymbol{\alpha}\cdot\boldsymbol{s}_p}, \\ &\boldsymbol{g}_{p,\ell}(\boldsymbol{\alpha}) = (\boldsymbol{\alpha}\times\boldsymbol{e}_{p,\ell})\,\mathrm{e}^{-ik\,\boldsymbol{\alpha}\cdot\boldsymbol{s}_p}, \end{aligned} \right. \qquad \boldsymbol{\alpha}\in S^2. \tag{4.6}$$

Then, the family of functions $\{\boldsymbol{f}_{p,\ell}, \boldsymbol{g}_{p,\ell};\ 1\le\ell\le 3,\ 1\le p\le M\}$ *is linearly independent in* $L^2_t(S^2)$. *Moreover, the functions* $\boldsymbol{f}_{p,\ell}$ *and* $\boldsymbol{g}_{p,\ell}$ *constitute approximate eigenfunctions of the limit far field operator* $\mathbf{F}^0$ *defined by* (3.19)–(4.1) *as* $kd\to\infty$*:*

$$\left\{ \begin{aligned} &\mathbf{F}^0\boldsymbol{f}_{p,\ell} = -\frac{8\pi}{3}\lambda_{p,\ell}\ \boldsymbol{f}_{p,\ell} + O\left((kd)^{-N}\right), \\ &\mathbf{F}^0\boldsymbol{g}_{p,\ell} = -\frac{8\pi}{3}\lambda'_{p,\ell}\ \boldsymbol{g}_{p,\ell} + O\left((kd)^{-N}\right) \end{aligned} \right. \qquad \forall N\in\mathbb{N}. \tag{4.7}$$

Proof. To see that the functions $\boldsymbol{f}_{p,\ell}$ and $\boldsymbol{g}_{p,\ell}$, for $\ell = 1,2,3$ and $p = 1,\dots,M$ are linearly independent, it suffices to note that these functions are exactly the far field patterns of electric and magnetic dipoles located at the points $\boldsymbol{s}_p$ and associated with electric or magnetic dipole moment $\boldsymbol{e}_{p,\ell}$. Consequently, by uniqueness of the far field pattern (which follows from Rellich's lemma; see [11]), the condition

$$\sum_{p=1}^{M}\sum_{\ell=1}^{3}(z_{p,\ell}\,\boldsymbol{f}_{p,\ell}+z'_{p,\ell}\,\boldsymbol{g}_{p,\ell})=0,\qquad z_{p,\ell},\,z'_{p,\ell}\in\mathbb{C},$$

implies that $z_{p,\ell}=z'_{p,\ell}=0$ for all $p=1,\dots,M$ and $\ell=1,2,3$.

Fix now $q\in\{1,\dots,M\}$ and $\ell\in\{1,2,3\}$, and let us compute $\mathbf{F}^0\boldsymbol{f}_{q,\ell}$. We have

$$\begin{cases} \boldsymbol{E}_I^{\boldsymbol{f}_{q,\ell}}(\boldsymbol{s}_p)=-\left(\displaystyle\int_{S^2}\Delta(\boldsymbol{\alpha})\,\mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot(\boldsymbol{s}_p-\boldsymbol{s}_q)}\,\mathrm{d}\boldsymbol{\alpha}\right)\boldsymbol{e}_{q,\ell}:=\boldsymbol{D}_{pq}\,\boldsymbol{e}_{q,\ell},\\ \boldsymbol{H}_I^{\boldsymbol{f}_{q,\ell}}(\boldsymbol{s}_p)=\displaystyle\int_{S^2}\boldsymbol{\alpha}\times[\boldsymbol{\alpha}\times(\boldsymbol{\alpha}\times\boldsymbol{e}_{q,\ell})]\,\mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot(\boldsymbol{s}_p-\boldsymbol{s}_q)}\,\mathrm{d}\boldsymbol{\alpha}:=\boldsymbol{D}'_{pq}\,\boldsymbol{e}_{q,\ell}. \end{cases}$$

A straightforward computation shows that

$$\boldsymbol{D}_{qq}=-\int_{S^2}\Delta(\boldsymbol{\alpha})\,\mathrm{d}\boldsymbol{\alpha}=-\frac{8\pi}{3}\mathbf{I},$$

while by symmetry

$$\boldsymbol{D}'_{qq}=\int_{S^2}\boldsymbol{\alpha}\times\big[\boldsymbol{\alpha}\times(\boldsymbol{\alpha}\times\boldsymbol{e}_{q,\ell})\big]\,\mathrm{d}\boldsymbol{\alpha}=0.$$

On the other hand, let us note that the elements of the 3×3 matrices $\boldsymbol{D}_{pq}$ and $\boldsymbol{D}'_{pq}$ for $p\neq q$ are oscillatory integrals of the form $\int_{S^2}\psi(\boldsymbol{\alpha})\,\mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot(\boldsymbol{s}_p-\boldsymbol{s}_q)}\,\mathrm{d}\boldsymbol{\alpha}$, where ψ is a smooth function. It follows then from the stationary phase theorem (see, for instance, [33, Chap. VIII]) that

$$\boldsymbol{D}_{pq}=\boldsymbol{D}'_{pq}=O\left((kd)^{-N}\right)\qquad\forall\,p\neq q,\ \forall N\in\mathbb{N}.$$

Consequently, formula (4.3) simplifies to

$$\begin{aligned}(\mathbf{F}^0\boldsymbol{f}_{q,\ell})(\boldsymbol{\beta}) &= -\frac{8\pi}{3}\Delta(\boldsymbol{\beta})\boldsymbol{\mathcal{P}}_q\boldsymbol{e}_{q,\ell}\,\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{s}_q}+O\left((kd)^{-N}\right),\\ &= -\frac{8\pi}{3}\lambda_{q,\ell}\,\Delta(\boldsymbol{\beta})\boldsymbol{e}_{q,\ell}\,\mathrm{e}^{-ik\,\boldsymbol{\beta}\cdot\boldsymbol{s}_q}+O\left((kd)^{-N}\right),\end{aligned}$$

which proves the first relation of (4.7). The second relation of (4.7) follows using the same arguments, since

$$\begin{cases}\boldsymbol{E}_I^{\boldsymbol{g}_{q,\ell}}(\boldsymbol{s}_p)=-\boldsymbol{H}_I^{\boldsymbol{f}_{q,\ell}}(\boldsymbol{s}_p)=-\boldsymbol{D}'_{pq}\,\boldsymbol{e}_{q,\ell},\\ \boldsymbol{H}_I^{\boldsymbol{g}_{q,\ell}}(\boldsymbol{s}_p)=\boldsymbol{E}_I^{\boldsymbol{f}_{q,\ell}}(\boldsymbol{s}_p)=\boldsymbol{D}_{pq}\,\boldsymbol{e}_{q,\ell},\end{cases}$$

and the proof is thus complete. □

REMARK 4.4. *In the special case of scattering by small triaxial ellipsoids (see* [12, Chap. 8]*) with semiaxes $a_{p,1}>a_{p,2}>a_{p,3}$, the electric and magnetic polarizability tensors admit in the basis constituted by the axis of each ellipsoid the diagonal form* (4.5)*, with*

$$\begin{cases}\lambda_{p,\ell}=\dfrac{4\pi}{3I_{p,\ell}},\\ \lambda'_{p,\ell}=\dfrac{4\pi}{3}\dfrac{a_{p,1}a_{p,2}a_{p,3}}{1-a_{p,1}a_{p,2}a_{p,3}I_{p,\ell}},\end{cases}\qquad \ell=1,2,3,$$

with

$$I_{p,\ell} = \frac{2\pi}{3} \int_0^\infty \frac{\mathrm{d}x}{(x + a_{p,\ell}^2)\sqrt{x^2 + a_{p,1}^2}\sqrt{x^2 + a_{p,2}^2}\sqrt{x^2 + a_{p,3}^2}}.$$

In the special case of spheres of radii a_p, *we have* $\boldsymbol{\mathcal{P}}_p = 2\boldsymbol{\mathcal{M}}_p = 4\pi a_p^3\, I$.

The next result provides the expected selective focusing properties of the eigenfunctions of the far field operator $\mathbf{F}^0$ (and thus of time reversal operator $\mathbf{T}^0 = (\mathbf{F}^0)^*\mathbf{F}^0$).

Theorem 4.5. *For* $p \in \{1, \dots, M\}$, *the approximate eigenfunctions* $(\boldsymbol{f}_{p,\ell}, \boldsymbol{g}_{p,\ell})_{1\le\ell\le3}$ *defined by* (4.6) *generate electromagnetic Herglotz waves that focus selectively on the scatterer* p.

Proof. Plugging the expression (4.6) of $\boldsymbol{f}_{p,\ell}$ and $\boldsymbol{g}_{p,\ell}$ into (2.5), we obtain that

$$\begin{cases} \boldsymbol{E}_I^{\boldsymbol{f}_{p,\ell}}(\boldsymbol{x}) = \boldsymbol{H}_I^{\boldsymbol{g}_{p,\ell}}(\boldsymbol{x}) = \displaystyle\int_{S^2} (\boldsymbol{\alpha} \times (\boldsymbol{\alpha} \times \boldsymbol{e}_{p,\ell}))\, \mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot(\boldsymbol{x}-\boldsymbol{s}_p)}\, \mathrm{d}\boldsymbol{\alpha}, \\ \boldsymbol{H}_I^{\boldsymbol{f}_{p,\ell}}(\boldsymbol{x}) = -\boldsymbol{E}_I^{\boldsymbol{g}_{p,\ell}}(\boldsymbol{x}) = -\displaystyle\int_{S^2} (\boldsymbol{\alpha} \times \boldsymbol{e}_{p,\ell})\, \mathrm{e}^{ik\,\boldsymbol{\alpha}\cdot(\boldsymbol{x}-\boldsymbol{s}_p)}\, \mathrm{d}\boldsymbol{\alpha}. \end{cases}$$

The conclusion follows once again from the stationary phase theorem, since for $\boldsymbol{x} \neq \boldsymbol{s}_p$ the above integrals behave like $O\left((k|x - s_p|)^{-N}\right)$ for all $N \in \mathbb{N}$ and are independent of k for $\boldsymbol{x} = \boldsymbol{s}_p$. □

THE FRAMEWORK OF k-HARMONICALLY ANALYTIC FUNCTIONS FOR THREE-DIMENSIONAL STOKES FLOW PROBLEMS, PART I*

MICHAEL ZABARANKIN†

Abstract. The framework of generalized analytic functions arising from the related potentials (so-called k-harmonically analytic functions) has been developed in application to three-dimensional (3D) axially symmetric Stokes flow problems. Cauchy's integral formula for the class of k-harmonically analytic functions has been obtained, and series representations for k-harmonically analytic functions for the regions exterior to sphere and prolate and oblate spheroids have been derived. As the central result in the developed framework, a solution form representing the velocity field and pressure for 3D axially symmetric Stokes flows has been constructed in terms of two 0-harmonically analytic functions. It has also been shown that it uniquely determines an external velocity field vanishing at infinity. With the obtained solution form, the problem of 3D Stokes flows due to the axially symmetric translation of a solid body of revolution has been reduced to a boundary-value problem for two 0-harmonically analytic functions, and the resisting force exerted on the body has been expressed in terms of a 0-harmonically analytic function entering the solution form. For regions in which Laplace's equation admits separation of variables, the boundary-value problem can be solved analytically via representations of 0-harmonically analytic functions in corresponding curvilinear coordinates. This approach has been demonstrated for the axially symmetric translation of solid sphere and solid prolate and oblate spheroids. As the second approach, the boundary-value problem has been reduced to an integral equation based on Cauchy's integral formula for k-harmonically analytic functions. As an illustration, the integral equation has been solved for the axially symmetric translation of solid bispheroids and the solid torus of elliptical cross-section for various values of a geometrical parameter.

1. Introduction.

This article is the first part of the developed two-part framework of k-harmonically analytic functions in application to three-dimensional (3D) Stokes flow problems. In this work, we obtain Cauchy's integral formula for k-harmonically analytic functions, construct series representations for k-harmonically analytic functions for the regions exterior to sphere and prolate and oblate spheroids, and develop the framework of 0-harmonically analytic functions for *axially symmetric* Stokes flow problems. Our second article, the sequel to this paper, develops the framework of k-harmonically analytic functions for *asymmetric* Stokes flow problems.

1.1. Generalized analytic functions.

Generalizations of the theory of functions of complex variables are represented mainly by the theories of generalized analytic functions (Vekua [24]), pseudoanalytic functions (Bers [5, 6]), and p-analytic functions (Položii [20]), which replace the classical Cauchy–Riemann system by certain systems of linear first-order partial differential equations (relating real and imaginary

parts). Generalized analytic and pseudoanalytic[1] functions satisfy the same Bers–Vekua system [24, 5, 6], whereas a class of p-analytic functions $P(r,z) = \widehat{U}(r,z) + i\,\widehat{V}(r,z)$ is introduced via Položii's system, $\frac{\partial \widehat{U}}{\partial r} = \frac{1}{p}\,\frac{\partial \widehat{V}}{\partial z}$ and $\frac{\partial \widehat{U}}{\partial z} = -\frac{1}{p}\,\frac{\partial \widehat{V}}{\partial r}$, where $p = p(r,z) \geq 0$. The aforementioned theories furnish integral representations for generalized analytic functions via ordinary analytic functions and generalize a majority of fundamental classical results, including Cauchy's integral formula, Cauchy-type integrals, power series, etc.

Special cases of Bers–Vekua and Položii systems arise in various 3D problems of hydrodynamics, aerodynamics, elastic medium, electromagnetism, etc., and are associated with subclasses of generalized analytic functions, tailored for specific applications. For example, in application to mechanics of continua, Bers and Gelbart investigated a class of functions defined by the system of equations of "mixed type" [7, 8], [6, p. 30], whose generalized version was used to determine a class of Σ-monogenic functions [4]. A special case of Položii's system for $p = r^k$, known also as generalized Stokes–Beltrami equations, finds its application in the 3D axially symmetric theory of elasticity [20] and was also studied in the context of generalized axially symmetric potential theory [28]. The relationship between p-analytic functions and the Schrödinger equation was discussed in [13].

In [30], we introduced a special class of generalized analytic functions that arise from the fundamental relationship between a scalar field ϕ and vectorial field $\mathbf{\Lambda}$:

$$\operatorname{grad}\phi = -\operatorname{curl}\mathbf{\Lambda}, \qquad \operatorname{div}\mathbf{\Lambda} = 0, \tag{1}$$

which maintains that ϕ and $\mathbf{\Lambda}$ are related scalar and vectorial potentials, respectively. This relationship is encountered in various areas of applied mathematics, particularly in hydrodynamics, the theory of elasticity, electromagnetism, etc.; see [30].

Example 1 (Stokes flows). The behavior of steady flows of a viscous incompressible fluid under the assumption of a zero (low) Reynolds number (so-called *Stokes creeping flows*) is described by the Stokes equations

$$\mu\,\mathbf{\Delta u} = \operatorname{grad}\wp, \qquad \operatorname{div}\mathbf{u} = 0, \tag{2}$$

where $\mathbf{u}$ is the fluid velocity field, $\wp$ is the pressure in the fluid, μ is the shear viscosity, and $\mathbf{\Delta u} \equiv \operatorname{grad}(\operatorname{div}\mathbf{u}) - \operatorname{curl}\operatorname{curl}\mathbf{u}$; see [11, 14]. With $\operatorname{div}\mathbf{u} = 0$, the first equation in (2) can be rewritten as $\operatorname{grad}\wp = -\mu\operatorname{curl}(\operatorname{curl}\mathbf{u})$, whence it follows that the vorticity $\boldsymbol{\omega} = \operatorname{curl}\mathbf{u}$ and pressure $\wp$ are related by $\operatorname{grad}\wp = -\mu\operatorname{curl}\boldsymbol{\omega}$ with $\operatorname{div}\boldsymbol{\omega} = 0$, and thus, $\wp$ and $\mu\,\boldsymbol{\omega}$ are related potentials satisfying (1).

In the two-dimensional (2D) case in Cartesian coordinates, (1) reduces to the classical Cauchy–Riemann system for ordinary analytic functions, and in the 3D axially symmetric case in the cylindrical coordinates[2] (r,φ,z), (1) defines so-called r-analytic functions; see [30]. In the 3D *asymmetric* case, (1) relates the kth harmonics of ϕ and $\mathbf{\Lambda}$, $k \in \mathbb{Z}_0^+$, with respect to φ, and reduces to a series of systems of two linear first-order partial differential equations

$$\left(\frac{\partial}{\partial r} - \frac{k}{r}\right) U^{(k)} = \frac{\partial}{\partial z} V^{(k+1)}, \qquad \frac{\partial}{\partial z} U^{(k)} = -\left(\frac{\partial}{\partial r} + \frac{k+1}{r}\right) V^{(k+1)}, \tag{3}$$

[1] In contrast to generalized analytic functions, pseudoanalytic functions are defined axiomatically via generators [6].

[2] In this case, the z-axis is the axis of symmetry, and ϕ and $\mathbf{\Lambda}$ are independent of the angular coordinate φ.

which for each $k \in \mathbb{Z}_0^+$ defines a class of generalized analytic functions $G^{(k)}(r,z) = U^{(k)}(r,z) + i\,V^{(k+1)}(r,z)$ with $i = \sqrt{-1}$; see [30]. In particular, for $k = 0$, the system (3) defines the class of r-analytic functions.

It follows from (3) that $U^{(k)}$ and $V^{(k+1)}$ are k-harmonic and $(k+1)$-harmonic functions, respectively; i.e., they satisfy

$$\Delta_k U^{(k)} = 0 \quad \text{and} \quad \Delta_{k+1} V^{(k+1)} = 0, \tag{4}$$

where Δ_k denotes the so-called k-harmonic operator:

$$\Delta_k \equiv \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2} - \frac{k^2}{r^2}. \tag{5}$$

To emphasize this fact and in particular that (3) is associated with the kth harmonics of the related potentials and also to differentiate this class from other classes of generalized analytic (or pseudoanalytic) functions, we call the functions defined by the system (3) *k-harmonically analytic functions*.

Introducing the complex variable $\zeta = r + i\,z$, its conjugate $\overline{\zeta} = r - i\,z$ (whence $r = \frac{1}{2}(\zeta + \overline{\zeta})$ and $z = \frac{1}{2i}(\zeta - \overline{\zeta})$), and corresponding partial derivatives

$$\frac{\partial}{\partial \zeta} = \frac{1}{2}\left(\frac{\partial}{\partial r} - i\,\frac{\partial}{\partial z}\right), \qquad \frac{\partial}{\partial \overline{\zeta}} = \frac{1}{2}\left(\frac{\partial}{\partial r} + i\,\frac{\partial}{\partial z}\right),$$

we can represent the system (3) in the form

$$\frac{\partial G^{(k)}}{\partial \overline{\zeta}} = \frac{1}{4r}\left((2k+1)\,\overline{G^{(k)}} - G^{(k)}\right), \tag{6}$$

which has an advantage over (3) in certain formal manipulations. However, we should note that there is a difference in defining $G^{(k)}$ by (3) and (6): the derivative $\partial/\partial\overline{\zeta}$ may exist when $\partial/\partial r$ and $\partial/\partial z$ do not. Further, we will formally write $G^{(k)}(\zeta) = G^{(k)}(r,z)$ without assuming analyticity of $G^{(k)}$. It follows from (6) that a k-harmonically analytic function multiplied by a real-valued constant remains k-harmonically analytic, and the sum and difference of any two k-harmonically analytic functions are again k-harmonically analytic. The last property, however, does not hold for the product of two arbitrary k-harmonically analytic functions.

The class of 0-harmonically analytic functions was studied by Alexandrov and Soloviev [1] in application to axially symmetric problems of the linear theory of elasticity. In particular, they generalized Cauchy's integral formula and constructed an integral representation for 0-harmonically analytic functions via ordinary analytic functions for an arbitrary region. Also, for this class of functions, the Hilbert formulae were derived for the regions exterior to cyclidal bodies (spindle, lens, bispheres, and torus) and used for obtaining analytic expressions of the pressure in 3D axially symmetric Stokes flows about solid spindle, lens, bispheres, and torus [32, 31, 30].

As discussed in [30], the system (3) is a particular case of the Bers–Vekua system and also, in some sense, can be viewed as a particular case of Položii's system with $p = r^{2k+1}$, $U^{(k)} = r^k \widehat{U}$, and $V^{(k+1)} = r^{-(k+1)}\widehat{V}$. However, specializing results of the theories of generalized analytic (pseudoanalytic) and p-analytic functions to the class of k-harmonically analytic functions is not straightforward. For example, obtaining Cauchy's integral formula in the framework of the Bers–Vekua system for each particular subclass requires solving certain singular integral equations for finding so-called "main solutions," which is a nontrivial task. Also, the existing Cauchy integral formula for p-analytic functions with the characteristic $p = r^{2k+1}$ cannot be translated directly to the one for functions satisfying (3), since the dependence between $G^{(k)}$ and P is established only through their real and imaginary parts. On the other hand, the fact that $U^{(k)}$ and $V^{(k+1)}$ solve (4) makes constructing representations for k-harmonically analytic functions in canonical regions[3] significantly easier via (3) than doing so as a corollary of the aforementioned theories. In this paper, we construct an integral representation for k-harmonically analytic functions via ordinary analytic functions and derive series representations for k-harmonically analytic functions for the regions exterior to sphere and prolate and oblate spheroids. Using the approach of Alexandrov and Soloviev [1], we also obtain Cauchy's integral formula for k-harmonically analytic functions, which plays a central role in solving Stokes flow problems for noncanonical regions.

1.2. Stokes model in axially symmetric case. As the central result of the first part of the developed framework, we obtain a representation (solution form) for the velocity field and pressure for 3D *axially symmetric* Stokes flows in terms of two 0-harmonically analytic functions. The representation is similar to Goursat's formula, representing a solution to a 2D biharmonic equation via two ordinary analytic functions, and reduces axially symmetric Stokes flow problems to boundary-value problems for two 0-harmonically analytic functions. For the canonical regions, the boundary-value problems can be solved analytically based on representations of 0-harmonically analytic functions in corresponding curvilinear coordinates, and for regions in which Laplace's equation does not admit separation of variables, they can be reduced to an integral equation[4] based on Cauchy's integral formula for 0-harmonically analytic functions. This is the main advantage of the suggested solution form compared to the stream function approach [11] widely used for solving axially symmetric Stokes flow problems. We also express the resisting (drag) force, exerted on a solid body of revolution in the axially symmetric translation, in terms of a 0-harmonically analytic function entering the solution form. In the second part of the developed framework (see [29]), we construct a representation (solution form) for the velocity field and pressure for 3D *asymmetric* Stokes flows in terms of three k-harmonically analytic functions and demonstrate the developed framework in solving several asymmetric Stokes flow problems.

The rest of the paper is organized into four sections. Section 2 presents main results for k-harmonically analytic functions: integral representation via ordinary analytic functions, representations for the regions exterior to sphere and prolate and oblate spheroids, Cauchy's integral formula, and some auxiliary results. Section 3 constructs the solution form for axially symmetric Stokes flow problems in terms of two 0-harmonically analytic functions, proves that the solution form uniquely determines an external velocity field, expresses the resisting force in terms of a 0-harmonically analytic function entering the solution form, and derives the integral equation based on Cauchy's integral formula for 0-harmonically analytic functions. Section 4 demonstrates the solution form in obtaining closed-form analytical solutions to the 3D Stokes flow problem for the axially symmetric translation of solid sphere and solid prolate and oblate spheroids and solves the integral equation for the axially symmetric translation of solid bispheroids[5] and a solid torus of elliptical cross-section for various values of a

[3] By canonical regions we mean those in which Laplace's equation admits separation of variables.

[4] For discussion of integral equation approaches and standard numerical techniques in application to hydrodynamic problems, the reader may refer to [21, 22].

[5] Bispheroids are two separate spheroids of equal size with the same axis of revolution.

geometrical parameter. The appendix presents the proof of Cauchy's integral formula for k-harmonically analytic functions.

2. *k*-harmonically analytic functions.

This section presents several results for k-harmonically analytic functions which are central in application to 3D Stokes flow problems: an integral representation via ordinary analytic functions, Cauchy's integral formula, series representations for the regions exterior to sphere and prolate and oblate spheroids, and some auxiliary results.

Let $\zeta = r + i\,z$, and let $G^{(k)}(\zeta) = U^{(k)}(\zeta) + i\,V^{(k+1)}(\zeta)$ be a k-harmonically analytic function satisfying (3) in a region $\mathcal{D}$. In this work, we consider $\mathcal{D}$ to be symmetric with respect to the z-axis. In this case, the boundary ℓ of $\mathcal{D}$ consists of the right part ℓ_+ ($\operatorname{Re}\zeta \geq 0$) and the left part ℓ_- ($\operatorname{Re}\zeta \leq 0$), which is the symmetric reflection of ℓ_+ with respect to the z-axis. The parts ℓ_+ and ℓ_- can be either closed curves or open contours with the endpoints lying on the z-axis. Since $G^{(k)}(\zeta)$ has "physical" meaning only for $\operatorname{Re}\zeta \geq 0$, we can define the function $G^{(k)}(\zeta)$ for $\operatorname{Re}\zeta < 0$ by the symmetry condition

$$G^{(k)}\left(-\overline{\zeta}\right) = (-1)^k\overline{G^{(k)}(\zeta)}, \tag{7}$$

which is dictated by formulae representing the velocity field of Stokes flows in terms of k-harmonically analytic functions.

For the class of 0-harmonically analytic functions, Cauchy's integral formula and integral representation via ordinary analytic functions were obtained by Alexandrov and Soloviev [1], who also suggested (7) for $k = 0$. Also, some results for k-harmonically analytic functions can be adopted from the theory of p-analytic functions [20] through the relationship between $G^{(k)}(\zeta)$ and a p-analytic function $P(\zeta) = \widehat{U} + i\,\widehat{V}$ with the characteristic $p = r^{2k+1}$:

$$P(\zeta) = r^{-k}U^{(k)}(\zeta) + i\,r^{k+1}V^{(k+1)}(\zeta). \tag{8}$$

2.1. Representations of *k*-harmonically analytic functions.

The following proposition constructs the main integral representation for k-harmonically analytic functions, which generalizes the integral representation for 0-harmonically analytic functions [1, formula (28.2), p. 248] and is a modification of the existing integral representation for p-analytic functions with $p = r^{2k+1}$ (see [20, p. 177]).

Proposition 1 (main integral representation). *In a simply connected region $\mathcal{D}$, a k-harmonically analytic function $G^{(k)}(\zeta)$ can be represented in the form*

$$G^{(k)}(\zeta) = \frac{1}{r^k|r|}\int_{-\overline{\zeta}}^{\zeta} f(\tau)\,(\zeta-\tau)^{k-\frac{1}{2}}\left(\overline{\zeta}+\tau\right)^{k+\frac{1}{2}}d\tau, \tag{9}$$

where $f(\tau)$ is an analytic function of $\tau = r_1 + i\,z_1$ in the region $\mathcal{D}$ such that $f\left(-\overline{\tau}\right) = \overline{f(\tau)}$; and the points $-\overline{\zeta}$ and ζ are connected by an arbitrary simple curve C lying in $\mathcal{D}$ and symmetric with respect to the z-axis. If $\mathcal{D}$ is unbounded, then convergence of the integral (9) requires $f(\tau) \sim \mathcal{O}\left(|\tau|^{-2k-1-\epsilon}\right)$ with $\epsilon > 0$ at $|\tau| \to \infty$.

Proof. We use the relationship (8) and the existing representations for the real and imaginary parts of a p-analytic function (see [20, p. 178, formulae (48) and (49)]) with $p = r^{2k+1}$ to formally write

$$U^{(k)}(\zeta) = \frac{1}{r^{k-1}|r|}\int_{-\overline{\zeta}}^{\zeta} f(\tau)\left[(\zeta-\tau)(\overline{\zeta}+\tau)\right]^{k-\frac{1}{2}}d\tau, \tag{10}$$

$$i\,V^{(k+1)}(\zeta) = \frac{1}{r^k|r|}\int_{-\overline{\zeta}}^{\zeta} f(\tau)(\tau - i\,z)\left[(\zeta-\tau)(\overline{\zeta}+\tau)\right]^{k-\frac{1}{2}}d\tau, \tag{11}$$

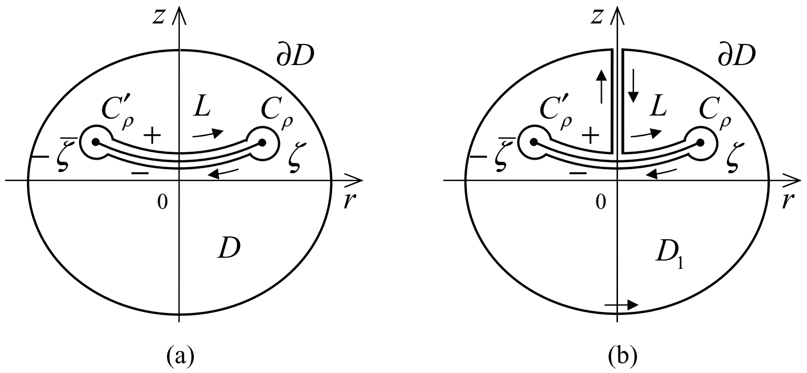
where a curve connecting ζ and $-\overline{\zeta}$ is simple and symmetric with respect to the z-axis. The representation (9) follows from (10) and (11). The absolute value of r in the multipliers at the integrals in (10) and (11) is introduced to satisfy the symmetry condition (7). We need to show that (9) is in fact a k-harmonically analytic function.

The function $\left[(\zeta-\tau)\left(\overline{\zeta}+\tau\right)\right]^{k-\frac{1}{2}}$ is analytic with respect to τ everywhere in the complex plane except for $\tau=\zeta$ and $\tau=-\overline{\zeta}$ and has two branches. With a branch cut connecting the points $-\overline{\zeta}$ and ζ, each branch is uniquely determined, and we choose the one which assumes nonnegative values at the upper bank of the branch cut (see Figure 1(a)). Consequently, at the upper and lower banks of the branch cut, the integral (9) has opposite signs, and we can equivalently represent it as the integral over the closed curve L consisting of parts of the upper and lower banks of the branch cut and of the circles C_ρ and C'_ρ with radius ρ and centers at ζ and $-\overline{\zeta}$, respectively (see Figure 1(a)):

$$G^{(k)}(\zeta)=\frac{1}{2r^k|r|}\int_L f(\tau)\,(\zeta-\tau)^{k-\frac{1}{2}}\left(\overline{\zeta}+\tau\right)^{k+\frac{1}{2}}d\tau. \tag{12}$$

Indeed, as $\rho\to 0$, the integrals of $g(\tau)=f(\tau)\,(\zeta-\tau)^{k-\frac{1}{2}}\left(\overline{\zeta}+\tau\right)^{k+\frac{1}{2}}$ over the circles C_ρ and C'_ρ for $k\geq 0$ vanish, and thus (12) reduces to the sum of the integrals along the upper and lower banks of the branch cut.

First, we show that (9) is independent of the curve C, connecting the points $-\overline{\zeta}$ and ζ within the region $\mathcal{D}$. Since C can be chosen to be the upper bank of the branch cut, we need to show that (9) is independent of the form of the branch cut. To this end, we use the representation (12) and make a crosscut in the region D connecting the closed curve L with the boundary ∂D and forming a simply connected region D_1; see Figure 1(b). In D_1, the function $g(\tau)$ is analytic, and, consequently, its integral over the boundary of D_1 vanishes. This means that the integral of $g(\tau)$ over L with an arbitrary branch cut in D equals the integral of $g(\tau)$ over ∂D with the opposite orientation.



(a) (b)

FIG. 1. (a) *Closed curve L consisting of parts of the upper and lower banks of the branch cut, connecting the points $-\overline{\zeta}$ and ζ, and of the circles C_ρ and C'_ρ with radius ρ and centers at ζ and $-\overline{\zeta}$, respectively;* (b) *The region D_1 is formed by connecting L with ∂D via a crosscut.*

Next, we show that (9) has continuous partial derivatives $\partial/\partial r$ and $\partial/\partial z$ in $\mathcal{D}$, in particular at $r=0$. We represent (9) in the form of (12). Since the curve L in (12) contains neither ζ nor $-\overline{\zeta}$, the integral (12) is continuously differentiable with respect to r and z. For the case of $r \to 0$, let ζ be close to the z-axis and let the branch cut connecting $-\overline{\zeta}$ and ζ be a segment, i.e., $\tau = r_1 + i\,z$, $r_1 \in [-r, r]$, and $d\tau = dr_1$. Using the condition $f\left(-\overline{\tau}\right) = \overline{f(\tau)}$ and the change of variable $\tau(x) = r\sin x + i\,z$, $x \in [0, \pi/2]$, we obtain

$$G^{(k)}(\zeta) = 2\,r^k \int_0^{\frac{\pi}{2}} \left(\mathrm{Re}\left[f\left(r\sin x + i\,z\right)\right] + i\,\sin x\;\mathrm{Im}\left[f\left(r\sin x + i\,z\right)\right]\right)(\cos x)^{2k}\,dx, \tag{13}$$

for which the derivatives $\partial/\partial r$ and $\partial/\partial z$ at $r = 0$ obviously exist and are continuous.

Finally, we show that (12) satisfies the Carleman system (6). Since the partial derivatives $\partial/\partial r$ and $\partial/\partial z$ of (9) are continuous in $\mathcal{D}$, the derivative $\partial/\partial\overline{\zeta}$ of (9) is also continuous in $\mathcal{D}$ and for $r > 0$ it takes the form

$$\frac{\partial}{\partial\overline{\zeta}} G^{(k)}(\zeta) = \frac{1}{4r}\left((-1)^k\,(2k+1)\,G^{(k)}\left(-\overline{\zeta}\right) - G^{(k)}(\zeta)\right). \tag{14}$$

Since $f\left(-\overline{\tau}\right) = \overline{f(\tau)}$, we have $G^{(k)}\left(-\overline{\zeta}\right) = (-1)^k\overline{G^{(k)}(\zeta)}$, which is the symmetry condition (7), and thus with (7), (14) is equivalent to (6). □

For $k = 0$, the formula (9) coincides with the one presented by Alexandrov and Soloviev [1] (with a necessary modification due to the difference in notation[6]).

We illustrate (9) in obtaining a series representation for a k-harmonically analytic function for the region exterior to a sphere. Let (R, ϑ, φ) be the spherical coordinates related to the cylindrical coordinates (r, φ, z) by $r = R\sin\vartheta$ and $z = R\cos\vartheta$ with $R \in \mathbb{R}_0^+$ and $\vartheta \in [0, \pi]$.

Example 2 (region exterior to a sphere). For the region exterior to a sphere, a k-harmonically analytic function $G^{(k)}$ is represented by

$$\begin{aligned} G^{(k)}(R,\vartheta) &= U^{(k)}(R,\vartheta) + i\,V^{(k+1)}(R,\vartheta) \\ &= \sum_{n=1}^{\infty} A_n R^{-n-k-1}\left\{n\,\mathrm{P}_{n+k}^{(k)}(\cos\vartheta) - i\,\mathrm{P}_{n+k}^{(k+1)}(\cos\vartheta)\right\}, \end{aligned} \tag{15}$$

where A_n, $n \geq 1$, is a real-valued constant, and $\mathrm{P}_m^{(k)}(\cos\vartheta)$ is the associated Legendre polynomial of the first kind of order m and rank k (for $k = 0$, the superscript is omitted). The behavior of A_n at $n \to \infty$ follows from the requirements for (15) to converge.

Detail. The region $\mathcal{D}$ exterior to a sphere with the branch cut along the ray $\vartheta = \pi$ is simply connected. For $\mathcal{D}$, an analytic function $f(\zeta)$, vanishing as $|\zeta|^{-2k-1-\epsilon}$, $\epsilon > 0$, at $|\zeta| \to \infty$ and satisfying the condition $f\left(-\overline{\zeta}\right) = \overline{f(\zeta)}$, can be represented by the series

$$f(\zeta) = \sum_{n=2(k+1)}^{\infty} a_n(-i\zeta)^{-n},$$

where a_n, $n \geq 1$, is a real-valued constant.

According to (10) and (11), for $r \geq 0$, the real and imaginary parts of a k-harmonically analytic function are represented by

$$U^{(k)}(\zeta) = \sum_{n=2(k+1)}^{\infty} a_n I_n(\zeta), \qquad i\,V^{(k+1)}(\zeta) = \sum_{n=2(k+1)}^{\infty} a_n J_n(\zeta), \tag{16}$$

[6] In [1], the complex variable ζ is introduced as $\zeta = z + i\,r$.

where

$$I_n(\zeta) = r^{-k} \int_{-\overline{\zeta}}^{\zeta} (-i\tau)^{-n} \left[(\zeta - \tau)(\overline{\zeta} + \tau)\right]^{k-\frac{1}{2}} d\tau,$$

$$J_n(\zeta) = r^{-k-1} \int_{-\overline{\zeta}}^{\zeta} (-i\tau)^{-n} (\tau - i\, z) \left[(\zeta - \tau)(\overline{\zeta} + \tau)\right]^{k-\frac{1}{2}} d\tau.$$

To calculate the integrals $I_n(\zeta)$ and $J_n(\zeta)$, let a curve connecting ζ and $-\overline{\zeta}$ be the arc of the circle with the radius $|\zeta|$ and center at $\zeta = 0$. In this case, in the spherical coordinates, we have $\zeta = i\, R\, \mathrm{e}^{-i\vartheta}$ and $\tau = i\, R\, \mathrm{e}^{-i\varphi}$, and thus, the arc is parameterized by $\varphi \in [-\vartheta, \vartheta]$ and does not intersect the ray $\vartheta = \pi$. Consequently, $(\zeta - \tau)(\overline{\zeta} + \tau) = 2R^2 \mathrm{e}^{-i\varphi}(\cos\varphi - \cos\vartheta)$, and the integrals I_n and J_n reduce to

$$\begin{aligned} I_n(R, \vartheta) &= 2^{k+\frac{1}{2}} R^{k-n} (\sin\vartheta)^{-k} \int_0^{\vartheta} \cos\left[\left(k + \tfrac{1}{2} - n\right) \varphi\right] (\cos\varphi - \cos\vartheta)^{k-\frac{1}{2}} d\varphi \\ &= (-2)^k \sqrt{\pi}\, \frac{\Gamma\left(k + \frac{1}{2}\right) \Gamma(n - 2k)}{\Gamma(n)} R^{k-n}\, \mathrm{P}_{n-k-1}^{(k)}(\cos\vartheta), \end{aligned} \tag{17}$$

$$\begin{aligned} J_n(R, \vartheta) = i\, 2^{k+\frac{1}{2}} R^{k-n} (\sin\vartheta)^{-k-1} \Bigg\{ &\int_0^{\vartheta} \cos\left[\left(k + \tfrac{1}{2} - n\right) \varphi\right] (\cos\varphi - \cos\vartheta)^{k+\frac{1}{2}} d\varphi \\ &- \int_0^{\vartheta} \sin\varphi \sin\left[\left(k + \tfrac{1}{2} - n\right) \varphi\right] (\cos\varphi - \cos\vartheta)^{k-\frac{1}{2}} d\varphi \Bigg\} \\ = -i\, (-2)^k \sqrt{\pi}\, &\frac{\Gamma\left(k + \frac{1}{2}\right) \Gamma(n - 2k - 1)}{\Gamma(n)} R^{k-n}\, \mathrm{P}_{n-k-1}^{(k+1)}(\cos\vartheta), \end{aligned} \tag{18}$$

where $\Gamma(\cdot)$ is the Gamma function, and we used the representation for the associated Legendre polynomial

$$\int_0^{\vartheta} \cos\left[\left(k + \tfrac{1}{2} - n\right) \varphi\right] (\cos\varphi - \cos\vartheta)^{k-\frac{1}{2}} d\varphi = \sqrt{\frac{\pi}{2}}\, (\sin\vartheta)^k\, \Gamma\left(k + \tfrac{1}{2}\right) \mathrm{P}_{n-k-1}^{(-k)}(\cos\vartheta);$$

see [3]. Denoting $A_n = (-2)^k \sqrt{\pi}\, \frac{\Gamma\left(k+\frac{1}{2}\right)\Gamma(n)}{\Gamma(n+2k+1)}\, a_{n+2k+1}$, and substituting (17) and (18) into (16), we obtain (15).

Another approach for deriving representations for the k-harmonically analytic function in a canonical region, i.e., in which Laplace's equation admits separation of variables, e.g., prolate and oblate spheroids, two spheres, torus, lens, spindle, etc., is based on Hilbert formulae [30, 31, 32] and usually requires less effort compared to that of making use of the general representation (9). This approach represents solutions to (4) in the form of integrals or series in curvilinear coordinates, associated with the geometry of the region, and finds a relationship between those integrals or series based on the system (3). It is shown in [30] that for the functions satisfying (4) and vanishing at infinity (in an outer region), it is sufficient to use only one equation of (3).

The next example illustrates this approach for the region exterior to a prolate spheroid. To this end, we introduce prolate spheroidal coordinates (ξ, η, φ) related to the cylindrical coordinates by

$$r = c \sinh\xi\, \sin\eta, \quad z = c \cosh\xi\, \cos\eta, \qquad \xi \in [0, \infty), \quad \eta \in [0, \pi], \tag{19}$$

where the angular coordinate $\varphi \in [0, 2\pi)$ coincides with the one in (r, φ, z) and c is a metric parameter. A prolate spheroid is determined by fixing the coordinate ξ, i.e., $\xi = \xi_0$.

Example 3 (region exterior to a prolate spheroid). For the region exterior to the prolate spheroid ($\xi \geq \xi_0$), a k-harmonically analytic function $G^{(k)}$ is represented by

$$\begin{aligned} G^{(k)}(\xi,\eta) &= U^{(k)}(\xi,\eta) + i\,V^{(k+1)}(\xi,\eta) \\ &= \sum_{n=0}^{\infty} A_n \Big\{ (n-k)(n+k+1)\,\mathrm{Q}_n^{(k)}(\cosh\xi)\,\mathrm{P}_n^{(k)}(\cos\eta) \\ &\qquad + i\,\mathrm{Q}_n^{(k+1)}(\cosh\xi)\,\mathrm{P}_n^{(k+1)}(\cos\eta) \Big\}, \end{aligned} \tag{20}$$

where A_n, $n \geq 1$, are real-valued constants and $\mathrm{Q}_n^{(k)}(\cosh\xi)$ is the associated Legendre function of the second kind.

Detail. It is known that the functions $U^{(k)}(\xi,\eta)$ and $V^{(k+1)}(\xi,\eta)$ that satisfy (4) in the region exterior to the prolate spheroid can be represented in the form of series (see [12, 16])

$$\begin{aligned} U^{(k)}(\xi,\eta) &= \sum_{n=0}^{\infty} a_n\,\mathrm{Q}_n^{(k)}(\cosh\xi)\,\mathrm{P}_n^{(k)}(\cos\eta), \\ V^{(k+1)}(\xi,\eta) &= \sum_{n=0}^{\infty} b_n\,\mathrm{Q}_n^{(k+1)}(\cosh\xi)\,\mathrm{P}_n^{(k+1)}(\cos\eta), \end{aligned} \tag{21}$$

where a_n and b_n are real-valued coefficients. In the prolate spheroidal coordinates (19), the system (3) takes the form

$$\begin{aligned} \left(\frac{\partial}{\partial\xi} - k\coth\xi\right) U^{(k)} &= -\left(\frac{\partial}{\partial\eta} + (k+1)\cot\eta\right) V^{(k+1)}, \\ \left(\frac{\partial}{\partial\eta} - k\cot\eta\right) U^{(k)} &= \left(\frac{\partial}{\partial\xi} + (k+1)\coth\xi\right) V^{(k+1)}. \end{aligned}$$

Substituting the series (21) into any equation of the system above, we obtain the relationship for a_n and b_n:

$$a_n = (n-k)(n+k+1)\,b_n.$$

Consequently, with $A_n = b_n$, the representation (20) follows.

The following example presents a k-harmonically analytic function in the form of series for the region exterior to an oblate spheroid. In the oblate spheroidal coordinates (ξ, η, φ) related to the cylindrical coordinates by

$$r = c\,\cosh\xi\,\sin\eta, \qquad z = c\,\sinh\xi\,\cos\eta, \qquad \xi \in [0,\infty), \quad \eta \in [0,\pi], \tag{22}$$

with the same angular coordinate φ (c is a metric parameter), the oblate spheroid is determined by fixing the coordinate ξ, i.e., $\xi = \xi_0$.

Example 4 (region exterior to an oblate spheroid). For the region exterior to the *oblate* spheroid ($\xi \geq \xi_0$), a k-harmonically analytic function $G^{(k)}$ is represented by

$$\begin{aligned} G^{(k)}(\xi,\eta) &= U^{(k)}(\xi,\eta) + i\,V^{(k+1)}(\xi,\eta) \\ &= \sum_{n=0}^{\infty} A_n\, i^{n+1} \Big\{ (n-k)(n+k+1)\,\mathrm{Q}_n^{(k)}(i\sinh\xi)\,\mathrm{P}_n^{(k)}(\cos\eta) \\ &\qquad + i\,\mathrm{Q}_n^{(k+1)}(i\sinh\xi)\,\mathrm{P}_n^{(k+1)}(\cos\eta) \Big\}, \end{aligned} \tag{23}$$

where A_n, $n \geq 1$, are real-valued constants and $i^{n+1}\,\mathrm{Q}_n^{(k)}(i\sinh\xi)$ and $i^{n+1}\,\mathrm{Q}_n^{(k+1)}(i\sinh\xi)$ are real-valued functions.

Detail. In the oblate spheroidal coordinates (22), the system (3) takes the form

$$\left(\frac{\partial}{\partial\xi} - k\tanh\xi\right)U^{(k)} = -\left(\frac{\partial}{\partial\eta} + (k+1)\cot\eta\right)V^{(k+1)},$$
$$\left(\frac{\partial}{\partial\eta} - k\cot\eta\right)U^{(k)} = \left(\frac{\partial}{\partial\xi} + (k+1)\tanh\xi\right)V^{(k+1)},$$

and the representation (23) is obtained similarly to (20).

Representations for k-harmonically analytic functions for the regions exterior to bispheres, torus, lens, and spindle are discussed in [32, 31, 30].

2.2. Cauchy's integral formula for *k*-harmonically analytic functions. In the previous section, we have transformed the integral representation for p-analytic functions with $p = r^{2k+1}$ into the integral representation (9) for k-harmonically analytic functions. However, doing the same for the existing Cauchy integral formula for p-analytic functions is not a straightforward task, since the relationship between p-analytic and k-harmonically analytic functions is established only via their real and imaginary parts. To derive Cauchy's integral formula for k-harmonically analytic functions, we use the approach of Alexandrov and Soloviev [1], who obtained Cauchy's integral formula for the class of 0-harmonically analytic functions.

In the rz-plane, let $\mathcal{D}^+$ be a bounded (inner) region symmetric with respect to the z-axis, and let $\mathcal{D}^-$ be the outer region with respect to $\mathcal{D}^+$ (i.e., the complement of int$\mathcal{D}^+$). $\mathcal{D}_0^+$ and $\mathcal{D}_0^-$ will denote $\mathcal{D}^+$ with $r \geq 0$ and $\mathcal{D}^-$ with $r \geq 0$, respectively, i.e., the right parts of the corresponding regions. Let ℓ be the common boundary of $\mathcal{D}^+$ and $\mathcal{D}^-$, and let ℓ_+ denote the right part of ℓ (ℓ for $r \geq 0$), which is either a closed curve or an open curve with the endpoints lying on the z-axis. Thus, $\ell = \ell_+ \bigcup \ell_-$, where ℓ_- is the reflection of ℓ_+ with respect to the z-axis. The boundary ℓ is positively oriented or traversed in the counterclockwise direction if $\mathcal{D}^+$ remains on the left side when one travels along ℓ in this direction.[7]

THEOREM 2 (Cauchy's integral formula for k-harmonically analytic functions). *Let $\mathcal{D}^+$ be a simply connected region with the smooth, positively oriented boundary $\ell = \ell_+ \bigcup \ell_-$ (symmetric with respect to the z-axis), and let $G^{(k)}(\zeta)$ be a k-harmonically analytic function in $\mathcal{D}_0^+$ satisfying the symmetry condition* (7) *and the Hölder condition*[8] *on ℓ. Cauchy's integral formula for the function $G^{(k)}(\zeta)$ is given by*

(24)
$$G^{(k)}(\zeta) = \frac{1}{2\pi i}\oint_\ell G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\,d\tau$$
$$\equiv \frac{1}{2\pi i}\int_{\ell_+}\left(G^{(k)}(\tau)\,\Omega_+^{(k)}(\zeta,\tau)\,\frac{d\tau}{\tau-\zeta} - \overline{G^{(k)}(\tau)}\,\Omega_-^{(k)}(\zeta,\tau)\,\frac{d\overline{\tau}}{\overline{\tau}+\zeta}\right), \quad \zeta \in \operatorname{int}\mathcal{D}^+,$$

[7] The orientation of a closed curve is always determined with respect to the corresponding inner region.

[8] This condition means that for some parametrization $\zeta(t)$ of the curve ℓ, the boundary value $G^{(k)}(\zeta(t))$ satisfies $|G^{(k)}(\zeta(t_2)) - G^{(k)}(\zeta(t_1))| \leq C\,|t_2 - t_1|^\beta$ for all t_1 and t_2, some $\beta \in (0,1]$, and nonnegative constant C.

where $\Omega_+^{(k)}(\zeta,\tau)$ *and* $\Omega_-^{(k)}(\zeta,\tau)$ *are real-valued functions determined by*

(25a)

$$\begin{aligned}\Omega_+^{(k)}(\zeta,\tau) = \frac{\left[\Gamma\left(k+\frac{3}{2}\right)\right]^2}{\Gamma(2(k+1))}\left|\frac{\tau+\overline{\tau}}{\zeta+\overline{\tau}}\right|[\lambda(\zeta,\tau)]^{2k}\\ \times\left(1-\lambda^2(\zeta,\tau)\right)\mathbb{F}\left(k+\tfrac{3}{2},k+\tfrac{3}{2},2(k+1),\lambda^2(\zeta,\tau)\right),\end{aligned}$$

(25b)

$$\Omega_-^{(k)}(\zeta,\tau) = \frac{\left[\Gamma\left(k+\frac{3}{2}\right)\right]^2}{\Gamma(2(k+1))}\left|\frac{\tau+\overline{\tau}}{\zeta+\overline{\tau}}\right|[\lambda(\zeta,\tau)]^{2k}\,\mathbb{F}\left(k+\tfrac{1}{2},k+\tfrac{3}{2},2(k+1),\lambda^2(\zeta,\tau)\right),$$

in which $\mathbb{F}(a,b,c,\kappa)$ *is the hypergeometric function*

$$\mathbb{F}(a,b,c,\kappa) = \frac{\Gamma(c)}{\Gamma(b)\Gamma(c-b)}\int_0^1 \frac{t^{b-1}(1-t)^{c-b-1}}{(1-\kappa\, t)^a}dt \tag{26}$$

and

$$\lambda^2(\zeta,\tau) = \frac{\left|\left(\zeta+\overline{\zeta}\right)\left(\tau+\overline{\tau}\right)\right|}{\left|\zeta+\overline{\tau}\right|^2}. \tag{27}$$

If in the above conditions $G^{(k)}(\zeta)$ *is instead k-harmonically analytic in* $\mathcal{D}_0^-$ *and vanishing at infinity, then* (24) *holds for* $\zeta\in\operatorname{int}\mathcal{D}^-$ *with negatively oriented* ℓ *(with respect to* $\mathcal{D}^+$*).*

Proof. The proof is presented in the appendix. □

We should note that $\frac{1}{2\pi i}\oint_\ell G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\,d\tau$ in Cauchy's integral formula (24) should be understood as an operator $\mathcal{A}\left(G^{(k)};\ell\right)$ rather than an ordinary integral. For example, it follows from the second line in (24) that $\mathcal{A}\left(c\,G^{(k)};\ell\right)\neq c\,\mathcal{A}\left(G^{(k)};\ell\right)$ for an arbitrary complex-valued constant c, whereas this fact does not come from the properties of integrals.

Remark 1. Cauchy's integral formula (24) holds for multiply connected regions. The proof is similar to that for Cauchy's integral formula for ordinary analytic functions in the case of a multiply connected region.

Remark 2. In Cauchy's integral formula (24), while $\lim_{\tau\to\zeta}\Omega_+^{(k)}(\zeta,\tau)=1$, the function $\Omega_-^{(k)}(\zeta,\tau)$ has a logarithmic singularity at $\tau=\zeta$:

(28)

$$\Omega_-^{(k)}(\zeta,\tau) = -(2k+1)\left(\ln\frac{|\tau-\zeta|}{|\zeta+\overline{\tau}|}+\frac{1}{2k+1}+\gamma+\psi\left(k+\tfrac{1}{2}\right)\right)+\mathcal{O}(|\tau-\zeta|)\ \text{ as } \tau\to\zeta,$$

where γ is the Euler constant and $\psi(\cdot)$ is the digamma function. This result follows from the asymptotic representation of $\mathbb{F}\left(k+1/2,k+3/2,2(k+1),\lambda^2(\zeta,\tau)\right)$ as $\lambda\to 1-$ (see the appendix). Note that there is no singularity at $\tau=\zeta$ if $\operatorname{Re}\zeta=0$.

Corollary 3 (Cauchy's integral formula for 0-harmonically analytic functions). *In the case of* 0*-harmonically analytic functions,* $\Omega_+^{(0)}(\zeta,\tau)$ *and* $\Omega_-^{(0)}(\zeta,\tau)$ *simplify (see also* [1]*):*

$$\Omega_+^{(0)}(\zeta,\tau) = \left|\frac{\tau+\overline{\zeta}}{\zeta+\overline{\zeta}}\right|\left\{\left(\lambda^2(\zeta,\tau)-1\right)\mathbb{K}(\lambda(\zeta,\tau))+\mathbb{E}(\lambda(\zeta,\tau))\right\},$$

$$\Omega_-^{(0)}(\zeta,\tau) = \left|\frac{\tau+\overline{\zeta}}{\zeta+\overline{\zeta}}\right|\left\{\mathbb{K}(\lambda(\zeta,\tau))-\mathbb{E}(\lambda(\zeta,\tau))\right\},$$

where $\mathbb{K}(\lambda(\zeta,\tau))$ and $\mathbb{E}(\lambda(\zeta,\tau))$ are complete elliptic integrals of the first and second kinds, respectively[9]*:*

$$\mathbb{K}(\lambda(\zeta,\tau)) = \int_0^{\frac{\pi}{2}} \frac{dt}{\sqrt{1-\lambda^2(\zeta,\tau)\sin^2 t}}, \qquad \mathbb{E}(\lambda(\zeta,\tau)) = \int_0^{\frac{\pi}{2}} \sqrt{1-\lambda^2(\zeta,\tau)\sin^2 t}\, dt.$$

The function $\mathbb{K}(\lambda)$ has a logarithmic singularity as $\lambda \to 1-$: $\mathbb{K}(\lambda) = -\frac{1}{2}\ln\left(1-\lambda^2\right) + \mathcal{O}(1)$.

Remark 3 (behavior at infinity). Let $\zeta = i\,R\,\mathrm{e}^{-i\vartheta}$, $\vartheta \in [0,\pi]$, in the spherical coordinates (R,ϑ,φ). At $|\zeta| \to \infty$, the asymptotic form for a k-harmonically analytic function, represented by Cauchy's integral formula (24), is determined by

$$G^{(k)}(\zeta) = \frac{1}{2\pi}\,(2k+1)\,\mathbb{B}\left(k+\tfrac{3}{2}, k+\tfrac{1}{2}\right) \mathrm{Re}\left[\int_{\ell_+} G^{(k)}(\tau)\,|\tau+\overline{\tau}|^{k+1}\,d\tau\right] \times \frac{(2\sin\vartheta)^k\,\mathrm{e}^{i\vartheta}}{|\zeta|^{k+2}} + \mathcal{O}\left(|\zeta|^{-(k+3)}\right), \qquad |\zeta| \to \infty,$$

where $\mathbb{B}\left(k+\frac{3}{2}, k+\frac{1}{2}\right)$ is the beta function.

Detail. Since $|\zeta| \to \infty$, we can represent

$$\frac{1}{\tau-\zeta} = -\frac{\zeta^{-1}}{1-\frac{\tau}{\zeta}} = -\sum_{n=0}^{\infty}\frac{\tau^n}{\zeta^{n+1}}, \qquad \frac{1}{\overline{\tau}+\zeta} = \frac{\zeta^{-1}}{1+\frac{\overline{\tau}}{\zeta}} = \sum_{n=0}^{\infty}(-1)^n\frac{\overline{\tau}^n}{\zeta^{n+1}}. \tag{29}$$

When $|\zeta| \to \infty$, we have $\lambda^2(\zeta,\tau) \sim 2\,|\tau+\overline{\tau}|\sin\vartheta/|\zeta|$ and

$$\begin{aligned} \Omega_+^{(k)}(\zeta,\tau) &= \left(k+\frac{1}{2}\right)\mathbb{B}\left(k+\tfrac{3}{2}, k+\tfrac{1}{2}\right)\frac{(2\sin\vartheta)^k\,|\tau+\overline{\tau}|^{k+1}}{|\zeta|^{k+1}} + \mathcal{O}\left(|\zeta|^{-(k+2)}\right), \\ \Omega_-^{(k)}(\zeta,\tau) &= \left(k+\frac{1}{2}\right)\mathbb{B}\left(k+\tfrac{3}{2}, k+\tfrac{1}{2}\right)\frac{(2\sin\vartheta)^k\,|\tau+\overline{\tau}|^{k+1}}{|\zeta|^{k+1}} + \mathcal{O}\left(|\zeta|^{-(k+2)}\right). \end{aligned} \tag{30}$$

Substituting (29) and (30) into (24), we obtain the statement of the remark.

2.3. Auxiliary results for k-harmonically analytic functions.

This section presents several auxiliary results for k-harmonically analytic functions.

Proposition 4. *Let $G^{(k)}(\zeta)$, $G_1^{(k)}(\zeta)$, and $G_2^{(k)}(\zeta)$ be k-harmonically analytic functions; then*

$$\text{(i)} \qquad \frac{\partial}{\partial\overline{\zeta}}\left(rG^{(k)}\right) = \frac{1}{4}\left((2k+1)\,\overline{G^{(k)}} + G^{(k)}\right),$$

$$\text{(ii)} \qquad \frac{\partial}{\partial\overline{\zeta}}\left(rG_1^{(k)}G_2^{(k)}\right) = \frac{1}{4}\,(2k+1)\left(\overline{G_1^{(k)}}G_2^{(k)} + G_1^{(k)}\overline{G_2^{(k)}}\right);$$

$$\textit{in particular,} \quad \frac{\partial}{\partial\overline{\zeta}}\left(r\left[G^{(k)}\right]^2\right) = \frac{1}{2}\,(2k+1)\,\overline{G^{(k)}}G^{(k)}.$$

Proof. Formulae (i) and (ii) follow from (6). □

[9] In Wolfram Research's Mathematica, $\mathbb{K}(\lambda)$ and $\mathbb{E}(\lambda)$ are defined by $\mathbb{K}(\lambda) = \int_0^{\frac{\pi}{2}} \frac{dt}{\sqrt{1-\lambda\sin^2 t}}$ and $\mathbb{E}(\lambda) = \int_0^{\frac{\pi}{2}} \sqrt{1-\lambda\sin^2 t}\,dt$.

PROPOSITION 5. *Let L be a piecewise smooth, positively oriented curve bounding a simply connected region $\mathcal{D}$, and let $\Phi(\zeta) = U(\zeta)+i\,V(\zeta)$ be a complex-valued function with continuous first-order partial derivatives in $\mathcal{D}$. Then*

$$\oint_L \Phi\,d\zeta = 2i \iint_{\mathcal{D}} \frac{\partial \Phi}{\partial \overline{\zeta}}\,drdz. \tag{31}$$

Proof. Using Green's theorem, we obtain

$$\begin{aligned}\oint_L \Phi\,d\zeta &= \oint_L (U dr - V dz) + i \oint_L (V dr + U dz)\\ &= -\iint_{\mathcal{D}} \left(\frac{\partial V}{\partial r} + \frac{\partial U}{\partial z}\right) drdz + i \iint_{\mathcal{D}} \left(\frac{\partial U}{\partial r} - \frac{\partial V}{\partial z}\right) drdz\\ &= -2 \iint_{\mathcal{D}} \operatorname{Im}\left[\frac{\partial \Phi}{\partial \overline{\zeta}}\right] drdz + 2i \iint_{\mathcal{D}} \operatorname{Re}\left[\frac{\partial \Phi}{\partial \overline{\zeta}}\right] drdz = 2i \iint_{\mathcal{D}} \frac{\partial \Phi}{\partial \overline{\zeta}}\,drdz,\end{aligned}$$

and the proposition is proved. □

PROPOSITION 6. *Let $G^{(0)}(\zeta)$ be a 0-harmonically analytic function, and let ℓ_+ be a simple, positively oriented, piecewise smooth curve in the right half of the rz-plane (ℓ_+ either is closed or has the endpoints lying on the z-axis). Then*

$$\operatorname{Re}\left[\int_{\ell_+} r\,G^{(0)}(\zeta)\,d\zeta\right] = -2 \lim_{z\to\infty} \left(z^2 \operatorname{Re} G^{(0)}(r,z)\Big|_{r=0}\right). \tag{32}$$

Proof. Let $\mathcal{D}_R$ be a region in the right half of the rz-plane with a piecewise smooth, *negatively* oriented boundary L, which consists of ℓ_+, segments of the z-axis, and semicircle L_R with large radius R (see Figure 2). Using Proposition 5 and formula (i) in Proposition 4, we have

$$\oint_L r\,G^{(0)}(\zeta)\,d\zeta = -i \iint_{\mathcal{D}_R} \operatorname{Re}\left[G^{(0)}(r,z)\right] drdz.$$

Taking the real part of this equality and using the fact that the function $r\,G^{(0)}$ vanishes at the z-axis, we obtain

$$\operatorname{Re}\left[\int_{\ell_+} r\,G^{(0)}(\zeta)\,d\zeta + \int_{L_R} r\,G^{(0)}(\zeta)\,d\zeta\right] = 0. \tag{33}$$

The integral of $r\,G^{(0)}$ over L_R can be determined as follows. Let (R,ϑ,φ) be the spherical coordinates related to the cylindrical coordinates (r,φ,z) in the ordinary way, and let the function $G^{(0)}$ be represented in the spherical coordinates by (15) for $k=0$, i.e.,

$$G^{(0)}(R,\vartheta) = \sum_{n=1}^{\infty} A_n R^{-n-1} \left\{n\,\mathrm{P}_n(\cos\vartheta) - i\,\mathrm{P}_n^{(1)}(\cos\vartheta)\right\} = A_1\,R^{-2} \mathrm{e}^{i\vartheta} + \mathcal{O}\left(R^{-3}\right). \tag{34}$$

For L_R with negative (clockwise) orientation, we have $\zeta = i\,R\,\mathrm{e}^{-i\vartheta}$, where $\vartheta \in [0,\pi]$, and

$$\int_{L_R} r\,G^{(0)}(\zeta)\,d\zeta = 2\,A_1 + \mathcal{O}(R^{-1}), \tag{35}$$

where A_1 can be expressed from (34) as $A_1 = \lim_{z\to\infty}\left(z^2 \operatorname{Re} G^{(0)}(r,z)\big|_{r=0}\right)$. Passing R to infinity in (35) and using (33), we obtain (32). □

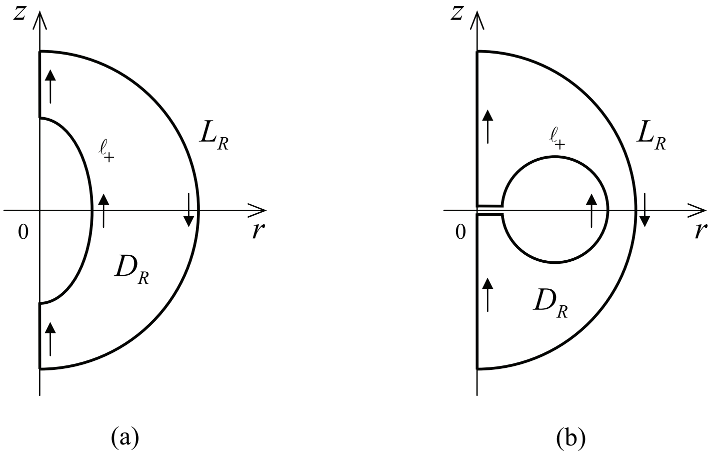


FIG. 2. *The region $\mathcal{D}_R$ with the piecewise smooth negatively oriented boundary L in two cases:* (a) *ℓ_+ is an open curve with the endpoints lying on the z-axis; and* (b) *ℓ_+ is a closed curve.*

3. Axially symmetric Stokes flows. In the axially symmetric case, in the cylindrical coordinates (r, φ, z) with the basis $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$ and the z-axis of symmetry, the velocity components u_r and u_z and the pressure $\wp$ for Stokes flows governed by (2) are independent of the angular coordinate φ, i.e.,

$$\mathbf{u} = u_r(r, z)\,\mathbf{e}_r + u_z(r, z)\,\mathbf{k}, \qquad u_\varphi \equiv 0, \qquad \wp = \wp(r, z).$$

To simplify notation, we will write a function of the variables of r and z as the function of ζ without assuming analyticity; e.g., $u_r(r, z)$ and $u_z(r, z)$ will be represented as $u_r(\zeta)$ and $u_z(\zeta)$, respectively.

A central result of this work is the representation of an external, axially symmetric velocity field and pressure that vanish at infinity in terms of two 0-harmonically analytic functions. This representation is similar to Goursat's formula with two ordinary analytic functions for a 2D biharmonic equation.

PROPOSITION 7 (representation of axially symmetric velocity field). *Let $G_1^{(0)}(\zeta) = U_1^{(0)}(\zeta) + i\,V_1^{(1)}(\zeta)$ and $G_2^{(0)}(\zeta) = U_2^{(0)}(\zeta) + i\,V_2^{(1)}(\zeta)$ be 0-harmonically analytic functions vanishing at infinity. Then in the axially symmetric case of the Stokes equations, the components u_r and u_z of an external velocity field vanishing at infinity can be represented in the form*

$$u_z(\zeta) + i\,u_r(\zeta) = \left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta), \tag{36}$$

and the pressure and vorticity also vanishing at infinity are determined by

$$\wp(\zeta) = \mu\,\mathrm{Re}\,G_1^{(0)}(\zeta), \qquad \mathrm{curl}\,\mathbf{u} = \mathrm{Im}\,G_1^{(0)}(\zeta)\;\mathbf{e}_\varphi. \tag{37}$$

Proof. In the axially symmetric case, the Stokes equations (2) reduce to

$$\mu\,\Delta_1 u_r = \frac{\partial \wp}{\partial r}, \qquad \mu\,\Delta_0 u_z = \frac{\partial \wp}{\partial z}, \tag{38}$$

and the continuity equation $\mathrm{div}\,\mathbf{u} = 0$ takes the form

$$\left(\frac{\partial}{\partial r} + \frac{1}{r}\right) u_r + \frac{\partial}{\partial z} u_z = 0, \tag{39}$$

where Δ_k is defined by (5). Our aim is to represent the velocity components u_r and u_z by linear combinations of 0-harmonically analytic functions (avoiding derivatives).

It follows from the Stokes equations (2) that the vorticity $\boldsymbol{\omega} = \operatorname{curl} \mathbf{u}$ satisfies $\boldsymbol{\Delta\omega} = 0$. In the axially symmetric case, $\boldsymbol{\omega}$ takes the form $\boldsymbol{\omega} = \left(\frac{\partial u_r}{\partial z} - \frac{\partial u_z}{\partial r}\right) \mathbf{e}_\varphi$, and the equation $\boldsymbol{\Delta\omega} = 0$ reduces to $\Delta_1 \left(\frac{\partial u_r}{\partial z} - \frac{\partial u_z}{\partial r}\right) = 0$. Consequently, $\boldsymbol{\omega}$ can be represented by $\boldsymbol{\omega} = V_1^{(1)}(\zeta)\, \mathbf{e}_\varphi$, where $V_1^{(1)}(\zeta)$ is a 1-harmonic scalar vorticity function, i.e., $\Delta_1 V_1^{(1)} = 0$.

The functions $\wp$ and $\boldsymbol{\omega}$ are related harmonic potentials (see Example 1). Consequently, $U_1^{(0)}(\zeta) = \wp(\zeta)/\mu$ and $V_1^{(1)}(\zeta)$ satisfy (3) for $k = 0$ and form the 0-harmonically analytic function $G_1^{(0)}(\zeta) = U_1^{(0)}(\zeta) + i\, V_1^{(1)}(\zeta)$, which under the condition $U_1^{(0)} \to 0$ and $V_1^{(1)} \to 0$ at $|\zeta| \to \infty$, is uniquely determined; see [30, Proposition 1]. Using the system (3) for $k = 0$, we can restate (38) as

$$\begin{aligned} \Delta_1 u_r &= \frac{\partial}{\partial r} U_1^{(0)} = \frac{\partial}{\partial z} V_1^{(1)}, \\ \Delta_0 u_z &= \frac{\partial}{\partial z} U_1^{(0)} = -\left(\frac{\partial}{\partial r} + \frac{1}{r}\right) V_1^{(1)}. \end{aligned} \tag{40}$$

With the identities

$$\begin{aligned} \Delta_1 \left(r\, U_1^{(0)}\right) &= 2\frac{\partial}{\partial r} U_1^{(0)}, \qquad & \Delta_1 \left(z\, V_1^{(1)}\right) &= 2\frac{\partial}{\partial z} V_1^{(1)}, \\ \Delta_0 \left(z\, U_1^{(0)}\right) &= 2\frac{\partial}{\partial z} U_1^{(0)}, \qquad & \Delta_0 \left(r\, V_1^{(1)}\right) &= 2\left(\frac{\partial}{\partial r} + \frac{1}{r}\right) V_1^{(1)}, \end{aligned}$$

equations (40) are integrated, and the components u_r and u_z can be represented in the form

$$\begin{aligned} u_r(\zeta) &= a\, r\, U_1^{(0)}(\zeta) + b\, z\, V_1^{(1)}(\zeta) + V_2^{(1)}(\zeta), \\ u_z(\zeta) &= c\, z\, U_1^{(0)}(\zeta) + d\, r\, V_1^{(1)}(\zeta) + U_2^{(0)}(\zeta), \end{aligned} \tag{41}$$

where a, b, c, and d are real-valued constants, and $U_2^{(0)}$ and $V_2^{(1)}$ are arbitrary 0-harmonic and 1-harmonic functions, respectively, i.e.,

$$\Delta_0 U_2^{(0)} = 0, \qquad \Delta_1 V_2^{(1)} = 0. \tag{42}$$

Substituting (41) into (40), we have

$$2a + 2b = 1, \qquad 2c - 2d = 1. \tag{43}$$

Then, substituting (41) into (39) and using (3) for $k = 0$, we obtain

$$\left(\frac{\partial}{\partial r} + \frac{1}{r}\right) V_2^{(1)} + \frac{\partial}{\partial z} U_2^{(0)} = 0, \tag{44}$$

provided that

$$a + d = 0, \qquad c - b = 0, \qquad 2a + c = 0. \tag{45}$$

Consequently, four constants a, b, c, and d satisfy five equations (43) and (45). However, these equations are dependent. Indeed, adding $a+b = 1/2$ and $c-b = 0$ and then subtracting $a + d = 0$ from the sum, we obtain the second equation in (43), i.e., $c - d = 1/2$. Excluding $c - d = 1/2$ from (43) and (45), we obtain four independent equations, whose unique solution is given by $a = -1/2$, $b = 1$, $c = 1$, and $d = 1/2$. Consequently, the representation (41) takes the form

$$\begin{aligned} u_r(\zeta) &= z\, V_1^{(1)}(\zeta) - \frac{1}{2}\, r\, U_1^{(0)}(\zeta) + V_2^{(1)}(\zeta), \\ u_z(\zeta) &= z\, U_1^{(0)}(\zeta) + \frac{1}{2}\, r\, V_1^{(1)}(\zeta) + U_2^{(0)}(\zeta). \end{aligned} \tag{46}$$

It follows from (42) and (44) that $U_2^{(0)}$ and $V_2^{(1)}$ form the 0-harmonically analytic function $G_2^{(0)}(\zeta) = U_2^{(0)}(\zeta) + i\, V_2^{(1)}(\zeta)$. Since $U_2^{(0)}$ and $V_2^{(1)}$ vanish at $|\zeta| \to \infty$, the function $G_2^{(0)}(\zeta)$ is uniquely determined; see [30, Proposition 1].

Thus, multiplying the first equation in (46) by i and adding with the second one in (46), we obtain the representation (36). $\square$

Remark 4. With $\mathbf{u}$ and $\wp$ vanishing at infinity in an unbounded region, (37) implies that $G_1^{(0)}|_\infty = 0$. According to Remark 3, such $G_1^{(0)}$ behaves as $\mathcal{O}\left(|\zeta|^{-2}\right)$ when $\zeta \to \infty$. Consequently, with this fact and $\mathbf{u}|_\infty = 0$, (36) implies that $G_2^{(0)}|_\infty = 0$.

Remark 5 (multiply connected region). The functions $G_1^{(0)}$ and $G_2^{(0)}$ are continuous and single-valued in multiply connected $\mathcal{D}_0^-$. Indeed, since the pressure and vorticity are continuous in $\mathcal{D}_0^-$, (37) implies that $G_1^{(0)}$ is continuous, and thus single-valued in $\mathcal{D}_0^-$. Also, since $\mathbf{u}$ is continuous in $\mathcal{D}_0^-$, the solution form (36) and continuity of $G_1^{(0)}$ imply that $G_2^{(0)}$ is continuous and thus single-valued in $\mathcal{D}_0^-$ as well.

Remark 6. The solution form (36) can be used for representing $\mathbf{u}$ for an inner Stokes flow problem. However, in this case, there is no requirement on $G_1^{(0)}$ and $G_2^{(0)}$ to vanish at infinity, and consequently $G_1^{(0)}$ and $G_2^{(0)}$ may not be uniquely determined.

The next proposition presents yet another solution form for the velocity field of axially symmetric Stokes flows in terms of 0-harmonically analytic and 1-harmonically analytic functions.

PROPOSITION 8. *Let $G_1^{(1)}(\zeta) = U_1^{(1)}(\zeta) + i\, V_1^{(2)}(\zeta)$ and $G_2^{(0)}(\zeta) = U_2^{(0)}(\zeta) + i\, V_2^{(1)}(\zeta)$ be 1-harmonically analytic and 0-harmonically analytic functions, respectively, vanishing at $|\zeta| \to \infty$; then the velocity field for an outer region in the axially symmetric case of the Stokes equations* (2) *can be represented in the form*

$$u_z(\zeta) + i\, u_r(\zeta) = r\, G_1^{(1)}(\zeta) + G_2^{(0)}(\zeta), \tag{47}$$

and the vorticity is determined by

$$\operatorname{curl} \mathbf{u} = -2 \operatorname{Re} G_1^{(1)}(\zeta)\, \mathbf{e}_\varphi.$$

Proof. The proof is similar to that of Proposition 7. $\square$

Let $\mathcal{D}^+$ and $\mathcal{D}^-$ denote the inner and outer regions with respect to the cross-section of the finite body of revolution in the rz-plane,[10] and let ℓ be the common boundary of $\mathcal{D}^+$ and $\mathcal{D}^-$. As in section 2.2, ℓ_+ denotes the right part of ℓ (i.e., ℓ with $r \geq 0$), which, being the contour of the body in the right half of the rz-plane, is either a closed curve or an open curve with the endpoints lying on the z-axis. The contour of the body in the rz-plane is, thus, $\ell = \ell_+ \bigcup \ell_-$, where ℓ_- is the reflection

[10] We always assume that the z-axis is the body's axis of revolution.

of ℓ_+ with respect to the z-axis. Also, $\mathcal{D}_0^+$ and $\mathcal{D}_0^-$ denote $\mathcal{D}^+$ with $r \geq 0$ and $\mathcal{D}^-$ $r \geq 0$, respectively, i.e., the right parts of the corresponding regions.

The representation (36) reduces an axially symmetric Stokes flow problem to a boundary-value problem for determining two 0-harmonically analytic functions.

Problem I (boundary-value problem for two 0-harmonically analytic functions). *Given a complex-valued function $f(\zeta)$ on ℓ_+ such that $f\left(-\overline{\zeta}\right) = \overline{f(\zeta)}$, find two* 0-*harmonically analytic functions $G_1^{(0)}(\zeta)$ and $G_2^{(0)}(\zeta)$ in (multiply connected) $\mathcal{D}_0^-$ that vanish at infinity and satisfy*

$$\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta) = f(\zeta), \quad \zeta \in \ell_+. \tag{48}$$

Remark 7. The relationship (48) is equivalent to $\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta) = f(\zeta)$ on ℓ. Indeed, with the symmetry condition for $f(\zeta)$ and $G^{(k)}(\zeta)$ (see (7)), $\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta) = f(\zeta)$ for $\zeta \in \ell_-$ can be restated as $\left(z + \frac{i}{2}\,r\right) G_1^{(0)}\left(-\overline{\zeta}\right) + G_2^{(0)}\left(-\overline{\zeta}\right) = f\left(-\overline{\zeta}\right)$ for $\zeta \in \ell_+$, or $\overline{\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta)} = \overline{f(\zeta)}$ for $\zeta \in \ell_+$, which is equivalent to (48).

There are two approaches to solving (48): (i) representing the functions $G_1^{(0)}(\zeta)$ and $G_2^{(0)}(\zeta)$ in the form of integrals or series in curvilinear coordinates associated with the geometry of the boundary ℓ_+ and finding unknown integral densities or series coefficients from (48); and (ii) reducing (48) to an integral equation based on Cauchy's integral formula for 0-harmonically analytic functions. For the second approach, Remark 7 is critical.

Problem I has a unique solution if it has only a zero homogeneous solution. The next proposition considers the homogeneous problem (48) for the outer region $\mathcal{D}_0^-$ and the inner region $\mathcal{D}_0^+$.

Proposition 9 (homogeneous boundary-value problems).

(i) *If functions $G_1^{(0)}(\zeta)$ and $G_2^{(0)}(\zeta)$ are* 0-*harmonically analytic in the outer (multiply connected) region $\mathcal{D}_0^-$ and vanish at infinity, then the homogeneous boundary-value problem*

$$\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta) = 0, \quad \zeta \in \ell_+, \tag{49}$$

has only a zero solution.

(ii) *If functions $G_1^{(0)}(\zeta)$ and $G_2^{(0)}(\zeta)$ are* 0-*harmonically analytic in the inner (multiply connected) region $\mathcal{D}_0^+$, and $\mathcal{D}_0^+$ consists of disjoint simply connected subregions $\mathcal{D}_j^+$, $1 \leq j \leq m$, then a solution to* (49) *is given by $G_1^{(0)}(\zeta) = a_j$ and $G_2^{(0)}(\zeta) = -a_j\left(z - \frac{i}{2}\,r\right)$ for $\zeta \in \mathcal{D}_j^+$, $1 \leq j \leq m$, where a_j is a real-valued constant.*

Proof. We first prove statement (i). Let a function $\Phi(\zeta)$ be defined by

$$\Phi(\zeta) = r\,G_1^{(0)}(\zeta)\left(\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta)\right), \tag{50}$$

and let $\mathcal{D}_R$ be a region in the right half of the rz-plane with piecewise smooth, *negatively* oriented boundary L, which consists of the positively oriented curve ℓ_+, segments of the z-axis, and semicircle L_R with large radius R (see Figure 2(a)). For multiply connected $\mathcal{D}_R$, the boundary L also contains crosscuts making $\mathcal{D}_R$ simply connected (see Figure 2(b)). Since $G_1^{(0)}$ and $G_2^{(0)}$ vanish at infinity as $\mathcal{O}\left(|\zeta|^{-2}\right)$ (see Remark 3), the integral of Φ over L_R vanishes at $R \to \infty$. Also, the function Φ vanishes on the z-axis. Consequently, we have

$$\lim_{R\to\infty} \oint_L \Phi\, d\zeta = \int_{\ell_+} \Phi\, d\zeta, \tag{51}$$

where, in the left-hand side, the integral over corresponding banks of the crosscuts vanishes, since Φ, being a combination of continuous single-valued functions $G_1^{(0)}$ and $G_2^{(0)}$ in $\mathcal{D}_0^-$ (see Remark 5), is continuous in $\mathcal{D}_0^-$ as well.

From (50) and Proposition 4(ii), it follows that

$$\operatorname{Im} \frac{\partial \Phi}{\partial \overline{\zeta}} = -\frac{1}{2} r \left(\operatorname{Im} G_1^{(0)}\right)^2 .$$

Consequently, using Proposition 5, we obtain

$$\lim_{R\to\infty} \operatorname{Re}\left[\oint_L \Phi\, d\zeta\right] = -\operatorname{Re}\left[2i \iint_{\mathcal{D}_0^-} \frac{\partial \Phi}{\partial \overline{\zeta}}\, drdz\right] = -\iint_{\mathcal{D}_0^-} r \left(\operatorname{Im} G_1^{(0)}\right)^2 drdz. \tag{52}$$

However, since $\Phi = 0$ on ℓ_+, (51) and (52) imply that the integral in the right-hand side in (52) vanishes, whence it follows that $\operatorname{Im} G_1^{(0)} = 0$ in $\mathcal{D}_0^-$. In this case, $\operatorname{Re} G_1^{(0)}$ can be a constant, which, however, equals zero, since $G_1^{(0)}$ vanishes at infinity. Thus, $G_1^{(0)} \equiv 0$ in $\mathcal{D}_0^-$, and the proof is finished.

Statement (ii) is proved similarly. Let $\widehat{\ell}_j$ be the part of ℓ_+ that corresponds to $\mathcal{D}_j^+$, $1 \le j \le m$. In this case, it is sufficient to conduct the proof for $\mathcal{D}_j^+$. The boundary of $\mathcal{D}_j^+$ is the closed, piecewise smooth, positively oriented curve L_j which either is the curve $\widehat{\ell}_j$ if $\widehat{\ell}_j$ is closed or consists of the curve $\widehat{\ell}_j$ and the segment of the z-axis connecting the endpoints of $\widehat{\ell}_j$ if $\widehat{\ell}_j$ is an open curve with the endpoints lying on the z-axis. For the same function (50), we have $\oint_{L_j} \Phi\, d\zeta = \int_{\widehat{\ell}_j} \Phi\, d\zeta$ and obtain a relationship similar to (52): $\operatorname{Re}[\oint_{L_j} \Phi\, d\zeta] = \iint_{\mathcal{D}_j^+} r(\operatorname{Im} G_1^{(0)})^2 drdz$. Consequently, since $\Phi = 0$ on $\widehat{\ell}_j$, we conclude that $G_1^{(0)}$ is a real-valued constant on each $\mathcal{D}_j^+$. Since $z - \frac{i}{2} r$ is a 0-harmonically analytic function in $\mathcal{D}_0^+$, statement (ii) follows. □

Alternatively, Proposition 9(i) can be proved based on the fact that the outer Stokes flow problem with the zero boundary condition $\mathbf{u}|_S = 0$ and with the velocity field and pressure vanishing at infinity has only a zero solution, i.e., $\mathbf{u} \equiv 0$; see [2, sections 2.8, 4.9]. Indeed, with (36), this implies that

$$\left(z - \frac{i}{2} r\right) G_1^{(0)}(\zeta) + G_2^{(0)}(\zeta) \equiv 0, \quad \zeta \in \mathcal{D}_0^-, \tag{53}$$

whence it follows that $\left(z - \frac{i}{2} r\right) G_1^{(0)}(\zeta)$ should be a 0-harmonically analytic function in $\mathcal{D}_0^-$. With (6), this requirement is equivalent to the equation

$$\frac{\partial}{\partial \overline{\zeta}} \left(\left(z - \frac{i}{2} r\right) G_1^{(0)}\right) = \frac{1}{4r} \left(\overline{\left(z - \frac{i}{2} r\right) G_1^{(0)}} - \left(z - \frac{i}{2} r\right) G_1^{(0)}\right), \quad \zeta \in \mathcal{D}_0^-,$$

which reduces to having

$$G_1^{(0)} = \overline{G_1^{(0)}}, \quad \zeta \in \mathcal{D}_0^- .$$

Consequently, $\operatorname{Im} G_1^{(0)} \equiv 0$ in $\mathcal{D}_0^-$, and (3) implies that $G_1^{(0)}$ is a real-valued constant a. Note that $z - \frac{i}{2}\, r$ is the 0-harmonically analytic function. Thus, the only solution to (53) in the class of 0-harmonically analytic functions is $G_1^{(0)} \equiv a$ and $G_2^{(0)} \equiv -a\left(z - \frac{i}{2}\, r\right)$. However, since $G_1^{(0)}$ and $G_2^{(0)}$ vanish at infinity, we conclude that $a = 0$, and statement (i) of Proposition 9 follows.

As one of the approaches to solving Problem I, we reduce (48) to an integral equation based on Cauchy's integral formula for 0-harmonically analytic functions.

Theorem 10 (integral equation in the axially symmetric case). *For the outer multiply connected region $\mathcal{D}_0^-$, Problem* I *reduces to the integral equation of the first kind,*

(54)

$$\frac{1}{\pi i}\int_{\ell_+}\left(\left[\left(z_1-\frac{i}{2}r_1\right)-\left(z-\frac{i}{2}r\right)\right]G_1^{(0)}(\tau)\,\Omega_+^{(0)}(\zeta,\tau)\,\frac{d\tau}{\tau-\zeta}\right.$$
$$\left. - \left[\left(z_1+\frac{i}{2}r_1\right)-\left(z-\frac{i}{2}r\right)\right]\overline{G_1^{(0)}(\tau)}\,\Omega_-^{(0)}(\zeta,\tau)\,\frac{d\overline{\tau}}{\overline{\tau}+\zeta}\right) = F(\zeta), \quad \zeta\in\ell_+,$$

where $\zeta = r + i\, z$ and $\tau = r_1 + i\, z_1$, and

$$F(\zeta) = f(\zeta) + \frac{1}{\pi i}\oint_{\ell} f(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\, d\tau. \tag{55}$$

If $\mathcal{D}_0^+$ consists of several disjoint, simply connected subregions $\mathcal{D}_j^+$, $1 \le j \le m$, and $\widehat{\ell}_j$ is the part of ℓ_+ that corresponds to $\mathcal{D}_j^+$ (obviously, $\ell_+ = \bigcup_{j=1}^m \widehat{\ell}_j$), then a solution to (54) *is determined with the accuracy of a real-valued constant a_j on each $\widehat{\ell}_j$.*[11] *Given a solution $\widetilde{G}_1^{(0)}(\zeta)$ to* (54)*, the constants are determined by*

$$a_j = \frac{1}{2}\widetilde{G}_1^{(0)}(\zeta) + \frac{1}{2\pi i}\oint_{\ell}\widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\, d\tau, \qquad \zeta\in\widehat{\ell}_j, \quad 1\le j\le m$$

(the right-hand side is constant for any $\zeta\in\widehat{\ell}_j$), and the solution to Problem I *takes the form*

$$G_1^{(0)}(\zeta) = \widetilde{G}_1^{(0)}(\zeta) - a_j, \qquad \zeta\in\widehat{\ell}_j, \quad 1\le j\le m. \tag{56}$$

Proof. The derivation of the integral equation (54) follows Muskhelishvili's approach, developed for solving 2D problems of an elastic medium; see [17, 18].

In view of Remark 7, Problem I for $\mathcal{D}_0^-$ is equivalent to the one for $\mathcal{D}^-$. Necessary and sufficient conditions for the functions $G_1^{(0)}$ and $G_2^{(0)}$ to be 0-harmonically analytic in the outer (multiply connected) region $\mathcal{D}^-$ and vanishing at infinity follow from the generalized Sokhotski–Plemelj formulae[12] and can be written in the form

$$G_1^{(0)}(\zeta) + \frac{1}{\pi i}\oint_{\ell} G_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\, d\tau = 0, \qquad \zeta\in\ell, \tag{57a}$$

$$G_2^{(0)}(\zeta) + \frac{1}{\pi i}\oint_{\ell} G_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\, d\tau = 0, \qquad \zeta\in\ell. \tag{57b}$$

[11] In other words, any function which is a real-valued constant on each $\widehat{\ell}_j$ is a homogeneous solution to (54).

[12] These formulae can be derived similarly to the Sokhotski–Plemelj formulae for ordinary analytic functions; see [1, formula (31.13)] and [9, formula (4.8)].

According to Remark 7, the boundary condition (48) on ℓ_+ is equivalent to (48) on ℓ. Expressing the boundary value of $G_2^{(0)}$ from (48),

$$G_2^{(0)}(\zeta) = f(\zeta) - \left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta), \quad \zeta \in \ell,$$

and substituting it into (57b), we obtain

$$\left(z - \frac{i}{2}\,r\right) G_1^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell \left(z_1 - \frac{i}{2}\,r_1\right) G_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = F(\zeta), \qquad \zeta \in \ell, \tag{58}$$

where $F(\zeta)$ is defined by (55). Then the combination (58) $-$ $\left(z - \frac{i}{2}\,r\right)\cdot$ (57a) reduces to the integral equation of the first kind

$$\frac{1}{\pi i}\oint_\ell \left[\left(z_1 - \frac{i}{2} r_1\right) - \left(z - \frac{i}{2} r\right)\right] G_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = F(\zeta), \qquad \zeta \in \ell, \tag{59}$$

which can equivalently be rewritten as (54).

Now we need to show that any function which is a real-valued constant on each $\widehat{\ell}_j$ is a homogeneous solution to (54) and that the solution to Problem I is determined by (56).

Let $\widetilde{G}_1^{(0)}$ solve (59). Adding the term $\left(z - \frac{i}{2}\,r\right)\widetilde{G}_1^{(0)}(\zeta)$ to the left-hand and right-hand sides of (59) and denoting $\widetilde{G}_2^{(0)}(\zeta) = f(\zeta) - \left(z - \frac{i}{2}\,r\right)\widetilde{G}_1^{(0)}(\zeta)$ for $\zeta \in \ell$, we rewrite (59) in the form

$$\begin{aligned}\left(z - \frac{i}{2}\,r\right)&\left(\widetilde{G}_1^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau\right)\\ &+ \widetilde{G}_2^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = 0, \qquad \zeta \in \ell.\end{aligned} \tag{60}$$

Let $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$ be determined by the generalized *Cauchy-type* integrals for the region $\mathcal{D}^+$ excluding its boundary ℓ:

$$\begin{aligned}\Phi^+(\zeta) &= \frac{1}{2\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \operatorname{int}\mathcal{D}^+,\\ \Psi^+(\zeta) &= \frac{1}{2\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \operatorname{int}\mathcal{D}^+.\end{aligned}$$

These functions are 0-harmonically analytic in $\operatorname{int}\mathcal{D}^+$, since $\mathcal{W}^{(0)}(\zeta,\tau)$ satisfies (6) for $k = 0$ with respect to ζ.[13] Then when ζ approaches ℓ from within $\mathcal{D}^+$, the boundary values of $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$ on ℓ are determined by the corresponding generalized Sokhotski–Plemelj formula:

$$\Phi^+(\zeta) = \frac{1}{2}\widetilde{G}_1^{(0)}(\zeta) + \frac{1}{2\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \qquad \zeta \in \ell, \tag{61a}$$

$$\Psi^+(\zeta) = \frac{1}{2}\widetilde{G}_2^{(0)}(\zeta) + \frac{1}{2\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \qquad \zeta \in \ell. \tag{61b}$$

[13] In fact, the generalized Cauchy-type integrals determine 0-harmonically analytic functions in the whole rz-plane, which are, however, discontinuous on the boundary ℓ; see [1, 9].

With (61a) and (61b), (60) reduces to

$$\left(z-\frac{i}{2}\,r\right)\Phi^{+}(\zeta)+\Psi^{+}(\zeta)=0,\qquad \zeta\in\ell, \tag{62}$$

which is a homogeneous boundary-value problem for the 0-harmonically analytic functions $\Phi^{+}(\zeta)$ and $\Psi^{+}(\zeta)$ in $\mathcal{D}^{+}$. Note that since $\Phi^{+}(\zeta)$ and $\Psi^{+}(\zeta)$ are determined by the generalized Cauchy-type integrals, they satisfy the symmetry condition (7) and thus, in view of Remark 7, the problem (62) is equivalent to (49) for $\mathcal{D}_0^{+}$. However, according to Proposition 9(ii), the only solution to (49) for $\mathcal{D}_0^{+}$ is $\Phi^{+}(\zeta)\equiv a_j$ and $\Psi^{+}(\zeta)\equiv -a_j\left(z-\frac{i}{2}\,r\right)$, $\zeta\in\mathcal{D}_j^{+}$, $1\le j\le m$, where a_j is a real-valued constant. Consequently, (61a) and (61b) imply that $G_1^{(0)}(\zeta)=\widetilde{G}_1^{(0)}(\zeta)-a_j$ and $G_2^{(0)}(\zeta)=\widetilde{G}_2^{(0)}(\zeta)+a_j\left(z-\frac{i}{2}\,r\right)$, $\zeta\in\widehat{\ell}_j$, $1\le j\le m$, satisfy (57a) and (57b), respectively, and thus are the boundary values of 0-harmonically analytic functions in $\mathcal{D}_0^{-}$. □

Remark 8. The first term in the integrand of (54) is regular:

$$\lim_{\tau\to\zeta}\frac{\left(z_1-\frac{i}{2}r_1\right)-\left(z-\frac{i}{2}r\right)}{\tau-\zeta}=\frac{i}{4}\left(\mathrm{e}^{-2i\lim\limits_{\tau\to\zeta}\arg[\tau-\zeta]}-3\right).$$

This expression is obtained by setting $\tau=\zeta+\rho\,\mathrm{e}^{i\beta}$ and passing $\rho\to 0$. Also, if $\zeta=\zeta(t)$ is a parameterization of smooth ℓ_{+}, then $\lim_{\tau\to\zeta}\arg[\tau-\zeta]=\arg[\zeta'(t)]$. The second term in (54) has a logarithmic singularity at $\tau=\zeta$ because of the function $\Omega_{-}^{(0)}(\zeta,\tau)$.

Remark 9 (integral equation for nonsmooth bodies). In the case when the surface of the body, i.e., spindle or lens, is nonsmooth, the necessary and sufficient condition for a function $G^{(0)}$ to be 0-harmonically analytic in $\mathcal{D}^{-}$ and vanishing at infinity follows from modified generalized Sokhotski–Plemelj formulae (see [1, (31.13a), (31.13b)]) and takes the form

$$h(\zeta)\,G^{(0)}(\zeta)+\frac{1}{\pi i}\oint_{\ell}G^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau=0,\quad \zeta\in\ell, \tag{63}$$

where $h(\zeta)=2-\alpha(\zeta)/\pi$ for $\operatorname{Re}\zeta\neq 0$ and $h(\zeta)=1+\cos(\alpha(\zeta)/2)$ for $\operatorname{Re}\zeta=0$ (if ℓ intersects the z-axis), and $\alpha(\zeta)$ is the angle between the right and left tangent vectors to the curve ℓ at the point ζ. For all points at which ℓ is smooth, $\alpha(\zeta)=\pi$ and $h(\zeta)=1$; see [1, (31.13a), (31.13b)].

As in the proof of Theorem 10, it can be shown that for bodies with nonsmooth surface, the integral equation (54) will be the same except for the right-hand side $F(\zeta)$, which in this case takes the form

$$F(\zeta)=h(\zeta)\,f(\zeta)+\frac{1}{\pi i}\oint_{\ell}f(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau. \tag{64}$$

Note that if $f(\zeta)$ is a 0-harmonically analytic function in $\mathcal{D}^{+}$, then $F(\zeta)=2f(\zeta)$.

The problem of axially symmetric Stokes flows that attracted much of the attention is the steady axially symmetric translation of a solid body of revolution with constant velocity v_z in the fluid. Let the body's axis of revolution coincide with the z-axis in the cylindrical coordinates. The fluid velocity $\mathbf{u}$ satisfies the Stokes equations (2) and no-slip boundary conditions on the surface S of the body:

$$\mathbf{u}|_{S}=v_z\,\mathbf{k}. \tag{65}$$

Also, $\mathbf{u}$ and $\wp$ vanish at infinity:

$$\mathbf{u}\big|_{\infty} = 0, \qquad \wp\big|_{\infty} = 0. \tag{66}$$

In terms of 0-harmonically analytic functions, this problem is a particular case of Problem I with $f(\zeta) = v_z$. Obviously, v_z satisfies the symmetry condition $f\left(-\overline{\zeta}\right) = \overline{f(\zeta)}$. In this case, since v_z is a 0-harmonically analytic function in $\mathcal{D}^+$, the right-hand side of (54) reduces to $F(\zeta) = 2v_z$.

The next proposition shows that the resisting (drag) force, exerted on the body of revolution in the axially symmetric translation, can be expressed in terms of $G_1^{(0)}$.

Proposition 11 (drag force in axially symmetric translation). *For the axially symmetric Stokes flow problem for the body translating along the z-axis,*[14] *let the velocity field be represented by* (36) *with the boundary conditions* (65) *and* (66). *The resisting force, exerted on the body, can be represented in two equivalent forms*

$$F_z = 2\pi\mu \, \mathrm{Re}\left[\int_{\ell_+} r\, G_1^{(0)}(\zeta)\, d\zeta\right], \tag{67a}$$

$$F_z = -4\pi\mu \lim_{z\to\infty} \left(z^2 \, \mathrm{Re}\, G_1^{(0)}(\zeta)\Big|_{r=0}\right), \tag{67b}$$

where ℓ_+ in (67a) *is positively oriented with respect to $\mathcal{D}_0^+$.*

Proof. First, we prove (67a).

The resulting force exerted by the fluid on a solid body is defined as the integral over the body's surface S:

$$\mathbf{F} = \iint_S \mathbf{P}_n \, dS, \qquad \mathbf{P}_n = 2\mu \frac{\partial \mathbf{u}}{\partial n} + \mu\left[\mathfrak{n} \times \operatorname{curl} \mathbf{u}\right] - \wp\, \mathfrak{n}, \tag{68}$$

where $\mathfrak{n} = n_r\, \mathbf{e}_r + n_z\, \mathbf{k}$ is the outer normal to the body's surface with $n_r = \frac{\partial r}{\partial n}$ and $n_z = \frac{\partial z}{\partial n}$; see [11].

It can be shown that for the axially symmetric velocity field with the boundary conditions (65),

$$\frac{\partial \mathbf{u}}{\partial n} = -[\mathfrak{n} \times \operatorname{curl} \mathbf{u}] \quad \text{on } S. \tag{69}$$

Indeed, in this case, in the cylindrical coordinates (r, φ, z), the velocity field is independent of the angular coordinate φ: $\mathbf{u} = u_r(r,z)\, \mathbf{e}_r + u_z(r,z)\, \mathbf{k}$ and $u_\varphi \equiv 0$, and we have $\operatorname{curl} \mathbf{u} = \left(\frac{\partial u_r}{\partial z} - \frac{\partial u_z}{\partial r}\right) \mathbf{e}_\varphi$. With $\mathfrak{n} = \frac{\partial r}{\partial n}\, \mathbf{e}_r + \frac{\partial z}{\partial n}\, \mathbf{k}$, we obtain

$$-[\mathfrak{n} \times \operatorname{curl} \mathbf{u}] = \frac{\partial z}{\partial n}\left(\frac{\partial u_r}{\partial z} - \frac{\partial u_z}{\partial r}\right) \mathbf{e}_r + \frac{\partial r}{\partial n}\left(\frac{\partial u_z}{\partial r} - \frac{\partial u_r}{\partial z}\right) \mathbf{k}. \tag{70}$$

Let (s, φ, n) be a characteristic coordinate system with the right-handed orthogonal basis $(\mathfrak{s}, \mathbf{e}_\varphi, \mathfrak{n})$, in which s has *negative* orientation. Then using the relationships

$$\frac{\partial r}{\partial s} = \frac{\partial z}{\partial n}, \qquad \frac{\partial r}{\partial n} = -\frac{\partial z}{\partial s}$$

[14] The z-axis is the body's axis of revolution.

and the continuity equation (39), we have

$$\begin{aligned}\frac{\partial z}{\partial n}\left(\frac{\partial u_r}{\partial z}-\frac{\partial u_z}{\partial r}\right)&=\frac{\partial u_r}{\partial n}-\frac{\partial u_z}{\partial s}-\frac{u_r}{r}\frac{\partial z}{\partial s},\\ \frac{\partial r}{\partial n}\left(\frac{\partial u_z}{\partial r}-\frac{\partial u_r}{\partial z}\right)&=\frac{\partial u_z}{\partial n}+\frac{\partial u_r}{\partial s}+\frac{u_r}{r}\frac{\partial r}{\partial s}.\end{aligned}\tag{71}$$

The boundary conditions (65) imply that on the surface S, the first and second equations in (71) reduce to $\partial u_r/\partial n$ and $\partial u_z/\partial n$, respectively, and thus (69) holds.

Consequently, for the axially symmetric translation, $\mathbf{P}_n$ in (68) is determined on the surface S by

$$\mathbf{P}_n=-\mu\left[\mathfrak{n}\times\operatorname{curl}\mathbf{u}\right]-\wp\,\mathfrak{n}\quad\text{on } S.\tag{72}$$

Finally, in the cylindrical coordinates, we have $dS=r\,ds\,d\varphi$, where ds is the differential of the curve length. In the axially symmetric case, $\operatorname{curl}\mathbf{u}$ and $\wp$ are represented by (37), and $\mathbf{F}$ has the component in the direction $\mathbf{k}$ only. Thus, the corresponding component of the integral (68) with (72) takes the form

$$F_z=(\mathbf{F}\cdot\mathbf{k})=-2\pi\mu\int_{\ell_+} r\left((\mathfrak{n}\cdot\mathbf{e}_r)\,\operatorname{Im}G_1^{(0)}(\zeta)+(\mathfrak{n}\cdot\mathbf{k})\,\operatorname{Re}G_1^{(0)}(\zeta)\right)ds.$$

With $(\mathfrak{n}\cdot\mathbf{e}_r)\,ds=dz$ and $(\mathfrak{n}\cdot\mathbf{k})\,ds=-dr$ (for positively oriented ℓ_+), the formula (67a) follows.

The formula (67b) follows from (67a) and Proposition 6. □

Remark 10. The formula (67a) is invariant with respect to adding a real-valued constant to $G_1^{(0)}|_{\ell_+}$. This means that the drag force F_z can be calculated by (67a) for any solution of the integral equation (54).

4. Exact solutions to axially symmetric Stokes flow problems. As an illustration to the developed framework, this section presents exact solutions in the form (36) to the problem of Stokes flows due to the steady axially symmetric translation of a solid body of revolution. In this case, the boundary conditions for the Stokes equations (2) are given by (65) and (66).

Example 5 (axially symmetric translation of a solid sphere). Let (R,ϑ,φ) be the spherical coordinates related to the cylindrical coordinates in the ordinary way, and let a solid sphere be centered at the origin and have radius c. For the axially symmetric translation of the sphere, the 0-harmonically analytic functions $G_1^{(0)}$ and $G_2^{(0)}$ in (36) are determined in the region $R\geq c$ by

$$G_1^{(0)}(R,\vartheta)=\frac{3v_zc}{2}\,R^{-2}\,\mathrm{e}^{i\vartheta},\qquad G_2^{(0)}(R,\vartheta)=-\frac{v_zc^3}{8}\,R^{-3}\left(1+3\,\mathrm{e}^{2i\vartheta}\right),\tag{73}$$

and the drag force $F_z=-6\pi c\mu v_z$ follows from (67b).

Detail. Let the velocity field be determined by (36). Representing $G_1^{(0)}$ and $G_2^{(0)}$ for the region exterior to the sphere by (15) with $k=0$,

$$\begin{aligned}G_1^{(0)}(R,\vartheta)&=\sum_{n=1}^{\infty}A_n\,R^{-n-1}\left\{n\,\mathrm{P}_n(\cos\vartheta)-i\,\mathrm{P}_n^{(1)}(\cos\vartheta)\right\},\\ G_2^{(0)}(R,\vartheta)&=\sum_{n=1}^{\infty}B_n\,R^{-n-1}\left\{n\,\mathrm{P}_n(\cos\vartheta)-i\,\mathrm{P}_n^{(1)}(\cos\vartheta)\right\},\end{aligned}$$

and substituting these series into (48) with $f(\zeta) = v_z$, we obtain $2A_1/(3c) = v_z$ and the following system:

$$c^2 \frac{n(n-1)}{2(2n-1)} A_{n-1} + \frac{(n+1)(3n+4)}{2(2n+3)} A_{n+1} + n\, B_n = 0, \qquad n \geq 1, \tag{74a}$$

$$c^2 \frac{(n-1)}{2(2n-1)} A_{n-1} + \frac{(3n+4)}{2(2n+3)} A_{n+1} + B_n = 0, \qquad n \geq 1. \tag{74b}$$

The difference (74a) $-\, n \cdot$ (74b) reduces to $A_{n+1} = 0$ for $n \geq 1$, and, hence, it follows from either (74a) or (74b) that $B_1 = 0$, $B_2 = -A_1 c^2/6$, and $B_n = 0$ for $n \geq 3$.

The next two examples present analytical solutions for the axially symmetric translation of solid prolate and oblate spheroids in the form (36). Analytical solutions to these problems in terms of a stream function can be found in [11].

Example 6 (axially symmetric translation of a solid prolate spheroid). Let a solid prolate spheroid be described in the prolate spheroidal coordinates (19) by $\xi = \xi_0$. For the axially symmetric translation of the prolate spheroid, the 0-harmonically analytic functions $G_1^{(0)}$ and $G_2^{(0)}$ in (36) are determined in the region $\xi \geq \xi_0$ by

$$\begin{aligned} G_1^{(0)}(\xi,\eta) &= \frac{q}{c} \, \frac{(\cos\eta + i\, \coth\xi \sin\eta)}{\cosh^2\xi - \cos^2\eta}, \\ G_2^{(0)}(\xi,\eta) &= \frac{q}{2}\left(1 + \cosh^2\xi_0\right)\left(\ln\left(\coth[\xi/2]\right) - \frac{\sinh[2\xi] + i\, \sin[2\eta]}{2\sinh\xi\left(\cosh^2\xi - \cos^2\eta\right)}\right), \end{aligned} \tag{75}$$

where $q = 2v_z \big/ \big(\left(1 + \cosh^2\xi_0\right)\ln\left(\coth[\xi_0/2]\right) - \cosh\xi_0 \big)$. The drag force $F_z = -4\pi c\mu q$ follows from (67b) and (75).

Detail. For the region exterior to the prolate spheroid, the 0-harmonically analytic functions $G_1^{(0)}$ and $G_2^{(0)}$ are determined by (20) for $k = 0$:

$$\begin{aligned} G_1^{(0)}(\xi,\eta) &= \sum_{n=1}^{\infty} A_n \left\{ n(n+1)\, \mathrm{Q}_n(\cosh\xi)\mathrm{P}_n(\cos\eta) + i\, \mathrm{Q}_n^{(1)}(\cosh\xi)\mathrm{P}_n^{(1)}(\cos\eta) \right\}, \\ G_2^{(0)}(\xi,\eta) &= \sum_{n=1}^{\infty} B_n \left\{ n(n+1)\, \mathrm{Q}_n(\cosh\xi)\mathrm{P}_n(\cos\eta) + i\, \mathrm{Q}_n^{(1)}(\cosh\xi)\mathrm{P}_n^{(1)}(\cos\eta) \right\}, \end{aligned} \tag{76}$$

and the boundary-value problem $((z - \frac{i}{2}\, r)G_1^{(0)} + G_2^{(0)})|_{\xi=\xi_0} = v_z$ reduces to

$$L_n(\xi_0)\, A_{n-1} + M_n(\xi_0)\, A_{n+1} + \mathrm{Q}_n^{(1)}(\cosh\xi_0)\, B_n = 0, \qquad n \geq 1, \tag{77a}$$

$$K_0(\xi_0)\, A_1 = v_z, \tag{77b}$$

$$N_n(\xi_0)\, A_{n-1} + K_n(\xi_0)\, A_{n+1} + n(n+1)\mathrm{Q}_n(\cosh\xi_0)\, B_n = 0, \qquad n \geq 1, \tag{77c}$$

where the functions $L_n(\xi_0)$, $M_n(\xi_0)$, $N_n(\xi_0)$, and $K_n(\xi_0)$ are defined by

$$\begin{aligned}
L_n(\xi_0) &= c\,\frac{(n-1)}{2n-1}\left(\cosh\xi_0\,\mathrm{Q}^{(1)}_{n-1}(\cosh\xi_0) + \frac{n}{2}\sinh\xi_0\,\mathrm{Q}_{n-1}(\cosh\xi_0)\right),\\
M_n(\xi_0) &= c\,\frac{(n+2)}{2n+3}\left(\cosh\xi_0\,\mathrm{Q}^{(1)}_{n+1}(\cosh\xi_0) - \frac{(n+1)}{2}\sinh\xi_0\,\mathrm{Q}_{n+1}(\cosh\xi_0)\right),\\
N_n(\xi_0) &= c\,\frac{n(n-1)}{2n-1}\left(n\cosh\xi_0\,\mathrm{Q}_{n-1}(\cosh\xi_0) + \frac{1}{2}\sinh\xi_0\,\mathrm{Q}^{(1)}_{n-1}(\cosh\xi_0)\right),\\
K_n(\xi_0) &= c\,\frac{(n+1)(n+2)}{2n+3}\left((n+1)\cosh\xi_0\,\mathrm{Q}_{n+1}(\cosh\xi_0)\right.\\
&\qquad\qquad\left.-\frac{1}{2}\sinh\xi_0\,\mathrm{Q}^{(1)}_{n+1}(\cosh\xi_0)\right).
\end{aligned}$$

The combination $\mathrm{Q}^{(1)}_n(\cosh\xi_0)\cdot(77\text{c}) - n(n+1)\mathrm{Q}_n(\cosh\xi_0)\cdot(77\text{a})$ reduces to

$$\left(-\widetilde{A}_{n-1} + \widetilde{A}_{n+1}\right)\delta_n(\xi_0) = 0, \qquad n \geq 2, \tag{78}$$

where $\widetilde{A}_n = \frac{n(n+1)}{2(2n+1)}\,A_n$ and

$$\begin{aligned}
\delta_n(\xi_0) &= \left(1+\cosh^2\xi_0\right)\mathrm{Q}_n(\cosh\xi_0)\,\mathrm{Q}^{(1)}_n(\cosh\xi_0)\\
&\quad + \sinh\xi_0\cosh\xi_0\left[\left(\mathrm{Q}^{(1)}_n(\cosh\xi_0)\right)^2 - n(n+1)\left(\mathrm{Q}_n(\cosh\xi_0)\right)^2\right].
\end{aligned}$$

From (77b), we have $\widetilde{A}_1 = v_z/(3K_0(\xi_0)) = q/(2c)$, and solving (77a) and (77c) for $n=1$, we obtain $\widetilde{A}_2 = 0$ and $B_1 = 0$. Consequently, since $\delta_n(\xi_0) \neq 0$ for $n \geq 2$, it follows from (78) that $\widetilde{A}_{2m+1} = \widetilde{A}_1$, $\widetilde{A}_{2m} = 0$, $B_{2m-1} = 0$, and

$$B_{2m} = -c\left(1+\cosh^2\xi_0\right)\frac{(4m+1)}{2m(2m+1)}\,\widetilde{A}_{2m-1}, \qquad m \geq 1.$$

Thus, the series (76) take the form

$$\begin{aligned}
G^{(0)}_1(\xi,\eta) &= 2\widetilde{A}_1\sum_{m=0}^{\infty}(4m+3)\left\{\mathrm{Q}_{2m+1}(\cosh\xi)\,\mathrm{P}_{2m+1}(\cos\eta)\right.\\
&\qquad\left.+\frac{i}{(2m+1)(2m+2)}\,\mathrm{Q}^{(1)}_{2m+1}(\cosh\xi)\,\mathrm{P}^{(1)}_{2m+1}(\cos\eta)\right\},\\
G^{(0)}_2(\xi,\eta) &= -c\left(1+\cosh^2\xi_0\right)\widetilde{A}_1\sum_{m=1}^{\infty}(4m+1)\left\{\mathrm{Q}_{2m}(\cosh\xi)\,\mathrm{P}_{2m}(\cos\eta)\right.\\
&\qquad\left.+\frac{i}{2m(2m+1)}\,\mathrm{Q}^{(1)}_{2m}(\cosh\xi)\,\mathrm{P}^{(1)}_{2m}(\cos\eta)\right\},
\end{aligned}\tag{79}$$

which reduce to (75) with the representations (see [3])

$$\begin{aligned}
\frac{1}{\cosh\xi-\cos\eta} &= \sum_{n=0}^{\infty}(2n+1)\,\mathrm{Q}_n(\cosh\xi)\,\mathrm{P}_n(\cos\eta),\\
\frac{\sin\eta}{\sinh\xi\,(\cosh\xi-\cos\eta)} &= \sum_{n=1}^{\infty}\frac{(2n+1)}{n(n+1)}\,\mathrm{Q}^{(1)}_n(\cosh\xi)\,\mathrm{P}^{(1)}_n(\cos\eta)
\end{aligned}\tag{80}$$

and the fact that $\mathrm{P}_n^{(k)}(-\cos\eta) = (-1)^{n+k}\,\mathrm{P}_n^{(k)}(\cos\eta)$ for integers n and k.

Example 7 (axially symmetric translation of a solid oblate spheroid). Let a solid oblate spheroid be described in the oblate spheroidal coordinates (22) by $\xi = \xi_0$. For the axially symmetric translation of the oblate spheroid, the 0-harmonically analytic functions $G_1^{(0)}$ and $G_2^{(0)}$ in (36) are determined in the region $\xi \geq \xi_0$ by

$$\begin{aligned} G_1^{(0)}(\xi,\eta) &= -\frac{q}{c}\,\frac{(\cos\eta + i\,\tanh\xi\sin\eta)}{\sinh^2\xi + \cos^2\eta}, \\ G_2^{(0)}(\xi,\eta) &= \frac{q}{2}\left(\sinh^2\xi_0 - 1\right)\left(\operatorname{arccot}[\sinh\xi] - \frac{\sinh[2\xi] - i\,\sin[2\eta]}{2\cosh\xi\left(\sinh^2\xi + \cos^2\eta\right)}\right), \end{aligned} \tag{81}$$

where $q = -2v_z \big/ \left(\sinh\xi_0 - \left(\sinh^2\xi_0 - 1\right)\operatorname{arccot}[\sinh\xi_0]\right)$. The drag force $F_z = 4\pi c\mu q$ follows from (67b) and (81).

Detail. The solution (81) is obtained similarly to (76).

We also solve the integral equation (54) for the axially symmetric translation of the sphere and prolate and oblate spheroids and compare the obtained solutions with the corresponding closed-form analytical solutions (73), (76), and (81).

Remark 11. In Problem I, the boundary conditions (65), corresponding to the axially symmetric translation, satisfy $f\left(\overline{\zeta}\right) = \overline{f(\zeta)}$ on ℓ_+. In this case, if, for a given body, $\mathcal{D}_0^+$ is symmetric with respect to the r-axis, then we have the symmetry condition[15] $G_1^{(0)}\left(\overline{\zeta}\right) = -\overline{G_1^{(0)}(\zeta)}$. If also $\mathcal{D}_0^+$ is simply connected, then this condition implies that a solution to (54) is uniquely determined (see Theorem 10).

For the sphere and prolate and oblate spheroids, $G_1^{(0)}\left(\overline{\zeta}\right) = -\overline{G_1^{(0)}(\zeta)}$, and a solution to (54) is uniquely determined (see Remark 11). For example, for the sphere of unit radius, we parameterize ℓ_+ by $r(t) = \cos t$ and $z(t) = \sin t$, $t \in [-\pi/2, \pi/2]$, and represent the boundary-value of the function $G_1^{(0)}$ on ℓ_+ by

$$G_1^{(0)}(\zeta(t)) = \sum\nolimits_{k=1}^{n} \left(a_k \sin[k\,t] + i\,b_k\cos[(k-1)t]\right), \qquad t \in [-\pi/2, \pi/2], \tag{82}$$

where the real and imaginary parts are odd and even functions of t, respectively, and the unknown coefficients a_k and b_k can be found by various techniques, e.g., by minimizing the total quadratic error of (54) with (82). For the sphere, we can take only first two terms in (82), i.e., $n = 2$, to obtain an exact solution coinciding with (73). For prolate and oblate spheroids, we solve (54) using the same approach with corresponding parameterization of r and z and obtain that with only $n = 8$ in (82), the drag force F_z, being compared to the corresponding exact values, has the relative error of 10^{-5}.

The next two examples illustrate solutions to the integral equation (54) for bispheroids (two separate spheroids of equal size and having the same axis of revolution) and a torus of elliptical cross-section for various values of a geometrical parameter.[16] The Stokes flow problem for two spheres was solved analytically in [23, 26, 30]. The axially symmetric problem of sedimentation of bispheroids was considered in [25] (see also [11]); however, the pressure was not investigated in this case.

Example 8 (axially symmetric translation of solid bispheroids). Let the centers of bispheroids lie on the z-axis, which is the axis of revolution, and have coordinates

[15] This condition should not be confused with the symmetry condition (7).

[16] The integral equation (54) holds for multiply connected regions.

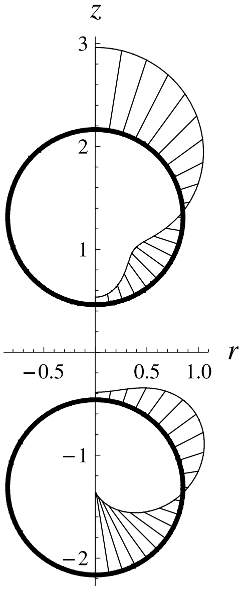

FIG. 3. *Profile of the pressure,* $\wp/(2v_z\mu)$*, on the surface of the solid bispheres (*$\varkappa = 1$*) in the axially symmetric translation along the* z*-axis.*

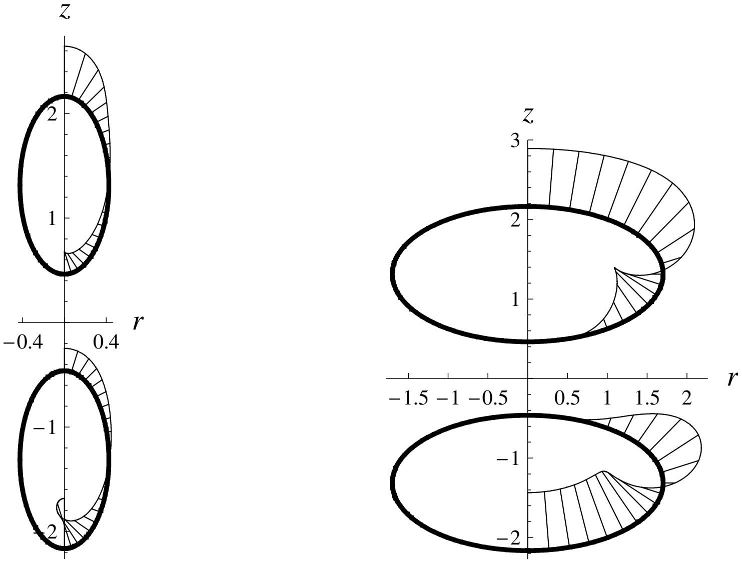

(a) $\wp/(8v_z\mu)$, prolate bi-spheroids

(b) $\wp/(v_z\mu)$, oblate bi-spheroids

FIG. 4. *Profile of the pressure on the surface of the solid bispheroids in the axially symmetric translation along the* z*-axis:* (a) $\wp/(8v_z\mu)$*, prolate bispheroids with* $\varkappa = 0.5$*;* (b) $\wp/(v_z\mu)$*, oblate bispheroids with* $\varkappa = 2$*.*

$z = \coth 1$ (upper spheroid) and $z = -\coth 1$ (lower spheroid). Let the upper spheroid be parameterized in the right half of the rz-plane by $r(t) = \varkappa \sin t/\sinh 1$, $z(t) = \coth 1 - \cos t/\sinh 1$, $t \in [0, \pi]$, where $\varkappa$ is a positive parameter. The case $\varkappa = 1$ corresponds to bispheres, for which a closed form solution to the axially symmetric

Stokes flow problem can be obtained in terms of a stream function [23, 30]. On ℓ_+ for $z \geq 0$ (upper spheroid), we represent $G_1^{(0)}(\zeta)$ by

$$G_1^{(0)}(\zeta(t)) = a_0 + \sum_{k=1}^{n} \left(a_k \cos[k\,t] + i\, b_k \cos[(k-1)t] \right), \qquad t \in [0, \pi],$$

and on ℓ_+ for $z \leq 0$ (lower spheroid), we determine $G_1^{(0)}(\zeta)$ using $G_1^{(0)}(\overline{\zeta}) = -\overline{G_1^{(0)}(\zeta)}$ (see Remark 11). Since for the bispheroids $\mathcal{D}_0^+$ is a doubly connected region, the function $g(\zeta)$ defined by $g(\zeta) = a_0$ on ℓ_+ for $z \geq 0$ and by $g(\zeta) = -a_0$ on ℓ_+ for $z \leq 0$ is a homogeneous solution to (54). Consequently, we solve (54) for $\widetilde{G}_1^{(0)}(\zeta(t)) = G_1^{(0)}(\zeta(t)) - a_0$ and then determine the constant a_0 by (see Theorem 10)

$$a_0 = -\frac{1}{2}\widetilde{G}_1^{(0)}(\zeta) - \frac{1}{2\pi i}\oint_{\ell} \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \qquad \zeta \in \ell_+.$$

Figures 3 and 4 illustrate profiles of the pressure on the surface of the bispheres ($\varkappa = 1$) and bispheroids for $\varkappa = 0.5$ and $\varkappa = 2$. Table 1 presents the ratio, d_z, of the drag, exerted on one of the two spheroids and calculated by (67a), to the drag of a single same-size spheroid[17] for $\varkappa = 0.5$, 1, and 2.

As another illustration, we solve the integral equation (54) for the axially symmetric translation of a torus of elliptical cross-section.[18] To the best of our knowledge, only the case of the torus of circular cross-section in this Stokes flow problem was addressed in the literature; see [19, 27, 10, 30].

Example 9 (axially symmetric translation of a solid torus of elliptical cross-section). Let the surface of a torus of elliptical cross-section be parameterized in the right half of the rz-plane by $r(t) = 2 + \cos t$, $z(t) = \varkappa \sin t$, $t \in [-\pi, \pi]$, where $\varkappa$ is a positive parameter. The case $\varkappa = 1$ corresponds to the torus of circular cross-section, for which a closed form solution can be obtained in terms of a stream function [10, 30]. According to Remark 11, $G_1^{(0)}\left(\overline{\zeta}\right) = -\overline{G_1^{(0)}(\zeta)}$, and a solution to (54) is uniquely determined and can be represented on ℓ_+ by

$$G_1^{(0)}(\zeta(t)) = \sum_{k=1}^{n} \left(a_k \sin[k\,t] + i\, b_k \cos[(k-1)t] \right), \qquad t \in [-\pi, \pi].$$

Figures 5, 6, and 7 illustrate profiles of the pressure on the surface of the torus of elliptical cross-section in the axially symmetric translation for $\varkappa = 1$, 0.5, and 2, respectively. Table 2 presents the drag F_z, calculated by (67a) and normalized to the drag of the circumscribed sphere with the radius 3 for $\varkappa = 0.5$, 1, and 2.

TABLE 1

The ratio, d_z, of the drag, exerted on one of the two spheroids to the drag of a single same-size spheroid in the axially symmetric translation along the z-axis for $\varkappa = 0.5$, 1, and 2.

$\varkappa$	0.5	1.0[§]	2
d_z	0.7736	0.7025[♭]	0.6332

[§] The case corresponds to the bispheres.

[♭] The value coincides with the one in [23]; see also [30].

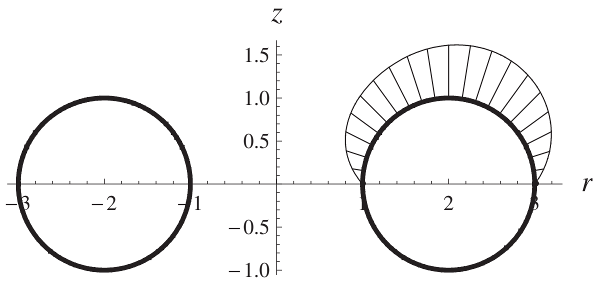

FIG. 5. *Profile of the pressure, $\wp/(v_z\mu)$, on the surface of the solid torus of circular cross-section ($\varkappa = 1$) in the axially symmetric translation along the z-axis (for $z < 0$, the profile is antisymmetric).*

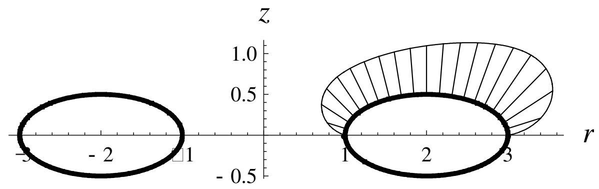

FIG. 6. *Profile of the pressure, $\wp/(v_z\mu)$, on the surface of the solid torus of elliptical cross-section for $\varkappa = 0.5$ in the axially symmetric translation along the z-axis (for $z < 0$, the profile is antisymmetric).*

The developed framework is not, however, limited to the case of smooth bodies.

Remark 9 states that for bodies with nonsmooth surfaces, we need to solve the integral equation (54) with the right-hand side $F(\zeta)$ in the form of (64). Since $f(\zeta) = v_z$ is a 0-harmonically analytic function in $\mathcal{D}^+$, (64), corresponding to the modified generalized Sokhotski–Plemelj formula, reduces to $F(\zeta) = 2v_z$. Thus, based on this fact and Remark 9, we conclude that (54) with the right-hand side of $2v_z$ holds for bodies with smooth and nonsmooth surfaces. In the next example, we solve (54) for a spindle-shaped body and biconvex lens and compare solutions to the analytical solutions obtained in our previous work [32, 31].

Example 10 (axially symmetric translation of a solid spindle and biconvex lens). In the first quadrant of the rz-plane, let the surface of the spindle be parameterized by

$$r(t) = \frac{\cos\left[\frac{2(\pi-\eta)t}{\pi}\right] + \cos\eta}{\sin\eta}, \quad z(t) = \frac{\sin\left[\frac{2(\pi-\eta)t}{\pi}\right]}{\sin\eta}, \quad t \in [0, \pi/2]\,,$$

and let the surface of the biconvex lens be parameterized by

$$r(t) = \frac{\sin\left[(\pi-\eta)\left(1-\frac{2t}{\pi}\right)\right]}{\sin\eta}, \;\; z(t) = \frac{\cos\left[(\pi-\eta)\left(1-\frac{2t}{\pi}\right)\right] + \cos\eta}{\sin\eta}, \;\; t \in [0, \pi/2]\,,$$

where $\eta \in (0, \pi)$[19] is a parameter coinciding with the coordinate η in the bispherical

[17] This spheroid has the size of one spheroid in the bispheroids.

[18] Special functions associated with the geometry of a torus of elliptical cross-section were considered in [15] and could potentially be used for obtaining analytical solutions to the corresponding Stokes flow problem.

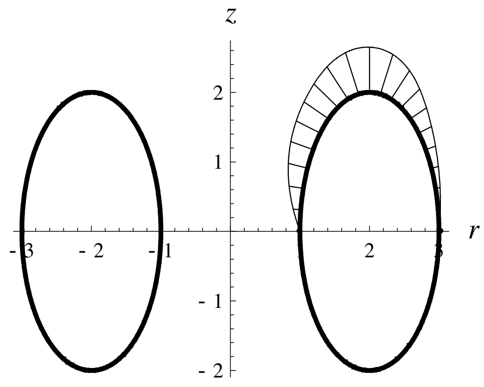

Fig. 7. *Profile of the pressure, $\wp/(v_z\mu)$, on the surface of the solid torus of elliptical cross-section for $\varkappa = 2$ in the axially symmetric translation along the z-axis (for $z < 0$, the profile is antisymmetric).*

Table 2

Normalized drag, $d_z = F_z/(18\pi\mu v_z)$, for the torus of elliptical cross-section in the axially symmetric translation along the z-axis for $\varkappa = 0.5$, 1, and 2.

$\varkappa$	0.5	1.0§	2
d_z	0.8667	0.9072♭	0.9982

§The case corresponds to the torus of circular cross-section.

♭The value coincides with the one in [10]; see also [30].

and toroidal coordinates (see [32, 31]).

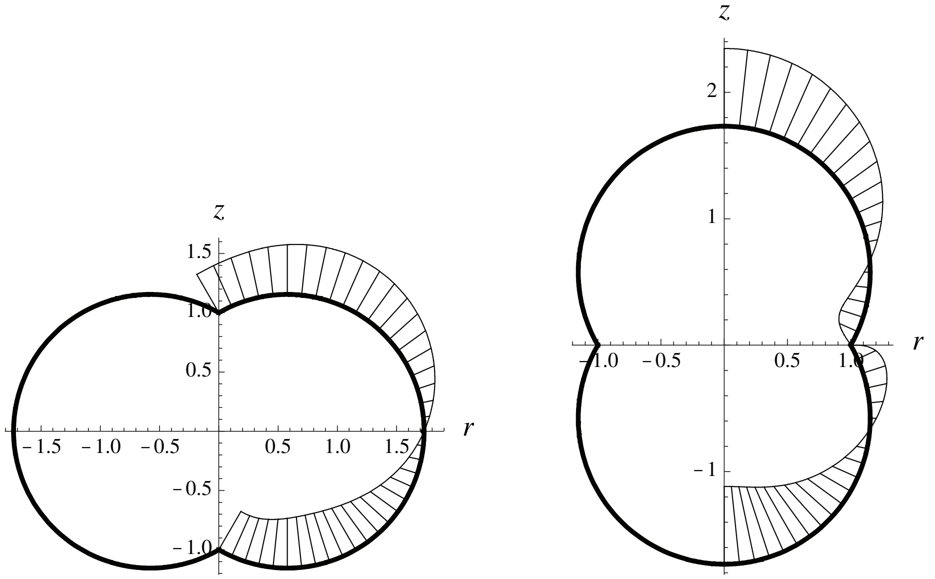
In both cases, the function $G_1^{(0)}$ can be represented on ℓ_+ for $z \geq 0$ by

$$G_1^{(0)}(\zeta(t)) = \sum_{k=1}^{n} (a_k + i\, b_k)\, T_{k-1}\left(\frac{4t}{\pi} - 1\right), \qquad t \in [0, \pi/2], \tag{83}$$

where $T_k(t)$ is the Chebyshev polynomial of the first kind and can be determined on ℓ_+ for $z < 0$ by the symmetry condition $G_1^{(0)}\left(\overline{\zeta}\right) = -\overline{G_1^{(0)}(\zeta)}$ (see Remark 11). It is known that both the pressure and vorticity are unbounded at $t = \pi/2$ for the spindle with $\eta > 2\pi/3$ and are unbounded at $t = 0$ for the biconvex lens with $\eta > \pi/2$ (see [32, 31]). Consequently, the representation (83) is valid for the spindle with $\eta < 2\pi/3$ and for the biconvex lens with $\eta \leq \pi/2$. Figure 8 shows profiles of the pressure on the surface of the solid spindle and biconvex lens with $\eta = \pi/3$ and $n = 16$. For the spindle and biconvex lens, the pressure, $\mu\,\mathrm{Re}\, G_1^{(0)}$, and vorticity, $\mathrm{Im}\, G_1^{(0)}$, on ℓ_+ coincide with the corresponding analytical expressions (see [32, 31]), and the values of the normalized drag $F_z/(6\pi\mu v_z)$ are 1.660188 (spindle) and 1.341761 (biconvex lens), which are accurate to within 10^{-6}, compared to the corresponding values obtained by the stream function approach in [32, 31].

Examples 8 and 10 and can be readily extended to the case of two unequal-size spheroids and two fused unequal-size spheres, respectively.

[19] For $\eta \in (0, \pi/2)$, the spindle resembles an "apple," while the biconvex lens is two fused equal spheres; for $\eta = \pi/2$, surfaces of both the spindle and the lens form a sphere; and for $\eta \in (\pi/2, \pi)$, the spindle resembles a "lemon."



(a) $\wp/(2v_z\mu)$, spindle ($\eta = \pi/3$) (b) $\wp/(2v_z\mu)$, biconvex lens ($\eta = \pi/3$)

FIG. 8. *Profiles of the pressure on the surface of the solid spindle and biconvex lens in the axially symmetric translation along the z-axis:* (a) *$\wp/(2v_z\mu)$, spindle with $\eta = \pi/3$ ("apple");* (b) *$\wp/(2v_z\mu)$, biconvex lens with $\eta = \pi/3$ (two fused equal spheres).*

Appendix. Derivation of Cauchy's integral formula for k-harmonically analytic functions.

In this section, we prove Cauchy's integral formula (24) for k-harmonically analytic functions using the approach of Alexandrov and Soloviev [1], who obtained Cauchy's integral formula for 0-harmonically analytic functions.

Let $\mathcal{D}$ be a region symmetric with respect to the z-axis in the rz-plane and having a smooth, positively oriented boundary $\ell = \ell_+ \bigcup \ell_-$, where ℓ_+ is the part of ℓ in the right half of the rz-plane ($r \geq 0$) and ℓ_- is the reflection of ℓ_+ with respect to the z-axis (ℓ_+ is either a closed curve or an open curve with the endpoints lying on the z-axis).

Let $G^{(k)}(\zeta)$ be a k-harmonically analytic function in the region $\mathcal{D}$. In order for the function $G^{(k)}(\zeta)$ to be represented in the form of Cauchy's integral formula,

$$G^{(k)}(\zeta) = \frac{1}{2\pi i}\oint_\ell G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\,d\tau, \qquad \zeta \in \operatorname{int}\mathcal{D}, \tag{84}$$

the following conditions should hold:

(C1) $\mathcal{W}^{(k)}(\zeta,\tau)$ is a k-harmonically analytic function with respect to the variable $\zeta = r + i\,z$; i.e., it solves the Carleman system (3) with respect to ζ.

(C2) The integral (84) is independent of the form of the curve ℓ enclosing the point ζ.

(C3) $\lim_{\tau\to\zeta}[(\tau-\zeta)(\mathcal{W}^{(k)}(\zeta,\tau) - \frac{1}{\tau-\zeta})] = 0$.

With the condition (7) and the symmetry of the contour ℓ with respect to the z-axis, the representation (84) can be reduced to the integral along the curve ℓ_+:

$$G^{(k)}(\zeta) = \frac{1}{2\pi i}\int_{\ell_+} G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\,d\tau + (-1)^k\overline{G^{(k)}(\tau)}\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)d\overline{\tau}. \tag{85}$$

From (85) and (7), it follows that

$$\mathcal{W}^{(k)}\left(-\overline{\zeta},-\overline{\tau}\right)=-\overline{\mathcal{W}^{(k)}(\zeta,\tau)}. \tag{86}$$

We begin with examining condition (C1). Substituting (85) into (6) and using (86), we obtain

$$\frac{1}{2\pi i}\int_{\ell_+}G^{(k)}(\tau)\mathcal{S}(\zeta,\tau)\,d\tau+(-1)^k\overline{G^{(k)}(\tau)}\mathcal{S}\left(\zeta,-\overline{\tau}\right)d\overline{\tau}=0, \tag{87}$$

where

$$\mathcal{S}(\zeta,\tau)=\frac{\partial}{\partial\overline{\zeta}}\mathcal{W}^{(k)}(\zeta,\tau)-\frac{1}{4r}\left((-1)^k\left(2k+1\right)\mathcal{W}^{(k)}\left(-\overline{\zeta},\tau\right)-\mathcal{W}^{(k)}(\zeta,\tau)\right).$$

Consequently, (87) holds if $\mathcal{S}(\zeta,\tau)=0$. This means that $\mathcal{W}^{(k)}(\zeta,\tau)$ satisfies the equation

$$\frac{\partial}{\partial\overline{\zeta}}\mathcal{W}^{(k)}(\zeta,\tau)-\frac{1}{4r}\left((-1)^k\left(2k+1\right)\mathcal{W}^{(k)}\left(-\overline{\zeta},\tau\right)-\mathcal{W}^{(k)}(\zeta,\tau)\right)=0. \tag{88}$$

Now we consider condition (C2). Let

$$\begin{aligned}U_1(\zeta,\tau)&=\operatorname{Re}\left[G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\right], & U_2(\zeta,\tau)&=\operatorname{Re}\left[(-1)^k\overline{G^{(k)}(\tau)}\mathcal{W}^{(k)}(\zeta,-\overline{\tau})\right],\\ V_1(\zeta,\tau)&=\operatorname{Im}\left[G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\right], & V_2(\zeta,\tau)&=\operatorname{Im}\left[(-1)^k\overline{G^{(k)}(\tau)}\mathcal{W}^{(k)}(\zeta,-\overline{\tau})\right];\end{aligned}$$

then the integral (85) can be rewritten as

$$\begin{aligned}G^{(k)}(\zeta)=\frac{1}{2\pi i}\int_{\ell_+}&\left(U_1(\zeta,\tau)+U_2(\zeta,\tau)\right)dr_1+\left(V_2(\zeta,\tau)-V_1(\zeta,\tau)\right)dz_1\\ &+i\left[\left(U_1(\zeta,\tau)-U_2(\zeta,\tau)\right)dz_1+\left(V_2(\zeta,\tau)+V_1(\zeta,\tau)\right)dr_1\right],\end{aligned} \tag{89}$$

where $r_1=\operatorname{Re}\tau$ and $z_1=\operatorname{Im}\tau$. By Green's theorem, (89) is independent of the form of ℓ_+, i.e., it satisfies (C2) if $\frac{\partial}{\partial r_1}(U_1-U_2)-\frac{\partial}{\partial z_1}(V_1+V_2)=0$ and $\frac{\partial}{\partial z_1}(U_1+U_2)-\frac{\partial}{\partial r_1}(V_2-V_1)=0$, which can be restated as

$$\frac{\partial}{\partial\overline{\tau}}\left(G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\right)-\frac{\partial}{\partial\tau}\left((-1)^k\overline{G^{(k)}(\tau)}\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)\right)=0. \tag{90}$$

Figure 9 shows that Green's theorem is applied to the integral (89) along a closed curve consisting of ℓ_+, ℓ'_+, and auxiliary segments. In the case when ℓ_+ is an open curve with the endpoints lying on the z-axis, $\mathcal{W}^{(k)}(\zeta,\tau)$ should vanish at $\operatorname{Re}\tau=0$; see Figure 9(a).

Since the function $G^{(k)}$ satisfies (6), equation (90) reduces to

$$G^{(k)}(\tau)\,\mathcal{T}_1(\zeta,\tau)-(-1)^k\overline{G^{(k)}(\tau)}\,\mathcal{T}_2(\zeta,\tau)=0, \tag{91}$$

where

$$\begin{aligned}\mathcal{T}_1(\zeta,\tau)&=\frac{\partial}{\partial\overline{\tau}}\mathcal{W}^{(k)}(\zeta,\tau)-\frac{1}{4r_1}\left((-1)^k\left(2k+1\right)\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)+\mathcal{W}^{(k)}(\zeta,\tau)\right),\\ \mathcal{T}_2(\zeta,\tau)&=\frac{\partial}{\partial\tau}\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)-\frac{1}{4r_1}\left((-1)^k\left(2k+\right)\mathcal{W}^{(k)}(\zeta,\tau)+\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)\right).\end{aligned} \tag{92}$$

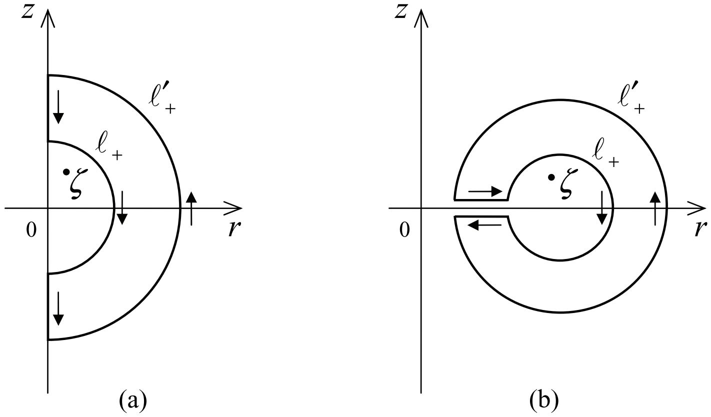


FIG. 9. *Green's theorem is applied to the integral* (89) *along a closed curve consisting of* ℓ_+, ℓ'_+, *and auxiliary segments:* (a) ℓ_+ *is an open curve with the endpoints lying on the* z*-axis;* (b) ℓ_+ *is a closed curve.*

It follows from (86) and (92) that $\mathcal{T}_2(\zeta,\tau) = -\overline{\mathcal{T}_1\left(-\overline{\zeta},\tau\right)}$, and consequently, (91) will hold for any $G^{(k)}$ if $\mathcal{T}_1(\zeta,\tau)=0$; i.e., $\mathcal{W}^{(k)}(\zeta,\tau)$ solves the equation

$$\frac{\partial}{\partial\overline{\tau}}\mathcal{W}^{(k)}(\zeta,\tau) - \frac{1}{4r_1}\Big((-1)^k\,(2k+1)\,\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right) + \mathcal{W}^{(k)}(\zeta,\tau)\Big) = 0. \tag{93}$$

Consequently, $\mathcal{W}^{(k)}(\zeta,\tau)$ solves (88) and (93). Noticing the similarity between (14) and (88), we can represent $\mathcal{W}^{(k)}(\zeta,\tau)$ in the form similar to (9)

$$\mathcal{W}^{(k)}(\zeta,\tau) = \frac{1}{r^k\,|r|}\int_{-\overline{\zeta}}^{\zeta} f(t,\tau)\,(\zeta-t)^{k-\frac{1}{2}}\left(\overline{\zeta}+t\right)^{k+\frac{1}{2}}dt, \tag{94}$$

where $f(t,\tau)$ is an analytic function in the region $\mathcal{D}$ with respect to t except for the points $t=\tau$ and $t=-\overline{\tau}$ lying on the boundary of $\mathcal{D}$. If $\mathcal{D}$ is unbounded, then we also require $f(t,\tau)\sim\mathcal{O}\left(|t|^{-2k-1-\epsilon}\right)$, $\epsilon>0$, at $|t|\to\infty$. However, in contrast to the representation (9), $f(t,\tau)$ is not required to satisfy $f\left(-\overline{\tau}\right)=\overline{f(\tau)}$. Making two branch cuts connecting each of the points ζ and $-\overline{\zeta}$ with the boundary $\mathcal{D}$, we can show that (94) is independent of the form of a simple curve that connects $-\overline{\zeta}$ and ζ in $\mathcal{D}$ and contains neither τ nor $-\overline{\tau}$ (similar to that in Proposition 1).

Substituting (94) into (93), we obtain an equation for $f(t,\tau)$:

$$\frac{\partial}{\partial\overline{\tau}}f(t,\tau) - \frac{1}{4r_1}\left((-1)^k\,(2k+1)\,f\left(t,-\overline{\tau}\right) + f(t,\tau)\right) = 0. \tag{95}$$

The similarity between (14) and (93) implies that the simplest solution to (95) can be determined by

$$f(t,\tau) = \frac{\left(k+\frac{1}{2}\right)r_1^k\,|r_1|}{(\tau-t)^{k+\frac{3}{2}}\left(\overline{\tau}+t\right)^{k+\frac{1}{2}}},$$

which is an analytic function with respect to t in the whole plane except for the points $t=\tau$ and $t=-\overline{\tau}$. Thus, $\mathcal{W}^{(k)}(\zeta,\tau)$, represented by (94), takes the form

$$\mathcal{W}^{(k)}(\zeta,\tau) = \left(k+\frac{1}{2}\right)\left(\frac{r_1}{r}\right)^k\left|\frac{r_1}{r}\right|\int_{-\overline{\zeta}}^{\zeta}\frac{1}{(\tau-t)(\zeta-t)}\left[\frac{\left(\overline{\zeta}+t\right)(\zeta-t)}{\left(\overline{\tau}+t\right)(\tau-t)}\right]^{k+\frac{1}{2}}dt. \tag{96}$$

It is seen that (96) satisfies (86) and the condition $\mathcal{W}^{(k)}(\zeta,\tau)=0$ at $\operatorname{Re}\tau=r_1=0$. First, we evaluate (96) and then show that (C3) holds. In order to evaluate (96), we assume that $r>0$ and consider two cases: $r_1>0$ and $r_1<0$, which correspond to $\mathcal{W}^{(k)}(\zeta,\tau)$ and $\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)$ in (85), respectively.

With four branch cuts connecting each of the points ζ, $-\overline{\zeta}$, τ, and $-\overline{\tau}$ with infinite points, the integral (96) does not depend on a curve connecting $-\overline{\zeta}$ and ζ, and consequently, for $\tau\neq\zeta$, we can choose a curve $t=t(x)$ determined by

$$t(x)=\frac{\zeta\left(\overline{\tau}-\overline{\zeta}\right)-\overline{\zeta}\,\overline{\tau}\cos^2 x}{\overline{\tau}+\zeta-\left(\zeta+\overline{\zeta}\right)\sin^2 x},\qquad x\in[0,\pi/2],\tag{97}$$

for which

$$\frac{\left(t(x)+\overline{\zeta}\right)\left(\zeta+\overline{\tau}\right)}{\left(t(x)+\overline{\tau}\right)\left(\zeta+\overline{\zeta}\right)}=\sin^2 x,\qquad x\in[0,\pi/2].$$

In the case when $r_1>0$, the integral (96) along the curve (97) reduces to

$$\mathcal{W}^{(k)}(\zeta,\tau)=2^{-2k}(2k+1)\frac{\lambda(\zeta,\tau)^{2k}\left(1-\lambda(\zeta,\tau)^2\right)}{\tau-\zeta}\left|\frac{\tau+\overline{\tau}}{\zeta+\overline{\tau}}\right|\int_0^{\frac{\pi}{2}}\frac{(\sin[2x])^{2k}\sin^2 x}{\left(1-\lambda^2\sin^2 x\right)^{k+\frac{3}{2}}}\,dx,\tag{98}$$

where $\lambda(\zeta,\tau)\in[0,1]$ is a real-valued function defined by (27). With the definition of the hypergeometric function (26), the integral (98) takes the form

$$\mathcal{W}^{(k)}(\zeta,\tau)=\frac{\Omega_+^{(k)}(\zeta,\tau)}{\tau-\zeta},\qquad \operatorname{Re}\zeta\geq 0,\quad \operatorname{Re}\tau\geq 0,$$

where $\Omega_+^{(k)}(\zeta,\tau)$ is determined by (25a).

In the case when $r_1<0$, we have

$$\begin{aligned}&\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)\\&=(-1)^{k+1}\left(k+\frac{1}{2}\right)\left(\frac{r_1}{r}\right)^k\left|\frac{r_1}{r}\right|\int_{-\overline{\zeta}}^{\zeta}\frac{1}{\left(\overline{\tau}+t\right)\left(\zeta-t\right)}\left[\frac{\left(\overline{\zeta}+t\right)\left(\zeta-t\right)}{\left(\overline{\tau}+t\right)\left(\tau-t\right)}\right]^{k+\frac{1}{2}}dt.\end{aligned}\tag{99}$$

Using the same curve (97), we obtain

$$\mathcal{W}^{(k)}\left(\zeta,-\overline{\tau}\right)=(-1)^{k+1}\frac{\Omega_-^{(k)}(\zeta,\tau)}{\overline{\tau}+\zeta},\qquad \operatorname{Re}\zeta\geq 0,\quad \operatorname{Re}\tau\geq 0,$$

where $\Omega_-^{(k)}(\zeta,\tau)$ is determined by (25b).

Now we are ready to verify (C3). Note that $\lambda\to 1-$ as $\tau\to\zeta$. Using the asymptotic representation for the hypergeometric functions

$$\begin{aligned}\mathbb{F}\left(k+\tfrac{3}{2},k+\tfrac{3}{2},2(k+1),\lambda^2\right)=&\frac{\Gamma(2(k+1))}{\left[\Gamma\left(k+\frac{3}{2}\right)\right]^2}\,\frac{1}{1-\lambda^2}+\frac{\Gamma(2(k+1))}{\left[\Gamma\left(k+\frac{1}{2}\right)\right]^2}\ln\left(1-\lambda^2\right)\\&+\mathcal{O}\left(1\right)\ \text{ as }\lambda\to 1-,\end{aligned}$$

$$\begin{aligned}\mathbb{F}\left(k+\tfrac{1}{2},k+\tfrac{3}{2},2(k+1),\lambda^2\right)=&-\frac{\Gamma(2(k+1))}{\Gamma\left(k+\frac{1}{2}\right)\Gamma\left(k+\frac{3}{2}\right)}\\&\times\left(\ln(1-\lambda^2)+2\left(\frac{1}{2k+1}+\gamma+\psi\left(k+\tfrac{1}{2}\right)\right)\right)\\&+\mathcal{O}\left((1-\lambda^2)\right)\ \text{ as }\lambda\to 1-,\end{aligned}$$

where γ is the Euler constant and $\psi(\cdot)$ is the digamma function, we have $\lim_{\tau\to\zeta}\Omega_+^{(k)}(\zeta,\tau) = 1$. Similarly, the asymptotic form of $\Omega_-^{(k)}(\zeta,\tau)$ as $\tau\to\zeta$ is determined by (28). In other words, the function $\Omega_-^{(k)}(\zeta,\tau)$ has a logarithmic singularity at $\tau=\zeta$,[†] and consequently, the difference $\mathcal{W}^{(k)}(\zeta,\tau)-\frac{1}{\tau-\zeta}$ has only integrable (logarithmic) singularity.

Finally, we show that Cauchy's integral formula (84) holds. Let C_ρ be the positively oriented circle of the radius ρ with the center at ζ; then the integral (85) along ℓ_+ equals the integral over C_ρ:

$$\begin{aligned}&\frac{1}{2\pi i}\int_{\ell_+} G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\,d\tau+(-1)^k\overline{G^{(k)}(\tau)}\mathcal{W}^{(k)}\,(\zeta,-\overline{\tau})\,d\overline{\tau}\\ &=\frac{1}{2\pi i}\oint_{C_\rho}\underbrace{G^{(k)}(\tau)\,\frac{\Omega_+^{(k)}(\zeta,\tau)}{\tau-\zeta}\,d\tau}_{I_1}-\underbrace{\overline{G^{(k)}(\tau)}\,\frac{\Omega_-^{(k)}(\zeta,\tau)}{\overline{\tau}+\zeta}\,d\overline{\tau}}_{I_2},\quad \zeta\in\operatorname{int}\mathcal{D}.\end{aligned}\tag{100}$$

Indeed, we can form a closed simple curve, consisting of ℓ_+, the circle C_ρ, and auxiliary segments (see Figure 10), that bounds the region in which $G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)$ has continuous partial derivatives, and then apply Green's theorem. Let $\tau=\zeta+\rho\,\mathrm{e}^{i\varphi}$. Since $\Omega_-^{(k)}(\zeta,\tau)$ has only logarithmic singularity as $\tau\to\zeta$, the integral I_2 in (100) vanishes at $\rho\to 0$; and since $\lim_{\tau\to\zeta}\Omega_+^{(k)}(\zeta,\tau)=1$, the integral I_1 reduces to $G^{(k)}(\zeta)$ when $\rho\to 0$, which completes the proof of Cauchy's integral formula for k-harmonically analytic functions.

Acknowledgment. We are grateful to the anonymous referees for their valuable comments and suggestions, which helped to improve the quality of the paper.

THE FRAMEWORK OF k-HARMONICALLY ANALYTIC FUNCTIONS FOR THREE-DIMENSIONAL STOKES FLOW PROBLEMS, PART II*

MICHAEL ZABARANKIN†

Abstract. A solution form representing the velocity field and pressure for asymmetric three-dimensional (3D) Stokes flows has been constructed in terms of three k-harmonically analytic functions. It has also been shown that it uniquely determines an external velocity field vanishing at infinity. With the obtained solution form, problems of 3D Stokes flows due to asymmetric motions of solid bodies of revolution have been reduced to boundary-value problems for the three k-harmonically analytic functions, and the resisting force and torque, exerted on bodies in corresponding motions, have been expressed in terms of the k-harmonically analytic functions entering the solution form. For regions, in which Laplace's equation admits separation of variables, the boundary-value problems can be solved in closed form via series or integral representations of k-harmonically analytic functions in corresponding curvilinear coordinates. This approach has been demonstrated for asymmetric translation and rotation of solid sphere and solid prolate and oblate spheroids. As the second approach, the boundary-value problems have been reduced to integral equations based on Cauchy's integral formula for k-harmonically analytic functions. As an illustration, the integral equations have been solved for asymmetric translation and rotation of solid bispheroids and a solid torus of elliptical cross-section for various values of a geometrical parameter.

Key words. asymmetric Stokes flows, generalized analytic functions, exact solution, generalized Cauchy's integral formula, integral equation

1. Introduction.

This article presents the second part of the developed two-part framework of k-harmonically analytic functions in application to three-dimensional (3D) Stokes flows. In the first part [32], we obtained Cauchy's integral formula for k-harmonically analytic functions and constructed a solution form for the velocity field and pressure for axially symmetric Stokes flows in terms of two 0-harmonically analytic functions. This work extends all the results obtained in [32] to *asymmetric* 3D Stokes flows.

1.1. Stokes equations.

The behavior of steady flows of a viscous incompressible fluid under the assumption of zero (low) Reynolds number (so-called *Stokes creeping flows*) is described by the Stokes equations

$$\mu\,\boldsymbol{\Delta}\mathbf{u} = \operatorname{grad}\wp, \qquad \operatorname{div}\mathbf{u} = 0, \tag{1}$$

where $\mathbf{u}$ is the fluid velocity field, $\wp$ is the pressure in the fluid, μ is the shear viscosity, and $\boldsymbol{\Delta}\mathbf{u} \equiv \operatorname{grad}(\operatorname{div}\mathbf{u}) - \operatorname{curl}(\operatorname{curl}\mathbf{u})$. In (1), the first equation is known as the Stokes creeping flow equation and the second one is the equation of continuity; see, e.g., [10, 9]. The model (1) can also be represented in the form $\operatorname{grad}\wp = -\mu\operatorname{curl}(\operatorname{curl}\mathbf{u})$, $\operatorname{div}\mathbf{u} = 0$, whence it follows that the pressure $\wp$ and vorticity $\boldsymbol{\omega} = \operatorname{curl}\mathbf{u}$ are related

scalar and vectorial potentials, i.e., they satisfy $\operatorname{grad}\wp = -\mu \operatorname{curl}\boldsymbol{\omega}$ with $\operatorname{div}\boldsymbol{\omega} = 0$; see [33, 32].

In this work, we consider asymmetric 3D Stokes flows due to motion of a solid body of revolution. By asymmetric motion of the body, we will understand translation along and rotation around axes transversal to the axis of revolution. Let S be the surface of the body and let the body move in the fluid with the velocity $\mathbf{u}_0$. The no-slip boundary conditions on the surface of the body are formulated by

$$\mathbf{u} = \mathbf{u}_0 \quad \text{on} \quad S, \tag{2}$$

and also the velocity field $\mathbf{u}$ and pressure $\wp$ vanish at infinity:

$$\mathbf{u}|_{\infty} = 0, \qquad \wp|_{\infty} = 0. \tag{3}$$

It is known that the Stokes flow problem (1)–(3) has a unique solution; see, e.g., [2, section 4.9]. This fact follows from the following proposition.

Proposition 1 (homogeneous Stokes flow problem). *The problem* (1) *and* (3) *with zero boundary conditions* $\mathbf{u}|_S = 0$ *has only a zero solution, i.e.,* $\mathbf{u} \equiv 0$*, in the corresponding outer region.*

Proof. The proof can be found in [2, section 4.9]. First, it is shown that the Stokes equations with (3) and $\mathbf{u}|_S = 0$ imply $\operatorname{curl}\mathbf{u} = 0$, and then it is proved that the problem $\operatorname{div}\mathbf{u} = 0$, $\operatorname{curl}\mathbf{u} = 0$ subject to (3) and $\mathbf{u}|_S = 0$ has only a zero solution. For the last problem, special attention is paid to multiply connected regions. For details, see [2, sections 2.8, 4.9]. □

Proposition 1 will be central in establishing uniqueness of solutions for the velocity field represented in terms of k-harmonically analytic functions.

Let (r, φ, z) be the cylindrical coordinate system with the basis $(\mathbf{e}_r, \mathbf{e}_\varphi, \mathbf{k})$. Without loss of generality, we can represent the velocity field $\mathbf{u}$ and pressure $\wp$ by

$$\begin{aligned}\mathbf{u}(r,\varphi,z) = \sum_{k=0}^{\infty} u_r^{(k)}(r,z) \left\{ \begin{array}{c} \cos \\ \sin \end{array} (k\varphi) \right\} \mathbf{e}_r + u_\varphi^{(k)}(r,z) \left\{ \begin{array}{c} \sin \\ -\cos \end{array} (k\varphi) \right\} \mathbf{e}_\varphi \\ + u_z^{(k)}(r,z) \left\{ \begin{array}{c} \cos \\ \sin \end{array} (k\varphi) \right\} \mathbf{k}\end{aligned} \tag{4}$$

and

$$\wp(r,\varphi,z) = \sum_{k=0}^{\infty} \wp^{(k)}(r,z) \left\{ \begin{array}{c} \cos \\ \sin \end{array} (k\varphi) \right\}, \tag{5}$$

where the choice of either upper or lower functions in the curly brackets depends on whether $\mathbf{u}$ and $\wp$ are even or odd functions with respect to φ. If $\mathbf{u}$ and $\wp$ are neither odd nor even, they are represented by sums of series, corresponding to even and odd parts of $\mathbf{u}$ and $\wp$, respectively.

For convenience, we denote

$$u_1^{(k)} = u_r^{(k)} - u_\varphi^{(k)}, \qquad u_2^{(k)} = u_r^{(k)} + u_\varphi^{(k)}. \tag{6}$$

The first equation in (1) reduces to a series of equations for $k \in \mathbb{Z}_0^+$:

$$\mu\,\Delta_{k-1} u_1^{(k)} = \left(\frac{\partial}{\partial r} + \frac{k}{r}\right)\wp^{(k)}, \quad \mu\,\Delta_{k+1} u_2^{(k)} = \left(\frac{\partial}{\partial r} - \frac{k}{r}\right)\wp^{(k)}, \quad \mu\,\Delta_k u_z^{(k)} = \frac{\partial}{\partial z}\wp^{(k)}, \tag{7}$$

where Δ_k denotes the so-called k-harmonic operator:

$$\Delta_k \equiv \frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{\partial^2}{\partial z^2} - \frac{k^2}{r^2}. \tag{8}$$

Similarly, the continuity equation $\operatorname{div} \mathbf{u} = 0$ reduces to

$$\left(\frac{\partial}{\partial r} - \frac{k-1}{r}\right) u_1^{(k)} + \left(\frac{\partial}{\partial r} + \frac{k+1}{r}\right) u_2^{(k)} + 2\frac{\partial}{\partial z} u_z^{(k)} = 0. \tag{9}$$

Since $\wp(r,\varphi,z)$ satisfies $\operatorname{div}(\operatorname{grad}\wp) = 0$, the function $\wp^{(k)}(r,z)$ is k-harmonic, i.e.,

$$\Delta_k\, \wp^{(k)} = 0, \tag{10}$$

and consequently, it follows from (7) and (10) that

$$\Delta_{k-1}^2\, u_1^{(k)} = 0, \qquad \Delta_{k+1}^2\, u_2^{(k)} = 0, \qquad \Delta_k^2\, u_z^{(k)} = 0. \tag{11}$$

In the axially symmetric case, all equations (7)–(11) are considered for $k = 0$, and in the case of asymmetric motion of a body of revolution, it is sufficient to consider (7)–(11) for only $k = 1$.

There are two well-known solution forms for the Stokes flow problem (1)–(3): one in terms of a stream function, which identically solves (9) for $k = 0$ and is applicable only for the axially symmetric case (see [9]), and the other due to Dean and O'Neill [6], which should satisfy the continuity equation. Both solution forms are mainly used for canonical regions, i.e., those in which Laplace's equation admits separation of variables. Stream-function solutions to the axially symmetric Stokes flow problem were obtained for particles of virtually all known canonical shapes, including *sphere* [23], *prolate* and *oblate spheroids* [14, 9], *circular disk* [14, 9], *spherical cap* [16, 5, 25], *two spheres* [22], *torus* [17, 28], *spindle* [18, 35], and *lens* [16, 34]. As for asymmetric problems, exact solutions in the form of Dean and O'Neill's were also constructed for the majority of particles of canonical shape as follows: *two spheres* [15, 27, 13], *torus* [28, 8, 24], *two fused equal spheres* [30], and *spindle* [31].

For particles of arbitrary shape, exact solutions to 3D Stokes flow problems can be obtained by integral equation approaches [20, 21]. A well-known approach uses integral representations for harmonic functions via Green's functions [21, 29]. Yet another approach can be contemplated based on the fact that for an incompressible isotropic elastic medium, the Lamé equation formally corresponds to the Stokes model (1) (see [25, 35]), and that in the axially symmetric case, the displacement vector $\mathbf{u}$ can be represented by a generalized Kolosov–Muskhelishvili formula in terms of two p-analytic functions (with $p = r$) and their derivatives [19, 1]. However, to the best of our knowledge, no representation of an *asymmetric* 3D velocity field in terms of either generalized analytic or pseudoanalytic functions has been encountered in the existing literature. Coupled with a corresponding generalized Cauchy's integral formula, such a representation would allow one to reduce 3D Stokes flow problems to integral equations.

As a central result of this work, we obtain a solution form for the velocity field and pressure for asymmetric 3D Stokes flow problems in terms of three k-harmonically analytic functions. This solution form is similar to Goursat's formula representing a solution to a 2D biharmonic equation via two ordinary analytic functions. Its main advantage is that, in contrast to Dean and O'Neill's solution form, it identically satisfies the continuity equation, and in contrast to generalized Kolosov–Muskhelishvili formulae, it does not involve derivatives of k-harmonically analytic functions.[1] It is applicable to obtaining closed-form analytical solutions for the canonical regions as well as to obtaining exact solutions via integral equations for arbitrary regions.

1.2. k-harmonically analytic functions. Here we define only k-harmonically analytic functions and refer the reader to the first part of this work [32], in which we derived a Cauchy's integral formula for k-harmonically analytic functions and constructed series representations for k-harmonically analytic functions for the regions exterior to a sphere and prolate and oblate spheroids.

For each $k \in \mathbb{Z}_0^+$, k-harmonically analytic functions $G^{(k)}(r,z) = U^{(k)}(r,z) + i\,V^{(k+1)}(r,z)$, $i = \sqrt{-1}$, constitute a class of generalized analytic functions [3, 4, 19, 26] and are determined by a particular case of the Bers–Vekua system

$$\left(\frac{\partial}{\partial r} - \frac{k}{r}\right) U^{(k)} = \frac{\partial}{\partial z} V^{(k+1)}, \qquad \frac{\partial}{\partial z}\, U^{(k)} = -\left(\frac{\partial}{\partial r} + \frac{k+1}{r}\right) V^{(k+1)}. \tag{12}$$

In [33], we showed that (12) arises from an asymmetric 3D case of the relationship

$$\operatorname{grad}\phi = -\operatorname{curl}\boldsymbol{\Lambda}, \quad \operatorname{div}\boldsymbol{\Lambda} = 0 \tag{13}$$

for a scalar field ϕ and vectorial field $\boldsymbol{\Lambda}$, which in view of (13) are called related potentials. In the 2D case in Cartesian coordinates, (13) reduces to the classical Cauchy–Riemann system for ordinary analytic functions, and in the axially symmetric 3D case in the cylindrical coordinates (r, φ, z),[2] (13) defines so-called r-analytic functions; see [33]. In the asymmetric 3D case, (13) reduces to (12), which relates kth harmonics of ϕ and $\boldsymbol{\Lambda}$ in the cylindrical coordinates with respect to the angular coordinate φ.

It follows from (12) that $U^{(k)}$ and $V^{(k+1)}$ are k-harmonic and $(k+1)$-harmonic functions, respectively:

$$\Delta_k U^{(k)} = 0 \quad \text{and} \quad \Delta_{k+1} V^{(k+1)} = 0.$$

To emphasize this fact, we call $G^{(k)}$ satisfying (12) a *k-harmonically analytic* function. In particular, for $k = 0$, the system (12) defines the class of r-analytic functions; see [33, 34, 35].

Let $\zeta = r + i\,z$ be a complex variable. Introducing the derivative $\frac{\partial}{\partial\bar\zeta} = \frac{1}{2}\left(\frac{\partial}{\partial r} + i\,\frac{\partial}{\partial z}\right)$, we can represent the system (12) in the form

$$\frac{\partial G^{(k)}}{\partial\bar\zeta} = \frac{1}{4r}\left((2k+1)\,\overline{G^{(k)}} - G^{(k)}\right). \tag{14}$$

[1] For example, in the asymmetric problem of Stokes flows due to transversal translation of a solid torus or two solid spheres (see [8, 27]), the continuity equation with Dean and O'Neill's solution form reduces to a second-order difference equation. This procedure relies substantially on the peculiar properties of the special functions associated with the bispherical and toroidal coordinates and is unlikely to be extended to the problem with a body of arbitrary shape. Also, the integral equation for the axially symmetric problem of an elastic isotropic medium obtained via generalized Kolosov–Muskhelishvili formulae (see [1, equation (46.40)]) involves a derivative of a generalized Cauchy's kernel, which complicates numerical analysis of the equation.

[2] In this case, the z-axis is the axis of revolution, and ϕ and $\boldsymbol{\Lambda}$ are independent of the angular coordinate φ.

Without assuming analyticity, we will formally write $G^{(k)}(\zeta) = G^{(k)}(r,z)$. A k-harmonically analytic function can be defined for $r < 0$ by introducing the symmetry condition

$$G^{(k)}\left(-\overline{\zeta}\right) = (-1)^k\overline{G^{(k)}(\zeta)}. \tag{15}$$

This condition is dictated by the representation of the velocity field in terms of k-harmonically analytic functions.

The paper is organized into three sections. Section 2 constructs the solution form for asymmetric Stokes flow problems in terms of three k-harmonically analytic functions; proves that the solution form uniquely determines an external velocity field vanishing at infinity; expresses the resisting force and torque, exerted on a solid body of revolution in the Stokes flow in terms of the k-harmonically analytic functions entering the solution form; and reduces Stokes flow problems to integral equations based on Cauchy's integral formula for k-harmonically analytic functions. Section 3 demonstrates the solution form in obtaining analytical solutions to the problems of Stokes flows due to transversal translation and rotation of a solid sphere and solid prolate and oblate spheroids. It also solves the integral equations for transversal translation and rotation of solid bispheroids and a solid torus of elliptical cross-section for various values of a geometrical parameter. The appendix presents two auxiliary results dealing with implementation of the necessary and sufficient condition for a function to be k-harmonically analytic in an outer region and vanishing at infinity.

2. Stokes equations in the asymmetric case.

This section constructs a representation for the velocity field and pressure for asymmetric 3D Stokes flows in terms of three k-harmonically analytic functions.

To simplify notation, we will write a function of the variables of r and z as the function of ζ without assuming analyticity.

PROPOSITION 2 (representation for the velocity field and pressure). *Let $G_1^{(k-1)}(\zeta) = U_1^{(k-1)}(\zeta) + i\,V_1^{(k)}(\zeta)$, $G_2^{(k-1)}(\zeta) = U_2^{(k-1)}(\zeta) + i\,V_2^{(k)}(\zeta)$, and $G_3^{(k)}(\zeta) = U_3^{(k)}(\zeta) + i\,V_3^{(k+1)}(\zeta)$ be k-harmonically analytic functions satisfying* (12) *for $k-1$, $k-1$, and k, respectively, and vanishing at $|\zeta| \to \infty$. Then for $k \geq 1$, the components of the velocity field in the asymmetric case of the Stokes equations can be represented in the form*

(16)

$$2\left(u_z^{(k)}(\zeta) + i\,u_r^{(k)}(\zeta)\right) = \left(\frac{k+1}{2k-1}\,r - i\frac{k-2}{2k-1}\,z\right)G_1^{(k-1)}(\zeta) + i\,G_2^{(k-1)}(\zeta) + G_3^{(k)}(\zeta),$$

$$2u_\varphi^{(k)}(\zeta) = \operatorname{Im}\left[\frac{k-2}{2k-1}(r+i\,z)\,G_1^{(k-1)}(\zeta) - i\,G_2^{(k-1)}(\zeta) + G_3^{(k)}(\zeta)\right],$$

and the kth harmonic of the pressure is determined by

$$\wp^{(k)}(\zeta) = \mu\,\operatorname{Im} G_1^{(k-1)}(\zeta), \quad k \geq 1. \tag{17}$$

Proof. For $k \geq 1$, the components $u_1^{(k)}$, $u_2^{(k)}$, and $u_z^{(k)}$ satisfy (7) and (9). We denote $\wp^{(k)}(\zeta) = V_1^{(k)}(\zeta)$, where $V_1^{(k)}$ is a k-harmonic function. Since $\wp^{(k)}(\zeta)$ vanishes at $|\zeta| \to \infty$, there exists a unique $(k-1)$-harmonic function $U_1^{(k-1)}(\zeta)$ also vanishing at $|\zeta| \to \infty$ such that $U_1^{(k-1)}$ and $V_1^{(k)}$ form a $(k-1)$-harmonically analytic function $G_1^{(k-1)}(\zeta) = U_1^{(k-1)}(\zeta) + i\,V_1^{(k)}(\zeta)$; see [33, Proposition 1]. Using the system (12) for

$k-1$, we can restate the Stokes equations (7) as

$$\begin{aligned}
\Delta_{k-1} u_1^{(k)} &= \left(\frac{\partial}{\partial r} + \frac{k}{r}\right) V_1^{(k)} = -\frac{\partial}{\partial z} U_1^{(k-1)}, \\
\Delta_{k+1} u_2^{(k)} &= \left(\frac{\partial}{\partial r} - \frac{k}{r}\right) V_1^{(k)}, \\
\Delta_k u_z^{(k)} &= \frac{\partial}{\partial z} V_1^{(k)} = \left(\frac{\partial}{\partial r} - \frac{k-1}{r}\right) U_1^{(k-1)}.
\end{aligned} \tag{18}$$

With the identities

$$\begin{aligned}
&\Delta_{k-1}\left(r\, V_1^{(k)}\right) = 2\left(\frac{\partial}{\partial r} + \frac{k}{r}\right) V_1^{(k)}, \qquad \Delta_{k-1}\left(z\, U_1^{(k-1)}\right) = 2\frac{\partial}{\partial z} U_1^{(k-1)}, \\
&\Delta_{k+1}\left(r\, V_1^{(k)}\right) = 2\left(\frac{\partial}{\partial r} - \frac{k}{r}\right) V_1^{(k)}, \qquad \Delta_{k}\left(r\, U_1^{(k-1)}\right) = 2\left(\frac{\partial}{\partial r} - \frac{k-1}{r}\right) U_1^{(k-1)}, \\
&\Delta_k\left(z\, V_1^{(k)}\right) = 2\frac{\partial}{\partial z} V_1^{(k)},
\end{aligned} \tag{19}$$

equations (18) are integrated, and the components $u_1^{(k)}$, $u_2^{(k)}$, and $u_z^{(k)}$ are represented in the form

$$\begin{aligned}
u_1^{(k)}(\zeta) &= a\, r\, V_1^{(k)}(\zeta) + b\, z\, U_1^{(k-1)}(\zeta) + U_2^{(k-1)}(\zeta), \\
u_2^{(k)}(\zeta) &= \frac{1}{2}\, r\, V_1^{(k)}(\zeta) + V_3^{(k+1)}(\zeta), \\
u_z^{(k)}(\zeta) &= c\, z\, V_1^{(k)}(\zeta) + d\, r\, U_1^{(k-1)}(\zeta) + W^{(k)}(\zeta),
\end{aligned} \tag{20}$$

where a, b, c, and d are real-valued constants and $U_2^{(k-1)}$, $V_3^{(k+1)}$, and $W^{(k)}$ are arbitrary functions that satisfy

$$\Delta_{k-1} U_2^{(k-1)} = 0, \qquad \Delta_{k+1} V_3^{(k+1)} = 0, \qquad \Delta_k W^{(k)} = 0$$

and vanish at $|\zeta| \to \infty$. Substituting (20) into (18), we have

$$2a - 2b = 1, \qquad 2c + 2d = 1. \tag{21}$$

Then substituting (20) into (9) and using (12) for $k-1$, we obtain

$$\left(\frac{\partial}{\partial r} - \frac{k-1}{r}\right) U_2^{(k-1)} + \left(\frac{\partial}{\partial r} + \frac{k+1}{r}\right) V_3^{(k+1)} + 2\frac{\partial}{\partial z} W^{(k)} = 0, \tag{22}$$

provided that

$$-a + 2d = \frac{1}{2}, \qquad b + 2c = 0, \qquad 2(1-k)a + 2c = -1. \tag{23}$$

As in the axially symmetric case [32, Proposition 7], (21) and (23) are dependent. Indeed, adding $a - b = 1/2$, $-a + 2d = 1/2$, and $b + 2c = 0$, we have $2c + 2d = 1$. Excluding, for example, $2c + 2d = 1$ from (21) and (23), we obtain the unique solution to the remaining four equations:

$$a = \frac{3}{2(2k-1)}, \quad b = -\frac{k-2}{2k-1}, \quad c = \frac{k-2}{2(2k-1)}, \quad d = \frac{k+1}{2(2k-1)},$$

where $2k - 1 \neq 0$ for any integer k.

Equation (22) becomes an identity for $W^{(k)}(\zeta) = \frac{1}{2}(U_3^{(k)}(\zeta) - V_2^{(k)}(\zeta))$, where $V_2^{(k)}(\zeta)$ is the imaginary part of the $(k-1)$-harmonically analytic function $G_2^{(k-1)}(\zeta) = U_2^{(k-1)}(\zeta) + i\,V_2^{(k)}(\zeta)$ and $U_3^{(k)}(\zeta)$ is the real part of the k-harmonically analytic function $G_3^{(k)}(\zeta) = U_3^{(k)}(\zeta) + i\,V_3^{(k+1)}(\zeta)$. Under the condition that $G_2^{(k-1)}$ and $G_3^{(k)}$ vanish at infinity, $G_2^{(k-1)}$ and $G_3^{(k)}$ are uniquely determined by $U_2^{(k-1)}$ and $V_3^{(k+1)}$, respectively; see [33, Proposition 1].

Consequently, the representation (20) takes the form

(24)
$$\begin{aligned}
u_1^{(k)}(\zeta) &= \frac{3}{2(2k-1)}\,r\,V_1^{(k)}(\zeta) - \frac{k-2}{2k-1}\,z\,U_1^{(k-1)}(\zeta) + U_2^{(k-1)}(\zeta),\\
u_2^{(k)}(\zeta) &= \frac{1}{2}\,r\,V_1^{(k)}(\zeta) + V_3^{(k+1)}(\zeta),\\
u_z^{(k)}(\zeta) &= \frac{k-2}{2(2k-1)}\,z\,V_1^{(k)}(\zeta) + \frac{k+1}{2(2k-1)}\,r\,U_1^{(k-1)}(\zeta) + \frac{1}{2}\left(U_3^{(k)}(\zeta) - V_2^{(k)}(\zeta)\right).
\end{aligned}$$

With the relationships $u_r^{(k)} = \frac{1}{2}(u_1^{(k)} + u_2^{(k)})$ and $u_\varphi^{(k)} = \frac{1}{2}(u_2^{(k)} - u_1^{(k)})$, the representation (16) follows from (24). □

PROPOSITION 3. *Another solution form for the asymmetric velocity field in terms of three k-harmonically analytic functions vanishing at infinity is given by*

(25)
$$\begin{aligned}
2\left(u_z^{(k)}(\zeta) + i\,u_r^{(k)}(\zeta)\right) &= \left(\frac{k+2}{2k+1}\,z + i\frac{k-1}{2k+1}\,r\right) G_1^{(k)}(\zeta) + i\,G_2^{(k-1)}(\zeta) + G_3^{(k)}(\zeta),\\
2u_\varphi^{(k)}(\zeta) &= \operatorname{Im}\left[\frac{k+2}{2k+1}(z - i\,r)\,G_1^{(k)}(\zeta) - i\,G_2^{(k-1)}(\zeta) + G_3^{(k)}(\zeta)\right]
\end{aligned}$$

for $k \geq 1$, and the kth harmonic of the pressure is determined by

$$\wp^{(k)}(\zeta) = \mu\,\operatorname{Re} G_1^{(k)}(\zeta), \quad k \geq 1.$$

Proof. The proof is similar to that of Proposition 2. □

Without loss of generality, an asymmetric motion of a solid body of revolution, whose axis of revolution is determined by the z-axis, can be decomposed into two motions: (i) translation of the body along the x-axis with the constant velocity v_x ("x-translation"), and (ii) rotation of the body around the y-axis with the constant angular velocity ϖ_y ("y-rotation"). For these motions, the no-slip boundary conditions (2) for the velocity field $\mathbf{u}$ on the body's surface S take the form

$$x\text{-translation:} \quad \mathbf{u} = v_x\mathbf{i} \quad \text{on} \quad S, \tag{26}$$
$$y\text{-rotation:} \quad \mathbf{u} = [\varpi_y\,\mathbf{j} \times (x\,\mathbf{i} + z\,\mathbf{k})] \quad \text{on} \quad S, \tag{27}$$

and in both problems, $\mathbf{u}$ and $\wp$ vanish at infinity, i.e., satisfy (3).

For the components (u_r, u_φ, u_z) of the velocity field in the cylindrical coordinates (r, φ, z), the boundary conditions (26) and (27) are reformulated as

$$x\text{-translation:} \quad u_r = v_x\cos\varphi, \ \ u_\varphi = -v_x\sin\varphi, \ \ u_z = 0 \quad \text{on} \quad S, \tag{28}$$
$$y\text{-rotation:} \quad u_r = \varpi_y\,z\,\cos\varphi, \ \ u_\varphi = -\varpi_y\,z\,\sin\varphi, \ \ u_z = -\varpi_y\,r\,\cos\varphi \quad \text{on} \quad S. \tag{29}$$

It follows from (28) and (29) that the velocity field $\mathbf{u}$ has only a first harmonic with respect to the angular coordinate φ, and consequently, its components can be represented in the form (16) for $k=1$:

$$u_z^{(1)}(\zeta)+i\,u_r^{(1)}(\zeta)=\frac{1}{2}\left((2r+i\,z)\,G_1^{(0)}(\zeta)+i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)\right), \tag{30a}$$

$$u_\varphi^{(1)}(\zeta)=\frac{1}{2}\,\mathrm{Im}\left[-(r+i\,z)\,G_1^{(0)}(\zeta)-i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)\right]. \tag{30b}$$

Consequently, asymmetric problems of 3D Stokes flows due to motion of the solid body of revolution reduce to boundary-value problems for two 0-harmonically analytic functions and one 1-harmonically analytic function.

In the rz-plane, let $\mathcal{D}^+$ and $\mathcal{D}^-$ denote the inner and outer regions with respect to the cross-section of the finite body of revolution.[3] By $\mathcal{D}_0^+$ and $\mathcal{D}_0^-$, we will understand $\mathcal{D}^+$ with $r\geq 0$ and $\mathcal{D}^-$ with $r\geq 0$, respectively, i.e., the right parts of the corresponding regions. In general, $\mathcal{D}_0^+$ is a multiply connected region, e.g., a cross-section of two spheres. Let ℓ be the common boundary of $\mathcal{D}^+$ and $\mathcal{D}^-$, and let ℓ_+ and ℓ_- denote the parts of ℓ for $r\geq 0$ (right part) and $r\leq 0$ (left part), respectively, which, being symmetric with respect to the z-axis, are either closed curves or open curves with the endpoints lying on the z-axis. The contour of the body in the rz-plane is thus $\ell=\ell_+\bigcup\ell_-$. It is positively oriented, i.e., traversed in the counterclockwise direction, if $\mathcal{D}^+$ remains on the left side when one travels along ℓ in this direction.[4]

Problem I. *Given a complex-valued function $f_1(\zeta)$ and real-valued function $f_2(\zeta)$ on ℓ_+ such that $f_1\left(-\overline{\zeta}\right)=-\overline{f_1(\zeta)}$ and $f_2\left(-\overline{\zeta}\right)=f_2(\zeta)$, find 0-harmonically analytic functions $G_1^{(0)}(\zeta)$ and $G_2^{(0)}(\zeta)$ and a 1-harmonically analytic function $G_3^{(1)}(\zeta)$ in $\mathcal{D}_0^-$ that vanish at $|\zeta|\to\infty$ and satisfy the boundary conditions*

$$(2r+i\,z)\,G_1^{(0)}(\zeta)+i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)=f_1(\zeta),\quad \zeta\in\ell_+, \tag{31a}$$

$$\mathrm{Im}\left[-(r+i\,z)G_1^{(0)}(\zeta)-i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)\right]=f_2(\zeta),\quad \zeta\in\ell_+. \tag{31b}$$

For example, for the x-translation (28), we have $f_1(\zeta)=2iv_x$ and $f_2(\zeta)=-2v_x$, and for the y-rotation (29), we have $f_1(\zeta)=-2\varpi_y\overline{\zeta}$ and $f_2(\zeta)=-2\varpi_y z$.

Remark 1. With the symmetry condition (15) and with $f_1\left(-\overline{\zeta}\right)=-\overline{f_1(\zeta)}$ and $f_2\left(-\overline{\zeta}\right)=f_2(\zeta)$, the boundary conditions (31a) and (31b) are equivalent to the boundary conditions on $\ell=\ell_+\bigcup\ell_-$:

$$(2r+i\,z)\,G_1^{(0)}(\zeta)+i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)=f_1(\zeta),\quad \zeta\in\ell, \tag{32a}$$

$$\mathrm{Im}\left[-(r+i\,z)G_1^{(0)}(\zeta)-i\,G_2^{(0)}(\zeta)+G_3^{(1)}(\zeta)\right]=f_2(\zeta),\quad \zeta\in\ell. \tag{32b}$$

For details, see Remark 7 in [32]. This fact will be critical in reducing Problem I to integral equations.

Remark 2. For multiply connected $\mathcal{D}_0^-$, the functions $G_1^{(0)}(\zeta)$, $G_2^{(0)}(\zeta)$, and $G_3^{(1)}(\zeta)$ are continuous and single valued. Indeed, in this case, $G_1^{(0)}(\zeta)$, $G_2^{(0)}(\zeta)$, and $G_3^{(1)}(\zeta)$ may contain multivalued terms analogous to a complex logarithm, which change their values along a continuous closed path enclosing a branch point lying in $\mathcal{D}_0^+$; see [1, formula (32.22)] and [11, formulae (35.2), (36.4)]. However, the solution form (30a)–(30b) and the continuity of the velocity field and pressure imply that those terms vanish.

[3] We always assume that the z-axis is the body's axis of revolution.

[4] The orientation of a closed curve is always determined with respect to the corresponding inner region.

Proposition 4. *Problem* I *has a unique solution in the outer region* D_0^-.

Proof. The proposition is equivalent to the fact that (31a) and (31b) have only a zero homogeneous solution in the specified class of functions. Since the Stokes flow problem (1) and (3) with zero boundary condition $\mathbf{u}|_S = 0$ has only a zero solution (see Proposition 1), we have $u_r^{(1)} \equiv 0$, $u_\varphi^{(1)} \equiv 0$ and $u_z^{(1)} \equiv 0$ in $\mathcal{D}_0^-$, which in terms of $G_1^{(0)}(\zeta) = U_1^{(0)}(\zeta) + i\,V_1^{(1)}(\zeta)$, $G_2^{(0)}(\zeta) = U_2^{(0)}(\zeta) + i\,V_2^{(1)}(\zeta)$, and $G_3^{(1)}(\zeta) = U_3^{(1)}(\zeta) + i\,V_3^{(2)}(\zeta)$ with (30a)–(30b) reduces to

$$2r\,U_1^{(0)} - z\,V_1^{(1)} - V_2^{(1)} + U_3^{(1)} = 0, \tag{33a}$$

$$2r\,V_1^{(1)} + z\,U_1^{(0)} + U_2^{(0)} + V_3^{(2)} = 0, \tag{33b}$$

$$-\left(r\,V_1^{(1)} + z\,U_1^{(0)}\right) - U_2^{(0)} + V_3^{(2)} = 0 \tag{33c}$$

in the whole region $\mathcal{D}_0^-$. We should prove that the system (33a)–(33c) has only a zero solution. Indeed, applying the 1-harmonic operator to (33a) and using the first equation of (12) for $G_1^{(0)}(\zeta)$, we obtain $\frac{\partial}{\partial r}U_1^{(0)} = 0$ in $\mathcal{D}_0^-$. Subtracting (33c) from (33b) and applying the 0-harmonic operator to the resulting equation, we have $\frac{\partial}{\partial z}U_1^{(0)} = 0$ in $\mathcal{D}_0^-$. Consequently, we conclude that $U_1^{(0)}$ is a constant, which however, equals zero, since $G_1^{(0)}$ vanishes at infinity. With $U_1^{(0)} \equiv 0$, (12) implies that $V_1^{(1)} = b/r$, where b is a constant, which also equals zero because of the same reason, and thus, $G_1^{(0)} \equiv 0$ in $\mathcal{D}_0^-$. Substituting this result into (33b) and (33c), we obtain $U_2^{(0)} \equiv 0$ and $V_3^{(2)} \equiv 0$. Similarly, in this case, the only $G_2^{(0)}$ and $G_3^{(1)}$ that vanish at infinity are zero functions. □

Remark 3. If in Problem I the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are not required to vanish at infinity, then in this case, Problem I has the homogeneous solution $G_1^{(0)}(\zeta) = a$, $G_2^{(0)}(\zeta) = -a\left(z - \frac{i}{2}r\right)$, and $G_3^{(1)}(\zeta) = -\frac{3}{2}a\,r$, where a is an arbitrary constant. This fact can be established by modifying the proof of Proposition 4.

Further, we will need the following result.

Proposition 5 (auxiliary homogeneous boundary-value problem). *For* 0*-harmonically analytic functions* $G_1^{(0)}(\zeta)$ *and* $G_2^{(0)}(\zeta)$ *in the inner (multiply connected) region* $\mathcal{D}_0^+$*, the homogeneous boundary-value problem*

$$\left((2r + i\,z)\,G_1^{(0)}(\zeta) + i\,G_2^{(0)}(\zeta)\right)\Big|_{\ell_+} = 0 \tag{34}$$

has only zero solution.

Proof. The proof is analogous to that of Proposition 9(ii) in [32]. We assume that $\mathcal{D}_0^+$ is simply connected. In the case when $\mathcal{D}_0^+$ is multiply connected and consists of disjoint simply connected subregions $\mathcal{D}_j^+$, $1 \le j \le m$, the proof is conducted for $\mathcal{D}_j^+$ instead of $\mathcal{D}_0^+$. Let a function $\Phi(\zeta)$ be defined by

$$\Phi(\zeta) = r\,G_1^{(0)}(\zeta)\left((2r + i\,z)\,G_1^{(0)}(\zeta) + i\,G_2^{(0)}(\zeta)\right), \tag{35}$$

and let L be the positively oriented boundary of $\mathcal{D}_0^+$, which either is ℓ_+ if ℓ_+ is closed or consists of ℓ_+ and the segment of the z-axis connecting the endpoints of ℓ_+ if ℓ_+ is an open curve with the endpoints lying on the z-axis. It follows from (35) and Proposition 4(ii) in [32] that

$$\operatorname{Re}\frac{\partial\Phi}{\partial\bar{\zeta}} = \frac{1}{2}r\left(3\left[\operatorname{Re}G_1^{(0)}\right]^2 + \left[\operatorname{Im}G_1^{(0)}\right]^2\right).$$

Consequently, using Propositions 5 in [32], we obtain

(36)
$$\operatorname{Im}\left[\oint_L \Phi\, d\zeta\right] = \operatorname{Im}\left[2i \iint_{\mathcal{D}_0^+} \frac{\partial \Phi}{\partial \overline{\zeta}}\, drdz\right] = \iint_{\mathcal{D}_0^+} r\left(3\left[\operatorname{Re} G_1^{(0)}\right]^2 + \left[\operatorname{Im} G_1^{(0)}\right]^2\right) drdz.$$

However, since $\Phi = 0$ on the z-axis and ℓ_+, the integral in the right-hand side of the last equality vanishes, whence it follows that $G_1^{(0)}(\zeta) \equiv 0$ in $\mathcal{D}_0^+$. □

Problem I can be reduced to integral equations based on the generalized Cauchy integral formula

$$G^{(k)}(\zeta) = -\frac{1}{2\pi i}\oint_\ell G^{(k)}(\tau)\mathcal{W}^{(k)}(\zeta,\tau)\, d\tau, \qquad \zeta \in \operatorname{int}\mathcal{D}^-,$$

for k-harmonically analytic functions in the outer region $\mathcal{D}^-$ that vanish at infinity, where $\mathcal{W}^{(k)}(\zeta,\tau)$ is a generalized Cauchy kernel and ℓ is the positively oriented boundary with respect to $\mathcal{D}^+$; see Theorem 2 in the first part of this work [32].

Theorem 6 (two integral equations in the asymmetric case). *For the outer multiply connected region $\mathcal{D}_0^-$, Problem* I *reduces to two integral equations for determining boundary values of $G_1^{(0)}(\zeta) = U_1^{(0)}(\zeta) + i\, V_1^{(1)}(\zeta)$ and $U_3^{(1)}(\zeta) = \operatorname{Re} G_3^{(1)}(\zeta)$:*

(37)
$$\begin{aligned}
&\frac{1}{\pi i}\int_{\ell_+}\Bigg([z - z_1 - 2i(r - r_1)]\, G_1^{(0)}(\tau)\, \Omega_+^{(0)}(\zeta,\tau)\, \frac{d\tau}{\tau - \zeta} \\
&\qquad\qquad - [z - z_1 - 2i(r + r_1)]\, \overline{G_1^{(0)}(\tau)}\, \Omega_-^{(0)}(\zeta,\tau)\, \frac{d\overline{\tau}}{\overline{\tau} + \zeta}\Bigg) \\
&+ \frac{1}{\pi i}\int_{\ell_+}\Bigg(\left[\frac{1}{2} r_1 V_1^{(1)}(\tau) + i\, U_3^{(1)}(\tau)\right]\left(\Omega_+^{(0)}(\zeta,\tau) - \Omega_+^{(1)}(\zeta,\tau)\right)\frac{d\tau}{\tau - \zeta} \\
&\qquad\qquad - \left[\frac{1}{2} r_1 V_1^{(1)}(\tau) - i\, U_3^{(1)}(\tau)\right]\left(\Omega_-^{(0)}(\zeta,\tau) + \Omega_-^{(1)}(\zeta,\tau)\right)\frac{d\overline{\tau}}{\overline{\tau} + \zeta}\Bigg) = F_1(\zeta), \quad \zeta \in \ell,
\end{aligned}$$

(38)
$$U_3^{(1)}(\zeta) - \frac{i}{2} r\, V_1^{(1)}(\zeta) + \frac{1}{\pi i}\oint_\ell \left(U_3^{(1)}(\tau) - \frac{i}{2} r_1\, V_1^{(1)}(\tau)\right)\mathcal{W}^{(1)}(\zeta,\tau)\, d\tau = F_2(\zeta), \quad \zeta \in \ell,$$

where $\zeta = r + i\, z$, $\tau = r_1 + i\, z_1$, the functions $\Omega_+^{(k)}(\zeta,\tau)$ and $\Omega_-^{(k)}(\zeta,\tau)$ are determined by (25a) *and* (25b) *in* [32], *and*

(39)
$$F_1(\zeta) = i\, f_1(\zeta) + \frac{1}{2\pi i}\oint_\ell (2i\, f_1(\tau) + f_3(\tau))\, \mathcal{W}^{(0)}(\zeta,\tau)\, d\tau + \frac{1}{2\pi}\oint_\ell i\, f_3(\tau)\mathcal{W}^{(1)}(\zeta,\tau)\, d\tau,$$

(40)
$$F_2(\zeta) = -\frac{i}{2} f_3(\zeta) - \frac{1}{2\pi i}\int_\ell i\, f_3(\tau)\mathcal{W}^{(1)}(\zeta,\tau)\, d\tau,$$

$$f_3(\zeta) = \operatorname{Im}[f_1(\zeta)] + f_2(\zeta).$$

Proof. As in the axially symmetric case [32, Theorem 10], the derivation of the integral equations follows Muskhelishvili's approach [11, 12] used for reducing 2D problems of an elastic medium to integral equations.

According to Remark 1, Problem I for $\mathcal{D}_0^-$ is equivalent to Problem I for $\mathcal{D}^-$. Necessary and sufficient conditions for the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ to be k-harmonically analytic in $\mathcal{D}^-$ for $k = 0$, 0, and 1, respectively, and vanishing at infinity follow from the corresponding generalized Sokhotski–Plemelj formulae[5] and are given by

$$G_1^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell G_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = 0, \quad \zeta \in \ell, \tag{41a}$$

$$G_2^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell G_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = 0, \quad \zeta \in \ell, \tag{41b}$$

$$G_3^{(1)}(\zeta) + \frac{1}{\pi i}\oint_\ell G_3^{(1)}(\tau)\mathcal{W}^{(1)}(\zeta,\tau)\,d\tau = 0, \quad \zeta \in \ell. \tag{41c}$$

Expressing the boundary value of $G_2^{(0)}$ from the boundary condition (32a),

$$G_2^{(0)}(\zeta) = -i\left(f_1(\zeta) - (2r + i\,z)\,G_1^{(0)}(\zeta) - G_3^{(1)}(\zeta)\right), \quad \zeta \in \ell, \tag{42}$$

and substituting (42) into (41b), we have

$$\begin{aligned}(2ir - z)\,G_1^{(0)}(\zeta) + i\,G_3^{(1)}(\zeta) + \frac{1}{\pi i}\oint_\ell \left((2ir_1 - z_1)G_1^{(0)}(\tau) + i\,G_3^{(1)}(\tau)\right)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau \\ = i\,f_1(\zeta) + \frac{1}{\pi i}\oint_\ell i\,f_1(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \ell.\end{aligned} \tag{43}$$

Similarly, expressing the boundary value of $V_3^{(2)}(\zeta)$ from the sum of (32b) and the imaginary part of (32a),

$$V_3^{(2)}(\zeta) = \frac{1}{2}\left(\mathrm{Im}[f_1(\zeta)] + f_2(\zeta) - r\,V_1^{(1)}(\zeta)\right), \quad \zeta \in \ell, \tag{44}$$

and substituting (44) into (41c), we obtain (38). Finally, substituting (44) into (43) and subtracting the combination $(2ir - z)\cdot(41\text{a}) + i\cdot(38)$ from (43), we obtain (37).

Now we need to show that if $\widetilde{G}_1^{(0)}(\zeta)$ and $\widetilde{U}_3^{(1)}(\zeta)$ solve (37) and (38), then $\widetilde{G}_1^{(0)}(\zeta)$, $\widetilde{G}_2^{(0)}(\zeta)$, determined by (42), and $\widetilde{G}_3^{(1)}(\zeta)$ satisfy (41a), (41b), and (41c), respectively.

With $\widetilde{V}_1^{(1)}$, the imaginary part $\widetilde{V}_3^{(2)}(\zeta)$ is determined by (44), and (38) can be restated as (41c) for $\widetilde{G}_3^{(1)}(\zeta) = \widetilde{U}_3^{(1)}(\zeta) + i\,\widetilde{V}_3^{(2)}(\zeta)$. Thus, $\widetilde{G}_3^{(1)}(\zeta)$ satisfies (41c). Similarly, with (44), (37) can be rewritten in terms of $\widetilde{G}_3^{(1)}(\zeta)$, and the combination $(37) + i\cdot(41\text{c})$ reduces to

$$\begin{aligned}&\frac{1}{\pi i}\left(\oint_\ell (2ir_1 - z_1)\widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau - (2ir - z)\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau\right) \\ &\qquad + i\,\widetilde{G}_3^{(1)}(\zeta) + \frac{1}{\pi i}\oint_\ell i\,\widetilde{G}_3^{(1)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau \\ &\qquad = i\,f_1(\zeta) + \frac{1}{\pi i}\oint_\ell i\,f_1(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \ell.\end{aligned} \tag{45}$$

[5] These formulae are derived similarly to the Sokhotski–Plemelj formulae for ordinary analytic functions; see [1, formula (31.13)] and [7, formula (4.8)].

Now adding $(2ir - z)\widetilde{G}_1^{(0)}(\zeta)$ to the right-hand and left-hand sides of (45) and using (42), we rewrite (45) in the form

$$\begin{aligned} &-(2ir - z)\left(\widetilde{G}_1^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau\right) \\ &\qquad + \widetilde{G}_2^{(0)}(\zeta) + \frac{1}{\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau = 0, \quad \zeta \in \ell. \end{aligned} \tag{46}$$

Let $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$ be determined by the generalized Cauchy-type integrals in the region $\mathcal{D}^+$ excluding its boundary ℓ:

$$\Phi^+(\zeta) = \frac{1}{2\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \operatorname{int}\mathcal{D}^+,$$
$$\Psi^+(\zeta) = \frac{1}{2\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \operatorname{int}\mathcal{D}^+.$$

These functions are 0-harmonically analytic in $\operatorname{int}\mathcal{D}^+$, since $\mathcal{W}^{(0)}(\zeta,\tau)$ satisfies (14) for $k = 0$ with respect to ζ. Then when ζ approaches ℓ from within $\mathcal{D}^+$, the boundary values of $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$ on ℓ are determined by the corresponding generalized Sokhotski–Plemelj formula

$$\Phi^+(\zeta) = \frac{1}{2}\widetilde{G}_1^{(0)}(\zeta) + \frac{1}{2\pi i}\oint_\ell \widetilde{G}_1^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \ell, \tag{47a}$$

$$\Psi^+(\zeta) = \frac{1}{2}\widetilde{G}_2^{(0)}(\zeta) + \frac{1}{2\pi i}\oint_\ell \widetilde{G}_2^{(0)}(\tau)\mathcal{W}^{(0)}(\zeta,\tau)\,d\tau, \quad \zeta \in \ell, \tag{47b}$$

and the relationship (46) reduces to

$$(2r + i\,z)\,\Phi^+(\zeta) + i\,\Psi^+(\zeta) = 0, \quad \zeta \in \ell,$$

which, in view of the symmetry condition (15),[6] is the auxiliary homogeneous boundary-value problem (34) for the 0-harmonically analytic functions $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$ in $\mathcal{D}_0^+$. According to Proposition 5, the only solution to this problem is $\Phi^+(\zeta) \equiv 0$ and $\Psi^+(\zeta) \equiv 0$. Consequently, (47a) and (47b) imply that $\widetilde{G}_1^{(0)}(\zeta)$ and $\widetilde{G}_2^{(0)}(\zeta)$ satisfy (41a) and (41b), respectively, and thus are the boundary values of 0-harmonically analytic functions in $\mathcal{D}^-$. □

Remark 4. The kernels of the integral equation (37) have only logarithmic singularity because of the functions $\Omega_-^{(0)}(\zeta,\tau)$ and $\Omega_-^{(1)}(\zeta,\tau)$ (see Remark 2 in [32]). Indeed,

$$\lim_{\tau\to\zeta} \frac{z - z_1 - 2i(r - r_1)}{\tau - \zeta} = \frac{i}{2}\left(3 + \mathrm{e}^{-2i \lim\limits_{\tau\to\zeta} \arg[\tau-\zeta]}\right),$$

which is obtained by setting $\tau = \zeta + \rho\,\mathrm{e}^{i\beta}$ and passing $\rho \to 0$ (also, if $\zeta = \zeta(t)$ is a parameterization of smooth ℓ_+, then $\lim_{\tau\to\zeta}\arg[\tau - \zeta] = \arg[\zeta'(t)]$), and

$$\lim_{\tau\to\zeta} \frac{\Omega_+^{(0)}(\zeta,\tau) - \Omega_+^{(1)}(\zeta,\tau)}{\tau - \zeta} = 0.$$

[6] The functions $\Phi^+(\zeta)$ and $\Psi^+(\zeta)$, being determined by the generalized Cauchy-type integrals, satisfy the symmetry condition (15).

Remark 5. Let ℓ_+ be symmetric with respect to the r-axis. If $f_1\left(\overline{\zeta}\right) = \overline{f_1(\zeta)}$ and $f_2\left(\overline{\zeta}\right) = -f_2(\zeta)$, then $G_3^{(1)}\left(\overline{\zeta}\right) = \overline{G_3^{(1)}(\zeta)}$, and (38) reduces to

$$U_3^{(1)}(\zeta) + \mathrm{Re}\left[\frac{1}{\pi i}\oint_\ell \left(U_3^{(1)}(\tau) - \frac{i}{2} r_1\, V_1^{(1)}(\tau)\right)\mathcal{W}^{(1)}(\zeta,\tau)\,d\tau\right] = \mathrm{Re}[F_2(\zeta)], \quad \zeta\in\ell,$$

and if $f_1\left(\overline{\zeta}\right) = -\overline{f_1(\zeta)}$ and $f_2\left(\overline{\zeta}\right) = f_2(\zeta)$, then $G_3^{(1)}\left(\overline{\zeta}\right) = -\overline{G_3^{(1)}(\zeta)}$, and (38) reduces to

$$-\frac{1}{2} r\, V_1^{(1)}(\zeta) + \mathrm{Im}\left[\frac{1}{\pi i}\oint_\ell \left(U_3^{(1)}(\tau) - \frac{i}{2} r_1\, V_1^{(1)}(\tau)\right)\mathcal{W}^{(1)}(\zeta,\tau)\,d\tau\right] = \mathrm{Im}[F_2(\zeta)], \ \ \zeta\in\ell.$$

These equations follow from Proposition 10 (see the appendix) applied to (41c) with (44).

The singular integral equation (38) can be reduced to an integral equation with a logarithmic singularity based on Proposition 11 (see the appendix) and the fact that (38) is (41c) with (44).

Now we represent the resisting force and torque, exerted on a solid body of revolution in the x-translation (26) and y-rotation (27), respectively, in terms of the functions $G_1^{(0)}$ and $G_2^{(0)}$, entering the solution form (30a)–(30b).

PROPOSITION 7 (resisting force in the asymmetric translation). *For the Stokes flow due to the x-translation* (28) *of the body,*[7] *let the velocity field be represented by* (30a)–(30b). *The resisting (drag) force, exerted on the body by the fluid, can be represented in two equivalent forms,*

$$F_x = 2\pi\mu\ \mathrm{Re}\left[\int_{\ell_+} r\, G_1^{(0)}(\zeta)\,d\zeta\right], \tag{48a}$$

$$F_x = -4\pi\mu \lim_{z\to\infty}\left(z^2\ \mathrm{Re}\, G_1^{(0)}(r,z)\Big|_{r=0}\right), \tag{48b}$$

where ℓ_+ in (48a) *is positively oriented with respect to $\mathcal{D}_0^+$.*

Proof. We first prove the formula (48a).

For the x-translation (28), the resulting force, exerted on the body of revolution, is the integral over the body's surface S and has the component in the direction $\mathbf{i}$ only:

$$F_x = \iint_S (\mathbf{i}\cdot\mathbf{P}_n)\,dS, \qquad \mathbf{P}_n = 2\mu\,\frac{\partial\mathbf{u}}{\partial n} + \mu\,[\mathfrak{n}\times\mathrm{curl}\,\mathbf{u}] - \wp\,\mathfrak{n}, \tag{49}$$

where $\mathfrak{n} = n_r\,\mathbf{e}_r + n_z\,\mathbf{k}$ is the outer normal to the body's surface with $n_r = \frac{\partial r}{\partial n}$ and $n_z = \frac{\partial z}{\partial n}$; see [9].

Using the representations (30a)–(30b) and (17) for $k=1$ that correspond to the boundary conditions (28), we have

$$\begin{aligned}
u_r(r,\varphi,z) &= \frac{1}{2}\left(z\,U_1^{(0)}(r,z) + 2r\,V_1^{(1)}(r,z) + U_2^{(0)}(r,z) + V_3^{(2)}(r,z)\right)\cos\varphi,\\
u_\varphi(r,\varphi,z) &= \frac{1}{2}\left(-z\,U_1^{(0)}(r,z) - r\,V_1^{(1)}(r,z) - U_2^{(0)}(r,z) + V_3^{(2)}(r,z)\right)\sin\varphi,\\
u_z(r,\varphi,z) &= \frac{1}{2}\left(2r\,U_1^{(0)}(r,z) - z\,V_1^{(1)}(r,z) - V_2^{(1)}(r,z) + U_3^{(1)}(r,z)\right)\cos\varphi,\\
\wp(r,\varphi,z) &= \mu\,V_1^{(1)}(r,z)\cos\varphi.
\end{aligned} \tag{50}$$

[7] The z-axis is the body's axis of revolution.

Let (s,φ,n) be a characteristic coordinate system with the right-hand orthogonal basis $(\mathfrak{s},\mathbf{e}_\varphi,\mathfrak{n})$, in which s has *negative* orientation. Then with the relationships

$$\frac{\partial r}{\partial s}=\frac{\partial z}{\partial n}, \qquad \frac{\partial r}{\partial n}=-\frac{\partial z}{\partial s},$$

the system (12) with $k=0$, defining the functions $G_1^{(0)}=U_1^{(0)}+i\,V_1^{(1)}$ and $G_2^{(0)}=U_2^{(0)}+i\,V_2^{(1)}$, can be represented by

$$\frac{\partial}{\partial s}U_j^{(0)}=\frac{1}{r}\frac{\partial}{\partial n}\left(rV_j^{(1)}\right), \qquad \frac{\partial}{\partial n}U_j^{(0)}=-\frac{1}{r}\frac{\partial}{\partial s}\left(rV_j^{(1)}\right), \quad j=1,2, \tag{51}$$

and (12) with $k=1$, defining the function $G_3^{(1)}=U_3^{(1)}+i\,V_3^{(2)}$, takes the form

$$\begin{aligned}\frac{\partial}{\partial s}U_3^{(1)}-\frac{1}{r}\frac{\partial r}{\partial s}U_3^{(1)}&=\frac{1}{r^2}\frac{\partial}{\partial n}\left(r^2V_3^{(2)}\right),\\ \frac{\partial}{\partial n}U_3^{(1)}-\frac{1}{r}\frac{\partial r}{\partial n}U_3^{(1)}&=-\frac{1}{r^2}\frac{\partial}{\partial s}\left(r^2V_3^{(2)}\right).\end{aligned} \tag{52}$$

In the cylindrical coordinates, $dS=r\,ds\,d\varphi$, where ds is the differential of the curve length (s is the same variable as in the system (s,φ,n)). Substituting (50) into (49) and also using (12) along with (51) and (52), we obtain

$$\begin{aligned}\int_0^{2\pi}(\mathbf{i}\cdot\mathbf{P}_n)\,d\varphi=\frac{\pi\mu}{2r}\Bigg(&4r\left(-\frac{\partial r}{\partial s}U_1^{(0)}+\frac{\partial z}{\partial s}V_1^{(1)}\right)\\ &+\frac{\partial}{\partial s}\left[r\left(5r\,U_1^{(0)}-3z\,V_1^{(1)}-3\,V_2^{(1)}+U_3^{(1)}\right)\right]\Bigg),\end{aligned}$$

and consequently, F_x in (49) reduces to

$$F_x=\int_{\ell_+}\left[\int_0^{2\pi}(\mathbf{i}\cdot\mathbf{P}_n)\,d\varphi\right]r\,ds=2\pi\mu\int_{\ell_+}r\left(-\frac{\partial r}{\partial s}U_1^{(0)}+\frac{\partial z}{\partial s}V_1^{(1)}\right)ds, \tag{53}$$

under the condition that

$$\int_{\ell_+}\frac{\partial}{\partial s}\left[r\left(5r\,U_1^{(0)}-3z\,V_1^{(1)}-3V_2^{(1)}+U_3^{(1)}\right)\right]ds=0,$$

which obviously holds, since the functions $G_1^{(0)}(\zeta)$, $G_2^{(0)}(\zeta)$, and $G_3^{(1)}(\zeta)$ are continuous in $\mathcal{D}_0^-$ (see Remark 2) and since ℓ_+ either is a closed curve or has the endpoints on the z-axis.

Finally, since ℓ_+ in (53) has positive orientation, $dr=-\frac{\partial r}{\partial s}ds$ and $dz=-\frac{\partial z}{\partial s}ds$ on ℓ_+, and thus, with these relationships, (53) can be represented in the form of (48a).

The formula (48b) follows from (48a) and Proposition 6 in [32]. □

PROPOSITION 8 (resisting torque in the asymmetric rotation). *For the Stokes flow due to the y-rotation* (29) *of the body,*[8] *let the velocity field be represented by* (30a)–(30b). *The resisting torque, exerted on the body by the fluid, can be represented in two equivalent forms,*

$$T_y=2\pi\mu\,\mathrm{Re}\left[\int_{\ell_+}r\left((2z-ir)\,G_1^{(0)}(\zeta)+G_2^{(0)}(\zeta)\right)d\zeta\right], \tag{54a}$$

$$T_y=4\pi\mu\left\{2\lim_{r\to\infty}\left(r^3\,\mathrm{Re}\,G_1^{(0)}(r,z)\Big|_{z=0}\right)-\lim_{z\to\infty}\left(z^2\,\mathrm{Re}\,G_2^{(0)}(r,z)\Big|_{r=0}\right)\right\}, \tag{54b}$$

where ℓ_+ in (54a) *is positively oriented with respect to $\mathcal{D}_0^+$.*

[8] The z-axis is the body's axis of revolution.

Proof. We first prove the formula (54a).

For the y-rotation (29), the resulting torque, exerted on the body of revolution, has the component in the direction $\mathbf{j}$ only:

$$T_y = \iint_S (\mathbf{j}\cdot[\mathfrak{r}\times\mathbf{P}_n])\,dS = \iint_S ([\mathbf{j}\times\mathfrak{r}]\cdot\mathbf{P}_n)\,dS, \tag{55}$$

where $\mathbf{P}_n$ is defined as in (49), $\mathfrak{r} = r\,\mathbf{e}_r + z\,\mathbf{k}$ is the radius vector, and $\mathfrak{n}$ is the outer normal to the body's surface as in (49).

As in the proof of Proposition 7, we introduce a characteristic coordinate system (s,φ,n) with the right-hand orthogonal basis $(\mathfrak{s},\mathbf{e}_\varphi,\mathfrak{n})$ and also have $dS = r\,ds\,d\varphi$ in the cylindrical coordinates with the length differential ds. For the boundary conditions (29), the velocity field can also be represented in the form (50).

Substituting (50) into (55) and using (12) along with (51) and (52), we obtain

$$\begin{aligned}
&\int_0^{2\pi} ([\mathbf{j}\times\mathfrak{r}]\cdot\mathbf{P}_n)\,d\varphi \\
&= \frac{\pi\mu}{2r}\left(-4r\left[r\left(\frac{\partial z}{\partial s}U_1^{(0)} + \frac{\partial r}{\partial s}V_1^{(1)}\right) + 2z\left(\frac{\partial r}{\partial s}U_1^{(0)} - \frac{\partial z}{\partial s}V_1^{(1)}\right) + \frac{\partial r}{\partial s}U_2^{(0)} - \frac{\partial z}{\partial s}V_1^{(1)}\right]\right. \\
&\qquad \left. + \frac{\partial}{\partial s}\left[r\left(7rz\,U_1^{(0)} + (4r^2-3z^2)V_1^{(1)} + 2r\,U_2^{(0)} - 3z\,V_2^{(1)} + z\,U_3^{(1)} + 2r\,V_3^{(2)}\right)\right]\right),
\end{aligned}$$

and consequently, T_y in (55) reduces to

$$\begin{aligned}
T_y = -2\pi\mu\int_{\ell_+} r\left[r\left(\frac{\partial z}{\partial s}U_1^{(0)} + \frac{\partial r}{\partial s}V_1^{(1)}\right) + 2z\left(\frac{\partial r}{\partial s}U_1^{(0)} - \frac{\partial z}{\partial s}V_1^{(1)}\right)\right. \\
\left. + \frac{\partial r}{\partial s}U_2^{(0)} - \frac{\partial z}{\partial s}V_1^{(1)}\right] ds,
\end{aligned} \tag{56}$$

under the condition that

$$\int_{\ell_+} \frac{\partial}{\partial s}\left[r\left(7rz\,U_1^{(0)} + (4r^2-3z^2)V_1^{(1)} + 2r\,U_2^{(0)} - 3z\,V_2^{(1)} + z\,U_3^{(1)} + 2r\,V_3^{(2)}\right)\right] ds = 0,$$

which holds, since $G_1^{(0)}(\zeta)$, $G_2^{(0)}(\zeta)$, and $G_3^{(1)}(\zeta)$ are continuous in $\mathcal{D}_0^-$ (see Remark 2) and since ℓ_+ either is closed or has the endpoints on the z-axis. As in the proof of Proposition 7, $dr = -\frac{\partial r}{\partial s}ds$ and $dz = -\frac{\partial z}{\partial s}ds$ on ℓ_+, which is positively oriented, and consequently, (56) can be represented in the form of (54a).

The formula (54b) is obtained from (54a). Indeed, it follows from Proposition 6 in [32] that $\operatorname{Re}[\int_{\ell_+} r\,G_2^{(0)}(\zeta)\,d\zeta] = -2\lim_{z\to\infty}(z^2\operatorname{Re}G_2^{(0)}(r,z)|_{r=0})$. Also, as in Proposition 6 in [32], it can be shown that

$$\operatorname{Re}\left[\int_{\ell_+} r\,(2z - ir)\,G_1^{(0)}(\zeta)\,d\zeta\right] = 4\lim_{r\to\infty}\left(r^3\operatorname{Re}G_1^{(0)}(r,z)\Big|_{z=0}\right),$$

and formula (54b) follows. □

3. Exact solutions to asymmetric Stokes flow problems. As an illustration for the developed framework, we solve asymmetric 3D Stokes flow problems for the x-translation (28) and y-rotation (29) of a solid sphere and solid prolate and oblate spheroids using the solution form (30a)–(30b) and series representations for k-harmonically analytic functions for corresponding regions. We also solve the integral equations (37) and (38) for the x-translation of solid bispheroids (two separate spheroids of equal size and having the same axis of revolution) and for the y-rotation of a solid torus of elliptical cross-section for various values of a geometrical parameter.

Example 1 (asymmetric translation and rotation of a solid sphere). Let (R, ϑ, φ) be the spherical coordinates related to the cylindrical coordinates in the ordinary way, and let a solid sphere be centered at the origin and have radius c.

(i) For the x-translation of the sphere, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ in (30a)–(30b) are determined in the region $R \geq c$ by

$$G_1^{(0)}(R,\vartheta) = \frac{3v_x c}{2}\, R^{-2}\, \mathrm{e}^{i\vartheta}, \quad G_2^{(0)}(R,\vartheta) = \frac{v_x c^3}{8}\, R^{-3}\left(1 + 3\,\mathrm{e}^{2i\vartheta}\right), \quad G_3^{(1)}(R,\vartheta) = -\frac{3v_x c^3}{4}\, R^{-3}\, \mathrm{e}^{i\vartheta}\, \sin\vartheta, \tag{57}$$

and the drag force $F_x = -6\pi\mu c v_x$ follows from (48b) and (57).

(ii) For the y-rotation of the sphere, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ in (30a)–(30b) are determined in the region $R \geq c$ by

$$G_1^{(0)}(R,\vartheta) \equiv 0, \qquad G_2^{(0)}(R,\vartheta) = 2\varpi_y c^3\, R^{-2}\, \mathrm{e}^{i\vartheta}, \qquad G_3^{(1)}(R,\vartheta) \equiv 0, \tag{58}$$

and the resisting torque $T_y = -8\pi\mu c^3 \varpi_y$ follows from (54b) and (58).

Detail. For the components $u_1^{(1)}$ and $u_2^{(1)}$, related to $u_r^{(1)}$ and $u_\varphi^{(1)}$ by (6), and $u_z^{(1)}$, the boundary conditions (28) and (29) for the sphere take the form

$$x\text{-translation:}\quad u_1^{(1)}\Big|_{R=c} = 2v_x,\quad u_2^{(1)}\Big|_{R=c} = 0,\quad u_z^{(1)}\Big|_{R=c} = 0, \tag{59}$$

$$y\text{-rotation:}\quad u_1^{(1)}\Big|_{R=c} = 2\varpi_y\, c\,\cos\vartheta,\quad u_2^{(1)}\Big|_{R=c} = 0,\quad u_z^{(1)}\Big|_{R=c} = -\varpi_y\, c\,\sin\vartheta. \tag{60}$$

We seek to find solutions that satisfy (59) and (60) in the form (30a)–(30b). For the region exterior to a sphere, the k-harmonically analytic functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are represented in the spherical coordinates by the series (15) in [32] for $k = 0$, 0, and 1, respectively:

$$\begin{aligned} G_1^{(0)}(R,\vartheta) &= \sum_{n=1}^{\infty} A_n R^{-n-1}\left\{n\,\mathrm{P}_n(\cos\vartheta) - i\,\mathrm{P}_n^{(1)}(\cos\vartheta)\right\},\\ G_2^{(0)}(R,\vartheta) &= \sum_{n=1}^{\infty} B_n R^{-n-1}\left\{n\,\mathrm{P}_n(\cos\vartheta) - i\,\mathrm{P}_n^{(1)}(\cos\vartheta)\right\},\\ G_3^{(1)}(R,\vartheta) &= \sum_{n=1}^{\infty} C_n R^{-n-2}\left\{n\,\mathrm{P}_{n+1}^{(1)}(\cos\vartheta) - i\,\mathrm{P}_{n+1}^{(2)}(\cos\vartheta)\right\}. \end{aligned} \tag{61}$$

From (59), (60), and (30a)–(30b), along with (61), we obtain second-order difference equations for the coefficients A_n, B_n, and C_n:

$$x\text{-translation:}\quad \frac{4}{3}c^{-1}A_1 = 2v_x,\quad \frac{13}{5}A_2 + B_1 = 0,\quad \frac{7}{10}A_2 + \frac{1}{2}B_1 = 0, \tag{62}$$

$$y\text{-rotation:}\quad \frac{4}{3}c^{-1}A_1 = 0,\quad \frac{13}{5}A_2 + B_1 = 2\varpi_y c^3,\quad \frac{7}{10}A_2 + \frac{1}{2}B_1 = \varpi_y\, c^3, \tag{63}$$

and (for the x-translation and y-rotation)

$$\text{(64a)} \qquad -c^2\frac{n(n-1)}{2(2n-1)}A_{n-1}+\frac{(n+1)(5n+8)}{2(2n+3)}A_{n+1}+n\,B_n=0, \qquad n\geq 2,$$

$$\text{(64b)} \qquad \frac{c^2}{2(2n-1)}A_{n-1}-\frac{1}{2(2n+3)}A_{n+1}-C_{n-1}=0, \qquad n\geq 2,$$

$$\text{(64c)} \quad -c^2\frac{(n-1)}{2(2n-1)}A_{n-1}+\frac{(3n+4)}{2(2n+3)}A_{n+1}+\frac{1}{2}\,B_n+\frac{(n-1)}{2}C_{n-1}=0, \quad n\geq 2.$$

The combination $2n\cdot$(64c) $+\,n(n-1)\cdot$(64b) $-$ (64a) reduces to having $A_{n+1}=0$ for $n\geq 2$, and consequently, it follows from (64a)–(64c) for $n\geq 3$ that $B_n=0$ and $C_{n-1}=0$ for $n\geq 3$.

Solving (62) and (64a)–(64c) for $n=2$, we obtain $A_1=3\,c\,v_x/2$, $A_2=0$, $B_1=0$, $B_2=c^3v_x/4$, and $C_1=c^3v_x/4$, which results in (57); similarly, solving (63) and (64a)–(64c) for $n=2$, we have $A_1=0$, $A_2=0$, $B_1=2\varpi_y c^3$, $B_2=0$, and $C_1=0$, which corresponds to the solution (58).

Example 2 (asymmetric translation and rotation of a solid prolate spheroid). Let (ξ,η,φ) be the prolate spheroidal coordinates related to the cylindrical coordinates by

$$\text{(65)} \qquad r=c\,\sinh\xi\,\sin\eta, \quad z=c\,\cosh\xi\,\cos\eta, \qquad \xi\in[0,\infty), \quad \eta\in[0,\pi],$$

where the angular coordinate $\varphi\in[0,2\pi)$ coincides with the one in (r,φ,z) and c is a metric parameter. In (ξ,η,φ), a solid prolate spheroid with the z-axis of revolution is determined by fixing the coordinate ξ, i.e., $\xi=\xi_0$. For the x-translation (28) and y-rotation (29), let the velocity field be represented by (30a)–(30b).

(i) For the x-translation, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are determined in the region $\xi\geq\xi_0$ by

(66)

$$\begin{aligned}
G_1^{(0)}(\xi,\eta)&=\frac{q_1}{c}\,\frac{(\cos\eta+i\,\coth\xi\sin\eta)}{\cosh^2\xi-\cos^2\eta},\\
G_2^{(0)}(\xi,\eta)&=\frac{q_1}{2}\left(\cosh^2\xi_0-3\right)\left(\frac{\sinh[2\xi]+i\,\sin[2\eta]}{2\sinh\xi\left(\cosh^2\xi-\cos^2\eta\right)}-\ln\left(\coth[\xi/2]\right)\right),\\
G_3^{(1)}(\xi,\eta)&=-\frac{q_1}{2}\,\sinh^2\xi_0\,\frac{\sin\eta}{\sinh\xi}\,\frac{(\cos\eta+i\,\coth\xi\sin\eta)}{\cosh^2\xi-\cos^2\eta},
\end{aligned}$$

where $q_1=4v_x\left/\left(\cosh\xi_0-(\cosh^2\xi_0-3)\ln\left(\coth[\xi_0/2]\right)\right)\right.$. The drag force $F_x=-4\pi\mu c q_1$ follows from (48b) and (66).

(ii) For the y-rotation, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are determined in the region $\xi\geq\xi_0$ by

(67)

$$\begin{aligned}
G_1^{(0)}(\xi,\eta)&=\frac{4q_2}{c}\left(\frac{\sinh[2\xi]+i\,\sin[2\eta]}{2\sinh\xi\left(\cosh^2\xi-\cos^2\eta\right)}-\ln\left(\coth[\xi/2]\right)\right),\\
G_2^{(0)}(\xi,\eta)&=q_2\left(\cosh^2\xi_0+3\right)\left(2\mathrm{Q}_1(\cosh\xi)\cos\eta-i\,\mathrm{Q}_1^{(1)}(\cosh\xi)\sin\eta\right)\\
&\qquad+2q_2\left(\cosh^2\xi_0-3\right)\frac{(\cos\eta+i\,\coth\xi\sin\eta)}{\cosh^2\xi-\cos^2\eta},\\
G_3^{(1)}(\xi,\eta)&=-q_2\,\sinh^2\xi_0\sin\eta\left(3\mathrm{Q}_1^{(1)}(\cosh\xi)+\frac{\sinh[2\xi]+i\,\sin[2\eta]}{\sinh^2\xi\left(\cosh^2\xi-\cos^2\eta\right)}\right),
\end{aligned}$$

where $q_2 = -\varpi_y c \big/ \left(\cosh\xi_0 - \left(\cosh^2\xi_0 + 1\right)\ln\left(\coth[\xi_0/2]\right)\right)$, and

$$\mathrm{Q}_1(\cosh\xi) = \cosh\xi\,\ln\left(\coth[\xi/2]\right) - 1,$$
$$\mathrm{Q}_1^{(1)}(\cosh\xi) = \sinh\xi\,\ln\left(\coth[\xi/2]\right) - \coth\xi.$$

The resisting torque $T_y = -16\pi\mu c^2 q_2 \cosh[2\xi_0]/3$ follows from (54b) and (67).

Detail. In terms of the components $u_1^{(1)}$, $u_2^{(1)}$, and $u_z^{(1)}$ (see (6)), the boundary conditions (28) and (29) for the prolate spheroid take the form

$$\text{(68a)}\qquad x\text{-translation:}\quad u_1^{(1)}\Big|_{\xi=\xi_0} = 2v_x,\quad u_2^{(1)}\Big|_{\xi=\xi_0} = 0,\quad u_z^{(1)}\Big|_{\xi=\xi_0} = 0,$$

$$\text{(68b)}\qquad \begin{aligned} y\text{-rotation:}\quad & u_1^{(1)}\Big|_{\xi=\xi_0} = 2\varpi_y\, c\,\cosh\xi_0\cos\eta,\quad u_2^{(1)}\Big|_{\xi=\xi_0} = 0,\\ & u_z^{(1)}\Big|_{\xi=\xi_0} = -\varpi_y\, c\,\sinh\xi_0\sin\eta. \end{aligned}$$

For the region exterior to the prolate spheroid, $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are represented in the prolate spheroidal coordinates (65) by the series (20) in [32] for $k = 0$, 0, and 1, respectively:

(69)
$$\begin{aligned} G_1^{(0)}(\xi,\eta) &= \sum_{n=1}^{\infty} A_n \left\{ n(n+1)\,\mathrm{Q}_n(\cosh\xi)\,\mathrm{P}_n(\cos\eta) + i\,\mathrm{Q}_n^{(1)}(\cosh\xi)\,\mathrm{P}_n^{(1)}(\cos\eta)\right\},\\ G_2^{(0)}(\xi,\eta) &= \sum_{n=1}^{\infty} B_n \left\{ n(n+1)\,\mathrm{Q}_n(\cosh\xi)\,\mathrm{P}_n(\cos\eta) + i\,\mathrm{Q}_n^{(1)}(\cosh\xi)\,\mathrm{P}_n^{(1)}(\cos\eta)\right\},\\ G_3^{(1)}(\xi,\eta) &= \sum_{n=2}^{\infty} C_n \left\{ (n-1)(n+2)\,\mathrm{Q}_n^{(1)}(\cosh\xi)\,\mathrm{P}_n^{(1)}(\cos\eta)\right.\\ &\qquad\qquad \left. + i\,\mathrm{Q}_n^{(2)}(\cosh\xi)\,\mathrm{P}_n^{(2)}(\cos\eta)\right\}. \end{aligned}$$

Substituting (30a)–(30b) with (69) into (68a) and (68b), we obtain second-order difference equations for the coefficients A_n, B_n, and C_n:

$$\text{(70)}\qquad x\text{-translation:}\quad \begin{aligned} &\widetilde{M}_0(\xi_0)A_1 = 2v_x,\\ &\widetilde{M}_1(\xi_0)A_2 + 2\mathrm{Q}_1(\cosh\xi_0)\,B_1 = 0,\\ &\widetilde{K}_1(\xi_0)A_2 - \frac{1}{2}\mathrm{Q}_1^{(1)}(\cosh\xi_0)\,B_1 = 0, \end{aligned}$$

$$\text{(71)}\qquad y\text{-rotation:}\quad \begin{aligned} &\widetilde{M}_0(\xi_0)A_1 = 0,\\ &\widetilde{M}_1(\xi_0)A_2 + 2\mathrm{Q}_1(\cosh\xi_0)\,B_1 = 2\varpi_y\, c\cosh\xi_0,\\ &\widetilde{K}_1(\xi_0)A_2 - \frac{1}{2}\mathrm{Q}_1^{(1)}(\cosh\xi_0)\,B_1 = \varpi_y\, c\sinh\xi_0, \end{aligned}$$

and for both problems of the x-translation and y-rotation for $n \geq 2$:

$$\widetilde{L}_n(\xi_0)A_{n-1} + \widetilde{M}_n(\xi_0)A_{n+1} + n(n+1)\mathrm{Q}_n(\cosh\xi_0)\, B_n = 0, \tag{72a}$$

$$\begin{aligned} -\frac{c\,\sinh\xi_0}{2(2n-1)}\mathrm{Q}^{(1)}_{n-1}(\cosh\xi_0)A_{n-1} + \frac{c\,\sinh\xi_0}{2(2n+3)}\mathrm{Q}^{(1)}_{n+1}(\cosh\xi_0)A_{n+1}& \\ + \mathrm{Q}^{(2)}_n(\cosh\xi_0)\, C_n = 0&, \end{aligned} \tag{72b}$$

$$\widetilde{N}_n(\xi_0)A_{n-1} + \widetilde{K}_n(\xi_0)A_{n+1} + \frac{1}{2}\mathrm{Q}^{(1)}_n(\cosh\xi_0)\,(-B_n + (n-1)(n+2)\,C_n) = 0, \tag{72c}$$

where the functions $\widetilde{L}_n(\xi)$, $\widetilde{M}_n(\xi)$, $\widetilde{N}_n(\xi)$, and $\widetilde{K}_n(\xi)$ are determined by

$$\begin{aligned} \widetilde{L}_n(\xi_0) &= c\,\frac{n(n-1)}{2n-1}\left(\frac{3}{2}\sinh\xi_0\,\mathrm{Q}^{(1)}_{n-1}(\cosh\xi_0) + n\cosh\xi_0\,\mathrm{Q}_{n-1}(\cosh\xi_0)\right), \\ \widetilde{M}_n(\xi_0) &= c\,\frac{(n+1)(n+2)}{2n+3}\left(-\frac{3}{2}\sinh\xi_0\,\mathrm{Q}^{(1)}_{n+1}(\cosh\xi_0)\right. \\ &\qquad\qquad \left. + (n+1)\cosh\xi_0\,\mathrm{Q}_{n+1}(\cosh\xi_0)\right), \\ \widetilde{N}_n(\xi_0) &= -c\,\frac{(n-1)}{2n-1}\left(\frac{1}{2}\cosh\xi_0\,\mathrm{Q}^{(1)}_{n-1}(\cosh\xi_0) + n\sinh\xi_0\,\mathrm{Q}_{n-1}(\cosh\xi_0)\right), \\ \widetilde{K}_n(\xi_0) &= c\,\frac{(n+2)}{2n+3}\left(-\frac{1}{2}\cosh\xi_0\,\mathrm{Q}^{(1)}_{n+1}(\cosh\xi_0) + (n+1)\sinh\xi_0\,\mathrm{Q}_{n+1}(\cosh\xi_0)\right). \end{aligned}$$

The combination

$$\begin{aligned} (72\text{c})\cdot\mathrm{Q}_n(\cosh\xi_0)\mathrm{Q}^{(2)}_n(\cosh\xi_0) - (72\text{b})\cdot\frac{1}{2}(n-1)(n+2)\mathrm{Q}_n(\cosh\xi_0)\mathrm{Q}^{(1)}_n(\cosh\xi_0)& \\ + (72\text{a})\cdot\frac{1}{2n(n+1)}\mathrm{Q}^{(1)}_n(\cosh\xi_0)\mathrm{Q}^{(2)}_n(\cosh\xi_0)& \end{aligned}$$

reduces to

$$c\left(-\widetilde{A}_{n-1} + \widetilde{A}_{n+1}\right)\widetilde{\delta}_n = 0, \qquad n \geq 2, \tag{73}$$

where $\widetilde{A}_n = \frac{n(n+1)}{2(2n+1)}\,A_n$ and

$$\begin{aligned} \widetilde{\delta}_n = \frac{n(n+1)}{2}&\sinh[2\xi_0]\,(\mathrm{Q}_n(\cosh\xi_0))^3 + \frac{\cosh^2\xi_0}{n(n+1)}\left(\mathrm{Q}^{(1)}_n(\cosh\xi_0)\right)^3 \\ &- \frac{\left(4\coth\xi_0 + (n^2+n-1)\sinh[2\xi_0]\right)}{2n(n+1)}\,\mathrm{Q}_n(\cosh\xi_0)\left(\mathrm{Q}^{(1)}_n(\cosh\xi_0)\right)^2 \\ &- \cosh[2\xi_0]\,(\mathrm{Q}_n(\cosh\xi_0))^2\,\mathrm{Q}^{(1)}_n(\cosh\xi_0). \end{aligned}$$

Since $\widetilde{\delta}_n \neq 0$ for $n \geq 2$, it follows from (73) and (72a)–(72c) that for both x-translation and y-rotation,

$$\widetilde{A}_{n+1} = \widetilde{A}_{n-1}, \qquad n \geq 2, \tag{74a}$$

$$B_n = c\left(\cosh^2\xi_0 - 3\right)\frac{(2n+1)}{n(n+1)}\,\widetilde{A}_{n-1}, \qquad n \geq 2, \tag{74b}$$

$$C_n = -c\,\sinh^2\xi_0\,\frac{(2n+1)}{n(n-1)(n+1)(n+2)}\,\widetilde{A}_{n-1}, \qquad n \geq 2. \tag{74c}$$

Solving (70) and (71), we obtain

$$\text{(75a)}\qquad x\text{-translation:}\qquad \widetilde{A}_1 = \frac{q_1}{2c}, \qquad \widetilde{A}_2 = 0, \qquad B_1 = 0,$$

$$\text{(75b)}\qquad y\text{-rotation:}\qquad \widetilde{A}_1 = 0, \qquad \widetilde{A}_2 = \frac{2q_2}{c}, \qquad B_1 = 2q_2\left(\cosh[2\xi_0] - 2\right).$$

Finally, substituting (74a)–(74c) along with (75a) and (75b) into (69), and using the representations (80) in [32] and also

$$\frac{\sin^2\eta}{\sinh^2\xi\,(\cosh\xi - \cos\eta)} = \sum_{n=2}^{\infty} \frac{(2n+1)}{(n-1)n(n+1)(n+2)}\,\mathrm{Q}_n^{(2)}(\cosh\xi)\,\mathrm{P}_n^{(2)}(\cos\eta),$$

we obtain (66) and (67). The resisting force and torque follow from (48b) and (54b), respectively.

Example 3 (asymmetric translation and rotation of a solid oblate spheroid). Let (ξ, η, φ) be the oblate spheroidal coordinates related to the cylindrical coordinates by

$$\text{(76)}\qquad r = c\cosh\xi\,\sin\eta, \qquad z = c\sinh\xi\,\cos\eta, \qquad \xi \in [0,\infty), \quad \eta \in [0,\pi],$$

where the angular coordinate $\varphi \in [0, 2\pi)$ coincides with the one in (r, φ, z) and c is a metric parameter. In (ξ, η, φ), a solid oblate spheroid with the z-axis of revolution is determined by fixing the coordinate ξ, i.e., $\xi = \xi_0$. For the x-translation (28) and y-rotation (29), let the velocity field be represented by (30a)–(30b).

(i) For the x-translation, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are determined in the region $\xi \geq \xi_0$ by

(77)

$$G_1^{(0)}(\xi,\eta) = -\frac{q_1}{c}\,\frac{(\cos\eta + i\,\tanh\xi\sin\eta)}{\sinh^2\xi + \cos^2\eta},$$

$$G_2^{(0)}(\xi,\eta) = \frac{q_1}{2}\left(\sinh^2\xi_0 + 3\right)\left(\frac{\sinh[2\xi] - i\,\sin[2\eta]}{2\cosh\xi\left(\sinh^2\xi + \cos^2\eta\right)} - \operatorname{arccot}[\sinh\xi]\right),$$

$$G_3^{(1)}(\xi,\eta) = \frac{q_1}{2}\,\cosh^2\xi_0\,\frac{\sin\eta}{\cosh\xi}\,\frac{(\cos\eta + i\,\tanh\xi\sin\eta)}{\sinh^2\xi + \cos^2\eta},$$

where $q_1 = 4v_x\big/\left(\sinh\xi_0 - \left(\sinh^2\xi_0 + 3\right)\operatorname{arccot}[\sinh\xi_0]\right)$. The drag force $F_x = 4\pi\mu c q_1$ follows from (48b) and (77).

(ii) For the y-rotation, the functions $G_1^{(0)}$, $G_2^{(0)}$, and $G_3^{(1)}$ are determined in the region $\xi \geq \xi_0$ by

(78)

$$G_1^{(0)}(\xi,\eta) = \frac{4q_2}{c}\left(-\operatorname{arccot}[\sinh\xi] + \frac{\sinh[2\xi] - i\,\sin[2\eta]}{2\cosh\xi\left(\sinh^2\xi + \cos^2\eta\right)}\right),$$

$$\begin{aligned} G_2^{(0)}(\xi,\eta) = {} & q_2\left(\sinh^2\xi_0 - 3\right)\left(-2\mathrm{Q}_1(-i\sinh\xi)\cos\eta + i\,\mathrm{Q}_1^{(1)}(-i\sinh\xi)\sin\eta\right) \\ & + 2q_2\left(\sinh^2\xi_0 + 3\right)\frac{(\cos\eta + i\,\tanh\xi\sin\eta)}{\sinh^2\xi + \cos^2\eta}, \end{aligned}$$

$$G_3^{(1)}(\xi,\eta) = q_2\cosh^2\xi_0\sin\eta\left(3\mathrm{Q}_1^{(1)}(-i\sinh\xi) - \frac{\sinh[2\xi] - i\,\sin[2\eta]}{\cosh^2\xi\left(\sinh^2\xi + \cos^2\eta\right)}\right),$$

where $q_2 = \varpi_y c \big/ \big(\sinh\xi_0 - \big(\sinh^2\xi_0 - 1\big)\,\mathrm{arccot}[\sinh\xi_0]\big)$, and

$$\begin{aligned}\mathrm{Q}_1(-i\sinh\xi) &= \sinh\xi\ \mathrm{arccot}(\cosh\xi) - 1,\\ \mathrm{Q}_1^{(1)}(-i\sinh\xi) &= \cosh\xi\ \mathrm{arccot}(\cosh\xi) - \tanh\xi.\end{aligned}$$

The resisting torque $T_y = -16\pi\mu c^2 q_2 \cosh[2\xi_0]/3$ follows from (54b) and (78).

Detail. Obtaining (77) and (78) is similar to how (66) and (67) have been obtained.

Similarly, exact solutions to 3D Stokes flow problems for asymmetric motion of a solid spindle, lens, bispheres, and torus of circular cross-section can be obtained in terms of (30a)–(30b) with integral or series representations for k-harmonically analytic functions for corresponding regions; see [35, 34, 33].

In the next two examples, we solve the integral equations (37) and (38) for the x-translation of solid bispheroids (two separate, equal-size spheroids with the same axis of revolution) and for the y-rotation of a solid torus of elliptical cross-section. Exact solutions to these asymmetric Stokes flow problems are available only for two spheres [27] and a torus of circular cross-section [8]. To determine (39) and (40) for the x-translation (28) and y-rotation (29), we have

x-translation:	$f_1(\zeta) = 2iv_x$,	$f_2(\zeta) = -2v_x$,	$f_3(\zeta) = 0$,
y-rotation:	$f_1(\zeta) = -2\varpi_y\overline{\zeta}$,	$f_2(\zeta) = -2\varpi_y z$,	$f_3(\zeta) = 0$.

Example 4 (x-translation of solid bispheroids). Let the centers of bispheroids lie on the z-axis, which is the axis of revolution, and have coordinates $z = \coth 1$ (upper spheroid) and $z = -\coth 1$ (lower spheroid). Let ℓ_+ for $z \geq 0$ (upper spheroid) be parameterized by $r(t) = \varkappa \sin t/\sinh 1$, $z(t) = \coth 1 - \cos t/\sinh 1$, $t \in [0,\pi]$, where $\varkappa$ is a positive parameter. The case $\varkappa = 1$ corresponds to bispheres. For the x-translation (28), we represent $G_1^{(0)}(\zeta(t))$ and $U_3^{(1)}(\zeta(t))$ on ℓ_+ for $z \geq 0$ (upper spheroid) by

$$\begin{aligned} G_1^{(0)}(\zeta(t)) &= \sum_{k=1}^{n} (a_k + i\,b_k)\cos[(k-1)t], \qquad t \in [0,\pi],\\ U_3^{(1)}(\zeta(t)) &= \sum_{k=1}^{n} c_k \cos[(k-1)t], \qquad t \in [0,\pi], \end{aligned} \tag{79}$$

and determine $G_1^{(0)}(\zeta(t))$ and $U_3^{(1)}(\zeta(t))$ on ℓ_+ for $z \leq 0$ (lower spheroid) using $G_1^{(0)}\left(\overline{\zeta}\right) = -\overline{G_1^{(0)}(\zeta)}$ and $U_3^{(1)}\left(\overline{\zeta}\right) = -U_3^{(1)}(\zeta)$ (see Remark 5). The integral equations (37) and (38) can be solved with respect to the coefficients a_k, b_k, and c_k in (79) either by minimizing the total quadratic error of (37) and (38) with (79) or by the collocation method. In both cases, a_k, b_k, and c_k are found from a system of linear equations. Figures 1 and 2 illustrate profiles of the pressure on the surface of the bispheres ($\varkappa = 1$) and bispheroids for $\varkappa = 0.5$ and 2. Table 1 presents the ratio, d_x, of the drag, exerted on one of the two spheroids and calculated by (48a), to the drag of a single same-size spheroid[9] in the x-translation for $\varkappa = 0.5$, 1, and 2.

[9] This spheroid has the size of one spheroid in the bispheroids.

TABLE 1

The ratio, d_x, of the drag, exerted on one of the two solid spheroids, to the drag of a single same-size solid spheroid in the asymmetric translation along the x-axis for $\varkappa = 0.5$, 1, and 2. The case $\varkappa = 1$ corresponds to the bispheres. The value 0.7996 for $\varkappa = 1$ coincides with the one provided in [27].

$\varkappa$	0.5	1.0	2
d_x	0.8486	0.7996	0.7365

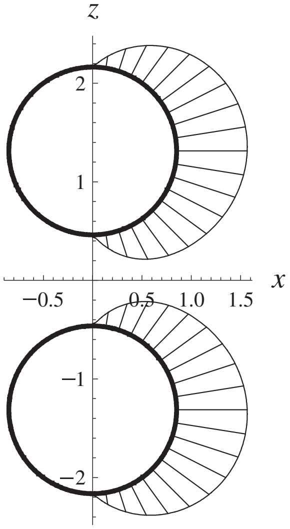

FIG. 1. *Profile of the pressure, $\wp/(2v_x\mu)$ on the surface of the solid bispheres ($\varkappa = 1$) in the asymmetric translation along the x-axis.*

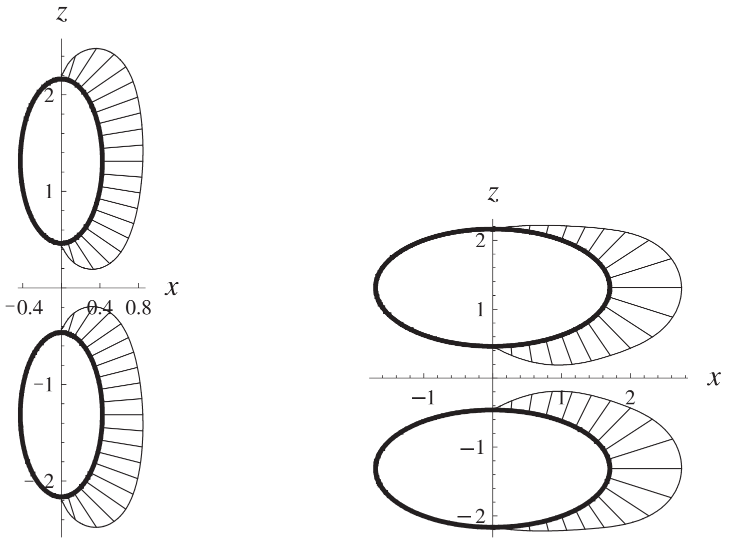

(a) $\wp/(5v_x\mu)$, prolate bispheroids (b) $\wp/(v_x\mu)$, oblate bispheroids

FIG. 2. *Profile of the pressure on the surface of the solid bispheroids in the asymmetric translation along the x-axis:* (a) $\wp/(5v_x\mu)$, *prolate bispheroids* ($\varkappa = 0.5$)*;* (b) $\wp/(v_x\mu)$, *oblate bispheroids* ($\varkappa = 2$).

Table 2

The normalized resisting torque, $t_x = T_x/(216\pi\mu\varpi_y)$, for the solid torus of elliptical cross-section in the asymmetric rotation around the y-axis for $\varkappa = 0.5$, 1, and 2. The case $\varkappa = 1$ corresponds to the torus of circular cross-section. The value 0.5590 *for $\varkappa = 1$ coincides with the one reported in* [8].

$\varkappa$	0.5	1.0	2
t_x	0.4636	0.5590	0.8903

Example 5 (y-rotation of a solid torus of elliptical cross-section). For torus of elliptical cross-section, let ℓ_+ be parameterized by $r(t) = 2 + \cos t$, $z(t) = \varkappa \sin t$, $t \in [-\pi, \pi]$, where $\varkappa$ is a positive parameter. The case $\varkappa = 1$ corresponds to the torus of circular cross-section. For the y-rotation (29), we represent $G_1^{(0)}(\zeta(t))$ and $U_3^{(1)}(\zeta(t))$ on ℓ_+ by

$$\begin{aligned} G_1^{(0)}(\zeta(t)) &= \sum_{k=1}^{n} \left(a_k \cos[(n-1)t] + i\, b_k \sin[k\, t] \right), \qquad t \in [-\pi, \pi], \\ U_3^{(1)}(\zeta(t)) &= \sum_{k=1}^{n} c_k \cos[(k-1)t], \qquad t \in [-\pi, \pi], \end{aligned} \tag{80}$$

for which $G_1^{(0)}\left(\overline{\zeta}\right) = \overline{G_1^{(0)}(\zeta)}$ and $U_3^{(1)}\left(\overline{\zeta}\right) = U_3^{(1)}(\zeta)$ on ℓ_+ (see Remark 5). The integral equations (37) and (38) can be solved with respect to the coefficients a_k, b_k, and c_k by the same methods as in Example 4. Figures 3, 4, and 5 illustrate profiles of the pressure on the surface of the torus of elliptical cross-section for $\varkappa = 1$, 0.5, and 2, respectively. Table 2 presents the ratio of the resisting torque, exerted on the torus and calculated by (54a), to the resisting torque, $216\pi\mu\varpi_y$, of the circumscribed sphere of radius 3 in the y-rotation for $\varkappa = 0.5$, 1, and 2.

Appendix. Auxiliary results for *k*-harmonically analytic functions. This section presents two auxiliary results dealing with implementation of the necessary and sufficient condition for a function $G^{(k)}$ to be k-harmonically analytic in an outer region and vanishing at infinity.

Let ℓ_+, ℓ, $\mathcal{D}^+$, $\mathcal{D}_0^+$, $\mathcal{D}^-$, and $\mathcal{D}_0^-$ be defined as in section 2, where $\mathcal{D}_0^+$ consists of disjoint simply connected subregions $\mathcal{D}_j^+$, $1 \le j \le m$. Also let $\widehat{\ell}_j$ be the part of the boundary ℓ_+ that corresponds to $\mathcal{D}_j^+$. It is either a closed curve or open curve with the endpoints lying on the z-axis. Obviously, $\ell_+ = \bigcup_{j=1}^m \widehat{\ell}_j$. We first establish the following result.

Proposition 9. *Let $G^{(k)}(\zeta) = U^{(k)}(\zeta) + i\,V^{(k+1)}(\zeta)$ be a k-harmonically analytic function in $\mathcal{D}_j^+$, $1 \le j \le m$, and let the functions $\left(\frac{\partial}{\partial r} - \frac{k}{r}\right) U^{(k)}$, $\frac{\partial}{\partial z} U^{(k)}$, $\left(\frac{\partial}{\partial r} + \frac{k+1}{r}\right) V^{(k+1)}$, and $\frac{\partial}{\partial z} V^{(k+1)}$ be continuously differentiable in $\mathcal{D}_j^+$, $1 \le j \le m$.*

(i) *If $U^{(k)}\big|_{\ell_+} = 0$, then $V^{(k+1)}(\zeta) = a_j\, r^{-k-1}$ in $\mathcal{D}_j^+$, where a_j is a real-valued constant.*

(ii) *If $V^{(k+1)}\big|_{\ell_+} = 0$, then $U^{(k)}(\zeta) = b_j\, r^k$ in $\mathcal{D}_j^+$, where b_j is a real-valued constant.*

Proof. First we prove (i). If $\widehat{\ell}_j$ is an open curve, we close it by connecting its

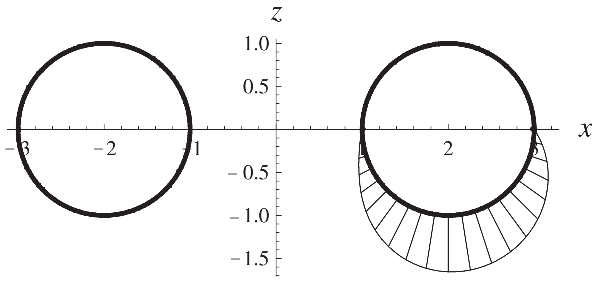

FIG. 3. *Profile of the pressure, $\wp/(4\varpi_y\mu)$, on the surface of the solid torus of circular cross-section ($\varkappa = 1$) in the asymmetric rotation around the y-axis (for $z > 0$, the profile is antisymmetric).*

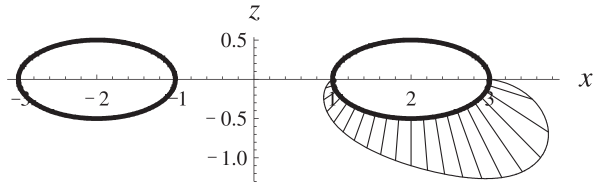

FIG. 4. *Profile of the pressure, $\wp/(4\varpi_y\mu)$, on the surface of the solid torus of elliptical cross-section with $\varkappa = 0.5$ in the asymmetric rotation around the y-axis (for $z > 0$, the profile is antisymmetric).*

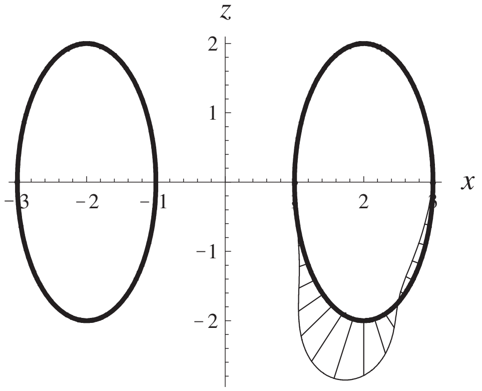

FIG. 5. *Profile of the pressure, $\wp/(4\varpi_y\mu)$, on the surface of the solid torus of elliptical cross-section with $\varkappa = 2$ in the asymmetric rotation around the y-axis (for $z > 0$, the profile is antisymmetric).*

endpoints by the segment on the z-axis. By Green's theorem, we have

$$\oint_{\widehat{\ell}_j} r\,U^{(k)}\left(\left[\left(\frac{\partial}{\partial r}-\frac{k}{r}\right)U^{(k)}\right]dz-\left[\frac{\partial}{\partial z}U^{(k)}\right]dr\right)$$

$$=\iint_{\mathcal{D}_j^+} r\,U^{(k)}\,\Delta_k U^{(k)}\,drdz+\iint_{\mathcal{D}_j^+} r\left(\left[\frac{\partial}{\partial z}U^{(k)}\right]^2+\left[\left(\frac{\partial}{\partial r}-\frac{k}{r}\right)U^{(k)}\right]^2\right)drdz.$$

Since $U^{(k)}\big|_{\ell_+}=0$ implies $U^{(k)}\big|_{\widehat{\ell}_j}=0$, the left-hand side of this equation is zero. Also the first integral in the right-hand side vanishes, since $U^{(k)}$ is a k-harmonic function, i.e., $\Delta_k U^{(k)} = 0$. Thus, $\left[\frac{\partial}{\partial z} U^{(k)}\right]^2 + \left[\left(\frac{\partial}{\partial r} - \frac{k}{r}\right) U^{(k)}\right]^2 \equiv 0$ in $\mathcal{D}_j^+$, whence $U^{(k)} = c_j\, r^k$, where c_j is a real-valued constant. However, from $U^{(k)}\big|_{\widehat{\ell}_j} = 0$, it follows that $c_j = 0$, and thus, $U^{(k)} \equiv 0$ in $\mathcal{D}_j^+$. Then, from (12), we have $V^{(k+1)} = a_j\, r^{-k-1}$ in $\mathcal{D}_j^+$, where a_j is a real-valued constant, and statement (i) is proved.

Statement (ii) is proved similarly. Observing that

$$\oint_{\widehat{\ell}_j} r\, V^{(k+1)} \left(\left[\left(\frac{\partial}{\partial r} + \frac{k+1}{r} \right) V^{(k+1)} \right] dz - \left[\frac{\partial}{\partial z} V^{(k+1)} \right] dr \right)$$
$$= \iint_{\mathcal{D}_j^+} r\, V^{(k+1)}\, \Delta_{k+1} V^{(k+1)}\, dr dz$$
$$+ \iint_{\mathcal{D}_j^+} r \left(\left[\frac{\partial}{\partial z} V^{(k+1)} \right]^2 + \left[\left(\frac{\partial}{\partial r} + \frac{k+1}{r} \right) V^{(k+1)} \right]^2 \right) dr dz,$$

and arguing as in the proof of part (i), we conclude that $V^{(k+1)} \equiv 0$ in $\mathcal{D}_j^+$, and the result follows. □

The necessary and sufficient condition for a function $G^{(k)}(\zeta) = U^{(k)}(\zeta) + i\, V^{(k+1)}(\zeta)$ to be k-harmonically analytic in the outer region $\mathcal{D}^-$ and vanishing at infinity follows from the generalized Sokhotski–Plemelj formulae and can be written in the form

$$G^{(k)}(\zeta) + \frac{1}{\pi i} \oint_{\ell} G^{(k)}(\tau) \mathcal{W}^{(k)}(\zeta, \tau)\, d\tau = 0, \quad \zeta \in \ell, \tag{81}$$

where ℓ is the boundary of $\mathcal{D}^-$.

Proposition 10. *Let $\mathcal{D}^-$ be symmetric with respect to the r-axis.*

(i) *If $G^{(k)}\left(\overline{\zeta}\right) = \overline{G^{(k)}(\zeta)}$, then* (81) *is equivalent to*

$$U^{(k)}(\zeta) + \operatorname{Re}\left[\frac{1}{\pi i} \oint_{\ell} G^{(k)}(\tau) \mathcal{W}^{(k)}(\zeta, \tau)\, d\tau \right] = 0, \quad \zeta \in \ell. \tag{82}$$

(ii) *If $G^{(k)}\left(\overline{\zeta}\right) = -\overline{G^{(k)}(\zeta)}$, then* (81) *is equivalent to*

$$V^{(k+1)}(\zeta) + \operatorname{Im}\left[\frac{1}{\pi i} \oint_{\ell} G^{(k)}(\tau) \mathcal{W}^{(k)}(\zeta, \tau)\, d\tau \right] = 0, \quad \zeta \in \ell. \tag{83}$$

Proof. The integral equations (82) and (83) are the real and imaginary parts of (81), respectively, and thus, any solution to (81) solves (82) and (83). We need to show that under the given conditions, the converse is also true.

First we prove statement (i). Let $G_*^{(k)}(\zeta)$, $\zeta \in \ell$, be a solution to (82) such that $G_*^{(k)}\left(\overline{\zeta}\right) = \overline{G_*^{(k)}(\zeta)}$, and let a k-harmonically analytic function $\Psi^+(\zeta)$ in $\operatorname{int} \mathcal{D}^+$ (the complement of $\mathcal{D}^-$) be determined by the generalized Cauchy-type integral

$$\Psi^+(\zeta) = \frac{1}{2\pi i} \oint_{\ell} G_*^{(k)}(\tau) \mathcal{W}^{(k)}(\zeta, \tau)\, d\tau, \quad \zeta \in \operatorname{int} \mathcal{D}^+.$$

In the case when ζ approaches ℓ from within the inner region $\mathcal{D}^+$, the boundary value of Ψ^+ on ℓ is determined by the corresponding generalized Sokhotski–Plemelj formula

$$\Psi^+(\zeta) = \frac{1}{2} G_*^{(k)}(\zeta) + \frac{1}{2\pi i} \oint_{\ell} G_*^{(k)}(\tau) \mathcal{W}^{(k)}(\zeta, \tau)\, d\tau, \quad \zeta \in \ell.$$

Since $G_*^{(k)}$ is a solution to (82), $\operatorname{Re}\Psi^+(\zeta) = 0$ on ℓ, whence $\operatorname{Re}\Psi^+(\zeta) = 0$ on ℓ_+. Then, by Proposition 9(i), we have $\operatorname{Im}\Psi^+(\zeta) = a_j\, r^{-k-1}$ in $\mathcal{D}_j^+$, where a_j is a real-valued constant, and $\mathcal{D}_j^+$, $1 \le j \le m$, are disjoint simply connected subregions of $\mathcal{D}_0^+$ such that $\mathcal{D}_0^+ = \bigcup_{j=1}^m \mathcal{D}_j^+$. However, since $G_*^{(k)}\left(\overline{\zeta}\right) = \overline{G_*^{(k)}(\zeta)}$, we have $\operatorname{Im}\Psi^+\left(\overline{\zeta}\right) = -\operatorname{Im}\Psi^+(\zeta)$, and consequently, $a_j = 0$ and $\Psi^+(\zeta) \equiv 0$ on ℓ_+. Thus, $G_*^{(k)}$ satisfies (81), and under the given condition the equivalence of (82) and (81) follows.

Statement (ii) is proved similarly. In this case, we have the same function $\Psi^+(\zeta)$ and use Proposition 9(ii). □

The necessary and sufficient condition for a function $f(\zeta)$ to be (ordinary) analytic in the outer region $\mathcal{D}^-$ and vanishing at infinity is given by $f(\zeta) + \frac{1}{\pi i}\oint_\ell \frac{f(\tau)}{\tau-\zeta}\,d\tau = 0$, $\zeta \in \ell$, which reduces to the nonsingular integral equation $2f(\zeta) + \frac{1}{\pi i}\oint_\ell \frac{f(\tau)-f(\zeta)}{\tau-\zeta}\,d\tau = 0$, $\zeta \in \ell$, with the fact that $c - \frac{1}{\pi i}\oint_\ell \frac{c}{\tau-\zeta}\,d\tau = 0$, $\zeta \in \ell$, for an arbitrary constant c. The next proposition extends this well-known technique for k-harmonically analytic functions, where the function r^k assumes the role of constant.

PROPOSITION 11. *The singular integral equation* (81) *reduces to*

$$\begin{aligned} 2\, r^k\, G^{(k)}(\zeta) + \frac{1}{\pi i}\int_{\ell_+} &\Big(r^k\, G^{(k)}(\tau) - r_1^k\, G^{(k)}(\zeta)\Big)\frac{\Omega_+^{(k)}(\zeta,\tau)}{\tau-\zeta}\,d\tau \\ &- \Big(r^k\,\overline{G^{(k)}(\tau)} - r_1^k\, G^{(k)}(\zeta)\Big)\frac{\Omega_-^{(k)}(\zeta,\tau)}{\overline{\tau}+\zeta}\,d\overline{\tau} = 0, \qquad \zeta \in \ell_+, \end{aligned} \tag{84}$$

where $r_1 = \operatorname{Re}\tau$. *Equation* (84) *has only logarithmic singularity because of the function* $\Omega_-^{(k)}$*; see Remark* 2 *in* [32].

Proof. Since r^k is a k-harmonically analytic function in $\mathcal{D}^+$ (the symmetry condition (15) holds), the generalized Sokhotski–Plemelj formula, corresponding to the case when ζ approaches ℓ from within $\mathcal{D}^+$, implies that

$$r^k - \frac{1}{\pi i}\oint_\ell r_1^k\, \mathcal{W}^{(k)}(\zeta,\tau)\,d\tau = 0, \qquad \zeta \in \ell. \tag{85}$$

The combination $r^k \cdot (81) + G^{(k)}(\zeta)\cdot(85)$ reduces to (84). □

Acknowledgment. We are grateful to the anonymous referees for their valuable comments and suggestions, which helped to improve the quality of the paper.

ESTIMATING A GREEN'S FUNCTION FROM "FIELD-FIELD" CORRELATIONS IN A RANDOM MEDIUM[*]

MAARTEN V. DE HOOP[†] AND KNUT SOLNA[‡]

Abstract. Traditional imaging methods use coherent signals as data. Here, we discuss recent developments in imaging that aim at exploiting as data incoherent noisy signals that are not associated with well-defined arrival times. Indeed, signal constituents that in a classical setting may be regarded as noise may contain important information about the medium to be imaged. We show how it is possible to use the statistics of such noisy signals, specifically, the second-order statistics, for imaging. We consider two particular situations: first, the estimation of an ("empirical") Green's function from noisy signals which can subsequently be used in imaging; second, the localization of a cluster of random sources from noisy signals (passive imaging). The analysis presented here is based on assuming a remote sensing scaling and the paraxial approximation, and it uses in part the results set forth in Papanicolaou, Ryzhik, and Solna [*SIAM J. Appl. Math.*, 64 (2004), pp. 1133–1155] that relate to time-reversal, statistical stability, and superresolution. Robustness with respect to modeling assumptions is illustrated by considering other scaling regimes also. We demonstrate how the estimation problem and its robustness can be considered as a dual to that of time-reversal and stable superresolution. We obtain a novel analysis and foundation for the use of ambient seismic noise in body-wave (tomographic) imaging, motivated by the recent successes of surface-wave tomography using ambient seismic noise.

Key words. empirical Green's function, random medium, paraxial approximation, statistical stability

1. Introduction.

1.1. Time-reversal and cross-correlation–based imaging.

Recent work on time-reversal of waves in a random medium has shown that medium fluctuations are not necessarily detrimental to, but may in fact enhance various operations with, waves. This has been analyzed mathematically as well as demonstrated experimentally [4, 20, 22, 25, 30, 31, 33]. In classical time-reversal, the wave received by an active transducer (receiver-emitter) array is recorded and then re-emitted into the configuration time-reversed; that is, the tails of the recorded signals are sent first. In the absence of absorption, the re-emitted signal will propagate back toward the source and focus, approximately, on it. This phenomenon has a large number of applications, in inverse problems, medical imaging, remote sensing, target identification, and secure communication, for instance. Here, we discuss the notion of "field-field" cross-correlations associated with noise observed at pairwise distinct receivers, to obtain an "empirical" Green's function. This notion is naturally related to the time-reversal mentioned above [13, 14]. We will give a precise characterization of the "empirical" Green's function, which can subsequently be used for imaging the interrogated

medium. To this end, we consider a configuration consisting of a randomly heterogeneous halfspace, possibly containing a scatterer, which is exposed to random *noisy sources* concentrated at the surface (that is, the top of the halfspace). The idea is to use *cross-correlations* between a set of measurements of noise to infer information about the medium in the halfspace as well as about the location of the scatterer.

With seismology as a key application in mind, the goal is to obtain an image of Earth's interior from all possible signals recorded at an array of receiver stations. Robust imaging requires, essentially, a regular distribution of sources. Effectively using receivers as sources through the mentioned "field-field" cross-correlations, this requirement can be satisfied, even where deterministic sources (earthquakes) are necessarily absent. The idea of using ambient noise for the retrieval of a body-wave reflection response, in a planarly layered medium, dates back to Claerbout [8]. He also conjectured that, in general media, cross-correlating ambient noise traces from two locations recaptures the wavefield at one of the locations, excited by a point source at the other location. An early example of a field application was reported by Scherbaum [37], who analyzed auto-correlations of recordings of low-magnitude earthquakes and generated *pseudoreflection seismograms*. Moreover, the cross-correlation method has been developed in helioseismology [16]. In recent years, the understanding of how cross-correlating diffuse fields recaptures the Green's function has been a topic of research [46, 42]. Cross-correlating (diffuse) coda waves [7] and ambient seismic noise [38, 39] resulted in the retrieval of surface waves observed at one station and excited at the other station; for a detailed study, see Yao, van der Hilst, and deHoop [43]. Furthermore, *turning* body waves have been observed in cross-correlating ambient noise [35]; in an exploration seismology setting, *reflected* body waves have also been recovered by cross-correlations [15]. The exploitation of a scattering medium in capturing the Green's function by field-field cross-correlations was studied by Derode et al. [14]. The mathematical analysis of field-field cross-correlations in the mentioned setting from the point of view of heterogeneous media has just begun. See [26] for analysis of the case with a layered random medium and [3] for a recent analysis based on the semiclassical approximation and that explicitly discusses stability of the traveltime estimates associated with the correlations which requires a careful analysis of the time scales involved. In [10], field-field cross-correlations from ambient noise, which is not necessarily localized or directional, are analyzed in the high-frequency limit, again making use of Egorov's theorem of microlocal analysis. Here, motivated by applications to propagation in the heterogeneous earth and the atmosphere, we will consider the far field regime and consider a stochastic modeling approach. We exploit the random fluctuations in the medium and consider a variety of (scaling) regimes. In the above, noisy sources are passive sources, while the medium is subjected to random fluctuations. Controlled sources can be used to retrieve the Green's function from cross-correlations of wavefields observed at pairwise distinct receivers as well. Time-reversal and Rayleigh's reciprocity relation can be combined to easily identify the cross-correlation as the Green's function in the interior of a compact domain with controlled sources (everywhere) on its boundary without knowledge of the (deterministic) medium [12]; applications of this general result in borehole seismic imaging can be found in [28, 47, 44]. Insights in extending this situation to the case with decorrelating random sources (on the boundary) can be found, for example, in [45].

A proper estimate of the Green's function between a set of locations can be used for robust imaging from ambient noise [27, 39, 43] and for encoding signals also. The technique of cross-correlations is furthermore relevant in the context of

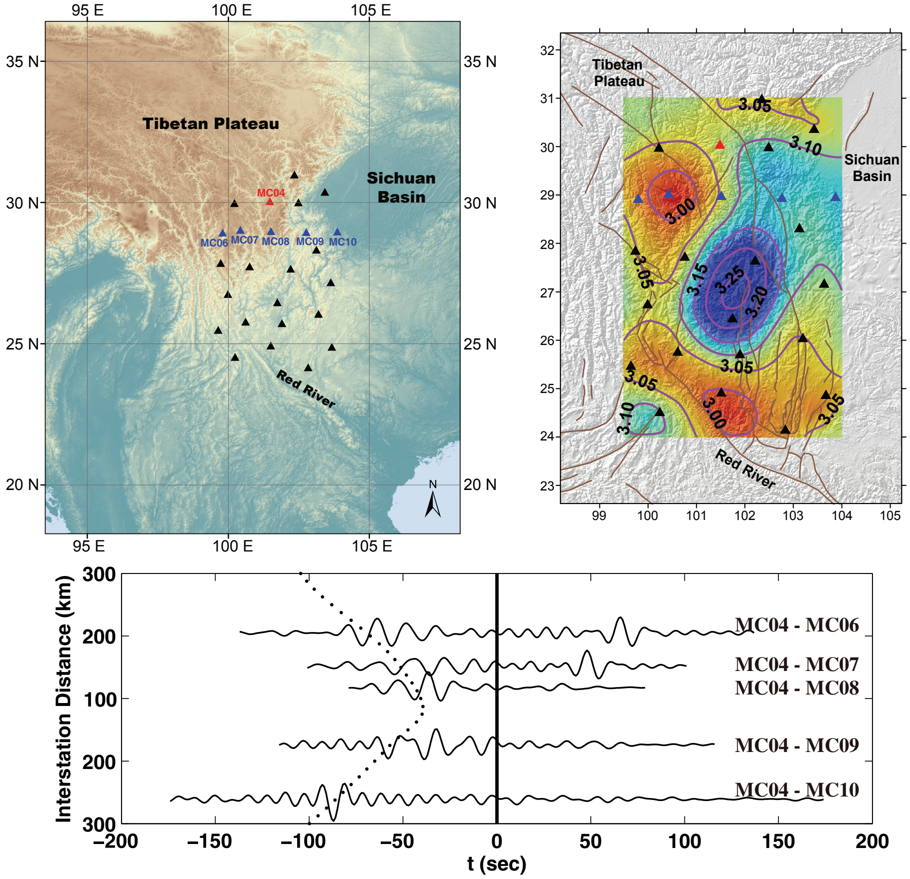

FIG. 1.1. *Top left: a map and the array of receivers. Top right: phase velocities at $T = 10\,s$ (obtained from the Green's function estimates between all pairs of receivers, and given in* [43]*); these phase velocities play the role of c_0. Bottom: Green's function estimates from* 10 *months of data cross-correlations. The positive times correspond to the Green's function from the "source" station MC*04 *(red) to receivers MC∗∗ (blue), while the negative times correspond to the Green's function from the "source" stations MC∗∗ (blue) to receiver station MC*04 *(red). We observe an asymmetry (in time) that will appear in the analysis presented here also. The dotted line indicates the traveltimes computed from the top right figure.*

communication in a waveguide [36] and synchronization of transducer array elements. Detection based on cross-correlations in a noisy environment is discussed in [1] and interferometric imaging in [6]. The theory for analysis of cross-correlations in layered media is presented in [25] with applications presented in, for instance, [23, 24]. While current studies relating to the heterogeneous earth mostly make use of surface-wave contributions to the Green's function estimate, we emphasize, here, the importance of understanding the behavior of body waves for future applications. In Figure 1.1 we illustrate surface-wave contributions to the Green's function estimate over an array in Southeastern Tibet (obtained from [43], upon cross-correlating noise between receiver pairs over a 10 month period).

In this paper, we analyze *estimation based on incoherent waves* in the context of the paraxial approximation and the associated Wigner distribution. We prove that,

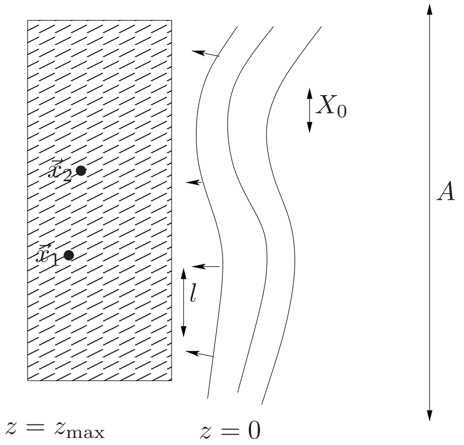

FIG. 1.2. *The experimental setup: A slab of random medium is located in* $(0, z_{\max})$. *In the plane* $z = 0$ *a set of random sources probe the medium, and we record the signal transmitted to the two points of observation* $\vec{x}_1$ *and* $\vec{x}_2$.

in principle, the Green's function can be recovered from cross-correlations, up to a filter that depends only mildly on the medium realization. Moreover, we show that much better estimates (when the Green's function is better resolved) may be obtained in a randomly inhomogeneous medium than in a deterministic (quasi-)homogeneous medium, as a consequence of the wider angular spread in the phase-space representation of a wave in the random medium; this is in agreement with the results of the experiment described in [13]. The enhanced resolution occurs due to an exponential damping factor that appears in the analysis of the cross-correlation and that involves the structure function of the medium; thus, relatively strong disorder gives relatively high resolution. The damping factor was also responsible for superresolution in the time-reversal experiment elucidated in [33], revealing an intrinsic connection. It appears to be important that the signals generating the cross-correlations are subjected to frequency-bandlimitation: The low frequencies must be removed to obtain accurate estimates.

Furthermore, we discuss the localization of a cluster of random sources from noisy signals, a problem which is closely related to the Green's function estimation.

1.2. Configuration and procedure. We consider a configuration and an experiment similar to the one described in [13], while motivated by the procedure and study described in [43]; the configuration is illustrated in Figure 1.2. We use $\mathbf{x} \in \mathbb{R}^d$, with $d \in \{1, 2\}$ denoting the lateral spatial dimension, to represent the "lateral" coordinate(s) and $z \in \mathbb{R}_{\geq 0}$ to represent the "principal" or "depth" coordinate; we write $\vec{x} = (z, \mathbf{x})$. The above-mentioned halfspace contains a heterogeneous slab, the random medium, with a large extent in the lateral directions and supported in $(0, z_{\max})$ in the principal direction. The sources are concentrated in the plane $z = 0$ and are independent of the random medium; they model the ambient noise field. The sources are incoherent and statistically stationary. The aperture, or lateral extent, of the source field is denoted A, and its correlation length X_0, while the correlation length of the random medium is denoted l. We observe the signal, u say, that is due to the noisy sources at the points, $\vec{x}_1$ and $\vec{x}_2$, which may be inside or outside ($z > z_{max}$) the random medium, over the time interval $(0, T)$. The key quantity considered is the cross-correlation function,

$$\mathcal{C}(\tau) = \frac{1}{T}\int_0^T u(t,\vec{x}_1)u(t+\tau,\vec{x}_2)\,dt\,, \tag{1.1}$$

for a large time window $(0,T)$. We will also consider the situation with more than two points of observation: $\vec{x}_1,\ldots,\vec{x}_N$, $N \geq 3$.

1.3. Outline. The outline of the paper is as follows. In section 1.2 we discussed the configurational setup that we will consider. In section 2 we describe the modeling of the sources, the medium, and the stochastic paraxial wave equation formulation. Using this model, we analyze the estimation based on (1.1) in section 3. The main result shows that the cross-correlations give the Green's function blurred by a statistically stable "filter"; cf. (3.19). A striking property of the filter is that its support may be much smaller in a random medium than in a (quasi-)homogeneous medium, which is the counterpart of superresolution in this context. In section 4 we develop an approach to localizing a cluster of random sources from noisy signals. The main aspects of the results we derive are general, and we demonstrate this by discussing different scaling regimes in section 5. In subsection 5.4 we touch upon the scaling regime anticipated in applying the analysis to Southeastern Tibet for the estimation of body-wave constituents from ambient noise. We provide some numerical examples in section 6, and concluding remarks in section 7.

2. High-frequency paraxial regime and modeling.

2.1. The random sources. We shall model the ambient or background far field noise in terms of a random field. The impinging noise will be modeled as an initial condition in the plane $z = 0$ supplementing the paraxial evolution equation to be introduced in the next subsection; see Figure 1.2.

Let ν be a random field in $\mathbb{R}\times\mathbb{R}^d$, and χ be a smooth, deterministic, envelope function. We assume that ν has zero mean, is isotropic in $\mathbf{x}$ and stationary, and is independent of the medium with spectrum,

$$\mathbb{E}[\nu(t',\mathbf{x}')\nu(t'+\tau,\mathbf{x}'+\Delta\mathbf{x})] = C_0\left(\tau,\Delta\mathbf{x}\right), \tag{2.1}$$

and with rapidly decaying correlations. The noisy sources are then collectively modeled as

$$Y(t,\mathbf{x}) = \sigma_y \nu\left(\frac{t}{T_0},\frac{\mathbf{x}}{X_0}\right)\chi\left(\frac{\mathbf{x}-\mathbf{x}_c}{A}\right). \tag{2.2}$$

The envelope function χ models the locality of the sources. We shall consider both an extended source field, with χ having a "large" support, and a concentrated source field, with χ having a "small" support. It is convenient to introduce a characteristic wavelength scale, λ_0, associated with the noise source spectrum,

$$\lambda_0 = c_0 T_0 = \frac{2\pi c_0}{\omega_0} = \frac{2\pi}{k_0}\,, \tag{2.3}$$

where T_0 is a characteristic time scale associated with the temporal noise correlations (cf. (2.2)) and c_0 background or homogenized medium wavespeed. Note that the central wavenumber is defined by

$$k_0 = \frac{\omega_0}{c_0}\,.$$

2.2. The parabolic wave equation. In recent decades the parabolic or paraxial wave equation has emerged as the primary tool to describe small scale scattering situations as they appear in radiowave propagation, radar, remote sensing, propagation in urban environments, and in underwater acoustics [29, 32, 41], as well as in propagation problems in the earth's crust [9]. The paraxial equation models wave propagation if the dominant scattering occurs in the direction(s) transverse to a principal propagation direction. Here, we take this model as our starting point and consider propagation in a random medium in the regime of waves propagating over distances that are large compared to the correlation length of the random inhomogeneities and the characteristic wavelength. The relevant wavelength scale is determined by the support of the noise auto-covariance function.

Fundamental to the problem at hand is the role of *scales*. Different scaling relations will give rise to different qualitative behavior of the estimation of the Green's function. The important scales are the following:

- z_1, the characteristic depth (longitudinal distance) from noisy sources to the recordings;
- A, the characteristic size for the support of noisy sources collectively;
- T_0, X_0, the temporal and lateral (spatial) extent of the noise spectrum;
- σ_c, the relative magnitude of medium fluctuations; see (2.5);
- l, the correlation length of the (isotropic) medium fluctuations; see (2.5).

The correlation length corresponds to the dominant spatial scale at which the medium fluctuates, and it typically defines the microscale in the problem.

To introduce the paraxial wave approximation, we consider first the wave equation governing the propagation of acoustic waves:

$$\frac{1}{c^2(\vec{x})}\frac{\partial^2 u}{\partial t^2} - \triangle u = 0\,, \quad t \in \mathbb{R}\,, \quad \vec{x} \in \mathbb{R}^{d+1}\,. \tag{2.4}$$

Here, the slowness squared, $c^{-2}(z, \mathbf{x})$, is given by

$$c^{-2}(z, \mathbf{x}) = c_0^{-2}\left[1 + \sigma_c\,\mu\left(\frac{z}{l}, \frac{\mathbf{x}}{l}\right)\right], \tag{2.5}$$

in which μ is a random field modeling the medium fluctuations; c_0 denotes the (deterministic) background wavespeed. In the regime of homogenization, with relatively rapidly fluctuating medium variations, the effective wavespeed is c_0. The regime of homogenization corresponds to the case when the wavelength is large relative to the correlation length of the medium fluctuations, and the propagation distance is on the order of the wavelength. However, in a regime of large propagation distances the effect of the randomness will build up, and this phenomenon will be captured by a random potential, namely through μ, in the paraxial wave equation. We shall here assume that the background wavespeed is constant; see [40] for a discussion of the case with a variable background.

Because "locally" the waves sense a homogeneous medium, it is common practice to introduce the following Fourier transform incorporating the centering in a frame moving with the effective wavespeed,

$$u(t, z, \mathbf{x}) = \frac{1}{2\pi}\int e^{\mathrm{i}\omega(z/c_0 - t)}\psi(z, \mathbf{x}, \omega/c_0)\,d\omega\,, \tag{2.6}$$

so that the complex amplitude $\psi(z, \mathbf{x}, k)$ satisfies the Helmholtz equation

$$2\mathrm{i}k\frac{\partial\psi}{\partial z} + \triangle_{\mathbf{x}}\psi + k^2(n^2 - 1)\psi = -\frac{\partial^2\psi}{\partial z^2}\,, \tag{2.7}$$

with $k = \omega/c_0$ being the wavenumber and $n = n(z, \mathbf{x}) = c_0/c(z, \mathbf{x})$ the random index of refraction relative to the background wavespeed c_0. The fluctuations in the refraction index attain the form

$$n^2(z, \mathbf{x}) - 1 = \sigma_c \, \mu \left(\frac{z}{l}, \frac{\mathbf{x}}{l} \right) . \tag{2.8}$$

We assume that the fluctuations are modeled by an isotropic and smooth in $\mathbf{x}$, zero mean, stationary rapidly decorrelating random field $\mu(\cdot, \cdot)$, which moreover is Markovian in z. The normalized and dimensionless covariance is given by

$$R(\Delta z, \Delta \mathbf{x}) = \mathbb{E}[\mu(z', \mathbf{x}')\mu(\Delta z + z', \Delta \mathbf{x} + \mathbf{x}')] , \tag{2.9}$$

with $R(0, 0) = 1$. We, again, assume rapidly decaying correlations. Note that the dimensionless function R is supported on the $\mathcal{O}(1)$ scale. Thus, the correlation radius of the medium fluctuations is l. We shall consider a specific scaling regime characterized by a certain relation between the parameters that we have introduced in the problem; this scaling regime essentially corresponds to the one introduced in [33]. The regime will follow from the next step where we introduce dimensionless coordinates. To this end, we introduce the characteristic length scales as

- l_x, the characteristic length scale in the lateral direction,
- l_z, the characteristic length scale in the principal (depth) direction.

The following dimensionless parameters will be important in the further analysis:

$$\varepsilon = \frac{l}{l_z} , \quad \delta = \frac{l}{l_x} , \quad \theta = \frac{k_0 l_x^2}{l_z} ; \tag{2.10}$$

θ is commonly referred to as the *Rayleigh* number, while ε and δ are the medium correlation length relative to, respectively, characteristic principal and lateral scales. We remark that we specify in (3.5) below how the correlation scale of the ambient noise field relates to these small parameters. The important scaling regime considered here is the *high-frequency paraxial scaling* as introduced in [33], with

$$\frac{1}{\theta} \ll \varepsilon \ll \delta \ll 1 . \tag{2.11}$$

We hasten to add that there are other relevant scaling regimes [2, 5, 18, 34]; we discuss some scaling alternatives in section 5. However, the regime set forth above is characteristic for the estimation problem at hand and captures key aspects of the physical phenomenon under discussion. Note that it follows from our scaling assumptions that $l_x \ll l_z$, which corresponds to the characteristic propagation distance being much larger than the characteristic aperture size and the classical paraxial or beam scaling. This follows, since with $\vec{x}_j = (z_j, \mathbf{x}_j)$ denoting the recording points as before, we shall assume a regime where

$$z_j' = \frac{z_j}{l_z} , \quad \mathbf{x}_j' = \frac{\mathbf{x}_j}{l_x} ,$$

as well as

$$A' = \frac{A}{l_x} , \quad z_{\max}' = \frac{z_{\max}}{l_z} ,$$

are fixed, while considering the limits $1/\theta, \varepsilon, \delta \to 0$. The dimensionless coordinates are

$$z' = \frac{z}{l_z} , \quad \mathbf{x}' = \frac{\mathbf{x}}{l_x} , \quad k' = \frac{k}{k_0} , \quad \omega' = \frac{\omega}{\omega_0} , \tag{2.12}$$

and we let

$$t' = \frac{2\pi t}{T_0} = \omega_0 t\,, \quad \bar{c} = \frac{c_0}{\omega_0 l_z} = \frac{1}{k_0 l_z}\,, \tag{2.13}$$

so that

$$\omega(z/c_0 - t) = \omega'(z'/\bar{c} - t')\,.$$

Note that we have $k' = \omega'$.

In the further analysis, we shall drop the primes in the nondimensionalized coordinates; in dimensionless variables $(z, \mathbf{x}, \omega)$, the paraxial wave equation then becomes

$$2\mathrm{i}\,(\theta k)\,\frac{\partial \psi}{\partial z} + \triangle_{\mathbf{x}}\psi + \frac{\delta}{\sqrt{\varepsilon}}\,(\theta^2 k^2)\,\mu\Big(\frac{z}{\varepsilon}, \frac{\mathbf{x}}{\delta}\Big)\,\psi = 0\,, \tag{2.14}$$

with $\psi = \psi(z, \mathbf{x}, k)$, upon the identification (cf. (2.7))

$$\sigma_c = \sqrt{\varepsilon}\left(\frac{\varepsilon}{\delta}\right) = \sqrt{l/l_z}\left(\frac{l_x}{l_z}\right)\,.$$

This is the product of the white noise normalization factor $\sqrt{\varepsilon}$ and the paraxial scaling parameter. These factors are small so that the modeling corresponds to relatively small medium fluctuations. This is exactly the scaling of the fluctuations that gives partly coherent propagation of the wavefield. The fluctuations are sufficiently strong so that the wavefield is affected beyond the homogenization situation, but not so strong that the field completely loses its coherence.

In the scaling regime considered, $\frac{\partial^2 \psi}{\partial z^2}$ on the right-hand side of (2.7) can be neglected. Equation (2.14) is an evolution equation, which is supplemented with the initial conditions (cf. (2.2))

$$\frac{1}{2\pi}\int e^{\mathrm{i}\omega(-t)}\psi(z = 0, \mathbf{x}, \omega)\,d\omega = Y\,(T_0 t, l_x \mathbf{x})\,. \tag{2.15}$$

Indeed, the paraxial field ψ satisfies an initial value problem rather than a boundary value problem as in the case of the Helmholtz equation. This reflects the fact that we consider a regime where lateral scattering is dominant over scattering along the principal direction.

2.3. White noise model. We shall consider functionals of the field, ψ, in the scaling regime in (2.11). Following [33], we introduce the Wigner distribution:

$$W_\theta(z, \mathbf{x}, \mathbf{p}; \omega) = \iint \frac{1}{(2\pi)^d} e^{\mathrm{i}\mathbf{p}\cdot\mathbf{y}}\psi\left(z, \mathbf{x} - \frac{\mathbf{y}}{2\theta}, \omega\right)\psi\left(z, \mathbf{x} + \frac{\mathbf{y}}{2\theta}, \omega\right)^* d\mathbf{y}\,, \tag{2.16}$$

where we have used "*" to represent complex conjugation. It can then be shown [17, 33] that in the *high-frequency* ($\theta \to \infty$) and *white noise* ($\varepsilon \to 0$) limit, the limiting Wigner transform that we denote as W_δ is characterized weakly (in law) by the Itô–Liouville stochastic partial differential equation, as follows.

PROPOSITION 2.1. *The Wigner distribution W_θ converges in the limit $1/\theta \to 0$ followed by $\varepsilon \to 0$ weakly in law to the process W_δ solving*

$$dW_\delta = \left[-\frac{\mathbf{p}}{k}\cdot\nabla_{\mathbf{x}}W_\delta + \frac{k^2 D}{2}\triangle_{\mathbf{p}}W_\delta\right]dz - \frac{k}{2}\nabla_{\mathbf{p}}W_\delta \cdot d\mathbf{B}\left(z, \frac{\mathbf{x}}{\delta}\right)\,. \tag{2.17}$$

Here, $\mathbf{B}(\mathbf{x}, z)$ is a vector-valued Brownian field with covariance

$$\mathbb{E}[B_i(z_1, \mathbf{x}_1)B_j(z_2, \mathbf{x}_2)] = -\left(\frac{\partial^2 R_0(\mathbf{x}_1 - \mathbf{x}_2)}{\partial x_i \partial x_j}\right) z_1 \wedge z_2\,, \tag{2.18}$$

where $z_1 \wedge z_2 = \min\{z_1, z_2\}$; in the assumed isotropic case, we have (cf. (2.9))

$$D = -\frac{R_0''(0)}{4}, \quad \text{with } R_0(\mathbf{x}) = \int_{-\infty}^{\infty} R(\zeta, \mathbf{x})\, d\zeta\,. \tag{2.19}$$

We remark that the second derivative of the (isotropic) medium correlation function is negative: $R_0''(0) < 0$ so that indeed (2.17) is well posed. It now follows directly from (2.17) that the mean, $\overline{W} = \mathbb{E}[W_\delta]$, is independent of δ and solves the advection-diffusion equation

$$\frac{\partial \overline{W}}{\partial z} + \frac{\mathbf{p}}{k} \cdot \nabla_{\mathbf{x}} \overline{W} = \frac{k^2 D}{2} \triangle_{\mathbf{p}} \overline{W}\,. \tag{2.20}$$

The explicit expression for the Green's function of (2.20) is

$$\begin{aligned} U(z, \mathbf{x}, \mathbf{p}; \mathbf{x}_0, \mathbf{p}_0) = \iint \frac{1}{\omega^d (2\pi)^{2d}} \exp\left(\mathrm{i}\left[\mathbf{w} \cdot (\mathbf{x} - \mathbf{x}_0) + \mathbf{r} \cdot \frac{(\mathbf{p} - \mathbf{p}_0)}{\omega} - z\mathbf{w} \cdot \frac{\mathbf{p}_0}{\omega}\right]\right) \\ \times \exp\left(-\frac{Dz}{2}\left[r^2 + z\mathbf{r} \cdot \mathbf{w} + \frac{w^2 z^2}{3}\right]\right) d\mathbf{w}\, d\mathbf{r}\,, \end{aligned} \tag{2.21}$$

with $r = \|\mathbf{r}\|_2$ and $w = \|\mathbf{w}\|_2$. This expression will be useful in order to characterize how the computed cross-correlations relate to the propagation Green's function of interest. That the computed cross-correlations give a stable and "low noise" estimate of the Green's function shall emerge as a consequence of assuming a stabilization regime. Indeed, here we shall assume the *stabilization* regime corresponding to the limit $\delta \to 0$, as discussed in [33]. The robust estimation of the empirical Green's function will be a consequence of the following stabilization result.

PROPOSITION 2.2. *Assume that the initial Wigner distribution, $W_I(\mathbf{x}, \mathbf{p})$, is uniformly bounded and Lipschitz continuous. Define*

$$I_\delta(z, \mathbf{x}, \mathbf{y}) = \iint W_\delta(z, \mathbf{x}, \mathbf{p}) e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}\, d\mathbf{p}. \tag{2.22}$$

Then

$$\lim_{\delta \to 0} \mathbb{E}\left\{I_\delta^2(z, \mathbf{x}, \mathbf{y})\right\} = \mathbb{E}^2\left\{I_\delta(z, \mathbf{x}, \mathbf{y})\right\}, \tag{2.23}$$

where $\mathbb{E}\{I_\delta(z, \mathbf{x}, \mathbf{y})\}$ is independent of δ.

This result is a slight generalization of the stability result derived in [33]; see the appendix.

3. Analysis of cross-correlations.

3.1. Time averaging.

The quantity of interest is the cross-correlation function,

$$\mathcal{C}_{\mathcal{H}}(\tau, \vec{x}_1, \vec{x}_2) = \int \mathcal{H}(t)\, u(t, \vec{x}_1) u(t + \tau, \vec{x}_2)\, dt\,, \tag{3.1}$$

in which $\mathcal{H}$ is a time-window function; cf. (1.1). Here, u is modeled from the solution of the paraxial wave equation (cf. (2.14)) subject to initial conditions (2.15). We introduce the notation $\check{v}$ for the partial Fourier transform of v with respect to time, and $\widehat{v}$ for the complete transform:

$$v(t,\mathbf{x}) = \frac{1}{2\pi}\int e^{-\mathrm{i}\omega t}\check{v}(\omega,\mathbf{x})\,d\omega = \frac{1}{(2\pi)^{d+1}}\iint e^{-\mathrm{i}(\omega t-\mathbf{p}\cdot\mathbf{x})}\widehat{v}(\omega,\mathbf{p})\,d\mathbf{p}\,d\omega\,.$$

Let G_θ be the Green's function associated with the paraxial wave equation (2.14); then we have in the standardized variables

$$u(t,\vec{x}) = \iint \widetilde{G}_\theta(t-s,\vec{x};\vec{x}_n)\,Y(T_0 s, l_x\mathbf{x}_n)\,d\mathbf{x}_n ds, \tag{3.2}$$

where $\vec{x}_n = (0,\mathbf{x}_n)$ and

$$\widetilde{G}_\theta(t,z,\mathbf{x};0,\mathbf{x}_n) = \frac{1}{2\pi}\int e^{\mathrm{i}\omega(z/\overline{c}-t)}G_\theta(\omega,z,\mathbf{x};0,\mathbf{x}_n)\,d\omega \tag{3.3}$$

(cf. (2.6)). Substituting (3.2) into (3.1) yields

$$\begin{aligned}\mathcal{C}_{\mathcal{H}}(\tau,\vec{x}_1,\vec{x}_2) = \iint &\mathcal{H}(t)\widetilde{G}_\theta(t-s_1,\vec{x}_1;\vec{x}_{n_1})Y(T_0 s_1, l_x\mathbf{x}_{n_1})\\ &\times \widetilde{G}_\theta(t+\tau-s_2,\vec{x}_2;\vec{x}_{n_2})Y(T_0 s_2, l_x\mathbf{x}_{n_2})\,dt\,ds_1\,ds_2\,d\mathbf{x}_{n_1}\,d\mathbf{x}_{n_2}\,.\end{aligned} \tag{3.4}$$

Note that by the result (2.20) the paraxial field decorrelates laterally on the scale $1/\theta$. We now assume that the ambient noise field decorrelates on this scale by choosing

$$X_0 = \frac{l_x}{\theta}\,. \tag{3.5}$$

When we substitute (2.2) into (3.4), we then obtain

$$\begin{aligned}\mathcal{C}_{\mathcal{H}}(\tau,\vec{x}_1,\vec{x}_2) = \iint \sigma_y^2 \left\{\int \mathcal{H}(t)\nu(t-v_1,\theta\mathbf{x}_{n_1})\,\nu(t-v_2,\theta\mathbf{x}_{n_2})\;dt\right\}\\ \times\,\widetilde{G}_\theta(v_1,\vec{x}_1;\vec{x}_{n_1})\widetilde{G}_\theta(v_2+\tau,\vec{x}_2;\vec{x}_{n_2})\chi\left(\frac{\mathbf{x}_{n_1}-\mathbf{x}_c}{A}\right)\chi\left(\frac{\mathbf{x}_{n_2}-\mathbf{x}_c}{A}\right)\,dv_1\,dv_2\,d\mathbf{x}_{n_1}\,d\mathbf{x}_{n_2}\,.\end{aligned} \tag{3.6}$$

We may choose for $\mathcal{H}$ the indicator function

$$\mathcal{H}_T(\cdot) = \frac{\mathcal{I}_{\left(-\frac{T}{2},\frac{T}{2}\right)}(\cdot)}{T}\,;$$

then

$$\lim_{T\to\infty}\int_{-\infty}^{\infty}\mathcal{H}_T(t)\nu(t-v_1,\theta\mathbf{x}_{n_1})\,\nu(t-v_2,\theta\mathbf{x}_{n_2})\,dt = C_0(v_2-v_1,\theta(\mathbf{x}_{n_2}-\mathbf{x}_{n_1}))\,,$$

the mean square with respect to the distribution of the impinging noise sources. Our interest is in such a regime where the time average effectively removes the fluctuations in the quantity of interest, *exploiting the randomness of the sources.* Substituting the above average into (3.6) leads to the introduction of

$$\begin{aligned}\langle\mathcal{C}\rangle_\theta(\tau,\vec{x}_1,\vec{x}_2) = \iint \sigma_y^2 C_0(v_2-v_1,\theta(\mathbf{x}_{n_2}-\mathbf{x}_{n_1}))\\ \times\,\widetilde{G}_\theta(v_1,\vec{x}_1;\vec{x}_{n_1})\widetilde{G}_\theta(v_2+\tau,\vec{x}_2;\vec{x}_{n_2})\chi\left(\frac{\mathbf{x}_{n_1}-\mathbf{x}_c}{A}\right)\chi\left(\frac{\mathbf{x}_{n_2}-\mathbf{x}_c}{A}\right)\,dv_1\,dv_2\,d\mathbf{x}_{n_1}\,d\mathbf{x}_{n_2}\,.\end{aligned} \tag{3.7}$$

3.2. Green's function filter and limits. We obtain the following representation for the quantity of interest.

PROPOSITION 3.1. *Let $\langle \mathcal{C} \rangle_\theta$ be as in* (3.7), *and assume the relative ordering*

$$z_1 < z_2 \,.$$

Then

$$\langle \mathcal{C} \rangle_\theta (\tau, \vec{x}_1, \vec{x}_2) \;=\; \iint \widetilde{G}_\theta\Big(\tau - s, z_2, \mathbf{x}_2; z_1, \mathbf{x}_1 - \frac{\mathbf{y}}{\theta}\Big)\, \Lambda_\theta\Big(z_1, s, \mathbf{x}_1 - \frac{\mathbf{y}}{2\theta}, \mathbf{y}\Big)\; ds\, d\mathbf{y}, \tag{3.8}$$

in which

$$\begin{aligned}\Lambda_\theta(z, \tau, \mathbf{x}, \mathbf{y}) = \int \frac{e^{-\mathrm{i}\omega\tau}}{2\pi} \Big\{ \iint & \sigma_y^2 \check{C}_0(\omega, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})) \\ & \times G_\theta\Big(\omega, z, \mathbf{x} - \frac{\mathbf{y}}{2\theta}; 0, \mathbf{x}_{n_2}\Big)\, G_\theta\Big(\omega, z, \mathbf{x} + \frac{\mathbf{y}}{2\theta}; 0, \mathbf{x}_{n_1}\Big)^* \\ & \times \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right)\, d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2} \Big\}\, \theta^{-d}\, d\omega \,.\end{aligned} \tag{3.9}$$

Here, Λ_θ is referred to as the Green's function filter.

Proof. We begin with substituting (3.3) into (3.7), and we obtain

$$\begin{aligned}\langle \mathcal{C} \rangle_\theta (\tau, \vec{x}_1, \vec{x}_2) = (2\pi)^{-2} & \iint \sigma_y^2 C_0(v_2 - v_1, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})) \\ \times\; G_\theta(\omega_1, z_1, \mathbf{x}_1; 0, \mathbf{x}_{n_1})^* e^{\mathrm{i}\omega_1(v_1 - z_1/\overline{c})} & \,G_\theta(\omega_2, z_2, \mathbf{x}_2; 0, \mathbf{x}_{n_2}) e^{-\mathrm{i}\omega_2((v_2+\tau)-z_2/\overline{c})} \\ \times\; \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right) & dv_1\, dv_2\, d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2}\, d\omega_1\, d\omega_2 \,,\end{aligned} \tag{3.10}$$

where we made use of the fact that $\widetilde{G}_\theta$ is real-valued. We carry out the integration over v_1 yielding a Fourier transform of C_0 with respect to its time argument; the integration over v_2 then gives a factor $\delta(\omega_2 - \omega_1)$:

$$\begin{aligned}\langle \mathcal{C} \rangle_\theta (\tau, \vec{x}_1, \vec{x}_2) &= (2\pi)^{-2} \iint \sigma_y^2 \check{C}_0(\omega_1, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})) \\ &\quad\times G_\theta(\omega_1, z_1, \mathbf{x}_1; 0, \mathbf{x}_{n_1})^* G_\theta(\omega_2, z_2, \mathbf{x}_2; 0, \mathbf{x}_{n_2})\, e^{-\mathrm{i}((\omega_2-\omega_1)v_2+\omega_2\tau)} e^{\mathrm{i}(\omega_2 z_2 - \omega_1 z_1)/\overline{c}} \\ &\quad\times \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right)\, dv_2\, d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2}\, d\omega_1\, d\omega_2 \\ &= (2\pi)^{-1} \iint \sigma_y^2 \check{C}_0\left(\omega, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})\right)\, e^{-\mathrm{i}\omega(\tau - (z_2 - z_1)/\overline{c})} \\ &\quad\times G_\theta(\omega, z_1, \mathbf{x}_1; 0, \mathbf{x}_{n_1})^* G_\theta(\omega, z_2, \mathbf{x}_2; 0, \mathbf{x}_{n_2}) \\ &\quad\times \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right)\, d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2}\, d\omega \,.\end{aligned} \tag{3.11}$$

We invoke the semigroup property of the solution operator to the paraxial wave equation, and, using that $z_2 > z_1$, we get

$$\begin{aligned}(3.12)\quad \left\langle \mathcal{C} \right\rangle_\theta (\tau, \vec{x}_1, \vec{x}_2) = \iint \frac{e^{-\mathrm{i}\omega(\tau-(z_2-z_1)/\bar{c})}}{2\pi} \Bigg\{ \iint \sigma_y^2 \check{C}_0(\omega, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})) \\ \times\, G_\theta(\omega, z_1, \mathbf{x}_1; 0, \mathbf{x}_{n_1})^* G_\theta(\omega, z_1, \mathbf{y}; 0, \mathbf{x}_{n_2})\, \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right) d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2} \Bigg\} \\ \times\, G_\theta(\omega, z_2, \mathbf{x}_2; z_1, \mathbf{y})\, d\omega\, d\mathbf{y}\,.\end{aligned}$$

We then change variables of integration,

$$\begin{aligned}(3.13)\quad \left\langle \mathcal{C} \right\rangle_\theta (\tau, \vec{x}_1, \vec{x}_2) = \iint \frac{e^{-\mathrm{i}\omega(\tau-(z_2-z_1)/\bar{c})}}{2\pi} \Bigg\{ \iint \sigma_y^2 \check{C}_0(\omega, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1})) \\ \times\, G_\theta(\omega, z_1, \mathbf{x}_1; 0, \mathbf{x}_{n_1})^* G_\theta\Big(\omega, z_1, \mathbf{x}_1 - \frac{\mathbf{y}}{\theta}; 0, \mathbf{x}_{n_2}\Big) \\ \times\, \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right) d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2} \Bigg\} G_\theta\Big(\omega, z_2, \mathbf{x}_2; z_1, \mathbf{x}_1 - \frac{\mathbf{y}}{\theta}\Big)\, \theta^{-d}\, d\omega\, d\mathbf{y} \\ = \iint \frac{e^{-\mathrm{i}\omega(\tau-(z_2-z_1)/\bar{c})}}{2\pi} G_\theta\Big(\omega, z_2, \mathbf{x}_2; z_1, \mathbf{x}_1 - \frac{\mathbf{y}}{\theta}\Big)\, \check{\Lambda}_\theta\Big(z_1, \omega, \mathbf{x}_1 - \frac{\mathbf{y}}{2\theta}, \mathbf{y}\Big)\, d\omega\, d\mathbf{y}\,,\end{aligned}$$

which gives the result (3.8). □

We will now make the following assumption.

Assumption 1.

$$(3.14)\qquad \sigma_y^2 = \theta^d\,.$$

The expression (3.9) then simplifies, and this assumption corresponds to letting the correlation radius of the impinging noise field be θ independent.

We remark that the paraxial Green's function will decorrelate in the lateral dimensions on the $1/\theta$ scale, and that this is the motivation for the choice of parameterization of the filter Λ_θ.

It will prove natural to introduce the Wigner distribution

$$\begin{aligned}(3.15)\quad W_\theta(z, \mathbf{x}, \mathbf{p}; \omega) = \iint \frac{e^{\mathrm{i}\mathbf{p}\cdot\mathbf{y}}}{(2\pi)^d}\, G_\theta\Big(\omega, z, \mathbf{x} - \frac{\mathbf{y}}{2\theta}; 0, \mathbf{x}_{n_2}\Big)\, G_\theta\Big(\omega, z, \mathbf{x} + \frac{\mathbf{y}}{2\theta}; 0, \mathbf{x}_{n_1}\Big)^* \\ \times\, \check{C}_0(\omega, \theta(\mathbf{x}_{n_2} - \mathbf{x}_{n_1}))\, \chi\left(\frac{\mathbf{x}_{n_1} - \mathbf{x}_c}{A}\right) \chi\left(\frac{\mathbf{x}_{n_2} - \mathbf{x}_c}{A}\right) d\mathbf{x}_{n_1}\, d\mathbf{x}_{n_2}\, d\mathbf{y}\,,\end{aligned}$$

so that

$$(3.16)\qquad \check{\Lambda}_\theta(z, \omega, \mathbf{x}, \mathbf{y}) = \iint W_\theta(z, \mathbf{x}, \mathbf{p}; \omega) e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}} d\mathbf{p}\,.$$

This Wigner distribution coincides with the one given in (2.16) subject to initial conditions that derive from (2.15), which follows from (2.6), (3.2), and (3.3). In the high-frequency ($\theta \to \infty$) and white noise ($\varepsilon \to 0$) limits, the Wigner distribution in (3.15) is characterized weakly (in law) by (2.17), while its mean satisfies (2.20).

The initial condition, at $z = 0$, for the Wigner distribution follows directly from the corresponding initial condition for the Green's function G_θ:

$$
\begin{aligned}
(3.17)\quad W_\theta(0,\mathbf{x},\mathbf{p};\omega) = \iint & \frac{e^{\mathrm{i}\theta\mathbf{p}\cdot 2(\mathbf{x}-\mathbf{x}_{n_2})}}{(2\pi)^d}\check{C}_0(\omega,\theta(2(\mathbf{x}_{n_2}-\mathbf{x})))\\
& \times \chi\left(\frac{2\mathbf{x}-\mathbf{x}_{n_2}-\mathbf{x}_c}{A}\right)\chi\left(\frac{\mathbf{x}_{n_2}-\mathbf{x}_c}{A}\right)\theta^d\, d\mathbf{x}_{n_2}\\
& \sim \widehat{C}_0\left(\omega,\mathbf{p}\right)\frac{\chi^2\left(\frac{\mathbf{x}-\mathbf{x}_c}{A}\right)}{(4\pi)^d} \equiv W_I(\mathbf{x},\mathbf{p};\omega) \quad \text{as } \theta\to\infty.
\end{aligned}
$$

We will apply this approximation below.

We now use the Green's function (2.21), and initial condition (3.17), in (3.16) and define the following Green's function filter,

$$
\begin{aligned}
\check{\Lambda}(z,\omega,\mathbf{x},\mathbf{y}) = & \iint \frac{e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}}{(2\pi)^{2d}}\exp\left(\mathrm{i}\left[\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_0)+\mathbf{r}\cdot\frac{(\mathbf{p}-\mathbf{p}_0)}{\omega}-z\mathbf{w}\cdot\frac{\mathbf{p}_0}{\omega}\right]\right)\\
& \times \exp\left(-\frac{Dz}{2}\left[r^2+z\mathbf{r}\cdot\mathbf{w}+\frac{w^2z^2}{3}\right]\right)\widehat{C}_0\left(\omega,\mathbf{p}_0\right)\\
& \times \frac{\chi^2\left(\frac{\mathbf{x}_0-\mathbf{x}_c}{A}\right)}{(4\pi)^d}\omega^{-d}\, d\mathbf{w}\, d\mathbf{r}\, d\mathbf{p}\, d\mathbf{x}_0\, d\mathbf{p}_0\\
= & \frac{1}{(4\pi)^d}\iint e^{\mathrm{i}\omega\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_c)}\exp\left(-\frac{\omega^2Dz}{2}\left[y^2+z\mathbf{y}\cdot\mathbf{w}+\frac{w^2z^2}{3}\right]\right)\\
(3.18)\qquad & \times\ \check{C}_0(\omega,\mathbf{y}+z\mathbf{w})\widehat{\chi}_A\left(\omega\mathbf{w}\right)\omega^d\, d\mathbf{w}\,,
\end{aligned}
$$

in which

$$
\widehat{\chi}_A\left(\mathbf{w}\right) = \iint e^{-\mathrm{i}\mathbf{w}\cdot\mathbf{x}_0}\,\chi^2\left(\frac{\mathbf{x}_0}{A}\right)d\mathbf{x}_0\,.
$$

The characterization of a statistically stable filter now follows from the representation (3.16) and Propositions 2.1 and 2.2, as follows.

Proposition 3.2. *The deterministic Green's function filter converges to a deterministic filter*

$$
(3.19)\qquad \lim_{\delta\to 0}\lim_{\varepsilon\to 0}\lim_{\theta\to\infty}\check{\Lambda}_\theta\left(z,\omega,\mathbf{x},\mathbf{y}\right) = \check{\Lambda}(z,\omega,\mathbf{x},\mathbf{y})
$$

in $L^2(\mathbb{P})$.

3.3. Effective filter. In order to obtain qualitative and quantitative insight on the Green's function filtering behavior, we shall assume that the spectrum of the envelope function and the spectrum of the noise covariance have Gaussian shapes. That is, we shall assume

$$
(3.20)\qquad \chi(\mathbf{x}) = \frac{1}{(2\pi)^{d/2}}e^{-\frac{|\mathbf{x}|^2}{2}}\,, \quad \check{C}_0\left(\omega,\mathbf{y}\right) = \widehat{f}_0(\omega)e^{\frac{-|\mathbf{y}|^2}{2\sigma_x^2}}\,.
$$

We recall that the filter will be evaluated at $z = z_1$, corresponding to the longitudinal distance from the source plane to the first recording point. We find that then

$$
\begin{aligned}
\check{\Lambda}(z,\omega,\mathbf{x},\mathbf{y}) = & \left(\frac{A}{4\pi\sqrt{2}}\right)^d\omega^d\widehat{f}_0(\omega)\iint e^{\mathrm{i}\omega\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_c)}\exp\left(-\frac{\omega^2Dz}{2}\left[y^2+z\mathbf{y}\cdot\mathbf{w}+\frac{w^2z^2}{3}\right]\right)\\
& \times e^{\frac{-|\mathbf{y}+z\mathbf{w}|^2}{2\sigma_x^2}}e^{\frac{-\omega^2|\mathbf{w}|^2A^2}{4}}\, d\mathbf{w}\,.
\end{aligned}
$$

We rewrite this expression as

(3.21)

$$\begin{aligned}\check{\Lambda}(z,\omega,\mathbf{x},\mathbf{y}) &= \left(\frac{A}{4\pi\sqrt{2}}\right)^{d} \omega^{d}\widehat{f}_0(\omega)\iint e^{\mathrm{i}\omega\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_c)}e^{-\omega^2\left(a_1 w^2+2a_2\mathbf{y}\cdot\mathbf{w}+a_3 y^2\right)/2}\,d\mathbf{w}\\ &= \left(\frac{A^2}{16\pi a_1}\right)^{d/2}\widehat{f}_0(\omega)e^{-\frac{|\mathbf{x}-\mathbf{x}_c|^2}{2a_1}}e^{-\omega^2(a_3-a_2^2/a_1)y^2/2}e^{-\mathrm{i}\omega(a_2/a_1)\mathbf{y}\cdot(\mathbf{x}-\mathbf{x}_c)}\end{aligned}$$

with

$$a_1(\omega)=\frac{A^2}{2}+\frac{z^2}{\omega^2\sigma_x^2}+\frac{Dz^3}{3},\quad a_2(\omega)=\frac{z}{\omega^2\sigma_x^2}+\frac{Dz^2}{2},\quad a_3(\omega)=\frac{1}{\omega^2\sigma_x^2}+Dz\,.$$

Furthermore, we shall assume that the noise source field has a temporal frequency spectrum of the form

$$\widehat{f}_0(\omega)=\frac{1}{2}\left(\widehat{f}\,(T_s(\omega-\omega_c))+\widehat{f}\,(T_s(\omega+\omega_c))\right)\,. \tag{3.22}$$

We can now associate two characteristic length scales and one characteristic temporal scale with the Green's function filter in the narrow band situation so that T_s is large:

- The *refocusing* length scale

$$\begin{aligned}l_f(\omega_c) &= \frac{\lambda_c}{2\pi\sqrt{a_3(\omega_c)-\frac{a_2^2(\omega_c)}{a_1(\omega_c)}}}\\ &= \frac{\lambda_c}{2\pi}\left(\frac{\frac{A^2}{2}+\frac{\lambda_c^2 z^2}{4\pi^2\sigma_x^2}+\frac{Dz^3}{3}}{\left(A^2+\frac{Dz^3}{6}\right)\frac{Dz}{2}+\left(\frac{A^2}{2}+\frac{Dz^3}{3}\right)\frac{\lambda_c^2}{4\pi^2\sigma_x^2}}\right)^{1/2},\end{aligned}$$

  for

$$\lambda_c = 2\pi/\omega_c$$

  with ω_c a characteristic frequency of the noise source spectrum. This length scale determines the smoothing scale in the spatial source coordinates of the Green's function estimate, since the Green's function is blurred on the scale l_f/θ; see (3.19), (3.21). Note that in the low-frequency limit with $\lambda_c \to \infty$ the estimate of the Green's function degrades since the refocusing length scale becomes large in this limit.
- The *effective aperture* length scale

$$l_a(\omega_c)=\sqrt{a_1(\omega_c)}=\sqrt{\frac{A^2}{2}+\frac{\lambda_c^2 z^2}{4\pi^2\sigma_x^2}+\frac{Dz^3}{3}}\,.$$

  This corresponds to the lateral range, relative to the center $\mathbf{x}_c$, of impinging noise sources contributing to the Green's function estimate through $\langle\mathcal{C}\rangle_\theta$. If the lateral separation between $\mathbf{x}_j$ and $\mathbf{x}_c$ is large relative to this length, then the filter will weaken the Green's function significantly. In the limit $\lambda_c \to 0$, l_a corresponds to the effective aperture in [33].

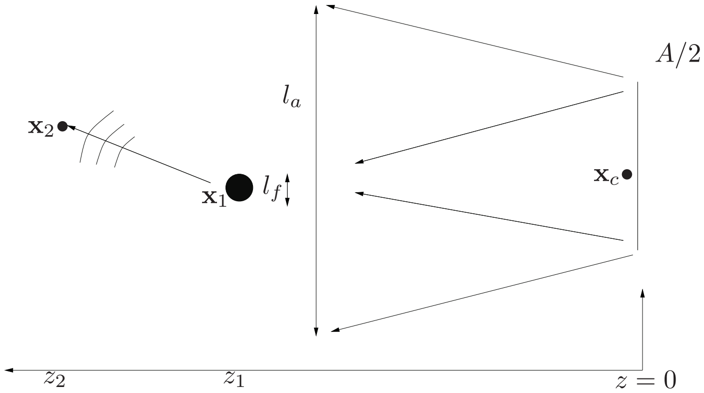

FIG. 3.1. *The effective aperture l_a and the refocusing length scale l_f.*

- The Green's function will be blurred in time, on the scale T_s, corresponding to the support of the ambient noise correlations in time.

The characteristic length scales are illustrated in Figure 3.1.

We comment on how the characteristic length scales depend on some of the parameters. In the case of a homogeneous medium, with $D = 0$ and low frequencies, we have

$$l_f(\omega_c)|_{D=0} \overset{\lambda_c \to \infty}{\sim} \left(\frac{\lambda_c z}{A}\right) \frac{1}{\sqrt{2}\pi} \,,$$

which corresponds to the classical *Rayleigh* resolution. While in the high-frequency limit and homogeneous medium case, with $D = 0$, we find

$$l_f(\omega_c)|_{D=0} \overset{\lambda_c \to 0}{\sim} \sigma_x \,,$$

that is, a length scale corresponding to that of the support of the ambient noise field in the lateral spatial dimensions. Next, we consider the limit of (relatively) strong medium fluctuations:

$$l_f(\omega_c) \overset{D \to \infty}{\sim} \frac{\lambda_c}{\pi\sqrt{zD}} \,,$$

which leads to a small refocusing scale.

4. Source location estimation. Here, we consider the case of narrow noise aperture, A, and discuss the problem of estimating the "source location" $\mathbf{x}_c$. We assume that the points of observation lie in the plane $z_2 = z_1 = z$. From (3.8) we then find that

$$\langle \mathcal{C} \rangle_\theta (\tau, z, \mathbf{x}_1, z, \mathbf{x}_2) = \theta^d \int \frac{e^{-\mathrm{i}\omega\tau}}{2\pi} \check{\Lambda}_\theta(z, \omega, \tfrac{1}{2}(\mathbf{x}_1 + \mathbf{x}_2), \theta(\mathbf{x}_1 - \mathbf{x}_2)) \, d\omega \,.$$

For two points separated on the $1/\theta$ scale, we write

$$\mathbf{x}_1 = \mathbf{x} + \frac{\mathbf{y}}{2\theta}, \quad \mathbf{x}_2 = \mathbf{x} - \frac{\mathbf{y}}{2\theta} \,. \tag{4.1}$$

In the case of source estimation, we replace assumption (3.14) by the following.

ASSUMPTION 2.

$$\sigma_y^2 \equiv 1 \,. \tag{4.2}$$

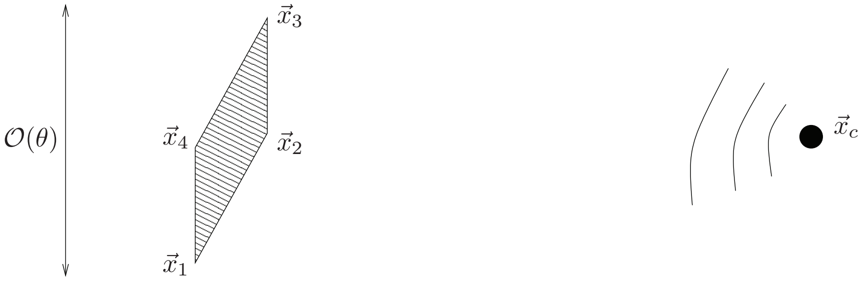

FIG. 4.1. *Estimation of source location: By computing the cross-correlations between the points* $\vec{x}_1, \ldots, \vec{x}_4$ *on the mirror, one obtains differential traveltimes, corresponding to* $|\vec{x}_i - \vec{x}_c| - |\vec{x}_j - \vec{x}_c|$, *which can be used to estimate the source location* $\vec{x}_c$.

Thus, the magnitude of the localized noise source field is now θ independent. We then have

$$\langle \mathcal{C} \rangle_\theta \Big(\tau, z, \mathbf{x} + \frac{\mathbf{y}}{2\theta}, z, \mathbf{x} - \frac{\mathbf{y}}{2\theta} \Big) = \int \frac{e^{-i\omega\tau}}{2\pi} \iint W_\theta(z, \mathbf{x}, \mathbf{p}; \omega) e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}} d\mathbf{p}\,,$$

and it follows by Proposition 2.2 that $\langle \mathcal{C} \rangle_\theta$ is statistically stable.

We consider, moreover, a tight lateral support for the noise field correlations: $\sigma_x \ll 1$ in the model (3.20). Then, using Proposition 3.2 and (3.18), we obtain

$$\begin{aligned} &\sigma_x^{-d} \langle \mathcal{C} \rangle_\theta \Big(\tau, z, \mathbf{x} + \frac{\mathbf{y}}{\theta}, z, \mathbf{x} - \frac{\mathbf{y}}{\theta} \Big) \\ &\qquad \sim \left(\frac{A^2}{16\pi z^2} \right)^{d/2} \int |\omega|^d \widehat{f}_0(\omega) \frac{e^{-\mathrm{i}\omega\tau}}{2\pi} e^{-\frac{\omega^2 \sigma_a^2 y^2}{2}} e^{-\mathrm{i}\omega \mathbf{y}\cdot(\mathbf{x}-\mathbf{x}_c)/z}\, d\omega \\ &\qquad = \left\{ \left(\frac{A^2}{16\pi z^2} \right)^{d/2} \widetilde{f}\,(\cdot) * \mathcal{N}_{\sigma_a}(\cdot) \right\} \left(\tau + \mathbf{y} \cdot \frac{\mathbf{x} - \mathbf{x}_c}{z} \right) \,, \end{aligned}$$

where "$*$" denotes convolution, $\mathcal{N}_\sigma$ is the Gaussian distribution with standard deviation σ, and we define

$$\begin{aligned} \sigma_a &= \sqrt{\frac{A^2}{2z^2} + \frac{Dz}{3}}\,, \\ \widetilde{f}(\tau) &= \int \frac{e^{-\mathrm{i}\omega\tau}}{2\pi} |\omega|^d \widehat{f}_0(\omega)\, d\omega. \end{aligned}$$

We remark that in the paraxial regime we have

$$\tau + \mathbf{y}\cdot(\mathbf{x} - \mathbf{x}_c)/z = \frac{2\pi}{T_0} \left\{ \widetilde{t} + \left(\frac{|\widetilde{\mathbf{x}}_1 - \widetilde{\mathbf{x}}_c|^2}{2\widetilde{z}c_0} - \frac{|\widetilde{\mathbf{x}}_2 - \widetilde{\mathbf{x}}_c|^2}{2\widetilde{z}c_0} \right) \right\} \approx \frac{2\pi}{T_0} (\widetilde{t} + (\widetilde{\tau}_{s1} - \widetilde{\tau}_{s2})\,, \tag{4.3}$$

with $\widetilde{t}, \widetilde{z}, \widetilde{\mathbf{x}}_j$, and $\widetilde{\mathbf{x}}_j$ denoting the original scaled coordinates and $\widetilde{\tau}_{sj}$ being the traveltime from the noise source at $\vec{x}_c$ to observation point $\vec{x}_j$. Thus, given observations at array points $\vec{x}_1, \ldots, \vec{x}_4$, separated as in (4.1), one can estimate the location of the source via differential traveltime estimates in the $(d+1) = 3$-dimensional case; see Figure 4.1. The resolution of the estimate is limited by the support of the noise correlation function, the strength of the medium fluctuations, and the aperture A. We remark that in contrast to the situation where one aims at estimating the Green's function, here, a large value for σ_a leads to a poor resolution.

5. White noise paraxial regimes and applications. In this section, we discuss alternative scaling scenarios that have been introduced in [34] and [20]. We demonstrate the robustness of the results derived above by showing that their essential features prevail under a wide range of scaling scenarios. Indeed, the general analysis will be the same, but the Green's function filter changes through replacing the function U in (2.21) by the Green's function associated with the relevant modification of (2.20). In subsection 5.4 we conclude the discussion on scaling scenarios by considering a particular application, namely, body-wave scattering in Southeastern Tibet motivated in the introduction, and its characteristic scales.

We consider a scaling and a nondimensionalization as above. We shall here discuss the situation with $\varepsilon \to 0$ being the smallest parameter. This limit gives the Itô form of (2.14):

$$2\mathrm{i}\,(\theta k)\,d_z\psi + \triangle_{\mathbf{x}}\psi\,dz + \frac{\mathrm{i}(\theta^3 k^3)\delta^2}{4} R_0(0)\psi\,dz + (\theta^2 k^2)\delta\psi d_z B\Big(z, \frac{\mathbf{x}}{\delta}\Big) = 0\,, \tag{5.1}$$

with the law of the Brownian flow ∇B coinciding with the law of the flow $\mathbf{B}$ in (2.17). This Itô form of the Schrödinger equation is discussed in, for instance, [11]. Now different regimes lead to different Wigner distributions and equations that they satisfy, and, hence, different Green's functions, which shape the Green's function filter.

5.1. Subsequent high-frequency scaling. First, we consider the situation with a subsequent high-frequency or geometrical optics limit followed by the large diversity scaling. That is, we have

$$\varepsilon \ll \frac{1}{\theta} \ll \delta \ll 1\,. \tag{5.2}$$

In this case, the Wigner distribution in (2.16) again satisfies (2.20)! Therefore, the Green's function estimation corresponds to the estimation discussed above.

5.2. The joint limit. We discuss next the joint limit with θ and δ going to zero simultaneously, that is,

$$\varepsilon \ll \frac{\xi}{\theta} = \delta \ll 1 \tag{5.3}$$

for $\xi = \mathcal{O}(1)$. As shown in [34], the Wigner distribution in (2.16) converges in the limit $\delta = \xi\theta \to 0$ weakly (in $\mathcal{S}'(\mathbb{R}^{2d})$) and in probability to $\widetilde{W}$, solving

$$\begin{aligned}\frac{\partial \widetilde{W}}{\partial z}(z,\mathbf{x},\mathbf{p}) &+ \frac{\mathbf{p}}{\omega}\cdot\nabla_{\mathbf{x}}\widetilde{W}(z,\mathbf{x},\mathbf{p}) \\ &= \frac{\omega^2\xi^2}{4}\iint_{-\infty}^{\infty}\frac{d\mathbf{q}}{(2\pi)^d}\widehat{R}_0(\mathbf{q})\left(\widetilde{W}(z,\mathbf{x},\mathbf{p}+\mathbf{q}) - \widetilde{W}(z,\mathbf{x},\mathbf{p})\right)\end{aligned} \tag{5.4}$$

(cf. (2.19) for the definition of R_0). The Green's function of (5.4) is explicitly given by

$$\begin{aligned}\widetilde{U}(z,\mathbf{x},\mathbf{p};\mathbf{x}^0,\mathbf{p}^0) = &\iint_{-\infty}^{\infty}\frac{1}{\omega^d(2\pi)^{2d}}\exp\left(\mathrm{i}\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}^0) + \mathrm{i}\mathbf{r}\cdot\frac{(\mathbf{p}-\mathbf{p}^0)}{\omega} - \mathrm{i}z\mathbf{w}\cdot\frac{\mathbf{p}^0}{\omega}\right) \\ &\times\exp\left(-\frac{\omega^2\xi^2}{4}\int_0^z D_R\left(\frac{\mathbf{r}+\mathbf{w}s}{\omega}\right)ds\right)d\mathbf{w}\,d\mathbf{r}\end{aligned} \tag{5.5}$$

and replaces U in (2.21). Here, D_R is the medium structure function,

$$D_R(\mathbf{r}) = R_0(\mathbf{0}) - R_0(\mathbf{r}); \tag{5.6}$$

cf. (2.19). The expression (3.18) for the Green's function filter then becomes

$$\begin{aligned}
\check{\tilde{\Lambda}}&(z,\omega,\mathbf{x},\mathbf{y};\sigma_t,\sigma_x) \\
&\approx \iint_{-\infty}^{\infty} \frac{e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}}{(2\pi)^{2d}} \exp\left(\mathrm{i}\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}^0) + \mathrm{i}\mathbf{r}\cdot\frac{(\mathbf{p}-\mathbf{p}^0)}{\omega} - \mathrm{i}z\mathbf{w}\cdot\frac{\mathbf{p}^0}{\omega}\right) \\
&\qquad \times \exp\left(-\frac{\omega^2\xi^2}{4}\int_0^z D_R\left(\frac{\mathbf{r}+s\mathbf{w}}{\omega}\right) ds\right) \\
&\qquad \times \widehat{C}_0\left(\omega,\mathbf{p}_0\right) \frac{\chi^2\left(\frac{\mathbf{x}_0-\mathbf{x}_c}{A}\right)}{(2\pi)^d} \left(\frac{1}{\omega}\right)^d d\mathbf{w}\, d\mathbf{r}\, d\mathbf{p}\, d\mathbf{x}_0\, d\mathbf{p}_0 \\
&= \frac{1}{(4\pi)^d} \iint e^{\mathrm{i}\omega\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}_c)}\, \check{C}_0(\omega,\mathbf{y}+z\mathbf{w})\, e^{-\frac{\omega^2\xi^2}{4}\int_0^z D_R(\mathbf{y}+s\mathbf{w})\, ds}\, \widehat{\chi}_A\left(\omega\mathbf{w}\right) \omega^d\, d\mathbf{w}\,.
\end{aligned} \tag{5.7}$$

In the case where the correlation length associated with the structure function D_R is large, we can expand this, assumed smooth, function D_R,

$$D_R(\mathbf{y}) \mapsto 2D|\mathbf{y}|^2\,,$$

and recover (3.18). In the joint scaling limit, however, the whole spectrum of the medium fluctuations is involved in the definition of the Green's function filter.

5.3. Long-range media. We finally comment on the situation with rough and long-range media as, for instance, in the turbulent atmosphere and heterogeneous regions of the earth's crust. Here we will consider a white noise limit, however, with the Fresnel number and lateral diversity scales fixed. In this scaling, which is analyzed in detail by Fannjiang and Solna [19, 20, 21], (2.14) becomes

$$2\mathrm{i}\,(\theta k)\,\frac{\partial\psi}{\partial z} + \triangle_{\mathbf{x}}\psi + \frac{1}{\sqrt{\varepsilon}}\left(\theta^2 k^2\right)\widetilde{\mu}\left(\frac{z}{\varepsilon},\mathbf{x}\right)\psi = 0, \tag{5.8}$$

where the power spectrum of the random field, $\widetilde{\mu}(\cdot,\cdot)$, is given by

$$\Phi(\vec{\mathbf{k}}) \approx \sigma_H |\vec{\mathbf{k}}|^{-1-2H} |\vec{\mathbf{k}}|^{-d}\,, \tag{5.9}$$

for $|\vec{\mathbf{k}}|$ in the inertial range, where $\vec{\mathbf{k}} \in \mathbb{R}^{d+1}$ is the spectral variable and H the Hurst exponent characterizing the roughness of the medium fluctuations. That is, we assume that the medium fluctuations follow a power law form over a set of scales called the intertial range, which corresponds to turbulent or long-range medium modeling. In this case, the Wigner distribution solves, in the white noise limit, in the sense of L^2-weak solutions, a Wigner–Itô equation driven by an operator-valued Brownian motion. In particular, the first moment in (2.20) now becomes

$$\frac{\partial\overline{W}}{\partial z} + \frac{1}{\omega}\mathbf{p}\cdot\nabla_{\mathbf{x}}\overline{W} = \mathcal{Q}_0\overline{W}\,, \tag{5.10}$$

with

$$\mathcal{Q}_0\overline{W} = \frac{\theta^2\omega^2}{4}\int \Phi(0,\mathbf{q})\left(-2\overline{W}(\mathbf{p}) + \overline{W}\left(\mathbf{p}+\frac{\mathbf{q}}{\theta}\right) + \overline{W}\left(\mathbf{p}-\frac{\mathbf{q}}{\theta}\right)\right) d\mathbf{q};$$

see [20] for details. The Green's function of (5.10) is

$$\widetilde{U}_\theta(z,\mathbf{x},\mathbf{p};\mathbf{x}^0,\mathbf{p}^0) = \iint_{-\infty}^{\infty} \frac{1}{\omega^d(2\pi)^{2d}} \exp\left(\mathrm{i}\mathbf{w}\cdot(\mathbf{x}-\mathbf{x}^0) + \mathrm{i}\mathbf{r}\cdot\frac{(\mathbf{p}-\mathbf{p}^0)}{\omega} - \mathrm{i}z\mathbf{w}\cdot\frac{\mathbf{p}^0}{\omega}\right)$$

$$\times \exp\left(-\frac{\omega^2\theta^2}{2}\int_0^z D_*\left(\frac{\mathbf{r}+\mathbf{w}s}{\theta\omega}\right)\right) d\mathbf{w}\, d\mathbf{r}\,, \tag{5.11}$$

corresponding to the form (5.5). The structure function can now be expressed as

$$D_*(\mathbf{x}) = \int \Phi(0,\mathbf{q})\left(1-e^{i\mathbf{x}\cdot\mathbf{q}}\right) d\mathbf{q}\,. \tag{5.12}$$

The Green's function filter is therefore again characterized by (5.7). For the power law medium we have the short distance asymptotic

$$D_*(\mathbf{x}) \approx C_*^2|\mathbf{x}|^{2H_*}\,, \tag{5.13}$$

where the effective Hölder exponent H_* is given by

$$H_* = \begin{cases} H+1/2 & \text{for } H\in(0,1/2), \\ 1 & \text{for } H\in(1/2,1]\,, \end{cases} \tag{5.14}$$

in which H is the Hölder exponent of the original medium and C_*^2 a structure parameter.

Note that the effective Hölder exponent H_* is always bigger than 1/2, corresponding to a "persistent" or a long-range power law. Using this asymptotic and considering a regime with relatively narrow support for the impinging noise field by setting

$$\check{C}_0\,(\sigma_t\omega,\mathbf{y}) \mapsto \widehat{f}_0\,(\omega)\delta(\mathbf{y})\,,$$

we find

$$\check{\Lambda}_H(z,\omega,\mathbf{x},\mathbf{y}) \approx \frac{\omega^d}{(4\pi z)^d} e^{-i\omega\mathbf{y}\cdot\mathbf{x}/z}\widehat{\chi}_A\left(\frac{-\omega\mathbf{y}}{z}\right)\widehat{f}_0\,(\omega)^*\, e^{-\frac{(\omega^2\theta^{2-2H_*}z|\mathbf{y}|^{2H_*})C_*^2}{2(2H_*+1)}}\,.$$

For the normalized noise field supported at the carrier frequency ω_c as in (3.22) we thus find that for a fixed Fresnel number the spatial support of the Green's function filter scales as ω_c^{-1/H_*}. That is, the resolution depends *nonlinearly* on the wavelength associated with the characteristic temporal scale of the impinging noise field. In the limit of rough media with $H_* \to 0$ the lateral spatial support of the Green's function filter scales like λ_c^2.

5.4. Applications. Here, we address the application of our analysis to passive seismic tomography, making use of continuous recordings in an array of detectors or receivers. We discuss which scaling regime would apply to the regional study in Southeastern Tibet [43]. In the latter study, the focus was on the "generation" of surface waves. Here, we seek insight into the behavior of body-wave contributions for future applications in the same region. Our analysis incorporates what seismologists refer to as "ambient noise" (our random source distribution) and "coda waves" (through random medium fluctuations).

Concerning the Southeastern Tibet data set discussed in section 1, we obtain the following characterization [43]. The characteristic distance between individual stations (receivers) is approximately $\mathcal{O}(100\text{km})$, and, similarly, the characteristic transversal distance between passive sources (magnitude $Mw > 5$) is $\mathcal{O}(100\text{km})$. (For smaller earthquakes—but with magnitude $Mw > 4$—the characteristic transversal distance reduces to $\mathcal{O}(10\text{km})$.) The distance from the array to the sources is $\mathcal{O}(5000\text{km})$; most of the sources are likely to be located in the Western Pacific margins and Eastern Indian Ocean margins. The dominant wavelength for shear (S) waves is $\mathcal{O}(20\text{km})$, while the dominant wavelength for compressional (P) waves is $\mathcal{O}(5\text{km})$. (Under certain simplifying conditions, shear waves have been modeled by a scalar wave equation, whence the current analysis would still be applicable.) The correlation length of medium fluctuations is, with the present knowledge, hard to estimate, but a value of $\mathcal{O}(10\text{km})$ is plausible, also, given the complexity in tectonics of the region. The "asymmetry" observed in the cross-correlations in [43] is explained and inherent in our setup based on the paraxial wave equation.

In our modeling, the characteristic transversal distance between stations or sources roughly corresponds to l_x, the distance from the array to the sources roughly corresponds to l_z, and the correlation length of medium fluctuations to l; the dominant wavelength is λ_0. For compressional body waves this results in $\delta \approx 10^{-1}$, $\varepsilon \approx 2\times 10^{-3}$, and $\theta^{-1} \approx 4 \times 10^{-1}$, thus, corresponding most closely to the scaling discussed in section 5.2.

6. Numerical illustrations. In this section we present a numerical illustration where we show the effect of the Green's function filter. We shall use the filter corresponding to the scaling regime discussed in section 3.3.

We assume that the medium is homogeneous for $z > z_1$ and plot the quantity

$$\mathcal{I}(\tau, \mathbf{x}_1; A, A_D) = \iint G_\theta\Big(\tau - s, z_2, \mathbf{x}_2; z_2 - z_1, \mathbf{x}_1 - \frac{\mathbf{y}}{\theta}\Big)\, \Lambda(z_1, s, \mathbf{x}_1, \mathbf{y})\; ds\, d\mathbf{y}\,,$$

using the approximation in (3.21) for the filter and where we introduce

$$A_D = \sqrt{A^2 + \frac{2D}{3}}\,.$$

We choose $d = 2$, and in the nondimensionalized coordinates we let

$$f_0(t) = e^{-\frac{t^2\mathcal{D}}{2}} \cos(f_c t)\,, \tag{6.1}$$

with $\mathcal{D} = 5$, and moreover choose

$$z_1 = 1\,, \quad \mathbf{x}_c = \mathbf{x}_2 = \mathbf{0}\,, \quad f_c = 30\,, \quad \sigma_x = 1\,.$$

In Figure 6.1, we plot $\mathcal{I}$ in the case with a homogeneous medium. We use the parameter values $A = A_D = 20$ in the left plot. The estimation then captures the wavefield and wavefront for relatively large lateral offsets for the Green's function. The right plot corresponds to the situation with a small aperture, $A = A_D = 1.5$, in which case the wavefield and corresponding "moveout" are not captured.

In Figure 6.2 we plot $\mathcal{I}$ in the case with a random medium. We use the parameter values $A = 1.5, A_D = 9.3$. We then recapture a large part of the wavefield and wavefront (following a hyperbolic "moveout").

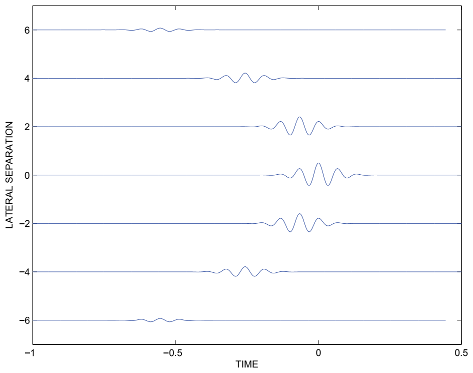

Fig. 6.2. *The normal moveout for a random medium with relatively large effective aperture.*

7. Conclusions. Pairwise cross-correlations between receivers forming arrays provide invaluable data sets where (deterministic) sources (earthquakes) are necessarily absent. The data sets are used to carry out tomography, or inverse scattering, to reveal the properties of the medium away from (below) the array. We tailored a scaling regime to applications in global earth seismology, generating "empirical" Green's functions and "virtual" source experiments. Characterization and knowledge about the structure of the incoherent waves and their correlations is crucial in this context. We have presented a first analysis of this approach to data acquisition in the framework of the paraxial wave approximation in a random medium. The analysis exploits the connection between cross-correlations and time-reversal. The connection is direct in the sense that the Green's function estimation problem can be articulated as the dual of time-reversal superresolution.

Important questions remain, for instance, how to design "optimal" filters, that is, how to combine optimally data in space and frequency to obtain stable and high-resolution estimates so that the filter Λ in (3.19) is near the identity, while enforcing statistical stability.

Appendix. Elements of the proof of Proposition 2.2. Consider the quantity

$$I_\delta(z,\mathbf{x},\mathbf{y}) = \iint W_\delta(z,\mathbf{x},\mathbf{p}) e^{-i\mathbf{p}\cdot\mathbf{y}}\, d\mathbf{p}\,.$$

The initial condition in (3.17),

$$W_\delta(0,\mathbf{x},\mathbf{p}) = W_I(\mathbf{x},\mathbf{p})\,,$$

is assumed to be uniformly bounded, Lipschitz continuous, and positive. As explained in [33] we can then write

$$W_\delta(z,\mathbf{x},\mathbf{p}) = W_I(\mathbf{X}_\delta(z,\mathbf{x},\mathbf{p}),\mathbf{P}_\delta(z,\mathbf{x},\mathbf{p}))\,,$$

for the stochastic flow $(\mathbf{X},\mathbf{P})$ satisfying

$$d\mathbf{X}_z = -\frac{1}{k}\mathbf{P}\,dz\,, \quad d\mathbf{P}_z = -\frac{k}{2}d\mathbf{B}(z)\,, \quad \mathbf{X}_0 = \mathbf{x}\,, \quad \mathbf{P}_0 = \mathbf{p}\,.$$

Observe first that

$$\iint \mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p})\right\} e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}\,d\mathbf{p} = \iint \mathbb{E}\left\{W_I(\mathbf{X}_\delta(z,\mathbf{x},\mathbf{p}),\mathbf{P}_\delta(z,\mathbf{x},\mathbf{p}))\right\} e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}\,d\mathbf{p}$$

is finite and independent of δ by (2.21). Writing the complex exponential in terms of its real and imaginary parts and decomposing the domain of integration for the corresponding integrals into subsets where $\cos(\mathbf{p}\cdot\mathbf{y})$ (respectively, $\sin(\mathbf{p}\cdot\mathbf{y})$) is positive (respectively, negative), we can apply Tonelli's theorem and interchange the order of integration and expectation and get

$$\mathbb{E}\{I_\delta(z,\mathbf{x},\mathbf{y})\} = \iint \mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p})\right\} e^{-\mathrm{i}\mathbf{p}\cdot\mathbf{y}}\,d\mathbf{p}; \tag{A.1}$$

thus, $I_\delta(z,\mathbf{x},\mathbf{y})$ is finite with probability one, and its expectation given by (A.1).

By a corresponding application of Tonelli's theorem we can write

$$\mathbb{E}\{I_\delta^2(z,\mathbf{x},\mathbf{y})\} = \iint \mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\right\} e^{-\mathrm{i}(\mathbf{p}_1+\mathbf{p}_2)\cdot\mathbf{y}}\,d\mathbf{p}_1\,d\mathbf{p}_2\,.$$

In [33] it is shown that $\mathbb{E}\{W_\delta^2(z,\mathbf{x},\mathbf{p})\}$ is integrable in $\mathbf{p}$, and that

$$\lim_{\delta\to 0}\mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p}_1)W_\delta(z,\mathbf{x},\mathbf{p}_2)\right\} = \mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p}_1)\right\}\mathbb{E}\left\{W_\delta(z,\mathbf{x},\mathbf{p}_2)\right\}.$$

By the Lebesgue dominated convergence theorem we can therefore conclude that

$$\lim_{\delta\to 0}\mathbb{E}\{I_\delta^2(z,\mathbf{x},\mathbf{y})\} = \mathbb{E}^2\{I_\delta(z,\mathbf{x},\mathbf{y})\}\,.$$

Acknowledgment. The authors would like to thank H. Yao for composing Figure 1.1.

ON STABLE, COMPLETE, AND SINGULARITY-FREE BOUNDARY INTEGRAL FORMULATIONS OF EXTERIOR STOKES FLOW*

O. GONZALEZ†

Abstract. A new boundary integral formulation of the second kind for exterior Stokes flow is introduced. The formulation is stable, complete, singularity-free, and natural for bodies of complicated shape and topology. We prove an existence and uniqueness result for the formulation for arbitrary flows and illustrate its performance via several numerical examples using a Nyström method with Gauss–Legendre quadrature rules of different order.

Key words. Stokes equations, boundary integral equations, single-layer potentials, double-layer potentials, parallel surfaces, Nyström discretization

1. Introduction.

In this article we study boundary integral formulations of exterior Stokes flow problems around arbitrary bodies with prescribed velocity data. For such problems it is well known that a formulation based on either of the classic single- or double-layer Stokes potentials is inadequate [29, 30]. A formulation based on the single-layer potential leads to a boundary integral operator which is unstable in the sense that its condition number is unbounded and incomplete in the sense that its range is deficient. Consequently, such a formulation is not optimal for numerical discretization and not capable of representing an arbitrary exterior flow. A formulation based on the double-layer potential leads to a boundary integral operator which is stable in the sense that its condition number is bounded but which is incomplete—even more so than the single-layer potential. Thus, in contrast to the single-layer case, a double-layer formulation is optimal for numerical discretization, but like the single-layer case, it is not capable of representing an arbitrary exterior flow.

Various authors have shown that a double-layer formulation can be modified so as to obtain completeness while retaining stability [14, 18, 20, 26, 28]. In Power and Miranda [28] it was shown that a complete formulation can be obtained by adding two classic singular flow solutions (a stokeslet and rotlet) to the double-layer potential, where the poles of the singular solutions are coincident and placed at an arbitrary location within the body. In Hebeker [14] it was shown that a complete formulation can be obtained by simply taking a positive linear combination of the classic single- and double-layer potentials. The approach of Power and Miranda has the desirable feature of being singularity-free in the sense that it leads to an integral equation involving only bounded integrands. In contrast, the approach of Hebeker leads to an integral equation with unbounded integrands. On the other hand, the approach of Power and Miranda is not natural for flows around bodies of complex shape or topology for which there is no distinguished point for the stokeslet and rotlet pole. In contrast, the approach of Hebeker is natural for flows around bodies of arbitrary shape.

†Department of Mathematics, The University of Texas at Austin, 1 University Station C1200, Austin, TX 78712 (og@math.utexas.edu).

Here we introduce a new boundary integral formulation for exterior Stokes flow which combines the strengths of the Power and Miranda and the Hebeker formulations. The new formulation is stable, complete, singularity-free, and natural for bodies of complicated shape and topology. The formulation is made complete by virtue of a positive linear combination of single- and double-layer potentials and is made singularity-free by mapping the single-layer potential onto an appropriate parallel surface. We prove an existence and uniqueness result for the formulation for arbitrary flows and illustrate its performance via several numerical examples using a standard Nyström method based on Gauss–Legendre quadrature rules. Our results show that a standard method applied to the singularity-free formulation provides a simple and viable alternative to specialized methods required by classic formulations.

Classic boundary integral formulations of the Stokes equations involve weakly singular kernels that require special treatment. Such formulations can be treated with variants of the Nyström method which employ kernel-adapted product integration rules [3, 19] or coordinate transformations and projections which effectively remove the singularity [33]. Several types of Galerkin and collocation methods [3, 5, 6, 19] can also be applied to these formulations, as well as spectral Galerkin [2, 10, 12] and wavelet-based methods [1, 21, 32]. However, these approaches generally require basis functions that may be difficult to construct or which may exist only for certain classes of geometries. Moreover, they require special techniques for computing weakly singular integrals, which can be expensive. Here we show that such issues associated with classic formulations can be avoided in a simple and efficient way by a straightforward discretization of the singularity-free formulation.

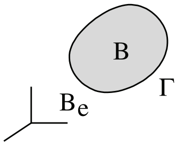
The presentation is structured as follows. In section 2 we outline the Stokes equations for the steady flow of an incompressible viscous fluid in an exterior domain. In sections 3 and 4 we establish notation and collect several results on singular solutions and surface potentials for the Stokes equations that will be employed throughout our developments. In sections 5 and 6 we summarize, for purposes of comparison, the Hebeker and the Power and Miranda formulations of the exterior Stokes problem and highlight several of their properties. In section 7 we introduce our new formulation and establish its solvability properties for arbitrary data. In section 8 we describe a numerical discretization of our formulation using a standard Nyström method with an arbitrary quadrature rule. In section 9 we illustrate our approach with numerical examples and summarize our conclusions.

2. The exterior Stokes problem.

In this section we define the boundary-value problem that we will study. We briefly outline standard assumptions which guarantee existence and uniqueness of solutions, and we introduce various flow quantities of interest that will be used to understand the properties of different boundary integral formulations.

2.1. Problem formulation.

We consider the steady motion of a body of arbitrary shape through an incompressible viscous fluid at a low Reynolds number. In a body-fixed frame, we denote the body domain by B, the fluid domain exterior to the body by B_e, and the body-fluid interface by Γ. Given a body velocity field $v : \Gamma \to \mathbb{R}^3$, the basic problem is to find a fluid velocity field $u : B_e \to \mathbb{R}^3$ and pressure field $p : B_e \to \mathbb{R}$ which satisfy the classic Stokes equations, which in nondimensional form are



$$\begin{aligned} &u_{i,jj} - p_{,i} = 0, && x \in B_e, \\ &u_{i,i} = 0, && x \in B_e, \\ &u_i = v_i, && x \in \mathit{\Gamma}, \\ &u_i, p \to 0, && |x| \to \infty. \end{aligned} \tag{2.1}$$

Equation $(2.1)_1$ is the local balance law of linear momentum for the fluid and $(2.1)_2$ is the local incompressibility constraint. Equation $(2.1)_3$ is the no-slip boundary condition which states that the fluid and body velocities coincide at each point of the boundary. The limits in $(2.1)_4$ are boundary conditions which are consistent with the fluid being at rest at infinity. Unless mentioned otherwise, all vector quantities are referred to a single basis and indices take values from one to three. Here and throughout we will use the usual conventions that a pair of repeated indices implies summation and that indices appearing after a comma denote partial derivatives.

2.2. Solvability. We assume $B \cup \mathit{\Gamma} \cup B_e$ fills all of three-dimensional space, B is open and bounded, and B_e is open and connected. Moreover, we assume $\mathit{\Gamma}$ consists of a finite number of disjoint, closed, bounded, and orientable components, each of which is a Lyapunov surface [13]. These conditions on $\mathit{\Gamma}$ imply that standard results from potential theory for the Stokes equations may be applied [20, 26, 29]. Moreover, together with the continuity of v, they are sufficient to guarantee that (2.1) has a unique solution (u, p) with the following decay properties [9, 20]:

$$u_i = O(|x|^{-1}), \quad u_{i,j} = O(|x|^{-2}), \quad p = O(|x|^{-2}) \quad \text{as} \quad |x| \to \infty. \tag{2.2}$$

The solution (u, p) is smooth in B_e but may possess only a finite number of bounded derivatives in $B_e \cup \mathit{\Gamma}$ depending on the precise smoothness of $\mathit{\Gamma}$ and v.

2.3. Basic flow quantities. The volume flow rate associated with a flow (u, p) and a given oriented surface S is defined by

$$Q = \int_S u_i(x) n_i(x)\, dA_x, \tag{2.3}$$

where $n : S \to \mathbb{R}^3$ is a given unit normal field and dA_x denotes an infinitesimal area element at $x \in S$. When S is closed and bounded, we always choose n to be the outward unit normal. In this case, Q quantifies the volume expansion rate of the domain enclosed by S.

The fluid stress field associated with a flow (u, p) is a function $\sigma : B_e \to \mathbb{R}^{3\times 3}$ defined by

$$\sigma_{ij} = -p\delta_{ij} + u_{i,j} + u_{j,i}, \tag{2.4}$$

where δ_{ij} is the standard Kronecker delta symbol. For each $x \in B_e$ the stress tensor σ is symmetric in the sense that $\sigma_{ij} = \sigma_{ji}$. The traction field $f : S \to \mathbb{R}^3$ exerted by the fluid on a given oriented surface S is defined by

$$f_i = \sigma_{ij} n_j. \tag{2.5}$$

The resultant force F and torque T, about an arbitrary point c, associated with f are

$$F_i = \int_S f_i(x)\, dA_x, \qquad T_i = \int_S \varepsilon_{ijk}(x_j - c_j) f_k(x)\, dA_x, \tag{2.6}$$

where ε_{ijk} is the standard permutation symbol. As before, when S is closed and bounded, we always choose n to be the outward unit normal field. In this case, F and T are loads exerted on S by the fluid exterior to S.

For convenience, we assume all quantities have been nondimensionalized using a characteristic length scale $\ell > 0$, a velocity scale $\vartheta > 0$, and a force scale $\mu\vartheta\ell > 0$, where μ is the absolute viscosity of the fluid. The dimensional quantities corresponding to $\{x, u, p, v\}$ are $\{\ell x, \vartheta u, \mu\vartheta\ell^{-1}p, \vartheta v\}$, and the dimensional quantities corresponding to $\{Q, \sigma, f, F, T\}$ are $\{\vartheta\ell^2 Q, \mu\vartheta\ell^{-1}\sigma, \mu\vartheta\ell^{-1}f, \mu\vartheta\ell F, \mu\vartheta\ell^2 T\}$.

3. Singular solutions of the Stokes equations. In this section we outline various classic singular solutions of the homogeneous, free-space Stokes equations

$$\begin{aligned} &u_{i,jj} - p_{,i} = 0, && x \neq y,\\ &u_{i,i} = 0, && x \neq y,\\ &u_i, p \to 0, && |x| \to \infty. \end{aligned} \tag{3.1}$$

Here y is a given point called the pole of the solution. Various representations of the solution of (2.1) can be derived and understood in terms of these solutions and their properties. Notice that, by linearity, any multiple or linear combination of solutions of (3.1) is also a solution where defined. In what follows, we let $z = x - y$ and $r = |z|$, and we let S_{int} and S_{ext} denote the interior and exterior domains associated with a given closed, bounded surface S. The notation and results outlined here will be employed throughout our developments.

3.1. Point-source solution. The point-source solution is defined by $u_i = U_i^{\text{PS}}$, $p = \varPi^{\text{PS}}$, $\sigma_{ik} = \varXi_{ik}^{\text{PS}}$, where

$$U_i^{\text{PS}} = \frac{z_i}{r^3}, \qquad \varPi^{\text{PS}} = 0, \qquad \varXi_{ik}^{\text{PS}} = \frac{2\delta_{ik}}{r^3} - \frac{6z_iz_k}{r^5}. \tag{3.2}$$

This solution may be derived from (3.1) by making the ansatz $u_i = \phi_{,i}$ and $p = 0$ for some radially symmetric function ϕ [30]. The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with an arbitrary closed, bounded surface S can be found by direct computation and depend on the relative location of the pole y. When $y \in S_{\text{ext}}$ the divergence theorem and (3.1) can be used to show that the relevant integrals over S all vanish. When $y \in S_{\text{int}}$ the divergence theorem and (3.1) can be used to transform the relevant integrals over S into integrals over an arbitrary sphere in S_{int} centered at y, which can then be evaluated directly. The results are

$$\begin{aligned} &F_i = 0, \quad && T_i = 0, \quad && Q = 4\pi, \quad && y \in S_{\text{int}},\\ &F_i = 0, && T_i = 0, && Q = 0, && y \in S_{\text{ext}}. \end{aligned} \tag{3.3}$$

3.2. Point-source dipole solution. The point-source dipole solution is defined by $u_i = U_{ij}^{\text{PSD}} g_j$, $p = \varPi_j^{\text{PSD}} g_j$, $\sigma_{ik} = \varXi_{ikj}^{\text{PSD}} g_j$, where g_j is an arbitrary vector independent of x and

$$\begin{aligned} &U_{ij}^{\text{PSD}} := \frac{\partial}{\partial y_j} U_i^{\text{PS}} = -\frac{\delta_{ij}}{r^3} + \frac{3z_iz_j}{r^5}, \qquad \varPi_j^{\text{PSD}} := \frac{\partial}{\partial y_j} \varPi^{\text{PS}} = 0,\\ &\varXi_{ikj}^{\text{PSD}} := \frac{\partial}{\partial y_j} \varXi_{ik}^{\text{PS}} = \frac{6(\delta_{ik}z_j + \delta_{ij}z_k + \delta_{kj}z_i)}{r^5} - \frac{30z_iz_kz_j}{r^7}. \end{aligned} \tag{3.4}$$

This solution is implied by the solution in (3.2) and the linearity of (3.1). The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with an arbitrary closed, bounded surface S can be computed as previously described. The results are

$$\begin{array}{llll} F_i = 0, & T_i = 0, & Q = 0, & y \in S_{\text{int}}, \\ F_i = 0, & T_i = 0, & Q = 0, & y \in S_{\text{ext}}. \end{array} \tag{3.5}$$

3.3. Point-force solution: Stokeslet. The point-force solution is defined by $u_i = U_{ij}^{\text{PF}} g_j$, $p = \Pi_j^{\text{PF}} g_j$, $\sigma_{ik} = \Xi_{ikj}^{\text{PF}} g_j$, where g_j is an arbitrary vector independent of x and

$$U_{ij}^{\text{PF}} = \frac{\delta_{ij}}{r} + \frac{z_i z_j}{r^3}, \qquad \Pi_j^{\text{PF}} = \frac{2z_j}{r^3}, \qquad \Xi_{ikj}^{\text{PF}} = -\frac{6 z_i z_k z_j}{r^5}. \tag{3.6}$$

Up to a normalizing constant, this solution corresponds to the classic fundamental solution of (3.1) and can be derived using the technique of Fourier transforms [20, 30]. It is typically referred to as a *stokeslet.* The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with an arbitrary closed, bounded surface S can be computed as previously described. The results are

$$\begin{array}{llll} F_i = -8\pi g_i, & T_i = -8\pi \varepsilon_{ijk}(y_j - c_j) g_k, & Q = 0, & y \in S_{\text{int}}, \\ F_i = 0, & T_i = 0, & Q = 0, & y \in S_{\text{ext}}. \end{array} \tag{3.7}$$

3.4. Point-force dipole solution: Stresslet, rotlet. The point-force dipole solution is defined by $u_i = U_{ijl}^{\text{PFD}} g_{jl}$, $p = \Pi_{jl}^{\text{PFD}} g_{jl}$, $\sigma_{ik} = \Xi_{ikjl}^{\text{PFD}} g_{jl}$, where g_{jl} is an arbitrary tensor independent of x and

$$\begin{aligned} U_{ijl}^{\text{PFD}} &:= \frac{\partial}{\partial y_l} U_{ij}^{\text{PF}} = \frac{\delta_{ij} z_l - \delta_{il} z_j - \delta_{jl} z_i}{r^3} + \frac{3 z_i z_j z_l}{r^5}, \\ \Pi_{jl}^{\text{PFD}} &:= \frac{\partial}{\partial y_l} \Pi_j^{\text{PF}} = -\frac{2\delta_{jl}}{r^3} + \frac{6 z_j z_l}{r^5}, \\ \Xi_{ikjl}^{\text{PFD}} &:= \frac{\partial}{\partial y_l} \Xi_{ikj}^{\text{PF}} = \frac{6(\delta_{il} z_k z_j + \delta_{kl} z_i z_j + \delta_{jl} z_i z_k)}{r^5} - \frac{30 z_i z_k z_j z_l}{r^7}. \end{aligned} \tag{3.8}$$

This solution is implied by the solution in (3.6) and the linearity of (3.1). By considering the decomposition $g_{jl} = g_{jl}^{sym} + g_{jl}^{skw}$, where $g_{jl}^{sym} = \frac{1}{2}(g_{jl} + g_{lj})$ and $g_{jl}^{skw} = \frac{1}{2}(g_{jl} - g_{lj})$, and by using the parameterization $g_{jl}^{skw} = \frac{1}{2}\varepsilon_{jml} g_m^{vec}$, we find that the point-force dipole solution can be decomposed as

$$\begin{aligned} U_{ijl}^{\text{PFD}} g_{jl} &= -U_i^{\text{PS}} \delta_{jl} g_{jl}^{sym} + U_{ijl}^{\text{STR}} g_{jl}^{sym} + U_{im}^{\text{ROT}} g_m^{vec}, \\ \Pi_{jl}^{\text{PFD}} g_{jl} &= -\Pi^{\text{PS}} \delta_{jl} g_{jl}^{sym} + \Pi_{jl}^{\text{STR}} g_{jl}^{sym} + \Pi_m^{\text{ROT}} g_m^{vec}. \end{aligned} \tag{3.9}$$

Here $(U_i^{\text{PS}}, \Pi^{\text{PS}})$ is the point-source solution given in (3.2) and $(U_{ijl}^{\text{STR}}, \Pi_{jl}^{\text{STR}})$ and $(U_{im}^{\text{ROT}}, \Pi_m^{\text{ROT}})$ are detailed below. By linearity, and the fact that g_{jl}^{sym} and g_m^{vec} are independent, we deduce that each of these pairs provides an independent solution of (3.1).

Stresslet solution. The stresslet solution is $u_i = U_{ijl}^{\text{STR}} h_{jl}$, $p = \Pi_{jl}^{\text{STR}} h_{jl}$, $\sigma_{ik} = \Xi_{ikjl}^{\text{STR}} h_{jl}$, where h_{jl} is an arbitrary tensor independent of x and

$$\begin{gathered} U_{ijl}^{\text{STR}} = \frac{3 z_i z_j z_l}{r^5}, \qquad \Pi_{jl}^{\text{STR}} = -\frac{2\delta_{jl}}{r^3} + \frac{6 z_j z_l}{r^5}, \\ \Xi_{ikjl}^{\text{STR}} = \frac{2\delta_{ik}\delta_{jl}}{r^3} + \frac{3(\delta_{ij} z_k z_l + \delta_{il} z_j z_k + \delta_{jk} z_i z_l + \delta_{lk} z_i z_j)}{r^5} - \frac{30 z_i z_j z_k z_l}{r^7}. \end{gathered} \tag{3.10}$$

Due to the symmetry of the above functions in the indices j and l we notice that only the symmetric part of h_{jl} contributes to the solution in concordance with (3.9). The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with an arbitrary closed, bounded surface S can be computed as previously described. The results are

$$\begin{array}{llll} F_i = 0, & T_i = 0, & Q = 4\pi h_{jj}, & y \in S_{\text{int}}, \\ F_i = 0, & T_i = 0, & Q = 0, & y \in S_{\text{ext}}. \end{array} \tag{3.11}$$

Rotlet (or couplet) solution. The rotlet solution is $u_i = U_{ij}^{\text{ROT}} h_j$, $p = \Pi_j^{\text{ROT}} h_j$, $\sigma_{ik} = \Xi_{ikj}^{\text{ROT}} h_j$, where h_j is an arbitrary vector independent of x and

$$U_{ij}^{\text{ROT}} = \frac{\varepsilon_{ijl} z_l}{r^3}, \qquad \Pi_j^{\text{ROT}} = 0, \qquad \Xi_{ikj}^{\text{ROT}} = \frac{3(\varepsilon_{ilj} z_k z_l + \varepsilon_{klj} z_i z_l)}{r^5}. \tag{3.12}$$

The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with an arbitrary closed, bounded surface S can be computed as previously described. The results are

$$\begin{array}{llll} F_i = 0, & T_i = -8\pi h_i, & Q = 0, & y \in S_{\text{int}}, \\ F_i = 0, & T_i = 0, & Q = 0, & y \in S_{\text{ext}}. \end{array} \tag{3.13}$$

Remarks 3.1.

1. It can be shown that all higher-order point-source solutions beginning with the dipole can be expressed in terms of the point-force solution [30]. In particular, we have

$$U_{ij}^{\text{PSD}} = -\frac{1}{2} \frac{\partial^2 U_{ij}^{\text{PF}}}{\partial y_k \partial y_k}, \qquad \Pi_j^{\text{PSD}} = -\frac{1}{2} \frac{\partial^2 \Pi_j^{\text{PF}}}{\partial y_k \partial y_k}.$$

   Thus the family of higher-order point-source solutions is contained within the family of higher-order point-force solutions.
2. One approach to solving the boundary-value problem in (2.1) is to consider a linear combination (discrete or continuous) of singular solutions with poles placed arbitrarily within the body domain B. The coefficients in the combination are then determined by enforcing the boundary condition on Γ. However, because arbitrary boundary conditions can in general not be satisfied exactly in this approach, it yields only approximate solutions of (2.1) [7, 30]. For example, slender-body theory is based on this approach [4, 15, 17].
3. A related approach to solving (2.1) is to consider a linear combination of singular solutions with poles distributed continuously over the surface Γ. The density of the distribution is then determined by enforcing the boundary condition on Γ. This approach leads to the classic theory of surface potentials for the Stokes equations and yields exact representations of the solutions of (2.1) [20, 26, 29, 30].

4. Surface potentials for the Stokes equations. In this section we outline the classic single- and double-layer surface potentials for the Stokes equations and summarize their main properties. All the boundary integral formulations that we will study are based on these potentials. In what follows Γ is an arbitrary closed, bounded surface with interior domain B and exterior domain B_e, as described in section 2.

4.1. Definition. Let $\psi : \mathit{\Gamma} \to \mathbb{R}^3$ be given. Then by the Stokes single-layer potentials on $\mathit{\Gamma}$ with density ψ we mean

$$\begin{aligned} V_i[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} U_{ij}^{\mathrm{PF}}(x,y)\psi_j(y)\,dA_y, \\ P_V[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} \mathit{\Pi}_j^{\mathrm{PF}}(x,y)\psi_j(y)\,dA_y, \end{aligned} \tag{4.1}$$

and by the Stokes double-layer potentials on $\mathit{\Gamma}$ with density ψ we mean

$$\begin{aligned} W_i[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} U_{ijl}^{\mathrm{STR}}(x,y)\psi_j(y)\nu_l(y)\,dA_y, \\ P_W[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} \mathit{\Pi}_{jl}^{\mathrm{STR}}(x,y)\psi_j(y)\nu_l(y)\,dA_y. \end{aligned} \tag{4.2}$$

Here $(U_{ij}^{\mathrm{PF}}, \mathit{\Pi}_j^{\mathrm{PF}})$ is the point-force or stokeslet solution in (3.6) with pole at y, $(U_{ijl}^{\mathrm{STR}}, \mathit{\Pi}_{jl}^{\mathrm{STR}})$ is the stresslet solution in (3.10) with pole at y, and ν is the unit normal field on $\mathit{\Gamma}$ directed outwardly from B. All densities ψ will be assumed continuous.

4.2. Analytic properties. For arbitrary density ψ the single-layer potentials $(V[\mathit{\Gamma},\psi], P_V[\mathit{\Gamma},\psi])$ and double-layer potentials $(W[\mathit{\Gamma},\psi], P_W[\mathit{\Gamma},\psi])$ are smooth at each $x \notin \mathit{\Gamma}$. Moreover, by virtue of their definitions as continuous linear combinations of stokeslets and stresslets, they satisfy the homogeneous Stokes equations $(2.1)_{1,2,4}$ at each $x \notin \mathit{\Gamma}$.

For arbitrary ψ the functions $V[\mathit{\Gamma},\psi]$ and $W[\mathit{\Gamma},\psi]$ are well defined for all $x \in B \cup \mathit{\Gamma} \cup B_e$. For $x \in \mathit{\Gamma}$ the integrands in $(4.1)_1$ and $(4.2)_1$ are unbounded functions of $y \in \mathit{\Gamma}$, but the integrals exist as improper integrals in the usual sense [13] provided that $\mathit{\Gamma}$ is a Lyapunov surface. The restrictions of $V[\psi,\mathit{\Gamma}]$ and $W[\psi,\mathit{\Gamma}]$ to $\mathit{\Gamma}$ are denoted by $\overline{V}[\psi,\mathit{\Gamma}]$ and $\overline{W}[\psi,\mathit{\Gamma}]$. These restrictions are continuous functions on $\mathit{\Gamma}$ [20]. Moreover, for any $x_0 \in \mathit{\Gamma}$ the following limit relations hold [20, 29, 30]:

$$\lim_{\substack{x\to x_0\\ x\in B_e}} V[\mathit{\Gamma},\psi](x) = \overline{V}[\mathit{\Gamma},\psi](x_0), \tag{4.3}$$

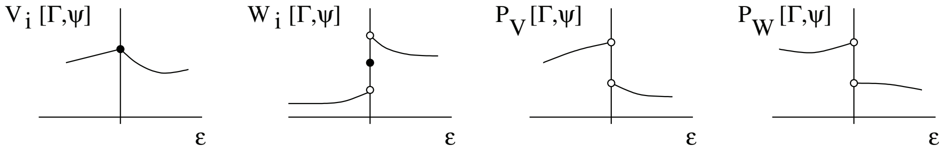
$$\lim_{\substack{x\to x_0\\ x\in B}} V[\mathit{\Gamma},\psi](x) = \overline{V}[\mathit{\Gamma},\psi](x_0), \tag{4.4}$$

$$\lim_{\substack{x\to x_0\\ x\in B_e}} W[\mathit{\Gamma},\psi](x) = \alpha\psi(x_0) + \overline{W}[\mathit{\Gamma},\psi](x_0), \tag{4.5}$$

$$\lim_{\substack{x\to x_0\\ x\in B}} W[\mathit{\Gamma},\psi](x) = -\alpha\psi(x_0) + \overline{W}[\mathit{\Gamma},\psi](x_0). \tag{4.6}$$

Here α is a constant that depends on the choice of normalization of the stresslet solution (3.10). For our choice we have $\alpha = 2\pi$. Notice that, by continuity of ψ and $\overline{W}[\mathit{\Gamma},\psi]$, the one-sided limits in (4.5) and (4.6) are themselves continuous functions on $\mathit{\Gamma}$.

In contrast to the case with $V[\mathit{\Gamma},\psi]$ and $W[\mathit{\Gamma},\psi]$, for arbitrary ψ the functions $P_V[\mathit{\Gamma},\psi]$ and $P_W[\mathit{\Gamma},\psi]$ do not exist as improper integrals in the usual sense when $x \in \mathit{\Gamma}$. In particular, the integrands in $(4.1)_2$ and $(4.2)_2$ are excessively singular functions of $y \in \mathit{\Gamma}$. Nevertheless, for sufficiently smooth $\mathit{\Gamma}$ and ψ, the functions $P_V[\mathit{\Gamma},\psi]$ and $P_W[\mathit{\Gamma},\psi]$ have well-defined limits as x approaches the surface $\mathit{\Gamma}$ [20, 29, 33]. Introducing $x_\epsilon = x_0 + \epsilon\nu(x_0)$, where $x_0 \in \mathit{\Gamma}$, the continuity properties of the functions $V[\mathit{\Gamma},\psi]$, $W[\mathit{\Gamma},\psi]$, $P_V[\mathit{\Gamma},\psi]$, $P_W[\mathit{\Gamma},\psi]$ around $\epsilon = 0$ can be illustrated as follows:



In general, the limits of the functions $V[\mathit{\Gamma},\psi]$, $W[\mathit{\Gamma},\psi]$, $P_V[\mathit{\Gamma},\psi]$, $P_W[\mathit{\Gamma},\psi]$ as x approaches $\mathit{\Gamma}$ from B_e or B have more physical significance than any directly defined values of these functions on $\mathit{\Gamma}$. In particular, physically meaningful boundary conditions are imposed on limit values and not on directly defined values. We remark that directly defined values of $P_V[\mathit{\Gamma},\psi]$ and $P_W[\mathit{\Gamma},\psi]$ on $\mathit{\Gamma}$ may be obtained by appealing to the theory of singular and hypersingular integrals [22, 24, 25].

4.3. Associated stress fields. For arbitrary ψ the stress fields associated with the single- and double-layer potentials are

$$\mathit{\Sigma}_V^{ik}[\mathit{\Gamma},\psi](x) = \int_{\mathit{\Gamma}} \mathit{\Xi}_{ikj}^{\mathrm{PF}}(x,y)\psi_j(y)\,dA_y, \tag{4.7}$$

$$\mathit{\Sigma}_W^{ik}[\mathit{\Gamma},\psi](x) = \int_{\mathit{\Gamma}} \mathit{\Xi}_{ikjl}^{\mathrm{STR}}(x,y)\psi_j(y)\nu_l(y)\,dA_y, \tag{4.8}$$

where $\mathit{\Xi}_{ikj}^{\mathrm{PF}}$ and $\mathit{\Xi}_{ikjl}^{\mathrm{STR}}$ are the stress functions corresponding to the point-force and stresslet solutions in (3.6) and (3.10). For arbitrary ψ the single-layer stress field $\mathit{\Sigma}_V[\mathit{\Gamma},\psi]$ is smooth at each $x \notin \mathit{\Gamma}$ and is the actual stress field associated with the Stokes flow with velocity field $V[\mathit{\Gamma},\psi]$ and pressure field $P_V[\mathit{\Gamma},\psi]$. A similar remark applies to the double-layer stress field $\mathit{\Sigma}_W[\mathit{\Gamma},\psi]$.

For $x \in \mathit{\Gamma}$ and arbitrary ψ the single-layer traction field $\mathit{\Sigma}_V[\mathit{\Gamma},\psi]\nu$ exists as an improper integral in the usual sense—but not the double-layer traction field $\mathit{\Sigma}_W[\mathit{\Gamma},\psi]\nu$. Moreover, for sufficiently smooth $\mathit{\Gamma}$ and ψ the following limit relations for $\mathit{\Sigma}_V[\mathit{\Gamma},\psi]\nu$ [20, 29] and $\mathit{\Sigma}_W[\mathit{\Gamma},\psi]\nu$ [29] hold for each $x_0 \in \mathit{\Gamma}$:

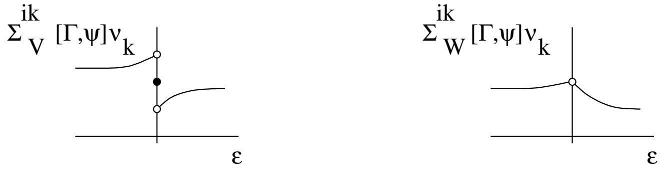
$$\lim_{\substack{\epsilon\to 0\\ \epsilon>0}} \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0) = \quad \beta\psi(x_0) + \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x_0)\nu(x_0), \tag{4.9}$$

$$\lim_{\substack{\epsilon\to 0\\ \epsilon<0}} \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0) = -\beta\psi(x_0) + \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x_0)\nu(x_0), \tag{4.10}$$

$$\lim_{\substack{\epsilon\to 0\\ \epsilon>0}} \mathit{\Sigma}_W[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0) = \lim_{\substack{\epsilon\to 0\\ \epsilon<0}} \mathit{\Sigma}_W[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0). \tag{4.11}$$

Here $x_\epsilon = x_0 + \epsilon\nu(x_0)$ and β is a constant that depends on the choice of normalization of the point-force solution (3.6). For our choice we have $\beta = -4\pi$. The result in (4.11) is commonly referred to as the Lyapunov–Tauber condition.

For arbitrary ψ and $x_0 \in \mathit{\Gamma}$ the continuity properties of $\mathit{\Sigma}_V[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0)$ and $\mathit{\Sigma}_W[\mathit{\Gamma},\psi](x_\epsilon)\nu(x_0)$ around $\epsilon = 0$ can be illustrated as follows:



We remark that, as with $P_W[\mathit{\Gamma},\psi]$, a directly defined value of $\mathit{\Sigma}_W[\mathit{\Gamma},\psi]\nu$ on $\mathit{\Gamma}$ may be obtained by appealing to the theory of hypersingular integrals.

4.4. Flow properties.

4.4. Flow properties. Let S be an arbitrary closed, bounded surface with $\mathit{\Gamma} \subset S_{\mathrm{int}}$, and let n be the outward unit normal field on S. For arbitrary ψ the resultant force $F_V[\mathit{\Gamma},\psi]$, torque $T_V[\mathit{\Gamma},\psi]$ about an arbitrary point c, and volume flow rate $Q_V[\mathit{\Gamma},\psi]$ associated with S and the single-layer flow $(V[\mathit{\Gamma},\psi], P_V[\mathit{\Gamma},\psi])$ are

$$F_V[\mathit{\Gamma},\psi] = \int_S \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x)n(x)\,dA_x = -8\pi\int_{\mathit{\Gamma}} \psi(y)\,dA_y, \tag{4.12}$$

$$T_V[\mathit{\Gamma},\psi] = \int_S (x-c)\times \mathit{\Sigma}_V[\mathit{\Gamma},\psi](x)n(x)\,dA_x = -8\pi\int_{\mathit{\Gamma}} (y-c)\times\psi(y)\,dA_y, \tag{4.13}$$

$$Q_V[\mathit{\Gamma},\psi] = \int_S V[\mathit{\Gamma},\psi](x)\cdot n(x)\,dA_x = 0. \tag{4.14}$$

These results follow from the definitions of the single-layer stress and velocity fields in (4.7) and (4.1) and the properties of the point-force solution in (3.6) and (3.7) with g_i replaced by ψ_i. Because the above results are independent of S with $\mathit{\Gamma} \subset S_{\mathrm{int}}$, we can pass to the limit and conclude that the resultant force, torque, and volume flow rate associated with $\mathit{\Gamma}$ and the exterior single-layer flow are also given by the above results.

Similar calculations can be performed in the double-layer case. For arbitrary ψ the resultant force $F_W[\mathit{\Gamma},\psi]$, torque $T_W[\mathit{\Gamma},\psi]$ about an arbitrary point c, and volume flow rate $Q_W[\mathit{\Gamma},\psi]$ associated with S and the double-layer flow $(W[\mathit{\Gamma},\psi], P_W[\mathit{\Gamma},\psi])$ are

$$F_W[\mathit{\Gamma},\psi] = \int_S \mathit{\Sigma}_W[\mathit{\Gamma},\psi](x)n(x)\,dA_x = 0, \tag{4.15}$$

$$T_W[\mathit{\Gamma},\psi] = \int_S (x-c)\times \mathit{\Sigma}_W[\mathit{\Gamma},\psi](x)n(x)\,dA_x = 0, \tag{4.16}$$

$$Q_W[\mathit{\Gamma},\psi] = \int_S W[\mathit{\Gamma},\psi](x)\cdot n(x)\,dA_x = 4\pi\int_{\mathit{\Gamma}} \psi(y)\cdot\nu(y)\,dA_y. \tag{4.17}$$

These results follow from the definitions of the double-layer stress and velocity fields in (4.8) and (4.2) and the properties of the stresslet solution in (3.10) and (3.11) with h_{jl} replaced by $\psi_j\nu_l$. As before, because the above results are independent of S with $\mathit{\Gamma} \subset S_{\mathrm{int}}$, we can pass to the limit and conclude that the resultant force, torque, and volume flow rate associated with $\mathit{\Gamma}$ and the exterior double-layer flow are also given by the above results.

5. Hebeker formulation.

In this section we outline the boundary integral formulation of (2.1) introduced by Hebeker [14] and highlight several of its properties for comparison. In what follows $\mathit{\Gamma}$ is an arbitrary closed, bounded surface with interior domain B and exterior domain B_e, as described in section 2.

5.1. Formulation.

Given an arbitrary density $\psi : \mathit{\Gamma} \to \mathbb{R}^3$ and number $\theta \in [0,1]$, define $u : B_e \to \mathbb{R}^3$ and $p : B_e \to \mathbb{R}$ by

$$u = \theta V[\mathit{\Gamma},\psi] + (1-\theta)W[\mathit{\Gamma},\psi], \qquad p = \theta P_V[\mathit{\Gamma},\psi] + (1-\theta)P_W[\mathit{\Gamma},\psi]. \tag{5.1}$$

By properties of the single- and double-layer potentials, the fields (u,p) are smooth at each $x \in B_e$ and satisfy the Stokes equations $(2.1)_{1,2,4}$ at each $x \in B_e$. The stress field $\sigma : B_e \to \mathbb{R}^{3\times 3}$ associated with (u,p) is given by

$$\sigma = \theta \Sigma_V[\Gamma,\psi] + (1-\theta)\Sigma_W[\Gamma,\psi], \tag{5.2}$$

and the resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with Γ are

$$F = \theta F_V[\Gamma,\psi], \quad T = \theta T_V[\Gamma,\psi], \quad Q = (1-\theta)Q_W[\Gamma,\psi]. \tag{5.3}$$

Here we have used linearity and the flow properties of the single- and double-layer potentials outlined in section 4.4.

In order for (u,p) to provide the unique solution of the exterior Stokes boundary-value problem (2.1), the boundary condition $(2.1)_3$ must be satisfied. In particular, given $v : \Gamma \to \mathbb{R}^3$, we require

$$\lim_{\substack{x\to x_0\\ x\in B_e}} u(x) = v(x_0) \qquad \forall x_0 \in \Gamma. \tag{5.4}$$

Substituting for u from (5.1) and using the limit relations in (4.3) and (4.5), we obtain a boundary integral equation for the unknown density ψ:

$$\theta\overline{V}[\Gamma,\psi](x_0) + (1-\theta)\overline{W}[\Gamma,\psi](x_0) + (1-\theta)\alpha\psi(x_0) = v(x_0) \qquad \forall x_0 \in \Gamma. \tag{5.5}$$

From this we can deduce that (u,p) defined in (5.1) will be the unique solution of (2.1) if and only if ψ satisfies (5.5). This equation can be written in the standard form

$$\int_\Gamma K_\theta(x,y)\psi(y)\,dA_y + c_\theta\psi(x) = v(x) \qquad \forall x \in \Gamma, \tag{5.6}$$

where x_0 has been replaced by x for convenience, $c_\theta = (1-\theta)\alpha$, and

$$K_\theta^{ij}(x,y) = \theta U_{ij}^{\mathrm{PF}}(x,y) + (1-\theta)U_{ijl}^{\mathrm{STR}}(x,y)\nu_l(y). \tag{5.7}$$

Remarks 5.1.

1. Assuming Γ is a Lyapunov surface the kernel function $K_\theta(x,y)$ can be shown to be weakly singular. Thus the solvability of the linear integral equation (5.6) can be assessed via the Fredholm theory [19, 23]. Notice that $c_\theta = 0$ when $\theta = 1$, and $c_\theta \neq 0$ when $\theta \in [0,1)$. Thus (5.6) is a Fredholm equation of the first kind when $\theta = 1$ and of the second kind when $\theta \in [0,1)$.
2. The case $\theta = 0$ in (5.1) corresponds to a classic double-layer representation of (u,p). It is well known that this representation is incomplete in the sense that it can represent only those flows for which the resultant force and torque on Γ vanish, that is, $F = 0$ and $T = 0$ [20, 26, 29, 30]. Equivalently, the range of the linear operator in (5.6) is deficient, leading to solvability conditions and nonuniqueness for ψ.
3. The case $\theta = 1$ in (5.1) corresponds to a classic single-layer representation of (u,p). It is well known that this representation is also incomplete in the sense that it can represent only those flows for which the volumetric expansion rate of Γ vanishes, that is, $Q = 0$ [20, 26, 29, 30]. Equivalently, the range of the linear operator in (5.6) is again deficient, leading to solvability conditions and nonuniqueness for ψ.

4. The main idea in Hebeker [14] was to consider a mixed representation corresponding to $\theta \in (0,1)$. The intuitive motivation is that, by considering a linear combination, each potential can make up for the deficiencies of the other. As outlined below, such a representation is complete in the sense that it can represent arbitrary flows and stable in the sense that the density ψ depends continuously on the boundary data v.

5.2. Solvability result. The following is a slight generalization of the solvability result given in Hebeker [14].

Theorem 5.1 (see [14]). *Assume Γ is a closed, bounded Lyapunov surface. If $\theta \in (0,1)$, then* (5.6) *possesses a unique continuous solution ψ for any continuous boundary data v.*

Thus arbitrary solutions of the exterior Stokes boundary-value problem (2.1) can be represented in the form (5.1) with a unique density ψ for each $\theta \in (0,1)$. The presence of the double-layer potential in (5.1) ensures that the representation is stable. In particular, because (5.6) is a uniquely solvable Fredholm equation of the second kind, the linear operator in (5.6) has a finite condition number and the density ψ depends continuously on the data v. The presence of the single-layer potential in (5.1) ensures that the representation is complete. In particular, the single-layer potential completes the deficient range associated with the double-layer potential. The smoothness properties of the density ψ depend on those of the surface Γ and the data v.

Remarks 5.2.

1. Aside from the restriction of solvability, the parameter θ is arbitrary and can be exploited. For example, $\theta \in (0,1)$ might be chosen by some means to optimize the conditioning of the linear operator in (5.6).
2. Numerical methods for (5.6), Nyström methods in particular, must deal with the singularities in the kernels of the single- and double-layer potentials. The singularity in the kernel of the double-layer potential can be removed in a simple, standard way by employing a well-known integral identity [11, 28, 30, 31] (see section 8). However, there seems to be no similar removal technique for the singularity in the kernel of the single-layer potential.
3. In general numerical treatments, the singularity in the kernel of the single-layer potential can be dealt with by employing a kernel-adapted product quadrature rule [3, 19], together with a local coordinate transformation such as a Duffy transformation [3, 8, 30], or a floating polar transformation [33]. The same techniques can also be applied to the double-layer potential. In view of the inconvenience associated with the single-layer potential, we investigate alternative formulations.

6. Power and Miranda formulation.

In this section we outline the boundary integral formulation of (2.1) introduced by Power and Miranda [28] and highlight several of its properties for comparison. In what follows Γ is an arbitrary closed, bounded surface with interior domain B and exterior domain B_e, as described in section 2. For simplicity, in this section we assume that B consists of only one connected component. All the results outlined generalize in a straightforward way to the case when B has a finite number of disjoint components [29].

6.1. Formulation. Given an arbitrary density $\psi : \Gamma \to \mathbb{R}^3$, number $\theta \in [0,1]$, and point $x_* \in B$, define $u : B_e \to \mathbb{R}^3$ and $p : B_e \to \mathbb{R}$ by

$$u = \theta Y[\Gamma,\psi] + (1-\theta)W[\Gamma,\psi], \qquad p = \theta P_Y[\Gamma,\psi] + (1-\theta)P_W[\Gamma,\psi], \tag{6.1}$$

where $Y[\mathit{\Gamma},\psi]$ and $P_Y[\mathit{\Gamma},\psi]$ are fields defined in terms of the point-force (stokeslet) and rotlet solutions as

$$\begin{aligned} Y_i[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} \Big(U^{\mathrm{PF}}_{ij}(x,x_*) + U^{\mathrm{ROT}}_{il}(x,x_*)\varepsilon_{lpj}(y_p - x_{*p})\Big)\psi_j(y)\,dA_y, \\ P_Y[\mathit{\Gamma},\psi](x) &= \int_{\mathit{\Gamma}} \Big(\mathit{\Pi}^{\mathrm{PF}}_{j}(x,x_*) + \mathit{\Pi}^{\mathrm{ROT}}_{l}(x,x_*)\varepsilon_{lpj}(y_p - x_{*p})\Big)\psi_j(y)\,dA_y. \end{aligned} \tag{6.2}$$

By properties of the point-force and rotlet solutions and the double-layer potentials, the fields (u,p) are smooth at each $x \in B_e$ and satisfy the Stokes equations $(2.1)_{1,2,4}$ at each $x \in B_e$. The stress field $\sigma : B_e \to \mathbb{R}^{3\times 3}$ associated with (u,p) is given by

$$\sigma = \theta\mathit{\Sigma}_Y[\mathit{\Gamma},\psi] + (1-\theta)\mathit{\Sigma}_W[\mathit{\Gamma},\psi], \tag{6.3}$$

where $\mathit{\Sigma}_Y[\mathit{\Gamma},\psi]$ is the stress field associated with the flow $(Y[\mathit{\Gamma},\psi], P_Y[\mathit{\Gamma},\psi])$, namely,

$$\mathit{\Sigma}^{ik}_Y[\mathit{\Gamma},\psi](x) = \int_{\mathit{\Gamma}} \Big(\mathit{\Xi}^{\mathrm{PF}}_{ikj}(x,x_*) + \mathit{\Xi}^{\mathrm{ROT}}_{ikl}(x,x_*)\varepsilon_{lpj}(y_p - x_{*p})\Big)\psi_j(y)\,dA_y. \tag{6.4}$$

The resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with $\mathit{\Gamma}$ are

$$F = \theta F_Y[\mathit{\Gamma},\psi], \quad T = \theta T_Y[\mathit{\Gamma},\psi], \quad Q = \theta Q_Y[\mathit{\Gamma},\psi] + (1-\theta)Q_W[\mathit{\Gamma},\psi], \tag{6.5}$$

where $F_Y[\mathit{\Gamma},\psi]$, $T_Y[\mathit{\Gamma},\psi]$, and $Q_Y[\mathit{\Gamma},\psi]$ are the resultant force, torque, and volume flow rate associated with the flow $(Y[\mathit{\Gamma},\psi], P_Y[\mathit{\Gamma},\psi])$. From the properties of the point-force and rotlet solutions given in (3.7) and (3.13), we deduce that $Q_Y[\mathit{\Gamma},\psi] = 0$ and

$$F_Y[\mathit{\Gamma},\psi] = -8\pi\int_{\mathit{\Gamma}} \psi(y)\,dA_y, \quad T_Y[\mathit{\Gamma},\psi] = -8\pi\int_{\mathit{\Gamma}} (y-c)\times\psi(y)\,dA_y. \tag{6.6}$$

In order for (u,p) to provide the unique solution of the exterior Stokes boundary-value problem (2.1), the boundary condition $(2.1)_3$ must be satisfied. In particular, given $v : \mathit{\Gamma} \to \mathbb{R}^3$, we require

$$\lim_{\substack{x\to x_0\\ x\in B_e}} u(x) = v(x_0) \qquad \forall x_0 \in \mathit{\Gamma}. \tag{6.7}$$

Substituting for u from (6.1) and using the limit relation in (4.5), we obtain a boundary integral equation for the unknown density ψ:

$$\theta Y[\mathit{\Gamma},\psi](x_0) + (1-\theta)\overline{W}[\mathit{\Gamma},\psi](x_0) + (1-\theta)\alpha\psi(x_0) = v(x_0) \qquad \forall x_0 \in \mathit{\Gamma}. \tag{6.8}$$

From this we can deduce that (u,p) defined in (6.1) will be the unique solution of (2.1) if and only if ψ satisfies (6.8). This equation can be written in the standard form

$$\int_{\mathit{\Gamma}} K_\theta(x,y)\psi(y)\,dA_y + c_\theta\psi(x) = v(x) \qquad \forall x \in \mathit{\Gamma}, \tag{6.9}$$

where x_0 has been replaced by x for convenience, $c_\theta = (1-\theta)\alpha$, and

$$\begin{aligned} K^{ij}_\theta(x,y) \quad = \quad & \theta U^{\mathrm{PF}}_{ij}(x,x_*) + \theta U^{\mathrm{ROT}}_{il}(x,x_*)\varepsilon_{lpj}(y_p - x_{*p}) \\ & \qquad\qquad + (1-\theta)U^{\mathrm{STR}}_{ijl}(x,y)\nu_l(y). \end{aligned} \tag{6.10}$$

Remarks 6.1.

1. As before, assuming Γ is a Lyapunov surface, the kernel function $K_\theta(x,y)$ can be shown to be weakly singular. Thus the solvability of the linear integral equation (6.9) can be assessed via the Fredholm theory [19, 23]. Notice that $c_\theta = 0$ when $\theta = 1$, and $c_\theta \neq 0$ when $\theta \in [0,1)$. Thus (6.9) is a Fredholm equation of the first kind when $\theta = 1$ and of the second kind when $\theta \in [0,1)$.
2. The main idea in Power and Miranda [28] can be described intuitively as follows. A double-layer potential is deficient in the sense that it can only produce flows with zero resultant force and torque on Γ. Thus, in view of the flow properties outlined in (3.7) and (3.13), the enhancement of a double-layer potential with point-force and rotlet solutions should produce flows with arbitrary resultant force and torque on Γ.
3. The intuitive arguments above are made rigorous by the results outlined below. They show that the representation in (6.1) with $\theta \in (0,1)$ is complete in the sense that it can represent arbitrary flows and stable in the sense that the density ψ depends continuously on the boundary data v.

6.2. Solvability result. The following is a slight generalization of the solvability result given in Power and Miranda [28].

THEOREM 6.1 (see [28]). *Assume Γ is a closed, bounded Lyapunov surface, and let $x_* \in B$ be arbitrary. If $\theta \in (0,1)$, then* (6.9) *possesses a unique continuous solution ψ for any continuous boundary data v.*

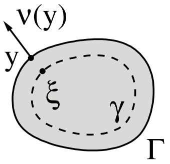
Thus arbitrary solutions of the exterior Stokes boundary-value problem (2.1) can be represented in the form (6.1) with a unique density ψ for each $x_* \in B$ and $\theta \in (0,1)$. The presence of the double-layer potential in (6.1) ensures that the representation is stable. In particular, because (6.9) is a uniquely solvable Fredholm equation of the second kind, the linear operator in (6.9) has a finite condition number and the density ψ depends continuously on the data v. The presence of the point-force and rotlet functions in (6.1) ensures that the representation is complete. In particular, these two singular solutions complete the deficient range associated with the double-layer potential. The smoothness properties of the density ψ depend on those of the surface Γ and the data v.

Remarks 6.2.

1. Aside from the restriction of solvability, the parameters θ and x_* are arbitrary and can be exploited. For example, $\theta \in (0,1)$ and $x_* \in B$ might be chosen by some means to optimize the conditioning of the linear operator in (6.9).
2. The boundary integral equation in (6.9) can be described as being singularity-free. The singularity in the point-force and rotlet contributions is avoided because their poles are contained in the body domain B. Moreover, the singularity in the kernel of the double-layer potential can be removed in a simple, standard way by employing a well-known integral identity [11, 28, 30, 31] (see section 8).
3. The above results hold for bodies of arbitrary shape. For certain types of bodies, for example convex or star-shaped bodies, there are various reasonable choices for the point $x_* \in B$. The center of volume is one obvious choice. In contrast, for other types of bodies, for example, toroidal or knotted tubular bodies, there seems to be no natural choice for the point $x_* \in B$. Motivated by this latter class of bodies, we investigate an alternative formulation.

7. A new formulation. Here we introduce a new boundary integral formulation of (2.1) which combines the strengths of the Power and Miranda and the Hebeker formulations. The new formulation is stable, complete, singularity-free, and natural for bodies of complicated shape and topology. In what follows $\mathit{\Gamma}$ is an arbitrary closed, bounded surface with interior domain B and exterior domain B_e, as described in section 2.

7.1. Formulation. Let γ be a surface parallel to $\mathit{\Gamma}$ offset toward B by a distance $\phi \geq 0$. In particular, γ is the image of the map $\xi = \zeta(y) : \mathit{\Gamma} \to \mathbb{R}^3$ defined by



$$\xi = y - \phi\, \nu(y). \tag{7.1}$$

By virtue of the fact that $\mathit{\Gamma}$ is a Lyapunov surface, it follows that the map $\zeta : \mathit{\Gamma} \to \gamma$ is continuous and one-to-one for all $\phi \in [0, \phi_{\mathit{\Gamma}})$, where $\phi_{\mathit{\Gamma}}$ is a positive constant. In the absence of any global obstructions, we have $\phi_{\mathit{\Gamma}} = 1/\kappa_{\mathit{\Gamma}}$, where $\kappa_{\mathit{\Gamma}}$ is the maximum of the signed principal curvatures of $\mathit{\Gamma}$ [27]. Here we use the convention that the curvature is positive when $\mathit{\Gamma}$ curves away from its outward unit normal ν. As a consequence, the principal curvatures are the eigenvalues of the gradient of ν (not $-\nu$) restricted to the tangent plane. From the geometry of parallel surfaces we have the following relations for all $y \in \mathit{\Gamma}$, $\xi = \zeta(y) \in \gamma$, and $\phi \in [0, \phi_{\mathit{\Gamma}})$ [27]:

$$n(\xi) = \nu(y), \quad dA_\xi = J^\phi(y)\, dA_y, \quad J^\phi(y) = 1 - 2\phi\kappa^m(y) + \phi^2\kappa^g(y). \tag{7.2}$$

Here n is the outward unit normal on γ, dA_ξ and dA_y are area elements on γ and $\mathit{\Gamma}$, and κ^m and κ^g are the mean and Gaussian curvatures of $\mathit{\Gamma}$. For $\phi \in [0, \phi_{\mathit{\Gamma}})$ we denote the inverse of $\xi = \zeta(y)$ by $y = \varphi(\xi)$. In view of (7.1) and $(7.2)_1$ we have $y = \xi + \phi n(\xi)$.

Given an arbitrary density $\psi : \mathit{\Gamma} \to \mathbb{R}^3$ and number $\theta \in [0, 1]$, define $u : B_e \to \mathbb{R}^3$ and $p : B_e \to \mathbb{R}$ by

$$u = \theta V[\gamma, \psi \circ \varphi] + (1 - \theta) W[\mathit{\Gamma}, \psi], \quad p = \theta P_V[\gamma, \psi \circ \varphi] + (1 - \theta) P_W[\mathit{\Gamma}, \psi]. \tag{7.3}$$

Notice that the double-layer potentials are defined on the surface $\mathit{\Gamma}$ with density ψ, while the single-layer potentials are defined on the parallel surface γ with density $\psi \circ \varphi$. In particular, the two types of potentials are defined on different surfaces but involve only one arbitrary density.

By properties of the single- and double-layer potentials, the fields (u, p) are smooth at each $x \in B_e$ and satisfy the Stokes equations $(2.1)_{1,2,4}$ at each $x \in B_e$. The stress field $\sigma : B_e \to \mathbb{R}^{3\times 3}$ associated with (u, p) is given by

$$\sigma = \theta \mathit{\Sigma}_V[\gamma, \psi \circ \varphi] + (1 - \theta) \mathit{\Sigma}_W[\mathit{\Gamma}, \psi], \tag{7.4}$$

and the resultant force F, torque T about an arbitrary point c, and volume flow rate Q associated with $\mathit{\Gamma}$ are

$$F = \theta F_V[\gamma, \psi \circ \varphi], \quad T = \theta T_V[\gamma, \psi \circ \varphi], \quad Q = (1 - \theta) Q_W[\mathit{\Gamma}, \psi]. \tag{7.5}$$

Here we have used linearity and the flow properties of the single- and double-layer potentials outlined in section 4.4.

In order for (u, p) to provide the unique solution of the exterior Stokes boundary-value problem (2.1), the boundary condition $(2.1)_3$ must be satisfied. In particular, given $v : \mathit{\Gamma} \to \mathbb{R}^3$, we require

$$\lim_{\substack{x \to x_0 \\ x \in B_e}} u(x) = v(x_0) \quad \forall x_0 \in \mathit{\Gamma}. \tag{7.6}$$

Substituting for u from (7.3) and using the limit relation in (4.5), we obtain a boundary integral equation for the unknown density ψ:

$$\theta V[\gamma, \psi \circ \varphi](x_0) + (1-\theta)\overline{W}[\mathit{\Gamma}, \psi](x_0) + (1-\theta)\alpha\psi(x_0) = v(x_0) \quad \forall x_0 \in \mathit{\Gamma}. \tag{7.7}$$

From this we can deduce that (u, p) defined in (7.3) will be the unique solution of (2.1) if and only if ψ satisfies (7.7). By definition of the single- and double-layer potentials, this equation can be written in integral form as

$$\begin{aligned} &\theta \int_\gamma U_{ij}^{\mathrm{PF}}(x,\xi)\psi_j(\varphi(\xi))\, dA_\xi \\ &\qquad + (1-\theta)\int_{\mathit{\Gamma}} U_{ijl}^{\mathrm{STR}}(x,y)\psi_j(y)\nu_l(y)\, dA_y + c_\theta\psi_i(x) = v_i(x) \quad \forall x \in \mathit{\Gamma}, \end{aligned} \tag{7.8}$$

where x_0 has been replaced by x for convenience and $c_\theta = (1-\theta)\alpha$. By performing a change of variable in the first integral, this equation can then be put into the standard form

$$\int_{\mathit{\Gamma}} K_\theta(x,y)\psi(y)\, dA_y + c_\theta\psi(x) = v(x) \qquad \forall x \in \mathit{\Gamma}, \tag{7.9}$$

where

$$K_\theta^{ij}(x,y) = \theta J^\phi(y) U_{ij}^{\mathrm{PF}}(x,\zeta(y)) + (1-\theta)U_{ijl}^{\mathrm{STR}}(x,y)\nu_l(y). \tag{7.10}$$

Remarks 7.1.

1. In all three formulations the kernel function $K_\theta(x,y)$ can be described as the positive linear combination of a double-layer kernel and a range completion term. In the Hebeker formulation (5.7), the completion term is an unbounded single-layer kernel. In the Power and Miranda formulation (6.10), the completion term is the sum of a point-force and a rotlet kernel, both of which are bounded and dependent on a point $x_* \in B$. In the new formulation (7.10), the completion term can be interpreted as a regularized single-layer kernel, where $\phi \geq 0$ is the regularization parameter. The regularized single-layer kernel is bounded when $\phi > 0$ and unbounded exactly as in the Hebeker formulation when $\phi = 0$.
2. Assuming $\mathit{\Gamma}$ is a Lyapunov surface, the kernel function $K_\theta(x,y)$ in (7.10) can be shown to be weakly singular. Thus the solvability of the linear integral equation (7.9) can be assessed via the Fredholm theory [19, 23]. Notice that $c_\theta = 0$ when $\theta = 1$ and $c_\theta \neq 0$ when $\theta \in [0,1)$. Thus (7.9) is a Fredholm equation of the first kind when $\theta = 1$ and of the second kind when $\theta \in [0,1)$.
3. As outlined below, the representation in (7.3) with $\theta \in (0,1)$ is complete in the sense that it can represent arbitrary flows and stable in the sense that the density ψ depends continuously on the boundary data v.

7.2. Solvability result. The following result establishes the solvability of the integral equation (7.9), or, equivalently, (7.7). Its proof is given in section 7.3 below.

THEOREM 7.1. *Assume $\mathit{\Gamma}$ is a closed, bounded Lyapunov surface, and let γ be a surface parallel to $\mathit{\Gamma}$ offset toward B by a distance $\phi \in [0, \phi_{\mathit{\Gamma}})$. If $\theta \in (0,1)$, then* (7.9) *possesses a unique continuous solution ψ for any continuous boundary data v.*

Thus arbitrary solutions of the exterior Stokes boundary-value problem (2.1) can be represented in the form (7.3) with a unique density ψ for each $\theta \in (0,1)$ and

$\phi \in [0, \phi_\Gamma)$. The presence of the double-layer potential in (7.3) ensures that the representation is stable. In particular, because (7.9) is a uniquely solvable Fredholm equation of the second kind, the linear operator in (7.9) has a finite condition number, and the density ψ depends continuously on the data v. The presence of the single-layer potential in (7.3) ensures that the representation is complete. In particular, the single-layer potential on the parallel surface γ completes the deficient range associated with the double-layer potential on the surface Γ. The smoothness properties of the density ψ depend on those of the surface Γ and the data v.

Remarks 7.2.

1. Aside from the restriction of solvability, the parameters θ and ϕ are arbitrary and can be exploited. For example, $\theta \in (0, 1)$ and $\phi \in [0, \phi_\Gamma)$ might be chosen by some means to optimize the conditioning of the linear operator in (7.9).
2. Just like the Power and Miranda formulation, the current boundary integral equation in (7.9) is singularity-free in the case when $\phi > 0$. The singularity in the single-layer potential is removed by virtue of the parallel surface. The singularity in the kernel of the double-layer potential can be removed in a simple, standard way by employing a well-known integral identity [11, 28, 30, 31] (see section 8).
3. Just like the Hebeker formulation, the current boundary integral formulation is natural for bodies of arbitrary shape. It seems particularly well suited for long, uniform, tubular bodies with complicated topology. In this case, the maximum offset distance ϕ_Γ can be explicitly identified as the tube radius, and Γ and γ would be parallel tubular surfaces of different radii centered on the same axial curve. In general, however, an explicit characterization of ϕ_Γ is not necessary, and the formulation is valid for any type of body.
4. All three formulations can be viewed as extensions to Stokes flow of ideas developed in classic potential theory. The idea of taking a linear combination of single- and double-layer potentials was considered in the work of Günter [13], and the idea of moving the single-layer potential to an inner surface, or limit thereof, was suggested in the work of Mikhlin [23]. (Mikhlin explicitly considered an inner point-source, which can be interpreted as the limit of a single-layer potential as the inner surface is squeezed to a point.) Other generalized formulations could also be considered. For example, the Power and Miranda formulation can be generalized by using a continuous distribution of stokeslet and rotlet singularities over an inner surface.

7.3. Proof of Theorem 7.1. Assume $\theta \in (0, 1)$ and consider the homogeneous version of (7.7). Replacing ψ by ψ^h for notational convenience, we have

$$\theta V[\gamma, \psi^h \circ \varphi](x_0) + (1-\theta)\overline{W}[\Gamma, \psi^h](x_0) + (1-\theta)\alpha\psi^h(x_0) = 0 \quad \forall x_0 \in \Gamma. \tag{7.11}$$

According to the Fredholm theory [19, 23], if (7.11) possesses only the trivial solution $\psi^h = 0$, then (7.7) possesses a unique continuous solution ψ for any continuous data v. To show that $\psi^h = 0$ is the only solution of (7.11), we proceed in four steps.

(1) Let ψ^h be an arbitrary solution of (7.11), and introduce fields $(u^{(1)}, p^{(1)})$ and $(u^{(2)}, p^{(2)})$ by

$$\begin{aligned} u^{(1)} &= (1-\theta)W[\Gamma, \psi^h], \quad & p^{(1)} &= (1-\theta)P_W[\Gamma, \psi^h], \\ u^{(2)} &= -\theta V[\gamma, \psi^h \circ \varphi], \quad & p^{(2)} &= -\theta P_V[\gamma, \psi^h \circ \varphi]. \end{aligned} \tag{7.12}$$

Then $(u^{(1)}, p^{(1)})$ and $(u^{(2)}, p^{(2)})$ satisfy the homogeneous Stokes equations $(2.1)_{1,2,4}$

in B_e. Moreover, from (7.11) and the limit relation for $W[\mathit{\Gamma}, \psi^h]$ in (4.5), we have

$$\lim_{\substack{x \to x_0 \\ x \in B_e}} u^{(1)}(x) - u^{(2)}(x) = 0 \quad \forall x_0 \in \mathit{\Gamma}. \tag{7.13}$$

Thus $u^{(1)} = u^{(2)}$ on $\mathit{\Gamma}$, and by uniqueness of solutions of the boundary-value problem (2.1), we have $(u^{(1)}, p^{(1)}) = (u^{(2)}, p^{(2)})$ in B_e. Furthermore, by properties of the single- and double-layer potentials defined in (4.1) and (4.2), we have $u^{(1)} = O(|x|^{-2})$ and $u^{(2)} = O(|x|^{-1})$ as $|x| \to \infty$, and $p^{(1)} = O(|x|^{-3})$ and $p^{(2)} = O(|x|^{-2})$. Thus we deduce

$$u^{(1)} = u^{(2)} = 0 \quad \text{and} \quad p^{(1)} = p^{(2)} = 0 \quad \forall x \in B_e. \tag{7.14}$$

(2) Since $u^{(1)} = 0$ in B_e and $1 - \theta \neq 0$, we deduce from (7.12) that $W[\mathit{\Gamma}, \psi^h] = 0$ in B_e, which implies

$$\lim_{\substack{x \to x_0 \\ x \in B_e}} W[\mathit{\Gamma}, \psi^h](x) = 0 \qquad \forall x_0 \in \mathit{\Gamma}. \tag{7.15}$$

Using the limit relation in (4.5), we get

$$\overline{W}[\mathit{\Gamma}, \psi^h](x_0) + \alpha \psi^h(x_0) = 0 \quad \forall x_0 \in \mathit{\Gamma}. \tag{7.16}$$

By well-known properties of the double-layer potential [20, 26], the above equation possesses exactly six independent eigenfunctions $\psi^{h,(1)}, \ldots, \psi^{h,(6)}$ defined for $x \in \mathit{\Gamma}$ by

$$\begin{aligned} \psi_i^{h,(a)}(x) &= \delta_{ia}, & a &= 1, 2, 3, \\ \psi_i^{h,(a)}(x) &= \varepsilon_{ij(a-3)} x_j, & a &= 4, 5, 6. \end{aligned} \tag{7.17}$$

Thus every solution ψ^h of (7.11) satisfies (7.16) and must necessarily be of the form

$$\psi^h(x) = \sum_{a=1}^{6} c_a \psi^{h,(a)}(x), \tag{7.18}$$

where $c_1, \ldots, c_6$ are arbitrary constants.

(3) Since $u^{(2)} = 0$ and $p^{(2)} = 0$ in B_e and $\theta \neq 0$, we deduce from (7.12) that $V[\gamma, \psi^h \circ \varphi] = 0$ and $P_V[\gamma, \psi^h \circ \varphi] = 0$ in B_e. Thus the resultant force and torque, about an arbitrary point q, exerted on $\mathit{\Gamma}$ by the exterior single-layer flow $(V[\gamma, \psi^h \circ \varphi], P_V[\gamma, \psi^h \circ \varphi])$ must vanish. By properties of the single-layer potentials outlined in section 4.4, and considering that $\gamma \subset \mathit{\Gamma}_{\text{int}}$ when $\phi > 0$ and $\gamma = \mathit{\Gamma}$ when $\phi = 0$, we find in both cases that

$$\begin{aligned} F_V[\gamma, \psi^h \circ \varphi] &= -8\pi \int_\gamma \psi^h(\varphi(\xi))\, dA_\xi = 0, \\ T_V[\gamma, \psi^h \circ \varphi] &= -8\pi \int_\gamma (\xi - q) \times \psi^h(\varphi(\xi))\, dA_\xi = 0. \end{aligned} \tag{7.19}$$

Dividing by -8π and substituting for ψ^h using (7.18) and (7.17), we find that the above equations yield a linear system for $c = (c_1, \ldots, c_6)$ of the form

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} c = 0, \tag{7.20}$$

where $A, B, C, D \in \mathbb{R}^{3\times 3}$ are defined by

$$\begin{aligned} A_{ij} &= \int_\gamma \delta_{ij}\, dA_\xi, \quad B_{ik} = \int_\gamma \varepsilon_{ijk}\varphi_j(\xi)\, dA_\xi, \\ C_{ij} &= \int_\gamma \varepsilon_{ipj}(\xi_p - q_p)\, dA_\xi, \quad D_{ik} = \int_\gamma \varepsilon_{ipl}\varepsilon_{ljk}(\xi_p - q_p)\varphi_j(\xi)\, dA_\xi. \end{aligned} \tag{7.21}$$

(4) For convenience, let the torque reference point q be the centroid of γ, and assume without loss of generality that $q = 0$. Then $C_{ij} = 0$ and (7.20) will possess only the trivial solution provided that the matrix D_{ik} is invertible. Notice that the matrix A_{ij} is always invertible since γ has positive measure. With $q = 0$ we have

$$D_{ik} = \int_\gamma \varepsilon_{ipl}\varepsilon_{ljk}\xi_p\varphi_j(\xi)\, dA_\xi. \tag{7.22}$$

Substituting $\varphi(\xi) = \xi + \phi n(\xi)$, where n is the outward unit normal field on γ (see section 7.1), and using the standard permutation symbol identity $\varepsilon_{ipl}\varepsilon_{ljk} = \delta_{ij}\delta_{pk} - \delta_{ik}\delta_{pj}$, we obtain

$$D_{ik} = \int_\gamma \xi_i\xi_k - \delta_{ik}\xi_j\xi_j\, dA_\xi + \phi\int_\gamma \xi_k n_i\, dA_\xi - \phi\delta_{ik}\int_\gamma \xi_j n_j\, dA_\xi. \tag{7.23}$$

Applying the divergence theorem to the last two integrals in the above equation, we get, after straightforward simplification,

$$D_{ik} = -[G_{ik} + 2\phi\,\mathrm{vol}(\gamma_{\mathrm{int}})\delta_{ik}]. \tag{7.24}$$

Here $\mathrm{vol}(\gamma_{\mathrm{int}}) > 0$ is the volume of the interior domain enclosed by γ and $G_{ik} = \int_\gamma \delta_{ik}|\xi|^2 - \xi_i\xi_k\, dA_\xi$ is the symmetric, positive-definite, second moment tensor associated with γ. Since D_{ik} is invertible for any $\phi \geq 0$, we deduce that (7.20) admits only the trivial solution $c = 0$. Combining this with (7.18), we deduce that (7.11) admits only the trivial solution $\psi^h = 0$. This completes the proof of Theorem 7.1.

8. Nyström approximation.

In this section we describe a numerical method for the formulation presented in section 7. We outline a singularity-free formulation of the boundary integral equation for the unknown density, discretize it using a straightforward Nyström method with an arbitrary quadrature rule, and introduce corresponding discretizations for various flow quantities of interest.

8.1. Singularity-free formulation.

Given arbitrary parameters $\theta \in (0, 1)$ and $\phi \in (0, \phi_\Gamma)$, the integral equation (7.9) can be written in the convenient form

$$\begin{aligned} \theta\int_\Gamma G(x,y)\psi(y)\, dA_y + (1-\theta)\int_\Gamma H(x,y)\psi(y)\, dA_y \\ + (1-\theta)\alpha\psi(x) = v(x) \quad \forall x \in \Gamma, \end{aligned} \tag{8.1}$$

where $G_{ij}(x,y) = J^\phi(y)U_{ij}^{\mathrm{PF}}(x,\zeta(y))$ is the regularized, bounded, single-layer kernel and $H_{ij}(x,y) = U_{ijl}^{\mathrm{STR}}(x,y)\nu_l(y)$ is the standard, weakly-singular, double-layer kernel. The singularity in $H(x,y)$ can be avoided in a simple way by exploiting the double-layer identity [11, 28, 30, 31]

$$\int_\Gamma H_{ij}(x,y)\, dA_y = -\alpha\delta_{ij} \quad \forall x \in \Gamma. \tag{8.2}$$

In particular, substitution of (8.2) into (8.1) gives

$$\begin{aligned}(8.3)\qquad &\theta \int_{\Gamma} G(x,y)\psi(y)\,dA_y \\ &\qquad + (1-\theta)\int_{\Gamma} H(x,y)[\psi(y)-\psi(x)]\,dA_y = v(x) \quad \forall x \in \Gamma.\end{aligned}$$

Assuming ν and ψ are Lipschitz continuous and Γ is a Lyapunov surface, it can be shown that the functions $G(x,y)\psi(y)$ and $H(x,y)[\psi(y)-\psi(x)]$ are uniformly bounded for all x and y on Γ. Thus (8.3) is singularity-free and can be discretized by Nyström methods.

Remarks 8.1.

1. Following standard practice [28, 30, 31], we define $H(x,y)[\psi(y)-\psi(x)]$ to be zero when $y = x$. This modification does not alter the value of the integral and is necessary to obtain a well-defined Nyström discretization, which requires a value for this function for arbitrary x and y. The results in [31] show that Nyström methods defined using this practice are, in general, convergent. However, there is generally an upper bound on the order of convergence of these methods because of the above modification.
2. There is some freedom in the treatment of the first term in (8.3). When written as an integral over Γ as above, the kernel function $G(x,y)$ contains the factor $J^{\phi}(y)$, which depends on the curvature of Γ (see section 7.1). By a change of variable, this term could also be written as an integral over the parallel surface γ. In this case, the curvature factor disappears, but an explicit parameterization of γ becomes necessary.

8.2. Approximation of integral equation. We suppose Γ can be decomposed into a union of nonoverlapping patches Γ_p, $p = 1,\dots,M_p$, where each patch is the image of a smooth map $y = \chi_p(s,t) : D_p \to \mathbb{R}^3$, and each D_p is a domain in $\mathbb{R}^2$. By subdividing each domain D_p into nonoverlapping subdomains D_p^e, $e = 1,\dots,M_e$, we decompose each patch Γ_p into curved, nonoverlapping patch elements Γ_p^e. In each patch element we introduce quadrature points $y_{p,e,q}$ and weights $W_{p,e,q}$, $q = 1,\dots,M_q$, such that

$$(8.4)\qquad \int_{\Gamma_p^e} f(y)\,dA_y = \int_{D_p^e} f(\chi_p(s,t))J_p(s,t)\,ds\,dt \approx \sum_{q=1}^{M_q} f(y_{p,e,q})W_{p,e,q}.$$

Here J_p is the Jacobian associated with the patch parameterization χ_p, which is assumed to be included in the weights $W_{p,e,q}$.

Let $\psi_{p,e,q}$ be an approximation to $\psi(y_{p,e,q})$, and for convenience let a and b denote values of the multi-index (p,e,q). Then a Nyström discretization of (8.3) is

$$(8.5)\qquad \theta\sum_{b} G_{ab}\psi_b W_b + (1-\theta)\sum_{b\neq a} H_{ab}[\psi_b-\psi_a]W_b = v_a \quad \forall a,$$

where $G_{ab} = G(x_a,y_b)$, $H_{ab} = H(x_a,y_b)$, and $v_a = v(x_a)$. Here the product $H_{ab}[\psi_b - \psi_a]$ has been set equal to zero when $b = a$. The above equation can be written in the standard form

$$(8.6)\qquad \sum_{b} A_{ab}\psi_b = v_a \quad \forall a,$$

where $A_{ab} \in \mathbb{R}^{3\times 3}$ are defined by

$$A_{ab} = \begin{cases} \theta G_{ab} W_b + (1-\theta) H_{ab} W_b, & a \neq b, \\ \theta G_{aa} W_a - (1-\theta) \sum_{c \neq a} H_{ac} W_c, & a = b. \end{cases} \tag{8.7}$$

Equation (8.6) is a linear system of algebraic equations for the approximate density values ψ_b at the quadrature points y_b. This system is dense and nonsymmetric and can be solved using any suitable numerical technique.

8.3. Approximation of flow quantities. Various flow quantities of interest take the form of an integral of ψ over Γ. For example, from (7.5), the resultant force and torque on Γ about an arbitrary point c are given by

$$F = -8\pi\theta \int_\gamma \psi(\varphi(\xi))\, dA_\xi, \quad T = -8\pi\theta \int_\gamma (\xi - c) \times \psi(\varphi(\xi))\, dA_\xi. \tag{8.8}$$

After a change of variable (see section 7.1), these integrals can be transformed from the parallel surface γ to the body surface Γ to obtain

$$F = -8\pi\theta \int_\Gamma J^\phi(y) \psi(y)\, dA_y, \quad T = -8\pi\theta \int_\Gamma J^\phi(y)(\zeta(y) - c) \times \psi(y)\, dA_y. \tag{8.9}$$

By discretizing these integrals using the same quadrature points and weights as before, we get the approximations

$$F^{\text{approx}} = -8\pi\theta \sum_b J_b^\phi \psi_b W_b, \quad T^{\text{approx}} = -8\pi\theta \sum_b J_b^\phi (\zeta_b - c) \times \psi_b W_b. \tag{8.10}$$

An approximation to the volume flow rate Q associated with Γ can be obtained in a similar manner.

9. Numerical experiments. Here we present results from numerical experiments on three different bodies: a sphere, torus, and helical tube with hemispherical endcaps. For one or more prescribed motions of each body, we computed the resultant force and torque about the origin of a body-fixed frame and examined various measures of convergence.

9.1. Methods. Following the general procedure outlined above, we decomposed the surface of each body into nonoverlapping patches Γ_p, each parameterized over a rectangular domain D_p. We subdivided each patch into curved, quadrilateral elements Γ_p^e, and in each element we used an $m \times m$ tensor product Gauss–Legendre quadrature rule, with order of accuracy $r_{\text{abs}} = 2m$ on absolute errors. For the sphere we employed six patches based on stereographic projection from the faces of a bounding cube. For the torus we employed a single patch based on an explicit parameterization of the axial curve. For the helical tube we employed multiple patches based on explicit parameterizations of the axial curve and endcaps.

The resultant force F and torque T on each body were computed by solving the linear algebraic system (8.6) of size $(3M_pM_eM_q) \times (3M_pM_eM_q)$. Because this system is nonsymmetric and was observed to be well conditioned, we used the GMRES iterative solver implemented in MATLAB with no preconditioning and a residual tolerance of 10^{-12}. Using the solution of (8.6), we computed approximations to F and T according to (8.10). The total number of quadrature points, $M_pM_eM_q$, was varied up to a maximum value of 4000 to 8000 depending on the example. All computations were performed with the parameter values $\theta = 1/2$ and $\phi/\phi_\Gamma = 1/2$, where ϕ_Γ is the maximum offset distance for the parallel surface associated with Γ.

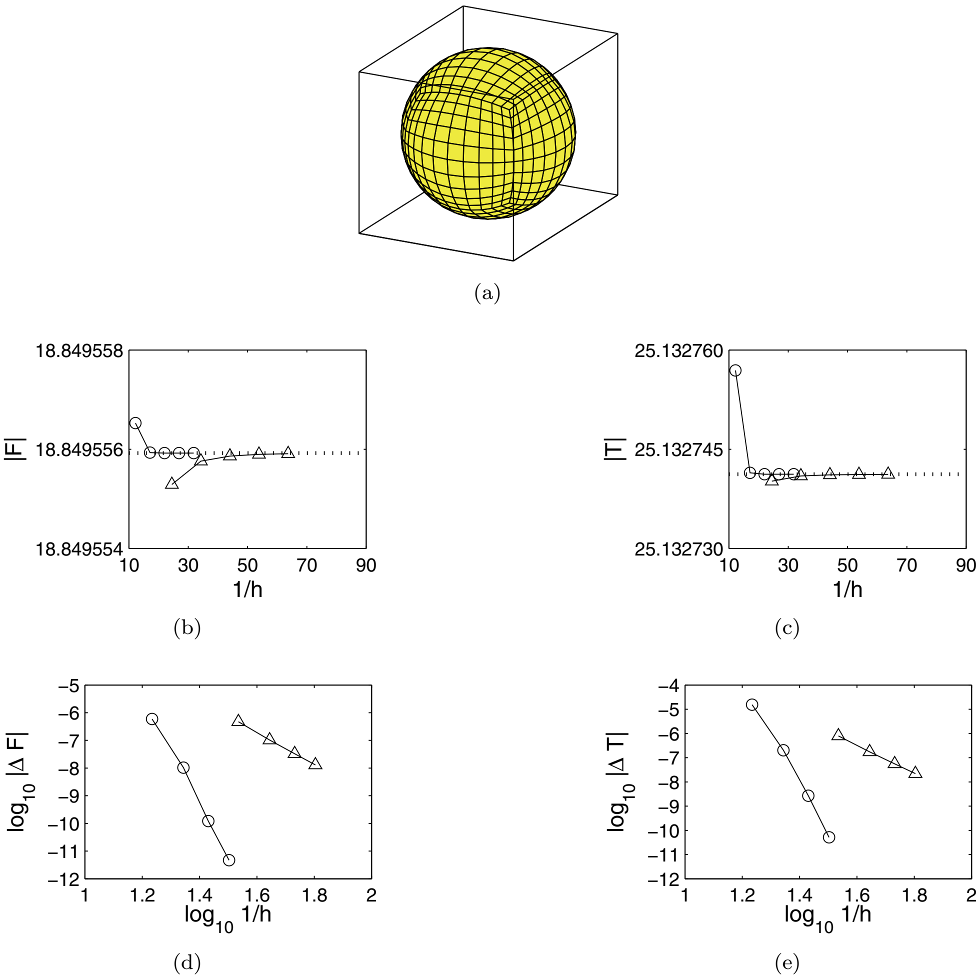


FIG. 9.1. *Convergence results for resultant force F and torque T on a sphere. Computations were performed with a sequence of meshes with element sizes h_k.* (a) *Sample mesh.* (b),(c) *Plots of $|F_{h_k}|$ and $|T_{h_k}|$ versus $1/h_k$ for the translational and rotational motion, respectively. The dotted horizontal lines indicate exact values.* (d),(e) *Plots of $\log_{10}|F_{h_k} - F_{h_{k-1}}|$ and $\log_{10}|T_{h_k} - T_{h_{k-1}}|$ versus $\log_{10}(1/h_k)$ for the translational and rotational motion, respectively. In all plots, triangles denote results for the 1×1 quadrature rule, and circles denote results for the 2×2 rule.*

9.2. Results. Figure 9.1 shows convergence results for the resultant force and torque about the origin on a sphere obtained with the 1×1 and 2×2 quadrature rules. The sphere had a radius $r = 1$ and was centered at the origin. For this surface, the maximum signed curvature is $\kappa_\Gamma = 1/r$, which gives a maximum offset distance of $\phi_\Gamma = r$. Results are given for two independent boundary conditions—translation along the x-axis with unit velocity, and rotation about the same axis with unit angular velocity. In these cases, exact values are known: $F = (-6\pi, 0, 0)$ and $T = (0, 0, 0)$ for the translational motion, and $F = (0, 0, 0)$ and $T = (-8\pi, 0, 0)$ for the rotational motion.

Plot (a) of Figure 9.1 illustrates the geometry and a sample mesh. In our computations, a sequence of five increasingly refined meshes were considered for each quadrature rule, with each mesh being relatively uniform. The meshes were chosen such that, at each stage in the sequence, the linear algebraic systems for the 1×1 and 2×2 quadrature rules were approximately the same size. The mesh shown in (a) is the coarsest used with the 1×1 rule. Plot (b) shows convergence results for the magnitude of F in the translational motion as a function of the element size parameter h, defined by $M_p M_e h^2 = 1$, where $M_p M_e$ is the total number of elements in a mesh. In particular, h is proportional to the average element size. Plot (c) shows similar convergence results for the magnitude of T in the rotational motion. In all computations, the appropriate entries in both F and T were found to be zero within machine precision for each type of motion. Thus the errors illustrated can be attributed to the appropriate nonzero components.

Plot (d) of Figure 9.1 shows the difference in the computed values of F between successive meshes as a function of h for the translational motion. Although an exact solution is available, we consider solution differences rather than absolute errors for purposes of later comparison. Plot (e) shows similar results for the difference in the computed values of T for the rotational motion. For an $m \times m$ Gauss–Legendre quadrature rule, the convergence rate r_{diff} for solution differences is expected to be $2m+1$, which is one order higher than the standard convergence rate r_{abs} for absolute errors. The plots show that the observed convergence rate for solution differences was significantly higher than expected. Considering both F and T, we have $5 \leq r_{\text{diff}} \leq 6$ for $m = 1$ and $19 \leq r_{\text{diff}} \leq 20$ for $m = 2$. On the finest two meshes used with the 2×2 rule, the relative change in F for the translational motion was of order 10^{-13}, and the relative change in T for the rotational motion was of order 10^{-12}.

Figure 9.2 shows convergence results for the resultant force and torque about the origin on a torus. The axial curve of the torus was a circle of radius $\rho = 1$ centered at the origin in the xy-plane, and the tube section was a circle of radius $r = \rho(1-\eta)/(1+\eta)$, where $\eta = \tanh^2(1)$. This value of the tube radius was chosen to compare results against an exact solution from [34]. For this surface, the maximum signed curvature is $\kappa_\Gamma = 1/r$, which gives a maximum offset distance of $\phi_\Gamma = r$. Results are given for two independent boundary conditions—translation along the z-axis with unit velocity, and rotation about the same axis with unit angular velocity. Symmetry implies that the force and torque have the form $F = (0, 0, F_z)$ and $T = (0, 0, 0)$ for the translational motion and $F = (0, 0, 0)$ and $T = (0, 0, T_z)$ for the rotational motion. For the translational motion, the force F_z has been characterized, and its approximate numerical value is $F_z = -20.7379$ [34]. For the rotational motion, the torque T_z has also been characterized [16], but its approximate numerical value does not appear to be well known.

Plots (a) through (e) of Figure 9.2 are analogous to the previous example. In our computations, we again found that the appropriate entries in both F and T were zero within machine precision for each type of motion. Moreover, the observed convergence rate for solution differences was again higher than expected. Considering both F and T, we have $9 \leq r_{\text{diff}} \leq 16$ for $m = 1$ and $6 \leq r_{\text{diff}} \leq 8$ for $m = 2$. Interestingly, for the range of meshes considered here, the 1×1 rule performed better than the 2×2 rule. On the finest two meshes used with the 1×1 rule, the relative change in F for the translational motion was of order 10^{-9}, and the relative change in T for the rotational motion was of order 10^{-6}.

Figure 9.3 shows convergence results for the resultant force and torque about the origin on a helical tube. The axial curve of the tube was a helical curve about the z-axis with radius $\rho = 2$, pitch $\lambda = 3$, and arclength $l = 2\pi$. The tube had uniform, circular cross-sections of radius $r = 0.2$ and hemispherical endcaps of the

same radius. These geometrical parameters were chosen so as to produce a tubular body of moderately high curvature. As with the torus, the maximum signed curvature is $\kappa_\Gamma = 1/r$, which gives a maximum offset distance of $\phi_\Gamma = r$. In contrast to the previous two examples, results are given for a single boundary condition—rotation about the x-axis with unit angular velocity. In this case, the resultant force and torque are not known exactly and are not known to have any special form.

Plots (a) through (e) of Figure 9.3 are analogous to the previous two examples, with the exception that only one type of motion is considered. For this single motion the force and torque were each found to possess three nonzero components, in contrast to the previous examples. The observed convergence rate for solution differences was again higher than expected. Considering both F and T, we have $3 \leq r_{\text{diff}} \leq 6$ for $m = 1$ and $8 \leq r_{\text{diff}} \leq 10$ for $m = 2$. For T we notice that the results from the 2×2 rule converge to a limiting value monotonically from below, whereas the results from the 1×1 rule converge nonmonotonically from above. On the finest two meshes used

with the 2×2 rule, the relative change in F was of order 10^{-6}, and the relative change in T was of order 10^{-7}.

9.3. Discussion. The examples outlined above suggest that the singularity-free boundary integral formulation introduced here leads to a viable numerical scheme for exterior Stokes flow problems. Issues associated with weakly singular integrals are avoided in a simple and efficient way without the need for product integration rules or specialized coordinate transformations and projections. In all three examples, the schemes exhibited convergence rates that were higher than expected and produced reasonably accurate results with reasonable meshes. For meshes of comparable size, the results for the torus and helical tube examples were less accurate than those for the sphere example. This is likely due to the relatively high curvature and more complicated shapes of the torus and helical tube. As can be expected, finer meshes are needed in these cases to achieve a level of accuracy similar to that for the sphere. The role of the parameters θ and ϕ in the conditioning and performance of these schemes for different classes of bodies will be investigated in a separate work.

MULTIPARASITOID-HOST INTERACTIONS WITH EGG-LIMITED ENCOUNTER RATES[*]

RYUSUKE KON[†] AND SEBASTIAN J. SCHREIBER[‡]

Abstract. To address the contentious issue of multiple parasitoid introductions in classical biological control, a discrete-time model of multiparasitoid-host interactions that accounts for host density dependence and egg limitation is introduced and analyzed. For parasitoids that are egg limited but not search limited, the model is proven to exhibit four types of dynamics: host failure in which the host becomes extinct in the presence or absence of the parasitoids; parasitoid-driven extinction in which the parasitoid complex invariably drives the host extinct; host persistence; and conditional host persistence in which, depending on the initial ratios of host to parasitoid densities, the host is either driven extinct or persists. In the case of host persistence, the dynamics of the system are shown to be asymptotic to the dynamics of an appropriately defined one-dimensional difference equation. The results illustrate how the establishment of one or more parasitoids can facilitate the invasion of another parasitoid and how a complex of parasitoids can drive a host extinct despite every species in the complex being unable to do so. The effects of including search limitation are also explored.

Key words. host-parasitoid dynamics, permanence, extinction, Lyapunov exponents

1. Introduction.

Classical biological control is the introduction of natural enemies of a pest species with the goal of suppressing the abundance of the pest to a level at which it no longer causes economic damage [23]. For insect pests, control is often achieved by parasitoids: organisms, typically wasps and flies, whose young develop on and eventually kill their hosts. One of the earliest successes of biological control was with the cottony cushion scale, a pest that was devastating the developing California citrus industry in the late 1800s [4]. A predatory insect, the vedalia beetle (which functions as a parasitoid), and a parasitoid fly were introduced from Australia to control the cottony cushion scale. Within several years, these natural enemies suppressed this pest to very low densities, where they remain to this day when not disrupted by the use of broad-spectrum insecticides [23]. Since this pioneering project, there have been more than 3,600 intentional introductions of parasitoids to control more than 500 insect pests around the world [8]. Of these introductions, only 30% have resulted in the natural enemy establishing successfully, and of these only 36% have lead to substantial control of the targeted pest [8]. Consequently, there have been extensive theoretical and empirical efforts to understand what factors contribute to the success or failure of biological control programs. One particular contentious issue in these studies concerns whether or not the release of a single species or several species of natural enemy will lead to a lower host density. On the one hand, scientists have argued that it is essential to screen all natural enemies and release only the most effective species [32, 34, 5]. Others have argued that testing for the best

parasitoid species takes too much time and money and, consequently, have advocated releasing all available natural enemies [33, 15]. Theoretical studies have shown that whether multiple species introductions are advisable depends on the details of the biology [21, 18, 2, 29]. For instance, May and Hassell [21] argued that, in general, multiple parasitoid introductions result in greater suppression of the host than single parasitoid introductions. This conclusion, however, relied on the assumption that the parasitoid species aggregate independently of one another and independently of host density. Indeed, Kakehashi, Suzuki, and Iwasa [18] showed that single parasitoid introductions are more effective when both parasitoid species aggregate to the same regions of space. These theoretical studies assume that the parasitoids are search limited and not egg limited. Moreover, their analysis is typically limited to numerical simulations and, occasionally, equilibrium stability analysis. In contrast to these earlier studies, we analyze the global dynamics for multiparasitoid-host interactions when the parasitoids are egg limited but not search limited.

All parasitoids experience egg limitation to some degree [6, 12, 17, 19]. For instance, synovigenic parasitoids, which continuously produce eggs over their lifetime, experience egg limitation whenever the number of hosts they encounter in a day exceeds their daily production of eggs. In a field study, Heimpel and Rosenheim [12] caught and dissected 270 synovigenic parasitoids of the species *Aphelinidae aonidiae.* They found 18% of the dissected individuals had an egg load of zero and, consequently, were extremely egg limited. Several theoretical studies have examined the combined effects of egg limitation and search limitation on host-parasitoid dynamics [6, 10, 26, 30, 27, 28]. If one takes a broad view that egg limitation is a form of predator saturation, then it can be said that Rogers [26] was the first to consider egg limitation by translating Holling's type II functional response to a host encounter rate. Analyzing Roger's model, May and Hassell [10] found that egg limitation tends to destabilize host-parasitoid interactions. It was not until two decades later that the interaction of this destabilizing factor with a stabilizing factor (heterogeneity in the distribution of parasitoid attacks) was considered. Studying models without host self-regulation, Getz and Mills [6] found that stability of the host-parasitoid equilibrium requires parasitic attacks to be sufficiently aggregated and the intrinsic fitness of the parasitoid to exceed the intrinsic fitness of the host. Including host regulation, Schreiber found that parasitoids with aggregated attacks and sufficiently weak search limitation can suppress their hosts to extremely low densities and even drive them to extinction [27, 28]. None of these studies, however, considered how egg limitation influences multiparasitoid-host interactions. Given that classical biological control programs often involve the release of multiple parasitoid species, and that most parasitoids experience some degree of egg-limitation, an important facet of host-parasitoid dynamics remains to be understood.

To address this gap in our knowledge about host-parasitoid dynamics, we introduce and analyze a model of multiparasitoid-host interactions that accounts for egg-limitation. This model is presented in section 2. Using a simple change of variables introduced in [27], we provide in sections 3 and 4 a rather detailed analysis of the global dynamics for purely egg-limited parasitoids. In section 5, we examine the combined effects of weak search limitation and egg limitation. In section 6, we discuss the implications of our results for classical biological control.

2. Model. The discrete-time model describes the dynamics of host-parasitoid interactions with synchronized generations. The host of density N is subject to parasitism by n parasitoids of densities $P_1, \dots, P_n$. The fraction $g_i(E_i)$ of hosts escaping parasitism for species i depends on the host encounter rate E_i of parasitoid species i, a function of host and parasitoid density that is described in further detail below. The fraction of hosts escaping intraspecific density-dependent mortality is $f(N)$. Intraspecific density-dependent mortality is assumed to precede mortality due to parasitism (see, e.g., [13, 22, 27]). One interpretation of this assumption is that the parasitoids are koinobionts. Hence, the host continues to develop after being parasitized and experiences density-dependent mortality (via the survival function $f(\cdot)$) independent of parasitism. Hosts escaping parasitism and density-dependent mortality produce on average λ progeny that survive to the next generation. Following the approach taken by May and Hassell [21], we assume that there is a competitive hierarchy amongst parasitoid larvae: within a parasitized host, larvae from species i always outcompete larvae from species j whenever $j > i$. This assumption is appropriate for two types of interactions that are frequently found in host-parasitoid systems [21]. First, it applies when parasitoid species 1 attacks first, species 2 attacks second, etc. In these cases, the older parasitoid larvae are usually able to eliminate the younger competitors by physical suppression [7]. This situation is common when the parasitoid species attack different developmental stages of the host, e.g., parasitoid 1 attacks the egg stage while parasitoid 2 attacks the larval or pupal stage. Second, the assumption can also apply when the parasitoids attack the same stage of the host but exhibit a competitive hierarchy. For instance, Chow and Mackauer [3] studied multiple parasitism of the pea aphid by the solitary hymenopterous parasites *Aphidius smithi* and *Praon pequodorum* in the laboratory. They found in larval competition, *P. pequodorum* was intrinsically superior to *A. smithi*, regardless of the latter's age. Finally, we assume that, on average, θ_i parasitoids emerge from a host parasitized by species i. Under these assumptions, the model is given by

$$(2.1)\qquad \begin{cases} N' &= \lambda f(N) N g_1(E_1) g_2(E_2)\cdots g_n(E_n),\\ P_1' &= \theta_1 f(N) N\{1-g_1(E_1)\},\\ P_2' &= \theta_2 f(N) N g_1(E_1)\{1-g_2(E_2)\},\\ &\vdots\\ P_n' &= \theta_n f(N) N g_1(E_1)\cdots g_{n-1}(E_{n-1})\{1-g_n(E_n)\}, \end{cases}$$

where N' and P_i' are the densities of the host and parasitoids, respectively, in the next generation. The state space for the host-parasitoid dynamics is $\mathbf{R}_+^{n+1} = \{(N,P) \in \mathbf{R}\times\mathbf{R}^n : N \ge 0, P_i \ge 0 \text{ for all } i\}$.

To complete the model, it is necessary to specify the density-dependent survivorship function $f(N)$, the encounter rate function E, and the escape functions g_i. Throughout this article, we assume the following:

A1. f is a continuous decreasing positive function such that $f(0) = 1$ and $\lim_{N\to\infty} f(N) = 0$.

Survivorship functions that satisfy assumption A1 include the generalized Beverton–Holt function $f(N) = \frac{1}{1+\alpha N^\beta}$ with $\alpha > 0$ and $\beta > 0$, the Ricker function $f(N) = \exp(-\alpha N)$ with $\alpha > 0$, and the Hassell function $f(N) = \frac{1}{(1+\alpha N)^\beta}$. To simultaneously account for search limitation and egg limitation, we follow the approach of Rogers [26] and define the average host encounter rate as

$$E_i = \frac{\alpha_i P_i}{1+\alpha_i b_i N},$$

where α is the searching efficiency of the parasitoid and b_i corresponds to the handling time or egg limitation of the parasitoid. For parsimony, we rewrite this average encounter rate as

$$E = \frac{P_i}{a_i + b_i N}, \tag{2.2}$$

where $a_i = \frac{1}{\alpha_i}$. One can view a_i as a measurement of search limitation. When there is no egg limitation (i.e., $b_i = 0$), the encounter rate reduces to the classical Nicholson–Bailey search limited encounter rate of $E_i = P_i/a_i$. Alternatively, when there is no search limitation (i.e., $a_i = 0$), the encounter rate reduces to the Thompson model $E_i = P_i/(b_i N)$ of egg-limited encounter rates [27, 31]. If eggs are randomly laid on hosts, then the fraction of hosts escaping parasitism is $\exp(-E_i)$. More generally, the Poisson escape term $\exp(-E_i)$ can be viewed as a limiting case of the negative binomial escape term $(1+E_i/k_i)^{-k_i}$ as $k_i \uparrow \infty$. This negative binomial escape function is commonly used to model nonrandom or aggregated parasitism events [6, 9, 13, 20]. In particular, $1/k_i$ can be interpreted as the coefficient of variation squared (CV^2) of the host encounter rate [11]. Consequently, larger values of k_i correspond to parasitic attacks being more evenly distributed across the hosts, while smaller values of k_i correspond to parasitoid attacks being aggregated on fewer hosts. To allow for this continuum of possibilities, we assume the following:

A2. $g_i(E_i) = \left(1 + \frac{E_i}{k_i}\right)^{-k_i}$ and $E_i = \frac{P_i}{a_i + b_i N_i}$ with $k_i > 0$ (possibly ∞), $a_i \geq 0$, and $b_i \geq 0$.

For ease of exposition, we write $k_i = \infty$ to refer to the Poisson escape function. The most important feature of escape function for the analysis is that $1/g_i$ is a concave function when $k_i < 1$ and $1/g_i$ is a convex function when $k_i > 1$.

Finally, to keep things meaningful, we assume the following:

A3. $\lambda, \theta_1, \ldots, \theta_n > 0$.

3. Egg-limited dynamics. Throughout this section, we assume that $a_i = 0$; i.e., there is no search limitation. For this case, we can make the change of variables

$$x = N, y_1 = E_1 = \frac{P_1}{b_1 N}, \ldots, y_n = E_n = \frac{P_n}{b_n N},$$

for which the dynamics of (2.1) partially decouple as follows:

$$\left\{ \begin{array}{rcl} x' &=& \lambda f(x) x g_1(y_1) g_2(y_2) \cdots g_n(y_n), \\ y_1' &=& \frac{\theta_1}{b_1 \lambda} \left(\frac{1}{g_1(y_1)} - 1 \right) \frac{1}{g_2(y_2)} \frac{1}{g_3(y_3)} \cdots \frac{1}{g_n(y_n)}, \\ y_2' &=& \frac{\theta_2}{b_2 \lambda} \left(\frac{1}{g_2(y_2)} - 1 \right) \frac{1}{g_3(y_3)} \cdots \frac{1}{g_n(y_n)}, \\ & \vdots & \\ y_{n-1}' &=& \frac{\theta_{n-1}}{b_{n-1} \lambda} \left(\frac{1}{g_{n-1}(y_{n-1})} - 1 \right) \frac{1}{g_n(y_n)}, \\ y_n' &=& \frac{\theta_n}{b_n \lambda} \left(\frac{1}{g_n(y_n)} - 1 \right). \end{array} \right. \tag{3.1}$$

To state our main result for this system, we need the following definition. Note that each $\frac{1}{g_i(y_i)} - 1$ is an increasing and strictly convex or concave function through the origin under assumption A2 and $k_i \neq 1$. Consequently, the nonnegative y_i^* defined below exist.

DEFINITION 3.1. *Assume* A2, A3, *and $k_i \neq 1$ for all i. Let $C = \{i : k_i > 1\}$. Define y_n^* to be the largest root of $y_n = \frac{\theta_n}{b_n \lambda}\left(\frac{1}{g_n(y_n)} - 1\right)$. Assuming y_j^* is defined for*

$j = i+1, \dots, n$, define y_i^* to be the largest root of

$$y_i = \frac{\theta_i}{b_i\lambda}\left(\frac{1}{g_i(y_i)} - 1\right)\frac{1}{g_{i+1}(\hat{y}_{i+1})}\cdots\frac{1}{g_n(\hat{y}_n)},$$

where

$$\hat{y}_j = \begin{cases} 0 & if\ j \in C, \\ y_j^* & if\ j \notin C. \end{cases}$$

Our main result is the following theorem. A key quantity in this theorem is $\lambda g_1(y_1)\dots g_n(y_n)$, which corresponds to the expected number of progeny produced per host.

THEOREM 3.2. *Assume* A1–A3, *$k_i \neq 1$ for all i, $a_i = 0$ for all i, $\theta_i \neq b_i\lambda\prod_{j=i+1}^n g_j(\hat{y}_j)$ for $1 \leq i \leq n-1$, and $\theta_n \neq b_n\lambda$. Let $C = \{i : k_i > 1\}$. Then we have the following:*

Host extinction. *If $y_i^* = 0$ for some $i \in C$, or $y_i^* > 0$ for all $i \in C$ (possibly $C = \emptyset$) and $\lambda g_1(\hat{y}_1)\dots g_n(\hat{y}_n) < 1$, then*

$$\lim_{t\to\infty}(N(t), P_1(t), \dots, P_n(t)) = (0, 0, \dots, 0)$$

whenever $N(0)\prod_{i=1}^n P_i(0) > 0$.

Host persistence. *If $C = \emptyset$ and $\lambda g_1(y_1^*)\dots g_n(y_n^*) > 1$, then there exists a positive constant $\delta > 0$ such that*

$$\liminf_{t\to\infty} N(t) \geq \delta \text{ and } \lim_{t\to\infty}\frac{P_i(t)}{b_i N(t)} = y_i^*$$

for all i whenever $N(0)\prod_{i=1}^n P_i(0) > 0$.

Conditional extinction. *If $y_i^* > 0$ for all $i \in C$, $C \neq \emptyset$, and $\lambda g_1(\hat{y}_1)\dots g_n(\hat{y}_n) > 1$, then there exist Borel sets $U, V \subset \mathbf{R}_+^{n+1}$ and $\delta > 0$ such that*

$$\liminf_{t\to\infty} N(t) \geq \delta, \qquad \lim_{t\to\infty}\prod_{i=1}^n P_i(t) = 0$$

whenever $(N(0), P_1(0), \dots, P_n(0)) \in U$, and

$$\lim_{t\to\infty}(N(t), P_1(t), \dots, P_n(t)) = (0, 0, \dots, 0)$$

whenever $(N(0), P_1(0), \dots, P_n(0)) \in V$. Moreover, U has positive (possibly infinite) Lebesgue measure, V has infinite Lebesgue measure, and $\mathbf{R}_+^{n+1} \setminus (U \cup V)$ has Lebesgue measure zero.

Theorem 3.2 (modulo equalities) characterizes the persistence and extinction dynamics of (2.1). In particular, host extinction can occur in two ways. If the host intrinsic fitness λ is less than one, then the host is unable to sustain itself and becomes extinct. Alternatively if $\lambda > 1$, then the host can persist in the absence of the parasitoids. However, if either $k_i > 1$ and $y_i^* = 0$ for a parasitoid or $\lambda\prod_{i=1}^n g_i(\hat{y}_i) < 1$, then the parasitoids drive the host extinct. Unconditional persistence of the host can occur only if the parasitoid attacks are sufficiently aggregated (i.e., $k_i < 1$ for all i) and the parasitoids do not overexploit their host (i.e., $\lambda\prod_{i=1}^n g_i(y_i^*) > 1$). How these different outcomes depend on the degree of egg limitation is illustrated in Figure 3.1

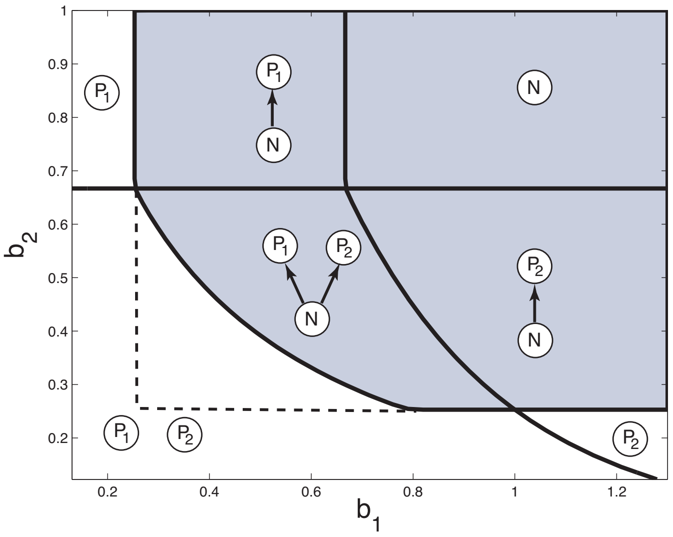

FIG. 3.1. *Ecological outcomes and how they vary with egg limitation. There are two parasitoids with conversion efficiencies $\theta_i = 1$ and aggregation parameters $k_i = 0.2$. The intrinsic fitness of the host is $\lambda = 1.5$. In the shaded region, the species that persist are shown. In the unshaded region, the host is driven to extinction by the indicated parasitoid(s). The dashed line delineates the region where both parasitoids but not a single parasitoid can drive the host to extinction.*

for parasitoids whose attacks are sufficiently aggregated. When egg limitation is sufficiently severe (i.e., b_i is sufficiently large) for a parasitoid species, the parasitoid is unable to establish itself. When egg limitation is sufficiently weak for a parasitoid species, it drives the host extinct. At intermediate levels of egg limitation, multiple parasitoids can drive the host to extinction when a single parasitoid species cannot (Figure 3.2 with parameter values from the dashed region in Figure 3.1).

When parasitoid attacks are sufficiently aggregated (i.e., $k_i < 1$ for all i), our results imply that the host dynamics have the limiting equation

$$N' = \lambda f(N) N \prod_{i=1}^{n} g_i(y_i^*),$$

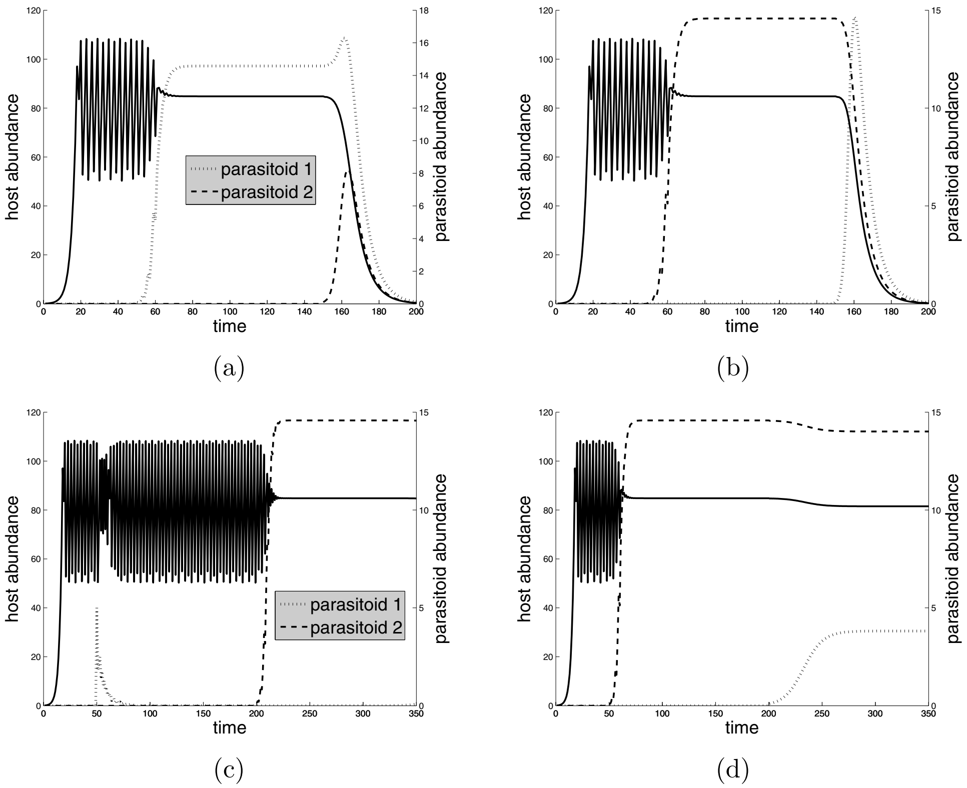
and the parasitoid dynamics track the host dynamics; i.e., asymptotically the ratio of the parasitoid to the host approaches $b_i y_i^*$ for parasitoid species i. Consequently, in this case a lot more can be said about the dynamics provided that the dynamics of the host are well understood. For instance, when the host dynamics can be described by the Beverton–Holt model, we get the following corollary of Theorem 3.2.

COROLLARY 3.3. *Suppose that $f(N) = \frac{1}{1+\alpha N}$, $k_i < 1$ for all i, and $\lambda^* := \lambda \prod_{i=1}^{n} g_i(y_i^*) > 1$. Then*

$$\lim_{t\to\infty} N(t) = \frac{\lambda^* - 1}{\alpha}, \qquad \lim_{t\to\infty} P_i(t) = \frac{b_i y_i^*(\lambda^* - 1)}{\alpha}$$

whenever $N(0)\prod_{i=1}^{n} P_i(0) > 0$.

Proof. Since $k_i < 1$ for all i and $\lambda^* > 1$, the second assertion of Theorem 3.2 applies. Let $Z(t) = (N(t), P_1(t), \dots, P_n(t))$ be a solution with $N(0)\prod_{i=1}^{n} P_i(0) > 0$.



(a) (b) (c) (d)

Fig. 3.2. *The effect of introducing one parasitoid at a time on the host-parasitoid dynamics. In* (a) *and* (c), *parasitoid* 1 *is introduced first, while parasitoid* 2 *is introduced later. In* (b) *and* (d), *the introduction order of parasitoids is reversed. In* (a) *and* (b), *the host is driven extinct only when both parasitoids are present. In* (c) *and* (d), *parasitoid* 1 *can establish itself only after parasitoid* 2 *has been established. In all figures,* $\lambda = 1.5$, $k_i = 0.2$, $f(N) = 1/(1 + (0.01N)^{10})$, *and* $\theta_i = 1.0$. *In* (a) *and* (b), $b_1 = b_2 = 0.4$. *In* (c) *and* (d), $b_1 = 0.75$ *and* $b_2 = 0.4$.

A result of Robinson [25] implies that the ω-limit set of $Z(t)$ is a chain recurrent set (see [25] for a definition). Theorem 3.2 implies that $\lim_{t\to\infty} \frac{P_i(t)}{N(t)} = b_i y_i^*$ for all i and $\liminf_{t\to\infty} N(t) > 0$. Since the only chain recurrent set in the invariant ray $\{(\eta, b_1 y_1^* \eta, \dots, b_n y_n^* \eta) : \eta > 0\}$ is the equilibrium $\frac{\lambda^* - 1}{\alpha}(1, y_1^* b_1, \dots, y_n^* b_n)$, the corollary follows. □

4. Proof of Theorem 3.2.

We begin with a lemma that shows that (2.1) is dissipative.

Lemma 4.1. *Assume* A1–A3. *There exists a constant* $M > 0$ *such that*

$$\limsup_{t\to\infty} N(t) \le M, \qquad \limsup_{t\to\infty} P_i(t) \le M$$

for all solutions $(N(t), P_1(t), \dots, P_n(t))$ *to* (2.1).

Proof. Assumption A1 implies that there exists $M_1 > 0$ such that $\lambda f(x) < 0.9$ for all $x \ge M_1$. Define $M_2 = \max\{M_1, \lambda M_1\}$ and

$$M = \max\{M_2, \theta_1 M_2, \dots, \theta_n M_2\}.$$

Let $(N(t), P_1(t), \dots, P_n(t))$ be a solution to (2.1). First, we will show that there exists a $T \geq 0$ such that $N(T) \leq M_2$. If $N(0) \leq M_2$, then we are done. Suppose $N(0), \dots, N(t) > M_2$. Since $g_1 \leq 1, \dots, g_n \leq 1$, f is decreasing, and $M_2 \geq M_1$, it follows that

$$N(t) = \lambda f(N(t-1))N(t-1)g_1(y_1(t-1)) \dots g_n(y_n(t-1)) \leq 0.9N(t-1).$$

Induction implies that $N(t) \leq 0.9^t N(0)$. Therefore, there exists $T \geq 0$ such that $N(T) \leq M_2$. Next, suppose that $N(T), \dots, N(T+t) \leq M_2$. Since $g_1 \leq 1, \dots, g_n \leq 1$, and f is decreasing, $N(T+t+1) \leq 0.9N(T+t) \leq 0.9M_2$ if $N(T+t) \geq M_1$, else $N(T+t+1) \leq \lambda M_1 \leq M_2$. Hence, induction implies that $N(t) \leq M_2 \leq M$ for all $t \geq T$. Finally, since $f \leq 1$ and $g_i \in [0,1]$ for $1 \leq i \leq n$,

$$P_i(t+1) \leq \theta_i N(t) \leq \theta_i M_2 \leq M$$

for all $t \geq T$. □

Define

$$G_i(y_i) = \frac{\theta_i}{b_i \lambda}\left(\frac{1}{g_i(y_i)} - 1\right).$$

LEMMA 4.2. *Assume* A2, A3, *and* $k_i \neq 1$. *Then*

$$z_i = c\, G_i(z_i) \tag{4.1}$$

has a nonnegative root for every $c \geq 0$. *For every* $c \geq 0$ *define* $z_i^*(c)$ *by the largest root of* (4.1). *Then the function* $z_i^* : \mathbf{R}_+ \to \mathbf{R}_+$ *is continuous.*

Proof. Since $0 = c\,G_i(0)$, $z_i = 0$ is always a root of (4.1). The function G_i is increasing and either strictly concave or strictly convex. Therefore, (4.1) has at most one positive root. This fact implies that z_i^* is a nonnegative function of c.

Consider the case where the function G_i is strictly concave, i.e., $k_i < 1$. In this case, (4.1) has a unique positive root if and only if $c > 1/G_i'(0)$. Therefore, $z_i^*(c) = 0$ if $c \in [0, 1/G_i'(0)]$ and $z_i^*(c) > 0$ if $c \in (1/G_i'(0), \infty)$. Since $z_i^*(c)$ is clearly continuous in $[0, 1/G_i'(0))$, it remains to show its continuity in $[1/G_i'(0), \infty)$. Define

$$F(c, z_i) = \begin{cases} 1 - cG_i'(0) & \text{if } z_i = 0, \\ 1 - cG_i(z_i)/z_i & \text{if } z_i > 0. \end{cases}$$

Then, by definition, $F(c, z_i^*(c)) = 0$ for all $c \in [1/G_i'(0), \infty)$. Furthermore, we can show that for each $c \in [1/G_i'(0), \infty)$,

$$\frac{\partial F}{\partial z_i} = \begin{cases} \frac{c\theta_i(1-k_i)}{2\lambda b_i k_i} \neq 0 & \text{if } z_i = 0, \\ \frac{c\theta_i}{\lambda b_i z_i^2}\left\{\left(1 + \frac{1-k_i}{k_i} z_i\right)\left(1 + \frac{z_i}{k_i}\right)^{k_i - 1} - 1\right\} \neq 0 & \text{if } z_i > 0. \end{cases}$$

Thus the application of the implicit function theorem to $F(c, z) = 0$ at $(c^*, z_i(c^*))$ with $c^* \in [1/G_i'(0), \infty)$ implies that there exists a continuous function $h(c)$ such that $F(c, h(c)) = 0$ holds in a neighborhood of $(c^*, z_i^*(c^*))$. Since a positive root of (4.1) is unique, h and z_i^* must be identical. The arbitrariness of c^* implies that $z_i^*(c)$ is continuous.

The case $k_i > 1$ can be proved similarly. In this case, (4.1) has a unique positive root if and only if $c\,G_i'(0) < 1$. ▯

LEMMA 4.3. *Assume* A2–A3 *and* $k_i \neq 1$. *Let* $z_i^*(c)$ *be the same as in Lemma* 4.2, *and let* $y_i(t)$ *be a solution to*

$$y_i(t+1) = G_i(y_i(t))c(t),$$

where $c(t)$ *is a positive sequence with* $\liminf_{t\to\infty} c(t) = \underline{c}$ *and* $\limsup_{t\to\infty} c(t) = \overline{c}$. *If* $k_i < 1$, *then*

$$z_i^*(\overline{c}) \geq \limsup_{t\to\infty} y_i(t) \geq \liminf_{t\to\infty} y_i(t) \geq z_i^*(\underline{c}).$$

If $k_i > 1$ *and* $\overline{c} = \underline{c}$, *then either*

$$\lim_{t\to\infty} y_i(t) = \infty, \lim_{t\to\infty} y_i(t) = z_i^*(\underline{c}) \textit{ or } \lim_{t\to\infty} y_i(t) = 0.$$

Proof. Suppose that $k_i < 1$. By assumption, for each $\epsilon > 0$ there exists a $T \geq 0$ such that

$$G_i(y_i(t))(\overline{c} + \epsilon) \geq y_i(t+1) \geq G_i(y_i(t))(\underline{c} - \epsilon)$$

for all $t \geq T$. Let $z(t)$ and $w(t)$ be the solutions of

$$z(t+1) = G_i(z(t))(\underline{c} - \epsilon) \text{ and } w(t+1) = G_i(w(t))(\overline{c} + \epsilon)$$

with $z(T) = w(T) = y_i(T)$. Then, by the monotonicity of G_i, $w(t) \geq y_i(t) \geq z(t)$ holds for all $t \geq T$. Since G_i is concave and $\lim_{x\to\infty} G_i(x)/x = 0$, it follows that $\lim_{t\to\infty} z(t) = z_i^*(\underline{c} - \epsilon)$ and $\lim_{t\to\infty} w(t) = z_i^*(\overline{c} + \epsilon)$. Therefore, we have

$$z_i^*(\overline{c} + \epsilon) \geq \limsup_{t\to\infty} y_i(t) \geq \liminf_{t\to\infty} y_i(t) \geq z_i^*(\underline{c} - \epsilon).$$

Since $\epsilon > 0$ is arbitrary and $z_i^*(c)$ is a continuous function, this inequality implies the first statement of the lemma.

Suppose that $k_i > 1$ and $\underline{c} = \overline{c}$. Suppose that $\limsup_{t\to\infty} y_i(t) < \infty$. Then the limit set of $y_i(t)$ is a compact internally chain recurrent set (see, e.g., [1]) for the dynamics of $y_i' = G_i(y_i)\underline{c}$. Since the only internally chain recurrent sets are the equilibria, 0, and $z_i^*(\underline{c})$ (possibly also 0), $\lim_{t\to\infty} y_i(t) = 0$ or $\lim_{t\to\infty} y_i(t) = z_i^*(\underline{c})$. Suppose that $\limsup_{t\to\infty} y_i(t) = \infty$. Since $\lim_{x\to\infty} G_i(x)/x = \infty$ (as $k_i > 1$) and G_i is convex, there exists $T > 0$, $M > 0$, and $\epsilon > 0$ such that

$$G_i(x)c(t) \geq (1+\epsilon)x$$

for all $t \geq T$ and $x \geq M$. Choose $T_2 > T$ such that $y_i(T_2) \geq M$. Then $y_i(T_2 + t) \geq (1+\epsilon)^t y_i(T_2)$ for all $t \geq 0$. Hence, $\lim_{t\to\infty} y_i(t) = \infty$. ▯

Let $(x(t), y_1(t), \ldots, y_n(t))$ be a positive solution to (3.1). An important implication of Lemma 4.3 is that $\liminf_{t\to\infty} y_i(t) \geq \hat{y}_i$. Indeed, Lemma 4.3 with $c(t) = 1$ applied to $y_n(t)$ implies $\liminf_{t\to\infty} y_n(t) \geq \hat{y}_n$. Suppose that $\liminf_{t\to\infty} y_i(t) \geq \hat{y}_i$ for $i = j+1, \ldots, n$. To prove the assertion for $i = j$, consider two cases. If $k_j > 1$, then $\hat{y}_j = 0$ and the assertion holds. If $k_j < 1$, then apply Lemma 4.3 with $c(t) = \prod_{i=j+1}^{n} 1/g_i(y_i(t))$.

To prove the first assertion of Theorem 3.2 about unconditional host extinction, we consider two cases. First, suppose that $y_i^* = 0$ for some $i \in C$. Then $G_i'(0)\hat{c} > 1$, where $\hat{c} = \frac{1}{g_{i+1}(\hat{y}_{i+1})} \cdots \frac{1}{g_n(\hat{y}_n)}$. Since $\liminf_{t\to\infty} y_j(t) \geq \hat{y}_j$ for all $i+1 \leq j \leq n$, continuity and monotonicity of g_j for $i \leq j \leq n$ imply that there exists a $T \geq 0$ and an $\eta > 1$ such that $y_i(t+1) \geq \eta y_i(t)$ for all $t \geq T$. Hence, $\lim_{t\to\infty} y_i(t) = \infty$. Since $P_i(t)$ is bounded by Lemma 4.1, it follows that $\lim_{t\to\infty} x(t) = 0$. For the second case, we assume that $y_i^* > 0$ for all $i \in C$ and $\lambda f(0) g_1(\hat{y}_1) \cdots g_n(\hat{y}_n) < 1$. Since $\liminf_{t\to\infty} y_i(t) \geq \hat{y}_i$ for all i and g_i are decreasing functions, there exist constants $\lambda_M < 1$ and $T \geq 0$ such that $\lambda f(0) g_1(y_1(t)) \cdots g_n(y_n(t)) \leq \lambda_M$ for all $t \geq T$. Therefore, $x(t+1) \leq \lambda_M x(t)$ holds for all $t \geq T$. Hence $\lim_{t\to\infty} x(t) = 0$.

To prove the second assertion of Theorem 3.2 about unconditional host persistence, assume that $C = \emptyset$ and $\lambda f(0) g_1(y_1^*) \cdots g_n(y_n^*) > 1$. Applying Lemma 4.3 inductively to $y_i(t)$ with $c(t) = \prod_{j=i+1}^n 1/g_j(y_j(t))$ implies that $\lim_{t\to\infty} y_i(t) = \hat{y}_i = y_i^*$ for all i. By the continuity of g_i, there exist $\lambda_M \geq \lambda_m > 1$ and $T_1 \geq 0$ such that

$$\lambda g_1(y_1(t)) \cdots g_n(y_n(t)) \in [\lambda_m, \lambda_M]$$

for all $t \geq T_1$. Since f is continuous, we can choose $\delta > 0$ such that $\lambda_m f(x) > 1$ for $x \in [0, \delta]$. Define $\alpha = \inf\{\lambda_m f(x) x : x > \delta\}$. Suppose $\alpha > 0$. Let $m = \min\{\delta, \alpha\}$. Since $\lambda_m f(x) x > x$ for all $x \in (0, m)$, there exists $T_2 \geq T_1$ such that $x(T_2) \in [m, \infty)$. By the definition of m, x does not escape from the interval (m, ∞). Finally, suppose $\alpha = 0$. Since $\lambda_M f(x) > 1$ for all $x \in [0, \delta]$ and $\lambda_M f(x) < 1$ for some $x > \delta$, the continuity of f ensures that the equation $\lambda_M f(x) = 1$ has a positive solution in the interval (δ, ∞). Since f is decreasing, there exists a unique positive solution, say $\bar{x} \in (\delta, \infty)$. Let $M = \max\{\lambda_M f(x) x : x \in [0, \bar{x}]\}$ and $\beta = \min\{\lambda_m f(x) x : x \in [\delta, M]\}$. Define $m = \min\{\delta, \beta\}$. By the definitions of m and M, if $x(t) \in [m, M]$ for some $t \geq T_1$, then $x(t)$ does not escape from the interval $[m, M]$. If $x(T_1) \in (M, \infty)$, then either $x(t) \in (M, \infty)$ for all $t \geq T_1$ or $x(T_2) \in (0, M]$ for some $T_2 \geq T_1$. Since the former case provides the desired conclusion, we consider the latter case. On the interval $(0, m)$, $\lambda_m f(x) x > x$ holds. Therefore, there exists a $T_3 \geq T_2$ such that $x(T_3) \in [m, M]$. This completes the proof of the second assertion of the theorem.

To prove the final assertion of Theorem 3.2, assume that $y_i^* > 0$ for all $i \in C$, $C \neq \emptyset$, and $\lambda g_1(\hat{y}_1) \ldots g_n(\hat{y}_n) > 1$. Assume $C = \{i_1, \ldots, i_k\}$ with $i_1 > i_2 > \cdots > i_k$. For each $1 \leq j \leq n$, define $U(j)$ as the set of initial conditions $(N(0), P_1(0), \ldots, P_n(0)) \in \mathbf{R}_+^{n+1}$ such that

$$N(0) \prod_{i=1}^n P_i(0) > 0 \text{ and } \lim_{t\to\infty} y_i(t) = \hat{y}_i \text{ for all } i \geq j,$$

and define $V(j)$ as the set of initial conditions such that

$$N(0) \prod_{i=1}^n P_i(0) > 0 \text{ and } \lim_{t\to\infty} y_i(t) = \infty \text{ for some } i \geq j.$$

For $j = i_1, i_2, \ldots, i_k$, we will prove inductively that $\mathbf{R}_+^{n+1} \backslash (U(j) \cup V(j))$ has Lebesgue measure zero.

As the first step of the induction, let $j = i_1$. If $j = n$, then convexity of G_n implies that $\lim_{t\to\infty} y_n(t) = \infty$ whenever $y_n(0) > y_n^*$, $y_n(t) = y_n^*$ for all t whenever $y_n(0) = y_n^*$, and $\lim_{t\to\infty} y_n(t) = 0$ whenever $y_n(0) < y_n^*$. Hence, $\mathbf{R}^{n+1} \backslash (U(j) \cup V(j))$ has Lebesgue measure zero. Assume that $j < n$. Since $k_i < 1$ for $i > j$, applying Lemma 4.3

inductively to $i = n, n-1, \dots, j+1$ with $c(t) = 1, 1/g_n(y_n(t)), \dots, \prod_{i=j+2}^{n} 1/g_i(y_i(t))$ implies that $\lim_{t\to\infty} y_i(t) = y_i^*$ for $i > j$ whenever $y_i(0) > 0$ for $i > j$. Applying Lemma 4.3 to $i = j$ with $c(t) = \prod_{i>j} 1/g_i(y_i(t))$ implies that either

$$\lim_{t\to\infty} y_j(t) = \hat{y}_j = 0, \ \lim_{t\to\infty} y_j(t) = y_j^*, \text{ or } \lim_{t\to\infty} y_j(t) = \infty.$$

The derivative of $y_j', \dots, y_n'$ in (3.1) with respect to $y_j, \dots, y_n$ is an upper triangular matrix whose diagonal elements are given by $d_i(y_i, \dots, y_n) = G_i'(y_i) \prod_{l=i+1}^{n} 1/g_l(y_l)$ for $i = j, \dots, n$. Since G_i are concave for $i = j+1, \dots, n$, G_j is convex, and $\theta_i \neq b_i \lambda \prod_{l=i+1}^{n} g_l(\hat{y}_l)$ for $1 \le i \le n$, it follows that $d_i(\hat{y}_i, \dots, \hat{y}_n) < 1$ for $i > j$ and $d_j(y_j^*, \hat{y}_{j+1}, \dots, \hat{y}_n) > 1$. Hence, $(y_j^*, \hat{y}_{j+1}, \dots, \hat{y}_n)$ is a hyperbolic equilibrium for the dynamics of (3.1) restricted to the $y_j, \dots, y_n$ subsystem. Moreover, the stable manifold of this equilibrium has codimension one in the $y_j, \dots, y_n$ hyperplane. Since the local stable manifold has Lebesque measure zero, and $y_j', \dots, y_n'$ in (3.1) is a diffeomorphism, the global stable manifold which is a countable union of preimages of the local stable manifold also has Lebesgue measure zero. Thus, $\mathbf{R}_+^{n+1} \setminus (U(j) \cup V(j))$ has Lebesgue measure zero.

For the next step of the induction, assume that $\mathbf{R}_+^{n+1} \setminus (U(j) \cup V(j))$ has Lebesgue measure zero for $j = i_1, \dots, i_l$. Let $j = i_{l+1}$. Suppose that $\lim_{t\to\infty} y_i(t) = \hat{y}_i$ for all $i \ge i_l$, i.e., $(N(0), P_1(0), \dots, P_n(0)) \in U(i_l)$. Since $k_i < 1$ for $i_{l+1} < i < i_l$, Lemma 4.3 applied inductively implies that $\lim_{t\to\infty} y_i(t) = \hat{y}_i$ for $i_{l+1} < i < i_l$, and consequently, $\lim_{t\to\infty} y_i(t) = \hat{y}_i$ for $i > i_{l+1}$. Since $k_j > 1$, Lemma 4.3 implies that either

$$\lim_{t\to\infty} y_j(t) = 0, \ \lim_{t\to\infty} y_j(t) = y_j^*, \text{ or } \lim_{t\to\infty} y_j(t) = \infty$$

Using an argument similar to the first step of the induction, the equilibrium $(y_j^*, \hat{y}_{j+1}, \dots, \hat{y}_n)$ is a hyperbolic equilibrium for the dynamics of (3.1) restricted to the $y_j, \dots, y_n$ hyperplane. Moreover, the stable manifold of this equilibrium has codimension greater than or equal to one. Hence, $U(i_l) \setminus (U(j) \cup V(j))$ has Lebesgue measure zero. Since $V(i_l) \subset V(j)$, $\mathbf{R}_+^{n+1} \setminus (U(j) \cup V(j))$ has Lebesgue measure zero.

Next, we need to show that $\mathbf{R}_+^{n+1} \setminus U(1) \cup V(1)$ has Lebesgue measure zero. If $i_k = 1$, then we are done by the prior induction. Assume that $i_k > 1$ and let $j = i_k$. Suppose that $\lim_{t\to\infty} y_i(t) = \hat{y}_i$ for $i \ge i_k$, i.e., $(N(0), P_1(0), \dots, P_n(0)) \in U(i_k)$. Applying Lemma 4.3 inductively implies that $\lim_{t\to\infty} y_i(t) = \hat{y}_i$ for all $i \ge 1$. Hence, $U(1) = U(i_k)$ and $V(1) = V(i_k)$. Thus, $\mathbf{R}_+^{n+1} \setminus (U(1) \cup V(1))$ has Lebesgue measure zero. Define $U = U(1)$ and $V = V(1)$. If $(N(0), P_1(0), \dots, P_n(0)) \in U$, then we can argue as in the proof of the second assertion of the theorem that $\liminf_{t\to\infty} N(t) \ge \delta$ for an appropriate choice of $\delta > 0$.

To complete the proof of the final assertion of Theorem 3.2, we need to show that $U(1)$ has positive (possibly infinite) Lebesque measure and that $V(1)$ has infinite Lebesgue measure. The equilibrium $(\hat{y}_1, \dots, \hat{y}_n)$ for $y_1', \dots, y_n'$ in (3.1) is linearly stable and its basin of attraction is an open subset of $\mathbf{R}_+^n$. Consequently, $U(1)$ is an open subset of $\mathbf{R}_+^{n+1}$ and has positive Lebesgue measure. To show that $V(1)$ has infinite Lebesgue measure, notice that if $y(0)$ is such that $|y_i(0) - y_i^*|$ is sufficiently small for $i > i_1$ (vacuously true if $i_1 = n$) and $y_{i_1}(0)$ is sufficiently large, then $\lim_{t\to\infty} y_{i_1}(t) = \infty$. Hence, $V(i_1)$ has infinite Lebesgue measure. Since $V(i_1) \subset V(1)$, the proof of the theorem is complete. □

5. Weakly search-limited parasitoids.

In this section, we examine the effect of including search limitation on the host-parasitoid dynamics.

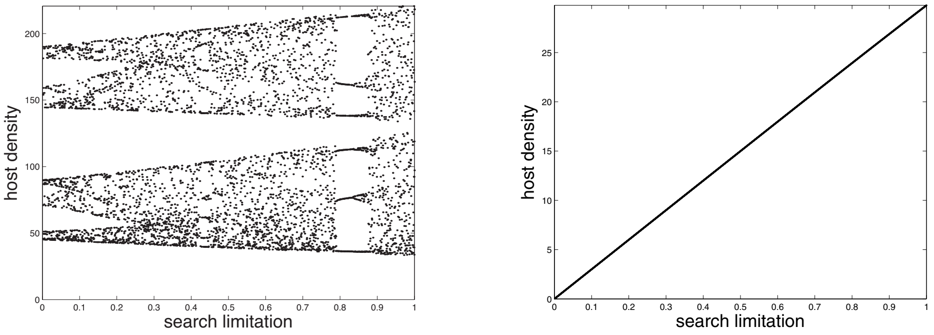
Proposition 5.1. *Assume* A1–A3. *If $\lambda > 1$ and $a_i > 0$, then there exists $\delta > 0$ such that*

$$\liminf_{t\to\infty} N(t) \geq \delta$$

for all solutions to (2.1) *with $N(0) > 0$.*

Proof. By dissipativity and continuity, system (2.1) has a compact forward invariant set that attracts all nonnegative solutions. Therefore, we can apply the theory of average Lyapunov functions (e.g., see Theorem 2.2 and Corollary 2.3 in [16]) and show that the face $N = 0$ is a repellor. More specifically, the application of the average Lyapunov function $L(N, P_1, \dots, P_n) = N$ shows that the face $N = 0$ is a repellor since every solution on the face $N = 0$ converges to the origin and $N'/N|_{(N,P_1,\dots,P_n)=(0,0,\dots,0)} = \lambda f(0)g_1(0)g_2(0)\cdots g_n(0) = \lambda > 1$. □

Although search-limited parasitoids cannot drive the host extinct, numerical simulations suggest that when purely egg-limited parasitoids can drive their host extinct, the inclusion of search limitation results in the host being suppressed to low equilibrium densities provided that parasitoid attacks are sufficiently aggregated (Figure 5.1b).



(a) only one parasitoid

(b) both parasitoids

Fig. 5.1. *The effect of single versus multiple parasitoid introductions when parasitoids exhibit search limitation. In* (a), *only one parasitoid is in the system. In* (b), *two parasitoids are in the system. In both figures, $\lambda = 10$, $k_i = 0.5$, $f(N) = 1/(1 + (0.01N)^4)$, $\theta_i = 2.0$, and $b_i = 0.1$. The parasitoids' searching limitations $a_1 = a_2$ vary as shown.*

Proposition 5.2. *Assume* A1–A3. *Let $(N(t), P_1(t), \dots, P_n(t))$ be a solution to* (2.1). *If $\lambda > 1$ and $\theta_m > b_m\lambda$, and $a_m > 0$ is sufficiently small, then there exists $\delta > 0$ such that*

$$\liminf_{t\to\infty} P_m(t) \geq \delta$$

whenever $N(0) > 0$ and $P_m(0) > 0$. Alternatively, if $\theta_i < b_i\lambda$ for $m \leq i \leq n$, then there exists a neighborhood U of the $P_m = P_{m+1} = \cdots = P_n = 0$ plane such that

$$\lim_{t\to\infty} (P_m(t) + \cdots + P_n(t)) = 0$$

whenever $(N(0), P_1(0), \dots, P_n(0))$ lies in U. Moreover, if $k_i < 1$ for $m \leq i \leq n$, then $U = \mathbf{R}_+^{n+1}$.

The first statement of Proposition 5.2 shows that if the reproductive ability of the parasitoid is higher than that of the host ($\theta_m/b_m > \lambda$) and there is weak search limitation (small $a_m > 0$), then the parasitoid coexists with its host. This type of coexistence is not always guaranteed if $a_m = 0$. However, if $a_m > 0$ is not small, numerical simulations suggest that the parasitoid may become extinct (see Figure 4 in [28]). The second statement of Proposition 5.2 considers the alternative situation ($\theta_m/b_m < \lambda$). In this case, the parasitoid whose population density is initially low becomes extinct irrespective of the intensity of search limitation. This attractivity result holds globally if the distribution of the parasitoid attack is aggregated ($k_m < 1$). However, this is not true if $k_m > 1$, since the system can have a positive fixed point or attractor. For instance, Figure 5.2 shows an example where a second positive fixed point bifurcates from the origin at $a_1 = 0$. As a_1 increases, this fixed point is stabilized and finally disappears due to a saddle node bifurcation. In this example, we also find a stable invariant loop in advance of the stabilization of the second fixed point (see Figure 5.2). Therefore, intermediate degrees of search limitation can produce a bistable system in which the initially rare parasitoid becomes extinct but the initially abundant parasitoid survives (see Figure 5.3).

Proof. Assume that $\lambda > 1$ and $\theta_m > b_m\lambda$. Proposition 5.1 implies that there is a compact attractor Γ such that the Γ does not intersect the $N = 0$ plane and such that the ω-limit set of $Z(t) = (N(t), P_1(t), \dots, P_n(t))$ lies in Γ whenever $N(0) > 0$. We will show that Γ intersected with the plane $P_m = 0$ is a repellor whenever $a_m > 0$ is sufficiently small. Let $Z(t) = (N(t), P_1(t), \dots, P_n(t))$ be a solution to (2.1) with $N(0) > 0$ and $P_m(0) = 0$. Since the ω-limit set of $Z(t)$ lies in Γ, we get that

$$\begin{aligned} 0 &= \lim_{t\to\infty} \frac{1}{t} \ln\left(\frac{N(t)}{N(0)}\right) \\ &= \lim_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln\left(f(N(s))g_1(E_1(s)) \dots g_n(E_n(s))\lambda\right), \end{aligned}$$

where $E_i(s) = \frac{P_i(s)}{a_i + b_i N(s)}$. It follows that

$$\lim_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln\left(f(N(s))g_1(E_1(s)) \dots g_n(E_n(s))\right) = -\ln\lambda. \tag{5.1}$$

Let

$$G_i(N, P_1, \dots, P_n) = \frac{\partial P_i'}{\partial P_i}.$$

The Lyapunov exponent [24] corresponding to the P_m direction is given by

$$\begin{aligned} &\liminf_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln G_m(Z(s)) \\ &\quad = \liminf_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln\left(\theta_m N(s) f(N(s)) g_1(E_1(s)) \dots g_{m-1}(E_i(s)) \frac{1}{a_m + b_m N(s)}\right) \\ &\quad = \liminf_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln\left(\theta_m N(s) \frac{1}{g_m(E_m(s))} \cdots \frac{1}{g_n(E_n(s))} \frac{1}{a_m + b_m N(s)} \frac{1}{\lambda}\right) \\ &\quad \geq \liminf_{t\to\infty} \frac{1}{t} \sum_{s=0}^{t-1} \ln\left(\theta_m N(s) \frac{1}{\lambda(a_m + b_m N(s))}\right), \end{aligned} \tag{5.2}$$

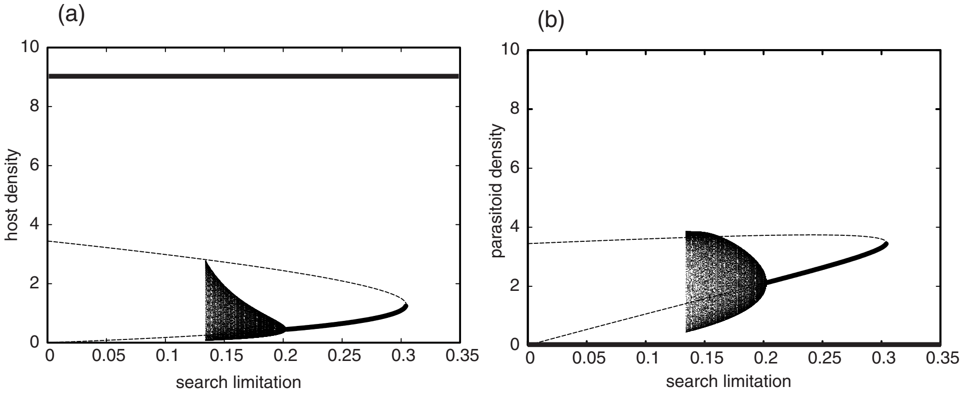


FIG. 5.2. *Bifurcation diagram of* (2.1) *with a single parasitoid species P_1, i.e., $n = 1$. The solid and dashed curves indicate stable and unstable fixed points, respectively. In both figures, $f(N) = 1/(1 + N)$, $\lambda = 10$, $b_1 = 1$, $k_1 = 2$, and $\theta_1 = 8$. If there is no search limitation ($a_1 = 0$), the parameters correspond to the conditional extinction case of Theorem* 3.2.

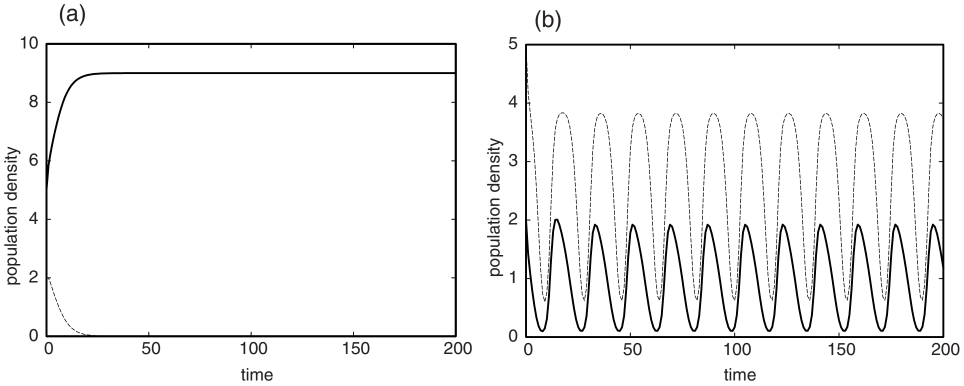

FIG. 5.3. *Bistable example of* (2.1) *with a single parasitoid species P_1, i.e., $n = 1$ The solid and dashed curves indicate the population density of host and parasitoid, respectively. In both figures, the survival function and parameters are $f(N) = 1/(1+N)$, $\lambda = 10$, $a_1 = 0.15$, $b_1 = 1$, $k_1 = 2$, and $\theta_1 = 8$. The initial conditions are* (a) $(N(0), P_1(0)) = (5, 2)$, *and* (b) $(N(0), P_1(0)) = (2, 5)$.

where the second line follows from (5.1) and the third line follows from $1/g_j \geq 1$ for all $1 \leq j \leq n$. If $\theta_m > b_m\lambda$ and $a_m > 0$ is sufficiently small, then (5.2) implies that there exists $\epsilon > 0$ such that

$$(5.3) \qquad \liminf_{t\to\infty} \frac{1}{t}\sum_{s=0}^{t-1} \ln G_m(Z(s)) \geq \epsilon$$

for all initial conditions with $N(0) > 0$ and $P_m(0) = 0$. Equation (5.3) and the average Lyapunov theory (e.g., see Theorem 2.2 in [16]) with the average Lyapunov function $L(N, P_1, \dots, P_n) = P_m$ implies that Γ intersected with the $P_m = 0$ plane is a repellor. This completes the proof of the first statement.

Assume $\theta_i < b_i\lambda$ for $m \leq i \leq n$ and $a_i \geq 0$ for all i. If $\lambda < 1$, then $\lim_{t\to\infty} P_i(t) = 0$ for all i as $P_i(t+1) \leq \theta_i N(t)$ and we are done. Assume $\lambda > 1$. Proposition 5.1 implies that there is a compact attractor Γ such that Γ does not intersect the $N = 0$ plane and such that the ω-limit set of $Z(t) = (N(t), P_1(t), \dots, P_n(t))$ lies in Γ whenever $N(0) > 0$. Let Γ_1 be given by Γ intersected with the $P_m = P_{m+1} = \cdots = P_n = 0$ plane. We will show that Γ_1 is an attractor by proving that all the normal Lyapunov exponents (i.e., the Lyapunov exponents corresponding to Lyapunov directions that are not tangential to the $P_m = P_{m+1} = \cdots = P_n = 0$ plane) are negative (see, e.g., [35, Thm. 4] or [14]). To this end, consider a solution $Z(t) = (N(t), P_1(t), \dots, P_n(t))$ to (2.1) such that $Z(0) \in \Gamma_1$. Using (5.1) and assuming $m \le i \le n$, we get

$$\begin{aligned}
&\limsup_{t\to\infty} \frac{1}{t}\sum_{s=0}^{t-1} \ln G_i(Z(s))\\
&\quad= \limsup_{t\to\infty} \frac{1}{t}\sum_{s=0}^{t-1} \ln\left(\theta_i N(s)\frac{1}{\lambda}\frac{1}{g_i(E_i(s))}\cdots\frac{1}{g_n(E_n(s))}\frac{1}{a_i + b_i N(s)}\right)\\
&\quad= \limsup_{t\to\infty} \frac{1}{t}\sum_{s=0}^{t-1} \ln\left(\frac{\theta_i}{\lambda}\frac{N(s)}{a_i + b_i N(s)}\right)\\
&\quad\le \ln\left(\frac{\theta_i}{\lambda b_i}\right) < 0,
\end{aligned}$$

where the second line follows from $E_j(s) = 0$ for $m \le j \le n$ and the third line follows from $\frac{N}{a_i+b_iN} \le \frac{1}{b_i}$ whenever $N > 0$. Hence, all the normal Lyapunov exponents are negative and Γ_1 is an attractor. Next, assume that $k_i < 1$ for $m \le i \le n$. Let $Z(t)$ be a solution to (2.1) such that $N(0) > 0$. We will prove that

$$\lim_{t\to\infty} P_i(t) = 0 \text{ for } m \le i \le n$$

by induction on i. Consider $i = n$. If $P_n(0) = 0$, then we are done. Assume $P_n(0) > 0$. Then

$$\begin{aligned}
&\limsup_{t\to\infty} \frac{1}{t} \ln\left(\frac{P_n(t)}{P_n(0)}\right)\\
&\quad= \limsup_{t\to\infty} \frac{1}{t}\sum_{s=0}^{t-1} \ln\left(\theta_n N(s) f(N(s)) g_1(E_1(s)) \dots g_{n-1}(E_{n-1}(s)) \frac{(1 - g_n(E_n(s))}{P_n(s)}\right)\\
&\quad= \limsup_{t\to\infty} \frac{1}{t}\sum_{s=1}^{t} \ln\left(\theta_n N(s)\frac{1}{\lambda}\left(\frac{1}{g_n(E_n(s))} - 1\right)\frac{1}{P_n(s)}\right)\\
&\quad\le \limsup_{t\to\infty} \frac{1}{t}\sum_{s=1}^{t} \ln\left(\frac{\theta_n}{\lambda}\frac{N(s)}{a_n + b_n N(s)}\right)\\
&\quad\le \ln\left(\frac{\theta_n}{\lambda\, b_n}\right) < 0,
\end{aligned}$$

where the second line follows from (5.1), the third line follows from $1/g_n(x) - 1$ being concave (i.e., $k_n < 1$), and the fourth line follows from the fact that $\frac{N}{a_n+b_nN} \le \frac{1}{b_n}$ whenever $N > 0$. Hence, we have shown that $\lim_{t\to\infty} P_n(t) = 0$. Next, we proceed to the inductive step. Assume that $\lim_{t\to\infty} P_i(t) = 0$ for $j + 1 \le i \le n$, where $j \ge m$. If

$P_j(0)=0$, then we are done. Assume $P_j(0)>0$. Then

$$\begin{aligned}
&\limsup_{t\to\infty}\frac{1}{t}\ln\left(\frac{P_j(t)}{P_j(0)}\right)\\
&\quad=\limsup_{t\to\infty}\frac{1}{t}\sum_{s=0}^{t-1}\ln\left(\theta_j N(s)f(N(s))g_1(E_1(s))\dots g_{j-1}(E_{j-1}(s))\frac{(1-g_j(E_j(s))}{P_j(s)}\right)\\
&\quad=\limsup_{t\to\infty}\frac{1}{t}\sum_{s=0}^{t-1}\ln\left(\theta_j N(s)\frac{1}{\lambda}\frac{1}{g_{j+1}(E_{j+1}(s))}\cdots\frac{1}{g_n(E_n(s))}\left(\frac{1}{g_j(E_j(s))}-1\right)\frac{1}{P_j(s)}\right)\\
&\quad=\limsup_{t\to\infty}\frac{1}{t}\sum_{s=0}^{t-1}\ln\left(\theta_j N(s)\frac{1}{\lambda}\left(\frac{1}{g_j(E_j(s))}-1\right)\frac{1}{P_j(s)}\right)\\
&\quad\le\limsup_{t\to\infty}\frac{1}{t}\sum_{s=0}^{t-1}\ln\left(\frac{\theta_j}{\lambda}\frac{N(s)}{a_j+b_jN(s)}\right)\\
&\quad\le\ln\left(\frac{\theta_j}{\lambda b_j}\right)<0,
\end{aligned}$$

where the second line follows (5.1), the third line follows from induction (i.e., $g_i(0)=1$ for $j<i\le n$), the fourth line follows from $1/g_j(x)-1$ being concave (i.e., $k_j<1$), and the final line follows from the fact that $\frac{N}{a_j+b_jN}\le\frac{1}{b_j}$ whenever $N>0$. Hence, we have shown that $\lim_{t\to\infty}P_j(t)=0$, and the proof is complete. ☐

6. Discussion. We have studied the multiparasitoid-host dynamics described by (2.1). Under the assumption that each parasitoid is purely egg limited (i.e., not search limited), the dynamics of (2.1) have been classified sharply with respect to the extinction and persistence dynamics (see Theorem 3.2). Our main result implies that for the systems considered here, multiple parasitoids regulate a host population more efficiently than a single parasitoid. This conclusion can be derived for the following three scenarios in which the parasitoids can regulate the host:

(i) There are parasitoids with aggregated attacks ($k_i<1$ for all i) such that $\lambda g_1(y_1^*)\cdots g_n(y_n^*)<1$. This assembly of parasitoids drives the host extinct. The definition of y_i^* and concavity of $1/g_i$ (as $k_i<1$) imply that y_i^* is greater when you include more parasitoid species. Since $g_i(y_i^*)<1$ and g_i is a decreasing function for all i, the inequality $\lambda g_1(y_1^*)\cdots g_n(y_n^*)<1$ is more likely to hold if there are multiple aggregately distributed parasitoids irrespective of their superiority within a parasitized host (see Figures 3.1 and 3.2(a),(b)).

(ii) There are parasitoids with aggregated attacks ($k_i<1$ for all i) such that $\lambda g_1(\hat{y}_1)\cdots g_n(\hat{y}_n)>1$. This assembly of parasitoids does not drive the host extinct. Rather, they coexist with the host. As mentioned in section 3 (see also Corollary 3.3), after the establishment of these parasitoids, the dynamics of the host are asymptotic to

$$N'=\lambda f(N)N\prod_{i=1}^{n}g_i(y_i^*).$$

This equation suggests that introductions of multiple parasitoids lead to more efficient regulation of the host population. In fact, the last factor of the equation depresses the host density at a coexistence equilibrium.

(iii) There exists a highly reproductive parasitoid ($y_i^* = 0$) whose attacks are weakly aggregated ($k_i > 1$). By the definition of y_i^*, $y_i^* = 0$ if

$$\theta_i > b_i \lambda g_{i+1}(\hat{y}_{i+1}) \cdots g_n(\hat{y}_n).$$

This inequality is more likely to hold if there are multiple aggregately distributed parasitoids that are superior competitors within the parasitized host (i.e., P_j with $k_j < 1$, $j > i$).

The conclusion that multiple parasitoid introductions are more effective than single parasitoid introductions could depend on model assumptions. The main assumptions in our model are that the parasitoids are egg limited; the host suffers density-dependent mortality between the events of parasitism and death due to the parasitism; and the distributions of attacks of parasitoids are independent of each other. Kakehashi, Suzuki, and Iwasa [18] found that introductions disrupted host regulation when the distributions of parasitoid attacks completely overlap. Therefore, we expect that incorporation of overlapping parasitoid distributions into our model may lead to a similar conclusion. Interestingly, our conclusion seems insensitive to other assumptions. For example, our conclusion agrees with that of May and Hassell [21], who assume purely search-limited parasitism and no host density dependence.

SENSITIVITY AND ROBUSTNESS IN CHEMICAL REACTION NETWORKS[*]

GUY SHINAR[†], URI ALON[†], AND MARTIN FEINBERG[‡]

Abstract. For a wide class of chemical reaction networks, including all those governed by detailed balanced mass-action kinetics, we examine the robustness of equilibrium species concentrations against fluctuations in the overall reactant supply. In particular, we present lower bounds on the individual species-concentration sensitivities that derive from reaction network structure alone, independent of kinetic parameters or even of the particular equilibrium state at which sensitivities are calculated. These bounds suggest that, in the class of reaction networks considered here, very high robustness (i.e., very low sensitivities) should be expected only when the various molecules are constructed from a large number of distinct elemental building blocks that appear in high multiplicity or that combine gregariously. This situation is often encountered in biology.

Key words. equilibrium points, chemical reaction networks, sensitivity, robustness, systems biology

1. Introduction.

1.1. Motivation.

Our interest is in understanding the relationship between the general features of a chemical reaction network and the sensitivity of its equilibria to changes in the overall supply of reactants.

Although our concerns are with reaction networks in general, we are motivated by questions that arise naturally in biology. The cell is highly dynamic. Nevertheless, it is reasonable to suppose that in the cytoplasm certain biochemical modules (reaction networks) act on a timescale that is fast relative to other cellular processes (e.g., relative to the production of large proteins or relative to the transport of small molecules across membranes). Thus, the concentrations of species participating in such a “fast” reaction network might be regarded as instantaneously at or near equilibrium.

At the same time, the “fast” biochemical module under consideration might be perturbed within the cell by slower changes in the overall reactant supply, as fresh proteins are produced or as smaller molecules enter the cell from its exterior. In response, the “fast” equilibrium composition would shift accordingly. For some purposes it might be advantageous for certain species concentrations within the module to be insensitive (robust) against such disturbances, while for other species great sensitivity might be highly desirable. Thus, as has been suggested by Veitia [25], it becomes important to understand how reaction network structure affects the responsiveness of its equilibrated species concentrations to changes in the ambient cellular environment.

The present inquiry is not dissimilar in nature to other lines of research. One is biochemical systems theory pioneered by Savageau [23]. Another is metabolic control analysis developed from work of Higgins [15] by Kacser and Burns [19] and Heinrich and Rapoport [13, 14]. Here we provide general results along similar lines, but results that depend only on network structure. These results apply, within a large and relevant class of chemical reaction systems, to networks of arbitrarily large size and complexity.

For our purposes, it will suffice to presume that the reaction networks we study are governed by mass-action kinetics conforming to what chemists call *detailed balance* [26, 20, 10]. In fact, even these presumptions are overly strong, for we shall require only that the system considered have what Horn and Jackson called the *quasi-thermostatic* property [16]. (Detailed balancing in mass-action systems is sufficient but not necessary to ensure quasi-thermostatic behavior.)

The remainder of this introduction is organized as follows: In section 1.2 we define, in the context of an informal example, what we mean by *species sensitivities.* In section 1.3, we indicate the type of theory we seek by stating one principal result: lower bounds for species sensitivities *that derive from network structure alone.* In very rough terms, these bounds suggest that *strong robustness (i.e., very low sensitivities) of equilibrium concentrations against variations in reactant supply can be expected only when the species are built from highly gregarious or multiplicitous building blocks—that is, from certain* elements *that associate indiscriminately with each other or that appear in high multiplicity within the compound species.* In section 1.4 we discuss the organization of the remainder of the article.

1.2. Sensitivities. To illustrate more concretely the problems that are of interest, it will be useful to consider, informally, the relatively simple reaction network

$$2A \rightleftharpoons A_2, \qquad A_2 + B \rightleftharpoons A_2B, \qquad A_2B + C \rightleftharpoons A_2BC. \tag{1.1}$$

Note. Network (1.1) is inspired by a regulated recruitment [22] model for a gene transcription control mechanism: Species A corresponds to a protein monomer that can dimerize to form A_2, an active transcription factor. The dimer A_2 (but not the monomer A) can bind the DNA promoter B to form the compound A_2B. The compound A_2B can subsequently recruit the enzyme RNA polymerase, denoted C, to form the active compound A_2BC. It is the concentration of this last compound that determines the system's activity—the rate of transcription of the gene downstream from B.

Although we shall eventually consider a far wider class of reaction networks, our example here is an instance of what we shall later call a *constructive network*: Network (1.1) contains, explicitly, certain elemental species A, B, and C, from which all other species are ultimately constructed. (It needn't be the case in a constructive network that, as with our example, all reactions merely add a monomer of one of the elements. Thus, for example, a reaction such as $A_2B + A_2BC \rightleftharpoons A_4B_2C$ might also be included.) Certainly not all reaction networks are of this kind, but here and in section 1.3 consideration of constructive networks will facilitate both an introduction to the questions of interest and a description of some results.

As indicated earlier, we suppose that the individual reactions in network (1.1) are governed by mass-action kinetics, with fixed positive rate constants. (In the case of network (1.1), the detailed balance requirements are automatically satisfied, with no constraints imposed on rate constant values [10].) For the purposes of our discussion, we suppose also that the reactions take place in the context of a closed vessel, the contents of which are maintained at a fixed volume and temperature. Corresponding to a certain initial supply of various species, the mixture composition will evolve in time and ultimately approach equilibrium.

Note that the reactions conserve the elements A, B, and C, although these elements may reside latently within the compound species A_2, A_2B, and A_2BC. In fact, if $c_s(t)$ indicates the molar concentration of species s at time t, we expect that, for all time, the conservation conditions

$$\begin{aligned} &c_A(t) + 2c_{A_2}(t) + 2c_{A_2B}(t) + 2c_{A_2BC}(t) = T_A, \\ &c_{A_2B}(t) + c_B(t) + c_{A_2BC}(t) = T_B, \\ &c_C(t) + c_{A_2BC}(t) = T_C \end{aligned} \tag{1.2}$$

would be respected. In (1.2) we have denoted by T_A, T_B, and T_C the time-invariant *total* molar concentrations of the elements A, B, and C, regardless of whether they appear overtly or latently.

For specified positive values of the total element concentrations, say T_A^*, T_B^*, and T_C^*, the (polynomial) mass-action differential equations for network (1.1), formulated in the usual way [7], will give rise to precisely one equilibrium composition $c_A^*, c_B^*, c_C^*, c_{A_2}^*, c_{A_2B}^*, c_{A_2BC}^*$, consistent with that specification. On the other hand, if the vessel is temporarily opened and additional amounts of A, B, and C are added (either directly or by the addition of A_2, A_2B, and A_2BC), the resealed vessel will eventually come to a new and different equilibrium $c_A^{**}, c_B^{**}, c_C^{**}, c_{A_2}^{**}, c_{A_2B}^{**}, c_{A_2BC}^{**}$, which is the equilibrium consistent with the, now different, total concentrations T_A^{**}, T_B^{**}, and T_C^{**} of the elements. As we shall see later in the article, the equilibrium concentrations of the six species are given by smooth functions of T_A, T_B, and T_C.

Our interest is in the way that equilibrium concentrations of the various species are affected by small variations in the supply of the elements A, B, and C. By the *sensitivity matrix* for the system we mean the array whose entries are given by

$$\left(\frac{\partial \ln \bar{c}_s}{\partial \ln T_e}\right), \tag{1.3}$$

where $s \in \{A, B, C, A_2, A_2B, A_2BC\}$, $e \in \{A, B, C\}$, and $\bar{c}_s(\cdot,\cdot,\cdot)$ is the function that gives, for each specification of T_A, T_B, and T_C, the equilibrium concentration of species s. Values of the entries in the sensitivity matrix will depend, of course, on the equilibrium composition at which they are evaluated (in particular, on the values of T_A, T_B, and T_C at that equilibrium). The entry $\frac{\partial \ln \bar{c}_{A_2BC}}{\partial \ln T_B}$, for example, indicates the magnitude, at a particular equilibrium, of the fractional change in the equilibrium concentration of A_2BC in response to a small fractional change in the total concentration of element B. (The use of logarithms to reflect *fractional* changes, which is common in biology [23], is especially compelling when the various species concentrations can be of very different magnitudes.)

By the *sensitivity of species s* at equilibrium composition c^*, denoted $\Lambda^s(c^*)$, we mean the largest of the absolute values of the entries in the sensitivity matrix row corresponding to species s. Thus, for example,

$$\Lambda^{A_2BC}(c^*) = \max\left\{\left|\frac{\partial \ln \bar{c}_{A_2BC}}{\partial \ln T_A}\right|, \left|\frac{\partial \ln \bar{c}_{A_2BC}}{\partial \ln T_B}\right|, \left|\frac{\partial \ln \bar{c}_{A_2BC}}{\partial \ln T_C}\right|\right\}_{c^*}. \tag{1.4}$$

In this instance, $\Lambda^{A_2BC}(c^*)$ gives an indication, at equilibrium c^*, of the most pronounced of the variations in the equilibrium concentration of A_2BC, as the mixture is perturbed, respectively, by variations in the supply of A, B, and C.

Our interest is in providing means to calculate the sensitivity matrix at a particular equilibrium composition and, even more, in coming to a qualitative understanding of how reaction network character imposes *intrinsic* lower bounds on its species sensitivities, *bounds that derive from the reaction network alone, independent of rate constant values or even of the equilibrium composition at which they are calculated.* Bounds of this kind are described in the next section.

1.3. Network-imposed sensitivity bounds: Gregarious or multiplicitous elements are necessary for highly robust equilibria. Our goal in this section is to describe, informally and in the context of constructive networks, ways in which the network itself places a lower bound on species sensitivities. For a constructive network, we denote by $\mathscr{S}$ the set of species and by $\mathscr{E}$ the set of elements. In the case of network (1.1), $\mathscr{S} = \{A, B, C, A_2, A_2B, A_2BC\}$ and $\mathscr{E} = \{A, B, C\}$. For each element $e \in \mathscr{E}$ and each species $s \in \mathscr{S}$ we denote by M_e^s the *e-content* of species s—that is, the content of element e in species s. Thus, in our example, $M_A^A = 1$, $M_A^B = 0$, $M_A^C = 0$, $M_A^{A_2} = 2$, $M_A^{A_2B} = 2$, $M_A^{A_2BC} = 2$, and so on. (Later on, beginning in section 3, the notion of "element" will have meaning for reaction networks broadly, not just for those that are constructive. Even in this broader context it will make sense to speak of "the e-content of species s." Results described in this section will then extend to reaction networks in general.)

For each pair of elements $e, e' \in \mathscr{E}$ we denote by $M_e^{max}(e')$ the maximal e-content that can be found as we search over all species that contain the element e' (i.e., over all species that have positive e'-content). In network (1.1), the species that contain A are A, A_2, A_2B, and A_2BC. Thus, for example,

$$M_B^{max}(A) = \max\left\{M_B^A, M_B^{A_2}, M_B^{A_2B}, M_B^{A_2BC}\right\} = \max\{0, 0, 1, 1\} = 1.$$

Evaluating $M_e^{max}(e')$ for all combinations of $e, e' \in \mathscr{E}$ in network (1.1), we obtain

$$\begin{aligned} &M_A^{max}(A) = 2, \qquad M_A^{max}(B) = 2, \qquad M_A^{max}(C) = 2,\\ &M_B^{max}(A) = 1, \qquad M_B^{max}(B) = 1, \qquad M_B^{max}(C) = 1,\\ &M_C^{max}(A) = 1, \qquad M_C^{max}(B) = 1, \qquad M_C^{max}(C) = 1. \end{aligned} \tag{1.5}$$

Note that in general $M_e^{max}(e')$ will be high when there is an e'-containing species in which e appears with high multiplicity.

The *degree* of element e is given by

$$\deg(e) = \sum_{e' \in \mathscr{E}} M_e^{max}(e'). \tag{1.6}$$

Thus, for network (1.1),

$$\deg(A) = 6, \qquad \deg(B) = 3, \qquad \deg(C) = 3. \tag{1.7}$$

Note that a high degree for a particular element will result if it is free to combine with many other element partners (*resulting in many nonzero terms in* (1.6)) *or if it is multiplicitous in at least one instance of those various liaisons* (*resulting in a high* *value for at least one of the terms in* (1.6)). Indeed, a very high degree for a particular element *requires* such gregarious or multiplicitous couplings (or a combination of both).

All this is relevant to the description of a result we shall present as Theorem 7.3, a theorem that provides a *network-imposed* lower bound on the species sensitivities: *At every equilibrium composition c^* and for each species $s \in \mathscr{S}$,*

$$\Lambda^s(c^*) \geq \max_{e \in \mathscr{E}} \left\{ \frac{M_e^s}{\deg(e)} \right\}. \tag{1.8}$$

It should be noted that the lower bound afforded by (1.8) *is an attribute of the network alone. It is independent of rate constant values and of the particular equilibrium compositions at which sensitivities are of interest.* For network (1.1) we have at every equilibrium composition c^*,

$$\begin{aligned} &\Lambda^A(c^*) \geq \frac{1}{6}, \qquad \Lambda^B(c^*) \geq \frac{1}{3}, \qquad \Lambda^C(c^*) \geq \frac{1}{3}, \\ &\Lambda^{A_2}(c^*) \geq \frac{1}{3}, \qquad \Lambda^{A_2B}(c^*) \geq \frac{1}{3}, \qquad \Lambda^{A_2BC}(c^*) \geq \frac{1}{3}. \end{aligned} \tag{1.9}$$

The bound given by (1.8) *tells us that for an equilibrium concentration of a particular species s to be very robust against fluctuations in the overall supply of elements (that is, if s is to have very low sensitivity), the elements of which s is composed should have very high degree (so they should be gregarious or multiplicitous).* It helps too if species s itself is composed of very *few* copies of the various elements—that is, if M_e^s is low for the various $e \in \mathscr{E}$, especially those elements of low degree. In the setting of constructive systems, if we consider the sensitivities of the elements themselves (that is, for $s = e$), we note that $M_{e'}^e = 1$ when $e' = e$ and 0 otherwise. Thus, for each $e \in \mathscr{E}$, (1.8) reduces to

$$\Lambda^e(c^*) \geq \frac{1}{\deg(e)}. \tag{1.10}$$

As indicated earlier, we have stated here just one principal result, carried by (1.8), and then only in the context of what we have called constructive networks. That restriction was solely for the purpose of this introduction. Our concerns extend to networks in general, and our interests are not limited to the establishment of bounds. We seek, for example, to provide means to determine how entries in the sensitivity matrix depend on the current equilibrium state.

1.4. Organization.

In section 2 we provide an introduction to the rudimentary aspects of chemical reaction network theory, in particular to properties of *quasi-thermostatic* systems.

In section 3 we introduce the idea of *elemented reaction networks.* These constitute a broad generalization of what we call constructive reaction networks in this section: The fact is that the differential equations that derive from reaction networks typically reflect certain "conservation conditions" (integrals of motion), although what is conserved cannot always be clearly associated with total concentrations of species appearing overtly in the network (A, B, and C in our example). Nevertheless, one can generally associate with the network certain "elements," not necessarily overt species, whose total concentrations are conserved along solutions of the differential equations that the network induces. (An element might, for example, be identified with a moiety that manifests itself latently within the various species of the network while not itself appearing overtly.) For a given network there can be many such choices of (independently) conserved elements, and a particular application might favor one choice over another. By an elemented reaction network we mean a reaction network taken with one such choice of elements.

In section 4 we begin to examine properties of elemented quasi-thermostatic systems. This will set the stage for a discussion of sensitivities in section 5. Extended to elemented systems generally, our interest (as in this introductory section) will be in the variations of the equilibrium concentrations of the species in response to variations in the total concentrations of its elements. In section 6 we provide computational means to determine the sensitivity matrix—that is, to determine *through explicit formulas* how its entries depend on the particular equilibrium state at which they are calculated.

In section 7 we deduce lower bounds on the species sensitivities, bounds that are induced by the network alone, independent of rate constants and even of the equilibrium state at which the sensitivities are calculated. As in this introductory section, these bounds will be related to the *degrees* of the various elements. For elemented networks generally, the degree of an element is again influenced by the extent to which it combines in a gregarious and multiplicitous fashion. In section 8, we define formally what we mean by a constructive system, and we state a result that is particular to them. In section 9 we offer some brief concluding remarks.

2. Some ideas from chemical reaction network theory.

In this section we provide a brief review of rudimentary material from chemical reaction network theory [10, 16, 7, 5, 6, 8, 9, 2, 3, 4, 17, 11]. (An introduction for mathematicians, with more motivational discussion, can be found in [7].) Although chemical reaction network theory addresses a wide variety of dynamical issues, our focus here is exclusively on what Horn and Jackson [16] called *quasi-thermostatic* behavior.

2.1. Notation.

We denote the real numbers by $\mathbb{R}$, the strictly positive real numbers by $\mathbb{R}_+$, and the nonnegative real numbers by $\bar{\mathbb{R}}_+$. For an arbitrary finite set I (usually the set of species in a reaction network) we denote by $\mathbb{R}^I$ the real vector space of all formal sums $\sum_{i \in I} u_i i$ in which all u_i are real. By $\mathbb{R}^I_+$ (respectively, $\bar{\mathbb{R}}^I_+$) we mean the set of all $u \in \mathbb{R}^I$ for which all u_i are positive (respectively, nonnegative). By the *support* of an element $u \in \mathbb{R}^I$ we mean the subset of I defined by $\operatorname{supp}(u) = \{i \in I : u_i \neq 0\}$.

We use the symbol "$\circ$" to indicate componentwise multiplication. That is, for every u and v in $\mathbb{R}^I$, $u \circ v$ is the element of $\mathbb{R}^I$ such that $(u \circ v)_i = u_i v_i$. We denote by "$\cdot$" the (standard) scalar product in $\mathbb{R}^I : u \cdot v = \sum_{i \in I} u_i v_i$.

The function $\ln(\cdot) : \mathbb{R}^I_+ \to \mathbb{R}^I$ is the componentwise logarithm. That is, for each $u \in \mathbb{R}^I_+$, $(\ln u)_i = \ln(u_i)$. The function $\exp(\cdot) : \mathbb{R}^I \to \mathbb{R}^I_+$ is defined similarly: For each $u \in \mathbb{R}^I$, $(\exp u)_i = \exp(u_i)$.

If I is an arbitrary finite set, then by $\#(I)$ we mean the number of distinct elements in I.

2.2. Chemical reaction networks and their differential equations.

We begin with a definition of a chemical reaction network. By the *complexes* of a reaction network we shall mean the linear combinations of the species that appear before and after the reaction arrows. In network (1.1) there are six complexes: $2A, A_2, A_2 + B, A_2B, A_2B + C, A_2BC$. If $\mathscr{S}$ is the set of species of the network, we view the complexes of the network to be members of $\bar{\mathbb{R}}^{\mathscr{S}}_+$. We take a reaction network to be a specification of its species, a specification of its complexes, and, finally, a specification of a "reacts to" relation among the complexes.

DEFINITION 2.1. *A* chemical reaction network *consists of three finite sets:*

1. *A set $\mathscr{S}$ of distinct* species *of the network;*
2. *a set $\mathscr{C} \subset \bar{\mathbb{R}}_+^{\mathscr{S}}$ of* complexes *of the network;*
3. *a set $\mathscr{R} \subset \mathscr{C} \times \mathscr{C}$ of* reactions, *with the following properties:*
   (a) *$(y, y) \notin \mathscr{R}$ for any $y \in \mathscr{C}$;*
   (b) *for each $y \in \mathscr{C}$ there exists $y' \in \mathscr{C}$ such that $(y, y') \in \mathscr{R}$ or such that $(y', y) \in \mathscr{R}$.*

Following the usual notation in chemistry we write $y \to y'$ to indicate the reaction whereby complex y reacts to complex y'. With each reaction $y \to y'$ we associate the *reaction vector* $y' - y \in \mathbb{R}^{\mathscr{S}}$. In the context of our example, the reaction vector corresponding to $A_2B + C \to A_2BC$ is $A_2BC - A_2B - C$. For reasons that will become apparent, the span of a network's reaction vectors has special significance. This serves as motivation for the following definition.

DEFINITION 2.2. *The* stoichiometric subspace *of a reaction network $\{\mathscr{S}, \mathscr{C}, \mathscr{R}\}$ is the set $\mathrm{S} \subset \mathbb{R}^{\mathscr{S}}$ defined by*

$$\mathrm{S} = \operatorname{span}\left\{y' - y \in \mathbb{R}^{\mathscr{S}} : y \to y' \in \mathscr{R}\right\}.$$

When a particular network is under discussion, it will be understood that the symbol S is reserved to denote its stoichiometric subspace. We denote by $\mathrm{S}^\perp \subset \mathbb{R}^{\mathscr{S}}$ the orthogonal complement of S relative to the standard scalar product in $\mathbb{R}^{\mathscr{S}}$. We reserve the symbol p $(= \#(\mathscr{S}) - \dim \mathrm{S})$ for the dimension of $\mathrm{S}^\perp$.

Note that if $M \in \mathbb{R}_+^{\mathscr{S}}$ is the vector of molecular weights of the species in a network and if $y \to y'$ is a reaction, then $y \cdot M$ is the total mass of molecules on the reactant side of the reaction, while $y' \cdot M$ is the total mass of molecules on the product side. If the reaction respects conservation of mass, then we expect that $y \cdot M = y' \cdot M$, or equivalently, that $(y' - y) \cdot M = 0$. If all the reactions in the network respect conservation of mass, then M should be orthogonal to each of the reaction vectors, which is to say that M should be a member of $\mathrm{S}^\perp$. Following Horn and Jackson [16], we say that a reaction network is conservative if there exists for it at least one positive member of $\mathrm{S}^\perp$ that might play the role of a vector of molecular weights, relative to which all reactions are mass conserving.

DEFINITION 2.3. *A chemical reaction network $\{\mathscr{S}, \mathscr{C}, \mathscr{R}\}$ is* conservative *if $\mathrm{S}^\perp \cap \mathbb{R}_+^{\mathscr{S}} \neq \emptyset$.*

In order to write the differential equations governing the species concentrations in a reaction network, it is first necessary to specify, at each mixture composition, the rate at which the various reactions occur. For each reaction network $\{\mathscr{S}, \mathscr{C}, \mathscr{R}\}$ we generally denote by $c \in \bar{\mathbb{R}}_+^{\mathscr{S}}$ the vector of molar concentrations of the species. That is, for each $s \in \mathscr{S}$, c_s is the molar concentration of species s. By a *rate function* for the reaction $y \to y'$ we mean a function $\mathscr{K}_{y\to y'}(\cdot) : \bar{\mathbb{R}}_+^{\mathscr{S}} \to \bar{\mathbb{R}}_+$ that gives information about the dependence of occurrence rate on mixture composition. In particular, $\mathscr{K}_{y\to y'}(c)$ is the molar occurrence rate per unit volume at composition c. It is natural to expect that, at a particular mixture composition c, $\mathscr{K}_{y\to y'}(c)$ will be positive if and only if all species appearing with nonzero stoichiometric coefficients in the *reactant complex* y are present at composition c—that is, if and only if $\operatorname{supp}(y) \subset \operatorname{supp}(c)$. Very often, rate functions are taken to be of *mass-action* type—monomials in the species concentrations reflecting the probability of an encounter between molecules appearing in the reactant complex.

Definition 2.4. *A* kinetics $\mathscr{K}$ *for a reaction network* $\{\mathscr{S},\mathscr{C},\mathscr{R}\}$ *is an assignment to each reaction* $y \to y' \in \mathscr{R}$ *of a continuous rate function* $\mathscr{K}_{y\to y'}(\cdot) : \bar{\mathbb{R}}_+^{\mathscr{S}} \to \bar{\mathbb{R}}_+$ *such that* $\mathscr{K}_{y\to y'}(c) > 0$ *if and only if* $\operatorname{supp}(y) \subset \operatorname{supp}(c)$. *A* mass-action kinetics *for the network is a kinetics of the following kind: For each reaction* $y \to y' \in \mathscr{R}$ *there is a positive* rate constant $k_{y\to y'}$ *such that*

$$\mathscr{K}_{y\to y'}(c) \equiv k_{y\to y'} \prod_{s\in\mathscr{S}} (c_s)^{y_s}. \tag{2.1}$$

A kinetic system *is a reaction network endowed with a kinetics. A* mass-action system *is a reaction network endowed with a mass-action kinetics.*

Definition 2.5. *The* species-formation-rate function *for a kinetic system* $\{\mathscr{S}, \mathscr{C},\mathscr{R},\mathscr{K}\}$ *is the function* $r(\cdot) : \bar{\mathbb{R}}_+^{\mathscr{S}} \to \mathbb{R}^{\mathscr{S}}$ *defined by*

$$r(c) = \sum_{y\to y'\in\mathscr{R}} \mathscr{K}_{y\to y'}(c)(y' - y), \tag{2.2}$$

and the associated differential equation *is*

$$\dot{c} = r(c). \tag{2.3}$$

We say that $c \in \bar{\mathbb{R}}_+^{\mathscr{S}}$ *is an* equilibrium composition *if* $r(c) = 0$. *By the* positive equilibrium set *for the kinetic system we mean the set*

$$E = \left\{c \in \mathbb{R}_+^{\mathscr{S}} : r(c) = 0\right\}. \tag{2.4}$$

Example 2.6. Network (1.1), taken with mass action kinetics, gives rise to the species-formation-rate function (2.5), which is constructed according to (2.1) and (2.2):

$$\begin{aligned} r_A(c) &= 2k_{A_2\to 2A}(c_{A_2}) - 2k_{2A\to A_2}(c_A)^2,\\ r_B(c) &= k_{A_2B\to A_2+B}(c_{A_2B}) - k_{A_2+B\to A_2B}(c_{A_2})(c_B),\\ r_C(c) &= k_{A_2BC\to A_2B+C}(c_{A_2BC}) - k_{A_2B+C\to A_2BC}(c_{A_2B})(c_C),\\ r_{A_2}(c) &= k_{2A\to A_2}(c_A)^2 - k_{A_2\to 2A}(c_{A_2})\\ &\quad + k_{A_2B\to A_2+B}(c_{A_2B}) - k_{A_2+B\to A_2B}(c_{A_2})(c_B),\\ r_{A_2B}(c) &= k_{A_2+B\to A_2B}(c_{A_2})(c_B) - k_{A_2B\to A_2+B}(c_{A_2B})\\ &\quad + k_{A_2BC\to A_2B+C}(c_{A_2BC}) - k_{A_2B+C\to A_2BC}(c_{A_2B})(c_C),\\ r_{A_2BC}(c) &= k_{A_2B+C\to A_2BC}(c_{A_2B})(c_C) - k_{A_2BC\to A_2B+C}(c_{A_2BC}). \end{aligned} \tag{2.5}$$

Remark 2.7. Note that the species-formation-rate function takes values in the stoichiometric subspace S, which, for a conservative system, will be a *proper* linear subspace of $\mathbb{R}^{\mathscr{S}}$. Because in (2.3) the "velocity vector" $\dot{c}$ is restricted to point along S, it is not difficult to see that a composition trajectory that begins at composition c' can pass through composition c'' only if $c'' - c'$ lies in S.

With this in mind we say that two compositions are *stoichiometrically compatible* if $c'' - c'$ lies in S. Stoichiometric compatibility is an equivalence relation that serves to partition the set $\bar{\mathbb{R}}_+^{\mathscr{S}}$ of all compositions into *stoichiometric compatibility classes* (and partition the set $\mathbb{R}_+^{\mathscr{S}}$ of strictly positive compositions into *positive stoichiometric compatibility classes*). Stoichiometric compatibility classes are those subsets of parallels of S that lie in $\bar{\mathbb{R}}_+^{\mathscr{S}}$. In particular, the stoichiometric compatibility class containing a composition c^0 is the intersection of $\bar{\mathbb{R}}_+^{\mathscr{S}}$ with the parallel $c^0 + \mathrm{S} = \{c^0 + \sigma \in \mathbb{R}^{\mathscr{S}} : \sigma \in \mathrm{S}\}$.

Because two compositions along a trajectory governed by (2.3) must be stoichiometrically compatible, it is evident that each composition trajectory must lie entirely within a stoichiometric compatibility class.

2.3. Quasi-thermostatic kinetic systems.

It is remarkable that a wide variety of mass-action systems fall into a class called by Horn and Jackson [16] *quasi-thermostatic*. Quasi-thermostatic systems are characterized by a simply described positive equilibrium set.

DEFINITION 2.8. *A kinetic system* $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{K}\}$ *is called* quasi-thermostatic *if it admits a positive equilibrium* $c^* \in \mathbb{R}_+^{\mathscr{S}}$ *and if its positive equilibrium set is given by*

$$E = \left\{c \in \mathbb{R}_+^{\mathscr{S}} : \ln c - \ln c^* \in \mathrm{S}^{\perp}\right\}. \tag{2.6}$$

Remark 2.9. Given the stoichiometric subspace for a quasi-thermostatic system, specification of its entire positive equilibrium set amounts to the specification of a single member, c^*. In fact, if c^{**} is any other member, then the positive equilibrium set has the alternative characterization

$$E = \left\{c \in \mathbb{R}_+^{\mathscr{S}} : \ln c - \ln c^{**} \in \mathrm{S}^{\perp}\right\}.$$

Remark 2.10. Not all mass-action systems are quasi thermostatic [16, 9, 2, 3, 4], but very important categories of them are. In particular, *detailed balanced* mass-action systems are quasi thermostatic [16]. In the terminology of chemistry, a kinetic system $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{K}\}$ is detailed balanced if all of its reactions are reversible (i.e., $y \to y'$ implies $y' \to y$) and if for each $y \to y' \in \mathscr{R}$ and at each equilibrium $c^* \in \mathbb{R}_+^{\mathscr{S}}$,

$$\mathscr{K}_{y \to y'}(c^*) = \mathscr{K}_{y' \to y}(c^*).$$

Not all reversible mass-action systems are detailed balanced: In some instances, reaction network structure alone will suffice to ensure detailed balancing, regardless of rate-constant values, but in other instances detailed balancing obtains only if the rate constants are suitably orchestrated [10]. It is a commonly held belief among chemists that closed mass-action systems occurring in nature *should* be detailed balanced (and, therefore, quasi thermostatic). This belief seems to go back to Wegscheider [26] and Lewis [20].

Horn and Jackson [16] showed that mass-action systems satisfying the far weaker condition of *complex balancing* are also quasi thermostatic. (Detailed balancing implies complex balancing, but the converse is not true.) In turn, Feinberg [5] and Horn [17] showed that for a large class of mass-action systems (those that derive from *weakly reversible deficiency zero* networks), complex balancing, and therefore quasi-thermostatic behavior, is a consequence of reaction network structure alone, independent of rate-constant values. Subsequently, Feinberg [7, 8, 11] showed that, regardless of rate-constant values, quasi-thermostatic behavior (but not necessarily complex balancing) is a property of mass-action systems that derive from a still wider class of networks, those satisfying the requirements of the *deficiency one theorem.*

The following proposition tells us that, for a quasi-thermostatic kinetic system, each positive stoichiometric compatibility class (Remark 2.7) contains exactly one member of the positive equilibrium set. A proof can be found in [16], and a somewhat different proof is given in Appendix B of [11].

PROPOSITION 2.11. *Let $\{\mathscr{S},\mathscr{C},\mathscr{R}\}$ be a reaction network with stoichiometric subspace* S*, and let c^*, c^0 be elements of $\mathbb{R}^{\mathscr{S}}_+$. Then the sets*

$$c^0 + \mathrm{S} = \left\{c^0 + \sigma \in \mathbb{R}^{\mathscr{S}} : \sigma \in \mathrm{S}\right\}$$

and

$$E = \left\{c \in \mathbb{R}^{\mathscr{S}}_+ : \ln c - \ln c^* \in \mathrm{S}^{\perp}\right\}$$

meet at exactly one point.

Remark 2.12. If, for a quasi-thermostatic system, we write the equilibrium set in the form

$$E = \left\{c \in \mathbb{R}^{\mathscr{S}}_+ : c = c^* \circ \exp(\gamma),\ \gamma \in \mathrm{S}^{\perp}\right\}, \tag{2.7}$$

it becomes clear that E is a p-dimensional smooth manifold ($p = \dim \mathrm{S}^{\perp}$) parametrized globally by the map $\tilde{c}(\cdot) : \mathrm{S}^{\perp} \to \mathbb{R}^{\mathscr{S}}$, where $\tilde{c}(\gamma) \equiv c^* \circ \exp(\gamma)$. (After choosing a basis for $\mathrm{S}^{\perp}$, one can of course identify $\mathrm{S}^{\perp}$ with $\mathbb{R}^p$.) Clearly, $\tilde{c}(0) = c^*$. For future reference we note that the derivative of $\tilde{c}(\cdot)$, evaluated at 0, and denoted $\mathrm{d}\,\tilde{c}[0] : \mathrm{S}^{\perp} \to \mathbb{R}^{\mathscr{S}}$, acts on each $\gamma \in \mathrm{S}^{\perp}$ in the following way: $\mathrm{d}\,\tilde{c}[0]\gamma = c^* \circ \gamma$. From this it is apparent that the linear subspace tangent to E at c^* is

$$c^* \circ \mathrm{S}^{\perp} = \left\{c^* \circ \gamma : \gamma \in \mathrm{S}^{\perp}\right\}. \tag{2.8}$$

3. Elemented reaction networks. By an *elemented reaction network* we mean a reaction network taken together with a distinguished choice of nonnegative basis for $\mathrm{S}^{\perp}$. As will be readily apparent, each basis vector gives rise to a linear combination of the species concentrations that is conserved along solutions of the differential equations associated with any kinetic system deriving from the network. Loosely speaking, then, each basis vector can be associated with an "indestructible element" whose total concentration is conserved by the reactions. In some instances, as in the case of network (1.1), these conserved elements (A, B, and C in our example) have natural interpretations and correspond to a natural choice of basis for $\mathrm{S}^{\perp}$. For a different network, the choice of elements might be more arbitrary and may, in fact, vary from one application to another.

As we shall see later, whatever the choice of elements, specification of their total (time-invariant) concentrations will serve to specify, bijectively, a particular stoichiometric compatibility class (Remark 2.7). For a quasi-thermostatic kinetic system, each positive stoichiometric compatibility class contains precisely one equilibrium (Proposition 2.11). In effect, then, the positive equilibrium set E can be parametrized by the total concentrations of the elements. As suggested in the introduction, our interest is in how the equilibria change in response to a change in the element concentrations, which, in fact, corresponds to a change in stoichiometric compatibility class.

DEFINITION 3.1. *An* elemented reaction network *consists of the following:*

1. *A reaction network $\{\mathscr{S},\mathscr{C},\mathscr{R}\}$;*
2. *a set $\mathscr{E}$ of p $(= \dim \mathrm{S}^{\perp})$ distinct members called the* elements *of the network;*
3. *a basis $\mathscr{M} = \{M_e\}_{e \in \mathscr{E}} \subset \bar{\mathbb{R}}^{\mathscr{S}}_+$ for $\mathrm{S}^{\perp}$.*

For each $e \in \mathscr{E}$ and $s \in \mathscr{S}$, the component M^s_e is called the e-content of species s*.*

Remark 3.2. Although we have not built such a requirement into the definition, we shall, in this article, suppose that all networks under consideration are conservative in the sense of Definition 2.3. (There are instances, not considered here, in which one might want to study the more general situation.) It is easy to see that, for a conservative network, it is always possible to choose a basis for $\mathrm{S}^{\perp}$ that lies in $\bar{\mathbb{R}}_{+}^{\mathscr{S}}$. Moreover, it is not difficult to see that, for an elemented conservative network, there exists for each species s at least one element e such that the e-content of s is not zero.

Example 3.3. One elemented network derived from (1.1) results from the choice $\mathscr{E} = \{A, B, C\}$ and the basis for $\mathrm{S}^{\perp}$ given by

$$\begin{aligned} M_A &= A + 2A_2 + 2A_2B + 2A_2BC, \\ M_B &= B + A_2B + A_2BC, \\ M_C &= C + A_2BC. \end{aligned} \tag{3.1}$$

In this case all of the elements are associated with certain species that appear explicitly in the network.

Example 3.4. It is instructive to consider a simple network of the general form

$$W + X \rightleftharpoons Y + Z, \tag{3.2}$$

for which $\dim \mathrm{S}^{\perp} = 3$. The network might be "elemented" in different ways, depending on the context. If, for example, $W = AQ_2$, $Y = AQ$, and $Z = XQ$, then (3.2) represents a transfer of a molecular component Q from species AQ_2 to species X. In this case, it is natural to take $\mathscr{E} = \{A, Q, X\}$ and

$$\begin{aligned} M_A &= AQ_2 + AQ = W + Y, \\ M_Q &= 2AQ_2 + AQ + XQ = 2W + Y + Z, \\ M_X &= X + XQ = X + Z. \end{aligned}$$

Note that the element X is an overt species, whereas the elements A and Q are not.

If, on the other hand, $W = AB$, $X = CD$, $Y = AC$, and $Z = BD$, then (3.2) represents a component exchange. One natural choice of elements is $\mathscr{E} = \{A, B, C\}$ and the basis for $\mathrm{S}^{\perp}$ given by

$$\begin{aligned} M_A &= AB + AC = W + Y, \\ M_B &= AB + BD = W + Z, \\ M_C &= CD + AC = X + Y. \end{aligned}$$

Still another choice is $\mathscr{E} = \{A, B, D\}$ and

$$\begin{aligned} M_A &= AB + AC = W + Y, \\ M_B &= AB + BD = W + Z, \\ M_D &= CD + BD = X + Z. \end{aligned}$$

With neither choice does any element appear explicitly as a species.

Recall that for the network discussed in the introduction we considered the *total concentrations* of the three elements. For each element e, the total concentration was calculated from the current mixture composition c by a sum of the following kind:

$$\sum_{s \in \mathscr{S}} M_e^s c_s,$$

where M_e^s is the e-content of species s. We now extend this idea using the following definition.

DEFINITION 3.5. *Let* $\{\mathscr{S},\mathscr{C},\mathscr{R},\mathscr{E},\mathscr{M}\}$ *be an elemented reaction network. The* element concentration functions $\bar{T}_e(\cdot):\mathbb{R}^{\mathscr{S}}\to\mathbb{R}$ *are defined for each* $e\in\mathscr{E}$ *by*

$$\bar{T}_e(x) := M_e \cdot x. \tag{3.3}$$

For use later, we define the function $\bar{T}(\cdot):\mathbb{R}^{\mathscr{S}}\to\mathbb{R}^{\mathscr{E}}$ by

$$\bar{T}(x) := \sum_{e\in\mathscr{E}} \bar{T}_e(x)e. \tag{3.4}$$

It is not difficult to see that the kernel of $\bar{T}(\cdot)$ is the stoichiometric subspace S.

Remark 3.6. Two compositions c' and c'' are associated with precisely the same element concentrations (i.e., $\bar{T}(c')=\bar{T}(c'')$) if and only if $c'-c''$ is a member of the stoichiometric subspace, which is to say that c' and c'' reside in the same stoichiometric compatibility class. In this way each specification of positive element concentrations (i.e., each member of $\bar{T}(\mathbb{R}_+^{\mathscr{S}})\subset\mathbb{R}_+^{\mathscr{E}}$) can be identified bijectively with a positive stoichiometric compatibility class.

DEFINITION 3.7. *An* elemented kinetic system *is an elemented reaction network endowed with kinetics.*

Remark 3.8. It is apparent from Remark 3.6 that the element concentrations remain invariant along solutions of the differential equations associated with an elemented kinetic system: Composition trajectories reside entirely within stoichiometric compatibility classes (Remark 2.7), and, within each stoichiometric compatibility class, all compositions give rise to the same element concentrations. The constancy of the element concentrations can, of course, be seen more directly: If $c(\cdot)$ is a solution of the differential equation for a particular elemented kinetic system, and if e is an element, then, at each t,

$$\frac{d}{dt}\bar{T}_e(c(t)) = M_e\cdot\frac{dc(t)}{dt} = M_e\cdot r(c(t)) = 0. \tag{3.5}$$

Here, of course, $M_e\in \mathrm{S}^{\perp}$ is the basis vector associated with element e, and $r(\cdot)$ is the species-formation-rate function for the kinetic system. The last equality in (3.5) follows from the fact that $r(\cdot)$ takes values in S.

4. Elemented quasi-thermostatic systems. We asserted in Remark 3.6 that, for an elemented network, there is a bijective correspondence between positive stoichiometric compatibility classes and distinct positive specifications of element concentrations. On the other hand, for a quasi-thermostatic system, each positive stoichiometric compatibility class contains precisely one equilibrium (Proposition 2.11). Thus, for a quasi-thermostatic elemented system, there is a bijective correspondence between the positive equilibrium set E and $\bar{T}(\mathbb{R}_+^{\mathscr{S}})$, the set of all (realizable) positive specifications of the element concentrations. Our goal in this section is to show that this correspondence is, in fact, a diffeomorphism. Then we will be able to speak of the smooth dependence of equilibrium species concentrations on the element concentrations, and the way will be paved for discussion and analysis of sensitivities, which were described only informally in the introduction.

We consider, therefore, a quasi-thermostatic elemented kinetic system $\{\mathscr{S},\mathscr{C},\mathscr{R},\mathscr{K},\mathscr{E},\mathscr{M}\}$ with positive equilibrium set $E\in\mathbb{R}_+^{\mathscr{S}}$. We denote by $\bar{T}_E(\cdot):E\to\bar{T}(\mathbb{R}_+^{\mathscr{S}})$ the restriction of $\bar{T}(\cdot)$ to E, taken with the indicated choice of codomain. (It is the function $\bar{T}_E(\cdot)$ that we want to show is a diffeomorphism.) Note that $\bar{T}_E(\cdot)$ is a map from the p-dimensional smooth manifold E to the p-dimensional smooth manifold $\bar{T}(\mathbb{R}_+^{\mathscr{S}})$ (an open set in $\mathbb{R}^{\mathscr{E}}$ by the open mapping theorem [1]). Recall from Remark 2.12 that if c^* is a member of E, then at c^* the space tangent to E is

$$c^* \circ \mathrm{S}^{\perp} = \left\{ c^* \circ \gamma : \gamma \in \mathrm{S}^{\perp} \right\}.$$

NOTATION 4.1. *Occasionally we will focus on a fixed but arbitrary positive equilibrium $c^* \in E$. It will be useful to have available a scalar product "$*$" in $\mathbb{R}^{\mathscr{S}}$ defined by*

$$x * y = x \cdot (c^* \circ y) \equiv \sum_{s \in \mathscr{S}} x_s c_s^* y_s.$$

LEMMA 4.2. *The derivative of $\bar{T}_E(\cdot)$ at an equilibrium $c^* \in E$ is the nonsingular map $\mathrm{d}\,\bar{T}_E\,[c^*]\,(\cdot) : c^* \circ \mathrm{S}^{\perp} \to \mathbb{R}^{\mathscr{E}}$ given for each $\gamma \in \mathrm{S}^{\perp}$ by*

$$\mathrm{d}\,\bar{T}_E\,[c^*]\,(c^* \circ \gamma) = \sum_{e \in \mathscr{E}} (M_e * \gamma) e. \tag{4.1}$$

Proof. Equation (4.1) derives from straightforward calculation. To see that the map $\mathrm{d}\,\bar{T}_E\,[c^*]\,(\cdot)$ is nonsingular, suppose that $\gamma^{\#} \in \mathrm{S}^{\perp}$ is such that $\mathrm{d}\,\bar{T}_E\,[c^*]\,(c^* \circ \gamma^{\#}) = 0$. This requires that $M_e * \gamma^{\#} = 0$ for each $e \in \mathscr{E}$. Thus, $\gamma^{\#} \in \mathrm{S}^{\perp}$ is orthogonal, with respect to the "$*$" scalar product, to each member of a basis for $\mathrm{S}^{\perp}$. Hence, $\gamma^{\#}$ and therefore $c^* \circ \gamma^{\#}$ are each the zero vector in $\mathbb{R}^{\mathscr{S}}$. □

PROPOSITION 4.3. *$\bar{T}_E(\cdot) : E \to \bar{T}(\mathbb{R}_+^{\mathscr{S}})$ is a diffeomorphism.*

Proof. To show that $\bar{T}_E(\cdot)$ is bijective, suppose that T^0 is some fixed but arbitrary member of $\bar{T}(\mathbb{R}_+^{\mathscr{S}})$. We will argue that there is precisely one member of E mapped to the point T^0 by $\bar{T}_E(\cdot)$. Because T^0 is a member of $\bar{T}(\mathbb{R}_+^{\mathscr{S}})$, there is a $c^0 \in \mathbb{R}_+^{\mathscr{S}}$ such that $\bar{T}(c^0) = T^0$. That is,

$$\bar{T}(c^0) = \sum_{e \in \mathscr{E}} (M_e \cdot c^0) e = T^0.$$

In fact, the full set of vectors in $\mathbb{R}^{\mathscr{S}}$ mapped by $\bar{T}(\cdot)$ to T^0 is $c^0 + \ker \bar{T}(\cdot) = c^0 + \mathrm{S}$. Our interest, then, is in the members of $c^0 + \mathrm{S}$ that are also members of E. If c^* is a member of E, then, for the quasi-thermostatic system under study, the equilibrium set is given by

$$E = \left\{ c \in \mathbb{R}_+^{\mathscr{S}} : \ln c - \ln c^* \in \mathrm{S}^{\perp} \right\}.$$

From Proposition 2.11, however, E meets $c^0 + \mathrm{S}$ in *exactly* one point. Thus, $\bar{T}_E(\cdot)$ is bijective.

Because from Lemma 4.2 we have that $\mathrm{d}\,\bar{T}_E\,[c^*]\,(\cdot)$ is nonsingular for each $c^* \in E$, the inverse function theorem [12] ensures that, at each point in $\bar{T}(\mathbb{R}_+^{\mathscr{S}})$, there is a local inverse of the smooth function $\bar{T}_E(\cdot)$ that is also smooth. Since any such local inverse must be a restriction of the (unique) global inverse whose existence was established above, it follows that the inverse of $\bar{T}(\cdot)$ is smooth. □

5. Sensitivities. Hereafter we consider an elemented quasi-thermostatic kinetic system $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{K}, \mathscr{E}, \mathscr{M}\}$, and we denote by c^* a fixed but arbitrary member of its positive equilibrium set E. We denote by $T^* \in \mathbb{R}^{\mathscr{E}}$ the value $\bar{T}(c^*)$. That is, T^* is the vector of element concentrations associated with the equilibrium composition c^*.

Proposition 4.3 tells us that the map $\bar{T}_E(\cdot) : E \to \bar{T}(\mathbb{R}^{\mathscr{S}}_+)$ gives a global coordinate system on E. That is, each equilibrium in E is characterized uniquely by a specification of the concentrations of the elements. We will choose to introduce a change in coordinates so that we can work instead with logarithms of the element concentrations. For this purpose we introduce the map $\ln \bar{T}_E(\cdot) : E \to \ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+)$ defined in the obvious way: For each $c \in E$, $\ln \bar{T}_E(c) = \ln(\bar{T}_E(c))$. As a variant of (4.1), it is not difficult to see that $\mathrm{d} \ln \bar{T}_E[c^*](\cdot) : c^* \circ \mathrm{S}^\perp \to \mathbb{R}^{\mathscr{E}}$ is given by

$$\mathrm{d} \ln \bar{T}_E[c^*](c^* \circ \gamma) = \sum_{e \in \mathscr{E}} \frac{1}{T^*_e}(M_e \cdot c^* \circ \gamma)e = \sum_{e \in \mathscr{E}} \frac{1}{T^*_e}(M_e * \gamma)e \tag{5.1}$$

for all $\gamma \in \mathrm{S}^\perp$.

Because $\ln \bar{T}_E(\cdot)$ amounts to the composition of the diffeomorphisms $\bar{T}_E(\cdot)$ and $\ln(\cdot) : \bar{T}(\mathbb{R}^{\mathscr{S}}_+) \to \ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+)$, it too is a diffeomorphism. Hereafter, we denote by $\bar{c}(\cdot) : \ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+) \to E$ the inverse of $\ln \bar{T}_E(\cdot)$. Thus, if $\ln T$ is a member of $\ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+)$ it makes sense to speak of "the equilibrium composition $\bar{c}(\ln T)$." Note that $\ln \bar{T}_E(c^*) = \ln \bar{T}(c^*) = \ln T^*$ and $\bar{c}(\ln T^*) = c^*$. Note too that $\mathrm{d}\,\bar{c}[\ln T^*](\cdot) : \mathbb{R}^{\mathscr{E}} \to c^* \circ \mathrm{S}^\perp$ is just the inverse of $\mathrm{d} \ln \bar{T}_E[c^*]$, which is given by (5.1). Thus we have

$$\mathrm{d}\,\bar{c}[\ln T^*]\left(\sum_{e \in \mathscr{E}} \frac{1}{T^*_e}(M_e * \gamma)e\right) = c^* \circ \gamma \tag{5.2}$$

for all $\gamma \in \mathrm{S}^\perp$.

We will also be interested in the map $\ln \bar{c}(\cdot) : \ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+) \to \ln E$ $(= \ln c^* + \mathrm{S}^\perp)$ defined in the obvious way. (Note that the tangent spaces of the manifolds $\ln \bar{T}(\mathbb{R}^{\mathscr{S}}_+)$ and $\ln c^* + \mathrm{S}^\perp$ are, respectively, everywhere $\mathbb{R}^{\mathscr{E}}$ and $\mathrm{S}^\perp$.) Because $\mathrm{d} \ln \bar{c}[\ln T^*](\cdot) : \mathbb{R}^{\mathscr{E}} \to \mathrm{S}^\perp$ is given by $\frac{1}{c^*} \circ \mathrm{d}\,\bar{c}[\ln T^*]$, it follows from (5.2) that

$$\mathrm{d} \ln \bar{c}[\ln T^*]\left(\sum_{e \in \mathscr{E}} \frac{1}{T^*_e}(M_e * \gamma)e\right) = \gamma \tag{5.3}$$

for all $\gamma \in \mathrm{S}^\perp$.

We are now in position to make precise definitions of the sensitivities discussed informally in the introduction.

Definition 5.1. *By the* sensitivity vector for element e at equilibrium composition c^* *we mean the vector in* $c^* \circ \mathrm{S}^\perp \subset \mathbb{R}^{\mathscr{S}}$ *given by*

$$\frac{\partial \ln \bar{c}}{\partial \ln T_e}(c^*) := \mathrm{d} \ln \bar{c}\,[\ln T^*]\,e. \tag{5.4}$$

By the sensitivity matrix at c^* *we mean the array whose elements are given by*

$$\left(\frac{\partial \ln \bar{c}_s}{\partial \ln T_e}(c^*)\right)_{s \in \mathscr{S},\, e \in \mathscr{E}}. \tag{5.5}$$

6. Means to calculate the sensitivity matrix. Here we provide means to calculate the sensitivity matrix at the equilibrium $c^* \in E$.[1] For the specified equilibrium c^*, we denote by $\{M^e\}_{e \in \mathscr{E}} \subset \mathrm{S}^\perp$ the basis for $\mathrm{S}^\perp$ that is reciprocal, relative

[1] We note that these calculations have points of contact with issues raised some years ago in two Ph.D. theses, by K. Israel [18] and J. Nailor [21], supervised by Michael Reed. Stated in very rough and somewhat inaccurate terms, their interest was in signs of entries in what we call the sensitivity matrix—signs that might be determined by experiment. The motivation was that such experimentally determined signs might provide clues about the underlying reaction network when the network is unknown.

to the "$*$" scalar product in $\mathbb{R}^{\mathscr{S}}$, to the basis $\mathscr{M} = \{M_e\}_{e\in\mathscr{E}}$. (Recall Notation 4.1.) That is, $M^{e'} * M_e = 1$ if $e' = e$ and is 0 otherwise. Because the "$*$" scalar product depends upon c^*, so will the reciprocal basis it induces. It is not difficult to determine such reciprocal bases computationally within the context of readily available symbolic mathematics programs.

THEOREM 6.1. *Let $\{\mathscr{S},\mathscr{C},\mathscr{R},\mathscr{K},\mathscr{E},\mathscr{M}\}$ be an elemented quasi-thermostatic kinetic system, let $c^* \in E$ be a positive equilibrium (corresponding to an element specification $T^* \in \mathbb{R}^{\mathscr{E}}$), and let $\{M^e\}_{e\in\mathscr{E}}$ be the basis for $\mathrm{S}^\perp$ reciprocal to $\mathscr{M}$ relative to the "$*$" scalar product in $\mathbb{R}^{\mathscr{S}}$. Then for each $e \in \mathscr{E}$, the sensitivity vector is given by*

$$\frac{\partial \ln \bar{c}}{\partial \ln T_e}(c^*) = T_e^* M^e. \tag{6.1}$$

Entries of the sensitivity matrix are given by

$$\frac{\partial \ln \bar{c}_s}{\partial \ln T_e}(c^*) = T_e^* M^{es} \tag{6.2}$$

for each $s \in \mathscr{S}$ and $e \in \mathscr{E}$.

Proof. Equation (6.1) results from a simple substitution in (5.3): To obtain the sensitivity vector for a particular element $e' \in \mathscr{E}$, set $\gamma = T_{e'}^* M^{e'}$. Equation (6.2) is just the component form of (6.1). □

Example 6.2. Consider network (6.3), which can serve to model a process whereby an active biomolecule A_2B_2 is assembled from elements A and B:

$$A + B \rightleftharpoons AB, \qquad 2AB \rightleftharpoons A_2B_2. \tag{6.3}$$

One elemented network derived from (6.3) is afforded by the choices $\mathscr{E} = \{A, B\}$ and $\mathscr{M} = \{M_A, M_B\}$, where

$$\begin{aligned} M_A &= A + AB + 2A_2B_2,\\ M_B &= B + AB + 2A_2B_2. \end{aligned} \tag{6.4}$$

If the kinetics for the network is mass action, then, for any choice of rate constants, detailed balance will obtain [10] and the system will be quasi thermostatic. Thus, Theorem 6.1 can be used to calculate all entries in the sensitivity matrix, evaluated at an arbitrary equilibrium c^*. In particular, the entries corresponding to the "active" species A_2B_2 are

$$\begin{aligned} \frac{\partial \ln \bar{c}_{A_2B_2}}{\partial \ln T_A}(c^*) &= \frac{2(c_A^* + c_{AB}^* + 2c_{A_2B_2}^*)c_B^*}{c_A^*c_B^* + (c_A^* + c_B^*)(c_{AB}^* + 4c_{A_2B_2}^*)},\\ \frac{\partial \ln \bar{c}_{A_2B_2}}{\partial \ln T_B}(c^*) &= \frac{2(c_B^* + c_{AB}^* + 2c_{A_2B_2}^*)c_A^*}{c_A^*c_B^* + (c_A^* + c_B^*)(c_{AB}^* + 4c_{A_2B_2}^*)}. \end{aligned} \tag{6.5}$$

7. Degree, connectivity, and network-imposed sensitivity bounds. As before, we consider an elemented quasi-thermostatic kinetic system $\{\mathscr{S},\mathscr{C},\mathscr{R},\mathscr{K},\mathscr{E},\mathscr{M}\}$, and we let c^* be a positive equilibrium, corresponding to an element concentration specification $T^* \in \mathbb{R}^{\mathscr{E}}$. Motivated by considerations discussed in the introduction, we have interest in understanding the extent to which the equilibrium concentration of a particular species $s \in \mathscr{S}$ might be robust against variations in the supply of elements. Our interest, then, is in the "worst case"—that is, in the most sensitive response in the concentration of s, taken against variation in each of the element concentrations.

Definition 7.1. *The* sensitivity of species $s \in \mathscr{S}$ at c^*, *denoted* $\Lambda^s(c^*)$, *is defined by*

$$\Lambda^s(c^*) = \max_{e \in \mathscr{E}} \left\{ \left| \frac{\partial \ln \bar{c}_s}{\partial \ln T_e}(c^*) \right| \right\}. \tag{7.1}$$

By the system sensitivity at c^*, *denoted* $\Lambda(c^*)$, *we mean the least of the species sensitivities. That is,*

$$\Lambda(c^*) = \min_{s \in \mathscr{S}} \Lambda^s(c^*). \tag{7.2}$$

Remark 7.2. In general, the species sensitivities and the system sensitivity will depend on the choice of basis $\mathscr{M}$ for $\mathrm{S}^{\perp}$.

If the system sensitivity is high at c^*, then *all* species sensitivities at c^* are high, so it makes sense to say that the system itself is highly sensitive to element concentration variations.

Our goal in this section is to provide lower bounds on the species sensitivities and on the system sensitivity, bounds that derive *from network properties alone*, independent of kinetic parameters and even of the equilibrium at which the sensitivities are calculated. By way of preparation, we posit formally some ideas that were discussed informally in the introduction. All the following are attributes of the elemented *network* underlying the kinetic system we have been studying:

For each $e \in \mathscr{E}$ we let

$$M_e^{max} = \max_{s \in \mathscr{S}} \{M_e^s\}. \tag{7.3}$$

That is, M_e^{max} is the largest number of copies of element e that can be found in any species. It is a measure of the extent to which element e combines in a multiplicitous way.

For each $e, e' \in \mathscr{E}$ we let

$$M_e^{max}(e') = \max_{s \in \operatorname{supp} M_{e'}} \{M_e^s\}. \tag{7.4}$$

That is, $M_e^{max}(e')$ is the largest number of copies of element e that can be found in any species *that also contains* e'. Clearly we have

$$M_e^{max}(e') \leq M_e^{max} \tag{7.5}$$

for each $e, e' \in \mathscr{E}$.

By the *degree* of element e we mean

$$\deg(e) = \sum_{e' \in \mathscr{E}} M_e^{max}(e'). \tag{7.6}$$

As we indicated in the introduction, an element will have high degree if it combines gregariously with many different elements or if it combines in high multiplicity with at least one of the elements.

THEOREM 7.3. *Let $\{\mathscr{S},\mathscr{C},\mathscr{R},\mathscr{K},\mathscr{E},\mathscr{M}\}$ be an elemented quasi-thermostatic kinetic system with positive equilibrium set E. For each $c^* \in E$ and each $s \in \mathscr{S}$,*

$$\Lambda^s(c^*) \geq \max_{e\in\mathscr{E}} \left\{ \frac{M_e^s}{\deg(e)} \right\}. \tag{7.7}$$

Moreover,

$$\Lambda(c^*) \geq \min_{s\in\mathscr{S}} \max_{e\in\mathscr{E}} \left\{ \frac{M_e^s}{\deg(e)} \right\}. \tag{7.8}$$

Proof. We begin with the equation

$$M_e = \mathrm{d}\ln\bar{c}\,[\ln T^*] \left(\sum_{e'\in\mathscr{E}} \frac{1}{T^*_{e'}} (M_{e'} * M_e) e' \right), \tag{7.9}$$

which is an immediate consequence of (5.3). Written in terms of components, (7.9) gives for each $e \in \mathscr{E}$ and $s \in \mathscr{S}$,

$$M_e^s = \sum_{e'\in\mathscr{E}} \frac{\partial \ln \bar{c}_s}{\partial \ln T_{e'}}(c^*) \frac{1}{T^*_{e'}} (M_{e'} * M_e). \tag{7.10}$$

From this we can write the inequality

$$M_e^s \leq \sum_{e'\in\mathscr{E}} \left| \frac{\partial \ln \bar{c}_s}{\partial \ln T_{e'}}(c^*) \right| \frac{1}{T^*_{e'}} (M_{e'} * M_e). \tag{7.11}$$

Note that for each $e', e \in \mathscr{E}$ we have

$$\begin{aligned} M_{e'} * M_e = \sum_{s\in\mathscr{S}} M^s_{e'} c^*_s M^s_e &= \sum_{s\in \operatorname{supp} M_{e'}} M^s_{e'} c^*_s M^s_e \\ &\leq M_e^{max}(e') \sum_{s\in \operatorname{supp} M_{e'}} M^s_{e'} c^*_s = M_e^{max}(e') T^*_{e'}. \end{aligned} \tag{7.12}$$

Thus, from inequalities (7.11) and (7.12) and equations (7.1) and (7.6) we obtain for every $e \in \mathscr{E}$ and $s \in \mathscr{S}$ the inequality

$$M_e^s \leq \Lambda^s(c^*) \sum_{e'\in\mathscr{E}} M_e^{max}(e') = \Lambda^s(c^*) \deg(e), \tag{7.13}$$

or equivalently,

$$\Lambda^s(c^*) \geq \frac{M_e^s}{\deg(e)}. \tag{7.14}$$

Since (7.14) holds for every element $e \in \mathscr{E}$, we in fact have, for each $s \in \mathscr{S}$, the bound given in (7.7). The bound (7.8) is then just a consequence of the definition of system sensitivity. □

Example 7.4. In the case of the elemented kinetic system of Example 6.2, we have from (6.4), (7.4), and (7.6) that

$$\deg(A) = 4, \qquad \deg(B) = 4. \tag{7.15}$$

From (6.4), (7.7), and (7.15) we obtain

$$\begin{aligned} \Lambda^{A}(c^*) &\geq \frac{1}{4}, & \Lambda^{B}(c^*) &\geq \frac{1}{4}, \\ \Lambda^{AB}(c^*) &\geq \frac{1}{4}, & \Lambda^{A_2B_2}(c^*) &\geq \frac{1}{2}. \end{aligned} \tag{7.16}$$

Note that the lower bound on the "active" species A_2B_2 is sharp: If, for example, $c^* = \epsilon A + \epsilon B + \epsilon AB + A_2B_2$, then, from (6.5) and (7.1), we have that $\Lambda^{A_2B_2}(c^*) = \frac{1}{2}(1+\epsilon) + o(\epsilon^2)$. Thus, as ϵ tends to zero, $\Lambda^{A_2B_2}$ tends to the lower bound $\frac{1}{2}$ in (7.16). We note that for any choice of c^* there is an assignment of rate constants for network (6.2) consistent with the existence of the equilibrium c^* and at which detailed balance obtains. Thus, there are quasi-thermostatic systems for which, at certain equilibria, the sensitivity of A_2B_2 approaches the stipulated lower bound arbitrarily closely.

Remark 7.5. In a conservative elemented network, for each species $s \in \mathscr{S}$ there exists an element $e \in \mathscr{E}$ such that the e-content of s is positive (Remark 3.2). Thus, inequality (7.7) implies that a species (or system) sensitivity of zero is impossible in conservative quasi-thermostatic systems. It should be noted, however, that kinetic systems exist that *do* allow for zero sensitivity. One such system, proposed in the context of bacterial signaling, is treated in [24]. In this system the quasi-thermostatic condition is *not* satisfied.

Remark 7.6. Because the sensitivities themselves will depend on the choice of elements, so will the bounds given by Theorem 7.3. Consider, for example, the very simple network

$$2A + B \rightleftharpoons A_2B. \tag{7.17}$$

This network can be elemented in various ways: One choice is given by

$$\begin{aligned} M_A &= A + 2A_2B, \\ M_B &= B + A_2B; \end{aligned} \tag{7.18}$$

another equally valid choice is given by

$$\begin{aligned} M_Q &= A + \epsilon B + (2+\epsilon)A_2B, \\ M_R &= A + 2\epsilon B + (2+2\epsilon)A_2B, \end{aligned} \tag{7.19}$$

where ϵ is a positive number much smaller than 1. From Theorem 7.3 we have that, for choice (7.18), the species sensitivities are bounded from below according to the inequalities $\Lambda^A(c^*) \geq \frac{1}{4}$, $\Lambda^B(c^*) \geq \frac{1}{2}$, and $\Lambda^{A_2B}(c^*) \geq \frac{1}{2}$. For the system sensitivity we have that $\Lambda(c^*) \geq \frac{1}{4}$. On the other hand, for choice (7.19) the same theorem gives the bounds $\Lambda^A(c^*) \geq \frac{1}{4} + o(\epsilon)$, $\Lambda^B(c^*) \geq o(\epsilon)$, $\Lambda^{A_2B}(c^*) \geq \frac{1}{2}$, and $\Lambda(c^*) \geq o(\epsilon)$. Thus, different choices of basis for $\mathrm{S}^{\perp}$ can lead to markedly different lower bounds. Note that while choice (7.18) carries a natural interpretation for the elements A and B as building blocks that appear either overtly as species or latently in the compound A_2B, choice (7.19) offers no immediate physical interpretation for the elements Q and R.

Note also, that in the general case, if each vector in the basis for $\mathrm{S}^{\perp}$ is multiplied by a (potentially different) scalar, then the lower bounds corresponding to the new basis remain unchanged.

The bounds given in Theorem 7.3 give rise to different (weaker) bounds that are stated not in terms of the *degrees* of the elements, but, rather, in terms of what we call the element *connectivities.* For each $e \in \mathscr{E}$ we denote by $\Gamma(e)$ the set of elements that appear together with e in at least one species. More precisely,

$$\Gamma(e) = \{e' \in \mathscr{E} : \operatorname{supp} M_{e'} \cap \operatorname{supp} M_e \neq \emptyset\}\,. \tag{7.20}$$

By the *connectivity* of e we mean the number of such elements:

$$\operatorname{conn}(e) := \#(\Gamma(e)). \tag{7.21}$$

From (7.5) and (7.6) it is not difficult to see that

$$\deg(e) \leq \operatorname{conn}(e) M_e^{max}. \tag{7.22}$$

Thus from Theorem 7.3 we have the following.

Corollary 7.7. *Let $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{K}, \mathscr{E}, \mathscr{M}\}$ be an elemented quasi-thermostatic system with positive equilibrium set E. For each $c^* \in E$ and each $s \in \mathscr{S}$,*

$$\Lambda^s(c^*) \geq \max_{e \in \mathscr{E}} \left\{ \frac{M_e^s}{\operatorname{conn}(e) M_e^{max}} \right\} \tag{7.23}$$

and

$$\Lambda(c^*) \geq \min_{s \in \mathscr{S}} \max_{e \in \mathscr{E}} \left\{ \frac{M_e^s}{\operatorname{conn}(e) M_e^{max}} \right\}. \tag{7.24}$$

8. Constructive reaction networks. By a *constructive reaction network* we mean an elemented network with special properties: Its elements can be identified with certain building blocks that appear explicitly as species of the network and from which all other species are constructed by means of the network's reactions. Example 3.3, which is based on network (1.1) in the introduction, is an example of a constructive reaction network.

Definition 8.1. *A* constructive reaction network *is an elemented reaction network $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{E}, \mathscr{M}\}$ such that $\mathscr{E} \subset \mathscr{S}$ and such that, for each $e \in \mathscr{E}$,*

$$M_e = e + \sum_{q \in \mathscr{Q}} M_e^q q, \tag{8.1}$$

where $\mathscr{Q} = \mathscr{S} \setminus \mathscr{E}$, and where the M_e^q take nonnegative integer values. The members of $\mathscr{Q}$ are called the compounds *of the network.*

For constructive networks the following proposition indicates the sense in which the compounds are built from the elements in terms of reactions appearing in the network.

Proposition 8.2. *Let $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{E}, \mathscr{M}\}$ be a constructive reaction network. Then the set*

$$\left\{ q - \sum_{e \in \mathscr{E}} M_e^q e : q \in \mathscr{Q} \right\} \tag{8.2}$$

is a basis for the stoichiometric subspace S.

Proof. Clearly, the vectors of (8.2) are linearly independent and their number is equal to dim S. To see that they are in fact members of S, it is enough to show that each of the vectors in (8.2) is orthogonal to all the vectors of (8.1). Toward this end, note that for each $q' \in \mathscr{Q}$ and each $e' \in \mathscr{E}$,

$$\left(q' - \sum_{e \in \mathscr{E}} M_e^{q'} e\right) \cdot \left(e' + \sum_{q \in \mathscr{Q}} M_{e'}^q q\right) = M_{e'}^{q'} - M_{e'}^{q'} = 0. \qquad \square$$

Remark 8.3. The vectors of (8.2) can be viewed as "reaction vectors" that derive from the "reactions"

$$\left\{\sum_{e \in \mathscr{E}} M_e^q e \to q : q \in \mathscr{Q}\right\}. \tag{8.3}$$

Each of these "reactions" can be regarded as representing the production of a particular compound *solely* from the elements. Of course, these "construction" reactions need not all be "true" reactions of the original network, but, at least in terms of stoichiometry, each of the "true" reactions can be regarded as a linear combination of the "construction" reactions. Similarly, each member of (8.3) can be viewed as an overall reaction—one for each compound—that derives from a linear combination of the "true" reactions. Hence, the "true" reactions can be viewed as machinery for constructing the compounds from the elements.

Remark 8.4. Proposition 8.2 provides a way to distinguish a reaction network that might be constructive (for a suitable choice of elements) from one that cannot be constructive. For example, network (3.2) has a one-dimensional stoichiometric subspace spanned by $Y + Z - X - W$. Thus, there is no partition of the species set into elements and compounds that is consistent with a basis for the stoichiometric subspace of the form (8.2).

We note that for a *constructive* kinetic system the elements themselves are species, and so it makes sense to speak of their sensitivities. Recall that for a constructive system we have, for each pair $e, e' \in \mathscr{E}$, that $M_e^{e'}$ is 0 if $e' \neq e$ and is 1 otherwise. This observation gives rise to the following corollary to Theorem 7.3.

Corollary 8.5. *Let $\{\mathscr{S}, \mathscr{C}, \mathscr{R}, \mathscr{K}, \mathscr{E}, \mathscr{M}\}$ be a constructive quasi-thermostatic system with positive equilibrium set E. For each $c^* \in E$ and each $e \in \mathscr{E}$,*

$$\Lambda^e(c^*) \geq \frac{1}{\deg(e)} \geq \frac{1}{\operatorname{conn}(e) M_e^{max}}. \tag{8.4}$$

Moreover,

$$\Lambda(c^*) \geq \min_{e \in \mathscr{E}} \left\{\frac{1}{\deg(e)}\right\} \geq \min_{e \in \mathscr{E}} \left\{\frac{1}{\operatorname{conn}(e) M_e^{max}}\right\}. \tag{8.5}$$

Remark 8.6. For any elemented network, it is apparent that, for each element $e \in \mathscr{E}$, $\operatorname{conn}(e) \leq \#(\mathscr{E})$. If we let

$$M^{max} := \max_{e \in \mathscr{E}} \{M_e^{max}\}, \tag{8.6}$$

then we have

$$\deg(e) \leq \operatorname{conn}(e) M_e^{max} \leq \#(\mathscr{E}) M^{max}. \tag{8.7}$$

For a constructive kinetic system in particular we get a crude bound on the system sensitivity:

$$\Lambda(c^*) \geq \frac{1}{\#(\mathscr{E})M^{max}}. \tag{8.8}$$

Although this bound is far less nuanced than (8.5), it already tells us that high system robustness (low sensitivity) requires that the system have a large number of elements or that it contain at least one species having high element content (or a combination of both).

9. Concluding remarks.

Remark 9.1. We emphasized both in the introduction and in section 7 that the species sensitivity bounds given in Theorem 7.3 depend on network structure alone, independent of kinetics or even of the equilibrium state at which they are evaluated. In fact, even the fine details of the reaction network are of limited consequence:

For a quasi-thermostatic kinetic system the entire equilibrium set is determined by specification of just one equilibrium state and the stoichiometric subspace for the underlying network of chemical reactions. This is to say that two elemented quasi-thermostatic systems that share a common equilibrium state and the same stoichiometric subspace have precisely the same positive equilibrium sets and, therefore, *the same species sensitivities (relative to the same choice of elements).* To the extent that the network influences the equilibrium set, then, that influence is felt through the stoichiometric subspace. In turn, the stoichiometric subspace is merely the span of the network's reaction vectors, but the same span might derive from two rather different reaction networks.

Certainly, though, there is *some* network information carried by the stoichiometric subspace S, and therefore, by its orthogonal complement $S^\perp$. Indeed, the sensitivity formulas given by Theorem 7.3 derive squarely from the nature of $S^\perp$ and the particular elemental basis chosen for it.

Remark 9.2. As we indicated earlier, the sensitivity bounds derived for elemented systems suggest that strong robustness (i.e., very low sensitivity) against fluctuations in the element concentrations requires that the elements manifest themselves within the species in high multiplicity or that the species combine with each other gregariously. There is a certain intuitive sense to these requirements, for when they are met, the effect of changes in an element's total concentration can be attenuated through propagation across many species or buffered within species containing multiple instances of that element. It is striking that the requirements for high robustness are highly suggestive of biochemistry, in which large molecules are often built from multiple copies of many distinct elements that readily combine with each other by means of relatively large reaction networks.

ANALYSIS OF HEPATITIS C VIRUS INFECTION MODELS WITH HEPATOCYTE HOMEOSTASIS[*]

TIMOTHY C. RELUGA[†], HAREL DAHARI[§], AND ALAN S. PERELSON[¶]

Abstract. Recently, we developed a model for hepatitis C virus (HCV) infection that explicitly includes proliferation of infected and uninfected hepatocytes. The model predictions agree with a large body of experimental observations on the kinetics of HCV RNA change during acute infection, under antiviral therapy, and after the cessation of therapy. Here we mathematically analyze and characterize both the steady state and dynamical behavior of this model. The analyses presented here not only are important for HCV infection but also should be relevant for modeling other infections with hepatotropic viruses, such as hepatitis B virus.

Key words. HCV, viral dynamics, bifurcation analysis

1. Introduction.

Approximately 200 million people worldwide [38] are persistently infected with the hepatitis C virus (HCV) and are at risk of developing chronic liver disease, cirrhosis, and hepatocellular carcinoma. HCV infection therefore represents a significant global public health problem. HCV establishes chronic hepatitis in 60%–80% of infected adults [46]. A vaccine against infection with HCV does not exist, and standard treatment with interferon-α and ribavirin has produced sustained virological response rates of approximately 50%, with no effective alternative treatment for nonresponders to this treatment protocol [13, 30].

A model of human immunodeficiency virus infection [40, 52] was adapted by Neumann et al. [37] to study the kinetics of chronic HCV infection during treatment. Since then viral kinetics modeling has played an important role in the analysis of HCV RNA decay during antiviral therapy (see Perelson [41], Perelson et al. [42]). The original Neumann et al. model for HCV infection [37] included three differential equations representing the populations of target cells, productively infected cells, and virus (Figure 1). A simplified version of the model, which assumes a constant population of target cells, was used to estimate the rates of viral clearance and infected cell loss by fitting to the model the decline of HCV RNA observed in patients during the first 14 days of therapy [37]. However, this simplified version of the model is not able to explain some observed HCV RNA kinetic profiles under treatment [4]. To model complex HCV kinetics, the assumption of a constant level of target cells needs to be relaxed, requiring one to model as correctly as possible the dynamics of the target cell population. Since it has been suggested that hepatocytes, the major cell type in the liver, are also the major producers of HCV [10, 3, 43], we assume here that the

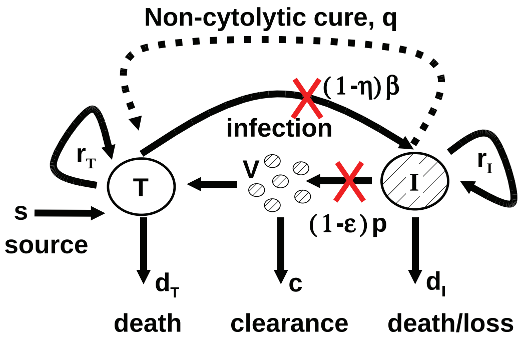

FIG. 1. *Schematic representation of HCV infection models. T and I represent target and infected cells, respectively, and V represents free virus. The parameters shown in the figure are defined in the text. The original model of Neumann et al.* [37] *assumed that there is no proliferation of target and infected cells (i.e., $r_T = r_I = 0$) and no spontaneous cure (i.e., $q = 0$). The extended model of Dahari, Ribeiro, and Perelson* [6]*, which was used for predicting complex HCV kinetics under therapy, includes target and infected cell proliferation without cure ($r_T, r_I > 0$ and $q = 0$). A model including both proliferation and the spontaneous cure of infected cells (dashed line; $q > 0$) was used to explain the kinetics of HCV in primary infection in chimpanzees* [5].

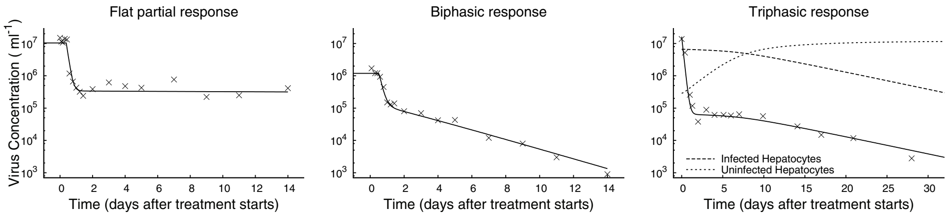
target cells of the model are hepatocytes.

The liver is an organ that regenerates, and due to homeostatic mechanisms, any loss of hepatocytes would be compensated for by the proliferation of existing hepatocytes [12, 32]. However, besides replication of existing hepatocytes, another mechanism of liver cell generation is present (termed here immigration), i.e., differentiation of liver progenitor cells or bone marrow cells [12].

In prior work, we have shown that including proliferation of both target cells and infected cells increases the ability of the model to explain experimental data [4, 6]. Because HCV infection is generally thought to be noncytopathic, i.e., infection per se does not kill a cell [31], proliferation of infected cells has been included in the model. Studying the effects of varying the rate of infected cell proliferation from zero (no proliferation) to rates in excess of the rate proliferation of uninfected cells [34], as might occur by an oncogenic effect, is one of the goals of this work.

HCV is an RNA virus that replicates in the cytoplasm of an infected cell [25]. Due to the action of endogenous nucleases or microRNAs, it is in principle possible for a cell to clear viral RNA [2, 39]. Some of our prior modeling of acute HCV infection in chimpanzees required the inclusion of this type of "cure" of infected cells in order to explain the kinetics of HCV clearance without a massive loss of liver cells that would have led to the animals' death [5]. Thus, the effects of cure of infected cells is also studied in the analysis provided below.

During antiviral therapy for HCV infection, patients may exhibit a flat partial response or a biphasic decline in HCV RNA (Figure 2(left) and (middle)). In addition, a triphasic pattern of HCV RNA decline (Figure 2(right)) has been observed in some treated patients [19]. In these patients, HCV RNA initially falls very rapidly, by 1–2 orders of magnitude during the first day or two of therapy. Then HCV RNA decline ceases, and a "shoulder phase" that can last from days to many weeks is observed. This shoulder phase can persist, in which case it has been called a flat second phase, or it can be followed by a renewed phase of HCV RNA decline; in this case the pattern



Flat partial response

Biphasic response

Triphasic response

FIG. 2. *Three example plots of observed changes in viral load (X) following the start of treatment, together with numerical solutions to system* (2.1) *(solid line). The initial condition of each numerical solution is the chronic-infection steady state. In some cases, there is a flat partial response to treatment (left), where viral load shows an immediate drop but then remains unchanged over time. In some cases, there is a biphasic response (middle), with a rapid initial drop and a slower asymptotic clearance. In some cases, there is a triphasic response, with a rapid initial drop, an intermediate shoulder phase during which there is little change, and then an asymptotic clearance phase. The initial rapid decline in virus load is the synchronization to the new quasi-steady state, following the start of treatment. Afterward, virus load closely tracks the number of infected cells (right). Treatment efficacies are* $\epsilon = 0.98, \eta = 0$ *(left),* $\epsilon = 0.9, \eta = 0$ *(middle), and* $\epsilon = 0.996, \eta = 0$ *(right). Other parameter values are shown in Table* 2.1*.*

has been called triphasic [4, 6]. Another of the goals of this paper is to understand the origin of the triphasic response and to compute from the model the length of the shoulder phase as a function of model parameters. As the length of the shoulder phase approaches zero, a triphasic response transforms into a biphasic response, and thus studying triphasic responses provides a general framework for understanding treatment response kinetics.

In order to accomplish our various goals, we first describe the model and its parameters. Then we study the model's steady states and their stability. Using a perturbation analysis approach, we show how the shoulder phase arises and provide an approximate formula from which one can calculate its length.

2. Model. The model proposed by Dahari and coworkers [6, 4] expands on the standard HCV viral-dynamic model [37] of infection and clearance by incorporating density-dependent proliferation and death (Figure 1). Uninfected hepatocytes, T, are infected at a rate β per free virus per hepatocyte. Infected cells, I, produce free virus at rate p per cell but also die with rate d_I. Free virus is cleared at rate c by immune and other degradation processes. Besides infection processes, hepatocyte numbers are influenced by homeostatic processes. Uninfected hepatocytes die at rate d_T. Both infected and uninfected hepatocytes proliferate logistically with maximum rates r_I and r_T, respectively, as long as the total number of hepatocytes is less than $T_{\max}$. Besides proliferation, uninfected hepatocytes may increase in number through immigration or differentiation of hepatocyte precursors that develop into hepatocytes at constitutive rate $\hat{s}$, or by spontaneous cure of infected hepatocytes through a noncytolytic process at rate $\hat{q}$. Treatment with antiviral drugs reduces the infection rate by a fraction η and the viral production rate by a fraction ϵ. The corresponding system of differential equations is

$$\frac{\mathrm{d}T}{\mathrm{d}\hat{\mathrm{t}}} = \hat{s} + r_T T \left(1 - \frac{T+I}{T_{\max}}\right) - d_T T - (1-\eta)\beta V T + \hat{q} I, \tag{2.1a}$$

$$\frac{\mathrm{d}I}{\mathrm{d}\hat{\mathrm{t}}} = r_I I \left(1 - \frac{T+I}{T_{\max}}\right) + (1-\eta)\beta V T - d_I I - \hat{q} I, \tag{2.1b}$$

$$\frac{\mathrm{d}V}{\mathrm{d}\hat{\mathrm{t}}} = (1-\epsilon) p I - cV, \tag{2.1c}$$

where the time $\hat{t}$ is measured in days. Table 2.1 shows estimated ranges for the parameters.

System (2.1) has a three-dimensional phase-space and a twelve-dimensional parameter space, so despite the relative simplicity, the full dynamics are difficult to classify. Fortunately, there are some natural simplifications. The range of rates of viral clearance shown in Table 2.1 is significantly faster than the other time-scale parameters. In numerical simulations (Figure 2), after an initial transient the viral dynamics closely track the dynamics of infected cells. This suggests that viral dynamics can be decomposed into two time scales: a fast time scale starting at $\hat{t}_0$ where the number of infected hepatocytes, I, is relatively constant and

$$V(\hat{t}) \approx \frac{(1-\epsilon)p}{c} I(\hat{t}_0) + \left[V(\hat{t}_0) - \frac{(1-\epsilon)p}{c} I(\hat{t}_0) \right] e^{-c(\hat{t}-\hat{t}_0)}, \tag{2.2}$$

and a slow time scale where

$$V(\hat{t}) \approx \frac{(1-\epsilon)p}{c} I(\hat{t}). \tag{2.3}$$

For patients in steady state before treatment, as is typically the case, $I(\hat{t}_0) = cV(\hat{t}_0)/p$, allowing one to simplify (2.2) to

$$V(\hat{t}) = (1-\epsilon)V(\hat{t}_0) + \epsilon V(\hat{t}_0) e^{-c(\hat{t}-\hat{t}_0)}. \tag{2.4}$$

On time scales longer than $1/c$, then, the dynamics of system (2.1) can be approximated by a system of two equations. If we now introduce the dimensionless time $t = (r_T - d_T)\hat{t}$, the dimensionless state variables

$$x = \frac{T}{T_{\max}}, \quad y = \frac{I}{T_{\max}}, \tag{2.5}$$

and the dimensionless parameters

$$\begin{gathered} s = \frac{\hat{s} r_T}{(r_T - d_T)^2 T_{\max}}, \quad b = \frac{p \beta T_{\max}}{c r_T}, \quad q = \frac{\hat{q}}{r_T - d_T}, \\ r = \frac{r_I}{r_T}, \quad d = \frac{d_I r_T - d_T r_I}{r_T (r_T - d_T)}, \quad 1 - \theta = (1-\epsilon)(1-\eta), \end{gathered} \tag{2.6}$$

then under the quasi-steady state approximation, system (2.1) is equivalent to the dimensionless system

$$\dot{x} = x\,(1 - x - y) - (1 - \theta)byx + qy + s, \tag{2.7a}$$

$$\dot{y} = ry\,(1 - x - y) + (1 - \theta)byx - dy - qy. \tag{2.7b}$$

Note that a fundamental assumption in the transformation to system (2.7) is that $r_T > d_T$, which we expect because of the hepatocyte population's ability to support itself and to regenerate itself after injury.

Immigration of new hepatocytes is believed to be slow ($< 1\%$ per day; Table 2.1) relative to the total number of hepatocytes (i.e., $s \ll 1$). Spontaneous cure from HCV has not yet been directly observed. It has been suggested to occur based on the kinetics of HCV clearance and liver damage in humans [51] and in chimpanzees [5]. Therefore, in a first analysis, we assume that $s = q = 0$. Later, we reintroduce these parameters and examine their effects via a perturbation analysis. Dropping the s and q terms, system (2.7) simplifies to

$$\dot{x} = x\,(1 - x - y) - (1 - \theta)byx, \tag{2.8a}$$

$$\dot{y} = ry\,(1 - x - y) + (1 - \theta)byx - dy. \tag{2.8b}$$

Most of the parameter ranges from Table 2.1 are captured by allowing $b \in [10^{-2}, 10^3]$ and $d \in [10^{-3}, 10^2]$. r_I has not yet been studied experimentally, and thus we cannot bound r beyond the trivial statement that $r \geq 0$.

Gómez-Acevedo and Li [14] have previously studied some of the properties of system (2.8) in the context of human T-cell lymphotropic virus type I. It is a simple model with only three independent parameters and dynamics that can be completely analyzed using phase-plane analysis and algebraic methods while still encapsulating the fundamental concepts of system (2.1). system (2.8) diverges from common viral dynamics models in the homeostasis parameter r. When $r = 0$, system (2.8) is naturally interpreted as an epidemic model, a viral infection model, or a predator-prey model. When the epidemic model is extended to include logistic homeostasis with $r > 0$, the infected cells can also proliferate independent of x but experience additional density-dependent mortality as a function of the total population size $x+y$. This paper explores the consequences of this homeostasis. We will first study systems (2.7) and (2.8) during acute infection. We will then study the response of these systems to treatment.

3. Dynamics without treatment ($\boldsymbol{\theta = 0}$).

When HCV first infects a person, the ensuing dynamics depend on the relative parameter values. Since newly infected individuals do not know that they are infected, we assume that there is initially no treatment ($\theta = 0$). At first glance, we might expect several different scenarios to ensue following exposure: infection may fade out without becoming established, infection may spread with limited success and infect only part of the liver, or infection may spread rapidly and infect the whole liver. To understand when the dynamics of system (2.7) under acute infection correspond to each of these situations, it is helpful to walk through the bifurcation structure of system (2.8).

3.1. Without immigration or spontaneous cure.

When there is no immigration ($s = 0$) or spontaneous cure ($q = 0$), the dynamics are described by system (2.8). system (2.8) is a variant of the Lotka–Volterra equations studied extensively in ecology [21]. The $\dot{x}$-nullclines are $x = 0$ and $y = (1 - x)/(1 + b)$. The $\dot{y}$-nullclines

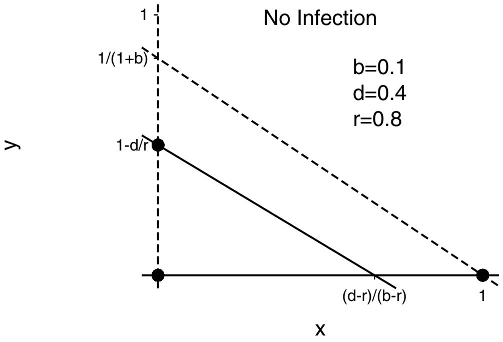

FIG. 3. *Example nullclines for system* (2.8) *when the disease-free equilibrium is globally attracting. The liver-free ($x = y = 0$), disease-free ($x = 1, y = 0$), and total-infection ($x = 0, y = 1 - d/r$) stationary solutions are marked with dots. The solid lines are the $\dot{y}$-nullclines, and the dotted lines are the $\dot{x}$-nullclines. The partial-infection stationary solution is not present for these parameter values.*

TABLE 3.1
Stationary solutions for system (2.8) *and their characteristics.*

Stationary point	Location	Bifurcation conditions	Local stability condition
Liver-free	$(0, 0)$	$r = d$	Never stable
Disease-free	$(1, 0)$	$b = d$	$b < d$
Total-infection	$(0, 1 - d/r)$	$r = d + d/b$, $r = d$	$r > d + d/b$
Partial-infection	$\left(\frac{db + d - br}{b(1 + b - r)}, \frac{b - d}{b(1 + b - r)}\right)$	$r = d + d/b$, $b = d$	$rb/(1 + b) < d < b$

are $y = 0$ and $y = 1 - d/r - (1 - b/r)x$ (see Figure 3). Up to four stationary solutions to system (2.8) can be found at the intersections of the $\dot{x}$ and $\dot{y}$ nullclines. They are

$$(0, 0), \quad (1, 0), \quad \left(0, 1 - \frac{d}{r}\right), \quad \text{and} \quad \left(\frac{db + d - br}{b(1 + b - r)}, \frac{b - d}{b(1 + b - r)}\right), \tag{3.1}$$

respectively the liver-free solution, the disease-free solution, the total-infection solution, and the partial-infection solution. The locations and stability conditions for the stationary solutions are summarized in Table 3.1.

The bifurcations and stability of these four stationary solutions depend on the parameter values in ways summarized in Table 3.1. system (2.8)'s Jacobian is

$$\mathbf{J} = \begin{bmatrix} 1 - 2x - y - by & -x(1 + b) \\ -ry + by & r(1 - x - 2y) - d + bx \end{bmatrix}. \tag{3.2}$$

The classification of the parameter space is summarized in Figure 4, with examples of each region's nullclines given in Figure 5. Before treatment, the reproductive number of infection

$$\mathcal{R} = \frac{b}{d} \tag{3.3}$$

at the disease-free equilibrium $(1, 0)$. In order for HCV to infect the liver, $\mathcal{R}$ must be greater than 1, indicating that on average an infected hepatocyte causes more than one uninfected cell to become infected. The eigenvalues at the disease-free equilibrium

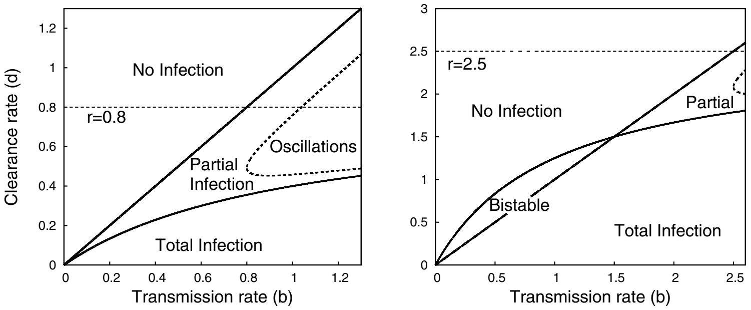

Fig. 4. *Plot representing the parameter regions for asymptotic dynamics of system* (2.8) *when* $r = 0.8$ *(left) or* $r = 2.5$ *(right). Within the region marked partial infection, the dotted line is the boundary between monotone convergence and oscillatory convergence to the partial infection steady state.*

are $\lambda = -1$, corresponding to the eigenvector $[1, 0]$, and $\lambda = b - d$, corresponding to the eigenvector $[-1 - b, 1 + b - d]$. If $\mathcal{R} < 1$, the disease-free solution $(1, 0)$ is locally attracting. If $\mathcal{R} > 1$, HCV infects new cells faster than infected cells die, and the asymptotic dynamics may correspond to either partial or total infection of the liver.

The liver-free stationary solution $(0, 0)$ is always unstable, switching between a saddle point when infected cells die quickly ($r < d$) and an unstable node when infected cells die slowly ($d < r$). If the proliferation rate is slower than the death rate ($r < d$), then HCV can never totally infect the liver. There is a transcritical bifurcation at $d = r$, and the total-infection stationary solution $(0, 1 - d/r)$ is feasible only when the proliferation rate of infected cells is greater than the excess death rate

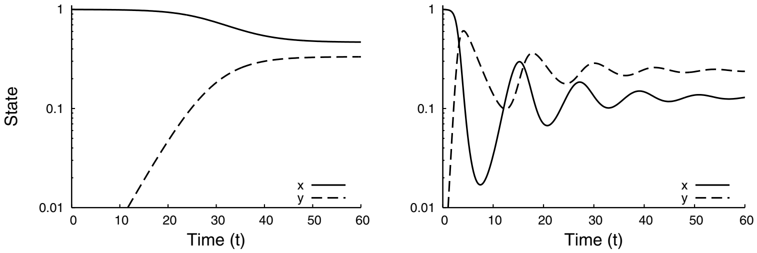

Fig. 6. *Time series for system* (2.7) *of monotone (left,* $r = 0.6, b = 0.6$*) and oscillatory (right,* $r = 0.1, b = 2.6$*) convergence to the partial infection stationary solution when* $d = 0.4$*.*

of infected cells (Figure 4). From the Jacobian, we see that if $d+d/b < r$ (equivalently, $d < rb/(1+b)$), total infection is locally stable, and from the general theory of Lotka–Volterra systems, it is globally stable, provided $d < \min\{b, \frac{rb}{1+b}\}$. This includes all cases where $d < 0$.

The partial-infection stationary solution is present whenever d lies between b and $\frac{rb}{1+b}$. The local stability of the partially infected stationary solution can be determined from the characteristic polynomial

$$\lambda^2 + \frac{d}{b}\lambda + \frac{(d-b)(br-bd-d)}{b(1+b-r)} = 0, \tag{3.4}$$

where λ is an eigenvalue. If $b < d < \frac{rb}{1+b}$, the constant term of the characteristic polynomial at the partial-infection stationary solution is negative, implying (by Decartes' rule of sign) that there is a single positive root and that the partial-infection steady state is a saddle point. In this situation, we can show that both the disease-free and the total-infection stationary solutions are locally stable. As first shown in Gómez-Acevedo and Li [14], the system is bistable, and the asymptotic dynamics will depend on the initial conditions. The constraint $r < 1$ is sufficient to preclude bistability.

When $b > d > \frac{rb}{1+b}$, the coefficients d/b and

$$\frac{(d-b)(br-bd-d)}{b(1+b-r)} \tag{3.5}$$

of the characteristic polynomial are both positive. From the Routh–Hurwitz conditions [35], it follows immediately that the partial-infection stationary solution is locally stable. From prior work on Lotka–Volterra equations [20], we know that it is also globally stable.

Convergence to the partial-infection stationary solution can be oscillatory if the eigenvalues are complex, or monotone if the eigenvalues are real (Figure 6). Calculation of the discriminant shows that the convergence is oscillatory whenever

$$\frac{d^2}{4b^2} - \frac{(b-d)(rb-db-d)}{b(r-1-b)} < 0. \tag{3.6}$$

This inequality is not easy to interpret by inspection, but it is quadratic in d, and so it is easy to handle numerically. The boundaries of the subset of parameter space where convergence is oscillatory asymptotically converge to $d(b) = r$ and $d(b) = b$ as b diverges to ∞. When convergence is oscillatory, the period of oscillations around

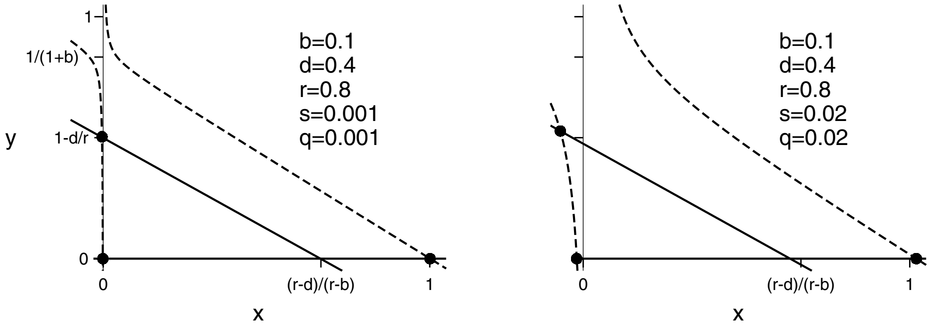

FIG. 7. *Example nullclines for system* (2.7) *when the disease-free equilibrium is globally attracting for immigration and spontaneous clearance rates* $s = q = 0.001$*(left) or* $s = q = 0.02$ *(right). The liver-free, disease-free, and total-infection stationary solutions are marked with dots. The liver-free and total-infection stationary solutions have negative* x *coordinates when the immigration and spontaneous clearance rates are positive. The solid lines are the* $\dot{y}$*-nullclines, and the dotted lines are the* $\dot{x}$*-nullclines. The partial-infection stationary solution is not present for these parameter values.*

the stationary solution is

$$\frac{2\pi}{\sqrt{\frac{d^2}{4b^2} - \frac{(b-d)(rb-db-d)}{b(r-1-b)}}}. \tag{3.7}$$

A sufficient condition for monotone convergence to the partial-infection stationary solution instead of oscillations is $b < r$, in which case the convergence rate is governed by the slowest eigenvalue,

$$-\frac{d}{2b} + \sqrt{\frac{d^2}{4b^2} + \frac{(b-d)\,(b\,r - d - b\,d)}{b\;(b+1-r)}}. \tag{3.8}$$

3.2. With immigration and spontaneous cure. Including immigration ($s > 0$) and spontaneous clearance ($q > 0$) in system (2.7) changes the dynamics of system (2.8) in small but important ways (Figure 7). The two $\dot{y}$-nullclines are $y = 0$ and

$$y = \left(\frac{b}{r} - 1\right)x + 1 - \frac{d+q}{r}. \tag{3.9}$$

Spontaneous clearance moves the nullcline given by (3.9) slightly to the left, but the $\dot{y}$-nullclines are basically the same as those of system (2.8). The change in the $\dot{x}$-nullclines is more pronounced. The only $\dot{x}$-nullcline in system (2.7) is

$$y = \frac{s + x(1-x)}{x + bx - q}. \tag{3.10}$$

The $\dot{x}$-nullclines have changed from a pair of intersecting lines in system (2.8) to a hyperbola in system (2.7). The shape of the hyperbola is still the same as those of system (2.8) except near the intersection point $(0, 1 - d/r)$. The hyperbola is also shifted slightly down and to the right compared to system (2.8) (Figure 7). For large positive and negative x, the nullcline is approximately equal to $(1-x)/(1+b)$. There

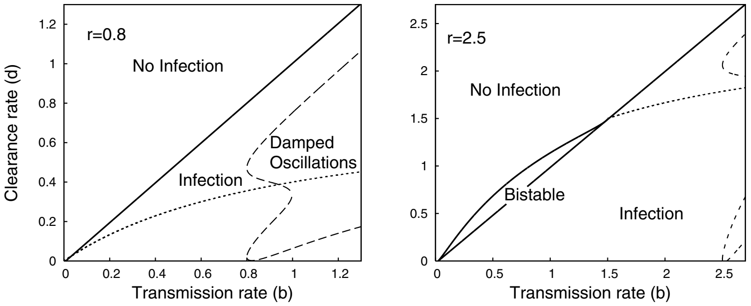

Fig. 8. *Plot representing the parameter regions for asymptotic dynamics of system* (2.7) *with* $s = 0.01$, $q = 0$ *when* $r = 0.8$ *(left) or* $r = 2.5$ *(right). Compare to Figure* 3. *The dashed line represents the boundary of the parameter region where convergence to the steady state exhibits damped oscillations. The dotted line represents the bifurcation boundary between partial and total infection when* $s = q = 0$. *However, there is no formal bifurcation between partial and total infection if* s *or* q *is positive because of the structural instability of the transcritical bifurcation in system* (2.8).

is a vertical asymptote at $x = q/(1 + b)$. The nullcline is positive just to the right of this asymptote and negative just to its left. The $\dot{x}$-nullcline's unique y-intercept is $y = -s/q$. This implies that there can be no biologically feasible stationary solutions with $x \leq q/(1 + b)$; i.e., total hepatocyte loss is no longer a stationary solution because the model now includes a perpetual source of new hepatocytes. This change also means that there is no longer a bifurcation between partial and total infection (see Figure 8).

Two stationary solutions to system (2.7) solve

$$x^2 - x - s = 0 \quad \text{with} \quad y = 0. \tag{3.11}$$

The exact solutions are

$$\left(\frac{1 \pm \sqrt{1 + 4s}}{2}, 0\right). \tag{3.12}$$

When s is very small, the solutions of (3.11) are approximately

$$(-s + o(s), 0) \quad \text{and} \quad (1 + s + o(s), 0). \tag{3.13}$$

The solution with the negative square root can never appear biologically because it predicts a negative number of uninfected hepatocytes.

The other two stationary solutions of system (2.7) solve

$$b\,(1 + b - r)\,x^2 + [(rb - db - d) + q\,(r - 1 - 2\,b)]\,x - sr - (r - d - q)\,q = 0, \tag{3.14a}$$

$$\text{with} \quad y = \left(\frac{b}{r} - 1\right) x + 1 - \frac{d + q}{r}. \tag{3.14b}$$

The solutions can be expressed in terms of radicals, but greater intuition of the effects of s and q relative to the stationary solutions of system (2.8) can be gained through perturbation analysis (see Appendix A). When $d < \min\{b, rb/(1 + b)\}$, the one biologically meaningful solution to (3.14) is

(3.15)

$$(x,y) = \left(\frac{q(r-d)+sr}{rb-bd-d} + o(s,q), 1 - \frac{d}{r} + \frac{(r-b)\,s}{d+bd-br} - \frac{\left(r^2-rd-d\right)q}{r\,(-d-bd+br)} + o(s,q) \right),$$

corresponding to the total-infection stationary solution of system (2.8) but with a small number of uninfected cells sustained by the sources s and q. The $o(s,q)$ terms in (3.16) hide higher order effects in s and q that vanish quadratically or faster as s and q approach zero. When $rb/(1+b) < d < b$,

$$x = \frac{d+db-rb}{b\,(1+b-r)} - \frac{rs}{rb-d-db} + \frac{\left(rb^2+rd-d-2db-db^2\right)}{b\,(1+b-r)\,(rb-d-db)}q + o(s,q), \tag{3.16a}$$

$$y = \frac{b-d}{b\,(1+b-r)} - \frac{s\,(b-r)}{rb-d-db} - \frac{\left(b^2-2\,db+rd-d\right)q}{b\,(1+b-r)\,(rb-d-db)} + o(s,q) \tag{3.16b}$$

is an approximate solution corresponding to the partial-infection stationary solution of system (2.8). The other solution of (3.14) is negative.

When $b < d < rb/(1+b)$, both solutions to (3.14) are positive. Again, this can occur only when $r > 1$, i.e., when infected cells proliferate faster than uninfected ones. Approximate locations are given by (3.15) and (3.16). The bifurcation between zero and two roots is a saddle-node bifurcation where the root with smaller x value is a stable node and the root with larger x value is a saddle. The calculation of the exact condition for bistability when s or q is positive is algebraically opaque, requiring the solution of a pair of polynomials that are quadratic in d and a test to distinguish bistability outside the positive quadrant from bistability inside the positive quadrant. The net effect in system (2.7) of this complexity is a minor perturbation of that found for system (2.8) (compare Figures 4 and 8). Immigration and spontaneous clearance shrink the bistable region of parameter space slightly and shift it so that it occurs for slightly smaller values of d.

The local stability of the stationary solutions to system (2.7) is predicted by the Jacobian matrix

$$\mathbf{J} = \begin{bmatrix} 1-2x-y-by & -x(1+b)+q \\ -ry+by & r\,(1-x-2y)-d+bx-q \end{bmatrix}. \tag{3.17}$$

The disease-free stationary solution loses stability through a transcritical bifurcation that occurs at $\det \mathbf{J} = 0$. Substituting $y = 0$ into $\mathbf{J}$, $\det \mathbf{J} = 0$ if $x = 1/2$ or $(b-r)x = d+q-r$. Using the approximation $x = 1+s+o(s)$, we can show that the disease-free stationary solution is stable when

$$(1+s)b < d+q+rs+o(s). \tag{3.18}$$

Local stability of the other stationary solutions to system (2.7) can also be approximated analytically, but resulting formulas are difficult to interpret.

4. Treatment effects.

Treatment effects appear in systems (2.7) and (2.8) only through a multiplicative factor $(1-\theta)$ reducing the transmission rate b, where θ is the dimensionless treatment efficacy. Thus, the stationary solution structure of systems (2.7) and (2.8) under treatment is summarized by replacing the x-axis labels

Table 4.1

Classification of the dynamics of system (2.7) *for* $b > d$, $0 < s \ll 1$, $0 < q \ll 1$. *These classifications are only approximate. Parameter values that fall near the boundaries of any of these regions may have dynamics that fit multiple classifications. See Figures* 9 *and* 10 *for graphical depictions and example time series.*

Pretreatment	Pretreatment state	Treatment	Treatment dynamics
$r < d$	Partial infection		
		$\theta < \theta_c$	Reduced infection
		$\theta > \theta_c$	Clearance, no treatment delay
$d < r < d + \frac{d}{b}$	Partial infection		
		$\theta < \theta_c$	Reduced infection
		$\theta > \theta_c$	Clearance, weak treatment delay
$d + \frac{d}{b} < r < d + 1$	Near total infection		
		$\theta < \theta_p$	No effect
		$\theta_p < \theta < \theta_c$	Reduced infection
		$\theta_c < \theta$	Clearance, strong treatment delay
$d + 1 < r$	Near total infection		
		$\theta < \theta_p$	No effect
		$\theta_p < \theta < \theta_c$	Bistable, no effect
		$\theta_c < \theta$	Clearance, strong treatment delay

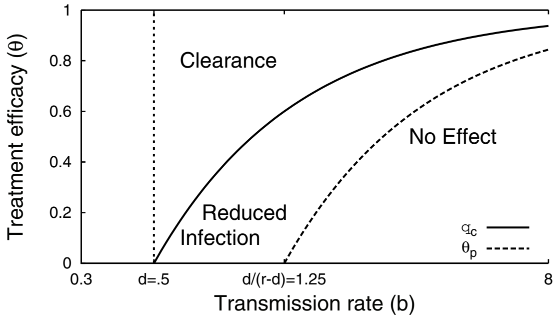

Fig. 9. *The treatment efficacy* θ *leading to specific dynamics for various transmission rates* b, *given* $d = 0.5$, $r = 0.9$, $s = 0$, *and* $q = 0$. *Treatment efficacies below* θ_p *have little or no effect on the number of infected hepatocytes. Treatment efficacies between* θ_c *and* θ_p *reduce the number of infected hepatocytes but are not sufficient for complete clearance. Treatment efficacies greater than* θ_c *lead to complete clearance of infection.*

in Figures 4 and 8 by $(1-\theta)b$. Taking b to be constant, the outcome of drug treatment depends on the drug efficacy θ (see Table 4.1 and Figure 9). There is a critical efficacy

$$\theta_c \approx \begin{cases} 1 - \frac{d+q+rs}{(1+s)b} & \text{if} \quad r < d+1, \\ 1 - \frac{d}{(r-d)b} & \text{if} \quad r > d+1 \end{cases} \tag{4.1}$$

such that $\theta > \theta_c$ implies that treatment will clear the infection. When $r < d + 1$, the critical efficacy θ_c corresponds to reducing the reproductive number to 1. When $r > d + 1$, the treatment efficacy must be large enough not only to reduce the reproductive number below 1, but also to overcome the local stability of the total-infection stationary solution in the region of bistability.

Below the critical efficacy θ_c, there is also a fuzzy partial-efficacy threshold

$$\theta_p \approx \begin{cases} 1 - \frac{d+q+rs}{(1+s)b} & \text{if} \quad r > d+1, \\ 1 - \frac{d}{(r-d)b} & \text{if} \quad d + d/b < r < d+1, \\ 0 & \text{if} \quad r < d + d/b. \end{cases} \tag{4.2}$$

The partial-efficacy threshold was derived using the approximate disease-free stability condition $(1-\theta)b(1+s) < d+q+rs$ and the approximate bifurcation condition $d = r(1-\theta)b/(1+(1-\theta)b)$ between partial and total infection. These conditions were chosen to correspond approximately to those of system (2.8).

A fuzzy threshold is a weaker form of the standard threshold conditions used in bifurcation analysis. Thresholds like the critical efficacy threshold θ_c indicate the location of a bifurcation or discontinuity of some form. On a given side of the threshold, changes in parameters can be interpreted as continuous smooth changes in the system. On opposite sides of the threshold, dynamics are qualitatively distinct, and parameter changes that cross the threshold typically cause nonsmooth and discontinuous changes in the system. But in many systems, important differences in dynamics are not separated by a discontinuity; the system can change in a continuous, smooth manner between qualitatively different extremes. Since there is no discontinuity in the system, we cannot define an exact threshold. As a next best recourse, we define a fuzzy threshold that in some sense separates regions of parameter space with different dynamics. Unlike standard thresholds, which are uniquely defined by their discontinuity, fuzzy thresholds are not uniquely defined; there are infinitely many fuzzy thresholds that distinguish well-separated points in parameter space, and points in the neighborhood of one fuzzy threshold may be classified in any variety of ways by other fuzzy thresholds. Still, fuzzy thresholds can serve as useful rules of thumb. θ_p is a fuzzy threshold because the transition between total infection and partial infection in system (2.7) does not generally coincide with a bifurcation.

Treatment efficacies between θ_p and θ_c can significantly reduce the fraction of hepatocytes that are infected but will not clear infection completely. Treatment efficacies $\theta < \theta_p$ do not significantly reduce the fraction of hepatocytes infected (Figure 9).

An important aspect of treatment response is the dynamics of the transition from the pretreatment state to the posttreatment stationary solution. When treatment is only partially effective ($\theta_p < \theta < \theta_c$), the dynamics converge to a new partial-infection stationary solution, and this convergence can be monotone, can overshoot, and can show damped oscillations, depending on the parameter values. When treatment is above the critical efficacy ($\theta_c < \theta$), infection asymptotically decays at rate $(1-\theta)b - d$. However, in situations with near-total infection, ($r > d + d/b$), there can be a significant delay before the number of infected hepatocytes begins to decay (see Figure 10). This delay may be a "strong" delay, where the number of infected hepatocytes does not change for an extended period of time after the start of treatment before decaying exponentially, or a "weak" delay, where the number of infected hepatocytes decays slowly at the start of treatment but then accelerates (Figure 10). The role of the relative proliferation rate r in treatment response is shown in Figure 11. These strong and weak delays are important because they may correspond to the "shoulder phase" observed in HCV viral load time series after the start of treatment [6].

Why does this delay occur? Suppose that treatment is highly effective ($\theta > \theta_c$). Biologically, treatment shifts the competitive advantage away from infected to uninfected hepatocytes, but there are initially too few uninfected hepatocytes to displace a

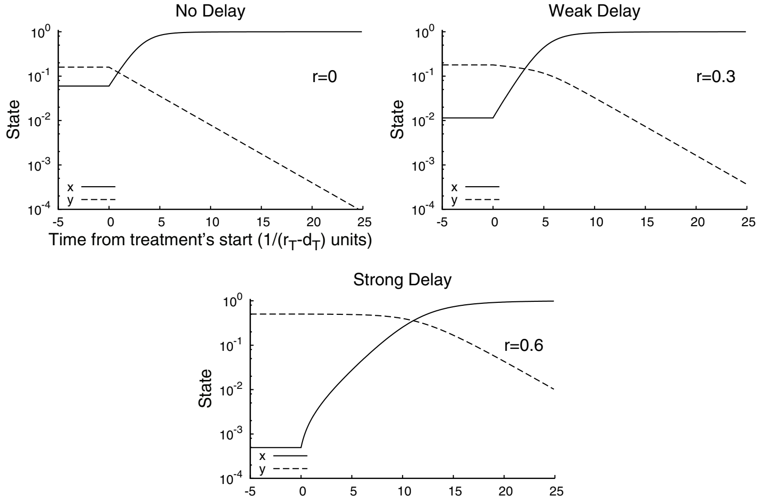

FIG. 10. *Time series for system* (2.7) *with treatment starting at* $t = 0$ *for* $r = 0$ *(top left),* $r = 0.3$ *(top right), and* $r = 0.6$ *(bottom). The initial condition is the pretreatment stationary solution. When the proliferation rate* r *is small (top left), there is no delay; the number of infected cells (y) decays at a constant rate from the start of treatment. For intermediate proliferation rates (top right), there is a weak delay between the start of treatment and the asymptotic clearance of infection. When* r *is large (bottom), there is a strong delay (about* 10 *units here) before the number of uninfected cells (x) reaches equality with the number of infected cells and the decay rate of infected cells accelerates to its exponential asymptotic rate. Parameter values* $s = 0.001, q = 0, d = 0.3, b = 5, \theta = 1$.

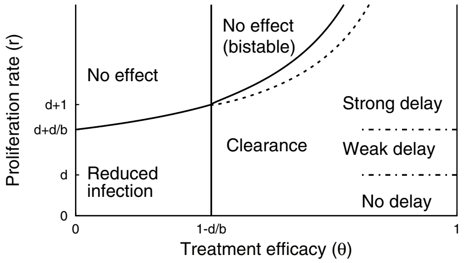

FIG. 11. *Classification of treatment-response as a function of* θ *and* r *when* $b > d$*;* $q = 0$*,* $s = 0.001$*,* $b = 0.9$*,* $d = 0.5$*. Regions are labeled according to the dynamics observed under treatment, assuming that the dynamics were at equilibrium prior to treatment. In the bistable region, both the disease-free and total-infection stationary solutions are locally stable under treatment. The boundaries between the regions of strong delay, weak delay, and no delay are fuzzy in the case of* $\theta = 1$*, and the boundaries are even fuzzier for* $\theta < 1$*. In the sliver between the dotted line and the solid line defining the bistable region our approximation to* t_d *in* (4.8) *fails because there is no nearby stationary solution to use for* $\mathbf{u}^*$ *(see Figure* 12*). In this sliver, the approximation method described in Appendix* C *can be used.*

significant portion of the infected hepatocytes. Infected hepatocytes begin to decline only when the number of uninfected hepatocytes reaches the same order of magnitude.

The rate of recovery depends on some details of the phase-plane geometry. Let's consider how the phase plane changes as we increase the efficacy θ when $r > d + 1$. While $\theta < \theta_p$ the total-infection stationary solution is attracting and the disease-free stationary solution is a saddle point. As θ increases to between θ_p and θ_c, the

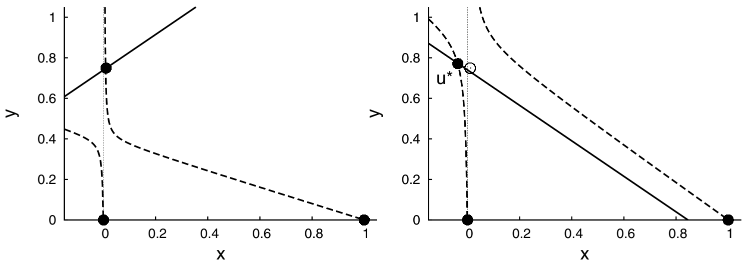

FIG. 12. *Nullclines of system* (2.7) *when* $s = 0.001$*,* $q = 0.008$*,* $r = 0.8$*,* $d = 0.2$*, and* $b = 1.5$ *with before treatment,* $\theta = 0$ *(left) and at the start of treatment,* $\theta = 14/15$ *(right). The solid dots represent stationary solutions. The open dot in the right-hand plot corresponds to the attracting stationary solution in the left-hand plot and is the initial condition for the dynamics when treatment begins. The adjacent solid dot* $\mathbf{u}^*$ *is the unstable stationary solution around which we linearize to approximate the treatment delay.*

disease-free stationary solution becomes locally stable, but the total-infection stationary solution is still stable and attracts orbits from the pretreatment initial condition. As θ is increased just beyond $\theta + c$, the total-infection stationary solution collides in a saddle-node bifurcation with the unstable partial-infection stationary solution, and both solutions disappear. Now, infection will be cleared by treatment. The rate of clearance is controlled by a bottleneck left in the region of the phase-plane where the saddle-node bifurcation occurred (see Appendix C). As the efficacy θ increases further, the bottleneck weakens, but another saddle-node bifurcation occurs in the second quadrant of the phase-plane. The saddle-node bifurcation introduces a new saddle-point stationary solution close to the pretreatment initial condition. As the bottleneck from the first saddle-node bifurcation is relaxed, the unstable manifold of the new saddle point becomes the primary factor controlling the recovery rate of uninfected hepatocytes.

The distinctions between a strong delay, a weak delay, and no delay (Figures 10 and 11) are empirically determined ones. When treatment completely prevents new infections ($\theta = 1$), we observe in numerical solutions strong delays when $r > d + d/b$, weak delays when $d + d/b > r > d$, but no delays when $r < d$. However, these are only observational distinctions, and the classification of delays is less clear for less efficient treatments.

The existence of a treatment delay is most clean-cut in cases like that of Figure 12, where almost all hepatocytes are infected before treatment and treatment is highly effective. We will now describe a method for approximating the dynamics at the start of treatment and determining the delay, t_d, before the number of infected hepatocytes begins to decline in these cases. We can use the linearization of system (2.7) near the new unstable stationary solution $\mathbf{u}^* = (x^*, y^*)$ (Figure 12) given by the solutions of

$$\begin{aligned}(4.3\text{a})\quad 0 = {}&(1-\theta)b\left(1+(1-\theta)b-r\right)(x^*)^2\\ &+\left[(r(1-\theta)b-d(1-\theta)b-d)+q\left(r-1-2\left(1-\theta\right)b\right)\right]x^*-sr-\left(r-d-q\right)q\end{aligned}$$

$$(4.3\text{b})\qquad \text{with}\quad y^* = \left(\frac{(1-\theta)b}{r}-1\right)x^*+1-\frac{d+q}{r}$$

that is nearest to the positive quadrant. In the neighborhood of $\mathbf{u}^*$, the solution of system (2.7) is approximately given by

$$\mathbf{u}(t) = \mathbf{u}^* + e^{\mathbf{J}(\mathbf{u}^*)t}\left(\mathbf{u}(0) - \mathbf{u}^*\right), \tag{4.4}$$

where $\mathbf{u}(0)$ is the pretreatment equilibrium and $\mathbf{J}(\mathbf{u}^*)$ is the Jacobian matrix at $\mathbf{u}^*$. The matrix exponential can be conveniently expressed in terms of the Lagrange interpolation formula [33]:

$$e^{\mathbf{J}t} = \sum_{n=1}^{N} e^{z_n t} \prod_{i \neq n} \left(\frac{\mathbf{J} - z_i \mathbf{I}}{z_n - z_i} \right), \tag{4.5}$$

where z_n is the nth eigenvalue and $\mathbf{I}$ is the identity matrix. When s and q are small, $\mathbf{u}^* = (x^*, y^*) \approx (0, 1 - d/r)$ (see Appendix A), so the Jacobian

$$\mathbf{J}(\mathbf{u}^*) \approx \begin{bmatrix} \frac{d}{r}\left(1 + (1-\theta)b\right) - (1-\theta)b & 0 \\ \left((1-\theta)b - r\right)\left(1 - \frac{d}{r}\right) & d - r \end{bmatrix}. \tag{4.6}$$

The eigenvalues are approximately

$$\frac{d}{r}\left(1 + (1-\theta)b\right) - (1-\theta)b \qquad \text{and} \qquad d - r. \tag{4.7}$$

Exact formulas can be obtained using the radical expressions for $\mathbf{u}^* = (x^*, y^*)$.

As the final part of the process of determining the treatment delay t_d, we have to identify a condition that marks the end of a treatment delay and agrees with our intuitive observations. There are many possible choices (see Appendix B for a discussion). We found that the condition $x(t_d) = y(t_d)$, corresponding to the point where the number of uninfected cells equals the number of infected cells, was simple, convenient, and robust for calculating t_d over the strong-delay parameter range. Solving for t_d, we find

$$t_d = \frac{r}{d + (1-\theta)b(d-r)} \log \left\{ \frac{[(r - (1-\theta)b)(r-d) + d](y^* - x^*)}{[2(r - (1-\theta)b)(r-d) + d](x(0) - x^*)} \right\}. \tag{4.8}$$

The dimensional delay time is $\hat{t}_d = \frac{t_d}{r_T - d_T}$ days. A side-by-side comparison of (4.8) to the actual value calculated by numerical solution of system (2.7) is shown in Figure 13. The figure shows that our approximation gives results that are very similar to the numerical solutions.

If the relative proliferation rate of infected cells r is fixed at a sufficiently large value ($r - d \geq 1$, for example), then the treatment delay increases as the excess death rate d decreases and the transmission rate b increases (see Figure 14). We see from Figures 15 and 16 that the treatment delay increases as r increases, until r is sufficiently large to introduce bistability, corresponding to $t_d \to \infty$. In the strong-delay region of Figure 11, the larger the immigration rate s of uninfected hepatocytes, the shorter the treatment delay because there are more uninfected hepatocytes at the start of treatment (compare Figures 15 and 16). The effect of spontaneous cure (q) is similar to that of immigration (s); more spontaneous cure shortens the treatment delay (Figure 17). The sensitivity to immigration and spontaneous cure decreases as the relative proliferation rate r of infected hepatocytes decreases.

There is a small range of values of r for which (3.14) has no solutions. For this region, $\mathbf{u}^*$ does not exist, and our approximation to t_d fails despite the presence of a positive but finite delay. The perturbation approximation to t_d continues to work for some of this region but also eventually fails for r just below the exact bistability threshold. Approximation of t_d in this region can be performed using dynamical systems theory, as described in Appendix C.

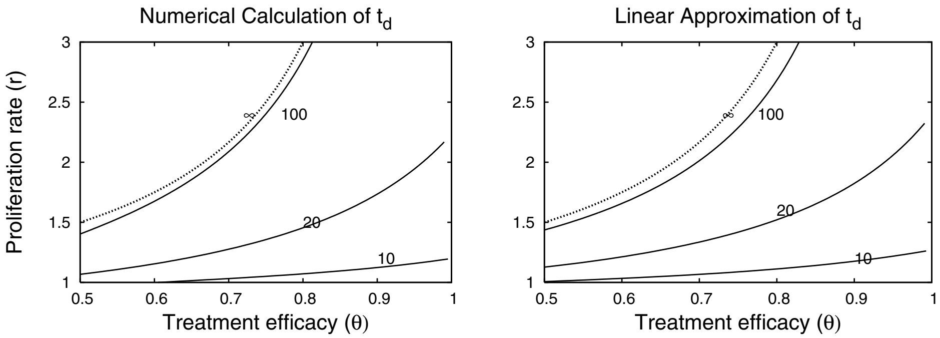

FIG. 13. *Side-by-side comparison of contour plots of the treatment delay t_d using numerical solution of system* (2.7) *(left) and the formula* (4.8) *derived from the linear approximation (right). The approximate bound on bistability, $r = d + \frac{d}{(1-\theta)b}$, labeled ∞, is the same in both plots. Contour heights are* 10*,* 20*,* 100*, and* ∞*. Parameter values $d = 0.5, b = 1, s = 10^{-3}, q = 0$. $\theta_c = 0.5$ when $r = 0$ in both plots.*

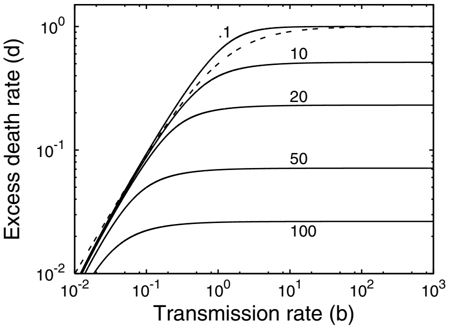

FIG. 14. *Contour plot of the treatment delay t_d from* (4.8) *as a function of d and b when $r = 1, \theta = 1, s = 10^{-3}$, and $q = 0$. Contours at* .1, 10, 20, 50, *and* 100*. The dotted line $d = rb/(1 + b)$ is an upper bound on the region of strong-delay effect.*

5. Discussion. Only about 20%–30% of HCV-infected individuals spontaneously clear the virus during the early phase of infection [44]. According to our model, when an individual is initially exposed to a small amount of virus, infection cannot be established unless the disease-free reproductive number is greater than 1. If the reproductive number is greater than 1, virus will spread among hepatocytes, eventually infecting some or all of the cells it targets. In addition, viral dynamics during this phase may be monotone or oscillatory but are expected to converge to a stationary equilibrium. Homeostatic proliferation of infected cells has only a small effect on the reproductive number, but diminishes oscillations [4] and increases the proportion of target hepatocytes infected at steady state. However, the dynamics may be bistable if the proliferation rate of infected hepatocytes is faster than that of uninfected hepatocytes. The HCV kinetics during primary infection, before the adaptive immune response against HCV is induced, both in humans [18] and chimpanzees [29], has been observed to be monotone; i.e., after a fast viral increase the virus stabilizes without observed oscillations in a high viral load steady state. This lack of observed oscillations supports our hypothesis that homeostatic proliferation of infected cells exists.

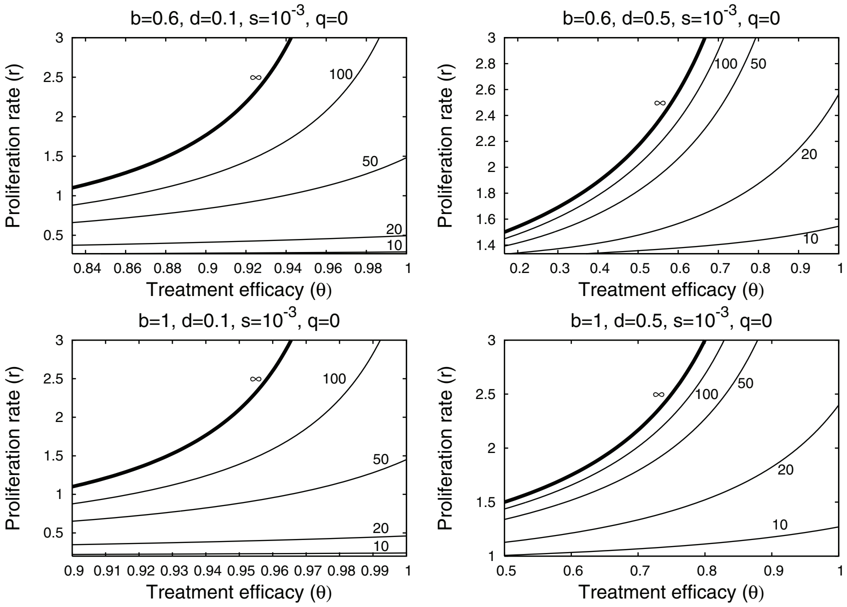

Fig. 15. *Four contour plots of treatment delay t_d in the strong-delay region of Figure* 11*, calculated from* (4.8) *when hepatocyte immigration is slow. In the parameter region above the ∞-contour, treatment is not sufficiently effective to overcome the local stability of the infected-cell population. Below the ∞-contour, treatment successfully clears infection, with the length of the delay given by the contour values. Parameter values are given at the top of each plot. The left-hand boundary in each plot corresponds to $\theta = \theta_c$ when $r = 0$.*

The typical HCV RNA decay observed during therapy with standard or pegylated interferon-α alone or in combination with ribavirin is biphasic—characterized by an initial rapid viral decline (first phase) followed by a slower decay (second phase) [37]. In about 30%–40% of treated patients triphasic viral declines have also been observed [19, 48, 1, 23]. In some patients (nonresponders) viral loads may not decline. In others, viral load initially declines (first phase) followed by maintenance of a steady level lower than baseline (flat partial responders). Here we have mathematically characterized a model of HCV dynamics [6] that encompasses the observed viral kinetic profiles under therapy. We speculate that in nonresponders the drug effectiveness, θ, may not exceed θ_p (Figure 9), and therefore viral load does not decline under therapy. Flat partial responders may be explained as a consequence of drug efficacy higher than θ_p but lower than the critical drug efficacy θ_c (Figure 9). Viral clearance occurs when $\theta > \theta_c$ via biphasic or triphasic viral decline when the hepatocyte proliferation rate, r, is lower or higher than the hepatocyte death rate, d, respectively (system (2.7) without "cure"; Figure 9).

Using perturbation theory, we showed that a delay can occur between the start of treatment and the first measurable decline in the number of infected hepatocytes under efficient therapy ($\theta > \theta_c$) because of the influence of a nearby saddle-node bifurcation in the system (Figure 12). Equation (4.8) can be used to approximate the duration of this delay. In terms of viral dynamics, this delay appears as a shoulder phase separating the initial decay in viral load at the start of treatment from the asymptotic clearance phase. One of the conditions for the existence of this delay between the initial decrease and asymptotic clearance is that the number of infected

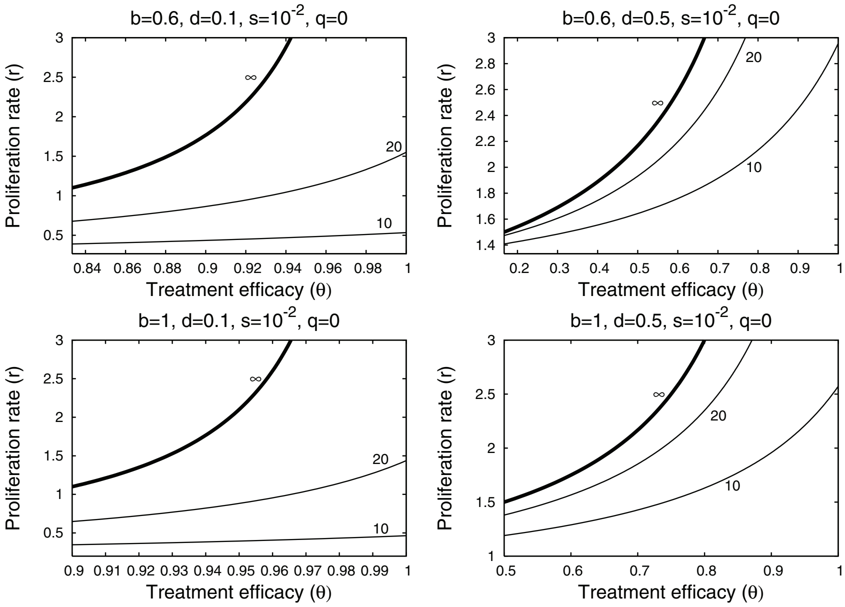

FIG. 16. *Four contour plots of treatment delay t_d in the strong-delay region of Figure* 11*, calculated from formula* (4.8)*. Parameter values are stated at the top of each plot. In the parameter region above the ∞-contour, treatment is not sufficiently effective to overcome the local stability of the infected-cell population. Below the ∞-contour, treatment successfully clears infection, with the length of the delay given by the contour values. In these plots, immigration is fast ($s = 10^{-2}$) and significantly reduces the delay before treatment reduces the number of infected cells, compared to Figure* 15*. The left-hand boundary in each plot corresponds to $\theta = \theta_c$ when $r = 0$.*

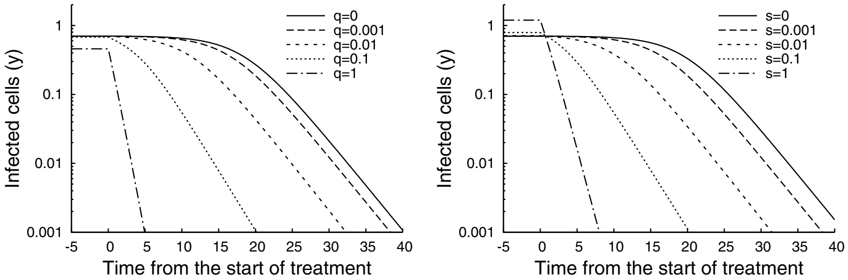

FIG. 17. *Time series plot of changes in the number of infected cells under treatment with $s = 0.001$ (left) and $q = 0.001$ (right). As the curing of infected cells q is increased from* 0 *to* 1*, the treatment delay decreases from* 15 *to* 0 *(left). Similarly, treatment delay decreases as the immigration rate s increases (right). Note that only very large values of s and q significantly affect the pretreatment state. Parameter values $d = 0.3, b = 3, \theta = 1, r = 1$.*

cells is much larger than the number of uninfected cells at the start of therapy. During therapy the number of uninfected cells increases. Because of density-dependent homeostatic processes, the proliferation of infected cells slows as the number of uninfected cells increases. When this proliferation slows to the point at which it no longer keeps up with the rate of infected cell loss, the number of infected cells start to decline. The shoulder persists until the ratio between uninfected cells and infected cells is approximately one. We found that the stopping condition, $T/I \approx 1$, for calculating when the shoulder phase ends, is simple and robust for calculating t_d over a large-shoulder parameter range. Other topping conditions $T/I \approx 1$ are discussed in Appendix B.

When using t_d in the context of the full model (system (2.1)), i.e., calculating the viral shoulder phase and hence a triphasic viral decay, our formula (4.8) has to be adjusted. Since interferon-α mainly inhibits viral production, and we assume that initially the infected cell number remains close to its level before therapy, then the model (system (2.1)) predicts that viral load will decline from its baseline value, V_0, according to the equation $V(t) = V_0\left(1 - \epsilon + \epsilon e^{-ct}\right)$ [37]. This equation for the first phase of viral decline predicts that at times long compared with $1/c$, the average free virion lifetime in serum, the viral load will decline to $(1-\epsilon)V_0$ over an interval of length $\ln(1-\epsilon)/c$ (Figure 2). Therefore, our formula (4.8), which estimates the length of time since the start of therapy and the beginning of the third phase of decline (Figure 2(right)) can be adjusted to the actual viral shoulder duration by subtracting the relaxation time $\ln(1-\epsilon)/c$ from the dimensional form of t_d.

We have previously predicted, using system (2.1), that the spontaneous curing (q) of infected cells by a noncytolytic immune response is necessary to prevent a significant loss of liver cells during acute HCV infection in chimpanzees [5]. Direct evidence for noncytolytic clearance of HCV from infected cells has not yet been found, but interferon-α has cured replicon cells [2], and clearance of hepatitis-B-virus-infected hepatocytes has been shown to occur through noncytolytic mechanisms [16]. In the context of treatment in chronic-HCV patients, our theory predicts that any shoulder phase will be shortened by a strong noncytolytic response.

HCV is the only known RNA virus with an exclusively cytoplasmic life cycle that is associated with cancer [47]. The mechanisms by which it causes cancer are unclear. It may be that the path to hepatocellular carcinoma in chronic hepatitis C shares some important features with human papillomavirus-induced carcinogenesis [17]. Interactions of HCV proteins with key regulators of the cell cycle, e.g., the retinoblastoma protein [34] and p53 [22], may lead to enhanced cellular proliferation over uninfected cells and may also compromise multiple cell cycle checkpoints that act to maintain genomic integrity [11], thus setting the stage for carcinogenesis. In light of these speculations, the proliferation of HCV-infected cells, r_I, may be higher than proliferation of uninfected cells, r_T. Therefore, in this study we also analyzed this assumption (i.e., $r_I > r_T$). We found that when $r_I > r_T$, bistability arises (under certain parameter values), and imposing $r_I < r_T$ is sufficient to preclude bistability. However, more experimental work is needed to test the consistency of this view of homeostatic proliferation with the behavior of hepatocytes in vivo. Our model makes some predictions regarding changes in the total hepatocyte numbers over the course of infection and treatment. Since liver function is correlated with hepatocyte numbers, the total number of hepatocytes may be an important medical indicator and may further inform our understanding of HCV.

On a mathematical note, there is as yet no global stability analysis of system (2.1). Of particular importance, a closer analysis of the quasi-steady-state approximation is needed. This is emphasized by numerical observations that a Hopf bifurcation of the partial-infection stationary solution can occur if the viral clearance rate c is not sufficiently large. Applications and extension of methods from De Leenheer and Smith [9], De Leenheer and Pilyugin [8], and Korobeinikov [24] may prove useful in further work.

The analyses presented here not only are important for HCV infection but also should be relevant for modeling other infections with hepatotropic viruses, such as hepatitis B virus. Many mathematical models for the study of hepatitis B virus DNA kinetics under therapy ignore the proliferation of virus-infected cells [36]. Interestingly, besides the typical biphasic decay in viral load, other kinetic profiles have been observed, such as triphasic. As our model allows one to predict more complex viral decay profiles, we hope that it will be useful for understanding complex HCV and HBV kinetics under therapy [7].

Appendix A. Perturbation approximations. Regular perturbation methods can be used to approximate the stationary solutions of system (2.7) in the limits of small s and q, based on the polynomials in (3.11) and (3.14a). Equation (3.11) is independent of q, so let $x = x_0 + sx_s + o(s)$. Substituting into (3.11), $(x_0 + sx_s)^2 - (x_0 + sx_s) = s$. Collecting like terms,

$$x_0(x_0 - 1) - (1 - 2x_0x_s + x_s)s + o(s) = 0. \tag{A.1}$$

From the zeroth-order term in s, $x_0 \in \{0, 1\}$, and to first order, $x_s = \frac{1}{2x_0-1}$. Thus, the two corresponding stationary solutions for small s and q are

$$(-s + o(s), 0) \quad \text{and} \quad (1 + s + o(s), 0). \tag{A.2}$$

Equation (3.14a) depends on both s and q, so let $x = x_0 + sx_s + qx_q + o(s, q)$. Substituting into (3.14a) and collecting like terms,

$$\begin{aligned} 0 = {} & b(1 + b - r)x_0^2 + (rb - db - d)x_0 \\ & - (-x_srb + x_sdb + x_sd - 2bx_0x_s - 2b^2x_0x_s + 2bx_0x_sr + r)s \\ & - (-bx_qr + x_qdb + x_qd - x_0r + x_0 + 2x_0b - 2(1 + b + r)bx_0x_q + r - d)q. \end{aligned} \tag{A.3}$$

To highest order,

$$x_0 \in \left\{0, \frac{d + db - rb}{b(1 + b - r)}\right\}. \tag{A.4}$$

The first-order corrections in s and q are

$$x_s = \frac{r}{2x_0b + 2b^2x_0 - 2bx_0r - d - bd + br}, \tag{A.5a}$$

$$x_q = \frac{r - x_0r + x_0 + 2x_0b - d}{2x_0b + 2b^2x_0 - 2bx_0r - d - bd + br}. \tag{A.5b}$$

Equation (3.14b) can then be used to determine y. In the special case of $x_0 = 0$, the stationary solution is given by (3.15). This can be used to approximate both the pretreatment and posttreatment (substituting $(1 - \theta)b$ for b) stationary solutions when applying (4.8).

Appendix B. Choosing a treatment delay threshold. Using (4.4), we can approximate the delay, t_d, before the number of infected hepatocytes begins to decline. But to do this, we have to find a quantitative rule for determining the end of the treatment delay. One way to do this is to choose a line, represented by a vector $\mathbf{k}$ and a constant k_0, such that the shoulder ends when the approximate solution intersects this line. Thus, t_d is defined such that

$$\mathbf{k}^T\mathbf{u}(t_d) = k_0. \tag{B.1}$$

Table B.1
Possible stopping condition choices for calculation of t_d.

Description	$\mathbf{k}$	k_0	Comment
Upper bound	$[1,1]$	1	$\mathbf{u}(t)$ may not intersect
$x(t) = y(t)$	$[1,-1]$	0	$\mathbf{u}(t)$ may not intersect
90% threshold	$[0,1]$	$.9\,(1-d/r)$	$\mathbf{u}(t)$ may not intersect
Uninfected cells only	$[1,0]$	$\dfrac{d}{r}$	$t_d \to 0$ as $d \to 0$, although the delay may not
Uninfected cells only	$[1,0]$	$.1$	May not correspond to the full delay

Since we are concerned only with the divergence from steady state, we can ignore the stable mode of (4.4), and then (B.1) leads to the formula

(B.2)
$$t_d = \frac{r}{d + (1-\theta)b(d-r)} \log\left\{ \frac{[(r-(1-\theta)b)(r-d)+d](\mathbf{k}_1\mathbf{u}_1^* + \mathbf{k}_2\mathbf{u}_2^* - k_0)}{[(\mathbf{k}_1 - \mathbf{k}_2)(r-(1-\theta)b)(r-d) + \mathbf{k}_1 d](\mathbf{u}_1^* - \mathbf{u}_1(0))} \right\}.$$

Several choices for $\mathbf{k}$ and k_0 are summarized in Table B.1, along with their drawbacks. The unstable manifold of $\mathbf{u}^*$ has the initial direction

$$\big[d - (r-d)((1-\theta)b - r), \quad (r-d)((1-\theta)b - r)\big]. \tag{B.3}$$

If we constrain the application of (B.2) to the region of Figure 11 where $\theta > \theta_c$ and $r > d$, we can show that the choice of $\mathbf{k} = [1,-1]$, $k_0 = 0$ always gives a solution for t_d. This is because the first component of the eigenvector is positive and the second is negative, ensuring that the orbit approximated by a line in the direction of the eigenvector will always intersect the line $y = x$. Numerical evidence indicates that this choice is reasonably consistent with the qualitative character of delays, and we will use it throughout this paper. However, it underestimates the delay time in cases where $r - d$ is small. In such situations, $\mathbf{k} = [1,1]$, $k_0 = 1$ gives better approximations to t_d.

Appendix C. Bottle neck calculations. When the growth rate r is slightly smaller than the critical value r^* that introduces bistability (Figure 11), (4.4) cannot be used to estimate the treatment delay t_d because there is no nearby equilibrium around which we can linearize. However, we can still approximate the treatment delay by transforming the system near the bifurcation point into normal form [15]. The normal form of a generic saddle-node bifurcation satisfies the first-order differential equation

$$\dot{u} = a_0(r^* - r) + a_2 u^2, \tag{C.1}$$

where r is the bifurcation parameter and $r = r^*$ is the bifurcation point with $a_0 > 0$ and $a_2 \neq 0$. Using elementary integration methods, we can show that for $r \approx r^*$ the time it takes for a solution to pass from a negative initial position to a positive final position, both far from the origin, is approximately given by

$$t_d \approx \sqrt{\pi^2/[a_0 a_2 (r^* - r)]}. \tag{C.2}$$

As r is increased toward r^*, the time becomes longer. If $r > r^*$, the time is infinite because solutions are trapped by an intermediate attracting state. For this HCV model, our task to calculate r^*, a_0, and a_2 by transforming system (2.7) into normal-form near the saddle-node bifurcation that introduces bistability.

We can determine the bifurcation point r^* by setting the discriminant of x in (3.14a) (with transmission rate $(1-\theta)b$ instead of b) equal to zero. The result is a quadratic polynomial for r^*, where the smaller solution corresponds to a saddle-node bifurcation for nonbiological values of x, and the larger solution corresponds to bifurcation which is biologically important.

Once r^* is known, we calculate the feasible nonhyperbolic equilibrium solution $(x^*(r^*), y^*(r^*))$ using (3.14) and transform system (2.7) using a change of variables of the form

$$x = x^* + M_{xu}u + M_{xv}v + M_{xr}(r - r^*), \tag{C.3a}$$

$$y = y^* + M_{yu}u + M_{yv}v + M_{yr}(r - r^*) \tag{C.3b}$$

such that locally the system has the form

$$\dot{u} = a_0(r^* - r) + a_2u^2 + o(r^* - r, u^2) + O(v), \tag{C.4a}$$

$$\dot{v} = -a_3v + o(v), \tag{C.4b}$$

where a_0 and a_2 satisfy the conditions given above and $a_3 > 0$. This transformation can be performed using the eigenvalue decomposition of the Jacobian at the equilibrium point and then choosing M_{xr} and M_{yr} to eliminate extra terms in $\dot{u}$ and $\dot{v}$. The $O(v)$ terms are neglected because v converges to 0 exponentially near the bifurcation. The procedure is easily implemented numerically, but we have not produced a simple analytic formula for the result.

Acknowledgments. T. Reluga thanks A. Zilman for helpful discussion concerning the calculations in Appendix C.

THE IDENTIFICATION OF THIN DIELECTRIC OBJECTS FROM FAR FIELD OR NEAR FIELD SCATTERING DATA*

NOAM ZEEV† and FIORALBA CAKONI†

Abstract. We consider the inverse scattering problem of determining the shape and the material properties of a thin dielectric infinite cylinder having an open arc as cross section from knowledge of the TM-polarized scattered electromagnetic field at a fixed frequency. We investigate two reconstruction approaches, namely the linear sampling method and the reciprocity gap functional method, using far field or near field data, respectively. Numerical examples are given showing the efficaciousness of our algorithms.

Key words. direct and inverse scattering, scattering from cracks, linear sampling method, electromagnetic scattering, reciprocity gap functional method, thin dielectric objects

1. Introduction.

Important problems in nondestructive evaluation include the detection of flaws in materials in specific (typically thin) areas, as well as the determination of the integrity of thin coatings. We refer the reader to the special issue of Inverse Problems [22] for a detailed account on different approaches to these problems using electromagnetic waves. In particular, considerable work has been done on inversion schemes using eddy-current approximation measurements to detect the presence of thin anomalies [3], [13], [29]. In related work [4], [24], the authors use electrostatic and electromagnetic measurements, respectively, to detect the shape of a thin target. In addition to the shape, it is of course desirable to obtain information on the material properties of the target. In this paper we show the applicability of qualitative methods in inverse scattering [7] to these problems. In particular, we investigate the inverse problem of using far field or near field time harmonic electromagnetic measurements to determine the shape and information about the thickness and physical properties of a thin dielectric film embedded in a known inhomogeneous background. Such problems arise in the study of optical devices in communication networks [27] (typical structures of this type can be found in [14]) or in the detection of thin air pockets inside structures [29]. In this work we assume that the obstacle is a thin dielectric right cylinder whose properties depend only on the cross section of the cylinder and that the incident electromagnetic field is E-polarized. After factoring out the term $e^{-i\omega t}$, where ω is the fixed frequency, the only nonzero component u of the total electric field satisfies the Helmholtz equation

$$\Delta u + k^2 n(x) u = 0$$

in the exterior of the cylinder, where the complex valued function $n(x)$ is the index of refraction of the background medium which satisfies $\operatorname{Re} n > 0$ and $\operatorname{Im} n \geq 0$. Difficulties arise in computing the total field inside the thin dielectric obstacle due to

the fact that the index of refraction and the thickness of the obstacle are of different scales. The direct scattering problem for a thin dielectric structure was studied in [1] and [27] where a perturbation approach was used to approximate the solution by solving a sequence of integral equations. Alternatively, based on asymptotic analysis with respect to the thickness of the obstacle (see [16]), a first approximate model of the wave propagation inside the obstacle is to replace the obstacle by an infinite cylinder having an open arc in $\mathbb{R}^2$ as its cross section and the interior field by an appropriate boundary condition on the arc. Both the perturbation method and the arc approximation model are based on asymptotic analysis of the exact model with respect to the thickness, and they therefore compute an approximation to the total field. The error analysis of the forward problem for the perturbation technique can be found in [1] and [27], and for the arc approximation model in [16].

Our analysis of the inverse problem uses the arc approximation model. Note that the physical properties and the thickness of the thin dielectric obstacle appear now as a boundary coefficient. We remark that this model is well suited to our inversion algorithm, especially since the noniterative inversion methods such as the linear sampling method and the reciprocity gap functional method are able to reconstruct boundary coefficients in addition to the support. More specifically, let h be the thickness and Γ the cross section of the mean surface of the dielectric medium. Assuming that the interior magnetic field is approximated up to $O(h)$ error, whereas the interior electric field is approximated up to $O(h^2)$ error, the following boundary conditions on the open arc Γ are obtained for the component u of the total electric field [15]:

$$\left[\frac{\partial u}{\partial \nu}\right] = 0 \qquad \text{and} \qquad [u] - i\lambda \frac{\partial u^+}{\partial \nu} = 0 \qquad \text{on } \Gamma,$$

where $u^{\pm}(x) = \lim_{h\to 0^+} u(x \pm h\nu)$ and $\frac{\partial u^{\pm}}{\partial \nu}(x) = \lim_{h\to 0^+} \nu \cdot \nabla u(x \pm h\nu)$ for $x \in \Gamma$, $[u] := u^+ - u^-$ and $\left[\frac{\partial u}{\partial \nu}\right] := \frac{\partial u^+}{\partial \nu} - \frac{\partial u^-}{\partial \nu}$ are the respective jumps across Γ, and the dimensionless positive valued function $\lambda > \lambda_0 > 0$ involves electric permittivity and magnetic permeability of the dielectric medium and the background as well as the thickness h and frequency ω. Note that the above condition can fail at the tips of the crack. Here we assume that $\Gamma \subset \mathbb{R}^2$ is a *simple piecewise smooth arc*, i.e., $\Gamma = \{\rho(s) : s \in [s_0, s_1]\}$, where the mapping $\rho : [s_0, s_1] \to \mathbb{R}^2$ is one-to-one, continuous, and piecewise smooth. The normal vector ν pointing to the right side of Γ is defined everywhere except at a finite number of points on Γ.

Hence we arrive at the following boundary value problem for the scattered field u^s due to an incident field u^i scattered by the crack Γ:

$$\Delta u^s + k^2 n(x) u^s = 0 \qquad \text{in } \mathbb{R}^2 \setminus \overline{\Gamma}, \tag{1.1}$$

$$\left[\frac{\partial (u^s + u^i)}{\partial \nu}\right] = 0 \qquad \text{on } \Gamma, \tag{1.2}$$

$$\left[(u^s + u^i)\right] - i\lambda \frac{\partial (u^s + u^i)^+}{\partial \nu} = 0 \qquad \text{on } \Gamma, \tag{1.3}$$

$$\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial u^s}{\partial r} - iku^s\right) = 0, \tag{1.4}$$

where the Sommerfeld radiation condition (1.4) is satisfied uniformly in $\hat{x} = x/|x|$ with $r = |x|$. Here we assume that, in general, the positive index of refraction $n(x) > 0$ for the background medium satisfies $n(x) = 1$ outside a large ball containing the crack and k is the wave number in the air. In this study the incident field can be a plane wave or the field generated by a point source, and this will become precise later.

The main concern of this paper is to solve the inverse problem of determining the shape Γ and some information on λ from measured far field or near field scattered data. In order to develop the mathematical tools to study the inverse problem, in the next section we investigate the well-posedness of the direct scattering problem (1.1)–(1.4). We apply a boundary integral equation method to obtain a Fredholm first kind integral equation on Γ for the scattered field. In section 3 we formulate and solve the inverse scattering problem using far field scattering data due to plane waves as incident fields. For simplicity in this section we assume that the crack is embedded in a homogeneous background; i.e., $n = 1$ everywhere. We apply the *linear sampling method*, which was first introduced in [6] for the case of an obstacle with empty interior, to determine the shape of the crack. After the reconstruction of Γ (without making a priori use of the boundary condition) we use the solution of the far field equation to reconstruct λ as well. For information on other solution methods for the inverse scattering problem for Dirichlet or Neumann cracks from far field data, we refer the reader to [2], [17], [18], and [21]. In section 4 we consider the case when the crack is embedded in a known inhomogeneous background and the data is the scattered field measured on a closed curve surrounding the crack due to a point source as incident field. We modify the reciprocity gap functional method which up to now has been developed only for obstacles with nonempty interior [8], [12]. The last section of this paper is dedicated to numerical implementation with examples of both algorithms for solving the inverse problem. We note that the solution of the inverse problem in both cases is based on solving an ill-posed linear equation whose right-hand side involves normal derivatives with respect to the unknown crack. We propose a new approach to deal with this difficulty which was left as an open question in [6].

2. The solution of the direct scattering problem.

In order to formulate the above scattering problems more precisely we need to properly define the trace spaces on Γ. To this end we extend the arc Γ to an arbitrary piecewise smooth, simply connected, closed curve ∂D enclosing a bounded domain D such that the normal vector ν on Γ coincides with the outward normal vector on ∂D, which we again denote by ν. The classical reference for the trace spaces is [23], and the notation there is different from those in [25]. However, in this work we use the notation in [25], because this is our main reference for the potential theory needed here. If $H^1_{loc}(\mathbb{R}^2)$, $L^2(\partial D)$, $H^{\frac{1}{2}}(\partial D)$, and $H^{-\frac{1}{2}}(\partial D)$ denote the usual Sobolev spaces, we define the following spaces:

$$\begin{aligned} L^2(\Gamma) &:= \{u|_\Gamma : u \in L^2(\partial D)\},\\ H^{\frac{1}{2}}(\Gamma) &:= \{u|_\Gamma : u \in H^{\frac{1}{2}}(\partial D)\},\\ \tilde{H}^{\frac{1}{2}}(\Gamma) &:= \{u \in H^{\frac{1}{2}}(\Gamma) : \operatorname{supp} u \subseteq \overline{\Gamma}\}. \end{aligned}$$

In other words, $\tilde{H}^{\frac{1}{2}}(\Gamma)$ contains functions $u \in H^{\frac{1}{2}}(\Gamma)$ such that their extension by zero to the whole boundary ∂D is in $H^{\frac{1}{2}}(\partial D)$ (Theorem 3.33 in [25]). (For the reader's convenience we remark that $\tilde{H}^{\frac{1}{2}}(\Gamma)$ coincides with the space $H^{\frac{1}{2}}_{00}(\Gamma)$ introduced by Lions and Magenes (see [23, p. 66]).) Now we denote by $H^{-\frac{1}{2}}(\Gamma)$ the dual space of $\tilde{H}^{\frac{1}{2}}(\Gamma)$ and by $\tilde{H}^{-\frac{1}{2}}(\Gamma)$ the dual space of $H^{\frac{1}{2}}(\Gamma)$. Hence we have the chain

$$\mathcal{D}(\Gamma) \subset \tilde{H}^{\frac{1}{2}}(\Gamma) \subset H^{\frac{1}{2}}(\Gamma) \subset L^2(\Gamma) \subset \tilde{H}^{-\frac{1}{2}}(\Gamma) \subset H^{-\frac{1}{2}}(\Gamma) \subset \mathcal{D}'(\Gamma),$$

where $\mathcal{D}(\Gamma) := C_0^\infty(\Gamma)$. We note that $\tilde{H}^{-\frac{1}{2}}(\Gamma)$ can also be identified with $H_{\overline{\Gamma}}^{-\frac{1}{2}}(\partial D) := \{u \in H^{-\frac{1}{2}}(\partial D) :\ \operatorname{supp} u \subset \overline{\Gamma}\}$ (see Theorem 3.29 in [25]).

The scattering problem (1.1)–(1.4) is a particular case of the following boundary value problem: Let $n(x)$ be a piecewise smooth complex valued function with piecewise continuous jump discontinuities such that $\operatorname{Re} n > 0$, $\operatorname{Im} n \geq 0$, and $n(x) = 1$ outside a large enough ball, whereas λ is a piecewise smooth function on Γ such that $\lambda(x) > \lambda_0 > 0$. Given $f \in H^{-\frac{1}{2}}(\Gamma)$ and $h \in H^{-\frac{1}{2}}(\Gamma)$, find $v \in H^1_{loc}(\mathbb{R}^2 \setminus \overline{\Gamma})$ satisfying

$$\Delta v + k^2 n(x) v = 0 \qquad \text{in } \mathbb{R}^2 \setminus \overline{\Gamma}, \tag{2.1}$$

$$\left[\frac{\partial v}{\partial \nu}\right] = f \qquad \text{on } \Gamma, \tag{2.2}$$

$$[v] - i\lambda \frac{\partial v^+}{\partial \nu} = h \qquad \text{on } \Gamma, \tag{2.3}$$

$$\lim_{r\to\infty} \sqrt{r}\left(\frac{\partial v}{\partial r} - ikv\right) = 0. \tag{2.4}$$

THEOREM 2.1. *The problem* (2.1)–(2.4) *has at most one solution.*

Proof. Denote by B_R a sufficiently large ball with radius R containing $\overline{D}$ and by ∂B_R its boundary. Let v be a solution of (2.1)–(2.4) with $f = h = 0$. Obviously $v \in H^1(B_R \setminus \overline{D}) \cup H^1(D)$ satisfies the Helmholtz equation in $B_R \setminus \overline{D}$ and D and the following transmission conditions on the complementary part $\partial D \setminus \overline{\Gamma}$ of ∂D:

$$v^+ = v^- \qquad \text{and} \qquad \frac{\partial v^+}{\partial \nu} = \frac{\partial v^-}{\partial \nu} \qquad \text{on } \partial D \setminus \overline{\Gamma}, \tag{2.5}$$

where the + denotes the limit approaching ∂D from inside D and − the limit approaching ∂D from outside of D. An application of Green's formula for u and $\overline{u}$ in D and $B_R \setminus \overline{D}$ and using the transmission conditions (2.5) yields

$$\int_{\partial B_R} v \frac{\partial \bar{v}}{\partial \nu} dx = \int_{B_R \setminus \bar{D}} |\nabla v|^2\, dx + \int_D |\nabla v|^2\, dx - k^2 \int_{B_R\setminus\bar{D}} \overline{n}\, |v|^2\, dx$$
$$- k^2 \int_D \overline{n}\, |v|^2\, dx + \int_\Gamma [v] \frac{\partial \bar{v}}{\partial \nu} dx.$$

Using the boundary conditions (2.2)–(2.3), we now obtain

$$\int_{\partial B_R} v \frac{\partial \bar{v}}{\partial \nu} dx = \int_{B_R \setminus \bar{D}} |\nabla v|^2\, dx + \int_D |\nabla v|^2\, dx - k^2 \int_{B_R\setminus\bar{D}} \overline{n}\, |v|^2\, dx$$
$$- k^2 \int_D \overline{n}\, |v|^2\, dx + i \int_\Gamma \lambda \left|\frac{\partial v}{\partial \nu}\right|^2 dx. \tag{2.6}$$

Since $\lambda > 0$ and $\operatorname{Im} \overline{n} \leq 0$, we conclude that

$$\operatorname{Im}\left(\int_{\partial B_R} v \frac{\partial \bar{v}}{\partial \nu} dx\right) \geq 0,$$

whence from [10, Theorem 2.12] and a unique continuation argument we obtain that $v = 0$ in $\mathbb{R}^2 \setminus \overline{\Gamma}$. □

THEOREM 2.2. *The problem* (2.1)–(2.4) *has a unique solution* v *which satisfies*

$$\|v\|_{H^1(B_R\setminus\overline{\Gamma})} \leq C\left(\|f\|_{H^{-\frac{1}{2}}(\Gamma)} + \|h\|_{H^{-\frac{1}{2}}(\Gamma)}\right), \quad x \in \mathbb{R}^2 \setminus \overline{\Gamma}, \tag{2.7}$$

where the positive constant C depends on R but not on f and h.

Proof. First we note that if $v \in H^1_{loc}(\mathbb{R}^2 \setminus \overline{\Gamma})$ is a solution to (2.1)–(2.4), then $[v] \in H^{\frac{1}{2}}(\partial D)$ and $\left[\frac{\partial v}{\partial \nu}\right] \in H^{-\frac{1}{2}}(\partial D)$. Now by local regularity for solutions of the Helmholtz equation we have that $v \in C^\infty$ away from Γ, whence $[v] = \left[\frac{\partial v}{\partial \nu}\right] = 0$ on $\partial D \setminus \overline{\Gamma}$. Therefore $[v] \in \tilde{H}^{\frac{1}{2}}(\Gamma)$ and $\left[\frac{\partial v}{\partial \nu}\right] \in \tilde{H}^{-\frac{1}{2}}(\Gamma)$. Let $\mathbb{G}(x,y)$ be the radiating Green function of the background medium that satisfies

$$\Delta\mathbb{G}(x,\, y) + k^2 n(x)\mathbb{G}(x,\, y) = \delta(x-y). \tag{2.8}$$

From the Green representation formula (see [25]) we have

$$v(x) = \begin{cases} \displaystyle\int_{\partial D} \frac{\partial v^+(y)}{\partial \nu_y}\mathbb{G}(x,y)ds_y - \int_{\partial D} v^+(y)\frac{\partial}{\partial \nu_y}\mathbb{G}(x,y)ds_y, & x \in D, \\ \displaystyle -\int_{\partial D} \frac{\partial v^-(y)}{\partial \nu_y}\mathbb{G}(x,y)ds_y + \int_{\partial D} v^-(y)\frac{\partial}{\partial \nu_y}\mathbb{G}(x,y)ds_y, & x \in \mathbb{R}^2 \setminus \overline{D}, \end{cases} \tag{2.9}$$

where D is the region bounded by the extension ∂D of Γ, and the $+$ sign denotes the limit approaching ∂D from inside D whereas $-$ denotes the limit approaching ∂D from outside of D. Using the jump relations of the single- and double-layer potentials across the boundary ∂D [25], eliminating the integrals over $\partial D \setminus \overline{\Gamma}$, and using the boundary conditions (2.2)–(2.3), we obtain that the jump $[v]$ satisfies

$$\left(\frac{i}{\lambda}I + T_\Gamma\right)[v] = \frac{i}{\lambda}h + \left(K'_\Gamma - \frac{I}{2}\right)f, \tag{2.10}$$

where the operators $K^{'}_{\Gamma} : \tilde{H}^{-1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ and $T_\Gamma : \tilde{H}^{1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ are defined by

$$(K'_\Gamma\psi)(x) := \int_\Gamma \psi(y)\frac{\partial}{\partial \nu_x}\mathbb{G}(x,y)\,ds_y \quad \text{for } x \in \Gamma,$$

$$(T_\Gamma\psi)(x) := \frac{\partial}{\partial \nu_x}\int_\Gamma \psi(y)\frac{\partial}{\partial \nu_y}\mathbb{G}(x,y)\,ds_y \quad \text{for } x \in \Gamma,$$

respectively. If (2.10) can be solved for $[v]$, then from the boundary conditions we know $\partial v^+/\partial\nu$ and $\partial v^-/\partial\nu$. Furthermore, it is easy to see that

$$\frac{1}{2}(v^+ + v^-) = -S_\Gamma\left[\frac{\partial u}{\partial \nu}\right] + K_\Gamma[u] \quad \text{on } \Gamma, \tag{2.11}$$

where now $S_\Gamma : \tilde{H}^{-1/2}(\Gamma) \to H^{1/2}(\Gamma)$ is defined by

$$(S_\Gamma\psi)(x) := \int_\Gamma \psi(y)\,\mathbb{G}(x,y)\,ds_y \quad \text{for } x \in \Gamma.$$

Hence the knowledge of $[v] = v^+ - v^-$ and (2.11) determines v^+ and v^- on Γ and therefore the solution v from the Green representation formula (2.9). To solve (2.10) we observe that $I : \tilde{H}^{1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ is a compact operator due to Rellich's embedding theorem and that T can be written as a sum of a coercive operator and a compact operator (see Theorems 7.8 and 7.10 in [25]). Hence, since $\lambda(x) > \lambda_0 > 0$, we conclude that $(\frac{i}{\lambda}I + T_\Gamma) : \tilde{H}^{1/2}(\Gamma) \to H^{-1/2}(\Gamma)$ is a Fredholm operator of index zero. Therefore, it suffices to prove only the injectivity of $\frac{i}{\lambda}I + T_\Gamma$. To this end let $\xi \in \tilde{H}^{1/2}(\Gamma)$ satisfy

$$\left(\frac{i}{\lambda}I + T_\Gamma\right)\xi = 0,$$

and define the following potential:

$$w(x) = \int_\Gamma \xi(y)\frac{\partial}{\partial \nu_y}\mathbb{G}(x,y)ds_y \quad \text{for } x \in \mathbb{R}^2 \setminus \overline{\Gamma}. \tag{2.12}$$

Approaching Γ and using the jump relations for the double layer potential, we obtain

$$\frac{\partial w^+}{\partial \nu} = \frac{\partial}{\partial \nu_x}\int_\Gamma \xi(y)\frac{\partial}{\partial \nu_y}\mathbb{G}(x,y)ds_y = T_\Gamma(\xi),$$

$$[w] = \xi \qquad \text{and} \qquad \left[\frac{\partial w}{\partial \nu}\right] = 0.$$

Hence we have

$$[w] - i\lambda\frac{\partial w^+}{\partial \nu} = \xi - i\lambda T_\Gamma \xi = -i\lambda\left(\frac{i}{\lambda}I + T_\Gamma\right)\xi = 0.$$

Therefore w defined by (2.12) satisfies (2.1)–(2.4) with $f = h = 0$, and from Theorem 2.1, $w = 0$ in $\mathbb{R}^2 \setminus \overline{\Gamma}$, which finally implies $[w] = \xi = 0$. This ends the proof. ◻

3. Reconstruction of the crack from far field data. In this section we assume that the thin dielectric film is embedded in a homogeneous background and the measurements are made from far away. In addition, we assume that the incident field is a time harmonic plane wave given by $u^i := e^{ikx\cdot d}$ for $x \in \mathbb{R}^2$, where the unit vector $d \in S := \{x \in \mathbb{R}^2 : |x| = 1\}$ is the incident direction. In this setting the scattered field u^s satisfies (2.1)–(2.4) with $n(x) = 1$, $f := -\big[\frac{\partial e^{ikx\cdot d}}{\partial \nu}\big] = 0$, and $h := -\big[e^{ikx\cdot d}\big] + i\lambda\frac{\partial e^{ikx\cdot d}}{\partial \nu} = i\lambda\frac{\partial e^{ikx\cdot d}}{\partial \nu}$. Note that $\mathbb{G}(x,y)$ is now the fundamental solution of the Helmholtz equation $\Phi(x,y) := \frac{i}{4}H_0^{(1)}(k|x-y|)$ with $H_0^{(1)}$ being the Hankel function of the first kind of order zero. It is shown in [10] that the scattered field, which now depends also on d, has the asymptotic behavior

$$u^s(x) = \frac{e^{ikr}}{\sqrt{r}}u_\infty(\hat{x}, d) + O(r^{-3/2}), \tag{3.1}$$

where u_∞ is the *far field pattern* of the scattered wave u^s, $\hat{x} = x/|x|$, and $r = |x|$.

The *inverse scattering problem* that we will consider in this section of our paper is to determine Γ and λ from a knowledge of $u_\infty(\hat{x}, d)$ for $\hat{x}$ and d on the unit circle S. Using [5], one can easily generalize the following analysis for the case of limited aperture data, i.e., for $\hat{x}, d \in S_0 \subset S$. For the unique determination of Γ and λ from the above data, see [28] (see also [7], [10]). We will use the *linear sampling method* to solve this inverse problem [6]. To this end, we define the *far field operator* $F : L^2(S) \to L^2(S)$ by

$$(Fg)(\hat{x}) := \int_S u_\infty(\hat{x}, d)g(d)\,ds(d) \tag{3.2}$$

and consider the *far field equation*

$$Fg = \Phi^e_\infty, \tag{3.3}$$

where Φ^e_∞ is the far field pattern of a suitable solution (to be defined later) to the scattering problem. The aim is to characterize the crack Γ by the behavior of an approximate solution g of the far field equation (3.3). We recall that a Herglotz wave function is a solution of the Helmholtz equation in $\mathbb{R}^2$ of the form

$$v_g(x) := \int_S g(d) e^{ikx\cdot d} ds(d), \tag{3.4}$$

where $g \in L^2(S)$ is the *kernel* of v_g. By superposition we have the following relation:

$$(Fg) = \mathcal{B}(i\lambda\mathcal{H}g),$$

where $\mathcal{H} : L^2(S) \to H^{-\frac{1}{2}}(\Gamma)$ is defined by

$$\mathcal{H}g := \frac{\partial v_g}{\partial \nu} \tag{3.5}$$

and $\mathcal{B} : H^{-\frac{1}{2}}(\Gamma) \to L^2(S)$ takes $h \in H^{-\frac{1}{2}}(\Gamma)$ to the far field pattern u_∞ of the solution to (2.1)–(2.4) with $n(x) = 1$, $f := 0$, and h. For $\beta \in \tilde{H}^{\frac{1}{2}}(\Gamma)$ we construct the double layer potential

$$\mathcal{D}(\beta)(x) := \int_\Gamma \beta(y) \frac{\partial}{\partial \nu_y} \Phi(x, y) ds(y),$$

which has as far field pattern $\gamma\mathcal{F}\beta$, where

$$\mathcal{F}\beta := \int_\Gamma \beta(y) \frac{\partial e^{-ik\hat{x}\cdot y}}{\partial \nu_y} ds(y)$$

and $\gamma = \frac{e^{i\pi/4}}{\sqrt{8\pi k}}$. The calculation

$$\int_S g(\hat{y}) \int_\Gamma \beta(x) \frac{\partial}{\partial \nu} e^{-ikx\cdot\hat{y}} ds(x) d(\hat{y}) = \int_\Gamma \beta(x) \int_S g(\hat{y}) \frac{\partial}{\partial \nu} e^{-ikx\cdot\hat{y}} ds(\hat{y}) ds(x)$$

shows that $\mathcal{H}g(-\hat{y})$ is the transpose of $\mathcal{F}\beta$ in the duality pairing between $\tilde{H}^{\frac{1}{2}}(\Gamma)$, $H^{-\frac{1}{2}}(\Gamma)$ and $L^2(S)$, $L^2(S)$, respectively, where $\mathcal{H} : L^2(S) \to H^{-\frac{1}{2}}(\Gamma)$ and $\mathcal{F} : \tilde{H}^{\frac{1}{2}}(\Gamma) \to L^2(S)$.

Lemma 3.1. *The compact operators* $\mathcal{F} : \tilde{H}^{\frac{1}{2}}(\Gamma) \to L^2(S)$ *and* $\mathcal{H} : L^2(S) \to H^{-\frac{1}{2}}(\Gamma)$ *are injective and have dense range, provided that there does not exist a nontrivial Herglotz wave function such that its normal derivative vanishes on* Γ.

Proof. From the above and Lemma 2.10 in [25] it suffices to show that both $\mathcal{F}$ and $\mathcal{H}$ are injective operators. To this end, if $\mathcal{F}(\beta) = 0$, then $\mathcal{D}\beta = 0$ in $\mathbb{R}^2 \setminus \overline{\Gamma}$, which implies $\beta := -[\mathcal{D}\beta] = 0$ from the jump relation. Next, the assumption of the theorem guarantees that $\mathcal{H}$ is also injective. Note that injectivity of $\mathcal{F}$ and consequently the denseness of the range of $\mathcal{H}$ do not require the assumption stated in the lemma. ∎

We remark that, from the above, the far field operator fails to be injective and have dense range if Γ is such that there exists a nontrivial Herglotz wave function with vanishing normal derivative on Γ. An instance of this situation is if Γ is part of a circle of radius r such that kr is a zero of J_1 Bessel function. It is interesting to notice that in the case of the exact model (namely, the obstacle D is a region with nonempty interior), the far field operator fails to be injective and have dense range if the wave number k is a transmission eigenvalue for D with eigenfunction being a Herglotz function (for details on transmission eigenvalues, see [7]). (Note that the injectivity and the denseness of the range of the far field operator are typically needed in most of the inversion schemes in order to use Tikhonov regularization technique.)

From the above analysis and the jump relations applied to the double layer potential $\mathcal{D}$ we see that

$$\mathcal{F}\beta = \gamma^{-1}\mathcal{B}\left(I - i\lambda T_\Gamma\right)\beta,$$

which implies the following factorization of the far field operator:

$$Fg = \gamma\mathcal{F}\left(I - i\lambda T_\Gamma\right)^{-1}\left(i\lambda\mathcal{H}g\right), \qquad g \in L^2(S). \tag{3.6}$$

Lemma 3.2. *For any simple piecewise smooth arc L and $\beta_L \in \tilde{H}^{\frac{1}{2}}(L)$ we define $\Phi^L_\infty \in L^2(S)$ by*

$$\Phi^L_\infty(\hat{x}) := \int_L \beta_L(y)\frac{\partial}{\partial\nu_y}e^{-ik\hat{x}\cdot y}ds_y. \tag{3.7}$$

Then $\Phi^L_\infty(\hat{x}) \in \operatorname{Range}(\mathcal{F})$ if and only if $L \subset \Gamma$.

Proof. First assume that $L \subset \Gamma$. Then since $\tilde{H}^{\frac{1}{2}}(L) \subset \tilde{H}^{\frac{1}{2}}(\Gamma)$ it follows directly from the definition of $\mathcal{F}$ that $\Phi^L_\infty(\hat{x}) \in \operatorname{Range}(\mathcal{F})$.

Now let $L \not\subset \Gamma$ and assume, on the contrary, that $\Phi^L_\infty(\hat{x}) \in \operatorname{Range}(\mathcal{F})$; i.e., there exists $\beta \in \tilde{H}^{\frac{1}{2}}(\Gamma)$ such that

$$\Phi^L_\infty(\hat{x}) = \int_\Gamma \beta(y)\frac{\partial}{\partial\nu_y}e^{-ik\hat{x}\cdot y}ds_y.$$

Hence by Rellich's lemma and the unique continuation principle we have that the potentials

$$\Phi^L(x) = \int_L \beta_L(y)\frac{\partial}{\partial\nu_y}\Phi(x,y)ds_y \qquad \text{and} \qquad \mathcal{D}(x) = \int_\Gamma \beta(y)\frac{\partial}{\partial\nu_y}\Phi(x,y)ds_y$$

coincide in $\mathbb{R}^2 \setminus (\overline{\Gamma} \cup \overline{L})$. Now let $x_0 \in L$, $x_0 \notin \Gamma$, and let $B_\epsilon(x_0)$ be a small ball with center at x_0 such that $B_\epsilon(x_0) \cap \Gamma = \emptyset$. Hence $\mathcal{D}$ is analytic in $B_\epsilon(x_0)$, while Φ^L has a singularity at x_0, which is a contradiction. This proves the lemma. □

Now using Lemma 3.2, the regularization theory for $\mathcal{F}\beta = \Phi^L_\infty$, and the fact that $\left(i\lambda T_\Gamma - I\right)\beta$ can be approximated by $i\lambda\mathcal{H}g$ in $H^{-\frac{1}{2}}(\Gamma)$, we have the following result for the solution of the *far field equation*:

$$(Fg)(\hat{x}) = \gamma\Phi^L_\infty(\hat{x}), \qquad \hat{x} \in S, \tag{3.8}$$

which is the basis of the linear sampling method for reconstructing Γ (cf. Theorem 8.45 of [6]).

Theorem 3.3. *Assume that Γ is a simple piecewise smooth arc and that there does not exist any nontrivial Herglotz wave function having vanishing normal derivative on Γ. Then if F is the far field operator corresponding to* (2.1)–(2.4) *with* $n(x) = 1$,

$f := 0$, and $h := i\lambda \frac{\partial e^{ikx\cdot d}}{\partial \nu}$, the following are true:

1. *If $L \subset \Gamma$, then for every $\epsilon > 0$ there exists a solution $g_\epsilon^L \in L^2(S)$ of the inequality*

$$\|Fg_\epsilon^L - \gamma \Phi_\infty^L\|_{L^2(S)} < \epsilon$$

such that $\mathcal{H}_{g_\epsilon^L}$ converges to a well-defined function in $H^{-\frac{1}{2}}(\Gamma)$.

2. *If $L \not\subset \Gamma$, then for every $\epsilon > 0$ all $g_\epsilon^L \in L^2(S)$ satisfying*

$$\|Fg_\epsilon^L - \gamma \Phi_\infty^L\|_{L^2(S)} < \epsilon$$

are such that

$$\lim_{\epsilon \to 0} \|g_\epsilon^L\|_{L^2(S)} = \infty \quad \textit{and} \quad \lim_{\epsilon \to 0} \|\mathcal{H}_{g_\epsilon^L}\|_{H^{-\frac{1}{2}}(\Gamma)} = \infty,$$

where $\mathcal{H}_{g_\epsilon^L}$ is defined by (3.5) with $v_{g_\epsilon^L}$ being the Herglotz wave function with kernel g_ϵ^L.

Remark 3.1. From the above analysis we notice that, for $L \subset \Gamma$, $i\lambda\mathcal{H}_{g_\epsilon^L}$ approximates $(I - i\lambda T_\Gamma)\beta_L$, where g_ϵ^L is the approximate solution of (3.8). In particular, in the $H^{-\frac{1}{2}}(\Gamma)$-norm we have

$$\frac{\partial v_{g_\epsilon^L}}{\partial \nu} \approx \frac{i\beta_L}{\lambda} - T_\Gamma \beta_L, \qquad L \subset \Gamma \quad \text{and} \quad \beta_L \in C_0^\infty(L), \tag{3.9}$$

which can be used to recover λ, provided that (a reconstruction of) Γ is now known (e.g., by using the linear sampling method based on Theorem 3.3).

4. Reconstruction of the crack from near field data. We now assume that the dielectric thin film is embedded in a known inhomogeneous medium with index of refraction $n(x)$ that satisfies the assumptions stated in section 2. The incident field is a point source given by $\Phi(x, x_0, k_s) := \frac{i}{4}H_0^{(1)}(k_s|x - x_0|)$ located at a point x_0 outside a bounded region Ω surrounding the crack and $k_s^2 = k^2 n(x_0)$ (see Figure 4.1). In this case the scattered field u^s satisfies (2.1)–(2.4) with $f := -\left[\frac{\partial\Phi(\cdot,x_0,k_s)}{\partial\nu}\right] = 0$ and $h := -\left[\Phi(\cdot, x_0, k_s)\right] + i\lambda\frac{\partial\Phi(\cdot,x_0,k_s)}{\partial\nu} = i\lambda\frac{\partial\Phi(\cdot,x_0,k_s)}{\partial\nu}$. Note that u^s is the sum of the scattered field due to the crack and the scattered field due to the medium. Let $u(\cdot, x_0) = u^s(\cdot, x_0) + \Phi(\cdot, x_0, k_s)$ denote the total field, let Λ be a closed curve containing Ω, and suppose that in a neighborhood of Λ the index of refraction $n(x)$ is constant and $k^2 n = k_s^2$. Note that Λ can be part of a closed analytic curve, and by an analycity argument the following analysis holds true as well. For technical reasons we write $u(\cdot, x_0) = u_c^s(\cdot, x_0) + \mathbb{G}(\cdot, x_0)$, where $u_c^s(\cdot, x_0)$ is the scattered field due to the crack and $\mathbb{G}(\cdot, x_0)$ is the total field due to the medium or the background Green's function satisfying (2.8).

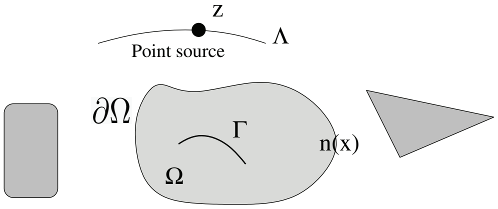

FIG. 4.1. *Geometry for the reciprocity gap functional method.*

The *inverse scattering problem* we are interested in now is to determine the crack Γ from a knowledge of $u(\cdot, x_0)$ and $\frac{\partial u(\cdot, x_0)}{\partial \nu}$ on the boundary $\partial\Omega$ for all point sources located at any $x_0 \in \Lambda$. These measurements in the case of Maxwell's equations correspond to measuring the tangential components of the electric and magnetic fields. To solve this inverse scattering problem we adapt the *reciprocity gap functional* method first introduced [12] for obstacles with nonempty interior. To this end, let

$$\mathbb{H}(\Omega) := \left\{ w \in H^1(\Omega) : \ \Delta w + k^2 n(x) w = 0 \quad \text{in } \Omega \right\}.$$

In a similar way as in Lemma 3.1 (see also the proof of Lemma 4.4 in [8]) it can be shown that the set

$$\left\{ (\mathcal{S}\varphi)(y) := \int_\Sigma \varphi(x)\Phi(x,y)\, ds_x \quad \text{for } \varphi \in L^2(\Sigma) \right\} \tag{4.1}$$

is dense in $\mathbb{H}(\Omega)$, where Σ is a open curve outside Ω and $\Phi(x,y)$ is the radiating fundamental solution of $\Delta u + k^2 \tilde{n}(x) u = 0$, where $\tilde{n}(x) = n(x)$ for $x \in \Omega$ and $\tilde{n}(x) = 1$ for $x \in \mathbb{R}^2 \setminus \Omega$ (or any other convenient extension). In particular, if $n(x) = n_0$ is constant in Ω, then $\Phi(x,y)$ is simply $\frac{i}{4} H_0^{(1)}(k\sqrt{n_0}|x - x_0|)$.

We define the *reciprocity gap operator* $\mathcal{R} : \mathbb{H}(\Omega) \to L^2(\Lambda)$ by

$$\mathcal{R}(w)(x_0) = \int_{\partial\Omega} \left(u(\cdot, x_0) \frac{\partial w}{\partial \nu} - w \frac{\partial u(\cdot, x_0)}{\partial \nu} \right) ds, \qquad x_0 \in \Lambda, \ w \in \mathbb{H}(\Omega). \tag{4.2}$$

THEOREM 4.1. *The compact operator $\mathcal{R} : \mathbb{H}(\Omega) \to L^2(\Lambda)$ is injective and has dense range, provided that there does not exist any $w \in \mathbb{H}(\Omega)$ such that $\partial w / \partial \nu = 0$ on Γ.*

Proof. If $\mathcal{R}(w) = 0$, applying Green's second identity and using the zero boundary condition for $u(\cdot, x_0)$, it is easy to see that

$$0 = \mathcal{R}(w)(x_0) = -i \int_\Gamma \lambda \frac{\partial u(\cdot, x_0)}{\partial \nu} \frac{\partial w}{\partial \nu} ds.$$

Noting that from the boundary condition $\lambda \partial u(\cdot, x_0)/\partial \nu \in \tilde{H}^{\frac{1}{2}}(\Gamma)$ it suffices to show that $\lambda \partial u(\cdot, x_0)/\partial \nu$ for $x_0 \in \Lambda$ are dense in $\tilde{H}^{\frac{1}{2}}(\Gamma)$. Indeed, this fact implies that $\partial w / \partial \nu = 0$, which contradicts the assumption of the theorem. To prove the denseness property let $\psi \in H^{-\frac{1}{2}}(\Gamma)$ such that

$$0 = \int_\Gamma \lambda(x) \psi(x) \frac{\partial u(x, x_0)}{\partial \nu}\, ds_x \qquad \text{for all } x_0 \in \Lambda,$$

where the integral is understood in the sense of duality pairing, and let $w \in H^1(\mathbb{R}^2 \setminus \overline{\Gamma})$ be the solution of (2.1)–(2.4) with $f := 0$ and $h := \lambda\psi$. Applying Green's second identity to w and u_c^s (note that both satisfy $\Delta u + k^2 n u = 0$ outside Γ) and the boundary condition for $u(\cdot, x_0)$, we obtain that

$$\begin{aligned}
0 &= \int_\Gamma \lambda(x)\psi(x)\frac{\partial u(x,x_0)}{\partial \nu}\, ds_x = \int_\Gamma \left([w] - i\lambda\frac{\partial w}{\partial \nu}\right)\frac{\partial\left(u_c^s + \mathbb{G}(\cdot,x_0)\right)}{\partial \nu}\, ds \\
&= \int_\Gamma \left([u_c^s] - i\lambda\frac{\partial u_c^s}{\partial \nu}\right)\frac{\partial w}{\partial \nu}\, ds + \int_\Gamma \left([w] - i\lambda\frac{\partial w}{\partial \nu}\right)\frac{\partial \mathbb{G}(\cdot,x_0)}{\partial \nu}\, ds \\
&= -\int_\Gamma \left([\mathbb{G}(\cdot,x_0)] + i\lambda\frac{\partial \mathbb{G}(\cdot,x_0)}{\partial \nu}\right)\frac{\partial w}{\partial \nu}\, ds + \int_\Gamma \left([w] - i\lambda\frac{\partial w}{\partial \nu}\right)\frac{\partial \mathbb{G}(\cdot,x_0)}{\partial \nu}\, ds \\
&= \int_\Gamma [w]\frac{\partial \mathbb{G}(\cdot,x_0)}{\partial \nu}\, ds \qquad \text{for all } x_0 \in \Lambda.
\end{aligned}$$

Hence $P(x_0) = \int_\Gamma [w(x)]\frac{\partial \mathbb{G}(x,x_0)}{\partial \nu}\, ds_x$ is a radiating solution as a function of x_0 which vanishes on Λ, which implies that $P(x_0) = 0$ outside the domain bounded by Λ and consequently in $\mathbb{R}^2 \setminus \overline{\Gamma}$ by unique continuation. Hence, using the jump relations, we have that $[w] = 0$ on Γ, which together with $[\partial w/\partial \nu] = 0$ on Γ implies $w = 0$ and consequently $\psi = 0$.

Next we show that $\mathcal{R}$ has dense range. Let $\alpha \in L^2(\Lambda)$ be such that $(\mathcal{R}w, \overline{\alpha})_{L^2(\Lambda)} = 0$ for all $w \in \mathbb{H}(\Omega)$. The bilinearity of $\mathcal{R}$ implies that

$$(4.3) \qquad (\mathcal{R}w, \overline{\alpha})_{L^2(\Lambda)} = \int_{\partial\Omega}\left(Q\frac{\partial w}{\partial \nu} - w\frac{\partial Q}{\partial \nu}\right) ds = -i\int_\Gamma \lambda\frac{\partial Q}{\partial \nu}\frac{\partial w}{\partial \nu} ds = 0$$

for all $w \in \mathbb{H}(\Omega)$, where

$$Q(x) = \int_\Lambda \alpha(x_0)u(x,x_0)\, ds(x_0) = \int_\Lambda \alpha(x_0)u_c^s(x,x_0)\, ds(x_0) + \int_\Lambda \alpha(x_0)\mathbb{G}(x,x_0)\, ds(x_0).$$

Hence (4.3) implies that $\partial Q/\partial \nu = 0$ on Γ since obviously the set $\{\partial w/\partial \nu :\ w \in \mathbb{H}(\Omega)\}$ is dense in $H^{-\frac{1}{2}}(\Gamma)$ and Q is smooth near Γ. Since $Q \in \mathbb{H}(\Omega)$, from the assumption we can conclude that $Q = 0$ in Ω and therefore by unique continuation in the domain bounded by Λ. Since Q is continuous across Λ we conclude that Q is a radiating solution and is zero on Λ which implies that $Q = 0$. Finally by the jump relation of the normal derivative of single layer potential we finally have that $\alpha = 0$, which ends the proof. □

Now we have all the ingredients to describe a sampling algorithm to determine Γ without knowing λ. Let L be an open arc in Ω and consider

$$\Phi^L(x) = \int_L \beta_L(y)\frac{\partial}{\partial \nu_y}\Phi(x,y)ds_y, \qquad \beta_L \in \tilde{H}^{\frac{1}{2}}(L),$$

where $\Phi(x,y)$ satisfies

$$\Delta\Phi(x,y) + k^2\tilde{n}(x)\Phi(x,y) = \delta(x,y)$$

and again $\tilde{n}(x) = n(x)$ for $x \in \Omega$ and $\tilde{n}(x) = 1$ for $x \in \mathbb{R}^2 \setminus \Omega$ (or any other convenient extension). Note that we need to know only the index of refraction of the background medium inside Ω, and this is the strength of this method compared to the linear sampling method. Again if $n(x) = n_0$ is constant in Ω, one can choose $\Phi(x,y) := \frac{i}{4}H_0^{(1)}(k\sqrt{n_0}|x-x_0|)$. The proposed algorithm consists of seeking for each open arc $L \subset \Omega$ a solution $\varphi \in L^2(\Sigma)$ to the first kind ill-posed linear equation

$$\mathcal{R}(\mathcal{S}\varphi)(x_0) = \mathcal{R}(\Phi^L)(x_0), \qquad x_0 \in \Lambda. \tag{4.4}$$

Note that in order to guarantee that $\mathcal{RS}$ is injective and has dense range from the proof of Theorem 4.1 it suffices to assume that there does not exist any potential in (4.1) with vanishing normal derivative on Γ. This condition is similar to the condition we imposed on the Herglotz functions in section 3, and it excludes some special types of cracks.

Note also that in (4.4), $\mathcal{S}\varphi$ can be replaced with any one parameter dense family of functions in $\mathbb{H}(\Omega)$. We refer the reader to [26] for a variational approach to constructing such a family. In particular, if $n(x)$ is constant in Ω, one could use the corresponding Herglotz wave functions using the result of [11].

Now, if $L \subset \Gamma$, from the proof of the first part of Theorem 4.1 we see that (4.4) has a unique solution if and only if $\frac{\partial \mathcal{S}\varphi}{\partial \nu} = \frac{\partial \Phi^L}{\partial \nu}$ on Γ. This can only be satisfied approximately for some $\varphi \in L^2(\Sigma)$ since the set $\left\{\partial\mathcal{S}\varphi/\partial\nu : \varphi \in L^2(\Sigma)\right\}$ is dense in $H^{-\frac{1}{2}}(\Gamma)$.

Next, if $L \not\subset \Gamma$, we can find φ_ϵ such that

$$\|\mathcal{R}(\mathcal{S}\varphi_\epsilon) - \mathcal{R}(\Phi^L)\|_{L^2(\Lambda)} < \epsilon$$

and $\|\partial\mathcal{S}\varphi_\epsilon/\partial\nu\|_{H^{-\frac{1}{2}}(\Gamma)} < C$. Since $u(\cdot,x_0) = u_c^s(\cdot,x_0) + \mathbb{G}(\cdot,x_0)$, using Green's formula we obtain

$$\begin{aligned}
\mathcal{R}(\Phi^L)(x_0) &= \int_{\partial\Omega}\left(u_c^s(x,x_0)\frac{\partial\Phi^L(x)}{\partial\nu} - \Phi_L(x)\frac{\partial u_c^s(x,x_0)}{\partial\nu}\right)ds_x \\
&\quad + \int_{\partial\Omega}\left(\mathbb{G}(x,x_0)\frac{\partial\Phi^L(x)}{\partial\nu} - \Phi_L(x)\frac{\partial\mathbb{G}(x,x_0)}{\partial\nu}\right)ds_x \\
&= w(x_0) + \int_L \beta_L(y)\frac{\partial}{\partial\nu_y}\int_{\partial\Omega}\left(\mathbb{G}(x,x_0)\frac{\partial\Phi(x,y)}{\partial\nu} - \Phi(x,y)\frac{\partial\mathbb{G}(x,x_0)}{\partial\nu}\right)ds_x\,ds_y \\
&= w(x_0) + \int_L \beta_L(y)\frac{\partial}{\partial\nu_y}\mathbb{G}(x_0,y)ds_y,
\end{aligned}$$

where $w(x_0)$ is a solution to $\Delta_{x_0}w + k^2 n(x_0)w = 0$. On the other hand,

$$\mathcal{R}(\mathcal{S}\varphi_\epsilon)(x_0) = -i\int_\Gamma \lambda\frac{\partial u(x,x_0)}{\partial\nu}\frac{\partial\mathcal{S}\varphi_\epsilon}{\partial\nu}ds.$$

Since $\|\partial\mathcal{S}\varphi_\epsilon/\partial\nu\|_{H^{-\frac{1}{2}}(\Gamma)} < C$, we can assume that there exists a sequence such that $\lim_{\epsilon\to 0}\partial\mathcal{S}\varphi_\epsilon/\partial\nu = \theta \in H^{-\frac{1}{2}}(\Gamma)$ weakly, whence

$$\lim_{\epsilon\to 0}\mathcal{R}(\mathcal{S}\varphi_\epsilon)(x_0) = -i\int_\Gamma \lambda\frac{\partial u(x,x_0)}{\partial\nu}\,\theta(x)ds_x.$$

Hence

$$-i\int_\Gamma \lambda \frac{\partial u_c^s(x,x_0)}{\partial \nu}\,\theta(x)ds_x - i\int_\Gamma \lambda \frac{\partial \mathbb{G}(x,x_0)}{\partial \nu}\,\theta(x)ds_x$$

$$= w(x_0) + \int_L \beta_L(x)\frac{\partial}{\partial \nu_x}\mathbb{G}(x_0,x)ds_x. \tag{4.5}$$

Since the first term on both sides can be extended as solution to $\Delta_{x_0}w+k^2n(x_0)w=0$ outside the domain bounded by Λ, we deduce by uniqueness and the unique continuation principle that (4.5) holds in $\mathbb{R}^2\setminus\overline{\Gamma}\cup\overline{L}$. Now we arrive at a contradiction since for $x_0\in L$, $x_0\notin\Gamma$, and $B_\epsilon(x_0)$ a small ball with center at x_0 such that $B_\epsilon(x_0)\cap\Gamma=\emptyset$ the left-hand side is analytic whereas the right-hand side has a singularity at x_0.

The above analysis has proven the following main theorem of this section, which is the basis of the linear sampling method based on the reciprocity gap functional for determining Γ.

Theorem 4.2. *Assume that* Γ *is simple piecewise smooth arc and that there does not exist any potential in* (4.1) *having zero normal derivative on* Γ. *Then if* $u(\cdot,x_0)$ *is the total field corresponding to* (2.1)–(2.4) *with* $f:=0$ *and* $h:=i\lambda\frac{\partial\Phi(\cdot,x_0,k_s)}{\partial\nu}$, *the following are true:*

1. *If* $L\subset\Gamma$, *then for every* $\epsilon>0$ *there exists a* $\varphi_\epsilon^L\in L^2(\Sigma)$ *satisfying*

$$\|\mathcal{R}(\mathcal{S}\varphi_\epsilon^L)-\mathcal{R}(\Phi^L)\|_{L^2(\Lambda)}<\epsilon$$

such that $\frac{\partial\mathcal{S}\varphi_\epsilon^L}{\partial\nu}$ *converges to* $\frac{\partial\Phi^L}{\partial\nu}$ *in* $H^{-\frac{1}{2}}(\Gamma)$.

2. *If* $L\not\subset\Gamma$, *then for every* $\epsilon>0$ *any* $\varphi_\epsilon^L\in L^2(\Sigma)$ *satisfying*

$$\|\mathcal{R}(\mathcal{S}\varphi_\epsilon^L)-\mathcal{R}(\Phi^L)\|_{L^2(\Lambda)}<\epsilon$$

is such that

$$\lim_{\epsilon\to0}\|\varphi_\epsilon^L\|_{L^2(\Sigma)}=\infty \quad \textit{and} \quad \lim_{\epsilon\to0}\left\|\frac{\partial\mathcal{S}\varphi_\epsilon^L}{\partial\nu}\right\|_{H^{-\frac{1}{2}}(\Gamma)}=\infty,$$

where $\mathcal{S}\varphi_\epsilon^L$ *is defined by* (4.1).

5. Numerical examples.

5.1. The linear sampling method.

In this section we will give some results of numerical experiments for identifying cracks based on the theory developed in section 3. The far field data we use are synthetic, but corrupted by random noise added pointwise to the measurements. The forward problem is numerically solved using a quadrature method for the first kind hypersingular integral equation (2.10) as developed by Kress and co-authors in [9], [19], and [20]. This method seems well suited to our problem since we need to invert a hypersingular integral operator. This claim is validated by our numerical results which show a convergence rate similar to that in [9]. However, the exact order of singularity of the solution of the forward problem at the tips of the crack still remains to be studied. The computed far field data is obtained as a trigonometric series $u_\infty=\sum_{n=-N}^{N}u_{\infty,n}\exp(in\theta)$. We then add random noise to the Fourier coefficients of u_∞ to obtain the approximate far field pattern $u_{\infty,a}=\sum_{n=-N}^{N}u_{\infty,a,n}\exp(in\theta)$, where $u_{\infty,a,n}=u_{\infty,n}(1+\epsilon\chi_n)$ with χ_n a random variable in $[-1,\ 1]$ ($\epsilon=0.05$ in our examples). We remark that this random noise is rather "special," since the far field data polluted in this way remains the far field of some radiating solution to the Helmholtz equation, as the decay rate of the Fourier coefficients is not modified. This may not be the case for the noise in measured data. Also, it would be interesting to test our inversion method using simulated data computed from the exact model of the forward problem. Unfortunately, we do not have available a forward code to do so. Notice that we do not commit any inverse crime since the method for solving the direct problem and the method for solving the inverse problem are completely different.

The inversion scheme is based on solving the following ill-posed first kind equation:

$$\int_S u_\infty(\hat{x}, d) g(d)\, ds(d) = \gamma \int_L \beta_L(y) \frac{\partial}{\partial \nu_y} e^{-ik\hat{x}\cdot y} ds_y \tag{5.1}$$

for an arbitrary open arc L and $\beta_L \in \tilde{H}^{\frac{1}{2}}(L)$. Then the crack can be reconstructed by using the fact that if $L \subset \Gamma$, we can find a bounded $g \in L^2(S)$ that satisfies (5.1) with discrepancy ϵ, whereas if $L \not\subset \Gamma$, all approximate solutions to (5.1) are unbounded. In this study we search for the crack by taking L to be a small segment centered at a sampling point z with unit normal vector n_z and β_L a sequence that converges to $\delta(z)$. Thus, in the limiting case, (5.1) is replaced by

$$\int_{-\pi}^{\pi} u_\infty(\hat{x}, \theta) g_{z,n_z}(\theta)\, d\theta = -ik\gamma\, n_z \cdot \hat{x}\, e^{-ik\hat{x}\cdot z}, \qquad \hat{x} \in S,\ z \in \mathbb{R}^2,\ n_z \in S. \tag{5.2}$$

Now, if $z \in \Gamma$ and n_z coincides with the normal vector to Γ at z, then we can find a bounded $g_{z,n_z} \in L^2(S)$ that approximately solves (5.2). Otherwise all such $g_{z,n_z} \in L^2(S)$ are unbounded.

In order to solve (5.2) we use Tikhonov regularization and the Morozov discrepancy principle to deal with the severe ill-posedness of this equation. In particular, using the above expression for $u_{\infty,a}$, (5.2) is rewritten as an ill-conditioned matrix equation for the Fourier coefficients of g, which we write in the form

$$A g_{z,\theta_z} = f_{z,\theta_z}, \qquad \text{where } \theta_z = n_z \cdot \hat{x} \in [-\pi, \pi]. \tag{5.3}$$

As already noted, this equation needs to be regularized. To do this, we begin by computing the singular value decomposition of A, i.e., $A = U\Lambda V^*$, where U and V are unitary and Λ is real diagonal with $\Lambda_{l,l} = \sigma_l,\ 1 \le l \le n$, where σ_l are the singular values of A. The solution of (5.3) is then equivalent to solving $\Lambda V^* g_{z,\theta_z} = U^* f_{z,\theta_z}$. Now letting $\rho_{z,\theta_z} = (\rho_1, \rho_2, \ldots, \rho_n)^\top = U^* f_{z,\theta_z}$, the Tikhonov regularization of (5.3) leads to the problem of solving

$$\min_{g_{z,\theta_z} \in \mathbb{R}^n} \|\Lambda V^* g_{z,\theta_z} - \rho_{z,\theta_z}\|_{l^2}^2 + \alpha \|g_{z,\theta_z}\|_{l^2}^2,$$

where $\alpha > 0$ is the regularization parameter [6]. The numerical procedure for locating the crack is the following: we consider a uniform grid of sampling points $\{z_i\}_{i=1,\ldots,N}$ in the probing area, and for each sampling point z_i we choose a finite number of angles $\theta_{z_i}^j$, $j = 1, \ldots, M$, and compute

$$\mathcal{G}(z_i, \theta_{z_i}^j) = \|f_{z_i,\theta_{z_i}^j}\|_{\ell^2} / \|g_{z,\theta_{z_i}^j}\|_{\ell^2}.$$

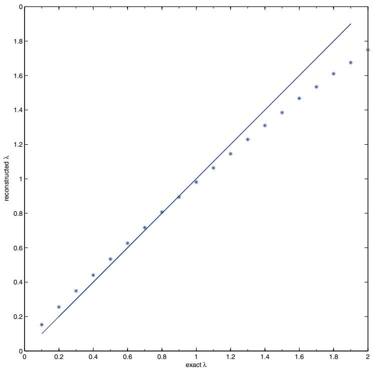

Fig. 5.1. *Here we show the reconstruction of different values of* λ *for the curved crack shown in Figure* 5.3(a). *The reconstructed values are shown by the little stars. The true reconstruction would be on the solid line.*

It is expected that $\mathcal{G}(z_i, \theta^j_{z_i})$ becomes relatively large if z_i is a point of Γ and $\theta^j_{z_i}$ is (near) the angle corresponding to the tangent line to Γ at z_i. In all our reconstruction examples we plot the indicator function

$$\mathbb{G}(z_i) = \sum_{j=1}^{M} \mathcal{G}(z_i, \theta^j_{z_i}) \qquad \text{for all sampling points } z_i \text{ on the grid.}$$

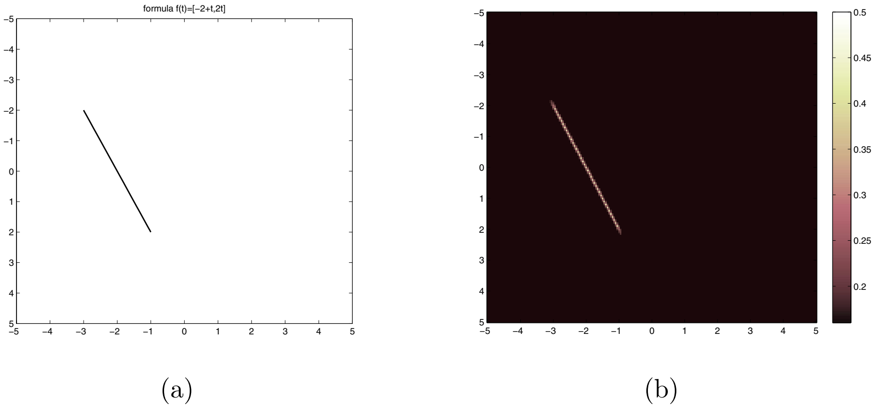
We found out that one obtains similar plots when taking the maximum over all $\theta^j_{z_i}$ for every fixed z_i instead of the summation. However, further investigation is needed to construct an indicator function that better captures the effect of the angles θ_z.

Having reconstructed Γ, it is possible to use (3.9) to reconstruct λ. In this work we have not investigated the best numerical strategy to implement (3.9) in the case when λ is a function. Here we present some preliminary results in the simplest case when λ is a constant. To this end it is natural to consider the imaginary part of (3.9). Hence the reconstruction formula is based on

$$\operatorname{Im} \frac{\partial v_{g^L_\epsilon}}{\partial \nu}(x) = \frac{1}{\lambda}\beta_L(x) - \operatorname{Im}(T_\Gamma \beta_L)(x), \qquad x \in \Gamma,$$

where $\beta_L \in C^\infty_0(L)$. (Note that the imaginary part of the potential T_Γ is an operator with a smooth kernel.) Now if λ is constant, we fix a point in $z \in \Gamma$ and the normal vector n_z to the crack at z and let g_{z,n_z} be the corresponding solution of the discrete far field equation. Then $\operatorname{Im}\frac{\partial v_{g_{z,n_z}}(z)}{\partial n_z}$ is approximately $1/\lambda A_z + B_z$, where A_z and B_z do not depend on λ. Hence, it is possible to avoid unstable computation of A_z and B_z, by computing the Herglotz wave function for two values of λ. Our preliminary examples show that the determination of A_z and B_z is robust. An example of reconstruction of λ based on this approach is shown in Figure 5.1. However, we note that more numerical study is needed to make the reconstruction formula for λ more practical especially for nonconstant λ. The information on λ is useful since it contains knowledge about the thickness of the dielectric object as well as its physical properties.

The numerical examples presented here consist of using the linear sampling method to reconstruct the shape of the dielectric crack, as explained above, for the following



(a) (b)

FIG. 5.2. *Panel* (a) *shows the exact crack and panel* (b) *the reconstruction using the linear sampling method. The wave number is* $k = 3$.

open arcs:

$$\Gamma := \{-2 + s, 2s : -1 \leq s \leq 1\},$$

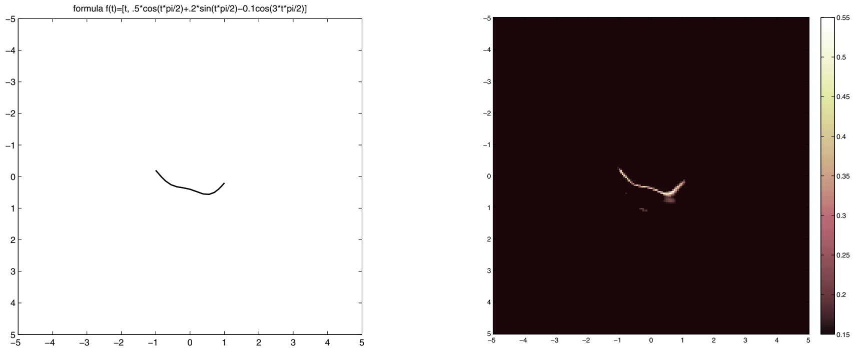
shown in Figure 5.2(a);

$$\Gamma := \left\{2\sin\left(\frac{3\pi}{2}s\right) + 2, \sin\left(\frac{3\pi}{2}s + \pi\right) : -1 \leq s \leq 1\right\},$$

shown in Figure 5.3(a); and

$$\Gamma := \left\{s, 0.5\cos\frac{\pi s}{2} + 0.2\sin\frac{\pi s}{2} - 0.1\cos\frac{3\pi s}{2} : -1 \leq s \leq 1\right\},$$

shown in Figure 5.4(a). The respective reconstructions are shown in Figures 5.2(b), 5.3(b), and 5.4(b). In all reconstructions we keep $k = 3$ and the noise level 5%.



(a) (b)

FIG. 5.4. *Panel* (a) *shows the exact crack and panel* (b) *the reconstruction using the linear sampling method. The wave number is* $k = 3$.

5.2. The reciprocity gap functional method. Here we assume that $n(x) = n_0$ for $x \in \overline{\Omega}$, where n_0 is a complex constant and $n(x) = 1$ outside Ω. Similarly to the case of the linear sampling method, we take L to be a small segment centered at a sampling point z with unit normal vector n_z and β_L a sequence converging to $\delta(z)$. Hence, in the same manner as for the linear sampling method, we can write (4.4) as

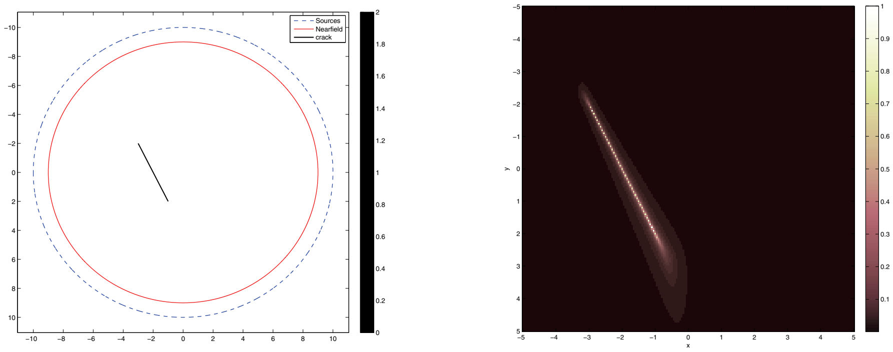
$$A\varphi_{z,n_z}(x_0) = f_{z,n_z}(x_0), \qquad x_0 \in \Lambda, \tag{5.4}$$

where $A : L^2(\Sigma) \to L^2(\Lambda)$ is the integral operator with kernel

$$K(x, x_0) := \mathcal{R}(H_0^{(1)}(k\sqrt{n_0}|x - (\cdot)|))(x_0)$$

and $f_{z,n_z}(x_0) = \mathcal{R}(ikn_z \cdot \nabla H_0^{(1)}(k\sqrt{n_0}|z - (\cdot)|))(x_0)$. Equation (5.4) is an ill-posed linear integral equation and is solved in the same way as explained in section 5.1. Similarly, the approximate solution φ_{z,n_z} is then used to identify the crack.

We end by showing an example of reconstruction for a linear crack embedded in a homogeneous medium surrounded by a circle with $n_0 = 1.5$. The data are measured on the upper half of a bigger circle. We are limited here to small contrast for the host medium, due only to the lack of forward data; it is not a limitation of the reciprocity gap functional method. We computed the data by adding the scattered field due to a crack embedded in a homogeneous media with $n = 1$ in $\mathbb{R}^2$ and the scattered field due to the disk with $n = 1.9$; i.e., we are ignoring multiple scattering effects. The example presented in Figure 5.5 indicates reliable performance of the RGF (reciprocity gap functionals) method based on sampling. Certainly, more numerical experiments are needed to validate it, including the case of absorbing background and limited aperture measurements.



(a) (b)

Fig. 5.5. *Panel* (a) *shows the configuration of the example. The crack is the black solid line embedded inside the red solid circle $\partial\Omega$ corresponding to $n_0 = 1.9$. The sources are paced on the upper half of the blue dashed circle denoted by Σ. The measurements are made on the red circle $\partial\Omega$. Panel* (b) *shows the reconstructed crack using the reciprocity gap functional method. A zoom of the area inside the red circle containing the crack is shown. The wave number is $k = 5$.*

MODELING, SIMULATION, AND DESIGN FOR A CUSTOMIZABLE ELECTRODEPOSITION PROCESS[*]

PRADEEP THIYANARATNAM[†], RUSSEL CAFLISCH[‡], PAULO S. MOTTA[§], AND JACK W. JUDY[¶]

Abstract. Judy and Motta developed a customizable electrodeposition process for fabrication of very small metal structures on a substrate. In this process, layers of metal of various shapes are placed on the substrate, then the substrate is inserted in an electroplating solution. Some of the metal layers have power applied to them, while the rest of the metal layers are not connected to the power initially. Metal ions in the plating solution start depositing on the powered layers and a surface grows from the powered layers. As the surface grows, it will touch metal layers that were initially unpowered, causing them to become powered and to start growing with the rest of the surface. The metal layers on the substrate are known as seed layer patterns, and different seed layer patterns can produce different shapes. This paper presents a mathematical model, a forward simulation method, and an inverse problem solution for the growth of a surface from a seed layer pattern. The model describes the surface evolution as uniform growth in the direction normal to the surface. This growth is simulated in two and three dimensions using the level set method. The inverse problem is to design a seed layer pattern that produces a desired surface shape. Some surface shapes are not attainable by any seed layer pattern. For smooth attainable shapes, we present a computational method that solves this inverse problem.

1. Electrodeposition.

Judy and Motta [7] developed a customizable electrodeposition process for fabrication of small metal structures on a substrate. As pictured schematically in Figure 1.1, two plates of metal (nickel) are placed in an electroplating solution, and voltage is applied across the two plates. This causes Ni ions to separate from the anode and deposit on the cathode. By insulating areas of metal on the cathode, they can control where the metal gets deposited. Altering the exposed metal allows them to produce different shapes. The patterns of exposed metal are called seed layer patterns. For complicated seed layer patterns, it may be difficult to predict the final shape of the object. Thus the experimental procedure may require some trial and error to determine the seed pattern that attains a desired shape. One application of this process is the fabrication of neural probes used to stimulate the brain in Parkinson's disease research [6]. When used in preclinical experiments involving small animal models (e.g., rat or mouse), the probes should be very small (e.g., a few 100 μm) so they can be inserted into the brain with precision and minimal

damage [7]. Figure 1.2 shows an example of a needle-shaped object produced in [7].

A mathematical model of electrodeposition may simplify and accelerate the design of seed layer patterns and reduce the number of experimental trials needed to attain a desired shape. Our model will employ the simplifying assumption that the surface grows uniformly in the normal direction. We will not consider nonuniform growth or possible diffusion of the growing surface. Experimental parameters, such as

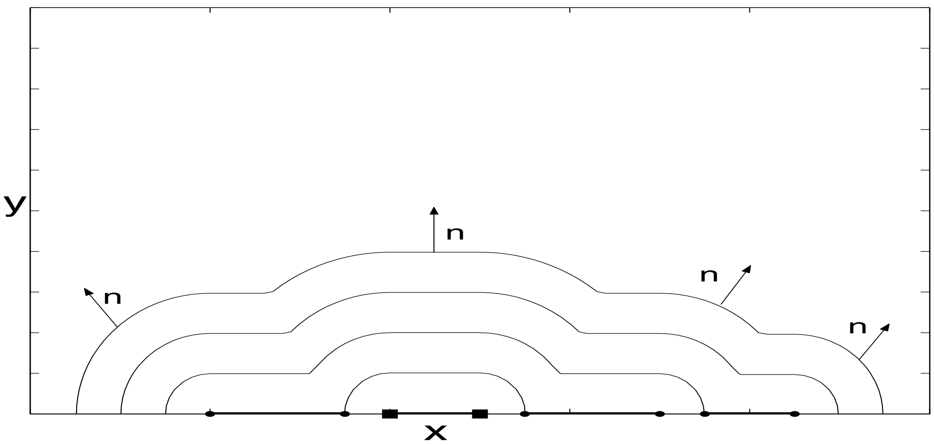

FIG. 1.3. *Stages of growth of the seed layer pattern. The segment with squares on the ends is powered and the segments with circles on ends are unpowered.*

temperature, will be also be ignored. These simplifications allow for a solution which is computationally fast and enable us to solve the inverse problem of determining a seed layer pattern that will produce a given shape.

Figure 1.3 shows a two-dimensional (2D) cross section of an object at various times as it grows uniformly in the normal direction, and indicates how the seed layer pattern controls the final shape. Initially, the segment with squares on the ends is a powered metal layer and the segments with circles on the ends are metal layers that are isolated from the power source. Although the object grows from the powered segment, it eventually touches an unpowered segment, which then becomes powered and starts to grow with the surface. As each unpowered segment is contacted by the growing object, it becomes powered and starts to grow.

The remainder of this paper is organized as follows: Section 2 describes the level set method that is the principal computational technique of our simulation method. Sections 3 and 4 describe the simulation method in two and three dimensions, respectively. The inverse design method in two and three dimensions is presented in sections 5 and 6, respectively. The methods for two and three dimensions are presented separately, since the 2D method is considerably simpler than the three-dimensional (3D) method. Conclusions and further work are discussed in section 7.

2. Level set method. The level set method is a way to represent complex geometric interfaces or shapes that evolve in time, with several nice properties, including the capability to easily merge shapes. The idea behind the level set method is to represent the interface (boundary) $\Gamma(t)$ of the object $\Omega(t)$ implicitly as the zero level set of a function ϕ, usually referred to as a level set function [8] (i.e., $\Gamma(t) = \{\mathbf{x} : \phi(\mathbf{x}, t) = 0\}$). We also set $\phi(\mathbf{x}, t) < 0$ inside $\Omega(t)$, and $\phi(\mathbf{x}, t) > 0$ outside $\Omega(t)$. This representation of $\Gamma(t)$ allows complicated topological changes, provides information about the interface, and makes computation of the evolving interface straightforward. For velocity $\mathbf{v}$ of the boundary $\Gamma(t)$, the level set function ϕ describes the evolution of $\Gamma(t)$ if ϕ satisfies

$$\phi_t + \mathbf{v} \cdot \nabla\phi = 0, \tag{2.1}$$

$$\{\mathbf{x} : \phi(\mathbf{x}, 0) = 0\} = \Gamma(0), \tag{2.2}$$

with the additional condition that ϕ is negative inside $\Omega(0)$ and positive outside $\Omega(0)$.

In the case of electrodeposition, the object $\Omega(t)$ grows normal to itself at a constant speed (i.e., the velocity is $\mathbf{v} = \nu\mathbf{n}$, in which ν is a constant and $\mathbf{n}$ is the outward unit normal vector to Γ). By rescaling time, we may take $\nu = 1$. Since the gradient $\nabla\phi$ of ϕ is in the outward normal direction $\mathbf{n}$, then $\mathbf{v} \cdot \nabla\phi = |\nabla\phi|$ and the PDE for ϕ becomes

$$\phi_t + |\nabla\phi| = 0. \tag{2.3}$$

A solution of (2.3) satisfying (2.2) is the function

$$\phi(\vec{x}, t) = d(\vec{x}) - t, \tag{2.4}$$

where $d(\vec{x})$ is the signed distance function for the initial object $\Omega_0 = \Omega(0)$ with boundary Γ_0. The function $d(\vec{x})$ is defined as

$$d(\vec{x}) = \begin{cases} -\min_{\vec{s}\in\Gamma_0} |\vec{x} - \vec{s}|\,, & x \in \Omega_0, \\ 0, & x \in \Gamma_0, \\ \min_{\vec{s}\in\Gamma_0} |\vec{x} - \vec{s}|\,, & x \notin \Omega_0, \end{cases} \tag{2.5}$$

and satisfies $|\nabla d| = 1$. It follows that $|\nabla\phi| = 1$ and $\phi_t = -1$ and that the level set $\phi = 0$ is the boundary Γ_0, so that ϕ solves (2.3).

For this model, it will be necessary to take the union of two objects and merge their boundaries. This can be done as follows: Let ϕ_1 and ϕ_2 be level set functions representing the interfaces $\Gamma_1 = \partial\Omega_1$ and $\Gamma_2 = \partial\Omega_2$, respectively. Then $\phi = \min(\phi_1, \phi_2)$ is a level set function representing the merged interface $\Gamma = \partial\Omega$ of the combined object $\Omega = \Omega_1 \cup \Omega_2$. It is important to note that merging two signed distance functions d_1 and d_2 will produce a level set function that is not necessarily a signed distance function (i.e., if $\phi = \min(d_1, d_2)$); then it is possible that $|\nabla\phi| \neq 1$ at some points inside the merged object. However, $|\nabla\phi(\vec{x})| = 1$ for $\vec{x}$ in the exterior of the interface (i.e., where $\phi(\vec{x}) > 0$). Since the interface is moving in the outer normal direction, the interface motion is still correctly described by the equation $\phi_t + 1 = 0$.

Previous applications of the level set method are found in [5, 9] for electrodeposition and in [1, 2, 3, 4] for more general deposition and materials processing.

3. Forward problem in 2D.

3.1. General idea of the solution for the forward 2D problem.

In the 2D case, the domain is $[a_1, a_2] \times [0, b_2]$. The seed layer is composed of powered and unpowered line segments placed on the x-axis, as illustrated in Figure 1.3. Suppose that there is only one powered line segment, given as $[p, q]$, and the unpowered line segments are given as $[L_i, R_i]$ for $1 \leq i \leq N$. Construct a level set function $\phi_0(x, y)$ that represents the powered line segment $[p, q]$ and solve (2.3) for $\phi(x, y, t)$, as described in section 2. The interface will grow from the powered line segment in the normal direction. After a time interval t, the interface comes in contact with (or has passed over) one of the unpowered line segments $[L_j, R_j]$ if $\phi(L_j, 0) \leq 0$ or $\phi(R_j, 0) \leq 0$. When this occurs, the jth unpowered segment becomes powered and starts to grow with the rest of the interface, which is simulated as follows:

1. Construct a level set function $\psi(x, y)$ representing the line segment $[L_j, R_j]$.
2. Merge the two interfaces by setting $\phi(x, y) = \min(\phi, \psi)$.

Now continue with the evolution starting from with the updated ϕ until another unpowered segment is contacted by the growing interface, then repeat the two steps above. For the case of multiple powered segments, steps similar to connecting an unpowered segment to the rest of the interface are performed. Suppose there are M powered segments, given by $[p_i, q_i]_{i=1}^M$ with corresponding level set functions $\phi_i(x, y)$. Then the level set function for all of the powered segments is $\phi_0(x, y) = \min_{1 \leq i \leq M}\{\phi_i(x, y)\}$, which provides the initial condition for the level set PDE (2.3).

3.2. Implementation of the solution for the forward 2D problem. In order to solve this problem computationally, space and time are discretized, with a uniform grid in space. If $[L, R]$ is a line segment, then a distance function representing it is

$$d_{[L,R]}(x, y) = \begin{cases} \sqrt{(x-L)^2 + y^2}, & x < L, \\ y, & L \leq x \leq R, \\ \sqrt{(x-R)^2 + y^2}, & x > R. \end{cases} \tag{3.1}$$

As described in section 2, the solution at discrete times $t_n = ndt$ is $\phi^{n+1} = \phi^n - dt$. The time step is chosen to be $dt = 0.1dx$, which ensures that the unpowered segments get turned on at accurate times. The initial data ϕ^0 is the distance function to the powered line segments. Contact with unpowered line segments is performed by the method of section 3.1.

Summarizing the above, if the powered segments are $[p_i, q_i]_{i=1}^M$ and the unpowered segments are $[L_i, R_i]_{i=1}^N$, the algorithm for forward growth is as follows:

```
1. Compute $\phi_0(x, y) = \min_{1 \leq i \leq M}\left(d_{[p_i,q_i]}(x, y)\right)$.
2. Set $n = 0$. Repeat the following until the final growth time $T_g$ is reached
   (i.e., when $n * dt = T_g$).
   • Set $\phi^{n+1} = \phi^n - dt$.
   • Find all unpowered segments that become powered during this time
     interval and merge them into the interface. For each unpowered segment
     $[L_k, R_k]$ do the following:
       – If $\phi^{n+1}(L_k, 0) \leq 0$ or $\phi^{n+1}(R_k, 0) \leq 0$, then compute $d_{[L_k,R_k]}(x, y)$
         and set $\phi^{n+1}(x, y) = \min\left(\phi^{n+1}(x, y), d_{[L_k,R_k]}(x, y)\right)$.
   • Set $n = n + 1$.
```

4. Forward problem in 3D.

4.1. General idea of the solution for the forward 3D problem. In the 3D case, the domain is $[a_1, a_2] \times [b_1, b_2] \times [0, c_2]$. The seed layers are on the $z = 0$ plane and can now take on any 2D shape, as illustrated in Figure 4.1. For an arbitrary shaped seed layer, initial construction of a level set function is a key step and is discussed in the section 4.3.

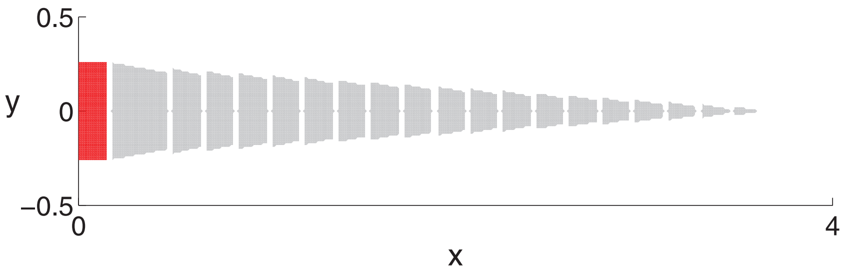

FIG. 4.1. *Seed layer used to grow the 3D needle-shaped object in Figure 1.2. The rectangle is powered and the trapezoids are the unpowered layers.*

Subsequent evolution of the level set function is essentially the same as in the 2D case: Suppose a level set function, $\phi_0(x, y, z)$, representing the powered layers is given. Using $\phi_0(x, y, z)$ as the initial condition, ϕ is evolved in time as specified by the level set PDE. The interface grows from the powered layer(s) in the normal direction. When the interface comes in contact with unpowered layers, they become powered and start to grow with the interface. In 3D, the boundaries of the layers consist of curves rather than points and some unpowered layers may have multiple boundaries, such as a ring shaped layer. Let γ be the boundary of one of the unpowered layers P. If $\min_\gamma \phi \leq 0$, then that unpowered layer has been contacted by the growing interface, it becomes powered, and it starts to grow with the interface. Merger of the layer P with the interface is performed through the following steps:

1. Construct a level set function $\psi(x, y, z)$ representing the layer P.
2. Merge the layer into the interface by setting $\phi = \min(\phi, \psi)$.

Continue with the evolution of ϕ until the growing interface contacts another unpowered layer, then repeat the two steps above.

4.2. Implementation of forward 3D method. In order to solve this problem computationally, discretize the space and time domains using a uniform grid in space. Since the seed layers lie in the plane $z = 0$, the 3D distance function $d_{3D}(x, y, z)$ is related to the 2D distance function $d_{2D}(x, y)$ within the plane $z = 0$ by

$$d_{3D}(x, y, z) = \sqrt{[\max(0, d_{2D}(x, y))]^2 + z^2}. \tag{4.1}$$

For an arbitrarily shaped seed layer U, we construct an approximate distance function $d_{2D}(x, y)$ by approximating P by an N-sided polygon with vertices $\{(x_i, y_i)\}_{i=1}^N$. A method to construct distance functions for polygons is discussed in section 4.3. Detecting contact requires evaluation of the level set function ϕ at the boundaries of the unpowered layer. In the numerical method, this is checked at a discrete set of points along the polygonal boundary. If $\phi \leq 0$ on any of the discrete points on the boundary, the unpowered polygonal layer has been contacted by the interface, becomes powered, and starts to grow with the interface. This is done by performing the following two steps:

1. Construct a distance function $d(x, y, z)$ representing the layer.
2. Take the union of the two interfaces by setting $\phi = \min(\phi, d)$.

As described in section 2 and the 2D case, the iteration to evolve the interface is $\phi^{n+1} = \phi^n - dt$, where ϕ^0 is the distance function representing the powered layer(s). The boundary points of each unpowered layer are checked for contact each time step.

Summarizing the above, let $\{P_i^p\}_{i=1}^M$ be the set of powered polygonal layers and $\{P_i^u\}_{i=1}^N$ the set of unpowered polygonal layers of a given seed layer pattern. The following steps detail forward growth in three dimensions:

1. Set $\phi^0(x, y, z) = \min_{1\leq i\leq M}(d_i(x, y, z))$ in which $d_i(x, y, z)$ is the distance function (see section 4.3) for the ith powered polygonal layer P_i^p.
2. Set $n = 0$. Repeat the following until the final growth time T_g is reached (i.e., when $n * dt = T_g$).
    - Set $\phi^{n+1} = \phi^n - dt$.
    - Check all of the unpowered polygonal layers that have not already been merged into the growing shape for contact by the interface. If $\phi^{n+1} \leq 0$ at one of the discretized boundary points of an unpowered polygonal layer, it has been contacted by the interface.
        - Suppose the kth unpowered polygonal layer P_k^u has been contacted

by the interface. Compute $d_k(x,y,z)$, and set

$$\phi^{n+1}(x,y,z) = \min\left(\phi^{n+1}(x,y,z), d_k(x,y,z)\right).$$

– Repeat the above step for any other newly contacted unpowered layer(s).

- Set $n = n + 1$.

4.3. Constructing signed distance functions for polygons. Suppose that $\{(x_k, y_k)\}_{k=1}^{N}$, $(x_k, y_k) \in [a_1, a_2] \times [b_1, b_2]$, are the vertices of a polygon traversed in either a clockwise or counterclockwise direction, with $(x_N, y_N) = (x_1, y_1)$. The goal is to create a signed distance function $d(x, y)$ whose zero level set is the polygon boundary. Since the level set computations are performed on a grid, it is only necessary to compute the distance function on the discrete set of grid points. The first step is to create a distance function $d_{k,k+1}(x, y)$ for each line segment $[(x_k, y_k), (x_{k+1}, y_{k+1})]$ (see the appendix for the formula). Note that $d_{k,k+1}(x, y) \geq 0$, since the line segment has no interior. Set $d_0(x, y) = \min_k \{d_{k,k+1}(x, y)\}$ to get a distance function $d_0(x, y)$ for the polygon defined on the grid. However, $d_0(x, y)$ is not a signed distance function since it takes positive values inside the polygon. The remaining step is to identify which grid points are inside the polygon, and negate the value of d_0 at those points.

The Jordan curve theorem states that a point is in the interior of a bounded region if the half line from that point to infinity intersects the boundary of the region an odd number of times. Conversely, the point is in the exterior of the region if the half line intersects the boundary an even number of times. The half line from the point in question to infinity can be taken in any direction. For the grid point (u, v), a natural choice is the horizontal half line $((-\infty, v), (u, v)]$. Since the polygon should be completely contained in the domain $[a_1, a_2] \times [b_1, b_2]$, only the horizontal line segment $[(a_1, v), (u, v)]$ needs to be checked for intersections with the polygon boundary. Since the boundary of the polygon is composed of line segments, it suffices to check for intersections between the horizontal line segment $[(a_1, v), (u, v)]$ and the polygon boundary segments.

In summary, the steps to form a signed distance function for a polygon on a grid are as follows:

1. Set $d_0(x, y) = \min_{1 \leq k < N}(d_{k,k+1}(x, y))$ in which $d_{k,k+1}(x, y)$ is the distance function from the line segment between vertices k and $k + 1$.
2. For each grid point (u, v), do the following:
    - Count the number of intersections of the line segment $[(a_1, v), (u, v)]$ with the polygon sides.
    - If the number of intersections is odd, set $d_0(x_i, y_j) = -d_0(x_i, y_j)$.

Once the 2D distance function $d_0(x, y)$ has been computed; the 3D distance function for the polygonal layer is $d_0(x, y, z) = \sqrt{[\max(d_0(x, y), 0)]^2 + z^2}$.

4.4. Results for forward 3D method. Figure 4.1 shows the seed layers that were used to grow the 3D needle shaped object pictured in Figure 1.2. The leftmost (rectangular) layer was powered and the others were unpowered initially. Figure 4.2 shows the results from simulation, using the method described in section 4.2, applied to the seed layer pattern given in Figure 4.1. The simulated object (Figure 4.2) is in excellent agreement with the object that was grown in the laboratory (Figure 1.2).

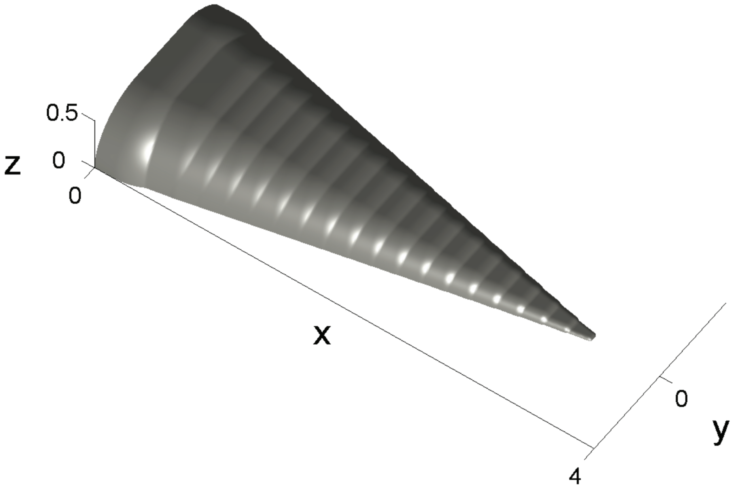

FIG. 4.2. *Simulated growth of the needle seed layer pattern of Figure* 4.1*, using the algorithm described in section* 4.2.

5. Inverse problem in two dimensions.

5.1. Problem description and solution. For the inverse problem, a shape is given, and the goal is to determine the seed layer pattern that would approximate that shape. In addition, we find that some shapes are not attainable.

Let the desired final shape Γ be given by $y = F(x)$, contained in the domain $[a_1, a_2] \times [0, b_2]$. The results of section 3 show that the ends of a line segment grow as quarter circles. The first step in solving the inverse problem is to approximate the curve Γ by an envelope of circles that are tangent to Γ and that have centers on the x-axis. Assume that $F \in C^1([a_1, a_2])$. For $s \in [a_1, a_2]$, the circle tangent to F at the point $(s, F(s))$ has center $(c_s, 0)$ and radius R_s given by the formulas

$$c_s = F'(s)F(s) + s, \tag{5.1}$$

$$R_s = F(s)\sqrt{[F'(s)]^2 + 1}. \tag{5.2}$$

A discrete representation of the curve Γ is given by points $\{(x_i, F(x_i))\}_{i=1}^N$ for a given set of points $x_i \in [a_1, a_2]$. Equations (5.1)–(5.2) then determine centers $\{(c_i, 0)\}_{i=1}^N$ and radii $\{R_i\}_{i=1}^N$ for a set of circles $\{C_i\}_{i=1}^N$ that are tangent to F at the points $(x_i, F(x_i))$. Remove any circle C_i whose center is not in the domain (i.e., $c_i \notin [a_1, a_2]$)) to get a possibly smaller sets of centers $\{(c_j, 0)\}_{j=1}^M$ and radii $\{R_j\}_{j=1}^M$, with $M \leq N$. See Figure 5.1 for an example of an envelope of circles tangent to the function $F(x) = \frac{1}{2}\sqrt{1 - x}$.

For simplicity, we assume that initially there is only a single powered point. It starts growing as a half circle whose radius is equal to the time that point has been powered (since the normal velocity is 1). More generally, the radius of a circle in the envelope is equal to the total time over which the circle should be powered. It follows that the total growth time $t = T_G$ should equal the maximal radius of the circles (i.e., $T_G = \max_j \{R_j\}$). Furthermore, since the jth circle should grow for time R_j, then its start time should be $T_j = T_G - R_j$. The circle C_j gets powered at time T_j if its

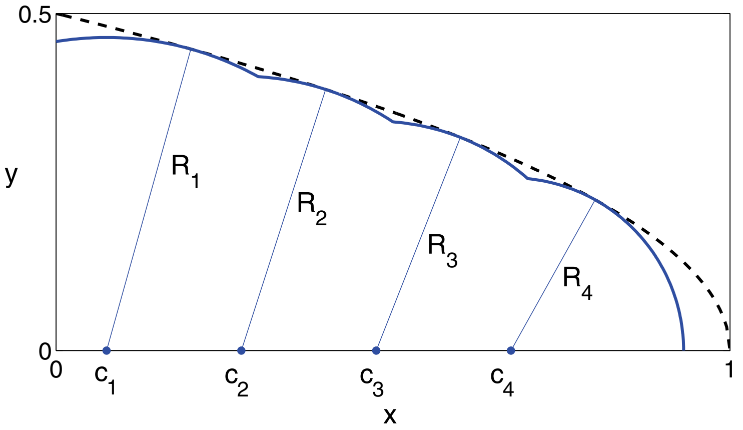

FIG. 5.1. *An envelope of* 4 *circles are used to form an approximation of* $y = F(x)$.

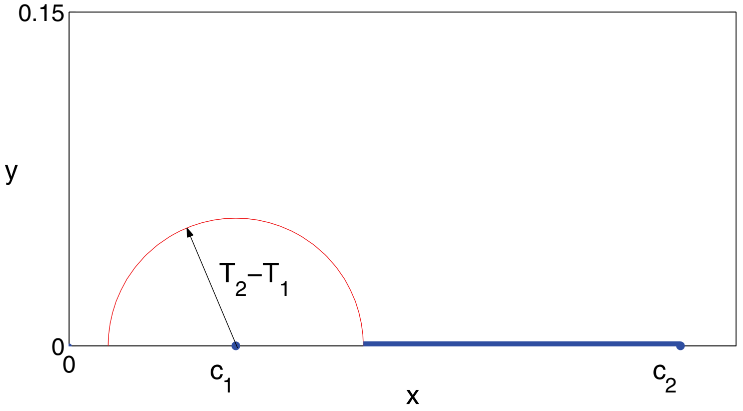

FIG. 5.2. *Shows the first circle at time* T_2 *and the unpowered segment that would power the second circle at time* T_2.

center is the endpoint of a segment that is contacted at time T_j by the circle that is growing from the center $(c_{j'}, 0)$ to its left or right that was powered before T_j.

This is illustrated in Figures 5.1–5.3. In the example shown in Figure 5.1, R_1 is the maximum radius, so $T_G = R_1$, $T_1 = 0$ and the point $(c_1, 0)$ should be powered initially. The point $(c_2, 0)$ should be powered at time T_2. Figure 5.2 shows the first circle at time T_2 turning on the point $(c_2, 0)$ by contacting the left edge of the segment $[\ell, c_2]$ at time T_2 with $\ell = c_1 + T_2 - T_1$. Figure 5.3 shows the interface at time T_3, including the growth of the unpowered segment calculated to turn on the second circle.

To summarize the procedure in general for finding the unpowered segment for the kth circle centered at $(c_k, 0)$, with start time T_k, it is necessary to find the closest circle to the kth circle with an earlier start time. Denote the closest circle as the pth circle with center $(c_p, 0)$ and start time T_p. If $c_p < c_k$, then the unpowered segment is on the left side of c_k and is given by $[\ell, c_k]$, where $\ell = c_p + T_k - T_p$. If $c_p > c_k$, then the unpowered segment is on the right side of c_k and is given by $[c_k, r]$, where $r = c_p - (T_k - T_p)$.

Three sufficient conditions on the curve $\Gamma = \{y = F(x)\}$ must be satisfied to

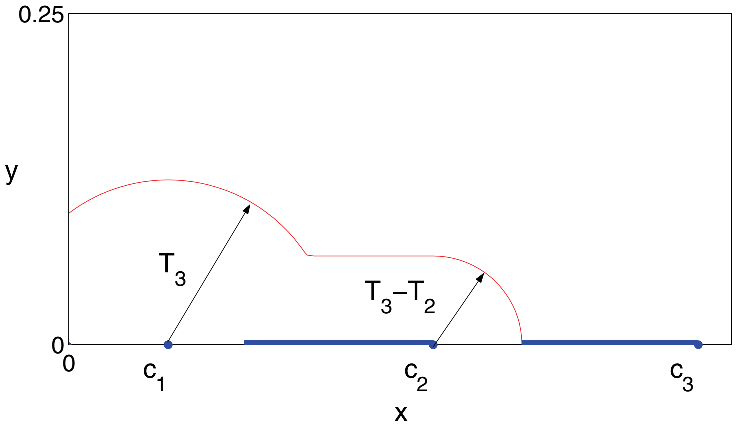

FIG. 5.3. *Shows the interface at time T_3, and the unpowered segment that powers the third circle at time T_3.*

enable a solution to the inverse problem:

1. $F \in C^1([a_1, a_2])$.
2. Γ is the envelope of circles with centers on the x-axis. Each circle intersects Γ at tangent points from below (i.e., the circle lies below Γ).
3. F can have only one local maxima, or if it has multiple local maxima, they must all have the same value.

Although there may exist a seed layer pattern for a given shape that is only in $C([a_1, a_2])$ (but still satisfies the other two conditions), the given algorithm requires that the derivative be continuous as well. The second condition is a necessary one. If that condition is violated, then the shape given by $F(x)$ will not be attainable. Figure 5.4 shows the function $F(x) = \frac{1}{4}\sin(\pi x^2)$, and a circle tangent to it at $(0.8, F(0.8))$ that also crosses F at another point, making that shape unattainable. The present model allows for powered points to be powered by an external source only at the same time. For example, there cannot be one point x_1 powered at time $t = 0$ and another point x_2 independently powered (meaning not powered by contact of the growing surface) at some later time. The third condition is therefore necessary since it ensures that an approximation of the given shape can be attained without needing powered points that start at different times.

5.2. Justification for the construction of the unpowered segments. In constructing the unpowered segments, it was assumed that the point $\ell = c_p + T_k - T_p$ was in between the two circle centers c_p and c_k (this assumes that the contact point is to the left of c_k, but the proof is similar if it were to the right). Here it will be shown that this is always the case if the attainability conditions of section 5.1 are satisfied. Showing that $\ell \in [c_p, c_k]$ is the same as showing that $\ell = c_p + T_k - T_p \le c_k$, or

$$T_k - T_p \le c_k - c_p.$$

Suppose this were not true, so that $T_k - T_p > c_k - c_p$. Using the relationships $T_k = T_g - R_k$ and $T_p = T_g - R_p$ gives $T_k - T_p = R_p - R_k$. Then $R_p - R_k > c_k - c_p$, or

$$R_p > d + R_k,$$

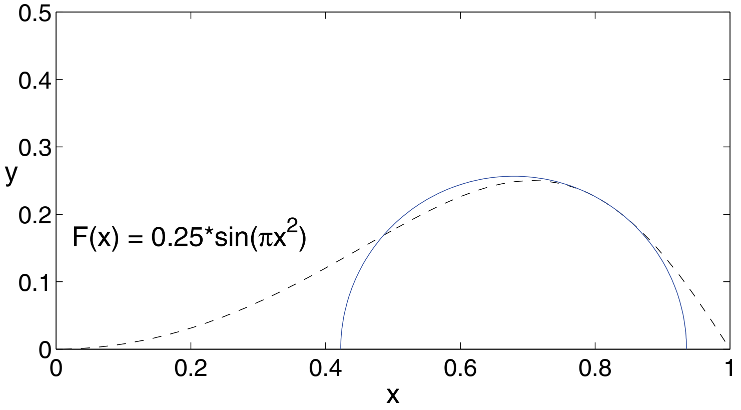

Fig. 5.4. *Example of a shape that is not attainable. The circle is tangent to F at* $(0.8, F(0.8))$*, but it crosses F at another point. This function is not attainable using the given procedure for calculating the seed layer pattern.*

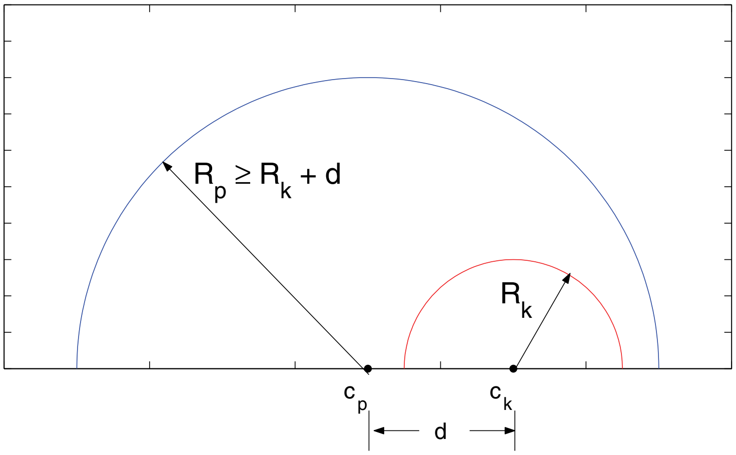

Fig. 5.5. *The figure shows that the circle centered at c_p completely encloses the circle centered at c_k if $T_k - T_p \geq c_k - c_p$.*

where $d = c_k - c_p$ is the distance between the two circle centers. This means that the circle centered at c_p has a radius so large that it completely encloses the circle centered at c_k (see Figure 5.5). This is impossible, since both circles are tangent to F from below by the second attainability condition in section 5.1. This contradiction shows that $\ell = c_p + T_k - T_p \leq c_k$.

5.3. Results of inverse 2D problem method. Figure 5.6 shows the solution of the inverse problem for the function $F(x) = x(x-1)^2$. For solution of the inverse problem, a single powered point and eight unpowered segments are allowed. The figure shows the desired function (dashed line), the calculated seed layer pattern, and the resulting growth from the seed layer pattern. The result is in good agreement with the target curve. Better agreement could be achieved by allowing more segments in the seed layer pattern.

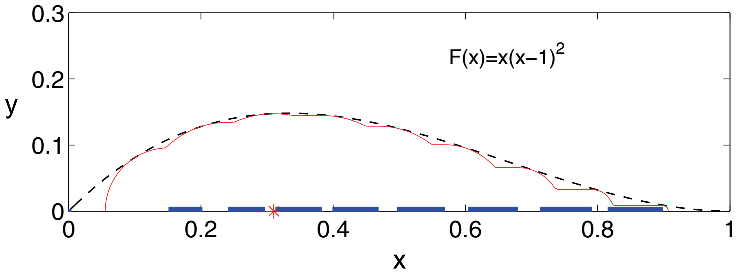

FIG. 5.6. *The desired shape is the dotted curve. The seed layer was calculated using the inverse procedure, and the growth of the seed layer is shown by the solid curve. The star is the powered point, and the line segments are the unpowered segments. Nine circles were used for the approximation.*

6. Inverse problem in three dimensions.

6.1. A continuous approach. The desired shape Γ is defined by the function $z = F(x, y)$ for (x, y) in the substrate domain $[a_1, a_2] \times [b_1, b_2]$. The goal is to find a seed layer pattern of polygonal layers that will grow to form an approximation of Γ. Instead of a discrete seed layer, consider a continuous seed layer, in which each point in the substrate can be powered at any time. Suppose that this continuous seed layer can grow a shape that exactly matches the given shape Γ at time T_g. This continuous seed layer can then be described by a function $T(x, y)$, which is defined to be the time at which power should be applied to the point (x, y). Although a continuous seed layer may be impractical, it is a useful theoretical construct.

Let $t_j \in (0, T_g)$ for $j = 1, \ldots, n$ be an increasing set of times such that $0 = t_0$, and define the contour curves

$$\gamma_i = \{(x, y) \in [a_1, a_2] \times [b_1, b_2] : T(x, y) = t_i\}\,. \tag{6.1}$$

Also, define β_i to be the curve that results from growing γ_i in the outward normal direction (i.e., the direction of increasing T) for time $(t_{i+1} - t_i)$.

The initial powered "layer" S_0 is defined to be the curve (or point) γ_0. For $m > 0$, the seed layer S_m is then defined to be the region in between the two curves γ_m and β_{m-1}. With this definition, we find that S_m is contacted by the growing surface and turns on at time t_m as desired. By its definition, S_0 is powered at time t_0. The rest follows by iteration: Since the curve γ_{m-1} becomes powered at time t_{m-1} it grows outward at normal speed 1, and at time t_m it hits the curve β_{m-1} which turns on S_m, which is the region in between β_{m-1} and γ_m. This is illustrated in Figure 6.1, which shows two contours γ_m and γ_{m-1} of some function $T(x, y)$. Also shown is β_{m-1}, which is the resulting curve of growing γ_{m-1} in the normal direction for time $t_m - t_{m-1}$.

All of the unpowered layers are constructed in the same way. When the above method is discretized, the powered curve γ_0 will usually not be a curve, but individual points. From a fabrication viewpoint, both individual points and curves as powered layers are not desirable, and it is better to have an actual polygonal powered layer. One simple approach to do this will be discussed later.

6.2. Discretizing and implementing the continuous approach. There are several tasks involved in solving the inverse problem computationally. Each of the following sections describes a task and a method to complete the task. Then, in section 6.2.7, the methods are brought together to give the solution to the inverse problem.

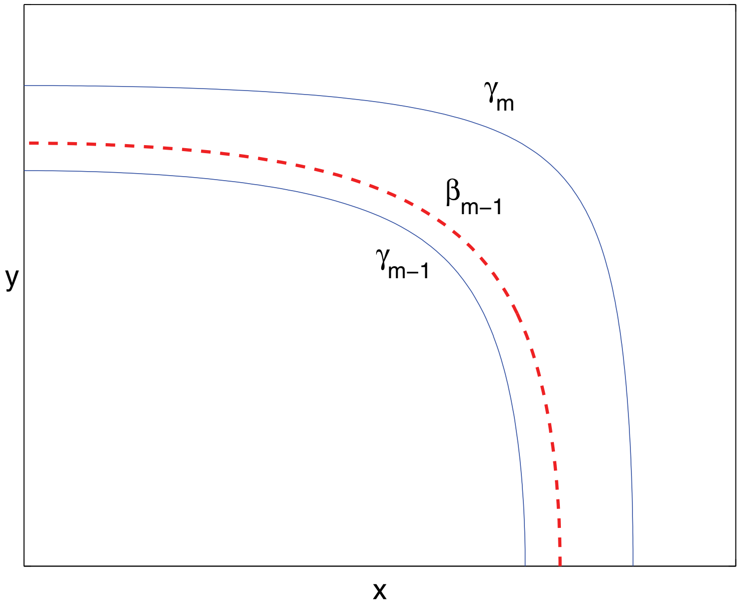

FIG. 6.1. *Two contours γ_{m-1} and γ_m of $T(x,y)$ are shown as solid curves. β_{m-1} is shown as the dashed curve. The unpowered layer is the region in between β_{m-1} and γ_m.*

6.2.1. Relationship between $T(x,y)$ and $F(x,y)$. A key component of the previous section was knowing $T(x,y)$ for a given shape Γ defined by $z = F(x,y)$. An equivalent condition will be stated and used here. Consider a seed layer that is only a single powered point. Since the growth is uniform in the normal direction with speed 1, the powered point will grow as a hemisphere, with a radius equal to the time the point has been powered. Let the given shape $z = F(x,y)$ satisfy the following conditions:

1. $F \in C^1([a_1,a_2] \times [b_1,b_2])$.
2. Γ can be formed as an envelope of hemispheres (with centers on the $z = 0$ plane) that are tangent to Γ from below (i.e., the sphere lies below the surface $z = F(x,y)$).
3. F has only one local maximum, or if it has multiple local maxima, F has the same value at all local maxima.

Under the above conditions, there should exist a function $R(x,y)$, $(x,y) \in [a_1,a_2]\times[b_1,b_2]$, that gives the radius of the sphere with center (x,y) that is tangent to the given shape F. A continuous seed layer can be defined by $R(x,y)$, since $R(x,y)$ is the length of time that a point (x,y) should be powered. Define $T_g = \max_{(x,y)} \{R(x,y)\}$, which is the length of time that power should be applied to the seed layer. Then $T(x,y) = T_g - R(x,y)$ is the time at which the point (x,y) should become powered. Therefore, finding $T(x,y)$ is equivalent to finding $R(x,y)$. By considering the equation of a sphere with center (x,y) on the $z = 0$ plane, the relationship between $R(x,y)$ and F is given by the following three equations:

$$x = F_x(x_s,y_s)F(x_s,y_s) + x_s, \tag{6.2}$$

$$y = F_y(x_s,y_s)F(x_s,y_s) + y_s, \tag{6.3}$$

$$R(x,y) = \sqrt{(x-x_s)^2 + (y-y_s)^2 + [F(x_s,y_s)]^2}. \tag{6.4}$$

The point $(x_s, y_s, F(x_s, y_s)$ is the point of tangency of the sphere to the surface $z = F(x, y)$.

6.2.2. Computing $\boldsymbol{T(x,y)}$. The first step in numerically solving the inverse problem is to discretize the domain of the substrate $[a_1, a_2] \times [b_1, b_2]$. A uniform grid is used. Let $N_x + 1$ be the number of grid points in x and $N_y + 1$ the number of grid points in y. Then the grid sizes are $dx = (a_2 - a_1)/N_x$ and $dy = (b_2 - b_1)/N_y$, and the grid points are $\{(x_i, y_j) = (a_1 + i * dx, b_1 + j * dy)\}$ for $0 \leq i \leq N_x$ and $0 \leq j \leq N_y$. The radius value $R(x_i, y_j)$ on the grid point (x_i, y_j) is found by solving the nonlinear equations (6.2)–(6.3). Numerical experiments indicate that the following simple functional iteration converges fairly quickly:

$$x_s^{n+1} = x_i - F_x(x_s^n, y_s^n)F(x_s^n, y_s^n), \tag{6.5}$$

$$y_s^{n+1} = y_j - F_y(x_s^n, y_s^n)F(x_s^n, y_s^n). \tag{6.6}$$

A good initial guess is $x_s^0 = x_i$ and $y_s^0 = y_j$: Once (x_s, y_s) is found, (6.4) is used to compute $R(x_i, y_j)$. This process is repeated to compute R for each grid point in the discretized domain. Then the growth time is determined by $T_g = \max_{[0 \leq i \leq N_x, 0 \leq j \leq N_y]} \{R(x_i, y_j)\}$ and the function T is given by $T(x_i, y_j) = T_g - R(x_i, y_j)$ on the discretized domain.

6.2.3. Calculating contour curves. Although any conventional methods can be employed to calculate the contour curves of $T(x, y)$, a simple method is presented here. Let $T(x, y)$ be given on the grid points defined in section 6.2.2. Linear interpolation is used to find the points of a contour curve $\gamma = \{(x, y) : T(x, y) = \alpha\}$ on a triangulated grid. Consider the lower triangular cell with corners (x_i, y_j), (x_{i+1}, y_j), and (x_{i+1}, y_{j+1}). If γ passes through that lower triangular grid cell, then γ can be approximated by a line segment $L_{i,j}^{\ell}$ inside the lower triangular grid cell. Linear interpolation can determine the endpoints of the line segment $L_{i,j}^{\ell}$, which could be on the horizontal grid cell boundary $[(x_i, y_j), (x_{i+1}, y_j)]$, the vertical grid cell boundary $[(x_{i+1}, y_j), (x_{i+1}, y_{j+1})]$, or the diagonal grid cell boundary $[(x_i, y_j), (x_{i+1}, y_{j+1})]$. Every lower triangular grid cell is checked to see if γ passes through it, and if so a line segment $L_{i,j}^{\ell}$ is computed. Similarly, the upper triangular grid cells with corners (x_i, y_j), (x_i, y_{j+1}), and (x_{i+1}, y_{j+1}) are also checked to see if they contain part of γ, and if so, a line segment $L_{i,j}^{u}$ is computed. The collection of all line segments $L_{i,j}^{\ell}$ and $L_{i,j}^{u}$ is then a representation of the contour curve γ. Connectivity of this curve is guaranteed, since the end of one line segment corresponds to the beginning of another line segment. Figure 6.2 illustrates the triangulated grid and the points in the triangular grid cell boundaries that define the ends of the line segments.

6.2.4. Evolving a curve in the normal direction. One step in section 6.1 for finding an unpowered layer requires growing a contour curve of $T(x, y)$ in the outward normal direction, which is performed using the level set method. Let γ be the contour $T(x, y) = \alpha$ that is to be moved in the outward normal direction for time τ. Using the method discussed in section 6.2.3, compute a set of line segments $\{L_k\}$ that represents the contour curve γ. Following steps similar to those outlined the section 4.3, a distance function representing the polygonal approximation of γ is computed as $\psi(x, y) = \min_k \{d_k(x, y)\}$, where $d_k(x, y)$ is the distance function for the line segment L_k (a formula is given in the appendix). Note that ψ will not be a signed distance function, since $d_k(x, y) \geq 0$. In general, γ will segment the domain into two parts: the interior region (where $T(x, y) < \alpha$) and the exterior region (where

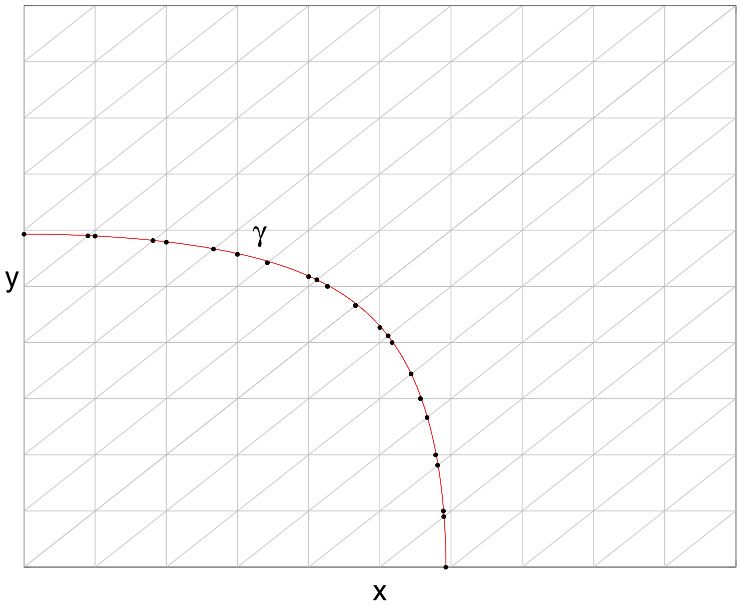

FIG. 6.2. *The circles are the endpoints of the line segments used for the discretization of the curve* γ.

$T(x, y) > \alpha$). To make a signed distance function, the value of ψ in the interior region must be negated. Therefore, a signed distance function ϕ for the curve γ is defined as

$$\phi(x, y) = \begin{cases} -\psi(x, y) & \text{if } T(x, y) < \alpha, \\ \psi(x, y) & \text{otherwise.} \end{cases}$$

Then the curve from growing γ in the normal direction for time τ is the zero level set of $\phi(x, y, 0) - \tau$. Again, the methods in section 6.2.3 can be used to form a polygonal approximation of the new curve.

6.2.5. Forming an unpowered layer from $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$. The final step in the construction of a layer S_m is to connect the two curves, β_{m-1} and γ_m, that define it in the $z = 0$ plane. Let $\{L_k^\beta\}$ and $\{L_k^\gamma\}$ be the set of line segments representing the curves β_{m-1} and γ_m, respectively. The unpowered layer is the region between these two curves consisting of points (x, y) with $t_{m-1} < T(x, y) < t_m$. In the simplest case, β_{m-1} and γ_m are each single connected curves. If they are closed curves, then S_m is the region between them. If they are not closed, then each of them has two endpoints that should lie on the boundary of the domain. In this case, one can easily identify the matching endpoints (by the condition $t_{m-1} < T(x, y) < t_m$) and form a curve connecting them along the domain boundary. In general, γ and β may have multiple disjoint pieces that define multiple layers (in such a case, these layers would all have the same start time). A more sophisticated approach to forming layers may have to be used to connect complicated curves, but this has not proved to be necessary in the numerous examples we have simulated.

6.2.6. The powered "layer." In the presentation above, the initially powered layer consists of a single point or curve that is discretized to a set of points. The powered points should have start time $t = 0$, so they are the points on the grid

$\{(x_k^P, y_k^P)\}_{k=1}^{N_P}$ that satisfy $T(x_k^P, y_k^P) = 0$. In order to calculate the first unpowered layer, the powered points will have to be grown for time t_1. The signed distance function for a point is (u, v) is $d_{(u,v)}(x, y) = \sqrt{(x-u)^2 + (y-v)^2}$. To grow the powered points for time t_1, the distance function for the powered points must first be computed as

$$d(x, y) = \min_{k=1,\dots,N_P} \{d_{(x_k^P, y_k^P)}(x, y)\}. \tag{6.7}$$

Then, the zero level set of $d(x, y) - t_1$ is the curve resulting from growing the powered points for time t_1.

6.2.7. Constructing the seed layer pattern. This section brings together all of the methods in the previous sections to formulate in detail a solution to the inverse problem. Let the substrate domain be $[a_1, a_2] \times [b_1, b_2]$, and assume that the surface $z = F(x, y)$ satisfies conditions (1)–(3) in section 6.2.1.

- Discretize the domain using a uniform grid, where $N_x + 1$ is the number of grid points in x and $N_y + 1$ is the number of grid points in y.
- Compute $R(x, y)$ on the grid using the method described in section 6.2.2. Define $T_g = \max_{[0 \le i \le N_x, 0 \le j \le N_y]} \{R(x_i, y_j)\}$.
- Set $T(x, y) = T_g - R(x, y)$ on the grid.
- Define a positive integer n, and choose a set of times $\{t_i\}_{i=1}^n$ such that $0 = t_0 < t_1 < t_2 < \cdots < t_n < T_g$.
- Find the powered points of the seed layer $\{(x_k^P, y_k^P)\}_{k=1}^{N_P}$ that satisfy $T(x_k^P, y_k^P) = 0$.
- Using the technique given in section 6.2.6, compute the distance function $d(x, y)$ for the powered points.
- Compute the parameterization of $\beta_0 = \{(x, y) \colon d(x, y) = t_1\}$ using the method in section 6.2.3.
- Compute the parameterization of $\gamma_1 = \{(x, y) \colon T(x, y) = t_1\}$ using the method in section 6.2.3.
- Use the method in section 6.2.5 to form the first unpowered layer that is in between β_0 and γ_1.
- For $m = 2, \dots, n$, repeat the following:
  - Grow γ_{m-1} in the outward normal direction for time $(t_m - t_{m-1})$ using the method in section 6.2.4 and label the resulting curve β_{m-1}.
  - Compute the parameterization of $\gamma_m = \{(x, y) : T(x, y) = t_m\}$ using the method in section 6.2.3.
  - Use the method in section 6.2.5 to construct the mth unpowered layer that is in between β_{m-1} and γ_m.

6.2.8. Justification for the construction of the unpowered layers. In the construction of the unpowered layers, it was assumed that the curve β_{m-1} is between γ_{m-1} and γ_m (i.e., that when γ_{m-1} moves in the normal direction for time $t_m - t_{m-1}$, it does not cross γ_m). We now prove this, assuming that the shape $z = F(x, y)$ satisfies the attainable conditions in section 6.2.1.

From any point (x^{m-1}, y^{m-1}) on γ_{m-1}, consider the line segment extending in the outer normal direction to a point (x^m, y^m) on the curve γ_m, and define the distance $d = |(x^{m-1}, y^{m-1}), (x^m, y^m)|$. The map from (x^{m-1}, y^{m-1}) to (x^m, y^m) is one-to-one if the curves are smooth and the distance between them is sufficiently small. Since the curve β_{m-1} is defined by moving γ_{m-1} a distance $t_m - t_{m-1}$, it suffices to show that $t_m - t_{m-1} \le d$.

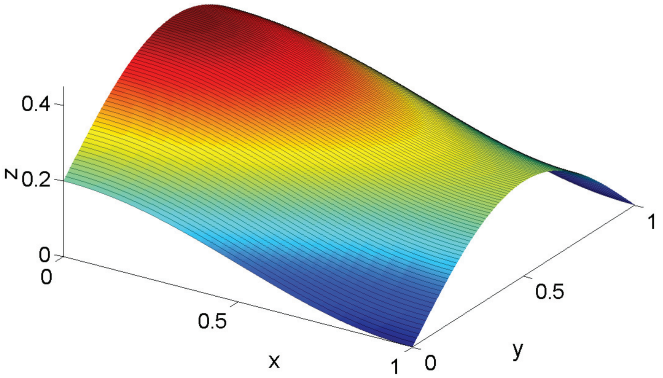

FIG. 6.3. *The desired shape is given by $F(x, y) = 0.1\cos(\pi x) + 0.25\sin(\pi y) + 0.1$. The color map is a function of height and is used only to aid visualization of the surface.*

Suppose that the opposite is true, so that $t_m - t_{m-1} > d$. By condition 2 in section 6.2.1, the sphere S_{m-1} centered at (x^{m-1}, y^{m-1}) with radius $R^{m-1} = T_g - t_{m-1}$ and the sphere S_m at (x^m, y^m) with radius $R^m = T_g - t_m$ are both tangent to the surface $z = F(x, y)$. It follows that $R^{m-1} \geq R^m + d$, which says that S_{m-1} strictly contains S_m, which is not possible if both are tangent from below by condition 2 in section 6.2.1. This contradiction shows that $t_m - t_{m-1} \leq d$, so that the curve β_{m-1} is between γ_{m-1} and γ_m.

6.2.9. A powered polygonal layer. The algorithm outlined in section 6.2.7 constructs the powered layer as points rather than the preferred polygonal shape. A simple way to construct a powered polygonal layer is to set the first unpowered layer as powered. The final growth time would then have to be reduced by t_1, the start time of the first unpowered layer. Doing this will increase the error of the final shape, but this error can be reduced by choosing t_1 to be small.

6.2.10. Results. Figures 6.3–6.5 show a prescribed shape $F(x, y) = 0.1\cos(\pi x) + 0.25\sin(\pi y) + 0.1$, the seed layer pattern calculated using the steps in section 6.2.7, and the result of the forward growth of the calculated seed layer pattern, respectively. Figures 6.6–6.8 show similar results for the prescribed shape $F(x, y) = -(x - 0.5)^2 - (y - 0.5)^2 + 0.25$. Both examples were computed on the domain $[0, 1] \times [0, 1]$ with $N_x = N_y = 100$ and $n = 12$. The computational time to construct the seed layer patterns for the above examples was about 5 seconds.

6.3. Error analysis. In this section, a computational analysis of the accuracy of the inverse algorithm of section 6.2 is presented using the two test problems in section 6.2.10 for various values of the number of grid points (N_x and N_y) and the parameter n, which determines the number of unpowered layers ($\geq n$). In order to resolve the seed layers, the number of grid points should be larger than the number of layers.

The accuracy of the inverse solution is measured by the error in the subsequent forward growth. The forward problem is performed on the computational domain $[0, 1] \times [0, 1] \times [0, 0.5]$, with a fixed number of grid points $N_x^F = 100$, $N_y^F = 100$, and $N_z^F = 50$, with grid sizes $dx^F = \frac{1}{N_x^F+1}$, $dy^F = \frac{1}{N_y^F+1}$, and $dz^F = \frac{0.5}{N_z^F+1}$. Most of the error in the forward growth itself is removed, since the start times of the layers

are all known. The resulting level set function $\phi(x, y, z)$ is converted to a function $z = F^{\phi}(x, y)$ defined on the fixed forward grid using linear interpolation. A numerical L^2 error between F^{ϕ} and F is computed as

$$\left\|F - F^{\phi}\right\| = \sqrt{\sum_{i=0,j=0}^{N_x^F, N_y^F} \left|F(x_i, y_j) - F^{\phi}(x_i, y_j)\right|^2 dx^F dy^F}. \tag{6.8}$$

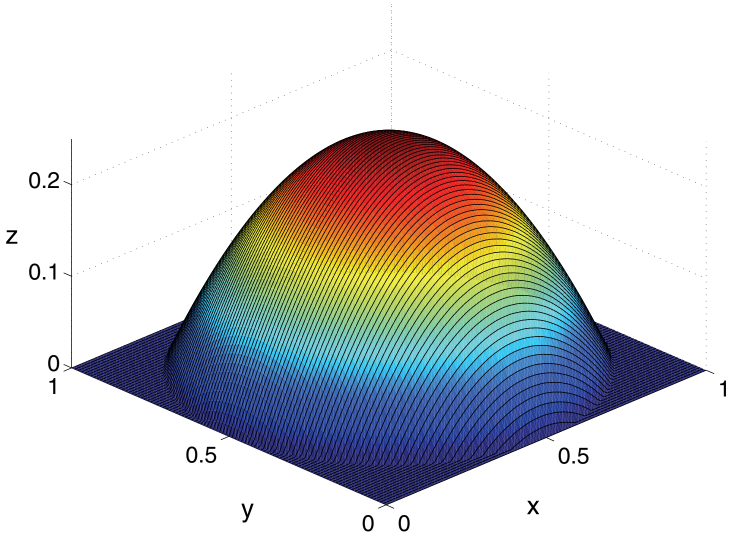

Fig. 6.6. *The desired shape is given by $F(x,y) = -(x-0.5)^2 - (y-0.5)^2 + 0.25$. The color map is a function of height and is used only to aid visualization of the surface.*

Three values of the number of grid points ($N_x = N_y = 50, 100, 200$) and three values for the number of start times ($n = 10, 20, 40$) are used for the inverse algorithm. More grid points make the boundaries of the layers smoother, and more start

n	Runtime, $N_x = 50$	Runtime, $N_x = 100$	Runtime, $N_x = 200$
10	0.421	2.714	20.159
20	0.762	5.188	38.746
40	1.462	10.195	76.701

times produce more unpowered layers in the seed layer. Tables 6.1 and 6.2 show the computed errors for the functions $F(x, y) = 0.1\cos(\pi x) + 0.25\sin(\pi y) + 0.1$ and $F(x, y) = -(x-0.5)^2 - (y-0.5)^2 + 0.25$, respectively. As the data indicate, the error has very little dependence on $N_x = N_y$ but has nearly linear dependence on n^{-1}. Table 6.3 shows the run times for the function $F(x, y) = 0.1\cos(\pi x) + 0.25\sin(\pi y) + 0.1$ with different numbers of grid points and different values of n. All computations were performed on a PC with an Intel M1.6GHz processor with 1.25GB of RAM.

Examining Tables 6.1 and 6.3 shows there is no benefit to using more grid points than needed for resolution of the layers. Using a larger n, however, does improve the accuracy of the seed layer, with only a linear increase in computational time.

7. Conclusions and future work.

The method presented here may face material limitations. An accurate fit to a desired shape can result in seed layer elements that are thin strips. The limit on the minimum geometry of the seed layer elements is governed by the photolithographic technology used to pattern them. Typically this ranges from about 1 μm, with readily available optical lithographic systems, to substantially less than 100 nm with electron-beam lithography and industry-leading optical photolithography systems.

Surface roughness could also limit the seed layer geometry. The process used to define the seed layer typically consists of a combination of photolithography, physical vapor deposition (PVD) (e.g., evaporation or sputtering), and chemical etching. The metal films deposited by PVD can be very thin ($<$ 100 nm) and are very smooth. The roughness of electrodeposited films can be highly variable and are subject to the specific process and recipe used. To obtain smoother electrodeposition, one can add chemicals (i.e., brighteners) and perform periodic current reversal.

The solution of the forward problem using the level set method depends on construction of a global distance function from the powered and (initially) unpowered segments. There are several ways to construct this distance function. Our method uses a time discretization that directly mimics the physical evolution of the front. It has some advantages in that additional physics could be easily included. An alternative method in both two and three dimensions would directly construct the distance function from the geometry of the segments.

One additional feature that can be introduced into seed layer patterns is solid boundaries. These solid boundaries are made of an insulated material and prevent growth of the metal shapes beyond the boundaries. This allows even more shape possibilities. Future work would include these solid boundaries in the model for forward growth and would attempt to incorporate them into the inverse procedure. Also, the current model is quite simple, and future work would add more physics into the model, such as nonuniform growth or perhaps some diffusion of the growing surface.

Appendix. The distance function for a line segment.

Let the line segment be given as $[(x_1, y_1), (x_2, y_2)]$. Without loss of generality, we shall assume that $x_1 < x_2$. There are 4 cases, depending on the slope of the line segment, which we denote as $m = \frac{y_2 - y_1}{x_2 - x_1}$.

1. $m = \pm\infty$.

$$d(x,y) = \begin{cases} \sqrt{(x-x_1)^2 + (y-y_b)^2} & \text{if } y < y_b, \\ |x - x_1| & \text{if } y_b \le y \le y_t, \\ \sqrt{(x-x_1)^2 + (y-y_t)^2} & \text{if } y > y_t, \end{cases}$$

where $y_b = \min(y_1, y_2)$ and $y_t = \max(y_1, y_2)$.

2. $m = 0$.

$$d(x,y) = \begin{cases} \sqrt{(x-x_1)^2 + (y-y_1)^2} & \text{if } x < x_1, \\ |y - y_1| & \text{if } x_1 \le x \le x_2, \\ \sqrt{(x-x_2)^2 + (y-y_1)^2} & \text{if } x > x_2. \end{cases}$$

3. $0 < m < \infty$.

$$d(x,y) = \begin{cases} \sqrt{(x-x_2)^2+(y-y_2)^2} & \text{if } y \geq (-\frac{1}{m}(x-x_2)+y_2), \\ \sqrt{(x-x_1)^2+(y-y_1)^2} & \text{if } y \leq (-\frac{1}{m}(x-x_1)+y_1), \\ \sqrt{(x-x_m)^2+(y-y_m)^2} & \text{otherwise,} \end{cases}$$

where $x_m = \left(\frac{1}{m+\frac{1}{m}}\right) * \left(mx_1 + \frac{x}{m} + y - y_1\right)$ and $y_m = m * (x_m - x_1) + y_1$.

4. $-\infty < m < 0$.

$$d(x,y) = \begin{cases} \sqrt{(x-x_2)^2+(y-y_2)^2} & \text{if } y \leq (-\frac{1}{m}(x-x_2)+y_2), \\ \sqrt{(x-x_1)^2+(y-y_1)^2} & \text{if } y \geq (-\frac{1}{m}(x-x_1)+y_1), \\ \sqrt{(x-x_m)^2+(y-y_m)^2} & \text{otherwise,} \end{cases}$$

where $x_m = \left(\frac{1}{m+\frac{1}{m}}\right) * \left(mx_1 + \frac{x}{m} + y - y_1\right)$ and $y_m = m * (x_m - x_1) + y_1$.

ACOUSTIC WAVES IN LONG RANGE RANDOM MEDIA[*]

RENAUD MARTY[†] AND KNUT SOLNA[‡]

Abstract. We consider waves propagating through multiscale media. Much is known about waves propagating through a medium that satisfies a scale separation assumption with random fluctuations on a microscale. Here we go beyond this situation and consider waves propagating through a medium defined in terms of a long range process. Such a medium can, for instance, be modeled in terms of a one-dimensional fractional Brownian motion with variations on a continuum of scales. Fractal medium models are used to model, for example, the heterogeneous earth and the turbulent atmosphere. We set forth a framework using the theory of rough paths in which propagation problems of this nature can be analyzed in the case with anticipative medium fluctuations with a Hurst exponent $H > 1/2$. We show how the wave interacts with the medium fluctuations in this case and that the interaction is qualitatively different from the situation where the medium satisfies a separation of scales assumption. In the long range case considered here the travel time depends strongly on the particular medium realization, but in fact the pulse shape does not.

Key words. wave propagation, random media, long range processes, fractional Brownian motion

1. Introduction.

Modeling in terms of a multiscale medium is important for propagation problems in, for instance, the earth's crust, the turbulent atmosphere, turbulent boundary layers, sea ice, and outer space [9, 15, 19, 20, 34, 42, 44]. Communication, remote sensing, and laser beam propagation schemes are affected by bad weather and multiscale medium variations. Large scale research projects (the ABLE ACE program Kirtland AFB, for instance [43]) have focused on gathering atmospheric turbulence data and numerically simulating propagation of wave fields through synthetic turbulence models that derive from these. Above a boundary layer atmospheric turbulence may occur within a stratified environment, and the turbulent temperature variations may be highly anisotropic; see [16, 36]. Rough and long range medium fluctuations associated with multiscale modeling are also important in medical imaging, device modeling, and nuclear technology, to name a few. The zone in between different tissue types (or in between different dielectrica) may in particular be strongly heterogeneous with variation on a continuum of scales. In general, the detailed pointwise variation of a multiscale medium, the refractive index, say, cannot be identified. However, the statistics of this variation can be characterized. Optimal design of, for instance, imaging and communication algorithms requires insight about how the wave is affected by the rough medium fluctuations, that is, the nonlinear coupling between medium and wave field statistics. This is particularly the case with modern high resolution sampling and imaging technology. Insight about the wave medium interaction is also important in a range of other applications like design of sound-absorbing materials and nondestructive evaluation of fractured materials. A good understanding

of how the wave interacts with variations on a continuum of small length scales is therefore important.

Propagation of high frequency waves in *smooth* media is well understood. A lot is also known about propagation in heterogeneous media that vary on a well-defined microscale. However, propagation in *rough* or *multiscale* media is not so well understood. We will look at how propagating pulses interact with rough variations in the medium. In [10, 11, 12] we considered propagation in rough media when the wave phenomenon was modeled in terms of the paraxial or forward approximation. In [37] we considered the full wave equation and a discrete multiscale medium. Here, we continue this line of research by analyzing the full wave equation in the context of a one-dimensional continuous multiscale medium modeled in terms of a long range process with slowly decaying correlations, and we consider in particular fractional Brownian motion–based media.

In the homogenization or effective medium regime, with the width of the propagating pulse being large compared to the scale of the medium fluctuations and propagation distances on the scale of the wavelength, the rapidly varying properties of the medium can be replaced by their homogenized or averaged values. However, over long propagation distances the accumulated effect of the scattering, associated with the medium microstructure, gradually changes the pulse *beyond* the geometrical effects of the high frequency analysis in the smooth homogenized medium. These modifications depend in general on the particular medium realization. Thus, to describe the propagation phenomenon it is not enough to consider only the mean wave field; one should also aim at describing the character of the fluctuations in the wave field. A mathematical theory for pulse propagation has been developed in [1, 6, 14, 25]. It deals with pulses in a particular realization of the random medium, and it explains why in many cases the evolution of the *pulse shape* is to leading order *deterministic*. We refer to this phenomenon as pulse *stabilization*. So far, two salient features of this "pulse shaping" theory have been that it assumes a one-dimensional medium and a separation of scales for the medium heterogeneities, that is, that the medium has features on microscales which are well separated from the macroscale. However, as explained above, many empirical studies suggest that, for instance, the earth's crust should be modeled as containing fluctuations on a continuum of length scales. Stabilization and pulse shaping in a two scale medium with slow lateral variations in the medium has been analyzed in [38]. Here, we generalize the pulse shaping theory for a two scale medium to the long range multiscale case.

We analyze acoustic waves propagating in a one-dimensional medium, modeled in terms of a long range process. As a particular example we consider media defined in terms of fractional Brownian motion. Fractional Brownian motion is a Gaussian (self-similar) stochastic process and is often used as a model for processes containing fluctuations on a continuum of length scales, for instance for modeling of turbulent environments. The Hurst exponent H characterizes the roughness of the fractional Brownian motion, and the value $H = 1/2$ gives standard Brownian motion. In the simplest case with $H = 1/2$ the medium model that we consider satisfies a separation of scales assumption. For $H \neq 1/2$ the medium contains long range interactions and variations on many scales. In this case the correlations in the medium have only polynomial decay, and our objective is to analyze the effects such long range correlations have on the propagating wave. Here, we shall analyze the case with $H > 1/2$ corresponding to persistent fluctuations so that consecutive increments of the process are positively correlated [13]. In fact, we shall show that the pulse shape is *not* affected by the random medium fluctuations to leading order. However, the travel time of the pulse depends on the particular medium realization, and the travel time fluctuations are large relative to the period of the pulse.

A number of studies of wave interaction with a fractal or multiscale object deal with scattering caused by fractal interfaces. However, some authors have explored wave-interaction with deterministic fractal media using numerical simulations [5, 21, 39]. Here, we present a mathematical analysis of acoustic pulse transmission through a random fractal and illustrate our theoretical results with numerical simulations. In section 2 we introduce the problem and review the basic wave decomposition approach and the classical scale separation result. Next, in section 3 we introduce the multiscale medium and summarize how the pulse shaping theory generalizes to these media. In section 4, we illustrate our theoretical results with numerical simulations. Finally, section 5 is devoted to the derivation of the main result.

2. Wave decomposition. The governing equations are the Euler equations giving conservation of moments and mass:

$$\rho(z)\frac{\partial u}{\partial t}(z,t)+\frac{\partial p}{\partial z}(z,t)=0\,, \tag{2.1}$$

$$\frac{1}{K(z)}\frac{\partial p}{\partial t}(z,t)+\frac{\partial u}{\partial z}(z,t)=0\,, \tag{2.2}$$

where t is the time, z is the depth into the medium, p is the pressure, and u the particle velocity. The medium parameters are the density ρ and the bulk-modulus K (reciprocal of the compressibility). We assume that ρ is a constant identically equal to one in our nondimensionalized units and that $1/K$ is modeled as follows:

$$\frac{1}{K(z)}=\begin{cases} 1+\varepsilon^{\kappa}\nu\left(\dfrac{z}{\varepsilon^2}\right) & \text{for } z\in[0,Z]\,,\\ 1 & \text{for } z\in\mathbb{R}-[0,Z]\,, \end{cases} \tag{2.3}$$

where $\kappa\geq 0$. We introduce the right- and left-going waves

$$A=p+u \quad \text{and} \quad B=u-p\,, \tag{2.4}$$

where the boundary conditions are of the form

$$A(z=0,t)=f(t/\varepsilon^{\tau}) \quad \text{and} \quad B(z=Z,t)=0\,, \tag{2.5}$$

for a positive real number $\tau>0$ and a source function f. In order to deduce a description of the transmitted pulse, we open a window of size ε^{τ} in the neighborhood of the travel time of the homogenized medium and define the processes

$$a^{\varepsilon}(z,s)=A(z,z+\varepsilon^{\tau}s) \quad \text{and} \quad b^{\varepsilon}(z,s)=B(z,-z+\varepsilon^{\tau}s)\,. \tag{2.6}$$

Observe that the background or homogenized medium in our scaling has a constant speed of sound equal to unity and that the medium is matched so that in the frame introduced in (2.6) the pulse-shapes of the right- and left-going waves are constant in the slab if $\nu\equiv 0$ or if we consider the homogenized medium [14]. We introduce next the Fourier transforms $\widehat{a}^{\varepsilon}$ and $\widehat{b}^{\varepsilon}$ of a^{ε} and b^{ε}, respectively,

$$\widehat{a}^{\varepsilon}(z,\omega)=\int e^{i\omega s}a^{\varepsilon}(z,s)ds \quad \text{and} \quad \widehat{b}^{\varepsilon}(z,\omega)=\int e^{i\omega s}b^{\varepsilon}(z,s)ds\,,$$

that satisfy

$$\frac{d\widehat{a}^\varepsilon}{dz} = \frac{i\omega}{2\varepsilon^{\tau-\kappa}}\nu\left(\frac{z}{\varepsilon^2}\right)\left(\widehat{a}^\varepsilon - e^{-2i\omega z/\varepsilon^\tau}\widehat{b}^\varepsilon\right), \qquad \widehat{a}^\varepsilon(0,\omega) = \widehat{f}(\omega)\,, \tag{2.7}$$

$$\frac{d\widehat{b}^\varepsilon}{dz} = \frac{i\omega}{2\varepsilon^{\tau-\kappa}}\nu\left(\frac{z}{\varepsilon^2}\right)\left(e^{2i\omega z/\varepsilon^\tau}\widehat{a}^\varepsilon - \widehat{b}^\varepsilon\right), \qquad \widehat{b}^\varepsilon(Z,\omega) = 0\,. \tag{2.8}$$

Following [6, 14], we express the previous system of equations in term of propagator $P^\varepsilon_\omega(z)$, which can be written as

$$P^\varepsilon_\omega(z) = \begin{pmatrix} \alpha^\varepsilon_\omega(z) & \overline{\beta^\varepsilon_\omega}(z) \\ \beta^\varepsilon_\omega(z) & \overline{\alpha^\varepsilon_\omega}(z) \end{pmatrix}, \tag{2.9}$$

and which satisfies

$$\frac{dP^\varepsilon_\omega}{dz}(z) = \frac{1}{\varepsilon^\gamma}H_\omega\left(\frac{z}{\varepsilon^\tau}, \frac{z}{\varepsilon^2}\right)P^\varepsilon_\omega(z)\,, \qquad P^\varepsilon_\omega(z=0) = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \tag{2.10}$$

with $\gamma = \tau - \kappa$ and

$$H_\omega(z_1, z_2) = \frac{i\omega}{2}\nu(z_2)\begin{pmatrix} 1 & -e^{-2i\omega z_1} \\ e^{2i\omega z_1} & -1 \end{pmatrix}.$$

Defining next the transmission coefficient T^ε_ω and the reflection coefficient R^ε_ω by

$$T^\varepsilon_\omega(z) = \frac{1}{\overline{\alpha^\varepsilon_\omega}(z)} \quad \text{and} \quad R^\varepsilon_\omega(z) = \frac{\beta^\varepsilon_\omega(z)}{\overline{\alpha^\varepsilon_\omega}(z)}\,, \tag{2.11}$$

we can write

$$a^\varepsilon(Z,s) = \frac{1}{2\pi}\int e^{-is\omega}T^\varepsilon_\omega(Z)\widehat{f}(\omega)\,d\omega \tag{2.12}$$

and

$$b^\varepsilon(0,s) = \frac{1}{2\pi}\int e^{-is\omega}R^\varepsilon_\omega(Z)\widehat{f}(\omega)\,d\omega\,. \tag{2.13}$$

Henceforth, we shall study the asymptotics of the propagator P^ε_ω in order to characterize a^ε and b^ε as ε goes to 0.

We recall now what happens in a "short range" model when $\tau = 1$ and $\kappa = 0$. We assume that ν is a centered Markov process with an invariant probability measure whose generator satisfies the Fredholm alternative. It is well known [6, 14] that under these assumptions, in order to characterize the transmitted pulse, the propagator equations P^ε_ω can be replaced by an effective system of stochastic differential equations from which we can deduce that, as ε goes to 0,

$$a^\varepsilon(Z,s) \longrightarrow \widetilde{a}(Z,s)\,, \tag{2.14}$$

with

$$\widetilde{a}(Z,s) = (f * G)(s - B)\,, \tag{2.15}$$

where G is a centered Gaussian density and B a Gaussian random variable. Proving this result involves using the diffusion approximation theorem [14] to get asymptotic expressions for specific propagator moments from which we can deduce the expression for the limit $\widetilde{a}(Z, s)$. Therefore, when we capture the pulse at its random arrival time we will see a pulse whose shape does not depend on the realization of the random medium. This shape is the original pulse shape convolved with a Gaussian pulse shaping kernel. Thus, the effects of the random medium fluctuations can be described in terms of a random travel time correction and an anomalous diffusion effect. By the same approach we can also prove that

$$b^{\varepsilon}(0, s) \longrightarrow 0\,. \tag{2.16}$$

This result shows that in the case with a constant homogenized medium the reflected wave will be negligible in the small ε limit. While the mathematical derivation of this "medium pulse shaping" result was first obtained in [6] and [26], it was first derived in the geophysical literature in [32] via a heuristic derivation. The approximation has since come to be known as the O'Doherty–Anstey (ODA) theory after the authors of the pioneering paper, which lead to a string of papers both in the mathematical and geophysical literature, reflecting its relevance. However, so far the problem has only been analyzed in short range media. Here we generalize to the situation with long range media and show that then we get a qualitatively different result. We explain in section 3.2 that in this case we have a strong travel time perturbation, as in the classic theory; however, in the case with long range media the pulse shape itself is *stable.*

3. Medium model and main result.

In this section we investigate the propagation in a long range medium. We first describe the model in detail, and then we establish the main result of the paper.

3.1. Long range model.

We assume $\gamma \in (0, 1)$ and that ν can be written as $\nu(z) = T(m(z))$ for every z where the following hold:

- T is a continuous function which is strictly bounded by 1 in absolute value, odd, and increasing. Note that our analysis remains valid in the case with T not being bounded; the boundedness by 1 is introduced to make the model physically pertinent: we recall that $1 + \varepsilon^{\kappa}\nu$ is the compressibility with $\kappa \geq 0$.
- m is a Gaussian process, centered, stationary and has a correlation function r_m which has the following asymptotic property as z goes to ∞:

$$r_m(z) = \mathbb{E}[m(0)m(z)] \sim c_m z^{-\gamma}\,. \tag{3.1}$$

Note that therefore the medium fluctuations ν themselves are not Gaussian in general; their distribution is controlled via the choice of T.

The property (3.1) is the so-called long range property. Its main consequence is that the covariance function r_m of m is not absolutely integrable:

$$\int_0^{\infty} |r_m(z)|\, dz = \infty\,.$$

Hence, this situation is in dramatic contrast with the classical mixing (or short range) case. Indeed, a mixing process has an integrable covariance function [22]. Another important consequence of (3.1) regards the choice of scales. We are given the correlation length of the medium $(1/\varepsilon^2)$, the amplitude (ε^{κ}), and the rate of decorrelation

($r_m(z) \sim c_m/z^\gamma$) of the random perturbations. Then, because our goal is to capture the behavior of the transmitted wave pulse and its interaction with the medium, we have to choose an appropriate size of the window to capture the critical wavelength interaction scale by taking $\tau = \gamma + \kappa$. We next explain this scaling choice. The propagator equation is essentially driven by the process $\varepsilon^{\kappa-\tau} m\left(z/\varepsilon^2\right)$, and, we shall see that indeed its analysis involves the study of the convergence of the antiderivative w^ε of this process:

$$w^\varepsilon(z) = \int_0^z \frac{1}{\varepsilon^{\tau-\kappa}} m\left(\frac{z'}{\varepsilon^2}\right) dz' .$$

However, it is known [35], as recalled in Lemma 1 just below, that the appropriate scale then is $\gamma = \tau - \kappa$. This gives convergence to a fractional Brownian motion. Let $H \in (0,1)$; then fractional (one-dimensional) Brownian motion (fBm) with Hurst parameter H is the centered Gaussian process $(B_H(z))_{z\in\mathbb{R}}$ with covariance function

$$\mathbb{E}[B_H(z_1)B_H(z_2)] = \frac{1}{2}\{|z_1|^{2H} + |z_2|^{2H} - |z_1 - z_2|^{2H}\} .$$

We refer the reader to Samorodnitsky and Taqqu's book [35] for a good reference. For the process w^ε we have the convergence given next.

Lemma 1. *Let $H = (2-\gamma)/2$. As ε goes to 0, the finite-dimensional distributions of w^ε converge to those of the fractional Brownian motion $c'_H B_H$, where ${c'_H}^2 = c_m H^{-1}(2H-1)^{-1}$.*

Now we give two examples of processes m:

- Fractional white noise with Hurst parameter $H = (2-\gamma)/2 \in (1/2, 1)$ that can be defined as

  $$m(z) = B_H(z+1) - B_H(z) , \tag{3.2}$$

  where B_H is the fBm with Hurst parameter H.
- The (stationary) fractional Ornstein–Uhlenbeck process with index $H = (2-\gamma)/2$ defined by

  $$m(z) = B_H(z) - e^{-z}\int_{-\infty}^z e^{z'} B_H(z')\, dz' , \tag{3.3}$$

  where B_H is the fBm with Hurst parameter H. As in the case with fractional white noise with index H, the fractional Ornstein–Uhlenbeck process is continuous, Gaussian, stationary, and centered and satisfies (3.1).

Notice that here we presented two examples for m in terms of an fBm, but all results in this paper are true and proved under the general assumptions on m presented above, in particular Gaussianity and slow correlation decay. Notice also that we shall consider here

$$H \in (1/2, 1) \quad \text{so that} \quad \gamma \in (0,1) . \tag{3.4}$$

We next introduce some notation. We denote by X a Gaussian, centered, and reduced random variable: $X \sim \mathcal{N}(0,1)$. Letting $\sigma_0 = \sqrt{\mathbb{E}[m(0)^2]}$, we will need the Hermite development of the function $T(\sigma_0 \times \cdot)$. We denote by H_k the kth Hermite polynomial and by $J(k)$ the kth Hermite coefficient of the function $T(\sigma_0 \times \cdot)$, that is to say, $J(k) = \mathbb{E}[T(\sigma_0 X)H_k(X)]$. Thanks to the assumptions on T, we have $J(0) = 0$

and $J(1) \neq 0$, so that the Hermite coefficient of T is 1. Therefore, we can write (see the appendix for more details about Hermite polynomials)

$$T(\sigma_0 \times X) = \sum_{k=1}^{\infty} \frac{J(k)}{k!} H_k(X) \,. \tag{3.5}$$

We conclude this subsection by establishing the long range behavior of ν.

LEMMA 2. *For $z \to \infty$ we have*

$$r_\nu(z) := \mathbb{E}[\nu(0)\nu(z)] \sim \frac{c_\nu}{z^\gamma} \,,$$

where $c_\nu = c_m J(1)^2/\sigma_0^2 = c_m \mathbb{E}[XT(\sigma_0 X)]^2/\sigma_0^2$.

Proof. In view of (3.5) we can write (using (A.1))

$$\nu(z) = \sum_{k=1}^{\infty} \frac{J(k)}{k!} H_k\left(\frac{m(z)}{\sigma_0}\right) \,, \tag{3.6}$$

so that (using (A.3))

$$\begin{aligned}\mathbb{E}[\nu(0)\nu(z)] &= \sum_{k=1}^{\infty} \frac{J(k)^2}{(k!)^2} \mathbb{E}\left[H_k\left(\frac{m(0)}{\sigma_0}\right) H_k\left(\frac{m(z)}{\sigma_0}\right)\right] \\ &= \sum_{k=1}^{\infty} \frac{J(k)^2}{k!\sigma_0^{2k}} r_m(z)^k \,.\end{aligned}$$

Therefore, we need to study the limit of

$$z^\gamma \mathbb{E}[\nu(0)\nu(z)] = \sum_{k=1}^{\infty} \frac{J(k)^2}{k!\sigma_0^{2k}} z^\gamma r_m(z)^k \,.$$

Observe that for $k = 1$ we have $z^\gamma r_m(z) \sim c_m$ as $z \to \infty$, and for $k > 1$ we have $z^\gamma r_m(z)^k \to 0$. Moreover, we have the uniform upper bound for z sufficiently large:

$$\frac{J(k)^2}{k!\sigma_0^{2k}} z^\gamma |r_m(z)|^k \leq \frac{J(k)^2}{k!} \,.$$

Using the fact that (by (A.2))

$$\sum_{k=1}^{\infty} \frac{J(k)^2}{k!} < \infty \,, \tag{3.7}$$

the result now follows from the uniform convergence theorem. □

3.2. Main result. Now we establish the main result of this paper. We shall see that the asymptotic behavior of the transmission coefficient is quite different in the long range case than in the short range case. Recall that we let $\tau = \gamma + \kappa > 0$.

THEOREM 1. *Under the above assumptions, as ε goes to 0, $\{a^\varepsilon(Z,s)\}_s$ converges in distribution in the space of continuous functions endowed with the uniform topology to the random process $\{\widetilde{a}(Z,s)\}_s$ that can be written as*

$$\widetilde{a}(Z,s) = f\left(s - \frac{c_H}{2} B_H(Z)\right) \,, \tag{3.8}$$

where B_H is a fractional Brownian motion with Hurst parameter $H = (2 - \gamma)/2$ and $c_H^2 = c_\nu H^{-1}(2H - 1)^{-1}$ with c_ν as introduced in Lemma 2. Moreover, the process $\{b^\varepsilon(0, s)\}_s$ converges to 0.

Therefore, we see that the pulse is stable and does not undergo a deterministic evolution in time as in the short range case. In the short range case the evolution of the pulse shape and the randomization of the pulse travel-distance takes place on the same time scale. In the long range case with persistent medium fluctuations and slow decorrelation the evolution of the pulse shape takes place on a relatively slow time scale, and in Theorem 1 we observe only the randomization of the travel distance while the pulse shape is stable. In the long range case with $H > 1/2$ the medium fluctuations are persistent and "smoother" than in the classic case, so that the traveltime perturbation corresponding to an accumulation of fluctuations effect becomes relatively stronger than the pulse transformation effect which is due to scattering and enhanced by the roughness of the medium. Note that the traveltime perturbation is in the long range case described by a fractional Brownian motion with a Hurst index that corresponds to the effective Hurst index for the medium perturbations, while in the classic case it is described by a standard Brownian motion.

From the point of view of modern applications of the theory of waves in random media the above result is relevant. Recently there has been a lot of interest in imaging schemes in the context of cluttered layered media [3, 14] exploiting the ODA approximation, for instance, as well as in nonlayered media [4]. This reflects the fact that classic imaging schemes deteriorates when the "background" medium becomes fluctuating. The above results show how this body of results applies to the long range situation, in which case the modeling of the travel time perturbation becomes the important aspect. We remark also that currently there is a lot of interest in the design of robust wireless communication schemes when the signalling takes place through clutter, through the turbulent atmosphere, for instance, which is relevant also in the context of remote sensing. Design of robust schemes requires a forward model that captures the interaction of the pulse with the medium, which in the long range persistent and layered case is described by Theorem 1. The derivation of this result, which is presented in section 5, sets forth a framework which we expect will be useful also in a more general context to describe other physical scaling scenarios, analogous to the case with short range medium fluctuations [17, 18].

4. Numerical illustration. We illustrate the results with some numerical simulations. In the numerical simulations we use a Gaussian initial pulse shape. In the normalized coordinates the support of the initial pulse is 10^{-3} and the total propagation distance is 1. The medium is defined as in (3.2) with $\kappa = 2H$ and, moreover, with $\epsilon = 10^{-2}$ and with a cutoff function that is the identity in the neighborhood of the origin with a smooth cutoff. We use a discretization corresponding to equal travel time sections and the method described in [33] to simulate the realizations of the medium fluctuations. In Figure 4.1 we show the result of three simulations when the propagated pulse is plotted relative to its random arrival time when $H = .6$ and on the fine scale ε^τ. Observe that indeed the pulse shape is to leading order not affected by random fluctuations in the medium, as predicted by Theorem 1. In Figure 4.2 we show the corresponding picture when $H = 1/2$. Note that in this case the pulse shape is modified via a convolution with a Gaussian kernel as described by the classical pulse shaping or ODA theory in the case of strong mixing.

5. Proof of Theorem 1. We first give an outline of the proof. As recalled in section 2 the process $\{a^\varepsilon(Z, s)\}_s$ can be written in terms of the propagator P^ε_ω, and

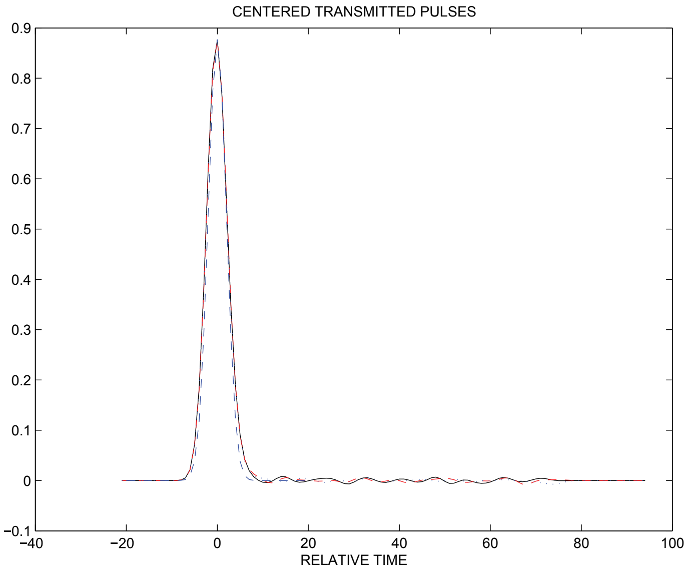

FIG. 4.1. *The transmitted wave shown at a fixed depth for several medium realizations and with $H = .6$. The dashed line is the original pulse shape.*

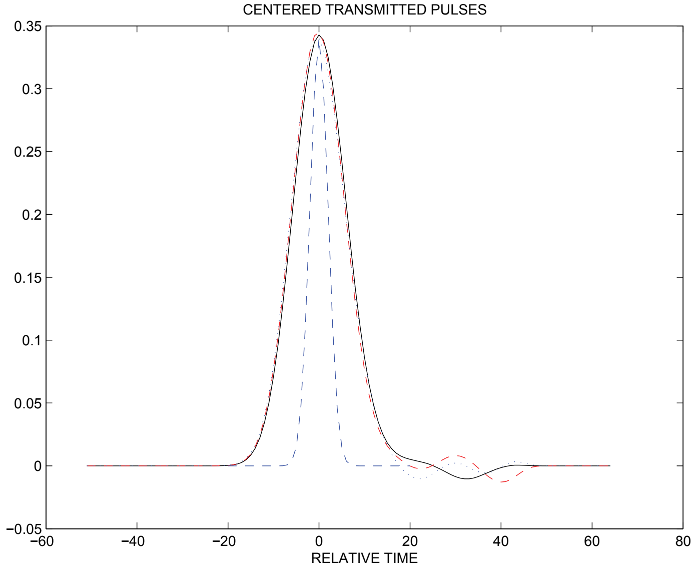

FIG. 4.2. *The transmitted wave shown at a fixed depth for several medium realizations and with $H = 1/2$. The dashed line is the original pulse shape.*

thus the study of the convergence of $\{a^\varepsilon(Z, s)\}_s$ can be analyzed via asymptotic properties of P^ε_ω. This convergence analysis will follow the lines of [30, 31]. The propagator P^ε_ω satisfies the equation

$$\frac{dP^\varepsilon_\omega}{dz}(z) = \frac{1}{\varepsilon^\gamma} H_\omega\left(\frac{z}{\varepsilon^\tau}, \frac{z}{\varepsilon^2}\right) P^\varepsilon_\omega(z)\,,$$

which we can write in the form

$$dP^\varepsilon_\omega(z) = \frac{i\omega}{2}\sum_{j=1}^{3} F_j P^\varepsilon_\omega \, dv^\varepsilon_j(z)\,, \tag{5.1}$$

where

$$F_1 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad F_2 = \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \quad \text{and} \quad F_3 = \begin{pmatrix} 0 & i \\ i & 0 \end{pmatrix},$$

and v^ε_1, v^ε_2, and v^ε_3 are three processes of bounded variation that we can write as

$$\begin{aligned} v^\varepsilon_1(z) &= \int_0^z \frac{1}{\varepsilon^\gamma}\nu\left(\frac{z'}{\varepsilon^2}\right) dz'\,, \\ v^\varepsilon_2(z) &= \int_0^z \frac{1}{\varepsilon^\gamma}\nu\left(\frac{z'}{\varepsilon^2}\right)\cos\left(2\omega\frac{z'}{\varepsilon^\tau}\right) dz'\,, \\ v^\varepsilon_3(z) &= \int_0^z \frac{1}{\varepsilon^\gamma}\nu\left(\frac{z'}{\varepsilon^2}\right)\sin\left(2\omega\frac{z'}{\varepsilon^\tau}\right) dz'\,. \end{aligned}$$

Thanks to Lyons's rough paths theory for which we recall some tools in section 5.1, we shall see that the convergence of P^ε_ω can be reduced for a convenient topology to the convergence of the process $\mathbf{v}^\varepsilon$ defined as

$$\mathbf{v}^\varepsilon := (v^\varepsilon_1, v^\varepsilon_2, v^\varepsilon_3)\,.$$

Hence, we first prove the convergence of $\mathbf{v}^\varepsilon$, then by Theorem 2 below we deduce the convergence of P^ε_ω, and thanks to (2.12) we finally conclude by the convergence of $\{a^\varepsilon(Z,s)\}_s$.

5.1. Rough paths.

In this section we fix $p \in [1,2)$ and consider a closed interval $I = [0, Z]$. We define the p-variation of a continuous function $w : I \to \mathbb{R}^n$ by

$$V_p(w) := \left(\sup_D \sum_{j=0}^{k-1} \|w(z_{j+1}) - w(z_j)\|^p\right)^{1/p},$$

where $\sup_D$ runs over all finite partitions $\{0 = z_0, \ldots, z_k = Z\}$ of I and where here and below $\|\cdot\|$ refers to the Euclidean norm. The space of all continuous functions of bounded variation (1-variation) is endowed with the p-variation distance

$$\|w\|_p = V_p(w) + \sup_{z\in[0,1]} |w(z)|$$

and is denoted by Ω^∞_p. The closure of this metric space is called the space of all geometric rough paths and is denoted by Ω_p. One of the most important theorems of rough paths theory is the following.

THEOREM 2 (Lyons's continuity theorem [27]). *Let*[1] $G : \mathbb{R}\times\mathbb{R}^d \to \mathcal{L}(\mathbb{R},\mathbb{R}^d)$ *and* $F : \mathbb{R}\times\mathbb{R}^d \to \mathcal{L}(\mathbb{R}^n,\mathbb{R}^d)$ *be two smooth functions. Let y be the unique solution of the differential equation*

$$dy(z) = G(z, y(z))\,dz + F(z, y(z))\,dw(z), \qquad y(z=0) = y_0\,,$$

[1] Here $\mathcal{L}(\mathbb{R},\mathbb{R}^d)$ (resp., $\mathcal{L}(\mathbb{R}^n,\mathbb{R}^d)$) denotes the space of all linear maps from $\mathbb{R}$ (resp., $\mathbb{R}^n$) to $\mathbb{R}^d$.

where w is a bounded variation function. Then the Itô map $\mathcal{I} : w \mapsto y$ is continuous with respect to the p-variation distance from $\Omega_p^\infty(\mathbb{R}^n)$ to $\Omega_p^\infty(\mathbb{R}^d)$. Therefore there exists a unique extension of this map (that we still denote by $\mathcal{I}$) to the space $\Omega_p(\mathbb{R}^n)$.

This theorem has been proved by Lyons and extensively studied and applied (see [8, 23, 24, 27, 28, 29]).

The proof of Theorem 1 is based on analysis of the tightness in the space of geometric rough paths. In the context of this we need to compute the p-variation for $p > 1$. To this effect we will need the following lemmas, of which the first can be found, for instance, in [24] and the second in [23, 24].

Lemma 3. *Let $q \in [1, 2)$ and $(v^\varepsilon)_{\varepsilon>0}$ be a family of continuous random processes of finite q-variation which is tight in the space of continuous functions on I and satisfies*

$$\lim_{A\to+\infty} \sup_{\varepsilon>0} \mathbb{P}[V_q(v^\varepsilon) > A] = 0\,. \tag{5.2}$$

Then $(v^\varepsilon)_{\varepsilon>0}$ is tight in Ω_p for every $p > q$.

Lemma 4. *For every $n \in \mathbb{N}$ and every $k = 0, 1, \ldots, 2^n$, we let $z_k^n := Zk/2^n$. Let $q \in [1, 2)$ and v be a function of finite q-variation. Then there exist two positive constants C_1, C_2 which do not depend on v such that*

$$V_q(v)^q \le C_1 \sum_{n=1}^{+\infty} n^{C_2} \sum_{k=1}^{2^n} \|v(z_k^n) - v(z_{k-1}^n)\|^q\,.$$

We conclude this subsection by mentioning an application of this theory to fractional Brownian motion introduced in section 3.1. From the definition of fBm B_H with index H we remark that if $H = 1/2$, the process B_H is the classical Brownian motion (cBm). However, if $H \ne 1/2$, W_H is neither a semimartingale nor a Markov process. As a consequence, the construction for the fBm of a stochastic calculus turns out to be more involved than for the cBm. This can be done by several way [7], and here we use the rough paths approach as in [8].

5.2. Convergence of the propagator. Using Theorem 2 and the expression (5.1), the asymptotic study of the propagator is reduced to finding the limit in a rough path space of $\mathbf{v}^\varepsilon := (v_1^\varepsilon, v_2^\varepsilon, v_3^\varepsilon)$. This is the subject of the following lemma.

Lemma 5. *Let $p > 2/(2-\gamma) \equiv 1/H$. As ε goes to 0, the increments of $\mathbf{v}^\varepsilon$ converge in Ω_p to those of W_H, which can be written as*

$$W_H = (c_H B_H, 0, 0),$$

where B_H is a fractional Brownian motion with Hurst parameter $H = (2 - \gamma)/2$.

The proof of Lemma 5 is based on establishing several technical lemmas that we derive next. Below we will repeatedly use the notation

$$w^\varepsilon(z) = \int_0^z \frac{1}{\varepsilon^\gamma} m\left(\frac{z'}{\varepsilon^2}\right) dz'\,.$$

We consider first v_1^ε.

Lemma 6. *As ε goes to 0, the finite-dimensional distributions of v_1^ε converge to those of the fractional Brownian motion $c_H B_H$ with ${c_H}^2 = c_\nu H^{-1}(2H - 1)^{-1}$.*

Lemma 6 is a continuous version of [40]. Moreover, a stronger version of this result was established in [41]. Nevertheless, we present here a (simple) proof of Lemma 6 for the sake of completeness.

Proof. In view of Lemma 1 it is enough to show that

$$\lim_{\varepsilon\to 0}\mathbb{E}\left[\left|v_1^\varepsilon(z)-\sqrt{\frac{c_\nu}{c_m}}w^\varepsilon(z)\right|^2\right]=0\,. \tag{5.3}$$

Consider the development of $T(\sigma_0\times\cdot)$ in the base of Hermite polynomials $\{H_j\}_{j=0,1,\dots}$,

$$T(m)=\sum_{j=1}^{\infty}\frac{J(j)}{j!}H_j\left(\frac{m}{\sigma_0}\right)\,,$$

and observe that $J(1)/\sigma_0=\sqrt{c_\nu/c_m}$; by (A.3) we then have

$$\begin{aligned}
\mathbb{E}\left[\left|v_1^\varepsilon(z)-\sqrt{\frac{c_\nu}{c_m}}w^\varepsilon(z)\right|^2\right]&=\mathbb{E}\left[\left|\varepsilon^{2H}\int_0^{z/\varepsilon^2}\sum_{j=2}^{\infty}\frac{J(j)}{j!}H_j\left(\frac{m(x)}{\sigma_0}\right)dx\right|^2\right]\\
&=\varepsilon^{4H}\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy\sum_{j=2}^{\infty}\left(\frac{J(j)}{j!}\right)^2\mathbb{E}\left[H_j\left(\frac{m(x)}{\sigma_0}\right)H_j\left(\frac{m(y)}{\sigma_0}\right)\right]\\
&=\varepsilon^{4H}\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy\sum_{j=2}^{\infty}\frac{J(j)^2}{j!}\left(\frac{r(x-y)}{\sigma_0^2}\right)^j\\
&\le\varepsilon^{4H}\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy\sum_{j=2}^{\infty}\frac{J(j)^2}{j!}\left(\frac{r(x-y)}{\sigma_0^2}\right)^2\\
&\le\varepsilon^{4H}C'\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy\,r(x-y)^2\,,
\end{aligned}$$

with

$$C'=\sum_{j=2}^{\infty}\frac{J(j)^2}{j!\sigma_0^4}<\infty\,.$$

As $u\to\infty$, we have $r(u)\sim cu^{-\gamma}$; therefore for every $\eta>0$ there exist z_η, C_η, and $\tilde{C}_\eta$ such that

$$\begin{aligned}
\varepsilon^{4H}\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy\,r(x-y)^2&\le\varepsilon^{4H}\sigma_0^4\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy1_{|x-y|\le z_\eta}\\
&\quad+\varepsilon^{4H}\eta\int_0^{z/\varepsilon^2}dx\int_0^{z/\varepsilon^2}dy|r(x-y)|\\
&\le\varepsilon^{4H-2}C_\eta+\eta|z|^{2-\gamma}\tilde{C}_\eta\,.
\end{aligned}$$

Then

$$\limsup_{\varepsilon\to 0}\mathbb{E}\left[\left|v_1^\varepsilon(z)-\sqrt{\frac{c_\nu}{c_m}}w^\varepsilon(z)\right|^2\right]\le\eta|z|^{2-\gamma}\tilde{C}_\eta$$

for every $\eta>0$, which concludes the proof. □

We consider next v_2^ε and v_3^ε.

LEMMA 7. *For every $z\in[0,Z]$, as ε goes to 0, the finite-dimensional distributions of $v_2^\varepsilon(z)$ and $v_3^\varepsilon(z)$ converge to those of the 0 process.*

Proof. Without loss of generality we present the proof only for $v_2^\varepsilon(z)$ and with $2\omega = 1$. We have

$$\begin{aligned}\mathbb{E}[v_2^\varepsilon(z)^2] &= \frac{1}{\varepsilon^{2\gamma}} \int_0^z dx \int_0^z dy \cos\left(\frac{x}{\varepsilon^\tau}\right) \cos\left(\frac{y}{\varepsilon^\tau}\right) r_\nu \left(\frac{x-y}{\varepsilon^2}\right) \\ &= I_1^\varepsilon(z) + I_2^\varepsilon(z)\,,\end{aligned}$$

with

$$\begin{aligned}I_1^\varepsilon(z) &= \frac{c_\nu}{\varepsilon^{2\gamma}} \int_0^z dx \int_0^z dy \cos\left(\frac{x}{\varepsilon^\tau}\right) \cos\left(\frac{y}{\varepsilon^\tau}\right) \left|\frac{x-y}{\varepsilon^2}\right|^{-\gamma}\,, \\ I_2^\varepsilon(z) &= \frac{1}{\varepsilon^{2\gamma}} \int_0^z dx \int_0^z dy \cos\left(\frac{x}{\varepsilon^\tau}\right) \cos\left(\frac{y}{\varepsilon^\tau}\right) \left(r_\nu\left(\frac{x-y}{\varepsilon^2}\right) - c_\nu \left|\frac{x-y}{\varepsilon^2}\right|^{-\gamma}\right)\,.\end{aligned}$$

Let $\delta > 0$; because $r_\nu(u) \sim c_\nu u^{-\gamma}$ as $u \to \infty$, we have that for $u > z_\delta$ (with z_δ sufficiently large) $|r_\nu(u) - c_\nu u^{-\gamma}| \le \delta u^{-\gamma}$. We then obtain

$$\begin{aligned}|I_2^\varepsilon(z)| &\le \frac{\delta}{\varepsilon^{2\gamma}} \int_0^z dx \int_0^z dy \cos\left(\frac{x}{\varepsilon^\tau}\right) \cos\left(\frac{y}{\varepsilon^\tau}\right) \left|\frac{x-y}{\varepsilon^2}\right|^{-\gamma} \\ &\quad + C \int_0^z dx \int_0^z dy |x-y|^{-\gamma} 1_{|x-y| \le \varepsilon^2 z_\delta} \\ &\le \delta \int_0^z dx \int_0^z dy |x-y|^{-\gamma} + C \int_0^z dx \int_0^z dy |x-y|^{-\gamma} 1_{|x-y|\le \varepsilon^2 z_\delta}\,,\end{aligned}$$

so that

$$\limsup_{\varepsilon\to 0} |I_2^\varepsilon(z)| \le \delta \int_0^z dx \int_0^z dy |x-y|^{-\gamma}\,.$$

The inequality above is valid for every $\delta > 0$, and we conclude

$$\lim_{\varepsilon \to 0} I_2^\varepsilon(z) = 0\,.$$

To complete the study of v_2^ε it remains to deal with $I_1^\varepsilon(z)$. We have

$$\begin{aligned}I_1^\varepsilon(z) &= c_\nu \varepsilon^{4-2\gamma} \int_0^{z/\varepsilon^2} dx \int_0^{z/\varepsilon^2} dy \cos(\varepsilon^{2-\tau} x) \cos(\varepsilon^{2-\tau} y) |x-y|^{-\gamma} \\ &= \frac{c_\nu}{2}\Big(I_{1,1}^\varepsilon(z) + I_{1,2}^\varepsilon(z)\Big)\,,\end{aligned}$$

where

$$\begin{aligned}I_{1,1}^\varepsilon(z) &= \varepsilon^{4-2\gamma} \int_0^{z/\varepsilon^2} dx \int_0^{z/\varepsilon^2} dy \cos(\varepsilon^{2-\tau}(x-y))|x-y|^{-\gamma}\,, \\ I_{1,2}^\varepsilon(z) &= \varepsilon^{4-2\gamma} \int_0^{z/\varepsilon^2} dx \int_0^{z/\varepsilon^2} dy \cos(\varepsilon^{2-\tau}(x+y))|x-y|^{-\gamma}\,.\end{aligned}$$

Using integration by parts, we get

$$I_{1,1}^\varepsilon(z) = 2\left(\varepsilon^{4-2\gamma} \int_0^{z/\varepsilon^2} dx \left(\int_0^{(z-x)/\varepsilon^2} dy \cos(\varepsilon^{2-\tau} y)|y|^{-\gamma}\right)\right) = 2(J_1^\varepsilon(z) - J_2^\varepsilon(z))\,,$$

where

$$J_1^\varepsilon(z) = \varepsilon^{2-2\gamma} z \int_0^{z/\varepsilon^2} dy \cos(\varepsilon^{2-\tau} y) y^{-\gamma}\,,$$
$$J_2^\varepsilon(z) = \varepsilon^{4-2\gamma} \int_0^{z/\varepsilon^2} dy \cos(\varepsilon^{2-\tau} y) y^{1-\gamma}\,.$$

We make the substitution $y \to y/\varepsilon^{2-\tau}$ in $J_1^\varepsilon(z)$ to obtain

$$J_1^\varepsilon(z) = \varepsilon^{\tau(1-\gamma)} z \int_0^{z/\varepsilon^\tau} dy \cos(y) y^{-\gamma}$$

and so $J_1^\varepsilon(z) = O(\varepsilon^{\tau(1-\gamma)})$. We also make the substitution $y \to y/\varepsilon^{2-\tau}$ in $J_2^\varepsilon(z)$ to obtain

$$J_2^\varepsilon(z) = \varepsilon^{\tau(2-\gamma)} \int_0^{z/\varepsilon^\tau} dy \cos(y) y^{1-\gamma}\,.$$

Using integration by parts, we obtain

$$\begin{aligned} J_2^\varepsilon(z) = \varepsilon^{\tau(2-\gamma)} \sin\left(\frac{z}{\varepsilon^\tau}\right) \left(\frac{z}{\varepsilon^\tau}\right)^{1-\gamma} \\ - \varepsilon^{\tau(2-\gamma)}(1-\gamma) \int_0^{z/\varepsilon^\tau} dy \sin(y) y^{-\gamma}\,, \end{aligned}$$

and so $J_2^\varepsilon(z) = O(\varepsilon^\tau)$. Therefore, we conclude

$$\lim_{\varepsilon\to 0} I_{1,1}^\varepsilon(z) = 0\,.$$

Consider finally $I_{1,2}^\varepsilon(z)$. Letting $x-y \to x$ and $x+y \to y$, we get

$$I_{1,2}^\varepsilon(s,t) = \varepsilon^{4-2\gamma} \iint_{D_1^\varepsilon \cup D_2^\varepsilon \cup D_3^\varepsilon \cup D_4^\varepsilon} dx\, dy\, |x|^{-\gamma} \frac{\cos(\varepsilon^{2-\tau} y)}{2},$$

where

$$\begin{aligned} D_1^\varepsilon &= \{(x,y) \in [0, z/\varepsilon^2] \times [0, z/\varepsilon^2] : x \le y\}\,, \\ D_2^\varepsilon &= \{(x,y) \in [0, z/\varepsilon^2] \times [z/\varepsilon^2, 2z/\varepsilon^2] : y \le -x + 2z/\varepsilon^2\}\,, \\ D_3^\varepsilon &= \{(x,y) \in [-z/\varepsilon^2, 0] \times [z/\varepsilon^2, 2z/\varepsilon^2] : y \le x + 2z/\varepsilon^2\}\,, \\ D_4^\varepsilon &= \{(x,y) \in [-z/\varepsilon^2, 0] \times [0, z/\varepsilon^2] : -y \le x\}\,. \end{aligned}$$

Let us deal with the integral on D_1^ε:

$$\varepsilon^{4-2\gamma} \iint_{D_1^\varepsilon} dx\, dy\, |x|^{-\gamma} \frac{\cos(\varepsilon^{2-\tau} y)}{2} = (2(1-\gamma))^{-1} J_2^\varepsilon(z) = O(\varepsilon^\tau)\,.$$

The integrals on D_2^ε, D_3^ε, and D_4^ε can be analyzed in a similar way; therefore, $I_{1,2}^\varepsilon(s,t) \to 0$. This finally shows

$$\lim_{\varepsilon\to 0} I_1^\varepsilon(z) = 0\,,$$

and then

$$\lim_{\varepsilon\to 0}\mathbb{E}[v_2^\varepsilon(z)^2]=0,$$

which concludes the proof. □

Now we deal with a technical lemma regarding increments of $\mathbf{v}^\varepsilon$.

LEMMA 8. *There exists a constant $C>0$ such that for every z, ζ, and $\varepsilon>0$ we have*

$$\mathbb{E}[\|\mathbf{v}^\varepsilon(z)-\mathbf{v}^\varepsilon(\zeta)\|^2]\le C|z-\zeta|^{2H}.$$

Proof. For every $j=1,2,3$, using (3.6), (3.7), and (A.3), we have (taking $z>\zeta$)

$$\begin{aligned}\mathbb{E}[|v_j^\varepsilon(z)-v_j^\varepsilon(\zeta)|^2] &\le \frac{1}{\varepsilon^{2\gamma}}\int_\zeta^z dx\int_\zeta^z dy\left|\mathbb{E}\left[\nu\left(\frac{x}{\varepsilon^2}\right)\nu\left(\frac{y}{\varepsilon^2}\right)\right]\right|\\
&\le \frac{C}{\varepsilon^{2\gamma}}\int_\zeta^z dx\int_\zeta^z dy\sum_{j=1}^\infty\left(\frac{J(j)}{j!}\right)^2\left|\mathbb{E}\left[H_j\left(\frac{m}{\sigma_0}\left(\frac{x}{\varepsilon^2}\right)\right)H_j\left(\frac{m}{\sigma_0}\left(\frac{y}{\varepsilon^2}\right)\right)\right]\right|\\
&\le \frac{C}{\varepsilon^{2\gamma}}\int_\zeta^z dx\int_\zeta^z dy\sum_{j=1}^\infty\frac{J(j)^2}{j!\sigma_0^{2j}}\left|r_m\left(\frac{x-y}{\varepsilon^2}\right)\right|^j\\
&\le \frac{C}{\varepsilon^{2\gamma}}\int_\zeta^z dx\int_\zeta^z dy\sum_{j=1}^\infty\frac{J(j)^2}{j!\sigma_0^{2}}\left|r_m\left(\frac{x-y}{\varepsilon^2}\right)\right|\\
&\le \frac{C'}{\varepsilon^{2\gamma}}\int_\zeta^z dx\int_\zeta^z dy\left|\frac{x-y}{\varepsilon^2}\right|^{-\gamma}\\
&\le \frac{2C'}{(1-\gamma)(2-\gamma)}\left|z-\zeta\right|^{2-\gamma},\end{aligned}$$

which concludes the proof. □

Using the above lemmas, we can deduce the following lemma, which deals with identification of the limit.

LEMMA 9. *As ε goes to 0, $\mathbf{v}^\varepsilon$ converges to W_H defined in Lemma 5 in the space of continuous functions endowed with the uniform norm.*

Proof. Lemmas 6 and 7 give the convergence of finite-dimensional distributions of $\mathbf{v}^\varepsilon$ to those of W_H. Using then the Kolmogorov criterion [2], Lemma 8, and the fact that $2H>1$, we get the tightness of $(\mathbf{v}^\varepsilon)_\varepsilon$ in the space of continuous functions endowed with the uniform norm, which establishes the proof. □

Thanks to Lemma 9 we conclude the proof of Lemma 5 by establishing the tightness in a rough paths sense.

LEMMA 10. *The sequence $(\mathbf{v}^\varepsilon)_\varepsilon$ is tight in Ω_p for $p>1/H$.*

Proof of Lemmas 5 *and* 10. Let $q\in(1/H,p)$. In view of Lemmas 3 and 9 it is enough to prove

$$\lim_{A\to+\infty}\sup_{\varepsilon>0}\mathbb{P}[V_q(\mathbf{v}^\varepsilon)>A]=0. \tag{5.4}$$

Using Chebyshev's inequality, the fact that $q < 2$, Lemma 4, the Hölder inequality, and Lemma 9, we find

$$\begin{aligned}\mathbb{P}[V_q(\mathbf{v}^\varepsilon) > A] &\le \frac{1}{A^q}\mathbb{E}[V_q(\mathbf{v}^\varepsilon)^q]\\ &\le \frac{C}{A^q}\sum_{n=1}^{+\infty} n^C \sum_{k=1}^{2^n} \mathbb{E}[\|\mathbf{v}^\varepsilon(z_k^n) - \mathbf{v}^\varepsilon(z_{k-1}^n)\|^q]\\ &\le \frac{C}{A^q}\sum_{n=1}^{+\infty} n^C \sum_{k=1}^{2^n} \mathbb{E}[\|\mathbf{v}^\varepsilon(z_k^n) - \mathbf{v}^\varepsilon(z_{k-1}^n)\|^2]^{q/2}\\ &\le \frac{C'}{A^q}\sum_{n=1}^{+\infty} n^C \sum_{k=1}^{2^n} \left(\frac{1}{2^n}\right)^{qH}\\ &\le \frac{C'}{A^q}\sum_{n=1}^{+\infty} n^C \left(\frac{1}{2^n}\right)^{qH-1},\end{aligned}$$

and since $qH > 1$ we deduce (5.4). □

Finally, we can now derive the following lemma, which deals with the convergence of the propagator.

LEMMA 11. *Let $\{\omega_1, \dots, \omega_n\}$ be a collection of frequencies. Then, as ε goes to 0, the propagator vector $(P^\varepsilon_{\omega_1}, \dots, P^\varepsilon_{\omega_n})$ converges to $(P_{\omega_1}, \dots, P_{\omega_n})$, which is the asymptotic propagator P_ω that we can write as*

$$P_\omega(z) = \begin{pmatrix} \exp\left(i\omega c_H/2B_H(z)\right) & 0 \\ 0 & \exp\left(-i\omega c_H/2B_H(z)\right)\end{pmatrix}.$$

Proof. By combining Theorem 2, (5.1), and Lemma 5, we get that, as ε goes to 0, P^ε_ω converges in distribution in the space of continuous functions (endowed with the uniform topology) to the solution P_ω of the following system of equations in the sense of rough paths:

$$dP_\omega(z) = \frac{i\omega c_H}{2}\begin{pmatrix} 1 & 0 \\ 0 & -1\end{pmatrix} P_\omega(z)\, dB_H(z)\,.$$

This concludes the proof. □

5.3. Conclusion of the proof. The remaining part of the proof of Theorem 1 follows the lines of [6, 14]; however, we present it here for completeness. Recall that, thanks to the formula (2.12), we can write $a^\varepsilon(Z, s)$ in a Fourier-type formula using the transmission coefficient,

$$a^\varepsilon(Z, s) = \frac{1}{2\pi}\int e^{-is\omega} T^\varepsilon_\omega(Z)\widehat{f}(\omega)\, d\omega\,, \tag{5.5}$$

with the transmission coefficient being a functional of the propagator P^ε_ω. We shall use Lemma 11 to deduce the convergence of the transmitted wave.

Let $n \in \mathbb{N}$, $s_1 \le \cdots \le s_n \in [0, \infty)$. We can write

$$\begin{aligned}\mathbb{E}[a^\varepsilon(Z, s_1)\cdots a^\varepsilon(Z, s_n)] &= \mathbb{E}\left[\frac{1}{(2\pi)^n}\prod_{j=1}^n \int e^{-is_j\omega} T^\varepsilon_\omega(Z)\widehat{f}(\omega)\, d\omega\right]\\ &= \frac{1}{(2\pi)^n}\int\cdots\int e^{-i\sum_{j=1}^n s_j\omega_j}\widehat{f}(\omega_1)\cdots\widehat{f}(\omega_n)\mathbb{E}[T^\varepsilon_{\omega_1}(Z)\cdots T^\varepsilon_{\omega_n}(Z)]\, d\omega_1\cdots d\omega_n.\end{aligned}$$

Thanks to Lemma 11 we have that as $\varepsilon \to 0$,

$$\mathbb{E}[T^\varepsilon_{\omega_1}(Z)\cdots T^\varepsilon_{\omega_n}(Z)] \to \mathbb{E}\left[\exp\left(\frac{ic_H B_H(Z)}{2}\sum_{j=1}^n \omega_j\right)\right],$$

and then

$$\begin{aligned}\mathbb{E}[a^\varepsilon(Z,s_1)\cdots a^\varepsilon(Z,s_n)] &\to \frac{1}{(2\pi)^n}\int\cdots\int e^{-i\sum_{j=1}^n s_j\omega_j}\widehat{f}(\omega_1)\cdots\widehat{f}(\omega_n)\\ &\quad\times\mathbb{E}\left[\exp\left(\frac{ic_H B_H(Z)}{2}\sum_{j=1}^n \omega_j\right)\right] d\omega_1\cdots d\omega_n\\ &= \mathbb{E}\left[\frac{1}{(2\pi)^n}\prod_{j=1}^n\int e^{-i(s_j - c_H B_H(Z)/2)\omega}\widehat{f}(\omega)\,d\omega\right]\\ &= \mathbb{E}\left[\prod_{j=1}^n f\left(s_j - \frac{c_H B_H(Z)}{2}\right)\right].\end{aligned}$$

The tightness proof is similar to the proof of Lemma 3.2 in [6], and the convergence of $a^\varepsilon(Z,s)$ follows. To conclude the proof of Theorem 1 it remains to prove the convergence of $b^\varepsilon(0,s)$. It is similar to the convergence of $a^\varepsilon(Z,s)$, up to substituting the application of (2.12) by that of (2.13).

Appendix A. Hermite polynomials.

In this appendix we recall some results regarding Hermite polynomials that we use in this paper. We denote the Gaussian probability density of a random variable $X \sim \mathcal{N}(0,1)$ by

$$g(x) = \frac{e^{-x^2/2}}{\sqrt{2\pi}},$$

and we define for every $k \in \mathbb{N}$ the kth Hermite polynomial by

$$H_k(x) = (-1)^k\frac{g^{(k)}(x)}{g(x)}.$$

The set of all Hermite polynomials $\{H_k,\ k = 0,1,2,\dots\}$ is an orthonormal base for the space $L^2(g(x)\,dx) = \{h : \mathbb{E}[|h(X)|^2] < \infty\}$. We denote by $J_h(k)$ (or $J(k)$ if there is no ambiguity) the projection coefficient of a function $h \in L^2(g(x)\,dx)$ on the subspace spanned by H_k, that is,

$$J_h(k) = \mathbb{E}[H_k(X)h(X)].$$

Then, we have the series representation

$$h(x) = \sum_{k=0}^\infty \frac{J_h(k)}{k!}H_k(x), \tag{A.1}$$

the convergence being in $L^2(g(x)\,dx)$. We can explicitly compute the second moments by

$$\mathbb{E}[|h(X)|^2] = \sum_{k=0}^\infty \frac{|J_h(k)|^2}{k!}. \tag{A.2}$$

This formula is a direct consequence of the following relation that we use in this paper: for a centered two-dimensional Gaussian vector (X_1, X_2) such that $\mathbb{E}[X_1^2] = \mathbb{E}[X_2^2] = 1$ we have

$$\mathbb{E}[H_j(X_1)H_k(X_2)] = \begin{cases} k!\mathbb{E}[X_1X_2]^k & \text{if} \quad k = l, \\ 0 & \text{if} \quad k \neq l. \end{cases} \tag{A.3}$$

THE UNSTEADY FLOW OF A WEAKLY COMPRESSIBLE FLUID IN A THIN POROUS LAYER I: TWO-DIMENSIONAL THEORY[*]

D. J. NEEDHAM[†], S. LANGDON[‡], G. S. BUSSWELL[§], AND J. P. GILCHRIST[§]

Abstract. We consider the problem of determining the pressure and velocity fields for a weakly compressible fluid flowing in a two-dimensional reservoir in an inhomogeneous, anisotropic porous medium, with vertical side walls and variable upper and lower boundaries, in the presence of vertical wells injecting or extracting fluid. Numerical solution of this problem may be expensive, particularly in the case that the depth scale of the layer h is small compared to the horizontal length scale l. This is a situation which occurs frequently in the application to oil reservoir recovery. Under the assumption that $\epsilon = h/l \ll 1$, we show that the pressure field varies only in the horizontal direction away from the wells (the outer region). We construct two-term asymptotic expansions in ϵ in both the inner (near the wells) and outer regions and use the asymptotic matching principle to derive analytical expressions for all significant process quantities. This approach, via the method of matched asymptotic expansions, takes advantage of the small aspect ratio of the reservoir, ϵ, at precisely the stage where full numerical computations become stiff, and also reveals the detailed structure of the dynamics of the flow, both in the neighborhood of wells and away from wells.

Key words. oil recovery, thin porous layer, matched asymptotics

1. Introduction.

It is standard practice in the oil and gas industry to use reservoir simulators based on numerical methods such as the finite difference or finite element techniques. This kind of approach has been shown to be enormously successful over the years in modeling a wide variety of physical processes in the reservoir e.g., faults, rock layering effects, complex fluid phase behavior, etc. While reservoir simulators of this type will continue to play a crucial role in the industry, it is well known that to use them takes considerable expertise and time. Because of the numerical nature of the modeling process, gridding, time-stepping, and convergence issues require care and attention. Long execution times are often necessary for certain types of problems, e.g., hydraulically fractured wells.

Analytic techniques, for the reasons outlined, can therefore play a valuable role in the industry. Such techniques, although they may have some simplifying assumptions, allow a reservoir or production engineer to perform a quick study of their reservoir in order to obtain a broad understanding of the dynamical processes and make approximate costing forecasts. Analytic solutions are extremely fast and provide none of the timestepping and convergence issues seen with a numerically based simulator. Also, a necessary step in many reservoir studies involves the history matching of observed data by optimizing model parameters. The history matched model is then used for

performance prediction. Given the speed and reliability of analytic results, there is a clear opportunity to exploit their use in history matching studies.

There has been much work in the literature regarding analytic approaches, particularly for well testing applications [10, 5, 15, 1, 9] but also from a full field reservoir standpoint, where multiple wells and reservoir boundaries must be accounted for to forecast production over the required timescales. Algorithms for full field simulation problems based on analytic approaches have been presented in the literature for porous media with homogeneous and anisotropic permeability in a variety of sources [4, 19, 13]. A more complex problem involves the application of analytic approaches to full field scenarios where the reservoir has inhomogeneous permeability and variable geometry [12, 14, 8, 18].

In this paper we introduce a new approach to solving full field reservoir problems with inhomogeneous and anisotropic permeability and variable reservoir geometry using the method of matched asymptotic expansions. Specifically, our problem involves determining analytical expressions for the pressure and velocity fields for a weakly compressible fluid flowing in a horizontal reservoir with variable upper and lower boundaries. Vertical wells injecting or extracting fluid from the reservoir can be considered as line sources and sinks, respectively. Numerical solution of the full equations of motion throughout the reservoir can be prohibitively expensive. However, under the condition that the depth scale of the reservoir h is small compared to the length scale of the reservoir l, as is often the case in geophysical applications, it can be shown (allowing further that the porous medium has inhomogeneous and anisotropic permeability) that the dimension of the problem can be reduced away from the wells, with solution of the full equations of motion being required only in a small domain around the wells where the geometry is radically simplified. Moreover, as the ratio h/l decreases, efficient application of numerical schemes becomes harder, while the problem becomes more amenable to solution via matched asymptotic theory.

Here, we restrict attention to the case of two-dimensional flow. The full three-dimensional problem will be dealt with in subsequent work [11]. We introduce the parameter $\epsilon = h/l$ and consider asymptotic solutions to the equations of motion of the fluid in increasing powers of ϵ, with $0 < \epsilon \ll 1$. In the vicinity of a well (the *inner* region) the pressure field is two-dimensional, but away from the wells (the *outer* region) the pressure field is only one-dimensional. This immediately leads to a reduction in complexity. Here, however, rather than solving the full equations of motion numerically in the inner and outer regions, we construct two-term expansions in both the inner and outer regions. These expansions in the inner and outer regions can then be matched, via the Van Dyke asymptotic matching principle [20], enabling us to derive amenable analytical expressions for all significant process quantities.

We begin in section 2 by deriving the equations of motion in the porous medium. Conservation of mass and momentum lead to a strongly parabolic linear initial boundary value problem for the dynamic fluid pressure (from which the fluid velocity field can be deduced), with Neumann boundary conditions, under the assumption that the walls are impenetrable to the fluid in the porous medium. This initial boundary value problem has a unique solution, but its direct computation would be expensive, primarily due to stiffness when $0 < \epsilon \ll 1$. We thus consider the associated steady state problem [SSP], a linear strongly elliptic Neumann problem, which also has a unique solution (up to a constant) under the further constraint that the sum of the total volume fluxes at the wells (the line sources and sinks) is zero. Solution of the steady state problem is considered in section 3. Subtracting the solution of the steady state problem from the solution of the initial value problem leads to a strongly parabolic homogeneous problem with no discontinuities across the sources and sinks. The solution of this problem leads to a regular self-adjoint eigenvalue problem [EVP] whose solution is considered in section 4.

Rather than solving [SSP] and [EVP] directly, the solution to each problem is considered in the asymptotic limit $\epsilon \to 0$, via the method of matched asymptotic expansions. For the two-dimensional problem these asymptotic solutions can be constructed analytically. To solve [SSP], we proceed first with the situation when the wells are well spaced and are away from the reservoir boundaries, after which the case of wells close to a boundary, or close together, is considered in sections 3.1 and 3.2. The asymptotic solution can be constructed directly in the outer region, up to $O(\epsilon^2)$. In the inner region, determination of the leading order terms reduces to the solution of a strongly elliptic problem whose solution can be written analytically in terms of the eigenvalues and corresponding eigenfunctions of a regular Sturm–Liouville eigenvalue problem. The asymptotic solution of [EVP] in section 4 also reduces to a regular Sturm–Liouville eigenvalue problem identical in structure to that discussed in section 3, and a consideration of this allows us to demonstrate that the solution to the full initial boundary value problem approaches the solution to the steady state problem through terms exponentially small with respect to time t as $t \to \infty$. With D_z being the permeability scale in the vertical direction and D_x being the permeability scale in the horizontal direction, the further generalization that $D_z = o(D_x)$ rather than $O(D_x)$ is considered in section 5, where it is shown that the structure of the solution is identical to that found for the case that $D_z = O(D_x)$, after a suitable redefinition of the parameter ϵ. The constraint on the sum of the total volume fluxes at the wells being zero is removed in section 6, and in section 7 we apply the theory to a simple model example. Finally in section 8 we draw some conclusions.

2. Equations of motion.

We consider the flow of a weakly compressible fluid in the presence of sources and sinks in a reservoir of porous medium with variable upper and lower boundary. The reservoir has permeability which is inhomogeneous and anisotropic. We restrict attention to the situation when the flow is two-dimensional. We denote the interior of the porous medium by $M \subset \mathbb{R}^2$ and its impermeable boundary by $\partial M \subset \mathbb{R}^2$, with $\bar{M} = M \cup \partial M$. We introduce rectangular Cartesian coordinates (x, z), with z pointing vertically upwards and x pointing horizontally. The vertical side walls of the reservoir are taken to be at $x = \pm l$, with $l > 0$. The upper and lower surface of the reservoir are described by $z = hz_+(x/l)$ and $z = hz_-(x/l)$, respectively, for $x \in [-l, l]$, with h (> 0) being the reservoir depth scale and $z_+, z_- : [-1, 1] \mapsto \mathbb{R}$ being such that $z_+, z_- \in C^1([-1, 1])$ and $z_+(x) > z_-(x)$ for all $x \in [-1, 1]$. Normal fields on the upper and lower surfaces are then given by $\mathbf{n}_+(x) = (-\frac{h}{l}z'_+(x), 1)$ and $\mathbf{n}_-(x) = (\frac{h}{l}z'_-(x), -1)$, respectively, for $x \in [-1, 1]$, with the normals directed out of $\bar{M}$. The situation is illustrated in Figure 2.1.

Embedded within $\bar{M}$ are $N (\in \mathbb{N})$ vertical line sources/sinks at locations $x_i \in (-l, l)$, $i = 1, \ldots, N$. Each line source/sink extends from the upper surface to the lower surface of $\bar{M}$ and represents a model of a vertical bore hole in the reservoir extending from the upper to the lower surface of the reservoir and extracting or injecting fluid along its whole length. This model is standard in the oil industry [3, 10]. The prescribed strength of each line source/sink then represents the details of the controlled volumetric extraction mechanism in the bore hole along its length. The two components of permeability, in the x- and z-directions, respectively, are given by

$$D_0 D_x\left(\frac{x}{l}, \frac{z}{h}\right) \geq D_m > 0, \quad D_0 D_z\left(\frac{x}{l}, \frac{z}{h}\right) \geq D_m > 0, \quad (x, z) \in \bar{M}, \tag{2.1}$$

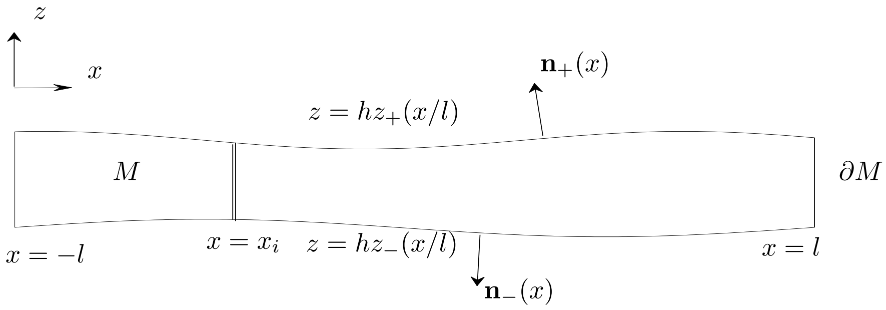

FIG. 2.1. *Porous layer $M \subset \mathbb{R}^2$, with impermeable boundary ∂M.*

with $D_x, D_z : \bar{M} \mapsto \mathbb{R}^+$ such that

$$D_x, D_z \in C^1(\bar{M}). \tag{2.2}$$

Here $D_0 > 0$ is a permeability scale for the layer and $D_m > 0$ is a lower bound on permeability in the layer. To avoid confusion, we emphasise here that subscripts x and z attached to the functions D_x and D_z do not indicate partial differentiation but merely denote the permeability direction.

We represent the fluid velocity field and pressure field at each point within the layer by $\mathbf{q} = \mathbf{q}(\mathbf{r}, t) = (u(\mathbf{r}, t), w(\mathbf{r}, t))$ and $p = p(\mathbf{r}, t)$, respectively, for each $(\mathbf{r}, t) \in \bar{M} \times [0, \infty)$. Here $t \geq 0$ represents time. The equation of conservation of fluid mass within the layer is then

$$\rho_t + (\rho u)_x + (\rho w)_z = \sum_{i=1}^{N} \rho s_i \left(\frac{z}{h}\right) \frac{1}{l} \delta \left(\frac{x - x_i}{l}\right), \quad (x, z) \in M, \quad t \in (0, \infty). \tag{2.3}$$

Here $\delta : \mathbb{R} \mapsto \mathbb{R}$ is the usual Dirac delta function, $\rho = \rho(\mathbf{r}, t)$ is the fluid density field for $(\mathbf{r}, t) \in \bar{M} \times [0, \infty)$, and the line source/sink volumetric strengths are represented by $s_i : \left[z_-\left(\frac{x_i}{l}\right), z_+\left(\frac{x_i}{l}\right)\right] \mapsto \mathbb{R}$, $i = 1, \ldots, N$. From practical considerations of the employed volumetric extraction mechanisms in bore holes, it is reasonable to take

$$s_i \in C\left(\left[z_-\left(\frac{x_i}{l}\right), z_+\left(\frac{x_i}{l}\right)\right]\right), \quad i = 1, \ldots, N. \tag{2.4}$$

The total volume flux per unit width from the ith line source/sink is then

$$Q_i = \int_{hz_-(x_i/l)}^{hz_+(x_i/l)} s_i \left(\frac{\lambda}{h}\right) \mathrm{d}\lambda, \quad i = 1, \ldots, N. \tag{2.5}$$

Conservation of momentum in the fluid is accounted for through the D'Arcy equation for flow in a porous media, giving

$$u = -D_0 D_x \left(\frac{x}{l}, \frac{z}{h}\right) p_x, \quad w = -D_0 D_z \left(\frac{x}{l}, \frac{z}{h}\right) (p_z + \rho g) \tag{2.6}$$

for all $(x, z) \in M$, $t \in (0, \infty)$, where g is the acceleration due to gravity. The effect of weak compressibility is accounted for through the equation of state,

$$\rho(p) = \rho_0(1 + c_t(p - p_0)), \tag{2.7}$$

with $c_t > 0$ being a constant isothermal expansion coefficient and ρ_0 and p_0 being positive reference density and pressure, respectively. Now, for a weakly compressible fluid, $0 < c_t p_0 \ll 1$, and the weakly compressible model is obtained by replacing $\rho(p)$ by its dominant contribution from (2.7) in both of the equations of motion (2.3) and (2.6). We obtain as our final model for the flow in the reservoir

$$c_t p_t + u_x + w_z = \sum_{i=1}^{N} s_i\left(\frac{z}{h}\right)\frac{1}{l}\delta\left(\frac{x-x_i}{l}\right), \tag{2.8}$$

$$u = -D_0 D_x\left(\frac{x}{l},\frac{z}{h}\right)p_x, \tag{2.9}$$

$$w = -D_0 D_z\left(\frac{x}{l},\frac{z}{h}\right)(p_z + \rho_0 g) \tag{2.10}$$

for all $(x, z) \in M$, $t \in (0, \infty)$. The equations of motion (2.8)–(2.10) form the basis for established models for weakly compressible flows in porous reservoirs [2], and we will take (2.8)–(2.10) as the model for the flow in the porous reservoir throughout the rest of the paper. We now set

$$Q = \sum_{i=1}^{N} |Q_i| \quad (> 0). \tag{2.11}$$

The natural scales are then $x \sim l$ and $z \sim h$, from the geometry of the porous layer, while $s_i \sim Q/h$, via (2.5). The continuity equation (2.8) then requires $u \sim Q/h$ and $w \sim Q/l$, while the momentum equation (2.9) requires $p \sim (lQ)/(hD_0)$. We therefore introduce the dimensionless variables,

$$x = lx',\ z = hz',\ s_i = \frac{Q}{h}s_i',\ u = \frac{Q}{h}u',\ w = \frac{Q}{l}w',\ p = \left(\frac{lQ}{hD_0}\right)p',\ t = \frac{c_t l^2}{D_0}t'. \tag{2.12}$$

On substitution from (2.12) into (2.8)–(2.10) (and dropping primes for convenience) we obtain the dimensionless equations of motion as

$$\bar{p}_t + u_x + w_z = \sum_{i=1}^{N} s_i(z)\delta(x - x_i), \tag{2.13}$$

$$u = -D_x(x,z)\bar{p}_x, \tag{2.14}$$

$$\epsilon^2 w = -D_z(x,z)\bar{p}_z \tag{2.15}$$

for all $(x, z) \in M'$, $t \in (0, \infty)$. Here, $p(x, z, t) = -\hat{\sigma}z + \bar{p}(x, z, t)$, with $\bar{p}$ being the dynamic fluid pressure, and the dimensionless parameters ϵ and $\hat{\sigma}$ are given by $\epsilon = h/l$ and $\hat{\sigma} = h^2\rho_0 g D_0/(lQ)$. The values of the model parameters will vary depending upon the details of the reservoir under consideration. However, for a typical field scenario the values $h \sim 200\,\mathrm{m}$, $l \sim 20{,}000\,\mathrm{m}$, $Q \sim 2\,\mathrm{m}^3/\mathrm{s}$, $c_t \sim 1.45 \times 10^{-9}\,\mathrm{m}^2/\mathrm{N}$, $p_0 \sim 2.76 \times 10^7\,\mathrm{N/m}^2$, and $D_0 \sim 10^{-10}\,\mathrm{m}^4/\mathrm{Ns}$ may be considered as representative. This gives a value for $c_t p_0 \sim 0.04$, which is entirely consistent with the adoption of the weakly compressible model proposed earlier. More significantly, the aspect ratio of a typical reservoir gives $\epsilon \sim 0.01$ (and this may be as small as 10^{-3} for large reservoirs). The dimensionless domain is now

$$M' = \{(x, z) \in \mathbb{R}^2 : x \in (-1, 1),\ z \in (z_-(x), z_+(x))\},$$

with closure $\bar{M}'$ and boundary $\partial M'$. The line source/sink locations are at $x_i \in (-1,1)$, $i = 1, \dots, N$. The volume flux condition (2.5) becomes

$$\alpha_i = \int_{z_-(x_i)}^{z_+(x_i)} s_i(\mu)\,\mathrm{d}\mu, \quad i = 1, \dots, N,$$

with $\alpha_i = Q_i/Q$, and hence $|\alpha_i| = |Q_i|/Q \le 1$, $i = 1, \dots, N$, and $\sum_{i=1}^N |\alpha_i| = \sum_{i=1}^N |Q_i|/Q = 1$, via (2.11). We next consider the boundary conditions. On the boundary $\partial M'$ the walls are impenetrable to the fluid in the porous layer. Thus

$$u(-1,z,t) = 0 \quad \text{for all } z \in [z_-(-1), z_+(-1)],\ t \in (0,\infty), \tag{2.16}$$

$$u(1,z,t) = 0 \quad \text{for all } z \in [z_-(1), z_+(1)],\ t \in (0,\infty), \tag{2.17}$$

$$w(x, z_+(x), t) - z_+'(x) u(x, z_+(x), t) = 0 \quad \text{for all } x \in (-1,1),\ t \in (0,\infty), \tag{2.18}$$

$$w(x, z_-(x), t) - z_-'(x) u(x, z_-(x), t) = 0 \quad \text{for all } x \in (-1,1),\ t \in (0,\infty). \tag{2.19}$$

Finally we have the initial condition

$$\bar{p}(x,z,0) = \bar{p}_0(x,z) \quad \text{for all } (x,z) \in \bar{M}', \tag{2.20}$$

with $\bar{p}_0 \in C(\bar{M}') \cap PC^1(\bar{M}')$, where $PC^1(\bar{M}')$ represents the class of piecewise continuously differentiable functions on $\bar{M}'$. The full problem for consideration is given by (2.13)–(2.15), (2.16)–(2.20), which we will refer to as [IBVP]. To proceed it is convenient to introduce $d_i = \{(x,z) \in \bar{M}' : x = x_i,\ z \in (z_-(x_i), z_+(x_i))\} \subset \bar{M}'$, for each $i = 1, \dots, N$, and $d = \bigcup_{i=1}^N d_i$. We require that a solution to [IBVP] has the following regularity, which is classical in the framework of the Dirac delta function formalism:

(i) $\bar{p} \in C(\bar{M}' \times [0,\infty)) \cap C^1((\bar{M}' \backslash \bar{d}) \times (0,\infty)) \cap C^2((M' \backslash d) \times (0,\infty))$,
$u \in C((\bar{M}' \backslash \bar{d}) \times (0,\infty)) \cap C^1((M' \backslash d) \times (0,\infty))$,
$w \in C(\bar{M}' \times (0,\infty)) \cap C^1((M' \backslash d) \times (0,\infty))$;

(ii) $\lim_{x \to x_i^\pm} \bar{p}_x$ and $\lim_{x \to x_i^\pm} \bar{p}_z$ both exist uniformly for $z \in [z_-(x_i), z_+(x_i)]$ at each $t \in (0,\infty)$, $i = 1, \dots, N$;

(iii) $[\bar{p}_z]_{x_i^-}^{x_i^+} = 0$, $[\bar{p}_x]_{x_i^-}^{x_i^+} = -s_i(z)/D_x(x_i, z)$ for all $z \in [z_-(x_i), z_+(x_i)]$ at each $t \in (0,\infty)$, $i = 1, \dots, N$.

We observe that (ii) requires, via (2.14), (2.15), that $\lim_{x \to x_i^\pm} u$ and $\lim_{x \to x_i^\pm} w$ both exist uniformly for $z \in [z_-(x_i), z_+(x_i)]$, and (iii) requires that

$$[u]_{x_i^-}^{x_i^+} = s_i(z), \quad [w]_{x_i^-}^{x_i^+} = 0$$

for all $z \in [z_-(x_i), z_+(x_i)]$ at each $t \in (0,\infty)$, $i = 1, \dots, N$. We now have the following preliminary result concerning [IBVP].

THEOREM 2.1. *For each $\epsilon > 0$,* [IBVP] *has a unique solution $u, w, \bar{p} : \bar{M}' \times [0,\infty) \mapsto \mathbb{R}$. Moreover,*

$$\left(\iint_{\bar{M}'} \bar{p}(x,z,t)\,\mathrm{d}x\,\mathrm{d}z \right)_t = \sum_{i=1}^N \alpha_i \tag{2.21}$$

for all $t \in (0,\infty)$.

Proof. Existence and uniqueness follow via regularity (2.2) and (2.4), with (2.1), on noting from (2.13)–(2.15) that [IBVP] is equivalent to the scalar initial boundary value problem

$$\bar{p}_t - \left\{(D_x(x,z)\bar{p}_x)_x + \left(\epsilon^{-2}D_z(x,z)\bar{p}_z\right)_z\right\} = \sum_{i=1}^{N} s_i(z)\delta(x-x_i), \tag{2.22}$$
$$(x,z)\in M', \quad t\in(0,\infty),$$
$$\bar{p}_x(-1,z,t)=0 \text{ for all } z\in[z_-(-1),z_+(-1)],\ t\in(0,\infty),$$
$$\bar{p}_x(1,z,t)=0 \text{ for all } z\in[z_-(1),z_+(1)],\ t\in(0,\infty),$$
$$D_z(x,z_+(x))\bar{p}_z(x,z_+(x),t)-\epsilon^2 z'_+(x)D_x(x,z_+(x))\bar{p}_x(x,z_+(x),t)=0$$
$$\text{for all } x\in(-1,1),\ t\in(0,\infty),$$
$$D_z(x,z_-(x))\bar{p}_z(x,z_-(x),t)-\epsilon^2 z'_-(x)D_x(x,z_-(x))\bar{p}_x(x,z_-(x),t)=0$$
$$\text{for all } x\in(-1,1),\ t\in(0,\infty),$$
$$\bar{p}(x,z,0)=\bar{p}_0(x,z) \quad \text{for all } (x,z)\in\bar{M}'.$$

The partial differential equation (2.22) is linear and strongly parabolic, with boundary conditions of nondegenerate (via (2.1)) weighted Neumann type, after which existence and uniqueness follow from the classical theory in [7, Chapter 3]. Equation (2.21) follows from an application of Green's theorem on the plane to (2.22) in $\bar{M}'$ on using the associated boundary conditions and regularity in (i)–(iii). □

The steady state problem associated with [IBVP] is

$$\hat{u}_x+\hat{w}_z=\sum_{i=1}^{N}s_i(z)\delta(x-x_i), \quad (x,z)\in M', \tag{2.23}$$
$$\hat{u}=-D_x(x,z)\hat{p}_x, \quad (x,z)\in M', \tag{2.24}$$
$$\epsilon^2\hat{w}=-D_z(x,z)\hat{p}_z, \quad (x,z)\in M', \tag{2.25}$$
$$\hat{u}(-1,z)=0 \quad \text{for all } z\in[z_-(-1),z_+(-1)], \tag{2.26}$$
$$\hat{u}(1,z)=0 \quad \text{for all } z\in[z_-(1),z_+(1)], \tag{2.27}$$
$$\hat{w}(x,z_+(x))-z'_+(x)\hat{u}(x,z_+(x))=0 \quad \text{for all } x\in(-1,1), \tag{2.28}$$
$$\hat{w}(x,z_-(x))-z'_-(x)\hat{u}(x,z_-(x))=0 \quad \text{for all } x\in(-1,1), \tag{2.29}$$

which we will refer to as [SSP]. Corresponding to (i)–(iii), a solution to [SSP] has the following regularity:

(si) $\hat{p}\in C(\bar{M}')\cap C^1(\bar{M}'\backslash\bar{d})\cap C^2(M'\backslash d)$, $\hat{u}\in C(\bar{M}'\backslash\bar{d})\cap C^1(M'\backslash d)$, $\hat{w}\in C(\bar{M}')\cap C^1(M'\backslash d)$;

(sii) $\lim_{x\to x_i^\pm}\hat{p}_x$ and $\lim_{x\to x_i^\pm}\hat{p}_z$ both exist uniformly for $z\in[z_-(x_i),z_+(x_i)]$ for each $i=1,\dots,N$;

(siii) $[\hat{p}_z]_{x_i^-}^{x_i^+}=0$, $[\hat{p}_x]_{x_i^-}^{x_i^+}=-s_i(z)/D_x(x_i,z)$ for all $z\in[z_-(x_i),z_+(x_i)]$ and each $i=1,\dots,N$.

As before, $\lim_{x\to x_i^\pm}\hat{u}$ and $\lim_{x\to x_i^\pm}\hat{w}$ exist uniformly for $z\in[z_-(x_i),z_+(x_i)]$, and

$$[\hat{u}]_{x_i^-}^{x_i^+}=s_i(z), \quad [\hat{w}]_{x_i^-}^{x_i^+}=0 \tag{2.30}$$

for all $z\in[z_-(x_i),z_+(x_i)]$ and for each $i=1,\dots,N$. Again, following standard theory for linear strongly elliptic weighted Neumann problems (see, for example, [7] or [17, Chapters 8, 9]), we have the following result.

Theorem 2.2. *For each $\epsilon > 0$,* [SSP] *has a unique (up to addition of a constant in $\hat{p}$) solution $\hat{u}, \hat{w}, \hat{p} : \bar{M}' \mapsto \mathbb{R}$ if and only if*

$$\sum_{i=1}^{N} \alpha_i = 0. \tag{2.31}$$

In what follows we will assume that the specified flux constants α_i, $i = 1, \dots, N$, satisfy condition (2.31). Now let $\tilde{u}, \tilde{w}, \tilde{p} : \bar{M}' \times [0, \infty) \mapsto \mathbb{R}$ be defined by $\tilde{u} = u - \hat{u}$, $\tilde{w} = w - \hat{w}$, $\tilde{p} = \bar{p} - \hat{p}$. It then follows that $\tilde{u}, \tilde{w}$, and $\tilde{p}$ are solutions to the problem

$$\tilde{p}_t - \left\{ \left(D_x(x,z)\tilde{p}_x\right)_x + \left(\epsilon^{-2} D_z(x,z)\tilde{p}_z\right)_z \right\} = 0,\ (x,z) \in M',\ t \in (0,\infty), \tag{2.32}$$

$$\tilde{p}_x(-1,z,t) = 0 \text{ for all } z \in [z_-(-1), z_+(-1)],\ t \in (0,\infty), \tag{2.33}$$

$$\tilde{p}_x(1,z,t) = 0 \text{ for all } z \in [z_-(1), z_+(1)],\ t \in (0,\infty), \tag{2.34}$$

$$\begin{gathered} D_z(x, z_+(x))\tilde{p}_z(x, z_+(x), t) - \epsilon^2 z_+'(x) D_x(x, z_+(x))\tilde{p}_x(x, z_+(x), t) = 0 \\ \text{for all } x \in (-1,1),\ t \in (0,\infty), \end{gathered} \tag{2.35}$$

$$\begin{gathered} D_z(x, z_-(x))\tilde{p}_z(x, z_-(x), t) - \epsilon^2 z_-'(x) D_x(x, z_-(x))\tilde{p}_x(x, z_-(x), t) = 0 \\ \text{for all } x \in (-1,1),\ t \in (0,\infty), \end{gathered} \tag{2.36}$$

$$\tilde{p}(x,z,0) = \bar{p}_0(x,z) - \hat{p}(x,z) = \tilde{p}_0(x,z) \quad \text{for all } (x,z) \in \bar{M}', \tag{2.37}$$

with regularity

$$\tilde{p} \in C(\bar{M}' \times [0,\infty)) \cap C^1(\bar{M}' \times (0,\infty)) \cap C^2(M' \times (0,\infty)), \tag{2.38}$$

after which

$$\tilde{u} = -D_x(x,z)\tilde{p}_x, \quad \tilde{w} = -\epsilon^{-2} D_z(x,z)\tilde{p}_z, \quad (x,z) \in \bar{M}' \times (0,\infty). \tag{2.39}$$

To fix the indeterminate constant in Theorem 2.2, we will take $\hat{p} : \bar{M}' \mapsto \mathbb{R}$ to be that steady state which satisfies

$$\iint_{\bar{M}'} \hat{p}(x,z)\,\mathrm{d}x\,\mathrm{d}z = \iint_{\bar{M}'} \bar{p}_0(x,z)\,\mathrm{d}x\,\mathrm{d}z =: I_0, \tag{2.40}$$

so that, via (2.37),

$$\iint_{\bar{M}'} \tilde{p}_0(x,z)\,\mathrm{d}x\,\mathrm{d}z = 0. \tag{2.41}$$

Now it follows from Theorem 2.1 that the strongly parabolic problem (2.32)–(2.39) has a unique solution in $\bar{M}' \times [0,\infty)$. We will now construct this solution. To this end we first consider the following self-adjoint eigenvalue problem in $\bar{M}'$:

$$\begin{gathered} \left(D_x(x,z)\phi_x\right)_x + \left(\epsilon^{-2} D_z(x,z)\phi_z\right)_z + \lambda\phi = 0, \quad (x,z) \in M', \\ \phi_x(-1,z) = 0 \quad \text{for all } z \in [z_-(-1), z_+(-1)], \\ \phi_x(1,z) = 0 \quad \text{for all } z \in [z_-(1), z_+(1)], \\ D_z(x, z_+(x))\phi_z(x, z_+(x)) - \epsilon^2 z_+'(x) D_x(x, z_+(x))\phi_x(x, z_+(x)) = 0 \text{ for all } x \in (-1,1), \\ D_z(x, z_-(x))\phi_z(x, z_-(x)) - \epsilon^2 z_-'(x) D_x(x, z_-(x))\phi_x(x, z_-(x)) = 0 \text{ for all } x \in (-1,1). \end{gathered}$$

We will denote this eigenvalue problem by [EVP], with $\lambda \in \mathbb{C}$ being the eigenvalue parameter. It follows from (2.1) that this is a regular, self-adjoint eigenvalue problem.

It then follows from standard theory that the eigenvalues of [EVP] are all real and given by $\lambda = \lambda_j(\epsilon)$, $j = 0, 1, 2, \ldots$, with

$$0 = \lambda_0(\epsilon) < \lambda_1(\epsilon) < \lambda_2(\epsilon) < \cdots \tag{2.42}$$

and $\lambda_j(\epsilon) \to +\infty$ as $j \to \infty$. Each corresponding eigenspace is spanned by a single eigenfunction $\phi_j : \bar{M}' \mapsto \mathbb{R}$, $j = 0, 1, 2, \ldots$, with

$$\phi_0(x, z, \epsilon) = (\text{meas}(\bar{M}'))^{-1/2} \quad \text{for all } (x, z) \in \bar{M}', \tag{2.43}$$

and meas$(\bar{M}')$ being the measure (area) of $\bar{M}' \subset \mathbb{R}^2$. Moreover,

$$\langle \phi_i, \phi_j \rangle = \iint_{\bar{M}'} \phi_i(x, z, \epsilon)\phi_j(x, z, \epsilon)\, \mathrm{d}x\, \mathrm{d}z = \delta_{ij},$$

for $i, j = 0, 1, 2, \ldots$, and δ_{ij} being the Kronecker delta symbol. Moreover, any function $\psi : \bar{M}' \mapsto \mathbb{R}$ such that $\psi \in C(\bar{M}') \cap PC^1(\bar{M}')$ and satisfies the same boundary conditions on $\partial M'$ as the set of eigenfunctions has the representation

$$\psi(x, z) = \sum_{r=0}^{\infty} \psi_r(\epsilon)\phi_r(x, z, \epsilon), \quad (x, z) \in \bar{M}', \tag{2.44}$$

with the convergence of the sum being uniform and absolute for $(x, z) \in \bar{M}'$, where

$$\psi_j(\epsilon) = \langle \psi, \phi_j \rangle = \iint_{\bar{M}'} \psi(x, z)\phi_j(x, z, \epsilon)\, \mathrm{d}x\, \mathrm{d}z, \tag{2.45}$$

for $j = 0, 1, 2, \ldots$ (see, for example, [17, Chapters 8, 9]). It is now straightforward to establish that the (unique) solution to (2.32)–(2.37) is given by

$$\tilde{p}(x, z, t) = \sum_{n=1}^{\infty} a_n(\epsilon)\mathrm{e}^{-\lambda_n(\epsilon)t}\phi_n(x, z, \epsilon), \quad (x, z) \in \bar{M}',\ t \in [0, \infty), \tag{2.46}$$

with $a_0(\epsilon) = 0$, via (2.37), (2.41), (2.43), (2.44), and (2.45), and

$$a_n(\epsilon) = \iint_{\bar{M}'} \tilde{p}_0(u, v)\phi_n(u, v, \epsilon)\, \mathrm{d}u\, \mathrm{d}v \tag{2.47}$$

for $n = 1, 2, \ldots$. We observe immediately from (2.46), with (2.42), that $\tilde{p}(x, z, t) \to 0$ as $t \to \infty$, uniformly for all $(x, z) \in \bar{M}'$, and also that $\tilde{p}_x(x, z, t), \tilde{p}_z(x, z, t) \to 0$ as $t \to \infty$, uniformly for all $(x, z) \in \bar{M}'$. Thus, we have established the following result.

THEOREM 2.3. *Let α_i, $i = 1, \ldots, N$, be such that $\sum_{i=1}^{N} \alpha_i = 0$. Then for each $\epsilon > 0$,* [IBVP] *has a unique solution $u, w, \bar{p} : \bar{M}' \times [0, \infty) \mapsto \mathbb{R}$ given by*

$$\begin{aligned}
\bar{p}(x, z, t) &= \hat{p}(x, z) + \tilde{p}(x, z, t),\\
u(x, z, t) &= \hat{u}(x, z) - D_x(x, z)\tilde{p}_x(x, z, t),\\
w(x, z, t) &= \hat{w}(x, z) - \epsilon^{-2}D_z(x, z)\tilde{p}_z(x, z, t),
\end{aligned}$$

for all $(x, z) \in \bar{M}'$ and $t \in [0, \infty)$. Here $\tilde{p} : \bar{M}' \times [0, \infty) \mapsto \mathbb{R}$ is given by (2.46), (2.47) *and $\hat{u}, \hat{w}, \hat{p} : \bar{M}' \mapsto \mathbb{R}$ is that solution to* [SSP] *which satisfies* (2.40). *Moreover,*

$$\bar{p}(x, z, t) \to \hat{p}(x, z), \quad u(x, z, t) \to \hat{u}(x, z), \quad w(x, z, t) \to \hat{w}(x, z) \quad \textit{as } t \to \infty$$

uniformly for $(x,z) \in \bar{M}'$.

We remark that since $\hat{p} \in C(\bar{M}') \cap PC^1(\bar{M}')$ and the initial data for [IBVP] $\bar{p}_0 \in C(\bar{M}') \cap PC^1(\bar{M}')$, then Theorem 2.3 implies global asymptotic stability (up to the addition of a constant to $\hat{p}$) for [SSP] with respect to perturbations in $C(\bar{M}') \cap PC^1(\bar{M}')$.

To complete the solution to the problem we are required to determine $\lambda_n(\epsilon)$ (> 0) and its corresponding eigenfunction $\phi_n : \bar{M}' \mapsto \mathbb{R}$ for each $n = 1, 2, 3, \dots$, together with the steady state $\hat{p}, \hat{u}, \hat{w} : \bar{M}' \mapsto \mathbb{R}$ which satisfies the constraint (2.40). In the next sections we focus attention on the study of [SSP] and [EVP] in turn.

In particular for a thin porous layer the parameter ϵ, which measures the aspect ratio of the layer, is small, so that $0 < \epsilon \ll 1$. In the next two sections we will consider the structure of the solutions to [SSP] and [EVP] in the asymptotic limit $\epsilon \to 0$, via the method of matched asymptotic expansions.

3. Asymptotic solution to the steady state problem [SSP] as $\boldsymbol{\epsilon \to 0}$. In this section we develop the uniform asymptotic structure of the solution to the steady state problem [SSP] (given by (2.23)–(2.29)) in the limit $\epsilon \to 0$, via the method of matched asymptotic expansions. We recall that existence and uniqueness, for each $\epsilon > 0$, follows from Theorem 2.2, and following Theorem 2.3, we require the solution of [SSP] that satisfies the constraint (2.40). Due to the initial scalings in the nondimensionalization (2.12), we anticipate that $\hat{u}, \hat{w}, \hat{p} : \bar{M}' \mapsto \mathbb{R}$ are such that

$$\hat{u}, \hat{w}, \hat{p} = O(1) \tag{3.1}$$

as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{M}' \backslash \bigcup_{i=1}^{N} \delta_i^\epsilon = \bar{N}'_\epsilon$, where δ_i^ϵ is an O(ϵ) neighborhood of $\bar{d}_i$, for each $i = 1, \dots, N$. Therefore, following (3.1), we introduce the outer region (this being $\bar{N}'_\epsilon$) asymptotic expansions

$$\begin{aligned} \hat{u}(x,z;\epsilon) &= \hat{u}_0(x,z) + \epsilon \hat{u}_1(x,z) + O(\epsilon^2), \\ \hat{w}(x,z;\epsilon) &= \hat{w}_0(x,z) + \epsilon \hat{w}_1(x,z) + O(\epsilon^2), \\ \hat{p}(x,z;\epsilon) &= \hat{p}_0(x,z) + \epsilon \hat{p}_1(x,z) + O(\epsilon^2), \end{aligned} \tag{3.2}$$

as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{N}'_\epsilon$. We substitute from (3.2) into [SSP] and condition (2.40). At leading order we obtain the following problem for $\hat{u}_0, \hat{w}_0, \hat{p}_0 : \bar{M}' \mapsto \mathbb{R}$:

$$\hat{u}_{0x} + \hat{w}_{0z} = \sum_{i=1}^{N} s_i(z) \delta(x - x_i), \quad (x,z) \in M', \tag{3.3}$$

$$\hat{u}_0 = -D_x(x,z) \hat{p}_{0x}, \quad (x,z) \in M', \tag{3.4}$$

$$0 = -D_z(x,z) \hat{p}_{0z}, \quad (x,z) \in M', \tag{3.5}$$

$$\hat{u}_0(-1,z) = 0, \quad z \in [z_-(-1), z_+(-1)], \tag{3.6}$$

$$\hat{u}_0(1,z) = 0, \quad z \in [z_-(1), z_+(1)], \tag{3.7}$$

$$\hat{w}_0(x, z_+(x)) - z'_+(x) \hat{u}_0(x, z_+(x)) = 0, \quad x \in (-1,1), \tag{3.8}$$

$$\hat{w}_0(x, z_-(x)) - z'_-(x) \hat{u}_0(x, z_-(x)) = 0, \quad x \in (-1,1), \tag{3.9}$$

$$\iint_{\bar{M}'} \hat{p}_0(x,z) \, \mathrm{d}x \, \mathrm{d}z = I_0. \tag{3.10}$$

We now construct the solution of (3.3)–(3.10). As a consequence of (2.1), equation (3.5) requires

$$\hat{p}_0(x,z) = A(x), \quad (x,z) \in \bar{M}', \tag{3.11}$$

with $A : [-1, 1] \mapsto \mathbb{R}$ to be determined. Equation (3.4) then gives

$$\hat{u}_0(x, z) = -D_x(x, z)A'(x), \quad (x, z) \in \bar{M}', \tag{3.12}$$

and the boundary conditions (3.6) and (3.7) then require $A'(-1) = A'(1) = 0$. We next substitute from (3.12) into (3.3), which becomes

$$\hat{w_0}_z = \sum_{i=1}^{N} s_i(z)\delta(x - x_i) + [D_x(x, z)A'(x)]_x, \quad (x, z) \in M'. \tag{3.13}$$

A direct integration of (3.13), together with an application of (3.9), leads to

$$\begin{aligned}\hat{w}_0(x, z) = &\sum_{i=1}^{N} F_i(z)\delta(x - x_i) \\ &+ \int_{z_-(x)}^{z} [D_x(x, \lambda)A'(x)]_x \,\mathrm{d}\lambda - z_-'(x)D_x(x, z_-(x))A'(x), \quad (x, z) \in \bar{M}',\end{aligned} \tag{3.14}$$

where

$$F_i(z) = \int_{z_-(x_i)}^{z} s_i(\lambda)\,\mathrm{d}\lambda, \quad z \in [z_-(x_i), z_+(x_i)], \tag{3.15}$$

for each $i = 1, \dots, N$. (Note that $F_i : [z_-(x_i), z_+(x_i)] \mapsto \mathbb{R}$ is such that $F_i \in C^1([z_-(x_i), z_+(x_i)])$, for each $i = 1, \dots, N$.) It remains to apply the boundary condition (3.8). The application of (3.8) using (3.12) and (3.15) finally requires that

$$\begin{aligned}&\int_{z_-(x)}^{z_+(x)} [D_x(x, \lambda)A'(x)]_x \,\mathrm{d}\lambda + \{z_+'(x)D_x(x, z_+(x)) - z_-'(x)D_x(x, z_-(x))\}A'(x) \\ &\qquad + \sum_{i=1}^{N} \alpha_i\delta(x - x_i) = 0, \quad x \in (-1, 1).\end{aligned} \tag{3.16}$$

We now rewrite the first term on the left-hand side of (3.16) as

$$\begin{aligned}&\int_{z_-(x)}^{z_+(x)} [D_x(x, \lambda)A'(x)]_x \,\mathrm{d}\lambda \\ &= \left(\int_{z_-(x)}^{z_+(x)} D_x(x, \lambda)A'(x)\,\mathrm{d}\lambda\right)' - \left\{z_+'(x)D_x(x, z_+(x)) - z_-'(x)D_x(x, z_-(x))\right\} A'(x) \\ &= (\bar{D}_x(x)A'(x))' - \left\{z_+'(x)D_x(x, z_+(x)) - z_-'(x)D_x(x, z_-(x))\right\} A'(x), \quad x \in (-1, 1).\end{aligned} \tag{3.17}$$

On substitution from (3.17) into (3.16) we obtain

$$(\bar{D}_x(x)A'(x))' = -\sum_{i=1}^{N} \alpha_i\delta(x - x_i), \quad x \in (-1, 1),$$

with

$$\bar{D}_x(x) = \int_{z_-(x)}^{z_+(x)} D_x(x, \lambda)\,\mathrm{d}\lambda, \quad x \in [-1, 1], \tag{3.18}$$

which represents the depth integrated permeability of the layer in the x-direction at each location $x \in [-1,1]$. We observe that $\bar{D}_x : [-1,1] \mapsto \mathbb{R}$ is such that $\bar{D}_x \in C^1([-1,1])$ and $\bar{D}_x(x) \geq \bar{D}_0 > 0$ for all $x \in [-1,1]$, via (2.1) and (2.2), for some positive constant $\bar{D}_0$. Thus $A : [-1,1] \mapsto \mathbb{R}$ is determined as the solution to the linear, inhomogeneous, boundary value problem (hereafter referred to as [BVP]),

$$[\bar{D}_x(x)A'(x)]' = -\sum_{i=1}^{N} \alpha_i \delta(x - x_i), \quad x \in (-1,1),$$
$$A'(-1) = A'(1) = 0,$$
$$\int_{-1}^{1} (z_+(x) - z_-(x))A(x)\,\mathrm{d}x = I_0,$$

with the final constraint arising via (3.10) on using (3.11). We observe the following.

REMARK 3.1. [BVP] *has a unique solution if and only if* $\sum_{i=1}^{N} \alpha_i = 0$.

This is in accord with condition (2.31) of Theorem 2.2. We now construct the solution to [BVP] (under condition (2.31)). It is straightforward to establish that the solution to [BVP] (with the usual Dirac delta function formalism) is given by

$$A(x) = \int_{-1}^{x} \frac{S(\lambda)}{\bar{D}_x(\lambda)}\,\mathrm{d}\lambda + A_0, \quad x \in [-1,1], \tag{3.19}$$

where here the function $S : [-1,1] \mapsto \mathbb{R}$ is the step function, given by

$$S(\lambda) = -\sum_{i=0}^{k} \alpha_i \quad \text{for all } \lambda \in [x_k, x_{k+1}), \tag{3.20}$$

and for each $k = 0, \ldots, N$, where we have defined $\alpha_0 = 0$, $x_0 = -1$, $x_{N+1} = 1$. The constant $A_0 \in \mathbb{R}$ is given by

$$A_0 = \frac{I_0}{\mathrm{meas}(\bar{M}')} - \frac{1}{\mathrm{meas}(\bar{M}')} \int_{-1}^{1} \frac{S(\lambda)\,\mathrm{meas}(\bar{M}'(\lambda))}{\bar{D}_x(\lambda)}\,\mathrm{d}\lambda, \tag{3.21}$$

where

$$\mathrm{meas}(\bar{M}'(\lambda)) = \int_{\lambda}^{1} (z_+(\mu) - z_-(\mu))\,\mathrm{d}\mu \quad \text{for all } \lambda \in [-1,1],$$

so that $\mathrm{meas}(\bar{M}'(-1)) = \mathrm{meas}(\bar{M}')$. We observe that $A \in C([-1,1]) \cap PC^2([-1,1])$, and that $A'(x_j^+) - A'(x_j^-) = -\alpha_j/\bar{D}_x(x_j)$ for each $j = 1, \ldots, N$. We can now reconstruct the solution to the leading order problem as

$$\hat{p}_0(x,z) = A(x), \quad (x,z) \in \bar{M}', \tag{3.22}$$

$$\hat{u}_0(x,z) = \frac{-D_x(x,z)}{\bar{D}_x(x)} S(x), \quad (x,z) \in \bar{M}', \tag{3.23}$$

$$\hat{w}_0(x,z) = S(x) \int_{z_-(x)}^{z} \left\{ \frac{D_x(x,\lambda)}{\bar{D}_x(x)} \right\}_x \mathrm{d}\lambda - \frac{z_-'(x) D_x(x, z_-(x)) S(x)}{\bar{D}_x(x)}, \quad (x,z) \in \bar{N}_\epsilon', \tag{3.24}$$

from (3.11), (3.12), (3.14), and (3.19). It follows from (3.22)–(3.24) that $\hat{p}_0 \in C(\bar{M}') \cap C^1(\bar{M}'\backslash\bar{d}) \cap C^2(M'\backslash d)$, $\hat{u}_0 \in C(\bar{M}'\backslash\bar{d}) \cap C^1(M'\backslash d)$, $\hat{w}_0 \in C(\bar{M}'\backslash\bar{d}) \cap C^1(M'\backslash d)$, and

$$[\hat{p}_{0z}]_{x_i^-}^{x_i^+} = 0, \tag{3.25}$$

$$[\hat{p}_{0x}]_{x_i^-}^{x_i^+} = \frac{-\alpha_i}{\bar{D}_x(x_i)}, \tag{3.26}$$

$$[\hat{u}_0]_{x_i^-}^{x_i^+} = \frac{D_x(x_i,z)\alpha_i}{\bar{D}_x(x_i)}, \tag{3.27}$$

$$[\hat{w}_0]_{x_i^-}^{x_i^+} = \left\{ \frac{z_-'(x_i)D_x(x_i,z_-(x_i))}{\bar{D}_x(x_i)} - \int_{z_-(x_i)}^{z} \left[\left\{ \frac{D_x(x,\lambda)}{\bar{D}_x(x)} \right\}_x \right]_{x=x_i} \mathrm{d}\lambda \right\} \alpha_i \tag{3.28}$$

for $z \in [z_-(x_i), z_+(x_i)]$ and for each $i = 1,\ldots,N$. We now proceed to $O(\epsilon)$. The problem for $\hat{u}_1, \hat{w}_1, \hat{p}_1 : \bar{M}' \mapsto \mathbb{R}$ is similar to the leading order problem and is not repeated here. We obtain

$$\begin{gathered} \hat{p}_1(x,z) = B(x), \quad (x,z) \in \bar{M}', \\ \hat{u}_1(x,z) = -D_x(x,z)B'(x), \quad (x,z) \in \bar{M}', \\ \hat{w}_1(x,z) = \int_{z_-(x)}^{z} [D_x(x,\lambda)B'(x)]_x \,\mathrm{d}\lambda - z_-'(x)D_x(x,z_-(x))B'(x), \quad (x,z) \in \bar{M}', \end{gathered} \tag{3.29}$$

where $B : [-1,1] \mapsto \mathbb{R}$ is the solution to the boundary value problem

$$\begin{gathered} [\bar{D}_x(x)B'(x)]' = 0, \quad x \in (-1,1), \\ B'(-1) = B'(1) = 0, \\ \int_{-1}^{1} (z_+(x) - z_-(x))B(x)\,\mathrm{d}x = 0. \end{gathered}$$

The unique solution $B \in C^1([-1,1]) \cap C^2((-1,1))$ is given by $B(x) = 0$ for all $x \in [-1,1]$, and so $\hat{p}_1(x,z) = \hat{u}_1(x,z) = \hat{w}_1(x,z) = 0$ for $(x,z) \in \bar{M}'$, via (3.29). The outer region asymptotic expansions are thus

$$\hat{u}(x,z;\epsilon) = \frac{-D_x(x,z)}{\bar{D}_x(x)}S(x) + O(\epsilon^2), \tag{3.30}$$

$$\hat{w}(x,z;\epsilon) = S(x)\int_{z_-(x)}^{z} \left\{ \frac{D_x(x,\lambda)}{\bar{D}_x(x)} \right\}_x \mathrm{d}\lambda - \frac{z_-'(x)D_x(x,z_-(x))S(x)}{\bar{D}_x(x)} + O(\epsilon^2), \tag{3.31}$$

$$\hat{p}(x,z;\epsilon) = A(x) + O(\epsilon^2), \tag{3.32}$$

as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{N}_\epsilon'$, with $A, S : [-1,1] \mapsto \mathbb{R}$ given by (3.19)–(3.21).

We now observe from (3.30)–(3.32), via (3.25)–(3.28), that all of the regularity requirements in (si), together with the limit conditions (sii), (siii), and (2.30), are not satisfied at $x = x_i$ for each $z \in [z_-(x_i), z_+(x_i)]$, with $i = 1,\ldots,N$ (although the integrated forms are satisfied). We conclude (as was anticipated earlier) that the outer region asymptotic expansions (3.30)–(3.32) become nonuniform when $(x,z) \in \delta_i^\epsilon$ as $\epsilon \to 0$, $i = 1,\ldots,N$. To obtain a uniform asymptotic representation to the solution to [SSP] when $(x,z) \in \delta_i^\epsilon$ as $\epsilon \to 0$, we must therefore introduce an inner region at each line source/sink location $x = x_i$, $i = 1,\ldots,N$. We now consider the inner region in the neighborhood of $x = x_i$ in detail. In the inner region, $x = x_i + O(\epsilon)$, $z = O(1)$, as $\epsilon \to 0$, with, from (3.30)–(3.32), $\hat{u} = O(1)$, $\hat{w} = O(\epsilon^{-1})$, $\hat{p} = A_i + O(\epsilon)$, as $\epsilon \to 0$, with $A_i = A(x_i)$, $i = 1, \dots, N$. Thus, in the inner region we write

$$x = x_i + \epsilon X, \tag{3.33}$$

with $X \in (-\infty, \infty)$ such that $X = O(1)$ as $\epsilon \to 0$, together with

$$\hat{u} = U, \quad \hat{w} = \epsilon^{-1} W, \quad \hat{p} = A_i + \epsilon P, \tag{3.34}$$

where $U, W, P : (-\infty, \infty) \times [z_-(x_i), z_+(x_i)] \mapsto \mathbb{R}$ are such that $U, W, P = O(1)$ as $\epsilon \to 0$. We now substitute from (3.33), (3.34) into the full problem [SSP] ((2.23), (2.24), (2.25), (2.28), (2.29), excluding conditions (2.26), (2.27) which lie outside the inner region in the limit $\epsilon \to 0$). The full problem in the inner region then becomes

$$U_X + W_z = s_i(z)\delta(X), \quad (X, z) \in D(\epsilon), \tag{3.35}$$

$$U = -D_x(x_i + \epsilon X, z) P_X, \quad (X, z) \in D(\epsilon), \tag{3.36}$$

$$W = -D_z(x_i + \epsilon X, z) P_z, \quad (X, z) \in D(\epsilon), \tag{3.37}$$

$$W - \epsilon z_+'(x_i + \epsilon X) U = 0, \quad X \in (-\infty, \infty), \quad z = z_+(x_i + \epsilon X), \tag{3.38}$$

$$W - \epsilon z_-'(x_i + \epsilon X) U = 0, \quad X \in (-\infty, \infty), \quad z = z_-(x_i + \epsilon X), \tag{3.39}$$

together with matching conditions to the outer region as $|X| \to \infty$. Here

$$D(\epsilon) = \{(X, z) \in \mathbb{R}^2 : X \in (-\infty, \infty) \text{ and } z \in (z_-(x_i + \epsilon X), z_+(x_i + \epsilon X))\}. \tag{3.40}$$

We now introduce the inner region asymptotic expansions as

$$\begin{aligned} U(X, z; \epsilon) &= U_0(X, z) + O(\epsilon), \\ W(X, z; \epsilon) &= W_0(X, z) + O(\epsilon), \\ P(X, z; \epsilon) &= P_0(X, z) + O(\epsilon), \end{aligned} \tag{3.41}$$

as $\epsilon \to 0$, with $(X, z) \in \bar{D}(\epsilon)$. On substitution from (3.41) into (3.35)–(3.40) we obtain the leading order problem as

$$U_{0X} + W_{0z} = s_i(z)\delta(X), \quad (X, z) \in D(0), \tag{3.42}$$

$$U_0 = -\tilde{D}_x(z) P_{0X}, \quad (X, z) \in D(0), \tag{3.43}$$

$$W_0 = -\tilde{D}_z(z) P_{0z}, \quad (X, z) \in D(0), \tag{3.44}$$

$$W_0(X, z_+^i) = 0, \quad X \in (-\infty, \infty), \tag{3.45}$$

$$W_0(X, z_-^i) = 0, \quad X \in (-\infty, \infty). \tag{3.46}$$

Here,

$$\tilde{D}_x(z) = D_x(x_i, z), \quad \tilde{D}_z(z) = D_z(x_i, z), \tag{3.47}$$

for all $z \in [z_-^i, z_+^i]$, with $z_-^i = z_-(x_i)$ and $z_+^i = z_+(x_i)$. Also, $\bar{D}(0)$, via (3.40), is now the unbounded region in the (X, z) plane contained between the coordinate lines $z = z_-^i$ and $z = z_+^i$; that is,

$$\bar{D}(0) = (-\infty, \infty) \times [z_-^i, z_+^i]. \tag{3.48}$$

The leading order problem (3.42)–(3.46) is completed by applying the asymptotic matching principle of Van Dyke [20]. It is straightforward to establish that matching of $\hat{p}$ is sufficient, after which matching of $\hat{u}$ and $\hat{w}$ follows automatically. We must apply Van Dyke's matching principle to the outer region asymptotic expansion for $\hat{p}$ taken to $O(\epsilon)$, (3.32), with the inner region asymptotic expansion for $\hat{p}$ taken to $O(\epsilon)$, (3.34) and (3.41). The appropriate matching condition is readily determined as

$$P_0(X,z) = A_i^{\pm\prime} X + o(1) \quad \text{as } X \to \pm\infty, \text{ uniformly for } z \in [z_-^i, z_+^i], \tag{3.49}$$

with

$$A_i^{+\prime} = A'(x_i^+) = -\frac{\sum_{j=0}^{i} \alpha_j}{\bar{D}_x(x_i)},\ A_i^{-\prime} = A'(x_i^-) = -\frac{\sum_{j=0}^{i-1} \alpha_j}{\bar{D}_x(x_i)},\ \text{for } i = 1, \dots, N, \tag{3.50}$$

via (3.19) and (3.20). Finally the regularity conditions (si)–(siii) with (2.30) require the following:

(Ii) $P_0 \in C(\bar{D}(0)) \cap C^1(\bar{D}(0)\backslash\bar{I}) \cap C^2(D(0)\backslash I)$, $U_0 \in C(\bar{D}(0)\backslash\bar{I}) \cap C^1(D(0)\backslash I)$, $W_0 \in C(\bar{D}(0)) \cap C^1(D(0)\backslash I)$, where $I = \{0\} \times (z_-^i, z_+^i)$;

(Iii) $\lim_{X\to 0^\pm} P_{0X}$ and $\lim_{X\to 0^\pm} P_{0z}$ both exist uniformly for $z \in [z_-^i, z_+^i]$;

(Iiii) $[P_{0z}]_{0^-}^{0^+} = 0$, $[P_{0X}]_{0^-}^{0^+} = -s_i(z)/\tilde{D}_x(z)$, $[U_0]_{0^-}^{0^+} = s_i(z)$, and $[W_0]_{0^-}^{0^+} = 0$ for all $z \in [z_-^i, z_+^i]$.

We can now eliminate U_0 and W_0, via (3.43) and (3.44), and obtain the following strongly elliptic problem for P_0, namely,

$$(\tilde{D}_x(z)P_{0X})_X + (\tilde{D}_z(z)P_{0z})_z = -s_i(z)\delta(X), \quad (X,z) \in D(0), \tag{3.51}$$

$$P_{0z}(X, z_+^i) = 0, \quad X \in (-\infty,\infty), \tag{3.52}$$

$$P_{0z}(X, z_-^i) = 0, \quad X \in (-\infty,\infty), \tag{3.53}$$

$$P_0(X,z) = A_i^{\pm\prime} X + o(1), \quad X \to \pm\infty, \quad \text{uniformly for } z \in [z_-^i, z_+^i], \tag{3.54}$$

together with (Ii)–(Iiii). The first step in obtaining the solution to (3.51)–(3.54) is to consider the regular Sturm–Liouville eigenvalue problem,

$$\begin{gathered}(\tilde{D}_z(z)\psi_z)_z + \bar{\lambda}\tilde{D}_x(z)\psi = 0, \quad z \in (z_-^i, z_+^i),\\ \psi_z(z_-^i) = \psi_z(z_+^i) = 0,\end{gathered}$$

which we refer to as [SL]. Here $\bar{\lambda} \in \mathbb{C}$ is the eigenvalue parameter. Classical Sturm–Liouville theory (see, for example, [6, Chapters 7, 8]) determines that the set of eigenvalues of [SL] is given by $\bar{\lambda} = \bar{\lambda}_r \in \mathbb{R}$, $r = 0, 1, 2, \dots$, with $0 = \bar{\lambda}_0 < \bar{\lambda}_1 < \bar{\lambda}_2 < \bar{\lambda}_3 < \cdots$, where $\bar{\lambda}_r \to +\infty$ as $r \to \infty$. The corresponding normalized eigenfunctions $\psi_r : [z_-^i, z_+^i] \mapsto \mathbb{R}$ form an orthonormal set, so that

$$\langle \psi_r, \psi_s \rangle = \int_{z_-^i}^{z_+^i} \tilde{D}_x(z)\psi_r(z)\psi_s(z)\,\mathrm{d}z = \delta_{rs} \quad \text{for } r, s = 0, 1, 2, \dots. \tag{3.55}$$

The set of eigenfunctions of [SL] are complete on the interval $[z_-^i, z_+^i]$. Completeness allows us to write the solution to (3.51) with conditions (3.52), (3.53) as

$$P_0(X,z) = \begin{cases} \sum_{n=0}^{\infty} \chi_n^+(X)\psi_n(z), & X > 0,\\ \sum_{n=0}^{\infty} \chi_n^-(X)\psi_n(z), & X < 0,\end{cases} \tag{3.56}$$

with $z \in [z_-^i, z_+^i]$. Substitution of (3.56) into (3.51) establishes that

$$\begin{aligned}\chi_n^+(X) &= A_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} + B_n \mathrm{e}^{-\bar{\lambda}_n^{1/2} X}, \quad X > 0,\\ \chi_n^-(X) &= D_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} + C_n \mathrm{e}^{-\bar{\lambda}_n^{1/2} X}, \quad X < 0,\end{aligned} \tag{3.57}$$

with $A_n, B_n, C_n, D_n \in \mathbb{R}$ constants, for $n = 1, 2, \ldots$. With $n = 0$, we have

$$\begin{aligned} \chi_0^+(X) &= A_0 + B_0 X, \quad X > 0, \\ \chi_0^-(X) &= C_0 + D_0 X, \quad X < 0, \end{aligned} \tag{3.58}$$

with $A_0, B_0, C_0, D_0 \in \mathbb{R}$ constants. At this stage we observe that

$$\psi_0(z) = \left\{ \int_{z_-^i}^{z_+^i} \tilde{D}_x(s)\,\mathrm{d}s \right\}^{-1/2} = \Psi_0, \quad z \in [z_-^i, z_+^i], \tag{3.59}$$

with $\Psi_0 > 0$. It then follows, via (3.56)–(3.59), that the boundary conditions (3.49) are satisfied if and only if

$$\begin{aligned} A_n &= 0, \quad n = 0, 1, 2, \ldots, \quad B_0 = A_i^{+\prime} \Psi_0^{-1}, \\ C_n &= 0, \quad n = 0, 1, 2, \ldots, \quad D_0 = A_i^{-\prime} \Psi_0^{-1}. \end{aligned} \tag{3.60}$$

Next, across $X = 0$, continuity of P_0, together with the condition $[P_{0z}]_{0^-}^{0^+} = 0$ of (Iiii), is satisfied if and only if, via (3.56)–(3.60),

$$B_n = D_n, \quad n = 1, 2, \ldots. \tag{3.61}$$

Finally, it remains to satisfy the condition $[P_{0X}]_{0^-}^{0^+} = -s_i(z)/\tilde{D}_x(z)$ of (Iiii), which requires, via (3.56)–(3.61), that

$$(A_i^{+\prime} - A_i^{-\prime}) - \sum_{n=1}^{\infty} 2\bar{\lambda}_n^{1/2} B_n \psi_n(z) = \frac{-s_i(z)}{\tilde{D}_x(z)}, \quad z \in [z_-^i, z_+^i]. \tag{3.62}$$

The completeness of the eigenfunctions $\psi_n(z)$ $(n = 0, 1, 2, \ldots)$ on the interval $[z_-^i, z_+^i]$ allows (3.62) to be satisfied uniquely, with, using (3.55),

$$A_i^{+\prime} - A_i^{-\prime} = -\frac{\int_{z_-^i}^{z_+^i} s_i(s)\,\mathrm{d}s}{\int_{z_-^i}^{z_+^i} \tilde{D}_x(s)\,\mathrm{d}s} = -\frac{\alpha_i}{\bar{D}_x(x_i)}$$

via (3.47) and (3.18), and which is automatically satisfied using (3.50), and

$$B_k = \frac{1}{2\bar{\lambda}_k^{1/2}} \int_{z_-^i}^{z_+^i} s_i(s)\psi_k(s)\,\mathrm{d}s, \quad k = 1, 2, \ldots. \tag{3.63}$$

Thus, the solution to (3.51)–(3.54), with regularity (Ii)–(Iiii), is given by

$$P_0(X, z) = \begin{cases} A_i^{+\prime} X + \sum_{n=1}^{\infty} B_n \mathrm{e}^{-\bar{\lambda}_n^{1/2} X} \psi_n(z), & X > 0, \\ A_i^{-\prime} X + \sum_{n=1}^{\infty} B_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} \psi_n(z), & X < 0, \end{cases} \tag{3.64}$$

with $z \in [z_-^i, z_+^i]$, and the coefficients B_n, $n = 1, 2, \ldots$, given by (3.63). $U_0(X, z)$ and $W_0(X, z)$ are now obtained directly from (3.43) and (3.44) as

$$U_0(X, z) = \begin{cases} -\tilde{D}_x(z) \left\{ A_i^{+\prime} - \sum_{n=1}^{\infty} \bar{\lambda}_n^{1/2} B_n \mathrm{e}^{-\bar{\lambda}_n^{1/2} X} \psi_n(z) \right\}, & X > 0, \\ -\tilde{D}_x(z) \left\{ A_i^{-\prime} + \sum_{n=1}^{\infty} \bar{\lambda}_n^{1/2} B_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} \psi_n(z) \right\}, & X < 0, \end{cases} \tag{3.65}$$

$$W_0(X, z) = \begin{cases} -\tilde{D}_z(z) \sum_{n=1}^{\infty} B_n \mathrm{e}^{-\bar{\lambda}_n^{1/2} X} \psi_n'(z), & X > 0, \\ -\tilde{D}_z(z) \sum_{n=1}^{\infty} B_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} \psi_n'(z), & X < 0, \end{cases} \tag{3.66}$$

with $z \in [z_-^i, z_+^i]$. The only remaining question is how to actually compute the eigenvalues and corresponding eigenfunctions of [SL]. If $\tilde{D}_x, \tilde{D}_z$, are constant with respect to z, then analytical solution of [SL] is trivial. More generally, since [SL] is a regular Sturm–Liouville problem, numerical methods are straightforward and very efficient and will not be discussed further here. The solution of the leading order problem is now complete.

It is of interest to obtain the expression for the pressure at the location of the ith line source/sink. From (3.34) and (3.41), this is given by $\hat{p}(x_i, z) = A_i + \epsilon P_0(0, z) + O(\epsilon^2)$, for $z \in [z_-^i, z_+^i]$. On using (3.64), this becomes

$$\hat{p}(x_i, z) = A_i + \epsilon \left(\sum_{n=1}^{\infty} B_n \psi_n(z) \right) + O(\epsilon^2) \quad \text{for } z \in [z_-^i, z_+^i]. \tag{3.67}$$

The pressure difference between the ith and jth line source/sinks is then

$$\begin{aligned} \Delta\hat{p}_{ij}(z) &= \hat{p}(x_i, z) - \hat{p}(x_j, z) \\ &= (A_i - A_j) + \epsilon \left(\sum_{n=1}^{\infty} [B_n^i \psi_n^i(z) - B_n^j \psi_n^j(z)] \right) + O(\epsilon^2) \end{aligned} \tag{3.68}$$

for $z \in [z_-^i, z_+^i]$, with superscripts i and j distinguishing evaluation at the ith and jth line source/sink, respectively. In (3.68), we recall that, via (3.19),

$$A_i - A_j = A(x_i) - A(x_j) = \int_{x_j}^{x_i} \frac{S(\lambda)}{\bar{D}_x(\lambda)}\, \mathrm{d}\lambda.$$

The asymptotic structure to the solution of [SSP] as $\epsilon \to 0$ is now complete. Two minor extensions are worthy of consideration at this stage and are given in the subsections that follow.

3.1. A line source/sink close to the boundary. In the above, the locations of the line source/sinks $x_i \in (-1, 1)$, $i = 1, \ldots, N$, are such that $(x_1 + 1)$, $(1 - x_N)$, and $x_{i+1} - x_i$ $(i = 1, \ldots, N-1)$ remain positive and finite $(O(1))$ as $\epsilon \to 0$. In this extension we consider the situation when $x_1 + 1 = O(\epsilon)$ as $\epsilon \to 0$, so that the line source/sink at $x = x_1$ lies within $O(\epsilon)$ of the layer boundary at $x = -1$. The structure of the outer region to [SSP] is unchanged. However, the inner region to [SSP] at $x = x_1$ now encompasses the boundary at $x = -1$, and so the leading order problem in this inner region, when $i = 1$, is modified. To formalize this we write

$$x_1 = -1 + \epsilon\bar{\sigma}, \tag{3.69}$$

with the constant $\bar{\sigma} > 0$. In terms of the inner coordinate X,

$$x = x_1 + \epsilon X, \tag{3.70}$$

via (3.33). Thus, via (3.69) and (3.70), in the inner region, the line source/sink is located at $X = 0$, while the layer boundary is located at $X = -\bar{\sigma}$. Without repeating details, the leading order problem in the inner region is now

$$U_{0X} + W_{0z} = s_1(z)\delta(X), \quad (X, z) \in D(0), \tag{3.71}$$

$$U_0 = -\tilde{D}_x(z) P_{0X}, \quad (X, z) \in D(0), \tag{3.72}$$

$$W_0 = -\tilde{D}_z(z) P_{0z}, \quad (X, z) \in D(0), \tag{3.73}$$

$$W_0(X, z_+^1) = 0, \quad X \in (-\bar{\sigma}, \infty), \tag{3.74}$$

$$W_0(X, z_-^1) = 0, \quad X \in (-\bar{\sigma}, \infty), \tag{3.75}$$

where now $\bar{D}(0)$ is the unbounded region in the (X,z) plane contained inside the coordinate lines $z = z_+^1$, $z = z_-^1$, and $X = -\bar{\sigma}$, so that

$$\bar{D}(0) = [-\bar{\sigma}, \infty) \times [z_-^1, z_+^1]. \tag{3.76}$$

The leading order problem (3.71)–(3.75) is completed with the condition

$$U_0(-\bar{\sigma}, z) = 0, \quad z \in [z_-^1, z_+^1], \tag{3.77}$$

$$P_0(X,z) = {A_1^{+}}'X + o(1), \text{ as } X \to +\infty, \text{ uniformly for } z \in [z_-^1, z_+^1], \tag{3.78}$$

with the latter being the matching condition to the outer region. The solution to (3.71)–(3.78) can be constructed as before, to obtain

$$P_0(X,z) = \begin{cases} {A_1^{+}}'X + \sum_{n=1}^{\infty} \bar{B}_n \mathrm{e}^{-\bar{\lambda}_n^{1/2}X} \psi_n(z), & X > 0, \\ \sum_{n=1}^{\infty} \frac{\bar{B}_n}{\cosh[\bar{\lambda}_n^{1/2}(X+\bar{\sigma})]} \cosh \bar{\lambda}_n^{1/2}(X+\bar{\sigma})\psi_n(z), & -\bar{\sigma} \le X < 0, \end{cases}$$

for $z \in [z_-^1, z_+^1]$, and with

$$\bar{B}_n = \frac{1}{\bar{\lambda}_n^{1/2}(1 + \tanh(\bar{\lambda}_n^{1/2}\bar{\sigma}))} \int_{z_-^1}^{z_+^1} s_1(s)\psi_n(s)\,\mathrm{d}s, \quad n = 1, 2, \ldots. \tag{3.79}$$

Equations (3.72)–(3.73) then give the corresponding expressions for $U_0(X,z)$ and $W_0(X,z)$. The pressure at the location of this first line source/sink is then given by

$$\hat{p}(x_1, z) = A_1 + \epsilon \left(\sum_{n=1}^{\infty} \bar{B}_n \psi_n(z) \right) + O(\epsilon^2) \tag{3.80}$$

for $z \in [z_-^1, z_+^1]$, with $\bar{B}_n$, $n = 1, 2, \ldots$, as given in (3.79). The difference in the expression for pressure at the wall close line source/sink (3.80), and at the interior line source/sink (3.67), occurs in the expressions for the sequence of constants B_n, (3.63), and $\bar{B}_n$, (3.79), $n = 1, 2, \ldots$.

3.2. Two closely located line source/sinks. In this extension, we consider the situation when the kth and $(k+1)$th line source/sinks are within $O(\epsilon)$ separation of each other. With $x_k, x_{k+1} \in (-1, 1)$, we write $x_{k+1} = x_k + \tilde{\sigma}\epsilon$, with the constant $\tilde{\sigma} > 0$. In terms of the inner coordinate X, $x = x_k + \epsilon X$, via (3.33). Thus both line source/sinks at $x = x_k$ and $x = x_{k+1}$ are located in the inner region at $x = x_k$, with their respective locations in this inner region being at $X = 0$ and $X = \tilde{\sigma}$. Without repeating details, the leading order problem in the inner region is now

$$U_{0X} + W_{0z} = s_k(z)\delta(X) + s_{k+1}(z)\delta(X - \tilde{\sigma}), \quad (X,z) \in D(0), \tag{3.81}$$

$$U_0 = -\tilde{D}_x(z)P_{0X}, \quad (X,z) \in D(0), \tag{3.82}$$

$$W_0 = -\tilde{D}_z(z)P_{0z}, \quad (X,z) \in D(0), \tag{3.83}$$

$$W_0(X, z_+^k) = 0, \quad X \in (-\infty, \infty), \tag{3.84}$$

$$W_0(X, z_-^k) = 0, \quad X \in (-\infty, \infty), \tag{3.85}$$

$$P_0(X,z) = \begin{cases} {A_{k+1}^{+}}'(X - \tilde{\sigma}) + \tilde{\sigma}{A_{k+1}^{-}}' + o(1), & X \to +\infty, \\ {A_k^{-}}'X + o(1), & X \to -\infty, \end{cases} \tag{3.86}$$
$$\text{uniformly for } z \in [z_-^k, z_+^k],$$

with $\bar{D}(0)$ as in (3.48) when $i = k$, and condition (3.86) being the appropriate matching condition to the outer region. The solution to (3.81)–(3.86) can be constructed as before, to obtain

$$P_0(X,z) = \begin{cases} {A_k^-}'X + \sum_{n=1}^{\infty} \hat{B}_n \mathrm{e}^{\bar{\lambda}_n^{1/2} X} \psi_n(z), & X < 0, \\ {A_{k+1}^-}'X + \sum_{n=1}^{\infty} (\hat{B}_n \cosh(\bar{\lambda}_n^{1/2} X) + \hat{D}_n \sinh(\bar{\lambda}_n^{1/2} X))\psi_n(z), & 0 < X < \tilde{\sigma}, \\ \{\tilde{\sigma}{A_{k+1}^-}' + {A_{k+1}^+}'(X - \tilde{\sigma})\} + \sum_{n=1}^{\infty} \hat{C}_n \mathrm{e}^{-\bar{\lambda}_n^{1/2}(X-\tilde{\sigma})} \psi_n(z), & X > \tilde{\sigma}, \end{cases} \tag{3.87}$$

with $z \in [z_-^k, z_+^k]$, and the coefficients

$$\hat{B}_n = \frac{1}{2\bar{\lambda}_n^{1/2}} \left\{ \frac{1}{[\cosh(\bar{\lambda}_n^{1/2}\tilde{\sigma}) + \sinh(\bar{\lambda}_n^{1/2}\tilde{\sigma})]} \int_{z_-^k}^{z_+^k} s_{k+1}(s)\psi_n(s)\,\mathrm{d}s + \int_{z_-^k}^{z_+^k} s_k(s)\psi_n(s)\,\mathrm{d}s \right\}, \tag{3.88}$$

$$\hat{D}_n = \frac{1}{2\bar{\lambda}_n^{1/2}} \left\{ \frac{1}{[\cosh(\bar{\lambda}_n^{1/2}\tilde{\sigma}) + \sinh(\bar{\lambda}_n^{1/2}\tilde{\sigma})]} \int_{z_-^k}^{z_+^k} s_{k+1}(s)\psi_n(s)\,\mathrm{d}s - \int_{z_-^k}^{z_+^k} s_k(s)\psi_n(s)\,\mathrm{d}s \right\},$$

$$\hat{C}_n = \frac{1}{2\bar{\lambda}_n^{1/2}} \left\{ \int_{z_-^k}^{z_+^k} s_{k+1}(s)\psi_n(s)\,\mathrm{d}s + [\cosh(\bar{\lambda}_n^{1/2}\tilde{\sigma}) - \sinh(\bar{\lambda}_n^{1/2}\tilde{\sigma})] \int_{z_-^k}^{z_+^k} s_k(s)\psi_n(s)\,\mathrm{d}s \right\}. \tag{3.89}$$

Equations (3.82)–(3.83) then give the corresponding expressions for $W_0(X,z)$ and $U_0(X,z)$. (Note that $\tilde{D}_x(z)$ and $\tilde{D}_z(z)$ in (3.82), (3.83) are evaluated at $x = x_k$.) The pressures at the line source/sinks at $x = x_k$ and $x = x_{k+1}$ are given by, via (3.87),

$$\hat{p}(x_k, z) = A_k + \epsilon \left(\sum_{n=1}^{\infty} \hat{B}_n \psi_n(z) \right) + O(\epsilon^2),$$

$$\hat{p}(x_{k+1}, z) = A_k + \epsilon \left(\tilde{\sigma}{A_{k+1}^-}' + \sum_{n=1}^{\infty} \hat{C}_n \psi_n(z) \right) + O(\epsilon^2),$$

with $\hat{B}_n$ and $\hat{C}_n$, $n = 1, 2, \ldots$, as given in (3.88) and (3.89). (Note in the above that $A_k + \epsilon\tilde{\sigma}{A_{k+1}^-}' = A_k + \epsilon\tilde{\sigma}A_k^{+'} + O(\epsilon^2) = A_{k+1} + O(\epsilon^2)$.)

The asymptotic solution to [SSP] as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{M}'$, is now complete. We now turn our attention to the eigenvalue problem [EVP].

4. Asymptotic solution to the eigenvalue problem [EVP] as $\epsilon \to 0$. In this section we develop the asymptotic solution to the eigenvalue problem [EVP] as $\epsilon \to 0$. We first employ the theory developed by Ramm [16] to establish that the set of eigenvalues to [EVP], (2.42), with $\epsilon > 0$, splits into two disjoint subsets as $\epsilon \to 0^+$, denoted by $S_- = \{\lambda_0^-(\epsilon), \lambda_1^-(\epsilon), \lambda_2^-(\epsilon), \ldots\}$ and $S_+ = \{\lambda_1^+(\epsilon), \lambda_2^+(\epsilon), \lambda_3^+(\epsilon), \ldots\}$, with $0 = \lambda_0^-(\epsilon) < \lambda_1^-(\epsilon) < \cdots$ and $0 < \lambda_1^+(\epsilon) < \lambda_2^+(\epsilon) < \cdots$. In particular,

$$\lambda_n^-(\epsilon) = O(n^2), \quad \lambda_n^+(\epsilon) = O(n^2\epsilon^{-2}) \tag{4.1}$$

as $\epsilon \to 0^+$, uniformly for $n = 1, 2, \ldots$. We will focus attention on the eigenvalues and corresponding eigenfunctions in the set S_-, so that in [EVP] we have $\lambda(\epsilon) = O(1)$ as $\epsilon \to 0^+$, via (4.1). Thus we expand $\phi : \bar{M}' \mapsto \mathbb{R}$ in the form

$$\phi(x,z;\epsilon) = \tilde{\phi}(x,z) + \epsilon^2\hat{\phi}(x,z) + o(\epsilon^2) \quad \text{as } \epsilon \to 0^+, \tag{4.2}$$

uniformly for $(x,z)\in\bar{M}'$, while we expand

$$\lambda(\epsilon)=\tilde{\lambda}+\epsilon^2\hat{\lambda}+o(\epsilon^2)\quad \text{as } \epsilon\to 0^+. \tag{4.3}$$

On substitution from (4.2) and (4.3) into [EVP], we obtain the leading order problem

$$\Big(D_z(x,z)\tilde{\phi}_z\Big)_z=0,\quad (x,z)\in M', \tag{4.4}$$

$$\tilde{\phi}_x(-1,z)=0,\quad z\in[z_-(-1),z_+(-1)], \tag{4.5}$$

$$\tilde{\phi}_x(1,z)=0,\quad z\in[z_-(1),z_+(1)], \tag{4.6}$$

$$\tilde{\phi}_z(x,z_+(x))=0,\quad x\in(-1,1), \tag{4.7}$$

$$\tilde{\phi}_z(x,z_-(x))=0,\quad x\in(-1,1). \tag{4.8}$$

A direct integration of (4.4) gives

$$\tilde{\phi}_z(x,z)=\frac{\tilde{B}(x)}{D_z(x,z)},\quad (x,z)\in\bar{M}', \tag{4.9}$$

while (4.7) and (4.8) require $\tilde{B}(x)=0$ for all $x\in[-1,1]$. Hence, from (4.9),

$$\tilde{\phi}(x,z)=\tilde{A}(x),\quad (x,z)\in\bar{M}', \tag{4.10}$$

with $\tilde{A}:[-1,1]\mapsto\mathbb{R}$ such that $\tilde{A}\in C^1([-1,1])\cap C^2((-1,1))$. Conditions (4.5) and (4.6) then require $\tilde{A}'(-1)=\tilde{A}'(1)=0$. At $O(\epsilon^2)$ we obtain the problem

$$\Big(D_z(x,z)\hat{\phi}_z\Big)_z=-\hat{\lambda}\tilde{A}(x)-\Big(D_x(x,z)\tilde{A}'(x)\Big)_x,\quad (x,z)\in M', \tag{4.11}$$

$$\hat{\phi}_x(-1,z)=0,\quad z\in[z_-(-1),z_+(-1)], \tag{4.12}$$

$$\hat{\phi}_x(1,z)=0,\quad z\in[z_-(1),z_+(1)], \tag{4.13}$$

$$D_z(x,z_+(x))\hat{\phi}_z(x,z_+(x))=z_+'(x)D_x(x,z_+(x))\tilde{A}'(x),\quad x\in(-1,1), \tag{4.14}$$

$$D_z(x,z_-(x))\hat{\phi}_z(x,z_-(x))=z_-'(x)D_x(x,z_-(x))\tilde{A}'(x),\quad x\in(-1,1). \tag{4.15}$$

The solvability requirement on the inhomogeneous boundary value problem (4.11)–(4.15) will provide the ordinary differential equation which must be satisfied by $\tilde{A}(x)$, $x\in(-1,1)$. On integrating (4.11) with respect to z (with $x\in(-1,1)$ fixed) between $z=z_-(x)$ and $z=z_+(x)$, we obtain

$$\begin{aligned}D_z(x,z_+(x))\hat{\phi}_z(x,z_+(x))-D_z(x,z_-(x))\hat{\phi}_z(x,z_-(x))&=-\tilde{\lambda}\tilde{A}(x)(z_+(x)-z_-(x))\\ -(\bar{D}_x(x)\tilde{A}'(x))'+[z_+'(x)D_x(x,z_+(x))&-z_-'(x)D_x(x,z_-(x))]\tilde{A}'(x)\end{aligned} \tag{4.16}$$

for all $x\in(-1,1)$. We next substitute into the left-hand side of (4.16) from (4.14) and (4.15), which, after cancellation, results in the ordinary differential equation

$$(\bar{D}_x(x)\tilde{A}'(x))'+\tilde{\lambda}(z_+(x)-z_-(x))\tilde{A}(x)=0,\quad x\in(-1,1). \tag{4.17}$$

Thus $\tilde{A}:[-1,1]\mapsto\mathbb{R}$ and $\tilde{\lambda}\in\mathbb{R}$ satisfy the regular Sturm–Liouville eigenvalue problem (which we denote hereafter by [SLP]),

$$\begin{gathered}(\bar{D}_x(x)\tilde{A}'(x))'+\tilde{\lambda}h(x)\tilde{A}(x)=0,\quad x\in(-1,1),\\ \tilde{A}'(-1)=\tilde{A}'(1)=0,\end{gathered}$$

with $\bar{D}_x(x)$ as defined in (3.18) and $h(x) = z_+(x) - z_-(x)$, $x \in [-1,1]$. Now, the classical Sturm–Liouville theory (see, for example, [6, Chapters 7, 8]) determines that the set of eigenvalues of [SLP] is given by $\tilde{\lambda} = \tilde{\lambda}_r$, $r = 0, 1, 2, \ldots$, with

$$0 = \tilde{\lambda}_0 < \tilde{\lambda}_1 < \tilde{\lambda}_2 < \cdots \quad \text{and} \quad \tilde{\lambda}_r = O(r^2) \quad \text{as } r \to \infty. \tag{4.18}$$

We remark also that [SLP] is identical in structure to the eigenvalue problem [SL] considered in section 3. Corresponding to each eigenvalue $\tilde{\lambda}_r$ ($r = 0, 1, 2, \ldots$), there is a unique normalized eigenfunction $\tilde{A}_r : [-1,1] \mapsto \mathbb{R}$ such that

$$\int_{-1}^{1} h(x)\tilde{A}_i(x)\tilde{A}_j(x)\,\mathrm{d}x = \delta_{ij} \quad \text{for } i,j = 0,1,2,\ldots. \tag{4.19}$$

We note that $\tilde{A}_0(x) = \{\int_{-1}^{1} h(s)\,\mathrm{d}s\}^{-1/2} = (\mathrm{meas}(\bar{M}'))^{-1/2}$ for all $x \in [-1,1]$. Thus, we have established for [EVP], via (4.2), (4.3), (4.10), that $\lambda_r^-(\epsilon) = \tilde{\lambda}_r + O(\epsilon^2)$ as $\epsilon \to 0$, uniformly for $r = 1, 2, \ldots$, with corresponding normalized eigenfunction $\phi_r^-(x,z;\epsilon) = \tilde{A}_r(x) + O(\epsilon^2)$ as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{M}'$.

We can now use the above theory to obtain the following expression for $\tilde{p} : \bar{M}' \times [0,\infty) \mapsto \mathbb{R}$, via (2.46) and (2.47):

$$\tilde{p}(x,z,t) = \sum_{r=1}^{\infty} c_r \mathrm{e}^{-\tilde{\lambda}_r t}\tilde{A}_r(x) + O(\epsilon^2 \mathrm{e}^{-\tilde{\lambda}_1 t}, \mathrm{e}^{-t/\epsilon^2}) \quad \text{as } \epsilon \to 0, \tag{4.20}$$

uniformly for $(x,z,t) \in \bar{M}' \times [\delta,\infty)$, for any $\delta > 0$. Here c_r, $r = 1, 2, \ldots$, are given by

$$c_r = \iint_{\bar{M}'} \tilde{p}_0(u,v)\tilde{A}_r(u)\,\mathrm{d}u\,\mathrm{d}v, \quad r = 1,2,\ldots. \tag{4.21}$$

We observe from (4.20) that

$$\tilde{p}(x,z,t) \sim (c_1\tilde{A}_1(x) + O(\epsilon^2))\mathrm{e}^{-\tilde{\lambda}_1 t} \tag{4.22}$$

as $t \to \infty$, uniformly for $(x,z) \in \bar{M}'$. Thus, the solution to [IBVP] approaches the solution to [SSP] as $t \to \infty$ through terms exponentially small in t as $t \to \infty$. The timescale for relaxation to the steady state is then $t_s \sim (\tilde{\lambda}_1)^{-1}$ in dimensionless variables, giving the dimensional relaxation timescale as $t_s^d \sim c_t l^2/(D_0\tilde{\lambda}_1)$, via (2.12).

5. The case of disparate permeabilities. In the previous sections, the theory has been developed for the situation when the permeability scale is comparable in both the x-direction and the z-direction. In some applications, this is not always the case, when the permeability in the z-direction is much weaker than that in the x-direction. In this case (2.1) should be replaced by

$$D_0^x D_x\left(\frac{x}{l}, \frac{z}{h}\right) \geq D_m > 0, \quad D_0^z D_z\left(\frac{x}{l}, \frac{z}{h}\right) \geq D_m > 0,$$

for $(x,z) \in \bar{M}$, with $D_0^x > 0$ being the permeability scale in the x-direction and $D_0^z > 0$ being the permeability scale in the z-direction, and now

$$0 < \delta = \frac{D_0^z}{D_0^x} \ll 1. \tag{5.1}$$

For such reservoirs δ is typically of $O(10^{-1})$. We now follow the same nondimensionalization as before, via (2.12), with D_0^x replacing D_0. The resulting full dimensionless problem is identical to [IBVP], except with ϵ replaced by $\tilde{\epsilon}$, where $\tilde{\epsilon} = \epsilon\delta^{-1/2}$. Thus all of the previous theory carries over to this situation, on simply replacing ϵ by $\tilde{\epsilon}$. In particular, the asymptotic theory as $\epsilon \to 0$ is now replaced by $\tilde{\epsilon} \to 0$, and so requires

$$0 < \tilde{\epsilon} \ll 1, \tag{5.2}$$

which, with (5.1), is equivalent to $0 < \epsilon \ll \delta^{1/2} \ll 1$, and with typically $\epsilon^2 \sim O(10^{-4})$ and $\delta \sim O(10^{-1})$, then this ordering is satisfied. It is worth noting here that for porous layers in which $\epsilon = O(1)$ and $\delta \gg 1$, then $\tilde{\epsilon} = \epsilon\delta^{-1/2} \ll 1$, so (5.2) is again satisfied, and the asymptotic theory developed before is again applicable.

6. The pseudosteady state. In this section we consider the situation when the specified flux constants α_i, $i = 1, \ldots, N$, do not satisfy the condition (2.31); that is, when $\sum_{i=1}^{N} \alpha_i = \alpha_T \neq 0$. In this case we introduce an associated pseudosteady state problem to [IBVP]. This corresponds to the steady state problem [SSP] ((2.23)–(2.30)), except that now (2.23) is modified to

$$\hat{u}_x + \hat{w}_z = \sum_{i=1}^{N} s_i(z)\delta(x - x_i) - \tilde{\alpha}_T, \quad (x, z) \in M',$$

with the constant $\tilde{\alpha}_T$ given by $\tilde{\alpha}_T = \alpha_T/\text{meas}(\bar{M}')$. The result corresponding to Theorem 2.2 is now, with the pseudosteady state problem referred to as [PSSP], the following.

THEOREM 6.1. *For each $\epsilon > 0$,* [PSSP] *has a unique (up to addition of a constant in $\hat{p}$) solution $\hat{u}, \hat{w}, \hat{p} : \bar{M}' \mapsto \mathbb{R}$.*

Again, we fix the indeterminate constant in [PSSP] to be that pseudosteady state which satisfies the condition (2.40). The result corresponding to Theorem 2.3 is now as follows.

THEOREM 6.2. *For each $\epsilon > 0$,* [IBVP] *has a unique solution $u, w, \bar{p} : \bar{M}' \times [0, \infty) \mapsto \mathbb{R}$ given by*

$$\begin{aligned}\bar{p}(x, z, t) &= \tilde{\alpha}_T t + \hat{p}(x, z) + \tilde{p}(x, z, t),\\ u(x, z, t) &= \hat{u}(x, z) - D_x(x, z)\tilde{p}_x(x, z, t),\\ w(x, z, t) &= \hat{w}(x, z) - \epsilon^{-2}D_z(x, z)\tilde{p}_z(x, z, t),\end{aligned}$$

for all $(x, z) \in \bar{M}'$ and $t \in [0, \infty)$. Here $\tilde{p} : \bar{M}' \times [0, \infty) \mapsto \mathbb{R}$ is given by (2.46), (2.47), *and $\hat{u}, \hat{w}, \hat{p} : \bar{M}' \mapsto \mathbb{R}$ is that solution to* [PSSP] *which satisfies* (2.40). *Moreover,*

$$\begin{aligned}\bar{p}(x, z, t) &= \tilde{\alpha}_T t + \hat{p}(x, z) + O(\mathrm{e}^{-\lambda_1(\epsilon)t}),\\ u(x, z, t) &= \hat{u}(x, z) + O(\mathrm{e}^{-\lambda_1(\epsilon)t}),\\ w(x, z, t) &= \hat{w}(x, z) + O(\mathrm{e}^{-\lambda_1(\epsilon)t}),\end{aligned}$$

as $t \to \infty$, uniformly for $(x, z) \in \bar{M}'$.

We remark that since $\hat{p} \in C(\bar{M}') \cap PC^1(\bar{M}')$ and the initial data for [IBVP] $\bar{p}_0 \in C(\bar{M}') \cap PC^1(\bar{M}')$, then Theorem 6.2 implies global asymptotic stability (up to the addition of a constant to $\hat{p}$) for the pseudosteady state to [IBVP] with respect to perturbations in $C(\bar{M}') \cap PC^1(\bar{M}')$.

We now explore the structure of the solution to [PSSP] as $\epsilon \to 0$. This involves only minor adjustments to the structure developed in section 3 for the solution to

[SSP]. Again the outer region asymptotic expansions are given by

$$\begin{aligned}\hat{u}(x,z;\epsilon) &= \frac{-D_x(x,z)}{\bar{D}_x(x)}\left\{S(x)+\tilde{\alpha}_T H(x)\right\}+O(\epsilon^2),\\ \hat{w}(x,z;\epsilon) &= S(x)\int_{z_-(x)}^{z}\left\{\frac{D_x(x,\lambda)}{\bar{D}_x(x)}\right\}_x \mathrm{d}\lambda\\ &\quad -\frac{z_-'(x)D_x(x,z_-(x))S(x)}{\bar{D}_x(x)}-\tilde{\alpha}_T(z-z_-(x))+O(\epsilon^2),\\ \hat{p}(x,z;\epsilon) &= A(x)+O(\epsilon^2),\end{aligned} \tag{6.1}$$

as $\epsilon \to 0$, uniformly for $(x,z) \in \bar{N}_\epsilon'$. Here, as before, $S : [-1,1] \mapsto \mathbb{R}$ is as given by (3.20), but now $A : [-1,1] \mapsto \mathbb{R}$ is the unique solution to the linear inhomogeneous boundary value problem,

$$[\bar{D}_x(x)A'(x)]' = -\sum_{i=1}^{N}\alpha_i\delta(x-x_i)+\tilde{\alpha}_T(z_+(x)-z_-(x)), \quad x\in(-1,1), \tag{6.2}$$

$$A'(-1)=A'(1)=0, \tag{6.3}$$

$$\int_{-1}^{1}(z_+(x)-z_-(x))A(x)\,\mathrm{d}x = I_0, \tag{6.4}$$

with $H : [-1,1] \mapsto \mathbb{R}$ defined by

$$H(x)=\int_{-1}^{x}(z_+(\lambda)-z_-(\lambda))\,\mathrm{d}\lambda, \quad x\in[-1,1]. \tag{6.5}$$

The solution to (6.2)–(6.4) is readily obtained as

$$A(x)=\int_{-1}^{x}\frac{[S(\lambda)+\tilde{\alpha}_T H(\lambda)]}{\bar{D}_x(\lambda)}\,\mathrm{d}\lambda + A_0, \quad x\in[-1,1], \tag{6.6}$$

with the constant A_0 given by

$$A_0=\frac{I_0}{\mathrm{meas}(\bar{M}')}-\frac{1}{\mathrm{meas}(\bar{M}')}\int_{-1}^{1}\frac{[S(\lambda)+\tilde{\alpha}_T H(\lambda)]}{\bar{D}_x(\lambda)}\,\mathrm{meas}(\bar{M}'(\lambda))\,\mathrm{d}\lambda. \tag{6.7}$$

Thus we now have

$$A_i = A(x_i)=\int_{-1}^{x_i}\frac{[S(\lambda)+\tilde{\alpha}_T H(\lambda)]}{\bar{D}_x(\lambda)}\,\mathrm{d}\lambda + A_0, \tag{6.8}$$

$$A_i^{+'} = A'(x_i^+) = -\frac{\sum_{j=0}^{i}\alpha_j}{\bar{D}_x(x_i)}+\frac{\tilde{\alpha}_T H(x_i)}{\bar{D}_x(x_i)}, \tag{6.9}$$

$$A_i^{-'} = A'(x_i^-) = -\frac{\sum_{j=0}^{i-1}\alpha_j}{\bar{D}_x(x_i)}+\frac{\tilde{\alpha}_T H(x_i)}{\bar{D}_x(x_i)}, \tag{6.10}$$

each for $i = 1,\ldots,N$. The details of the inner regions are precisely as before in section 3, but now A_i and $A_i^{\pm'}$ are given by (6.8)–(6.10). The modifications are now complete.

7. An example. We finally apply the theory developed in the previous sections to a simple situation. We consider a rectangular porous layer, with $z_{\pm}(x) = \pm 1/2$, $x \in [-1,1]$, with the permeability of the layer in the x-direction independent of x, so that $D_x(x,z) = D_x(z)$, $(x,z) \in \bar{M}'$. Thus,

$$\bar{D}_x(x) = \int_{-1/2}^{1/2} D_x(z)\,\mathrm{d}z = \bar{D}_x\ (>0), \quad x \in [-1,1],$$

with $\bar{D}_x$ a constant. We include a single source/sink at $x = x_1 = x_s \in (-1,1)$, with normalized flux constant $\alpha = \alpha_1 = \alpha_s = \pm 1$, with -1 for extraction and $+1$ for injection. We take the initial pressure field to be uniform, so that

$$\bar{p}_0(x,z) = \bar{p}_0, \quad (x,z) \in \bar{M}', \tag{7.1}$$

with $\bar{p}_0$ a constant. The pressure field in the porous layer is then given by

$$\bar{p}(x,z,t;\epsilon) = \frac{1}{2}\alpha_s t + A(x) + c_1 \tilde{A}_1(x)\mathrm{e}^{-\tilde{\lambda}_1 t} + O(\epsilon, \mathrm{e}^{-\tilde{\lambda}_2 t}, \epsilon^2 \mathrm{e}^{-\tilde{\lambda}_1 t}, \mathrm{e}^{-t/\epsilon^2}), \tag{7.2}$$

as $\epsilon \to 0$, uniformly for $(x,z,t) \in \bar{M}' \times [\delta,\infty)$ (for any $\delta > 0$), via Theorem 6.2, together with (6.1), (3.34), (3.41), and (4.20)–(4.22). From (4.17)–(4.19),

$$\tilde{\lambda}_1 = \frac{1}{4}\bar{D}_x \pi^2, \qquad \tilde{\lambda}_2 = \bar{D}_x \pi^2, \qquad \tilde{A}_1(x) = \cos\frac{1}{2}\pi(x+1), \quad x \in [-1,1], \tag{7.3}$$

with, via (4.21), (7.1), and (6.1),

$$c_1 = -\int_{-1}^{1} A(\lambda)\cos\frac{1}{2}\pi(\lambda+1)\,\mathrm{d}\lambda. \tag{7.4}$$

It also follows from (6.2)–(6.7) that

$$A(x) = \begin{cases} \frac{\alpha_s}{4\bar{D}_x}(x+1)^2 + A_0, & x \in [-1, x_s), \\ \frac{\alpha_s}{4\bar{D}_x}(x+1)^2 - \frac{\alpha_s}{\bar{D}_x}(x - x_s) + A_0, & x \in [x_s, 1], \end{cases} \tag{7.5}$$

with $A_0 = \bar{p}_0 - \frac{\alpha_s}{12\bar{D}_x}(1 + 6x_s - 3x_s^2)$. The pressure at the line source/sink is thus

$$\bar{p}(x_s,z,t;\epsilon) = \frac{1}{2}\alpha_s t + A(x_s) + c_1 \tilde{A}_1(x_s)\mathrm{e}^{-\tilde{\lambda}_1 t} + O(\epsilon, \mathrm{e}^{-\tilde{\lambda}_2 t}, \epsilon^2 \mathrm{e}^{-\tilde{\lambda}_1 t}, \mathrm{e}^{-t/\epsilon^2}),$$

from which it follows, via (7.3)–(7.5), that

$$\begin{aligned} \bar{p}(x_s,z,t;\epsilon) = \frac{1}{2}\alpha_s t + \bar{p}_0 + \frac{\alpha_s}{6\bar{D}_x}(1+3x_s^2) + c_1 \mathrm{e}^{-\frac{\bar{D}_x\pi^2}{4}t}\cos\frac{1}{2}\pi(x_s+1) \\ + O\left(\epsilon, \mathrm{e}^{-\bar{D}_x\pi^2 t}, \epsilon^2 \mathrm{e}^{-\frac{\bar{D}_x\pi^2}{4}t}, \mathrm{e}^{-t/\epsilon^2}\right) \end{aligned} \tag{7.6}$$

as $\epsilon \to 0$, uniformly for $(z,t) \in [-1/2,1/2] \times [\delta,\infty)$. To obtain the correction at $O(\epsilon)$ to (7.2), we note that a composite expansion must first be obtained using the inner and outer expansions for $\bar{p}$, but this is not necessary at leading order. As $t \to \infty$, (7.6) gives

$$\bar{p}(x_s,z,t;\epsilon) \sim \bar{p}_0 + \frac{1}{2}\alpha_s\left[t + \frac{1}{3\bar{D}_x}(1+3x_s^2)\right]. \tag{7.7}$$

Finally, denoting the dimensionless atmospheric pressure by $\bar{p}_a$, then with the initial layer pressure $\bar{p}_0 \gg \bar{p}_a$, we may use (7.7) to obtain the time span during which the single well is self-producing at the specified extraction rate. With an extraction well, $\alpha_s = -1$ in (7.7), and the time limit of self-production is $t = t_c$, where

$$\bar{p}(x_s, z, t_c; \epsilon) = \bar{p}_a. \tag{7.8}$$

On using (7.7) in (7.8), we obtain

$$t_c = 2(\bar{p}_0 - \bar{p}_a) - \frac{1}{3\bar{D}_x}(1 + 3x_s^2). \tag{7.9}$$

It follows from (7.9) that t_c is optimized by locating the extraction well at $x = x_s = 0$, that is, at the center of the porous layer as should be expected due to the symmetry in this simple example. The point is that, in less symmetrical examples, optimization can be achieved with little more effort through the corresponding version of (7.9), which is still readily available. In dimensional terms, (7.9) becomes, via (2.12),

$$t_c^d = \frac{ac_t}{Q}(p_0^d - p_a) - \frac{hc_t}{3\bar{D}_x^d}(l^2 + 3x_s^{d^2}),$$

with t_c^d the dimensional self-extraction time, $a = 2hl$ the cross-sectional area of the porous layer, Q the volumetric extraction rate per unit width, p_0^d the dimensional initial layer pressure, p_a the dimensional atmospheric pressure, $\bar{D}_x^d$ the dimensional depth integrated permeability in the x-direction, and x_s^d the dimensional location of the extraction well.

8. Conclusions.

In this paper we have considered the unsteady flow of a weakly compressible fluid in a horizontal layer of an inhomogeneous and anisotropic porous medium with variable upper and lower boundaries, in the presence of line sources and sinks. We have derived a strongly parabolic linear initial boundary value problem for the dynamic fluid pressure and shown that this problem has a unique solution. We have then constructed the solution to this problem when the layer aspect ratio $0 < \epsilon \ll 1$, via the method of matched asymptotic expansions. First, we have derived a matched asymptotic solution to the steady state problem, under the constraint that the sum of the total volume fluxes at the wells is zero. (This constraint is removed in section 6, leading to a pseudosteady state problem whose solution is almost identical in structure.) In the outer region this has been constructed directly, with the solution given by (3.30)–(3.32). In the inner region the solution is given by (3.63)–(3.66), together with (3.34) and (3.41). This solution is written in terms of the eigenvalues and eigenvectors of a regular Sturm–Liouville eigenvalue problem [SL], which can be solved analytically in the case that the permeability at each line source/sink is constant in the vertical direction, but whose numerical solution is straightforward in the more general case. The pressure at any line source or sink is then given by (3.67).

By subtracting the solution of the steady state problem from the solution of the initial value problem, we have then constructed a strongly parabolic homogeneous problem with no discontinuities across the line sources and sinks, whose solution can be written in terms of the eigenvalues and eigenfunctions of a regular self-adjoint eigenvalue problem. Asymptotic solution of this reduces to solution of a regular Sturm–Liouville eigenvalue problem identical in structure to [SL]. It has further been shown, via (4.20)–(4.22), that the solution of the initial value problem approaches the solution of the steady state problem through terms exponentially small with respect to time t as $t \to \infty$. Generalizations to cases where a line source or sink is near a boundary wall, where line sources and sinks are not well spaced, and to the case of disparate permeabilities have also been considered, in sections 3.1, 3.2, and 5, respectively. An example demonstrating an application of the theory to a simple situation is provided in section 7.

We finally remark that since the initial boundary value problem is solved for a general C^1 initial condition, the effect of time dependent transient effects due to temporal changes in the well discharge rates can easily be accounted for.

GROWTH DYNAMICS OF CELL ASSEMBLIES*

MAU-HSIANG SHIH† AND FENG-SHENG TSAI†

Abstract. We explore an evolutionary network model of pulse-coupled neurons in which the changes of evolutionary coupling strengths are based on Hebbian synaptic plasticity. We show that the ongoing changes of the evolutionary network's nodal-and-coupling dynamics will eventually result in group synchrony and sync-dependent circuits. We also tackle the problem of the stability of neural synchrony and the problem of determining the size of synchronously firing neural groups. This leads to describing a phenomenon underlying synchrony and stability of synchrony that neural synchrony allows positive feedback from which a monotonically increasing sequence of coupling strengths and a monotonically increasing region of states for initializing the stability process arise.

Key words. synaptic plasticity, cell assemblies, synchronization, stability, self-organization, spontaneous order, complex networks, nonlinear dynamics

1. Introduction.

The brain is considered to be a complex, self-organizing system. It consists of enormous numbers of interacting neurons and perpetually weaves its intricate web [7, 21, 42, 50, 52]. What underlies such activation is plasticity; it emerges as a source of change altering the structure of the brain. In 1949, Donald O. Hebb proposed an activity-dependent mechanism for synaptic modification, which was the first neurophysiological description in what is now called "Hebbian synaptic plasticity." It rested on his most famous statement: "When an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased." Synapses that exhibit this coincidence-detection rule are now called "Hebb synapses" [21, 41]. Hebb went further and suggested that cortical circuits might admit self-sustaining reverberatory activity to bind association-area neurons into structural interconnectivity if the changes of synaptic strengths could be based on coincidence detection [21, 41]. The hypothesis is now called the "Hebbian cell-assembly postulate," which is one of the most influential postulates in relation to the behavior and neural interactions in the brain [1, 21]. According to the Hebbian cell-assembly postulate, the circulating neural impulses between populations of association-area neurons would continue to circulate, forming a diffuse self-assembling structure called "cell assemblies" [21, 36, 41].

Being on the trail of the growth of cell assemblies always accompanies complicated integration of neuronal and synaptic activity [20, 34, 38]. It stimulates an intensive effort to promote the building of computer or network models of the brain [2, 3, 17, 23, 57] and leads to a shift towards explaining cognitive function in terms of large-scale interactions of neuronal populations [11, 13, 15, 16, 40, 47]. This development may lead to the current research on self-organization, which probes the interplay between neural activity and synaptic plasticity. It lends substance to the formation

of connectivity structures in cortical development and gives birth to abstract neural network models incorporated with dynamical and structural complexity [18, 25, 29, 30, 31, 54, 56].

Self-organization may proceed on a layer-by-layer basis, in which the synaptic strengths are repeatedly modified in response to input patterns and in accordance with the rules underlying plasticity. Willshaw and Malsburg in 1976 proposed a mathematical topography formation model which was capable of forming topographic connections between two layers [56]. Also, Kohonen in 1982 proposed the self-organizing map (SOM) algorithm, which describes a competitive learning rule to form a topology preserving mapping [27, 28, 29]. An almost-sure convergence of the SOM algorithm was given by Forte and Pagés [14]. Additionally, within the next few years, various extensions to the SOM algorithm were proposed. Examples include the temporal Kohonen map [8], which extends the SOM by adding the activity of leaky integrators to the SOM, and the recursive SOM [19, 53], which extends the SOM by establishing feedback to represent time. More recently, Lücke and Malsburg have discussed a self-organization process which reflects the hierarchical nature of receptive field formation [30, 31]. They take a minicolumn to consist of excitatory McCulloch–Pitts neurons and show that if the dynamics is weakly coupled to input by afferent fibers and subjects to Hebbian synaptic plasticity, then a self-organization of minicolumnar receptive fields is induced.

Alternatively, self-organization may proceed on a recurrent network. Hopfield in 1982 initiated a recurrent network of nerve cells, whose couplings are established in response to input patterns and in accordance with Hebbian synaptic plasticity [23]. He used the approach of energy minimization to show that the network's dynamics will tend toward a stable equilibrium state when the retrieval operation is performed asynchronously. The Hopfield network was designed to work as a content-addressable memory (CAM) on the basis of collective dynamics and computing with attractors. Meanwhile, Cohen and Grossberg in 1983 initiated a general model of a nonlinear cooperative-competitive neural network [9, 17]. Cohen and Grossberg constructed a global Lyapunov function for assessing the stability of network dynamics and described a general principle for designing CAM networks.

However, the previous models for self-organization are inherently static, with time taking a secondary role in network architecture [37]. These models require preprocessors to encode input patterns in synaptic weight matrices, thereby converting temporal dynamic information into static spatial information outside the network. Hebbian synaptic plasticity is used in the construction of a synaptic weight matrix only for the initial input patterns but not for network evolution.

This motivates us to study self-organization by proceeding on a neural network entwined with nonlinearity and dynamism. What we need is the quest for a deep theory of complex networks, which allows for describing structural complexity, network evolution, dynamical complexity, and meta-complication [49]. We build a model of an evolutionary network consisting of enormous numbers of McCulloch–Pitts neurons, each simple, but myriad interactions between them could be extremely complicated. The influence of McCulloch–Pitts neurons was very much in the thoughts of von Neumann as he developed his ideas for the modern digital computer [5, 17], and was very much in the work of Minsky in automata theory and theory of computation [35].

In our model of the evolutionary network, the time- and activity-dependent nodal-and-coupling changes are based on an algorithmic aspect of Hebbian synaptic plasticity. Each change reflects the interplay and large-scale integration between neuronal and synaptic activity. We take the view that Hebb synapses are crucial to the generation of neural synchrony [46, 48, 52, 58] and to the development of diffuse structure of cell assemblies [20, 36, 41]. This leads to addressing the mathematical problems of the tendency of neurons to synchronize underlying Hebbian synaptic plasticity, the stability of neural synchrony, the effect of neural synchrony, and the determination of the size of synchronously firing neural groups.

2. Evolutionary network model. According to the all-or-none character of neural activity, McCulloch and Pitts in 1943 introduced a binary processing unit which performed simple threshold logic. They pointed out that the brain was potentially a powerful logic and computational device [3, 33]. Here, through the use of McCulloch–Pitts neurons, we will construct an evolutionary network which straightens out an alternating change in its nodal and coupling dynamics. The model of the evolutionary network we are concerned with consists of a population of n distinct integrate-and-fire processing units (McCulloch–Pitts neurons or neurons) [33, 35]; each constantly integrates all incoming signals transferred from synapses on its cell body and dendrites, and fires action potentials to send signals to other neurons when the combined effect reaches its threshold. Name those *neurons* $1, \dots, n$ and denote by the ordered pair (i, j) the *evolutionary coupling* linking neuron j to neuron i. All the evolutionary couplings are fundamentally dynamic, be they symmetrical [23, 57] or unsymmetrical, hierarchical, small-world [54], or reverberating-circuit [44], to reflect the interconnected neurons in the brain. To each neuron i there is associated the *threshold* b_i and the *active state variable* $x_i = 0$ or 1, and to each evolutionary coupling (i, j) there is associated the *coupling strength variable* a_{ij}. The phase space of the evolutionary network of n coupled neurons is denoted by $\{0, 1\}^n$, the binary code consisting of all 01-strings $x_1x_2 \cdots x_n$ of fixed-length n.

Fix $t = 0, 1, \dots$ for the moment. The corresponding *neuronal active state* and *evolutionary coupling state* are denoted by $x(t) = (x_1(t), x_2(t), \dots, x_n(t))$ and $A(t) = [a_{ij}(t)]_{n\times n}$, respectively. The function *hea* is the Heaviside function: $hea(u) = 1$ for $u \geq 0$, otherwise 0, which describes an instantaneous unit pulse. To generate the neuronal active state $x(t + 1)$ and the evolutionary coupling state $A(t + 1)$, we have to introduce the function $H_{A(t),s(t)}$ and the plasticity parameter $\mathcal{D}_{x(t)\to x(t+1)} a_{ij}$. We associate to t a nonempty subset $s(t)$ of $\{1, 2, \dots, n\}$ (denoting the neurons that adjust their activity at time t) and a function $H_{A(t),s(t)} : \{0, 1\}^n \longrightarrow \{0, 1\}^n$ whose ith component is defined by

$$[H_{A(t),s(t)}(x)]_i = x_i \quad \text{if } i \notin s(t),$$

otherwise

$$[H_{A(t),s(t)}(x)]_i = hea\left(\sum_{j=1}^{n} a_{ij}(t)x_j - b_i\right),$$

such that

$$x(t + 1) = H_{A(t),s(t)}(x(t)). \tag{1}$$

For every $i, j = 1, 2 \dots, n$, denote by $\mathcal{D}_{x(t)\to x(t+1)} a_{ij}$ the parameter which is a representative for a choice of real numbers, so that the evolutionary coupling state $a_{ij}(t + 1)$ at (i, j) is given by the parametric equation

$$a_{ij}(t + 1) = a_{ij}(t) + \mathcal{D}_{x(t)\to x(t+1)} a_{ij}. \tag{2}$$

When $\mathcal{D}_{x(t)\to x(t+1)}a_{ij}$ varies, $a_{ij}(t+1)$ changes. And this is how plasticity is created in the dynamics of the evolutionary network. The parameter $\mathcal{D}_{x(t)\to x(t+1)}a_{ij}$ in (2) is called the *plasticity parameter* of the evolutionary coupling (i,j), which varies with respect to the neuronal active state changing from $x(t)$ to $x(t+1)$. Now let t vary. The alternating nature of (1) and (2) reveals a dynamical-combinatorial process in which the neuronal active state and the evolutionary coupling state keep changing, looping back on one another with extremely fast switches (at the millisecond level) and giving rise to patterns of indescribable complexity. The neuronal active state changing from $x(t)$ to $x(t+1)$ by (1) leads to the choices of plasticity parameters and results in the changes of the evolutionary coupling state from $a_{ij}(t)$ to $a_{ij}(t+1)$ by (2). The changes of the evolutionary coupling state loop back on the changes of the neuronal active state from $x(t+1)$ to $x(t+2)$ by (1), and then on the changes of the evolutionary coupling state from $a_{ij}(t+1)$ to $a_{ij}(t+2)$ by (2), and continue recursively. So we have a nonlinear dynamical system of the n coupled neurons modeled by the following nonlinear parametric equations:

$$x(t+1) = H_{A(t),s(t)}(x(t)), \quad t = 0,1,\ldots, \tag{3}$$

$$A(t+1) = A(t) + D_{x(t)\to x(t+1)}A, \quad t = 0,1,\ldots, \tag{4}$$

where $H_{A(t),s(t)}(x)$ are the time-and-state varying functions encoding the dynamics, and each $\mathcal{D}_{x(t)\to x(t+1)}A$ is an n-by-n real matrix whose (i,j)-entry is $\mathcal{D}_{x(t)\to x(t+1)}a_{ij}$. The plasticity parameters quantify plasticity of evolutionary couplings that allows the system as a whole to undergo spontaneous organization.

There are many different ways in which we carry out the updating specified by the choice of $s(t)$ for $t = 0,1,\ldots$. Let us call that the discrete flow $x(t)$ generated by (3) and (4) *iterates asynchronously* if $s(t)$ is a singleton for all $t = 0,1,\ldots$ and the union $\cup_{t\geq\tau}s(t)$ equals $\{1,2,\ldots,n\}$ for any $\tau \geq 0$. We can begin asynchronous updating in the way that we select at random a neuron to adjust its activity at each time step $t = 0,1,\ldots,$ or equivalently, from an autonomous point of view, we can begin asynchronous updating in the way that each neuron independently chooses to adjust its activity with some constant probability per unit time [22]. The latter can generate a random sequence of updating neurons in time because there is vanishingly small probability of two neurons choosing to adjust themselves at exactly the same moment. Here we adopt asynchronous updating which allows us to concentrate on the alternating changes between the nodal and coupling dynamics.

Let us note that based on asynchronous updating, we can generate a specific evolutionary network whose dynamics obey the Gauss–Seidel iteration. To see this, consider the case $s(t) = (t/n - [t/n])n + 1$, where $[t/n]$ denotes the greatest integer less than or equal to t/n for $t = 0,1,\ldots,$ and let $x(t)$ and $A(t)$ denote the corresponding neuronal activity state and evolutionary coupling state generated by (3) and (4), respectively. Put $y(t) = x(tn)$ and $w_{ij}(t) = a_{ij}(tn+i-1)$ for every $i,j = 1,2,\ldots,n$ and $t = 0,1,\ldots$. Then we obtain an evolutionary network whose coupling architecture at time t can be defined by the matrix $[w_{ij}(t)]_{n\times n}$, with the sequence of neuronal activity states $\{y(t);\ t = 0,1,\ldots\}$ encoding the network's dynamics. In this evolutionary network, the updating of y_i fulfills the Gauss–Seidel iteration

$$y_i(t+1) = hea\left(\sum_{j=1}^{i-1} w_{ij}(t)y_j(t+1) + \sum_{j=i}^{n} w_{ij}(t)y_j(t) - b_i\right).$$

3. Coincidence-detection evolving algorithm and synchronization problem. In what follows we introduce the coincidence-detection evolving algorithm which provides a way for the choices of plasticity parameters. This algorithm represents a generalized learning rule analogous to the coincidence-detection rule of Hebbian synaptic plasticity. Synaptic modification determined by the coincidence between pre- and postsynaptic activity is used as the bridging mechanism that guides the alternating changes of the evolutionary network's nodal and coupling dynamics.

For every $i, j = 1, 2, \ldots, n$ we first define the *indicator* δ_{ij} on $\{0, 1, \ldots\}$ as follows:

(i) Put $\delta_{ij}(0) = 0$.

(ii) Given $t = 0, 1, \ldots$ and the neuronal active state changing from $x(t)$ to $x(t+1)$ according to the dynamics (3).
If $(x_i(t), x_j(t)) = (1, 1)$ and $(x_i(t+1), x_j(t+1)) = (0, 1)$, put $\delta_{ij}(t+1) = 1$.
If $(x_i(t), x_j(t)) = (0, 1)$ and $(x_i(t+1), x_j(t+1)) = (1, 1)$, put $\delta_{ij}(t+1) = 1$.
If $(x_i(t), x_j(t)) = (1, 1)$ and $(x_i(t+1), x_j(t+1)) = (1, 1)$, put $\delta_{ij}(t+1) = \delta_{ij}(t)$.
If $(x_i(t), x_j(t)) = (0, 1)$ and $(x_i(t+1), x_j(t+1)) = (0, 1)$, put $\delta_{ij}(t+1) = \delta_{ij}(t)$.

(iii) If the pair of $(x_i(t), x_j(t))$ and $(x_i(t+1), x_j(t+1))$ is not in the case of (ii), put $\delta_{ij}(t+1) = 0$.

The binary value $\delta_{ij}(t+1)$ signifies whether the active state of neuron j at time t has a tendency to change the active state of neuron i at time $t+1$. Armed with the indicator δ_{ij}, we define now the *coincidence-detection evolving algorithm*:

For every $t = 0, 1, \ldots$ and $1 \leq i, j \leq n$,

(I) $\mathcal{D}_{x(t)\to x(t+1)} a_{ij} \geq 0$ if $i, j \in \mathbf{1}(x(t+1))$; otherwise $\mathcal{D}_{x(t)\to x(t+1)} a_{ij} \leq 0$;

(II) if $\delta_{ij}(t+1) > \delta_{ji}(t+1)$, then $|\mathcal{D}_{x(t)\to x(t+1)} a_{ij}| \geq |\mathcal{D}_{x(t)\to x(t+1)} a_{ji}|$.

Rule (I) suggests that if two neurons are not active synchronously, the coupling strength between two neurons can be either unchanged or weakened. To be more specific, if the coupling strength is selectively to be unchanged, then rule (I) reduces to an algorithmic aspect of Hebbian synaptic plasticity.

The algorithm basically describes the tendency for changing the evolutionary coupling strengths from $a_{ij}(t)$ to $a_{ij}(t+1)$, which might keep the active (resp., quiescent) neurons active (resp., quiescent) from time $t+1$ to $t+2$. So we obtain, when t varies, myriad groups of neurons (which allow overlapping communities) that are prone to be active or quiescent transiently, dedicating to drive themselves into sustained activity of synchrony. The evolving time the dynamics involves determines the role the coincidence-detection rule plays in accumulating vast numbers of time- and activity-dependent changes in evolutionary couplings, in places forming uncertainty that can grow in the diversity of network evolution (see Figure 1).

Undergoing the dynamical-combinatorial process of network evolution, the neuronal active state $x(t)$ and the evolutionary coupling state $A(t)$ can be generated by (3) and (4), respectively, and we say that neurons in a subset V of $\{1, \ldots, n\}$ are *synchronized* with respect to $x(t)$ if there is a $T \geq 0$ such that the condition $\mathbf{1}(x(t)) = V$ holds true for all $t \geq T$, where $\mathbf{1}(x(t))$ denotes the collection of all active neurons at time t. In the present paper we wish to explore the synchronization problem: *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Do there exist a finite $T \geq 0$ and a subset V of $\{1, \ldots, n\}$ such that $\mathbf{1}(x(t)) = V$ for all $t \geq T$?* To be more specific, the synchronization problem is the mathematical equivalent of the separation problem (see Figure 2): *Do there exist a finite $T \geq 0$ and a subset V of $\{1, \ldots, n\}$*

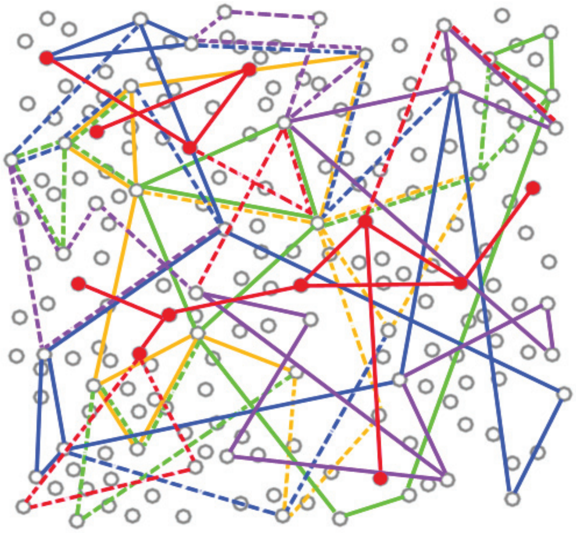

FIG. 1. *The coupling changes based on the coincidence-detection evolving algorithm. Fix t and consider the corresponding active neurons (red nodes). It follows from the coincidence-detection evolving algorithm that the evolutionary couplings will be strengthened (solid red lines) if they are within the group of active neurons (red nodes); otherwise the evolutionary couplings will be weakened (dashed red lines). The nodal dynamics lead to myriad groups of active neurons which can bring about cumulative changes in the shape of interconnectedness. Colors indicate different changes of evolutionary couplings on time steps* $t = 0, 1, \ldots$ *(solid lines: positive plasticity parameters; dashed lines: negative plasticity parameters).*

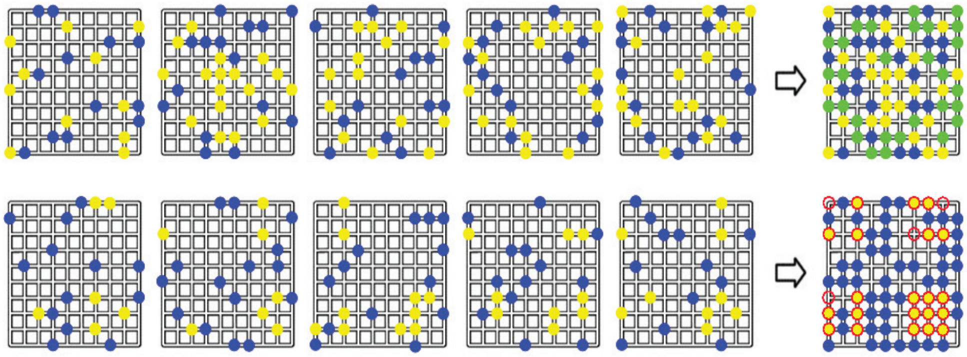

FIG. 2. *The spatial distributions of the positive and negative plasticity parameters. The positive plasticity parameters are represented geometrically as yellow grid points on the* n*-by-*n *grids (for clarity we put* $n = 10$*), and the negative plasticity parameters as blue ones. As the evolutionary network evolves, the spatial distributions of the positive and negative plasticity parameters change from left to right, and the grids at the end of the two rows show the cumulative changes of these distributions (yellow: positive; blue: negative; green: both positive and negative have occurred). The grids in the first row display bewildering patterns, in which the yellow and blue grid points are located in a nearly random way, whereas the grids in the second row exhibit a spontaneously organized process, in which the yellow and blue grid points are located in two fixed clusters separated by red circles (the evolutionary couplings relating to a group of synchronized firing neurons). The separation of the grid points exhibits self-sustaining activity of coupling strengthening when neurons fire in synchrony.*

such that

$$\bigcap_{t\geq T}\{(i,j);\ \mathcal{D}_{x(t)\to x(t+1)}a_{ij}\geq 0\}\supset V\times V\supset\bigcup_{t\geq T}\{(i,j);\ \mathcal{D}_{x(t)\to x(t+1)}a_{ij}>0\}?$$

We notice that previous models of network dynamics have focused on a logical strategy necessary for networked systems to optimize some aspect of their performance, such as using a gradient descent method to minimize the mean square error (the LMS algorithm [55] or the backpropagation algorithm [39]) or using a global Lyapunov method to provide absolute stability of global pattern formation (see [23] for the discrete time Lyapunov function, [9] for an explicit construction of a global Lyapunov function given by Cohen and Grossberg, and [17] for a survey of the Cohen–Grossberg model and its relations to a number of popular models of content-addressable memory). By contrast, the coincidence-detection evolving algorithm we describe here offers predictions in measurable coupling changes merely based on the coincidence-detection rule of Hebbian synaptic plasticity. It reveals that many intricate, outwardly indecipherable patterns of organization can be determined by small changes of coupling strengths depending on the nodal dynamics. Plasticity in evolutionary couplings implies a degree of uncertainty in the dynamics of networked systems, which need not navigate to arrive at a local minimum or maximum of a performance function. Related lines of research in switched linear networked systems have also provided a concise theoretical framework similar to this point [24, 43]. It has shown that in a switched linear networked system all switching sequences of coupled matrices can be asymptotically stable [43, 45], but no common quadratic Lyapunov function exists through the use of a theoretical result of optimal joint spectral radius range for the simultaneous contractibility of coupled matrices [4]. Finding a common quadratic Lyapunov function in such a switched linear networked system becomes increasingly hard as the complexity of coupled matrices and the dimension of the networked system go up [4]. The above discussion suggests that the use of a Lyapunov function might have its own limitations to study the synchronization problem formulated in a high-dimensional nonlinear evolutionary networked system.

4. Driving forces. To solve the synchronization problem, we introduce two evolutionary quantities to measure the driving forces of the evolutionary network's dynamics. We consider the "driving forces" derived from the evolutionary network's nodal and coupling activity, without invoking any Lyapunov function or "physical energy" to control system dynamics.

For any 01-string $x=x_1x_2\cdots x_n$ we define

$$\mathbf{1}(x)=\{i;\ x_i=1,\ 1\leq i\leq n\}$$

and

$$\mathbf{0}(x)=\{i;\ x_i=0,\ 1\leq i\leq n\}.$$

Denote by $\langle\cdot,\cdot\rangle$ the usual scalar product in $\mathbb{R}^n$. Given any two subsets U and V of $\{1,2,\dots,n\}$ and any $t=0,1,\dots$ we define

$$l_t(U,V)=\langle A(t)u,v\rangle,$$

where $u,v\in\{0,1\}^n$ with $\mathbf{1}(u)=U$ and $\mathbf{1}(v)=V$. For every $t=0,1,\dots,$ let

$$[x(t)]^+=\mathbf{0}(x(t))\cap\mathbf{1}(x(t+1))$$

and

$$[x(t)]^- = \mathbf{1}(x(t)) \cap \mathbf{0}(x(t+1)).$$

The *fired-driven strength evaluated at time* t, denoted as $FS(t)$, and the *unfired-driven strength evaluated at time* t, denoted as $US(t)$, are defined by

$$FS(t) = l_t(\mathbf{1}(x(t)), [x(t)]^+)$$

and

$$US(t) = l_t(\mathbf{1}(x(t)), [x(t)]^-).$$

The fired-driven strength $FS(t)$ is not necessarily greater than the unfired-driven strength $US(t)$ over time, but when the discrete flow $x(t)$ behaves in the way that $x(t_*) = x(t^*) \neq x(\hat{t})$ with $t_* < \hat{t} < t^*$ (a feedback loop initiated by active neurons at time t_*), the fired-driven strengths and the unfired-driven strengths in the period of t_* and t^* emerge the orderliness. The order comes from the combined effect of the structural and dynamical complexity of the evolutionary network, in which the updating neuron $s(t)$ and the plasticity parameter $\mathcal{D}_{x(t)\to x(t+1)} a_{ij}$ are arbitrarily chosen for all $t = 0, 1, \dots$ and $i, j = 1, 2, \dots, n$ (see Figure 3).

THEOREM 1. *If $x(t)$ iterates with $x(t_*) = x(t^*) \neq x(\hat{t})$ for some $t_* < \hat{t} < t^*$, then the orderliness*

$$\begin{aligned} FS(t_*) + &FS(t_*+1) + \cdots + FS(t^*-1) \\ &> US(t_*) + US(t_*+1) + \cdots + US(t^*-1) \end{aligned} \tag{5}$$

emerges.

Proof. Let

$$\Lambda^+ = \{t;\ [x(t)]^+ \neq \emptyset,\ t_* \le t < t^*\}$$

and

$$\Lambda^- = \{t;\ [x(t)]^- \neq \emptyset,\ t_* \le t < t^*\}.$$

Then $\Lambda^+ \neq \emptyset$ and $\Lambda^- \neq \emptyset$. Indeed, if $\Lambda^+ = \emptyset$ or $\Lambda^- = \emptyset$, then either

$$\mathbf{1}(x(t_*)) \supset \mathbf{1}(x(t_*+1)) \supset \cdots \supset \mathbf{1}(x(t^*)) \tag{6}$$

or

$$\mathbf{1}(x(t_*)) \subset \mathbf{1}(x(t_*+1)) \subset \cdots \subset \mathbf{1}(x(t^*)). \tag{7}$$

Either (6) or (7) with the condition $x(t_*) = x(t^*)$ gives

$$x(t_*) = x(t_*+1) = \cdots = x(\hat{t}) = \cdots = x(t^*-1) = x(t^*),$$

contradicting the assumption $x(t^*) \neq x(\hat{t})$. The dynamics (3) ensures that

$$[x(t)]^+, [x(t)]^- \subset s(t) \quad \text{for each } t = 0, 1, \dots,$$

$$FS(t) \geq \sum_{j \in [x(t)]^+} b_j \quad \text{for each } t \in \Lambda^+,$$

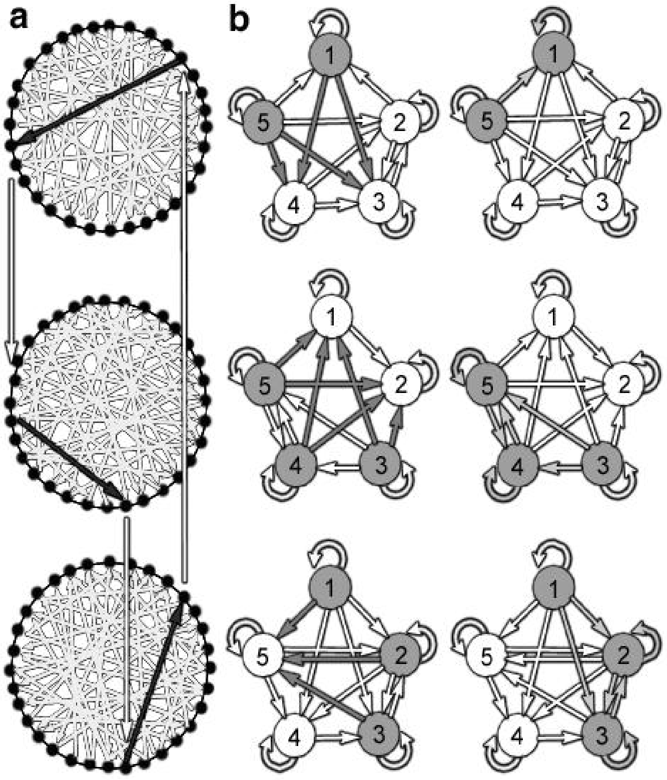

Fig. 3. *The driving forces underlying the evolutionary network's dynamics.* (a) *Each of the three wiring diagrams starts with a ring lattice of* 2^n *nodes (for clarity* $n = 5$ *is shown here); each node denotes one of the neuronal active states in the phase space* $\{0,1\}^n$. *Links (arrows) in each diagram wired from one node* i *to another node* j *indicate the possibility of the changes of neuronal active states from node* i *(at time* t*) to node* j *(at time* $t+1$*). There are many different links starting from each node because of the choices of plasticity parameters. The black arrows show a feedback loop* $x(t) = 10001$, $x(t+1) = 00111$, $x(t+2) = 11100$, *and* $x(t+3) = 10001$ *of one possible discrete flow in the phase space* $\{0,1\}^n$. (b) *The active neurons at time* t, $t+1$, *and* $t+2$, *as seen in* (a), *are indicated by gray nodes in each diagram (from top to bottom). The gray arrows in the left column give a specific way of determining the fired-driven strengths that make quiescent neurons fired at the next time (*t*: neurons* 3 *and* 4*;* $t+1$*: neurons* 1 *and* 2*;* $t+2$*: neuron* 5*), and the gray arrows in the right column illustrate the unfired-driven strengths that make active neurons quiescent at the next time (*t*: neuron* 1*;* $t+1$*: neurons* 4 *and* 5*;* $t+2$*: neurons* 2 *and* 3*). All of the gray arrows exhibit a fundamental law governing the interactions between nodal and coupling dynamics.*

and

$$US(t) < \sum_{j \in [x(t)]^-} b_j \quad \text{for each } t \in \Lambda^-.$$

Therefore

$$FS(t_*) + FS(t_*+1) + \cdots + FS(t^*-1) \geq \sum_{t \in \Lambda^+} \sum_{j \in [x(t)]^+} b_j \tag{8}$$

and

$$US(t_*) + US(t_*+1) + \cdots + US(t^*-1) < \sum_{t \in \Lambda^-} \sum_{j \in [x(t)]^-} b_j. \tag{9}$$

Since

$$\begin{aligned}&\sum_{t\in\Lambda^+}\sum_{j\in[x(t)]^+} b_j - \sum_{t\in\Lambda^-}\sum_{j\in[x(t)]^-} b_j\\ &= \sum_{t\in\Lambda^+}\sum_{j\in\mathbf{1}(x(t+1))\setminus\mathbf{1}(x(t))} b_j - \sum_{t\in\Lambda^-}\sum_{j\in\mathbf{1}(x(t))\setminus\mathbf{1}(x(t+1))} b_j\\ &= \sum_{t_*\le t<t^*}\langle x(t+1)-x(t), b\rangle = 0,\end{aligned}$$

inequality (5) follows from (8) and (9), and the proof is complete. □

5. Synaptic plasticity and neural synchrony. Theorem 1 exhibits a global, universal feature of the driving forces zeroing in on the order shared in the rise of diversity of network evolution. By contrast, the coincidence-detection evolving algorithm displays a local, uncertain feature of a generalized learning rule focusing on the time- and activity-dependent changes in coupling strengths. Combining the two distinct concepts gives a concise picture of regulation, concentrating on the assembling coordination of excitability within groups of neurons.

For this, define $E_U(t_*, t^*)$ to be $\sum_{i\in U}\min(\{a_{ii}(t);\ t = t_*, \ldots, t^*\})$, a quantity that measures the minimal total excitability within the group of neurons U in the period of time t_* and t^* with $t_* \le t^*$, where the coupling strength variable a_{ii} is considered to be a measure of excitability with respect to neuron i and, according to the working of neuron i, the increased excitability has a tendency to decrease the threshold for generating action potentials. Several lines of evidence in neuroscience have shown that activity-dependent modulation in intrinsic neuronal excitability could have a crucial role in modifying the integrative properties of neurons and their circuit dynamics [6, 10, 12, 26, 32, 51, 59]. This motivates us to use all those quantities $E_U(t_*, t^*)$ as an index for determining the existence of excitability coordination between groups of neurons, and we say that the minimal total excitability in the period of time $t = t_*, t_*+1, \ldots, t^*$ satisfies the *assembling coordination* if

$$E_U(t_*, t^*) \ge \sum_{i,j\in U}\max(\{a_{ij}(t) - a_{ji}(t);\ t = t_*, \ldots, t^*\}\cup\{0\}) \tag{10}$$

for each nonempty subset U of $\{1, 2, \ldots, n\}$.

Armed with the concept of assembling coordination, a solution to the synchronization problem, mentioned in section 2, may be stated as follows.

THEOREM 2. *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Given any initial neuronal active state $x(0)$ in the phase space $\{0,1\}^n$ and letting the discrete flow $x(t)$ iterate asynchronously, then a finite $T \ge 0$ can be determined so that if the minimal total excitability in the period of time $t = 0, 1, \ldots, T$ satisfies the assembling coordination, then a subset V of $\{1, 2, \ldots, n\}$ can be sorted out such that $\mathbf{1}(x(t)) = V$ for all $t \ge T$.*

Proof. Let $x(0)$ be any initial neuronal active state in $\{0,1\}^n$, and let $x(t)$ iterate asynchronously, guided by the dynamics (3), (4) and the coincidence-detection evolving algorithm.

We shall establish the following.

ASSERTION. *Given any $t_*, t^* = 0, 1, \ldots$ with $t_* \le t^*$, if the minimal total excitability in the period of time $t = t_*, t_*+1, \ldots, t^*$ fulfills the assembling coordination,* *then a feedback loop cannot occur in the fragment* $x(t_*), x(t_*+1), \ldots, x(t^*)$ *of the discrete flow* $x(t)$.

We will prove the assertion by arguing indirectly: assume that there exists $\hat{t}$ with $t_* < \hat{t} < t^*$ such that $x(t_*) = x(t^*) \neq x(\hat{t})$. The asynchronous updating of $x(t)$ implies that for every $t = t_*, t_* + 1, \ldots, t^* - 1$,

$$\sharp[x(t)]^+ + \sharp[x(t)]^- \leq 1. \tag{11}$$

Since

$$\sum_{t_* \leq t < t^*} (x_j(t+1) - x_j(t)) = 0 \tag{12}$$

for every $j = 1, 2, \ldots, n$, we deduce that

$$\bigcup_{t_* \leq t < t^*} [x(t)]^+ = \bigcup_{t_* \leq t < t^*} [x(t)]^-. \tag{13}$$

We can write (13) as a set of distinct elements

$$\{m_1, m_2, \ldots, m_q\}, \tag{14}$$

and for any $j = 1, 2, \ldots, q$ we put

$$M_j^+ = \{t;\ [x(t)]^+ = \{m_j\},\ t_* \leq t < t^*\},$$

$$M_j^- = \{t;\ [x(t)]^- = \{m_j\},\ t_* \leq t < t^*\}.$$

Then

$$\sharp M_j^+ = \sharp M_j^- \quad \text{for } j = 1, 2, \ldots, q \tag{15}$$

by (12). Consider the backward shift of the discrete flow $x(t)$ in the period of time t_* and t^*, and put

$$y(t) = x(t-1) \ \text{ for every } t = t_* + 1, \ldots, t^* \text{ and } y(t_*) = y(t^*).$$

For any $t = t_*, \ldots, t^* - 1$ we introduce two new quantities as follows:

$$\widetilde{FS}(t) = l_t(\mathbf{1}(y(t+1)), \mathbf{0}(y(t+1)) \cap \mathbf{1}(y(t)))$$

and

$$\widetilde{US}(t) = l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1)) \cap \mathbf{0}(y(t))).$$

A computation shows that

$$
\begin{aligned}
&\sum_{t_* \le t < t^*} (FS(t) - US(t)) + \sum_{t_* \le t < t^*} (\widetilde{FS}(t) - \widetilde{US}(t)) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^-) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1))) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^+) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^-) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^-) \qquad (16) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1))) \\
&= \sum_{t_* \le t < t^*} l_t([x(t)]^-, [x(t)]^+) + \sum_{t_* \le t < t^*} l_t([x(t)]^+, [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t([x(t)]^+, [x(t)]^+) - \sum_{t_* \le t < t^*} l_t([x(t)]^-, [x(t)]^-) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^-) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1)))
\end{aligned}
$$

and

$$
\begin{aligned}
&\sum_{t_* \le t < t^*} (FS(t) - US(t)) - \sum_{t_* \le t < t^*} (\widetilde{FS}(t) - \widetilde{US}(t)) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1))) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), \mathbf{1}(x(t))) \qquad (17) \\
&\quad + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t([x(t)]^+, \mathbf{1}(x(t))) + \sum_{t_* \le t < t^*} l_t([x(t)]^-, \mathbf{1}(x(t))) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t))) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))).
\end{aligned}
$$

Claim 1.

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t([x(t)]^+,[x(t)]^+)+\sum_{t_*\le t<t^*} l_t([x(t)]^-,[x(t)]^-)\\ \ge&\sum_{1\le j,k\le q} 2\min(\{\sharp M_j^-,\sharp M_k^-\})\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\ldots,t^*\}\cup\{0\}).\end{aligned}$$

Proof of Claim 1. We first construct an array of dots as follows:

$$\begin{array}{ccccccc}
\bullet & \bullet & \bullet & \bullet & & \bullet & \bullet\\
\bullet & \bullet & & \bullet & & \bullet & \bullet\\
 & \bullet & & \bullet & \cdots & \bullet & \bullet\\
 & \bullet & & \bullet & & & \bullet\\
 & \bullet & & & & & \bullet\\
 & & & & & & \bullet
\end{array}$$

The array consists of q columns, q being the number of m_j's in (14). For each $j=1,2,\ldots,q$ the dots in the jth column are arranged consecutively from the top, and the number of dots in the jth column is equal to $\sharp M_j^-$, and so to $\sharp M_j^+$ by (15). Let r denote the number of rows in the array and for every $i=1,2,\ldots,r$ we define

$$V_i=\{j;\ \text{the } (i,j)\text{-entry of the array is equipped with } \bullet\ ,\ j=1,2,\ldots,q\}.$$

For each $i=1,2,\ldots,r$ and for each choice of $j\in V_i$, we assign to the dot in the ith row and jth column of the array, a pair (t_{ij},u_{ij}) with

$$t_{ij}\in M_j^+ \quad\text{and}\quad u_{ij}\in M_j^-,$$

such that

$$t_{1j}<t_{2j}<\cdots<t_{(\sharp M_j^+)j}$$

and

$$u_{1j}<u_{2j}<\cdots<u_{(\sharp M_j^-)j}.$$

So according to this construction and applying the assembling coordination (10) to $U=V_i$, we deduce that

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t([x(t)]^+,[x(t)]^+)+\sum_{t_*\le t<t^*} l_t([x(t)]^-,[x(t)]^-)\\
=&\sum_{1\le i\le r}\sum_{j\in V_i} a_{m_jm_j}(t_{ij})+\sum_{1\le i\le r}\sum_{j\in V_i} a_{m_jm_j}(u_{ij})\\
\ge&\sum_{1\le i\le r}\sum_{j\in V_i}\min(\{a_{m_jm_j}(t);\ t=t_*,\ldots,t^*\})+\sum_{1\le i\le r}\sum_{j\in V_i}\min(\{a_{m_jm_j}(t);\ t=t_*,\ldots,t^*\})\\
\ge&\sum_{1\le i\le r}\sum_{j,k\in V_i} 2\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\ldots,t^*\}\cup\{0\})\\
=&\sum_{1\le j,k\le q} 2\min(\{\sharp M_j^-,\sharp M_k^-\})\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\ldots,t^*\}\cup\{0\}),\end{aligned}$$

establishing Claim 1.

Claim 2.

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t)),[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t)),[x(t)]^-)\\&-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t)))+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t)))\\ \le&\sum_{1\le j,k\le q}\sum_{1\le i\le \sharp M_j^+}(x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij})-a_{m_km_j}(t_{ij})))\\&-\sum_{1\le j,k\le q}\sum_{1\le i\le \sharp M_j^-}(x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij})-a_{m_km_j}(u_{ij}))).\end{aligned}$$

Proof of Claim 2. For any $k\in\{1,2,\ldots,n\}\setminus\{m_1,m_2,\ldots,m_q\}$, we have either

$$\mathbf{1}(x(t))\cap\{k\}=\emptyset \quad\text{for all}\quad t=t_*,t_*+1,\ldots,t^*-1$$

or

$$\mathbf{1}(x(t))\cap\{k\}=\{k\} \quad\text{for all}\quad t=t_*,t_*+1,\ldots,t^*-1.$$

Case 1. $\mathbf{1}(x(t))\cap\{k\}=\emptyset$ *for all* $t=t_*,t_*+1,\ldots,t^*-1$. Then

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^-)\\&-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t))\cap\{k\})+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t))\cap\{k\})=0.\end{aligned}$$

Case 2. $\mathbf{1}(x(t))\cap\{k\}=\{k\}$ *for all* $t=t_*,t_*+1,\ldots,t^*-1$. Then

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^-)\\&-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t))\cap\{k\})+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t))\cap\{k\})\\=&\sum_{1\le j\le q}\sum_{1\le i\le \sharp M_j^-}(a_{m_jk}(t_{ij})-a_{m_jk}(u_{ij}))-\sum_{1\le j\le q}\sum_{1\le i\le \sharp M_j^-}(a_{km_j}(t_{ij})-a_{km_j}(u_{ij})).\end{aligned}$$

Fix $1\le j\le q$. Then (12) implies

$$\sum_{t_*\le t<t^*}(x_{m_j}(t+1)-x_{m_j}(t))=0,$$

and therefore

$$t_{1j}<u_{1j}<t_{2j}<u_{2j}<\cdots<t_{(\sharp M_j^+)j}<u_{(\sharp M_j^-)j} \tag{18}$$

or

$$u_{1j}<t_{1j}<u_{2j}<t_{2j}<\cdots<u_{(\sharp M_j^-)j}<t_{(\sharp M_j^+)j}. \tag{19}$$

Inequality (18) implies that for any $i = 1, 2, \ldots, \sharp M_j^+$,

$$\begin{aligned} (x_{m_j}(t_{ij}), x_k(t_{ij})) &= (0, 1), \\ (x_{m_j}(t_{ij}+1), x_k(t_{ij}+1)) &= (1, 1), \\ &\vdots \\ (x_{m_j}(u_{ij}-1), x_k(u_{ij}-1)) &= (1, 1), \\ (x_{m_j}(u_{ij}), x_k(u_{ij})) &= (1, 1). \end{aligned}$$

Thus for every $t = t_{ij}, t_{ij}+1, \ldots, u_{ij}-1$, we have

$$\delta_{m_j k}(t+1) = 1 \qquad \text{and} \qquad \delta_{k m_j}(t+1) = 0,$$

and according to the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)} a_{m_j k} \geq \mathcal{D}_{x(t)\to x(t+1)} a_{k m_j} \geq 0.$$

Therefore

$$\begin{aligned} &\sum_{1\leq i\leq \sharp M_j^-} (a_{m_j k}(t_{ij}) - a_{m_j k}(u_{ij})) - \sum_{1\leq i\leq \sharp M_j^-} (a_{k m_j}(t_{ij}) - a_{k m_j}(u_{ij})) \\ (20) \qquad &= \sum_{1\leq i\leq \sharp M_j^-} (-\mathcal{D}_{x(t_{ij})\to x(t_{ij}+1)} a_{m_j k} - \cdots - \mathcal{D}_{x(u_{ij}-1)\to x(u_{ij})} a_{m_j k}) \\ &\quad - \sum_{1\leq i\leq \sharp M_j^-} (-\mathcal{D}_{x(t_{ij})\to x(t_{ij}+1)} a_{k m_j} - \cdots - \mathcal{D}_{x(u_{ij}-1)\to x(u_{ij})} a_{k m_j}) \leq 0. \end{aligned}$$

On the other hand, (19) implies that for any $i = 1, 2, \ldots, \sharp M_j^-$,

$$\begin{aligned} (x_{m_j}(u_{ij}), x_k(u_{ij})) &= (1, 1), \\ (x_{m_j}(u_{ij}+1), x_k(u_{ij}+1)) &= (0, 1), \\ &\vdots \\ (x_{m_j}(t_{ij}-1), x_k(t_{ij}-1)) &= (0, 1), \\ (x_{m_j}(t_{ij}), x_k(t_{ij})) &= (0, 1). \end{aligned}$$

Thus for every $t = u_{ij}, u_{ij}+1, \ldots, t_{ij}-1$, we have

$$\delta_{m_j k}(t+1) = 1 \qquad \text{and} \qquad \delta_{k m_j}(t+1) = 0,$$

and by the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)} a_{m_j k} \leq \mathcal{D}_{x(t)\to x(t+1)} a_{k m_j} \leq 0.$$

Therefore

$$\begin{aligned} &\sum_{1\leq i\leq \sharp M_j^-} (a_{m_j k}(t_{ij}) - a_{m_j k}(u_{ij})) - \sum_{1\leq i\leq \sharp M_j^-} (a_{k m_j}(t_{ij}) - a_{k m_j}(u_{ij})) \\ (21) \qquad &= \sum_{1\leq i\leq \sharp M_j^-} (\mathcal{D}_{x(u_{ij})\to x(u_{ij}+1)} a_{m_j k} + \cdots + \mathcal{D}_{x(t_{ij}-1)\to x(t_{ij})} a_{m_j k}) \\ &\quad - \sum_{1\leq i\leq \sharp M_j^-} (\mathcal{D}_{x(u_{ij})\to x(u_{ij}+1)} a_{k m_j} + \cdots + \mathcal{D}_{x(t_{ij}-1)\to x(t_{ij})} a_{k m_j}) \leq 0. \end{aligned}$$

Inequalities (20) and (21) imply

$$\sum_{1\le j\le q}\sum_{1\le i\le \sharp M_j^-}(a_{m_jk}(t_{ij})-a_{m_jk}(u_{ij}))-\sum_{1\le j\le q}\sum_{1\le i\le \sharp M_j^-}(a_{km_j}(t_{ij})-a_{km_j}(u_{ij}))\le 0.$$

Combining Cases 1 and 2 gives

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap\{k\},[x(t)]^-)\\&-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t))\cap\{k\})+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t))\cap\{k\})\le 0\end{aligned}$$

for every $k\in\{1,2,\dots,n\}\setminus\{m_1,m_2,\dots,m_q\}$. Put

$$M=\{m_1,m_2,\dots,m_q\}.$$

Then

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t)),[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t)),[x(t)]^-)\\&\quad-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t)))+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t)))\\&\le\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap M,[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t))\cap M,[x(t)]^-)\\&\quad-\sum_{t_*\le t<t^*} l_t([x(t)]^+,\mathbf{1}(x(t))\cap M)+\sum_{t_*\le t<t^*} l_t([x(t)]^-,\mathbf{1}(x(t))\cap M)\\&=\sum_{1\le j\le q}\sum_{1\le i\le\sharp M_j^+}\sum_{1\le k\le q}(x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij})-a_{m_km_j}(t_{ij})))\\&\quad-\sum_{1\le j\le q}\sum_{1\le i\le\sharp M_j^-}\sum_{1\le k\le q}(x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij})-a_{m_km_j}(u_{ij})))\\&=\sum_{1\le j,k\le q}\sum_{1\le i\le\sharp M_j^+}(x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij})-a_{m_km_j}(t_{ij})))\\&\quad-\sum_{1\le j,k\le q}\sum_{1\le i\le\sharp M_j^-}(x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij})-a_{m_km_j}(u_{ij}))).\end{aligned}$$

Claim 3.

$$\begin{aligned}&\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t+1)),[x(t)]^+)-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t+1)),[x(t)]^-)\\&-\sum_{t_*\le t<t^*} l_t(\mathbf{1}(y(t+1)),\mathbf{1}(y(t+1)))+\sum_{t_*\le t<t^*} l_t(\mathbf{1}(x(t+1)),\mathbf{1}(x(t)))\le 0.\end{aligned}$$

Proof of Claim 3. Using $y(t) = x(t-1)$ for $t = t_* + 1, \dots, t^*$, we can derive the following string of identities:

$$\begin{aligned}
&\sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^+) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), [x(t)]^-) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(y(t+1)), \mathbf{1}(y(t+1))) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))) \\
&\quad - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), \mathbf{1}(x(t))) + \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t))) \\
&= \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) - \sum_{t_* \le t < t^*} l_t(\mathbf{1}(x(t)), \mathbf{1}(x(t))) \\
&= \sum_{t_* \le t < t^*-1} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) + l_{t^*-1}(\mathbf{1}(x(t^*)), \mathbf{1}(x(t^*))) \\
&\quad - l_{t_*}(\mathbf{1}(x(t_*)), \mathbf{1}(x(t_*))) - \sum_{t_* \le t < t^*-1} l_{t+1}(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) \\
&= \sum_{t_* \le t < t^*-1} l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) - \sum_{t_* \le t < t^*-1} l_{t+1}(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) \\
&\quad + \sum_{t_* \le t < t^*-1} l_{t+1}(\mathbf{1}(x(t_*)), \mathbf{1}(x(t_*))) - \sum_{t_* \le t < t^*-1} l_t(\mathbf{1}(x(t_*)), \mathbf{1}(x(t_*))).
\end{aligned}$$

Note that for any $t = 0, 1, \dots,$ we have

$$\begin{aligned}
&l_{t+1}(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) - l_t(\mathbf{1}(x(t+1)), \mathbf{1}(x(t+1))) \\
&= \sum_{i,j \in \mathbf{1}(x(t+1))} (a_{ij}(t+1) - a_{ij}(t)) \\
&= \sum_{i,j \in \mathbf{1}(x(t+1))} \mathcal{D}_{x(t) \to x(t+1)} a_{ij}
\end{aligned} \tag{22}$$

and

$$\begin{aligned}
&l_{t+1}(\mathbf{1}(x(t_*)), \mathbf{1}(x(t_*))) - l_t(\mathbf{1}(x(t_*)), \mathbf{1}(x(t_*))) \\
&= \sum_{i,j \in \mathbf{1}(x(t_*))} (a_{ij}(t+1) - a_{ij}(t)) \\
&= \sum_{i,j \in \mathbf{1}(x(t_*))} \mathcal{D}_{x(t) \to x(t+1)} a_{ij}.
\end{aligned} \tag{23}$$

The coincidence-detection evolving algorithm implies that for every $t = 0, 1, \dots$ and $i, j = 1, 2, \dots, n$,

$$\text{if } \mathcal{D}_{x(t) \to x(t+1)} a_{ij} > 0, \text{ then } i, j \in \mathbf{1}(x(t+1)),$$

$$\text{if } \mathcal{D}_{x(t) \to x(t+1)} a_{ij} < 0, \text{ then either } i \notin \mathbf{1}(x(t+1)) \text{ or } j \notin \mathbf{1}(x(t+1)),$$

so that

$$\sum_{i,j \in \mathbf{1}(x(t+1))} \mathcal{D}_{x(t) \to x(t+1)} a_{ij} \ge \sum_{i,j \in \mathbf{1}(x(t_*))} \mathcal{D}_{x(t) \to x(t+1)} a_{ij}. \tag{24}$$

Combining (22), (23), and (24) gives

$$\begin{aligned}&\sum_{t_*\le t<t^*-1} l_t(\mathbf{1}(x(t+1)),\mathbf{1}(x(t+1))) - \sum_{t_*\le t<t^*-1} l_{t+1}(\mathbf{1}(x(t+1)),\mathbf{1}(x(t+1)))\\ &+\sum_{t_*\le t<t^*-1} l_{t+1}(\mathbf{1}(x(t_*)),\mathbf{1}(x(t_*))) - \sum_{t_*\le t<t^*-1} l_t(\mathbf{1}(x(t_*)),\mathbf{1}(x(t_*))) \le 0.\end{aligned}$$

Composing the a priori estimates in Claims 1, 2, and 3 with the inequality

$$\begin{aligned}&\sum_{1\le j,k\le q}\ \sum_{1\le i\le \sharp M_j^+} (x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij})-a_{m_km_j}(t_{ij})))\\ (25)\quad &-\sum_{1\le j,k\le q}\ \sum_{1\le i\le \sharp M_j^-} (x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij})-a_{m_km_j}(u_{ij})))\\ &\le \sum_{1\le j,k\le q} 2\min(\{\sharp M_j^-,\sharp M_k^-\})\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\dots,t^*\}\cup\{0\}),\end{aligned}$$

we conclude from (11), (16), and (17) that

$$\begin{aligned}&2((FS(t_*)+\cdots+FS(t^*-1))-(US(t_*)+\cdots+US(t^*-1)))\\ &=\sum_{t_*\le t<t^*}(FS(t)-US(t))+\sum_{t_*\le t<t^*}(\widetilde{FS}(t)-\widetilde{US}(t))\\ &\quad+\sum_{t_*\le t<t^*}(FS(t)-US(t))-\sum_{t_*\le t<t^*}(\widetilde{FS}(t)-\widetilde{US}(t))\\ &\le-\sum_{1\le j,k\le q} 2\min(\{\sharp M_j^-,\sharp M_k^-\})\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\dots,t^*\}\cup\{0\})\\ &\quad+\sum_{1\le j,k\le q}\ \sum_{1\le i\le \sharp M_j^+} (x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij})-a_{m_km_j}(t_{ij})))\\ &\quad-\sum_{1\le j,k\le q}\ \sum_{1\le i\le \sharp M_j^-} (x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij})-a_{m_km_j}(u_{ij})))\le 0,\end{aligned}$$

in contradiction to Theorem 1. So to complete the proof of the assertion, it remains to show that (25) holds. To see this, fix $1\le j,k\le q$ with $j\ne k$, and think of the set $M_k^+\cup M_k^-$ as the holes in a sieve that filters the set $M_j^+\cup M_j^-$. Thus we divide the sets

$$\begin{aligned}M_j^+&=\{t_{1j},t_{2j},\dots,t_{(\sharp M_j^+)j}\},\\ M_j^-&=\{u_{1j},u_{2j},\dots,u_{(\sharp M_j^-)j}\}\end{aligned}$$

into mutually disjoint ν classes

$$E_1^j,E_2^j,\dots,E_\nu^j$$

such that

(a) $E_1^j\cup E_2^j\cup\cdots\cup E_\nu^j=M_j^+\cup M_j^-$,

(b) $\max(E_\eta^j)<\min(E_{\eta+1}^j)$ for $\eta=1,2,\dots,\nu-1$,

(c) there does not exist t in $M_k^+\cup M_k^-$ such that $\min(E_\eta^j)\le t\le\max(E_\eta^j)$ for $\eta=1,2,\dots,\nu$,

(d) there exists t in $M_k^+ \cup M_k^-$ such that $\max(E_\eta^j) < t < \min(E_{\eta+1}^j)$ for $\eta = 1, 2, \ldots, \nu - 1$.

According to (a) we have

$$\begin{aligned}
&\sum_{1\le i\le \sharp M_j^+} (x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij}) - a_{m_km_j}(t_{ij}))) \\
&- \sum_{1\le i\le \sharp M_j^-} (x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij}) - a_{m_km_j}(u_{ij}))) \\
&= \sum_{1\le\eta\le\nu} \sum_{t\in M_j^+\cap E_\eta^j} (x_{m_k}(t)(a_{m_jm_k}(t) - a_{m_km_j}(t))) \\
&- \sum_{1\le\eta\le\nu} \sum_{t\in M_j^-\cap E_\eta^j} (x_{m_k}(t)(a_{m_jm_k}(t) - a_{m_km_j}(t))).
\end{aligned} \tag{26}$$

Fix $1 \le \eta \le \nu$. Then (c) implies that either

$$x_{m_k}(t) = 0 \quad \text{for } \min(E_\eta^j) \le t \le \max(E_\eta^j) \tag{27}$$

or

$$x_{m_k}(t) = 1 \quad \text{for } \min(E_\eta^j) \le t \le \max(E_\eta^j). \tag{28}$$

Case 1. *$\sharp E_\eta^j$ is even.* According to (27) and (28) we have to distinguish between two subcases.

Subcase 1-1. *$x_{m_k}(t) = 0$ for $\min(E_\eta^j) \le t \le \max(E_\eta^j)$.* Then

$$\sum_{t\in M_j^+\cap E_\eta^j} (x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))-\sum_{t\in M_j^-\cap E_\eta^j} (x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t))) = 0.$$

Subcase 1-2. *$x_{m_k}(t) = 1$ for $\min(E_\eta^j) \le t \le \max(E_\eta^j)$.* According to (b) we can write E_η^j as

$$\{t_1, t_2, \ldots, t_{\sharp E_\eta^j/2}, u_1, u_2, \ldots, u_{\sharp E_\eta^j/2}\},$$

where $t_i \in M_j^+$ and $u_i \in M_j^-$ for $i = 1, 2, \ldots, \sharp E_\eta^j/2$, such that either

$$t_1 < u_1 < t_2 < u_2 < \cdots < t_{\sharp E_\eta^j/2} < u_{\sharp E_\eta^j/2} \tag{29}$$

or

$$u_1 < t_1 < u_2 < t_2 < \cdots < u_{\sharp E_\eta^j/2} < t_{\sharp E_\eta^j/2}. \tag{30}$$

Inequality (29) implies that for any $i = 1, 2, \ldots, \sharp E_\eta^j/2$,

$$\begin{aligned}
(x_{m_j}(t_i), x_{m_k}(t_i)) &= (0, 1), \\
(x_{m_j}(t_i + 1), x_{m_k}(t_i + 1)) &= (1, 1), \\
&\vdots \\
(x_{m_j}(u_i - 1), x_{m_k}(u_i - 1)) &= (1, 1), \\
(x_{m_j}(u_i), x_{m_k}(u_i)) &= (1, 1).
\end{aligned}$$

Thus for every $t = t_i, t_i + 1, \dots, u_i - 1$, we have

$$\delta_{m_j m_k}(t+1) = 1 \qquad \text{and} \qquad \delta_{m_k m_j}(t+1) = 0,$$

and according to the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)} a_{m_j m_k} \geq \mathcal{D}_{x(t)\to x(t+1)} a_{m_k m_j} \geq 0.$$

Therefore

$$\begin{aligned}
&\sum_{t\in M_j^+ \cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t))) - \sum_{t\in M_j^- \cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t)))\\
&= \sum_{1\leq i\leq \sharp E_\eta^j/2} (a_{m_j m_k}(t_i) - a_{m_j m_k}(u_i)) - \sum_{1\leq i\leq \sharp E_\eta^j/2} (a_{m_k m_j}(t_i) - a_{m_k m_j}(u_i))\\
&= \sum_{1\leq i\leq \sharp E_\eta^j/2} (-\mathcal{D}_{x(t_i)\to x(t_i+1)} a_{m_j m_k} - \dots - \mathcal{D}_{x(u_i-1)\to x(u_i)} a_{m_j m_k})\\
&\quad - \sum_{1\leq i\leq \sharp E_\eta^j/2} (-\mathcal{D}_{x(t_i)\to x(t_i+1)} a_{m_k m_j} - \dots - \mathcal{D}_{x(u_i-1)\to x(u_i)} a_{m_k m_j}) \leq 0.
\end{aligned}$$

On the other hand, (30) implies that for any $i = 1, 2, \dots, \sharp E_\eta^j/2$,

$$\begin{aligned}
(x_{m_j}(u_i), x_{m_k}(u_i)) &= (1,1),\\
(x_{m_j}(u_i+1), x_{m_k}(u_i+1)) &= (0,1),\\
&\vdots\\
(x_{m_j}(t_i-1), x_{m_k}(t_i-1)) &= (0,1),\\
(x_{m_j}(t_i), x_{m_k}(t_i)) &= (0,1).
\end{aligned}$$

Thus for every $t = u_i, u_i + 1, \dots, t_i - 1$, we have

$$\delta_{m_j m_k}(t+1) = 1 \qquad \text{and} \qquad \delta_{m_k m_j}(t+1) = 0,$$

and according to the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)} a_{m_j m_k} \leq \mathcal{D}_{x(t)\to x(t+1)} a_{m_k m_j} \leq 0.$$

Therefore

$$\begin{aligned}
&\sum_{t\in M_j^+ \cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t))) - \sum_{t\in M_j^- \cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t)))\\
&= \sum_{1\leq i\leq \sharp E_\eta^j/2} (a_{m_j m_k}(t_i) - a_{m_j m_k}(u_i)) - \sum_{1\leq i\leq \sharp E_\eta^j/2} (a_{m_k m_j}(t_i) - a_{m_k m_j}(u_i))\\
&= \sum_{1\leq i\leq \sharp E_\eta^j/2} (\mathcal{D}_{x(u_i)\to x(u_i+1)} a_{m_j m_k} + \dots + \mathcal{D}_{x(t_i-1)\to x(t_i)} a_{m_j m_k})\\
&\quad - \sum_{1\leq i\leq \sharp E_\eta^j/2} (\mathcal{D}_{x(u_i)\to x(u_i+1)} a_{m_k m_j} + \dots + \mathcal{D}_{x(t_i-1)\to x(t_i)} a_{m_k m_j}) \leq 0.
\end{aligned}$$

Case 2. $\sharp E^j_\eta$ *is odd.*

Subcase 2-1. $x_{m_k}(t) = 0$ *for* $\min(E^j_\eta) \le t \le \max(E^j_\eta)$. Then

$$\sum_{t\in M^+_j\cap E^j_\eta}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t))) - \sum_{t\in M^-_j\cap E^j_\eta}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t))) = 0.$$

Subcase 2-2. $x_{m_k}(t) = 1$ *for* $\min(E^j_\eta) \le t \le \max(E^j_\eta)$. According to (b) we can write E^j_η as

$$\{t_1, t_2, \ldots, t_{(\sharp E^j_\eta-1)/2}, t_{(\sharp E^j_\eta+1)/2}, u_1, u_2, \ldots, u_{(\sharp E^j_\eta-1)/2}\},$$

where $t_i \in M^+_j$ for $i = 1, 2, \ldots, (\sharp E^j_\eta+1)/2$, $u_i \in M^-_j$ for $i = 1, 2, \ldots, (\sharp E^j_\eta-1)/2$ and

$$t_1 < u_1 < t_2 < u_2 < \cdots < t_{(\sharp E^j_\eta-1)/2} < u_{(\sharp E^j_\eta-1)/2} < t_{(\sharp E^j_\eta+1)/2}, \tag{31}$$

or as

$$\{t_1, t_2, \ldots, t_{(\sharp E^j_\eta-1)/2}, u_1, u_2, \ldots, u_{(\sharp E^j_\eta-1)/2}, u_{(\sharp E^j_\eta+1)/2}\},$$

where $t_i \in M^+_j$ for $i = 1, 2, \ldots, (\sharp E^j_\eta-1)/2$, $u_i \in M^-_j$ for $i = 1, 2, \ldots, (\sharp E^j_\eta+1)/2$ and

$$u_1 < t_1 < u_2 < t_2 < \cdots < u_{(\sharp E^j_\eta-1)/2} < t_{(\sharp E^j_\eta-1)/2} < u_{(\sharp E^j_\eta+1)/2}. \tag{32}$$

Inequality (31) implies that for any $i = 1, 2, \ldots, (\sharp E^j_\eta-1)/2$,

$$\begin{aligned}(x_{m_j}(t_i), x_{m_k}(t_i)) &= (0, 1),\\ (x_{m_j}(t_i+1), x_{m_k}(t_i+1)) &= (1, 1),\\ &\vdots\\ (x_{m_j}(u_i-1), x_{m_k}(u_i-1)) &= (1, 1),\\ (x_{m_j}(u_i), x_{m_k}(u_i)) &= (1, 1).\end{aligned}$$

Thus for every $t = t_i, t_i+1, \ldots, u_i-1$, we have

$$\delta_{m_jm_k}(t+1) = 1 \qquad \text{and} \qquad \delta_{m_km_j}(t+1) = 0,$$

and by the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)}a_{m_jm_k} \ge \mathcal{D}_{x(t)\to x(t+1)}a_{m_km_j} \ge 0.$$

Then

$$\begin{aligned}&\sum_{t\in M^+_j\cap E^j_\eta}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t))) - \sum_{t\in M^-_j\cap E^j_\eta}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\\ &= \sum_{1\le i\le(\sharp E^j_\eta-1)/2}(a_{m_jm_k}(t_i)-a_{m_jm_k}(u_i)) - \sum_{1\le i\le(\sharp E^j_\eta-1)/2}(a_{m_km_j}(t_i)-a_{m_km_j}(u_i))\\ &\quad + a_{m_jm_k}(t_{(\sharp E^j_\eta+1)/2}) - a_{m_km_j}(t_{(\sharp E^j_\eta+1)/2})\\ &= \sum_{1\le i\le(\sharp E^j_\eta-1)/2}(-\mathcal{D}_{x(t_i)\to x(t_i+1)}a_{m_jm_k} - \cdots - \mathcal{D}_{x(u_i-1)\to x(u_i)}a_{m_jm_k})\end{aligned}$$

$$
\begin{aligned}
&- \sum_{1\le i\le (\sharp E_\eta^j-1)/2} (-\mathcal{D}_{x(t_i)\to x(t_i+1)} a_{m_k m_j} - \cdots - \mathcal{D}_{x(u_i-1)\to x(u_i)} a_{m_k m_j})\\
&+ a_{m_j m_k}(t_{(\sharp E_\eta^j+1)/2}) - a_{m_k m_j}(t_{(\sharp E_\eta^j+1)/2})\\
\le\ & a_{m_j m_k}(t_{(\sharp E_\eta^j+1)/2}) - a_{m_k m_j}(t_{(\sharp E_\eta^j+1)/2})\\
\le\ & \max(\{a_{m_j m_k}(t) - a_{m_k m_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}).
\end{aligned}
$$

On the other hand, (32) implies that for any $i = 1, 2, \dots, (\sharp E_\eta^j - 1)/2$,

$$
\begin{aligned}
(x_{m_j}(u_i), x_{m_k}(u_i)) &= (1,1),\\
(x_{m_j}(u_i+1), x_{m_k}(u_i+1)) &= (0,1),\\
&\vdots\\
(x_{m_j}(t_i-1), x_{m_k}(t_i-1)) &= (0,1),\\
(x_{m_j}(t_i), x_{m_k}(t_i)) &= (0,1).
\end{aligned}
$$

Thus for every $t = u_i, u_i+1, \dots, t_i-1$, we have

$$\delta_{m_j m_k}(t+1) = 1 \qquad \text{and} \qquad \delta_{m_k m_j}(t+1) = 0,$$

and using the coincidence-detection evolving algorithm, we conclude that

$$\mathcal{D}_{x(t)\to x(t+1)} a_{m_j m_k} \le \mathcal{D}_{x(t)\to x(t+1)} a_{m_k m_j} \le 0.$$

Then

$$
\begin{aligned}
&\sum_{t\in M_j^+\cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t))) - \sum_{t\in M_j^-\cap E_\eta^j} (x_{m_k}(t)(a_{m_j m_k}(t) - a_{m_k m_j}(t)))\\
=\ & \sum_{1\le i\le (\sharp E_\eta^j-1)/2} (a_{m_j m_k}(t_i) - a_{m_j m_k}(u_i)) - \sum_{1\le i\le (\sharp E_\eta^j-1)/2} (a_{m_k m_j}(t_i) - a_{m_k m_j}(u_i))\\
&- a_{m_j m_k}(u_{(\sharp E_\eta^j+1)/2}) + a_{m_k m_j}(u_{(\sharp E_\eta^j+1)/2})\\
=\ & \sum_{1\le i\le (\sharp E_\eta^j-1)/2} (\mathcal{D}_{x(u_i)\to x(u_i+1)} a_{m_j m_k} + \cdots + \mathcal{D}_{x(t_i-1)\to x(t_i)} a_{m_j m_k})\\
&- \sum_{1\le i\le (\sharp E_\eta^j-1)/2} (\mathcal{D}_{x(u_i)\to x(u_i+1)} a_{m_k m_j} + \cdots + \mathcal{D}_{x(t_i-1)\to x(t_i)} a_{m_k m_j})\\
&- a_{m_j m_k}(u_{(\sharp E_\eta^j+1)/2}) + a_{m_k m_j}(u_{(\sharp E_\eta^j+1)/2})\\
\le\ & a_{m_k m_j}(u_{(\sharp E_\eta^j+1)/2}) - a_{m_j m_k}(u_{(\sharp E_\eta^j+1)/2})\\
\le\ & \max(\{a_{m_k m_j}(t) - a_{m_j m_k}(t);\ t = t_*, \dots, t^*\} \cup \{0\}).
\end{aligned}
$$

Let

$$\Delta = \{\eta;\ \sharp E_\eta^j \text{ is odd},\ \eta = 1, 2, \dots, \nu\}.$$

Combining Cases 1 and 2 gives

$$\begin{aligned}
&\sum_{1\le\eta\le\nu}\sum_{t\in M_j^+\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\\
&\quad-\sum_{1\le\eta\le\nu}\sum_{t\in M_j^-\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\\
&=\sum_{\eta\notin\Delta}\left(\sum_{t\in M_j^+\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\right.\\
&\qquad\left.-\sum_{t\in M_j^-\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\right)\\
&\quad+\sum_{\eta\in\Delta}\left(\sum_{t\in M_j^+\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\right.\\
&\qquad\left.-\sum_{t\in M_j^-\cap E_\eta^j}(x_{m_k}(t)(a_{m_jm_k}(t)-a_{m_km_j}(t)))\right)\\
&\le\sum_{\eta\in\Delta,\max(E_\eta^j)\in M_j^+}\max(\{a_{m_jm_k}(t)-a_{m_km_j}(t);\ t=t_*,\dots,t^*\}\cup\{0\})\\
&\quad+\sum_{\eta\in\Delta,\max(E_\eta^j)\in M_j^-}\max(\{a_{m_km_j}(t)-a_{m_jm_k}(t);\ t=t_*,\dots,t^*\}\cup\{0\}).
\end{aligned}\tag{33}$$

Since

$$\sharp E_1^j+\sharp E_2^j+\cdots+\sharp E_\nu^j=\sharp(M_j^+\cup M_j^-),$$

$\sharp\Delta$ is even. Let us write

$$\Delta=\{\eta_1,\eta_2,\dots,\eta_{2\beta}\},$$

where $\beta\ge 0$ and $\eta_1<\eta_2<\cdots<\eta_{2\beta}$. Then

$$2\beta\le\nu\le 2\sharp M_j^-$$

and (d) gives

$$\nu-1\le\sharp(M_k^+\cup M_k^-).$$

Hence

$$\beta\le\frac{1}{2}\nu\le\min\left(\left\{\sharp M_j^-,\frac{1}{2}+\sharp M_k^-\right\}\right),$$

and so

$$\beta\le\min(\{\sharp M_j^-,\sharp M_k^-\}).$$

Note that for each $i = 1, 2, \dots, 2\beta - 1$, if $\max(E^j_{\eta_i})$ belongs to M^+_j (resp., M^-_j), then $\max(E^j_{\eta_{i+1}})$ belongs to M^-_j (resp., M^+_j). Thus

$$\begin{aligned}
&\sum_{\eta\in\Delta,\max(E^j_\eta)\in M^+_j} \max(\{a_{m_jm_k}(t) - a_{m_km_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&\quad + \sum_{\eta\in\Delta,\max(E^j_\eta)\in M^-_j} \max(\{a_{m_km_j}(t) - a_{m_jm_k}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&= \beta \max(\{a_{m_jm_k}(t) - a_{m_km_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \qquad (34)\\
&\quad + \beta \max(\{a_{m_km_j}(t) - a_{m_jm_k}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&\le \min(\{\sharp M^-_j, \sharp M^-_k\}) \max(\{a_{m_jm_k}(t) - a_{m_km_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&\quad + \min(\{\sharp M^-_j, \sharp M^-_k\}) \max(\{a_{m_km_j}(t) - a_{m_jm_k}(t);\ t = t_*, \dots, t^*\} \cup \{0\}).
\end{aligned}$$

So we conclude from (26), (33), and (34) that

$$\begin{aligned}
&\sum_{1\le j,k\le q} \sum_{1\le i\le \sharp M^+_j} (x_{m_k}(t_{ij})(a_{m_jm_k}(t_{ij}) - a_{m_km_j}(t_{ij}))) \\
&\quad - \sum_{1\le j,k\le q} \sum_{1\le i\le \sharp M^-_j} (x_{m_k}(u_{ij})(a_{m_jm_k}(u_{ij}) - a_{m_km_j}(u_{ij}))) \\
&\le \sum_{1\le j,k\le q} \min(\{\sharp M^-_j, \sharp M^-_k\}) \max(\{a_{m_jm_k}(t) - a_{m_km_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&\quad + \sum_{1\le j,k\le q} \min(\{\sharp M^-_j, \sharp M^-_k\}) \max(\{a_{m_km_j}(t) - a_{m_jm_k}(t);\ t = t_*, \dots, t^*\} \cup \{0\}) \\
&= \sum_{1\le j,k\le q} 2\min(\{\sharp M^-_j, \sharp M^-_k\}) \max(\{a_{m_jm_k}(t) - a_{m_km_j}(t);\ t = t_*, \dots, t^*\} \cup \{0\}),
\end{aligned}$$

establishing (25) and completing the proof of the assertion.

Since the discrete flow $x(t)$ iterates asynchronously, there exists a sequence of time steps $T_1, T_2, \dots$ with $0 < T_1 < T_2 < \cdots$ such that

$$\bigcup_{T_j\le t<T_{j+1}} s(t) = \{1, 2, \dots, n\} \tag{35}$$

for any $j = 1, 2, \dots$. The assertion and the above choice of $T_1, T_2, \dots$ in effect imply that a finite $k > 1$ and a subset V of $\{1, 2, \dots, n\}$ can be determined so that if the minimal total excitability in the period of time $t = 0, 1, \dots, T_k$ satisfies the assembling coordination, then

$$\mathbf{1}(x(t)) = V \quad \text{for all} \quad T_{k-1} \le t \le T_k. \tag{36}$$

(A passing remark: Without the coincidence-detection evolving algorithm support, (3), (4), and (36) cannot generically arrive at the conclusion that $\mathbf{1}(x(t)) = V$ for all $t \ge T_k$.) Set

$$T' = T_{k-1} \quad \text{and} \quad T = T_k.$$

Armed with (36), we now claim that for all $t \geq T$ the discrete flow $x(t)$ undergoing the coincidence-detection evolving algorithm satisfies

$$\mathbf{1}(x(t)) = V. \tag{37}$$

For the proof, put

$$\gamma(t) = \left(\mathbf{1}(x(t)) \cap \left\{ i; \sum_j a_{ij}(t)x_j(t) < b_i \right\}\right) \cup \left(\mathbf{0}(x(t)) \cap \left\{ i; \sum_j a_{ij}(t)x_j(t) \geq b_i \right\}\right)$$

for $t = 0, 1, \ldots$. Then, by (36) and the coincidence-detection evolving algorithm, we have for any given $i = 1, 2, \ldots, n$ and $T' < t \leq T$

$$\begin{aligned} &\sum_{1\leq j\leq n} a_{ij}(t)x_j(t) \\ &= \sum_{1\leq j\leq n} (a_{ij}(t-1) + \mathcal{D}_{x(t-1)\to x(t)} a_{ij})x_j(t) \\ &= \sum_{1\leq j\leq n} a_{ij}(t-1)x_j(t-1) + \sum_{1\leq j\leq n} \mathcal{D}_{x(t-1)\to x(t)} a_{ij} x_j(t) \\ &\geq \sum_{1\leq j\leq n} a_{ij}(t-1)x_j(t-1) \end{aligned}$$

if $i \in \mathbf{1}(x(t))$; otherwise

$$\begin{aligned} &\sum_{1\leq j\leq n} a_{ij}(t)x_j(t) \\ &= \sum_{1\leq j\leq n} (a_{ij}(t-1) + \mathcal{D}_{x(t-1)\to x(t)} a_{ij})x_j(t) \\ &= \sum_{1\leq j\leq n} a_{ij}(t-1)x_j(t-1) + \sum_{1\leq j\leq n} \mathcal{D}_{x(t-1)\to x(t)} a_{ij} x_j(t) \\ &\leq \sum_{1\leq j\leq n} a_{ij}(t-1)x_j(t-1). \end{aligned}$$

Thus we have

$$\gamma(T') \supset \gamma(T'+1) \supset \cdots \supset \gamma(T). \tag{38}$$

Furthermore, $\gamma(T) = \emptyset$. To see this, suppose $\gamma(T) \neq \emptyset$. Then (35) and (38) imply that there is τ with $T' \leq \tau < T$ such that $\gamma(\tau) \cap s(\tau) \neq \emptyset$, and so $\mathbf{1}(x(\tau+1)) \neq V$, which contradicts (36). We apply now the condition $\gamma(T) = \emptyset$ to prove the assertion (37), which shows that a transient period of synchronization of neural firing *propagates* to the whole period of time $t \geq T$. (As illustrated in Figure 4, the condition $\gamma(T) = \emptyset$ means that a transition state of neural activity occurs at time T. The accumulation of both excitability coordination and activity-dependent changes of coupling strengths causes a group of neurons to come into synchronized activity prior to time T. When a transient period of synchronization of neural firing occurs, we need only the support of coincidence detection to produce a sort of positive feedback that admits the synchronized neural impulses between populations of neurons to continue to synchronize posterior to time T.)

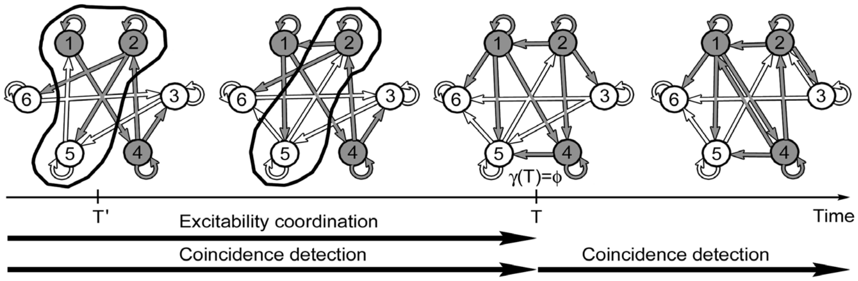

FIG. 4. *A monotonically decreasing sequence of $\gamma(t)$ (the nodes encompassed by closed curves in the period of time T' and T) can be generated in a transient period of synchronization of neural firing. The condition $\gamma(T) = \emptyset$ determines a transition state of neural activity at time T.*

We prove the assertion (37) by induction on time $t \geq T$. The case of $t = T$ follows from (36). Assume that $t > T$ and the assertion (37) is true for all cases of time less than t (except the cases of time less than T). Then, by induction hypothesis and the coincidence-detection evolving algorithm, we have

$$\gamma(T) \supset \gamma(T+1) \supset \cdots \supset \gamma(t-1).$$

Since $\gamma(T) = \emptyset$, we get $\gamma(t-1) = \emptyset$, so that

$$\sum_j a_{ij}(t-1)x_j(t-1) \geq b_i \quad \text{for all} \quad i \in \mathbf{1}(x(t-1)), \tag{39}$$

$$\sum_j a_{ij}(t-1)x_j(t-1) < b_i \quad \text{for all} \quad i \in \mathbf{0}(x(t-1)). \tag{40}$$

Inequalities (39), (40) and the induction hypothesis together imply that $\mathbf{1}(x(t)) = V$. This completes the inductive proof of the assertion (37) and concludes the proof of the theorem. □

6. Stability of neural synchrony. This section is devoted to the study of the stability problem of neural synchrony underlying the nonlinear dynamical system modeled by the parametric equations (3) and (4). The question may be stated as follows: *Would small perturbations of the initial neuronal active state cause only small variations of the discrete flow which iterates to a state of synchronous neuronal firing?*

To solve this, we first introduce a quantity to clarify the mathematical meaning of disturbance of neuronal activity states, and then introduce the phenomenon of local absorption of the discrete flow.

For any given n-by-n real matrix $A = [a_{ij}]_{n\times n}$ and $s \in \{1, 2, \ldots, n\}$, the *state transition function* $H_{A,s} : \{0,1\}^n \longrightarrow \{0,1\}^n$ is defined by $[H_{A,s}(x)]_i = hea(\sum_{j=1}^n a_{ij}x_j - b_i)$ if $i = s$; otherwise x_i, $i = 1, 2, \ldots, n$. For each pair x, y of distinct points of $\{0,1\}^n$, we define the *proximal number from x to y* with respect to the state transition functions $H_{A,\cdot}$ by

$$Pro_A(x,y) = \min\{r;\ H_{A,s_{r-1}} \circ H_{A,s_{r-2}} \circ \cdots \circ H_{A,s_0}(x) = y\},$$

and let $Pro_A(x,x) = 0$. Here the operation " ∘ " denotes the composition of two functions. For each nonempty subset Ω of $\{0,1\}^n$, the *proximal number from x to Ω*

with respect to the state transition functions $H_{A,\boldsymbol{\cdot}}$ is defined to be the minimum of proximal numbers $Pro_A(x, y)$, where y is taken over all elements in Ω. The proximal number $Pro_A(x, y)$ measures the absorption of x into y underlying the state transition functions $H_{A,\boldsymbol{\cdot}}$.

Let $x(t)$ iterate according to the parametric equations (3) and (4). We show now that, based on the coincidence-detection evolving algorithm, the establishment of the evolutionary couplings enables the states locally absorbed by $x(t)$ to be absorbed by $x(t+1)$ for all $t = 0, 1, \ldots$. This phenomenon is aptly called *local absorption* of the discrete flow $x(t)$, which reveals an underlying principle of the coincidence-detection rule to stabilize neural synchrony.

Theorem 3. *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Let the discrete flow $x(t)$ iterate asynchronously and let $A(t)$ satisfy the condition of assembling coordination described in Theorem* 2. *If the plasticity parameters satisfy*

$$\left| \sum_{j \in \mathbf{1}(x(t+1)), j \neq i} \mathcal{D}_{x(t) \to x(t+1)} a_{ij} \right| \geq \max_{j \in \mathbf{0}(x(t+1))} |\mathcal{D}_{x(t) \to x(t+1)} a_{ij}| \tag{41}$$

for all $i \in \mathbf{1}(x(t+1))$ and $t = 0, 1, \ldots,$ then

$$\{y;\ Pro_{A(t)}(y, x(t)) \leq 1\} \subset \{y;\ Pro_{A(t+1)}(y, x(t+1)) \leq 2\} \tag{42}$$

for all $t = 0, 1, \ldots$.

Proof. Let $x(0)$ be any initial neuronal active state in $\{0, 1\}^n$, and let $x(t)$ iterate asynchronously, guided by the dynamics (3), (4) and the coincidence-detection evolving algorithm. Fix $\tau \geq 0$ and consider the fragment $x(\tau), x(\tau+1), x(\tau+2), x(\tau+3)$ of the discrete flow $x(t)$. We may first suppose that, in the period of time $\tau, \tau+1, \tau+2$, the minimal total excitability fulfills the assembling coordination and the plasticity parameters satisfy (41). According to (3) and (4), there are $A(\tau), A(\tau+1), A(\tau+2)$ and $s(\tau), s(\tau+1), s(\tau+2)$ such that

$$x(t+1) = H_{A(t), s(t)}(x(t)) \quad \text{for } t = \tau, \tau+1, \tau+2,$$

and by (4) we have

$$l_{t+1}(\mathbf{1}(x(\tau)), s(\tau)) = l_t(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j \in \mathbf{1}(x(\tau))} \mathcal{D}_{x(t) \to x(t+1)} a_{s(\tau)j} \tag{43}$$

for $t = \tau, \tau+1$. To prove (42), we have to claim that

$$x(\tau+1) = H_{A(\tau+1), s(\tau)}(x(\tau)) \tag{44}$$

and

$$x(\tau+1) = H_{A(\tau+2), s(\tau)}(x(\tau)). \tag{45}$$

To prove (44), we consider (43) at time $t = \tau$, that is,

$$l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) = l_\tau(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j \in \mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau) \to x(\tau+1)} a_{s(\tau)j}.$$

By the asynchronous iteration of $x(t)$, we split the arguments into three cases.

Case 1. $\mathbf{1}(x(\tau)) \subsetneq \mathbf{1}(x(\tau+1))$. Then $s(\tau) = \mathbf{0}(x(\tau)) \cap \mathbf{1}(x(\tau+1))$, and according to the coincidence-detection evolving algorithm, we have

$$\mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \geq 0 \quad \text{for all } j \in \mathbf{1}(x(\tau)). \tag{46}$$

Since $x(\tau+1) = H_{A(\tau),s(\tau)}(x(\tau))$, we have

$$l_\tau(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}, \tag{47}$$

and hence, together with (46), we conclude that

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) &= l_\tau(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \\ &\geq l_\tau(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}. \end{aligned} \tag{48}$$

This implies that

$$H_{A(\tau+1),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (44).

Case 2. $\mathbf{1}(x(\tau)) \supsetneq \mathbf{1}(x(\tau+1))$. Then $s(\tau) = \mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+1))$, and according to the coincidence-detection evolving algorithm, we have

$$\mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \leq 0 \quad \text{for all } j \in \mathbf{1}(x(\tau)). \tag{49}$$

Since $x(\tau+1) = H_{A(\tau),s(\tau)}(x(\tau))$, we have

$$l_\tau(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}, \tag{50}$$

and hence, together with (49), we conclude that

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) &= l_\tau(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \\ &\leq l_\tau(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}. \end{aligned} \tag{51}$$

This implies that

$$H_{A(\tau+1),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (44).

Case 3. $\mathbf{1}(x(\tau)) = \mathbf{1}(x(\tau+1))$. Then either $s(\tau) \in \mathbf{1}(x(\tau))$ or $s(\tau) \in \mathbf{0}(x(\tau))$. If $s(\tau) \in \mathbf{1}(x(\tau))$, then, according to the coincidence-detection evolving algorithm, we have

$$\mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \geq 0 \quad \text{for all } j \in \mathbf{1}(x(\tau)). \tag{52}$$

Since $x(\tau+1) = H_{A(\tau),s(\tau)}(x(\tau))$, we have

$$l_\tau(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}, \tag{53}$$

and hence, together with (52), we conclude that

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) &= l_\tau(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \\ &\geq l_\tau(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}. \end{aligned} \tag{54}$$

This implies that

$$H_{A(\tau+1),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1).$$

On the other hand, if $s(\tau) \in \mathbf{0}(x(\tau))$, then, according to the coincidence-detection evolving algorithm, we have

$$\mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \le 0 \quad \text{for all } j \in \mathbf{1}(x(\tau)). \tag{55}$$

Since $x(\tau+1) = H_{A(\tau),s(\tau)}(x(\tau))$, we have

$$l_\tau(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}, \tag{56}$$

and hence, together with (55), we conclude that

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) &= l_\tau(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s(\tau)j} \\ &\le l_\tau(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}. \end{aligned} \tag{57}$$

This implies that

$$H_{A(\tau+1),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (44).

We turn now to establish (45). Since $x(t)$ iterates asynchronously, we need only consider three cases.

Case 1. $\mathbf{1}(x(\tau)) \subsetneq \mathbf{1}(x(\tau+1))$. Then

$$s(\tau) = \mathbf{0}(x(\tau)) \cap \mathbf{1}(x(\tau+1)) \tag{58}$$

and, by (43) and (48), we have

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &\ge b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}. \end{aligned} \tag{59}$$

Subcase 1-1. $\mathbf{1}(x(\tau+1)) \subsetneq \mathbf{1}(x(\tau+2))$. Then, by (58), we have

$$s(\tau) \in \mathbf{1}(x(\tau+2)) \quad \text{and} \quad \mathbf{1}(x(\tau)) \subset \mathbf{1}(x(\tau+2)),$$

and according to the coincidence-detection evolving algorithm, we see that

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \ge 0 \quad \text{for all } j \in \mathbf{1}(x(\tau)).$$

Thus, by (59), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) \ge b_{s(\tau)}.$$

Combining this with (47) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 1-2. $\mathbf{1}(x(\tau+1)) \supsetneq \mathbf{1}(x(\tau+2))$. Then $s(\tau) \neq s(\tau+1)$. Indeed, if $s(\tau) = s(\tau+1)$, then, applying (48), (58), and the assembling coordination (10) to $U = s(\tau)$, $t_* = \tau$, and $t^* = \tau+2$, we get

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau+1)) &= l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau)) \\ &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + l_{\tau+1}(s(\tau), s(\tau)) \\ &\geq b_{s(\tau)} + a_{s(\tau)s(\tau)}(\tau+1) \\ &\geq b_{s(\tau)}. \end{aligned} \tag{60}$$

Since $s(\tau+1) = s(\tau) \in \mathbf{1}(x(\tau+1))$, inequality (60) implies that

$$x(\tau+2) = H_{A(\tau+1), s(\tau+1)}(x(\tau+1)) = x(\tau+1),$$

contradicting the assumption $\mathbf{1}(x(\tau+1)) \supsetneq \mathbf{1}(x(\tau+2))$. Now combining $s(\tau) \neq s(\tau+1)$ with the fact that

$$s(\tau) \in \mathbf{1}(x(\tau+1)) \quad \text{and} \quad s(\tau+1) = \mathbf{1}(x(\tau+1)) \cap \mathbf{0}(x(\tau+2))$$

gives

$$s(\tau) \in \mathbf{1}(x(\tau+2)). \tag{61}$$

Thus, together with (58), we have

$$\begin{aligned} s(\tau+1) &= \mathbf{1}(x(\tau+1)) \cap \mathbf{0}(x(\tau+2)) \\ &= (\mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+2))) \cup (s(\tau) \cap \mathbf{0}(x(\tau+2))) \\ &= \mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+2)) \end{aligned} \tag{62}$$

and

$$\begin{aligned} \mathbf{1}(x(\tau+2)) \setminus s(\tau) &= (\mathbf{1}(x(\tau+1)) \cap \mathbf{1}(x(\tau+2))) \setminus (s(\tau) \cap \mathbf{1}(x(\tau+2))) \\ &= (\mathbf{1}(x(\tau+1)) \setminus s(\tau)) \cap \mathbf{1}(x(\tau+2)) \\ &= \mathbf{1}(x(\tau)) \cap \mathbf{1}(x(\tau+2)). \end{aligned} \tag{63}$$

From (62) and (63), we see that

$$\begin{aligned} &\sum_{j \in \mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)j} \\ &= \sum_{j \in \mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+2))} \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)j} + \sum_{j \in \mathbf{1}(x(\tau)) \cap \mathbf{1}(x(\tau+2))} \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)j} \\ &= \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)s(\tau+1)} + \sum_{j \in \mathbf{1}(x(\tau+2)), j \neq s(\tau)} \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)j}, \end{aligned}$$

and hence, by (41), (61), and the coincidence-detection evolving algorithm, we have

$$\sum_{j \in \mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1) \to x(\tau+2)} a_{s(\tau)j} \geq 0.$$

Thus, by (59), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}.$$

Combining this with (47) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 1-3. $\mathbf{1}(x(\tau+1)) = \mathbf{1}(x(\tau+2))$. Then, by (58), we have

$$s(\tau) \in \mathbf{1}(x(\tau+2)) \quad \text{and} \quad \mathbf{1}(x(\tau)) \subset \mathbf{1}(x(\tau+2)),$$

and according to the coincidence-detection evolving algorithm, we see that

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \geq 0 \ \text{ for all } j \in \mathbf{1}(x(\tau)).$$

Thus, by (59), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}.$$

Combining this with (47) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Case 2. $\mathbf{1}(x(\tau)) \supsetneq \mathbf{1}(x(\tau+1))$. Then

$$s(\tau) = \mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+1)) \tag{64}$$

and, by (43) and (51), we have

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &< b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}. \end{aligned} \tag{65}$$

Subcase 2-1. $\mathbf{1}(x(\tau+1)) \subsetneq \mathbf{1}(x(\tau+2))$. Then $s(\tau) \neq s(\tau+1)$. Indeed, if $s(\tau) = s(\tau+1)$, then, applying (51), (64), and the assembling coordination (10) to $U = s(\tau)$, $t_* = \tau$, and $t^* = \tau+2$, we get

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau+1)) &= l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau)) \\ &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) - l_{\tau+1}(s(\tau), s(\tau)) \\ &< b_{s(\tau)} - a_{s(\tau)s(\tau)}(\tau+1) \\ &\leq b_{s(\tau)}. \end{aligned} \tag{66}$$

Since $s(\tau+1) = s(\tau) \in \mathbf{0}(x(\tau+1))$, inequality (66) implies that

$$x(\tau+2) = H_{A(\tau+1),s(\tau+1)}(x(\tau+1)) = x(\tau+1),$$

contradicting the assumption $\mathbf{1}(x(\tau+1)) \supsetneq \mathbf{1}(x(\tau+2))$. Now combining $s(\tau) \neq s(\tau+1)$ with the fact that

$$s(\tau) \in \mathbf{0}(x(\tau+1)) \quad \text{and} \quad s(\tau+1) = \mathbf{0}(x(\tau+1)) \cap \mathbf{1}(x(\tau+2))$$

gives

$$s(\tau) \in \mathbf{0}(x(\tau+2)). \tag{67}$$

From (67) and the coincidence-detection evolving algorithm, we see that

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \leq 0 \ \text{ for all } j \in \mathbf{1}(x(\tau)).$$

Thus, by (65), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}.$$

Combining this with (50) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 2-2. $\mathbf{1}(x(\tau+1)) \supsetneq \mathbf{1}(x(\tau+2))$. Then, by (64), we have $s(\tau) \in \mathbf{0}(x(\tau+2))$, and hence, according to the coincidence-detection evolving algorithm, we see that

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \leq 0 \ \text{ for all } j \in \mathbf{1}(x(\tau)).$$

Thus, by (65), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}.$$

Combining this with (50) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 2-3. $\mathbf{1}(x(\tau+1)) = \mathbf{1}(x(\tau+2))$. Then, by (64), we have $s(\tau) \in \mathbf{0}(x(\tau+2))$, and hence, according to the coincidence-detection evolving algorithm, we see that

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \leq 0 \ \text{ for all } j \in \mathbf{1}(x(\tau)).$$

Thus, by (65), we have

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) < b_{s(\tau)}.$$

Combining this with (50) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Case 3. $\mathbf{1}(x(\tau)) = \mathbf{1}(x(\tau+1))$. Then the assertion holds: *If* $x(\tau+1) \neq x(\tau+2)$, *then* $s(\tau) \neq s(\tau+1)$. Indeed, if $s(\tau) = s(\tau+1)$, then, by (54) and (57), we have

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau+1)) &= l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau)) \\ &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) \\ &\geq b_{s(\tau)} \quad \text{if } s(\tau) \in \mathbf{1}(x(\tau)) \end{aligned} \tag{68}$$

and

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau+1)) &= l_{\tau+1}(\mathbf{1}(x(\tau+1)), s(\tau)) \\ &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) \\ &< b_{s(\tau)} \quad \text{if } s(\tau) \in \mathbf{0}(x(\tau)). \end{aligned} \tag{69}$$

Inequalities (68) and (69) together imply that

$$x(\tau+2)=H_{A(\tau+1),s(\tau+1)}(x(\tau+1))=x(\tau+1),$$

contradicting the assumption $x(\tau{+}1)\neq x(\tau{+}2)$. This contradiction shows the validity of the assertion, and next we have to consider three subcases.

Subcase 3-1. $\mathbf{1}(x(\tau+1))\subsetneq \mathbf{1}(x(\tau+2))$. Then

$$s(\tau+1)=\mathbf{0}(x(\tau+1))\cap\mathbf{1}(x(\tau+2)) \tag{70}$$

and, according to the assertion, we have

$$s(\tau)\neq s(\tau+1). \tag{71}$$

Since $\mathbf{1}(x(\tau))=\mathbf{1}(x(\tau+1))$, we have either

$$s(\tau)\in\mathbf{1}(x(\tau))=\mathbf{1}(x(\tau+1)) \tag{72}$$

or

$$s(\tau)\in\mathbf{0}(x(\tau))=\mathbf{0}(x(\tau+1)). \tag{73}$$

In case of (72), we see that

$$s(\tau)\in\mathbf{1}(x(\tau+2)) \quad\text{and}\quad \mathbf{1}(x(\tau))\subset\mathbf{1}(x(\tau+2)), \tag{74}$$

and from (43) and (54) we have

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)),s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)),s(\tau))+\sum_{j\in\mathbf{1}(x(\tau))}\mathcal{D}_{x(\tau+1)\to x(\tau+2)}a_{s(\tau)j}\\ &\geq b_{s(\tau)}+\sum_{j\in\mathbf{1}(x(\tau))}\mathcal{D}_{x(\tau+1)\to x(\tau+2)}a_{s(\tau)j}. \end{aligned} \tag{75}$$

Thus we conclude from (74), (75), and the coincidence-detection evolving algorithm that

$$l_{\tau+2}(\mathbf{1}(x(\tau)),s(\tau))\geq b_{s(\tau)}.$$

Combining this with (53) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau))=H_{A(\tau),s(\tau)}(x(\tau))=x(\tau+1).$$

On the other hand, in case of (73) we have

$$s(\tau)\in\mathbf{0}(x(\tau+2))$$

by combining (70), (71), and (73). Hence, by the coincidence-detection evolving algorithm, we have

$$\mathcal{D}_{x(\tau+1)\to x(\tau+2)}a_{s(\tau)j}\leq 0 \quad\text{for all } j\in\mathbf{1}(x(\tau)). \tag{76}$$

Combining (76) with (43) and (57) implies that

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)),s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)),s(\tau))+\sum_{j\in\mathbf{1}(x(\tau))}\mathcal{D}_{x(\tau+1)\to x(\tau+2)}a_{s(\tau)j}\\ &< b_{s(\tau)}+\sum_{j\in\mathbf{1}(x(\tau))}\mathcal{D}_{x(\tau+1)\to x(\tau+2)}a_{s(\tau)j}\\ &\leq b_{s(\tau)}. \end{aligned}$$

Thus, together with (56), we have

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 3-2. $\mathbf{1}(x(\tau+1)) \supsetneq \mathbf{1}(x(\tau+2))$. Then

$$s(\tau+1) = \mathbf{1}(x(\tau+1)) \cap \mathbf{0}(x(\tau+2)) \tag{77}$$

and, according to the assertion, we have

$$s(\tau) \neq s(\tau+1). \tag{78}$$

Since $\mathbf{1}(x(\tau)) = \mathbf{1}(x(\tau+1))$, we have either

$$s(\tau) \in \mathbf{1}(x(\tau)) = \mathbf{1}(x(\tau+1)) \tag{79}$$

or

$$s(\tau) \in \mathbf{0}(x(\tau)) = \mathbf{0}(x(\tau+1)). \tag{80}$$

In case of (79), we have

$$s(\tau) \in \mathbf{1}(x(\tau+2)) \tag{81}$$

by combining (77), (78), and (79). Since

$$\begin{aligned}\mathbf{1}(x(\tau)) \cap \mathbf{1}(x(\tau+2)) &= \mathbf{1}(x(\tau+1)) \cap \mathbf{1}(x(\tau+2))\\ &= \mathbf{1}(x(\tau+2))\end{aligned}$$

and

$$\begin{aligned}\mathbf{1}(x(\tau)) \cap \mathbf{0}(x(\tau+2)) &= \mathbf{1}(x(\tau+1)) \cap \mathbf{0}(x(\tau+2))\\ &= s(\tau+1),\end{aligned}$$

we conclude from (43) and (54) that

$$\begin{aligned}l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}\\ &\geq b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau))\cap\mathbf{1}(x(\tau+2))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}\\ &\quad + \sum_{j\in\mathbf{1}(x(\tau))\cap\mathbf{0}(x(\tau+2))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}\\ &= b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau+2))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j}\\ &\quad + \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)s(\tau+1)}.\end{aligned} \tag{82}$$

According to (41), (81), and the coincidence-detection evolving algorithm, we get

$$\begin{aligned}&\sum_{j\in\mathbf{1}(x(\tau+2))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} + \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)s(\tau+1)}\\ &= \sum_{j\in\mathbf{1}(x(\tau+2)),j\neq s(\tau)} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} + \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)s(\tau)}\\ &\quad + \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)s(\tau+1)}\\ &\geq \sum_{j\in\mathbf{1}(x(\tau+2)),j\neq s(\tau)} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} + \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)s(\tau+1)} \geq 0.\end{aligned} \tag{83}$$

Thus, from (82) and (83), we see that

$$l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) \geq b_{s(\tau)}.$$

Combining this with (53) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1).$$

On the other hand, in case of (80) we have

$$s(\tau) \in \mathbf{0}(x(\tau+2))$$

and, from (43), (57), and the coincidence-detection evolving algorithm, we see that

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &< b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &\leq b_{s(\tau)}. \end{aligned}$$

Combining this with (56) implies that

$$H_{A(\tau+2),s(\tau)}(x(\tau)) = H_{A(\tau),s(\tau)}(x(\tau)) = x(\tau+1),$$

proving (45).

Subcase 3-3. $\mathbf{1}(x(\tau+1)) = \mathbf{1}(x(\tau+2))$. Then, by (43), (54), and the coincidence-detection evolving algorithm, we have

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &\geq b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau+2))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &\geq b_{s(\tau)} \quad \text{if } s(\tau) \in \mathbf{1}(x(\tau)), \end{aligned} \tag{84}$$

and, on the other hand, by (43), (57), and the coincidence-detection evolving algorithm we have

$$\begin{aligned} l_{\tau+2}(\mathbf{1}(x(\tau)), s(\tau)) &= l_{\tau+1}(\mathbf{1}(x(\tau)), s(\tau)) + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &< b_{s(\tau)} + \sum_{j\in\mathbf{1}(x(\tau))} \mathcal{D}_{x(\tau+1)\to x(\tau+2)} a_{s(\tau)j} \\ &\leq b_{s(\tau)} \quad \text{if } s(\tau) \in \mathbf{0}(x(\tau)) = \mathbf{0}(x(\tau+2)). \end{aligned} \tag{85}$$

Combining (84) and (85) accordingly with (53) and (56) implies that

$$x(\tau+2) = H_{A(\tau+1),s(\tau+1)}(x(\tau+1)) = x(\tau+1),$$

proving (45).

Having completed the proof of the claims (44) and (45), we turn now to establish (42). To see this, let $T \geq 0$ be determined by Theorem 2 so that the minimal total excitability in the period of time $t = 0, 1, \ldots, T$ satisfies the assembling coordination and that

$$\mathbf{1}(x(t)) = V \quad \text{for all} \quad t \geq T.$$

Given $\tau = 0, 1, \ldots, T-1$ and $y \in \{y;\ Pro_{A(\tau)}(y, x(\tau)) \leq 1\}$, then either

$$y = x(\tau) \tag{86}$$

or

$$H_{A(\tau),(\mathbf{1}(x(\tau))\cap\mathbf{0}(y))\cup(\mathbf{0}(x(\tau))\cap\mathbf{1}(y))}(y) = x(\tau). \tag{87}$$

In case of (86), it is readily seen that

$$y \in \{y;\ Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2\}$$

since $H_{A(\tau+1),s(\tau)}(x(\tau)) = x(\tau+1)$ by (44). In case of (87), we consider the discrete flow $z(t)$ given by $z(0) = y$, $z(1) = x(\tau)$, $z(2) = x(\tau+1), \ldots$ so that

$$H_{W(t),\widetilde{s}(t)}(z(t)) = z(t+1) \quad \text{for } t = 0, 1, \ldots,$$

where

$$W(0) = A(\tau), W(1) = A(\tau), W(2) = A(\tau+1), \ldots$$

and

$$\widetilde{s}(0) = (\mathbf{1}(x(\tau)) \cap \mathbf{0}(y)) \cup (\mathbf{0}(x(\tau)) \cap \mathbf{1}(y)), \widetilde{s}(1) = s(\tau), \widetilde{s}(2) = s(\tau+1), \ldots.$$

Let $\mathcal{D}_{w(t)\to w(t+1)} w_{ij} = w_{ij}(t+1) - w_{ij}(t)$ for all $i, j \in \{1, 2, \ldots, n\}$ and $t = 0, 1, \ldots$. Then, based on the construction of $x(t)$, $A(t)$, and $W(0) = W(1)$, it is readily seen that $z(t)$ will be one of the discrete flows guided also by the dynamics (3), (4) and the coincidence-detection evolving algorithm. Further, since $\tau + 1 \leq T$ and the assembling coordination, associated to $x(t)$, is satisfied in the period of time $t = 0, 1, \ldots, T$, we have

$$\begin{aligned}\sum_{i\in U} \min(\{w_{ii}(t);\ t = 0, 1, 2\}) &\geq \sum_{i\in U} \min(\{a_{ii}(t);\ t = 0, \ldots, T\}) \\ &\geq \sum_{i,j\in U} \max(\{a_{ij}(t) - a_{ji}(t);\ t = 0, \ldots, T\} \cup \{0\}) \\ &\geq \sum_{i,j\in U} \max(\{w_{ij}(t) - w_{ji}(t);\ t = 0, 1, 2\} \cup \{0\})\end{aligned}$$

for each nonempty subset U of $\{1, 2, \ldots, n\}$. Thus, according to (45) and the fact that the choice of $\mathcal{D}_{w(t)\to w(t+1)} w_{ij}$ satisfies (41), we have

$$H_{W(2),\widetilde{s}(0)}(z(0)) = z(1). \tag{88}$$

Since

$$H_{W(2),\widetilde{s}(1)}(z(1)) = z(2) \tag{89}$$

by (44), we conclude from (88) and (89) that

$$H_{A(\tau+1),\widetilde{s}(1)} \circ H_{A(\tau+1),\widetilde{s}(0)}(y) = x(\tau+1),$$

proving (42) for $t = 0, 1, \ldots, T-1$. Now let $\tau \geq T$ be given and consider y satisfying $Pro_{A(\tau)}(y, x(\tau)) \leq 1$. If $y = x(\tau)$, then

$$Pro_{A(\tau+1)}(y, x(\tau+1)) = Pro_{A(\tau+1)}(x(\tau), x(\tau)) = 0,$$

so

$$y \in \{y;\ Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2\}.$$

If $y \neq x(\tau)$, then $Pro_{A(\tau)}(y, x(\tau)) = 1$, and hence exactly one of the following holds:

$$\mathbf{1}(x(\tau)) \cap \mathbf{0}(y) \neq \emptyset \quad \text{or} \quad \mathbf{0}(x(\tau)) \cap \mathbf{1}(y) \neq \emptyset. \tag{90}$$

Since $Pro_{A(\tau)}(y, x(\tau)) = 1$, the former of (90) implies that

$$l_\tau(\mathbf{1}(y), \mathbf{1}(x(\tau)) \cap \mathbf{0}(y)) \geq b_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)}.$$

Thus

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(y), \mathbf{1}(x(\tau)) \cap \mathbf{0}(y)) &= l_\tau(\mathbf{1}(y), \mathbf{1}(x(\tau)) \cap \mathbf{0}(y)) \\ &\quad + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)j} \\ &\geq b_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)} + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)j}. \end{aligned}$$

Since $\mathbf{0}(x(\tau)) \cap \mathbf{1}(y) = \emptyset$ and $\mathbf{1}(x(\tau)) = \mathbf{1}(x(\tau+1))$, we have

$$\mathcal{D}_{x(\tau)\to x(\tau+1)} a_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)j} \geq 0 \quad \text{for all } j \in \mathbf{1}(y).$$

This implies that

$$l_{\tau+1}(\mathbf{1}(y), \mathbf{1}(x(\tau)) \cap \mathbf{0}(y)) \geq b_{\mathbf{1}(x(\tau))\cap\mathbf{0}(y)},$$

and hence

$$H_{A(\tau+1),\mathbf{1}(x(\tau))\cap\mathbf{0}(y)}(y) = x(\tau) = x(\tau+1).$$

So we have

$$Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2.$$

On the other hand, suppose the latter of (90) holds. Then

$$l_\tau(\mathbf{1}(y), \mathbf{0}(x(\tau)) \cap \mathbf{1}(y)) < b_{\mathbf{0}(x(\tau))\cap\mathbf{1}(y)}.$$

Since $\mathbf{0}(x(\tau)) = \mathbf{0}(x(\tau+1))$, we have

$$\begin{aligned} l_{\tau+1}(\mathbf{1}(y), \mathbf{0}(x(\tau)) \cap \mathbf{1}(y)) &= l_\tau(\mathbf{1}(y), \mathbf{0}(x(\tau)) \cap \mathbf{1}(y)) \\ &\quad + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{\mathbf{0}(x(\tau))\cap\mathbf{1}(y)j} \\ &< b_{\mathbf{0}(x(\tau))\cap\mathbf{1}(y)} + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{\mathbf{0}(x(\tau))\cap\mathbf{1}(y)j} \\ &\leq b_{\mathbf{0}(x(\tau))\cap\mathbf{1}(y)}. \end{aligned}$$

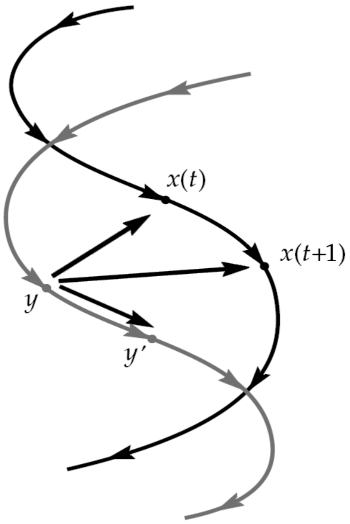

FIG. 5. *A schematic illustration of what local absorption effects. Consider the discrete flow $x(t)$ (the black curve) and its perturbation (the gray curve). Based on the local absorption of the discrete flow $x(t)$, each state y absorbed by $x(t)$ underlying $H_{A(t),\cdot}$ (the arrow from y to $x(t)$) can also be absorbed by $x(t+1)$ underlying $H_{A(t+1),\cdot}$ (the arrow from y to $x(t+1)$). Thus, as the state y transits (the arrow from y to y'), it can only cause small variations of the state $x(t+1)$.*

This implies that

$$H_{A(\tau+1),\mathbf{0}(x(\tau))\cap\mathbf{1}(y)}(y) = x(\tau) = x(\tau+1),$$

completing the proof of (42) for $t = T, T+1, \ldots,$ and the proof of Theorem 3 is complete. □

Theorem 3 is applied to show that neural synchrony is stable (see Figure 5 for an illustration). To accomplish this, let $x(t)$, $A(t)$, and $s(t)$ be defined by (3) and (4), and consider the perturbed system

$$(91) \qquad y(t+1) = H_{A(t),\widetilde{s}(t)}(y(t)), \quad t = 0, 1, \ldots,$$

where $\widetilde{s}(t) \in \{1, 2, \ldots, n\}$ for $t = 0, 1, \ldots.$

THEOREM 4. *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Let the discrete flow $x(t)$ iterate asynchronously, and let $A(t)$ satisfy the condition of assembling coordination described in Theorem* 2. *If the regime of plasticity parameters* (41) *holds, then for any $y(0) \in \{0,1\}^n$ with*

$$(92) \qquad Pro_{A(0)}(y(0), x(0)) \leq 2,$$

there are discrete flows $y(t)$ for the perturbed system (91) *such that*

$$Pro_{A(t)}(y(t), x(t)) \leq 2$$

for all $t = 0, 1, \ldots.$

Proof. Choose $y(0) \in \{0,1\}^n$ so that

$$Pro_{A(0)}(y(0), x(0)) \leq 2.$$

Having chosen $y(0), y(1), \ldots, y(\tau)$, it is readily seen that if $Pro_{A(\tau)}(y(\tau), x(\tau)) = 0$, then

$$\{H_{A(\tau),s}(y(\tau)), s = 1, 2, \ldots, n\} \cap \{y;\ Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2\} \neq \emptyset;$$

and if $Pro_{A(\tau)}(y(\tau), x(\tau)) \neq 0$, then, by (42), we have

$$\begin{aligned} &\{H_{A(\tau),s}(y(\tau)), s = 1, 2, \ldots, n\} \cap \{y;\ Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2\} \\ \supset\ &\{H_{A(\tau),s}(y(\tau)), s = 1, 2, \ldots, n\} \cap \{y;\ Pro_{A(\tau)}(y, x(\tau)) \leq 1\} \neq \emptyset. \end{aligned}$$

Choose $y(\tau+1)$ in

$$\{H_{A(\tau),s}(y(\tau)), s = 1, 2, \ldots, n\} \cap \{y;\ Pro_{A(\tau+1)}(y, x(\tau+1)) \leq 2\}.$$

Then

$$Pro_{A(\tau+1)}(y(\tau+1), x(\tau+1)) \leq 2,$$

and further we have

$$y(\tau+1) \in \{H_{A(\tau),s}(y(\tau)), s = 1, 2, \ldots, n\}.$$

Thus the discrete flow $y(t)$ is constructed for the perturbed system (91) such that

$$Pro_{A(t)}(y(t), x(t)) \leq 2 \quad \text{for all } t = 0, 1, \ldots,$$

and the proof is complete. $\square$

7. Nonlinear effect of neural synchrony. Synchrony and stability of synchrony may lead to formulating evolutionary network architecture. To visualize this, we first show that the effect of synchronization admits self-sustaining activity of strengthening in evolutionary couplings, and then show that such strengthening gives the robust stability of neural synchrony.

The first of these follows immediately from the coincidence-detection evolving algorithm. In fact, we have shown in Theorem 2 that the discrete flow $x(t)$ can iterate to a state x^* of synchronous neuronal firing, that is, a finite $T \geq 0$ can be determined so that

$$x(t) = x^* \quad \text{for all } t \geq T. \tag{93}$$

By the alternating nature of (3) and (4), and by the coincidence-detection evolving algorithm, we see that the assertion (93) is equivalent to saying that for each $t \geq T$, we have the following chain of implications:

$$\begin{aligned} & x(t) = x(t+1) = x^* \\ \Longrightarrow & \begin{cases} a_{ij}(t+1) - a_{ij}(t) = \mathcal{D}_{x(t) \to x(t+1)} a_{ij} \geq 0 & \text{if } i, j \in \mathbf{1}(x(t+1)) = \mathbf{1}(x^*), \\ a_{ij}(t+1) - a_{ij}(t) = \mathcal{D}_{x(t) \to x(t+1)} a_{ij} \leq 0 & \text{otherwise.} \end{cases} \\ \Longrightarrow & x(t+1) = x(t+2) = x^* \\ \Longrightarrow & \begin{cases} a_{ij}(t+2) - a_{ij}(t+1) = \mathcal{D}_{x(t+1) \to x(t+2)} a_{ij} \geq 0 & \text{if } i, j \in \mathbf{1}(x(t+2)) = \mathbf{1}(x^*), \\ a_{ij}(t+2) - a_{ij}(t+1) = \mathcal{D}_{x(t+1) \to x(t+2)} a_{ij} \leq 0 & \text{otherwise.} \end{cases} \\ \Longrightarrow & x(t+2) = x(t+3) = x^* \\ \Longrightarrow & \cdots. \end{aligned}$$

The chain of implications demonstrates how synchrony could indeed specify positive feedback. It is positive feedback to give rise to the consolidation of sync-dependent circuitry, which feeds back to reinforce the neurons to fire in synchrony.

To see the second of these, let us consider the evolutionary coupling states $A(T)$, $A(T+1), \ldots$, each containing distinctive sync-dependent circuitry resulting from the positive feedback. Given a fixed $A(\tau),\ \tau = T, T+1, \ldots$, it follows from (39) and (40) that for any choice of $s \in \{1, 2, \ldots, n\}$,

$$H_{A(\tau),s}(x^*) = x^*.$$

Thus x^* is a *common fixed point* of state transition functions $H_{A(\tau),s}$ for all $s = 1, 2, \ldots, n$, and x^* corresponds to an equilibrium state of the dynamical system being modeled by the nonlinear parametric equations

$$\begin{aligned} z(t+1) &= H_{W(t),s(t)}(z(t)), \quad t = 0, 1, \ldots, \\ W(t+1) &= W(t) + D_{z(t)\to z(t+1)}W, \quad t = 0, 1, \ldots, \end{aligned} \tag{94}$$

where $W(0) = A(\tau)$ and $z(t)$ iterates asynchronously, guided by the coincidence-detection evolving algorithm. By Theorem 4, we can associate to each $A(\tau)$ a region

$$\{y;\ Pro_{A(\tau)}(y, x^*) \le 2\} \tag{95}$$

such that for any $y(0)$ chosen from (95), there are discrete flows $y(t)$ for the perturbed system of (94) satisfying

$$Pro_{W(t)}(y(t), x^*) \le 2 \ \text{ for all } t = 0, 1, \ldots. \tag{96}$$

Therefore, (96) indicates that to every distinctive construction of sync-dependent circuitry $A(\tau)$, $\tau = T,\ T+1,\ \ldots$, there corresponds the region of states (95) which initializes the stability process of x^*.

With the notion above, we can show that, under the conditions of Theorem 4, the inclusions

$$\{y;\ Pro_{A(T)}(y, x^*) \le 2\} \subset \{y;\ Pro_{A(T+1)}(y, x^*) \le 2\} \subset \cdots \tag{97}$$

hold. This reveals the *robust stability* of neural synchrony, meaning that the synchronization state x^* is not only stable but also capable of expanding the region of states for initializing its stability process. For the proof of (97), let $\tau \ge T$ be given and y satisfy $Pro_{A(\tau)}(y, x^*) \le 2$. If $Pro_{A(\tau)}(y, x^*) \le 1$, then, by Theorem 3, we have

$$Pro_{A(\tau+1)}(y, x^*) \le 2.$$

On the other hand, if $Pro_{A(\tau)}(y, x^*) = 2$, then there exist $s_0, s_1 \in \{1, 2, \ldots, n\}$ with $s_0 \ne s_1$ such that

$$H_{A(\tau),s_1} \circ H_{A(\tau),s_0}(y) = x^*. \tag{98}$$

These y, $H_{A(\tau),s_0}(y)$, and x^* are mutually distinct. Let $y' = H_{A(\tau),s_0}(y)$. We have to show that

$$y' = H_{A(\tau+1),s_0}(y) \quad \text{and} \quad x^* = H_{A(\tau+1),s_1}(y'). \tag{99}$$

Case 1. $s_0, s_1 \in \mathbf{1}(x^*)$. Then, by (98), we have

$$\mathbf{1}(y) \subsetneq \mathbf{1}(y') \subsetneq \mathbf{1}(x^*),$$

and

$$s_0 = \mathbf{0}(y) \cap \mathbf{1}(y') \quad \text{and} \quad s_1 = \mathbf{0}(y') \cap \mathbf{1}(x^*).$$

This implies that

$$l_\tau(\mathbf{1}(y), s_0) \geq b_{s_0} \quad \text{and} \quad l_\tau(\mathbf{1}(y'), s_1) \geq b_{s_1}.$$

Hence, according to the coincidence-detection evolving algorithm, we have

$$l_{\tau+1}(\mathbf{1}(y), s_0) = l_\tau(\mathbf{1}(y), s_0) + \sum_{j \in \mathbf{1}(y)} \mathcal{D}_{x(\tau) \to x(\tau+1)} a_{s_0 j} \geq b_{s_0}$$

and

$$l_{\tau+1}(\mathbf{1}(y'), s_1) = l_\tau(\mathbf{1}(y'), s_1) + \sum_{j \in \mathbf{1}(y')} \mathcal{D}_{x(\tau) \to x(\tau+1)} a_{s_1 j} \geq b_{s_1},$$

proving (99).

Case 2. $s_0, s_1 \in \mathbf{0}(x^*)$. Then, by (98), we have

$$\mathbf{0}(y) \subsetneq \mathbf{0}(y') \subsetneq \mathbf{0}(x^*),$$

and

$$s_0 = \mathbf{1}(y) \cap \mathbf{0}(y') \quad \text{and} \quad s_1 = \mathbf{1}(y') \cap \mathbf{0}(x^*).$$

This implies that

$$l_\tau(\mathbf{1}(y), s_0) < b_{s_0} \quad \text{and} \quad l_\tau(\mathbf{1}(y'), s_1) < b_{s_1}.$$

Hence, according to the coincidence-detection evolving algorithm, we have

$$l_{\tau+1}(\mathbf{1}(y), s_0) = l_\tau(\mathbf{1}(y), s_0) + \sum_{j \in \mathbf{1}(y)} \mathcal{D}_{x(\tau) \to x(\tau+1)} a_{s_0 j} < b_{s_0}$$

and

$$l_{\tau+1}(\mathbf{1}(y'), s_1) = l_\tau(\mathbf{1}(y'), s_1) + \sum_{j \in \mathbf{1}(y')} \mathcal{D}_{x(\tau) \to x(\tau+1)} a_{s_1 j} < b_{s_1},$$

proving (99).

Case 3. $s_0 \in \mathbf{1}(x^*)$ *and* $s_1 \in \mathbf{0}(x^*)$. Then, by (98), we have

$$\mathbf{1}(y) \subsetneq \mathbf{1}(y') \quad \text{and} \quad \mathbf{1}(y') \supsetneq \mathbf{1}(x^*),$$

and

$$s_0 = \mathbf{0}(y) \cap \mathbf{1}(y') \quad \text{and} \quad s_1 = \mathbf{1}(y') \cap \mathbf{0}(x^*).$$

This implies that

$$l_\tau(\mathbf{1}(y), s_0) \geq b_{s_0} \quad \text{and} \quad l_\tau(\mathbf{1}(y'), s_1) < b_{s_1}.$$

Since

$$\begin{aligned}\mathbf{1}(y) \cap \mathbf{1}(x^*) &= (\mathbf{1}(y) \cup \mathbf{0}(y')) \cap \mathbf{1}(x^*)\\ &= \mathbf{1}(x^*) \setminus (\mathbf{0}(y) \cap \mathbf{1}(y'))\\ &= \mathbf{1}(x^*) \setminus s_0\end{aligned}$$

and

$$\begin{aligned}\mathbf{1}(y) \cap \mathbf{0}(x^*) &= (\mathbf{1}(y') \cap \mathbf{0}(x^*)) \setminus (\mathbf{0}(y) \cap \mathbf{1}(y') \cap \mathbf{0}(x^*))\\ &= (\mathbf{1}(y') \cap \mathbf{0}(x^*)) \setminus (s_0 \cap s_1)\\ &= s_1,\end{aligned}$$

it follows from (41) and the coincidence-detection evolving algorithm that

$$\begin{aligned}\sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j} &= \sum_{j\in\mathbf{1}(y)\cap\mathbf{1}(x^*)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j} + \sum_{j\in\mathbf{1}(y)\cap\mathbf{0}(x^*)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j}\\ &= \sum_{j\in\mathbf{1}(x^*), j\neq s_0} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j} + \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 s_1} \geq 0.\end{aligned}$$

Thus

$$l_{\tau+1}(\mathbf{1}(y), s_0) = l_\tau(\mathbf{1}(y), s_0) + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j} \geq b_{s_0}.$$

On the other hand, since $s_1 \in \mathbf{0}(x^*)$, it follows from the coincidence-detection evolving algorithm that

$$l_{\tau+1}(\mathbf{1}(y'), s_1) = l_\tau(\mathbf{1}(y'), s_1) + \sum_{j\in\mathbf{1}(y')} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_1 j} < b_{s_1},$$

proving (99).

Case 4. $s_0 \in \mathbf{0}(x^*)$ *and* $s_1 \in \mathbf{1}(x^*)$. Then, by (98), we have

$$\mathbf{1}(y) \supsetneq \mathbf{1}(y') \quad \text{and} \quad \mathbf{1}(y') \subsetneq \mathbf{1}(x^*)$$

and

$$s_0 = \mathbf{1}(y) \cap \mathbf{0}(y') \quad \text{and} \quad s_1 = \mathbf{0}(y') \cap \mathbf{1}(x^*).$$

This implies that

$$l_\tau(\mathbf{1}(y), s_0) < b_{s_0} \quad \text{and} \quad l_\tau(\mathbf{1}(y'), s_1) \geq b_{s_1}.$$

Hence, according to the coincidence-detection evolving algorithm, we have

$$l_{\tau+1}(\mathbf{1}(y), s_0) = l_\tau(\mathbf{1}(y), s_0) + \sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_0 j} < b_{s_0}$$

and

$$l_{\tau+1}(\mathbf{1}(y'), s_1) = l_\tau(\mathbf{1}(y'), s_1) + \sum_{j\in\mathbf{1}(y')} \mathcal{D}_{x(\tau)\to x(\tau+1)} a_{s_1 j} \geq b_{s_1},$$

proving (99). This implies that

$$Pro_{A(\tau+1)}(y, x^*) \leq 2,$$

completing the proof of (97).

With the notation and the arguments above, we describe the mathematical feature of neural synchrony as follows.

THEOREM 5. *If x^* is a synchronization state, then*

(i) $a_{ij}(t+1) \geq a_{ij}(t)$ *for all* $t \geq T$ *if* $i, j \in \mathbf{1}(x^*)$*; otherwise* $a_{ij}(t+1) \leq a_{ij}(t)$ *for all* $t \geq T$*;*

(ii) $\{y;\ Pro_{A(T)}(y, x^*) \leq 2\} \subset \{y;\ Pro_{A(T+1)}(y, x^*) \leq 2\} \subset \cdots.$

8. Determination of the size of neural synchrony. We have shown in Theorem 2 that, after a finite number of time steps, synchronously firing neural groups emerge. But it is possibly the case that the dynamics can evolve to zero activity or tend to synchronize the entire network. In that case it seems to be irrelevant to the brain function. This raises a question: *How is the size of the synchronous group determined?*

To solve this, we need a criterion for predicting neuronal activty states posterior to each time t. We show that for any given $t = 0, 1, \ldots$ and $x(t), A(t), s(t)$ such that

$$x(t+1) = H_{A(t),s(t)}(x(t))$$

by (3) and (4), the regions of all possible neuronal activity states generated at times $t+2$ and $t+3$ can be dominated by the regions of states generated according to the former $A(t)$ and $x(t+1)$.

THEOREM 6. *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Let the discrete flow $x(t)$ iterate asynchronously and let $A(t)$ satisfy the condition of assembling coordination described in Theorem* 2*. Then for each $t = 0, 1, \ldots,$ the inclusion holds:*

$$\{y;\ Pro_{A(t+1)}(x(t+1), y) \leq 1\} \subset \{y;\ Pro_{A(t)}(x(t+1), y) \leq 1\}. \tag{100}$$

If, in addition, the plasticity parameters satisfy (41)*, then*

$$\{y;\ Pro_{A(t+2)}(x(t+2), y) \leq 1\} \subset \{y;\ Pro_{A(t)}(x(t+2), y) \leq 1\} \tag{101}$$

and

$$\{y;\ Pro_{A(t+2)}(x(t+2), y) \leq 1\} \subset \{y;\ Pro_{A(t)}(x(t+1), y) \leq 2\}. \tag{102}$$

Proof. Let $x(0)$ be any initial neuronal active state in $\{0,1\}^n$, and let $x(t)$ iterate asynchronously, guided by the dynamics (3), (4) and the coincidence-detection evolving algorithm. To prove (100), it suffices to show that for each $t = 0, 1, \ldots,$ if there exists y with $Pro_{A(t+1)}(x(t+1), y) = 1$, then $Pro_{A(t)}(x(t+1), y) = 1$. Fixing t and y, we split the arguments into two cases.

Case 1. $\mathbf{1}(x(t+1)) \subsetneq \mathbf{1}(y)$. Let $s = \mathbf{0}(x(t+1)) \cap \mathbf{1}(y)$. Since

$$Pro_{A(t+1)}(x(t+1), y) = 1,$$

we have

$$H_{A(t+1),s}(x(t+1)) = y.$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+1)), s) \geq b_s. \tag{103}$$

Since

$$l_{t+1}(\mathbf{1}(x(t+1)), s) = l_t(\mathbf{1}(x(t+1)), s) + \sum_{j \in \mathbf{1}(x(t+1))} \mathcal{D}_{x(t) \to x(t+1)} a_{sj}$$

and $s \in \mathbf{0}(x(t+1))$, it follows from (103) and the coincidence-detection evolving algorithm that

$$l_t(\mathbf{1}(x(t+1)), s) \geq l_{t+1}(\mathbf{1}(x(t+1)), s) \geq b_s.$$

This implies that

$$H_{A(t),s}(x(t+1)) = y,$$

and hence

$$Pro_{A(t)}(x(t+1), y) = 1.$$

Case 2. $\mathbf{1}(x(t+1)) \supsetneq \mathbf{1}(y)$. Let $s = \mathbf{1}(x(t+1)) \cap \mathbf{0}(y)$. Since

$$Pro_{A(t+1)}(x(t+1), y) = 1,$$

we have

$$H_{A(t+1),s}(x(t+1)) = y.$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+1)), s) < b_s. \tag{104}$$

Since

$$l_{t+1}(\mathbf{1}(x(t+1)), s) = l_t(\mathbf{1}(x(t+1)), s) + \sum_{j \in \mathbf{1}(x(t+1))} \mathcal{D}_{x(t) \to x(t+1)} a_{sj}$$

and $s \in \mathbf{1}(x(t+1))$, it follows from (104) and the coincidence-detection evolving algorithm that

$$l_t(\mathbf{1}(x(t+1)), s) \leq l_{t+1}(\mathbf{1}(x(t+1)), s) < b_s.$$

This implies that

$$H_{A(t),s}(x(t+1)) = y,$$

and hence

$$Pro_{A(t)}(x(t+1),y)=1,$$

proving (100).

To prove (101) and (102), we have to claim that

$$\{y;\ Pro_{A(t+1)}(x(t+2),y)\le 1\}\subset\{y;\ Pro_{A(t)}(x(t+2),y)\le 1\}. \tag{105}$$

So, together with (100), we have

$$\begin{aligned}\{y;\ Pro_{A(t+2)}(x(t+2),y)\le 1\}&\subset\{y;\ Pro_{A(t+1)}(x(t+2),y)\le 1\}\\ &\subset\{y;\ Pro_{A(t)}(x(t+2),y)\le 1\}.\end{aligned}$$

Also, by (100), we get

$$Pro_{A(t)}(x(t+1),x(t+2))\le Pro_{A(t+1)}(x(t+1),x(t+2))\le 1.$$

Thus for each y with $Pro_{A(t+2)}(x(t+2),y)\le 1$, we have

$$Pro_{A(t)}(x(t+1),y)\le Pro_{A(t)}(x(t+1),x(t+2))+Pro_{A(t)}(x(t+2),y)\le 2.$$

To prove (105), it suffices to show that if there exists y with

$$Pro_{A(t+1)}(x(t+2),y)=1,$$

then

$$Pro_{A(t)}(x(t+2),y)=1.$$

Case 1. $\mathbf{1}(x(t+2))\subsetneq\mathbf{1}(y)$. Let $s=\mathbf{0}(x(t+2))\cap\mathbf{1}(y)$. Since

$$Pro_{A(t+1)}(x(t+2),y)=1,$$

we have

$$H_{A(t+1),s}(x(t+2))=y.$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+2)),s)\ge b_s. \tag{106}$$

Since

$$l_{t+1}(\mathbf{1}(x(t+2)),s)=l_t(\mathbf{1}(x(t+2)),s)+\sum_{j\in\mathbf{1}(x(t+2))}\mathcal{D}_{x(t)\to x(t+1)}a_{sj},$$

it follows from (106) and the coincidence-detection evolving algorithm that

$$l_t(\mathbf{1}(x(t+2)),s)\ge l_{t+1}(\mathbf{1}(x(t+2)),s)\ge b_s \tag{107}$$

if $s\in\mathbf{0}(x(t+1))$. Indeed, if $s\notin\mathbf{0}(x(t+1))$, then, according to the asynchronous iteration of $x(t)$, we have

$$s=\mathbf{1}(x(t+1))\cap\mathbf{0}(x(t+2))$$

and

$$H_{A(t+1),s}(x(t+1)) = x(t+2).$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+1)), s) < b_s,$$

and hence, applying the assembling coordination (10) to $U = s$, $t_* = 0$ and $t^* = t+1$, we get

$$\begin{aligned} l_{t+1}(\mathbf{1}(x(t+2)), s) &= l_{t+1}(\mathbf{1}(x(t+1)), s) - a_{ss}(t+1) \\ &< b_s - a_{ss}(t+1) \leq b_s, \end{aligned}$$

contradicting (106). Thus, by (107), we conclude that

$$H_{A(t),s}(x(t+2)) = y,$$

and hence

$$Pro_{A(t)}(x(t+2), y) = 1.$$

Case 2. $\mathbf{1}(x(t+2)) \supsetneqq \mathbf{1}(y)$. Let $s = \mathbf{1}(x(t+2)) \cap \mathbf{0}(y)$. Since

$$Pro_{A(t+1)}(x(t+2), y) = 1,$$

we have

$$H_{A(t+1),s}(x(t+2)) = y.$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+2)), s) < b_s. \tag{108}$$

Further we have $s \in \mathbf{1}(x(t+1))$. Indeed, if $s \notin \mathbf{1}(x(t+1))$, then, according to the asynchronous iteration of $x(t)$, we have

$$s = \mathbf{0}(x(t+1)) \cap \mathbf{1}(x(t+2))$$

and

$$H_{A(t+1),s}(x(t+1)) = x(t+2).$$

This implies that

$$l_{t+1}(\mathbf{1}(x(t+1)), s) \geq b_s.$$

Applying the assembling coordination (10) to $U = s$, $t_* = 0$, and $t^* = t+1$, we get

$$\begin{aligned} l_{t+1}(\mathbf{1}(x(t+2)), s) &= l_{t+1}(\mathbf{1}(x(t+1)), s) + a_{ss}(t+1) \\ &\geq b_s + a_{ss}(t+1) \geq b_s, \end{aligned}$$

contradicting (108). Thus, by the coincidence-detection evolving algorithm, we have

$$\sum_{j \in \mathbf{1}(x(t+2))} \mathcal{D}_{x(t) \to x(t+1)} a_{sj} \geq 0 \tag{109}$$

if $\mathbf{1}(x(t+2)) \subset \mathbf{1}(x(t+1))$, and together with (41) and applying the assembling coordination (10) to $U = s$, $t_* = 0$, and $t^* = t+1$, we see that

$$\begin{aligned}\sum_{j\in\mathbf{1}(x(t+2))} \mathcal{D}_{x(t)\to x(t+1)} a_{sj} = & \sum_{j\in\mathbf{1}(x(t+1)),j\neq s} \mathcal{D}_{x(t)\to x(t+1)} a_{sj} + \mathcal{D}_{x(t)\to x(t+1)} a_{ss} \\ & + \mathcal{D}_{x(t)\to x(t+1)} a_{s\mathbf{0}(x(t+1))\cap\mathbf{1}(x(t+2))} \geq 0\end{aligned} \tag{110}$$

if $\mathbf{1}(x(t+2)) \not\subset \mathbf{1}(x(t+1))$. Since

$$l_{t+1}(\mathbf{1}(x(t+2)), s) = l_t(\mathbf{1}(x(t+2)), s) + \sum_{j\in\mathbf{1}(x(t+2))} \mathcal{D}_{x(t)\to x(t+1)} a_{sj},$$

we conclude from (108), (109), and (110) that

$$l_t(\mathbf{1}(x(t+2)), s) \leq l_{t+1}(\mathbf{1}(x(t+2)), s) < b_s.$$

This implies

$$H_{A(t),s}(x(t+2)) = y,$$

and hence

$$Pro_{A(t)}(x(t+2), y) = 1,$$

proving (105), and the theorem follows. □

Theorem 6 yields the determination of the size of neural synchrony.

THEOREM 7. *Consider the evolutionary network of n coupled neurons subject to the dynamics* (3) *and* (4) *and obeying the coincidence-detection evolving algorithm. Let the discrete flow $x(t)$ iterate asynchronously, the evolutionary coupling state $A(t)$ satisfy the condition of assembling coordination described in Theorem* 2, *and the plasticity parameters satisfy* (41). *Let Ω be a nonempty subset of $\{0,1\}^n$ with $0 \in \Omega$ and $k = 1, 2$. Suppose for every $y \in \{0,1\}^n$, $z \in \Omega$ with*

$$Pro_{A(t)}(x(t+1), y) = k-1 \quad \textit{and} \quad Pro_{A(t)}(y, z) = 1,$$

the plasticity parameters $\mathcal{D}_{x(t)\to x(t+1)} a_{ij}$ satisfy the conditions

$$\sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(t)\to x(t+1)} a_{sj} \geq b_s - \sum_{j\in\mathbf{1}(y)} a_{sj}(t) \ \textit{ whenever } s = \mathbf{1}(x(t+1)) \cap \mathbf{1}(y) \cap \mathbf{0}(z), \tag{111}$$

$$\sum_{j\in\mathbf{1}(y)} \mathcal{D}_{x(t)\to x(t+1)} a_{sj} < b_s - \sum_{j\in\mathbf{1}(y)} a_{sj}(t) \ \textit{ whenever } s = \mathbf{0}(x(t+1)) \cap \mathbf{0}(y) \cap \mathbf{1}(z). \tag{112}$$

If $Pro_{A(0)}(x(0), \Omega) > k$, then

$$Pro_{A(t)}(x(t), \Omega) > k \ \textit{ for } t = 1, 2, \ldots, \tag{113}$$

and

$$\lim_{t\to\infty} x(t) \notin \Omega. \tag{114}$$

Proof. It suffices to prove (113), because (114) follows immediately from (113) and Theorem 2. Fix $k = 1, 2$, and let $x(0)$ and $A(0)$ be the initial states satisfying

$$Pro_{A(0)}(x(0), \Omega) > k.$$

Having chosen $x(0), x(1), \ldots, x(\tau)$ and $A(0), A(1), \ldots, A(\tau)$ with

$$Pro_{A(t)}(x(t), \Omega) > k \quad \text{for } t = 0, 1, \ldots, \tau,$$

we see from (3) and (4) that $x(\tau + 1)$ satisfies

$$Pro_{A(\tau)}(x(\tau + 1), \Omega) \geq k.$$

Then, by (111) and (112), we see that the construction of $A(\tau + 1)$ satisfies

$$Pro_{A(\tau+1)}(x(\tau + 1), \Omega) \neq k. \tag{115}$$

Indeed, if there exists $z \in \Omega$ such that $Pro_{A(\tau+1)}(x(\tau + 1), z) = k$, then we can find $s_0, s_1, \ldots, s_{k-1} \in \{1, 2, \ldots, n\}$ such that

$$H_{A(\tau+1),s_{k-1}} \circ H_{A(\tau+1),s_{k-2}} \circ \cdots \circ H_{A(\tau+1),s_0}(x(\tau + 1)) = z.$$

Put

$$\begin{aligned} z(0) &= x(\tau), \\ z(1) &= x(\tau + 1), \\ z(2) &= H_{A(\tau+1),s_0}(z(1)), \\ &\vdots \\ z(k + 1) &= H_{A(\tau+1),s_{k-1}}(z(k)) \end{aligned}$$

and

$$W(0) = A(\tau), W(1) = W(2) = \cdots = W(k) = A(\tau + 1).$$

Then $z(0), z(1), \ldots, z(k+1)$ are mutually distinct. Since $Pro_{W(1)}(z(1), z(k)) = k-1$, it follows from Theorem 6 that

$$Pro_{W(0)}(z(1), z(k)) = k - 1.$$

Since $Pro_{W(k)}(z(k), z(k + 1)) = 1$, it follows from Theorem 6 that

$$Pro_{W(0)}(z(k), z(k + 1)) = 1.$$

Note that $z(k + 1) = z \in \Omega$, and

$$\begin{aligned} \mathbf{1}(z(k)) \cap \mathbf{0}(z(k + 1)) &\subset \mathbf{1}(z(k - 1)) \cap \mathbf{1}(z(k)), \\ \mathbf{0}(z(k)) \cap \mathbf{1}(z(k + 1)) &\subset \mathbf{0}(z(k - 1)) \cap \mathbf{0}(z(k)), \end{aligned}$$

so by (111) and (112), we have

$$\sum_{j \in \mathbf{1}(z(k))} a_{sj}(\tau + 1) \geq b_s \quad \text{if } s = \mathbf{1}(z(k)) \cap \mathbf{0}(z(k + 1))$$

and

$$\sum_{j\in\mathbf{1}(z(k))} a_{sj}(\tau+1) < b_s \quad \text{if } s = \mathbf{0}(z(k)) \cap \mathbf{1}(z(k+1)),$$

in contradiction to

$$z(k+1) = H_{A(\tau+1),s_{k-1}}(z(k)).$$

Now, according to the inductive assumption

$$Pro_{A(\tau)}(x(\tau+1),\Omega) \geq k$$

and the inclusion derived from Theorem 6,

$$\{y;\ Pro_{A(\tau+1)}(x(\tau+1),y) \leq k-1\} \subset \{y;\ Pro_{A(\tau)}(x(\tau+1),y) \leq k-1\},$$

we have

$$Pro_{A(\tau+1)}(x(\tau+1),\Omega) \geq k.$$

Combining this with (115) implies that

$$Pro_{A(\tau+1)}(x(\tau+1),\Omega) > k,$$

completing the inductive proof of (113) and the proof of Theorem 7 (see Figure 6 for an illustration). ☐

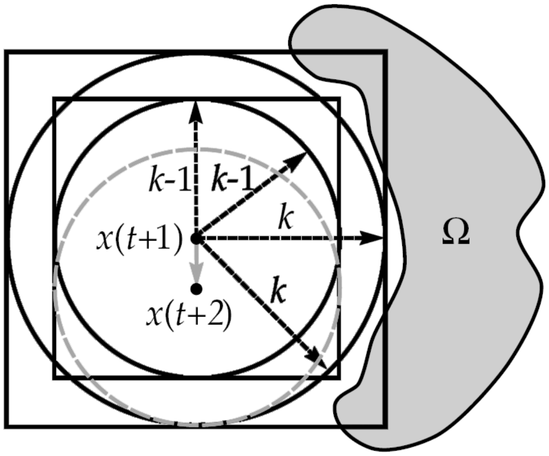

FIG. 6. *The regime of plasticity parameters described in Theorem* 7 *reveals an inductive scheme for the construction of the evolutionary coupling strengths so that the synchronously firing groups of neurons can be determined by a nonempty subset* Ω *of* $\{0,1\}^n$*. For each* $t = 0,1,\ldots$ *and each choice of* $A(t)$*, if* $Pro_{A(t)}(x(t+1),\Omega) \geq k$ *(illustrated by the bigger square that meets* Ω *and the smaller square that doesn't meet* Ω*), then we need only focus on the choice of* $A(t+1)$ *such that* $Pro_{A(t+1)}(x(t+1),\Omega) \neq k$*, and according to Theorem* 6*, it is guaranteed that* $Pro_{A(t+1)}(x(t+1),\Omega) > k$ *(illustrated by both the bigger and the smaller black circles that don't meet* Ω*). Therefore, when* $x(t+1)$ *iterates (the gray arrow), we have* $Pro_{A(t+1)}(x(t+2),\Omega) \geq k$ *(the gray circle centered at* $x(t+2)$ *is a translation of the smaller black circle centered at* $x(t+1)$ *and it doesn't meet* Ω*), yielding the inductive scheme.*

For a specialized region

$$\Omega = \{x;\ x_1 + \cdots + x_n = l_1\} \cup \{x;\ x_1 + \cdots + x_n = l_2\},$$

where $0 < l_1 \ll l_2 < n$, if the initial state $x(0)$ satisfies

$$l_1 + k < x_1(0) + \cdots + x_n(0) < l_2 - k$$

for $k = 1, 2$ and the discrete flow $x(t)$ fulfills the parameter regime of Theorem 7, then Theorem 7 implies that the evolutionary network will eventually evolve to a state of a synchronously firing group of neurons whose size is greater than l_1 and less than l_2. This implies that, with the Hebbian synaptic plasticity, there are regimes of plasticity parameters such that global synchrony or zero activity cannot occur in the dynamics of the evolutionary network.

9. Conclusions.

We describe a model of evolutionary neural networks and unravel its meta-complication of nodal and coupling dynamics. We show that there are time- and activity-dependent nodal-and-coupling changes in the dynamics of the evolutionary network and prove that the dynamics will eventually result in a state of synchronization if those changes are based on Hebbian synaptic plasticity.

Furthermore, we study the stability problem of neural synchrony. We introduce the proximal number to quantify the disturbance of neuronal activity states and reveal the phenomenon of local absorption in a network's dynamics. We show that, underlying Hebbian synaptic plasticity, small perturbations of the initial neuronal active state can cause only small variations of the discrete flow which iterates to a state of neural synchrony.

The combined effect of neural synchrony and its stability shows that neural synchrony is not only to spark tighter connections between neurons but also to generate a monotonically increasing region of states for initializing the stability process. This implies the robust stability of neural synchrony.

We also show that, with Hebbian synaptic plasticity, there is a criterion for predicting neuronal activity states while the evolutionary network evolves. It represents an inductive scheme for the determination of the size of synchronous groups.

Our model of neural processing reflects, in a deep mathematical sense, that plasticity emerges not only as a source of computational power but a source of spontaneous order as well. The extent of plasticity, synchrony, and stability, and the laws it depicts, may find use across many levels in nature and society, appealing to the understanding of the growth dynamics of assemblies, clusters, or communities to interpret the organization of hierarchical architecture in complex systems.

THE STRONGLY CONFINED SCHRÖDINGER–POISSON SYSTEM FOR THE TRANSPORT OF ELECTRONS IN A NANOWIRE*

NAOUFEL BEN ABDALLAH†, FRANCOIS CASTELLA‡, FANNY DELEBECQUE-FENDT‡, AND FLORIAN MÉHATS‡

Abstract. We study the limit of the three-dimensional Schrödinger–Poisson system with a singular perturbation, to model a quantum electron gas that is strongly confined near an axis. For well-prepared data, which are polarized on the ground space of the transversal Hamiltonian, the resulting model is the cubic defocusing nonlinear Schrödinger equation. Our main tool is a refined analysis of the Poisson kernel when acting on strongly confined densities. In that direction, an appropriate scaling of the initial data is required, to avoid divergent integrals when the gas concentrates on the axis.

Key words. Schrödinger–Poisson system, asymptotic analysis, singular perturbation, quantum transport, nanowire, nanoelectronics

1. Introduction.

1.1. The physical problem and the singularly perturbed system.

Artificially confined structures are now routinely realized in the nanoelectronic industry, and the functioning of many electronic devices is based on the transport of charged particles which are bounded in transversal directions; see, e.g., [AFS, Bas, FG, VW]. The confinement can be typically monodimensional, like in quantum wells where two directions remain for the transport, or bidimensional, like in quantum wires where the transport is in dimension one. In this work we are interested in the second case, and this paper is devoted to the rigorous derivation of a dynamic one-dimensional quantum model with space-charge effects describing the transport of electrons confined in a nanowire. Compared with some previous works that treat problems of quantum confinement, as, for instance, [CDR] about an asymptotic model for two particles on the surface of a nanotube (see also references therein), our concern here is to deal more specifically with the nonlinear Poisson term.

Our strategy is inspired by that in [BAMP, BMSW, BCM] and consists of an asymptotic analysis of the three-dimensional Schrödinger–Poisson system (or Hartree system), that will be referred to as our "starting model," with a singular perturbation modeling a strong potential confining the electron gas in a wire. The interesting point concerning the reduced model obtained in the limit is that the nonlinearity describing space-charge effects is now *localized*, this reduced model taking the form of a cubic defocusing nonlinear Schrödinger (NLS) equation.

Let us describe the starting model. The space variable is written (x, z_1, z_2), where $x \in \mathbb{R}$ is the direction in which the electron gas is transported free from any external

force and $z = (z_1, z_2) \in \mathbb{R}^2$ are the confined directions. We consider the following singularly perturbed Schrödinger–Poisson system:

$$i\partial_t \Psi^\varepsilon = -\Delta\Psi^\varepsilon + \frac{1}{\varepsilon^2} V_c\left(\frac{z}{\varepsilon}\right)\Psi^\varepsilon + \mathbb{V}^\varepsilon \Psi^\varepsilon, \tag{1.1}$$

$$\mathbb{V}^\varepsilon = \frac{1}{4\pi r} * \left(|\Psi^\varepsilon|^2\right). \tag{1.2}$$

The unknown in this system is the pair $(\Psi^\varepsilon, \mathbb{V}^\varepsilon)$ made of the electronic wave function Ψ^ε and the self-consistent potential $\mathbb{V}^\varepsilon$ due to space charge effects, written here as a convolution with the Poisson kernel. We use the notation $r(x,z) = \sqrt{x^2 + |z|^2}$. The main modeling assumption is that a strong external potential is applied to the gas, written here $\frac{1}{\varepsilon^2} V_c(\frac{z}{\varepsilon})$, where $V_c(z)$ is a prescribed function satisfying the following assumption.

Assumption 1.1. *The function $V_c : \mathbb{R}^2 \mapsto \mathbb{R}$ belongs to $L^2_{loc}(\mathbb{R}^2)$, and there exists $\alpha > 0$ and $C > 0$ such that*

$$V_c(z) \geq C\,|z|^\alpha.$$

The crucial assumption here is the growth at infinity, which determines the strength of the confinement. The parameter $\varepsilon \in (0,1)$ is the scaled thickness of the electron gas. As we will see after a rescaling in the next section, the normalization term $\frac{1}{\varepsilon^2}$ is natural in order to balance the strong external potential with the Laplace operator in the z variable.

This paper studies the asymptotic behavior of $(\Psi^\varepsilon, \mathbb{V}^\varepsilon)$ as ε goes to zero. Of course, an initial datum $\Psi^\varepsilon(0,x,z)$ needs to be prescribed for (1.1), whose specific form is made precise in the next section.

1.2. Scaling of the initial data and formal limit. In this section, we derive heuristically the asymptotic model satisfied by the solution of (1.1)–(1.2) as ε goes to zero. Precise and rigorous statements will be made in the next section. Let us introduce the following notation for averages upon the transversal variables:

$$\langle f \rangle = \int_{\mathbb{R}^2} f(z)dz.$$

The singular term $\frac{1}{\varepsilon^2} V_c(\frac{z}{\varepsilon})$ in the Schrödinger equation (1.1) induces a concentration of the density on the axis $z = 0$. We expect that, as $\varepsilon \to 0$, the density takes the form of a line density multiplied by a delta function:

$$|\Psi^\varepsilon(t,x,z)|^2 \sim \left\langle |\Psi^\varepsilon(t,x,\cdot)|^2 \right\rangle \delta(z). \tag{1.3}$$

The crucial point is the consequence of (1.3) on the self-consistent potential. Indeed, we can prove (see Proposition 2.1) that, near the axis $z = 0$, the solution of (1.2) looks like

$$\mathbb{V}^\varepsilon(t,x,z) \sim -\frac{1}{2\pi} \log\varepsilon \left\langle |\Psi^\varepsilon(t,x,\cdot)|^2 \right\rangle. \tag{1.4}$$

This estimate suggests the following choice of initial data: we choose $\Psi^\varepsilon(0,x,z)$ to be small, of order $|\log\varepsilon|^{-1/2}$ (e.g., in $L^2(\mathbb{R}^3)$).

In order to observe the system at the scale of the gas, we work with rescaled space variables, setting

$$\Psi^\varepsilon(t,x,z) = \frac{1}{\varepsilon\sqrt{|\log\varepsilon|}}\,\psi^\varepsilon\left(t,x,\frac{z}{\varepsilon}\right), \qquad \mathbb{V}^\varepsilon(t,x,z) = \frac{1}{|\log\varepsilon|}V^\varepsilon\left(t,x,\frac{z}{\varepsilon}\right).$$

The system in the new unknowns ψ^ε, V^ε becomes

$$i\partial_t\psi^\varepsilon = -\partial_x^2\psi^\varepsilon + \frac{1}{\varepsilon^2}H_z\psi^\varepsilon + \frac{1}{|\log\varepsilon|}V^\varepsilon\psi^\varepsilon\,, \tag{1.5}$$

$$V^\varepsilon = \frac{1}{4\pi r^\varepsilon} * |\psi^\varepsilon|^2, \qquad r^\varepsilon(x,z) = \sqrt{x^2+\varepsilon^2|z|^2}, \tag{1.6}$$

$$\psi^\varepsilon(0,x,z) = \psi_0^\varepsilon(x,z), \tag{1.7}$$

where the Hamiltonian in the z direction is

$$H_z = -\Delta_z + V_c(z).$$

Inserting (1.4) into (1.5), we obtain that, asymptotically, ψ^ε satisfies

$$i\partial_t\psi^\varepsilon = -\partial_x^2\psi^\varepsilon + \frac{1}{\varepsilon^2}H_z\psi^\varepsilon + \frac{1}{2\pi}\left\langle|\psi^\varepsilon|^2\right\rangle\psi^\varepsilon\,, \tag{1.8}$$

$$\psi^\varepsilon(0,x,z) = \psi_0^\varepsilon(x,z). \tag{1.9}$$

This is our reduced model. An elementary remark is that the term $\left\langle|\psi^\varepsilon|^2\right\rangle$ in the nonlinearity does not depend on the z variable. It is thus easy to filter out the oscillations in time induced by the $\frac{1}{\varepsilon^2}H_z$ term. Indeed the function

$$\phi^\varepsilon = e^{itH_z/\varepsilon^2}\,\psi^\varepsilon$$

satisfies the following problem, independent of ε:

$$i\partial_t\phi^\varepsilon = -\partial_x^2\phi^\varepsilon + \frac{1}{2\pi}\left\langle|\phi^\varepsilon|^2\right\rangle\phi^\varepsilon\,, \tag{1.10}$$

$$\phi^\varepsilon(0,x,z) = \psi_0^\varepsilon(x,z), \tag{1.11}$$

where we used the fact that e^{itH_z/ε^2} is an isometry on $L_z^2(\mathbb{R}^2)$, i.e.,

$$\left\langle|\phi^\varepsilon|^2\right\rangle = \left\langle|\psi^\varepsilon|^2\right\rangle.$$

The limit model can be seen as a system of NLS equations in dimension one. To see this, let us introduce the eigenfunctions $(\chi_k(z))_{k\geq 1}$ of the operator H_z and the associated eigenvalues $(E_k)_{k\geq 1}$. Note that Assumption 1.1 implies that the operator H_z is self-adjoint (see, e.g., [RS, Vol. 2, Theorem X.28]) and, defined as a sum of quadratic forms, is an operator with compact resolvent (see [RS, Vol. 4, Theorem XIII.67]). It possesses purely discrete spectrum and a complete set of eigenfunctions.

The reduced model (1.10), (1.11) can be projected on the χ_k's and is equivalent to the system

$$i\partial_t \varphi_k = -\partial_x^2 \varphi_k + \frac{1}{2\pi}\left(\sum_{j=1}^{\infty} |\varphi_j|^2\right)\varphi_k\,, \tag{1.12}$$

$$\varphi_k(0,x) = \int_{\mathbb{R}} \psi_0(x,z)\,\chi_k(z)dz, \qquad k \in \mathbb{N}^*. \tag{1.13}$$

The solution of the rescaled initial problem is then—formally—asymptotically close to

$$\psi^\varepsilon(t,x,z) = \sum_{k=1}^{\infty} e^{-itE_k/\varepsilon^2}\,\varphi_k(t,x)\,\chi_k(z).$$

1.3. Statement of the main result. Let us introduce the energy space

$$\mathcal{H} = \{u \in H^1(\mathbb{R}^3),\ \sqrt{V_c}u \in L^2(\mathbb{R}^3)\}, \tag{1.14}$$

endowed with the norm

$$\|u\|^2_{\mathcal{H}} = \|u\|^2_{H^1(\mathbb{R}^3)} + \|\sqrt{V_c}u\|^2_{L^2(\mathbb{R}^3)} = \|\partial_x u\|^2_{L^2(\mathbb{R}^3)} + \|H_z^{1/2}u\|^2_{L^2(\mathbb{R}^3)}.$$

Note that Assumption 1.1 yields the following control for functions in the energy space:

$$\forall u \in \mathcal{H}, \qquad \int_{\mathbb{R}^3} |z|^\alpha |u|^2\,dxdz \leq C\|u\|^2_{\mathcal{H}}\,. \tag{1.15}$$

Consider for the rescaled starting model (1.5)–(1.7) a sequence of initial data $(\psi_0^\varepsilon)_{\varepsilon>0}$ satisfying the following assumption.

ASSUMPTION 1.2. *The sequence $(\psi_0^\varepsilon)_{\varepsilon>0}$ is uniformly bounded in $\mathcal{H}$ and converges in $L^2(\mathbb{R}^3)$ to a function ψ_0.*

Standard techniques [BM, Caz, IZL, Cas] allow us to prove that for any $\varepsilon \in (0,1)$ the three-dimensional Schrödinger–Poisson system (1.5)–(1.7) admits a unique global weak solution $(\psi^\varepsilon, V^\varepsilon)$ for $t \in \mathbb{R}$ in the energy space. In order to analyze its limit as $\varepsilon \to 0$, let us summarize the available estimates on ψ^ε. The first one is the L^2 estimate. For all t we have

$$\|\psi^\varepsilon(t)\|^2_{L^2(\mathbb{R}^3)} = \|\psi_0^\varepsilon\|^2_{L^2(\mathbb{R}^3)} \leq C. \tag{1.16}$$

Unfortunately (see Proposition 2.1), this estimate alone does not enable us to bound the self-consistent potential, and one needs at least an estimate on the derivative of ψ^ε with respect to x. Let us now examine the second natural estimate for the Schrödinger–Poisson system, namely, the energy estimate. It reads, in rescaled variables:

$$\begin{aligned} &\|\partial_x\psi^\varepsilon(t)\|^2_{L^2(\mathbb{R}^3)} + \frac{1}{\varepsilon^2}\|H_z^{1/2}\psi^\varepsilon(t)\|^2_{L^2(\mathbb{R}^3)} + \frac{1}{|\log\varepsilon|}\left\|V^\varepsilon(t)|\psi^\varepsilon(t)|^2\right\|_{L^1(\mathbb{R}^3)} \\ &\quad = \|\partial_x\psi_0^\varepsilon\|^2_{L^2(\mathbb{R}^3)} + \frac{1}{\varepsilon^2}\|H_z^{1/2}\psi_0^\varepsilon\|^2_{L^2(\mathbb{R}^3)} + \frac{1}{|\log\varepsilon|}\left\|V^\varepsilon(0)|\psi_0^\varepsilon|^2\right\|_{L^1(\mathbb{R}^3)}\,. \end{aligned} \tag{1.17}$$

Multiplying this equation by ε^2, one can deduce a bound for $\|H_z^{1/2}\psi^\varepsilon(t)\|_{L^2(\mathbb{R}^3)}$ (see the beginning of section 3), *but not for* $\|\partial_x\psi^\varepsilon(t)\|_{L^2(\mathbb{R}^3)}$. However, for a certain set of well-prepared initial data it can be easily proved that this quantity is bounded. As it was remarked in [BMSW], it suffices to consider initial data which are polarized on the first eigenmode χ_1 of the transverse Hamiltonian H_z. This leads to the following theorem, which is our main result.

THEOREM 1.3. *Under Assumptions* 1.1 *and* 1.2, *assume, moreover, that the initial data is nearly polarized on the first eigenmode* χ_1 *of* H_z, *associated with the eigenvalues* E_1 *in the sense:*

$$\left\|(H_z - E_1)^{1/2}\,\psi_0^\varepsilon\right\|_{L^2(\mathbb{R}^3)} \le C\,\varepsilon. \tag{1.18}$$

Then there exist $C > 0$ *such that the solution* ψ^ε *of* (1.5)–(1.7) *satisfies*

$$\|\partial_x\psi^\varepsilon(t)\|_{L^2} \le C, \quad \textit{independently of } \varepsilon > 0 \textit{ and } t \in \mathbb{R}, \tag{1.19}$$

and the following convergence result holds, for all $T > 0$*:*

$$\left\|\psi^\varepsilon(t,x,z) - e^{-itE_1/\varepsilon^2}\varphi(t,x)\,\chi_1(z)\right\|_{L^2(\mathbb{R}^3)} \underset{\varepsilon\to 0}{\longrightarrow} 0 \qquad \textit{uniformly on } [-T,T],$$

where $\varphi(t,x)$ *solves the cubic defocusing NLS equation*

$$i\partial_t\varphi = -\partial_x^2\varphi + \frac{1}{2\pi}|\varphi|^2\varphi\,, \qquad \varphi(0,x) = \int_{\mathbb{R}} \psi_0(x,z)\chi_1(z)dz. \tag{1.20}$$

Note that (1.20) is a particular case of the limit model (1.12), (1.13) derived formally in the previous subsection. The keystone of the convergence proof is the L^2 estimate (1.19) of $\partial_x\psi^\varepsilon$. In the general case of initial data bounded in $\mathcal{H}$ but *not* polarized on the first eigenmode, the following partial result can be proved as an easy extension of Theorem 1.3. *Under the assumption that* (1.19) *holds*, the function $e^{itH_z/\varepsilon^2}\psi^\varepsilon$ converges locally uniformly in $L^2(\mathbb{R}^3)$ to the solution ϕ of

$$i\partial_t\phi = -\partial_x^2\phi + \frac{1}{2\pi}\left\langle|\phi|^2\right\rangle\phi\,, \qquad \phi(0,x,z) = \psi_0(x,z).$$

The outline of the paper is the following. In section 2, we give an asymptotic expansion as $\varepsilon \to 0$ of the solution of the rescaled Poisson equation (1.6), for wavefunctions ψ^ε in a suitable functional space. Section 3 is devoted to the proof of Theorem 1.3. As a first step we use the energy estimate for well-prepared data in order to get an estimate of $\|\partial_x\psi^\varepsilon\|_{L^2}$ in that case. We conclude the proof using a stability result for the cubic NLS equation.

2. Approximation of the Poisson kernel.

In this section, we study the convolution with the Poisson kernel when ε is close to zero. We consider the Poisson potential V^ε, after the rescaling $z \mapsto \varepsilon z$, $x \mapsto x$, and let $\varepsilon \to 0$ in (1.6). In order to make a precise statement, let us first recall the definition of the finite part of a singular integral. For $u \in C^{0,\eta}(\mathbb{R}) \cap L^1(\mathbb{R})$, with $\eta \in (0,1)$, we have

$$\begin{aligned}\mathrm{FP}\int_{\mathbb{R}} \frac{u(x')}{|x-x'|}\,dx' &= \lim_{\eta\to 0}\left(\int_{|x-x'|>\eta} \frac{u(x')}{|x-x'|}dx' + 2u(x)\log\eta\right)\\ &= \int_{|x-x'|<1} \frac{u(x')-u(x)}{|x-x'|}dx' + \int_{|x-x'|>1} \frac{u(x')}{|x-x'|}dx'\,.\end{aligned} \tag{2.1}$$

Both quantities are well defined whenever $u \in \mathcal{C}^{0,\eta}(\mathbb{R}) \cap L^1(\mathbb{R})$. Our aim here is to prove the following result.

PROPOSITION 2.1. *Consider ψ in the energy space $\mathcal{H}$ defined by (1.14), and let*

$$G^\varepsilon(\psi) = \int_{\mathbb{R}} \int_{\mathbb{R}^2} \frac{|\psi(x',z')|^2}{\sqrt{(x-x')^2 + \varepsilon^2 |z-z'|^2}}\, dx' dz'.$$

Then we have the following asymptotic expansion,

$$G^\varepsilon(\psi) = -2 \log \varepsilon \langle |\psi(x,\cdot)|^2 \rangle + R_1(\psi) + R_2^\varepsilon(\psi), \tag{2.2}$$

where

$$R_1(\psi) = -2 \int_{\mathbb{R}^2} \log|z-z'| |\psi(x,z')|^2 dz' + 2\log 2 \langle |\psi(x,\cdot)|^2 \rangle + \mathrm{FP} \int_{\mathbb{R}} \frac{\langle |\psi(x',\cdot)|^2 \rangle}{|x-x'|} dx',$$

and for all $u \in \mathcal{H}$ we have

$$\|R_1(\psi) u\|_{L^2} \le C \|\psi\|_{\mathcal{H}}^2 \, \|u\|_{\mathcal{H}} , \qquad \|R_2^\varepsilon(\psi) u\|_{L^2} \le C_\beta \, \varepsilon^\beta \|\psi\|_{\mathcal{H}}^2 \, \|u\|_{\mathcal{H}} \tag{2.3}$$

for all $\beta < \min(1/2, \alpha/2)$, α being defined according to Assumption 1.1.

Proof. Let us first list some useful available estimates deduced from Sobolev embeddings and from (1.15): for all $u \in \mathcal{H}$, we have

$$\|\partial_x u\|_{L^2(\mathbb{R}^3)} + \|u\|_{L^\infty_x L^2_z} + \|\partial_z u\|_{L^2(\mathbb{R}^3)} + \|(1+|z|^{\alpha/2}) u\|_{L^2(\mathbb{R}^3)} \le C \, \|u\|_{\mathcal{H}}. \tag{2.4}$$

Let us now decompose

$$\begin{aligned} G^\varepsilon(\psi) &= \int_{\mathbb{R}^3} \frac{|\psi(x',z')|^2}{\sqrt{(x-x')^2 + \varepsilon^2|z-z'|^2}} dx' dz' \\ &= \int_{\mathbb{R}^2} \int_{|x-x'|<1} \frac{|\psi(x',z')|^2 - |\psi(x,z')|^2}{\sqrt{(x-x')^2 + \varepsilon^2|z-z'|^2}} dx' dz' \\ &\quad + \int_{\mathbb{R}^2} \int_{|x-x'|<1} \frac{|\psi(x,z')|^2}{\sqrt{(x-x')^2 + \varepsilon^2|z-z'|^2}} dx' dz' \\ &\quad + \int_{\mathbb{R}^2} \int_{|x-x'|\ge 1} \frac{|\psi(x',z')|^2}{\sqrt{(x-x')^2 + \varepsilon^2|z-z'|^2}} dx' dz' \\ &= I_1 + I_2 + I_3 \, . \end{aligned} \tag{2.5}$$

We first analyze the term I_1 by rewriting it as

$$I_1 = \int_{\mathbb{R}^2} \int_{|x-x'|<1} \frac{|\psi(x',z')|^2 - |\psi(x,z')|^2}{|x-x'|} dx' dz' + r_1^\varepsilon, \tag{2.6}$$

where r_1^ε is to be upper-bounded later. Using

$$|\psi(x,z) - \psi(x',z)| \le C|x-x'|^{1/2} \left(\int_{\mathbb{R}} |\partial_x \psi(y,z)|^2 \, dy \right)^{1/2}, \tag{2.7}$$

we deduce that the first term on the right-hand side is well defined and can be bounded thanks to (2.4):

$$\begin{aligned} \left| \int_{\mathbb{R}^2} \int_{|x-x'|<1} \frac{|\psi(x',z')|^2 - |\psi(x,z')|^2}{|x-x'|} dx' dz' \right| &\le C \, \|\partial_x \psi\|_{L^2} \, \|\psi\|_{L^\infty_x L^2_z} \int_0^1 \frac{1}{\xi^{1/2}} d\xi \\ &\le C \|\psi\|_{\mathcal{H}}^2. \end{aligned}$$

In order to estimate the remainder r_1^ε, we remark that for all $\gamma \in [0,2]$ there holds

$$0 \leq \frac{1}{|x-x'|} - \frac{1}{\sqrt{(x-x')^2+\varepsilon^2|z-z'|^2}} \leq \frac{\varepsilon^\gamma |z-z'|^\gamma}{|x-x'|^{1+\gamma}}. \tag{2.8}$$

Pick β such that $0<\beta<\min(\frac{1}{2},\frac{\alpha}{2})$ and take $\gamma=\beta$. One can estimate the remainder as

$$|r_1^\varepsilon| \leq C\varepsilon^\beta \int_{\mathbb{R}^2}\int_{|x-x'|<1} \frac{\|\partial_x\psi(\cdot,z')\|_{L^2_x}}{|x-x'|^{1/2+\beta}} \left(|z|^\beta+|z'|^\beta\right)\left(|\psi(x',z')|+|\psi(x,z')|\right) dx'dz',$$

where we used (2.8) and (2.7). By the Cauchy–Schwarz estimate, for all $u\in\mathcal{H}$ we get

$$\begin{aligned}\|r_1^\varepsilon u\|_{L^2} \leq C\varepsilon^\beta \|\partial_x\psi\|_{L^2}\left(\||z|^\beta\psi\|_{L^2}\,\|u\|_{L^\infty_x L^2_z} + \|\psi\|_{L^\infty_x L^2_z}\,\||z|^\beta u\|_{L^2}\right)\int_0^1 \frac{1}{\xi^{1/2+\beta}}d\xi \\ + C\varepsilon^\beta\|\partial_x\psi\|_{L^2}\|uw\|_{L^2}\end{aligned}$$

with

$$w(x) := \int_{|x-x'|<1} \frac{(\int_{\mathbb{R}^2}|z'|^{2\beta}|\psi(x',z')|^2dz')^{1/2}}{|x-x'|^{1/2+\beta}}dx'\,.$$

The first line of the right-hand side is bounded thanks to (2.4) and $\beta<\frac{1}{2}$. To bound the last term, we use Hölder and Hardy–Littlewood–Sobolev inequalities:

$$\|uw\|_{L^2} \leq \|w\|_{L^{1/\beta}}\,\|u\|_{L_x^{2/(1-2\beta)}L^2_z} \leq C\,\||z|^\beta\psi\|_{L^2}\,\|u\|_{L_x^{2/(1-2\beta)}L^2_z} \leq C\,\|\psi\|_{\mathcal{H}}\,\|u\|_{\mathcal{H}}\,,$$

where we used (2.4) and the fact that $\beta<\frac{\alpha}{2}$ and $\frac{2}{1-2\beta}>2$. Finally, we have

$$\|r_1^\varepsilon u\|_{L^2} \leq C\,\varepsilon^\beta\,\|\psi\|^2_{\mathcal{H}}\,\|u\|_{\mathcal{H}}.$$

For the term I_2, a direct computation of the integral with respect to x' gives

$$I_2 = 2(-\log\varepsilon+\log 2)\langle|\psi(x,\cdot)|^2\rangle - 2\int_{\mathbb{R}^2}\log|z-z'||\psi(x,z')|^2dz' + r_2^\varepsilon\,, \tag{2.9}$$

with

$$r_2^\varepsilon = 2\int_{\mathbb{R}^2}|\psi(x,z')|^2\log\left(\frac{1+\sqrt{1+\varepsilon^2|z-z'|^2}}{2}\right)dz'.$$

Let us first estimate the dominant term in (2.9). The term $\langle|\psi(x,\cdot)|^2\rangle$ is clearly bounded in L^∞ by (2.4). In order to bound the second term

$$v = \int_{\mathbb{R}^2}\log|z-z'||\psi(x,z')|^2dz',$$

we remark that

$$|\log|z-z'|| \leq C\left(\frac{\mathbf{1}_{|z-z'|<1}}{|z-z'|^{1/2}} + 1 + |z|^{\alpha/2} + |z'|^{\alpha/2}\right),$$

and from Hardy–Littlewood–Sobolev and Gagliardo–Nirenberg inequalities we get, pointwise in x,

$$\int_{|z-z'|<1} \frac{1}{|z-z'|^{1/2}} |\psi(x,z')|^2 dz' \leq C\|\psi(x,\cdot)\|_{L^4}^2 \leq C\|\psi(x,\cdot)\|_{L^2}\|\partial_z\psi(x,\cdot)\|_{L^2}.$$

Hence, for all $u \in \mathcal{H}$,

$$\begin{aligned}\|uv\|_{L^2} \leq C\,\|\psi\|_{L^\infty_x L^2_z}\,\|\partial_z\psi\|_{L^2}\,\|u\|_{L^\infty_x L^2_z} + C\||z|^{\alpha/2}\psi\|_{L^2}^2\,\|u\|_{L^\infty_x L^2_z} \\ + C\|\psi\|_{L^\infty_x L^2_z}^2\,\|(1+|z|^{\alpha/2})u\|_{L^2} \leq C\,\|\psi\|_{\mathcal{H}}^2\,\|u\|_{\mathcal{H}},\end{aligned}$$

where we used (2.4). Let us now estimate the remainder r_2^ε. With the above choice of $\beta \leq \frac{1}{2} < 2$, we have

$$\log\left(\frac{1+\sqrt{1+t^2}}{2}\right) \leq Ct^\beta \qquad \forall t > 0,$$

and thus, for all $u \in \mathcal{H}$,

$$\begin{aligned}\|r_2^\varepsilon u\|_{L^2} &\leq C\,\varepsilon^\beta\|\psi\|_{L^\infty_x L^2_z}(\||z|^\beta\psi\|_{L^2}\,\|u\|_{L^\infty_x L^2_z} + \|\psi\|_{L^\infty_x L^2_z}\,\||z|^\beta u\|_{L^2}) \\ &\leq C\,\varepsilon^\beta\,\|\psi\|_{\mathcal{H}}^2\,\|u\|_{\mathcal{H}},\end{aligned}$$

where we used again (2.4) and $\beta < \frac{\alpha}{2}$.

Consider now the term I_3, which we write as

$$I_3 = \int_{|x-x'|\geq 1} \frac{\left\langle |\psi(x',z')|^2 \right\rangle}{|x-x'|} dx' + r_3^\varepsilon, \tag{2.10}$$

with the following immediate bound for the dominant term:

$$0 \leq \int_{|x-x'|\geq 1} \frac{\left\langle |\psi(x',z')|^2 \right\rangle}{|x-x'|} dx' \leq \|\psi\|_{L^2}^2\,.$$

Moreover, from (2.8), the following estimate can be deduced for the remainder:

$$\begin{aligned}|r_3^\varepsilon| &\leq C\,\varepsilon^\beta \int_{\mathbb{R}^2}\int_{|x-x'|\geq 1} \frac{|z-z'|^\beta\,|\psi(x',z')|^2}{|x-x'|^{1+\beta}} dx'dz' \\ &\leq C\,\varepsilon^\beta\,\left(|z|^\beta\|\psi\|_{L^2}^2 + \||z|^{\beta/2}\,\psi\|_{L^2}^2\right).\end{aligned}$$

This is enough to conclude that

$$\|r_3^\varepsilon\,u\|_{L^2} \leq C\,\varepsilon^\beta\,\|\psi\|_{\mathcal{H}}^2\,\|u\|_{\mathcal{H}}\,.$$

To complete the proof of the proposition, it suffices to gather (2.6), (2.9), and (2.10), and then to use (2.1). ▯

3. Proof of the main theorem. As we said in the introduction, the system (1.5)–(1.7) admits two natural conservation laws: the conservation of the L^2 norm (1.16) and the energy estimate (1.17). Whereas it is immediate to deduce from the first one a uniform estimate of the L^2 norm of ψ^ε, let us examine the second one. Multiplied by ε^2, it gives

$$\|H_z^{1/2}\psi^\varepsilon(t)\|^2_{L^2(\mathbb{R}^3)} \leq \varepsilon^2\|\partial_x\psi_0^\varepsilon\|^2_{L^2(\mathbb{R}^3)} + \|\psi_0^\varepsilon\|^2_{\mathcal{H}} + \frac{\varepsilon^2}{|\log\varepsilon|}\|V^\varepsilon(0)|\psi_0^\varepsilon|^2\|_{L^1(\mathbb{R}^3)}\,. \tag{3.1}$$

From Proposition 2.1 and the Cauchy–Schwarz inequality, we get

$$\begin{aligned}\frac{1}{|\log\varepsilon|}\|V^\varepsilon(0)|\psi_0^\varepsilon|^2\|_{L^1} \leq\ & \frac{1}{|\log\varepsilon|}\|V^\varepsilon(0)\psi_0^\varepsilon\|_{L^2}\|\psi_0^\varepsilon\|_{L^2}\\ &= \frac{1}{4\pi|\log\varepsilon|}\|G^\varepsilon(\psi_0)\,\psi_0^\varepsilon\|_{L^2}\|\psi_0^\varepsilon\|_{L^2} \leq C\,\|\psi_0^\varepsilon\|^4_{\mathcal{H}},\end{aligned} \tag{3.2}$$

and thus

$$\|H_z^{1/2}\psi^\varepsilon(t)\|^2_{L^2(\mathbb{R}^3)} \leq \|\psi_0^\varepsilon\|^2_{\mathcal{H}} + C\,\varepsilon^2\|\psi_0^\varepsilon\|^4_{\mathcal{H}}, \tag{3.3}$$

which is uniformly bounded, thanks to Assumption 1.2. In order to have a bound for ψ^ε in the energy space $\mathcal{H}$, it remains to bound the L^2 norm of $\partial_x\psi^\varepsilon$. This is done in the next subsection for well-prepared initial data.

3.1. Energy estimate for well-prepared data. We name "well-prepared data" a sequence of initial data $(\psi_0^\varepsilon)_{\varepsilon>0}$ in $\mathcal{H}$ which are polarized on the first eigenmode χ_1 of H_z, associated with the eigenvalue E_1 in the sense (1.18).

We now prove that, under Assumptions 1.1 and 1.2 and the assumption of well-prepared data, estimate (1.19) holds true. This relies only on the two conservation laws (1.16) and (1.17). Since E_1 is the bottom of the spectrum of H_z, we have

$$\|H_z^{1/2}u\|^2_{L^2} - E_1\|u\|^2_{L^2} = \int_{\mathbb{R}^3}\overline{u}\,(H_z - E_1)u\,dxdz = \|(H_z-E_1)^{1/2}u\|^2_{L^2}\,;$$

thus subtracting $\frac{E_1}{\varepsilon^2}\times$ (1.16) from (1.17) leads to the identity

$$\begin{aligned}\|\partial_x\psi^\varepsilon(t)\|^2_{L^2} + \frac{1}{\varepsilon^2}\|(H_z-E_1)^{1/2}\psi^\varepsilon(t)\|^2_{L^2} + \frac{1}{|\log\varepsilon|}\left\|V^\varepsilon(t)|\psi^\varepsilon(t)|^2\right\|_{L^1}&\\ = \|\partial_x\psi_0^\varepsilon\|^2_{L^2} + \frac{1}{\varepsilon^2}\|(H_z-E_1)^{1/2}\psi_0^\varepsilon\|^2_{L^2} + \frac{1}{|\log\varepsilon|}\left\|V^\varepsilon(0)|\psi_0^\varepsilon|^2\right\|_{L^1}&.\end{aligned}$$

By Assumption 1.2, (1.18), and (3.2), the right-hand side of this inequality is bounded independently of ε. Hence

$$\|\partial_x\psi^\varepsilon(t)\|^2_{L^2} + \frac{1}{\varepsilon^2}\|(H_z-E_1)^{1/2}\psi^\varepsilon(t)\|^2_{L^2} \leq C. \tag{3.4}$$

This estimate has two consequences. First, with (3.3) it gives

$$\|\psi^\varepsilon(t)\|_{\mathcal{H}} \leq C, \tag{3.5}$$

uniformly with respect to t. Second, this estimate shows that ψ^ε remains polarized on the first mode for all time. More precisely, denote

$$r^\varepsilon(t,x,z) = \psi^\varepsilon(t,x,z) - \chi_1(z)\int\psi^\varepsilon(t,x,z')\chi_1(z')dz'.$$

Remarking that $(H_z - E_1)^{1/2} \geq (E_2 - E_1)^{1/2} > 0$ in the operator sense on $\mathcal{H}$, the following estimate can be deduced from (3.4):

$$\|r^\varepsilon(t)\|_{\mathcal{H}} \leq C\varepsilon. \tag{3.6}$$

3.2. The convergence theorem. In this section, we prove the convergence result stated in Theorem 1.3. Let

$$\psi^\varepsilon(t,x,z) = e^{-itE_1/\varepsilon^2}\varphi_1^\varepsilon(t,x)\chi_1(z) + r^\varepsilon(t,x,z). \tag{3.7}$$

Inserting (3.7) into (1.5) and projecting on $Span(\chi_1)$ leads to the following equation:

$$i\partial_t \varphi_1^\varepsilon = -\partial_x^2 \varphi_1^\varepsilon + \frac{e^{itE_1/\varepsilon^2}}{|\log\varepsilon|}\int_{\mathbb{R}^2} V^\varepsilon(t,x,z)\psi^\varepsilon(t,x,z)\chi_1(z)dz. \tag{3.8}$$

To deal with the nonlinear term, we use the decomposition given by Proposition 2.1, with $V^\varepsilon = \frac{1}{4\pi}G^\varepsilon(\psi^\varepsilon)$. Remarking that, by orthogonality, we have

$$\left\langle |\psi^\varepsilon|^2 \right\rangle = |\varphi_1^\varepsilon|^2 + \left\langle |r^\varepsilon|^2 \right\rangle,$$

we get from (2.2)

$$\frac{e^{itE_1/\varepsilon^2}}{|\log\varepsilon|}\int_{\mathbb{R}^2} V^\varepsilon(t,x,z)\psi^\varepsilon(t,x,z)\chi_1(z)dz = \frac{1}{2\pi}|\varphi_1^\varepsilon|^2\varphi_1^\varepsilon + f^\varepsilon,$$

with

$$f^\varepsilon = \frac{1}{2\pi}\left\langle |r^\varepsilon|^2 \right\rangle \varphi_1^\varepsilon + \frac{e^{itE_1/\varepsilon^2}}{4\pi|\log\varepsilon|}\int_{\mathbb{R}^2}\left(R_1(\psi^\varepsilon) + R_2^\varepsilon(\psi^\varepsilon)\right)\psi^\varepsilon\chi_1 dz.$$

We clearly have

$$\|f^\varepsilon\|_{L^2(\mathbb{R})} \leq C\left\|\left\langle |r^\varepsilon|^2\right\rangle\right\|_{L^\infty(\mathbb{R})}\|\psi^\varepsilon\|_{L^2} + \frac{C}{|\log\varepsilon|}\left(\|R_1(\psi^\varepsilon)\psi^\varepsilon\|_{L^2} + \|R_2^\varepsilon(\psi^\varepsilon)\psi^\varepsilon\|_{L^2}\right).$$

In order to bound the first term, we notice that by the Cauchy–Schwarz estimate,

$$\left|\partial_x \left\langle |r^\varepsilon|^2\right\rangle\right|^{1/2} = \frac{\left|\mathcal{R}e \int \overline{r^\varepsilon}\,\partial_x r^\varepsilon\,dz\right|}{\left\langle |r^\varepsilon|^2\right\rangle^{1/2}} \leq \|\partial_x r^\varepsilon\|_{L^2_z},$$

and thus by the Sobolev embedding $H^1(\mathbb{R}) \hookrightarrow L^\infty(\mathbb{R})$,

$$\left\|\left\langle |r^\varepsilon|^2\right\rangle\right\|_{L^\infty(\mathbb{R})} \leq C\left\|\left\langle |r^\varepsilon|^2\right\rangle^{1/2}\right\|_{H^1(\mathbb{R})}^2 \leq C\left(\|r^\varepsilon\|_{L^2(\mathbb{R}^3)}^2 + \|\partial_x r^\varepsilon\|_{L^2(\mathbb{R}^3)}^2\right) \leq C\varepsilon^2,$$

where we used (3.6). Therefore, one deduces directly from (2.3) and (3.5) that

$$\|f^\varepsilon\|_{L^2(\mathbb{R})} \leq \frac{C}{|\log\varepsilon|}. \tag{3.9}$$

Now, the conclusion stems from a stability result for the cubic NLS equation in dimension one. Indeed, the functions φ_1^ε and φ solve, respectively,

$$i\partial_t\varphi_1^\varepsilon = -\partial_x^2\varphi_1^\varepsilon + \frac{1}{2\pi}|\varphi_1^\varepsilon|^2\varphi_1^\varepsilon + f^\varepsilon\,, \qquad \varphi_1^\varepsilon(0,x) = \int_{\mathbb{R}}\psi_0^\varepsilon(x,z)\chi_1(z)dz \tag{3.10}$$

and

$$i\partial_t \varphi = -\partial_x^2 \varphi + \frac{1}{2\pi}|\varphi|^2\varphi\,, \qquad \varphi(0,x) = \int_{\mathbb{R}} \psi_0(x,z)\chi_1(z)dz. \tag{3.11}$$

We remark that both functions are bounded in $H^1(\mathbb{R})$, and thus in $L^\infty(\mathbb{R})$, uniformly in time. For φ_1^ε this property is a direct consequence of (3.5), as $\|\varphi_1^\varepsilon\|_{H^1(\mathbb{R})} \leq \|\psi^\varepsilon\|_{\mathcal{H}}$. For φ, this stems from the energy conservation for the defocusing NLS equation (3.11) and from the fact that, by Assumption 1.2, the initial data $\varphi(0,\cdot)$ belongs to $H^1(\mathbb{R})$. Then it is easily seen that for all t we have

$$\begin{aligned}\|\varphi_1^\varepsilon(t) - \varphi(t)\|_{L^2} &\leq \|\psi_0^\varepsilon - \psi_0\|_{L^2} + \int_0^t \left(\frac{1}{2\pi}\left\||\varphi_1^\varepsilon|^2\varphi_1^\varepsilon - |\varphi|^2\varphi\right\|_{L^2} + \|f^\varepsilon(s)\|_{L^2}\right) ds \\ &\leq \|\psi_0^\varepsilon - \psi_0\|_{L^2} + C\int_0^t \|\varphi_1^\varepsilon(s) - \varphi(s)\|_{L^2} ds + \int_0^t \|f^\varepsilon(s)\|_{L^2} ds;\end{aligned}$$

so it follows from (3.9), from Assumption 1.2, and from the Gronwall lemma that for all $T > 0$

$$\|\varphi_1^\varepsilon - \varphi\|_{L^\infty([-T,T],L^2(\mathbb{R}))} \xrightarrow[\varepsilon\to 0]{} 0.$$

3.3. Towards a more precise approximation. According to (3.9), the convergence rate in Theorem 1.3 is at most $\mathcal{O}\left(\frac{1}{|\log\varepsilon|}\right)$. To go further, Proposition 2.1 suggests the form of the next term in the approximation of the initial model. Taking into account the R^1 term, one can consider the following system:

$$i\partial_t \widetilde{\varphi} = -\partial_x^2 \widetilde{\varphi} + \frac{1}{2\pi}|\widetilde{\varphi}|^2\widetilde{\varphi} + \frac{1}{4\pi|\log\varepsilon|}\left(\gamma|\widetilde{\varphi}|^2 + \mathrm{FP}\int_{\mathbb{R}} \frac{|\widetilde{\varphi}(x')|^2}{|x-x'|}\,dx'\right)\widetilde{\varphi}, \tag{3.12}$$

where

$$\gamma = -\int_{\mathbb{R}^4} \log\left(\frac{|z-z'|^2}{4}\right)|\chi_1(z)|^2|\chi_1(z')|^2 dz dz'$$

and

$$\widetilde{\varphi}(0,x) = \int_{\mathbb{R}^2} \psi_0^\varepsilon(x,z)\chi_1(z)dz.$$

From the approximation result given by Proposition 2.1, one could expect a better convergence rate:

$$\|\psi^\varepsilon(t,x,z) - e^{itH_z/\varepsilon^2}\widetilde{\varphi}(t,x)\chi_1(z)\|_{L^2} \leq C\,\varepsilon^\beta$$

with $\beta > 0$ as in Proposition 2.1. At the level of this article, this refined convergence result is a conjecture, as is the existence of the solution $\widetilde{\varphi}$ of (3.12). These questions will be investigated in a future work.

BLOOMING IN A NONLOCAL, COUPLED PHYTOPLANKTON-NUTRIENT MODEL*

A. ZAGARIS[†], A. DOELMAN[†], N. N. PHAM THI[‡], and B. P. SOMMEIJER[§]

Abstract. Recently, it has been discovered that the dynamics of phytoplankton concentrations in an ocean exhibit a rich variety of patterns, ranging from trivial states to oscillating and even chaotic behavior [J. Huisman, N. N. Pham Thi, D. M. Karl, and B. P. Sommeijer, *Nature*, 439 (2006), pp. 322–325]. This paper is a first step towards understanding the bifurcational structure associated with nonlocal coupled phytoplankton-nutrient models as studied in that paper. Its main subject is the linear stability analysis that governs the occurrence of the first nontrivial stationary patterns, the *deep chlorophyll maxima* (DCMs) and the *benthic layers* (BLs). Since the model can be scaled into a system with a natural singularly perturbed nature, and since the associated eigenvalue problem decouples into a problem of Sturm–Liouville type, it is possible to obtain explicit (and rigorous) bounds on, and accurate approximations of, the eigenvalues. The analysis yields bifurcation-manifolds in parameter space, of which the existence, position, and nature are confirmed by numerical simulations. Moreover, it follows from the simulations and the results on the eigenvalue problem that the asymptotic linear analysis may also serve as a foundation for the secondary bifurcations, such as the oscillating DCMs, exhibited by the model.

1. Introduction.

Phytoplankton forms the foundation of most aquatic ecosystems [16]. Since it transports significant amounts of atmospheric carbon dioxide into the deep oceans, it may play a crucial role in climate dynamics [6]. Therefore, the dynamics of phytoplankton concentrations have been studied intensely and from various points of view (see, for instance, [7, 11, 15] and the references therein). Especially relevant and interesting patterns exhibited by phytoplankton are the *deep chlorophyll maxima* (DCMs), or *phytoplankton blooms*, in which the phytoplankton concentration exhibits a maximum at a certain, well-defined depth of the ocean (or, in general, of a vertical water column). Simple, one-dimensional, scalar—but nonlocal—models for the influence of a depth-dependent light intensity on phytoplankton blooms have been studied since the early 1980s [14]. The nonlocality of these models is a consequence of the influence of the accumulated plankton concentration on the light intensity at a certain depth z (see (1.2) below). Numerical simulations and various mathematical approaches (see [5, 7, 8, 10, 12]) show that these models may, indeed, exhibit DCMs, depending on the manner in which the decay of the light intensity with depth is modeled and for certain parameter combinations.

The analysis in [14] establishes that, for a certain (large) class of light intensity functions, the scalar model has a stationary global attractor. This attractor may be trivial; i.e., the phytoplankton concentration W may decrease with time to $W \equiv 0$. If this trivial pattern is spectrally unstable, either the global attractor is a DCM or the phytoplankton concentration is maximal at the surface of the ocean (this latter case is called a *surface layer* (SL) [10, 15]). It should be noted here that *benthic layers* (BLs) [15]—i.e., phytoplankton blooms that become maximum at the bottom of the water column—cannot occur in the setting of [14], due to the choice of boundary conditions. Although the analysis in [14] cannot be applied directly to all scalar models in the literature, the main conclusion—that such models may only exhibit stationary nontrivial patterns (DCMs, SLs, or BLs)—seems to be true for each one of these models.

In sharp contrast to this, it has been numerically discovered recently [11] that systems—i.e., nonscalar models in which the phytoplankton concentration W is coupled to an evolution equation for a nutrient N—may exhibit complex behavior ranging from periodically oscillating DCMs to chaotic dynamics. These nonstationary DCMs have also been observed in the Pacific Ocean [11].

In this paper, we take a first step towards understanding the rich dynamics of the phytoplankton-nutrient models considered in [11]. Following [11], we consider the one-dimensional (i.e., depth-dependent only), nonlocal model,

$$\left\{ \begin{array}{l} W_t = D\,W_{zz} - V\,W_z + [\mu\,P(L,N) - l]\,W, \\ N_t = D\,N_{zz} - \alpha\,\mu\,P(L,N)\,W, \end{array} \right. \tag{1.1}$$

for $(z,t) \in [0, z_B] \times \mathbf{R}_+$ and where $z_B > 0$ determines the depth of the water column. The system is assumed to be in the turbulent mixing regime (see, for instance, [5, 10]), and thus the diffusion coefficient D is taken to be identically the same for W and N. The parameters V, l, α, and μ measure, respectively, the sinking speed of phytoplankton, the species-specific loss rate, the conversion factor, and the maximum specific production rate, and they are all assumed to be positive (see Remark 1.1 also). The light intensity L is modeled by

$$L(z,t) = L_I\,\mathrm{e}^{-K_{bg}z - R\int_0^z W(\zeta,t)\,d\zeta}, \tag{1.2}$$

where L_I is the intensity of the incident light at the water surface, K_{bg} is the light absorption coefficient due to nonplankton components, and R is the light absorption coefficient due to the plankton. Note that L is responsible for the introduction of nonlocality into the system. The function $P(L,N)$, which is responsible for the coupling, models the influence of light and nutrient on the phytoplankton growth, and it is taken to be

$$P(L,N) = \frac{LN}{(L+L_H)(N+N_H)}, \tag{1.3}$$

where L_H and N_H are the half-saturation constants of light and nutrient, respectively. We note that, from a qualitative standpoint, the particular form of P is of little importance. Different choices for P yield the same qualitative results, as long as they share certain common characteristics with the function given in (1.3); see Remark 1.1. Finally, we equip the system with the boundary conditions

$$D\,W_z - V\,W|_{z=0,z_B} = 0, \quad N_z|_{z=0} = 0, \quad \text{and} \quad N|_{z=z_B} = N_B, \tag{1.4}$$

i.e., no-flux through the boundaries except at the bottom of the column where N is at its maximum (prescribed by N_B). We refer the reader to Remark 1.1 for a discussion of more general models. To recast the model in nondimensional variables, we rescale time and space by setting

$$x = z/z_B \in (0,1) \quad \text{and} \quad \tau = \mu t \geq 0;$$

we introduce the scaled phytoplankton concentration ω, nutrient concentration η, and light intensity j,

$$\omega(x,\tau) = \frac{l\alpha z_B^2}{DN_B}\, W(z,t), \quad \eta(x,\tau) = \frac{N(z,t)}{N_B}, \quad j(x,\tau) = \frac{L(z,t)}{L_I};$$

and thus we recast (1.1) in the form

$$\text{(1.5)} \qquad \begin{cases} \omega_\tau = \varepsilon\omega_{xx} - \sqrt{\varepsilon}a\,\omega_x + (p(j,\eta) - \ell)\omega, \\ \eta_\tau = \varepsilon\left(\eta_{xx} - \frac{1}{\ell}p(j,\eta)\omega\right). \end{cases}$$

Here,
(1.6)

$$j(x,\tau) = \exp\left(-\kappa x - r\int_0^x \omega(s,\tau)\,ds\right), \quad \text{with} \quad \kappa = K_{bg}z_B \quad \text{and} \quad r = \frac{RDN_B}{l\alpha z_B},$$

and

$$\text{(1.7)} \qquad \varepsilon = \frac{D}{\mu z_B^2}, \quad a = \frac{V}{\sqrt{\mu D}}, \quad \ell = \frac{l}{\mu}, \quad \text{and} \quad p(j,\eta) = \frac{j\eta}{(j+j_H)(\eta+\eta_H)},$$

where $j_H = L_H/L_I$, $\eta_H = N_H/N_B$. The rescaled boundary conditions are given by

$$\text{(1.8)} \qquad \left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(0) = \left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(1) = 0, \quad \eta_x(0) = 0, \quad \text{and} \quad \eta(1) = 1.$$

These scalings are suggested by realistic parameter values in the original model (1.1) as reported in [11]. Typically,

$$D \approx 0.1\,\text{cm}^2/\text{s}, \quad V \approx 4.2\,\text{cm/h}, \quad z_B \approx 3\cdot 10^4\,\text{cm}, \quad l \approx 0.01/\text{h}, \quad \text{and} \quad \mu \approx 0.04/\text{h},$$

so that

$$\text{(1.9)} \qquad \varepsilon \approx 10^{-5}, \quad a \approx 1, \quad \text{and} \quad \ell \approx 0.25$$

in (1.5). Thus, realistic choices of the parameters in (1.1) induce a *natural singularly perturbed structure* in the model, as is made explicit by the scaling of (1.1) into (1.5). In this article, ε will be considered as an asymptotically small parameter, i.e., $0 < \varepsilon \ll 1$.

The simulations in [11] indicate that the DCMs bifurcate from the trivial stationary pattern,

$$\text{(1.10)} \qquad \bar{\omega}(x,\tau) \equiv 0, \quad \bar{\eta}(x,\tau) \equiv 1 \quad \text{for all } (x,\tau) \in [0,1] \times \mathbf{R}_+;$$

see also section 3. To analyze this (first) bifurcation, we set

$$(\omega(x,\tau), \eta(x,\tau)) = \left(\tilde{\omega}e^{\lambda\tau}, 1 + \tilde{\eta}e^{\lambda\tau}\right), \quad \text{with} \quad \lambda \in \mathbf{C},$$

and consider the (spectral) stability of $(\bar{\omega}, \bar{\eta})$. This yields the linear eigenvalue problem

$$\left\{ \begin{array}{r} \varepsilon\omega_{xx} - \sqrt{\varepsilon}a\,\omega_x + (f(x) - \ell)\omega = \lambda\omega, \\ \varepsilon\left(\eta_{xx} - \frac{1}{\ell}f(x)\omega\right) = \lambda\eta, \end{array} \right. \tag{1.11}$$

where we have dropped the tildes with a slight abuse of notation. The boundary conditions are

$$\left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(0) = \left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(1) = 0 \quad \text{and} \quad \eta_x(0) = \eta(1) = 0, \tag{1.12}$$

while the function f is the linearization of the function $p(j, \eta)$,

$$f(x) = \frac{1}{(1 + \eta_H)(1 + j_H \mathrm{e}^{\kappa x})}. \tag{1.13}$$

The linearized system (1.11) is *partially decoupled*, so that the stability of $(\bar{\omega}, \bar{\eta})$ as solution of the *two-component system* (1.5) is determined by two *one-component* Sturm–Liouville problems,

$$\begin{array}{c} \varepsilon\,\omega_{xx} - \sqrt{\varepsilon}\,a\,\omega_x + (f(x) - \ell)\omega = \lambda\omega, \\ \left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(0) = \left(\sqrt{\varepsilon}\omega_x - a\,\omega\right)(1) = 0, \end{array} \tag{1.14}$$

with η determined from the second equation in (1.11), and

$$\varepsilon\,\eta_{xx} = \lambda\eta \quad \text{with} \quad \eta_x(0) = \eta(1) = 0, \tag{1.15}$$

with ω identically equal to zero. The second of these problems, (1.15), is exactly solvable and describes the diffusive behavior of the nutrient in the absence of phytoplankton. Thus, it is not directly linked to the phytoplankton bifurcation problem that we consider, and we will not discuss it further. The phytoplankton behavior that we focus on is described by (1.14) instead, and hence we have returned to a scalar system as studied in [5, 7, 8, 10, 12, 14, 15]. However, our viewpoint differs significantly from that of those studies. The simulations in [11] (and section 3 of the present article) suggest that the destabilization of $(\bar{\omega}, \bar{\eta})$ into a DCM is merely the first in a series of bifurcations. In fact, section 3 shows that this DCM undergoes "almost immediately" a second bifurcation of Hopf type; i.e., it begins to oscillate periodically in time. According to [14], this is impossible in a scalar model (also, it has not been numerically observed in such models), and so the Hopf bifurcation must be induced by the *weak* coupling between ω and η in the full model (1.5).

Our analysis establishes that the largest eigenvalue λ_0 of (1.14) which induces the (stationary) DCM as it crosses through zero is the first of a sequence of eigenvalues λ_n that are only $\mathcal{O}(\varepsilon^{1/3})$ apart (see Figure 3.3, where $\varepsilon^{1/3} \approx 0.045$). The simulations in section 3 show that the distance between this bifurcation and the subsequent Hopf bifurcation of the DCM is of the same magnitude; see Figure 3.3 especially. Thus, the stationary DCM already destabilizes while λ_0 is still asymptotically small in ε, which indicates that the amplitude of the bifurcating DCM is also still asymptotically small and determined (at leading order) by $\omega_0(x)$, the eigenfunction associated with λ_0. This agrees fully with our linear stability analysis, since $\omega_0(x)$ indeed has the structure of a DCM (see sections 2 and 7). As a consequence, the *leading order* (in ε) stability analysis of the DCM is also governed by the partially decoupled system (1.11). In other words, although what drives the secondary bifurcation(s) is the coupling between $\omega(x)$ and $\eta(x)$ in (1.5), the leading order analysis is governed by the eigenvalues and eigenfunctions of (1.14). Naturally, the next eigenvalues and their associated eigenfunctions will play a key role in such a secondary bifurcation analysis, as will the eigenvalues and eigenfunctions of the trivial system (1.15).

Therefore, a detailed knowledge of the nature of the eigenvalues and eigenfunctions of (1.14) forms the foundation of analytical insight in the bifurcations exhibited by (1.5). This is the topic of the present paper; the subsequent (weakly) nonlinear analysis is the subject of work in progress.

The structure of the eigenvalue problem (1.14) is rather subtle, and therefore we employ two different analytical approaches. In sections 4–6, we derive explicit and rigorous bounds on the eigenvalues in terms of expressions based on the zeroes of the Airy function of the first kind and its derivative; see Theorem 2.1. We supplement this analysis with a WKB approach in section 7, where we show that the critical eigenfunctions have the structures of a DCM or a BL. This analysis establishes the existence of, first, the aforementioned sequence of eigenvalues that are $\mathcal{O}(\varepsilon^{1/3})$ apart, which is associated with the bifurcation of a DCM; and second, of another eigenvalue which also appears for biologically relevant parameter combinations and which is associated with the bifurcation of a BL—this bifurcation was not observed in [11]. This eigenvalue is isolated, in the sense that it is not part of the eigenvalue sequence associated with the DCMs—instead, it corresponds to a zero of a linear combination of the Airy function of the second kind and its derivative. Depending on the value of the dimensionless parameter a, the trivial state $(\bar{\omega}, \bar{\eta})$ bifurcates either into a DCM or into a BL. Our analysis establishes the bifurcation sets explicitly in terms of the parameters in the problem (section 2.2) and is confirmed by numerical simulations (section 3). Note that the codimension 2 point, at which DCM- and BL-patterns bifurcate simultaneously and which we determine explicitly, is related to that studied in [20]. Nevertheless, the differences are crucial—for instance, [20] considers a two-layer ODE model where, additionally, the DCM interacts with an SL instead of a BL (an SL cannot occur in our setting because $V > 0$ in (1.1); see Remark 1.1).

The outcome of our analysis is summarized in section 2, in which we also summarize the bio-mathematical interpretations of this analysis. We test and challenge the results of the stability analysis by numerical simulations of the full model in section 3. Although our insights are based only on linear predictions, and we do not yet have analytical results on the (nonlinear) stability of the patterns that bifurcate, we do find that there is an excellent agreement between the linear analysis and the numerical simulations. Thus, our analysis of (1.14) yields explicit bifurcation curves in the biological parameter space associated with (1.1). For any given values of the parameters, our analysis predicts whether one may expect a phytoplankton pattern with the structure of a (possibly oscillating) DCM, a pattern with the structure of a BL, or whether the phytoplankton will become extinct. Moreover, we also briefly consider secondary bifurcations into time-periodic patterns. These bifurcations are not directly covered by our linear analysis, but the distance between the first and second bifurcation in parameter space implies that the linearized system (1.14) must play a crucial role in the subsequent (weakly) nonlinear analysis; see the discussion above.

Remark 1.1. Our approach and findings for the model (1.1) (equivalently, (1.5)) are also applicable and relevant for more extensive models:

• In [11], (1.1) was extended to a model for various phytoplankton species $W_i(z,t)$ $(i = 1, \ldots, n)$. A stability analysis of the trivial pattern $W_i \equiv 0$, $N \equiv N_B$ yields n uncoupled copies of (1.14) in which the parameters depend on the species, i.e., on the index i. As a consequence, the results of this paper can also be applied to this multispecies setting.

- It is natural to include the possibility of horizontal flow and diffusion in the model (1.1). In the most simple setting, this can be done by allowing W and N to vary with (x, y, z, t) and to include horizontal diffusion terms in (1.1), i.e., $D_H(W_{xx}+W_{yy})$ and $D_H(N_{xx}+N_{yy})$ with $D_H \neq D$, in general—see [17], for instance. Again, the linear stability analysis of the trivial state is essentially not influenced by this extension. The exponentials in the ansatz following (1.10) now need to be replaced by $\exp(\lambda\tau + i(k_x\tilde{x} + k_y\tilde{y}))$, where k_x and k_y are wave numbers in the (rescaled) x and y directions. As a consequence, one only has to replace ℓ by $\ell - D_H(k_x^2 + k_y^2)$ in (1.14).
- The fact that we assign specific formulas to the growth and light intensity functions $P(L, N)$ (see (1.3)) and $L(z, t)$ (see (1.2)) is inessential for our analysis. One needs only that $f(x)$ is *decreasing* and *bounded* in $[0, 1]$—both assumptions are natural from a biological standpoint.
- We have considered "sinking" phytoplankton species in our model, i.e., $V > 0$ in (1.1) and thus $a > 0$ in (1.14). Our analysis can also be applied to buoyant species ($V \leq 0$). In that case, the bifurcating DCMs may transform into SLs—see also [10, 15].
- The values of ε, a, and ℓ in (1.9) are typical of oceanic settings [11]. These values differ in an estuary, and ε can no longer be assumed to be asymptotically small; see [19] and the references therein. Moreover, phytoplankton blooms in an estuary are strongly influenced by the concentration of suspended sediment and typically occur not only at a certain depth z, but also at a certain horizontal position in the estuary. Thus, (1.14) must be extended to account for such blooms; however, it may still play an important role as a limiting case or a benchmark [19].

2. The main results.

In the first part of this section, we present our main results in full mathematical detail. In section 2.2, we present a bio-mathematical interpretation of these results.

2.1. Mathematical analysis.

We define the parameter $\nu = 1/(1+\eta_H)$, the function F through

$$F(x) = F(x; j_H, \kappa, \nu) = f(0) - f(x) \geq 0 \quad \text{for all} \quad x \in [0,1] \tag{2.1}$$

(see (1.13)), and the constants $\sigma_L = \sigma_L(\kappa, j_H, \nu)$ and $\sigma_U = \sigma_U(\kappa, j_H, \nu)$ so that

$$\sigma_L\, x \leq F(x) \leq \sigma_U\, x \quad \text{for all} \quad x \in [0,1]. \tag{2.2}$$

The optimal values of σ_U and σ_L can be determined explicitly. This (simple yet technical) analysis is postponed until after the formulation of Theorem 2.1; see Lemma 2.1 and Figures 2.2 and 2.3. Next, we define the parameters

$$A = \frac{a^2}{4}, \quad \beta = \sqrt{\frac{A}{\sigma}}, \quad \text{and} \quad 0 < \gamma \equiv \left(\frac{\varepsilon}{\sigma}\right)^{1/3} \ll 1, \tag{2.3}$$

with a as in (1.7) and σ an a priori parameter. (Later, σ will be set equal to either σ_L or σ_U.) Furthermore, we write Ai and Bi for the Airy functions of the first and second kind [1], respectively, and $A_n < 0$, $n \in \mathbf{N}$, for the nth zero of $\mathrm{Ai}(x)$; see Figure 2.1. We also define the functions

$$\Gamma(\mathrm{Ai}, x) = \mathrm{Ai}(x) - \sqrt{\gamma}\,\beta^{-1}\,\mathrm{Ai}'(x) \quad \text{and} \quad \Gamma(\mathrm{Bi}, x) = \mathrm{Bi}(x) - \sqrt{\gamma}\,\beta^{-1}\,\mathrm{Bi}'(x) \tag{2.4}$$

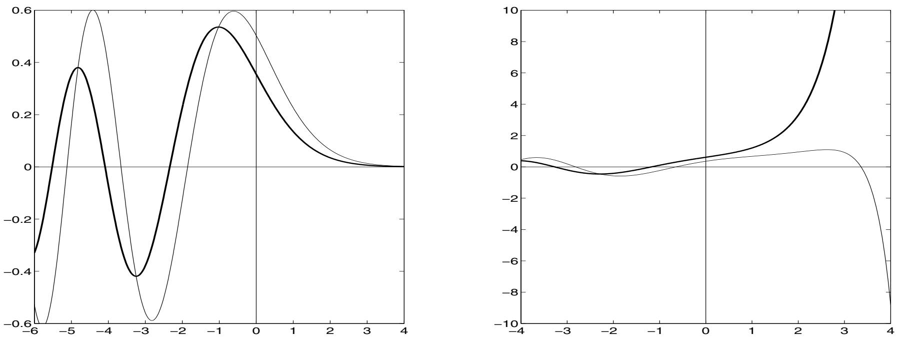

FIG. 2.1. *Left: Airy function of the first kind (thick line) plotted with the function* $\Gamma\,(\mathrm{Ai},\cdot)$ *(thin line). Right: Airy function of the second kind (thick line) plotted with* $\Gamma\,(\mathrm{Bi},\cdot)$ *(thin line). Here,* $\varepsilon = 0.1$*,* $a = 3$*, and* $\sigma = 2$*.*

(see Figure 2.1 and section 5.1) and write $A'_{n,\sigma}$ for the nth zero of $\Gamma\,(\mathrm{Ai}, x)$ $(n \in \mathbf{N})$—which is $\mathcal{O}(\sqrt{\gamma})$ close to A_n—and $B_{0,\sigma}$ for the positive zero of $\Gamma\left(\mathrm{Bi}, \gamma^{-1}(1+x)\right)$—which exists for all $\beta > 1$ and is equal to $\beta^2 - 1$ at leading order in γ; see Lemma A.2 for more accurate estimates. Finally, we let

$$\lambda^* = f(0) - \ell - A, \quad \lambda_0^{*,\sigma} = \lambda^* + A\,\beta^{-2}\,B_{0,\sigma}, \quad \lambda_n^{*,\sigma} = \lambda^* - \gamma\,A\,\beta^{-2}\,\left|A'_{n,\sigma}\right|, \quad n \in \mathbf{N}, \tag{2.5}$$

and we note that $\lambda_0^{*,\sigma}$ and $\lambda_n^{*,\sigma}$ are decreasing functions of σ. We can now formulate our main result.

THEOREM 2.1. *Let* $M \in \mathbf{N}$*. There exists an* $\varepsilon_0 > 0$ *and a constant* $C > 0$ *such that, for all* $0 < \varepsilon < \varepsilon_0$ *and* $0 \le n \le M$*, the first* $M+1$ *eigenvalues* $\lambda_0 > \cdots > \lambda_M$ *of* (1.14) *satisfy the following:*

(a) *For each* $0 < \sigma_U < A$*, there exists a constant* $B > 0$ *such that*

$$\lambda_0^{*,\sigma_U} - C\,\varepsilon^{2/3}\,\mathrm{e}^{-B/\sqrt{\varepsilon}} \le \lambda_0 \le \lambda_0^{*,\sigma_L} + C\,\varepsilon^{2/3}\,\mathrm{e}^{-B/\sqrt{\varepsilon}}$$

and

$$\lambda_n^{*,\sigma_U} - C\,\varepsilon^{1/6}\,\mathrm{e}^{-B/\sqrt{\varepsilon}} \le \lambda_n \le \lambda_n^{*,\sigma_L} + C\,\varepsilon^{1/6}\,\mathrm{e}^{-B/\sqrt{\varepsilon}} \quad \textit{for all} \quad 1 \le n \le M.$$

(b) *For each* $\sigma_L > A$*, there exists a constant* $B > 0$ *such that*

$$\lambda_{n+1}^{*,\sigma_U} - C\,\varepsilon^{1/6}\,\mathrm{e}^{-B/\sqrt{\varepsilon}} \le \lambda_n \le \lambda_{n+1}^{*,\sigma_L} + C\,\varepsilon^{1/6}\,\mathrm{e}^{-B/\sqrt{\varepsilon}} \quad \textit{for all} \quad 0 \le n \le M.$$

Theorem 2.1 and (2.5) establish that, for any $M \in \mathbf{N}$ and for sufficiently small $\varepsilon > 0$ (equivalently, for sufficiently small $\gamma > 0$), all first $M+1$ eigenvalues of (1.14) are $\mathcal{O}(\varepsilon^{1/3})$ close to λ^*, except for the special eigenvalue λ_0 if $\sigma_U < A$. Both types of eigenvalues correspond to biologically relevant patterns in (1.1)—to DCMs and BLs, respectively; see section 2.2. This dependence on the parameters is quite subtle; further, the weakly nonlinear stability analysis must be based on a detailed understanding of the linear eigenvalue problem including all of the eigenmodes associated with the asymptotically close eigenvalues (see also the introduction). As a result, the required analysis becomes rather extensive. For this reason, we defer the proof of Theorem 2.1 to sections 4–6.

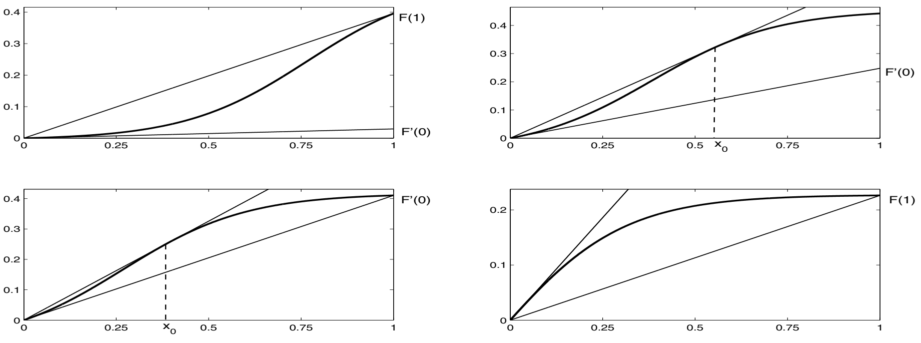

FIG. 2.2. *The function F (thick curve) and the linear functions bounding it (thin lines). Here, $\eta_H = 1$, $\kappa = 6$, and $j_H = 0.01 < j_H^{(1)}$ (top left panel), $j_H^{(1)} < j_H = 0.1 < j_H^{(2)}$ (top right panel), $j_H^{(2)} < j_H = 0.2 < 1$ (bottom left panel), and $j_H = 1.2 > 1$ (bottom right panel).*

Moreover, this analysis establishes that the bounds on the eigenvalues are, up to exponentially small terms, explicitly given in terms of zeroes of the Airy functions $\mathrm{Ai}(x)$ and $\mathrm{Bi}(x)$ (and their derivatives (2.4)) and of the bounds $\sigma_L\, x$ and $\sigma_U\, x$ on $F(x)$ in (2.2). This enables us (by unscaling) to explicitly quantify the regions in the parameter space associated with (1.1) in which DCMs or BLs can be expected to appear (see sections 2.2 and 3).

The following lemma provides explicit control on $\sigma_L\, x$ and $\sigma_U\, x$.

LEMMA 2.1. *Let*

$$j_H^{(1)}(\kappa) = \frac{\mathrm{e}^{-\kappa} - 1 + \kappa}{\mathrm{e}^{\kappa} - 1 - \kappa} \qquad \textit{and} \qquad j_H^{(2)}(\kappa) = \frac{\mathrm{e}^{-\kappa}}{j_H^{(1)}(\kappa)},$$

so that $0 < j_H^{(1)}(\kappa) < j_H^{(2)}(\kappa) < 1$ for all $\kappa > 0$. Also, for all $\kappa > 0$ and $j_H \in (j_H^{(1)}(\kappa), 1)$, define the point $x_0 = x_0(\kappa, j_H) \in (0,1)$ via $F(x_0) = x_0\, F'(x_0)$. Then,

$$(2.6) \qquad \sigma_L = \begin{cases} F'(0), & 0 < j_H \le j_H^{(2)}, \\ F(1), & j_H > j_H^{(2)}, \end{cases} \qquad \sigma_U = \begin{cases} F(1), & 0 < j_H \le j_H^{(1)}, \\ F'(x_0), & j_H^{(1)} < j_H < 1, \\ F'(0), & j_H \ge 1, \end{cases}$$

and

$$(2.7) \qquad \sigma_L(\kappa, j_H, \nu) = \nu\, \sigma_L(\kappa, j_H, 1), \qquad \sigma_U(\kappa, j_H, \nu) = \nu\, \sigma_U(\kappa, j_H, 1).$$

This lemma is proved by straightforward calculus. Figures 2.2 and 2.3 give a graphical representation of the lemma for various representative subcases.

As we shall see in section 3, the eigenvalue bounds established in Theorem 2.1 are quite sharp and predict very well the bifurcations of the full unscaled model (1.1). Nevertheless, the rigorous analysis of sections 4–6 yields no information on the characteristics of the associated eigenfunctions, which are of particular interest to the nature of the patterns generated by (1.1) as λ_0 crosses through zero (see section 3). Moreover, the width of the intervals bounding the eigenvalues of (1.14) is of the same order in ε—namely of $\mathcal{O}(\varepsilon^{1/3})$—as the distance between successive eigenvalues. This

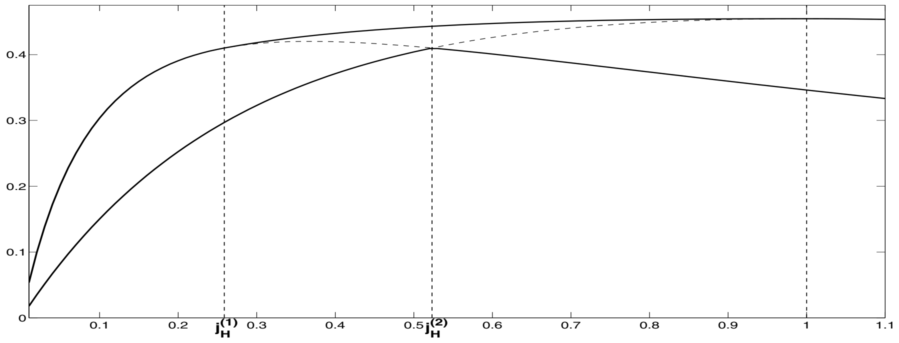

FIG. 2.3. *The quantities σ_U (upper thick curve), σ_L (lower thick curve), $F(1)$ (dashed curve to the left), and $F'(0)$ (dashed curve to the right) as functions of j_H and for $\eta_H = 0.1$, $\kappa = 2$. Note that $F(1)$ merges with σ_U for $j_H \le j_H^{(1)}$ and with σ_L for $j_H \ge j_H^{(2)}$, while $F'(0)$ merges with σ_L for $j_H \le j_H^{(2)}$ and with σ_U for $j_H \ge 1$. Also note that the WKB method (see section 7) yields that the location of the eigenvalue close to $\lambda_0^{*,\sigma}$ (see Theorem 2.1) is determined by $F(1)$, at leading order, whereas the locations of the eigenvalues close to $\lambda_n^{*,\sigma}$, $n \in \mathbf{N}$, are determined by $F'(0)$ at leading order.*

is especially relevant in the transitional case $\sigma_L < A < \sigma_U$, for which Theorem 2.1 offers no information.

For these reasons, we complete our analysis of (1.14) with an asymptotic WKB approximation (section 7). We derive asymptotic formulas for the eigenvalues and for the corresponding eigenfunctions. Using these formulas, we show the following:

- In case (a) of Theorem 2.1, the profile of the eigenfunction ω_0 corresponding to the largest eigenvalue λ_0 is of boundary layer type near the bottom. In terms of the phytoplankton concentration, this profile corresponds to a BL.
- In case (b) of the same theorem, ω_0 has the shape of a spike around the point $x = x_{\mathrm{DCM}}$, where x_{DCM} is determined, to leading order in ε, by $F(x_{\mathrm{DCM}}) = A$ (see Figure 7.1). This profile corresponds to a DCM around x_{DCM}.
- The transitional region between cases (a) and (b) in Theorem 2.1 is described, to leading order in ε, by the equation $A = F(1)$. Indeed, the leading order approximation to λ_0 is

(2.8)
$$\lambda_{0,0} = f(1) - \ell \qquad \text{in the region } F(1) = f(0) - f(1) < A \text{ (and } \omega_0 \text{ is a BL)},$$
(2.9)
$$\lambda_{0,0} = \lambda^* = f(0) - \ell - A \quad \text{in the region } F(1) = f(0) - f(1) > A \text{ (and } \omega_0 \text{ is a DCM)}.$$

Recalling Lemma 2.1, we see that this transition occurs at a value of A which is, to leading order in ε, equal to σ_U when $0 < j_H \le j_H^{(1)}$, equal to σ_L when $j_H \ge j_H^{(2)}$, and between σ_U and σ_L when $j_H^{(1)} < j_H < j_H^{(2)}$.

2.2. Bio-mathematical interpretation. The agreement between the numerical simulations and the field data reported in [11] establishes the biological relevance of model problem (1.1) and of its dynamics. This paper contains the first steps towards a bio-mathematical understanding of this model, especially in relation to the existing models in the literature that exhibit only simple, stationary patterns [5, 7, 8, 10, 12, 14].

The fact that (1.1) can be scaled into the singularly perturbed equation (1.5) for biologically relevant choices of the parameters is essential to the analysis in this paper. Moreover, together with the linear stability analysis, these scalings enable us to understand the fundamental structure of the twelve-dimensional parameter space associated with (1.1) and its boundary conditions (1.4) (in the biologically relevant region). In fact, it follows from Theorem 2.1 and (2.8)–(2.9) that the dimensionless parameters A, ℓ, $f(0)$, and $f(1)$, which are defined in section 2.1, are the main parameter combinations in the model as they capture its most relevant biological aspects.

Our stability analysis determines the regions in parameter space in which phytoplankton may persist, i.e., in which the trivial solution of (1.1) and (1.4) corresponding to absence of phytoplankton ($W(z,t) \equiv 0$ in (1.1)) is unstable. In that case, nontrivial patterns with $W(z,t) > 0$, for all t, bifurcate from the trivial solution, which implies that the model admits stable, positive phytoplankton populations. Theorem 2.1 establishes the existence of two distinct types of phytoplankton populations at onset. One is formed by a large—in fact infinite—family of "DCM-modes" and occurs for A below the threshold value $f(0) - f(1)$; the region where these modes become stable is determined by $\lambda^* = f(0) - \ell - A$; see (2.9). Within this family, the phytoplankton concentrations are negligible for most z, except for a certain localized (spatial) region in which the phytoplankton population is concentrated—see Figure 7.1 in which the first, most unstable member of this family is plotted (in scaled coordinates). These are the DCM-patterns observed in [11]. Our analysis shows that many different DCM-patterns appear almost instantaneously. More precisely, as a parameter enters into the region in which the trivial solution is unstable, a succession of asymptotically close bifurcations in which different types of DCM-patterns are created takes place. In other words, even asymptotically close to onset, there are many competing DCM-modes. This partly explains why the "pure" DCM-mode as represented in Figure 7.1 can be observed only very close to onset (see [11] and section 3.2): it may be destabilized by the competition with other modes.

The second type of phytoplankton population that may appear at onset occurs for A above the threshold value $f(0) - f(1)$ and has the structure of a BL: the phytoplankton population is concentrated near $z = z_B$, i.e., at the bottom of the water column. Unlike the DCM-modes, there is a *single* BL-mode; the region where this mode becomes stable is determined, in this case, by $f(1)-\ell$; see (2.8). This mode may also dominate the dynamics of (1.1) in a part of the biologically relevant parameter space, as may be seen in section 3.2. Note that the BL-mode has not been observed in [11]; naturally, this is hardly surprising since one can sample numerically only a very limited region of a twelve-dimensional parameter space. From the biological point of view, the fact that the model (1.1) allows for attractors of the BL type may be the most important finding of this paper. Like DCMs, BLs have been observed in field data (see [15] and references therein). The analysis here quantifies the parameter values for which DCM- or BL-patterns occur. Hence, our results may be used to determine oceanic regions and/or phytoplankton species for which BLs may be expected to exist. It would be even more interesting to locate a setting in which DCMs and BLs interact, as they are expected to do because of the existence of the codimension 2 point at which the (first) DCM-mode and the BL-mode bifurcate simultaneously; see section 3.

3. Bifurcations and simulations.

3.1. The bifurcation diagram. In this section, we use the WKB expressions (2.8)–(2.9) for the first few eigenvalues to identify the bifurcations that system (1.14) undergoes. In this way, we identify the regions in the parameter space where the BL

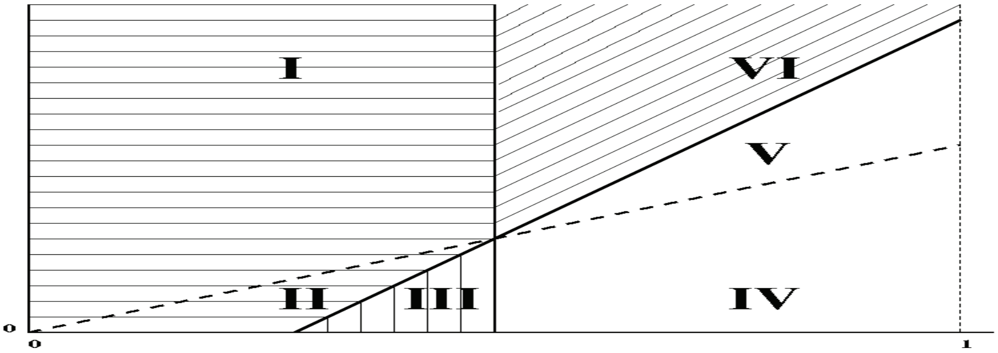

FIG. 3.1. *The bifurcation diagram in the (ν, A)-plane. The horizontal axis corresponds to $\nu = 1/(1+\eta_H)$, while the vertical one corresponds to $A = a^2/4$. In the region shaded horizontally, the trivial zero state is stable. In the region shaded vertically, DCMs bifurcate, while BL profiles remain damped. In the region shaded diagonally, BL profiles bifurcate, while DCM profiles remain damped. Finally, in the unshaded region, both profiles grow linearly.*

and DCM steady states become stable. As already mentioned in the Introduction, we are primarily interested in the effect of environmental conditions—in particular, of nutrient concentration and diffusion—on phytoplankton. For this reason, we choose to vary the parameters $\eta_H = N_H/N_B$ (which encapsulates information pertaining to the nutrient levels and nutrient absorption by phytoplankton) and $a = V/\sqrt{\mu D}$ (which is a measure of diffusion; see (1.7)). The remaining four dimensionless parameters (ε, κ, j_H, and ℓ) are kept constant. We recall here the definitions $\nu = 1/(1+\eta_H)$ and $A = a^2/4$.

The curves separating the regions in the (ν, A)-plane which are characterized by qualitatively different behavior of the rescaled model (1.5), (1.8) may be found by recasting (2.9) and (2.8) in terms of the rescaled parameters. In particular, using (1.13), (2.1), and (2.5), we find (see Figure 3.1) the following:

- In regions I and II, λ_0 is given, to leading order, by (2.8) (in region I) and by (2.9) (in region II). In either case, $\lambda_0 < 0$, and hence the zero (trivial) state is stable.
- In region III, λ_0 is given by (2.9) and is positive. In fact, the further into this region one goes, the more eigenvalues cross zero and become positive, since they are $\mathcal{O}(\varepsilon^{1/3})$ apart by Theorem 2.1. All of these eigenvalues are associated with DCMs.
- In region VI, λ_0 is given by (2.8) and is positive, while all other eigenvalues are negative. Thus, the only bifurcating patterns in this regime are BL profiles.
- Finally, in regions IV and V, eigenvalues associated with both BL and DCM profiles are positive, and thus no further info can be derived from our linear analysis.

The boundaries of these regions may be deduced explicitly in the aforementioned manner. First, setting the expression for λ_0 in (2.8) equal to zero, we obtain, to leading order, the vertical line separating the regions I, II, and III from the regions IV, V, and VI,

$$\nu = \ell\,(1 + \mathrm{e}^{\kappa} j_H).$$

Next, setting the expression for λ_0 in (2.9) equal to zero, we obtain, to leading order, the diagonal line separating the regions I, II, and VI from III, IV, and V,

$$A = \frac{1}{1+j_H}\,\nu - \ell.$$

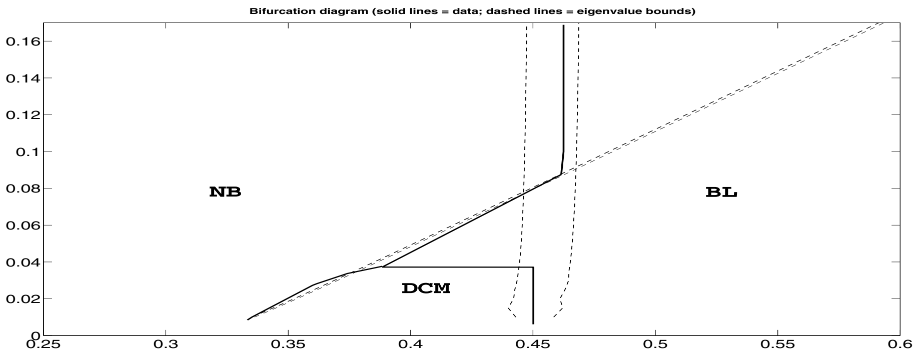

FIG. 3.2. *The bifurcation diagram in the* (ν, A)*-plane for* $\varepsilon = 9 \cdot 10^{-5}$, $\ell = 0.2$, $j_H = 0.5$, $\kappa = 1$. *("NB" stands for "no blooming.") The solid curves correspond to numerical simulations, while the dashed ones correspond to the bounds predicted theoretically; see Theorem* 2.1.

Finally, setting the expressions for λ_0 in (2.8) and (2.9) equal to each other, we obtain the transitional regime $A = F(1)$. In terms of the rescaled parameters, we find

$$A = \left(\frac{1}{1 + j_H} - \frac{1}{1 + \mathrm{e}^{\kappa} j_H} \right) \nu.$$

Since the physical region $n_H > 0$ corresponds to the region $0 < \nu < 1$, these formulas imply that

(a) for $0 < \ell < (1 + \mathrm{e}^{\kappa} j_H)^{-1}$, both a BL and a DCM may bifurcate,

(b) for $(1 + \mathrm{e}^{\kappa} j_H)^{-1} < \ell < (1 + j_H)^{-1}$, only a DCM may bifurcate,

(c) for $\ell > (1 + j_H)^{-1}$, the trivial state is stable.

Remark 3.1. Similar information may be derived by the rigorous bounds in Theorem 2.1, with the important difference that the dividing curves have to be replaced by regions of finite thickness.

3.2. Numerical simulations. In this section, we present numerical simulations on the full model (1.1)–(1.4), and we compare the results with our theoretical predictions. The parameters are chosen in biologically relevant regions [11].

We considered first the validity of our asymptotic analysis; i.e., we checked whether the analytically obtained bounds for the occurrence of the DCMs and BLs—see Theorem 2.1, section 3.1, Figure 3.1, and Remark 3.1—can be recovered by numerical simulations of the PDE (1.1)–(1.4). We used the numerical method described in Remark 3.2 at each node of a two-dimensional grid of a part of the (ν, A)-parameter plane (keeping all other parameters fixed) to determine the attracting pattern generated by (1.1)–(1.4) and chose the initial profile at each node in the parameter space to be the numerically converged pattern for an adjacent node at the previous step.

In Figure 3.2, we present the region near the codimension 2 point in the (ν, A)-parameter plane at which both the DCMs and the BLs bifurcate (with all other parameters fixed: $\varepsilon = 9 \cdot 10^{-5}$, $\ell = 0.2$, $j_H = 0.5$, $\kappa = 1$). Away from this codimension 2 point, the numerically determined bifurcation curves are clearly within the bounds given by Theorem 2.1 and thus confirm our analysis. Note that this suggests that the bifurcations have a supercritical nature—an observation that does not follow from our linear analysis. Near the codimension 2 point, a slight discrepancy between

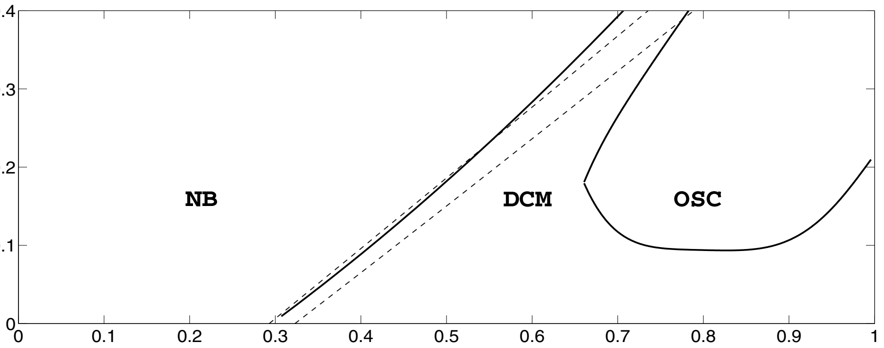

Fig. 3.3. *The bifurcation diagram in the* (ν, A)*-plane for* $\varepsilon = 9 \cdot 10^{-5}$, $\ell = 0.25$, $j_H = 0.033$, $\kappa = 20$. *Region NB corresponds to no blooming, and region OSC to oscillatory DCMs. The solid curves correspond to numerical simulations, and the dashed ones to the points at which* λ_0 *(left line) and* λ_1 *(right line) cross zero; see* (2.9) *and Figure* 3.1. *For these parameter values, the bifurcation of the BLs occurs in a nonphysical part of the domain.*

our analysis and the numerical findings becomes apparent. First, we note that the bifurcation from the trivial state (no phytoplankton) to the DCM state is not exactly in the region determined by Theorem 2.1. However, for this combination of parameters, this region is quite narrow—in fact, it is narrower than the width of the rectangular grid of the (ν, A)-parameter plane that we used to determine Figure 3.2, which implies that the simulations do not disagree with the analysis. The other discrepancy, namely the occurrence of a small "triangle" of BL patterns in the region where one would expect DCMs, is related to the presence of the codimension 2 point. To understand the true nature of the dynamics, one needs to perform a weakly nonlinear analysis near this point and, presumably, a more detailed numerical analysis that distinguishes between DCMs, BLs, and patterns that have the structure of a combined DCM and BL. This is the topic of work in progress.

Unlike the simulations presented in [11], here we considered the secondary bifurcations only briefly. Figure 3.3 shows the primary bifurcation of the trivial state into a DCM and the secondary bifurcation (of Hopf type) of the DCM into an oscillating DCM—see [11] for more (biological) details on this behavior. A priori, one would expect that our linear stability analysis of the trivial state could not cover this Hopf bifurcation. However, in Figure 3.3 we also plotted the leading order approximations of the curves at which the first two eigenvalues associated with the stability of the trivial state, λ_0 and λ_1, cross through the imaginary axis. It follows that the distance (in parameter space) between the primary and the secondary bifurcations is asymptotically small in ε, and similar to the distance between the successive eigenvalues λ_n. This observation is based on several simulations realized for different values of ε. It is crucial information for the subsequent (weakly) nonlinear analysis, since the fact that the DCM undergoes its secondary Hopf bifurcation for parameter combinations that are asymptotically close (in ε) to the primary bifurcation implies that the above a priori expectation is not correct; instead, the stability and bifurcation analysis of the DCM can, indeed, be based on the linear analysis presented here. The higher order eigenvalues $\lambda_1, \lambda_2, \ldots$, the associated eigenfunctions $\omega_1(x), \omega_2(x), \ldots$, and their "slaved" η-components $\eta_1(x), \eta_2(x), \ldots$ (which can be determined explicitly using (1.11)) will serve as necessary inputs for this nonlinear analysis.

Thus, a “full” linear stability analysis of the uncoupled system (1.14) as presented here may serve as a foundation for the analysis of secondary bifurcations that can only occur in the coupled system (see the introduction and [14]). This feature is very special and quite uncommon in explicit models. It is due to the *natural singularly perturbed nature* of the scaled system (1.5), and it provides an opportunity to obtain fundamental insight into phytoplankton dynamics. This analysis, including the aforementioned codimension 2 analysis and the associated secondary bifurcations of BLs, is the topic of work in progress.

Remark 3.2. The numerical results were obtained by the “Method of Lines” approach. First, we discretized the spatial derivatives approximating the diffusion terms in the model using second-order symmetric formulas and employing a third-order upwind-biased method to discretize the advection term (see [13] for the suitability of these schemes to the current problem). Next, we integrated the resulting system of ODEs forward in time with the widely used time-integration code VODE (see [3] and http://www.netlib.org/ode). Throughout all simulations, we combined a spatial grid of a sufficiently high resolution with a high precision time integration to ensure that the conclusions drawn from the simulations are essentially free of numerical errors.

4. Eigenvalue bounds.

As a first step towards the proof of Theorem 2.1, we recast (1.14) in a form more amenable to analysis. First, we observe that the operator involved in this eigenvalue problem is self-adjoint only if $a = 0$. Applying the Liouville transformation

$$w(x) = \mathrm{e}^{-\sqrt{A/\varepsilon}\,x}\omega(x) = \mathrm{e}^{-(\beta/\gamma^{3/2})\,x}\omega(x), \tag{4.1}$$

we obtain the self-adjoint problem

$$\begin{gathered} \varepsilon\, w_{xx} + (f(x) - \ell - A)w = \lambda\, w, \\ \left(\sqrt{\varepsilon}\, w_x - \sqrt{A}\, w\right)(0) = \left(\sqrt{\varepsilon}\, w_x - \sqrt{A}\, w\right)(1) = 0. \end{gathered}$$

Recalling (2.1) and (2.5), we write this equation in the form

$$\mathcal{L}\, w = \mu\, w, \quad \text{with} \quad \mathcal{G}\,(w,0) = \mathcal{G}\,(w,1) = 0. \tag{4.2}$$

The operator $\mathcal{L}$, the scalar μ, and the linear functionals $\mathcal{G}(\cdot, x)$ are defined by

$$\mathcal{L} = -\varepsilon\frac{d^2}{dx^2} + F(x), \quad \mu = \lambda^* - \lambda, \quad \mathcal{G}\,(w,x) = w(x) - \sqrt{\frac{\varepsilon}{A}}\, w_x(x). \tag{4.3}$$

This is the desired form of the eigenvalue problem (1.14). To prove Theorem 2.1, we decompose the operator $\mathcal{L}$ into a self-adjoint part for which the eigenvalue problem is exactly solvable and a positive definite part. Then, we use the following comparison principle to obtain the desired bounds.

THEOREM 4.1 (see [18, sections 8.12–8.13]). *Let $\hat{\mathcal{A}}$ and $\mathcal{A}$ be self-adjoint operators bounded below with compact inverses, and write their eigenvalues as $\hat{\mu}_0 \leq \hat{\mu}_1 \leq \cdots \leq \hat{\mu}_n \leq \cdots$ and $\mu_0 \leq \mu_1 \leq \cdots \leq \mu_n \leq \cdots$, respectively. If $\mathcal{A} - \hat{\mathcal{A}}$ is positive semidefinite, then $\hat{\mu}_n \leq \mu_n$ for all $n \in \{0, 1, \ldots\}$.*

4.1. Crude bounds for the eigenvalues of $\mathcal{L}$.

First, we derive crude bounds for the spectrum $\{\mu_n\}$ of $\mathcal{L}$ to demonstrate the method and establish that $\mathcal{L}$ satisfies the boundedness condition of Theorem 4.1.

LEMMA 4.1. *The eigenvalues μ_n satisfy the inequalities*

$$-A \leq \mu_0 \leq F(1) - A \quad \textit{and} \quad \varepsilon n^2\pi^2 \leq \mu_n \leq F(1) + \varepsilon n^2\pi^2, \quad n \in \mathbf{N}. \tag{4.4}$$

Proof. Let $c \in \mathbf{R}$. We start by decomposing $\mathcal{L}$ as

$$\mathcal{L} = \mathcal{L}^{0,c} + \mathcal{F}^{0,c}, \quad \text{where} \quad \mathcal{L}^{0,c} = -\varepsilon\frac{d^2}{dx^2} + c \quad \text{and} \quad \mathcal{F}^{0,c} = F(x) - c. \tag{4.5}$$

Then, we write $\{\mu_n^{0,c}\}$ for the set of eigenvalues of the problem

$$\mathcal{L}^{0,c}w^{0,c} = \mu^{0,c}w^{0,c}, \quad \text{with} \quad \mathcal{G}\left(w^{0,c}, 0\right) = \mathcal{G}\left(w^{0,c}, 1\right) = 0, \tag{4.6}$$

with the eigenvalues arranged so that $\mu_0^{0,c} \leq \mu_1^{0,c} \leq \cdots \leq \mu_n^{0,c} \leq \cdots$.

For $c = c_L = 0$, the operator $\mathcal{L}^{0,c_L}$ is self-adjoint, while $\mathcal{F}^{0,c_L} = F(x) \geq 0$ is a positive definite multiplicative operator. Thus, using Theorem 4.1, we obtain the inequalities

$$\mu_n^{0,c_L} \leq \mu_n \quad \text{for all} \quad n \in \mathbf{N} \cup \{0\}. \tag{4.7}$$

Next, for $c = c_U = F(1)$, the operator $\mathcal{F}^{0,c_U} = F(x) - F(1) \leq 0$ is negative definite, while $\mathcal{L}^{0,c_U}$ is self-adjoint. Hence, we may write

$$\mathcal{L}^{0,c_U} = \mathcal{L} - \mathcal{F}^{0,c_U},$$

where $-\mathcal{F}^{0,c_U}$ is now positive definite. The fact that the spectrum $\{\mu_n\}$ of $\mathcal{L}$ is bounded from below by (4.7) allows us to use Theorem 4.1 to bound each μ_n from above,

$$\mu_n \leq \mu_n^{0,c_U} \quad \text{for all} \quad n \in \mathbf{N} \cup \{0\}.$$

Combining this bound and (4.7), we obtain

$$\mu_n^{0,c_L} \leq \mu_n \leq \mu_n^{0,c_U} \quad \text{for all} \quad n \in \mathbf{N} \cup \{0\}. \tag{4.8}$$

Naturally, the eigenvalue problem (4.6) may be solved exactly to obtain

$$\mu_0^{0,c} = c - A \quad \text{and} \quad \mu_n^{0,c} = c + \varepsilon n^2\pi^2, \quad n \in \mathbf{N}. \tag{4.9}$$

Combining these formulas with (4.8), we obtain the inequalities (4.4). □

4.2. Tight bounds for the eigenvalues of $\mathcal{L}$. The accurate bounds for the eigenvalues of (4.2) described in Theorem 2.1 may be obtained by bounding F by linear functions; see (2.2) and Lemma 2.1. In the next lemma, we bound the eigenvalues μ_n by the eigenvalues $\mu_n^{1,\sigma}$ of a simpler problem. Then, in Lemma 4.3, we obtain strict, exponentially small bounds for $\mu_n^{1,\sigma}$.

LEMMA 4.2. *Let $\sigma \in \{\sigma_L, \sigma_U\}$, with σ_L and σ_U as defined in Lemma* 2.1*, define the operator $\mathcal{L}^{1,\sigma} = -\varepsilon\frac{d^2}{dx^2} + \sigma x$, and write $\{\mu_n^{1,\sigma}\}$ for the eigenvalues corresponding to the problem*

$$\mathcal{L}^{1,\sigma}w = \mu^{1,\sigma}w, \quad \textit{with} \quad \mathcal{G}(w,0) = \mathcal{G}(w,1) = 0. \tag{4.10}$$

Let $\{\mu_n^{1,\sigma}\}$ be arranged so that $\mu_0^{1,\sigma} \leq \mu_1^{1,\sigma} \leq \cdots \leq \mu_n^{1,\sigma} \leq \cdots$. Then,

$$\mu_n^{1,\sigma_L} \leq \mu_n \leq \mu_n^{1,\sigma_U} \quad \textit{for all} \quad n \in \mathbf{N} \cup \{0\}. \tag{4.11}$$

Proof. First, we decompose $\mathcal{L}$ as

$$\mathcal{L} = \mathcal{L}^{1,\sigma} + \mathcal{F}^{1,\sigma}, \quad \text{where} \quad \mathcal{L}^{1,\sigma} = -\varepsilon \frac{d^2}{dx^2} + \sigma x, \quad \mathcal{F}^{1,\sigma} = F(x) - \sigma x, \tag{4.12}$$

and $\sigma \in \{\sigma_L, \sigma_U\}$. We note here that $\mathcal{L}^{1,\sigma}$ is self-adjoint.

Next, $\mathcal{F}^{1,\sigma_L}$ is a positive definite multiplicative operator, since $F(x) \geq \sigma_L x$ (see (2.2)). Thus, $\mu_n^{1,\sigma_L} \leq \mu_n$ for all $n \in \mathbf{N} \cup \{0\}$, by Theorem 4.1. In contrast, $\mathcal{F}^{1,\sigma_U}$ is negative definite, since $F(x) \leq \sigma_U x$. Therefore, we write

$$\mathcal{L}^{1,\sigma_U} = \mathcal{L} - \mathcal{F}^{1,\sigma_U},$$

where now $-\mathcal{F}^{1,\sigma_U}$ is positive definite. The fact that the spectrum $\{\mu_n\}$ is bounded from below by Lemma 4.1 allows us to use Theorem 4.1 to bound each μ_n from above, $\mu_n \leq \mu_n^{1,\sigma_U}$. Combining both bounds for each n, we obtain (4.11). □

Hence, it remains to solve the eigenvalue problem (4.10). Although this problem is not explicitly solvable, the eigenvalues may be calculated up to terms exponentially small in ε. Letting

$$\mu_0^{*,\sigma} = \lambda^* - \lambda_0^{*,\sigma} = -A\,\beta^{-2}\,B_{0,\sigma} \quad \text{and} \quad \mu_n^{*,\sigma} = \lambda^* - \lambda_n^{*,\sigma} = \gamma\,A\,\beta^{-2}\,\left|A'_{n,\sigma}\right| > 0, \quad n \in \mathbf{N}, \tag{4.13}$$

where we have recalled the definitions in section 2, we can prove the following lemma.

Lemma 4.3. *Let $M \in \mathbf{N}$ be fixed, and define*

$$\delta_{0,\sigma} = \gamma^2 \exp\left(-\tfrac{2}{3}\gamma^{-3/2}\left[3(1+B_{0,\sigma}-B)^{3/2} - 2(B_{0,\sigma}-B)^{3/2} - (1+B_{0,\sigma}+B)^{3/2}\right]\right),$$
$$\delta_{n,\sigma} = \sqrt{\gamma}\,A^{1/6}\,\beta^{-1/3}\exp\left(-\tfrac{4}{3}\,\gamma^{-3/2} + 2\,|A_{n+1}|\,\gamma^{-1/2}\right) \quad \textit{for all} \quad 1 \leq n \leq M+1$$

and for all $0 < B < B_{0,\sigma}$ for which the exponent in the expression for $\delta_{0,\sigma}$ is negative. Then, for each such B, there exists an $\varepsilon_0 > 0$ and positive constants $C_0, \ldots, C_{M+1}$ such that, for all $0 < \varepsilon < \varepsilon_0$ and $0 \leq n \leq M$, the first $M+1$ eigenvalues $\mu_0^{1,\sigma}, \ldots, \mu_M^{1,\sigma}$ corresponding to (4.10) *satisfy the following:*

(a) *For $\beta > 1$, $\left|\mu_0^{1,\sigma} - \mu_0^{*,\sigma}\right| < C_0\,\delta_{0,\sigma}$ and $\left|\mu_n^{1,\sigma} - \mu_n^{*,\sigma}\right| < C_n\,\delta_{n,\sigma}$ for all $1 \leq n \leq M$.*

(b) *For $0 < \beta < 1$, $\left|\mu_n^{1,\sigma} - \mu_{n+1}^{*,\sigma}\right| < C_{n+1}\,\delta_{n+1,\sigma}$ for all $0 \leq n \leq M$.*

Lemmas 4.2 and 4.3 in combination with definitions (2.5) and (4.13) yield Theorem 2.1. The bounds on $\mu_0^{1,\sigma}, \ldots, \mu_M^{1,\sigma}$ are derived in section 5. The fact that these are indeed the $M+1$ first eigenvalues corresponding to (4.10) is proved in section 6. Note that Theorem 2.1 follows immediately from this lemma, in combination with the above analysis and the observation that the condition $\beta > 1$ is equivalent to $0 < \sigma < A$, and the condition $0 < \beta < 1$ equivalent to $\sigma > A$.

5. The eigenvalues $\boldsymbol{\mu_0^{1,\sigma}, \ldots, \mu_M^{1,\sigma}}$.

In this section, we derive the bounds on $\mu_0^{1,\sigma}, \ldots, \mu_M^{1,\sigma}$ of Lemma 4.3. In section 5.1, we reduce the eigenvalue problem (4.10) to the algebraic one of locating the roots of an Evans-type function $\mathcal{D}$. In section 5.2, we identify the roots of $\mathcal{D}$ with those of two functions $\mathcal{A}$ and $\mathcal{B}$ which are related to the Airy functions and simpler to analyze than $\mathcal{D}$. Finally, in section 5.3, we identify the relevant roots of $\mathcal{A}$ and $\mathcal{B}$ and thus also of $\mathcal{D}$.

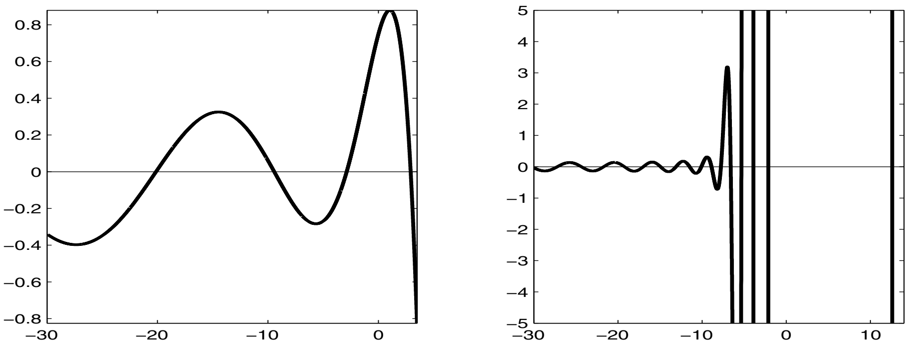

FIG. 5.1. *The function $\mathcal{D}(\bar{\chi})$ for $a = 3$, $\sigma = 1$, and $\varepsilon = 0.1$ (left panel), $\varepsilon = 0.001$ (right panel).*

5.1. Reformulation of the eigenvalue problem.

First, we derive an algebraic equation, the solutions of which correspond to the eigenvalues of (4.10). We start by rescaling the eigenvalue $\mu^{1,\sigma}$ and the independent variable x via

$$\bar{\chi} = -\gamma^{-1} A^{-1} \beta^2 \mu^{1,\sigma} \quad \text{and} \quad x = \gamma(\chi - \bar{\chi}). \tag{5.1}$$

Then, we define the linear functional

$$\Gamma(w, \bar{\chi}) = w(\bar{\chi}) - \sqrt{\gamma}\,\beta^{-1} w'(\bar{\chi}) \quad \text{for all differentiable functions } w, \tag{5.2}$$

and we remark that, for w equal to Ai or Bi, this definition agrees with that given in (2.4). Further introducing the Wronskian

$$\mathcal{D}(\bar{\chi}) = \Gamma(\mathrm{Ai}, \bar{\chi})\,\Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right) - \Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)\Gamma(\mathrm{Bi}, \bar{\chi}) \tag{5.3}$$

(see also Figure 5.1), we can prove the following lemma.

LEMMA 5.1. *The eigenvalue problem* (4.10) *has $\mu^{1,\sigma}$ as an eigenvalue if and only if $\mathcal{D}(\bar{\chi}) = 0$.*

Proof. Using (5.1), we rewrite problem (4.10) in the form

$$\begin{gathered} \frac{d^2 w}{d\chi^2} = \chi w, \quad \chi \in [\bar{\chi}, \gamma^{-1} + \bar{\chi}], \\ \Gamma(w, \bar{\chi}) = \Gamma\left(w, \gamma^{-1} + \bar{\chi}\right) = 0. \end{gathered} \tag{5.4}$$

This is an Airy equation and thus has the general solution

$$w(\chi) = D_A \,\mathrm{Ai}(\chi) + D_B \,\mathrm{Bi}(\chi). \tag{5.5}$$

The boundary conditions become

$$\begin{array}{rclcl} \Gamma(w, \bar{\chi}) & = & D_A \Gamma(\mathrm{Ai}, \bar{\chi}) + D_B \Gamma(\mathrm{Bi}, \bar{\chi}) & = & 0, \\ \Gamma\left(w, \gamma^{-1} + \bar{\chi}\right) & = & D_A \Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right) + D_B \Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right) & = & 0. \end{array} \tag{5.6}$$

The sufficient and necessary condition for the existence of nontrivial solutions to this system is that its determinant—which is the Wronskian $\mathcal{D}$ given in (5.3)—vanishes, and the lemma is proved. ☐

5.2. Product decomposition of the function $\mathcal{D}$. In the preceding section, we saw that the values of $\bar{\chi}$ corresponding to the eigenvalues $\mu^{1,\sigma}$ must be zeroes of $\mathcal{D}$. In the next section, we will prove that the first few zeroes of $\mathcal{D}$ are all $\mathcal{O}(1)$, in the case $0 < \beta < 1$, and both $\mathcal{O}(1)$ and $\mathcal{O}(\gamma^{-1})$ in the case $\beta > 1$. To identify them, we rewrite $\mathcal{D}$ in the form

$$\mathcal{D}(\bar{\chi}) = \Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right)\mathcal{A}(\bar{\chi}) = \Gamma\left(\mathrm{Ai}, \bar{\chi}\right)\mathcal{B}(\bar{\chi}), \tag{5.7}$$

where we have defined the functions

$$\mathcal{A}(\bar{\chi}) = \Gamma\left(\mathrm{Ai}, \bar{\chi}\right) - \frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)}{\Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right)}\Gamma\left(\mathrm{Bi}, \bar{\chi}\right), \tag{5.8}$$

$$\mathcal{B}(\bar{\chi}) = \Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right) - \frac{\Gamma\left(\mathrm{Bi}, \bar{\chi}\right)}{\Gamma\left(\mathrm{Ai}, \bar{\chi}\right)}\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right). \tag{5.9}$$

Here, $\mathcal{A}$ is well defined for all $\bar{\chi}$ such that $\Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right) \neq 0$, while $\mathcal{B}$ is well defined for all $\bar{\chi}$ such that $\Gamma\left(\mathrm{Ai}, \bar{\chi}\right) \neq 0$. Equation (5.7) implies that the roots of $\mathcal{A}$ and $\mathcal{B}$ are also roots of $\mathcal{D}$.

In the next section, we will establish that the $\mathcal{O}(1)$ roots of $\mathcal{D}$ coincide with roots of $\mathcal{A}$ and the $\mathcal{O}(\gamma^{-1})$ ones with roots of $\mathcal{B}$. To prove this, we first characterize the behaviors of $\mathcal{A}$ and $\mathcal{B}$ for $\mathcal{O}(1)$ and $\mathcal{O}(\gamma^{-1})$ values of $\bar{\chi}$, respectively, by means of the next two lemmas. In what follows, we write $E(x) = \exp(-(2/3)x^{3/2})$ for brevity and $||\cdot||_{[X_L,X_R]}$ for the W^1_∞-norm over any interval $[X_L, X_R]$,

$$||w||_{[X_L,X_R]} = \max_{\bar{\chi}\in[X_L,X_R]} |w(\bar{\chi})| + \max_{\bar{\chi}\in[X_L,X_R]} |w'(\bar{\chi})|. \tag{5.10}$$

LEMMA 5.2. *Let $X < 0$ be fixed. Then there is a $\gamma_0 > 0$ and a constant $c_A > 0$ such that*

$$||\mathcal{A}(\cdot) - \Gamma\left(\mathrm{Ai}, \cdot\right)||_{[X,0]} < c_A\, \gamma^{-1/2}\, E(\gamma^{-1}(2 + 3\,\gamma\, X)^{2/3}) \quad \text{for all} \quad 0 < \gamma < \gamma_0. \tag{5.11}$$

For the next lemma, we switch to the independent variable $\bar{\psi} = \gamma\bar{\chi}$ to facilitate calculations. We analyze the behavior of $\mathcal{B}(\gamma^{-1}\bar{\psi})$ for $\mathcal{O}(1)$ values of $\bar{\psi}$ (equivalently, for $\mathcal{O}(\gamma^{-1})$ values of $\bar{\chi}$) as $\gamma \downarrow 0$.

LEMMA 5.3. *Let $0 < \Psi_L < \Psi_R$ be fixed. Then there is a $\gamma_0 > 0$ and a constant $c_B > 0$ such that, for all $0 < \gamma < \gamma_0$,*

$$\begin{aligned} &\left|\left|E(\gamma^{-1}(1 + \bar{\psi}))\left[\mathcal{B}\left(\gamma^{-1}\bar{\psi}\right) - \Gamma\left(\mathrm{Bi}, \gamma^{-1}(1 + \bar{\psi})\right)\right]\right|\right|_{\bar{\psi}\in[\Psi_L,\Psi_R]} \\ &\qquad < c_B\, \gamma^{-1/4}\left[\frac{E(\gamma^{-1}(1 + \Psi_L))}{E(\gamma^{-1}\Psi_L)}\right]^2. \end{aligned}$$

The proofs of these lemmas are given in Appendices B and C, respectively.

5.3. Zeroes of $\mathcal{D}$. Using Lemma 5.2 and an auxiliary result, we can locate the roots of $\mathcal{D}$.

LEMMA 5.4. *Let $M \in \mathbf{N}$ be fixed, $A'_{n,\sigma}$ and $B_{0,\sigma}$ be defined as in section 2, and B, $\delta_{0,\sigma}, \ldots, \delta_{M,\sigma}$ be defined as in Lemma 4.3. Then, for each admissible B, there is a $\gamma_0 > 0$ and positive constants $c_0, \ldots, c_M$ such that, for all $0 < \gamma < \gamma_0$, $\mathcal{D}(\bar{\chi})$ has roots $\bar{\chi}_0 > \bar{\chi}_1 > \cdots > \bar{\chi}_M$ satisfying the following bounds:*

(a) *For $\beta > 1$,*

$$\left|\bar{\chi}_0 - \gamma^{-1}B_{0,\sigma}\right| < c_0\, \gamma^{-1}\, \delta_{0,\sigma} \quad \text{and} \quad \left|\bar{\chi}_n - A'_{n,\sigma}\right| < c_n\, \gamma^{-1}\, \delta_{n,\sigma} \quad \text{for all} \quad 1 \leq n \leq M.$$

(b) *For* $0 < \beta < 1$,

$$\left|\bar{\chi}_n - A'_{n+1,\sigma}\right| < c_n\, \gamma^{-1}\, \delta_{n+1,\sigma} \quad \textit{for all} \quad 0 \le n \le M.$$

The proof of this lemma requires the following elementary result.

LEMMA 5.5. *Let C and G be real-valued continuous functions and H be real-valued and differentiable. Let $\delta > 0$ and $z_0 \in [Z_L, Z_R] \subset \mathbf{R}$ be such that*

$$H(z_0) = 0, \quad \max_{[Z_L,Z_R]} H' = -H_0 < 0, \quad \max_{[Z_L,Z_R]} |C(G - H)| < \delta,$$
$$\textit{and} \quad \min_{[Z_L,Z_R]} C = C_0 > 0.$$

If $\delta < C_0 H_0 \min(z_0 - Z_L, Z_R - z_0)$, then G has a zero z_* such that $|z_* - z_0| \le \delta/(C_0 H_0)$.

Proof. Let $z_\ell = z_0 - \delta/(C_0 H_0)$ and $z_r = z_0 + \delta/(C_0 H_0)$. Since $Z_L < z_\ell < z_0 < z_r < Z_R$, we have

$$G(z_\ell) = H(z_\ell) + G(z_\ell) - H(z_\ell) \ge \int_{z_0}^{z_\ell} H'(z)\, dz - \frac{\max_{[Z_L,Z_R]} |C(G - H)|}{\min_{[Z_L,Z_R]} C}$$
$$> (z_0 - z_\ell) H_0 - \frac{\delta}{C_0} = 0.$$

Similarly, we may prove that $G(z_r) < 0$, and the desired result follows. □

Proof of Lemma 5.4. (a) First, we prove the existence of a root $\bar{\chi}_0$ satisfying the desired bound. We recall that $\bar{\psi}$ was defined above via $\bar{\psi} = \gamma\bar{\chi}$; hence, it suffices to show that there is a root $\bar{\psi}_0$ of $\mathcal{D}(\gamma^{-1}\bar{\psi})$ satisfying the bound $|\bar{\psi}_0 - B_{0,\sigma}| < c_0\, \delta_0$ for some $c_0 > 0$. Equation (5.7) reads $\mathcal{D}(\gamma^{-1}\bar{\psi}) = \Gamma\,(\mathrm{Ai}, \gamma^{-1}\bar{\psi})\, \mathcal{B}(\gamma^{-1}\bar{\psi})$. Here, $\Gamma\,(\mathrm{Ai}, \gamma^{-1}\bar{\psi})$ has no positive roots, by definition of Γ and because $\mathrm{Ai}(\gamma^{-1}\bar{\psi}) > 0$ and $\mathrm{Ai}'(\gamma^{-1}\bar{\psi}) < 0$ for all $\bar{\psi} > 0$. Thus, $\bar{\chi}_0$ must be a root of $\mathcal{B}$. Its existence and the bound on it follow from Lemmas 5.3 and 5.5. Indeed, let $z_0 = B_{0,\sigma}$, $Z_L = B_{0,\sigma} - B$, $Z_R = B_{0,\sigma} + B$, $C = E$ (see section 5.2), $G = B$, and $H = \Gamma\,(\mathrm{Bi}, \cdot)$. Lemma 5.3 provides a bound δ on $||C(G - H)||_{[Z_L,Z_R]}$. Also, using Corollary A.1, we may calculate

$$\begin{array}{rcccl} C_0 & = & \min_{[Z_L,Z_R]} E(\gamma^{-1}(1 + \bar{\psi})) & = & E(\gamma^{-1}(1 + Z_R)), \\ -H_0 & = & \max_{[Z_L,Z_R]} \Gamma\left(\mathrm{Bi}', \gamma^{-1}(1 + \bar{\psi})\right) & < & -c\,\gamma^{5/4}\left[E(\gamma^{-1}(1 + Z_L))\right]^{-1}. \end{array}$$

Now, δ satisfies the condition $\delta < C_0 H_0 B$ of Lemma 5.5 for all γ small enough. Thus, we may apply Lemma 5.5 to obtain the desired bound on $\bar{\chi}_0$.

Next, we show that $\mathcal{A}$ has the remaining roots $\bar{\chi}_1, \dots, \bar{\chi}_M$. We fix $A_{M+1} < X < A_M$ and let $I_1, \dots, I_M$ be disjoint intervals around the first M zeroes of Ai, $A_1, \dots, A_M$, respectively. Lemma 5.2 states that $\mathcal{A}(\bar{\chi})$ and $\Gamma\,(\mathrm{Ai}, \bar{\chi})$ are exponentially close in the W^1_∞-norm over $[X, 0]$. Thus, for all $0 < \gamma < \gamma_0$ (with γ_0 small enough), $\mathcal{A}$ has M distinct roots $\bar{\chi}_1 \in I_1, \dots, \bar{\chi}_M \in I_M$ in $[X, 0]$ by Lemma A.2. Since $\Gamma\left(\mathrm{Bi}, \gamma^{-1} + \bar{\chi}\right)$ can be bounded away from zero over $[X, 0]$ using Lemma A.1 (with $p = 1$ and $q = \bar{\chi}$), we conclude that $\mathcal{D}$ has the M distinct roots $\bar{\chi}_1, \dots, \bar{\chi}_M$ in $[X, 0]$.

(b) The argument used in part (a)—where $\beta > 1$—to establish the bounds on the $\mathcal{O}(1)$ roots of $\mathcal{A}$ does not depend on the sign of $\beta - 1$. Therefore, it applies also to this case—where $0 < \beta < 1$—albeit in an interval $[X, 0]$, with $A_{M+2} < X < A_{M+1}$, yielding $M + 1$ roots which we label $\bar{\chi}_0, \dots, \bar{\chi}_M$.

On the other hand, $B_{0,\sigma} < 0$ for $0 < \beta < 1$, because of the estimate on $B_{0,\sigma}$ in Lemma A.2. As a result, the argument used to identify that root does not apply any more, since now $B_{0,\sigma} < 0$ and thus Lemma 5.3 may not be applied to provide the bound δ needed in Lemma 5.5. In fact, were this root to persist and remain close to $\gamma^{-1}B_{0,\sigma}$ as in case (a), it would become *large* and *negative* by the estimate in Lemma A.2 and hence smaller than the roots $\bar{\chi}_0, \ldots, \bar{\chi}_M$ obtained above. Thus, it could never be the leading eigenvalue in this parameter regime. □

6. The eigenfunctions $w_0^{1,\sigma}, \ldots, w_M^{1,\sigma}$.

In the previous section, we located some of the eigenvalues $\mu^{1,\sigma}$. In this section, we show that the eigenvalues we identified are the largest ones. To achieve this, we derive formulas for the eigenfunctions $w_0^{1,\sigma}, \ldots, w_M^{1,\sigma}$ associated with $\mu_0^{1,\sigma}, \ldots, \mu_M^{1,\sigma}$, respectively, and show that $w_n^{1,\sigma}$ has n zeroes in the interval $[\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]$ (corresponding to the interval $[0,1]$ in terms of x; see (5.1)). The desired result follows, then, from standard Sturm–Liouville theory [4]. In particular, we prove the following lemma.

LEMMA 6.1. *Let $M \in \mathbf{N}$. Then, there is a $\gamma_0 > 0$ such that, for all $0 < \gamma < \gamma_0$ and for all $n = 0, 1, \ldots, M$, the eigenfunction $w_n^{1,\sigma}$ corresponding to the eigenvalue $\mu_n^{1,\sigma}$ has exactly n zeroes in the interval $[\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]$.*

The proof of this lemma occupies the rest of this section. Parallel to it, we show that the profile of ω_0 associated with w_0 through (4.1) is that of (a) a boundary layer near the bottom of the water column (BL) for $\beta > 1$, and (b) an interior, nonmonotone boundary layer (a *spike* [9]) close to the point $0 < x_{\mathrm{DCM}} = \beta^2 < 1$ (DCM) for $0 < \beta < 1$.

We start by fixing $\bar{\chi}$ to be $\bar{\chi}_n$, for some $n = 1, \ldots, M$. The corresponding eigenvalue is $\mu_n^{1,\sigma} = -\gamma\sigma\bar{\chi}_n$ (see (5.1)), while the corresponding eigenfunction w_n is given by (5.5),

$$w_n^{1,\sigma}(\chi) = D_A \operatorname{Ai}(\chi) + D_B \operatorname{Bi}(\chi), \quad \text{where } \chi \in [\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]. \tag{6.1}$$

Here, the coefficients D_A and D_B satisfy (5.6),

$$D_A \Gamma_{L,n}(\operatorname{Ai}) + D_B \Gamma_{L,n}(\operatorname{Bi}) = D_A \Gamma_{R,n}(\operatorname{Ai}) + D_B \Gamma_{R,n}(\operatorname{Bi}) = 0,$$

where $\Gamma_{L,n}(\cdot) = \Gamma(\cdot, \bar{\chi}_n)$ and $\Gamma_{R,n}(\cdot) = \Gamma\left(\cdot, \gamma^{-1} + \bar{\chi}_n\right)$. We treat the cases $\beta > 1$ and $0 < \beta < 1$ separately.

6.1. The case $\beta > 1$.

In this section, we select D_A and D_B so that (6.1) becomes

$$w_n^{1,\sigma}(\chi) = D_n \operatorname{Bi}(\chi) - \operatorname{Ai}(\chi), \quad \text{with } D_n = \frac{\Gamma_{L,n}(\operatorname{Ai})}{\Gamma_{L,n}(\operatorname{Bi})} = \frac{\Gamma_{R,n}(\operatorname{Ai})}{\Gamma_{R,n}(\operatorname{Bi})}. \tag{6.2}$$

Using this formula, we prove Lemma 6.1 and verify that ω_0 is of boundary layer type near $x = 1$.

6.1.1. The eigenfunction $w_0^{1,\sigma}$.

First, we show that $w_0^{1,\sigma}$ has no zeroes in the corresponding interval. Using Lemma A.1 and the estimates of Lemmas 5.4 for $\bar{\chi}_0$ and A.2 for $B_{0,\sigma}$, we estimate

$$D_0 = \left(\frac{\Delta_1^2}{2} + \bar{C}_0(\gamma)\right) \exp\left(-4\left(\frac{(\beta^2-1)^{3/4}}{3\gamma^{3/2}} + \sqrt{1 - \frac{1}{\beta^2}}\right)\right).$$

Here, $\Delta_1 = \beta + \sqrt{\beta^2 - 1}$ and $\left|\bar{C}_0(\gamma)\right| < c_0\sqrt{\gamma}$, for some $c_0 > 0$. Thus also, $D_0 > 0$.

It suffices to show that $w_0^{1,\sigma}$ is positive in this interval, and thus that $(w_0^{1,\sigma})' > 0$ everywhere on the interval and $w_0^{1,\sigma}(\bar{\chi}_0) > 0$. For $n = 0$, (6.2) yields $(w_0^{1,\sigma})'(\chi) =$

$D_0\,\mathrm{Bi}'(\chi) - \mathrm{Ai}'(\chi)$, while Lemma 5.4 shows that $[\bar{\chi}_0, \gamma^{-1} + \bar{\chi}_0] \subset \mathbf{R}_+$. Hence, $\mathrm{Bi}'(\chi) > 0$ and $\mathrm{Ai}'(\chi) < 0$ for all χ in this interval. Since $D_0 > 0$, we conclude that $(w_0^{1,\sigma})' > 0$, as desired. Next, we determine the sign of $w_0^{1,\sigma}(\bar{\chi}_0)$. This function is given in (6.2) with $n = 0$, while the definition of $\Gamma_{L,0}$ yields

$$\mathrm{Ai}(\bar{\chi}_0) = \Gamma_{L,0}(\mathrm{Ai}) + \beta^{-1}\sqrt{\gamma}\,\mathrm{Ai}'(\bar{\chi}_0) \quad \text{and} \quad \mathrm{Bi}(\bar{\chi}_0) = \Gamma_{L,0}(\mathrm{Bi}) + \beta^{-1}\sqrt{\gamma}\,\mathrm{Bi}'(\bar{\chi}_0).$$

Substituting into (6.2), we calculate $w_0^{1,\sigma}(\bar{\chi}_0) = \beta^{-1}\sqrt{\gamma}\,[D_0\,\mathrm{Bi}'(\bar{\chi}_0) - \mathrm{Ai}'(\bar{\chi}_0)]$. Thus, $w_0^{1,\sigma}(\bar{\chi}_0)$ is positive by our remarks on the signs of Bi', Ai', and D_0, and the proof is complete.

Next, we study the profile of the associated solution ω_0 to the original problem (1.14). Equations (4.1) and (5.1) yield

$$\omega_0(x) = \exp\left(\frac{\beta}{\gamma^{3/2}}\,x\right)\left[D_0\,\mathrm{Bi}(\gamma^{-1}x + \bar{\chi}_0) - \mathrm{Ai}(\gamma^{-1}x + \bar{\chi}_0)\right], \quad x \in [0,1].$$

Using the estimation of Lemma 5.4 for $\bar{\chi}_0$ and the estimations of Lemma A.1 for Ai and Bi, we find

$$\omega_0(x) = C_I(x)\left(x + \beta^2 - 1\right)^{-1/4}\exp\left(\frac{\beta}{\gamma^{3/2}}x\right)\sinh(\theta_1(x)), \quad x \in [0,1],$$

where $C_I(x) = C_{I,0} + C_{I,1}(x)$, $\sup_{[0,1]}|C_{I,1}(x)| < c_I\sqrt{\gamma}$, for some $c_I > 0$, and

$$\theta_1(x) = \frac{2}{3\gamma^{3/2}}\left[\left(x+\beta^2-1\right)^{3/2} - \left(\beta^2-1\right)^{3/2}\right] + \frac{2}{\beta}\left[\left(x+\beta^2-1\right)^{1/2} - \left(\beta^2-1\right)^{1/2}\right] + \log\Delta_1.$$

The first two terms on the right-hand side of the expression for ω_0 are bounded, while the other two correspond to localized concentrations (boundary layers) at $x = 1$. Thus, ω_0 also corresponds to a boundary layer of width $\mathcal{O}(\gamma^{3/2}) = \mathcal{O}(\sqrt{\varepsilon})$ at the same point.

6.1.2. The eigenfunctions $w_1^{1,\sigma}, \ldots, w_M^{1,\sigma}$. Next, we show that the eigenfunction $w_n^{1,\sigma}$ has n zeroes in $[\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]$, where $n = 1, \ldots, M$. The eigenfunction $w_n^{1,\sigma}$ is given by (6.2). Here also, Lemmas A.1 and 5.4 yield

$$D_n = \left(\frac{\Delta_2^2}{2} + \bar{C}_n(\gamma)\right)\exp\left(-\frac{4}{3\gamma^{3/2}} + 2\frac{|A_n|}{\sqrt{\gamma}} - \frac{2}{\beta}\right), \tag{6.3}$$

where $\Delta_2 = (\beta+1)^{1/2}(\beta-1)^{-1/2}$ and $\left|\bar{C}_n(\gamma)\right| < c_n\sqrt{\gamma}$, for some $c_n > 0$. Hence, $D_n > 0$.

First, we show that the function $w_n^{1,\sigma}$ has exactly $n-1$ zeroes in $[\bar{\chi}_n, 0]$. The estimate (6.3) and the fact that Bi is uniformly bounded on $[\bar{\chi}_n, 0]$ imply that, for all $0 < \gamma < \gamma_0$ (with γ_0 small enough), the functions $w_n^{1,\sigma}$ and $-\mathrm{Ai}$ are exponentially close in the W^1_∞-norm over that interval,

$$\left|\left|w_n^{1,\sigma} + \mathrm{Ai}\right|\right|_{[\bar{\chi}_n,0]} < c_n\exp\left(-\frac{4}{3\gamma^{3/2}} + 2\frac{|A_n|}{\sqrt{\gamma}}\right) \quad \text{for some } c_n > 0. \tag{6.4}$$

As a result, we may use an argument exactly analogous to the one used in the proof of Lemma 5.4 to show that $w_n^{1,\sigma}$ has at least $n-1$ distinct zeroes in $[\bar{\chi}_n, 0]$, each of which is exponentially close to one of $A_1, \ldots, A_{n-1}$. Observing that $\bar{\chi}_n$ is *algebraically*

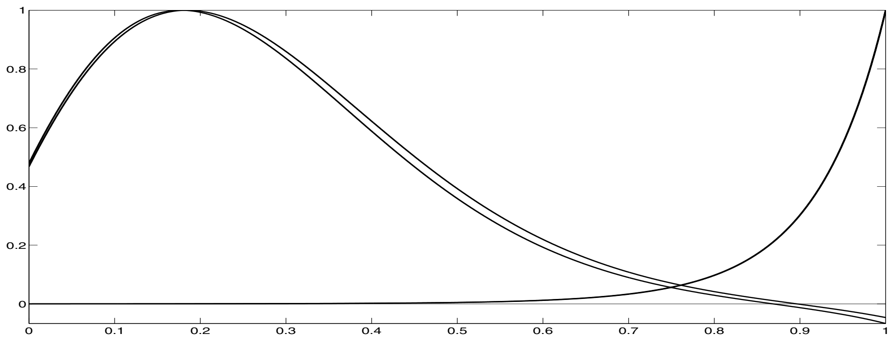

FIG. 6.1. *The eigenfunctions $w_0^{1,\sigma_L}, w_0^{1,\sigma_U}$ (always positive and coinciding within plotting accuracy) and $w_1^{1,\sigma_L}, w_1^{1,\sigma_U}$ (changing sign). Here, $a = 0.775$, $n_H = 0.667$, $\varepsilon = 0.001$, $\kappa = 1$, $\ell = 0.25$, and $j_H = 0.5$, which yields $\sigma_L = 0.1333$, $\sigma_U = 0.1457$ (and thus $\sigma_L < \sigma_U < a^2/4$), $0.0104 \leq \lambda_0 \leq 0.0222$, and $-0.0541 \leq \lambda_1 \leq -0.0512$. Note that $\lambda_1 < \lambda_0$ and that none of w_0^{1,σ_L} and w_0^{1,σ_U} has zeroes in $[0,1]$, while w_1^{1,σ_L} and w_1^{1,σ_U} have exactly one zero in the same interval.*

larger than A_n, by Lemmas 5.4 and A.2, while $w_n^{1,\sigma}$ is *exponentially* close to $-\operatorname{Ai}$, by estimate (6.4), we conclude that the zero of $w_n^{1,\sigma}$ close to A_n lies to the left of $\bar{\chi}_n$ (and hence outside $[\bar{\chi}_n, 0]$) and thus there are no other zeroes in $[\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]$.

It remains to show only that there is a unique zero of $w_n^{1,\sigma}$ in $[0, \gamma^{-1} + \bar{\chi}_n]$. We work as in section 6.1.1 and show that $w_n^{1,\sigma}$ is increasing and changes sign in that interval. First, we calculate $(w_n^{1,\sigma})'(\chi) = D_n \operatorname{Bi}'(\chi) - \operatorname{Ai}'(\chi) > 0$, where we have used that $\operatorname{Bi}'(\chi) > 0$, $\operatorname{Ai}'(\chi) < 0$, and $D_n > 0$. Also, $w_n^{1,\sigma}(0) < 0$ (by $\operatorname{Ai}(0) > 0$ and (6.4)) and, working as in section 6.1.1,

$$w_n^{1,\sigma}(\gamma^{-1} + \bar{\chi}_n) = \beta^{-1}\sqrt{\gamma}\,\left[D_n \operatorname{Bi}'(\gamma^{-1} + \bar{\chi}_n) - \operatorname{Ai}'(\gamma^{-1} + \bar{\chi}_n)\right] > 0.$$

This completes the proof.

6.2. The case $0 < \beta < 1$. In this section, we select D_A and D_B so that (6.1) becomes

$$w_n^{1,\sigma}(\chi) = \operatorname{Ai}(\chi) + D_n \operatorname{Bi}(\chi), \quad \text{with } D_n = -\frac{\Gamma_{L,n}(\operatorname{Ai})}{\Gamma_{L,n}(\operatorname{Bi})} = -\frac{\Gamma_{R,n}(\operatorname{Ai})}{\Gamma_{R,n}(\operatorname{Bi})}. \tag{6.5}$$

Using this formula, we prove Lemma 6.1 and verify that the profile of ω_0 has a spike around $x_\beta = \beta^2$.

We shall show that the eigenfunction $w_n^{1,\sigma}$ $(n = 0, \ldots, M)$ has n zeroes in $[\bar{\chi}_n, \gamma^{-1} + \bar{\chi}_n]$; see Figure 6.1. The proof is entirely analogous to that in section 6.1.2. Here also, the nth eigenvalue is $\mu_n^{1,\sigma} = -\gamma\sigma\bar{\chi}_n$, while the corresponding eigenfunction $w_n^{1,\sigma}$ is given by (6.5). The constant D_n may be estimated by

$$D_n = \left(\frac{\Delta_3^2}{2} + \hat{C}_n(\gamma)\right) \exp\left(-\frac{4}{3\gamma^{3/2}} + 2\frac{|A_{n+1}|}{\sqrt{\gamma}} - \frac{2}{\beta}\right), \tag{6.6}$$

where $\Delta_3 = \sqrt{1+\beta}/\sqrt{1-\beta}$ and $\left|\hat{C}_n\right| < c_n' \sqrt{\gamma}$ for some $c_n' > 0$. This is an estimate of the same type as (6.3) but with A_{n+1} replacing A_n. Thus, the estimate (6.4) holds here as well with the same change. Recalling that $\bar{\chi}_n$ is algebraically larger than

A_{n+1} (see Lemmas 5.4 and A.2), we conclude that $w_n^{1,\sigma}$ has n distinct zeroes, each of which is exponentially close to one of $A_1, \ldots, A_n$. Next, we show that $w_n^{1,\sigma} > 0$ in $[0, \gamma^{-1} + \bar{\chi}_n]$ and thus has no extra zeroes. First, $w_n^{1,\sigma}(\chi) = \operatorname{Ai}(\chi) + D_n \operatorname{Bi}(\chi)$. Now, $\operatorname{Bi}(\chi) > 0$ and $\operatorname{Ai}(\chi) > 0$, for all $\chi \in [0, \gamma^{-1} + \bar{\chi}_n]$, while $D_n > 0$ by (6.6). Hence, $w_n^{1,\sigma} > 0$, and the proof is complete.

Next, we examine the solution ω_0 associated with w_0. Working as in section 6.1.1, we calculate

$$\omega_0(x) = C_{II}(x) x^{-1/4} \exp\left(\frac{\beta}{\gamma^{3/2}} x\right) \cosh(\theta_2(x)), \quad x \in [0,1],$$

where $C_{II}(x) = C_{II,0} + C_{II,1}(x)$, $\sup_{[0,1]} |C_{II,1}(x)| < c_{II}\sqrt{\gamma}$ for some $c_{II} > 0$, and

$$\theta_2(x) = \frac{2}{3\gamma^{3/2}}\left(1 - x^{3/2}\right) - \left(\frac{|A_1|}{\sqrt{\gamma}} - \frac{1}{\beta}\right)(1 - \sqrt{x}) - \log \Delta_3.$$

The first two terms on the right-hand side of the expression for ω_0 are bounded, while the other two correspond to boundary layers at $x = 1$ and $x = 0$, respectively. A straightforward calculation shows that ω_0 corresponds to a spike of width $\mathcal{O}(\gamma^{3/4}) = \mathcal{O}(\varepsilon^{1/4})$ around the point x_β, where

$$\left|x_\beta - \left(\beta^2 + |A_1|\,\gamma\right)\right| < c\gamma^2 \quad \text{for some} \quad c > 0. \tag{6.7}$$

We remark that x_β does *not* correspond to the position of the DCM for the problem (1.14) involving the function f. This information is obtained in the next section, instead, through a WKB analysis.

7. The WKB approximation.

In the previous sections, we derived strict bounds for the eigenvalues $\mu_1, \ldots, \mu_M$ of $\mathcal{L}$ and summarized them in Theorem 2.1. In this section, we use the WKB method to derive explicit (albeit asymptotic) formulas for these eigenvalues. The outcome of this analysis has already been summarized in section 2.1.

7.1. The case $A < \sigma_L$.

7.1.1. WKB formulas for w.

The eigenvalue problem (4.2) reads

$$\varepsilon w_{xx} = (F(x) - \mu)\, w, \quad \text{with} \quad \mathcal{G}(w, 0) = \mathcal{G}(w, 1) = 0. \tag{7.1}$$

Since we are interested in the regime $\sigma_L > A$, Lemma 4.3 states that the eigenvalues $\mu_0, \ldots, \mu_M$ lie in a $\mathcal{O}(\varepsilon^{1/3})$ region to the right of zero. Thus, for any $0 \le n \le M$,

$$F(x) < \mu_n \quad \text{for } x \in [0, \bar{x}_n), \quad \text{and} \quad F(x) > \mu_n \quad \text{for } x \in (\bar{x}_n, 1].$$

Here, $\bar{x}_n$ corresponds to a *turning point*, i.e., $F(\bar{x}_n) = \mu_n$, and it is given by the formula

$$\bar{x}_n = \frac{1}{\kappa} \log \frac{1 + \mu_n(1 + \eta_H)(1 + j_H^{-1})}{1 - \mu_n(1 + \eta_H)(1 + j_H)}. \tag{7.2}$$

Lemmas 4.3 and A.2 suggest that the eigenvalue μ_n may be expanded asymptotically in powers of $\varepsilon^{1/6}$ starting with $\mathcal{O}(\varepsilon^{1/3})$ terms, $\mu_n = \sum_{\ell=2}^{\infty} \varepsilon^{\ell/6} \mu_{n,\ell}$. Thus, we also find

$$\bar{x}_n = \varepsilon^{1/3} \sigma_0^{-1} \mu_{n,2} + \varepsilon^{1/2} \sigma_0^{-1} \mu_{n,3} + \mathcal{O}\left(\varepsilon^{2/3}\right), \quad \text{where } \sigma_0 = F'(0). \tag{7.3}$$

The solution in the region $(\bar{x}_n, 1]$, where $F(x) - \mu_n > 0$, can be determined using standard formulas (see [2, section 10.1]),

$$w_n(x) = [F(x)-\mu_n]^{-1/4}\left[C_a \exp^{-\int_{\bar{x}_n}^{x} \sqrt{(F(s)-\mu_n)/\varepsilon}\, ds} + C_b\, \mathrm{e}^{\int_{\bar{x}_n}^{x} \sqrt{(F(s)-\mu_n)/\varepsilon}\, ds}\right]. \tag{7.4}$$

Here, C_a and C_b are arbitrary constants, to leading order in ε. (Higher order terms in the asymptotic expansions of C_a and C_b generally depend on x; see [2] for details.) Using this information and the asymptotic expansion for μ_n, we may determine the principal part of the solution w_n,

$$w_{n,0}(x) = [F(x)]^{-1/4}\left[C_{a,0}\, \mathrm{e}^{-\theta_3(x)} + C_{b,0}\, \mathrm{e}^{\theta_3(x)}\right], \tag{7.5}$$

for arbitrary constants $C_{a,0}$ and $C_{b,0}$ and where

$$\theta_3(x) = \frac{1}{\varepsilon^{1/2}}\int_0^x \sqrt{F(s)}\, ds - \frac{1}{\varepsilon^{1/6}}\frac{\mu_{n,2}}{2}\int_0^x \frac{ds}{\sqrt{F(s)}} + \frac{\mu_{n,2}}{\sqrt{\sigma_0}} - \frac{2}{3}\sqrt{\sigma_0} - \frac{\mu_{n,3}}{2}\int_0^x \frac{ds}{\sqrt{F(s)}}. \tag{7.6}$$

To determine the solution in $[0, \bar{x}_n)$, we change the independent variable through

$$x = \varepsilon^{1/3}\sigma_0^{-1/3}(\chi - \bar{\chi}_n), \quad \text{where} \quad \bar{\chi}_n = -\sigma_0^{1/3}\,\varepsilon^{-1/3}\,\bar{x}_n = -\sigma_0^{-2/3}\mu_{n,2} + \mathcal{O}\left(\sqrt{\varepsilon}\right) < 0, \tag{7.7}$$

and expand $F(x) - \mu_n = F(x) - F(\bar{x}_n)$ asymptotically:

$$F(x) - F(\bar{x}_n) = F(\varepsilon^{1/3}\sigma_0^{-1/3}(\chi - \bar{\chi}_n)) - F(-\varepsilon^{1/3}\sigma_0^{-1/3}\bar{\chi}_n) = \varepsilon^{1/3}\sigma_0^{2/3}\chi + \mathcal{O}(\sqrt{\varepsilon}). \tag{7.8}$$

As a result, (7.1) becomes the Airy equation $(w_n)_{\chi\chi} = \chi w_n$, to leading order, whence

$$w_{n,0}(\chi) = D_{a,0}\,\mathrm{Ai}(\chi) + D_{b,0}\,\mathrm{Bi}(\chi), \quad \text{with } \chi \in (-\sigma_0^{-2/3}\mu_{n,2}, 0]. \tag{7.9}$$

7.1.2. Boundary conditions for the WKB solution. Next, we determine the coefficients appearing in (7.5) and (7.9). Formula (7.5) represents the solution in the region $(\bar{x}_n, 1]$, and thus it must satisfy the boundary condition $\mathcal{G}\,(w_n, 1) = 0$. Using (4.3), we find, to leading order,

$$C_{a,0}\,(a + 2\sqrt{\sigma_1})\,\mathrm{e}^{-\theta_3(x)} + C_{b,0}\,(a - 2\sqrt{\sigma_1})\,\mathrm{e}^{\theta_3(x)} = 0, \quad \text{where } \sigma_1 = F(1). \tag{7.10}$$

Next, the formula given in (7.9) is valid for $\chi \in (-\sigma_0^{-2/3}\mu_{n,2}, 0]$ (equivalently, for $x \in [0, \bar{x}_n)$), and thus it must satisfy the boundary condition $\mathcal{G}\,(w, 0) = 0$. Recasting the formula for $\mathcal{G}$ given in (4.3) in terms of χ, we obtain to leading order the equation

$$D_{a,0}\,\mathrm{Ai}\left(-\sigma_0^{-2/3}\mu_{n,2}\right) + D_{b,0}\,\mathrm{Bi}\left(-\sigma_0^{-2/3}\mu_{n,2}\right) = 0. \tag{7.11}$$

Finally, (7.5) and (7.9) must also match in an intermediate length scale to the right of $x = \bar{x}_n$ (equivalently, of $\chi = 0$). To this end, we set $\psi = \varepsilon^d\,(x - \bar{x}_n)$, where $1/5 < d < 1/3$ [2, section 10.4], and recast (7.5) in terms of ψ. We find, to leading order and for all $\mathcal{O}(1)$ and positive values of ψ,

$$w_{n,0}(x(\psi)) = \varepsilon^{-d/4}\,\sigma_0^{-1/4}\,\psi^{-1/4}\left[C_{a,0}\,\mathrm{e}^{-\theta_4(\psi)-\sigma_0^{-1}(\mu_{n,2})^{3/2}} + C_{b,0}\,\mathrm{e}^{\theta_4(\psi)+\sigma_0^{-1}(\mu_{n,2})^{3/2}}\right],$$

where $\theta_4(\psi) = (2/3)\,\varepsilon^{(3d-1)/2}\,\sqrt{\sigma_0}\,\psi^{3/2}$. Similarly, (7.9) yields

$$w_{n,0}(\chi(\psi)) = \varepsilon^{1/12-d/4}\,\sigma_0^{-1/12}\,\pi^{-1/2}\,\psi^{-1/4}\left[\frac{D_{a,0}}{2}\,\mathrm{e}^{-\theta_4(\psi)} + D_{b,0}\,\mathrm{e}^{\theta_4(\psi)}\right].$$

The matching condition around the turning point then gives

$$(7.12)\quad C_{a,0} = \varepsilon^{1/12}\frac{\sigma_0^{1/6}}{2\sqrt{\pi}}\mathrm{e}^{\sigma_0^{-1}(\mu_{n,2})^{3/2}}D_{a,0} \quad \text{and} \quad C_{b,0} = \varepsilon^{1/12}\frac{\sigma_0^{1/6}}{\sqrt{\pi}}\mathrm{e}^{-\sigma_0^{-1}(\mu_{n,2})^{3/2}}D_{b,0}.$$

7.1.3. The eigenvalues $\boldsymbol{\mu_0, \dots, \mu_n}$. The linear system (7.10)–(7.12) has a nontrivial solution if and only if the determinant corresponding to it vanishes identically:

$$\begin{aligned} &2\,(a - 2\sqrt{\sigma_1})\,\mathrm{e}^{\theta_3(1) - \sigma_0^{-1}(\mu_{n,2})^{3/2}}\,\mathrm{Ai}(\sigma^{-2/3}\mu_{n,2}) \\ &\qquad + (a + 2\sqrt{\sigma_1})\,\mathrm{e}^{-\theta_3(1) + \sigma_0^{-1}(\mu_{n,2})^{3/2}}\,\mathrm{Bi}(\sigma^{-2/3}\mu_{n,2}) = 0. \end{aligned}$$

Since $\sigma_1 \geq \sigma_L$ by Lemma 2.1 and $\sigma_L > A$ by assumption, $a - 2\sqrt{\sigma_1}$ is $\mathcal{O}(1)$ and negative. Also, $\theta_3(1)$ is $\mathcal{O}(1)$ and positive by (7.6). Thus, the determinant condition reduces to $\mathrm{Ai}(\sigma^{-2/3}\mu_{n,2}) = 0$, whence $\mu_{n,2} = -\sigma_0^{2/3}\,A_{n+1} = \sigma_0^{2/3}\,|A_{n+1}| > 0$. Hence, we find for the eigenvalues of (1.14)

$$(7.13)\qquad \lambda_n = \lambda^* - \varepsilon^{1/3}\sigma_0^{2/3}\,|A_{n+1}| + \mathcal{O}(\sqrt{\varepsilon}).$$

Working in a similar way, we find $\mu_{n,3} = -2\sigma_0/a$.

Recalling that $\sigma_0 = F'(0) = -f'(0)$ by (2.1) and Lemma 2.1 (see also Figure 2.3), we find that the WKB formula (7.13) coincides—up to and including terms of $\mathcal{O}(1)$ and $\mathcal{O}(\varepsilon^{1/3})$—(a) for $0 < j_H < j_H^{(2)}$, with the rigorous lower bound for λ_n derived in Theorem 2.1, and (b) for $j_H > 1$, with the rigorous upper bound for λ_n derived in the same theorem. For the remaining values of j_H, (7.13) yields a value for λ_n which lies in between the upper and lower bounds derived in Theorem 2.1—indeed, in that case, $\sigma_L < F'(0) < \sigma_U$; see Figure 2.3.

7.1.4. The eigenfunctions $\boldsymbol{w_0, \dots, w_n}$. Finally, one may determine the constants C_a, C_b, D_a, and D_b corresponding to the eigenfunction w_n, and thus also w_n itself, through (7.10)–(7.12). The principal part of w_n is given by the formula

$$(7.14)\qquad w_{n,0}(x) = \begin{cases} \mathrm{Ai}\left(A_{n+1} + \varepsilon^{-1/3}\sigma_0^{1/3}x\right) & \text{for } x \in [0, \varepsilon^{1/3}\sigma_0^{-1/3}\,|A_{n+1}|), \\ C\,[F(x)]^{-1/4}\cosh\Theta(x) & \text{for } x \in (\varepsilon^{1/3}\sigma_0^{-1/3}\,|A_{n+1}|\,, 1]. \end{cases}$$

Here,

$$(7.15)\quad C = \varepsilon^{1/12}\,\frac{\sigma_0^{1/6}}{2\sqrt{\pi}}\,\Delta_4\,\mathrm{e}^{|A_{n+1}|^{3/2} - \Theta_3(1)}, \quad \text{where } \Delta_4 = \left(\frac{\sqrt{\sigma_1} + \sqrt{A}}{\sqrt{\sigma_1} - \sqrt{A}}\right)^{1/2},$$

$$(7.16)\qquad \Theta(x) = \varepsilon^{-1/2}\int_x^1 \sqrt{F(s)}\,ds - \left(\varepsilon^{-1/6}\,\frac{\sigma_0^{2/3}\,|A_{n+1}|}{2} - \frac{\sigma_0}{a}\right)\int_x^1 \frac{ds}{\sqrt{F(s)}} + \log\Delta_4.$$

Recalling (4.1), we find

$$(7.17)\qquad \omega_{n,0}(x) = \begin{cases} \mathrm{e}^{\sqrt{A/\varepsilon}\,x}\,\mathrm{Ai}\left(A_{n+1} + \varepsilon^{-1/3}\sigma_0^{1/3}x\right) & \text{for } x \in [0, \varepsilon^{1/3}\sigma_0^{-1/3}\,|A_{n+1}|), \\ C\,[F(x)]^{-1/4}\,\mathrm{e}^{\sqrt{A/\varepsilon}\,x}\cosh\Theta(x) & \text{for } x \in (\varepsilon^{1/3}\sigma_0^{-1/3}\,|A_{n+1}|\,, 1]. \end{cases}$$

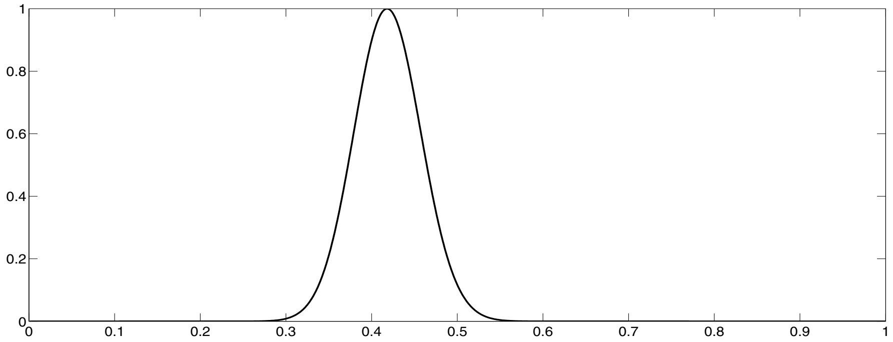

FIG. 7.1. *The eigenfunction ω_0 as given by* (7.17). *Here,* $a = 0.5$, $n_H = 0.667$, $\varepsilon = 2 \cdot 10^{-7}$, $\kappa = 1$, *and* $j_H = 0.5$. *The eigenfunction has been scaled so that its maximum value is equal to one.*

A straightforward calculation shows that ω_0 corresponds to a spike around the point

$$x_{\mathrm{DCM}} = x_{\mathrm{DCM},0} + \mathcal{O}(\varepsilon^{1/3}), \tag{7.18}$$

where $x_{\mathrm{DCM},0}$ is the unique solution to $F(x_{\mathrm{DCM},0}) = A = a^2/4$; see also Figure 7.1, where ω_0 is plotted for specific parameter values. Thus, $\omega_{0,0}$ indeed corresponds to a DCM. Furthermore, the location of the maximum phytoplankton concentration is expressed explicitly by this equation in terms of the rescaled biological parameters κ, η_H, j_H, and a.

7.2. The case $A > \sigma_U$. To obtain the eigenvalues and their corresponding eigenfunctions in this case, we work as in the preceding section. Here also, the eigenvalue problem (4.2) has the form (7.1). Since $A > \sigma_U$, the eigenvalue μ_0 is $\mathcal{O}(1)$ and negative, while $\mu_1, \ldots, \mu_M$ are $\mathcal{O}(\varepsilon^{1/3})$ and positive; see Lemma 4.3. Due to the qualitative difference between μ_0 and the eigenvalues of higher order, we consider them separately.

We start with the case $1 \leq n \leq M$. Then, for each such n, the eigenvalue problem (7.1) has a unique turning point $\bar{x}_n$ given by (7.2), and the analysis presented in the preceding section applies here also. The formulas for μ_n and ω_n, $1 \leq n \leq M$, are identical to those of the preceding section, with the sole modification that A_n in (7.13)–(7.16) must be replaced by A_{n-1}. This completes the analysis for the case $1 \leq n \leq M$.

Next, we treat the case $n = 0$. Since $\mu_0 < 0 < F(x)$ for all $x \in [0, 1]$, the eigenvalue problem (7.1) corresponding to μ_0 has no turning points. Thus, the WKB formula (7.4), with $n = 0$ and $\bar{x}_n$ replaced by zero, is valid for all $x \in [0, 1]$. Lemmas 4.3 and A.2 suggest that μ_0 may be expanded asymptotically as $\mu_0 = \sum_{\ell=0}^{\infty} \varepsilon^{\ell/2} \mu_{0,\ell}$. Using this expansion, we calculate the principal part of w_0,

$$w_{0,0}(x) = [F(x) - \mu_{0,0}]^{-1/4} \left[C_{a,0}\, \mathrm{e}^{-\theta_5(x)} + C_{b,0}\, \mathrm{e}^{\theta_5(x)} \right], \tag{7.19}$$

where $C_{a,0}$ and $C_{b,0}$ are arbitrary constants and

$$\theta_5(x) = \frac{1}{\varepsilon^{1/2}} \int_0^x \sqrt{F(s) - \mu_{0,0}}\, ds - \frac{\mu_{0,1}}{2} \int_0^x \frac{ds}{\sqrt{F(s) - \mu_{0,0}}}. \tag{7.20}$$

Next, recalling the boundary conditions $\mathcal{G}\,(w,0) = \mathcal{G}\,(w,1) = 0$, we obtain, to leading order,

$$\begin{aligned} C_{a,0}\,(a + 2\sqrt{-\mu_{0,0}}) + C_{b,0}\,(a - 2\sqrt{-\mu_{0,0}}) &= 0, \\ C_{a,0}\,(a + 2\sqrt{\sigma_1 - \mu_{0,0}})\,\mathrm{e}^{-\theta_5(1)} + C_{b,0}\,(a - 2\sqrt{\sigma_1 - \mu_{0,0}})\,\mathrm{e}^{\theta_5(1)} &= 0, \end{aligned} \tag{7.21}$$

where we recall that $\sigma_1 = F(1)$. Here, $\theta_5(1)$ is $\mathcal{O}(1)$ and positive by (7.20), while $a + 2\sqrt{-\mu_{0,0}} > 0$. Thus, we obtain $\mu_{0,0} = F(1) - A$, to leading order, whence

$$\lambda_{0,0} = f(1) - \ell.$$

This is precisely (2.8). Using this formula, one may also determine $C_{a,0}$ and $C_{b,0}$ to obtain $w_{0,0}$,

$$w_{0,0}(x) = \,[F(x) - \mu_{0,0}]^{-1/4} \sinh \Phi(x), \tag{7.22}$$

for $x \in [0,1]$ and up to a multiplicative constant. Here,

$$\Phi(x) = \frac{1}{\varepsilon^{1/2}} \int_0^x \sqrt{F(s) - \mu_{0,0}}\, ds - \frac{\mu_{0,1}}{2} \int_0^x \frac{ds}{\sqrt{F(s) - \mu_{0,0}}} + \log \Delta_5,$$

where

$$\Delta_5 = \beta_1 + \sqrt{\beta_1^2 - 1} \quad \text{and} \quad \beta_1 = \frac{\sqrt{A}}{F(1)}.$$

Recalling (4.1), we find

$$\omega_{0,0}(x) = [F(x) - \mu_{0,0}]^{-1/4}\, \mathrm{e}^{ax/2\sqrt{\varepsilon}} \sinh \Phi(x) \quad \text{for } x \in [0,1].$$

The profile of ω_0 corresponds to a boundary layer at the point $x = 1$.

7.3. The transitional regime $\boldsymbol{\sigma_L < A < \sigma_U}$.

Equations (2.9) and (2.8) may be used to derive information for the transitional regime $\sigma_L < A < \sigma_U$ (see Theorem 2.1 and the discussion in section 2). In particular, the transition between the case where λ_0 is associated with a boundary layer (in biological terms, with a BL) and the case where it is associated with a spike (that is, with a DCM) occurs, to leading order, when $f(1) - \ell = \lambda^*$. Recalling (2.5), we rewrite this equation as

$$F(1) = f(0) - f(1) = A. \tag{7.23}$$

This condition reduces, to leading order, to $A = \sigma_U$ for $0 < j_H \leq j_H^{(1)}$, and to $A = \sigma_L$ for $j_H \geq j_H^{(2)}$. For $j_H^{(1)} < j_H < j_H^{(2)}$, this transitional value of A lies between σ_U and σ_L; see section 2 and Figure 2.3.

Appendix A. Basic properties of the Airy functions.

In this section, we summarize some properties of the Airy functions Ai and Bi which we use repeatedly.

LEMMA A.1. *Let $p > 0$ and q be real numbers. Then,*

$$\begin{aligned} &\Gamma\left(\mathrm{Ai}, \gamma^{-1} p + q\right) \\ &\quad = (\pi^{-1/2}/2)\left(\gamma\, p^{-1}\right)^{1/4} \exp\left(-\,(2/3)\left(\gamma^{-1} p\right)^{3/2} - q\left(\gamma^{-1} p\right)^{1/2}\right) \\ &\qquad \cdot \left[\left(1 + \beta^{-1}\sqrt{p}\right)\left(1 - (q^2/4)\left(\gamma\, p^{-1}\right)^{1/2} + (q/4)\left(q^3/8 - 1\right)\gamma\, p^{-1}\right)\right. \\ &\qquad \left. -\,(1/48)\left(5 - 5q^3 + q^6/8 - \left(43 - q^3 - q^6/8\right)\beta^{-1}\sqrt{p}\right)\left(\gamma\, p^{-1}\right)^{3/2}\right], \quad \gamma \downarrow 0, \end{aligned}$$

$$
\begin{aligned}
&\Gamma\left(\mathrm{Bi},\gamma^{-1}p+q\right)\\
&\quad= \pi^{-1/2}\left(\gamma\, p^{-1}\right)^{1/4}\exp\left((2/3)\left(\gamma^{-1}p\right)^{3/2}+q\left(\gamma^{-1}p\right)^{1/2}\right)\\
&\qquad\cdot\Big[\left(1-\beta^{-1}\sqrt{p}\right)\left(1+\left(q^2/4\right)\left(\gamma\, p^{-1}\right)^{1/2}+(q/4)\left(q^3/8-1\right)\gamma\, p^{-1}\right)\\
&\qquad+(1/48)\left(5-5q^3+q^6/8+\left(43-q^3-q^6/8\right)\beta^{-1}\sqrt{p}\right)\left(\gamma\, p^{-1}\right)^{3/2}\Big], \quad \gamma\downarrow 0,
\end{aligned}
$$

where the remainders of $\mathcal{O}(\gamma^2)$ *were omitted from within the square brackets.*

Proof. We derive only the first of these asymptotic expansions. The second one is derived in an entirely analogous manner. Definition (5.2) yields

$$
\Gamma\left(\mathrm{Ai},\gamma^{-1}\,p+q\right)=\mathrm{Ai}\left(\gamma^{-1}\,p+q\right)-\sqrt{\gamma}\,\beta^{-1}\,\mathrm{Ai}'\left(\gamma^{-1}\,p+q\right).
$$

Then, we recall the standard asymptotic expansions [2]

$$
\begin{aligned}
\mathrm{Ai}(z)&=\left(\pi^{-1/2}\,z^{-1/4}/2\right)\exp\left(-(2/3)z^{3/2}\right)\left[1-(5/48)\,z^{-3/2}+\mathcal{O}(z^{-3})\right], \quad z\uparrow\infty,\\
\mathrm{Ai}'(z)&=-\left(\pi^{-1/2}\,z^{1/4}/2\right)\exp\left(-(2/3)z^{3/2}\right)\left[1+(7/48)\,z^{-3/2}+\mathcal{O}(z^{-3})\right], \quad z\uparrow\infty,
\end{aligned}
$$

$$
\left(\gamma^{-1}p+q\right)^r=p^r\gamma^{-r}+\sum_{k=1}^{\infty}\frac{1}{k!}\left(\prod_{j=0}^{k-1}(r-j)\right)p^{r-k}q^k\,\gamma^{k-r}.
$$

The desired equation now follows by combining these asymptotic expansions. □

Corollary A.1. *Let* p *and* q *be as in Lemma* A.1. *Then, for* $\gamma\downarrow 0$,

$$
\begin{aligned}
\Gamma\left(\mathrm{Ai}',\gamma^{-1}\,p+q\right)&=-\left(\pi^{-1/2}/2\right)\left(\gamma^{-1}\,p\right)^{1/4}\exp\left(-(2/3)\left(\gamma^{-1}p\right)^{3/2}-q\left(\gamma^{-1}p\right)^{1/2}\right)\\
&\quad\cdot\Big[\left(1+\beta^{-1}\sqrt{p}\right)\left(1-\left(q^2/4\right)\left(\gamma\, p^{-1}\right)^{1/2}\right)\\
&\quad+(q/4)\left(\left(q^3/8-1\right)+\left(q^3/8+3\right)\beta^{-1}\sqrt{p}\right)\gamma\, p^{-1}\\
&\quad-(1/48)\left(-19+q^3+q^6/8+\left(-7+7q^3+q^6/8\right)\beta^{-1}\sqrt{p}\right)\left(\gamma\, p^{-1}\right)^{3/2}\Big],\\
\Gamma\left(\mathrm{Bi}',\gamma^{-1}\,p+q\right)&=\pi^{-1/2}\left(\gamma^{-1}\,p\right)^{1/4}\exp\left((2/3)\left(\gamma^{-1}\,p\right)^{3/2}+q\left(\gamma^{-1}\,p\right)^{1/2}\right)\\
&\quad\cdot\Big[\left(1-\beta^{-1}\sqrt{p}\right)\left(1+\left(q^2/4\right)\left(\gamma p^{-1}\right)^{1/2}\right)\\
&\quad+(q/4)\left(\left(q^3/8-1\right)-\left(q^3/8+3\right)\beta^{-1}\sqrt{p}\right)\gamma\, p^{-1}\\
&\quad+(1/48)\left(-19+q^3+q^6/8-\left(-7+7q^3+q^6/8\right)\beta^{-1}\sqrt{p}\right)\left(\gamma\, p^{-1}\right)^{3/2}\Big],
\end{aligned}
$$

where the remainders of $\mathcal{O}(\gamma^2)$ *were omitted from within the square brackets.*

Proof. Definition (5.2) and the identities $\mathrm{Ai}''(z)=z\,\mathrm{Ai}(z)$ and $\mathrm{Bi}''(z)=z\,\mathrm{Bi}(z)$ yield

$$
\begin{aligned}
\Gamma\left(\mathrm{Ai}',\gamma^{-1}p+q\right)&=\mathrm{Ai}'\left(\gamma^{-1}p+q\right)-\sqrt{\gamma}\,\beta^{-1}\left(\gamma^{-1}\,p+q\right)\mathrm{Ai}\left(\gamma^{-1}\,p+q\right),\\
\Gamma\left(\mathrm{Bi}',\gamma^{-1}+\bar{\chi}\right)&=\mathrm{Bi}'\left(\gamma^{-1}\,p+q\right)-\sqrt{\gamma}\,\beta^{-1}\left(\gamma^{-1}\,p+q\right)\mathrm{Bi}\left(\gamma^{-1}\,p+q\right).
\end{aligned}
$$

The desired result now follows from Lemma A.1. □

Lemma A.2. *The function* $\Gamma\left(\mathrm{Ai},\bar{\chi}\right)$ *has no positive roots. Further, for any* $M\in\mathbf{N}$, *there is an* $\varepsilon_0>0$ *such that, for all* $0<\varepsilon<\varepsilon_0$, $\Gamma\left(\mathrm{Ai},\bar{\chi}\right)$ *has roots* $A'_{M,\sigma}<\cdots<A'_{1,\sigma}<0$ *satisfying*

$$
\left|A'_{n,\sigma}-\left(A_n+\sqrt{\gamma}\,\beta^{-1}\right)\right|<c_a\,\gamma \quad \textit{for some} \quad c_a>0.
$$

Here, $A_n < 0$ is the nth root of Ai *(see Figure* 2.1*), and β, γ are given in* (2.3)*. For $\beta > 1$ (equivalently, for $0 < \sigma < a^2/4$), the function $\Gamma\left(\mathrm{Bi}, \gamma^{-1}(1+\bar{\psi})\right)$ defined in* (2.4) *has a root $B_{0,\sigma} > 0$ satisfying*

$$\left|B_{0,\sigma} - \left(\beta^2 - 1 + 2\,\gamma^{3/2}\,\beta^{-1}\right)\right| < c_b\,\gamma^3 \quad \textit{for some} \quad c_b > 0.$$

Proof. The fact that there exist no positive roots of $\Gamma\,(\mathrm{Ai}, \bar{\chi})$ is immediate by the definition of $\Gamma\,(\mathrm{Ai}, \bar{\chi})$ (see (2.4)) and the fact that $\mathrm{Ai}(\bar{\chi}) > 0$ and $\mathrm{Ai}'(\bar{\chi}) < 0$ for all $\bar{\chi} > 0$.

Next, the existence of M discrete and negative roots may be proved as follows. Fix $|A_M| < X < |A_{M+1}|$ and let $I_1, \ldots, I_M$ be disjoint intervals around $A_1, \ldots, A_M$, respectively. Definition (2.4) implies that $\Gamma\,(\mathrm{Ai}, \cdot)$ is $\mathcal{O}(\sqrt{\gamma})$ close to Ai over $[-X, 0]$ in the norm introduced in (5.10). Thus, for all $0 < \gamma < \gamma_0$ and γ_0 small enough, $\Gamma\,(\mathrm{Ai}, \bar{\chi})$ has M distinct roots $A'_{1,\sigma} \in I_1, \ldots, A'_{M,\sigma} \in I_M$ in $[-X, 0]$. That these are ordered as $A'_{M,\sigma} < \cdots < A'_{1,\sigma}$ follows from $A_{M,\sigma} < \cdots < A_{1,\sigma}$ and the fact that $I_1, \ldots, I_M$ were chosen to be disjoint. The bounds on $A'_{1,\sigma}, \ldots, A'_{M,\sigma}$ may be derived by writing $A'_{n,\sigma} = \sum_{\ell \geq 0} \varepsilon^{\ell/6}\, a^{(\ell)}_{n,\sigma}$, substituting into the equation $\Gamma\,(\mathrm{Ai}, \bar{\chi}) = 0$, and expanding asymptotically.

The existence of $B_{0,\sigma} > 0$ and the bound on it may be established using Lemma A.1 (with $p = 1 + \bar{\psi}$ and $q = 0$). □

Appendix B. Proof of Lemma 5.2. Using definition (5.8), we calculate

$$\mathcal{A}(\bar{\chi}) - \Gamma\,(\mathrm{Ai}, \bar{\chi}) = -\frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)}{\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})}\Gamma\,(\mathrm{Bi}, \bar{\chi})\,. \tag{B.1}$$

To estimate the fraction on the right-hand side, we apply standard theory for Airy functions [2]; see Appendix A. Using Lemma A.1 (with $p = 1$ and $q = \bar{\chi}$), we find that

$$\sup_{\bar{\chi} \in [X,0]} \left| \exp\left(\frac{4}{3\gamma^{3/2}} + \frac{2\bar{\chi}}{\gamma^{1/2}}\right) \frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)}{\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})} - \frac{1}{2}\frac{\beta + 1}{\beta - 1} \right| < c_1 \sqrt{\gamma},$$

for some $c_1 > 0$ and γ small enough. Therefore,

$$\sup_{\bar{\chi} \in [X,0]} \left| \frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)}{\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})} \right| < c_2 \exp\left(-\frac{4 + 6\,\gamma\,X}{3\gamma^{3/2}}\right), \tag{B.2}$$

for some $c_2 > 0$. Next, $\sup_{[X,0]} |\Gamma\,(\mathrm{Bi}, \cdot)| \leq c_3$ for some $c_3 > 0$, since Bi and Bi$'$ are uniformly bounded over $[X, 0]$. Combining these estimates, we find

$$\sup_{\bar{\chi} \in [X,0]} |\mathcal{A}(\bar{\chi}) - \Gamma\,(\mathrm{Ai}, \bar{\chi})| < c_4 \exp\left(-\frac{4 + 6\,\gamma\,X}{3\gamma^{3/2}}\right), \tag{B.3}$$

for some $c_4 > 0$ and for all γ small enough.

Next, differentiating (B.1), we calculate

$$\begin{aligned} \mathcal{A}'(\bar{\chi}) - \Gamma(\mathrm{Ai}', \bar{\chi}) = {} & \left(\frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right) \Gamma\left(\mathrm{Bi}', \gamma^{-1} + \bar{\chi}\right)}{[\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})]^2} - \frac{\Gamma\left(\mathrm{Ai}', \gamma^{-1} + \bar{\chi}\right)}{\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})} \right) \Gamma\,(\mathrm{Bi}, \bar{\chi}) \\ & - \frac{\Gamma\left(\mathrm{Ai}, \gamma^{-1} + \bar{\chi}\right)}{\Gamma\,(\mathrm{Bi}, \gamma^{-1} + \bar{\chi})} \Gamma\left(\mathrm{Bi}', \bar{\chi}\right). \end{aligned} \tag{B.4}$$

Using Lemma A.1, we may bound the term in parentheses by

$$\frac{c_1'}{\sqrt{\gamma}} \exp\left(-\frac{4+6\,\gamma\,X}{3\,\gamma^{3/2}}\right),$$

for some $c_1' > 0$. Next, $\Gamma\left(\mathrm{Bi}, \bar{\chi}\right)$ was uniformly bounded by a constant c_3 above. Also, the term $\Gamma\left(\mathrm{Bi}', \bar{\chi}\right)$ may be bounded by a constant c_3', since

$$\Gamma\left(\mathrm{Bi}', \bar{\chi}\right) = \mathrm{Bi}'(\bar{\chi}) - \sqrt{\gamma}\,\beta\,\mathrm{Bi}''(\bar{\chi}) = \mathrm{Bi}'(\bar{\chi}) - \sqrt{\gamma}\,\beta\,\bar{\chi}\,\mathrm{Bi}(\bar{\chi}),$$

and the term multiplying it in (B.4) was bound in (B.2). These inequalities yield, then,

$$||\mathcal{A}'(\cdot) - \mathrm{Ai}'(\cdot)||_{[X,0]} < c_2'\,\gamma^{-1/2} \exp\left(-\frac{4+6X\gamma}{3\gamma^{3/2}}\right), \tag{B.5}$$

for some $c_2' > 0$ and for all γ small enough. Equation (5.11) follows now from (B.3) and (B.5). □

Appendix C. Proof of Lemma 5.3. Definition (5.9) yields

$$\mathcal{B}(\gamma^{-1}\bar{\psi}) - \Gamma\left(\mathrm{Bi}, \gamma^{-1}(1+\bar{\psi})\right) = -\frac{\Gamma\left(\mathrm{Bi}, \gamma^{-1}\bar{\psi}\right)}{\Gamma\left(\mathrm{Ai}, \gamma^{-1}\bar{\psi}\right)}\Gamma\left(\mathrm{Ai}, \gamma^{-1}(1+\bar{\psi})\right). \tag{C.1}$$

To estimate the right-hand side, we work as in Appendix B. Using Lemma A.1 twice (once with $p = \bar{\psi}$, $q = 0$ and once with $p = 1+\bar{\psi}$, $q = 0$), we obtain

$$\begin{aligned} &\sup_{\bar{\psi}\in[\Psi_R,\Psi_L]} \left| E(\gamma^{-1}(1+\bar{\psi}))\,\frac{\Gamma\left(\mathrm{Bi}, \gamma^{-1}\bar{\psi}\right)}{\Gamma\left(\mathrm{Ai}, \gamma^{-1}\bar{\psi}\right)}\Gamma\left(\mathrm{Ai}, \gamma^{-1}(1+\bar{\psi})\right)\right| \\ &\qquad < c_1\,\gamma^{1/4}\left[\frac{E(\gamma^{-1}(1+\Psi_L))}{E(\gamma^{-1}\Psi_L)}\right]^2, \end{aligned} \tag{C.2}$$

for some $c_1 > 0$ and γ small enough.

Next, differentiating (C.1), we calculate

$$\begin{aligned} \mathcal{B}'(\gamma^{-1}\bar{\psi}) - \Gamma'(\mathrm{Bi}, \gamma^{-1}(1+\bar{\psi})) &= -\frac{\Gamma\left(\mathrm{Bi}, \gamma^{-1}\bar{\psi}\right)}{\Gamma\left(\mathrm{Ai}, \gamma^{-1}\bar{\psi}\right)}\Gamma\left(\mathrm{Ai}', \gamma^{-1}(1+\bar{\psi})\right) \\ &+ \left(\frac{\Gamma\left(\mathrm{Bi}, \gamma^{-1}\bar{\psi}\right)\Gamma\left(\mathrm{Ai}', \gamma^{-1}\bar{\psi}\right)}{[\Gamma\left(\mathrm{Ai}, \gamma^{-1}\bar{\psi}\right)]^2} - \frac{\Gamma\left(\mathrm{Bi}', \gamma^{-1}\bar{\psi}\right)}{\Gamma\left(\mathrm{Ai}, \gamma^{-1}\bar{\psi}\right)}\right)\Gamma\left(\mathrm{Ai}, \gamma^{-1}(1+\bar{\psi})\right). \end{aligned}$$

Using Lemma A.1 and Corollary A.1 to estimate the right-hand side, we find

$$\begin{aligned} &\sup_{\bar{\psi}\in[\Psi_R,\Psi_L]} \left| E(\gamma^{-1}(1+\bar{\psi}))\left[\mathcal{B}'(\gamma^{-1}\bar{\psi}) - \Gamma'(\mathrm{Bi}, \gamma^{-1}(1+\bar{\psi}))\right]\right| \\ &\qquad < c_1'\,\gamma^{-1/4}\left[\frac{E(\gamma^{-1}(1+\Psi_L))}{E(\gamma^{-1}\Psi_L)}\right]^2, \end{aligned} \tag{C.3}$$

for some $c_1' > 0$ and γ small enough.

The desired result follows from (C.2) and (C.3). □

THE COMPLETE CLASSIFICATION FOR DYNAMICS IN A NINE-DIMENSIONAL WEST NILE VIRUS MODEL*

JIFA JIANG† AND ZHIPENG QIU‡

Abstract. Bowman et al. [*Bull. Math. Biol.*, 67 (2005), pp. 1107–1133] proposed a nine-dimensional system of ordinary differential equations modelling West Nile virus in a mosquito–bird-human community and presented some mathematical analysis and its biological explanation. Jiang et al. [*Bull. Math. Biol.*, 2008, DOI 10.1007/s11538-008-9374-6] continued to study the existence and classification of all equilibria and all their local stability and dealt with saddle-node bifurcation of the system. The previous investigation shows that the unique positive equilibrium is globally asymptotically stable if the basic reproduction number is greater than one and the bird death rate is suitably small, but numerical simulations suggest that the unique endemic equilibrium is globally asymptotically stable even if for a large value of the bird death rate. So, they all leave it an open problem. The present paper is to provide a thorough classification of dynamics for this system. In particular, if the reproduction number is greater than one, then a unique endemic equilibrium exists and is globally asymptotically stable in the interior of the feasible region, and the disease persists at an endemic equilibrium if it initially exists, which completely solves the open problem above. Besides, the sufficient and necessary conditions for switch phenomena of the model are obtained if the reproduction number is smaller than one. The results show that the reproduction number alone is not enough to determine whether West Nile virus can prevail or not. Meanwhile, the dynamics of the model for the critical case where the reproduction number is one is also analyzed.

1. Introduction.

Compartmental epidemiological models have played a significant role in the development of a better understanding the mechanism of epidemic transmission and the various preventive strategies used against it. Since the pioneering work of Kermack-Mckendrick, susceptible-infective-recovered (SIR)/susceptible-exposed-infective recovered (SEIR) epidemiological models have received much attention from scientists (see [1, 2, 3] and references therein). West Nile virus (WNV), a single-stranded ribonucleic acid (RNA) virus of the genus *Flavivirus* and the family *Flaviviridae*, remains a significant threat to public health in the world. Since the first outbreak in New York in the late summer of 1999 [4], WNV has been keeping spread through the continent of North America for the last several years. In the United States between 1999 and 2001, WNV was associated with 149 cases of neurological diseases in humans, 814 cases of equine encephalitis, and 11,932 deaths in the avian population. During 2003, 9,858 human cases and 14 deaths were reported [5]. It is, therefore, imperative to gain some insights into the transmission dynamics of WNV

so that we can assess the various anti-WNV preventive strategies. The purpose of the paper is to use mathematical modelling to understand the transmission dynamics of WNV in the mosquito–bird-human population.

A brief review of the salient features of WNV transmission will be useful. WNV is an "arbovirus," which means it is carried by an arthropod, usually an insect, from host to host. WNV is primarily an avian virus and is usually transmitted from bird to bird by mosquitoes. When a mosquito bites an infected bird (to feed on its blood), virus particles in the bird's blood are picked up. These particles make their way to the salivary glands of the mosquito, where they are reproduced. The mosquito then injects them into the next bird it bites. Virus particles injected into susceptible species recognize, and infect, the cells of particular tissues and co-opt those cells into making more virus particles. These particles then leave the cells and circulate in the blood, where they can be picked up by biting mosquitoes; this is how mosquitoes become infected. Humans, horses, and probably other vertebrates are circumstantial hosts; that is, they can be infected if bitten by an infectious mosquito but they do not transmit the disease.

Recently, there has been some effort in the mathematical modelling of the transmission of WNV. Lord and Day [6] carried out simulation studies of St. Louis encephalitis and WNV using a model of differential equations. Thomas and Urena [7] formulated a difference equation model for WNV, targeting its effects on New York City. Wonham, de-Camino-Beck, and Lewis [8] presented a single season ordinary differential equations model for WNV transmission in the mosquito-bird population. Kenkre et al. [9] provided a theoretical framework for the analysis of the WNV epidemic and for dealing with mosquito diffusion and bird migration. Liu et al. [10] studied the impact of the directional dispersal of birds on the spatial spreading of WNV. In a more recent work by Bowman et al. [11], they proposed a single-season ordinary differential equation model for the transmission dynamics of WNV in a mosquito–bird-human community, with birds as reservoir hosts and culicine mosquitoes as vectors. The model in paper [11] is described by the following equations:

$$
\left\{
\begin{aligned}
\frac{dM_u}{dt} &= \Pi_M - \frac{b_1(N_M,N_B,N_H)\beta_1 M_u B_i}{N_B} - \mu_M M_u,\\
\frac{dM_i}{dt} &= \frac{b_1(N_M,N_B,N_H)\beta_1 M_u B_i}{N_B} - \mu_M M_i,\\
\frac{dB_u}{dt} &= \Pi_B - \frac{b_1(N_M,N_B,N_H)\beta_2 M_i B_u}{N_B} - \mu_B B_u,\\
\frac{dB_i}{dt} &= \frac{b_1(N_M,N_B,N_H)\beta_2 M_i B_u}{N_B} - \mu_B B_i - d_B B_i,\\
\frac{dS}{dt} &= \Pi_H - \frac{b_2(N_M,N_B,N_H)\beta_3 M_i S}{N_H} - \mu_H S,\\
\frac{dE}{dt} &= \frac{b_2(N_M,N_B,N_H)\beta_3 M_i S}{N_H} - \mu_H E - \alpha E,\\
\frac{dI}{dt} &= \alpha E - \mu_H I - \delta I,\\
\frac{dH}{dt} &= \delta I - \mu_H H - d_H H - \tau H,\\
\frac{dR}{dt} &= \tau H - \mu_H R.
\end{aligned}
\right.
\tag{1.1}
$$

The above model is based on monitoring the temporal dynamics of the populations of uninfected female mosquitoes $M_u(t)$, infected female mosquitoes $M_i(t)$, uninfected birds $B_u(t)$, infected birds $B_i(t)$, susceptible humans $S(t)$, asymptomatically infected humans $E(t)$, symptomatically infected humans $I(t)$, hospitalized WNV-infected humans $H(t)$, and recovered humans $R(t)$. In (1.1), $N_M(t) = M_u(t) + M_i(t)$ is the total population of female mosquitoes in the community, $N_B(t) = B_u(t) + B_i(t)$ is the total population of birds in the community, and $N_H(t) = S(t) + E(t) + I(t) + H(t) + R(t)$ is the total human population. Π_M, Π_B, and Π_H are the recruitment of uninfected (susceptible) mosquitoes, birds, and human (either by birth or immigration), respectively; $b_1(N_M, N_B, N_H), b_2(N_M, N_B, N_H)$ is the per capita biting rate of mosquitoes on the primary host (birds) and on humans, respectively. In paper [11], it was always assumed that $b_1(N_M, N_B, N_H) = b_1$ and $b_2(N_M, N_B, N_H) = b_2$ are positive constants. β_1, β_2, and β_3 are the probability of WNV transmission from infected birds to uninfected mosquitoes, from mosquitoes to birds, and from mosquitoes to humans, respectively; μ_M, μ_B, and μ_H are the natural death rate of mosquitos, birds, and humans, respectively; d_B, d_H denote the WNV-induced death rate of birds and humans; α is the development rate from asymptomatically infected humans into the symptomatically infected humans; δ is the hospitalization rate from the symptomatic population to the population of hospitalized individuals; τ is the recovery rate from the population of hospitalized individuals into the recovered population.

In paper [11], by investigating the qualitative features of the system, an important epidemiological threshold, known as the basic reproduction number, was determined, and sufficient conditions for the local and global stability of the associated equilibria were obtained; all parameters were estimated by real data, and detailed explanations were given for their theoretic results. Applying the theory of K-competitive dynamical systems [19] and index theory of dynamical systems on a surface, Jiang et al. [12] considered a subsystem for the primary mosquito-bird cycle and obtained sufficient and necessary conditions for local stability of equilibria of the subsystem. The results in paper [12] suggested that the basic reproduction number alone is not enough to determine whether WNV can prevail or not, and that more attention should be paid to the initial state of WNV.

However, there remain some problems. Although the global stability of the endemic equilibrium was proved in [11] with the assumption that d_B is sufficiently small and the basic reproduction number is above unity, Bowman et al. [11] were not able to show the global dynamics of system (1.1) for all $d_B > 0$, and mass numerical simulations in [11, 12] suggest that the unique endemic equilibrium is globally asymptotically stable even for large values of d_B. However, "rigorous proof for the global stability of the endemic equilibrium in the case when the basic reproduction number is greater than 1 remains an open problem" [12]. In addition, paper [12] classified the equilibria and their local stability for the subsystem of system (1.1), which involves only the mosquitoes and birds. Therefore, we expect to obtain the complete dynamical behavior of system (1.1) and give it a good explanation in reality. In this paper we will not only give a positive answer for the above conjecture, but we also completely classify the dynamics of the WNV model even for the critical case.

The remaining part of this paper is organized as follows: In section 2, we mainly classify the existence of equilibria and investigate their local stability. In section 3, we study the dynamics of the limiting subsystem involving only the mosquitoes and birds. Based on the dynamics of the limiting system, we provide a thorough classification for the dynamics of (1.1) in section 4. In the last section we conclude the paper with a discussion.

2. The existence of equilibria and their local stability. Since $N_M(t) = M_u(t) + M_i(t)$, system (1.1) is equivalent to

$$\left\{\begin{array}{l} \frac{dN_M}{dt} = \Pi_M - \mu_M N_M, \\ \frac{dM_i}{dt} = \frac{b_1\beta_1 M_u B_i}{N_B} - \mu_M M_i, \\ \frac{dB_u}{dt} = \Pi_B - \frac{b_1\beta_2 M_i B_u}{N_B} - \mu_B B_u, \\ \frac{dB_i}{dt} = \frac{b_1\beta_2 M_i B_u}{N_B} - \mu_B B_i - d_B B_i, \\ \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_3 M_i S}{N_H} - \mu_H S, \\ \frac{dE}{dt} = \frac{b_2\beta_3 M_i S}{N_H} - \mu_H E - \alpha E, \\ \frac{dI}{dt} = \alpha E - \mu_H I - \delta I, \\ \frac{dH}{dt} = \delta I - \mu_H H - d_H H - \tau H, \\ \frac{dR}{dt} = \tau H - \mu_H R. \end{array}\right. \tag{2.1}$$

Since the equilibrium for N_M is

$$N_M(t) = \frac{\Pi_M}{\mu_M},$$

the limiting system of (2.1) is

$$\left\{\begin{array}{l} \frac{dM_i}{dt} = \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{B_i + B_u} - \mu_M M_i, \\ \frac{dB_u}{dt} = \Pi_B - \frac{b_1\beta_2 M_i B_u}{B_i + B_u} - \mu_B B_u, \\ \frac{dB_i}{dt} = \frac{b_1\beta_2 M_i B_u}{B_i + B_u} - \mu_B B_i - d_B B_i, \\ \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_3 M_i S}{N_H} - \mu_H S, \\ \frac{dE}{dt} = \frac{b_2\beta_3 M_i S}{N_H} - \mu_H E - \alpha E, \\ \frac{dI}{dt} = \alpha E - \mu_H I - \delta I, \\ \frac{dH}{dt} = \delta I - \mu_H H - d_H H - \tau H, \\ \frac{dR}{dt} = \tau H - \mu_H R. \end{array}\right. \tag{2.2}$$

Therefore, the dynamics of (1.1) or (2.1) is qualitatively equivalent to it given by (2.2) (e.g., see [14, 15, 16, 17, 30]), we investigate only (2.2) hereafter. In this section, we mainly investigate the existence of equilibria for system (2.2) and their local stability.

Let

$$\mathcal{D} = \left\{ (M_i, B_u, B_i, S, E, I, H, R) \in \mathbb{R}_+^8 : 0 < M_i \le \frac{\Pi_M}{\mu_M}, \right.$$
$$\left. \frac{\Pi_B}{\mu_B + d_B} < N_B \le \frac{\Pi_B}{\mu_B}, 0 < N_H \le \frac{\Pi_H}{\mu_H} \right\}.$$

Then it follows from paper [11] that all solutions of the system (2.2) starting in $\mathcal{D}$ remain in $\mathcal{D}$ for all $t > 0$. Thus, $\mathcal{D}$ is positively invariant, and it is sufficient to consider solutions in $\mathcal{D}$. In this region, the usual existence, uniqueness, and continuation results hold for the system (2.2). In what follows, we always assume that the initial points lie in $\mathcal{D}$.

It is well known that one of the most important subjects in epidemic models is to obtain a threshold or reproduction number R_0 that determines the persistence and extinction of a disease. There are many papers investigating the reproduction number for systems modelled by ordinary and delay differential equations [1, 2, 3, 18]. The basic reproduction number for the system (2.2) was calculated in [11]:

$$R_0 = \sqrt{\frac{b_1^2 \beta_1 \beta_2 \mu_B \Pi_M}{\mu_M^2 (\mu_B + d_B) \Pi_B}}.$$

Adopting the notations in [12], we denote

$$\begin{aligned} a_2 &= \frac{d_B(\mu_M d_B - b_1 \beta_1 \mu_B)}{b_1 \beta_2 \mu_B}, \\ a_1 &= \frac{b_1 \beta_1 \Pi_M}{\mu_M} - \frac{(2\mu_M d_B - b_1 \beta_1 \mu_B)\Pi_B}{b_1 \beta_2 \mu_B}, \\ a_0 &= \frac{\mu_M \Pi_B^2 (1 - R_0^2)}{b_1 \beta_2 \mu_B}, \\ \Delta &= a_1^2 - 4 a_0 a_2, \\ B_{i2}^* &= \frac{\Pi_B}{\mu_B + d_B}. \end{aligned}$$

Now we are able to state the result on the existence of equilibria for system (2.2).

THEOREM 2.1. *The system* (2.2) *can have up to three equilibria. More precisely, we have the following:*

(1) *The boundary equilibrium, the disease-free equilibrium (DEF)* $E_0(0, \frac{\Pi_B}{\mu_B}, 0, \frac{\Pi_H}{\mu_H}, 0, 0, 0, 0)$ *always exists.*

(2) *Assume* $R_0 > 1$. *Then system* (2.2) *has a unique positive equilibrium* $E^*(M_i^*, B_u^*, B_i^*, S^*, E^*, I^*, H^*, R^*)$, *where* $0 < B_i^* < B_{i2}^* = \frac{\Pi_B}{\mu_B + d_B}$.

(3) *Assume* $R_0 < 1$. *Then we have*

(3a) *if* $a_2 \le 0$, *system* (2.2) *has no positive equilibrium;*

(3b) *if* $a_2 > 0$, *system* (2.2) *has either no or two possible equilibria. Moreover, system* (2.2) *has two positive equilibria* $E^1(M_i^1, B_u^1, B_i^1, S^1, E^1, I^1, H^1, R^1)$ *and* $E^2(M_i^2, B_u^2, B_i^2, S^2, E^2, I^2, H^2, R^2)$, *where* $0 < B_i^1 < B_i^2 < B_{i2}^* = \frac{\Pi_B}{\mu_B + d_B}$, *if and only if*

$$\Delta > 0 \text{ and } 0 < \frac{-a_1}{2a_2} < \frac{\Pi_B}{\mu_B + d_B}.$$

These two equilibria coalesce into one equilibrium $E^1(M_i^1, B_u^1, B_i^1, S^1, E^1, I^1, H^1, R^1)$ *if and only if* $0 < \frac{-a_1}{2a_2} < \frac{\Pi_B}{\mu_B + d_B}$ *and* $\Delta = 0$.

(4) *Assume* $R_0 = 1$. *Then system* (2.2) *has no positive equilibrium if* $\mu_M(d_B - \mu_B) \le b_1 \beta_1 \mu_B$, *and if* $\mu_M(d_B - \mu_B) > b_1 \beta_1 \mu_B$, *system* (2.2) *has a unique positive equilibrium* $E^*(M_i^*, B_u^*, B_i^*, S^*, E^*, I^*, H^*, R^*)$.

The proof of Theorem 2.1 is based on a simple algebraic analysis, and the reader can refer to the papers [11] and [12].

Now let $E^{\#}(M_i^{\#}, B_u^{\#}, B_i^{\#}, S^{\#}, E^{\#}, I^{\#}, H^{\#}, R^{\#})$ be an arbitrary equilibrium of the system (2.2) and

$$N_H^{\#} = S^{\#} + E^{\#} + I^{\#} + H^{\#} + R^{\#}.$$

Then the Jacobian matrix of the vector field corresponding to system (2.2), evaluated at $E^{\#}$, is

$$J(E^{\#}) = \begin{bmatrix} A_{11} & 0 \\ A_{21} & A_{22} \end{bmatrix},$$

where

$$A_{11} = \begin{bmatrix} -\left(\mu_M + \dfrac{b_1\beta_1 B_i^{\#}}{B_i^{\#}+B_u^{\#}}\right) & -\dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i^{\#})B_i^{\#}}{(B_i^{\#}+B_u^{\#})^2} & \dfrac{b_1\beta_2 M_i^{\#} B_u^{\#}}{(B_i^{\#}+B_u^{\#})^2} \\ -\dfrac{b_1\beta_2 B_u^{\#}}{B_i^{\#}+B_u^{\#}} & -\left(\dfrac{b_1\beta_2 M_i^{\#} B_i^{\#}}{(B_i^{\#}+B_u^{\#})^2} + \mu_B\right) & \dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i^{\#})B_u^{\#}}{(B_i^{\#}+B_u^{\#})^2} \\ \dfrac{b_1\beta_2 B_u^{\#}}{B_i^{\#}+B_u^{\#}} & \dfrac{b_1\beta_2 M_i^{\#} B_i^{\#}}{(B_i^{\#}+B_u^{\#})^2} & -\left(\mu_B + d_B + \dfrac{b_1\beta_2 M_i^{\#} B_u^{\#}}{(B_i^{\#}+B_u^{\#})^2}\right) \end{bmatrix},$$

$$A_{22} = \left[\begin{array}{ccc} -\dfrac{b_2\beta_3 M_i^{\#}(N_H^{\#} - S^{\#})}{(N_H^{\#})^2} - \mu_H & \dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} & \dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} \\ \dfrac{b_2\beta_3 M_i^{\#}(N_H^{\#} - S^{\#})}{(N_H^{\#})^2} & -\dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} - \mu_H - \alpha & -\dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} \\ 0 & \alpha & -(\mu_H + \delta) \\ 0 & 0 & \delta \\ 0 & 0 & 0 \end{array}\right.$$

$$\left.\begin{array}{cc} \dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} & \dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} \\ -\dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} & -\dfrac{b_2\beta_3 M_i^{\#} S^{\#}}{(N_H^{\#})^2} \\ 0 & 0 \\ -(\mu_H + d_H + \tau) & 0 \\ \tau & -\mu_H \end{array}\right],$$

and

$$A_{21} = \begin{bmatrix} -\dfrac{b_2\beta_3 S^{\#}}{N_H^{\#}} & 0 & 0 \\ \dfrac{b_2\beta_3 S^{\#}}{N_H^{\#}} & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}.$$

After extensive algebraic calculations [11], the characteristic equation associated with A_{22} is given by

$$(\lambda+\mu_H)\Bigg[(\lambda+\mu_H+d_H+\tau)(\lambda+\mu_H+\delta)(\lambda+\mu_H+\alpha)\left(\lambda+\mu_H+\frac{b_2\beta_3 M_i^{\#}}{N_H^{\#}}\right)-\frac{d_H\delta\alpha b_2\beta_3 M_i^{\#}S^{\#}}{(N_H^{\#})^2}\Bigg]=0.$$

The constant term in the above polynomial is positive, and the Routh–Hurwitz conditions show that all eigenvalues of the matrix A_{22} have negative real parts. Thus the stability of the equilibrium $E^{\#}$ is determined by the eigenvalues of the matrix A_{11}, since the eigenvalues of the matrix $J(E^{\#})$ are made up of the eigenvalues of the matrices A_{11} and A_{22}. The stability of the matrix A_{11} is discussed in paper [12]. Combining Theorems 3.4 and 3.5 in paper [12] and the stability of the matrix A_{22}, we have the following results.

THEOREM 2.2. (1) *Assume $R_0 > 1$. Then the disease-free equilibrium E_0 is unstable, and the unique positive equilibrium E^* is locally asymptotically stable.*

(2) *Assume $R_0 < 1$. Then the unique boundary equilibrium E_0 is locally asymptotically stable, and we have*

(2a) *if $a_2 > 0$, $\Delta > 0$, and $0 < \frac{-a_1}{2a_2} < \frac{\Pi_B}{\mu_B+d_B}$, then the positive equilibrium E^1 is a saddle point and the positive equilibrium E^2 is locally asymptotically stable. Moreover,* $\dim W^s(E^1)=7$, $\dim W^u(E^1)=1$, *and* $\dim W^s(E^2)=8$*;*

(2b) *if $a_2 > 0, 0 < \frac{-a_1}{2a_2} < \frac{\Pi_B}{\mu_B+d_B}$, and $\Delta = 0$, then the unique positive equilibria E^1 is unstable and* $\dim W^s(E^1)=7$, $\dim W^c(E^1)=1$.

3. The dynamics of a subsystem.

Since humans do not feed back into the mosquito-bird cycle, the subsystem involving only the mosquitoes and birds is independent. The dynamics of the subsystem for the primary mosquito-bird cycle is governed by the following three-dimensional differential equations:

$$\begin{cases} \frac{dM_i}{dt} = \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M}-M_i)B_i}{B_i+B_u} - \mu_M M_i,\\ \frac{dB_u}{dt} = \Pi_B - \frac{b_1\beta_2 M_i B_u}{B_i+B_u} - \mu_B B_u,\\ \frac{dB_i}{dt} = \frac{b_1\beta_2 M_i B_u}{B_i+B_u} - \mu_B B_i - d_B B_i. \end{cases} \tag{3.1}$$

In this section, we mainly provide a complete classification for system (3.1). In paper [12], Jiang et al. provided the classification for equilibria of system (3.1) and by applying the theory of K-competitive dynamical systems [19] and index theory of dynamical systems on a surface, sufficient and necessary conditions for local stability of equilibria are also obtained if the basic reproduction number is not unity. In the following, we will study the dynamics of system (3.1) further and provide a through classification of dynamics for system (3.1).

First, let us present some preliminary results for system (3.1). As in [12], we set

$$\Gamma = \left\{(M_i,B_u,B_i)|\ 0\le M_i\le \frac{\Pi_M}{\mu_M}, \frac{\Pi_B}{\mu_B+d_B}\le B_u+B_i\le\frac{\Pi_B}{\mu_B}\right\}.$$

Then we have what follows.

PROPOSITION 3.1 (see [12]). *All solutions of the system* (3.1) *with nonnegative initial conditions remain nonnegative. Moreover, Γ is a global attractor in $\mathbb{R}^3_+$ and positively invariant for* (3.1).

In what follows, we always assume that the initial points $(M_i(0), B_u(0), B_i(0))$ of system (3.1) lie in Γ. From the last section, it is easy to verify that if $E^{\#}(M_i^{\#}, B_u^{\#}, B_i^{\#},$

$S^{\#}, E^{\#}, I^{\#}, H^{\#}, R^{\#})$ is an equilibrium of (2.2), then $\hat{E}^{\#}(M_i^{\#}, B_u^{\#}, B_i^{\#})$ is an equilibrium of (3.1), and $E^{\#}$ and $\hat{E}^{\#}$ have the same stability. For convenience, we still denote the equilibrium $\hat{E}^{\#}$ by $E^{\#}$.

By analyzing the vector field of system (3.1) on the boundary $\partial\mathbb{R}^3_+ \bigcap \Gamma$, we have that $\partial\mathbb{R}^3_+ \bigcap \Gamma$ contains only positive B_u-axis as its invariant set, in other words, any positive orbit from a point in $\partial\mathbb{R}^3_+ \bigcap \Gamma$ but not in the positive B_u-axis will enter $\text{Int}\mathbb{R}^3_+$. In particular, any periodic orbit if it exists lies in $\text{Int}\mathbb{R}^3_+$.

Let $M = Df(E_0)$ and $\lambda_1 < \lambda_2 = -\mu_b < \lambda_3$ be its eigenvalues and $v_1, v_2 = (0, 1, 0), v_3$ be their eigenvector, respectively. From the Perron–Frobenius theorem, we may assume $v_1 \gg_K 0$. Let Π be the plane spanned by v_1 and v_2. We claim that if any solution $(M_u(t), B_u(t), B_i(t))$ is convergent to E_0 as $t \to \infty$ and tangent to Π at E_0, then $M_u(t) = B_i(t) = 0$. This implies that there is neither homoclinic nor heteroclinic orbit initiating from E_0.

PROPOSITION 3.2. (1) *If the system* (3.1) *has a periodic orbit, then the periodic orbit lies in* $\text{Int}\mathbb{R}^3_+$*;*

(2) *The system* (3.1) *has neither homoclinic nor heteroclinic orbit from* E_0.

The Jacobian of system (3.1) is

$$\begin{bmatrix} -\left(\mu_M + \dfrac{b_1\beta_1 B_i}{B_i + B_u}\right) & -\dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} & \dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} \\ -\dfrac{b_1\beta_2 B_u}{B_i + B_u} & -\left(\dfrac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} + \mu_B\right) & \dfrac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} \\ \dfrac{b_1\beta_2 B_u}{B_i + B_u} & \dfrac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} & -\left(\mu_B + d_B + \dfrac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) \end{bmatrix}.$$

It follows from paper [19] that the system (3.1) is K-competitive in Γ, with $K = \{(M_i, B_u, B_i) \mid M_i > 0, B_u > 0, B_i < 0\}$. From the expressions of $M_i^1, B_u^1, B_i^1, M_i^2, B_u^2, B_i^2, M_i^*, B_u^*, B_i^*$, it is easy to see that the equilibria E^1, E^2, E_0 or E_0, E^* are unordered in the K-order. It follows from Proposition 3.2 in [20] and Proposition 1.3 in [21] that there exists a two-dimensional compact Lipschitz submanifold Σ such that $E^1, E^2 \in \text{Int}\Sigma$ or $E^* \in \text{Int}\Sigma$, $E_0 \in \partial\Sigma$. Moreover, Σ is K-balanced. Since Σ is a two-dimensional compact Lipschitz submanifold and homeomorphic to a compact domain in the plane, it is obvious that the Poincaré–Bendixson theorem holds for the dynamics of (3.1) on Σ. This finding is the key point we can completely analyze for the global behavior for the system (3.1). Moreover, we have the following useful result.

PROPOSITION 3.3. *If the system* (3.1) *has no positive equilibrium, then the disease-free equilibrium* E_0 *is globally asymptotically stable in* Γ.

Proof. Since system (3.1) has the Pioncaré–Bendixson property, the assumption that system (3.1) has no positive equilibrium implies that there is no nontrivial periodic orbit for (3.1). Thus every positive limit set contains the unique equilibrium E_0. If E_0 is not globally asymptotically stable, then there is an entire orbit converging to E_0 in either direction, since asymptotical behavior for three-dimensional competitive system is reduced to two dimension (see [19]), i.e., system (3.1) has a homoclinic orbit from E_0. This contradicts Proposition 3.2. The contradiction implies that the disease-free equilibrium E_0 of system (3.1) is globally asymptotically stable and completes the proof of Proposition 3.3 □

3.1. The global stability of system (3.1) for the case $R_0 > 1$. In this subsection we mainly study the dynamics of system (3.1) for the case $R_0 > 1$. We start with a general mathematical framework for proving global stability, which will be used to prove the principal result in this subsection. The framework is developed in the paper of Muldowney [23, 24, 27]. The presentation here follows from [24].

Let $x \to f(x) \in \mathbb{R}^3$ be a C^1 function defined in $\mathbb{R}^3_+$. We consider the autonomous system in $\Gamma \subset \mathbb{R}^3_+$

$$\dot{x} = f(x). \tag{3.2}$$

Let $x(t, x_0)$ denote the solution of (3.2) such that $x(0, x_0) = x_0$. The linear variational equation of (3.2) with respect to $x(t, x_0)$ is given by

$$\dot{y}(t) = Df(x(t, x_0))y(t), \tag{3.3}$$

where Df is the Jacobian matrix of f. *The second compound equation* with respect to the solution $x(t, x_0) \in \Gamma$ to (3.3) can be described by

$$\dot{z}(t) = Df^{[2]}(x(t, x_0))z(t). \tag{3.4}$$

$Df^{[2]}$ is the second additive compound matrix of the Jacobian matrix Df of f. Generally speaking, for a 3×3 matrix $A = (a_{ij})_{3\times 3}$, *the second additive compound matrix* of A is the matrix $A^{[2]}$ defined as follows:

$$\begin{bmatrix} a_{11} + a_{22} & a_{23} & -a_{13} \\ a_{32} & a_{11} + a_{33} & a_{12} \\ -a_{31} & a_{21} & a_{22} + a_{33} \end{bmatrix}.$$

Suppose system (3.2) has a periodic solution $x = p(t)$, with the least positive period $\omega > 0$ and the orbit $\gamma = \{p(t) : 0 \le t \le \omega\}$. The orbit is *orbitally stable* if for each $\epsilon > 0$, there exists a $\delta > 0$ such that any solution $x(t)$, for which the distance of $x(0)$ from γ is less than δ, remains at a distance less than ϵ from γ for all $t \ge 0$. It is *asymptotically orbitally stable* if the distance of $x(t)$ from γ also tends to zero as $t \to \infty$. This orbit γ is asymptotically orbitally stable with asymptotic phase if it is asymptotically orbitally stable and there is a $b > 0$ such that any solution $x(t)$, for which the distance of $x(0)$ from γ is less than b, satisfies $|x(t) - p(t - \nu)| \to 0$ as $t \to \infty$ for some ν which may depend on $x(0)$.

The following is a criterion given in [23] and [24].

Lemma 3.4 (see [24]). *A sufficient condition for a periodic orbit $\gamma = \{p(t) : 0 \le t \le \omega\}$ of* (3.2) *to be asymptotically orbitally stable with asymptotic phase is that the linear system*

$$\dot{z}(t) = Df^{[2]}(p(t))z(t) \tag{3.5}$$

is asymptotically stable.

Theorem 3.5. *The trajectory of any nonconstant periodic solution to* (3.1), *if it exists, is asymptotically orbitally stable with asymptotic phase.*

Proof. The Jacobian matrix $J(M_i, B_u, B_i)$ of system (3.1) is given by

$$\begin{bmatrix} -\left(\mu_M + \dfrac{b_1\beta_1 B_i}{B_i + B_u}\right) & -\dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} & \dfrac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} \\ -\dfrac{b_1\beta_2 B_u}{B_i + B_u} & -\left(\dfrac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} + \mu_B\right) & \dfrac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} \\ \dfrac{b_1\beta_2 B_u}{B_i + B_u} & \dfrac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} & -\left(\mu_B + d_B + \dfrac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) \end{bmatrix}.$$

Suppose that the solution $(M_i(t), B_u(t), B_i(t))$ is periodic with the least period $\omega > 0$. The second compound system of (3.1) along a periodic solution $(M_i(t), B_u(t), B_i(t))$ is

$$\begin{aligned} \dot{X} &= -\left(\mu_M + \mu_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2}\right) X + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} Y \\ &\quad - \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} Z, \\ \dot{Y} &= \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} X - \left(\mu_M + \mu_B + d_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) Y \\ &\quad - \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} Z, \\ \dot{Z} &= -\frac{b_1\beta_2 B_u}{B_i + B_u} X - \frac{b_1\beta_2 B_u}{B_i + B_u} Y - \left(2\mu_B + d_B + \frac{b_1\beta_2 M_i}{B_i + B_u}\right) Z. \end{aligned} \tag{3.6}$$

To show that (3.6) is asymptotically stable, we construct a Lyapunov function

$$V(X, Y, Z; M_i, B_u, B_i) = \sup\left\{\frac{B_i}{M_i}(|X| + |Y|), |Z|\right\}.$$

It follows from Proposition 3.2 that any periodic orbit, if it exists, lies in $\text{Int}\mathbb{R}^3_+$. Thus any periodic solution $(M_i(t), B_u(t), B_i(t))$ is at a positive distance from the boundary, and there exists a constant $c_1 > 0$ such that

$$V(X, Y, Z; M_i, B_u, B_i) \geq c_1 \sup\{|X|, |Y|, |Z|\}$$

for all $(X, Y, Z) \in \mathbb{R}^3$ and $(M_i(t), B_u(t), B_i(t)), t \in [0, \omega]$. The right derivative of V along a solution $(X(t), Y(t), Z(t))$ to (3.6) and $(M_i(t), B_u(t), B_i(t))$ can be estimated as follows:

(3.7)

$$\begin{aligned} D_+|X(t)| &\leq -\left(\mu_M + \mu_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2}\right) |X(t)| \\ &\quad + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} |Y(t)| + \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} |Z(t)|, \\ D_+|Y(t)| &\leq \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} |X(t)| - \left(\mu_M + \mu_B + d_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) |Y(t)| \\ &\quad + \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} |Z(t)| \end{aligned}$$

and

(3.8)

$$\begin{aligned} D_+|Z(t)| &\leq \frac{b_1\beta_2 B_u}{B_i + B_u} |X(t)| + \frac{b_1\beta_2 B_u}{B_i + B_u} |Y(t)| - \left(2\mu_B + d_B + \frac{b_1\beta_2 M_i}{B_i + B_u}\right) |Z(t)| \\ &= \frac{b_1\beta_2 B_u M_i}{(B_i + B_u)B_i} \frac{B_i}{M_i}(|X(t)| + |Y(t)|) - \left(2\mu_B + d_B + \frac{b_1\beta_2 M_i}{B_i + B_u}\right) |Z(t)|. \end{aligned}$$

Therefore,

$$\begin{aligned}
&D_+\frac{B_i}{M_i}(|X(t)|+|Y(t)|)\\
&=\left(\frac{\dot{B}_i}{B_i}-\frac{\dot{M}_i}{M_i}\right)\frac{B_i}{M_i}(|X(t)|+|Y(t)|)+\frac{B_i}{M_i}D_+(|X(t)|+|Y(t)|)\\
&\le\left(\frac{\dot{B}_i}{B_i}-\frac{\dot{M}_i}{M_i}-\mu_M-\mu_B-\frac{b_1\beta_1B_i}{B_i+B_u}\right)\frac{B_i}{M_i}(|X(t)|+|Y(t)|)\\
&\quad+\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M}-M_i)B_i}{(B_i+B_u)M_i}|Z(t)|.
\end{aligned}$$

We conclude that (3.7) and (3.8) lead to

$$D_+V(t)\le\sup\{g_1(t),g_2(t)\}V(t), \tag{3.9}$$

where

$$g_1(t)=\frac{\dot{B}_i}{B_i}-\frac{\dot{M}_i}{M_i}-\mu_M-\mu_B-\frac{b_1\beta_1B_i}{B_i+B_u}+\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M}-M_i)B_i}{(B_i+B_u)M_i}, \tag{3.10}$$

$$g_2(t)=\frac{b_1\beta_2B_uM_i}{(B_i+B_u)B_i}-2\mu_B-d_B-\frac{b_1\beta_2M_i}{B_i+B_u}. \tag{3.11}$$

Rewriting (3.1), we find that

$$\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M}-M_i)B_i}{(B_i+B_u)M_i}=\frac{\dot{M}_i}{M_i}+\mu_M,\frac{b_1\beta_2B_uM_i}{(B_i+B_u)B_i}=\frac{\dot{B}_i}{B_i}+\mu_B+d_B. \tag{3.12}$$

From (3.10)–(3.12) we have

$$\sup\{g_1(t),g_2(t)\}\le\frac{\dot{B}_i}{B_i}-\mu_B,$$

and thus

$$\int_0^\omega\sup\{g_1(t),g_2(t)\}dt\le\log B_i(t)|_0^\omega-\mu_B\omega=-\mu_B\omega<0,$$

since $B_i(t)$ is periodic with the least period ω. This relation and (3.9) imply that $V(t)\to0$ as $t\to+\infty$, and, in turn, that $(X(t),Y(t),Z(t))\to0$ as $t\to+\infty$. As a result, the linear system (3.6) is asymptotically stable, and the periodic solution $(M_i(t),B_u(t),B_i(t))$ is asymptotically orbitally stable with asymptotic phase by Lemma 3.4. This completes the proof. ▯

Our principal result in this subsection can be stated as follows.

THEOREM 3.6. *Assume that* $R_0>1$. *Then the unique endemic equilibrium* E^* *is globally stable in* IntΓ.

Proof. Firstly, we claim that system (3.1) has no nontrivial periodic orbit if $R_0>1$. Suppose not, then there is a nontrivial periodic orbit γ with every point positive. Therefore, there exists a two-dimensional compact Lipschitz submanifold Σ, which must contain E^* in its interior. Without loss of generality, we may assume that γ is the nearest periodic orbit from E^* in Σ. From the stability of E^*, γ is unstable on Σ, contradicting Theorem 3.5. This implies that every positive limit set contains an equilibrium.

Secondly, we analyze the geometrical behavior of the stable manifold $W^s(E_0)$. Direct calculation yields that $\lambda_1 < \lambda_2 = -\mu_B < 0 < \lambda_3$, where $\lambda_1, \lambda_2, \lambda_3$ are the eigenvalues of the linearized matrix at E_0. Therefore, $W^s(E_0)$ is tangent to the plane Π spanned by v_1 and v_2. Therefore, $W^s(E_0) \bigcap \mathbb{R}^3_+ = \{(0, \mu, 0) : \mu > 0\}$. This shows that any solution from a positive initial point cannot converge to E_0.

Finally, for any initial point $P = (M_i(0), B_u(0), B_i(0))$, with $(M_i(0))^2 + (B_i(0))^2 \neq 0$, we conclude that $\omega(P) = \{E^*\}$. Otherwise, there exists such a P such that $\omega(P) \neq \{E^*\}$. By the stability of E^*, E^* is not in $\omega(P)$. By the arguments in the first and second paragraph, $\omega(P)$ contains E_0 and is not a singleton. Since asymptotical behavior for the three-dimensional competitive system is reduced to two dimensions (see [19]), $\omega(P)$ contains an entire orbit which is convergent to E_0 as $t \to \pm\infty$. The second paragraph implies that such an entire orbit lies in positive B_u-axis, a contradiction. This completes the proof of Theorem 3.6. □

We remark that Theorem 3.5 also holds for the case $R_0 \leq 1$. In the proof of Theorem 3.6, we use only Theorem 3.5 and the fact that the unique positive equilibrium E^* is locally asymptotically stable and the boundary equilibrium E_0 is unstable, with the stable manifold two-dimensional and unstable manifold one-dimensional.

3.2. The global stability of system (3.1) for the critical case $R_0 = 1$. Now let us state the main result of this subsection.

THEOREM 3.7. *Assume $R_0 = 1$. If $\mu_M(d_B - \mu_B) \leq b_1\beta_1\mu_B$, then the disease-free equilibrium E_0 of system* (3.1) *is globally asymptotically stable; if $\mu_M(d_B - \mu_B) > b_1\beta_1\mu_B$, the unique positive equilibrium E^* of system* (3.1) *is globally asymptotically stable in* $\mathrm{Int}\mathbb{R}^3_+$.

Proof. If $R_0 = 1$ and $\mu_M(d_B - \mu_B) \leq b_1\beta_1\mu_B$, it follows from Theorem 2.1 that the disease-free equilibrium E_0 is the unique equilibrium. Proposition 3.3 implies that the disease-free equilibrium E_0 of system (3.1) is globally asymptotically stable and completes the proof of the first conclusion.

Now we present the proof of the second conclusion. Assume that $R_0 = 1$ and $\mu_M(d_B - \mu_B) > b_1\beta_1\mu_B$. It follows from Theorem 2.1 that system (3.1) has a unique boundary equilibrium E_0 and a unique positive equilibrium E^*. Recall the remark for Theorem 3.6, in order to prove the second conclusion, it then suffices to show that E^* is locally asymptotically stable and E_0 is unstable, with the stable manifold two-dimensional and unstable manifold one-dimensional.

We first claim that E^* is locally asymptotically stable. After extensive algebraic calculations [12], the characteristic equation of the linearized system of (3.1) at E^* can be read

$$\lambda^3 + A_1\lambda^2 + A_2\lambda + A_3 = 0, \tag{3.13}$$

where

$$\begin{aligned}
A_1 = {} & \frac{1}{(\Pi_B - d_B B_i^*)(\Pi_B - (\mu_B + d_B)B_i^*)}[b_1\beta_1\mu_B B_i^*(\Pi_B - (\mu_B + d_B)B_i^*) \\
& + (\Pi_B - d_B B_i^*)[(\mu_M + 2\mu_B + d_B)(\Pi_B - (\mu_B + d_B)B_i^*) + (\mu_B + d_B)\mu_B B_i^*]]; \\
A_2 = {} & \frac{\mu_M\mu_B\Pi_B}{(\Pi_B - (\mu_B + d_B)B_i^*)} + \frac{(\mu_B + d_B)\mu_B[(\Pi_B - d_B B_i^*)^2 + d_B\mu_B B_i^* B_i^*]}{(\Pi_B - d_B B_i^*)(\Pi_B - (\mu_B + d_B)B_i^*)} \\
& + \frac{\Pi_B\mu_B^2 b_1\beta_1 B_i^*}{(\Pi_B - d_B B_i^*)(\Pi_B - (\mu_B + d_B)B_i^*)} + \frac{b_1\beta_1\mu_B(\mu_B + d_B)B_i^*}{\Pi_B - d_B B_i^*}; \\
A_3 = {} & \frac{(\mu_B + d_B)\mu_B B_i^*}{(\Pi_B - d_B B_i^*)^2(\Pi_B - (\mu_B + d_B)B_i^*)}[d_B(\mu_B + d_B)(b_1\beta_1\mu_B - d_B\mu_M)(B_i^*)^2 \\
& + 2\Pi_B d_B(d_B\mu_M - b_1\beta_1\mu_B)B_i^* + \Pi_B^2(b_1\beta_1\mu_B + \mu_M\mu_B - d_B\mu_M)].
\end{aligned}$$

We also have

$$A_1A_2 - A_3 = D_2b_1^2 + D_1b_1 + D_0,$$

where

$$\begin{aligned}
D_2 &= \frac{((\mu_B+d_B)(\Pi_B-(d_B+\mu_B)B_i^*)+\Pi_B\mu_B)(\beta_1\mu_BB_i^*)^2}{(\Pi_B-d_BB_i^*)^2(\Pi_B-(\mu_B+d_B)B_i^*)};\\
D_1 &= \frac{\mu_B\beta_1B_i^*\mu_M((d_B+\mu_B)(\Pi_B-(d_B+\mu_B)B_i^*)+2\Pi_B\mu_B)}{(\Pi_B-d_BB_i^*)(\Pi_B-(\mu_B+d_B)B_i^*)}\\
&\quad + \frac{\mu_B\beta_1B_i^*((d_B+\mu_B)(\Pi_B-(d_B+\mu_B)B_i^*)+\Pi_B\mu_B)^2}{(\Pi_B-d_BB_i^*)(\Pi_B-(\mu_B+d_B)B_i^*)^2};\\
D_0 &= \frac{\Pi_B\mu_B\mu_M^2}{\Pi_B-(\mu_B+d_B)B_i^*} + \frac{1}{(\Pi_B-d_BB_i^*)(\Pi_B-(\mu_B+d_B)B_i^*)^2}\\
&\quad \times\{\Pi_B\mu_B\mu_M((\mu_B+d_B)(\Pi_B-(\mu_B+d_B)B_i^*)^2\\
&\quad +(2\mu_B+d_B)(\Pi_B-(\mu_B+d_B)B_i^*)(\Pi_B-d_BB_i^*)+(\mu_B+d_B)\mu_BB_i^*(\Pi_B-d_BB_i^*))\\
&\quad +\mu_B(\mu_B+d_B)[(d_B+\mu_B)(\Pi_B-(\mu_B+d_B)B_i^*)\\
&\quad +\Pi_B\mu_B]((\Pi_B-d_BB_i^*)^2+\mu_Bd_B(B_i^*)^2)\}.
\end{aligned}$$

Thus it is clear that

$$A_1A_2 - A_3 = D_2b_1^2 + D_1b_1 + D_0 > 0, A_1 > 0,$$

since $0 < B_i^* < \frac{\Pi_B}{\mu_B+d_B}$.

Let $\bar{\lambda}_1, \bar{\lambda}_2, \bar{\lambda}_3$ be the roots of (3.13) and assume $\mathrm{Re}\bar{\lambda}_1 \le \mathrm{Re}\bar{\lambda}_2 \le \mathrm{Re}\bar{\lambda}_3$. The Perron–Frobenius theorem implies that $\bar{\lambda}_1 < 0$. Since $R_0 = 1$ and $\mu_M(d_B - \mu_B) > b_1\beta_1\mu_B$, direct calculation yields that $\Delta \neq 0$. It follows from Proposition 3.2 in paper [12] that $A_3 \neq 0$. The compact of Σ, together with the fact that the dynamics of system (3.1) on Σ is positively invariant, implies that $A_3 = -\bar{\lambda}_1\bar{\lambda}_2\bar{\lambda}_3 > 0$. Thus we have $A_1 > 0, A_3 > 0, A_1A_2 - A_3 > 0$. By the Routh–Huriwitz criterion, we obtain that $\mathrm{Re}\bar{\lambda}_1 < 0, \mathrm{Re}\bar{\lambda}_2 < 0, \mathrm{Re}\bar{\lambda}_3 < 0$. Thus the positive equilibrium E^* is locally asymptotically stable.

It is easy to see that the linearized matrix for (3.1) at E_0 has two negative eigenvalues and 0. Suppose that E_0 is locally asymptotically stable. Then, pick up a point which is neither in the basin of attraction for E^* nor in the basin of attraction for E_0. The positive limit set for this point contains no equilibrium and hence is a nontrivial periodic orbit, contradicting Theorem 3.5. Thus, E_0 is unstable with the stable manifold two-dimensional and unstable manifold one-dimensional.

Using the same way as in the proof of Theorem 3.6, we conclude that E^* is globally asymptotically stable in this case. □

3.3. The global stability of system (3.1) for the case $R_0 < 1$.

In this subsection, we mainly prove the following principal results.

THEOREM 3.8. *Assume that $R_0 < 1$. The dynamics of system (3.1) are determined by the number of the positive equilibria, and there are three cases:*

(1) *If $a_2 > 0$, $0 < \frac{-a_1}{2a_2} < B_{i2}^*$, and $\Delta > 0$, then system (3.1) has switch phenomenon. That is, a two-dimensional stable manifold for E^1 separates $\mathrm{int}\mathbb{R}_+^3$ into two parts, denoted by V, U, respectively. Part V contains E_0 and one branch $W_1^u(E^1)$ of the unstable manifold for E^1, and part U contains E^2 and the other branch $W_2^u(E^1)$ of the unstable manifold for E^1. Moreover, if $(M_i(0), B_u(0), B_i(0)) \in V$,*

then $(M_i(t), B_u(t), B_i(t)) \to E_0$ *as* $t \to \infty$*; if* $(M_i(0), B_u(0), B_i(0)) \in U$*, then* $(M_i(t), B_u(t), B_i(t)) \to E^2$ *as* $t \to \infty$*; otherwise,* $(M_i(0), B_u(0), B_i(0)) \in W^s(E^1)$ *and* $(M_i(t), B_u(t), B_i(t)) \to E^1$ *as* $t \to \infty$*.*

(2) *If* $a_2 > 0$*,* $0 < \frac{-a_1}{2a_2} < B^*_{i2}$*, and* $\Delta = 0$*, then system* (3.1) *also has a two-dimensional stable manifold for* E^1 *which also separates* $\mathrm{int}\mathbb{R}^3_+$ *into two parts, denoted by* V, U*, respectively. Part* V *contains* E_0 *and one branch* $W^c_1(E^1)$ *of the center manifold for* E^1*, and part* U *contains no positive equilibrium and the other branch* $W^c_2(E^1)$ *of the center manifold for* E^1*. Moreover, if* $(M_i(0), B_u(0), B_i(0)) \in V$*, then* $(M_i(t), B_u(t), B_i(t)) \to E_0$ *as* $t \to \infty$*; otherwise,* $(M_i(t), B_u(t), B_i(t)) \to E^1$ *as* $t \to \infty$*.*

(3) *Otherwise, the disease-free equilibrium* E_0 *is globally asymptotically stable.*

Proof. First, let us consider the case $a_2 > 0$, $0 < \frac{-a_1}{2a_2} < B^*_{i2}$, and $\Delta > 0$. By Theorems 2.1 and 2.2, (3.1) has three equilibria E_0, E^1, E^2. Moreover, E_0, E^2 are locally asymptotically stable, the positive equilibrium E^1 is a saddle point, and $W^s(E^1) = 2, W^u(E^1) = 1$. Let U be the basin of attraction of the positive equilibrium E^2 in $\mathrm{Int}\mathbb{R}^3_+$. Then U is an open *simply connected set*, i.e., each closed curve in U can be continuously deformed to a point within U. Let $\overline{U}$ be the closure of the set U in $\mathrm{Int}\mathbb{R}^3_+$. Since E_0 is locally asymptotically stable, it follows that $E_0 \notin \overline{U}$. The result that any positive orbit from a point in $\partial\mathbb{R}^3_+$ but not in positive B_u-axis will enter $\mathrm{Int}\mathbb{R}^3_+$ implies that there exists constant $\xi > 0$ such that

$$\liminf_{t\to\infty} M_i(t) > \xi, \liminf_{t\to\infty} B_u(t) > \xi, \liminf_{t\to\infty} B_i(t) > \xi,$$

provided that the initial points $(M_i(0), B_u(0), B_i(0))$ lie in $\overline{U}$ by [25]. Thus there exists a compact absorbing set $J \subset \overline{U}$.

Denote by W the Euclidean unit ball in R^2, and let $\overline{W}$ and ∂W be its closure and boundary, respectively. A function $\varphi \in Lip(\overline{W} \to \overline{U})$ will be described as a simply connected rectifiable 2-surface in $\overline{U}$; a function $\psi \in Lip(\partial W \to \overline{U})$ is a closed rectifiable curve in $\overline{U}$ and will be called simple if it is one to one.

We claim that there is not any simple closed rectifiable curves which are invariant with respect to system (3.1) in $\overline{U}$. Assume that our claim is not true, i.e., there exists a simple closed rectifiable curve $\psi \in Lip(\partial W \to \overline{U})$ in $\overline{U}$, which is invariant with respect to system (3.1). Since system (3.1) is K-competitive and $\mathrm{dimW^u(E^1)} = 1$, we have that $\psi \in \Sigma$.

Denote

$$\Pi(\psi, \overline{U}) = \{\varphi \in Lip(\overline{W} \to \overline{U}) : \varphi(\partial W) = \psi(\partial W)\}.$$

Then $\Pi(\psi, \overline{U})$ is nonempty, since Σ is a two-dimensional compact Lipschitz manifold. Define a functional S on $\Pi(\psi, \overline{U})$ by

$$S\varphi = \int_{\overline{W}} \left| P(\varphi) \frac{\partial \varphi}{\partial u_1} \wedge \frac{\partial \varphi}{\partial u_2} \right|,$$

where $(u_1, u_2) \in \overline{W}$, $\wedge$ is Grassman product, and

$$P(M_i, B_u, B_i) = \begin{pmatrix} \frac{B_i}{M_i} & 0 & 0 \\ 0 & \frac{B_i}{M_i} & 0 \\ 0 & 0 & 1 \end{pmatrix}.$$

From Proposition 2.2 of [26] and the fact that $|P^{-1}(M_i, B_u, B_i)|$ is uniformly bounded for (M_i, B_u, B_i) in any compact subset of $\overline{U}$, for each compact $F \subset \overline{U}$ there exists

$\delta > 0$ such that

$$S\varphi \geq \delta \tag{3.14}$$

for all $\varphi \in \Pi(\psi, \overline{U})$ such that $\varphi(\overline{W}) \subset F$. Let $x = (M_i, B_u, B_i)$ and $f(x)$ denote the vector field of (3.1), and let $\varphi_t = x(t, \varphi)$. Then $y_i(t) = \frac{\partial \varphi_t}{\partial u_i}, i = 1, 2$, are solutions of the linear variational equation of (3.1)

$$\dot{y}(t) = Df(x(t, \varphi))y(t), \tag{3.15}$$

where

$$Df(x(t,\varphi)) = \begin{bmatrix} -(\mu_M + \frac{b_1\beta_1 B_i}{B_i + B_u}) & -\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} & \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} \\ -\frac{b_1\beta_2 B_u}{B_i + B_u} & -\left(\frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} + \mu_B\right) & \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} \\ \frac{b_1\beta_2 B_u}{B_i + B_u} & \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} & -\left(\mu_B + d_B + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) \end{bmatrix}$$

and $z(t) = \frac{\partial \varphi_t}{\partial u_1} \wedge \frac{\partial \varphi_t}{\partial u_2}$ is a solution of the second compound equation of (3.15) (see [22, 23])

$$\dot{z}(t) = Df^{[2]}(x(t, \varphi))z(t), \tag{3.16}$$

where

$$Df^{[2]}(x(t,\varphi)) = \begin{bmatrix} -\left(\mu_M + \mu_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2}\right) & \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2} & -\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i + B_u)^2} \\ \frac{b_1\beta_2 M_i B_i}{(B_i + B_u)^2} & -\left(\mu_M + \mu_B + d_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_u}{(B_i + B_u)^2}\right) & -\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)^2} \\ -\frac{b_1\beta_2 B_u}{B_i + B_u} & -\frac{b_1\beta_2 B_u}{B_i + B_u} & -\left(2\mu_B + d_B + \frac{b_1\beta_2 M_i}{B_i + B_u}\right) \end{bmatrix}. \tag{3.17}$$

Straightforward differentiation shows that $w(t) = P(\varphi_t)\frac{\partial \varphi_t}{\partial u_1} \wedge \frac{\partial \varphi_t}{\partial u_2}$ satisfies the differential equation

$$\dot{w}(t) = B(\varphi_t(u))w(t),$$

where

$$B = P_f P^{-1} + P\frac{\partial f}{\partial x}^{[2]} P^{-1},$$

where the matrix P_f is obtained by replacing each entry p_{ij} of P by its derivative in the direction of f, p_{ij_f}. The matrix $B = P_f P^{-1} + P\frac{\partial f}{\partial x}^{[2]} P^{-1}$ can be written in the following block form:

$$B = \begin{pmatrix} B_{11} & B_{12} \\ B_{21} & B_{22} \end{pmatrix},$$

with

$$B_{11} = \begin{pmatrix} \begin{array}{c} \frac{\dot{B}_i}{B_i} - \frac{\dot{M}_i}{M_i} - \Big(\mu_M + \mu_B + \\ \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_i}{(B_i+B_u)^2}\Big) \end{array} & \frac{b_1\beta_2 M_i B_u}{(B_i+B_u)^2} \\ \frac{b_1\beta_2 M_i B_i}{(B_i+B_u)^2} & \begin{array}{c} \frac{\dot{B}_i}{B_i} - \frac{\dot{M}_i}{M_i} - \Big(\mu_M + \mu_B + \\ d_B + \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_2 M_i B_u}{(B_i+B_u)^2}\Big) \end{array} \end{pmatrix},$$

$$B_{12} = \begin{pmatrix} -\frac{B_i}{M_i}\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_u}{(B_i+B_u)^2} \\ -\frac{B_i}{M_i}\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i+B_u)^2} \end{pmatrix},$$

$$B_{21} = \begin{pmatrix} -\frac{M_i}{B_i}\frac{b_1\beta_2 B_u}{B_i+B_u} & -\frac{M_i}{B_i}\frac{b_1\beta_2 B_u}{B_i+B_u} \end{pmatrix},$$

$$B_{22} = -\left(2\mu_B + d_B + \frac{b_1\beta_2 M_i}{B_i + B_u}\right).$$

Let $z = (u, v, w)$ denote the vectors in $\mathbb{R}^3$; we select a norm in $\mathbb{R}^3$ as

$$|(u, v, w)| = \sup\{|u| + |v|, |w|\}.$$

Let $\mu(B)$ be the *Lozinskiĭ measure* of B with respect to the induced matrix norm $|\cdot|$ in $\mathbb{R}^3$, defined by

$$\mu(B) = \lim_{h\to 0^+} \frac{|I + hB| - 1}{h}.$$

Then the *Lozinskiĭ measure* $\mu(B)$ with respect to $|\cdot|$ can be estimated as follows (see [28] and [29]):

$$\mu(B) \le \sup\{\zeta_1, \zeta_2\},$$

where

$$\zeta_1 = \mu_1(B_{11}) + |B_{12}| \le \frac{\dot{B}_i}{B_i} - \frac{\dot{M}_i}{M_i} - \mu_M - \mu_B - \frac{b_1\beta_1 B_i}{B_i + B_u} + \frac{b_1\beta_1(\frac{\Pi_M}{\mu_M} - M_i)B_i}{(B_i + B_u)M_i}, \tag{3.18}$$

$$\zeta_2 = B_{22} + |B_{21}| \le \frac{b_1\beta_2 B_u M_i}{(B_i + B_u)B_i} - 2\mu_B - d_B - \frac{b_1\beta_2 M_i}{B_i + B_u}. \tag{3.19}$$

Note that $\mu_1(B_{11})$ is the *Lozinskiĭ measure* of the 2×2 matrix B_{11} with respect to the l_1 norm in $\mathbb{R}^2$, $|B_{12}|$ and $|B_{21}|$ are the operator norms of B_{12} and B_{21} when they are regarded as mappings from $\mathbb{R}$ to $\mathbb{R}^2$ and from $\mathbb{R}^2$ to $\mathbb{R}$, respectively, and $\mathbb{R}^2$ is endowed with the l_1 norm. Also note that since B_{22} is a scalar, its *Lozinskiĭ measure* with respect to any vector norm in $\mathbb{R}$ is equal to B_{22}.

Rewriting (3.1), we find that

$$\frac{b_1\beta_1(\frac{\Pi_M}{\mu_M}-M_i)B_i}{(B_i+B_u)M_i}=\frac{\dot{M}_i}{M_i}+\mu_M,\frac{b_1\beta_2B_uM_i}{(B_i+B_u)B_i}=\frac{\dot{B}_i}{B_i}+\mu_B+d_B. \tag{3.20}$$

From (3.18)–(3.20) we have

$$\mu(B)\le\frac{\dot{B}_i}{B_i}-\mu_B.$$

A solution $(M_i(t),B_u(t),B_i(t))$ to system (3.1) with $(M_i(0),B_u(0),B_i(0))$ in the absorbing set J exists for all $t>0$. Thus there exists $T>0$ such that $t>T$ implies that

$$\int_0^t\mu(B)dt\le\log\frac{B_i(t)}{B_i(0)}-\mu_Bt<-\frac{\mu_B}{2}t$$

for all $(M_i(0),B_u(0),B_i(0))\in J$. From a property of *Lozinskiĭ measure*, we have

$$\begin{aligned}S\varphi_t&=\int_{\overline{W}}\left|P(\varphi_t)\frac{\partial\varphi_t}{\partial u_1}\wedge\frac{\partial\varphi_t}{\partial u_2}\right|\\&\le\int_{\overline{W}}\left|P(\varphi)\frac{\partial\varphi}{\partial u_1}\wedge\frac{\partial\varphi}{\partial u_2}\right|\exp\left(\int_0^t\mu(B(\varphi_s(u))ds)\right)\\&\le S\varphi\exp\left(-\frac{\mu_B}{2}t\right).\end{aligned}$$

Therefore, $S\varphi_t\to0$ as $t\to\infty$. This contradicts (3.14), since ψ is invariant with respect to system (3.1), $\psi_t\in\Pi(\psi,\overline{U})$, and $\varphi_t(\overline{W})\subset J$ for all sufficiently large t. This contradiction implies that no simple closed rectifiable curve in $\overline{U}$ is invariant with respect to system (3.1). In particular, it rules out not only periodic trajectories but also homoclinic trajectories and heteroclinic loops, since each case gives rise to a simple closed rectifiable curve in $\overline{U}$.

We secondly claim that there is no period orbit on Σ. Suppose not, then there is a nontrivial periodic orbit χ in Σ, which must contain E^2 in its interior. Without loss of generality, we may assume that χ is the nearest periodic orbit from E^2 in Σ. This implies that $\chi\subset\overline{U}$, contradicting the above discussion. Similarly, we can conclude that there is no homoclinic orbit in Σ. Thus every positive limit set contains an equilibrium.

Since E_0 is locally asymptotically stable, let V be the basin of attraction on the equilibrium E_0. Pick up an initial point $Q=(M_i(0),B_u(0),B_i(0))$ and $Q\in\text{Int}\mathbb{R}^3_+\setminus(U\cup V)$. Then we can easily conclude that $\omega(Q)=\{E^1\}$, since every positive limit set contains an equilibrium, i.e., $Q\in W^s(E^1)$. This completes the proof of the first conclusion.

Second, let us consider the case $a_2>0$, $0<\frac{-a_1}{2a_2}<B^*_{i2}$, and $\Delta=0$. It follows from Theorem 2.1 that two positive equilibria E^1,E^2 coalesce into one positive equilibrium E^1. By Theorem 2.2, E_0 is locally asymptotically stable. This, together with the index theory of dynamics system on a two-dimensional compact manifold Σ which is positive invariant, implies that E^1 is unstable. Thus there is no period and homoclinic

orbit, and every positive limit set contains an equilibrium. Using the same way as in the proof of the first conclusion, we can conclude that the second conclusion is true.

Otherwise, by Theorem 2.1, there is no positive equilibrium on Σ. It follows from Proposition 3.3 that the disease-free equilibrium E_0 is globally asymptotically stable. This completes the proof of Theorem 3.8. $\square$

4. The classification for global behavior of system (2.2). In this section, we mainly study the dynamics of system (2.2). First, let us consider the dynamics of the following subsystem:

$$\tag{4.1} \begin{cases} \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_3 M_i S}{N_H} - \mu_H S, \\ \frac{dE}{dt} = \frac{b_2\beta_3 M_i S}{N_H} - \mu_H E - \alpha E, \\ \frac{dI}{dt} = \alpha E - \mu_H I - \delta I, \\ \frac{dH}{dt} = \delta I - \mu_H H - d_H H - \tau H, \\ \frac{dR}{dt} = \tau H - \mu_H R. \end{cases}$$

Combining Theorems 3.6, 3.7, and 3.8, all solutions of system (2.2) starting in $\mathcal{D}$ satisfy that $M_i(t) \to M_i^{\#}$ as $t \to +\infty$, where $M_i^{\#}$ is constant. Consequently, the limiting system of (4.1) is

$$\tag{4.2} \begin{cases} \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_3 M_i^{\#} S}{N_H} - \mu_H S, \\ \frac{dE}{dt} = \frac{b_2\beta_3 M_i^{\#} S}{N_H} - \mu_H E - \alpha E, \\ \frac{dI}{dt} = \alpha E - \mu_H I - \delta I, \\ \frac{dH}{dt} = \delta I - \mu_H H - d_H H - \tau H, \\ \frac{dR}{dt} = \tau H - \mu_H R. \end{cases}$$

After simple algebraic analysis, system (4.2) has a unique positive equilibrium $\tilde{E}^{\#}(S^{\#}, E^{\#}, I^{\#}, H^{\#}, R^{\#})$. The Jacobian matrix of the system (4.2) associated with $\tilde{E}^{\#}$ is the matrix A_{22} defined in section 2. Then, it follows from section 2 that the unique positive equilibrium $\tilde{E}^{\#}$ is locally asymptotically stable.

Using the change of variables $X_H = N_H + \frac{d_H}{\tau} R$, $X_1 = S + E$, and $X_2 = S + E + I$, system (4.2) can be written as

$$\tag{4.3} \begin{cases} \frac{dX_H}{dt} = \Pi_H - \mu_H X_H, \\ \frac{dX_1}{dt} = \Pi_H - (\mu_H + \alpha) X_1 + \alpha S, \\ \frac{dX_2}{dt} = \Pi_H - (\mu_H + \delta) X_2 + \delta X_1, \\ \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_2 M_i^{\#} S}{N_H} - \mu_H S, \\ \frac{dN_H}{dt} = \Pi_H - (\mu_H + d_H + \tau) N_H + d_H X_2 + \tau X_H. \end{cases}$$

It follows from the first equation of system (4.3) that $X_H(t) \to \frac{\Pi_H}{\mu_H}$ as $t \to +\infty$. Then, the limiting system of (4.3) is

$$(4.4)\qquad \begin{cases} \frac{dX_1}{dt} = \Pi_H - (\mu_H + \alpha)X_1 + \alpha S, \\ \frac{dS}{dt} = \Pi_H - \frac{b_2\beta_2 M_i^{\#} S}{N_H} - \mu_H S, \\ \frac{dN_H}{dt} = \Pi_H - (\mu_H + d_H + \tau)N_H + d_H X_2 + \tau\frac{\Pi_H}{\mu_H}, \\ \frac{dX_2}{dt} = \Pi_H - (\mu_H + \delta)X_2 + \delta X_1. \end{cases}$$

Straightforward calculation yields that system (4.4) has only one positive equilibrium $(X_1^{\#}, S^{\#}, N_H^{\#}, X_2^{\#}) = (S^{\#} + E^{\#}, S^{\#}, N^{\#}, S^{\#} + E^{\#} + I^{\#})$ in $\mathbb{R}_+^4$. From the Jacobian of system (4.4), we can easily verify that system (4.4) is a cooperative irreducible system in $\mathbb{R}_+^4$ [19]. By Theorem 3.1 in [19] or the result in [13], we conclude that the equilibrium $(X_1^{\#}, S^{\#}, N_H^{\#}, X_2^{\#})$ is globally asymptotically stable in $\mathbb{R}_+^4$. Since system (4.4) is the limiting system of (4.3) and system (4.3) is the limiting system of (4.2), it follows from Theorem 2.3 in paper [15] that the unique positive equilibrium $\tilde{E}^{\#}$ is a globally asymptotically stable equilibrium of system (4.2).

Therefore, the dynamics of system (2.2) can be easily derived from Theorems 3.6, 3.7, 3.8, and the above discussion.

THEOREM 4.1. (A) *If $R_0 > 1$ or $R_0 = 1$ and $\mu_M(d_B - \mu_B) > b_1\beta_1\mu_B$, then the unique positive equilibrium E^* of system* (2.2) *is globally asymptotically stable in $\mathcal{D}$.*

(B) *If $R_0 < 1$, then*

(B1) *if $a_2 > 0$, $0 < \frac{-a_1}{2a_2} < B_{i2}^*$, and $\Delta > 0$, then system* (2.2) *has switch phenomenon. That is, system* (2.2) *has a seven-dimensional stable manifold for E^1 which separates* $\text{int}\mathbb{R}_+^8$ *into two parts $V \times \mathbb{R}_+^5$ and $U \times \mathbb{R}_+^5$. If an initial point lies in $V \times \mathbb{R}_+^5$, then the solution $(M_i(t), B_u(t), B_i(t), S(t), E(t), I(t), H(t), R(t)) \to E_0$ as $t \to \infty$; if an initial point lies in $U \times \mathbb{R}_+^5$, then $(M_i(t), B_u(t), B_i(t), S(t), E(t), I(t), H(t), R(t)) \to E^2$ as $t \to \infty$; otherwise, the solution $(M_i(t), B_u(t), B_i(t), S(t), E(t), I(t), H(t), R(t)) \to E^1$ as $t \to \infty$;*

(B2) *if $a_2 > 0$, $0 < \frac{-a_1}{2a_2} < B_{i2}^*$, and $\Delta = 0$, then system* (2.2) *also has a seven-dimensional stable manifold for E^1 which also separates* $\text{int}\mathbb{R}_+^8$ *into two parts. If an initial point lies in $V \times \mathbb{R}_+^5$, then the solution $(M_i(t), B_u(t), B_i(t), S(t), E(t), I(t), H(t), R(t)) \to E_0$ as $t \to \infty$; otherwise, the solution $(M_i(t), B_u(t), B_i(t), S(t), E(t), I(t), H(t), R(t)) \to E^1$ as $t \to \infty$.*

(C) *Otherwise, the disease-free equilibrium E_0 is globally asymptotically stable.*

5. Discussion. In this section, we mainly summarize our results and make some further remarks.

In this article, we have mainly studied the asymptotical behavior of a nine-dimensional WNV model. By applying an asymptotically autonomous convergence theorem, competitive and cooperative theory, and a criterion for the orbital stability of periodic orbits associated with higher-dimensional nonlinear autonomous systems, we provide a complete classification of dynamics for this model in Theorem 4.1, which includes the critical case. It is shown that the dynamics of system (2.2) is determined by the basic reproduction number and the number of the positive equilibria. There are only four cases:

(1) If there is no positive equilibrium, then the unique disease-free equilibrium E_0 is globally asymptotically stable. In this case, the dynamics of the model on Σ can be depicted in Figure 1(a).

(2) If $R_0 \geq 1$ and system (2.2) has a unique positive equilibrium, then the unique endemic equilibrium is globally asymptotically stable in the interior of the feasible

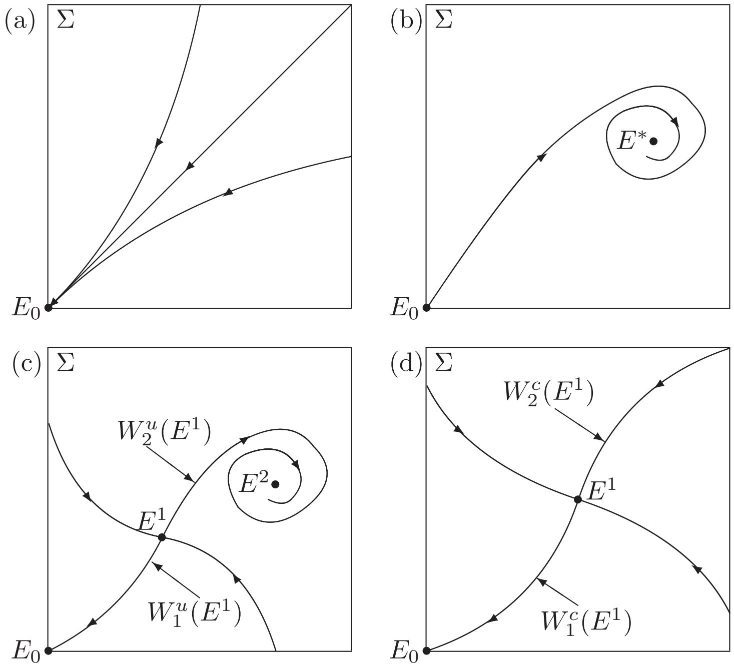

FIG. 1. *The possible dynamics of system* (2.2) *on* Σ.

region, and the disease persists at an endemic equilibrium if it initially exists. In particular, when $R_0 > 1$, system (2.2) has a unique positive equilibrium, and the unique positive is globally asymptotically stable in $\mathrm{Int}\mathbb{R}^8_+$. This result provides a positive answer for the conjecture proposed in [11, 12]. In this case, the dynamics of the model on Σ can be depicted in Figure 1(b).

(3) If system (2.2) has two positive equilibria E^1, E^2, then system (2.2) has switch phenomenon, that is, a seven-dimensional stable manifold for E^1 separates $\mathrm{int}\mathbb{R}^8_+$ into two parts. One contains E_0 and one branch $W_1^u(E^1)$ of the unstable manifold for E^1, the other contains E^2 and the other branch $W_2^u(E^1)$ of the unstable manifold for E^1. All solutions not in $W^s(E^1)$ are convergent to either E_0 or E^2. This result indicates that the reproduction number can't simply describe whether WNV will prevail or not and suggests that we should pay attention to the initial states of WNV. In this case, the dynamics of the model on Σ can be depicted in Figure 1(c).

(4) Otherwise, system (2.2) has a unique positive equilibrium E^1 which has one-dimensional center manifold, and there exists a seven-dimensional stable manifold for E^1 which also separates $\mathrm{int}\mathbb{R}^8_+$ into two parts. One contains E_0 and one branch $W_1^c(E^1)$ of the center manifold for E^1, the other contains no positive equilibrium and the other branch $W_2^c(E^1)$ of the center manifold for E^1. All solutions are convergent to either E_0 or E^1, respectively. In this case, the dynamics of system (2.2) on Σ can be depicted in Figure 1(d).

The basic reproduction number R_0 of the model can be expressed by

$$R_0 = \sqrt{\frac{b_1^2\beta_1\beta_2\mu_B\Pi_M}{\mu_M^2(\mu_B + d_B)\Pi_B}}.$$

Now let us explain the biological means of R_0. If system (1.1) has no infected female mosquitoes and infected birds and is in balance, then Theorem 2.1 implies that the numbers of the susceptible female mosquitos and birds are $\frac{\Pi_M}{\mu_M}$ and $\frac{\Pi_B}{\mu_B}$, respectively. On these conditions, the average times that one infected bird is bitten by mosquitoes can be defined by

$$\hat{b}_1 := \frac{b_1 \frac{\Pi_M}{\mu_M}}{\frac{\Pi_B}{\mu_B}}.$$

Since the mean lifespan of the infected bird is

$$\hat{\tau}_B := \frac{1}{\mu_B + d_B},$$

the average number of the infected female mosquitoes generated by infection of the infected bird can be defined as

$$\hat{M}_i := \hat{b}_1 \beta_1 \hat{\tau}_B = \frac{b_1 \beta_1 \frac{\Pi_M}{\mu_M}}{\frac{\Pi_B}{\mu_B}} \frac{1}{\mu_B + d_B}.$$

The average number of the infected birds generated by infection of the infected female mosquitoes can be defined as

$$\hat{B}_i := b_2 \beta_2 \frac{1}{\mu_M}.$$

Therefore, the total number of secondary cases generated by transmission of one infected bird can be defined by

$$\tilde{R_0} := \hat{B}_i \hat{M}_i = \frac{b_1 \beta_1 \frac{\Pi_M}{\mu_M}}{\frac{\Pi_B}{\mu_B}} \frac{1}{\mu_B + d_B} b_2 \beta_2 \frac{1}{\mu_M} = (R_0)^2$$

when the numbers of the susceptible mosquitoes and birds are $\frac{\Pi_M}{\mu_M}$ and $\frac{\Pi_B}{\mu_B}$, respectively. If $R_0 > 1$, i.e., $\tilde{R_0} > 1$, Theorem 4.1(A) implies that the WNV will prevail, since an infective bird will be replaced with greater than one new case. If $R_0 < 1$ is less than one, Theorem 4.1(B) implies that the WNV will be likely to fade out, since an infective individual will be replaced with less than one new case.

It follows from the expression of R_0 that the quantity R_0 grows with the recruitment of uninfected mosquito population, the natural death rate of birds, and the per capita rate of the mosquitoes on the birds but falls with the natural death rate of mosquitoes, the recruitment of uninfected birds, and the WNV-induced death rate of birds. Thus, this result implies that the WNV spreads more rapidly if birds migrate to a region with higher mosquito density, and it also implies that it is an efficient way to halt the spread of WNV by using the mosquito-reduction strategies. However, the decreasing of the recruitment of the uninfected birds and the increasing natural death rate of the birds is beneficial to the prevalence of the WNV. This tells us that it is a risk factor for the spread of WNV to kill the birds during the period that the WNV prevails. By contraries, we should increase the recruitment of the uninfected birds.

Additionally, in this paper we consider only the dynamics of the model with WNV transmission among one single mosquito–bird-human community. However, the effect of seasonality and migration of birds are important factors, since, for nontropical regions, the cold season signals the end of the epidemic season, while the heterogeneity and migration of birds from region to region plays a key role in the viral amplification process. Also, it is feasible that infected birds can migrate from one region to another. Thus, it is also interesting to study how the dynamics of the model incorporates infected birds can migrate from one region to another. We leave these for future investigations.

Acknowledgments. The problem for global stability of the unique equilibrium was first proposed to the first author by Prof. Wu Jianhong in the summer of the year 2004 when he visited Prof. Wu at York University. The first author greatly appreciates Prof. Wu for his encouragement and many good suggestions during studying the problem for past years. Both authors are also grateful to Prof. Zhu Huaiping for his biological explanation for this model.

STABILITY OF CURVED INTERFACES IN THE PERTURBED TWO-DIMENSIONAL ALLEN–CAHN SYSTEM*

DAVID IRON[†], THEODORE KOLOKOLONIKOV[†], JOHN RUMSEY[†], AND JUNCHENG WEI[‡]

Abstract. We consider the singular limit of a perturbed Allen–Cahn model on a bounded two-dimensional domain: $\begin{cases} u_t = \varepsilon^2 \Delta u - 2(u-\varepsilon a)(u^2-1), & x \in \Omega \subset \mathbb{R}^2 \\ \partial_n u = 0, & x \in \partial\Omega \end{cases}$ where ε is a small parameter and a is an $O(1)$ quantity. We study equilibrium solutions that have the form of a curved interface. Using singular perturbation techniques, we fully characterize the stability of such an equilibrium in terms of a certain geometric eigenvalue problem, and give a simple geometric interpretation of our stability results. Full numerical computations of the time-dependent PDE as well as of the associated two-dimensional eigenvalue problem are shown to be in excellent agreement with the analytical predictions.

Key words. Allen–Cahn equation, interface motion, spectral analysis, matched asymptotic expansions

1. Introduction.

We consider a perturbed two-dimensional Allen–Cahn equation,

$$\begin{cases} u_t = \varepsilon^2 \Delta u + f(u) + \varepsilon g(u), & x \in \Omega \subset \mathbb{R}^2\,, \\ \partial_n u = 0, & x \in \partial\Omega\,. \end{cases} \tag{1}$$

Here, Ω is a smooth two-dimensional domain and $f(u)$ is a smooth function having the following properties:

1. f has three roots $u_- < u_0 < u_+$ with $f'(u_\pm) < 0$,
2. $\int_{u_-}^{u_+} f(u)\,du = 0$,

and $g(u)$ is any smooth function function with $\int_{u_-}^{u_+} g(u)\,du \neq 0$.

The standard Allen–Cahn equation corresponds to $g = 0$, $f = -2u(u^2-1)$. This model was introduced in [2] as a simple model of evolution of antiphase boundaries and is now well understood. In the limit $\varepsilon \to 0$, the solution forms a sharp interface layer. On one side of the interface, $u \sim u_-$, while on the other, $u \sim u_+$. Once the interface layer is formed, its motion is described by the mean curvature law which minimizes the perimeter of the interface ([5], [9]). The stable stationary solution corresponds to an interface with a minimal perimeter that intersects the boundary orthogonally ([12]). Therefore, any nontrivial stable steady equilibrium of the unperturbed Allen–Cahn equation consists of a straight interface. The stability of such an interface has been analyzed by several authors in variety of settings; see for instance [1], [10], [11], [14], [16], [18]. The main result is that such an interface can be stable provided the domain contains a "neck". More precisely, as shown in [10], [11], in the limit $\varepsilon \to 0$,

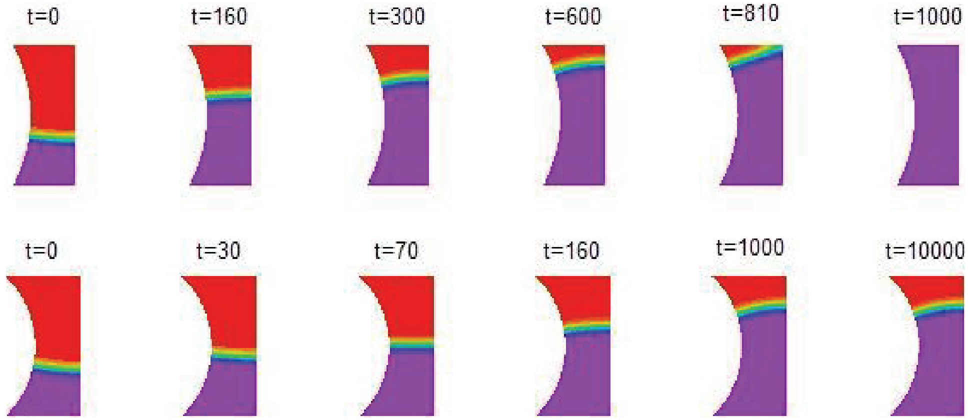

FIG. 1. *Motion of an interface for the perturbed Allen–Cahn model given by* $u_t = \varepsilon^2 \Delta u - 2(u - \varepsilon a)(u^2 - 1)$*, with* $a = 0.3, \varepsilon = 0.07$*. Top row: the interface is unstable and eventually disappears. Bottom row: The interface gets "stuck" in the middle of the domain; a nontrivial equilibrium is reached. The domain height is* 1.5 *and the distance between the side boundaries is* 0.5*. The radius of the left boundary is* 1.5 *for the top row and* 1.0 *for the bottom row.*

the interface stability depends only on the curvatures κ_+, κ_- of the boundary at the two points that intersect the interface, and the interface length ℓ. The interface is stable provided that $\ell + \kappa_+^{-1} + \kappa_-^{-1} < 0$. Geometrically, the threshold case corresponds to the two boundaries that are locally concentric.

More generally, the perturbed Allen–Cahn equation (1) is used as a prototype model of wave propagation in various contexts. In two or higher dimensions, a small perturbation leads to *weakly curved fronts*. For an overview, see [15], Chapter 2.2. In the absence of boundaries, the front becomes a closed curve which lies on a perimeter of some circle. Moreover, such a front is unstable, and either shrinks to a point or else expands indefinitely, depending on the initial conditions [15]. A typical nonlinearity is $f + \varepsilon g = -2(u - A)(u^2 - 1)$ where A is close to 0. This system (but without the assumption that A is small) was used as a simple model of spreading depressions in the human brain that are associated with cerebral strokes [4]. (When A is replaced by an inhomogeneous term $a(x)$, it is called the Fife–Greenlee problem [8], [6].) For convex domains, it is known ([3] [13]) that the only stable solution is a trivial equilibrium. Indeed any interface propagates until it merges with the boundary and disappears.

However, when the domain consists of two boxes of different heights, it was shown in [4] that the interface can get "stuck" at the juncture between the two boxes, provided their dimensions are sufficiently different. A similar phenomenon was reported in [17], where the propagation of chemical pulses in complex geometries with corners and junctures was studied numerically and experimentally.

The perturbation by a small term $\varepsilon g(u)$ has a large effect on the shape and stability of the interface. In particular, the equilibrium solution now consists of a *curved* interface. In the limit $\varepsilon \to 0$, this curve is part of a circular arc whose radius $\hat{R}$, given by (2) below and is independent of the domain shape. For non-convex domains, it is possible to get a stable interface. One such domain is illustrated in Figure 1. It consists of a rectangle with a circular cutout. In the first simulation (top row), the interface propagates through the domain without reaching any equilibrium, whereas in the second simulation (second row) the interface settles to a steady state somewhere in the middle of the domain. The only difference between the two simulations is the curvature of the left boundary of the domain, which has been increased in the second simulation.

In this paper, we fully characterize the stability of curved interfaces. First, we provide the necessary and sufficient conditions that describe the stability of an interface. Second, we give a simple geometric interpretation of our stability results.

Before stating our stability result, we characterize the radius of the steady state. This simple result was already given in [16], Appendix A. We summarize it here as following.

Proposition 1. *Let U be a solution to*

$$U''(y) + f(U) = 0, \qquad U \to u_{\pm} \quad \text{as } y \to \pm\infty$$

and define

$$\hat{R} = -\frac{\int_{-\infty}^{\infty} U'^2(y)dy}{\int_{u_-}^{u_+} g(u)du}. \tag{2}$$

Suppose that there exists a circle of radius $\hat{R}$ which intersects $\partial\Omega$ orthogonally, and let p be its center. Then in the limit $\varepsilon \to 0$ we have

$$u(x) \sim U\left(\frac{\hat{R} - |p - x|}{\varepsilon}\right), \quad \varepsilon \to 0. \tag{3}$$

Moreover, any solution to (1) *of the form* (3) *must satisfy* (2).

We are now ready to state our main result.

Theorem 2. *Let $u(x)$ be the steady-state solution as given in Proposition* 1 *and $\hat{R}$ its radius as defined in* (2). *Let ℓ be the length of the interface and let κ_+, κ_- be the curvatures of the boundary at the points which intersect the interface. Consider the stability problem associated with* (1),

$$\begin{cases} \lambda\phi = \varepsilon^2\Delta\phi + f'(u)\phi + \varepsilon g'(u)\phi, & x \in \Omega \\ \partial_n\phi = 0, \quad x \in \partial\Omega. \end{cases} \tag{4}$$

In the limit $\varepsilon \to 0$, the eigenvalues λ are of $O(\varepsilon^2)$ given by

$$\lambda = \varepsilon^2\lambda_0, \tag{5a}$$

where λ_0 solves the following geometric eigenvalue problem*:*

$$\begin{cases} T'' + \left(\hat{R}^{-2} - \lambda_0\right)T = 0 \\ T'(-\ell/2) + \kappa_- T(-\ell/2) = 0 \\ T'(\ell/2) - \kappa_+ T(\ell/2) = 0. \end{cases} \tag{5b}$$

Thus, the interface is stable if all solutions λ_0 of (5b) *are negative, and unstable if at least one solution is positive. Equivalently, λ_0 solves*

$$\lambda_0 = \frac{1}{\hat{R}^2} - \mu^2 \quad \text{where} \quad \tan(\mu\ell) = -\frac{\mu(\kappa_+ + \kappa_-)}{\mu^2 - \kappa_+\kappa_-} \tag{6}$$

or

$$\arctan\left(\frac{-\kappa_+}{\mu}\right) + \arctan\left(\frac{-\kappa_-}{\mu}\right) = \mu\ell \tag{7}$$

for some branch of arctan.

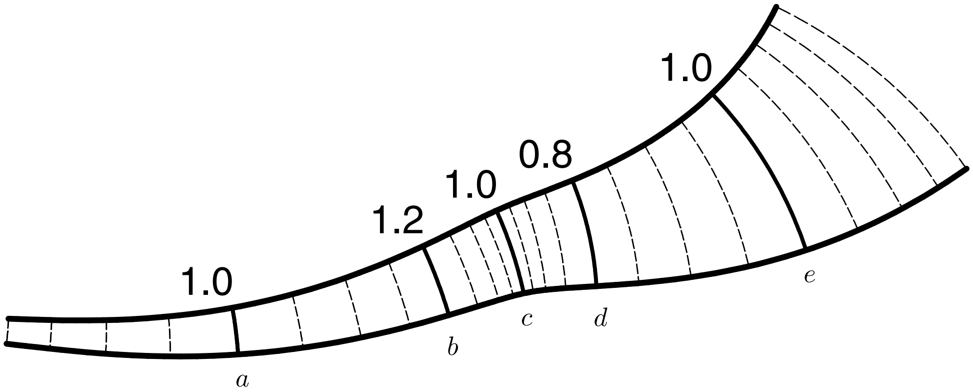

Fig. 2. *Geometric interpretation of stability criterion (see Theorem* 3*). The numbers indicate the radius of the corresponding interface below that number. The maximum and minimum radius is* 1.2 *and* 0.8*, respectively. If* $\hat{R} = 1$*, then curve c represents the location of a stable interface, whereas curves a and e correspond to unstable interfaces.*

Remark. Suppose that $\lambda_0 \neq 0$, i.e., the geometric eigenvalue problem (5b) has no zero eigenvalue. Then the existence of such steady state can be rigorously proved, following the lines of [11]. We omit the details.

In the case of the unperturbed Allen–Cahn equation ($g = 0, \quad \hat{R} = \infty$), the geometric eigenvalue problem (5b) is identical to (1.5) obtained by Kowalczyk in [10], [11]. However, here we use a somewhat different method using solvability condition and test functions.

The stability criterion (5b) has a natural geometric interpretation which we now discuss. Consider a domain such as shown in Figure 2. Parameterize the top boundary in terms of arclength s, from left to right, and let $q(s)$ be the corresponding point on the top boundary. We suppose that there is a unique circle that goes through $q(s)$ and that intersects both top and bottom boundaries orthogonally. Let $R(s)$ denote the radius of such a circle. Then we have the following.

Theorem 3. *Let $\hat{R}$ be the radius of a steady interface as defined in Proposition* 1*, let $R(s)$ be as defined above, and suppose that $R(s) = \hat{R}$ for some s. Then the interface is stable if $R'(s) < 0$ and it is unstable if $R'(s) > 0$.*

For example, for the domain as shown in Figure 2, if $\hat{R} \in (0.8, 1.2)$, then there exists a stable steady interface between curves b and d. On the other hand, any interface to the left of b or to the right of d is unstable. To our knowledge, this is the first result that combines both the effects of perturbation and the effects of the boundary.

The rest of the paper is outlined as follows. Proposition 1 is derived in section 2. The main result, Theorem 2, is then derived in section 3. Finally we prove Theorem 3 in section 4. We conclude with numerical calculations in section 5 and some discussions and open problems in section 6.

2. Equilibrium front solution.

In this section we construct the steady state consisting of a single interface. The main goal is to derive (2) of Proposition 1.

We seek a solution which divides the domain into two regions. In one of the regions $u \sim u_+$ and in the other $u \sim u_-$. The two regions are separated by an interface, or front, of thickness $O(\varepsilon)$. We expect the interface to be localized about a circle segment which intersects the boundary of Ω orthogonally. Let $\hat{R}$ be the radius

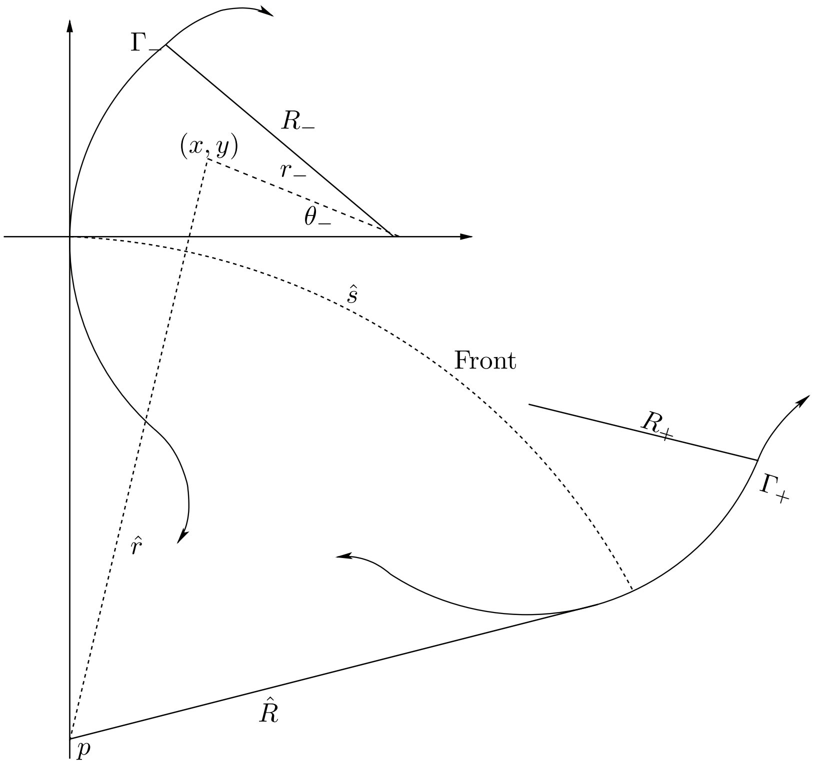

FIG. 3. *Schematic used for the derivation of coordinate systems in the interior of the domain and localized near the boundaries.*

of the interface and define the following coordinate system as illustrated in Figure 3:

$$x = R_- - r_- \cos(\theta_-) = \hat{r}\sin(\hat{s}/\hat{R})\,, \tag{8}$$

$$y = r_- \sin(\theta_-) = \hat{r}\cos(\hat{s}/\hat{R}) - \hat{R}\,. \tag{9}$$

Near the boundaries, we define localized coordinates $\rho_\pm$ and $t_\pm$ as follows:

$$\rho_\pm \equiv \frac{r_\pm - R_\pm}{\varepsilon}\,, \qquad t_\pm \equiv \frac{R_\pm \theta_\pm}{\varepsilon}\,. \tag{10}$$

Here, + and − are used to denote the right and left curved boundaries, respectively. The ± will be dropped whenever the meaning is clear. We also define coordinates localized near the front by

$$\hat{\rho} \equiv \frac{\hat{r} - \hat{R}}{\varepsilon}\,. \tag{11}$$

We can then write $\hat{\rho}$ as a function of t and ρ:

$$\hat{\rho} = t - \varepsilon\left(\frac{\rho t}{R} - \frac{\rho^2}{2\hat{R}}\right) + \cdots\,. \tag{12}$$

In the interior of the domain, we expect the front to be radially symmetric. Thus, in the new coordinate system, the equilibrium front will satisfy

$$u_{\hat{\rho}\hat{\rho}} + \frac{\varepsilon}{\hat{R} + \varepsilon\hat{\rho}} u_{\hat{\rho}} + f(u) + \varepsilon g(u) = 0\,, \tag{13}$$

in the interior of the domain. We expand

$$u = u_0 + \varepsilon u_1 + \varepsilon^2 u_2 + \cdots\,, \tag{14}$$

substitute into (13), and collect powers of ε to obtain,

$$u_0'' + f(u_0) = 0\,, \tag{15}$$

$$u_1'' + f'(u_0)u_1 = -\frac{1}{\hat{R}}u_0' - g(u_0)\,, \tag{16}$$

$$u_2'' + f'(u_0)u_2 = \frac{1}{\hat{R}^2}\hat{\rho}u_0' - \frac{1}{\hat{R}}u_1' - \frac{f''(u_0)u_1^2}{2} - g'(u_0)u_1\,. \tag{17}$$

From here on $'$ denotes differentiation with respect to $\hat{\rho}$ when associated with u_i. In all other cases $'$ will represent differentiation with respect to the appropriate argument. At this point it is convenient to define the operator $L\psi \equiv \psi'' + f'(u_0)\psi$.

From conditions 1 and 2 following (1), u_0 will be given by the unique heteroclinic orbit connecting u_+ to u_-. For the case $f(u) = 2u(1-u^2)$, we have the exact solution $u_0 = \tanh(\hat{\rho})$. We note that by differentiating (15) with respect to $\hat{\rho}$, $Lu_0' = 0$.

To determine $\hat{R}$, we consider the steady-state system,

$$\varepsilon^2 \Delta u + f(u) + \varepsilon g(u) = 0\,. \tag{18}$$

We multiply (18) by u_0' and integrate over the domain,

$$\int_\Omega u_0'(\varepsilon^2 \Delta u + f(u) + \varepsilon g(u))\, dA = 0\,. \tag{19}$$

Applying Green's identity to (19) we obtain

$$-\varepsilon^2 \int_{\partial\Omega} u\, \partial_n u_0'\, ds + \int_\Omega \varepsilon^2 u\, \Delta(u_0') + u_0'(f(u) + \varepsilon g(u))\, dA = 0\,. \tag{20}$$

We now use (14) and (11) in (20) and collect powers of ε to obtain

$$\begin{aligned} -\varepsilon^2 \int_{\partial\Omega} u_0 \partial_n u_0'\, ds + \int_\Omega \Bigg(&(u_0(u_0')'' + f(u_0)u_0') + \varepsilon \\ &\left((u_0')''u_1 + \frac{1}{\hat{R}}(u_0')'u_0 + f'(u_0)u_1u_0' + g(u_0)u_0' \right) \Bigg)\, dA = 0\,. \end{aligned} \tag{21}$$

Integrating over $\hat{\rho}$ by parts and using $\lim_{\hat{\rho}\to\pm\infty} u_0' = 0$ yields

$$\int_\Omega (u_0')''u_0\, dA = \int_\Omega u_0''u_0'\, dA\,, \tag{22}$$

$$\int_\Omega (u_0')'u_0\, dA = \int_\Omega (u_0')^2\, dA\,. \tag{23}$$

Using (15) and $Lu_0 = 0$, (21) may be written as

$$-\varepsilon \int_{\partial\Omega} \partial_n u_0' u_0\, ds = -\int_\Omega \left(\frac{u_0'}{\hat{R}} + g(u_0) \right) u_0'\, dA\,. \tag{24}$$

Using (12) we find the leading order behavior of $\partial_n u_0'|_{\partial\Omega}$:

$$\partial_n u_0'|_{\partial\Omega} \sim \frac{\partial}{\partial\rho} u_0' \left(t - \varepsilon \left(\frac{\rho t}{R} - \frac{\rho^2}{2\hat{R}} \right) \right) \bigg|_{\rho=0} , \tag{25}$$

$$= -\varepsilon u_0'' \frac{t}{R} . \tag{26}$$

Thus, the boundary term in (24) is of a much lower order, and the equilibrium radius of the front is given by

$$\hat{R} \sim - \frac{\int_{-\infty}^{\infty} (u_0')^2 \, dt}{\int_{u_-}^{u_+} g(y) \, dy} . \tag{27}$$

This shows, that to leading order, $\hat{R}$ is independent of the domain shape and completes the derivation of Proposition 1.

3. Proof of Theorem 2. We now construct a solvability condition to determine the principal eigenvalues of (4). Since u_0' is of one sign and $Lu_0' = 0$, we expect that the principal eigenvalue is small and to leading order the principal eigenfunction will behave like u_0' in the interior of the domain. Such an eigenfunction is often referred to as a translation eigenfunction as it is associated with the near translation invariance of the front in the interior of the domain with respect to the radial co-ordinate. In this case, $\hat{s}u_0'$ also satisfies (4) to leading order and as a result, we will need two solvability conditions to determine the principal eigenvalue.

We construct our solvability conditions by multiplying (4) by test function v and integrating over the domain we obtain

$$\int_\Omega v \left(\varepsilon^2 \Delta\phi + f'(u)\, \phi \right) dA + \varepsilon \int g'(u)\, \phi \, v \, dA = \lambda \int_\Omega \phi \, v \, dA , \tag{28}$$

where v is of the form

$$v(\hat{s}, \hat{\rho}) = w(\hat{s}) \, u_0'(\hat{\rho}) \tag{29}$$

and $w(\hat{s})$ is an arbitrary test function.

Using Green's identity and applying the boundary conditions in (4) results in

$$-\varepsilon^2 \int_{\partial\Omega} \phi \, \partial_n v \, ds + \int_\Omega \Big(\varepsilon^2 \Delta v + f'(u)\, v + \varepsilon \, g'(u)\, v \Big) \phi \, dA = \lambda \int_\Omega \phi \, v \, dA . \tag{30}$$

Here, s is arc length along the boundary and dA is an element of area in the interior. From (10) and (11),

$$ds = R \, d\theta = \varepsilon \, dt , \tag{31}$$

$$dA = \frac{\hat{r}}{\hat{R}} \, d\hat{r} \, d\hat{s} = \varepsilon \left(1 + \varepsilon \frac{\hat{\rho}}{\hat{R}} \right) d\hat{\rho} \, d\hat{s} . \tag{32}$$

Consider the $\int_\Omega \Big(\varepsilon^2 \Delta v + f'(u)\, v + \varepsilon \, g'(u)\, v \Big) \phi \, dA$ term in (30), in which v, u, ϕ are written in the interior coordinates $\hat{r}$ and $\hat{s}$. Expand ϕ:

$$\phi = \phi_0 + \varepsilon \phi_1 + \varepsilon^2 \phi_2 + \cdots . \tag{33}$$

Use (11), (32), (33), and (14) to write $\int_\Omega \Big(\varepsilon^2\Delta v + f'(u)\,v + \varepsilon\, g'(u)\,v\Big)\phi\,dA$ in terms of the coordinates, $\hat\rho$ and $\hat s$:

$$\begin{aligned}
&\Big(\varepsilon^2\Delta v(\hat r) + f'(u)\,v(\hat r) + \varepsilon\, g'(u)\,v(\hat r)\Big)\phi\,dA\\
&\quad\sim \left[\varepsilon^2\left(\frac{1}{\varepsilon^2}\,v_{\hat\rho\hat\rho} + \frac{1}{\hat R+\varepsilon\hat\rho}\,\frac{1}{\varepsilon}v_{\hat\rho} + v_{\hat s\hat s}\right) + f'\left(u_0+\varepsilon\,u_1+\varepsilon^2\,u_2\right)\,v\right.\\
&\qquad\quad \left. +\ \varepsilon\, g'\left(u_0+\varepsilon\,u_1+\varepsilon^2\,u_2\right)\,v\right]\Big[\phi_0+\varepsilon\phi_1+\varepsilon^2\phi_2\Big]\left[\varepsilon\left(1+\varepsilon\,\frac{\hat\rho}{\hat R}\right)d\hat\rho\,d\hat s\right]\\
&\quad\sim \left\{\varepsilon^2\left[\frac{1}{\hat R}\,v_{\hat\rho}\,\phi_0 + u_1\,f''(u_0)\,v\,\phi_0 + g'(u_0)\,v\,\phi_0\right]\right.\\
&\qquad\quad + \varepsilon^3\Bigg[v_{\hat s\hat s}\phi_0 + u_2\,f''(u_0)\,v\,\phi_0 + \frac{1}{2}\,u_1^2\,f'''(u_0)\,v\,\phi_0 + u_1\,g''(u_0)\,v\,\phi_0\\
&\qquad\qquad + \frac{1}{\hat R}\,v_{\hat\rho}\,\phi_1 + u_1\,f''(u_0)\,v\,\phi_1 + g'(u_0)\,v\,\phi_1\\
&\qquad\qquad \left.+ \frac{\hat\rho}{\hat R}\,u_1\,f''(u_0)\,v\,\phi_0 + \frac{\hat\rho}{\hat R}\,g'(u_0)\,v\,\phi_0\Bigg]\right\}\,d\hat\rho\,d\hat s
\end{aligned}\tag{34}$$

since $v = w(\hat s)u_0^{'}(\hat\rho)$ is in the kernel of L.

Equation (34) has terms involving u_1 and u_2, so we must examine (16) and (17) for these terms. We take the derivative of (16) with respect to $\hat\rho$ and multiply by $w\phi_0$, integrate, and use Green's identity to obtain

$$\int_{\partial\Omega}\partial_n u_1' w\phi_0\,ds = \int_\Omega\left(-\frac{1}{\hat R}u_0'' - f''(u_0)u_0'u_1 - g'(u_0)u_0'\right)w\phi_0\,dA\,. \tag{35}$$

It will become evident that $\lambda = O(\varepsilon^2)$. To avoid tedious calculations, we will write $\lambda = \varepsilon^2\lambda_0 + \cdots$. In this way, λ_0 terms will enter at the correct order. We substitute (31) and (32) into (35), multiply by ε, and arrange the terms to match the u_1 term in (34):

$$\begin{aligned}
&\varepsilon^2\int_\Omega f''(u_0)u_0'u_1 w\phi_0\,d\hat\rho\,d\hat s\\
&\qquad = -\,\varepsilon^2\left(\int_\Omega\left(\frac{1}{\hat R}u_0'' + g'(u_0)\,u_0'\right)w\phi_0\,d\hat\rho\,d\hat s + \int_{\partial\Omega}\partial_n u_1' w\phi_0\,dt\right)\\
&\qquad\quad + \varepsilon^3\int_\Omega\left(-\frac{1}{\hat R}u_0'' - f''(u_0)u_0'u_1 - g'(u_0)\,u_0'\right)\frac{\hat\rho}{\hat R}w\phi_0\,d\hat\rho\,d\hat s + \cdots\,.
\end{aligned}\tag{36}$$

We repeat the above procedure to handle the u_2 term in (34). First we differentiate (17) with respect to $\hat\rho$,

$$\begin{aligned}
\Delta(u_2') + f'(u_0)u_2' = {}& -\frac{1}{\hat R}u_1'' + \frac{1}{\hat R^2}\hat\rho u_0'' + \frac{1}{\hat R^2}u_0' - f''(u_0)u_0'u_2\\
&-\ \frac{f'''(u_0)u_0'u_1^2}{2} - f''(u_0)u_1u_1' - g''(u_0)u_0'u_1 - g'(u_0)u_1'\,.
\end{aligned}\tag{37}$$

We multiply the above expression by ϕ_0, integrate over the domain, apply Green's identity to the right-hand side, and multiply by ε^3 to match the u_2 term in (34) which results in the following:

$$
\begin{aligned}
\varepsilon^3\!\int_\Omega f''(u_0)u_0'u_2w\phi_0\,d\hat\rho\,d\hat s = \varepsilon^3\!\int_\Omega \Bigg(&-\frac{1}{\hat R}u_1''+\frac{1}{\hat R^2}\hat\rho u_0''+\frac{1}{\hat R^2}u_0'-\frac{f'''(u_0)u_0'u_1^2}{2}\\
&-f''(u_0)u_1u_1'-g''(u_0)u_0'u_1-g'(u_0)u_1'\Bigg)w\phi_0\,d\hat\rho\,d\hat s\\
&+\varepsilon^3\!\int_{\partial\Omega}\partial_n u_2' w\phi_0\,dt+\cdots\ . \qquad (38)
\end{aligned}
$$

Since ϕ is a translation eigenfunction, in the interior we may write

$$\phi_i = T(\hat s)u_i'(\hat\rho). \qquad (39)$$

We also note that

$$\int_\Omega \frac{1}{\hat R}u_1''w\phi_0\,d\hat\rho\,d\hat s = -\int_\Omega\frac{1}{\hat R}w\phi_0'u_1'\,d\hat\rho\,d\hat s\,. \qquad (40)$$

Using (40), (39), (38), (36), and (34) we can write (28) as

$$
\begin{aligned}
(41)\quad &\varepsilon^2\lambda_0\int_\Omega v\phi_0\,d\hat\rho\,d\hat s\\
&=\varepsilon^2\!\int_\Omega\left(v_{\hat s\hat s}\phi_0+\frac{2}{\hat R}\phi_1 v_{\hat\rho}+\frac{1}{\hat R^2}w\phi_0\right)d\hat\rho\,d\hat s-\varepsilon^2\!\int_{\partial\Omega}(\phi_0\partial_n v+w\phi_0\partial_n u_1')\,dt+\cdots,
\end{aligned}
$$

where, from (38), the boundary integral involving $\partial_n u_2'$ is of higher order. The eigenfunction $\phi_0 = T(\hat s)u_0'$ is the derivative of a monotonic front and is, thus, of one sign and hence is the principal eigenfunction. The principal eigenfunction of L must be even in the radial direction and the function v' will be odd in the radial direction. Thus, the term $\int_\Omega \frac{2}{\hat R}\phi_1 v'\,d\hat\rho\,d\hat s$ will be zero to leading order.

For the boundary integral involving $\partial_n v$, we need to find $\partial_n v$ on $\partial\Omega$. Away from the points where the front and boundary intersect, $\partial_n v$ will be exponentially small, so we will only consider the two components of the boundary $\Gamma_\pm$. Since the front meets $\Gamma_\pm$ orthogonally,

$$\partial_n v|_{\Gamma_\pm} = \left.\frac{\partial v}{\partial r}\right|_{\Gamma_\pm}. \qquad (42)$$

We note from (8), (9), (10), and (11),

$$\left.\frac{\partial\hat s}{\partial r}\right|_{\Gamma_\pm}\sim\pm1 \quad\text{and}\quad \left.\frac{\partial\hat\rho}{\partial r}\right|_{\Gamma_\pm}\sim\left.\frac{t}{R}\right|_{\Gamma_\pm}. \qquad (43)$$

Thus,

$$\partial_n v\big|_{\Gamma_\pm}\sim\left.\left(\pm w'(\hat s)u_0'(t)+w(\hat s)u_0''(t)\frac{t}{R}\right)\right|_{\Gamma_\pm}. \qquad (44)$$

We let ℓ be the length of the interface and place $\hat s = 0$ such that $\hat s = \pm\ell/2$ on $\Gamma_\pm$. Then, using (39), (29), $\hat\rho\sim t$ on $\Gamma_\pm$ and $\int tu_0''u_0 = -\frac{1}{2}\int {u_0'}^2$ with (44) results in

$$
\begin{aligned}
-\int_{\partial\Omega}\partial_n v\phi_0\,dt &\sim w'(-\ell/2)T(-\ell/2)\int_{-\infty}^{\infty}(u_0'(t))^2\,dt+\frac{w(-\ell/2)T(-\ell/2)}{2R_-}\int_{-\infty}^{\infty}(u_0'(t))^2\,dt\\
&\quad-w'(\ell/2)T(\ell/2)\int_{-\infty}^{\infty}(u_0'(t))^2\,dt+\frac{w(\ell/2)T(\ell/2)}{2R_+}\int_{-\infty}^{\infty}(u_0'(t))^2\,dt\,. \qquad (45)
\end{aligned}
$$

For the boundary integral involving $\partial_n u_1'$, we have that, near $\partial\Omega$,

$$u \sim u_0(\hat\rho) + \varepsilon\, u_1 = u_0(t) + \varepsilon \left(\frac{\rho\, t}{R} + \frac{\rho^2}{2\hat R} \right) u_0'(t) + \varepsilon\, u_1 + \cdots . \tag{46}$$

Also, on $\partial\Omega$, we have $\partial_n u = 0$, so that, on $\partial\Omega$

$$\partial_n u_1 \sim - \frac{\partial}{\partial\rho} \left[\frac{1}{\varepsilon}\, u_0(t) + \left(\frac{\rho\, t}{R} + \frac{\rho^2}{2\hat R} \right) u_0'(t) \right] \Bigg|_{\rho=0} = - \frac{t}{R}\, u_0'(t) \Bigg|_{\Gamma_\pm} . \tag{47}$$

Then

$$\partial_n u_1' \sim - \frac{1}{R}\, u_0'(t) - \frac{t}{R}\, u_0''(t) \tag{48}$$

and

$$\begin{aligned} - \int_{\partial\Omega} \partial_n u_1' w \phi_0 \, dt \sim & \int_{\Gamma_-} w(-\ell/2) T(-\ell/2) \left(u_0''(t) u'(t) \frac{t}{R} + u_0'(t)^2 \frac{1}{R} \right) dt \\ & + \int_{\Gamma_+} w(\ell/2) T(\ell/2) \left(u_0''(t) u'(t) \frac{t}{R} + u_0'(t)^2 \frac{1}{R} \right) dt \,, \\ = & \left(\frac{w(\ell/2)T(\ell/2)}{2R_+} + \frac{w(-\ell/2)T(-\ell/2)}{2R_-} \right) \int_{-\infty}^{\infty} (u_0'(t))^2 \, dt \,. \end{aligned} \tag{49}$$

Substitute (44) and (49) into (41) to obtain

$$\begin{aligned} \left(\lambda_0 - \frac{1}{\hat R^2} \right) \int_\Omega v \phi_0 \, d\hat\rho \, d\hat s \sim \int_\Omega v_{\hat s \hat s} \phi_0 \, d\hat\rho \, d\hat s + & \left(w'(-\ell/2)T(-\ell/2) + \frac{w(-\ell/2)T(-\ell/2)}{2R_-} \right. \\ & \left. - w'(\ell/2)T(\ell/2) + \frac{w(\ell/2)T(\ell/2)}{2R_+} \right) \int_{-\infty}^{\infty} (u_0'(t))^2 \, dt \,. \end{aligned} \tag{50}$$

The eigenfunctions will depend on both $\hat s$ and $\hat\rho$. We thus substitute the ansatz $\phi = T(\hat s)\Phi(\hat\rho)$ into the eigenvalue problem (4),

$$\left(\Phi'' + \frac{\varepsilon}{\hat R} \Phi' - \varepsilon^2 \frac{\hat\rho}{\hat R^2} \Phi' + f'(u)\Phi + \varepsilon g'(u)\Phi \right) T + \varepsilon^2 T'' \Phi = \varepsilon^2 \lambda_0 T \Phi \,. \tag{51}$$

We divide both sides by $T\Phi$,

$$\left(\frac{\Phi'' + \frac{\varepsilon}{\hat R}\Phi' - \varepsilon^2 \frac{\hat\rho}{\hat R^2}\Phi' + f'(u)\Phi + \varepsilon g'(u)\Phi}{\Phi} \right) + \varepsilon^2 \frac{T''}{T} = \varepsilon^2 \lambda_0 \,. \tag{52}$$

Since T is independent of $\hat\rho$, the term in the brackets must be independent of $\hat\rho$ or equal to a constant α:

$$\Phi'' + \frac{\varepsilon}{\hat R} \Phi' - \varepsilon^2 \frac{\hat\rho}{\hat R^2} \Phi' + f'(u)\Phi + \varepsilon g'(u)\Phi = \alpha \Phi \,. \tag{53}$$

We expand $\Phi = \Phi_0 + \varepsilon\Phi_1 + \varepsilon^2\Phi_2 + \cdots$ and $\alpha = \alpha_0 + \varepsilon\alpha_1 + \varepsilon\alpha_2 + \cdots$. The lowest order terms satisfy

$$\Phi_0'' + f'(u_0)\Phi_0 = \alpha_0 \Phi_0 \,. \tag{54}$$

Thus, $\Phi_0 = u_0'(\hat\rho)$ and $\alpha_0 = 0$. The $O(\varepsilon)$ terms satisfy

$$\Phi_1'' + f'(u_0)\Phi_1 = \alpha_1\Phi_0 - \frac{1}{\hat R}\Phi_0' - f''(u_0)u_1\Phi_0 - g'(u_0)\Phi_0\,. \tag{55}$$

Differentiating (16) results in the following solvability condition,

$$\int_{-\infty}^{\infty} f''(u_0)u_1(u_0')^2\,d\hat\rho = -\int_{-\infty}^{\infty} g'(u_0)(u_0')^2\,d\hat\rho\,. \tag{56}$$

Applying (56) to the solvability condition for (55) yields $\alpha_1 = 0$. The $O(\varepsilon^2)$ terms satisfy

$$\begin{aligned}\Phi_2'' + f'(u_0)\Phi_2 &= \alpha_2\Phi_0 - \Phi_1'\frac{1}{\hat R} + \frac{1}{\hat R^2}\hat\rho\Phi_0' \\ &\quad - f''(u_0)u_1\Phi_1 - f''(u_0)u_2\Phi_0 - \frac{1}{2}f'''(u_0)u_1^2\Phi_0 - g''(u_0)u_1\Phi_0 - g'(u_0)\Phi_1\,.\end{aligned} \tag{57}$$

We have the following solvability condition:

$$\begin{aligned}\alpha_2\int_{-\infty}^{\infty}\Phi_0^2\,d\hat\rho =& \frac{1}{2}\int_{-\infty}^{\infty} f'''(u_0)u_1^2\Phi_0^2\,d\hat\rho + \int_{-\infty}^{\infty} g''(u_0)u_1\Phi_0^2\,d\hat\rho + \int_{-\infty}^{\infty} g'(u_0)\Phi_1\Phi_0\,d\hat\rho \\ &+ \int_{-\infty}^{\infty} f''(u_0)u_2\Phi_0^2\,d\hat\rho + \int_{-\infty}^{\infty} f''(u_0)u_1\Phi_1\Phi_0\,d\hat\rho - \int_{-\infty}^{\infty}\frac{1}{\hat R^2}\hat\rho\Phi_0'\Phi_0\,d\hat\rho \\ &+ \int_{-\infty}^{\infty}\frac{1}{\hat R}\Phi_1'\Phi_0\,d\hat\rho\,.\end{aligned} \tag{58}$$

Differentiating (17) results in the solvability condition,

$$\begin{aligned}&-\int_{-\infty}^{\infty} f''(u_0)u_2(u_0')^2\,d\hat\rho - \int_{-\infty}^{\infty}\frac{1}{\hat R}u_1''u_0'\,d\hat\rho + \frac{1}{\hat R^2}\int_{-\infty}^{\infty}\hat\rho u_0''u_0'\,d\hat\rho + \frac{1}{\hat R^2}\int_{-\infty}^{\infty}(u_0')^2\,d\hat\rho \\ &-\int_{-\infty}^{\infty} f''(u_0)u_1u_1'u_0'\,d\hat\rho - \frac{1}{2}\int_{-\infty}^{\infty} f'''(u_0)u_1^2(u_0')^2\,d\hat\rho - \int_{-\infty}^{\infty} g''(u_0)u_1(u_0')^2\,d\hat\rho \\ &-\int_{-\infty}^{\infty} g'(u_0)u_1'u_0'\,d\hat\rho = 0\,.\end{aligned} \tag{59}$$

Now we use $\int_{-\infty}^{\infty}\hat\rho u_0''u_0'\,d\hat\rho = -\frac{1}{2}\int_{-\infty}^{\infty}(u')^2\,d\hat\rho$ and (58) in (57) to yield

$$\alpha_2 = \frac{1}{\hat R^2}\,. \tag{60}$$

Now we can substitute (53) into (52) using $\alpha = \frac{\varepsilon^2}{\hat R^2} + \cdots$ to get

$$T'' = \left(\lambda_0 - \frac{1}{\hat R^2}\right)T\,. \tag{61}$$

Note that

$$\left(\lambda_0 - \frac{1}{\hat{R}^2}\right) \int_\Omega v\phi_0 \, d\hat{\rho} \, d\hat{s} \sim \left(\lambda_0 - \frac{1}{\hat{R}^2}\right) \int_{-\ell/2}^{\ell/2} wT d\hat{s} \int_{-\infty}^{\infty} (u_0'(t))^2 \, dt \tag{62}$$

$$\int_\Omega v_{\hat{s}\hat{s}}\phi_0 \sim \int_{-\ell/2}^{\ell/2} w^{''} T d\hat{s} \int_{-\infty}^{\infty} (u_0'(t))^2 \, dt \, . \tag{63}$$

Substituting (61), (62), and (63) into (50), integrating by parts, we obtain

$$w(-\ell/2)\left[T^{'}(-\ell/2) + \frac{1}{R_-}T(-\ell/2)\right] + w(\ell/2)\left[-T^{'}(\ell/2) + \frac{1}{R_+}T(\ell/2)\right] = 0.$$

Since w is an arbitrary test function, we see that T satisfies the following boundary conditions:

$$T^{'}(-\ell/2) + \frac{1}{R_-}T(-\ell/2) = 0, \;\; -T^{'}(\ell/2) + \frac{1}{R_+}T(\ell/2) = 0. \tag{64}$$

Equations (61) and (64) prove that T satisfies the geometric eigenvalue problem (5b). Hence, $\lambda_0 = \frac{1}{\hat{R}^2} - \alpha$ where α satisfies

$$\begin{cases} T'' + \alpha T = 0, \\ T'(-\ell/2) + \kappa_- T(-\ell/2) = 0, \\ T'(\ell/2) - \kappa_+ T(\ell/2) = 0, \end{cases} \tag{65}$$

where $\kappa_\pm \equiv \frac{1}{R_\pm}$ and $\kappa_\pm > 0$ corresponds to a convex domain as in Figure 3.

If $\alpha \leq 0$, then $\lambda_0 \geq \frac{1}{\hat{R}^2}$. If $\alpha = \mu^2 > 0$, (where $\mu > 0$), then it is easy to see that μ must satisfy the following transcendental relation:

$$\tan(\mu\ell) = \frac{\mu(\kappa_+ + \kappa_-)}{\kappa_+\kappa_- - \mu^2} \, , \tag{66}$$

and the eigenvalues of (4) are given by

$$\varepsilon^2\lambda = \frac{1}{\hat{R}} - \mu^2 \, , \tag{67}$$

which is precisely (6). Formula (7) is seen to be identical to (6) by applying the identity

$$\tan(x+y) = \frac{\tan x + \tan y}{1 - \tan x \tan y}. \tag{68}$$

This completes the proof of Theorem 2. □

4. Proof of Theorem 3. In this section we show that the geometric condition of Theorem 3 is a direct consequence of Theorem 2.

Fix a point q_+ on the top boundary and consider a circular arc going through q_+ and intersecting both top and bottom boundaries orthogonally (refer to Figure 4). Let p be the center of this arc and let R denote its radius. First, we shall show that $\frac{dR}{dq_+} = 0$ if and only if the formula (5) holds with $\lambda_0 = 0$. By zooming into the point where $\frac{dR}{dq_+} = 0$, we can assume that locally, p moves along a straight line as q_+ moves along the boundary, and that the boundaries are segments of circles of radii $\mathcal{R}_\pm$, as

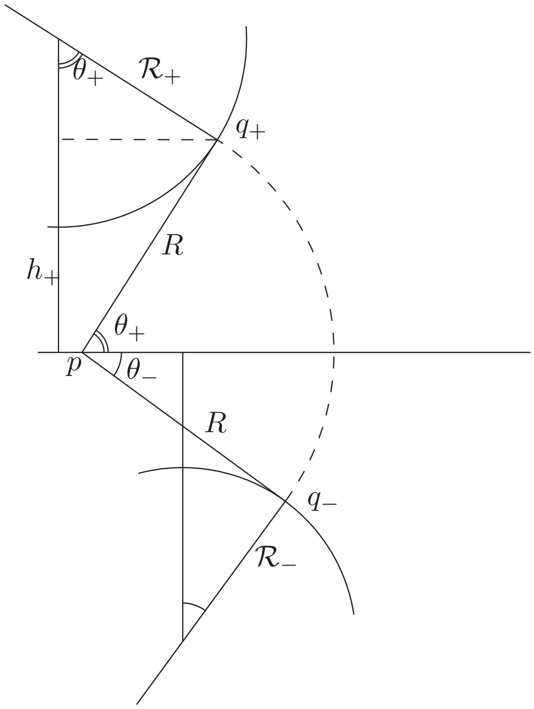

FIG. 4. *Setup for proof of Theorem* 3.

shown in Figure 4. In general, $\mathcal{R}_\pm$ may be positive or negative; for convenience, as shown in the figure, we chose $\mathcal{R}_\pm = -\frac{1}{\kappa_\pm}$ with $\kappa_\pm < 0$ so that $\mathcal{R}_\pm$ is positive. Now from geometry, we find the relationship

$$R = \frac{\mathcal{R}_+(1-\cos\theta_+) + h_+}{\sin\theta_+},$$

where h_+, θ_+ are as shown in Figure 4. We obtain

$$\frac{\partial R}{\partial \theta_+} = \frac{\mathcal{R}_+ - (\mathcal{R}_+ + h_+)\cos\theta_+}{\sin^2\theta_+}$$

so that upon eliminating h_+ we obtain

$$\frac{\partial R}{\partial \theta_+} = 0 \iff \frac{R}{\mathcal{R}_+} = \tan\theta_+ \tag{69}$$

and similarly with + replaced by −. Since $\theta_\pm$ are functions of q_+, we find that at the point where $\frac{dR}{dq_+} = 0$, we have

$$\arctan\frac{R}{\mathcal{R}_\pm} = \theta_\pm.$$

Now from geometry, $\theta_+ = \ell_+/R$, $\theta_- = \ell_-/R$, and $\ell = \ell_+ + \ell_-$. Therefore, upon adding the two equations in (69) we obtain

$$\arctan\frac{R}{\mathcal{R}_+} + \arctan\frac{R}{\mathcal{R}_-} = \theta_+ + \theta_- = \frac{\ell}{R}.$$

But this is precisely (7) with $\lambda_0 = 0$ after substituting $\mathcal{R}_\pm = -\frac{1}{\kappa_\pm}$.

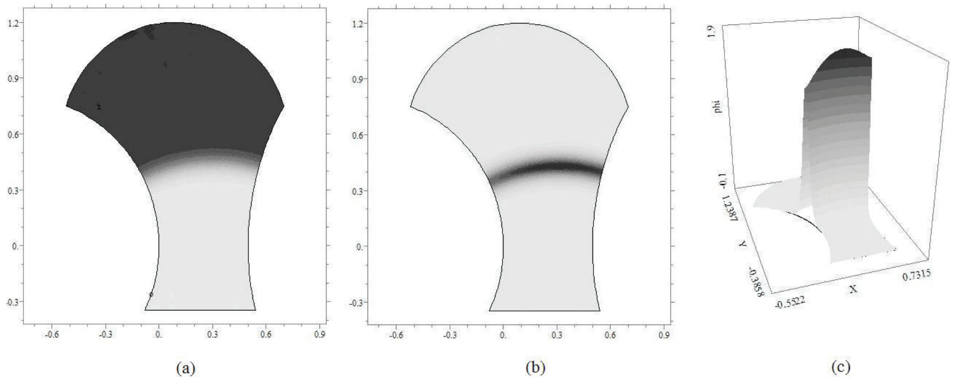

FIG. 5. *Numerical computation of interface and eigenvalue. Left: the steady-state solution $u(x)$ of* (70). *Dark denotes $u \sim 1$ and light denotes $u \sim -1$. Middle: The shape of the corresponding eigenfunction ϕ. Right: surface plot of ϕ. Note the sinusoidal shape along the direction of the interface boundary. Note also a corner layer that is evident near the boundary of the domain. See section* 5 *for parameter values.*

Next, we note that in the case of a cone ($\kappa_+ = \kappa_- = 0$), (7) yields $\lambda_0 = \frac{1}{R^2} > 0$ so that the interface is unstable for a cone domain, for which $R' > 0$. Since λ_0 can only be real, it follows by continuity that λ_0 crosses zero if and only if $R' = 0$, and λ_0 is negative if and only if $R' < 0$. This concludes the proof. □

5. Numerical example.

We now provide a numerical example of Theorem 2. All computations were done using using the software FlexPDE [19].

Consider a domain as shown in Figure 5. Its left and right boundaries consist of arcs of circles of radii $\mathcal{R}_- = 0.8, \ \ \mathcal{R}_+ = 1.5$, so that $\kappa_- = -1.25, \ \ \kappa_+ = -0.667$. The distance between these two boundaries was chosen to be 0.5. The shape of the top and bottom boundaries does not affect the computation as long as they are located $O(1)$ distance from the interface. We chose the nonlinearity to be

$$u_t = \varepsilon^2 \Delta u - 2(u - \varepsilon a)(u-1)(u+1) \tag{70}$$

with $a = 0.55, \ \ \varepsilon = 0.06$. From Proposition 1 we obtain the theoretical value of the interface radius to be $\hat{R} = \frac{1}{2a} = 0.9091$. To estimate the numerical value of $\hat{R}$, we have used FlexPDE to compute the steady state solution to (70), using $u = \tanh(y/\varepsilon)$ as initial conditions. The resulting steady state is shown on Figure 5(a). Next, we computed the coordinates of the intersection of the middle of the interface ($u = 0$) with the boundary, and then used geometry to obtain $\hat{R}_{\text{numerical}} = 0.9066$. This is in excellent agreement with the theoretical prediction. Geometry then yields an estimate of $l = 0.6486$.

Next, we have solved the eigenvalue problem (4) numerically. Using a global error tolerance of 0.5×10^{-4}, we obtained a numerical estimate of $\lambda_{\text{numerical}} = 0.00504$. This required about 10,000 gridpoints (FlexPDE uses adaptive gridding, and chooses the mesh size based on the global tolerance setting. We have also verified that this result is correct to two significant digits by changing the tolerance). On the other hand, solving (6) gives the theoretical estimate of $\lambda = 0.00506$. Excellent agreement (within 0.5%) is observed.

6. Discussion.

In this paper we have characterized the stability of curved interfaces of the perturbed AC system on a bounded domain. On one hand, it is a

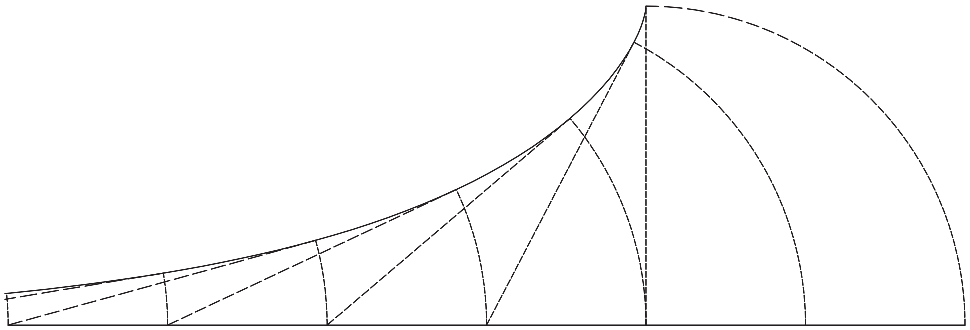

FIG. 6. *A tractrix: the threshold case where all circles intersecting the boundary have identical radius. Theorem* 3 *does not apply to such a domain.*

generalization of the geometric eigenvalue problem derived in [10], [11] for the Allen–Cahn equation without perturbations, which only admits straight interfaces. On the other hand, the perturbed system (1) has been studied on the whole space $\mathbb{R}^2$ without the boundaries—see, for example, [16], [15]. We show that the presence of *both* boundaries and a perturbation can stabilize a curved front. By contrast, the curved front is always unstable in the absence of boundaries—it either shrinks to a point or expands indefinitely depending on the initial conditions [15]. To our knowledge, the characterization of stability that combines both the curvature of the interface and the boundary effect is new.

Algebraically, the stability condition is given by Theorem 2. Geometrically, Theorem 3 states that if $R(s)$ denotes the radius of an arc that intersects the boundary orthogonally at $q_{\pm}(s)$, then the interface is stable if $R'(s) < 0$ whenever $R = \hat{R}$, whereas the interface is unstable if $R'(s) > 0$ at that point (see Figure 2). In particular, this shows explicitly the well-known result that an interface at equilibrium cannot be stable in a convex domain [3]; on the other hand we have shown numerical and theoretical examples where such interface is stable when the domain is nonconvex.

In general, the relationship between the radius R of a circle that intersects the boundary orthogonally and the domain boundary $q = (x, y)$ is given by

$$x = p_1 + R\cos\theta, \qquad y = p_2 + R\sin\theta,$$

where $p = (p_1, p_2)$ is the center of the arc of radius R; p_1, p_2, R are arbitrary functions of s; and θ satisfies a differential equation

$$R\frac{d\theta}{ds} = p_1' \sin\theta - p_2' \cos\theta.$$

An interesting threshold case corresponds to $R = \hat{R}$ for all s. If the bottom boundary is the x-axis and $R = \hat{R}$ for all s, then the top boundary forms a *tractrix* (see Figure 6.) This is a well-known curve that is also generated when a ball is dragged on a fixed string by a tractor moving along the x-axis. Implicitly, this curve is given by

$$x = \hat{R}(-t + \tanh(t)), \quad y = \hat{R}\,\mathrm{sech}(t).$$

It is an open problem to describe either the stability or the location of the interface for such a domain.

An interesting conjecture arises in studying the propagation of fronts around a concave corner. Such domains were used in [17], where the propagation of chemical fronts was considered. An interface passing through the corner may get “stuck” at the corner or go through it, depending on the geometry. If we “smooth out” the corner and take ε sufficiently small, then we can apply Theorem 3. The result is that the interface will get stuck at the corner if there exists a circle that intersects orthogonally with one boundary, and that passes through the corner point, and whose radius is at most $\hat{R}$. This is essentially the geometrical condition described in section III.B in [17] and it agrees well with numerical results presented there. However, the construction of an interface at a corner point is an open theoretical problem.

THREE LIMIT CYCLES IN A LESLIE–GOWER PREDATOR-PREY MODEL WITH ADDITIVE ALLEE EFFECT*

PABLO AGUIRRE†, EDUARDO GONZÁLEZ-OLIVARES‡, AND EDUARDO SÁEZ†

Abstract. In this work, a bidimensional continuous-time differential equations system is analyzed which is derived of Leslie-type predator-prey schemes by considering a nonmonotonic functional response and Allee effect on population prey. For the system obtained we describe the bifurcation diagram of limit cycles that appears in the first quadrant, the only quadrant of interest for the sake of realism. We show that, under certain conditions over the parameters, the system allows the existence of three limit cycles: The first two cycles are infinitesimal ones generated by Hopf bifurcation; the third one arises from a homoclinic bifurcation. Furthermore, we give conditions over the parameters such that the model allows long-term extinction or survival of both populations. In particular, the presence of a weak Allee effect does not imply extinction of populations necessarily for our model.

Key words. stability, limit cycles, homoclinic orbits, bifurcations, predator-prey models, Allee effect

DOI. 10.1137/070705210

1. Introduction.

This work deals with a continuous predator-prey model considering the following: (i) the Allee effect [6, 13, 16, 34] affecting the prey population, (ii) the functional response of predators of nonmonotonic type, and (iii) a predator growth function of logistic type. Other inherent assumptions for the model are that population size varies only in time and it is uniformly distributed in space, there is no division of ages or sex, and it is not affected by abiotic factors.

It is known that the Allee effect refers to a positive density dependence in prey population growth at low prey densities [34], and it occurs whenever fitness of an individual in a small or sparse population decreases as the population size or density also declines [6]. To be able to recognize the consequences of the Allee effect on reproduction, conservation and behavior of species has become an important aim over the last years. The analysis and understanding of this phenomenon can bring important benefits not only for ecology but also for various applied engineering disciplines such as agropecuary, fishing, and forestal industries.

Different mechanisms generating Allee effects have been suggested (see Table 1 in [6]), being largely studied as singular entities and usually describing a situation in which the population growth rate decreases under some minimum critical density [5] or when a limited population growth capacity is observed [15]. In some cases this growth rate might be even negative, causing an extinction threshold [5]. In other words, the Allee effect may be understood as the cause of the increase in extinction risk at low densities [16], introducing in some cases a population threshold that has to be exceeded by population to be able to grow. This effect is also named in population dynamics as the *negative competition effect* [38]; in fisheries sciences, it is called *depensation*

[9, 16], and in epidemiology, its analogous is the *eradication threshold*, the population level of susceptible individuals below which an infectious illness is eliminated from a population [5].

More precisely, the (component) Allee effect is any positive relationship between any measurable component of individual fitness and population size or density [6, 13, 34], and it might be the *strong Allee effect* [6] or *critical depensation* [9] that implies the existence of a threshold population level [5, 9], whereas the *weak Allee effect* [34] or *noncritical depensation* [9] does not have it. When the species is submitted to a strong Allee effect, it may have a bigger tendency to be less able to overcome these additional mortality causes, to have a slower recovery, and to be more prone to extinction than other species [34].

In most predation models it has been considered that the Allee effect has influence only on the prey population, and this effect is independent of the functional response or consumption rate that reflects the change on predation due to the prey's population size. Quantitatively, it is assumed that the functional response has influence on the extension of the bistability region [15].

The Allee effect has been modeled in different ways using various mathematical tools and, in a first approach, like a deterministic phenomenon frequently associated to population's stochastic fluctuations [5]. For instance, if $x = x\left(t\right)$ indicates the population size, the most usual continuous growth equation to express the Allee effect is given by

$$\frac{dx}{dt} = r\ \left(1 - \frac{x}{K}\right)\left(x - m\right)x,$$

featuring the *multiplicative Allee effect.* Clearly, if $m = 0$, we have the weak Allee effect and if $m > 0$, it has the strong Allee effect.

Other mathematical forms have been proposed to describe this phenomenon [8]. In this work, we consider the natural growth function deduced in [16] and [34] given by the equation

$$\frac{dx}{dt} = r\ \left(1 - \frac{x}{K} - \frac{m}{x+b}\right)x \tag{1}$$

that we call *additive Allee effect.*

Recent ecological research suggests the possibility that two or more Allee effects generate mechanisms acting simultaneously on a single population (see Table 2 in [6]), and the combined influence of some of these phenomena has been named the *multiple Allee effects.*

In the interacting populations, the predation can be largely reduced due to better ability of prey to avoid predation when their population size is large enough [42, 43]; but at low population densities, there could be a low effectiveness of antipredator vigilance, which reflects an Allee effect. For some marine species it has been shown that the per capita growth decreases as the size population is reduced below some critical level, and two proposed causes of depensation or Allee effect are the following: reduced breedings success at low densities of the population and increased relative predation on small populations [21]. This situation has happened in many real fisheries as a result of overfishing when man acts as predator [9].

Considering these aspects, (1) can be rewritten as

$$\frac{dx}{dt} = \frac{r\ x}{x+b}\ \left(1 - \frac{x}{x_K}\right)(x - x_m)x, \tag{2}$$

where $x_m = \frac{1}{2}(K - b - \sqrt{\frac{1}{r}(r(K+b)^2 - 4mK)})$ and $x_K = \frac{1}{2}(K - b + \sqrt{\frac{1}{r}(r(K+b)^2 - 4mK)})$ for $r(K+b)^2 - 4mK > 0$. Hence, (2) represents two types of Allee effect affecting the same population since x_m expresses the minimum of viable population and the factor $r\,(x) = \frac{r\,x}{x+b}$ indicates the impact of an Allee effect due to other causes affecting the intrinsic growth rate, for example, the predation reducing breeding success at low densities [9, 21].

On the other hand, the *functional response of predators* or *consumption rate function* refers to the change in the density of prey attached per unit time per predator as the prey density changes [20, 42]. In most predator-prey models considered in the ecological literature, the predator response to prey density is assumed to be monotonic increasing, the inherent assumption being that as there is more prey in the environment, it is better for the predator [20].

However, there is evidence that indicates that this need not always be the case, for instance, when a type of antipredator behavior (APB) exists. *Group defense* is one of these, and the term is used to describe the phenomenon whereby predators decrease, or are even prevented altogether, due to the increased ability of the prey to better defend or disguise themselves when their number is large enough [20, 42, 39, 43], and in this case a nonmonotonic functional response is better. For example, lone musk ox can be successfully attacked by wolves; however, large herds of them can be attacked but with rare success.

Another manifestation of an APB in which a nonmonotonic functional response (or Holling-type IV or Monod Haldane) can be used is the phenomenon of *aggregation*, a social behavior of prey in which prey congregate on a fine scale relative to the predator so that the predator's hunting is not spatially homogeneous [36], such as succeeds with mile-long schools of certain class of fishes. In this case, a primary advantage of schooling seems to be confusion of the predator when it attacks. The more important benefit of aggregation is an increasing in wariness. Moreover, aggregation can both decrease the vulnerability to be attacked and increase the time that group members can devote to activities other than surveillance [36].

Other related examples of nonmonotone consumption occur at the microbial level where evidence indicates that when faced with an overabundance of nutrient the effectiveness of the consumer can begin to decline. This is often seen when microorganisms are used for waste decomposition or for water purification, a phenomenon that is called *inhibition* [20, 42, 43].

In these cases, the functional response curves have an upper bound on the rate of predation per individual predator at some prey density, in contrast to the old Lotka–Volterra model which assumed a linear relationship between prey density and the rate of predation over the entire range of prey densities [36]. In this work, we use the function $h(x) = \frac{qx}{x^2+a}$, also employed in [28, 42, 39, 43] and corresponding to the Holling-type IV functional response [36], which is generalized as $h(x) = \frac{qx}{x^2+bx+a}$ in [44, 40] for a Gause model. This generalized expression is derived by Collings [12], who affirms that this type of functional response seems a reasonable possibility if it is assumed that prey and webbing densities are directly related. In [40], for the corresponding Gause model the existence of two limit cycles is proven. Moreover, this Gause model exhibits bifurcation of cusp type with codimension two [4, 23] or Bogdanov–Takens bifurcation [44, 40].

We note that the phenomena of the Allee effect and aggregation described by a nonmonotonic functional response are quite compatible and justify our assumptions in the model studied.

The last aspect in our equations is a feature of Leslie-type predator-prey models [37] or the Leslie–Gower model [27], in which the conventional environmental carrying capacity K_y is proportional to prey abundance x [31], that is, $K_y = nx$, as in the May–Holling–Tanner model [4] and other models recently analyzed [28, 45].

In [37] it is affirmed that Leslie models can lead to anomalies in their predictions since they predict that even at very low prey density, when the consumption rate by an individual predator is essentially zero, predator population can nevertheless increase if predator population size is even smaller than prey population size. However, Leslie models are recently employed to model vole-weasel dynamics with a parameter time dependent [25], and the autonomous model proposed in [24] is analyzed in [45]. This scheme of modeling differs from a more common Gause-type model [40] in which the predator equation is based on the mass action principle, since the numerical response is dependent on functional response.

Although it may seem that the two aspects considered in the model contradict each other since the prey population exhibits the Allee effect for low densities, while a nonmonotone functional response is suggested for the aggregation (group defense) when the prey population size is large, it is known that predation induces an Allee effect.

Strikingly, a wide range of predator-driven Allee effects have been reported (see Table 2 in [22]); in particular, there is the case of the Atlantic cod (*Gadus morhua*) that forms schools during the day, since commercial fishing (man as predator) provokes stock collapse because a higher proportion of this aggregative population is caught per unit effort when population declines [10].

Also, for obligately cooperative breeders as the African wild dog (*Lycaon pictus*) and meerkat (*Suricata suricatta*), there is a similar situation, because juvenile survival is lower in small groups than large groups in areas with high predator densities but lower in large groups than small groups in areas with low predator densities [14, 22].

From a mathematical point of view, simple models for the Allee effect may reveal a lot about its dynamics, and, reciprocally, different nonequivalent dynamics for the same model will have different biological interpretations. For instance, in our model we obtain the existence of a subset of parameter values for which three limit cycles appear but surrounding different equilibrium points. These limit cycles are not only periodic solutions of the system but also along the attractive behavior of the origin, allowing the phenomenon of *multistability* of our predator-prey system, that is, the existence of four ω-limit sets in the first quadrant.

This paper is structured as follows: The model and the main results are presented in section 2. In section 3 we give the proofs of the main statements. Finally, an interpretation of the results is given in section 4, complemented with some numerical simulations.

2. The model. Let us consider the bidimensional system of ordinary differential equations

$$X_\mu : \begin{cases} \dot{x} = \left[r\left(1-\frac{x}{k}\right) - \frac{m}{x+b}\right]x - \frac{qxy}{x^2+a}, \\ \dot{y} = sy\left(1-\frac{y}{nx}\right), \end{cases} \tag{3}$$

where $(x, y) \in \mathcal{A} = \{(x, y) |\, x > 0, y \geq 0\}$ and $\mu = (r, a, b, k, m, n, q, s) \in \mathbb{R}^8_+$. In system (3), $x(t)$ and $y(t)$ denote prey and predator densities, respectively, as functions of time t. Furthermore, the parameters have the following meanings:

(a) r and s are the intrinsic growth rates or biotic potential of the prey and predators, respectively.

(b) q is the maximal predator per capita consumption rate, i.e., the maximum number of prey that can be eaten by a predator in each time unit.
(c) a is the number of prey necessary to achieve one-half of the maximum rate q.
(d) n is a measure of the food quality that the prey provides for conversion into predator births.
(e) k is the prey environment carrying capacity [12].
(f) m and b are constants that indicate the severity of the Allee effect that has been modeled.

In order to describe the dynamics of X_μ we will consider a C^∞-equivalent polynomial extension by the following change of coordinates:

$$\zeta : \mathbb{R}^2 \times \mathbb{R}_0^+ \longrightarrow \mathbb{R}^2 \times \mathbb{R}_0^+ \text{ such that } \zeta(u, v, \tau) = \left(u, nv, \frac{u(u+b)(u^2+a)\,\tau}{s}\right) = (x, y, t), \tag{4}$$

where $\det D\zeta(u,v,\tau) = \frac{nu(u+b)(u^2+a)}{s} > 0$.

Also, let us consider new parameters given by $\varphi_1 : \mathbb{R}_+^8 \longrightarrow \mathbb{R} \times \mathbb{R}_+^7$,

$$\varphi_1(r, a, b, k, m, n, q, s) = \left(\frac{br-m}{s}, a, b, k, \frac{m}{s}, n, \frac{nq}{s}, s\right) := (L, a, b, k, M, n, c, s),$$

with Jacobian $\det D\varphi_1(r, a, b, k, m, n, q, s) = \frac{s^3}{bn} > 0$, which says that φ_1 is invertible. For simplicity, let us rename the new coordinates $u \to x, v \to y$. Then in the new coordinates we have the vector field $Y_\eta = \zeta_* X_\mu = (D\zeta)^{-1} \circ X_\mu \circ \zeta$, where

$$Y_\eta : \begin{cases} \dot{x} = x\left((a+x^2)\left[\frac{(b+x)(L+M)}{b}\left(1-\frac{x}{k}\right) - M\right]x - cxy(b+x)\right), \\ \dot{y} = (b+x)(a+x^2)(x-y)y, \end{cases} \tag{5}$$

with $(x, y) \in \bar{\Omega} = \{(x,y) | x, y \geq 0\}$ and the new vector of parameters $\eta = (L, a, b, k, M, c) \in \mathcal{D}_0$ is given by the natural projection, where

$$\mathcal{D}_0 = \left\{\eta \in \mathbb{R} \times \mathbb{R}_+^5 \,|\, M + L > 0\right\}. \tag{6}$$

Notice that vector field (5) is a polynomial extension of the original system (3) to the whole first quadrant $\overline{\Omega}$ including axis $x = 0$. Moreover, Y_η and X_μ are clearly C^∞-equivalent in Ω.

First, we study the local behavior of singularities in the coordinate axis, that is, in absence of prey and predator, respectively. In system (5), it is immediate that $Y_\eta(0, y) = -aby^2 \frac{\partial}{\partial y}$. Then the $x = 0$ axis in $\overline{\Omega}$ is an invariant manifold of vector field (5) and the origin is its only singularity, being an attracting one. Moreover, if we denote $Y_\eta(x, y) = P(x, y)\frac{\partial}{\partial x} + Q(x, y)\frac{\partial}{\partial y}$, we have $Y_\eta(x, 0) = P(x, 0)\frac{\partial}{\partial x}$. Hence, the $y = 0$ axis in $\overline{\Omega}$ is also an invariant manifold of (5).

For vector field Y_η let us define $Sing(E)$ and $Sing(\Omega)$ as the sets of singularities of (5) in the $y = 0$ axis in $\overline{\Omega}$ and in the open set Ω, respectively. In order to describe the dynamics of singularities in $Sing(E)$, we consider the following regions in parameter space $\mathcal{D}_0$:

$\Lambda_1 = \Delta^{-1}(-\infty, 0) \cup \left(\Delta^{-1}(0, \infty) \cap \Theta^{-1}(0, \infty) \cap \Upsilon^{-1}(-\infty, 0)\right)$;	
$\Lambda_2 = \Delta^{-1}(0, \infty) \cap \Theta^{-1}(\infty, 0) \cap \Upsilon^{-1}(-\infty, 0)$;	$\Lambda_3 = \{\eta \in \mathcal{D}_0 \,\vert\, 0 < L < b\}$;
$\Lambda_4 = \{\eta \in \mathcal{D}_0 \,\vert\, 0 < b \leq L\}$;	$D = \Delta^{-1}(0) \cap \Theta^{-1}(0, \infty)$;
$\Theta_+ = \Theta^{-1}[0, \infty) \cap \Upsilon^{-1}(0)$;	$\Theta_- = \Theta^{-1}(-\infty, 0) \cap \Upsilon^{-1}(0)$;
$\Gamma_+ = \Gamma^{-1}(0, \infty) \cap \Upsilon^{-1}(0)$;	$\Gamma_- = \Gamma^{-1}(-\infty, 0] \cap \Upsilon^{-1}(0)$;

(7)

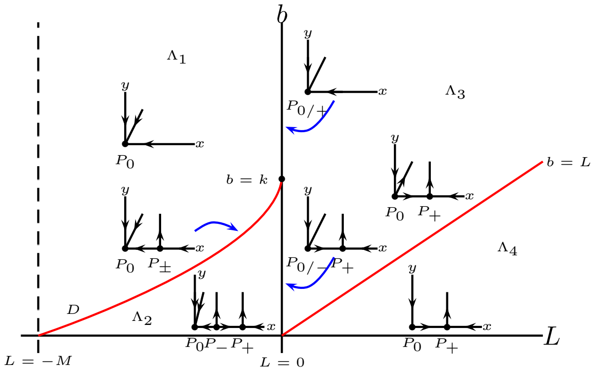

FIG. 1. *Bifurcation diagram in plane $Lb = \{\eta \in \mathcal{D}_0 |\, a, k, M, c \text{ are constant}\}$ in parameter space for singularities in the $y = 0$ axis.*

where $\Upsilon(\eta) = sign(L)$, $\Theta(\eta) = b - k$, and

$$\Delta(\eta) = (M + L)(k - b)^2 + 4bkL,$$
$$\Gamma(\eta) = -2kcb + a\sqrt{M}\left(-a\sqrt{M} + \sqrt{aM + 4k^2c}\right).$$

Moreover, in the xy plane let us consider the points $P_0 = (0, 0)$, $P_+ = (x_+, 0)$, and $P_- = (x_-, 0)$, with

$$x_\pm = \frac{(M + L)(k - b) \pm \sqrt{(M + L)\Delta(\eta)}}{2(M + L)}. \tag{8}$$

LEMMA 1. *For vector field Y_η the origin P_0 is a non-hyperbolic singularity and it satisfies the following:*

(i) *It has two hyperbolic sectors divided by a repulsing separatrix if $\eta \in \Gamma_+ \cap \Theta_+$.*
(ii) *It has only a hyperbolic sector if $\eta \in \Lambda_4$.*
(iii) *It has a hyperbolic sector and a repulsing parabolic sector if $\eta \in \Lambda_3 \cup (\Theta_- \cap \Gamma_+)$.*
(iv) *It has a hyperbolic sector and an attracting parabolic sector if $\eta \in \Theta_- \cap \Gamma_-$.*
(v) *It is a local attractor if $\eta \in D \cup \Lambda_1 \cup \Lambda_2 \cup (\Theta_+ \cap \Lambda_-)$.*

A qualitative diagram of these results in plane $Lb = \{\eta \in \mathcal{D}_0 |\, a, k, M, c \text{ are constant}\}$ is shown in Figure 1.

LEMMA 2. *For vector field Y_η the following statements hold:*

(i) *$P_+ \in Sing(E)$ if $\eta \in D \cup \Theta_- \cup \Lambda_3 \cup \Lambda_4$. Moreover, P_+ is a saddle node if $\eta \in D$; otherwise, it is a hyperbolic saddle.*
(ii) *$P_- \in Sing(E)$ if $\eta \in \Lambda_2$. Moreover, P_- is a hyperbolic repulsing node.*

A qualitative diagram of these results in plane $Lb = \{\eta \in \mathcal{D}_0 |\, a, k, M, c \text{ are constant}\}$ is shown in Figure 1.

About the boundness of the system, in [1] it is proven that no trajectory of vector field Y_η has the infinity as ω-limit. Since the coordinate axes are invariant, then our system is bounded. We now state the same result but with a different approach.

THEOREM 3. *Consider $\mathcal{A}_w = \{(x, y) \in \mathbb{R}^2 : 0 \leq x \leq w, 0 \leq y\}$. For every $\eta \in \mathcal{D}_0$, there is a $w^* \geq 0$ such that if $w > w^*$, then $\mathcal{A}_w$ is a trapping domain for system (5), meaning that it is invariant for positive time evolution and also captures all trajectories starting in $\overline{\Omega}$.*

We take care now of the dynamics at the interior of the first quadrant. It is clear that every singularity of system (5) in the open quadrant Ω must be over the diagonal $y = x$. Furthermore, over the isocline $y = x$ the vector field Y_η has the form $Y_\eta(x, x) = x^2 p_4(x)\frac{\partial}{\partial x}$, where $p_4(x)$ is a polynomial of degree 4 in x. Therefore, the existence of equilibrium points in the open first quadrant is given by the existence of real and positive roots of the polynomial $p_4(x)$. In order to describe the bifurcation diagram for an equilibrium point of Y_η in Ω, we change parameters $\eta = (L, a, b, k, M, c)$ to get a new vector $\xi = (L, a, b, k, V, q)$ by means of the transformation

$$\varphi_2 : \mathbb{R}^6 \longrightarrow \mathbb{R}^6, (L, a, b, k, V, q) \mapsto (L, a, b, k, M(\xi), c(\xi)), \tag{9}$$

with

$$\boxed{\begin{aligned} c(\xi) &= \frac{aLq^4(b-k+2q)-q^6(2b^2+kL-b(2k+L-4q)-2(k+L)q+2q^2)}{kq^6} - \frac{(b-k+q)V}{kq^6b^2(b+q)^5(a+q^2)^2(a+3q^2)},\\ M(\xi) &= \frac{-bq^4(b+q)^6(a+q^2)^2(a+3q^2)(aL+(L-2b)q^2)+V}{bq^6(b+q)^4(a+q^2)^3(a+3q^2)}. \end{aligned}}$$

Let $\mathcal{D}_1 = \varphi_2^{-1}(\mathcal{D}_0)$ be the new admissible region in parameter space, and let us consider the projection

$$\pi : \mathbb{R}^6 \longrightarrow \mathbb{R}^3 \quad \text{such that} \quad \pi(L, a, b, k, q, V) = (L, b, k).$$

If we name

$$\mathcal{D}_2 = \pi\left(\mathcal{D}_1 \cap \{(L, a, b, k, q, V)|\ a = 3b^2, q = b, V > 0\}\right) \cap E^{-1}(0, \infty) \subset \mathbb{R} \times \mathbb{R}^2_+,$$

with

$$E(L, b, k) = -18432b^{19}L + V,$$

it is easy to check that $\mathcal{D}_2 = F^{-1}(0, \infty) \cap E^{-1}(0, \infty)$, with

$$F(L, b, k) = 12288b^{19}(b - 2L) + V.$$

Changing the time $t \mapsto bkt$, let us call Y_ξ to the new vector field qualitatively equivalent to (5). Now, it is straightforward to check that there is a singularity in the isocline $y = x$ at the point with coordinates (b, b). In order to describe the bifurcation diagram of this singularity of vector field Y_ξ in parameter space (L, b, k), we consider the projection (see Figure 2)

$$\pi_R : S^2_R \longrightarrow \mathbb{R}^2 \quad \text{such that} \quad \pi_R(L, b, k) = (L, b),$$

where $S^2_R = \{(L, b, k)|\, L^2 + b^2 + k^2 = R^2, b, k, R > 0\}$. Since function $F(L, b, k)$ does not depend on k, it is clear that in $\mathcal{D}_2 \subset \mathbb{R} \times \mathbb{R}^2_+$ the surface $F^{-1}(0)$ is a straight half-cylinder with axis parallel to the k axis, so $\pi_R\left(F^{-1}(0) \cap S^2_R\right)$ is exactly the curve

$$\mathcal{F} = \{(L, b)|\, F(L, b, k) = 0,\ k > 0\} \cap \pi_R\left(\mathcal{D}_2 \cap S^2_R\right),$$

which is located in the interior of the first quadrant of plane Lb because equation $F(L, b, k) = 0$ defines implicitly $L = \frac{b}{2} + \frac{V}{24576b^{19}} > 0$. Furthermore, $(0, 0) \in F^{-1}(0, \infty)$, so the origin is in the admissible region for parameters in the upper half-plane Lb. The same arguments follow to sketch the curve $\pi_R\left(E^{-1}(0) \cap S^2_R\right)$. With this, the qualitative shape of domain $\pi_R(\mathcal{D}_2 \cap S^2_R)$ is shown in Figure 3(a).

FIG. 3. (a) *Qualitative shape of parameters domain* $\pi_R\left(\mathcal{D}_2 \cap S^2_R\right)$. (b) *Qualitative shape of curves H and $\Sigma^2_0(R)$ in parameters domain.*

Finally, in $\pi_R\left(\mathcal{D}_2 \cap S^2_R\right)$ in plane Lb, we define the sets

$$\begin{aligned} \Sigma_1^{sg(\epsilon)}(R) &= \pi_R\left(\{(L,b,k) \in \mathcal{D}_2 |\, sg(T(L,b,K)) = sg(\epsilon)\} \cap S^2_R\right), \\ \Sigma_2^{sg(\epsilon)}(R) &= \pi_R\left(\{(L,b,k) \in \mathcal{D}_2 |\, sg(G(L,b,K)) = sg(\epsilon)\} \cap S^2_R\right), \\ H &= \Sigma_1^0(R), \end{aligned} \tag{10}$$

with

$$\begin{aligned} T(L,b,k) &= -36864b^{21} + 55296b^{20}L - 18432b^{19}kL - 3bV + kV, \\ G(L,b,k) &= 1811939328b^{39}(b+L)(b+2L) - 8bV^2, \end{aligned}$$

and the qualitative shape of curves H and $\Sigma^0_2(R)$, in terms of R, is as in Figure 3(b). Moreover, $H \cap \Sigma^0_2(R)$ consists of four points as in Figure 3(b), that is,

$$H \cap \Sigma^0_2(R) = \{p_i = (L_i, b_i); i = 1, \ldots, 4\}. \tag{11}$$

LEMMA 4. *The singularity (b,b) of vector field Y_ξ is an order two weak focus if $(L,b) \in H \cap \Sigma^0_2(R) = \{p_i = (L_i, b_i); i = 1, \ldots, 4\}$. Moreover, the focus is repellor at p_1 and p_2 and attractor at p_3 and p_4.*

THEOREM 5.

(i) *The system Y_ξ has a bifurcation diagram as indicated in Figures* 4(a)–(d) *in a neighborhood of $H \cap \Sigma^0_2(R)$.*

(ii) *The bifurcation curve S_{34} of semistable limit cycle of the system Y_ξ in the parameter space $\Sigma^-_1(R)$ is as indicated in Figure* 4(d).

(iii) *The bifurcation curve HC of a homoclinic loop surrounding the focus (b,b) of system Y_ξ is as indicated in Figure* 4(a), *in a tubular neighborhood of curve H in sector $\Sigma^-_2(R)$ in parameter space.*

LEMMA 6. *In parameter space $\xi = (L,a,b,k,q,V) \in \mathcal{D}_1$ of system Y_ξ, there exists an open subset $\Upsilon \subset \left(\pi^{-1} \circ \pi_R^{-1}(p_3)\right) \cap \{\xi \,|\, L < 0\}$, where the following statements hold:*

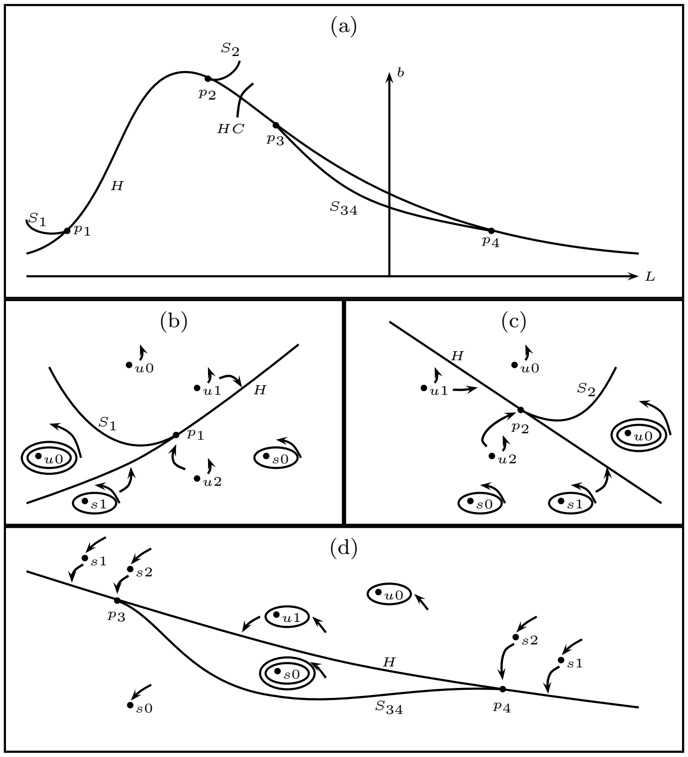

FIG. 4. (a) *Bifurcation curves for focus* (b, b) *of vector field* Y_ξ*, where* H *is a Hopf bifurcation curve,* S_1, S_2*, and* S_{34} *are semistable limit cycle bifurcation curves, and* HC *is a Homoclinic bifurcation curve.* (b) *Bifurcation diagram for focus* (b, b) *in a neighborhood of* $p_1 \in H$*.* (c) *Bifurcation diagram for focus* (b, b) *in a neighborhood of* $p_2 \in H$*.* (d) *Bifurcation diagram for focus* (b, b) *in a tubular neighborhood of curve* H *between* p_3 *and* p_4*. Notation* $\bullet_{ij}$ *means a focus with local stability* $i \in \{s, u\}$ *and weakness* $j \in \{0, 1, 2\}$*.*

(i) Y_ξ *has two foci* $(b, b), (x_f, x_f)$ *and two saddle points* $(x_s, x_s), (x_N, x_N)$ *in the interior of the first quadrant* Ω*, where* $0 < x_s < b < x_N < x_f$*.*

(ii) *There exists an open subset* $\mathcal{O} \in \mathbb{R}_+$ *and a continuous function* $\mathfrak{H} : \mathcal{O} \longrightarrow \mathbb{R}_+$ *such that if* $V = \mathfrak{H}(b)$*, then there is a homoclinic loop* $\mathcal{L}_0$ *for vector field* Y_ξ *passing through saddle* (x_N, x_N) *and surrounding focus* (x_f, x_f)*, with* (x_N, x_N) *and* (x_f, x_f) *as in part* (i)*. Moreover, this homoclinic orbit is inner unstable.*

LEMMA 7. *Let* $\Upsilon, \mathfrak{H}$*, and* $\mathcal{L}_0$ *be as in Lemma* 6*. There exist* $\delta > 0$ *and* $\varepsilon > 0$ *such that, for every* b, V *with* $|\mathfrak{H}(b) - V| < \varepsilon$*, the vector field* Y_ξ *has, at most, one limit cycle* $\mathcal{L}$ *in the inner* δ*-neighborhood of* $\mathcal{L}_0$*, and* $\mathcal{L}$ *is unstable.*

THEOREM 8. *There exists an open subset in parameter space such that vector field* Y_η *in* (5) *has three hyperbolic limit cycles in the interior of the first quadrant* Ω*. Two of them are infinitesimal cycles surrounding a hyperbolic attracting focus* (b, b)*; moreover, the outermost limit cycle is stable and the innermost unstable. The third limit cycle is unstable and surrounds a hyperbolic attracting focus* (x_f, x_f)*, with* $0 < b < x_f$*.*

3. Proofs of the main results. The proofs of Lemmas 1 and 2 are straightforward and follow from the blowing-up method [17] for $(0, 0)$ and the central manifold and Hartman's theorems for P_+ and P_-; for details, see [1].

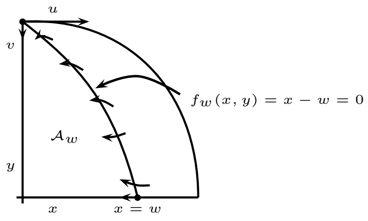

FIG. 5. *The set* $\mathcal{A}_w = f_w^{-1}(-\infty, 0) \cap \overline{\Omega}$ *is an invariant set under* $\Phi_{Y_\eta}(t; \cdot)$, *as stated in the proof of Theorem* 3.

Proof of Theorem 3. We will prove that for every $\eta \in \mathcal{D}_0$ (see (6) for definition), there exists some $w = w(\eta) > 0$ such that the integral curves $\Phi_{Y_\eta}(t; \cdot)$ of vector field Y_η, for $t > 0$, enter an invariant subset $\mathcal{A}_w \subset \overline{\Omega}$ and do not leave again.

Let us define the function $f_w : \mathbb{R}^2 \longrightarrow \mathbb{R}$ given by $f_w(x,y) = x - w$. For each $w > 0$ consider the line

$$L_w = f_w^{-1}(0) \cap \overline{\Omega}.$$

If we consider the Poincaré compactification of system (5) given by

$$\Psi_y : \mathbb{R}^2 \times \mathbb{R}_0^+ \longrightarrow \mathbb{R}^2 \times \mathbb{R}_0^+, \;\; \Psi_y(u, v, \tau) = (u/v, 1/v, \tau) = (x, y, t),$$

it is straightforward to check that the line $\Psi_y^{-1}(L_w)$ contains the point $(u,v) = (0,0)$. Hence, we will show that for w sufficiently large, in the Poincaré compactification of system (5), the compact set $\mathcal{A}_w = f_w^{-1}(-\infty, 0) \cap \overline{\Omega}$ is an invariant set under $\Phi_{Y_\eta}(t; \cdot)$ (see Figure 5).

Recall that the axes $x = 0$ and $y = 0$ are invariant under $\Phi_{Y_\eta}(t; \cdot)$, so it is sufficient to prove that the scalar product $Y_\eta \cdot \nabla f_w < 0$ in L_w for appropriate $w > 0$ as in Figure 5. We have that for $(x,y) \in L_w$

$$Y_\eta \cdot \nabla f_w \,|_{x=w} = -cw^2(b+w)y + \frac{w^2\left(a+w^2\right)}{bk}\,\phi(w),$$

where $\phi(w) = -(M+L)w^2 + (k-b)(M+L)w + bkL$. The discriminant of ϕ as a quadratic polynomial in w is $(M+L)\Delta(\eta)$ (see (7) for definition). Therefore, since $M + L > 0$ in $\mathcal{D}_0$, if $\Delta < 0$, then $Y_\eta \cdot \nabla f_u \,|_{x=w} < 0$ for every $w > 0$. On the other side, if $\Delta \geq 0$, the roots of $\phi(w)$ are x_- and x_+ (see (8) for definition); hence, the statement holds for every $w > x_+$ if $x_+ > 0$ and for every $w > 0$ if $x_+ \leq 0$. This concludes the proof of Theorem 3. □

Proof of Lemma 4. Let $(L,b) \in \pi_R(\mathcal{D}_2 \cap S_R^2)$. In order to study the singularity (b,b) in vector field Y_ξ, we translate (b,b) to the origin and change the time by means of

$$\zeta : \mathbb{R}^2 \times \mathbb{R}_0^+ \longrightarrow \mathbb{R}^2 \times \mathbb{R}_0^+,$$
$$(x,y,t) \mapsto \left(x+b, y+b, \frac{8b^3E(L,b,k)}{768b^{15}}\,t\right),$$

where

$$E(L,b,k) = -18432b^{19}L + V.$$

So if $(L,b,k) \in E^{-1}(0,\infty)$, ζ is a $\mathcal{C}^\infty$-equivalence. Let $Z_\xi = \zeta_* Y_\xi$; then we have

$$\mathrm{tr} DZ_\xi(0,0) = \frac{8E(L,b,k)T(L,b,k)}{589824 b^{25}},$$

with

$$T(L,b,k) = -\left(36864b^{21} - 55296b^{20}L + 18432b^{19}kL + 3bV - kV\right).$$

Moreover, if $(L,b) \in H = \pi_R(T^{-1}(0) \cap S_R^2)$, we have $\det DZ_\xi(0,0) = V > 0$, so the origin is a weak focus of order, at least, one for Z_ξ. In order to recognize the topological type of the origin as $(L,b) \in H$, we bring Z_ξ onto its Jordan canonical form at $(0,0)$. For that, consider the $\mathcal{C}^\infty$-equivalence $\varphi : \mathbb{R}^2 \times \mathbb{R}_0^+ \longrightarrow \mathbb{R}^2 \times \mathbb{R}_0^+$,

$$\varphi(u,v,\tau) = \left(192b^{10}u - \sqrt{V}\,v, 192b^{10}u, \tau/\sqrt{V}\right) = (x,y,t).$$

The qualitatively equivalent vector field in the new coordinates is $Z_\xi^J = \varphi_* Z_\xi$, and we have in a neighborhood of the origin

$$Z_\xi^J(u,v) = \left(-v + \sum_{i,j=2}^{5} A_{i,j}u^i v^j + \text{H.O.T.}\right)\frac{\partial}{\partial u} + \left(u + \sum_{i,j=2}^{5} B_{i,j}u^i v^j + \text{H.O.T.}\right)\frac{\partial}{\partial v},$$

where H.O.T. denotes the higher order term and $A_{i,j} = A_{i,j}(b,V,L)$, $B_{i,j} = B_{i,j}(b,V,L)$.

For $j = 0,1,2$, let l_j be the first three Lyapunov quantities at the origin [2, 7, 33] of the vector field Z_ξ^J. Since the trace of the linear part of the vector field at the origin is zero, we have that $l_0 = 0$. Now, as l_1 depends on the 3-jet of Z_ξ^J, see [17], then

$$l_1 = (A_{02}A_{11} + A_{12} + A_{11}A_{20} + 3A_{30} + 2A_{02}B_{02} + 3B_{03} - B_{02}B_{11} - 2A_{20}B_{20} - B_{11}B_{20} + B_{21})/8.$$

Using the Mathematica software [41] we have

$$l_1 = \frac{36864b^{20} + V}{8192b^{13}V^{3/2}}\, G(L,b,k),$$

with

$$G(L,b,k) = 1811939328b^{39}(b+L)(b+2L) - 8bV^2.$$

Thereby, if $(L,b) \in H \cap \Sigma_2^0(R)$ (see (10) and (11)), the weakness of the origin depends only on l_2. On the other hand, it is known that l_2 depends on the 5-jet of Z_ξ^J. Then, again using the Mathematica software, as $l_0 = l_1 = 0$, we obtain

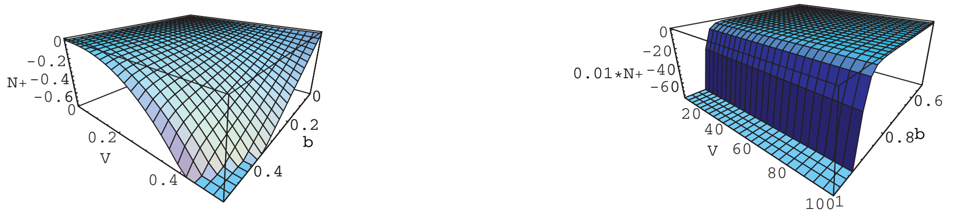
$$l_{2_\pm} = \frac{36864b^{20} + V}{98304b^{15}V^{3/2}} N_\pm,$$

where

$$\begin{aligned} N_\pm = -\big(&-221259535220736b^{61} - 135895449606b^{41}V - 1963008b^{21}V^2 - 57bV^3 \\ &\pm\sqrt{3}\left(303499837744b^{40} + 2211840b^{20}V + 43V^2\right)\sqrt{28311552b^{42} + b^2V^2}\,\big) \end{aligned}$$

and the sign ± denotes the branch

$$L_\pm = \frac{-27648b^{39} \pm \sqrt{3}\sqrt{g(b)}}{36864b^{38}} \tag{12}$$



(a) (b)

FIG. 6. *Graphics of the function* $N_+ = N_+(b, V)$ *where we can see that* $N_+ < 0$*:* (a) *graphic of* N_+ *for* $(b, V) \in [0, 0.5] \times [0, 0.5]$*;* (b) *graphic of* $10^{-2} \times N_+$ *for* $(b, V) \in [0.6, 1] \times [10, 100]$.

of curve $\Sigma_2^0(R)$ given implicitly by equation $G(L, b, k) = 0$, where $g(b) = 28311552b^{78} + b^{38}V^2 > 0$. Since the branch L_- intersects curve H at points p_1 and p_2 (see Figure 3(b)), then if $(L, b) \in \{p_1, p_2\} \subset H \cap \Sigma_2^0(R)$, $l_2 > 0$ and the origin is a repellor weak focus of order two for Z_ξ^J.

On the other hand, the branch L_+ intersects curve H at points p_3 and p_4 (see Figure 3(b)), and by looking at the graphic of N_+ as a function of b and V it can be verified that $N_+ < 0$. Figure 6(a) shows the graphic of N_+ for the range $(b, V) \in [0, 0.5] \times [0, 0.5]$, meanwhile in Figure 6(b) there is the graphic of $10^{-2} \times N_+$ for $(b, V) \in [0.6, 1] \times [10, 100]$, made with the software Mathematica [41]; here it can be seen that if $b > 0, V > 0$, as in our case, then by continuity $N_+ < 0$. Therefore, if $(L, b) \in \{p_3, p_4\} \subset H \cap \Sigma_2^0(R)$, $l_2 < 0$ and the origin is an attracting weak focus of order two for Z_ξ^J. □

Proof of Theorem 5(i). It is clear that $T^{-1}(0)$ and S_R^2 are transversal manifolds in the parameter space and, by Lemma 4, there are four points

$$p_1, p_2, p_3, p_4 \in \pi_R \left(T^{-1}(0) \cap S_R^2\right) = H,$$

where H is a Hopf bifurcation curve and where the singularity (b, b) is a repellor weak focus of order 2 of system Y_ξ at p_1 and p_2 and an attractor weak focus of order two at p_3 and p_4; i.e., the eigenvalues of $DY_\xi(b, b)$ are on the imaginary axes and nonzero. Moreover, $p_1, p_2, p_3,$ and p_4 have codimension two, since the Lyapunov quantities $l_0 = l_1 = 0$ and $l_2 \neq 0$.

Thereby, let $(L, b) \in H - \{p_1, p_2, p_3, p_4\}$. Then we have the following (see Figure 7):

(a) In a neighborhood of p_4, when (L, b) is below $l_1^{-1}(0)$, the singularity (b, b) of system Y_ξ is an order one attractor weak focus, because $l_1 < 0$. Therefore, if $\epsilon > 0$ is sufficiently small, the point $(L + \epsilon, b + \epsilon)$ is over the curve H; then the stability of system Y_ξ at the singularity (b, b) is reversed; hence, a unique hyperbolic stable limit cycle bifurcates (Hopf bifurcation).

(b) When (L, b) is above $l_1^{-1}(0)$ in a neighborhood of p_4, the singularity (b, b) is an order one repellor weak focus surrounded by a hyperbolic stable limit cycle, because $l_1 > 0$; then Hopf bifurcation from p_4 occurs. Therefore, if $\epsilon > 0$ is sufficiently small, the point $(L + \epsilon, b)$ is over the curve H; hence, the stability of system Y_ξ at the singularity (b, b) does not change and the limit cycle persists because it is hyperbolic.

(c) When the point (L, b) is as in case (b), for $\epsilon > 0$ sufficiently small, the point $(L - \epsilon, b)$ is under the curve H; then the stability of system Y_ξ at the singularity (b, b) is reversed; hence, a new Hopf bifurcation occurs and a

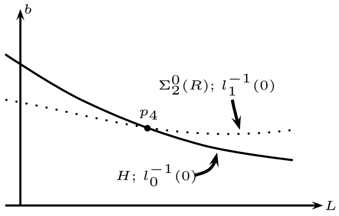


FIG. 7. *Hopf bifurcation curve H near point p_4 in parameter space, where the singularity (b, b) of vector field Y_ξ is an order two attracting weak focus.*

second hyperbolic limit cycle bifurcates, which is surrounded by a hyperbolic stable limit cycle.

By normal forms theory [17, 23], p_4 has a 2-parameter versal unfolding. Under the same hypothesis that we have here, Takens [35] and Arrowsmith and Place [3] describe in detail the bifurcation diagram for codimension two singularity type. By using their results, we have that there exists a neighborhood $\mathcal{V}_\delta(p_4)$, with $\delta > 0$, such that it has a diagram as in Figure 4, where S_{34} is a curve in which the unstable and stable limit cycles collapse (semistable limit cycle). The analysis near points p_1, p_2, and p_3 follows in the same way.

Proof of Theorem 5(ii). From part (i) of this Theorem, there is an open set $\mathcal{C}(R) \subset \Sigma_1^-(R)$ where system Y_ξ has two hyperbolic limit cycles surrounding the singularity (b, b). Moreover, $\mathcal{C}(R)$ is upperly bounded by the segment of curve H between p_3 and p_4, because at any point in that segment focus (b, b) is surrounded by a unique infinitesimal limit cycle.

On the other hand, at $\Sigma_1^-(R) \backslash \mathcal{C}(R)$, the singularity (b, b) has no infinitesimal limit cycle in its vicinity, so $\mathcal{C}(R)$ is bounded and the lower bound must correspond to a bifurcation curve where both limit cycles collapse into a semistable limit cycle; hence, by versality of the unfolding of the singularity (b, b) at p_3 and p_4 described in part (i) (see [35, 3]), it is clear that the semistable limit cycle bifurcation curve S_{34} must be as in Figure 4(d).

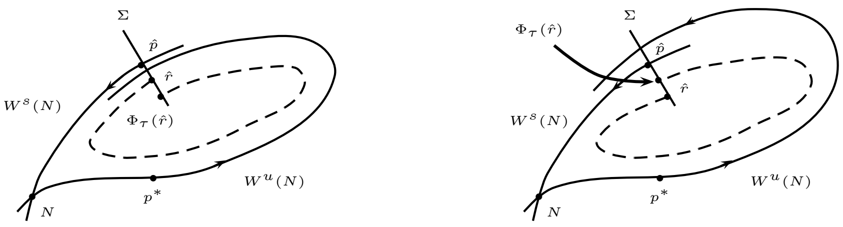
Proof of Theorem 5(iii). By Hartman–Grobman's theorem it is straightforward to see that vector field Y_ξ has a hyperbolic saddle singularity $P_s = (s, s)$ with $0 < s < b$ if $(L, b) \in H \cap \Sigma_2^-(R)$.

Let $(L, b) \in H \cap \Sigma_2^-(R)$ in a neighborhood of p_3. By part (i), (b, b) is an attracting weak focus of order one with no limit cycle in its vicinity, and it can be checked that $P_s \in \alpha-\lim(b, b)$. As we move along segment $H \cap \Sigma_2^-(R)$ towards p_2, the topological type of focus (b, b) remains the same according part (i); however, if $(L, b) \in H \cap \Sigma_2^-(R)$ in a neighborhood of p_2, $P_s \in (\alpha-\lim(b, b))^c$ and an infinitesimal limit cycle exists surrounding (b, b). Therefore, there exist $\delta > 0$ sufficiently small and a differentiable function

$$\Psi : V_\delta(H) \longrightarrow \mathbb{R} \quad \text{such that} \quad (L, b) \mapsto \Psi(L, b),$$

defined in a tubular neighborhood $V_\delta(H)$ of radius δ of segment $H \cap \Sigma_2^-(R)$ such that vector field Y_ξ has a homoclinic loop passing through the saddle P_s and surrounding focus (b, b), if $(L, b) \in HC = \Psi^{-1}(0)$.

Remark. An extended and deeper proof of the existence of a homoclinic loop surrounding another singularity is given in Lemma 6. Nevertheless, the same arguments might have been used in this case as well. □



(a) (b)

FIG. 8. *Poincaré map for orbits near* $W^s(N)$ *in two cases:* (a) $W^u(N) \cap W^s(x_f) \neq \emptyset$; (b) $W^u(N) \cap W^s(x_f) = \emptyset$.

Proof of Lemma 6(i). Let $(L, b) = p_3 \in H \cap \Sigma_2^0$. It is easy to check that Y_ξ has four singularities in isocline $y = x$ at Ω, if $L < 0$. According to Lemma 4, one of these equilibria is an attracting weak focus of order two in (b, b). Due to Hartman–Grobman's theorem, it is straightforward to see that the other singularities are a hyperbolic attracting focus in (x_f, x_f) and two saddles (x_s, x_s), (x_N, x_N) with $0 < x_s < b < x_N < x_f$. The statement follows directly.

Proof of Lemma 6(ii). Let (x_N, x_N) and (x_f, x_f) be as in the proof of part (i). If we name $N = (x_N, x_N)$, let us consider the function

$$\mathfrak{D}(N) = \nabla \cdot Y_\xi(N),$$

and let $\Phi_t = \Phi_{Y_\xi}(t; \cdot)$ be the flow of Y_ξ and $p^* = (x^*, y^*)$ be a point in $W^u(N)$ with $x_N < x^*$. Let Σ be a one-dimensional local cross section to $W^s(N) \cup W^u(N)$ as in Figure 8. Let $\hat{p} = (\hat{p}_1, \hat{p}_2)$ the unique point of $\Sigma \cap W^s(N)$ which never returns to Σ by the flow Φ_t with $0 < t < \infty$, and let $U \subset \Sigma$ be some neighborhood of $\hat{p}$. In Σ let us choose local coordinates given by the chart $h : \Sigma \longrightarrow \mathbb{R}$, $h(x, y) = y - \hat{p}_2$.

Let us consider the *Poincaré map* $\mathcal{P} : U \longrightarrow \Sigma$ defined for a point $r \in U$ by $\mathcal{P}(r) = \Phi_\tau(r)$, where $\tau = \tau(r)$ is the time taken for the orbit $\Phi_\tau(r)$ based at r to first return to Σ. Now consider the displacement function $d : U \longrightarrow \mathbb{R}$ given by

$$r \mapsto d(r) = \mathcal{P}(r) - r.$$

Finally, let $\hat{r}$ be a point in U located below $\hat{p}$ as in Figure 8.

Let $b = 1$ and $V = 300$. Then it can be seen by means of numerical simulations on Matlab [30] that $\mathfrak{D}(N) > 0, W^u(N) \cap W^s(x_f) \neq \emptyset, W^u(N) \cap W^s(N) = \emptyset$, and $\omega - \lim \Phi_t(p^*) = \{(x_f, x_f)\}$. In the local coordinates given by h this implies that

$$d(\hat{r}) < 0. \tag{13}$$

A qualitatively equivalent situation is shown in Figure 8(a).

Instead, if $b = 1$ and $V = 400$, it can be checked (numerically as well) that $\mathfrak{D}(N) > 0$, $W^u(N) \cap W^s(x_f) = \emptyset$, and $W^u(N) \cap W^s(N) = \emptyset$; there exists $y^\dagger > x_N$ such that the point $(x_N, y^\dagger) \in \Phi_t(p^*) \subset W^u(N)$. Therefore, we have (see Figure 8(b))

$$d(\hat{r}) > 0. \tag{14}$$

Hence, by the continuous dependence of the orbits of the vector field on parameters, there exists V^*, $300 < V^* < 400$, such that for $b = 1$ and $V = V^*$ we have $W^u(N) \cap W^s(N) \neq \emptyset$; that is, there is a homoclinic loop $\mathcal{L}_0 \subset W^u(N) \cap W^s(N)$.

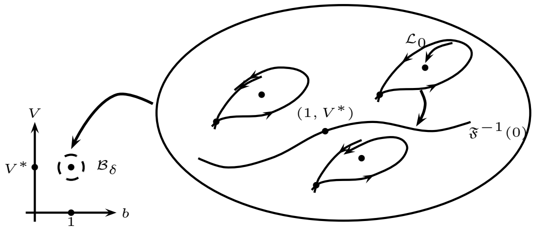


FIG. 9. *Existence of a homoclinic orbit along the curve* $\mathfrak{F}^{-1}(0)$ *in plane* bV.

Therefore, there exists $\delta > 0$ such that in a δ-ball $\mathcal{B}_\delta(1, V^*) \subset \mathbb{R}^2_+$ of the point $(1, V^*)$ in plane bV in parameter space, there is a locally differentiable function

$$\mathfrak{F} : \mathcal{B}_\delta(1, V^*) \longrightarrow \mathbb{R}, \ \ (b, V) \mapsto \mathfrak{F}(b, V),$$

such that if $(b, V) \in \mathfrak{F}^{-1}(0)$, there exists an inner unstable homoclinic loop $\mathcal{L}_0$ for vector field Y_ξ (see Figure 9). The existence of the function $\mathfrak{H} : \mathcal{O} \longrightarrow \mathbb{R}_+$ in the statement follows from the implicit function theorem, due to the transversality shown in passing from (13) to (14). □

Proof of Lemma 7. Let the function $d : U \longrightarrow \mathbb{R}$, the saddle $N = (x_N, x_N)$, and the point $\hat{r}$ be as in the proof of Lemma 6 (see Figure 8). From the previous lemma, a homoclinic bifurcation (see [29]) occurs as $V = \mathfrak{H}(b)$ since, by continuity, $\mathfrak{D}(N) = \nabla \cdot Y_\xi(N) > 0$, N is a *strong* saddle [29], and $\mathcal{L}_0$ is inner unstable. Then, for U sufficiently small, by carrying out a perturbation on parameters, such that $d(\hat{r}) > 0$, the homoclinic cycle breaks out and an unstable limit cycle appears surrounding the attracting focus (x_f, x_f). □

Proof of Theorem 8. From Lemmas 4 and 7, in parameter space $\xi = (L, a, b, k, q, V) \in \mathcal{D}_1$ of system Y_ξ, there exists an open subset $\Upsilon_{\mathcal{L}} \subset \left(\pi^{-1} \circ \pi_R^{-1}(p_3)\right) \cap \{\xi \,|\, L < 0\}$, where system Y_ξ has four singularities in the interior of the first quadrant Ω: two saddles $(x_s, x_s), (x_N, x_N)$, a two-order attracting weak focus (b, b), and a hyperbolic attracting focus (x_f, x_f) surrounded by an unstable limit cycle $\mathcal{L}$, with $0 < x_s < b < x_N < x_f$. Moreover, this limit cycle is hyperbolic, so it persists in an open subset of $\pi^{-1}(\pi_R^{-1}(\mathcal{C}(R)))$ in parameter space, where $\mathcal{C}(R)$ is the bounded sector in plane Lb (see Figure 4(d)) where system Y_ξ also has two infinitesimal limit cycles surrounding focus (b, b), due to the proof of Theorem 5(ii).

The statement of the theorem is immediate after recalling that vector field Y_ξ is induced by a vector field $\mathcal{C}^\infty$-equivalent to Y_η by means of the local difeomorphism φ_2 in (9), since

$$\det D\varphi_2(\xi) = \frac{V}{b^3 q^{12} (b+q)^{10} (a+q^2)^4 (a+3q^2)^3} > 0,$$

where $\xi \in \mathcal{D}_1 \cap \pi^{-1}(T^{-1}(0))$. □

4. Discussion. In this paper, a predator-prey model with the Allee effect [5, 16, 34, 38] and a Holling-type IV [36] functional response was considered, making a qualitative analysis of a bidimensional system of ordinary differential equations of polynomial type, which is topologically equivalent to the original one, with only six parameters. Employing a reparameterization and a time change, we showed that b, k, and $L = \frac{br-m}{s}$ are the most significative parameters of this predator-prey model. We note that this model predicts that, when $L < 0$, the system has three equilibria

P_0, P_-, and P_+ for which the predator density is null; moreover, at low population densities, both predator and prey populations may disappear, since the equilibrium $P_0 = (0, 0)$ is an attractor; furthermore, P_- is a repelling node, and P_+ is a saddle.

Unlike other models, in this work we show that the weak Allee effect does not imply extinction of species necessarily for certain parameter values, which, as far as we know, is a completely new feature for the continuous model that has not been reported in the above works. As $L = 0$, P_- collapses with the origin and a weak Allee effect is obtained if P_+ remains an isolated singularity. In this case, the model predicts two phenomena depending on parameter values. In the first one, the origin has a separatrix dividing a repelling parabolic sector and a hyperbolic sector; see Lemma 1(iii). This means that every solution with initial conditions (x_0, y_0) in the interior of the first quadrant near the origin ultimately tends to go away from the origin allowing both populations to not extinct.

The second case is more usual, see Lemma 1(iv), and has been observed in previous works [19, 32]; that is, the origin has a parabolic attracting sector and a hyperbolic sector divided by an attracting separatrix, representing a critical line which has to be trespassed for populations in order to survive in time and not extinct.

In this work, we also show in Theorem 8 that, for an open subset of the parameter values, three limit cycles can coexist in the open quadrant Ω. This result has been recently observed [26] but just in general cubic polynomial systems. In our case, only two of these limit cycles are concentric though, since infinitesimal ones are generated by Hopf bifurcation, and the third one is generated by a homoclinic bifurcation [23, 29] and surrounds another focus as stated in Lemma 6 and Theorem 8.

Furthermore, the model can achieve the phenomenon of *multistability* by the existence of four ω-limit sets in the first quadrant as $L < 0$ and a strong Allee effect is present. A locally stable cycle surrounds a locally stable equilibrium point in the first quadrant as well as an unstable limit cycle, which serves as their separatrix in the phase plane; i.e., there is a range for population sizes for which there exists both autoregulation for the predator-prey system and prey and predator populations approach equilibrium, depending upon the population size. The third ω-limit set is the origin, stating that extinction is always possible in the presence of a strong Allee effect in our model. The fourth ω-limit set is a stable focus surrounded by the third limit cycle mentioned above.

In order to illustrate the result stated in Theorem 8 and the *multistability*, Figure 10 shows a numerical simulation for system (5), which was affected with the software MATLAB [30]. Here $a = 3$, $b = 1$, $k = 6.79211$, $M = 4.07697$, $c = 4.05116$, and $L = L_+ + 0.000001 \approx -0.498898$ (see (12)). Initial conditions at $(x(0), y(0))$ are $(0.8, 0.8)$, $(1.01, 1.01)$, $(2, 2)$, $(2.2, 2.2)$, $(1, 0.95)$, and $(0.4, 0.1)$.

In Figure 10 it is clear that a limit cycle lies between the orbits by the points $(2, 2)$ and $(2.2, 2.2)$, respectively, since the ω-limit of $(2, 2)$ is the origin, but the ω-limit of $(2.2, 2.2)$ is the stable focus located in the diagonal near $x = 2.5$. On the other hand, the two infinitesimal limit cycles are surrounding the singular point $(1, 1)$, but they are too small for both the scale of this figure and these values of parameters. Hence, we present another numerical simulation in Figure 11 where both infinitesimal limit cycles are more visible. Here $a = 3$, $b = 1$, $k = 6.56102$, $M = 4.16516$, $c = 4.16276$, and $L = L_+ + 0.01 \approx -0.480256$ (see (12)). Initial conditions at $(x(0), y(0))$ are $(0.6, 0.6)$, $(0.8, 0.8)$, and $(0.95, 0.95)$.

Behaviors of the three positive oriented orbits in Figure 11 imply that, between two of them, attracting and repelling limit cycles exist. Furthermore, it can be easily verified that, for these values of parameters, the divergence of vector field (5) in singu-

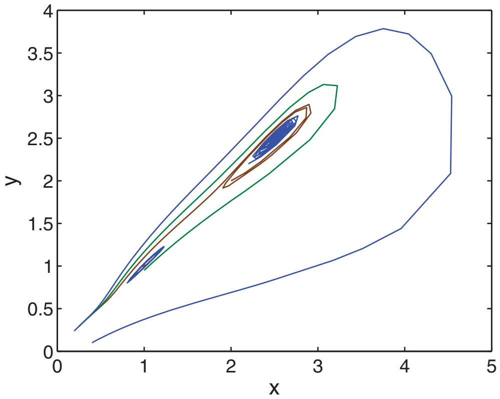

FIG. 10. *Numerical simulation of the results of Theorem* 8.

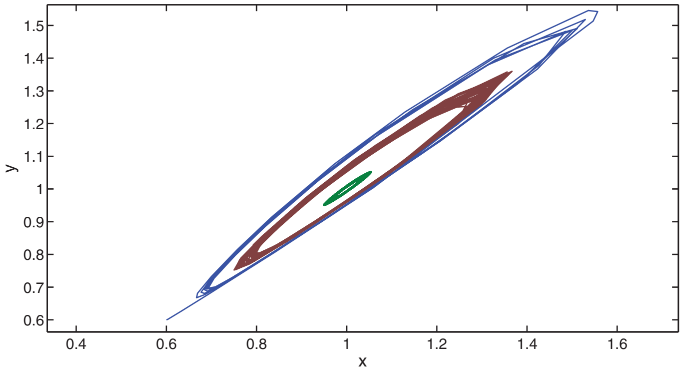

FIG. 11. *Numerical simulation of the infinitesimal limit cycles.*

larity $(1, 1)$ is negative, and, consequently, this equilibrium point is a local attractor and the innermost limit cycle is the unstable one.

Several natural predator-prey communities have been studied, each one of them featuring an ecologically stable cycle, that is, a periodic orbit that must be somewhat insensitive to the perturbations outer to the interaction.

In this work, we have answered partially one of the almost impossible projects proposed in [11] which is the following: Find a predator-prey or other interacting system in nature, or construct one in the laboratory, with at least two ecologically stable cycles.

This shows the ecological relevance of the existence of multiple limit cycles in predation models and the importance of our result, which should serve for the outlined problem to be actually feasible in a biological lab with appropriate little creatures [11].

DOUBLE-DIFFUSIVE CONVECTION IN A POROUS LAYER IN THE PRESENCE OF VIBRATION*

NATALIA STRONG†

Abstract. The present paper examines the effect of vertical harmonic vibration on the onset of convection in an infinite horizontal layer of a binary fluid mixture saturating a porous medium. A constant temperature and concentration distribution are assigned on the rigid boundaries, so that there exist vertical temperature and concentration gradients. The mathematical model is described by equations of filtration convection in the Darcy–Oberbeck–Boussinesq approximation. The linear stability analysis for the quasi-equilibrium solution is performed using Floquet theory. Employing the method of continued fractions allows derivation of the dispersion equation for the Floquet exponent in an explicit form. The neutral curves of the Rayleigh number versus horizontal wave number are constructed for the three types of instability modes: synchronous, subharmonic, and complex conjugate. Asymptotic formulas for these curves are derived for large values of vibration frequency using the method of averaging. It is shown that, at some finite frequencies of vibration, there exist regions of parametric instability. Investigations carried out in the paper demonstrate that, depending on the governing parameters of the problem, vertical vibration can significantly affect the stability of the system by increasing or decreasing its susceptibility to convection. In addition, even in the presence of vibration, the onset of convection in the system is affected by variations in the concentration of the solute in the mixture.

1. Introduction.

Natural double-diffusive convection in fluid-saturated porous media has received much attention during the last few decades and has practical importance in many fields such as geophysics, oceanography, ecology, chemistry, and metallurgy. Specific areas of application range from the flow of groundwater to oil recovery, underground storage of waste products, food processing, and building insulation.

Double-diffusive convection in an infinite horizontal layer of a porous medium was first investigated by Nield using linear stability analysis [1] and was later extended by Taunton and Lightfoot [2]. Rudraiah, Srimani, and Friedrich [3] applied nonlinear stability analysis to the case of a porous layer with isothermal and isosolutal boundaries. Further works on double-diffusive convection in porous media include Brand and Steinberg [4], Murray and Chen [5], and Mamou and Vasseur [6]. An extensive review of the literature on natural convection in fluid-saturated porous media may be found in the fundamental monograph by Nield and Bejan [7].

In addition to free convection in porous media, an important class of problems involves convective instability in the presence of time-dependent body forces, one of which is vibration. The time-dependent gravitational field is of great interest, for example, in space laboratory experiments, crystal growth, petroleum production, and large-scale atmospheric convection.

Although much has been published on convection in the presence of vibration in fluids, only limited attention has been given to this phenomenon in porous media. The onset of convection in a region of fluid saturating a porous medium subjected to high-frequency vibration of arbitrary direction has been examined by Zen'kovskaya [8] and Zen'kovskaya and Rogovenko [9] using the averaging method. It was shown that the direction of vibration has a significant effect on the stability of the system. Malashetty and Padmavathi [10] performed asymptotical analysis of the linear stability of a horizontal fluid-saturated porous layer heated from below for the case of small-amplitude gravity modulation. Bardan and Mojtabi [11] studied, numerically and analytically, convection in a rectangular saturated porous cavity heated from below and subjected to high-frequency vibration. They concluded that high-frequency vibration moves the onset of convection toward higher values of the Rayleigh number. Jounet and Bardan [12] generalized the work described above to the case of a binary mixture saturating a porous medium. They found that high-frequency vibration can delay or speed up the onset of convection depending on the governing parameters of the problem. Govender [13] analytically investigated convection in a porous layer heated from below for the case of low-amplitude vibration and showed that increasing the frequency of vibration stabilizes the convection.

In the present paper, we generalize the work on the pure fluid case [14] to a binary fluid mixture saturating a porous medium. Specifically, we investigate the effect of vertical vibration of arbitrary frequency and amplitude on the onset of convection in a horizontal layer of a porous medium saturated by a binary fluid mixture. Previous studies of this problem were restricted to the case of high frequency and/or small amplitude of vibration due to the limitations of the methods used. This paper's novel application of the method of continued fractions to the above-described problem eliminates these restrictions and enables consideration of vibration of arbitrary frequency and amplitude. Moreover, employing the method of continued fractions allows derivation of the dispersion equation for the Floquet exponent in an explicit form. This dispersion equation is used to find the critical values of parameters and to construct the neutral curves corresponding to the three types of transition to instability: the synchronous, subharmonic, and complex conjugate modes. In the case of high-frequency vibration, the system is investigated using the method of averaging, which reduces the dispersion equation for the Floquet exponent to a cubic equation. Comparing the results obtained by the two methods described above allows us to find the range of vibration parameter values for which the method of continued fractions can be replaced by the method of averaging in numerical computations.

The structure of the paper is as follows. Section 2 describes the mathematical model and the mechanical quasi-equilibrium solution to the system. Linear stability analysis of this quasi-equilibrium solution is performed in section 3 following Floquet theory and employing the method of continued fractions. The case of high-frequency vibration of the layer is considered in section 4 using the averaging method. Section 5 presents and discusses the results of the numerical computations.

2. Problem description and basic equations. We consider an infinite horizontal layer of a porous medium saturated by a binary mixture of nonreacting components. The layer and its boundaries are subjected to vertical harmonic vibration. We assume that the fluid component of the mixture is viscous and incompressible, the porous medium is homogeneous and isotropic, and the boundaries are rigid and impermeable, with slip allowed. Constant and uniform temperature and concentration distributions are specified at the boundaries, so that there exist vertical temperature and concentration gradients.

The equation of state has the following form:

$$\rho = \rho_0[1 - \beta(T - T_0) + \beta_c(C - C_0)],$$

where ρ is the density of the fluid mixture, T is the temperature of the fluid mixture and the porous medium, and C is the concentration of the heavier component of the fluid mixture; $\rho_0 = \rho(T_0, C_0)$ is the density at some reference temperature T_0 and concentration C_0, β is the coefficient of the thermal expansion of the fluid mixture, and β_c is the coefficient of the concentration expansion of the fluid mixture ($\beta > 0$ and $\beta_c > 0$). We assume that $T_0 = 0$, $C_0 = 0$, and variations of the temperature and concentration in the fluid are sufficiently small.

The basic governing equations for the problem are the momentum equation for a porous medium, the energy conservation equation, the mass conservation equation, and the continuity equation. We assume that the Oberbeck–Boussinesq approximation is valid, which implies that the density variation is included only in the gravitational term of the momentum equation. In the Cartesian coordinate system inflexibly fixed to the oscillating horizontal layer, with the z-axis directed vertically upward and the origin at the lower plate, the governing equations have the following form:

$$\frac{1}{\varphi}\frac{\partial \mathbf{v}}{\partial t} = -\frac{1}{\rho}\nabla p - \frac{\nu}{K}\mathbf{v} + g(t)\left(\beta T - \beta_c C\right)\mathbf{k}, \tag{2.1}$$

$$\varkappa\frac{\partial T}{\partial t} + \mathbf{v}\cdot\nabla T = \chi\nabla^2 T, \tag{2.2}$$

$$\varphi\frac{\partial C}{\partial t} + \mathbf{v}\cdot\nabla C = D_m\nabla^2 C, \tag{2.3}$$

$$\nabla\cdot\mathbf{v} = 0, \tag{2.4}$$

where $\mathbf{v} = (v_1, v_2, v_3)$ is the relative filtration velocity of the fluid mixture, p is the convective pressure, φ is the porosity of the medium, ν is the kinematic viscosity of the fluid mixture, K is the intrinsic permeability of the porous medium, $\mathbf{k}$ is the unit vector directed upward, $\varkappa$ is the heat capacity ratio (porous medium versus fluid), χ is the thermal diffusivity of the porous medium, and D_m is the mass diffusivity of the porous medium.

Due to the vertical vibration of the layer, the gravitational field $g(t)$ in the momentum equation consists of two parts: $g(t) = g_0 + g_e(t)$. The first term g_0 is the steady acceleration due to the static gravity. The second term $g_e(t) = \frac{A}{\varphi}\,\Omega^2 f''(\tau)$ represents the vibrational acceleration and implies that the vertical motion of the layer is described by the formula $z = Af(\tau)$. Here $\tau = \Omega t$, A is the amplitude, Ω is the frequency of vibration, and $f(\tau)$ is a 2π-periodic function with zero 2π-average:

$$\langle f\rangle := \frac{1}{2\pi}\int_0^{2\pi} f(\tau)d\tau = 0.$$

We consider the boundary conditions

$$z = 0: \qquad v_3 = 0, \qquad T = T_1, \qquad C = C_1, \tag{2.5}$$

$$z = h: \qquad v_3 = 0, \qquad T = T_2, \qquad C = C_2, \tag{2.6}$$

which imply constant and uniform distribution of temperature and concentration along the rigid and impermeable walls, where slip is allowed. No assumptions are made about the relative size of the temperature boundary conditions (T_1 versus T_2) or concentration boundary conditions (C_1 versus C_2), meaning that the temperature and concentration gradients can be of any sign.

The system (2.1)–(2.6) has a solution corresponding to the quasi-equilibrium basic state:

$$\mathbf{v}^0 = 0, \quad T^0 = T_1 - \frac{1}{h}(T_1 - T_2)z, \quad C^0 = C_1 - \frac{1}{h}(C_1 - C_2)z,$$
$$p^0 = \rho g(t)\left[\left(\beta T_1 - \beta_c C_1\right)z - \frac{1}{2h}\Big(\beta(T_1 - T_2) - \beta_c(C_1 - C_2)\Big)z^2\right]. \tag{2.7}$$

To analyze the stability of this basic state by using the linearization method, we introduce small perturbations of the variables:

$$\mathbf{v} = \mathbf{v}^0 + \mathbf{u}, \qquad p = p^0 + q, \qquad T = T^0 + \theta, \qquad C = C^0 + S. \tag{2.8}$$

The following scales are used to nondimensionalize the variables:

$$(x, t, \mathbf{v}, p, T, C) \to \left(h, \frac{h^2}{\nu}, \frac{\nu}{h}, \frac{\rho\nu^2}{K}, ah, bh\right),$$

where $a = (T_1 - T_2)/h$ and $b = (C_1 - C_2)/h$ are the quasi-equilibrium temperature and concentration gradients, respectively. The dimensionless linearized system has the following form (with notation for the dimensionless variables being the same as for corresponding dimensional variables):

$$c\frac{\partial \mathbf{u}}{\partial t} = -\nabla q - \mathbf{u} + \left(1 + \eta f''(\tau)\right)\left(\mathrm{Gr}\,\theta - \mathrm{Gr}_c S\right)\mathbf{k}, \tag{2.9}$$
$$\varkappa\frac{\partial \theta}{\partial t} - u_3 = \frac{1}{\mathrm{Pr}}\nabla^2\theta, \tag{2.10}$$
$$\varphi\frac{\partial S}{\partial t} - u_3 = \frac{1}{\mathrm{Sc}}\nabla^2 S, \tag{2.11}$$
$$\nabla \cdot \mathbf{u} = 0, \tag{2.12}$$

where $c = \frac{K}{\varphi h^2}$, $\mathrm{Gr} = \frac{\beta a h^2 g_0 K}{\nu^2}$ is the thermal Grashoff number, $\mathrm{Gr_c} = \frac{\beta_c b h^2 g_0 K}{\nu^2}$ is the concentration Grashoff number, $\mathrm{Pr} = \frac{\nu}{\chi}$ is the Prandtl number, $\mathrm{Sc} = \frac{\nu}{D_m}$ is the Schmidt number, and $\eta = \frac{A\Omega^2}{\varphi g_0}$ and $\omega = \frac{\Omega h^2}{\nu}$ are the nondimensional amplitude and frequency of vibration, respectively. Dimensionless boundary conditions are

$$z = 0: \qquad u_3 = \theta = S = 0, \tag{2.13}$$
$$z = 1: \qquad u_3 = \theta = S = 0. \tag{2.14}$$

3. Derivation of the dispersion equation for the Floquet exponent $\boldsymbol{\sigma}$. In order to eliminate pressure and the horizontal components of velocity from the system (2.9)–(2.14), we apply the curl operator twice to (2.9). The z-component of the resulting equation has the following form:

$$\left(c\frac{\partial}{\partial t} + 1\right)\nabla^2 u_3 = \Big(1 + \eta f''(\tau)\Big)\left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)\Big[\mathrm{Gr}\,\theta - \mathrm{Gr}_c S\Big]. \tag{3.1}$$

Now we consider the system of equations (2.10), (2.11), and (3.1) with the boundary conditions (2.13)–(2.14). The x- and y-variables can be separated from this system by introducing the following representation for the perturbations of vertical velocity, temperature, and concentration:

$$\begin{bmatrix} u_3 \\ \theta \\ S \end{bmatrix} (x, y, z, t) = \begin{bmatrix} \widetilde{u_3} \\ \widetilde{\theta} \\ \widetilde{S} \end{bmatrix} (z, t)\ e^{i(\alpha_1 x + \alpha_2 y)}.$$

Substituting this representation into the system of equations (2.10), (2.11), and (3.1) reduces it to the following form:

$$\left(c\frac{\partial}{\partial t} + 1\right) \left[\frac{\partial^2}{\partial z^2} - \alpha^2\right] \widetilde{u_3} = -\alpha^2 \Big(1 + \eta f\,''(\tau)\Big) \left[\mathrm{Gr}\ \widetilde{\theta} - \mathrm{Gr}_c\ \widetilde{S}\right], \tag{3.2}$$

$$\varkappa \frac{\partial \widetilde{\theta}}{\partial t} - \widetilde{u_3} = \frac{1}{\mathrm{Pr}} \left(\frac{\partial^2}{\partial z^2} - \alpha^2\right) \widetilde{\theta}, \tag{3.3}$$

$$\varphi \frac{\partial \widetilde{S}}{\partial t} - \widetilde{u_3} = \frac{1}{\mathrm{Sc}} \left(\frac{\partial^2}{\partial z^2} - \alpha^2\right) \widetilde{S}, \tag{3.4}$$

where $\alpha^2 = \alpha_1^2 + \alpha_2^2$ is the square of the overall horizontal wave number. Boundary conditions for this system are

$$z = 0,\ z = 1: \qquad \widetilde{u_3} = \widetilde{\theta} = \widetilde{S} = 0. \tag{3.5}$$

Now we separate the z-variable from the system (3.2)–(3.4) using the following representation:

$$\begin{bmatrix} \widetilde{u}_3 \\ \widetilde{\theta} \\ \widetilde{S} \end{bmatrix} (z, t) = \begin{bmatrix} \widehat{u}_3 \\ \widehat{\theta} \\ \widehat{S} \end{bmatrix} (t) \sin(\pi \ell z), \qquad \ell = 1, 2, 3, \dots.$$

After the substitutions $t = \widehat{t}\sqrt{\mathrm{Pr}\,\varkappa c}$ and $\omega = \widehat{\omega}/\sqrt{\mathrm{Pr}\,\varkappa c}$, we obtain a system of ODEs with periodic coefficients:

$$\frac{c}{r}\frac{d\widehat{u}_3}{d\widehat{t}} = -\widehat{u}_3 + \frac{\alpha^2}{m^2}\Big(1 + \eta f\,''(\tau)\Big)\left(\mathrm{Gr}\ \widehat{\theta} - \mathrm{Gr}_c \widehat{S}\right), \tag{3.6}$$

$$\frac{\varkappa}{r}\frac{d\widehat{\theta}}{d\widehat{t}} = \widehat{u}_3 - \frac{m^2}{\mathrm{Pr}}\widehat{\theta}, \tag{3.7}$$

$$\frac{\varphi}{r}\frac{d\widehat{S}}{d\widehat{t}} = \widehat{u}_3 - \frac{m^2}{\mathrm{Sc}}\widehat{S}, \tag{3.8}$$

where $m^2 = \alpha^2 + (\pi\ell)^2$ and $r = \sqrt{\mathrm{Pr}\,\varkappa c}$. For the rest of the paper, we omit the hat in $\widehat{t}$ and $\widehat{\omega}$ and assume that $f(\tau) = \cos\omega t$ in (3.6).

Following Floquet theory (see [15]), we search for the solution to the system (3.6)–(3.8) in the form of a Fourier series:

$$\begin{bmatrix} \widehat{u}_3 \\ \widehat{\theta} \\ \widehat{S} \end{bmatrix} (t) = e^{\sigma t} \sum_{n=-\infty}^{+\infty} \begin{bmatrix} w_n \\ \theta_n \\ S_n \end{bmatrix} e^{in\omega t}. \tag{3.9}$$

The Floquet exponent σ needs to be chosen in such a way that solution (3.9) is nonzero. The set of all possible values of σ defines the *Floquet spectrum* of the system

(3.6)–(3.8). The behavior of solution (3.9), and therefore the stability of the quasi-equilibrium basic state (2.7) of the original system, is determined by the distribution of the Floquet spectrum with respect to the imaginary axis in the complex σ-plane. If the whole spectrum is located in the left half-plane, the basic state (2.7) is asymptotically stable. If at least one point of the spectrum is located in the right half-plane, the basic state (2.7) is unstable. The points of the spectrum where $\operatorname{Re}(\sigma) = 0$ correspond to the *neutral curves* (or *marginal curves*) in the parameter space, which separate regions of stability and instability.

Substituting representation (3.9) into the system (3.6)–(3.8) and collecting coefficients of $e^{in\omega t}$ for each n, we obtain an infinite system of linear algebraic equations for the Fourier coefficients w_n, θ_n, S_n:

$$\begin{aligned}\frac{2m^2}{\alpha^2\eta}\left[c(\sigma+in\omega)+1\right]w_n &= \mathrm{Gr}_c\left(S_{n-1}+S_{n+1}-\frac{2}{\eta}S_n\right)\\ &\quad-\mathrm{Gr}\left(\theta_{n-1}+\theta_{n+1}-\frac{2}{\eta}\theta_n\right),\\ w_n &= \left[\varkappa(\sigma+in\omega)+\frac{m^2}{\mathrm{Pr}}\right]\theta_n,\\ w_n &= \left[\varphi(\sigma+in\omega)+\frac{m^2}{\mathrm{Sc}}\right]S_n, \qquad n=0,\pm1,\pm2,\dots.\end{aligned}$$

By eliminating the variables w_n and S_n from this system, we transform it into an infinite tridiagonal system of linear algebraic equations for the coefficients θ_n:

$$M_n\theta_n + q_{n-1}\theta_{n-1} + q_{n+1}\theta_{n+1} = 0, \qquad n = 0, \pm1, \pm2, \dots, \tag{3.10}$$

$$\text{with} \qquad M_n = (\sigma+\ in\omega)^2 + \left(\frac{m^2}{P}+P\right)(\sigma+\ in\omega) + \left(m^2 - \frac{2q_n}{\eta}\right), \tag{3.11}$$

$$q_n = \frac{\alpha^2\eta}{2m^2}\left[\mathrm{Ra} - \mathrm{Rs}\frac{(\sigma+\ in\omega)+\dfrac{m^2}{P}}{\mathrm{L}(\sigma+\ in\omega)+\dfrac{m^2}{P}}\right], \quad \mathrm{L} = \mathrm{Le}\,\frac{\varphi}{\varkappa}, \quad P = \sqrt{\frac{\mathrm{Pr}\,\varkappa}{c}}\,. \tag{3.12}$$

Here $\mathrm{Ra} = \mathrm{Gr}\cdot\mathrm{Pr}$ is the thermal Rayleigh number, $\mathrm{Rs} = \mathrm{Gr_c}\cdot\mathrm{Sc}$ is the concentration Rayleigh number, and $\mathrm{Le} = \mathrm{Sc}/\mathrm{Pr}$ is the Lewis number.

We use the method of continued fractions to solve the system (3.10) (see Meshalkin and Sinai [16], followed by Yudovich [17], Markman and Yudovich [18], and Yudovich et al. [19]). Substituting $\zeta_n = \frac{\theta_{n-1}}{\theta_n}$ (in the assumption that $\theta_n \neq 0$, which is verified in [18]) transforms the system (3.10) into

$$M_n + q_{n-1}\zeta_n + \frac{q_{n+1}}{\zeta_{n+1}} = 0, \qquad n = 0, \pm1, \pm2, \dots,$$

which can be used to derive two recurrence relations for the unknown ζ_n:

$$\begin{aligned}\zeta_n &= -\frac{1}{q_{n-1}}\left(M_n + \frac{q_{n+1}}{\zeta_{n+1}}\right),\\ \zeta_n &= \frac{-q_n}{M_{n-1}+\zeta_{n-1}\,q_{n-2}}.\end{aligned}$$

Each of these two relations for ζ_n yields a corresponding continued fraction expression:

$$\zeta_n = -\frac{M_n}{q_{n-1}} - \cfrac{q_{n+1}/q_{n-1}}{-\cfrac{M_{n+1}}{q_n} - \cfrac{q_{n+2}/q_n}{-\cfrac{M_{n+2}}{q_{n+1}} - \cfrac{q_{n+3}/q_{n+1}}{-\cfrac{M_{n+3}}{q_{n+2}} - \cdots}}}\,, \tag{3.13}$$

$$\zeta_n = \cfrac{q_n}{-M_{n-1} - \cfrac{q_{n-1}q_{n-2}}{-M_{n-2} - \cfrac{q_{n-2}q_{n-3}}{-M_{n-3} - \cdots}}}\,. \tag{3.14}$$

The right-hand sides of relations (3.13) and (3.14) are equal to each other for any integer value of n. Therefore, assigning $n = 0$, we obtain the dispersion equation for the Floquet exponent σ in the explicit form

$$M_0 - \cfrac{q_0\ q_1}{M_1 - \cfrac{q_1\ q_2}{M_2 - \cfrac{q_2\ q_3}{M_3 - \cdots}}} = \cfrac{q_0\ q_{-1}}{M_{-1} - \cfrac{q_{-1}q_{-2}}{M_{-2} - \cfrac{q_{-2}q_{-3}}{M_{-3} - \cdots}}}. \tag{3.15}$$

Equation (3.15) can be used to determine the Floquet spectrum of the system (3.6)–(3.8) with all the values of parameters being fixed. Alternatively, (3.15) can be used to determine the critical values of parameters, corresponding to transition from stability to instability of the basic state (2.7), and to construct the corresponding neutral curves.

Convergence of continued fractions from (3.15) was verified numerically. Moreover, the sufficient condition for the absolute convergence of the continued fraction in the left-hand side of (3.15) is

$$|M_n| \geq 1 + |q_{n-1}\, q_n|, \qquad n = 1, 2, 3, \ldots. \tag{3.16}$$

It follows from (3.11) and (3.12) that $|M_n|$ is proportional to n^2 and $|q_n|$ is proportional to $O(1)$. Hence, there exists some N such that condition (3.16) is satisfied for any $n \geq N$. This fact guarantees the conditional convergence of the continued fraction in the left-hand side of (3.15) (see [20]). The same argument (with n being replaced by $-n$) can be used to prove conditional convergence of the continued fraction in the right-hand side of (3.15).

Now we consider two particular cases for which (3.15) simplifies to a real form:

1. For the case $\sigma = 0$, corresponding to synchronous modes with period $2\pi/\omega$, the expressions for M_n and q_n are simplified so that

$$M_{-n} = \overline{M_n} \qquad \text{and} \qquad q_{-n} = \overline{q_n}\,.$$

Therefore, dispersion equation (3.15) for the case $\sigma = 0$ transforms into

$$\operatorname{Re}\left(\cfrac{q_0\ q_1}{M_1 - \cfrac{q_1\ q_2}{M_2 - \cfrac{q_2\ q_3}{M_3 - \cdots}}} \right) = \frac{M_0}{2}. \tag{3.17}$$

2. For the case $\sigma = \frac{i\omega}{2}$, corresponding to subharmonic modes with period $4\pi/\omega$, the expressions for M_n and q_n are simplified so that
$$M_{-n} = \overline{M_{n-1}} \qquad \text{and} \qquad q_{-n} = \overline{q_{n-1}}\,.$$
Therefore, dispersion equation (3.15) for the case $\sigma = \frac{i\omega}{2}$ transforms into
$$\left| M_0 - \cfrac{q_0\ q_1}{M_1 - \cfrac{q_1\ q_2}{M_2 - \cfrac{q_2\ q_3}{M_3 - \cdots}}} \right|^2 = q_0^2. \tag{3.18}$$

Transcendental equations (3.17) and (3.18) were investigated numerically to obtain the neutral curves of the Rayleigh number Ra versus the horizontal wavenumber α for the synchronous and subharmonic modes. In addition to the synchronous and subharmonic modes, which also occur in the case of a pure fluid saturating a porous medium, instability in the binary mixture case can occur via a complex conjugate mode. In order to construct the neutral curves $\mathrm{Ra}(\alpha)$ for complex conjugate modes, we solve a complex equation (3.15) for the two variables: the thermal Rayleigh number and the frequency of neutral oscillations. Results of the numerical computations are presented in section 5.

4. The case of a rapidly oscillating external force. In the limiting case of high-frequency vibration, we apply the Krylov–Bogoliubov averaging method to investigate the stability of the basic state (2.7) of the original system (see [21], [8], [9]). First, we eliminate the variable $\widehat{u}_3$ from the system (3.6)–(3.8) (with the hat omitted in $\widehat{t}$ and $\widehat{\omega}$) and reduce it to the form
$$\begin{aligned}\widehat{\theta}\,''(t) + \left(\frac{m^2}{P} + P\right)\widehat{\theta}\,'(t) + \left(m^2 - \frac{\alpha^2}{m^2}\mathrm{Ra}\,(1 - \eta\cos\omega t)\right)\widehat{\theta}(t)\\ + \frac{\alpha^2}{m^2}\,\mathrm{Rs}\ \mathrm{Le}^{-1}\,(1 - \eta\cos\omega t)\,\widehat{S}(t) = 0,\end{aligned} \tag{4.1}$$
$$\widehat{\theta}\,'(t) + \frac{m^2}{P}\widehat{\theta}(t) = \frac{\varphi}{\varkappa}\ \widehat{S}\,'(t) + \frac{m^2}{P}\mathrm{Le}^{-1}\widehat{S}(t). \tag{4.2}$$

Now, assuming $\omega \to \infty$, we represent the nondimensional amplitude of vibration in the form $\eta = B\omega$, where $B = \frac{b\,\nu}{\varphi\,g_0 h^2} = O(1)$ is the nondimensional amplitude of vibration velocity. Following the averaging method, we introduce a new "fast" time variable $\tau = \omega t$ and decompose the solution to the system (4.1)–(4.2) in the following way:
$$\begin{bmatrix} \widehat{\theta} \\ \widehat{S} \end{bmatrix}(t) \sim \begin{bmatrix} \bar{\theta} \\ \bar{S} \end{bmatrix}(t) + \frac{1}{\omega}\begin{bmatrix} \widetilde{\theta} \\ \widetilde{S} \end{bmatrix}(\tau, t), \tag{4.3}$$
where $\big(\bar{\theta}(t),\ \bar{S}(t)\big)$ is a slowly varying part, which is a function of the "slow" time t only, and $\big(\widetilde{\theta}(\tau,t),\ \widetilde{S}(\tau,t)\big)$ is a rapidly oscillating part, which is a function of τ and t. The functions $\widetilde{\theta}(\tau,t)$ and $\widetilde{S}(\tau,t)$ are assumed to be 2π-periodic in τ and have zero mean with respect to τ. Substituting representation (4.3) into the system (4.1)–(4.2)

and retaining the principal ($O(1)$) terms, we obtain a system of equations for the rapidly oscillating part $\big(\widetilde{\theta}(\tau,t),\ \widetilde{S}(\tau,t)\big)$:

$$\widetilde{\theta}_{\tau\tau}(\tau,t) = \frac{\alpha^2}{m^2} B\cos\tau\big(\mathrm{Rs}\,\mathrm{Le}^{-1}\bar{S}(t) - \mathrm{Ra}\,\bar{\theta}(t)\big), \tag{4.4}$$

$$\frac{\varphi}{\varkappa}\,\widetilde{S}_{\tau}(\tau,t) = \widetilde{\theta}_{\tau}(\tau,t). \tag{4.5}$$

Integrating this system with respect to the "fast" time τ (under the assumption that $\bar{\theta}(t)$ and $\bar{S}(t)$ do not depend on τ) gives us expressions for the rapidly oscillating part:

$$\widetilde{\theta}(\tau,t) = \frac{\alpha^2}{m^2} B\cos\tau\left(\mathrm{Ra}\;\bar{\theta}(t) - \mathrm{Rs}\;\mathrm{Le}^{-1}\bar{S}(t)\right), \tag{4.6}$$

$$\widetilde{S}(\tau,t) = \frac{\alpha^2}{m^2}\frac{\varkappa}{\varphi} B\cos\tau\left(\mathrm{Ra}\;\bar{\theta}(t) - \mathrm{Rs}\;\mathrm{Le}^{-1}\bar{S}(t)\right). \tag{4.7}$$

Now we substitute these expressions back into (4.3), then substitute the resulting expressions for $\widehat{\theta}(t)$ and $\widehat{S}(t)$ into the system (4.1)–(4.2), and take the average of this system with respect to the "fast" time τ over the modulation period 2π. This process leads to the system of averaged equations for the slowly varying component $\big(\bar{\theta}(t),\ \bar{S}(t)\big)$:

$$\begin{aligned}\bar{\theta}''(t) + \left(\frac{m^2}{P} + P\right)\bar{\theta}'(t) + \left(m^2 - \frac{\alpha^2}{m^2}\mathrm{Ra}\right)\bar{\theta}(t) + \frac{\alpha^2}{m^2}\;\mathrm{Rs}\;\mathrm{Le}^{-1}\bar{S}(t)\\ + \frac{\alpha^4 B^2}{2m^4}\left(\mathrm{Ra}\,\bar{\theta}(t) - \mathrm{Rs}\;\mathrm{Le}^{-1}\bar{S}(t)\right)\left(\mathrm{Ra} - \frac{\varkappa}{\varphi}\,\mathrm{Rs}\;\mathrm{Le}^{-1}\right) = 0,\end{aligned} \tag{4.8}$$

$$\bar{\theta}'(t) - \frac{\varphi}{\varkappa}\;\bar{S}'(t) = \frac{m^2}{P}\left(\mathrm{Le}^{-1}\;\bar{S}(t) - \bar{\theta}(t)\right). \tag{4.9}$$

This is a system of autonomous equations with constant coefficients. Searching for the solution to this system in the form

$$\begin{bmatrix}\bar{\theta}(t)\\ \bar{S}(t)\end{bmatrix} = \begin{bmatrix}C_1\\ C_2\end{bmatrix} e^{\sigma t}, \quad \text{where} \quad C_1, C_2 = \mathrm{const},$$

yields the characteristic equation for the complex growth rate σ, which determines the stability of the quasi-equilibrium basic state (2.7) in the limiting case of $\omega \to \infty$:

$$b_0\sigma^3 + b_1\sigma^2 + b_2\sigma + b_3 = 0, \tag{4.10}$$

$$\text{where} \quad \mathrm{L} = \mathrm{Le}\,\frac{\varphi}{\varkappa}, \qquad b_0 = \mathrm{L}, \qquad b_1 = \frac{m^2}{P}\,(\mathrm{L}+1) + \mathrm{L}\,P,$$

$$b_2 = \frac{\alpha^4 B^2}{2m^4\mathrm{L}}\,(\mathrm{Rs} - \mathrm{Ra}\,\mathrm{L})^2 + \frac{\alpha^2}{m^2}\,(\mathrm{Rs} - \mathrm{Ra}\;\mathrm{L}) + \left(\frac{m^2}{P} + P\right)\frac{m^2}{P},$$

$$b_3 = \frac{m^2}{P}\left[\frac{\alpha^4 B^2}{2m^4\,\mathrm{L}}\,(\mathrm{Rs} - \mathrm{Ra}\,\mathrm{L})\,(\mathrm{Rs} - \mathrm{Ra}) + \frac{\alpha^2}{m^2}\,(\mathrm{Rs} - \mathrm{Ra}) + m^2\right].$$

For the case of transition to monotonic instability ($\sigma = 0$), the equation for the neutral curves is obtained from the characteristic equation (4.10) and has the form $b_3 = 0$, or

$$\frac{\alpha^4 B^2}{2m^4\,\mathrm{L}}\,(\mathrm{Rs} - \mathrm{Ra}\,\mathrm{L})\,(\mathrm{Rs} - \mathrm{Ra}) + \frac{\alpha^2}{m^2}\,(\mathrm{Rs} - \mathrm{Ra}) + m^2 = 0. \tag{4.11}$$

For the case of transition to oscillatory instability, which occurs via a complex conjugate mode ($\sigma = is,\ s \neq 0$), the equation for the neutral curves is obtained from the characteristic equation (4.10) and has the form $b_0 b_3 - b_1 b_2 = 0$, or

$$\begin{aligned} &\frac{m^2}{P}\mathrm{L}\left[\frac{\alpha^4 B^2}{2m^4\,\mathrm{L}}\,(\mathrm{Rs}-\mathrm{Ra}\,\mathrm{L})\,(\mathrm{Rs}-\mathrm{Ra}) + \frac{\alpha^2}{m^2}\,(\mathrm{Rs}-\mathrm{Ra}) + m^2\right] \\ &\quad = \left(\frac{\alpha^4 B^2}{2m^4\mathrm{L}}\,(\mathrm{Rs}-\mathrm{Ra}\,\mathrm{L})^2 + \frac{\alpha^2}{m^2}\,(\mathrm{Rs}-\mathrm{Ra}\ \mathrm{L}) + \left(\frac{m^2}{P}+P\right)\frac{m^2}{P}\right) \\ &\quad \times \left(\frac{m^2}{P}\,(\mathrm{L}+1) + \mathrm{L}\,P\right). \end{aligned} \tag{4.12}$$

The formula for the square of the frequency s of the neutral oscillations has the form $s^2 = b_2/b_0$, or

$$s^2 = \frac{1}{\mathrm{L}}\left[\frac{\alpha^4 B^2}{2m^4\mathrm{L}}\,(\mathrm{Rs}-\mathrm{Ra}\,\mathrm{L})^2 + \frac{\alpha^2}{m^2}\,(\mathrm{Rs}-\mathrm{Ra}\,\mathrm{L}) + \left(\frac{m^2}{P}+P\right)\frac{m^2}{P}\right]. \tag{4.13}$$

In order to construct the neutral curves for the complex conjugate modes (the case of oscillatory instability), we solve a system of equations (4.12) and (4.13) for the thermal Rayleigh number Ra and the frequency of neutral oscillations s. Neutral curves in the parameter space (Ra, α) obtained by the method of averaging for the cases of monotonic and oscillatory instability are presented in section 5. Note that, for the system of a pure fluid saturating a porous medium in the presence of vibration, instead of a cubic equation (4.10) we have a quadratic equation for the growth rate σ (see [14]), which can be used to prove that oscillatory instability is not possible in this case. Further analysis of (4.11) and (4.12) allows additional conclusions concerning the stability of the system under the influence of vibration and the presence of solute in the mixture. For example, under zero gravity, vertical vibration can cause instability in the binary mixture case, but not in the case of pure fluid.

5. Numerical results. The purpose of the performed numerical computations is twofold. First, we investigate the behavior of the resonant instability regions of the basic state (2.7), obtained by the method of continued fractions. Second, we find the range of vibration parameter values that provide close agreement between the results obtained by the method of continued fractions and the averaging method.

The computer code (in MATLAB) for constructing the neutral curves by the method of continued fractions solves (3.17) for the case of synchronous modes and (3.18) for the case of subharmonic modes. The continued fractions are truncated once the desired precision (10^{-4} for this paper) is achieved. For all the figures in this section, parameters not specified on the plots are chosen to be $\mathrm{Pr} = 0.733$, $l = 1$, and $c = 1$.

Neutral curves in the parameter space (Ra, α) obtained by the method of continued fractions for the synchronous and subharmonic modes are presented in Figures 5.1 and 5.2. Negative values of the thermal Rayleigh number Ra, corresponding to heating of the layer from the top, are considered in both cases. The concentration Rayleigh number Rs is chosen to be positive in Figure 5.1 (corresponding to higher concentration of the heavier component on the bottom of the layer) and negative in Figure 5.2 (corresponding to higher concentration of the heavier component on the top of the layer). Regions inside the neutral curves indicate the resonant instability of the quasi-equilibrium basic state (2.7). The alternating pattern of the instability regions

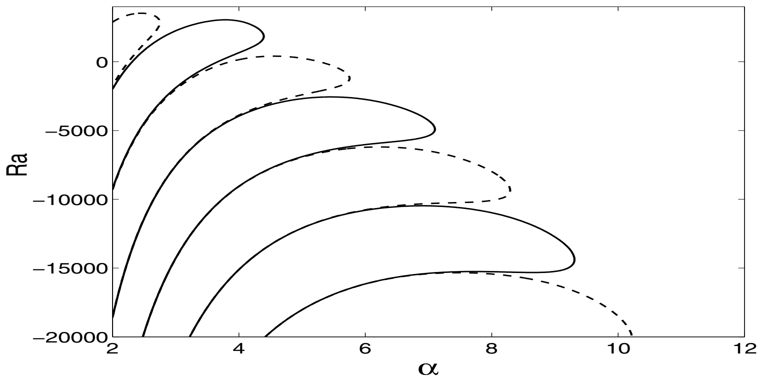

Fig. 5.1. *Neutral curves of* Ra *versus* α *for synchronous (solid line) and subharmonic (dashed line) modes, obtained by the method of continued fractions;* $\omega = 30,\ \eta = 3,\ \mathrm{Rs} = 5000,\ \mathrm{L} = 0.5.$

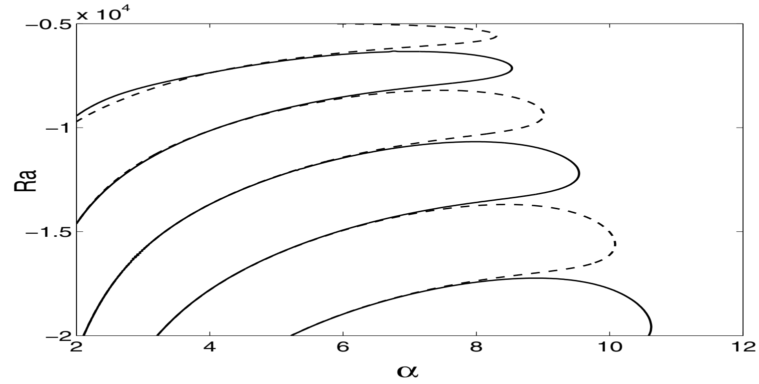

Fig. 5.2. *Neutral curves of* Ra *versus* α *for synchronous (solid line) and subharmonic (dashed line) modes, obtained by the method of continued fractions;* $\omega = 30,\ \eta = 3,\ \mathrm{Rs} = -5000,\ \mathrm{L} = 0.5.$

corresponding to synchronous and subharmonic modes can be observed in Figures 5.1 and 5.2. The values of parameters in Figures 5.1 and 5.2 correspond to the stable regime of the basic state for the case with no vibration (see [7]). Hence, the existence of the instability regions demonstrates that vertical vibration can destabilize a stable system by inducing convection in it.

Comparison of Figures 5.1 and 5.2 shows that decreasing the value of Rs (with the values of all the other parameters being fixed) causes the regions of instability to change shape (become more elongated) and move toward lower values of Ra along the vertical axis. In general, how (and if) the shape of the instability regions changes with Rs depends on the value of parameter $\mathrm{L} = \mathrm{Le}\,\varphi/\varkappa$. The change in shape observed by comparison of Figures 5.1 and 5.2 corresponds to $\mathrm{L} = 0.5$ or, more generally, $\mathrm{L} < 1$. When $\mathrm{L} > 1$, the regions of instability become more elongated as the value of Rs increases. When $\mathrm{L} = 1$, the instability regions do not change in shape with varying of Rs but simply move upward or downward along the vertical axis. The fact that the change in the instability regions depends on L can be observed by considering formula (3.12).

Neutral curves (synchronous modes) in the parameter space (Ra, α) obtained by the method of continued fractions and the averaging method are presented in Figure

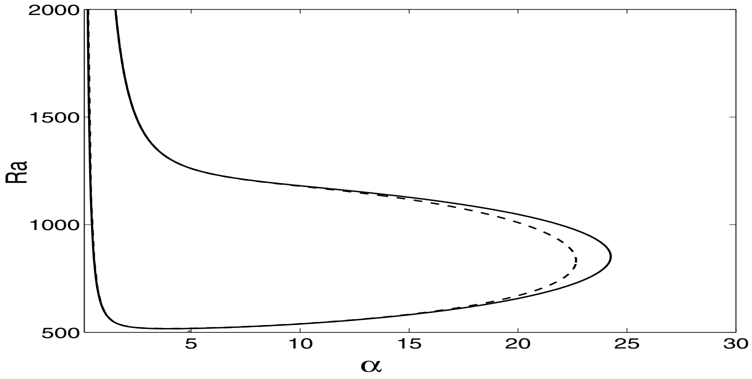

FIG. 5.3. *Neutral curves of* Ra *versus* α *for synchronous modes, obtained by the method of continued fractions (dashed line) and by the method of averaging (solid line);* $\omega = 5000$, $\eta = 500$ *for the method of continued fractions;* $\mathrm{Rs} = 500$, $\mathrm{L} = 0.5$.

5.3. The computer code (in MATLAB) solves (3.17) for constructing the neutral curves by the method of continued fractions and (4.11) for constructing the neutral curves by the method of averaging. Positive values of Ra, corresponding to heating of the layer from below, are considered in Figure 5.3. The value of the frequency ω for the curve obtained by the method of continued fractions is chosen to be 5000, which provides reasonably close agreement with the curve obtained by the averaging method in the assumption $\omega \to \infty$. This agreement improves as the value of the frequency ω in the method of continued fractions increases. Table 5.1 provides some illustrative examples using the data in Figure 5.3.

TABLE 5.1

Values of Ra *from the lower neutral curves in Figure* 5.3 *obtained by the method of continued fractions and the method of averaging (rows with* $\omega = 5000$*). Values of* Ra *obtained by setting* $\omega = 10000$ *are shown for comparison, and percent errors are shown for the method of averaging relative to the method of continued fractions.*

α	ω	Ra cont. fractions	Ra averaging method	relative error (%)
5	5000	518.54	517.78	0.15
5	10000	534.61	534.19	0.08
15	5000	582.91	581.39	0.26
15	10000	679.19	678.78	0.06

The region inside the neutral curves corresponds to instability of the basic state (2.7). The whole range of values of Ra in Figure 5.3 corresponds to the monotonic instability regime of the basic state in the unmodulated case. Hence, based on this figure, we can conclude that vertical vibration can reduce the instability region of the basic state and therefore stabilize the system.

An interesting phenomenon, which is discovered using the averaging method in the binary mixture case (and is not present in the case of a pure fluid), is the existence of closed regions of instability of the basic state (2.7). Such instability regions in the parameter space (Ra, α) are shown in Figures 5.4 and 5.5 for the case of monotonic instability and oscillatory instability, respectively. Analytically, existence of these closed regions can be predicted by considering (4.11) and (4.12) as quadratic equations for Ra. Double roots of these equations indicate the points in the parameter

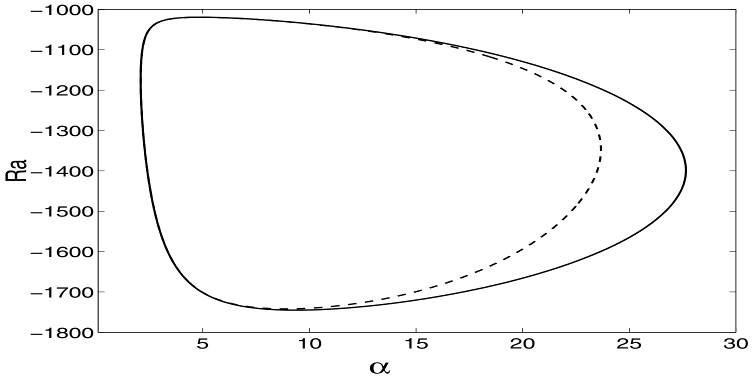

FIG. 5.4. *Neutral curves of* Ra *versus* α *for synchronous modes, obtained by the method of continued fractions (dashed line) and by the method of averaging (solid line);* $\omega = 5000,\ \eta = 500$ *for the method of continued fractions;* $\mathrm{Rs} = -1000,\ \mathrm{L} = 0.5$.

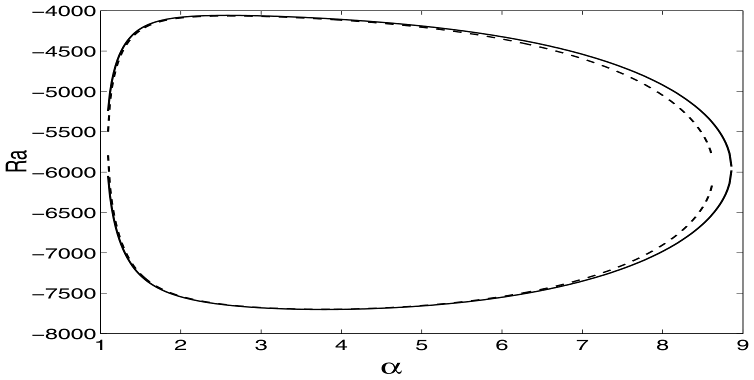

FIG. 5.5. *Neutral curves of* Ra *versus* α *for complex conjugate modes, obtained by the method of continued fractions (dashed line) and by the method of averaging (solid line);* $\omega = 2000,\ \eta = 400$ *for the method of continued fractions;* $\mathrm{Rs} = -2000,\ \mathrm{L} = 0.5$.

space where two branches of the neutral curves $\mathrm{Ra}(\alpha)$ meet, forming closed regions of instability. The fact that these regions are closed makes it difficult to locate them. To our knowledge, they were not discovered in any previous works on this problem. These regions grow in size with the growth in the absolute value of Rs, demonstrating that convective instability in the binary mixture in the presence of vibration is affected by variations in the solute concentration.

As a summary of the numerical results, sufficiently intensive vertical vibration can destabilize the system that is stable in the unmodulated case by inducing convection or stabilize an unstable system by delaying or even suppressing convection. In addition, even in the presence of vibration, the onset of convection in the system is affected by variations in the concentration of the solute in the mixture. Therefore, by varying the vibration parameters (frequency and amplitude) and the concentration of the solute, we can control convective instability in a horizontal layer of a binary fluid mixture saturating a porous medium.

TIME-DOMAIN METHODS FOR DIFFUSIVE TRANSPORT IN SOFT MATTER*

JOHN FRICKS†, LINGXING YAO‡, TIMOTHY C. ELSTON§, AND
M. GREGORY FOREST¶

Abstract. Passive microrheology [T. G. Mason and D. A. Weitz, *Phys. Rev. Lett.*, 74 (1995), pp. 1250–1253] utilizes measurements of noisy, entropic fluctuations (i.e., diffusive properties) of micron-scale spheres in soft matter to infer bulk frequency-dependent loss and storage moduli. Here, we are concerned exclusively with diffusion of Brownian particles in viscoelastic media, for which the Mason–Weitz theoretical-experimental protocol is ideal and the more challenging inference of bulk viscoelastic moduli is decoupled. The diffusive theory begins with a generalized Langevin equation (GLE) with a memory drag law specified by a kernel. We start with a discrete formulation of the GLE as an autoregressive stochastic process governing microbead paths measured by particle tracking. For the inverse problem (recovery of the memory kernel from experimental data) we apply time series analysis (maximum likelihood estimators via the Kalman filter) directly to bead position data, an alternative to formulas based on mean-squared-displacement statistics in frequency space. For direct modeling, we present statistically exact GLE algorithms for individual particle paths as well as statistical correlations for displacement and velocity. Our time-domain methods rest upon a generalization of well-known results for a single-mode exponential kernel to an arbitrary M-mode exponential series, for which the GLE is transformed to a vector Ornstein–Uhlenbeck process.

Key words. generalized Langevin equation, maximum likelihood, Kalman filter, microrheology, anomalous diffusion, time series analysis

1. Introduction.

In this paper we focus on the diffusive transport of micron-scale particles in viscoelastic media. We are motivated by applications to pathogen or drug transport in pulmonary liquids (mucus) or in other biological protective barriers. We are interested in inverse methods (inference of diffusive transport properties from the primitive experimental data) and in direct simulation tools to generate both experimental time series and statistical properties such as mean-squared-displacement (MSD) and velocity autocorrelations.

To accomplish these goals, we borrow the theoretical and experimental framework from passive, single-particle microrheology as proposed by Mason and Weitz [12]. Their goal was more ambitious: from diffusive transport statistics (MSD) of dispersed microbeads, they infer bulk viscoelastic properties of the material. The Mason–Weitz (MW) theory thus combines two essential elements: a generalized Langevin equation (GLE) with a memory drag law to model the diffusion process, together with a gen-

eralized Stokes–Einstein relation (GSER) that relates the GLE memory kernel to the bulk viscoelastic modulus of the medium. We adopt only the first element, since we are exclusively interested in particle diffusion, thereby avoiding the harder problem of a direct relationship between diffusive properties and dynamic bulk moduli of the host material. The time series methods applied here are ideal for single-particle tracking experiments, which our colleagues R. Superfine, D. Hill, and J. Cribb (all at UNC) perform.

There are numerous complexities in soft matter, and especially biological materials, that frustrate a direct association of the diffusive memory kernel with the bulk viscoelastic modulus. Particle surface chemistry with the host material, particle size relative to material network lengthscales (e.g., mesh size), and heterogeneity each present nontrivial challenges. However, these issues are all circumvented for our less ambitious goal: to infer diffusive transport properties from displacement path data of microbeads. Then, one simply has to focus on inference of the memory kernel in the GLE from experimental data. We therefore choose to call the GLE memory kernel a "diffusive transport modulus," to emphasize that we are not attempting to link diffusive transport properties and bulk viscoelastic moduli.

Our inverse method applies directly to path data from particle tracking experiments, namely, position time series. This has potential advantages over ensemble averaging in frequency space, the standard approach. First, the information from individual paths is utilized, and far less data is required for parameter inversion. Second, unlike traditional microrheometry, we aim to use the results of inverse characterization to directly simulate single-particle diffusion (single paths and statistics) in biological layers. For this purpose, a time-domain representation of the memory kernel is required, which our approach yields. The MW method [11, 12] yields the unilateral Fourier transform of the imaginary part of the memory kernel, followed by application of Kramers–Kronig relations to get the real part. We refer to a very nice review article by Solomon and Lu [20] for discussions of the numerical methods associated with mapping the kernel back to the time domain.

Our second goal of direct simulations of diffusive transport processes requires forethought with respect to how one will numerically implement the modulus information gained from the inversion step. In standard inverse characterization in rheology, it is sufficient to restrict data-fitting and modulus characterization in the frequency domain. For direct simulations, we need the time-domain kernel. Thus we propose a time-domain method of inversion of the memory kernel that avoids issues with inverse transforms as discussed in [20]. Indeed, our long term goal is to couple the GLE with other dynamic processes in the biological context, e.g., pathogen diffusion in advected pulmonary liquids, or general situations where there are deterministic forces and particle-particle interactions.

Another motivation for time-domain methods is the possibility of inversion from much smaller data sets, e.g., single paths which may not be sufficient for frequency binning whereas statistical analysis of individual time series data may prove sufficient. Finally, for very small volume materials there will be constraints on the amount of sample path data that can be collected (e.g., low bead volume fractions can easily introduce colloidal effects), and a low number of sample paths may not be statistically significant for ensemble averaging. Perhaps the most compelling reason for the method proposed here is that inversion is performed directly on the physically measured data. *In this paper, we present the conceptual framework and a proof-of-principle illustration of our time-domain methods, for the Langevin and generalized Langevin models.* Particle displacement data is first generated from direct GLE simulations with a prescribed diffusive transport modulus (memory kernel); we then analyze the data with the inverse methods as though the data were path data from particle tracking experiments. A comparison of prescribed versus recovered modulus parameters is the accuracy benchmark enforced in this "methods" paper. We also compute MSD statistics directly from our formulation of the GLE and show agreement with ensemble averaging of path data.

The inverse characterization strategy introduced here is based on statistical tools developed in the field of time series analysis. These tools yield the following:

i. estimates of the viscoelastic material parameters directly from single or multiple time traces of Brownian particles,
ii. standard errors for those estimated parameters, and
iii. goodness of fit criteria.

Thus, the methods convey whether the parametrized memory kernels accurately fit the data and, in practice, how many discrete modes are needed to get a best fit. We also explore protocols for experimental sampling times and their impact on parameter inversion.

We consider an exponential (Prony) series approximation to the memory kernel, which turns out to be particularly efficient for both inversion and direct simulations. Aside from special GLE kernels, such as Rouse- and Zimm-type which are special cases of the class considered here, there is very little known about the anomalous (subdiffusive scaling on intermediate timescales) behavior of Brownian particles. We refer the reader to [17, 21] for details. For this paper, we show that our direct simulation tools recover classical Rouse and Zimm scaling properties of MSD statistics when the kernel is prescribed according to the Rouse or Zimm relaxation spectra.

The remainder of the paper is organized as follows. The standard Langevin equation for a particle diffusing in a viscous fluid is presented as a tutorial to introduce the statistical methods. In particular, we illustrate the relationship between the exact Langevin quadrature solution for particle position and autoregressive (AR) time series models. We also use the Langevin equation to introduce maximum likelihood methods for performing statistical inference of the single material parameter in the Langevin model, the fluid viscosity. Furthermore, we formulate the parameter inversion methods when only partial observations of the system are measurable (position but not velocity of Brownian particles), which is the situation in microbead rheology. Next, we show how this methodology naturally extends to multivariate AR models for GLEs with memory kernels that can be written as the sum of exponentials. The single-mode exponential kernel is presented as another tutorial example of the direct and inverse methods, since this example can also be analyzed in explicit closed form. Next, 4-mode kernels, of classical Rouse and Zimm form, are used as a nontrivial illustration of the direct and inverse methods, and finally a 22-mode Rouse kernel is presented to show that the direct simulations are not limited to a sparse discrete spectrum.

A significant by-product of these investigations arises from two critical observations:

- GLEs with arbitrary finite-mode, exponential kernels are exactly integrable with a quadrature solution [7]; and
- the quadrature formula extends from the continuous GLE process to a discretized dynamics.

These two observations yield a statistically exact, discrete-time AR process model of a Brownian particle in a viscoelastic medium. The first-order Taylor approximation of this discrete process corresponds to a first-order Euler numerical integration scheme. *This class of discrete GLE models thereby provides a highly efficient and accurate direct time-domain simulation method.* We can generate realizations of Brownian particles in a viscoelastic fluid, based on matrix function evaluation rather than a low-order numerical integration of the stochastic GLE model. Furthermore, *average properties (MSD and velocity correlations) also have explicit quadrature representations, so that statistical correlations may be simulated directly, avoiding the arduous alternative of generating sample paths and then averaging.* In examples presented below, we benchmark the numerical tools by confirming agreement between the two ways of computing MSD statistics. These direct simulation results thus afford the ability to simulate time-domain experimental data of individual particles as well as statistical scaling properties of Brownian particles for any given exponential series form of the memory kernel in the GLE model.

For arbitrary M-mode kernels with $M > 1$, there is one numerical analysis result required to assure accurate computation of matrix exponentials in the discrete and continuous quadrature formulas, which we provide in the appendix. With this result, numerical simulations are carried out in the body through various explicit examples. It is worth emphasizing that *this approach*—replacing stochastic numerical integration by matrix function evaluation in a discrete GLE process, for individual paths as well as for average properties of the process—*is guaranteed to be statistically correct, even for sufficiently long time series.* This strategy removes two dominant sources of numerical error in the direct problem of time-domain simulation: the error at each time step from a low-order integration method instead of an exponential-order method, and the cumulative error in time-stepping, which is completely avoided. Because many generic memory kernels can be approximated to arbitrary accuracy with a sum of exponentials, this simulation method should find utility in diverse applications outside of pulmonary liquids. The range of diffusive dynamic scaling behavior of individual Brownian particle paths, and of ensemble averages, is a topic for future study to understand the range of diffusive transport statistics possible for GLEs with exponential series kernels. The known theoretical results for Rouse and Zimm spectra will be illustrated and confirmed below as rigorous benchmarks on our direct simulation strategy, as well as for inverse characterization benchmarks of the maximum likelihood method.

2. The Langevin equation and statistical methods.

In this section, we review the basic properties of the classical Langevin equation for a microscopic particle diffusing in a viscous fluid, as a transparent context for introducing our statistical approach. The solution of the Langevin equation can be exactly represented as a Gaussian AR statistical model (cf. [8]). Thus, a maximum likelihood approach can be used to estimate model parameters from time series data. To illustrate the methodology, the statistical tools are developed first, assuming that the velocity of the particle is directly measured. However, in microscopy experiments the particle position (and not velocity) is measured. Thus, using standard techniques, we next generalize the statistical framework to a two-dimensional Langevin equation for both position and velocity, *in which only position observations are required for statistical inference of model parameters.* All advantages of maximum likelihood estimation are preserved in this formulation, which we illustrate numerically.

2.1. The Langevin equation and quadrature solution.

The scalar Langevin equation for a diffusing particle with velocity v is

$$m\frac{dv}{dt} = -\xi v + \sqrt{2k_BT\xi}f(t), \tag{2.1}$$

where m is the particle mass, k_BT is the Boltzmann constant times the absolute temperature, and the friction coefficient $\xi = 6\pi a\eta$, where a is the radius of the particle and η is the viscosity of the fluid. The stochastic term $f(t)$ is taken to be Gaussian white noise with zero mean and covariance,

$$\langle f(t)f(s)\rangle = \delta(t-s). \tag{2.2}$$

Equation (2.1) represents a 2-parameter linear stochastic differential equation (SDE), written equivalently in the standard form of an Ornstein–Uhlenbeck process:

$$\frac{dv(t)}{dt} = -\alpha v(t) + \sigma f(t), \tag{2.3}$$

where the two parameters in the process are

$$(\alpha, \sigma) = (\xi/m, \sqrt{2k_BT\xi/m^2}). \tag{2.4}$$

Ornstein–Uhlenbeck processes have several important properties—Markovian, stationary (given an appropriate initial condition), and Gaussian—that are amenable to mathematical and statistical analysis.

- If the initial velocity $v(0)$ is normally distributed with mean zero and variance $\sigma^2/(2\alpha)$,

  $$v(0) \sim \mathcal{N}\left(0, \frac{\sigma^2}{2\alpha}\right), \tag{2.5}$$

  then $v(t)$ has the same distribution for all t, and the velocity autocorrelation function (ACF) is given by

  $$\langle v(t)v(s)\rangle = \frac{\sigma^2}{2\alpha}e^{-\alpha|t-s|}. \tag{2.6}$$

- An Ornstein–Uhlenbeck process can be written in terms of a stochastic integral:

  $$v(t) = e^{-\alpha t}v(0) + \sigma\int_0^t e^{-\alpha(t-s)}f(s)ds, \tag{2.7}$$

  which is a quadrature solution to the SDE (2.3).
- This representation is useful, as shown below, for developing efficient statistical techniques for estimating the parameters α and σ from time series data sampled on finite intervals.
- From the exact solution, the tracer position $x(t)$ is given by

  $$x(t) = x_0 + \int_0^t v(s)ds, \tag{2.8}$$

  where $x_0 = x(t=0)$. The variance of the tracer position (MSD) is likewise explicit [3]:

  $$\langle[x(t) - x(0)]^2\rangle = \frac{2k_BT}{\alpha m}\left[t - \frac{1}{\alpha}(1 - e^{-\alpha t})\right]. \tag{2.9}$$

Next we introduce and apply statistical methods that take advantage of the Gaussian evolution and integrability of the Langevin equation to recover α and σ from time series data. These features will be shown in subsequent sections to carry over to the GLE and thereby to inversion of viscoelastic parameters from tracer time series data.

2.2. AR processes and exact discrete Langevin equations. Suppose we want to match Brownian tracer experimental data with a discrete model of the Langevin equation (2.3), where the discrete time step Δ has to be sufficiently small to resolve the underlying stochastic process. The velocity of a particle diffusing in a viscous fluid can be modeled by discretizing equation (2.3) using an Euler approximation, which yields

$$v_n - v_{n-1} \approx -\alpha v_{n-1}\Delta + \sigma\sqrt{\Delta}\epsilon_n, \tag{2.10}$$

where ϵ_n is a sequence of independent standard normal random variables and $v_n = v(n\Delta)$. Rearranging the above equation yields

$$v_n \approx (1-\alpha\Delta)v_{n-1} + \sigma\sqrt{\Delta}\epsilon_n. \tag{2.11}$$

With this discretization, v_n is a *first-order autoregressive (AR) process*. An AR process is one in which the current observation is a weighted sum of the previous observations plus a noise term that is independent of previous noise terms. Alternatively, we can *exploit the quadrature solution* (2.7) and replace the approximate discretization by the *exact discrete Langevin process*,

$$v_n = e^{-\alpha\Delta}v_{n-1} + \epsilon_n, \tag{2.12}$$

where ϵ_n, $n = 1, \ldots, N$, is a sequence of independent standard Gaussian random variables with variance

$$s(\alpha,\sigma) = \sigma^2 \frac{1-e^{-2\alpha\Delta}}{2\alpha}. \tag{2.13}$$

The Euler approximation is recovered as a first-order Taylor series expansion of the coefficients in this exact discretization. The advantages of this exact discretization are that one can accurately generate sample paths, and furthermore, the time series are guaranteed to be statistically consistent with the process (which might otherwise be polluted by cumulative errors in a numerical integration scheme). We will apply this discrete process to simulate an experiment, from which experimental time series are extracted by sampling the full data set.

2.3. Maximum likelihood methods for parameter inversion. We turn now to maximum likelihood methods which give a general framework for obtaining point estimators and standard errors for the model parameters, α and σ, given a time series $v_0, v_1, \ldots, v_N$. The likelihood function is computed from the joint probability density for an observed velocity time series. Noting that the time series is Markov, that the conditional distribution of v_n given v_{n-1} is normal with mean $e^{-\alpha\Delta}v_{n-1}$ and variance (2.13), and assuming that the initial velocity v_0 is known, the likelihood function is given by

$$\begin{aligned} L(\alpha,\sigma) &= g(v_1,\ldots,v_N|v_0,\alpha,\sigma) \\ &= \prod_{n=1}^{N} h(v_n|v_{n-1},v_0,\alpha,\sigma) \\ &= (2\pi s(\alpha,\sigma))^{-n/2}\exp\left(-\sum_{n=1}^{N}\left(\frac{v_n - e^{-\alpha\Delta}v_{n-1}}{2s(\alpha,\sigma)}\right)^2\right), \end{aligned}$$

where $g(\cdot|v_0, \alpha, \sigma)$ is the joint density of $v_1, \dots, v_N$ and $h(\cdot|\cdot, v_0, \alpha, \sigma)$ is the transition density for the process. Given a sequence of velocity measurements, the likelihood function is numerically maximized to obtain estimates, $\hat{\alpha}$ and $\hat{\sigma}$, for α and σ. Hereafter in the paper, parameter estimates are denoted by $\hat{\cdot}$.

One of the benefits of maximum likelihood estimation is that, under fairly general conditions to be given in the appendix, asymptotic probability distributions for these estimators may be obtained. Note that while α is not random, $\hat{\alpha}$ depends on the random time series $v_0, \dots, v_N$ and is a random variable; given a new time series, one obtains a new realization of the random variable. In the present context, we know a priori that the estimator $\hat{\alpha}$ is asymptotically (for long time series, i.e., large number of observations N) normal with mean equal to the true parameter α and variance of $\hat{\alpha}$ equal to $1/N(-\partial_\alpha^2 \log L(\alpha, \sigma))^{-1}$. We obtain an estimate for the variance of $\hat{\alpha}$ by numerically calculating the derivative of the log likelihood function at the maximized value.

We emphasize that model parameters may be estimated from a single time series of the process; this will be illustrated in the proof-of-principle illustrations below. If that single-particle path is sufficiently long, then the MW approach and our approach should be consistent. (A final example addresses this point.) If multiple paths are available and they are presumed to be independent, the overall likelihood function will be defined as the product of likelihood functions for the individual paths, and maximum likelihood estimators may be obtained as before including the additional observations. This methodology will be valid assuming statistical independence of the paths. The methods introduced here can be applied even if the data set is not large; this corresponds either to a large Δ or a low number of iterations in the discrete process. We will return to this issue below in a discussion of over- and underresolution of the underlying stochastic process, and in comparisons of quality of fits versus number of observations.

2.4. Extension to the full system of position and velocity. In general, microrheology experiments measure the position of the particle, not the velocity. It is of course unwise to approximate the velocity by differencing the experimental data; information is lost and unnecessary errors are introduced. Alternatively, we formulate a vector Langevin model for the position and velocity of the particle, and then develop maximum likelihood methods assuming only partial observations of the process variables. Specifically, we can observe $x_0, x_1, \dots, x_n$ but cannot observe $v_0, v_1, \dots, v_n$. The system can be written in vector form as

$$\frac{d}{dt}Y(t) = AY + Kf(t), \tag{2.14}$$

where

$$Y = \begin{pmatrix} x(t) \\ v(t) \end{pmatrix}, \quad A = \begin{pmatrix} 0 & 1 \\ 0 & -\alpha \end{pmatrix}, \quad K = \begin{pmatrix} 0 \\ \sigma \end{pmatrix}, \tag{2.15}$$

and $f(t)$ is a scalar Gaussian white noise process defined above. The *quadrature solution* to (2.14) is [15]

$$Y(t) = e^{At}Y(0) + \int_0^t e^{A(t-s)}Kf(s)ds. \tag{2.16}$$

As noted above, special properties of the exact solution can be exploited when performing parameter estimation. The process is Gaussian and therefore uniquely defined by its mean and covariance. So, given an initial condition $Y_0 = Y(0)$ and a time increment Δ, we can determine the exact distribution of $Y_1 = Y(\Delta)$ and by iteration define a vector AR process, as in (2.12) above.

Conditioning on Y_{n-1}, the distribution of Y_n is Gaussian with mean $e^{A\Delta}Y_{n-1}$ and covariance matrix [8, 15]

$$S(\Delta) = \int_0^\Delta e^{A(\Delta-s)}KK^T e^{A^T(\Delta-s)}ds. \tag{2.17}$$

Furthermore, it is straightforward to generate exact realizations of the stochastic process at finite time intervals, with the caveat that one must be able to accurately calculate S. (For A, K in (2.15), this is trivial; for the GLE of viscoelastic fluids, we address this issue in section 3.1.) For a particle starting in state Y_0, we generate a Gaussian vector ϵ_n with covariance matrix S and add this to $e^{A\Delta}Y_0$ to obtain Y_1, and then simply iterate this procedure. That is,

$$Y_n = e^{A\Delta}Y_{n-1} + \epsilon_n, \tag{2.18}$$

where ϵ_n is an independent sequence of zero mean Gaussian random vectors with covariance S. Thus, we have an AR representation for the vector process $Y_0, \ldots, Y_N$ associated with the scalar process (2.12).

2.5. The likelihood function for position measurements. Now that we have cast the Langevin model in the form of a vector AR process, we are in position to calculate the appropriate likelihood function for estimating parameters, given a time series of particle positions $x_0, x_1, \ldots, x_N$. In this section, we outline key steps in the derivation of the likelihood function, leaving a detailed derivation for the appendix. The derivation relies on the Kalman filter, which was developed to estimate the current state of a dynamical system from noisy time series data of partial observations of the process. (This use of the Kalman filter as a method to calculate the likelihood function has become standard, and further discussion can be found in [2] and [8].) Recall that discrete observations generated from the Langevin equation satisfy (2.18), where the noise has a covariance structure given by (2.17). Experimentally, only the position of the particle is observed, and no other components of the vector Y. That is, at the nth time interval the observable is

$$x_n = CY_n, \quad C = \begin{pmatrix} 1 & 0 \end{pmatrix}. \tag{2.19}$$

Assuming that the model parameters, Θ, are known, a Kalman filter is generally used to recursively estimate the current state, Y_n, given the observations $x_1, \ldots, x_n$. Using this and the AR structure of the process, we may also give a predictive density for Y_{n+1} given $x_1, \ldots, x_n$. From this we may obtain the density of x_{n+1} given $x_1, \ldots, x_n$, which we denote by $h(x_{n+1}|x_m, m < n+1, \Theta, x_0)$. We may then decompose the joint density for the time series into a product of these conditional densities and obtain

$$g(x_1, x_2, \ldots, x_N|\Theta, x_0) = \prod_{n=2}^{N} h(x_n|x_m, m < n, \Theta, x_0). \tag{2.20}$$

Because the process is Gaussian, the above equation can be rewritten as

$$\begin{aligned} -\log L(\Theta) &= -\log g(x_1, x_2, \ldots, x_N|\Theta, x_0) \\ &= \frac{1}{2}\sum_{n=1}^{N}\left(\log 2\pi + \log Q_{n-1} + \frac{(x_n - \hat{x}_{n|n-1})^2}{Q_{n-1}}\right), \end{aligned} \tag{2.21}$$

where the conditional mean and variance of x_n given $x_1, \dots, x_{n-1}$ are

$$\hat{x}_{n|n-1} = Ce^{A\Delta}\hat{Y}_{n-1} \tag{2.22}$$

and

$$Q_{n-1} = CR_{n-1}C^t, \tag{2.23}$$

respectively, and the matrix R_n is defined in the appendix. Therefore, once we have $x_0, x_1, \dots, x_N$ we may numerically maximize this likelihood function with respect to the parameters to obtain an estimate for Θ. An important feature of this Kalman derivation of the likelihood function is that it may be calculated recursively; this dramatically reduces the time necessary to calculate the likelihood function since we do not have to calculate the full covariance matrix of the entire time series. Use of the Kalman filter to calculate the likelihood function of dependent data is a common procedure in time series analysis and is the most accurate and efficient method to calculate the likelihood function for a number of common models such as the ARIMA model [6, 18].

This method requires numerical calculation of the matrices S and $e^{A\Delta}$, but this calculation has to be done only *once* for each trial parameter set in the maximization process. This numerical calculation is, of course, trivial for 2×2 systems, but presents a potential limitation for the GLE, which we will soon formulate in this precise vector AR setting, and where the matrix size scales with the number of exponential modes. Below, we overcome this potential limitation due to the special form of the matrices that arise for GLEs with exponential kernels.

As with the univariate case, there are asymptotic results for the distribution of our maximum likelihood estimators $\hat{\Theta}$. Under certain reasonable conditions given in the appendix, $\hat{\Theta}$ is asymptotically normal with mean Θ and covariance given by $\text{cov}(\hat{\Theta}) = 1/N(-\nabla \log L(\Theta))^{-1}$, which may be approximated by numerical evaluation of the quantity $1/N(-\nabla^2 \log L(\hat{\Theta}))^{-1}$. Thus, to build a $1-\alpha$ confidence interval for θ_m, we start with

$$P\left(-z_{\alpha/2} \leq \frac{\hat{\Theta}_m - \theta_m}{\text{cov}(\hat{\Theta})_{m,m}} \leq z_{\alpha/2}\right) \approx 1 - \alpha, \tag{2.24}$$

where $z_{\alpha/2}$ is the value that satisfies $P(Z > z_{\alpha/2}) = \alpha/2$ and Z is a standard Gaussian random variable. We use the notation $A_{m,n}$ to denote the element in the mth row and nth column of the matrix A. Some algebra yields

$$\theta_m \in (\hat{\Theta}_m - z_{\alpha/2}\text{cov}(\hat{\Theta})_{m,m}, \hat{\Theta}_m + z_{\alpha/2}\text{cov}(\hat{\Theta})_{m,m}), \tag{2.25}$$

which is the desired confidence interval for θ_m.

2.6. The autocorrelation function (ACF). A common diagnostic tool for determining important timescales in time series data is the *discrete autocorrelation function.* This function represents a scaled and discretized estimate of the true autocovariance function

$$\text{Cov}\,(U(t)U(s)) = \langle U(t)U(s)\rangle - \langle U(t)\rangle\langle U(s)\rangle. \tag{2.26}$$

For a discrete time series $U_1, \dots, U_N$, where $U_k = U(k\Delta)$ and the data is normalized to have mean zero, the discrete ACF is defined to be

$$ACF(j) = \frac{\sum_{n=j+1}^{N} U_n U_{n-j}}{\sum_{n=1}^{N} U_n^2}.$$

From now on the acronym ACF denotes the discrete autocorrelation function unless explicitly stated otherwise. Note that for zero time lag, the ACF is normalized to one. A general guide for verifying that a process is white noise (independent identically distributed sequence of random variables) is that for all lags greater than or equal to one the ACF will be less than $2/\sqrt{N}$, where N is the number of observations [19]. We illustrate the application of the ACF diagnostic in examples below.

2.7. Illustration of the statistical toolkit. We present a simple example, Brownian diffusion and simple Langevin dynamics, to show how these methods work and test their accuracy. The example illustrates the importance of the experimental sampling time relative to the physical timescales in the model. We always assume (and enforce in numerical simulations) that the discrete time step Δ in the direct simulation of sample paths is small enough to resolve the stochastic fluctuation timescales in the model. This yields a faithful resolution of the physical process from which we can then sample the resolved data on any coarse timescale, analogous to an experimental sampling time. With these protocols, we are able to provide measures and indicators of experimental over- and undersampling.

Throughout the paper, we measure time in milliseconds (ms), mass in milligrams (mg), and length in microns (μm). Consider a neutrally buoyant particle of diameter 1 μm and mass 5×10^{-10}mg moving in a fluid with viscosity 1.5 Pa-s (similar to glycerol). This corresponds to $\alpha = 26 \times 10^6 (\text{ms})^{-1}$ and $\sigma = 65 (\text{ms})^{-3/2}$. First, we simulate the exact discrete Langevin process (2.17), (2.18) for a highly resolved time step $\Delta = 10^{-10}$ms, which is three orders of magnitude smaller than the viscous timescale set by the drag coefficient, $\alpha^{-1} = \text{m}/\zeta \approx 0.37 \times 10^{-7}$ms. We generate one sample path with 10^5 data points. The examples to follow will strobe this data set at the prescribed lag Δ; if Δ is $10^{-10+\delta}$, then each observation corresponds to 10^{δ} numerical time steps.

The ACF is first computed using a coarse sampling time $\Delta = 5 \times 10^{-7}$ms, which is 13.4 times the viscous timescale α^{-1}. The process yields the ACF signature of white noise, Figure 1(top). That is, the ACF nearly approximates a delta distribution versus lag with most of the weight at zero lag time, and therefore at this sampling interval the process appears to be white noise. On the other hand, if the sampling interval is shortened ($\Delta = 10^{-8}$ms) so that it is consistent with the viscous timescale, then the ACF falls off exponentially, as in Figure 1(bottom).

Next, we use maximum likelihood methods to generate the estimators $\hat{\alpha}$ and $\hat{\sigma}$ for five decades of lags Δ (Figure 2). Note that the estimator (open circles) is most accurate and the variance (vertical bars) is minimized when the lag time $\Delta \approx 10^{-8}$–10^{-9}ms, consistent with the ACF diagnostic (Figure 1(bottom)) showing exponential decay. Note further that the estimator $\hat{\alpha}$ degrades as Δ increases, and the variance grows, consistent with the ACF of Figure 1(top) for coarse sampling. For Δ very small, e.g., $\Delta = 10^{-10}$ms, the variance of α again grows, but the estimator remains quite accurate.

This simple example illustrates a method for choosing an appropriate time interval for sampling. If the observations are too far apart (underresolved), e.g., $\Delta = 10^{-7}$ms, then the autocovariance of the velocity is near zero after one time step. Indeed, one can compute the AR matrix

$$e^{A\Delta} = \begin{pmatrix} 1 & \frac{1-e^{-\alpha\Delta}}{\alpha} \\ 0 & e^{-\alpha\Delta} \end{pmatrix} \overset{\Delta=10^{-7}}{\approx} \begin{pmatrix} 1 & 3.7\cdot 10^{-8} \\ 0 & 1.5\cdot 10^{-6} \end{pmatrix}. \tag{2.27}$$

Looking at the discrete process (2.18) and (2.17), there is little information carried

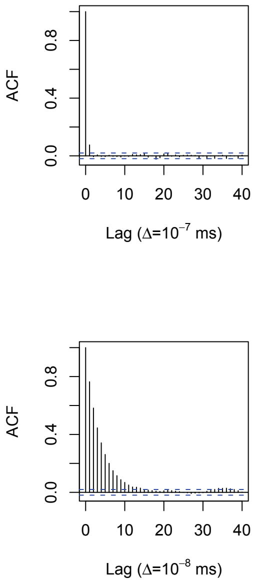

Fig. 1. *ACF of Langevin equation velocity time series: The ACF of the velocity at two different sampling intervals, one showing underresolution and the other indicating accurate resolution.*

over except the previous position, so the process is nearly a discrete white noise process. Nonetheless, the time series approaches can often still give reasonable estimates of the parameters, as shown in Figure 2. By contrast, a reasonable sampling time, like $\Delta \sim 10^{-8}$ms, will reflect an exponential ACF, signalling good resolution of the process. In the extremely improbable situation where observations are too frequent (overresolved), e.g., $\Delta = 10^{-10}$ms, then the AR matrix will be close to the identity,

$$e^{A\Delta} \overset{\Delta=10^{-10}}{\approx} \begin{pmatrix} 1 & 9.9{\cdot}10^{-5} \\ 0 & 9.9{\cdot}10^{-1} \end{pmatrix},$$

and the velocity will appear to be nonstationary with a linear decay in the ACF. These signatures of the ACF are tools that can be used with experimental data to identify an appropriate sampling time, and even to estimate the smallest physical timescale in the underlying process.

3. The GLE and statistical methods.

3.1. Mathematical framework: Quadrature solution for exponential series kernels. The starting point for modeling the diffusive properties of microscopic Brownian particles in viscoelastic materials is the GLE [1, 7, 12, 16, 22, 23]:

$$m\frac{dV(t)}{dt} = -\int_0^t \varphi(t-\tau)V(\tau)d\tau + \tilde{F}(t). \tag{3.1}$$

For passive microrheology, $\tilde{F}(t)$ is a Gaussian colored noise, correlated with the memory kernel $\varphi(t)$ through the fluctuation-dissipation relation,

$$\langle \tilde{F}(t), \tilde{F}(s)\rangle = k_B T\varphi(t-s), \quad t > s. \tag{3.2}$$

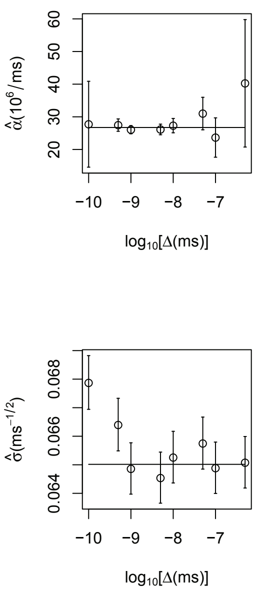

FIG. 2. *Parameter estimates versus sampling time Δ of the drag α and noise σ for the Langevin model. The bands represent* 95% *confidence intervals for the estimates. The true parameter is represented by a horizontal line.*

For consistency with the Langevin illustration, we divide both sides of (3.1) by m and redefine the memory kernel appropriately to obtain

$$\frac{dV(t)}{dt} = -\int_0^t \xi(t-\tau)V(\tau)d\tau + \sqrt{\frac{k_BT}{m}}F(t), \tag{3.3}$$

with

$$\langle F(t), F(s)\rangle = \xi(t-s), \quad t > s. \tag{3.4}$$

Throughout the remainder of the paper when we refer to the memory kernel, we will mean $\xi(\cdot)$, which is scaled by $1/m$.

In this section, we show that for a certain class of memory kernels, specifically a sum of exponentials, the GLE can be expressed as a set of coupled linear SDEs *of the same form as* (2.14), in which the velocity and position are the first two components. Therefore, all Langevin equation properties and techniques carry over immediately to the GLE. In particular, we can (1) apply maximum likelihood methods for parameter estimation, (2) exactly simulate the stochastic process instead of low-order numerical integration, and (3) write down explicit formulas for statistical quantities of interest, such as ACFs for position and velocity.

Suppose the memory kernel is a single exponential,

$$\xi(t) = ce^{-\frac{t}{\lambda}}, \quad c = \frac{6\pi aG}{m}, \tag{3.5}$$

where a and m are the particle radius and mass, which corresponds to a single-mode Maxwell fluid with shear modulus G, relaxation time λ, and zero strain rate viscosity

$\eta = \lambda G$. The noise $F(t)$, (3.3)–(3.4), for the single exponential kernel can be expressed as an Ornstein–Uhlenbeck process,

$$\frac{dF(t)}{dt} = -\frac{1}{\lambda}F(t) + \sqrt{\frac{2c}{\lambda}}f(t), \tag{3.6}$$

where $f(t)$ is white noise. Note that the Langevin equation for viscous diffusion is obtained in the limit $\lambda \to 0$; that is, (3.6) becomes (with $\xi = 6\pi a\eta$)

$$F(t) = \sqrt{\frac{2\xi}{m}}f(t). \tag{3.7}$$

Analogous to the scalar Ornstein–Uhlenbeck process (2.3), the system (3.3)–(3.6) may be solved explicitly, which has been noted in several classical references [1, 7, 16, 22, 23]. To see this, define the variable $Z(t)$ by

$$Z(t) = \int_0^t e^{-\frac{t-\tau}{\lambda}}V(\tau)d\tau, \tag{3.8}$$

which yields

$$\frac{dZ(t)}{dt} = -\frac{1}{\lambda}Z(t) + V(t). \tag{3.9}$$

Now, the full system can be written in matrix form as

$$\frac{d}{dt}Y(t) = AY(t) + KW(t) \tag{3.10a}$$

with

$$A = \begin{pmatrix} 0 & 1 & 0 & 0 \\ 0 & 0 & -c & \sqrt{\frac{k_BT}{m}} \\ 0 & 1 & -\frac{1}{\lambda} & 0 \\ 0 & 0 & 0 & -\frac{1}{\lambda} \end{pmatrix}, \quad K = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & \sqrt{\frac{2c}{\lambda}} \end{pmatrix}, \tag{3.10b}$$

$$Y(t) = (X(t), V(t), Z(t), F(t))^T, \tag{3.10c}$$

and $W(t)$ is a vector of independent white noise processes.

This system (3.10a)–(3.10c) is *identical* in form to (2.14), and therefore another vector Langevin equation, whose quadrature solution is given by (2.16) and (2.17) with these Y, A, and K. Following the Langevin example above, we can now generate the corresponding viscoelastic AR process for a Brownian particle with this specified memory kernel, starting from $Y_0 = Y(0)$.

More generally, suppose that the memory kernel $\xi^M(t)$ is given by an M-mode exponential series:

$$\xi^M(t) = c_1e^{-\frac{t}{\lambda_1}} + c_2e^{-\frac{t}{\lambda_2}} + \cdots + c_Me^{-\frac{t}{\lambda_M}}, \tag{3.11}$$

where $c_i = 6\pi aG_i/m$. Similarly, the total noise $F^M(t)$ can be written as

$$F^M(t) = F_1(t) + F_2(t) + \cdots + F_M(t), \tag{3.12}$$

where each $F_i(t)$ is an independent Ornstein–Uhlenbeck process characterized by the ith relaxation time λ_i. That is,

$$\frac{dF_i(t)}{dt} = -\frac{1}{\lambda_i}F_i(t) + \sqrt{\frac{2c_i}{\lambda_i}}f_i(t), \tag{3.13}$$

where $f_i(t)$, $i = 1, \dots, M$, are independent white noise processes.

Therefore, $F^M(t)$ is a mean-zero Gaussian process with covariance consistent with the fluctuation-dissipation theorem,

$$\langle F^M(t)F^M(s)\rangle = c_1 e^{-\frac{t-s}{\lambda_1}} + c_2 e^{-\frac{t-s}{\lambda_2}} + \cdots + c_M e^{-\frac{t-s}{\lambda_M}}. \tag{3.14}$$

This formulation of the GLE yields once again a vector Langevin process of the form (36), with the following definitions for Y, A, and K:

(3.15)

$$Y = \begin{pmatrix} X(t) \\ V(t) \\ Z_1(t) \\ \dots \\ Z_M(t) \\ F_1(t) \\ \dots \\ F_M(t) \end{pmatrix}, \quad A = \begin{pmatrix} 0 & 0 & 1 & \dots & 0 & 0 & \dots & 0 \\ 0 & 0 & -c_1 & \dots & -c_M & \sqrt{\frac{k_BT}{m}} & \dots & \sqrt{\frac{k_BT}{m}} \\ 0 & 1 & -1/\lambda_1 & \dots & 0 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 1 & 0 & \dots & -1/\lambda_M & 0 & \dots & 0 \\ 0 & 0 & 0 & \dots & 0 & -1/\lambda_1 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & 0 & \dots & 0 & 0 & \dots & -1/\lambda_M \end{pmatrix},$$

$$K = \begin{pmatrix} 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & 0 \\ 0 & 0 & \dots & 0 & 0 & \sqrt{\frac{2c_1}{\lambda_1}} & \dots & 0 \\ \dots & \dots & \dots & \dots & \dots & \dots & \dots & \dots \\ 0 & 0 & \dots & 0 & 0 & 0 & \dots & \sqrt{\frac{2c_M}{\lambda_M}} \end{pmatrix}.$$

Again, an *exact solution of this system* is given in the form (2.16) and (2.17) with these matrix formulas. Thus, all properties of the Langevin equation have been extended to the GLE for the class of M-mode exponential series kernels. Likewise, the machinery from section 2 applies for generating direct realizations of GLE processes and performing statistical analysis of time series for partial observations (of position).

These formulas are valuable to the extent that we can numerically calculate the matrix exponential e^A. The special form of A, (3.15), lends itself to an explicit and straightforward determination of the eigenvalues and eigenvectors for any mode number M. Furthermore, this calculation only has to be done once, both to generate the direct process (or statistics of the process) and to perform parameter inversion for each M-mode model. The procedures for computing the spectrum and then the covariance matrix are given in the appendix.

3.2. GLE direct and inverse illustration with a single exponential kernel.

We first illustrate the GLE direct and inverse strategy, analogous to the Langevin illustration in section 2, for the simplest case: a single-mode exponential kernel (3.5)

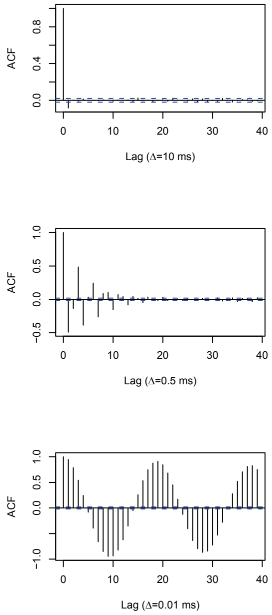

FIG. 3. *ACF versus sampling interval Δ for a GLE with single-mode exponential kernel with relaxation timescale $\lambda_1 \sim 1.5ms$. Top: Underresolved with $\Delta \sim 6\lambda_1$. Middle: Resolved with $\Delta \sim .3\lambda_1$. Bottom: Overresolved with $\Delta \sim .01\lambda_1$.*

for which the GLE is given by (3.10a)–(3.10c). We select physical parameter values as follows: $\lambda_1 = 1.546$ ms, $G_1 = 1.035 \times 10^{-5}mg/ms^2\mu$m. The model parameter c_1 then has the value $c_1 = 4.440 \times 10^{-3}$ms^{-2}. Data are generated by a direct simulation with time step Δ ms; we explore various sampling intervals relative to λ to identify signatures of over-, under-, and "good" sampling times in the ACF and the estimators $(\hat{\lambda}_1, \hat{c}_1)$. For each Δ, we generate a single sample path consisting of 5×10^4 observations, or a total experimental simulation of $5 \times 10^4 \Delta$ ms.

We begin with the effect of sampling interval Δ on the ACF for velocity, as shown in Figure 3. The data for bead velocity were created by differencing the position data for a sample path of length 50,000. The first plot in Figure 3 corresponds to a very long sampling interval (6 times the relaxation time λ_1) and shows that the velocities at consecutive time steps are nearly independent of one another. We can see this by analyzing the matrix $e^{A\Delta}$, and we notice

$$v_{n+1} \approx 0.036 v_n + \epsilon, \tag{3.16}$$

where ϵ is white noise, which explains why the ACF of velocity approximates white noise. The second plot shows a more reasonable ACF at a sampling interval $\Delta = 0.5$ms. The last ACF plot in Figure 3 corresponds to a very fast sampling interval $\Delta = 0.01$ms. Note that for this sampling rate, the ACF appears to fall off linearly, rather than exponentially as expected, indicative of a process that has been oversampled. This behavior is similar to the Langevin equation, where very short time steps yield a strong dependence from one velocity to the next. Recall that this scenario yields a likelihood function that is relatively insensitive to parameter values.

Figure 4 shows the maximum likelihood estimate $\hat{\lambda}_1$ of a single relaxation time, λ_1, from numerically generated data and demonstrates the effect of the sampling

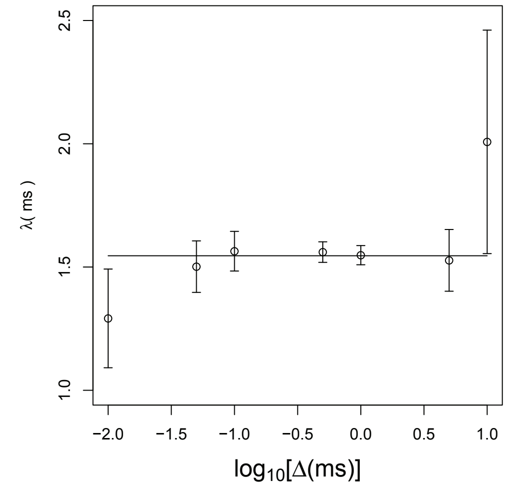

FIG. 4. *Estimators of the relaxation time* $\hat{\lambda}_1$ *versus sampling resolution* Δ*, with data taken from a direct discrete GLE simulation with a single-mode exponential memory kernel. The exact value* $\lambda_1 = 1.546ms$ *is denoted by the horizontal line. The hollow circle indicates the value of the estimator, and the error bars indicate* 95% *confidence intervals.*

interval on the estimation of λ_1. The horizontal line represents the true value of λ_1, while the error bars represent 95% confidence intervals which are symmetric about the estimate represented by open circles. As with the ordinary Langevin case, there is an optimal sampling interval. Note that the natural timescale for this parameter is on the order of milliseconds; this is approximately the sampling interval at which the minimum variance of the estimator is obtained.

It is important to note here that for each sampling rate the number of discrete observations used for inference is being held constant. This implies that the real time interval over which the observations are being taken is much shorter for the faster sampling rates and considerably longer for the slowest sampling rates. This shorter real time interval could partially explain the large variance of the estimator at these faster rates. However, one should also note that the observations taken at longer than optimal sampling intervals occur over a longer real time interval and yet also perform poorly. This demonstrates that both sampling rate and number of observations play a role in the performance of the method, which is worthy of further investigation.

In Figure 5, the estimate $\hat{c}_1$ of the model parameter c_1 versus sampling interval Δ is illustrated. As seen when estimating λ_1, the estimates improve as the sampling interval becomes longer. However, beyond the interval of Δ values in this plot the quality of the estimator declines quickly. Note that this parameter has a natural timescale of $1/\sqrt{c_1}$ which is approximately $10^{-\frac{3}{2}}$ms. Note also that there is little overlap between the very good estimates of c_1 and the good estimates of λ_1. This points to a general problem for a system with different relevant timescales. The quality of relative estimates within a parameter set will be partially determined by the sampling interval.

In Figure 6, we show the effect of the number of experimental observations on parameter estimation. Parameter estimates improve with the length of the time series

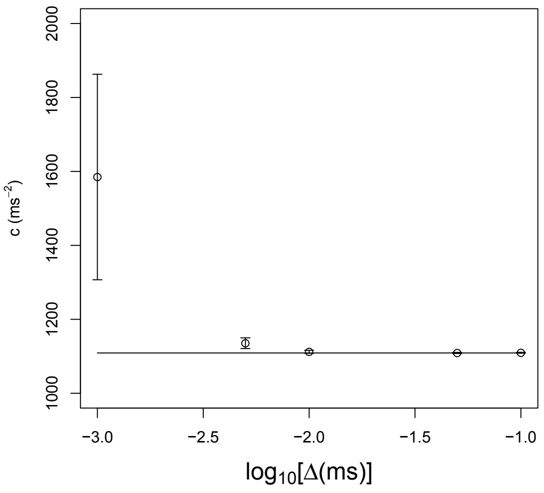

FIG. 5. *Effect of sampling resolution Δ on estimation of c_1 for the single-mode GLE example in Figures* 3 *and* 4. *The horizontal line represents the true value of $c_1 = 1.109 \times 10^3 ms^{-2}$, while the error bars represent* 95% *confidence intervals, which are symmetric about the estimates represented by a hollow point.*

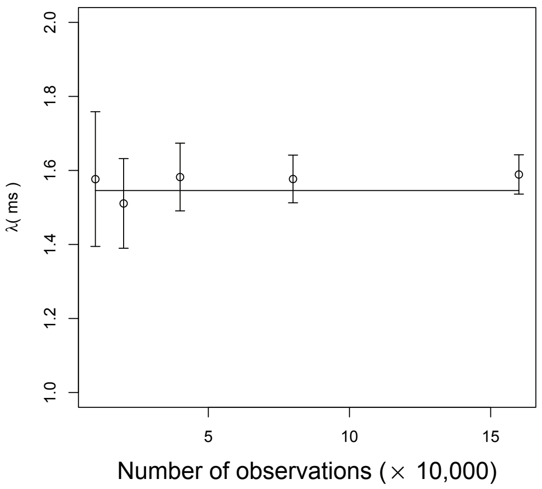

FIG. 6. *Parameter estimation as a function of the number of observations for the single-mode GLE of Figures* 3–5. *The sampling interval is fixed, $\Delta = 0.1ms$, which is a good sampling rate to estimate $\lambda_1 = 1.5ms$, as shown in Figure* 4. *The horizontal line represents the true value of λ_1, and the error bars represent* 95% *confidence intervals which are symmetric about the estimates represented by a hollow point.*

for a given sampling time. This is a general feature of maximum likelihood estimators, and its theoretical verification is given in Appendix B as a consequence of the asymptotic normality of the estimators.

With a single-mode exponential kernel, the quadrature solution of the GLE can be extended to an explicit formula for ensemble averages, particularly for autocorrelations of velocity and displacement (cf. [7]). We drop the subscript 1 on all parameters for these 1-mode formulas. The velocity autocorrelation is given by

$$\langle V(t)V(t')\rangle = \frac{k_BT}{m\beta(1-\beta)}e^{-\frac{1-\beta}{2\lambda}|t-t'|} - \frac{k_BT}{m\beta(1+\beta)}e^{-\frac{1+\beta}{2\lambda}|t-t'|}, \tag{3.17}$$

while the MSD is

$$\begin{aligned}\langle[X(t)-X(t')]^2\rangle = \frac{4k_BT}{m}\Bigg\{&\frac{2\lambda}{1-\beta^2}|t-t'| - \frac{2\lambda^2(3+\beta^2)}{(1-\beta^2)^2}\\ &+ \frac{\lambda^2}{\beta(1-\beta^2)^2}\left(e^{-\frac{1-\beta}{2\lambda}|t-t'|}(1+\beta)^3 - e^{-\frac{1+\beta}{2\lambda}|t-t'|}(1-\beta)^3\right)\Bigg\},\end{aligned} \tag{3.18}$$

where $\beta = \sqrt{1-4c\lambda^2}$ and $c = 6\pi aG/m$ from (3.5). For sufficiently short times, the MSD (3.18) exhibits ballistic behavior, $\langle[x(t)-x(0)]^2\rangle \approx k_BTt^2/m$, and for sufficiently long times, diffusive scaling emerges, $\langle[x(t)-x(0)]^2\rangle \approx 2k_BTt/m\lambda c$. For intermediate times, a power law fit of the MSD yields a range of exponents depending on the window in which one chooses to fit.

We note that the parameter β can be purely imaginary, as pointed out in [7], which is clear from the formula (3.18). Oscillations are predicted in the velocity correlation and MSD whenever physical parameters obey $4c\lambda^2 > 1$. When extended to the more general case of multiple exponentials, similar oscillations appear since the relevant matrix A often has a pair of complex eigenvalues.

This GLE model phenomenon predicts high frequency (short time) oscillations in experimental path data, *even after ensemble averaging of path time series*, which translates to a source of high frequency error of MSD in experimental measurements because of the phase mismatch between these inherent oscillations and experimental sampling time. We do not know if this property is generic for a wider class of kernels.

3.3. GLE model illustration with a 4-mode Rouse kernel.

A classical model due to Rouse (cf. [5]) yields a special class of M-mode kernels for which GLE diffusive transport properties are explicitly solvable. A 4-mode Rouse kernel is implemented now to further illustrate the direct and inverse tools, and to benchmark our direct simulations against exact MSD scaling laws. To construct a Rouse kernel, polymer chains are divided into spherical mass segments connected by linear springs of equilibrium length b (beads in polymer chain); and a kernel function of a series of exponentials with same weight and different characteristic time is then followed [4, 17]. A Zimm kernel, in which a different exponential spectra is derived, is presented next. More complex molecular models may incorporate overlap and entanglements of polymer chains, or even chemical interactions between Brownian particles and local environment. Our focus in this paper is to model the fluctuations without attempting to dissect the various sources. Our goals in this example are once again as follows: for inversion, to find the best GLE kernel to fit measured path data; for direct prediction, to simulate particle paths or the statistics of paths for a known prescribed GLE kernel.

To prescribe the kernel for a Rouse chain solution, each segment in a polymer chain is assigned friction coefficient ξ_b, and the weight and characteristic times for the exponentials of the ith mode are given by (with N_m the number of segments in a

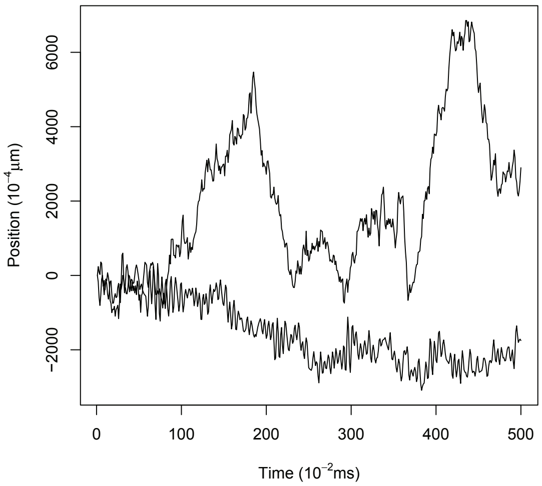

FIG. 7. *Sample discrete AR simulation for a GLE with a* 4*-mode Rouse kernel (top path) compared to a Brownian motion (Langevin equation path) with the same local variance.*

polymer chain)

$$G_i = G_0 = \nu k_B T, \quad \lambda_i = \frac{\xi_b}{16 k_B T \beta_b^2 \sin^2(i\pi/2(N_m+1))}, \tag{3.19}$$

where ν is the number density of polymer chains and $\beta_b = 3/(N_m b^2)$. In the example to follow, we choose $\nu = 2\%$. We now specify all parameter values in the 4-mode Rouse-GLE model. The passive tracer bead is 1μm in diameter of mass $m = 1.05 \times 10^{-9}$mg. The single weight factor is given by $G_0 = G = 1.035 \times 10^{-5}mg/ms^2\mu$m, so that our rescaled parameters are $c = c_i = 6\pi a G_0/m = 4.440 \times 10^{-4}(\text{ms})^{-2}$. The Rouse relaxation times are, from (3.19), $\lambda_1 = .02415$, $\lambda_2 = .04294$, $\lambda_3 = 0.09661$, and $\lambda_4 = .38643$ in units of ms. Figure 7 shows a typical time series for particle position for this GLE-Rouse kernel, extracted from the full vector AR simulation. For comparison, we have included a sample path for a random walk with independent steps. The variance of the steps for both time series are the same; therefore, the figure gives a clear illustration of the effect of dependency alone in suppressing the diffusion of a particle.

We simulate 200 paths with sampling time $\Delta = 10^{-3}$ms for 10^4 steps. Figure 8 shows the ACF (MSD) for the position of the paths, computed by ensemble averaging of the 200 paths (green dots). This result is compared with the analytical scaling law (yellow dashed curve) for a Rouse chain [4, 17]. (Later in this section, we present a more general result from vector Langevin stochastic processes: an explicit quadrature formula for the autocorrelation matrix of the vector Langevin process. This formula allows one to bypass single paths and ensemble averaging of them to directly simulate MSD and velocity autocorrelations.) Note that the MSD starts out with ballistic scaling for times far below the shortest relaxation time and eventually becomes diffusive for times longer than the largest relaxation time. Subdiffusive scaling occurs between the shortest ($t = 0.02415$ms) and longest ($t = 0.38643$ms) relaxation times, consistent with Rouse behavior.

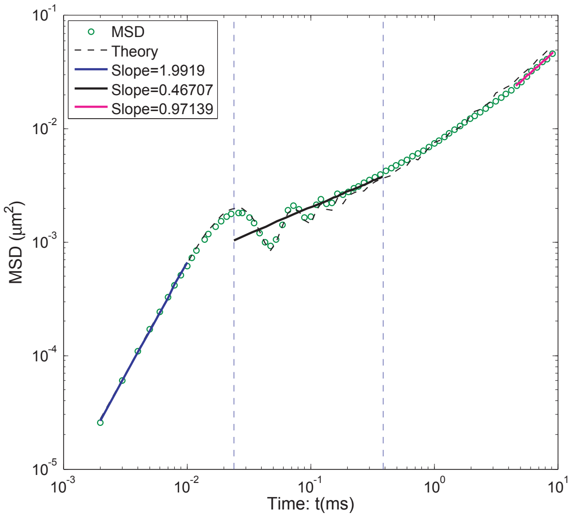

FIG. 8. *MSD of GLE sample paths for a 4-mode Rouse diffusive transport modulus.* 200 *paths are generated for a* 1 μm *diameter bead at* $293K$*. The Rouse relaxation times are* $\lambda_1 = .02415$*,* $\lambda_2 = .04294$*,* $\lambda_3 = 0.09661$*, and* $\lambda_4 = .38643$ *in units of* ms*, with equal weights for each mode,* $G_0 = 1.035 \times 10^{-5} mg/ms^2\mu m$*. To benchmark analytical scaling laws, a linear fit between the two vertical dashed lines (from the shortest to longest relaxation times) confirms the MSD power law of* 0.5 *for the Rouse model. The short term ballistic and long term diffusive scaling are also confirmed.*

Now we turn to the application of inverse methods for the path data, treating the data as though it were generated experimentally. To reveal the effective memory in this system, we first "preprocess" one sample time series to get an estimate of the ACF for velocity, which is obtained by differencing the position data. We use this proxy for the ACF of velocity to obtain initial conditions for the maximum likelihood method of fitting memory kernels. The ACF result is shown in Figure 9. Note the oscillatory behavior of the ACF, clearly indicating that the process is not consistent with a particle diffusing in a purely viscous fluid. (This remark relates to the earlier analysis of oscillations that arise in single-mode GLE models, which persist for this Rouse kernel.)

The ACF in this context is being used as an exploratory tool to gauge the amount of dependency present in the data before using the maximum likelihood techniques to fit the model. The ACF gives a proxy here for the longest relaxation time seen in the data which gives an initial guess for the single-mode model. If no significant lags were seen, then it is likely that all relaxation times are below the sampling rate and more frequent observations are necessary to estimate relaxation times. If the researcher suspects well-separated relaxation times over several orders of magnitude, then one could use more coarsely sampled data to fit the longest times and after fitting use a finer grid to fit shorter relaxation times. The ACF can be used to guide these explorations of widely separated times.

In general, the number of exponential modes that best fit the underlying process that generated the data is not known. The strategy begins by positing a single exponential to fit the data, from which the ACF produces a rough guess of 0.04 ms for the relaxation time. Our experience with numerical and experimental data indicates that fitting the data to a single-mode kernel tends to be quite stable, and this initial step consistently gives the same results independent of the initial guess for the

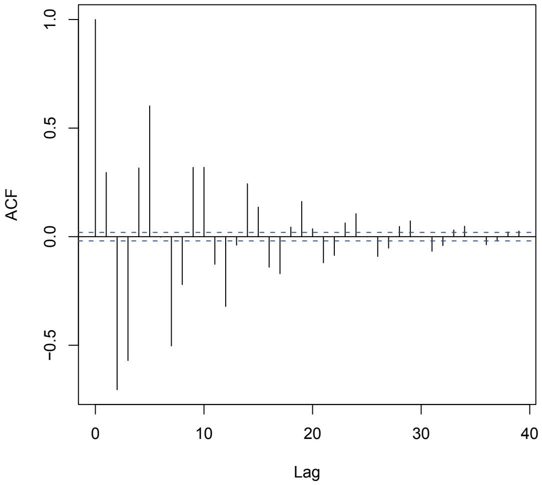

FIG. 9. *ACF for velocity approximated by differencing of position data for the discrete AR process corresponding to a GLE with the* 4*-mode Rouse kernel of Figure* 8*.*

relaxation time. The estimated parameter values are $\hat{\lambda}_1 = 5.519 \pm 0.071(10^{-2}\text{ms})$ and $\hat{c} = 1.77 \pm 0.003(10^{-3}\text{ms}^{-2})$. Not surprisingly the estimated value of c is almost exactly four times the true value since the data was generated from a 4-mode model. (Fitting a single-mode model is essentially the same as fitting a 4-mode model where all the modes have the same relaxation time, thus yielding a $\hat{c}$ that is roughly four times the true value.)

We would like to be able to assess the quality of the fits being performed. One diagnostic tool for investigating how well the model predicts the data is *the ACF of the residuals*. This is shown in Figure 10. If the model has successfully captured all the dependencies in the data, then we expect the ACF of the residuals to be consistent with white noise. Note that the first few lags show a significant negative correlation, indicating that the single-mode model cannot account for all the dependency in the data.

We proceed to a 2-mode kernel which requires initial guesses for each relaxation time. If $\hat{\lambda}_1$ is the estimate for the single-mode case, one reasonable approach is to use $\hat{\lambda}_1 \pm \hat{\lambda}_1/2$ as the initial guesses for the 2-modes. In this way, each time we add an additional mode to the model, we split the longest relaxation time and use the estimates obtained from fitting the previous model as an initial guess for the remaining relaxation spectra. That is, for an M-mode model, our initial guesses for the λ's will consist of the $(\hat{\lambda}_1, \ldots, \hat{\lambda}_{M-2})$ obtained by fitting an $M-1$ model, and for the two longest relaxation times we use $\lambda_{M-1} = \hat{\lambda}_{M-1} - (\hat{\lambda}_{M-1} - \hat{\lambda}_{M-2})/2$ and $\lambda_M = \hat{\lambda}_{M-1} + (\hat{\lambda}_{M-1} - \hat{\lambda}_{M-2})/2$. Therefore, for the 2-mode model, we choose initial conditions of 0.0275ms and 0.0825ms for the λ's and use $\hat{c}$ from the single-mode model as the initial condition for c. This produces $\hat{\lambda}_1 = 3.023 \pm 0.043(10^{-2}\text{ms})$, $\hat{\lambda}_2 = 19.30 \pm 0.73(10^{-2}\text{ms})$, and $\hat{c} = 0.886 \pm 0.001(10^{-3}\text{ms}^{-2})$. In this case the estimate for c is roughly twice the true value.

The ACF for the residuals of the 2-mode fit (not shown) indicates that we have captured most of the dependencies in the data. Figure 11 shows a plot of the sum of

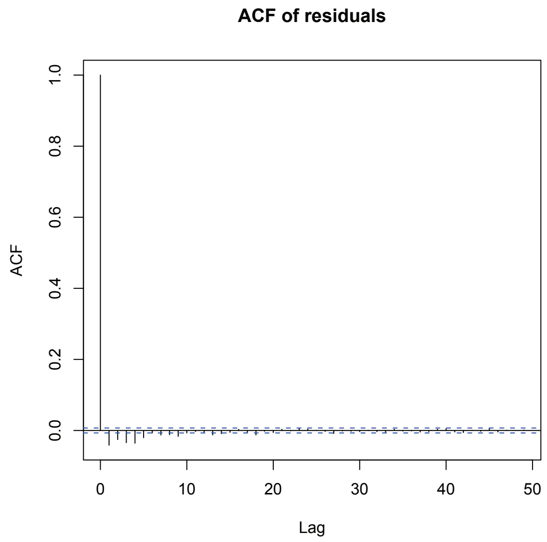

FIG. 10. *ACF of residuals for fitting a single-mode GLE kernel to data generated from a discrete AR process with a* 4*-mode kernel.*

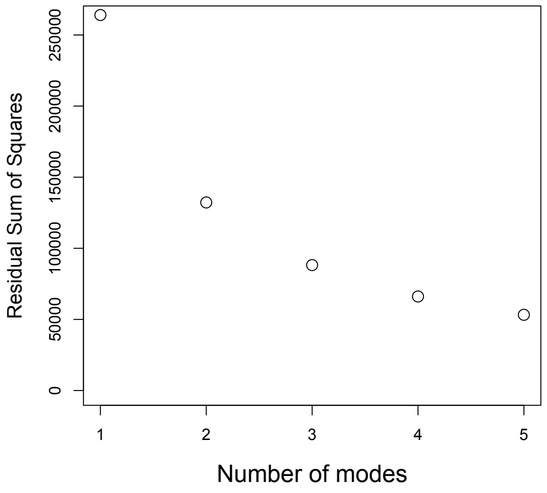

FIG. 11. *The sum of squared residuals when fitting kernels with* 1–5 *modes to* 4*-mode data.*

the squared residuals as a function of the number of modes used to fit the data. Note that there is a large reduction in the sum of the squared residuals in going from one to two modes, but there is no evidence of convergence yet.

We next fit a 3-mode kernel. Using the method described above, the initial guesses for the λ's (in 10^{-2}ms) are 3.023, 11.0, and 27.0. The estimated values for the relaxation times (in 10^{-2}ms) are $\hat{\lambda}_1 = 2.525 \pm 0.060$, $\hat{\lambda}_2 = 7.020 \pm 0.461$, and $\hat{\lambda}_3 = 25.50 \pm 1.99$, and the estimate of c is $\hat{c} = 0.592 \pm 0.001(10^{-3}\text{ms}^{-2})$.

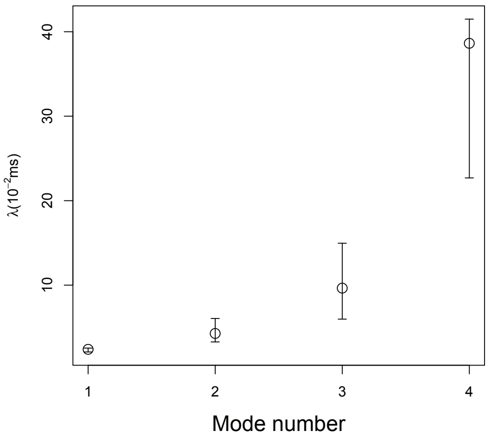

Fig. 12. *Proof-of-principle: Maximum likelihood recovery of a* 4*-mode Rouse relaxation spectrum from numerical time series data. The error bars are symmetric about the estimate, with the open circles being the true values.*

As expected, the estimated value of c is roughly $4/3$ the true value. Note that there is still a significant drop in the sum of the squared residuals (Figure 11). Figure 12 shows results for the estimated values of the relaxation times when a 4-mode kernel is used. For this case the initial guesses for the λ's (in 10^{-2}ms) are 2.525, 7.02, 16.0, and 43.0. Notice that the true λ values all lie within the error bars. For c, we obtain an estimate of $0.443622 \pm 0.00074(10^{-3}\text{ms}^{-2})$, which is very close to the true value.

Attempting to fit a 5-mode kernel with initial guesses of $\lambda_i = 2.322$, 4.670, 10.47, 21.0, and 43.0 (in units of (10^{-2}ms), we obtain estimates for the λ's of 2.179, 3.748, 7.23, 14.947, and 33.897 (in 10^{-2}ms). However, the estimated covariance matrix has negative values on the diagonal, indicating a problem with the maximization process. There is also not a very large reduction in the sum of the squared residuals (Figure 11), which means that the additional parameter does not meaningfully contribute to explaining the data.

While additional parameters will almost always lead to a decrease in the residual sum of squares, it is clear in this case that the fit is unreliable since the approximated covariance matrix is not positive definite. Therefore we conclude that four modes provide an accurate representation of the data.

Next, we perform simulations to gauge the convergence of the parameter estimates with increased data and to test the dependency of the fit on changes in the sampling interval. Figure 13 shows the estimated values of λ_3 and λ_4 as a function of the number of data points in the time series. (The fits for the other two relaxation times are significantly better and omitted for clarity.) The convergence rate appears to be on the order of $n^{-1/2}$, consistent with the earlier derivation of the confidence interval. Figure 14 shows the estimated values of λ_3 and λ_4 as functions of the sampling time Δ. The results are similar to those for the Langevin equation (Figure 2). That is, the method has difficulties estimating the relaxation times if too short or too long a sampling time is used.

3.4. Direct GLE simulations of MSD and velocity autocorrelations. Ensemble average information for vector Langevin equations can be expressed in quadra-

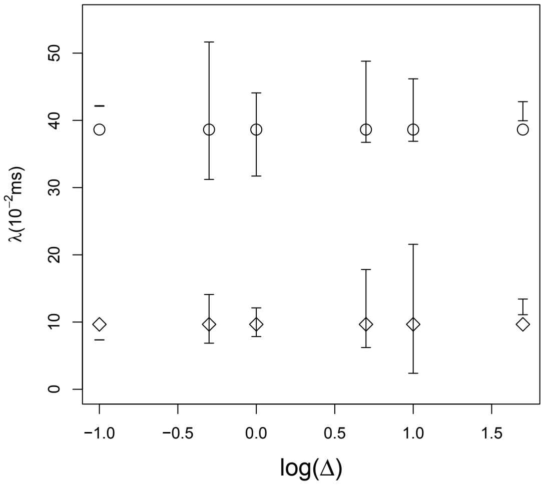

FIG. 13. *Parameter estimation versus sampling rate for the longest relaxation times* λ_3 *and* λ_4 *in a* 4*-mode kernel. The error bars are symmetric about the estimate with the open circles being the true values. The x-axis represents the log of* Δ *(sampling time).*

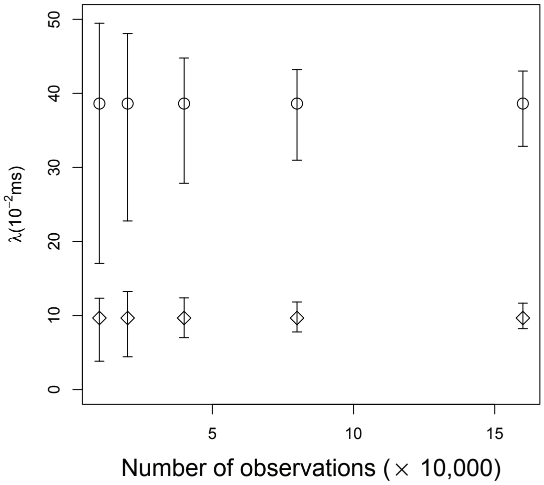

FIG. 14. *Parameter estimation versus number of observations (in units of* 10^4*) for the two longest relaxation times* λ_3 *and* λ_4 *in a* 4*-mode kernel. The error bars are symmetric about the estimate with the open circles being the true values.*

ture form by the appropriate averaging of the exact quadrature formula for individual paths. The full matrix of autocorrelations for a vector Ornstein–Uhlenbeck process is

$$\langle Y(t)Y^T(t')\rangle = \int_0^t \int_0^{t'} ds_1 ds_2 \delta(s_1 - s_2) e^{A(t-s_1)} K K^T e^{A^T(t'-s_2)}. \tag{3.20}$$

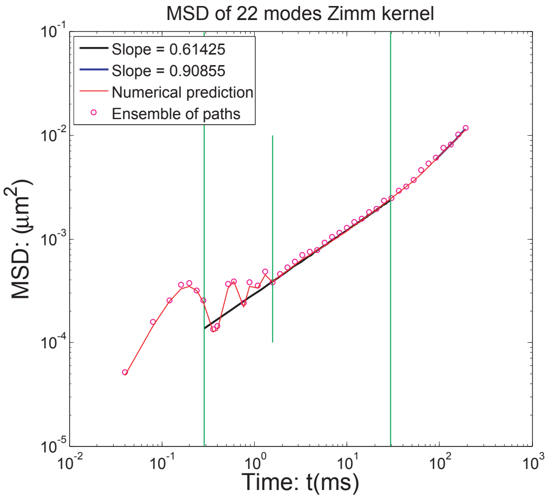

FIG. 15. *MSD of the GLE with a* 22*-mode Zimm kernel. The smallest relaxation time is* 0.2885*ms, the longest is* 29.77*ms; the two vertical lines mark the time span between them, over which a power law of* 0.62 *fairly well approximates the theoretical Zimm model value of* $\frac{2}{3}$.

The (1,1) entry of the resulting matrix gives the MSD, and the (2,2) entry gives the velocity autocorrelation. *The practical ramification of this formula is that one can directly generate statistical properties for a known GLE M-mode diffusive transport modulus without the need to generate sample paths and then take ensemble averages.* For the special case of a single-mode exponential kernel, the integral representation can be solved explicitly, which gives the result presented earlier in (3.17), (3.18).

In Figure 8 for the 4-mode Rouse kernel, the MSD is computed two ways: from averaging of 200 sample paths generated from the GLE model and depicted by (blue) circles; and then directly from the autocovariance formula (3.20) and depicted by the (yellow) dashed line. Figure 8 convincingly reproduces the correct MSD power law behavior of Rouse theory, namely an exponent of $\frac{1}{2}$ when fitted over intermediate times between the relaxation spectra. This comparison provides another benchmark on the direct simulation tools, both for sample paths and for the autocovariance of GLE processes.

We now illustrate that the methods are not "mode limited," by running direct simulations for beads of the same size and mass as in Figure 8, but with a GLE diffusive transport modulus specified by a 22-mode Zimm kernel. The model posits 1100 monomers along each polymer chain, which we divide into 22 subunits, which gives 22 modes and an explicit relaxation spectrum. Figure 15 shows the MSD statistics, again generated both by ensemble averaging of paths and by the ACF (3.20). The simulations predict an MSD power law scaling exponent of 0.62 when fitted between the shortest and longest relaxation spectra, which reasonably approximates the $\frac{2}{3}$ theoretical value of the Zimm model.

3.5. Comparison with the MW inverse method. The inverse characterization framework for the memory kernel proposed in this paper focuses on single path information in the time domain, which is a complement to the transform space formulation of Mason and Weitz [10, 11, 12]. We now compare the two approaches on data generated by the GLE with the 4-mode Rouse kernel above. To make a fair

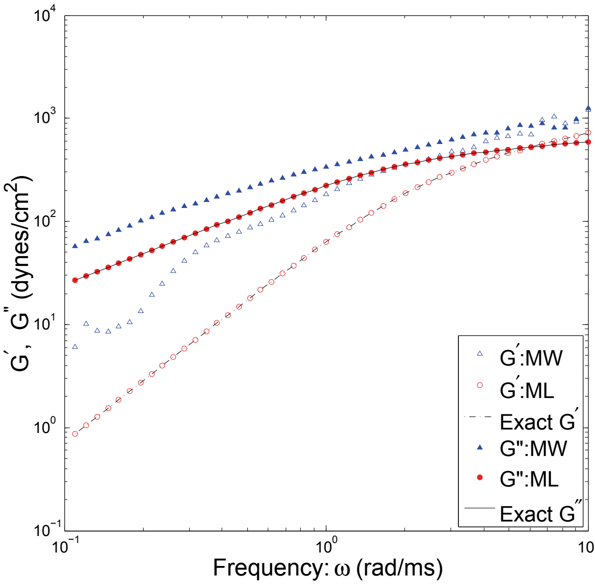

Fig. 16. *The real ($G'(\omega)$) and imaginary ($G''(\omega)$) parts of the transform of the GLE memory kernel, recovered from the same numerical GLE data with a* 4*-mode Rouse kernel, by the maximum likelihood and MW methods. The maximum likelihood results correspond to a best* 4*-mode exponential kernel fit.*

comparison, we simulate an experiment which gathers many bead paths.

In Mason and Weitz's original contribution [12], the memory kernel is transformed to frequency space following the standard definitions and notations of linear viscoelasticity [5]. The unilateral Fourier transform of the kernel, recalled below, is assumed to be proportional to the frequency-dependent shear viscosity function: $m\xi^* = 6\pi a\eta^*$, which is the generalized Stokes–Einstein relation. Recall that the transformed shear modulus G^* is proportional to the transformed viscosity function, $G^* = i\omega\eta^*$, i.e.,

$$G^*(\omega) \equiv i\omega \int_0^\infty \eta(t) e^{-i\omega t} dt = G^{'} + iG^{''}. \tag{3.21}$$

If we now assume the 4-mode Rouse kernel, the corresponding real and imaginary parts of G^* are

$$G'(\omega) = \sum_{i=1}^{4} \frac{G_0 \omega^2 \lambda_i^2}{1+\omega^2\lambda_i^2}, \quad G''(\omega) = \sum_{i=1}^{4} \frac{G_0 \omega \lambda_i}{1+\omega^2\lambda_i^2}, \tag{3.22}$$

where G_0 and λ_i are defined in (3.19).

The "experimental data" consists of 200 paths of 1μm diameter tracer beads, generated from the GLE algorithm described earlier. First we implement the MW method. We calculate the MSD from these 200 paths, shown in Figure 8. Next, the MSD versus t is transformed to the frequency domain, together with the GSER, to arrive at G^* (see [10] for details). We note that the MW method is applied only over the monotone part of the MSD curve in Figure 8, which optimizes the accuracy of the MW reconstruction of $G^*(\omega)$. The results are graphed in Figure 16. Second, we apply the maximum likelihood method to gain the best 4-mode fit to the path data. G^* is then given by (3.22) with the maximum likelihood estimators, graphed in Figure 16. The MW method overestimates G' and G'' in this frequency range.

If we further wanted to invert $G^*(\omega)$ to recover $G(t)$, clearly the maximum likelihood method requires no work. From the MW estimate $G^*(\omega)$, we refer to [14, 20] for numerical strategies to estimate $G(t)$, including an exponential fit.

We comment that this comparison is made on data for which our methods are designed to do well. The real test, on experimental data, remains for future comparisons.

4. Conclusions. A time-domain statistical strategy has been developed for passive microbead rheology which serves two purposes: as an inversion toolkit for recovery of the diffusive transport modulus in a generalized Langevin equation from experimental time series, and as a direct simulation toolkit for pathogen diffusion of single particles and statistical correlations if the diffusive transport modulus is known. These direct and inverse algorithms combine to a general package for anomalous diffusive transport of pathogens in soft matter, which we anticipate to be complementary to the MW experimental and theoretical protocol [10, 11, 12]. These tools are presently being applied to characterization of pulmonary liquids with our colleagues Superfine, Hill, and Cribb in the Virtual Lung Project at UNC.

We mention another related approach based on fractional Brownian diffusion developed by Kou, Xie, and coworkers [9, 13]. The approach taken in that work is to formulate the GLE using fractional Brownian white noise as the stochastic driving force. A benefit of this formulation is that the number of parameters is limited; the modeling feature that is distinct from our methods is that the autocovariance function decays as a specific power law uniformly in time. If MSD experimental data reflects a uniform power law scaling over the experimental time series, then the fractional Brownian diffusion model should be strongly considered. The method of fitting relies on estimating the autocovariance function for velocity and then fitting the parameterized autocovariance to this estimated function. Standard errors may then be obtained via simulation. The drawbacks include stochastic approximation in the simulation methods and the difficulty in estimating the autocovariance of the velocity when only position is observed. Our method overcomes these difficulties but is limited to models consistent with autocovariance functions which for long lags have an exponential decay. Our formulation also allows for a greatly simplified simulation method and a maximum likelihood parameter estimation procedure which may use experimental data more efficiently.

An open question relates to the range and timescales of power law behavior in the MSD that are possible for GLE models with the class of M-mode exponential kernels considered in this paper. So far, we have reproduced the classical Rouse and Zimm MSD scalings on intermediate timescales between the shortest and longest relaxation times for kernels with the Rouse and Zimm relaxation spectra. Our preliminary numerical studies show that a wide range of power law behavior is possible as the relaxation spectrum and the respective weights for each mode are varied, and recent, unpublished analytical results of Scott McKinley at Duke University confirm this numerical evidence.

These tools are viewed as a foundation for further extensions of the single-bead and two-bead models and experiments. The ability to separate local bead-fluid interactions from the bulk viscoelastic modulus, and to identify heterogeneity from single-particle and two-particle statistical correlations, are key future applications of these tools.

Appendix A. The Kalman filter. Similar discussions to the following, based on [19], may be found in numerous texts [8, 2]. The framework of the Kalman filter is to take a linear system model and an observation model which depends linearly on the state of the system. We call this general setup a linear state space model and use the following notation: The system equation is

$$Y_n = BY_{n-1} + \epsilon_n, \tag{A.1}$$

where $\epsilon_n \sim N(0, S)$, and the observation equation is

$$U_n = CY_n + \xi_n, \tag{A.2}$$

where $\xi_n \sim N(0, D)$. Also, note that ϵ_n and ξ_n are independent sequences and independent of each other. (Here we have included an error term for U_n which is the case in the standard Kalman filter. In the present paper, we assume no observation error, and so the D matrix will be zero.)

The goal of the Kalman filter is to calculate the conditional distribution of Y_n, given the observations $U_1, \ldots, U_n$. The mean of this conditional distribution is an estimate (which is optimal in certain ways) of Y_n. We are estimating the "hidden" elements of the process by conditioning on the observed elements of this process. For this procedure to be computationally feasible, a recursive algorithm is necessary. In other words, we would like to calculate the new conditional distribution of Y_n given $U_1, \ldots, U_n$ using only the conditional distribution of Y_{n-1} given $U_1, \ldots, U_{n-1}$ and a new observation U_n.

As a preliminary, the calculations of the Kalman filter rely on a basic theorem from multivariate statistical analysis which allows us to calculate the distribution of a portion of a Gaussian random vector conditioned on the other portion. For a normal random vector, A,

$$A = \begin{pmatrix} A_1 \\ A_2 \end{pmatrix} \sim \mathcal{N}\left[\begin{pmatrix} \mu_1 \\ \mu_2 \end{pmatrix}, \begin{pmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{pmatrix}\right], \tag{A.3}$$

we have that the distribution of A_1, given that $A_2 = a$, is

$$\mathcal{N}[\mu_1 + \sigma_{12}\Sigma_{22}^{-1}(a - \mu_2), \Sigma_{11} - \Sigma_{12}\Sigma_{22}^{-1}\Sigma_{21}]. \tag{A.4}$$

This also works in reverse—if $A_2 \sim \mathcal{N}[\mu_2, \Sigma_{22}]$ and the distribution of A_1 is given in (A.4), then the joint distribution is given by (A.3). (We are using the notation $\mathcal{N}[\mu, \Sigma]$ for multivariate normal distribution with mean vector μ and covariance matrix Σ.)

As mentioned, we would like to find a set of recursive equations such that if we had the new observation U_n and the distribution of $Y_{n-1}|U_1, \ldots, U_{n-1}$ (which we write as $Y_{n-1|n-1}$ throughout), then we can find the distribution $Y_{n|n}$. This distribution is the Kalman filter at time n. So, let's assume that we have the conditional distribution of $Y_{n-1|n-1}$, where we call the conditional mean of this random vector $\hat{Y}_{n-1}$ and the conditional covariance P_{n-1}. Now, using (A.1), we can calculate the distribution for $Y_{n|n-1}$ which will be

$$Y_{n|n-1} = \mathcal{N}[B\hat{Y}_{n-1}, BP_{n-1}B^t + S]. \tag{A.5}$$

For simplicity, we use the notation $R_{n-1} = BP_{n-1}B^t + S$ for the covariance matrix. Combining (A.2) and (A.5) yields

$$\begin{pmatrix} U_{n|n-1} \\ Y_{n|n-1} \end{pmatrix} \sim \mathcal{N}\left[\begin{pmatrix} CB\hat{Y}_{n-1} \\ B\hat{Y}_{n-1} \end{pmatrix}, \begin{pmatrix} D + CR_{n-1}C^t & CR_{n-1} \\ R_{n-1}C^t & R_{n-1} \end{pmatrix}\right]. \tag{A.6}$$

Right now, we need only to condition $Y_{n|n-1} = Y_n|(U_1, \dots, U_{n-1})$ on $U_{n|n-1} = U_n|(U_1, \dots, U_{n-1})$ to give us $Y_{n|n} = Y_n|(U_1, \dots, U_n)$, which is what we want. Another application of the theorem gives us that the mean of $Y_{n|n}$ is

$$\hat{Y}_n = B\hat{Y}_n + R_{n-1}C^t(D + CR_{n-1}C^t)^{-1}(U_n - CB\hat{Y}_{n-1}) \tag{A.7}$$

and the covariance is

$$P_n = R_{n-1} - R_{n-1}C^t(D + CR_{n-1}C^t)^{-1}CR_{n-1}. \tag{A.8}$$

So, we have derived the necessary recursions to take a new observation at time n and the filter at time $n-1$ (i.e., the distribution of Y_{n-1}, given the observations up to time $n-1$) and obtain the value of the filter at time n.

For our application, one element is particularly important—the one-step prediction for the observation process which is the distribution of U_n given $U_1, \dots, U_{n-1}$, i.e., $U_{n|n-1}$. This is given, however, in the first entry of the combined vector on the left-hand side of (A.6). Explicitly,

$$U_{n|n-1} \sim \mathcal{N}[CB\hat{Y}_{n-1}, D + CR_{n-1}C^t]. \tag{A.9}$$

This calculation is used in the error-prediction decomposition approach to calculating the likelihood function.

Appendix B. Asymptotic normality of maximum likelihood estimators. A key benefit of the maximum likelihood method is the ability to calculate standard errors on the estimates. In general, one starts with a model that depends on the parameters Θ, and then maximizes the likelihood function with respect to the model parameters to obtain the best estimate $\hat{\Theta}$ for the parameters. Under certain conditions, $\sqrt{N}(\hat{\Theta} - \Theta)$ converges to a multivariate normal with mean zero and covariance matrix $I^{-1}(\Theta)$, where $I(\Theta)$ is the information matrix [8] given as

$$I(\Theta) = -E\nabla^2 \log L(\Theta). \tag{B.1}$$

The necessary conditions that need to be satisfied are the following:

1. $I^{-1}(\Theta)$ must be positive definite.
2. $\hat{\Theta}$ must be in the interior of the parameter space.
3. $\log L(\Theta)$ has third-order continuous derivatives in the neighborhood of the true parameter values Θ.
4. Θ is identifiable. In other words, for each set of data, $L(\Theta)$ is a one-to-one function of Θ.

We approximate $I^{-1}(\Theta)$ by finding the Hessian of the logarithm likelihood function numerically with respect to the parameters evaluated at the maximum.

Appendix C. Evaluation of autocovariance. We discuss how the covariance matrix S for a GLE with M-mode kernel in (2.17), while $(2M+2) \times (2M+2)$ coefficient matrices A and K are defined as in (3.15), can be numerically calculated accurately and efficiently. The only difficulty is in finding all $2M+2$ eigenvalues of A; the remaining steps are straightforward.

C.1. Calculation of eigenvalues. For simplicity, we introduce parameters

$$c_i = \frac{6\pi a G_i}{m} = \frac{6\pi a \eta_i}{m\lambda_i}, \quad \sigma_i = \sqrt{\frac{k_B T}{m}}, \quad \kappa_i = \sqrt{\frac{2c_i}{\lambda_i}}. \tag{C.1}$$

Clearly, M eigenvalues, $\{-1/\lambda_i\}_{i=1}^{M}$, are easy to get. The remaining $2M+2$ are determined by the roots of the polynomial equation

$$P_d(x) = x\left(x\prod_{i=1}^{M}\left(x+\frac{1}{\lambda_i}\right)+\sum_{i=1}^{M}c_i\prod_{j\neq i}^{M}\left(x+\frac{1}{\lambda_j}\right)\right)=0. \tag{C.2}$$

First we factor out the simple zero eigenvalue associated with the position equation and then consider the remaining $M+1$ eigenvalues by studying the roots of the polynomial equation

$$P(x) = x\prod_{i=1}^{M}\left(x+\frac{1}{\lambda_i}\right)+\sum_{i=1}^{M}c_i\prod_{j\neq i}^{M}\left(x+\frac{1}{\lambda_j}\right)=0. \tag{C.3}$$

If we rewrite the above polynomial (C.3) by dividing it with $\prod_{i=1}^{M}(x+1/\lambda_i)$, we have a new function

$$Q(x) = x + \sum_{i=1}^{M}\frac{c_i}{x+1/\lambda_i}, \tag{C.4}$$

which has the same roots as $P(x)$. Recall $0<\lambda_1<\cdots<\lambda_M$. Clearly $Q(x)$ changes sign, and therefore has one zero, in each interval $(-1/\lambda_i,-1/\lambda_{i+1})$. These are easily found by iteration. This yields $M-1$ eigenvalues, denoted $\{x_i\}_{i=1}^{M-1}$, and only two remain.

The polynomial $P(x)$ of (C.3) has the form

$$P(x) = (x^2+bx+d)\prod_{i=1}^{M-1}(x-x_i)=0, \tag{C.5}$$

where d and b are given explicitly from $\{-1/\lambda_i\}_{i=1}^{M}, \{x_i\}_{i=1}^{M-1}$:

$$\begin{aligned} d &= \frac{P(0)}{\prod_{i=1}^{M-1}(-x_i)} = \frac{\sum_{i=1}^{M}c_i\prod_{j\neq i}^{M}\frac{1}{\lambda_j}}{\prod_{i=1}^{M-1}(-x_i)} = \frac{\sum_{i=1}^{M}c_i\prod_{j\neq i}^{M}\frac{1}{\lambda_j}}{\prod_{i=1}^{M-1}|x_i|} > 0,\\ b &= \frac{\prod_{i=1}^{M}(1+\frac{1}{\lambda_i})}{\prod_{i=1}^{M-1}(1-x_i)} + \frac{\sum_{i=1}^{M}c_i\prod_{j\neq i}^{M}(1+\frac{1}{\lambda_j})}{\prod_{i=1}^{M-1}(1-x_i)} - 1 - d > 0. \end{aligned} \tag{C.6}$$

This completes the calculation of all $2M+1$ eigenvalues, and we note that the last two roots have negative real part due to $b>0$. If the last two roots are complex conjugates, then the matrix A is diagonalizable only in the complex space.

Similarly, for the matrix As in (2.17), where s is a scalar, all the eigenvalues scale explicitly with s and the eigenvectors remain the same.

For $M=1,2,3$, there are analytical formulas for the roots of the polynomial. In the single-mode case, $M=1$, the eigenvalues are

$$\omega_1 = -\frac{1}{\lambda},\quad \omega_2 = -\frac{1}{2}\left(\frac{1}{\lambda}+\sqrt{\frac{1}{\lambda^2}-4c_1}\right),\quad \omega_3 = -\frac{1}{2}\left(\frac{1}{\lambda}-\sqrt{\frac{1}{\lambda^2}-4c_1}\right),\quad \omega_4 = 0, \tag{C.7}$$

with easily calculated eigenvectors. The covariance matrix S of (2.17) can thus be calculated in closed form.

For general M, from (C.5) and (C.6), fast and efficient numerical schemes could be found for the calculation of eigenvalues and eigenvectors.

C.2. Calculation of the covariance matrix S. Given this detailed spectral information for A, we can precompute the covariance matrix, as shown below.

First we assume that the matrix A has full span of eigenvectors R (its inverse is R^{-1}),

$$A = R\Lambda R^{-1}, \quad A^2 = AA = R\Lambda R^{-1}R\Lambda R^{-1} = R\Lambda^2 R^{-1}, \tag{C.8}$$

where Λ is a diagonal matrix whose diagonal components are the eigenvalues of A.

By definition,

$$e^A = \sum_{n=0}^{\infty} \frac{A^n}{n!} = \sum_{n=0}^{\infty} \frac{R\Lambda^n R^{-1}}{n!} = R\left(\sum_{n=0}^{\infty} \frac{\Lambda^n}{n!}\right) R^{-1} = Re^{\Lambda}R^{-1}, \tag{C.9}$$

where $e^{\Lambda} = e^{\Lambda^T}$ is diagonal and the covariance matrix S can be written as

$$\begin{aligned} &S = R\left(\int_0^{\Delta} e^{\Lambda(\triangle - s)} R^{-1}KK^T(R^{-1})^T e^{\Lambda^T(\triangle - s)} ds\right) R^T \\ \overset{\triangle - s = u}{\Longleftrightarrow}\ &S = R\left(\int_0^{\Delta} e^{\Lambda u} C e^{\Lambda u} du\right) R^T, \end{aligned} \tag{C.10}$$

where we define $C = (R^{-1}K)(R^{-1}K)^T$.

Next, we take advantage of the above properties of the matrix A, as follows. Denoting by $e^{\omega_i u}$ the ith diagonal component of the matrix $e^{\Lambda u}$, where w_i is the ith eigenvalue of the matrix A and C_{ij} is the ith row and jth column component of the matrix C, we see (here $(\bullet_{ij})_{M\times M}$ denotes an M-by-M matrix with ith row and jth column component $\bullet_{ij}$)

$$\begin{aligned} e^{\Lambda u} C e^{\Lambda u} &= (C_{ij} e^{w_i u})_{(2M+2)\times(2M+2)} e^{\Lambda u} \\ &= (C_{ij} e^{(w_i + w_j)u})_{(2M+2)\times(2M+2)}. \end{aligned} \tag{C.11}$$

So the covariance matrix admits

$$\begin{aligned} S &= R\left(C_{ij}\int_0^{\Delta} e^{(\omega_i + \omega_j)u} du\right) R^T \\ &= R\left(C_{ij}\frac{e^{(\omega_i + \omega_j)\Delta} - 1}{\omega_i + \omega_j}\right) R^T, \end{aligned} \tag{C.12}$$

and after all the eigenvalues ω_i of A are determined, the integral form of S can be precalculated according to the above result, and the integration of the matrix function can be avoided.

DIFFRACTION BY A SEMI-INFINITE INTERFACIAL CRACK SANDWICHED BETWEEN TWO ISOTROPIC HALF PLANES*

V. KUBZINA[†‡], A. K. GAUTESEN[§], AND L. JU. FRADKIN[†]

Abstract. This paper addresses the canonical two dimensional problem of diffraction of the plane wave by a semi-infinite interfacial crack sandwiched between two isotropic solids. We restrict ourselves to a ubiquitous case of solids whose contact boundary does not support the Stoneley wave. Its solution can be used in applications to model diffraction from curved cracks with curvature that is small compared to a wavelength.

Key words. diffraction, interfacial crack, semianalytical approach

DOI. 10.1137/070711517

1. Introduction.

Finding a semianalytical solution to the problem of diffraction by a semi-infinite crack sandwiched between two different solids is a well-known problem in the mathematical theory of diffraction. In this paper we consider a two dimensional case involving two different isotropic half planes. Apart from being mathematically challenging, diffraction problems of this kind are of interest in ultrasonic NDE (nondestructive evaluation), particularly because interfacial cracks are often found in laminated composites. It is well known that ultrasonic inspection of such cracks is a challenging engineering problem, and detection of crack tip diffraction is particularly difficult. As a consequence, the defect size can be underestimated. Nevertheless, the advanced phased array transducers offer an improved performance [1], and models of the underlying diffraction process would allow the NDE inspectors to establish whether, in a given configuration, the amplitude of the edge diffracted echoes could exceed the detection threshold [2].

Over the years purely numerical approaches to this kind of problem based on finite differences, finite elements, or boundary integral techniques proved unreliable, because it is difficult to take into account the singularity condition at the crack tip and thus render a solution unique. It is also difficult to keep adjusting numerical schemes to account for different types of wave interaction [3, 4, 5]. Another well-known line of attack is to reformulate the problem in terms of a system of functional equations and to solve those using a numerical Wiener–Hopf factorization technique (see, e.g., [6]). So far, this approach has also met with numerous numerical difficulties and has produced no entirely satisfactory scheme.

In this paper we follow a semianalytical approach of [7, 8, 9, 10], developed to derive a solution of the elastodynamic equations formulated in terms of displacements, which it reduces to a system of regular integral equations for their Fourier transforms. We start with the elastodynamic integral equation for the displacement based on Green's formula and the extinction theorem for each isotropic half plane and then use operations of dilatation (or divergence) and rotation (or curl) to separate transverse and longitudinal motions. Since the incident wave can be considered as radiated by a line load, we represent the two dimensional free space Green's tensors in terms of the Hankel function of the first kind of the zeroth order and its derivatives. Using the boundary conditions, the Fourier transform of the elastodynamic integral equation is reduced to a system of four functional equations in eight "half unknowns." Then, the problem is reformulated in terms of traction and crack opening displacement, both of which can be decomposed into singular and nonsingular parts. The singular parts relate to the well-known geometricoelastodynamic (GE) body waves. The nonsingular parts constitute new unknowns. By using a Hilbert-type integral transform, the functional equations are transformed into four regular integral equations in four unknowns. In turn, these are solved numerically. In the far field, diffraction body wave coefficients are obtained. The method can be generalized to model transversely isotropic media.

2. The problem statement.

We consider a two dimensional semi-infinite crack (see Figure 2.1) sandwiched between two different isotropic media $I^{(j)}$, where superscript $j = 1$ corresponds to the medium occupying the "upper" half plane and $j = 2$ means the "lower" half plane. Let the crack be irradiated by a longitudinal ($n = 1$) or transverse ($n = 2$) plane wave, which is incident from the medium $I^{(m)}$, $m = 1$ or 2, and propagates there with the speed $c_n^{(m)}$, where m and n are both fixed throughout the paper. Further, let us assume without loss of generality that the longitudinal speed $c_1^{(1)}$ in the medium $I^{(1)}$ is greater than the longitudinal speed $c_1^{(2)}$ in the medium $I^{(2)}$. Let us further introduce a Cartesian base $\{\mathbf{e}_1, \mathbf{e}_2\}$, with $\mathbf{e}_1$ running along the crack surface and $\mathbf{e}_2$ perpendicular to $\mathbf{e}_1$ and pointing into the "upper" medium. In this base, every vector can be presented in terms of the corresponding coordinates, so that every position vector $\mathbf{x} = (x_1, x_2)$, every displacement vector $\mathbf{u} = (u_1, u_2)$, etc.

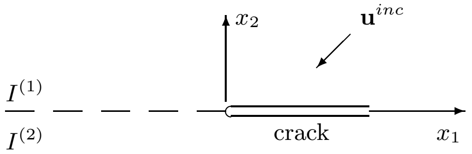

FIG. 2.1. *The problem geometry.*

Let $\mathbf{u}(\mathbf{x}) \exp(-i\omega t)$ be a time harmonic displacement vector in an elastic medium, where t is time, ω is the angular frequency, and the exponential time factor $\exp(-i\omega t)$ is understood but suppressed everywhere below. Using the two dimensional Green's tensors (see Appendix A) and introducing a fictitious bottom medium that has the properties of the upper half space, and a fictitious top medium which has the properties of the bottom half space, the above problem can be recast in the form of a generalized reciprocity relation [11] or the extinction theorem (by analogy with the electromagnetic case—see [12]; the detailed derivation is given in [13]; also see Appendix B). This states that the total displacement for a medium $I^{(j)}$ satisfies the integral equation

$$H[(-1)^{j+1}x_2]u_k^{(j)}(\mathbf{x}) = u_k^{inc(j)}(\mathbf{x}) + (-1)^j \sum_{i=1}^{2} \int_{-\infty}^{-\infty} [\sigma_{2ik}^{G(j)}(x_1 - y_1, x_2)u_i^{(j)}(y_1, 0)$$

$$+ u_{ik}^{G(j)}(x_1 - y_1, x_2)\sigma_{2i}^{(j)}(y_1, 0)]dy_1, \quad j, k = 1, 2, \tag{2.1}$$

where $u^{G(j)}(\mathbf{x} - \mathbf{y})$ and $\sigma^{G(j)}(\mathbf{x} - \mathbf{y})$ are the free space Green's tensor and Green's stress tensor, respectively; $\sigma^{(j)}(\mathbf{x})$ is the stress tensor corresponding to displacement $\mathbf{u}^{(j)}(\mathbf{x})$; $H(x)$ is the Heaviside step function,

$$H(x) = \begin{cases} 1, & x \geq 0, \\ 0, & x < 0; \end{cases} \tag{2.2}$$

and in the medium $I^{(j)}$, $j = 1, 2$, the plane wave $\mathbf{u}^{inc(j)}(\mathbf{x})$, which is incident from $I^{(m)}$, is

$$\mathbf{u}^{inc(j)}(\mathbf{x}) = \delta_{mj}\mathbf{d}^{n(m)}e^{-ik_n^{(m)}(p_1^{inc}x_1 - (-1)^m p_2^{inc}x_2)}, \tag{2.3}$$

with δ_{mj}—the Kronecker delta, $\mathbf{p}^{inc} = (p_1^{inc}, p_2^{inc})$—the incoming unit wave vector with $p_2^{inc} > 0$, and $k_n^{(m)} = \omega/c_n^{(m)}$—a wave number (see, e.g., [11]). The longitudinal displacement unit vector $\mathbf{d}^{1(m)}$ is

$$\mathbf{d}^{1(m)} = (-p_1^{inc}, (-1)^m p_2^{inc}), \tag{2.4}$$

and when the motions are transverse the displacement unit vector $\mathbf{d}^{2(m)}$ is

$$\mathbf{d}^{2(m)} = ((-1)^{m+1}p_2^{inc}, -p_1^{inc}). \tag{2.5}$$

To complete the problem statement we require that on the contact boundary, $\{(x_1, x_2) : x_2 = 0,\ x_1 < 0\}$, the displacement and normal stress components be continuous,

$$\begin{aligned} &u_i^{(1)}(x_1, 0) = u_i^{(2)}(x_1, 0), \\ &\sigma_{2i}^{(1)}(x_1, 0) = \sigma_{2i}^{(2)}(x_1, 0), \quad x_1 < 0, \quad i = 1, 2; \end{aligned} \tag{2.6}$$

on the crack $\{(x_1, x_2) : x_2 = 0,\ x_1 > 0\}$ the normal stress components be zero,

$$\sigma_{2i}^{(1)}(x_1, 0) = \sigma_{2i}^{(2)}(x_1, 0) = 0, \quad x_1 > 0, \quad i = 1, 2; \tag{2.7}$$

at infinity, the radiation conditions be satisfied in the form of the limiting absorption principle; and at the crack tip, the mean energy of the diffracted field be bounded. In combination with (2.1), the last condition amounts to requiring that we have

$$\sigma \sim O(r^{-1/2 \pm i\nu_0}), \tag{2.8}$$

with $\nu_0 > 0$ a real bimaterial constant (see, e.g., [14]) and r the distance to the origin $r = \sqrt{x_1^2 + x_2^2}$. The condition (2.8) suggests the oscillatory motions near the crack tip, which is nonphysical. However, this region is often extremely small and in most cases can be ignored. (For further discussion, see Williams [15], Erdogan [16, 17], and Rice and Sih [18]; the related static case has been considered in [19]). Below, if not used as a subscript, $i = \sqrt{-1}$.

3. The functional equations for the Fourier transforms of displacements and stresses in the crack plane. For any field $\varphi(y_1)$ let us define the decomposition

$$\varphi(y_1) = \varphi^+(y_1) + \varphi^-(y_1), \tag{3.1}$$

where the superscripts + and − denote functions that vanish for the negative and positive values of y_1, respectively. Let us use these fields to introduce new "half unknowns," components of the four dimensional vector $\mathbf{v}^\pm(y_1)$ given by

$$\begin{aligned} &v_i^-(y_1) = u_i^{(1)}(y_1, 0) = u_i^{(2)}(y_1, 0), \qquad y_1 < 0,\\ &v_{i+2}^-(y_1) = -\frac{i}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(1)}(y_1, 0) = -\frac{i}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(2)}(y_1, 0), \qquad y_1 < 0,\\ &v_i^+(y_1) = u_i^{(1)}(y_1, 0), \qquad y_1 > 0,\\ &v_{i+2}^+(y_1) = u_i^{(2)}(y_1, 0), \qquad y_1 > 0,\ i = 1, 2. \end{aligned} \tag{3.2}$$

Let us make use of operators of dilatation (or divergence) and rotation (or curl) and denote the dilatation of any tensor $\phi_{ik}^{(j)}(x_1, x_2)$ by the superscript ^{1} and the rotation by the superscript ^{2}, so that we can write

$$\phi_i^{(j)1}(\mathbf{x}) = [\phi_{i1}^{(j)}(\mathbf{x})]_{,1} + [\phi_{i2}^{(j)}(\mathbf{x})]_{,2}\,, \quad \phi_i^{(j)2}(\mathbf{x}) = [\phi_{i2}^{(j)}(\mathbf{x})]_{,1} - [\phi_{i1}^{(j)}(\mathbf{x})]_{,2}\,. \tag{3.3}$$

Applying the dilatation ($l = 1$) and rotation ($l = 2$) to (2.1) in the half plane where the argument of the Heaviside function is negative ($(-1)^j x_2 > 0$) and using the boundary conditions (2.6) and (2.7), the extinction theorem can be rewritten as

$$\begin{aligned} &ik_n^{(m)}\delta_{mj}\delta_{nl}e^{-ik_n^{(m)}(x_1p_1^{inc}+(-1)^{m+1}p_2^{inc}x_2)}\\ &\quad + (-1)^j\int_0^\infty [\sigma_1^{G(j)l}(x_1 - y_1, x_2)v_{2j-1}^+(y_1) + \sigma_2^{G(j)l}(x_1 - y_1, x_2)v_{2j}^+(y_1)]dy_1\\ &\quad + (-1)^j\int_{-\infty}^0 \{\sigma_1^{G(j)l}(x_1 - y_1, x_2)v_1^-(y_1) + \sigma_2^{G(j)l}(x_1 - y_1, x_2)v_2^-(y_1)\\ &\qquad\qquad + ik_1^{(1)}\mu^{(1)}[u_1^{G(j)l}(x_1 - y_1, x_2)v_3^-(y_1)\\ &\qquad\qquad + u_2^{G(j)l}(x_1 - y_1, x_2)v_4^-(y_1)]\}dy_1 = 0, \quad j, l = 1, 2, \end{aligned} \tag{3.4}$$

or in the matrix form as

$$\begin{aligned} &\int_0^\infty A^+(x_1 - y_1, x_2)\mathbf{v}^+(y_1)dy_1 + \int_{-\infty}^0 A^-(x_1 - y_1, x_2)\mathbf{v}^-(y_1)dy_1\\ &\qquad = -ik_n^{(m)}\mathbf{U}^{inc}e^{ik_n^{(m)}\mathbf{x}\cdot\mathbf{d}^{1(m)}}, \end{aligned} \tag{3.5}$$

where $\mathbf{d}^{1(m)}$ is the displacement unit vector of a longitudinal wave defined in (2.4), $\mathbf{U}^{inc}$ is the four dimensional vector

$$\mathbf{U}^{inc} = [\delta_{1m}\delta_{1n},\ \delta_{1m}\delta_{2n},\ \delta_{2m}\delta_{1n},\ \delta_{2m}\delta_{2n}]^T, \tag{3.6}$$

and 4×4 matrices $A^+(\mathbf{x})$ and $A^-(\mathbf{x})$ are

$$A^+(\mathbf{x}) = \begin{pmatrix} -\sigma_1^{G(1)1}(\mathbf{x}) & -\sigma_2^{G(1)1}(\mathbf{x}) & 0 & 0 \\ -\sigma_1^{G(1)2}(\mathbf{x}) & -\sigma_2^{G(1)2}(\mathbf{x}) & 0 & 0 \\ 0 & 0 & \sigma_1^{G(2)1}(\mathbf{x}) & \sigma_2^{G(2)1}(\mathbf{x}) \\ 0 & 0 & \sigma_1^{G(2)2}(\mathbf{x}) & \sigma_2^{G(2)2}(\mathbf{x}) \end{pmatrix},$$

$$A^-(\mathbf{x}) = \begin{pmatrix} -\sigma_1^{G(1)1}(\mathbf{x}) & -\sigma_2^{G(1)1}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_1^{G(1)1}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_2^{G(1)1}(\mathbf{x}) \\ -\sigma_1^{G(1)2}(\mathbf{x}) & -\sigma_2^{G(1)2}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_1^{G(1)2}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_2^{G(1)2}(\mathbf{x}) \\ \sigma_1^{G(2)1}(\mathbf{x}) & \sigma_2^{G(2)1}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_1^{G(2)1}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_2^{G(2)1}(\mathbf{x}) \\ \sigma_1^{G(2)2}(\mathbf{x}) & \sigma_2^{G(2)2}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_1^{G(2)2}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_2^{G(2)2}(\mathbf{x}) \end{pmatrix}, \tag{3.7}$$

with dilatations and rotations $u_i^{G(j)l}(\mathbf{x})$ and $\sigma_i^{G(j)l}(\mathbf{x})$ given in Appendix A.

Everywhere below, let the hat $\widehat{}$ denote the Fourier transform with respect to the nondimensionalized variable $k_1^{(1)}y_1$, so that for any function $\varphi(y_1)$ we have

$$\widehat{\varphi}(\xi) = k_1^{(1)} \int_{-\infty}^{\infty} \varphi(y_1) e^{ik_1^{(1)}\xi y_1} dy_1. \tag{3.8}$$

Let us then take the Fourier transform of (3.5) and evaluate the result on the boundary. For this purpose, let us multiply (3.5) by $\exp(ik_1^{(1)}\xi x_1)$, integrate it over x_1, and set $x_2 = 0$. Applying the convolution theorem, we obtain

$$\begin{aligned} &\frac{1}{k_1^{(1)}} \left[\int_{-\infty}^{\infty} A^+(\mathbf{x}) e^{ik_1^{(1)}\xi x_1} dx_1 \right] \widehat{\mathbf{v}}^+(\xi) \\ &\quad + \frac{1}{k_1^{(1)}} \left[\int_{-\infty}^{\infty} A^-(\mathbf{x}) e^{ik_1^{(1)}\xi x_1} dx_1 \right] \widehat{\mathbf{v}}^-(\xi) = p(\xi)\mathbf{U}^{inc}, \end{aligned} \tag{3.9}$$

where, using the notation $\xi^{inc} = \kappa_n^{(m)} p_1$, $\kappa_n^{(m)} = c_1^{(1)}/c_n^{(m)}$, we have

$$p(\xi) = 2\pi\ i\delta(\xi - \xi^{inc}) = \lim_{\epsilon \to 0} \left(-\frac{1}{\xi - \xi^{inc} + i\epsilon} + \frac{1}{\xi - \xi^{inc} - i\epsilon} \right). \tag{3.10}$$

Multiplying the vector equation in (3.9) by $-2i$ and the first and the third scalar equations there by $[\kappa_2^{(1)}]^2$ and $[\kappa_2^{(2)}/\kappa_1^{(2)}]^2$, respectively, we obtain the system of four scalar functional equations

$$\widehat{A}^+(\xi)\widehat{\mathbf{v}}^+(\xi) + \widehat{A}^-(\xi)\widehat{\mathbf{v}}^-(\xi) = p(\xi)\mathbf{v}^{inc}, \tag{3.11}$$

where the vector $\mathbf{v}^{inc}$ is such that

$$\mathbf{v}^{inc} = 2i \left[(\kappa^{(1)})^2 \delta_{1m}\delta_{1n},\ \delta_{1m}\delta_{2n},\ (\kappa^{(2)})^2 \delta_{2m}\delta_{1n},\ \delta_{2m}\delta_{2n} \right]^T \tag{3.12}$$

with $\kappa^{(j)} = c_1^{(j)}/c_2^{(j)}$; and matrices $\widehat{A}^+(\xi)$ and $\widehat{A}^-(\xi)$ in (3.11) are given by

$$\widehat{A}^+(\xi) = \begin{pmatrix} 2\xi & \frac{a_1(\xi)}{\gamma_1^{(1)}(\xi)} & 0 & 0 \\ -\frac{a_1(\xi)}{\gamma_2^{(1)}(\xi)} & 2\xi & 0 & 0 \\ 0 & 0 & 2\xi & -\frac{a_2(\xi)}{\gamma_1^{(2)}(\xi)} \\ 0 & 0 & \frac{a_2(\xi)}{\gamma_2^{(2)}(\xi)} & 2\xi \end{pmatrix}, \tag{3.13}$$

$$\widehat{A}^-(\xi) = \begin{pmatrix} 2\xi & \frac{a_1(\xi)}{\gamma_1^{(1)}(\xi)} & -\frac{\xi}{\gamma_1^{(1)}(\xi)} & -1 \\ -\frac{a_1(\xi)}{\gamma_2^{(1)}(\xi)} & 2\xi & 1 & -\frac{\xi}{\gamma_2^{(1)}(\xi)} \\ 2\xi & -\frac{a_2(\xi)}{\gamma_1^{(2)}(\xi)} & \frac{\mu\,\xi}{\gamma_1^{(2)}(\xi)} & -\mu \\ \frac{a_2(\xi)}{\gamma_2^{(2)}(\xi)} & 2\xi & \mu & \frac{\mu\,\xi}{\gamma_2^{(2)}(\xi)} \end{pmatrix}, \tag{3.14}$$

with $a_j(\xi) = (\kappa_2^{(j)})^2 - 2\xi^2$, $\gamma_i^{(j)}(\xi) = \sqrt{[\kappa_i^{(j)}]^2 - \xi^2}$, and $\mu = \mu^{(1)}/\mu^{(2)}$.

The dilatation and rotation of the Green's tensor and Green's stress tensor in (3.7) can be expressed in terms of $H_0(k_i^{(j)}r)$, the Hankel function of the first kind of zero order and its derivatives (see Appendix A). Therefore, the matrices $\widehat{A}^{\pm}(\xi)$ have been evaluated with the help of the following identity:

$$\int_{-\infty}^{\infty} H_0(k_i^{(j)}r)e^{ik_1^{(1)}\xi x_1}dx_1 = \frac{2}{k_1^{(1)}}\frac{1}{\gamma_i^{(j)}}e^{ik_1^{(1)}\gamma_i^{(j)}|x_2|} \tag{3.15}$$

(see, e.g., [20]). Note that (3.11) involves singularities, which are described in Appendix C. Using the definition of plus and minus functions together with (3.8), it is easy to check that $\widehat{\mathbf{v}}^+(\xi)$ and $\widehat{\mathbf{v}}^-(\xi)$ are analytic in the upper and lower halves, respectively, of the complex ξ-plane.

Let us cast (3.11) in another form through multiplying by the matrix $[\widehat{A}^-(\xi)]^{-1}$. Then we obtain the vector functional equation

$$\widehat{\mathbf{v}}^-(\xi) + B^+(\xi)\widehat{\mathbf{v}}^+(\xi) = p(\xi)\mathbf{T}^{inc}, \tag{3.16}$$

where the vector on the right-hand side is

$$\mathbf{T}^{inc} = [\widehat{A}^-(\xi^{inc})]^{-1}\mathbf{v}^{inc}; \tag{3.17}$$

the matrix $B^+(\xi) = [\widehat{A}^-(\xi)]^{-1}\widehat{A}^+(\xi)$ is given by

(3.18)

$$B^+(\xi) = \frac{\mu}{S(\xi)} \cdot$$

$$\begin{pmatrix} b_{21}b_{12} - g_1g_2 + \mu R_1h_2 & -(b_{21}g_1 + b_{11}g_2) & b_{11}b_{22} - g_1g_2 + \frac{R_2h_1}{\mu} & b_{21}g_1 + b_{11}g_2 \\ b_{22}g_1 + b_{12}g_2 & b_{22}b_{11} - g_1g_2 + \mu R_1h_2 & -(b_{22}g_1 + b_{12}g_2) & b_{12}b_{21} - g_1g_2 + \frac{R_2h_1}{\mu} \\ -\frac{d_2}{\mu} & \frac{e}{\mu} & \frac{d_2}{\mu} & -\frac{e}{\mu} \\ -\frac{e}{\mu} & -\frac{d_1}{\mu} & \frac{e}{\mu} & \frac{d_1}{\mu} \end{pmatrix},$$

with the Rayleigh functions $R_j(\xi)$, b_{ij}, g_j, $i, j = 1, 2$, and the Stoneley function $S(\xi)$ defined in Appendix C; and

$$\begin{aligned} d_j(\xi) &= R_2(\xi)b_{1j}(\xi) + \mu R_1(\xi)b_{2j}(\xi), \\ e(\xi) &= R_2(\xi)g_1(\xi) - \mu R_1(\xi)g_2(\xi), \quad j = 1, 2. \end{aligned} \tag{3.19}$$

In the case under consideration, the equation $|\widehat{A}^{-}(\xi)| = 0$ has no solutions (see Appendix C), and therefore the matrix $B^{+}(\xi)$ is bounded. Equation (3.16) is a vector functional equation, which has no known analytical solution and is difficult to solve numerically.

4. The functional equations for nonsingular unknowns. Let us reformulate (3.16) as a vector functional equation for nonsingular components of the displacements and stresses in the crack plane. We start by introducing two new unknown vector functions, the crack opening displacement (COD) $\mathbf{u}^{COD}(y_1)$ and $\mathbf{t}(y_1)$, as

$$\begin{aligned} \mathbf{u}^{COD}(y_1) &= \mathbf{u}^{(1)}(y_1, 0) - \mathbf{u}^{(2)}(y_1, 0), \\ \mathbf{t}(y_1) &= \frac{1}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(1)}(y_1, 0). \end{aligned} \tag{4.1}$$

Then using the definition (3.2), their Fourier transforms $\widehat{\mathbf{u}}^{COD}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ may be expressed in terms of components of the old half unknowns $\mathbf{v}^{\pm}(\xi)$ as

$$\begin{aligned} \widehat{u}_l^{COD}(\xi) &= \widehat{v}_l^{+}(\xi) - \widehat{v}_{2+l}^{+}(\xi), \\ \widehat{t}_l(\xi) &= i\widehat{v}_{l+2}^{-}(\xi), \quad l = 1, 2. \end{aligned} \tag{4.2}$$

The last two equations in (3.16) can be rewritten in terms of the new unknowns $\widehat{\mathbf{u}}^{COD}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ as

$$-i\widehat{\mathbf{t}}(\xi) + \tilde{B}^{+}(\xi)\widehat{\mathbf{u}}^{COD}(\xi) = p(\xi)\tilde{\mathbf{T}}^{inc}, \tag{4.3}$$

where $p(\xi)$ is defined in (3.10); the matrix $\tilde{B}^{+}(\xi)$ and vector $\tilde{\mathbf{T}}^{inc}$ are bounded and are

$$\tilde{B}^{+}(\xi) = \frac{1}{S(\xi)}\begin{pmatrix} -d_2(\xi) & e(\xi) \\ -e(\xi) & -d_1(\xi) \end{pmatrix}, \qquad \tilde{\mathbf{T}}^{inc} = (T_3^{inc}, T_4^{inc})^T. \tag{4.4}$$

The right-hand side of the above equation has two poles, $\xi^{inc} + i0$ and $\xi^{inc} - i0$, which lie infinitely close to each other. Let us isolate one of them by introducing

$$\widehat{\mathbf{s}}(\xi) = -i\widehat{\mathbf{t}}(\xi) - \frac{1}{\xi - \xi^{inc} - i0}\tilde{\mathbf{T}}^{inc}. \tag{4.5}$$

Then the second pole $\xi^{inc} - i0$ can be shifted back to the real axis. For this reason, everywhere below we use ξ^{inc} to mean $\xi^{inc} - i0$. Using (4.5), the functional equation (4.3) can be rewritten as

$$\widehat{\mathbf{s}}(\xi) + \tilde{B}^{+}(\xi)\widehat{\mathbf{u}}^{COD}(\xi) = -\frac{1}{\xi - \xi^{inc}}\tilde{\mathbf{T}}^{inc}. \tag{4.6}$$

The function $\widehat{\mathbf{u}}^{COD}(\xi)$ is analytic in the upper half plane. Therefore, its domain contains both Rayleigh poles $-\xi^{R(j)}$, $j = 1, 2$, the incident pole $\xi = \xi^{inc}$, and also

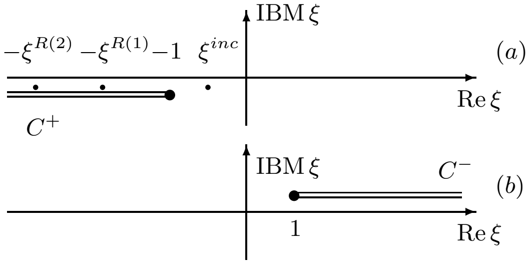

FIG. 4.1. *The poles and branch cuts of* (a) $\widehat{\mathbf{u}}^{COD}(\xi)$ *and* (b) $\widehat{\mathbf{s}}(\xi)$.

the branch cut C^+ (see Figure 4.1(a) and Appendix C). This means that we can decompose $\widehat{\mathbf{u}}^{COD}(\xi)$ as follows:

$$\widehat{\mathbf{u}}^{COD}(\xi) = \frac{G(\xi^{inc})}{G(\xi)}\widehat{\mathbf{w}}^{ge+}(\xi) + \frac{G(\xi)}{[\xi+\xi^{R(1)}][\xi+\xi^{R(2)}]}\widehat{\mathbf{w}}^{+}(\xi), \tag{4.7}$$

where $G(\xi)$ is defined in Appendix D, $\widehat{\mathbf{w}}^{ge+}(\xi)$ has the pole at $\xi = \xi^{inc}$, and $\widehat{\mathbf{w}}^{+}(\xi)$ is a new unknown vector describing the edge diffracted body and surface waves. Note that as $\xi \to \infty$, the function $G(\xi) \sim \xi$, and therefore $\widehat{\mathbf{w}}^{+}(\xi)$ behaves as $\xi\widehat{\mathbf{u}}^{COD}(\xi)$.

The function $\widehat{\mathbf{w}}^{ge+}(\xi)$ can be chosen to be

$$\begin{aligned}\widehat{\mathbf{w}}^{ge+}(\xi) = &-\frac{1}{\xi-\xi^{inc}}\tilde{B}^{-}(\xi^{inc})\tilde{\mathbf{T}}^{inc}\\ &+\frac{1}{\xi-\xi^{inc}}\frac{1}{G(\xi^{inc})}\sum_{k=1}^{4}F_k^{+}(\xi,\xi^{inc})\Delta_k^{+}[G(\xi)\tilde{B}^{-}(\xi)]\big|_{\xi=\xi^{inc}}\tilde{\mathbf{T}}^{inc},\end{aligned} \tag{4.8}$$

where the auxiliary functions $F_k^{+}(\xi,\zeta)$, $k = 1,\dots,4$, are defined in Appendix D; we have

$$\tilde{B}^{-}(\xi) = \frac{1}{R_1(\xi)R_2(\xi)}\begin{pmatrix} -d_1(\xi) & -e(\xi) \\ e(\xi) & -d_2(\xi)\end{pmatrix}, \tag{4.9}$$

and for any function $\Phi(\xi)$ we denote by $\Delta_k^{+}\Phi(\xi)$ the jump of $\Phi(\xi)$ over the branch cut C_k^{+} defined in (D.4) of Appendix D.

Analogously, the function $\widehat{\mathbf{s}}(\xi)$ is analytic in the lower half plane, and we can write the decomposition

$$\widehat{\mathbf{s}}(\xi) = \widehat{\mathbf{w}}^{ge-}(\xi) + \widehat{\mathbf{w}}^{-}(\xi), \tag{4.10}$$

where $\widehat{\mathbf{w}}^{ge-}(\xi)$ is introduced to cancel the extraneous incident pole appearing on the negative side of the branch cut C^- (see Figure 4.1(b)) and $\widehat{\mathbf{w}}^{-}(\xi)$ is a new unknown vector. The function $\widehat{\mathbf{w}}^{ge-}(\xi)$ can be chosen to be

$$\widehat{\mathbf{w}}^{ge-}(\xi) = -\frac{1}{\xi-\xi^{inc}}\sum_{k=1}^{4}F_k^{-}(\xi,\xi^{inc})\Delta_k^{-}[\tilde{B}^{+}(\xi)]\big|_{\xi=\xi^{inc}}\tilde{B}^{-}(\xi^{inc})\tilde{\mathbf{T}}^{inc}, \tag{4.11}$$

where the auxiliary functions $F_k^{-}(\xi,\zeta)$ are defined in Appendix D and $\Delta_k^{-}\Phi(\xi)$ denotes a jump of a function $\Phi(\xi)$ over the branch cut C_k^{-} defined in (D.4). It can be shown that whether or not $\xi = \xi^{inc}$ lies close to the branch cut C^-, we can always use the definition (4.11).

Let us substitute decompositions (4.7) and (4.10) into the functional equation (4.6) to obtain a functional equation for the new unknowns $\widehat{\mathbf{w}}^+(\xi)$ and $\widehat{\mathbf{w}}^-(\xi)$,

$$\widehat{\mathbf{w}}^-(\xi) + M^+(\xi)\widehat{\mathbf{w}}^+(\xi) = \mathbf{V}^{inc-}(\xi), \tag{4.12}$$

where the matrix $M^+(\xi)$ is given by

$$M^+(\xi) = \frac{G(\xi)}{(\xi^{R(1)} + \xi)(\xi^{R(2)} + \xi)}\tilde{B}^+(\xi) \tag{4.13}$$

and the vector $\mathbf{V}^{inc-}(\xi)$ on the right-hand side of (4.12) can be written as

$$\mathbf{V}^{inc-}(\xi) = -\frac{1}{\xi - \xi^{inc}}\tilde{\mathbf{T}}^{inc} - \frac{G(\xi^{inc})}{G(\xi)}\tilde{B}^+(\xi)\widehat{\mathbf{w}}^{ge+}(\xi) - \widehat{\mathbf{w}}^{ge-}(\xi). \tag{4.14}$$

Multiplying (4.12) by the inverse matrix $[M^+(\xi)]^{-1}$, we obtain the functional equation

$$\widehat{\mathbf{w}}^+(\xi) + M^-(\xi)\widehat{\mathbf{w}}^-(\xi) = \mathbf{V}^{inc+}(\xi), \tag{4.15}$$

where $M^-(\xi) = [M^+(\xi)]^{-1}$, so that we have

$$M^-(\xi) = \frac{(\xi^{R(1)} + \xi)(\xi^{R(2)} + \xi)}{G(\xi)R_1(\xi)R_2(\xi)} \begin{pmatrix} -d_1(\xi) & -e(\xi) \\ e(\xi) & -d_2(\xi) \end{pmatrix}, \tag{4.16}$$

and the vector $\mathbf{V}^{inc+}(\xi)$ is

$$\mathbf{V}^{inc+}(\xi) = M^-(\xi)\mathbf{V}^{inc-}(\xi). \tag{4.17}$$

The functional vector equations (4.12) and (4.15) form a system of four functional equations in four unknowns.

5. The system of integral equations.

Since the vector $\widehat{\mathbf{w}}^+(\xi)$ introduced in the decomposition (4.7) has no poles and vanishes at infinity, it can be represented as a Hilbert transform

$$\widehat{\mathbf{w}}^+(\xi) = -\frac{1}{2\pi i}\int_1^\infty \frac{\Delta\mathbf{w}^+(\xi')}{\xi' + \xi}d\xi', \tag{5.1}$$

where $\Delta\mathbf{w}^+(\xi)$ is a jump of $\widehat{\mathbf{w}}^+(\xi)$ over the branch cut C^+ (see Figure 4.1(a)); i.e., we have

$$\Delta\mathbf{w}^+(\xi) = \widehat{\mathbf{w}}^+(-\xi + i0) - \widehat{\mathbf{w}}^+(-\xi - i0), \quad \xi > 1. \tag{5.2}$$

Also, the vector $\widehat{\mathbf{w}}^-(\xi)$ introduced in (4.10) can be represented as

$$\widehat{\mathbf{w}}^-(\xi) = -\frac{1}{2\pi i}\int_1^\infty \frac{\Delta\mathbf{w}^-(\xi')}{\xi' - \xi}d\xi', \tag{5.3}$$

where, for $\xi \in C^-$, $\Delta\mathbf{w}^-(\xi)$ is a jump of $\widehat{\mathbf{w}}^-(\xi)$ over the branch cut C^-(see Figure 4.1(b)); i.e., we have

$$\Delta\mathbf{w}^-(\xi) = \widehat{\mathbf{w}}^-(\xi - i0) - \widehat{\mathbf{w}}^-(\xi + i0), \quad \xi > 1. \tag{5.4}$$

Note that $\widehat{\mathbf{w}}^+(\xi)$ and $\widehat{\mathbf{w}}^-(\xi)$ have the same branches as $\widehat{\mathbf{v}}^+(\xi)$ and $\widehat{\mathbf{v}}^-(\xi)$, respectively (see, e.g., [9]).

Let us now substitute (5.1) into (4.15), (5.3) into (4.12), and calculate the jumps in the resulting equations across the branch cuts C^+ and C^-, respectively. Then for $\xi > 1$ we have

$$\begin{aligned} &\Delta\mathbf{w}^+(\xi) + \Delta M^-(-\xi)\widehat{\mathbf{w}}^-(-\xi) = \Delta\mathbf{V}^{inc+}(\xi), \\ &\Delta\mathbf{w}^-(\xi) + \Delta M^+(\xi)\widehat{\mathbf{w}}^+(\xi) = \Delta\mathbf{V}^{inc-}(\xi), \end{aligned} \tag{5.5}$$

where Δ denotes the jump over the cut, $\xi \in C^-$, and we use the notation

$$\Delta M^\pm(\pm\xi) = 2i\,\mathrm{IBM}\,M^\pm(\pm\xi), \quad \xi \geq 1. \tag{5.6}$$

In view of (3.10), (4.16), (5.2), (5.4), and the definitions of the functions $F_k^\pm(\xi, a)$, $k = 1, \dots, 4$ (see Appendix D), the apparent poles $\xi = \xi^{R(j)}$ and $\xi = \pm\xi^{inc}$ in (5.5) are in fact absent (their residues are zero). Decompositions (4.8) and (4.11) have been chosen in order to achieve this regularization.

Equation (5.5) can be rewritten as the system of coupled integral equations

$$\begin{aligned} &\Delta\mathbf{w}^+(\xi) - \frac{1}{\pi}\mathrm{IBM}\,[M^-(-\xi)] \int_1^\infty \frac{\Delta\mathbf{w}^-(\xi')}{\xi+\xi'}d\xi' = \Delta\mathbf{V}^{inc+}(\xi), \\ &\Delta\mathbf{w}^-(\xi) - \frac{1}{\pi}\mathrm{IBM}\,[M^+(\xi)] \int_1^\infty \frac{\Delta\mathbf{w}^+(\xi')}{\xi+\xi'}d\xi' = \Delta\mathbf{V}^{inc-}(\xi). \end{aligned} \tag{5.7}$$

6. The numerical scheme. As mentioned above, we seek the solution of (5.7) that allows the tip condition (2.8) to be satisfied, that is, exhibit the asymptotic behavior

$$\Delta\mathbf{w}(\xi) \to \xi^{-1/2}[\mathbf{D}^+\cos(\nu_0 \ln\xi) + \mathbf{D}^-\sin(\nu_0\ln\xi)], \quad \xi \to \infty, \tag{6.1}$$

where ν_0 is a bimaterial constant; $\mathbf{D}^\pm$ are unknown four dimensional constant vectors, and $\Delta\mathbf{w}(\xi) = (\Delta w_1^+(\xi), \Delta w_2^+(\xi), \Delta w_1^-(\xi), \Delta w_2^-(\xi))$ is the unknown four dimensional vector function.

Let us rewrite the system of (5.7) as one vector integral equation,

$$\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\int_1^\infty \frac{\Delta\mathbf{w}(\xi')}{\xi'+\xi}d\xi' = \Delta\mathbf{V}^{inc}(\xi), \tag{6.2}$$

where we use the notation

$$\Delta\mathbf{V}^{inc}(\xi) = (\Delta V_1{}^{inc+}(\xi), \Delta V_2{}^{inc+}(\xi), \Delta V_1{}^{inc-}(\xi), \Delta V_2{}^{inc-}(\xi))^T,$$

with $\Delta V_i{}^{inc\pm}(\xi),\ i = 1, 2$, being the right-hand side of (5.5) and $M(\xi)$ being the 4×4 matrix that can be written as

$$M(\xi) = \begin{pmatrix} 0_2 & \mathrm{IBM}\,[M^-(-\xi)] \\ \mathrm{IBM}\,[M^+(\xi)] & 0_2 \end{pmatrix}. \tag{6.3}$$

Then there exists a constant L_2 such that for $\xi \geq L_2$ the solution $\Delta\mathbf{w}(\xi)$ exhibits the behavior (6.1) and we can rewrite (6.2) as

$$\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\int_1^{L_2} \frac{\Delta\mathbf{w}(\xi')}{\xi'+\xi}d\xi' - \frac{1}{\pi}M(\xi)[\mathbf{D}^+I^+(\xi) + \mathbf{D}^-I^-(\xi)] = \Delta\mathbf{V}^{inc}(\xi), \tag{6.4}$$

where we use the notation

$$\begin{aligned} I^{+}(\xi) &= \frac{1}{2}\left(\int_{L_2}^{\infty} \frac{x^{-1/2+i\nu_0}}{x+\xi}dx + \int_{L_2}^{\infty} \frac{x^{-1/2-i\nu_0}}{x+\xi}dx\right), \\ I^{-}(\xi) &= \frac{1}{2i}\left(\int_{L_2}^{\infty} \frac{x^{-1/2+i\nu_0}}{x+\xi}dx - \int_{L_2}^{\infty} \frac{x^{-1/2-i\nu_0}}{x+\xi}dx\right). \end{aligned} \tag{6.5}$$

The integral in (6.4) can be approximated using N collocation points $\xi_i,\ i = 1, N$, and weights $W_i,\ i = 1, N$, so that (6.4) may be approximated by

$$\Delta\mathbf{w}(\xi) - \frac{1}{\pi}M(\xi)\sum_{i=1}^{N}\frac{\Delta\mathbf{w}(\xi_i)}{\xi_i+\xi}W_i - \frac{1}{\pi}M(\xi)[\mathbf{D}^{+}I^{+}(\xi) + \mathbf{D}^{-}I^{-}(\xi)] = \Delta\mathbf{V}^{inc}(\xi), \tag{6.6}$$

which at $\xi = \xi_j,\ j = 1, N$, becomes

$$\begin{aligned} \Delta\mathbf{w}(\xi_j) - \frac{1}{\pi}M(\xi_j)\sum_{i=1}^{N}\frac{\Delta\mathbf{w}(\xi_i)}{\xi_i+\xi_j}W_i - \frac{1}{\pi}M(\xi_j)[\mathbf{D}^{+}I^{+}(\xi_j) + \mathbf{D}^{-}I^{-}(\xi_j)] &= \Delta\mathbf{V}^{inc}(\xi_j), \\ j &= 1, \ldots, N. \end{aligned} \tag{6.7}$$

System (6.7) contains $4N$ equations with $4N+8$ unknowns $\Delta w_i(\xi_j),\ i = 1, 4,\ j = 1, N$, and $D_i^{\pm},\ i = 1, 4$, and is thus underdetermined. Four extra equations are provided by the continuity of the solution at the point $\xi_N = L_2$ and can be written as

$$\Delta\mathbf{w}(\xi_N) = \xi_N^{-1/2}\left[\mathbf{D}^{+}\cos(\nu_0 \ln \xi_N) + \mathbf{D}^{-}\sin(\nu_0 \ln \xi_N)\right]. \tag{6.8}$$

Four more can be supplied by the relation (E.15) (see Appendix E). The resulting algebraic system of $4N + 8$ equations in $4N + 8$ unknowns can be written as

$$M\Delta\mathbf{w} = \mathbf{f}, \tag{6.9}$$

where the $4N + 8$ dimensional vectors are

$$\begin{aligned} \Delta\mathbf{w} &= (\Delta w_1(\xi_1), \Delta w_2(\xi_1), \Delta w_3(\xi_1), \Delta w_4(\xi_1), w_1(\xi_2), \ldots, \\ &\qquad \Delta w_4(\xi_N), D_1^{+}, \ldots, D_4^{+}, D_1^{-}, \ldots, D_4^{-}), \\ \mathbf{f} &= (\Delta V_1^{inc}(\xi_1), \ldots, \Delta V_4^{inc}(\xi_1), \Delta V_1^{inc}(\xi_2), \ldots, \Delta V_4^{inc}(\xi_N), 0, 0, 0, 0, 0, 0, 0, 0), \end{aligned} \tag{6.10}$$

and matrix M may be given in a block form as

$$M = \begin{pmatrix} I_4 - \frac{M(\xi_1)W_1}{2\pi\xi_1} & -\frac{M(\xi_1)W_2}{\pi(\xi_1+\xi_2)} & \cdots & -\frac{M(\xi_1)W_{N-1}}{\pi(\xi_1+\xi_{N-1})} & -\frac{M(\xi_1)W_N}{\pi(\xi_1+\xi_N)} & M^D(\xi_1) \\ -\frac{M(\xi_2)W_1}{\pi(\xi_1+\xi_2)} & I_4 - \frac{M(\xi_2)W_2}{2\pi\xi_2} & \cdots & -\frac{M(\xi_2)W_{N-1}}{\pi(\xi_2+\xi_{N-1})} & -\frac{M(\xi_2)W_N}{\pi(\xi_2+\xi_N)} & M^D(\xi_2) \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ -\frac{M(\xi_N)W_1}{\pi(\xi_1+\xi_N)} & -\frac{M(\xi_N)W_2}{\pi(\xi_2+\xi_N)} & \cdots & -\frac{M(\xi_N)W_{N-1}}{\pi(\xi_N+\xi_{N-1})} & I_4 - \frac{M(\xi_N)W_N}{2\pi\xi_N} & M^D(\xi_N) \\ 0_4 & 0_4 & \cdots & 0_4 & I_4 & M^{V1} \\ 0_4 & 0_4 & \cdots & 0_4 & 0_4 & M^{V2} \end{pmatrix}, \tag{6.11}$$

where we use the notation

$$\begin{aligned} M^D(\xi) &= -\frac{1}{\pi} M(\xi) J\left(I^+(\xi), I^-(\xi)\right), \\ M^{V1} &= -J\left(\xi_N^{-1/2}\cos(\nu_0 \ln \xi_N), \xi_N^{-1/2}\sin(\nu_0 \ln \xi_N)\xi_N)\right), \end{aligned} \tag{6.12}$$

with matrix $J\left(f_1(\xi), f_2(\xi)\right)$ given by

$$J\left(f_1(\xi), f_2(\xi)\right) = \begin{pmatrix} f_1(\xi) & f_2(\xi) & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & f_1(\xi) & f_2(\xi) & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & f_1(\xi) & f_2(\xi) & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & f_1(\xi) & f_2(\xi) \end{pmatrix}, \tag{6.13}$$

and

$$M^{V2} = \begin{pmatrix} I_2 & -\sqrt{\frac{m_\infty^-}{m_\infty^+}} I_2 & 0_2 & 0_2 \\ 0_2 & 0_2 & I_2 & -\sqrt{\frac{m_\infty^-}{m_\infty^+}} I_2 \end{pmatrix}. \tag{6.14}$$

To evaluate integrals $I^{\pm}(\xi)$ in (6.5), we consider two cases:

- Case 1: $\xi \le L_2$. It is easy to see that we can write

$$\frac{x}{x+\xi} = \sum_{k=0}^{\infty} (-1)^k \left(\frac{\xi}{x}\right)^k, \tag{6.15}$$

where the right-hand side is the geometric series with the common ratio $-\xi/x$ such that $|\xi/x| < 1$. Therefore, we have

$$\int_{L_2}^{\infty} \frac{x^{-1/2 \pm i\nu_0}}{x+\xi} dx = \int_{L_2}^{\infty} x^{-3/2 \pm i\nu_0} \sum_{k=0}^{\infty} (-1)^k \left(\frac{\xi}{x}\right)^k dx. \tag{6.16}$$

Exchanging in the right-hand side the order of summation and integration and evaluating the resulting integrals, we obtain

$$\int_{L_2}^{\infty} \frac{x^{-1/2 \pm i\nu_0}}{x+\xi} dx = (L_2)^{-1/2 \pm i\nu_0} \sum_{k=0}^{\infty} \frac{(-1)^k}{0.5 + k \mp i\nu_0} \left(\frac{\xi}{L_2}\right)^k. \tag{6.17}$$

Substituting (6.17) into (6.5) gives us

$$\begin{aligned} I^+(\xi) &= \frac{1}{\sqrt{L_2}} \left\{ S_1\left(\frac{\xi}{L_2}\right) \cos(\nu_0 \ln L_2) - \nu_0 S_2\left(\frac{\xi}{L_2}\right) \sin(\nu_0 \ln L_2) \right\}, \\ I^-(\xi) &= \frac{1}{\sqrt{L_2}} \left\{ S_1\left(\frac{\xi}{L_2}\right) \sin(\nu_0 \ln L_2) + \nu_0 S_2\left(\frac{\xi}{L_2}\right) \cos(\nu_0 \ln L_2) \right\}, \end{aligned} \tag{6.18}$$

where we use the notation

$$S_1(\xi) = \sum_{k=0}^{\infty} \frac{(-1)^k (0.5+k)}{(0.5+k)^2 + \nu_0^2} \xi^k, \qquad S_2(\xi) = \sum_{k=0}^{\infty} \frac{(-1)^k}{(0.5+k)^2 + \nu_0^2} \xi^k. \tag{6.19}$$

Note that, according to the Leibnitz theorem, the alternating series $S_i(\xi/L_2)$, $i=1,2$, converge. The difference between the infinite series and partial sum $S_{iN}(\xi/L_2)$ does not exceed the $(N+1)$th term. This property can be used to establish the number of terms necessary to achieve the required accuracy. The latter can be improved further if instead of a partial sum S_{iN} we use S_{iN} plus one half of the $(N+1)$th term. Then the error in $S_i(\xi/L_2)$, $i=1,2$, is $O(k^{-i-1})$ rather than $O(k^{-i})$.

- Case 2: $\xi > L_2$. Let us rewrite each term in (6.5) as

$$\int_{L_2}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \int_0^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx - \int_0^{L_2} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx. \tag{6.20}$$

The first integral can be evaluated to give

$$\int_0^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \frac{\pi}{\cosh \pi\nu_o}\xi^{-1/2\pm i\nu_0} \tag{6.21}$$

(see, e.g., [20]). The integrand of the second term in (6.20) can be represented as

$$\frac{x^{-1/2\pm i\nu_0}}{x+\xi} = \sum_{k=0}^{\infty} \frac{x^{-1/2+k\pm i\nu_0}}{\xi^{k+1}}. \tag{6.22}$$

Integrating both sides of (6.22) over $\xi \in [0, L_2]$ and using (6.21), the integral (6.20) can be represented as

(6.23)

$$\int_{L_2}^{\infty} \frac{x^{-1/2\pm i\nu_0}}{x+\xi}dx = \frac{\pi}{\cosh \pi\nu_o}\xi^{-1/2\pm i\nu_0} - \frac{(L_2)^{0.5\pm i\nu_0}}{\xi}\sum_{k=0}^{\infty} \frac{(-1)^k}{0.5+k\pm i\nu_0}\left(\frac{L_2}{\xi}\right)^k.$$

Therefore, (6.5) becomes

$$\begin{aligned} I^+(\xi) &= -\frac{\sqrt{L_2}}{\xi}\left\{S_1\left(\frac{L_2}{\xi}\right)\cos(\nu_0 \ln L_2) + \nu_0 S_2\left(\frac{L_2}{\xi}\right)\sin(\nu_0 \ln L_2)\right\} \\ &\quad + \frac{\pi}{\sqrt{\xi}\cosh \pi\nu_0}\cos(\nu_0 \ln \xi), \\ I^-(\xi) &= -\frac{\sqrt{L_2}}{\xi}\left\{S_1\left(\frac{L_2}{\xi}\right)\sin(\nu_0 \ln L_2) - \nu_0 S_2\left(\frac{L_2}{\xi}\right)\cos(\nu_0 \ln L_2)\right\} \\ &\quad + \frac{\pi}{\sqrt{\xi}\cosh \pi\nu_0}\sin(\nu_0 \ln \xi). \end{aligned} \tag{6.24}$$

Note that, similarly to the previous case, according to the Leibnitz theorem, the alternating series $S_i(L_2/\xi)$, $i=1,2$, converge, and instead of the partial sum S_{iN}, we can utilize S_{iN} plus one half of the $(N+1)$th term.

The resulting linear system (6.9) can be solved numerically using the LU decomposition subroutines from the LAPACK library. After the unknowns are evaluated at the nodes, system (6.6) can be used to extrapolate the solution for any $\xi \geq 1$. Note that in system (6.9) the integrals $I^{\pm}(\xi)$ are calculated at $\xi \leq L_2$, and therefore when solving this system we utilize only (6.18). When extrapolating, (6.24) is used instead. It is easy to see that, whatever the case, the integrals $I^{\pm}(\xi)$ are real valued.

7. The diffraction coefficients.

7.1. The diffraction coefficients for bulk waves. Let us first define the function

$$E(k_i^{(j)}r) = \sqrt{\frac{i}{8\pi}}\frac{e^{ik_i^{(j)}r}}{\sqrt{k_i^{(j)}r}}e^{-ik_i^{(j)}y_1p_1}, \tag{7.1}$$

where $\mathbf{p} = (\cos\theta, \sin\theta)$ is a unit vector in the direction of the diffracted wave, with the angle θ such that $\cos\theta = x_1/r$ and r is the distance to the origin. Let $\mathbf{p}^{\perp}$ be another unit vector, which is orthogonal to $\mathbf{p}$. It then can be chosen to be $\mathbf{p}^{\perp} = (-p_2, p_1) = (-\sin\theta, \cos\theta)$. It is easy to check that as $k_i^{(j)}r \to \infty$, the leading term in the expansion of the argument gives

$$\begin{aligned} H_0\left(k_i^{(j)}\sqrt{(x_1-y_1)^2+x_2^2}\right) &= H_0\left(k_i^{(j)}\left[r - y_1\cos\theta + O\left(\frac{1}{r}\right)\right]\right) \\ &\approx H_0(k_i^{(j)}r) \approx -4iE(k_i^{(j)}r). \end{aligned} \tag{7.2}$$

In the far field, the Green's tensor and Green's stress can be decomposed as

$$\begin{aligned} u_{ik}^{G(j)}(x_1-y_1,x_2) &= u_{ik}^{G1(j)}(x_1-y_1,x_2) + u_{ik}^{G2(j)}(x_1-y_1,x_2), \\ \sigma_{2ik}^{G(j)}(x_1-y_1,x_2) &= \sigma_{2ik}^{G1(j)}(x_1-y_1,x_2) + \sigma_{2ik}^{G2(j)}(x_1-y_1,x_2), \end{aligned} \tag{7.3}$$

where the superscript $i(j)$ refers to longitudinal ($i = 1$) or transverse ($i = 2$) wave in the medium $I^{(j)}$, and in the far field, as $k_i^{(j)}r \to \infty$, we can use approximations

$$\begin{aligned} u_{ik}^{G1(j)}(x_1-y_1,x_2) &\approx \left[\frac{1}{\mu^{(j)}}(\kappa^{(j)})^{-2}p_iE(k_1^{(j)}r)\right]p_k, \\ \sigma_{2ik}^{G1(j)}(x_1-y_1,x_2) &\approx ik_1^{(j)}\left[(\delta_{i2} - 2(\kappa^{(j)})^{-2}p_1p_i^{\perp})E(k_1^{(j)}r)\right]p_k, \\ u_{ik}^{G2(j)}(x_1-y_1,x_2) &\approx \left[\frac{1}{\mu^{(j)}}p_i^{\perp}E(k_2^{(j)}r)\right]p_k^{\perp}, \\ \sigma_{2ik}^{G2(j)}(x_1-y_1,x_2) &\approx ik_2^{(j)}\left[(p_2p_i^{\perp} + p_1p_i)E(k_2^{(j)}r)\right]p_k^{\perp} \end{aligned} \tag{7.4}$$

(see [11], [21], or Appendix A).

To continue, for the scattered field $\mathbf{u}^{sc(j)}(\mathbf{x})$, the integral representation (2.1) can be rewritten as

$$\begin{aligned} H[(-1)^{j+1}x_2]u_k^{sc(j)}(\mathbf{x}) = (-1)^j\sum_{i=1}^{2}\int_{-\infty}^{\infty}&[\sigma_{2ik}^{G(j)}(x_1-y_1,x_2)u_i^{sc(j)}(y_1,0) \\ &+ u_{ik}^{G(j)}(x_1-y_1,x_2)\sigma_{2i}^{(j)sc}(y_1,0)]dy_1 \end{aligned} \tag{7.5}$$

(see, e.g., [11]). Substituting (7.4) into (7.3) and the result into the version of (2.1) applicable to the scattered field, for $0 < \theta < 2\pi$ we can write

$$H(\pi-\theta)u_k^{tip(j)} \approx D^{1(j)}(\theta)\frac{e^{ik_1^{(j)}r}}{\sqrt{k_1^{(j)}r}}p_k + D^{2(j)}(\theta)\frac{e^{ik_2^{(j)}r}}{\sqrt{k_2^{(j)}r}}p_k^{\perp},$$

where the diffraction coefficients for diffracted body waves can be expressed in terms of the displacement vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, and traction vector $\widehat{\mathbf{t}}(\xi)$ in the following manner:

$$\begin{aligned}
D^{1(1)}(\theta) &= -\sqrt{\frac{-i}{8\pi}}(\kappa^{(1)})^{-2}\Big\{2p_1p_2\widehat{u}_1^{(1)}(-p_1)+[(\kappa^{(1)})^2-2p_1^2]\widehat{u}_2^{(1)}(-p_1)\\
&\qquad\qquad +p_1\widehat{t}_1(-p_1)+p_2\widehat{t}_2(-p_1)\Big\},\\
D^{1(2)}(\theta) &= \sqrt{\frac{-i}{8\pi}}\left[\kappa_1^{(2)}\{2(\kappa^{(2)})^{-2}p_1p_2\widehat{u}_1^{(2)}(-\kappa_1^{(2)}p_1)+[1-2(\kappa^{(2)})^{-2}p_1^2]\widehat{u}_2^{(2)}(-\kappa_1^{(2)}p_1)\}\right.\\
&\qquad \left.+\mu(\kappa^{(2)})^{-2}\{p_1\widehat{t}_1(-\kappa_1^{(2)}p_1)+p_2\widehat{t}_2(-\kappa_1^{(2)}p_1)\}\right],\\
D^{2(1)}(\theta) &= -\sqrt{\frac{-i}{8\pi}}\left[\kappa^{(1)}\{[p_1^2-p_2^2]\widehat{u}_1^{(1)}(-\kappa_2^{(1)}p_1)+2p_1p_2\widehat{u}_2^{(1)}(-\kappa_2^{(1)}p_1)\}\right.\\
&\qquad \left.-p_2\widehat{v}_3^-(-\kappa_2^{(1)}p_1)+p_1\widehat{v}_4^-(-\kappa_2^{(1)}p_1)\right],\\
D^{2(2)}(\theta) &= \sqrt{\frac{-i}{8\pi}}\left[\kappa_2^{(2)}\{[p_1^2-p_2^2]\widehat{u}_1^{(2)}(-\kappa_2^{(2)}p_1)+2p_1p_2\widehat{u}_2^{(2)}(-\kappa_2^{(2)}p_1)\}\right.\\
&\qquad \left.+\mu\{-p_2\widehat{v}_3^-(-\kappa_2^{(2)}p_1)+p_1\widehat{v}_4^-(-\kappa_2^{(2)}p_1)\}\right],
\end{aligned}\tag{7.6}$$

where if $\widehat{\mathbf{s}}(\xi)$ is known, $\widehat{\mathbf{t}}(\xi)$ can be found using (4.5). An additional difficulty is presented by the fact that, for $\xi>1$, $\widehat{\mathbf{s}}(\xi)$ as defined in (4.10) contains a singular integral (5.3). Since in (7.6) the arguments of all $\widehat{\mathbf{t}}$ components are given in the form $\xi=-\kappa_i^{(j)}p_1$, the function that needs evaluating is $\widehat{\mathbf{s}}(-\kappa_i^{(j)}p_1)$. When $p_1\geq 0$ the evaluation can be carried out using (4.10), and when $p_1\leq 0$ the combination of (4.7) and (4.6) should be used instead. To calculate the displacement vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, we note that the system (3.11) can be rewritten in terms of $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, and $\widehat{\mathbf{t}}(\xi)$ as

$$p(\xi)\mathbf{v}^{(j)inc}=\widehat{A}^{(j)+}(\xi)\widehat{\mathbf{u}}^{(j)}(\xi)+\widehat{A}^{(j)-}(\xi)\widehat{\mathbf{t}}(\xi),\quad j=1,2,\tag{7.7}$$

where $\widehat{A}^{(j)\pm}(\xi)$ are 2×2 matrices, which form matrices $\widehat{A}^{\pm}(\xi)$ in (3.11), so that we have

$$\widehat{A}^{+}(\xi)=\left(\begin{array}{cc}\widehat{A}^{(1)+}(\xi) & 0\\ 0 & \widehat{A}^{(2)+}(\xi)\end{array}\right),\qquad A^{-}(\xi)=\left(\begin{array}{cc}\widehat{A}^{(1)+}(\xi) & \widehat{A}^{(1)-}(\xi)\\ \widehat{A}^{(2)+}(\xi) & \widehat{A}^{(2)-}(\xi)\end{array}\right),\tag{7.8}$$

and vectors $\mathbf{v}^{(j)inc}(\xi)$ are

$$\mathbf{v}^{(1)inc}(\xi)=\left(\begin{array}{c}v_1^{inc}(\xi)\\ v_2^{inc}(\xi)\end{array}\right),\quad \mathbf{v}^{(2)inc}(\xi)=\left(\begin{array}{c}v_3^{inc}(\xi)\\ v_4^{inc}(\xi)\end{array}\right).\tag{7.9}$$

Therefore, after $\widehat{\mathbf{t}}(\xi)$ is found, vectors $\widehat{\mathbf{u}}^{(j)}(\xi),\ j=1,2$, can be calculated using (7.7). Note that since $|\kappa_i^{(j)}p_1|\leq\max\{\kappa_i^{(j)}\}<\xi^{R(j)}$, matrices $\widehat{A}^{(j)+}(-\kappa_i^{(j)}p_1)$ are regular.

7.2. The Rayleigh diffraction coefficients. On each of the traction-free surfaces $(x_2=0, x_1>0)$ the Rayleigh wave can be defined as

$$\mathbf{u}^{R(j)}(y_1,0)=D^{(j)R}\mathbf{v}^{(j)R}e^{ik^{R(j)}y_1},\qquad y_1>0,\tag{7.10}$$

where the so-called Rayleigh diffraction coefficient $D^{(j)R}$ is its amplitude, $k^{R(j)} = k_1^{(1)}\xi^{R(j)}$, and the unit vector $\mathbf{v}^{(j)R}$ is a nonzero solution of the homogeneous equation

$$\widehat{A}^{+}(-\xi^{R(j)})\mathbf{v}^{(j)R} = \mathbf{0}. \tag{7.11}$$

It can be shown that the unit vector $\mathbf{v}^{(j)R}$ is

$$\mathbf{v}^{(j)R} = \left(-\frac{2\xi^{R(j)}\gamma_2^{(j)}(\xi^{R(j)})}{[\kappa_2^{(j)}]^2}, (-1)^{j+1}\frac{a_j(\xi^{R(j)})}{[\kappa_2^{(j)}]^2}\right)^T. \tag{7.12}$$

Applying the Fourier transform to (7.10), we obtain

$$\widehat{\mathbf{u}}^{R(j)}(\xi) = \frac{iD^{(j)R}\mathbf{v}^{(j)R}}{\xi + \xi^{R(j)}}. \tag{7.13}$$

Multiplying (7.7) by $[\widehat{A}^{(j)+}(\xi)]^{-1}$ gives us

$$p(\xi)[\widehat{A}^{(j)+}(\xi)]^{-1}\mathbf{v}^{(j)inc} = \widehat{\mathbf{u}}^{(j)}(\xi) + \frac{1}{R_j}\widehat{B}^{(j)-}(\xi)\widehat{\mathbf{t}}(\xi), \quad j = 1, 2, \tag{7.14}$$

with a finite matrix

$$\widehat{B}^{(j)-}(\xi) = \mu_j \begin{pmatrix} (-1)^j b_{j1}(\xi) & -g_j(\xi) \\ g_j(\xi) & (-1)^j b_{j2}(\xi) \end{pmatrix}, \quad j = 1, 2. \tag{7.15}$$

Let us now evaluate the residue of both sides of (7.14) at $\xi = -\xi^{R(j)}$. This can be done by multiplying them by $\xi + \xi^{R(j)}$ and finding the limits when $\xi \to -\xi^{R(j)}$. By definition of $p(\xi)$, the left-hand side of the resulting equation is zero. The residue of the displacement vector at the Rayleigh pole $\xi = -\xi^{R(j)}$ is

$$\operatorname*{Res}_{\xi=-\xi^{R(j)}} \widehat{\mathbf{u}}^{(j)}(\xi) = \lim_{\xi\to-\xi^{R(j)}}(\xi + \xi^{R(j)})\widehat{\mathbf{u}}^{R(j)}(\xi) = iD^{(j)R}\mathbf{v}^{(j)R}, \quad j = 1, 2. \tag{7.16}$$

Therefore, (7.14) leads to

$$iD^{(j)R}\mathbf{v}^{(j)R} + \frac{1}{R_j'(-\xi^{R(j)})}\widehat{B}^{(j)-}(-\xi^{R(j)})\widehat{\mathbf{t}}(-\xi^{R(j)}) = \mathbf{0}, \quad j = 1, 2, \tag{7.17}$$

where $R_j'(\xi)$ is the derivative of the Rayleigh function $R_j(\xi)$. It follows that, for each medium $I^{(j)}$, $j = 1, 2$, the respective Rayleigh diffraction coefficient can be expressed via $\widehat{\mathbf{t}}(\xi)$ as

$$D^{(j)R} = \frac{i[\widehat{B}_{11}^{(j)-}(-\xi^{R(j)})\widehat{t}_1(-\xi^{R(j)}) + \widehat{B}_{12}^{(j)-}(-\xi^{R(j)})\widehat{t}_2(-\xi^{R(j)})]}{R_j'(-\xi^{R(j)})v_1^{(j)R}}, \quad j = 1, 2. \tag{7.18}$$

8. Numerical results. We have developed a FORTRAN90 program for computing the diffraction coefficient $D^{i(j)}(\theta)$ using (7.6), where the displacements and tractions are evaluated at $\xi = -\kappa_i^{(j)}\cos\theta$, with θ being an observation angle.

As has been discussed above, $\widehat{\mathbf{u}}^{(j)}(\xi)$ and $\widehat{\mathbf{t}}(\xi)$ are both singular at the GE pole $\xi = \xi^{inc}$. At the real angles $\theta = \theta^{sh}$, which satisfy the equation

$$\kappa_i^{(j)}\cos(\theta^{sh}) = -\kappa_n^{(m)}\cos(\theta^{inc}), \tag{8.1}$$

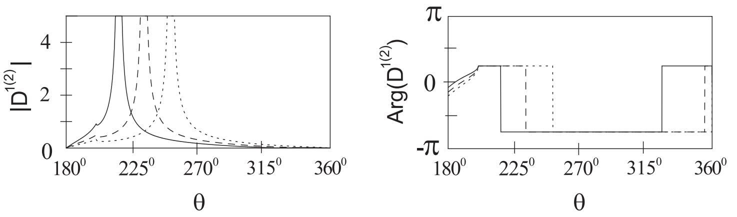

FIG. 8.1. *The longitudinal diffraction coefficient in the lower medium. The solid line corresponds to the angle of incidence of $\theta^{inc} = 30^{o}$, the dashed line to* 50^{o}, *and the dotted line to* 70^{o}.

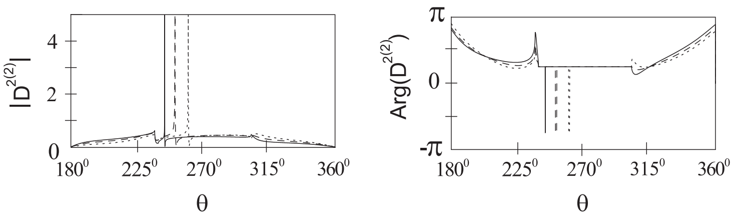

FIG. 8.2. *The transverse diffraction coefficient in the lower medium. The key is as above.*

the estimates of $|D^{i(j)}(\theta)|$ (incorrect near these angles) are infinite and the estimates of $\text{Arg}[D^{i(j)}(\theta^{sh})]$ experience a π jump. When $|\kappa_n^{(m)} \cos(\theta^{inc})/\kappa_i^{(j)}| > 1$, (8.1) has no real valued solutions and $D^{i(j)}(\theta)$ are correct estimates, continuous at all observation angles. The solution of (8.1) is

$$\theta^{sh} = \pi + (-1)^j \arccos\left(\frac{\kappa_n^{(m)}}{\kappa_i^{(j)}} \cos(\theta^{inc})\right). \tag{8.2}$$

When (8.2) defines a real valued angle, it is the shadow boundary of either the reflected or refracted wave in the incident medium, or either the transmitted longitudinal or transverse wave in the other medium.

Other special angles, which can be seen on the graphs in this section, are the so-called critical angles θ^{cr}. They describe the boundaries of the regions that support head waves and correspond to the branch points, that is, satisfy the equation

$$\pm\kappa_k^{(l)} = -\kappa_i^{(j)} \cos\theta^{cr}, \qquad l, k = 1, 2. \tag{8.3}$$

These critical angles do not depend on the angle of incidence. Again, the approximation method used in section 7.1 fails in their vicinity, and they show up on the graphs as small blips.

As an illustration, Figures 8.1–8.4 present diffraction coefficients for a semi-infinite crack, which is sandwiched between aluminum and steel.

The incident plane wave is a longitudinal wave, incoming from the aluminum half plane. The amplitudes of the diffraction coefficients are presented on the left and phases on the right. The model parameters are as follows. In medium 1 (aluminum), density $\rho^{(1)} = 2700$ kg/m^3, longitudinal speed $c_1^{(1)} = 6300$ m/s, and shear speed $c_2^{(1)} = 3100$ m/s. In medium 2 (steel), density $\rho^{(2)} = 7800$ kg/m^3, longitudinal speed $c_1^{(2)} = 5900$ m/s, and shear speed $c_2^{(2)} = 3200$ m/s. We can see the geometrical shadow boundaries described by (8.2), where the amplitude of the formally evaluated

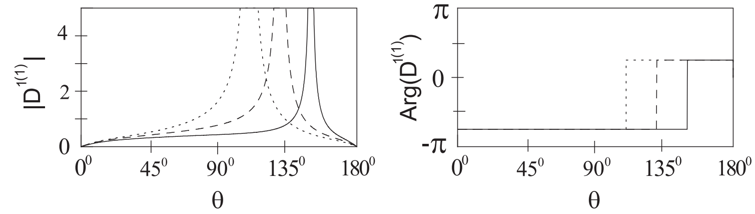

FIG. 8.3. *The longitudinal diffraction coefficient in the upper medium. The key is as in Figure* 8.1.

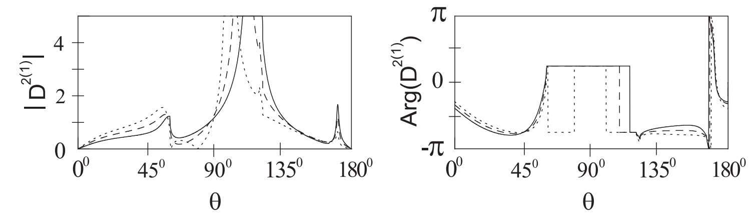

FIG. 8.4. *The transverse diffraction coefficient in the upper medium. The key is as in Figure* 8.1.

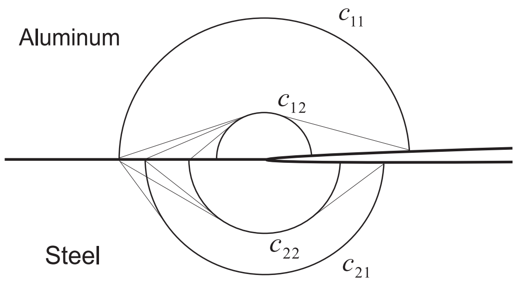

FIG. 8.5. *Head wave fronts.*

diffraction coefficient is infinite and the phase experiences a π jump. Since the critical angles do not depend on the angle of incidence, the corresponding blips appear at the same place for all three curves. The corresponding head wave fronts are shown in Figure 8.5. It can be seen that in the upper medium, the diffracted longitudinal wave is not affected by head waves. This is due to the fact that in aluminum the longitudinal speed is greater than in steel.

In Figure 8.1 the critical angle is $\theta \approx 200^o$. The head wave affects $D^{2(2)}$ at $\theta \approx 237.2^o$, $\theta \approx 239.5^o$, and $\theta \approx 328^o$. In Figure 8.2 only two blips are seen at about $\theta \approx 237^o$ and $\theta \approx 303.6^o$. This is due to the small difference between the first two critical angles $\theta \approx 237.2^o$ and $\theta \approx 239.5^o$. By decreasing both the discretization step and the interval of observation angles, the critical angles separate. The head wave affects $D^{2(1)}$ at $\theta \approx 60.5^o$, $\theta \approx 119.5$, $\theta \approx 121.7^o$, and $\theta \approx 165.6^o$. Again, in Figure 8.4 the critical angles $\theta \approx 119.5^o$ and $\theta \approx 121.7^o$ lie too close to each other. The overall conclusion is that for, say, the 30^o incidence, the longitudinal tip diffracted waves, which propagate in the upper medium, can be best detected at observation angles between 40^o and 130^o. As the angle of incidence increases, the range of advantageous observation angles shortens (see Figure 8.3).

The Rayleigh diffraction coefficients do not depend on the observation angle and are calculated using (7.18). Note that the Rayleigh speeds for aluminum and steel are $c_{Al} = 2894$ m/s and $c_{St} = 2964$ m/s, respectively, and the bimaterial constant is $\nu_0 = 0.0330434$. For the angle of incidence $\theta^{inc} = 30^{\text{o}}$, in aluminum $D^{(1)R} = -0.1208 - 0.206i$, and in steel $D^{(2)R} = 0.1428 - 0.2128i$; for $\theta^{inc} = 50^{\text{o}}$, $D^{(1)R} = -0.1004 - 0.3094i$ and $D^{(2)R} = 0.1285 - 0.3272i$; and for $\theta^{inc} = 70^{\text{o}}$, $D^{(1)R} = -0.0517 - 0.4005i$ and $D^{(2)R} = 0.0784 - 0.4285i$.

We finish this section by discussing the code testing. As already mentioned, the critical angles and positions of the shadow boundaries of reflected and refracted waves, when calculated independently, agree with the above graphs. We also know the phase (either $\pi/4$ or $-3\pi/4$) on those portions of the wave front which are not occupied by the head waves—these are correct. Another stringent internal test is to evaluate the left-hand side of (4.6) on the interval $\xi \epsilon [-1, 1]$. The right-hand side of this equation is known. The left-hand side has been computed using our code. The maximum relative error of each component has been found to be 2%, which is satisfactory. Finally, one could make another check by considering the limiting case of the two identical half planes: In this case, the off-diagonal terms in (4.4) become zero, and (4.3) reduces to the equivalent of the decoupled Wiener–Hopf equations for the crack opening displacements as found in the studies of the isotropic case, e.g., [11]. However, no numerical check of this nature has been conducted, because, when both half planes are the same, (4.7) contains a dipole instead of a pole, and although one could use this representation, it would require additional careful programming: In (4.7) one would have to use the sum of the two poles instead of the product. Even then, numerical difficulties would still arise for nearly identical top and bottom media.

9. Conclusions. We have developed a semianalytical approach to calculating diffraction coefficients for a semi-infinite crack sandwiched between two different isotropic media. We have introduced a stable numerical scheme for solving the resulting system of integral equations, (5.7). Our main achievement has been to produce a fast computer code, which is applicable to any pair of (sufficiently different) isotropic materials which do not support the Stoneley wave and are irradiated by a plane wave incident from either medium. The incident wave can be longitudinal or transverse and incoming at an arbitrary angle. The absence of the Stoneley wave does not constitute a serious restriction, since this case is ubiquitous in applications. Nevertheless, we plan to publish another paper modeling materials where the Stoneley wave is present too. As an illustration, we have presented plots of diffraction coefficients for a crack sandwiched between aluminum and steel.

Appendix A. The two dimensional Green's tensor and Green's stress tensor. Since the incident wave can be considered as radiated by a line load, both the two dimensional Green's tensor and Green's stress tensor can be represented in terms of the Hankel function of the first kind of the zeroth order, $H_0 \equiv H_0^{(1)}$, and its derivatives (see [11], [21]), so that at any observation point $\mathbf{x}$ we have

$$-4i\mu^{(j)}u^{G(j)}_{ik}(\mathbf{x}) = \frac{1}{[k_2^{(j)}]^2}\left[-H_0(k_1^{(j)}r) + H_0(k_2^{(j)}r)\right]_{,ik} + H_0(k_2^{(j)}r)\delta_{ik},$$

$$-4i\sigma^{G(j)}_{2ik}(\mathbf{x}) = \left\{1 - 2\left[\frac{c_2^{(j)}}{c_1^{(j)}}\right]^2\right\}\left[H_0(k_1^{(j)}r)\right]_{,k}\delta_{2i} - \frac{2}{(k_2^{(j)})^2}\left[H_0(k_1^{(j)}r) - H_0(k_2^{(j)}r)\right]_{,2ik}$$

$$+\left[H_0(k_2^{(j)}r)\right]_{,2}\delta_{ik} + \left[H_0(k_2^{(j)}r)\right]_{,i}\delta_{2k}, \tag{A.1}$$

where $\mu^{(j)},\ j=1,2$, is the shear modulus in medium $I^{(j)}$; r is the distance to the origin; and an index, say k, after the comma refers to differentiation with respect to the corresponding spatial variable x_k. Applying operations of dilatation and rotation to both sides of (A.1) gives us

$$\begin{aligned}
&4i\mu^{(j)}u_i^{G(j)1}(\mathbf{x}) = \left[\frac{c_2^{(j)}}{c_1^{(j)}}\right]^2 \left[H_0(k_1^{(j)}r)\right]_{,i}\,,\\
&-4i\sigma_i^{G(j)1}(\mathbf{x}) = (k_1^{(j)})^2\left\{\left[2\left(\frac{c_2^{(j)}}{c_1^{(j)}}\right)^2-1\right]H_0(k_1^{(j)}r)\delta_{2i}+\frac{2}{(k_2^{(j)})^2}\left[H_0(k_1^{(j)}r)\right]_{,2i}\right\},\\
&-4i\mu^{(j)}u_i^{G(j)2}(\mathbf{x}) = \left[H_0(k_2^{(j)}r)\right]_{,1}\delta_{2i}-\left[H_0(k_2^{(j)}r)\right]_{,2}\delta_{1i},\\
&-4i\sigma_i^{G(j)2}(\mathbf{x}) = \left[H_0(k_2^{(j)}r)\right]_{,12}\delta_{2i}-\left[H_0(k_2^{(j)}r)\right]_{,22}\delta_{1i}+\left[H_0(k_2^{(j)}r)\right]_{,1i}\,.
\end{aligned}$$
(A.2)

Appendix B. The extinction theorem. The extinction theorems are easily proved for finite sources and obstacles using Green's theorem. Difficulties arise when the incident waves are plane and obstacles infinite. One approach to dealing with this complication is to develop methods such as those offered in [22] and references therein (also see [23]). Below we offer an alternative justification.

Let us focus on the scattered field in the upper plane. Any identity involving the incident field can be established by direct integration. For simplicity of presentation, we omit the superscript $^{(1)}$. Then solving the Fourier transform of the equations of motion for the elastic solid gives

$$\widehat{\mathbf{u}}^{sc}(\xi,x_2)=A(\xi)(-\xi,\gamma_1)^Te^{ik_1\gamma_1x_2}+B(\xi)(\gamma_2,\xi)^T\mathrm{e}^{ik_1\gamma_2x_2},\quad x_2>0, \tag{B.1}$$

where $A(\xi)$ and $B(\xi)$ are unknown. The solutions proportional to $\exp[-ik_1\gamma_ix_2]$, $i=1,2$, are rejected because they do not satisfy the radiation conditions: Either they are incoming from infinity or else, when we move the branches off the real axis (see Figure C.1 below) as $x_2\to\infty$, they become unbounded. It follows that on the top face of the crack, $x_2=0^+$, we have

$$\widehat{\mathbf{u}}^{sc}(\xi,0^+)=A(\xi)(-\xi,\gamma_1)^T+B(\xi)(\gamma_2,\xi)^T. \tag{B.2}$$

It can easily be verified that a similar formula holds for the traction related vector $\widehat{\mathbf{t}}^{sc}$ (see (4.1)),

$$\widehat{\mathbf{t}}^{sc}(\xi,0^+)=-i[A(\xi)(2\xi\gamma_1,2\xi^2-\kappa_2^2)^T+B(\xi)(2\xi^2-\kappa_2^2,-2\xi\gamma_2)^T]. \tag{B.3}$$

The solution to the Fourier transform of the equations of motion, which is valid in both half planes, is

(B.4)
$$\widehat{\mathbf{u}}^{sc}(\xi,x_2)=A_1(\xi)(-\xi,\gamma_1\mathrm{sgn}(x_2))^Te^{ik_1\gamma_1|x_2|}+B_1(\xi)(\gamma_2\mathrm{sgn}(x_2),\xi)^T\mathrm{e}^{ik_1\gamma_2|x_2|},\ x_2>0,$$

where we have

$$\begin{aligned}
2\kappa_2^2\gamma_1A_1(\xi)&=-2\xi\gamma_1\mathrm{sgn}(x_2)\widehat{u}_1^{sc}(\xi,0^+)+(\kappa_2^2-2\xi^2)\widehat{u}_2^{sc}(\xi,0^+)\\
&\quad+i[\xi\widehat{t}_1^{sc}(\xi,0^+)-\gamma_1\mathrm{sgn}(x_2)\widehat{t}_2^{sc}(\xi,0^+)],\\
2\kappa_2^2\gamma_2B_1(\xi)&=(\kappa_2^2-2\xi^2)\widehat{u}_1^{sc}(\xi,0^+)+2\xi\gamma_2\mathrm{sgn}(x_2)\widehat{u}_2^{sc}(\xi,0^+)\\
&\quad-i[\gamma_2\mathrm{sgn}(x_2)\widehat{t}_1^{sc}(\xi,0^+)+\xi\widehat{t}_2^{sc}(\xi,0^+)].
\end{aligned} \tag{B.5}$$

Substituting (B.2) and (B.3) into (B.5) yields

$$(A_1(\xi), B_1(\xi)) = (A(\xi), B(\xi))H(x_2). \tag{B.6}$$

Thus, the scattered field defined by (B.4) agrees with (B.1) in the upper half plane and is identically zero in the fictitious half plane $x_2 < 0$. The inverse transform of (B.4) leads to the extinction theorem (2.1) for the scattered field.

Appendix C. Singularities in (3.11). Let us describe all singularities of functions that appear in (3.11). First, in view of (3.10), the left-hand side of (3.11) has simple poles at $\xi = \xi^{inc} + i0$ and $\xi = \xi^{inc} - i0$, which correspond to the incident and reflected bulk waves, respectively. They give rise to GE bulk waves.

Second, it is easy to check that the determinant of the matrix $\widehat{A}^+(\xi)$, $|\widehat{A}^+(\xi)|$ is a product of two Rayleigh functions, $R_1(\xi)$ and $R_2(\xi)$,

$$R_j(\xi) = a_j^2(\xi) + 4\xi^2\gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi), \tag{C.1}$$

where the subscript $j = 1, 2$ refers to medium $I^{(j)}$ (see, e.g., [21]). Thus, the solutions $\xi = \pm\xi^{R(j)}$ of the equation $|\widehat{A}^+(\xi)| = 0$ are zeros of $R_1(\xi)$ and $R_2(\xi)$ and can be shown to be simple (distinct). The zeros $\xi = -\xi^{R(j)}$ are known to give rise to the outgoing Rayleigh surface waves.

It is equally easy to check that $|\widehat{A}^-(\xi)|$ is the well-known Stoneley function

$$S(\xi) = \mu^2 R_1(\xi)h_2(\xi) + R_2(\xi)h_1(\xi) + \mu[b_{11}(\xi)b_{22}(\xi) + b_{21}(\xi)b_{12}(\xi) - 2g_1(\xi)g_2(\xi)] \tag{C.2}$$

(see, e.g., [24]), where we use the notation

$$\begin{aligned} &b_{j1}(\xi) = [\kappa_2^{(j)}]^2\gamma_2^{(j)}(\xi), \qquad b_{j2}(\xi) = [\kappa_2^{(j)}]^2\gamma_1^{(j)}(\xi),\\ &g_j(\xi) = \xi[2\gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi) - a_j(\xi)], \qquad h_j(\xi) = \gamma_1^{(j)}(\xi)\gamma_2^{(j)}(\xi) + \xi^2, \quad j = 1, 2. \end{aligned} \tag{C.3}$$

In general, the zero of $S(\xi) = 0$ (which is also simple) can give rise to an outgoing Stoneley wave. Using Cagniard's method (see [24]) we have established that for the set of parameters used in this paper such a solution does not exist, and therefore no Stoneley surface wave runs between materials under study. We remark in passing that this situation is common, and Cagniard [24] refers to the Stoneley wave as "a rather special phenomenon," meaning that it exists only in narrow ranges of material parameters.

To continue, both matrices $\widehat{A}^{\pm}(\xi)$ involve multivalued radicals $\gamma_i^{(j)}(\xi)$ defined below (3.14). In order to render the matrices single valued we introduce the branch cuts $C_i^{(j)\mp}$, $i, j = 1, 2$, which run between branch points $\pm\kappa_i^{(j)}$, defined below (3.9), and $\pm\infty$, respectively. Let us apply the limiting absorption principle and replace $\kappa_i^{(j)}$ by $\kappa_i^{(j)} + i\epsilon_1$, $\epsilon_1 > 0$. This shifts the branch cuts away from the real axis as indicated in Figure C.1, and when performing the inverse Fourier transform, the corresponding singularities give rise to the waves, which satisfy the radiation condition, that is, are outgoing to infinity.

The radicals $\gamma_i^{(j)}(\xi)$ can be factorized so that we have

$$\gamma_i^{(j)}(\xi) = \gamma_i^{(j)+}(\xi)\gamma_i^{(j)-}(\xi), \tag{C.4}$$

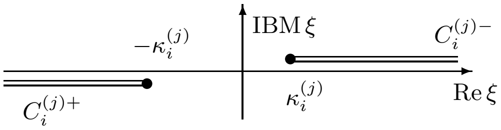

Fig. C.1. *The branch cuts of* $\gamma_i^{(j)}(\xi)$.

where we use the notation

$$\gamma_i^{(j)+}(\xi) = \sqrt{\kappa_i^{(j)} + \xi}, \quad \gamma_i^{(j)-}(\xi) = \gamma_i^{(j)+}(-\xi), \tag{C.5}$$

and only the cut $C_i^{(j)+}$ is required to render $\gamma_i^{(j)+}(\xi)$ single-valued. The radical $\gamma_i^{(j)-}(\xi)$ is rendered single-valued by $C_i^{(j)-}$. Note that if $\xi = -\zeta$ lies on the branch cut $C_i^{(j)+}$, the definition implies that ξ lies on the upper side of the cut, so that $\xi = -\zeta + i0$. It follows that $\gamma_i^{(j)+}(-\zeta)$ is well defined. As ξ tends to $-\zeta$ from below the branch cut, we have

$$\gamma_i^{(j)+}(\xi) \to -\gamma_i^{(j)+}(-\zeta) \equiv \gamma_i^{(j)+}(-\zeta - i0). \tag{C.6}$$

Note that in the main text we drop a combination of subscript and superscript ${}_1^{(1)}$ in the symbol for the longest branch cut $C_1^{(1)\pm}$. To summarize, the known functions in (3.11) involve two GE poles $\xi^{inc} \pm i0$, two Rayleigh poles $-\xi^{R(1)}$ and $-\xi^{R(2)}$, as well as two branch cuts $C^{\pm}$.

Appendix D. Auxiliary functions and vectors. Let us now describe auxiliary functions used in the main text. Let four branch points be sorted in order of the descending moduli, with $\kappa_1 = \min\{\kappa_i^{(j)}\}$ and $\kappa_4 = \max\{\kappa_i^{(j)}\}$, $i, j = 1, 2$, denoting the corresponding radicals $\gamma_i^{\pm}(\xi) = \sqrt{\kappa_i \pm \xi}$ and the respective branch cuts $C_i^+ = \{\xi : \xi \le -\kappa_i\}$ and $C_i^- = \{\xi : \xi \ge \kappa_i\}$, $i = 1, 2, 3, 4$.

For each pair of numbers $a \neq -\kappa_i$ and ξ, let us introduce the auxiliary functions $H_i^{\pm}(\xi, a)$,

$$H_i^+(\xi, a) = \frac{\gamma_i^+(a) - \gamma_i^+(\xi)}{2\gamma_i^+(a)} \left[\frac{a_0 - \gamma_i^+(a)}{a_0 + \gamma_i^+(\xi)}\right]^{2n+1}, \qquad H_i^-(\xi, a) = H_i^+(-\xi, -a), \tag{D.1}$$

where $n \ge 3$ and a_0 lies far away from the branch cut C_i^+. To be specific, let $a_0 = 1+i$. Then the function H_i^+ has the following properties:

- It has no poles in ξ.
- The branch cut C^+ renders it single-valued.
- For any $\xi \in C_i^+$ we have

$$H_i^+(\xi + i0, \xi) = 0 \quad \text{and} \quad H_i^+(\xi - i0, \xi) = 1, \tag{D.2}$$

  where, as the above notation suggests, $H_i^+(\xi + i0, a)$ and $H_i^+(\xi - i0, a)$ are values of $H_i^+(\xi, a)$ evaluated on the upper and lower sides of C_i^+, respectively. (We recall that, unless stated otherwise, ξ lies on the positive side of the cut.)
- For any $\xi \in C_i^-$ such that Re $\zeta \gg 1$ we have

$$H_i^+(-\xi + i0, a) - H_i^+(-\xi - i0, a) \sim \frac{\text{constant}}{[\gamma_i^+(-\xi)]^{2n}}. \tag{D.3}$$

Let us now define branch cuts

$$\begin{aligned}
&C^-_{ii+1} = \{\xi : \kappa_i \le \xi \le \kappa_{i+1}\}, \qquad i = 1, 2, 3,\\
&C^-_{45} = \{\xi : \xi \ge \kappa_4\},\\
&C^+_{ii+1} = \{\xi : -\kappa_{i+1} \le \xi \le -\kappa_i\}, \qquad i = 1, 2, 3,\\
&C^+_{45} = \{\xi : \xi \le -\kappa_4\},
\end{aligned} \tag{D.4}$$

and introduce the auxiliary functions

$$\begin{aligned}
&F^\pm_i(\xi, a) = H^\pm_i(\xi, a) - H^\pm_{i+1}(\xi, a), \quad i = 1, 2, 3,\\
&F^\pm_4(\xi, a) = H^\pm_4(\xi, a).
\end{aligned} \tag{D.5}$$

It is easy to see that each function $F^\pm_i(\xi, a)$ has a branch cut $C^\pm_{ii+1}$, $i = 1, 2, 3, 4$, and $F^\pm_i(\xi, \xi) = 1$ on the negative side of its branch cut and 0 everywhere else. Let us introduce a function $G(\xi)$ as

$$G(\xi) = \left(\sqrt{1+\xi} + \sqrt{\kappa^{(1)}_2 + \xi}\right)^2, \tag{D.6}$$

which is real outside the interval $(-\kappa^{(1)}_2, -1)$ and $O(\xi)$ at infinity.

Appendix E. Auxiliary relationships. Let us determine eight scalar constants $D^\pm_i$, $i = 1, 2, 3, 4$, introduced in (6.1). Let us show that they are linearly dependent, and therefore that the total number of unknowns can be decreased by four. Let us do this by analyzing the asymptotic behavior of both sides of (6.2). As $\xi \to \infty$, matrix $M(\xi) \to M_\infty$,

$$M_\infty = \begin{pmatrix} 0_2 & m^-_\infty I_2 \\ m^+_\infty I_2 & 0_2 \end{pmatrix}, \tag{E.1}$$

where matrices 0_2 and I_2 denote the zero and identity 2×2 matrices, respectively; $m^\pm_\infty$ are known constants,

$$\begin{aligned}
&m^-_\infty = -\frac{1}{8}\left\{\frac{[\kappa^{(1)}_2]^2}{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2} + \mu\frac{[\kappa^{(2)}_2]^2}{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2}\right\},\\
&m^+_\infty = -8[S_\infty]^{-1}\left([\kappa^{(1)}_2]^2\{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2\} + \mu[\kappa^{(2)}_2]^2\{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2\}\right);
\end{aligned} \tag{E.2}$$

and we use the notation $S_\infty = \lim_{\xi\to\infty} S(\xi)/\xi^2$. Using the Stoneley function $S(\xi)$ defined in (C.2), we find

$$\begin{aligned}
S_\infty = {}&\mu^2\{[\kappa^{(1)}_2]^2 - [\kappa^{(1)}_1]^2\}\{[\kappa^{(2)}_2]^2 + [\kappa^{(2)}_1]^2\} + \{[\kappa^{(1)}_2]^2 + [\kappa^{(1)}_1]^2\}\{[\kappa^{(2)}_2]^2 - [\kappa^{(2)}_1]^2\}\\
&+ 2\mu\{[\kappa^{(1)}_2]^2[\kappa^{(2)}_2]^2 + [\kappa^{(1)}_1]^2[\kappa^{(2)}_1]^2\}.
\end{aligned} \tag{E.3}$$

The right-hand side of (6.2) decays faster than the left-hand side. It can be shown that it has the asymptotic behavior

$$\Delta\mathbf{V}^{inc}(\xi) \to \frac{1}{\xi}, \qquad \xi \to \infty. \tag{E.4}$$

The asymptotic solution of (6.2) can be rewritten using (6.1) as

$$\Delta\mathbf{w}(\xi) = \xi^{-\nu}\mathbf{W}, \quad \nu = \frac{1}{2} \pm i\nu_0. \tag{E.5}$$

Then the Cauchy integral of the latter can be found in [20] to behave as

$$\frac{1}{\pi}\int_1^\infty \frac{\mathbf{W}d\zeta}{\zeta^\nu(\xi+\zeta)} \to \frac{\beta}{\xi^\nu}\mathbf{W}, \quad \xi \to \infty, \tag{E.6}$$

where $\beta = 1/\sin\nu\pi$. Therefore, using (E.1) and (E.4), as $\xi \to \infty$, the system (6.2) becomes

$$\frac{1}{\xi^\nu}(I_4 - \beta M_\infty)\mathbf{W} = \mathbf{0}. \tag{E.7}$$

The matrix in the above equation must have a zero determinant,

$$\det(I_4 - \beta M_\infty) = \begin{vmatrix} I_2 & -\beta m_\infty^- I_2 \\ -\beta m_\infty^+ I_2 & I_2 \end{vmatrix} = 1 - \beta^2 m_\infty^+ m_\infty^-. \tag{E.8}$$

This determines β, and hence, by its definition, the parameter ν_0:

$$\beta = \frac{1}{\sin\left(\frac{1}{2} \pm i\nu_0\right)\pi} = \frac{1}{\cosh(\pi\nu_0)} = \frac{1}{\sqrt{m_\infty^+ m_\infty^-}}. \tag{E.9}$$

Using one of the Dundurs parameters, which can be represented as

$$\beta_D = \frac{1 - [\kappa^{(2)}]^2 + \mu([\kappa^{(1)}]^2 + 1)}{\mu[\kappa^{(2)}]^2([\kappa^{(1)}]^2 - 1) + [\kappa^{(1)}]^2([\kappa^{(2)}]^2 - 1)} \tag{E.10}$$

(see [25]), as well as expressions (E.2) for $m_\infty^\pm$, we can write

$$\tanh(\pi\nu_0) = \beta_D. \tag{E.11}$$

Now it can be shown that there are two linearly independent vectors $\mathbf{W}^{(1)}$ and $\mathbf{W}^{(2)}$ such that $(I_4 - \beta M_\infty)\mathbf{W} = \mathbf{0}$. They are

$$\mathbf{W}^{(1)} = \begin{pmatrix} m \\ 0 \\ 1 \\ 0 \end{pmatrix}, \quad \mathbf{W}^{(2)} = \begin{pmatrix} 0 \\ m \\ 0 \\ 1 \end{pmatrix}, \quad m = \sqrt{\frac{m_\infty^-}{m_\infty^+}}. \tag{E.12}$$

It follows that as $\xi \to \infty$, the vector $\Delta\mathbf{w}$ behaves as

$$\Delta\mathbf{w}(\xi) \to \xi^{-1/2}\left[\left(\frac{A^+}{\xi^{i\nu_0}} + \frac{A^-}{\xi^{-i\nu_0}}\right)\mathbf{W}^{(1)} + \left(\frac{B^+}{\xi^{i\nu_0}} + \frac{B^-}{\xi^{-i\nu_0}}\right)\mathbf{W}^{(2)}\right], \qquad \xi \to \infty. \tag{E.13}$$

Rewriting the above equation in the form of (6.1) leads us to the following relationship:

$$\begin{aligned} \mathbf{D}^+ &= (A^+ + A^-)\mathbf{W}^{(1)} + (B^+ + B^-)\mathbf{W}^{(2)}, \\ \mathbf{D}^- &= -i[(A^+ - A^-)\mathbf{W}^{(1)} + (B^+ - B^-)\mathbf{W}^{(2)}]. \end{aligned} \tag{E.14}$$

Substituting (E.12) into (E.14) gives us a simple relationship between the components of $\mathbf{D}^\pm$,

$$D_1^\pm = \sqrt{\frac{m_\infty^-}{m_\infty^+}} D_3^\pm, \qquad D_2^\pm = \sqrt{\frac{m_\infty^-}{m_\infty^+}} D_4^\pm. \tag{E.15}$$

Acknowledgments. We are indebted to Profs. V. A. Borovikov and G. Mishuris for numerous enlightening discussions, and to an anonymous referee for insightful comments on the extinction theorems.

DIFFRACTION BY A SEMI-INFINITE INTERFACIAL CRACK SANDWICHED BETWEEN TWO ISOTROPIC HALF PLANES*

V. KUBZINA[†‡], A. K. GAUTESEN[§], AND L. JU. FRADKIN[†]

Abstract. This paper addresses the canonical two dimensional problem of diffraction of the plane wave by a semi-infinite interfacial crack sandwiched between two isotropic solids. We restrict ourselves to a ubiquitous case of solids whose contact boundary does not support the Stoneley wave. Its solution can be used in applications to model diffraction from curved cracks with curvature that is small compared to a wavelength.

Key words. diffraction, interfacial crack, semianalytical approach

DOI. 10.1137/070711517

1. Introduction.

Finding a semianalytical solution to the problem of diffraction by a semi-infinite crack sandwiched between two different solids is a well-known problem in the mathematical theory of diffraction. In this paper we consider a two dimensional case involving two different isotropic half planes. Apart from being mathematically challenging, diffraction problems of this kind are of interest in ultrasonic NDE (nondestructive evaluation), particularly because interfacial cracks are often found in laminated composites. It is well known that ultrasonic inspection of such cracks is a challenging engineering problem, and detection of crack tip diffraction is particularly difficult. As a consequence, the defect size can be underestimated. Nevertheless, the advanced phased array transducers offer an improved performance [1], and models of the underlying diffraction process would allow the NDE inspectors to establish whether, in a given configuration, the amplitude of the edge diffracted echoes could exceed the detection threshold [2].

Over the years purely numerical approaches to this kind of problem based on finite differences, finite elements, or boundary integral techniques proved unreliable, because it is difficult to take into account the singularity condition at the crack tip and thus render a solution unique. It is also difficult to keep adjusting numerical schemes to account for different types of wave interaction [3, 4, 5]. Another well-known line of attack is to reformulate the problem in terms of a system of functional equations and to solve those using a numerical Wiener–Hopf factorization technique (see, e.g., [6]). So far, this approach has also met with numerous numerical difficulties and has produced no entirely satisfactory scheme.

In this paper we follow a semianalytical approach of [7, 8, 9, 10], developed to derive a solution of the elastodynamic equations formulated in terms of displacements, which it reduces to a system of regular integral equations for their Fourier transforms. We start with the elastodynamic integral equation for the displacement based on Green's formula and the extinction theorem for each isotropic half plane and then use operations of dilatation (or divergence) and rotation (or curl) to separate transverse and longitudinal motions. Since the incident wave can be considered as radiated by a line load, we represent the two dimensional free space Green's tensors in terms of the Hankel function of the first kind of the zeroth order and its derivatives. Using the boundary conditions, the Fourier transform of the elastodynamic integral equation is reduced to a system of four functional equations in eight "half unknowns." Then, the problem is reformulated in terms of traction and crack opening displacement, both of which can be decomposed into singular and nonsingular parts. The singular parts relate to the well-known geometricoelastodynamic (GE) body waves. The nonsingular parts constitute new unknowns. By using a Hilbert-type integral transform, the functional equations are transformed into four regular integral equations in four unknowns. In turn, these are solved numerically. In the far field, diffraction body wave coefficients are obtained. The method can be generalized to model transversely isotropic media.

2. The problem statement.

We consider a two dimensional semi-infinite crack (see Figure 2.1) sandwiched between two different isotropic media $I^{(j)}$, where superscript $j = 1$ corresponds to the medium occupying the "upper" half plane and $j = 2$ means the "lower" half plane. Let the crack be irradiated by a longitudinal ($n = 1$) or transverse ($n = 2$) plane wave, which is incident from the medium $I^{(m)}$, $m = 1$ or 2, and propagates there with the speed $c_n^{(m)}$, where m and n are both fixed throughout the paper. Further, let us assume without loss of generality that the longitudinal speed $c_1^{(1)}$ in the medium $I^{(1)}$ is greater than the longitudinal speed $c_1^{(2)}$ in the medium $I^{(2)}$. Let us further introduce a Cartesian base $\{\mathbf{e}_1, \mathbf{e}_2\}$, with $\mathbf{e}_1$ running along the crack surface and $\mathbf{e}_2$ perpendicular to $\mathbf{e}_1$ and pointing into the "upper" medium. In this base, every vector can be presented in terms of the corresponding coordinates, so that every position vector $\mathbf{x} = (x_1, x_2)$, every displacement vector $\mathbf{u} = (u_1, u_2)$, etc.

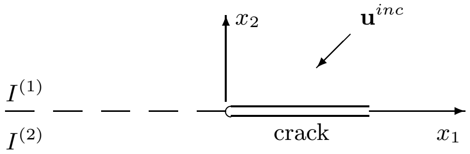

FIG. 2.1. *The problem geometry.*

Let $\mathbf{u}(\mathbf{x}) \exp(-i\omega t)$ be a time harmonic displacement vector in an elastic medium, where t is time, ω is the angular frequency, and the exponential time factor $\exp(-i\omega t)$ is understood but suppressed everywhere below. Using the two dimensional Green's tensors (see Appendix A) and introducing a fictitious bottom medium that has the properties of the upper half space, and a fictitious top medium which has the properties of the bottom half space, the above problem can be recast in the form of a generalized reciprocity relation [11] or the extinction theorem (by analogy with the electromagnetic case—see [12]; the detailed derivation is given in [13]; also see Appendix B). This states that the total displacement for a medium $I^{(j)}$ satisfies the integral equation

$$H[(-1)^{j+1}x_2]u_k^{(j)}(\mathbf{x}) = u_k^{inc(j)}(\mathbf{x}) + (-1)^j \sum_{i=1}^{2} \int_{-\infty}^{-\infty} [\sigma_{2ik}^{G(j)}(x_1 - y_1, x_2)u_i^{(j)}(y_1, 0)$$

$$+ u_{ik}^{G(j)}(x_1 - y_1, x_2)\sigma_{2i}^{(j)}(y_1, 0)]dy_1, \quad j, k = 1, 2, \tag{2.1}$$

where $u^{G(j)}(\mathbf{x} - \mathbf{y})$ and $\sigma^{G(j)}(\mathbf{x} - \mathbf{y})$ are the free space Green's tensor and Green's stress tensor, respectively; $\sigma^{(j)}(\mathbf{x})$ is the stress tensor corresponding to displacement $\mathbf{u}^{(j)}(\mathbf{x})$; $H(x)$ is the Heaviside step function,

$$H(x) = \begin{cases} 1, & x \geq 0, \\ 0, & x < 0; \end{cases} \tag{2.2}$$

and in the medium $I^{(j)}$, $j = 1, 2$, the plane wave $\mathbf{u}^{inc(j)}(\mathbf{x})$, which is incident from $I^{(m)}$, is

$$\mathbf{u}^{inc(j)}(\mathbf{x}) = \delta_{mj}\mathbf{d}^{n(m)}e^{-ik_n^{(m)}(p_1^{inc}x_1 - (-1)^m p_2^{inc}x_2)}, \tag{2.3}$$

with δ_{mj}—the Kronecker delta, $\mathbf{p}^{inc} = (p_1^{inc}, p_2^{inc})$—the incoming unit wave vector with $p_2^{inc} > 0$, and $k_n^{(m)} = \omega/c_n^{(m)}$—a wave number (see, e.g., [11]). The longitudinal displacement unit vector $\mathbf{d}^{1(m)}$ is

$$\mathbf{d}^{1(m)} = (-p_1^{inc}, (-1)^m p_2^{inc}), \tag{2.4}$$

and when the motions are transverse the displacement unit vector $\mathbf{d}^{2(m)}$ is

$$\mathbf{d}^{2(m)} = ((-1)^{m+1}p_2^{inc}, -p_1^{inc}). \tag{2.5}$$

To complete the problem statement we require that on the contact boundary, $\{(x_1, x_2) : x_2 = 0,\ x_1 < 0\}$, the displacement and normal stress components be continuous,

$$\begin{aligned} &u_i^{(1)}(x_1, 0) = u_i^{(2)}(x_1, 0), \\ &\sigma_{2i}^{(1)}(x_1, 0) = \sigma_{2i}^{(2)}(x_1, 0), \quad x_1 < 0, \quad i = 1, 2; \end{aligned} \tag{2.6}$$

on the crack $\{(x_1, x_2) : x_2 = 0,\ x_1 > 0\}$ the normal stress components be zero,

$$\sigma_{2i}^{(1)}(x_1, 0) = \sigma_{2i}^{(2)}(x_1, 0) = 0, \quad x_1 > 0, \quad i = 1, 2; \tag{2.7}$$

at infinity, the radiation conditions be satisfied in the form of the limiting absorption principle; and at the crack tip, the mean energy of the diffracted field be bounded. In combination with (2.1), the last condition amounts to requiring that we have

$$\sigma \sim O(r^{-1/2 \pm i\nu_0}), \tag{2.8}$$

with $\nu_0 > 0$ a real bimaterial constant (see, e.g., [14]) and r the distance to the origin $r = \sqrt{x_1^2 + x_2^2}$. The condition (2.8) suggests the oscillatory motions near the crack tip, which is nonphysical. However, this region is often extremely small and in most cases can be ignored. (For further discussion, see Williams [15], Erdogan [16, 17], and Rice and Sih [18]; the related static case has been considered in [19]). Below, if not used as a subscript, $i = \sqrt{-1}$.

3. The functional equations for the Fourier transforms of displacements and stresses in the crack plane. For any field $\varphi(y_1)$ let us define the decomposition

$$\varphi(y_1) = \varphi^+(y_1) + \varphi^-(y_1), \tag{3.1}$$

where the superscripts + and − denote functions that vanish for the negative and positive values of y_1, respectively. Let us use these fields to introduce new "half unknowns," components of the four dimensional vector $\mathbf{v}^{\pm}(y_1)$ given by

$$\begin{aligned}
&v_i^-(y_1) = u_i^{(1)}(y_1, 0) = u_i^{(2)}(y_1, 0), \qquad y_1 < 0,\\
&v_{i+2}^-(y_1) = -\frac{i}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(1)}(y_1, 0) = -\frac{i}{k_1^{(1)}\mu^{(1)}}\sigma_{2i}^{(2)}(y_1, 0), \qquad y_1 < 0,\\
&v_i^+(y_1) = u_i^{(1)}(y_1, 0), \qquad y_1 > 0,\\
&v_{i+2}^+(y_1) = u_i^{(2)}(y_1, 0), \qquad y_1 > 0,\ i = 1, 2.
\end{aligned} \tag{3.2}$$

Let us make use of operators of dilatation (or divergence) and rotation (or curl) and denote the dilatation of any tensor $\phi_{ik}^{(j)}(x_1, x_2)$ by the superscript ^{1} and the rotation by the superscript ^{2}, so that we can write

$$\phi_i^{(j)1}(\mathbf{x}) = [\phi_{i1}^{(j)}(\mathbf{x})]_{,1} + [\phi_{i2}^{(j)}(\mathbf{x})]_{,2}\,, \quad \phi_i^{(j)2}(\mathbf{x}) = [\phi_{i2}^{(j)}(\mathbf{x})]_{,1} - [\phi_{i1}^{(j)}(\mathbf{x})]_{,2}\,. \tag{3.3}$$

Applying the dilatation ($l = 1$) and rotation ($l = 2$) to (2.1) in the half plane where the argument of the Heaviside function is negative ($(-1)^j x_2 > 0$) and using the boundary conditions (2.6) and (2.7), the extinction theorem can be rewritten as

$$\begin{aligned}
&ik_n^{(m)}\delta_{mj}\delta_{nl}e^{-ik_n^{(m)}(x_1p_1^{inc}+(-1)^{m+1}p_2^{inc}x_2)}\\
&\quad + (-1)^j\int_0^\infty [\sigma_1^{G(j)l}(x_1 - y_1, x_2)v_{2j-1}^+(y_1) + \sigma_2^{G(j)l}(x_1 - y_1, x_2)v_{2j}^+(y_1)]dy_1\\
&\quad + (-1)^j\int_{-\infty}^0 \{\sigma_1^{G(j)l}(x_1 - y_1, x_2)v_1^-(y_1) + \sigma_2^{G(j)l}(x_1 - y_1, x_2)v_2^-(y_1)\\
&\qquad\qquad + ik_1^{(1)}\mu^{(1)}[u_1^{G(j)l}(x_1 - y_1, x_2)v_3^-(y_1)\\
&\qquad\qquad + u_2^{G(j)l}(x_1 - y_1, x_2)v_4^-(y_1)]\}dy_1 = 0, \quad j, l = 1, 2,
\end{aligned} \tag{3.4}$$

or in the matrix form as

$$\begin{aligned}
&\int_0^\infty A^+(x_1 - y_1, x_2)\mathbf{v}^+(y_1)dy_1 + \int_{-\infty}^0 A^-(x_1 - y_1, x_2)\mathbf{v}^-(y_1)dy_1\\
&\qquad = -ik_n^{(m)}\mathbf{U}^{inc}e^{ik_n^{(m)}\mathbf{x}\cdot\mathbf{d}^{1(m)}},
\end{aligned} \tag{3.5}$$

where $\mathbf{d}^{1(m)}$ is the displacement unit vector of a longitudinal wave defined in (2.4), $\mathbf{U}^{inc}$ is the four dimensional vector

$$\mathbf{U}^{inc} = [\delta_{1m}\delta_{1n},\ \delta_{1m}\delta_{2n},\ \delta_{2m}\delta_{1n},\ \delta_{2m}\delta_{2n}]^T, \tag{3.6}$$

and 4×4 matrices $A^+(\mathbf{x})$ and $A^-(\mathbf{x})$ are

$$A^+(\mathbf{x}) = \begin{pmatrix} -\sigma_1^{G(1)1}(\mathbf{x}) & -\sigma_2^{G(1)1}(\mathbf{x}) & 0 & 0 \\ -\sigma_1^{G(1)2}(\mathbf{x}) & -\sigma_2^{G(1)2}(\mathbf{x}) & 0 & 0 \\ 0 & 0 & \sigma_1^{G(2)1}(\mathbf{x}) & \sigma_2^{G(2)1}(\mathbf{x}) \\ 0 & 0 & \sigma_1^{G(2)2}(\mathbf{x}) & \sigma_2^{G(2)2}(\mathbf{x}) \end{pmatrix},$$

$$A^-(\mathbf{x}) = \begin{pmatrix} -\sigma_1^{G(1)1}(\mathbf{x}) & -\sigma_2^{G(1)1}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_1^{G(1)1}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_2^{G(1)1}(\mathbf{x}) \\ -\sigma_1^{G(1)2}(\mathbf{x}) & -\sigma_2^{G(1)2}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_1^{G(1)2}(\mathbf{x}) & -ik_1^{(1)}\mu^{(1)}u_2^{G(1)2}(\mathbf{x}) \\ \sigma_1^{G(2)1}(\mathbf{x}) & \sigma_2^{G(2)1}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_1^{G(2)1}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_2^{G(2)1}(\mathbf{x}) \\ \sigma_1^{G(2)2}(\mathbf{x}) & \sigma_2^{G(2)2}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_1^{G(2)2}(\mathbf{x}) & ik_1^{(1)}\mu^{(1)}u_2^{G(2)2}(\mathbf{x}) \end{pmatrix}, \tag{3.7}$$

with dilatations and rotations $u_i^{G(j)l}(\mathbf{x})$ and $\sigma_i^{G(j)l}(\mathbf{x})$ given in Appendix A.

Everywhere below, let the hat $\widehat{\ }$ denote the Fourier transform with respect to the nondimensionalized variable $k_1^{(1)}y_1$, so that for any function $\varphi(y_1)$ we have

$$\widehat{\varphi}(\xi) = k_1^{(1)} \int_{-\infty}^{\infty} \varphi(y_1) e^{ik_1^{(1)}\xi y_1} dy_1. \tag{3.8}$$

Let us then take the Fourier transform of (3.5) and evaluate the result on the boundary. For this purpose, let us multiply (3.5) by $\exp(ik_1^{(1)}\xi x_1)$, integrate it over x_1, and set $x_2 = 0$. Applying the convolution theorem, we obtain

$$\begin{aligned} &\frac{1}{k_1^{(1)}} \left[\int_{-\infty}^{\infty} A^+(\mathbf{x}) e^{ik_1^{(1)}\xi x_1} dx_1\right] \widehat{\mathbf{v}}^+(\xi) \\ &\quad + \frac{1}{k_1^{(1)}} \left[\int_{-\infty}^{\infty} A^-(\mathbf{x}) e^{ik_1^{(1)}\xi x_1} dx_1\right] \widehat{\mathbf{v}}^-(\xi) = p(\xi)\mathbf{U}^{inc}, \end{aligned} \tag{3.9}$$

where, using the notation $\xi^{inc} = \kappa_n^{(m)} p_1$, $\kappa_n^{(m)} = c_1^{(1)}/c_n^{(m)}$, we have

$$p(\xi) = 2\pi\ i\delta(\xi - \xi^{inc}) = \lim_{\epsilon \to 0} \left(-\frac{1}{\xi - \xi^{inc} + i\epsilon} + \frac{1}{\xi - \xi^{inc} - i\epsilon}\right). \tag{3.10}$$

Multiplying the vector equation in (3.9) by $-2i$ and the first and the third scalar equations there by $[\kappa_2^{(1)}]^2$ and $[\kappa_2^{(2)}/\kappa_1^{(2)}]^2$, respectively, we obtain the system of four scalar functional equations

$$\widehat{A}^+(\xi)\widehat{\mathbf{v}}^+(\xi) + \widehat{A}^-(\xi)\widehat{\mathbf{v}}^-(\xi) = p(\xi)\mathbf{v}^{inc}, \tag{3.11}$$

where the vector $\mathbf{v}^{inc}$ is such that

$$\mathbf{v}^{inc} = 2i\left[(\kappa^{(1)})^2\delta_{1m}\delta_{1n},\ \delta_{1m}\delta_{2n},\ (\kappa^{(2)})^2\delta_{2m}\delta_{1n},\ \delta_{2m}\delta_{2n}\right]^T \tag{3.12}$$

with $\kappa^{(j)} = c_1^{(j)}/c_2^{(j)}$; and matrices $\widehat{A}^+(\xi)$ and $\widehat{A}^-(\xi)$ in (3.11) are given by

$$\widehat{A}^+(\xi) = \begin{pmatrix} 2\xi & \frac{a_1(\xi)}{\gamma_1^{(1)}(\xi)} & 0 & 0 \\ -\frac{a_1(\xi)}{\gamma_2^{(1)}(\xi)} & 2\xi & 0 & 0 \\ 0 & 0 & 2\xi & -\frac{a_2(\xi)}{\gamma_1^{(2)}(\xi)} \\ 0 & 0 & \frac{a_2(\xi)}{\gamma_2^{(2)}(\xi)} & 2\xi \end{pmatrix}, \tag{3.13}$$

$$\widehat{A}^-(\xi) = \begin{pmatrix} 2\xi & \frac{a_1(\xi)}{\gamma_1^{(1)}(\xi)} & -\frac{\xi}{\gamma_1^{(1)}(\xi)} & -1 \\ -\frac{a_1(\xi)}{\gamma_2^{(1)}(\xi)} & 2\xi & 1 & -\frac{\xi}{\gamma_2^{(1)}(\xi)} \\ 2\xi & -\frac{a_2(\xi)}{\gamma_1^{(2)}(\xi)} & \frac{\mu\,\xi}{\gamma_1^{(2)}(\xi)} & -\mu \\ \frac{a_2(\xi)}{\gamma_2^{(2)}(\xi)} & 2\xi & \mu & \frac{\mu\,\xi}{\gamma_2^{(2)}(\xi)} \end{pmatrix}, \tag{3.14}$$

with $a_j(\xi) = (\kappa_2^{(j)})^2 - 2\xi^2$, $\gamma_i^{(j)}(\xi) = \sqrt{[\kappa_i^{(j)}]^2 - \xi^2}$, and $\mu = \mu^{(1)}/\mu^{(2)}$.

The dilatation and rotation of the Green's tensor and Green's stress tensor in (3.7) can be expressed in terms of $H_0(k_i^{(j)} r)$, the Hankel function of the first kind of zero order and its derivatives (see Appendix A). Therefore, the matrices $\widehat{A}^\pm(\xi)$ have been evaluated with the help of the following identity:

$$\int_{-\infty}^{\infty} H_0(k_i^{(j)} r) e^{ik_1^{(1)}\xi x_1} dx_1 = \frac{2}{k_1^{(1)}} \frac{1}{\gamma_i^{(j)}} e^{ik_1^{(1)}\gamma_i^{(j)}|x_2|} \tag{3.15}$$

(see, e.g., [20]). Note that (3.11) involves singularities, which are described in Appendix C. Using the definition of plus and minus functions together with (3.8), it is easy to check that $\widehat{\mathbf{v}}^+(\xi)$ and $\widehat{\mathbf{v}}^-(\xi)$ are analytic in the upper and lower halves, respectively, of the complex ξ-plane.

Let us cast (3.11) in another form through multiplying by the matrix $[\widehat{A}^-(\xi)]^{-1}$. Then we obtain the vector functional equation

$$\widehat{\mathbf{v}}^-(\xi) + B^+(\xi)\widehat{\mathbf{v}}^+(\xi) = p(\xi)\mathbf{T}^{inc}, \tag{3.16}$$

where the vector on the right-hand side is

$$\mathbf{T}^{inc} = [\widehat{A}^-(\xi^{inc})]^{-1}\mathbf{v}^{inc}; \tag{3.17}$$

the matrix $B^+(\xi) = [\widehat{A}^-(\xi)]^{-1}\widehat{A}^+(\xi)$ is given by

(3.18)

$$B^+(\xi) = \frac{\mu}{S(\xi)} \cdot$$
